The penis is dissected into three components—the right and left corpora with their associated hemiglans and the urethral wedge (urethral plate with its associated spongiosa) (see Fig 124–23). The dissection as in the Cantwell-Ransley repair begins on the ventral aspect of the penis. The dissection moves medially just above Buck fascia but is taken down to the tunica albuginea of the corpora. Care is taken to preserve the spongiosum with the urethral wedge, and this dissection is carried posteriorly to the area of the bladder neck. The penis is then separated into the three previously mentioned components. Several authors have found problems getting the reconstructed urethra back to the tip of the glans and have recommended interrupted suturing of the urethral plate or leaving the most distal part of the urethral plate attached to the glans as in the Cantwell-Ransley repair. Others have found the need to make the patients hypospadiac and then perform a later hypospadias repair due to a shortened urethral plate. The rate of hypospadias created has been reported to be from 30% to 70% of cases. If the urethra can be brought up to each hemiglans, an orthotopic meatus is configured. The glans is brought together using interrupted mattress sutures of PDS followed by horizontal mattress sutures of 7-0 nonfilament sutures to bring the glanular epithelium together. The urethra is matured to the glans with interrupted sutures of 7-0 braided polygalactin sutures. The corpora are then brought over the reconstructed urethra with interrupted sutures. Skin closure is similar to that of standard hypospadiac with fine absorbable sutures. If concomitant exstrophy closure is to be done, the dissection then moves proximally into the pelvis to be able to move the structures into the pelvis (see section on CPRE repair).

Female Exstrophy

The principles of repair of both female and male exstrophy are similar. However, in the female the authors recommend the following: (1) radical dissection of the bladder and urethra from surrounding structure; (2) dissection of the lateral aspects of the

posterior vesicourethral and vaginal unit from their attachments to the pelvic floor; (3) tension-free closure of the abdomen, bladder/urethra, and external genitalia; and (4) judicious use of osteotomy and proper immobilization of the pelvis and extremities.

As in the male, if the pelvic bones are separated more than 4 cm or are not malleable under anesthesia, an osteotomy is then performed. The transverse innominate osteotomy along with vertical iliac osteotomy is commonly used in our practice. Intrafragmentary pins are placed, and the fixator is applied after the soft tissue surgery has been completed. An interesting finding in more than 928 exstrophies in the authors' database is that even with a large bladder template the diastasis tends to be narrower than in males. Thus female exstrophy patients are easier to close and do not require an osteotomy as commonly as males.

The vagina is prepped with an iodine prep so that if it is violated during the dissection, it can simply be closed. In the closure, the authors start their dissection along the medial aspect of the clitoral/corporal halves and move deeply into the pelvis. Pinpoint electrocautery at a low setting is used to limit both bleeding and tissue injury. The dissection of the vagina proceeds laterally and posteriorly. The urethrovaginal septum is left intact to preserve its blood supply. As in the male, the dissection proceeds posterior and downward until the levator hiatus is reached with the urogenital diaphragm fibers lateral and posterior to the vesicourethral plate and vaginal incision. This maneuver allows placement of the unit deeply into the pelvis, and more importantly it keeps it from being displaced anteriorly when the pelvic bones are brought together.

The bladder is closed with a single figure-of-eight layer of 3-0 polygalactin suture to maximize postclosure bladder volume. The urethra is closed with a single layer of 4-0 to 5-0 polygalactin depending on the thickness of the tissue. An indwelling suprapubic tube is brought out through the dome of the bladder along with two small feeding tubes, which act as stents and are left in place for 4 full weeks and exit the neoumbilicus. No tubes are brought out through the neourethra because this can be associated with wound infection and prolapse or dehiscence. A No. 2 nylon suture in a horizontal mattress fashion is used to bring the pubic bones into apposition. Once the pubic bones are brought together, a routine subcutaneous and skin closure is performed. A mons plasty is then performed, and the subcutaneous tissues of the clitorides are brought together with 5-0 polygalactin and the epithelium with 6-0 polygalactin sutures. If needed, a Y-V labioplasty is performed for better exteriorization of the vaginal introitus.

If an osteotomy has been performed, the external fixator is then placed and a pelvic radiograph obtained. If pin and fixator placement are optimal, then the infant is placed in modified Buck traction for 4 weeks. If an osteotomy was not performed, the infant is placed in Bryant traction for 4 weeks. Postoperative care is the same as in the male with excellent pain control delivered by an indwelling epidural catheter and bladder spasms controlled by both the epidural and oral oxybutinin.

Continence and Antireflux Procedure

Although some modern exstrophy repairs claim to establish suitable continence without formal bladder neck repair, many patients are referred to our unit still incontinent after only prior newborn repair or after newborn repair and multiple injections of various substances into the bladder neck area. Likewise, other groups have reported their outcomes with newborn repair and most recommended some sort of outlet procedure. In our unit each child has a cystoscopy and gravity cystogram under anesthesia yearly after newborn closure to assess bladder growth. Prior data by Gearhart and Jeffs (1989b) have shown that after newborn exstrophy closure there should be an average increase in bladder capacity by 54 mL in 24 months. Recently, Purves and colleagues (2009b) found that, in selected exstrophy patients who underwent closure, epispadias repair, and bladder neck reconstruction at the authors' institution, a median bladder capacity of 100 mL was more common in the group that was completely dry after bladder neck reconstruction. Most of these children were 4 to 5 years of age and were ready emotionally, maturationally, and intellectually to participate in a postoperative voiding program. Continence and antireflux procedures performed at the authors' institution are illustrated in Figure 124–26. The bladder is open through a transverse incision at the bladder neck with a vertical extension. The later midline closure of this incision is the width of the bladder neck and enlarges the vertical dimension of the bladder, which in exstrophy is often short (see Fig. 124–26A). A Cohen transtrigonal ureteral reimplantation or a cephalotrigonal reimplantation is performed to move the ureter across the bladder, above the trigone, or to direct the ureter cephalad up onto the edge of the trigone (see Fig. 124–26B and C) (Canning et al, 1992). In addition, if the ureters are low on the trigone, there is a need to move the ureteral hiatus higher on the trigone. The hiatus is simply cut in a cephalad direction, and cross-trigonal reimplants are performed at the upper aspect of the trigone (see Fig. 124–26C).

The continence procedure is begun by selecting a posterior strip of mucosa 15 to 18 mm wide and 30 mm long that extends distally from the midtrigone to the prostate or posterior urethra (see Fig. 124–26D). Bladder muscle lateral to the mucosal strip is denuded from the mucosa. It is often helpful at this juncture to use one or two epinephrine-soaked sponges to aid in the control of bleeding and the visualization of the denuded area. Tailoring of the denuded lateral muscle triangles is aided by multiple small incisions on the free edge bilaterally that allow the area of the reconstruction to assume a more cephalad position (see Fig. 124–26E). **These muscle flaps are not only smaller but also not incised transversely at their cephalad extent as described in the original Young-Dees procedure. The authors believe that, if these flaps are incised medially at the cephalad border only where they join the floor of the bladder, there is a significant risk of denervation and ischemia that will harm the bladder neck repair. The basic premise is to create a mucosa-lined tube inside a muscular funnel that narrows from its junction with the floor of the bladder that extends caudally.** The edges of the mucosa and underlying muscle are closed with interrupted sutures of 4-0 polyglycolic acid (see Fig. 124–26F). The adjacent denuded muscle flaps are overlapped and sutured firmly in place with a 3-0 polydiaxone suture to provide reinforcement of the bladder neck and urethral reconstruction (see Fig. 124–26G to I). An 8-Fr urethral stent may be used as a guide during urethral reconstruction, but it is removed after the bladder neck reconstruction is completed. After the bladder neck repair is completed, the repair is suspended to the rectus fascia (see Fig. 124–26J; see inset).

Very radical dissection of the bladder, bladder neck, and posterior urethra is required, not only within the pelvis but also from the posterior aspect of the pubic bar to provide enough mobility for the bladder neck reconstruction. This maneuver allows adequate bladder neck narrowing and tightening of the bladder neck repair and subsequent anterior suspension of the newly created posterior urethra and

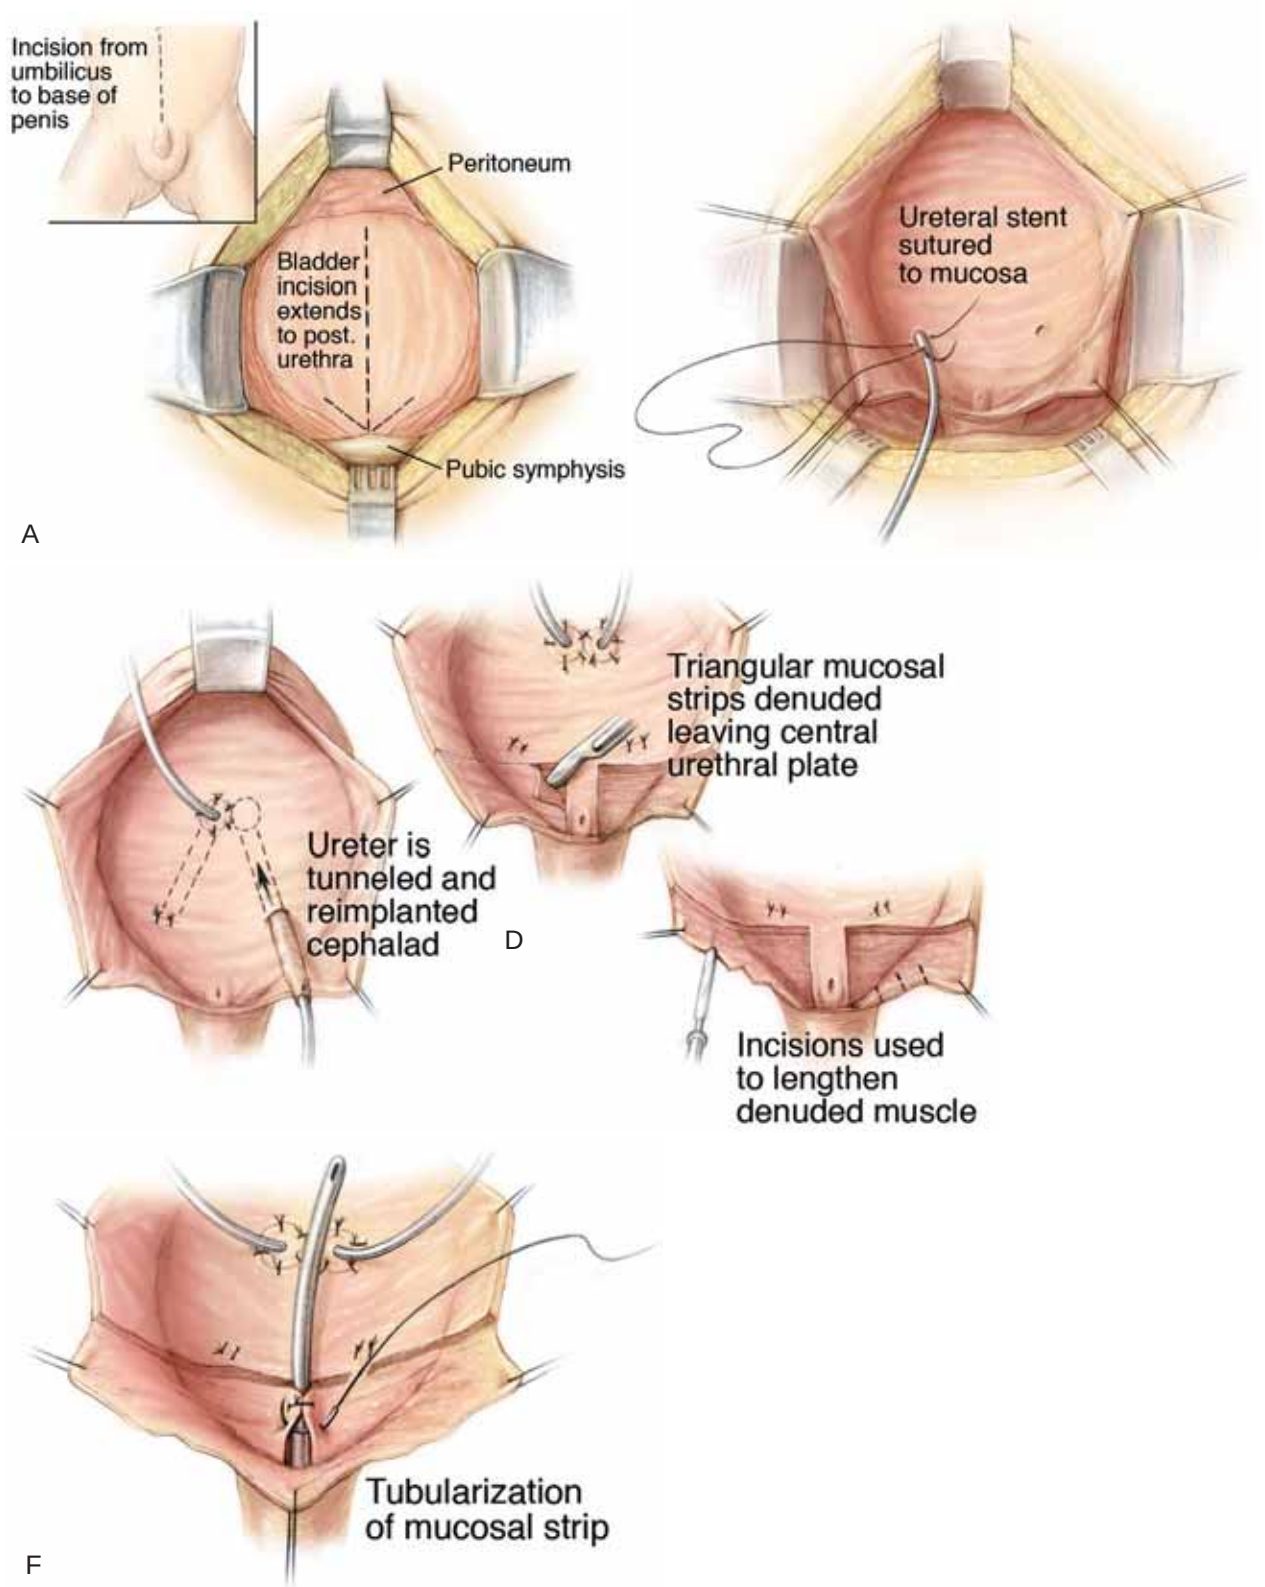

Figure 124–26. Modified Young-Dees-Leadbetter bladder neck reconstruction. **A,** Vertical bladder incision with distal transverse extension where the bladder and posterior urethra are under the pubic bar. **B** and **C,** Ureters are identified, mobilized, and reimplanted in a cephalotrigonal position. **D** and **E,** Segments of mucosa are excised from either side of a median strip (1.5 cm × 3 cm) that will form the neourethra. Short incisions in the muscle will permit extension of the bladder neck. **F,** Urethra is tubularized using a continuous running suture.

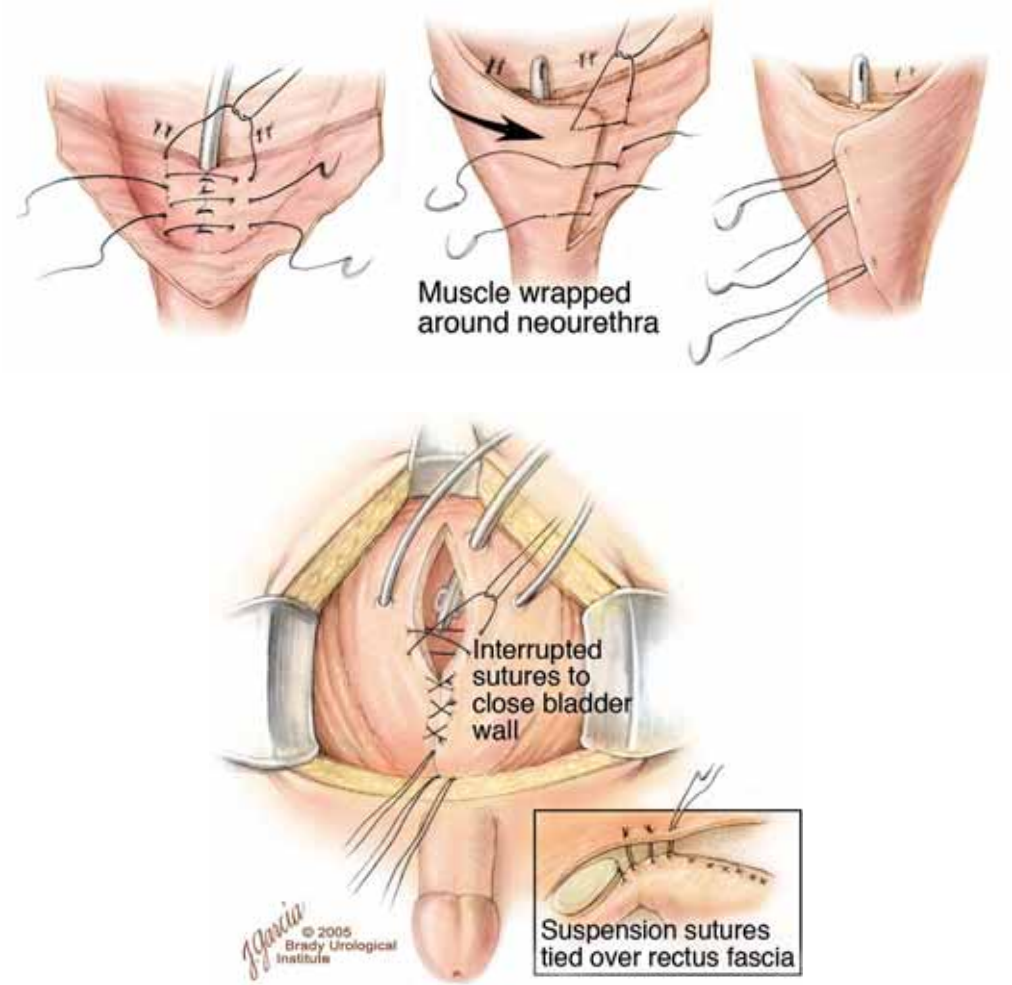

Figure 124–26, cont'd. **G,** Posterior urethra and bladder neck are reconstructed. **H** and **I,** Bladder muscle is brought together in a double-breasted fashion over the neourethra. **J,** Bladder closure is completed, and the distal suspensory sutures are tied over the abdominal wall (see inset). Suprapubic tube and stents are left in place; however, the urethra is left unstented. (© Brady Urological Institute.)

bladder neck. In patients who present after CPRE repair in the newborn period and who had a vesicocutaneous fistula after closure, great care must be taken anteriorly during mobilization of the bladder neck because the tissues are more adherent to the back of the intrasymphyseal bar than in those who underwent bladder neck tailoring as typically seen in that repair. If visualization of the posterior urethra is problematic, the intrasymphyseal bar can be cut, thus providing a widened field of exposure. The intrasymphyseal bar is approximated with 2-0 sutures of polydioxanone. If the intrasymphyseal bar is cut, mobility of the child should be restricted in the postoperative period to allow proper healing of the intrasymphyseal bar.

Postoperative Care

Ureteral stents are placed in the reimplanted ureters and brought out through the wall of the bladder, and the bladder is drained by suprapubic tube, which is left indwelling for a 3-week period. **At the end of 3 weeks the suprapubic tube is clamped, and the patient is allowed to attempt to void. Initially, the tube should not be clamped for more than 1 hour. If voiding does not occur, the child is given an anesthetic and an 8-Fr Foley catheter is placed.** This is left in place for 5 days and removed, and then another voiding trial is begun. This part of the postoperative period is most demanding on the patient, family, and surgeon. Some children require several catheter placements before voiding is initiated. If the child can empty the bladder satisfactorily, the suprapubic tube is removed. Frequent bladder and renal ultrasound examinations are required in the first few months after bladder neck repair.

MODERN INITIAL REPAIR OF BLADDER EXSTROPHY: OUTCOMES AND RESULTS

The use of functional reconstruction in bladder exstrophy has resulted in dramatic improvement in the success of reconstruction. Several recent series (Purves et al, 2008, 2009b; Grady and Mitchell, 1999) have demonstrated the success and applicability of early newborn closure with or without pelvic osteotomy to bladder exstrophy. Other important but older series have shown acceptable continence rates with preservation of renal function in a majority of patients treated in early life (Table 124-1).

Two of the most reliable predictors of eventual urinary continence are the size of the bladder template at birth and a successful primary closure. Regardless of the technique used, a complication-free newborn closure of the abdomen, pelvis, bladder, and proximal/complete urethra paves the way for an optimal

Table 124–1.

Urinary Continence after Functional Bladder Closure

SERIES	NO. OF CLOSURES EVALUATED	PATIENTS CONTINENT
Perlmutter et al (1991)	15	77%
Mollard et al (1994)	73	69%
McMahon et al (1996)	33	70%
Lottmann et al (1998)	57	67%
Purves et al (2008)	67	70%

Table 124–2.

Urologic/Orthopedic/Neurologic Complications in 185 Primary Bladder Closures

UROLOGIC COMPLICATIONS	NO. OF PATIENTS
Bladder prolapse/dehiscence	6
Post-outlet obstruction	4
Suprapubic tube removal	2
Intrapubic stitch erosion	4
Febrile urinary tract infection	6
Wound infection	3
Bladder calculi	5
Orthopedic Complications	
Nonunion osteotomy	2
Leg length inequity	1
Persistent joint pain	1
Pelvic osteomyelitis	1
Pinsite infection	3
Pressure sore	1
Neurologic Complications	
Femoral nerve palsy	4

long-term result. A large series by Surer and colleagues (2001b) has demonstrated in a large group of exstrophy patients who underwent early closure with importance of a successful primary closure. Sixty-eight patients (57 males and 11 females) were referred for bladder neck reconstruction after primary closure at many other centers. Twenty percent had concomitant pelvic osteotomy at the time of closure. The majority of patients were closed within the first 72 hours of life. Mean capacity at the time of bladder neck repair was 121 mL. Eighty-three percent are continent and voiding per urethra. This application of early successful closure and follow-up reconstruction by a second surgeon shows convincingly that a successful primary closure is one of the most important determinants of eventual bladder capacity and compliance regardless of who originally performed the repair.

Initial Closure

Long-term data on all modern types of exstrophy repair can be difficult to obtain. Nonetheless, this section deals with what has been gleaned from the recent literature. Most data come from the MSRE and CPRE groups. In a large series reported by Purves and colleagues (2008), 189 patients who had undergone primary closure between 1988 and 2004 were extracted. The records of 131 patients (95 males) who underwent MSRE with a modified Cantwell-Ransley repair by a single surgeon in 1988-2004 were reviewed with a minimum of 5-year follow-up. Complications from bladder closure and additional procedures to correct these complications are presented in Table 124–2. The importance of a successful initial closure is emphasized by Oesterling and Jeffs (1987) and Husmann and colleagues (1989), who found that the onset of continence was quicker and the continence rate higher in those who underwent a successful primary closure with or without osteotomy. In addition, Novak and colleagues (2010) reported on patients with bladder exstrophy who underwent more than one attempt at primary closure. If a patient underwent two closures, the chance of having an adequate bladder capacity for bladder neck repair was 60% and the chance of voided continence was 17% overall. Patients who underwent three closures had only a 50% chance of an adequate capacity and less than 16% chance of voided continence. In an evaluation of this select group it was found that at the time of primary closure, 80% of patients had no form of pelvic osteotomy. Thus the chance of obtaining an adequate bladder capacity and eventual continence after more than one exstrophy closure is markedly diminished. These poor results underline the paramount importance of a secure abdominal, bony pelvis, and posterior vesicourethral unit with or without epispadias repair in the newborn exstrophy.

Also, compared with many of the other repairs, data are available from several units on their results with the CPRE repair. In a recent series by Shnorhavorian and coworkers (2008) there were 2 instances of dehiscence of the fascia, and 9 of 37 developed a vesicocutaneous fistula. Complications seen in the CPRE repair are much as those seen in the MSRE. However, some that are particular to this repair have been seen. A large series of vesicocutaneous fistula was reported from a single institutional study, in which some patients had an osteotomy and others did not (Shoukry et al, 2009). In addition, several series have reported the need for early ureteral reimplantation after closure and the occurrence of significant upper tract changes in many patients (Grady and Mitchell, 1999). This has prompted the call for ureteral reimplantation at the time of exstrophy closure by one group (Braga et al, 2008a).

Although most published series are not large, the incidence of bladder prolapse and dehiscence is reported to be small. In a recent series of primary CPRE repairs by Shoukry and colleagues (2009), the incidence of major prolapse and dehiscence was 15.8% even with the use of osteotomy. In this author's series, we have seen a number of referred patients with complete dehiscence and major bladder prolapse after newborn CPRE repair. However, the complicating factors we have seen, along with the previously mentioned factors, have been significant losses of soft tissue including partial or complete loss of the glans in nine patients and the loss of the urethrovaginal septum in two. In a series by Hammouda (2003), 5 of 42 patients had ischemic loss of glans tissue after CPRE repair. Thus the complications of closure between the CPRE and MSRE are similar but more serious if soft tissue loss occurs.

Data from Baka-Jakubiak (2000) and colleagues from Warsaw involved 100 primary closures. Complete dehiscence occurred in 31 patients, of whom 24 had no osteotomy and 7 a posterior iliac osteotomy only. Of those who were closed at less than 72 hours ($n = 47$) and no osteotomy performed, dehiscence occurred in 13 patients. All were immobilized with a modified spica "chair" cast for 3 weeks and then an elastic bandage for 3 weeks. The authors currently recommend osteotomy for all newborns with a diastasis greater than 5 cm and in those closed after 72 hours.

In a recent publication of the Erlangen repair by Rosch and colleagues (1997) of 100 closures, the complications were generally mild with urethrocutaneous fistulae in 2. Minimal hydronephrosis occurred in 20%, and 3% had severe hydronephrosis requiring further surgery. There were no incidents of bladder

prolapse or dehiscence. Osteotomy was not used in any patient, but a sophisticated coaptation technique involving the obturator foramen was used in all patients. In a recent report by Kelly and colleagues (2008) of 26 patients, there was a reported incidence of bladder prolapse requiring treatment in 25%. Soft tissue loss of glanular tissue was noted in 2 of 26 patients.

Interest in the outcomes of exstrophy closure has expanded to interest in the economic outcomes of the treatment of this major birth defect and who should be doing these types of operations in the newborn. In a paper by Nelson and colleagues (2005), high-volume hospitals (those closing more than five exstrophies per year) had lower overall costs per patient than low-volume hospitals (fewer than five exstrophies per year). In addition, Nelson and colleagues (2005) found that successful newborn closure had overall markedly less costly inflation-adjusted hospital charges than reclosures due to shorter operating times and shorter length of stay.

A corollary to these papers was one from Meldrum and colleagues (2005), who found that when exstrophy closures failed and had to be reclosed, the success rates and ultimate continence were better among fellowship-trained pediatric urologists rather than other surgeons (general urologists, non–fellowship-trained pediatric urologists, and general pediatric surgeons).

In the evaluation of this group of selected exstrophy patients, it was found that at the time of initial closure 19 of 23 patients had no form of osteotomy. Six of the patients had obtained bladder capacity suitable for bladder neck reconstruction; three were dry, and three were incontinent. Bladder size was inadequate in nine patients after being monitored for bladder growth. The chance of obtaining an adequate bladder capacity and eventual continence after more than one closure attempt is markedly diminished. These less than satisfactory results underline the paramount importance of a secure abdominal wall, posterior urethra, and bladder closure in these complex cases. Lastly, the importance of early initial closure was emphasized by data from Husmann and colleagues (1989) showing that only 10% of the patients who undergo bladder closure before 1 year of age but 40% of those who have the procedure at a later age require eventual augmentation.

Epispadias Repair

Although urinary incontinence remains the most significant problem for patients with classic bladder exstrophy and epispadias, anxiety about inadequate and unattractive genitalia still poses the greatest concern to male patients. The authors began using the modified Cantwell-Ransley repair in patients with classic exstrophy or epispadias in 1988 and have reported their early experience (Gearhart et al, 1992, 1995c, 2004).

Since 1988, the modified Cantwell-Ransley repair has been performed for 129 male patients with either classic bladder exstrophy (97 patients) or epispadias (32 patients) (Baird et al, 2005b). At the time of surgery, the patients' age ranged from 1 to 18 years with an average age of 19 months. Of the 97 patients with bladder exstrophy, 31 had a short urethral groove requiring paraexstrophy skin flaps for penile lengthening at the time of initial bladder exstrophy closure. Of the 32 epispadiac patients, 26 had penopubic and 6 had penile epispadias at presentation.

This technique was used for primary urethroplasty in 106 patients with bladder exstrophy and 32 with epispadias. The modified Cantwell-Ransley repair was used as a secondary procedure after failed urethroplasty in 15 patients with exstrophy and 8 with epispadias and was combined with reclosure of bladder exstrophy in 18 patients. Early epispadias repair was performed when the patients were 6 months to 1 year of age. However, because of concerns about getting the urethra deeper under the corpora at the glanular level, beginning in 1994 we further modified the Cantwell-Ransley repair by detaching the mucosal plate from the corona except for the distal 0.5 to 1 cm of the plate. Intramuscular testosterone enanthate in oil was given to all children at a dose of 2 mg/kg at approximately 5 weeks and again at 2 weeks before surgery.

One hundred twenty patients had a horizontal or downward-angled penis while standing. The incidence of urethrocutaneous fistula in the immediate postoperative period was 16%, and at 3 months it was 12%. Nine patients developed a urethral stricture of the proximal anastomotic site, and 12 had minor skin separation of the dorsal skin closure. Cystoscopy with catheterization in 120 patients revealed an easily negotiable channel in all. Eight patients required further penile-straightening surgery. Fifteen patients older than 16 years had engaged in satisfactory intercourse, and all reported orgasms and ejaculation with a straight penis on erection. One patient reported that his penis was shorter following surgery.

Modern penile reconstructive techniques should create a straight and functional penis with a glanular meatus, an easily catheterizable neourethral channel (if needed), and an acceptable cosmetic appearance. Many adolescents considered their odd-appearing genitalia with a short, widened penis that deviated upward to be a greater psychosocial problem than incontinence, and therefore every effort should be made to restore the penis to a normal condition. In 1989, Ransley and colleagues introduced a concept to release dorsal chordee by incision and anastomosis of the dorsomedial aspect of the corpora over the urethra and urethral meatotomy at the distal end of the glans, to move the meatus to a more normal position and secure good direction of the urinary stream (IPGAM). Ransley's group reported their long-term experience with 95 patients in whom the modified Cantwell-Ransley repair was used: Fistula occurred in only 4% of patients, and a urethral stricture in only 5% (Kajbafzadeh et al, 1995).

Dissection of the urethral strip to inside the glans penis provides a ventral position of the urethra and the glans and submerges the urethra well below the corpora at the glans level. This approximation of raw surface of glanular tissues dorsally over the urethra is clearly why the incidence of fistula in the area of the corona is rare compared with the Young repair. Fistulae in the authors' patients usually appear at the base of the penis, where the urethra comes up proximally between the corporal bodies. In modern exstrophy reconstructive techniques, most surgeons try to preserve the urethral plate at the time of exstrophy closure. Interestingly, the authors do not find a significant difference for fistula formation between those in whom paraexstrophy skin flaps were used at the time of initial closure and those in whom they were not. Despite the positive findings with regard to fistula formation, the use of paraexstrophy skin flaps has been noted to be associated with the development of strictures. Use of these flaps is therefore limited to selected patients in whom penile lengthening cannot be achieved with standard techniques.

Papers from several institutions have reported their results with the Mitchell-Bagli penile disassembly technique. Complications are similar to other methods of epispadias repair (i.e., fistula and urethral stricture) (Zaontz et al, 1998; Kibar et al, 2009a). Although not a complication, a high percentage is made hypospadiac as the completely dissected urethral plate fails to reach the tip of the glans. The rate of being made hypospadiac has been reported from 38% to 83% (Mitchell and Bagli, 1996; El-Sherbiny and Hafez, 2005). As mentioned in the section on exstrophy closure, reports

of ischemic loss of the glans, urethral plate, and corpora have been reported by Hammouda (2003) and Husmann and Gearhart (2004). Repair of the hypospadias in these patients has been reported by the Seattle group as not difficult or associated with major complications. However, data from Hafez and colleagues (2005) and Gearhart and Baird (2005) show difficulties that can be associated with these repairs. In an attempt to deal with the issues and prevent them, El-Sherbiny and Hafez (2005) have modified the Mitchell repair as with the modified Cantwell-Ransley repair (Gearhart and Baird, 2005) to keep the urethral plate attached to the distal glans to obviate the need for making the child hypospadiac at the time of isolated epispadias repair or when associated with CPRE.

In the authors' opinion, none of the current epispadias repairs offers any significant gain in penile length by removal of the entire urethral plate from the glans or even the use of a free graft. Data reported by Silver and colleagues (1997b) clearly showed that, although anterior corporal length is significantly less in patients with exstrophy, the posterior corporal length is normal. These findings suggest that penile lengthening procedures at the time of epispadias repair improve apparent penile length and straighten the penis but do not transfer additional tissue (i.e., length) to the corporal bodies. The authors have observed that the modified Cantwell-Ransley repair effectively corrects corporal chordee and adds some penile length. It can be hoped that dorsal penile curvature, which is often seen during the growth spurt at puberty, will be resisted. After significant experience with adolescent exstrophy males with significant dorsal chordee, the authors agree that movement of the neurovascular bundles along with incision and grafting of the resultant defect gives better results long term than incision and corpora cavernostomy. In the patients in whom corporal rotation is used without corporal incision and anastomosis, the neurovascular bundle is left intact and not dissected from its bed. However, if incision and anastomosis are necessary, mobilization of the neurovascular bundle is required. Typically in the authors' experience, incision and rotation are used only for older patients with marked chordee. Although review of findings reveals that almost all penises are straight or deflected downward, many of these patients are still young children. The long-term assessment of penile and urethral reconstruction in exstrophy patients by the modified Cantwell-Ransley repair has shown that in patients with bladder exstrophy and epispadias there is some increase in penile length, and a relatively straight penis with an adequate urethral caliber, which is adequate to void and ejaculate through, can be achieved with minimal morbidity. Long-term reports with the penile disassembly technique have also demonstrated a reasonably straight penis (Grady et al, 2003).

Bladder Neck Repair

Bladder neck reconstruction results in the exstrophy population have been reported by several groups. Some large experiences have come from the European groups in Lyon and Paris. Mouriquand and colleagues (2003) reported on 80 children with bladder exstrophy and 25 with incontinent epispadias. Follow-up ranged from 1 to 11 years. Forty-five percent of the group with exstrophy and 52% of those with epispadias had a dry interval greater than 3 hours. Although the continence rate was low, many of the exstrophy patients were not closed until 6 to 12 months of age. Also, many had their epispadias repair after bladder neck reconstruction, a factor known to influence both eventual capacity and continence. Lottmann and colleagues (1998) presented a long-term follow-up study of Cendron's exstrophy patients who underwent complete reconstruction. With the Young-Dees repair they achieved urinary continence in 71% of male patients and 53% of females. Overall continence was 65% with a mean follow-up of 12 years after bladder neck repair. Series from North America using mainly the classic Young-Dees-Leadbetter repair reported continence rates ranging from 60% to 82% (Husmann et al, 1989; Mergurian et al, 1991; Perlmutter et al, 1991; Franco et al, 1994; McMahon et al, 1996; Chan et al, 2001; Cole et al, 2003) (see Fig. 124–2). **The most important long-term factor gleaned from a review of all these series is the fact that bladder capacity at the time of bladder neck reconstruction is an important determinant of eventual success.**

Records of 95 patients who underwent all stages of MSRE by a single surgeon at our institution between 1988 and 2004 were reviewed by Purves and colleagues (2008). Sixty-seven patients with bladder neck reconstruction and minimum 5-year follow-up were available for analysis. The current voiding status of each patient was obtained from parental or patient interview or direct observation by the nursing and physician staff. The patients were categorized as spontaneous voiding not on intermittent catheterization and were assigned a status of (1) completely dry day and night; (2) socially continent, being dry at least 3 hours during the day with occasional wet nights; or (3) wet being dry for less than 3 hours during the day and wet at night (Table 124–3).

Of the 67 male patients who underwent bladder neck repair, the mean age for primary closure was 4 months (range 6 hours to 4 months). The mean age at bladder neck repair was 4.8 years (range 40 to 60 months), and these patients had a mean bladder capacity before repair of 98 mL (range 75 to 185 mL). Of the 67 patients, 47 (70%) are continent and voiding urethrally without the need for augmentation or intermittent catheterization. Seven patients (10%) had social continence with occasional wet nights. The renal units of all patients who underwent bladder neck repair were evaluated by intravenous pyelography or ultrasound postoperatively on multiple occasions to assess preservation of renal function after the outlet procedure. One patient had reflux and hydronephrosis after the outlet procedure and bilateral reimplantation and developed left pyelonephritis with resultant mild scarring. DMSA revealed nearly normal bilateral function. Conservative follow-up revealed resolution of the reflux with time. One patient developed ureteral obstruction and required reoperative reimplantation. Prolonged outlet obstruction required cystoscopy and placement of an 8-Fr catheter in 19 patients, and prolonged suprapubic drainage was required in 13 patients. Thirteen (19%) failed bladder neck repair completely, six underwent continent diversion, and seven awaited further surgery. The mean time to daytime continence was 14 months (range 4 to 23 months), and the mean time to nighttime dryness was 23 months (range 11 to 34 months).

Table 124–3.

Urinary Continence after 67 Initial Bladder Neck Reconstructions

RESULT	AVERAGE DRY INTERVAL	NO. OF PATIENTS	% OF PATIENTS
Continent	3 hr	47	70%
Social continence (dry daytime, occasional wet nights)	3 hr	7	10%
Wet	<3 hr	13	19%

No correlation was found between age at bladder neck reconstruction and age at achieving continence.

The findings in this series were that continence was more likely in patients who underwent primary exstrophy closure before 72 hours of age or after 72 hours of age with an osteotomy. These results coincide with those of Husmann and colleagues (1989) who found that patients who underwent delayed closure without osteotomy showed a continence rate of only 10%. There was another revealing factor in this study. Bladder capacity at the time of bladder neck repair gave a strong indication of not only who would be dry but also who would be dry sooner. If the patients were divided into those with a preoperative bladder capacity greater than or less than 100 mL, results showed that the group with the larger capacity had a high rate of continence (42/50 dry and voiding versus 5/17 in the lower-capacity group). In addition, the mean time to dryness in the higher- and lower-capacity group was 10 months and 21 months, respectively (14 months in the group overall).

In a similar series by Purves and Gearhart (2008), the results in females mirrored those of the male group with a slightly higher continence rate of 74% (dry day and night) and social continence again in 10%. Again, patients with capacity greater than 100 mL had better outcomes. In a phenomenon not seen in the males, six patients (20%) became continent after bladder and pelvic closure alone.

A continence procedure should be delayed until the bladder reaches a capacity of 100 mL, and the child is motivated to be dry and participate in a postoperative voiding program. The onset of continence is an interesting phenomenon in these patients. The vast majority achieve daytime dryness within 12 months after bladder neck repair. A few patients gain a longer daytime dry interval during the second year after their outlet procedure. However, patients who are not dry within 2 years are considered incontinent and failures. The onset of nighttime continence varies but takes longer than the time needed for daytime continence and can be 2 to 3 years. Caione and colleagues (1999) showed that use of desmopressin acetate (DDAVP) can increase the onset and number of dry nights in these patients. In the series by Purves and Gearhart (2008), 25% of patients required either DDAVP or oxybutynin to establish nighttime dryness.

Urodynamic evaluation by Dave and colleagues (2001) showed that patients with good continence after bladder neck repair had high cystometric bladder capacity and compliance compared with those who were incontinent. However, unstable contractions were seen in both groups. Also, higher-end filling pressures were reported and those patients had a high incidence of nonobstructive hydronephrosis. These findings in addition to those of Bolduc and colleagues (2002) indicate that careful lifelong follow-up is essential in these patients after successful childhood reconstruction.

OTHER MODERN EXSTROPHY REPAIRS: CONTINENCE OUTCOMES

Warsaw Approach

The long-term reported outcomes of this repair include 36 patients with classic exstrophy and 37 with epispadias. Eighty-nine percent of patients with epispadias were continent during the day, but more than 40% were still wet at night. Seventy-five percent of patients with classic exstrophy had daytime continence, but nine had occasional wet nights. Eleven boys required short-term intermittent catheterization, which was easily performed by the patient and family. All but two began voiding within 3 to 5 months, and only two have continued with intermittent catheterization. Complications in seven boys included two urethrocutaneous fistulas and five urethral strictures (Baka-Jakubiak, 2000). All of these responded to urethral dilatation or endoscopic incision. There were no instances of abdominal wall dehiscence or glanular or corporal loss. Ureteral reimplantation was not performed at the time of bladder neck reconstruction and epispadias repair, but many patients required later reimplantation for gradually worsening hydronephrosis.

Compared with this experience, Mathews and Gearhart (2003) reported on a group of patients who had ureteral reimplantation performed at the time of bladder neck reconstruction and epispadias repair. None of these patients developed reflux or worsening hydronephrosis. Baka-Jakubiak (2000) recommends performance of this combined procedure if the bladder capacity is documented to be above 100 mL and the penis is large enough for epispadias repair. Follow-up urodynamic studies demonstrated the presence of normal detrusor function in most, although some patients developed high voiding pressures and some had poor detrusor contractility. If poor detrusor contractility was noted, prolonged intermittent catheterization was required and high voiding pressures were managed with anticholinergic therapy. Most patients were managed later in life, and the standard addition of ureteral reimplantation at the time of reconstruction should probably be universally performed.

Erlangen Approach

In a recent review by Ebert and colleagues (2010), who have reported on 100 patients, using this technique has occurred in both newborns and failed closures. Ninety-one children with exstrophy (69 boys and 22 girls) and nine with complete epispadias (7 boys and 2 girls) have had this procedure performed. The complete single-stage repair was performed in 47 children and included pelvic closure without osteotomy, bladder neck reconstruction, an antireflux procedure, and epispadias repair using the Cantwell-Ransley technique. An additional 53 patients had primary reconstruction elsewhere and then had bladder neck reconstruction and epispadias repair performed. Continence was defined as dryness for more than 3 hours and no nocturnal enuresis. Partial continence was defined as dry for 1 to 3 hours or longer with occasional stress incontinence or wet nights. Patients dry for less than 1 hour were considered incontinent. Among the patients undergoing single-stage repair, 72% (34 of 39) are dry voiding per urethra, 2 on clean intermittent catheterization (CIC), and 3 on CIC following augmentation. Four patients are partially continent, and two are dry on desmopressin. Four patients are incontinent, and three have had continent diversion. Of 53 patients who had primary closure elsewhere, 55% are continent and 7 have been augmented. Fourteen are partially continent and 10 are incontinent, 4 of whom have had continent diversion. The authors have emphasized the superiority of this repair for primary rather than failed closures.

Complete Repair

Various series have been published about outcomes including the need for ureteral reimplantation in the first year of life, the number of patients requiring hypospadias repair after this procedure, and the complication rates of this procedure. However, little has been published about the long-term continence results of the need for bladder neck reconstruction in this group of patients. Borer and

colleagues (2005) reported that ultimately 65% to 70% of patients undergoing CPRE in the newborn period will require a bladder outlet procedure. In an update series, Borer and colleagues (2005) found that four of six patients with long-term follow-up have suitable continence after bladder neck repair. In a large series by Hafez and colleagues (2005), some of whom were delayed or failed primary closures, 84% of males and 50% of females required bladder neck repair to be dry. Some of these require concomitant bladder augmentation to be dry. In another large series by Shoukry and colleagues (2009), none were continent after CPRE alone and most required augmentation to be dry. More importantly, early dry intervals did not translate into later continence.

New data from Shnorhavorian and coworkers (2008) reviewed their total experience with the CPRE repair. This was a total of 39 patients since 1989. Daytime voided continence was achieved in 74% of males and females with 4 years of follow-up. However, only 20% and 43% of boys and girls, respectively, achieved continence without the need for bladder neck repair. Eighteen percent achieved dryness with bladder neck injection only. In a recent series of CPRE patients referred for reclosure or after successful closure for bladder neck reconstruction, the results were interesting (Gearhart et al, 2007). All patients were operated on by an experienced senior surgeon who does not routinely do newborn CPRE repairs. None of the 14 patients who underwent successful CPRE in the newborn period was continent for any appreciable interval after closure. Of the 19 patients who underwent bladder neck reconstruction after complications with their newborn closure, only 25% were voiding from the urethra and continent. In the group with a successful primary closure ($n = 14$), 57% were dry day and night and 28% were dry during the day only (Purves et al, 2009a). Of interest, all patients who were dry after bladder neck reconstruction had a successful primary closure with pelvic osteotomy and hypospadias repair before 1 year of age. None required ureteral reimplantation before bladder neck repair. These data clearly show that in the majority of cases, "complete repair" patients will need to undergo bladder neck repair. However, as in all of the major repairs, in a successful primary closure with fewer bladder violations with interval surgeries, the chance for voided continence, although reasonable, still needs to be improved.

Other methods have combined epispadias repair with bladder exstrophy in the male patient. In a series of 38 boys with classic exstrophy, Baird and colleagues (2005c) evaluated patients with either failed or delayed primary closures. The complications were those seen with routine exstrophy repairs including urethrocutaneous fistula and urethral strictures. Three boys were dry with combined closure alone. Nineteen boys went on to modified Young-Dees-Leadbetter bladder neck repair. During both day and night, 12 of 19 were totally dry. These data, as well as the data of Mitchell and Grady, clearly show that epispadias repair and exstrophy closure can be combined with acceptable results. However, the complications are real and can portend the loss of any chance at volitional voiding and should only be performed by experienced exstrophy surgeons and not the occasional surgeon.

Kelly Repair

There are not many papers with long-term follow-up of the Kelly technique. However, a recent presentation by the Melbourne group gives the best and most current results that can be found with this repair. Data was collected in children older than 4 years. Complete continence was defined as dry for more than 3 hours day and night (with two or fewer wet nights per months). Partial continence was dry for 2 or more hours during the day and three or more wet nights per month and/or stress incontinence. Twenty-four of 31 Kelly patients voided spontaneously, and 17 of 31 voided in an unaided fashion (without IC or augmentation). Overall continence was 71% with 3 of 17 (18%) who voided in an unaided fashion enjoying complete continence, Nine of 17 (53%) had partial continence. The 18% dry and voiding rate compares favorably with that recently reported by Shnorhavorian and colleagues (Jarzebowski et al, 2009).

EXSTROPHY RECONSTRUCTION FAILURES

Failed Closure

After any form of repair, failures can manifest as complete bladder dehiscence, bladder prolapse, neourethral stricture and obstruction, and soft tissue loss. Meldrum and colleagues (2005) reported on a select group of children who failed exstrophy reconstruction before referral to a tertiary care facility. In the cohort of 101 children, 51 had primary surgical management performed by a fellowship-trained pediatric urologist, 18 by a general urologist, 6 by a pediatric surgeon, and 9 by an unknown surgeon. Following successful reclosure, 38 patients eventually developed adequate bladder capacity for bladder neck reconstruction, and only 26% (10) eventually achieved dryness. These data emphasize the need for initial successful reconstruction and suggest that individuals undertaking this reconstruction should be comfortable with the complexity of repair. It is prudent for the surgeon who may see only a few patients with this condition to consider referral of these complex management situations to a center where special expertise and experience exist.

In a recent large series by Schaeffer and colleagues (2008), 185 patients who underwent closure by one of two surgeons were reviewed for both major and minor complications (see Table 124–2). Sixty-three underwent osteotomy at the time of primary closure. There were 14 major complications (11%) and 27 minor complications (14%). Major urologic complications included bladder prolapse or dehiscence in six male patients (3%), all which were successfully reclosed. Major orthopedic complications including nonunion in two patients, leg length inequality in one, and persistent joint pain in one developed in 4 of 63 patients (6%) who underwent osteotomy. Major neurologic complications included femoral nerve palsy in four patients (2%). There were 21 minor urologic complications (11%) including posterior bladder outlet obstruction in four cases, urethrocutaneous fistula in two, suprapubic tube removal in two, intrapubic stitch erosion in four, febrile UTI in six, and surgical site infection in three. Six patients (3%) had minor orthopedic complications including pelvic osteomyelitis in one, pin site infection in three, and a pressure sore from immobilization in one.

Dehiscence, which may be precipitated by incomplete mobilization of the pelvic diaphragm and inadequate pelvic immobilization postoperatively, wound infection, abdominal distention, or urinary tube malfunction, necessitates a 6-month recovery period before a second attempt at closure can be made (Gearhart and Jeffs, 1991a; Gearhart et al, 1993b) (Fig. 124–27A). Dehiscence and prolapse have also been reported following the CPRE and may be associated with glandar, corporal, urethral plate, and other major soft tissue loss (Fig. 124–27B). Tension-free reclosure with osteotomy and immobilization are important factors in initial and subsequent closures. Unfortunately, the chance of obtaining adequate bladder

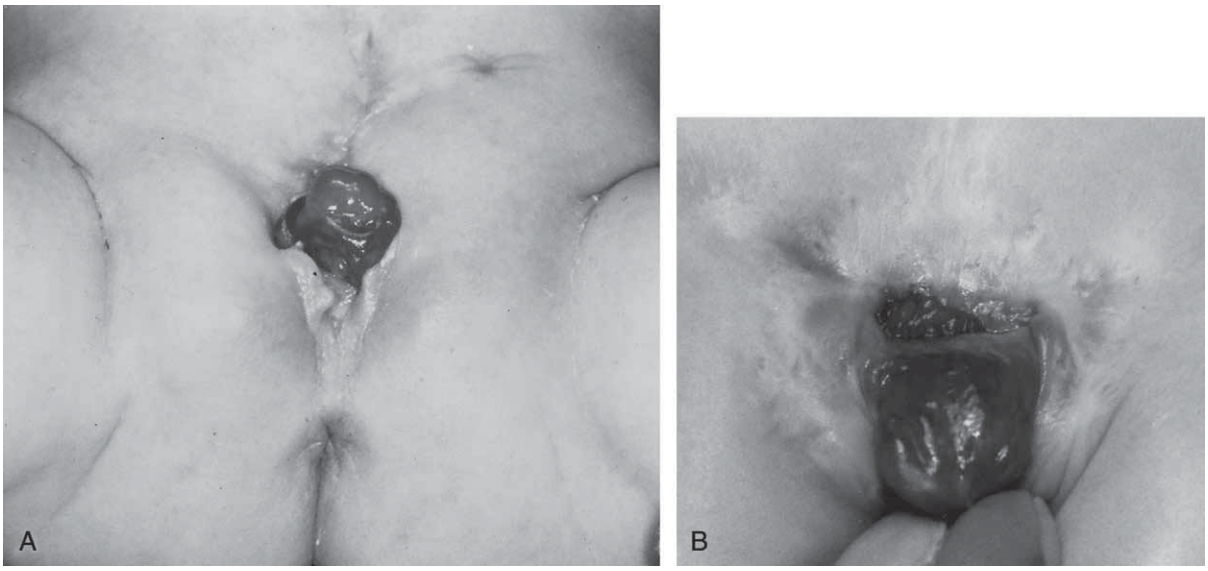

Figure 124–27. **A,** Complete dehiscence of bladder closure in a child who had reconstruction without osteotomy. **B,** Dehiscence of a patient who had bladder closure using the complete reconstruction technique.

capacity for bladder neck plasty and eventual continence after multiple closures is markedly diminished (Gearhart et al, 1996a). Similarly, bladder prolapse is considered a failure and requires bladder reclosure or revision. In a recent series from a single institution of 122 patients who underwent reclosure with a mean follow-up of 14 years, the voided continence rate was 16% (Novak et al, 2010). In a patient with significant bladder prolapse or dehiscence, at the time of secondary closure the authors combine epispadias repair with bladder, posterior urethra, and abdominal wall closure (Gearhart et al, 1998). The patient is given testosterone enanthate intramuscularly 5 weeks and 2 weeks before surgical repair and undergoes an osteotomy with concomitant bladder, urethral, and abdominal wall closure. Major soft tissue loss that is seen following CPRE requires extensive preoperative planning and may require use of buccal mucosal or full-thickness grafts or tissue expansion (Gearhart and Baird, 2005).

Gearhart and Baird (2005) reported on 38 boys undergoing combined exstrophy closure and epispadias repair along with osteotomy, and 30 had failed prior reconstruction. Complications in this group were limited to urethrocutaneous fistulae and urethral strictures. Although the results after reclosure are not as good as those obtained with a successful primary closure, they are respectable and may obviate the need for bladder augmentation.

Erosion of the intrapubic stitch into the posterior urethra during the healing process can present as a UTI, increasingly dry diapers, or high residual urine in the immediate postoperative state before removal of the suprapubic tube. In any of these cases or if any hydronephrosis is seen on postoperative ultrasound, immediate cystoscopy should be performed to rule out obstruction. If the stitch has eroded into the urethra and the child is older than 4 months, it can be removed easily through a small suprapubic incision. If it occurs early, the authors usually leave the postoperative tube for 8 to 12 weeks before stitch removal.

Neourethral stricture is often associated with paraexstrophy skin flap use, pubic suture reaction, erosion, or the use of urethral stents. This may be somewhat subtle; however, warning signs consist of UTIs, detectable increased bladder volumes on ultrasonography, bladder stones, prolonged dry intervals, and unexplained rectal prolapse. In a review by Baker and colleagues (1999), posterior urethral obstruction was found in 41 patients. Most episodes occurred within 60 days after primary closure. If diversion was used for longer than 6 months, the ultimate fate of the bladder was augmentation. If diversion was used for less than 6 months, most reconstructions were ultimately bowel free. The authors have also seen outlet obstruction including complete obliteration after both the CPRE and Kelly repair (Hernandez et al, 2008). Whether this is due to ischemic damage to the urethral plate or technical error is unclear. Regardless, because there is a paucity of long-term data from these two repairs, the outlet must be monitored carefully as with all exstrophy patients after primary closure. Ultimately, posterior urethral obstruction after exstrophy closure markedly decreased the success of any repair. This complication presents a significant risk to the upper urinary tract and should be detected early.

Although all closed exstrophy bladders have vesicoureteral reflux, upper tract deterioration is the ultimate fate of significant outlet obstruction. At this point the management includes urethral dilation (incision), open urethroplasty, or upper tract diversion. If renal function is compromised, the choice must achieve unquestionable free drainage to allow the upper tracts and kidneys to recover fully. Further bladder neck or urethral reconstruction should not be performed until the posterior urethral stricture is clearly repaired and free drainage has been achieved. After CPRE repair, up to 50% of patients will require bilateral ureteral reimplantation during the first year following their operation because of UTIs and increasing hydronephrosis.

Despite satisfactory closure, some bladders never achieve adequate capacity to act as functional bladders. It has become clear that multiple bladder closures, bladder prolapse, dehiscence, bladder calculi, recurrent infections, and vesicostomy have a negative impact on the potential of the exstrophy bladder (Silver et al, 1997b). The authors have used transurethral injection of collagen around the bladder neck to increase outlet resistance and stimulate the bladder to grow. However, in our hands this has not been as successful as reported by Caione and colleagues (Caione et al, 1993a, 1993b) from Italy. If the bladder does not grow to a sufficient size for bladder neck reconstruction, bladder augmentation is recommended in this situation. If the bladder neck or urethra

or both are problematic, a catheterizable continent stoma with or without bladder neck plasty or transection is performed, along with augmentation (Gearhart et al, 1995b).

Failed Bladder Neck Repair

Early successful bladder closure with or without pelvic osteotomy with a good bladder template is the first step to achieve voided continence. Early epispadias repair with good bladder growth (>100 mL) is the second step in this sequence. Proper patient selection with a motivated family and, lastly, proper execution in the operating room are the final steps in this journey. Nonetheless, missteps can occur and there remains a subgroup of children with urinary incontinence after bladder neck reconstruction secondary to (1) inadequate outlet resistance; (2) a small bladder capacity (lack of growth after bladder neck reconstruction); (3) decreased compliance; and (4) a combination of these factors.

If urinary continence, defined as a 3-hour dry interval, is not achieved within 2 years after bladder neck reconstruction, failure to achieve dryness has resulted. Occasionally, the dry interval is nearly acceptable for daytime dryness (i.e., longer than 2 hours). In these situations, collagen injections into the bladder neck can move the dry interval up to 3 hours, but more than one injection may be required (Ben-Chaim et al, 1995a). Data from Lottmann with the use of dextranomer implant (Deflux) have shown improvement in the dry interval when used following partial success with bladder neck reconstruction. Some successes have been seen with repeated Young-Dees-Leadbetter repair if the bladder neck is patulous, the bladder capacity is adequate, and urodynamic evaluation reveals a stable bladder (Gearhart et al, 1991). In a series by Gearhart and colleagues (1991), only 50% of patients with a failed prior bladder neck reconstruction were candidates for reoperative surgery. In this highly select group, continence rates were acceptable after reoperative bladder neck reconstruction. All of these patients had excellent bladder capacity (>100 mL) and were stable on urodynamics before the redo repair. A majority of bladder neck failures require eventual augmentation or continent diversion. The artificial urinary sphincter has been used with some success in patients who have a good bladder capacity. However, in most of these failures the bladder capacity is small and augmentation is required. At the time of reoperative surgery, either the bladder neck is transected proximal to the prostate with a Mitrofanoff substitution or a continence procedure such as an artificial sphincter or collagen injection, or both, are performed. In the authors' extensive experience with failed bladder neck reconstructions, most of the patients have had several surgeries and need to be dry. In a recent large series of 31 patients who had undergone prior bladder neck reconstruction, studied by Novak and colleagues (2009), most patients had undergone multiple prior repairs to achieve continence. Bladder neck transaction along with enterocystoplasty was performed with initial continence achieved in 86%. Seven patients underwent further bladder neck surgery, and 90% achieve dryness by intermittent catheterization. One renal unit was lost, nonobstructive hydronephrosis developed in 8, and bladder stones formed in 30%.

Delayed urinary continence has been reported at the onset of puberty in some males and has been attributed to prostatic growth. On MRI, the prostate of exstrophy patients is clover shaped and absent anteriorly, and its mean weight and maximal cross section and volume are normal (Gearhart et al, 1992). Therefore it is doubtful that growth of this abnormally configured prostate can have much impact on later urinary continence after failed bladder neck repair.

Failed Genitourethral Reconstruction

Common complications of modern epispadias repair include urethrocutaneous fistula formation. This has been reported in as little as 4% and up to 19% of cases (Kajbafzadeh et al, 1995; Surer et al, 2001a). Urethral tortuosity with difficult catheterization or strictures is uncommon with modern epispadias repair. Since the application of the penile disassembly for epispadias reconstruction, newer, more significant complications have been noted (Hammouda, 2003). Gearhart and Baird (2004) have reported loss of the glans, corpora, or both in addition to loss of penile skin and the urethral plate. Whether this is secondary to surgical misadventure, vagaries in the blood supply of the penis, or the intrinsic difficulties in the procedure remains a topic of debate. Reconstruction of these complications has required additional techniques including tissue expansion, full-thickness skin grafting, buccal mucosal grafting, and other complex techniques. In some patients with significant losses, tissue engineering may eventually provide the material for final cosmetic reconstruction.

At an older age, unsightly penile scars and a short phallus may prompt further surgical intervention. Scar excision can be closed in a plastic fashion if enough penile skin is available. Otherwise, flaps or full-thickness skin grafts can be used. In severe cases, tissue expanders can be placed under the penile skin and gradually inflated over 6 weeks to allow more penile skin and obviate the need for grafting. Freeing all scar tissues and suspensory ligament tissue can maximize available penile length. A dorsal dermal corporal graft or ventral corporal plication or rotation may additionally help lengthen and correct any chordee. However, it must be recognized that the exstrophy penis, when compared with age- and race-matched controls, is congenitally deficient in anterior corporal tissue as assessed by MRI (Silver et al, 1997b). Therefore overly aggressive attempts at penile lengthening may result only in corporal denervation and devascularization without additional lengthening.

Alternative Techniques of Reconstruction

Not all children with bladder exstrophy are candidates for primary repair at initial evaluation because of a small bladder plate or significant hydronephrosis. Additional reasons for seeking other methods of treatment include failure of initial closure with a small remaining bladder or failure of continence surgery, or both. Excluding the patients in whom initial treatment fails, this discussion deals with options available when modern repair is not chosen by the surgeon or for other reasons has not been suitable.

Ureterosigmoidostomy

Whichever urinary diversion is chosen, the upper tracts and renal function are initially normal. This allows the reimplantation of normal-sized ureters in a reliable, nonrefluxing manner into the colon or other suitable reservoir. Historically, ureterosigmoidostomy was the first form of diversion to be popularized for patients with exstrophy. Although the initial series was associated with multiple metabolic problems, results improved markedly with newer techniques of reimplantation (Zarbo and Kay, 1986; Koo et al, 1996). Ureterosigmoidostomy is favored by some because of the lack of an abdominal stoma. **However, this form of**

diversion should not be offered until one is certain that anal continence is normal and after the family has been made aware of the potential serious complications including pyelonephritis, hyperkalemic acidosis, rectal incontinence, ureteral obstruction, and delayed development of malignancy (Spence et al, 1979; Duckett and Gazak, 1983). More recently, ureterosigmoidostomy has been proposed again as an initial treatment of bladder exstrophy with acceptable continence and renal preservation on follow-up of 10 years or longer. In a recent long-term study by Gobet and colleagues (2009) of 42 patients, 50% had their ureterosigmoidostomy in place and were fecally continent at 50 years of age. One had suffered a colonic malignancy, and 60% had normal renal function.

Stein and colleagues (1999) treated a group of 128 patients with bladder exstrophy-epispadias with the Mainz technique for ureterosigmoidostomy. The Mainz Sigma pouch is constructed, and the ureters are reimplanted in a nonrefluxing manner. The abdominal wall is reconstructed and the bladder is closed as a seminal receptacle above the prostate. The penis is then reconstructed at a later date. D'elia and colleagues (2004) reported on 26 patients with the exstrophy-epispadias complex who showed excellent continence rates with long-term upper tract preservation when compared with standard ureterosigmoidostomy. Continence was achieved in 95% of patients with a rectal reservoir. Their recommendation for treatment in a number of patients with severely impaired renal function was that a colonic conduit was the best method of choice for diversion. In the patients with a normal or slightly dilated upper tract and intact anal sphincters, a Mainz rectal reservoir was recommended. Although the group from Mainz reported no cancer in a long-term follow-up study of patients who underwent ureterosigmoidostomy, the risk for malignancy still exists and must be carefully considered in a young child. Patients who have had mixing of urine and feces at any time during reconstruction remain at high risk for the development of cancers (Smeulders and Woodhouse, 2001). Bladder exstrophy patients who have failed an initial reconstruction and have polyposis at the time of repeated closure may also be at higher risk for the later development of malignancy (Novak et al, 2005). This is especially true in today's mobile society, in which careful long-term follow-up may be difficult to guarantee.

Continent Urinary Diversion in the Exstrophy Patient

In modern pediatric urology there is usually little need for incontinent urinary diversion in the patient with bladder exstrophy. In a young child with a bladder that is too small to close, or in a failed closure where the bladder template is too small to reclose, the authors recommend a nonrefluxing colon conduit. This protects the kidneys from vesicoureteral reflux, and undiversion can be performed when clinically indicated at an older age.

Advances in the reconstruction of the lower urinary tract in the past several years have been applied to the patient with exstrophy (Cervellione et al, 2008). Most commonly, further reconstruction is required in the patient in whom bladder neck reconstruction has failed. If a patient does not meet the criteria for bladder neck reconstruction (i.e., inadequate bladder capacity or inability to conform to a voiding regimen), deferring surgery is advisable. Patients in whom bladder neck reconstruction fails are most often destined to augmentation cystoplasty and continent urinary diversion. Surer and colleagues (2003) reported on 91 patients with the exstrophy-epispadias complex who underwent continent urinary diversion. Eight patients had bladder exstrophy, eight had cloacal exstrophy, and three had complete epispadias. The majority had undergone prior failed bladder neck reconstruction ($n = 62$). Seventy-nine patients (87%) had exstrophy closure before referral, 53 had also undergone bladder neck reconstruction, and 29 patients had never reached adequate capacity for bladder neck reconstruction. Ten of the 53 patients had undergone one prior attempt, 35 had two prior attempts, and 8 had three prior attempts at bladder neck reconstruction. A combined augmentation cystoplasty, continent urinary diversion, and bladder neck closure was performed in 59 patients (65%), and reaugmentation and continent urinary diversion was performed in 18 children. Ileocystoplasty was used in 41 patients, and sigmoid cystoplasty was performed in 30 patients. The appendix was used as the continent urinary diversion in 67 patients. Continence using intermittent catheterization through the stoma was achieved in 93% of children with the most common complication reported being that of bladder stones, noted in 26%. Although low, failures can occur with continent urinary diversion in exstrophy (Frimberger et al, 2003). The most common mode of failure was a deintussusception of a nipple valve, inadequate tunnel for an appendiceal channel, or continued bladder neck incompetence. The vast majority of these complications can be successfully repaired. Equally successful outcomes have been reported by Baird and colleagues (2005a) in adolescents who had undergone a mean of eight prior procedures before their definitive repair.

Continence can be achieved in most patients with exstrophy following failure of bladder neck reconstruction. This continence is typically obtained through augmentation cystoplasty and revision of the bladder neck reconstruction or closure. If a patient is unlikely to develop adequate capacity for eventual bladder neck reconstruction, moving early to continent urinary diversion is preferable. One long-term concern has been the risk of malignancy in these patients over the long term. Recent data by Higuchi and colleagues (2010) revealed that the overall rate of malignancy is low unless associated with coexisting carcinogenic stimuli (prolonged tabacco/chronic immunosuppression) or the inherent risk associated with bladder exstrophy.

Key Points: Bladder Exstrophy—Priorities in Management

- Size and quality of bladder template
- Extent of pubic diastasis and malleability of the pelvis
- Need for osteotomy
- Length and width of urethral plate
- Penile size
- Associated anomalies

CLOACAL EXSTROPHY

Cloacal exstrophy includes a spectrum of abnormalities but is primarily an anterior abdominal wall defect. A reported incidence of 1:200,000 to 1:400,000 makes this one of the rarer urologic abnormalities (Hurwitz et al, 1987). Although prior reports have suggested a male/female ratio of 2:1 (Gearhart and Jeffs, 1998), a large study by Boyadjiev and colleagues (2004a) indicated that the sex ratio may be 1:1. Most cases are sporadic, and isolated incidences of unbalanced translocations have been reported to be potentially causative (Thauvin-Robinet et al, 2004); however, one report noted recurrence in siblings, perhaps indicating a more multifactorial etiology. Associated defects of the neurospinal axis,

intestinal tract, and urogenital and skeletal systems are frequently noted. When neurospinal defects and omphalocele coexist with cloacal exstrophy, the term *OEIS complex* (*o*mphalocele, *ex*strophy, *i*mperforate anus, *s*pinal defects) has been used (Keppler-Noreiul, 2001). Advances in critical care of children have resulted in most patients surviving into adult life and modified the focus to improving quality of life (Mathews et al, 1998).

Anatomic Considerations

The classic constellation of anomalies that are noted in children with cloacal exstrophy includes exstrophy of the bladder, complete phallic separation, wide pubic diastasis, exstrophy of the terminal ileum between the two halves of the bladder, a rudimentary hindgut, imperforate anus, and the presence of an omphalocele (Fig. 124–28). Many children have associated spinal defects, and various lower extremity malformations may be noted (Loder and Dayioglu, 1990; Jain and Weaver, 2004). The urogenital anomalies in cloacal exstrophy are similar to those seen with classic bladder exstrophy (see earlier), although they are typically of greater severity.

Neurospinal Abnormalities

Abnormalities of the spinal cord or vertebral column, or both, have been noted in 85% to 100% of children with cloacal exstrophy (Appignani et al, 1994; McLaughlin et al, 1995). Although most patients have lumbar myelodysplasia (80%), thoracic defects may be noted in 10% with the remaining having sacral defects. In a large series of 34 patients from a single center with cloacal exstrophy and associated spinal defects, Mathews and colleagues (1998) noted lipomeningocele in 17, myelomeningocele in 8, and spina bifida and isolated cord tethering in 7 and 2 patients, respectively. The nearly universal incidence of spinal abnormalities has led some authors to suggest MRI for all patients with a diagnosis of cloacal exstrophy (Cohen, 1991). Spinal ultrasound evaluation, which is easily performed, has been noted to be comparable with MRI for the diagnosis of spinal anomalies in infants with cloacal exstrophy (Dick et al, 2001). Karrer and colleagues (1988) noted that only one in five children with spinal dysraphism noted on ultrasonography had a sacral abnormality visible on the skin surface.

The embryologic basis for the neurospinal defects associated with cloacal exstrophy has been postulated to be secondary to problems with the disruption of the tissue of the dorsal mesenchyme rather than failure of neural tube closure (McLaughlin et al, 1995). Alternatively, it has been suggested that the defects that lead to the formation of cloacal exstrophy may lead to the developing spinal cord and vertebrae being pulled apart (Cohen, 1991). Functional deficits can range from patients who have almost normal sensation of the pelvis and lower extremity to patients who are wheelchair bound. The presence of a clinically significant neurologic anomaly was found to affect negatively the development of continence (Husmann et al, 1999) and led to a significant reduction in continence when compared with patients

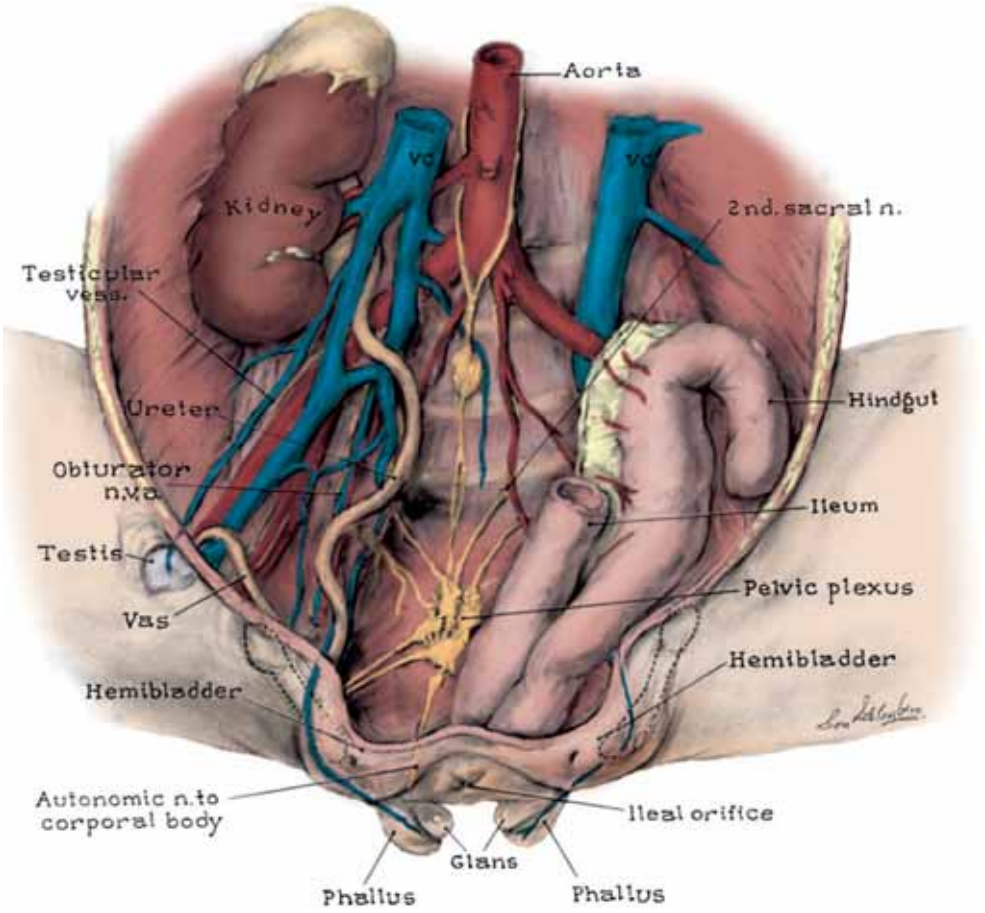

Figure 124–28. Internal view of a patient with cloacal exstrophy. Pudendal vessels, nerves, and other vessels and autonomic innervation of the corporal bodies are demonstrated. Internal structures of the pelvis along with duplication of the vena cava in this dissected specimen are also shown.

with bladder exstrophy. Only 1 of 13 neurologically impaired patients in this series developed voided continence.

The neuroanatomic dissections performed by Schlegel and Gearhart (1989) further indicate that the neuroanatomic landmarks in the infant with cloacal exstrophy are different from those in the normal newborn with the autonomic bladder innervation being derived from a more medial location (see Fig. 124–28). This potentially puts the nerve supply in jeopardy during initial bladder dissection and reconstruction and may leave the bladder neuropathic following reconstruction (Husmann et al, 1999). **Innervation to the duplicated corporal bodies arises from the sacral plexus, travels in the midline, perforates the interior portion of the pelvic floor, and courses medially to the hemibladders** (Schlegel and Gearhart, 1989). Innervation abnormalities were also noted at a histologic level in the studies by Rosch and colleagues (1997). When compared with those in patients with bladder exstrophy, the neural elements identified on immunohistochemical evaluation were found to show significant structural abnormalities.

Skeletal System Abnormalities

Anomalies of the skeletal system are universally noted in children with cloacal exstrophy (Suson et al, 2009). The pelvic defects that are seen with classic bladder exstrophy are noted with greater severity in the patient with cloacal exstrophy. Sponseller and colleagues (1995), studying patients with the exstrophy complex, noted that the posterior segment of the pelvis in children with cloacal exstrophy was angled farther posteriorly and there was a greater likelihood of asymmetry between the two sides. Similarly, the anterior segment of the pelvis had more severe degrees of external rotation. The actual length of the bone segments, however, was similar between those with cloacal and classic exstrophy. The interpubic distance (diastasis) in children with cloacal exstrophy was noted to be almost twice that of children with classic bladder exstrophy. Malformation of the sacroiliac joints and side-to-side asymmetry were also noted. These issues become of increasing importance, and most children with cloacal exstrophy require osteotomy for successful reconstruction. Stec and colleagues (2003) noted that, microscopically, the bones in children with cloacal exstrophy were similar to those in normal controls and were developing at a similar rate, indicating that the potential for growth was also similar.

Vertebral anomalies that were not associated with myelodysplasia were noted in 8 of 37 children with cloacal exstrophy (Mathews et al, 1998). Loder and Dayioglu (1990) noted vertebral anomalies in three of five children with cloacal exstrophy. Absence or shortening of limbs was also noted, as were clubfoot malformations. **Skeletal and limb anomalies were also reported by** Diamond (1990) **in 12% to 65% of cases.** The vast majority were clubfoot deformities, although absence of feet, severe tibial or fibular deformities, and congenital hip dislocations were commonly noted in this group of patients. A similar high incidence of foot abnormalities and greater than normal abduction of the hips was noted in a study by Greene and colleagues (1991).

Intestinal Tract Abnormalities

Gastrointestinal tract anomalies occur in virtually all patients with cloacal exstrophy. **In Diamond's series** (1990), **the incidence of omphalocele was 88% and a majority of all series reported an incidence of 95% or greater.** In the series reported by Mathews and colleagues (1998), 100% had an omphalocele. Omphaloceles do vary in size and usually contain small bowel or liver, or both. Immediate closure of the omphalocele defect in the newborn period is advised to prevent subsequent rupture.

Hurwitz and colleagues (1987), in a large review of cloacal exstrophy patients, reported a 46% incidence of associated gastrointestinal tract anomalies, with malrotation, duplication anomalies, and anatomically short bowel occurring with equal frequency. A hindgut remnant of varying size is also noted in most patients (Sawaya et al, 2010). Hurwitz noted a 23% incidence of short gut syndrome, which is compatible with the 25% incidence reported by Diamond (Hurwitz et al, 1987; Diamond, 1990). It now seems well accepted that short gut syndrome may occur in the presence of normal small bowel length, suggesting absorptive dysfunction and emphasizing the absolute need to preserve as much large bowel as possible. If not used for incorporation into the fecal stream, the hindgut remnant may be preserved for use in urogenital tract reconstruction (Mathews et al, 1998).

Genitourinary Abnormalities

Müllerian anomalies have been frequently noted in conjunction with cloacal exstrophy. **The most commonly reported müllerian anomaly was uterine duplication, seen in 95% of patients** (Diamond, 1990). The vast majority of these patients had partial uterine duplication, predominantly a bicornate uterus. Vaginal duplication occurred in 65% of cases, and vaginal agenesis was seen in 25% to 50% of patients. In a report by Hurwitz and colleagues (1987), cases of complete duplication of the uterus and fallopian tubes associated with both vaginal duplication and vaginal agenesis were noted. Gearhart and Jeffs (1991b) recommended preservation of all müllerian duplication anomalies for possible utilization in reconstructing the lower urinary tract.

Upper urinary tract anomalies occurred in 41% to 60% of patients in Diamond's review. The most common anomalies were pelvic kidney and renal agenesis, both occurring in up to one third of patients. Hydronephrosis and hydroureter were common, occurring in one third of patients. Multicystic dysplastic kidneys and fusion anomalies were seen less frequently. Ectopic ureters draining to the vasa in the male and into the uterus, vagina, or fallopian tubes in the female were also reported (Diamond, 1990). A similar incidence of upper tract defects was noted by Mathews and colleagues (1998). Ureteral duplication, congenital stricture, and megaureter were also reported.

Genital anomalies in the male have typically included complete separation of the two phallic halves and accompanied separation of the scrotal halves. Asymmetry of these structures can also be seen and provide additional challenges to successful reconstruction. Testes may be noted in the scrotum but are frequently noted to be undescended, and associated inguinal hernias are a common finding. Girls typically have widely divergent clitoral halves.

The lower urinary tract is typically composed of two exstrophied hemibladders flanking the exstrophied intestinal segment. Each bladder half usually drains the ipsilateral ureter and is closely related to the ipsilateral phallic segment. Variations of anatomy, however, are frequently seen and every patient has unique anatomic features.

Additional System Anomalies

Life-threatening cardiovascular and pulmonary anomalies are rarely seen in cloacal exstrophy. Reported cases included two patients with cyanotic heart disease and one with aortic duplication. A bilobed lung was reported in two patients and an atretic right upper lung in one. Also, Schlegel and Gearhart (1989) reported caval duplication in their anatomic dissection of a patient with cloacal exstrophy.

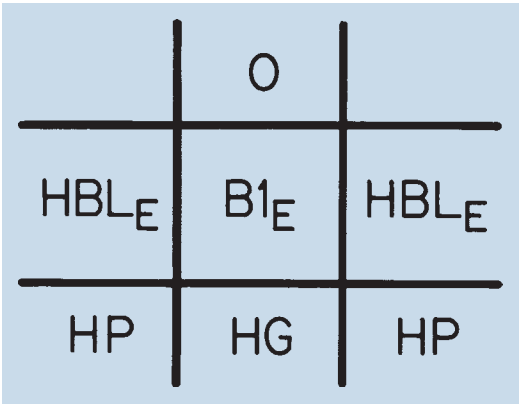

Figure 124–29. Coding grid used to describe cloacal exstrophy and its variants. O, omphalocele; HBLE, hemibladder; B1E, everted bowel; HP, hemiphallus; HG, hindgut. (From Hurwitz RS, Manzoni GA, Ransley PG, Stephen FD. Cloacal exstrophy: a report of 34 cases. J Urol 1987;138:1060.)

Because of the complexity and the multisystem nature of cloacal exstrophy, Hurwitz and coauthors (1987) have devised a grid for the clarification of anatomy in each patient and to permit planning for reconstruction (Fig. 124–29). This permits the standard form of cloacal exstrophy to be separated from variants and allows the soft tissue components of the defect to be described systematically.

Prenatal Diagnosis

Since its initial description in the early 1980s, further refinements in the prenatal diagnosis of cloacal exstrophy have occurred (Meizner and Bar-Ziv, 1985). These authors indicated that the three main criteria used to identify the diagnosis were a large midline infraumbilical anterior abdominal wall defect, lumbosacral myelomeningocele, and failure to visualize the urinary bladder. Chitrit and colleagues (1993) reported the diagnosis of monozygotic twins with cloacal exstrophy detected during antenatal ultrasound screening. Since these initial reports, there have been only occasional case reports of prenatal diagnosis of cloacal exstrophy, and only 15% of patients with this anomaly have been diagnosed by prenatal ultrasonography, according to the literature. With the marked improvements in survival of patients with cloacal exstrophy in the past 20 years and the common application of fetal ultrasonography, early diagnosis may permit appropriate prenatal counseling for parents and expedite postnatal care.

Austin and colleagues (1998) reviewed 20 patients with this abnormality, expanded on the diagnostic findings, and proposed major and minor criteria for the prenatal diagnosis of cloacal exstrophy on the basis of the frequency of occurrence rather than the severity of individual findings. A criterion was considered major if it was present in more than 50% of cases. The gestational age at diagnosis of cloacal exstrophy ranged from 15 to 32 weeks (mean, 22 weeks). Major diagnostic criteria included nonvisualization of the bladder in 91%, a large midline infraumbilical anterior wall defect or a cystic anterior wall structure in 82%, an omphalocele in 77%, and a myelomeningocele in 68%. Minor criteria included lower extremity defects in 23%, renal anomalies in 23%, ascites in 41%, widened pubic arches in 18%, narrow thorax in 9%, hydrocephalus in 9%, and a single umbilical artery in 9%. Hamada and colleagues (1999) reported a single case in which ultrasonography revealed a wavy cordlike segment of soft tissue protruding from the anterior abdominal wall of the fetus below the umbilicus. This was found to be prolapsed terminal ileum, which resembled the trunk of an elephant. The authors suggested that this sonographic image be added to the criteria described by Austin and colleagues (1998) for making a prenatal diagnosis of cloacal exstrophy.

Universal use of antenatal ultrasonography has permitted diagnosis of cloacal exstrophy to be made at a time when parental counseling may lead to possible pregnancy termination. Extensive parental counseling regarding the significant anatomic anomalies that constitute the complex is appropriate in conjunction with psychologic support.

SURGICAL RECONSTRUCTION OF CLOACAL EXSTROPHY

The initial successful reconstruction of cloacal exstrophy was reported by Rickham (1960). Survival in the 1970s remained at about 50%; however, the institution of intensive postnatal care led to improvement in survival in the 1980s to almost 100%.

Evaluation and Management at Birth

Immediate management is directed to the medical stabilization of the infant. Complete physical examination and determination of the various anatomic defects present allow short- and long-term management strategies to be created (Table 124–4). This initial planning stage should include decisions about gender assignment. The bowel and bladder segments are kept moist with protective plastic dressings as with bladder exstrophy (Gearhart and Jeffs, 1998). Presence of neurospinal abnormalities requires immediate neurosurgical evaluation. Consultations from social work, pediatric orthopedic surgery, and other disciplines should be obtained. Evaluation of the genitalia and gender assignment should be made by a gender assignment team including a pediatric urologist, pediatric surgeon, pediatrician, pediatric endocrinologist, and child psychologist or psychiatrist. Gender assignment decisions should be made in conjunction with appropriate parental counseling and involvement. In a large medical center with experience in dealing with complex malformations, these multiple consultations should be done in a short period of time. If there are medical concerns, delayed closure after initial intestinal diversion is appropriate (Mathews et al, 1998).

Gender Assignment

Because of the significant separation of the corpora of the penis and scrotum and the reduction in corporal size noted in boys with cloacal exstrophy, early reports had recommended universal gender reassignment of boys (46,XY) with cloacal exstrophy to functional females (Tank and Lindenaur, 1970). To this end, bilateral orchiectomy was combined with phallic reconstruction as a functional clitoris and early or delayed vaginoplasty. Reiner (2004) has reported on 29 males with cloacal exstrophy who had gender reassignment to female. Psychosexual evaluation indicated that all of these patients had a marked male shift in psychosexual development despite having no pubertal hormonal surges. A comparison of patients with cloacal exstrophy and other cloacal anomalies at the Great Ormond Street, however, indicated no difference in social or behavioral competence or psychologic problems. Gender assignment was not associated

Table 124–4.

Modern Functional Reconstruction of Cloacal Exstrophy

Immediate Neonatal Assessment

Evaluate associated anomalies
Decide whether to proceed with reparative surgery

Functional Bladder Closure (Soon after Neonatal Assessment)

ONE-STAGE REPAIR (FEW ASSOCIATED ANOMALIES)

Excision of omphalocele
Separation of cecal plate from bladder halves
Joining and closure of bladder halves and urethroplasty
Bilateral anterior innominate and vertical iliac osteotomy
Gonadectomy in males with unreconstructible phallus
Terminal ielostomy/colostomy
Genital revision if needed

TWO-STAGE REPAIR

First stage (newborn period)
- Excision of omphalocele
- Separation of cecal plate from bladder halves
- Joining of bladder halves
- Gonadectomy in male with unreconstructible phallus

Terminal ileostomy/colostomy
Second stage
- Closure of joined bladder halves and urethroplasty
- Bilateral anterior innominate and vertical iliac osteotomy
- Genital revision if necessary

Anti-Incontinence/Reflux Procedure (age 4-5 yr)

Bladder capacity ≥ 85 mL (small select group of patients)
- Young-Dees-Leadbetter bladder neck reconstruction
- Bilateral Cohen ureteral reimplantations
- Bowel and/or stomach segment used to augment bladder

or

- Continent diversion with abdominal/perineal stoma

Vaginal Reconstruction

Vagina constructed or augmented using colon, ileum, or full-thickness skin graft

Figure 124–30. A 46,XY child with cloacal exstrophy with a dominant right hemiphallus. This child was reconstructed and reared as male.

with childhood psychologic, emotional, or behavioral problems (Baker Towell and Towell, 2003). Schober and colleagues (2002), reporting on 14 children who had undergone early gender reassignment, indicated that although patients had masculine childhood behavior, they had a feminine gender identity. Currently, however, most authors recommend assigning gender that is consistent with karyotypic makeup of the individual if at all possible (Fig. 124–30). This policy can be supported by a report indicating that the histology of the testis at birth is normal (Mathews et al, 1999a). Furthermore, with evolution of techniques for phallic reconstruction, a functional and cosmetically acceptable phallus can now be constructed (Husmann et al, 1989).

Immediate Surgical Reconstruction

Cloacal exstrophy patients should undergo carefully planned and individualized reconstructions (Ricketts et al, 1991; Lund and Hendren, 1993; Mathews et al, 1998). For infants with spinal dysraphism and myelocystocele, neurosurgical consultation should be obtained and closure undertaken as soon as the infant is medically stable. After closure of the myelocystocele, long-term follow-up is mandatory to evaluate for subtle changes in the neurologic evaluation that could herald cord tethering. Symptomatic spinal cord tethering can be seen in up to 33% of children (McLaughlin et al, 1995).

Neonatal omphalocele closure is recommended to prevent untimely rupture and is typically combined with intestinal diversion. Formerly, initial attempts focused on ileostomy with resection of the hindgut remnant. **Since the recognition of the metabolic changes that occur in patients with ileostomy, an attempt has always been made to use the hindgut remnant to provide additional length of bowel for fluid absorption** (Husmann et al, 1989; Mathews et al, 1998). Enlargement of the hindgut remnant and increased water absorption have been noted in children who have had this segment incorporated into construction of a fecal colostomy. The hindgut segment may be anastomosed in an isoperistaltic or retroperistaltic fashion to increase motility and generate formed stool. Children who have anal stenosis and not imperforate anus may have the capability for later continence and may be treated with a pull-through procedure (Ricketts et al, 1991). If the hindgut remnant is not used for bowel reconstruction, it should be left as a mucus fistula to be used for later bladder augmentation or vaginal reconstruction (Lund and Hendren, 1993; Mathews et al, 1998). If gastrointestinal reconstruction is combined with bladder closure, approximation of the pubis, usually with osteotomies, is beneficial in reconstruction of the pelvic ring and increases the potential for successful bladder and abdominal wall closure (Mathews et al, 1998). Some authors have suggested that gastrointestinal reconstruction after initial fecal diversion be delayed for 1 to 2 years of observation (Soffer et al, 2000). After this time, radiographic evaluation is performed to determine residual colonic length. If near-normal colonic length is noted, a pull-through procedure is performed. If there is short colon but the patient is able to make solid stool, the patient may still be a candidate for pull-through procedures. Patients who are unable to make solid stool are typically managed with a permanent fecal stoma.

At the initial stage of omphalocele closure, if it is determined that bladder and abdominal wall closure may not be accomplished, the bladder halves are approximated in the midline without further dissection and the defect is converted to a bladder exstrophy (Ricketts et al, 1991; Mathews et al, 1998). This permits abdominal distention to allow enlargement of this bladder plate for later closure. If the hindgut segment is not used in the initial reconstruction of the bowel, it is left as a mucus fistula.

Urinary Reconstruction

Modern Staged Reconstruction

The staged management of the urinary tract follows that used for the management of bladder exstrophy (Gearhart and Jeffs, 1991b). Once the bladder halves have been approximated posteriorly, the lateral edges are separated from the abdominal wall and brought together in the midline. As in the patient with classic exstrophy, placement of the bladder and posterior urethra deep into the pelvis remains a key factor in the successful surgical reconstruction of the urinary tract. Inguinal hernias that are noted should be repaired at the time of closure. In genetic females and in genotypic male subjects undergoing gender reassignment, reconstruction should be performed to improve the appearance of the genitalia. Recent reports by Thomas and colleagues (2007) in a series using a staged approach found successful results in a series of seven patients all with tethered cords.

Reconstruction of the external genitalia in the immediate postnatal period is performed to make the infant appear more congruent with the gender assigned. The psychiatric studies of children who have had gender assignment have fueled interest in male gender assignment if adequate unilateral or bilateral corporal tissue is present (Reiner, 2004). Histologic studies indicate normal histology in the testes of male subjects who have had gender reassignment despite the presence of cryptorchidism (Mathews et al, 1999a). Results of phallic reconstruction in male patients with minimal or no penile tissue in the past have been disappointing. For male-to-female reassignment, initial female genital reconstruction should bring the phallic halves together in the midline as a clitoris.

However, in instances with adequate corporal tissue, either unilaterally or bilaterally, epispadias repair can be performed at around age 1 using the standards identified for the staged reconstruction. Vaginal reconstruction can be performed early in the genetic female patient. In gender-converted male patients who require reconstruction of a neovagina, delayed reconstruction is appropriate. Reconstruction may be performed by using a preserved hindgut segment or expanded perineal skin. Long-term dilatation of the neovagina may be required.

Pubic approximation permits abdominal wall closure and usually requires osteotomy and fixation with postoperative traction. External fixation and traction are typically maintained for 6 to 8 weeks to permit healing.

Role of Osteotomy

Infants who are medically stable may be considered for urinary tract reconstruction in the immediate postnatal period. Osteotomy is indicated in all children with cloacal exstrophy at the time of bladder closure because of the wide diastasis that is invariably present (Mathews et al, 1998). Osteotomy allows the pelvic ring, bladder, and abdominal wall to be closed without undue tension on the closure. Reduction in dehiscence and postoperative ventral hernias has been noted in patients treated with osteotomy. In a large series reported by Ben-Chaim and colleagues (1995c), significant complications occurred in 89% of patients who underwent closure of the cloacal exstrophy without osteotomy but in only 17% of patients who underwent osteotomy at the time of initial cloacal exstrophy closure. Interestingly, the patients who underwent osteotomy and those who did not were similar in terms of size of the omphalocele, presence of myelomeningocele, and time of primary closure. However, it is not surprising that osteotomy had no effect on eventual continence of patients with cloacal exstrophy.

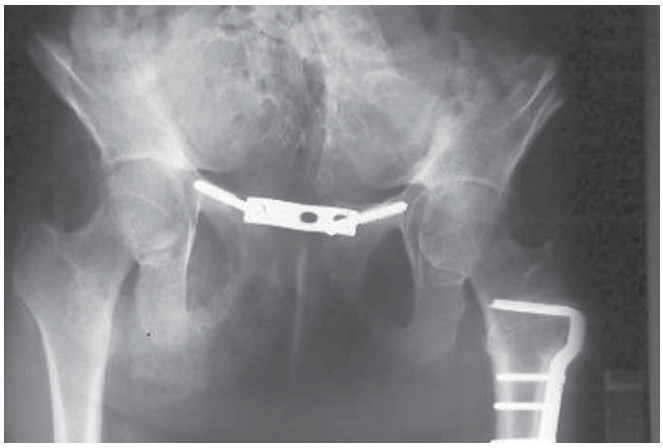

Figure 124–31. Pubic approximation and maintenance with a stainless steel plate in a child with cloacal exstrophy.

Currently, combined anterior innominate and vertical iliac osteotomies are routinely used at our institution (Silver et al, 1999). This approach does not require the patient to be repositioned on the operating table before commencing bladder and abdominal wall closure. In addition, this method obviates the use of a posterior approach and any complication of the procedure related to the spinal or back closure. **In a series of five patients with extreme pubic diastasis greater than 10 cm, Silver and colleagues (1999) described initial pelvic osteotomy and gradual pelvic closure of the fixator for 1 to 2 weeks, followed by abdominal wall closure and bladder closure.** Closure was successful in all patients without technical problems or complications. This technique of staged pelvic closure may provide reliable initial secondary repair in patients with cloacal exstrophy in whom one-stage pelvic closure is not feasible, even with pelvic osteotomy. An interpubic stainless bar has been added to permit stabilization of the pubic approximation and maintain the reduction in diastasis (Fig. 124–31) (Mathews et al, 2005). Because of the possible asymmetry that can be noted in the pelvic bones, care must be used when performing osteotomies and fixation. In patients who have lower extremity abnormalities, providing postoperative traction can also be challenging.

Single-Stage Reconstruction

Grady and Mitchell (1999) have reported using a single-stage reconstruction in cloacal exstrophy—a procedure similar to that done for bladder exstrophy. Delay in urinary tract reconstruction has also been advised by these authors if there is a large omphalocele or other medical instability. In this situation, the conversion to a bladder exstrophy and subsequent reconstruction of the bladder and penis as a single step is performed. Among the small number of patients who have had this type of management strategy, occasional patients have been reported to be able to have voided continence. As with staged reconstruction, most patients have required augmentation cystoplasty for continence.

Techniques to Create Urinary Continence

Urinary continence is possible in most children but usually requires bladder augmentation and the use of intermittent catheterization. Multiple series by Gearhart and

Jeffs (1991b), Mitchell and colleagues (1990), and Hendren (1992) have shown the applicability of modern techniques for lower tract reconstruction to help these patients achieve urinary continence. Enhancement of bladder capacity may be performed using a hindgut segment, if available; ileum; or stomach. Continence appears to be more difficult to achieve in male patients who undergo gender reassignment, and a continent stoma may be most applicable in this special group of patients (Mathews et al, 1998). In genetic female patients, successful continence has been achieved after Young-Dees-Leadbetter bladder neck reconstruction, but the vast majority of patients have required intermittent catheterization (Husmann et al, 1999). Similar findings were reported in a series by Mitchell and colleagues (1990). Husmann and colleagues (1999) reported that the success rate of Young-Dees-Leadbetter bladder neck reconstruction in the cloacal exstrophy population was closely related to the presence of coexisting neurologic abnormalities.

Urinary continence can be achieved in these individuals in many ways. An orthotopic urethra can be constructed from local tissue, vagina, ileum, stomach, or ureter. A catheterizable stoma can be constructed from ileum when enough bowel is present and fluid loss is not a problem. The bladder may be augmented with unused hindgut, ileum, or stomach. However, surgery to provide a continent urinary reservoir should be delayed until a method of evacuation can be taught and the child is old enough to participate in self-care. The choice between a catheterizable urethra and an abdominal stoma depends on the adequacy of the urethra and bladder outlet, interest and dexterity of the child, and orthopedic status regarding the spine, hip joints, braces, and ambulation. In a series by Gearhart and Jeffs (1991b) and in another series by Mitchell and colleagues (1990), multiple techniques were used to produce continence in patients with cloacal exstrophy. An innovative approach is required to find a suitable solution for each individual patient according to the patient's bladder size and function and mental, neurologic, and orthopedic status. With the advent of modern pediatric anesthesia and intensive care, the newborn survival rate is high. Improving survivorship makes reconstructive techniques applicable in a large percentage of patients born with this condition.

LONG-TERM ISSUES IN CLOACAL EXSTROPHY

Because survival has become almost universal, the focus has changed in cloacal exstrophy to improving quality of life. Improvement in functional outcomes has become the mainstay of improving the quality of life. Patients presenting with significant neurologic defects need intensive management to provide improvement in quality of life. In this population, management of the bowel with permanent diversion and using continent catheterization channels for urinary management provide independence and promote improvement in self-esteem. When neurologic issues are minimal or absent, bowel pull-through and voided continence would be ideal. Ricketts and colleagues (1991) have presented a continence score that can be used in this group of children. Using a six-point scoring system to determine bowel and bladder continence (6 = best; 0 = worst), they evaluated 12 patients who had been managed over time. They had seven patients with a continence score of 1 (colostomy and incontinent bladder) and only one patient who had a score of 5 (enema program and a continent bladder), attesting to the difficulties presented with surgical reconstruction.

Some children have required permanent ileostomy for management of their gut. Husmann and colleagues (1989) noted that patients undergoing permanent ileostomy, in comparison with terminal colostomy, had greater initial morbidity; however, bowel adaptation appeared to occur by age 3 years with resolution of the short gut syndrome in most. If patients with terminal ileostomy were aggressively managed with hyperalimentation, growth characteristics in the two groups were similar.

Attempts at phallic reconstruction in the past had minimal success because of the diminutive nature of the corpora in boys and the wide pubic separation. Modern reconstructive surgical techniques may allow some boys to have complete phallic reconstruction performed with forearm grafts. Fertility appears to be universally compromised in boys, but girls have normal fertility and pregnancy has been reported. Girls have higher degrees of cervical prolapse when compared with their counterparts with bladder exstrophy.

Summary

Evolution in management of cloacal exstrophy has permitted near-universal survival with significant improvement in cosmetic and functional outcomes. Debate continues regarding the issue of gender reassignment, and long-term data are still accruing on the best strategy for management. Continence can be achieved with appropriate reconstruction and the use of intermittent catheterization. Despite the extensive malformations noted, many patients have gone on to live fruitful lives.

Key Points: Cloacal Exstrophy—Priorities in Management

- Assure medical stabilization of infant.
- Discuss and evaluate gender assignment with parents and consulting physicians.
- Discuss with all consultants colonic functionalization and presentation.
- Assume complete separation of the bladder from the mid-gut plate.
- Evaluate the need and potential for genital reconstruction.

EPISPADIAS

Epispadias varies from a mild glanular defect in a covered penis to the penopubic variety with complete incontinence in males or females. It is most commonly noted as a component of bladder and cloacal exstrophy.

Male Epispadias

Isolated male epispadias is a rare anomaly, with a reported incidence of 1 in 117,000 males. Most male epispadias patients (about 70%) have complete epispadias with incontinence (Gearhart and Jeffs, 1998). Epispadias consists of a defect in the dorsal wall of the urethra. The normal urethra is replaced by a broad, mucosal strip lining the dorsum of the penis extending toward the bladder, with potential incompetence of the sphincter mechanism. The displaced meatus is free of deformity, and occurrence of urinary incontinence is related to the degree of the dorsally displaced urethral meatus (Gearhart and

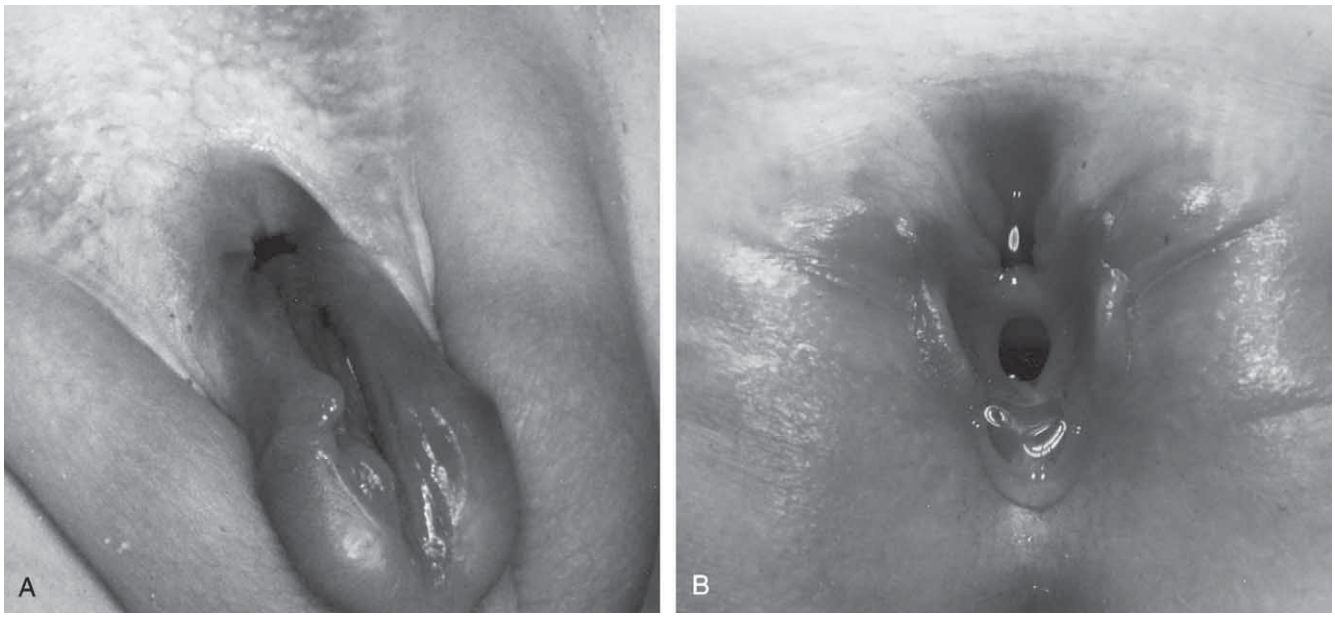

Figure 124–32. **A,** Three-month-old boy with complete epispadias. **B,** Six-month-old girl with complete female epispadias.

Jeffs, 1998). The displaced meatus may be found on the glans, penile shaft, or in the penopubic region. All types of epispadias are associated with varying degrees of dorsal chordee. In penopubic or subsymphyseal epispadias, the entire penile urethra is opened and the bladder outlet may be large enough to admit the examining finger, indicating obvious gross incontinence (Fig. 124–32A). To a lesser extent than those with classic bladder exstrophy, patients with epispadias have a characteristic widening of the symphysis pubis caused by outward rotation of the innominate bones. This separation of the pubis causes divergent penopubic attachments that contribute to the short, pendular penis with dorsal chordee. Therefore the penile deformity is virtually identical to that observed in bladder exstrophy. The reported male-to-female ratio of epispadias varies between 3 : 1 (Dees, 1949) and 5 : 1 (Kramer and Kelalis, 1982a).

Kramer and Kelalis (1982a) reviewed their experience with 82 male patients with epispadias. Penopubic epispadias occurred in 49 cases, penile epispadias in 21, and glanular epispadias in 12. Urinary incontinence was observed in 46 of 49 patients with penopubic epispadias, in 15 of 21 patients with penile epispadias, and in no patient with glanular epispadias. The goals of the treatment of complete male epispadias include creation of normal urinary control and establishment of a straight, cosmetically acceptable penis of adequate length that is functional for normal sexual intercourse. It has been postulated that complete male epispadias is similar to classic bladder exstrophy except that in complete epispadias the bladder is closed and bladder closure procedures are not required.

Associated Anomalies

Anomalies associated with complete epispadias are usually confined to deformities of the external genitalia, diastasis of the pubic symphysis, and deficiency of the urinary continence mechanism. The only renal anomaly observed in 11 cases of epispadias was agenesis of the left kidney (Campbell, 1952). In a review by Arap and colleagues (1988), 1 case of renal agenesis and 1 ectopic kidney occurred among 38 patients.

The ureterovesical junction is inherently deficient in complete epispadias, and the incidence of reflux has been reported in a number of series to be between 30% and 40% (Kramer and Kelalis, 1982a; Arap et al, 1988). In a review by Ben-Chaim and colleagues (1995b) of a series of 15 patients with complete male epispadias treated at our institution, a lower rate of vesicoureteral reflux was noted compared with male patients with classic bladder exstrophy (100% vs. 82%, respectively); the rate of inguinal hernias (33%) was also significantly lower. A possible explanation for the lower incidence of reflux in complete male epispadias is that the pouch of Douglas is not as enlarged and deep. Therefore the distal ureter enters the bladder in a more oblique fashion than in classic exstrophy (Gearhart and Jeffs, 1998).

Surgical Management

The objectives of repair of penopubic epispadias include achievement of urinary continence with preservation of the upper urinary tracts and the reconstruction of cosmetically acceptable genitalia. The surgical management of incontinence in penopubic epispadias is virtually identical to that in closed bladder exstrophy.

Young (1922) reported the first cure of incontinence in a male patient with complete epispadias. Since this initial report, continence following surgical reconstruction has progressively improved (Burkholder and Williams, 1965; Kramer and Kelalis, 1982a; Arap et al, 1988; Mollard et al, 1998; Peters et al, 1988). In patients with complete epispadias and good bladder capacity, epispadias and bladder neck reconstruction can be performed in a single-stage operation. Urethroplasty formerly was performed after bladder neck reconstruction (Kramer and Kelalis, 1982a; Arap et al, 1988). However, improvements in bladder capacity in the small bladder associated with exstrophy (Gearhart and Jeffs, 1989a) and that associated with epispadias (Peters et al, 1988) have led us to perform urethroplasty and penile elongation before bladder neck reconstruction. A small, incontinent bladder with reflux is hardly an ideal situation for bladder neck reconstruction and ureteral reimplantation. Before bladder neck reconstruction there was an average increase in bladder capacity of 95 mL within 18 months after epispadias repair in the patients with an initial small bladder capacity and a continence rate of 87% after the continence

procedure (Peters et al, 1988). **In a series by Ben-Chaim and colleagues (1995b) composed exclusively of patients with complete male epispadias, bladder capacity increased by an average of 42 mL within 18 months after urethroplasty.** Nine (82%) of 11 patients were dry day and night after an average of 9 months.

In epispadias, as in the bladder exstrophy, bladder capacity is the predominant indicator of eventual continence (Ritchey et al, 1988). Arap and colleagues (1988) reported higher continence rates in patients who had an adequate bladder capacity before bladder neck reconstruction than in those with inadequate capacity (71% vs. 20%, respectively). In addition, in Arap's group of patients with complete epispadias, most obtained continence within 2 years, similar to results in patients with classic bladder exstrophy.

A firm intrasymphyseal band typically bridges the divergent symphysis, and an osteotomy is not usually performed. The Young-Dees-Leadbetter bladder neck plasty, Marshall-Marchetti-Krantz suspension, and ureteral reimplantation are performed when the bladder capacity reaches approximately 80 to 85 mL, which usually occurs between 4 and 5 years of age. Genital reconstruction procedures in epispadias and exstrophy are similar. The following reconstructive maneuvers must take place: release of dorsal chordee and division of the suspensory ligaments; dissection of the corpora from their attachments to the inferior pubic ramus; lengthening of the urethral groove; and lengthening of the corpora, if needed, by incision and anastomosis or grafting or by medial rotation of the ventral corpora in a more downward direction.

Urethral reconstruction in complete epispadias has been performed in many ways. A transverse island flap was used by Monfort and colleagues (1987). The urethra, once reconstructed, can be positioned between and below the corpora (Cantwell, 1895; Ransley et al, 1989; Gearhart et al, 1992, 1995c). Mitchell and Bagli (1996) reported their experience with a complete penile disassembly technique, and a multicenter experience with the technique was later reported in a total of 17 patients from four institutions (Zaontz et al, 1998). Chordee was reliably corrected, erectile function was preserved, the urethra was eventually situated in a cosmetic fashion, and satisfactory cosmesis was achieved. A recent small series by Kropp and colleagues (2008) of patients with complete epispadias showed that complications using the disassembly repair were in the acceptable range. Unlike the use of this in the exstrophy group, there was no ischemia of the glans or corpora. However, most required additional surgery because hypospadias was created in a number of patients. Ransley and colleagues reported excellent results using the modified Cantwell-Ransley procedure, saving cavernocavernostomy for patients with severe chordee and especially those in the older age group (Kajbafzadeh et al, 1995; Surer et al, 2001a). For a detailed description of the surgical reconstruction, see the previous discussion in the section on bladder exstrophy.

Achievement of urinary continence after epispadias repair in patients with isolated epispadias is summarized in Table 124–5. A majority of these patients underwent reconstruction by means of a Young-Dees-Leadbetter bladder neck plasty. Urinary continence was obtained in 82% of male patients (Ben-Chaim et al, 1995b). As in the exstrophy population, repair of the epispadiac deformity results in an increase of outlet resistance and possible increase in bladder capacity before bladder neck reconstruction. Although both complete epispadias and bladder exstrophy patients achieve improvement in bladder capacity after epispadias repair, the mean increase in overall capacity is higher in those with complete epispadias. This increase in bladder capacity may account for increased continence in this group compared with the classic bladder exstrophy population. **Clinically, these bladders are more supple, easier to mobilize, and more amenable to bladder neck reconstruction.** Ben-Chaim and colleagues (1995b) reported that the mean time to initial continence following bladder neck reconstruction was 90 days in patients with complete male epispadias compared with 110 days in those with bladder exstrophy. These results suggest that, for patients with complete epispadias, bladder capacity before reconstruction and the rate of achieving continence afterward are better than for patients with bladder exstrophy. The reason might be that the bladder is not exposed in utero and does not have any scarring from prior closure; therefore its potential for expansion is higher.

It was formerly thought that the effect of urethral lengthening and prostatic enlargement might be significant in complete epispadias by increasing outlet resistance if continence was not perfect as the child became older. Earlier in a series by Arap and colleagues (1988), the establishment of continence had no relation to puberty and usually occurred within 2 years, usually preceding puberty by several years. In the series reported by Ben-Chaim and colleagues (1995b), as stated previously, all patients obtained daytime continence at a mean of 9 months after

Table 124–5.

bladder neck reconstruction, and 9 (82%) of 11 patients attained total day and night continence. All patients voided spontaneously. After a mean follow-up of 7 years, all patients maintained normal upper tracts and kidney function. All of them had cosmetically pleasing genitalia, as judged by parents, patients, and physicians, and experienced normal erections. A 36-year-old patient was married and had fathered three children. Many of the patients were younger than 16 years of age and had not yet become sexually active.

Results of urethroplasty in epispadias have been reported in a number of publications (Mesrobian et al, 1986; Ransley et al, 1989; Kajbafzadeh et al, 1995; Zaontz et al, 1998). In a modern series of modified Cantwell-Ransley repairs reported by Surer and colleagues (2001a), the incidence of postoperative fistula in the 3-month period after surgery was 19%, and the incidence of urethral stricture formation was less than 10%. Catheterization and cystoscopy could easily negotiate the neourethral channel in all patients who underwent a modified Cantwell-Ransley epispadias repair. In another modern series reported by Mollard and colleagues (1998), the continence rate was 84% and the fistula rate was less than 10%. In Mollard's series with long-term follow-up, patients had normal erections; the vast majority had regular sexual intercourse, and most had normal ejaculation or had fathered children. Most of Surer's patients were quite young, and assessment of genital reconstruction must be deferred until these patients are sexually mature and active (2001a). In a large series of Hammouda (2003) using the penile disassembly technique, 6% of boys were made hypospadiac and 1% had partial glandar loss. Although many methods of epispadias repair exist, meticulous follow-up of the urethra, selection of patients, and surgical experience remain the milestones of success. Lastly, Ransley and colleagues (Kajbafzadeh et al, 1995) obtained good results using a modified Cantwell-Ransley repair in a large number of patients with epispadias. The fistula rate was 4%, and the urethral stricture rate was 5.3%. Baird and colleagues (2005b) reported on 129 boys who underwent a modified Cantwell-Ransley repair. Of this group, 32 had penopubic epispadias. Twenty-four were primary repairs, and 8 were secondary repairs. Urethrocutaneous fistula occurred in 13% of primary and 25% of secondary repairs. A urethral stricture occurred in one patient.

In a different approach to the treatment of incontinence associated with epispadias reported by Duffy and Ransley (1998), 12 boys aged 3 to 7 years underwent endoscopic submucosal injection of plastic microspheres. All patients had undergone a modified Cantwell-Ransley epispadias repair before injection. The procedure was performed 24 times, with a total volume of 83 mL of material injected into 59 sites in the posterior urethra. Mean follow-up was 10.8 months. Three patients (25%) were rendered completely dry, the degree of incontinence was improved in six, and there was no change in three. The authors offered this as an alternative to bladder neck reconstruction in patients with primary epispadias. Ben-Chaim and colleagues (1995a) reported that submucosal injection of collagen in the bladder neck area can have a role in improving stress incontinence when the patient with complete epispadias has incomplete urinary control or as an adjunct after bladder neck reconstruction. In a recent study by Kibar and colleagues (2009b) of complete epispadias, 1 patient out of 12 was continent after bladder neck injection.

Kramer and colleagues (Mesrobian et al, 1986) reported the success of genital reconstruction in epispadias, with good long-term follow-up ending with a straight penis angled downward in almost 70% of patients, with normal erectile function. Of this group, 80% had satisfactory sexual intercourse, and of 29 married patients, 19 had fathered children. These results were mirrored in the long-term follow-up study of Mollard and colleagues (1998).

A carefully constructed and well-planned approach to the management of urinary incontinence in genital deformities associated with complete epispadias should provide a satisfactory cosmetic appearance, normal genital function, and preservation of fertility potential in most patients.

Female Epispadias

Female epispadias is a rare congenital anomaly; it occurs in 1 of every 484,000 female patients (Gearhart and Jeffs, 1998). The authors use the classification of Davis (1928), which describes three degrees of epispadias in female patients. In the least degree of epispadias, the urethral orifice simply appears patulous. In intermediate epispadias, the urethra is dorsally split along most of the urethra. In the most severe degree of epispadias, the urethral cleft involves the entire length of the urethra and sphincteric mechanism and the patient is rendered incontinent (see Fig. 124–32B). The genital defect is characterized by a bifid clitoris. The mons is depressed in shape and coated by a smooth, glabrous area of skin. Beneath this area, there may be a moderate amount of subcutaneous tissue and fat, or the skin may be closely applied to the anterior and inferior surface of the symphysis pubis. The labia minora are usually poorly developed and terminate anteriorly at the corresponding half of the bifid clitoris, where there may be a rudiment of a preputial fold. These external appearances are most characteristic: On minimal separation of the labia, one sees the urethra, which may vary considerably, as mentioned previously. The symphysis pubis is usually closed but may be represented by a narrow fibrous band. The vagina and internal genitalia are usually normal.

Associated Anomalies

The ureterovesical junction is inherently deficient in cases of epispadias, and the ureters are often laterally placed in the bladder with a straight course so that reflux occurs. The incidence of reflux is reported to be 30% to 75% (Kramer and Kelalis, 1982b; Gearhart et al, 1993a). Because there is no outlet resistance, the bladder is small and the wall is thin. However, after urethral reconstruction, the mild urethral resistance created allows the bladder to develop an acceptable capacity for potential later bladder neck reconstruction.

Surgical Objectives

Objectives for repair of female epispadias parallel those devised for male patients: (1) achievement of urinary continence, (2) preservation of the upper urinary tracts, and (3) reconstruction of functional and cosmetically acceptable external genitalia.

Operative Techniques

With the patient in the lithotomy position, the defect of the female epispadias with incontinence is apparent (Fig. 124–33A). The two halves of the clitoris are widely separated, and the roof of the urethra is cleft between the 9 o'clock and 3 o'clock positions. The smooth mucosa of the urethra tends to blend cephalad with the thin, hairless skin over the mons. The urethral incision is begun at the cephalad extent of the vertical incision at the base of the mons and is brought inferiorly through the full thickness of the urethral wall at the 9 o'clock and 3 o'clock positions (Fig. 124–33B). Sutures can be placed in the urethra to permit downward traction on the urethra so that the roof of the urethra is

excised to a level near the bladder neck (Fig. 124–33C). Often, one finds the dissection proceeding under the symphysis. An inverting closure of the urethra is then performed over a 12- or 10-Fr Foley catheter. Suturing is begun near the bladder neck and progresses distally until closure of the neourethra is accomplished (Fig. 124–33D). Attention is then given to denuding the medial half of the bifid clitoris and the labia minora so that proper genital coaptation can be obtained.

After this is done, fat from the mons and subcutaneous tissue can be used to cover the suture line and obliterate the space in front of the pubic symphysis (Fig. 124–33E and F). The two halves of the clitoris and labia minora are brought together using interrupted sutures of 6-0 polyglycolic acid. The corpora may be partially detached from the anterior ramus of the pubis to aid in the urethral closure. Also, bringing these tissues together may contribute by adding resistance to the urethra. Mons closure is further aided by mobilizing subcutaneous tissue laterally and bringing it medially to fill any prior depression that remains (Fig. 124–33G). The subcutaneous layer is closed with 4-0 polyglactin suture in an interrupted fashion (Fig. 124–33H). The skin is closed with interrupted sutures of 6-0 polypropylene (Fig. 124–33I to K). A 10-Fr catheter is left indwelling for 5 to 7 days. Should the patient undergo simultaneous bladder neck reconstruction, a Foley catheter is not left in the urethra and the patient is placed in the supine position for the abdominal part of the procedure.

Achievement of a satisfactory cosmetic appearance of the external genitalia and urinary continence in the female child with epispadias represents a surgical challenge. Many operations have been reported to control continence in the epispadias group, but the results are disappointing. These procedures include transvaginal plication of the urethra and bladder neck, muscle transplantations, urethra twisting, cauterization of the urethra, bladder flap, and Marshall-Marchetti vesicourethral suspension (Stiles, 1911; Davis, 1928; Marshall et al, 1949; Gross and Kresson, 1952). These procedures may increase urethral resistance, but they do not correct incontinence or the malformed anatomy of the urethra, bladder neck, and genitalia.

The challenge of the small bladder in the female epispadias patient is comparable with a situation seen in some patients with closed bladder exstrophy. The small, incontinent bladder, with or without reflux, is hardly an ideal setting for a successful bladder neck reconstruction and ureteral reimplantation. A third of all incontinent epispadias patients have a bladder capacity of less than 60 mL, in the authors' experience and that of Kramer and Kelalis (1982b). Bladder augmentation, injection of polytetrafluoroethylene (Teflon) in the bladder neck area, and simultaneous bladder neck reconstruction and bladder neck augmentation have been offered as a solution to this challenge. However, primary closure of the epispadiac urethra in children with closed exstrophy was found to increase bladder capacity without causing hydronephrosis, and this approach has been applied to male and female patients with epispadias (Peters et al, 1988; Gearhart and Jeffs, 1989a; Ben-Chaim et al, 1995b). Although the authors typically perform urethral and genital reconstruction at about 1 year of age, they advocate delaying bladder neck reconstruction until the child is 4 to 5 years old. Not only does this delay allow the bladder to increase in capacity, it also allows the child to accept essential instructions for toilet training, which is critical to achieving satisfactory continence in the postoperative state. Data from deJong and colleagues (2000) combined a standard exterior genitoplasty plus urethroplasty with a percutaneous bladder neck suspension. The authors felt the suspension moved the bladder neck into an intra-abdominal position. In this small series one was dry and voiding, two required bladder neck bulking agents, and one was on CIC. In another small series from India, Bhat and colleagues (2008) performed a urethroplasty and the perineal musculature was double-breasted over the urethral closure from the bladder neck distally. They report impressive results with two patients totally continent, one partially continent, and one continent after bladder neck reconstruction.

Surgical Results

The continence rate of 87.5% in our female patients is comparable with that of Hanna and Williams (1972), who found a 67% continence rate in female patients with good bladder capacity, and

that of Kramer and Kelalis (1982b), who reported an 83% continence rate in patients with adequate bladder capacity. All of the authors' patients seen for primary treatment have achieved a capacity in excess of 80 mL (see Table 124–5).

Hendren (1981) and Kramer and Kelalis (1982b) showed that genitourethral reconstruction can be accomplished with satisfactory results. At our institution, patients who underwent prior urethral and genital reconstruction had a mean bladder capacity at bladder neck reconstruction of 121 mL, making the bladder suitable for the reconstruction and eventual continence without the use of augmentation cystoplasty or need for intermittent catheterization.

The time interval to achieve continence in our patients was a mean of 18 months for those who underwent genitourethral and bladder neck reconstruction in one procedure and 23 months for those who underwent preliminary urethroplasty and genital reconstruction after bladder neck reconstruction. In a series by Klauber and Williams (1974), the mean interval to acceptable continence was 2.25 years. Also, in a series by Kramer and Kelalis (1982b), some patients became continent within a short period, whereas complete continence was delayed for several years in others. The time delay for achieving continence may represent increased pelvic muscular development, as suggested by Kramer and Kelalis (1982b). In regard to the interval to continence, no advantage appears to be gained by preliminary urethroplasty. However, the authors believe that the advantage gained by increased bladder capacity at the time of bladder neck reconstruction outweighs any advantage gained by a combined approach. In the series by Bhat and colleagues (2008) and deJong and coworkers (2000), continence rates were between 40% and 60% without further bladder neck repair or injection.

Key Points: Epispadias—Priorities in Management

- The length and width of the urethral plate on the male is assessed.
- The length and width of the urethral plate and genitalia relationships in the female is assessed.
- The bladder size is measured under anesthesia by gravity cystogram.
- The bladder neck sphincter (if present) is assessed by cystoscopy.
- Any associated anomalies are assessed.

ADOLESCENTS AND ADULTS WITH EXSTROPHY

Male Concerns

The mainstay of male concerns is the length, appearance, and axis deviation (chordee) associated with exstrophy. In the typical adolescent and adult these three concerns are all intertwined. In this author's significant experience, most boys seek consultation for all of these concerns around the time they begin showering at school. More penile length can be achieved (around an inch) by degloving the penis and cutting all scar tissue and any remnants of the suspensory ligaments. A conscious decision about the appearance must be made preoperatively because the authors have found that the placement of tissue expanders and expanding the penile skin if satisfactory is superior to full-thickness skin grafting (Fig. 124–34). If the penile skin is inferior and not a good candidate to be expanded, then full-thickness grafting is a suitable alternative (Hernandez et al, 2008). Residual dorsal chordee lasting from childhood is not uncommon because the corporal anatomy is longer on the ventrum than the dorsum, and this oftentimes remains to be adequately corrected. The use of grafts (dermal grafts, tunica vaginalis, human alloderm) can be used to lengthen the dorsal aspect of the penis. The authors' preference is human alloderm because it is readily available, durable, and easy to use. Because of its anatomy, the penis must be opened dorsally for one half of its circumference as described by Perovic and Djinovic (2007) to both lengthen and straighten the penis. Early measurements and determinations from artificial erections must be adequate because after grafting, the artificial erections can leak saline through the suture lines and give misleading information about the adequacy of correction.

Figure 124–34. Tissue expander recently placed under the penile shaft on the right.

In rare cases the penis is so inadequate that a neophallus must be constructed. The authors and their pediatric plastic surgery colleagues have used a radical free-flap phalloplasty in five patients with excellent results (Gearhart and Redett, 2010).

Female Concerns

The three main female concerns are the appearance of the external genitalia, adequacy of the vaginal opening, and uterine prolapse. Although the authors correct the female external genitalia defect at birth, sometimes "touch-up" surgery needs to be performed at puberty. The three cosmetic concerns are the appearance of the lower abdominal wall, the mons veneris, and the clitorides. The authors' group has found that in females who underwent pelvic osteotomy at the time of newborn closure, the appearance of the mons veneris is more cosmetic and in less need of repair while in the patients who do not have an osteotomy the mons is thin, inelastic, and flat appearing. To repair this in adolescence, the mons flaps are raised laterally and brought to the midline and sewn to the fascia and themselves easily. In extreme cases with an extremely scarred flat mons veneris, tissue expanders are placed laterally and gradually inflated over 6 weeks. These flaps are moved medially and used to reconstruct the mons. The pseudocapsules are rolled together in the midline to give the mons a more elevated appearance. This oftentimes involves the lower abdominal wall as well. Dissection is performed laterally, the lateral flaps are mobilized, and the midline scars are all excised to improve the

appearance. This same defect is seen in the clitorides when an osteotomy is not performed at birth. They tend to be separated and scarred. Mobilizing lateral mons veneris flaps brings the clitoral halves closer to the midline and makes them easier to bring into apposition. Local estrogen cream is used three times daily for 2 weeks before any external genital surgery to soften scars, increase skin availability, and improve local vascularity. The vaginal orifice is more vertical and somewhat stenotic in exstrophy females compared with normal females. The young women appear at puberty having difficulty inserting tampons and also with intromission. These are easily repaired by an inverted U-flap of perineal skin inserted into the posterior vaginal wall, which is incised vertically (Stein et al, 1995). Beware that the cervix in exstrophy females is in the anterior vaginal wall, and sometimes opening the stenotic opening allows for uterine prolapse, which would have occurred anyway. If the patient is not sexually active, a vaginal dilator is used once daily until sexual activity occurs.

As in the genitalia and lower abdominal wall, prolapse of the uterus is more common in those who did not undergo osteotomy at birth. However, the authors have still seen it in those who did undergo pelvic closure with an osteotomy. The degree of prolapse depends on the degree of pubic bone divergence and the diameter of the opening in the levator hiatus for the vagina and rectum (Miles-Thomas et al, 2006). Because of the rarity of this condition, the average gynecologist has often never seen an adolescent or adult woman with it. The authors suspend the uterus to the sacrum with human alloderm or "pelvicoil." The suspensory substance is sewn to the uterus from the cervix and dome of the uterus so that it can be snugly suspended to the ligaments on the front of the uterus. The authors do this prophylactically in adolescents undergoing continent diversion or other major abdominal procedures (Stein et al, 1999).

SEXUAL FUNCTION AND FERTILITY IN THE EXSTROPHY PATIENT

Male Patient

Reconstruction of the male genitalia and preservation of fertility were not primary objectives in early surgical management of bladder exstrophy. **Sporadic instances of pregnancy or the initiation of pregnancy by males with bladder exstrophy have been reported.** In two large exstrophy series, male fertility was documented. Only 3 of 68 men in one study (Bennett, 1973) and 4 of 72 in another (Woodhouse et al, 1983) had successfully fathered children. In a large series of 2500 patients with exstrophy and epispadias (Shapiro et al, 1985), there were 38 males who had fathered children.

Hanna and Williams (1972) compared semen analyses in men who had undergone primary closure and ureterosigmoidostomy. A normal sperm count was found in only one of eight men after functional closure and in four of eight men with diversion. The difference in observed fertility potential is probably attributable to iatrogenic injury to the verumontanum during functional closure or bladder neck reconstruction. Retrograde ejaculation may also account for low sperm counts after functional bladder closure. **In a long-term study from our institution, Ben-Chaim and colleagues (1996) found that 10 of 16 men reported they ejaculated a few cubic centimeters of volume, 3 ejaculated only a few drops, and 3 had no ejaculation. Semen analysis was obtained in four patients: Three had azoospermia, and one had oligospermia. The average ejaculated volume of the patients who had sperm counts was 0.4 mL.** In another large series by Stein and colleagues (1994) from Germany, the authors found that none of the patients who had reconstruction of the external genitalia could ejaculate normally, nor had they fathered children. Five patients who did not undergo reconstruction had normal ejaculation, and two had fathered children. The conclusion was that male patients with genital reconstruction and closure of the urethra demonstrated high risk of infertility. In a recent large study of successful primary closure from a large exstrophy center by Ebert and colleagues (2008), sperm parameters were poor in 18 of 21 patients and FSH was increased in 25% of patients (Ebert et al, 2010).

Assisted reproductive techniques have been applied to the exstrophy population. **Bastuba and colleagues (1993) reported pregnancies achieved with the use of assisted reproductive techniques. In a small series from the Netherlands, all patients delivered a normal infant after ICSI** (D'Hauwers et al, 2008). **Regardless of the method of reconstruction of the external genitalia and bladder neck, newer techniques such as gamete intrafallopian transfer (GIFT) or intracytoplasmic sperm injection (ICSI)** can be used to assist these patients in their goal of pregnancy achievement. Use of GIFT or ICSI in 21 men with exstrophy led to successful pregnancy with no instances of exstrophy in any of the offspring in our exstrophy population.

Sexual function and libido in exstrophy patients are normal (Woodhouse, 1998). The erectile mechanism in patients who have undergone epispadias repair appears to be intact because 87% of boys and young men in the Hopkins series experienced erections after repair of epispadias (Surer et al, 2001a). Poor or absent ejaculation may occur after genital reconstruction. Complete absence of ejaculation is rare, but the emission that does occur may be slow and may occur for several hours. Milking the urethra in an antegrade fashion from proximal to distal has provided pregnancy in some cases (Woodhouse, 1999). In papers from both Woodhouse (1998) and Ben-Chaim and colleagues (1996) and Ebert and colleagues (2008), most patients reported satisfactory orgasm; half of the men and all of the women described intimate relationships as serious and long term. In the series by Ben-Chaim, the only patients who had no ejaculation were two patients who had undergone cystectomy. Overall, it seems from the experience in England, Germany, and the United States that most men with exstrophy achieve erection and have a reasonable sex life.

With better reconstructive techniques, patients with bladder exstrophy are living long and fruitful lives. The authors have recently reported a case of prostate cancer in a reconstructed male exstrophy and have seen two others in the recent past.

Female Patient

Further reconstruction of the female genitalia may be necessary during adolescent years. In our experience, the external genitalia are fully reconstructed at the time of initial exstrophy closure because with the use of osteotomy, a suitable mons pubis can be created and the bifid clitoris and labia can easily be brought together in the midline. **Vulvoplasty is sometimes indicated in patients before they become sexually active or start using tampons. In Woodhouse's experience** (1999), **most patients required vaginoplasty before intercourse could take place.** Woodhouse reported successful intercourse in all of his patients, but three found it painful. Stein and colleagues (1995) from Germany reviewed a large series of patients with exstrophy

and found that a cut-back vaginoplasty was required before intercourse in 23 patients. The authors have also seen several patients who have not had vulvoplasty, have two clitoral halves, have a normal sex life and normal orgasm, and desire no surgical repair of this condition.

Mathews and colleagues (2003) reported on a large series of girls and women with the exstrophy complex. All girls older than 18 years indicated that they had normal sexual desire, and many were sexually active. Mean age for commencement of sexual activity was 19.9 years. Although a few patients complained of dyspareunia, most indicated normal orgasms. Other studies by Baird and colleagues (2005a) and Ben-Chaim and colleagues (1996) confirmed the results of the larger study by Mathews. Some patients indicated that they restricted sexual activity because of the cosmetic appearance of their external genitalia. Mons plasty is therefore important to obtain a cosmetically pleasing appearance either in infancy or in adolescence because hair-bearing skin and fat should be used to cover the midline defect. As mentioned earlier, the authors perform this procedure at the time of initial closure. It certainly can be done in adolescence with the use of rhomboid flaps, as popularized by Kramer and Jackson (1986).

Obstetric Implications

Review of the literature reveals 45 women with bladder exstrophy who successfully delivered 49 normal offspring. The main complication after pregnancy was cervical and uterine prolapse, which occurred frequently (Krisiloff et al, 1978). Burbage and colleagues (1986) described 40 women ranging from 19 to 36 years of age who were treated in infancy for bladder exstrophy; 14 pregnancies in 11 of these women resulted in 9 normal deliveries, 3 spontaneous abortions, and 2 elective abortions. Uterine prolapse occurred in 7 of the 11 patients during pregnancy. All had undergone prior permanent urinary diversions. Spontaneous vaginal deliveries were performed in those women, and cesarean sections were performed in women with functional bladder closures to eliminate stress on the pelvic floor and to avoid traumatic injury to the urinary sphincter mechanism (Krisiloff et al, 1978). With modern reconstructive techniques, successful pregnancies have been reported in female patients who have undergone continent urinary diversion (Kennedy et al, 1993).

Woodhouse (1999) reported prolapse in a number of patients, and it was said to be a considerable problem to correct. Seven patients had total prolapse, one of whom had never had intercourse or a pregnancy. Woodhouse believes that prolapse may occur in up to half of patients after pregnancy. In a report from Mathews and colleagues (2003), vaginal prolapse and uterine prolapse were noted commonly and even quite early in life (mean age 16 years). Uterine suspension provided only modest success for the prevention of recurrent prolapse. Stein and colleagues (1995), in a large exstrophy series from Germany, found that uterine fixation was required to correct prolapse in 13 patients with long-term follow-up of more than 25 years. The anterior displacement of the vaginal os and the marked posterior displacement of the dorsorectalis sling with its deficient anterior component were postulated as reasons for prolapse. With the modern use of osteotomy with resultant recreation of the pelvic floor, the authors have seen less uterine prolapse in their series.

Regardless of the method of repair, the uterus must be anchored in such a way that it is fixated in the pelvis and less susceptible to prolapse. Some authors have advocated fixation of the uterus to the anterior abdominal wall in childhood; this, they say, prevents prolapse but still allows normal pregnancy. Woodhouse (1999) believed that, although prophylactic surgery may be helpful, once prolapse occurs, anterior fixation is insufficient to correct uterine prolapse in the exstrophy patient. The authors fix both sides of the uterus from the cervix to the top of the uterus bilaterally to the presacral ligaments.

LONG-TERM ADJUSTMENT ISSUES

Interest has increased in long-term adjustment issues in patients with bladder exstrophy. Children with exstrophy undergo multiple reconstructive surgeries and have potential problems with respect to urinary incontinence and sexual dysfunction. However, the ultimate outcome would be better measured by how these children adjust overall in society. The severe nature of the exstrophy disorder could predict that this birth defect could have substantial psychologic implications. Parental reaction to the child's medical condition may change the way the parents interact with the child. Incontinence may have a negative impact on social function and self-esteem. Multiple hospitalizations may interfere with the ability to be like other children. Concerning the potential medical and psychologic implications of this anomaly, children born with exstrophy may be at increased risk for difficulties.

Formerly, there was a limited amount of information in the literature concerning this condition and its treatment and whether or not it has a deleterious effect on children and their families. Montagnino and colleagues (1998) evaluated younger children who performed more poorly and had disturbed behavior, specifically in skills related to function in school. Children who achieved continence after the age of 5 years were more likely to have problems with acting-out behavior. There were no differences in adjustment on the basis of male or female sex, bladder versus cloacal exstrophy, type of continence strategy, or gender reassignment versus no reassignment. **The conclusions of this long-term study were that children with exstrophy do not have clinical psychopathology** (Montagnino et al, 1998). There was acting-out behavior rather than depression or anxiety, suggesting that improved outcomes may be achieved through a focus on normal adaptation rather than potential psychologic stress. In addition, earlier achievement of continence through reconstructive efforts is potentially of psychologic benefit. This work was further supported by Catti and colleagues (2006), who found in adults that quality of life was better in those who were continent with a good body image (Catti et al, 2006).

Reiner (1999) studied 42 children with exstrophy and presented preliminary results suggesting that these patients tend to have more severe behavioral and developmental problems than children with other anomalies, significant body distortion, and self-esteem problems. Reiner has recommended early intervention with the exstrophy patient and family and continuation with long-term psychiatric support into adult life. In a study from Europe, Feitz and colleagues (1994) found a more positive picture when they evaluated 11 women and 11 men with exstrophy, of whom 9 women (82%) and 10 men (91%) did not manifest any clinical levels of psychologic stress. The authors concluded that these adults had a positive attitude toward life. With the use of structured instruments and appropriate evaluation and interviews, Reiner and Gearhart (2006) indicated that all 20 patients evaluated met criteria for at least one anxiety disorder. Older patients experienced waning of anxiety associated peer discovery of incontinence following successful surgical reconstruction, and all noted intensified sexual activity with age. New data from Reiner and colleagues (2008) of a large series of male patients found that 14%

experienced suicidal ideation. As they became older, 31% experienced this phenomenon and a few attempted adolescent/early adulthood suicide. One succeeded. These findings underline the importance of screening patients as they become older for psychopathology.

In an important study by Lee and colleagues (2006), females were found to have more close friendships, fewer disadvantages in relation to healthy peers, and more partnerships than males. There were no gender differences in adjustment within educational and professional careers, which overall were good. Ebert and colleagues (2005) reviewed by questionnaire a group of 100 exstrophy adolescents. Education and social integration were high. All patients were heterosexual, and almost 50% were sexually active. Almost 60% expressed anxiety about sexual activity. The most important finding was that 94% of patients expressed an interest in psychologic assistance. These exciting new data underline the importance of early childhood intervention.

Being born with exstrophy does not result in childhood psychopathology. **Children with exstrophy exhibit some tendency toward increased problems with acting out or lack of attainment of age-appropriate adaptive behavior** (Montagnino et al, 1998; Reiner, 1999). Therefore all experts in childhood psychology tend to agree that counseling should come from the nursing and medical staff early in the exstrophy condition. Likewise, the patient and parents should be served by an experienced exstrophy support team, and psychologic support and counseling should be extended into adult life.

Acknowledgment

This chapter is dedicated to the memory of Dr. Jean Cendron (1923-2008) and Dr. Robert D. Jeffs (1924-2006), the pioneers of modern exstrophy surgery.

Bladder Anomalies in Children

Dominic C. Frimberger, MD ● Bradley P. Kropp, MD, FAAP

Bladder and Urachal Development

Classification of Bladder Anomalies

Conclusion

Although anomalies of the urogenital tract are among the most commonly diagnosed antenatal malformations, the incidence of all congenital bladder anomalies is low (Carrera et al, 1995). **Additionally, bladder anomalies are often a reaction to infravesical obstruction or part of a more serious disorder rather than a true isolated structural malformation.** Bladder anomalies can be severe, cause urinary obstruction, and even lead to renal failure. Early detection and intervention are crucial to prevent future decompensation of the genitourinary tract. Anomalies can be detected prenatally or postnatally using ultrasound but often require voiding studies for definite diagnosis. This chapter reviews congenital bladder abnormalities in the prenatal and postnatal period and focuses on malformations not caused by infravesical obstruction. This chapter includes a discussion of the initial presentation, diagnosis, and current treatment options for the different entities and a classification based on the prenatal and postnatal presentations of bladder anomalies.

BLADDER AND URACHAL DEVELOPMENT

A comprehensive understanding of the embryologic development of the bladder and urachus is mandatory to correctly interpret the prenatal and postnatal findings and to counsel the parents toward the optimal management.

Between the fourth and sixth weeks of gestation, the urorectal septum divides the endodermal cloaca into a ventral urogenital sinus and a dorsal rectum. The cranial part of the urogenital sinus is continuous with the allantois and develops into the bladder and pelvic urethra. The caudal portion gives rise to the phallic urethra in males and the distal vagina in females. Unlike in males, the entire female urethra is derived from the pelvic part of the urogenital sinus. The allantois develops as an extraembryonic cavity from the yolk sac and connects with the cranioventral portion of the cloaca, the future bladder. Around the fourth to fifth month of gestation, the allantoic duct and the ventral cloaca involute as the bladder descends into the pelvis. The descent causes the allantoic duct to elongate because it does not grow with the embryo. This epithelialized fibromuscular tube continues to become narrower until it obliterates into a thick fibrous cord, the urachus (Moore, 1982). The obliterated urachus becomes the median umbilical ligament and connects the apex of the bladder with the umbilicus (Nix et al, 1958).

Normal Antenatal Sonographic Findings of the Bladder

The fetal bladder presents as an elliptical structure filled with anechoic fluid within the pelvis. It is bordered laterally by the umbilical arteries. The pubic bones mark the anterior border, and the rectosigmoid indicates the posterior border. The bladder wall thickness should not exceed 3 mm. The mucosa and musculature present with a similar echogenicity to other structures in the pelvis (McHugo and Whittle, 2001). **The bladder can be visualized in about 50% of cases in the fetal pelvis at the tenth week of gestation, concurrent with the onset of urine production** (Green and Hobbins, 1988). **The detection rate increases with fetal age to 78% at 11 weeks, 88% at 12 weeks, and almost 100% at 13 weeks** (Rosati and Guariglia, 1996). Compared with abdominal ultrasound, transvaginal ultrasound increases the quality of the obtained images and detection rate. Because the fetal bladder empties every 15 to 20 minutes, a second ultrasound in the same setting is mandatory in case of nonvisualization of the bladder. The bladder's diameter increases during the first trimester but should not be more than 6 to 8 mm.

The fetal sex, amount of amniotic fluid, and appearance of the umbilical cord become increasingly important in the interpretation and differential diagnosis of abnormal bladder findings. Fetal sex is difficult to determine before week 14 and should not be based on the presence or absence of a phallus but on the visualization of testes (Efrat et al, 1999). The measurement of amniotic fluid as an indicator of fetal urine production is a critical portion of every antenatal ultrasound. Until 16 weeks of gestation, the amniotic fluid is mainly consistent with placental transudate, at which time it changes to predominantly fetal urine (Takeuchi et al, 1994). The umbilical cord should contain two arteries and one vein without evidence of a fluid-filled urachus (Bronsthein et al, 1990).

CLASSIFICATION OF BLADDER ANOMALIES

Bladder anomalies can present as either abnormal findings during prenatal ultrasound or postnatally due to symptoms or as a part of an unrelated workup.

Classifying bladder anomalies is difficult due to the large variety of possible malformations, the relatively low incidence of the anomalies, and the common association with other congenital anomalies. Therefore it seems reasonable to classify the different presentations into two main groups:

- Prenatally detected
  - Dilated
  - Nondilated
- Postnatally detected
  - Urachal abnormalities
  - Bladder diverticulum
  - Bladder duplication
  - Other bladder anomalies

Prenatally Detected Bladder Anomalies

The fetal bladder can either appear dilated, hypoplastic, or absent on ultrasound. If the bladder is dilated, the condition can be due to obstruction or caused by incomplete empting of the bladder itself without evidence of a mechanical obstruction. In nondil ated conditions, the bladder is either completely absent or is unrecognizable as a fluid-filled structure due to incomplete formation.

Dilated Fetal Bladder

In the first trimester, the fetal bladder is considered to be dilated if larger than 7 mm on ultrasound. If, on subsequent ultrasounds, the bladder continues to retain urine and shows no evidence of urine cycling, concern regarding obstruction should be raised. If the amniotic fluid does not increase, this may indicate the progression to oligohydramnios. **Determination of the sex of the child is important because of the male gender predominance of certain diseases such as posterior urethral valves (PUVs) or prune-belly syndrome.** It can be difficult to distinguish in utero if the dilatation is due to obstruction. In a retrospective study, Kaefer and colleagues (1997) described 15 patients with marked bladder dilatation in utero, 8 with and 7 without obstruction. All of the obstructed cases presented with moderate to severe oligohydramnios and a marked increase in renal echogenicity, while all but one of the nonobstructed bladders had normal amniotic fluid levels and regular renal echogenicity (Kaefer et al, 1997). Therefore fetuses with nonobstructive dilatation appear to pass enough urine to maintain renal function and adequate amniotic fluid levels throughout the pregnancy (Mandell et al, 1992).

Dilatation Caused by Obstruction

Urethral Anomalies and External Bladder Outlet Obstruction. **Dilatations of the fetal bladder caused by anatomic obstructions are mostly due to urethral anomalies or external obstruction.** Urethral anomalies include congenital urethral strictures, anterior and posterior urethral valves, and urethral atresia. Compression of the bladder outlet region can be due to obstructing syringoceles, a sacrococcygeal teratoma or pelvic neuroblastoma, an anterior sacral myelomeningocele, a dilated vagina in a girl with a cloacal anomaly, or with rectal anomalies. The observed bladder changes are due to mechanical obstruction and affect bladder development at a critical time point, which can lead to bladder wall hypertrophy and remodeling (Pagon et al, 1979; Beasley et al, 1988; Stephens and Gupta, 1994).

Dilatation in Nonobstruction

Prune-Belly Syndrome and Neurogenic Bladder Disease. Affected patients do not demonstrate any sign of obstruction on postnatally performed voiding studies or cystoscopic evaluations, except when urethral atresia is also present. In this case the presentation is similar to posterior urethral valve patients. However, it is possible that the largely distended bladder, as in prune-belly syndrome, is caused by a transient obstruction in utero, and in some cases the presence of urethral atresia has been noted with prune-belly syndrome. Another possibility for the distention is the presence of neurologic disorders leading to an inability to empty the bladder in utero.

Congenital Megacystis

The term *megacystis* is often used to describe any condition leading to a distended fetal bladder in utero, without referring to the cause of the dilation. Historically, congenital megacystis was thought to be caused by bladder neck obstruction, leading to massive bilateral vesicoureteral reflux (VUR) and a thin bladder wall (Williams, 1957; Paquin et al, 1960). Even the describing authors recognized that surgical interventions at the bladder neck level did not change the future outcome. Harrow (1967) revisited the subject and recognized that all patients had normal urethras and complete emptying of their bladders on voiding cystourethrography. Therefore **the observed reflux is not an aftereffect of obstruction, but rather the cause of the bladder dilatation from continuous recycling of the urine between the upper tract and bladder** (Harrow, 1967). Congenital megacystis is defined currently as a dilated, thin-walled bladder with a wide and poorly developed trigone. The wide-gaping ureteral orifices are displaced laterally, causing massive reflux (Fig. 125–1). Bladder contractility is normal, although a majority of the urine refluxes into the ureters with each void. No neurogenic abnormalities are described. Most patients are recognized prenatally and should be placed on prophylactic antibiotics after birth (Mandell et al, 1992). **Correcting the reflux often restores normal voiding dynamics and should be performed after 6 months of age.** Reduction cystoplasty can be performed but is usually unnecessary (Burbige et al, 1984). Although the bladder is large enough to accommodate the tapered ureters even in a young infant, the operation can be difficult due to the bladder wall's thinness.

Congenital megacystis has been recognized in association with microcolon-intestinal hypoperistalsis syndrome. This syndrome is a rare congenital disorder characterized by a dilated, nonobstructive urinary bladder and hypoperistalsis of the gastrointestinal tract. The syndrome can be identified by antenatal ultrasound by the appearance of a largely dilated bladder. It has been reported mostly in females and is usually considered lethal (Srikanth et al, 1993; Lashley et al, 2000). So far there are only 10 patients who lived beyond the first year of life, and almost all need total parental nutrition. Once identified after birth, the distended bladder requires drainage via intermittent catheterization or vesicostomy placement. Long-term data concerning the urinary tract are not available due to the short life span of the patients (Bloom and Kolon, 2002).

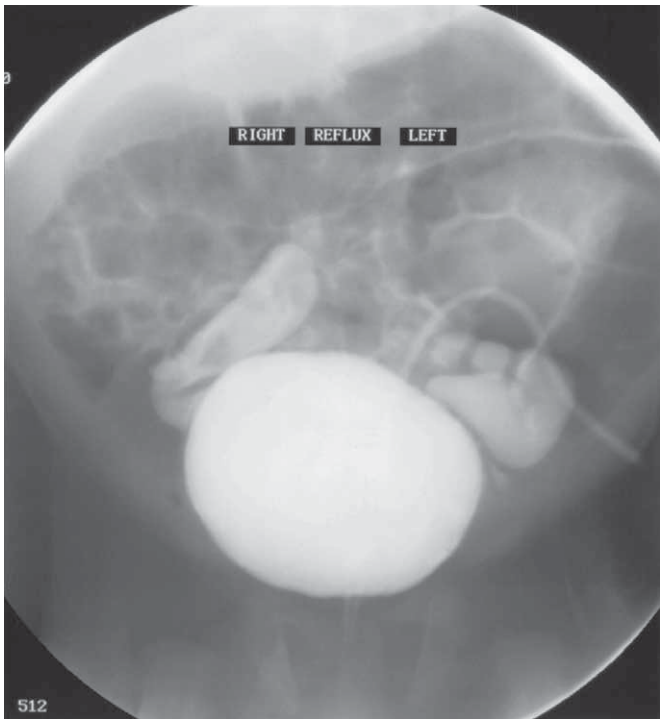

Figure 125–1. Megacystis. Vesicoureterogram image of congenital megacystis with associated reflux.

Nondilated or Absent Fetal Bladder

In order to truly diagnose an absent fetal bladder on ultrasound, the examination has to be repeated after 15 to 20 minutes to rule out that the fetus has not simply emptied the bladder.

Cloacal and Bladder Exstrophy. Bladder exstrophy conditions are characterized by the presence of a bladder template only. Therefore it can be suspected in the absence of regular bladder filling during fetal ultrasound. Bladder exstrophy can be distinguished from bladder agenesis by the bladder template on the lower abdominal wall, which, along with the amniotic fluid level, remains normal throughout the pregnancy (Mirk et al, 1986; Gearhart et al, 1995).

Bladder Hypoplasia. The bladder can be hypoplastic due to inadequate filling or storing of urine during fetal life. Although the bladder is formed during fetal development and can be detected on antenatal ultrasound throughout pregnancy, it never reaches an adequate capacity. Conditions caused by inadequate bladder outlet resistance (e.g., severe epispadias), separation defects (e.g., urogenital sinus abnormalities), abnormalities of renal development (e.g., bilateral renal dysplasia or agenesis), or urine bypassing the bladder (e.g., ureteral ectopia) can all lead to underdevelopment of the fetal bladder. Some of these bladders grow once the malformation is corrected; however, later bladder augmentation is often required to reach adequate capacity (Gearhart, 2002).

Bladder Agenesis. Embryologic development of bladder agenesis remains difficult to explain. The division of the cloaca into the urogenital sinus and the anorectum is apparently regular because the hindgut is usually normal. Therefore the defect can be due to either atrophy of the cranial part of the urogenital sinus or a failure to incorporate the mesonephric ducts and ureters into the trigone (Krull et al, 1988). The absence of the bladder is often associated with neurologic, orthopedic, or other urogenital anomalies such as renal dysplasia or agenesis or absence of the prostate, seminal vesicles, penis, and vagina (Aragona et al, 1988). It is a rare anomaly; only 16 live births have been reported out of the 45 known cases in the English literature. All but two were female (Adkes et al, 1988; Gopal et al, 1993; DiBenedetto et al, 1999). The defect is only compatible with life if the ureters drain ectopically into normally developed müllerian structures in the female or in the rectum in males. In surviving infants, the diagnosis can be confirmed by retrograde ureteronephrograms via the ectopic openings. Renal function can be preserved after creation of an ureterosigmoidostomy or external stoma (Glenn, 1959; Berrocal et al, 2002).

Key Points: Prenatally Detected Bladder Anomalies

- Prenatally detected bladder anomalies can be categorized into dilated and nondilated anomalies.
- Dilated bladders can be caused by anatomic or functional obstruction. They are commonly associated with severe anomalies, are often the cause for oligohydramnios, and can require fetal or immediate postnatal intervention to prevent fetal demise.
- Nondilated anomalies are associated with the most severe forms of congenital urologic malformations like bladder and cloacal exstrophy. Usually normal amniotic fluid levels are found.
- Bladder agenesis is only compatible with life if the ureters drain ectopically.

Postnatally Detected Bladder Anomalies

The malformations in this group can be diagnosed by antenatal ultrasound. However, most patients are diagnosed postnatally due to symptomatic disease or during workup for a nonrelated disease. Malformations listed in the prenatally detected group usually severely affect fetal development, are often associated with other malformations, and require prenatal or postnatal interventions. **Postnatal-detected defects, on the other hand, usually do not affect fetal development and generally can be treated with conservative measures or a single surgical intervention.** Bladder anomalies in the infant or child are suspected in cases of urinary tract infections, hematuria, voiding difficulties, anatomic malformations and masses, or umbilical site drainage.

Urachal Anomalies

Understanding the embryologic development of the urachus and its unique location is the key to understanding congenital urachal anomalies. The urachus is located preperitoneal in the center of a pyramid-shaped space. This space is lined by the obliterated umbilical arteries, with its base on the anterior dome of the bladder and the tip directed toward the umbilicus (Fig. 125–2). The urachal length varies from 3 to 10 cm. It has a diameter between 8 and 10 mm and can connect with one or both obliterated umbilical arteries. Microscopically, three layers can be identified. An inner layer consists of either transitional or cuboidal epithelial cells, surrounded by a layer of connective tissue. A smooth muscle layer in continuity with the detrusor muscle comprises the outer layer. Because the urachus is surrounded by the umbilicovesical fascia, disease processes usually remain contained

Figure 125–2. Urachal anatomy. (From Cullen TS. Embryology, anatomy and diseases of the umbilicus. Philadelphia: WB Saunders; 1916.)

inside the pyramid-shaped space (Hammond et al, 1941). The urachus can remain either completely open or obliterate partially, leading to the formation of cystic structures at any site throughout its course.

Ashley and colleagues (2007) examined the medical records of 176 patients diagnosed with an urachal anomaly, and urachal remnants were found in 46 children and 130 adults. Children mostly presented with umbilical drainage or on physical examination, and 74% underwent excision, while 66% of adults had hematuria or pain and underwent excision in 90%. Surgical treatment in children consisted of simple excision, whereas more than 50% of adults required partial or radical cystectomy due to malignancy. They concluded that urachal anomalies present and progress differently in pediatric and adult populations and recommended urachal excision in early childhood to prevent later problems or cancer formation. **There was no reported evidence that a persistent urachal remnant in childhood was the cause of later cancer development** (Ashley et al, 2007). Galati and colleagues (2008) reported 23 children with urachal remnants, 10 of whom underwent excision due to symptomatic problems. In their treatment protocol, asymptomatic remnants are managed with physical and sonographic examination. **They found that spontaneous resolution with nonoperative management is likely with remnants in patients younger than 6 months.** However, if symptoms persist or the remnant fails to resolve after age 6 months, they recommend excision (Galati et al, 2008). Four different urachal anomalies have been described (Fig. 125–3).

- Patent urachus (50%)
- Umbilical-urachus sinus (15%)
- Urachal cyst (30%)
- Vesicourachal diverticulum (3% to 5%)

Patent Urachus

Patent urachus is explained by nondescent of the bladder or, more commonly, failure of the epithelial-lined urachal canal to obliterate (Gearhart, 2002). Bladder obstruction during fetal development has been blamed for the urachus remaining tubular. The fact that urachal patency is often absent with severely obstructed bladders in utero, however, casts doubt on this theory. Additionally, only up to 14% of patients with a patent urachus have postnatal confirmation of in utero bladder obstruction (Schrenck and Campbell, 1972; Mesrobian et al, 1997). It seems possible that obliteration of the urachus may be independent from the level of bladder distention. Therefore retubularization, rather than primary patency, might be the cause for urinary drainage from the umbilicus. This theory is supported by reports of umbilical urinary fistulas in acquired bladder obstructions later in life (Schubert et al, 1983; Berman et al, 1988).

A patent urachus is suspected in the neonatal period by continuous or intermittent drainage of fluid from the umbilicus. The most common organisms cultured from the umbilical drainage include *Staphylococcus aureus, Escherichia coli, Enterococcus, Citrobacter,* and rarely *Proteus* species (Mesrobian et al, 1997). Additional presentations include an enlarged or edematous umbilicus and delayed healing of the cord stump (Razvi et al, 2001; Schiesser et al, 2003). The diagnosis is confirmed by demonstration of the fluid-filled canal on longitudinal ultrasound or contrast filling on retrograde fistulogram or voiding cystourethrogram (VCUG) (Fig. 125–4) (Mesrobian et al, 1997). Computed tomography (CT) scans can aid in the diagnosis but are usually dependent on the bladder's filling status. Differentiating the condition from a patent omphalomesenteric duct is important. The presences of both anomalies in the same patient are rare (Mendoza et al, 1968).

Management of an infected urachus with abscess formation includes initial drainage under antibiotic coverage. Once the infection has subsided, complete excision of the patent urachus including a bladder cuff is required (Nix et al, 1958). Removing all anomalous tissue is important. This avoids recurrences or stone formation and prevents the rare event of later transformation into a malignant adenocarcinoma (Blichert-Toft and Nielson, 1971; Sheldon et al, 1984; Goldman et al, 1988; Upadhay and Kukkady, 2003).

Traditionally, the patent urachus is surgically excised using a transverse or midline infraumbilical incision. Before surgery, a balloon catheter is used to distend the bladder. In infants, a small transverse subumbilical incision is often possible because the bladder dome is still high.

A feeding tube or small catheter is placed into the patent urachus for better intraoperative identification. The urachus can be incised circumscriptly, without removing the umbilicus for

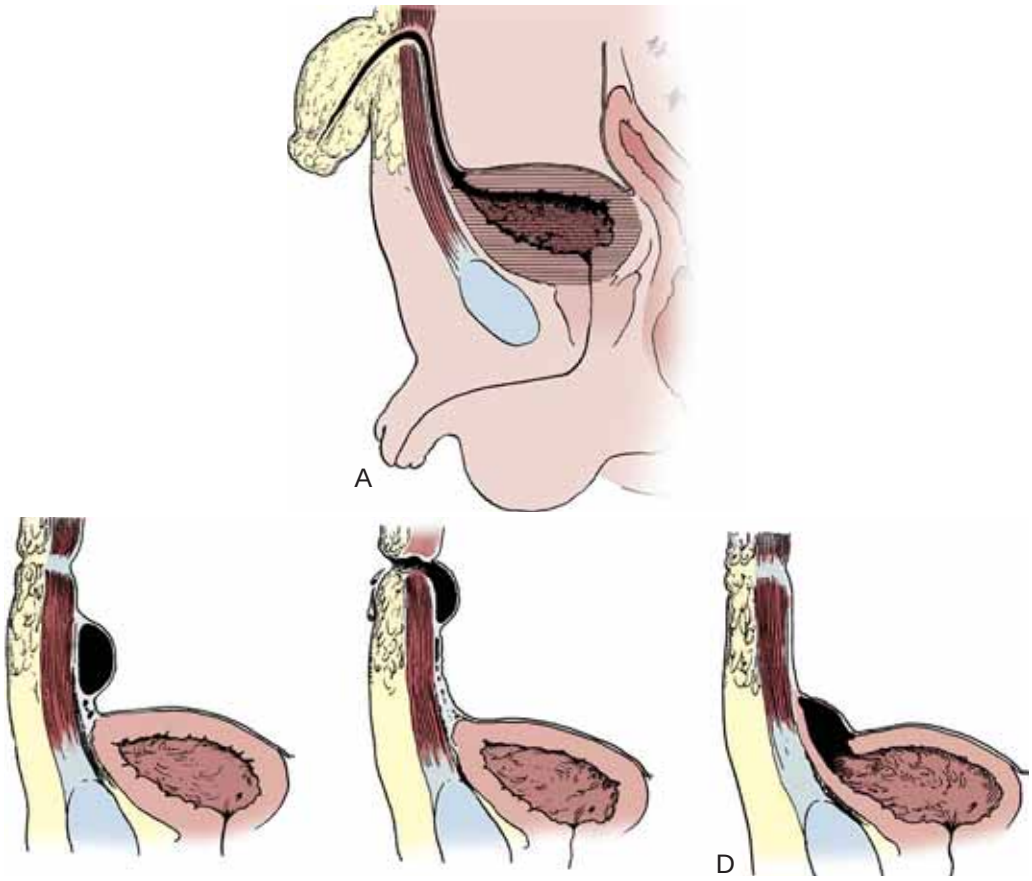

Figure 125–3. Urachal anomalies. **A,** Patent urachus. **B,** Urachal cyst. **C,** Umbilical-urachus sinus. **D,** Vesicourachal diverticulum.

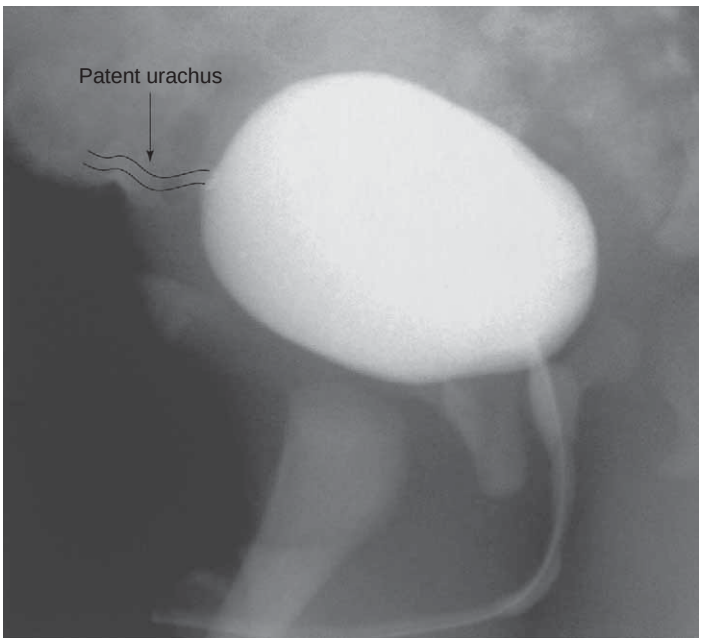

Figure 125–4. Patent urachus. Vesicoureterogram image of patent urachus in a newborn. Retrograde contrast filling of patent canal with contrast pooling in umbilicus.

cosmetic reasons. The rectus fascia is incised in a longitudinal fashion, muscles spread apart, and the dome of the distended bladder identified. The urachus is identified, isolated, and a vessel loop placed. The dissection continues extraperitoneally toward the umbilicus until the previously incised umbilical portion is free and can be pulled into the surgical field. It is then removed. A bladder cuff including the urachal insertion is marked and excised using electrocautery. The bladder is closed watertight in two layers. The catheter can be left in place overnight and removed the following morning.

Alternatively, urachal remnants can be removed laparoscopically. This can be done even in children younger than 6 months of age (Fahlenkamp et al, 1995; Cadeddu et al, 2000; Khurana and Borzi, 2002). Khurana and Borzi described their laparoscopic experience with four children between 5 months and 10 years and found the procedure to be safe in children of all ages. Technically, they suggested a three-port approach, with the camera port in the midline between the umbilicus and the xiphoid and two working ports on either site in the upper quadrant. Turial and colleagues (2007) reported 27 children with a median age of 4.7 years. Early in their series they inserted the camera port at the umbilicus with working ports into the right and left upper abdomen. Later they preferred to place the camera into the left lower abdominal wall with 2-mm working ports at the left lower and upper abdomen for better visualization of the urachus at the umbilicus. They reported no intraoperative or postoperative complications, no recurrences, and a median operating time of 35 minutes (Turial et al, 2007). The advantage of the laparoscopic technique is the

good visualization of the course of the urachus and the bladder dome. However, laparoscopic techniques require an intra-abdominal approach and pose the potential risk of spilling infected or malignant material into the abdominal cavity.

Umbilical-Urachus Sinus

In this situation the urachus obliterates at the bladder level but remains open at the umbilical site, causing a continuously draining sinus. The presentation is similar to the patent urachus. The diagnosis is made by sinogram. The caudal part of the urachus is filled with desquamated epithelial cells, and no connection to the bladder can be identified. The presence of a persistent omphalomesenteric duct must be considered. This would present as a Meckel's diverticulum connected to the umbilicus. These structures can be difficult to differentiate from an umbilical-urachus sinus because no connection to the bladder or bowel can be seen on sinogram. However, the surgical approach to both anomalies requires the complete excision of all tissue. Unlike urachal structures, omphalomesenteric remnants can show gastric or small bowel mucosa on histologic examination.

Urachal Cyst

There is no communication of the cyst with the bladder or umbilicus. However, the fluid-filled cyst can drain through the umbilicus or into the bladder intermittently. Urachal cysts are found more commonly in the distal part of the urachus and present more commonly in adults than in infants or children (Cilento et al, 1998). The cyst material consists of desquamated epithelial cells. These cells can become infected; *S. aureus* has been identified as the most common organism (Mesrobian et al, 1997).

Once infected, urachal cysts can present as umbilical abscess formation or bladder infections. Additional symptoms include localized lower abdominal pain, voiding symptoms, or even a painful and palpable mass. The diagnosis is confirmed by ultrasound, demonstrating the localized cyst between the anterior abdominal wall and the peritoneum. In a case of massive infection or difficult presentation, a CT scan can clarify the anatomy and extent of disease (Berrocal et al, 2002). If unrecognized, the infected cyst can perforate into the bladder (Maruschke et al, 2003) or peritoneal cavity. This can cause peritonitis and formation of an enteric fistula (Ohgaki et al, 2003; Quek et al, 2003). Treatment consists of draining the infected cyst, followed by complete excision of the urachal remnant structures.

Vesicourachal Diverticulum

The urachus obliterates almost completely, except at the level of bladder apex. Here it forms a diverticulum of varying size. These lesions are usually nonsymptomatic and found incidentally on nonrelated radiographic workups. Although the diverticulum can enlarge in size in case of urinary obstruction, it rarely causes problems because it tends to have a large opening and drain into the bladder well. There have been reports of stone formation and urinary infections, especially in the case of a narrowed neck causing the need for intervention.

Bladder Diverticulum

Bladder diverticula are caused by infravesical obstruction, bladder surgery (iatrogenic), or congenital defects. Independent from the cause, all diverticula develop as herniation of bladder mucosa between defects of bladder smooth muscle fibers. The neck of the resulting diverticulum depends on the size of the muscular defect. The incidence is reported to be low, with 1.7% in a selected pediatric population of children undergoing radiographic evaluation for symptomatic disease (Blane et al, 1994). In adult males the incidence tends to be much higher due to the higher occurrence of infravesical obstruction. The true incidence in children is difficult to evaluate because many of the congenital diverticula remain asymptomatic and are probably never detected.

In his landmark article, Hutch (1961) describes two kinds of diverticula at the ureteral hiatus.

- **Primary paraureteral diverticula** are seen in smooth-walled bladders, occur isolated with no other diverticula, are intermittent in presentation, and happen in children with no infravesical obstruction.
- **Secondary paraureteral diverticula** are found in trabeculated bladders as one of many diverticula in the bladder, are always present, and are caused by infravesical obstruction.

Primary diverticula arise as a localized herniation of bladder mucosa through the ureteral hiatus between the intravesical ureter and the roof of the ureteral hiatus. These primary diverticula are also known as *congenital diverticula* and are most likely caused by a congenitally deficient bladder wall (Fig. 125–5). Some authors have implied an isolated defect in Waldeyer sheet; however, congenital diverticula often occur on one side only, and a unilateral defect seems unlikely (Stephens, 1963). Congenital diverticula are often found in children with generalized connective tissue diseases such as Ehlers-Danlos, Williams Elfin-Facies, or Menkes syndrome (Babbitt et al, 1979; Daly and Rabinovitch, 1981; Levard et al, 1989). These diverticula can be resected if symptomatic; however, due to the impaired healing in patients with connective tissue disease, recurrence and wound healing complications are more common.

Secondary paraureteral diverticula are acquired and develop due to existing infravesical obstruction. The resulting increased infravesical pressure forces the bladder mucosa to bulge between the muscle fibers. These diverticula are usually just one of many "pop-off" mechanisms that can occur throughout the bladder. These diverticula can also be caused by weakening in the bladder muscle by infection (Barrett et al, 1976) or development of a muscular defect after bladder surgery (Sheu et al, 1998).

In both types of paraureteral diverticula, Waldeyer sheet eventually becomes damaged as the diverticulum expands in size. The increasing diverticulum pulls the intravesical ureter out of its anchored position, causing dysfunction of the ureterovesical junction. Eventually, the enlarged diverticulum can become responsible for ureteral obstruction. This has even been associated with renal dysplasia (Amar, 1972; Livne and Gonzales, 1985).

Key Points: Urachal Anomalies

- Urachal anomalies are usually detected postnatally due to umbilical drainage.
- Infected urachal remnants are initially treated with drainage and antibiotics, followed by surgical excision. Conservative treatment with observation is justified in asymptomatic cases due to possible spontaneous resolution.
- Imaging possibilities include ultrasound, CT, and VCUG.
- Nonresolved urachal remnants should be excised due to the increased risk of later adenocarcinoma formation.

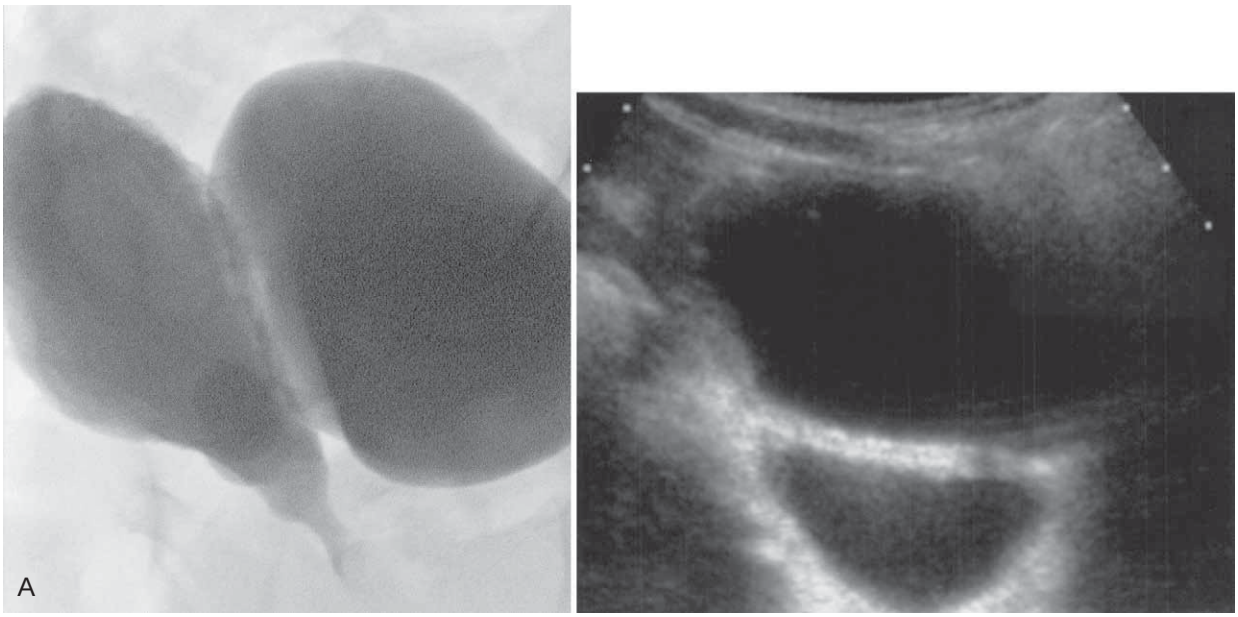

Figure 125–5. Primary paraureteral diverticulum. **A,** Vesicoureterogram image of large primary paraureteral diverticulum. **B,** Ultrasound image of the same diverticulum.

Paraureteral diverticula or diverticula located in the lower part of the bladder can become so large that they compress the bladder neck or posterior urethra. The resulting bladder outlet obstruction starts a vicious circle by continuously filling and expanding the diverticulum. This increases the obstructing and subsequently causes complete urinary retention (Sheldon and Essig, 1994; Zia-Ul-Miraj, 1999).

Bladder diverticula can be detected on prenatal ultrasound (Gaudet et al, 1999) but are mostly discovered during workup for infection, hematuria, incontinence, or obstruction. They can be suspected during ultrasound examination, especially if the bladder is viewed in different filling stages. The gold standard remains VCUG, which will reveal possible accompanying VUR. If no VUR is present, an intravenous pyelogram (IVP) with oblique views can help determine the relationship of the ureter with the diverticulum if there is hydronephrosis. Alternatively, nuclear renal studies can be used to obtain information concerning anatomy, kidney function, and ureteral obstruction. It is important to remember that congenital diverticula can have a dynamic nature and might not be present on every study. Radiographic studies may need to be repeated in cases of continuous clinical suspicion.

Small, asymptomatic congenital diverticula detected during unrelated workups can be treated conservatively with regular observation. Many surgeons tend to recommend excision of paraureteral diverticula if they are accompanied by VUR. Girls will show spontaneous resolution of their diverticula in association with VUR more frequently than boys. In his review of 304 patients with VUR, Amar (1972) confirmed the lesser resolution rate in boys. He attributed it to higher voiding pressures even without the presence of infravesical obstruction.

In acquired bladder diverticula, the infravesical obstruction has to be eliminated first. After bladder outlet resistance is normalized, the bladder can reshape and diverticulectomy might become unnecessary. If symptomatic, the diverticulum should be excised. The ipsilateral ureter should be reimplanted if it is near or included in the diverticulum. This traditionally has been performed intravesically; however, the procedure can be safely performed via an extravesical approach (Jayanthi et al, 1995; Yu, 2002). Laparoscopic excision has also been successfully performed in a 6-year-old child (Kok et al, 2000). Endoscopic subureteral injection of dextranomer/hyaluronic acid (Deflux) has been used for the correction of VUR, even in the presence of a primary paraureteral diverticulum (Perez-Brayfield et al, 2004).

Key Points: Bladder Diverticulum

- Bladder diverticula can be detected on prenatal ultrasound, but the gold standard remains VCUG, which will reveal possible accompanying VUR.
- Primary diverticula arise as a localized herniation of bladder mucosa at the ureteral hiatus and are most likely caused by a congenitally deficient bladder wall.
- Secondary paraureteral diverticula are acquired and develop due to existing infravesical obstruction.
- Symptomatic diverticula, especially in conjunction with VUR, should be treated surgically.

Bladder Duplication

Duplication of the bladder and urethra can be complete or incomplete. It can occur either in the coronal or sagittal plane. Abrahamson attempted to classify the various bladder duplication anomalies and found complete duplication in the sagittal plane the most common (Abrahamson, 1961). In incomplete duplications, the two bladder halves communicate and are usually drained by a single urethra. In complete duplications, the two bladders are fully separated entities with normal mucosa and a full-thickness musculature wall divided by a peritoneal fold (Fig. 125–6). Although the size and quality of each entity can be different, they are usually supplied

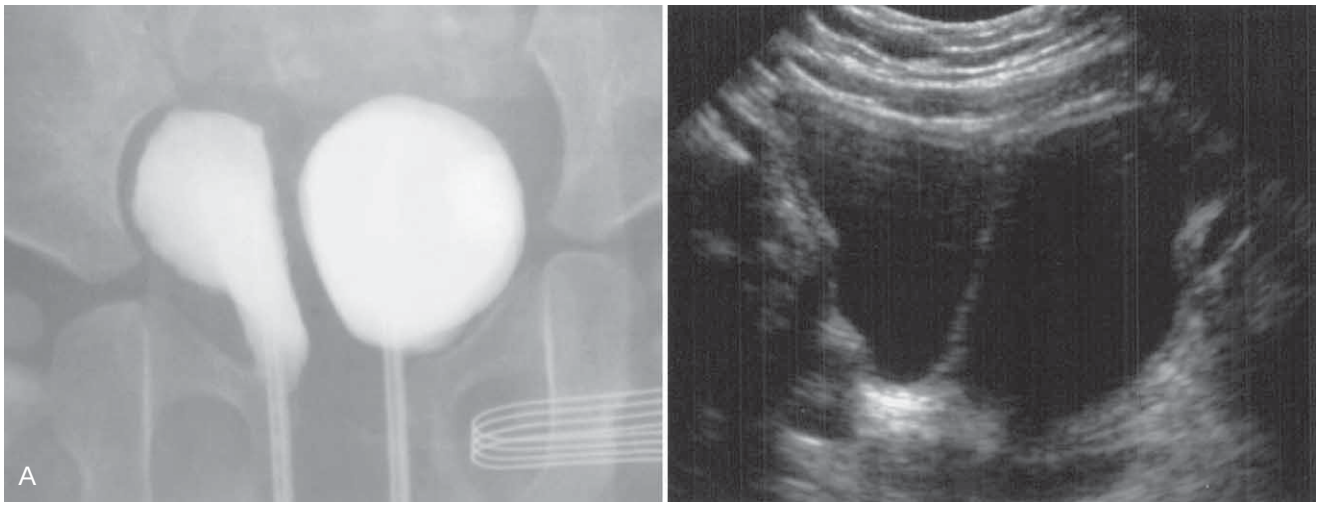

Figure 125–6. Complete bladder duplication. **A,** Vesicoureterogram image of complete bladder duplication with catheters inserted into each individual urethra. Note the size discrepancy. **B,** Ultrasound image of the same patient.

with their own ureter and are drained by an individual urethra and external meatus (Esham and Holt, 1980). In rare cases, one bladder can lack a urethra. This leads to ipsilateral renal dysplasia via complete obstruction (Cheng and Maizels, 1996). Both bladders may possess a sufficient continence mechanism, or one side is compromised, causing incontinent episodes.

Associated duplication anomalies of the external genitalia have been reported in up to 90% of cases; associated duplication anomalies of the lower gastrointestinal tract have been reported in up to 42% of cases (Kossow and Morales, 1973). Duplicated vaginas can be connected to a separate unicornuate uterus. Duplicated penises are supplied with an individual urethra. Additional urologic abnormalities such as VUR, renal ectopia, or dysplasia are commonly found. Association with other nonurologic congenital anomalies are more frequent in sagittal than in coronal duplications. Multiple manifestations have been described including gastrointestinal malformations, duplications of the spine, spina bifida conditions, and various fistula formation between the urogenital and gastrointestinal tract (Berrocal et al, 1999). In duplication variations of the classical cloacal-bladder exstrophy complex, patients present with an exstrophic bladder and urethra in addition to a closed regular intra-abdominal bladder (Perren and Frey, 1998).

The embryologic development of the various duplication anomalies remains poorly understood. Complete duplication of the bladder and hindgut is thought to occur due to partial twinning of the tail portion of the embryo (Ravitch and Scott, 1953). It is also suggested that the development of a sagittal fissure on the cloacal plate occurs when the urorectal septum separates the urogenital from the digestive sinus (Bellagha et al, 1993).

The wide range of anatomic manifestations of duplicate bladders explains the different time points and modes of presentation. With associated malformations of the gastrointestinal or external genital tract, the diagnosis is often made in the newborn period. However, many children are not diagnosed until recurrent infections or incontinence initiates a urologic workup. Although similarities exist, each case is different and warrants individual management. Complete preoperative diagnostic evaluations with karyotype, ultrasound, IVP, video-urodynamic studies, genitogram, and gastrointestinal tract imaging are useful to determine the anatomic situation. VCUG and nuclear renal scans can supply additional information regarding VUR and renal function. Complete understanding of the various anomalies can be difficult. Often the final treatment plan has to be deferred until the time of endoscopic and surgical exploration of the malformation. **Initial treatment is directed toward renal preservation and prevention of infections by relieving possibly obstructed genitourinary tracts.** Long-term goals include achieving continence and reconstructing the internal and external genitalia. Incomplete duplications may not require surgical procedures if both bladder halves are sufficiently drained by a common urethra. In complete duplications, the two bladders can be combined into one. If both sphincter complexes are competent, the distal urethras are connected. If one is incompetent, the corresponding bladder neck can be closed and the connected urethra excised. Duplicated vaginas are combined in the midline, and a vulvoplasty is performed. The urogenital duplications can also be left uncorrected if the patient is asymptomatic; Gastol and colleagues (2000) reported two successful pregnancies in a 26-year-old woman. Due to the rarity of the disease and the large variety of presentations, the surgeries must be individualized and should be performed in centers experienced in complex urogenital reconstruction.

Key Points: Bladder Duplication

- Bladder duplication is often associated with duplication anomalies of the external genitalia and lower gastrointestinal tract.
- Initial treatment is directed toward renal preservation and prevention of infections by relieving possibly obstructed genitourinary tracts.
- Long-term goals include achieving continence and reconstructing the internal and external genitalia.
- Due to the rarity of the disease and the large variety of presentations, the surgeries must be individualized.

Other Bladder Anomalies

Nephrogenic Adenoma

Nephrogenic adenoma of the urinary bladder is a rare benign tumor mostly found in adults. Sporadic case reports in children describe the lesion as a reaction to infection, lithiasis, and trauma or in response to surgery. Heidenreich and colleagues (1999) found a significant predominance of girls compared with boys (5:1), typically presenting with hematuria or irritative bladder symptoms. The diagnosis is established after cystoscopy with biopsy. Treatment consists of transurethral fulguration or resection and can be combined with long-term antibiotic prophylaxis. Although malignant transformation was not reported, tumor recurrence developed in 80% of the children with a latency period of 4 years.

Hungerhuber and colleagues (2008) reported a case of an adenocarcinoma in a 25-year-old who developed a neurogenic bladder after a car accident. He subsequently developed a nephrogenic adenoma, which was resected several times. Although the initial pathology was benign, a moderately differentiated adenocarcinoma was found after several resections. He underwent a radical cystectomy and remained tumor free.

Eosinophilic Cystitis

Eosinophilic cystitis in children is sporadically described in case reports with a predominance in boys. **The etiology remains unclear, and the histopathologic examination includes inflammatory cells with numerous eosinophils throughout all layers of the bladder wall** (Tsakiri et al, 2004). Presenting symptoms include dysuria, hematuria, suprapubic pain, and urinary retention. It can be detected on ultrasound, but the diagnosis is made by cystoscopy with transurethral biopsy of the lesion (Fig. 125–7). Immunologic diseases and allergies have been suggested to be causative for the development of the lesions. In his large review of 135 cases, van den Ouden (2000) found transurethral resection combined with corticosteroids, antihistaminics, or antibiotics to be most successful for all age groups. In neonates and young children the disease can be self-limited and observation is justified (Al-Omar et al, 2005).

Bladder Hemangioma

These benign vascular tumors are mostly seen in association with Klippel-Trenaunay syndrome and can be solitary or on multiple locations throughout the bladder. The leading symptom is macrohematuria, and the vascular tumors are found during cystoscopy. Treatment consists of Nd:YAG laser fulguration of the affected areas (Kato et al, 2000).

Bladder Hernia

In rare cases the bladder has been found in hernia sacs during a routine hernia repair. It can be suspected in an unusual large hernia sac, urine drainage during or after surgery, or the new onset of hematuria postoperatively. Manatt and colleagues (2006) reported a bladder hernia in a premature infant found during a cystogram performed due to hydronephrosis. The bladder was reduced during hernia repair, and no further problems were encountered.

CONCLUSION

Isolated congenital bladder anomalies are rare. Most published information relies on case reports of various malformations and their individualized management. Many of the detected anomalies are due to infravesical obstruction or are part of a syndrome affecting other parts of the genitourinary or nonurologic systems. Prenatal ultrasound allows early detection of bladder changes and has vastly influenced the prenatal and postnatal management of the described malformations. However, due to the rarity of the various presentations, large series with adequate follow-up are missing. Management and treatment remain individualized. Severe anomalies are often difficult to understand, and treatment should be centralized in specialized centers.

POSTERIOR URETHRAL VALVES

Description, Classification, and Embryology

Congenital obstruction of the urethra is one of the most devastating anomalies that occur in the urinary tract and is one of the few that are life threatening in the neonatal period. These lesions usually result in lifelong disabilities with incontinence and decreased renal function despite optimal medical management. The condition of posterior urethral valves is still relatively common and makes up the vast majority of congenital urethral obstructions.

Langenbeck is credited with first reporting congenital obstruction of the prostatic urethra in 1802 (Dewan et al, 1999). Despite this observation it was left for Hugh Hampton Young, over a century later, to define and name the condition as posterior urethral valves (Young et al, 1919). His remarkably accurate observations were made only with gross pathologic dissection and with the primitive cystoscopic instruments of his day. Young observed the anatomic variability of the anomaly and developed a classification that is still used almost 100 years later.

The term *valves* is unfortunate because it implies function. This obstructive membrane has no active function and is not a developmental stage in the embryology of the urethra. It is simply a passive barrier to urine flow. Young adopted this term when he found that a urethral sound would pass easily from the urethral meatus into the bladder in a retrograde manner while the same sound (or urine for that matter) would not pass antegrade out of the bladder and down the urethra. This unidirectional access through the urethra suggested to Young the function of a one-way valve, and he described the condition as such.

Posterior urethral valves occur in 1 in 8000 to 25,000 live births and make up 10% of urinary obstructions diagnosed in utero (Atwell, 1983; Thomas and Gordon, 1989; Casale, 1990). The diagnosis has been made on average in 1 in 1250 fetal ultrasound screenings (Gunn et al, 1995). There are reported cases of congenital urethral obstruction in females, but the classic posterior urethral valves occur only in males (Nesbit et al, 1964). The incidence of posterior urethral valves is dropping in some populations due to the effects of prenatal diagnosis and subsequent termination of affected fetuses. In one report, fetuses diagnosed with valves were electively terminated in 46% of cases (Cromie et al, 2001).

Despite several alternative proposals, Young's classification is still most commonly used (Dewan, 1993) (Fig. 126–1). He described three types of posterior urethral valves:

> Type I. In the most common type there is a ridge lying on the floor of the urethra, continuous with the verumontanum, which takes an anterior course and divides into two forklike processes in the region of the bulbomembranous junction. These processes are continued as thin membranous sheets, directed upward and forward, which may be attached to the urethra throughout its entire circumference. In the majority of cases of this general type the fusion of the valves anteriorly is not complete, there existing at this point a slight separation of the folds. However, in a few of the cases…the anterior fusion is complete while a cleft exists between the folds posteriorly.

Recently it has been proposed that all boys with valves originally have complete fusion along the anterior urethra, leaving only an open channel along the posterior urethral wall. The frequently observed cleft in the membrane may be iatrogenic, created by instrumentation or catheterization that erodes the valve tissue in the anterior midline and splits the valve in two leaflets (Robertson and Hayes, 1969; Dewan et al, 1992).

Young's type I valves make up 95% of all posterior urethral obstructions (Fig. 126–2).

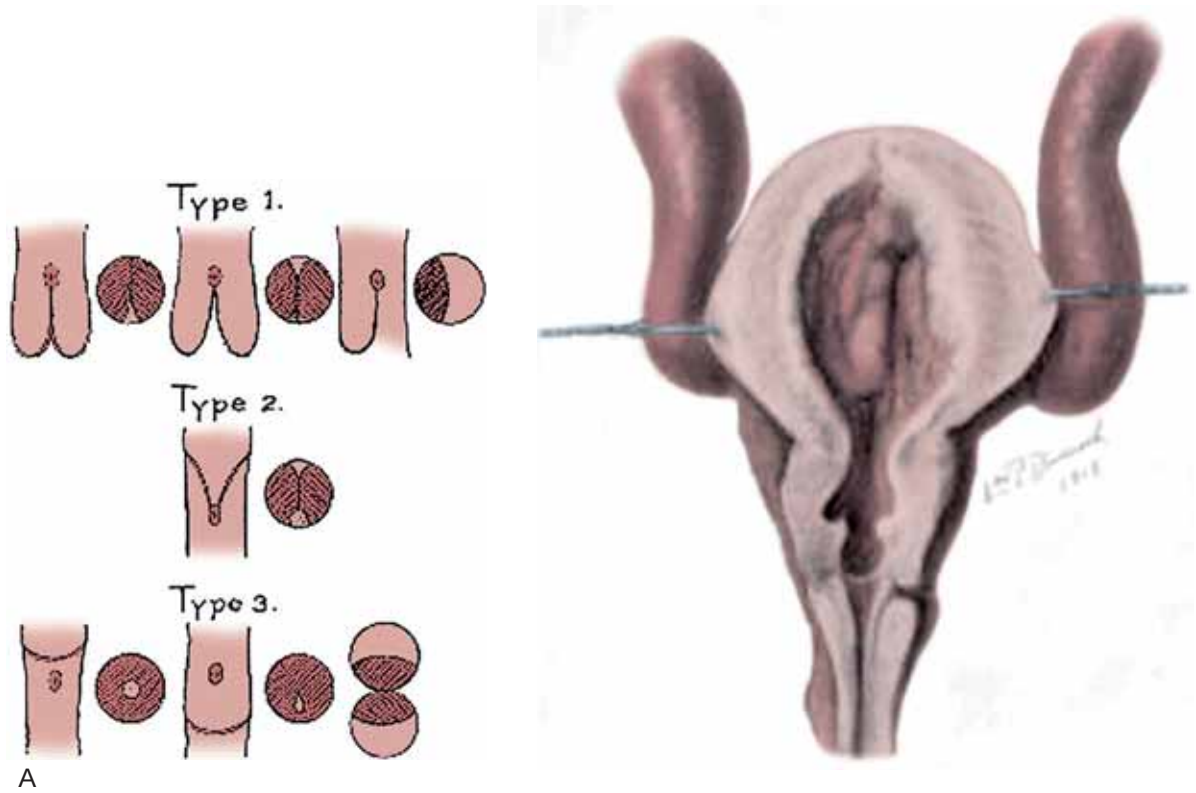

Figure 126–1. **A,** Young's original figures from his 1919 article. He described three types of posterior urethral valves and diagrammed them. **B,** William P. Didusch drew this pathologic dissection that shows the features of posterior urethral valves, the thickened bladder wall with an elevated bladder neck, and enlarged posterior urethra. The two valve leaflets of type I valves are seen. The ureters are massively dilated. (From Young HH, Frontz WA, Baldwin JC. Congenital obstruction of the posterior urethra. J Urol 1919;3:289.)

The thickness of the valves themselves varies from rigid, thick tissue to thin, almost transparent membranes. The valve itself is made of a fibrous stroma covered on each side by transitional epithelium. There is no muscle within the valve. The degree of obstruction also varies widely and, in turn, the amount of damage to the urinary tract.

The embryology of posterior urethral valves is speculative but may be related to an abnormal insertion of the mesonephric ducts into the fetal cloaca. Evidence supporting this theory lies in the fact that type I valve patients lack plicae colliculi, mucosal folds found in the normal male urethra that are believed to represent a remnant of the normal pathway of migration of the mesonephric ducts toward the verumontanum (Stephens, 1983).

Young described a type II valve as arising from the verumontanum and extending along the posterior urethral wall toward the bladder neck. This description was based on the similar appearance of these folds to the membranes found in type I. These type II folds are not obstructive and probably result from hypertrophy of muscles of the superficial trigone and prostatic urethra in response to high voiding pressure from distal obstruction. They can be seen in response to many obstructive conditions such as urethral strictures, posterior urethral valves, anterior urethral valves, and detrusor-sphincter dyssynergia. These type II folds are no longer referred to as valves.

Young described type III valves as a membrane lying transversely across the urethra with a small perforation near its center (Fig. 126–3). The membrane is distal to the verumontanum and sometimes is elongated like a wind sock reaching the bulbous urethra (Field and Stephens, 1974). Type III valves make up only 5% of the total. Young described them as follows:

> There is a third type which has been found at different levels of the posterior urethra and which apparently bears no such relation to the verumontanum as the types just considered....This obstruction was attached to the entire circumference of the urethra, there being a small opening in the center. Incomplete varieties of this type have been described, the most common being a more or less crescentic or semicircular fold crossing the urethra and being attached either to the roof or floor.

The embryologic origin of type III valves has been attributed to incomplete dissolution of the urogenital portion of the cloacal membrane. Type III valves present in the same manner and are managed in the same way as the more common type I, although there is some evidence that type III valves have a worse prognosis (Rosenfeld et al, 1994).

The inheritance of posterior urethral valves is poorly understood and may involve several genes and inheritance patterns (Livne et al, 1983; Weber et al, 2005). Valves have occurred in siblings, twins, and in successive generations (Farkas and Skinner, 1976; Hanlon-Lundberg et al, 1994; Morini et al, 2002; Maruotti et al, 2006). The timing of valve development is also speculative, but it would appear that they become obstructive during or after the eighth week of life by which time the prostatic urethra has developed from the urogenital sinus (Mitchell and Close, 1996). In a recent review of the literature, Baskin and colleagues concluded that the precise origins regarding the anatomy and embryology of posterior urethral valves remain undefined. Although theories of etiology abound, there are a limited number of modern

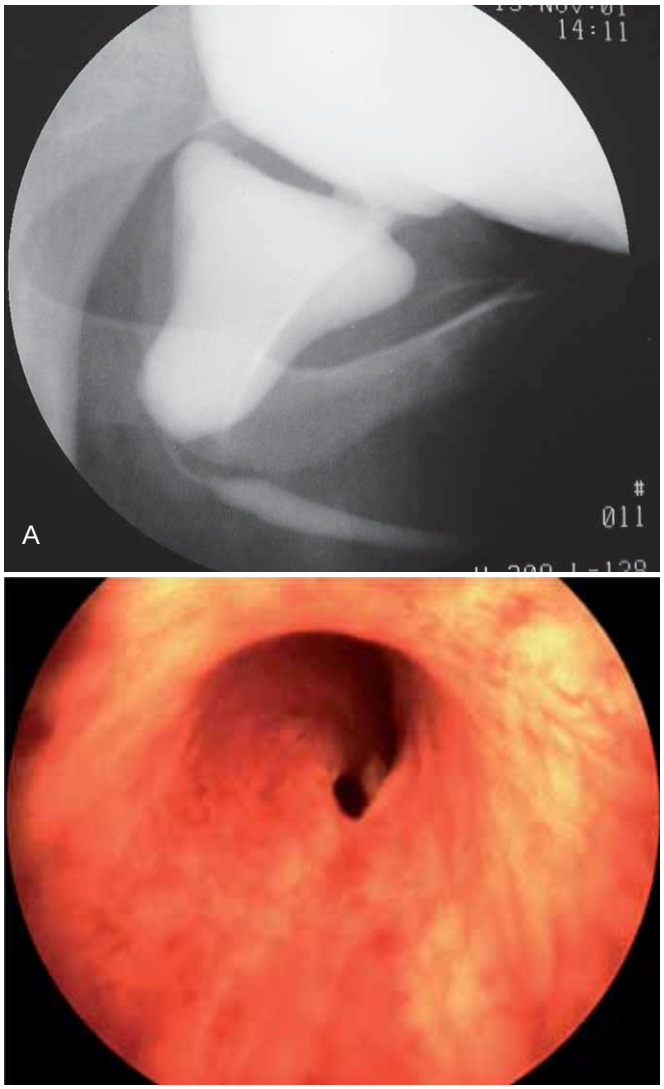

Figure 126–2. **A,** Voiding cystourethrogram demonstrates a typical type I posterior urethral valve with a dilated posterior urethra, elevated bladder neck, and valve leaflets obstructing the flow of contrast material from the bladder. **B,** This cystoscopic image from the distal urethra shows the valve leaflets forced into the lumen with the bladder full, illustrating their obstructive effect.

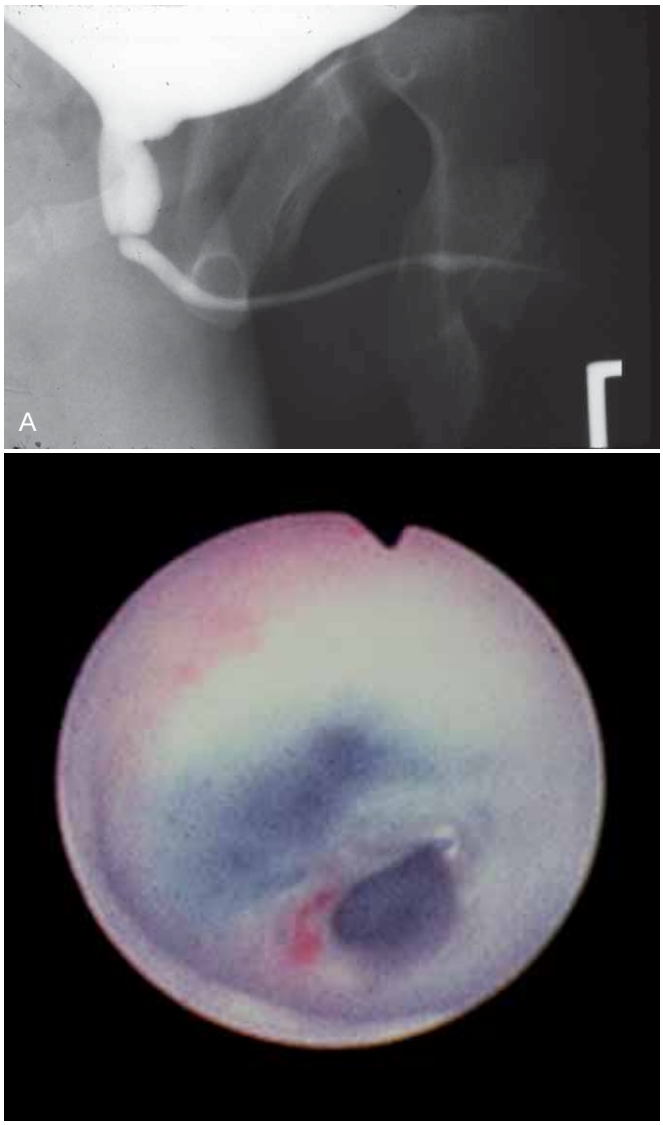

Figure 126–3. **A,** Voiding cystourethrogram demonstrates a typical type III posterior urethral valve with a transverse septum crossing the urethra at a right angle distal to the verumontanum. **B,** A cystoscopic image from the distal urethra shows the thin membrane and a small off-center opening.

methodical anatomic and histiologic studies to support them (Krishnan et al, 2006).

Pathophysiology

The effects of congenital obstruction of the urethra are reflected in the entire urinary tract above the level of obstruction (Table 126–1). Proximal urethra, prostate, bladder neck, bladder, ureters, and kidneys are all affected and suffer various forms of damage.

Lower Urinary Tract

The injury to the lower urinary tract appears to be caused by high-pressure urine storage and voiding (McConnell, 1989; Keating, 1994). Bladder histology of fetuses with posterior urethral valves shows hypertrophy and hyperplasia of the detrusor muscle along with increased connective tissue. The ratio of muscle to connective tissue is the same as in normal bladders, but there is conflicting evidence that the type of collagen within the bladder is altered (Kim et al, 1991; Ewalt et al, 1992). Some bladder findings in neonates such as wall thickness and poor compliance will improve after relief of obstruction, but the valve bladders seldom if ever achieve normal function.

High voiding pressures distend and thin the prostatic urethra. The storage capacity of the prostatic urethra sometimes exceeds that of the bladder because of the relative lack of muscle there. The verumontanum is distorted, and the ejaculatory ducts may be dilated from refluxing urine. The bladder neck is rigid and hypertrophied (Fig. 126–4). This high bladder neck was once mistaken as another cause of obstruction and was surgically incised to facilitate bladder emptying. Unfortunately, this practice often resulted in total incontinence. Today it is understood that the appearance

Table 126–1.

Damage Due to Posterior Urethral Valves

ORGAN	EFFECT	NATURAL HISTORY
Lung	Pulmonary hypoplasia	May be fatal in newborns; if infant survives, there are few long-term problems
Kidney		
Glomerular injury		
Obstructive uropathy	Reversible renal insufficiency	Usually improves with initial treatment but can recur with bladder dysfunction
Dysplasia	Irreversible renal insufficiency	Permanent level of renal damage that limits growth; leads to progressive renal failure and hypertension
Tubular injury	Inability to limit sodium and water loss	Progressive with age; nephrogenic diabetes insipidus
Bladder	Poor sensation, hypercontractility, low compliance, and eventual myogenic failure all may contribute to incontinence and poor emptying	Bladder problems are lifelong and change with age
Ureters	Poor contractility and inability to coapt and transport urine	Most will improve initially, but most have chronic hydronephrosis

of the bladder neck is a result of distal obstruction and not obstructive lesion itself. Bladder neck appearance and function usually improves after the obstructive valves are destroyed.

Upper Urinary Tract

Ureteral damage is usually severe. The appearance and function of the ureters are markedly abnormal. The ureteral wall is thickened and the lumen massively dilated. The ureter is at the mercy of the ureterovesical junction (UVJ). If this junction functions to prevent reflux, the ureter and kidney are somewhat protected from the complete force of the bladder contractions. If the junction allows reflux, the entire pressure of the thickened and hypercontractile bladder is transmitted directly to the upper tract with severe consequences. Virtually all valve patients have hydroureteronephrosis, and this can be the result of obstruction from the valves, the UVJ, or both. Although reflux is variable, hydroureteronephrosis is a constant in these patients. Severely dilated ureters coapt poorly and contract weakly, if at all (Gearhart et al, 1995). The propulsion of urine down the ureter is diminished in the infant, and this ureteral dysfunction may persist throughout life despite relief of distal obstruction.

The nature of the renal injury in boys with posterior urethral valves is complex and appears to have two distinct components. Some damage, described as obstructive uropathy, is caused by persistent high pressure. It is ongoing and can be progressive, but it is potentially reversible with relief of high pressures. Other damage, termed *renal dysplasia,* may be due to either increased pressure during the development of the kidney or abnormal embryologic development. Renal dysplasia is not reversible, and therefore the degree of dysplasia is critical in determining eventual renal function in valve patients.

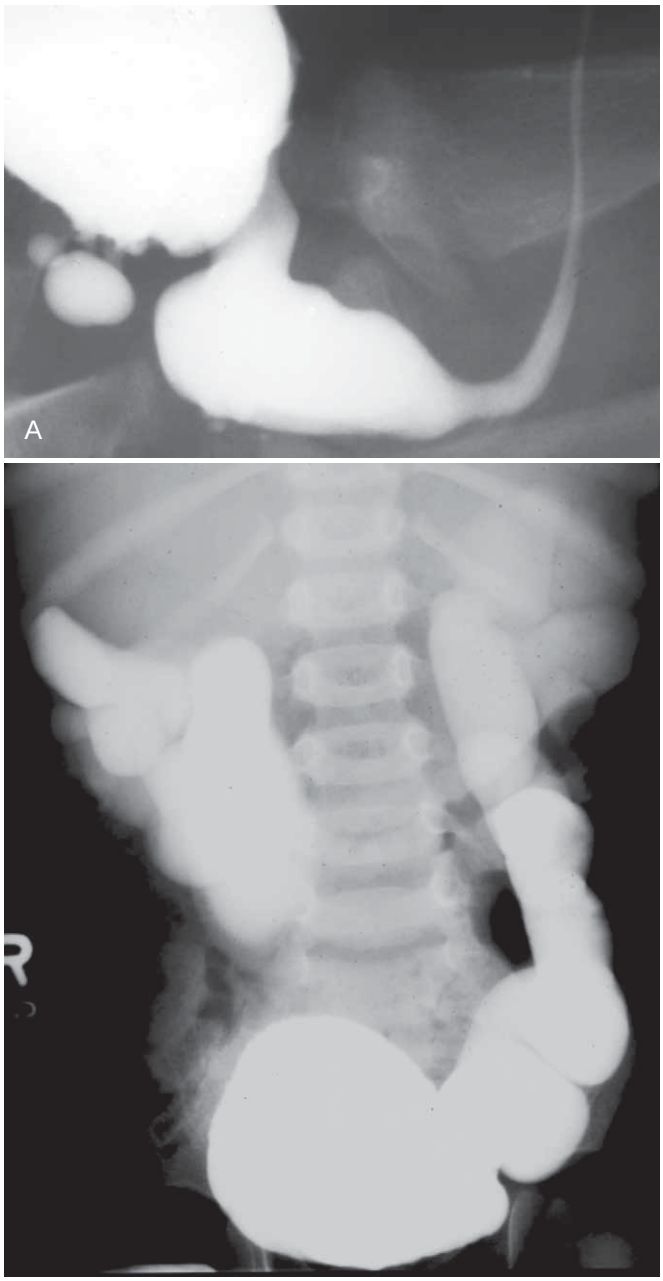

Figure 126–4. **A,** Voiding cystourethrogram shows a posterior bladder diverticulum near the base of the bladder and an extremely high bladder neck. A catheter passed blindly can fail to pass over the bladder neck and coil in the dilated posterior urethra. **B,** Massive vesicoureteral reflux in a boy with valves.

Dysplasia is, in fact, a histologic diagnosis and depends on identifying a fundamental disorganization of the renal parenchyma on a cellular and tissue level. The elements of dysplasia include embryonic tubules, cartilage, cysts, and mesenchymal connective tissue. The particular type of dysplasia in valve patients is termed *microcystic* and can be observed primarily in the peripheral cortical zone of the kidney.

The exact cause of dysplasia is a matter of continued debate. Beck and Glick demonstrated that dysplasia could be produced by early urinary obstruction in lambs (Beck, 1971; Glick et al, 1984). Maizels and colleagues (1983) also produced a form of dysplasia in chicken embryos by obstructing the fetal urinary tract. Ample evidence indicates that a form of dysplasia can be induced by early fetal urinary obstruction and resultant high intrarenal urinary pressure.

On the other hand, Stephens and Henneberry (1980) have demonstrated that dysplasia may be found in patients who do not seem to have a history of obstruction but instead have abnormal ureteral development. In patients with severe vesicoureteral reflux, the ureteral orifice is usually in an abnormal position. These patients frequently demonstrate renal dysplasia, and the degree of dysplasia is proportional to how much the position of the ureter deviates from normal. Stephens postulated that this dysplasia was the result of a faulty ureteral bud arising in an abnormal position along the mesonephric duct. Because the ureteral bud induces the development of the kidney, it follows that an abnormal bud may induce an abnormal kidney.

Dysplasia therefore occurs in association with obstruction and with reflux, seemingly unrelated conditions. Both theories are plausible and not exclusive. **Whatever the cause, dysplasia is the defining factor in long-term renal function in most patients with valves. Because this type of renal damage is not reversible, the extent of dysplasia will ultimately determine the growth and functional potential of the infant's kidneys. A number of other related factors may contribute to declining renal function in valve patients including infection, persistent obstruction, hypertension, hyperfiltration of damaged parenchyma, and perhaps high-protein diet, but none are as important as the degree of dysplasia** (Brenner et al, 1982; Klahr, 1989; Farnham et al, 2005).

All posterior urethral valve patients have a degree of associated obstructive uropathy. Obstructive uropathy involves both glomerular injury and tubular injury. Glomerular injury occurs when high pressures result in decreased renal perfusion and filtration. These changes are partially reversible when pressures are dropped and obstruction is relieved. The potential for recovery is felt to be time sensitive, and early relief of obstruction should favor recovery. **Some degree of scarring and fibrosis within the parenchyma persists, but unlike dysplasia, obstructive uropathy usually improves with treatment.**

Tubular damage from increased urinary pressure results in failure to concentrate and acidify the urine. This occurs in up to 59% of valve patients and sometimes occurs in patients without evidence of glomerular injury (Parkhouse and Woodhouse, 1990; Dinneen et al, 1995). **Concentrating defects in the form of nephrogenic diabetes insipidus lead to increased urine output independent of the patient's state of hydration. Patients are at risk for electrolyte imbalances and dehydration due to inability to conserve sodium and water even in the face of dehydration** (Gonzales, 1978). **Pathologically large urine output also stresses the ureters and bladder and contributes to persistent hydroureteronephrosis and bladder dysfunction. Tubular damage worsens with age despite early relief of obstruction in many patients, and resultant high urine volumes contribute to the deterioration of renal and bladder function in late childhood.**

Key Points: Pathophysiology

- Posterior urethral valves damage the entire urinary tract proximal to the valve.
- Pulmonary hypoplasia is the most common cause of mortality in valve patients.
- Most renal damage occurs early in fetal life.
- Bladder dysfunction is usually a lifelong problem resulting in incontinence and poor emptying.
- Persistent hydronephrosis is common and may be due to either ureteral or bladder dysfunction.
- Reflux usually improves and often resolves after valve ablation.

Vesicourethral Reflux and Dysplasia and Pop-Off Mechanisms

Hoover and Duckett identified the relationship between valves, reflux, and dysplasia (Hoover and Duckett, 1982). **They recognized that valve infants with unilateral reflux had markedly different renal function when comparing refluxing and nonrefluxing kidneys. Reflux was consistently associated with dsyplastic and damaged kidneys. They postulated that the reflux allowed the high bladder pressures to focus on the refluxing kidney, sparing and protecting the nonrefluxing kidney.** The vesicoureteral reflux and dysplasia (VURD) relationship is found in 13% of valve patients, and interestingly the refluxing kidney is on the left side in 92%.

The proposed mechanism of this protection is that the refluxing collecting system acts as a pressure pop-off valve. The belief was that the protected kidney would ultimately lead to a better long-term prognosis compared with boys without unilateral reflux. The long-term protective effect of VURD has not been as helpful as originally thought. Longitudinal studies in VURD patients have shown that by midchildhood both serum creatinine and glomerular filtration rate (GFR) were significantly decreased compared with normal children (Cuckow et al, 1997). In addition, scarring has been observed with dimercaptosuccinic acid scanning in half of the contralateral, nonrefluxing kidneys with possible negative long-term consequences (Narasimhan et al, 2005). Other types of pop-off pressure systems include bladder diverticuli, urinomas, and urinary ascites (Rittenberg et al, 1988). The protective effect of these clinical situations is highly variable.

Clinical Presentation

In the past boys with posterior urethral valves presented with a variety of symptoms and at various ages (Hendren, 1971). **They ranged from newborns with life-threatening renal and pulmonary conditions to older children with minor voiding dysfunction.** In general, the symptoms are age dependent with the more severely affected boys presenting earlier in life (Dinneen and Duffy, 1996).

Neonates

Today, most patients with posterior urethral valves are diagnosed with prenatal ultrasound. Obstruction leads to decreased fetal urine output and results in

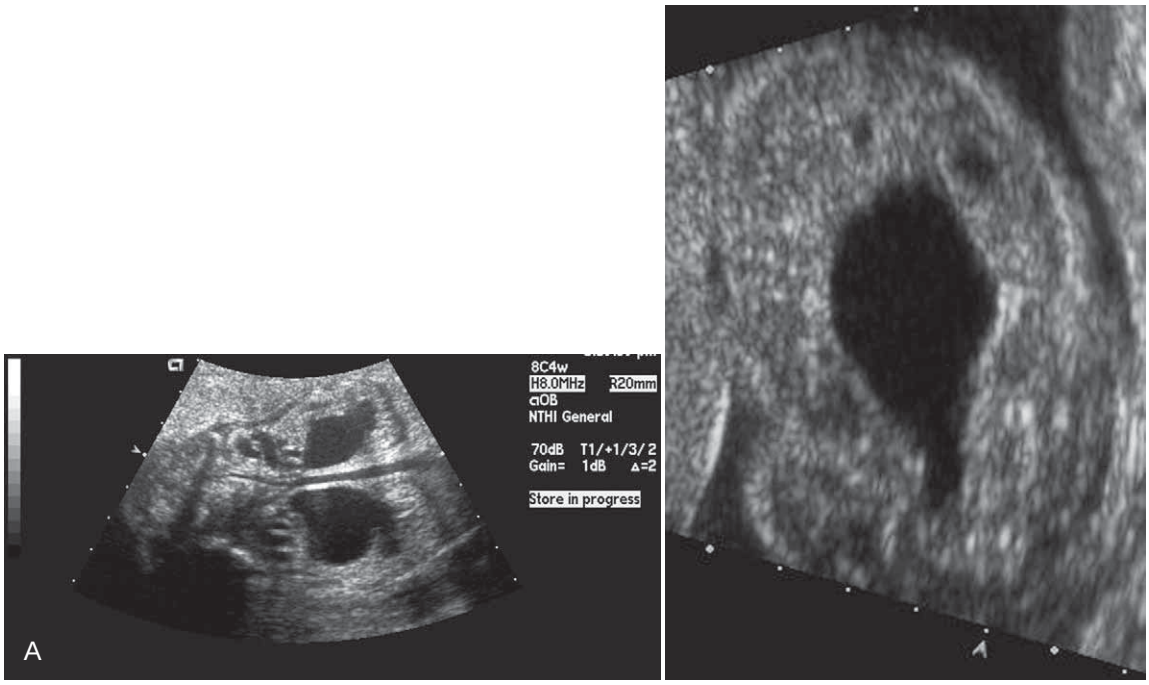

Figure 126–5. **A,** Ultrasound examination shows severe hydroureteronephrosis in a fetus with posterior urethral valves. **B,** Fetal ultrasound examination demonstrates a severely thickened bladder wall with a distended bladder and posterior urethra. These two fluid collections, a larger one above the smaller one, produce the "keyhole" sign indicative of posterior urethral valves.

oligohydramnios. The observation of marked hydroureteronephrosis, a distended bladder, and a thickened bladder wall in utero strongly support the diagnosis of valves (Fig. 126–5). Often the urologist has been consulted long before delivery, and in some cases intervention has been undertaken in utero.

Pulmonary Hypoplasia. **The most severe clinical problem facing the neonate with posterior urethral valves is pulmonary hypoplasia.** The infants are often cyanotic and require respiratory support at delivery. Pulmonary hypoplasia is a direct result of oligohydramnios and accounts for most of the mortality today (Churchill et al, 1990). The exact etiology of the pulmonary hypoplasia is unclear, but contributing factors include physical restriction of fetal breathing motion (Landers and Hanson, 1990). The lack of amniotic fluid to surround and buffer the fetus from intra-abdominal pressure leads to a small chest cavity and prevents chest wall breathing motion and normal musculoskeletal development. Amniotic fluid may be important in development of the fetal pulmonary tree by providing needed intraluminal pressure, volume, and flow. In addition, the amniotic fluid may provide some cellular or molecular stimulus to the developing lung. The results of oligohydramnios are often life threatening, and some infants succumb despite heroic measures. The mortality of valves has decreased significantly over the past two decades with development of better methods to manage pulmonary hypoplasia by neonatology. It is rare to have an infant die today with the quality of pulmonary support available in the newborn intensive care unit (Dejter and Gibbons, 1989; Gibbons et al, 1993).

Renal Insufficiency. **In addition to pulmonary distress, the newborn with posterior urethral valves usually presents with signs of severe systemic illness such as intrauterine growth retardation, failure to thrive, lethargy, and poor feeding. The infants may be pale and have poor muscle tone. They may demonstrate the classic signs of oligohydramnios such as Potter facies and bowed and deformed limbs with pressure dimples over knees and elbows from intrauterine pressure. Examination of the abdomen may reveal masses due to hydroureteronephrosis and a distended bladder. The infant may suffer from extensive edema and urinary ascites.** The caregivers may notice a diminished force of urinary stream, but this sign is not reliable to predict valves (Smith et al, 1996). If not diagnosed in utero, the most severely affected valve patients present as newborns. Often urinary tract infection or urosepsis precipitates evaluation and diagnosis.

Ascites. **Forty percent of neonatal ascites is caused by urinary conditions** (Fig. 126–6) (Adzick et al, 1985). Urinary ascites occurs when high intraluminal pressure forces urine to extravasate from the kidney, usually across a renal fornix. Urine then enters the retroperitoneum and travels across the peritoneum as a transudate. If aspirated from the peritoneal cavity, the ascites or extravasated urine contains electrolyte and creatinine levels similar to serum. The urine within the peritoneum is subject to the large absorptive mesothelial surface that quickly normalizes these values, masking the identity of ascitic fluid as urine. The diagnosis of urinary ascites may be difficult and may require definitive upper tract drainage in the form of nephrostomy tubes in order to establish the etiology of the ascites and allow its resolution. Urinary ascites in the case of distal obstruction may serve to lower urinary pressures and offer some protection to the developing kidneys (Conner et al, 1988).

Patel and colleagues (2003) reviewed a large group of 615 valve patients and analyzed the protective effect of ascites compared with unilateral and bilateral urinomas. The authors found that the kidney associated with a unilateral urinoma is often impaired. Bilateral urinomas are associated with good renal function, but

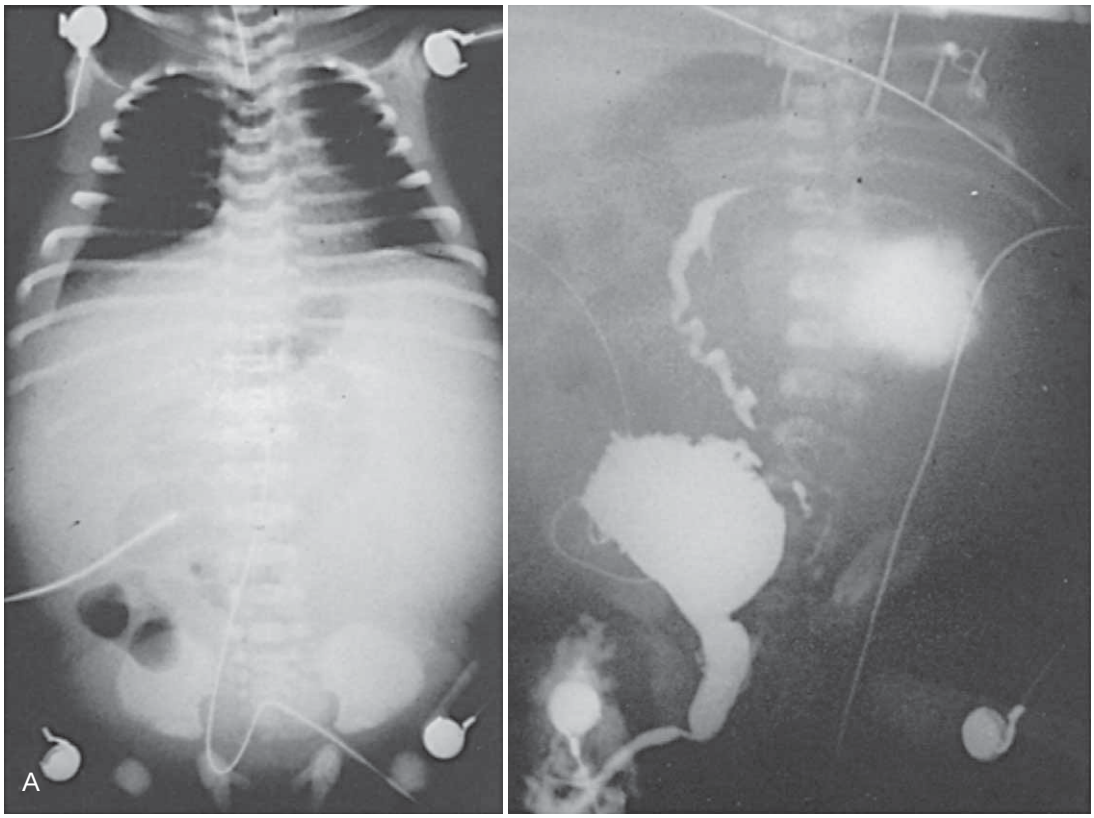

Figure 126–6. **A,** Abdominal radiograph shows the ground-glass appearance of an infant with ascites. **B,** Voiding cystourethrogram demonstrates reflux of contrast material, which is then seen extravasating into a urinoma and later flowing into the abdominal cavity as urinary ascites. (From Gonzales ED. Posterior urethral valves and other ureteral anomalies. In: Walsh PC, Retik AB, Vaughan ED, Wein AJ, editors. Campbell's urology. 8th ed. Philadelphia: WB Saunders; 2002.)

urinary ascites alone has a poorer prognosis. The GFR of patients with urinary ascites alone was 29 mL/min per 1.73 m^3 compared with 36 mL for boys with unilateral urinoma alone, 74 mL for boys with urinoma plus ascites, and 104 mL for bilateral urinomas.

Heikkila and colleagues (2008a) studied 200 patients with valves and found that the incidence of urinoma approached 15% after the introduction of ultrasound. This group included nine with perirenal urine collections, six with urinary ascites, and two with urothorax. They found initial and post-treatment serum creatinine levels, incidence of reflux, median split renal function, and risk for end-stage renal disease (ESRD) in the 17 patients with urinoma to be statistically similar to a control group of valve patients without urinoma. Their conclusion was that renal function is similar in patients with or without urinoma. Other authors have also found no association between renal function and urinoma formation in valve patients (Kleppe et al, 2006).

Older Children

The majority of boys who present later in life do so with urinary tract infection and/or voiding dysfunction. With a better understanding of functional voiding disorders, valves are now an uncommon cause of minor voiding dysfunction (Pieretti, 1993). Due to widespread prenatal ultrasound, it is now rare to see a new patient with posterior urethral valves past the neonatal period. Although boys who present later in life are generally believed to have more normal urinary tracts, this is not a uniform finding. One series reported that patients who presented at school age suffered renal insufficiency in 35% of cases (Bomalaski et al, 1999).

Initial Diagnostic Evaluation

Ultrasound

The widespread use of maternal ultrasound in the past 25 years in the United States has resulted in at least 80% of women undergoing ultrasound screening study during pregnancy. **Posterior urethral valves is the third most common antenatal genitourinary diagnosis made today and accounts for 10% of all fetal uropathy** (Thomas and Gordon, 1989). Although it was reported that two thirds of patients with valves presented on fetal ultrasound during the 1990s, this percentage has continued to rise (Greenfield, 1997). The quality and availability of ultrasound technology continues to improve, and with it the ability to image the fetus.

Ultrasound is sensitive in detecting fetal hydronephrosis, but the specific diagnosis of posterior urethral valves is more difficult. The differential diagnosis of bilateral hydronephrosis includes posterior urethral valves, prune-belly syndrome, bilateral ureteropelvic junction obstruction, bilateral high-grade vesicoureteral reflux, bilateral ureterovesical junction obstruction, congenital urethral atresia, and anterior urethral obstruction. Valves were correctly diagnosed in only 66% of 18 fetuses who were identified with hydronephrosis (Skolder et al, 1988). In a review of 42 patients with valves, only 45% were detected on antenatal ultrasound (Dinneen et al, 1993).

The timing of screening for fetal uropathy is an important factor in accuracy. There is compelling evidence that valves may be missed if the screening ultrasound is

done before 24 weeks' gestation (Jee et al, 1993; Hutton et al, 1994). In Dinneen's series, 92% of the 36 patients scanned before 24 weeks' gestation were not detected. The classic ultrasound findings in patients with valves include bilateral hydroureteronephrosis, distended bladder, dilated posterior urethra, and a thickened bladder wall. The "keyhole" sign of a dilated bladder above a dilated prostatic urethra is also helpful. Bladder wall thickness is an important diagnostic sign. The findings of an excessively thick bladder wall and a distended bladder indicate distal obstruction (Kaefer et al, 1997a).

Renal echogenicity is another parameter that may aid in the diagnosis of valves. Increased echogenicity predicted an obstructive process in a study of fetuses with bilateral hydroureteronephrosis and distended bladders (Kaefer et al, 1997b). Patients with a nonobstructive process such as megacystis-megaureter association failed to demonstrate increased echogenicity, while 87.5% of valve patients had increased echogenicity at a mean gestational age of 26 weeks. The same predictive value was found with oligohydramnios. **Any male fetus with bilateral hydroureteronephrosis, decreased amniotic fluid, and a distended bladder should be considered to have posterior urethral valves until proved otherwise.** The ultrasound findings of a neonate with posterior urethral valves are identical to those of a fetus.

Voiding Cystourethrography

The voiding cystourethrogram (VCUG) remains the most important study in diagnosing posterior urethral valves because it defines the anatomy and gross function of the bladder, bladder neck, and urethra (Fig. 126–7). **When the diagnosis of valves is in question, a VCUG should be obtained as soon as possible. On imaging the bladder and upper tracts of children with neuropathic bladder, urethral stricture, anterior urethral obstruction, and posterior urethral valves may all appear identical. Images of the urethra during voiding are necessary to make the correct diagnosis.**

Figure 126–7. Voiding cystourethrogram reveals massive vesicoureteral reflux in an infant with posterior urethral valves.

In posterior urethral valves the bladder is thickened and trabeculated. The VCUG often demonstrates bladder diverticuli and severe vesicoureteral reflux. From the lateral projection the bladder neck is elevated. The proximal urethra is quite dilated, and the actual valve structure is often visible. Vesicoureteral reflux is present in at least 50% of valve patients at the time of diagnosis (Churchill et al, 1990). The incidence of reflux has been found to be higher in neonates than in older children. Because most valve patients are now discovered in utero, the incidence of reflux may continue to increase compared with historical studies. There is an 80% incidence of reflux on the left side in patients with unilateral reflux for no apparent reason (Hoover and Duckett, 1982).

Ultrasound imaging of the posterior urethra from the perineum has been suggested as a noninvasive way to diagnose valves (Good et al, 1996). Valve leaflets can be visualized on ultrasound while bladder wall thickness and posterior urethral diameter before and during voiding is increased in valve patients. Although this application has little to add to the newborn evaluation, it can be used to evaluate older children without catheterization.

Radionuclide Renal Scan

In addition to the VCUG and renal ultrasound, the radionuclide renal scan has become an important part of the evaluation. Mercaptoacetyltriglycine (MAG-3) is the most useful agent for this imaging because it provides functional data and adequate imaging of both the parenchyma and collecting system. Scans provide differential renal function and some insight about drainage of the upper urinary tracts. **In patients with reflux the bladder must be emptied during the entire study with a catheter in order to avoid artificial enhancement of renal function by reflux of the isotope from the bladder.** If the catheter cannot keep the bladder empty through gravity, it may be necessary to aspirate it with a syringe during the study.

Laboratory Evaluation

Initial laboratory evaluation of the newborn with valves is usually misleading due to the effects of maternal renal

Key Points: Diagnosis and Evaluation

- Most cases of posterior urethral valves are diagnosed on antenatal ultrasound screening.
- The VCUG with urethral imaging is the key study in the diagnosis of valves.
- Evaluation of the infant's renal function often takes several days to allow for maternal effects on serum chemistries to resolve.
- Urodynamics are necessary in understanding bladder function throughout life.
- Nuclear renal scans and in some cases Whitaker perfusion tests are necessary in some patients to evaluate persistent hydroureteronephrosis.

function mediated through the placenta. Initial creatinine and blood urea nitrogen (BUN) levels may be artificially low, and it will take approximately 48 hours for the serum levels to accurately represent the child's intrinsic renal function. Creatinine, BUN, and electrolytes should be followed twice daily for the first few days of life until they plateau. Serum bicarbonate, sodium, and potassium are all critical factors to monitor.

Initial Management of Posterior Urethral Valves

Bladder Drainage

Initial management of all patients with posterior urethral valves requires the immediate establishment of urinary catheter drainage from the bladder. This should be performed even if the diagnosis has not been confirmed by VCUG. Neonates can be catheterized with a 3.5- or 5-Fr pediatric feeding tube. Foley catheters have been used with success, but there have also been reports that the balloon causes irritation and resultant bladder spasms. The bladder may be extremely irritable, and the presence of any catheter can cause spasms so severe as to obstruct the flow of urine into the bladder (Noe and Jerkins, 1983; Jordan and Hoover, 1985). Accurate catheter placement in the bladder must be documented either by irrigation of the catheter or by bladder imaging. Because it is difficult to pass the catheter over the elevated bladder neck and to avoid placing the catheter in the dilated prostatic urethra instead of the bladder, a one-shot cystogram is often advisable.

The ill newborn with posterior urethral valves is usually in the hands of the neonatal service for the management of the most threatening issues such as pulmonary hypoplasia and renal insufficiency. It is in these areas where improvement of medical management has decreased early mortality in valve babies (Nakayama et al, 1986). These infants may require maximal ventilatory support, extracorporeal membrane oxygenation, dialysis, parenteral nutrition, control of hypertension, and a host of other services provided by neonatology and pediatric nephrology (Gibbons et al, 1993).

Valve Ablation

After successful initial bladder drainage and when the patient's medical condition has stabilized, the next step is to permanently destroy the valves. In the past, destruction of valves was done by open surgery or patients were managed with long-term suprapubic tube drainage (Gonzalez et al, 1990). Both of these early therapies can lead to unacceptable complications such as incontinence, stones, and infection (Churchill et al, 1983).

Today a number of successful surgical techniques are available to disrupt or destroy posterior urethral valves including hooks, balloon catheters, and valvulotomes (Deane et al, 1988; Kolicinski, 1988; Cromie et al, 1994; Chandna et al, 1996; Chertin et al, 2002). One of the more common methods uses the Whitaker hook. This instrument looks like a crochet hook and has been used successfully to cut valves either blindly or with fluoroscopic control (Whitaker and Sherwood, 1986). **New, smaller pediatric cystoscopes with improved optics are favored today because of the ability to perform the procedure under direct vision. A bugbee electrode or a pediatric resectoscope with a hook or cold knife can be used to incise the valves** (Fig. 126–8). A number of authors report using a cystoscope and laser to disrupt valves (Ehrlich and Shanberg, 1988; Biewald and Schier, 1992; Gholdoian et al, 1998). Although most surgeons incise the valves from a retrograde position viewed through the urethra, others have found that an antegrade approach through a vesicostomy or suprapubic puncture of the bladder is helpful (Zaontz and Firlit, 1985).

Originally surgeons attempted to completely resect the valves. This practice produced frequent complications from urethral stricture resulting from electrosurgical and instrument damage to the urethra. Modern appropriately sized cystoscopic equipment and limited use of electrosurgery have reduced the incidence of urethral injury to 5% (Nijman and Scholtmeyer, 1991). **Today the goal is not to remove the valves but to incise them so that they are not suspended across the urethra obstructing urine flow. Well-placed incisions can disrupt their integrity and allow the valves to lie freely along the walls of the urethra when the child voids. The exact point of incision can vary; some surgeons prefer the 12**

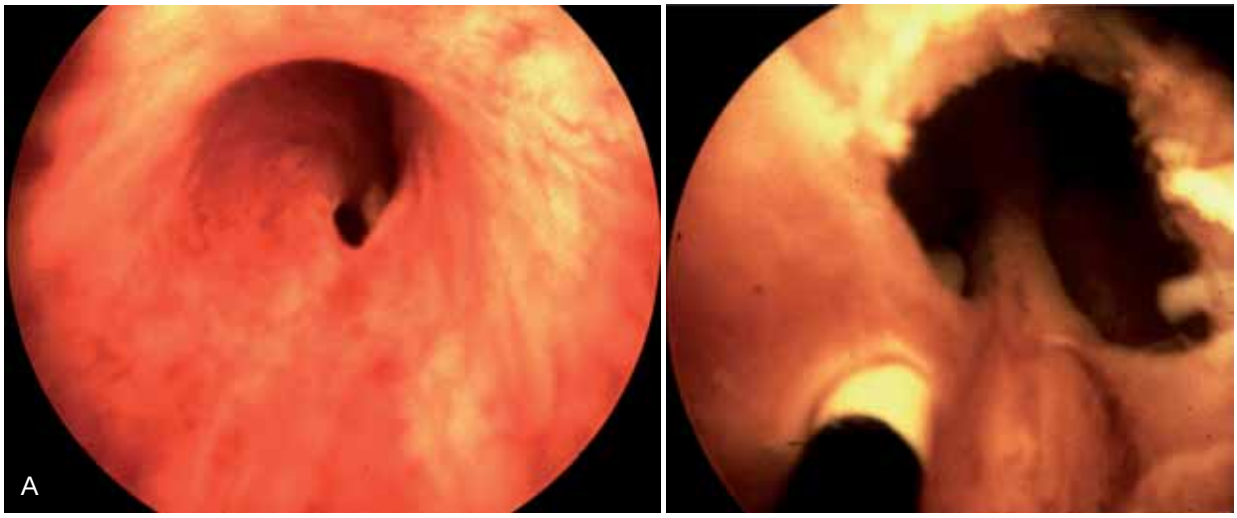

Figure 126–8. Cystoscopic photographs made from the distal urethra show the posterior urethral valves before ablation **(A)** and after ablation **(B).** The ureteral catheter has been passed through a perforation in the valve leaflet.

o'clock position, others prefer incisions at 4 and 8 o'clock, and others all three. Although most valves are quite thin and do not bleed at surgery, it is sometimes preferable to leave a catheter in place for 24 hours after incision. The valve remnants involute after incision, and there is often no evidence of them on later cystoscopic examination.

Documenting that the valve remnants are no longer obstructive after valve ablation is imperative. The timing of a postoperative VCUG is debatable, but one should be done to not only view the urethra but also evaluate bladder size and reflux. Decreased trabeculation, resolution of reflux, and a more uniform urethral diameter are all signs of successful relief of obstruction. One can measure the ratio of the diameter of the posterior urethra to that of the anterior urethra as an indicator of obstruction. A postablation urethral ratio of 2.5 to 3.0 is considered an acceptable postoperative result at 12 weeks (Gupta et al, 2009). **Evidence indicates that early valve ablation allows the bladder to cycle, thus improving compliance and bladder stability in infancy and resulting in less bladder dysfunction in older children** (Youssif et al, 2009).

Transurethral incision of the bladder neck at the time of valve incision has not been part of standard management; however, there is a report that this procedure has produced improved bladder performance with fewer inhibited contractions, lower mean maximum voiding pressures, and less need for anticholinergic medications than an age-matched control group after 4 years (Kajbafzadeh et al, 2008). Additional study of the modern use of this procedure is necessary.

Cutaneous Vesicostomy

If the infant is too small to instrument safely for valve ablation, then a cutaneous vesicostomy can be performed as a temporary measure (Fig. 126–9). Temporary vesicostomy drainage allows the urologist to incise the valves later when the patient is older and healthier. The vesicostomy has proven to be a safe and efficient treatment with long-term results in preserving renal function and somatic growth equal to primary valve ablation (Walker and Padron, 1990; Narasimhan et al, 2004). The vesicostomy provides adequate drainage of the upper tracts in more than 90% of cases (Krahn and Johnston, 1993). Vesicostomy itself is not without complication, however, and one study reported an 8.6% reoperation rate (Noe and Jerkins, 1985). Some people have questioned whether vesicostomy would cause permanent loss of bladder volume, but this has not proven to be true and vesicostomy does not significantly affect bladder capacity (Khoury et al, 1990). Some authors report that compliance may be decreased in vesicostomy bladders compared with those treated with primary ablation (Kim et al, 1996; Podesta et al, 2000). In general, primary ablation is the preferred surgical procedure to treat posterior urethral valves and vesicostomy is reserved for very small or very ill infants. Vesicostomy remains an excellent alternative treatment in these difficult situations.

Upper Tract Diversion

In the past, initial management of posterior urethral valves relied on upper tract diversion with ureterostomy or pyelostomy (Johnston, 1963). Diversion was effective in decompressing the upper tracts and controlling infection. Infants with high urinary diversion, however, often faced difficult urinary reconstructive problems later in life. In addition, high diversion produces stomas that present chronic management problems with incontinence. Even with these difficulties urinary diversion provided the best management available for valve patients for many years.

With the development of new cystoscopic equipment, Johnston demonstrated that endoscopic ablation could be performed safely and with good initial results (Johnston, 1966). Once the option of primary valve ablation was available, a long and thorough debate over the relative merits of initial upper tract diversion versus primary valve ablation followed.

Because both approaches yield good initial control of infection and adequate decompression of the upper urinary tract in most cases, the controversy focused on long-term results and measured renal function, bladder function, and somatic growth in each group. Conflicting data have been found regarding ultimate renal function and somatic growth, with Krueger and colleagues (1980) presenting data supporting ureterostomy from the large Toronto experience. He found that patients initially diverted had better eventual renal function and somatic growth. On the other hand, Reinberg, Duckett, and Hendren presented data supporting the conclusion that there was no significant difference in long-term outcomes between the two initial treatments (Hendren, 1978; Duckett and Norris, 1989; Reinberg et al, 1992a). Although more study may help clarify the situation, the current consensus is that neither initial treatment is superior in promoting renal function and somatic growth.

Despite early concerns that a bladder that is left without urine flow by proximal diversion would deteriorate from disuse, more recent data have shown that most of these bladders do not lose significant function. After upper tract diversion, urodynamics have shown that bladder capacity is preserved in 80% and compliance in 69% (Lome et al, 1972; Tanagho, 1974; Ghanem and Nijman, 2005). **Primary valve ablation may give the best chance for optimal bladder rehabilitation because of the ability of the bladder to cycle, but temporary supravesical diversion remains a reasonable alternative in the complex valve patient and usually leads to a marginal, if any, decrease in long-term bladder function** (Close et al, 1997; Podesta et al, 2002).

The current consensus is that both approaches eventually yield similar results and that infants who undergo initial upper tract diversion are at the disadvantage of needing more surgical procedures. Today upper tract diversion is usually limited to those patients who fail to respond to bladder level drainage. The specific clinical situation for upper tract diversion in posterior urethral valves today develops when bladder level drainage is insufficient to prevent infection or adequately drain the upper tracts. The decision to perform upper tract diversion relies on renal function, infection, and to a lesser extent, degree of hydronephrosis. Kidney development and growth in early life is critical, and neonatal kidneys may potentially recover function and continue to produce new cells during this period (Mayor et al, 1975; Hayslett, 1983). It is compelling to place these damaged kidneys in the best possible physiologic situation to recover, but this must be balanced with the knowledge that although upper tract diversion does initially improve renal function and drainage, there is no evidence that it offers any long-term advantage over primary ablation.

After the bladder has been adequately decompressed, the decision of whether to perform upper tract diversion is one of clinical judgment. Because hydronephrosis usually takes months to improve significantly, renal function is a better early parameter to follow. If the serum creatinine level drops below 2.0 it is safe

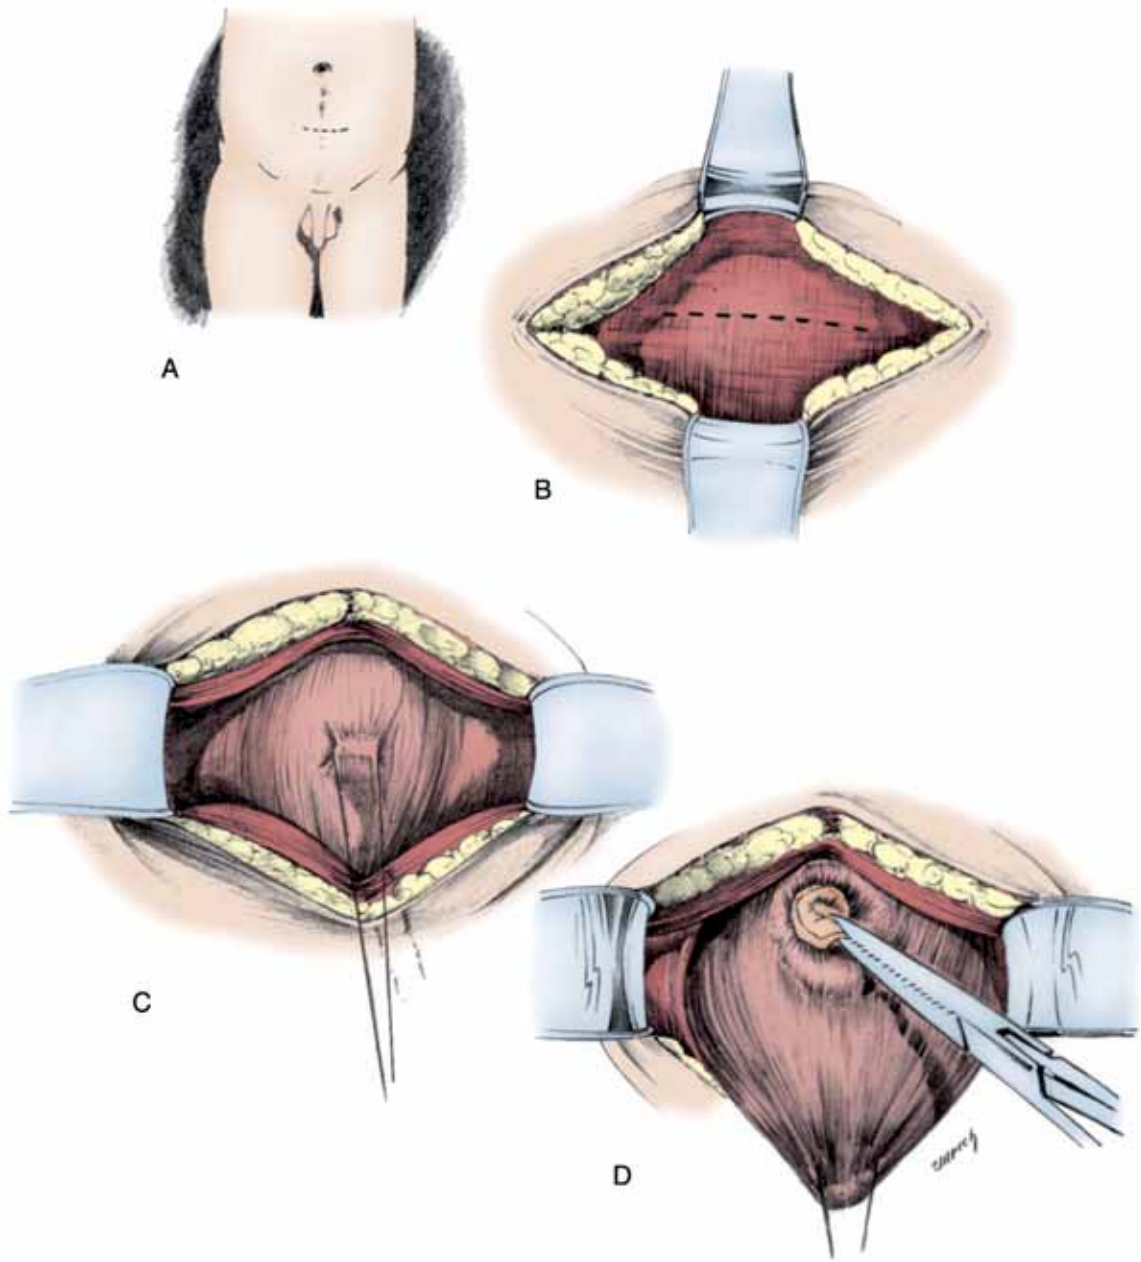

Figure 126–9. Blocksom technique for performance of cutaneous vesicostomy. **A,** After the bladder is filled, a transverse incision is made at the upper limit of the filled bladder and near the midpoint between the pubis and umbilicus. **B,** A transverse incision is made in the rectus fascia. **C** and **D,** The bladder is mobilized with a stay stitch and blunt dissection to free the peritoneum away from the bladder dome.

Continued

to rely on improved bladder drainage for additional kidney improvement. If the creatinine level remains above 2.0 after 10 days of adequate bladder decompression and if hydronephrosis is unimproved, then upper tract diversion may be considered. The type of diversion remains the surgeon's choice, and there are proponents of high loop ureterostomy, ring ureterostomy, pyelostomy, and end ureterostomy (Sober, 1972; Williams and Cromie, 1975; Kitchens et al, 2007). The type of upper tract diversion the authors prefer is a low loop ureterostomy because it provides adequate drainage, places the stoma under the diaper, and offers the most logical and simple reconstruction later.

If upper tract diversion is performed, reconstructive surgery to internalize the urinary tract should be delayed until the bladder and upper tracts have improved as much as can be expected. Practically this usually occurs between 3 and 5 years of age. If the patient is destined to reach ESRD, then reconstruction should be delayed until transplantation can be performed (Sheldon et al, 1992). It is imperative to establish an efficient method to empty the bladder, either by voiding or intermittent catheterization, before undiversion (Fig. 126–10).

Management of Vesicoureteral Reflux

Between 50% and 70% of patients with posterior urethral valves will have vesicoureteral reflux at the time of diagnosis (Fig. 126–11) (Hulbert and Duckett, 1992). Scott

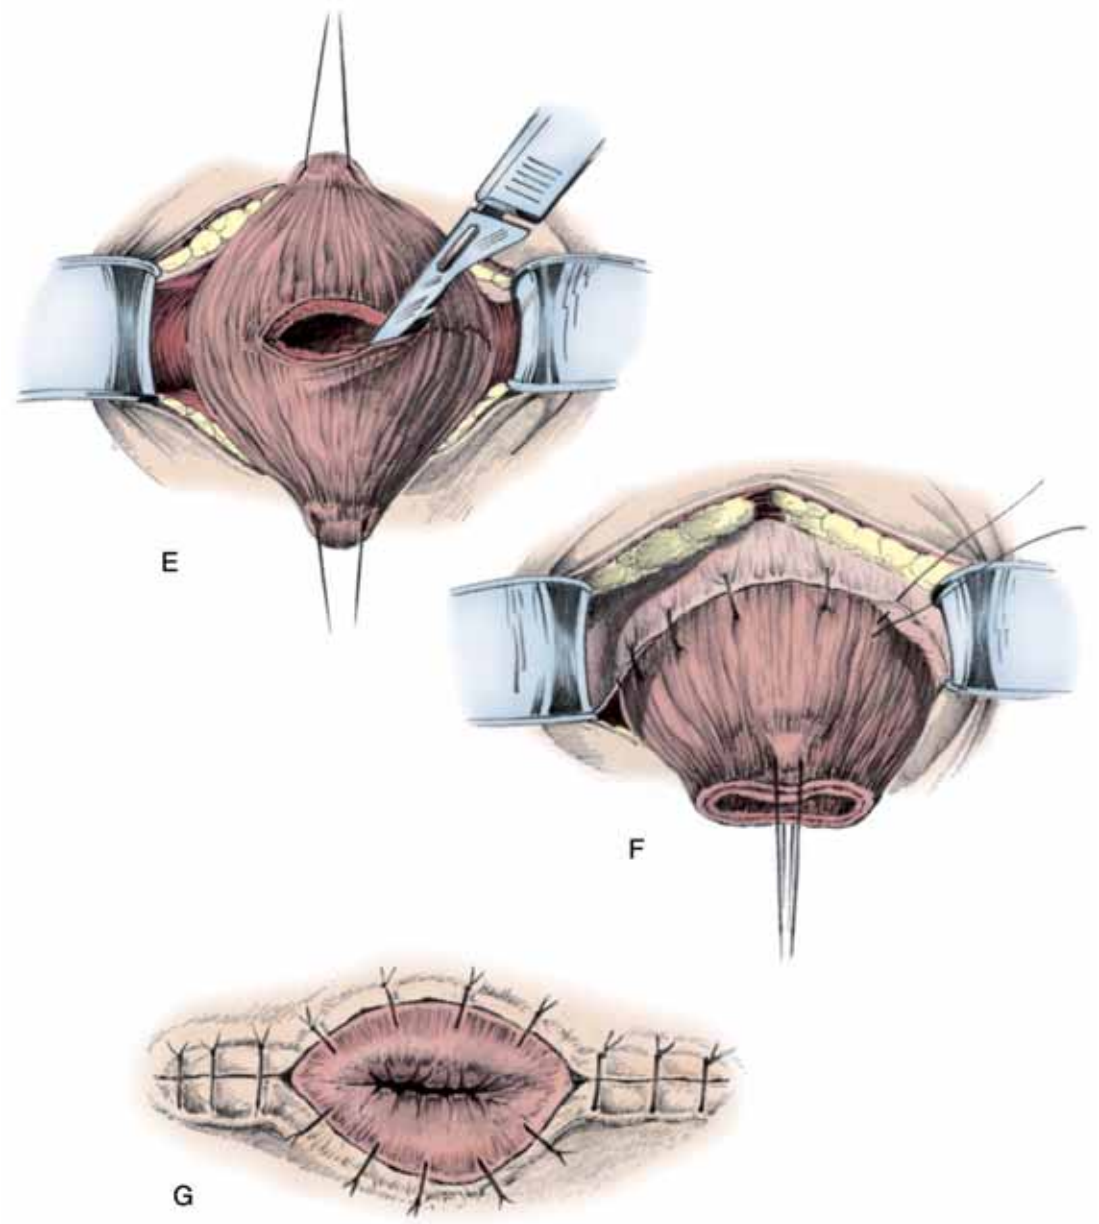

Figure 126–9, cont'd. **E,** A transverse incision is made into the bladder. **F,** The bladder is sewn to the rectus fascia, placing these sutures 1 cm away from the edge of the bladder incision. **G,** The bladder wall is sewn flush to the skin. (From Gonzales ED. Posterior urethral valves and other ureteral anomalies. In: Walsh PC, Retik AB, Vaughan ED, Wein AJ, editors. Campbell's urology. 8th ed. Philadelphia: WB Saunders; 2002.)

(1985) studied 46 affected boys with valves and found reflux in 72% of patients and in 53% of ureters. Bilateral reflux occurred in 32% of this study group.

Reflux in posterior urethral valves is considered secondary to bladder outlet obstruction so that the initial management of reflux is relief of obstruction. Reflux resolves after valve ablation in between 20% and 32% of refluxing ureters (Scott, 1985). Most reflux resolves within several months, but some can take as long as 3 years. Reflux is more likely to resolve when associated with a better functioning kidney. Hassan found that reflux resolved in only 10% of kidneys with less than 20% split renal function in a series of 73 boys with valves (Hassan et al, 2003). Children with initial bilateral reflux are more likely to have reflux resolve than those with unilateral reflux. As with all children with vesicoureteral reflux, they must be maintained on prophylactic antibiotics to prevent infection.

If persistent high-grade reflux is a clinical problem because of urinary tract infections or incontinence, then bladder function and drainage must be reviewed. Bladder dysfunction in the form of inadequate emptying and high storage pressures are the usual causes of persistent reflux. Surgery to repair reflux in valve patients must be undertaken with great care, and reimplanting ureters into a valve bladder that has not been adequately rehabilitated will lead to a high failure and complication rate (Warshaw et al, 1985; Hulbert et al, 1992; El-Sherbiny, 2002a).

The first step in evaluation of persistent reflux is to repeat the VCUG to look for persistent valve remnants. If no remnants are

Figure 126–10. Figure 126–11. Voiding cystourethrogram shows persistent high-grade vesicoureteral reflux in a boy with posterior urethral valves. Note the large-capacity, mildly trabeculated bladder.

found, then urodynamics are necessary to evaluate the bladder. If the bladder function is adequate and persistent reflux remains a problem, surgery to correct reflux may be necessary. **Ureteroneocystostomy is usually limited to the situation where infections cannot be controlled and bladder function is adequate.**

High-grade reflux is often associated with severe dysplasia and nonfunction in the associated kidney in valve patients (Heikkila and Rintala, 2009). In the past these nonfunctional kidneys and dilated collecting systems were removed early in life. It has become evident that there is no urgency to remove these units as long as they do not lead to recurrent infection. They are best retained until the bladder has rehabilitated as much as possible. The dilated collecting system could possibly be used as a ureteral augmentation if bladder volume or pressure warrants (Bellinger, 1993). Ureter is the best material available for augmentation cystoplasty because it is lined with urothelium and the ureteral muscle will not contribute to high pressures from detrusor contractions (Landau et al, 1994). It is also possible to leave these nonfunctional units in place and successfully repair the reflux (Kim et al, 1997a). This is a reasonable alternative when faced with the need for reimplant surgery on the contralateral side.

Management of Hydronephrosis

Almost all patients with posterior urethral valves have severe hydroureteronephrosis at diagnosis. Scott found hydronephrosis in 96.5% of valve patients, and in 78% it was

bilateral (Scott, 1985). Hydronephrosis may or may not be associated with reflux. **Like reflux, hydronephrosis is a secondary phenomenon in valve patients and like reflux, it often resolves once the primary pathology, obstruction, is relieved.** Nonrefluxing hydronephrosis resolves in 49% of patients and may do so quite rapidly after valve ablation. This leaves a significant population of valve patients with persistent hydronephrosis for years despite adequate bladder emptying (Johnston and Kulatilake, 1971). Hulbert and Duckett (1988) found that 25% of valve patients have dilated upper tracts 5 to 15 years after successful valve ablation.

The majority of patients with persistent hydronephrosis do not have obstruction either at the bladder outlet or the ureterovesical junction. Whitaker developed his antegrade perfusion test specifically to examine chronic hydronephrosis in valve patients and document pressures within the upper urinary tract and across the UVJ (Whitaker, 1973). Tietjen also used the Whitaker test to evaluate 25 valve patients with persistent hydronephrosis and found only 8% of patients to have an element of obstruction at the ureterovesical junction (Tietjen et al, 1997). The majority of patients with hydronephrosis had a measured mean perfusion pressure of only 3 cm of H_2O (normal is <15 cm of H_2O). The ureterovesical junction may be functionally obstructed before ablation of the valves, but this usually resolves with bladder rehabilitation (Glassberg et al, 1982).

VALVE BLADDER SYNDROME

The *valve bladder* or *full valve bladder* are terms coined by Mitchell to describe a chronic condition in valve patients where despite successful valve ablation, intrinsic bladder dysfunction leads to deterioration of the upper urinary tracts and incontinence (Mitchell, 1982). **The combination of poor sensation, high bladder volumes, and poor compliance produce storage pressures high enough to prevent adequate drainage of the upper tracts. These boys are comfortable with large bladder volumes at high pressures. They frequently have overflow incontinence and void infrequently and incompletely.** Videourodyanmics are necessary to diagnose this condition, and there is a direct correlation of abnormal urodynamics indicating poor compliance and detrusor overactivity with poor renal function (Ghanem et al, 2004). Initial management is usually timed voiding, but if this does not successfully lower pressures and empty the bladder, α blockers or clean intermittent catheterization (CIC) can be used (Austin et al, 1999). α Blockers can be effective in reducing postvoid residual urine and improving the urinary stream. Abraham and colleagues (2009) studied 42 children with valves, and residual urine volume was significantly reduced in 95%. The mean reduction of residual volume was 85%.

Glassberg (2001) has suggested that proactive urodynamic-directed bladder management might improve long-term bladder outcome. Koff and colleagues (2002) also proposed that valve bladder syndrome is not a permanent state due to prenatal bladder damage but is an induced condition due to a combination of polyuria, impaired bladder sensation, and residual urine volume. Bladder decompensation in response to this situation results in increasing residual urine, upper tract dilation, and renal injury.

Koff proposed intermittent catheterization with continuous nocturnal bladder emptying. He found a significant improvement of hydronephrosis in 10 boys with valves treated in this manner. Nguyen also found significant improvement in frequency of urinary tract infection, upper tract dilatation, and continence in valve patients who underwent overnight bladder drainage (Nguyen et al, 2005). Holmdahl and colleagues (2003) studied 35 boys with valve bladder and found that intermittent catheterization not only improved GFR but also improved bladder compliance and capacity more than expected for age and when compared with valve patients who did not catheterize.

Glassberg and colleagues (1982) categorized the hydronephrotic upper tracts of valve patients into three types: those that drain independent of bladder volume, those that drain efficiently only with the bladder empty, and those that are obstructed independent of bladder volume. Duckett applied this classification to 100 valve patients and found only four cases of true obstruction of the upper tracts independent of bladder dysfunction, and all had undergone ureteral reimplantation (Smith and Duckett, 1996).

Evaluation of persistent hydronephrosis in valve patients is complex and may require measurement of voided volumes to evaluate the relationship between renal tubular competence and bladder function, videourodynamics to evaluate the ability of the bladder to hold and empty adequate volumes at acceptable pressures, ultrasound to evaluate degree of hydronephrosis, lasix renography to evaluate relative renal function and induced drainage, and Whitaker perfusion test to measure intrarenal pressures at a given drainage rate. Access to all of these modalities is necessary to choose proper management of the valve patient with persistent hydronephrosis. Luckily, most children with persistent hydronephrosis do not need surgical therapy outside of valve ablation and attention to bladder function.

Management of Bladder Dysfunction

Posterior urethral valves affect no organ more consistently and profoundly than the bladder. The degree of damage varies considerably, and it is the rare patient who does not suffer significant lifelong bladder dysfunction. The bladder causes two types of long-term problems for the valve patient: interference with upper tract drainage and incontinence. The bladder subjects the upper tracts to a form of obstruction at two points of life, as newborns and late in childhood. At birth the bladder is thick and trabeculated with saccules and diverticuli. It contracts with great force, and compliance is low. Although urodynamics are difficult to perform in infants, particularly in the presence of reflux and diverticuli, the bladder can be seen on imaging to undergo strong contractions. This stage of bladder dysfunction can persist for months despite successful valve ablation. Voiding pressures are high in male infants with valves but no higher than their normal peers. Furthermore, high voiding pressures are not associated with reduced kidney function (Taskinen et al, 2009). Storage pressures, compliance, and ability to empty are other key elements of bladder function in these children.

Late in childhood the bladder is less contractile but displays poor compliance, and this along with poor sensation leads to the valve bladder syndrome discussed earlier. Both the hypercontractile bladder of infancy and the rigid bladder of late childhood inhibit upper tract drainage.

Incontinence is a major problem for valve patients. A review of 100 patients revealed 81% had delayed day and night continence at age 5 years (Smith et al, 1996). **Another large series discovered that only 53% were dry by age 12** (Churchill et al, 1990). This problem improves in most by age 20, but the delay in attaining continence creates painful difficulties during adolescence (Parkhouse et al, 1988). In the past, incontinence was felt to be due to sphincter injuries and bladder neck

dysfunction, but today this problem is thought to be multifactorial and due to a combination of poor bladder sensation, poor bladder compliance, detrusor instability, and polyuria. Renal tubular damage, which progresses during childhood, leads to inability to conserve sodium and free water and can lead to nephrogenic diabetes insipidus and urine volumes up of several liters per day. These exaggerated volumes can overcome any bladder's functional ability, especially one with limited potential.

Peters identified three urodynamics patterns in valve boys: myogenic failure, detrusor hyperreflexia, and decreased compliance/small capacity (Peters et al, 1990). **Myogenic failure usually occurs in older children and leads to overflow incontinence and incomplete bladder emptying. Management includes timed voiding, double voiding, α blockers, and intermittent catheterization.** The urinary frequency and urge incontinence due to detrusor hyperreflexia is managed with anticholinergic medications. Anticholinergics may also help with those patients with small poorly compliant bladders but may not be sufficient to prevent the need for augmentation cystoplasty to provide adequate urine storage necessary for continence and upper tract drainage. Inappropriate use of anticholinergic medications may induce iatrogenic myogenic failure and therefore they should only be used with urodynamic monitoring (Misseri et al, 2002).

Holmdahl and colleagues (1995) **studied valve patients with urodynamics over many years to assess changes in bladder function. They found that the functional patterns outlined by Peters overlap in the majority of patients and that the dominant pattern changed with age. They concluded that these patterns are stages of development. In infants, poor compliance dominates; in older children instability from hypercontractility is the dominant pattern; in postpubertal boys myogenic failure becomes the norm. The valve bladder is surely one in constant transition during childhood. Urodynamics are necessary to track changes and to alter management in these patients throughout the first two decades of life** (Kim et al, 1997b).

Boys with valves who present later in childhood frequently have only voiding complaints and a more functional urinary tract. In a study of 70 children who presented at average age of 7.5 years, Schober and Dulabon (2004) found that ablation of valves will dramatically improve symptoms of urinary frequency and diurnal and nocturnal enuresis. Despite this improvement, most boys will continue to have a degree of hydronephrosis and some voiding difficulties.

In some boys with valves, bladder performance is not adequate to protect the upper tracts from the deleterious effects of high storage pressures and recurrent infection despite maximal medical management. Treatment of these children depends on their age and their ability to undergo CIC in most cases. If the boy can be catheterized, then anticholinergics and CIC will often improve the bladder environment enough to allow the bladder to rehabilitate and develop a better compliance and pressure profile. If this approach fails, then a vesicostomy is usually an excellent alternative.

After the age of toilet training the expectations change, and if anticholinergics and CIC fail to provide either a safe environment for the kidneys or the boy remains incontinent, then augmentation cystoplasty may be indicated (Kajbafzadeh et al, 1995; Bhatti et al, 2007). Although ileal augmentation is the historical norm and works well, it carries the disadvantages of mucous production, risk of rupture, stone production, and the potential for bladder cancers later in life. Because many valve patients have massive hydronephrosis and some have a unilateral nonfunctional kidney, ureteral augmentation is a somewhat popular alternative (Fisang et al, 2010). Ureteral augmentation has the advantage of leaving the bladder lined only with native urothelium and avoiding mucus, stones, and cancer. Bladder performance in 13 of 17 patients (10 with valves) after ureteral augmentation was significantly improved with a mean follow-up of 4.5 years when measured by capacity, mean end filling pressure, and compliance (Johal et al, 2008).

Augmentation in valve patients was more popular in the past before the national history of valve bladder development, and the pathophysiology of tubular damage in dysplastic kidneys was as well defined. Today it is somewhat rare and many patients are managed medically with CIC, medicine, and nighttime catheter drainage until their bladder pressures decrease and/or their renal failure is treated definitively with transplantation.

Catheterizable urinary channels are useful in many boys because the urethra is sensate and the high bladder neck often makes catheterization technically difficult (Cain et al, 1999). Appendicovesicostomy is slightly more difficult in valve patients because of the thickness and relative fibrotic bladder wall, but once accomplished it works well. This gives the boys easy access for CIC and nighttime catheter drainage. The authors perform appendicovesicostomy routinely in all older valve boys who require CIC.

In summary, management of bladder dysfunction in boys with posterior urethral valves is an intensively individualized process with close monitoring of urodynamics, urine volumes, renal function, infections, and hydronephrosis. Patients may need anticholinergics, α blockers, intermittent catheterization, continuous nocturnal bladder drainage, timed voiding, or any combination of management options. In addition, because the bladder is in transition throughout most of childhood, their management needs will change as they mature.

Management of Glomerular Injury and Renal Function

The primary goal of management in posterior urethral valves is to preserve renal function and to maximize renal growth and development. Renal injury in posterior urethral valves includes two initial glomerular insults: dysplasia and obstructive uropathy. Dysplasia is by far the most important because it is irreversible and not only produces a level of renal insufficiency at diagnosis but also limits future growth and development of the kidney. Obstructive uropathy may produce ongoing injury and is potentially reversible. It is mandatory to provide low-pressure storage and drainage of urine in order to prevent further renal damage.

Other threats to glomerular function come from persistent or progressive obstruction and infection. Hyperfiltration has been recognized in animal models as a cause of additional injury, but its importance in humans remains undocumented (Brenner et al, 1982). As somatic growth makes additional demands on the kidneys, valve patients can experience proteinuria, hypertension, and progressive loss of renal function (Tejani et al, 1986; Burbige and Hensle, 1987; Parkhouse et al, 1988; Reinberg et al, 1992a; Farnham et al, 2005). Poorly controlled hypertension also can add to renal deterioration. **Consistent and regular urologic care with monitoring of bladder**

function and infection will place the kidneys in the best position to grow and develop to their full potential.

ANTENATAL DIAGNOSIS AND MANAGEMENT

The incidence of urologic anomalies is 1 in 500 fetuses detected on ultrasounds (Colodny, 1987). **Posterior urethral valves are the most common cause of bilateral hydronephrosis in male fetuses.** Most valve patients are diagnosed by prenatal ultrasound, and the ability to image the fetus continues to improve with the technology of ultrasound. The accuracy of ultrasound diagnosis is proportional to fetal age, and valves may be missed in scans done before 24 weeks' gestation (Skolder et al, 1988; Abbott et al, 1998). **The differential diagnosis of a male fetus with bilateral hydroureteronephrosis and a distended bladder includes prune-belly syndrome and severe reflux. Bladder wall thickness is impressively increased only with valves. Fetal urine parameters may also be useful in predicting renal damage in utero. Aspirated fetal bladder urine with high sodium content and isosthenuria compared with serum values suggests poor renal function and that fetal intervention would not be helpful from a renal standpoint** (Glick et al, 1985).

Valves have emerged as the only urologic anomaly to be considered for antenatal intervention. Fetal intervention, although championed in the 1980s, has become quite rare due to a lack of objective evidence that it alters renal development (Reinberg et al, 1992b; Freedman et al, 1999). Although antenatal decompression of the urinary tract and the subsequent restoration of amniotic fluid are usually accomplished by placing a vesicoamniotic shunt, there have been reports of fetal valve ablation (Quintero et al, 1995). Restoring the volume of amniotic fluid can be a life-saving maneuver because of its effect on pulmonary function (Harrison et al, 1982). For optimal results this intervention must be performed during the appropriate stage of pulmonary development, older than 20 weeks and younger than 32 weeks. Oligohydramnios earlier than 20 weeks is usually incompatible with life due to pulmonary hypoplasia, and if diagnosed later than 32 weeks early delivery is preferable to fetal intervention. The decision to undertake fetal intervention must weigh the potential benefit for the fetus versus the risk of complications to both fetus and mother that occurred in 44% of those cases reviewed by the International Fetal Surgery Registry (Elder et al, 1987) (Fig. 126–12).

Key Points: Management of Posterior Urethral Valves

- Immediate catheter drainage is the initial management in all suspected valve patients.
- Primary valve ablation is the preferred initial surgical treatment in most valve patients.
- If the infant is too small or ill for endoscopic valve ablation, a vesicostomy is an excellent form of temporary diversion and provides drainage of the urinary tract.
- Initial management of hydronephrosis and reflux is valve ablation and observation with antibiotic prophylaxis.
- Bladder and renal function are often unstable in valve patients and usually change throughout life, requiring lifelong monitoring.

Figure 126–12. This boy had a vesicoamniotic shunt placed at 18 weeks of gestational age. The shunt has been attached to a drainage bag in the intensive care unit. The structure extending from the shunt site is herniated omentum. There is a significant risk of abdominal wall hernia at the shunt site.

PROGNOSTIC INDICATORS OF RENAL FUNCTION

Four basic predictors of renal function exist in patients with posterior urethral valves: ultrasound appearance, serum chemistries, age at diagnosis, and presence of reflux. Ultrasound, age at diagnosis, and presence of reflux can be determined at diagnosis, but serum chemistries require some time to develop.

Ultrasound appearance is a method of estimating the amount of dysplasia present in the kidneys. Dysplasia, strictly speaking, is a histologic diagnosis of tissue disorganization and includes fibrosis and cysts. This disorganization appears more echogenic on ultrasound and may be obvious by comparing the kidney to the liver and spleen as controls (Sanders et al, 1988). Kidneys that are considerably brighter than the liver usually contain significant dysplasia. Hyperechogenic kidneys diagnosed on ultrasound before 25 weeks' gestational age were predictive of renal dysplasia on postmortem examination of 24 male fetuses with urethral obstruction (Robyr et al, 2005). Loss of the normal corticomedullary junction normally visible on ultrasound has also been correlated with poor long-term renal function (Hulbert et al, 1992).

Age at diagnosis may be helpful in predicting prognosis. In the past, infants who presented younger than 1 year of age had a worse prognosis than those who presented later in life. Older boys usually present with voiding difficulty. They were long considered to represent the least affected of valve patients, but recent evidence has shown that some boys who present later in life suffer significant renal damage (Pieretti, 1993; El-Sherbiny et al, 2002b).

One study of boys who presented older than 5 years revealed that 35% had renal insufficiency and 10% reached ESRD (Bomalaski et al, 1999).

In a review of 70 boys who presented at the mean age of 7.5 years, Schober found that all had a normal serum creatinine (Schrober et al, 2004). Ansari and colleagues (2008) compared 95 patients with valves who presented before 2 years of age to 99 patients who presented after 2 years. They found that the incidence of azotemia at presentation, mean serum creatinine level, and risk for ESRD were worse in the boys who presented after age 2 years. The conflicting data in numerous studies seem to indicate that postnatal age at diagnosis alone is not a reliable factor in predicting outcome in valve patients, but it may be helpful in understanding the risks for an individual when considered with other clinical factors.

Today with most infants diagnosed antenatally and improved prenatal care, mortality of newborns with valves has decreased from almost 50% to between 3% and 10% (Williams, 1954; Churchill et al, 1990). Despite this improvement in mortality, positive effects of prenatal diagnosis on long-term renal function have been difficult to determine. Multiple authors have found that early gestational age at the time of diagnosis (before 24 weeks) is a significant negative factor in predicting long-term renal failure (Hutton et al, 1994; Sarhan et al, 2008).

Reflux in valve patients carries a poor prognosis. Johnston reviewed a series of valve patients in which the mortality was 57% in patients with bilateral reflux, 17% with unilateral reflux, and 9% with no reflux (Johnston, 1979). Many other authors have noted the grave effect of bilateral reflux on patients with posterior urethral valves (Parkhouse et al, 1988; Churchill et al, 1989). The commonly accepted explanation is that the incompetent ureterovesical junction that allows free reflux into the kidney also transmits the high pressures generated by the bladder. On the other hand, Stevens and others believe that severe reflux is associated with dysplasia primarily because the ureteric bud is abnormal and, in turn, induces an abnormal kidney.

The final prognostic factor is based on serum chemistries and relies on serial measurements of renal performance over time. **Warshaw reported that a nadir creatinine of less than or equal to 0.8 mg/dL during the first year of life predicts likely good long-term renal function** (Warshaw et al, 1985). **Other authors found the same relationship with a nadir creatinine level of 1 mg/dL during the first year of life** (Conner and Burbige, 1990; Sarhan et al, 2009; Ansari et al, 2010). Early renal function may be a helpful predictor as well. Denes reported on 32 patients with posterior urethral valves treated with immediate drainage. Serum creatinine was measured at diagnosis, after 4 days of drainage, and the nadir in the first year of life. After a mean of 10 years the authors found that patients fell into two groups, one with a GFR of greater than 70 mL/1.73 m^2 and the other with a GFR less than 70. The group with worse long-term function had initial creatinine of 3.6 mg/dL, a postdrainage creatinine of 2.4, and a nadir of 1.7. The group with better long-term renal function had initial creatinine of 1.3 mg/dL, postdrainage creatinine 0.6, and a 1-year nadir of 0.4 (Denes et al, 1997).

In a multivariate analysis of 119 valve patients seen over 30 years with approximately half presenting as newborns, DeFoor identified two independent risk factors that were statistically significant in predicting ESRD: increased nadir serum creatinine and severe bladder dysfunction. Reflux was associated with an increased risk of ESRD, but this did not reach statistical significance (DeFoor et al, 2008). Ansari studied 260 valve patients and found that nadir serum creatinine level, severe bladder dysfunction, and bilateral reflux were significant predictors of eventual ESRD (Ansari et al, 2010). The most powerful tools yet proposed in predicting outcomes in posterior urethral valves may lie at the genetic or molecular level (Woolf and Winyard, 2000).

TRANSPLANTATION IN VALVE PATIENTS

Obstructive uropathy is the most common cause of ESRD in children and accounts for 16.3% of children presenting for transplantation (Seikaly et al, 2001). **The most common condition producing this degree of dysfunction is posterior urethral valves. Up to 50% of boys with posterior urethral valves will reach ESRD in their lifetime.** Most of these will need dialysis or transplantation during the first two decades of life. Because renal transplantation allows a better quality of life and optimal somatic growth, it is the preferred method of managing ESRD in children and adolescents. The damaged bladder of valve patients presents a technical challenge for renal transplantation, and abnormal bladder function has been considered a threat to the success of transplantation.

Early transplant series in children with valves demonstrated significantly decreased success in transplant graft survival and in graft function compared with those who suffered ESRD due to reflux nephropathy (Churchill et al, 1988; Reinberg et al, 1988). The principal cause of graft failure was chronic rejection, and the relationship between bladder function and rejection was not apparent. Valve patients are known to have decreased bladder compliance and increased storage pressures, but in the absence of obstructive hydronephrosis or infection these factors can be managed successfully to protect the kidney.

More recent data have shown improved results with some series demonstrating good graft survival but a statistically significant increase in serum creatinine levels compared with controls (Bryant et al, 1991; Salomon et al, 2000). Still others have found no significant difference between valve patients and others in either graft survival or renal function (Groenewegen et al, 1993; Ross et al, 1994; DeFoor et al, 2003; Mendizabal et al, 2005; Otukesh et al, 2008). **Because the lower urinary tract is markedly abnormal in valve patients, it is not surprising that urologic complications are higher than in patients with normal bladders.** Urethral strictures, stones, and urinary retention were among the urologic complications that occurred in 19% of valve patients undergoing transplantation (Ross et al, 1994). Mochon found an increased risk of urinary tract infection in valve patients compared with others after transplantation, but this relationship may have been present before transplant and did not affect graft function (Mochon et al, 1992).

It is safe to say that renal transplantation is an important part of management of some valve patients and that success rates are high. It must be undertaken with the knowledge that urinary tract management may be more complex and complications more common than with other children undergoing transplantation. Careful urodynamic evaluation of bladder function before transplantation is vital, and the patient may need intermittent catheterization and/or augmentation cystoplasty in order to function safely with the new kidney (Zaragoza et al, 1993; Indudhara et al, 1998; Koo et al, 1999; Salomon et al, 2000; Mendizabal et al, 2005; Ozcan et al, 2006).

QUALITY OF LIFE WITH POSTERIOR URETHRAL VALVES

Although study in this area is somewhat limited, with modern management of renal insufficiency and bladder dysfunction most boys with posterior urethral valves feel they have a good quality of daily life (Hellström et al, 2006). Intermittent catheterization is seen as an obstacle in the company of friends and has required boys to develop strategies to perform this discreetly. Overall, boys with valves saw their treatment as a small part of their lives and valued friends, being able to participate in health care decisions, and having their own doctor and nurse.

The generally positive attitude toward life by valve patients can lead to their being lost from the health care system, and almost half of a group of 31- to 44-year-olds with valves had not been checked since adolescence. Among this group, a third was uremic and 40% had signs of bladder dysfunction despite being continent. The ability to father children was dependent on the presence of uremia. This study highlights the importance of lifelong follow-up care to monitor the often silent complications of valves, which ultimately affect quality of life (Holmdahl and Sillen, 2005). Boys with posterior urethral valves have a higher incidence of cryptorchidism (16%) and inguinal hernia (11%) (Heikkila et al, 2008b).

ANTERIOR URETHRAL VALVES

Anterior urethral obstruction is rare compared with posterior urethral valves. Although these obstructive structures may be called valves, they often occur in the form of a diverticulum of the urethra with one wall acting as an obstructive "valve" (Fig. 126–13) (Tank, 1987). There are also some reported cases of urethral flaps or valves in the anterior urethra (DeCastro et al, 1987; Scherz et al, 1987). The first case was reported in 1906, and the total number in the literature is small (Watts, 1906; Williams and Retik, 1969; Firlit et al, 1978).

Anterior urethral diverticuli typically occur where there is a defect of the corpus spongiosum, leaving a thin-walled urethra (Fig. 126–14). This segment of urethra balloons during voiding and causes a mass that is sometimes visible along the ventral wall of the penis. The mass resolves as urine drains from it between voids, and when full, urine can be expressed from the diverticulum by applying pressure. The distal edge of the diverticulum forms a flap that obstructs the flow of urine, and the effects of anterior urethral valves can be as damaging to the urinary tract as those of the posterior urethra. The embryology of these structures remains unclear but seems to be unrelated to the development of posterior urethral valves.

Boys with anterior urethral valves often present later in childhood with infection, straining to void, or incontinence. One third present with voiding symptoms, a third with antenatal hydronephrosis, and the remainder with a visible diverticulum (Van Savage et al, 1997). The degree of obstruction can be severe and produce pressures as high as with the posterior urethral valve. Spontaneous rupture of the fetal bladder in anterior urethral valves has been reported (Merrot et al, 2003).

Diagnosis depends on VCUG or cystoscopy. It may be difficult to pass a catheter into the bladder because the catheter often easily enters the diverticulum and becomes trapped. Treatment is similar to that of posterior urethral valves in that relief of obstruction is the most important goal. In severely ill children or young infants a vesicostomy is a good option for temporary drainage, allowing the urinary tract to decompress and delaying urethral repair until conditions are optimal (Rushton et al, 1987).

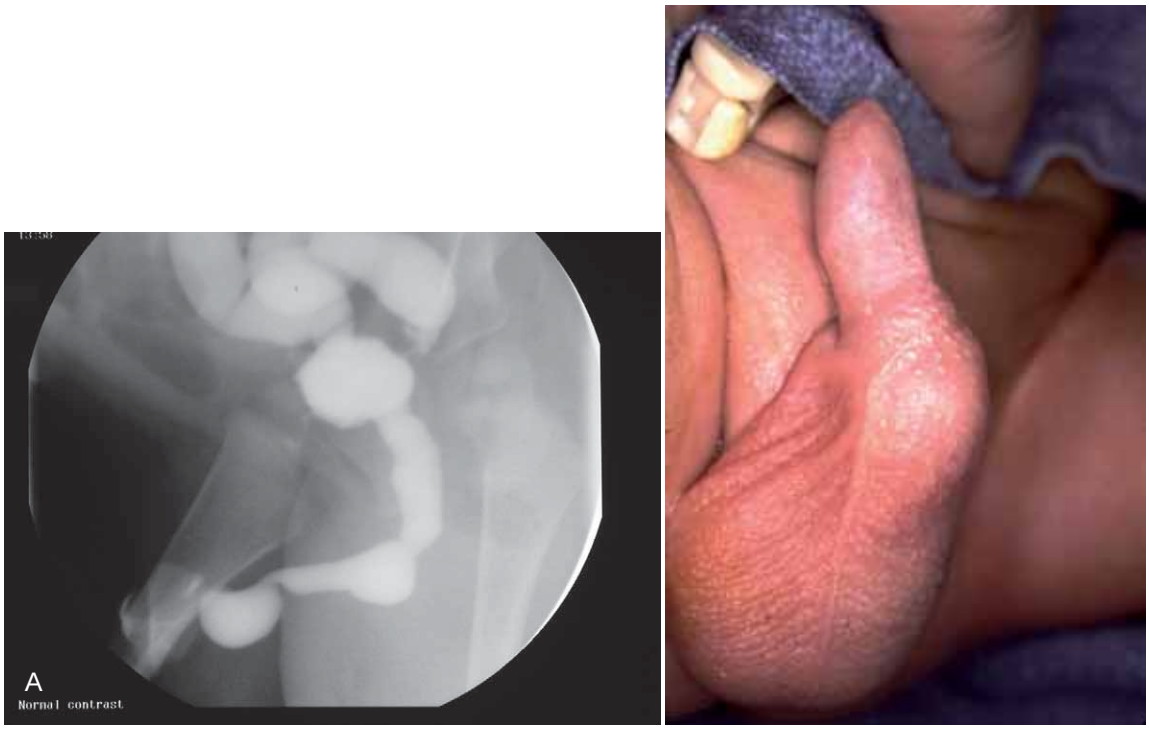

Figure 126–13. **A,** Voiding cystourethrogram shows a severe case of anterior urethral valves. The bladder is almost empty, and there is massive reflux. The valve is in the form of a diverticulum. **B,** The filled diverticulum can sometimes be seen as a mass on the penis that resolves between voids. Pressing on the mass may express urine for some time after voiding.

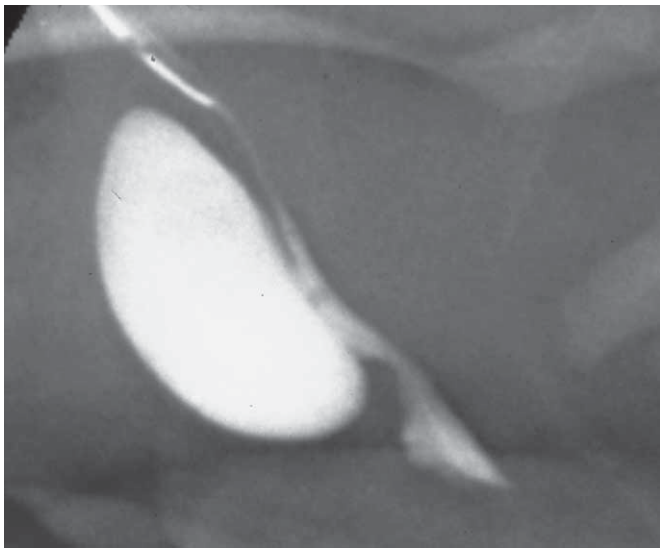

Figure 126–14. Voiding cystourethrogram demonstrates an anterior urethral diverticulum trapping urine during voiding.

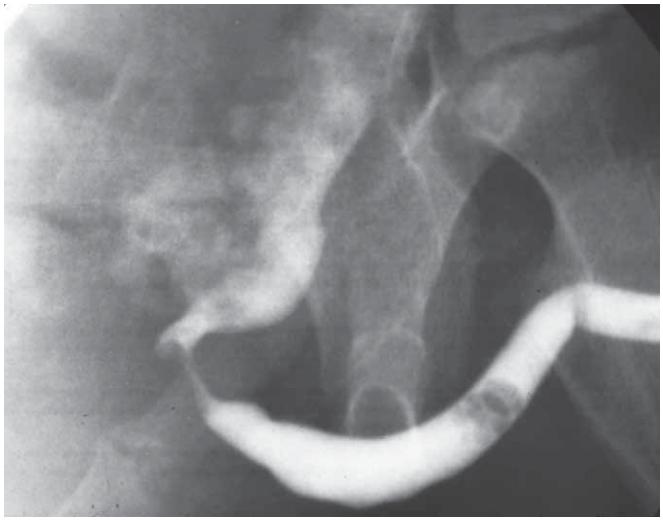

Figure 126–15. Voiding cystourethrogram shows a congenital urethral stricture. These rare conditions cause a clinical situation similar to posterior urethral valves.

Treatment of anterior urethral valves may include transurethral incision to allow free flow of urine or open urethral reconstruction. If the diverticulum is small or there is a urethral flap, transurethral incision is preferred. If the diverticulum is large, it will usually cause pooling of urine and repeated infection. The best option is an open excision of diverticulum and repair of the urethra. This can be difficult surgery and requires catheter drainage to facilitate urethral healing.

The long-term outcome of anterior urethral obstruction is similar to that of the posterior urethra. In general the severity of obstruction, degree of hydronephrosis, and incidence of renal failure is usually better in anterior urethral valves (Rawat et al, 2009). Less than 5% of patients with anterior urethral valves have reached ESRD compared with more than 30% of those with posterior urethral valves (Kaplan and Scherz, 1992).

CONGENITAL URETHRAL STRICTURE

Congenital urethral strictures are rare anomalies that produce the same pathologic and clinical problems as posterior urethral valves (Fig. 126–15) (Currarino and Stephens, 1981). They occur in the posterior urethra and lead to oligohydramnios, bilateral hydroureteronephrosis, and a distended bladder (Narborough et al, 1990). **Initial treatment in the newborn is almost always vesicostomy.** Because these strictures are usually too long to incise and too tight to dilate with sounds, they may be dilated gradually with increasingly larger catheters with good results (Passerini-Glazel et al, 1988).

URETHRAL POLYPS

Urethral polyps are rare anomalies of the male urethra (Fig. 126–16). **Patients with urethral polyps usually present with intermittent voiding complaints such as hematuria, stranguria, and dysuria** (Raviv et al, 1993; Walsh et al, 1993). Unlike urethral valves, polyps do not produce extensive damage to the urinary tract. They usually occur in the prostatic urethra near the bladder neck and may be quite mobile on a long stalk. Anterior urethral polyps have been reported (Coleman and Nense, 1991).

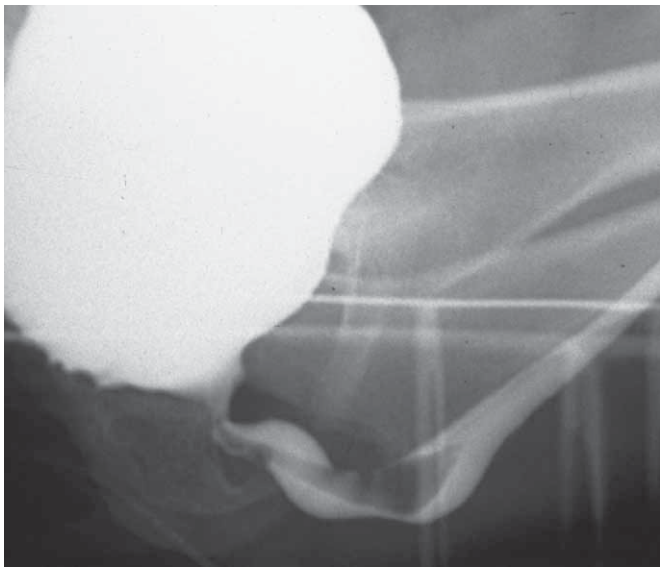

Figure 126–16. This urethral polyp is on a long stalk and caused intermittent dysuria and straining to void.

The polyps are usually diagnosed on VCUG, and the diagnosis is confirmed by cystoscopy. They are benign but may be confused with rhabdomyosarcoma of the prostate. Benign urethral polyps are usually solitary, whereas the polypoid form of rhabdomyosarcoma usually presents with multiple polyps and a mass extending beyond the bladder or prostate. Transurethral resection is curative in urethral polyps (Gleason et al, 1994).

URETHRAL DUPLICATION

Duplication of the urethra is a rare anomaly. Various types and several classification systems exist (Fig. 126–17) (Effmann et al, 1976; Woodhouse and Williams, 1979). In practice, urethral duplication is so rare that it is usually described by anatomic landmarks. Most urethral duplications occur in the same sagittal plane and can be divided into either dorsal or ventral.

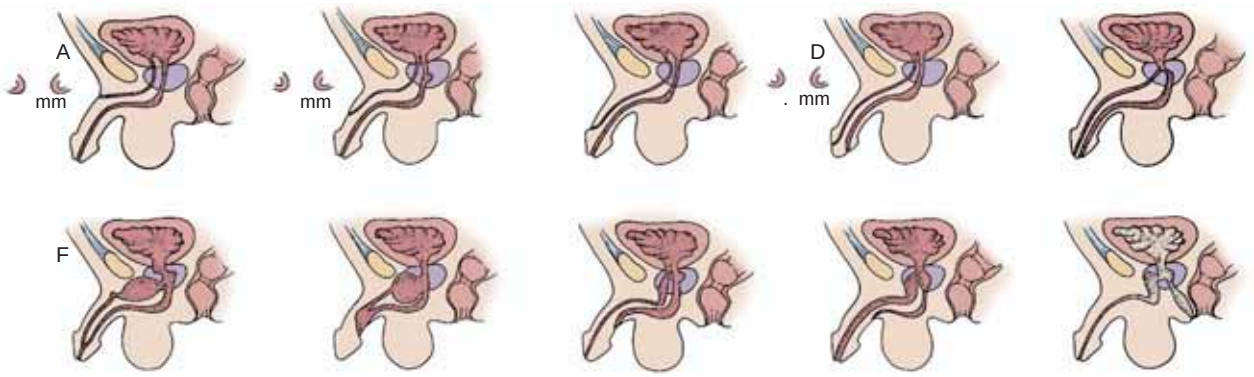

Figure 126–17. **A** to **J,** Variations of urethral duplications in the sagittal plane. Each of these drawings shows the ventral urethra as the functional one as it passes through the prostate and sphincter. (From Colodny A. Urethral lesions in infants and children. In: Gillenwater JT, Howards SS, Duckett JW, editors. Adult and pediatric urology. 2nd ed. St Louis: Mosby-Year Book; 1991. p. 2013.)

Some more rare duplications occur in the same horizontal plane, and the urethras lie next to one another, one left and one right. This horizontal type may be associated with duplicated phallus or complete bladder duplication (Woodhouse and Williams, 1979). Some patients present with incontinence or infection, but most are discovered in infancy on examination by the mother or pediatrician.

Dorsal urethral duplication occurs when there is a normal urinary meatus, dorsal chordee of the penis, and a second epispadiac meatus along the dorsal aspect of the penis. The foreskin may be incomplete dorsally, and the epispadiac meatus can occur anywhere along the midline of the penis (Sharma et al, 1987). The normal urethra is the ventral one that ends on the glans. The epispadiac duplicate urethra may be blind ending or extend to the bladder. If it communicates with the bladder, the patient may be incontinent. These patients may have a widened symphysis pubis similar to epispadias or exstrophy.

Ventral urethral duplications are extremely rare and may also be complete or incomplete with a blind-ending urethra. There may be a normally placed urethra on the glans and a second along the ventral aspect of the penis or even along the perineum. The dorsal urethra may be of normal caliber or narrow. The ventral urethra is considered the more normal because it usually passes out of the bladder neck and sphincter (Salle et al, 2000). The "Y" duplication occurs when the prostatic urethra splits into two channels with one extending to the glans and the more functional ventral one coursing to the perineum near the rectum.

Diagnosis of urethral duplication depends on the type of anomaly. If the duplication is complete, a VCUG will demonstrate both urethras during voiding (Fig. 126–18) (Hoekstra et al, 1985). If the duplication is blind ending, a retrograde injection of contrast and cystoscopy may be required to delineate the anatomy (Fig. 126–19) (Podesta et al, 1998).

Management of urethral duplication varies with symptoms and the severity of the anomaly. Some patients do not require treatment if they are free from infection and incontinence. Simple accessory duplicate urethras may be fulgurated with a bugbee and allowed to scar and close (Holst and Peterson, 1988). Others need to be excised to make the patient dry and prevent infection. If both urethras are functional and end adjacent to one another on the glans, the septum between the two can be excised at the meatus, giving the patient a single urinary meatus. The most complex "Y" fistulae may require extensive urethroplasties requiring tissue transfer such as buccal mucosa grafts (Ortolano and Nasaralloh, 1986).

URINARY FISTULA IN BOYS WITH ANORECTAL ANOMALIES

More than 80% of boys born with anorectal malformations have a fistula between the rectum and the urinary tract (Hong et al, 2002) (Fig. 126–20). **The vast majority have imperforate anus, but occasionally a congenital fistula occurs between the urinary tract and the rectum in a boy with an external anal opening (H-type fistula).** Fistulae are usually discovered by the pediatric general surgery service in their evaluation of the newborn with an anorectal anomaly and may be demonstrated with a VCUG. Because the initial treatment of most patients with anorectal anomalies is a diverting colostomy, many fistulae are diagnosed at 6 months of age with a distal colostogram. The distal colostogram is done by injecting contrast into the distal limb of the diverting colostomy before surgical repair of the anus.

Pediatric urologists are involved early in the child's life when recurrent urinary infections are a problem due to distal colostomy limb bacterial overgrowth, which leads to contamination of the bladder or urethra. This may be treated with antibiotic prophylaxis, enemas to empty the distal bowel, surgical separation of the proximal and distal limbs of the colostomy to prevent spillage, or in some cases early repair of the anus with a pull-through procedure. Upper urinary tract anomalies have been reported in up to 60% of boys with anorectal anomalies and may include vesicoureteral reflux, renal anomalies including solitary kidney, and hydronephrosis (Misra et al, 1996). Because 40% of these patients have sacral anomalies and 55% of those have severe lower urinary tract dysfunction comparable with patients with myelodysplasia, the threat of continued contamination of the urinary tract is serious (Boemers et al, 1996).

Definitive treatment of congenital recto-urinary fistulae is done at the time of anoplasty by the pediatric general surgery service. If this procedure is successful, the fistula is taken down at the time of rectal repair. Urethral injuries occur in 3% to 25% and may present immediately or in a delayed fashion (see Fig. 126–20). Fistulae may be either persistent or recurrent after rectal surgery or acquired by injuring the urethra at the time of anoplasty. In addition, a section of the rectum may be left attached to the fistula, creating a urethral diverticulum that may present with incontinence or UTI later in childhood. Rarely, the urethra may be divided or injured so severely that it causes stricturing.

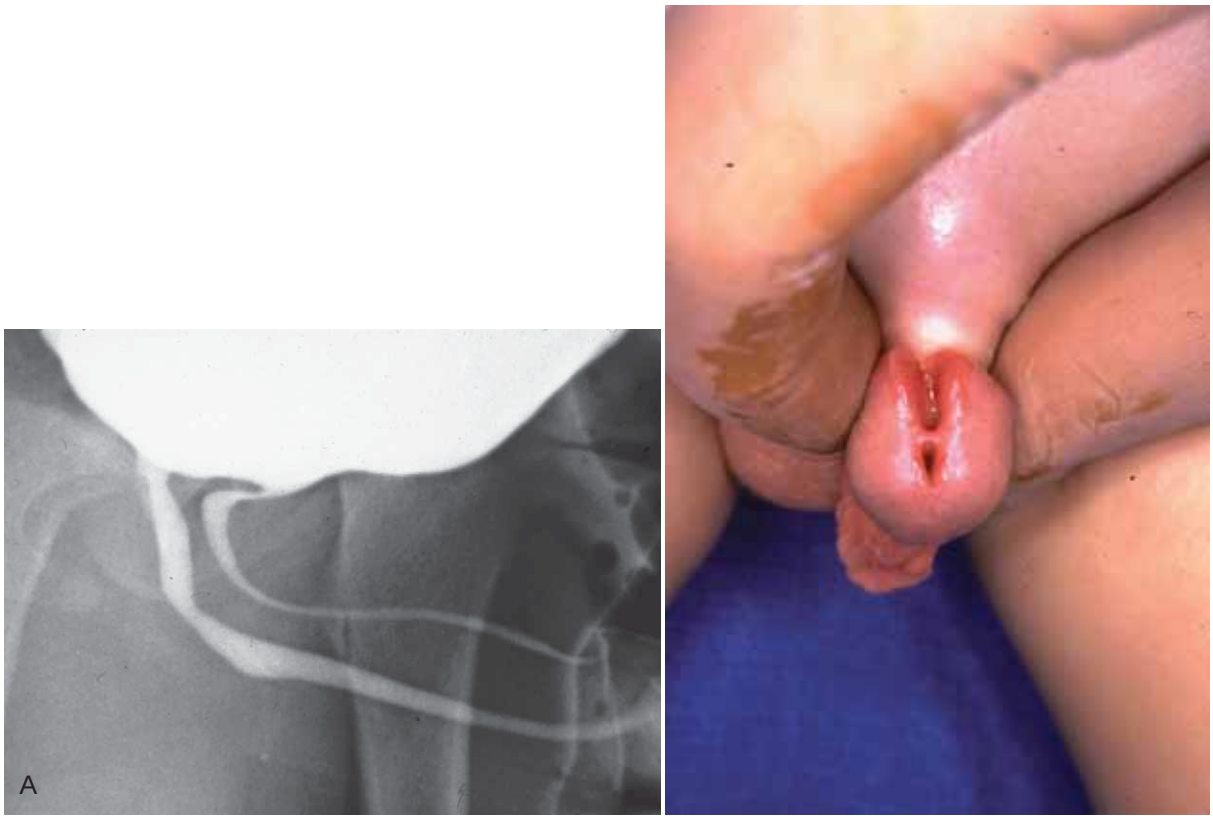

Figure 126–18. **A,** Voiding cystourethrogram shows a complete duplication of the urethra with an epispadiac dorsal segment. **B,** The ventral urethra is in the center of the glans, and the dorsal urethra ends in the dorsal glans cleft in an epispadiac location.

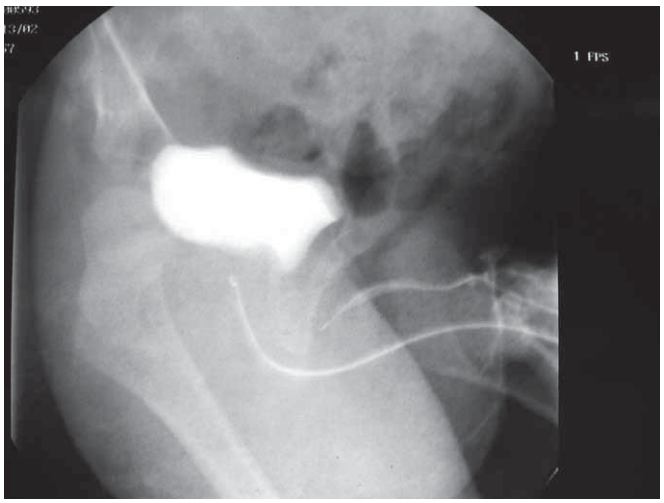

Figure 126–19. This urethral duplication has a blind-ending dorsal segment that ends under the pubis.

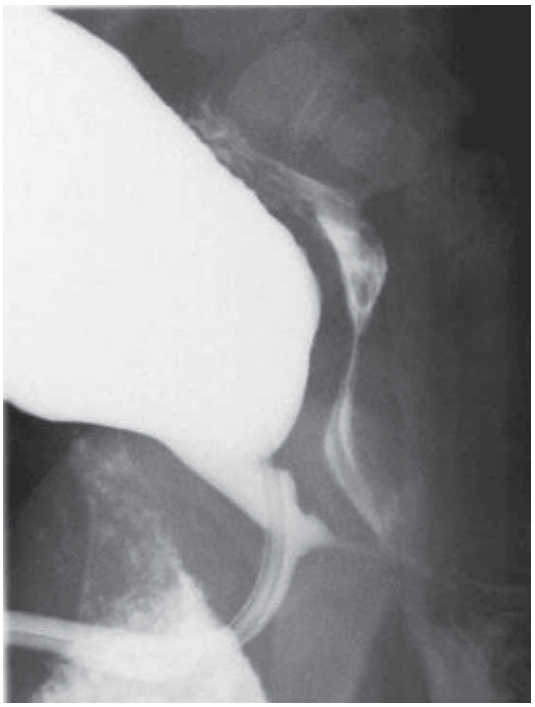

Figure 126–20. This voiding cystourethrogram demonstrates a posterior urethral fistula to the rectum discovered after an anoplasty. The patient presented with recurrent urinary tract infection and diarrhea due to urine passing into the rectum.

The urologist should be involved with injuries to the urethra or bladder. Cystoscopy with catheterization of the fistula and imaging will often be helpful to the surgeon, and if the urinary injury is more than a simple persistent fistula the pediatric urologist should repair the urinary tract. **Repair of fistula in infants and children follows the same set of operative rules that apply to adults. Any obstructive element of the urethra must be eliminated, the rectum and urethra (or bladder) must be adequately separated, the fistula must be ligated, and healthy tissue must be interposed between the urinary tract and gut.** Often, pediatric surgeons pull down fresh bowel at the time of revision and uninjured rectal wall opposes the urinary fistula, allowing healing. If this is not possible, it may be necessary to interpose omentum or a Dartos fascial flap as a barrier to repeat fistula (Youssef et al, 1998). The importance of having a catheter in the urethra during any rectal surgery cannot be overstated. In addition, adequate preoperative imaging with VCUG, colostogram, and magnetic resonance imaging will give the operating surgeon the best opportunity to have a successful outcome to this difficult surgical problem. Symptomatic urethral diverticuli must be excised using many of the same surgical techniques.

After any type of fistula or diverticulum repair, a urinary catheter should be left in place for at least 7 days. These children will need lifelong monitoring due to the risk of stricture, recurrent fistulae, or neurogenic bladder dysfunction.

Summary

Our increasing understanding and recognition of non-neuropathic lower urinary tract dysfunction as a cause of various urologic disorders in childhood has had a profound influence on our management strategies over the past decade. What was known as primary or idiopathic, such as primary vesicoureteral reflux (VUR) or primary nocturnal enuresis, is often associated with underlying bladder dysfunctions evident on urodynamics and resolves with successful correction of the bladder physiology (Koff and Murtagh, 1983; Homsy et al, 1985; Watanabe et al, 1994; Yeung et al, 1998, 1999). Conversely, failure of recognition and treatment of the associated problem can result in persistence or even further deterioration.

The understanding of the spectrum of dysfunction of the bladder and even of normal bladder physiology in infants and young children is complex. Not only are the dynamics and functional disturbances of the lower urinary tract different from those in adults, but the evolution in normal bladder-sphincteric function during growth and maturation in children poses continuous changes (Yeung, 1995; Yeung et al, 1995; Sillen et al, 1996; Holmdahl, 1997). More confusingly, one type of bladder dysfunction may often progress with time and evolve imperceptibly into another, without a sharp distinction between the different stages. This is further confounded by a lack of age- and sex-specific normal reference values for various urodynamic parameters, especially for the very young age groups (Yeung et al, 1995).

Recent advances and development in the use of urodynamic techniques specially designed for infants and young children have allowed more accurate assessment of bladder function and provided much better understanding of bladder pathophysiology. This has allowed for better recognition of functional disorders, as well as to provide a scientific basis for their therapy (Hjalmas, 1988; Perez et al, 1992; Bauer, 1997; Nevéus et al, 2007). In view of the important association of bladder dysfunctions with various common urologic disorders, urologists should be acquainted with the spectrum of dysfunction and the techniques to facilitate proper diagnosis and treatment.

NORMAL BLADDER FUNCTION IN INFANTS AND CHILDREN

Anatomy of Bladder

The bladder is a unique organ of the human body in that it not only carries a dual function of both storage and emptying of urine but also has a complex innervation of voluntary and involuntary control of function. Understanding of the functional anatomy of the lower urinary tract stems from extensive postmortem studies carried out over decades (Gosling et al, 1981; Gosling, 1985; DeLancey, 1988; de Groat, 1993; Zvara et al, 1994).

The bladder is an abdominal organ, and when full it can be readily palpable in infants and young children

due to a shallow pelvis (Wiegel, 1990). The bladder wall consists of three layers: mucosa, detrusor, and adventitia. The detrusor consists of a meshwork of smooth muscle fibers arranged into a single functioning unit with an ability to elicit nearly maximum active tension over a wide range of length. This allows the bladder to fill with urine from the upper tract at low pressures (compliance) (Mattiasson, 1994). The ability of the bladder to store urine (reservoir function) is determined by the concomitant activity of the detrusor muscle and the bladder outlet (consisting of the bladder neck, proximal urethra, and striated muscle of the pelvic floor) (de Groat, 1993).

The bladder sphincter (external and internal) plays a major role in urinary continence by closure of the bladder neck and proximal urethra. The anatomy of the external urinary sphincter consists of a cylindrical structure, which is accentuated anteriorly and thinned out or actually absent posteriorly, thus giving a characteristic horseshoe or omega shape on cross section. It has an inner layer of smooth muscle and an outer layer of striated muscle, extending from the apex of the prostate to invest the length of the membranous urethra in males. In the females this is less well developed and extends from the bladder neck to the midurethra. The internal sphincter, however, has not been well delineated anatomically. It has generally been accepted that it consists of smooth muscle fibers continuing from the bladder base and trigone, which traverse inferiorly through the bladder neck to extend toward the proximal urethra. Its existence has been better delineated on radiologic and urethral pressure measurement studies. **During micturition, the bladder base, bladder neck, and proximal urethra can be shown to contract simultaneously as a unit, producing a funneling effect that opens up the bladder outlet with initiation of voiding.**

Little, too, is known about the natural course of development or maturation of the structure and function of the sphincter mechanism. **Literature suggests that immature detrusor-sphincter coordination, manifested as detrusor hypercontractility and interrupted voiding, commonly occurs in the first 1 to 2 years of life, causing some degree of functional bladder outflow obstruction** (Sillen et al, 1992; Yeung et al, 1998). In a postmortem study of the ontogeny of the external urinary sphincter in human fetuses, infants, and young children, Kokoua and Homsy found significant age-related differences in the histologic structure of the sphincter as compared with that in adults. Striated muscle fibers of the sphincter first appeared at around 20 weeks of gestation and then became arranged in a concentric pattern as a closed ring, fused posteriorly to form a tail-like structure that was directed to the perineal body. Posterior splitting of the striated sphincter, starting first caudally and progressively in a cephalad manner, then occurred during the first year of life, coinciding in parallel with gradual resorption of the "tail," to eventually giving way to a mature omega-shaped structure (Kokoua et al, 1992). As a complete closed ring of striated sphincteric muscle was present up to 1 year of age in more than 40% of cases, it may well be conjectured that this could be related to the high intravesical pressures and interrupted voiding that are commonly observed during urodynamic studies in infants (Sillen et al, 1992; Yeung et al, 1995, 1998).

Innervation of Bladder

Activation, coordination, and integration of various parts of the bladder-sphincteric complex involve both the central somatic and autonomic nervous systems through three sets of peripheral nerves: sacral parasympathetic (pelvic nerve), thoracolumbar sympathetic (hypogastric nerves and sympathetic chain), and sacral somatic nerves (primarily the pudendal nerve) (Fig. 127–1) (deGroat, 1993; Mattiasson, 1994).

Parasympathetic nerve fibers run in the pelvic nerve (S_2-S_4) to supply the pelvic and vesical plexuses before entering the bladder. Parasympathetic ganglia are found within these plexuses and in the bladder wall. Sympathetic nerves arise from segments T_{10}-L_2 of the spinal cord and go to the inferior mesenteric ganglion through the sympathetic trunk. From the inferior mesenteric ganglion the nerve fibers pass to the pelvic plexus and bladder through the hypogastric nerves. There is also sympathetic innervation originating from T_{10}-L_2 supplying the detrusor and urethral sphincter (Bradley et al, 1974). The somatic nervous system (pudendal nerve) supplies the periurethral pelvic floor musculature (Mattiasson, 1994). The sensory and motor nerves carried by all three nerves innervate both the bladder and urethral sphincter. They originate from parasympathetic ganglia located in the second, third, and fourth segments of the sacral spinal cord (Bradley et al, 1974). Within the spinal cord, information from bladder afferents is integrated with that from other viscera and somatic sources and projected to the brainstem centers that coordinate the micturition cycle (Harrison and Abrams, 1994).

Development of Normal Bladder Function and Micturition Control

Urodynamic studies on normal infant bladders have shown that bladder function in young children is different from that in adults. During the first 2 to 3 years of life there is progressive development from an initially indiscriminate infantile voiding pattern to a more socially conscious and voluntary or adult type of micturition. This is achieved through an active learning process whereby the child acquires the ability to voluntarily inhibit or initiate voiding at socially convenient times. **This natural evolution of bladder control entails an intact nervous system and depends on at least three main events occurring in parallel: (1) a progressive increase in bladder functional storage capacity; (2) maturation of voluntary control over the urethral striated muscle sphincter; and, perhaps most importantly, (3) development of direct volitional control over the bladder-sphincteric unit so that the child can voluntarily initiate or inhibit the micturition reflex.** This process can also be influenced by an awareness of the accepted social norms in families during toilet training (Yeung et al, 2010).

Change in Bladder Functional Parameters

Voiding Frequency. During the third trimester of pregnancy, the fetus is voiding at the rate of approximately 30 times every 24 hours (Goellner et al, 1981). However, immediately after birth, this drops dramatically for the first few days of life, only to increase again after the first week to reach a peak by weeks 2 to 4 to an average of once per hour. Subsequently this rate declines again to about 10 to 15 times per day between 6 and 12 months and to about 8 to 10 times per day by 2 to 3 years (Goellner et al, 1981; Yeung, 1995; Holmdahl et al, 1996). **This reduction in voiding frequency observed during the first few years of life appears to be related mainly to an increase in bladder capacity in parallel to body growth,** which is proportionately greater than simultaneous increase in urine volume

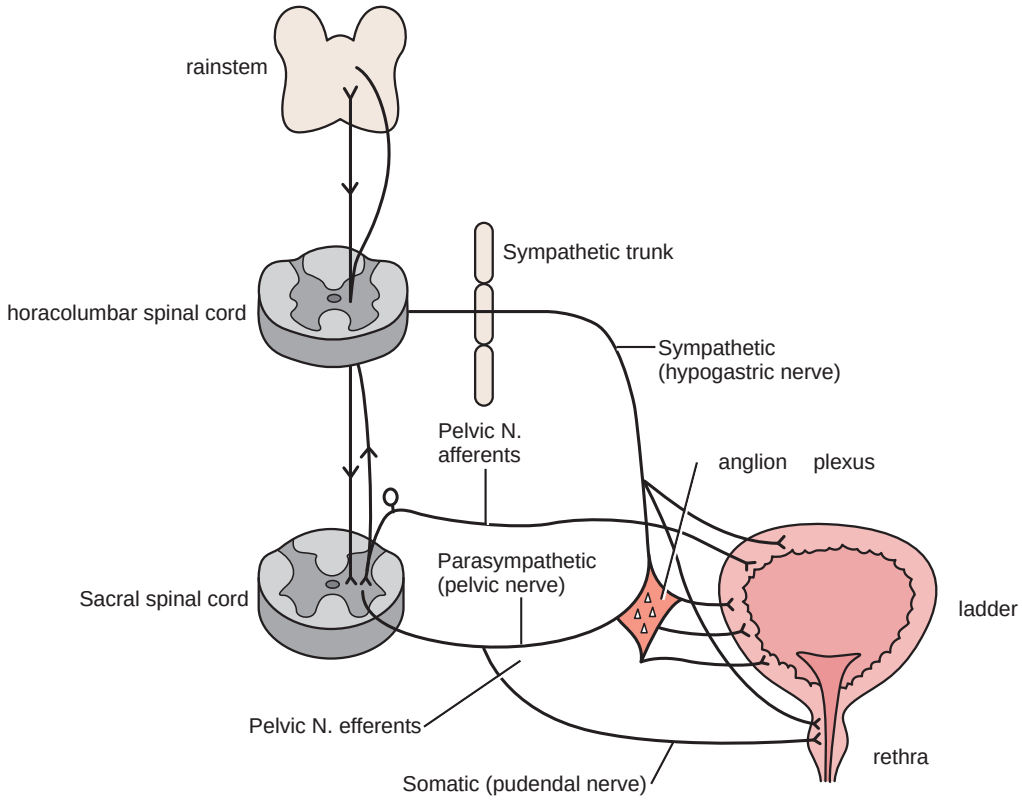

Figure 127–1. Diagram to illustrate the innervation of the bladder-sphincter complex. (From Yeung CK, Barker GM, Läckgren G. Pathophysiology of bladder dysfunction. In: Gearhart JP, Rink RC, Mouriquand PDE, editors. Pediatric urology. 2nd ed. Philadelphia: Elsevier Saunders; 2010. p. 353–65.)

production (Yeates, 1973; Koff, 1997). By the age of 12, the voiding pattern is similar to that in an adult and usually comprises 4 to 6 voids per day (Fig. 127–2).

Bladder Capacity, Voided Volume, and Emptying Efficiency. The increase in bladder capacity with the growth of the child is a crucial step in the development of bladder function and urinary continence. **An adequate reservoir function for urine storage is necessary to meet the increased rate of urine production and decreased voiding frequency in the growing child.**

Several studies have shown that functional bladder capacity at a certain age can be accurately estimated and expressed as a function of age with no difference in sex. For young infants it can be expressed as:

$$\text{Bladder capacity (mL)} = 38 + 2.5 \times \text{Age (months)}$$
(Holmdahl et al, 1996)

For older children, one of the most widely accepted formulas is the Koff formula:

$$\text{Bladder capacity (mL)} = [\text{Age (years)} + 2] \times 30 \text{ (Koff, 1983)}$$

Or similarly, the Hjalmas formula follows:

$$\text{Bladder capacity (mL)} = 30 + [\text{Age (years)} \times 30] \text{(Hjalmas, 1976, 1988)}$$

In parallel to the increase in bladder capacity, the mean voided volume of each micturition increases with age. Of note, urodynamic studies have shown that a significant proportion of infants with incomplete maturation of detrusor-sphincter coordination

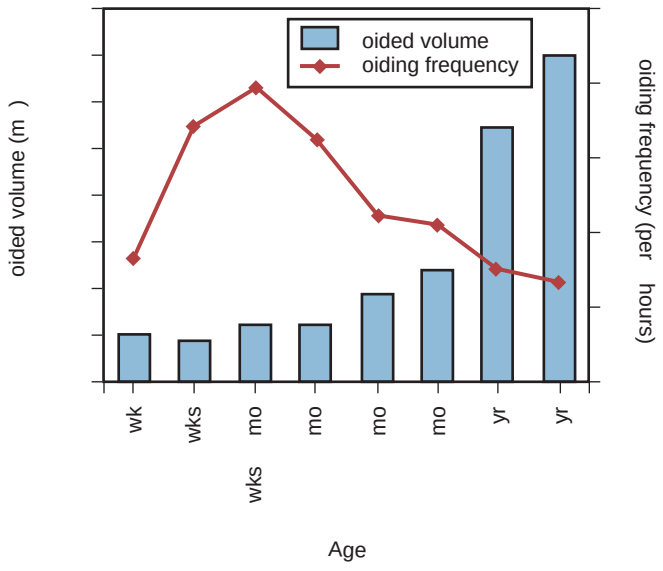

Figure 127–2. Changes in voided volume and micturition frequency from neonates to early infancy.

before the age of 1 are still able to achieve satisfactory bladder emptying (>80% efficacy) (Yeung, 1995; Yeung et al, 1995, 1998; Holmdahl et al, 1996; Bachelard et al, 1999; Sillen et al, 2000).

Detrusor Pressure at Voiding. Studies on detrusor pressures at voiding in normal infants are limited due to (1) the technical difficulties involved in performing urodynamic studies in young infants and (2) an ethical consideration in justifying doing so. From the data in a natural filling cystometric study of infants with

normal lower urinary tracts (as indicated by a normal micturating cystourethrogram) and who had undergone either dismembered pyeloplasty for pelviureteric junction obstruction or nephrectomy for dysplastic kidney, **the authors have documented significantly higher maximum detrusor pressures with micturition (Pdetmax) than in normal adults. It was also noted that male infants voided with significantly higher pressures than females (mean Pdetmax: 118 versus 75 cm H_20 respectively, $P < .03$)** (Yeung et al, 1995a, 1995b, 1998). Similar findings were reported in healthy, asymptomatic infant siblings of children with VUR (Bachelard et al, 1999).

Studies have also shown that these high detrusor pressures noted during micturition were mainly observed only during the first year of life and decreased progressively with age. Furthermore, an interrupted or "staccato" type of urinary stream was noted in more than half of the patients (Yeung et al, 1995a, 1995b, 1998). This was demonstrated by fluctuations of the detrusor pressure when it reached maximum during voiding and resumption of urinary stream in conjunction with a sharp fall in the detrusor pressure. The high detrusor pressures during voiding are thought to represent variations among individual infants in the maturation process of detrusor and sphincter coordination during the first 1 to 2 years of life (Yeung et al, 1995, 1998; Holmdahl et al, 1996; Bachelard et al, 1999; Sillen et al, 2000).

The authors have further confirmed this finding using video cystometry under fluoroscopy combined with natural fill urodynamics and perineal electromyography (EMG) in infants with a history of urinary tract infections (UTIs). Periods of increase in perineal or sphincteric EMG activities were noted during voiding and associated with a sudden cessation of urinary flow with a simultaneous isometric rise or high peak of detrusor pressure. In contrast, resumption of urinary flow was associated with relaxation of the external urinary sphincter and a paradoxical drop in detrusor pressure. Also, the detrusor pressure associated with the initiation of urinary flow was usually significantly lower than the maximal detrusor pressure during micturition (Pdetmax) and that the Pdetmax was significantly higher than those recorded in normal adults (Fig. 127–3).

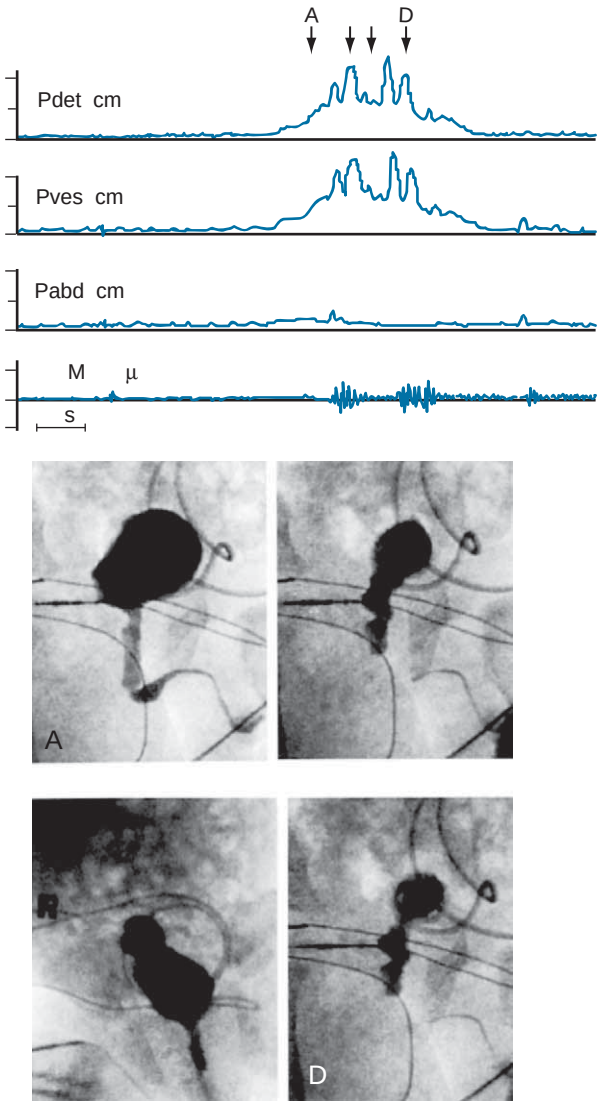

Figure 127–3. Interrupted voiding pattern due to detrusor-sphincter discoordination as revealed by urodynamic study with simultaneous perineal electromyographic (EMG) monitoring and videocystourethrography. *Arrows with letters in top graph* correspond to urethrograms at bottom. **A**, Urinary flow started. **B**, Premature sphincteric contraction and urethral closure as evidenced by the urethrogram and increase in sphincteric EMG activities, leading to a sharp spike of detrusor pressure (isometric increase) associated with a paradoxical abrupt cessation of urinary flow. **C**, Urinary flow resumed in parallel with sphincter relaxation. **D**, Repeated sphincteric contraction leading to another sharp increase in detrusor pressure and paradoxical interruption of urinary flow. P abd, abdominal pressure; Pdet, detrusor pressure; Pves, intravesical pressure. (From Yeung CK, Barker GM, Läckgren G. Pathophysiology of bladder dysfunction. In: Gearhart JP, Rink RC, Mouriquand PDE, editors. Pediatric urology. 2nd ed. Philadelphia: Elsevier Saunders; 2010. p. 353–65.)

Evolution of Normal Micturition Control

Traditionally, it has been assumed that micturition in newborns and young infants occurs automatically with a full bladder by a simple spinal cord reflex, with little or no mediation by the higher neural centers, and that with progressive maturation, voluntary inhibition of the bladder emptying reflex is achieved by adulthood. A delay in the normal maturation of bladder control was attributed to certain conditions such as primary nocturnal enuresis and hence the traditional belief that all enuretics would get better with age (Nash, 1949). However, more recent studies have indicated that this is an oversimplification of what actually occurs. **Even in full-term fetuses and newborns, it has been shown that micturition is modulated by higher centers.** Ohel and colleagues (1995) showed that intrauterine micturition almost exclusively occurs while the fetus is awake rather than randomly distributed over various behavioral (sleep/arousal) states. Furthermore, it has been observed that micturition in a full-term fetus can be elicited by vibroacoustic stimulation, all of which indicates that the micturition reflex is probably under higher neural control even at near gestational term (Zimmer et al, 1993). Further extensive modulation occurs during the postnatal period.

Studies on normal neonates using ambulatory bladder monitoring techniques in conjunction with polysomnographic recordings have shown that even in newborns, micturition does not occur during sleep (Yeung et al, 1995). During sleep the bladder is normally quiescent and stable with lack of facilitation of detrusor contractions, whereas during wakefulness marked detrusor overactivity is observed. Clear electroencephalographic (EEG) evidence of cortical arousal or actual awakening occurs in response to bladder distension, and sleeping infants are noted to wake up before bladder activity

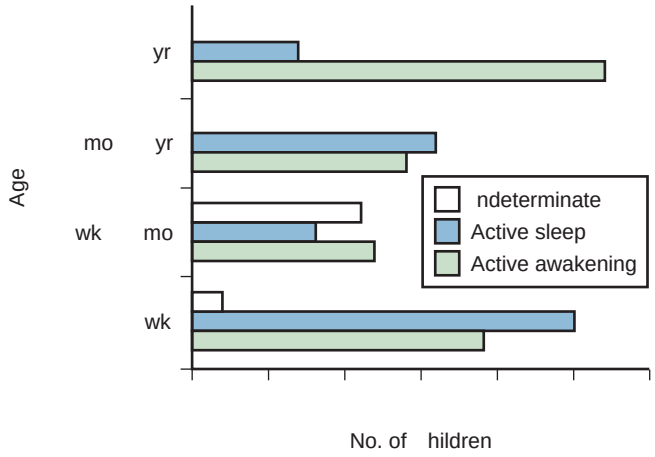

Figure 127–4. Incidence of micturition during different sleep states, according to age group.

returns and voiding occurs. However, this arousal period may often be transient with the infant crying or moving for a brief period, micturating, and then going back to sleep without being noticed to have awakened. This wakening response to bladder distension probably involves more complicated neural pathways and higher centers than has been appreciated up until now (Fig. 127–4).

These results also correlate with recent animal studies showing a sophisticated integration of preexisting central and peripheral neural pathway in micturition control at birth with remodulation occurring in the early postnatal period (Maggi et al, 1986; Thor et al, 1989). Extensive studies using experimental animals by de Groat and colleagues (1993, 1998) have indicated that early postnatal maturation of bladder function probably occurs at different levels: (1) changes in the properties of detrusor muscle; (2) developmental modifications in the peripheral innervation of the bladder; and (3) alterations in central synaptic circuitry and neuroplasticity in the parasympathetic reflex pathways to the bladder (Sugaya and de Groat, 1994; Araki and de Groat, 1997; Sugaya et al, 1997). Recordings of spontaneous activity in bladder smooth muscle in neonatal rats showed much larger amplitude and more synchronous rhythmic contractions compared with those observed in adult rats (Sugaya and de Groat, 1994). This suggests that there is a progressive reduction in intercellular communication between detrusor smooth muscle cells, resulting in less spontaneous activities and hence more efficient urine storage, during early postnatal development. In addition, peripheral and central neural mechanisms also change extensively during this period. In cats (and some other species) micturition during the newborn period is dependent on an exteroreceptive somatovesical reflex triggered when the mother licks the perineum of the kittens (de Groat et al, 1993, 1998; Araki and de Groat, 1997). This somatovesical reflex, processed in the sacral spinal cord, disappears in older animals but may reappear after spinal cord injury. Further neuroanatomic studies have indicated that spinal bladder reflexes are mediated via interneurons located immediately adjacent to, and synapsing with, the sacral preganglionic neurons (Sugaya et al, 1997). This interneuron–preganglionic neuron synaptic transmission is efficient immediately after birth but is abruptly downregulated during the third postnatal week when the mature supraspinal micturition reflexes start to appear (Araki and de Groat, 1997). Transection of the spinal cord prevents this downregulation, indicating that the higher neural centers play an important role in this synaptic remodeling, which contributes to postnatal development of micturition reflexes.

During the second or third year of life there is progressive development toward a socially conscious continence and a more voluntary or adult type of micturition control. The child becomes more aware of the sensation of bladder distension and the urge to urinate, as well as the social norm and embarrassment associated with urinary incontinence. Through an active learning process, the child acquires the ability to voluntarily inhibit and delay voiding until a socially convenient time and then actively initiate urination even when the bladder is not very full and allow it to proceed to completion. **This natural evolution of micturition control mechanisms depends on an intact neural pathway and awareness of social norms, as well as multiple factors including the gradual increase in functional bladder capacity, maturation of detrusor-sphincter coordination, and progressive development of voluntary control over the whole bladder-sphincteric-perineal complex.** The final steps are usually achieved at around the age of 3 to 4 years, when most children have developed the adult pattern of urinary control and will be dry both day and night. The child has learned to inhibit a micturition reflex, postpone voiding, and voluntarily initiate micturition at socially acceptable and convenient times and places. This development of continence and voluntary micturition is also dependent on behavioral learning and can be influenced by toilet training, which in turns depends on the cognitive perception of the maturing urinary tract. It is understandable therefore that this series of complex events is highly susceptible to the development of various types of dysfunctions.

Neurologic control of normal micturition occurs at different levels of the central nervous system (CNS), from the spinal cord with the "sacral micturition center," to the brainstem with the "pontine micturition center," the cerebellum, basal ganglia, limbic system, thalamus and hypothalamus, and cerebral cortex (Blaivas, 1982; McLorie and Husman, 1987; de Groat, 1993; Fernandes et al, 1994). It should be noted that the bladder is unique among other visceral organs in that its function is under the control of both the somatic and the autonomic nervous system. Besides acetylcholine and norepinephrine, various other neurotransmitters including prostaglandin substance P, opioid peptides, vasoactive intestinal peptide, and neuropeptide Y are involved during bladder stimulation (Fernandes et al, 1994). Simple manipulation of adrenergic and cholinergic receptors may only partially abolish the effect of neural stimulation, which explains why pharmacologic blockage of the classic neurotransmitters (acetylcholine and norepinephrine) alone may fail to elicit the expected full clinical response.

Transitory Detrusor-Sphincter Discoordination in Infancy

Studies have shown that in making the transition from an infantile to an adult pattern of micturition control, all children may transiently display some degree of abnormal bladder-sphincteric function (Koff, 1997). For instance, it has been clearly shown that a significant proportion of normal infants exhibit prominent detrusor-sphincter discoordination and interrupted voiding during the first 1 to 2 years of life. This is manifested by a discoordinated and interrupted urine flow, which may even be brought to a complete stop for 1 to 2 minutes before restarting, producing a pattern of repeated small voidings in quick succession (Yeung et al, 1995a, 1995b, 1998). **Urodynamic findings show**

association with high voiding pressures and interruption of flow but no impairment of overall bladder emptying. However, this type of dysfunction resolved with a period of successful toilet training and was only transitory or intermittent and did not persist. One must therefore be cautious in the assessment of young children with apparent voiding dysfunctions and resist the temptation to overinterpret intermittent or transient symptoms as pathologic and hence overinvestigate. However, if voiding dysfunctions are persistent well beyond the period of toilet training, especially if associated with urinary complications like recurrent urosepsis, then the possibility of underlying anatomic and neurologic causes must be considered and duly evaluated.

Key Points: Normal Bladder Function and Development in Infants and Children

- The bladder has dual function (storing and emptying) and dual innervation (central somatic and autonomic nervous systems).
- Evidence indicates that micturition is modulated by higher neural centers even in full-term fetuses and newborns and that micturition almost always occurs during wakefulness.
- In the transition from an infantile to adult bladder, detrusor-sphincteric discoordination may be a normal transient phenomenon that resolves after toilet training.
- The natural evolution of micturition control involves the gradual increase in functional bladder capacity, maturation of detrusor-sphincter coordination, and progressive development of voluntary control over the whole bladder-sphincteric-perineal complex.

EPIDEMIOLOGY AND CLASSIFICATION OF NON-NEUROPATHIC BLADDER-SPHINCTER DYSFUNCTION IN CHILDREN

Epidemiology and Prevalence

Non-neuropathic bladder-sphincter dysfunction in children is probably more common than what meets the eye, but many times it only presents to us when UTI, VUR, or urinary incontinence is manifested. It has been reported that 15% of 6-year-old children suffer this condition (Hoebeke, 2002).

Categorization of Non-Neuropathic Bladder-Sphincter Dysfunction in Children

Various conditions have been described under the category of non-neuropathic bladder-sphincter dysfunction, but it must be emphasized that these conditions should not be viewed rigidly as separate and distinct entities but rather as transitional phases of a complex sequence of events. For instance, a girl with dysfunctional voiding may start with having detrusor instability associated with sphincter and pelvic floor overactivity, then gradually evolve to develop fractionated voiding with increasing postmicturition residues, and finally develop bladder decompensation and the "lazy bladder" syndrome (van Gool et al, 1992). It must also be emphasized that **use of the term "non-neuropathic" is based purely on the fact that no obvious and identifiable neurologic lesions can be identified.** However, conditions like the urofacial syndrome complex (Ochoa syndrome) and the Hinman syndrome behave almost identically to the typical neuropathic bladder-sphincter dysfunctions. It is indeed conceivable that they do have an organic underlying neurologic cause, although the exact neuroanatomic lesion has not yet been identified. Hence the distinction between neuropathic and non-neuropathic bladder dysfunctions may not be as clear as traditionally thought.

In adults, lower urinary tract function has been well understood and standardization of terminology has been established by a committee working under the International Continence Society (ICS) since the early 1970s (Bates et al, 1976a, 1976b, 1979). In contrast, neural control over the bladder-sphincter unit in children is age dependent and is much more variable and complex. Definitions of normal versus abnormal lower urinary tract function have therefore been far less standardized. Various classifications for bladder dysfunctions in children have been described over the past few decades (Bellinger, 1996; Lapides, 1970; Wein, 1998). To avoid confusion, the classification proposed by the International Children's Continence Society in 2007, with a standardized set of terminology and definitions for different lower urinary tract dysfunctions, was adopted (Nevéus et al, 2007).

Etiologic Classification of Bladder Dysfunction

Dysfunction of the lower urinary tract in children can be secondary to derangement of nervous control, disorders of detrusor and sphincteric muscle function, structural abnormalities, and other unclassified conditions (Nevéus et al, 2007).

Derangement of Nervous Control Conditions. These include the following:

- Congenital malformations of the CNS (e.g., myelomeningocele, spina bifida occulta, caudal regression syndrome, tethered cord syndrome)
- Developmental disturbances (e.g., mental retardation, dysfunctional voiding, urge syndrome)
- Acquired conditions (e.g., cerebral palsy, progressive degenerative diseases of the CNS associated with spasticity, transverse myelitis, multiple sclerosis, vascular malformations, and trauma of the spinal cord)

Disorders of Detrusor and Sphincteric Muscle Function. These include the following:

- Congenital conditions (e.g., muscular dystrophy, neuronal dysplasia, megacolon-megacystis syndrome)
- Acquired conditions (e.g., chronic bladder distension, fibrosis of detrusor or bladder wall)

Structural Abnormalities. These include the following:

- Congenital conditions (e.g., bladder exstrophy, epispadias, cloacal anomaly, ureteroceles, posterior urethral valves and other urethral anomalies, prune-belly syndrome)
- Acquired conditions (e.g., traumatic stricture or damage to the sphincter or urethra)

Other Unclassified Conditions. These include the following:

- Giggle incontinence
- Hinman syndrome
- Ochoa syndrome (urofacial syndrome)

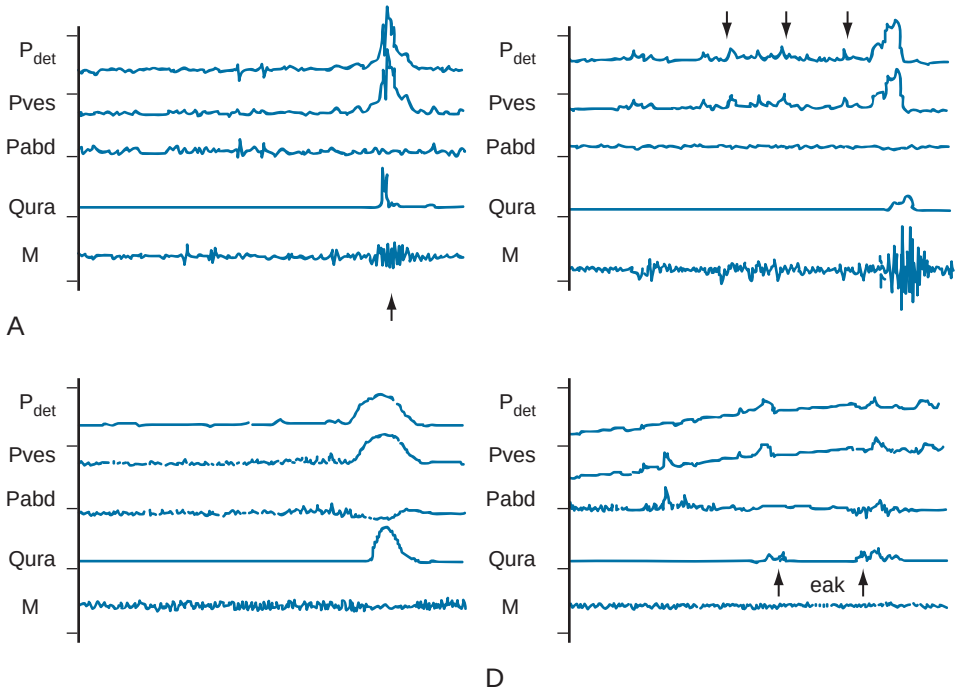

Figure 127–5. Various bladder functional patterns. **A**, Dyssynergic patterns with an increase in sphincteric electromyographic activities during micturition *(arrow),* leading to an interrupted urinary flow. **B**, Overactive bladder, characterized by frequent unstable detrusor contractions *(arrows)* during the filling phase. **C**, Normal female micturition pattern; note the pelvic floor relaxation as evidenced by a drop in abdominal pressure during micturition. **D**, Bladder with low (poor) compliance as evidenced by a rapid increase in intravesical pressure during filling, often associated with urinary leakage *(arrows)*. EMG, electromyogram; Pabd, abdominal pressure; Pdet, detrusor pressure; Pves, intravesical pressure; Qura, uroflow. (From Yeung CK, Barker GM, Läckgren G. Pathophysiology of bladder dysfunction. In: Gearhart JP, Rink RC, Mouriquand PDE, editors. Pediatric urology. 2nd ed. Philadelphia: Elsevier Saunders; 2010. p. 353–65.)

Functional Classification of Bladder Dysfunction

This is based on the functional state of the bladder-sphincteric complex with respect to detrusor activity, bladder sensation, bladder compliance and capacity, and urethral function both during the filling and the voiding phase of cystometry (Fig. 127–5) (Nevéus et al, 2007).

During the Filling (Storage) Phase

Detrusor Activity. *Normal* bladder volume increases during filling without a significant rise in detrusor pressure or involuntary phasic contractions despite provocation.

***Overactive* bladder is characterized by phasic involuntary detrusor contractions, which may occur either spontaneously or on provocation.** The exact pathogenesis for detrusor overactivity has not been resolved. Various underlying causes have been proposed: (1) failure of maturation of CNS control mechanisms; (2) low detrusor levels of inhibitory vasoactive intestinal peptide; (3) abnormal enkephalin-mediated inhibitory neurotransmission; (4) denervation hypersensitivity; and (5) alterations in the properties of the detrusor myocytes (Wein and Barrett, 1992; Harrison and Abrams, 1994; Brading, 1997). Detrusor overactivity was frequently found in children with both diurnal and nocturnal enuresis (Bauer et al, 1980; Nevéus et al, 2007). However, the precise relationship between detrusor overactivity contraction exhibited on a cystometrogram and different types of urinary incontinence is still debated (Nevéus et al, 2007). Children with an unstable bladder typically present with a sudden urge to void that can be only be partially suppressed. Often a girl with an unstable bladder will squat down on the heel of one foot, demonstrating the pathognomonic sign of Vincent curtsy.

Detrusor overactivity may also be qualified when possible according to cause into neurogenic detrusor overactivity (formerly called detrusor hyperreflexia) when there is objective evidence of a relevant neurologic disorder.

BLADDER SENSATION. This can be normal, increased (hypersensitive), reduced (diminished), or absent (no sensation).

BLADDER CAPACITY. This can be normal, high, or low.

COMPLIANCE. This can be normal, high, or low. During normal bladder filling, little or no pressure change occurs but there are no standardized reference ranges for compliance in children.

Urethral Function. *Normal* positive urethral closure pressure is maintained during filling, even in the presence of increased abdominal pressure (guarding reflex), but it decreases immediately before micturition to allow flow.

Incompetent leakage of urine occurs in the absence of detrusor contraction despite urethral closure.

During the Voiding (Emptying) Phase

Detrusor Activity

NORMAL. Voiding is achieved by voluntarily initiated detrusor contraction that is sustained and cannot usually be suppressed voluntarily until at least after the age of 4 years. Complete bladder emptying is achieved in the absence of bladder outlet obstruction.

UNDERACTIVE. Detrusor contraction is of inadequate magnitude and/or duration to effect bladder emptying with a normal time span. The term should be reserved for describing detrusor activity during micturition because it is not readily visible during the filling phase of the cystometrogram. It is often observed in the overdistended postobstructive bladder.

ACONTRACTILE. This is due to an abnormality of nervous control and denotes the complete absence of centrally coordinated contractions.

Urethral Function

NORMAL. The urethra opens to allow bladder emptying.

OBSTRUCTIVE. This may be due to sphincteric overactivity or mechanical obstruction due to obstructive urethral lesions such as congenital obstructive posterior urethral membrane or syringoceles (Dhillon et al, 1993; Dewan and Goh, 1995).

Dysfunctional Elimination Syndrome

The association of constipation with urologic pathologies has been described in the literature since the 1950s, but it was only over the past decade that clinicians have paid more attention to this relationship and recognized its existence with the term *dysfunctional elimination syndrome* (DES). This term is used to reflect the broad spectrum of functional disturbances that may affect the urinary tract, including that of functional bowel disturbances, and can be classified as follows:

- Functional disorder of filling: overactive bladder, overdistension of bladder or insensate bladder, which may be associated with fecal impaction or rectal distension with infrequent call to stool.
- Functional disorder of emptying: over-recruitment of pelvic floor activity during voiding, causing interrupted and/or incomplete emptying also associated with defecation difficulties due to nonrelaxation of pubo-rectalis, pain on defecation, or even anismus (Bower et al, 2005).

Koff and colleagues (1998) showed that the pattern of DES significantly influenced clinical outcome of ureteric reimplantation surgery for VUR in children. Children with constipation had the highest likelihood of developing a breakthrough UTI and thus required surgery. DES also had an adverse effect on the rate of spontaneous reflux resolution, with children requiring an average of 1.6 years longer to outgrow reflux than children without DES. For those requiring surgery, both the results and postoperative complications seemed to be negatively influenced by DES. Postoperative UTIs developed in 78% of children with DES. All children who had persistent reflux, recurrent reflux after 2 years, and contralateral reflux after unilateral reimplantation had DES.

Loening-Baucke (1997) looked at resolution of urinary incontinence and UTIs in children after treatment of their constipation. This study showed that after successful treatment of constipation, 89% of those with daytime incontinence and 63% with nighttime incontinence became dry. None of the children who had UTI had recurrence after treatment of constipation.

It therefore seems from these data that management of the underlying dysfunction should be given priority in the treatment protocol of children with conditions such as VUR, incontinence, and UTI because successful management may significantly improve outcome. Thus more attention should be paid to evaluate for the presence of functional bowel disturbances even in cases of urologic pathologies.

BLADDER-SPHINCTER DYSFUNCTION DURING BLADDER FILLING

Overactive Bladder, Urge Syndrome, and Urge Incontinence

Overactive bladder (OAB) is the most common term currently used in clinical medicine to describe a complex of lower urinary tract symptoms (LUTS). **Traditionally, the infant bladder has been described as unstable (replaced with OAB now) or uninhibited, but recent studies using prolonged natural filling bladder monitoring techniques have shown that to the contrary, the bladder is normally quiescent and stable even in newborns** (Yeung et al, 1995). Clinically, the condition of OAB is best exhibited by urge syndrome with or without urge incontinence. The syndrome, characterized by frequent attacks of sudden and imperative sensations of urge, due to detrusor overactivity during the filling phase, is more prevalent in girls. This burning sensation or urge to void occurs even with small bladder capacities. The unstable contractions are often counteracted by voluntary contraction of the pelvic floor muscles in an attempt to externally compress the urethra (hold maneuvers) exhibited as squatting (Vincent curtsy sign) in many cases (Vincent, 1966; van Gool and de Jonge, 1989). However, despite this move, urge incontinence can still occur with frequent urine leakage onto the underpants. Urge incontinence usually consists of small quantities of urine loss and occurs most often in the afternoon or when the child is preoccupied in play or other activities and is not alert enough to contract the pelvic floor in response to the urge sensation. Children with urge syndrome have small bladder capacities for age and often choose to drink extremely little in order to escape from the social embarrassment of frequent imperative urges to go to the toilet and from urinary incontinence, but otherwise they have complete relaxation of the pelvic floor musculature in most instances. In addition, habitual voluntary pelvic floor contraction to counteract every urge to void may often lead to inappropriate postponement of defecation, constipation, and fecal soiling (Vincent, 1966; O'Regan et al, 1986). This should not be confused with encopresis in children with behavioral problems.

Functional Urinary Incontinence

This can be defined as the involuntary loss of urine due to a failure of control of the bladder-sphincteric unit, which is frequent enough to constitute a social or hygienic problem, and in the absence of underlying anatomic causes (Nevéus et al, 2007). Apart from urge incontinence that is associated with detrusor overactivity and urge syndrome as described earlier, other forms of functional urinary incontinence exist as a result of failure of the bladder storage and/or sphincteric control mechanisms. ***Stress incontinence*** **represents the involuntary leakage of urine occurring at times when the intravesical pressure exceeds the bladder outlet or urethral resistance, in the absence of measurable detrusor contraction.** Unlike in adults and particularly in elderly women, true stress incontinence is extremely uncommon in neurologically normal children and is in general not associated with any demonstrable urodynamic abnormalities. It should therefore be differentiated from urge incontinence and detrusor overactivity. Insufficient bladder outlet or urethral resistance is usually not a main factor. Because the amount of urine leakage in most patients is usually small, the incontinence may at times be only scarcely discernible. It is possible therefore that the actual incidence of this condition may be underestimated.

Giggle Incontinence

Giggle incontinence is usually seen in girls and is characterized by involuntary and typically unpredictable wetting during giggling or laughter. In contrast to stress incontinence, it produces a much larger volume of urine leakage, often amounting to complete bladder emptying. Similar to stress incontinence, however, cystometry may be completely normal or occasionally demonstrate

some detrusor overactivity. Treatment is notoriously difficult, but sometimes a course of anticholinergic drugs may help to ameliorate the symptoms.

BLADDER-SPHINCTER DYSFUNCTION DURING BLADDER EMPTYING

Dysfunctional Voiding

Dysfunctional voiding is characterized by incomplete relaxation or overactivity of the pelvic floor muscles during micturition. It can manifest in different patterns depending on the degree of functional outflow obstruction caused, as well as the status of the detrusor activity. As outlined earlier, the underlying bladder-sphincter dysfunction may evolve progressively and change with time through a transitional phase of a complex sequence of events of bladder functional development.

Staccato and Fractionated Voiding

In staccato voiding the urinary stream is often delayed after the onset of detrusor contraction and is typically interrupted, resulting in a few small squirts of urine passed in quick succession. The interrupted voiding is caused by periodic bursts of pelvic floor muscle activities during micturition, resulting in the characteristic abrupt elevation or spikes of voiding pressures, coinciding with paradoxical cessation of urinary flow. The flow time is usually prolonged and bladder emptying is often incomplete, resulting in increased postmicturition residues and hence a predisposition to UTIs.

***Fractionated voiding* is characterized by infrequent and incomplete emptying secondary to detrusor inactivity.** Micturition occurs in several small, discontinuous fractions due to poor and unsustained detrusor contractions, leaving significant postvoid residual urine volumes. Abdominal straining is usually evident as an effort to improve bladder emptying. However, this is often paradoxically counteracted by a reflex increase in activities of the pelvic floor muscles that is triggered by an increase in intravesical pressure. The bladder capacity is usually large for age and may gradually increase as the condition further progresses. Overflow incontinence may ultimately develop.

Infrequent Voiding and Underactive Bladder Syndrome ("Lazy Bladder")

These two conditions are described together because they represent a spectrum of disease that more commonly occurs in girls. The old entity "lazy bladder" is now replaced by the term *underactive bladder.* At one end of the spectrum, the underactive bladder is generally regarded as the end point of long-standing dysfunctional voiding culminating in a fully decompensated system. **As a result of the chronic functional bladder outflow obstruction, there is a gradual deterioration in detrusor contractility and emptying efficiency.** Postmicturition residual urine and bladder capacity progressively increase, eventually developing into a large, floppy bladder with inefficient emptying. The child uses abdominal straining as the main driving force for bladder emptying, and detrusor contractions are small and unsustained with low pressures, at times being completely undetectable using conventional cystometry. **Because urge sensation is either absent or diminished, voiding is infrequent and occasionally the child may not void for 8 to 10 hours or even longer if engaged in activities.** The typical presentation of a child with *infrequent voiding syndrome* is where the mother always complains that the child never voids unless told to do so. The resultant large volume of postmicturition residual urines predispose to recurrent UTIs, which often constitute the primary complaint bringing the child to the pediatric urologist. Overflow incontinence is usually evident, which may be further associated with constipation and/or fecal soiling. Urodynamic studies typically reveal a large-capacity bladder with high compliance on filling. Detrusor contractions are noticeably absent, and voiding is associated with increased abdominal pressures, resulting in a fractionated flow pattern. Electromyography often shows increased activity in the pelvic floor muscle with each abdominal strain.

Hinman Syndrome and Occult Neuropathic Bladder

Hinman, Allen, and Dorfman first coined the terms *non-neurogenic neurogenic bladder* or *subclinical neurogenic bladder,* and later *Hinman syndrome* to describe a **presumably acquired form of bladder-sphincter dysfunction in children that was characterized by a combination of bladder decompensation with incontinence, poor emptying, and recurrent urinary infections** (Dorfman et al, 1969; Hinman and Baumann, 1973; Allen, 1977; Hinman, 1986). **Most children also have significant bowel dysfunction including encopresis, constipation, and fecal impaction.** In British literature the condition is often referred to as "occult neuropathic bladder" after the article by D. Innes Williams and colleagues (1975). The condition has all the clinical and urodynamic features typical of neuropathic bladder dysfunction, but no neurologic pathology can be demonstrated. Hinman and Baumann initially hypothesized that the condition could be ascribed to acquired psychologically abnormal behavior with voluntary discoordination between the detrusor muscle and the pelvic floor–external urethral sphincter complex during voiding (Hinman and Baumann, 1973). This notion, however, has not received strong support from later studies, and controversies still exist as to whether a subtle or occult spinal pathology can occur to account for an isolated bladder neuropathy in a child who does not exhibit other somatic neurologic deficits and has normal magnetic resonance imaging of the spinal cord. Urodynamic studies often revealed marked sphincteric overactivity and abrupt contractions of the pelvic floor as the child attempted to control incontinence from uninhibited bladder contractions. In its severe form, the bladder-sphincter dysfunction can cause full-blown bladder decompensation with day-and-night wetting, large postmicturition residual urine volumes, recurrent urinary infections, and significant damage to the upper urinary tracts (Dorfman et al, 1969; Hinman and Baumann, 1973; Williams et al, 1975; Allen, 1977; Hinman, 1986, 1997; Jayanthi et al, 1997). Imaging studies often reveal profound changes in the upper urinary tracts, with about two thirds of the children developing hydroureteronephrosis and over half having VUR. Nearly every patient has a grossly trabeculated, large-capacity bladder with a considerable volume of postmicturition residual urine. Treatment should therefore entail measures to control infection and to restore normal bladder storage and emptying function. Due to the great similarities to neuropathic bladder dysfunction, the management strategy in these children generally follows similar principles for the former condition.

Another piece of indirect evidence that a subtle or occult neurologic lesion may account for some cases of "non-neurogenic neurogenic" bladder-sphincteric dysfunction is the Ochoa

(urofacial) syndrome. **Children with this syndrome exhibit all the classical features of dysfunctional voiding including urinary incontinence, recurrent UTI, constipation, reflux and upper tract damage, but in addition have a peculiar painful or apparently crying facial expression during smiling** (Ochoa and Gorlin, 1987; Ochoa, 1992). The condition has an autosomal recessive inheritance and the gene has been located on chromosome 10. Urodynamic studies characteristically showed a sustained contraction of the external sphincter during voiding. The resulting severe bladder-sphincter dysfunction is often associated with a dismal outcome. Of the 66 children reported by Ochoa, 33% had renal functional impairment, 26% had hypertension, and 24% had end-stage renal failure. Five patients received renal transplantation and 17 were dead (Ochoa, 1992). Because the neural ganglia controlling the facial muscles are situated close to the pontine micturition center, it is tempting to speculate that a small, genetically predetermined, congenital neurologic lesion in this area may be responsible for both the peculiar facial expression and the bladder dysfunction. Further studies in this direction may help to resolve some of the continuing dilemma.

Postvoid Dribbling

Postvoid dribbling refers to involuntary leakage of urine immediately after voiding. Typically this refers to post–toilet-trained girls who dribble soon after standing up following a void and are otherwise normal with no other associated urinary symptoms. In these circumstances **it may be a result of vesicovaginal reflux whereby urine is trapped in the vagina during voiding, and once the child stands the urine begins to dribble out.** When in doubt, it can be confirmed by performing a micturating cystourethrogram. The condition is harmless and tends to resolve with age, but the child may also be taught to empty her vagina by simply voiding with her thighs apart and leaning forward after voiding before getting up.

DYSFUNCTIONAL ELIMINATION SYNDROME, CONSTIPATION, AND BLADDER DYSFUNCTION

It has long been recognized that children with dysfunctional voiding and recurrent urinary infections often have associated bowel dysfunction including constipation, fecal impaction, and encopresis. However, only recently has the term *dysfunctional elimination syndrome* been given to recognize the existence of this relationship. Studies have been performed to explain how constipation and chronic rectal dilatation may interfere with the normal function of the lower urinary tract, resulting in bladder dysfunction, reflux, and UTIs (Yazbeck et al, 1987; O'Regan et al, 1997). **The close proximity of the rectum to the posterior wall of the bladder makes it possible that any gross distension of the rectum by impacted feces can result in mechanical compression of the bladder and bladder neck leading to urinary obstruction** (Shopfner, 1968; O'Regan et al, 1997). **In addition, it has been observed that large fecal impaction may induce significant detrusor instability and other bladder dysfunctions, which in turn will result in urge syndrome, UTI, and reflux** (Shopfner, 1968; Yazbeck et al, 1987; O'Regan et al, 1997). O'Regan and colleagues have reported a high incidence of enuresis in children with urinary infection and constipation. It has been noted that in constipated enuretic children who had detrusor instability, treatment of concomitant constipation resulted in cessation or improvement of enuresis (O'Regan et al, 1985, 1986). Animal studies have also revealed an increased predisposition to bacteriuria in rats with surgically induced fecal retention (Breda et al, 1975). The evidence available so far therefore strongly suggests that there is an important relationship among constipation, detrusor instability, reflux, UTI, and enuresis. Proper attention to associated bowel dysfunction should therefore form an integral part of the overall management in children with bladder dysfunctions.

RELATIONSHIP AMONG BLADDER-SPHINCTER DYSFUNCTION, VESICOURETERAL REFLUX, AND RECURRENT URINARY TRACT INFECTIONS

Impairment in the functions of the lower urinary tract often coexists with recurrent UTIs and VUR, without any identified neurologic or other causal pathology (Koff and Murtag, 1983; Griffiths and Scholtmeijer, 1987; Sillen et al, 1992; Chandra et al, 1996; Yeung et al, 1998). Incidence of higher intravesical pressure, detrusor overactivity, detrusor-sphincter dyssynergia, or incomplete voiding have been reported in a significant proportion of children with VUR and conversely, micturating cystourethrograms (MCUs) performed in children with bladder dysfunctions often find concomitant VUR. **The most common abnormalities of the lower urinary tract found to coexist with VUR are predominantly detrusor overactivity and uncoordinated detrusor-sphincter function during micturition.** These abnormalities may occur secondary to urinary infection or can be acquired during the period when voluntary control of micturition is being established. Although the bladder instability can occur in most children with VUR, it is unlikely to have its role in initiating VUR (Koff and Murtag, 1984). However, **reflux from incompetence of the ureterovesical junction (UVJ) may be worsened by detrusor instability** (Stephens, 1979). The urethral sphincteric dysfunction or discoordination is characterized urodynamically by obstruction during voiding due to involuntary constriction of the urinary sphincter and is believed to be the normal response of the individual to an uninhibited bladder contraction while attempting not to void (Scholtmeijer and Griffifths, 1990; Koff, 1992; Homsy, 1994; Scholtmeijer and Nijman, 1994). It is considered as the most serious dysfunction because it has been reported that patients with this dysfunction often have bilateral high-grade reflux and injured upper renal tracts (Griffiths and Scholtmeijer, 1987; Orellana et al, 2004). The discoordinated bladder also regularly decompensates, and a significant number of children with moderate or severe VUR were reported to have overdistended bladder with weak contractions and high capacity (Hjalmas et al, 1994; Koff et al, 2002; Garat Barredo et al, 2004).

Previous studies showed that infants with UTI and VUR have a high prevalence of high voiding detrusor pressure (Fig. 127–6) (Sillen et al, 1992, 1996; Yeung et al, 1998). **Male refluxers are characterized by considerably higher maximum voiding pressures associated with detrusor overactivity, which may represent a more pronounced form of detrusor-sphincter dyssynergia, as compared with age-matched female refluxers and normal nonrefluxing infants.** In contrast, in the majority of female refluxing infants no detrusor

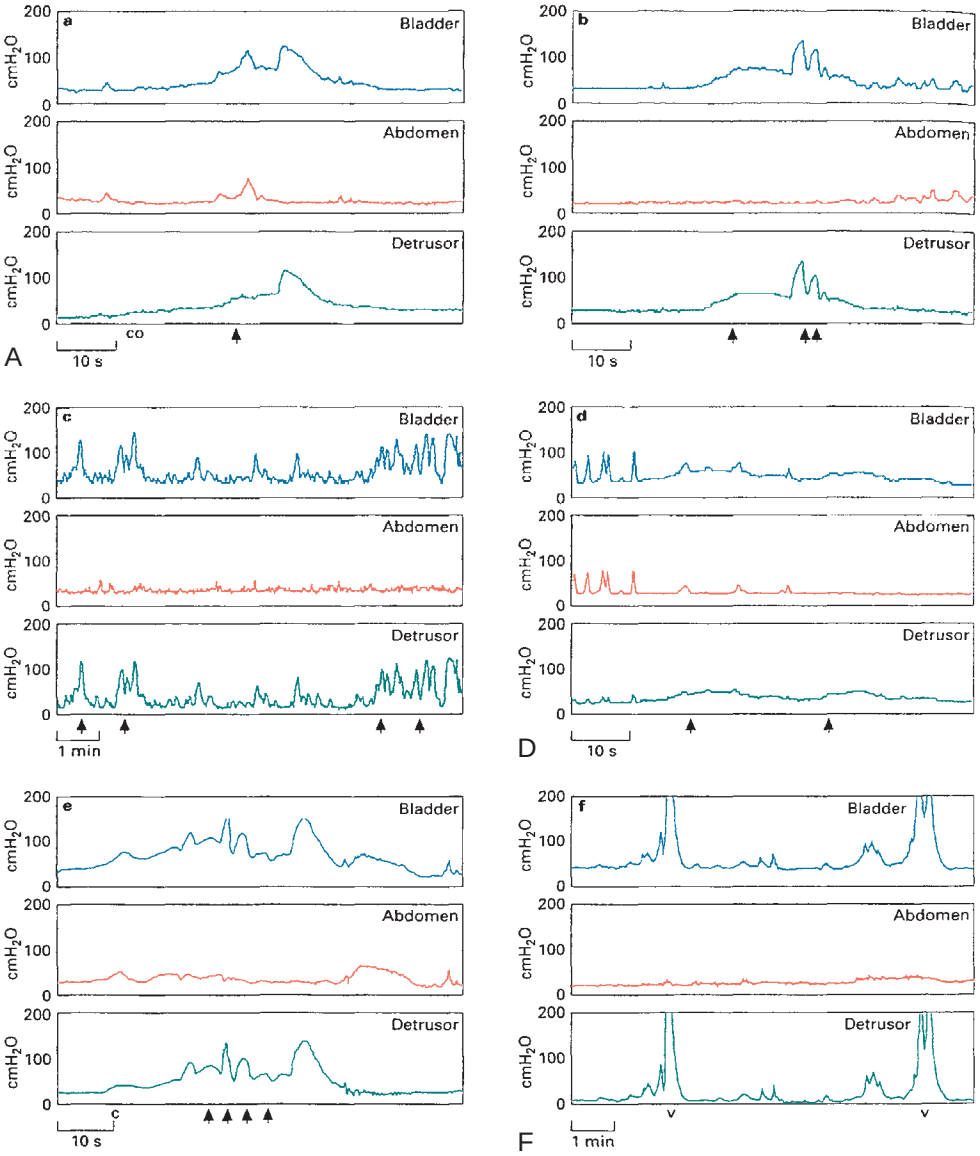

Figure 127–6. Urodynamic patterns in infants with vesicoureteral reflux. **A**, Normal: a period of low-pressure detrusor contraction (co) preceded a more formal contraction associated with the onset of urinary flow *(arrow)*. **B**, Immature: urinary flow *(arrows)* was interrupted during periods of sudden elevation of detrusor pressure. **C**, Unstable: frequent high-pressure unstable bladder contractions associated with occasional leakage of urine *(arrows)*. **D**, Inadequate: unsustained low-pressure detrusor contractions associated with the passage of small dribbles of urine *(arrows)* and a large PVR. **E**, Dyssynergic: significant interruption of urinary flow *(arrows)* associated with spikes of increase in detrusor pressure. **F**, Obstructive: note frequent voiding (v) with high detrusor pressures, greater than 20 cm H_2O. (From Yeung CK, Godley ML, Dhillon HK, et al. Urodynamic patterns in infants with normal lower urinary tracts or primary vesico-ureteric reflux. Br J Urol 1998;81:461–7.)

hypercontractility was noted and instead they often displayed a urodynamic pattern with normal voiding pressures and relatively large bladder capacity with or without emptying inefficiency and postmicturition residues. The finding of higher voiding detrusor pressure in male infants compared with female infants may be attributed to higher urethral resistance of the longer male urethra and smaller urethral meatus and anatomic difference in the configuration of external sphincter. Studies have also shown that high intravesical pressure significantly contributes to the development and severity of VUR. It was shown that infants with bilateral high-grade VUR had significantly higher voiding detrusor pressures and higher prevalence of detrusor overactivity than those with lower-grade or unilateral VUR (Chandra and Maddix, 2000).

It has been further shown that the spontaneous resolution of VUR may be delayed in the presence of abnormal dynamics of the bladder (Godley et al, 2001; Sofia et al, 2004). Bladder dysfunction was shown to have a powerful relationship with the nonresolution of high-grade infant VUR. It is generally accepted that bladder dysfunction delays the spontaneous resolution of reflux in older children (Koff and Murtag, 1984; Taylor et al, 1982). Studies have also shown that there is a strong correlation between recurrent infections and nonresolution, which probably reflects the fact that most infections were seen in infants and children with bladder dysfunction. Therefore recurrent infections can be regarded as a marker of bladder dysfunction, indicating an investigation of bladder function (Sofia et al, 2004).

Moreover, successful treatment of the underlying bladder dysfunction resulted in marked increase in the rate of spontaneous resolution of reflux and significant reduction in recurrent UTIs. Therefore early detection and proper management of underlying lower urinary tract abnormalities are crucial in the treatment of VUR in infants and children. The first step in management in those children presenting postnatally with VUR or UTI should be a detailed evaluation of bladder function to choose an appropriate treatment modality and to prevent renal deterioration.

Why do children who have VUR have such a high incidence of bladder dysfunction? The correlation of this maturational lag in the bladder function and development of the CNS is the other untouched area of investigation. A similar association between gastroesophageal reflux and cerebral palsy is now well studied; understood and effective surgical treatment protocol has evolved over the past 2 decades.

Key Points: Epidemiology and Classification of Non-Neuropathic Bladder-Sphincter Dysfunction in Children

- Bladder dysfunctions during filling include overactive bladders, urge syndrome, functional urinary incontinence, and giggle incontinence.
- Bladder dysfunctions during emptying include dysfunctional voiding, staccato voiding, infrequent voiding, Hinman syndrome, Ochoa syndrome, and postvoid dribbling.
- It is now well recognized that dysfunctional voiding often has associated bowel dysfunction, and together this is known as the dysfunctional elimination syndrome.
- VUR may be secondary to underlying bladder dysfunction, particularly in girls. Treatment should aim at correcting the voiding dysfunction before contemplating surgery.

EVALUATION OF NON-NEUROPATHIC BLADDER-SPHINCTER DYSFUNCTION

History

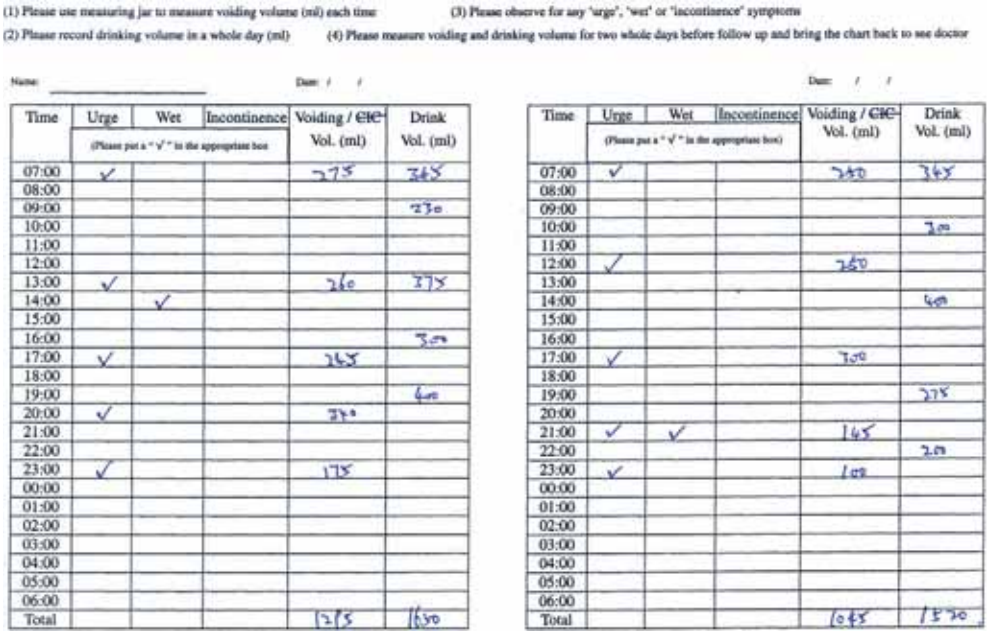
The majority of children with non-neuropathic bladder-sphincter dysfunction typically present after toilet training with symptoms of either nighttime or daytime urinary incontinence or both. Occasionally they can be recognized at an earlier age when the child presents for investigation of UTIs or VUR. In any case, it is important to obtain a detailed history from the child and guardian. This should include relevant questions to exclude neurologic and congenital abnormalities. Bowel dysfunction can coexist in the form of encopresis, constipation, and fecal impaction and should be noted during history-taking. The urinary history should focus on symptoms related to both the storage and evacuation of urine.

Voiding Diary

A voiding diary is used to record daily fluid intake and urine output at home under normal conditions. When properly filled in, it can be informative and give us clues to the underlying dysfunction. The number of voidings per day, the distribution of voids during the day, and each voided volume are recorded. It can also record any episodes of urgency and leakage. It is a useful tool to help identify those who may warrant further studies, as well as in follow-up of patients (Fig. 127–7).

Physical Examination

Physical examination is usually normal in children with non-neuropathic bladder-sphincter dysfunction, but careful examination is required to exclude those who may require further neurologic evaluation. Occasionally, in an otherwise normal child,



(1) Please use measuring jar to measure voiding volume (ml) each time (3) Please observe for any 'urge', 'wet' or 'incontinence' symptoms
(2) Please record drinking volume in a whole day (ml) (4) Please measure voiding and drinking volume for two whole days before follow up and bring the chart back to see doctor

one may find a palpable bladder on abdominal examination in cases of decompensated bladders. **Abnormalities of the lower spine should be sought specifically to exclude the possibility of an occult spinal dysraphism.** Lesions such as an asymmetric gluteal fold, hairy patch, dermovascular malformation, or lipomatous abnormality of the sacral region should prompt further imaging evaluation. The external genitalia may be examined to exclude any obvious anatomic problems that can explain the urinary symptoms in question. Rectal examination may reveal fecal impaction or distended rectum in those with chronic constipation. In the absence of any positive findings on examination, further investigations may be warranted.

Laboratory Investigations

Laboratory investigations are generally not routinely required unless the child presents with complications such as UTIs. However, to complement a full workup, urinalysis may be performed to rule out bacteriuria and glucosuria. Serum and urine osmolality may be looked at in cases of nocturnal enuresis to assess renal concentrating ability.

Ultrasonography

Ultrasonography (USG) is often the first-line investigation in children with non-neuropathic bladder-sphincter dysfunction because it is a simple, readily available, and noninvasive tool that is able to provide information both on anatomic and functional problems when performed by experienced pediatric radiologists.

Ultrasonography has been increasingly used in the study of the pelvic floor musculature. In boys the external sphincter, puborectalis, and bulbocavernosus have been observed to contract during a hold maneuver on USG. In girls, lengthening of the urethra and movement of the bladder neck in the direction of the symphysis are seen. However, **in patients with non-neuropathic bladder-sphincter dysfunction, approximately one third of the children were unable to elicit movement of the pelvic floor or had paradoxical movement.** The clinical significance of this remains unclear, but when introduced to a program of urotherapy, marked improvement of symptoms was reported. Similarly, the USG had been employed in the study of bladder neck mobility. Studies have shown that in a proportion of girls with hyperlaxity of joints, coughing or straining would result in a wide opening of the bladder neck and urethra. In this group of girls, urotherapy would prove difficult and occasionally some would go on to require surgery to the bladder neck (deJong, 2005).

More recently, the ultrasound has been used to measure bladder parameters used in calculating a "bladder volume and wall thickness index" (BVWI). This BVWI can be classified into normal, thick, or thin according to the measured parameters. Studies have shown that these classification corresponded closely to urodynamic findings of underlying bladder dysfunctions and can act as a reliable tool to guide for further invasive investigations (Yeung et al, 2004).

Other Imaging Studies

Radiologic examination of the spine may be necessary to rule out any neurogenic causes of bladder-sphincter dysfunction.

A micturating cystourethrogram may be performed in patients to rule out VUR. Information on the bladder emptying efficiency may be obtained, and the status of the urethra can be assessed to exclude any outflow obstruction.

Urodynamic Studies

Urodynamic studies are employed to describe the physiologic parameters involved in the bladder mechanics during filling and voiding.

Uroflowmetry

All urodynamics should be preceded by or combined with a uroflow study. When performing uroflowmetry, the child must experience normal desire to void for it to be representative and repeated recordings should be performed. Preferably, the voiding should be observed and correct sitting or standing position ascertained. **In children, normal flow rates are different from adults and there is usually a poor correlation between maximal flow rate (Qmax) and outflow resistance as the detrusor is able to exert much stronger contractions to counteract any increased resistance.** It is therefore important to study the pattern of the flow curve in addition to the flow rates in children. The precise shape of the flow curve is determined by detrusor contractility, the presence of any abdominal straining, and the bladder outlet. The normal pattern is that of a smooth *bell* shape. A *tower*-shaped curve produced by an explosive voiding contraction is seen in overactive bladders, and a low *plateau*-shaped curve is representative of an outlet obstruction. A *staccato* pattern is seen with sphincteric overactivity during voiding with peaks and troughs throughout voiding, and an *interrupted* flow is seen in acontractile or underactive bladders. When combined with cystometry and perineal EMG studies, further information on the different spectrum of functional bladder outflow obstructions can be analyzed (Nijman, 1997).

Conventional Fill Urodynamic Studies

This involves more sophisticated instruments and becomes more invasive to the patient, requiring a bladder catheter introduced transurethrally or suprapubically. The use of suprapubic catheterization has been suggested as a better alternative to transurethral catheterization. Although it may be considered more invasive, it is much more physiologic than to try to void with a catheter in the urethra, particularly in children. Not only is it obstructive to flow, but the trauma of placing the catheter just before the investigation may cause significant discomfort. For suprapubic catheterization, a 6-Fr double-lumen catheter is placed suprapubically under sedation and left in situ for 24 hours before commencement of the urodynamic study.

The suprapubic catheter is connected to a computer system and used to measure intravesical pressure. Another catheter is placed in the rectum to measure intra-abdominal pressure surrounding the bladder. By subtracting the latter from the intravesical pressure, one can calculate the detrusor pressure. Sphincteric activity can also be measured with simultaneous perineal EMG recordings. All the measured data are directly fed into a computer for analysis and display of graphical measurements. The urodynamic study looks at both the filling and voiding phases of the bladder. Bladder filling and storage are described according to bladder sensation, detrusor activity, bladder compliance, and bladder capacity. Pressure flow studies are carried out during the voiding phase.

Traditionally, the bladder is filled artificially with water/normal saline to speed up the procedure. The child is asked to indicate his or her desire to void (if old enough to do so) and then void into a specially designed seat with a uroflowmeter attached. The investigator observing the study should also make note of any events occurring during the study (e.g., any large movements of the patient, coughing, or in particular any urinary dribbling).

By combining cystometry with fluoroscopy, video-urodynamics can be performed with fluoroscopic images of the bladder, bladder neck, and urethra captured. Conventional fill urodynamics is performed in the usual manner with the child sitting in a specially designed chair with a uroflowmetry device in the fluoroscopy suite. Fluoroscopic images are taken during filling and voiding. This has the added advantage of being able to observe the shape of the bladder during filling and voiding, observing for signs of VUR, as well as the configuration of the urethra and pelvic floor.

Natural Fill Urodynamic Studies

More recently, studies have shown that the nonphysiologic filling of the bladder during conventional fill urodynamics, even at low filling rates, can lead to misrepresentations of true bladder activity during normal situations. Therefore natural fill urodynamic studies may be performed whereby the child is asked to drink to allow the bladder to fill up on its own rate. Urodynamic studies in children with urge syndrome usually reveal detrusor overactivity associated with a small bladder capacity but may occasionally be normal with incontinence only barely perceptible, particularly if conventional fill cystometry rather than natural filling cystometry is used. It appears that the **artificial filling may inhibit the detrusor response and attenuate its maximum contractile potential, rendering detrusor instability much less pronounced and undetectable.** Therefore natural fill cystometry is the preferred technique in children, or better still, the combined use of artificial and natural filling urodynamic studies is helpful to accurately delineate the underlying bladder dysfunction (Yeung et al, 1995).

Ambulatory Urodynamic Studies

The unfamiliar hospital and urodynamic laboratory environment, as well as the presence of a urodynamics investigator, can sometimes cause significant distress, particularly to young children. To overcome this, an ambulatory urodynamic study may be performed. This study is performed with ambulatory equipment strapped to the child and relies on infrared telemetry while the investigator sits behind a one-way mirror (Yeung, 1998).

The system consists of an ambulatory urodynamic recorder with a specially designed built-in extension board that converts digital pressure signals to a modulated infrared wave. Two external infrared leads are connected to the output and fixed to the clothing of the patient (Fig. 127–8). The optimal emission from the recorder has a 10-m range and completes the circuit of the infrared on-line link by cable to the computer. Direct line of sight from the transmitter to the receiver is unnecessary because the infrared signals reflect from the walls of the room before reaching the receiver. For active and uncooperative patients, more than one receiver connected in parallel with the power unit and computer can be used at the same time to enhance signal collection. The first receiver to receive valid signals transmits the data to the computer and inhibits the other receivers simultaneously (Fig. 127–9).

During the investigation the infant can conduct normal activities, be totally mobile, and be accompanied by one or both of the parents undisturbed in a private cubicle. From an adjoining room the hidden investigator observes and records the patient's activities, including urinary dribbling and micturition, through a one-way mirror, while real-time on-line pressure signal displays are monitored continuously on the computer. Only natural fill studies are possible by this means. Overall, it allows for a continuous monitoring of bladder function under near-natural conditions for the child.

Figure 127–8. The ambulatory urodynamic recorder with the external infrared leads mounted in a plastic holder that can be attached to the patient. (From Yeung CK. Continuous real-time ambulatory urodynamic monitoring in infants and young children using infrared telemetry. Br J Urol 1998:81;76–80.)

More recently, the Bluetooth system has been introduced. This works in much the same way as the infrared system but is much less bulky for the patient to carry around. It offers even more freedom of movement with a much longer transmission range and more reliable reception. If coupled with a camera recorder in the room the child is in, there is no need for the investigator to sit behind a one-way mirror throughout the procedure. With such advances in technology, it will not be surprising if urodynamics can soon be performed in the setting of one's own home!

Key Points: Evaluation of Non-Neuropathic Bladder-Sphincter Dysfunction in Children

- An adequate history should include congenital abnormalities, voiding and wetting patterns (including a voiding diary), and assessment of bowel function.
- Abnormalities of the lower spine should be sought specifically to exclude the possibility of an occult spinal dysraphism.
- Ultrasonography is useful to assess bladder function and wall thickness, as well as pelvic floor function.
- In children, normal flow rates are different from adults and there is usually a poor correlation between maximal flow rate (Qmax) and outflow resistance.
- Urodynamic study looks at both the filling and voiding phases of the bladder.
- Artificial filling may inhibit the detrusor response and attenuate its maximum contractile potential, rendering detrusor instability much less pronounced and undetectable.

MANAGEMENT OF NON-NEUROPATHIC BLADDER-SPHINCTER DYSFUNCTION

Behavior Modification and Standard Urotherapy

Urotherapy is a nonpharmacologic and nonsurgical combination of cognitive, behavioral, and physical therapy

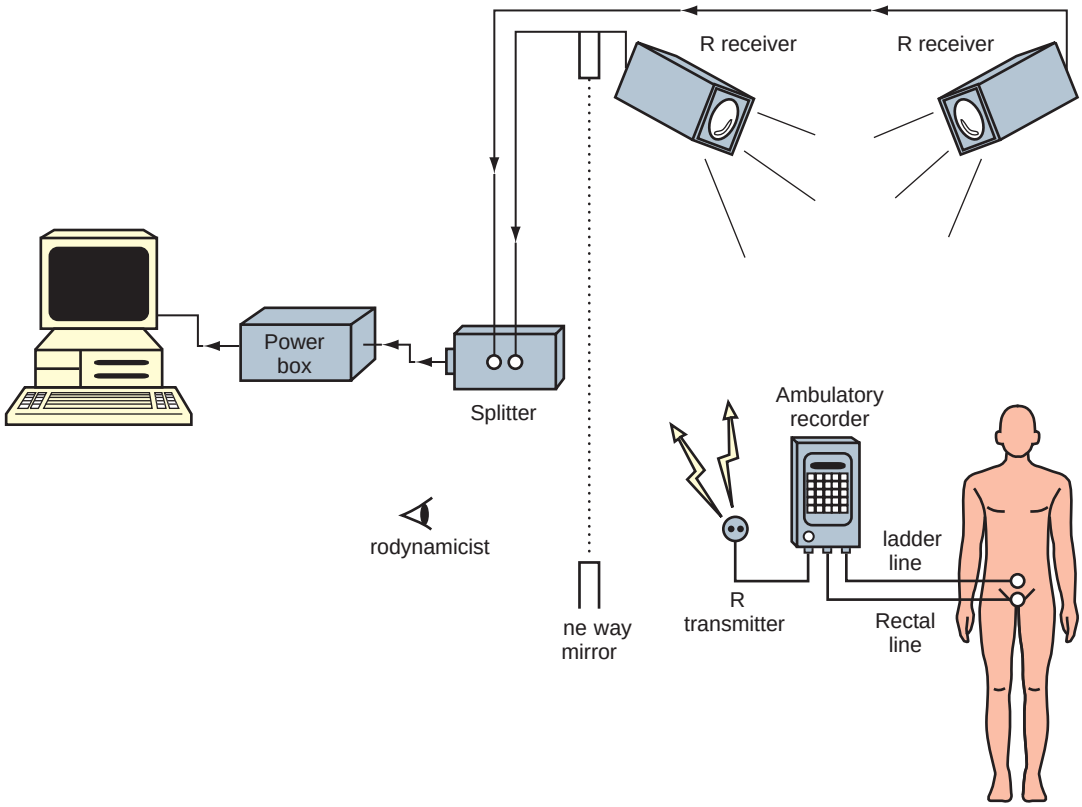

Figure 127–9. Schematic diagram to show the setup for continuous real-time ambulatory urodynamics using infrared telemetry. (From Yeung CK. Continuous real-time ambulatory urodynamic monitoring in infants and young children using infrared telemetry. Br J Urol 1998:81;76–80.)

with an aim to normalize micturition pattern and prevent further functional disturbances of the lower urinary tract. The children and their parents are educated on proper voiding mechanics, and their specific problem is explained to them to provide motivation for improvement. Specific instructions are then given as to how and when to void. Children are assessed and taught correct sitting or standing positions for voiding. They are taught how to relax the pelvic floor and avoid straining. Their drinking and voiding habits are studied and modified accordingly to include proper hydration with timed voiding. A proper assessment of their bowel function is imperative to successful management. To achieve good results, strong patient support with adequate motivation of both the child and the parents is essential.

Biofeedback and Pelvic Floor Rehabilitation

Biofeedback is based on the concept of building self-perception on detrusor contractions and pelvic floor relaxation in the patient. By combining uroflowmetry with real-time monitoring, the child is able to see how well he or she is voiding. It also helps the child understand what can be altered with voluntary control and with relaxation of the pelvic floor. Biofeedback as a treatment modality for children with dysfunctional voiding is based on this concept and has proven to be highly effective either on its own or in combination with standard urotherapy (Figs. 127–10 through 127–12).

Figure 127–10. Urotherapy. Pelvic floor rehabilitation with real-time biofeedback monitoring.

Neuromodulation, Acupuncture, and Other Treatment Modalities

Recent studies reported that transcutaneous electrical nerve stimulation (TENS) is a simple, cost-effective, noninvasive treatment modality for the management of a wide variety of lower urinary tract disorders with few side effects. The mechanisms of action of

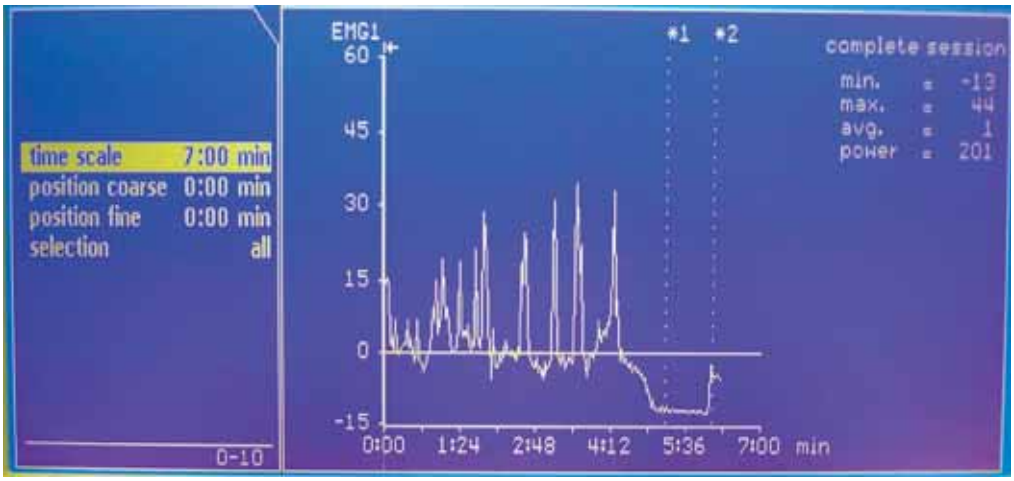

Figure 127–11. Urotherapy. Example of real-time pelvic floor rehabilitation biofeedback tracing showing voluntary contraction and relaxation of pelvic muscles.

Figure 127–12. Urotherapy. Biofeedback with real-time uroflowmetry.

the reported techniques remain unclear, but symptomatic improvements are common. Some reports indicate changes in urodynamic parameters during transcutaneous stimulation, suggesting that the TENS therapy was capable of inhibiting detrusor contractions. The beneficial effects of TENS over the sacral dermatomes (S2-S3) in patients with lower urinary tract symptoms associated with detrusor overactivity have been reported. **The use of low-frequency electrical current to inhibit detrusor activity in adults is common and appears to modulate excitatory and inhibitory components of bladder control.** Such studies provide the rationale for the application of TENS therapy to modulate detrusor function in patients with functional detrusor dysfunction.

Traditional acupuncture has also reported high efficacy in the treatment of nocturnal enuresis with low relapse rate. Reports have used acupoints innervated by sacral segments S2-S4, and stimulation involved both manual and electrostimulation. However, its use in the pediatric population remains limited by the intrinsic fear of needling in children with subsequent lack of cooperation (Bower et al, 2005).

Bowel Management

The principles of bowel management include rectal emptying of impacted stool and the maintenance of regular soft stools. A reliable bowel habit pattern can only be established when the child is able to achieve pain-free defecation of soft stool. An initial cleanout of the bowel can be achieved by oral laxatives and rectal enemas on a regular basis until there is complete disimpaction of the rectum. Occasionally, high-colonic washouts may be necessary to achieve a good result. Only when this has been achieved should the second stage of management commence. This involves prevention of further stool accumulation with continuation of regular oral laxatives and/or stool softeners, as well as dietary modification. Correct toileting posture and correct recruitment of abdominal muscles in the defecation process aids in the effectiveness of bowel emptying. However, success of a bowel management program can only be achieved with sound support from the family. Parental education is necessary in order to reinforce and encourage correct toileting habits at home.

Medications

Pharmacologic control of the lower urinary tract (LUT) can either act via the central nervous system (CNS) or peripherally. Several CNS regions have been identified to be involved with micturition control including the cortex, pontine tegmentum, medulla, and spinal structures. All these regions are modulated by several different neurotransmitters, which have become targets for drug treatment. However, **many of the drugs developed with CNS action are not sufficiently selective to affect only the lower urinary tract, increasing the possibility of these drugs causing adverse drug reactions.** Pharmacologic targets for treating bladder dysfunction may be aimed at the bladder, urethra, ganglia, or peripheral nerves. **The main targets for**

drug therapy are receptors or ion channels known to be involved in bladder contraction (muscarinic receptors, L-type calcium channels). More recently, research has been focused more on alternative neurotransmission and modulation of afferent signaling from the LUT.

Antimuscarinics

Antimuscarinics are the gold standard in treatment of overactive bladders. Muscarinic receptors are found in the human detrusor muscle, and bladder contractions are initiated by stimulation of these receptors with the release of acetylcholine from cholinergic nerves. The main action of antimuscarinics is on the M1 and M3 receptor subtypes, which are thought to be responsible for the pathogenesis of detrusor overactivity. Antimuscarinics, such as oxybutynin, **act by reducing the frequency and intensity of involuntary contractions, resulting in an increase in the functional bladder capacity.** The clinical efficacy depends on various factors such as receptor affinity, pharmacokinetics, and the specificity for the bladder. Latest developments have focused on receptor specificity and efficacy-to-side-effect ratio. **The nonselective pattern of activity and penetration of the blood-brain barrier are known to induce systemic and central side effects.**

α-Adrenergic Blockers

The body of the bladder receives relatively sparse innervation by noradrenergic nerves. The density of noradrenergic nerves increases markedly toward the bladder neck, where the smooth muscle receives a dense noradrenergic nerve supply, particularly in males. **The normal response to noradrenaline is relaxation of the detrusor and contraction of the bladder neck. α Blockers are therefore used in patients with evidence of bladder neck dysfunction for relaxation of the bladder neck.**

Other Medications

Tricyclic antidepressants such as imipramine have been found to be effective for increasing urine storage by both decreasing the detrusor contractility and increasing outlet resistance. However, the precise mechanism of action is not well explained. Its possible effect on the bladder outlet has been described by inhibition of norepinephrine reuptake producing α-adrenergic stimulation. These agents are associated with a high incidence of side effects, and their use should be judicious.

β-Adrenergic agonists can cause significant increases in bladder capacity but can cause significant cardiovascular side effects.

Parasympathicomimetics, calcium antagonists, potassium channel openers, and prostaglandin inhibitors have all been described for use with effect on the bladder, but these are rarely used in children either due to their unfavorable side effects or due to a lack of proven efficacy.

Clean Intermittent Catheterization

Clean intermittent catheterization (CIC) may become necessary in children with decompensated bladders or lazy bladder syndrome in which bladder emptying efficiency is compromised and upper urinary tract dilatation may exist. Regular emptying of the bladder to achieve low-pressure emptying improves detrusor contractility and bladder emptying function. Therefore a regular CIC program can allow for bladder retraining. Some of these children may be able to eventually wean from use of CIC.

Surgery

When conservative management with nonpharmacologic and pharmacologic treatment fails, surgical approaches should be considered. **Bladder augmentation may be performed to help produce a low-pressure system with increased bladder capacity.** Augmentation may be performed using intestinal segments such as colon, ileum, or stomach. However, the complications that may ensue must be considered including mucus production, electrolyte imbalance, and even possible metaplasia/malignancy.

Surgical means have also been employed to reduce urethral/sphincteric pressure as an alternative to α blockers. Recent studies have focused on the use of balloon dilatation of the bladder neck and botulinum A toxin injection into the urethral urinary sphincter in children with non-neuropathic bladder-sphincter dysfunction with promising results. However, these methods seem to require repeated attempts, and long-term effects and efficacy have yet to be presented.

Key Points: Management of Non-Neuropathic Bladder-Sphincter Dysfunction in Children

- Urotherapy is a nonpharmacologic and nonsurgical combination of cognitive, behavioral, and physical therapy with an aim to normalize micturition pattern and prevent further functional disturbances of the lower urinary tract.
- Biofeedback is based on the concept of building self-perception on detrusor contractions and pelvic floor relaxation in the patient.
- The use of low-frequency electrical current (TENS) to inhibit detrusor activity in adults is common and appears to modulate excitatory and inhibitory components of bladder control.
- The principles of bowel management include rectal emptying of impacted stool and the maintenance of regular soft stools.
- Many of the drugs developed with CNS action are not sufficiently selective to affect only the lower urinary tract, increasing the possibility of these drugs causing adverse drug reactions.
- Antimuscarinics are the gold standard in treatment of overactive bladders.
- α Blockers are therefore used in patients with evidence of bladder neck dysfunction for relaxation of the bladder neck.

NOCTURNAL ENURESIS

Etiologic Factors for Nocturnal Enuresis

Primary nocturnal enuresis (PNE) is a common disorder among children. Despite extensive research there is still significant controversy regarding its etiology, and it is now generally accepted that multiple pathologic factors are probably involved. Among others, a common finding is that the nocturnal urine output in many enuretic children is in excess of the bladder reservoir capacity during sleep at night (Norgaard et al, 1985; Hjalmas, 1997, 1998). **Nocturnal polyuria can be either absolute—which is usually associated with a derangement of the circadian rhythm of antidiuretic hormone (ADH) secretion—or relative, mainly due to a reduced functional bladder**

capacity during sleep at night. However, whether it is an increased urine production or a reduced bladder capacity that results in the mismatch between nocturnal bladder capacity and the amount of urine produced during sleep at night, there must be a simultaneous arousal failure in response to bladder fullness before bedwetting can occur.

Bladder-Sphincter Dysfunction in Nocturnal Enuresis

The exact role of bladder dysfunction in the pathogenesis of PNE has until recently remained largely controversial. Although some workers have observed markedly reduced functional bladder capacities among enuretic children compared with age-matched nonenuretic controls, others have previously reported that enuretic episodes were triggered by a full bladder and that bladder capacities in the enuretic children were completely normal (Starfield, 1967; Norgaard, 1989; Jarvelin et al, 1990). However, recent studies have convincingly proven that in **a significant proportion of children with severe nocturnal enuresis, especially those who were refractory to conservative treatment and failed to respond to desmopressin therapy, there was a marked reduction in functional bladder capacities when compared with age-matched normal controls** (Watanabe et al, 1994; Kirk et al, 1995; Rushton et al, 1996; Eller et al, 1998; Yeung et al, 1999). Furthermore, it has been shown that other types of bladder dysfunctions, notably dysfunctional voiding and marked detrusor overactivity with extremely high voiding pressures suggestive of an obstructive pattern, are not uncommon among enuretic children (Figs. 127–13 through 127–15) (Yeung et al, 1999).

Sleep Arousal Disturbance and Brainstem Dysfunction in Nocturnal Enuresis

More recently, the involvement of the central nervous system in the etiology of childhood nocturnal enuresis has been assessed. **Enuretic boys were shown to be more difficult to arouse than age-matched controls. The arousal inability in patients with nocturnal enuresis may relate to either elevated arousal thresholds or the presence of spontaneous uninhibited bladder contractions.**

There is also accumulating evidence that a small functional bladder capacity and detrusor overactivity may play an important role in the pathophysiology of nocturnal enuresis and can further provide reliable predictive clues to the treatment response. Most interestingly, **overnight studies in enuretic children with simultaneous sleep EEG and cystometry have revealed marked detrusor instability only after sleep at night but not during wakeful periods in the daytime** (Watanabe, 1995; Yeung et al, 1999). This per se can result in a marked reduction in the nocturnal functional bladder capacity (Watanabe, 1995; Rushton et al, 1996; Eller et al, 1998; Yeung et al, 1999). Because this pattern has not been observed in normal nonenuretic subjects even during the newborn period, one may hypothesize that this could be due to a small neurologic lesion affecting a tiny area surrounding the vicinity of the pontine micturition center, the posterior hypothalamus (responsible for secretion of ADH), and the locus coeruleus (which is thought to play an important role in the initiation of cortical arousal and release of noradrenaline) (Yeung et al, 1995, 1998, 1999).

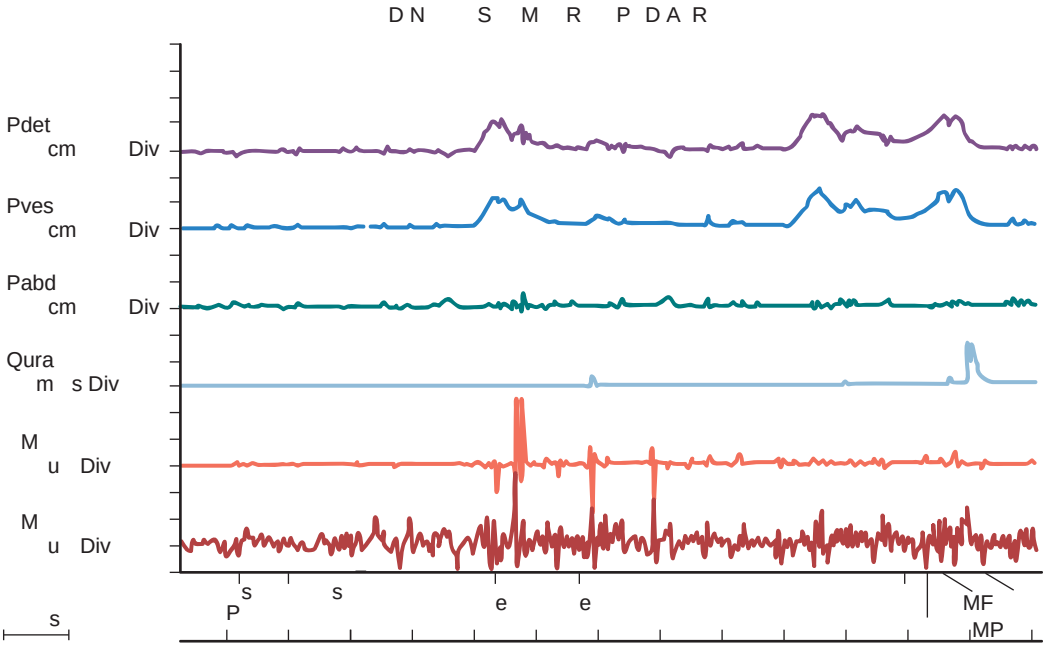

Figure 127–13. Urodynamic tracing showing primary bladder neck dysfunction characterized by a marked delay in initiation of flow after onset of detrusor contraction, often associated with high detrusor pressure but minimal pelvic electromyographic activities.

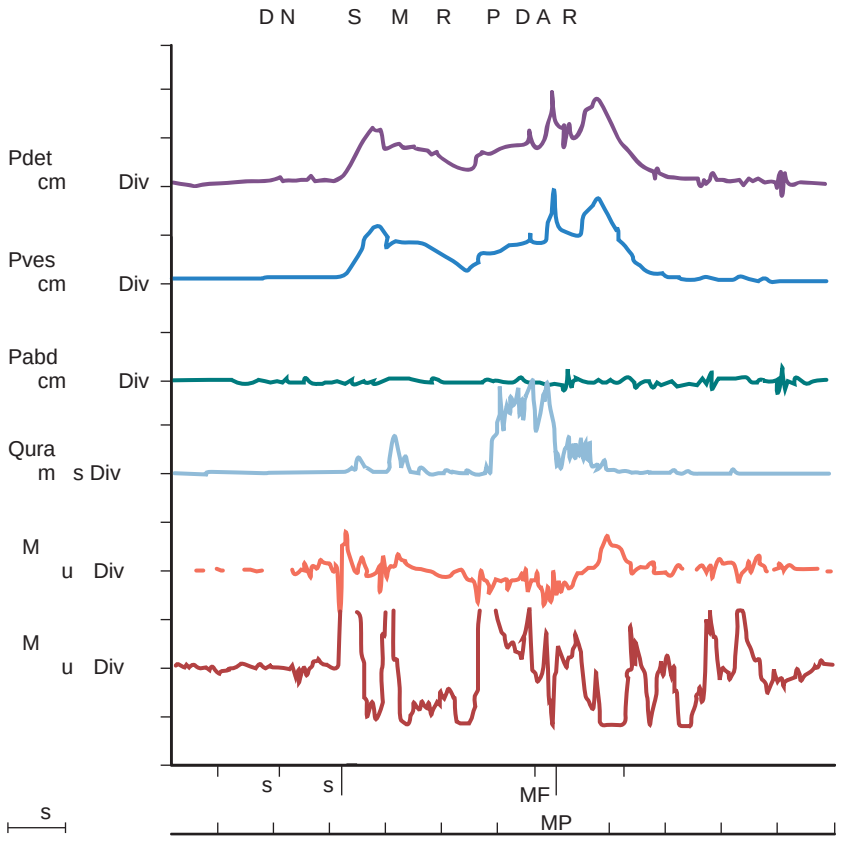

Figure 127–14. Urodynamic tracing showing detrusor-sphincter dyssynergia characterized by marked staccato or interrupted voiding, often associated with detrusor overactivity and/or evidence of increased electromyographic activities.

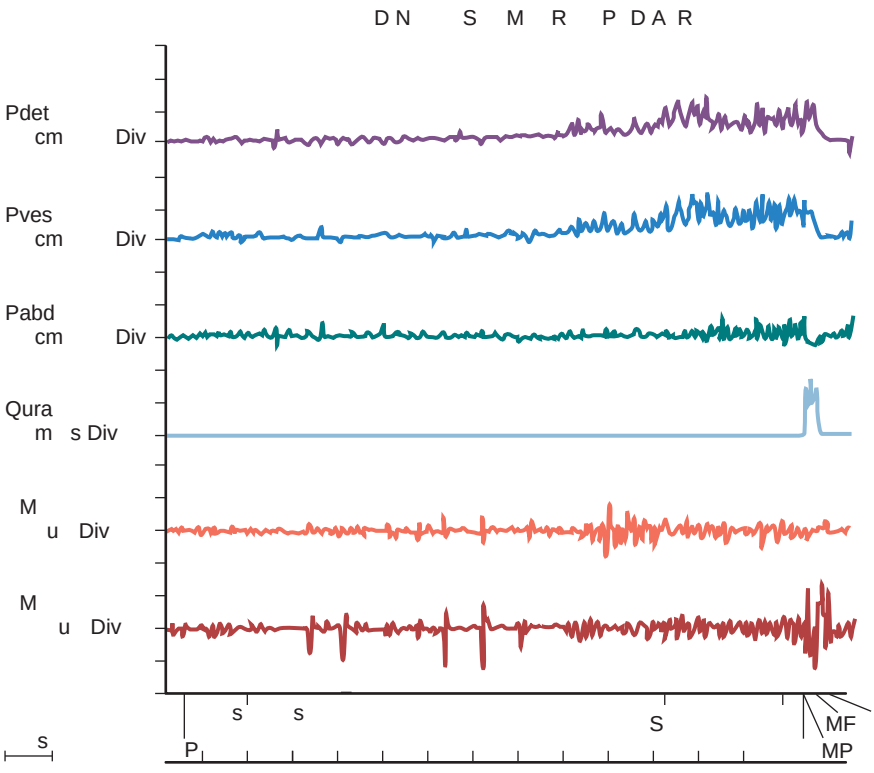

Figure 127–15. Urodynamic tracing showing dysfunctional voiding characterized by abdominal/pelvic straining (holding maneuver) immediately before initiation of micturition, often associated with detrusor overactivity and evidence of increased pelvic electromyographic activities.

It should be noted that despite the high prevalence of underlying bladder dysfunction among patients with severe, refractory PNE, many have no identifiable daytime urinary symptoms including incontinence, frequency, and urgency. A detailed urodynamic study would, however, reveal detrusor instability in 30% to 90% of patients. The authors' experience has shown that many enuretic children with reduced functional bladder capacity have learned, either consciously but more probably subconsciously, to restrain fluid intake during the daytime as an attempt to avoid the social inconvenience of urinary frequency and urge incontinence. This could often be easily spotted by a detailed home-recorded voiding diary by an extraordinarily low fluid intake and infrequent, small-volume voiding. By giving these patients a standard fluid intake and then asking them to repeat a home recording of micturition frequency and urinary volume, one could quite easily obtain a highly reliable estimation of the functional bladder capacity and hence identify those patients with reduced bladder capacities (Rittig et al, 1997; Yeung et al, 1999).

Relationship between Bladder and Brain Dysfunctions (Bladder-Brain Dialogue)

A deficiency of prepulse inhibition (PPI) of startle has been reported in enuretic children such that prestimulation 120 msec before the main stimulus resulted in significantly less inhibition of the blink reflex among enuretic children than healthy controls. Prepulse inhibition is based on an inhibition of the startle pathway by the pedunculopontine tegmental nucleus, which lies in close proximity to the pontine micturition center in the brainstem. It has been postulated that a deficient PPI and reduced ability to inhibit micturition during sleep might both originate from a common dysfunction in the pontine tegmentum. This suggests that a relationship may exist between nocturnal bladder function and brainstem functions in humans (Diao et al, 2005; Ornitz et al, 1999, 2000).

Furthermore, it has also been shown that following successful treatment of nocturnal enuresis in these children, both the sleep arousal threshold and the PPI of startle improved. This suggests that brainstem dysfunction may be a secondary effect to the underlying bladder dysfunction, further supporting the "bladder-brain dialogue" concept whereby there is a bidirectional communication between the bladder and the brain.

Key Points: Nocturnal Enuresis

- A significant proportion of children with severe nocturnal enuresis have marked reduction in functional bladder capacities.
- Most patients with nocturnal enuresis are found to have underlying bladder dysfunction.
- Studies have shown that brainstem dysfunction may be related and secondary to underlying bladder dysfunction in patients with nocturnal enuresis.
- Treatment may consist of behavioral modification, standard urotherapy, biofeedback, pelvic floor rehabilitation, neuromodulation, bowel management, drug therapy, and/or surgery.

SUMMARY

Despite extensive clinical and animal research, it is perhaps embarrassing to admit that the exact neurologic mechanisms of the development of micturition control from newborn to infancy and later childhood, as well as the pathophysiologic pathways that are involved in various types of bladder dysfunction, have as yet remained largely unclear. It is, however, certain that the bladder and the brain talk with each other all the time as early as in the fetus, and there are extremely rapid and extensive changes and modulation of micturition reflexes during the early postnatal period, leading to copious potentials for developmental errors and voiding dysfunctions. Over the past decade experts have learned that both normal and abnormal bladder function are much more dynamic than previously believed. New investigative tools and research have allowed physicians to study in much greater details and precision the various components including neurologic, muscular, urodynamic, and hormonal mechanisms that may intricately interact to produce different patterns of bladder dysfunctions, as well as their relentless, dynamic changes.

chapter 128

Neuropathic Dysfunction of the Lower Urinary Tract

Dawn Lee MacLellan, MD, FRCSC ● Stuart B. Bauer, MD

Urodynamic Evaluation
Neurospinal Dysraphisms
Central Nervous System Insults

Many of the clinical problems seen in pediatric urology are the result of neurologic lesions that affect lower urinary tract function. As pediatric urology developed in the latter half of the 20th century, urinary diversion initially was the mainstay of treatment for these children with either intractable incontinence or normal or abnormal upper urinary tracts (Smith, 1972). The advent of clean intermittent catheterization (CIC) in the early 1970s by Lapides and associates (1972), refinements in techniques of urodynamic studies in children (Gierup and Ericsson, 1970; Blaivas et al, 1977; Blaivas, 1979), and the development of surgical modalities in conjunction with CIC to manage incontinence dramatically changed the way this group of children was traditionally managed. Most pediatric urologic centers consider functional assessment of the lower urinary tract as an integral element in the evaluation process and almost if not as important as radiographic visualization in characterizing and managing these abnormal conditions (McGuire et al, 1981; Bauer et al, 1984). The natural outcome of early functional investigation has been the advocacy of proactive or early aggressive management in the children who are at risk for urinary tract deterioration based on specific hostile urodynamic parameters (Perez et al, 1992; Edelstein et al, 1995; Kaufman et al, 1996). This has resulted in (1) a statistically significant decrease in upper urinary tract deterioration, compared with those children followed expectantly in the past, and (2) a dramatic reduction in the need for augmentation cystoplasty (Wu et al, 1997; Kaefer et al, 1999; Bauer, 2000). Furthermore, there is now evidence that molecular changes occur intracellularly when prophylactic treatment is begun as early as possible (Park et al, 1999; Ohnishi et al, 2000). Because urodynamic testing has become such an integral part of any discussion of the subject, the testing process as it applies to children is discussed first and then various neurologic abnormalities that are prevalent in children are elaborated upon. For purposes of minimizing ambiguity the terminology used in this chapter is based on the International Continence Society (ICS) standardization of terminology documents (Abrams et al, 2002, 2003; Neveus, 2006).

URODYNAMIC EVALUATION

Before a urodynamic study is performed it is important for the child and the family to have full knowledge of the procedure. Therefore an explanation of the test is sent to each family before the appointment. Attempts are made to minimize anxiety in children by providing reasons for specific portions of the test and explaining exactly what the child will experience. Premedication is rarely given. Parents are instructed to make sure the child has a bowel movement the night before the study.

In males a topical anesthetic cream is applied to the perineum about 45 minutes before the electromyography (EMG) needle is inserted to record sphincter activity. If possible, the child is instructed to come to the urodynamic suite with a full bladder to obtain an initial representative uroflow. The time of the child's previous urination (or catheterization) is noted to calculate an average rate of urine production per unit of time. The flowmeter is located in a private bathroom that contains a one-way mirror so that voiding can be viewed unobtrusively. This allows the investigator to see what position the child assumes when voiding and whether a Credé or a Valsalva maneuver is employed by the child to help empty.

Next, the nurse reviews the test and shows the child all the equipment in an attempt to make the patient feel as comfortable as possible. The child is catheterized with either a No. 7 Fr or a No. 11 Fr triple-lumen urodynamic catheter (Cook Urological, Inc, Spencer, IN)—the smaller, the better—after a small amount of liquid lidocaine (Xylocaine) (1%) has been injected into the urethra and held in place for a moment or two. First, the intravesicular pressure is recorded. Then the bladder is drained and the residual urine is carefully measured, yielding a pressure at residual volume (Kaefer et al, 1997). Sometimes it is necessary to aspirate the catheter to get the accurate volume of residual urine, especially if the bladder is underactive (particularly if the child is taking anticholinergic medication) or has been previously augmented and secretes mucus (because it may not drain completely after insertion of a catheter).

A small balloon catheter is passed into the rectum at this time to measure intra-abdominal pressure during the cystometrogram to identify artifacts of motion and monitor increases in abdominal pressure during the filling and emptying phases of the study (Bates et al, 1970; Bauer, 1979).

Before the bladder is filled, a urethral pressure profile is sometimes obtained by infusing saline through the side-hole channel at a rate of 2 mL/min as the catheter is withdrawn at a rate of 2 mm/sec (Yalla et al, 1980). Many centers have eliminated urethral pressure profile measurements in favor of monitoring detrusor leak point pressure (the subtracted detrusor pressure at

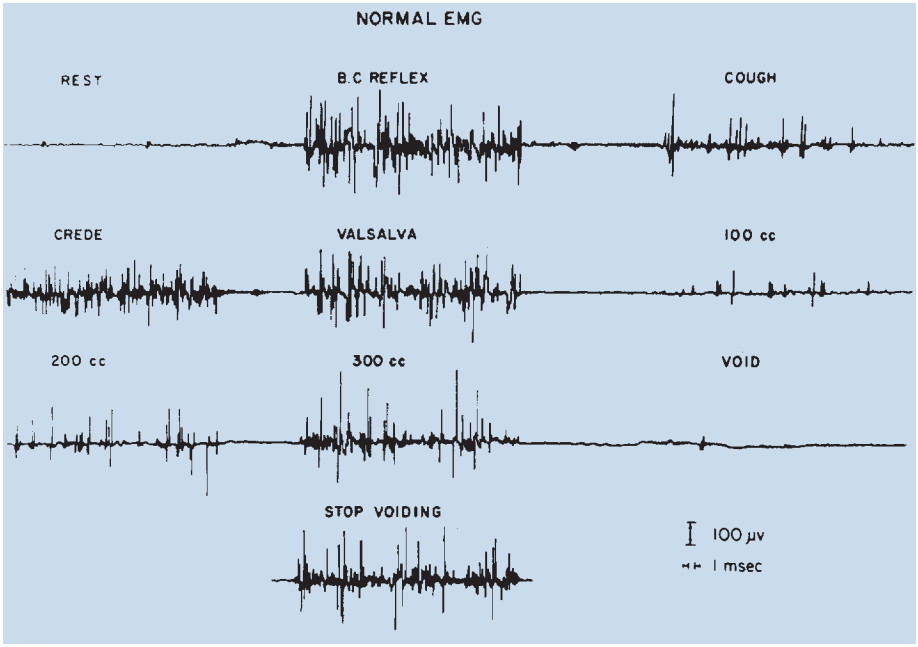

Figure 128–1. Normal reaction of the external urethral sphincter on electromyogram to all the sacral reflexes and to bladder filling and emptying. (From Bauer SB. Urodynamic evaluation and neuromuscular dysfunction. In: Kelalis PP, Kin LR, Belman AB, editors. Clinical pediatric urology. 2nd ed, vol. 1. Philadelphia: WB Saunders; 1985. p. 283–310.)

which the child leaks when the bladder is filled to its functional or maximal capacity). Abdominal leak point pressure is the abdominal pressure at which the child leaks when straining or coughing but that is not as accurate as the detrusor leak point pressure, which is a proportional reflection of outlet resistance (McGuire et al, 1996).

External urethral sphincter EMG is performed using a 24-gauge concentric needle electrode (Diokno et al, 1974; Blaivas et al, 1977b) inserted perineally in boys or paraurethrally in girls and advanced into the skeletal muscle component of the sphincter until individual motor unit action potentials are seen or heard on a standard EMG recorder. Alternatively, perineal electrodes (Maizels and Firlit, 1979) or abdominal patch electrodes (Koff and Kass, 1982) have been used to record the bioelectric activity in the sphincter muscle. Disagreements exist concerning the accuracy of these surface electrode measurements, compared with those obtained with needle electrodes, particularly during voiding. The intactness of sacral spinal cord function is easily measured with needle electrodes by (1) looking at the characteristic waveform of individual motor unit action potentials when the patient is relaxed and the bladder is empty, (2) performing and recording the responses to bulbocavernosus and anal stimulation and to Credé and Valsalva maneuvers, (3) asking the patient to voluntarily contract and relax the external sphincter, and (4) seeing the reaction of the sphincter to filling and emptying of the bladder (Fig. 128–1) (Blaivas et al, 1977a; Blaivas, 1979b).

The rate of bladder filling per minute is selected by first calculating the child's predicted or known capacity (see Chapter 127) and then dividing the result by 10 in order to fill the bladder slowly. In children with myelodysplasia, the average bladder capacity (in milliliters) fits the following formula: 24.5 × age in years + 62 (Palmer et al, 1997). It has been shown that more rapid filling rates may yield falsely low levels of detrusor compliance and may minimize an overactive detrusor (Turner-Warwick, 1975; Joseph, 1992). The bladder is filled slowly with saline warmed to 37° C to avoid this problem (Chin-Peuckert et al, 2004). When it is important to determine very mild degrees of poor compliance, even slower rates of filling are used to measure its true incidence (Kerr et al, 1994; Yeung et al, 1995; Zermann et al, 1997). Some investigators have recorded pressure at residual volume to measure natural filling pressure as the most accurate means of denoting poor compliance (Kaefer et al, 1997; Walter et al, 1998). During filling, it is helpful to try to divert the child's attention by asking unrelated questions, reading a story aloud, or showing a movie or cartoon. If the examiner wishes to elicit detrusor overactivity, the child is asked to cough (Mayo, 1978); alternatively, a cold solution may be instilled at a rapid rate. Most urodynamic parameters do not change with a child's position (sitting vs. supine). However, the sitting position is preferred for the detection of detrusor overactivity and incontinence (Lorenzo et al, 2007).

The study is not considered complete until the child urinates and voiding pressures are measured in those children who urinate on their own. The small size of the urodynamic catheter does not seem to affect micturition pressures adversely, even in very young children. The normal voiding pressure varies from 55 to 80 cm H_2O in boys and from 30 to 65 cm H_2O in girls (Blaivas et al, 1977b; Blaivas, 1979a; Gierup et al, 1979). Infants tend to have higher voiding pressures than older children. Sometimes it is difficult to get the child to void; patience and time are needed in this situation. Placing a urine collection device under the buttocks of the child when supine or dripping tepid water on the genital area often stimulates the child sufficiently to begin urinating. Once the child has voided, it is important to do the following:

1. Analyze the pressure curve to determine whether the contraction is sustained until voiding is complete.
2. Determine whether abdominal pressure has been used to facilitate the emptying process.
3. Listen to changes in EMG activity of the sphincter to determine whether it remained quiet throughout the voiding process and/or resumed prematurely before emptying was complete.
4. Note whether the flow rate curve was bell shaped, intermittent, or prolonged.
5. Measure the voided volume.
6. Calculate whether the patient voided to completion.
7. Observe whether an after-contraction occurred.

Video-urodynamics has gained popularity since its introduction in 1970 (Bates et al, 1970). Visualization of the bladder and bladder neck during filling and of the urethra during voiding has added a dimension for more accurately integrating all aspects of lower urinary tract function and characterizing an abnormality (Glazier et al, 1997). Incompetency of the bladder neck or pelvic floor or the location of any posterior urethral obstruction can be correlated with pressure measurements and external urethral sphincter EMG activity recorded simultaneously (Zerin et al, 1990). Sometimes, aberrations noted on pressure monitoring of sphincter EMG tracings can be confirmed, enhancing these findings (Passerini-Glazel et al, 1992; Weerasinghe and Malone, 1993). Ambulatory urodynamics has become available and feasible in children with the development of microtransducers mounted on small catheters positioned in the bladder (McInerney et al, 1991; Kulseng-Hanssen and Klevmark, 1996).

Often, because it is appropriate to see the effects of drug administration, studies are repeated under similar circumstances several weeks to months later. This is especially true when one is trying to treat reduced detrusor compliance or overactivity medically. To determine the maximal effect, the usual dose of most drugs is taken 2 to 3 hours before the test is performed a second time. The most commonly used drugs that affect lower urinary tract function are listed in Table 128–1, along with their appropriate dose ranges.

Table 128–1.

Drugs That Affect Lower Urinary Tract Function

TYPE	Dosage† Minimum	Dosage† Maximum
Cholinergic		
Bethanechol (Urecholine)	0.7 mg/kg tid	0.8 mg/kg qid
Anticholinergic		
Propantheline (Pro-Banthine)	0.5 mg/kg bid	0.5 mg/kg qid
Oxybutynin (Ditropan)	0.2 mg/kg bid	0.2 mg/kg qid
Glycopyrrolate (Robinul)	0.01 mg/kg bid	0.03 mg/kg tid
Hyoscyamine (Levsin)	0.03 mg/kg bid	0.1 mg/kg tid
Tolterodine (Detrol)	0.01 mg/kg bid	0.04 mg/kg bid
Trospium (Sanctura)*	10 mg/day	20 mg/day
Solifenacin (Vesicare)*	5 mg/day	10 mg/day
Darifenacin (Enablex)*	7.5 mg day	15 mg day
Propiverine (Detrunorm)*	0.1 mg/kg bid	0.4 mg/kg bid
α-Sympathomimetic		
Phenylpropanolamine	2.5 mg/kg tid	2.5 mg/kg qid
Ephedrine	0.5 mg/kg tid	1.0 mg/kg tid
Pseudoephedrine	0.4 mg/kg bid	0.9 mg/kg tid
α-Sympatholytic		
Prazosin (Minipress)	0.05 mg/kg bid	0.1 mg/kg tid
Phenoxybenzamine	0.3 mg/kg bid	0.5 mg/kg tid
β-Sympatholytic		
Propranolol	0.25 mg/kg bid	0.5 mg/kg bid
Smooth Muscle Relaxant		
Flavoxate (Urispas)	3.0 mg/kg bid	3.0 mg/kg tid
Dicyclomine (Bentyl)	0.1 mg/kg tid	0.3 mg/kg tid
Other		
Imipramine (Tofranil)	0.7 mg/kg bid	1.2 mg/kg tid

NEUROSPINAL DYSRAPHISMS

Myelodysplasia

The most common cause of neurogenic bladder dysfunction in children is abnormal development of the spinal canal and internecine spinal cord. Formation of the spinal cord and vertebral column begins at about the 18th day of gestation. Closure of the canal proceeds in a caudal direction from the cephalad end and is complete by 35 days. The exact mechanism that results in closure and what produces a dysraphic state are yet to be elucidated, but numerous factors have been implicated. The incidence was reported as 1 per 1000 births in the United States (Stein et al, 1982), but there has been a definite decrease in this rate in the past 20 years (Laurence, 1989; Lary and Edmonds, 1996; CDC, 2004; Williams et al, 2005). With the advent of prenatal screening, many affected fetuses are being identified and the pregnancies terminated before 16 weeks of gestation, thereby lowering the number of children born with this disease (Palomaki et al, 1999). The addition of folate supplements to the diet of women of childbearing age has also reduced the incidence of spina bifida worldwide (Committee on Genetics, American Academy of Pediatrics, 1999). The incidence of myelodysplasia (per 1000 live births) in the general population is 1.0, for a mother with one affected child it is 20 to 50, and for a patient with myelodysplasia it is 40 (Scarff and Fronczak, 1981; Stein et al, 1982). Therefore when the disease is already present in a family, the Medical Research Council Vitamin Study Group recommends that women of childbearing age take 4000 μg (4.0 mg) of folic acid per day beginning at least 2 months before the time they plan on becoming pregnant (Committee on Genetics, American Academy of Pediatrics, 1999). There is strong evidence that folate deficiency can lead to a myelodysplastic abnormality de novo; therefore, maternal ingestion of 400 μg of folate per day in all women of childbearing age can reduce the incidence of spina bifida by 50% (Laurence et al, 1981; MRC Vitamin Study Research Group, 1991; Czeizel and Dudas, 1992; Centers for Disease Control and Prevention, 2004). It is now mandatory that enriched grain products be fortified with folic acid (U.S. Food and Drug Administration, 1996). Since these recommendations have been followed worldwide, there has been a reduction in neural tube defects in the United States (Williams et al, 2005) and elsewhere (Botto et al, 2005). In some cases, however, despite increased folic acid intake, women may still give birth to a child with spina bifida owing to antibodies that have developed in response to the increased folate ingestion, thus negating its salutary effect (Rothenberg et al, 2004).

Pathogenesis

Myelodysplasia is an all-inclusive term used to describe the various abnormal conditions of the vertebral column that affect spinal cord function. More specific labels for each abnormality include the following: a *meningocele* occurs when just the meninges but no neural elements extend beyond the confines of the vertebral canal; in a *myelomeningocele,* neural tissue, either nerve roots or portions of the spinal cord, has evaginated with the meningocele (Fig. 128–2); the term *lipomyelomeningocele* denotes that fatty tissue has developed with the cord structures and both are extending with the protruding sac. **Myelomeningocele accounts for more than 90% of all open spinal dysraphic states** (Stark, 1977). Most spinal defects occur at the level of the lumbar vertebrae, with the sacral, thoracic, and cervical areas, in decreasing order of frequency, less affected (Bauer et al, 1977) (Table 128–2).

Figure 128–2. Typical appearance of an open myelomeningocele in a neonate.

Table 128–2.
Spinal Level of Myelomeningocele

LOCATION	INCIDENCE (%)
Cervical–high thoracic	2
Low thoracic	5
Lumbar	26
Lumbosacral	47
Sacral	20

An overwhelming number of meningoceles are directed posteriorly, but on rare occasions they may protrude anteriorly, particularly in the sacral area. Usually the meningocele is made up of a flimsy covering of transparent tissue, but it may be open and leaking cerebrospinal fluid. For this reason urgent repair is necessary, with sterile precautions being followed in the interval between birth and spinal canal closure. In 85% of affected children there is an associated Arnold-Chiari malformation, in which the cerebellar tonsils have herniated down through the foramen magnum, obstructing the fourth ventricle and preventing the cerebrospinal fluid from entering the subarachnoid space surrounding the brain and spinal cord.

In the past several years, several centers in the United States have begun closing the defect in fetuses between 19 and 25 weeks of gestation in an attempt to improve the neurologic defect in these children (Adzick et al, 1998; Bruner et al, 1999; Holzbeierlein et al, 2000). Thus far, this procedure has not altered the incidence of abnormal findings in the lower extremities (Farmer et al, 2003) or on urodynamic assessment in the postnatal period (Koh et al, 2003), but, surprisingly, aqueduct obstruction and, consequently, hydrocephalus has not occurred at birth to the same incidence or extent (Johnson et al, 2003). **It is possible that leakage of cerebrospinal fluid from the open spinal column accounts for herniation of the posterior brainstem down the foramen magnum, leading to the development of hydrocephalus.**

The neurologic lesion produced by the myelomeningocele can be variable, depending on what neural elements, if any, have everted with the meningocele sac. The bony vertebral level often provides little or no clue to the exact neurologic level or lesion produced. The height of the bony level may differ from the highest extent of the neurologic lesion for one to three vertebrae in either direction (Bauer et al, 1977). Furthermore, there may be differences in function from one side of the body to the other at the same neurologic level and from one neurologic level to the next, owing to asymmetry of the affected neural elements. It is important to remember that no two children have the same neurourologic defect. In addition, in 20% of affected children a vertebral bony or intraspinal abnormality occurs more cephalad than the vertebral defect and meningocele, and this can affect function in those portions of the cord. Children with thoracic or upper lumbar meningoceles often have complete reconstitution of the spine in the sacral area, and these individuals frequently have intact sacral reflex arc function involving the sacral spinal roots (in the authors' series of patients with high-level lesions, 74% of neonates and 54% of older children were affected thusly) (Pontari et al, 1995). In fact, it is more likely that children with upper thoracic or cervical lesions will have just a meningocele and no myelomeningocele. Children with neurologic deficits at S1 or lower may also manifest a variety of findings on urodynamic testing, ranging from normal function to upper and/or lower motor neuron lesions involving either the bladder and/or the external urethral sphincter (Dator et al, 1992). Upper motor neuron lesions are characterized by an overactive detrusor, exaggerated sacral reflexes, absence of voluntary control over sphincter function, detrusor-sphincter dyssynergia (DSD), and no EMG evidence of denervation potentials in the sphincter (White and Klauber, 1976; Koff and DeRidder, 1977; Guzman et al, 1983; Capitanucci et al, 1997). The bladder tends to be thick walled (or trabeculated) with a closed bladder neck on voiding cystourethrography (VCUG) or ultrasonography. A lower motor neuron lesion is noted when an acontractile detrusor and partial or complete denervation of the external urethral sphincter with diminished or absent sacral reflexes may be seen. In these instances the bladder is usually small and smooth walled with an open bladder neck (Wilmshurst et al, 1999). The presence or absence of the bulbocavernosus reflex is an indicator (although not a foolproof one) of an upper or a lower motor neuron lesion, respectively (Schlussel et al, 1994). Approximately 10% of neonates with

Key Points: Neurogenic Bladder Dysfunction

- At least 25% of the clinical problems seen in pediatric urology are the result of neurologic lesions that affect lower urinary tract function.
- The most common cause of neurogenic bladder dysfunction in children is abnormal development of the spinal canal and internecine spinal cord.
- Myelomeningocele accounts for more than 90% of all open spinal dysraphic states.
- The neurologic lesion produced by this condition can be variable. The bony vertebral level provides little or no clue to the exact neurologic level or lesion produced.

myelomeningocele exhibit no abnormality on urodynamic testing (Tarcan et al, 2001). Finally, the differing growth rates of the vertebral bodies and the elongating spinal cord add a dynamic factor in the developing fetus that further confounds the picture (Lais et al, 1993). Twenty-four percent of children with normal lower urinary tract function at birth develop upper motor neuron changes over time (Tarcan et al, 2001). Superimposed on all this is the Arnold-Chiari malformation, which can have a profound effect on the brainstem and pontine mesencephalic center, areas that are involved in control of lower urinary tract function.

Therefore the neurologic lesion produced by this condition influences lower urinary tract function in a variety of ways and cannot be predicted just by looking at the spinal abnormality or the neurologic function of the lower extremities. Even careful assessment of the sacral area may not provide sufficient information to make a concrete inference. As a result, urodynamic evaluation in the neonatal period is now the standard of care at most pediatric centers in the United States, because it not only provides a clear picture of the function of the sacral spinal cord and lower urinary tract but also has predictive value in infants at risk for future urinary tract deterioration and progressive neurologic change (McGuire et al, 1981; Van Gool et al, 1982; Bauer, 1984b; Sidi et al, 1986). The advent of hostility scores and the reliability of urodynamic risk factors have led many clinicians to initiate prophylactic therapy in those neonates considered to be at risk for urinary tract deterioration (Perez et al, 1992). There are some, however, who do not consider urodynamic testing an important factor but rely solely on physical examination and radiologic assessment to direct their decision-making process (Hopps and Kropp, 2003), a concept not shared by many.

Neonatal Assessment

Ideally, it would be best to perform urodynamic testing immediately after the infant is born, but the risk of spinal infection and the urgency for closure have not made this a viable option. It was accomplished in one study, however, and the results showed that 1 in 30 children (3.2%) experienced a change in neurologic status as a result of the spinal canal closure (Kroovand et al, 1990). Therefore, **renal ultrasonography and measurement of residual urine are performed as early as possible after birth,** either before or immediately after the spinal defect is closed. Urodynamic studies are delayed until it is safe to transport the child to the urodynamic suite and place him or her on the back or side for the test. The initial urodynamic study should be performed within the first 3 months of life. If the infant cannot empty the bladder after a spontaneous void or with a Credé maneuver, CIC is begun even before urodynamic studies are conducted. If the Credé maneuver is effective in emptying the bladder, it is performed on a regular basis instead of using CIC until the lower urinary tract can be fully investigated. The normal bladder capacity in the neonatal period is 10 to 15 mL; therefore, a residual urine volume of less than 5 mL is acceptable. Other tests that should be performed in the neonatal period include a urinalysis and culture, serum creatinine determination, and careful neurologic examination of the lower extremities.

Once the spinal closure has healed sufficiently, a renal ultrasonogram is performed to reassess upper urinary tract architecture. Next, VCUG and urodynamic study are conducted. **These studies meet several objectives: they provide baseline information about the radiologic appearance of the upper and lower urinary tracts as well as the condition of the sacral spinal cord and the central nervous system (CNS); they provide information that can be compared with findings on subsequent assessments, so that early signs of deterioration of urinary tract function and drainage, or of progressive neurologic denervation, can be detected; they help to identify infants at risk for urinary tract deterioration as a result of a poorly compliant or overactive detrusor or outflow obstruction from DSD, which predetermines the need to initiate prophylactic measures before any deterioration in upper urinary tract architecture and function actually takes place; and they help the physician to counsel parents about the child's future bladder and sexual function** (McGuire et al, 1981; Bauer et al, 1984; Bauer, 1984a; Sidi et al, 1986; Lais et al, 1993). If an abnormality is detected on renal ultrasonography or vesicoureteral reflux is demonstrated, a dimercaptosuccinic acid (DMSA) renal scan is recommended.

Findings

Fifteen to 20 percent of neonates have an abnormal urinary tract on radiologic examination when first evaluated (Bauer, 1985); 3% have hydroureteronephrosis secondary to spinal shock, probably from the spinal canal closure (Chiaramonte et al, 1986), and 15% have abnormalities that developed in utero as a result of abnormal lower urinary tract function in the form of outlet obstruction (Bauer, 2003).

Urodynamic studies in the neonatal period have shown that 63% of infants have bladder contractions. This is also true for an equivalent number of children with upper lumbar or thoracic lesions in whom the sacral spinal cord is spared, 50% of whom have detrusor overactivity (Pontari et al, 1995). Thirty-seven percent have an acontractile detrusor with compliance during filling that is either good (20%) or poor (17%) in this subgroup (Bauer et al, 1984; Bauer, 2003). EMG assessment of the external urethral sphincter demonstrates an intact sacral reflex arc with no evidence of lower motor neuron denervation in 40% of neonates; partial denervation is seen in 24%; and complete loss of sacral cord function is noted in 36% (Lais et al, 1993; Bauer, 2003).

A combination of bladder contractility and external sphincter activity results in **three categories of lower urinary tract dynamics: synergic (26%), dyssynergic with and without poor detrusor compliance (37%), and complete denervation (36%)** (Fig. 128–3) (Bauer et al, 1984; Sidi et al, 1986; Bauer, 2003). DSD occurs when the external sphincter fails to decrease or actually increases its activity during a detrusor contraction or a sustained increase in intravesical pressure as the bladder is filled to capacity (Blaivas et al, 1986). Frequently, a poorly compliant bladder with high intravesical pressure occurs in conjunction with a dyssynergic sphincter, resulting in a bladder that empties only at high intravesical pressure (Van Gool et al, 1982; Sidi et al, 1986). Synergy is characterized by complete silencing of the sphincter during a detrusor contraction or when capacity is reached at the end of filling. Voiding pressures are usually within the normal range. Complete denervation is noted when no bioelectric potentials are detectable in the region of the external sphincter at any time during the micturition cycle or in response to sacral stimulation or a Credé maneuver.

The categorization of lower urinary tract function in this way has been extremely useful because it reveals which children are at risk for urinary tract changes, who should be treated prophylactically, who need close surveillance, and who can be monitored at shorter or longer intervals. Within the first 3 years of life, 71% of neonates

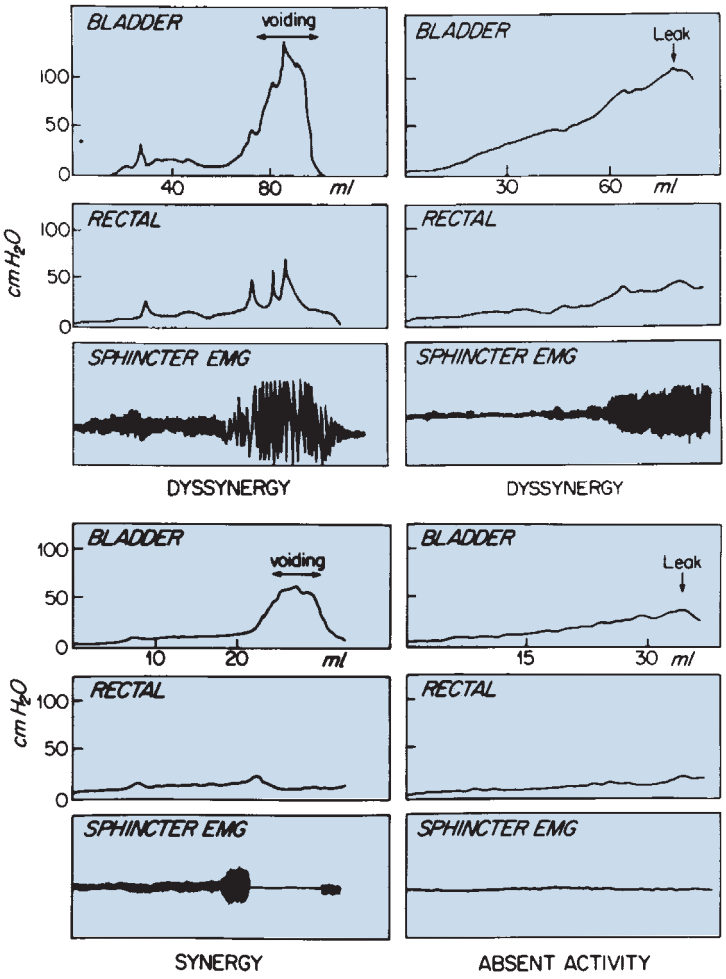

Figure 128–3. Various patterns of urodynamic findings on electromyography (EMG) in neonates with myelodysplasia. Note that a hypertonic detrusor with a nonrelaxing sphincter is also labeled dyssynergy. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, editor. Urologic surgery in neonates and young infants. Philadelphia: WB Saunders; 1988. p. 252–64.)

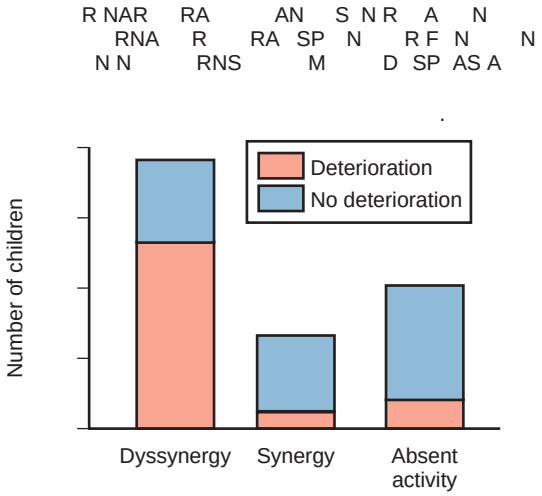

Figure 128–4. Urinary tract deterioration is related to outflow obstruction and is most often associated with dyssynergy. Children with synergy converted to dyssynergy, and patients with complete denervation developed fibrosis with a fixed high outlet resistance in the external sphincter, before any changes occurred in the urinary tract. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, editor. Urologic surgery in neonates and young infants. Philadelphia: WB Saunders; 1988. p. 252–64.)

Key Points: Neonatal Assessment for Neurogenic Bladder Dysfunction

- Renal ultrasonography and measurement of residual urine are performed as early as possible after birth.
- Initial evaluation can be compared with findings on subsequent assessments, so that early signs of deterioration of urinary tract function and drainage, or of progressive neurologic denervation, can be detected.
- Infants at risk for urinary tract deterioration as a result of a poorly compliant or overactive detrusor or outflow obstruction from DSD need to be identified.
- This determines the need to initiate prophylactic measures before any deterioration in upper urinary tract architecture and function take place.
- Fifteen to 20 percent of neonates have an abnormal urinary tract on radiologic examination when first evaluated.
- Three categories of lower urinary tract dynamics may be detected: synergic (26%), dyssynergic with and without poor detrusor compliance (37%), and complete denervation (36%).

with DSD had urinary tract deterioration on initial assessment or subsequent studies whereas only 17% of synergic children and 23% of completely denervated individuals developed similar changes (Fig. 128–4). Infants in the synergic group who showed deterioration did so only after they converted to a dyssynergic pattern of sphincter function. Among the infants with complete denervation, the ones who showed deterioration were those who had increased levels of urethral resistance, presumably caused by fibrosis of the skeletal muscle component of the external sphincter. Therefore, it appears that outlet obstruction is a major contributor to the development of urinary tract deterioration in these children (Fig. 128–5). Poor detrusor compliance plays an important role in this regard, especially when outlet resistance exceeds 40 cm H_2O (McGuire et al, 1981; Landau et al, 1994; Tanaka et al, 1999). Detrusor compliance seems to be worse in children with high levels of outlet resistance (Ghoniem et al, 1989). Bloom and colleagues (1990) and then Park and associates (2001) noted an improvement in compliance when outlet resistance was reduced after gentle urethral dilation in these children; however, the reasons for this change are unclear, and the long-term effect of this maneuver on ultimate continence and lower urinary tract function remains uncertain.

It may be that detrusor filling pressures need to be looked at in a more critical way to determine whether they are an important factor in upper urinary tract deterioration. **Landau and colleagues** (1994) **developed the concept of low detrusor filling pressure (<30 cm H_2O)** at specific volumes adjusted for age and not at maximal capacity. Applying this idea, they noted significantly improved sensitivity in predicting upper urinary tract deterioration. The ability to predict accurately which neonates are at risk for urinary tract deterioration prompted the initiation of prophylactic therapy with CIC and anticholinergic drugs (Geranoitis et al, 1988; Kasabian et al, 1992). Long-term success has been achieved in preventing reflux and hydronephrosis and

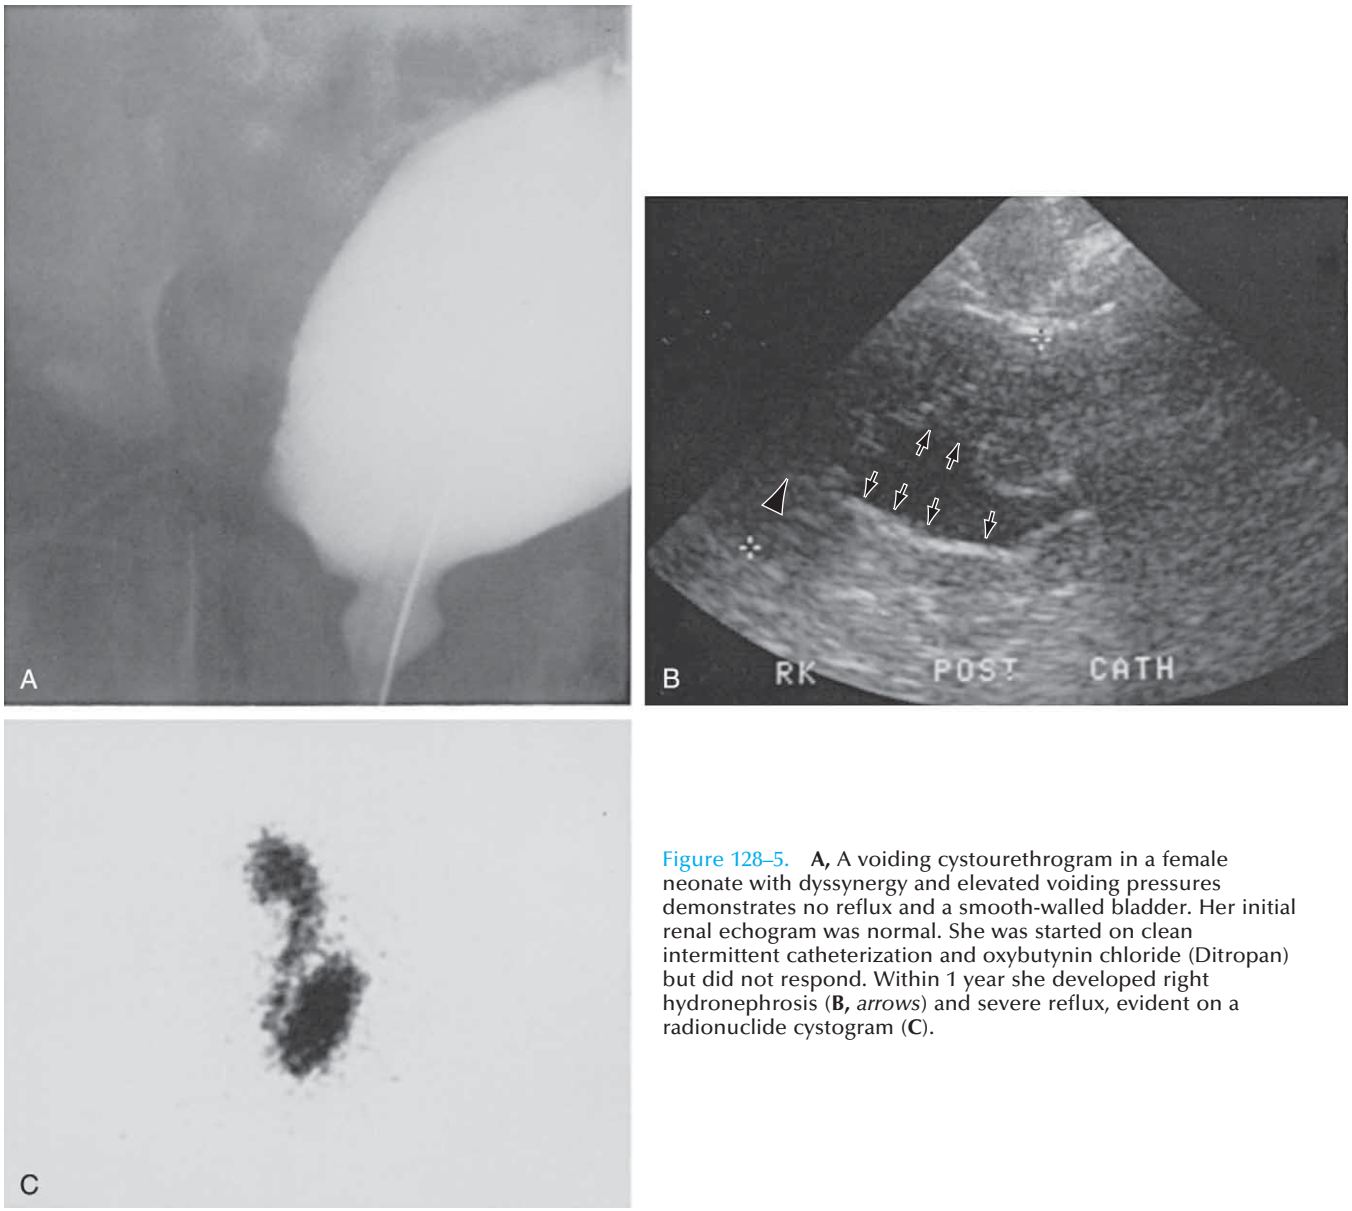

Figure 128–5. **A,** A voiding cystourethrogram in a female neonate with dyssynergy and elevated voiding pressures demonstrates no reflux and a smooth-walled bladder. Her initial renal echogram was normal. She was started on clean intermittent catheterization and oxybutynin chloride (Ditropan) but did not respond. Within 1 year she developed right hydronephrosis (**B,** *arrows*) and severe reflux, evident on a radionuclide cystogram (**C**).

in reducing the need for augmentation cystoplasty, from between 27% and 41% to between 11% and 17% (Edelstein et al, 1995; Wu et al, 1997; Kaefer et al, 1999). Others believe that aggressive observation and prompt intervention yields similar long-term results with less morbidity from catheterization (Teichman et al, 1994), but only time will delineate which avenue of treatment is most efficacious (Tanaka et al, 1999; Hopps and Kropp, 2003).

Management Principles

Because expectant treatment has revealed that infants with outlet obstruction in the form of DSD are at considerable risk for urinary tract deterioration, the idea of treating these children prophylactically has emerged as an important alternative. When CIC is begun in the neonatal period, it is easy for parents to master, even in uncircumcised boys, and for children to accept as they grow (Joseph et al, 1989). Complications such as meatitis, epididymitis, and urethral injury are rarely encountered, and urinary infections occur in fewer than 30% (Kasabian et al, 1992), although asymptomatic bacteriuria can be seen in almost 70% (Schlager et al, 2001).

CIC alone or in combination with anticholinergic agents, when detrusor filling pressures exceed 40 cm H_2O and voiding pressures are higher than 80 to 100 cm H_2O, resulted in an incidence of urinary tract deterioration of only 8% to 10% (Geranoitis et al, 1988; Kasabian et al, 1992; Edelstein et al, 1995). This represents a significant drop in the occurrence of detrimental changes compared with children observed expectantly (McGuire et al, 1981; Bauer et al, 1984; Sidi et al, 1986; Teichman et al, 1994; Wu et al, 1997). Oxybutynin is administered in a dose of 0.2 to 0.4 mg/kg divided two or three times daily with no apparent side effects. On rare occasions when an overactive or poorly compliant bladder fails to respond to these measures, augmentation cystoplasty may be needed with cutaneous vesicostomy almost never required (Duckett, 1974; Mandell et al, 1981).

Neurologic Findings and Recommendations

The neurologic lesion in myelodysplasia is a dynamic disease process in which changes take place throughout childhood (Epstein, 1982; Reigel, 1983; Venes and Stevens, 1983; Oi et al, 1990), especially in early infancy (Spindel et al, 1987) and

later at puberty (Begger et al, 1986), when the linear growth rate accelerates again. When a change is noted on neurologic, orthopedic, or urodynamic assessment, radiologic investigation of the CNS often reveals (1) tethering of the spinal cord (Fig. 128–6), (2) a syringomyelia, a dilation and fluid collection within the spinal cord, (3) increased intracranial pressure due to a shunt malfunction, or (4) partial herniation of the brainstem and cerebellum. Children with completely intact or only partially denervated sacral cord function are particularly vulnerable to progressive changes. Magnetic resonance imaging (MRI) is the test of choice because it reveals anatomic details of the spinal column and CNS (Just et al, 1990). However, it is not a functional study and when used alone it cannot provide exact information about a changing neurologic lesion.

Key Points: Management Principles

- Bladder pressures should be maintained below 30 cm H_2O as much as possible to prevent urinary tract deterioration.
- CIC alone or in combination with anticholinergic agents, when detrusor filling pressures exceed 30 to 40 cm H_2O and voiding pressures are higher than 80 to 100 cm H_2O, can reduce the incidence of urinary tract deterioration.
- The neurologic lesion in myelodysplasia is a dynamic disease process in which changes take place throughout childhood.
- Sequential urodynamic testing on a yearly basis beginning in the neonatal period and continuing until the child is 5 years old provides a means of monitoring these children.
- Vesicoureteral reflux occurs in 3% to 5% of neonates with myelodysplasia.
- The indications for antireflux surgery are not very different from those applicable to children with normal bladder function.

Sequential urodynamic testing on a yearly basis beginning in the neonatal period and continuing until the child is 5 years old provides a means of carefully monitoring these children to detect signs of change, thus offering the hope that early detection and neurosurgical intervention may help to arrest or even reverse a progressive pathologic process. Changes occurring in a group of neonates monitored in this manner involved both the sacral reflex arc and the pontine-sacral reflex interaction (Fig. 128–7) (Lais et al, 1993). Most children who experience such changes tend to do so in the first 3 years of life (Phuong et al, 2002) (Fig. 128–8). Twenty-two of 28 children in whom the neurologic picture became worse underwent a second neurosurgical procedure; 11 of them had a beneficial effect from

the surgery and showed improvement in urethral sphincter function (Lais et al, 1993). Infants with only sacral level deficits have a 47% risk of deterioration (Dator et al, 1992). Even children with normal neurourologic function at birth have a 32% risk of developing a tethered spinal cord with the development of DSD with or without detrusor overactivity (Tarcan et al, 2001).

As a result of these developments **it is recommended that all infants with myelodysplasia be monitored according to the guidelines set forth in Table 128–3.** It is not enough to look at just the radiologic appearance of the urinary tract; scrutiny of the functional status of the lower urinary tract is important as well. In addition to the reasons cited previously, it may be necessary to repeat a urodynamic study if the upper urinary tract dilates secondary to impaired drainage from a poorly compliant detrusor.

Beyond the age of 5 years renal ultrasonography every 18 months until puberty and then every 2 years thereafter is recommended. Urodynamic studies are indicated to evaluate the development of new neurologic symptoms, new hydronephrosis, or changes in continence. VCUG should be done if recurrent urinary tract infections are experienced.

Management of Reflux

Vesicoureteral reflux occurs in 3% to 5% of neonates with myelodysplasia, usually in association with poor detrusor compliance, detrusor overactivity, and/or DSD (Flood et al, 1994). It is rare to find reflux in any neonate without these urodynamic findings (Bauer, 1984b; Geranoitis et al, 1988; Edelstein et al, 1995). If left untreated, the incidence of reflux in these infants at risk increases with time until 30% to 40% are afflicted by 5 years of age (Bauer, 1984a; Seki et al, 1999). Prophylactic treatment that lowers detrusor filling and voiding pressures with anticholinergic agents and empties the bladder by means of CIC significantly reduces this rising incidence of reflux (Edelstein et al, 1995).

In children with reflux grades 1 to 3 (International Classification) who void spontaneously or have complete lesions with little or no outlet resistance and empty their bladder completely, management consists solely of prophylaxis with antibiotics to prevent recurrent infection. In children with high-grade reflux (grade 4 or 5), CIC is begun to ensure complete emptying. Children who cannot empty their bladder spontaneously, regardless of the grade of reflux, are treated with CIC to empty the bladder efficiently. Children with poor detrusor compliance with or without hydroureteronephrosis are also started on anticholinergic agents to lower intravesical pressure and ensure adequate upper urinary tract decompression (Flood et al, 1994). When reflux is managed in this manner there has been a dramatic response, with reflux resolving in 30% to 55% of individuals (Kass et al, 1981; Bauer, 1984b; Joseph et al, 1989; Flood et al, 1994; Agarwal et al, 1997; Hopps and Kropp, 2003). Although bacteriuria can be seen in as many as 56% of children on CIC it is not harmful except in the presence of high-grade reflux, because symptomatic urinary infection and renal scarring rarely occur with lesser grades of reflux (Kass et al, 1981; Cohen et al, 1990).

Credé voiding should be avoided in children with reflux, especially those with a reactive external urethral sphincter. In this circumstance, the Credé maneuver results in a reflex response in the external sphincter that increases urethral resistance and raises the pressure needed to expel urine from the bladder (Barbalais et al, 1983) (Fig. 128–9). This has the effect of aggravating the degree of reflux and accentuating its water-hammer effect on the kidneys. Vesicostomy drainage (Duckett, 1974; Mandell et al, 1981) is rarely required today but is reserved for those infants (1) who have such severe reflux that CIC and anticholinergic medication fail to improve upper urinary tract drainage, (2) whose parents cannot adapt to the catheterization program, or (3) who are not good candidates for augmentation cystoplasty (Morrisroe et al, 2005).

The indications for antireflux surgery in this group of children are not very different from those applicable to children with normal bladder function. They include recurrent symptomatic (febrile) urinary infection while receiving adequate antibiotic therapy and appropriate catheterization techniques; persistent hydroureteronephrosis despite effective emptying of the bladder and lowering of intravesical pressure; severe reflux with an anatomic abnormality at the ureterovesical junction; reflux that persists into puberty; and the presence of reflux in any child undergoing surgery to increase bladder outlet resistance. Although some clinicians do not advocate reimplanting ureters in patients with low-grade reflux who are undergoing augmentation cystoplasty to lower intravesical pressure, this concept is not universally accepted (Nasrallah and Aliabadi, 1991).

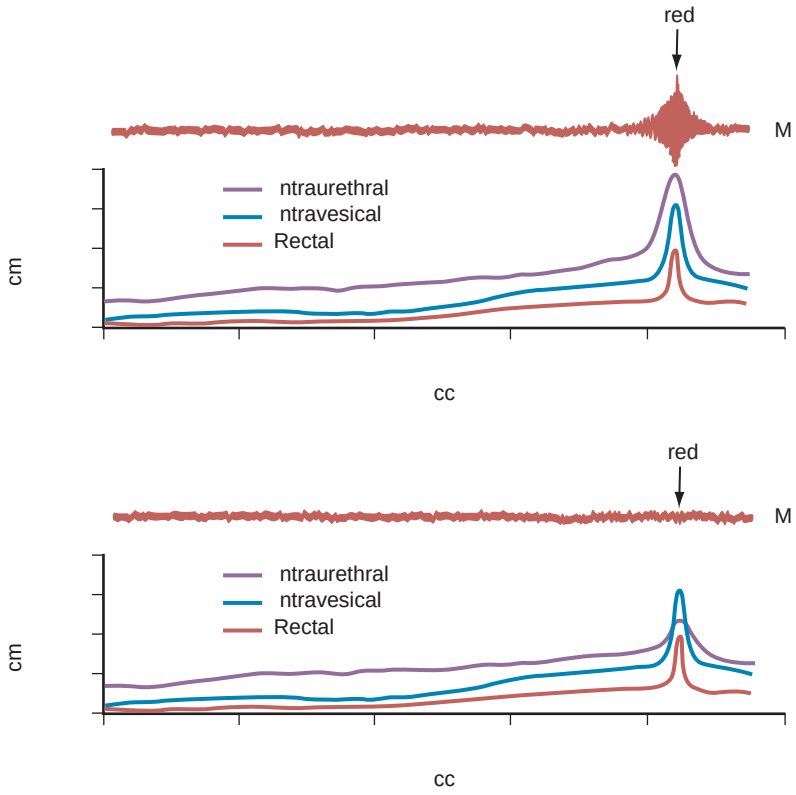

Figure 128–9. When the external sphincter is reactive *(top)*, a Credé maneuver produces a reflex increase in electromyographic (EMG) activity of the sphincter and a concomitant rise in urethral resistance, resulting in high voiding pressure. A child whose sphincter is denervated and nonreactive *(bottom)* will not have a corresponding rise in EMG activity, urethral resistance, or voiding pressure. A Credé maneuver here will not be detrimental. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, editor. Urologic surgery in neonates and young infants. Philadelphia: WB Saunders; 1988. p. 252–64.)

Jeffs and colleagues (1976) were the first to show that **antireflux surgery can be very effective in children with neurogenic bladder dysfunction as long as it is combined with measures to ensure complete bladder emptying.** Before this observation was made, the results of ureteral reimplantation were so dismal that most physicians treating these children advocated urinary diversion as a means of managing reflux (Smith, 1972; Cass, 1976). Since the advent of CIC, success rates for antireflux surgery have approached 95% (Kass et al, 1981; Woodard et al, 1981; Bauer et al, 1982; Kaplan and Firlit, 1983). Bilateral surgery for unilateral disease need not be done, because contralateral reflux does not occur postoperatively (Bauer, 1984a). The endoscopic injection of various materials has altered the management of reflux in children with myelomeningocele (Elder et al, 2004; Schlussel, 2004). A recent meta-analysis demonstrated that the success rate of endoscopic treatment is less in children with neurogenic bladder than those with normal bladder function (62% vs. 74%) (Elder et al, 2004). Studies comparing the effectiveness of open surgical to endoscopic management in this population show a significantly greater success rate for traditional open procedures (61% to 72.5% vs. 84.3% to 95.5%) (Engel, 1997; Granata, 1999). Thus, the endoscopic approach is a reasonable alternative to ureteroneocystotomy; however, the long-term outcomes are not defined.

Continence and Prevention of Upper Urinary Tract Deterioration

The primary goals of management for children with myelomeningocele are the attainment of social continence and preservation of normal renal function. These goals can be achieved for most children with a combination of medical and surgical therapies.

Urinary continence is becoming an increasingly important issue that demands attention at an early age. It has been shown that children who are continent have higher ratings in self-confidence and social acceptance than boys and girls who are wet; thus this issue becomes paramount as the children grow up and attend school (Moore et al, 2004). **Initial attempts at achieving continence include CIC and drug therapy designed to maintain low intravesical pressures and a reasonable level of urethral resistance** (Figs. 128–10 and 128–11). Although these measures can be initiated on a trial-and-error basis, it is more efficient to use exact treatment protocols based on specific urodynamic findings. As a result, urodynamic testing is performed if initial attempts with CIC and oxybutynin fail to achieve continence. Without urodynamic studies it is hard to know whether (1) a single drug is effective, (2) the dose should be increased, (3) a second drug should be added to the regimen, or (4) alternative methods of treatment (i.e., augmentation cystoplasty) should be contemplated.

At this point, if poor detrusor compliance and/or overactivity have not been dealt with effectively the dose of the anticholinergic drug may be increased. If this is not successful, another anticholinergic agent may be combined with or given instead of oxybutynin (see Table 128–1). A recent study in adults with neurogenic bladder has shown the addition of a second anticholinergic agent to an existing double-dose anticholinergic agent resulted in improved urodynamic parameters and continence in 85% of patients who had failed single-agent therapy with minimal adverse effects (Amend, 2008). Glycopyrrolate is the most potent oral anticholinergic drug available today, but it may have the typical belladonna-like side effects common to all these drugs. Tolterodine, a newly approved anticholinergic drug, is equally effective as oxybutynin in reducing detrusor overactivity and improving compliance, but with fewer side effects, especially constipation (Goessl et al, 2000). Hyoscyamine produces fewer side effects still, but its potency is even less. Intravesical instillation of oxybutynin has been proven to be successful in lowering detrusor pressure and has fewer side effects compared with oral administration; serum

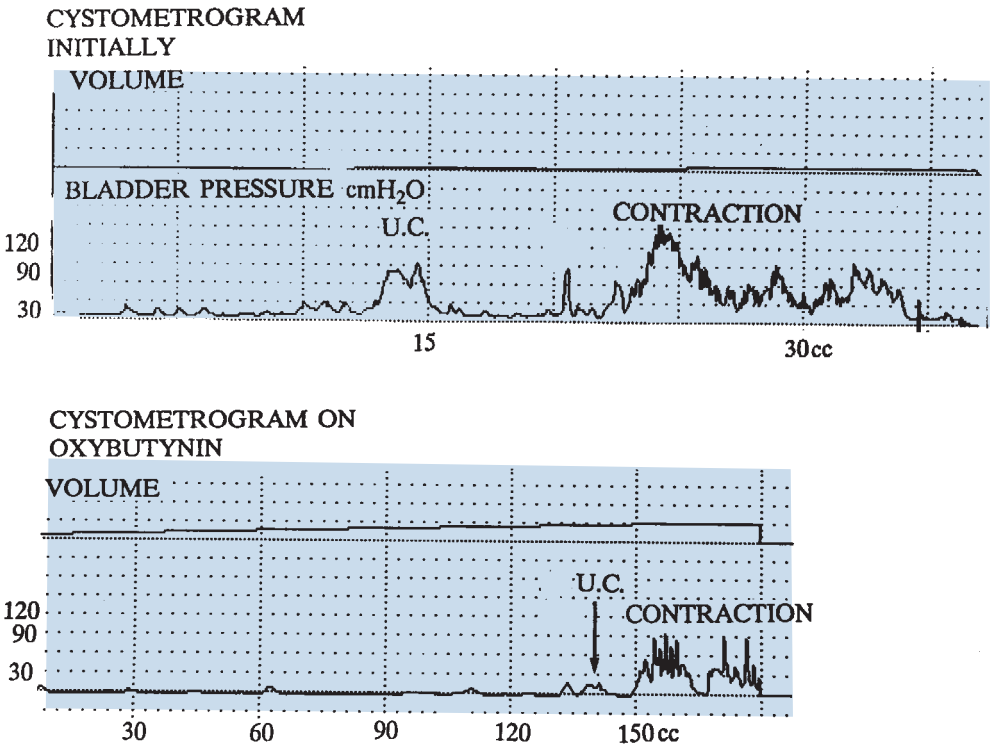

Figure 128–10. Oxybutynin is a potent anticholinergic agent that dramatically delays detrusor contractions and lowers contraction pressure, as demonstrated on these two graphs. U.C., uninhibited contraction.

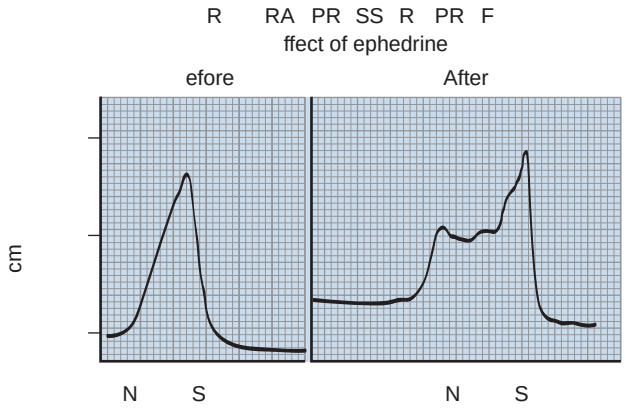

Figure 128–11. α-Sympathomimetic agents potentially have their greatest effect in the bladder neck region, where the highest concentration of α-adrenergic receptor sites exists. They can raise outlet resistance and improve continence in many individuals. BN, bladder neck; ES, external sphincter.

concentrations may reach similar levels regardless of the route of intake (Greenfield and Fera, 1991; Massad et al, 1992). Inconvenience of administration, however, seems to preclude its long-term use (Kasabian et al, 1994). Trospium chloride, a recently approved quaternary ammonium compound with antimuscarinic activity that has a high binding affinity for muscarinic receptors M_1, M_2, and M_3 but not nicotinic or cholinergic receptors holds promise because it has a more direct effect on detrusor function with fewer systemic side effects than anticholinergic agents (Rovner, 2004; Doroshyenko et al, 2005; Kim et al, 2005). Solifenacin, darifenacin, and propiverine are muscarinic receptor antagonists with high affinity for the M_3 receptor. Propiverine also has calcium channel–blocking effects. These three novel agents may reduce adverse events; however, their safety and effectiveness has not yet been established in children. If conservative management with medications and CIC fail to achieve continence or prevent upper urinary tract deterioration, more aggressive intervention is warranted. In up to 80% of children, nocturnal bladder emptying has been shown to improve hydronephrosis, bladder compliance and capacity, urinary tract infections, and continence (Koff, 2005).

If urodynamic testing reveals that urethral resistance is inadequate to maintain continence because either the sphincter fails to react to increases in abdominal pressure or its resistance drops with bladder filling, α-sympathomimetic agents

Key Points: Continence in Neurogenic Bladder Dysfunction

- Initial attempts at achieving continence include CIC and drug therapy designed to maintain low intravesical pressures and a reasonable level of urethral resistance.
- If urodynamic testing reveals that urethral resistance is inadequate to maintain continence, α-sympathomimetic agents are added.
- Overnight Foley drainage has been effective in lowering bladder filling pressure and in maintaining a stable upper urinary tract in some children at risk.
- Surgery becomes a viable option when drug therapy fails to achieve continence.
- If bladder neck or urethral resistance is insufficient to allow adequate storage capacity, several operations are available to improve this continence mechanism.
- Continent urinary diversion with closure of the bladder neck (or compression via a fascial sling) has been used to provide a better quality of life for those with intractable urethral incompetence.

are added to the regimen (see Table 128–1); phenylpropanolamine is the most effective drug in this regard.

Some children will ultimately require surgical intervention. A persistent poorly compliant or overactive detrusor may be treated either with enterocystoplasty (Mitchell and Piser, 1987; Sidi et al, 1987; Hernandez et al, 1994), autoaugmentation (Cartwright and Snow, 1989a, 1989b), or a combination thereof (Duel et al, 1998). Sigmoid, cecum, and small intestine, in that order, have been used to enlarge the bladder. The ileocecal segment is avoided in children with myelodysplasia because removing it might aggravate the bowel dysfunction in these children. Detubularization of the bowel is needed to minimize the intrinsic contractions of the intestinal segment and prevent it from causing intractable incontinence once it has been added to the bladder (Goldwasser et al, 1987; Hinman, 1988). **Concerns have surfaced about gastric segments because they can cause hyponatremic hypochloremic metabolic alkalosis** (Gosalbez et al, 1993) or the hematuria dysuria syndrome (Nguyen et al, 1996). Except for children with progressive or end-stage renal failure, gastrocystoplasty has not been recommended as a routine form of augmentation (Leonard et al, 2000; Plaire et al, 2000).

With the long view of hindsight it is becoming evident that augmentation cystoplasty with any segment of the gastrointestinal tract can lead to long-term consequences in acid-base balance, vitamin B_{12} deficiency, fat absorption, renal function, bone metabolism, growth retardation, recurrent urinary tract infection, stone formation, and even cancer risk (Gilbert and Hensle, 2005). Consequently, there is considerable interest in developing new techniques for replacing the bladder without the need for bowel substitution (i.e., tissue-engineered autologous augments; see also Chapter 19).

The well-documented development of malignancy in patients with intestinal and gastric bladder augmentation mandates careful surveillance of these patients. Most studies note a 10-year minimum lag time between the augmentation and presentation of disease. Thus, **10 years after augmentation an annual surveillance cystoscopy with site-directed biopsies at the anastomotic suture line is recommended** (Soergel et al, 2004; Castellan et al, 2007; Vemulakonda et al, 2008). Symptoms and signs such as new-onset hydronephrosis, hematuria, or bladder wall thickening warrant prompt evaluation (Castellan et al, 2007; Vemulakonda et al, 2008).

If bladder neck or urethral resistance is insufficient to allow adequate storage capacity, several operations are available to improve this continence mechanism. Bladder neck reconstruction can be undertaken in a variety of ways, including the Young-Dees or Leadbetter procedures (Young, 1919; Dees, 1949; Leadbetter, 1964) or the Kropp approach (Kropp and Angwafo, 1986), modified by Salle to make catheterization easier (Salle et al, 1994). A fascial sling procedure suspending the bladder neck and buttressing it against the undersurface of the pubis has been advocated enthusiastically by several clinicians (McGuire et al, 1986; Raz et al, 1988; Bauer et al, 1989). Artificially derived material, small intestine submucosa (SIS) (Colvert et al, 2002), and a rectus muscle "fascial" wrap around the bladder neck (Walker et al, 2000) have been as effective as rectus fascia in increasing bladder neck resistance and their effectiveness does not seem to dissipate over time (Elder, 1990; Castellan et al, 2005). Even though it is applicable to males it has not been as effective as in females (Nguyen et al, 2001; Castellan et al, 2005). Each of these operations, however, necessitates the use of CIC to empty the bladder postoperatively. It is most effective when combined with augmentation cystoplasty to ensure an adequate reservoir with good compliance (Castellan et al, 2005). The use of a bladder neck sling in conjunction with continent cutaneous catheterizable channel has been proposed to avoid bladder augmentation in some patients with neurogenic bladder. These children have a similar improvement in their continence level but may have a shorter interval between catheterization and require more anticholinergic agents than children with slings and augmentation (Snodgrass et al, 2009). However, this approach is controversial because of the potential risk of bladder deterioration related to increasing bladder pressures and lack of sufficient long-term follow-up. The artificial sphincter (Barrett and Furlow, 1982; Light and Scott, 1983; Light et al, 1983) also increases bladder outlet resistance, and its mechanism of action allows emptying at low urethral pressure. Any patient who can empty his or her bladder before the device is implanted should be able to do so afterward without the need for CIC. In fact, this is the only bladder neck procedure that allows for spontaneous voiding yet is compatible with CIC when needed (Herndon et al, 2003). However, children who have had bladder augmentation or an artificial sphincter placed before puberty are much more likely to require CIC to empty the bladder postpubertally (Catti, 2008). Poor detrusor compliance can develop postoperatively if the preoperative cystometrogram is not carefully scrutinized for signs of increased filling pressure (Woodside and McGuire, 1982; Bauer et al, 1986), and this may lead to progressive renal failure if not treated in a timely fashion with medication or augmentation cystoplasty (Bauer et al, 1993). Long-term results with the artificial sphincter have shown that it is a viable option in children with neurogenic bladder dysfunction (Bosco et al, 1991; Levesque et al, 1996; Kryger et al, 1999; Kryger et al, 2001; Herndon et al, 2003); however, device removal may be required in 9% to 20% (Lopez Pereira et al, 2006; Bauer, 2008; Catti, 2008).

An alternative, minimally invasive option to increase bladder outlet resistance is the endoscopic injection of bulking agents in the bladder neck (Ben-Chiam et al, 1995). Various bulking agents have been used. Early reports are usually promising; however, long-term results are less favorable (Perez et al, 1996; Silveri et al, 1998; Guys et al, 2001). Long-term data on newly developed injectable agents are not available (Caione and Capozza, 2002; Misseri et al, 2005).

Urinary diversion, once considered a panacea for children with myelodysplasia, has turned out to be a Pandora's box of new clinical problems (Schwarz and Jeffs, 1975; Shapiro et al, 1975). Pyelonephritis and renal scarring, calculi, ureterointestinal obstruction, strictures of the conduit, and stomal stenosis are often encountered in children who are monitored on a long-term basis. Although antirefluxing colon conduits seem to have fewer complications, they are still not ideal. In the past 15 years very successful attempts have been made to reverse a urinary tract diversion in children who probably would not have undergone the procedure today (Hendren, 1973, 1990). Few children undergo urinary diversion now; if they do, it is in association with a continent catheterizable stoma.

Continent urinary diversion with complete closure of the bladder neck (or compression via a fascial sling) has been used to provide a better quality of life for those with intractable urethral incompetence despite bladder outlet surgery or to make it easier to catheterize those individuals who cannot easily catheterize themselves via their native urethra (MacNeily et al, 2005).

Several operations have been devised, but the ones that achieved the most publicity initially were the Kock pouch in

adults (Kock, 1971; Skinner et al, 1987) and the Indiana reservoir in children (Rowland et al, 1987). **Mitrofanoff** (1980) **created a continence mechanism by tunneling one end of the vermiform appendix into the bladder, as if reimplanting the ureter to prevent reflux, with the other end being brought out through the skin as a continent catheterizable stoma. This principle has been extended to the ureter.** After the ureter is transected at the pelvic brim, a proximal transureteroureterostomy is performed and the cut end of the distal segment is brought to the skin as a stoma (Duckett and Snyder, 1986). Continence is achieved by the intramural detrusor tunnel of the ureter. Other narrow structures (e.g., fallopian tube, a rolled strip of stomach, a tapered or reconfigured ileal segment) have been implanted either into the native bladder or along the tinea of a detubularized portion of sigmoid or cecum when the latter act as a urinary reservoir (Woodhouse et al, 1989; Reidmiller et al, 1990; Bihrie et al, 1991; Montie et al, 1997). The success rate for achieving continence has been excellent, approaching 85%, primarily owing to the flap valve effect of the intramural tunnel (Hinman, 1990; Watson et al, 1995; Kaefer et al, 1997; Gerharz et al, 1998). For this reason, it is now the preferred method for continent urinary diversion (Harris et al, 2000).

An alternative option for achieving continence and improving urodynamic parameters is the intravesical injection of botulinum-A toxin, which is a neurotoxin protein produced by *Clostridium botulinum* that acts by inhibiting acetylcholine release, resulting in muscle paralysis. The commonly injected dose ranges from 5 to 12 IU/kg, with a maximum total dose of up to 360 IU. Sixty-five to 87 percent of children who have failed conservative medical management and CIC have achieved dryness with a botulinum-A injection. Improvements in urodynamic parameters include decreased maximum detrusor pressure (33% to 57%); increased maximum cystometric capacity (34% to 165%); and improved compliance (121% to 183%) (Schulte-Baukloh et al, 2002; Riccabona et al, 2004; Altaweel et al, 2006; Kajbafzadeh et al, 2006). The duration of response ranges from 6 to 10.5 months. It appears that repeated injections continue to be effective with the interval between repeated injections increasing with each series of injections (Schulte-Baukloh et al, 2005; Altaweel et al, 2006). Complete lack of a response to botulinum-A injection has been linked to the presence of botulinum-A antibodies (Schulte-Baukloh et al, 2008).

The artificial somatic-autonomic reflex pathway is a promising new therapeutic approach to restore bladder function in children with spina bifida. The procedure involves a limited laminectomy and a lumbar ventral root to S3 ventral root microanastomosis. The L5 dorsal root is left intact as the afferent branch of the somatic-autonomic reflex pathway after axonal regeneration (Xiao et al, 2005). In a series of 20 children with spina bifida, 17 developed satisfactory bladder control and continence within 12 months of the procedure. Those children with DSD and overactivity demonstrated nearly normal storage and synergic voiding on follow-up urodynamic studies (Xiao, 2005). A recent study at an independent center confirmed early favorable results with improved continence and spontaneous voiding in 30% of the spina bifida patients (median age 8 years) who underwent intradural lumbar to sacral motor root microanastomosis. Postoperative complications included prolonged wound drainage, ipsilateral footdrop, and temporary lower extremity muscle weakness (Peters et al, 2010). Thus this novel approach appears to have promising results when preformed by experts. The long-term results and general application of the procedure are yet to be determined.

Sexuality

Sexuality in this population is becoming an increasingly important issue as more individuals reach adulthood and want to marry or to have intimate relationships (Cromer et al, 1990). Investigators are looking into the concerns, fears, self-imagery, and desires of teenagers and young adults and at the ability of males to procreate and females to bear children (Bomalaski et al, 1995). However, few studies are available that look critically at sexual function in these patients. Mental disability, poor manual dexterity, lack of education regarding normal and abnormal sexual function, invasion of personal privacy, and overprotective parents often prevent independent behavior and, as a result, lead to poor understanding of sexual issues (Joyner et al, 1998; Woodhouse, 2005).

In several studies, researchers interviewed groups of teenagers and reported that **28% to 40% of them had had one or more sexual encounters and almost all of them had a desire to marry and ultimately to bear children** (Cromer et al, 1990; Palmer et al, 1999a). In one study, 72% of male subjects claimed they were able to have an erection, and two thirds of these were able to ejaculate (Decter et al, 1997). Medical therapy has been shown to be effective in this population. Sildenafil improved erectile function in 80% of men with meningomyelocele in a randomized, double-blind, placebo-controlled trial (Palmer et al, 2000). Other studies revealed that 70% to 80% of myelodysplastic women were able to become pregnant and to have an uneventful pregnancy and delivery, although urinary incontinence in the latter stages of gestation was common in many, as was delivery by cesarean section (Laurence and Beresford, 1975; Cass et al, 1986; Bomalaski et al, 1995; Arata et al, 2000). In the same studies, 17% to 39% of male subjects claimed that they were able to father children and another 25% had a good prognosis for fathering them (Laurence and Beresford, 1975; Bomalaski et al, 1995; Decter et al, 1997). It is more likely that men will have problems with erectile and ejaculatory function because the sacral spinal cord is frequently involved, whereas reproductive function in women, which is under hormonal control, is not affected. Men with neurologic lesions at S1 or lower are likely to have normal or adequate reproductive sexual function, but only 50% of those with lesions above that level have adequate function (Woodhouse, 1994, 2005). Poor semen quality (Reilly and Oates, 1992) and Sertoli cell–only histology on testis biopsy (Glass and Soni, 1999) have been reported as reasons (in addition to erectile dysfunction) for infertility in males with spina bifida.

The degree of sexuality is inversely proportional to the level of neurologic dysfunction (Joyner et al, 1998; Palmer et al, 1999b). Until recently, however, this subject has been taboo (Decter et al, 1997). Sexual identity, education, and social mores have been taken out of the realm of secrecy and are now openly discussed. **However, parents of children with spina bifida are more overprotective than parents of normal children and are less willing to grant autonomy to them for adequate peer and sexual development** (Holmbeck et al, 2002); this tends to lead to less self-assurance regarding social interaction with the opposite sex and diminished sexual identity. Boys reach puberty at an age similar to the age for normal males, whereas breast development and menarche tend to start as much as 2 years earlier than usual in myelodysplastic compared with normal girls. The cause of this early hormonal surge is uncertain, but it may be related to changes in pituitary function in girls secondary to hydrocephalus (Hayden, 1985).

Bowel Function

There is no unanimity regarding the ideal bowel management program for myelodysplastic children. The external anal sphincter is innervated by the same (or similar) nerves that modulate the external urethral sphincter, whereas the internal anal sphincter is under the influence of more proximal nerves from the sympathetic nervous system. In addition, the internal anal muscle reflexively relaxes in response to anal distention. Consequently, **bowel incontinence is frequently unpredictable and is not associated with the attainment of urinary continence;** it is often related to the consistency of fecal material and how rapidly the anal area refills after an evacuation, the degree of intactness of sacral cord sensation and motor function, and reflex reactivity of the external anal sphincter muscle (Younoszai, 1992).

A majority of pediatricians managing these children believe that a regular and efficient bowel emptying regimen is paramount and mandatory. Most programs begin at about 1 year of age, but the best method of attaining these objectives is still controversial. Usually the children are placed on diets that are intended to create formed but not severely constipated stool. Roughage in the form of fruits and bran and stool softeners (in older children) are given to achieve this goal. Suppositories that help evacuate the rectum are used on a regular basis to help train the lower bowel to fill and empty. Some physicians believe that enemas are more effective in evacuating a greater portion of the lower bowel, but one problem with them is the difficulty of retaining the solution when the anal sphincter muscle is lax. Biofeedback training programs to strengthen the external anal sphincter are no more effective than a good bowel management program in attaining fecal continence (Loening-Baucke et al, 1988). Whereas electrostimulation of the bowel has had a variable effect in fecal continence, ranging from 0% to 36% (Marshall and Boston, 1997; Palmer et al, 1997), intravesical bladder stimulation has had a more pronounced effect on bowel continence (Han et al, 2004). When a carefully constructed bowel regimen is adhered to, most children with myelomeningocele can achieve some degree of fecal continence (Myers, 1984), but the uncertainty of accidents always makes this a tenuous situation. Often the urinary incontinence is effectively managed with CIC, drugs, and/or surgery but episodes of fecal soiling remain a problem, particularly in socially minded adolescents (Hayden, 1985; Krogh et al, 2003). When diet, medications, and manual evacuation fail to achieve predictable bowel emptying without soiling, a continent cutaneous pathway from the lower abdominal wall to the cecum may be created using the vermiform appendix; this is called the ACE procedure, for *A*ntegrade *C*ontinence *E*nema (Griffiths and Malone, 1995). When the appendix is unavailable, a small segment of the bowel may be reconfigured to act as a conduit. Alternatively, a button cecostomy provides effective access for antegrade continence enemas (Duel, 1999). Enemas consisting of either Golytely, saline, or tap water, sometimes in combination with bisacodyl, are instilled daily or every other day to evacuate the colon. Cleansing the colon in this manner has resulted in complete continence in 89% of children in whom it has been tried (Squire et al, 1993; Gerharz et al 1997; Yerkes et al, 2002). Older children readily become independent in managing their bowel function, leading to improved self-esteem and sociability (Bau et al, 2001; Aksnes et al, 2002).

Key Point: Bowel Function

- Bowel incontinence is frequently unpredictable and is not associated with the attainment of urinary continence.

Cauda equina tumor

Lipomeningocele and Other Spinal Dysraphisms

Diagnosis

There is a group of congenital defects that affect the formation of the spinal column but do not result in an open vertebral canal (James and Lassman, 1972) (Table 128–4). They occur once in 4000 live births, but with the ease of MRI screening of children with suspected lesions the incidence of these defects is increasing (Bruce and Schut, 1979). In a recent study the incidence of lipomeningocele in families was calculated to be 0.043% (Sebold et al, 2005). These lesions can be very subtle and have no obvious outward signs, but in more than 90% of children there is a cutaneous abnormality overlying the lower spine (Anderson, 1975; Pierre-Kahn et al, 1997). This varies from a small dimple or skin tag to a tuft of hair, a dermal vascular malformation, a very noticeable subcutaneous lipoma, or an asymmetrically curving gluteal cleft (Fig. 128–12). In addition, on careful inspection of the legs, one may note a high arched foot or feet; hammer toes or claw toes; a discrepancy in muscle size, shortness, and decreased strength in one leg compared with the other, typically at the ankle; and/or a gait abnormality, especially in older children (Dubrowitz et al, 1965; Weissert et al, 1989; Jindal and Mahaptra, 2000). Absent perineal sensation, back pain, and secondary incontinence after a period of dryness are common symptoms in older children and young adults (Linder et al, 1982; Yip et al, 1985; Weissert et al, 1989). Lower urinary tract function is abnormal in 40% to 90% of affected older individuals, with the incidence of an abnormality increasing proportionately with age (Mandell et al, 1980; Koyangi et al, 1997; Pierre-Kahn et al, 1997; Sarica et al, 2003). The child may experience difficulty with toilet training, urinary incontinence after an initial period of dryness once toilet trained (especially during the pubertal growth spurt), recurrent urinary infection, and/or fecal soiling. Occasionally, some patients without an obvious back lesion escape detection until they develop urinary (66%) or lower extremity (19%) symptoms or back pain (14%) after puberty caused by delayed traction on the spinal cord (Satar et al, 1995).

Findings

When these children are evaluated in the neonatal period or early infancy, **a majority have a perfectly normal neurologic examination** (Atala et al, 1992). Urodynamic testing, however, reveals abnormal lower urinary tract function in about one third of infants younger than 18 months of age (Keating et al, 1988) (Fig. 128–13). Such studies may provide the only evidence of a neurologic injury involving the lower spinal cord (Keating et al, 1988; Foster et al, 1990; Atala et al, 1992, Satar et al, 1997; Nogueira et al, 2004). When present, the most likely abnormality is an upper motor neuron lesion characterized by an overactive

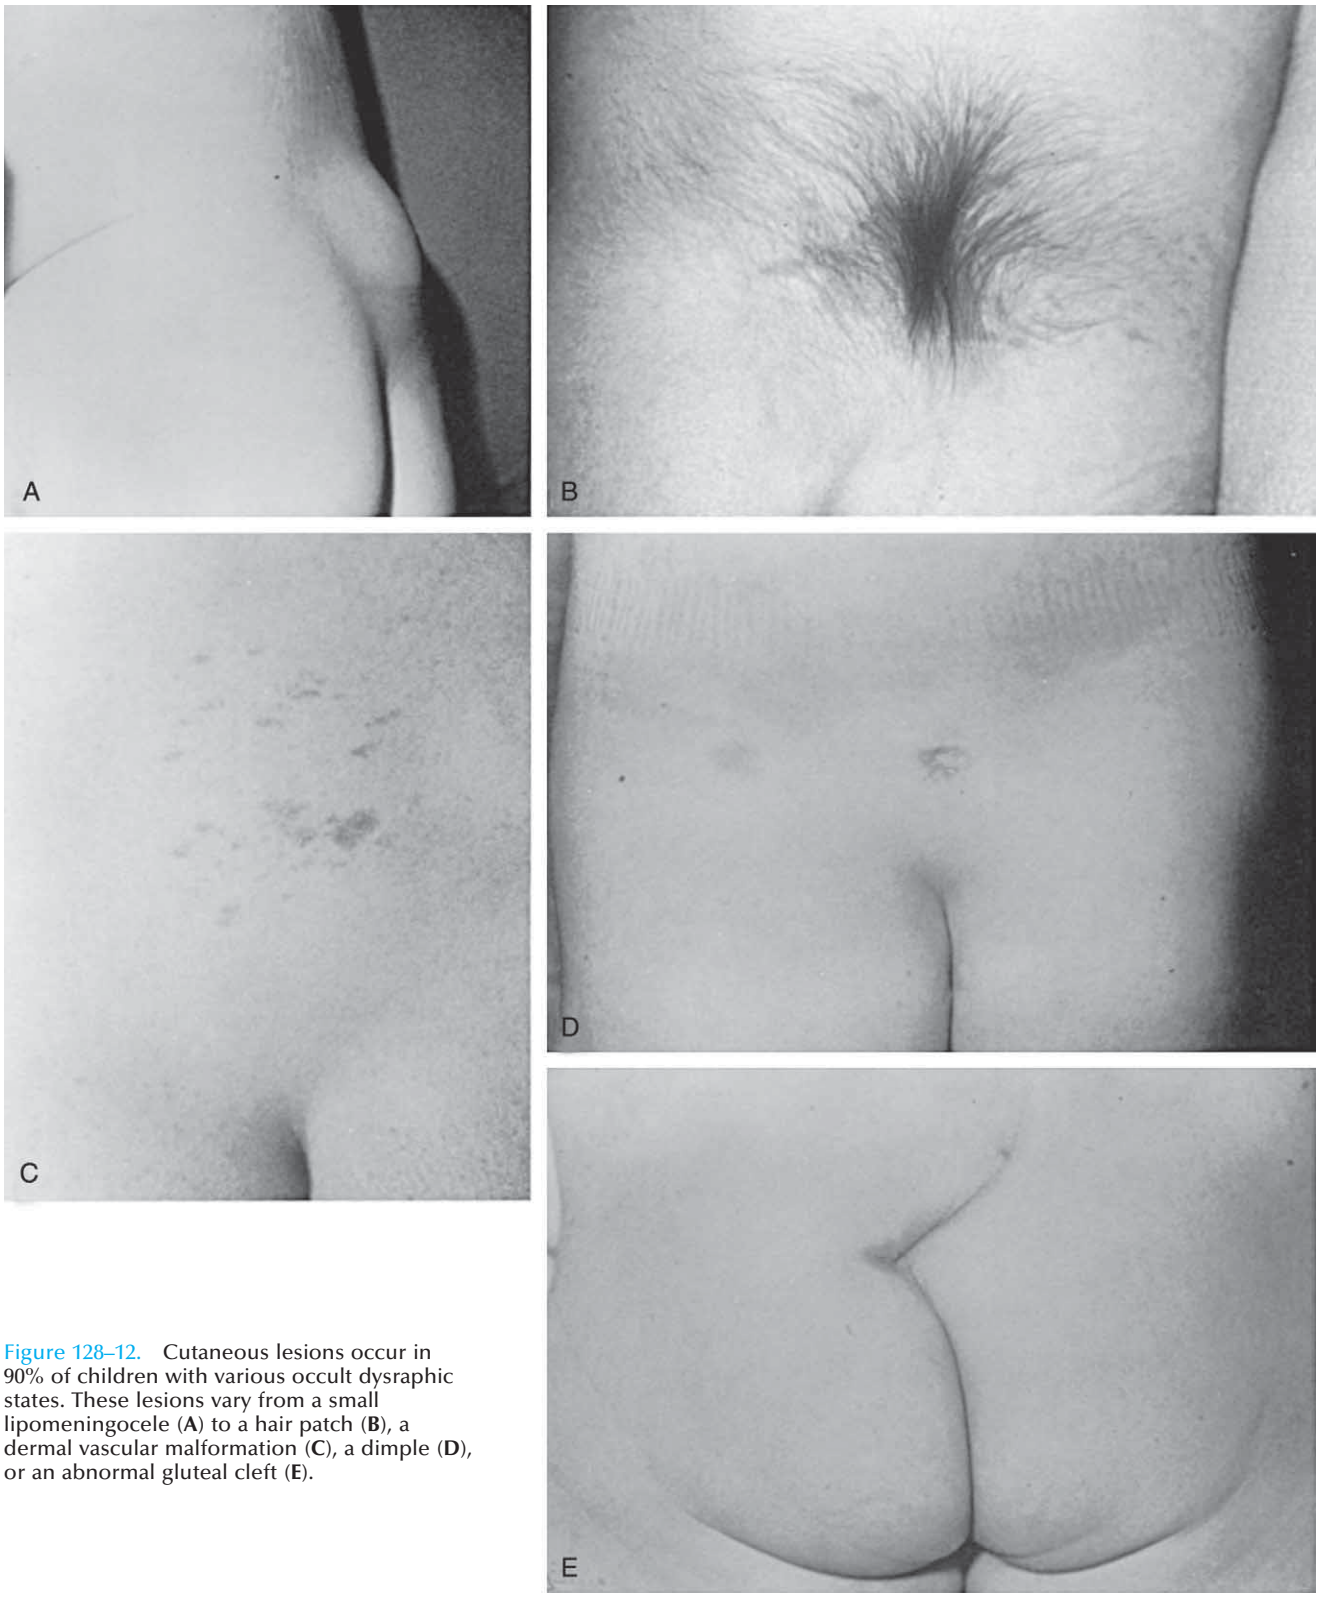

Figure 128–12. Cutaneous lesions occur in 90% of children with various occult dysraphic states. These lesions vary from a small lipomeningocele (**A**) to a hair patch (**B**), a dermal vascular malformation (**C**), a dimple (**D**), or an abnormal gluteal cleft (**E**).

detrusor and/or hyperactive sacral spinal cord reflexes (Fone et al, 1997; Pierre-Kahn et al, 1997); mild forms of DSD are rarely noted. Lower motor neuron signs with denervation potentials in the sphincter or an acontractile detrusor occur in only 10% of young children.

In contrast, practically all individuals older than 3 years of age who have not been operated on or in whom an occult dysraphism has been belatedly diagnosed have either an upper or lower motor neuron lesion or a combination thereof on urodynamic testing (92%) (see Fig. 128–13) or neurologic signs of lower extremity dysfunction (Yip et al, 1985; Kondo et al, 1986; Keating et al, 1988; Atala et al, 1992; Satar et al, 1997; Nogueira et al, 2004). When such children were observed expectantly from infancy after the diagnosis was

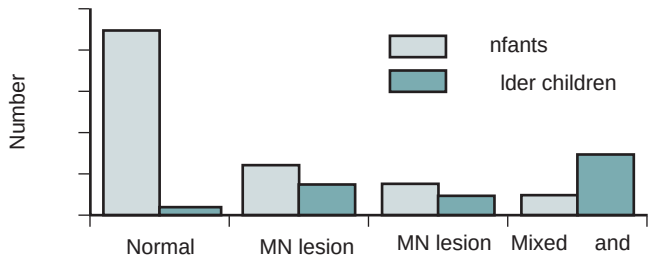

Figure 128–13. Most neonates with an occult spinal dysraphism have normal lower urinary tract function, whereas older children tend to have both upper motor neuron (UMN) and lower motor neuron (LMN) lesions.

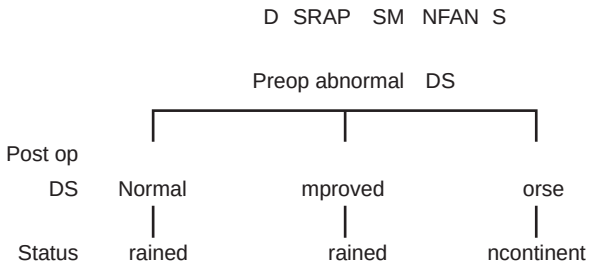

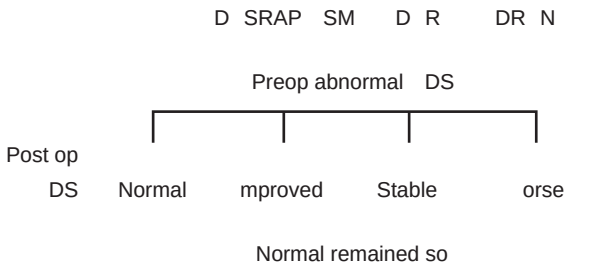

Figure 128–14. The potential for recoverable function is greatest in infants (6 of 10, 60%) and less so in older children (3 of 11, 27%). The risk of damage to neural tissue at the time of exploration to those with normal function is small (2 of 19, 11%). UDS, urodynamic study.

Key Points: Lipomeningocele and Other Spinal Dysraphisms

- There is a group of congenital defects that affect the formation of the spinal column but do not result in an open vertebral canal.
- Practically all individuals older than 3 years of age who have not been operated on or in whom an occult dysraphism has been belatedly diagnosed have either an upper or lower motor neuron lesion or a combination thereof.
- A majority of infants have a perfectly normal neurologic examination.
- Early detection and early intervention can both reverse or at least stabilize the progression of the lesion; this does not happen in older children.

made, 58% experienced deterioration of their disorder within 2 years (Andar et al, 1997; Cornette et al, 1998). There does not seem to be a preponderance of one type of lesion over another (i.e., upper vs. lower motor neuron); and often the child shows signs of both (Hellstrom et al, 1986; Kondo et al, 1986). In one study of children older than 3 years of age, 43% had denervation in the sphincter and 52% detrusor areflexia, with a total of 81% having an abnormality (Satar et al, 1995).

Pathogenesis

Various occult spinal dysraphic lesions produce different neurourologic findings. When they do cause an abnormality, lipomas of the cauda equina invariably cause an upper motor neuron lesion (70%), alone or in combination with a lower motor neuron deficit (30%) (Satar et al, 1997). The split cord syndrome results in an isolated upper or lower motor neuron lesion in 25% each or a combined lesion in 50% (Proctor et al, 2000).

The reason for this difference in neurologic findings may be related to (1) compression on the cauda equina or sacral nerve roots by an expanding lipoma or lipomeningocele (Yamada et al, 1983), **(2) tension on the spinal cord from tethering secondary to differential growth rates in the bony vertebrae and neural elements while the lower end of the cord is held in place by the lipmoa or by a thickened filum terminale** (Dubrowitz et al, 1965), **or (3) fixation of the split lumbosacral cord by an intravertebral bony spicule or fibrous band** (Pang, 1992; Pang et al, 1992; Andar et al, 1997). The overt stretching that invariably occurs when there is a forcible flexion and/or extension of the spinal cord with normal movement leads to changes in oxidation/reduction of cytochrome oxidase, most notably in the lumbosacral spinal neurons when there is no intraspinal pathologic process (Yamada et al, 2004; Henderson et al, 2005). Under normal circumstances the conus medullaris ends just below the L2 vertebra at birth and recedes upward to T12 by adulthood (Barson, 1970). When the cord does not "rise" or is fixed in place owing to one of these lesions, ischemic injury may ensue (Yamada et al, 1981, 2004). Correcting the lesion in infancy has resulted not only in stabilization but also in improvement in the neurologic picture in many instances (Koyangi et al, 1997, Cornette et al, 1998; Proctor et al, 2000) (Fig. 128–14). Sixty percent of infants with abnormal urodynamic findings preoperatively revert to normal postoperatively, with improvement noted in 30%; 10% become worse with time. In older children there is a less dramatic change after surgery, with only 27% becoming normal, 27% improving, 27% stabilizing, but 19% actually becoming worse with time (see Fig. 128–14) (Keating et al, 1988; Satar et al, 1997). Older children with an overactive detrusor tend to improve, whereas those with acontractile bladders do not (Hellstrom et al, 1986; Kondo et al, 1986; Flanigan et al, 1989). Finally, 5% to 27% of children operated on in early childhood develop secondary tethering when observed for several years, suggesting that early surgery has both beneficial and sustaining effects in patients with this condition (Pierre-Kahn et al, 1997; Satar et al, 1997; Proctor et al, 2000).

As a result of these findings, it is apparent that urodynamic testing may be the only way to document that an occult spinal dysraphism is actually affecting lower spinal cord function (Keating et al, 1988; Khoury et al, 1990; Sarica et al, 2003). The serial use of electromyography of the external urethral sphincter using a needle electrode to monitor individual motor unit action potentials provides a precise mechanism for measuring changes in innervation that may occur over time. Some investigators have

shown that posterior tibial somatosensory evoked potentials are an even more sensitive indicator of tethering and should be an integral part of the urodynamic evaluation (Roy et al, 1986). The implication of these findings lies in the fact that **early detection and early intervention can either reverse or at least stabilize the progression of the lesion, which does not happen in older children** (Yamada et al, 1983; Tami et al, 1987; Kaplan et al, 1988) and offers a degree of protection from subsequent tethering (Pierre-Kahn et al, 1997; Satar et al, 1997; Proctor et al, 2000), which seems to be a frequent occurrence when the lesion is not dealt with expeditiously in infancy (Chapman, 1982; Seeds and Jones, 1986).

Recommendations

In addition to MRI studies (Tracey and Hanigan, 1990), urodynamic testing including EMG of the external urethral sphincter should be performed in every child who has a questionable cutaneous or bony abnormality of the lower spine, especially if there is a radiologic abnormality of the spinal cord (Packer et al, 1986; Campobasso et al, 1988; Hall et al, 1988; Meyrat et al, 2003). This test provides the most accurate measure of sacral spinal cord function at diagnosis and provides a basis for comparison with subsequent studies when the children are either operated on or carefully observed. **In children younger than 3 months of age the vertebral bones have not ossified; thus a window of opportunity exists for ultrasonography to be a useful screening tool in visualizing the spinal canal** (Fig. 128–15) (Raghavendra et al, 1983; Scheible et al, 1983). **At this age there is good correlation between the ultrasound imaging and MRI findings; however, if a spinal cord abnormality is identified the latter provides for a better definition of the spinal cord lesion. Consequently, ultrasonography should not be used as the definitive imaging modality** (Hughes et al, 2003). Older children with an occult spinal cord lesion may have urologic symptoms in 20% of cases (Hsieh et al, 2006), and 50% to 60% may have abnormal urodynamic findings preoperatively (Geurra et al, 2006). Resolution of the abnormal urodynamic parameters is noted in 50% to 60% of cases after detethering (Hseih et al, 2006; Geurra et al, 2006). Therefore, urodynamic study is recommended for all children with an occult spinal dysraphism before and after spinal cord detethering procedures.

In the past, most of these conditions were treated by excising the superficial skin lesion, without dissecting further into the spinal canal to remove or repair the entire abnormality. Currently, most neurosurgeons advocate laminectomy and removal of the intraspinal process as completely as possible without injuring the nerve roots or cord to release the tether and prevent further injury with subsequent growth (Linder et al, 1982; Kondo et al, 1986; Kaplan et al, 1988; Foster et al, 1990; Atala et al, 1992; Pierre-Kahn et al, 1997; Proctor et al, 2000; Jindal and Mahapatra, 2000; Nogueira et al, 2004).

Sacral Agenesis

Sacral agenesis has been defined as the absence of part or all of two or more lower vertebral bodies. The cause of this condition is still uncertain, but teratogenic factors may play a role, because insulin-dependent diabetic mothers have a 1% chance of giving birth to a child with this disorder. Conversely, 16% or more of children with sacral agenesis have a mother who is insulin dependent with diabetes mellitus (Passarge and Lenz, 1966; Guzman et al, 1983; Wilmshurst et al, 1999). Often the mothers have only gestational insulin-dependent diabetes. The

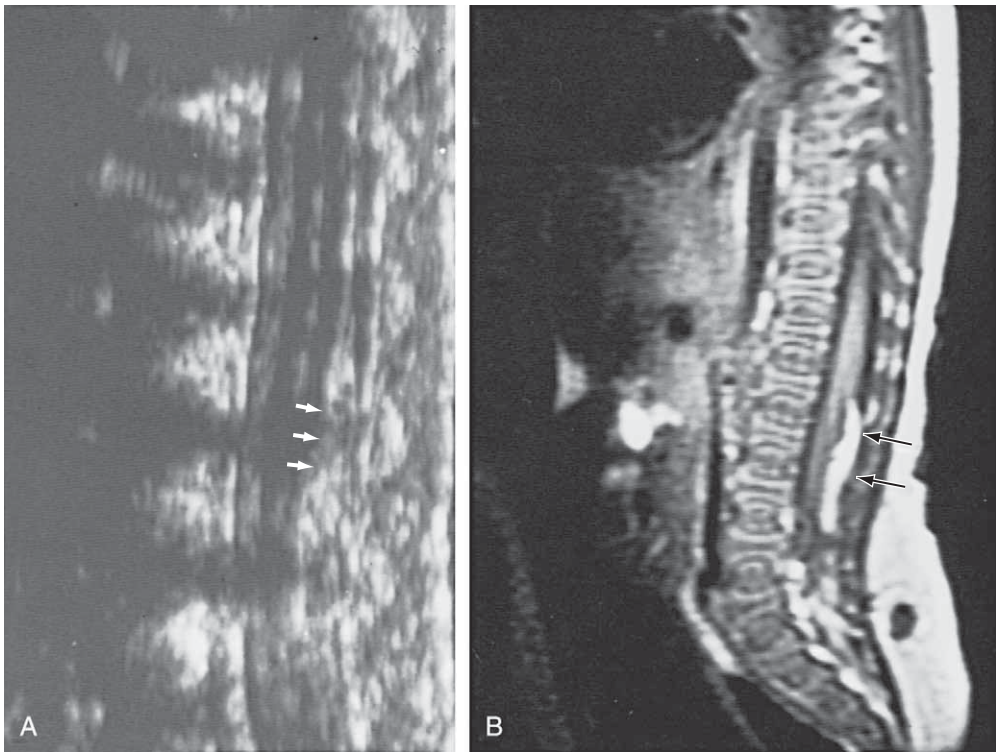

Figure 128–15. **A,** During the first few months of life, ultrasonography can clearly demonstrate intravertebral anatomy because the posterior arches have not completely ossified. Note that the spinal cord along with its central canal is displaced anteriorly *(white arrows)* beginning at L3 because of an intradural lipoma. **B,** The MR image is juxtaposed to confirm the ultrasound findings. The longitudinal white intraspinal mass *(black arrows)* is the lipoma; the longitudinal gray mass is the spinal cord.

disease has been reproduced in chicks by exposing embryos to insulin (Landauer, 1945; White and Klauber, 1976). Maternal insulin-antibody complexes have been noted to cross the placenta, and their concentration in the fetal circulation is directly correlated with macrosomia (Menon et al, 1990). It is possible that a similar cause-and-effect phenomenon occurs in sacral agenesis. There is evidence that a deletion of the seventh chromosome (7q36) leading to the absence of a transcription factor may be responsible for this anomaly (Papapetrou et al, 1999). In addition, maternal drug exposure (i.e., minoxidil) has been reported to cause sacral agenesis (Rojansky et al, 2002).

In familial cases of sacral agenesis associated with the Currarino syndrome (presacral mass, sacral agenesis, and anorectal malformation), deletions in chromosome 7 (7q) resulting in *HLXB9* genetic mutations have been found (Ross et al, 1998). A mutation in *HLXB9,* a homeodomain gene of a 403 amino acid protein that appears to be responsible for neural plate infolding, has been identified in 20 of 21 patients with familial cases and in 2 of 7 sporadic cases of Currarino syndrome (Hagan et al, 2000; Kochling et al, 2001). Heterozygote carriers within these families have also been identified (Lynch et al, 2000). Thus, sacral agenesis may represent one point on a spectrum of abnormalities that encompass sacral meningoceles and anorectal malformations (Bernbeck et al, 2004).

Diagnosis

The presentation is bimodal, with more than three fourths of the disorders being detected in early infancy and the remainder discovered between 4 and 5 years of age (Wilmshurst et al, 1999). With the increased use of prenatal ultrasonography, it is being diagnosed with increased frequency before birth. Sacral vertebral bony ossification begins at 15 weeks, so it is possible to detect the lesion after 18 weeks of gestation on an ultrasound examination and then to confirm it by fetal MRI (De Biasio et al, 2003). When not detected prenatally or at birth, the diagnosis is often delayed until failed attempts at toilet training bring the child to the attention of a physician. Sensation, including that in the perianal dermatomes, is usually intact, and lower extremity function is normal (Koff and DeRidder, 1977; Jakobson et al, 1985; Capitanucci et al, 1997). Because these children have normal sensation and little or no orthopedic deformity in the lower extremities (although high arched feet or claw toes or hammer toes may be present), the underlying lesion is often overlooked. In fact, 20% escape detection until the age of 3 or 4 years (Guzman et al, 1983). The only clue, besides a high index of suspicion, is flattened buttocks and a low, short gluteal cleft (Bauer, 1990) (Fig. 128–16). Palpation of the coccyx is helpful in detecting the absent vertebrae (White and Klauber, 1976). The diagnosis is most easily confirmed with a lateral film of the lower spine, because this area is often obscured by the overlying gas pattern on an anteroposterior projection (White and Klauber, 1976; Guzman et al, 1983) (Fig. 128–17). MRI has been used to visualize the spinal cord in these cases; its imaging reveals a sharp cutoff of the conus at T12 as a consistent finding (Pang, 1993; Diel et al, 2001) (Fig. 128–18).

Findings

On urodynamic evaluation an almost equal number of individuals manifest either an upper or a lower motor neuron lesion (35% vs. 40%, respectively); 25% have no sign of denervation (Guzman et al, 1983; Boemers et al, 1994). The number of affected vertebrae does not seem to correlate with the type of motor neuron lesion present (Boemers et al, 1994) (Fig. 128–19). The injury appears to be stable and rarely shows signs of progressive denervation as the child grows. Sacral sensation is relatively spared, even in the presence of extensive sacral motor deficits (Boemers et al, 1994; Schlussel et al, 1994). Urinary tract infection may be detected in 75% of children over time, with vesicoureteral reflux diagnosed in 37%. Reflux is most likely to occur in those with an upper (75%) (irrespective of whether they have synergy or dyssynergy) versus a lower (40%) motor neuron lesion (Schlussel et al, 1994; Wilmshurst et al, 1999).

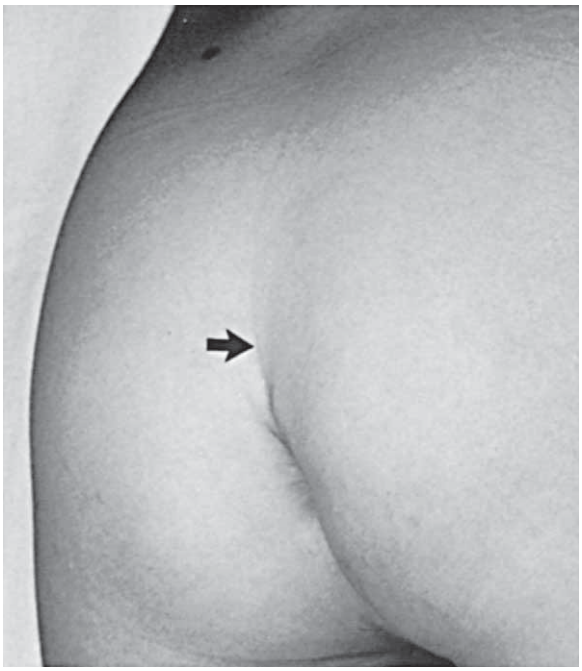

Figure 128–16. Characteristically, in sacral agenesis the gluteal crease is short and is seen only inferiorly *(below arrow)* because of the flattened buttocks.

Key Points: Sacral Agenesis

- Sacral agenesis has been defined as the absence of part or all of two or more lower vertebral bodies.
- On urodynamic evaluation an almost equal number of individuals manifest either an upper or a lower motor neuron lesion (35% vs. 40%, respectively); 25% have no sign of any denervation.
- Management depends on the specific type of neurourologic dysfunction seen on urodynamic testing.

Recommendations

Because most children who are diagnosed with this condition have a neurologic deficit, urodynamic testing is mandatory at the time of diagnosis. **Renal ultrasonography and nuclear or conventional cystography should be included as part of the evaluation process, especially if the child has a history of urinary tract infection or findings of an upper motor neuron lesion on urodynamic testing.** Additional imaging studies may be required based on the child's history and findings from baseline studies.

Management depends on the specific type of neurourologic dysfunction seen on urodynamic testing. Anticholinergic agents should be given to children with upper motor neuron findings of detrusor overactivity, whereas CIC and

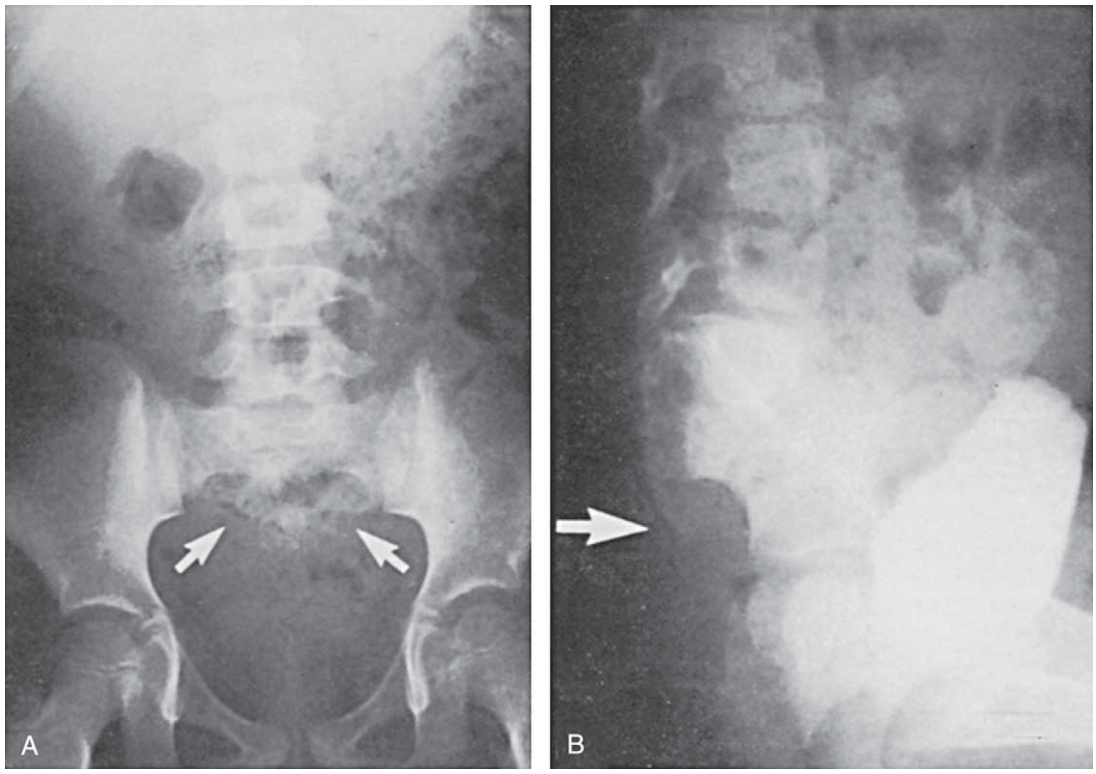

Figure 128–17. The diagnosis of partial or complete sacral agenesis *(arrows)* is easily confirmed on an anteroposterior (**A**) or lateral (**B**) radiograph of the spine if bowel gas obscures the sacral area. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, editor. Urologic surgery in neonates and young infants. Philadelphia: WB Saunders; 1988. p. 283–310.)

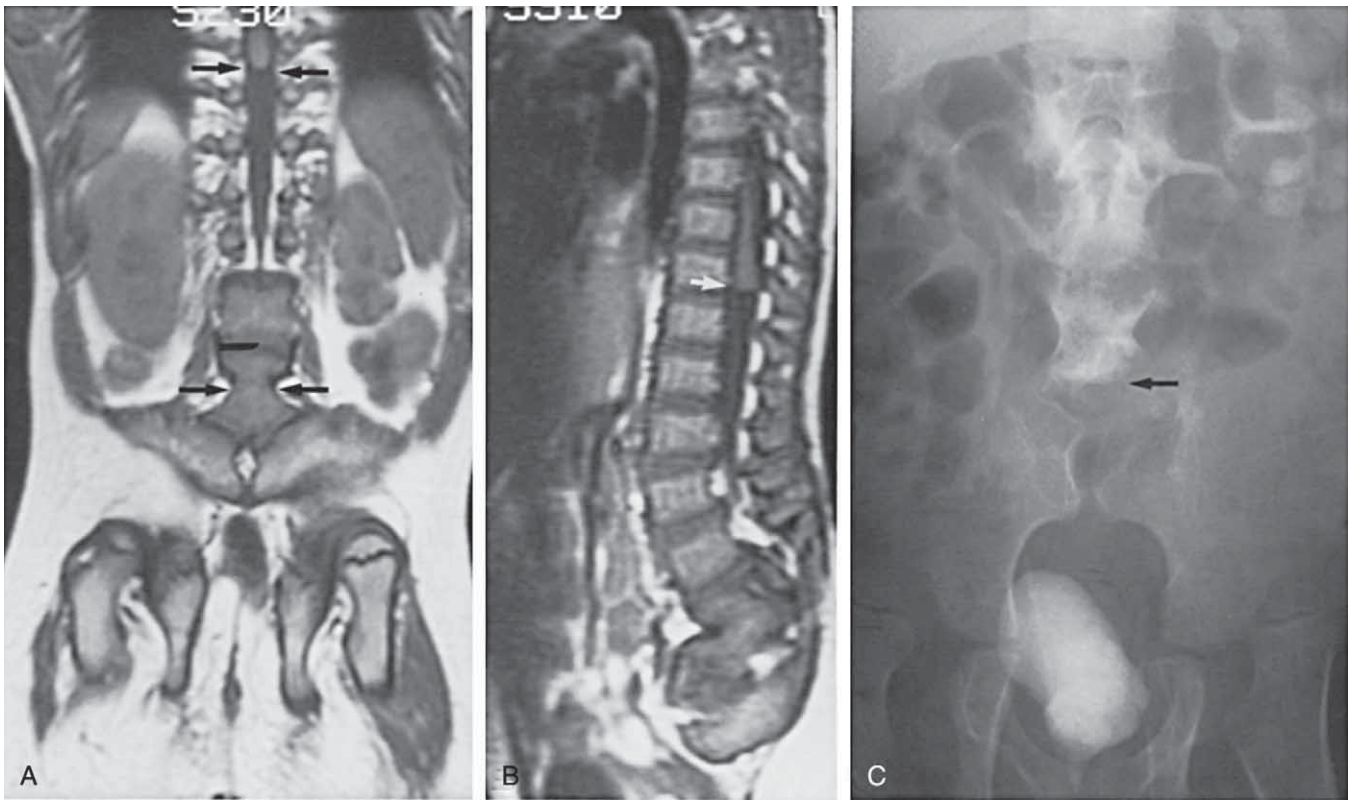

Figure 128–18. Coronal (**A**) and sagittal (**B**) MR images in a 10-year-old boy with sacral agenesis beginning at L5. Note the squared lower limit of the cord adjacent to T11 (**A,** *upper arrows;* **B,** *white arrow*) and the two sacroiliac joints (**A,** *lower arrows*), which are in the midline because of absence of the sacrum. **C,** An anteroposterior radiograph from an excretory urogram shows no vertebral bodies below L4 *(arrow)*.

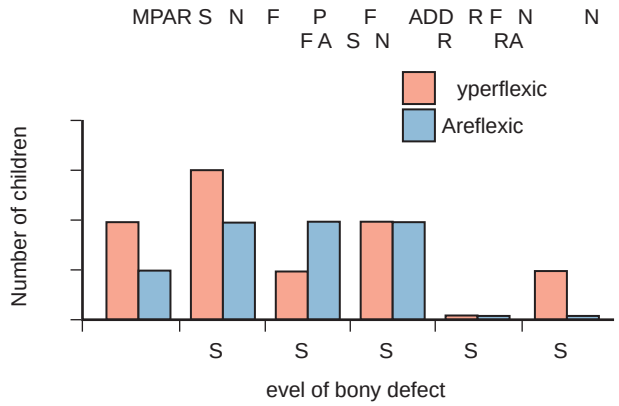

Figure 128–19. Bladder contractility is unrelated to the number of absent vertebrae. (From Bauer SB. Early evaluation and management of children with spina bifida. In: King LR, editor. Urologic surgery in neonates and young infants. Philadelphia: WB Saunders; 1988. p. 283–310.)

α-sympathomimetic medications may have to be given to individuals with lower motor neuron deficits who cannot empty their bladders or stay dry between catheterizations. When anticholinergic medication is ineffective in controlling the overactive detrusor, augmentation cystoplasty may be required to attain an adequate organ for urinary storage. Failure of α-sympathomimetic agents may require either endoscopic injection of bulking agents or even artificial urinary sphincter implantation to increase bladder outlet resistance. The bowels manifest a similar picture of dysfunction and need as much characterization and treatment as the lower urinary tract. Anorectal manometry has identified abnormalities in the internal anal sphincter and in voluntary anal sphincter squeeze pressure, leading to weakness of the muscle and concomitant fecal incontinence (Morera and Nurko, 2003). It is important to identify these individuals as early as possible so that they can become continent and out of diapers at an appropriate age, thus avoiding the social stigma of fecal or urinary incontinence.

Imperforate Anus

Imperforate anus is a condition that can occur alone or as part of a constellation of anomalies that have been called the VATER or VACTERL syndrome (Barry and Auldist, 1974). This mnemonic denotes all the regions or structures that can possibly be affected (*v*ertebral, *a*nal, *c*ardiac, *t*racheo-*e*sophageal fistula, *r*enal, *l*imb). The incidence of anorectal malformations varies between 1 in 4000 to 1 in 5000 live births (Templeton and O'Neill, 1986). There is a male predominance of 1.5:1. The majority of female patients have low lesions, whereas males tend to have high ones (Santulli et al, 1971). Several classification systems have been devised, but the most commonly used one is the Wingspread Workshop on Anorectal Malformations (Table 128–5) (Shaul and Harrison, 1997). This format attempts to divide the lesions into high, intermediate, or low, depending on whether the rectum ends above, at, or below the levator ani muscle, respectively. The relative incidence for the various levels of the defect is 36% high, 14% intermediate, 47% low, and 1% a cloacal lesion. Imperforate anus may be part of a spectrum of hindgut abnormalities that include sacral agenesis and even a presacral mass or meningocele recently labeled as Currarino syndrome (Currarino et al, 1981; Hagan et al, 2000), which has genetic implications (Ross et al, 1998).

Table 128–5.
Wingspread Classification of Anorectal Malformations

	FEMALE	MALE
High	Anorectal agenesis With rectovaginal fistula Without fistula Rectal atresia	Anorectal agenesis With rectourethral (prostatic) fistula Without fistula Rectal atresia
Intermediate	Rectovestibular fistula Rectovaginal fistula Anal agenesis without fistula	Rectovestibular urethral fistula Anal agenesis without fistula
Low	Anovestibular fistula Anocutaneous fistula Anal stenosis Cloacal malformation Rare malformation	Anocutaneous fistula Anal stenosis Rare malformation

Associated Findings

A fistulous communication with the lower urinary tract is a common occurrence, related in part to the sex of the child and the extent of the lesion: 87% of male and 79% of female infants with a high or intermediate lesion have a connection, whereas 7% of male and 10% of female children with a low lesion have such a communication (Templeton and O'Neill, 1986; Holschneider et al, 1994). Urinary tract abnormalities have been noted in 26% to 52% of affected children, with renal agenesis (primarily left-sided) and vesicoureteral reflux as the most common associated findings (Parrott, 1985). Again, the highest incidence of an abnormality is in those children with a high (70%) versus a low (infralevator) (35%) lesion (Shaul and Harrison, 1997; Emir and Soylet, 1998), with boys more prone than girls to having an anomaly (50% vs. 29%) (Metts et al, 1997). Spinal bony abnormalities range in incidence from 30% to 44%, but patients with a high lesion are more likely to be affected (48% to 54%) than those with a low lesion (15% to 27%) (Carson et al, 1984; Tsakayannis and Shamberger, 1995; Long et al, 1996). Spinal cord abnormalities including a tethered cord, thickened or fatty filum terminale, and a lipoma have been noted in 18% to 50% of patients, with the incidence varying proportionately in relation to the height of the rectal lesion (Shaul and Harrison, 1997). **Not all patients with a spinal cord abnormality have a bony defect, so intraspinal imaging is mandatory to ensure the presence of a normal spinal cord, especially in cases of high lesions** (Rivosecchi et al, 1995). On occasion, an abnormal spinal cord can be found in patients even without one of these commonly associated other anomalies. Neurogenic bladder dysfunction is a frequent finding (Kakizaki et al, 1994), usually manifesting as incontinence, but its occurrence is rare when no spinal cord malformation exists (Hulthen de Medina et al, 2004) (Fig. 128–20). It often manifests when the child is older and the parents have difficulty with toilet training. It is not certain whether the dysfunction is caused by a spinal cord defect or by trauma to the nerves supplying the lower urinary tract or the pelvic floor musculature occasioned during surgery to repair the spinal cord or rectal defect (Parrott and Woodard, 1979). With the advent of the Peña posterior sagittal midline approach, the latter etiology is less likely (Peña, 1986; Boemers et al, 1994). Despite careful dissection

Figure 128–20. **A** and **B,** A 1-year-old girl with an imperforate anus and bony vertebral abnormalities has a tethered cord and bilateral hydronephrosis on MRI. **C,** Voiding cystourethrogram reveals significant trabeculation and reflux on the left. **D,** Excretory urogram demonstrates bilateral hydronephrosis secondary to the reflux on the left and a ureterovesical junction obstruction on the right. Subsequent urodynamic study revealed poor detrusor compliance and dyssynergy.

techniques, 37% still have long-term problems with fecal incontinence (Peña and Hong, 2000).

Neonatal Assessment

Initial evaluation in the neonatal period should include a careful inspection of the perineum looking for a fistulous site from the bowel, an examination of the upper and lower extremities, and an assessment of the spine and spinal cord (Carson et al, 1984; Mosiello et al, 2003). A prone cross-table lateral image with the child held in that position for 3 minutes and a radiopaque marker placed on the perineum will help delineate the distance from the end of the rectum to the skin in order to classify the extent of the rectal defect. Gas, meconium, or a gram-negative infection in the urine strongly suggests a rectal/urinary tract fistula, which then necessitates a divided colostomy very early in the postnatal period. Once the child is stable clinically, radiologic investigation of the urinary tract is begun, first with renal ultrasonography and then with VCUG, to define the presence of an abnormality and discover any clues for possible neurogenic bladder dysfunction.

Vertebral bony anomalies, especially sacral level lesions, often signify an underlying spinal cord abnormality (Boemers et al, 1996). Thus any bony abnormality warrants ultrasonography of the spine if the child is younger than 3 months of age because the vertebral bodies have not ossified and a spinal MRI to rule out any abnormal intraspinal process (see Fig. 128–20) (Barnes et al, 1986; Tunell et al, 1987; Emir and Soylet 1998; Karrer et al, 1988; Mosiello et al, 2003). Urodynamic studies including sphincter electromyography are reserved for those children with either a bony abnormality of the spine, a spinal cord defect, or the telltale signs of dysfunction on VCUG or renal ultrasonography (Taskinen et al, 2002; Mosiello et al, 2003). These studies should be conducted early in infancy before the child has had any definitive surgery for the imperforate anus and again after a pull-through operation has been performed on the rectum to determine, respectively, the true incidence of neurogenic bladder dysfunction and any changes that might have occurred as a result of the surgery. The presence of an abnormality on urodynamic testing in early infancy may warrant either intervention at that time to correct a spinal cord defect or watchful waiting to determine whether the lesion is progressive. Urodynamic studies are repeated subsequently or performed for the first time if secondary urinary or fecal incontinence ensues (Taskinen et al, 2002).

The most common finding on urodynamic testing is an upper motor neuron lesion with an overactive detrusor and/or DSD (Boemers et al, 1994; Taskinen et al, 2002), but a lower motor neuron lesion with an acontractile detrusor and a denervated sphincter may be seen as well (see Fig. 128–20) (Greenfield and Fera, 1991; Taskinen et al, 2002). EMG assessment of the perianal musculature at this time helps determine the exact location of the future anus. In addition, it can provide precise information about the innervation to the levator ani muscle and its competence to function as a sphincter. The posterior midline approach espoused by Peña (1986) minimizes the chances of injuring the pelvic nerves that innervate the pelvic floor muscles and therefore reduces the risk of an iatrogenic cause for neurogenic bladder dysfunction.

CENTRAL NERVOUS SYSTEM INSULTS

Cerebral Palsy

Pathogenesis

Cerebral palsy is a nonprogressive injury of the brain occurring in the perinatal period that results in either a neuromuscular disability, a specific symptom complex, or cerebral dysfunction (Kuban and Leviton, 1994). Its incidence is approximately 1.5 per 1000 births, but the incidence is increasing as smaller and younger premature infants survive in intensive care units (Kuban and Leviton, 1994). The condition is usually caused by a perinatal infection (e.g., sepsis, meningoencephalitis) or by a period of anoxia (or hypoxia) that affects the CNS (Nelson and Ellenberg, 1986; Naeye et al, 1989). It most commonly appears in infants who were premature, weighed less than 2 kg at birth, had intraventricular hemorrhage, and received mechanical ventilation for a prolonged time in the postnatal period and in premature infants weighing more than 2 kg who experienced a neonatal seizure (Kim et al, 1999). Maternal urinary infection in the later stages of pregnancy increases the risk of having an affected child by four to five times (Polivka et al, 1997).

Diagnosis

Affected children have delayed gross motor development, abnormal fine motor performance, altered muscle tone, abnormal stress gait, and exaggerated deep tendon reflexes. These findings can vary substantially, from obvious to very subtle when no discernible lesion is present, unless a careful neurologic examination is performed. These abnormalities may not manifest in the postnatal period, but they do become evident over time, because myelination of axons and maturation of neurons in the basal ganglia are required before spasticity, dystonia, and athetosis become apparent (Kyllerman et al, 1982). The lesions are classified according to which extremities are involved (monoplegia, hemiplegia, diplegia, and quadriplegia) and what kind of neurologic dysfunction is present (spastic, hypotonic, dystonic, athetotic, or a combination thereof). Among the more overtly affected individuals, spastic diplegia is the most common of the five types of dysfunction that characterize this disease, accounting for almost two thirds of the cases (Kuban and Leviton, 1994).

Findings

Most children with cerebral palsy develop total urinary control. Incontinence is a feature in some, but the exact incidence has never been truly determined (McNeal et al, 1983; Decter et al, 1987). In a recent survey of questionnaires sent to over 600 families with an affected child aged 4 to 18 years, 23.5% had persistent urinary incontinence (Roijen et al, 2001). When urinary continence was achieved, its development was delayed when compared with normal children of similar age. With further analysis of the data, 80% of children with spastic diplegia, 54% with tetraplegia, and 38% with low intellectual capacity attained continence. The presence of incontinence is often related to the extent of the physical impairment, because the handicap prevents the child from getting to the bathroom on time, causing an episode of wetting (Murphy et al, 1995). A number of children have such a severe degree of mental retardation that they are not trainable. They either do not recognize the need to void or cannot relate this fact to caregivers early enough to be toileted successfully (Roijen et al, 2001). The majority, however, have sufficient intelligence to learn basic societal protocols with patient and persistent handling. When continence is achieved (usually at a later than expected age), diurnal continence is attained first with nocturnal continence occurring within the subsequent year (Roijen et al, 2001). Therefore, urodynamic evaluation is reserved for children who appear to be trainable and do not seem to be hampered too much by their physical impairment but who have not achieved continence by late childhood or early puberty.

In one review (Decter et al, 1987), urodynamic studies were performed in 57 children with cerebral palsy (Table 128–6). **Forty-nine (86%) had the expected picture of a partial upper motor neuron type of dysfunction,** with exaggerated sacral reflexes, an overactive detrusor and/or DSD (Fig. 128–21), even though they manifested voluntary control over voiding. Six (11%) of the 57 had evidence of both upper and lower motor neuron denervation with an acontractile detrusor or abnormal motor unit potentials on sphincter EMG assessment (Table 128–7). Most of the children who exhibited these latter findings were found to have an episode of cyanosis in the perinatal period when their records were analyzed on a retrospective basis (Table 128–8). Therefore, a lower motor neuron lesion may be seen in addition to the expected upper motor neuron dysfunction. Similar findings have been noted subsequently (Mayo, 1992; Reid and Borzyskowski, 1993).

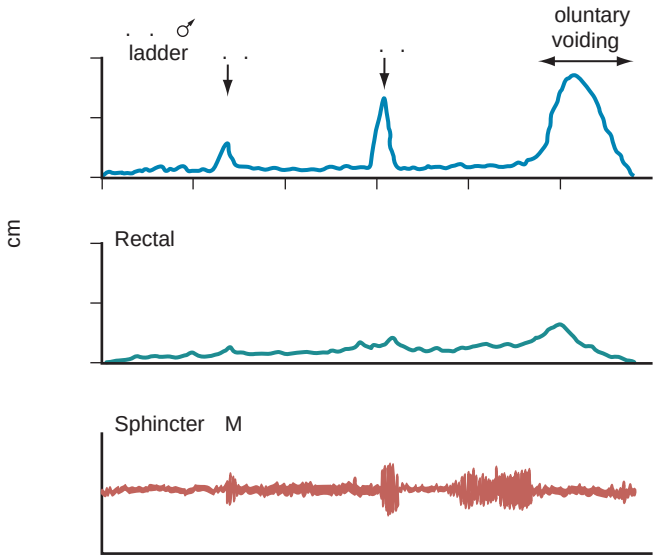

Figure 128–21. Electromyogram (EMG) of an 8-year-old boy with spastic diplegia shows a typical partial upper motor neuron type bladder with uninhibited contractions (U.C.) associated with increased sphincter activity but normal voiding dynamics at capacity. Wetting is caused by these contractions when they are unaccompanied by the heightened sphincter activity.

Table 128–6.

Lower Urinary Tract Function in Cerebral Palsy

TYPE	NO. PATIENTS	%
Upper motor neuron lesion	49	86
Mixed upper + lower motor neuron lesion	5	9.5
Incomplete lower motor neuron lesion	1	1.5
No urodynamic lesion	2	3

In two more recent reviews **of 65 children with cerebral palsy undergoing urodynamic studies** (Bross et al, 2004; Karaman et al, 2005), **abnormal bladder and urethral sphincter function was found in almost all.** In the first study involving 29 (Bross et al, 2004), 23 had incontinence and/or urinary tract infection whereas 6 were asymptomatic; urodynamic studies demonstrated poor compliance in 21 of the 23 symptomatic and 2 of the 6 asymptomatic children, an overactive detrusor in all symptomatic and 5 of 6 asymptomatic children, and high leak point pressure in 16 of 23 and 4 of 6 symptomatic and asymptomatic children, respectively. VCUG revealed bladder trabeculation in 58% and reflux in 9% of symptomatic children, and trabeculation in 50% but no reflux in the asymptomatic children. In the other study (Karaman et al, 2005), 66% had dysfunctional voiding symptoms, including 47.2% with daytime incontinence and 44.4% with difficulty urinating. Neurogenic detrusor overactivity was present in 47.2%, and dyssynergy between the bladder and sphincter was noted in 11%. In a meta-analysis of all published reports of urodynamic findings in children with cerebral palsy, detrusor overactivity was seen in 80%, dyssynergy between the bladder and sphincter in 5%, and normal function in only 12% (Decter et al, 1987; Mayo and Burns, 1990; Reid et al, 1993; Bross et al, 2004; Karaman et al, 2005). From these reports it is apparent that urodynamic studies can be very revealing in all children, whether they have urinary symptoms (Bross et al, 2004), but are especially useful if frequent toileting or initial anticholinergic treatment fails to improve incontinence, the child develops urinary infection, or renal ultrasonography reveals hydronephrosis. Upper urinary tract imaging is usually normal even in children with upper motor neuron lesions (Brodak et al, 1994).

Key Points: Cerebral Palsy

- Cerebral palsy is a nonprogressive injury of the brain occurring in the perinatal period that results in either a neuromuscular disability, a specific symptom complex, or cerebral dysfunction.
- Affected children have delayed gross motor development, abnormal fine motor performance, altered muscle tone, an abnormal stress gait, and exaggerated deep tendon reflexes.
- Most children with cerebral palsy develop total urinary control.
- The presence of incontinence is often related to the extent of the physical impairment; abnormal bladder and urethral sphincter function was found in almost all.
- Treatment usually centers on abolishing the overactive detrusor using anticholinergic medication, but residual urine must be monitored closely to ensure complete evacuation with each void.

Recommendations

Treatment usually centers on abolishing the overactive detrusor using anticholinergic medication, but residual urine must be monitored closely to ensure complete evacuation with each void. CIC may be required for those who cannot empty their bladder. Selective dorsal rhizotomy has improved bladder capacity, reduced the detrusor overactivity, and increased compliance, thus rendering the patient more continent, in a selected group of children who failed to respond to less invasive measures (Houle et al, 1998). The risk of neurourologic deterioration from this procedure is extremely low, with less than 5% developing incontinence if careful mapping of dorsal nerve roots are identified (Huang, 1997; Steinbok and Schrag, 1998; Liu et al, 1999). Upper and lower urinary tract imaging is not recommended unless urinary tract infection has occurred (Reid and Borzyskowski, 1993).

Traumatic Injuries to the Spine

Diagnosis

Despite increased exposure to and the potential for traumatic spinal cord injuries, **such injuries are rarely encountered in children. The incidence in Sweden is 2.6 cases per million children per year** (Augutis and Levi, 2003). **The incidence tends to increase geometrically with age** (Anderson and Schutt, 1980) (Fig. 128–22). When an injury does occur, it is more likely to happen in a male than a female child, and it is usually the result of a motor vehicle or bicycle accident (24% to 52%), a fall from a high place, a gunshot wound, or a diving or sports incident (Cass et al, 1984; Hadley et al, 1988; Decter and Bauer, 1993; Brown et al, 2001; Augutis and Levi 2003; Cirak et al, 2004). The type of causative injuries varies with age, with infants more prone to an injury from a motor vehicle accident (71%), toddlers and children injured secondary to a fall (48% and 34%, respectively) and adolescents having a sports-related event (29%) (Cirak et al, 2004). An injury may also occur iatrogenically after surgery to correct scoliosis, kyphosis, or other intraspinal processes or congenital aortic anomalies or after ligation of a patent ductus arteriosus (Cass et al, 1984; Batista et al, 1995). Neonates are particularly prone to a hyperextension injury during a high forceps delivery (Adams et al, 1988; Lanska et al, 1990). Among younger children, girls are affected as often as boys (Ruge et al, 1988).

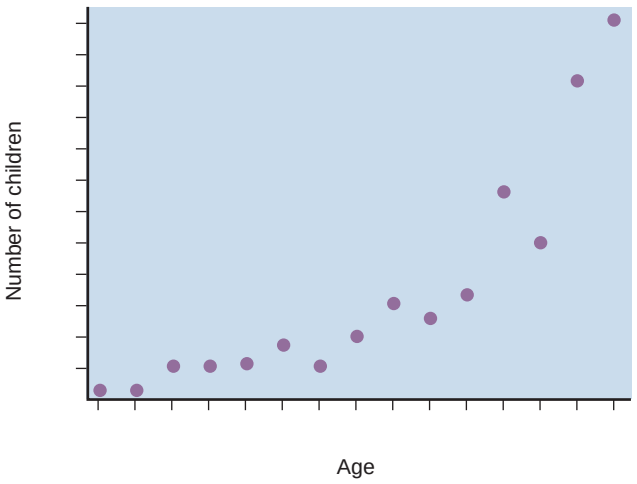

Figure 128–22. Increasing frequency of spinal injury with age. (From Anderson JM, Schutt AH. Spinal injury in children: a review of 156 cases seen from 1958 through 1980. Mayo Clin Proc 1980;55:499–504.)

Pathogenesis

Spinal cord injuries in children are intrinsically different from those in adults because of a variety of factors, including the mechanism of injury and the difference in configuration of the brainstem and spinal cord in children compared with adults. In addition, the horizontal versus vertical orientation of the facet joints in vertebral bodies that predisposes to anteroposterior subluxation in children, the delayed supportive effect of the paraspinous musculature and ligaments, and the relative heaviness of the head, which causes a fulcrum of maximal flexion of the upper cervical region in infants and young children, all contribute to a high degree of hypermobility that places the child's spinal cord at risk for ischemic necrosis (Decter and Bauer, 1993).

Key Points: Traumatic Injuries to the Spine

- The incidence in Sweden is 2.6 cases per million children per year. The incidence increases geometrically with age.
- Spinal cord injuries in children are intrinsically different from those in adults because of a variety of factors, including the mechanism of injury and the difference in configuration of the brainstem and spinal cord in children compared with adults.
- Patients with an upper thoracic or cervical lesion are likely to exhibit autonomic dysreflexia with a spontaneous discharge of α_1-stimulants during bladder filling and with contractions of the detrusor.
- Monitoring of blood pressure and availability of α-antagonists are mandatory during VCUG or urodynamic studies.
- Upper spinal cord injuries produce an upper motor neuron type lesion with an overactive detrusor and DSD. The potential danger from this outflow obstruction is obvious.

Findings

The lower urinary tract dysfunction that ensues is not likely to be an isolated event but is usually associated with loss of sensation and paralysis of the lower limbs. Radiologic investigation of the spine may not reveal any bony abnormality, although momentary subluxation of osseous structures resulting from the elasticity of the vertebral ligaments can result in a neurologic injury (Pollack et al, 1988). This condition has been seen only in children (usually younger than 8 years old) and has been labeled *s*pinal *c*ord *i*njury *w*ith*o*ut *r*adiologic *a*bnormality (SCIWORA) (Pang and Wilberger, 1982; Pang and Pollack, 1989). Overall, SCIWORA can account for up to 38% of spinal cord injuries in children (Brown et al, 2001). Myelography and computed tomography show swelling of the cord below the level of the lesion (Adams et al, 1988; Lanska et al, 1990). **Often, what appears to be a permanent lesion initially turns out to be a transient phenomenon with time.** Although sensation and motor function in the lower extremities may be restored relatively quickly, the dysfunction involving the bladder and rectum may persist considerably longer.

During the acute phase of the injury the bladder is often acontractile and the urethral sphincter nonreactive, although normal-appearing bioelectric potentials can be recorded on sphincter EMG (spinal shock). Over a variable period of time, detrusor

contractility and sphincter reactivity return as spinal cord edema subsides. With this return of function, an overactive detrusor and bladder-sphincter dyssynergy develop if the lateral reticulospinal cord pathways to and from the brainstem have been disrupted. When the lesion affects the cauda equina there is probably little to no return of bladder or urethral sphincter function. Sacral sensation and peripheral reflexes are not good indicators of ultimate lower urinary tract function (Shenot et al, 1998). Over time, the predominant urodynamic pattern in patients with a thoracic-level lesion is an overactive detrusor with DSD, high voiding pressures, eventual hydronephrosis, and vesicoureteral reflux. Often children exhibit a highly compliant bladder for a portion of bladder filling but then have C-fiber–mediated, small, ineffective rhythmic contractions of the detrusor with simultaneous waxing and waning of external urethral sphincter activity. Some urinary leakage may occur with these contractions, but in general the bladder does not empty with them. **Patients with an upper thoracic or cervical lesion are likely to exhibit autonomic dysreflexia with a spontaneous discharge of α_1-stimulants during bladder filling and with contractions of the detrusor. Monitoring of blood pressure and availability of α-antagonists are mandatory during VCUG or urodynamic studies** (Perkash, 1997; Vaidyanathan et al, 1998b).

Management

If urinary retention occurs immediately after the injury, an indwelling Foley catheter is passed into the bladder and left in place for as short a time as possible, until the patient's condition is stable and aseptic intermittent catheterization can be started safely on a regular basis (Guttmann and Frankel, 1966; Barkin et al, 1983). There is no difference in the incidence of urinary infection or in the development of stones in patients using sterile versus clean catheterization techniques to empty the bladder (Prieto-Fingerhut et al, 1997; VanHala et al, 1997). Rates of infection range as high as 60% to 80% (Biering-Sorensen et al, 1999), and stone formation occurs in 1.5% to 3% within the first 5 years after the trauma (Donnellan and Bolton, 1999; McKinley et al, 1999). When the child starts to void again, the timing of catheterization can be regulated so that it is used as a means of measuring the residual urine after a spontaneous void. Residual urine volumes of 25 mL or less are considered safe enough to allow reducing the frequency or even stopping the catheterization program (Barkin et al, 1983). After 4 to 6 weeks, if there is no improvement in lower urinary tract function, urodynamic studies are conducted to determine whether the condition is the result of spinal shock or an actual nerve root or spinal cord injury. An acontractile detrusor is not uncommon under these circumstances (Iwatsubo et al, 1985). On the other hand, EMG recording of the sphincter often reveals normal motor units without fibrillation potentials but absent sacral reflexes and a nonrelaxing sphincter with bladder filling, a sign that transient spinal shock has occurred (Iwatsubo et al, 1985). The outcome of this situation is guarded but good, because most cases resolve completely as edema of the cord in response to the injury subsides, leaving no permanent damage (Iwatsubo et al, 1985; Fanciullacci et al, 1988).

If and when bladder function returns and emptying is incomplete, it has been shown in the cat (Xiao et al, 1999) that peripheral L7 dermatome stimulation initiates a micturition reflex without DSD. In a preliminary study of 15 adults with spinal cord injury, detrusor overactivity, and DSD, the creation of an artificial somatic/CNS/autonomic reflex pathway resulted in satisfactory bladder control in 67% of patients. Follow-up urodynamic study revealed a change to almost normal storage and synergic voiding without DSD (Xiao et al, 2003). A more recent study showed satisfactory bladder control in 75% of patients with complete suprasacral spinal cord injury within 6 to 12 months. However, the mean and median time since the injury was 9 months, so the time from injury may have been a factor in this study (Lin et al, 2009). Incomplete emptying may be enhanced by the judicious use of α-sympatholytic agents (Al-Ali et al, 1999). **The goal is balanced voiding at pressures lower than 40 cm H_2O,** which reduces the 30% risk for urinary tract deterioration seen in poorly managed patients (Giannantoni et al, 1998; Kim et al, 1998). If this cannot be achieved, then CIC is continued. Anticholinergics, either orally or intravesically (Vaidyanathan et al, 1998a; Wein, 1998), or capsaicin (an inhibitor of C-fiber stimulation [Wiart et al, 1998]) have been added and are effective in reducing an overactive detrusor, but at the cost of significant side effects. Alternative treatments that have been effective to ensure complete emptying at low pressure include external urethral sphincterotomy (Kim et al, 1998), urethral stent placement (Chancellor et al, 1999), or injection of botulinum-A toxin into the external sphincter (Schurch et al, 1997, 2000; Kuo, 2003; Tai et al, 2005). In some cases, a continent catheterizable abdominal urinary stoma may be created to facilitate self-catheterization in patients with low cervical or upper thoracic lesions who cannot easily catheterize themselves, in order to minimize the embarrassment of periodic genital organ exposure when care providers need to repeatedly catheterize the bladder (Sylora et al, 1997).

Recommendations

Most permanent traumatic injuries involve either the upper thoracic or the cervical spinal cord but some affect the cauda equina region. The sacral cord injury most likely produces a lower motor neuron deficit of the striated urethral sphincter that usually leads to low pressure bladder emptying with little risk of upper urinary tract deterioration. However, it probably necessitates medical and/or surgical therapy to achieve continence. On the other hand, upper spinal cord injuries produce an upper motor neuron type lesion with an overactive detrusor and DSD. The potential danger from this outflow obstruction is obvious (Donnelly et al, 1972). Substantial residual urine volumes, high-pressure reflux, urinary infections, and their sequelae are the leading causes of long-term morbidity and mortality in patients with spinal cord injury (Giannantoni et al, 1998). Even patients who voluntarily urinate and are continent or who involuntarily but spontaneously void to completion are not immune to urinary tract changes (Decter and Bauer, 1993). Urodynamic studies are imperative to identify which patients are at risk (Barkin et al, 1983). These studies should be performed within 2 to 3 months after the injury, again 6 to 9 months later, and possibly at 2 years after the trauma to determine the stability of lower urinary tract function, the need for continued CIC, and whether adjuvant drug or surgical therapy should be added (or continued) to achieve good long-term success. When these measures are employed judiciously, effective management can be achieved (Pannek et al, 1997). Renal ultrasonography early in the course and VCUG if signs of bladder outlet obstruction are present on urodynamic testing or if recurrent urinary infection ensues are also recommended. Radionuclide cystography is indicated if the patient has repeated urinary tract infection or develops hydronephrosis (Phillips et al, 1997). Because stone formation can be insidious, periodic imaging of the kidneys and bladder is necessary. Early identification and proper management may prevent the signs and effects of bladder outlet obstruction before they become

apparent on radiographic examination of the urinary tract (Pearman, 1976; Ogawa et al, 1988; Watanabe et al, 1996).

Urinary Tract Reconstruction in Children

Mark C. Adams, MD, FAAP ● David B. Joseph, MD, FACS, FAAP

The "Functional" Urinary Tract
Evaluation of the Patient
Preparation of the Patient
Antireflux
Bladder Neck Reconstruction
Augmentation Cystoplasty
Continent Urinary Diversion
Continence Mechanisms and Catheterizable Segments
Antegrade Continence Enemas
Urinary Refunctionalization
Summary

The goal of this chapter is to review techniques for lower urinary tract reconstruction in pediatric patients and the principles that guide their use. In general, such intervention is taken to reestablish or to construct anew a system that protects renal function, avoids significant infection, and eventually provides for urinary continence. Those, in simplistic terms, are functions of a "normal" urinary tract.

The scope of the chapter is large. Many specific techniques are presented in detail, particularly those used primarily in the pediatric population. When techniques have been used more extensively in adults, descriptions are brief with focus on adaptations for and results of use in children. Urinary diversion, both temporary and permanent with bowel, is discussed elsewhere in this text. Augmentation cystoplasty is reviewed in detail from preoperative evaluation and surgical techniques to long-term results and newer alternatives. In few areas of urology have intestinal segments been used more extensively than for bladder augmentation in pediatric patients. This experience with augmentation cystoplasty established the groundwork for later work with continent urinary diversions and orthotopic neobladders.

Complex patients with bladder dysfunction may have bladder neck and external sphincteric problems as well. This chapter covers techniques to increase native outflow resistance in the pediatric population. Certain techniques, such as Young-Dees-Leadbetter bladder neck repair, are presented elsewhere in this section of this text. Others (i.e., sling, collagen injection, and artificial urinary sphincter) have been used more extensively in adults; again, in that setting, the focus in this chapter is on adaptations of those procedures for children. **Perhaps the most important contribution affecting lower urinary tract reconstruction was the introduction of clean intermittent catheterization (CIC) by Lapides and colleagues** (1972, 1976). Because many pediatric patients with bladder and sphincteric dysfunction will not void adequately after reconstruction, a reliable means for easy catheterization without discomfort is an important part of their care. The work of Mitrofanoff (1980) stimulated interest in continent abdominal wall stomas within pediatric urology, and several effective techniques have since been developed. That experience serves as a nice lead into a discussion of continent urinary diversion in children because construction of an effective efferent limb that provides continence and a reliable means for catheterization is often the most challenging aspect of such diversion. "Pure" continent urinary reservoirs, such as Indiana and Kock pouches, are occasionally performed in children, and that experience is reviewed. More frequently in children, some of the patient's native urinary tract is used in the reconstruction. This is done to maintain as much urothelium-lined tissue in the urinary tract as possible, to minimize the amount of needed bowel, and, potentially at least, to minimize the morbidity to the patient. The result then is a spectrum of repairs between bladder augmentation and continent urinary diversion but rarely a continent urinary reservoir in the classic sense.

Several decades ago, many such reconstructions were performed after previous, permanent urinary diversion with use of bowel (Hendren, 1998). Today, however, few children are initially treated with permanent diversion. **Most reconstructive procedures are now undertaken primarily to correct a problem in the native urinary tract (hydronephrosis, infection, incontinence) unresponsive to medical management or after temporary diversion. Children with bladder and sphincteric dysfunction are among the most complex seen in pediatric urology; among others, patients with diagnoses such as exstrophy, persistent cloaca and urogenital sinus, posterior urethral valves, bilateral single ectopic ureters, and prune-belly syndrome may be**

involved. For most pediatric urologists, patients with myelomeningocele make up the majority of patients requiring this type of surgical intervention. Consequently, many of the results discussed herein focus on the neurogenic population.

Many children with anomalies affecting the bladder and outlet are managed so that surgical intervention is not necessary, and a primary goal of pediatric urologists is to minimize the number of children requiring many of these techniques. Once conservative, medical therapy fails, surgical reconstruction remains an important and effective tool. When reconstruction is considered, it is imperative that the patient be thoroughly evaluated. Each child is unique, and the particular pathophysiologic changes must be understood so that surgical techniques available may be used thoughtfully to optimize results while minimizing morbidity. **The most important factor influencing the outcome of urinary tract reconstruction in children is the commitment of the patient and family to achieving good care.** Determining that commitment may at times be difficult, but its importance should not be underestimated.

THE "FUNCTIONAL" URINARY TRACT

The renal pelves and ureters should empty effortlessly into the bladder without any increase in pressure or element of obstruction. The normal ureterovesical junction prevents vesicoureteral reflux. Bladder physiology can be characterized as two different dynamic phases: passive and active. During the passive storage phase the bladder functions as a reservoir, allowing an appropriate volume of urine to be stored without leakage while maintaining low pressure. In the active voiding phase the bladder contracts for elimination of urine.

Basic Bladder Function

Passive: Storage

Appropriate urinary storage requires a reservoir that is compliant and of age-appropriate capacity. Age-based capacity may be estimated by formulas proposed by Koff (1983):

$$\text{Volume (mL)} = 30(\text{age in years} + 2)$$

or by Kaefer and associates (1997c) for children younger than 2 years:

$$\text{Volume (mL)} = 32(2 \times \text{age in years} + 2)$$

and for children older than 2 years:

$$\text{Volume (mL)} = 30(\text{age in years} \div 2 + 6)$$

Compliance is defined as the change in bladder volume divided by the change in pressure. Normally, the bladder is considered a highly compliant vesicle in that it will accommodate an increasing volume of urine without a corresponding increase in intravesical pressure. Multiple factors contribute to this property. Initially, the bladder is in a collapsed state that allows the storage of urine at low pressure by simple unfolding. As it expands, detrusor properties of elasticity and viscoelasticity take effect. Elasticity allows the detrusor muscle to stretch without an increase in tension until it reaches a critical volume. This volume should be greater than the expected bladder capacity. The viscoelastic bladder property allows a subtle continuous pressure change that occurs with bladder filling. It is associated with a small rise in pressure as the bladder stretches, balanced by a corresponding rapid pressure decay (Zinner et al, 1976; Wagg and Fry, 1999). With slow natural bladder filling there should be no net change in bladder pressure until capacity is reached. This viscoelastic bladder property is also defined as stress relaxation and can be overcome when the rate of bladder filling exceeds normal parameters, resulting in a pattern consistent with poor compliance (Mundy, 1984; Finkbeiner, 1999). This artifact of testing is often noted when urodynamic assessment is performed at an excessive filling rate for the child's age or size (Bauer and Joseph,1990; Joseph, 1992). These properties of elasticity and viscoelasticity will eventually be overcome in every child, and at that point the bladder pressure rapidly rises. **Favorable dynamics for urine storage include a thin bladder wall with an appropriate composition of muscle and collagen allowing expression of normal elastic and viscoelastic properties.** Factors adversely affecting normal compliance include detrusor hypertrophy, fibrosis, outlet obstruction, and recurrent urinary tract infections (Mundy, 1984; Joseph, 1994).

Continence during urinary storage requires a closed bladder neck at times supported by a contracted external urinary sphincter. Fixed obstruction, neurogenic dysfunction, and chronic inflammation can affect any or all of these passive parameters, resulting in resting bladder hostility and clinical manifestations of poor compliance, upper tract deterioration, and incontinence (Brading, 1997).

Active: Voiding

Under normal conditions the active phase of voiding requires the bladder to contract after descent of the bladder neck (Morrison, 1997). Reflexive opening of the bladder neck and sequential relaxation of the external urinary sphincter allow low-pressure balanced voiding and complete elimination of urine. Again, obstruction, neurogenic dysfunction, and chronic infection can cause physiologic changes preventing coordinated function of the detrusor, bladder neck, and external sphincter, defined as dyssynergy (Mundy et al, 1985). A poorly functioning external sphincter from denervation fibrosis may also prevent appropriate relaxation, causing elevated voiding pressure against a fixed outlet. Finally, detrusor pathophysiologic changes may prevent a sustained, coordinated bladder contraction and full elimination of all urine.

Dysfunction

Upper Tracts

It is critical to understand the dynamics of the entire urinary tract before any major reconstructive procedure. Careful evaluation is imperative. In the presence of hydronephrosis, upper tract obstruction must be excluded. With severe and long-standing bladder problems, particularly those involving poor bladder compliance and emptying, upper tract obstruction is often secondary to the bladder abnormality. Nuclear renography with a catheter in the bladder to keep the bladder empty and at low pressure may be useful to rule out a primary upper tract problem. Antegrade perfusion studies with fluoroscopy and pressure measurement are occasionally necessary. Certainly, if upper tract obstruction is present it should be corrected at the time of bladder-sphincter reconstruction.

Much like obstruction, vesicoureteral reflux in the presence of a bladder abnormality may be primary or secondary. Differentiation between the two can be difficult. On occasion the history is helpful. If reflux was not present initially in a patient with neurogenic dysfunction but developed later, it is typically secondary to

bladder hostility. Most reflux in patients with neurogenic dysfunction requiring bladder augmentation is likely to be secondary; reflux in patients with other problems (exstrophy, prune-belly syndrome, or posterior urethral valves) may be either primary or a fixed secondary problem if it persists until the time that bladder reconstruction is necessary. Previous work has suggested that reflux truly secondary to bladder dysfunction may not need surgical correction if the bladder is adequately managed. In those reports, neurogenic bladder patients requiring augmentation did not undergo reimplantation for secondary reflux, and virtually all of the low-grade reflux resolved with augmentation alone (Nasrallah and Aliabadi, 1991; Morioka et al, 1998; Lopez Pereira et al, 2001; Soylet et al, 2004; Juhasz et al, 2008). It is interesting to speculate whether reflux is even a significant problem if a large, compliant bladder is achieved (Soylet et al, 2004). Bacteria may ascend without reflux after reconstruction (Gonzalez and Reinberg, 1987). Experience with certain forms of continent diversion has not shown an increased risk of pyelonephritis in the absence of any antireflux mechanism if the reservoir is adequate (Helal et al, 1993; Pantuck et al, 2000). Although the authors agree that most low-grade secondary reflux is likely to resolve with adequate treatment of the bladder alone, our preference is to correct reflux at the time of bladder reconstruction, unless it is low grade or clearly secondary, because the morbidity is low. After bladder reconstruction, many patients have chronic bacteriuria, particularly those who catheterize to empty, and the absence of reflux, at least theoretically, may decrease the likelihood of ascent to the kidney. Caution must be taken when the treatment of chronically dilated and scarred ureters is considered. Correction of reflux in that setting is certainly appropriate, but one must be careful not to trade reflux for more problematic obstruction. Overaggressive tapering or tunneling of such ureters may be fraught with complications.

Dysfunction in the upper urinary tract is usually manifested by hydronephrosis, pyelonephritis, or impairment of renal function. When such problems are present in patients with lower tract dysfunction, thoughtful evaluation and treatment are necessary. All problems should be addressed at reconstructive surgery to provide the best result for the patient.

Bladder Dysfunction

Bladder dysfunction is a composite of physiologic abnormalities, and it is helpful to assess each component of passive and active bladder function independently. **Elevated passive filling pressure becomes clinically pathogenic when a pressure higher than 40 cm H_2O is chronically reached** (McGuire et al, 1981; Wang et al, 1988; Weston et al, 1989). Pressures at this level sustained for a time impair ureteral drainage, which may result in pyelocalyceal changes, hydroureteronephrosis, and decreased glomerular filtration rate. In addition, persistent elevation in filling pressure can result in acquired vesicoureteral reflux (Sidi et al, 1986a; Cohen et al, 1990).

Pharmacologic management can play a role in decreasing filling pressure, particularly when hyperreflexic detrusor contractions are present. A combination of medications and intermittent catheterization has a positive impact, particularly in children with neurogenic dysfunction (Rink and Mitchell, 1984; Aslan et al, 2002; Verpoorten et al, 2008). Bladders that are poorly compliant because of irradiation or chronic inflammatory processes are not as likely to respond in a positive fashion to this form of therapy. When compliance is unaffected by medical management, augmentation cystoplasty will be required to improve the storage characteristics. It is expected that detrusor contractions resulting in effective emptying will be significantly diminished after augmentation. **With rare exceptions, intermittent catheterization should be taught to and accepted by the patient and caretaker before urinary reconstruction is contemplated.**

One of the most important contributions in the care of children with bladder dysfunction came with the acceptance of CIC described by Lapides and colleagues (1972, 1976) **based on the work of Guttmann and Frankel** (1966). The effective use of CIC has allowed the application of augmentation and lower tract reconstruction to groups of patients who had not previously been candidates. The principle of intermittent catheterization allows the reconstructive surgeon to aggressively correct storage problems by providing an adequate reservoir and good outflow resistance. Good spontaneous voiding, although a goal, is not imperative because catheterization can be used for emptying. Intermittent catheterization can maintain a physiologic state of complete emptying on a regular basis.

Urinary incontinence is a prominent sign of bladder dysfunction. Continence is based on outflow resistance generated by the bladder neck and external urinary sphincter. Outflow resistance must remain greater than resting bladder pressure during storage throughout normal daily activity. When outflow resistance is diminished because of an abnormal bladder neck and external urinary sphincter, incontinence often will occur. Pharmacologic management with α-adrenergic agents can enhance outflow resistance when needed, but operative reconstruction is more commonly required in that setting.

When incontinence occurs during the filling phase because of poor outlet resistance, it is essential to evaluate not only the bladder neck and external urinary sphincter but also the detrusor characteristics. Clinical experience has shown that once appropriate resistance is achieved at the bladder neck through operative intervention, adverse detrusor characteristics may become unmasked and result in high-pressure urinary storage or uninhibited contractions not previously documented (Bauer et al, 1986; Churchill et al, 1987; Dave et al, 2008b). For that reason, provocative urodynamic assessment with occlusion of the bladder neck is important before any bladder neck reconstruction in an attempt to identify children who will be at risk.

Normal synergistic voiding occurs when the bladder neck descends, relaxes, and opens followed by relaxation of the external urinary sphincter and subsequent detrusor contraction. The cascade results in low-pressure voiding. Dysfunctional voiding during this active bladder phase occurs from discoordinated activity of the bladder neck, external urinary sphincter, and detrusor and can result in urinary incontinence. In addition, when neurogenic dysfunction leads to detrusor-sphincter dyssynergy, high-pressure voiding results during a period of time, having a negative impact on the bladder and upper urinary tract (Mundy et al, 1982; Bauer et al, 1984). A similar clinical situation occurs with a fixed, fibrotic external sphincter. Initial treatment usually involves pharmacologic management and mechanical elimination of urine from the bladder through CIC in an attempt to bypass the abnormal voiding mechanics.

Other Considerations

Renal function should be assessed in any patient undergoing bladder reconstruction, particularly if hydronephrosis or severe renal scarring is present. **Demos** (1962) **and Koch and McDougal** (1985) **have demonstrated that urinary solutes, particularly chloride, are absorbed from urine in contact**

with the mucosa of small and large bowel. For patients with normal renal function, the kidneys are able to handle the reabsorbed load of chloride and acid without obvious difficulty. Patients with decreased renal function, however, may develop significant metabolic acidosis secondary to such reabsorption. If acidosis exists preoperatively, it will invariably worsen if urine is stored in small or large intestinal segments (Mitchell and Pizer, 1987). The first component of renal function to deteriorate after obstruction or infection is typically concentrating ability. Patients with compromised function may generate enormous volumes of urine. **The bladder volume achieved through bladder reconstruction must accommodate the patient's urinary output for an acceptable time, usually about 4 hours.** Patients with renal failure or other medical problems may conversely develop oliguria. Low urinary output may affect an augmented bladder or bowel reservoir because there is greater potential for collection and inspissation of mucus. There is also less urine for dilution and buffering of gastric secretions if stomach is used.

Abnormal function of other organ systems also influences the risk of bladder reconstruction with use of intestinal segments. Reabsorption of ammonia by large or small intestinal segments in contact with urine may be dangerous for patients with hepatic failure (McDougal, 1992a). Some medications excreted in urine may be reabsorbed by bowel mucosa (Savauagen and Dixey, 1969). Therefore, liver function tests and arterial blood gas studies may be appropriate for some patients. Careful history should be taken of the patient's preoperative bowel function; this is particularly true of adult patients who may have acquired, or secondary, gastrointestinal problems. Obviously, short-gut syndrome is a concern among patients with cloacal exstrophy, prior bowel resections, or a history of significant irradiation. A history of chronic diarrhea or fecal incontinence preoperatively should signal concern about use of the ileocecal valve in urinary reconstruction.

A critical factor to consider is the commitment of the patient and family. Urinary incontinence, at times, protects some patients from infection and upper tract deterioration. Effective storage can put the patient at risk for such problems if emptying is not accomplished on a regular basis. All must be aware of the responsibility that goes along with bladder reconstruction and urinary continence.

The timing of appropriate surgical intervention may vary dramatically among patients. It is sometimes necessary to perform early reconstruction when the upper tracts and renal function are threatened. This situation most often occurs in the presence of high outflow resistance and poor bladder compliance. More commonly, intervention may be undertaken later to achieve urinary continence. The age at which urinary incontinence becomes socially unacceptable varies among patients and families.

When appropriate, it is beneficial for the patient and family to wait for bladder reconstruction until all needs of the patient are identified. With intervention because of infection or hydronephrosis this is not always possible. When reconstruction is undertaken to achieve continence it is most efficient to identify all reconstructive issues and to address them with one operation. Good urodynamic assessment is usually necessary to determine whether a procedure to increase outflow resistance is necessary in addition to bladder augmentation or replacement. Introduction of intermittent catheterization preoperatively is mandatory in that it allows the patient to demonstrate the ability and desire to do so on a regular basis. It is also helpful in determining whether a continent abdominal wall stoma may help improve the reliability of catheterization and increase the patient's independence. Likewise, particularly in the neurogenic population, it is advantageous to identify the patient who may also benefit from an antegrade colonic enema. It is certainly better for the patient and surgeon to address all of these issues at one operative sitting rather than with sequential procedures that may add morbidity.

EVALUATION OF THE PATIENT

Each patient should have upper tract imaging before bladder reconstruction. Most patients with significant bladder problems will have had routine ultrasonography as part of their surveillance. **If hydronephrosis is present, obstruction and vesicoureteral reflux should be sought with a functional renal study and voiding cystography.** Nuclear renography with a catheter in the bladder is usually adequate to rule out a primary upper tract obstruction. Reflux should be excluded with a voiding study, although that study may be done as part of videourodynamics. In the presence of any hydronephrosis, each patient should have determinations of serum electrolytes, blood urea nitrogen, and serum creatinine. For patients with elevation of the serum creatinine concentration or significant hydronephrosis, a 24-hour urine collection for both creatinine clearance and urine volume should be obtained.

Urodynamics

Bladder Dynamics: Capacity and Compliance

Urodynamic assessment of the lower urinary tract plays an essential role in considering bladder reconstruction. It can provide reproducible results in infants and children but requires meticulous attention to detail (Joseph, 1994). Several mechanical factors may adversely influence urodynamics data, creating artifacts that can have a negative impact on the validity of the evaluation if they are not recognized. Testing is typically performed with transurethral catheter placement in this population of patients. The size of the catheter can lead to the appearance of elevated leak or voiding pressure and the inability to empty well, particularly in infants and young boys (Decter and Harpser, 1992). Suprapubic catheter placement circumvents this problem but is not practical in most cases. The testing medium and infusion rate can influence the results. Carbon dioxide is not as reliable as fluid infusion, particularly in evaluation of bladder compliance and capacity. The most common fluids used for testing are saline and iodinated contrast medium, both of which provide reproducible results (Joseph, 1993). Use of testing media at body temperature is also appropriate (Joseph, 1996). End filling pressure, and therefore bladder compliance, can be dramatically affected by simply changing the filling rate (Joseph, 1992). Bauer (1979) has suggested that cystometrography be performed at a fill rate of no more than 10% of the predicted bladder capacity per minute.

Sphincter Dynamics: Outflow Resistance

The bladder neck and external urinary sphincter work in synergy, but only one is required to maintain urinary continence. Often, neurogenic dysfunction leads to abnormalities of both the bladder neck and external urinary sphincter, resulting in diminished outlet resistance during storage or dyssynergic function with voiding. Monitoring of external urinary sphincter electrical activity is required to evaluate coordinated voiding and dyssynergic detrusor-sphincter activity. Perineal surface electrodes, abdominal wall sensors, anal plugs, vaginal monitors, electrical wires, and concentric needle electrodes have all been used for electromyography (Joseph, 1996). In children with neurogenic dysfunction, a concentric needle electrode or dual needle electrodes placed

through a 25-gauge needle increase accuracy in measuring sphincter activity (Blaivas et al, 1977; Joseph, 1996).

The functional length of the external urinary sphincter also plays a role in outflow resistance, and its measurement can be undertaken with urethral pressure profilometry. Unfortunately, the short length and small diameter of the pediatric urethra make this study technically more difficult to perform than in the adult because the mechanical pulling device is not practical for pediatric use. To assess urethral pressure profile, a constant infusion of testing medium at a rate of 2 mL/min with use of a continuous Harvard pump is required (Joseph, 1996) to eliminate pressure wave artifacts noted with the standard roller ball infusion pumps. Hand withdrawal of the catheter is done while every 5 mm is marked on the recording strip. With practice, reliable measurements can be obtained. There is limited value in comparing specific urethral pressure profile results for a patient against a standard uroflow nomogram; however, a preoperative urethral pressure profile for a given patient provides baseline information that can be beneficial in assessing the intraoperative and postoperative functional urethral length.

Some surgeons use leak point pressure to evaluate outflow resistance, the bladder pressure causing leakage per urethra, which can be determined during passive filling and Valsalva maneuver. Fluoroscopy can be informative during those events. The leak point pressure may be artifactually elevated by the urodynamics catheter in a small male urethra (Decter and Harpser, 1992). Much work remains to determine how well such measurable parameters correlate and identify which patients require a procedure on the outlet to achieve adequate continence.

Bladder Emptying

The patient's ability to empty the bladder before reconstruction should be assessed carefully. Useful parameters related to bladder emptying include synergistic relaxation of the external sphincter on electromyography, urinary flow rates, and measurements of postvoid residual urine. Neurologically normal patients who are able to empty the bladder well preoperatively are much more likely to do so after reconstruction than are patients who have neurogenic dysfunction or those who are unable to empty well preoperatively. **No test ensures that a patient will be able to void spontaneously and empty well after bladder augmentation or other reconstruction.** Therefore, all patients must be prepared to perform CIC postoperatively. The native urethra should be examined for the ease of catheterization. Ideally, the patient should learn CIC and practice it preoperatively until the patient, family, and surgeon are comfortable that catheterization can and will be done reliably. Physical and psychosocial limitations of the patient must be considered in regard to the ability to self-catheterize and to perform self-care. **Failure to catheterize and empty reliably after bladder reconstruction may result in upper tract deterioration, urinary tract infection, or bladder perforation despite a technically perfect operation.** Most patients who may catheterize per native urethra or an abdominal wall stoma will overwhelmingly prefer the latter (Horowitz et al, 1995).

PREPARATION OF THE PATIENT

Bladder and sphincter reconstructive procedures remain some of the most challenging in urology. The general status of patients should be optimized so that they have the best chance to achieve a good result with the least risk of morbidity. Each patient's general nutritional and hydration status should be determined and corrected, if necessary, before surgery. Coexisting medical problems, particularly cardiac and pulmonary, should be well managed preoperatively.

Bowel Preparation

Historically, each patient has undergone preoperative bowel preparation to minimize the potential risk of surgery if the use of any bowel is contemplated. Even when ureterocystoplasty or other alternatives are planned, intraoperative findings may dictate the need for use of a bowel segment. A clear liquid diet for 2 days before bowel preparation aids in clearing solid stool. The patient should then undergo full mechanical bowel preparation the day before surgery. Such bowel preparations have usually been done in the hospital (O'Donnell, 2007); however, recent trends find this changing to an outpatient setting. Major reconstructive procedures often require many hours of operative time with large fluid shifts. It is critical that the patient be well hydrated at the time of surgery. There should be a low threshold for the use of intravenous fluids during the preoperative day. The use of oral antibiotics in bowel preparation, once dogma, is now a matter of personal preference (Breckler et al, 2007). Special attention must be paid to the bowel preparation of patients with neurogenic dysfunction. Most of these patients have chronic constipation. Good bowel cleansing is difficult in such patients and should be done aggressively. Several days of oral cathartics and a clear liquid diet at home may be helpful. Patients with renal insufficiency should be observed carefully during bowel preparation for dehydration and electrolyte disturbances.

Theoretically, gastric contents are sterile, and parenteral antibiotics and a routine bowel preparation are not necessary before gastrocystoplasty. In one study (Gundeti et al, 2006) it was suggested that routine bowel preparation may not be necessary before ileocystoplasty in children.

Urine Culture

All patients should have a urine culture performed several days before bladder reconstruction. The bladder should not be opened with infected urine, which will spill intraperitoneally. Any patient with a positive preoperative urine culture should undergo treatment with either oral or intravesical antibiotics and have a second culture documenting sterile urine before the procedure. Many pediatric patients undergoing augmentation cystoplasty have spina bifida and a ventriculoperitoneal shunt. With a negative urine culture and good bowel preparation the incidence of shunt infection or problems should be low (Yerkes et al, 2001; Hayashi et al, 2008).

Cystoscopy

Preoperative cystoscopy may be the final step in evaluating the native bladder, outflow, or ureteral orifices in pediatric patients. Endoscopy should be performed immediately before bladder reconstruction under the same anesthetic. In adult patients with interstitial cystitis or irritative bladder symptoms requiring augmentation cystoplasty, cystoscopy should be performed well before augmentation to rule out urothelial carcinoma in situ. Bladder biopsy and cytologic examination of the urine may be helpful in excluding tumor. On the basis of history, an occasional patient may warrant endoscopic or radiographic gastrointestinal evaluation.

Key Points: Evaluation and Preparation

- Evaluation for renal function, upper tract obstruction, and vesicoureteral reflux should be performed if hydronephrosis is present, although most such changes are secondary to the bladder dysfunction.
- Careful urodynamic evaluation is critical to understand all of the problems that may contribute to the dysfunction.
- The patient is likely to require CIC after reconstruction and must be capable of doing so on a reliable basis.
- Commitment of the patient and family is essential.
- Basic preoperative preparation includes sterile urine and thorough bowel cleansing.

ANTIREFLUX

Ureteral reimplantation into a native bladder, whether the ureter is dilated or not, is a standard procedure familiar to all pediatric urologists and reconstructive surgeons. The long-term success rate is good, and complications are rare. Such reimplantation is certainly preferable and usually possible during lower tract reconstruction.

Transureteroureterostomy and Single Ureteral Reimplantation

On occasion, the urinary bladder is so small that it is inadequate for bilateral reimplantation, and alternatives must be considered. It is preferable to reimplant both ureters separately, although **if the native urinary bladder is small and adequate for only a single ureteral tunnel, transureteroureterostomy and a single reimplant may be helpful** (Fig. 129–1).

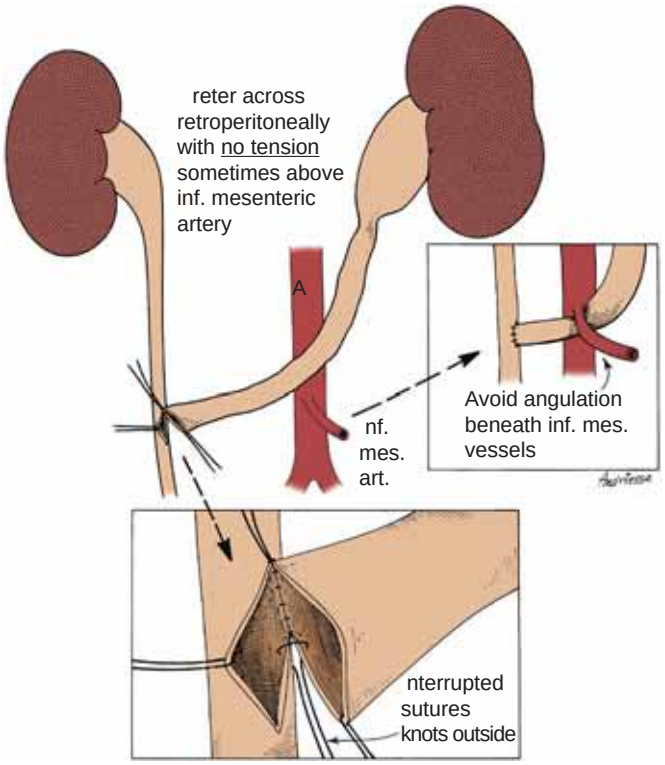

Figure 129–1. Technique for transureteroureterostomy. AO, aorta; Inf. mes. art., inferior mesenteric artery. (Courtesy of W. Hardy Hendren.)

Typically, the better ureter should be implanted into the bladder, draining the other across into it. The crossing ureter should be mobilized to swing gently across the abdomen to the recipient side in a smooth course without tension. It should be carefully mobilized with all of its adventitia and as much periureteral tissue as possible to preserve blood supply. Care must be taken not to angulate the crossing ureter immediately beneath the inferior mesenteric artery. The crossing ureter is widely anastomosed to the posteromedial aspect of the recipient ureter. The recipient is not mobilized or brought medially to meet the end of the other ureter. Transureteroureterostomy, when it is fashioned appropriately, is successful and carries minimal risk for leakage or obstruction (Hodges et al, 1963; Hendren and Hensle, 1980; Noble et al, 1997; Mure et al, 2000). A history of previous calculi remains a relative contraindication to transureteroureterostomy.

The manner in which the bladder is opened may optimize its use for a single reimplant. Rather than incision of the bladder in the anterior midline, a wide, anterior U-shaped incision based cephalad can be made. This potentially elongates the bladder as a posterior plate that can be brought to one side or the other to meet a single ureter. Incision of the bladder in this way may also be useful in placing a continent catheterizable stoma to the umbilicus when the native bladder otherwise will not reach that far. For ureteral reimplantation after such an incision, a psoas hitch of the bladder fixes the bladder in position for a long, straight ureteral tunnel.

Psoas Hitch

Fixation of the bladder to the psoas muscle allows precise control of both the length and direction of a ureteral reimplant. Securing the bladder in this manner helps the bladder reach a short ureter or development of a long tunnel when necessary. A psoas hitch should prevent any angulation of the ureter with bladder filling. Such angulation may be particularly problematic or obstructive with a dilated and scarred ureter. The bladder should be secured to the psoas muscle and fascia with nonabsorbable sutures. Those sutures must not enter the bladder lumen or stones will occur. Broad, shallow purchases of the psoas muscle and fascia should be used to hold long term without trapping the sciatic nerve. The hitching sutures should not be tied so tightly that they cut through either bladder or psoas muscle. The contralateral bladder pedicle may be divided to increase bladder mobility and the length of the hitch on occasion. In general, the ureteral reimplantation should be performed before the bladder psoas hitch (Fig. 129–2).

Antireflux with Intestinal Segments

Necessity of ureteral reimplantation into an intestinal segment may occasionally determine the segment to be used for bladder augmentation or replacement. Long experience with ureterosigmoidostomy and colon conduit diversion has established an effective means of antireflux into a colonic segment. A flap valve mechanism can be constructed by tunneling the ureter beneath a taenia. Important principles learned from ureterosigmoidostomy include a direct mucosa-to-mucosa anastomosis and a submucosal tunnel of adequate length. This technique, familiar to most urologists, has provided favorable long-term results since the 1950s (Nesbit, 1949; Goodwin et al, 1953; Leadbetter and Clarke, 1954) and is based on the initial work of Coffey (1911). Implantation may be done from inside the reservoir with the intestinal segment open or from without after the intestinal segment has been completely reconfigured and closed.

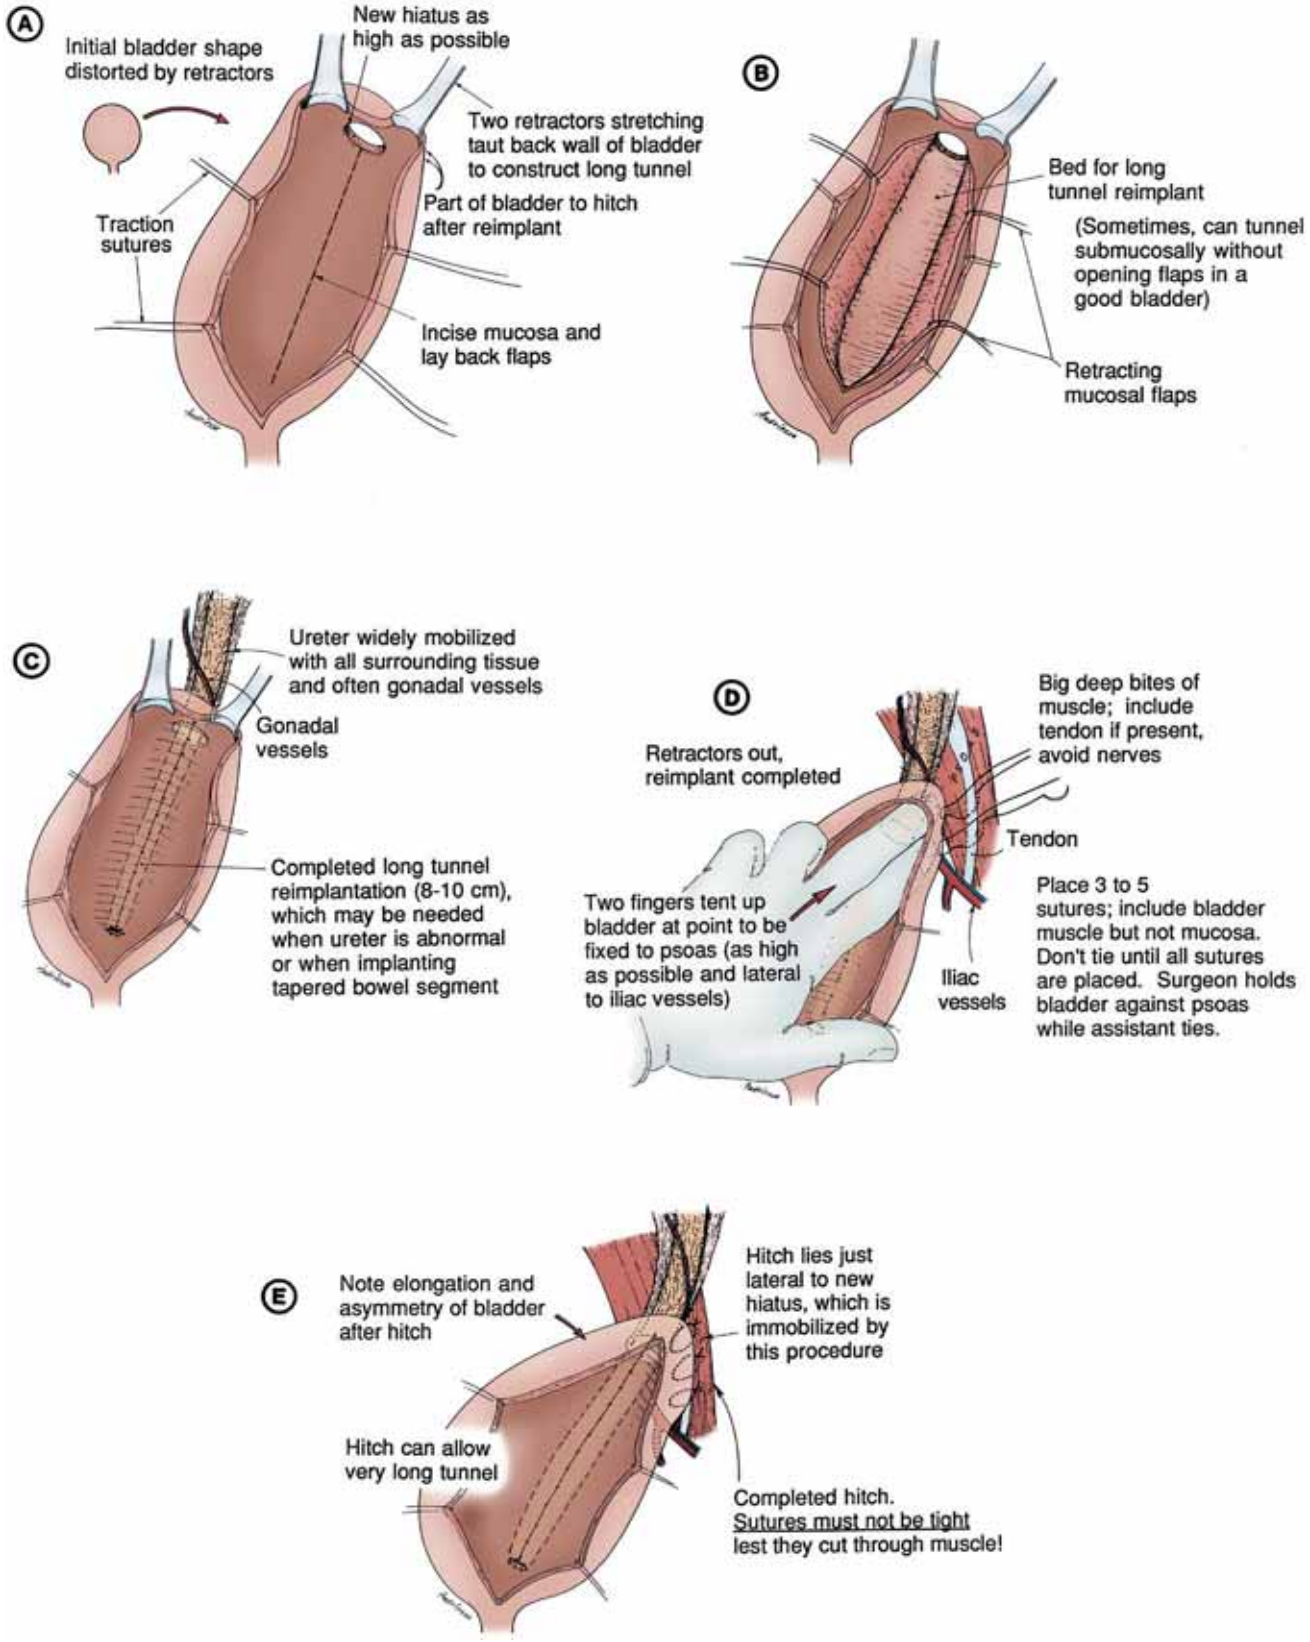

Figure 129–2. **A** to **E**, Technique for psoas hitch, which allows the construction of a long reimplantation tunnel and prevents angulation of the ureter or tapered bowel segment when the bladder fills. Monofilament nonabsorbable suture material is used to fix the bladder to psoas muscle. Care must be taken to avoid entering the bladder, which might cause stone formation on a suture. (Courtesy of W. Hardy Hendren.)

If a gastric segment is used for bladder augmentation or replacement, ureters may be reimplanted into the stomach in a manner remarkably similar to that used in the native bladder. It is easy to form a submucosal tunnel with good muscle backing. The same principles for choosing the length of tunnel relative to the width of the ureter are used as with bladder. Construction of an effective antireflux mechanism into an ileal segment is more difficult. The split-nipple technique described by Griffith may prevent reflux at least at low reservoir pressure (Turner-Warwick and Ashken, 1967; Patil et al, 1976; Stone and MacDermott, 1989; Sagalowsky, 1995). A short longitudinal incision is made in the distal ureter and the ureteral wall turned back on itself. The nipple should be at least twice as long as the width of the ureter. The cuff is stabilized by suturing the ureter to itself. The adventitia of the ureter immediately proximal to the cuff is then approximated to the full thickness of the ileal wall at the hiatus so that the cuff protrudes into the lumen. Le Duc and associates (1987) described a technique in which the ureter is brought through a hiatus in the ileal wall. From that hiatus the ileal mucosa is incised and the edges are mobilized to construct a trough for the ureter. The spatulated ureter is laid into the trough and approximated to the mucosa at the distal end. The ileal mucosa is sutured to the lateral edges of the ureter and should eventually grow over it. Long-term results with these two techniques have been conflicting but generally have not proved as reliable as a tunneled ureterocolonic anastomosis in preventing reflux (Patil et al, 1976; Le Duc et al, 1987; Rowland, 1996; Bihrle, 1997), with one exception (Lugagne et al, 1997). It is also possible to construct an antirefluxing, serosa-lined tunnel between two limbs of ileum as described by Abol-Enein and Ghoneim (1999; Soygur et al, 2005).

Reinforced nipple valves of ileum have been used extensively for antireflux with the Kock pouch (Skinner et al, 1989). After several modifications by Skinner, good long-term results have been achieved. This technique requires a relatively long segment of ileum and use of permanent staples. Attempts have been made to secure the nipple long term without staples or mesh (Hanna and Bloiso, 1987; Gosalbez and Gousse, 1998; Tsuchiya et al, 2004). Maintenance of the intussuscepted cuff is the key to a successful result. The same forces that compress the nipple to achieve antireflux or continence tend to evert or destabilize it. An ileal nipple valve may be particularly useful with short, dilated ureters; an isoperistaltic segment of ileum may be left with the nipple to replace a short ureter. Likewise, the antireflux mechanism is based on the ileal segment and not the ureter. Consequently, a very dilated ureter may be anastomosed to the ileum without tapering. In some neobladders, an isoperistaltic limb of ileum is positioned between the reservoir and ureters to discourage reflux, at least at low pressures (Studer and Zingg, 1997).

Key Points: Antireflux

- Ureteral reimplantation into native bladder is preferable when necessary; the initial bladder incision may facilitate such a procedure.
- An antireflux mechanism can be constructed with any bowel segment but is most challenging with ileum.

BLADDER NECK RECONSTRUCTION

One of the greatest technical challenges facing the surgeon in bladder reconstruction is providing adequate outflow resistance. The bladder neck may be incompetent due to neurogenic dysfunction secondary to spinal dysraphism. Other underlying pathologic conditions, such as exstrophy, bilateral ectopic ureters, and ureteroceles, are unique problems that must be considered in addressing outlet resistance. Many operative techniques have been described for bladder neck reconstruction, indicating that no single option is best for all patients (Kryger et al, 2000; Cole et al, 2003; Lemelle et al, 2006; Dave et al, 2008a). Khoury and associates (2008) have challenged the need for bladder neck reconstruction in the incontinent neurogenic patient with severe bladder trabeculation. **The necessity of preoperative evaluation and thorough knowledge of the patient's specific physiologic limitations cannot be overstated.**

The capability for a sustained bladder contraction to result in complete emptying by voiding or the absence of hyperreflexic contractions may influence the technique selected for gaining outlet resistance. Any operative technique that increases outlet resistance may do so at the expense of detrusor contractibility. For reasons not clearly defined, increasing outlet resistance can change the behavior of the detrusor into a noncompliant hostile environment (Bauer et al, 1986; Burbige et al, 1987; Churchill et al, 1987). Provocative cystometry may identify only some patients at risk, and close postoperative observation is mandatory (Kronner et al, 1998b).

A spectrum of techniques are available for repair; these encompass tightening of the bladder neck, construction of a flap valve mechanism, placement of artificial or autologous bulking agents, and the artificial urinary sphincter. **The selected option should be individualized to the patient's pathologic process, needs, and personal goals.**

An important consideration is the patient's ability to empty well before reconstruction and the likelihood that the patient can afterward. Some of these repairs may prohibit spontaneous voiding. In many patients, particularly patients with neurogenic dysfunction also requiring bladder augmentation, voiding cannot be expected and the major concern is providing adequate outflow resistance. For those with other diagnoses, especially if augmentation cystoplasty is not necessary, spontaneous voiding remains a key goal.

The following discussion covers a variety of operative techniques used to achieve urinary continence through bladder neck and external urinary sphincter reconstruction. Most of the results are based on experience in individuals with spinal dysraphism, but the techniques may be used with other pathogenic conditions. All techniques have a learning curve, which necessitates careful analysis of results and forthright reporting. An evidence-based review of operative bladder neck procedures found assessment of results to be limited by several factors, including the lack of a true, consistent definition of "success" and "continence," consideration of patients with and without concomitant bladder augmentation, and evaluation of small populations of patients with mixed pathologic conditions (Joseph et al, 2003).

Young-Dees-Leadbetter Repair

The Young-Dees-Leadbetter bladder neck reconstruction is one of the most recognized operative techniques to increase outlet resistance. The original Young procedure has evolved and remains of primary consideration in reconstruction of the exstrophic bladder neck (Ferrer et al, 2001). It has been used in patients with many diagnoses.

Technique. Young's initial description (1919) of excising a portion of the bladder neck and significantly tightening the

bladder neck over a silver probe was modified by Dees (1949), who extended the length of excised tissue through the trigone. Leadbetter (1964) followed by elevating the ureters off the trigone, placing them in a more cephalad position on the bladder floor. This allowed tubularization of the trigone and further enhanced lengthening of the urethra. A detailed description and illustrations are found in Chapter 124.

Results. Reports of success with the Young-Dees-Leadbetter bladder neck reconstruction in children with neurogenic sphincter dysfunction are limited, not only in the number of patients but also in overall improvement. Tanagho (1981) and Leadbetter (1985) independently reviewed their long-term results and showed minimal success in individuals with neurogenic dysfunction. They speculated that the lack of success was due to a lack of muscle tone and activity in the wrapped muscle related to the underlying neurogenic problem. Many patients in the early series did not undergo bladder augmentation, possibly compromising the continence achieved. Contrary to the results reported in exstrophy patients, the majority of individuals with neurogenic deficiency of the bladder neck will require bladder augmentation and intermittent catheterization. Sidi and colleagues (1987b) documented a 4-hour continence interval in 7 of 11 patients after such repair, although 10 required catheterization and 9 required augmentation. Five of the 7 needed reoperation to achieve continence. This small series represents one of the more recent long-term results of the Young-Dees-Leadbetter reconstruction in children with neurogenic dysfunction because it has largely fallen out of favor. In an attempt to enhance the Young-Dees-Leadbetter procedure, Mitchell and Rink (1983) described the addition of external support and compression achieved through the placement of a silicone sheath around the reconstructed bladder neck. This was somewhat done to establish a plane for future placement of an artificial sphincter cuff, if necessary. In place, it seemed to improve the function of the repair by either improving coaptation or by maintaining the proximal repair in a better anatomic position. Unfortunately, most of the thicker Silastic sheaths eventually eroded and disrupted the repairs (Kropp et al, 1993). Quimby and colleagues (1996) used a thinner Silastic sheath without the same risk of erosion. They also wrapped omentum between the repair and Silastic wrap. The authors reported better results for continence and thought that placement of an artificial sphincter cuff was much easier when needed.

Donnahoo and coworkers (1999) reviewed one of the largest series of the repair used in treatment of neurogenic incontinence (38 children, 25 of whom were girls). A primary repair was performed in 24 children, a secondary procedure in 6, and a primary repair in conjunction with a silicone sheath in 8. Partial continence was achieved after the initial repair in 26 children (68%). All children with the silicone sheath were initially continent, but erosion occurred in 5. More critically, 35 (92%) of the children required augmentation cystoplasty to become continent. The authors found that although continence could be achieved with this technique, it was at the expense of augmentation cystoplasty and multiple procedures. Their results are similar to those reported by Cole and associates (2003).

Fascial Sling

Sling procedures were developed in an attempt to increase resistance at the bladder neck. Both artificial and natural tissue have been used with similar technique. Resultant coaptation and elevation of the bladder neck should cause approximation of opposing epithelial surfaces and increased outlet resistance that is greater than the resting bladder pressure and the pressure achieved during stressful activity or Valsalva behavior. With sling coaptation, the bladder neck remains fixed; and although a strong detrusor contraction can establish a voiding pressure leading to urine flow, it rarely allows adequate bladder emptying in the face of anatomic or neurologic problems. The majority of pediatric patients who undergo a sling procedure must be prepared for intermittent catheterization. The resistance achieved with bladder neck slings can potentially be overcome by hyperreflexic bladder contractions or elevated pressure due to diminished bladder compliance. Therefore simultaneous bladder augmentation has again been reported in 55% to 100% of patients who achieve urinary continence after a sling procedure (Bauer et al, 1989; Elder, 1990; Decter, 1993; Kakizaki et al, 1995; Perez et al, 1996a; Dik et al, 1999, 2003; Walker et al, 2000; Bugg and Joseph, 2003; Cole et al, 2003; Godbole et al, 2003). Snodgrass and associates (2007) have reviewed their series of 30 consecutive patients with neurogenic incontinence who underwent bladder neck fascial sling only. They conclude continence can be achieved without upper tract damage and the adverse effect of enterocystoplasty. Others have cautioned taking this approach (Dave et al, 2008b). Alternatives to fascia, such as an expanded fluorocarbon polymer (Gore-Tex), have been used in a similar fashion, although early continence has not been maintained (Godbole and Mackinnon, 2004). Good early results have been noted with small intestinal submucosa and other biodegradable scaffolds (Colvert et al, 2002; Misseri et al, 2005).

Technique. The bladder neck is exposed by clearing fatty tissue overlying the bladder neck and the lateral endopelvic fascia. An incision is made within the endopelvic fascia for approximately 2 cm. The junction between the bladder neck and proximal urethra can be identified by placing a transurethral catheter into the bladder and gently pulling down on the catheter to lodge the balloon at the bladder neck. By blunt dissection, a plane between the posterior bladder neck and vagina in girls or rectal wall in boys is developed. The proper plane may be more easily developed from the cul-de-sac by dissecting behind the bladder and ureters from above (Lottmann et al, 1999; Badiola et al, 2000). If the landmarks are not easily defined, as in a secondary repair, the dissection becomes difficult. It may be appropriate to open the bladder to help prevent inadvertent dissection into the urethra or posterior structures. Storm and associates (2008) reported on a robotic-assisted laparoscopic approach for posterior bladder neck dissection and placement of the sling. This may become more appealing as robotic technology expands into bladder reconstruction. Dik and colleagues (2003) proposed a transvaginal approach, eliminating the need to open the bladder or to dissect between the bladder neck and anterior vagina.

When fascial tissue is used the technique is based on that described by McGuire and Lytton (1978) for stress urinary incontinence. Rectus abdominis fascia 1 cm in width and an appropriate length is harvested. This fascia can be taken in either vertical or horizontal fashion, depending on the initial skin incision. Fascia from other sites has been used in a similar fashion but requires a second incision. Often poor nutritional states and prior abdominal procedures limit the availability of rectus fascia, resulting in the use of alternative material such as small intestinal submucosa, cadaveric tissue, biodegradable scaffolds, and bladder wall (Colvert et al, 2002; Misseri et al, 2005; Albouy et al, 2007). All are generally secured to the anterior rectus fascia on either side. Autologous fascial tissue has been used, combining the benefits of a compressive wrap and suspension of the proximal urethra and bladder neck. Several variations of fascial placement and configuration have been described (Woodside and Borden, 1982; McGuire et al,

1986; Elder, 1990; Perez et al, 1996a; Bugg and Joseph, 2003; Dik et al, 2003). When fascial slings and wraps are used for neurogenic sphincter incontinence there is not as much concern for making a wrap or sling that is too tight because most patients are preferentially managed with CIC.

Results. Fascial slings have been used more extensively and with better results in girls with neurogenic sphincter incompetence, although some success has recently been reported in boys. Overall long-term success with fascial slings in the neurogenic population has varied greatly from 40% to 100% (Kryger et al, 2000; Castellan et al, 2005; Misseri et al, 2005; Snodgrass et al, 2007). A variation thought to contribute to a higher success includes a circumferential fascial wrap around the bladder neck. A circumferential wrap may equalize the compressive pressure over a greater surface area of bladder neck and posterior urethra (Walker et al, 1995; Strang et al, 2006). With a 360-degree wrap, simultaneous suspension has also been applied (Bugg and Joseph, 2003). Success rates have varied so much that it is difficult to determine whether any modification of the sling accounts for an increase in continence. Most patients who have undergone a fascial sling or wrap have also had simultaneous bladder augmentation. **Success of the sling, as with most repairs, appears to be improved with augmentation cystoplasty in this patient population by almost all reports** (Castellan et al, 2005). Perez and associates (1996a) reviewed the outcome of sling cystourethropexy in 39 children, 15 of whom were boys. One of four techniques was performed. When postoperative continence was evaluated on the basis of age, sex, underlying diagnosis, preoperative urodynamics, surgical technique, and enterocystoplasty, only concomitant enterocystoplasty was predictive of a successful outcome.

Contrary to the Silastic sheath, fascial sling erosion rarely occurs. Gormley and coworkers (1994) reported a revision rate with fascial slings of 15%. Placement of a fascial sling does not eliminate the possibility of later placement of an artificial urinary sphincter (Decter, 1993; Barthold et al, 1999). It is not unreasonable to consider placement of a fascial sling in a child with a marginally competent bladder neck and posterior urethra if the child is undergoing augmentation cystoplasty and already requires intermittent catheterization.

Bladder Neck Bulking Agents

Vorstman and colleagues (1985) reported one of the initial descriptions of injection therapy with a bulking agent into the bladder neck of incontinent children. The initial enthusiasm for use of polytetrafluoroethylene was quickly tempered because of concern about migration of particles to regional and distant sites including pelvic nodes, lungs, brain, kidney, and spleen found in animal models (Malizia et al, 1984). The technique remains of interest, and several alternatives to polytetrafluoroethylene have been assessed, including glutaraldehyde cross-linked collagen, dextranomer/hyaluronic acid copolymer, and polydimethylsiloxane (Leonard et al, 1990a; Guys et al, 2006; Knudson et al, 2006; Lottmann et al, 2006; Dean et al, 2007). Bovine collagen should not be used in latex-sensitive children with spina bifida because the product is not latex free (Kryger et al, 2000). In an attempt to achieve an ideal substance for injection, investigation is ongoing with autologous cartilage cells harvested from a separate site and then grown in an alginate matrix for endoscopic implantation (Bent et al, 2000). Although preliminary results have been obtained in adult women with stress incontinence, the material has not achieved an enthusiastic use in pediatrics. Whether this or other materials will be an appropriate alternative for neurogenic sphincter incontinence in children is yet to be seen.

In an attempt to alleviate the risks with injection of a foreign biologic product, alternatives to collagen and bovine have been investigated. Polydimethylsiloxane is one such agent. It is composed of sterile solid textured silicone particles, with an average size of 200 μg, suspended in a biologic hydrogen carrier. The large size of the particles should virtually eliminate lymphatic and distant migration (Beisang and Ersek, 1992; Guys et al, 1999; Halachmi et al, 2004; Guys et al, 2006). Contemporary reports favor the use of dextranomer/hyaluronic acid (Lottmann et al, 2006; Dean et al, 2007; Dyer et al, 2007).

Technique. Endoscopic exposure is used to localize the proximal urethra and bladder neck. Injection can be done directly through the working channel of the endoscope, often one with an offset lens system. Ideal placement of the material is in a subepithelial space, mobilizing the epithelium toward the lumen of the bladder neck. When it is completed in a circumferential fashion, adequate epithelial coaptation may occur that effectively raises outlet resistance. Alternatively, periurethral injection in women with a long needle placed from the perineum or through a suprapubic approach has been used. Dean and associates (2007) advocate simultaneous antegrade and retrograde endoscopic injection. Evidence is lacking whether the exact approach affects success, but accurate placement is important and transurethral injection generally preferred.

Results. The durability and success of bladder neck and proximal urethral injection remain in doubt for the pediatric population, particularly those with neurogenic dysfunction. True continence, as defined by a 4-hour dry period between voidings or catheterization, has been reported to be at most 64% and has ranged as low as 5% (Leonard et al, 1990a; Capozza et al, 1995; Bomalaski et al, 1996; Perez et al, 1996b; Sundaram et al, 1997; Silveri et al, 1998; Guys et al, 2001, 2006; Godbole et al, 2003; Halachmi et al, 2004; Lottmann et al, 2006; Dean et al, 2007). Several factors play a role in the outcome, one of which is a history of any previous operative bladder neck repair. Success is enhanced by elevation of the epithelium of the bladder neck, which may be compromised by scarring from previous operative procedures. **The concept of a minimally invasive operation used to enhance a marginal result gained from a more formal bladder neck repair is enticing; unfortunately, the data are lacking to show that bladder neck injection is of lasting value in that setting.**

Sundaram and colleagues (1997) reported on the efficacy and durability of glutaraldehyde cross-linked bovine collagen in 20 children, 12 of whom had neurogenic sphincter dysfunction. More than half of the children required two or three independent injections. Success was achieved in only 1 patient (5%), who was considered dry; 5 had some improvement, and 10 had either no change or transient improvement of only 2 to 90 days. Thus collagen therapy only delayed the ultimate need for bladder neck reconstruction.

Submucosal bladder neck injection of bovine dermal collagen was used by Perez and coworkers (1996b) in 32 patients. Continence was achieved after a single injection in only 20% of the children with neurogenic dysfunction. Complications were limited to febrile urinary infections, one episode of urinary retention, and worsening incontinence in 2 patients. The authors concluded that even though their success was limited the low morbidity and ease of placement justified submucosal injection in selected children.

Guys and associates (2006) treated 49 children with polydimethylsiloxane, 41 of whom had neurogenic bladder neck and

sphincter incontinence. The level of continence continued to deteriorate through 18 months, then stabilized. At an average follow-up of 73 months, success was achieved in 16 (33%) and 7 (14%) were improved. Godbole and colleagues (2003), Halachmi and associates (2004), and Dyer and coworkers (2007) independently came to the conclusion that regardless of the material injected (polytetrafluoroethylene, collagen, polydimethylsiloxane, dextranomer/hyaluronic acid), short-term success is not long lasting.

Kitchens and colleagues (2007) evaluated the use of dextranomer/hyaluronic acid to correct incontinence in patients who had previously undergone bladder neck reconstruction. They achieved success or improvement in 70% of select patients at 17 months, indicating this may be an alternative to other salvage therapy.

Overall, the cost of the bulking agents can be excessive and there does not appear to be any financial benefit over a formal repair (Kryger et al, 2000). **At present, bulking agents play a limited role for increasing outlet resistance and should be reserved for a select group of patients. The exact criteria that define that group have not been established.** Patients with marginal native outflow resistance are probably better candidates than are those with minimal preoperative function.

Artificial Urinary Sphincter

The artificial urinary sphincter has been recognized as a device that can result in prompt continence in select children while preserving their ability to void spontaneously. The artificial urinary sphincter was introduced by Scott in 1974. The general concept and design of the initial model have been retained; however, improvements and enhancements have evolved that have positive impact on the long-term success of the artificial urinary sphincter. The current 800 model includes a seamless, pressurized balloon reservoir, nonkink tubing, and changes in the cuff that facilitate its placement and effectiveness with coaptation of the bladder neck and proximal urethra (Light and Reynolds, 1992; Barrett et al, 1993; Lai et al, 2007). Alternatives to the AS800 model have also been explored (Vilar et al, 2004).

Technique. Placement of the cuff should be at the level of the bladder neck in all female patients and prepubertal boys (Fig. 129–3). It is also the most desirable and effective location in pubertal boys and adult men with neurogenic sphincter incompetence. The bulbar urethra can be used as an alternative site in adult men with mature spongiosum. Levesque and associates (1996) have indicated that age is not a factor in placement of the cuff around the bladder neck. They found that children do not outgrow the artificial urinary sphincter as they progress through puberty and that replacement of the cuff is not routinely necessary. The artificial urinary sphincter cuff can be positioned around intestinal segments used in total urinary reconstruction but is more susceptible to erosion there. Several authors have described the successful placement of the cuff around a bowel segment, particularly when omentum is interposed between the cuff and the segment (Burbige et al, 1987; Weston et al, 1991; Light et al, 1995).

Placement of an artificial sphincter in children is the same as that described for adults. Development of the proper plane for the cuff is virtually identical to that described for a fascial sling. The cuff should be sized snugly, but not tightly, around the bladder neck. Obviously, a sterile environment is critical in considering placement of the artificial urinary sphincter to avoid infection. For that reason, preoperative antibiotics are a necessity, and confirmation of sterile urine is required. With those precautions there is freedom to open the bladder in dissecting around the bladder neck. This will often facilitate the dissection and ensure proper placement. The AS800 model has a locking mechanism in the pump that permits the artificial urinary sphincter to be deactivated and activated without a second operative procedure. Experience has shown that leaving the unit deactivated with the cuff deflated after placement allows formation of a pseudocapsule around the cuff and decreases the risk of erosion (Furlow, 1981; Sidi et al, 1984). The noncycled artificial urinary sphincter

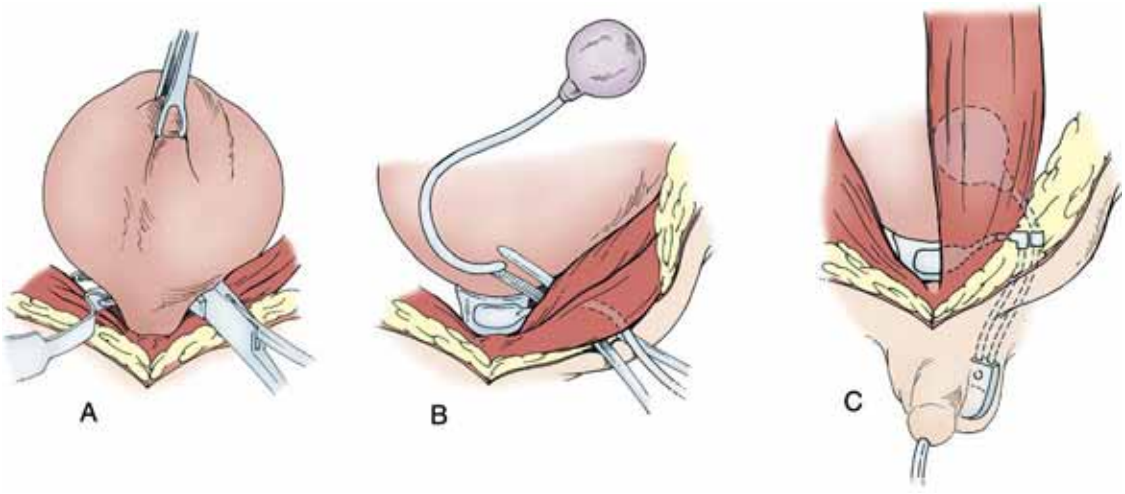

Figure 129–3. Artificial urinary sphincter placement in children. **A**, The cuff is placed around the bladder neck in prepubertal children. Dissection may be facilitated by palpation of a urethral catheter and balloon or by a posterior approach. If dissection is difficult, the bladder can be opened. **B**, The reservoir is placed beneath the rectus muscle. **C**, A tunnel is then made into the scrotum or labia for positioning of the pump on the same side as the reservoir. Tubing connections are made ventral to the rectus fascia, and the device is initially left deactivated.

occasionally may provide enough resistance for continence, eliminating the disadvantages of activation (Herndon et al, 2004a).

Results. There are substantial short- and long-term data regarding continence after placement of the artificial urinary sphincter, with the largest series presented by Herndon and associates (2003). **In investigation of continence, it must be placed in context of the cost experienced by the patient defined by mechanical malfunctions resulting in secondary operative procedures and more catastrophic complications, such as device infection and erosion.** Dramatic improvement regarding the need for secondary procedures has occurred with the technical refinements in the device. Ten- to 15-year long-term follow-up of the artificial urinary sphincter in children has been reported (Levesque et al, 1996; Kryger et al, 1999, 2001; Castera et al, 2001; Hafez et al, 2002; Herndon et al, 2003; Lopez Pereira et al, 2006; Ruiz et al, 2006). All groups report an impressive continence rate of 80% and a functioning sphincter in 95% of patients. These reports are consistent with older series in children reporting continence rates of 75% to 90% and a functioning sphincter in 85% to 97% (Nurse and Mundy, 1988; Gonzalez et al, 1989a; Bosco et al, 1991; O'Flynn and Thomas, 1991; Aprikian et al, 1992; Singh and Thomas, 1996; Simeoni et al, 1996; Catti et al, 2008). Herndon and colleagues (2003) presented the most comprehensive long-term data. They achieved overall continence in 86% of 142 patients with an average follow-up of 10 years. Age at implementation does not appear to affect continence (Kryger et al, 2001).

Whereas the artificial urinary sphincter is one of the few surgically created continence mechanisms that does not negatively affect spontaneous voiding, intermittent catheterization remains an important adjunct in approximately 75% of children with neurogenic sphincter incompetence and can be performed successfully through the cuff (Diokno and Sonda, 1981; Gonzalez et al, 1995; Levesque et al, 1996; Kryger, 1999, 2001; Castera et al, 2001; Hafez et al, 2002; Herndon et al, 2003). As boys approach puberty, spontaneous voiding may become progressively inadequate. It has been speculated that growth of the prostate causes an increase in native outlet resistance. Kaefer and associates (1997a) evaluated increases in cuff size to facilitate spontaneous voiding in boys. In their limited series, they did not find that up-sizing restored the ability to void spontaneously. Jumper and colleagues (1990) reported on prostatic development and sexual function in pubertal boys with spinal dysraphism who had been treated with the artificial urinary sphincter. They found that the artificial sphincter did not alter sexual development, prostatic growth, or morphologic features.

Herndon and associates (2003) reported device malfunction in 64% with the pre-AS800 model and 30% with the AS800. Sphincter erosion was similar for the pre-AS800 and AS800, occurring at 19% and 16%, respectively, in their experience. Fastidious attention to detail and sterile technique diminish the risk of infection but do not eliminate it. When infection occurs without erosion, the unit can be removed and later replaced (Nurse and Mundy, 1988). Infections are minimized by sterilization of the urine preoperatively, meticulous cleaning of the wound site, preoperative bowel preparation, perioperative parenteral antibiotics, and copious antibiotic wound irrigation. Newer cuff design and a 6-week delay in activation of the device help formation of a thickened pseudocapsule that substantially decreases bladder neck and proximal urethral erosion. Kryger and associates (1999) indicated that erosion can be virtually eliminated when the cuff is placed as the primary treatment for bladder neck incompetence. They and others (Aliabadi and Gonzalez, 1990; Gonzalez et al, 1995; Simeoni et al, 1996; Levesque et al, 1996; Castera et al, 2001; Hafez et al, 2002; Herndon et al, 2003) noted that the risk of erosion substantially increases after previous failed repairs but this has not been the experience of others (Ruiz et al, 2006). Identification of the correct plane between the bladder neck and vagina in female patients or rectum in male patients preserves the vascularity of the bladder neck and proximal urethra and may decrease the rate of erosion (Aliabadi and Gonzalez, 1990). Initial exposure through a posterior bladder approach as described by Lottmann and coworkers (1999) may be helpful. Shankar and colleagues (2001) suggested that there is an advantage to exposure of the bladder neck with a transperitoneal approach by decreasing the potential of bleeding from the prostatic venous plexus and improving visualization of the rectal wall.

Levesque and associates (1996) evaluated the long-term outcome of the artificial urinary sphincter on the basis of date of insertion and location of the placement. Before 1985 the artificial urinary sphincter had been inserted in 36 children. Between 1985 and 1990, an additional 18 children underwent placement. In the original group, 24 of the 36 sphincters were in place and 22 functional; 12 had required at least one revision. The mean survival of the device was 12.5 years. Success rates at 5 and 10 years were 75% and 72%, respectively. In the group implanted after 1985, 78% retained a functioning sphincter. The overall continence rate in both groups was 59%; sphincter survival probability at 10 years was approximately 70%. There was no difference found between failure rates in males and females with the exception that female patients who had previously undergone bladder neck surgery were more likely to suffer an erosion. The ability to void independently without the use of intermittent catheterization was retained in 36 children (67%). Those findings are supported by contemporary series (Levesque et al, 1996; Kryger, 1999, 2001; Castera et al, 2001; Hafez et al, 2002; Herndon et al, 2003; Lopez Pereira et al, 2006; Ruiz et al, 2006; Catti et al, 2008).

Upper urinary tract changes including hydronephrosis have been reported to occur in up to 15% of children after placement of the artificial urinary sphincter (Light and Pietro, 1986; Churchill et al, 1987; Gonzalez et al, 1995; Levesque et al, 1996; Kryger et al, 1999). In extreme cases, renal insufficiency has resulted. **It is now recognized that occlusion of the bladder neck in children with neurogenic sphincter incompetence can result in the unmasking or development of detrusor hostility manifested by a decrease in bladder compliance or increase in detrusor hyperreflexia** (Bauer et al, 1986). **Careful preoperative urodynamic assessment helps identify only some of the children who are at risk** (Kronner et al, 1998b). When hostile bladder characteristics are found preoperatively, anticholinergic medications can be beneficial for hyperreflexic contractions but augmentation cystoplasty is usually required for diminished compliance. Churchill and associates (1987) showed that favorable parameters can be maintained after placement of the artificial urinary sphincter; however, close observation is still recommended in any child undergoing bladder neck reconstruction to identify any early deterioration in bladder dynamics before upper tract changes.

Some children undergoing sphincter placement need bladder augmentation as well, and the timing of the two procedures may be questioned because of the concern for artificial urinary sphincter infection. Light and colleagues (1995) reported a 50% infection rate with simultaneous augmentation compared with 9.5% when the procedures were staged. On the contrary, a contemporary review by Miller and coworkers (1998) found that infection necessitating removal of the device occurred in only 2 of 29 such

patients (7%). This low rate is similar to that noted by others (Strawbridge et al, 1989; Gonzalez et al, 1989b). Several reports have evaluated various factors and found that the intestinal segment selected for augmentation appeared to be the only parameter affecting results; gastric augmentation was the least offensive regarding infection (Ganesan et al, 1993; Miller et al, 1998; Holmes et al, 2001). Gonzalez and associates (2002) reported an alternative technique using a seromuscular colocystoplasty and simultaneous placement of the artificial urinary sphincter. They achieved continence in 89% without the need for additional procedures and no deterioration of the upper urinary tract.

The AS800 is the subject of most reviews when the artificial urinary sphincter is discussed, but alternative devices have been reported (Lima et al, 1996; de O Vilar et al, 2004). An alternative device is a one-piece adjustable cuff connected to an injection port for inflation. The injection port is placed subcutaneously and made available for percutaneous access. This allows for adjusting the pressure within the cuff in order to achieve continence. It is particularly convenient for individuals with limited ability to actively pump the AS800. The periurethral constrictor is wider and more fluid than the AS800. It can be deactivated and reactivated by tapping the subcutaneous port.

The ultimate benefits of the artificial urinary sphincter lie in its ability to achieve a high rate of continence while maintaining the potential for spontaneous voiding. For practical purposes, when intermittent catheterization is required along with augmentation cystoplasty, use of native tissue for continence eliminates the long-term concern for infection or erosion and the risk of mechanical failure.

Urethral Lengthening

Young's original description of bladder neck reconstruction (1919) consisted of two components: excision of a segment of anterior urethral bladder neck tissue and narrowing of the adjacent remaining posterior portion. This, however, ultimately led to failure because the tubularized segment remained unsupported within the bladder. Refinements by Dees (1949) and Leadbetter (1964) maximized good muscle tone at the bladder neck and extension of the urethral tube through the trigone.

With similar principles, Tanagho (1981) described a cephalad-based anterior detrusor wall tube. Closure of the tubularized bladder neck formed circularly oriented muscle fibers that Tanagho described as a sphincter mechanism. However, he cautioned against the use of this technique in the neurogenic population. Because of potential breakdown of that tubularized bladder neck and poor results, other techniques have been developed on the basis of the concept of a flap valve mechanism for urinary retention. Kropp and Angwafo (1986) described urethral lengthening and construction of a flap valve for neurogenic bladder neck and sphincter dysfunction. The technique is based on an anterior detrusor wall tube that is kept in continuity with the urethra, tubularized, and implanted into a submucosal tunnel within the trigone. Conceptually, this is effective; however, difficulty with catheterization is a common problem and significant concern.

Technique. A Foley catheter is placed intravesically and the bladder filled to capacity. The bladder is exposed through either a midline or low transverse abdominal incision. The bladder neck is then identified with application of gentle catheter traction. A 6 × 2-cm rectangular flap based on the bladder neck and urethra is then isolated. Stay sutures are placed, and the flap is mobilized in continuity with the proximal urethra. The detrusor musculature at the bladder neck is then divided, separating the bladder and urethra, or the muscle may be left intact at the 5- and 7-o'clock positions. The anterior vaginal wall is exposed in girls; the seminal vesicles are exposed in boys. The rectangular strip based on the urethra is tubularized posteriorly around the urethral catheter with a continuous absorbable suture. The distal portion of the tubularized strip should be approximated in an interrupted fashion to facilitate excision of excessive tissue without jeopardizing the suture line. A capacious submucosal tunnel through the trigone is then developed posteriorly for the proximal neourethra (Fig. 129–4). A wide tunnel is required to prevent kinking at the level of the bladder neck, which will impede catheterization. It is important to eliminate dead space at the entrance of the urethra into the bladder, and this can be accomplished by placement of lateral anchoring sutures in the region of the bladder neck. The detrusor tube must be pulled straight through the tunnel without curve or deviation to facilitate catheterization. Waters and colleagues (1997) and Kropp (1999) have not found it necessary to reimplant all ureters in a cephalic location; they now typically reimplant only refluxing ureters (Kropp, 1999). When the bladder is closed, the lateral wings in the region of the bladder neck are approximated and incorporate adventitia of the tubularized urethra. This enhances a watertight closure and is continued for 2 to 3 cm anteriorly, often up to the area of augmentation. The tubularized neourethra should be long enough to reach the true lumen of the bladder, where it is exposed to pressure as an effective flap valve.

Because of the difficulties with catheterization, modifications of the Kropp bladder neck procedure have been described. Belman and Kaplan (1989) suggested a simplified approach. They harvested a rectangular strip from the anterior bladder wall similar to that described by Kropp. The lateral and posterior muscles at the bladder wall are not incised, however, and the proximal urethra and bladder are not separated. The flap is tubularized over an 8-Fr catheter. The epithelium on the floor of the bladder is incised, contrary to the tunnel made by Kropp. The tube is placed within the trough with the proximal meatus secured on the floor of the bladder. The epithelial edges of the trough are then secured to the lateral aspect of the tube. As in the initial description, the suture line for tubularization of the urethra is posterior against trigonal muscle. Closure of the bladder begins with reapproximation of the lateral walls of the bladder to the tube until the bladder edges meet. The remaining portion of the bladder is covered by an augmentation. Regardless of any modification to the Kropp bladder neck procedure, catheterization potentially remains problematic and therefore the patient should be prepared for a catheterizable abdominal-vesicle channel.

Results. Snodgrass (1997) examined the results in 23 children, 22 of whom had neurogenic sphincter incompetence and noted continence in more than 90% of the children. The most common complication was difficult catheterization, particularly in boys. Less than half of the boys in Snodgrass' series catheterize through the native urethra; the majority do so through an abdominal wall stoma. Postoperative vesicoureteral reflux was identified in 9 of 18 children, and Snodgrass speculated that this was due to lateral retraction of the ureters. The recommendation was made to leave the posterior bladder wall open and flat in receiving the augmentation to prevent this distortion. Kropp (1999) has not had as much problem with catheterizations in his patients and likewise has achieved a high rate of continence without a high incidence of new reflux.

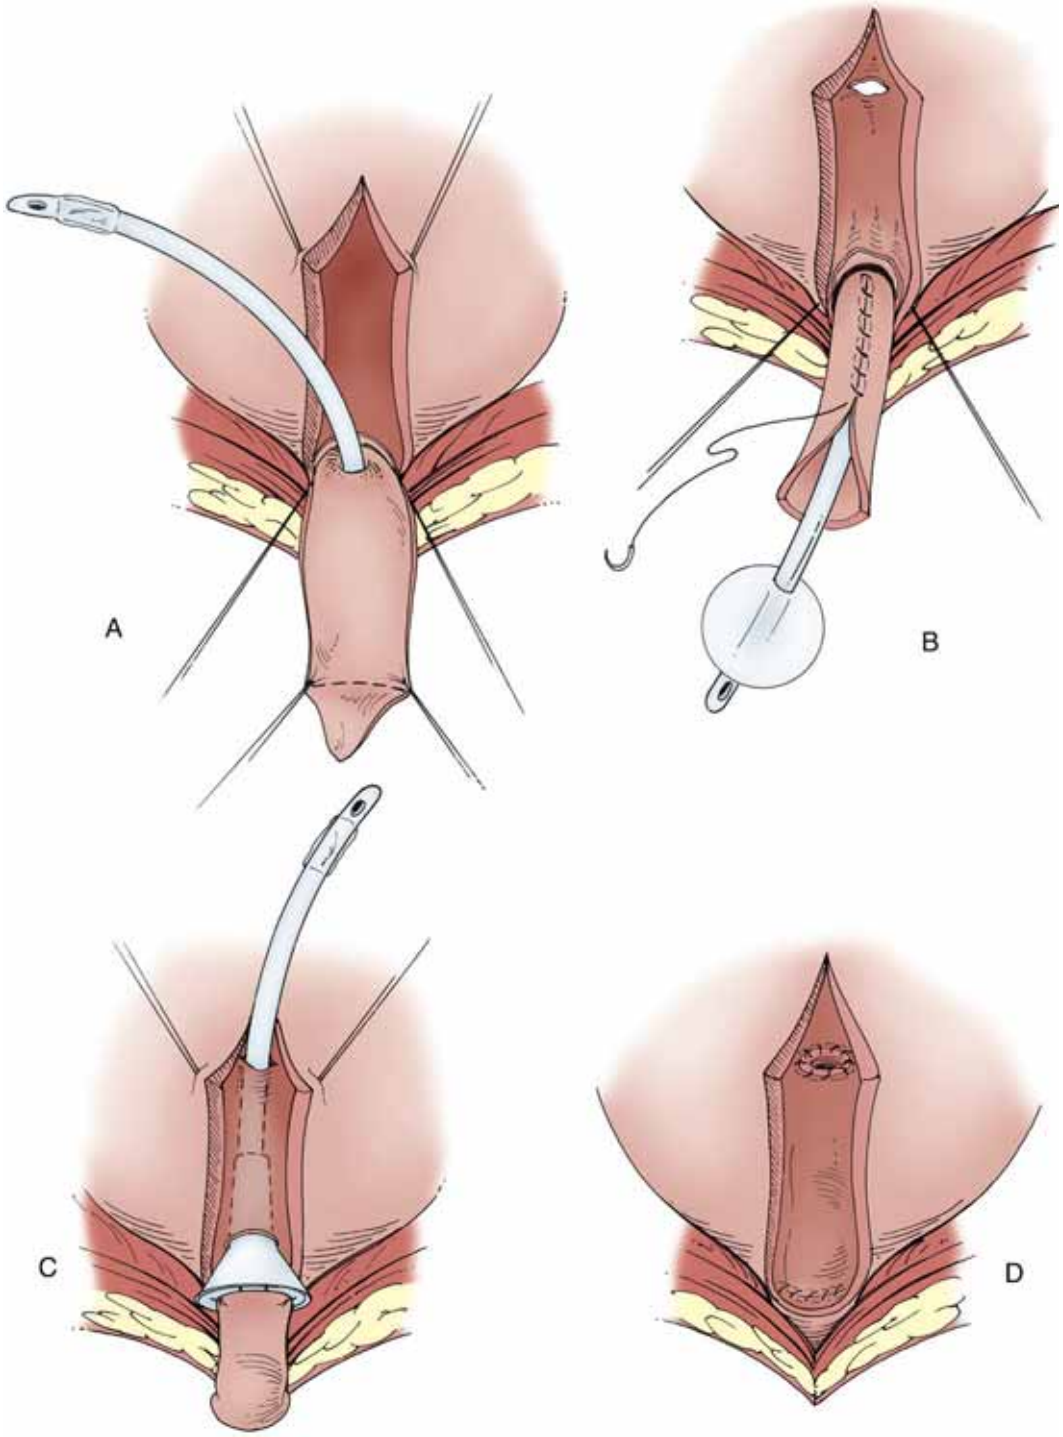

Figure 129–4. Kropp anterior detrusor tube. **A**, An anterior flap of bladder (2 cm wide × 5 to 6 cm long) is developed in continuity with the urethra. **B**, The anterior flap is tubularized over a catheter. A tunnel beneath the mucosa of the trigone is made between the ureteral orifices for the length of the tube. **C**, The tubularized flap is brought through the tunnel. **D**, The detrusor tube is secured to the floor of the trigone with interrupted absorbable suture in a straight course.

Some patients with an effective flap valve mechanism constructed by urethral lengthening will virtually never leak per urethra. This potentially puts them at risk for upper tract deterioration or bladder rupture, particularly if they do not or cannot catheterize reliably. Snodgrass (1997) thought that his modification was beneficial in that it resulted in a shorter intravesical tunnel for the neourethra, allowing leakage per urethra with overfilling.

Pippi-Salle Procedure

In an attempt to maximize the benefits of the Kropp technique and to decrease problems with catheterization, Salle (1994) **reported an anterior bladder onlay flap.** With this technique the posterior wall of the neourethra is intact, theoretically providing less potential hang-up during catheterization. Modifications have been made since the first report to

improve flap viability, to minimize fistula formation, and to extend the indications for the procedure beyond that of the neurogenic bladder (Salle et al, 1997).

Technique. An anterior, full-thickness bladder wall flap 5 × 1 cm is mobilized to the bladder neck with 0.1 cm of its epithelial edges excised to avoid overlapping suture lines. Two parallel incisions down to the level of the muscle are made in the mucosa of the trigone from the native bladder neck. The anterior flap is secured to the midline strip of trigone mucosa to form a tube of lengthened urethra with absorbable suture. The muscle on either side of the posterior epithelial strip may be incised superficially to provide an edge to which the muscle of the anterior flap may be approximated with a second layer of suture in an effort to avoid fistula (Fig. 129–5). The more lateral mucosa of the trigone is mobilized and closed over the midline urethra. Distally, the muscle of the bladder neck is wrapped fairly tightly around the urethra with closure. More proximally, the lengthened urethra should extend well into the lumen of the bladder.

Results. Initial complications of this procedure included persistent incontinence, urethrovesical fistula, and partial necrosis of the intravesical neourethra. Widening the base of the urethra at the level of the bladder neck may decrease these problems. Children who have previously undergone bladder surgery can have a secondary Salle repair if the anterior bladder flap is lateralized slightly to avoid any old midline suture line and increased potential for scarring or necrosis.

Salle and coworkers (1997) found that continence was achieved in 12 of 17 patients (70%) for more than 4 hours. Catheterization difficulties occurred in only 3 of 17 children, 1 of whom subsequently underwent an appendicovesicostomy. Fistula formation at the base of the flap between the proximal, intravesical urethra and bladder occurred in 2 children and resulted in recurrent incontinence. This problem appears to be diminished by making a wider base to the flap and generously trimming the epithelial edges. Jawaheer and Rangecroft (1999) reported a diurnal continence rate of 61% for 3 hours or longer with the Salle procedure. However, only 44% of their patients were dry through the night. Less trouble with catheterization has occurred relative to the Kropp technique, and it rarely remains a problem. Continence rates have not been quite as high in most series (Rink et al, 1994; Mouriquand et al, 1995; Cole et al, 2003).

Canales and coworkers (2006) capitalized on both the Kropp and Pippi-Salle techniques. They evaluated a miniature intravesical urethral lengthening. The primary difference relates to a diminished tunnel (3 cm) and radius of the anterior detrusor tube (8 Fr) with the intent of enhancing resistance, maintaining a popoff mechanism, limiting the use of bladder tissue, and avoiding the need for ureteral reimplantation. At follow-up of 2.5 years, 8 of 9 patients were dry, had normal upper tracts, and had an average leak point pressure of 71 cm H_2O.

Bladder Neck Division

The ultimate procedure to increase bladder outlet resistance is to divide the bladder neck so that it is no longer in continuity with the urethra. It must be accompanied by construction of a continent abdominal wall stoma and should be performed only in patients who will reliably catheterize. If effective, it prevents any leakage or popoff per urethra and potentially increases the risk for upper tract deterioration or bladder rupture if emptying is not performed. Division is seldom performed as a primary procedure but may be considered if the previously mentioned repairs fail (Khoury et al, 1999; Bergman et al, 2006).

Such a procedure effectively moves the reconstructive effort into the realm of continent urinary diversion. The bladder neck is abandoned from a physiologic standpoint, although the bladder may be used as part of the reservoir. Effective division of the bladder neck is not a simple procedure. The bladder must be aggressively mobilized away from the urethra. The bladder should be closed distally in several layers after the posterior lip of bladder neck and trigone are rolled anteriorly and widely separated from the distal urethra. Omentum has generally been interposed. Without these steps, fistulization and leakage per urethra can occur (Khoury et al, 1999; Nguyen and Baskin, 2003). With aggressive mobilization, the fistula rate should be low (Thomasch et al, 2009).

Key Points: Bladder Neck Reconstruction

- Any bladder neck repair other than placement of an artificial urinary sphincter, particularly in combination with augmentation cystoplasty, is likely to make spontaneous voiding inadequate.
- Young-Dees-Leadbetter bladder neck repair in the spina bifida population may have variable success related to the underlying neurogenic dysfunction.
- Fascial slings have been used more extensively and with better results in girls than in boys with neurogenic sphincter incompetence, although those results have varied greatly.
- Experience does not yet suggest that injection of bladder neck bulking agents has a lasting effect on severe neurogenic sphincter incompetence.
- A functioning, well-positioned artificial urinary sphincter device generally provides good outflow resistance and is best suited for patients who can empty adequately with spontaneous voiding.
- Urethral lengthening procedures construct an effective flap value mechanism for continence that disrupts any chance of spontaneous voiding and may make catheterization per urethra difficult.
- The success of most bladder neck repairs in the neurogenic population is improved when the repair is associated with bladder augmentation.
- Any bladder neck repair may unmask or result in new bladder hostility; careful follow-up is mandatory.

AUGMENTATION CYSTOPLASTY

The initial approach to the patient for augmentation cystoplasty is similar regardless of the bowel segment to be used. Cystoscopy should be performed preoperatively to identify any unsuspected anatomic abnormalities that may affect the surgery or postoperative care. If other bladder procedures, such as ureteral reimplantation, are to be performed, the bladder is left full after cystoscopy. If only augmentation is indicated, the bladder is emptied to allow easy access to the peritoneal cavity.

As a general rule, a midline incision is preferred for intestinal cystoplasty, although these procedures can be performed through a lower transverse incision if there has been no previous abdominal surgery. Laparoscopic assistance with mobilization of the intestine may allow

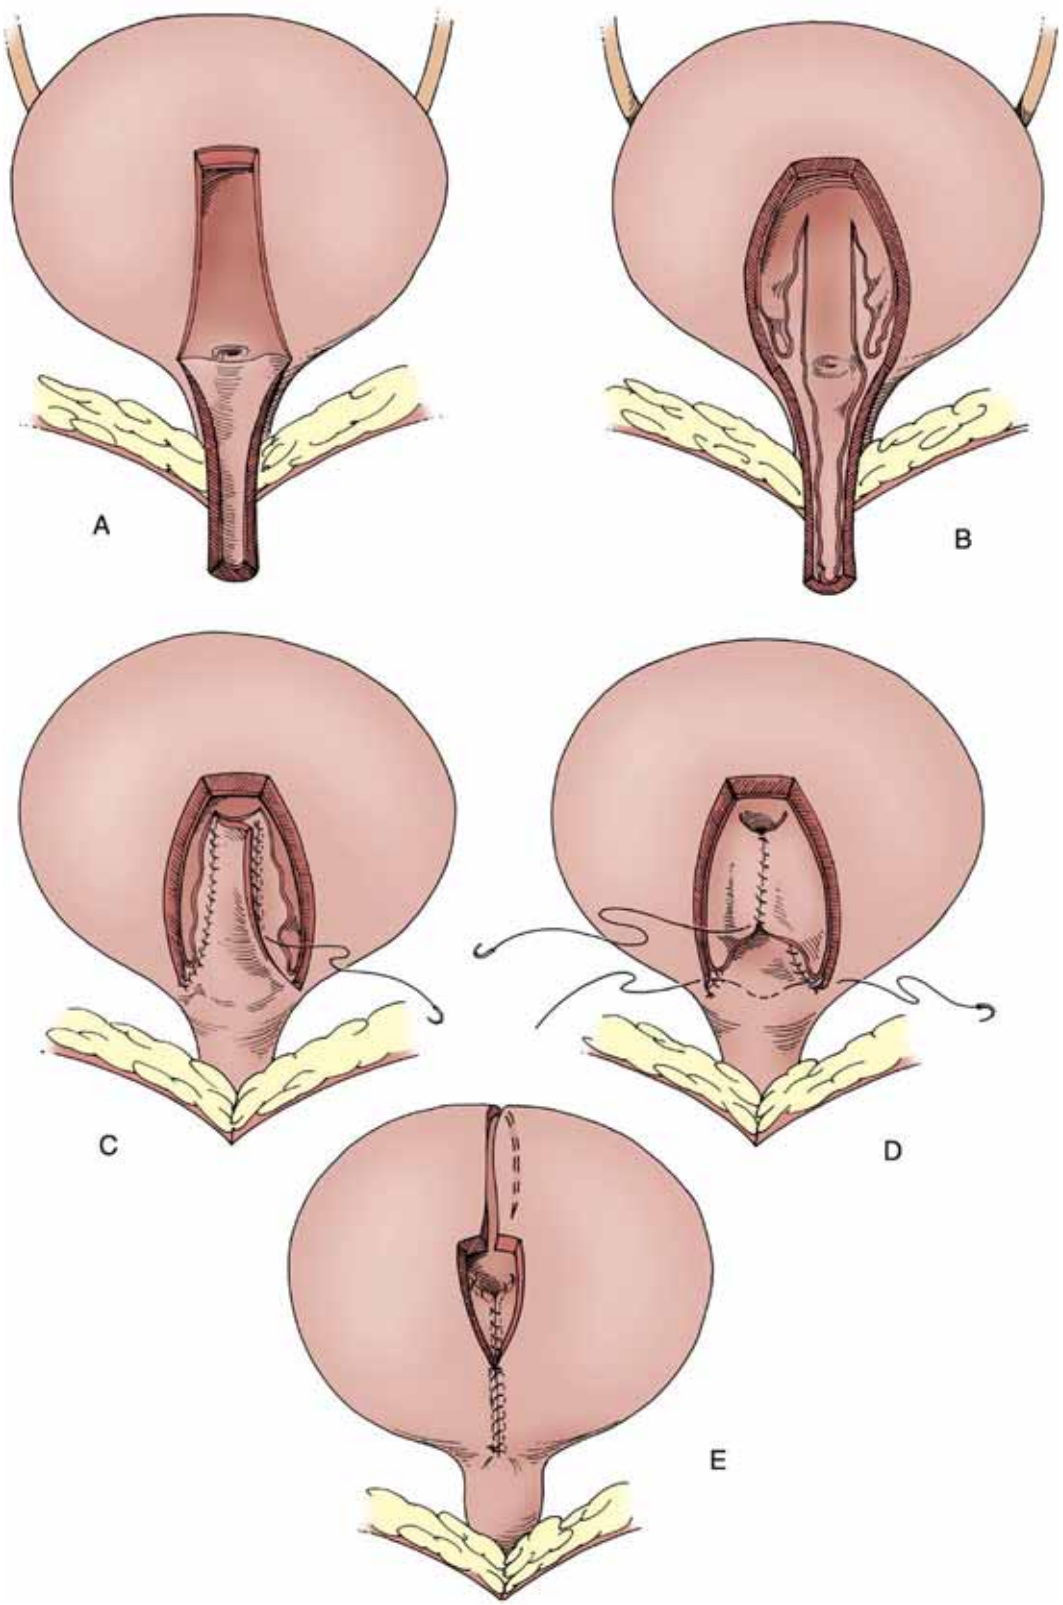

Figure 129–5. Pippi-Salle anterior detrusor tube onlay. **A**, An anterior detrusor tube (1 cm × 4 to 5 cm) is mobilized to the level of the bladder neck. **B**, A central strip on the floor of the bladder is developed by incision of the epithelium on either side. **C**, The anterior detrusor flap is secured to the strip in a two-layer fashion, approximating the epithelium with the first layer and muscle with the second. **D**, The lateral mucosa of the trigone is mobilized and secured over the lengthened urethra. Distally, the bladder is closed to itself and should incorporate a portion of the anterior detrusor flap to ensure a watertight seal. **E**, After distal closure the remaining portion of the bladder is left open if augmentation cystoplasty is necessary.

augmentation through a smaller, lower incision (Hedican et al, 1999). Augmentation cystoplasty may eventually be performed completely by laparoscopy with or without use of a robotic system (Lorenzo et al, 2007a, 2007b; Wang et al, 2007; Passerotti et al, 2008). Associated bladder procedures should be performed before the peritoneal cavity is opened to minimize third-space fluid loss. For gastrocystoplasty the incision needs to extend from the pubis to xiphoid to allow more cephalad exposure.

Management of the Native Bladder

In the past it had been recommended that the majority of the "diseased" bladder be excised in preparation for augmentation. This meant removal of the supratrigonal bladder, leaving only a small cuff of higher bladder for anastomosis to the intestinal segment. Despite the cuff, a relatively small area is left for anastomosis to the bowel segment; most of the bowel is approximated to itself. **Most surgeons now preserve the native bladder as long as it is widely opened to prevent a narrow-mouthed anastomosis, which can result in the augmentation segment's behaving like a diverticulum** (Fig. 129–6). A sagittal incision to bivalve the bladder is generally useful (Fig. 129–7). The incision is carried from a point several centimeters cephalad to the bladder neck anteriorly to a position just above the trigone posteriorly. Such an incision allows a technically easier anastomosis to the bowel segment and leaves the native bladder to add to the overall capacity. A greater circumference for the anastomosis can be provided, if needed, by opening the bladder in a stellate fashion with a second transverse incision into the two bladder halves. There have been reports of severe penile or perineal pain in sensate boys after augmentation with preservation of the native bladder (Phelps and Malone, 2004). Although four such patients required secondary excision of the bladder, similar problems have not been frequent enough to warrant routine excision at the time of augmentation.

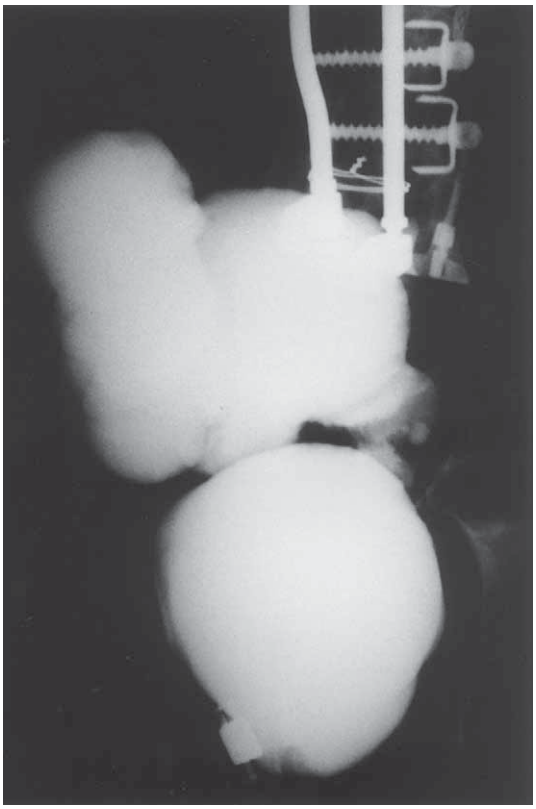

Figure 129–6. Cystogram after augmentation demonstrates a narrow anastomosis of the bowel segment to bladder. The segment behaves like a diverticulum.

Management of Intestinal Segments

Hinman (1988) and Koff (1988) have demonstrated the advantages of opening a bowel segment on its antimesenteric border, with subsequent detubularization and reconfiguration of that intestinal segment. **Reconfiguration into a spherical shape provides multiple advantages, including maximization of the volume achieved for any given surface area, blunting of bowel contractions, and improvement of overall capacity and compliance.** All intact, tubular intestinal segments have been noted to generate pressures of 60 to 100 cm H_2O with contractions, including ileum (Kock, 1969; Light and Engleman, 1985; Fowler 1988; Camey et al, 1991). Detubularization lowered the maximal contractile pressure from 63 to 42 cm H_2O in the right colon and 81 to 28 cm H_2O with use of ileum (Goldwasser et al, 1987). Furthermore, a shorter intestinal segment can be used to achieve the same capacity than when it is left in tubular form. **Detubularization and reconfiguration should always be performed during augmentation cystoplasty.**

Mathematical models based on the length and width of the bowel segment used may predict the volume needed but are cumbersome (Rink and Mitchell, 1990). Depending on the volume needed, 20 to 40 cm of ileum or approximately 20 cm of colon is generally used for cystoplasty. This somewhat depends on the volume of the native bladder being augmented. If the cystoplasty is being done on a bladder of moderate volume that generates high pressure by uninhibited contractions, less bowel is necessary than for one that is tiny in capacity. Unless it is otherwise contraindicated, the surgeon should err by making the bladder too large rather than too small. Appreciation of the patient's urinary volumes also should influence the size of the bladder required. Patients with upper tract damage, particularly to concentrating ability, may make huge volumes of urine and require a larger capacity.

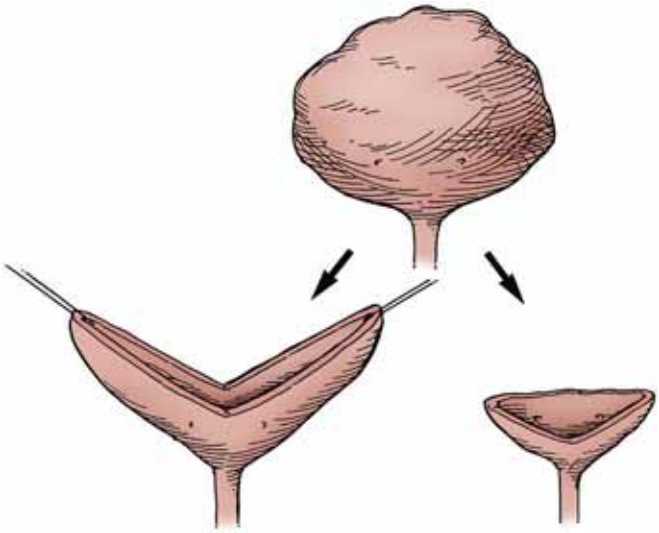

Figure 129–7. The native bladder can be managed by supratrigonal excision of the diseased bladder. More typically, the bladder is opened widely in a sagittal plane (*left*).

Ileocystoplasty

Goodwin and associates (1959) were among the first to demonstrate the numerous ways of anastomosing a patch of ileum to the native bladder after the ileum was detubularized and reconfigured to achieve the most spherical shape possible.

Technique. **A segment of ileum at least 15 to 20 cm proximal to the ileocecal valve should be selected.** The distal portion of terminal ileum is unique from a physiologic standpoint and should be avoided. The isolated segment should be 20 to 40 cm in length, depending on the patient's size, native bladder capacity, and desired final capacity. With short ureters, an extra tail of isoperistaltic ileum can be useful to reach the foreshortened ureters. This requires construction of an ileal nipple valve to prevent reflux as in the Kock or hemi-Kock pouch. This type of construction may require up to 60 cm of small intestine. **The segment to be used should have an adequate mesentery to reach the native bladder without tension.**

After selection of the appropriate segment, the mesentery is cleared from the bowel at either end for a short distance to make a window. The bowel is divided at those ends, and a hand-sewn ileoileostomy or stapled anastomosis is performed. The mesenteric window at the bowel anastomosis is closed to prevent an internal hernia. The harvested ileal segment is irrigated clear with 0.25% neomycin solution and opened on its antimesenteric border (Fig. 129–8A). **The ileum is folded in a** U **shape most commonly, although longer segments can be folded further into an** S **or** W **configuration.** The ileum is anastomosed to itself with running absorbable sutures (Fig. 129–8B). The suture line should approximate the full thickness of ileum to ileum while inverting

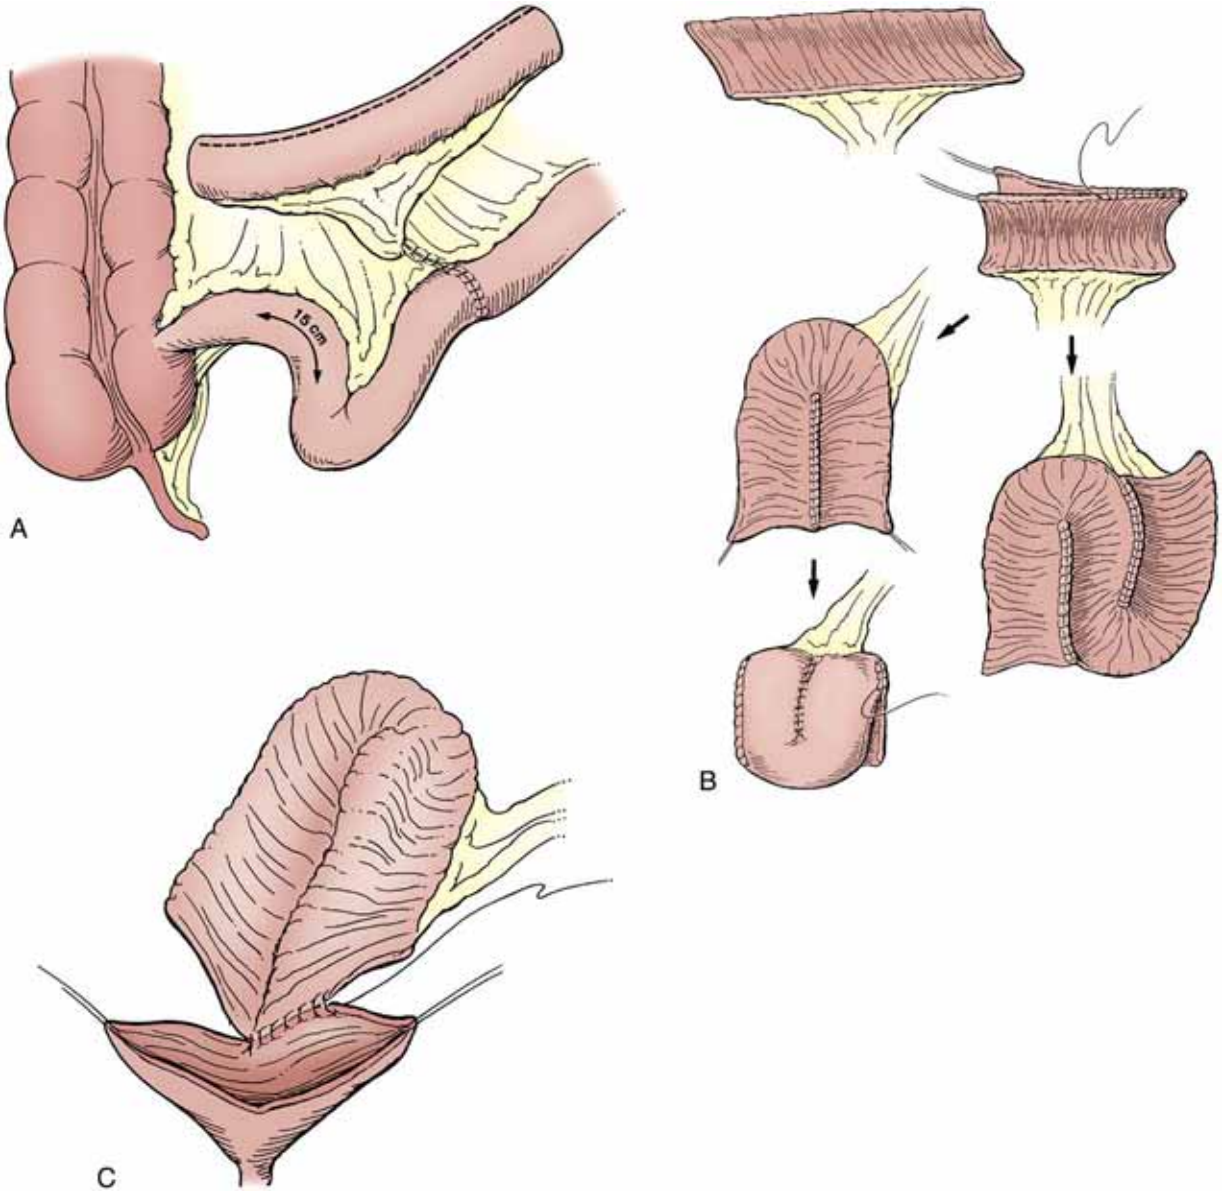

Figure 129–8. **A**, Ileocystoplasty. A 20- to 40-cm segment of ileum at least 15 cm from the ileocecal valve is removed and opened on its antimesenteric border. Ileoileostomy reconstitutes the bowel. **B**, The opened ileal segment should be reconfigured. This can be done in a U, S, or W configuration. It can be further folded as a cup patch. **C**, The reconfigured ileal segment is anastomosed widely to the native bladder.

the mucosa. If the bladder was not opened previously, it is incised in a sagittal plane. The anastomosis of the ileum to native bladder is easily done when it is started posteriorly. The anastomosis may be done in a one- or two-layer fashion, always using absorbable suture and inverting the mucosa to the lumen (Fig. 129–8C). Permanent sutures should never be used for any cystoplasty because they serve as a nidus for stone formation.

A suprapubic tube is brought out through the native bladder when possible and secured. The anterior aspect of the anastomosis is then completed. A drain is placed near the bladder and brought out of the pelvis through a separate stab incision. It should be removed promptly if it is not draining urine, particularly in neurogenic patients with a ventriculoperitoneal shunt. The wound is thoroughly irrigated and the abdomen is closed in layers.

Cecocystoplasty and Ileocecocystoplasty

Couvelaire described the use of the cecum for augmentation cystoplasty in 1950, and numerous reports of simple cecocystoplasty have appeared since then. Presently, cecocystoplasty is an uncommon operative procedure and is not discussed because it has largely been replaced by various forms of ileocecocystoplasty. With this technique, the cecum is opened, reconfigured, and used to augment the bladder alone, leaving a segment of ileum to reach the ureters or for construction of a continent abdominal wall stoma based on imbrication of the ileocecal valve and proximal ileum. Conversely, the ileal segment can be opened and used as a patch on the cecal segment before augmentation cystoplasty. Many modifications of the technique exist, but all start with mobilization of the cecum and right colon by incision of the peritoneum along the white line of Toldt up to the hepatic flexure. Fifteen to 30 cm of the terminal ileum is used. The length of the ileal segment depends on the technique employed. As with all intestinal cystoplasties, before division of the bowel segment it should be noted that it will reach the bladder without tension (Fig. 129–9A).

Technique. The isolated ileocecal segment is irrigated clear with neomycin solution and opened on its antimesenteric border through the ileocecal valve for its entire length. In the typical ileocecal augmentation the ileal and cecal segments are of equivalent length such that the borders of the open segment can be anastomosed and then folded on themselves to form a cup cystoplasty (Fig. 129–9B). The anastomosis of the reconfigured segments is done in either a one- or two-layer closure with absorbable suture. The opening should be left large enough to provide a wide anastomosis to the bivalved bladder. **If more volume is necessary, the ileal segment can be significantly longer, allowing it to be folded before anastomosis to the cecum.** The Mainz ileocecocystoplasty uses an ileal segment twice the length of the cecal segment. The opened edge of the cecal portion is anastomosed to the first portion of the ileal segment. The first and second portions of the ileal segment are next approximated. The compound ileocecal patch is then anastomosed to the bladder (Fig. 129–10). The mesenteric window is closed, and a suprapubic tube is placed through the native bladder and secured through the abdominal wall.

Appendix. One potential advantage of ileocecocystoplasty is the presence of the appendix. Particularly in children the appendix is useful in construction of a reliable continent abdominal wall stoma. The appendix may be removed with a small cuff of cecal wall and tunneled into the native bladder or a taenia of the cecal segment to provide a continence mechanism. Likewise, it may be left in situ and the base safely tunneled beneath a taenia. If the appendix is not to be used, an appendectomy is performed with standard ileocecocystoplasty.

Ileocecal Valve. The ileocecal segment has been used extensively in the adult population undergoing reconstruction and bladder replacement. It has been used less frequently so in children because the majority of patients undergoing augmentation cystoplasty do so for neurovesical dysfunction. Those patients generally have neurapraxic bowel dysfunction as well. Removal of the ileocecal valve in such children can result in intractable diarrhea (Gonzalez and Cabral, 1987; King, 1987). Use of the ileocecal valve in such

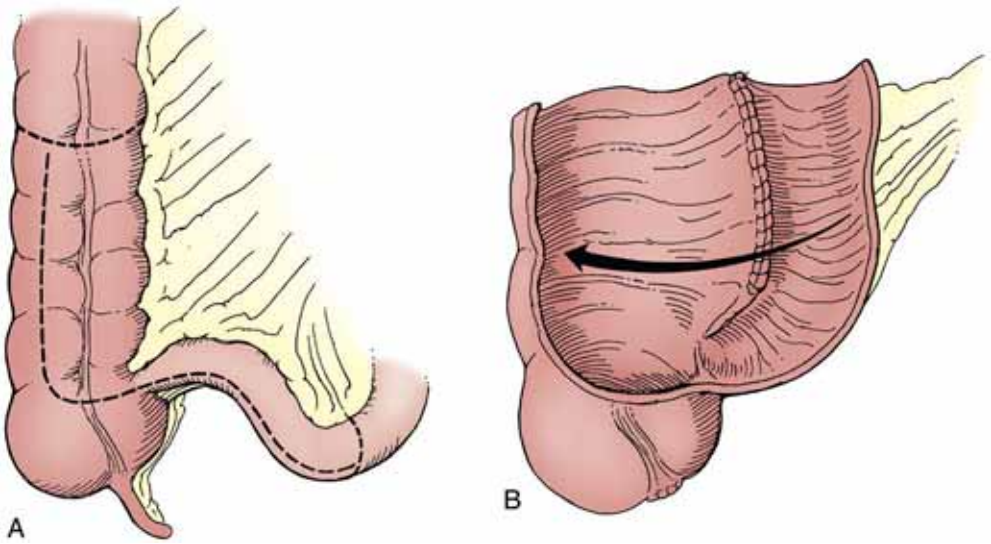

Figure 129–9. Ileocecocystoplasty. **A**, An ileocecal segment is selected. The length of segment chosen depends on the technique employed. After removal, it is opened on the antimesenteric border (*dashed lines*). **B**, The opened ileal and cecal segments are anastomosed to form a cup in the standard ileocecal cystoplasty.

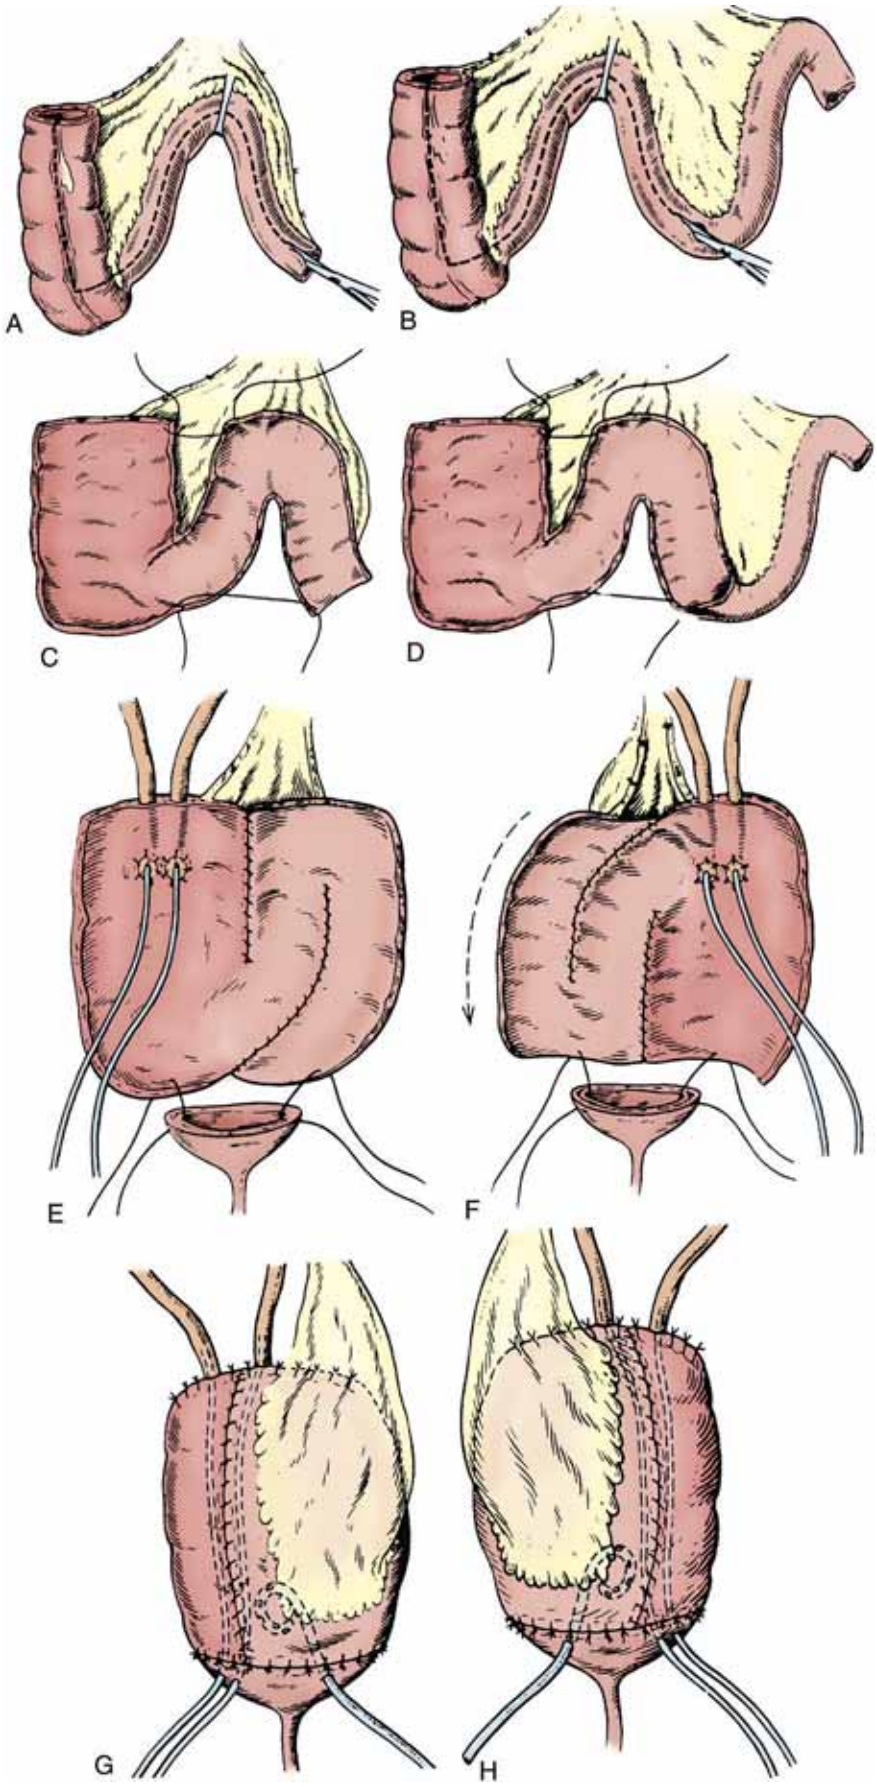

Figure 129–10. The Mainz ileocecocystoplasty. **A** and **B**, The ileal segment is twice the length of the cecal segment. **C** and **D**, It is opened on the antimesenteric border. **E** and **F**, The ureters can be reimplanted into the opened cecal segment if necessary. **G** and **H**, The ileocecal segment is anastomosed to the native bladder. (From Thuroff JW, et al. In: King LR, Stone AR, Webster GD, editors. Bladder reconstruction and continent urinary diversion. Chicago: Year Book; 1987.)

patients should be avoided unless other advantages of the segment outweigh the risk of diarrhea and fecal incontinence.

There are potential advantages to the use of the ileocecal segment. Antireflux tunnels can easily be performed into the taenia of the cecum when necessary. Again, for the short ureter, a tail of ileum can be left intact to bridge the gap and the imbricated ileocecal valve used for antireflux. The same imbrication technique can be used to construct a continent abdominal wall stoma as with the appendix. Cain and associates (Cain and Husmann, 1994; Cain et al, 1999) have proposed use of the ileocecal segment for augmentation with the plicated ileal segment brought to the abdominal wall as a catheterizable stoma as in the Indiana pouch.

Sigmoid Cystoplasty

Use of the sigmoid colon for augmentation cystoplasty was first reported by Lemoine in 1912 (Charghi et al, 1967) and continues to be used commonly. **Because of the strong unit contractions of the sigmoid, it is imperative to detubularize and reconfigure the segment to provide maximal compliance and disruption of contractions.**

Technique. Fifteen to 20 cm of sigmoid colon is identified and mobilized. The mesentery is transilluminated to identify the vascular arcade to the segment. After identification of this blood supply the surgeon must ensure that the segment can reach the bladder without tension. If so, the bowel segment is divided between clamps and a colocolostomy performed (Fig. 129–11A). The remainder of the abdominal cavity is carefully packed to prevent contamination from the open sigmoid segment. Detubularization and reconfiguration are done in a fashion determined by the surgeon's preference. The sigmoid patch is anastomosed to the bivalved bladder in a manner similar to that previously described for ileocystoplasty. Again, a large suprapubic tube is brought out through the native bladder and secured to the bladder and skin exit sites. Drains are placed as previously noted.

Reconfiguration of Sigmoid. Sigmoid colon segments are generally reconfigured in one of two ways. Mitchell (1986) suggested closing the two ends and then opening the segment longitudinally opposite its blood supply. The segment easily fits on the bivalved bladder in either the sagittal or coronal plane (Fig. 129–11B). More radical reconfiguration, and perhaps breakup of unit contractions, may be achieved by folding the sigmoid segment in a U shape similar to that described for ileocystoplasty (Sidi et al, 1987a) (Fig. 129–11C). A slightly longer segment of sigmoid may be necessary for effective reconfiguration in this manner.

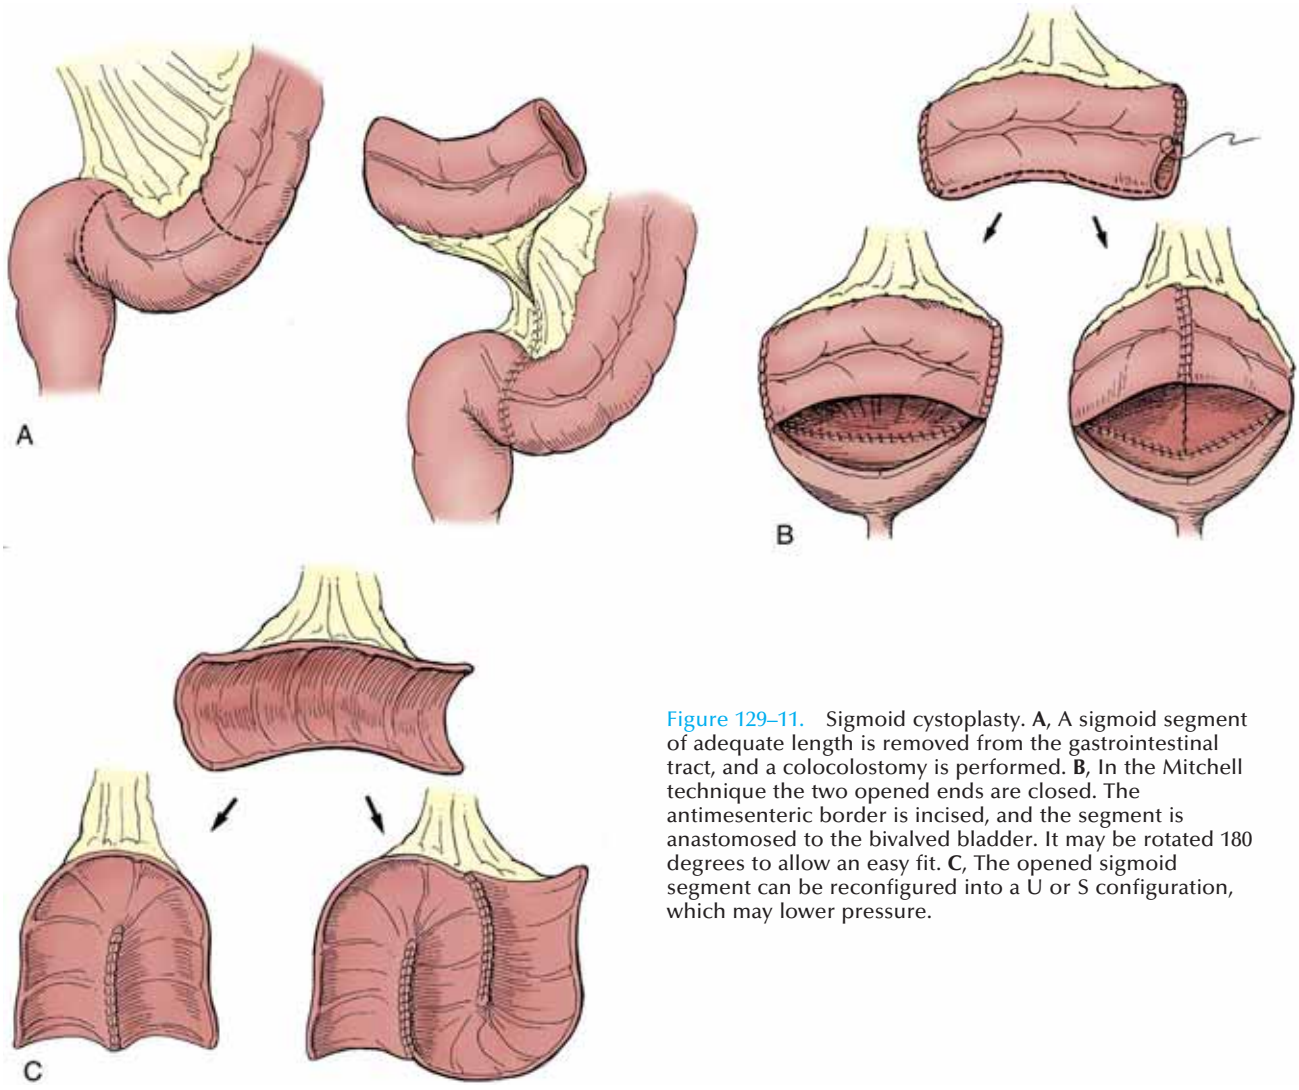

Figure 129–11. Sigmoid cystoplasty. **A**, A sigmoid segment of adequate length is removed from the gastrointestinal tract, and a colocolostomy is performed. **B**, In the Mitchell technique the two opened ends are closed. The antimesenteric border is incised, and the segment is anastomosed to the bivalved bladder. It may be rotated 180 degrees to allow an easy fit. **C**, The opened sigmoid segment can be reconfigured into a U or S configuration, which may lower pressure.

Gastrocystoplasty

Two basic techniques exist for use of stomach in bladder augmentation.

Technique with Use of Gastric Antrum. Leong and Ong (1972) described the use of the entire gastric antrum with a small rim of body for bladder replacement. With their technique the left gastroepiploic artery is always used as a vascular pedicle. If the right gastroepiploic artery is dominant and the left vessel ends high of the greater curvature, a strip of body along the greater curvature from the left gastroepiploic artery to the antrum is maintained and provides adequate blood supply (Leong, 1988). Continuity of the upper gastrointestinal tract is restored by a Billroth I gastroduodenostomy.

Technique with Use of Gastric Body. A gastric wedge based on the midportion of the greater curvature may be used (Adams et al, 1988) (Fig. 129–12A). **The gastric segment used in this technique is made up mainly of body and consequently has a higher concentration of acid-producing cells. The right or left gastroepiploic artery may be used as a vascular pedicle to this segment.** The right artery is commonly dominant and thus more frequently used. The wedge-shaped segment

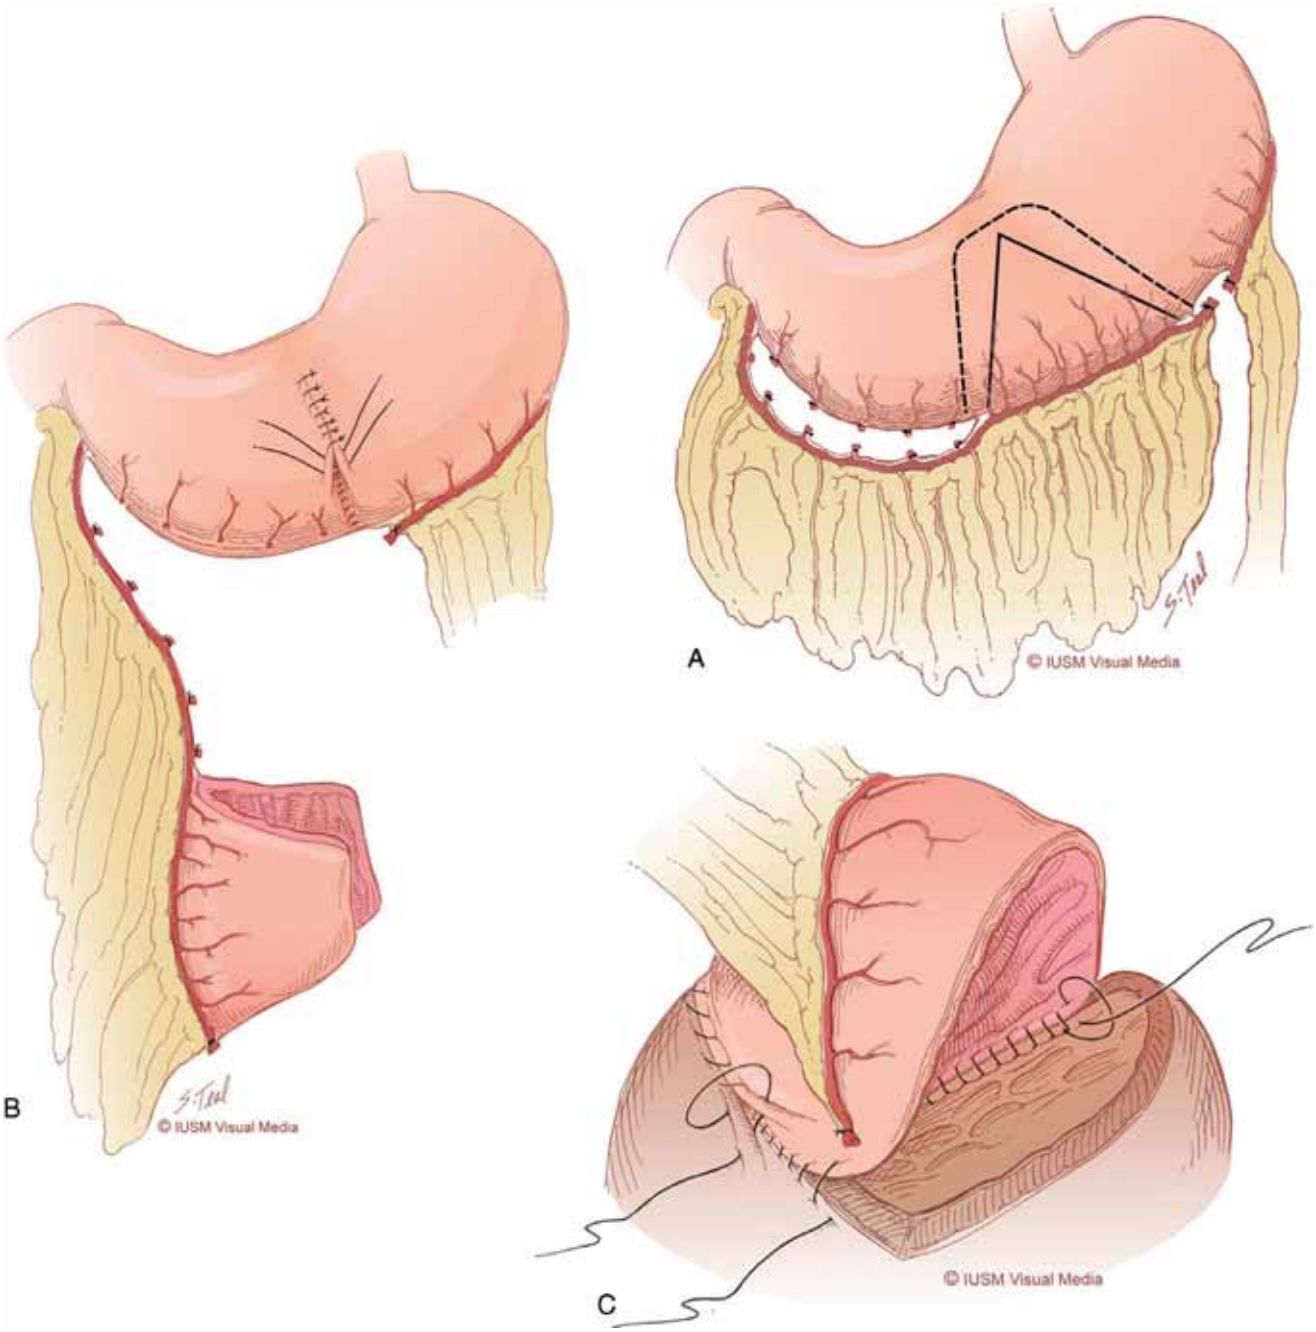

Figure 129–12. Gastrocystoplasty with use of the body. **A**, Gastric segment of body is mobilized on the right gastroepiploic artery. The left vessel may also be used; neither vessel as a pedicle should be free floating through the peritoneum. **B**, A longer gastric segment along the greater curvature with wider apex provides more surface area for augmentation. **C**, The gastric segment is anastomosed to the bivalved bladder with the mucosa inverted. (© Indiana University Medical Illustration Department.)

of stomach includes both the anterior and posterior wall. The segment used may be 10 to 20 cm along the greater curvature, depending on the patient's age and size as well as the needed volume (Fig. 129–12B). The incision into the stomach is stopped just short of the lesser curvature to avoid injury to branches of the vagus nerve controlling the gastric outlet. Branches of the left gastric artery just cephalad to the apex of this incision are suture ligated in situ before incision to avoid significant bleeding. Parallel atraumatic bowel clamps are placed on either side of the gastric incisions to avoid excessive bleeding or spillage of gastric contents. Alternatively, the stomach may be incised by use of a gastrointestinal stapling device that places a double row of staples on each side of the incision (Mitchell et al, 1992). The staple lines, however, must eventually be excised. The native stomach is closed in two layers with permanent sutures on the outer seromuscular layer.

Branches of the gastroepiploic artery to the antrum on the right or to the high corpus on the left are divided to provide mobilization of the gastroepiploic pedicle. For the eventual pedicle to be long enough to reach the bladder, the appropriate segment may be higher on the greater curvature if the right vessel is used as a pedicle or lower if it is based on the left. The vascular pedicle, with omentum, should not be free floating through the abdomen. The segment and pedicle may be passed through windows in the transverse mesocolon and mesentery of the distal ileum and carefully secured to the posterior peritoneum. Despite careful consideration for an adequate pedicle length, on occasion the gastric segment initially may not reach the bladder without tension. Either gastroepiploic artery may be mobilized closer to its origin for further length. The first few branches from the gastroepiploic artery to the isolated gastric segment may also be divided. Because of the rich submucosal arterial plexus in the stomach, devascularization of the isolated segment does not result. Rarely, it may be necessary to approximate some of the isolated gastric segment to itself in one corner. The gastric segment should be approximated to the native bladder with one or two layers of absorbable sutures, with care taken to invert the mucosa (Fig. 129–12C).

Raz and colleagues (1993) and Lockhart and associates (1993) have described the use of a much longer, more narrow segment of stomach based along the greater curvature. Use of this segment, which includes both body and antrum, somewhat narrows the lumen of the stomach along its entire length except at the fundus and pylorus. Raz and colleagues have isolated this segment with a gastrointestinal stapler so that the native stomach is never open. The segment used in both of these series is similar to that first described by Sinaiko (1956), the first surgeon to use stomach in bladder replacement. **Postoperative bladder and gastric drainage is no different from that described for intestinal cystoplasty.** Histamine-2 (H_2) blockers are often given in the early postoperative period to promote healing (Rink et al, 2000).

Postoperative Management

Early Management

Care of patients after cystoplasty is similar regardless of the gastrointestinal segment used in the procedure. Typically, **all patients have been maintained on nasogastric decompression until bowel function recovers, although in two studies** (Gundeti et al, 2006; Erickson et al, 2007) **it was suggested that nasogastric suction may not be necessary after ileocystoplasty. Attention to fluid and electrolyte management is important because third-space losses may be significant after extensive reconstructive surgery.**

Continuous drainage of the bladder is achieved by suprapubic cystostomy. Mucus production from small or large bowel may be excessive and can potentially occlude the drainage catheter. **The suprapubic tube should be irrigated at least three times daily and whenever drainage is slowed by mucus.** Extravesical drains may be removed after several days if drainage of urine is not apparent. The drains are generally removed more promptly in patients with a ventriculoperitoneal shunt to avoid potential infection. Some surgeons prefer a cystogram before discharge of the patient; others wait approximately 3 weeks for the study before clamping the suprapubic tube. All patients should begin on CIC every 2 to 3 hours during the day and one or two times at night after bladder healing is documented. The suprapubic tube is removed after catheterization is successfully under way and well tolerated. The duration between catheterizations is gradually increased during several weeks but should not exceed 4 to 5 hours during the day. Patients without neurologic impairment may eventually attempt to void spontaneously. All should check postvoid residual volumes and continue catheterizations if the residual urine amounts are significant.

Late Management

Routine radiographic surveillance of the upper urinary tract is indicated at 6 weeks, 6 months, and 1 year after augmentation cystoplasty. Most such surveillance may be done with ultrasonography. Serum electrolyte, blood urea nitrogen, and creatinine determinations along with urine cultures are performed several times in the first year after surgery. Not all positive urine cultures need to be treated in patients on CIC. Certainly, symptomatic cystitis or infections involving urea-splitting organisms should be cleared. Evaluation by ultrasonography and serum chemistries is then appropriate once a year. Eventually, yearly endoscopy for tumor surveillance may be performed. No consensus exists about the initiation or frequency of cystoscopic examination; however, we generally begin such surveillance approximately 5 years after augmentation. Husmann (2009) has suggested that surveillance may be of greater yield in patient populations at greater risk such as valve patients that are on immunosuppression after transplantation or exstrophy patients with their inherent increased risk for bladder adenocarcinoma. There is no experience demonstrating that routine endoscopy is cost effective or successful in this population.

Results and Complications

The effect of cystoplasty on the patient should be considered in two main categories. One must first consider the effect of removal of a relatively small portion of the gastrointestinal tract for use in urinary reconstruction. **Any more than rare development of gastrointestinal problems would be prohibitive, even if results were perfect from the standpoint of the urinary bladder.** Second, the effect of augmentation cystoplasty on the urinary bladder must be reviewed. The primary goal of augmentation is to provide a compliant urinary reservoir. **Therefore, the main consideration after augmentation is the storage pressure and capacity that are achieved. Any other effect on the urinary bladder is a side effect or complication that exists because bowel is not a perfect physiologic substitute for native bladder. It is clear that approximately one third of patients will require further surgery after augmentation cystoplasty because of various problems** (Metcalfe et al, 2006).

Gastrointestinal Effects

Postoperative bowel obstruction is uncommon after augmentation cystoplasty, occurring in approximately 3% of patients after augmentation (Gearhart et al, 1986; King, 1987; Mitchell and Pizer, 1987; Hollensbe et al, 1992; Rink et al, 1995a). **The rate of obstruction is equivalent to that noted after conduit diversion or continent urinary diversion** (McDougal, 1992b). Delicate handling of tissues, closure of mesenteric windows, and elimination of sites of internal herniation help avoid obstruction. Occasional series have suggested differing rates of bowel obstruction, depending on the segment used. These differences have not been consistent in most series and therefore are not likely to be significant; the incidence of bowel obstruction is low regardless of the gastrointestinal segment used and should not influence the choice of a particular segment for enterocystoplasty.

Reports of chronic diarrhea after bladder augmentation alone have been rare. Diarrhea can occur after removal of large segments of ileum from the gastrointestinal tract, although the lengths of the segments typically used for augmentation are rarely problematic unless other problems coexist. Much longer segments required for continent urinary diversion may increase the risk. The use of a typical colonic segment for augmentation only rarely results in a change in bowel function. **Removal of a segment from the gastrointestinal tract including the ileocecal valve is more likely to cause diarrhea.** Some children with neurogenic impairment depend on controlled constipation for fecal continence. Removal of the ileocecal valve from the gastrointestinal tract may significantly decrease bowel transit time. Loss of the valve can also allow bacterial backflow into the ileum, and the organisms may interfere with fat and vitamin B_{12} metabolism. Studies have noted chronic diarrhea in 10% to 23% of patients with neurogenic dysfunction after displacement of the ileocecal valve (King, 1987; Roth et al, 1995), although the risk may be lower for carefully selected patients (Husmann and Cain, 1999).

Ileum is the sole site of vitamin B_{12} absorption. **Removal of the distal ileum from the gastrointestinal tract may therefore result in vitamin B_{12} deficiency and megaloblastic anemia. Certainly, the terminal 15 to 20 cm of ileum should not be used for augmentation, although problems may arise even if that segment is preserved** (Waters et al, 1987; Steiner and Morton, 1991; Racioppi et al, 1999). Again, the risk is greater if longer segments of ileum are used as with continent diversion. Thirty-five percent of patients observed for 5 years after a Kock pouch were found to be deficient in vitamin B_{12} in one series (Akerlund et al, 1989). In general, the length of ileum used for augmentation is less than half of that used for a Kock pouch, so that vitamin B_{12} deficiency seems unlikely after routine bladder augmentation. Canning and associates (1989) evaluated 26 patients after bladder augmentation or replacement and found no patients with either fat malabsorption or vitamin B_{12} deficiency. Only 3 patients, however, were observed longer than 3 years, and longer observation is necessary because existing body vitamin B_{12} storage may last considerably longer (Stein et al, 1997a). Eventually, determination of vitamin B_{12} levels or routine injections of the vitamin may be appropriate after ileocystoplasty.

Early satiety may occur after gastrocystoplasty but usually resolves with time. Disorders of gastric emptying should be extremely rare, particularly when gastric body is used.

Bladder Compliance after Augmentation

An early lesson of past clinical experience with augmentation cystoplasty is the value of detubularization and reconfiguration of the bowel segment (Hinman, 1988; Koff, 1988). **Bowel in its native, tubular form continues to display peristalsis or mass contraction. The tubular form does not maximize the volume achieved for the surface area of bowel used.** Hinman (1988) demonstrated with a mathematical model that the maximum volume achieved for a given surface area occurs when a sphere is formed. No finished cystoplasty is a perfect sphere but should approach it as nearly as possible.

Some surgeons with extensive experience in augmentation cystoplasty and continent diversion have concluded that ileum is superior to other segments in terms of compliance after augmentation, although controlled experimental examination of similarly sized and used bowel or gastric segments is lacking (Goldwasser and Webster, 1986; Rink and McLaughlin, 1994; Studer and Zingg, 1997). On the contrary, one report has suggested superior results with colon compared with ileum (Shekarriz et al, 2000) when a longer colonic segment reconfigured into a U shape was utilized. Good results have been achieved with all segments in most cases, and it is more important to use a bowel segment well than to choose a particular bowel segment for every patient.

Most problems with pressure after augmentation cystoplasty occur from uninhibited contractions, apparently in the bowel segment. It is extremely rare not to achieve an adequate capacity or flat tonus limb unless a technical error has occurred with use of the bowel segment. On occasion, a small, scarred pelvis may prevent adequate expansion of the augmented bladder. When pressure contractions occur in the bladder after augmentation they are often noted in a rhythmic or sinusoidal pattern occasionally with increasing amplitude (Fig. 129–13). Contractions that begin at low amplitude later in filling and progress only near capacity may be of no clinical significance at all. Early contractions of higher pressure may occasionally result in persistent incontinence, delayed perforation, hydronephrosis, or vesicoureteral reflux. If patients have such clinical problems after augmentation, repeated urodynamic testing is necessary. One cannot assume the bladder is compliant after augmentation. Rhythmic contractions have been noted postoperatively with all bowel segments, although ileum seems the least likely to demonstrate remarkable urodynamic abnormalities and stomach the most likely.

After bladder augmentation or replacement, some urodynamic evaluation has suggested that colonic segments, whether cecum or sigmoid, still generate more pressure than ileum despite detubularization (Berglund et al, 1987; Jakobsen et al, 1987; Thuroff et al, 1987; Lytton and Green, 1989; Studer and Zingg, 1997). Other work has suggested that pressure contractions from the colon decrease with time (Hedlund et al, 1984; Sidi et al, 1986b). Nonetheless, Goldwasser and coworkers' review (1987) of enterocystoplasty demonstrated contractions above 15 cm H_2O in 42% of patients after ileocystoplasty versus 60% of those after colocystoplasty. Significant contractions, defined as those above 40 cm H_2O at a volume of less than 200 mL, were not noted in any of the ileal augmentations but persisted in 10% of colocystoplasties. Their work agreed with that of Berglund and colleagues (1987) and Studer and Zingg (1997) in suggesting that ileal reservoirs have lower basal pressures and less motor activity. None of these studies critically controlled for the size of the bowel segment or the technique in which it was used. In fact, a canine model of partial bladder replacement using identically sized segments failed to

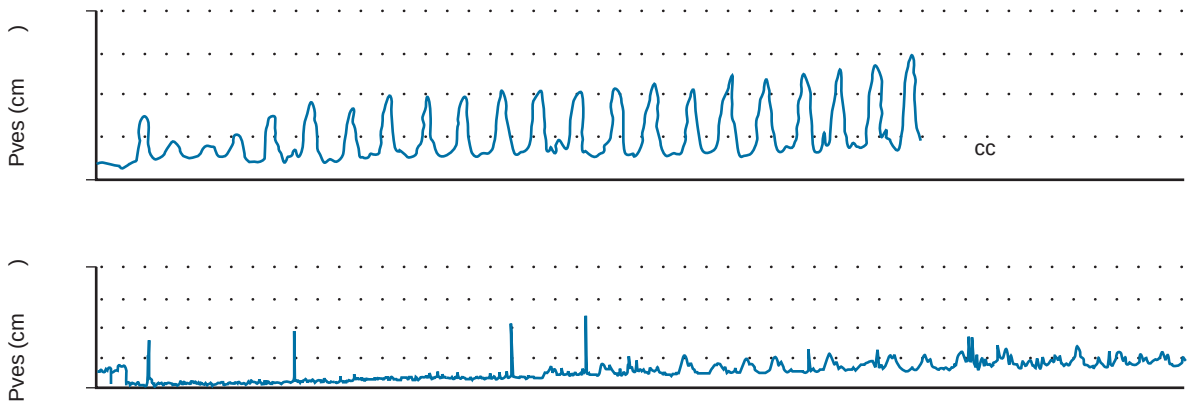

Figure 129–13. Rhythmic, sinusoidal contractions (*top*) may occur after bladder augmentation, in this case with stomach. Contractions of significant amplitude early in filling occasionally require secondary augmentation. After secondary augmentation with ileum (*bottom*), urodynamics show that contractions still occur but are much lower in pressure and occur later in filling.

demonstrate in vitro or in vivo any differences between the gastrointestinal segments (Nelson et al, 2005).

Rhythmic contractions after gastrocystoplasty have been noted in up to 62% of patients (Adams et al, 1988; Atala et al, 1993a; Gosalbez et al, 1993a; Roth et al, 2000). The segment of stomach initially described for augmentation with the body was much smaller than segments of ileum or colon commonly used for cystoplasty. Use of a slightly larger gastric segment that is longer along the greater curvature results in improved urodynamics after augmentation with less prominent contractions (Adams et al, 1995; Kurzrock et al, 1998; Koraitim et al, 1999; DeFoor et al, 2003b). Leong (1988) has suggested that an antral segment of stomach is less likely to demonstrate such contractions.

In perhaps the largest experience with pediatric bladder augmentation, Hollensbe and associates at Indiana University found that approximately 5% of several hundred patients had significant uninhibited contractions after augmentation cystoplasty causing clinical problems (Hollensbe et al, 1992). Pope and Rink (1999) found that 6% of more than 300 patients required secondary augmentation of a previously augmented bladder for similar problems in long-term follow-up. With longer follow-up, the same group has eventually performed reaugmentation in 9% of patients (Metcalfe et al, 2006). These secondary augmentations represent true failures of the primary cystoplasty, not from any side effect or complication but from failure to achieve the objective—capacity and compliance. In that series, sigmoid colon followed by stomach and then ileum were more likely to require reaugmentation. A colonic segment closed at the ends and not generally reconfigured otherwise was typically used in that experience. Other studies have suggested that stomach is more likely than colon to require secondary intervention (El-Ghoneimi et al, 1998).

Metabolic Complications

Chloride Absorption and Acidosis. **The first recognized metabolic complication related to storage of urine within intestinal segments was the occasional development of hyperchloremic metabolic acidosis after ureterosigmoidostomy** (Ferris and Odel, 1950). Patients with this metabolic derangement were noted to have fatigue, weakness, anorexia, and polydipsia. Koch and McDougal (1985) **demonstrated the mechanisms by which acid is absorbed from urine in contact with intestinal mucosa.** Resorption in the form of ammonium results in chronic acid loading. Patients with normal renal function are generally able to handle the resorbed load of chloride and acid without frank acidosis. Mitchell and Piser (1987) **noted that essentially every patient after augmentation with an intestinal segment had an increase in serum chloride concentration and a decrease in serum bicarbonate level, although full acidosis was rare if renal function was normal.** Similar trends of increased serum chloride and decreased bicarbonate have been noted with ileal conduits (Malek et al, 1971) and continent urinary reservoirs (Allen et al, 1985; McDougal, 1986; Ashken, 1987; Thuroff et al, 1987; Boyd et al, 1989). More severe acidosis and electrolyte disturbances requiring treatment have been reported despite normal renal function (Schmidt et al, 1973; Whitmore and Gittes, 1983). Such derangements may be debilitating to the patient if they are not recognized and treated, and death of patients has been reported (Heidler et al, 1979). Hall and colleagues (1991) noted that there is an increase in the urinary acid load with wasting of bone buffers even in the absence of frank acidosis. Such wasting may result in bone demineralization and could potentially cause retarded growth in children after augmentation cystoplasty (Abes et al, 2003; Hafez et al, 2003; Vajda et al, 2003). Patients with acidosis should receive bicarbonate therapy. Whether all patients with intestine in the lower urinary tract might benefit from supplemental bicarbonate is controversial. Nurse and Mundy (1989) have suggested that arterial blood gas values may be more sensitive than serum bicarbonate or chloride levels for detecting acidosis. Stein and associates (1998) thought that measurements of arterial blood gas for base deficit allowed early treatment of acidosis and avoidance of bone demineralization. In severe cases of acidosis, chloride transport can be blocked with chlorpromazine and nicotinic acid.

Although jejunum is rarely used for bladder reconstruction, storage of urine in this segment results in a unique metabolic pattern of hyponatremic, hypochloremic, and hyperkalemic metabolic acidosis. The problem is often associated with significant hypovolemia.

Gastric mucosa is a barrier to chloride and acid resorption and, in fact, secretes hydrochloric acid (Piser et al, 1987). This difference was the primary factor in the initial consideration of stomach for use in the urinary tract. This secretory nature was shown to be of benefit in azotemic animals during acid loading (Piser et al, 1987; Kennedy et al, 1988). **Serum chloride does decrease and serum bicarbonate increases slightly**

after gastrocystoplasty, whether antrum or body is used in patients with normal and impaired renal function (Adams et al, 1988; Ganesan et al, 1991; Kurzrock et al, 1998). In 21 patients with renal insufficiency, serum bicarbonate improved in all patients except one after gastrocystoplasty, and many patients requiring oral bicarbonate therapy before cystoplasty did not do so after gastrocystoplasty (Ganesan et al, 1991). A similar benefit has been noted in a smaller group of patients with renal failure (Sheldon and Gilbert, 1991).

Patient Growth. Delayed or slowed growth in some children after intestinal cystoplasty has previously been recognized (Wagstaff et al, 1991, 1992; Mundy and Nurse, 1992). A delay in linear growth was noted in 20% of almost 200 pediatric patients without any gross biochemical abnormalities. However, no control patients were included in the series, and body habitus and growth are difficult to measure and predict in children with myelodysplasia. Such patients make up the majority in most series of augmentation cystoplasty. Gros and colleagues (2000) evaluated growth in exstrophy patients. Patients requiring augmentation were matched retrospectively with a similar group not requiring bladder augmentation. Hydronephrosis was not mentioned in the patients but was unlikely with a diagnosis of exstrophy. Only 1 patient was noted to have acidosis in either group. Other factors that might affect growth, such as urinary tract infection, were not controlled. Of 17 patients with adequate measurements before and after augmentation cystoplasty, 14, or 82%, had a decline in percentile height postoperatively. The decline corresponded to a 1.5-inch decrease in expected height. The pattern of growth was significantly different between patients with and without augmentation in the series. That series is small, and no evaluation of familial growth patterns or ultimate height was possible; however, the findings are worrisome, particularly because Feng and coworkers (2002) noted similar differences in exstrophy patients. In the absence of any serum abnormalities the exact mechanism of delayed growth was not evident, although it seems likely to be related to chloride absorption and subclinical acidosis (Koch and McDougal, 1988; Bushinsky, 1989; Hochstetler et al, 1997). It should be noted that Taskinen and coworkers (2008) found no adverse effect on longitudinal growth after bladder augmentation in the exstrophy population. Three recent series did show the effect of bowel cystoplasty on bone mineral density in some patients (Abes et al, 2003; Hafez et al, 2003; Vajda et al, 2003), although Mingin and associates (2002) noted no such changes. One must be careful to determine whether any such changes are due to augmentation cystoplasty or the underlying pathologic process (Boylu et al, 2006; Taskinen et al, 2007). Better analysis of subtle metabolic alterations after enterocystoplasty may establish better understanding of the effect on growth, minimize changes, or aid in early treatment to avoid the complication (Brkovic et al, 2004).

Alkalosis. The secretory nature of gastric mucosa may at times be detrimental to the patient and can result in two unique complications of gastrocystoplasty. Severe episodes of hypokalemic, hypochloremic metabolic alkalosis that followed acute gastrointestinal illnesses have been noted in 5 of 37 patients after gastrocystoplasty (Hollensbe et al, 1992). The episodes were significant enough to require hospitalization in all cases and were recurrent in 2 patients. Three of the 5 patients suffering the complication had renal insufficiency and would not have been good candidates for augmentation with other segments because of acidosis. Ganesan and associates (1991) noted similar episodes of alkalosis in 5 of 21 patients with renal insufficiency after gastrocystoplasty. **Those patients with the primary indication for consideration of gastrocystoplasty may be the ones at greatest risk for this unusual complication.** It has been proposed that the alkalosis results from ongoing chloride loss from the gastric segment in the bladder in the presence of decreased oral intake. McDougal (1992a) suggested that the decreased ability to excrete bicarbonate from an impaired kidney may compound the problem. Gosalbez and associates (1993b) demonstrated persistently increased fractional excretion of chloride despite profound hypochloremia, suggesting that inappropriate gastric secretion is likely to be the primary mediator. One patient in their series eventually required resection of three fourths of the gastric segment in the bladder because of recurrent problems with alkalosis, and several required therapy with H_2 blockers or H^+,K^+ pump inhibitors.

All patients and families should be made aware of this potential problem because it has been reported to occur intermittently in between 3% and 24% of patients. A composite reservoir of stomach and ileum or colon may provide a more metabolically neutral reservoir (McLaughlin et al, 1995; Austin et al, 1997, 1999, 2001), although they have typically been constructed in only complex circumstances. Duel and associates (1996) have used stomach and colon together to advantage in a staged fashion for oncology patients; patients initially diverted with a colon conduit after cystectomy had a composite reservoir constructed later after cure from tumor was ensured.

Hematuria-Dysuria Syndrome

Acid secretion by gastric mucosa may result in another unique problem after gastrocystoplasty: the hematuria-dysuria syndrome. Mitchell's group has characterized this syndrome well (Nguyen et al, 1993; Plaire et al, 1999). **Virtually all patients after gastrocystoplasty with normal sensation have occasional hematuria or dysuria with voiding or catheterization beyond that which is expected with other intestinal segments** (Leonard et al, 1999). All patients should be warned of this potential problem, although these symptoms are intermittent and mild in most patients and do not require treatment. The problem has led one group to recommend avoiding gastrocystoplasty in patients with bladder exstrophy (El-Ghoneimi et al, 1998). The dysuria is certainly not as problematic in patients with neurogenic dysfunction. In the experience of Nguyen and colleagues (1993), 36% of patients have developed signs or symptoms of the hematuria-dysuria syndrome after gastrocystoplasty; 14% of patients have required treatment with medications, including 9% on a regular basis. They believe that patients who are incontinent or have decreased renal function are at increased risk. Others have noted a similar requirement for short-term and chronic medical therapy (Hollensbe et al, 1992; Adams et al, 1995). In the authors' experience and that of Nguyen and colleagues, the symptoms of the hematuria-dysuria syndrome respond well to H_2 blockers and H^+ pump blockers. Bladder irrigation with baking soda may also be effective. It has been demonstrated that urine pH may decrease remarkably after meals following gastrocystoplasty (Bogaert et al, 1995). The signs and symptoms of the hematuria-dysuria syndrome are most likely secondary to acid irritation. Recent work has suggested that *Helicobacter pylori* may play a role in this complication as it may in acid complications in the native stomach (Celayir et al, 1999). Such problems can occur but are less frequent after antral cystoplasty where there is a smaller load of parietal cells (Ngan et al, 1993).

Acid in the urine may also cause external irritation. Leong first noted glanular excoriation after gastrocystoplasty in a patient with voiding symptoms (Ngan et al, 1993). Similar meatal irritation has

been noted in other patients after gastrocystoplasty; most have had significant dysuria. Nguyen and associates (1993) noted skin excoriation in 8 of 57 patients after gastrocystoplasty; all 8 patients had some element of urinary incontinence. **It is imperative to achieve reliable urinary continence in patients undergoing gastrocystoplasty because urine leakage may result in the exposure of the skin to gastric secretions and in gastric secretions that are poorly diluted and buffered.** Such dilution is important; Reinberg and coworkers (1992) reported a perforation of a gastric segment in a defunctionalized bladder after gastrocystoplasty. They then evaluated the influence of urine on gastrocystoplasties in dogs (Castro-Diaz et al, 1992). The animals developed marked inflammation of the gastric segment and native bladder after construction of a dry gastrocystoplasty; three of nine dogs developed ulceration and perforation. Use of H_2 blockers resulted in some protection for the animals; however, such a clinical situation should certainly be avoided. Rare perforations and ulcerations have been noted clinically without defunctionalization (El-Ghoneimi et al, 1998; Mingin et al, 1999b).

Mucus

Intestinal segments continue to produce mucus after placement in the urinary tract. The proteinaceous material can potentially impede bladder drainage during voiding or CIC, particularly in pediatric patients in whom the use of small-caliber catheters is necessary. Mucus may serve as a nidus for infection or stone formation when it remains in the bladder for long periods. Mucus production often increases after cystoplasty in the presence of cystitis. Kulb and associates (1986) have shown experimentally in dogs that colonic segments produce more mucus than ileum does and that gastric segments produce the least amount. This has been noted clinically as well. Most patients do not require any routine bladder irrigations for mucus after gastrocystoplasty. Villous atrophy in the ileum has been documented after long-term placement in the urinary tract. It has been suggested that such atrophy may result in decreased mucus production (Gearhart, 1987), although laboratory demonstration of any decrease in production with time has not been evident (Murray et al, 1987). Hendren and Hendren (1990) noted a decrease in mucus production from colonic segments over years; however, others have not been impressed with such changes (Rink et al, 1995a). Glandular atrophy in colonic mucosa has not been noted histologically (Mansson et al, 1984). **Routine use of daily bladder irrigations to prevent mucus buildup may minimize complications of enterocystoplasty, such as urinary tract infection and calculi** (Hensle et al, 2004).

Urinary Tract Infection

Bacteriuria is common after intestinal cystoplasty, particularly among patients requiring intermittent catheterization (Gearhart et al, 1986; Hendren and Hendren, 1990; King, 1991). Recent experience with bowel neobladders has demonstrated that patients who are able to spontaneously void to completion frequently maintain sterile urine. **It appears that the use of CIC is a prominent factor in the development of bacteriuria in patients after augmentation cystoplasty.** Bacteriuria has been noted even when patients are maintained on daily oral antibiotics or antibiotic irrigation (Gearhart et al, 1986; Casale et al, 1999). In Hirst's (1991) experience, persistent or recurrent bacteriuria occurred in 50% of patients augmented with sigmoid colon versus 25% of those after ileocystoplasty. Hollensbe and coworkers (1992) noted bacteriuria much more commonly in patients requiring CIC regardless of the segment considered. The incidence of symptomatic cystitis after cystoplasty probably depends on the length of follow-up and the diligence with which symptoms are sought. All patients and families should be told to expect some signs or symptoms of cystitis. Recurrent episodes of symptomatic cystitis requiring treatment occurred in 23% of patients after ileocystoplasty, 17% after sigmoid cystoplasty, 13% after cecocystoplasty, and 8% after gastrocystoplasty at Indiana University (Hollensbe et al, 1992). Febrile urinary tract infections occurred in 13% of those 231 patients after augmentation. The same trend among different bowel segments was noted for febrile infections, although there was no statistically significant difference among the various segments. **The incidence of pyelonephritis after augmentation cystoplasty, as long as upper tract problems are corrected, is similar to that noted for conduit diversion, whether refluxing or not** (McDougal, 1992b). Recurrent infections resulting in deterioration of renal function in the absence of other problems have been rare after effective augmentation. Infections may occasionally be more problematic in an immunocompromised patient (Alfrey et al, 1997).

Not every episode of asymptomatic bacteriuria requires treatment in patients performing CIC. Bacteriuria should be treated for significant symptoms, such as incontinence or suprapubic pain, and perhaps for hematuria, foul-smelling urine, or remarkably increased mucus production. **Bacteriuria should be treated if the urine culture demonstrates growth of a urea-splitting organism that may lead to stone formation.** To minimize infection, patients requiring CIC must perform it on a regular basis to avoid increased reservoir pressures and work to empty the bladder completely. This process may require periodic irrigation of mucus as well as patience with the catheter in place. Special care must be taken by patients catheterizing through a continent abdominal wall stoma. Such patients may have more difficulty completely emptying the bladder from a nondependent stoma. Most can do so with effort (Ludlow et al, 1995). Although catheterization is not routinely a sterile technique, proper clean technique should be emphasized.

Calculi

Another long-term complication of augmentation cystoplasty is bladder calculus formation. In the early 1990s, several series reported calculi in 18% of patients after augmentation cystoplasty (Hendren and Hendren, 1990; Hirst, 1991). Blyth and associates (1992) noted calculus formation in 30% of such patients; they found that patients catheterizing through an abdominal wall stoma have the highest risk, probably because of incomplete emptying. Palmer and associates (1993) noted urolithiasis in 52% of patients after augmentation cystoplasty. Metcalfe and colleagues (2006) noted a 15% rate of bladder stone formation in 500 patients with long-term follow-up after enterocystoplasty; the reasons for these remarkable differences are not clear. **The majority of bladder stones in this population of patients are struvite, and bacteriuria has been thought to be an important risk factor.** Any infection with a urea-splitting organism should therefore be treated aggressively. All patients requiring CIC, particularly those who have already formed stones, should make every effort to empty the bladder completely with each catheterization. If stones are found in patients voiding spontaneously after augmentation, the adequacy of emptying should be reevaluated. The association of urinary stasis with stone formation is well established. Routine bladder irrigations to avoid buildup of inspissated mucus may remove a nidus for stone

formation. The group at Indiana University and others have stressed irrigations and asked patients and families to routinely irrigate the bladder several times a day after augmentation (Rink et al, 1995a; Hensle et al, 2004). Compliance with such irrigations may lower the frequency of stone formation.

Stones have been noted after the use of all intestinal segments, with no significant difference noted between small and large intestine. Struvite stones are less likely after gastrocystoplasty (Kaefer et al, 1998; Kronner et al, 1998a), probably because of decreased mucus production and acid that minimizes bacteriuria. Uric acid calculi have rarely been noted in the bladder after gastrocystoplasty (Kaefer et al, 1998). Clearly, any foreign body will serve as a nidus for stone formation; the use of permanent suture or staples in the urinary tract should be avoided during enterocystoplasty. Khoury and associates (1997) looked for metabolic problems in patients after augmentation and noted low urinary citrate levels in patients with and without stones. They thought that poor emptying and mucus buildup were more significant factors.

Tumor Formation

A well-recognized complication of ureterosigmoidostomy has been the development of tumors, primarily adenocarcinoma, at the ureterocolonic anastomotic site. In Husmann and Spence's (1990) review of reported tumors after ureterosigmoidostomy the latency for development of such tumors averaged 26 years and ranged from 3 to 53 years. Adenocarcinomas were the prominent tumors that developed, but benign polyps and other types of carcinoma were also found. Eraklis and Folkman (1978) estimated that the risk for development of such tumors is increased by 7000-fold over that of age-matched controls after ureterosigmoidostomy. The exact basis for the increased risk is unknown; however, *N*-nitroso compounds thought to originate from a mixture of urine and feces may be carcinogenic. These compounds have been noted in the urine of patients with conduit diversion and augmentation (Treiger and Marshall, 1991). Husmann and Spence (1990) suggested that those compounds are more likely to be enhancing agents rather than a lone cause of tumor development. It has been proposed that inflammatory reaction at the anastomotic site may induce growth factor production, which in turn increases cellular proliferation.

Filmer and Spencer (1990) **identified 14 patients who have developed adenocarcinoma in an augmented bladder, and several more have been reported since then.** Nine of those tumors occurred after ileocystoplasty and 5 after colocystoplasty. One study has noted a relatively high incidence of tumor after gastrocystoplasty (Castellan et al, 2007). **Experimental work in the rat demonstrated hyperplastic growth in the augmented bladder with use of all intestinal segments; no segment showed any particular increased risk** (Klee et al, 1990; Buson et al, 1993; Spencer et al, 1993; Little et al, 1994). The applicability of such findings to humans is uncertain. The long latency noted for tumor development after ureterosigmoidostomy suggests that short-term follow-up after augmentation cystoplasty is not adequate to evaluate tumor formation. The earliest reported tumor after augmentation was found only 4 years after cystoplasty (Carr and Hershown, 1997). **Patients undergoing augmentation cystoplasty should be made aware of a potential increased risk for tumor development. Yearly surveillance of the augmented bladder with endoscopy should eventually be performed; the latency period until such procedures are necessary is not well defined** (Vajda et al, 2002). The earliest reported tumor after augmentation was found only 4 years after cystoplasty (Carr and Herschorn, 1997). Transitional cell carcinoma, hyperplasia, and dysplasia have also been noted near the anastomosis in humans (Gregoire et al, 1993; Barrington et al, 1997; Soergel et al, 2004). Transitional cell carcinomas associated with augmentation cystoplasty have been aggressive; often the patients have metastatic disease at presentation (Metcalfe et al, 2006; Higuchi et al, 2010). Urothelium adjacent to the anastomosis has been demonstrated to be genetically unstable on biopsy in one study (Appanna et al, 2007). Urine cytology or flow cytometry may ultimately become useful in surveillance.

Delayed Spontaneous Bladder Perforation

Perhaps the most disturbing complication of augmentation cystoplasty is delayed bladder perforation. Patients presenting with spontaneous perforation after augmentation cystoplasty are generally quite ill with abdominal pain, distention, and fever. Sepsis has been common. Nausea, decreased urine output, and shoulder pain from diaphragmatic irritation have also been noted. Perforations have been found in evaluation of asymptomatic pelvic masses (Pope et al, 1999). **Patients with neurogenic dysfunction often have impaired lower abdominal sensation and present later in the course of the illness; severe sepsis and death have occurred.** Patients with perforation after gastrocystoplasty often present promptly because of acid irritation. **A high index of suspicion for perforation is necessary. Contrast cystography is diagnostic in most cases** (Braverman and Lebowitz, 1991; Rosen and Light, 1991; Bauer et al, 1992) (Fig. 129–14). Thorough technique is important to identify as many true positives as possible with cystography (Braverman and Lebowitz, 1991). Some reports of perforations have noted a significant false-negative rate on cystography (Rushton et al, 1988; Sheiner and Kaplan, 1988; Pope et al, 1999) and suggested that ultrasonography and computed tomography improve diagnostic accuracy. They recommended that one of those studies be done in any child thought to have a perforation if the initial cystogram is normal.

Etiology. **The etiology of delayed perforations within a bowel segment is unknown.** It has been suggested that perforation might be secondary to traumatic catheterization in some cases (Elder et al, 1988; Rushton et al, 1988). Perforation of a

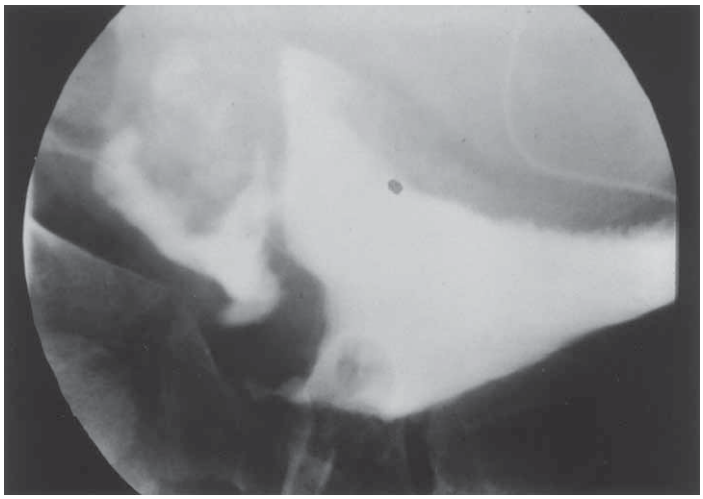

Figure 129–14. After complete filling, a sagittal view on the cystogram demonstrates a spontaneous bladder perforation on the post-drain view.

bladder not previously augmented has been recognized after CIC (Reisman and Preminger, 1989). It seems unlikely that catheterization trauma is the lone cause in most patients. The location of the perforations has been variable among patients and even in a single patient with multiple perforations. Perforations have occurred after augmentation in patients who did not catheterize at all. Others have suggested that trauma to the bowel because of fixed adhesions resulting in shearing forces with emptying and filling may result in perforation (Elder et al, 1988). Chronic, transmural infection of the bladder wall has also been proposed as a cause. **Histologic examination of bowel segments adjacent to areas of perforation has noted necrosis, vascular congestion, hemorrhage, and hemosiderin deposition compatible with chronic bowel wall ischemia** (Crane et al, 1991). **Chronic overdistention of the bladder might result in such ischemia.** Decreased perfusion in dog bowel used for augmentation can be induced experimentally with high intravesical pressure (Essig et al, 1991). Those changes were noted more prominently at the antimesenteric border of the bowel. Chronic ischemia may thus play a significant role in at least some delayed bladder perforations. Anderson and Rickwood (1991) have reported perforations occurring in bladders with significant uninhibited contractions after augmentation, as have others (Pope et al, 1998). **High outflow resistance may maintain bladder pressure rather than allow urine leakage and venting of the pressure, potentially increasing ischemia** (Martinez del Castillo et al, 2005). Hyperreflexia alone is not likely to be a solitary cause of perforation; the complication was essentially never recognized in the era before bowel detubularization and reconfiguration when persistent pressure contractions were more common after augmentation cystoplasty. **Once bowel is reconfigured, however, it may be more susceptible to ischemia if high pressure does persist.** Failure to perform CIC on a regular basis when needed to empty may exacerbate such issues (DeFoor et al, 2003a; Martinez del Castillo et al, 2005).

The majority of patients suffering perforations after augmentation cystoplasty have had myelodysplasia. The incidence of perforation has been lower in series of patients with other diagnoses requiring bladder reconstruction (Hendren and Hendren, 1990). The role of neurogenic dysfunction in the etiology of these perforations is unclear. No matter what the etiology there is likely to be some field effect on the entire segment. Once a patient has suffered a spontaneous perforation, the chance of recurrence is significant (Hollensbe et al, 1992; Martinez del Castillo et al, 2005; Metcalfe et al, 2006). One fourth of patients with ruptures in one very large series had a recurrence (Metcalfe et al, 2006). Consideration must eventually be given to removal of the original segment and replacement by another after repeated perforation.

Incidence. Early postoperative leaks from the bowel-to-bowel or bowel-to-bladder anastomoses after augmentation cystoplasty are rare and represent a technical error or problem with early healing. **Delayed perforations more commonly occur within the bowel segment itself and represent a problem with long-term storage of urine within an intestinal segment.** There may be no particular increased risk of one intestinal segment over another. At Indiana University, perforations were noted in 43 of 500 patients (8.6%) undergoing cystoplasty (Metcalfe et al, 2006) an average of 4.3 years after augmentation. Analysis of this experience suggested that the use of sigmoid colon was the only significantly increased risk. Several other large series of patients with sigmoid cystoplasty have noted a low incidence of delayed perforation (Sidi et al, 1987a; Hendren and Hendren, 1990; Shekarriz et al, 2000). At Children's Hospital Boston, the incidence of perforation after augmentation was highest in ileum (9.3%) and less frequent in ileocecal, sigmoid, and gastric segments (Bauer et al, 1992).

With inconsistent differences across multiple large series it is unlikely that any given enteric segment is at significantly increased risk for perforation and that likely multiple factors influence the risk for the complication. Pope, Rink, and the Indiana group (1999) still believe strongly from their experience that sigmoid colon has a greater risk for perforation based on a four-time higher rate than ileum there. Some other experienced surgeons think the same (Ransley, 1998). The highest rate of perforation noted has been 16.6% in one relatively small series (Martinez del Castillo et al, 2005); however, it is reasonable to present an expected risk of about 9% to patients and families based on experience at Indiana University (Metcalfe et al, 2006).

Treatment. **The standard treatment of spontaneous perforation of the augmented bladder is surgical repair, as it is for intraperitoneal rupture of the bladder after trauma.** There are reported series of conservative management for suspected perforation (Slaton and Kropp, 1994). Conservative management including catheter drainage, antibiotics, and serial abdominal examinations was successful in 87% of the patients, although only 2 of the 13 patients with suspected ruptures had x-ray documentation unequivocally identifying a perforation. Even patients who do well with conservative management during the acute episode often require eventual surgical intervention (Pope et al, 1999). Such management may be a consideration in a stable patient with sterile urine. The surgeon should certainly have a low threshold for surgical exploration and repair. The majority of patients with perforations have myelodysplasia and present late in the course of the disease because of impaired sensation. Increasing sepsis and death of the patient may result from a delay in diagnosis or treatment.

Pregnancy

Good success has been reported for female patients after bladder augmentation, bladder neck repair, or continent urinary diversion in terms of continence and upper tract preservation. Little note has been made of fertility issues. **Limited information exists regarding the outcome of pregnancy in women who have undergone augmentation cystoplasty, because many of these patients are just reaching childbearing age.** Older women undergoing bladder replacement for oncologic reasons often are rendered infertile by the nature of the disease and treatment.

Three major issues are raised in the context of pregnancy and bladder reconstruction: how the expanding uterus will affect the pedicle of the reconstruction; how to manage bacteriuria during pregnancy; and whether cesarean section is needed in all or some of these patients and, when it is performed, how to manage the pedicle of the augmentation patch.

Experience during pregnancy related to the pedicle of a prior bladder augmentation is limited. Hatch and colleagues (1991) and Schumacher and coworkers (1997) have noted that the mesenteric pedicle to bladder augmentations did not appear to be stretched at the time of cesarean section. In those cases the pedicle was not located near the exposed anterior uterus but deflected laterally. Schilling and colleagues (1996) recognized a difference between urinary diversion and augmentation. With diversion, the pedicle of the intestinal segment extended cranially and laterally away from the uterus, whereas the pedicle covered the uterus after bladder augmentation. Neither process prevented the rise of the

uterus during pregnancy. Those authors speculated that the mesentery underwent changes that enabled deflection or stretch without any adverse effect on circulation. Loss of the augmentation due to mechanical effect on the pedicle from the enlarging uterus has not been reported. Pregnancy itself has not had a reported detrimental effect on the augmentation other than temporary incontinence in some patients, particularly during the third trimester. Successful pregnancy with spontaneous vaginal delivery has been observed in a few cases with bladder augmentations (Quenneville et al, 2003) and other forms of urinary reconstruction, such as ureterosigmoidostomy and ileal conduit urinary diversion (Pedlow, 1961; Asif and Uehling, 1969). Schumacher and coworkers (1997) reviewed their experience with pregnancy and delivery in patients who had undergone continent catheterizable ileocecal diversion and found no major complications. It is likely that this would also be true for other forms of reconstruction (Wren et al, 2003). Urgency and late difficulty with catheterization have been noted with Kock continent ileostomies (Ojerskog et al, 1988) and can occur with any continent abdominal wall stoma (Greenwell et al, 2003).

Urinary tract infections may be problematic during pregnancy in women who have undergone urinary reconstruction including bladder augmentation. Ureteral dilation, increased residual urine, and diminished tone to the upper tract may all be important risk factors (Hill et al, 1990; Hatch et al, 1991). Asymptomatic bacteriuria is usually treated immediately in pregnancy women because of an increased rate of progression to symptoms and pyelonephritis and because of the potential significant consequences of pyelonephritis. Asymptomatic bacteriuria is often not treated routinely in a woman on intermittent catheterization after cystoplasty when not pregnant. There is little consensus about the role of antibiotics and the risk of asymptomatic bacteriuria in the same population once pregnant (Thomas and Adams, 2009). Antibiotics, if used, must not be teratogenic.

Patients with preexisting hydronephrosis may be at increased risk not only for infection but also for worsening hydronephrosis. Some may require stent or nephrostomy tube placement (Gitlin et al, 2002). The patients at greatest risk during pregnancy after reconstruction are those with renal insufficiency. Some may demonstrate deterioration of function or permanent failure (Jones and Hayslett, 1996). Uterine prolapse has been noted to occur at a higher rate with pregnancy, particularly in exstrophy patients (Kennedy et al, 1993). Because of such concerns, Stein and associates (1994) suggested fixation of the uterus during reconstructive surgery.

The need for cesarean section is probably not universal for all women with bladder reconstructions. Adequate progression of spontaneous vaginal delivery, however, may require flaccid, distensible pelvic tissues, which may not be present after extensive pelvic surgery. It is unknown if tissues fixed from previous operative repairs can undergo the trauma of delivery and resume the same level of function as before the pregnancy. The authors' bias would be that women having undergone extensive bladder neck repair should consider cesarean delivery, particularly if the progression toward spontaneous vaginal delivery is slowed or difficult at all. Although there are reports of spontaneous vaginal delivery in the presence of an artificial urinary sphincter (Fishman and Scott, 1993; Creagh et al, 1995), the presence of such a prosthetic device raises a concern for erosion with a long, difficult delivery.

If cesarean section is required or selected, it is imperative to protect the augmentation or continent stoma and its vascular pedicle. The anterior uterus can typically be exposed atraumatically, although some time and patience may be required to protect the bladder. Such exposure may be more difficult if multiple abdominal stomas are present. The reconstructive urologist familiar with the patient and her anatomy should be present during cesarean section to maximize safety.

Choice of Segment

The use of bowel for augmentation of the bladder was first described experimentally by Tizzoni and Foggi in 1888 and in humans by Mikulicz in 1898 (Orr et al, 1958). Extraordinary advances have been made in the use of the bowel in urinary tract reconstruction since then. Bladder augmentation is used for patients with bladder dysfunction related to a small-capacity, noncompliant reservoir. **Enterocystoplasty improves bladder capacity and compliance in most cases when medical management fails.** It is obvious from the preceding discussion that there is no one single bowel segment that is perfect for augmentation in all patients. All gastrointestinal segments have been used and continue to be used with good results. Unremitting medical problems are relatively rare after augmentation cystoplasty if used appropriately in well-selected patients. No one bowel segment has a clear advantage over another when all such problems are considered. Diagnosis, anatomy, and physiology may suggest that one bowel segment is preferable for a particular patient. Each surgeon interested in augmentation cystoplasty should be familiar with the advantages and disadvantages of each segment in different settings.

In many routine cases, any gastrointestinal segment may be chosen for cystoplasty purely on the basis of the personal preference and familiarity of the surgeon. The surgeon's experience and confidence in using a segment are important. **The authors believe that no one bowel segment is the best choice in**

Key Points: Augmentation Cystoplasty

- No matter the gastrointestinal segment used, that segment should be reconfigured and widely anastomosed to the native bladder to maximize capacity and compliance.
- Failures to achieve adequate compliance are rare (5%-10%) and are usually related to rhythmic pressure contractions.
- Gastrointestinal effects are rare, although chronic diarrhea may occur if the ileocecal segment is used in the neurogenic population.
- Ammonium resorption from urine in contact with intestinal mucosa can cause chronic metabolic acidosis, particularly among patients with renal insufficiency.
- Acid secretion after gastrocystoplasty results in two unique potential complications: hematuria-dysuria syndrome and acute metabolic alkalosis.
- Bacteriuria is common after cystoplasty and does not always require treatment.
- Bladder calculi, usually struvite, occur in 10% to 30% of patients after augmentation cystoplasty but may be minimized by routine irrigations for mucus.
- Adenocarcinoma in the intestinal segment has been reported as early as 4 years after augmentation cystoplasty but, thus far, has not occurred with the frequency noted after ureterosigmoidostomy.
- Delayed spontaneous perforation of the bowel segment can be expected in 5% of patients after augmentation. It has occurred most frequently in colonic segments used in the neurogenic population.

all patients and that optimal results are achieved when the bowel segment is chosen on the basis of the needs of the particular patient. The segment must then be used correctly. Ileum is preferred if there is no clear advantage to or reason for use of another segment. Stomach is reserved for children with renal insufficiency and acidosis, short-gut syndrome, and heavy irradiation. Sigmoid cystoplasty is used in select patients without reservation; clearly, good results can be expected for most patients with any segment if it is used properly.

Alternatives to Gastrointestinal Cystoplasty

Largely because of the complications and side effects just reviewed, alternative methods that can achieve a large-capacity, compliant reservoir remain attractive. Efforts have covered the spectrum from synthetic materials and autologous grafts to construction of a bladder diverticulum (autoaugmentation) and to various forms of neural stimulation. **Some of these alternatives appear to hold promise, but none has stood the test of time for true comparison to intestinal cystoplasty.**

An ideal tissue for increasing capacity and improving compliance would have transitional epithelium to be relatively impermeable and avoid metabolic changes. The lining would also not produce mucus and carry no increased potential for tumor development. The ability to augment the bladder without violation of the peritoneal cavity would also decrease potential morbidity. Two such alternative procedures are ureterocystoplasty and autoaugmentation. With ureterocystoplasty there is good muscle backing of transitional epithelium; collagen eventually backs the transitional mucosa of an autoaugmentation.

Ureterocystoplasty

It has been noted for years that in patients with posterior urethral valves, unilateral reflux may behave like a "popoff" valve to lower intravesical pressures and protect the contralateral upper tract (Hoover and Duckett, 1982; Rittenberg et al, 1988; Kaefer et al, 1995). In many of these patients the refluxing ureter is massively dilated, draining a poorly functioning or nonfunctioning kidney. **It was a logical extension to use this ureteral tissue to augment the bladder.**

Technique. Ureterocystoplasty may be performed through a midline, intraperitoneal incision. This incision provides access to the intestine should mobilization of the ureter for augmentation be unsatisfactory. **Bellinger** (1993), **Dewan and colleagues** (1994a), **and Reinberg and associates** (1995) **have shown that ureterocystoplasty can be done through two incisions, remaining completely extraperitoneal.** The general technique is the same. A standard nephrectomy is performed with great care to preserve the renal pelvic and upper ureteral blood supply. All adventitia and periureteral tissue is swept from the peritoneum toward the ureter during mobilization to protect the ureteral blood supply. Proximally, this blood supply typically arises medially. As the ureter enters the true pelvis the blood supply arises posterior and laterally. After mobilization of the ureter into the pelvis the bladder is opened in the sagittal plane. Posteriorly, this incision has typically been carried off-center directly into and through the ureteral orifice of the ureter used for cystoplasty. The ureter is *not* detached from the bladder but is opened longitudinally along its entire length, with care taken to avoid its main blood supply (Fig. 129–15). The incision in the bladder and distal ureter should avoid branches of the superior vesical artery that serves as an important blood supply to the mobilized ureter. The ureter is folded on itself, and the ureter-to-ureter and ureter-to-bladder anastomosis is performed with running absorbable suture. A suprapubic tube is left indwelling through the native bladder for 3 weeks during healing. After cystography documents the absence of leakage, CIC is started. Patients, particularly those without neurogenic dysfunction, may attempt to void spontaneously, although all must prove that they can empty appropriately by checking postvoid residual urine amounts.

Alternatively, the bladder incision can be stopped approximately 2 cm from the orifice and a similar length of distal ureter left in situ and intact without incision. The resulting small loop of intact ureter does not cause clinical problems or adversely affect

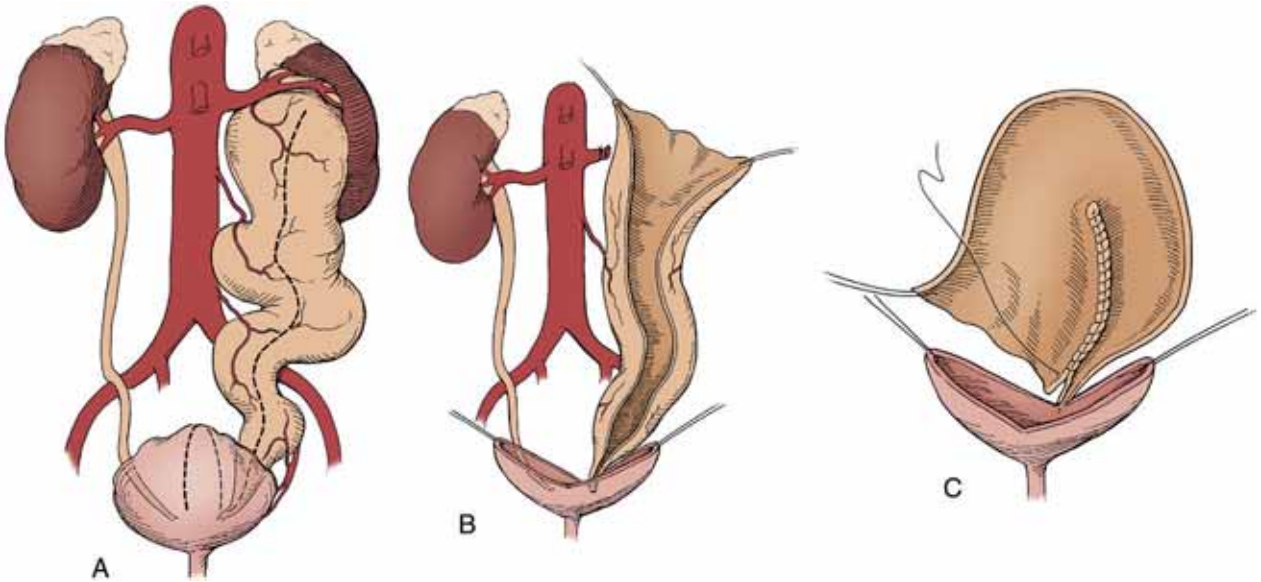

Figure 129–15. Ureterocystoplasty. **A**, After nephrectomy, the bladder is bivalved, with the posterior aspect of the incision carried off the midline to enter the ureteral orifice. The ureter is not detached from the bladder. **B**, The ureter is opened opposite its main blood supply. **C**, The ureter is reconfigured as in intestinal cystoplasty before anastomosis to the bladder.

the end volume in a significant manner (Adams et al, 1998). This modification of technique is easier and may be safer in that it avoids potential injury to the blood supply of the mobilized ureter near the ureterovesical junction.

Results. Early reports suggested that ureterocystoplasty could be achieved after nephrectomy by bivalving the bladder through the vesicoureteral junction and laying in the open ureter (Mitchell et al, 1992; Bellinger, 1993). Later reports modified and improved the procedure by noting that with meticulous care the vascularity to the entire renal pelvis could be preserved, allowing more tissue for cystoplasty (Churchill et al, 1993; Landau et al, 1994; McKenna and Bauer, 1995; Reinberg et al, 1995). As with intestinal cystoplasty, folding the ureter into a more spherical configuration maximizes the volume that can be achieved. If a massively dilated ureter drains a functioning kidney the distal ureter alone may be used for augmentation; the proximal ureter is either reimplanted into the bladder or anastomosed to the contralateral ureter (Bellinger, 1993).

Numerous series have reported good results after augmentation with use of ureter, some with follow-up as long as 8 years. The upper tracts have remained stable or improved in virtually all patients. Complications have been uncommon, with only a rare early extravasation of urine reported (Churchill et al, 1993). Landau and colleagues (1994) compared age-matched and diagnosis-matched children having ureterocystoplasty or ileocystoplasty. **The total mean bladder capacity was 470 mL in the ureterocystoplasty group and 381 mL in the ileocystoplasty group. Bladder volumes at 30 cm H_2O were 413 mL and 380 mL after ureterocystoplasty and ileocystoplasty, respectively.** Ureter effectively enhanced both volume and compliance. There was one failure in the group that occurred in a child in whom the distal ureter did not provide enough volume. Work has shown that one dilated ureter typically is enough for cystoplasty (Zubieta et al, 1999).

The main disadvantage to ureterocystoplasty is the limited population of patients with a nonfunctioning kidney draining into a megaureter. McKenna and Bauer (1995) have reported the use of a normal-sized ureter. The ultimate success of ureterocystoplasty with normal ureter requires further follow-up, particularly since Gonzalez (1999) has stated that one fourth of his patients with posterior urethral valves have failed ureterocystoplasty with a dilated ureter because of their huge urinary volume. Husmann and colleagues (2004) noted even worse results if the ureter used was less than 1.5 cm in diameter. Atala and colleagues (1994) presented an experimental technique to slowly dilate a normal ureter for later use. Work continues to develop such a technique that is clinically applicable for patients (Stifelman et al, 1998; Desai et al, 2003).

Autoaugmentation

Techniques and Results. Cartwright and Snow (1989a, 1989b) described an ingenious method to improve bladder compliance and capacity with use of native urothelial tissue. In their procedure, known as autoaugmentation, they excised the detrusor muscle over the dome of the bladder, leaving the mucosa intact to protrude as a wide-mouth diverticulum. Initially, they made a midline incision through the bladder muscle (Fig. 129–16A). With the bladder distended with saline so that mucosa bulged from the incision, the muscle was then mobilized and excised laterally in each direction (Fig. 129–16B). The lateral edges of the detrusor muscle were then secured to the psoas muscle bilaterally to prevent collapse of the diverticulum (Fig. 129–16C). The early

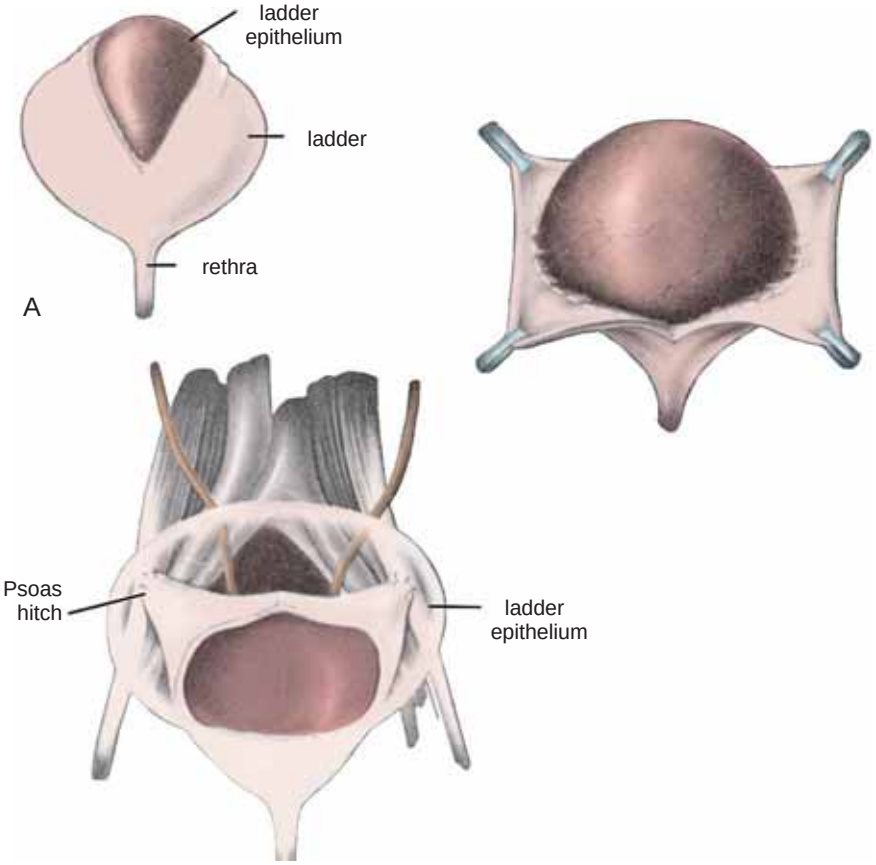

Figure 129–16. Autoaugmentation. **A**, The detrusor is incised. **B**, Detrusor is stripped and excised from mucosa. **C**, The detrusor muscle is anchored bilaterally so that the mucosa bulges with bladder filling. (From Cartwright PC, Snow BW. Bladder autoaugmentation: early clinical experience. J Urol 1989;142:505.)

experience of these investigators noted improved compliance in most, and increased capacity in some, patients (Cartwright and Snow, 1989a).

This procedure has since been modified by a number of surgeons, each providing a different name for the procedure, depending on whether the detrusor muscle is simply incised or excised to make the diverticulum. In an effort to determine if incision or excision provided superior results, Johnson and colleagues (1994) performed 16 vesicomyotomies and 16 vesicomyectomies in rabbits after previously reducing the bladder capacity. Functional bladder capacity in the animals increased by 43.5%, and there was no statistical difference between the two techniques. They then performed vesicomyotomies (incision) in 12 patients with neurogenic bladder dysfunction and demonstrated a mean increase in capacity of 40% and a mean decrease in leak point pressure of 33% (Stothers et al, 1994). They concluded that detrusor excision offered no advantage over incision. All patients demonstrated some increase in capacity (15% to 70%), and no patient in early follow-up clinically deteriorated and required enterocystoplasty.

Detrusorectomy, leaving a small cap of muscle at the dome through which a suprapubic tube can be placed, has been proposed by Landa and Moorehead (1994). **They have been concerned that although these procedures usually improve compliance, increase in volume is "modest at best," a concern shared by others** (Snow and Cartwright, 1996; Cartwright and Snow, 1998). In a report of 12 detrusorectomies, five patients were considered to have excellent results, two had acceptable results, and one was lost to follow-up. There were four failures (one hydronephrosis, two persistent incontinence, one worsening renal insufficiency); three patients have undergone gastrocystoplasty or ileocystoplasty (Landa and Moorehead, 1994). Overall, only 52% of patients had a good result with autoaugmentation; 20% had a poor outcome (Snow and Cartwright, 1996). Reoperative enterocystoplasty was not hampered by the prior detrusorectomy. The urothelial diverticulum at the time of augmentation cystoplasty was noted to be thick and fibrous, similar to a leather bag.

There are obvious advantages to autoaugmentation and its variants. Native urothelial tissue is used. It is an extraperitoneal procedure, which shortens operative time and avoids the risks of intestinal surgery and adhesions. Autoaugmentation is compatible with CIC and does not seem to complicate subsequent intestinal cystoplasty when it is necessary.

Complications from the procedures are generally uncommon. Perforation, a major concern after intestinal cystoplasty, has not been reported. Inadvertent opening of the mucosa during the procedure can make subsequent mobilization more difficult and may promote prolonged postoperative extravasation. Such extravasation usually stops with bladder drainage (Landa and Moorehead, 1994; Stothers et al, 1994). Prolonged drainage, however, may result in compromised results from collapse of the diverticulum. If concomitant ureteral reimplantation or bladder neck surgery is necessary, various authors have recommended that it be done first and the bladder then closed before detrusorectomy (Stothers et al, 1994).

Ehrlich and Gershman (1993) first reported laparoscopic myotomy (incision). A laparoscopic approach uses a smaller incision and perhaps shortens postoperative hospitalization; it may make effective fixation of the detrusor muscle in an open fashion to allow good bulging more difficult.

Concerns. **The main disadvantage of autoaugmentation is a limited increase in bladder capacity such that adequate preoperative volume may be the most important predictor of success** (Landa and Moorehead, 1994). If the maximum capacity and the volume of urine held at 40 cm H_2O are similar the patient may be better served by immediate intestinal cystoplasty. It is of note that some patients have demonstrated clinical improvement after these procedures without a significant change in urodynamics. The reason for the improvement in that setting is unknown.

In most series of autoaugmentation, no matter what the technique, it has been noted in occasional patients or concern has existed at the time of the initial procedure that adequate expansion was not achieved. In most such cases it was elected to proceed with enterocystoplasty immediately at the time (Landa and Moorehead, 1994). These patients are not included in the failure rate of autoaugmentation. The patient and surgeon must be prepared for such an event on occasion. Stohrer's group (1999) as well as Leng and associates (1999) reported good results with the technique among patients with hyperreflexia. In terms of capacity, even if adequate expansion is achieved initially, there is concern that any improvement may not persist long term (Dewan et al, 1994b). In animals the surface area of the autoaugmentation site was noted to decrease approximately 50% at 12 weeks. Progressive thickening and contracture of the site have been noted because of collagenous infiltrate (Johnson et al, 1994). Milam (2000) has noted that almost half of his adult patients with hyperreflexia who had a good early result after autoaugmentation have failed with longer follow-up. Similar delayed failures have been noted in pediatric patients (Lindley et al, 2003), including one series with very poor results (MacNeily et al, 2003).

At this point, autoaugmentation should probably be considered only in patients who have reasonable capacity but poor compliance due to uninhibited contractions. **If a significant increase in capacity is needed, autoaugmentation is unlikely to be as definitive as other techniques.**

Seromuscular Enterocystoplasty

Based on concerns about collagen deposition and contraction around autoaugmentation, efforts have been made to cover the bulging urothelium with demucosalized enteric segments. The use of enteric segments without bowel mucosa within the bladder is not new. As far back as the 1950s, seromuscular augmentation cystoplasty was performed with the serosal side of the bowel turned to the bladder lumen (Shoemaker and Marucci, 1955; Shoemaker et al, 1957). Urothelium soon covered the serosa. Gonzalez's group experienced good results with reversed seromuscular cystoplasty in rats, as did others with rabbits (Celayir et al, 1995), but contracture of the patch occurred in larger animals (De Badiola et al, 1991; Long et al, 1992). Others left the exposed submucosa facing the bladder lumen and noted reepithelialization with urothelium in animals (Oesch, 1988; Salle et al, 1990). Despite the reepithelialization, patch contracture occurred (Salle et al, 1990). Several recent series have reevaluated demucosalized augmentation in humans after taking care to preserve the submucosa. Better results have been noted (Lima et al, 1998, 2004; de Badiola et al, 1999; Dayanc et al, 1999), although regrowth of metaplastic enteric mucosa was found in the second study. Early placement of a silicone balloon or mold may help prevent contracture (Lima et al, 2004).

Techniques and Results. **To avoid contracture, a combination of autoaugmentation after detrusorectomy and coverage with a demucosalized enteric segment has now been used.** This has been done to potentially preserve the advantages of both procedures. In a similar fashion the combination has

been undertaken with both colon and stomach. Buson and colleagues (1994) used reconfigured, demucosalized sigmoid colon placed over the urothelium (seromuscular colocystoplasty lined with urothelium). They and others noted that the intestinal submucosa should be preserved to avoid contracture (Buson et al, 1994; Vates et al, 1997) (Fig. 129–17). This procedure has been performed clinically with early reports of good results in most patients (Gonzalez et al, 1994). Postoperative bladder capacity increased an average of 2.4-fold (139 to 335 mL) in 14 of 16 patients, and end filling pressure decreased from an average of 51.6 to 27.7 cm H_2O. Two patients experienced failure of the procedure and required ileocystoplasty; their urodynamic data were excluded. Two other patients developed an hourglass deformity (Gonzalez et al, 1994). Endoscopic biopsy of the segments has been interesting. Of 10 biopsies performed in the series, in 1 urothelium with islands of colonic mucosa was noted and in 2 others only colon mucosa was found. Removal of all of the enteric mucosa is important when sigmoid is used to prevent mucoceles or overgrowth of intestinal mucosa (Gonzalez et al, 1994; Lutz and Frey, 1994). Dewan and associates (1997) thought that preservation of the submucosa eventually promoted regrowth of bowel mucosa. The interaction of the two different tissues will be interesting to follow. The long-term effects on the urothelium by the seromuscular segment and vice versa are unknown. Work has shown that persistent transitional lining will protect from metabolic problems and mucus production (Denes et al, 1997).

Dewan and Byard (1993) and Close and associates (2004) alternatively used demucosalized stomach to cover an autoaugmentation, first in sheep and then in patients. Early results showed improved bladder function both clinically and by urodynamics (Horowitz and Mitchell, 1993; Dewan et al, 1994c; Horowitz et al, 1994; Robinson et al, 1994), although long-term results are not as encouraging (Carr et al, 1999). These procedures are technically more demanding than simple augmentation or autoaugmentation and are associated with more blood loss and a longer operative time (Gonzalez et al, 1994; Horowitz et al, 1994). Increased bleeding is particularly true when stomach is used. These urothelium-lined, seromuscular augmentations are theoretically attractive. Thus far, the failure and reoperation rate after such procedures remains higher than that noted for standard enterocystoplasty (Vates et al, 1997; Carr et al, 1999; Shekarriz et al, 2000). The results have been reported with colon (Shekarriz et al, 2000). Those results may be partially attributed to the learning curve with a new, complex procedure. Longer follow-up and more experience are necessary to determine whether the complication rate will decrease with experience or increase because of problems with the combination.

Bladder Regeneration

Other efforts to find alternatives to intestinal cystoplasty in the 1950s included the use of alloplastic materials for bladder substitution (Gleeson and Griffith, 1992; Kanematsu et al, 2007; Lewis et al, 2007; Yamzon et al, 2008). Early research efforts met with limited success due to foreign body complications but provided the foundation for regenerative medicine, which uses cells and biomaterials to establish regrowth of healthy tissue. This led to a focus on biodegradable, collagen-rich tissues serving as a scaffold for bladder regeneration (Kelami, 1971; Fishman et al,

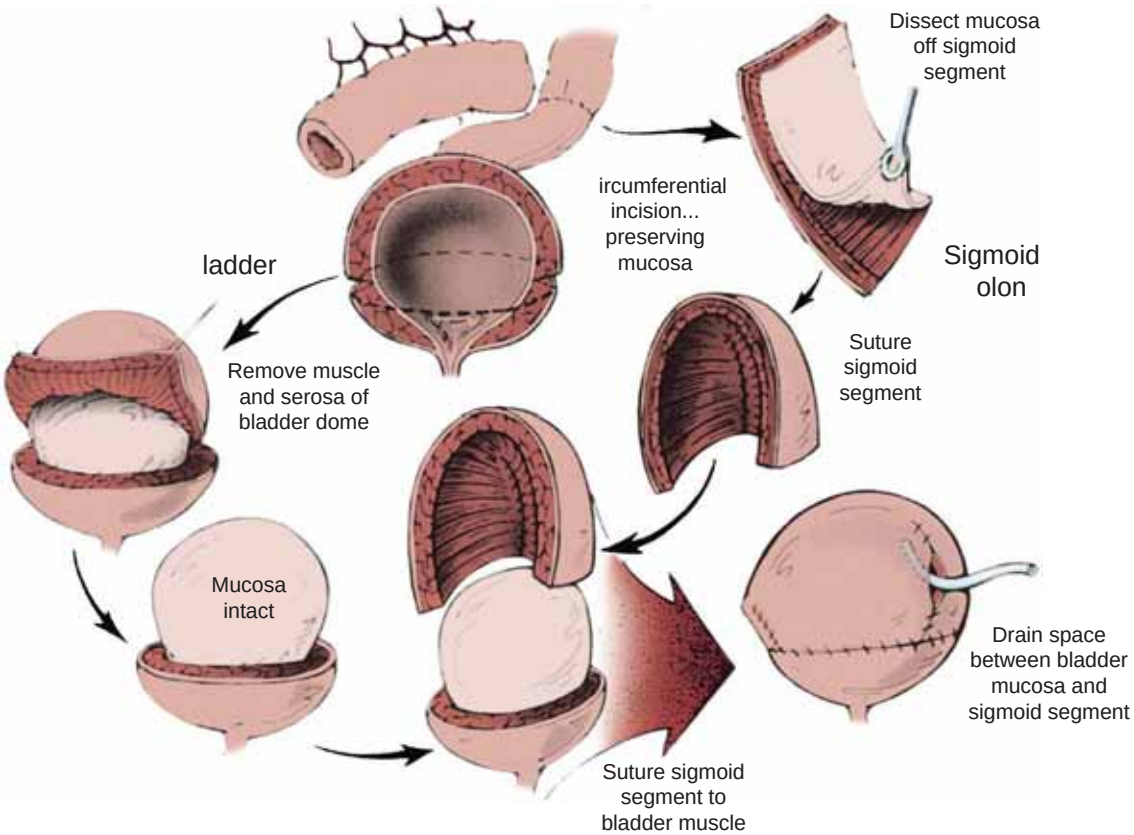

Figure 129–17. Seromuscular enterocystoplasty with use of sigmoid colon. Detrusor incision is performed as in autoaugmentation; however, the bulging mucosa is covered with a demucosalized segment of sigmoid colon. (From Buson H, Manivel JC, Dayanc M, et al. Seromuscular colocystoplasty lined with urothelium: experimental study. Urology 1994;44:745.)

1987; Kambic et al, 1992; Kropp et al, 1995a, 1995b, 2004; Zhang et al, 2004; Harrington et al, 2008). Successful regeneration using this technology has been produced in the laboratory with either "unseeded" or cell "seeded" regenerative growth. Atala and associates (2006) provide the first reported data using a seeded biodegradable construct for augmentation in the neurogenic population. Seven children underwent autologous augmentation. No major complications were reported. Encouraging subjective response to the augmentation was obtained, but uniform urodynamic improvement was not universally appreciated. This work by Atala and associates has provided the foundation for an industry-supported prospective multi-institution investigation using a neobladder construction (Joseph et al, 2009). The study enrolled 11 children, and 10 underwent neobladder augmentation. All 10 patients have completed the primary 12-month endpoint. Results similar to Atala and associates' initial findings have been encountered. Subjective improvement has been reported by some families but has not been correlated with objective urodynamic changes (Joseph et al, 2009). Although these results remain promising, to date an objective successful clinical outcome using autologous regenerative tissue for bladder augmentation is limited. Using autologous tissue from a neuropathic source may potentiate growth of abnormal tissue, but an alternative cell source for regenerative tissue such as stem cells may circumvent that concern. However, the clinical use of stem cells carries its own set of obstacles (Aboushwareb and Atala, 2008; Aitken and Bägli, 2009; Soler et al, 2009). Further investigation into the clinical applicably of regenerative tissue engineering is required. This technology remains poised to significantly alter the field of reconstructive bladder surgery (Atala et al, 1992, 1993b; Cilento et al, 1994; Kropp et al, 1995b; Oberpenning et al, 1997; Probst et al, 1997; Fauza et al, 1998; Kropp, 1998; Yoo et al, 1998; Reddy et al, 2000; Lai et al, 2002; Zhang et al, 2004; Wood and Southgate, 2008; Aitken and Bägli, 2009; Soler et al, 2009).

A Decreasing Necessity?

Although augmentation cystoplasty works well for most patients who require it, and work on alternatives to bowel cystoplasty may lower morbidity for the patient, a primary goal for every pediatric urologist is to minimize the number of patients needing cystoplasty. Newer medical regimens and neuromodulation may prove effective for some patients who presently do not respond to conservative measures (Aslan and Kogan, 2002). Xiao (2005) continues to refine an artificial somatic-autonomic reflex pathway in children with neurogenic bladder due to spinal cord injury and spina bifida. Through a limited laminectomy, the dorsal nerve root of L5 is identified and transected and an anastomosis is made with the distal end of the S3 ventral root. Scratching the dermatome supported by L5 creates reflex stimulation of the bladder initiating a contraction. Improvement in bladder compliance may occur. Other centers are exploring this technique (Peters et al, 2010). No matter what the diagnosis, earlier and more aggressive treatment of bladder dysfunction may minimize the insult to the bladder and maximize recovery as well as ultimate bladder function. Early urodynamic evaluation of boys with posterior urethral valves may identify treatable bladder problems and improve the prognosis from the standpoint of the kidneys and bladder (Misseri et al, 2002). Grady and colleagues (2003) have suggested that complete primary repair of bladder exstrophy results in early bladder cycling that improves eventual bladder function and decreases the likelihood of augmentation cystoplasty.

With perhaps the most compelling evidence to date, Kaefer and associates (1999b) found that only 17% of patients with hostile neurogenic bladder dysfunction treated immediately on diagnosis required augmentation cystoplasty compared with 41% of similar patients treated expectantly. Although the series included no collaborative urodynamic data and might be subject to lag time bias, the authors thought that there was a significant difference in the outcomes for the two groups. Because there are no prospective, randomized trials evaluating early evaluation and treatment of pediatric bladder dysfunction, recommendations that expectant treatment may lower the necessity for augmentation cystoplasty (Bauer, 2003; Mitchell, 2003) remain a personal bias rather than a scientific fact. Thus far, early bladder management has not decreased the rate of augmentation cystoplasty (Lendvay et al, 2006). Critical, prospective evaluation of such treatment is needed and will, it is hoped, demonstrate how to manage these patients. It is likely that such improvements will minimize the need for cystoplasty but not completely remove it.

Improving Quality of Life?

Reconstruction to achieve continence has been assumed to improve health-related quality of life. Early evaluation of small numbers of patients undergoing reconstruction including augmentation cystoplasty do not always show improved status on objective questionnaires compared with preoperative studies or control patients without surgery despite what generally would be considered to be good clinical results (Macneily et al, 2005; Parekh et al, 2006). Patient-reported scores also do not always correlate with those noted by their parents. Most evaluation of surgical techniques to date has focused on results and complications from the perspective of surgeons. Future evaluation should include objective, patient-reported consideration. Tools to acquire that information must be validated for longitudinal study of these patients and their disease processes.

Key Points: Alternatives to Gastrointestinal Cystoplasty

- Ureterocystoplasty avoids the complications associated with bowel segments but may not provide adequate volume if the ureter is not remarkably dilated.
- Autoaugmentation, no matter what the technique, seldom adds significant capacity and may not always improve compliance long term.
- More experience and longer follow-up with seromuscular enterocystoplasty are needed to determine its appropriate role.
- Care for the underlying bladder dysfunction should be improved to lower the need for augmentation cystoplasty.

CONTINENT URINARY DIVERSION

The frequency with which continent urinary diversion is performed in children depends on one's definition of continent diversion. In adults, total bladder replacement is not uncommon after cystectomy for transitional cell carcinoma. This has led to extensive experience with continent urinary diversion and orthotopic neobladders that allow spontaneous voiding. Tumors resulting in cystectomy among children are much less common. It is in that setting, and the occasional child in whom the bladder is

congenitally absent or so small as to be virtually useless, that a pure continent urinary diversion in the classic sense of an Indiana or Kock pouch might be performed. Very good results with continent diversion in children have been achieved, equivalent to those reported in adults (Stein et al, 2005). Orthotopic neobladders in children are performed infrequently. Neurogenic or anatomic problems at the outlet prevent spontaneous voiding in many cases. Even among patients having undergone cystectomy for tumors, irradiation can interfere with voiding. On occasion, a child with neurogenic dysfunction may be a candidate for orthotopic bladder substitution (Stein et al, 2000, 2005). It is not clear how many of those patients with neurogenic dysfunction can be expected to void adequately.

More frequently in children, a series of continent diversion have included patients undergoing a mix of the techniques discussed in this chapter. Some authors have defined combinations of bladder augmentation, continent abdominal wall stoma, and some procedure at the outlet as continent diversions (Kaefer et al, 1997b). Division and closure of the bladder neck to prevent incontinence per native urethra has typically meant inclusion. Certainly, maximal use of the native urinary tract is beneficial to the child. Much like urinary refunctionalization, these procedures typically have been performed in complex patients with multiple problems that must be addressed, often after numerous previous surgeries.

Considerations

The amount of bowel used in continent urinary diversion may vary according to the patient. Total bladder replacement requires much more intestine than simple augmentation. Typically, a 40-cm segment of small bowel is used for an ileal reservoir in a Kock pouch compared with the 20 cm often used for augmentation. Likewise, the entire right colon with the hepatic flexure may be used in an Indiana pouch with or without a patch of small intestine, whereas only 15 to 20 cm of colon is needed for colocystoplasty. Because of the potential morbidity associated with use of a larger intestinal segment the native bladder is often incorporated in children if it provides any significant volume. To do so, however, may require repair of the outlet if outflow resistance is low. Otherwise, incontinence per native urethra will result.

Imbrication of the ileocecal valve and terminal ileum has proved to be a simple and reliable means for construction of an effective efferent limb in continent diversion among adults and children. Despite reports to the contrary in select patients (Husmann and Cain, 1999), concern about fecal incontinence secondary to use of the ileocecal valve persists for patients with neurogenic dysfunction. The flap valve continence mechanism provides numerous alternatives for those surgeons with such concerns in continent diversion. The good results achieved with the appendix or tapered intestinal segments has led to their increased use in recent years.

Whereas maintenance of the native urethra for catheterization is ideal, it may not be appropriate or possible in all individuals. As indicated previously, reconstructive bladder neck procedures are often subject to difficulty with catheterization. **Children with neurogenic sphincter incompetence may have associated neurologic limitations that prevent easy access to the native urethra. This is particularly true for the wheelchair-bound child. For children without neurologic deficits, normal sensation in the native urethra can prevent compliance with a routine catheterization schedule because of discomfort. For these reasons, a continent catheterizable stoma provides an adequate and sometimes a more reliably useful alternative.**

CONTINENCE MECHANISMS AND CATHETERIZABLE SEGMENTS

Ureterosigmoidostomy and Its Variants

Ureterosigmoidostomy can be an effective form of continent urinary diversion in some patients. Its major advantage is the potential for spontaneous emptying by evacuation of urine with stool. The significant complications of hyperchloremic acidosis, infection, hydronephrosis, and the development of colonic malignant neoplasms have led to disfavor and disuse, particularly in the United States. **Although good results with standard ureterosigmoidostomy have been reported in some children, the procedure is rarely performed as originally described. The morbidity of acidosis and upper tract changes may increase with time, making those complications particularly worrisome for children with a long life expectancy. The significant risk of adenocarcinoma commits the patients to a lifetime of close surveillance for an avoidable tumor.** It is unlikely that ureterosigmoidostomy, as classically described, will regain acceptance for children.

Several modifications of ureterosigmoidostomy have been developed in an attempt to decrease the significant complication rate. **The most basic of the modifications is the sigma rectum or the Mainz II pouch.** The colon is incised along the antimesenteric border for 6 cm both proximal and distal to the rectosigmoid junction. The ureters are implanted in an antirefluxing fashion, and that portion of colon is then reconfigured and closed. This is done to create a rectosigmoid reservoir of lower pressure to protect the upper tracts. The Mainz II pouch has been used in children primarily with bladder exstrophy (Stein et al, 1997a). Continence in appropriately selected patients is good, although acidosis is still a significant problem because of exposure of the entire colon to urine (Fisch et al, 1996; Gerharz et al, 1999; Mingin et al, 1999a). The potential for development of adenocarcinoma still exists with this technique. Long-term follow-up is necessary to determine if the reconfiguration of the sigmoid in the area of ureteral implantation is truly effective for protection of the upper tracts. Stricture at the ureterocolonic anastomosis has been the most common complication in relatively short follow-up (Fisch et al, 1996).

In an effort to control the amount of colon to which urine is exposed, Kock and associates (1988) **described a colorectal valve to confine urine to the distal segment.** The intussuscepted nipple valve is stabilized with permanent staples. The distal rectal segment is opened and patched with ileum to lower pressure. With short-term follow-up, the valve is effective in that the authors noted no necessity for sodium bicarbonate or potassium citrate therapy (Kock et al, 1988), a finding duplicated by others (Mahran et al, 1999). An increased risk for tumor development probably still exists with this modification because the ureterocolic anastomoses are still exposed to an admixture of stool and urine. Urodynamic evaluation has revealed low pressure in the rectal reservoir (Kock et al, 1988). Long-term follow-up of its use in children is needed to see if it is truly less morbid in terms of infection and upper tract deterioration. If placement of a colorectal valve avoids most complications of metabolic acidosis from ureterosigmoidostomy and construction of a reservoir with lower pressure better protects the upper tracts,

then the last remaining major concern about ureterosigmoidostomy is tumor development. The concern is significant; of 94 children observed in Boston after ureterosigmoidostomy, adenocarcinoma developed in 7, of whom 4 died of the tumor (Rink and Retik, 1991). Kock and coworkers (1988), followed by Skinner and associates (1989), used a hemi-Kock pouch to augment the distal rectal segment. A colorectal valve was made to isolate urine to the distal colonic reservoir. The afferent nipple valve kept stool away from the ureteroileal anastomoses, perhaps lowering the risk for tumor development. Simoneau and Skinner (1995) reported their results with the procedure in 15 patients, including 4 children. Their complication rate, both early and late, was relatively high. This is not surprising, considering the relatively complex nature of the procedure. They did think that the pediatric patients were better suited for the procedure. Rink and Retik (1991) suggested that the rectum could be augmented with a nonrefluxing ileocecal conduit in a similar fashion.

Before any variant of ureterosigmoidostomy is considered, competence of the anal sphincter must be ensured. Tests used to assess sphincter integrity include manometry, electromyography, and practical evaluation of the ability to retain an oatmeal enema in the upright position for a time without soilage. Incontinence of a mixture of stool and urine results in foul soilage and must be avoided. Consequently, most patients with neurogenic dysfunction, who are incapable of fecal continence in the presence of diarrhea, are not candidates for these procedures. Procedures that separate the fecal and urinary streams within the rectal sphincter have been described but have not been widely used among children.

Nipple Valves

The greatest experience with nipple valves used to achieve urinary continence has been with the Kock pouch. Skinner and associates (1989) made a series of modifications to aid in maintenance of the efferent nipple. Despite experience and use of these modifications, a failure rate of 15% or higher can be expected (Benson and Olsson, 1998) (Fig. 129–18). Several authors have reported a reoperative rate of approximately 33% with the Kock pouch, most frequently related to the efferent nipple (deKernion et al, 1985; Waters et al, 1997). Equivalent results with the nipple valve and a Kock pouch have been achieved in children (Hanna and Bloiso, 1987; Skinner et al, 1988; Kaefer et al, 1997b; Abd-El-Gawad et al, 1999). The last report noted a significant incidence of hyperchloremic acidosis and new hydronephrosis, although those complications were likely due to the complex nature of the patients rather than the particular continent diversion used.

Intussuscepted nipple valves have also been used with colonic and ileocolonic reservoirs, particularly the Mainz I pouch. Again, evolution of the nipple valve in the Mainz pouch occurred over time (Thuroff et al, 1986, 1988; Hohenfellner et al, 1990; Stein et al, 1995). Most recently, the intussuscepted ileum was fixed with staples, passed through the intact ileocecal valve, and fixed again. Much as with the Kock pouch, the incidence of incontinence decreased with experience and modifications. The Mainz I pouch has been used in children with good results and low rates of incontinence with the latest modifications (Stein et al, 1995, 1997a, 2000; Steiner et al, 1998). Maintenance of normal upper tracts has been good, and metabolic problems are rare (Stein et al, 1997b). In fact, improvement of preexisting hydronephrosis has been more common than worsening. For the past several years, the group in Mainz has used a flap valve mechanism and the appendix for a continent catheterizable stoma with less incontinence (Stein et al, 1995; Gerharz et al, 1997).

Flap Valves and the Mitrofanoff Principle

Mitrofanoff (1980) described a continence mechanism with use of the appendix and ureter to make a flap valve. He recognized that any tubular structure could be implanted effectively into a low-pressure reservoir. This continence mechanism circumvents many of the secondary potential complications associated with harvesting of the ileocecal valve or use of other gastrointestinal segments.

The foundation for the success of the Mitrofanoff principle is based on construction of a submucosal tunnel for a supple, small-diameter conduit. As the reservoir fills, the rise in intravesical pressure is transmitted through the epithelium and to the implanted conduit, coapting its lumen (Fig. 129–19). **The appendix is an ideal natural tubular structure that can be safely removed from the gastrointestinal tract without significant morbidity. The small caliber of the appendix**

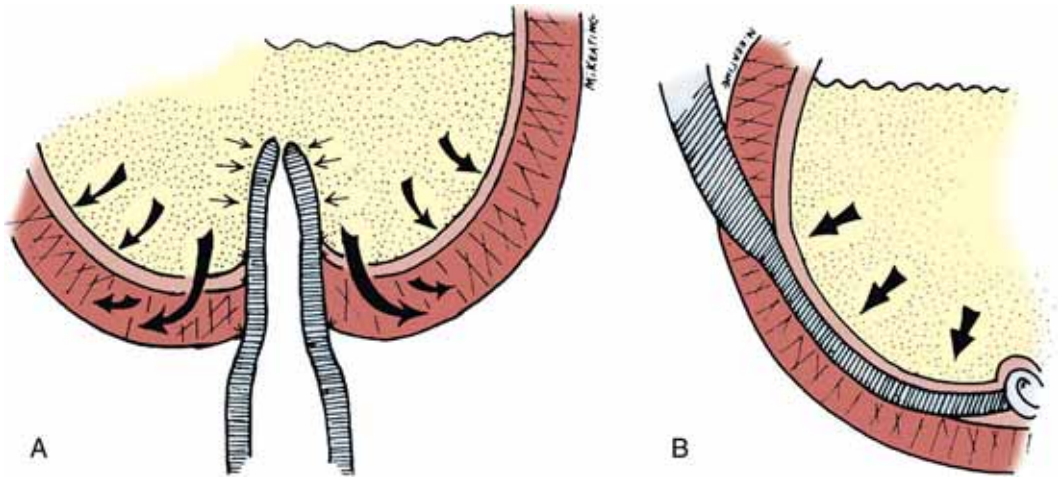

Figure 129–18. Continence mechanisms. **A**, The same pressures that create continence tend to efface nipple valves. **B**, This is not true of flap valves, which have been more reliable in pediatric reconstruction.

facilitates construction of a short functional tunnel with the bladder wall. Experience has shown that continence can be achieved with only a 2-cm appendiceal tunnel (Kaefer and Retik, 1997). Whether in a continent urinary reservoir or native bladder the appendix has been used as an efferent limb with very good results (Hampel et al, 1995; Jayanthi et al, 1995; Kaefer et al, 1997b; Mollard et al, 1997; Cain et al, 1999). The appendix has been particularly useful in children because it is relatively longer and the abdominal wall generally thinner. The flap valve is probably the most reliable of all of the surgically constructed continence mechanisms. This is good in terms of continence when the patient is catheterized reliably. Many patients with good flap valves will virtually never leak per stoma. This potentially puts them at greater risk for upper tract deterioration or spontaneous rupture of the bladder or reservoir if catheterization is not performed.

If the appendix is used in situ as a continence mechanism in a continent urinary reservoir, the reservoir by necessity will include the right colon. Duckett and Snyder (1986, 1987) used the right colon and appendix with good results in children. The mesoappendix, in most cases, allows mobilization of the appendix for use in the native bladder or virtually any reservoir.

Technique. Appropriate preoperative planning is required to position the skin incision to allow adequate mobilization of the appendix to the bladder. In most children this can be achieved through a low midline or a transverse incision. On occasion, the cecum may be high in the abdomen. Mobilization of the ascending colon along the line of Toldt may be required to gain mobilization of the appendix and its mesentery. Cadeddu and Docimo (1999) have used laparoscopy to aid in mobilization of the ascending colon and cecum. Once the cecum has been mobilized the base of the appendix is amputated, leaving a small cuff of cecum with the appendix. Use of the cuff at the stoma may decrease the risk of stenosis. The cecum is closed in a fashion similar to an open appendectomy. If the length of the appendix is marginal, then a greater portion of the cecum can be harvested, which effectively increases the functional length of the appendix (Cromie et al, 1991). A portion may be tubularized with the appendix (Bruce and McRoberts, 1998).

After harvesting, a location is selected for implantation of the appendix into the bladder. The location is based on the length of the appendix, the mobility of the bladder, and the location for the appendiceal stoma. Typically, the distal end of the appendix is tunneled into a posterolateral position within the bladder (see Fig. 129–19).

The base of the appendix is brought to the abdominal wall in a location chosen preoperatively to suit the patient. If a patient wears a supportive brace, stomal positioning must take this into account. The appendix should be brought up to reach the skin without tension, and care must be taken not to twist the pedicle or to occlude it as it passes through the abdominal wall fascia. The base of the appendix often can be hidden within the umbilicus, which allows elimination of a small but obvious abdominal stoma. Because of the small circular diameter of the appendiceal base, stomal stenosis is common; and techniques have been described to prevent this problem. Various flaps have been described as a method for avoiding stomal stenosis (Keating et al, 1993; Kajbafzadeh et al, 1995; Kaefer and Retik, 1997; Frane-Guimond et al, 2006; Berrettini et al, 2008; Landau et al, 2008). The VQZ stomaplasty and its variations have been described in an attempt to prevent exposing intestinal mucosa from the catheterizable channel and decreasing the risk of stomal stenosis (Frane-Guimond et al, 2006; Berrettini et al, 2008; Landau et al, 2008). Regardless of the technique, stomal stenosis will remain a primary complication. Chronic nighttime catheterization with a stent placed into the channel but not reaching the bladder may further decrease the risk of superficial stenosis (Mickelson et al, 2009). **For prevention of kinking and problems with catheterization it is advisable to maintain as short a conduit as possible.** Securing the appendix and bladder wall to the peritoneum beneath the fascia will help diminish the problem of conduit kinking with reservoir filling. When appendix or any catheterizable stoma is used, it is advisable to repeatedly catheterize the channel after each step in reconstruction to confirm easy passage. If the catheter does not pass easily into the reservoir, the preceding step needs to be revised. Problems with catheterization by the surgeon during the operative procedure usually result in more difficulty for the patient afterward. It is also beneficial to catheterize at variable reservoir volumes to confirm proper fixation of the reservoir and the absence of any kinking. A 6- to 10-Fr Silastic stent is typically left for 10 to 14 days within the efferent catheterizable channel during the healing process. It is advisable for the surgeon to

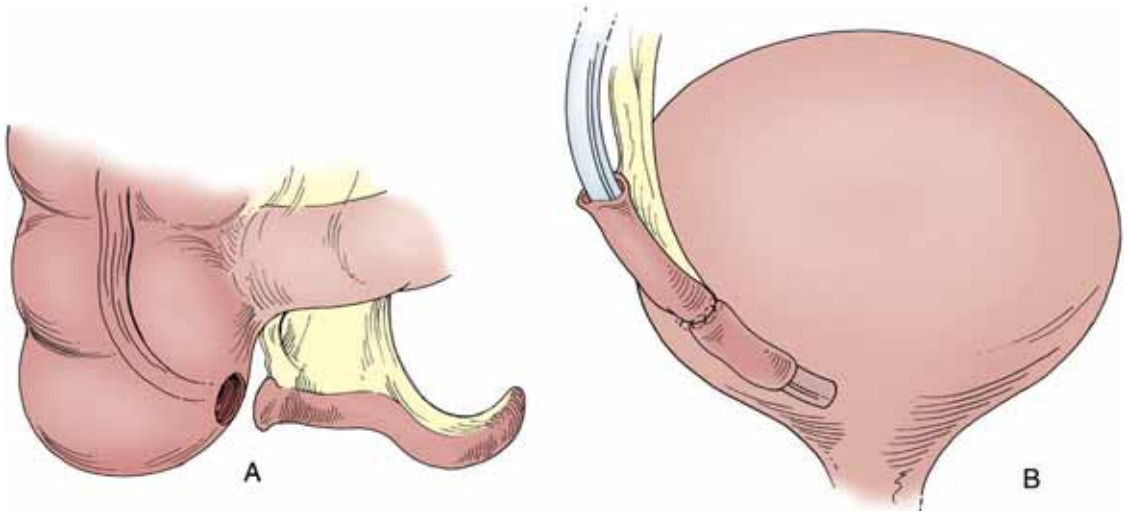

Figure 129–19. Appendicovesicostomy. **A**, The appendix is harvested with a cuff of cecum on a wide pedicle based on the appendiceal artery. A flap of cecum can be harvested in continuity with the appendix and tubularized to increase the length. **B**, The distal appendix is tunneled into the bladder to provide continence after the end is amputated. The proximal end of the appendix, the cecal cuff, is brought to the umbilicus or right lower quadrant as a catheterizable stoma.

personally catheterize the efferent limb before allowing the patient or other family members to do so. Catheterization should be repeated at least every 4 hours during the day for reservoir drainage, maintenance of patency, and minimalization of the risk of stomal stenosis.

The appendix may not be available for use in all patients because of previous appendectomy, its location or length, congenital absence, involvement with adhesions, or its use for continence enemas. Histologic abnormalities of the appendix have been reported to occur in as many as 30% of patients (Liebovitch et al, 1992) and to increase with age. They rarely are of enough clinical significance to preclude use (Mulvihill et al, 1983).

Results. Several papers have reviewed large series of patients after appendicovesicostomy (Kaefer et al, 1997b; Cain et al, 1999, Harris et al, 2000; Thomas et al, 2006; Welk et al, 2008). The populations of patients have been typical of most pediatric groups, the majority having neurogenic dysfunction. Inability to use the appendix, other than because it was needed in situ for antegrade continence enemas, has been rare. The results, in terms of continence, have been superb, usually above 95% (Gerharz et al, 1997, 1998; Kaefer and Retik, 1997d; Mor et al, 1997; Suzer et al, 1997; Gosalbez et al, 1998; Cain et al, 1999; Castellan et al, 1999; Liard et al, 2001; Thomas et al, 2006; Welk et al, 2008). **Incontinence is a rare event with the Mitrofanoff principle and may result from inadequate length of the flap valve mechanism or persistently elevated reservoir pressure.** Urodynamic evaluation is required to evaluate the cause of the incontinence. Injection of collagen or other biomaterials is a possible treatment for inadequate outflow resistance, with success reported up to 50% but long-term durability unknown (Welk et al, 2008). A more formal approach with takedown and revision of the leaking Mitrofanoff valve is usually required (Kaefer and Retik, 1997d). **The most common complication has been stomal stenosis, which has generally occurred in 6% to 10% of patients** (Thomas et al, 2006; Welk et al, 2008). Such stenosis resulting in difficult catheterization may occur early in the postoperative course and require formal revision (Harris et al, 2000). Another recognized complication has been appendiceal perforation. Most problems with stomal stenosis and creation of a false passage (perforation) occur in the first few years after reconstruction (Thomas et al, 2006). Stricture and necrosis, particularly of cecal extensions of the appendix, have occurred rarely. Abdominal stomas may be associated with a higher risk of reservoir calculi because of the potential for incomplete emptying.

Follow-up in the recent series has averaged approximately 4 years. Patients from Mitrofanoff's early experience (1980) should now have follow-up of more than 20 years, suggesting that the appendix may provide a durable alternative for pediatric patients with a long life expectancy, a finding also noted by others (Cain et al, 1999; Harris et al, 2000; Liard et al, 2001). Whereas the majority of the experience with the Mitrofanoff technique has been in children, similar outcomes with successful durable continence has been achieved in the adult population (Gowda et al, 2008; Van der Aa et al, 2009).

Alternatives

When the appendix is unavailable for use, other tubular structures can provide a similar mechanism for catheterization and continence. Mitrofanoff (1980) described a similar technique with ureter (Kaefer et al, 1997b). Care must be taken to preserve the distal blood supply to prevent ischemia. Refluxing ureters have even been used after extravesical reimplantation (Ashcraft and Dennis, 1986; Duel et al, 1996; Kaefer et al, 1997b). Stomal stenosis seems to be more problematic with use of the ureter compared with the appendix, possibly owing to compromised blood supply. In addition, distention of the ureter due to catheter passage has caused discomfort in some individuals (Duckett and Lofti, 1993).

Woodhouse and MacNeily (1994) as well as others have used the fallopian tube, which can accommodate catheterization. Stenosis again appears to be a significant problem with the fallopian tube. In addition, the effect on fertility should be considered when there is a normal ipsilateral gonad. Bihrle and associates (1991) fashioned a gastric tube mobilized on the gastroepiploic artery for implantation in continent reservoirs. Acid irritation of the skin was a problem in some patients. They then used a tapered segment of ileum as well (Adams et al, 1992). By narrowing the segment longitudinally along the mesenteric border with permanent staples in series, they were able to construct a uniform tube of adequate length that was easy to catheterize and provided good continence rates. Others (Hasan et al, 1994; Woodhouse and MacNeily, 1994) have had similar good results. It is ideal for such tubes to be long enough to reach from the reservoir to skin without tension; however, they should then be kept as short and straight as possible to facilitate easy catheterization. Any unnecessarily long catheterizable channel that is mobile within the abdomen can potentially kink and result in difficult catheterization or perforation.

Monti and colleagues (1997) **have been credited with a novel modification of the tapered intestinal segment that can be reimplanted according to the Mitrofanoff principle. Recognition should also be directed to another report of this procedure by** Yang (1993). A very short (1 to 2 cm) segment of small bowel is opened longitudinally along the antimesenteric border and then closed transversely (Fig. 129–20). By this reconfiguration, the initial circumference of the segment is converted to length, and the original length to circumference, of the reconfigured tube. A uniform tube is made with a small mesentery toward the center. The two ends are devoid of mesentery, making them easy to tunnel into bladder and bring through the abdominal wall. If the first incision is made directly at the antimesenteric border, both limbs are of equal length. By making the incision well around one side, one limb may be made much longer than the other. Experience has shown that one need not achieve a long tunnel in the bladder or reservoir to achieve continence with such a small tube, and the longer limb has typically been used to reach the skin through a thick abdominal wall.

Very good results have been achieved with the Yang-Monti tube as a catheterizable stoma, and it is certainly an efficient use of bowel (Thomas et al, 2006). Some surgeons have suggested that it may be easier to catheterize than an ileal segment tapered longitudinally because circular mucosal folds are redirected longitudinally in the direction of catheter passage. Stomas constructed with ileum may have a lower rate of stomal stenosis than those made with appendix (Kaefer et al, 1999a). The one potential disadvantage of the Yang-Monti tube is that it remains relatively short and may not reach the skin without tension in obese patients. Despite extensive use of skin flaps, such tension may lead to stomal stenosis. Two separate reconfigured tubes can be anastomosed together for better length (Kaefer and Retik, 1997). Casale (1999) has used an initial segment that was twice as long that was partially split in the middle and then opened in a spiral fashion on opposite sides to make a longer strip that could be tubularized in continuity. Narayanaswamy and colleagues (2001) noted difficulty with catheterizations through Yang-Monti

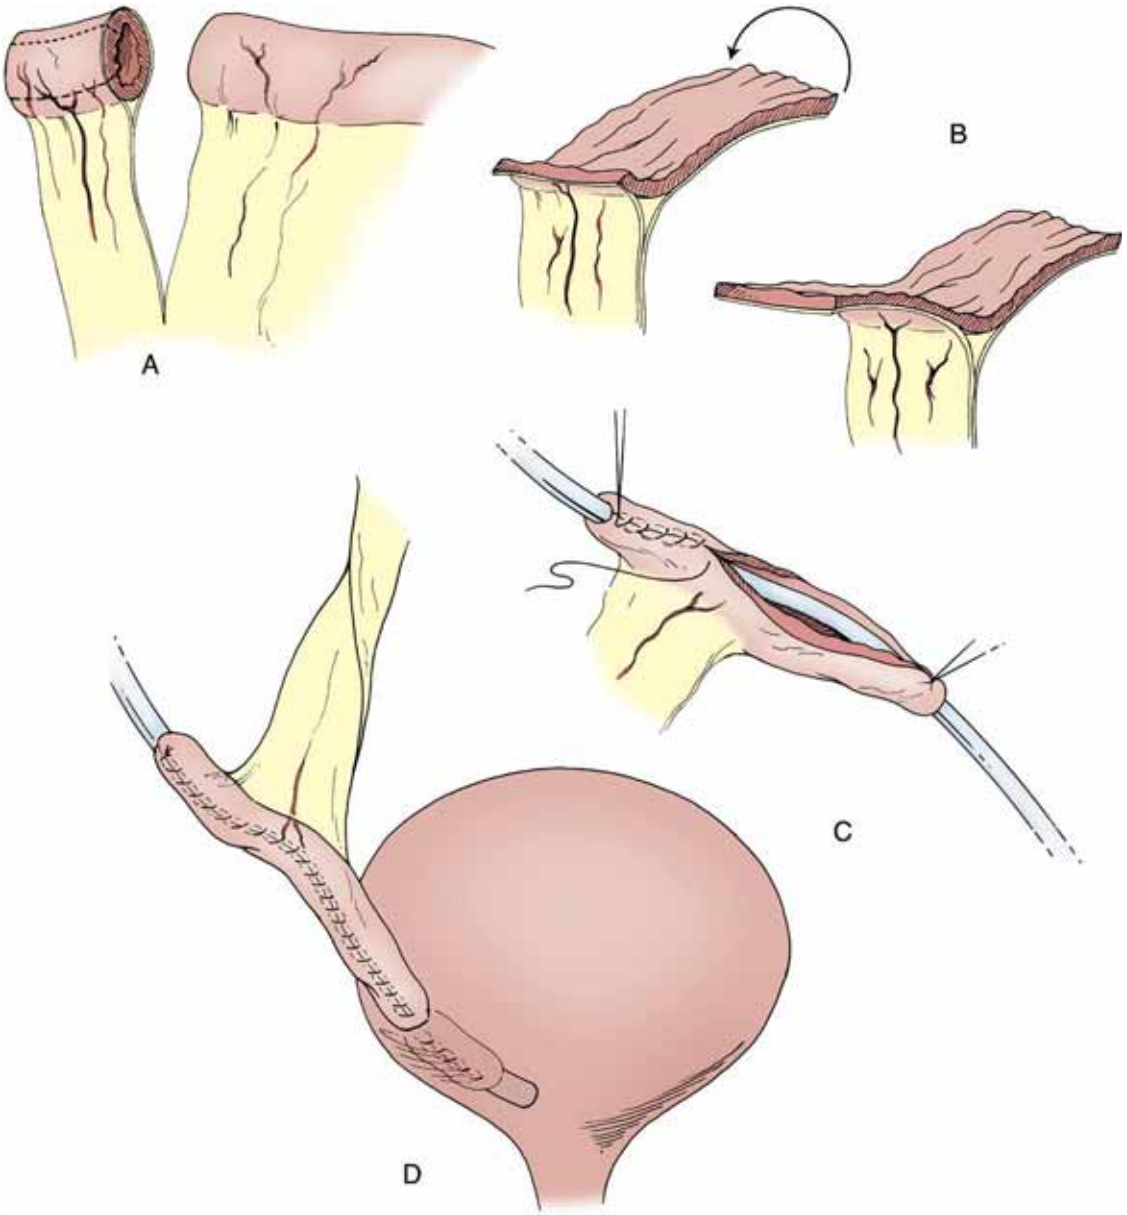

Figure 129–20. Yang-Monti technique to efficiently construct a catheterizable tube. **A**, A 2-cm length of ileum is harvested either independently or next to a segment for augmentation cystoplasty. The segment is opened horizontally and tubularized in a longitudinal fashion. **B**, If the segment is opened directly on the antimesenteric border, two equal-length limbs result with a central mesenteric pedicle. Initial incision may be made to one side to form a shorter limb for implantation in the bladder and a longer one to be brought through the abdominal wall. **C**, The reconfigured ileal segment is tubularized over a 12-Fr catheter in a two-layer technique with absorbable sutures. **D**, A continent catheterizable stoma is constructed.

channels in 28% of a large series of patients due to "pouchlike dilatation." Such a problem has been avoidable in most series.

Ileocecal Valve

Use of the ileocecal valve as a continence mechanism began with Gilchrist (1950) and was popularized by the Indiana group (Rowland et al, 1985; Bihrle, 1997). Various modifications exist. In general, a short segment of terminal ileum, whether imbricated or tailored, is used as an efferent limb. This segment should be kept as short and straight as possible to facilitate easy intermittent catheterization. Continence is based on the imbricated ileocecal valve, not the length of the efferent limb. The imbrication is usually secured with interrupted, permanent sutures, involving the very distal ileum and ileocecal valve, and the imbrication is carried well onto the cecum. The reservoir itself is constructed from reconfigured right colon up through the hepatic flexure, with or without a patch of ileum. Standard ureterocolonic anastomoses are done beneath the taenia to prevent reflux. Staplers using absorbable staples have been used for reconfiguration of the reservoir (Kirsch et al, 1996) and may shorten the operative time for reconstruction.

The Indiana pouch has been used in children with excellent results, as it has in adults. Besides the appendix, this continence mechanism is perhaps the simplest and has the shortest learning curve to achieve reliable results. Continence rates as high as 95%

have been reported with preservation of normal upper tracts (Rowland et al, 1985; Lockhart et al, 1990; Rink and Bihrle, 1990; Hensle and Ring, 1991; Rowland, 1995; Kaefer et al, 1997b). Rare reports have noted higher rates of incontinence (Canning, 1998). Husmann and Cain (1999) have used the cecal segment for bladder augmentation and the efferent limb to construct a continent catheterizable stoma with equally good results. They noted a low incidence of detrimental effect on gastrointestinal function in a select group of patients with neurogenic dysfunction.

Hydraulic Valves

Benchekroun (1982, 1989) developed an interesting hydraulic valve as a continence mechanism that was modified by Guzman and coworkers (1989). Urine from the reservoir and any pressure generated there is allowed to enter a sleeve of ileum around the catheterizable channel. Compression of the inner tube theoretically provides continence, and early results were encouraging. Initial continence rates approached 75% and then 90% with a single revision (Benchekroun et al, 1989). Others have not been able to duplicate those results (Sanda et al, 1988; Leonard et al, 1990b), and the valve has largely been abandoned.

Koff and associates (1989) added hydraulic compression to the terminal ileum of an Indiana pouch by anastomosing a segment of tubular ileum to the cecum and then wrapping it around the efferent limb. The procedure has not gained popularity, probably because of the excellent success of the standard Indiana pouch.

Continent Vesicostomy

Yachia (1997) described construction of a bladder tube fashioned from a wide flap of the anterior bladder wall. No attempt was made to produce continence at the level of the bladder. The continence mechanism was fashioned by weaving the bladder tube through the rectus muscle to produce compression and continence. Continence in the small, short-term series was reported at 100% but has not been duplicated.

Hanna and colleagues (1999) described a continence mechanism based on either a flap of bladder or intestinal tissue fashioned after prior enterocystoplasty. A rectangular flap in continuity with the bladder is tubularized over a 14- to 16-Fr catheter. The bladder is plicated around the proximal 3 cm of the tube with nonabsorbable suture to make a type of nipple similar to gastric fundoplication. No significant morbidity has been identified in a limited series of five children, and all children have remained dry on intermittent catheterization. Macedo and Srougi (2000) described a similar continence mechanism made at the time of initial augmentation. They achieved acceptable continence in eight of their first nine patients. Their technique is potentially appealing for patients requiring augmentation and having no appendix because of the simplicity; however, continence is based on a type of nipple valve that historically has been difficult to keep fixed. The same forces that create continence tend to efface the continence mechanism.

Casale (1991) has described a form of continent vesicostomy in which the continence mechanism is based on a flap valve made from a tubularized strip of bladder mucosa. It is particularly suitable when the bladder is compliant and of large capacity. An anterior detrusor strip is also used to construct a catheterizable limb.

Technique. Parallel incisions 3 cm apart are made into the anterior bladder and used to form a long rectangular flap. The abdominal wall should be measured to ensure that the strip is long enough to reach the skin without tension. The full-thickness strip is tubularized down to the bladder, typically in two layers. The muscle portion is left broad to come around without tension and provide good blood supply. The mucosa may be trimmed in width before tubularization to avoid redundancy. A strip of mucosa within the bladder, 2 to 3 cm in length and 1.5 cm in width, is incised in a direct line and in continuity with the mobilized bladder tube. The edges of this strip are mobilized until it can be tubularized along its entire length. It may be beneficial to mobilize only one edge over to the other side, which allows one to avoid overlapping suture lines. Casale (1991) originally incised the mucosa transversely at the end of the intravesical strip to be tubularized; Rink and associates (1995b) then suggested that it could be left intact (Fig. 129–21). The bladder mucosa from either side of the tube is then mobilized and closed over the mucosal tube to create a flap valve. More extensive mobilization of the side opposite that mobilized for the inner tube allows closure without overlapping suture lines, which may help avoid fistula formation and incontinence. A soft stent is usually left through the tube for 3 weeks during healing to prevent stenosis. It does tend to close if it is not catheterized regularly and may be even more susceptible than other catheterizable channels to stomal stenosis (Cain et al, 2002; Thomas et al, 2005).

Results. Continence rates have been good, as with most flap valve mechanisms (Cain et al, 1999, 2002). Stomal stenosis remains a significant problem—45% in the experience at Indiana University (Cain et al, 2002). Skin flaps and avoidance of tension to reach the skin may minimize this risk but not remove it. Advantages include avoidance of an intraperitoneal procedure and bowel anastomosis; the appendix can be reserved for use with enemas. It does use some bladder and decreases capacity, which may not be appropriate for some patients.

Results with Pediatric Continent Diversion

Continent urinary reservoirs have been performed in children with very good results, equivalent to those achieved for adults. Construction of an adequate reservoir and an antireflux mechanism has generally been straightforward. For review of issues concerning compliance of the reservoir or mechanisms by which reflux can be prevented, the reader may review earlier parts of this chapter or the information on continent urinary diversion in adults elsewhere in this textbook. The most challenging aspect of continent diversion remains construction of an efferent limb that provides reliable continence and easy catheterization. The continence mechanism most familiar to pediatric urologists is the flap valve. The appendix is simple to use, suitable for most children, and associated with very good continence rates. If the appendix is not present or is to be used for antegrade colonic enemas, tapered intestinal segments provide a nice alternative. Nipple valves are the most complex continence mechanism and therefore their creation requires a longer learning curve. Continence rates of approximately 85% can be expected with stapled nipple valves (Kaefer et al, 1997b; Benson and Olsson, 1998), even with extensive experience. With use of the other efferent limbs, continence rates above 90% and approaching 95% have routinely been reported in children (Duckett and Snyder, 1986; Hensle and Ring, 1991; Kaefer et al, 1997b; Surer et al, 2003). Those continence rates have been achieved with preservation of the upper tracts. With proper selection of patients and appropriately performed continent diversion, hydronephrosis in children is rare

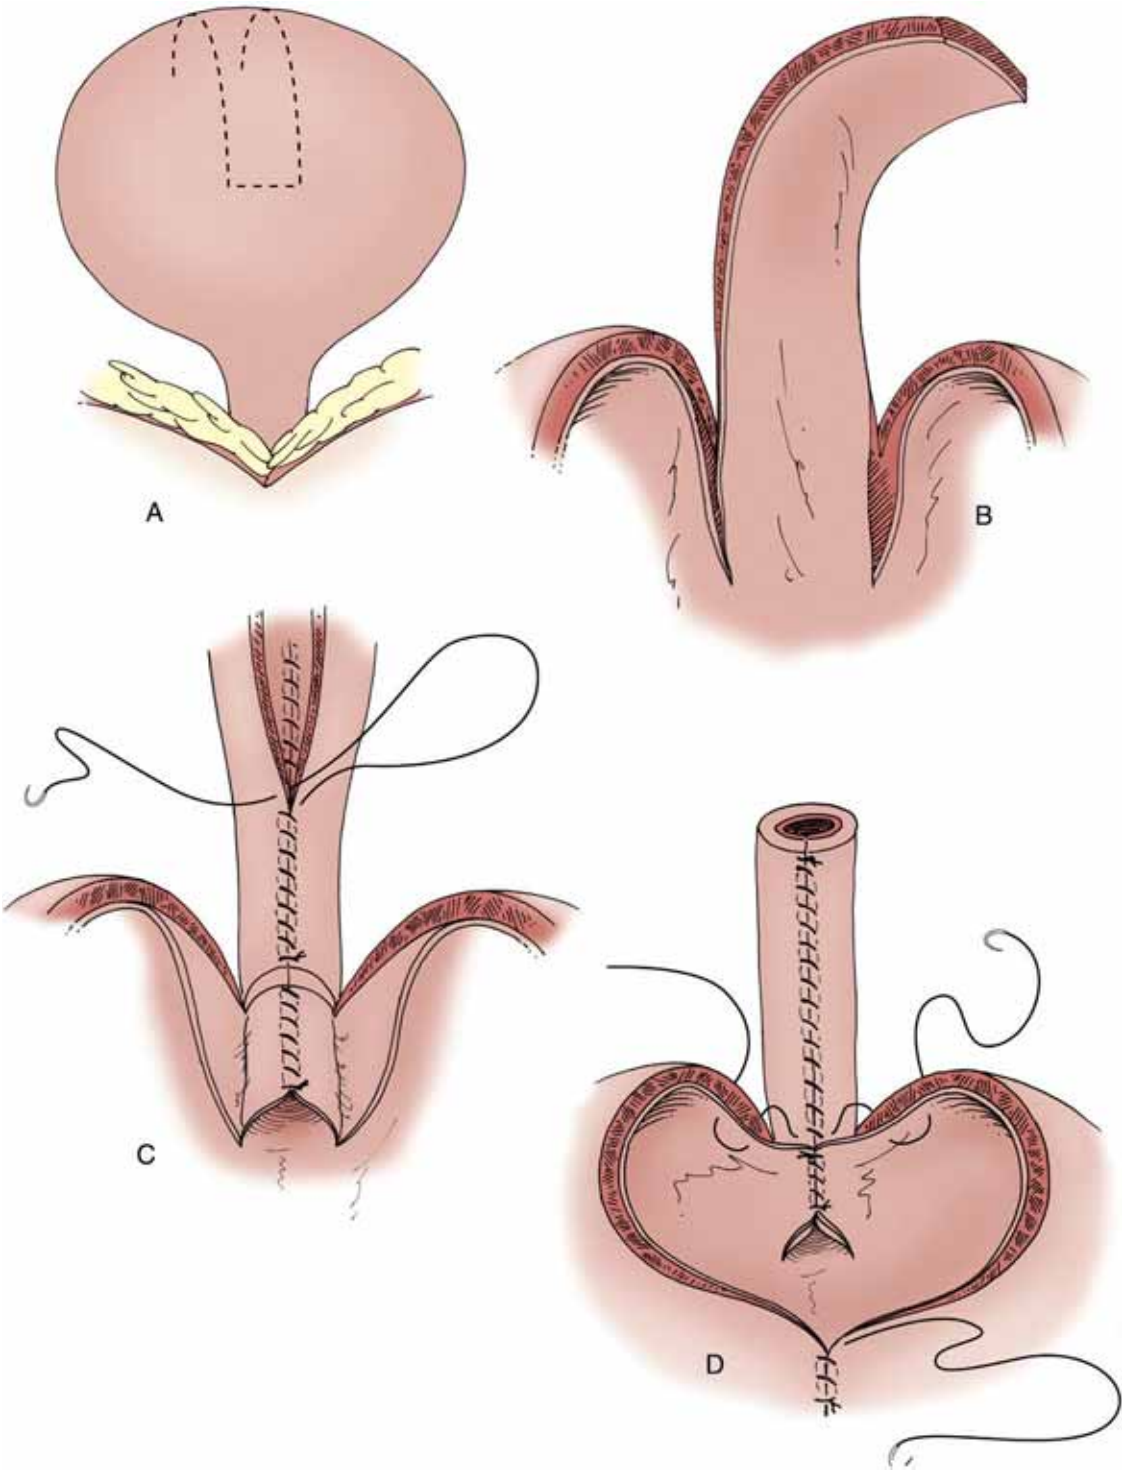

Figure 129–21. Casale continent catheterizable stoma. **A**, Parallel incisions are made in the bladder dome, forming a full-thickness bladder strip. **B**, The epithelium of the bladder is then incised for an additional 2.5 cm. The edges of the epithelium are mobilized, allowing tubularization. **C**, The epithelium is tubularized from the bladder out to the tip of the strip with an absorbable suture. The muscle of the bladder strip is then tubularized with an absorbable suture. **D**, The lateral edges of the epithelium within the bladder are reapproximated over the tubularized bladder segment with absorbable suture. The bladder is then closed with absorbable suture, incorporating the bladder tube with the initial sutures to prevent kinking.

postoperatively. Particularly if catheterization is not performed reliably, new hydronephrosis can occur (Abd-El-Gawad et al, 1999). There is no evidence that children suffer more hydronephrosis after continent diversion compared with conduit diversion (Stein et al, 2000).

Children undergoing continent diversion have a long life expectancy. The incidence of complications after continent diversion will probably increase with longer follow-up. Those patients will be subject to the same complications discussed at length for bladder augmentation. All of those complications, including

infection, hydronephrosis, calculi, spontaneous perforation, and tumor, have been reported after continent diversion in adults if not in children. These are largely a function of the use of intestine as a urinary reservoir. Because more intestine is usually required in continent diversion than in bladder augmentation, the incidence of complications may ultimately be higher than with simple augmentation as follow-up increases. Certainly, serum changes of increased chloride, decreased bicarbonate, and acidosis have been noted in some patients after continent diversion (Allen et al, 1985; Ashken, 1987; Thuroff et al, 1987; Boyd et al, 1989; McDougal, 1992a). Spontaneous perforation has occurred in up to 1.5% of patients (Mansson et al, 1997).

The most common complication in pediatric continent diversion thus far has been stomal stenosis. Such stenosis occurs more commonly at the umbilicus and when appendix is used compared with tapered ileal segments (Fichtner et al, 1997; Kaefer et al, 1999a). Various skin flaps may be placed into the terminal end of the appendix or intestinal segment to lower the rate of stenosis but do not eliminate it (Kajbafzadeh et al, 1995). Bladder calculi have also been common problems (Surer et al, 2003).

Key Points: Continent Urinary Diversion

- "Pure" continent diversions in children have been used with good results similar to those expected in adults.
- Variants of ureterosigmoidostomy may lower morbidity; however, they are rarely used in pediatric patients, and concerns about tumor development remain.
- Flap valves provide a reliable continence mechanism with appendix or reconfigured intestinal channels.
- The efferent limb should be kept short and straight to facilitate catheterization.
- Stomal stenosis is the most common complication of pediatric continent diversion.
- The appendix may be best used for antegrade continence enemas in some pediatric patients.

ANTEGRADE CONTINENCE ENEMAS

Fecal incontinence may be more socially debilitating to patients than urinary incontinence. In a sense, it has been easier to work surgically on urinary incontinence because urologists and their patients have intermittent catheterization to reliably empty. Unfortunately, that has not been the case with constipation and fecal incontinence, particularly among patients with neurogenic dysfunction. **Malone and colleagues** (1990) **have described use of the appendix for antegrade continence enemas (i.e., the MACE procedure) to control constipation and achieve fecal continence in patients with complex gastrointestinal disorders refractory to conservative management.** These enemas, usually performed once a day, provide a thorough cleansing in a short time. Patients, particularly those with neurogenic dysfunction, often will not stool again until their next enema (Curry et al, 1999). Cecostomy tubes, cecostomy buttons, and tapered intestinal segments tunneled into the cecum have been used for the enemas when the appendix is not suitable or is unavailable (Stanton et al, 2002; Kim et al, 2006a; Yagmurlu et al, 2006; Biyani et al, 2007b; Lorenzo et al, 2007b; Heshmat et al, 2008). Antegrade continence enemas as originally described by Malone have been used extensively in the neurogenic population (Koyle et al, 1995; Curry et al, 1999; Kim et al, 2006a; Vande Velde et al, 2007; Bani-Hani et al, 2008b; Sinha et al, 2008b). Enemas can be performed using saline, but tap water has been found to be equally suitable (Hyde et al, 2008). Metabolic derangements are unusual, although water treated in a softener should be avoided because it can cause hypernatremia (Yerkes et al, 2000).

Average irrigating volumes in most series have approached 650 mL but occasionally reach 1000 mL. The transit time for the enema after insertion varies among patients but averages 25 minutes and ranges from 15 minutes to an hour (Hyde et al, 2000; Hinds et al, 2004; Bani-Hani et al, 2008b). Smaller volumes and less transit time may be required for left colon antegrade enemas (Churchill et al, 2003). Additives to the irrigant may decrease the transit time in some patients (Kajbafzadeh and Chubak, 2000; Bani-Hani et al, 2008b). The enemas are begun daily as soon as bowel function returns after reconstructive surgery. The initial volume used is low and typically increased every 2 or 3 days until adequate decompression is achieved. Fecal continence until the next enema has been consistent for most patients with neurogenic dysfunction and ranges from 67% to above 90% (Hensle et al, 1998; Herndon et al, 2004b; Kim et al, 2006a; Vande Velde et al, 2007; Bani-Hani et al, 2008b; Sinha et al, 2008b). Hensle and colleagues (1998) noted occasional soilage requiring a pad in one fourth of their patients performing the enemas routinely. The majority of patients can perform the enemas independently. Almost universally, the patients and families have continued to perform the enemas on a regular basis in these series, which is good evidence that they find the results to be worth any time and effort involved (Yerkes et al, 2003; Herndon et al, 2004b). Rare patients may have severe colonic spasms with flushing that preclude use (Bau et al, 2000). They occasionally respond better to multiple flushings with smaller volumes. The most common complication, as with use of the appendix as a catheterizable stoma elsewhere, has been stomal stenosis, although stenosis may not occur as commonly as when the appendix is moved to the bladder (Kaefer et al, 2000). Some children require catheterization of the appendix twice a day to avoid contracture or a cicatrix at the skin level. Mickelson and associates (2009) have described the use of an L stent with or without steroid cream placed nightly to maintain patency. Fecal and irrigant incontinence can occur and is socially unacceptable. Reassessment of irrigating technique is important along with radiographic confirmation of irrigant transit through the colon. Endoscopic injection of a bulking agent at the junction of the catheterizable channel and the cecum can be tried (Koivusalo et al, 2006). Formal open revision and reinforcement of the catheterizable channel may be required. Perforation of the appendix has been noted with catheterization, as has false passage parallel to the appendix. Subsequent intraperitoneal injection of the enema fluid has resulted in peritonitis. Such patients require antibiotics and close observation. They do not routinely require reoperation (Brock, 2000). Kokoska and associates (2004) reported two cases of cecal volvulus among 164 patients using these enemas.

The appendix can be used easily in situ (Fig. 129–22). In review of a large experience, Bani-Hani and colleagues (2008a) have noted fewer complications after in-situ use of the appendix than with other techniques. Windows in the mesoappendix may be made and permanent Lembert sutures used to approximate the cecal wall in each window. This effectively wraps the cecum around the base of the appendix to prevent spillage. Alternatively, one taenia leading to the appendix may be incised longitudinally and reapproximated in the windows of the

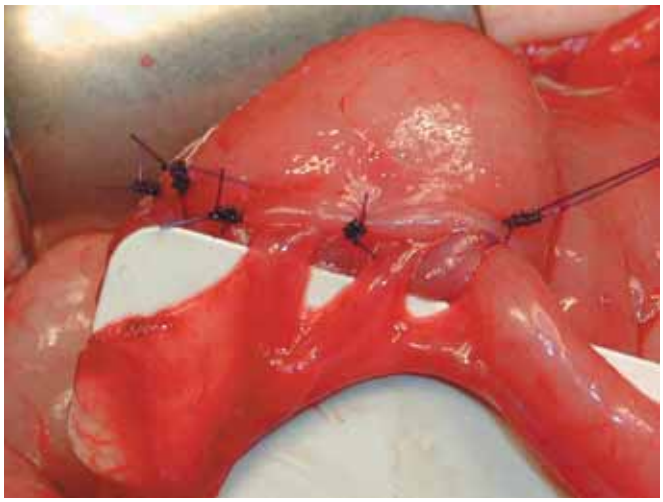

Figure 129–22. The appendix used in situ for antegrade continence enema or urinary continent catheterizable stoma. The appendix and its mesentery are mobilized without detachment from the cecum. Windows are carefully made in the mesentery between vessels to the proximal appendix. The taeniae from either side of the cecum are approximated in those windows with permanent sutures to ensure continence of the stoma. The distal end of the appendix is brought to the abdominal wall for catheterization.

mesoappendix. Others have made no attempt to construct a continence mechanism at the appendicocecal junction, particularly surgeons performing antegrade continence enemas laparoscopically (Cadeddu and Docimo, 1999; Casale et al, 2004; Nanigian et al, 2008). A left colonic catheterizable channel has been advocated especially when the appendix is not available. The results are similar to an appendicocecostomy, with continence reported to be 74% to 94% and stomal stenosis at a rate of 26% (Kim et al, 2006b; Sinha et al, 2008a). Most MACE procedures are performed by urologists at the time of a major reconstructive procedure involving the bladder (Casale et al, 2006). Their long experience with construction of continent catheterizable stomas for the urinary bladder has taught them the principles to achieve a good result, but about 15% of patients will require some revisional surgery (Bani-Hani et al, 2008a). The authors' preference is to provide some continence mechanism at the base of the appendix in this setting to avoid any spillage (Donohoe et al, 2004).

URINARY REFUNCTIONALIZATION

The clinical need for urinary refunctionalization has changed dramatically during the past several decades. Before the acceptance of CIC (Lapides et al, 1976), many children were not candidates for complex reconstructive procedures because of an inability to empty afterward. Many were initially treated with permanent urinary diversions with use of an intestinal segment with high expectations. Over time, it became clear that such diversions had significant complications, including infection, stones, and nephropathy (Smith, 1972; Richie et al, 1974; Shapiro et al, 1975; Middleton and Hendren, 1976; Pitts and Muecke, 1979). With the recognition of those complications and the routine use of CIC, urinary refunctionalization became a relatively common procedure for the reconstructive surgeon (Hendren, 1974, 1987, 1990; Perlmutter, 1980). Fewer patients now require diversion. Better anesthetic and perioperative surgical care has allowed safe definitive repair of primary problems in younger infants. The occasional diversion presently done in extreme cases is usually temporary rather than a permanent one using bowel. Consequently, urinary refunctionalization now is infrequent and typically involves closure of some urinary stoma rather than takedown of an intestinal segment.

Permanent diversions in children are now typically confined to cancer patients. When their outcome is good, they may then be candidates for urinary refunctionalization and conversion to continent urinary diversion. The Boston group has favored initial temporary diversion with a transverse colon conduit to avoid irradiated bowel when cystectomy is required. Once cure is ensured, the conduit can be converted to a continent reservoir by augmenting the colonic segment with stomach to provide an adequate reservoir and by providing a continent catheterizable efferent limb (Duel et al, 1996).

The key to urinary refunctionalization is understanding the original pathologic process that led to diversion. This may be relatively easy if the surgeon involved has cared for the patient throughout his or her course. If the original diversion was done by someone else years previously, such understanding may be difficult and require thorough investigation. Accurate understanding of the underlying disease may be made more difficult because of defunctionalization of the remaining urinary tract. It is important to review the patient's original history and studies to understand the pathophysiologic changes before any intervention. For example, failure of the urinary bladder in a patient with neurogenic dysfunction to respond adequately to anticholinergic medication and intermittent catheterization before vesicostomy diversion might well predict that it will not do so after vesicostomy closure. Special nuances in the current evaluation may also be necessary. Urodynamic evaluation of a bladder diverted for several years with a vesicostomy will virtually always show a small capacity. A repeated study after several days of bladder cycling or occlusion of the vesicostomy may be more predictive of bladder function. The bladder may respond to bladder cycling quickly (Bauer et al, 1986; McGuire, 1996). Temporary occlusion of a vesicostomy with a gastrostomy button may be informative (de Badiola et al, 1995). Occlusion of the vesicostomy during urodynamics may be necessary to achieve good bladder filling and to accurately define the adequacy of outflow resistance. Such parameters must be evaluated before urinary refunctionalization and may have changed since the time of diversion, particularly in patients with neurogenic dysfunction. Antegrade perfusion studies may be helpful and necessary in evaluation of the upper tract previously diverted by ureterostomy or pyelostomy.

Correction of Original and New Pathologic Processes. It is essential that all pathophysiologic change is appreciated, whether it is original or new. Failure to do so can result in recurrent clinical problems for the patient (i.e., renal insufficiency, hydronephrosis, infection, and incontinence) in the presence of a technically perfect operation. Once the reconstructive surgeon understands those problems the reconstructive options available for urinary refunctionalization should be assessed on an individual basis. Considerations include the length, dilation, and scarring of the ureters; the volume, compliance, and fibrosis of the native bladder; and the function of the outlet in terms of resistance for continence and synergistic relaxation for emptying. More global problems, such as renal insufficiency and neurogenic dysfunction, may influence the choices of technique as well. In patients with an existing permanent diversion involving an intestinal segment, the quality,

length, and volume of that segment should be considered to determine how it might best be used in reconstruction. An existing ileal conduit might be used as an ileal ureter, as a segment for bladder augmentation, or for tapering as a continent stoma, depending on the needs of the patient.

For examples that illustrate the potentially complex nature of many urinary refunctionalization cases, the reader is referred to Dr. Hendren's chapter on undiversion in prior editions of this text (Hendren, 1998). No one has more experience, and his cases demonstrate the total command of all surgical alternatives that is required to manage these patients well. The illustrated cases there are typical of the types of patients that historically underwent undiversion.

Results. Hendren (1998) reported a 26-year experience with urinary refunctionalization in 216 patients. Two thirds of the patients had permanent diversions, often of long duration. He noted that many of the patients had impaired renal function, either from their underlying problems or as morbidity related to the diversion. More than 10% of the patients had already required renal transplantation after undiversion, and even more were progressing toward it. With successful relief of obstruction, prevention of reflux, and provision of a compliant bladder, Hendren noted that urinary refunctionalization prolonged the time to renal failure in some patients and may have avoided it entirely in others. Urinary refunctionalization may protect renal function rather than contribute to any decline if it is properly selected and performed.

In Hendren's series, management of the bladder was relatively straightforward and effective with bladder augmentation as necessary. Inadequate outflow resistance was usually treated with Young-Dees-Leadbetter bladder neck repair. Most complications were related to the ureters: 23 patients required reoperation for persistent reflux; 10 did so for partial obstruction of the ureter. Those reoperation rates are indicative of the difficulty one faces in dealing with short, dilated, and scarred ureters that may be present after urinary diversion (Hendren, 1998). Others have had similar good success (Gonzalez et al, 1986; Mitchell and Rink, 1987) with urinary refunctionalization.

The success of many of the techniques necessary for urinary refunctionalization should be similar to the success of those done in primary reconstruction. In other words, the good results of ileocystoplasty or appendicovesicostomy should be equivalent whether they are done as part of a urinary refunctionalization or not. As noted in Hendren's cases and series, many problems may be present and multiple techniques might be required for a given patient. **The key to achieving a good result in urinary refunctionalization is to understand all of the patient's problems and to correct each. The most difficult measure of complex urinary refunctionalization, and the one most prone to complication, relates to the short, dilated, and chronically scarred ureter that may be the residual of the original problem or secondary to prior surgery including diversion.**

In occasional cases of urinary undiversion, conversion to a continent urinary reservoir is appropriate. This is true of cases in which the native bladder is congenitally absent, removed, or heavily irradiated. In those rare cases, the volume and quality of the patient's native tissue may be so poor that inclusion in the reconstruction is not warranted. **In the majority of cases of urinary refunctionalization, reconstruction of the native urinary tract is preferable to continent diversion.** Such reconstruction can minimize morbidity to the patient by utilizing more tissue line by urothelium.

Key Points: Urinary Refunctionalization

- Most urinary refunctionalization procedures now involve takedown of a urinary stoma rather than an intestinal diversion.
- It is key to understand the patient's underlying pathophysiologic process as well as any problems related to diversion.
- Chronically scarred and shortened ureters may be a challenge in these patients.

SUMMARY

Every effort should be made to treat pediatric bladder dysfunction, no matter what the etiology, early and aggressively to minimize the number of patients requiring reconstructive surgery for bladder and sphincter dysfunction. Some such surgery will still be necessary, and the patients must be carefully evaluated so that all problems are identified and addressed. The surgeon should then be flexible and prepared to use the bowel segments and techniques that best fit each patient. **Whereas a given surgeon's result with any technique may improve with experience and confidence, each patient's unique problems and anatomy may make some choices better than others. Forcing one procedure to fit every patient should be avoided.**

Preoperative evaluation should identify upper tract obstruction or vesicoureteral reflux. Such problems should be corrected at the time of surgery, although low-grade secondary reflux will usually resolve spontaneously with correction of bladder dysfunction. It is imperative to provide the patient with an adequate bladder or reservoir, one capable of holding at low pressure a urinary volume that will be produced between voidings or catheterizations. This can be accomplished by either augmentation or construction of a continent reservoir with use of any gastrointestinal segment. Each has its own set of advantages and disadvantages that should be considered. If adequate outflow resistance is lacking, it should be created at the bladder neck to prevent incontinence. Any patient undergoing reconstructive surgery for bladder or sphincter dysfunction must be prepared to perform and be capable of performing intermittent catheterization on a reliable basis; most will require it routinely. This is particularly true of those patients with neurogenic dysfunction.

As much of the patient's native urinary tract as possible should be preserved in pediatric urologic reconstruction. The urothelial lining avoids much of the morbidity associated with intestinal segments. If necessary, however, virtually any portion of the lower urinary tract may be reconstructed or replaced with intestine. Unfortunately, occasional complications do occur when intestinal segments are used in that manner. They are not perfect physiologic substitutes. Patients after reconstruction require a lifetime of follow-up, and that observation should include careful evaluation of their true quality of life. The most important factor in avoiding problems with such complex pediatric patients is the motivation of the patient and family to achieve a successful outcome. Assessment of that commitment is critical.

Associated Anomalies
Preoperative Evaluation and Management
General Aspects of Surgical Repair
Historic Background
Hypospadias Surgery
Assessing Surgical Outcomes
Urethroplasty Complications
Reoperations
Limitations of Hypospadias Literature

Hypospadias is believed to result from arrested penile development, leaving a proximal urethral meatus. It has challenged generations of reconstructive surgeons trying to extend the urethra while straightening associated penile curvature and managing ventral skin deficiency, with the goal of restoring as normal function and appearance as is possible. The current understanding of the etiology of hypospadias and current methods for its surgical correction are discussed in this chapter.

An emphasis is given to those procedures most commonly used today, and this selection inevitably omits some techniques that a minority of surgeons prefers. For example, meatoplasty and glansplasty (MAGPI) and Mathieu flip-flap are not discussed in detail, but technical aspects of these procedures have not significantly changed since their description in prior editions of this textbook.

Objective outcomes data are provided for described techniques to the extent available, usually summarized in the tables. Total complications may exceed the number of patients with complications due to multiple problems in some patients. Numbers appear only in columns designating outcomes specifically mentioned by authors.

EMBRYOLOGY OF PENILE DEVELOPMENT

The external genital anlage is initially indifferent and develops the female phenotype unless exposed to androgens during the critical gestational time period of 8 to 12 weeks. 5α-Reductase type 2 is highly expressed in mesenchymal stroma while the androgen receptor is concentrated in epithelium of the urethral plate (Kim et al, 2002). Dihydrotestosterone derived from 5α-reduced testosterone mediates the key steps in penis formation: elongation of the genital tubercle and fusion of urethral folds.

The urethral plate develops as an extension of endoderm from the cloaca along the ventral midline of the genital tubercle. Proliferating mesenchyme to either side creates urethral folds and establishes the urethral groove. Fusion of the urethral folds begins proximally and continues distally at least to the glans. Two theories are proposed for glanular urethra development: ectodermal ingrowth cannulating the glans to the urethral plate (Glenister, 1954) versus urethral plate tubularization to the tip of the glans (Kurzrock et al, 1999).

Embryo studies suggest the penis initially exhibits ventral curvature (VC) during formation, which can persist in hypospadias when normal development arrests (Kaplan and Lamm, 1975). This VC originally was ascribed to fibrous tissue bands. However, histology from both embryos and resected surgical specimens demonstrate well-vascularized tissues without fibrosis (Baskin et al, 1998; Snodgrass et al, 2000).

Preputial development begins with a cellular lamella oriented dorsally at the coronal sulcus, with ventral fusion into the frenulum delayed until after urethral formation is completed.

Neither the molecular mechanisms involved in normal penis development nor those disturbances resulting in hypospadias are currently known. In mice, Sonic hedgehog (Shh) expressed by distal urethral plate epithelium is needed for genital tubercle outgrowth, with targeted deletion resulting in penile and clitoral agenesis (Haraguchi et al, 2001). Shh regulates fibroblastic growth factor-8 (fgf8), also known as androgen-induced growth factor, which upregulates expression of fgf10 involved in glans morphogenesis. Fgf10 also is expressed in midline mesenchyme during urethral fold fusion (Haraguchi et al, 2000), and deficient mutant mice exhibit a hypospadias-like phenotype that Yucel and associates (2004) believe indicates its crucial role in distal urethral plate tubularization. Fgf receptor 2 (Fgfr2) similarly is expressed in the urethral plate and prepuce in mice, and mice lacking it manifest proximal hypospadias (Petiot et al, 2005). Androgen receptor antagonists result in loss of Fgf10 and Fgfr2 expression in the urethra and hypospadias phenotype, indicating these genes are downstream targets involved in urethral formation (Petiot et al, 2005). The B-subclass of cell-surface Ehp and ephrin molecules also plays an important role in murine urethral formation, with heterozygous mutant males demonstrating perineal hypospadias (Yucel et al, 2007).

However, extrapolation of these findings in mice to human development is currently uncertain. Although Baskin and coworkers (2004) state the murine urethra tubularizes proximally to distally by urethral fold fusion similar to humans, others describe canalization of the urethral plate without fusion of urethral folds in rats and mice (Uda et al, 2004).

ETIOLOGY

The underlying cause for nonsyndromic hypospadias in most individual cases is unknown. Based on knowledge of normal penis formation and the presumption that hypospadias represents arrested development, several causes may exist.

Genetic Factors

Familial aggregation is found in 4% to 10% of hypospadias cases, including first-, second-, and third-degree relatives (Calzolari et al, 1986; Harris and Beaty, 1993; Fredell et al, 2002; Schnack et al, 2008). A recent national registration-based study from Denmark (Schnack et al, 2008) included 1.2 million males with 5380 hypospadias cases, reporting hypospadias equally transmitted through maternal and paternal sides of the family, with recurrence risk ratios similar for twin brothers, brothers, and sons. Difficulties in establishing recurrence risks include heterogeneity in the severity of hypospadias in probands, reliance on family histories introducing recall bias, and inclusion of patients with unrecognized syndromal hypospadias (Harris and Beaty, 1993; Schnack et al, 2008). Despite these limitations, a consistent conclusion is that familial aggregation is best explained by genetic factors rather than environmental exposure (Calzolari et al, 1986; Stoll et al, 1990; Schnack et al, 2008).

Endocrinopathies

The pivotal role of androgens in normal penis development suggests endocrinopathies impacting hormone production or action may underlie hypospadias. Leydig cell dysfunction was implicated by findings of elevated basal luteinizing hormone and reduced testosterone response to human chorionic gonadotropin stimulation in prepubertal boys with hypospadias versus controls (Nonomura et al, 1984). Defects in the testosterone biosynthetic pathway, specifically, impaired 3β-hydroxysteroid dehydrogenase alone or with impaired 17,20-lyase or 17α-hydroxylase activity, were reported in proximal hypospadias (Aaronson et al, 1997) but not confirmed in subsequent studies (Feyaerts et al, 2002; Holmes et al, 2004). Although enzymatic assays for 5α-reductase type 2 activity in isolated hypospadias are normal, mutations in its coding gene *SRD5A2* on chromosome 2 were reported in 9% of patients with hypospadias not found in controls (Silver and Russell, 1999). Androgen receptor gene mutations are considered a rare cause of hypospadias (Batch et al, 1993; Hiort et al, 1994; Allera et al, 1995; Sutherland et al, 1996) but were not detected by others (Feyaerts et al, 2002).

Problems linking disturbed androgen activity to hypospadias were summarized by Holmes and associates (2004): little evidence has been found to suggest that nonsyndromic hypospadias without other genital anomalies is associated with defects in testosterone production, its conversion to dihydrotestosterone, or androgen receptor activity. Furthermore, the autosomal recessive pattern of inheritance characterizing steroidogenic enzyme disorders does not correlate with the genetics of hypospadias.

Gene Mutations

Murine studies indicating androgen receptor activity regulates *Fgf8, Fgf10,* and *Fgfr2* involved in urethral development have led to screening for defects in these candidate genes in patients with hypospadias. Among cases of nonsyndromic familial hypospadias variants have been found in *FGF8* and *FGFR2* not seen in normal controls (Beleza-Meireles et al, 2007a).

Estrogens play a role in male development, with specific nuclear estrogen receptors, predominantly ER2, found in proximity to the androgen receptor. Variants of ER2 influence serum testosterone levels and have been described in patients with hypospadias (Beleza-Meireles et al, 2007b). Further evidence implicating estrogen-related events in urethral maldevelopment was the finding that several estrogen-responsive genes are upregulated in hypospadias patients, including *ACT3, Cyr61, CTGF,* and *CADD45β* (Wang et al, 2007). Polymorphisms of *ACT3* were subsequently reported associated with hypospadias, as were less common mutations (Beleza-Meireles et al, 2008).

Endocrine Disruptors

A hypothesis that natural or synthetic compounds exerting estrogen-like and/or antiandrogen effects could result in hypospadias potentially is supported by several observations. First are reports that the incidence of hypospadias is increasing in Western nations where exposure to industrial compounds is presumed widespread. In addition, pregnant animals exposed to various chemicals in pesticides exerting estrogen-like or antiandrogen effects produce male offspring with urogenital anomalies, including hypospadias (Gray et al, 2004). Similarly, an increased risk for hypospadias has been identified in males after assisted reproduction, possibly attributable to progesterone administered to mothers. Finally, there is recognition that the estrogen receptor influences androgen activity as mentioned earlier, suggesting exposure to estrogen-like compounds may explain abnormal masculinization in the absence of demonstrated defects in testosterone production, 5α-reductase type 2 activity, or the androgen receptor.

However, although human penis development is potentially vulnerable to endocrine disruption, to date xenobiotics have not been linked to hypospadias (Baskin et al, 2001; Safe, 2005). Furthermore, the reported increase in hypospadias that suggests environmental endocrine disturbance has been challenged by recent epidemiologic studies (see later).

Syndromes with Hypospadias

Nearly 200 syndromes are associated with hypospadias (Edery, 2007).

Smith-Lemli-Opitz syndrome results from autosomal recessive mutation of the *DHCR7* gene on chromosome 11q13 coding for 7-dehydrocholesterol reductase. Affected individuals have mental retardation, facial dysmorphism, microcephaly, and syndactyly. *DHCR7* regulates Sonic hedgehog signaling, and so association of this syndrome with hypospadias potentially links to observations in mice regarding the role of Shh in penis development.

Deletion in chromosome 11q13 results in WAGR syndrome (*W*ilms tumor, *A*niridia, *G*enital anomalies, mental *R*etardation), associated with hypospadias due to altered *WT1* gene activity. One study screening for *WT1* gene defects in boys with nonsyndromic hypospadias reported no mutations (Nordenskjold et al, 1999).

Hand-foot-genital syndrome is an extremely rare autosomal dominant condition due to mutations in *HOXA13* on chromosome 7p14-15, resulting in bilateral thumb and great toe hypoplasia. Hypospadias in mice mutant for *Hoxa13* also have loss of *Fgf8* and bone morphogenetic protein-7 in the urethral plate (Beleza-Meireles et al, 2007a).

Opitz G syndrome (Opitz G/BBB syndrome) occurs from X-linked mutations in midline 1 gene or autosomal dominant deletions in chromosome 22q11. The resultant phenotype includes hypertelorism, tracheoesophageal defects, cleft lip/palate, and mild mental retardation as well as hypospadias.

Wolf-Hirschhorn syndrome derives from deletions in chromosome 4p, resulting in mental retardation, seizures, abnormal facies, and midline defects, including hypospadias.

13q deletion syndrome is characterized by mental retardation, facial dysmorphia, imperforate anus, and hypospadias with penoscrotal transposition. The critical region mediating anorectal and genital anomalies has been localized to 13q33.1-34, containing 20 annotated genes including *EFNB2* (Garcia et al, 2006). Partial loss of ephrin B-2 function altering ephrin signaling in mice is associated with hypospadias, as discussed earlier.

EPIDEMIOLOGY

Prevalence

In the 1800s both Bouisson and Rennes reported that hypospadias occurred in 1 of 300 males (Beck, 1917). Data from birth registries in the United States during the late 1960s demonstrated a similar incidence (Paulozzi et al, 1997). Subsequent studies in the 1970s and 1980s indicated an apparent doubling in hypospadias occurrence in the United States, Hungary, and England, with upward trends in Denmark, Norway, and Sweden (Paulozzi et al, 1997; Aho et al, 2000a; Toppari et al, 2001). A simultaneous increase in the ratio of severe to mild forms of the condition in the Metropolitan Atlanta Congenital Defects Program suggested the increase was due to growing incidence rather than to more frequent reporting of distal cases (Paulozzi et al, 1997). Together these data from national birth registries have been taken as evidence for the influence of environmental toxins.

However, a review of surgically treated cases versus live births in Finland from 1970 to 1986 found prevalence of hypospadias unchanged despite the apparent increase noted in the national malformation registry (Aho et al, 2000a). Further investigation suggested hypospadias was previously underreported in the Finnish national malformation registry, as well as in Swedish and Danish registries (Kallen et al, 1986). Therefore, the apparent increase in hypospadias rate in these countries may only indicate changes in reporting.

In addition, various national databases have differences in reporting requirements. For example, in Australia and Japan only cases with the urethral opening on the penile shaft, scrotum, or perineum are registered, omitting the more common coronal and glanular forms (Toppari et al, 2001). Similarly, a comparison between surgical registries and the National Congenital Anomaly System in England found significant disparity in hypospadias rates attributed to a decision in 1990 to exclude reporting of distal cases (Nelson et al, 2007). Consequently, data from such registries cannot be used to accurately determine either incidence of hypospadias or geographic variations in its occurrence.

Other Associations

Placental dysfunction in early pregnancy has been implicated in risk for offspring with hypospadias, given its role in hormone production. Significant associations have been found to low birth weight (<10th percentile), preterm birth (<37 weeks), prepregnancy maternal obesity and diabetes, and maternal hypertension (Porter et al, 2005; Nordenskjold and Frisen, 2007; Akre et al, 2008). Both decreased (<24 years) and increased (>40 years) maternal age have been reported (Porter et al, 2005; Akre et al, 2008). Males have greater risk when paired with another male, versus female, twin, but the observation that twin pregnancy is associated with hypospadias may be explained by low birth weight (Nordenskjold and Frisen, 2007).

Assisted reproduction is associated with an increased hypospadias risk, which has been attributed to hormonal manipulations during and after the procedures (Macnab and Zouves, 1991; Silver et al, 1999), as well as paternal subfertility and twin pregnancy (Wennerholm et al, 2000).

DIAGNOSIS

Hypospadias is diagnosed by physical examination, first suspected by the ventrally deficient prepuce and confirmed by the proximal meatus (Fig. 130–1). **Other**

Figure 130–1. Spectrum of hypospadias. **A,** Coronal hypospadias. **B,** Penoscrotal hypospadias. **C,** Scrotal hypospadias with scrotal transposition.

Figure 130–2. Megameatus intact prepuce hypospadias variant. **A,** Apparently normal penis with complete foreskin. **B,** Foreskin retracted, revealing coronal hypospadias.

abnormal ventral findings potentially include downward glans tilt, deviation of the median penile raphe, VC, scrotal encroachment onto the penile shaft, midline scrotal cleft, and penoscrotal transposition.

A variant subset has a normally formed foreskin concealing a glanular to distal shaft hypospadias termed *megameatus intact prepuce* (MIP) (Fig. 130–2). Diagnosis is made after elective neonatal circumcision or in later childhood when the foreskin retracts.

Patients with ventrally deficient foreskins but a normally located urethral meatus are diagnosed as having *chordee without hypospadias*. The term implies ventral penile curvature, although, in the majority, apparent downward bending is corrected by simply degloving the ventral skin. This categorization has included patients with a glanular meatus but deficient corpus spongiosum and thin distal urethra that others consider hypospadias variants. To end confusion, **boys with a hooded prepuce and bending should be diagnosed with *congenital ventral curvature* if the urethra is grossly normal or otherwise with hypospadias** (Snodgrass, 2008).

ASSOCIATED ANOMALIES

Cryptorchidism

Retrospective chart reviews (Kaefer et al, 1999; Wu et al, 2002) and a case-control study from the Danish National Patient Register (Weidner et al, 1999) report that approximately 7% of hypospadias patients also have cryptorchidism. In a series of 356 patients with hypospadias the incidence of cryptorchidism was 3.4% of 88 with distal versus 10% of 234 with proximal hypospadias (Wu et al, 2002).

Prostatic Utricle

An enlarged utricle sometimes hinders catheter placement during urethroplasty. After excluding patients with a disorder of sex development (DSD), urethrography demonstrates that enlarged utricles are uncommon in penile shaft hypospadias, with increasing incidence as severity progresses from penoscrotal to perineal cases (Devine et al, 1980; Ikoma et al, 1985).

Disorders of Sex Development

Although hypospadias is considered arrested masculinization, by convention it is distinguished from DSD. As discussed earlier, defects in testosterone production, its conversion to dihydrotestosterone, or androgen receptor activity that characterizes various disorders of sexual differentiation are uncommonly detected in isolated hypospadias.

The simultaneous occurrence of hypospadias with cryptorchidism increases the likelihood for DSD. Overall reported incidence in patients considered to have a male-appearing phenotype ranges from 0% to 30% and is greater with increasing severity of hypospadias and nonpalpable testes (Rajfer and Walsh, 1976; Kaefer et al, 1999; McAleer and Kaplan, 2001; Cox et al, 2008). Kaefer and colleagues reported DSD in approximately 50% of patients with a nonpalpable testis and hypospadias.

The most frequent finding is mixed gonadal dysgenesis, followed by ovotesticular disordered sexual differentiation. Incomplete androgen insensitivity, 5α-reductase type 2 deficiency, and testicular dysgenesis have also been reported. However, likely differences in defining male appearance versus ambiguity and failure to perform uniform genetic, biochemical, and radiologic evaluation in hypospadias patients with cryptorchidism make determination of the incidence of DSD uncertain.

Coexistence of hypospadias and cryptorchidism can be explained by other associations than DSD. For example, a case-control study examining risk factors independently for the two conditions within the same nationwide cohort in Sweden found low birth weight and prematurity positively correlated with each (Akre et al, 1999).

Malformation Syndromes

Hypospadias most often occurs in infants without additional known medical conditions. The finding of other anomalies increases the likelihood that hypospadias is part of a malformation syndrome. From the description of various syndromes just given these include developmental delay, facial dysmorphy, anorectal malformations, and other genital anomalies, including penoscrotal transposition and cryptorchidism.

Key Points: Penile Development

- Hypospadias is considered arrested penile development; the underlying etiology is unknown for most cases.
- Ventral curvature (VC) results from arrest during normal development when the penis is curved, rather than from fibrous bands previously termed *chordee*.
- Hypospadias with undescended testes may indicate a disorder of sexual differentiation, indicating need for karyotyping.
- Hypospadias with developmental delay, dysmorphic facies, and/or anorectal or scrotal malformations also suggests need for karyotyping.

PREOPERATIVE EVALUATION AND MANAGEMENT

Karyotyping

A karyotype may help categorize hypospadias as syndromic when there are other nongenital anomalies, especially developmental delay, dysmorphic facies, and/or anorectal or scrotal malformations. It may also detect gonadal DSD, especially when there is also cryptorchidism. The role for karyotyping in isolated hypospadias, even proximal cases, is unclear because most reports concern hypospadias associated with cryptorchidism (Rajfer and Walsh, 1976; Kaefer et al, 1999; McAleer and Kaplan, 2001; Cox et al, 2008) or do not state the severity of isolated hypospadias (Moreno-Garcia and Miranda, 2002).

Radiologic Studies

No prospective studies report the incidence of radiologically detected urinary tract anomalies associated with hypospadias. Initial retrospective reviews concerned intravenous pyelography, and of these the largest series found upper tract anomalies are not increased with nonsyndromic hypospadias (McArdle and Lebowitz, 1975; Lutzker et al, 1977; Cerasaro et al, 1986). Routine voiding cystourethrography to demonstrate an enlarged utricle is not necessary, because the most common clinical manifestation is difficult catheterization that can be managed intraoperatively. Imaging can be reserved for screening patients with suspected syndromic hypospadias or DSD.

Timing of Surgery

There are no data regarding optimal timing for hypospadias surgery in children, and so guidelines are derived from expert opinion. The 1996 Action Committee for the American Academy of Pediatrics Section on Urology reviewed psychological factors, anesthetic considerations, and technical aspects of hypospadias repair before recommending surgery be performed between 6 and 12 months, assuming the surgeon, anesthesiologist, and facility were experienced in the care of infants (American Academy of Pediatrics, 1996). Same-day surgery can be performed after 50 gestational weeks in otherwise healthy boys, leading the author to routinely recommend repair at 3 months of age or older for distal hypospadias and selected proximal cases with an apparently normal-sized phallus. Infants with proximal hypospadias and a small-appearing glans are reassessed at 3 months and then administered hormonal stimulation, as discussed later, before surgery at approximately 6 months of age.

Optimal timing for surgery in children presenting at an older age is uncertain. From 18 months to approximately 3 years of age has been described as a difficult period for hospitalization, leading to a recommendation that repair be postponed to age greater than 3 years (Manzoni et al, 2004). However, the American Academy of Pediatrics Action Committee observed that surgery from 30 to 65 months of age may increase the child's anxiety for physical injury. One study compared health-related quality of life assessment after hypospadias surgery done at less than 18 months of age versus more than 18 months of age and found no differences related to age at operation (Weber et al, 2008). **Preoperative sedatives, minimal separation from family, same-day surgery, anesthetic blocks that reduce early postoperative pain, dressings that fall off spontaneously, and urinary diversion into diapers all may reduce psychological stress from hypospadias repair.**

Preoperative Hormonal Stimulation

Androgenic stimulation has been advocated to increase penile size, reduce VC, and improve vascularity. Although several reports involving small numbers of patients with varied severity of hypospadias document increased penile size, glans circumference, and/or transverse length of the inner prepuce, no prospective randomized trial has determined that hormonal therapy favorably impacts objective surgical outcomes. Furthermore, no available data establish mean and standard deviations for normal glans size in children of varying ages.

One reported regimen is intramuscular testosterone enanthate 2 mg/kg given 5 and 2 weeks preoperatively (Gearhart and Jeffs, 1987; Luo et al, 2003). A comparison between a mixture of testosterone propionate and enanthate providing a dose of 2 mg/kg/wk administered twice daily topically or intramuscularly weekly found no differences in response regarding penile length or diameter. Elevated serum levels greater than 10 ng/mL only were noted after topical therapy, possibly from excessive application (Chalapathi et al, 2003).

Reported mean increases in penile length range from approximately 0.5 to nearly 3 cm, with partial to complete loss of these gains by 3 to 12 months after stimulation (Gearhart and Jeffs, 1987; Davits et al, 1993; Chalapathi et al, 2003). Side effects include pubic hair growth and aggressive behavior; accelerated linear height and bone age have not been documented (Gearhart and Jeffs, 1987; Davits et al, 1993; Chalapathi et al, 2003), but few patients have had bone age assessed after stimulation.

The author prefers two to three intramuscular injections of testosterone enanthate 2 mg/kg over a 6- to 12-week period. Hormonal stimulation has been used in less than 1% of distal repairs versus 25% of proximal to perineal cases and is recommended when the glans appears small, recognizing there are no published criteria to define normal or adequate glans diameter (Snodgrass and Yucel, 2007).

GENERAL ASPECTS OF SURGICAL REPAIR

Suture Materials

No randomized controlled trials (RCTs) compare suture materials while controlling other factors that may

Table 130–1.
Sutures and Needles for Hypospadias Repair

SUTURE SIZE AND MATERIAL	NEEDLE
7-0 polyglactin	TG 140-8
6-0 polyglactin	S 29
4-0, 5-0 polyglactin	RB
6-0 polypropylene	BV 1
6-0, 7-0 polydioxanone	BV 1
4-0, 5-0 polydioxanone	RB

influence outcomes, including severity of hypospadias, type of repair, and suturing technique. Recommendations therefore reflect the surgeon's preference. Available needles for various sutures may also influence choice and outcomes but are rarely reported in hypospadias literature. Sutures and needles preferred by the author are listed in Table 130–1.

Perioperative Antibiotics

No RCTs have been performed to determine if hypospadias surgical outcomes are influenced by preoperative intravenous antibiotics. One RCT comprising 101 patients compared intraoperative intravenous cefonicid plus postoperative oral cephalexin to intravenous cefonicid alone. There were no differences in the two groups regarding surgical complications, but both asymptomatic bacilluria (21% vs. 51%, $P < .05$) and febrile urinary tract infection (6% vs. 23%, $P < .05$) were more common without postoperative antibiotics (Meir and Livne, 2004). Postoperative antibiotics are commonly used during urinary diversion; the author prefers trimethoprim/sulfamethoxazole.

Postoperative Urinary Diversion

One RCT randomized 64 toilet-trained boys (median age 6 years, range 2 to 17) undergoing tubularized incised plate (TIP) repair by a single surgeon to postoperative bladder catheterization or not, decided at the conclusion of the procedure. There were no differences in urethroplasty complications; however, dysuria (14% vs. 45%, $P < .01$), urinary retention (0% vs. 24%, $P < .05$), and urinary extravasation (0% vs. 17%, $P < .05$) occurred significantly more often in the unstented group (El-Sherbiny, 2003).

A prospective observational study by the same surgeon involved 32 consecutive non–toilet-trained boys (mean age 18 ± 6 months) undergoing TIP repair with no urinary diversion. Urinary extravasation developed in one patient the second postoperative day resulting in catheter placement. There were no urethroplasty complications with mean follow-up of 9 months (Almodhen et al, 2008).

Another prospective study compared 36 patients undergoing Mathieu repair with catheter ($n = 17$, mean age 4.1 years) versus without diversion ($n = 19$, mean age 4.6 years) and no difference was reported in urethroplasty complications at 6 months or longer follow-up (McCormack et al, 1993).

The author prefers urinary diversion to avoid the occasional need for early postoperative catheterization due to retention or extravasation. However, should the catheter inadvertently be dislodged prematurely it is not replaced unless urinary retention or extravasation occurs. A 6-Fr bladder stent is used for all repairs in prepubertal boys regardless of age, or a 12- to 14-Fr catheter is used in patients after puberty.

Dressings

Two RCTs, one having 100 patients operated on by one surgeon (Van Savage et al, 2000) and the other comprising 120 patients and four surgeons (McLorie et al, 2001), were done to evaluate the role of postoperative bandages. In the first study patients had an adhesive film versus no dressing, whereas the second compared postoperative topical antibiotic ointment alone to an adhesive film or compressive wrap followed by topical antibiotic ointment applied after dressing removal. In both, 2% of patients were excluded from randomization owing to bleeding at the conclusion of the procedure resulting in a bandage. Parents in both studies were instructed to remove the bandage by postoperative day 2 (Van Savage et al, 2000) or when it appeared loose (McLorie et al, 2001). Neither study reported the appearance of the penis on catheter removal (e.g., extent of edema or hematoma formation). **Urethroplasty outcomes were not impacted by dressings versus no dressings.** Both studies noted greater numbers of telephone calls from parents of boys with bandages, although one did not state if these calls specifically related to the dressing.

Both these studies concluded that bandages are not needed after hypospadias repair, and when they are used they increase parental anxiety. However, in both, parental concern also might relate to instructions to remove the dressings. McLorie and colleagues (2005) specifically noted that half the parents did not remove the bandage as instructed and that 38% of boys with adhesive films and 82% with compressive wraps experienced pain with dressing removal.

The lack of benefit to compressive wrap dressings and the greater likelihood of discomfort for the child with their removal argues against their use. Otherwise, in both studies a major argument against dressings is the bother for parents in removing them. Because adhesive films nearly always fall off spontaneously, surgeons who prefer bandages might consider their use—combined with assurances that the parents need not be concerned with dressings.

HISTORIC BACKGROUND

Although it is commonly written that more than 200 repairs have been described, hypospadias urethroplasty can be summarized into three basic categories: tubularization of the urethral plate, supplementation or substitution of the urethral plate with skin flaps, or urethral plate substitution with grafts (Fig. 130–3). Of these, today the most common primary surgery is urethral plate tubularization. This is also the most recently introduced concept, given that the urethral plate—tissues extending distally from the hypospadias meatus that normally form the urethra—was only recognized as a distinct structure in the late 1980s.

Hypospadias surgery that began in the early 1800s originally focused on repair for proximal defects. VC often found in these cases was ascribed to fibrous bands, and by the 1940s the belief that these fibrous tissues represented dysplastic corpus spongiosum extending fanlike from the meatus became firmly entrenched. This "chordee tissue," now recognized as the urethral plate, was resected for straightening. Consequently, substitution urethroplasty was necessary, most often accomplished using preputial flaps. Variations of these flaps account for most of the different repairs described.

Modern hypospadias surgery dates to 1980. Duckett (1980) mobilized inner preputial flaps on a vascular pedicle away from dorsal shaft skin, providing greater flexibility to transpose them ventrally. The following year he described the meatoplasty and glanuloplasty (MAGPI) technique for glanular defects (Duckett,

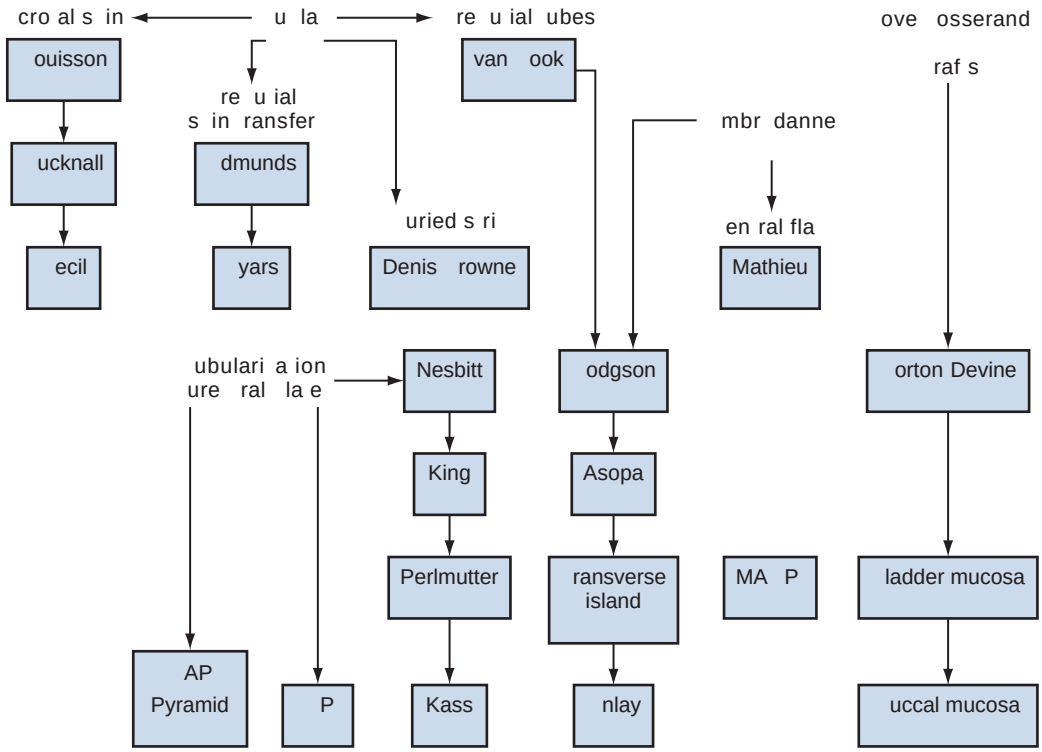

Figure 130–3. Genealogy of hypospadias urethroplasty. Duplay is considered the father of tubularized skin flaps, Ombredanne inspired ventral flaps, and Nove-Josserand pioneered grafts. The urethral plate was not recognized as a distinct structure until the late 1980s, and so procedures utilizing the plate are the most recently described. GAP, glans approximation procedure; MAGPI, meatoplasty and glansplasty; TIP, tubularized incised plate.

1981), opening the door for routine distal repair that today comprises most hypospadias surgery. It was also Duckett who defined the urethral plate and then modified his tubularized preputial flap ("transverse island") to the onlay version supplementing, rather than substituting, the plate after realizing routine "chordee" excision was not necessary (Baskin et al, 1994). By the end of the decade nearly all primary hypospadias could be repaired using MAGPI, onlay, or tubularized preputial flaps.

Although tubularization of the broad or deeply grooved urethral plate had been reported sporadically, in 1994 the midline incision was described to tubularize the narrow or flat plate without the need for supplemental skin flaps (Snodgrass, 1994). The TIP repair subsequently gained widespread use for its perceived simplicity and improved cosmetic outcomes versus flap repairs. Its application to proximal hypospadias followed increased realization that the urethral plate is not fibrous scar but well-vascularized tissues that potentially can be preserved for urethroplasty, even in some cases with VC.

HYPOSPADIAS SURGERY

Ventral Curvature

Etiology

The penis exhibits VC during normal development (Kaplan and Lamm, 1975), which implies that persistent bending in hypospadias reflects arrested development. Consequently, ventral tissues—including shaft skin, dartos, corpus spongiosum, urethral plate, and overlying tunics of the corpora cavernosa—may be shortened relative to the dorsal surface. Previous concepts that dysplastic dartos and corpus spongiosum coalesce into fibrous "chordee" tissues that require resection have been disproved by histologic studies in both embryos and surgical specimens referenced earlier (Baskin et al, 1998; Snodgrass et al, 2000).

Extent of Curvature

Prevalence and severity of VC after release of shaft skin varies by extent of hypospadias. From the author's experience since 2000, VC occurred in 50 (11%) of 440 primary distal cases undergoing artificial erection (Snodgrass et al, 2010), 12 of 40 (30%) midshaft repairs (Snodgrass and Yucel, 2007), and 57 of 70 (81%) proximal repairs (Snodgrass and Prieto, 2009). VC in all patients with distal and midshaft repairs was less than 30 degrees.

VC in consecutive proximal shaft to perineal hypospadias was less than 30 degrees in 22 patients (31%) and more than 30 degrees in 35 patients (50%). Half of these patients with proximal hypospadias either had no VC after the penis was degloved or had minor bending readily correctable with a single dorsal plication.

It is also important to consider what extent of VC impairs sexual activity. Reports concerning adult men seeking medical attention suggest bending 30 degrees or more is present before sexual dysfunction occurs (Bracka, 1989; Thiounn et al, 1998; Van Der Horst et al, 2004; Greenfield et al, 2006).

Preoperative and Intraoperative Assessment

Preoperative assessment cannot accurately predict either the extent of curvature or the means required for straightening. Apparent bending may improve or resolve as the skin is degloved, so the common maneuver of compressing penopubic and penoscrotal tissues at the base of the penis to better visualize the penile shaft may falsely suggest or exaggerate VC by traction on deficient ventral skin. The finding that skin adjacent to the meatus may retract as far as the penoscrotal junction during

degloving provides additional proof that relatively short ventral skin contributes to curvature.

Cephalad traction on the glans stay suture causes the bent (>30 degrees) penis to pivot from side to side. Such observations formed the basis for determining VC and its correction until saline corporeal injection was described by Gittes and McLaughlin in 1974. Artificial erection induced by saline injection remains the most commonly used means to assess presence and severity of VC, as well as to document successful correction. Criticisms of the technique include the potential for supraphysiologic or subphysiologic intracorporeal pressure during injection to distort findings. After ventral dissection of tissues from the tunica albuginea and/or ventral lengthening procedures for the corpora cavernosa (see later discussion), repeat erection may be difficult, owing to corporeal leakage.

Vasoactive drugs have also been injected to induce erection during hypospadias repair (Perovic et al, 1997; Kogan, 2000), with the proposed advantage being more physiologic assessment in contrast to saline injection. However, dose regimens are empirical in children, erection lasts longer than with saline irrigation unless a reversal agent is injected, and there may be increased bleeding from the prolonged erection.

It should also be noted that reported degrees of curvature, including those by this author, most likely were subjectively determined by visual estimate without direct measurement with a protractor.

Straightening Maneuvers

Curvature up to 30 degrees can be corrected by midline dorsal plication into the tunica albuginea of the corpora cavernosa directly opposite the area of greatest bending (Fig. 130–4). Baskin and colleagues (1998) reported lack of sensory nerves in this location, and straightening without corporotomy can be achieved.

There are few reports concerning sutures used, efficacy, or durability of plication, and assessment is complicated by lack of objective determination of intraoperative and postoperative extent of curvature. The only outcomes data for midline plication to date are found in a retrospective review of 43 prepubertal boys, 53% with VC greater than 30 degrees, whose curvature was straightened using one or two polypropylene 4-0 or 5-0 sutures. At median 16 months' follow-up, 93% of patients were thought to maintain a straight penis (Bar Yosef et al, 2004). In contrast, the author uses only a single 6-0 polypropylene suture for midline plication of bending less than 30 degrees, preferring alternative methods to multiple plications when curvature is greater.

Similarly, optimal management of VC greater than 30 degrees remains uncertain. Multiple plications using 5-0 to 4-0 polypropylene are described, although concerns for both recurrent curvature and loss of penile length increase when more than one plication is performed (Braga et al, 2008). This extent of bending after skin degloving and ventral dartos dissection is considered disproportion between the ventral and dorsal aspects of the corpora cavernosa (Baskin et al, 1994). Ventral lengthening traditionally involves transection of the urethral plate followed by transverse incision from the 3- to 9-o'clock position into the tunica albuginea to expose erectile tissues of the corpora in the region of greatest curvature. The resultant defect has been closed using dermal grafts, small intestine submucosa, or tunica vaginalis flaps or grafts (Fig. 130–5). No evidence indicates the outcome is significantly influenced by choice of materials for corporotomy repair. Most proponents of the use of small intestine submucosa have used single-layer material; use of four-layer small intestine submucosa was reported in two small series and was associated with recurrent curvature in one (2 of 12 cases) (Soergel et al, 2003) but not in another (0 of 21 cases) (Elmore et al, 2007).

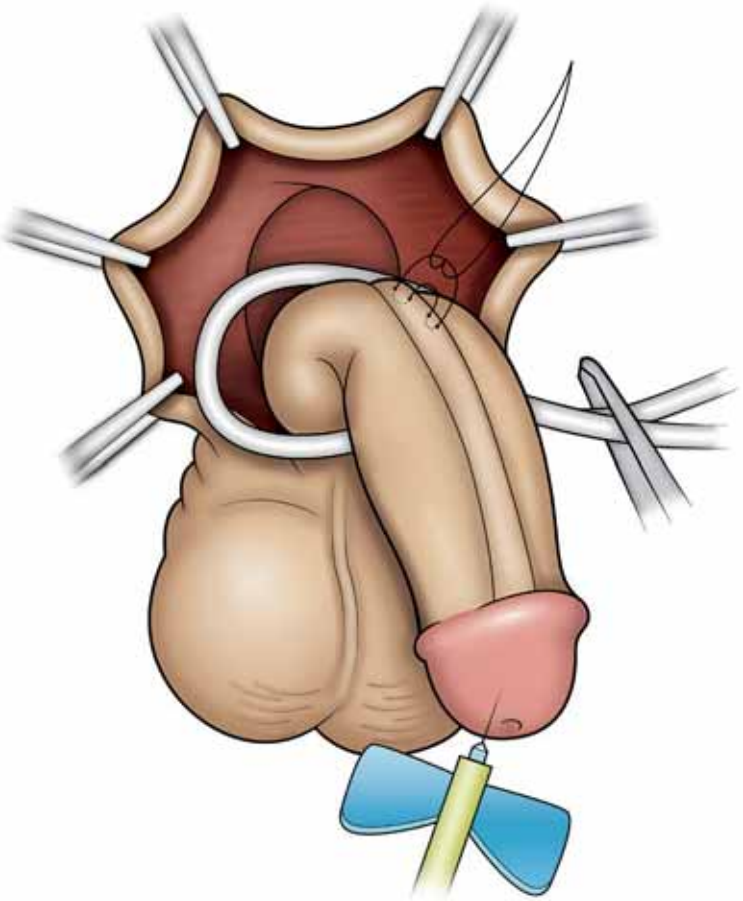

Figure 130–4. Midline dorsal plication. The surface of the corpora cavernosa is exposed in the midline opposite the region of curvature, avoiding the dorsal veins; and then polypropylene suture is placed, burying the knot.

Urethral plate transection to facilitate corporeal grafting requires substitution urethroplasty using preputial flaps or grafts in either one or two stages. Alternatively, the urethral plate and adjacent corpus spongiosum can be preserved and dissected from the underlying surface of the corpora cavernosa. Elevation of the plate alone has been reported to correct curvature (Mollard and Castagnola, 1994), or it can be combined with corporotomy and grafting (Kajbafzadeh et al, 2007). Dissection under the urethral plate can also be continued proximally to near the membranous junction, elevating the normal urethra from the corpora (Fig. 130–6). This maneuver was adapted from urethral stricture repair in which mobilization of the urethra combined with its inherent elasticity allows gaps to 5 cm in adults to be bridged (Warwick et al, 1997). After dissection of the urethral plate and urethra, residual VC can be corrected by dorsal plication or ventral corporotomy (Riccabona et al, 2003; Bhat, 2007; Snodgrass and Prieto, 2009). Rather than a single corporotomy with grafting, two to three transverse incisions can be made into the tunica albuginea without exposing erectile spongy tissue or need for grafting (see Fig. 130–5) (Devine, 1983; Snodgrass and Prieto, 2009). The preserved urethral plate can then be incorporated into TIP repair or onlay urethroplasty.

VC that persists despite mobilization of the urethral plate and urethra requires urethral plate transection for

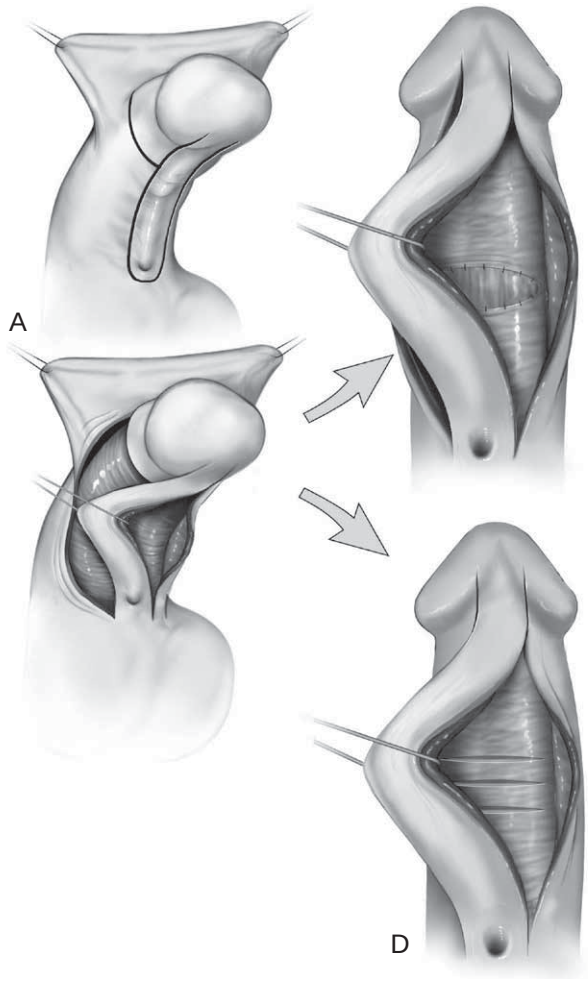

Figure 130–5. Ventral corporeal lengthening to correct ventral curvature. **A,** Ventral penile curvature showing skin incisions preserving the urethral plate. **B,** Urethral plate dissected from the corpora cavernosa. **C,** Ventral corporotomy with grafting. **D,** Multiple corporotomies without grafting.

straightening. In the author's experience 15 patients with penoscrotal to perineal hypospadias have undergone urethral plate elevation alone (3 patients) or combined with urethral mobilization (12 patients), of which 3 patients had persistent bending despite dissection to the membranous region, visibly due to tethering by a short urethral plate (Snodgrass and Prieto, 2009).

A proposed algorithm for correcting penile curvature is outlined in Figure 130–7.

Congenital Penile Curvature

Description of patients diagnosed with "chordee without hypospadias" is complicated by varying inclusion or exclusion of patients with divergent corpus spongiosum and a hypoplastic urethra. In series excluding such cases, VC is attributed most often to deficient ventral shaft skin and dartos, followed by corpora cavernosa disproportion, with a shortened urethra the least common finding (Donnohoo et al, 1998; Tang et al, 2007).

Outcomes of Straightening after Puberty

No report describes effects of pubertal growth on straightening achieved by dorsal plication. A single series comprising 16 patients, 14 with proximal hypospadias and 2 with congenital penile

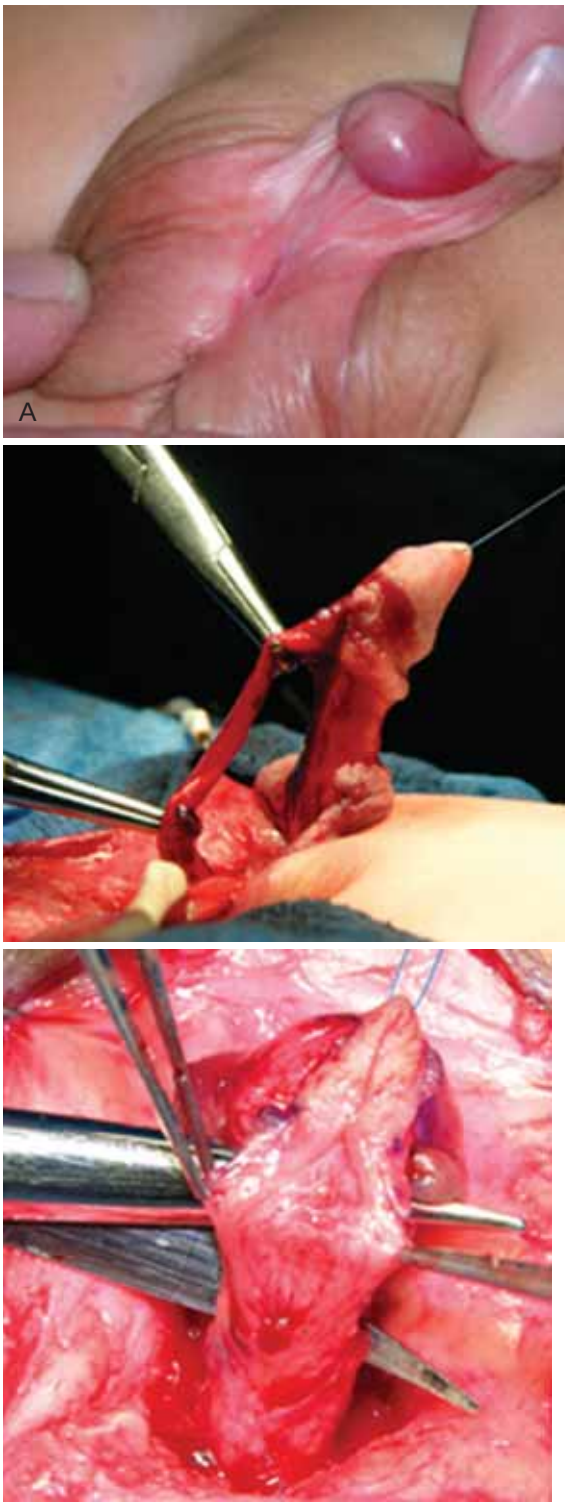

Figure 130–6. Mobilization of urethral plate and proximal urethra. **A,** Scrotal hypospadias with ventral curvature. **B,** Penis straightening included dissection of the urethral plate and proximal urethra off the corpora cavernosa. The picture shows there is no tension on the urethra after mobilization. Ventral corporeal lengthening and/or dorsal plication can also be used with this maneuver as needed to correct ventral curvature. **C,** Despite elevation of the urethral plate from the corpora, a dorsal midline incision for TIP urethroplasty can still be performed without creating separate strips. (Reprinted from Snodgrass W, Prieto J. Straightening ventral curvature while preserving the urethral plate in proximal hypospadias repair. J Urol 2009;182[Suppl. 4]:1720–5.)

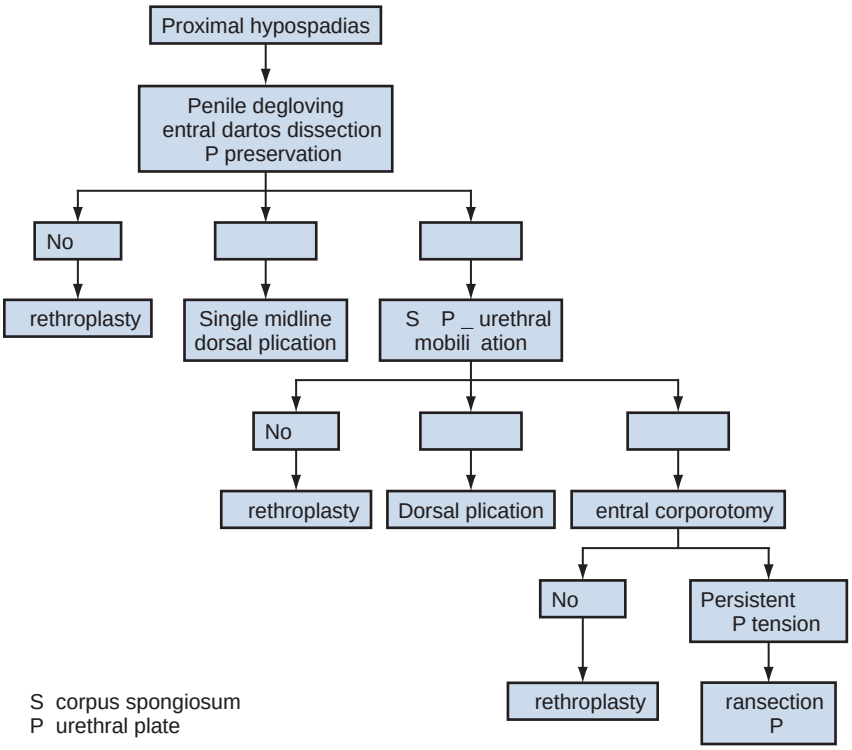

Figure 130–7. Algorithm for straightening ventral curvature (VC) with hypospadias.

curvature without hypospadias, provides information after corporotomy and dermal grafting (Badawy and Morsi, 2008). Although all patients were postpubertal at final review, only 3 were sexually active. Fifteen reported firm erection, but 1 patient undergoing repair after puberty subsequently noted impaired erection despite sildenafil, requiring intracorporeal injection for sufficient firmness. The authors reported weakness and bulging at the site of his graft.

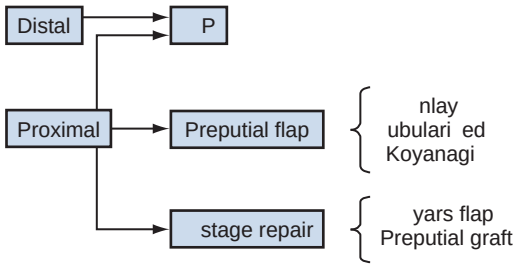

Figure 130–8. Urethroplasty options for primary hypospadias repair. TIP, tubularized incised plate.

Key Points: Ventral Curvature

- VC may resolve with ventral degloving and dartos dissection.
- VC less than or equal to 30 degrees remaining after ventral dissection can be corrected by midline dorsal plication.
- VC greater than or equal to 30 degrees after ventral dissection can be straightened by either single ventral corporeal incision with grafting or multiple ventral corporeal incisions without grafting. During these maneuvers the urethral plate and adjacent corpus spongiosum often can be maintained intact by elevating them from the corpora.
- Persistent VC after these maneuvers requires urethral plate transection.

Urethroplasty

The most commonly used options for primary hypospadias urethroplasty are summarized in Figure 130–8. It is traditional to describe repairs in separate categories for distal, midshaft, and proximal defects based on meatal position after skin degloving and correction of VC, although an alternative classification would be to consider primary repairs accomplished by tubularizing the urethral plate versus options when the plate is not maintained for urethroplasty (Sozubir and Snodgrass, 2003), most notably when VC greater than 30 degrees results in plate transection.

Distal Hypospadias

The most commonly performed operation to repair distal hypospadias is the TIP repair. Although other procedures such as MAGPI, Mathieu flip-flap, and urethral advancement remain in use, a survey of current practices indicates these together account for less than 10% of distal procedures (Cook et al, 2005). Technical aspects of these operations are little changed from prior descriptions in this textbook, with the exception of V incision into the ventral lip of flip-flaps, which attempts to create a vertical meatus (Boddy and Samuel, 2000). However, a study correlating preoperative configuration of the urethral plate (deep vs. moderate or shallow groove) to cosmetic results after V incision into onlay preputial flaps questions the reliability of this maneuver to achieve a vertical neomeatus unless the plate already is deeply grooved (Hayashi et al, 2007).

Figure 130–9 depicts TIP repair. The key step is midline incision of the urethral plate, which widens a narrow plate and

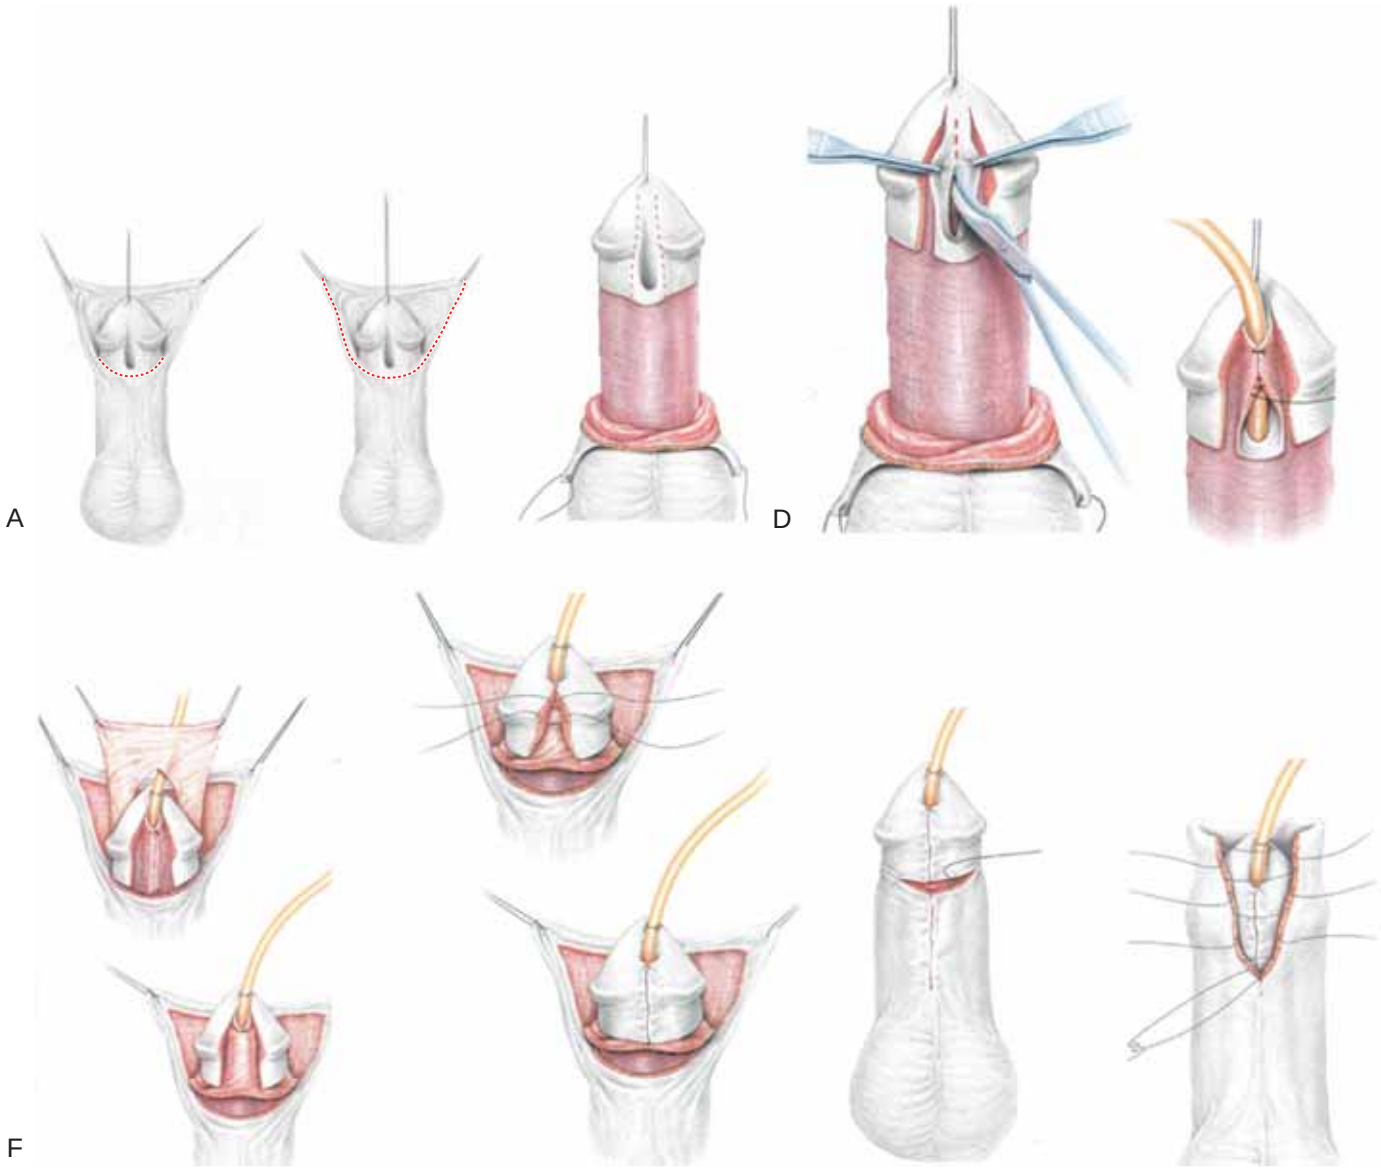

Figure 130–9. Distal tubularized incised plate repair. **A,** Circumscribing incision is made approximately 2 mm below meatus when circumcision is desired. **B,** Ventral V incision when foreskin reconstruction is planned. **C,** Penis degloved (or only ventral surface exposed during foreskin preservation). Visible junction of glans wings to urethral plate is marked and then infiltrated with 1:100,000 epinephrine. **D,** Midline incision of the urethral plate extends from within the meatus to the end of the plate, without entering the distal glans. Incision continues to near the corpora cavernosa. **E,** Urethral plate tubularization begins distally approximately 3 mm from the end of the plate, ensuring an oval, not rounded, meatus. Subepithelial running 7-0 polyglactin sutures proceed proximally. A knot is tied, and then suturing returns distally to complete a two-layer closure. **F,** Dartos flap is dissected from the dorsal prepuce and shaft skin, buttonholed, and transposed ventrally to cover the neourethra. A flap can usually be developed from the ventrolateral dartos in patients undergoing foreskin reconstruction **G,** Glansplasty begins distally, and a 7-0 polyglactin suture is used to create the meatus at the desired location, independent of the underlying urethral plate tubularization. A second 7-0 polyglactin suture under the first reinforces this distal approximation. Then a single layer of 6-0 polyglactin interrupted subepithelial sutures completes the glans wings closure to the corona. **H,** Shaft skin closure for circumcision after excising excess prepuce and approximating the inner preputial collar ventrally. Interrupted subepithelial 7-0 polyglactin is used. **I,** Foreskin reconstruction performed in three layers using 7-0 polyglactin sutures: inner prepuce, dartos, and outer shaft skin are separately approximated using subepithelial 7-0 polyglactin. (Reprinted from Snodgrass WT. Snodgrass technique for hypospadias repair. BJU Int 2005;95[4]:683–93.)

converts a flat into a deep plate groove (Fig. 130–10), ensuring a vertical, slit neomeatus and a normal-caliber neourethra. Tubularization should not continue beyond approximately the midpoint of the dissected glans wings, corresponding to a point some 3 mm proximal to the distal extent of the plate, to avoid iatrogenic meatal stenosis. Glansplasty approximates the glans halves distally to create a normal-appearing meatus independent of plate tubularization (Fig. 130–11), because the opening of the urethral plate is not sutured to the glans as is commonly done with flaps.

Contraindications. Whether urethral plate characteristics (flat vs. deeply grooved, narrow vs. wide) determine the appropriate use of TIP repair has been debated. Some consider a flat and/or narrow urethral plate a contraindication to TIP repair (Holland and Smith,

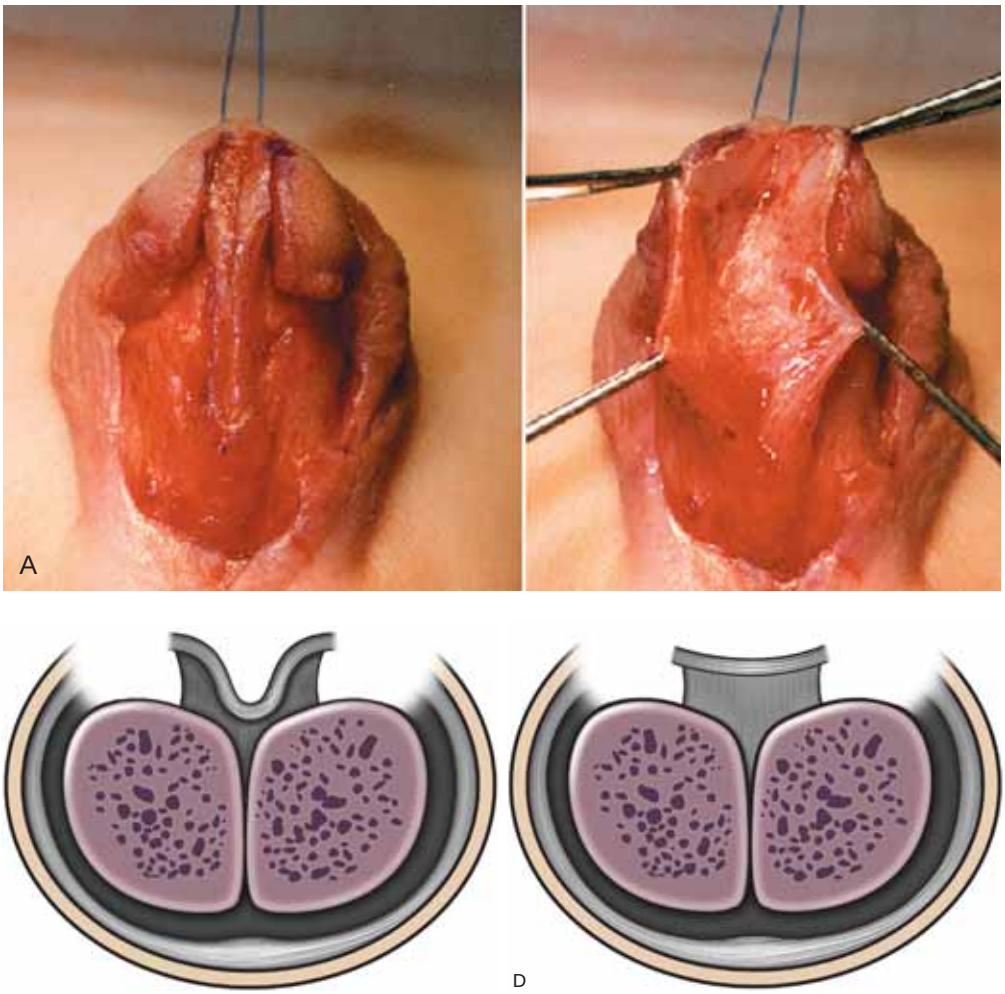

Figure 130–10. Urethral plate incision. **A,** Urethral plate before dorsal incision. **B,** Dorsal incision widens and deepens the plate. Incision depth varies according to urethral plate configuration. A deep plate (**C**) that already extends near the corpora may not need incision, whereas the flat plate **(D)** requires deep incision. (**A** and **B,** Reprinted from Snodgrass W, Koyle M, Manzoni G, et al. Tubularized incised plate hypospadias repair: results of a multicenter experience. J Urol 1996;156[2 Pt. 2]:839–41; **C** and **D** reprinted from Snodgrass WT. Tubularized incised plate hypospadias repair: indications, technique, and complications. Urology 1999;54[1]:6–11.)

2000), whereas others report TIP repair reliably corrects distal hypospadias regardless of urethral plate configuration (Nguyen and Snodgrass, 2004). The author has not found an alternative procedure necessary for distal hypospadias repair in over 500 consecutive cases (Snodgrass et al, 2010).

Outcomes. Table 130–2 summarizes published short-term results for TIP distal urethroplasty. The longest reported mean follow-up is 2 years, and to date no series describes outcomes after puberty in patients operated on when children.

One purported advantage to the TIP repair over alternative procedures for distal hypospadias is improved appearance of the meatus, creating a vertical slit neomeatus in contrast to the sometimes rounded configuration after Mathieu or other flap repairs. In addition to meatal shape, however, normal cosmesis requires sufficient glans approximation below the meatus to the corona so that the neomeatus appears correctly positioned. Two to three sutures closing the glans wings between the meatus and corona are needed and are readily placed in the TIP repair because glans closure is independent of urethral plate tubularization. In contrast, it may be difficult to mature the neomeatus created with flaps to glans wings and maintain sufficient glans to allow these additional two to three stitches proximally to the corona.

Two studies objectively assess cosmesis. One used postoperative photographs blindly scored by a panel of medical professionals that ranked TIP repair results superior to those from Mathieu and onlay flaps (Ververidis et al, 2005). A second administered Likert scale questionnaires to parents and the operating surgeon after TIP repair or circumcision. No significant differences occurred between surgeon and parents in either group or in satisfaction after TIP repair for hypospadias versus elective circumcision in boys with a normal penis (Snodgrass et al, 2008).

Midshaft Hypospadias

In a consecutive series of boys with midshaft hypospadias none had VC greater than 30 degrees, indicating the urethral plate can be maintained for urethroplasty in most cases (Snodgrass and Yucel, 2007). Accordingly, options for repair include TIP repair or onlay preputial flap. Technical aspects of TIP repair are unchanged

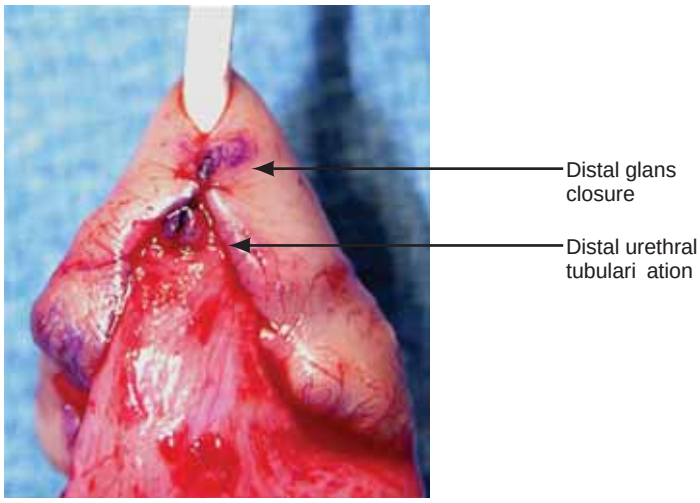

Figure 130–11. Tubularized incised plate (TIP) glansplasty. The most distal stitch approximating glans wings, creating the neomeatus, usually is beyond the most distal stitch of the tubularized urethral plate. It is not necessary to suture the glans wings to the urethral plate in TIP repair.

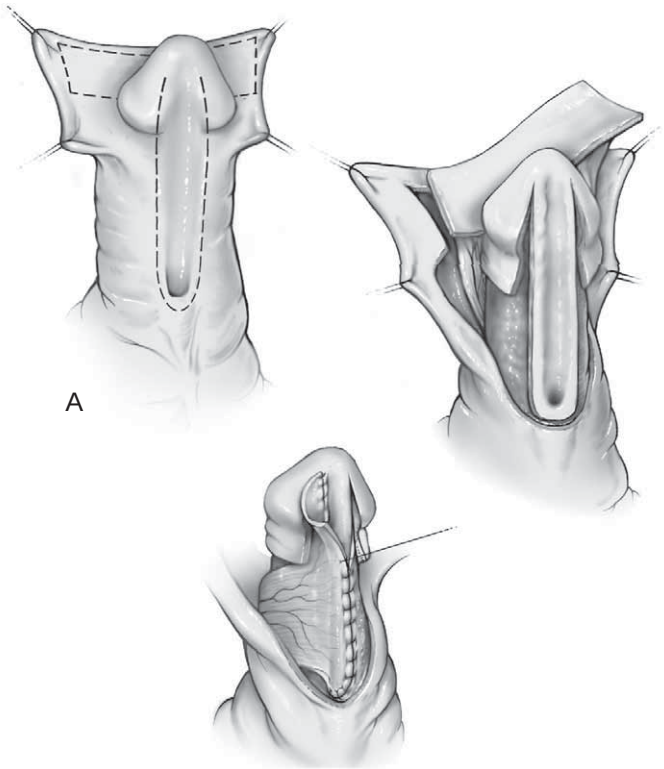

Figure 130–12. Onlay preputial flap. **A,** Lines of incision to create the preputial flap and preserve the urethral plate. **B,** Preputial flap mobilized on its vascular pedicle. **C,** Flap sewn to the urethral plate.

from distal operations described earlier, with the addition that divergent corpus spongiosum can be dissected from the underlying corpus cavernosa and released from glans wings to approximate over the shaft portion of the neourethra to near the corona (Yerkes et al, 2000).

An onlay preputial flap is depicted in Figure 130–12. Thin skin proximal to the urethral meatus is incised to the midline convergence of corpus spongiosum wings. Then inner prepuce is harvested on its vascular pedicle from either the dorsal hood or from one side of Byars flaps after the dorsal hood is incised (Sedberry-Ross et al, 2007). The flap should be gently stretched to fit the urethral plate without redundancy. Distally, flaps are secured to the glans wings to create the neomeatus. The vascular pedicle or a separate dartos flap can be used to cover the exposed suture line.

Outcomes. Reports concerning midshaft TIP repair most often combine outcomes with patients having either more distal or proximal defects. The two largest series with results specifically for midshaft hypospadias found urethroplasty complications in 13% and 16% (Snodgrass and Yucel, 2007; Al-Ghorairy et al, 2009).

Similarly, onlay preputial flap results specifically for midshaft repair are not readily obtainable. The procedure originally was described for distal to midshaft cases not amenable to MAGPI, and to enable use for distal hypospadias the meatus was incised proximally to create a defect of sufficient length to accommodate the flap. The most recent publication providing outcomes for midshaft hypospadias reported 29% urethroplasty complications in 51 patients (Sedberry-Ross et al, 2007).

Proximal Hypospadias

The greatest controversy in primary hypospadias surgery concerns decision making for proximal cases. Options depend on whether the urethral plate is available for urethroplasty after associated VC is straightened. If so, then either TIP repair or an onlay preputial flap can be used. When the urethral plate is transected a one-stage urethroplasty can be accomplished by tubularized preputial flaps or the Koyanagi flap or a two-stage repair done with Byars flaps or preputial grafts.

Tubularized Incised Plate Repair. Steps for a proximal TIP repair are illustrated in Figure 130–13. There are several important distinctions between distal and proximal TIP repairs. First, correction of VC may lead to dissection of the urethral plate, and proximal urethra, from the corpora cavernosa. Midline incision can still be performed without creating separate strips (see Fig. 130–6C). The neourethra is tubularized with interrupted subepithelial sutures reinforced by a second running layer. Divergent corpus spongiosum is next sewn over the neourethra, followed by a tunica vaginalis flap (Fig. 130–14). To reduce chances for secondary partial concealment of the penis, shaft skin at the penoscrotal junction is secured to the corpora cavernosa with subepithelial 5-0 polydioxanone to either side of the ventral midline before skin closure.

Outcomes. In a cohort of 56 boys with proximal shaft to perineal hypospadias, the author corrected 36 (64%) using the TIP procedure while the other 20 (36%) underwent staged repairs after urethral plate transection during straightening (Snodgrass and Yucel, 2007). After that report, urethral plate/proximal urethral dissection with superficial transverse corporotomies were incorporated into the algorithm for straightening, resulting in more frequent preservation of the plate. In 22 consecutive proximal shaft to perineal repairs, 19 (86%) had TIP repair versus only 3 (14%) undergoing a two-stage repair (Snodgrass and Prieto, 2009).

Urethroplasty complications occurred in 8 (53%) of the original 15 patients undergoing proximal TIP repair by the author, which were mostly fistulas in 5 (33%) despite a dartos flap over the neourethra in every case. After technical modifications described earlier (two-layer subepithelial tubularization and spongioplasty) the complication rate in the next 20 cases decreased to five complications (25%), including two (10%) fistulas. After substituting

tunica vaginalis rather than dartos for the barrier layer, in the most recent 22 cases there were no fistulas, the single complication (4.5%) being glans dehiscence.

Table 130–3 shows other published results for proximal TIP repair, excluding those in which proximal outcomes cannot be distinguished from more distal cases. Selection bias must be considered in these reports, because none except the study of Yucel and Snodgrass states the total number of proximal cases operated during the study period to determine the relative use of TIP repair versus other techniques.

Onlay Preputial Flap. Need for a longer flap usually requires the inner prepuce to be dissected from an intact dorsal hood and then

Tunica vaginalis barrier flap. **A,** The testis is delivered and the tunica vaginalis opened transversely. **B,** The tunica vaginalis flap is dissected to near the external ring to avoid tension on either the testis or the penis. **C,** Flap covers the entire neourethra. The testis is pexed into its scrotal compartment, which is then sutured closed.

rotated ventrally on its pedicle. Otherwise, steps in the procedure are as already shown in Figure 130–12.

Outcomes. Reports specifically concerning outcomes of onlay preputial flaps for proximal hypospadias are summarized in Table 130–4.

Tubularized Preputial Flap. This procedure is illustrated in Figure 130–15. After excision of the urethral plate and required straightening maneuvers, the required length of inner prepuce is harvested, tubularized, and transferred ventrally. The native urethra is secured to the corpora cavernosa and then spatulated before anastomosis to the flap to reduce incidence of stricture, and then the tube is gently stretched distally, with its suture line facing dorsally, and anchored to the corpora cavernosa with interrupted stitches. Glans wings are sewn to the flap to create the neomeatus.

Alternatively, the open flap is brought ventrally and then one side is secured to the corpora cavernosa just lateral to the midline with interrupted subepithelial sutures. The flap is gently stretched, excess tissues are excised, and then the other side is similarly anchored to the corpora to complete tubularization. This tube is tailored proximally to approximately the caliber of the native urethra before the anastomosis is made (Canning, 2007).

Outcomes. Tubularized preputial flaps (also referred to as "transverse island preputial flaps") were originally used when MAGPI was not possible before development of the onlay preputial flap. Consequently, much of the outcomes data mixes large numbers of patients with distal hypospadias without separately reporting results in proximal cases that today comprise the only use of this procedure. Table 130–4 summarizes outcomes specifically after proximal hypospadias repairs.

Koyanagi Flap. Use of the Koyanagi repair is determined from the outset of the operation based on the surgeon's impression that VC will lead to urethral plate excision, and so decision making for this procedure differs from all others described in this section.

The Koyanagi repair updates the Russell operation (Russell, 1900), primarily by maintaining blood supply to the flaps as illustrated in Figure 130–16. These flaps are brought together ventrally, sewn into a single strip, and then tubularized proximally to distally.

Outcomes. Proponents offer varied opinions for managing the dartos vascular pedicle to the lateral skin flaps. Koyanagi and colleagues (1994) split the contiguous flap into a Y at the 12-o'clock position. Others attribute complications to devascularization of the distal region and instead maintain the loop, passing the glans dorsally through a 12-o'clock buttonhole in the dartos pedicle (Hayashi et al, 2001b). Alternatively, in the largest reported series the pedicle was removed from the distal 2 cm of the flap, which was treated as a tubularized graft (Sugita et al, 2001). Results are shown in Table 130–4.

Byars Flaps. A two-stage flap repair (Fig. 130–17) divides the dorsal preputial hood, transposes the resultant flaps ventrally, and reapproximates them in the midline from the native urethral meatus to the glans tip. Glans wings should be widely separated to allow sufficient skin to be placed for later tubularization. The author previously maintained the urethral plate within the glans to combine distal TIP repair with a proximal Byars flap urethroplasty (Snodgrass et al, 1998) but discontinued that approach due to complications (see later). After a period of approximately 6 months, second-stage tubularization of the skin flaps is accomplished.

Outcomes. Table 130–5 shows outcomes data for staged skin flap repairs. The largest series did not state the number of patients with follow-up or duration of follow-up. Nearly half the patients operated on by Greenfield and coworkers (1994) had midshaft or more distal hypospadias, all of which corrected by the Belt-Fuque technique, but outcomes were included because this is a two-stage preputial flap procedure.

Cheng and colleagues (2003) transected the urethral plate proximally, preserving the distal portion, and used Byars flaps to bridge the gap to the native urethra. Diverticula formed in 2 of 14

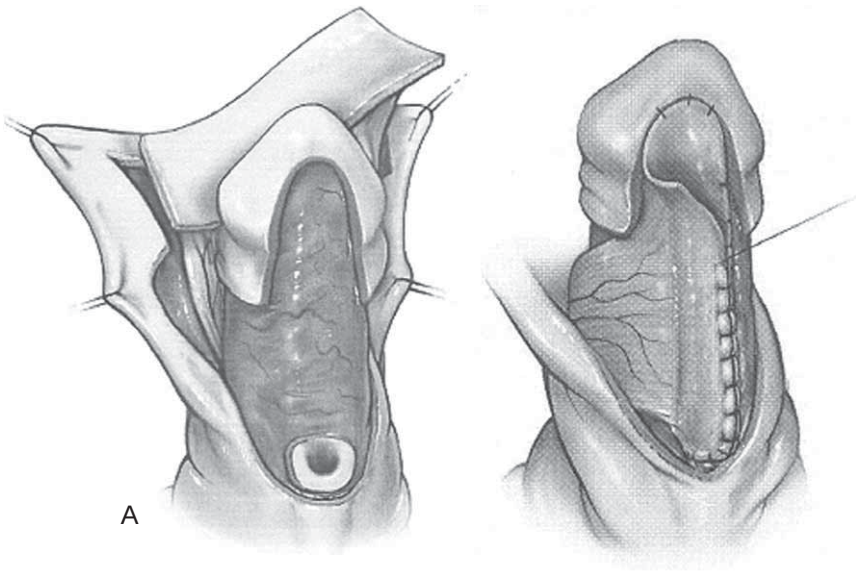

Figure 130–15. Tubularized preputial flap. **A,** After degloving and release of ventral dartos, persisting ventral curvature greater than 30 degrees led to excision of the urethral plate (see text for additional straightening maneuvers to attempt preservation of urethral plate). Inner preputial flap approximately 10 mm wide is dissected on its dartos vascular pedicle and transposed ventrally. This flap can be tubularized, with the proximal end anastomosed to the spatulated native urethra and distal end to the glans wings. **B,** Alternatively, one edge of the flap can be fixed with interrupted sutures to the corpora cavernosa from the proximal meatus distally into the glans and then the flap is trimmed and the opposite edge sutured along the first to create a tube with uniform caliber. Glansplasty and skin closure is similar to that described for onlay preputial flaps.

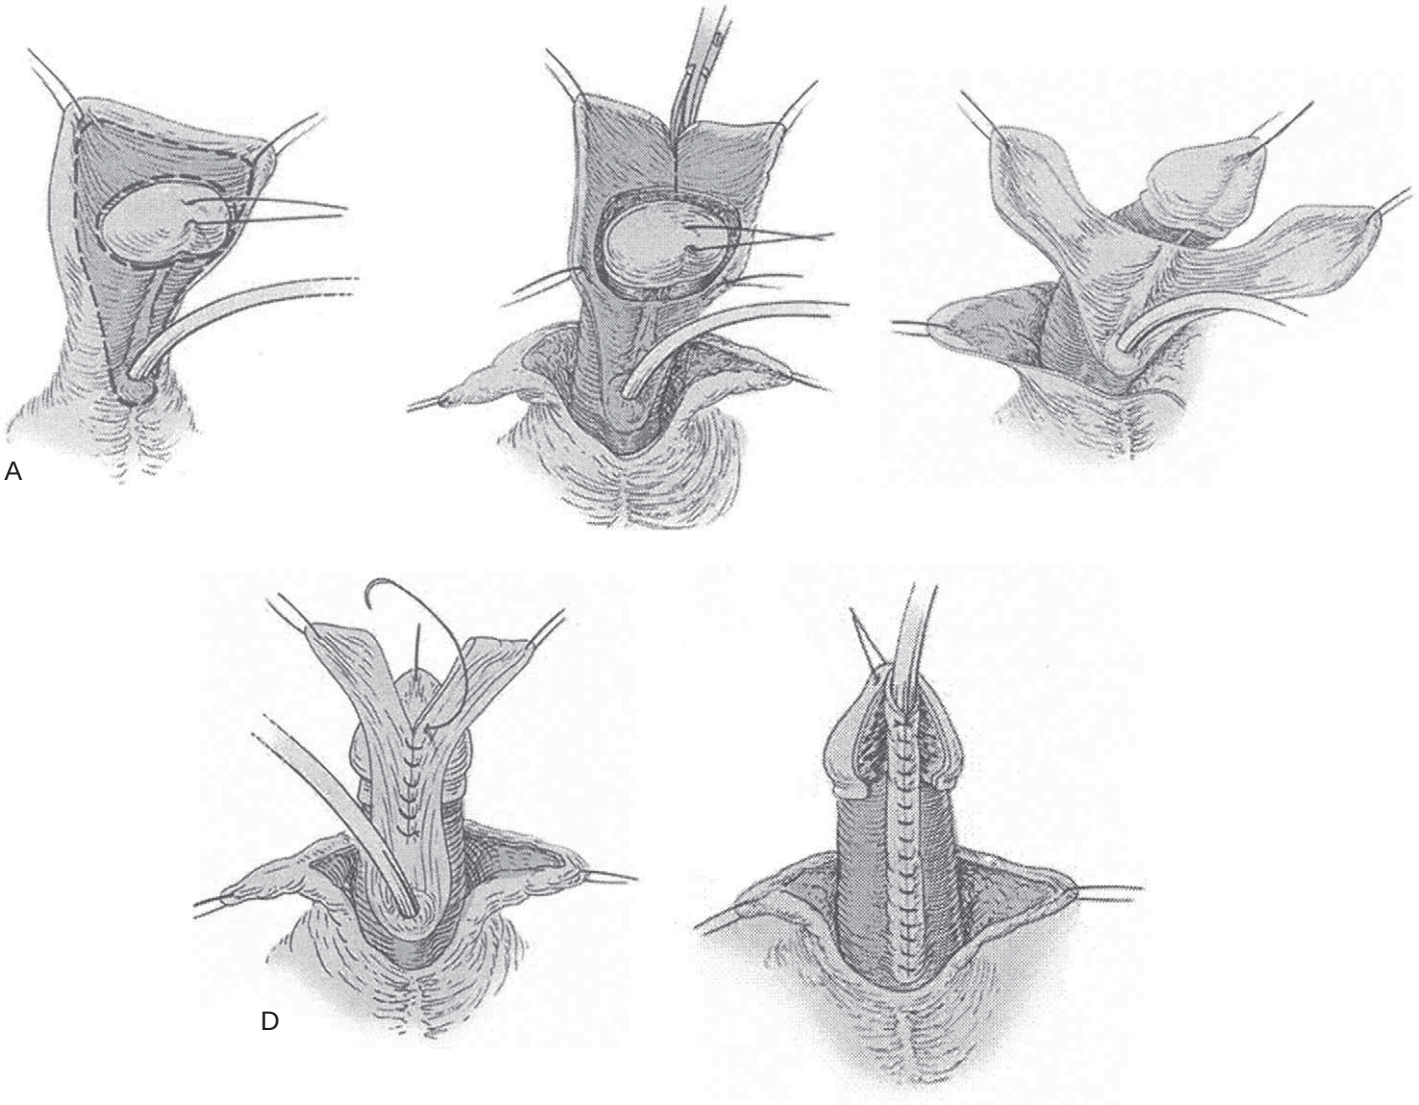

Figure 130–16. Koyanagi flap. **A,** Proposed lines of incisions to create flap. **B,** The flap can be divided into two wings as shown or maintained in one piece with a central buttonhole to transpose it ventrally. **C,** The urethral plate in the center of the flap is dissected from the corpora to near the meatus, and the glanular portion of the plate is excised as glans wings are made. **D,** Inner flap margins are reapproximated, and excess flap skin is excised. **E,** The outer margins are closed to complete tubularization using 7-0 polyglactin or polydioxanone subepithelial interrupted or running sutures. Glansplasty and skin closure are as described for other preputial flaps.

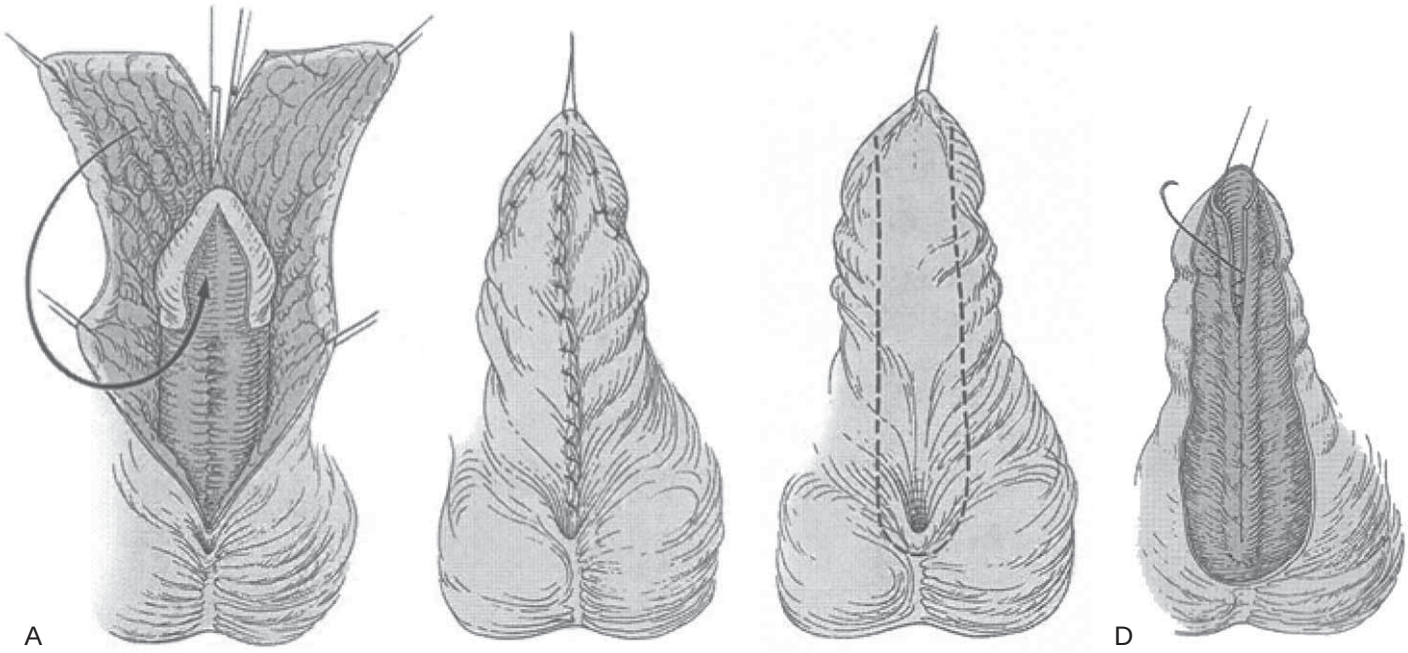

Figure 130–17. Byars flap. **A,** After degloving and release of ventral dartos, persisting ventral curvature greater than 30 degrees led to excision of the urethral plate (see text for additional straightening maneuvers to attempt preservation of urethral plate). The dorsal preputial hood is incised in the midline and the two flaps transposed ventrally on either side of the penis. The prepuce is advanced into the glans; alternatively, the urethral plate can be maintained within the glans. **B,** Flap edges are approximated in the midline. **C,** Six months later a U-shaped incision is made approximately 10 mm wide. **D,** The resultant strip is tubularized in two layers.

patients from the interposed skin flaps without distal obstruction. The authors preserved the glanular urethral plate in eight of nine Byars flap repairs. The complication rate was 100%, including five diverticula and two strictures at the flap/urethral plate junction. Of the diverticula, four had no distal obstruction except for the presumed increased resistance to flow created by the glans. Considering diverticulum formation without obstruction evidence of preputial skin distensibility, another 4 patients had buccal grafts—thought less elastic—interposed between the distally preserved urethral plate and proximal native urethra, but a diverticulum still developed in one, leading the author to abandon these techniques.

Preputial Grafts. Inner prepuce can be harvested as a graft to bridge the defect from native urethra to glans tip when the urethral plate is excised. This approach has not been commonly used in the United States because curvature leading to urethral plate transection most often has been corrected by corporeal incision and grafting, meaning subsequent addition of a urethral graft would place one graft onto another. Preputial grafts are an option when remaining VC after urethral plate excision is less than 30 degrees or if multiple superficial transverse corporotomies are used for correcting VC without corporeal grafting.

The procedure is shown in Figure 130–18. After excision of the plate the ventral native urethra is sewn to surrounding skin edges to establish a proximal meatus, and the glans wings are widely opened. Inner prepuce is harvested, and the dartos is excised from its undersurface. Then it is secured to the dorsal lip of the native urethra and gently stretched distally. Sutures anchor it to adjacent shaft skin and glans wings, with subepithelial stitches used along the glans tip to avoid tracks at the neomeatus during the second stage. Additional rows of stitches "quilt" the graft to the corpora cavernosa to facilitate neovascularization by limiting fluid collection under the graft. A tie-over dressing further immobilizes the graft during the first week of healing. Six months later this neourethral plate is tubularized and covered with tunica vaginalis.

Outcomes. Cloutier described two-stage grafting in 1962, but Bracka is credited with stimulating modern interest in this approach. His report (Bracka, 1995) mixes primary cases of all extents with reoperations, and so data specifically for primary proximal hypospadias are not available. Of the three publications summarized in Table 130–6, two similarly combine data mostly from midshaft to distal repair with results from a smaller number of proximal hypospadias. Only the report by Ferro and colleagues (2002) focused on proximal repairs using Bracka's technique. In all these, complications from grafting occurred in less than 5%, consisting of partial graft loss that did not require an additional procedure for correction before second-stage tubularization.

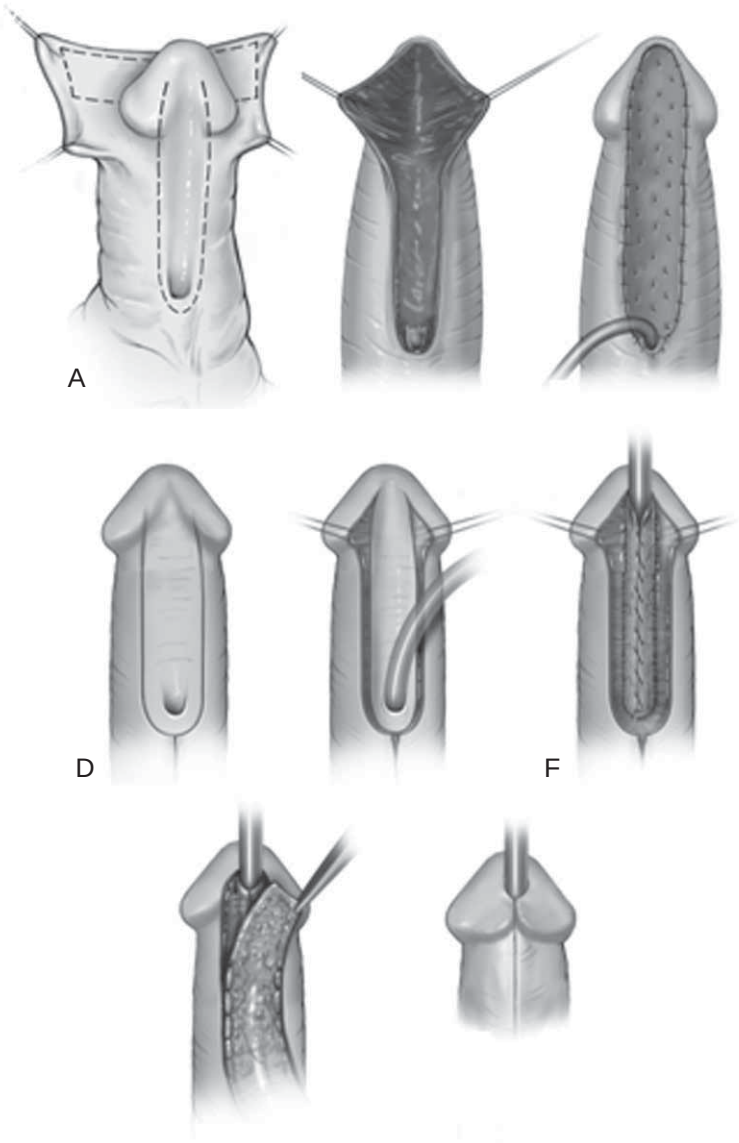

Figure 130–18. Two-stage preputial graft. **A,** Ventral curvature leads to urethral plate excision. **B,** Wide dissection of glans wings. Graft is outlined on inner prepuce. **C,** Graft is harvested from the inner prepuce and secured to the meatus proximally, along shaft skin, and into the glans using interrupted 7-0 polyglactin. Subepithelial glans sutures minimize suture marks. Additional 6-0 polyglactin quilting stitches are placed down the midline and to either side at 0.5-cm intervals to minimize space where a seroma or hematoma could collect under the graft. An RB needle facilitates anchoring the graft to the underlying corporeal surface. **D,** U-shaped incision at least 6 months after first-stage surgery. **E,** Glans wings developed. **F,** Tubularization of the neourethral plate. **G,** Tunica vaginalis flap covers the neourethra. **H,** Skin closure using subepithelial sutures.

Skin Closures

Inner Preputial Collar

The ventral preputial deficiency found in most hypospadias patients includes its inner "mucosal" surface, which normally provides coverage between the corona and shaft skin. Instead, shaft skin occupies the space from the margins of the open glans wings to the urethral plate and meatus. To create the appearance of a normal circumcised penis, this shaft skin must be removed and ventral midline closure done using inner prepuce transposed from the dorsal hood. Firlit (1987) described a chevron incision dorsally to create bilateral "darts" for ventral midline approximation (Fig. 130–19).

Although it has been suggested that divergence between the darts may preclude midline approximation, necessitating rotational flaps (Redman, 2006), the author has not encountered this situation. The proximal corners of the darts are first approximated using a 7-0 polyglactin subepithelial suture, which then provides ventral traction. Midline closure proceeds distally with interrupted subepithelial stitches. The space immediately below the glans is repaired using 9-0 polyglactin stitches placed through the epithelium. The postoperative appearance with the mucosal collar is contrasted to examples in which the collar was not formed, illustrating the importance of this step for optimal cosmetic outcomes (Fig. 130–20).

Circumcision versus Foreskin Reconstruction

The abnormal prepuce can be removed for circumcision or reconstructed ventrally if a natural, nonoperated appearance is preferred. For circumcision, a circumferential skin incision is made initially, creating lateral darts to approximate the mucosal collar ventrally, as described in the preceding section. When foreskin reconstruction is desired, the initial skin incision extends in a V from the corners of the dorsal prepuce ventrally to below the meatus, without a circumferential incision.

In patients to be circumcised, after completion of urethroplasty, glansplasty, and ventral mucosal collar the dorsal prepuce is incised in the midline proximally to the level of the mucosal collar and then stitched to it with a subepithelial 7-0 polyglactin suture. Next, the ventral median raphe is approximated from proximally to near the mucosal collar using interrupted subepithelial sutures. Excess lateral skin is excised and remaining skin edges are closed with subepithelial sutures to minimize the likelihood of suture tracks (Snodgrass, 1999a).

Foreskin repair begins with subepithelial closure of the inner surface with the dorsal foreskin retracted proximally. Then the prepuce is extended distally and the dartos approximated to reinforce closure of the inner layer. Finally, the outer skin margins are sutured together with subepithelial stitches, avoiding iatrogenic distal phimosis. The family is instructed not to retract the foreskin until the surgeon determines postoperatively that edema and tissue reaction have subsided, usually after 6 weeks.

Outcomes. Preputioplasty is an option in nearly all distal hypospadias surgeries, although occasionally the prepuce is too narrow to close ventrally. Foreskin reconstruction also can be considered for midshaft to proximal repairs, unless flap urethroplasty leaves insufficient skin. Although typically done without a circumscribing incision, when VC suggests need for dorsal plication the penis can be degloved with subsequent preputioplasty (Snodgrass et al, 2006).

Klijn and coworkers (2001) reported increased urethroplasty and skin complications with foreskin reconstruction versus circumcision during distal hypospadias repair, but these may have resulted from their reliance on skin flap (Mathieu) urethroplasty and their instructions to parents to begin foreskin retraction only 2 weeks postoperatively. In a comparison of matched cohorts undergoing distal TIP repair with foreskin reconstruction versus circumcision, Suoub and associates (2008) found no differences in urethroplasty or skin complications, which is also the experience of the author (unpublished data).

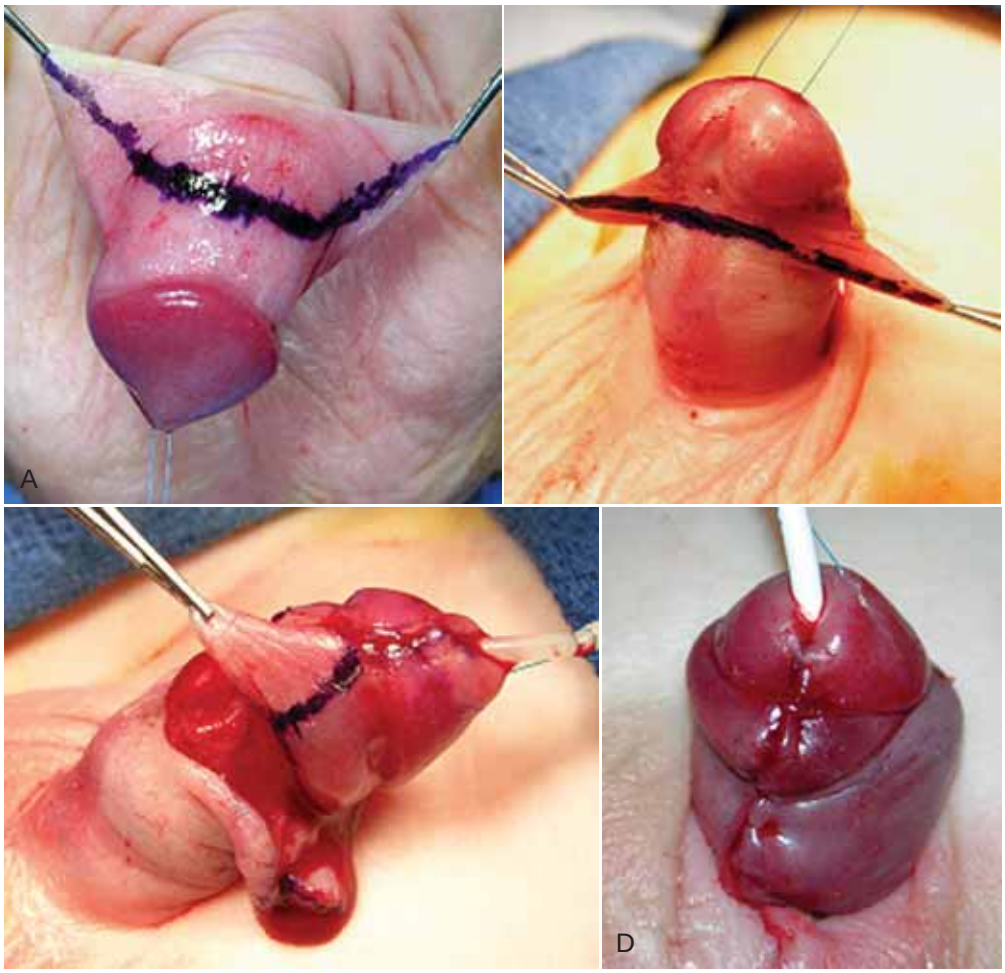

Figure 130–19. Inner preputial collar. Line for dorsal (**A**) and ventral (**B**) skin incision. **C,** Excision of perimeatal shaft skin after urethroplasty and glansplasty. **D,** Completed inner preputial collar. Interrupted subepithelial 7-0 polyglactin approximates the sides proximally, and 9-0 polyglactin is used through the epithelium at the corona, because it is unlikely to produce visible suture tracks.

Minor and Major Scrotoplasty

Scrotal encroachment onto the ventral penile shaft can occur associated with any extent of hypospadias. This sometimes creates a false impression that the meatus is penoscrotal when it is actually found located on the distal shaft after penile degloving moves the scrotum proximally. Midline scrotal cleft and varying degrees of superolateral extension of scrotum alongside the penis most often are encountered in proximal hypospadias, in some cases combined with a rugated, feminized appearance at the dorsal penopubic junction. Collectively these findings are commonly referred to as *penoscrotal transposition,* although this term also describes the rare condition in which the penis is actually located completely below the scrotum.

Encroachment onto the penile shaft is corrected by release of the scrotum as the penis is degloved, with subsequent suture fixation to the correct penoscrotal location more proximally. Scrotal clefts are excised and resultant edges sutured to create a median raphe. Minor superolateral encroachment with a rugated penopubic junction is corrected by incising the ventral junction of scrotum and penile shaft skin to approximately the 4- and 8- or 3- and 9-o'clock positions and then affixing the shaft skin to the desired penoscrotal junction (Fig. 130–21). Pronounced extensions of scrotum superolaterally to the penis are moved ventrally as rotation flaps and secured to the penoscrotal junction (Fig. 130–22).

An alternative method for correction involves completely removing shaft skin from the penis, maintaining its vascular pedicle, and then subsequently moving both above the scrotum through a "buttonhole" (Kolligian et al, 2000).

Attention to vascular pedicles allows simultaneous correction of scrotal encroachment with urethroplasty, because penile and scrotal tissues derive from distinct embryologic anlage.

Outcomes. There are few reports specifically concerning scrotoplasty outcomes. In one retrospective series, 5 of 37 patients with scrotal flap rotation developed penile tethering or secondary cryptorchidism (Pinke et al, 2001). Simultaneous Koyanagi repair with rotational scrotal flaps has been reported without apparent increased scrotoplasty or urethroplasty complications (Glassberg et al, 1998; Nonomura et al, 1988).

Key Points: TIP Repair

- Midline urethral plate incision widens and deepens the urethral plate for tubularization without skin flaps.
- Urethral plate tubularization carried too far distally can create iatrogenic meatal stenosis.
- TIP glansplasty is independent of underlying urethral plate tubularization, meaning it is not necessary to suture the glans wings to the end of the plate.

Figure 130–20. Cosmetic skin closure. Appearance with (**A**) and without (**B-D**) inner preputial collar.

ASSESSING SURGICAL OUTCOMES

The goal of hypospadias repair is to improve function and appearance as near to normal as possible. Therefore, success requires more than straightening curvature and extending the urethra to the glans. Reports from teens and adults operated on when children emphasize that cosmetic results are as important as functional outcomes (Bracka, 1989; Mureau et al, 1995; Aho et al, 2000b). Furthermore, a glanular meatus without obstruction or fistula does not ensure the patient can void with a straight and compact stream.

Initial Postoperative Follow-up

Ideal frequency and duration of follow-up after surgery are ill defined. The author prefers postoperative examinations after distal to midshaft hypospadias repair at 6 weeks and 6 months, whereas those undergoing proximal surgery are recommended to have additional annual follow-up until toilet training.

Although it is often stated that periodic assessment should continue to puberty, it is unlikely many patients operated on while infants will have adult follow-up. Accordingly, there are few data regarding outcomes in adults operated on while children. Furthermore, long-term results that are reported often concern operations no longer in common usage due to ongoing evolution in surgical techniques.

Means to assess results and detect complications beyond simple visual inspection of the penis also are not standardized. Furthermore, the time at which various complications usually appear are poorly reported, which makes minimum duration of follow-up to detect the majority of problems unclear.

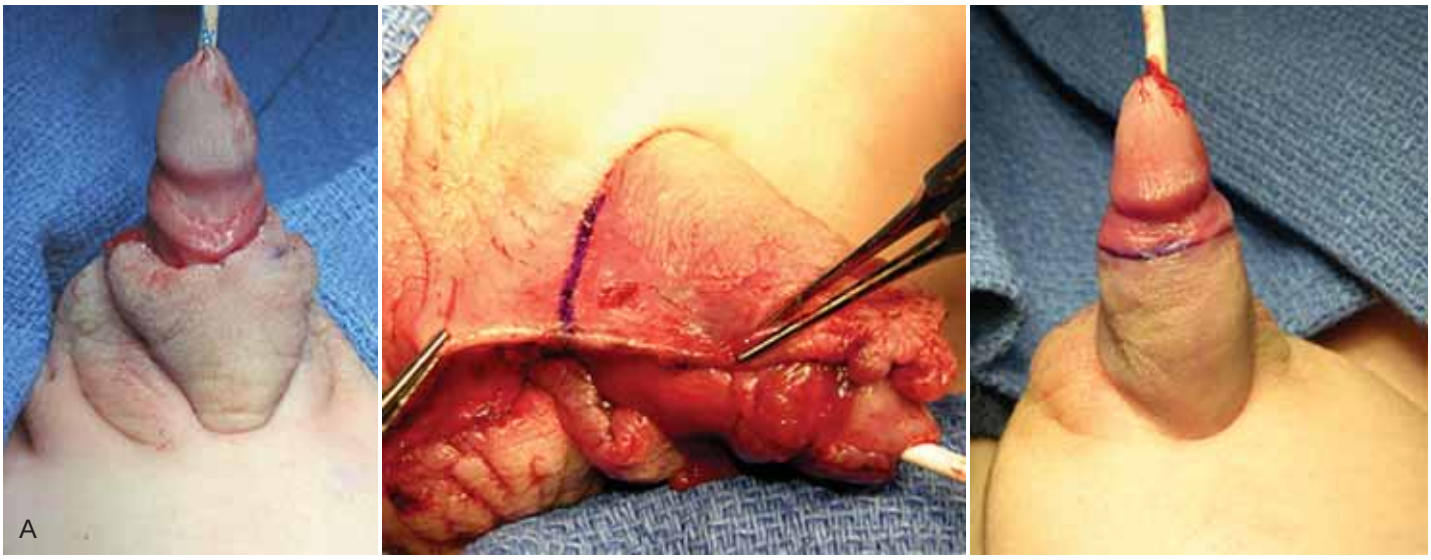

Figure 130–21. Minor scrotoplasty. **A,** Minor scrotal encroachment on the penopubic junction. **B,** Ventral incisions at the penoscrotal junction allow ventral rotation of shaft skin and scrotum. Incision continues to approximately the 3- to 4- and 8- to 9-o'clock positions, with subsequent ventral approximation of the shaft skin. **C,** Smooth penopubic junction with normal-appearing scrotum.

Neourethral Calibration

Passage of a sound or bougie can be done to determine if a small-appearing neomeatus is stenotic and to exclude neourethral stricture, especially in pre–toilet-trained boys in whom uroflowmetry is not practical. The author performs a single calibration in pre–toilet-trained patients 6 months postoperatively; but given the low rates of meatal stenosis and neourethral stricture, instrumentation could be reserved for those with suspected obstructive voiding symptoms. The normal caliber of the meatus varies with age; the minimum is variously reported from less than or equal to 8 French (Litvak et al, 1976) to greater than or equal to 10 French (Yang et al, 2001b).

Uroflowmetry

Uroflowmetry is advocated as a noninvasive means to assess neourethral function. Parameters considered include both maximum flow rate and appearance of the curve, defined as bell versus plateau shaped. Obstruction is suspected in plateau curves with maximum flow rates more than 2 standard deviations below the mean of age-matched controls (Garibay et al, 1995).

Reported results after repairs with TIP and onlay and tubularized preputial flaps indicate the majority of patients have maximum flow rates greater than the 5th percentile (Jayanthi et al, 1995; Snodgrass, 1999b; Marte et al, 2001; Hammouda et al, 2003), although many are below the 50th percentile (Jayanthi et al, 1995; Hammouda et al, 2003). Limiting the interpretation of postoperative uroflowmetry data has been reluctance to perform additional testing to confirm anatomic obstruction in patients with maximum flow rates less than the 5th percentile when they are asymptomatic or have postvoid residual urine volumes thought insignificant (<10% voided volume) (Jayanthi et al, 1995; Hammouda et al, 2003). Those who have investigated patients with maximum flow rates less than the 5th percentile report finding meatal stenosis or neourethral stricture (Garibay et al, 1995; Marte et al, 2001; Kaya et al, 2007), which suggests peak flow rates reduced to this degree should prompt calibration or cystoscopy. Postoperative plateau curves and peak flow rates between the 5th and 50th percentiles without apparent anatomic obstruction likely indicate the surgically created neourethra lacks the elasticity and smooth luminal surface of the normal urethra (Holmdahl et al, 2006; Braga et al, 2007).

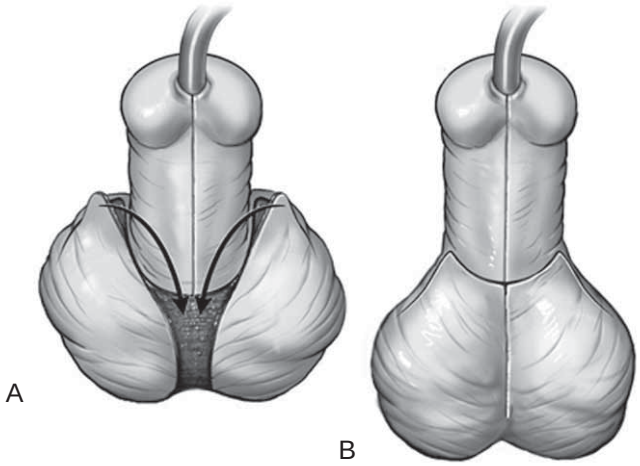

Figure 130–22. Major scrotoplasty. **A,** After completion of urethroplasty, skin incisions are made along the abnormal extensions of scrotum to either side of the penis. These flaps are rotated down and to the midline. **B,** Skin closure using subepithelial sutures.

Lack of universal agreement regarding normal values and minimum acceptable voided volumes limits comparisons between reported series. Significance of peak flow rates between the mean and –2 standard deviations in otherwise asymptomatic patients is unknown.

Questionnaires

Questionnaires potentially facilitate objective determination of patient perceptions regarding penile appearance and function after hypospadias repair. Various reports using questionnaires in

teens and adults previously operated on with a number of different techniques provide important insights. First, cosmetic outcomes are important (Bracka, 1989; Mureau et al, 1995; Aho et al, 2000b), with patients indicating a meatus at the proper glans location is preferable to the coronal position advocated in the past (Mureau et al, 1996). In cultures that do not practice routine circumcision the appearance of the circumcised penis after hypospadias repair increases self-awareness of the prior defect (Mureau et al, 1996). Patient versus surgeon impressions of cosmetic results may vary significantly, with patients generally (Mureau et al, 1996), but not always (Weber et al, 2008), more likely to express a negative perception of their genitalia. Some factors of concern to patients, such as scars and meatal position, can be influenced by surgical technique, although others, including overall penile size, cannot. There is apparent disagreement concerning impact of the age at surgery and number of operations, because some report that older age and increasing number of operations negatively impact sexual adjustment (Mureau et al, 1995) whereas others state these factors do not necessarily relate to the patient's genital perception (Bubanj et al, 2004).

A survey of men who underwent Koyanagi repair found 41% dissatisfied with penile appearance, but this was not significantly different from the 34% dissatisfaction reported by normal men, emphasizing the need for controls to understand the significance of responses (Moriya et al, 2006). In contrast, a cohort of teens and adults after prior two-stage preputial flap repair found 92% pleased with penile appearance, with 88% stating it was normal (Lam et al, 2005). Comparable data have not been published after other preputial flap or graft repairs described earlier or for TIP repair. However, responses by parents to questionnaires regarding the appearance of the penis after TIP repair were the same as those given by patients whose normal boys underwent elective circumcision (Snodgrass et al, 2008).

Voiding disturbances, including "spraying" (a broad stream), stream deflection, and/or postvoid dribbling are commonly reported by men after skin flap urethroplasties (Kumar and Harris, 1994; Aho et al, 2000b; Lam et al, 2005). However, one study with controls cautioned that while these voiding complaints were significantly more common in patients, half the normal men stated they had spraying, deflection, or dribbling (Moriya et al, 2006). The need to milk ejaculate has also been noted in 14% to 45% of patients (Bubanj et al, 2004; Lam et al, 2005; Moriya et al, 2006).

Persistent curvature during erection has been reported by 14% to 40% of previously operated men (Kumar and Harris, 1994; Aho et al, 2000b; Bubanj et al, 2004; Moriya et al, 2006), although normal controls had similar (Bubanj et al, 2004) or increased self-reported curvature (Moriya et al, 2006). None of these studies correlated extent of original curvature and means for straightening to these postpubertal findings.

No standardized questionnaire to determine penile appearance, micturition, or sexual function after hypospadias repair has gained widespread acceptance.

URETHROPLASTY COMPLICATIONS

Univariate analysis of factors potentially contributing to complications after TIP repair found increased likelihood with running versus interrupted two-layer subepithelial urethral plate tubularization, proximal versus distal/midshaft hypospadias, no barrier layer over the neourethra versus a dartos flap ± spongioplasty, and initial versus later experience of the operating surgeon. Of these, multivariate logistic regression analysis indicated proximal hypospadias and lack of a barrier layer as independent risk factors (El-Sherbiny et al, 2004). Comparable analyses have not been reported for other urethroplasty techniques, but generally complications are greater with more proximal hypospadias repair regardless of procedure. **Periodic review by surgeons of their outcomes may prompt modifications to address specific identified problems (El-Sherbiny et al, 2004; Gapany et al, 2007) and should be considered a routine practice in hypospadias surgery**.

Urethroplasty complications may occur singly or in combination, mandating thorough assessment of the neourethra when a problem is suspected. Surgical correction for the following complications is described under Reoperations.

Fistulas

Urethrocutaneous fistulas are the most common complication after hypospadias urethroplasty. Potential causes remain a matter of conjecture, and no multivariable analyses of suspected factors have been reported. For example, realization that overlapping suture lines from urethroplasty and skin closure potentially increase likelihood for fistulas dates to Duplay's first procedure, but other factors such as larger suture size (4-0) and different suture materials (catgut, horsehair) then commonly used could also have contributed to their development.

Technical steps thought to reduce fistula risk include two-layer subepithelial closure of the neourethra and subsequent coverage with a barrier flap, usually dartos. Of these, there are more data regarding barrier layers. One RCT randomized patients with distal hypospadias undergoing TIP repair with foreskin reconstruction to receive a ventral dartos barrier flap or not, reporting a significant reduction in fistulas within the cohort assigned dartos coverage (23% vs. 8%, $P = .03$) (Savanelli et al, 2007). Similarly, a prospective study found addition of a dartos flap significantly reduced fistulas (26% to 3.5%, $P < .01$) during TIP repair in comparison to retrospectively obtained results from a second cohort of consecutive patients thought otherwise similar in age and extent of hypospadias repaired without a dartos flap (Gapany et al, 2007). Neither study provided details regarding number of layers and suturing technique (subepithelial vs. through epithelium) for urethroplasty, nor overlying glansplasty and skin closure, but stated these were similar among included patients.

Other retrospective reviews give conflicting outcomes. For example, a dartos flap significantly reduced fistulas after two-stage graft repair in one study (63% to 4.5%, $P < .001$), but the extent of hypospadias and whether operations were primary versus reoperative were not stated to ensure the two groups were otherwise comparable (Telfer et al, 1998). Splitting the dorsal dartos flap to create a "double-layer" barrier was found to significantly reduce fistulas versus a single-layer dartos flap (14% to 0%) in one series of TIP repair (Bakan and Yildiz, 2007) but not another (4% versus 0%, $P = .5$) (Kamal, 2005). The author has reported prospectively collected data indicating a 33% fistula incidence in proximal TIP urethroplasty despite using a dartos flap in every case (Snodgrass and Yucel, 2007), although a dartos flap did significantly reduce fistulas in mostly distal TIP reoperations (Nguyen and Snodgrass, 2004).

An alternative consideration to prevent fistulas is application of fibrin sealant over the neourethra. Use has been investigated in one RCT of proximal tubularized preputial flap repairs (Gopal et al, 2008) and another prospective cohort study (Ambriz-Gonzalez et al, 2007), both reporting significant decreases in fistulas with use.

Fistulas can occur at any location along the urethroplasty and can be an isolated finding or associated with other complications,

including distal obstruction from meatal stenosis or neourethral stricture or turbulent urinary flow in a diverticulum. Although most often noted in the first few months after surgery, they can be overlooked in infants until evident at toilet training and also can occur years after apparently successful hypospadias repair. Fistulas occasionally close spontaneously, and there are anecdotal reports that fibrin glue can promote closure. The majority require reoperation.

Meatal Stenosis

Obstructive narrowing at the neomeatus can result from technical error, ischemia, or balanitis xerotica obliterans (BXO). Tubularization of the urethral plate too far distally is most likely the main cause for meatal stenosis after TIP repair. As mentioned earlier, the plate should not be tubularized beyond approximately the mid-glans point, leaving an oval terminal opening. Mistaken belief that the glans wings must be sutured to the neourethra probably has caused some to extend plate tubularization too far distally to approximate the wings without leaving a glanular hypospadias.

Meatal stenosis is suspected when the neomeatus appears small, the child strains to void, and/or when uroflowmetry demonstrates peak flow below the 5th percentile with a plateau-shaped tracing. These are nonspecific findings that require verification by calibration to establish the diagnosis.

Neourethra Stricture

Strictures of the neourethra, like meatal stenosis, may indicate technical error, ischemia, or BXO and similarly present as obstructive voiding symptoms and/or signs. Urinary tract infections after hypospadias repair can also suggest neourethral obstruction. The diagnosis can be suspected by inability to pass sounds, but retrograde or voiding urethrography and/or cystoscopy are needed for confirmation. Despite dorsal urethral plate incision, strictures are rarely reported after TIP repair. The most common site for neourethral strictures is at the proximal anastomosis of the neourethra to native urethra in flap and graft repairs. Circumferential anastomoses have been considered at greater risk for stricture, but comparisons of onlay to tubularized preputial flaps have not shown a statistically significant difference (Wiener et al, 1997; Castanon et al, 2000).

Dehiscence

Partial or complete wound separation results in recurrent hypospadias. Causes potentially include technical factors (suture materials and/or technique during glansplasty), glans size, traumatic catheter displacement, or wound infection. The author found proximal repairs were significantly more likely to result in glans dehiscence than mid-distal shaft repair, possibly indicating that smaller glans size increases risk (Snodgrass et al, 2010). Preoperative testosterone injections in patients subjectively thought to have a smaller glans did not reduce dehiscence compared with nontreated patients presumably with a larger glans, although use was not randomized and glans size before and after treatment was not measured.

Glans dehiscence correlates with graft source when oral mucosa is used in staged urethroplasty. Cheek grafts, which are visibly thicker than lip grafts, are more often associated with dehiscence (Snodgrass and Elmore, 2004; Snodgrass et al, 2009).

Diverticulum

Ballooning of the neourethra during voiding with subsequent postvoid dribbling indicates diverticulum formation. Contributing factors include distal obstruction, turbulent urinary flow, and ability of tissues used for urethroplasty to expand. Accordingly, diverticula are most often noted after tubularized preputial flap repairs and are rarely encountered after tubularization of the urethral plate or buccal grafts, which presumably have a more regular luminal surface and are less prone to distention than is penile skin.

Balanitis Xerotica Obliterans

Late development of meatal stenosis or neourethral stricture can indicate BXO. A characteristic white appearance to involved tissues should prompt consideration of the condition (Fig. 130–23), as should development of obstruction several years after apparently successful urethroplasty. The importance of recognizing BXO is that repair requires excision of all involved tissues and their replacement with nonskin tissues, usually buccal mucosa, because reoperation using skin results in high recurrence rates (Bracka, 1995; Depasquale et al, 2000).

Key Points: Complications

- Fistulas are the most common complication after hypospadias repair. Factors thought to reduce their incidence include a two-layer subepithelial suture closure of the neourethra with interposition of dartos or tunica vaginalis barrier flap between the neourethra and shaft skin.
- Late development of meatal stenosis or urethral stricture may indicate BXO, especially if the meatus has a whitish discoloration.

Figure 130–23. Balanitis xerotica obliterans. The diagnosis is suspected from the white discoloration of the meatus in a patient with symptomatic meatal stenosis.

Figure 130–24. Ventral incision for hypospadias reoperations. Ventral incision for reoperative urethroplasty and glansplasty provides exposure to ventral dartos for barrier flap and facilitates cosmetic skin revision without need to deglove the penis.

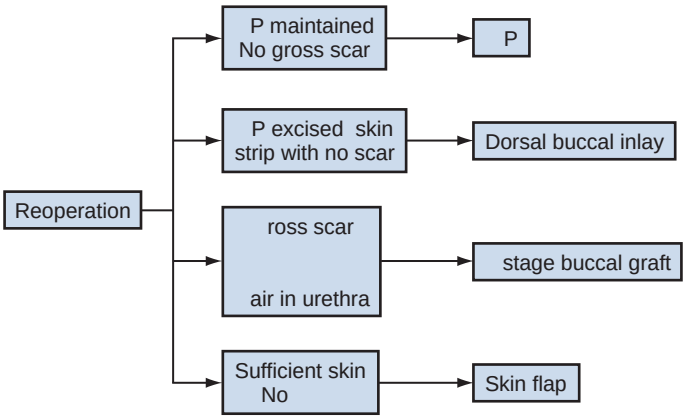

Figure 130–25. Algorithm for hypospadias reoperations. BXO, balanitis xerotica obliterans; TIP, tubularized incised plate; UP, urethral plate; VC, ventral curvature.

REOPERATIONS

Reoperations are required to correct various complications after hypospadias repair discussed in the preceding section or to replace the neourethra. Those for fistula, meatal stenosis or urethral stricture, diverticulum, or wound dehiscence can all be performed through a ventral midline incision, extended onto the glans wings to either side of the urethral plate in cases of glans dehiscence (Fig. 130–24). This approach provides exposure without need to re-deglove the penis, allows correction of presenting and associated complications, gives access to ventral dartos or tunica vaginalis for a barrier layer before skin closure, and facilitates cosmetic skin revision.

The algorithm in Figure 130–25 outlines options for urethroplasty reoperations. Although most techniques used for primary hypospadias urethroplasty can be adapted to reoperations, the greater complications rates that result support concerns that previously operated tissues have diminished vascularity (Jayanthi et al, 1994).

Fistulas

Fistula repair begins with examination to exclude contributing conditions, especially distal obstruction, and distention of the urethra with methylene blue–tinted fluid to detect additional fistulas. The fistula tract is dissected to the neourethra, excised and closed with subepithelial absorbable sutures, and then covered with a ventral dartos or tunica vaginalis flap to avoid overlapping suture lines during skin closure. Surgery has been described using circular incision immediately adjacent to the fistula tract with subsequent advancement of a skin flap with its underlying dartos over the repair. The author prefers a larger midline incision though the median raphe.

Fistulas occurring at the corona potentially require alternative management. If only a thin bridge of skin connects the glans wings distally, reoperation with glansplasty is needed for fistula repair. However, if the glans wings are well approximated, coronal fistulas can be closed by dissection under the glans without need to reopen the wings and perform glansplasty (Fig. 130–26).

Multiple fistulas, or fistulas associated with meatal stenosis, neourethral stricture, or diverticulum require reoperative urethroplasty. Fistulas approximately 5 mm or greater also likely require reoperative urethroplasty for successful closure without narrowing the neourethra lumen.

Success with isolated repair of small fistulas has been reported in 76% to 96% of cases (Hayashi et al, 1998; Shankar et al, 2002; Santangelo et al, 2003). Fistulas greater than 2 mm were more likely to recur in one series (Shankar et al, 2002). Dartos flaps or full-thickness skin flaps were used routinely by some (Waterman et al, 2002; Santangelo et al, 2003) but not found to influence outcomes versus repairs without flaps by others (Hayashi et al, 1998; Shankar et al, 2002). Stents were not used for urinary diversion in one series (Santangelo et al, 2003) and not found to impact results in another (Waterman et al, 2002). These series did not systematically report the original hypospadias defect and means for repair, location and size of the fistula, sutures used for overlying skin closure, or duration of postoperative follow-up. No series reports multivariable analysis of factors possibly influencing outcomes.

Meatal Stenosis, Neourethral Stricture

Although repetitive dilation has been reported for meatal stenosis, it is unlikely to provide long-term resolution of scarring from overzealous plate tubularization or ischemia. Meatotomy can be considered if there is no evidence for BXO and the procedure can be accomplished without re-creating a hypospadias defect. Otherwise reoperation is required (see later).

Strictures discovered within 3 months of surgery have been reported more responsive to dilation or direct vision internal urethrotomy (DIVU) than those found subsequently (Scherz et al, 1988), although follow-up in successful cases of “at least 1 year” may have been insufficient to observe later failures. Overall success with DIVU for hypospadias strictures followed a minimum of 2 years is less than 25% (Duel et al, 1998; Husmann and Rathbun,

Figure 130–26. Coronal fistulas. **A,** Only a thin skin bridge separates the fistula from the meatus. Closure requires reoperative urethroplasty and glansplasty. **B,** Glansplasty intact beyond the coronal fistula, allowing repair without reoperative urethroplasty/glansplasty. Dissection under the glans (**C**) exposes the fistula for closure, and a ventral dartos flap accessed through a midline ventral incision will next be used to cover the repair.

2006). Technique in prior hypospadias repair may influence response to DIVU, because one prospective study of 72 cases found urethrotomy after tubularized flaps or grafts was successful in only 4% and resulted in progression of stricture length in 56% versus success in 68% and progression in 9% after onlay or urethral plate tubularizations (Husmann and Rathbun, 2006). This report also found that adjunctive urethral dilation after DIVU did not improve outcomes over DIVU alone. Failure of DIVU should not be treated with a second DIVU but should instead prompt open urethroplasty (Hsiao et al, 2003; Husmann and Rathbun, 2006).

Neourethral strictures not amenable to, or recurrent after, DIVU are corrected using dorsal inlay grafting (see later).

Dehiscence

Wound dehiscence below the coronal margin requires reoperative urethroplasty according to principles and techniques discussed later.

Diverticulum

After excluding distal obstruction and fistulas, a midline ventral skin incision is made exposing the ballooned neourethra, which also is opened in the midline. Excess tissues are excised and the urethra is retubularized over a urinary stent and then covered with a dartos or tunica vaginalis flap. If diverticulum is encountered after onlay preputial flap repair, the flap can be excised preserving its vascular pedicle for the barrier layer, with reoperative TIP urethroplasty done using the remaining urethral plate. If obstruction is encountered distally, excised tissue from the diverticulum can be used for inlay grafting (Fig. 130–27).

Tubularized Incised Plate Reoperation

Indications for TIP reoperation include coronal fistulas with only a thin distal skin bridge approximating the glans, meatal stenosis, and dehiscence when the urethral plate is not grossly scarred. Patients with multiple fistulas or diverticulum after prior onlay flap repair can also undergo TIP reoperation with excision of the preputial flap. The author considers gross scarring of the plate or its prior excision contraindications to reoperative TIP.

Most reported patients undergoing TIP reoperation failed one prior repair, with persistent distal hypospadias. Outcomes for reoperative TIP repair are the same after previous urethral plate incision (TIP, MAGPI) versus no prior incision (flap-flap, onlay flap, glans approximation procedure) (Nguyen and Snodgrass, 2004; Ziada et al, 2006; Elicevik et al, 2007). Likelihood for postoperative fistulas is significantly reduced by dartos flap barrier layers (Nguyen and Snodgrass, 2004).

Two reports with 14 and 5 patients, respectively, describe TIP reoperation using a preserved skin strip from the meatus to glans tip as a pseudo-urethral plate when the native plate was previously removed (Luo and Lin, 1999; Hayashi et al, 2001a). Neither report mentioned postoperative neourethral stricture, suggesting dorsal skin incision potentially heals by re-epithelialization.

TIP reoperation begins with a Y-shaped ventral incision extending along each glans wing, joining on the midline shaft and then continuing to the penoscrotal junction (see Fig. 130–24). This incision provides access to ventral dartos to create a barrier flap after urethroplasty. Repair otherwise is as described earlier for primary TIP repair.

Outcomes. Published outcomes are summarized in Table 130–7.

One-Stage Dorsal Inlay Graft Reoperation

When the urethral plate has been excised in prior surgery but a strip of skin without gross scarring remains in its place, midline incision of the skin strip with grafting of the resulting dorsal defect can be used for single-stage reoperative urethroplasty (Fig. 130–28). Surgical technique is the same as for TIP reoperation with graft obtained from penile or hairless groin skin or buccal mucosa (see later) quilted into place onto the corpora cavernosa using absorbable sutures at 0.5- to 1.0-cm intervals to facilitate revascularization.

Inlay grafting is also applicable to repair of neourethral strictures after hypospadias surgery but should not be used when there is possibility for BXO, because involved tissues must be excised in this condition.

Outcomes. Published reports are shown in Table 130–7. Whereas reoperative TIP repair has generally been avoided when the urethral plate is grossly scarred, Schwentner and associates (2006) reported inlay grafting successful in patients with a mean of four prior operations, including those with urethral plate scar. Their

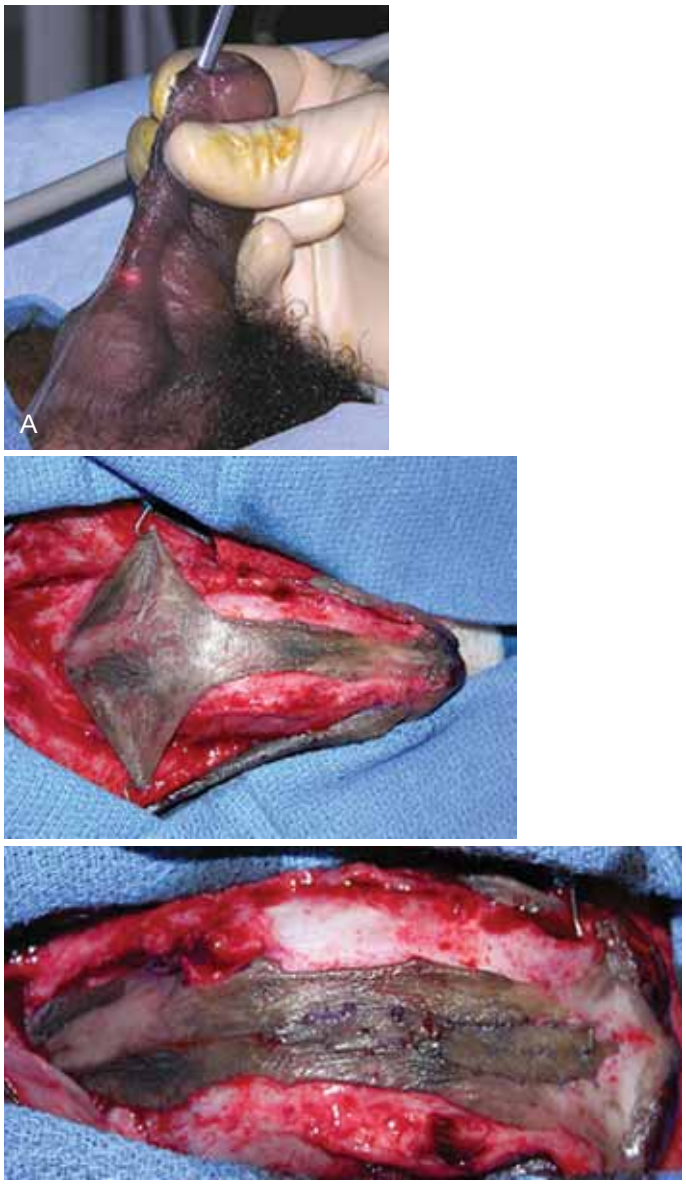

Figure 130–27. Diverticulectomy with distal inlay graft. **A,** Proximal diverticulum with functional distal obstruction. **B,** Neourethra opened, showing proximal diverticulum and relative distal narrowing. **C,** Excised diverticulum tissue used for midline inlay grafting to widen the distal segment before tubularization.

experience suggests one-stage inlay grafting is an alternative consideration to two-stage graft procedures unless there are specific indications to excise the remnant neourethra, such as BXO, hair, or persistent VC.

Two-Stage Buccal Graft Reoperation

Replacement urethroplasty is needed for gross scarring of the neourethra or when the neourethra contains BXO or extensive hair or is contracted and thereby creating recurrent penile curvature.

The first stage begins with excision of scarred or undesired tissues, which most often comprises the entire neourethra back to native urethra (Fig. 130–29). Dissection continues to the surface of the corpora cavernosa, including reestablishment of glans wings with a deep glanular cleft. Urethrostomy is created by suturing urethra to skin from the 5- to 7-o'clock position proximally.

Buccal graft is then harvested, infiltrating lines of incision with 1:100,000 epinephrine for hemostasis. The parotid duct is identified adjacent to the second molar and avoided when cheek mucosa is used. Dissection remains superficial to facial musculature. The graft donor site can be left open, coated with fibrin glue, or sutured closed. Grafts harvested from the lip are not sutured to avoid distorting the vermillion border.

The graft should fill the ventral penile defect without tension. It is next incised proximally in the midline for 5 to 10 mm and placed along both lateral margins of the urethrostomy to minimize the likelihood both of incorporating skin follicles into the neourethra at the second stage or developing a stricture at the graft-urethrostomy junction.

Then the graft is sutured to shaft skin and glans along its perimeter with interrupted polyglactin, using subepithelial stitching in the glans to avoid suture tracks. The midline of the graft is sutured to underlying corpora cavernosa, followed by additional quilting to the corpora on either side at 5- to 10-mm intervals to minimize the opportunity for fluid collection under the graft. An RB-1 needle facilitates quilting, which is done with 6-0 polyglactin in children and 5-0 in adults.

Tie-over polypropylene sutures secure a roll of petrolatum gauze onto the graft to further reduce graft movement or fluid accumulation that might impair revascularization. The tie-over sutures and urinary catheter are removed 7 days postoperatively.

During a healing phase of 6 months the graft can be visually inspected for focal scar or contracture. Partial contracture can be managed during the planned second stage by either including adjacent shaft skin in the neourethra or by inlay buccal regrafting. Scars or more extensive contracture may necessitate excision of the involved area with regrafting as an additional step before ultimate tubularization to create the neourethra (Fig. 130–30).

At the second stage the neourethral plate is tubularized by two-layer subepithelial suture closure and then covered with a dartos or tunica vaginalis flap. Buccal tissue should not be visible at the meatus, because exposed mucosa keratinizes and sheds. A urethral catheter provides urinary diversion for approximately 14 days.

Outcomes. Although Bracka (1995) has advocated staged buccal graft reoperations, he has not published detailed outcomes. Partial or complete failure of graft take requiring an additional operation to repair the neoplate before its tubularization occurs in 10% (Andrich et al, 2003; Elmore and Snodgrass, 2004). Overall complications after urethroplasty are reported in 26% to 38% (Price et al, 2003; Elmore and Snodgrass, 2004, Snodgrass et al, 2009).

In the author's experience, grafts using buccal tissue placed into the glans have had increased likelihood for glans dehiscence than thinner grafts of lip tissue (Snodgrass et al, 2009). Consequently, lip tissue is recommended to be used to graft the space between glans wings extending onto the shaft of the penis, with cheek tissue continuing proximally to the meatus, when needed. Lip will resurface from the glans to the penoscrotal junction in prepubertal boys if harvested, as shown in Fig. 130–31.

The author's patients undergoing two-stage buccal graft reconstructions had a mean of 4.3 previously failed operations. Buccal graft provides a neourethral plate in this setting where penile skin is both lacking and partially devascularized. The staged approach allows inspection of the neourethral plate before its tubularization with the opportunity to revise areas of scarring or contracture. Accordingly, no neourethral strictures have occurred. Scar tissue removal from the glans and subsequent neourethral plate tubularization create a vertical meatus and normal-appearing glans (Fig. 130–32).

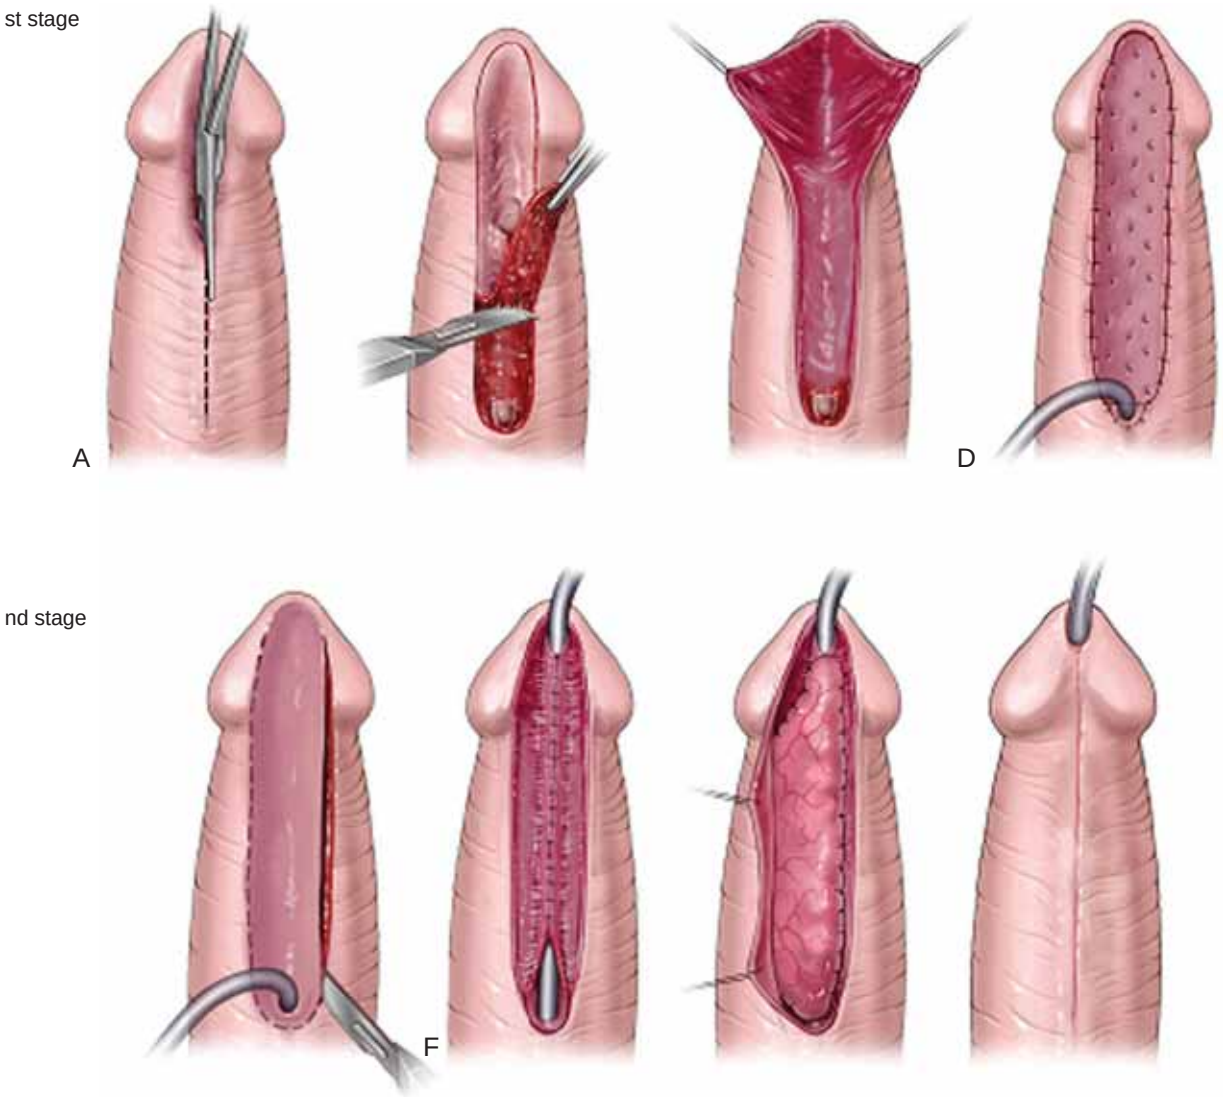

Figure 130–29. Two-stage buccal graft reoperation. **A,** Neourethra is opened with ventral incision. **B,** All unhealthy tissues, and usually the entire neourethra, are excised. **C,** Deep glans groove is reestablished, and proximal urethrostomy is completed. **D,** Buccal graft is quilted into place from meatus to glans tip. Lip tissue is used within the glans and subcoronal region, and cheek tissue is used along the penile shaft. The junction of lip to cheek is made diagonally to minimize contraction. **E,** U-shaped incision along perimeter of neourethra 6 months later. **F,** Two-layer tubularization of the neourethra using interrupted subepithelial polyglactin followed by continuous polydioxanone. **G,** Barrier flap, usually of tunica vaginalis, covers the entire neourethra. **H,** Glansplasty and skin closures completed with subepithelial sutures. (Reprinted from Snodgrass W, Elmore J. Initial experience with staged buccal graft [Bracka] hypospadias reoperations. J Urol 2004;172[4 Pt. 2]:1720–4.)

Others have tubularized the buccal graft or used it as an onlay urethra patch for one-stage reoperations, with resultant complications ranging from 28% to 57% (Snodgrass and Elmore, 2004), which is similar to urethroplasty outcomes after two-stage repairs. However, obstructive complications (meatal stenosis and urethral stricture) are reported in a mean of 18% of patients with one-stage (Snodgrass, 2004) versus approximately 5% of patients with two-stage operations (Elmore and Snodgrass, 2004; Snodgrass et al, 2009), most likely indicating improved graft revascularization with the two-stage approach.

Donor site morbidity was determined by systematic literature review to occur in 4% of adult patients, with no differences in overall complications between cheek versus lip harvest sites (Markiewicz et al, 2008), although most series have not systematically assessed and reported harvest site outcomes. Initial postoperative complaints include pain, numbness, and difficulty in mouth opening and ingestion. Analog pain scales indicate mid-range discomfort levels (Wood et al, 2004; Jang et al, 2005) that are similar whether donor sites are sutured closed or left open (Wood et al, 2004). Pain diminishes over the first 5 days and is resolved or mild by 1 to 6 months (Dublin and Stewart, 2004; Jang et al, 2005; Kamp et al, 2005). Lip donor sites were associated with significantly greater pain duration than cheek sites in one report (Kamp et al, 2005) but not another (Jang et al, 2005). Initial and long-term paresthesia has been found significantly increased after lip versus cheek harvest by some (Jang et al, 2005; Kamp et al, 2005) but not others (Wood et al, 2004). Impaired mouth opening usually resolves within the first month but may persist in a minority of patients for 6 months or longer (Wood et al, 2004), or patients may note

Figure 130–30. Graft scar and contracture. **A,** Stellate scar in midportion of graft, **B,** Distal graft contracture. **C,** Desired healthy appearance of well-vascularized graft. continued "tightness" without restriction (Dublin and Stewart, 2004).

There are very limited data regarding morbidity associated with oral mucosa harvest sites in children. One evaluation at a mean of 6.9 years postoperatively found 19% mentioned concerns for appearance or occasional pain or numbness after lip harvest with wound suturing versus no problems after cheek harvests (Nelson et al, 2005).

Skin Flaps

Mathieu flip-flap and onlay or tubularized preputial flaps have been used for hypospadias reoperation. Technical details of the procedure including sutures preferred and use of barrier flaps were not reported in most the publications listed in Table 130–8. Most patients in these studies failed one prior attempt at hypospadias repair. As the number of failed previous surgeries increases, the likelihood that sufficient well-vascularized skin remains to create flaps for urethroplasty decreases. Jayanthi and associates (1994) stated that an unspecified number of additional patients did not undergo skin flap reoperations owing to lack of supple skin, whereas in a series of patients with a mean of 1.6 failed repairs Bar-Yosef and coworkers (2005) stated that 15% had scar that prevented reoperation with skin flaps.

Key Points: Reoperations

- TIP reoperation is an option for persistent hypospadias when the urethral plate remains without gross scar.
- Persistent hypospadias after urethral plate replacement with skin potentially can be corrected in one stage using TIP-like widening of a skin strip with dorsal inlay grafting of the resultant defect.
- Failed hypospadias surgery with persistent VC, hair in the urethra, and/or gross scarring can be salvaged by excision of all unhealthy tissues with two-stage buccal graft urethroplasty.
- Balanitis xerotica obliterans requires complete excision with two-stage buccal graft urethroplasty, because the condition recurs in both penile and nongenital skin.
- Buccal grafting is best done using lip within the glans and cheek along the penile shaft.

LIMITATIONS OF HYPOSPADIAS LITERATURE

The main objective of scientific reporting is to relate experience so that other surgeons and their patients potentially can benefit from lessons learned. The following observations regarding

hypospadias literature highlight recurring shortcomings that limit this communication between specialists.

Failure to Report Technical Details of Procedures

Results of hypospadias surgery can be impacted by such variables as suture type and size, suturing techniques, and barrier layers as discussed earlier in the various outcomes sections. Accordingly, authors should describe these technical aspects of their procedures in detail for straightening curvature, urethroplasty, glansplasty, and skin closure so that readers can compare and contrast their own materials, methods, and results.

In addition, because needles available for different suture sizes vary worldwide, this information should also be provided. For example, the 6-0 polyglactin used by the author has a S29 needle but in other countries is only available from the same manufacturer on RB needles. Whether needle size accounts for some of the wide variation in outcomes reported for the same procedure cannot currently be determined from published literature.

Failure to Segregate Results for Patient Groups with Different Outcomes

Complications increase with increasing severity of hypospadias, and so results for distal, midshaft, and proximal hypospadias should be separately described. Because reoperations have greater incidence of complications than primary repairs, data from patients undergoing secondary versus primary surgery also should be separately reported. Manuscripts combining the outcomes for several surgeons in one or multiple centers should specifically highlight any differences in technical variables mentioned earlier and provide analysis that their individual results were statistically similar.

Lack of Uniform Follow-up

Because the time that complications are first noted is not routinely reported, it is unclear what minimum duration of follow-up is needed to identify the majority of postoperative problems. Means to determine results are not standardized and are in part dependent on the age when surgery is performed; for example, infants cannot provide uroflowmetry as can older boys. Whereas fistulas, wound dehiscences, and diverticula are visually apparent, obstructive lesions are not always easily recognizable, and a small-appearing meatus may be normal in caliber. Consequently, reports of meatal stenosis and/or neourethral stricture should specifically describe how these diagnoses were made. Lack of a universally accepted means to assess cosmetic outcomes makes comparisons between techniques and reported series difficult and likely inaccurate. The common phrase that cosmetic results were "satisfactory" does not inform readers if the penis looked normal and if not why not.

The current trend by surgeons to increasingly rely on fewer procedures to correct the spectrum of hypospadias defects offers an opportunity to standardize and perfect these reconstructive operations. Better reporting combined with quality review of individual results by hypospadiologists should reduce the sometimes wide disparity in outcomes reported by different centers as well as isolate causes for complications.

Abnormalities of the External Genitalia in Boys

Jeffrey S. Palmer, MD, FACS, FAAP

Normal Male External Genitalia
Penile Anomalies
Scrotal Anomalies
Vascular Lesions of the Genitalia

The normal anatomy of the penis includes the prepuce (foreskin), glans, urethral meatus, coronal sulcus, and penile shaft. The ventral surface of the penile shaft has the median raphe that is contiguous with the scrotal raphe. Anomalies of the penis and scrotum are common and may be congenital, acquired, or iatrogenic. **The congenital anomalies may result from a disorder of sexual differentiation, genital differentiation, or genital growth and may be associated with other syndromes** (Table 131–1) or organ systems. For example, up to 50% of children with congenital anorectal malformations also have an associated urologic malformation.

Although ultrasonographic technology has evolved in the past decade permitting earlier fetal sex determination (Efrat et al, 2006), it is inaccurate and is not recommended before 12 weeks of gestation (Odeh et al, 2009). However, prenatal ultrasonography is accurate in sex determination in 99% to 100% of cases after 13 weeks of gestation without malformed external genitalia (Odeh et al, 2009) (Fig. 131–1). In-utero ultrasonography has identified abnormal male genitalia including ambiguous genitalia and penoscrotal transposition (Cheikhelard et al, 2000; Vijayaraghavan et al, 2002; Pinette et al, 2003). More recent ultrasonographic technology, including three-dimensional ultrasonography, is being used to evaluate the fetal external genitalia but there are no definitive results suggesting this as an enhanced diagnostic modality (Verweerd-Dikkeboom et al, 2008; Abu-Rustum et al, 2009).

The understanding of the normal anatomy and embryologic development of the male external genitalia is essential to recognizing and treating penile and scrotal anomalies. Most genital abnormalities noted in neonates do not result in an ambiguous appearance but rather more common conditions such as inconspicuous penis or abnormal penile orientation. **The American Academy of Pediatrics (AAP) Committee on Genetics and Sections on Endocrinology and Urology** (2000) **published a guide to the normal embryology of the external genitalia and the altered embryology, evaluation, and management of ambiguous genitalia.**

NORMAL MALE EXTERNAL GENITALIA

Embryology

Normal embryogenesis of the male genitalia involves the formation of the penis and scrotum. **The early development of the external genitalia in the two sexes is similar before the 9th week of gestation** (Ammini et al, 1997). Understanding factors and sequential steps in normal embryogenesis is fundamental in the comprehension of the pathogenesis of male genital anomalies. **These factors include testosterone synthesis by the fetal testis and its enzymatic conversion into dihydrotestosterone by 5α-reductase and the presence of androgen receptors able to recognize the androgenic hormones. The influence of dihydrotestosterone on the androgen receptors results in the differentiation of the genital tubercle, genital (labioscrotal) folds, and genital swelling between 9 and 13 weeks of gestation into the male structures of the glans penis, penile shaft, and scrotum, respectively**.

The male develops in a proximal to distal manner. As the penis forms from the elongation and enlargement of the phallus, the lateral walls of the urethral groove form from the ventrally located genital folds. The genital folds then fuse in the midline. The glanular urethra forms from the ingrowth of surface epithelium, but this long-held theory has been challenged with evidence suggesting that it is due to the fusion of the urethral plate (Glenister, 1921; Ammini et al, 1997). The scrotum forms through the inferomedial migration and midline fusion of the genital folds as delineated by the scrotal raphe. **In females and in males with abnormalities in testosterone and/or dihydrotestosterone production, 5α-reductase deficiency, or androgen receptor insufficiency, the genital tubercle, genital folds, and genital swellings passively become the clitoris, labia minora, and labia majora, respectively.**

Penile Length and Tanner Classification

Penile length significantly increases with gestational age (6 mm at 16 weeks to 26.4 mm at 38 weeks) (Johnson and Maxwell, 2000; Zalel et al, 2001) and during the first 3 months of life. The latter growth is a result of an increase in Leydig cell production of testosterone owing to the loss of the inhibitory effect of maternal estrogens on the fetal pituitary at birth, thereby causing a surge in gonadotropins. During the rest of childhood, penile length increases more slowly until adolescence when the length extensively increases again until the final size is reached. **The normal penile size in a full-term male neonate is 3.5 ± 0.7 cm in the stretched length and 1.1 ± 0.2 cm in diameter compared with 13.3 ± 1.6 cm at adulthood.** The penile stretched lengths from birth to adulthood are listed in Table 131–2.

Table 131–1.

Male Genital Anomalies That Commonly Occur in Various Syndromes (Microphallus, Hypospadias, Ambiguous Genitalia, and Bifid Scrotum)

ANOMALY	FEATURES
Anencephaly	
Aniridia–Wilms tumor association	WAGR syndrome: Wilms tumor, Aniridia, Genitourinary abnormalities or gonadoblastoma, and mental Retardation
Bladder exstrophy	
Börjeson-Forssman-Lehman syndrome	Microcephaly, mental retardation, large ears
Carpenter syndrome	Acrocephaly, polydactyly and syndactyly of feet, congenital heart disease
CHARGE association	Coloboma, Heart malformation, Atresia choanae, Retarded growth and development, Genital anomalies, Ear anomalies and/or deafness
Cloacal syndrome	
Fraser syndrome	Cryptophthalmos, mental retardation, ear anomalies
Johanson-Blizzard syndrome	Hypoplastic alae nasi, hypothyroidism, mental retardation, pancreatic insufficiency, deafness
Meckel-Gruber syndrome	Occipital encephalomeningocele, micrognathia, polydactyly, cystic renal dysplasia
Noonan syndrome	Webbed neck, pectus excavatum, pulmonic stenosis, short stature
Opitz syndrome	Hypertelorism, hypospadias, mild to moderate mental retardation
Pallister-Hall syndrome	Hypothalamic hamartoblastoma, hypopituitarism, imperforate anus
Popliteal pterygium syndrome	Popliteal web, cleft palate, lower lip pits
Prader-Willi syndrome	Hypotonia, obesity, small hands and feet, mild to moderate mental retardation
Rapp-Hodgkin ectodermal dysplasia syndrome	Hypohidrosis, oral clefts, dysplastic nails
Rieger syndrome	Iris dysplasia, hypodontia
Robinow syndrome	"Fetal face syndrome"; flat facial profile, hypertelorism, short forearms, thoracic hemivertebrae
Schinzel-Giedion syndrome	Growth deficiency, mental retardation, widely patent fontanelles, short forearms and legs, renal anomalies
Smith-Lemli-Opitz syndrome	Ptosis of eyelids, syndactyly of second and third toes, microcephaly, failure to thrive with short stature, mental retardation
Triploidy syndrome	
Trisomy 4p, 9p, 18, 20p, 21, 22, 9p, 10q, 11p, or 15q deficiency

Data from Feldman KW, Smith DW. Fetal phallic growth and penile standards for newborn male infants. J Pediatr 1975;86:895; Schonfeld WA, Beebe GW. Normal growth and variation in the male genitalia from birth to maturity. J Urol 1987;30:554; and Tuladhar R, Davis PG, Batch J, Doyle LW. Establishment of a normal range of penile length in preterm infants. J Paediatr Child Health 1998;34:471.

Tanner stages are a set of recognizable changes that occur to pubic hair, penis, and testes during puberty that are helpful in evaluating patients (Table 131–3). The stages range from preadolescent penis and testes with no pubic hair (stage 1) to adult-size penis and scrotum with adult pubic hair distribution (stage 5).

PENILE ANOMALIES

Prepuce (Foreskin)

Phimosis and Paraphimosis

At birth, a physiologic phimosis (Fig. 131–2A) with either partial or complete inability to retract the prepuce exists owing to natural adhesions between the glans and inner preputial skin and/or due to a preputial ring. Two factors are involved in the separation of the prepuce from the glans: (1) epithelial debris, referred to as smegma, accumulates during the first 3 to 4 years of age under the prepuce, and (2) intermittent penile erections. **Preputial retractability increases with age, with 90% of uncircumcised boys 3 years of age with completely retractable prepuces and less than 1% by 17 years of age with phimosis** (Oster, 1968; Kayaba et al, 1996). **Therefore, primary phimosis is almost always resolvable during childhood without intervention.** Secondary phimosis can result from several causes, including forceful retraction and balanitis xerotica obliterans (BXO). Forceful preputial retraction is usually not recommended because it can result in a cicatrix of the prepuce.

Penile problems associated with the uncircumcised penis include paraphimosis, infection, urinary tract infection (UTI), and cancer. Paraphimosis (Fig. 131–2B), the entrapment of the prepuce behind the glans penis, can result in gangrene if not reduced in a timely fashion by manipulation, dorsal slit procedure, or circumcision. Severe edema of the foreskin occurs within several hours, depending on the tightness of the tip of the foreskin, and makes reduction more difficult. In most cases, manual compression of the glans with placement of distal traction on the edematous foreskin allows reduction of the paraphimotic ring. Other treatments include application of an iced glove for 5 minutes, application of granulated sugar for 1 to 2 hours, and placement of multiple punctures in the edematous skin (Mackway-Jones and Teece, 2004).

Indications to enhance preputial retractability include persistent primary phimosis, secondary phimosis, balanitis, posthitis (i.e., inflammation of the prepuce), BXO, and UTIs. Several topical corticosteroid creams using different regimens have been successfully used to treat phimosis with a relatively small number of side effects. Palmer and Palmer (2008) compared the efficacy of two different topical betamethasone treatment regimens with respect to outcome and untoward effects. Children were treated twice daily for 30 days (i.e., 60 doses) or three times daily for 21 days (63 doses). There was an 84.5% and 87% response rate, respectively. Only one child had an untoward effect (candidal dermatitis).

Table 131–3.

Tanner Classification of Sexual Maturity Stages in Boys

STAGE	PUBIC HAIR	PENIS	TESTES
1	None	Preadolescent	Preadolescent
2	Scanty, long	Slight enlargement; slightly pigmented	Enlarged scrotum, pink, texture altered
3	Darker, starts to curl, small amount	Longer	Larger
4	Resembles adult type but less in quantity; coarse, curly	Larger; glans and breadth increase in size	Larger, scrotum dark
5	Adult distribution, spread to medial surface of thighs	Adult size	Adult size

Modified from Tanner JM. Growth at adolescence. 2nd ed. Oxford (UK): Blackwell Scientific Publications; 1962.

Circumcision

Circumcision dates back more than 6000 years ago with the oldest documented evidence thought to date to sixth dynasty (2345-2181 BC) tomb artwork in Egypt. Since that time different religions, countries, and cultures have adopted various views on circumcision (Palmer, 2009a). Many theories have been proposed

Figure 131–2. Conditions associated with the uncircumcised penis. **A,** Phimosis due to a preputial ring. **B,** Paraphimosis with associated entrapped prepuce behind the glans penis.

to the etiology of circumcision, including as a religious sacrifice, rite of passage, aid to hygiene, a way to differentiate cultural groups, and a method to discourage masturbation.

Elective circumcision in the neonate is a controversial topic. **In 1989 the AAP concluded, "Newborn circumcision has potential medical benefits and advantages as well as disadvantages and risks. When circumcision is being considered, the benefits and risks should be explained to the parents and informed consent obtained"** (AAP Task Force on Circumcision, 1989). More recently, the AAP again updated its policy statement (AAP Task Force on Circumcision, 1999; Lannon et al, 2000). Its position was essentially unchanged, with the exception that it emphasized the importance of local anesthesia for the procedure. The AAP does not endorse routine circumcision.

There are several techniques for neonatal circumcision, including the Gomco clamp, Mogen clamp, and Plastibell device. There should be complete separation of the prepuce from the glans with complete visualization of the meatus and circumferential visualization of the corona to confirm that there are no anomalies, including hypospadias. **When neonatal circumcision is performed, local anesthesia is recommended.** Available options include the topical application of a cream containing eutectic mixture of local anesthetic (EMLA; lidocaine and prilocaine), a dorsal penile nerve block, and a penile ring block (Hardwick-Smith et al, 1998). Randomized controlled trials have demonstrated that a dorsal penile nerve block is more effective than EMLA cream (Howard et al, 1999; Taddio et al, 2000) because prilocaine in the EMLA cream poses a low risk for methemoglobinemia (Couper, 2000). Circumcision can be performed under local anesthesia even in older boys. For example, Jayanthi and colleagues (1999) reported a series of 287 infants aged 3 days to 9 months (20% older than 3 months) who underwent office circumcision with local anesthesia. However, typically older infants and children are circumcised under general anesthesia rather in the office using a free-hand sleeve resection technique.

Circumcision should not be performed in neonates with other penile conditions that require surgical correction. These conditions include hypospadias, penile curvature, dorsal hood deformity, buried penis, and webbed penis (see the corresponding sections). Other conditions commonly seen in neonates that should be taken into consideration are a large hydrocele or inguinal hernias, which are more likely to develop secondary phimosis, buried penis, and trapped penis. A patient with a coagulopathy is another contraindication.

Circumcision has several potential benefits, including the prevention of penile cancer, UTIs, sexually transmitted diseases including human immunodeficiency virus (HIV) infection, and phimosis, as well as lessening of the risk of balanitis. Although some have alleged that neonatal circumcision can lead to sexual dysfunction, long-term studies have not supported this view (Fink et al, 2002; Bleustein et al, 2005). Schoen and associates (2006) determined that neonatal circumcision has a cost benefit compared with postneonatal circumcision, including procedure charges and reduction in future health care costs.

Carcinoma of the penis develops almost exclusively in men who are not circumcised at birth. Phimosis is a significant risk factor (Tsen et al, 2001). Schoen and coworkers (2000b) reported that of 89 men in a large health maintenance organization with invasive penile cancer, only 2 (2%) had been circumcised at birth. Furthermore, of 116 men with penile carcinoma in situ, 16 (14%) had had a neonatal circumcision.

Uncircumcised neonates and infants are predisposed to UTIs (Singh-Grewal et al, 2005). In a study of 100 neonates with a UTI, Ginsburg and McCracken (1982) found that only 3 (5%) of the 62 boys who developed a UTI were circumcised. Subsequently, Wiswell and colleagues (1985) studied more than 2500 male infants and found that 41 had symptomatic UTIs; 88% of these infants were uncircumcised. Uncircumcised boys were almost 20 times more likely than circumcised neonates to develop a UTI. Other studies of larger groups of infants have confirmed these reports (Wiswell, 2000; Zorc et al, 2005) and have demonstrated that neonatal circumcision is less costly than treating UTIs in uncircumcised boys (Schoen et al, 2000a). The increased risk seems to affect boys at least through 5 years of age (Craig et al, 1996), and the incidence of epididymitis is reduced (Bennett et al, 1998). The increased risk of UTIs can be attributed to colonization of the prepuce by urinary pathogens (Gunsar et al, 2004; Bonacorsi et al, 2005). It has been calculated that it takes 111 neonatal circumcisions to prevent one UTI (Singh-Grewal et al, 2005). However, Shim and colleagues (2009) evaluated 190 infants with confirmed normal urinary systems and diagnosed with their first febrile UTI. They assessed the incidence of recurrent UTI during the following year and several risk factors, including acute pyelonephritis. In infants with persistent nonretractile prepuces, recurrent UTI developed in 34%, compared with 17.6% of infants with retractile prepuces.

Whether circumcision reduces the risk of sexually transmitted diseases has been controversial. Several recent reports of a large population of men have demonstrated reduced incidence of HIV infection among men, with a protective effect of 60% (Gray et al, 2007; Bailey et al, 2007). However, a recent study compared 922 uncircumcised, HIV-infected, asymptomatic men in whom 474 underwent immediate circumcision with 448 who were not circumcised to evaluate transmission of HIV to HIV-uninfected female partners (Wawer et al, 2009). After 24 months of follow-up, 18% and 12% of women acquired HIV, respectively, thereby demonstrating that circumcision of HIV-infected men did not reduce HIV transmission to female partners. It has been reported that circumcision may reduce the risk of ulceration, bacterial vaginosis, and trichomonas in female partners (Gray et al, 2009).

Several clinical trials of the effect of circumcision on the prevention of human papillomavirus (HPV) infection, herpes simplex virus type 2 (HSV-2) infection, and other sexually transmitted diseases (Auvert et al, 2009; Nielson et al, 2009; Tobian et al, 2009) have been done. Tobian and associates (2009) evaluated 5534 HIV-negative, uncircumcised males, with 3393 being HSV-2 seronegative at enrollment. Of the 3393 men, 1684 underwent immediate circumcision while 1709 were not circumcised in order to evaluate HSV-2 and HPV transmission. At 24 months' follow-up, HSV-2 seroconversion was 7.8% and 10.3%, respectively, whereas prevalence of high-risk (carcinogenic) HPV genotypes was 18.0% and 27.9%, respectively. This study underscores the benefit of circumcision in reducing the incidence of HSV-2 infection and the prevalence of HPV infection.

Circumcision Complications

The risk of complications after circumcision is 0.2% to 5% (Baskin et al, 1996; Christakis et al, 2000; Ben Chaim et al, 2005). Complications can occur immediately or months to years after a circumcision. **The most common complication is bleeding, which occurs in 0.1% and is more common in older children.** There usually is bleeding from the frenulum or, less frequently, from a large blood vessel on the penile shaft. The

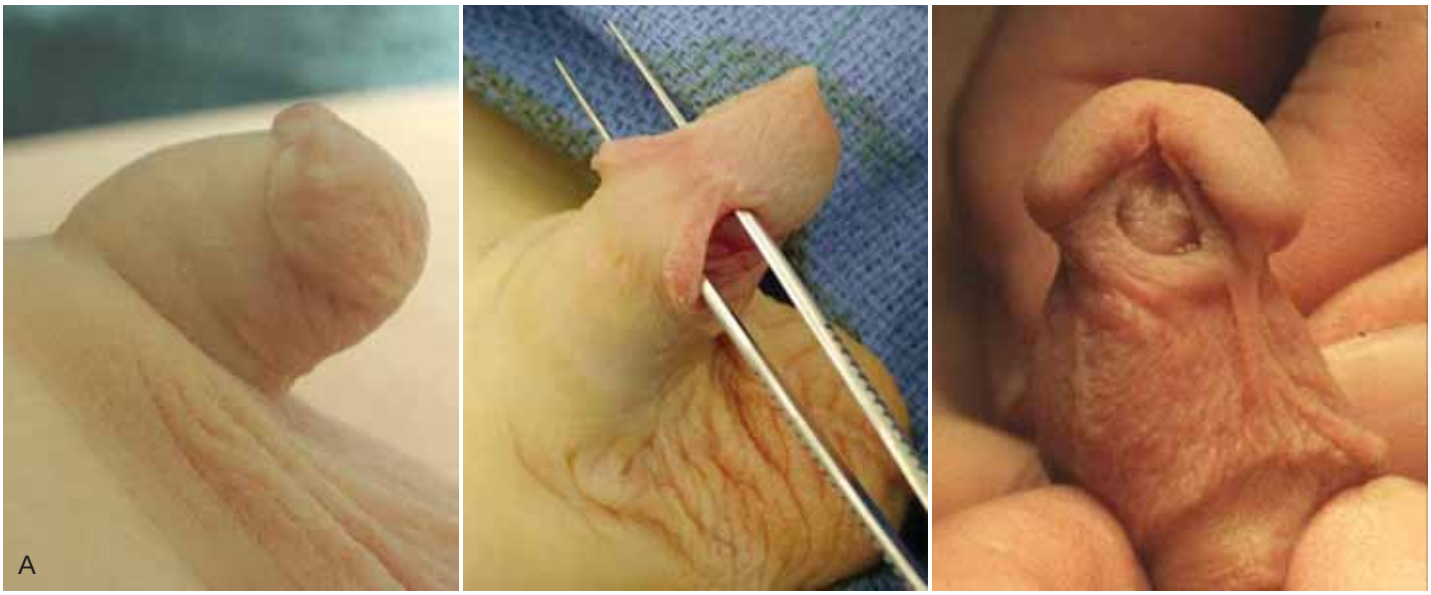

Figure 131–3. Complications associated with circumcision. **A,** Asymmetrical redundant penile skin. **B,** Penile skin bridge. **C,** Urethral and glanular resection.

Key Points: Circumcision

- Primary phimosis is almost always resolvable during childhood without intervention; less than 1% of 17-year-old boys have phimosis.
- Indications to enhance preputial retractability include persistent primary phimosis, secondary phimosis, balanitis, posthitis, BXO, and UTIs.
- The American Academy of Pediatrics does not endorse routine circumcision.
- When neonatal circumcision is performed, local anesthesia is recommended.
- Circumcision should not be performed in neonates with other penile conditions that require surgical correction or micropenis.
- Circumcision has several potential benefits, including the prevention of penile cancer, UTI, sexually transmitted disease including HIV infection, balanitis, and phimosis.
- In boys with phimosis, topical application of corticosteroid cream loosens the phimotic ring in 70% to 80%.

bleeding is usually self-limiting or may require compression. Occasionally cautery with an ophthalmic cautery or silver nitrate stick or a suture may be necessary. Wound infection is another complication, but it is rare and antibiotic ointment (e.g., bacitracin) use after circumcision usually prevents this from occurring. Also, penile degloving due to excess amount of skin removed or the edges of the penile skin not adhering to the mucosal collar can occur after circumcision. The penile shaft will usually epithelize, bridging the defect without any intervention other than the use of antibiotic ointment to the denuded region and warm baths to prevent eschar formation. Immediate suturing of the skin edges and skin grafting are not recommended to bridge the gap.

Penile Skin Complications. The amount of penile skin excised can also lead to complications after circumcision. Insufficient or asymmetrical prepuce excision can result in a cosmetic and social dilemma for the parents and child, especially as the child gets older (Fig. 131–3A). **Unlike neonatal circumcision, circumcision revision requires general anesthesia.** Several techniques have been described (Redman, 1995; Brisson et al, 2002; Ching and Palmer, 2008a). Excessive skin excision can result in penile chordee, torsion, and lateral deviation. These conditions, if necessary to repair, may require penile skin flaps or Z-plasty for closure. Excessive skin removal can also result in a trapped penis from a cicatricial scar. The trapped penis can be managed with betamethasone (Palmer et al, 2005), vertical relaxation incision, and formal repair. The use of 0.05% betamethasone in conjunction with manual retraction in children with a trapped penis due to a dense cicatrix of the residual foreskin distal to the glans has a 79% success in softening of the cicatrix with easy exposure of the glans or mild persistence of the cicatrix amenable to vertical relaxation incision (Palmer et al, 2005). Surgical correction includes excision of the cicatrix with possible need for penile skin flaps or Z-plasty for closure.

Glanular Adhesions and Skin Bridges. Glanular adhesions and skin bridges, attachments of the glans and penile shaft, are also common complications associated with circumcision and are usually noticed by the caregiver or primary medical provider. **Both can occur in the well-circumcised penis and are usually the result of the physiologic retraction of the penis due to a suprapubic fat pad and diaper irritation of the penis.** Glanular adhesions are attachments between the inner prepuce or circumcision incision line attaching to the glans with an incidence decreasing with age owing to epithelial separation of the adhesions (71% of infants, 28% of 1- to 5-year-olds, 8% of 1- to 9-year olds, and 2% of children older than age 9 years) (Van Howe, 1997; Ponsky et al, 2000). **Persistent adhesions can be lysed in the office with the application of topical analgesia such as EMLA cream and Pain Ease (Gebauer Company; 1,1,1,3,3-pentafluoropropane, 1,1,1,2-tetrafluoroethane)** (Palmer, 2009b). **Use of low-dose corticosteroids has been relatively unsuccessful in lysing adhesions.** Skin bridges (Fig. 131–3B) are epithelized adhesions that can lead to penile chordee and torsion, which can be excised

in the office with the application of analgesia (Palmer, 2009b) or in the operating room with the use of general anesthesia and may require suturing of the glanular and shaft defects.

Meatal Stenosis. **Meatal stenosis is a condition that occurs in children almost only after circumcision during infancy** (Fig. 131–4A). It can be congenital, which occurs primarily in neonates with hypospadias, or acquired. **The normal urethral meatus is 10 French before 4 years of age, 12 French from 4 to 10 years of age, and 14 French after 10 years of age** (Litvak et al, 1976); **this can be calibrated with a bougie à boule or sound.** There are several proposed causes of secondary meatal stenosis. One theory is that after disruption of the normal adhesions between the prepuce and glans and removal of the foreskin a significant inflammatory reaction occurs, resulting in a severe meatal inflammation and cicatrix formation. Other theories are frenular devascularization or chronic meatitis from diaper irritation of the exposed, unprotected meatus (Persad et al, 1995; Hensle, 1996). BXO is another cause of meatal stenosis (see later). A relatively small percentage of children will develop symptomatic meatal stenosis after neonatal circumcision. **Symptoms include (1) typical urinary stream deviation in an upward direction resulting from a meatal baffle** (Fig. 131–4B) **or ventral web located at the inferior of the meatus, (2) a narrow, high-velocity stream, and (3) penile pain at the initiation of micturition.** Urinary tract imaging usually does not reveal any obstructive changes in the urinary tract without other urologic issues but may be indicated for associated UTI or urinary incontinence. Meatotomy or meatoplasty to treat secondary meatal stenosis can be performed in the office with the use of topical lidocaine and prilocaine (EMLA) (Cartwright et al, 1996) or under general anesthesia by making a ventral incision long enough to create a normal meatal caliber. The suturing of the urethral mucosa to the glans with fine, rapidly absorbable sutures tends to reduce the risk of recurrence.

Penile Trauma. The most serious complications associated with circumcision are penile trauma, including urethral injury, excision of the glans and/or penile shaft, and penile necrosis (see Fig. 131–3C). Urethral injury requires a urethroplasty with the technique dependent on the severity of the excision. **Excision of the glans can be repaired by suturing the excised tissue back to the penis without usually requiring the need for microscopic repair** (Sherman et al, 1996) **and with usually good results if performed within 8 hours.** Penile necrosis can result from thermal injury due to several causes, including cautery contacting the metal ring applied to the prepuce being excised or the inappropriate use of lasers to perform a circumcision. Several options are available without ideal outcomes, including penile reconstruction and female gender reassignment with bilateral orchiectomy (Gearhart and Rock, 1989; Bradley et al, 1998). Although the cosmetic and functional results of phallic reconstruction have advanced, they are still being refined (De Castro et al, 2007; Hoebeke et al, 2009). The issues with gender reassignment can include these children growing up with a male identity believed to result from in-utero and neonatal androgen imprinting (Reiner, 1996; Diamond and Sigmundson, 1997; Diamond, 1999).

Balanitis Xerotica Obliterans. **Lichen sclerosus et atrophicus, or BXO, is a chronic infiltrative and cicatrizing skin condition resulting in pathologic phimosis** (Chalmers et al, 1984) (Fig. 131–5). **BXO can also affect the glans and meatus, as well as the urethra.** The inability to retract the prepuce is the common presentation at puberty and is rare in children younger than 5 years of age (Oster, 1968). Other presenting symptoms include local infection, irritation, discomfort after micturition, bleeding, and occasionally acute urinary retention or urinary incontinence (Bale et al, 1987). Older patients and those with BXO involving the meatus may have a more severe clinical course (Gargollo et al, 2005). The etiology of BXO has not been determined; there is no identified viral or bacterial cause or familial predisposition. The association of BXO and penile cancer in children is also not established.

Treatment of BXO includes medical and surgical management. The use of topical corticosteroids has had limited benefit to treat mild BXO of the prepuce with minimal scar formation (Vincent and Mackinnon, 2005). **Circumcision is the preferred treatment along with meatotomy or meatoplasty if there is**

Figure 131–4. Meatal complications associated with circumcision. **A,** Meatal stenosis. **B,** Meatal baffle.

meatal involvement. Children with meatal involvement should be observed postoperatively because of the risk of recurrent meatal stenosis.

Key Points: Circumcision Complications

- The risk of complications after circumcision is 0.2% to 5%, with the most common complication being bleeding.
- Unlike neonatal circumcision, circumcision revision requires general anesthesia.
- Meatal stenosis is a condition that occurs almost only in children after circumcision in infancy.
- Unlike the treatment of primary phimosis, corticosteroid cream does not cause separation of secondary glanular adhesions after circumcision.
- The normal urethral meatus is 10 French before 4 years of age, 12 French from 4 to 10 years of age, and 14 French after 10 years of age.
- Lichen sclerosus et atrophicus or balanitis xerotica obliterans is a chronic infiltrative and cicatrizing skin condition resulting in pathologic phimosis.

Abnormal Penile Number

Aphallia

Penile agenesis results from failure of development of the genital tubercle (Roth et al, 1981) (Fig. 131–6). The disorder is rare and has an estimated incidence of 1 in 10 to 30 million births. **The karyotype almost always is 46,XY, and the usual appearance is that of a well-developed scrotum with descended testes and an absent penile shaft.** The anus is usually displaced anteriorly. The urethra often opens at the anal verge adjacent to a small skin tag, or it can open into the rectum. The incidence of stillbirth or neonatal death is approximately one third of cases (Gilbert et al, 1990).

Associated malformations are common and include cryptorchidism, vesicoureteral reflux, horseshoe kidney, renal agenesis, imperforate anus, and musculoskeletal and cardiopulmonary abnormalities (Skoog and Belman, 1989; Evans et al, 1999). The connection between the genitourinary and gastrointestinal tract is variable. Skoog and Belman (1989) reviewed 60 reports of aphallia and found that the more proximal the urethral meatus, the greater the likelihood of neonatal death and the higher the incidence of other anomalies. Sixty percent of patients had a postsphincteric meatus located on a peculiar appendage at the anal verge. This group of patients had the highest survival rate (87%) and the lowest incidence of other anomalies (1.2 per patient). Twenty-eight percent of patients had presphincteric urethral communications (prostatorectal fistula), and there was a 36% neonatal mortality rate. Twelve percent had urethral atresia and a vesicorectal fistula for drainage. This group had the highest incidence of other anomalies and a 100% mortality rate.

Children with this lesion should be evaluated immediately by a multidisciplinary approach. Testing should include a karyotype and other appropriate studies to determine whether there are associated malformations of the urinary tract or other organ systems. Magnetic resonance imaging (MRI) may be beneficial in determining the severity of the defect (Lapointe et al, 2001). Prompt gender assignment is important. Some of these patients have a male gender identity despite reconstruction as a female, presumably because of in-utero or postnatal sex steroid imprinting (Reiner, 1996; Diamond and Sigmundson, 1997; Diamond, 1999).

Figure 131–6. **A**, Neonate with aphallia. **B**, Urethral meatus at skin tag on anal verge.

Consequently, the recommendation to perform gender reassignment should be made carefully and only after full evaluation by an ambiguous genitalia assessment team and parental counseling. As a male the patient would potentially be fertile, but currently there is an inability to construct a cosmetically acceptable phallus that would allow normal urinary, sexual, and reproductive function (De Castro et al, 2007; Hoebeke et al, 2009). Gender reassignment involves orchiectomy and feminizing genitoplasty in the neonatal period (Gluer et al, 1998; Bruch et al, 1996). At a later age, construction of a neovagina is necessary. Urinary tract reconstruction with simultaneous construction of an intestinal neovagina through a posterior sagittal and abdominal approach in patients with penile agenesis has been described (Hensle and Dean, 1992; Hendren, 1997).

Diphallia

Duplication of the penis is a rare anomaly with an incidence of 1 in 5 million live births (Hollowell et al, 1977) **and has a range of appearances from a small accessory penis to complete duplication** (Gyftopoulos et al, 2002). In some cases, each phallus has only one corporeal body and urethra, whereas others seem to be a variant of twinning, with each phallus having two corpora cavernosa and a urethra. The penises are usually unequal in size and lie side by side. Other associated anomalies are common, including hypospadias, bifid scrotum, bladder duplication, renal agenesis or ectopia, and diastasis of the pubic symphysis (Maruyama et al, 1999). Anal and cardiac anomalies are also common. **Evaluation should include imaging of the entire urinary tract, including a renal ultrasonogram and voiding cystourethrogram.** Ultrasonography and MRI can also be done to assess penile development (Marti-Bonmati et al, 1989; Lapointe et al, 2001). The etiology has not been delineated. Treatment must be individualized with consideration of the associated anomalies with the goal of attaining a satisfactory functional and cosmetic result (Dean and Horton, 1991).

Inconspicuous Penis

An inconspicuous penis refers to a penis that appears to be small with a normal stretched penile length measured from the pubic symphysis to the tip of the glans (see Table 131–2) **and normal diameter of the penile shaft** (Bergeson et al, 1993). This condition can be congenital or acquired and is usually of great concern for parents. Several entities are included in this disorder, including buried penis, trapped penis, and webbed penis (Palmer and Kogan, 1995). **These conditions must be differentiated from micropenis, in which the penis is abnormally small.** When an infant has an inconspicuous penis, prompt evaluation is necessary for proper treatment and the family must be informed as to whether the penis is or is not normal. The stretched penile length should be measured from the pubic symphysis to the tip of the glans. In addition, the diameter of the penile shaft may be measured by palpation.

Buried Penis

A buried penis, also referred to as hidden or concealed penis, is a form of inconspicuous penis (Cromie et al, 1998). A buried penis is a normally developed penis that is hidden away by the suprapubic fat pad. **This condition can be classified into three categories based on etiology for the concealment** (Maizels et al, 1986; Casale et al, 1999): **(1) poor penopubic fixation of the skin at the base of the penis, (2) obesity, and (3) a trapped penis from cicatricial scarring after penile surgery, typically a circumcision.**

The congenital form of buried penis is believed to be due to the inelasticity of the dartos fascia, which normally allows the penile skin to slide freely on the deep layers of the shaft, with restricted extension of the penis because the penile skin is not anchored to the deep fascia (Fig. 131–7). The acquired form from obesity typically seen in older children and adolescents is due to abundant fat on the abdominal wall hiding the penile shaft. The other acquired form, a trapped penis, results from embedding of the penis in the

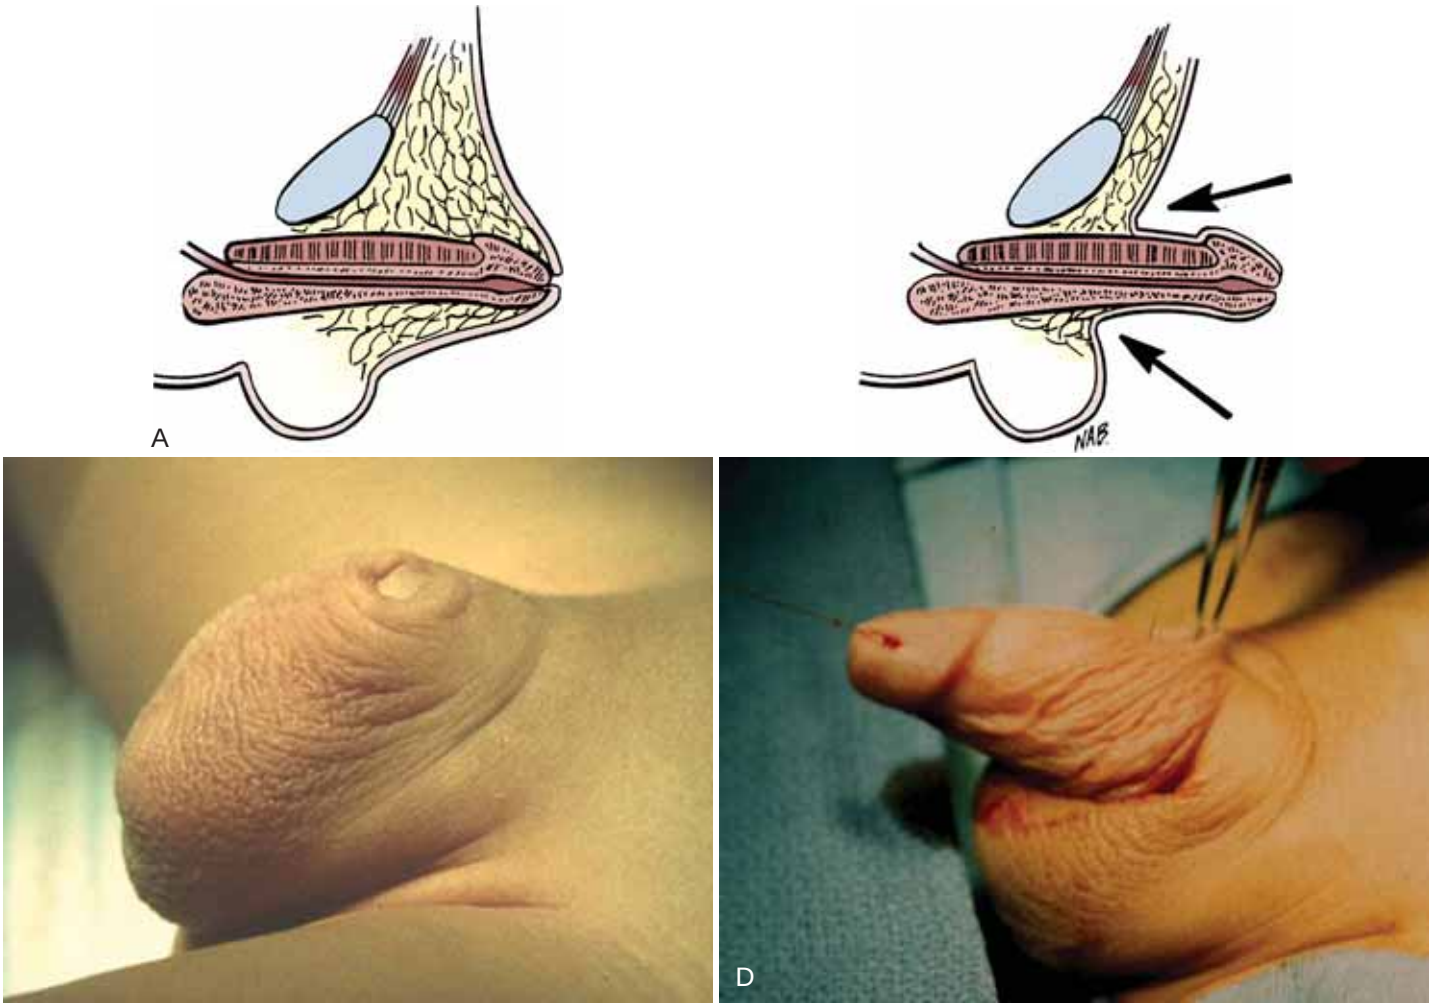

Figure 131–7. Buried penis (**A** and **C**), which may be visualized by retraction of the skin lateral to the penile shaft (**B** and **D**).

suprapubic fat pad from scar formation over the glans. This deformity may occur after neonatal circumcision in an infant with significant scrotal swelling due to a hernia or hydrocele or after routine circumcision in an infant with a webbed penis. Also, in some neonates the penile shaft seems to retract naturally into the scrotum; and if circumcision is performed in this situation, the skin at the base of the penis may form a cicatrix over the retracted phallus. This condition should be differentiated from a transient buried penis resulting from a large suprapubic fat pad noted in early childhood that resolves with increased age and ambulation (Eroglu et al, 2009).

On examination, a buried penis must be differentiated from a micropenis, with the latter not having a normal penile stretched length. The clinician should determine whether the glans can be exposed by retracting the skin covering the glans (see Fig. 131–7). If so, it remains the surgeon's judgment whether correction is warranted. However, if the penis is trapped by physiologic phimosis in the uncircumcised or cicatricial scarring (Fig. 131–8A) in the circumcised penis, this increases the chance of difficulty voiding, maintaining proper hygiene, balanitis, UTIs, and psychosocial issues (Fig. 131–8B) (Kon, 1983).

The treatment options for children with buried penis are based on etiology. Patients with buried penis secondary to obesity should have the underlying condition treated. Referral of the child back to the primary care provider for a weight loss and exercise program is essential, with surgical intervention usually not necessary. Young children with secondary cicatricial scarring after penile surgery can be managed with forceful dilation of the cicatrix with a fine hemostat in the office after the application or injection of analgesia. Another option is the combination of topical betamethasone and manual retraction (Palmer et al, 2005). This combination may result in complete resolution of the condition in the majority of boys or may release the closing cicatrix and allow for a simple incision of the constricting phimotic ring, thus reducing the need for formal surgical repair by 79%. If topical corticosteroid application is ineffective, correction under general anesthesia is necessary with the usually recommendation of elective repair when the child is at least 6 months of age. The surgical technique is similar to that for the congenital buried penis.

A number of surgical techniques have been described to correct the buried penis (Maizels et al, 1986; Casale et al, 1999; Elder, 2001; Frenkl et al, 2004; Gillett et al, 2005; Borsellino et al 2007; Karapetian and Palmer, 2007). The indications and timing for reconstructive surgery are controversial. In moderately severe cases the dysgenic bands of tissue, which are located primarily on the dorsal surface of the shaft of the penis, must be removed. The prepuce should be unfurled and used for ventral skin coverage. In addition, the subcutaneous tissue on the dorsal aspect of the penis should be fixed to the pubic fascia and then the subcutaneous tissue of the scrotum should be fixed to the ventral aspect of the

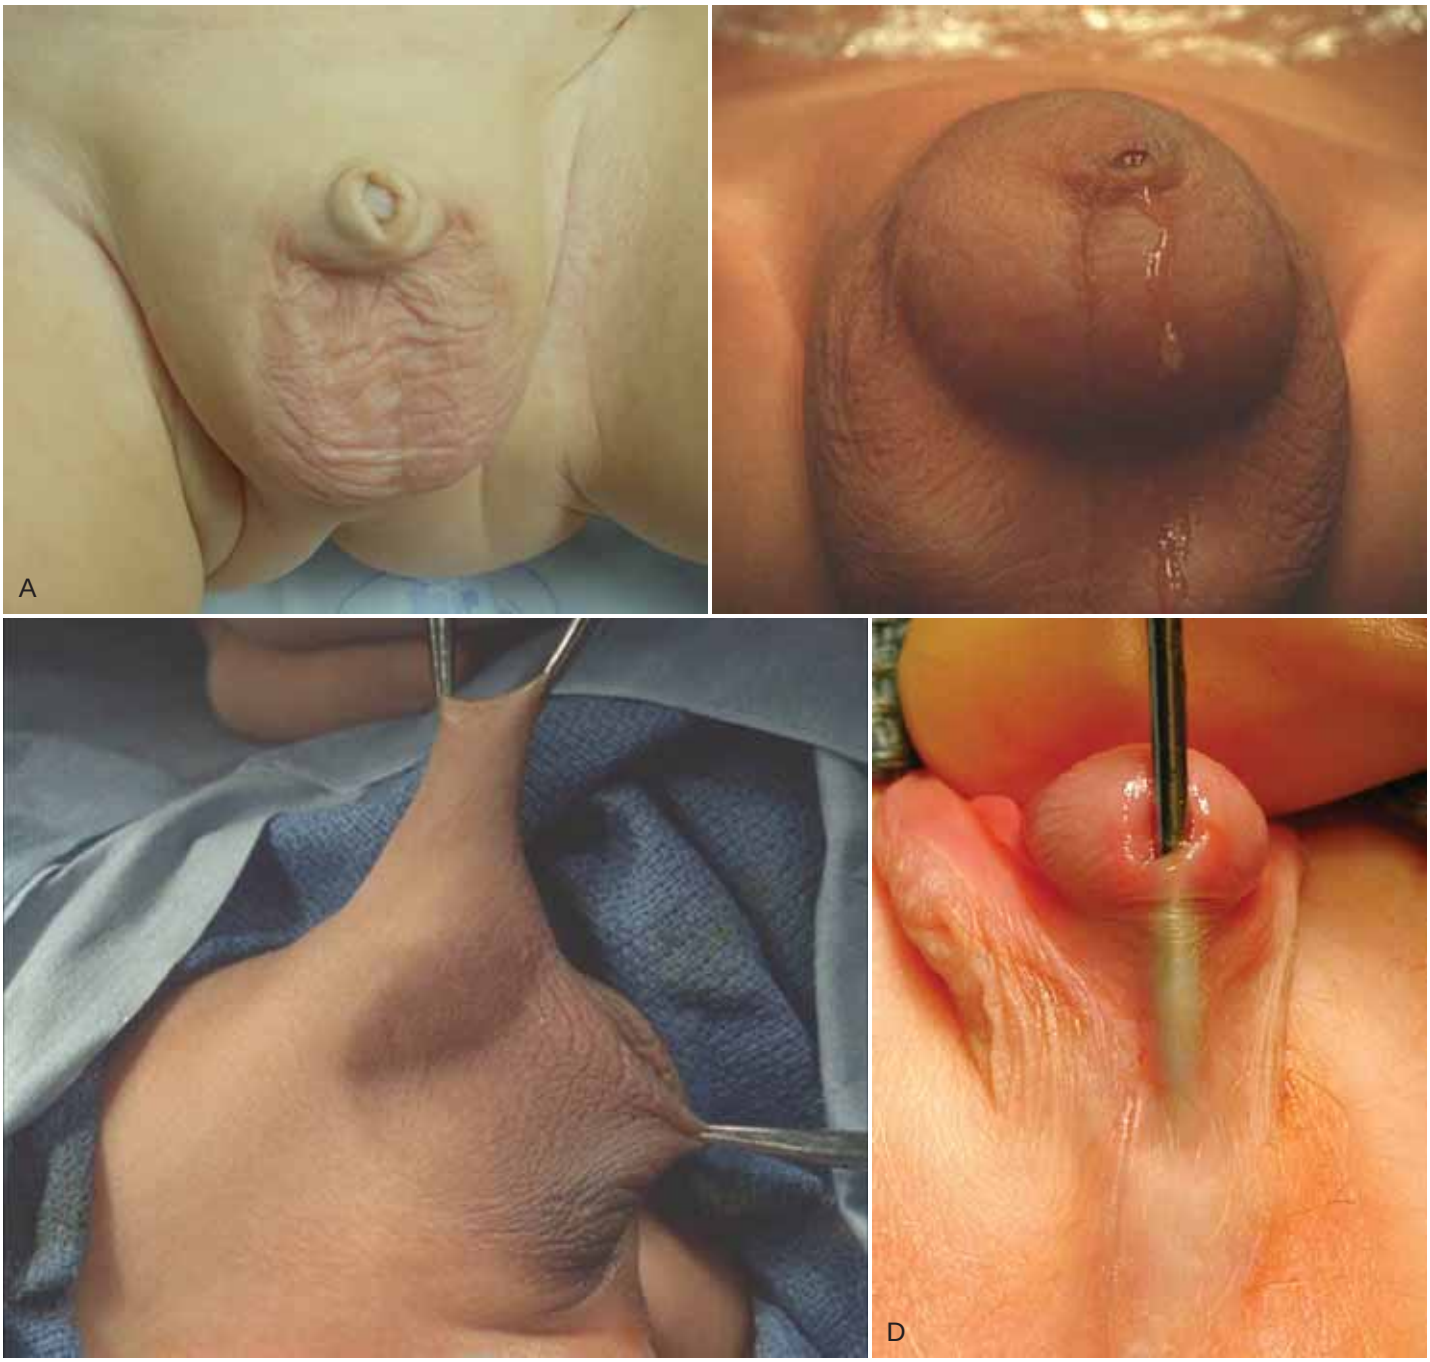

Figure 131–8. Inconspicuous penis. **A,** Trapped penis by cicatricial scarring resulting from neonatal circumcision. **B,** Urine pooling due to cicatricial scarring, increasing susceptibility to urinary tract infections. **C,** Penoscrotal web resulting in a webbed penis. **D,** Webbed penis with hypoplastic distal urethra.

base of the penile shaft with nonabsorbable suture. During correction one must be careful to avoid injury to the neurovascular bundles (Baskin, 1999; Baskin et al, 2000). Skin coverage can also be accomplished by penoscrotal Z-plasty, lateral penile shaft Z-plasty, island pedicle of ventral preputial skin, or a skin graft. Rarely in the most severe cases the suspensory ligament of the penis must be divided, the suprapubic fat excised, and the spermatic cords protected. Liposuction has been reported to be helpful in severe cases (Maizels et al, 1986; Shenoy et al, 2000). However, this technique should be reserved for adolescent boys because prepubertal boys may lose their fat pad with somatic growth.

Webbed Penis

Webbed penis, also known as penoscrotal fusion, is a congenital or acquired condition resulting from the scrotal skin extending onto the ventrum of the penis. The congenital form of a penoscrotal web represents an abnormality of the attachment between the penis and the scrotum, whereas the penis, urethra, and remainder of the scrotum are normal (Fig. 131–8C). The acquired condition results from circumcision or other penile surgery due to excessive removal of ventral penile skin.

Although the penoscrotal web is usually asymptomatic, the cosmetic appearance is often unacceptable. There are several

surgical techniques that can be implemented to correct this condition. Similar to the treatment of a buried penis, one technique involves the fixation of the subcutaneous tissue of the scrotum to the ventral aspect of the base of the penile shaft with nonabsorbable suture. On occasion, this condition may be corrected by incision of the web transversely, separation of the penis from the scrotum, and closure of the skin vertically. In other cases a circumferential incision is made 1.5 cm proximal to the coronal sulcus, a Byar preputial skin flap is transferred to the ventral surface of the penis, and the redundant foreskin is excised. In rare cases the distal urethra is hypoplastic, necessitating urethral reconstruction (Fig. 131–8D).

Micropenis

Micropenis is a normally formed penis that is at least 2.5 standard deviations (SD) below the mean size in stretched length for age (Aaronson, 1994) (Fig. 131–9). The ratio of the length of the penile shaft to its circumference is usually normal, but occasionally the corpora cavernosa are severely hypoplastic. The testes are usually small and frequently cryptorchid, whereas the scrotum is usually fused and often diminutive.

Stretched penile length is used because it correlates more closely with erectile length than does the relaxed penile length. The measurements should be compared with standards for penile length (see Table 131–2). Stretched penile length is determined by measuring the penis from its attachment to the pubic symphysis to the tip of the glans. One must be careful to depress the suprapubic fat pad completely to obtain an accurate measurement, especially in an obese infant or child. **In general, the penis of a full-term neonate should be at least 1.9 cm long.** One must differentiate buried penis or webbed penis from the micropenis, with the former having a normal penile shaft.

Micropenis results from a hormonal abnormality that occurs after 14 weeks of gestation. Differentiation of the male external genitalia is complete by the 12th week of gestation and requires a normal testis producing testosterone, stimulated by maternal human chorionic gonadotropin (hCG). During the second and third trimesters, growth of the penis occurs under the direction of fetal androgen, which is controlled by the secretion of fetal luteinizing hormone (LH). An abnormality in the production or use of testosterone results in a small penis and hypospadias, whereas a true micropenis often seems to be a consequence of a deficiency of gonadotropic hormones.

The causes of micropenis are numerous (Table 131–4) and include isolated gonadotropin defects without involvement of other organ systems and generalized endocrinopathies that may be associated with central nervous system defects. **The most common causes of micropenis are hypogonadotropic hypogonadism, hypergonadotropic hypogonadism (primary testicular failure), and idiopathic** (Lee et al, 1980b). Furthermore, micropenis is often associated with major chromosomal defects, including Klinefelter syndrome (47,XXY) and other X polysomy syndromes, deletions, translocations, and trisomy involving chromosomes 8, 13, and 18 (Aaronson, 1994).

Figure 131–9. Micropenis resulting from hypogonadotropic hypogonadism.

Table 131–4.

Etiology of Micropenis

Deficient Testosterone Secretion
Hypogonadotropic hypogonadism
Isolated, including Kallmann syndrome
Associated with other pituitary hormone deficiencies (e.g., CHARGE association)
Prader-Willi syndrome
Laurence-Moon syndrome
Bardet-Biedl syndrome
Rud syndrome
Primary hypogonadism
Anorchia
Klinefelter syndrome and poly X syndrome
Gonadal dysgenesis (incomplete)
Luteinizing hormone receptor defects (incomplete)
Genetic defects in testosterone steroidogenesis (incomplete)
Noonan syndrome
Down syndrome
Robinow syndrome
Bardet-Biedl syndrome
Laurence-Moon syndrome
Defects in Testosterone Action
Growth hormone/insulin-like growth factor 1 deficiency
Androgen receptor defects (incomplete)
5α-Reductase deficiency (incomplete)
Fetal hydantoin syndrome
Developmental Anomalies
Aphallia
Cloacal exstrophy
Idiopathic
Associated with Other Congenital Malformations

Modified from Bin-Abbas B, Conte FA, Grumbach MM, Kaplan SL. Congenital hypogonadotropic hypogonadism and micropenis: effect of testosterone treatment on adult penile size—why sex reversal in not indicated. J Pediatr 1999;134:579.

The most common cause of micropenis is hypogonadotropic hypogonadism, which is the failure of the hypothalamus to produce an adequate amount of gonadotropin-releasing hormone (GnRH). This condition may result from hypothalamic dysfunction, which can occur in Prader-Willi syndrome, Kallmann syndrome (genital-olfactory dysplasia), Laurence-Moon-Biedl syndrome (Walsh et al, 1978; Danish et al, 1980), and the CHARGE association (Ragan et al, 1999). Other causes include an associated growth hormone deficiency or neonatal hypoglycemia secondary to congenital hypopituitarism, congenital pituitary aplasia, and midline brain defects, such as agenesis of the corpus callosum and occipital encephalocele.

Primary testicular failure is another cause of micropenis. Micropenis secondary to hypergonadotropic hypogonadism may result from rudimentary testes syndrome or gonadal dysgenesis. It also occurs in Robinow syndrome (Lee et al, 1980b). **The test most frequently used to identify this subgroup is the failure of serum testosterone concentration to rise appropriately after stimulation by hCG.** However, in patients with Kallmann syndrome and cryptorchidism, the serum testosterone level may not increase after the administration of hCG. Rarely, a patient with partial androgen insensitivity syndrome has micropenis, but sexual ambiguity is more common. Micropenis may also result from improper timing or delayed onset of gonadotropin stimulation in the fetus (Lee et al, 1980a). These patients have an idiopathic form of micropenis and a normal hypothalamic-pituitary-testicular axis.

The initial evaluation of a child with micropenis should include a thorough medical history and a karyotype at birth. Accurate measurement of the penile length, palpation of the corporeal bodies, and evaluation for cryptorchidism are several important aspects of the physical examination. Consultation with a pediatric endocrinologist is also usually obtained to assist in the determination of the cause of the micropenis and to assess whether other abnormalities are also present. Several issues need to be addressed, including the growth potential of the penis and the etiology of the micropenis. The etiology may be testicular or central (hypothalamic-pituitary axis). **Testicular function may be assessed by measuring serum testosterone levels before and after hCG stimulation. Primary testicular failure produces an absent response and elevated basal concentrations of LH and follicle-stimulating hormone (FSH).** In some cases, a GnRH stimulation test is also performed. Anterior pituitary screening tests include serial measurements of serum glucose, sodium, potassium, and serum cortisol concentrations and thyroid function tests. The endocrine evaluation of patients with micropenis is not standardized. MRI of the head should be done to determine the anatomic integrity of the hypothalamus and the anterior pituitary gland as well as the midline structures of the midbrain.

Before extensive evaluation of the hypothalamic-pituitary-testicular axis, androgen therapy should be administered to determine the end organ response. In general, intramuscular testosterone enanthate is given for 3 months. Although prolonged treatment might advance skeletal maturation, short courses of treatment do not affect height. Transdermal testosterone also has been used in these patients (Choi et al, 1993). If androgen treatment in a neonate successfully increases the penis so that its size falls within the normal range, the effects at puberty have not been clearly delineated. In a mouse model of hypogonadotropic hypogonadal micropenis there was evidence that significant prepubertal exposure of the penis to androgens reduced the ultimate growth response to androgens (Husmann and Cain, 1994; McMahon et al, 1995). Bin-Abbas and coworkers (1999) described eight boys with micropenis who were treated with androgens both at birth and at puberty. The final penile stretched length averaged 10.3 cm and was in the normal range in all cases. Therefore, exogenous stimulation at birth and at puberty with testosterone enanthate seems most reasonable (Tietjen et al, 1998) and is recommended until longer-term studies are available.

If the penis does not respond to testosterone, gender reassignment is an option but is controversial. Previously, gender reassignment was recommended, but this position has more recently come under criticism owing to the implication that biologic factors during the prenatal period may have an impact in gender identity. One of the factors is testosterone-induced male brain imprinting (Diamond and Sigmundson, 1997). Therefore, the lack of long-term data regarding the risks and benefits of reassigning these patients to a female gender (Calikoglu, 1999; Diamond, 1999) has resulted in a conservative use of this treatment modality. Husmann (2004) described 20 adult men born with micropenis who had a suboptimal response to testosterone therapy and were raised as males. At adulthood, 90% had a micropenis and all had a male gender identity; five were undergoing psychiatric counseling for fear of rejection, and eight had not been sexually active.

Several studies have demonstrated that although ultimate penile size may not be within a normal range, men born with micropenis have a male gender identity and the majority can have satisfactory sexual function. Reilly and Woodhouse (1989) described 20 patients with a primary diagnosis of micropenis in infancy. Almost all had received androgen therapy during childhood, but none of the adults had a penis within the normal range of size. All of the boys stood to urinate. Parents of patients in the prepubertal group considered their children to be normal boys and thought that the penile appearance was satisfactory; however, they expressed concern about penile size and future sexual function. All of the patients in the adult group had a strong male identity, and 9 of the 12 patients were sexually active. In a study of 22 adult men born with micropenis, Lee and Houk (2004) had similar findings. Wisniewski and Migeon (2002) reported that their patients had a male gender identity but were generally dissatisfied with their genital appearance and function.

Key Points: Micropenis

- Micropenis is a normally formed penis that is at least 2.5 SD below the mean size in stretched length for age (i.e., <1.9 cm in a term neonate). A buried penis must be differentiated from a micropenis, with the former having a normal penile stretched length.
- The most common causes of micropenis are hypogonadotropic hypogonadism, hypergonadotropic hypogonadism (primary testicular failure), and idiopathic.
- Evaluation includes karyotype; determination of serum LH and FSH concentrations; measurement of testosterone levels before and after hCG stimulation; serum studies of anterior pituitary function; MRI of the head to assess the hypothalamus, anterior pituitary, and midbrain; and assessment of penile growth after androgen stimulation.
- If the penis does not respond to testosterone, gender reassignment is an option, but this is controversial.
- In adulthood, most men born with micropenis have male gender identity and satisfactory sexual function, even if penile size is less than what is considered in the normal range.

Abnormal Penile Orientation

Penile Curvature

Curvature of the penis may occur along the vertical (i.e., ventral or dorsal direction) or horizontal (i.e., lateral direction) plane of the penis. Penile curvature may be congenital or acquired from circumcision, other penile surgery, or trauma and has cosmetic significance and future sexual difficulties. **Penile curvature is most commonly in the ventral direction, referred to as *chordee*, and is commonly associated with hypospadias.** However, chordee may occur without hypospadias and with or without a dorsal hood of prepuce (Fig. 131–10) and is commonly associated with a deficiency of the ventral skin (Cendron and Melin, 1981). Ventral curvature in boys without hypospadias can generally be corrected by degloving of the penis, excision of fibrous tissue that is usually confined to the region superficial to Buck fascia, and development of a Byar flap for penile skin coverage as necessary. In more severe cases, simple dorsal plication, Nesbit dorsal excision, or corporeal rotation may be necessary. In the most severe cases the urethra is short and urethral reconstruction, for example, an interposition island flap of dorsal foreskin, must be performed. Intraoperative artificial erection with injectable normal saline may be necessary to confirm that complete chordee correction has been performed. Some cases of chordee may be aggravated by a prominent frenulum, resulting in distal penile chordee with ventral glanular deflection. In these cases, frenulotomy will improve and may correct the chordee.

Congenital dorsal penile curvature may be an isolated condition with or without asymmetrical penile skin or associated with epispadias and a ventral hood of prepuce. Some individuals may have hypospadias. Surgical repair of this condition without associated urethral anomalies is similar to chordee correction, involving degloving of the penis, excision of fibrous tissue that is usually confined to the region superficial to Buck fascia, and development of skin flaps for penile skin coverage as necessary. During correction, one must be careful to avoid injury to the neurovascular bundles (Baskin, 1999; Baskin et al, 2000). More severe cases involve plication and/or excision of ellipses from the ventral corporeal bodies. Intraoperative artificial erection may be necessary.

Lateral penile curvature is usually congenital and caused by overgrowth or hypoplasia of one corporeal body. However, asymmetrical penile skin excision or postoperative scarring after circumcision or other penile surgery may also be a secondary cause. Lateral penile curvature may be unrecognized until later in childhood because the penis is normal when flaccid and only recognized as being curved with an erection. Surgical repair of congenital lateral penile curvature involves degloving the penis and performing a plication and/or excision of ellipses from the corporeal bodies from the site of maximum curvature to allow straightening of the penis. Secondary lateral penile curvature follows the same principles as for vertical curvature with degloving of the penis, excision of fibrous tissue that is usually confined to the region superficial to the Buck fascia, and development of skin flaps for penile skin coverage as necessary. Intraoperative artificial erection may be necessary.

Penile Torsion

Penile torsion is a rotational deformity of the penile shaft usually in the counterclockwise direction (i.e., to the left side) (Fig. 131–11). In most cases, penile size is normal and the condition is unrecognized until circumcision is performed or until the foreskin is retracted. Penile torsion may also be associated with hypospadias, chordee, and other abnormalities involving the penile skin shaft, such as dorsal hood deformity without a urethral abnormality. In most cases of penile torsion the median raphe spirals obliquely around the shaft and inserts atypically rather than at the base of the glans below the urethral meatus. The etiology of penile torsion has not been clearly delineated but may be due to an anomalous arrangement of penile shaft skin.

Most forms of penile torsion are mild, are less than 60 degrees, and are of primarily cosmetic significance, with correction typically necessary only if the rotation is at least 60 to 90 degrees from the midline. If surgical repair is being considered, neonatal circumcision is discouraged because it can be performed at the time of penile detorsion. Although the glans may be directed more than 90 degrees from the midline, the orientation of the corporeal bodies and the corpus spongiosum at the base of the

Figure 131–10. Penile chordee and dorsal hood of foreskin without hypospadias.

Figure 131–11. Penile torsion. Patient also has redundant penile skin after a neonatal circumcision.

penis is normal. In mild forms of penile torsion, correction typically involves degloving the penile skin, rotating the glans in the direction opposite to the defect (i.e., clockwise rotation for a counterclockwise abnormality), and suturing the glans to the penile skin, resulting in a glans in a normal configuration (Bar-Yosef et al, 2007). In some instances the median raphe may take a very serpentine direction, preventing restoration to a normal position, which is not critical as long as the meatus has a normal configuration. However, in boys with penile torsion of 90 degrees or more, simple rearrangement of the skin on the shaft of the penis is insufficient. Instead, the base of the penis must be mobilized so that dysgenic bands of fibrous tissue can be identified and incised. If the penis still remains rotated, correction may be accomplished by placing nonabsorbable anchoring sutures at the base of the corpora cavernosa (Pomerantz et al, 1978; Slawin et al, 1992; Elder, 2001). Other surgical techniques have been described, including the use of a dorsal dartos flap (Bauer et al, 2009) and mobilization of the urethral plate and urethra (Bhat et al, 2009).

Penile Masses

Penile cysts, congenital or acquired, are the most common penile masses in children. A history of onset, previous surgery, and changes in appearance or size are important in the evaluation of these lesions.

Parameatal Urethral Cyst

The parameatal urethral cyst is another rare anomaly and appears as a small blister in proximity to the urethral meatus (Fig. 131–12A). Shiraki (1975) suggested that these cysts may result from occlusion of paraurethral ducts or in other cases from faulty preputial separation from the glans along the coronal sulcus. The cyst wall may consist of transitional and squamous as well as columnar epithelium. Treatment is complete excision of the cyst under anesthesia, with care taken not to cause meatal stenosis.

Inclusion Cysts

The most common acquired cystic lesion of the penis is smegma under the unretractable prepuce. The mass may appear yellow due to smegma. The prepuce usually does not need to be retracted because it almost always retracts on its own with time. **Epidermal inclusion cysts may form after penile surgery, including circumcision and hypospadias repair, owing to islands of epithelium within the subcutaneous tissue** (Fig. 131–13). Excision of the epidermal inclusion is recommended.

Cyst of the Median Raphe

Congenital epidermal cysts tend to form along the median penile raphe on the glans or penile shaft, scrotum, or perineum (see Fig. 131–12B and C) (Little et al, 1992; Krauel et al, 2008). These congenital lesions may result from epithelial rests that become buried during the urethral infolding process. Excision with the use of general anesthesia is recommended unless the cysts are small and asymptomatic.

Congenital Penile Nevi

Congenital penile nevi are pigmented lesions that can form on the glans and penile shaft (Fig. 131–14). Nevi can be classified based on the location of melanocytes: dermal (involving only the dermis), junctional (involving only the dermal-epidermal junction), and compound (involving the dermis and dermal-epidermal junction). **They tend to be superficial and benign and should be excised** (Papali et al, 2008).

Juvenile Xanthogranulomas

Juvenile xanthogranulomas is an uncommon benign, self-limiting lesion of the penis predominantly seen in infancy or early childhood. These lesions appear as solitary or multiple pigmented (yellow, orange, gold, brown, or red) nodules of rapid onset. They measure 2 to 20 mm in diameter and are well

demarcated, firm, and rubbery. These lesions can affect the penis (Hautmann and Bachor, 1993; Bradford and Choudhary, 2009) or scrotum (Goulding and Traylor, 1983; Dehner et al, 2003) with as many as 20% being present at birth. The lesion is often self-limited, and a period of 1 year of expectant monitoring is advised to avoid potentially unnecessary ablative genital surgery.

Accessory Urethral Openings

Congenital Urethral Fistula

Normally the urethral meatus is located at the tip of the glans, but accessory urethral openings may rarely occur. **Congenital urethral fistula is a condition whereby the urethra and meatus are normal and a urethrocutaneous fistula is present, typically located in the coronal or subcoronal position. This abnormality is usually an isolated deformity** (Tennenbaum and Palmer, 1994), **but it may be associated with imperforate anus or ventral chordee** (Ritchey et al, 1994). In a series of 14 boys with a congenital fistula, 4 had distal hypospadias and 2 had chordee (Caldamone et al, 1999). The etiology is unknown but may involve a focal defect in the urethral plate that prevents fusion of the urethral folds. Some patients have undergone circumcision before diagnosis (Caldamone et al, 1999), raising the possibility that the fistula may have been iatrogenic rather than congenital in some of these cases. Treatment usually consists of one of two techniques: the fistula can be circumscribed and then closed in multiple layers, similar to a urethrocutaneous fistula after hypospadias repair; or if the glans bridge is thin, the ventral glans can be opened through the distal urethra and the distal urethra is then closed by a Thiersch-Duplay tubularization or incision of the urethral plate and tubularization.

Urethral Duplication

Urethral duplication is another rare congenital anomaly, with roughly 200 cases reported in the literature (Salle et al, 2000; Slavov et al, 2007). **The duplication most commonly occurs in the sagittal plane with one urethra located ventrally and the other dorsally** (Fig. 131–15). **Collateral urethral duplication in which urethral duplication occurs in the same horizontal plane is extremely rare** (Ching and Palmer, 2008b). In a series by Salle and colleagues (2000), sagittal plane duplication accounted for 94% of urethral duplication. Usually the dorsal urethra is considered the accessory urethra with or without a urinary stream while the ventral urethra contains the urine stream and the anatomic landmarks such as the external sphincter and verumontanum. The most commonly used classification of urethral duplication is that of Effman (Fig. 131–16), which categorizes the sagittal urethral duplication into three types: types I and II distinguish between partial and complete urethral duplication, whereas type III describes urethral duplication as part of bladder duplication (Effman et al, 1976). The embryology of urethral duplication is not well established, with

Figure 131–15. Urethral duplication with catheters through meatus at tip of the glans penis and at perineum.

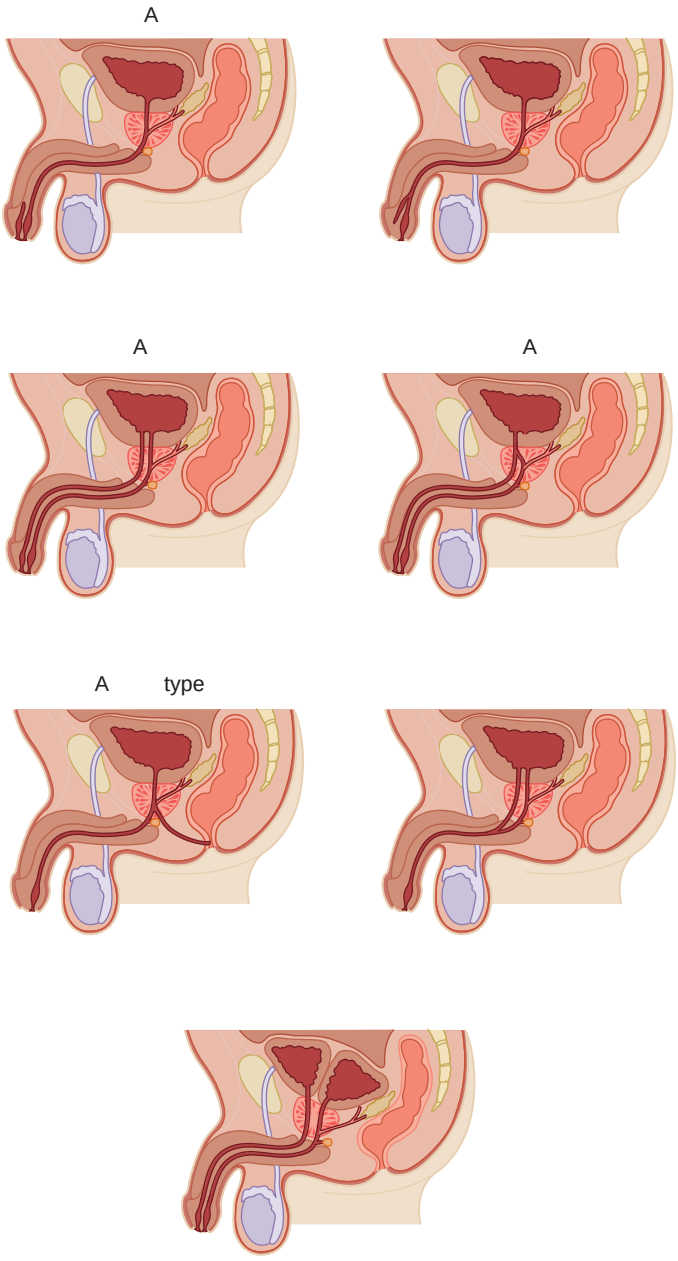

Figure 131–16. Effman classification.

explanations including ischemia (Woodhouse and Williams, 1979; Podesta et al, 1998) and abnormal müllerian duct termination (Das and Brosman, 1977). Effman and coworkers (1976) suggested caudal duplication may be related to division of the notochord with subsequent formation of two hindguts, allantoises, and cloacae.

Anomalies have been described in the genitourinary, gastrointestinal, and musculoskeletal system. In the review by Podesta and colleagues (1998), 6 of 7 patients with urethral duplication had other associated anomalies, with vesicoureteral reflux being the most common. Other anomalies included renal agenesis, bilateral cryptorchidism, sacral agenesis, imperforate anus, tracheoesophageal fistula, and radial hypoplasia. There appears to be an association with other midline defects such as duplicated bladder, duplicated colon, imperforate anus and anorectal agenesis, bifid glans, thoracic hemivertebrae, and partial sacral agenesis (Woodhouse and Williams, 1979; Fenster et al 1980; Kennedy et al, 1988; Salle et al, 2000).

The most common presentation of urethral duplication is a double meatus and double urinary stream (Kennedy et al, 1988; Urakami et al, 1999; Salle et al, 2000). Incontinence and recurrent UTIs are other common presentations. Less common conditions include penile chordee and urinary obstruction secondary to a mucosal flap at the urethral bifurcation acting as an occluding valve during voiding (Effman et al, 1976; Das and Brosman, 1977; Salle et al, 2000). The presence of incontinence is dependent on the site of origin of the accessory urethra, with the more proximal the site of urethral duplication, the higher the incidence and the greater the degree of incontinence (Farrell and Sparnon, 1987).

Patient evaluation should include a voiding cystourethrogram, retrograde urethrogram, and direct visualization of the anatomy during cystourethroscopy. Evaluation of the other associated anomalies should also be performed. Treatment of urethral duplication is usually reserved for the symptomatic child (Urakami et al, 1999). Cosmesis alone, however, has been advocated by some as a valid indication for intervention (Middleton and Melzer, 1992). The accessory urethra should not be used as the primary urethra secondary to being hypoplastic with the risk of inadequate urine flow (Salle et al, 2000). Surgical repair includes complete accessory tract excision, electrofulguration or injection of sclerosing agents into the accessory tract, septotomy if the septum between the two urethras is thin, and urethrourethrostomy of the accessory tract into the functional urethra. Management is dependent on the anatomy of the urethral duplication (Farrell and Sparnon, 1987; Podesta et al, 1998).

Genital Lymphedema

Lymphedema of the genitalia, congenital or acquired, is a disfiguring disorder characterized by impaired lymphatic drainage that causes progressive penile or scrotal swelling. Congenital lymphedema may be sporadic (85%) or inherited (15%) and can be expressed at various ages (McDougal, 2003). Milroy disease is an autosomal-dominant inherited trait, whereas Meige disease is probably autosomal dominant with variable penetrance and occurs in the first or second decade (Wheeler et al, 1981). If the genital lymphedema occurs at puberty and is sporadic, it is termed *lymphedema praecox*. Approximately 80% of patients with congenital lymphedema demonstrate onset of the disease at puberty (McDougal, 2003). The lymphedema may involve the penis, scrotum, or both. Congenital lymphedema has been associated with several syndromes, including Turner, Noonan, Klinefelter, and intestinal lymphangiectasia syndromes. Lower extremity involvement may occur in many individuals with congenital lymphedema.

Initial management involves observation, but surgical therapy is necessary if the lymphedema remains significant or progresses. The goal of surgical treatment is to remove all involved tissue. On the penile shaft, the penis is degloved and all tissue between Buck fascia and the skin as well as redundant penile skin must be excised. If the patient is uncircumcised, the prepuce may be unfurled to provide coverage of the penile shaft (Shenoy et al, 2001). If the scrotum is involved, most of the scrotal skin must be excised, with the exception of the posterior skin, and the spermatic cords and testes should be preserved (Ross et al, 1998). The penis may be covered with local skin flaps, and the scrotal contents may be covered with uninvolved posterior skin flaps (Bolt et al, 1998; Ross et al, 1998). Split-thickness skin flaps may be needed to cover the penis and scrotum if inadequate healthy skin is available (McDougal, 2003). Parents should be counseled that lymphedema in adjacent areas may recur after definitive surgical therapy.

Priapism

Priapism, a prolonged penile erection, sustained for greater than 4 hours with the absence of both physical and psychological stimulation, is commonly painful. Tumescence is usually restricted to the corpora cavernosa (Montague et al, 2003), and in some cases the corpus spongiosum involves the glans. Priapism can be categorized into three types:

1. **Ischemic (veno-occlusive, low-flow) priapism** is characterized by little or no cavernous blood flow, and cavernous blood gases are hypoxic, hypercapnic, and acidotic. The corpora are rigid and tender to palpation.
2. **Nonischemic (arterial, high-flow) priapism** is caused by unregulated cavernous arterial inflow. Typically, the penis is neither fully rigid nor painful. There is often a history of antecedent trauma resulting in a cavernous artery/corpora cavernosa fistula.
3. **Stuttering (intermittent) priapism** is a recurrent form of ischemic priapism with painful erections with intervening periods of detumescence.

Low-flow priapism is most commonly secondary to homozygous sickle cell disease, which is characterized by predominance of sickle hemoglobin (Hb S). Other causes include leukemia, local malignancies, other hemoglobinopathies, and local malignancy (Dewan et al, 1989; Friedman, 1998). Sickle cell–induced priapism occurs in 2% to 29% of males with the disease (Tarry et al, 1987; Hamre et al, 1991; Miller et al, 1995; Mantadakis et al, 1999). The priapism associated with sickle cell disease is generally related to a low-flow state, secondary to sickling of red blood cells within the sinusoids of the corpora cavernosa during normal erection, resulting in venous stasis. This situation results in decreased pH and local oxygen tension, which potentiates further stasis and sickling (Bruno et al, 2001). Priapism typically occurs during sleep, when mild hypoventilatory acidosis depresses oxygen tension and pH in the corpora. The pain that is experienced is a sign of ischemia.

Transient prolonged erections lasting less than 2 hours, known as stuttering priapism, is more common than prolonged erections in the patient with sickle cell disease. Pseudoephedrine, an oral α-adrenergic agent, given at bedtime can be used to treat stuttering priapism in boys by promoting muscle contraction within the erectile tissue. If this treatment is unsuccessful, other therapeutic agents can be used, including an oral β agonist. Recently, preliminary findings suggest that the use of continuous, long-term oral phosphodiesterase-5 (PDE5) inhibitor therapy may prevent recurrent priapism based on the hypothesis that PDE5 dysregulation may be involved in priapism (Burnett et al 2006; Burnett, 2008).

The initial treatment of low-flow priapism resulting from sickle cell disease is conservative, with hydration, oxygenation, alkalization, analgesia, and transfusion with the goal of reducing Hb S concentration (Seeler, 1973; Hamre, 1991; and Miller et al, 1995). **Evacuation of blood and irrigation of the corpora cavernosa along with intracavernous injections of α-adrenergic sympathomimetic agents, such as phenylephrine or epinephrine solution, can be a concurrent therapy** (Montague et al, 2003)**.** Surgical intervention to allow corporeal drainage by shunt procedures is indicated if there is a lack of response to medical therapy (Tarry et al, 1987; Miller et al, 1995; Chakrabarty et al, 1996). Surgical shunting bypasses the veno-occlusive mechanism of the corpora cavernosa and thereby enhances blood drainage. Shunt procedures include distal cavernoglandular shunt (Winter, Ebbehoj, and El-Gorab shunts) (Ebbehoj, 1974; Winter, 1976; Ercole et al, 1981), proximal cavernospongiosal shunt (Quackels and Sacher shunts) (Quackels, 1964; Sacher et al, 1972), or saphenous vein anastomosis to one of the corpora cavernosa (Grayhack shunt) (Grayhack et al, 1964). Parents should be educated on the potential side effects from intervention, including cavernosal fibrosis and erectile dysfunction.

High-flow priapism is usually due to perineal trauma, such as a straddle injury. Other causes include Fabry disease and sickle cell anemia (Ramos et al, 1995; Callewaert et al, 1998; Volkmer et al, 2001). Corporeal irrigation is diagnostic and therapeutic. Typically, the aspirated blood is bright red and the aspirate is similar to arterial blood on blood gas analysis. Color Doppler ultrasonography often will demonstrate the fistula. The initial management is observation (Montague et al, 2003) because spontaneous resolution may occur. Superselective embolization of cavernous and penile arteries (Callewaert et al, 1998; Volkmer et al, 2001; Montague et al, 2003; Kuefer et al, 2005) is the next line of therapy.

A fourth type of priapism is a spontaneously resolving form observed in neonates (Walker and Casale, 1997). Causes may include idiopathic, birth trauma, and polycythemia. No intervention is necessary because the priapism usually resolves in 2 to 6 days without adverse results.

Key Points: Priapism

- Priapism can be ischemic (veno-occlusive, low flow), nonischemic (arterial, high flow), and stuttering (intermittent).
- The most common cause in children is sickle cell disease (ischemic).
- The initial treatment of low-flow priapism resulting from sickle cell disease is conservative, with hydration, oxygenation, alkalization, analgesia, and transfusion. Evacuation of blood and irrigation of the corpora cavernosa along with intracavernous injections with α-adrenergic sympathomimetic agents can be a concurrent therapy.
- High-flow priapism is usually due to perineal trauma, such as a straddle injury. Angiographic embolization is necessary if spontaneous resolution does not occur.
- Transient prolonged erections lasting less than 2 hours are known as stuttering priapism. Pseudoephedrine, an oral α-adrenergic agent, given at bedtime can provide effective treatment.

SCROTAL ANOMALIES

Penoscrotal Transposition (Scrotal Engulfment)

Penoscrotal transposition may be partial or complete (Fig. 131–17), with its less severe forms having been termed *bifid scrotum, doughnut scrotum, prepenile scrotum*, and *shawl scrotum*. The embryologic cause may result from incomplete or failed inferomedial migration of the labioscrotal swellings. **Frequently, the condition occurs in conjunction with perineal, scrotal, or penoscrotal hypospadias with chordee** (Pinke et al, 2001). Penoscrotal transposition has also been associated with caudal regression (Lage et al, 1987), sex chromosome abnormalities (Yamaguchi et al, 1989), and Aarskog syndrome (Shinkawa et al, 1983). As many as 75% of patients with complete penoscrotal transposition and a normal scrotum have a significant urinary tract abnormality, including renal agenesis and dysplasia (MacKenzie et al, 1994; Parida et al, 1995), and other nongenitourinary anomalies have been reported. These patients should be evaluated with renal ultrasonography and voiding cystourethrography.

Figure 131–17. Penoscrotal transposition.

Surgical repair is usually performed during hypospadias or other penile repair. Several scrotoplasty techniques have been described (Glenn and Anderson, 1973; Ehrlich and Scardinol, 1982; Levy et al, 1997) with the goal of freeing the penis from the scrotum, developing skin flaps, relocating the scrotum to a dependent position, and moving the penis superiorly. When scrotal engulfment is associated with severe hypospadias, hypospadias repair is often accomplished by a transverse preputial island flap in conjunction with Thiersch-Duplay tubularization of the proximal urethra. To minimize the possibility of devascularization of the preputial flap, correction of the scrotal engulfment is usually done as a second-stage procedure 6 months later (Elder and Duckett, 1990; Germiyanoglu et al, 1994). If the penis is normal, scrotoplasty can be accomplished when the child is 6 to 12 months of age.

Scrotoplasty is performed by circumscribing the superior aspects of each half of the vertical aspect of the scrotum and extending these incisions laterally to include at least half of the scrotum (Fig. 131–18). The medial aspects of the incision are joined on the ventral aspect of the penis, and the incision is carried down the midline along the median raphe. The injection of a solution of lidocaine with epinephrine into the subcutaneous tissue can be used to develop tissue planes and also help to diminish bleeding. Care must be taken not injure the tunica vaginalis and spermatic cord during deeper dissection. The scrotal wings are rotated medially under the penis and sutured together in the midline in an everted manner. Although in most cases there is no deficiency of the ventral penile shaft skin, in more severe cases of penoscrotal transposition this may not be the situation; dorsal interposition flaps may then be necessary, allowing caudal advancement of the skin of the abdominal wall (Pinke et al, 2001).

An alternative technique is to identify the correct position for the penis and make a buttonhole by excising a plug of epidermis, dermis, and suprapubic fat (Kolligian et al, 2000). The penis is then degloved, and the penile shaft is brought through the buttonhole. The penile shaft skin remains behind, is split down the

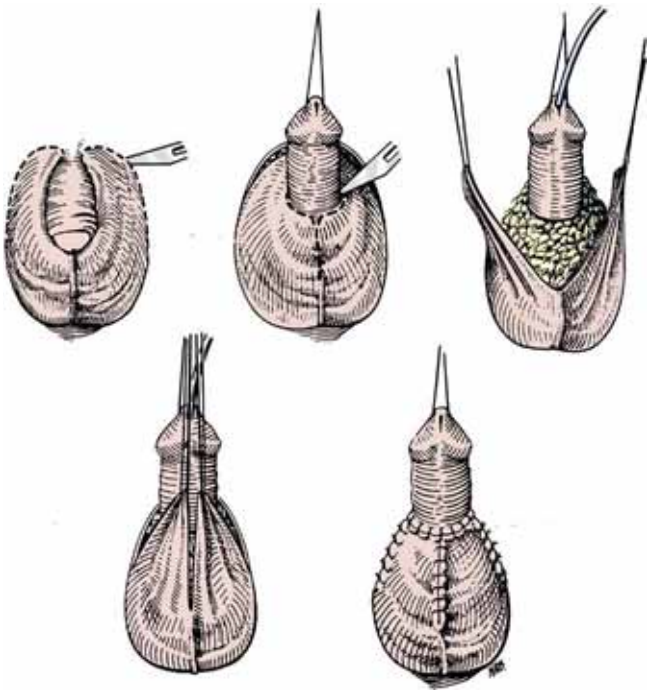

Figure 131–18. Repair of penoscrotal transposition (see discussion in text).

ventrum, and is mobilized superiorly to the penile shaft. A window of the dartos pedicle is made, and the penile shaft is brought through this window. The degloved penis is then resurfaced with shaft skin.

Bifid Scrotum

Bifid scrotum refers to the deformity in which the labioscrotal folds are completely separated and without a median raphe. This anomaly is most often associated with proximal hypospadias. Surgical repair is usually performed during hypospadias repair. The technique is similar to that used for repair of penoscrotal transposition.

Ectopic Scrotum

Ectopic scrotum (Fig. 131–19), the anomalous position of one hemiscrotum along the inguinal canal, is a rare condition. The location can be suprainguinal (most common), infrainguinal, or perineal (Lamm and Kaplan, 1977; Elder and Jeffs, 1982). This anomaly has been associated with cryptorchidism, inguinal hernia, and bladder exstrophy as well as with the popliteal pterygium syndrome (Cunningham et al, 1989). In one review, 70% of boys with a suprainguinal ectopic scrotum exhibited ipsilateral upper urinary tract anomalies, including renal agenesis, renal dysplasia, and ectopic ureter (Elder and Jeffs, 1982). Another study indicated that an associated perineal lipoma was found in 83% of these children; 68% of those with a lipoma had no associated anomalies, whereas 100% of those without a lipoma had associated genital or renal malformations (Sule et al, 1994). Because of the embryology of the gubernaculum and scrotum being intimately related chronologically and anatomically, the ectopic scrotum may result from a defect in gubernacular formation that prevents migration of the labioscrotal swellings (Hoar et al, 1998). Patients with an ectopic scrotum should undergo upper urinary tract imaging with ultrasonography. Scrotoplasty and orchiopexy may be performed at 6 to 12 months of age or earlier if other surgical procedures are necessary for associated anomalies.

Figure 131–19. Ectopic scrotum.

Scrotal Hypoplasia

Scrotal hypoplasia, the underdevelopment of one or both sides of the scrotum, **occurs most commonly in boys with an undescended testis** and frequently is noted in infants with genital ambiguity. The deformity may result from lack of gubernacular swelling of the labioscrotal folds.

Scrotoschisis

Meconium peritonitis may occasionally cause genital manifestations, including meconium hydrocele (Ring et al, 1989) and congenital rupture of the scrotum, termed *scrotoschisis* (Gongaware et al, 1991; Salle et al, 1992; Chun and St-Vil, 1997; Kojori et al, 2007; Premkumar et al, 2009). This can result in one or both testes being extruded from the scrotal sac. When scrotoschisis is detected the clinician should suspect meconium peritonitis and proceed with the appropriate evaluation. Treatment involves scrotal exploration with orchiopexy and primary closure of the scrotal wall defect.

VASCULAR LESIONS OF THE GENITALIA

Vascular lesions of the genitalia are uncommon without a consensus on classification, etiology, and treatment. These deformities include hemangiomas and vascular malformations. **Hemangiomas are on the skin**, are often congenital, and may show significant growth in the postnatal period followed by slow involution. **Vascular malformations are present at birth in the subcutaneous tissues** and tend to persist or to enlarge, which can occur secondary to trauma, sepsis, or hormonal changes (Ramos et al, 1999). **Vascular malformations can be subdivided into either slow-flow (capillary, lymphatic, venous) or fast-flow (arterial, arteriovenous) types.**

Congenital Hemangiomas

Congenital hemangiomas are common and affect the genitalia in approximately 1% of all hemangiomas (Alter et al, 1993). The origin of these lesions and the mechanisms regulating their growth and involution are controversial (Ritter et al, 2007). **Strawberry hemangiomas are the most common type and result from proliferation of immature capillary vessels.** These are also categorized as cutaneous hemangiomas because they occur on the skin. Although the lesions may undergo a period of rapid growth lasting 3 to 6 months, gradual involution is common, and most

lesions require no treatment (Casale and Menashe, 1989; Girard et al, 2006). If ulceration develops, intervention is necessary to prevent complications from bleeding. The most popular form of therapy is short-term oral corticosteroid therapy. Treatment with laser therapy allows selective photothermolysis and destruction of superficial blood vessels (Kennedy et al, 1993; Ward et al, 1998). In some cases, surgical excision is necessary.

Subcutaneous Hemangiomas

Subcutaneous hemangiomas, also referred to as cavernous hemangiomas, are much less common than the cutaneous variety (Sule et al, 1993; Ferrer and McKenna, 1995) and are probably more appropriately classified as a vascular malformation. They may be detected at birth or later in life. In contrast to cutaneous hemangiomas, which tend to involute, cavernous hemangiomas tend to enlarge gradually and should be treated with care. Physical examination reveals a "bag of worms" sensation similar to that of a varicocele, although the lesions tend to be firm and do not decompress when the patient is recumbent. Ultrasonography with color Doppler imaging, computed tomography, or MRI is recommended to delineate the size of the hemangioma (Aizenstein et al, 1996) because examination does not disclose the extent of the lesion. Definitive treatment by en bloc resection is advised, and preoperative angioembolization may reduce the size of the mass and the risk of bleeding.

Klippel-Trénaunay-Weber Syndrome

Klippel-Trénaunay-Weber syndrome is a triad of cutaneous vascular malformation, most commonly nevus flammeus, in combination with soft tissue and bone hypertrophy. The anomaly is present at birth and usually involves a lower extremity, but the trunk or face may be involved. These vascular lesions have a propensity to bleed. In a review of 214 patients from a single institution, Husmann and colleagues (2005) found that 30% had genitourinary cutaneous or visceral involvement. Of the 48 (22%) who had cutaneous genital involvement, 29% developed intractable bleeding. Excision of the hemangiomas was associated with significant blood loss.

Vascular Malformations

The penis may also be affected by vascular malformations. These lesions are congenital but are usually not diagnosed until the teenage years or young adulthood. The lesions are characterized as a faint blue patch or a soft blue mass. If the lesion affects the glans penis, the neodymium:yttrium-aluminum-garnet laser may yield a better result than surgical excision (Ramos et al, 1999).

Abnormalities of the Testis and Scrotum and Their Surgical Management

Julia Spencer Barthold, MD

Embryology of Testicular Development and Descent
Cryptorchidism (Undescended Testis)
Varicocele
Hernias and Hydroceles
Acute Scrotum
Epididymal, Vasal, and Scrotal Anomalies

Developmental abnormalities of the testis and inguinoscrotal region, including cryptorchidism, varicocele, hernia/hydrocele, and torsion of the spermatic cord or testicular appendages comprise some of the most common anomalies seen in male children. Despite their frequency, relatively little is known of the underlying factors contributing to the pathogenesis of these diseases. All may be associated with significant short- or long-term morbidity. Moreover, their clinical presentation may overlap and at times present diagnostic challenges. Our ability to define the degree to which cryptorchidism and varicocele affect global testicular function in individual patients remains limited. Therefore management options remain controversial in part because of difficulty correlating early childhood therapies with long-term reproductive outcomes.

EMBRYOLOGY OF TESTICULAR DEVELOPMENT AND DESCENT

Testicular Development

The human gonadal ridge containing somatic and germ cells is first identified on the medial urogenital ridge at 32 days after ovulation and is indistinguishable between males and females (Hanley et al, 1999). Primordial germ cells migrate from the yolk sac and differentiate into gonocytes during the 5th week of gestation. Expression of the earliest testis (Sertoli cell)-specific genetic markers, *SRY* (sex-determining region Y) and *SOX9* (SRY-box 9), begins at between 41 and 44 days (Hanley et al, 2000) followed by the histologic appearance of Sertoli cells and testicular cords in male fetuses by 9 weeks of age (Ostrer et al, 2007). Migrating mesonephric cells contribute to testis cord formation as well as testicular endothelial cells (Cool and Capel, 2009) The germ cell marker, c-KIT, first identified at 7 weeks of age, is present in an increasing number of cells until 12 weeks, with subsequent reduced expression as maturation to intermediate germ cells progresses (Ostrer et al, 2007). By the third trimester, a third stage of germ cells, prespermatogonia, predominates within the testis. Leydig cells can be identified by cell-specific staining by 9 weeks and by peritubular myoid cells by 12 weeks of age.

Gonadal differentiation is more complicated than the original concept of ovarian development as the default pathway because emerging evidence suggests that activation of specific gene pathways is required for both male and female sex determination in mice (Blecher and Erickson, 2007; Cool and Capel, 2009). *Sry* has been considered the master male gene, but other genes required for gonadal determination act upstream of *Sry* and its downstream effects on *Sox9* expression are indirect via derepression of an intermediate gene, likely *Rspo1* (R-spondin homolog). Testicular determination is directly dependent on activation of *Sox9* and *Fgf9* (fibroblast growth factor-9), whereas ovarian determination is dependent on activation of *Rspo1* and *Wnt4* (wingless-related MMTV integration site-4) and the appropriate dosage of the X-linked *Nr0b1* (nuclear receptor subfamily 0, group B, member 1, also known as *Dax1*) gene.

Hormonal function of the human fetal testis is critical for masculinization of the reproductive tract and testicular descent. Fetal Leydig cell development is divided into three phases: a proliferation and differentiation phase between 7 and 14 weeks' gestation, a maturation phase until 18 weeks, and an involution phase that continues until term (Svechnikov and Soder, 2008). Synthesis of testosterone by fetal Leydig cells starts as early as 6 to 7 weeks' gestation and appears to be initially independent of gonadotropin stimulation. However, placental human chorionic gonadotropin (hCG) stimulates a peak in androgen production at 14 to 16 weeks' gestation and the testis then becomes responsive to fetal luteinizing hormone (LH). Insulin-like 3 (INSL3) of Leydig cell origin is measurable in human amniotic fluid as early as 13 weeks' gestation (the earliest time point studied) and peaks at 15 to 17 weeks (Anand-Ivell et al, 2008; Bay et al, 2008). Fetal Sertoli cells produce antimüllerian hormone (AMH; also called müllerian-inhibiting substance [MIS]) soon after they differentiate; the human fetal müllerian duct is responsive to AMH before week 8 of gestation, and the process of regression occurs between 9 and 10 weeks (Josso et al, 2006). **Evidence from animal models and indirect clinical evidence suggests that INSL3 and testosterone are the key hormones required for testicular descent.**

Steroid hormones exert their effects via sex steroid receptors in the reproductive tract and testis. Recent studies show that androgen receptor (AR) and estrogen receptor-β (ERβ) are expressed in the undifferentiated gonad at 7 weeks of age, although their role in testicular development is unclear (Shapiro et al, 2005; Boukari et al, 2007). AR is present primarily in peritubular myoid cells and in some Leydig and interstitial cells but absent in Sertoli cells during the fetal period. Because androgens inhibit AMH production by Sertoli cells, the absence of an AR in these cells during fetal life allows unfettered expression of AMH during this period (Boukari et al, 2009). ERβ localization is most extensive, being observed in germ, peritubular myoid, Sertoli, and some Leydig cells by 13 weeks and decreasing by 22 to 24 weeks, whereas expression of estrogen receptor-α (ERα) is limited (Shapiro et al, 2005) or absent (Boukari et al, 2007) in the human fetal testis. Concomitant expression of aromatase during the same time frame suggests that locally produced estrogen may play a role in testicular development.

Significant changes in reproductive hormone secretion and testicular development occur in the neonatal period (Grumbach, 2005). Fetal Leydig cells regress after birth, followed by emergence of a neonatal Leydig cell population at 2 to 3 months of age (Prince, 2001) and a peak in testosterone and INSL3 levels (Bay et al, 2007) that follows a surge in serum gonadotropin levels. As postnatal hormonal levels wane, the fetal Leydig cells either degenerate or regress to immature Leydig/interstitial cells that are partially differentiated and less responsive to LH. In the first months of life, intratubular gonocytes migrate to the basement membrane and differentiate into type A spermatogonia, which comprise a subset of spermatogonial stem cells (Culty, 2009). Sertoli cell proliferation occurs in the first year of life and is a major determinant of ultimate testicular size (Sharpe et al, 2003). The characteristics of testicular growth during childhood vary depending on the method of analysis. Main and colleagues reported significant growth of normal testes between birth and 3 months of age based on ultrasound measurements and on significantly larger testicular size in Finnish as compared with Danish boys at birth and 3 and 18 months, a difference attributable to genetic and/or environmental effects (Main et al, 2006b). Kuijper and coworkers observed a peak in testicular ultrasound volume at 6 months of age followed by a decline to baseline (Kuijper et al, 2008). In contrast, in an autopsy series, Berensztein and associates noted doubling of testicular weight during the first 3 weeks of life with slowed growth thereafter, suggesting that major growth occurs prior to the postnatal hormone surge and a gonadotropin-independent mechanism (Berensztein et al, 2002). This growth was associated with a rate of proliferation exceeding the rate of apoptosis in Leydig, germ, and Sertoli cells before the second month of age with increased apoptosis thereafter and little subsequent growth of the testes before age 6. In their autopsy series of older children, Müller and Skakkebaek (1983) reported a 2.6-fold increase in testicular size between the first year of life and age 10, with a significant increment between all age groups (birth to 1, 1 to 5, and 5 to 10 years) in both size and tubular length. Overall, the data suggest a major increment in testicular growth during the neonatal period, but the factors responsible for age-specific cellular proliferation, gonocyte differentiation, and testicular growth are not clearly defined.

Gubernacular Development and Testicular Descent

The physiology of normal testicular descent and the etiology of abnormal descent in humans remain poorly understood, whereas the morphologic events have been well studied in mammals. Knowledge of the regulation of testicular descent is inferred from studies of human diseases that include cryptorchidism and/or from animal models.

The human indifferent gonad develops adjacent to and becomes suspended from the mesonephros, which has replaced the pronephros by 5 weeks' gestational age (Lemeh, 1960). A rudimentary cranial mesonephric ligament connects to the diaphragm, disappearing by 13 weeks as the mesonephros regresses (Barteczko and Jacob, 2000) (Fig. 132–1). There is no direct connection between the gonad and this ligament; therefore no "cranial gonadal ligament" exists in humans as noted in other species. Using fixed sections, Barteczko and Jacob observed an "inner" or transabdominal descent of the human testis from a position at vertebral levels C7-T8 to T9-L3 between 5 and 7 weeks' gestation and to the sacral level by 10 weeks; using dissections, others described the testis at the level of L4 by the 7th week (Lemeh, 1960) or always "close to the groin" (Wyndham, 1943). Caudal movement of the ovary is prevented by the ovarian ligament and development of the müllerian ducts.

Barteczko and Jacob (2000) described five major phases of testicular descent in the human fetus (Fig. 132–2):

- *Phase 1:* The caudal mesonephros contacts the future gubernaculum at the internal inguinal ring (5 weeks' gestation).
- *Phase 2:* The genitofemoral nerve accompanies the newly formed gubernaculum (abdominal, interstitial, and subcutaneous portions) and processus vaginalis (7 weeks).
- *Phase 2a:* Growth of the gubernaculum, deepening of the processus vaginalis, and extension of cremaster muscle fibers into the interstitial gubernaculum occurs (8 to 10 weeks).
- *Phase 3:* Growth of the testis and regression of the müllerian ducts and mesonephros occurs; the gubernaculum remains a thin cord in both sexes (10 to 12 weeks).
- *Phase 3a:* The testis overrides the genital ducts and contacts the gubernaculum, which begins its swelling phase in males (12 to 14 weeks).
- *Phase 4:* Swelling of the gubernaculum, development of the cremaster muscle, and migration of the processus vaginalis produce widening of the inguinal canal (14 to 20 weeks).

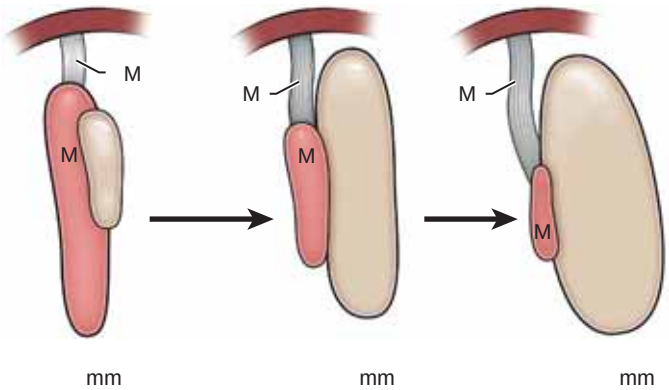

Figure 132–1. Development of the cranial mesonephric ligament (CML) and gonad (G) during embryonic regression of the mesonephros (M). *Asterisks* denote the anlage of the diaphragm; *long arrows* show the cranial mesonephric ligament. (From Barteczko KJ, Jacob MI. The testicular descent in human: origin, development and fate of the gubernaculum Hunteri, processus vaginalis peritonei, and gonadal ligaments. Adv Anat Embryol Cell Biol 2000;156:III-X, 1–98.)

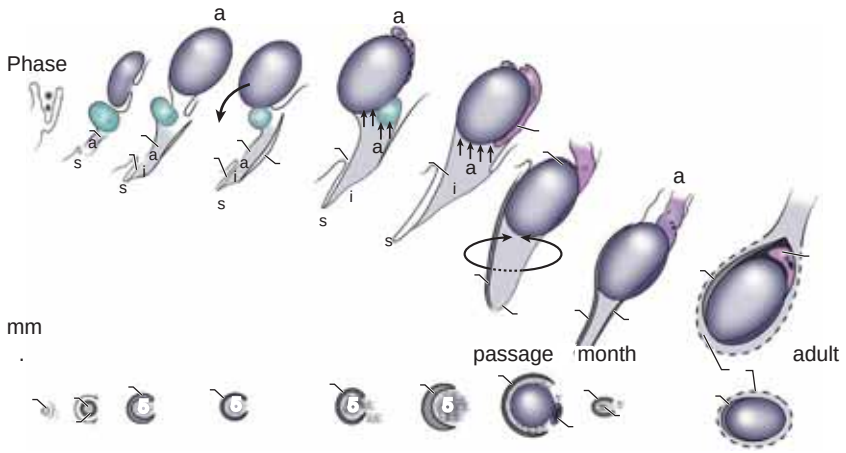

Figure 132–2. Overview of human testicular descent. Sagittal view *(top)* and transverse sections *(bottom)* of 1, gonad; 2, mesonephros; 3, wolffian and müllerian duct; 4, vas deferens/epididymis; 5, gubernaculum—a, abdominal; i, interstitial; s, subcutaneous part; 6, processus vaginalis; 7, internal inguinal ring; 8, external inguinal ring. *Straight arrows* (phase I) show ventral side; *asterisks* (phases I to IIIa) show the link between the caudal pole of the testis and dorsal mesenchyme of genital ducts; *curved arrow* (phase III) shows direction of testicular migration; *short arrows* (phases IIIa to IV) indicate attachment between the testis or epididymis and gubernaculum; *oval arrowline* (phase V) indicates no connection between the boltlike gubernaculum and neighboring structures. (From Barteczko KJ, Jacob MI. The testicular descent in human: origin, development and fate of the gubernaculum Hunteri, processus vaginalis peritonei, and gonadal ligaments. Adv Anat Embryol Cell Biol 2000;156:III-X, 1–98.)

Phase 5: Release of the distal subcutaneous attachment of the gubernaculum and transinguinal passage of the testis occur (20 to 28 weeks).

Phase 5a: Further caudal movement of the testis into the scrotum is accompanied by regression of the gubernaculum (7th month and beyond).

The careful in-situ anatomic observations by Barteczko and Jacob (2000) throughout gestation help clarify some aspects of human testicular descent. For example, transabdominal movement of the testis occurs before sexually dimorphic changes in the gubernaculum and is presumably not a male hormone–specific event. The subsequent male-specific swelling of the gubernaculum parallels the peak in Leydig cell secretion of testosterone (14 to 16 weeks) and INSL3 (15 to 17 weeks). The genitofemoral nerve accompanies and precedes the gubernaculum and developing processus vaginalis in both sexes beginning at an early stage (7 weeks), and both smooth (abdominal) and skeletal (interstitial and subcutaneous) muscle fibers occur within the three segments of the gubernaculum. Both muscle types were also observed by some (Wyndham, 1943; Lemeh, 1960) but not others (Heyns, 1987; Costa et al, 2002; Niikura et al, 2008) observers. However, studies of the in-situ gubernaculum beginning at 20 weeks clearly show the presence of peripherally and centrally located striated muscle bundles (Barteczko and Jacob, 2000; Niikura et al, 2008) and infiltration of the gubernaculum by the genital branch of the genitofemoral nerve (Tayakkanonta, 1963). Controversy exists as to whether these skeletal cremaster muscle fibers are of similar origin and/or originate from abdominal wall musculature or from within the gubernaculum itself (van der Schoot, 1996; Barteczko and Jacob, 2000; Niikura et al, 2008). The processus vaginalis and cremaster muscle may facilitate transit of the testis and gubernaculum, but their exact role remains unknown.

Swelling of the gubernaculum is critically important to allow enlargement of the inguinal canal and testicular passage and is the result of both cellular proliferation and production of extracellular matrix (Heyns, 1987). Once the canal is created, unknown mechanical factors trigger a typically rapid transinguinal passage of the testis. The

Figure 132–3. The distally unattached human gubernaculum at 25 weeks of gestation (215 mm CRL) just before transinguinal testicular descent. T, testis; G, gubernaculum; P, penis; S, scrotum. (From Heyns CF. The gubernaculum during testicular descent in the human fetus. J Anat 1987;153:93–112.)

gubernaculum is unattached distally during and after transinguinal passage (Fig. 132–3). Settling of the gubernaculum and testis into the preformed scrotum is gradual. The scrotum itself develops from genital swellings that are first visible at 7 weeks and fuse by 10 to 12 weeks in response to circulating dihydrotestosterone. Passage of the testis into the inguinal canal rarely occurs prior to week 22 in the human fetus, and the majority of testes are scrotal

after week 27; time spent in the inguinal canal seems to be limited for the majority of human fetal testes (Heyns, 1987; Sampaio and Favorito, 1998). Early innervation of the gubernaculum and the importance of the genitofemoral nerve in testicular descent in rodents, as well as the rapidity of transinguinal passage, suggest a neuromuscular mechanism.

Regulation of Testicular Descent

Direct evidence for hormonal control of testicular descent is based entirely on studies in animal models, primarily rodents. The relevance of rodent data to humans is controversial because of anatomic differences, which in mice and rats include a less prominent interstitial gubernaculum, a cranial gonadal ligament, an elongated cord connecting the gubernaculum to the epididymis, a well-developed intrinsic cremaster muscle located in the outer layer of the gubernaculum, an absent inguinal canal, and failure of closure of the processus vaginalis (Wensing, 1988). However, some observers argue that the similarities between species are sufficiently strong to warrant translational studies of these models (van der Schoot, 1996; Harnaen et al, 2007).

Rodent studies provide strong evidence that testicular INSL3 and androgen signaling pathways are the primary contributors to gubernacular development and testicular descent (Zimmermann et al, 1999; Adham et al, 2000; Overbeek et al, 2001). According to a paradigm developed by Hutson, testicular descent occurs in two phases—transabdominal and transinguinal—regulated by INSL3 and by androgens via the genitofemoral nerve, respectively (Hutson and Hasthorpe, 2005). However, animal models show that INSL3 and androgen synergistically stimulate cellular proliferation and growth of the gubernaculum (Adham et al, 2000; Emmen et al, 2000; Kubota et al, 2002) and that both INSL3 binding and androgen receptor expression are present before and during the swelling phase of the fetal rat gubernaculum (Koskimies et al, 2003; McKinnell et al, 2005; Staub et al, 2005). Moreover, INSL3 and testosterone levels peak after week 12 in the human fetus, concomitant with gubernacular swelling, although transabdominal testicular descent occurs earlier, prior to 10 weeks' gestation. In mice, INSL3 signaling promotes development of the processus vaginalis, and androgen signaling causes regression of the cranial gonadal ligament (Adham et al, 2002; Koskimies et al, 2003; Adham and Agoulnik, 2004), a structure that does not exist in the human fetus. Clues about other gene pathways that participate in the process of testicular descent are provided by known transgenic mouse models and human syndromes with phenotypes that include cryptorchidism (Barthold, 2008; Foresta et al, 2008). Transgenic deletion of either of two homeobox genes, *Hoxa10* and *Hoxa11,* is associated with isolated cryptorchidism in mice. *Hoxa10* appears to function independently of gonadotropin or INSL3 signaling (Feng et al, 2006). At present, little is known of the role of these and other gene candidates in the process of testicular descent.

A role for the genitofemoral nerve in guiding and/or promoting passage of the gubernaculum is supported by rodent studies of Hutson and colleagues, who propose that release of calcitonin gene-related peptide (CGRP) from the nerve stimulates development and function of the gubernaculum (Yamanaka et al, 1993; Chan et al, 2009). Studies of rats with inherited cryptorchidism suggest that innervation and/or muscle development within the gubernaculum is disrupted (Hrabovszky et al, 2001; Barthold et al, 2008). While a role for CGRP release from the genitofemoral nerve in human fetuses remains undefined, it is clear that the human gubernaculum contains and is surrounded by muscle and is innervated by the nerve beginning as early as at 7 weeks' gestation (Lemeh, 1960; Tayakkanonta, 1963; Barteczko and Jacob, 2000; Niikura et al, 2008).

In summary, the gubernaculum develops in both sexes beginning early in the second month of gestation and testicular hormones stimulate development of the gubernaculum and testicular descent in the second and third trimesters. Enlargement, distal detachment and migration of the gubernaculum are key events that facilitate and direct caudal movement of the testis. In humans, the factors required for these events are incompletely known but likely include secretion of INSL3 and androgen and presumably intact innervation by the genitofemoral nerve.

Key Points: Embryology of Testicular Development and Descent

- Gonadal determination involves separate genetic pathways for development of testis and ovary.
- *Sry* is a master switch that derepresses the critical testis determining genes *Sox9* and *Fgf9*.
- Differentiation of gonocytes and Sertoli and Leydig cells occurs between 5 and 9 weeks' gestation.
- Levels of the Leydig cell hormones testosterone and INSL3 peak between 14 and 17 weeks' gestation and are critical for testicular descent.
- The gubernaculum, the guide for testicular descent, appears at 7 weeks' gestation and begins male-specific proliferation and swelling between 12 and 14 weeks.
- Dramatic swelling of the gubernaculum sets the stage for testicular descent, and innervation via the genitofemoral nerve may trigger transinguinal passage of the testis.
- The testis finishes transabdominal descent by 10 weeks, rapidly passes through the inguinal canal between 20 and 28 weeks, and is dependent in the scrotum in most boys by birth.

CRYPTORCHIDISM (UNDESCENDED TESTIS)

Cryptorchidism is one of the most common disorders encountered in pediatric urology and has been studied extensively. Despite this, knowledge of the causes and prediction of the consequences of the disease remains limited. Moreover, the quality of evidence that is used to support clinical guidelines for diagnosis and treatment is surprisingly low (Gapany et al, 2008; Turner, 2009).

Definitions

Differing terminology has been used to describe patients with nonscrotal testes; use of the following definitions is recommended. ***Normal scrotal position*** has been defined as positioning of the midpoint of the testis at or below the midscrotum (Wohlfahrt-Veje et al, 2009). Although "high scrotal testes" are not routinely considered undescended by most clinicians, they have been included in the definition of undescended testis in some epidemiologic studies (Sijstermans et al, 2008). This is likely a heterogeneous group that includes stable descended testes that reside above the scrotal midpoint and undescended "gliding" testes (Hack et al, 2007), which are not stable. ***Undescended testis*** is the absence of one or both testes in normal scrotal position and during initial

clinical evaluation may refer to palpable ***cryptorchid testes*** or to nonpalpable testes, which are either cryptorchid or absent. Most absent testes are ***vanishing,*** present initially in development but are lost owing to vascular accident or torsion unilaterally ***(monorchia)*** or, very rarely, bilaterally ***(anorchia)*** (Abeyaratne et al, 1969). ***Agenesis*** refers to a testis that was never present and therefore associated with ipsilateral müllerian duct persistence. ***Congenital cryptorchidism*** refers to testes that are extrascrotal at birth, and ***recurrent cryptorchidism*** is when testes descend spontaneously postnatally but subsequently return to a nonscrotal position. The terms ***testicular ascent*** or ***acquired cryptorchidism*** are used in situations when cryptorchid testes are documented as scrotal at a previous examination without intervening inguinal surgery. ***Secondary cryptorchidism*** and ***testicular retraction*** apply to testes that are suprascrotal after inguinal hernia repair and as a complication of orchidopexy, respectively. Testicular malposition after hernia repair is due to either postoperative scarring or primary maldescent. ***Retractile testes*** are scrotal testes that retract easily out of the scrotum but can be manually replaced in a stable scrotal position and remain there at least temporarily. Testes that are significantly retractile, that is, those that rarely remain in a stable scrotal position (spontaneously or with manipulation) and/or are located at rest in the high scrotum, may or may not be truly undescended.

Epidemiology and Pathogenesis

Cryptorchidism is one of the most common congenital anomalies, occurring in 1% to 4% of full-term and 1% to 45% of preterm male neonates (Sijstermans et al, 2008). It is a component of over 390 syndromes (Winter-Baraitser Dysmorphology Database, http://www.lmdatabases.com); the most common are listed in recent reviews (Foresta et al, 2008; Virtanen and Toppari, 2008). The majority of cases are isolated, with the ratio of nonsyndromic to syndromic cryptorchidism reported as greater than 6:1 in a large cohort (Boyd et al, 2006). In a small percentage of syndromic cases associated with deficiency or insensitivity of hypothalamic-pituitary-gonadal (HPG) axis hormones, the etiology of testicular maldescent is known. **The pathogenesis of isolated cryptorchidism remains largely unknown but is most likely multifactorial, involving both genetic and environmental risk factors.**

Nonsyndromic Congenital Cryptorchidism

Studies of the prevalence of isolated cryptorchidism at birth are complicated by confounding factors that include subjectivity of the examination and differences in the definition of undescended testis (inclusion/exclusion of high scrotal testes) and in study populations and study design (Sijstermans et al, 2008). Although most studies support a prevalence at birth of 2% to 4% and at 3 months of age of 1% to 2%, this varies geographically, with frequency as high as 8% in some studies (Virtanen and Toppari, 2008), supporting the possibility of an increase over time. However, other data suggest that country-specific trends are not increasing (Abdullah et al, 2007; Cortes et al, 2008; Bonney et al, 2009) and overall there do not appear to be reproducible trends in prevalence (Sijstermans et al, 2008). Perinatal risk factors associated with cryptorchidism include prematurity, low birth weight/small for gestational age, breech presentation, and maternal diabetes (Damgaard et al, 2008; Virtanen and Toppari, 2008).

The reported frequency of spontaneous testicular descent after birth also appears to vary substantially between studies, likely owing to similar confounding factors. Of 95 patients with cryptorchidism referred to a urology practice when younger than 6 months of age, 16% had spontaneous testicular descent versus 0% of those presenting after 6 months; in contrast, previous studies reported a 50% to 75% rate of spontaneous postnatal testicular descent (Wenzler et al, 2004). Suomi and associates (2006) noted spontaneous descent in significantly more Danish (68%) than Finnish (45%) boys at 3 months of age, likely owing to increased severity of the disease in the latter group. Similarly, in a recent longitudinal study, extrascrotal testes were much less likely to descend by 1 year of age (50%) than high scrotal testes defined as cryptorchid at birth (87.5%) (Acerini et al, 2009). The long-term risk of recurrent cryptorchidism was not determined in these studies and is difficult to ascertain because of short follow-up. Spontaneous descent is more likely and may occur later in premature infants.

Retractile and Acquired Undescended Testes

In the past, cryptorchidism was considered a congenital anomaly identifiable at birth, with spontaneous descent possible during the postnatal period. However, since first reported more than 30 years ago (Myers and Officer, 1975), **substantial evidence indicates that the diagnosis of cryptorchidism may be "acquired," that is, made in cases of apparent full descent at birth or after spontaneous descent of a cryptorchid testis** (Barthold and Gonzalez, 2003; Taghizadeh and Thomas, 2008). Except for diagnosis at an average age of 8 to 9 years and lower testicular position, other characteristics of testicular "ascent" or "acquired" cryptorchidism are similar to those observed in cases of congenital cryptorchidism. The reason for a later diagnosis remains unknown; theories include presence of a fibrous remnant of the processus vaginalis that tethers or foreshortens the cord over time or mobility of the testis within an open sac. However, it is most likely that the testis is incompletely descended from birth, because many are localized within the superficial inguinal pouch (Barthold and Gonzalez, 2003). These testes may be highly mobile and initially appear descended until somatic growth results in relative widening of the distance between testis and scrotum (Redman, 2005; Agarwal et al, 2006).

A diagnosis of cryptorchidism beyond the neonatal period may be more likely in boys with retractile testes. In an unselected population, the testis was reported to be suprascrotal on initial examination in up to 30% of boys at 4 years of age but intrascrotal in 100% by age 12 (Farrington, 1968). Both prospective and retrospective studies of the natural history of retractile testes support the concept that a subset of these becomes undescended over time. However, a selection bias exists in studies of the risk of cryptorchidism in boys with retractile testes, because those referred for follow-up by specialists are those with the most severe retractility. For example, Wyllie (1984) prospectively studied a cohort of 100 boys with unilateral retractile testis and identified 64 cases in which testicular position, as documented by the distance between the pubic tubercle and midtestis, and/or testicular size, as estimated by orchidometer, was reduced after 5 years of follow-up. Orchidopexy was performed in 45 of these cases, although specific documentation of testicular position and size as indications for surgery were not reported. Findings of retrospective case series also suggest that cryptorchidism is ultimately diagnosed in about 33% of boys with significantly retractile testes followed longitudinally by the same observer(s) (La Scala and Ein, 2004; Agarwal et al, 2006). In contrast, only 7% of 172 boys followed a mean of 26 months required orchidopexy in a more recent study (Stec et al, 2007). These data suggest that a significant minority of retractile testes become suprascrotal over time. **Careful, often**

serial, physical examination may be necessary to accurately determine testicular position and need for intervention.

Two recent longitudinal population-based cohort studies have provided some preliminary information regarding the risk of acquired cryptorchidism in the general population during childhood (Acerini et al, 2009; Wohlfahrt-Veje et al, 2009). In a study from the United Kingdom, 742 infants were followed with serial examinations for 2 years after birth with complete follow-up in 326. The prevalence of extrascrotal testes was 2.7% at birth (27% nonpalpable, surgical findings not reported); and 0.2%, 1.8%, 0.3%, and 0% of testes in the studied population became extrascrotal at 3, 12, 18, and 24 months, respectively. Including high scrotal testes, a total of 5.7% were identified as cryptorchid at birth and 1% to 4% rose to a high scrotal position with each follow-up visit. As expected, suprascrotal testes in neonates were much less likely to descend spontaneously (41%) than high scrotal testes (84%). In a series from Finland, cryptorchidism was present at birth in 94 of 1072 boys (0.9%) and 509 of the noncryptorchid boys were followed at 6- to 18-month intervals until 4.5 to 10 years of age. Of those observed, seven testes became suprascrotal and five became high scrotal, with the change in position occurring during the first 36 months of life. These studies suggest regional differences in both congenital and acquired cryptorchidism, but both suggest a low risk that scrotal testes will become suprascrotal in the first few years of life. **However, cases diagnosed during childhood comprise a significant number of those requiring orchidopexy and yearly well-child screening is indicated.**

Genetic Susceptibility

Genetic studies of cryptorchidism suggest that the disease is heritable but that susceptibility is likely polygenic and multifactorial. Clustering of cryptorchidism has been reported in a number of families affecting multiple individuals in the same generation and variable phenotype (Minehan and Touloukian, 1974; Pardo-Mindan et al, 1975; Czeizel et al, 1981; Savion et al, 1984). Extended pedigrees were not usually examined, but autosomal dominance with reduced penetrance was most often cited as the probable mode of inheritance. Population case-control studies also support genetic contribution to the disease. Familial aggregation suggesting moderate genetic risk was reported in a recent large cohort study of more than 1 million male births in the Netherlands based on extensive hospital registry data (Schnack et al, 2008). Recurrence risk ratio (RR) was 10.1 in twins, 3.5 in brothers, and 2.3 in offspring and were significantly higher in maternal than in paternal half-brothers. Previous smaller studies reported a 5- and 7- to 10-fold increased risk of cryptorchidism in fathers and brothers, respectively, of affected as compared with unaffected subjects (Czeizel et al, 1981; Jones and Young, 1982; Elert et al, 2003). These and another recent study (Jensen et al, 2010) support the possibility that maternal factor(s), or X-linked risk alleles, influence expression of the disease.

Based on mouse models, *INSL3,* its receptor, relaxin/insulin-like family peptide receptor 2 *(RXFP2), HOXA10,* and *HOXA11* were considered the most likely candidate genes for human nonsyndromic cryptorchidism. However, case-specific DNA coding variants of *INSL3* and *RXFP2* are reported in only 0.6% to 1.8% and 1.6% to 2.9% of persistently cryptorchid males, respectively, and in-vitro assays suggest that few of these appear to be functionally significant (Foresta et al, 2008). Notably, apparent mutations in these genes are associated with a range of phenotypes encompassing unilateral/bilateral and persistent/spontaneously resolving presentations and apparently deleterious mutations may exist in normal family members, as recently noted for an *INSL3* mutation showing reduced receptor activation (El Houate et al, 2007). A nonsynonymous polymorphism of the *RXFP2* gene, T222P, was considered a strong etiologic candidate for cryptorchidism based on absence in normal controls and in-vitro studies showing curtailed cell membrane localization and activation of the abnormal receptor (Bogatcheva et al, 2007). However, cases and controls in a different European population subset were found to have a similar frequency of the T222P allele (Nuti et al, 2008). Although these data suggest that mutations of *INSL3* and *RXFP2* are infrequent in cases of cryptorchidism, it is possible that noncoding variants that alter expression levels of the protein have yet to be identified.

Analysis of other potential candidate genes for human cryptorchidism has failed to yield reproducible results. *HOXA10* mutations reported by Kolon and colleagues (1999) were not confirmed in additional series, nor were mutations identified in *HOXA11* (Bertini et al, 2004; Wang et al, 2007). A specific haplotype of the gene encoding ERα (*ESR1*) has not shown consistent association with cryptorchidism in three case-control series (Yoshida et al, 2005; Galan et al, 2007; Wang et al, 2008). Similar varying results have been reported in studies of trinucleotide repeat number in exon 1 of the androgen receptor, although more recent work suggests a possible association with cryptorchidism (Ferlin et al, 2007). Microdeletions of the Y chromosome have also been studied in infertile men with and without a history of cryptorchidism, and no consistent association was observed (reviewed in Gurbuz et al, 2008). A specific polymorphism of the steroidogenic factor 1 (SF1) gene that encodes a transcription factor that regulates expression of *INSL3, RXFP2,* and steroidogenesis genes was recently reported to exist more commonly in cryptorchid Japanese males (Wada et al, 2006). Failure to identify consistent differences in genomic variants for many of these candidates may be influenced by confounding factors such as race and by insufficient sample size. **Although multiple genetic variants likely contribute to the risk of nonsyndromic cryptorchidism, most remain unknown at this time.**

Environmental Risk Factors

Sharpe and Skakkebaek (2008) proposed that nonsyndromic cryptorchidism is one component of the "testicular dysgenesis syndrome," a constellation of reproductive abnormalities including testicular cancer, hypospadias, and reduced sperm counts associated with exposure to antiandrogenic and/or estrogenic environmental endocrine-disrupting chemicals (EDCs). However, some question both the existence of testicular dysgenesis syndrome in humans, because of lack of epidemiologic association between these abnormalities, and the evidence for environmental etiology (Akre and Richiardi, 2009). The concern for a link between EDCs and cryptorchidism arose because of a reported increased risk of cryptorchidism after maternal exposure to diethylstilbestrol (DES) (Gill et al, 1979). This association was observed in rodents but was not confirmed in other clinical case-control studies (Leary et al, 1984); however, in a recent large cohort study of 1197 men previously exposed to DES and 1038 unexposed men, the relative risk (RR) of cryptorchidism was 1.9 overall (confidence interval [CI] 1.1 to 3.4). When data were subdivided based on gestational age of less than 11 weeks and exposure greater than or equal to 5 g, the relative risks were 2.9 (CI 1.6 to 5.2) and 3.2 (CI 1.7 to 6.0), showing that early and significant exposure presents the clearest risks (Palmer et al, 2009). Data supporting a link between other EDCs and cryptorchidism are less clear. Animal models suggest a

relationship between prenatal exposure to antiandrogenic EDCs and risk of cryptorchidism and other reproductive endpoints and suggest additive effects of chemical mixtures, although levels of exposure are much higher than applicable clinically (Rider et al, 2009). In humans, data supporting a correlation between exposure to antiandrogenic and/or estrogenic EDCs such as pesticides, flame retardants, and phthalates and occurrence of cryptorchidism are mostly indirect or suggestive (Weidner et al, 1998; Pierik et al, 2004; Damgaard et al, 2006; Main et al, 2006a, 2007; Fernandez et al, 2007; Krysiak-Baltyn et al, 2010). Strong correlations between single chemicals or classes of EDCs and risk of cryptorchidism may be difficult to demonstrate in view of the presumed heterogeneity of susceptibility to the disease, but the wide variety of EDCs to which humans are exposed may allow for synergistic effects that are difficult to measure. **However, at present, epidemiologic data are suggestive but do not strongly support the theory that environmental chemicals increase susceptibility to cryptorchidism.**

Testicular hormones are required for testicular descent; therefore, if defective hormone production and/or action contribute to the pathogenesis of cryptorchidism, hormone deficiency may persist postnatally. A number of prospective studies of varying size and quality are available that report postnatal hormone levels in cryptorchidism; although some data suggest that the HPG axis is abnormal, the results are conflicting. In the first reported series of cryptorchid and control boys undergoing hormonal evaluation in the first few months of life, serum testosterone was lower in 7 of 17 (41%) persistently cryptorchid boys but comparable to control levels in 4 of 25 boys with spontaneous testicular descent (Gendrel et al, 1978). In a small series of 60-day-old bilaterally cryptorchid (9) and control (14) boys, Facchinetti and associates (1983) also observed reduced plasma testosterone levels but no difference in plasma LH between groups. Raivio and coworkers (2003) reported both significantly reduced plasma testosterone as well as nonmeasurable androgen bioactivity in 3-month-old cryptorchid boys (n = 45; 31% bilateral, 44% with spontaneous descent), but androgen bioactivity was measurable in only 21 of 55 controls.

Additional infant hormone studies did not show lower levels in cryptorchid infants (De Muinck Keizer-Schrama et al, 1988, Barthold et al, 2004), but more recent data from the Netherlands did show reduced testosterone levels in cryptorchid infants (Pierik et al, 2009). In the largest study to date, Suomi and colleagues (2006) showed geographic differences in serum inhibin-B and follicle-stimulating hormone (FSH) levels but no differences in testosterone levels in cryptorchid infants from Finland (n = 88, 36% spontaneous descent) and Denmark (n = 34, 68% spontaneous descent) as compared with 300 and 399 control boys, respectively. In a related cohort, INSL3 levels were reduced in cord blood but not in serum obtained at 3 months of age in persistently cryptorchid males (Bay et al, 2007).

Other studies of Sertoli/germ cell function as determined by serum assays in boys with cryptorchidism suggest that abnormalities may exist but data are inconsistent between studies. In a longitudinal study of 27 boys (mean age 4.8 years) undergoing orchidopexy, an increase in serum inhibin B was identified in a majority of cases 6 months postoperatively (Irkilata et al, 2004), but in another series of 62 boys (mean age 7.7 years) no differences were identified in inhibin B (or in serum LH, FSH, or testosterone) levels before or after hCG stimulation (Christiansen et al, 2002). AMH levels were measured in three prospective studies of boys with cryptorchidism as compared with age-matched controls. Lower AMH levels were seen in a subset of patients younger than 8 years of age included in a study of 104 cryptorchid boys (mean age 4 to 5 years) (Yamanaka et al, 1991) and also in a case-control study of 12-month-old boys (n = 20 per group) in whom levels did not change after orchidopexy (Demircan et al, 2006). However, in another study no differences in AMH levels were seen in 1- to 6-month-old cryptorchid (n = 43) versus control (n = 113) boys (Pierik et al, 2009).

These studies suggest that at least a subset of boys with cryptorchidism have measurable abnormalities in pituitary and/or gonadal hormone secretion during infancy without syndromic endocrine dysfunction. Inconsistent findings between studies are likely based on timing and type of assays, sample size, and heterogeneity based on age, severity, genetic background, and/or other interindividual differences. Lifestyle factors may also interfere with testicular descent and function via hormonal or nonhormonal effects; examples are the recent observation that smoking is associated with cryptorchidism in some case-control series (Thorup et al, 2006; Jensen et al, 2007) and the reduced expression of the Desert hedgehog *(DHH)* gene that is involved in Leydig cell differentiation in human fetuses (Fowler et al, 2008). Multiple genetic and environmental factors likely contribute to cryptorchidism, complicating identification of risk factors in case-control studies.

Syndromic Cryptorchidism

Undescended testes are frequently present in diseases associated with reduced androgen production and/or action, such as androgen biosynthetic defects, androgen insensitivity, Leydig cell agenesis, and gonadotropin deficiency disorders (Barthold et al, 2000; Foresta et al, 2008) that are typically associated with generalized failure of masculinization and are not reviewed here. AMH biosynthesis or receptor defects are also associated with cryptorchidism or transverse testicular ectopia (Josso et al, 2006). Gubernacular defects that are observed in these patients may be due to hindrance of descent by retained müllerian ducts (Barteczko and Jacob, 2000) and/or through loss of direct proliferative effects of AMH on the gubernaculum (Kubota et al, 2002). The frequency of Klinefelter syndrome (47,XXY) is 1.8% in large series of primarily nonsyndromic cryptorchidism but is more frequent when other anomalies, particularly hypospadias, are present (Sasagawa et al, 1996; Moreno-Garcia and Miranda, 2002). Other genomic rearrangements and trisomies, including Down syndrome (trisomy 21), are associated with cryptorchidism (Hadziselimovic, 1983).

Certain anomalies are associated with increased risk of cryptorchidism, many related to musculoskeletal, central nervous system (CNS), or abdominal wall/gastrointestinal defects. These include all cases of classic prune-belly (triad or Eagle-Barrett) syndrome; 80% of those of spigelian hernia (Durham and Ricketts, 2006); and 41% to 54% of cerebral palsy (Rundle et al, 1982; Cortada and Kousseff, 1984), 38% of arthrogryposis (Fallat et al, 1991), 15% of myelomeningocele (Ferrara et al, 1998), 16% to 33% of omphalocele, 5% to 15% of gastroschisis (Kaplan et al, 1986; Koivusalo et al, 1998), 19% of imperforate anus (Cortes et al, 1995b), 12% to 16% of posterior urethral valve (Krueger et al, 1980; Heikkila et al, 2008), and 6% of umbilical hernia (Kaplan et al, 1986) patients. Multisystem anomalies are often associated with omphalocele (80%) and prune-belly syndrome (45%), suggesting a syndromic etiology (Loder et al, 1992; Koivusalo et al, 1998). Depue (1988) also reported a significant association of cryptorchidism with CNS dysfunction, particularly cerebral palsy (RR = 34), low intelligence quotient (RR = 2.7), and hypotonia (RR = 3.6). Cortes and associates (1998) identified an association between renal and T10 to S5 spinal anomalies and cryptorchidism, with the affected

testis on the same side as the renal anomaly in 90% of cases. In addition, cryptorchidism associated with syndromes and CNS malformations is more commonly bilateral (Cendron et al, 1993; Cortes et al, 1995a). These data support common origins of cryptorchidism and abnormalities of urogenital ridge, abdominal wall, lumbosacral spine, and CNS development.

Diagnosis and Classification

To best determine testicular position, boys should be examined in supine and, if possible, upright cross-legged and standing positions. Abduction of the thighs contributes to inhibition of the cremaster reflex, or testicular elevation elicited by scratching the inner thigh. The examination should include documentation of testicular palpability, position, mobility, size, and possible associated findings such as hernia, hydrocele, penile size, and urethral position. Patient distraction, a warm room and hands, use of liquid soap on the examiner's hands, and repeated examinations also help to localize the testis and to limit cremaster muscle activity and resultant difficulty in determining testicular position.

In large clinical series, the majority (75% to 80%) of undescended testes are palpable and 60% to 70% are unilateral; involvement of the right side is more common overall but less frequent in series of nonpalpable testes (Hadziselimovic, 1983; Cendron et al, 1993; Cortes et al, 2001; Giannopoulos et al, 2001). Position of undescended testes varies markedly with the population studied. In a comprehensive review of surgical patients, testes were abdominal in 34%, near the internal ring ("peeping") in 12%, canalicular in 27%, and beyond the external ring in 27% (Docimo, 1995) whereas in a large single institutional series testes were abdominal in 3% to 10% of total cases, canalicular in 16% to 27%, with the majority distal to the external ring (Hadziselimovic, 1983; Moul and Belman, 1988; Cendron et al, 1993). In a large multiinstitutional review of almost 40,000 European cryptorchid boys reported by Hadziselimovic (1983), 8% of testes were abdominal, 63% canalicular, 24% prescrotal, and 11% in the superficial inguinal pouch or ectopic. Moul and Belman classified all subinguinal testes with a lateral gubernacular attachment as ectopic (66% of their total cases).

Associated genital findings may warrant additional diagnostic studies that are best completed in the neonatal period. If both testes are nonpalpable, particularly if penile development is abnormal, karyotype and hormonal analyses are performed to rule out congenital adrenal hyperplasia and obviate the potential adverse effects of undiagnosed salt wasting. Hypospadias is associated with cryptorchidism in 12% to 24% of cases (Cendron et al, 1993; Moreno-Garcia and Miranda, 2002; Cox et al, 2008). If proximal hypospadias is present, chromosomal analysis is warranted because the frequency of abnormalities is high (32%) (Cox et al, 2008). Penile size may be small in boys with bilateral vanishing testes (also called testicular regression syndrome) or with hypogonadotropic hypogonadism, in whom undescended testes are most commonly inguinal. In these cases, measurement of testosterone, LH, and FSH levels in the first few months of life can facilitate identification of hormone deficiency or anorchia.

Palpable Testes

Undescended testes may be located along the line of normal descent between the abdomen and scrotum or in an ectopic position that is most commonly the superficial inguinal pouch (anterior to the rectus abdominis muscle) or, more rarely, in a perirenal, prepubic, femoral, peripenile, perineal, or contralateral scrotal position. Careful examination of these areas is needed to correctly classify a testis as palpable or nonpalpable, a critical step that influences further diagnosis and treatment. Every effort should be made by the examiner to determine the lowest position attainable by a palpable undescended testis. Manual downward pressure with one hand along the ipsilateral inguinal canal from the anterior iliac spine to the scrotum and palpation with the opposite hand helps to identify the lowest position of a palpable testis.

Difficulty in the clinical classification of cryptorchidism when the testis is palpable is related to both documentation of testicular position and differentiation of truly undescended from retractile testes, complicated by the fact that these entities may coexist. The gold standard for diagnosis remains careful examination of a child in several positions and confirmation of incomplete descent of the testis to a dependent scrotal position after induction of anesthesia. Prospective studies of intraobserver and interobserver variation show major differences in documentation of testicular position between examiners (Wit et al, 1987; Olsen, 1989). Olsen (1989) noted complete agreement between two examiners on scaled measures of testicular position and mobility in only 5 (13.5%, 95% CI 4.5% to 28.8%) of 37 boys. Cendron and coworkers (1993) reported that preoperative testicular position correlates poorly with intraoperative findings. Variation in observed testicular position preoperatively and postoperatively may influence assessment of prognosis and outcome in boys with cryptorchidism.

Nonpalpable Testes

When a testis is nonpalpable, possible clinical findings at surgery include (1) abdominal or transinguinal "peeping" location (25% to 50%), (2) complete atrophy ("vanishing" testis, 15% to 40%), and (3) extra-abdominal location but nonpalpable due to body habitus, testicular size, and/or limited cooperation of the patient (10% to 30%) (Cendron et al, 1993; Cisek et al, 1998; Kirsch et al, 1998; Radmayr et al, 2003; Patil et al, 2005). If both testes are nonpalpable and not distal to the internal inguinal ring in a genetic male, at least 95% are abdominal with bilateral vanishing testis occurring rarely (Cendron et al, 1993; Moore et al, 1994). If neither vas nor spermatic artery is found at the time of laparoscopy, laparoscopic or surgical dissection of the paravesical area and retroperitoneum up to the level of the kidney is required to exclude the presence of a testis. Pararenal or other abdominal testes may be associated with multicystic dysplastic or absent ipsilateral kidneys and/or nonunion of the testis and epididymis (Zaccara et al, 2004; Foley et al, 2005; Kim et al, 2005).

The etiology of vanishing testis is most likely torsion or vascular accident occurring after completion of genital masculinization but before fixation of the testis in the scrotum. Evidence supporting this etiology includes the presence of hemosiderin in remnant testicular "nubbins" excised at surgery (Turek et al, 1994) and reported cases of contralateral postnatal torsion (Gong et al, 1996). An enlarged contralateral testis (Huff et al, 1992) and absence of palpable intrascrotal "appendage" tissue (processus vaginalis, wolffian structures, or gubernaculum) are highly predictive of vanishing testis (Mesrobian et al, 2002). However, **diagnosis of a vanishing testis requires documentation of blind-ending spermatic vessels in the abdomen, inguinal canal, or scrotum.** Endocrine evaluation in cases of suspected bilateral vanishing testis (anorchia) include elevated basal serum gonadotropin levels and no response to hCG stimulation; however, gonadotropins may be unexpectedly low in mid childhood in boys who are also unresponsive to hCG (Lustig et al, 1987; Lee, 2000). Therefore laparoscopic or surgical documentation of anorchia is critical to avoid leaving small or dysgenetic abdominal

testes in situ. AMH and inhibin-B levels may be useful in documenting the presence of functioning testicular tissue (Grumbach, 2005).

Inguinoscrotal ultrasonography and magnetic resonance imaging (MRI) are not usually helpful in the diagnosis and management of nonpalpable testis (Elder, 2002). However, if a testis is nonpalpable when evaluated by an experienced examiner, the sensitivity of ultrasonography in identifying inguinal testes is reported to be as high as 95% to 97%, and abdominal testes are also seen in some cases (Cain et al, 1996; Nijs et al, 2007). Some of these testes are "peeping," however, and best mobilized via a laparoscopic approach. Similarly, although MRI can be useful in some cases to identify nonpalpable abdominal testes, its accuracy is variable and the procedure requires sedation in younger children and often may not change the management approach (Yeung et al, 1999; Siemer et al, 2000). The superior accuracy of magnetic resonance angiography in localizing and differentiating viable from vanished testes (96% of 23 nonpalpable testes in 21 boys, mean age 2.5 years) has not been replicated in a recent study of younger boys (57% of 29 testes in 26 boys, mean age 13 months) (Yeung et al, 1999; Desireddi et al, 2008). One indication for MRI may be identification of an ectopic abdominal testis not localized by laparoscopy.

Diagnostic laparoscopy followed by laparoscopic orchidopexy if the testis is abdominal has become the preferred approach of many clinicians. Important observations include size and position of the spermatic vessels and vas; testicular size, quality, and position; and patency of the internal inguinal ring. The combination of a closed internal ring and a blind-ending spermatic artery and vas is most consistent with an abdominal vanishing testis, whereas a hernia is frequently but not always associated with a viable abdominal or distal testis (Elder, 1994; Moore et al, 1994). An atretic spermatic cord coursing through a closed inguinal ring is suggestive of a distal vanishing testis, but this finding may be subjective; and, conversely, normal-appearing vessels may be associated with both viable and vanishing testes (Zaccara et al, 2004). Moreover, the laparoscopic view may suggest abdominal blind-ending vessels despite a testis being present distally or in an ectopic abdominal position (Zaccara et al, 2004; Kim et al, 2005; Ellsworth and Cheuck, 2009).

The need for excision and contralateral scrotal orchidopexy in cases of vanishing testis remains controversial. Germ cells and/or tubules are consistently present in 5% to 15% of excised testicular remnants (Moore et al, 1994; Tennenbaum et al, 1994; Turek et al, 1994; Cortes et al, 1995a; De Luna et al, 2003; Renzulli et al, 2005), but the risk of malignancy is unknown. A single case of carcinoma in situ was reported by Rozanski and associates (1996) in a testicular remnant. Excision may be appropriate for remnants distal to an internal ring to allow confirmation that a viable testis is absent, because the laparoscopic appearance of the spermatic vessels and processus vaginalis may be deceiving and may not reliably exclude the presence of an inguinal testis (Ellsworth and Cheuck, 2009). Storm and colleagues (2007) performed laparoscopic excision of vanishing testes in 56 patients without significant morbidity, although the position of the remnants in these patients was not clear. Because the testicular remnant is often in or near the scrotum, some advocate a primary scrotal approach when contralateral testicular hypertrophy (testicular length ≥ 1.8 cm) and a palpable scrotal "nubbin" are present (Belman and Rushton, 2003; Snodgrass et al, 2007). However, in cases of abdominal vanishing testes, a transscrotal search is time consuming and unproductive. Moreover, in cases of testicular-epididymal dissociation, scrotal nubbins may be mistaken for testicular remnants that would otherwise be identified by laparoscopy (Wolffenbuttel et al, 2000; De Luna et al, 2003). **Laparoscopy is the procedure of choice to confirm or exclude the presence of a viable or remnant abdominal testis, unless a prominent scrotal nubbin is palpable with other clinical signs of monorchism.**

The need for contralateral fixation of a solitary testis in cases of monorchism is not clear. The possibility that prenatal torsion is the etiology of vanishing testis (Gong et al, 1996) does not imply that the contralateral testis is likely to undergo a similar fate after the postnatal period. However, some surgeons recommend contralateral fixation to eliminate the risk of such a devastating complication (Rozanski et al, 1996) and/or because a contralateral bell-clapper deformity (incomplete testicular fixation to the tunica vaginalis) may be present (Bellinger, 1985; Al-Zahem and Shun, 2006).

Associated Pathology

Testicular Maldevelopment

Many observational studies of the histologic development of prepubertal cryptorchid testes have been published. More than 40 years ago, Mancini and associates (1965) systematically reported germ cell counts and related arrested development of spermatogonia with progressive loss in cryptorchid testes. Subsequently, several large series, some with additional normal autopsy (Hedinger, 1982) or affected (hernia, hydrocele) (Hadziselimovic et al, 1987a) control data and others that refer to these established age-dependent norms (Schindler et al, 1987; Huff et al, 1993; McAleer et al, 1995; Gracia et al, 2000; Cortes et al, 2001), have provided mainly consistent findings in cryptorchid boys. These data show that the number of spermatogonia per tubule (S/T) is reduced after infancy and fails to increase normally with age in cryptorchid and, to a lesser degree, in contralateral scrotal testes. The frequency of abnormal histology in the contralateral testis varies between studies, ranging from 22% to 95%, and is likely reflective of differences in patient populations, use of control data, and methodology. Moreover, variability within and between biopsy specimens from single testes is reported (Hedinger, 1982; Schindler et al, 1987). **However, these data provide strong evidence that abnormal germ cell development is often present after early infancy in cryptorchid testes.** The degree of pathology was similar in true ectopic, superficial inguinal pouch, and ascending testes (Herzog et al, 1992; Hutcheson et al, 2000b; Rusnack et al, 2002) and was more severe in limited samples from patients with myelomeningocele, posterior urethral valves, and prune-belly syndrome (Orvis et al, 1988; Patel et al, 2008). Findings are similar in retracted testes after hernia repair, suggesting primary instead of secondary cryptorchidism (Fenig et al, 2001). In other studies, higher S/T counts were correlated with reduced age-dependent interstitial fibrosis (Suskind et al, 2008), lower age at surgery, and increased likelihood of palpability (Tasian et al, 2009), but not volume (Noh et al, 2000), of cryptorchid testes. Regional differences in S/T counts were recently reported, potentially reflecting population differences in environmental exposures (Zivkovic et al, 2009).

Detailed studies of peritubular myoid and Sertoli cells in cryptorchidism are lacking, but their abnormal development or function may contribute to the observed germ cell abnormalities. The available data suggest disruption of prepubertal Sertoli cell morphology, failure of maturation at puberty, and evidence for reduced

number after 4 months of age in cryptorchid testes (Lackgren and Ploen, 1984; Rune et al, 1992; Regadera et al, 2001; Zivkovic and Hadziselimovic, 2009). Reduced expression of type IV collagen, a product of both Sertoli and myoid cells that may function in cell-cell communication, was reduced in basement membranes of undescended and contralaterally descended testes (Santamaria et al, 1990).

Impaired transformation of gonocytes to spermatogonia is reported in cryptorchid testes and may be a key determinant of fertility potential. In normal testes, germ cell number decreases after birth as gonocytes either degenerate by apoptosis or migrate to the basement membrane and differentiate into spermatogonia (Hadziselimovic et al, 1986; Huff et al, 2001). Although the ratio of gonocytes to spermatogonia appears to be normal in cryptorchid testes at about 1.5 months of age, delayed disappearance of gonocytes and appearance of adult dark (Ad) spermatogonia occurs in the undescended as compared with the contralateral descended testis. Ad spermatogonia are likely the reserve stem cells of the germ cell pool (Dym et al, 2009). The mechanisms involved in migration and/or differentiation of gonocytes into stem cells are not clearly defined but appear to involve ADAM-integrin-tetraspanin complexes, retinoic acid, platelet-derived growth factor receptor, and c-KIT (Culty, 2009). Hadziselimovic and colleagues hypothesize that failure of gonocyte differentiation in cryptorchidism reflects failure of postnatal activation of the HPG axis (Hadziselimovic et al, 1986); however, although they occur concurrently there are no data confirming a direct relationship between the two events.

Kollin and colleagues (2006, 2007) studied testicular growth in undescended and scrotal testes and measured the effect in orchidopexy on testicular size using serial ultrasonography in prospective randomized studies. They showed that the undescended testis is not significantly smaller at birth but grows less well than the scrotal testis, and orchidopexy at age 9 months allows partial catch-up growth of the cryptorchid testis up to 4 years of age. In contrast, testes that remained cryptorchid until 3 years of age did not grow significantly before or after orchidopexy. The cellular components responsible for these differences in volume are not known. In scrotal testes, ethnic differences in testicular size as reported by Main and associates (2006b) were associated with increased inhibin-B levels and interpreted to primarily reflect differences in Sertoli cell number (Sharpe, 2006).

Anomalies of the Epididymis, Processus Vaginalis, and Gubernaculum

The epididymis is often abnormal in boys with cryptorchidism (Marshall and Shermeta, 1979), with a reported frequency of 35% to 75% (Heath et al, 1984; Gill et al, 1989; Mollaeian et al, 1994). Anatomic findings in decreasing order of frequency include anomalies of fusion between the caput and/or cauda epididymis, elongation and/or looping, and atresia. The occurrence of epididymal anomalies correlates with both the severity of cryptorchidism and the degree of closure of the processus vaginalis (Elder, 1992; Barthold and Redman, 1996). The degree to which these anomalies contribute to the risk of subfertility in males with a history of cryptorchidism remains undefined. Similarly, failure of closure of the processus vaginalis and attachment of the gubernacular remnant are common in association with cryptorchidism. In their study of 759 patients, Cendron and colleagues (1993) identified a persistently patent processus vaginalis ipsilateral to 87% of unilateral and 71% of bilateral undescended testes. Specific notation of the gubernacular position available from this and another large study indicates aberrant attachment lateral to the scrotum in 66% to 75% of cases (Moul and Belman, 1988). The processus is patent in approximately 50% of boys presenting with ascending testes, possibly related to older patient age and/or reduced severity of cryptorchidism in this group (Barthold and Gonzalez, 2003). **Anomalies of the tunica and processus vaginalis in cryptorchidism predispose to development of testicular torsion or clinical hernia, respectively, in rare cases.** Torsion of an undescended testis can occur at any age (reviewed by Zilberman et al, 2006) and may be confused with an incarcerated inguinal hernia. The risk of torsion is much higher in an undescended as compared with a descended testis and may be particularly high in children with neuromuscular disease such as cerebral palsy. Delay in diagnosis is common, and a high index of suspicion and education of family and referring physicians is needed to reduce the high risk of testicular loss.

Other Testicular Anomalies Associated with Cryptorchidism

Several rare anomalies of testicular development associated with cryptorchidism, each with 100-150 reported cases in the literature, include polyorchidism, splenogonadal fusion, and transverse testicular ectopia. Because abdominal cryptorchidism commonly occurs in these cases, laparoscopy is useful in both diagnosis and treatment.

Polyorchidism is the presence of a supernumerary testis that is more commonly unilateral and on the left side, with rare cases of bilateral duplication or triplication reported in a comprehensive review of the pediatric and adult literature (Bergholz and Wenke, 2009). The cause is unknown, but most authors speculate that this anomaly is related to duplication or division of the genital ridge with or without the wolffian duct, as illustrated by Danrad and colleagues (2004). Testes are reported to be scrotal, inguinal, and abdominal in 75%, 20%, and 5% of cases, respectively (Kumar et al, 2008). Affected individuals are frequently asymptomatic, and the polyorchidism is identified at the time of orchidopexy or hernia repair, although a scrotal or inguinal mass and pain with or without torsion may occur and persistent müllerian remnants may coexist. Various classification schemes have been proposed, with a recent trend toward categorizing testes based on epididymal and vasal configuration (Bergholz et al, 2007; Khedis et al, 2008; Kumar et al, 2008). Kumar and colleagues (2008) suggest a classification that differentiates between testes that are drained by a vas deferens: *type A1*—separate epididymis and vas, *type A2*—separate epididymis, and *type A3*—shared epididymis and vas from those with no vasal drainage: *type B1*—epididymis present and *type B2*—no epididymis or vas. This classification can aid in management decisions that should be based not only on the anatomy of the accessory ducts but also the position, size, and attachments of the testis. Observation and periodic self-examination without surgery should be considered for sonographically normal scrotal testes and orchidopexy for testes that are undescended but with intact ductal drainage (Spranger et al, 2002; Bergholz et al, 2007; Khedis et al, 2008). Occasional cases of testicular tumor have been reported in supernumerary testes, but it is unclear if this is a risk related to polyorchidism per se or to associated cryptorchidism or persistent müllerian duct syndrome (Spranger et al, 2002; Ghose et al, 2007).

Splenogonadal fusion is a defect characterized by continuous or discontinuous fibrous union between splenic tissue and the gonad, a condition much more commonly recognized in males (Khairat and Ismail, 2005). Approximately 30% of affected

individuals have cryptorchidism, with the majority of cases abdominal and bilateral (59%) and 65% and 26% involving the left and right sides, respectively (Cortes et al, 1996). The continuous form of splenogonadal fusion is more commonly syndromic, associated with limb defects, micrognathia, microglossia, anal atresia, and pulmonary hypoplasia (McPherson et al, 2003), whereas cryptorchidism is associated with both continuous and discontinuous forms and most commonly coexists with bilateral amelia (Cortes et al, 1996). The pathogenesis of the anomaly is not understood but based on the constellation of defects observed is hypothesized to represent a developmental field defect with aberrant migration of spleen cells occurring at 5 to 8 weeks' gestation. Most cases present incidentally at the time of orchidopexy or inguinal hernia repair or with scrotal swelling related to illness-related reactive changes within the splenic tissue. Testicular malignancy is reported rarely in association with cryptorchidism and not likely related to the splenic anomaly. Treatment should focus on recognition of the defect at the time of orchidopexy and avoidance of unnecessary orchiectomy.

Transverse testicular ectopia may occur as an isolated anomaly in otherwise normal males with cryptorchidism or vanishing testes or be associated with persistent müllerian duct syndrome in 20% to 50% of cases (De Luna et al, 2003; Wuerstle et al, 2007; Thambidorai and Khaleed, 2008). The classic presentation is inguinal hernia with contralateral nonpalpable testis, although both testes may be palpable in the same hemiscrotum. The etiology may be related to mechanical hindrance to descent by fusion of wolffian duct derivatives (Chacko et al, 2006) or persistent müllerian ducts or to a primary gubernacular defect. Interestingly, complete loss of the gubernacular attachment, transverse ectopia, and/or torsion were observed in transgenic mice null for *Insl3* (Nef and Parada, 1999; Zimmermann et al, 1999). Orchidopexy may be performed using open surgical or laparoscopic techniques, but in cases of vasal fusion the involved testis is mobilized ipsilaterally and a transseptal approach is used to place the testis in the contralateral scrotum (Chacko et al, 2006; Thambidorai and Khaleed, 2008).

Treatment

Correction of cryptorchidism is indicated to optimize testicular function, potentially reduce and/or facilitate diagnosis of testicular malignancy, provide cosmetic benefits, and prevent complications such as clinical hernia or torsion. Except in certain cases of associated complex medical illness or in the postnatal period, treatment should proceed after confirmation of the diagnosis. A flow diagram (Fig. 132–4) shows the recommended approach to palpable and nonpalpable testes in patients confirmed to have undescended testis by an experienced examiner.

In infants, observation is indicated for the first 6 postnatal months to allow spontaneous testicular descent. **If descent does not occur in the postnatal period, present consensus supports surgical treatment at 6 months of age.** Support for this approach is based on the following rationale: (1) descent is unlikely in full-term males after age 6 months (Wenzler et al, 2004); (2) testicular growth is restored after early orchidopexy (Kollin et al, 2007); (3) hormone therapy is not considered efficacious (Ritzen et al, 2007); and (4) orchidopexy for abdominal testes may be facilitated in young infants soon after the hormonal surge. In boys with a history of prematurity, spontaneous descent may be delayed and therefore continued observation for 6 months beyond the expected date of delivery or, especially if testicular position is marginal, until a year of age may be warranted. **However, even if spontaneous descent occurs, continued observation is needed because of the risk for recurrent cryptorchidism, or "re-ascent" of a spontaneously descended testis.**

Recently, two groups from the Netherlands published reports of the outcome of boys with acquired undescended testes who were observed expectantly (Sijstermans et al, 2006; Eijsbouts et al, 2007). These authors reported spontaneous descent in 75 of 132 (57%) and 98 of 129 (75%) testes, respectively, most by mid puberty. The mean volume of descended testes in the study by Eijsbouts and coworkers was closer to those of normal contralateral testes as compared with boys who underwent orchidopexy. However, in both of these series high scrotal testes comprised the majority and of those that descended and low scrotal "unstable" testes (likely retractile) were also included. On the other hand, Eijsbouts and coworkers reported that 19 of 82 unilateral cases had previous contralateral orchidopexy and that 10 boys required orchidopexy because of clinical hernia, pain, or torsion, suggesting a higher likelihood of true cryptorchidism in these cases. **Because these studies were not randomized and provide no long-term data regarding testicular outcome, observation is not recommended for acquired cryptorchidism.**

Medical Therapy

Hormonal therapy has been used for a variety of indications in patients with cryptorchidism, including differentiation of retractile from true undescended testes, stimulation of testicular descent or germ cell maturation, and as an adjunct to abdominal orchidopexy. These therapies may be used sporadically, but none is considered the standard of care, likely because of limited availability of some medications, lack of rigorous data supporting their efficacy, and concerns about possible adverse effects (Thorsson et al, 2007).

Several published reports address the usefulness of hormonal therapy in distinguishing retractile from true undescended testes. In prospective series reporting the response of putative retractile testes to hCG, success rates vary from 58% to 100% and may be dependent not only on age, degree of retractility, and accuracy of diagnosis but also on the dosage regimen used (Rajfer et al, 1986; Miller et al, 2003; Metin et al, 2005). In patients treated by Miller and associates (2003), nonresponders undergoing surgery had typical findings associated with true cryptorchidism, including a patent processus vaginalis and superficial inguinal pouch location, and follow-up was short (6 to 12 months). **These data suggest that hCG fails to reliably distinguish retractile from cryptorchid testes and therefore does not eliminate the need for serial examinations in these patients.**

LH-releasing hormone (LHRH) and/or hCG have been used as hormonal therapy to induce descent of testes for more than 70 years based on the premise that androgens promote testicular descent, but the efficacy of this therapy is questionable (Pyorala et al, 1995; Henna et al, 2004; Thorsson et al, 2007). Even when analysis is limited to randomized, placebo-controlled trials the reliability of the data is limited in that many series did not confirm exclusion of retractile or nonpalpable (potentially absent) testes, adequacy of randomization procedures, and/or long-term efficacy of the treatment. Although the efficacy of either hormonal treatment is about 20% and superior to placebo in randomized trials, this effect is not clearly clinically significant. Although lower testicular position shows a clear correlation with response to therapy, no consistent differences in response based on age or laterality

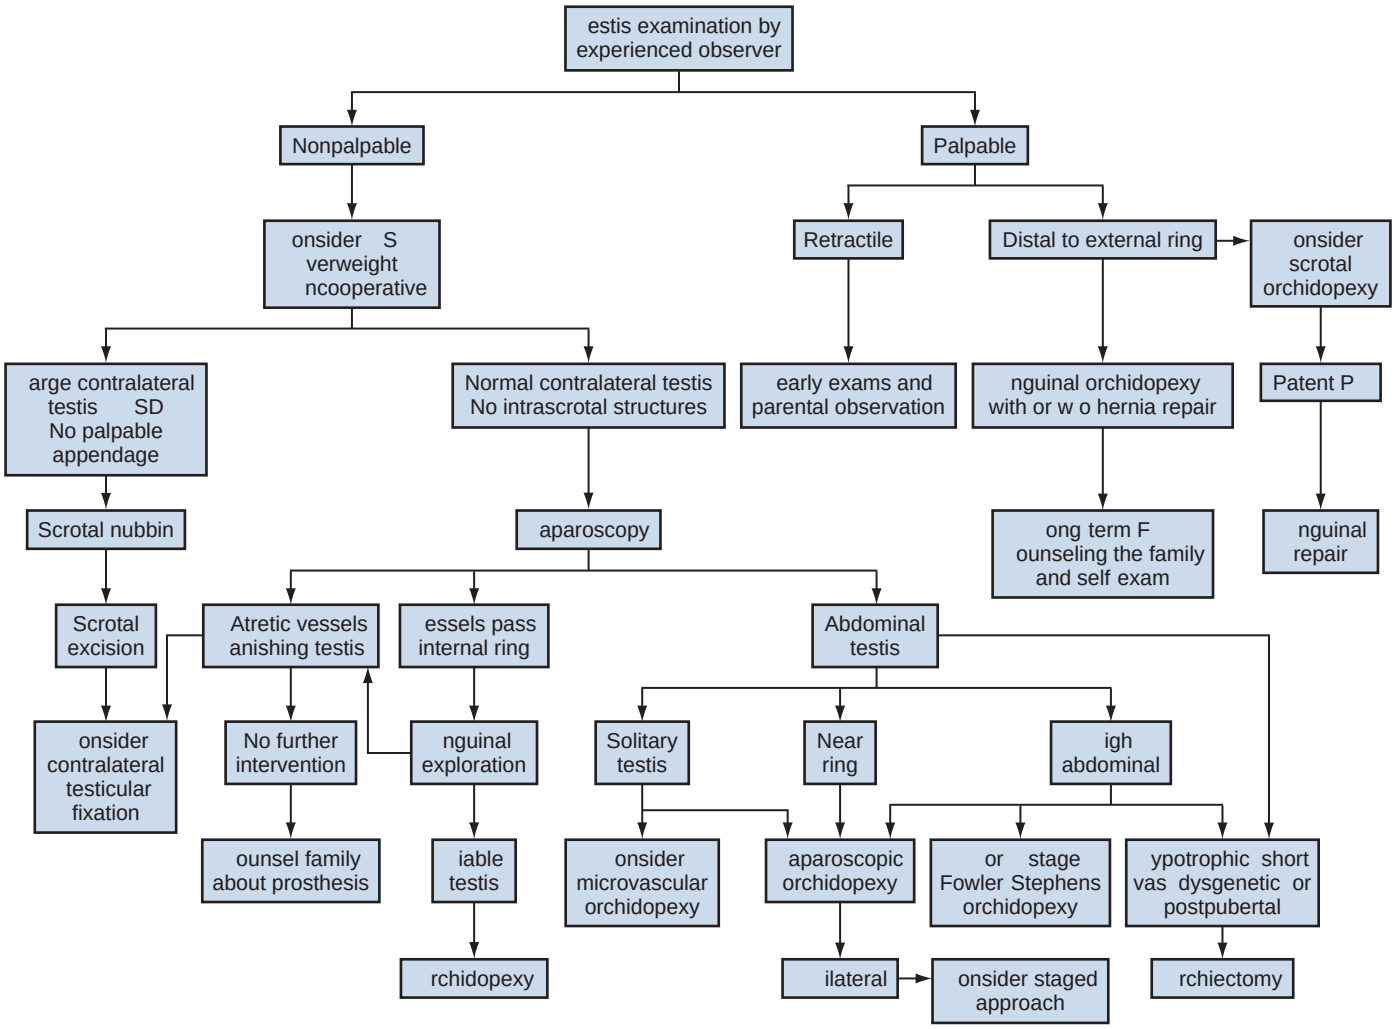

Figure 132–4. Algorithm for management of the undescended testis. This is the recommended approach to diagnosis and treatment of palpable and nonpalpable testes in patients confirmed to have undescended testis by an experienced examiner. F/U, follow-up; PV, processus vaginalis; US, ultrasonography.

have been reported in randomized trials. **Overall, the evidence from rigorous studies indicates that LHRH therapy for cryptorchidism is only marginally more effective than placebo; although not studied in randomized placebo-controlled trials because of its route of administration, hCG also shows limited efficacy.** Other uses of hCG including treatment of acquired cryptorchidism and to facilitate palpability and/or treatment of the abdominal testis (Polascik et al, 1996; Baker et al, 2001; Bukowski et al, 2001) also have limited efficacy.

The question of the effect of therapeutic doses of hCG or LHRH on germ cell development has been addressed in several conflicting studies that are limited by small sample size, absent or suboptimal randomization, and variable availability of biopsy data (Ong et al, 2005). In small, retrospective studies, hCG treatment was associated with increased germ cell apoptosis at biopsy and lower adult testis volume (Dunkel et al, 1997) and previous hCG or LHRH therapy was associated with reduced S/T counts in 1- to 3-year-old boys as compared with surgery alone (Cortes et al, 2000). In contrast, Schwentner and associates randomized young boys (mean age 33 months, 21 per group) to LHRH or no hormonal therapy before surgery and reported that mean S/T count was higher (1.05 ± 0.71) in LHRH-treated as compared with non-treated (0.52 ± 0.39) testes (Schwentner et al, 2005). In view of a lack of large prospective studies, it is unclear if hormone therapy for cryptorchidism is beneficial or harmful to germ cells in the short or long term.

Hadziselimovic and colleagues (1987b) have advocated use of low-dose, long-term (every other day for 6 months) LHRH analogue (buserelin) therapy for stimulation of germ cell development in conjunction with orchidopexy. In a retrospective study of non-randomized, non–age-matched patients receiving buserelin versus surgery only, S/T counts were significantly higher in the treated group. A subset of patients from this same cohort with the most severe testicular histology underwent rebiopsy after completion of therapy and were compared with a group of 8 boys of unknown age who required reoperative orchidopexy (Hadziselimovic et al, 1987a). A significant improvement in mean S/T ratio was seen in the buserelin-treated but not the surgical group. Similarly, in a smaller select group of boys treated with low doses of a related LHRH agonist, nafarelin, improved histology was observed in one or both testes at rebiopsy in 8 of 12 boys. In a randomized study of clinically matched boys receiving buserelin and hCG, placebo and hCG, or surgery alone (19 to 25/group), S/T counts were also significantly higher in those treated with buserelin (Bica and Hadziselimovic, 1992). More recently, Hadziselimovic (2008) published a nonrandomized retrospective study showing that

buserelin-treated males (most also received hCG) with a history of unilateral cryptorchidism and poor pretreatment S/T counts had much higher sperm counts than patients who underwent surgery only (n = 15 per group). Unfortunately, these two groups were small and not clinically matched prospectively to limit other potential confounding factors, such as testicular position, and sperm counts in the surgery-only group were lower than typical for unilateral cryptorchidism. Overall, these studies provide preliminary, suggestive evidence that buserelin may have both short- and long-term effects on testicular histology and/or fertility potential. However, the suboptimal design of the studies on which this evidence is based mandates that future well-designed prospective studies are necessary before routine use of buserelin treatment in cryptorchidism.

In summary, little if any high-quality evidence exists showing a benefit of hormonal therapy for cryptorchidism or for stimulation of germ cells. **A recent statement by the Nordic Consensus group recommends that testicular biopsy and hormonal therapy not be used in standard clinical care of boys with cryptorchidism** (Ritzen et al, 2007), although not all clinicians concur (Hadziselimovic and Zivkovic, 2007).

Surgical Approach to the Palpable Testis

The standard treatment for palpable testes is inguinal orchidopexy with repair of an associated hernia if present (Hutcheson et al, 2000a), although in recent years a primary scrotal approach as originally described and advocated by Bianchi and colleagues (Bianchi and Squire, 1989; Iyer et al, 1995) has been advocated by some. The recommended age for surgical intervention has gradually declined over the years and presently is age 6 months in full-term males in whom the testes have failed to descend. However, the average age of orchidopexy remains about 4 years in many series, likely owing to the frequency of milder "acquired" cases as well as delayed referral of some cases diagnosed at birth (Barthold and Gonzalez, 2003). An option for pubertal and postpubertal boys is orchiectomy, especially if the testis is abdominal or difficult to mobilize because poor spermatogenesis and hypotrophy are usually present and the risk of carcinoma in situ and torsion exist (Rogers et al, 1998).

Inguinal Orchidopexy. After induction of anesthesia, the patient is reexamined to confirm that the testis is palpable and to identify the lowest testicular position. In the standard inguinal approach, a low transverse incision in Langer's lines at or below the inguinal crease is made superolateral to the pubic tubercle. Dissection of the subcutaneous tissue should include a search for a testis within the superficial inguinal pouch. The external oblique fascia is incised to expose the canal with care to avoid injury to the ilioinguinal nerve. Testis position is recorded relative to the inguinal canal. The spermatic cord is isolated, and the testis is dissected distally to its attachment to the gubernacular remnant. Transection of the gubernaculum distal to the sac will avoid potential injury to a long-looping vas. Longitudinal incision of the internal spermatic fascia allows free mobilization of an intact hernia sac, if present, and minimizes skeletonization of the vas and spermatic vessels. After transection, the sac is mobilized to the level of the internal inguinal ring and suture ligated. Incision of the internal spermatic and transversalis fascia at the level of the ring facilitates additional retroperitoneal mobilization of the vas and vessels, if needed. Further maneuvers to provide spermatic cord length include transection of lateral fascial bands along the cord, cranial retroperitoneal dissection, medial transposition of the testis beneath the epigastric vessels (Prentiss maneuver) and, if required, cranial extension of the incision. Very rarely, the testis cannot be brought to dependent scrotal position after these maneuvers and a two-stage procedure may be considered as an alternative to orchiectomy, which is preferentially reserved for grossly abnormal or atrophic testes. Dessanti and associates (2009) describe a novel two-stage technique for high canalicular or abdominal testes that involves placement of a polytetrafluoroethylene membrane around the mobilized cord, fixation of the testis to the invaginated scrotum with a pledget, followed by a 9- to 12-month delay that allowed spontaneous scrotal localization of the testis in 82% of 45 testes.

A large clamp or a finger can be used to create a tunnel just anterior to the pubis and a scrotal or subdartos pouch created after transverse incision of the scrotal skin (Ritchey and Bloom, 1995). The testis is passed through an opening in the dartos without twisting of the spermatic cord. Existing appendages should be excised and the epididymis inspected and any anomalies recorded. Recording of testicular volume by direct caliper measurement in three dimensions and similar (estimated) measurements of contralateral testicular volume can establish a baseline for postoperative assessment. Secure fixation of the testis within the pouch can be achieved by tension-free closure of the opening in the dartos around the cord, incorporating the cut edge of the tunica vaginalis. If needed, additional absorbable fixation sutures can be placed between the visceral tunica vaginalis and the dartos. Sutures through the tunica albuginea of the testis are not recommended because of possible injury to the testis via inflammatory or vascular insult; suture fixation of the testis is in any event not needed if mobilization is adequate and a subdartos pouch technique is used. Closure is completed with absorbable sutures. Supplemental local or regional techniques for perioperative pain control are advisable and may include local anesthetic infiltration or caudal anesthesia; the latter is particularly useful in younger patients undergoing bilateral inguinal or concomitant penile surgery.

Testicular biopsy has been performed routinely in some centers and is advocated by Hadziselimovic and colleagues (2007) as a method to determine prognosis for fertility. This approach is controversial and not recommended outside of research protocols because it does not change the current approach to treatment (Ritzen et al, 2007; Beckers and van der Horst, 2008). The risk to the cryptorchid testis from biopsy is theoretical; although long-term effects do not appear to include increased risk of microlithiasis or antisperm antibody formation (Patel et al, 2005), other more subtle effects cannot be excluded from the available data. Biopsy is indicated in cases of sexual ambiguity or if clinical evidence of testicular dysgenesis is present.

A minimum of 6 months' follow-up is needed to determine testis position and size once stabilized, and long-term follow-up is indicated for counseling of the patient regarding fertility issues, risk of testicular malignancy, and self-examination. Complications of inguinal orchidopexy for a palpable testis are uncommon; those of greatest frequency and concern include testicular retraction or atrophy. In a comprehensive literature review in 1995, Docimo (1995) concluded that the overall risk of atrophy or nonscrotal position was approximately 15% overall in published reports, significantly higher in abdominal or peeping testes (24%) compared with those distal to the internal ring (10%) and higher in boys operated after 6 years of age. Torsion of a scrotal testis after orchidopexy has been reported but is very rare, and the risk may be minimized by using a subdartos pouch. If complete intrascrotal testicular atrophy occurs postoperatively, further intervention is not needed but the option of testicular prosthesis placement should be offered to the patient and family (Bodiwala et al, 2007).

Implantation of a testicular prosthesis should occur at least 6 months after any inguinoscrotal procedure or after puberty and is best performed through an inguinal approach. Closure of the scrotal fascia above the implant using a purse-string nonabsorbable suture is required. Risks including displacement, pain, or infection occur in less than 5% of cases. Clinical experience suggests that cryptorchid boys may request prosthesis implantation less frequently than males with acute testicular loss after puberty (Bodiwala et al, 2007). Elder and associates (1989) recommended that prepubertal prosthesis placement be considered, but it is not clear whether this approach is preferable to placement after puberty.

Reoperation is indicated if a testis is nonscrotal after orchidopexy. If the testis is prescrotal, a primary scrotal approach can be considered and may allow adequate mobilization of the testis. If inguinal exploration is needed to provide sufficient cord length, several approaches are available. Redman (2000) described a useful technique for primary or secondary orchidopexy that involves a lateral approach to the cord after mobilization of the external oblique and cremaster fasciae. This approach avoids traversal of the previously scarred layers anterior to the cord and a clearer view of the anatomy. Cartwright and colleagues (1993) described mobilization of the intracanicular cord with an overlying patch of external spermatic fascia. The importance of correcting a persistently patent processus vaginalis and/or of adequate retroperitoneal mobilization of the cord in cases of high recurrent cryptorchidism has been stressed (Redman, 2000; Pesce et al, 2001; Ziylan et al, 2004). The results of secondary orchidopexy appear to be similar to the primary procedure, although the risk of vascular and vasal injury is theoretically higher (Pesce et al, 2001).

Transscrotal Orchidopexy. A primary scrotal approach can be considered when the testis is palpable (Bianchi and Squire, 1989; Iyer et al, 1995), although some surgeons reserve this approach for testes that are close to or can be drawn into the scrotum (Russinko et al, 2003; Rajimwale et al, 2004; Bassel et al, 2007; Takahashi et al, 2009). An incision along the superior scrotal border is made and the distal sac and overlying cremaster mobilized. Once dissected free, the sac can be placed on traction and freed as far cranially as possible, "high above the inguinal canal" (Iyer et al, 1995), although some cases require conversion to an inguinal approach (Parsons et al, 2003; Dayanc et al, 2007). Rajimwale and coworkers confirmed in several cases that the hernia sac had been effectively ligated above the internal ring via the scrotal incision when a secondary inguinal incision was required for further mobilization of the testis (Rajimwale et al, 2004). Fixation sutures through the tunica albuginea were used in many series of scrotal orchidopexy (Jawad, 1997; Russinko et al, 2003; Bassel et al, 2007; Dayanc et al, 2007; Takahashi et al, 2009). The risk of testicular retraction or atrophy was reported as 0% to 2% in most of these series after follow-up ranging from 1 month to 3 years. However, postoperative hernia was reported in about 3% of cases in two series containing a larger proportion of canalicular testes (Dayanc et al, 2007; Al-Mandil et al, 2008) and in 2% of hernias repaired by Bianchi's group using a scrotal approach (Iyer et al, 1995). Although the risk of this complication appears low, follow-up is not sufficient in reported series to fully define the risk.

Surgical Approach to the Abdominal Testis

Once an abdominal testis has been identified by laparoscopy or other means, a decision is made whether to proceed with an open or laparoscopic, one- or two-stage orchidopexy with or without spermatic vessel transection. Orchiectomy is appropriate for patients with testes that are poorly viable and/or at higher risk for tumor, such as very small or dysgenetic prepubertal or in postpubertal patients, and is best performed laparoscopically.

Open Transabdominal Orchidopexy. Extensive dissection of the vas and vessels is facilitated by a longitudinal opening of the internal oblique and peritoneum through an extended inguinal incision (Kirsch et al, 1998) or via a higher incision medial to the pubic tubercle and a preperitoneal approach (Gheiler et al, 1997; Jones and Bagley, 1979). In the procedure described by Jones and Bagley the internal ring is approached via a muscle-splitting incision, the peritoneum is opened, the testis is delivered, and the vas and vessels are freed from their peritoneal attachments. A tunnel is created to the scrotum, and the testis is secured in place as for an inguinal orchidopexy. The reported success rate for this procedure for abdominal testes was 95% (Gheiler et al, 1997).

Laparoscopic Orchidopexy and Fowler-Stephens Orchidopexy. Operative laparoscopy emerged over 15 years ago as the procedure of choice for abdominal orchidopexy (Caldamone and Amaral, 1994; Jordan and Winslow, 1994), and the basic surgical approach and high success rates have stood the test of time (Table 132–1). The feasibility of primary versus Fowler-Stephens orchidopexy depends on the length of the vas and vessels, presence or absence of looping ductal structures, and age of the patient. Although laparoscopy allows the surgeon to assess some of these features before choosing a specific surgical procedure, the choice may be difficult (Yucel et al, 2007). Observed testicular position alone may correlate poorly with the ultimate length of the cord after mobilization.

After induction of anesthesia, a further attempt to palpate the testis is made, although a laparoscopic approach may be considered for mobilization of high canalicular testes as well. After decompression of the bladder and stomach, an infraumbilical 5-mm trocar is placed for passage of a 30-degree lens and both internal rings are visualized. An open Hasson or Bailez technique is preferable for umbilical trocar placement in the pediatric age group to minimize the risk of injury (Franc-Guimond et al, 2003). CO_2 pneumoperitoneum to a maximum pressure of 8 to 12 mm Hg is used. The size and position of the testis within the abdomen is determined before further decision making. For single-stage laparoscopic orchidopexy, additional 2- or 3-mm trocars are placed in the right and left lower quadrants to triangulate with the umbilicus and ipsilateral internal ring or in the midclavicular line at the level of the umbilicus bilaterally. The major steps are mobilization of any structures extending distal to the internal ring, including epididymis/vas and gubernacular remnant, transection of the peritoneum lateral to the vessels and distal to the vas, and proximal mobilization of the vessels while maintaining collateral blood supply between the vas and spermatic vessels if a Fowler-Stephens maneuver becomes necessary. Samadi and associates (2003) advocate initial mobilization of the gubernaculum to be used as a handle for further mobilization of the testis, and minimal use of cautery during this maneuver. Ability to mobilize the testis to the opposite internal ring has been used as a measure of adequate length for placement in the scrotum but is not predictable in some series. Once mobilized, the testis is brought through a new hiatus at the level of the medial umbilical ligament or through the existing internal inguinal ring. This maneuver can be completed using a transscrotal clamp or port. With tension on the extra-abdominal testis, peritoneal attachments overlying the cord can be more easily transected, thus providing additional length. In some cases the testis can only be brought into the upper scrotum; the long-term adequacy of this approach is not clear. Excessive tension on

*Reported results of abdominal, one- and two-stage Fowler-Stephens (FS) orchidopexy in.series with at least 20 treated testes. Age is mean for entire series unless otherwise noted. High position refers to testes not in dependent scrotal position.

†Position within scrotum not clearly documented. Overall success refers to the frequency of nonatrophic testes in satisfactory scrotal position according to criteria used by the authors.

the vessels during placement of the testis should be avoided, however, because injury or avulsion of the spermatic vessels may occur (Esposito et al, 2002). A key strategy should be preservation of the blood supply between the vas and spermatic artery during dissection so that the Fowler-Stephens procedure can be performed if necessary.

Formal closure of the dissected internal ring, irrespective of whether the mobilized testes passes through it, does not appear to be necessary (Handa et al, 2005; Riquelme et al, 2007); indeed, previous experience with open hernia repair suggests that ligation is not needed if the internal ring is dissected (Mohta et al, 2003). A contralateral patent processus vaginalis was identified in 9% of boys undergoing laparoscopic orchidopexy in one series (Palmer and Rastinehad, 2008), and laparoscopic repair was performed and recommended. The necessity for this approach in preventing clinical hernia formation is questionable based on studies of boys undergoing laparoscopic or open contralateral hernia repair (see Schier, 2007b, and discussion in the later section Hernias and Hydroceles).

For testes that are not near (variably defined as 2 to 4 cm above) the internal inguinal ring, transection of the spermatic vessels as originally described by Fowler and Stephens (1959) may be necessary; a long-looping vas facilitates but is not required for testicular mobilization to the scrotum. The Fowler-Stephens procedure is now typically performed laparoscopically with spermatic vessel clipping (Bloom, 1991) followed by laparoscopic or open testicular mobilization 6 months later or in one stage. Although most surgeons transect the spermatic vessels 1.5 to 3 cm above the testis, Koff and Sethi (1996) proposed that ligation close to the testis is preferable. This group subsequently studied the effect of low versus high transection of the vessels in prepubertal rats and showed a reduction in adult testicular sperm numbers that was similar in both groups (Srinivas et al, 2005). In human studies, testicular biopsies before and after spermatic vessel transection also showed a reduction in S/T count, a finding that was significant in younger boys (Thorup et al, 1999; Rosito et al, 2004). In general, the preferred approach is avoidance of spermatic vessel transection whenever possible; the available data suggest this is

possible in the majority of cases of abdominal orchidopexy. In rare cases, particularly if the testis is retrovesical, the vas is too short to allow scrotal placement of the testis and orchiectomy is ultimately required (Perovic and Janic, 1997).

The success rates for laparoscopic procedures as shown in Table 132–1 (Jordan and Winslow, 1994; Esposito and Garipoli, 1997; Hay et al, 1999; Baker et al, 2001; Lotan et al, 2001; Esposito et al, 2002; Radmayr et al, 2003; Samadi et al, 2003; Handa et al, 2005; Robertson et al, 2007; Yucel et al, 2007; Chang and Franco, 2008; Denes et al, 2008; Kaye and Palmer, 2008) appear to compare favorably with the corresponding 74%, 63%, and 77% overall success rates for open surgical and one- and two-stage Fowler-Stephens procedures, respectively, reported by Docimo (1995). Variation in reported results in these series may reflect inherent selection bias due to differences in patient age, testicular position, length of follow-up, and/or criteria used to define success, such as "intrascrotal" versus "dependent scrotal" position. Some authors recommend that ultrasound be used to confirm testicular viability postoperatively (Esposito et al, 2002). Other complications of laparoscopic orchidopexy appear to be rare and potentially include bladder or vascular injury, hypercapnia, and delayed small bowel obstruction (Esposito et al, 2003; Hsieh et al, 2009).

Laparoscopic techniques may be applicable in unusual cases, including bilateral orchidopexy, abdominal wall defects, polyorchidism, splenogonadal fusion, and transverse testicular ectopia with or without persistent müllerian ducts. Many authors recommend simultaneous bilateral abdominal orchidopexy (Kaye and Palmer, 2008), but the surgeon should consider a staged approach if both testes are very high or the viability of a testis is questioned during the course of orchidopexy. Depending on the outcome of the first procedure at 6 months' follow-up, the surgeon can choose an operative approach to the contralateral side that would appear to minimize the risk of bilateral testicular atrophy (Thorup et al, 2007). Some surgeons have considered microvascular orchidopexy to be a preferred approach to the solitary abdominal testis, particularly with historical success rates of 88% as compared with lower rates for open procedures (Docimo, 1995). At a center with substantial experience using the microvascular approach, long-term success rates of 96% for standard and 88% for laparoscopically assisted autotransplantation were reported (Bukowski et al, 1995b; Tackett et al, 2002). The advantage of this approach is preservation of the spermatic vessels, at the cost of longer operative time and requirements for an experienced microvascular surgeon and hospital stay.

Prognosis

Risk of Subfertility

Although there is strong evidence that a history of cryptorchidism is associated with subfertility in individual patients, the effects of age at diagnosis, type of treatment, and/or severity of disease on outcome remain incompletely defined. Major limitations in the interpretation of cryptorchidism outcome studies include selection bias due to incomplete follow-up of large patient cohorts, heterogeneity of diagnosis and timing/type of treatment, and other methodologic concerns, including lack of age-matched controls, failure of abstinence before semen analysis, and/or analysis of a single semen sample. In a large review of retrospective studies published in the 50 previous years that did not take these concerns into consideration and did not include a statistical meta-analysis, Chilvers and colleagues (1986) reported overall rates of oligospermia and/or azoospermia in 75% of formerly bilaterally and 43% of formerly unilaterally cryptorchid men. The limited available data comparing earlier (age < 9 years) and later treatment did not show differences in the frequency of subfertility after unilateral (281 cases) or bilateral (123 cases) orchidopexy. Similarly, subset analysis failed to identify any effect of hCG treatment. Two subsequent large studies of semen parameters in men who underwent orchidopexy in childhood also found differences between bilateral and unilateral cryptorchidism but less consistent overall results. Okuyama and associates (1989) reported normal sperm density in 0%, 72%, 77%, and 42% of men after bilateral orchidopexy (61 patients), unilateral orchidopexy (149 patients), unilateral orchiectomy (26 patients), and no treatment (38 patients) for inguinal testes without hormone therapy. All of these subjects had three semen analyses. In contrast, Gracia and colleagues (2000) reported normal semen samples in 10 of 55 (18%) men with a history of bilateral and 57 of 171 (33%) men with previous unilateral cryptorchidism. The majority of testes in this series were canalicular, and 80% of subjects received preoperative hCG therapy. These authors noted no differences based on testicular position, and semen quality was not correlated with age of surgery in either series. In a cohort of 91 patients with unilateral cryptorchidism who underwent orchidopexy after the onset of puberty (age 14 to 29), the risk of azoospermia or oligospermia was 84% (Grasso et al, 1991), a trend in keeping with the data reported previously (Okuyama et al, 1989). Puri and O'Donnell (1988) studied 142 men who underwent unilateral (119 men) or bilateral (23 men) orchidopexy at age 7 years or older and reported normal sperm density in 84% and 50% of cases, respectively.

Mean S/T counts obtained at biopsy show correlation with long-term fertility potential as measured by mean semen analysis parameters in series but may not be predictive in individuals (Engeler et al, 2000; Cortes et al, 2003a; Rusnack et al, 2003). Other data suggest a better correlation between the number of Ad spermatogonia in cryptorchid testes and sperm count in adulthood after previous unilateral or bilateral orchidopexy with or without prior hormonal therapy (Hadziselimovic et al, 2007; Hadziselimovic and Hoecht, 2008). In non–hormonally treated cases, total sperm count was normal (>40 million/ejaculate) in 84% of 25 men with Ad spermatogonia present in both testicular biopsy specimens, whereas it was subnormal in all 18 men (10 of the 19 men in this series had a history of bilateral cryptorchidism) in whom biopsies were negative for Ad spermatogonia. Total germ cell counts were reportedly not predictive of sperm concentration in this series (Hadziselimovic and Hoecht, 2008). **Both Ad spermatogonia count and germ cell absence appear promising as measures of fertility prognosis, but their predictive value has not been confirmed in additional studies to date.** Further prospective studies of these parameters are indicated.

Outcome studies of semen analysis in men with a history of cryptorchidism are believed to provide useful information that predicts fertility potential. However, a large population study of fertile and infertile men with fertile partners suggests that there is large overlap between semen parameters in men with and without proven paternity (Guzick et al, 2001). In this study, the authors established lower infertile threshold levels for density (13.5×10^6/mL), motility (>35%), and normal morphology (>9%) than had been established by World Health Association criteria. About 3% of fertile men in this series had a sperm density of less than 10×10^6/mL, and measurements between 13.4 and 48×10^6/mL were considered indeterminate. Repeated semen analyses, rarely obtained in studies of formerly cryptorchid men, are needed to provide reliable data in normal men (Oshio et al, 2004).

Consequently, determination of paternity status is an alternative measure of fertility that should be considered when determining prognosis. Limitations of this approach include paternal discrepancy and variability in the timing and degree of interest in attempts at paternity. Although of concern and not ethically retrievable, a recent review (Bellis et al, 2005) found that the median level of paternal discrepancy in 17 studies of unselected populations in Europe and the Americas is only 3.7% (interquartile range, 2% to 9.6%).

Two retrospective cohort studies of men with previous cryptorchidism assessed paternity in 145 (Gilhooly et al, 1984) and 40 (Cendron et al, 1989) cases. Together, these studies identified successful paternity in 100 of 123 (81%) men with a history of unilateral and 19 of 54 (35%) of men with a history of bilateral cryptorchidism. Lee and colleagues published a series of well-designed case control studies of fertility in cryptorchidism (Lee et al, 1996, 1997, 2000; Coughlin et al, 1999; Lee and Coughlin, 2001, 2002b; Bellis, 2005; Lee, 2005) Questionnaire, hormone, semen analysis, and paternity data were analyzed for a large cohort of men who underwent orchidopexy between 1955 and 1975 and a control group of similar age who were matched for timing of unrelated surgery. For all married or cohabitating men, 32 of 88 (36%) former bilateral, 322 of 609 (53%) former unilateral, and 413 of 708 (58%) controls had fathered children. **Of those attempting paternity, 32 of 49 (65%) former bilateral, 322 of 359 (90%) former unilateral, and 413 of 443 (93%) controls were successful.** There were no significant differences between the unilateral and control groups and no differences between groups in the frequency of attempted paternity or in other lifestyle factors that may adversely affect fertility. The frequency of successful paternity did not differ between men with previous unilateral cryptorchidism who had undergone orchiectomy and the control group. Relative risk for infertility was increased after hCG treatment (RR 4.7, $P = .002$) but not with higher testicular position or age at orchidopexy. Sperm density was less than or equal to 13×10^6/mL in all 8 patients with bilateral cryptorchidism that were studied; however, 3 of these men had fathered children (Lee and Coughlin, 2001). In contrast to previous studies, 83% of men in the unilateral group had normal sperm density and sperm motility and morphology did not differ from control values. Although hormone levels alone did not correlate directly with fertility, abnormal levels of serum inhibin-B, FSH, and/or sperm density provided cumulative risk of decreased fertility. However, the authors conclude that prediction of infertility is difficult in the absence of azoospermia or severe oligospermia. These investigators also found differences in basal and stimulated LH and in serum testosterone levels when comparing fertile and infertile or subfertile formerly cryptorchid men and suggest that global testicular dysfunction occurs in cryptorchid males. Moreover, there is some evidence from these studies of a relationship between improved testosterone, inhibin-B, and FSH levels in males who underwent earlier orchidopexy (Coughlin et al, 1999; Lee and Coughlin, 2002a).

Limited evidence suggests that defective spermatogenesis may exist in some adult patients with persistently retractile testis or with milder forms of acquired cryptorchidism with or without apparent spontaneous descent of the testis at puberty. In small, retrospective outcome studies, Puri and Nixon (1977) reported 74% paternity and normal testicular volume in a series of 43 adults with untreated retractile testes in childhood. Conversely, Nistal and Paniagua (1984) and Caroppo and colleagues identified 23 and 34 males, respectively, from infertility clinic data and identified poor semen parameters in the majority of cases, but the duration and severity of retractility was poorly documented in these series. These studies do not provide sufficient evidence for infertility risk in uncomplicated cases of retractile testis. Two series reported varying degrees of abnormal germ or Sertoli cell development in retractile testes of boys who underwent elective orchidopexy as compared with boys with descended testes; differences were qualitatively similar to findings in cryptorchid testes (Hadziselimovic et al, 1987a; Cinti et al, 1993). However, small sample size per subgroup limits interpretation of these data. Han and associates (1999) compared 61 retractile with 83 cryptorchid testis biopsies and noted similar trends but did not include a control group. In a retrospective series of 45 adults with spontaneous descent of bilaterally undescended testes after age 10 by history, Brenholm Rasmussen and coworkers (1988) observed testicular volumes of less than 15 mL in 62% and sperm counts below 20 million/mL in 44% of patients. Large, prospective studies of persistently retractile testes and cases of acquired cryptorchidism are needed to better define diagnosis and prognosis in these groups of patients.

In summary, available data provide strong evidence that fertility potential is compromised in men with a history of bilateral cryptorchidism but the frequency of abnormal hormonal and sperm parameters in unilateral cases is higher than the relative risk of infertility as measured by paternity data. Unfortunately, the number of formerly bilaterally cryptorchid men who have been comprehensively studied is limited. Although data suggest some association between age at surgery or hormone therapy and risk of infertility, further studies are needed to elucidate the relationships between these factors.

Risk of Malignancy

The increased risk of testicular germ cell tumor (TGCT) in males with a history of cryptorchidism has been known for many years. Both seminoma and nonseminomatous germ cell tumors (NSGCT) develop from carcinoma in situ (CIS) of the testis, also called intratubular germ cell neoplasia, unclassified (ITGCNU), and are believed to be developmental in origin (Rajpert-de Meyts and Hoei-Hansen, 2007). The hypothesis that persistent gonocytes are the precursors of testicular CIS has existed for some time, and recent gene expression data indeed support a common origin for the two cell types (Sonne et al, 2009). The histologic data suggesting that gonocytes fail to transform normally in cryptorchid testes may coincide with eventual transformation of these persistent cells into CIS and TGCT. However, to date no evidence directly links germ cell maldevelopment in individual patients to eventual malignant transformation. Using placenta-like alkaline phosphatase (PLAP) as a marker of ITGCNU, Engeler and associates (2000) identified PLAP-positive cells in 5% of 440 patients, most (82%) younger than 3 years of age, who had undergone testicular biopsy and orchidopexy several years earlier. Whereas up to 50% of adults with ITGCNU are expected to develop TGCT over time, no tumor was detected in the 15 of 22 affected individuals that the authors were able to evaluate a median of 21 years later. However, PLAP immunopositivity may be a normal finding in infants during the first year of life (Jorgensen et al, 1993). Similarly, Cortes and coworkers (2003b) identified multinucleated spermatogonia in 13 (8%) of 163 consecutive patients undergoing biopsy at the time of orchidopexy. This finding occurred in younger boys and was associated with an S/T count that was usually normal and higher than the mean for the majority of cases. Although not identified in normal boys, the relevance of this finding to tumor risk remains completely unknown.

Recently, in their exhaustive analysis of the literature Wood and Elder (2009) clarified the nature of increased TGCT risk in the previously cryptorchid and contralateral descended testis. Men with a history of cryptorchidism comprise about 10% of those presenting with TGCT. **The relative risk of malignant transformation in an undescended testis is 2.5 to 8 overall and 2 to 3 in boys undergoing prepubertal orchidopexy, which is lower than historical estimates.** This incidence correlates with the reported risk of CIS of 2% to 3% in previously cryptorchid men (Giwercman et al, 1989); a much lower risk (0% to 0.4%) was reported in children with nonsyndromic cryptorchidism (Cortes et al, 2001; Husmann, 2005). TGCT may occur in the contralateral descended testis of men with a history of unilateral cryptorchidism, but Wood and Elder (2009) conclude that the relative risk of only 1 to 2 indicates a level comparable to the general population that is not related to cryptorchidism per se. However, a recent meta-analysis shows that the relative risk of 6.3 (95% CI, 4.30 to 9.31) in the ipsilateral and 1.7 (95% CI, 1.01 to 2.98) in the contralateral testis is significant compared with controls (Akre et al, 2009). In another meta-analysis, Walsh and associates (2007) determined that the relative risk of testicular cancer was 5.8 (95% CI, 1.8 to 19.3) in men who underwent orchidopexy after age 10 to 11 as compared with those undergoing earlier correction. However, recent population-based data are conflicting, showing twice the risk of malignancy in orchidopexy cases operated at or after age 13 in one series (Pettersson et al, 2007) but no age-dependent differences in another (Myrup et al, 2007), possibly related to ascertainment bias in the latter series. Further studies are needed to clarify the relationship between age at orchidopexy and risk of testicular cancer. Review of tumor pathology in treated versus untreated cryptorchidism shows that seminoma is associated with persistently cryptorchid testes (74%) and nonseminoma is present in the majority of scrotal testes (63%) (Wood and Elder, 2009).

Certain subgroups with undescended testis are at increased risk for TGCT, including those with chromosomal defects and other genital anomalies (Cortes et al, 2001; Husmann, 2005). Husmann (2005) recommends that biopsy be performed in these individuals and in boys older than 12 undergoing orchidopexy, although the age cutoff and usefulness of biopsy during pubertal orchidopexy have not been clearly defined. Orchiectomy should be considered the preferred treatment of cryptorchid testes from puberty to the age of 50 (Wood and Elder, 2009). Swerdlow and associates (1997) reported in a retrospective cohort study that testicular biopsy at orchidopexy was associated with a relative risk of 6.7 for future TGCT compared with orchidopexy without biopsy, but the indications for biopsy in this series were not clearly known. A subsequent report from a large Scandinavian cohort showed that universal biopsy did not appear to increase the risk for TGCT beyond what is expected for previously cryptorchid men (Moller et al, 1998).

Testicular microlithiasis, characterized by multiple spectral calcifications within the testicular parenchyma (Fig. 132–5), is more frequently present in men with ITGCNU and germ cell tumors but is also present in 5% to 10% of the normal population and in a similar proportion of previously cryptorchid men (Patel et al, 2005; van Casteren et al, 2009). **Although concern exists that the risk for TGCT may be higher when cryptorchidism coexists with microlithiasis in individual patients, the appropriate follow-up strategy remains undefined.** Even less well defined is the significance of microlithiasis in general, which is not clearly shown to be an independent risk factor for TGCT. A recent population-based analysis of the prevalence of microlithiasis in primarily white boys shows that the prevalence is 4.2% and increases with age (Goede et al, 2009). In about half of these cases, the degree of microlithiasis was limited, defined as less than five lesions per testis, and not considered clinically significant. Slaughenhoupt and associates (2009) reported a case and reviewed pediatric reports of TGCT or yolk sac tumor in boys with microlithiasis but without other risk factors; they recommend periodic examination and ultrasonography in all cases. In contrast, biopsies are performed in adults with microlithiasis and one other risk factor for tumor, such as cryptorchidism, but if the biopsy is negative then no specific follow-up other than self-examination is recommended (van Casteren et al, 2009). **Testicular self-examination, which requires education and counseling of the patient, remains a mainstay of testicular cancer screening.** A description exists (http://www.cwpeds.com/pdfs/adolescents/TesticularExam.pdf), and it should be taught to all patients with a history of cryptorchidism after they reach puberty, preferably by the pediatric urologist or operating surgeon in addition to the primary care practitioner.

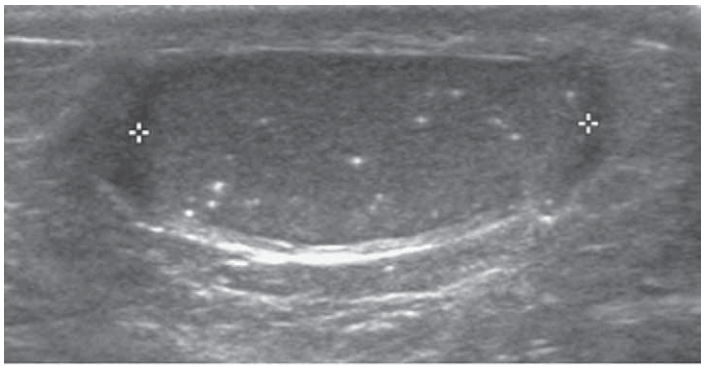

Figure 132–5. Testicular microlithiasis found incidentally in a 13-year-old boy with early puberty (Tanner stage II) and a clinical appendix testis torsion. The remainder of the study showed normal Doppler flow to testis, increased epididymal flow, and no visible appendage. The examination findings normalized within 1 week.

VARICOCELE

A scrotal varicocele is an abnormal dilation and tortuosity of the internal spermatic veins within the pampiniform plexus of the spermatic cord. Like cryptorchidism, varicocele is a common finding in otherwise normal males, may contribute significantly to the risk of infertility in adulthood, and is associated with a natural history that is poorly understood. Although varicocele is clearly a risk for subfertility in certain individuals, its effect on paternity is less clear because about 85% of men with varicocele in population-based studies have fathered children (Pinto et al, 1994; Safarinejad, 2008). There are few well-designed prospective studies of adult or pediatric populations that clarify the risk factors for associated testicular dysfunction in males with varicocele. Moreover, recent data add further confusion to the debate regarding which varicoceles require treatment during adolescence.

Epidemiology and Pathogenesis

Although considered a congenital lesion, varicocele is rarely diagnosed before school age, and the frequency and severity vary with age, method of diagnosis, and Tanner stage. Population data from large groups of children and adolescents suggest that the majority

Key Points: Cryptorchidism

- Cryptorchidism occurs in 1% to 4% of full-term males; postnatal spontaneous descent and reascent of testes are common.
- The causes of cryptorchidism are largely unknown, but birth weight, gestational age, genetic, and environmental risk factors likely contribute to disease risk.
- The diagnosis of cryptorchidism may be "acquired," that is, made in cases of apparent full descent at birth or after spontaneous descent of a cryptorchid testis and may be more common in boys with retractile testes. Yearly testicular examinations are recommended.
- About 80% of undescended testes are palpable, and 60% to 70% are unilateral.
- Many boys with nonsyndromic cryptorchidism have epididymal anomalies and a patent processus vaginalis, and some have reduced LH and/or testosterone levels during the postnatal surge.
- Orchidopexy is recommended for testes that remain undescended after 6 months of age; hormone therapy is not recommended.
- Laparoscopy is the procedure of choice, and imaging studies have limited value in the diagnosis and treatment of intra-abdominal cryptorchidism.
- Sperm counts are reduced in at least 25% of formerly unilateral and the majority of formerly bilateral cryptorchid men, but paternity rates in the unilateral group are similar to those of control men.
- Adult dark (Ad) spermatogonia counts may predict fertility potential in males with cryptorchidism.
- The relative risk of malignancy in cryptorchid testes is 2 to 8 and may be 2 to 3 after prepubertal orchidopexy.

appear after the age of 10 and that the risk rises with progression through puberty, reaching a peak at Tanner stage 3 (Kumanov et al, 2008). **The prevalence rate of clinically diagnosed varicoceles in this population is 8% to 16%, similar to that reported for the adult population, but ranges from 3% to 43% between studies** (Niedzielski et al, 1997; Skoog et al, 1997; Akbay et al, 2000; Stavropoulos et al, 2002; Kumanov et al, 2008; Zampieri and Cervellione, 2008). Although almost all reported varicoceles were left sided in older studies, some recent series report a 7% to 10% bilateral incidence and color Doppler ultrasonography (CDUS)–based evaluation identified additional subclinical left or bilateral varicoceles in 7% to 17% of adolescent cases (Akbay et al, 2000; Pfeiffer et al, 2006; Cervellione et al, 2008). Bilateral repair of palpable (primarily grade 1) varicoceles was performed in one third of 10- to 24-year-old males in a recent series (Decastro et al, 2009), suggesting that a right-sided varicocele may be more common in adolescents than previously recognized. In adults, bilaterality is reported in 15% to 50% of cases (Zini and Boman, 2009).

The cause for the appearance and, in some cases, progressive severity of varicoceles in children and adolescents has not been clearly defined, but susceptibility is likely determined by genetic predisposition, body habitus, and/or intrinsic venous abnormalities. Genetic factors likely contribute to the risk, but not necessarily the severity, of varicoceles. The risk of varicocele in first-degree relatives was four to eight times the risk in fertile men undergoing vasectomy or male kidney donors and especially high in brothers (Raman et al, 2005; Mokhtari et al, 2008). Studies using CDUS show that risk of varicocele progression during adolescence may be related to the prevalence of continuous or spontaneous as opposed to Valsalva-induced spermatic venous reflux (Pfeiffer et al, 2006; Cervellione et al, 2008; Zampieri and Cervellione, 2008). The underlying pathologic process is unknown but assumed to be related to the unique angle of the spermatic vein/renal confluence on the left side coupled with increased hydrostatic pressure and/or valvular incompetence (Zini and Boman, 2009). The "nutcracker phenomenon," defined as compression of the left renal vein between the aorta and superior mesenteric artery, was identified in a subset of affected boys by venography and CDUS and may contribute to the pathogenesis of varicocele (Coolsaet, 1980; Kim et al, 2006). Increased height and relatively lower weight and body mass index (BMI), a classic tall, thin body habitus, is associated with varicocele in adolescents and adults in clinical as well as screening populations (Handel et al, 2006; May et al, 2006b; Nielsen et al, 2006; Kumanov et al, 2008; Tsao et al, 2009) and may contribute to risk via increased spermatic vein length and/or hydrostatic pressure. Alternatively, the diagnosis may be less common in obese individuals owing to increased scrotal wall fat that reduces diagnostic sensitivity. In a recent study not yet confirmed by other investigators, Sakamoto and Ogawa reported greater peak and antegrade flow and venous diameter in the prostatic venous plexus of men with bilateral varicoceles, who comprised 33% of their series of 141 men with varicoceles, compared with controls and men with unilateral varicoceles (Sakamoto and Ogawa, 2008). These data are consistent with other studies showing increased risk of saphenofemoral junction incompetence (Karadeniz-Bilgili et al, 2003) and varicose veins (Kilic et al, 2007) in cases of varicocele, reflecting the possibility of a generalized venous abnormality.

Diagnosis and Classification

Although screening programs exist in some communities, the majority of varicoceles in children and adolescents are identified incidentally by a primary care practitioner and less commonly due to patient complaints of discomfort or scrotal swelling. Associated pain is reported in 2% to 11% of cases (Zampieri et al, 2008a) and may be a more common finding in some geographic regions. In rare cases, a varicocele is diagnosed after rupture due to sports-related or other trauma.

The patient is examined in a warm room in the supine and standing positions. The scrotum is observed for visible swelling, and the spermatic cord is palpated at rest and during the Valsalva maneuver. The standard grading system used for varicoceles is *grade 1*, palpable only with Valsalva; *grade 2*, easily palpable but not visible, and *grade 3*, easily visible. A large varicocele should decompress in the supine position; failure to decompress, particularly on the right side, is an extremely rare finding but warrants evaluation for an abdominal mass (Roy et al, 1989). *Grade 0* (subclinical) varicoceles are visualized by CDUS but are nonpalpable. As noted earlier, the use of CDUS to diagnose varicoceles increases the disease prevalence in any given population because subclinical varicoceles are identified. In adults, a subclinical right-sided varicocele was diagnosed about 10 times more often when thermography (measurement of scrotal temperature), CDUS, or venography was used as compared with physical examination only (Gat et al, 2004). However, significant controversy exists even in the infertile adult population regarding the need to diagnose and treat nonpalpable varicoceles.

The appropriate criteria for varicocele diagnosis using CDUS are controversial in adults, and experience with this use is limited in the pediatric and adolescent population. As reviewed by Lee and associates (2008), standards used for spermatic vein diameter (typically > 3 mm) and presence of retrograde flow vary in adult studies, although diagnostic accuracy may be increased using a combination of criteria. In a study of 625 boys with varicocele and 50 normal controls, Niedzielski and colleagues (1997) measured spermatic vein diameter in the standing position and venous reflux with Valsalva maneuvers. Using 2 mm as the upper limit of normal spermatic vein diameter based on findings in normal boys, these researchers obtained normal measurements in 95%, 70%, and 4% of boys with grades 1, 2, and 3 varicoceles, respectively. Similarly, spermatic venous diameter as measured in the supine position was a poor criterion for clinical varicocele and did not predict risk of testicular volume loss in a smaller series of boys with varicocele (Kozakowski et al, 2009). In studies of spermatic venous blood flow, reflux was identified in two thirds of boys with grade 2 or 3 varicoceles and flow velocity measured in the standing position correlated with grade of varicocele and sperm motility (Niedzielski et al, 1997). Kozakowski and coworkers (2009) measured supine peak retrograde spermatic vein flow with Valsalva maneuvers and noted that high flow rates (>38 cm/sec) were strongly associated with testicular volume asymmetry. The significance of these data is unclear, because the usefulness of spermatic vein flow measurement in adolescents will require standardization and prospective correlation with functional outcome.

Testicular size and consistency should be documented at the initial examination and at intervals during follow-up. The affected testis may be unusually soft, but the prevalence and relevance of this finding is not well documented. Although analysis of bilateral testicular volume is important, there is no consensus regarding the appropriate method of analysis. Options include calipers to measure testicular length, width, and depth or one of two commonly used orchidometers. The Prader orchidometer is a chain of 12 solid wooden ellipsoids with volumes of 1 to 6, 8, 10, 12, 15, 20, and 25 mL that are visually compared with the size of each testis. The Takihara orchidometer comprises 15 elliptical rings with inner dimensions corresponding to ellipsoid volumes of 1 to 6, 8, 10, 12, 14, 16, 19, 22, 26, and 30 mL that are placed over the widest circumference of the testis. Alternatively, ultrasonic placement of electronic calipers in three dimensions can be used with volume calculated by one of several formulas, the most common being the Lambert formula, 0.71(length × width × depth) or the volume of a rotational ellipsoid, 0.52(length × width × depth) or 0.52(length × depth^2). Costabile and colleagues (1992) performed blinded measurements of models of known volume using ultrasonography and the rotational ellipsoid formula and showed an overall standard deviation of 1.6 mL but less variation for volumes less than 10 mL. Studies assessing the relative accuracy of measurements obtained using ultrasonography and orchidometers in children and adolescents suggest that while all techniques are reliable, ultrasonography is more sensitive in determining differences in size between the left and right testis (Costabile et al, 1992; Chipkevitch et al, 1996; Diamond et al, 2000). Because orchidometer volume estimates are routinely greater than those determined using ultrasound and the rotational ellipsoid formula, calculation of differential volume using the following formula

(Right [unaffected] testicular volume – left [affected] testicular volume)/right testicular volume

will likely yield greater differential volumes when ultrasonography is used. However, based on studies of the 6- to 13-mL canine testis, ultrasound measurements and the Lambert formula provide the most accurate and precise testicular volume estimates (Paltiel et al, 2002).

Associated Pathologic Processes

There is abundant evidence that a varicocele may alter testicular growth, spermatogenesis, and fertility potential. The etiology of testicular injury is presumed to be related to increased scrotal temperature, but the pathogenesis remains poorly understood. Moreover, the ability to conceive exists in the majority of men with varicoceles. **The appropriate treatment of children and adolescents with varicoceles should be selective, based on the presence of risk factor(s) predictive of long-term subfertility.**

Testicular Hypotrophy

The association of varicocele with a relative decrease in volume of the left testis has been known for many years (Lipshultz and Corriere, 1977). In his population-based survey of adolescents and young adults, Steeno (1976) observed but did not quantify an adverse effect of grade 2 and 3 varicoceles on testicular volume and/or consistency. Subsequently, others (Lyon et al, 1982; Kass and Belman, 1987) showed that relative left testicular volume loss is common in adolescents with varicocele, may improve or resolve after varicocele correction, and therefore may reflect significant testicular injury. Significant left hypotrophy is variously defined as a 10%, 15%, 20%, 2- or 3-mL relative difference in testicular size and reportedly present in 10% to 77% of cases (Lyon et al, 1982; Okuyama et al, 1988; Akbay et al, 2000; Thomas and Elder, 2002; Diamond et al, 2004b; Kolon et al, 2008; Preston et al, 2008). Variability of this finding is likely related to the method of measurement (visual estimation, orchidometer, or ultrasound with varying computational formulas used), referral patterns, and the formula used to determine percent difference between testes. Moreover, population-based data show that a rapid increase in testicular size may occur as early as 10 years of age and persist until age 19, depending on the population studied and the Tanner stage of pubertal development (Tables 132–2 and 132–3) (Schonfeld, 1943; Rundle and Sylvester, 1962; Zachmann et al, 1974; Daniel et al, 1982; Matsuo et al, 2000) and can vary widely between individuals particularly between 13 and 14 years of age (Marshall and Tanner, 1970). Therefore longitudinal measurements over several years may define testicular hypotrophy more accurately than single measurements, particularly in early puberty. Most often, size differential is calculated as follows:

Percent difference = 100 × (right testicular volume – left testicular volume)/right testicular volume,

although Kolon and associates (2008) use the formula:

100 × (right testicular volume/total testicular volume – left testicular volume/total testicular volume).

Varicocele grade is positively associated with risk of left testicular hypotrophy in some studies (Thomas and Elder, 2002; Zampieri et al, 2008b) but not others (Alukal et al, 2005; Kolon et al, 2008).

Table 132–2.

Tanner Stages

Pubic Hair	
1	No pubic hair
2	Sparse growth of long, slightly pigmented downy hair primarily at base of penis
3	Darker, coarser, and more curled hair spreading sparsely over the pubic region
4	Adult-type hair covering an area smaller than in most adults
5	Adult-type hair in typical adult male distribution extending up linea alba and to medial surface of thighs
(6)	Further spread of hair after puberty (not used routinely)
Genitalia	
1	Testes, penis, and scrotum same proportional size as in early childhood
2	Enlargement of scrotum and testes with change in texture and reddening of scrotal skin
3	Growth of the penis, first in length and then breadth; further growth of scrotum and testes
4	Further growth of penis in length and breath; development of glans and testes; scrotum further enlarged and darkened
5	Genitalia adult size and shape without further enlargement

Table 132–3.

Testicular Volumes Based on Tanner Stage

	Daniel et al, 1982†				Zachmann et al, 1974‡	
	Left Testis (cm^3)		Right Testis (cm^3)		Total (mL)	
TANNER STAGE*	Mean	SD	Mean	SD	Mean	SD
1	4.8	2.8	5.2	3.9	6.0	2.6
2	6.4	3.2	7.1	3.9	6.8	3.6
3	14.6	6.5	14.8	6.1	9.3	3.8
4	19.8	6.2	20.4	6.8	12.6	4.2
5	28.3	8.5	30.2	9.6	16.3	4.6
6					18.9	4.0

*Pubic hair staging (Zachmann et al, 1974) or mean of genital and pubic hair staging (Daniel et al, 1982).
†Data based on length and width measurements ($0.52 \times L \times W^2$) of 348 U.S. males age 12 to 19 years.
‡Data based on orchidometer measurements of 2139 Swiss males age 12.5 to 20 years.

Kass and colleagues (2001) compared 434 varicocele cases and 70 controls of similar age (mean 14 years) and noted that right testicular size was also significantly reduced compared with control values in Tanner stage 4 to 5 males with grade 3 varicocele. Okuyama and coworkers (1988) reported testicular hypotrophy (size < 2 SD below the mean for Japanese boys) on the side contralateral to a grade 2 or 3 varicocele in 22% of their patients, and their data suggested lower sperm density in patients with bilaterally small testes. Mean right testicular volume increased significantly after left varicocele repair but not in untreated control groups in several other studies (Laven et al, 1992; Yamamoto et al, 1995; Paduch and Niedzielski, 1997). Paduch and Niedzielski (1996) reported a correlation between total testicular volume and sperm concentration in adolescents but did not observe a significant decrease in right testicular size between varicocele patients and controls. Consequently, the significance of global testicular size in boys with left varicocele remains poorly defined. Although not presently available, ultrasound-derived size measurements for each testis based on population-specific norms and comparison with outcome would provide further insight into this question.

"Catch-up" growth, defined as normalization of left relative to right testicular size, occurs in 32% to 83% of patients after varicocele repair (Cayan et al, 2002; Greenfield et al, 2002; Yaman et al, 2006; Castagnetti et al, 2008; Feber and Kass, 2008; Decastro et al, 2009; Poon et al, 2009; Zampieri et al, 2009) and in 55% to 70% of boys on average in various series (Barroso et al, 2009). A conclusion that postoperative testicular catch-up growth is less likely in boys older than 14 (Cayan et al, 2002) was not supported by another study addressing this issue (Decastro et al, 2009). Most clinicians believe that postoperative resolution of left testicular hypotrophy is evidence that varicocele repair improves testicular function in adolescents. However, a clear understanding of the relationship between varicocele repair and restoration of testicular growth is complicated by observations that testicular size differential may improve spontaneously in untreated patients, varicocele may affect growth of both testes, testicular edema or venous stasis may hypothetically contribute to testicular enlargement, catch-up growth may occur despite surgical failure, and improvement in sperm counts does not necessarily correlate with catch-up growth. In an early observational study, Paduch and Niedzielski (1997) observed some improvement in mean testicular volume differential in boys followed expectantly without surgery. Kolon and coworkers (2008) reviewed serial ultrasound studies performed at least 6 months apart (≥3) in 71 boys observed without intervention for an average of 3.5 years and noted asynchronous testicular growth in many. Using a 15% volume differential as a normal cutoff, these authors observed hypotrophy in 54% of boys initially and only 15% at final follow-up, suggesting that the majority of potential surgical candidates may normalize with time without treatment. Similarly, Preston and colleagues (2008) reported normalization of hypotrophy in 50% of 33 boys followed a median of 2.12 years; neither of these studies showed deterioration to greater than 20% hypotrophy during observation. In contrast, other investigators rarely noted spontaneous catch-up growth but reported worsening or development of significant hypotrophy in 10% to 26% of boys over time (Thomas and Elder, 2002; Kozakowski et al, 2009; Zampieri and Cervellione, 2008), whereas others reported no statistical difference in either direction in longitudinal studies (Diamond et al, 2004b). **The fact that intraindividual testicular volume differential may change significantly over time supports the conclusion** (reached by Kolon et al, 2008) **that normal pubertal testicular development may be asynchronous. Alternatively, testicular size may appear variable over time because of inherent error in measurement techniques.** These same factors may bias reported postoperative results showing testicular volume improvement that do not include an untreated comparison group.

Kocvara and colleagues (2003) reported significant testicular growth as early as 6 weeks after surgery, enhanced catch-up growth with lymphatic and arterial ligation, and intratubular edema in several biopsies obtained at hydrocele repair several years after non–lymphatic-sparing varicocelectomy with or without artery sparing. Their hypothesis that lymphatic ligation may contribute to increased testicular volume is not consistent with data from other centers showing no difference in rates of catch-up growth based on lymphatic (Poon et al, 2009) and/or arterial (Barroso et al, 2009) preservation. Moreover, Laven and associates (1992) noted that varicocele repair increased the volume of small but not normal-sized testes in their series. Postoperative left testicular hypertrophy (>10% size differential relative to the right testis) is

reported in several studies and attributed to non–lymphatic-sparing procedures or to a rebound effect on spermatogenesis in the affected testis (Gershbein et al, 1999; Cayan et al, 2002; Kocvara et al, 2005).

To date, no studies clearly define the natural history and relationship, if any, between testicular hypotrophy in adolescence and that seen in adulthood. In a retrospective review, Sayfan and colleagues (1997) reported long-term follow-up data in 32 men who underwent varicocele repair at 11 to 15 years of age, comprising 27% of a cohort treated between 1972 and 1982. In comparing this group with normal controls and untreated men with varicoceles, they noted similar semen quality and no testicular volume differential in treated and control groups, and significantly lower sperm counts and smaller left testes in the untreated group, but did not clarify how this latter population was identified. Despite these data, it is important to note in the general adult population with varicoceles that testicular hypotrophy is not a clear risk factor for infertility. Mean testicular volume differential in unselected fertile men with varicoceles (3.1 ± 0.3 mL) was not significantly different from that found in infertile men with varicoceles (2.5 ± 0.6 mL), and 82% of all men with varicoceles and 68% of those with grade 3 (not statistically different from the entire group) had evidence for normal fertility (Pinto et al, 1994). Other studies support the finding that left testicular volume is smaller in both fertile and infertile men with varicoceles but that bilateral hypotrophy is more common in the infertile group (Pasqualotto et al, 2005; Shiraishi et al, 2009). Shiraishi and associates (2009) suggest that additional cofactors contribute to the risk of infertility in men with varicoceles. In 611 patients with varicoceles (45% with grade 2 or 3) presenting for infertility evaluation, Sigman and Jarow (1997) reported testicular size discrepancy of at least 3 mL in 50%, with higher grade and lower total motile sperm counts (corrected for grade) in those with this finding. In contrast, in another study of 245 men presenting for infertility with varicoceles (90% with grade 2 or 3), bilateral but not unilateral hypotrophy was a significant predictor of abnormal total motile sperm count (Wu et al, 2008).

Significant discrepancy between left and right testicular size is considered the most reliable clinical risk factor available and remains the primary indication for varicocele correction. Unfortunately, the available data do not provide a clear picture of the effect of varicocele or its correction on testicular growth and function in individual patients. The presence of hypotrophy is not invariably associated with reduced fertility potential, but other predictors such as varicocele grade, global testicular growth, and hormonal studies have not been critically evaluated in adolescents. **Prospective, randomized studies are needed to clearly establish whether unilateral and/or bilateral testicular hypotrophy or catch-up growth accurately predict fertility potential in adolescent varicocele.**

Testicular Histology

Although extensively studied in adults (reviewed by Hienz et al, 1980), histologic data from testicular biopsies of adolescents with varicocele have been limited and inconsistent. These biopsy findings vary from normal histology by light and electron microscopy in all (Fideleff et al, 2000) or most normal men with severe hypospermatogenesis in a minority of cases (Kass et al, 1987; Aragona et al, 1994) to degenerative tubular changes, altered Leydig cell number, and/or proliferative lesions of the vasculature in the majority of cases (Hienz et al, 1980). In a small retrospective series of men who underwent testicular biopsy at the time of adolescent varicocele repair, Hadziselimovic and associates (1995) observed abnormal tubular maturation and Leydig cell number but were unable to correlate these data with ultimate sperm quality in adulthood.

Hormonal Function

Kass and colleagues (1993a) reported an exaggerated LH and FSH response to gonadotropin-releasing hormone (GnRH) stimulation in about 30% of boys with varicocele, although they were unable to show a correlation with testicular hypotrophy. Similar data were reported in a smaller study that also included inhibin-B measurements (Carrillo et al, 1999), which have also not shown consistent correlation with testicular size or semen parameters in adolescents or adults with varicocele (Turkyilmaz et al, 2006; Romeo et al, 2007; Basar et al, 2010). Aragona and associates (1994) identified severe germ cell abnormalities in 3 of 15 adolescents with grade 2 to 3 left varicocele and 2 of these boys had exaggerated LH and FSH response to GnRH, but 2 others with increased LH response had normal histology, and none of their patients had more than 12% left testicular hypotrophy. Baseline LH and FSH levels are not consistently different in the presence or absence of varicocele during adolescence in most studies (Laven et al, 1992; Yamamoto et al, 1995; Cayan et al, 2005; Ku et al, 2005). Guarino and coworkers (2003) observed increased LH, FSH, and simulated FSH levels in 20 varicocele patients with abnormal semen parameters (age 16 to 19, Tanner stage 5) compared with 56 with normal semen, but 6 of the former group had bilateral varicoceles, a history of inguinal surgery, or cryptorchidism. Basal and stimulated gonadotropin levels were not consistently different in varicocele patients when compared with controls and did not improve after surgery in another series (Fideleff et al, 2000). GnRH stimulation testing is not presently used routinely as an indication for varicocele surgery in adolescents because of lack of correlation with testicular size differential; however, further studies are warranted because hypotrophy itself does not always correlate with outcome or with histologic changes in the testis.

Semen Quality

Despite many variables associated with collection and interpretation of semen analysis samples, semen quality is considered the most useful indicator of fertility potential. Because of wide variation in sexual maturation, age alone is not a good criterion to establish reliability of semen analysis results. Janczewski and Bablok (1985a to 1985d) compared bone age, testicular size, Tanner stage, hormone levels, and timing of first ejaculation with attainment of normospermia in a series of 134 Polish boys aged 12 to 19 years old. In these studies the first ejaculation occurred beginning at a bone age of 13 years, 16 months or earlier after the beginning of puberty, and the majority of boys met criteria for normospermia by a bone age of 17. Tanner stage 5 was associated with asthenozoospermia and occasional oligozoospermia in addition to normospermia. Mean testicular size based on caliper measurements increased with progression in semen quality but showed a large standard deviation in boys achieving normospermia, and a significant drop in LH and FSH levels occurred with attainment of normospermia. **Because progressive improvement in sperm quality may parallel continued growth of the testis through the teenage years, semen analyses may not reliably predict testicular function in boys with varicocele before completion of testicular growth.**

A number of studies are now available that report semen analysis data in males diagnosed with varicocele, usually grade 2 or 3, in adolescence (Table 132–4). In the majority of these studies, at

Table 132–4.

Semen Analysis Results in Adolescent Varicocele

STUDY	GROUPS	AGE	SEMEN ANALYSIS	GRADE	FINDINGS
Randomized Cases vs. Controls					
Laven et al, 1992	27 treated 26 untreated 16 controls	17-20	2	2-3	Initial SC 43-52 ± 32-44 × 10^6/mL (NS between groups); treated group increased to 69 × 10^6/Ml ($P < .01$) at 1 year; no consistent correlation of semen quality with catch-up growth
Yamamoto et al, 1995	29 treated 22 untreated 18 controls	15-19 17-21 14-20	1	1-2	Initial SC 49-51 ± 16-32 × 10^6/mL (NS between groups); treated group increased to 74 × 10^6/mL ($P < .002$) at 1 year
Untreated Cases vs. Controls					
Haans et al, 1991	67 untreated 21 controls	17-21	2	2 (15) 3 (52)	SC < 20 × 10^6/mL in 19% controls, 20% grade 2 and 13% grade 3 (NS). Correlation (r = .26, $P = .03$) between left testicular volume and total sperm count but not SC
Paduch and Niedzielski, 1996	36 untreated 38 controls	17-19	2	2-3	SC 53 ± 31 × 10^6/mL in cases and 56 ± 36 × 10^6/mL in controls (NS); significant differences in motility and vitality between groups; sperm concentration correlated with total testicular volume
Cedenho et al, 2002	20 untreated 20 controls	Mean 16	1	2-3	SC 57 ± 55 × 10^6/mL in cases and 73 ± 54 × 10^6/mL in controls (NS), impaired sperm–zona pellucida binding capacity (cases)
Bertolla et al, 2006	20 untreated 20 controls	15-17 T4-5	1	2-3 bilat	SC 78 ± 17 × 10^6/mL in cases and 86 ± 25 × 10^6/mL in controls (NS), increased sperm DNA fragmentation (cases)
Mori et al, 2008	67 untreated 160 controls + grade 1	14-18 T4-5	1	2 (49) 3 (18)	SC 50 ± 52 × 10^6/mL in grade 2, 37 ± 41 × 10^6/mL in grade 3, and 88 ± 76 × 10^6/mL in controls + grade 1 ($P = .0003$)
Treated vs. Untreated Cases					
Okuyama et al, 1988	13 treated 10 untreated	18	≥3	2-3	Normal SA* in 69% treated and 20% untreated cases ($P < .05$)
Zampieri and Cervellione, 2008	92 treated 127 untreated	18	2	2-3	WHO criteria† met in 64% treated (all with hypotrophy) and 80% untreated (none with hypotrophy) (NS); no correlation of SA with varicocele grade or catch-up growth
Preoperative vs. Postoperative					
Cayan et al, 2005	33 preoperative and postoperative	Mean 16.4 preoperative	1	2-3 (48% bilateral)	SC 22 ± 3.6 (SE) × 10^6/mL before and 40 ± 5.7 × 10^6/mL at 28 ± 13 months (mean ± SD) after artery/lymphatic sparing repair ($P = .007$)
Ku et al, 2005	35 preoperative and postoperative	15-20	2	Most 2-3	SC 32 ± 3 (SE) × 10^6/mL before and 41 ± 3 (SE) × 10^6/mL at 6 months after artery/lymphatic sparing repair; % motile sperm increased ($P < .001$); most surgeries performed for pain
Untreated Cases					
Guarino et al, 2003	68 untreated	16-19 T5	2	Most 2-3	21% with abnormal OMI (SC × % motile × % oval sperm), no correlation with testicular volume
Diamond et al, 2007	57 untreated	14-20 T5	1-2	Most 2-3	TMSC: <10% hypotrophy ($n = 27$), 64 (32-134) 10-20% hypotrophy ($n = 18$), 32 (13-94) >20% hypotrophy ($n = 12$), 10 (3-82) $P = .02$ > 20% vs. < 10%; no correlation with grade

*Normal SA defined as ≥30 × 10^6 sperm/mL, ≥60% motility, and ≥70% normal morphology.
†World Health Organization (WHO) criteria ≥20 × 10^6 sperm/mL, ≥50% motility, and ≥30% normal morphology.
NS, not significant; SA, semen analysis; SC, sperm concentration, mean ± SD unless noted; T, Tanner stage; TMSC, total motile sperm count (volume × concentration × % motile sperm), expressed as median (25th to 75th percentiles).

least two semen samples were obtained using techniques meeting World Health Organization criteria in older teenagers, although Tanner stage 5 was not always specified. In two randomized studies comparing treated and untreated cases with controls, no differences were found in semen quality at initial or follow-up analysis between groups, except for a significant postoperative increase noted in the treated group in both studies that exceeded sperm concentrations seen in controls (Laven et al, 1992; Yamamoto et al, 1995). The cause for improvement in semen quality above control levels was not clear to these investigators, but Laven and coworkers (1992) hypothesized a rebound in spermatogenesis. Significant increases in sperm concentration were also reported in uncontrolled studies, but these may be biased by variations in semen quality that occur with time in late adolescence. The majority of series comparing untreated cases with controls of similar age found no significant differences in semen between groups or consistent differences between nonrandomized treated versus untreated cases. Correlations between left or total testicular volume and semen parameters were noted by some investigators (Haans et al, 1991; Paduch and Niedzielski, 1996; Diamond et al, 2007) but not others (Guarino et al, 2003). Investigators were unable to correlate postoperative increases in left testicular volume or varicocele grade with semen analysis data in controlled (Laven et al, 1992) and uncontrolled (Cayan et al, 2002; Diamond et al, 2007; Zampieri and Cervellione, 2008) studies. **Although there are insufficient data from randomized prospective studies, the available data suggest trends toward poorer sperm quality that may be limited to a subset of affected males with varicocele, but that grade and postoperative testicular catch-up growth do not reliably predict ultimate semen quality.**

Intratesticular Varicocele

In less than 2% of patients, a large varicocele may be associated with an intratesticular component that is diagnosed by ultrasound and otherwise unsuspected (Diamond et al, 2004a). Although it may be confused with lesions of the testis or rete testis, the diagnosis is easily made by demonstration of venous flow in anechoic structures greater than 2 mm in diameter near the mediastinum testis that is enhanced by the Valsalva maneuver. Approximately one third are reported to be bilateral. Diamond and associates (2004a) suggest that these lesions may reflect increased risk to the testis and that surgery is therefore indicated.

Treatment

In the past, varicocele was considered a progressive lesion because of its higher prevalence in men with secondary as opposed to primary infertility (Gorelick and Goldstein, 1993). However, in a more recent study the distribution of varicoceles by grade and the prevalence of unilateral and bilateral testicular hypotrophy were similar in both groups, although sperm counts were higher, suggesting a female factor, in secondarily infertile men (Walsh et al, 2009). Moreover, an 8-year longitudinal study of men with varicocele and normal sperm counts did not show worsening of semen quality over time (Lund and Larsen, 1998). These and other data do not support the belief that the effect of varicocele on testicular function is progressive or that unilateral testicular hypotrophy is necessarily indicative of infertility in men with varicocele (Jarow, 2001). Therefore observation remains the approach of choice for the majority of adolescents with varicocele. **Despite pitfalls associated with the use of significant testicular hypotrophy as the primary criterion for surgical intervention and evidence that testicular size discrepancy may be variable during adolescence, the main indications for surgical intervention remain significant left (≥20%) or bilateral testicular hypotrophy, pain or abnormal semen analysis, the latter most reliable in boys of Tanner stage 5 and/or at least 18 years of age.** Although not studied in detail, bilateral hypotrophy may be more ominous and an indication for intervention but must be determined based on nomograms specific for the population, the patient's Tanner stage, and the measurement technique being used. Pain is a rare indication for surgery, reported in only 2% to 10% of patients in most series and relieved by the procedure in 68% to 88% of patients (Zampieri et al, 2008a).

Surgical Repair of Varicocele

As in adults, several techniques are used for repair of adolescent varicocele, including inguinal/subinguinal, laparoscopic/retroperitoneal, or venographic approaches. The most commonly used techniques are the microscopic subinguinal approach and the suprainguinal open or laparoscopic approach with either mass ligation of the cord above the vas (Palomo) or with lymphatic and/or artery-sparing techniques. The choice of procedure is dependent on surgeon preference, experience, and complication rates that vary based on technique and length of follow-up (Table 132–5: Poddoubnyi et al, 2000; Misseri et al, 2001; Greenfield et al, 2002; Esposito et al, 2004; Cayan et al, 2005; Kocvara et al, 2005; Schiff et al, 2005; Yaman et al, 2006; Castagnetti et al, 2008; Feber and Kass, 2008; Glassberg et al, 2008; Barroso et al, 2009; Diamond et al, 2009; Tong et al, 2009 and references therein). There are no existing long-term outcome data available to support the use of any particular approach. Differences between subinguinal and suprainguinal approaches are primarily based on type and frequency of complications. In some series, the length of postoperative follow-up may be inadequate to identify potential recurrences, which as opposed to cases of persistence are first identified 6 months or more postoperatively (Glassberg et al, 2008). The latency period for appearance of a hydrocele may vary from a mean or median of a few months to almost 2 years postoperatively, and some are not diagnosed for several years or longer (Misseri et al, 2001; Esposito et al, 2004; Feber and Kass, 2008). Although these may resolve spontaneously, up to one half may require intervention. Esposito and associates (2004) most commonly treated postoperative hydrocele with scrotal aspiration, which was required a median of three times under anesthesia

Table 132–5.
Results of Adolescent Varicocele Repair

PROCEDURE	RECURRENCE/ PERSISTENCE	HYDROCELE	TESTICULAR ATROPHY
Open suprainguinal (Palomo)	2%-4%	0%-30% (10%)*	
Laparoscopic			
Nonlymphatic/ artery sparing	0%-9%	11%-32% (7%)*	
Artery and/or lymphatic sparing	1%-7%	0%-4%	
Microscopic subinguinal	0%-10%	0%-6%	Rare
Nonmicroscopic inguinal	7%-33%	8%-14%	
Sclerotherapy	6%-35%	Occasional	Rare

*Number in parentheses refers to meta-analysis of Barroso et al, 2009.

before resolution. Most surgeons proceed with formal scrotal hydrocele repair only in cases of large or symptomatic hydrocele, with repair ranging from 5% to 50% of affected patients in several recent series (Misseri et al, 2001; Esposito et al, 2004; Feber and Kass, 2008; Diamond et al, 2009).

Subinguinal/Inguinal Microsurgical Varicocelectomy

The *subinguinal microscopic approach* provides the advantages of facilitated artery- and lymphatic-sparing, high rate of success, and low risk of hydrocele but may be time consuming and requires microscopic surgical skills. Some advocate this approach to optimize artery sparing, based on the assumption that it is more likely to optimize testicular function (Goldstein, 1995). The procedure used in children is similar to that used in adults as originally published (Goldstein et al, 1992; Schiff et al, 2005). A 2.5- to 3-cm incision is made over or just above the external inguinal ring, and the spermatic cord is isolated with or without opening the external oblique fascia. In the procedure described by Goldstein and colleagues (1992) the testis is delivered and all external spermatic and gubernacular veins are ligated, although not all surgeons deliver the testis. After incision of the internal spermatic fascia, the cord is examined using 10× to 25× magnification. Lower degrees of magnification (e.g., loupes) can be used but probably provide inferior results (Greenfield et al, 2002; Cayan et al, 2005; Diamond et al, 2009). External, internal, and vasal veins greater than 2.5 mm in diameter are ligated, and the spermatic artery and accompanying lymphatics are identified and spared. Schiff and associates recommend applying pressure to the testis after ligation is completed to determine whether an impulse can be felt in the ligated veins. The artery is identified by visualization of pulsations under higher (25×) magnification, application of 1% papaverine, use of a Doppler probe, and/or elevation with partial occlusion followed by release and visualization of pulsations within the vessel suspected to be an artery (Raman and Goldstein, 2004). The subinguinal approach is associated in rare cases with testicular atrophy (necrosis), which has not been reported for suprainguinal procedures (Diamond et al, 2009). The cause of necrosis is unclear but may be related to total venous occlusion, as may occur in some cases of sclerotherapy, or to compromise of both spermatic and vasal arteries.

Open/Laparoscopic Suprainguinal Varicocelectomy

The *suprainguinal approach* with spermatic artery ligation is a simple procedure performed either open or laparoscopically and associated with high success rates but also higher rates of hydrocele formation. Lymphatic and/or artery sparing is associated with a reduction in the incidence of postoperative hydrocele, but identification and preservation of these vessels may be difficult, even with magnification afforded by the use of laparoscopy. In retrospective studies, Zampieri and associates (2007a, 2007b) report that artery sparing is associated with improved semen quality but no randomized prospective data exist that clearly define the effect of artery sparing on testicular function. Theoretically, testicular compromise may occur with spermatic artery ligation in patients with a history of previous inguinal surgery (Skoog et al, 1997) but was not reported to occur in a small series of boys after a laparoscopic Palomo procedure (Barqawi et al, 2002). Similarly, a risk to the testis exists after non–artery-sparing varicocelectomy with subsequent compromise to the vasal artery or vein, as in vasectomy.

In the standard open procedure, a muscle-splitting incision is made just medial to the anterior superior iliac spine and the peritoneum is identified and mobilized medially. The entire bundle of spermatic vessels above the vas is mobilized, isolated, and clipped or suture-ligated. Open or laparoscopic Palomo techniques are performed with and without transection of the vessels, but no evidence supports a preference for either approach. A microscopic lymphatic-sparing procedure may be performed through a retroperitoneal incision, with initial data in a small series showing no hydrocele or recurrence after short-term follow-up (Wong et al, 2009).

Laparoscopic varicocele repair is performed after standard placement of an umbilical trocar, which is usually performed in children using an open (Hassan) technique. The patient is placed in slight Trendelenburg position, and the bladder is emptied. After intraperitoneal insufflation with CO_2, the spermatic cord is visualized and two additional port sites are placed under direct vision in the left midclavicular line just inferior to the umbilicus and in the lower midline or right lower quadrant for a left-sided varicocele, triangulating with the umbilical port and the internal ring. Alternatively, some surgeons use ports in both lower quadrants. A peritoneal incision is made several centimeters or more superior to the internal ring and lateral to the spermatic vessels, and the vascular bundle and surrounding tissue are mobilized away from the peritoneum. For spermatic artery preservation, approaches similar to those used for subinguinal procedures can be used, including a laparoscopic Doppler probe and papaverine in addition to the magnification provided by the laparoscope. Kocvara and colleagues (2005) recommend initially grasping the largest lateral vein to facilitate mobilizing the entire bundle. They noted that 1 to 3 lymphatics, which appear as clear tubular structures, accompany the artery and smaller veins and that in typical lymphatic-sparing procedures 5 to 12 can be identified and preserved. The injection of vital dyes into the paratesticular tissues for visualization of the majority of lymphatics along the spermatic vessels has been reported but is not universally used because of potential technical challenges and risks associated with inadvertent intratesticular injection (Schwentner et al, 2006; Makari et al, 2007). Options for vascular ligation include permanent (usually silk) sutures tied extracorporeally, locking metal clips to avoid slippage, or transection using the harmonic scalpel or vessel-sealing devices. To avoid recurrence, vein(s) accompanying the artery should be identified and ligated. In a variation of the usual approach, Cimador and colleagues (2008) used CDUS to search for dilated, refluxing deferential veins in the iliac fossa, which if present were ligated at the time of a laparoscopic Palomo procedure. The necessity of this approach in preventing persistent or recurrent varicoceles has not been shown, and a theoretical concern for vasal artery injury with concomitant spermatic artery ligation exists. Injury to the genitofemoral nerve has been reported in a limited number of adolescent and adult series of laparoscopic varicocelectomy, comprising a total of 3% of cases, and may be more commonly associated with use of cauterizing instrumentation (Muensterer, 2008). This complication presents as postoperative paresthesias in the distribution of the nerve along the proximal anterior thigh that slowly resolves over weeks or months.

Sclerotherapy/Embolotherapy

Antegrade or retrograde injection of sclerosant or embolizing material has been used for many years to treat adults with varicocele, but published experience in children and adolescents is limited. In general, both retrograde (Reyes et al, 1994; Mazzoni et al, 1999; Alqahtani et al, 2002; Sivanathan and Abernethy, 2003; May et al, 2006a; Beutner et al, 2007; Granata et al, 2008; Reiner et al, 2008) and antegrade procedures are less successful

than open or laparoscopic procedures (see Table 132–5) and require significant radiation exposure. Venous occlusion is achieved in retrograde procedures using sclerosants such as 3% sodium tetradecyl sulfate or polidocanol, with or without intravascular coils or balloons. The procedure can be accomplished under local anesthesia and is typically performed at centers with expertise in interventional radiology. In series comprised primarily of children and adolescents the procedure is reported to be unfeasible for technical reasons in 5% to 22% of cases; and with varying degrees of follow-up (rarely more than 1 or 2 years), rates of persistence or recurrence are 6% to 35%. Self-limiting complications include pain, epididymo-orchitis, phlebitis, or scrotal swelling; partial testicular atrophy and hydrocele occur rarely. Antegrade techniques entail use of a small subinguinal or upper scrotal incision, isolation of a vein or veins amenable to cannulation with or without fluoroscopic confirmation of antegrade flow into the internal spermatic vein, and injection of a sclerosant followed by ligation of the vein (Ficarra et al, 2004; Zaupa et al, 2006; Carmignani et al, 2009). This also can be performed under local anesthesia, and success rates are reported to be 4% to 12%, lower than for retrograde sclerotherapy, but complications are similar. Recently, Lebed and colleagues (2008) reported adjuvant use of sodium morrhuate sclerotherapy at the time of subinguinal or inguinal varicocele repair with or without use of the operating microscope. Their reported recurrence rate overall is similar to that reported for the subinguinal open approach alone, although they suggest that the additional use of a sclerosant may reduce the risk of recurrence owing to unrecognized proximal collateral veins.

Key Points: Varicocele

- The prevalence of adolescent varicocele is 8% to 16%, similar to that found in adults.
- Susceptibility to varicocele is determined by genetic predisposition, a tall, thin body habitus, and/or intrinsic venous abnormalities.
- Pain is the presenting complaint in less than 10% of adolescents with varicocele.
- Treatment of adolescent varicocele should be selective, because about 85% of adults with varicocele do not present with problems related to fertility.
- Ultrasonography is the most sensitive method for determining volume discrepancy between testes, and the Lambert formula (length × width × depth × 0.71) is preferable for volume calculation.
- A 15% to 20% reduction in volume (hypotrophy) of the affected testis is common in boys presenting with varicocele; hypotrophy resolves in 55% to 70% of cases after varicocele repair but may also improve spontaneously with progression through adolescence.
- Hypotrophy but not varicocele grade is inversely correlated with semen quality in some series, but postoperative testicular catch-up growth does not necessarily imply improved semen quality.
- Testicular hypotrophy involving the affected or both testes, abnormal semen analysis, and pain are current indications for adolescent varicocele repair.
- Laparoscopic or microscopic subinguinal artery- and lymphatic-sparing techniques for varicocele repair are associated with the lowest risk of both recurrence and hydrocele.

HERNIAS AND HYDROCELES

Definitions

The processus vaginalis and inguinal canal develop in both sexes in the first trimester of gestation (Barteczko and Jacob, 2000), although subsequent development of the processus vaginalis is more prominent in males to allow transinguinal passage of the testis. In males, the full length of the processus within and distal to the inguinal canal (the funicular process) becomes obliterated but the distal portion remains open as the tunica vaginalis within the scrotum. In an autopsy study, complete closure of the processus vaginalis was observed in only 18% of full-term infants at birth (Mitchell, 1939). Contralateral exploration of 1965 children with a unilateral inguinal hernia revealed that the processus vaginalis was patent in 63% of patients younger than 2 months and about 40% of those 1 to 2 years of age, with similar frequency up until age 16 (Rowe et al, 1969). The time frame for closure of the processus vaginalis in individuals without a hernia is not clear; however, the incidence of incidental patency observed in older children and adults at autopsy or laparoscopy is about 20% (Ajmani and Ajmani, 1983; van Wessem et al, 2003).

Persistent patency of all or a portion of the processus vaginalis within the inguinal canal may but does not always result in a symptomatic hernia or hydrocele (Fig. 132–6). If the processus remains widely patent, allowing passage of abdominal viscera, a clinical ***indirect inguinal hernia*** is present extending into the canal, labium, or scrotum. If fluid alone passes into a patent processus vaginalis and surrounds the testis within the tunica vaginalis, a ***communicating hydrocele*** is present (see Fig. 132–6A). Other forms of hydrocele include a ***spermatic cord hydrocele,*** which is associated with obliteration of the processus distally and in some cases proximally (see Fig. 132–6B and C), and noncommunicating simple ***scrotal hydrocele*** or ***abdominoscrotal hydrocele.*** Partial closure of a communicating sac may occur within the canal, producing both a proximal hernia and a distal noncommunicating hydrocele. Simple patency of the processus vaginalis is required but not sufficient for development of a hernia or communicating hydrocele.

Epidemiology and Pathogenesis

The risk of pediatric hernia is highest in neonates, particularly premature boys; in contrast, the prevalence of hydrocele varies with age and etiology. Hydroceles that persist or first appear after birth are more likely to be associated with hernias, whereas those that disappear in infancy or appear at or after puberty are more commonly noncommunicating and due to delayed fluid absorption or abnormal fluid dynamics within the tunica vaginalis. Rare causes of nonpainful hydrocele include tumor or inflammatory processes within the scrotum.

Inguinal Hernia and Communicating Hydrocele

The incidence of inguinal hernia in childhood is 1% to 5%, with a male to female ratio of 5 to 10:1 and an increased propensity for right-sidedness, unilaterality (75% to 90%), and occurrence in premature infants (up to 30%) as noted for cryptorchidism (Jones et al, 1998; Kapur et al, 1998; Brandt, 2008). A clinical hernia or hydrocele may present at any time during childhood, but the average age in most large series is 3 to 4 years, although a third of pediatric hernias present in the first few months of life (Kapur et al, 1998). The vast majority of pediatric hernias are indirect inguinal hernias, although direct and femoral hernias also occur.

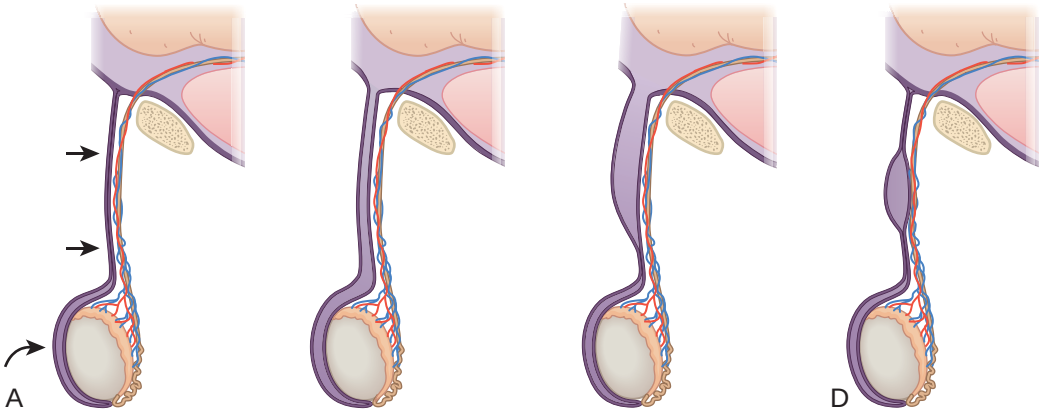

Figure 132–6. Anatomy of the processus vaginalis in hydrocele. **A**, Normal closure of the processus vaginalis; *straight arrows* indicate the funicular process; *curved arrow* is the tunica vaginalis. **B**, Communicating hydrocele with complete patency of the processus vaginalis; **C**, Funicular hydrocele with distal closure of the processus vaginalis; communication with the peritoneal cavity may also result in hernia. **D**, Encysted hydrocele of the spermatic cord. (From Martin LC, Share JC, Peters C, Atala A. Hydrocele of the spermatic cord: embryology and ultrasonographic appearance. Pediatr Radiol 1996;26:528–30.)

In a large series of 6361 consecutive pediatric hernias treated at a single institution, 19% were associated with hydroceles (70% scrotal only, 26% cord, and 4% both), although this may reflect referral bias (Ein et al, 2006).

Newly apparent hydroceles may be associated with a processus vaginalis that is freely communicating proximally but closed at some level along the cord (see Fig. 132–6) with or without encysted or multiloculated segments (Martin et al, 1996). Most are asymptomatic, but rarely a portion of the sac or hydrocele may undergo acute torsion (Tillett et al, 2006). Although the circumference of the sac as measured at surgery tends to be smaller in communicating hydroceles as compared with hernias, the predictive value of this finding is limited (Tanyel et al, 2000). In an unusual observational study, 59% of 302 newly identified hydroceles presenting between 1 and 18 (mean 4.4) years of age were clinically communicating, that is, with a clear history of fluctuation, and 6% were spermatic cord hydroceles (Christensen et al, 2006). Seventy (65%) of the apparent noncommunicating and 5 (29%) of the cord hydroceles were observed without surgery and, of these, 39 and 3, respectively, appeared to resolve spontaneously during follow-up. However, surgical findings were not reported in this series so the overall frequency of processus vaginalis patency in these patients is not known. In several series of all boys undergoing hydrocele repair during a defined period, the processus vaginalis was completely obliterated in 0% to 22% of cases (Elder, 1992; Barthold and Redman, 1996; Han and Kang, 2002). **These data indicate that the majority of new hydroceles occurring after birth and before puberty are associated with a patent processus vaginalis.**

Noncommunicating Hydroceles

Simple hydroceles not associated with hernias occur in both infancy and in older boys. Stable, nonfluctuating scrotal hydroceles that occur in at least 5% in male neonates (Osifo and Osaigbovo, 2008) are presumably related to delayed closure of the processus vaginalis, are typically bilateral, and often resolve with time as the processus closes in the perinatal period and reabsorption of tunica vaginalis fluid occurs. Similarly, the majority of hydroceles occurring at or after puberty are noncommunicating, although the exact proportion that are associated with a hernia and the overall incidence of hydrocele in this population are unclear. In a study specifically relating patient age to patency of the processus vaginalis, Wilson and associates (2008) studied 101 boys from birth to 20 years of age (mean 5.7) presenting with hydrocele and noted patency in 29% and 88% of those older and younger than 10, respectively.

Genetic and Other Risk Factors

The risk of inguinal hernia during childhood is increased in families, with a 28% risk in other family members and a higher relative risk in first-degree relatives (6.9) and particularly female siblings (17.8) of affected girls (Gong et al, 1994; Jones et al, 1998). Detailed pedigree analysis suggests dominant inheritance with reduced penetrance and sex influence. The gene(s) influencing susceptibility to congenital (indirect) inguinal hernia remain unknown but may overlap with those determining risk of cryptorchidism because there is overlap in familial risk and in susceptibility factors for both traits. Congenital hernia and cryptorchidism are both associated with low birth weight, bladder exstrophy, epididymal anomalies, connective tissue disorders, cystic fibrosis, posterior urethral valves (Heikkila et al, 2008), and, in some studies, increased risk for testicular cancer (Pottern et al, 1985; Tollerud et al, 1985). Inguinal hernia is also a component of over 200 syndromes (80 also include cryptorchidism; Winter-Baraitser Dysmorphology Database, http://www.lmdatabases.com) and is more common in patients with ventriculoperitoneal shunts and other causes of ascites (Grosfeld et al, 1991).

Diagnosis

The most common presentations of pediatric inguinal hernia are inguinal or inguinoscrotal swelling in infancy and new onset of scrotal swelling in older children. Typically the child is asymptomatic, but the swelling is observed with crying or straining or may be preceded by a bout of vomiting, constipation, or respiratory illness. Communicating hydroceles usually fluctuate and may appear larger after activity or at the end of the day as compared with early morning. Rarely acute scrotal swelling is accompanied by pain, and other causes of acute scrotum must be ruled out. Nausea, vomiting, and in some cases fever suggest incarceration. The risk of incarceration is highest in infancy,

particularly in ex-premature males, and is uncommon after 5 years of age.

Multiple approaches are described to increase intra-abdominal pressure and confirm the presence of a hernia on physical examination, including immobilization of the extremities to induce crying in infants, and coughing, blowing bubbles, or blowing up balloons and laughing in older children (Brandt, 2008). Suggestive physical findings include asymmetrical widening of the inguinal region and the "silk glove" sign, which is elicited by palpation of the spermatic cord over the pubis, resulting in a sensation of layers of the sac slipping over each other. Hydroceles often appear bluish, can be transilluminated, and may be partially or fully decompressable. Swelling that extends into and above the inguinal canal is more likely a hernia if reducible and/or if crepitus associated with bowel loops is present. In contrast, abdominoscrotal hydroceles are ballotable on bimanual scrotal-abdominal examination and cannot be decompressed. Attention should be paid to palpation and documentation of the position of the ipsilateral testis. Additional parental observation and/or office examinations may be warranted if an inguinal bulge is not elicited or if there is no clear history of fluctuation of an asymptomatic scrotal hydrocele.

Inguinoscrotal ultrasonography can be used to differentiate bowel loops from simple fluid and to visualize the testis, patent processus vaginalis, or hernia sac. If the testis is not palpable, ultrasonography is useful in determining whether a tumor with secondary hydrocele or cryptorchidism is present. Preoperative knowledge of these entities is critical for defining preoperative evaluation, parental counseling, and surgical approach. Toki and coworkers (2003) classified the appearance of the internal ring by ultrasonography. Using visualization of an open processus vaginalis of at least 20 mm in length as a criterion for contralateral inguinal exploration surgery, they observed a reduced risk of metachronous hernia after 2 years' follow-up. Although its use is not routine, ultrasonography may be helpful in defining fluid or intra-abdominal content in the inguinal canal with increased abdominal pressure in patients with suspected hernia or communicating hydrocele and questionable findings on routine examination. Alternatively, laparoscopy can be used to diagnose and treat inguinal hernia, as discussed later.

Associated Pathologic Processes

Several diseases associated with inguinal hernia and/or similar presentation require a high index of suspicion for diagnosis. Incomplete testicular descent may coexist with clinical hernia and should be excluded or corrected at the time of repair. Other genital anomalies such as polyorchidism, transverse testicular ectopia with or without persistent müllerian ducts, and splenogonadal fusion may present at the time of hernia repair. Abnormal epididymal-testicular attachment correlates with degree of closure of the processus vaginalis (Elder, 1992; Barthold and Redman, 1996). In phenotypic females, rare cases of androgen insensitivity syndrome may be identified at the time of hernia repair by examination of the abdominal or inguinal gonads, careful genital examination, and calibration of vaginal length.

Surgical Repair

Once a diagnosis of inguinal hernia or communicating hydrocele is made, timely elective repair is indicated. If ipsilateral cryptorchidism is present in an infant with a clinically apparent hernia, repair should proceed without observation for spontaneous testicular descent. Repair is performed as an outpatient procedure except in cases of ex-premature infants, who receive apnea monitoring in the hospital overnight if less than 50 to 52 weeks' postconceptional age. Some authors recommend delaying surgery until after this time point versus proceeding with repair before discharge from the hospital, although the reliability of the family and the higher risk of incarceration in infants (Stylianos et al, 1993; Chen et al, 2009) should be taken into account. In contrast, neonatal hydroceles should be observed for spontaneous resolution, because they are not associated with a persistently patent processus vaginalis in the majority of cases and most resolve in the first or second year of life.

Standard Inguinal Hernia Repair

The traditional inguinal approach to hernia/hydrocele repair is the preferred approach for most surgeons in view of a high success rate, low morbidity, limited degree of associated pain, and good cosmesis. A small incision in Langer's lines at or below the inguinal skin crease and superolateral to the pubic tubercle is made (Kogan, 2007). The external oblique fascia is exposed and incised through the external inguinal ring with care to avoid the ilioinguinal nerve. The spermatic cord is exposed and the hernia sac visualized and dissected free, open or closed, from the adjacent spermatic cord structures, which is facilitated by longitudinal incision of the external spermatic fascia. A long-held principle is the importance of high ligation of the hernia sac at the level of the internal inguinal ring to avoid risk of recurrence (Grosfeld et al, 1991). If the sac is large or thickened, it should be opened before transection to identify prolapsed bowel, omentum, or a sliding component, which if present is reduced before closure. Tightening of the internal ring with absorbable suture is recommended in cases of significant widening (Ein et al, 2006; Brandt, 2008). If a loculated hydrocele is present, it is exposed from above after distal mobilization of the overlying cremaster muscle and fascia in a bloodless plane and incised longitudinally for complete decompression. If the testis is easily visualized, the surgeon should remove any testicular or epididymal appendage that is present. The testis is then grasped and pulled caudally to a dependent scrotal position and if not dependent an orchidopexy should be performed. In pubertal boys with hydrocele, a primary inguinal approach is preferred if there is clinical evidence of a communicating hydrocele; otherwise a transscrotal hydrocele repair is performed as in adults and an inguinal incision made only if a proximal communication is identified. Pain control is augmented by an ilioinguinal or caudal nerve block.

Early postoperative complications are rare after repair of pediatric hernia via an inguinal approach. The reported risk of recurrence is 0.7% to 1% and may be related to failure of high ligation of the sac, size of the hernia, injury to the floor of the canal or sac, and/or comorbid conditions that affect wound healing (Grosfeld et al, 1991; Vogels et al, 2009). Wound infection and bleeding are similarly rare. Persistence of a hydrocele is very rare after decompression at the time of hernia repair (0.1% in the series by Ein and associates [2006]) and should be observed for spontaneous resolution for at least 1 year. If persistent, secondary scrotal hydrocele repair is indicated or reoperative hernia repair is required if fluctuation suggests a recurrent hernia.

Complications related to the genital tract including secondary cryptorchidism, testicular atrophy, and vasal injury occur, but their incidence is not well defined. Some cases of undescended testis after previous hernia repair may reflect milder primary forms of incomplete descent that were not clinically evident

preoperatively. Patients should be examined postoperatively on a yearly basis to ensure that testicular position does not change. Likewise, close observation is needed to identify testicular atrophy. The risk of this complication in general is unknown, but a 0.3% incidence was reported in the large single center series of Ein and associates (2006). Excised hernia sac tissue reportedly contains portions of vas deferens in 0.13% to 0.3% of cases, although embryonal remnants not representing true ductal structures are much more common (1.5% to 2.9%) (Popek, 1990; Partrick et al, 1998; Steigman et al, 1999). However, these data reflect results at high-volume pediatric centers and may be lower than those applicable to other practices. The risk of vasal injury may also be higher in young infants and/or cases of incarceration. Of course, injury to the vas may occur without transection and be manifest as vasal obstruction later in life. Indeed, pediatric hernia repair was the most common cause of vasal obstruction in a series of men presenting to a large infertility practice; the prevalence of this outcome in all boys undergoing repair using present surgical techniques is not known but in a review of older publications was estimated to be 0.8% to 2% (Sheynkin et al, 1998). Manipulation or stretching of the vas in adult rats (reviewed in Brandt, 2008) can produce obstructive lesions or even testicular atrophy, but the degree to which these effects are applicable to humans is unknown. The overall risk of this significant complication and its potential to cause clinical subfertility is undefined because many cases may be unilateral.

Scrotal Approach to Inguinal Hernia Repair

Concurrent with recent reports advocating a scrotal approach to orchidopexy, some authors suggest a similar approach to inguinal hernia and communicating hydrocele (Lais and Ferro, 1996; Fearne et al, 2002; Gokcora and Yagmurlu, 2003). Initial data suggest no major differences in the rates of success or degree of morbidity using this approach compared with standard inguinal surgery. Fearne and colleagues (2002) ligated the processus vaginalis at the level of the external inguinal ring, with one recurrence in 195 repairs in boys followed a mean of 13 months postoperatively. Potential issues related to the level of sac ligation based on technique and patient age have not been fully addressed (Wilson et al, 2008). Long-term data are needed to define the benefits and limitations of the scrotal approach to inguinal hernia repair.

Laparoscopic Inguinal Hernia Repair

With increase in the use of minimally invasive surgical techniques in recent years, laparoscopic repair of hernias in children has become an alternative to the standard open procedure. Two major techniques are reported: peritoneal closure of the defect (Schier, 2006) and an extraperitoneal approach (Takehara et al, 2006; Endo et al, 2009).

With experience, the operative time may be similar to open surgery; however, even in very large series the risk of recurrence (as high as 4%) is higher than with open repair but may decrease with increasing experience (Saranga Bharathi et al, 2008) and appears to be lower (<1%) with extraperitoneal approaches. However, Schier observed that some recurrences are not associated with an open internal inguinal ring on laparoscopic reexploration and may be related to a lipoma within the inguinal canal that would normally be addressed in an open repair (Schier, 2007a). Decreased pain and operative time after laparoscopic as compared with open repair was reported in one small prospective study (Chan et al, 2005), but the opposite conclusion was reached in a similar study (Koivusalo et al, 2009). The risk of persistence after laparoscopic repair of communicating hydrocele and long-term potential for vasal obstruction has yet to be addressed in the literature. However, the risk of testicular atrophy appears to be low in reported series. Laparoscopy has also been advocated to facilitate repair of recurrent and incarcerated hernias (Saranga Bharathi et al, 2008).

Assessment of the Contralateral Internal Ring

A long-standing controversy relating to pediatric inguinal hernia repair is the need for identification and repair of a contralateral patent processus vaginalis. In the past, contralateral exploration was used routinely in subsets of patients considered at higher risk for metachronous hernia based on age, prematurity, gender, or associated disease. The processus is patent on the opposite side in 40% of children with unilateral clinical hernia undergoing laparoscopy (Miltenburg et al, 1998), up to 60% of contralateral explorations (Tackett et al, 1999), and in 20% of adults at autopsy (Ajmani and Ajmani, 1983). In contrast, two systematic literature analyses conclude that the risk of developing a contralateral hernia during follow-up is about 10%, and the majority of these cases present within 5 years with a trend toward decreased risk with age (Miltenburg et al, 1997; Ron et al, 2007). In a prospective study no consistent factors were associated with significantly increased risk of metachronous hernia, except perhaps a previous history of incarceration (Tackett et al, 1999). The risk of contralateral hydrocele after unilateral communicating hydrocele repair is not known but is likely lower. **Consequently, even selective exploration or repair of the opposite side in cases of unilateral pediatric inguinal hernia is no longer recommended.** An exception may be children at significantly higher anesthetic risk (Tackett et al, 1999). For surgeons who perform laparoscopic herniorrhaphy, contralateral repair is less invasive; and thus many surgeons recommend repair of an open processus vaginalis identified at the time of laparoscopy. However, the pros and cons of such an approach should be reviewed with the patient's family with the knowledge that an open internal ring is not equivalent to an inguinal hernia (Schier, 2007b).

Abdominoscrotal Hydrocele

Abdominoscrotal hydrocele is an unusual form of noncommunicating hydrocele, comprising 1.25% of all pediatric hydroceles in a large series (Avolio et al, 2000). Unlike the typical neonatal hydrocele, it is large and tense, and bimanual examination usually confirms the presence of a ballotable abdominoscrotal mass. Ultrasonography can be used to visualize the degree of proximal extension and the testis but is not required in typical cases (Belman, 2001). Abdominoscrotal hydrocele usually presents in the neonatal period or in infancy and may initially be limited to the scrotum with progressive enlargement over time (Celayir et al, 2001; Cuervo et al, 2009). In other cases, spontaneous resolution (Upadhyay et al, 2006) or improvement (Cozzi et al, 2008) was reported. In the larger published series, abdominoscrotal hydrocele was bilateral in about 30% of cases (Ferro et al, 1995; Nagar and Kessler, 1998; Belman, 2001; Bayne et al, 2008; Cozzi et al, 2008). In addition, associated diagnoses may include ipsilateral or contralateral cryptorchidism, contralateral hernia, hydrocele, or vanishing testis. A single case of associated malignant mesothelioma was reported (Velasco et al, 1988). Progressive proximal enlargement, characteristics of the hydrocele fluid, and nonpatency of the processus vaginalis suggest that the most likely cause is enlargement and extension of a scrotal hydrocele into the

retroperitoneal or properitoneal space after the processus has closed. Bayne and associates (2008) reported that abdominoscrotal hydrocele fluid is exudative and theorize that increasing size and pressure lead to lymphatic obstruction and worsening over time. Massive enlargement in some cases may extend into the upper abdomen and be associated with hydroureteronephrosis, lower extremity edema, or appendicitis (reviewed by Cuervo et al, 2009). Chamberlain and colleagues (1995) first reported dysmorphic elongation of the testis in an infant with bilateral abdominoscrotal hydrocele, and others have confirmed this observation, presumably related to high pressures within the sac (Bayne et al, 2008).

The surgical approach to this rare entity is controversial, related to what is perceived as a higher risk to the cord and testis during repair because of the size of the lesion and the young age of the patient. The traditional approach to repair is via an inguinal incision with proximal dissection of the sac from its abdominal attachments and distal complete or partial mobilization, with or without orchidopexy. Some authors use orchidopexy routinely, irrespective of the preoperative position of the testis (Nagar and Kessler, 1998; Bayne et al, 2008). Failure to excise the abdominal portion of the sac may lead to its persistence. Alternative, rarely reported approaches to the intra-abdominal portion include a higher or midline (for bilateral cases) incision or laparoscopic decompression followed by inguinal excision (Serels and Kogan, 1996; Abel et al, 2009). Some authors recommend leaving a strip of the lining of the sac along the cord to avoid injury to the vas or vessels (Ferro et al, 1995; Cuervo et al, 2009), a rarely reported complication (Serels and Kogan, 1996). Tightening of a patulous internal ring is described, but the necessity for this maneuver is unclear because the processus vaginalis is invariably closed and the risk for postoperative hernia appears to be rare. Because the procedure may be prolonged and tedious, some surgeons use scrotal drains, preoperative antibiotic prophylaxis, and postoperative hospitalization.

An alternative simplified surgical technique for abdominoscrotal hydrocele that may be underutilized is the primary scrotal approach described by Belman (2001). The hydrocele is approached through a scrotal incision, and extensive plication without excision is performed as for the Lord procedure. Prolonged scrotal edema associated with involution of the sac is expected, but this approach is appealing because the processus vaginalis is closed in most if not all cases and dissection is limited. Although Belman did not present detailed outcome data using this approach, Cozzi and colleagues (2008) reported reduced morbidity and similar efficacy for the scrotal as compared with the inguinal approach in 18 cases (5 bilateral). This latter series is unique in that detailed outcome was reported in 13 and 5 patients undergoing inguinal and scrotal surgery, respectively, with a median follow-up of 4 years. Persistent scrotal swelling, hematoma, and undescended and/or hypoplastic testis were reported in 11 of 13 inguinal cases and infection in 2 scrotal cases. These authors also observed that 78% of testes were dysmorphic preoperatively but that 15 of 18 regained normal shape and size postoperatively, suggesting that fluid pressure dynamics contribute to this finding. The prognosis for adult testicular function in abdominoscrotal hydrocele and the risk of possible long-term postoperative complications remain unknown.

ACUTE SCROTUM

The new onset of pain, swelling, and/or tenderness of intrascrotal contents is referred to as *acute scrotum* and is a common presenting complaint in pediatric urology. The signs and symptoms of diseases associated with acute scrotal pain vary markedly with extensive diagnostic overlap. Although some clinical features are more reliable than others, few if any details of history, physical examination, or imaging are absolutely diagnostic of particular intrascrotal pathologic processes. Thus the clinician should make a prompt diagnosis based on all the available findings, which may include those obtained at scrotal exploration, particularly if the duration of pain is short (<6 hours), the presenting signs lack sufficient reliability, or the diagnosis remains unclear after clinical evaluation.

Etiology and Differential Diagnosis

Individuals with many types of inguinoscrotal pathology may present with acute scrotal pain or swelling (Table 132–6). In some patients with scrotal pathology the pain may be localized to the inguinal or abdominal regions or poorly localized, particularly in younger children. Historical information of potential importance includes the onset, quality, duration, and consistency of pain; history of previous episodes; exacerbation with activity; presence

Table 132–6.

Differential Diagnosis of Pediatric/Adolescent Acute Scrotal Pain

- Appendage torsion
  - Appendix testis
  - Other appendage (epididymis, paradidymis, vas aberrans)
- Spermatic cord torsion
  - Intravaginal, acute or intermittent
  - Extravaginal
- Epididymitis
  - Infectious
    - Urinary tract infection
    - Sexually transmitted disease
    - ?Viral
  - Sterile or traumatic
- Scrotal edema/erythema
  - Diaper dermatitis, insect bite, or other skin lesions
  - Idiopathic scrotal edema
  - Early Fournier gangrene
- Orchitis
  - Associated with epididymitis with or without abscess
  - Vasculitis (e.g., Henoch-Schönlein purpura)
  - Viral illness (mumps)
- Trauma
  - With hematocele or scrotal contusion
  - With testicular rupture
- Hernia/hydrocele
  - Inguinal hernia with or without incarceration
  - Communicating hydrocele
  - Encysted hydrocele with or without torsion
  - Associated with acute abdominal pathology (e.g., appendicitis, peritonitis, splenic rupture)
- Varicocele
  - With pain
  - With acute rupture or thrombosis
- Intrascrotal mass
  - Cystic dysplasia or tumor of testis
  - Epididymal cyst/spermatocele or tumor
  - Other paratesticular tumors
- Musculoskeletal pain due to inguinal tendonitis or muscle strain
- Referred pain (e.g., ureteral calculus or anomaly)

of associated symptoms such as nausea, vomiting, irritative voiding, penile discharge, fever, and other illness; and trauma, sexual, and immunization history. In a large series of surgically treated pediatric patients, appendix testis torsion is the most common diagnosis (40% to 60%), followed by spermatic cord torsion (20% to 30% excluding neonates), epididymitis (5% to 15%), and other or no pathology (~10%) (Anderson and Giacomantonio, 1985; Sidler et al, 1997; Van Glabeke et al, 1999; Mushtaq et al, 2003; Murphy et al, 2006; Makela et al, 2007). In general, appendage torsion is most common after infancy and before puberty whereas epididymitis and spermatic cord torsion are most common in the perinatal and pubertal periods. However, any of these diseases can occur at any time during childhood and adolescence.

Spermatic Cord Torsion

Acute spermatic cord torsion with reduction or cessation of blood flow to the testis may occur in susceptible individuals. Intravaginal spermatic cord (testicular) torsion occurs when the testis twists within the tunica vaginalis, whereas extravaginal testicular torsion occurs in the perinatal period before fixation of the tunica vaginalis within the scrotum.

Acute Intravaginal Spermatic Cord Torsion

Predisposing Factors. The anatomic abnormality predisposing to torsion of the spermatic cord, the bell-clapper deformity, was identified in 12% of males in an autopsy series (Caesar and Kaplan, 1994a). This anatomic variant is due to partial or complete failure of fusion of the tunica vaginalis along the epididymis, resulting in incomplete attachment of the testis/epididymis to the scrotum (Fig. 132–7) or to an abnormally wide attachment of testis to epididymis. Despite the high prevalence of the bell-clapper deformity, the prevalence of torsion is much lower, reported as 8.6 per 100,000 males aged 10 to 19 per year in the United States (Mansbach et al, 2005) with some evidence for a familial predisposition (Cunningham, 1960; Collins and Broecker, 1989). The direct precipitating event in susceptible individuals is unknown but may include cold temperature, sudden movement or trauma with activation of the cremasteric reflex, and/or rapid growth of the testis at puberty. Some studies suggest an inverse correlation between the prevalence of torsion and atmospheric temperature (Srinivasan et al, 2007; Lyronis et al, 2009). Undescended testes are at higher risk for torsion, although the prevalence in this group as a whole is low. Rarely, torsion may occur after previous orchidopexy for cryptorchidism or testicular torsion. In these cases the etiology may be related to failure of suture (absorbable or nonabsorbable) fixation of a testis that remains within an intact tunica vaginalis (Redman and Barthold, 1995; Frank and O'Brien, 2002; Mor et al, 2006).

Clinical Presentation. Although intravaginal testicular torsion may occur in any young male, the peak age at occurrence is 12 to 16 years, with additional cases occurring in postpubertal males and 86% to 93% occurring after age 10 (Anderson and Giacomantonio, 1985; Sidler et al, 1997; Mushtaq et al, 2003; Mansbach et al, 2005; Murphy et al, 2006; Makela et al, 2007). The prevalence of testicular torsion in these retrospective surgical series is 20% to 30% with left-sided predominance; however, in another large series, testicular torsion comprised only 6% of 626 patients younger than 17 years of age (Lam et al, 2005). Very rarely, torsion occurs bilaterally. Classically, patients complain of sudden, severe scrotal pain that may occur at rest, with activity or sports, or during sleep, and a history of previous similar episodes of pain, usually on the ipsilateral side, may be present. Alternatively, patients may have milder, less acute, or even no scrotal pain or may have inguinal or abdominal pain. The patient may report direct scrotal trauma, which may precipitate twisting of the cord, a historical feature that should not alter the diagnostic

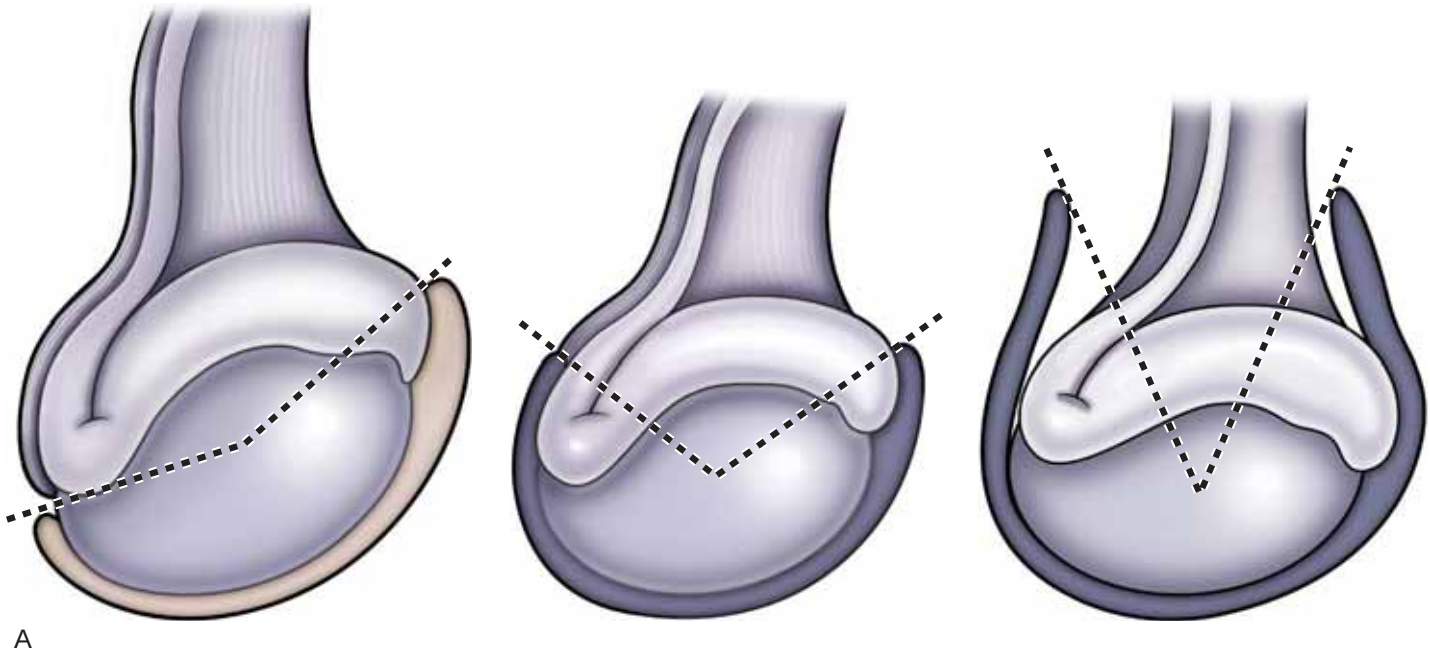

Figure 132–7. Variable degrees of bell-clapper deformity show normal (**A**), partial (**B**), and complete (**C**) variants. Angles drawn represent variations in attachment of tunica vaginalis. (From Bentley DF, Ricchiuti DJ, Nasrallah PF, McMahon DR. Spermatic cord torsion with preserved testis perfusion: initial anatomical observations. J Urol 2004;172:2373–6.)

approach to the patient (Lrhorfi et al, 2002). **Most retrospective series report that boys presenting early, especially within 6 hours of onset of pain, are more likely to have testicular torsion than other intrascrotal pathology.** Nausea and vomiting occurs in 10% to 60% of boys with intravaginal testicular torsion and may be more common in pubertal and postpubertal boys (Williamson, 1976; Knight and Vassy, 1984; Jefferson et al, 1997; Sessions et al, 2003; Makela et al, 2007). Scrotal edema and erythema may be present depending on the duration or degree of torsion. Dysuria and fever are occasionally reported.

The most common physical findings are generalized testicular tenderness and absence of the cremasteric reflex. This genitofemoral reflex arc is normally present in boys after 2 years of age (Caesar and Kaplan, 1994b), is elicited by scratching the inner thigh with resultant elevation of the testis within the scrotum, and is one of the most useful and specific signs ruling out testicular torsion. Although some studies suggested that the reflex is reduced or absent in all cases of testicular torsion (Caldamone et al, 1984; Rabinowitz, 1984; Kadish and Bolte, 1998) the reflex was intact in up to 10% of proven cases of torsion (Hughes et al, 2001; Nelson et al, 2003; Karmazyn et al, 2005; Murphy et al, 2006). **A normal cremasteric reflex is strongly correlated with intact blood flow to the testis but does not infallibly indicate normal testicular perfusion, especially if the clinical presentation is otherwise suggestive of torsion.** Similarly, a blue dot sign, considered specific for appendix testis torsion, has been reported in association with normal scrotal ultrasound findings in a case of testicular torsion (Murphy et al, 2006). In some cases elevation of the testis from its dependent scrotal position, abnormal lie, or anterior epididymal position, thickening of the cord suggestive of a twist, testicular induration, loss of boundaries between the testis and epididymis, scrotal edema, and/or erythema are present but vary depending on the age of the patient and duration of torsion but may be helpful in supporting the diagnosis of torsion.

Diagnostic Studies. Urinalysis is performed to identify pyuria and/or bacteriuria, findings that may be associated with epididymitis, or hematuria, which may indicate urinary tract calculus. Although the findings on urinalysis are usually normal in cases of testicular torsion, pyuria may be present and create diagnostic confusion (Anderson and Giacomantonio, 1985; Jefferson et al, 1997). Scrotal imaging is used more routinely in recent years, particularly in cases of prolonged (>24 hours) pain associated with preservation of the cremasteric reflex and severe scrotal swelling with loss of intrascrotal landmarks. Radionuclide imaging is primarily of historic interest owing to lack of specificity and prompt availability at many centers. CDUS can be used to visualize testicular architecture and intraparenchymal blood flow; and with the improved sensitivity of current technology flow is visible in most normal testes, irrespective of age. CDUS findings consistent with established testicular torsion include reduced or absent Doppler waveforms, parenchymal heterogeneity, and/or altered echotexture compared with the contralateral testis (Fig. 132–8). Kaye and colleagues (2008b) reported that all testes with a heterogeneous echogenicity as shown by CDUS were necrotic and were removed or atrophied after orchidopexy, whereas homogeneous echogenicity predicted a reduced risk of orchiectomy but long-term outcome was not provided. Enthusiasm for CDUS as a reliable modality to exclude testicular torsion was based on data suggesting that this approach is highly reliable (Kass et al, 1993b). With further experience and possibly due to enhanced detection of flow with newer equipment and/or user-dependent characteristics, **the established sensitivity of CDUS in confirming decreased or absent blood flow in proven cases of spermatic cord torsion is a disappointing 63% to 90%** (Steinhardt et al, 1993; Stehr and Boehm, 2003; Bentley et al, 2004; Kalfa et al, 2004; Karmazyn et al, 2005). In reviewing false-negative cases in their series and those of others, Bentley and coworkers (2004) observed that arterial blood flow can persist in the presence of established torsion (see Fig. 132–8) and theorize, based on preliminary data, that preservation of flow may be more likely in males with a preexisting thick spermatic cord. Cassar and colleagues (2008) retrospectively evaluated Doppler waveforms in cases of torsion with decreased or preserved testicular flow and observed subtle waveform abnormalities, including increase or decrease in amplitude relative to the normal testis and reversal of diastolic flow. These may help increase the sensitivity of CDUS in cases of torsion. In addition, increased epididymal size and/or echogenicity and altered epididymal vascularity, usually absent or reduced but occasionally increased, may provide additional support for the diagnosis of torsion (Nussbaum Blask and Rushton, 2006).

High-resolution ultrasonography (HRUS) of the length of the spermatic cord using a 10- to 20-mHz probe may provide a promising new approach for identifying torsion in equivocal cases. Kalfa and colleagues (2004) used HRUS in children and young adults to directly identify the twisted cord superior to the testis. They visualized the cord twist as a 1- to 3-cm snail-shaped mass in 43 patients, and confirmation was suspected but difficult in an additional patient with an inguinal testis. Conversely, a completely linear cord is visualized in nontorsion cases. In a multiinstitutional retrospective series of 919 cases of acute scrotum, these authors reported HRUS visualization of a cord twist in 96% of 208 surgically proven torsion cases and 100% sensitivity of the combination of cord twist and/or reduced blood flow in diagnosing torsion (Kalfa et al, 2007). However, Karmazyn and coworkers (2005) observed normal testicular blood flow and no visible spermatic cord twist in 2 of 41 boys with partial or intermittent torsion. Although this technique is promising, prospective studies are needed with surgical confirmation of diagnoses and prolonged careful follow-up to ensure that it is reproducible in other settings and that varying presentations of torsion are not missed.

Potentially useful diagnostic modalities that have been studied in animal models but not yet tested clinically include contrast-enhanced pulse-inversion ultrasonography and infrared thermography. Pulse-inversion imaging in a rabbit model showed superior quantitative assessment of perfusion of the experimentally torsed testis as compared with conventional CDUS (Paltiel et al, 2006). In a sheep model an infrared thermographic camera showed significant reduction in scrotal temperature by 1 hour after 720-degree torsion and prompt normalization with detorsion (Capraro et al, 2008). Infrared thermography is presently used clinically for diagnosis of varicocele in adults (Nogueira et al, 2009).

Surgical Treatment and Findings. With increasing availability and use of urgent CDUS, and more recently HRUS, and the relatively low (6-30%) prevalence of testicular torsion in children and adolescents with acute scrotal pain, a strategy of managing essentially all patients surgically to confirm absence of torsion (Anderson and Giacomantonio, 1985; Watkin et al, 1996; Sidler et al, 1997; Mushtaq et al, 2003; Makela et al, 2007) has shifted toward selective surgical exploration (Caldamone et al, 1984; Kass et al, 1993b; Kalfa et al, 2004; Lam et al, 2005). Most surgeons currently use

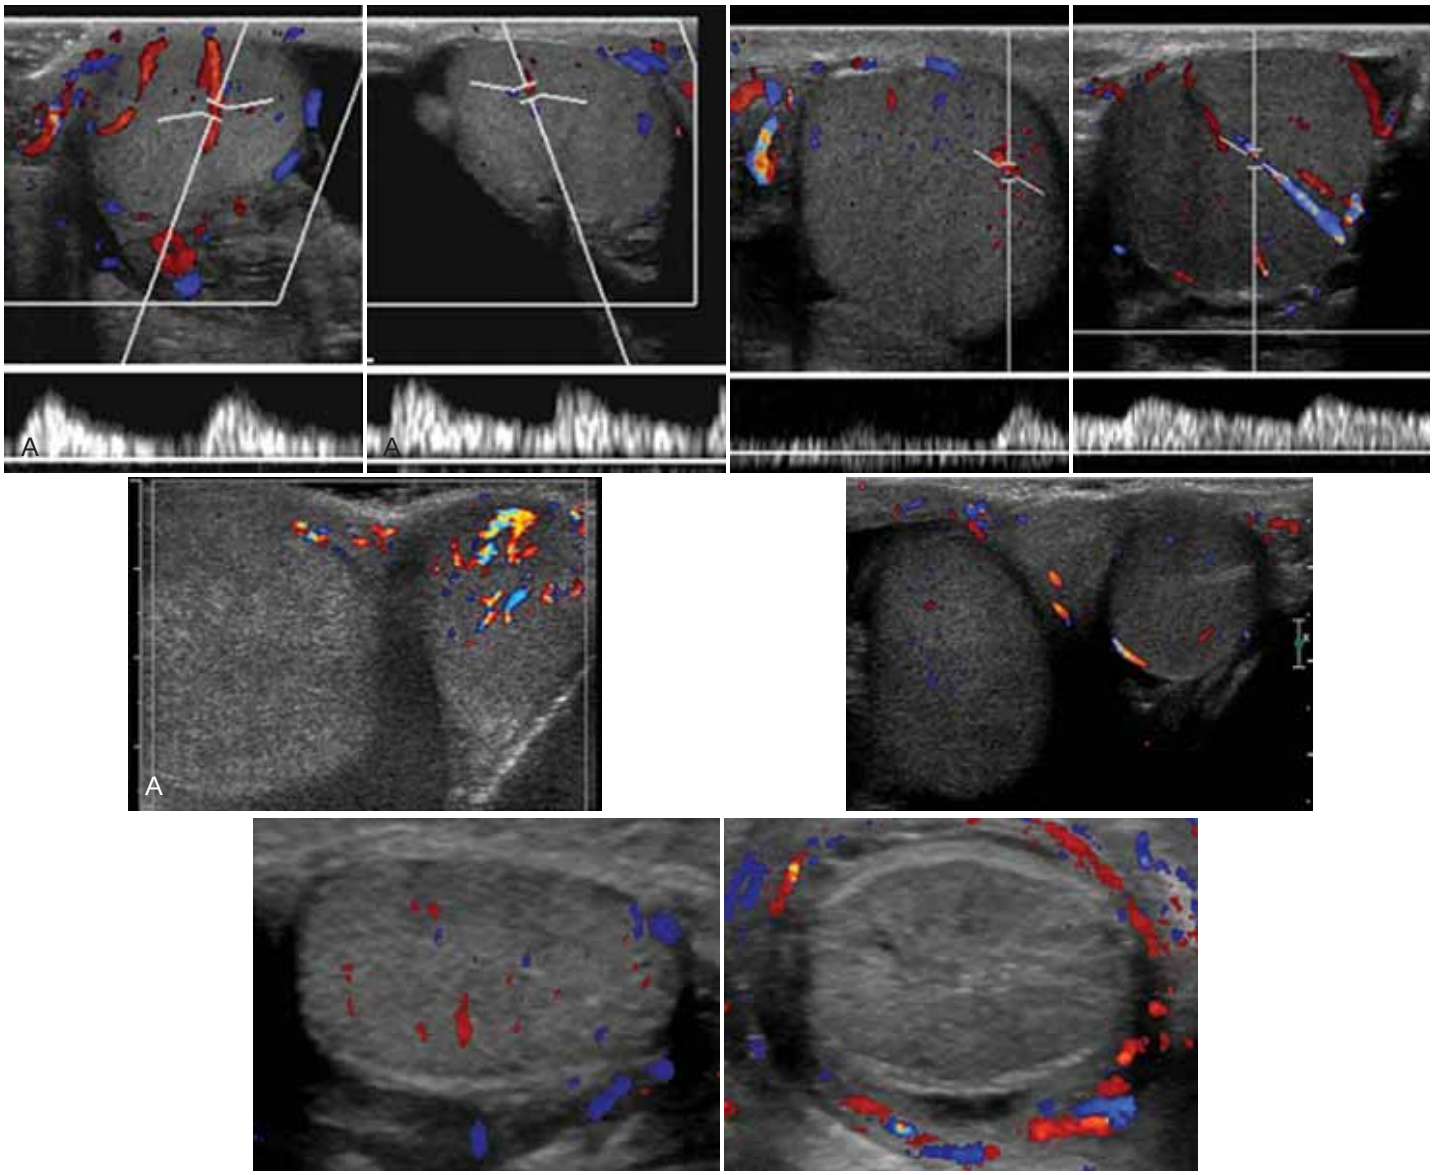

Figure 132–8. Imaging of intravaginal spermatic cord torsion. **A**, Intermittent torsion. Color Doppler ultrasonography (CDUS) in a 14-year-old boy with 12 hours of right testicular pain and intact cremasteric reflex shows preserved arterial flow to testis at an initial emergency department visit and loss of flow and increased heterogeneity of right testicular parenchyma when patient returned with increased pain. Exploration confirmed 360-degree intravaginal torsion. **B**, Acute torsion with reduced arterial flow. CDUS in an 18-year-old boy with variable right testicular pain shows reduced arterial flow to testis and increased echogenicity on transverse view comparing both testes. Right epididymal hyperemia and enlargement were also noted. Exploration confirmed 540-degree torsion with prompt return of vascularity with detorsion. **C**, Prolonged torsion. CDUS in a case of a 9-year-old boy presenting with prolonged left testicular pain shows heterogeneous echotexture, absence of arterial or venous flow, and a hyperechoic parenchymal ring; testicular necrosis was found at scrotal exploration.

this selective approach, but a minority continue to recommend urgent surgical intervention for all cases of acute scrotum to avoid any risk of inaccuracy associated with the clinical and imaging diagnosis of testicular torsion (Murphy et al, 2006). Indeed, most series report cases with atypical presentation and/or false-negative imaging in which surgical exploration was delayed and the testis lost, but the clinician's goal should be to minimize the risk of such cases. **When findings support or are suspicious for spermatic cord torsion, emergent scrotal exploration is indicated and should not be delayed to obtain scrotal ultrasonography or any other diagnostic test.** The increased sensitivity provided by HRUS and potentially newer noninvasive diagnostic techniques may in future more reliably support nonsurgical treatment of the majority of boys presenting with an acute scrotum without torsion.

Some clinicians recommend preoperative manual detorsion based on the assumption that twisting of the testis occurs in a medial direction. However, in a retrospective review of 186 surgical explorations for torsion, Sessions and associates determined that lateral twisting (Fig. 132–9) occurred in 33% and manual detorsion attempts in 30% of the total group failed to completely relieve the torsion in 32% of cases (Sessions et al, 2003). The resolution of symptoms after manual detorsion did not correlate with the presence or absence of persistent torsion.

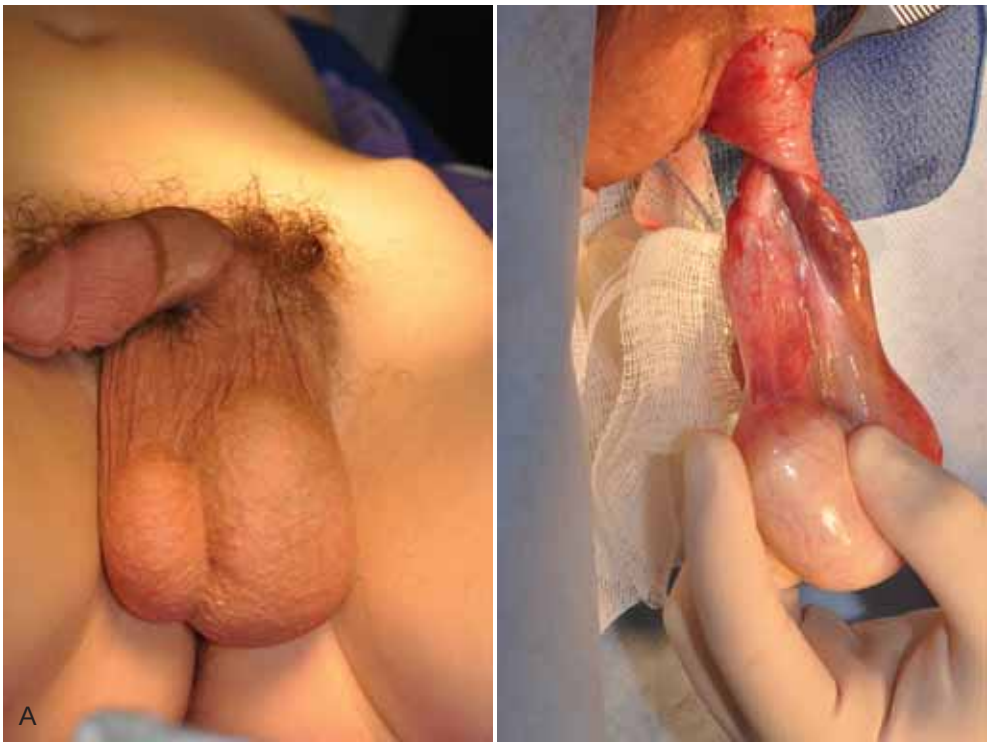

Figure 132–9. **A** and **B**, Intravaginal spermatic cord torsion with a viable testis. Findings at scrotal exploration in a 15-year-old boy with less than 6 hours of intravaginal torsion, 360-degree lateral rotation of the cord, and a viable testis. Color Doppler ultrasonography showed reduced arterial flow.

Jefferson and colleagues (1997) noted a similar frequency of residual intraoperative torsion after attempts at manual detorsion. Therefore although this maneuver may be attempted, it should not delay transfer to the operating room for definitive detorsion and fixation of the testis.

After induction of anesthesia, the affected testis should be approached first through a hemiscrotal transverse or midline incision. Once delivered, the surgeon should perform detorsion and document the number of cord rotations and the presence and degree of bell-clapper deformity. The testis is observed for improvement in color, but the decision to remove or retain the affected testis is subjective and, although based on the appearance of the testis, is likely also biased by the age of the patient and the degree and duration of torsion. A Doppler flow probe or incision of the tunica albuginea (Arda and Ozyaylali, 2001) with assessment of bleeding can be used to document intratesticular flow after detorsion, but the usefulness of these maneuvers in predicting viability of the testis has not been validated. Kutikov and colleagues (2008) suggest that compartment syndrome may contribute to testicular injury based on the improved appearance and lower intraparenchymal pressures they observed after detorsion and incision of the tunica albuginea. They covered the testicular defect with a vascularized tunica vaginalis patch to maintain lower intraparenchymal pressure and reduce the likelihood of ongoing ischemia. The long-term outcome of these patients is not available, and larger prospective studies are required to determine the benefit of this approach.

The overall frequency of orchiectomy when testes appear nonviable after surgical detorsion is 30% to 70% in large pediatric studies (Sessions et al, 2003; Murphy et al, 2006; Makela et al, 2007; Kaye et al, 2008b) and 34% in a population-based review of males aged 1 to 25 (Mansbach et al, 2005). Sessions and associates (2003) noted at operation that the median degree of rotation was 540 degrees in patients undergoing orchiectomy (38% of cases) and 360 degrees when the testis was salvaged, with a range of 180 to 1080 degrees in both groups. There is no clear-cut clinical evidence that orchidopexy or orchiectomy provides superior results in maximizing ultimate testicular function (see later). However, attempts should be made to salvage the testis if there is any sign of reperfusion after detorsion. The surgeon may biopsy questionably viable testes that are left in place to document the presence or absence of necrosis. Any testicular appendage should be removed. **Intrascrotal fixation of the testis must be performed bilaterally because a contralateral bell-clapper deformity usually exists and may lead to metachronous torsion.** Techniques of fixation that secure the testis within a subdartos pouch may reduce the risk of recurrent torsion within an intact tunica vaginalis if sutures between the testis and scrotal wall fail (Redman and Barthold, 1995; Frank and O'Brien, 2002; Mor et al, 2006). One approach allows obliteration of the tunica vaginalis and secure fixation of the testis without transparenchymal sutures within a scrotal pouch (Redman and Barthold, 1995). An incision is made in the upper third of the scrotum on each side. After delivery of the testis and eversion of the parietal tunica vaginalis along the cord, the cut edges of the inverted tunica are closed bilaterally with absorbable suture. This prevents retraction of the testis back into a tunica vaginalis–lined scrotal cavity. A subdartos pouch is created, and the testis is secured in the pouch by placement of sutures between the tunical layer covering the cord and the dartos. Follow-up for at least 6 months is mandatory to determine the presence and degree of testicular volume loss. For cases of testicular loss, prosthesis

placement is offered after complete healing, usually 6 or more months later.

Prognosis. The long-term outcome of males with a history of testicular torsion is poorly defined because of difficulties inherent in completing follow-up studies, particularly for boys treated before puberty. Visser and Heyns (2003) collected data from available clinical series and observed a stepwise decrease in testicular salvage and increase in late testicular atrophy with increasing duration of torsion. In their review of the testicular salvage rate in 1140 patients, the risk of orchiectomy was approximately 5%, 20%, 40%, 60%, 80%, and 90% at 0 to 6, 7 to 12, 13 to 18, 19 to 24, more than 24, and more than 48 hours after onset of pain, respectively. The approximate risk of late atrophy in 535 patients was less than 10%, 40%, and 75% after less than 12, 12 to 24, and more than 24 hours of pain, respectively, in those treated with orchidopexy. However, data from individual series suggest that at least partial (<25%) testicular atrophy is not rare in patients who underwent operative detorsion as little as 4 hours after onset of pain (Krarup, 1978; Anderson and Williamson, 1986; Tryfonas et al, 1994; Sessions et al, 2003). These data suggest that ischemic injury may occur rapidly, even if the testis appears viable at the time of detorsion. Even partial testicular volume loss may reflect significant loss of spermatogenesis in the testis (Turner et al, 2004), but the resultant impact on overall fertility potential is less clear. Available data suggest that subtle abnormalities of semen quality are common after testicular torsion: semen density is often in the normal range yet seems to show a positive correlation with shorter duration of torsion and reduced atrophy (Puri et al, 1985; Fisch et al, 1988; Anderson et al, 1992; Brasso et al, 1993; Arap et al, 2007). Unfortunately, these studies are small and heterogeneous, with limited semen analysis and minimal paternity data.

Sperm density is reduced in patients with testicular loss due to trauma relative to normal controls (Lin et al, 1998), but paternity in males with congenital monorchism appears to be normal (Lee and Coughlin, 2002b). In comparison, concern exists that fertility potential after torsion may be further reduced as compared with other males with a single testis because of bilateral testicular pathology in cases of unilateral torsion. As reviewed in Visser and Heyns (2003), existing contralateral testicular biopsy data are limited but suggest that global testicular dysfunction may exist in males with torsion. Whether this is a primary or secondary defect, or both, remains undefined. The observation that increasing duration of torsion is inversely correlated with semen quality suggests an adverse effect of torsion itself. A hypothesis that this effect may be related to an autoimmune phenomenon (Anderson and Williamson, 1990) was not supported by analysis of antisperm antibodies in individuals with torsion (Puri et al, 1985; Anderson et al, 1992; Brasso et al, 1993; Arap et al, 2007). Animal models suggest a contralateral deleterious effect of torsion in some studies but not others, and the applicability of animal models for study of testis injury after torsion is controversial (Filho et al, 2004), but available animal and human data support a role for ischemia-reperfusion injury after release of testicular torsion (Kehinde et al, 2003; Turner et al, 2004). Additional clinical data are needed to determine long-term outcome after testicular torsion and the efficacy of adjunctive treatment (e.g., antioxidant therapy) in optimizing fertility potential in patients with torsion.

Intermittent Intravaginal Spermatic Cord Torsion

As many as 30% to 50% of patients presenting with acute spermatic cord torsion report a history of previous scrotal pain episodes (Stillwell and Kramer, 1986; Williamson, 1976). These episodes typically begin and resolve rapidly, last minutes to hours, and may occur at any interval from days to months. In a retrospective review of cases ultimately diagnosed as intermittent torsion, Hayn and associates (2008) observed that the frequency of pain episodes correlated with the risk for eventual persistent torsion and testicular loss in children and adolescents. Of 17 boys presenting emergently with ongoing torsion, 71% were diagnosed on previous occasions with epididymitis or appendage torsion and 53% had acute or delayed testicular loss. Horizontal testicular lie may be present in patients with intermittent torsion (Schulsinger et al, 1991) but was documented in less than half of patients presenting either urgently or electively and was not seen in prepubertal males in the series of Hayn and associates (2008). Eaton and coworkers (2005) reported that the cremasteric reflex was absent in only 3 of 15 patients and that CDUS showed reduced or absent intratesticular blood flow in only 5 of 12 patients examined during a bout of pain. Six of 38 patients in this series had increased flow to the testis or epididymis. One fourth of patients had nausea and vomiting, a sign the authors suggested could be used to rule out epididymitis. Of those with complete surgical documentation, 15% did not have a bell-clapper deformity and 1 patient in the series continued to have pain postoperatively.

These reports underscore the difficulties inherent in identification and treatment of intermittent spermatic cord torsion, because patients may present with acute pain suggestive of torsion but with physical and imaging findings that appear normal as the torsion improves or resolves during the acute episode. The diagnosis requires a high index of suspicion in males with recurrent bouts of pain. CDUS may be most helpful in the midst of pain symptoms, particularly if intratesticular blood flow is reduced, but if results are normal or increased may provide unwarranted reassurance to the clinician. In cases of torsion-detorsion, prompt elective bilateral orchidopexy is indicated with the knowledge that in some cases absolute confirmation of the diagnosis may not be possible, and patients and parents should be advised that pain symptoms could persist postoperatively.

Extravaginal Spermatic Cord Torsion (Perinatal Testicular Torsion)

Perinatal spermatic cord torsion is due to rotation of the testis, entire cord, and tunica vaginalis before established fixation between the tunica vaginalis and dartos within the scrotum. This event is more common before birth and, depending on the timing, may present as a nonpalpable "vanishing" testis in a child evaluated for cryptorchidism or as an abnormal scrotal testis on the first postnatal examination. Perinatal torsion may also occur within the first month of life, although partial degrees of extravaginal torsion are also reported as late as 9 months after birth. Rarely, cases of neonatal testicular infarction are attributable to necrosis without spermatic cord torsion or to intravaginal torsion (John et al, 2008).

The presentation of perinatal torsion is variable, depending on the timing of the torsion event, and may be insidious. Because of the rarity of the disease, most of the available data are based on small retrospective case series. As such, predisposing factors such as large birth weight and/or difficult delivery are postulated (John et al, 2008; Kaye et al, 2008a) but not confirmed in controlled studies. In a population-based study, John and coworkers (2008) estimated an incidence of 6.1 per 100,000 births, and familial cases have been reported (Castilla et al, 1975). Suggestive

clinical findings at birth include testicular induration and scrotal erythema or dark discoloration with or without edema. The infant is typically asymptomatic, and testicular tenderness may or may not be present. A hydrocele may coexist, complicating the testicular examination. In a significant minority of cases, the symptoms present in the neonatal period or later, after documentation of a normal neonatal examination. Reports vary as to the frequency of bilateral versus unilateral perinatal torsion, with the former reported in 5% and 22% of cases in two large series (Yerkes et al, 2005; Baglaj and Carachi, 2007). Several recent series indicate that bilateral perinatal torsion is more common than suggested in the older literature and that asynchronous torsion may occur in boys in whom the primary event occurs prenatally or postnatally (Beasley and McBride, 2005; Yerkes et al, 2005; Al-Salem, 2007; John et al, 2008). In a review of the literature by Baglaj and Carachi (2007), asynchronous torsion comprised one third of all bilateral cases.

Although imaging of the testis may be obtained in cases of suspected perinatal torsion, its usefulness and reliability is questionable. Maternal ultrasonography may show in-utero torsion as early as the 33rd week of gestation, and postnatally CDUS may reveal typical findings of parenchymal heterogeneity, calcification, and absent blood flow (Fig. 132–10) that are helpful in confirming the diagnosis of nonacute antenatal torsion (Arena et al, 2006). However, intact blood flow in cases of perinatal torsion is not uncommon, suggesting that postnatal CDUS may be unreliable (Yerkes et al, 2005; Al-Salem, 2007; Cuervo et al, 2007; John et al, 2008). Some advocate use of ultrasound to differentiate rare neonatal testicular or peritesticular tumors from torsion (Kaye et al, 2008a), but its reliability in this regard may also be questionable (Calonge et al, 2004; Al-Salem, 2007). Therefore, clinical findings usually provide the basis for diagnosis of perinatal torsion, particularly because imaging may delay treatment and many clinicians now advocate urgent surgical exploration.

The treatment of perinatal testicular torsion remains controversial. Some surgeons support the view that exploration and contralateral orchidopexy is best performed electively in cases of perinatal torsion because most cases occur prenatally and are not salvageable (Das and Singer, 1990; Brandt et al, 1992; Stone et al, 1995; Kaye et al, 2008a). However, partial or complete testicular salvage may be possible when urgent or emergent surgery is performed (Sorensen et al, 2003; Al-Salem, 2007; Cuervo et al, 2007). In other reported cases, unexpected torsion or atrophy of the contralateral testis was found at the time of exploration at varying intervals after the ipsilateral diagnosis, indicating that the clinical signs of extravaginal torsion may indeed be subtle, delayed, and easily overlooked even by observant parents (Yerkes et al, 2005; Al-Salem, 2007; Baglaj and Carachi, 2007; John et al, 2008). Theoretical concerns regarding the anesthetic risks associated with urgent surgery for perinatal torsion are not confirmed by available data, but neonatal anesthesia expertise is recommended in these cases (Pinto et al, 1997; Sorensen et al, 2003; Yerkes et al, 2005). **Therefore, to minimize loss of testicular tissue and the risk of anorchia, the most prudent approach is urgent exploration and contralateral orchidopexy once the diagnosis of perinatal torsion is made.** To avoid the theoretical risk of transscrotal surgery in the event a tumor is found, some surgeons advocate an inguinal approach whereas others routinely use a scrotal incision. Retention of the testis is advisable if any chance of viability is present, particularly in postnatal or bilateral cases, to optimize the likelihood of retained endocrine function. As with other management controversies in urology, the pros and cons of alternative approaches to care should be discussed thoroughly with the patient's family.

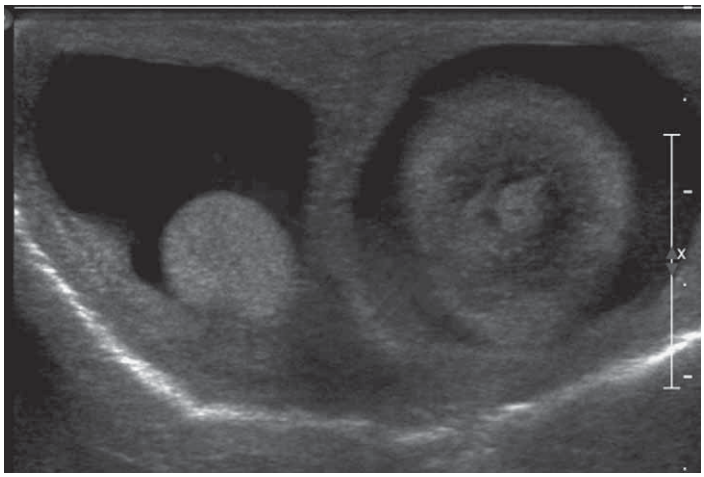

Figure 132–10. Extravaginal spermatic cord torsion. Transverse ultrasound image shows both testes in a neonate with left prenatal torsion. Note enlarged testis with heterogeneous parenchyma and bilateral hydroceles.

Appendage Torsion

The most common intrascrotal appendages are the appendix testis and appendix epididymis, remnants of the cranial müllerian and wolffian ducts, and present in 76% to 83% and 22% to 28% of testes, respectively (Dresner, 1973; Jacob and Barteczko, 2005). The vas aberrans and paradidymis, both appendages of wolffian duct origin, are rare (1% to 3% of patients). Appendage anatomy varies between individuals but includes sessile and pedunculated types; testicular appendices were more commonly sessile in a prenatal study (Jacob and Barteczko, 2005) but pedunculated in a postnatal torsion series (Jones, 1962). The appendix testis is located at the cranial testicular pole or in the groove between the testis and epididymis, and the appendix epididymis is located along the caput. The cause of torsion of an appendage is not known but may be related to anatomy, trauma, and/or prepubertal enlargement.

Appendage torsion is the most common cause of acute scrotum in prepubertal children. The peak age at occurrence is 7 to 12 years (mean 8 to 9 years) (Anderson and Giacomantonio, 1985; Mushtaq et al, 2003; Lyronis et al, 2009). Symptoms include sudden or gradual onset of testicular pain, which may be mild or severe and intermittent in some cases. Some series fail to show significant differences in the presenting complaints of boys with appendage as compared with testicular torsion, but, in general, patients with appendage torsion are less likely to present early in the course of symptoms or to have nausea and vomiting or generalized testicular tenderness. In addition, pain may increase with activity and resolve at rest.

Physical findings depend on the severity of inflammation and duration of symptoms (Rakha et al, 2006). A blue dot sign was first described by Dresner (1973) as a discoloration seen through the scrotal wall in prepubertal boys when the skin is stretched over the upper pole of the testis early in the course of the disease. This sign is reportedly present in 0% to 52% of patients (Caldamone et al, 1984; Van Glabeke et al, 1999; Karmazyn et al, 2005; Murphy et al, 2006; Lyronis et al, 2009) but was uncommon (10%) in one of the largest series of boys whose diagnoses were confirmed surgically (Makela et al, 2007). A single false-positive

case of a blue dot sign in a patient with testicular torsion has been reported (Murphy et al, 2006). Other associated early signs supportive of the diagnosis include a tender nodule superior to the testis with limited testicular tenderness, a symmetrical (present or absent) cremasteric reflex, and intact epididymal landmarks. However, with longer duration there may be increasing difficulty in differentiating appendage torsion from other causes of acute scrotum, because many of the symptoms are nonspecific and the scrotal examination may show increasing testicular enlargement and tenderness and marked scrotal swelling and erythema. These secondary signs may progress even in the absence of worsening pain and contribute to prolonged resolution. In a large series of 840 boys with scrotal pain, 5% required reexploration for metachronous contralateral appendiceal torsion (Ben-Meir et al, 2006).

CDUS in cases of appendage torsion is operator dependent and may show hyperperfusion of the epididymis with or without an enlarged (typically > 5 mm) appendix testis or may appear normal (Baldisserotto et al, 2005). When visible by CDUS, the normal appendix testis contains no internal blood flow and has a mean diameter of 3.1 ± 0.8 mm (Yang et al, 2005) whereas the twisted appendage may appear as an ovoid hyperechoic, hypoechoic, or heterogeneous nodule without blood flow (Fig. 132–11). When visible this finding is helpful, but its absence does not rule out appendage torsion. Similarly, epididymal hyperemia may indicate epididymitis or testicular detorsion.

The high prevalence of appendiceal torsion and long-recognized expectation of spontaneous resolution with conservative management supports nonsurgical management of the majority of patients, particularly in boys in whom the diagnosis is clear (Koff and De Ridder, 1976). In most cases symptoms resolve spontaneously with strict limitation of activities until pain resolves and use of a nonsteroidal anti-inflammatory agent such as ibuprofen. In some cases pain and swelling is exacerbated by athletic activities. Rarely, prolonged and severe pain or recurrent episodes warrant surgical excision of the appendage to reduce pain and morbidity.

Epididymitis

In children, the true incidence and cause of infectious or noninfectious inflammation of the epididymis, or epididymitis, is poorly defined and controversial (Lau et al, 1997; Merlini et al, 1998; Cappele et al, 2000; Somekh et al, 2004; Al-Taheini et al, 2008; Sakellaris and Charissis, 2008). Nonoperative series suggest a higher prevalence (40% to 60%) than that reported for operative series (5% to 15%), probably owing to difficulty differentiating epididymitis from appendix testis torsion clinically (Kadish and Bolte, 1998; Lam et al, 2005; Lyronis et al, 2009). In many series peaks in prevalence occur in infancy and at puberty (Sidler et al, 1997; Mushtaq et al, 2003; Makela et al, 2007). Symptoms are similar to those reported for other causes of acute scrotal pain but may be more gradual in onset. Nausea and vomiting are extremely rare, but fever or voiding symptoms may be present. Localized epididymal enlargement and tenderness are present, and the cremasteric reflex is symmetric. CDUS shows increased epididymal size and blood flow (Fig. 132–12) as well as increased testicular flow in some cases; however, it is important to note that these same physical and imaging findings may be associated with intermittent testicular or appendix testis torsion. Associated pyuria and/or bacteriuria are reported in 20% to 40% of cases that were confirmed intraoperatively (Anderson and Giacomantonio, 1985; Sidler et al, 1997; Mushtaq et al, 2003; Murphy et al, 2006; Makela et al, 2007). Known risk factors for both urinary tract infection and epididymitis include neurogenic and non-neurogenic voiding dysfunction; clean intermittent catheterization (CIC); urethral abnormalities including hypospadias, urethrorectal fistula, and stricture (Karmazyn et al, 2009); and congenital anomalies of the ejaculatory duct (see Fig. 132–12) (Pimpalwar et al, 2002; Yanai et al, 2005). Boys with anomalies are more likely to have severe inflammation of the epididymis and recurrent episodes (Karmazyn et al, 2009). Noninfectious epididymitis is attributed to milder forms of bladder dysfunction, unusual bacterial or viral infections, or trauma, but conclusive evidence supporting these causes is unavailable (Bukowski et al, 1995a; Somekh et al, 2004). Sexually transmitted disease is the most likely cause in postpubertal sexually active males.

Because the historical, physical, and imaging findings are nonspecific and the disease is rare in prepubertal children, some clinicians diagnose epididymitis only when signs of infection are present. Al-Taheini and coworkers have proposed strict criteria for diagnosis that include acute scrotal pain and epididymal hyperemia on CDUS in addition to at least two of the following: fever

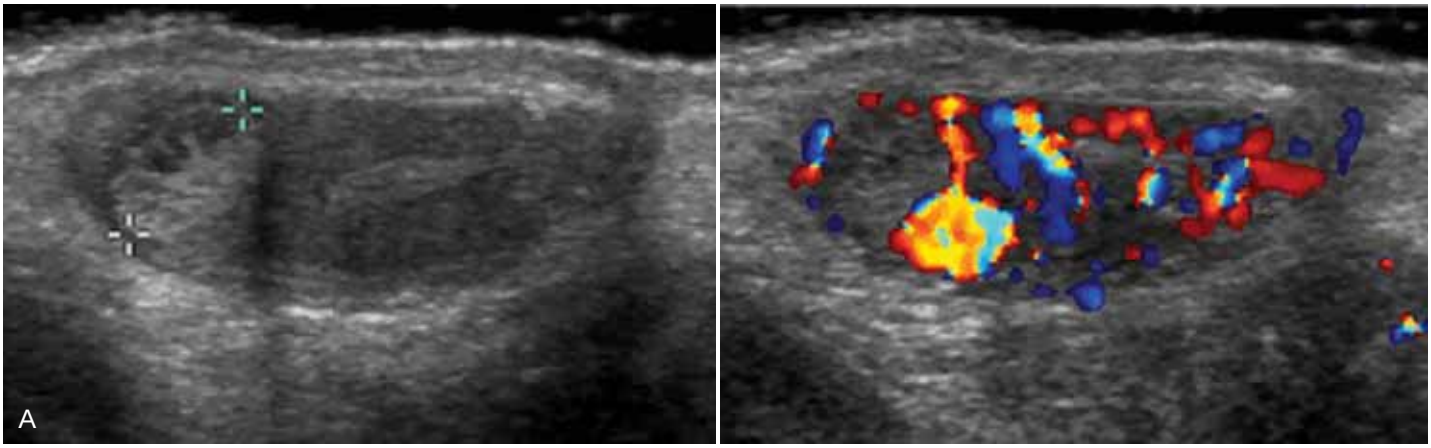

Figure 132–11. Torsion of a testicular appendage. CDUS shows (**A**) a heterogeneous enlarged appendix of 7 mm in greatest diameter and (**B**) increased flow to testis and epididymis and avascular appendix. The patient was treated conservatively, and the examination findings normalized within 1 week.

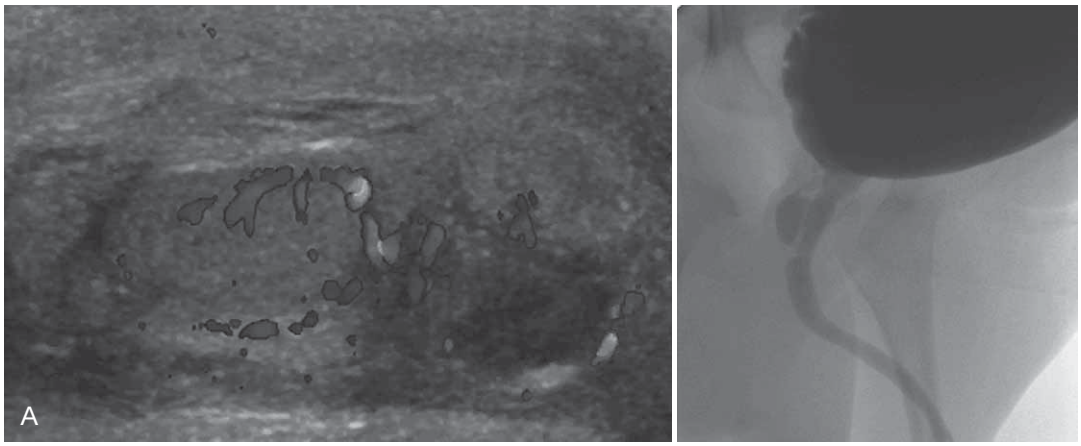

Figure 132–12. Epididymitis with utricle and seminal vesicle reflux in a male 3-month-old with trisomy 21, micropenis, and *Escherichia coli* urinary tract infection. **A**, Color Doppler ultrasonography shows an enlarged, hyperemic, and heterogeneous right epididymis; **B**, Voiding cystourethrography shows reflux into the right ejaculatory duct and seminal vesicle.

greater than or equal to 37.5° C, leukocytosis, pyuria (>10 white blood cells per high-powered field), and/or positive urine culture (Al-Taheini et al, 2008). Using these criteria they identified 16 patients with epididymitis; of these 10 had a documented urinary tract infection, 15 had a normal renal ultrasound study, and 1 of 13, a boy with a history of imperforate anus, had an abnormal voiding cystourethrogram. Other clinical series document a low risk of urinary tract anomalies in boys with epididymitis, although infants may be at higher risk (Merlini et al, 1998; Sakellaris and Charissis, 2008). However, anomalies such as pyelectasis, low-grade vesicoureteral reflux, and renal duplication that comprise the majority of findings may be incidental whereas direct contributing factors such as urethral or ureteral obstruction, ejaculatory duct, or vasal anomalies are rare.

In the absence of urinary tract infection, symptoms improve spontaneously without antibiotic therapy (Lau et al, 1997) and the need for urinary tract imaging in otherwise normal boys remains controversial. Recommendations include renal ultrasonography only (Al-Taheini et al, 2008) or no imaging unless the problem is recurrent (Cappele et al, 2000). In cases of documented urinary tract infection associated with epididymitis or progression to epididymo-orchitis, aggressive treatment including intravenous antibiotics and hospitalization may be necessary and imaging workup of the urinary tract, including renal ultrasonography and voiding cystourethrography, is indicated after resolution of the infection. In recurrent cases, endoscopy may reveal ejaculatory duct abnormalities that are not evident on voiding cystourethrography (Pimpalwar et al, 2002; Yanai et al, 2005). Recurrent epididymo-orchitis in these cases may require excision of a utricle or ejaculatory duct cyst with vasovasostomy or vasectomy.

Other Causes of Acute Scrotal Pain

A large number of conditions affecting the scrotum or intrascrotal contents may present as scrotal pain and/or swelling (see Table 132–6). Trauma, although not uncommonly reported in boys with testicular or appendage torsion, may also lead to acute scrotal swelling and pain in cases of hematocele due to *testicular rupture* or to intra-abdominal injury in the presence of a communicating hydrocele. CDUS appears to be sensitive in diagnosing testicular fracture in adolescents, and surgical intervention is indicated (Adams et al, 2008). Boys with *idiopathic scrotal edema* are typically prepubertal (2 to 12 years old) and present with unilateral or bilateral scrotal redness and swelling with or without pain (Klin et al, 2002; Lee et al, 2009). Associated findings may include local spread of erythema or edema to the inguinal or perineal region, inguinal lymphadenopathy, leukocytosis, and/or eosinophilia, the latter suggesting an allergic cause although the etiology is most likely multifactorial. Distinctive characteristics include minimal or no pain, scrotal but not testicular tenderness, and thickening of the scrotal wall by ultrasonography. Treatment is observation and possible use of antihistamines with resolution expected over several days. *Henoch-Schönlein purpura* is a form of acute vasculitis affecting the skin, joints, gastrointestinal tract, and kidneys that presents as scrotal findings in 2% to 38% of cases and may include edema or erythema; testicular hematoma, torsion or infarction; or cord thrombosis or epididymitis (Turkish et al, 1976; Diana et al, 2000; Ioannides and Turnock, 2001). A typical purpuric rash of the buttocks, perineum, and lower limbs is usually present but may not precede the scrotal findings. Urgent scrotal exploration is indicated if clinical findings suggest concomitant testicular torsion. *Cystic dysplasia of the rete testis* may present as acute scrotal swelling and pain (Noh et al, 1999; Smith et al, 2008; Jeyaratnam and Bakalinova, 2010). Rarely, an associated ureteral anomaly may lead to chronic testicular pain (McGee et al, 2009). Cystic dysplasia is associated with ipsilateral renal dysplasia, agenesis, or ureteral anomalies in the majority of cases and likely represents a failure of normal wolffian duct development. The diagnosis is confirmed by ultrasonography, which shows multiple small centrally located cysts within the testis. Treatment is conservative enucleation, which may be associated with recurrence, or observation, which is associated with regression in some cases.

EPIDIDYMAL, VASAL, AND SCROTAL ANOMALIES

Congenital anomalies of accessory testicular structures are often associated with primary diseases affecting testicular descent and genital development but may occur as isolated anomalies or as part of syndromes that do not primarily affect the genitalia.

Epididymal cysts are anechoic simple cystic structures that may be palpable by the patient or examining physician or found incidentally by ultrasonography (Homayoon et al, 2004). These

may be clinically indistinguishable from spermatoceles except that the latter occur postpubertally and contain sperm. The pathophysiology of epididymal cysts is unknown but may be related to an altered hormonal environment because they are linked to DES exposure (Palmer et al, 2009). These lesions are different ultrasonographically and pathologically from the multicystic/solid epididymal cystadenomas that occur in von Hippel-Lindau disease (Choyke et al, 1997). Homayoon and associates (2004) observed spontaneous resolution of many cysts observed in their pediatric series, and surgical intervention is rarely needed.

Congenital absence of the vas deferens (CAVD) is in most cases associated with specific mutations of the cystic fibrosis gene *CTFR* (cystic fibrosis transmembrane regulator) that are less severe than those encountered in patients with cystic fibrosis (McCallum et al, 2001; Kolettis and Sandlow, 2002). The disease can be bilateral (CBAVD) or unilateral (CUAVD) with a normal or obstructed contralateral vas and may be associated with renal agenesis or ectopia and/or partial or complete agenesis of the epididymis and seminal vesicles. *CTFR* mutations are more common in males with CBAVD, and renal anomalies are more common in cases of CUAVD. These patients typically present with infertility. Abnormal vasal development may also result in a **persistent mesonephric duct** anomaly that is associated with ipsilateral renal and seminal vesicle agenesis and vasoureteral fusion (Kajbafzadeh and Payabvash, 2006). Reflux into the fused wolffian remnants results in urinary tract infection and epididymo-orchitis. Other associated anomalies may include imperforate anus, hypospadias, tracheoesophageal fistula, tetralogy of Fallot, or coarctation of the aorta.

Scrotal anomalies including **ectopic scrotum** and **penoscrotal transposition** are rare but frequently occur in association with other congenital anomalies (Parida et al, 1995; Hoar et al, 1998). An ectopic scrotum may be suprainguinal, inguinal/femoral, or perineal (accessory). The suprainguinal form is unilateral, associated with an ectopic intrascrotal or cryptorchid testis, and often associated with ipsilateral renal anomalies. The femoral ectopic scrotum may be unilateral or bilateral and is associated with lip, palate, and limb anomalies, whereas the perineal (accessory) scrotum is commonly associated with a perineal lipoma (Park and Hong, 2006). Similarly, penoscrotal transposition occurs in severe hypospadias (Pinke et al, 2001) but is also associated with multisystem renal, CNS, vertebral, limb, and/or cardiac defects (Parida et al, 1995). Perineal lipomas may occur in association with a spectrum of scrotal anomalies, suggesting that they represent a cause or consequence of abnormal development of the labioscrotal folds (Park and Hong, 2006).

Key Points: Hernia/Hydrocele and Acute Scrotum

- Routine contralateral exploration in cases of unilateral inguinal hernia is not recommended.
- Noncommunicating scrotal hydroceles are more common in neonates and adolescents; the rare abdominoscrotal variant occurs primarily in infancy and requires repair.
- Diagnoses in cases of acute scrotum include appendix testis torsion (40% to 60%), spermatic cord torsion (20% to 30%), epididymitis (5% to 15%) and other or no pathology (10%).
- The anatomic abnormality predisposing to torsion of the spermatic cord is the bell-clapper deformity and occurs in about 12% of males.
- Findings most suggestive of spermatic cord torsion include puberty, absent cremasteric reflex, short duration (<6 hours) of pain, and reduced or absent blood flow and/or a visible spermatic cord twist on ultrasound imaging.
- Findings most suggestive of appendix testis torsion include prepuberty, a localized tender nodule at the superior testis pole, a blue dot sign, and a preserved cremasteric reflex.
- When findings support or are suggestive of spermatic cord torsion, emergent scrotal exploration is indicated and should not be delayed for diagnostic testing.
- Intrascrotal fixation of the testis must be performed bilaterally because a contralateral bell-clapper deformity usually exists and may lead to metachronous torsion.
- Epididymitis associated with urinary tract infection or with recurrent episodes warrants urinary tract evaluation with imaging to rule out urethral or ureteral anomalies.

Sexual Differentiation: Normal and Abnormal

David Andrew Diamond, MD ● Richard N. Yu, MD, PhD

Normal Sexual Differentiation

Abnormal Sexual Differentiation

Evaluation and Management of the Newborn with Ambiguous Genitalia

Disorders of sexual differentiation are among the most fascinating and complex disease processes encountered by the urologist. This field has undergone a striking evolution over the past few decades. Remarkable advances in molecular biology and genetic research have provided new insight into the precise mechanisms responsible for sexual differentiation and for specific disorders of sexual development. In addition, there has been a major shift in nomenclature in order to promote precise communication among colleagues and respect for the sensitivity of patients by eliminating terms such as *pseudohermaphroditism,* which have been regarded as pejorative by patients. The term *intersex disorders* has been replaced by *disorders of sex development* (DSDs).

NORMAL SEXUAL DIFFERENTIATION

Under normal circumstances, sexual differentiation is a dynamic and sequential process. According to the Jost paradigm, three steps must occur: establishment of chromosomal sex at fertilization, which determines development of the undifferentiated gonads into testes or ovaries, and subsequent differentiation of the internal ducts and external genitalia as a result of endocrine functions associated with the type of gonad present (Jost et al, 1973). Therefore sexual development occurs as a result of different but complementary processes: genotypic effects, phenotypic events, and gender identity formation. Interference with this highly ordered process at any step can result in a disorder of sexual differentiation.

Normal Genotypic Development

Chromosomal Sex

In 1921, Painter demonstrated cytologically that humans have X and Y chromosomes. Based on chromosomal studies of *Drosophila,* it was assumed that sex was determined by the X chromosomes possessed by the individual (Bridges, 1921). The Y chromosome was thought to impart no genetic information until karyotyping of mammalian chromosomes, developed in the 1950s, demonstrated that the Y chromosome specified development of the testis. Specifically, reports in the late 1950s describing the karyotype 47,XXY as male with Klinefelter syndrome and 45,XO as female with Turner syndrome demonstrated that the presence of a Y chromosome, independent of the number of X chromosomes, resulted in the development of a male embryo, whereas in the absence of a Y chromosome the embryo developed as a female (Ford et al, 1959; Jacobs and Strong, 1959). Therefore, the Y chromosome appeared to possess a gene or genes that determined the destiny of the bipotential gonad as a testis or ovary. **In the human, the hypothetical Y-chromosomal gene was termed the *testis-determining factor* (TDF).**

During the following years the search for the TDF was the focus of intense research. The observation that antibodies raised in inbred female mice transplanted with male skin grafts resulted in graft rejection whereas female-to-male skin grafts were accepted in the same strain of mice led to the proposal that the histocompatibility-Y, or H-Y, antigen was the product of TDF (Eichwald, 1955). Assays for quantifying H-Y antigen were developed. With the use of these assays it was discovered that the presence of a testis resulted in serologically detectable levels of H-Y antigen. This was confirmed in normal patients, patients with DSDs, and males of other species. **Therefore, it was believed that the H-Y gene was the TDF** (Wachtel, 1977). **This theory was considered valid for more than 10 years.**

Problems with the H-Y antigen theory developed, however. A number of women with 45,X gonadal dysgenesis were found to be H-Y antigen positive. In addition, a mouse model for the male sex reversal syndrome (XX male) was studied in which mice have two X chromosomes and testes owing to a fragment of Y chromosome translocated onto one of the X chromosomes (McLaren et al, 1984). These mice were H-Y antigen negative and azoospermic. **As a result of these findings the hypothesis that the H-Y antigen was the product of TDF was excluded. Further study of the Y chromosome suggested that the genetic information responsible for maleness was on the short arm of the chromosome near the centromere.** This theory was supported by data from animals with naturally occurring sex chromosome abnormalities. Gain or loss of DNA from the short arm of the Y chromosome on an XX genetic background resulted in either a male or female phenotype, respectively. Further progress was made by studying paradoxical, 46,XX males who develop as phenotypic males in the presence of a presumably normal female 46,XX karyotype (Magenis et al, 1982). The simplest explanation for their sex reversal would be the presence of Y-chromosomal material (including TDF), owing to mosaicism or to

submicroscopic cellular quantities. The application of molecular techniques to evaluate Y-chromosomal sequences present in XX males, as well as deletions of the Y chromosome in XY females, led to the cloning of TDF (Lukusa et al, 1992). **Deletion maps based on the genomes of these individuals were constructed by a number of laboratories, and TDF was mapped to the most distal aspect of the Y-unique region of the short arm of the Y chromosome, adjacent to the pseudoautosomal boundary** (Fig. 133–1).

ZFY and *SRY*

Page and coworkers (1987) constructed a more detailed genomic map and defined a 140-kilobase (kb) interval thought to contain the TDF by aligning the Y-specific DNA present in an XX male with a Y chromosome deletion of the same region in an XY female. These investigators identified a gene encoding a protein with multiple "zinc finger" domains, characteristic of a class of proteins that bind DNA in a sequence-specific manner and regulate transcription. In addition, these sequences demonstrated evolutionary conservation. **Based on its position and structural similarity to other transcription factors, *ZFY* (zinc finger gene on Y chromosome) was proposed as a candidate for the TDF.**

However, in subsequent years, data were accumulated that excluded *ZFY* as the TDF. This included the discovery that in marsupials *ZFY* was located not on the sex chromosomes but on autosomes (Sinclair et al, 1988). ***ZFY* was excluded with certainty as a candidate for TDF when four individuals with testicular development were found to have inherited a fragment of the Y chromosome that did not include *ZFY*** (Palmer et al, 1989).

The renewed search for TDF led to the discovery of Y-specific sequences in XX males lacking *ZFY* and imposing new limits on the location of TDF to a 35-kb region adjacent to the pseudoautosomal boundary (Fig. 133–2). **Using probes from this region, Sinclair and colleagues** (1990) **discovered a single-copy male-specific sequence that was evolutionarily conserved. This gene was termed *SRY* (sex-determining region Y gene) in humans and *Sry* in mice.** Analysis of the SRY protein sequence demonstrated a highly conserved, 78 amino acid region with homology to a DNA-binding motif of the high-mobility group (HMG) family of proteins (Fig. 133–3). When DNA encoding the HMG box was used to probe a genomic library, a subfamily of closely related genes was identified. Members of this family, defined as those encoding a region with 60% or greater amino acid similarity to the SRY HMG-box motif, are called *SOX* (SRY-box-related) genes (Goodfellow and Lovell-Badge, 1993).

Considerable evidence has accumulated that *SRY* is the TDF. In the mouse, expression of *Sry* correlates with testicular determination in the gonadal ridge (Koopman et al, 1990). *SRY* is an evolutionarily conserved gene on the Y chromosome of mammals. Chromosomal fragments related to *SRY* (i.e., the *SOX* genes) are very much conserved evolutionarily, being demonstrated in various vertebrates and marsupials. ***SRY* is localized to the smallest region of the Y chromosome capable of inducing testicular differentiation in humans and in mice** (Gubbay et al, 1992). In fact, Koopman and coworkers (1991) introduced into XX mouse embryos a 14-kb mouse genomic DNA fragment containing *Sry* and no other Y-linked gene sequences and demonstrated that it was capable of giving rise to normal testicular development in the transgenic mice. **The *SRY* protein**

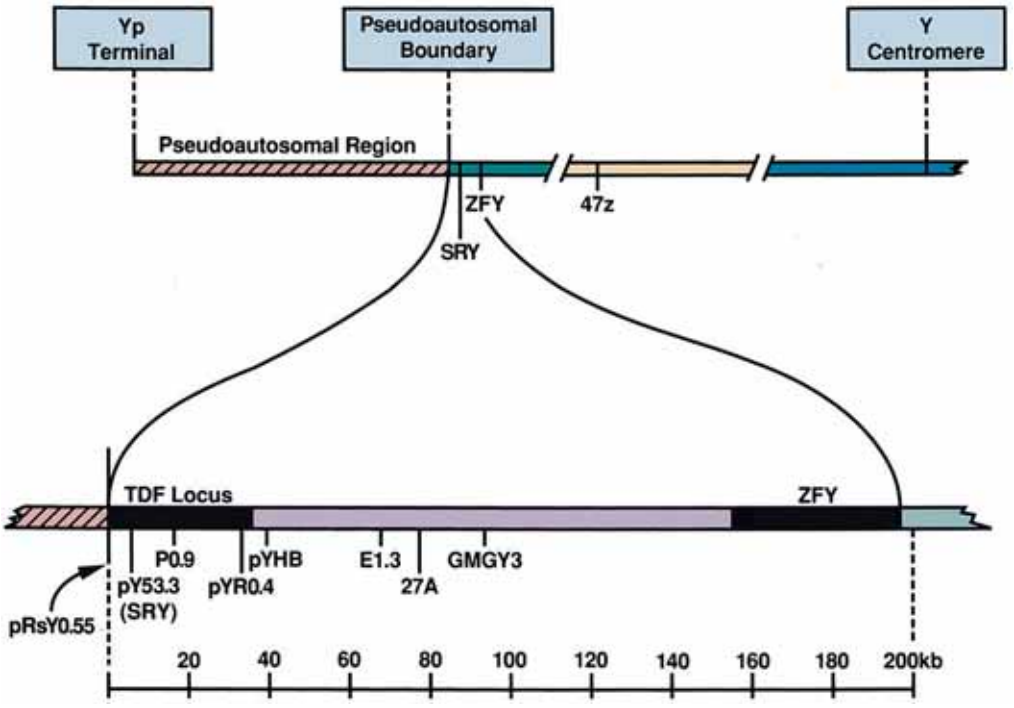

Figure 133–1. Genetic map of the short arm of the human Y chromosome. The top of the diagram shows the pseudoautosomal region of the short arm of the Y chromosome and the locus of the *SRY* and *ZFY* genes near the pseudoautosomal boundary. The lower part of the diagram represents an enlargement of the Y chromosome near the pseudoautosomal boundary and the location of the *SRY* and *ZFY* genes. (From Migeon CJ, Berkovitz GD, Brown TR. Sexual differentiation and ambiguity. In: Kappy MS, Blizzard RN, Migeon CJ, editors. Wilkins: the diagnosis and treatment of endocrine disorders in childhood and adolescence. Springfield [IL]: Charles C. Thomas; 1994. p. 588.)

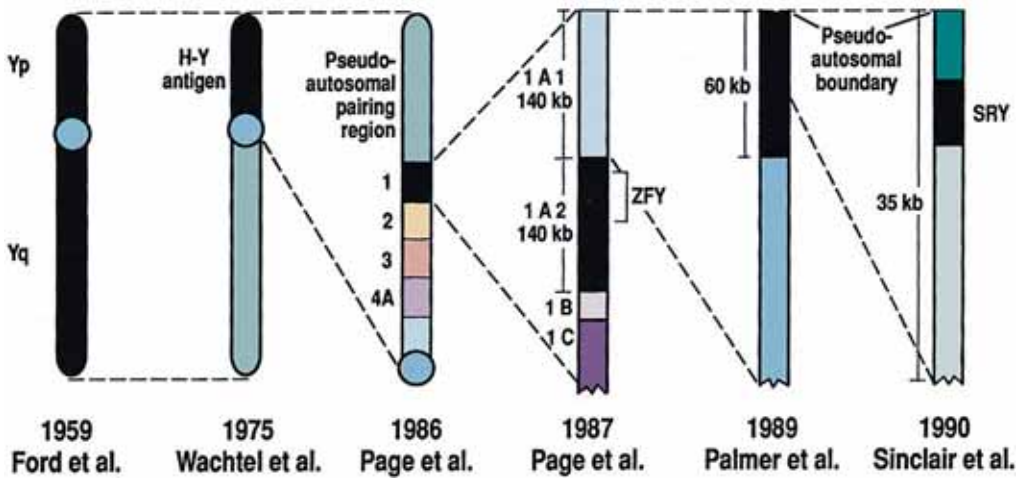

Figure 133–2. Diagrammatic representation of the historical search for the testis-determining factor (TDF). The *shaded area* on the Y chromosome is the region to which this factor has been localized. (From Grumbach MM, Conte FH. Disorders of sex differentiation. In: Wilson JD, Foster DW, editors. Williams textbook of endocrinology. Philadelphia: WB Saunders; 1998. p. 1315.)

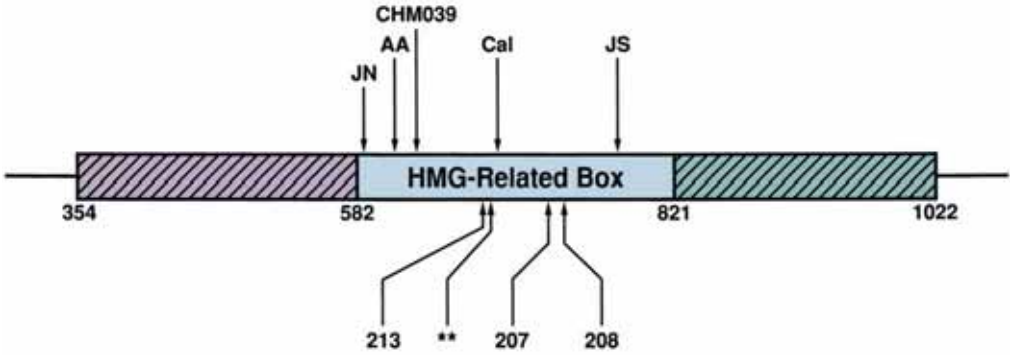

Figure 133–3. Diagram of the *SRY* (sex-determining region on the Y gene) locus, with the so-called high-mobility group (HMG)-related box in the center. The HMG box encodes the DNA-binding region of the SRY protein. Various *arrows* represent the location of the mutations that have been identified in patients with 46,XY complete gonadal dysgenesis. (From Migeon CJ, Berkovitz GD, Brown TR. Sexual differentiation and ambiguity. In: Kappy MS, Blizzard RN, Migeon CJ, editors. Wilkins: the diagnosis and treatment of endocrine disorders in childhood and adolescence. Springfield [IL]: Charles C. Thomas; 1994. p. 620.)

functions as a transcription factor that, by binding and producing bending of the DNA, promotes protein-protein interaction and is able to activate downstream gene expression. An expectation for TDF was that mutations in its protein sequence would result in sex reversal. Examination of the *SRY* sequence in XY females has identified more than 20 mutations in the protein-coding sequence. All but one of these point mutations and microdeletions lie within the DNA-binding domain. Another prediction for TDF is that its presence can cause XX male sex reversal. All but one XX male with Y-specific sequences have been found to contain *SRY* (Goodfellow and Lovell-Badge, 1993). This suggested a causative role of *SRY* in these cases of XX sex reversal. **Therefore, genetic and molecular data have established that *SRY* can be equated to the TDF.**

Additional insights have been gained regarding *SRY* function as a molecular switch that promotes testis development. *SRY* is expressed and functions in the supporting cells of the developing male urogenital ridge. These cells participate in cord formation and ultimately develop into Sertoli cells.

Key Points: Chromosomal Sex

- Sinclair and colleagues (1990) discovered the testis-determining factor (TDF), a single-copy male-specific sequence that was evolutionarily conserved.
- This gene was termed *SRY* (sex-determining region Y gene) in humans and *Sry* in mice.

Additional Genes Involved in Gonadal Determination

Several additional genes involved in gonadal development have been identified and characterized. These include, but are not limited to, *WT1, SF1, SOX9, DAX1, WNT4, RSPO1,* and *FOXL2* (Fig. 133–4; Table 133–1). Newer data suggest that these factors function in defined but interrelated differentiation pathways during gonadal formation and determination.

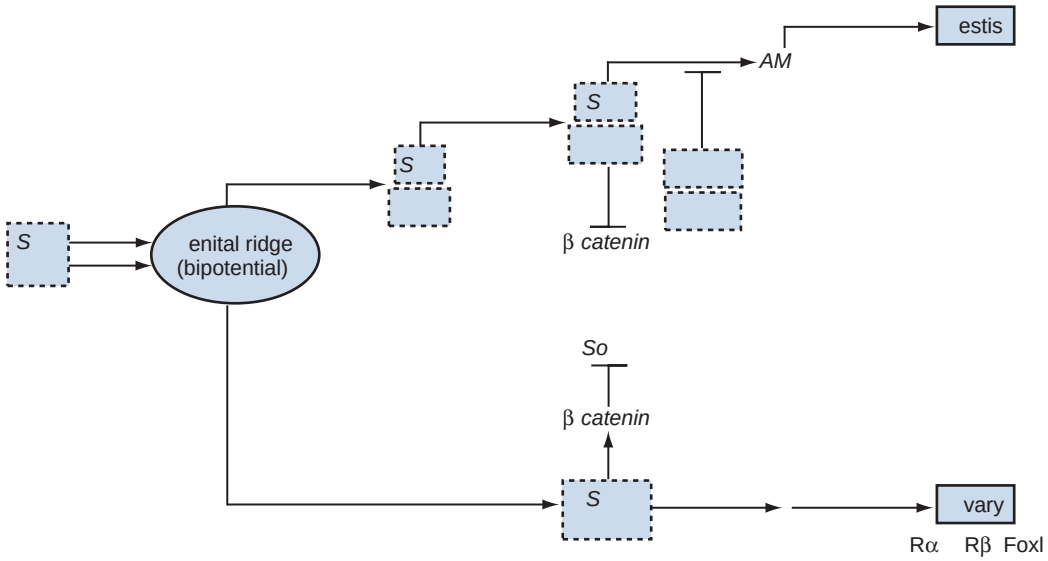

Figure 133–4. Genes determining testis or ovarian differentiation from bipotential gonad. (After Hughes IA. Intersex. BJU Int 2002;90:771; and Sekido R, Lovell-Badge R. Sex determination and SRY: down to a wink and a nudge? Trends Genet 2008;25[1]:19–29.)

Table 133–1.

Loss of Function Phenotype (Human Data)

GENE	CHROMOSOME	XY	XX
SRY	Yp11.3	Female; gonadal dysgenesis (Swyer syndrome)	
SOX9	17q24.3-q25.1	Female; camptomelic dysplasia; ovaries to gonadal dysgenesis	Female; camptomelic dysplasia
WT1	11p13	Female; Wilms tumor; gonadal dysgenesis, mesangial sclerosis (Denys-Drash syndrome); streak gonads, glomerulosclerosis (Frasier syndrome)	Female; Wilms tumor; gonadal dysgenesis, mesangial sclerosis (Denys-Drash syndrome); streak gonads, glomerulosclerosis (Frasier syndrome)
NR5A1(SF1)	9q33	Female; adrenal insufficiency; gonadal dysgenesis	
NR0B1 (DAX1)	Xp21.3-p21.2	Male; gonadal dysgenesis, hypogonadotropic hypogonadism; adrenal hypoplasia	
WNT4	1p36.23-p35.1		Male; aberrant müllerian structure development; wolffian development
RSPO1	1p34.3		Male; palmoplantar keratoderma; aberrant müllerian development; ovotestis
FOXL2	3q23		Male; prophase oocytes; activated somatic testicular development

WT1. The *WT1* gene was originally isolated in cloning experiments that identified an oncogene on human chromosome 11 as being involved in the etiology of Wilms tumor (Call et al, 1990). This gene, originally localized by examining chromosomal deletions in children with WAGR syndrome (*W*ilms tumor, *a*niridia, *g*enitourinary abnormalities, gonadoblastoma, and mental *r*etardation), was found to be expressed primarily in the kidney and gonads of the developing human embryo (Kreidberg et al, 1993). The first reported mutations in the Denys-Drash syndrome, which includes Wilms tumor, renal failure, and gonadal and genital abnormalities, were found to involve the WT1 protein (Pelletier et al, 1991a, 1991b). Indeed, mutations involving *WT1* have been found responsible for both the Frasier and Denys-Drash syndromes, which appear to represent a spectrum of genetically induced abnormalities involving the gonads and kidneys, owing to the earlier involvement of *WT1* in the differentiation of both structures. Frasier syndrome is characterized by both gonadal dysgenesis and renal abnormalities that result in streak gonads and a nephrotic syndrome (MacLaughlin and Donahoe, 2004). If it occurs in the XY genotype, sex reversal results. As a result of alternative splicing of the *WT1* gene, patients with Frasier syndrome are not susceptible to Wilms tumor whereas those with Denys-Drash syndrome are (Koziell and Grundy, 1999). In addition, with the Denys-Drash syndrome, gonads differentiate more completely than with Frasier syndrome. Research on *Wt1* in the mouse suggests that it exerts its effects upstream of *Sry* and is likely to be necessary for commitment and maintenance of gonadal tissue (Lim and Hawkins, 1998).

SF1. Experiments in the mouse have demonstrated that nuclear receptor steroidogenic factor 1 (*SF1*) is expressed in all steroidogenic tissues, including adrenal cortex, testis (Leydig cells), ovarian theca, granulosa cells, and corpus luteum. *SF1* appears to be a key regulator of enzymes involved in steroid production, including the sex hormones, and may directly regulate pituitary gonadotropin expression (Parker et al, 2002). In addition, it appears to play a role in early gonadal development at multiple levels of the

reproductive endocrine axis (Ingraham et al, 1994; Luo et al, 1994). ***SF1*** also **appears to act synergistically with *WT1* in the regulation of müllerian-inhibiting substance** (MIS) expression (Shen et al, 1994; Imbeaud et al, 1995; Nachtigal et al, 1998) and may regulate *DAX1* expression (Yu et al, 1998).

SOX9. The *SOX9* gene was originally identified in patients with camptomelic dysplasia, a congenital disease of bone and cartilage formation that is often associated with XY sex reversal (Wagner et al, 1994). **The *SOX9* gene is structurally quite similar to *SRY*, with a 71% sequence similarity of the high-mobility group (HMG) domain to that of *SRY*.** Expression of the gene in adults is greatest in the testes. **Interestingly, *SOX9* gene activity increases immediately after SRY expression and cell lineage analyses show that SOX9 protein is expressed in cells determined to become Sertoli cells** (Sekido and Lovell-Badge, 2009). **Therefore, the *SOX9* gene may be a key downstream effector of SRY action. The activity of SRY on *SOX9* is synergistic with the activity of an additional transcription factor, steroidogenic factor 1 (SF1), which is essential for gonadal and adrenal development** (Sekido and Lovell-Badge, 2008). **A role for *SOX9* in male gonadal determination is further supported by data from genotypic males with *SOX9* mutations (46,XY) that exhibit ovarian development and male-to-female sex reversal** (Foster et al, 1994; Wagner et al, 1994). *SOX9* also upregulates *AMH* gene expression (MacLaughlin and Donahoe, 2004).

***DAX1* and Dosage-Sensitive Sex Reversal (DSS).** The first indication that an X-specific gene was involved in human sex determination was provided in 1978 with the identification of a family with an X-linked mode of inheritance of 46,XY gonadal dysgenesis. Subsequent studies of a number of sex-reversed subjects confirmed the presence of additional X chromosomal genetic material and a normal Y chromosome (Ogata et al, 1992). **This finding suggested that duplication of an X-specific gene causes XY sex reversal by expressing a double dose of a region normally subject to X inactivation. Screening of XY females with a normal *SRY* gene detected such a submicroscopic duplication, involving a 160-kb region designated as the dosage-sensitive sex reversal (DSS) critical region** (Bardoni et al, 1994). Parallel studies examining 46,XY males with gonadal dysgenesis, hypogonadotropic hypogonadism, and congenital adrenal hypoplasia resulted in the identification of a candidate gene, *NR0B1 (DAX1),* within the DSS critical region (Muscatelli et al, 1994; Zanaria et al, 1994). Interestingly, *DAX1* can act to suppress or promote the testis determination pathway (Yu et al, 1998; Meeks et al, 2003). Although *DAX1* was initially believed to be the primary gene involved in DSS, several sex-reversed 46,XY patients have been identified with duplication of the DSS region in the absence of *DAX1* duplication, which suggests that the gene dosage effects of this region may be associated with an additional gene or genes (Zanaria et al, 1995).

WNT4. *WNT4* on chromosome 1p34 appears to be involved in müllerian duct regression and may also function by antagonizing SRY activity (Kim et al, 2006; Bernard and Harley, 2007). Early inactivation of *Wnt4* in mice causes failure of the formation of müllerian duct derivatives in both sexes. In addition, inactivation of *Wnt4* in female mice leads to wolffian duct development without testicular tissue formation and female external genitalia. Furthermore, a recent report supports the role of *WNT4* in development and maintenance of the female phenotype in women by regulating müllerian duct development and ovarian steroidogenesis (Biason-Lauber et al, 2004).

Normal Phenotypic Development

Gonadal Stage of Differentiation

During the first 6 weeks of embryonic development, the gonadal ridge, germ cells, internal ducts, and external genitalia are bipotential in both 46,XY and 46,XX embryos. Under the genetic influences of sex determination, the bipotential gonadal ridges differentiate into either ovaries or testes and germ cells develop into either oocytes or spermatocytes. Primordial germ cells can be recognized in the third week of gestation on the posterior wall of the secondary yolk sac. **Migration of the germ cells begins in the fifth week of gestation as a result of ameboid movements through the mesentery to the medial ventral aspect of the urogenital ridge** (Jirasek, 1998) (Fig. 133–5). This process is dependent on chemoattractants and cell adhesion molecules (Hughes, 2002). Overall, a population of 1000 to 2000 primordial germ cells reaches the gonadal blastema by the sixth week of gestation.

Transformation of the germ cells into spermatogonia and oogonia results from differentiation of the epithelial gonadal compartments referred to as testicular and ovarian "cords." ***SRY* initiates the switch that induces a cascade of genes directing the indifferent gonad toward testicular organogenesis.** The precise moment at which this occurs remains unknown. Initially, differentiation of Sertoli cells is noted as testicular cords form at 6 to 7 weeks' gestation, creating the basement membrane, or blood-testis barrier, of spermatogonia and Sertoli cells on one side and mesenchymal fibroblasts on the other. **The differentiation of Sertoli cells is associated with the production of MIS, a glycoprotein encoded by a gene on the short arm of chromosome 19** (Haqq et al. 1994). In males, a second line of primordial cells of steroidogenic mesenchyme remain among the testicular cords and represent future Leydig cells, which differentiate at 8 to 9 weeks. **In the absence of *SRY,* ovarian organogenesis results.** Little is known about the genetic control of ovarian development. To date, no genes whose products direct development of the ovary have been identified. **It does appear necessary that there be duplicate copies of at least one X chromosomal locus (which presumably explains the dysgenetic ovaries in the 45,XO Turner syndrome patients).** A potential candidate may lie within the DSS critical region on Xp-21, which, when duplicated, promotes male-to-female "sex reversal" (Bardoni et al, 1994; Lopez et al, 1998).

Unlike the testis, which functions primarily as a fetal endocrine organ, the ovary has primarily exocrine activity. **In embryonal ovaries, germ cells undergo intense mitotic proliferation (preceding the onset of meiotic prophase) and in the process exhaust their entire mitotic potential prenatally, reaching a maximum endowment of 20 million cells by 20 weeks' gestation.** The presence of two X chromosomes appears to be responsible for differentiation of the granulosa cells into the protective mantle of the granulosa layer and "rescue" of 30% of germ cells (approximately 2 million) (Byskov and Westergaard, 1998).

Key Point: Gonadal State of Differentiation

- During the first 6 weeks of embryonic development the gonadal ridge, germ cells, internal ducts, and external genitalia are bipotential in both 46,XY and 46,XX embryos.

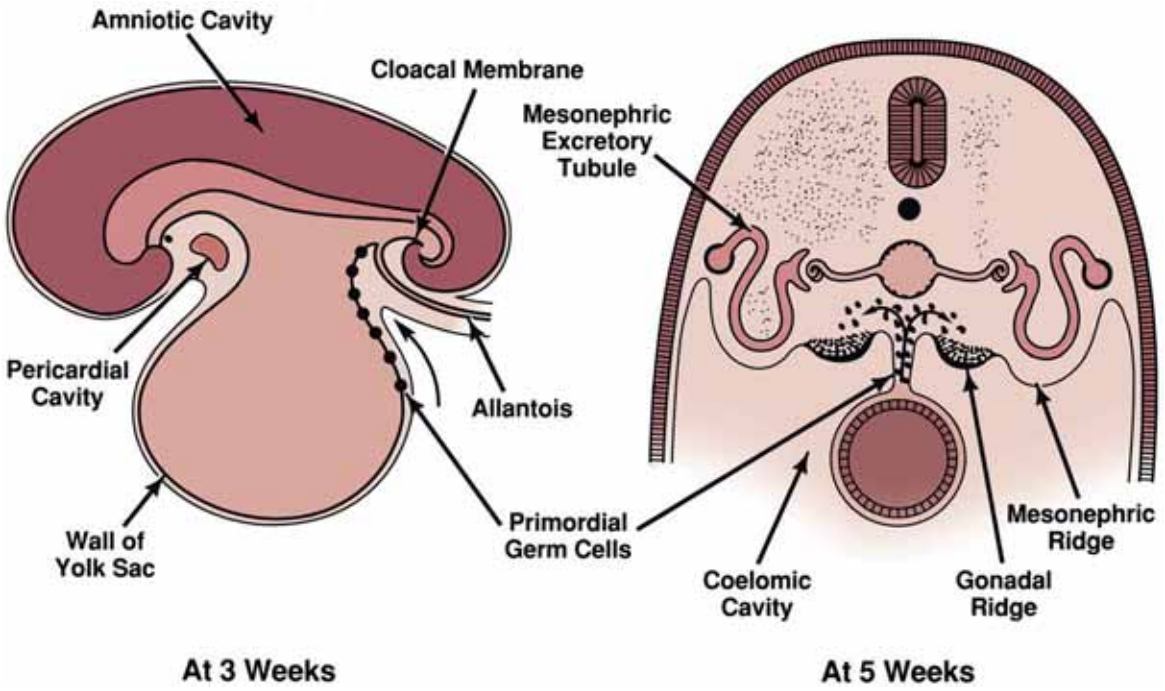

Figure 133–5. Migration of primordial germ cells. At 3 weeks, primordial germ cells are being formed and migrate along the wall of the yolk sac to reach the caudal part of the fetus. By 5 weeks, they have reached the level of the gonadal ridge. (From Migeon CJ, Berkovitz GD, Brown TR. Sexual differentiation and ambiguity. In: Kappy MS, Blizzard RN, Migeon CJ, editors. Wilkins: the diagnosis and treatment of endocrine disorders in childhood and adolescence. Springfield [IL]: Charles C. Thomas; 1994. p. 584.)

Gonadal Function

The initial endocrine function of the fetal testes is the secretion of MIS by the Sertoli cells at 7 to 8 weeks' gestation. MIS, one of the two hormones necessary for male sexual differentiation, acts locally to produce müllerian regression. It is a member of the transforming growth factor-β (TGF-β) family, and the human gene has been cloned and mapped to chromosome 19 (Cate et al, 1986). Little is known about the cellular mechanism of action of MIS. Because the hallmark of MIS-mediated müllerian duct regression is the formation of a ring of connective tissue around the epithelial cells, it is likely that the mesenchyme is the primary target of MIS. **Testosterone secretion by the fetal testes is detectable shortly after the formation of Leydig cells in the interstitium at approximately 9 weeks' gestation** (Siiteri and Wilson, 1974). There is a rise in serum and testicular testosterone to a peak concentration at 13 weeks and then a decline. The rate-limiting enzyme for fetal testosterone synthesis is 3β-hydroxysteroid dehydrogenase, which is concentrated approximately 50 times more highly in the fetal testes than in the ovary. Androgens are synthesized by the Leydig cells, initially autonomously, but then dependent on placental human chorionic gonadotropin (hCG) secretion. Later in gestation, with declining hCG concentrations, androgen synthesis is controlled by luteinizing hormone (LH) secretion by the fetal pituitary gland. Jost and colleagues (1973) **clearly demonstrated that androgen is essential for virilization of wolffian duct structures, the urogenital sinus, and genital tubercle. Testosterone, the major androgen secreted by the testes, enters target tissues by passive diffusion.** Organs such as the wolffian duct, adjacent to the fetal testis, also take up testosterone by pinocytosis. **The local source of androgen is important for wolffian duct development, which does not occur if testosterone is supplied only via the peripheral circulation. In some cells, such as those in the urogenital sinus, testosterone is converted to dihydrotestosterone (DHT) by intracellular 5α-reductase. Testosterone** or DHT then binds to a high-affinity intracellular receptor protein, and this complex enters the nucleus, where it binds to acceptor sites on DNA, resulting in new messenger RNA and protein synthesis (Fig. 133–6). The androgen receptor has been characterized as a high-affinity receptor that mediates the action of testosterone and DHT in all androgen-dependent tissues. In disorders of the androgen receptor, such as androgen insensitivity syndrome, testosterone production is normal but the hormone is unable to reach the nucleus and interact with DNA. Various defects in the androgen receptor result in a spectrum of phenotypic abnormalities in the genetic male. Because gonadal females have androgen receptor within their tissues, exogenous androgen produces virilization. **DHT binds to the androgen receptor with greater affinity and stability than does testosterone. Therefore, in tissues equipped with 5α-reductase at the time of sexual differentiation (e.g., prostate, urogenital sinus, external genitalia), DHT is the active androgen** (George and Peterson, 1988). The 5α-reductase activity has two optimal pH values in cultured genital skin fibroblasts—one at pH 5.5 and a second one near pH 8—that correspond to two distinct enzymes (Jenkins et al, 1992). The alkaline enzyme, human steroid 5α-reductase type 1, was cloned first; however, the primary enzyme in the prostate is 5α-reductase type 2 (Andersson and Russell, 1990). A deletion in the gene coding for this enzyme has been discovered in intersex patients with 5α- reductase deficiency (Andersson et al, 1991). The gene encoding the androgen receptor has been cloned and mapped to the X chromosome at Xq11-12 (Lubahn et al, 1988).

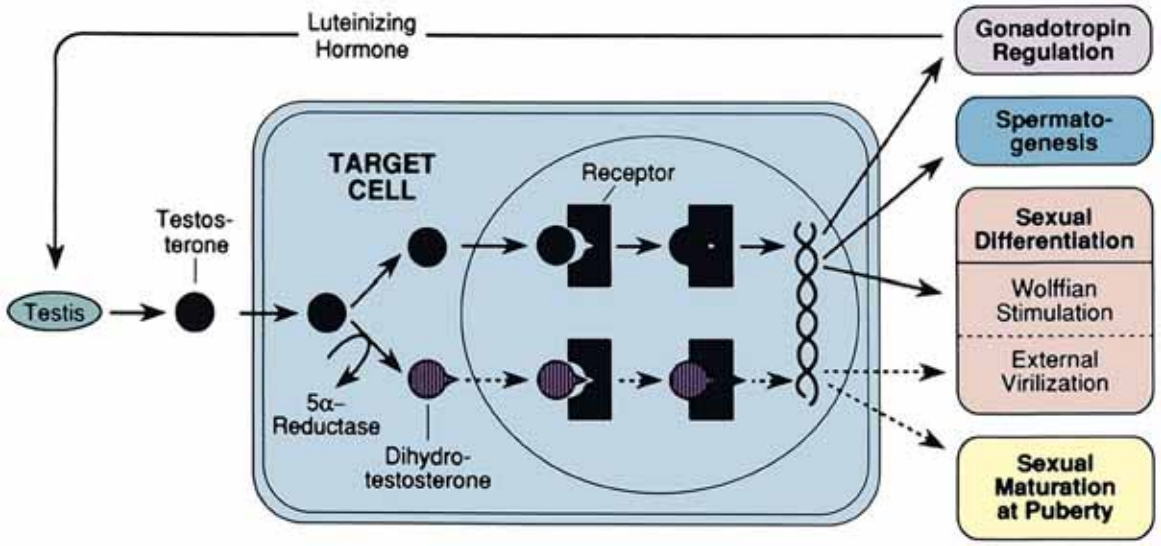

Figure 133–6. Schematic diagram of normal androgen physiology. The major actions of androgens are listed on the right. Testosterone enters androgen target tissues and either binds to the androgen receptor in cell nuclei or is converted by 5α-reductase to dihydrotestosterone (DHT). DHT binds to the same receptor but with greater affinity. Androgen actions mediated by testosterone are indicated by *solid arrows,* and those mediated by DHT are indicated by *dashed arrows.* (From Griffin JE, Wilson JD. Syndromes of androgen resistance. Hosp Pract 1987;22:99–114.)

Key Point: Gonadal Function

- DHT binds to the androgen receptor with greater affinity and stability than does testosterone. Therefore in tissues equipped with 5α-reductase at the time of sexual differentiation (e.g., prostate, urogenital sinus, external genitalia), DHT is the active androgen.

Ovary

Estrogen synthesis is detectable in the female embryo just after 8 weeks of gestation. The rate-limiting enzyme is aromatase, which is higher in the fetal ovary than in the fetal testis. Estrogens are not required for normal female differentiation of the reproductive tract, but they can interfere with male differentiation. Estrogen can block the effect of MIS on müllerian ducts, and prenatal estrogen treatment of mothers has been associated with male reproductive tract abnormalities (Gill et al, 1979; Vigier et al, 1989).

Phenotypic Sexual Differentiation

Before the 8th week of gestation the urogenital tract is identical in the two sexes. Both the wolffian and the müllerian duct systems are present as anlagen of the internal accessory organs of reproduction (Fig. 133–7). In addition, at this stage, the anlagen of the external genitalia of male and female embryos are indistinguishable (Fig. 133–8). **In the male fetus, Sertoli cells produce MIS, which acts locally and unilaterally to suppress the müllerian ducts, and Leydig cells produce testosterone, which permits local development of the wolffian ducts.** By 10 weeks of gestation, degeneration of the müllerian ducts is almost complete and the wolffian ducts have become more prominent (see Fig. 133–7). Adjacent to the testes,

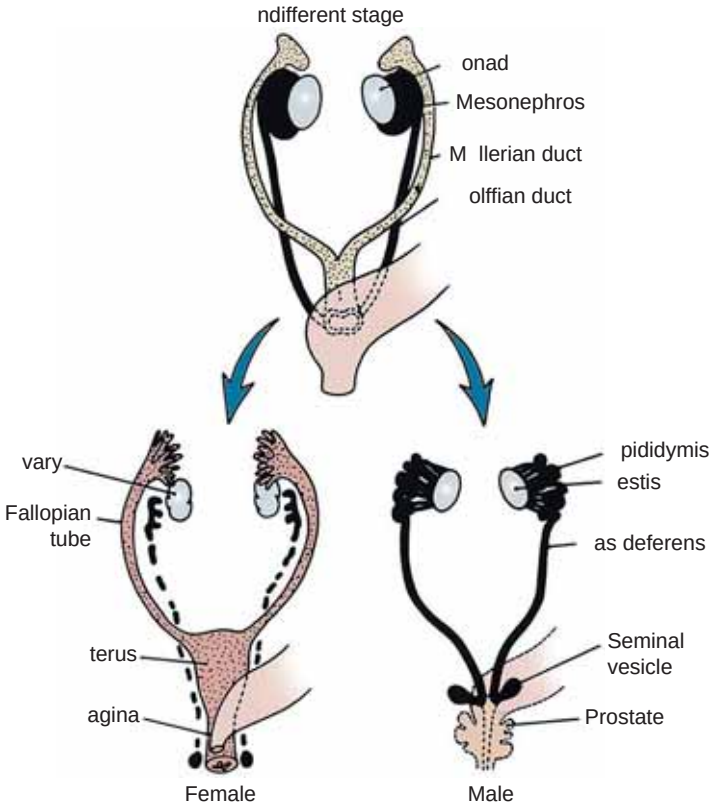

Figure 133–7. Differentiation of the wolffian and müllerian duct and urogenital sinus in the male and female. (From Wilson JD. Embryology of the genital tract. In: Harrison HH, Gittes RF, Perlmutter AD, et al, editors. Campbell's urology. 4th ed. Philadelphia: WB Saunders; 1979. p. 1473.)

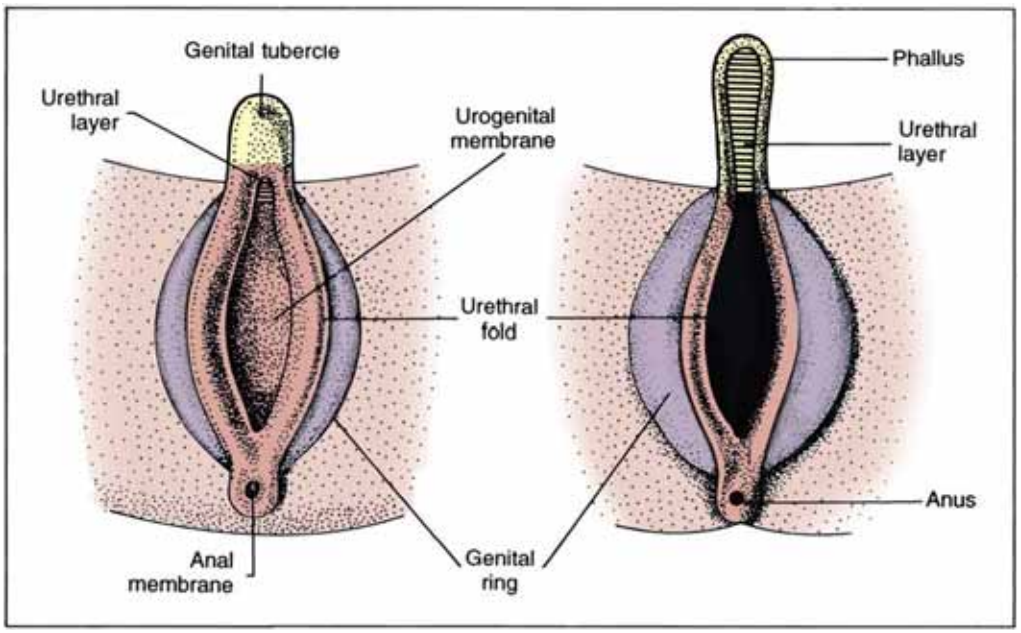

Figure 133–8. Schematic diagram of external genitalia in the undifferentiated period. (From Martinez-Mora J. Development of the genital tract. In: Martinez-Mora J, editor. Intersexual states: disorders of sex differentiation. Barcelona: Ediciones Doymer; 1994. p. 52.)

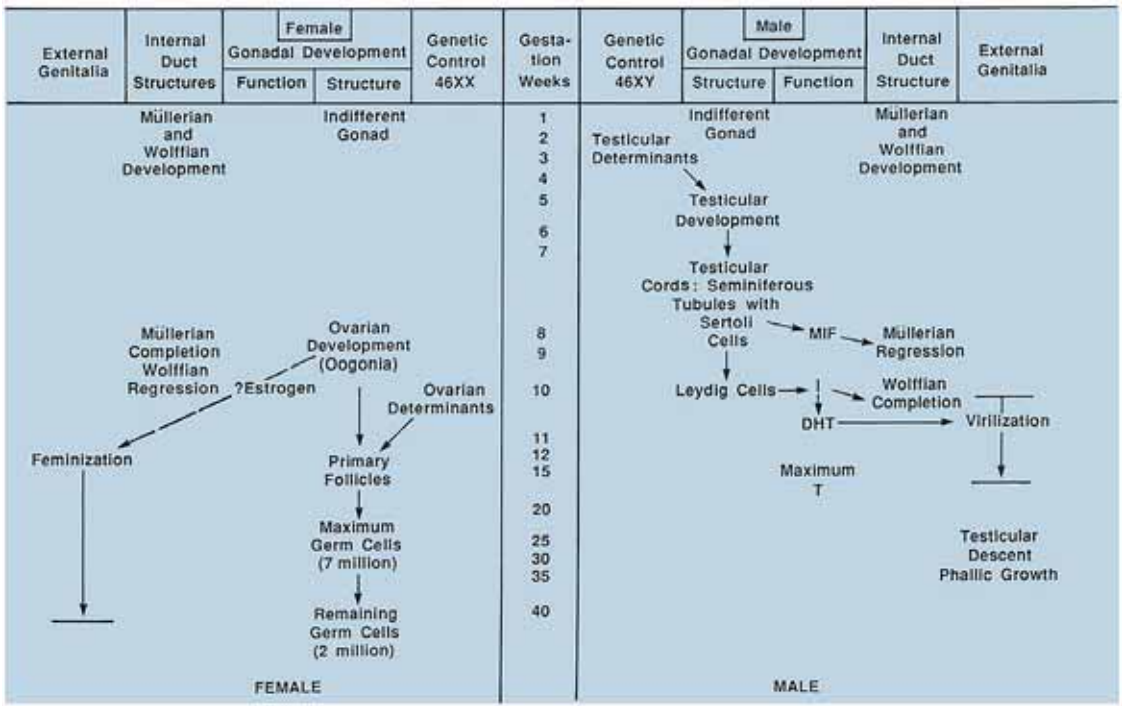

Figure 133–9. Timetable of normal sexual differentiation. DHT, dihydrotestosterone; MIF, müllerian inhibiting factor. (From Diamond D. Intersex disorders: I and II. AUA Update Series, vol. IX, lessons 9 and 10. Houston: American Urological Association Office of Education; 1990.)

convolutions of the ducts organize to form the epididymis. The wolffian ducts of the epididymis join with the collecting portion of the testicular tubules (rete testes). Distally, the ducts join the urogenital sinus by about 30 days' gestation, where they develop into the seminal vesicles. In the female fetus, testosterone is not secreted by the ovaries and therefore the wolffian ducts regress. Because the ovary does not produce MIS, the müllerian ducts are maintained and develop into the female internal reproductive tract. The cephalic ends are anlagen of the fallopian tubes, and the caudal ends fuse to form the uterus (see Fig. 133–7). Contact of the müllerian ducts with the urogenital sinus induces formation of the uterovaginal plate, which ultimately forms the lumen of the vagina. The relative contributions of the müllerian ducts and urogenital sinus to the formation of the vagina remain somewhat controversial; however, there is some agreement that the proximal two thirds of the vagina is contributed by the müllerian ducts and the distal one third by the urogenital sinus. Masculinization of the male fetus starts between 7 and 8 weeks of gestation (Fig. 133–9). The first sign of male phenotypic differentiation is degeneration of the müllerian ducts adjacent to the testes as a result of MIS

secretion by the Sertoli cells. Whereas the effects of androgen on the wolffian ducts are related to diffusion of testosterone from the adjacent gonad, masculinization of the external genitalia results from the systemic delivery of testosterone with local conversion to dihydrotestosterone. By 10 weeks, an increase in distance between genital tubercle and anal folds can be seen. The genital tubercle thickens and elongates to become the penis, and the urethral folds fuse from posterior to anterior over the urethral groove (Fig. 133–10). Near the bladder, the urethra is surrounded by the prostate. The urogenital swellings migrate posteriorly to the genital tubercle and fuse to form the scrotum. **By 12 to 13 weeks' gestation, the genitalia of the male fetus is completed with closure of the elongated urogenital cleft.** Under the influence of androgen secreted by the fetal testes, penile growth and testicular descent occur in the third trimester (see Fig. 133–9). In the female fetus the absence of circulating testosterone maintains the appearance of the external genitalia at the 6-week gestational stage. The genital tubercle develops only slightly to form the clitoris. The lateral genital swellings become the labia majora, and the adjacent urethral folds become the labia minora (Fig. 133–11). Between the labia minora will develop the vaginal introitus and urethral meatus.

Gender Identity, Gender Role, and Gender Orientation

Psychosexual Differentiation

Humans have been recognized as having sexually dimorphic behavior, which has several aspects: (1) *gender identity,* the identification of self as either male or female; (2) *gender role*, aspects of behavior in which males and females appear to differ; (3) *gender orientation*, or choice of sexual partner (heterosexual, homosexual, or bisexual); and (4) *cognitive differences* (Grumbach and Conte, 1998). Gender identity is a complex and poorly understood phenomenon in humans, and the mechanisms appear multifactorial. Experience in patients with congenital adrenal hyperplasia (CAH) who were exposed prenatally to androgen and in patients reared in a sex opposite to their chromosomal or gonadal sex have provided evidence to indicate that gender identity is not merely a function of chromosomal complement or prenatal endocrine milieu. Postnatal environmental factors and learning appear to have an important effect. However, strong evidence has accumulated for the impact of prenatal hormonal influences on sexually dimorphic behavior or gender role. For example, long-term

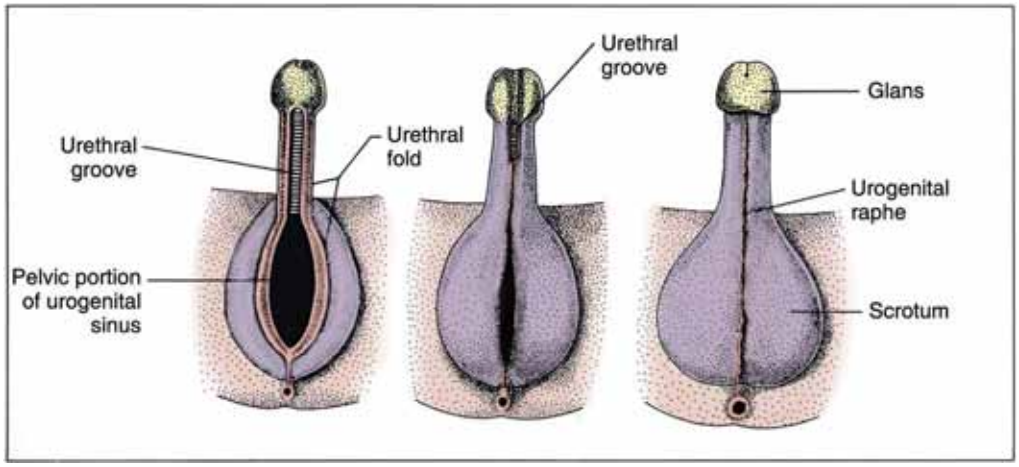

Figure 133–10. Schematic diagram of differentiation of the male external genitalia. (From Martinez-Mora J. Development of the genital tract. In: Martinez-Mora J, editor. Intersexual states: disorders of sex differentiation. Barcelona: Ediciones Doymer; 1994. p. 53.)

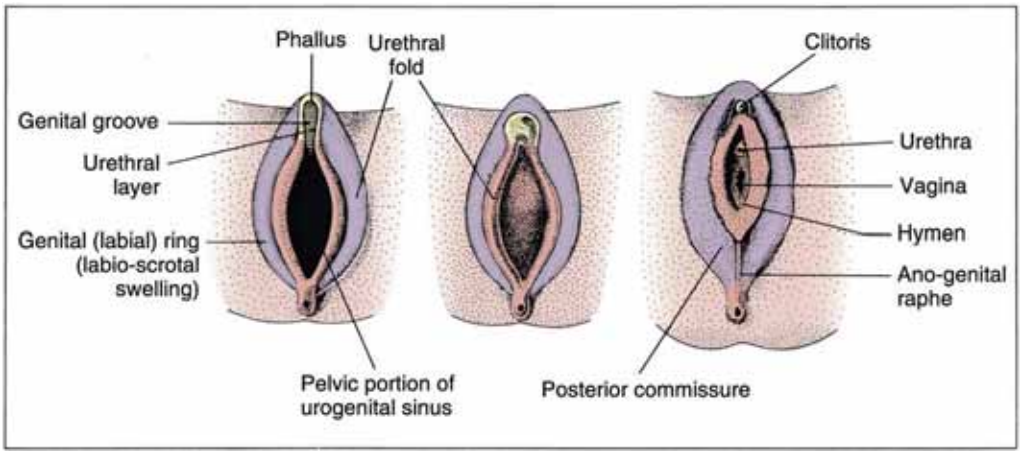

Figure 133–11. Schematic diagram of differentiation of the female external genitalia. (From Martinez-Mora J. Development of the genital tract. In: Martinez-Mora J, editor. Intersexual states: disorders of sex differentiation. Barcelona: Ediciones Doymer; 1994. p. 52.)

follow-up with CAH patients has supported a greater interest in "tomboyish behavior" than in unaffected girls, although these patterns are not abnormal in relation to female behavior in Western society (Ehrhardt and Meyer-Bahlburg, 1981). Additional information regarding the influence of androgens on gender identity and gender role has arisen from one study of males with cloacal exstrophy who underwent gender reassignment within the first few months of life. A majority of these patients had behaviors and attitudes that reflected strong male-typical characteristics regardless of whether they were raised as males or females (Reiner and Gearhart, 2004). However, a subsequent British study of a similar 46,XY cloacal exstrophy cohort presented contradictory findings (Baker Towell and Towell, 2003). The previously accepted dogma that children are psychosexually neutral at birth and capable of being environmentally oriented (the blue room/pink room theory) has been seriously challenged by those who support the concept of prenatal psychosexual differentiation (Money and Ehrhardt, 1972; Diamond and Sigmundson, 1997). Support for either theory in humans is based on the assessment of a limited number of affected patients. An improved understanding of the "nature versus nurture" controversy will probably prove important in the optimal management of patients with DSDs. However, our increased awareness of physiologically normal patients with genuine "gender dysphoria" has illustrated the complexity of this process.

Key Point: Psychosexual Differentiation

- The previously accepted dogma that children are psychosexually neutral at birth and capable of being environmentally oriented (the blue room/pink room theory) has been seriously challenged by those who support the concept of prenatal psychosexual differentiation.

ABNORMAL SEXUAL DIFFERENTIATION

The classification of DSDs (previously "intersex disorders") has undergone evolutionary change as understanding of the etiologic mechanisms of normal and abnormal sexual differentiation has improved. As a result, classification systems vary. The authors have borrowed from the system utilized by Grumbach and Conte (1998), which incorporates the historical emphasis on classification by gonadal morphology and introduced more contemporary terminology (Hughes et al, 2006). Descriptive terms for abnormal gonadal histology have been retained, with the exception of *true hermaphroditism,* which has been replaced by *ovotesticular DSD.* But, for masculinized 46,XX females with two ovaries, *female pseudohermaphroditism* has been replaced by 46,XX DSD. And, for undermasculinized 46,XY males the term *male pseudohermaphroditism* has been replaced by 46,XY DSD. The first category comprises disorders of gonadal differentiation, the second includes ovotesticular DSD, the third includes 46,XX DSD (the masculinized female, that is, ovaries present but external genitalia exhibiting evidence of masculinization), the fourth includes 46,XY DSD (the undermasculinized male, that is, testes present but genital ducts and/or external genitalia incompletely masculinized), and the fifth category comprises unclassified forms. Within each category, remarkable advances in chromosomal and biochemical information have allowed subclassification of disorders based on etiologic mechanisms, contributing to a more rational classification system (Table 133–2).

Table 133–2.

Abnormal Sexual Differentiation

1. Disorders of Gonadal Differentiation

Seminiferous tubule dysgenesis
Klinefelter syndrome
46,XX male
Syndromes of gonadal dysgenesis
  Turner syndrome
  Pure gonadal dysgenesis
  Mixed gonadal dysgenesis
  Partial gonadal dysgenesis (dysgenetic male pseudohermaphroditism)
  Bilateral vanishing testis/testicular regression syndromes

2. Ovotesticular DSD (True Hermaphroditism)

3. 46,XX DSD (Masculinized Female)

Congenital adrenal hyperplasia (21-hydroxylase, 11β-hydroxylase, 3β-hydroxysteroid dehydrogenase deficiencies)
Maternal androgens

4. 46,XY DSD (Undermasculinized Male)

Leydig cell agenesis, unresponsiveness
Disorders of testosterone biosynthesis
Variants of congenital adrenal hyperplasia affecting corticosteroid and testosterone synthesis
  StAR deficiency (congenital lipoid adrenal hyperplasia)
  Cytochrome P450 oxidoreductase (POR) deficiency
  3β-Hydroxysteroid dehydrogenase deficiency
  17β-Hydroxylase deficiency
Disorders of testosterone biosynthesis
  17,20-Lyase deficiency
  17β-Hydroxysteroid oxidoreductase deficiency
Disorders of androgen-dependent target tissue
  Androgen receptor and postreceptor defects
  Syndrome of complete (severe) androgen insensitivity
  Syndrome of partial androgen insensitivity
  Mild androgen insensitivity syndrome (MAIS)
Disorders of testosterone metabolism by peripheral tissues
  5α-Reductase deficiency
  Disorders of synthesis, secretion, or response to müllerian-inhibiting substance
Persistent müllerian duct syndrome

5. Unclassified Forms

In females
  Mayer-Rokitansky-Küster-Hauser syndrome

Disorders of Gonadal Differentiation and Development

Seminiferous Tubule Dysgenesis (Klinefelter Syndrome and Variants)

In 1942, Klinefelter, Reifenstein, and Albright described a syndrome characterized by eunuchoidism, gynecomastia, azoospermia, increased gonadotropin levels, and small, firm testes. By 1959, these patients were noted to have a 47,XXY karyotype (Jacobs and Strong, 1959).

Klinefelter syndrome represents the most common major abnormality of sexual differentiation. By definition, males with at least one Y chromosome and at least two X chromosomes have Klinefelter syndrome. The classic 47,XXY complement arises as a result of nondisjunction during meiosis; it occurs in 1 of 600 liveborn males (Morris et al, 2008). But the phenotype is also associated with 48,XXYY and 49,XXXYY, and an exaggerated form of the phenotype is associated with 48,XXXY and 49,XXXXY. The

mosaic form 46,XY/47,XXY is associated with a milder version of the phenotypic features of classic 47,XXY Klinefelter syndrome. Perhaps as a result of phenotypic variability, Klinefelter syndrome is believed to be underdiagnosed, with a 25% diagnostic rate in one Danish study (Bojesen et al, 2004).

In 47,XXY adults, seminiferous tubules degenerate and are replaced with hyaline. As a result, testes are firm and small, less than 3.5 cm in length. Histologically, Leydig cells appear to be present in large numbers, because they are seen in large clumps in certain areas of the testes, sometimes resembling Leydig cell tumors. However, the absolute volume of Leydig cells is not increased and is probably lower than normal. Serum levels of testosterone are low-normal and those of gonadotropins are elevated. Plasma estradiol levels tend to be high, with gynecomastia the result of an increased ratio of estradiol to testosterone. The vast majority of patients are azoospermic, and the presence of sperm suggests 46,XY/47,XXY mosaicism. There does appear to be a depletion of germ cells with the onset of puberty (Wikström et al, 2004). Fertility, with the benefit of testicular sperm extraction and intracytoplasmic sperm injection, has been reported in patients with Klinefelter syndrome (Koga et al, 2007). Some infertility experts advocate coupling intracytoplasmic sperm injection with preimplantation diagnosis given the lower rate of normal embryos from Klinefelter syndrome patients (54%) versus controls (77%) (Staessen et al, 2003).

The decreased androgen production prevents normal secondary sexual development. Muscle development is poor, and the fat distribution is more female than male. Normal amounts of pubic and axillary hair may be present, but facial hair is sparse. Patients tend to be taller than average, mainly because of the disproportionate length of their legs, which is present even in childhood. Otherwise, few if any distinguishing features are present in the prepubertal child.

Gynecomastia, which can be quite marked, is a common pubertal development in patients with Klinefelter syndrome. As a result, these patients have eight times the risk for development of breast carcinoma compared with normal males (Harnden et al, 1971). In addition, they are predisposed to developing malignant neoplasms of extragonadal germ cell origin as well as Leydig and Sertoli cell tumors (Völkl et al. 2006). Therefore, routine surveillance scrotal ultrasonography has been advocated for postpubertal patients with Klinefelter syndrome.

An intriguing area of research has been in the neuropsychiatric function of Klinefelter syndrome patients. Studies have demonstrated depressed verbal ability and limitations in frontal executive functioning. Recent imaging studies have shown selective volume differences in corresponding areas of Klinefelter syndrome patients' brains versus normal subjects (Giedd et al, 2009). Other studies have demonstrated altered cerebral perfusion in Klinefelter syndrome, corresponding to impaired verbal skills (Itti et al, 2003).

Management of Klinefelter syndrome entails careful androgen supplementation in selected male patients to improve libido and reduction mammoplasty if necessary. Surveillance for testicular tumor and breast carcinoma is also appropriate. Assisted reproductive techniques now offer potential fertility to non-mosaic Klinefelter syndrome patients.

46,XX Males

The condition of 46,XX maleness, which occurs in 1 of every 20,000 males, may be closely related to that of Klinefelter syndrome. Historically, the genetic analysis of subjects with sex reversal who had a phenotypic sex different from that anticipated based on karyotype was crucial for identification of the *SRY* gene.

XX maleness, first recognized by de la Chappelle and coworkers in 1964, is characterized by testicular development in subjects who have two X chromosomes and lack a normal Y chromosome. Most of these subjects have normal male external genitalia, but 10% have hypospadias and all are infertile. Among infertile adults, 2% have XX maleness (Van Dyke et al, 1991).

Two categories of patients with XX maleness have been identified: the 90% who are *SRY* positive and those who are *SRY* negative (Ergun-Longmire et al, 2005). The *SRY*-positive group rarely have genital abnormalities, but they have phenotypic features of Klinefelter syndrome, including hypogonadism, gynecomastia, azoospermia, and hyalinization of seminiferous tubules with altered hormonal levels at puberty (low testosterone, increased follicle-stimulating hormone [FSH] and LH) (Fechner et al, 1993). Often, the diagnosis is made in a pubertal male who presents for evaluation of gynecomastia. **These patients differ from those with Klinefelter syndrome in that they are shorter (mean height, 168 cm) and have normal skeletal proportions.** The 10% of XX males with no detectable *SRY* more commonly have genital ambiguity.

Three mechanisms have been proposed to explain XX sex reversal. **The most common is translocation of Y chromosomal material, including *SRY,* to the X chromosome**. Clearly, this can be proven in the majority of patients. Alternatively, sex reversal could result either from the mutation of an autosomal or X chromosomal gene, permitting testicular differentiation downstream from *SRY,* or from undetected mosaicism with a Y-bearing cell line. Clinical studies have demonstrated XX sex reversal to be a genetically and phenotypically heterogeneous condition (Fechner et al, 1993).

Treatment of XX maleness is similar to that for Klinefelter syndrome. Androgen replacement benefits selected patients, and reduction mammoplasty may be beneficial. It is likely that these patients will also be at increased risk for breast carcinoma and testis tumor. Because of their lack of germ cell elements, those classic patients presenting with infertility would not benefit from testicular biopsy for potential intracytoplasmic sperm injection.

Syndromes of Gonadal Dysgenesis

Turner Syndrome. In 1938, Henry Turner described the combination of sexual infantilism, webbed neck, and cubitus valgus (increased carrying angle at the elbows) as a distinct entity. Subsequently, gonadal dysgenesis was recognized as part of this syndrome (Hall and Gilchrist, 1990). It was not until 1959 that Ford recognized that one missing X chromosome was the etiologic basis for the syndrome. Subsequent chromosomal studies showed that **Turner syndrome is characterized by the presence of only one normally functioning X chromosome.** The other sex chromosome may be absent or abnormal, or mosaicism may be present.

Turner syndrome, with a 45,X karyotype, is associated with four classic features: female phenotype, short stature, lack of secondary sexual characteristics, and a variety of somatic abnormalities. But the clinical features of Turner syndrome are quite variable, and almost any combination of physical features may be seen with any X chromosomal abnormality. The severity of phenotypic features does not necessarily correlate with karyotypic findings. The diagnosis of Turner syndrome should be considered in any infant with lymphedema or any young woman with short stature or primary amenorrhea. Deletions in the short stature homeobox gene *(SHOX)* located on the pseudoautosomal region of the X and Y chromosomes have

been suggested as the basis for the short stature in this syndrome.

Turner syndrome has an incidence of 1 in 2500 live births. Half of the patients have a 45,X karyotype in all cells; this is believed to be secondary to loss of an X chromosome through nondisjunction in gametogenesis or an error in mitosis. From 12% to 20% of patients with Turner syndrome have an isochrome X (duplication of one arm of the X chromosome with loss of the other arm). Mosaicism—the presence of two or more chromosomally different cell lines—occurs in 30% to 40% of these patients, the majority (10% to 15%) being 45,X/46,XX and 2% to 5% being 45,X/46,XY (Zinn et al, 1993). **The presence of Y chromosomal material is of critical importance in patients with Turner syndrome because it predisposes them to potential masculinization and gonadoblastoma.**

Turner syndrome may be diagnosed prenatally on the basis of a variety of ultrasound findings (increased nuchal translucency, lymphedema, cystic hygroma, coarctation of the aorta, renal anomalies) or by abnormal results of fetal karyotyping. Affected fetuses often abort spontaneously. Whereas a 45,X fetus identified prenatally has a prognosis similar to that of a child with Turner syndrome diagnosed postnatally, approximately 90% of fetuses in whom a 45,X/46,XX or 45,X/46,XY karyotype is incidentally diagnosed prenatally will have a normal female or male phenotype at birth. This so-called ascertainment bias in Turner syndrome has profound implications for prenatal counseling.

It is postulated that in Turner syndrome follicular cells that normally surround the germ cells and provide a protective mantle for the oocytes are inadequate (Stanhope et al, 1992). As a result, the rate of attrition of oocytes due to apoptosis is so rapid that by birth few or no oocytes remain in the **ovaries, which become streaks** (Epstein, 1990). Typically, these streaks are white, fibrous structures, 2 to 3 cm long and approximately 0.5 cm wide, located in the broad ligament. Histologically, the streak possesses interlacing waves of dense fibrous stroma that is devoid of oocytes but is otherwise indistinguishable from normal ovarian stroma. Both estrogen and androgen are decreased, and levels of FSH and LH are increased. Secondary sexual development does not occur in the majority of patients. Pubic and axillary hair fails to develop in normal abundance, and the well-differentiated external genitalia, vagina and müllerian derivatives, and breasts remain small (Saenger, 1996). Turner syndrome is a common cause of primary amenorrhea, and the diagnosis is frequently made because pubertal development never occurs. Spontaneous pubertal development may occur in up to 30% of Turner syndrome patients, however.

The associated congenital anomalies that are thought typical in Turner syndrome include short stature, broad chest, widespread nipples, webbing of the neck, peripheral edema at birth, short fourth metacarpal, hypoplastic nails, multiple pigmented nevi, coarctation of the aorta, bicuspid aortic valve, and renal anomalies (Fig. 133–12). The majority of the associated congenital anomalies can be explained by the presence of lymphedema at critical points in development, leading to an imbalance in growth forces. This may be secondary to failed opening of embryonic lymphatic channels (Zinn et al, 1993).

Of paramount importance in the assessment of the patient with Turner syndrome is identification of Y chromosomal material or 45,X/46,XY mosaicism, whose detection has been enhanced by use of the polymerase chain reaction (PCR) (Bianco et al, 2006). **In patients with occult Y chromosomal material, the risk of gonadoblastoma, an in-situ germ cell cancer, is 12% and is being further defined** (Schoemaker et al, 2008). Gonadoblastoma is associated with dysgerminoma or other germ cell neoplasms in 50% to 60% of cases, sometimes associated with virilization. **Because the age of occurrence of gonadoblastoma is variable and has been reported as early as age 26 months** (Peters, personal communication, 2005), **timely prophylactic excision of the streak gonads in the Y mosaic Turner syndrome patient is advised.** This may be well performed laparoscopically. Streak gonads confirmed to be in 45,XO patients need not be removed. In the recent British national cohort study there was also an increased risk of bladder cancer in Turner syndrome patients followed into adulthood (Schoemaker et al, 2008).

Figure 133–12. Patient with Turner syndrome exhibiting short stature, low-set ears, webbed neck, shield chest, and widely spaced, hypoplastic nipples. (From Diamond D. Intersex disorders: I and II. AUA Update Series, vol. IX, lessons 9 and 10. Houston: American Urological Association Office of Education; 1990.)

Between 33% and 60% of patients with Turner syndrome have structural or positional abnormalities of the kidney; this occurs most frequently in the classic 45,XO karyotype (Hall and Gilchrist, 1990). **Horseshoe kidney accounts for 10%, duplication or renal agenesis for 20%, and malrotation for 15% of these abnormalities.** Multiple renal arteries have been noted in 90% of patients with Turner syndrome as a result of their cardiovascular evaluation (Hall and Gilchrist, 1990).

The contemporary treatment of patients with Turner syndrome has undergone considerable advances. In the neonate, it entails a concerted search for occult Y chromosomal material, including fluorescent in-situ hybridization (FISH) or polymerase chain reaction (PCR) and, subsequently, prophylactic gonadectomy if necessary, as well as ultrasound screening for renal and cardiac abnormalities. **In the child, human growth hormone has successfully been employed** to achieve increased adult height (Pasquino, 2004). At an appropriate age, typically between 12

and 15 years, exogenous hormonal therapy to induce puberty and then to maintain a normal female endocrine status is begun. An improved understanding of the long-term medical management of these patients, including cardiac surveillance and management of glucose intolerance and osteoporosis, has also resulted in considerable progress. **Finally, with the remarkable advances in assisted reproductive technology, pregnancy is a realistic possibility for patients with Turner syndrome, although spontaneous fertility is rare** (Sybert and McCauley, 2004). A spectrum of potential gonadal function has been noted in large series of patients with Turner syndrome (Kaneko et al, 1990). In one series, nonstreak gonads were reported in one third of such patients and were more commonly noted in girls with loss of only the short arm of the X chromosome. In 2% to 5% of Turner patients, spontaneous menses will occur with a potential to achieve pregnancy independently (Saenger et al, 2001). This appears most likely in women with mosaicism for a normal 46,XX cell line, a 47,XXX cell line, or distal Xp deletion. To date, more than 160 pregnancies have been reported among spontaneously menstruating Turner syndrome patients. For the vast majority with true streak gonads, for whom egg donor implantation is used, 40% to 50% pregnancy rates have been reported by centers specializing in in-vitro fertilization (Saenger, 1993). However, among these rare pregnancies, the rates of miscarriage, stillbirth, and malformed infants is high (Abir et al, 2001). A recent area of interest has been the laparoscopic retrieval of follicles in girls with Turner syndrome for cryopreservation (Hreinsson et al, 2002). The technique is regarded as experimental and not yet recommended for clinical use. One concern relates to confirmation of normalcy of the harvested oocytes.

It is of great interest that neuroanatomic imaging studies of 45,XO Turner syndrome patients have demonstrated differences in parietal and temporal lobe anatomy and posterior fossa morphology that appear to correlate with certain established neurophysiologic and cognitive deficits (Brown et al, 2004; Rae et al, 2004).

Key Point: Turner Syndrome

- In patients with Turner syndrome and occult Y chromosomal material, the risk of gonadoblastoma, an in-situ germ cell cancer, is 12% and is being further defined.

46,XX "Pure" Gonadal Dysgenesis. Patients with 46,XX "pure" gonadal dysgenesis are closely related to those with Turner syndrome. **They are characterized by normal female external genitalia, normal müllerian ducts with absence of wolffian duct structures, a normal height, bilateral streak gonads, sexual infantilism, and a normal 46,XX karyotype.** The streak gonads result in elevated serum gonadotropins. **Because these subjects exhibit none of the somatic stigmata associated with Turner syndrome and their condition entails gonadal dysgenesis only, it has been regarded by some authors as "pure."**

A familial incidence of 46,XX gonadal dysgenesis has been reported as an autosomal recessive trait (Espiner et al, 1970). This suggests the possibility that autosomal genes in addition to genes on the X chromosome may be involved in ovarian maintenance.

Management of patients with 46,XX "pure" gonadal dysgenesis entails proper cyclic hormone replacement with estrogen and progesterone. In contrast to Turner syndrome, growth is not abnormal with this condition, and therefore growth hormone should not be required. Because, by definition, these patients have no Y chromosomal material, gonadectomy is not required.

Mixed Gonadal Dysgenesis. The term *mixed gonadal dysgenesis* was coined by Sohval in 1963. In 1975, Zah and associates reported on their series of more than 100 patients with 45,X/46,XY karyotypes, 72 of whom had mixed gonadal dysgenesis with a streak gonad on one side and a testis on the other.

Mixed gonadal dysgenesis is characterized by a unilateral testis, which is often intra-abdominal, a contralateral streak gonad, and persistent müllerian structures associated with varying degrees of inadequate masculinization. Most patients with mixed gonadal dysgenesis have a 45,XO/46,XY karyotype, which is probably the result of anaphase lag during mitosis. The 45,X/46,XY mosaicism is the most common form of mosaicism involving the Y chromosome.

The phenotypic spectrum of patients with XO/XY mosaicism extends from phenotypic females with Turner syndrome (25%), to those with ambiguous genitalia, to, rarely, those appearing as normal males (Berkovitz et al, 1991). **In the neonatal period, mixed gonadal dysgenesis is the second most common cause of ambiguous genitalia (after CAH) and must be in the differential diagnosis.** The majority of these patients present with varying degrees of phallic development, a urogenital sinus with labioscrotal fusion, and an undescended testis. In virtually all of these patients, a uterus, vagina, and fallopian tube are present. Short stature and associated somatic stigmata are variable features.

Key Point: Mixed Gonadal Dysgenesis

- In the newborn period, mixed gonadal dysgenesis is the second most common cause of ambiguous genitalia (after CAH) and must be in the differential diagnosis.

The phenotypic asymmetry of the internal ducts epitomizes the mechanism of local testosterone and MIS production on müllerian and wolffian duct regression and development. In the series of Mendez and colleagues (1993) comprising 16 patients, all had a fallopian tube accompanied by a streak gonad, consistent with absent MIS. **Therefore, whereas a dysgenetic or streak gonad is associated with ipsilateral müllerian derivatives (uterus, fallopian tube)** (Fig. 133–13), **a well-differentiated testis with functional Sertoli and Leydig cells will have ipsilateral wolffian but no müllerian ducts** (Davidoff and Federman, 1973). In addition, the presence of severe external genital ambiguity in many of these patients suggests that testosterone production in utero was inadequate to promote complete differentiation of the external genitalia. Paradoxically, the dysgenetic testis is capable of responding to gonadotropins and secreting testosterone in normal quantities at puberty. Yet, despite normal postpubertal endocrine function, it is postulated that fetal testicular endocrine function is either delayed or deficient. Histologically, the testes lack germinal elements, so infertility is the rule.

The risk of developing a gonadal tumor (gonadoblastoma, dysgerminoma) is increased in mixed gonadal dysgenesis, with

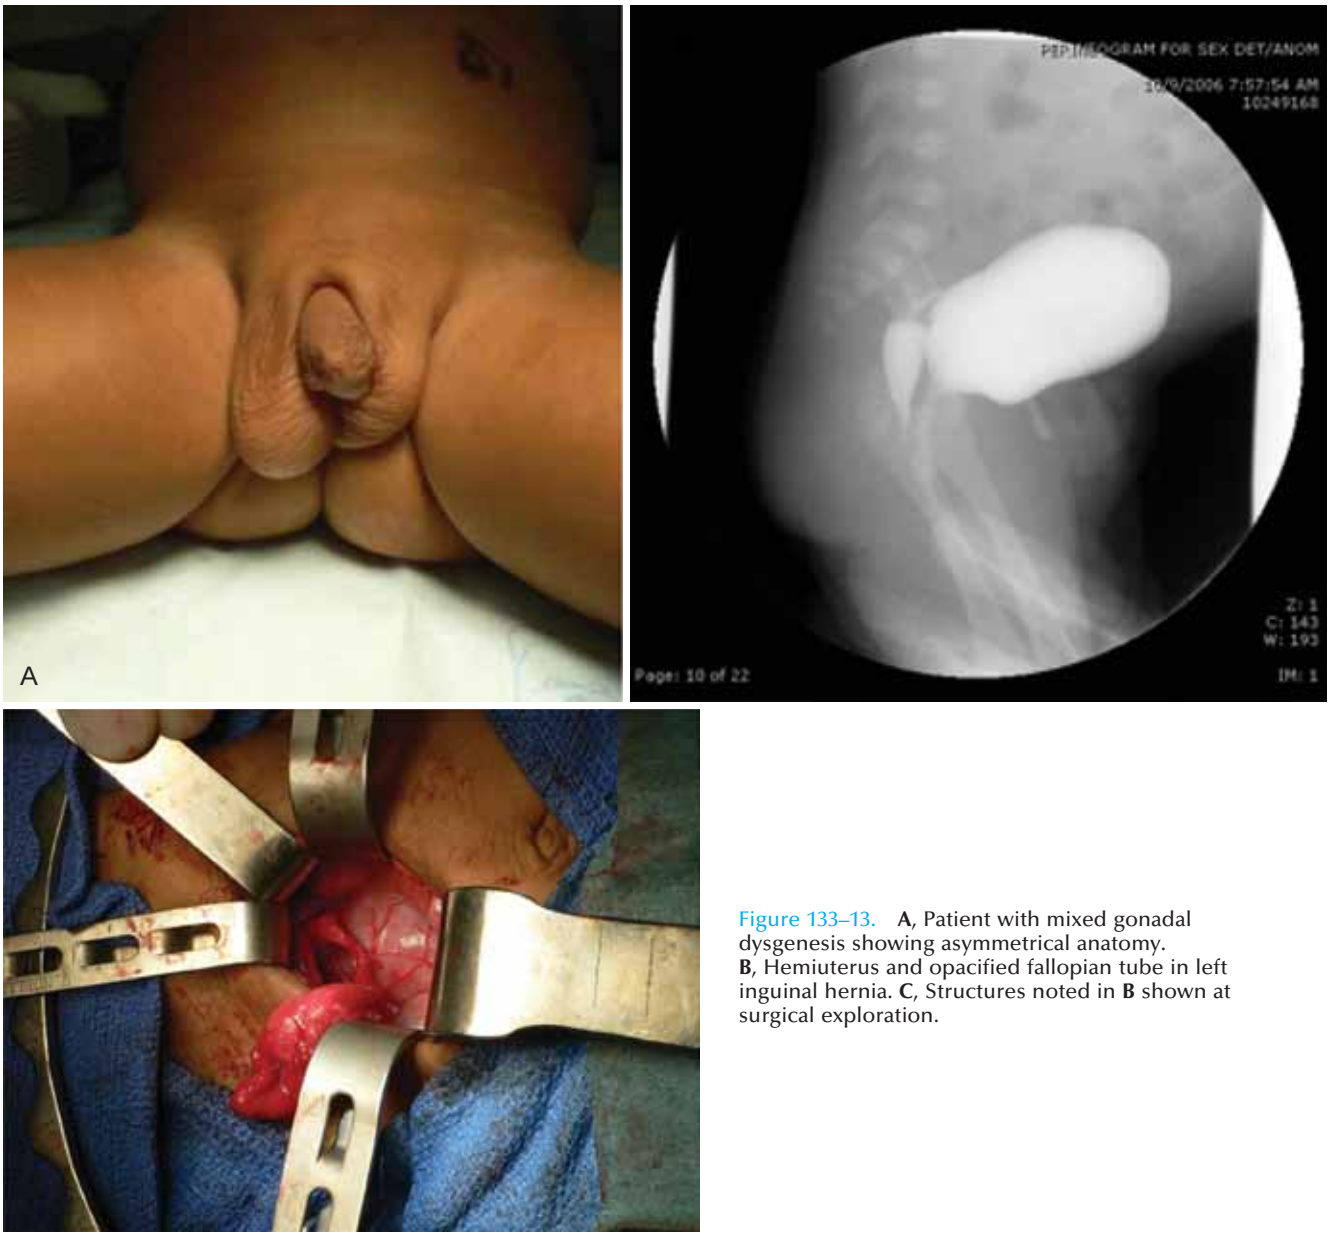

Figure 133–13. **A**, Patient with mixed gonadal dysgenesis showing asymmetrical anatomy. **B**, Hemiuterus and opacified fallopian tube in left inguinal hernia. **C**, Structures noted in **B** shown at surgical exploration.

an estimated incidence of 15% to 35% (Robboy et al, 1982; Wallace and Levin, 1990). Gonadoblastoma, a tumor of low malignant potential, is the most common. It was so named because it recapitulates gonadal development more completely than any other tumor (Scully, 1970). **Although germ cell tumors occur both in the dysgenetic testes and in the streak gonads of individuals with 46,X/46,XY mosaicism, the risk of tumor is higher in the former** (Verp and Simpson, 1987).

Patients with mixed gonadal dysgenesis are also at increased risk for Wilms tumor. Rajfer (1981) reported that 50% of 10 patients with an intersex disorder and Wilms tumor had mixed gonadal dysgenesis. He postulated that there was a genetic or teratogenetic defect involving the urogenital ridge, the common embryonic anlage of both kidney and gonad. This concept was borne out by improved understanding of the Denys-Drash syndrome, now clearly associated with mutations in the Wilms tumor suppressor gene *(WT1)*. In 1967, Denys and colleagues described a child with XX/XY mosaicism, nephropathy, genital abnormalities, and Wilms tumor. Drash and coworkers (1970) reported two further examples in 1970. **The full triad of the syndrome includes nephropathy, characterized by the early onset of proteinuria and hypertension, and progressive renal failure in most of the patients.** Renal histology demonstrates diffuse focal mesangial sclerosis. **Because incomplete forms of the syndrome may occur, the nephropathy has become regarded as the common denominator of the syndrome** (Habib et al, 1985). Wilms tumor may be diagnosed before, after, or simultaneously with presentation with nephropathy. The majority of the tumors are of favorable triphasic histology (Beckwith and Palmer, 1978). However, there is a high incidence of bilateral Wilms tumor in this syndrome. The genital abnormalities include frank ambiguity, hypospadias, and cryptorchidism. **A large number of patients with Denys-Drash syndrome have been noted to have mixed gonadal dysgenesis.** These have an increased risk of gonadal tumor of 40% (Table 133–3) (Lee et al, 2006). A relatively new and consistent finding with Denys-Drash

syndrome is that of caliceal blunting without obstruction (Jadresic et al, 1990). The high mortality rate associated with this syndrome has prompted an aggressive treatment approach with prophylactic bilateral nephrectomy in an attempt to improve the prognosis for these children (Jadresic et al, 1990).

Frasier syndrome, a related disorder due to mutations in the alternative splice donor site of exon 9 on *WT1,* presents in similar fashion to Denys-Drash syndrome but with certain important distinctions (Klamt et al, 1998). The nephropathy caused by focal segmental glomerulosclerosis occurs later in life with a more gradual progression to renal failure (Koziell et al, 1999). There is no known predisposition to Wilms tumor. Gonadoblastomas in 46,XY individuals are far more common in Frasier syndrome than in Denys-Drash syndrome with a gonadal tumor risk of 60% (see Table 133–3). Because 46,XX individuals with Frasier syndrome have normal gonadal development, they would present with renal failure. But, it is presumed that many such 46,XX individuals go undiagnosed. Frasier syndrome should be considered for girls presenting with steroid-resistant nephrotic syndrome, primary amenorrhea, and pubertal delay (Gwin et al, 2008).

The management of mixed gonadal dysgenesis entails gender assignment, appropriate gonadectomy, and proper screening for Wilms tumor. If the diagnosis is made in the neonatal period, the decision regarding sex of rearing should be based on the potential for normal function of the external genitalia and gonads. Historically, two thirds of patients with mixed gonadal dysgenesis have been raised as female. Potential fertility is not a significant issue in this disorder, and therefore the anatomy of the reproductive tract may direct the decision making. The likelihood of significant androgen imprinting is greater in association with a better-masculinized phenotype, and this may serve as the best clinical guide. For patients with Turner syndrome stigmata and growth below the fifth percentile, growth hormone therapy may be appropriate. If the male gender is elected and the testis can be brought to the scrotum, the decision between careful screening for gonadoblastoma (with physical examination and ultrasonography) versus prophylactic gonadectomy and androgen replacement must be made.

Table 133–3.

Risk of Germ Cell Malignancy According to Diagnosis

RISK GROUP	DISORDER	MALIGNANCY RISK, %
High	GD*(+Y)† intra-abdominal	15-35
	PAIS nonscrotal	50
	Frasier	60
	Denys-Drash (+Y)	40
Intermediate	Turner (+Y)	12
	17β-hydroxysteroid	28
	GD (+Y)† scrotal	Unknown
	PAIS scrotal gonad	Unknown
Low	CAIS	2
	Ovotesticular DSD	3
	Turner (-Y)	1

*Gonadal dysgenesis (including not further specified, 46,XY, 46,X/46,XY, mixed, partial, and complete).

†GBY region positive, including the TSPY (testis-specific protein Y encoded) gene.

CAIS, complete androgen insensitivity syndrome; PAIS, partial androgen insensitivity syndrome.

From Lee PA, Houk CP, Ahmed F, et al. Consensus statement on management of intersex disorders. Pediatrics 2006;118:e488–e500.

The expanded use of prenatal diagnosis has changed the understanding of 45,X/46,XY mosaicism. Studies have shown that 90% to 95% of all infants with 45,X/46,XY mosaicism have normal-appearing male genitalia (Hsu, 1989). Approximately 25% have abnormal gonadal histology (Chang et al, 1990). Because only a small proportion of those with dysgenetic gonads actually have ambiguous genitalia, the possibility exists that some males with gonadal dysfunction have 45,X/46,XY mosaicism.

Partial Gonadal Dysgenesis (Dysgenetic Male Pseudohermaphroditism). In 1967, Federman coined the term *dysgenetic male pseudohermaphroditism,* which is **a condition closely related to mixed gonadal dysgenesis in that patients with abnormal sex differentiation have two dysgenetic testes rather than one dysgenetic testis and a streak gonad.** Others have applied the term *partial gonadal dysgenesis* to this condition, to distinguish it from mixed and complete forms of gonadal dysgenesis. As with mixed gonadal dysgenesis, these individuals typically have a 45,X/46,XY or 46,XY karyotype. They may present with a spectrum of external genital abnormalities, depending on the capability of the dysgenetic gonads to produce testosterone. Similarly, persistent müllerian structures are typically present, but to varying degrees depending on MIS secretion by the dysgenetic gonads.

On histology, the dysgenetic testis is found to be composed of immature hypoplastic seminiferous tubules and persistent stroma resembling that seen in the streak gonad.

Patients with partial gonadal dysgenesis (dysgenetic male pseudohermaphroditism) are at increased risk for gonadal malignancy. Manuel and colleagues (1976) reported that the incidence of gonadoblastoma or dysgerminoma was 46% by age 40 years. These patients are also at risk for Denys-Drash syndrome (Borer et al, 1995).

The management of partial gonadal dysgenesis (dysgenetic male pseudohermaphroditism), in terms of gender assignment and surveillance for malignancy, is similar to that for patients with mixed gonadal dysgenesis.

46,XY Complete (Pure) Gonadal Dysgenesis (Swyer Syndrome). Just as 46,XX males were of great importance in discovery of the TDF, so too have been the 46,XY females. **Patients with 46,XY complete gonadal dysgenesis are characterized by normal female genitalia, well-developed müllerian structures, bilateral streak gonads, and a nonmosaic karyotype.** Because there is complete absence of testicular determination in this condition, ambiguity of genitalia is not an issue but sexual infantilism is the primary clinical problem.

The etiology of 46,XY complete gonadal dysgenesis may well be an abnormality of the *SRY* gene that eliminates SRY function, or loss of another gene downstream from *SRY* that is necessary for SRY protein action. In either case, the absence of testicular determination would permit ovarian differentiation. To date, mutations in the *SRY* gene are the cause of 46,XY complete gonadal dysgenesis in 10% to 15% of cases. Recently, a mutation in the Desert hedgehog *(DHH)* gene was noted in 3 of 6 patients with 46,XY complete gonadal dysgenesis, suggesting that the genetic origin of this entity is heterogeneous and the *DHH* is likely an important gene in gonadal differentiation (Canto et al, 2004). Investigation of a group of individuals with 46,XY complete gonadal dysgenesis has helped to narrow the chromosome interval containing the sex reversal gene to 9p24—a very small region (McDonald et al, 1997).

The majority of individuals with 46,XY complete gonadal dysgenesis present in their teens with delayed

Figure 133–14. **A** and **B**, External genitalia of a 15-year-old female presenting with amenorrhea and hirsutism who was diagnosed with 46,XY gonadal dysgenesis, demonstrating clitoromegaly and urogenital sinus. (Courtesy of S. Bauer, MD.)

puberty. In addition to amenorrhea, breast development is usually absent. The serum concentration of gonadotropins is abnormally elevated, which leads the clinician to the determination of karyotype and the subsequent diagnosis (Grumbach and Conte, 1998). The high concentration of serum LH in these patients is thought to be responsible for the increased androgen levels that lead to clitoromegaly in some individuals (Fig. 133–14).

The histology of the streak gonad is similar to that of Turner syndrome, with fibrous connective tissue resembling wavy ovarian stroma but without follicles. Some histologic variability has been noted, with more proliferative-appearing stroma in some and, rarely, preservation of intact primordial follicles. This variability in ovarian histology is thought to support the hypothesis that these gonads developed as ovaries in utero (German et al, 1978). This would resemble the process that occurs in the streak gonad of Turner syndrome.

Patients with 46,XY complete or pure gonadal dysgenesis are at significant risk for germ cell tumors. There appears to be up to a 35% risk of tumor development by age 30 years (Manuel et al, 1976; see Table 133–3). Gonadoblastoma is most common, and it is frequently bilateral (Fig. 133–15). Other tumors that may arise in this patient population include embryonal carcinoma, endodermal sinus tumor, choriocarcinoma, and immature teratoma. These more highly malignant tumors occur in fewer than 10% of patients with 46,XY complete gonadal dysgenesis (Scully, 1981).

Management of 46,XY complete gonadal dysgenesis entails removal of both streak gonads and proper cyclic hormone replacement with estrogen and progesterone.

Encapsulated nests of gonadoblastoma comprise small sex cord–type cells arranged around rounded spaces of amorphous eosinophilic material and interspersed germ cells. (Courtesy of S. Bauer, MD.)

Embryonic Testicular Regression and Bilateral Vanishing Testes Syndromes

The syndromes of embryonic testicular regression and bilateral vanishing testes are characterized by **patients with a 46,XY karyotype and absent testes in whom there is clear evidence of testicular function at some point during embryogenesis.** The syndrome entails the presence of testes that "vanish" during embryogenesis and is distinguished from pure gonadal dysgenesis, in which there is no evidence of testicular function in utero.

These syndromes have been regarded as synonymous by some authors. Other authors, including Migeon and colleagues (1994), have suggested a rational stratification whereby "embryonic testicular regression" refers to loss of testicular tissue within the first trimester and is associated with ambiguity of external genitalia, whereas "bilateral vanishing testes syndrome" refers to individuals in whom male sexual differentiation of ducts and genitalia took place but loss of testicular tissue occurred subsequently in utero.

The etiology of these disorders remains unclear. **It is possible that regression of the testes in utero is caused by a genetic mutation, a teratogen, or bilateral torsion.** A genetic cause is supported by the finding of familial instances of XY agonadism that might be consistent with the rare recessive trait. Marcantonio and associates (1994) suggested the possibility that embryonic testicular regression represents a variant of 46,XY gonadal dysgenesis. They noted a group of patients with absent testes but evidence of incongruity between the extent of Leydig cell and Sertoli cell function, suggesting that gonadal tissue in these subjects was intrinsically abnormal before the testicular regression occurred. The occurrence of embryonic testicular regression in several subjects from one family in their series suggested a genetic basis for the condition, and the pattern of inheritance implicated the involvement of an X chromosome gene. In another group of patients, these authors noted multiple congenital anomalies, suggesting either a mutation in a single gene that functions in several developmental pathways or a defect of multiple genes that might be the result of a large chromosomal deletion. Recently, a heterozygous mutation in SF1 has been noted in a series of patients with bilateral vanishing testes syndrome with micropenis (Philibert et al, 2007).

Clinically, these two syndromes represent a spectrum of phenotypes ranging in severity from complete female, to varying degrees of genital ambiguity in the embryonic testicular regression syndrome, to a normal male phenotype with microphallus and empty scrotum in the bilateral vanishing testes syndrome (Edman et al, 1977). **The diagnosis can be made on the basis of a 46,XY karyotype and castrate levels of testosterone despite persistently elevated serum LH and FSH** (Jarow et al, 1986). In the most severe form of embryonic testicular regression syndrome, agonadism is discovered in a 46,XY phenotypic female with no internal genital structures. This picture is presumed to result when the testis has elaborated MIS but vanishes at approximately day 60 to 70 of gestation, before the elaboration of androgen. Due to the absence of gonadal androgens later in fetal development and transient expression of MIS, the individual goes on to develop a sexually infantile female phenotype but lacks any internal ductal structures. At an intermediate point in the clinical spectrum is the 46,XY patient with absent gonads and internal ductal structures but with ambiguous genitalia owing to incomplete elaboration of androgen by the vanishing testes. Finally, in bilateral vanishing testes syndrome, patients may present as agonadal XY phenotypic males with fully developed wolffian structures but an empty scrotum, absent prostate, and microphallus. This represents testicular loss after complete anatomic development of the male external genitalia within the first trimester.

On surgical exploration of patients with bilateral vanishing testes syndrome, rudimentary cord structures are usually identified and biopsy of their distal ends demonstrates no recognizable testicular tissue histologically (Bergada et al, 1962). Atrophic epididymal remnants are occasionally seen.

The management of patients with embryonic testicular regression syndrome or bilateral vanishing testes syndrome is dictated by their position in the clinical spectrum of either disorder. Sexually infantile phenotypic females require estrogen supplementation at the time of expected puberty for development of secondary sexual characteristics and may require vaginal dilation or vaginoplasty. Similarly, phenotypic males require long-term androgen replacement beginning at the time of expected puberty. A study of 21 males so treated demonstrated that replacement therapy started at the correct time caused a normal pubertal growth spurt with normal secondary sex characteristics including penile growth, together with normal bone maturation (Aynsley-Green et al, 1976). In addition, these patients may benefit from placement of testicular prostheses. Patients with embryonic testicular regression syndrome and ambiguous genitalia require individualized assessment to determine the optimal gender assignment.

Ovotesticular DSD (True Hermaphroditism)

Ovotesticular DSD describes individuals who have both testicular tissue with well-developed seminiferous tubules and ovarian tissue with primordial follicles, which may take the form of one ovary and one testis or, more commonly, one or two ovotestes.

Both the external genitalia and internal duct structures of ovotesticular DSD display gradations between male and female. **In most patients the external genitalia are ambiguous but masculinized to variable degrees, and 75% are raised as male.** Among those raised as male, hypospadias and chordee occur in approximately 80%. Among those patients raised as females, two thirds have clitoromegaly. Virtually all patients have a urogenital sinus, and in most cases a uterus is present (Figs. 133–16 and 133–17). The ovary is found in a normal location, more commonly on the left side. The testis or ovotestis may reside at any point along the path of testicular descent. Testes and ovotestes are more commonly located on the right side (Blyth and Duckett, 1991; Mittwoch, 2000). Sixty percent of gonads palpable in the inguinal canal or labioscrotal folds are ovotestes, which may be clinically suspected on the basis of a difference in firmness at either end of the gonad, consistent with polar segregation of ovarian and testicular tissue (Grumbach and Conte, 1998).

Approximately 60% of ovotesticular DSDs have a 46,XX karyotype; 33% are mosaics with a second cell line containing a Y chromosome (46,XX/46,XY; 46,XX/46,XXY), and 7% are 46,XY. Chimerism (mosaicism) has been thought to result from fertilization infusion of an ovum and its polar body, fusion of two nuclei, or double fertilization. It has also been suggested that ovotesticular DSD may result from hidden mosaicism with a Y cell line. Ortenberg and colleagues (2002) demonstrated the *SRY* gene in ovotestes of all eight cases of ovotesticular DSD studied, supporting somatic mosaicism. Other studies have demonstrated heterogeneity of Y-specific DNA regions detected in patients with ovotesticular DSD

Figure 133–16. Infant with penile hypospadias, chordee, and bilaterally undescended testes who was found to have true hermaphroditism. (From Diamond D. Intersex disorders: I and II. AUA Update Series, vol. IX, lessons 9 and 10. Houston: American Urological Association Office of Education; 1990.)

Figure 133–17. Laparotomy findings from a true hermaphrodite noted in Figure 133–16; clamp is on uterus with bilateral, fimbriated fallopian tubes and bilateral ovotestes. (From Diamond D. Intersex disorders: I and II. AUA Update Series, vol. IX, lessons 9 and 10. Houston: American Urological Association Office of Education; 1990.)

(Hadjiathanasiou et al, 1994). This supports a non–Y chromosome-related mechanism responsible for 46,XX ovotesticular DSD, such as mutation in an autosomal or X-linked gene involved in sex determination. Berkovitz and colleagues (1991) suggested that 46,XY ovotesticular DSD may be a form of partial gonadal dysgenesis. According to this theory, a partial defect in testis determination results in both testicular and ovarian development. This is supported by the finding of ovarian stroma in some dysgenetic testes.

Just as the differentiation of external genitalia is variable in ovotesticular DSD, differentiation of the internal ducts is also quite variable and is related to the function of the ipsilateral gonad. Fallopian tubes are consistently present on the side of the ovary, and a vas deferens is always present adjacent to a testis (Berkovitz et al, 1991). The ovotestis, which comprises two thirds of gonads in ovotesticular DSD, is associated with a fallopian tube in two thirds of cases and with either a vas deferens only or both structures in one third of cases.

The ovarian portion of the ovotestis is frequently normal, whereas the testicular portion is typically dysgenetic. Therefore, although ovulation and pregnancy have been reported for female 46,XX ovotesticular DSDs, male fertility has not been clearly documented.

The incidence of gonadal tumors is approximately 3% in 46,XY ovotesticular DSD and rare in 46,XX ovotesticular DSD. Both gonadoblastoma and dysgerminoma have been described (Verp and Simpson, 1987).

The most important aspect of management in ovotesticular DSD is gender assignment. Sex assignment should be based on the functional potential of external genitalia, internal ducts, and gonads, according to the findings at laparoscopy or laparotomy. **Unlike patients with most other forms of gonadal dysgenesis, individuals with ovotesticular DSD have the potential for fertility if raised as female with the appropriate ductal structures.** Pregnancies have been reported in patients with ovotesticular DSD, the majority with the 46,XX karyotype (Starceski et al, 1988). If the patient is to be raised as female, all testicular and wolffian tissue should be removed. For those patients with an ovary, this is straightforward; if an ovotestis is present, surgical cleavage of the gonad with excision of the testicular portion has been performed successfully by Nihoul-Fekete and colleagues (1984). They recommend postoperative stimulation with human chorionic gonadotropin (hCG) to confirm that all testicular tissue has been removed. In some settings the cleavage plane between testicular and ovarian tissues is unclear and gonadectomy is advisable. When ovarian tissue is preserved, normal ovarian function can occur at puberty, although hormonal replacement may be necessary. Careful surveillance for potential gonadal tumors in the patient raised as female is also advisable. If a male gender is assigned, as has been most common historically, all ovarian and müllerian tissue should be removed. Consideration should be given to gonadectomy at puberty with appropriate androgen replacement in this setting, given the high risk of malignancy and unlikelihood of male fertility. At the very least, long-term gonadal surveillance ultrasound for tumor development would seem appropriate.

46,XX DSD (Masculinized Female)

46,XX DSD (masculinized female) is a disorder of phenotypic sexual development in which 46,XX individuals with ovaries have a partially masculinized phenotype and ambiguous genitalia. By far the most common cause of the masculinized female is CAH, which is the most common cause of ambiguous genitalia in the newborn. Two very rare causes of 46,XX DSD (masculinized female) are maternal ingestion of androgens and virilizing tumors in the mother.

Congenital Adrenal Hyperplasia

The adrenogenital syndrome caused by CAH is a classic example of an inborn error of metabolism—in this case, an error involving cortisol synthesis. A defect in any one of the five enzymes involved in the cortisol biosynthetic pathway (cholesterol side chain cleavage enzyme, 3β-hydroxysteroid dehydrogenase, 17-hydroxylase, 21-hydroxylase, and 11-hydroxylase) may result in CAH. **The most commonly recognized syndromes result from a deficiency of one of the terminal two enzymes of glucocorticoid synthesis (21-hydroxylase or 11-hydroxylase)** (New and Levine, 1984) (Fig. 133–18). As a result of deficiency of either terminal enzyme, formation of hydrocortisone is impaired, causing a compensatory increase in the

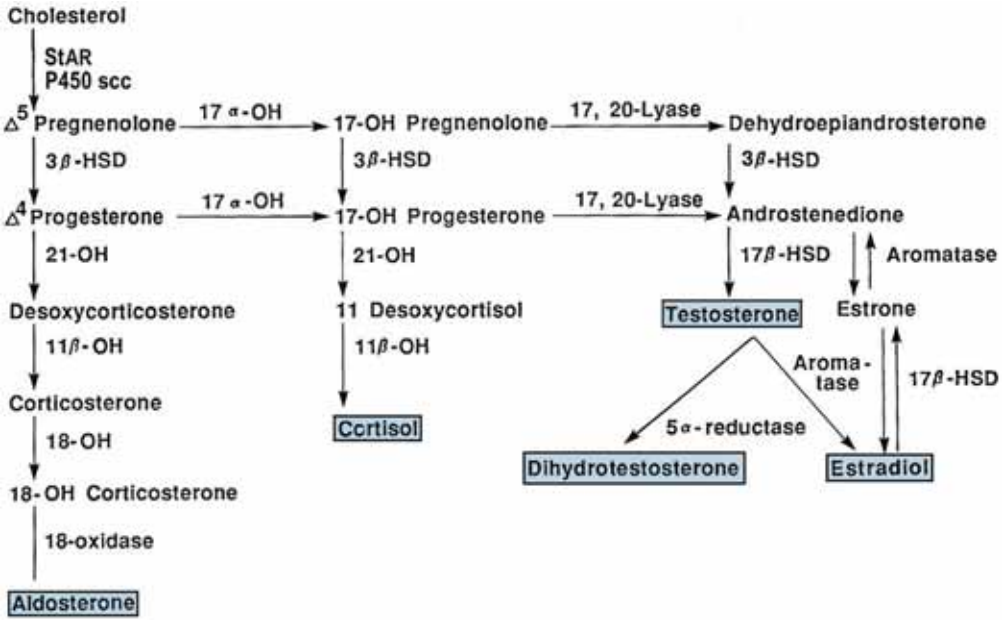

Figure 133–18. Steroid biosynthetic pathway for mineralocorticoid, glucocorticoid, and sex steroid hormone production.

secretion of adrenocorticotrophic hormone (ACTH). This increase enhances formation of adrenal steroids proximal to the enzymatic defect and a secondary increase in the formation of testosterone, the active androgen in CAH.

Key Point: Congenital Adrenal Hyperplasia

- The most commonly recognized syndromes of CAH result from a deficiency of one of the terminal two enzymes of glucocorticoid synthesis (21-hydroxylase or 11-hydroxylase).

A deficiency of steroid 21-hydroxylase is responsible for 95% of cases of CAH; it occurs with an incidence ranging from 1 in 5000 to 1 in 15,000 in the United States and Europe. The highest incidence, 1 in 490, is reported in the Yupik Alaskan Eskimo population (New et al, 1994). **Clinically, patients are divided into three categories: (1) salt wasters (patients with virilization and aldosterone deficiency), (2) simple virilizers (patients with virilization, but without salt wasting), and (3) nonclassic patients (those without evidence of virilization or salt wasting).** Dramatic progress has been made in understanding the molecular basis of CAH, and 95% of the mutations that account for CAH have been identified. The wide clinical spectrum of the disease appears to represent different degrees of enzymatic compromise conferred by specific, identifiable genetic defects.

The 21-hydroxylase gene *(CYP21A2)* is located on chromosome 6p21.3 within the major human leukocyte antigen (HLA) complex and is transmitted in an autosomal recessive pattern (Wilson et al, 1995). Adjacent to the *CYP21A2* gene, separated by 30 kb, and adjacent to and alternating with *C4B* and *C4A* genes encoding the fourth component of serum complement is the CYP21 pseudogene *(CYP21PA1),* so called because it encodes no proteins and is therefore inactive (Tusie-Luna and White, 1995). The inactive *CYP21PA1* is 98% homologous to the active gene *CYP21A2*. During meiosis, a gene conversion may occur that transfers segments from the *CYP21PA1* gene to the *CYP21A2* gene, rendering it inactive. Thus far, all mutations causing 21-hydroxylase deficiency appear to result from either a complete deletion of the genes *C4B* and *CYP21B* (a product of misalignment and unequal crossing-over between chromatids during meiosis). To date approximately 15 mutations constitute 90% to 95% of alleles and are derived from intergenic recombination of DNA sequences between the *CYP21A2* gene and the highly homologous *CYP21PA1*, whereas the remaining are spontaneous mutations (Forest, 2004). Approximately 100 different *CYP21* mutations have been reported.

The majority of patients with CAH secondary to 21-hydroxylase deficiency exhibit one of the two classic forms of the disease: **75% present with salt wasting and 25% with simple virilization** (Kohn et al, 1995). The higher proportion of patients with the salt-wasting form of the disease recognized in more recent series has been attributed to improved diagnostic capabilities and a high level of clinical suspicion as well as to increased survival owing to the prenatal screening and proper mineralocorticoid supplementation (Fife and Rappaport, 1983). Neonatal screening programs for CAH have been credited with increasing the rate and shortening the time to diagnosis, particularly in males with the salt-wasting form of the disease. This has also proven to be an important means of diagnosing the simple virilizing form in the male and the nonclassic forms in some males and females (Brosnan et al, 1999).

In the female with the classic salt-wasting and simple virilizing forms of the disorder, a masculinized female results. Because impaired steroidogenesis begins early in life—at the time of formation of the external genitalia (beginning at 10 weeks' gestation)—there is virtually always evidence of some degree of masculinization at birth. This is manifested by enlargement of the clitoris and varying degrees of labial fusion (Fig. 133–19). In addition, the vagina and urethra open into a common urogenital sinus. The enlargement of the clitoris may be so dramatic as to make it appear to be a hypospadiac penis with bilateral cryptorchidism or, rarely, a fully masculinized urethra to the tip of an apparent glans penis (Fig. 133–20). The severity of the virilization is usually greater in

infants who experience salt wasting but not uniformly so. Prader (1958) classified the degrees of virilization of external genitalia in females with CAH (Fig. 133–21). The müllerian structures in these patients are typically normal. A recent study suggests an increased incidence (Nabhan and Eugster, 2007) of upper tract abnormalities (hydronephrosis, duplication) in CAH.

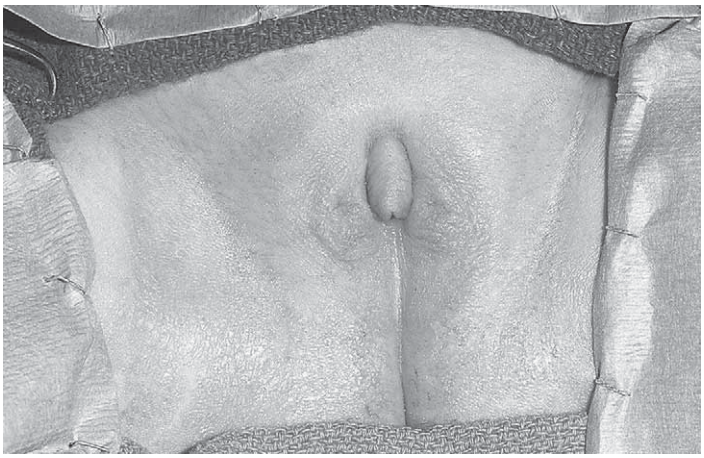

Figure 133–19. External genitalia of a patient with congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency, showing labioscrotal fusion and clitoromegaly.

Figure 133–20. Prader V patient with congenital adrenal hyperplasia secondary to 21-hydroxylase deficiency demonstrating complete virilization of phallus.

In both males and females with the salt-losing variant of CAH, symptoms begin within the first few weeks after birth, with failure to regain birth weight, progressive weight loss, and dehydration. In severely affected infants, adrenal crises occur within the first 10 to 21 days of life (Grumbach and Conte, 1998). **Vomiting is prominent and can be so extreme that a mistaken diagnosis of pyloric stenosis is made, particularly in the male.** Without therapy, death may rapidly ensue from hyperkalemia, dehydration, and shock. In the male infant, in particular, the classic fluid and electrolyte abnormalities of CAH may be mimicked by urosepsis secondary to reflux or obstructive uropathy, which should be ruled out (Mastrandrea et al, 2005). After birth there is progression of masculinization of the untreated female; pubic and axillary hair develop prematurely, acne appears, and the voice deepens. There is rapid somatic maturation, resulting in premature epiphyseal closure and short adult stature. Although the internal genitalia are female, breast development and menstruation do not occur unless the excessive androgen production is suppressed by adequate steroid therapy.

In the male without salt wasting the chief clinical manifestations are those of isosexual precocity. The infant appears normal at birth, but signs of sexual and somatic precocity appear within the first 2 to 3 years of life. Although the testes remain normal in size, enlargement of the penis, scrotum, and prostate occur, accompanied by the appearance of pubic hair, acne, and deepening of the voice. The musculature is well developed (prompting the descriptive term "little Hercules"), and bone age is more advanced than appropriate for the chronologic age. The syndrome often goes unrecognized in the non–salt-wasting male until signs of androgen excess, such as accelerated height and precocious pubic hair, appear later in childhood.

In the non–salt-wasting male, two major long-term implications are short stature as well as infertility in 20% to 40%. Premature epiphyseal closure will result unless early medical control is instituted. This emphasizes the value of neonatal screening. Infertility has been noted in 30% of CAH males, often related to the finding of adrenal rest nodules most reliably diagnosed with scrotal ultrasonography. These nodules, present in 25% to 30% of males with CAH, represent hypertrophy of adrenal rests due to ACTH stimulation and when associated with impaired fertility warrant periodic scrotal ultrasonography, intensified glucocorticord suppression, and possibly testis-sparing excision (Claahsen-van der Grinten et al, 2008). Some advocate sperm cryopreservation in postpubertal males with adrenal rest tumors. In addition, poor control of the disease in boys with classic CAH has been associated with small testes and infertility with reduced sperm counts (New and Wilson, 1999). This is due to peripheral aromatization of

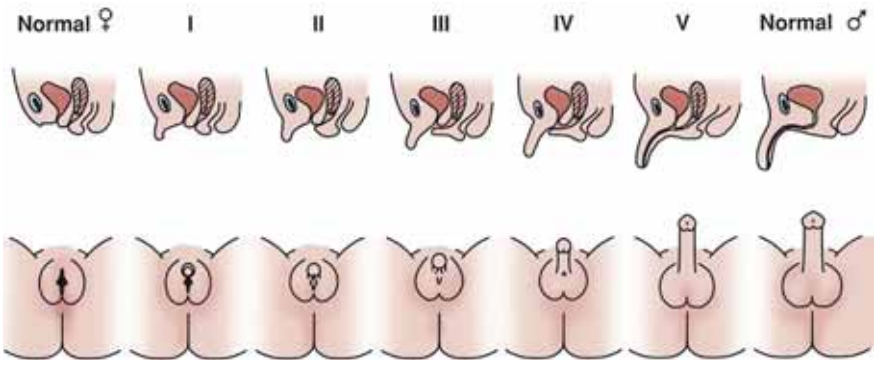

Figure 133–21. Classification by Prader of the various degrees of masculinization of the external genitalia in females with congenital adrenal hyperplasia that has been applied by some authors to intersexual states in general. (From Prader A. Die Haufigkeit der kongenitalen androgenitalen Syndroms. Helv Pediatr Acta 1958;13:426.)

excess androgen to estrogen that suppresses pituitary gonadotropins.

In classic 21-hydroxylase deficiency, plasma levels of progesterone and 17-hydroxyprogesterone are markedly elevated. Urinary levels of 17-ketosteroids and pregnanetriol are elevated. **The diagnosis may be made biochemically with the use of radioimmunoassay of plasma 17-hydroxyprogesterone,** which has replaced the more cumbersome 24-hour urine collection of metabolites (e.g., pregnanetriol). **A pelvic ultrasound study demonstrating the presence of müllerian tissues is confirmatory.** Some investigators have suggested that the finding of abnormally enlarged or "cerebriform"-appearing adrenal glands on neonatal ultrasonography, available before biochemical results, may represent the earliest diagnostic tool for CAH (Hernanz-Schulman et al, 2002).

More aggressive screening for 21-hydroxylase deficiency has provided considerable benefits. In one series, despite sexual ambiguity, one third to one half of the affected female newborns were not diagnosed as having 21-hydroxylase deficiency until they were identified by the screening test (Pang et al, 1985).

Nonclassic 21-hydroxylase deficiency represents an attenuated, late-onset form that is variable in its clinical severity due to partial deficiency of 21-hydroxylase and timing of onset. These patients do not have cortisol deficiency but present with hyperandrogenism. New and Wilson (1999) found the nonclassic 21-hydroxylase deficiency to be the most common autosomal recessive disorder in humans, with an incidence of 1 in 100. The presenting symptoms in females are commonly hirsutism and oligomenorrhea, male pattern baldness, and polycystic ovaries. In a recent study, 32% of women with nonclassic 21-hydroxylase deficiency were diagnosed only after delivering an offspring diagnosed with 21-hydroxylase deficiency CAH. In men with the nonclassic form of 21-hydroxylase deficiency, oligospermia and subfertility have been presenting features and reversal of infertility with glucocorticoid therapy has been reported. Typically, lower doses of glucocorticoid are required for management of the nonclassic form of CAH.

A deficiency of 11β-hydroxylase accounts for roughly 5% of cases of CAH. Both classic and mild forms have been recognized. Unlike 21-hydroxylase, 11β-hydroxylase is not human leukocyte antigen linked. The defect results from mutations in the *CYP11B1* gene located on the long arm of chromosome 8 (Merke et al, 1998). To date, more than 50 mutations have been described that result in enzyme inactivation (Nimkarn and New, 2008). Like 21-hydroxylase deficiency, the nonclassic variant of 11β-hydroxylase deficiency (late onset) is characterized by signs and symptoms of androgen excess in childhood or adolescence. **Hypertension is a common finding in patients with this type of CAH, and it is believed to be secondary to increased serum levels of deoxycorticosterone (DOC).** Although most of the patients are hypertensive, some are normotensive and others experience only intermittent hypertension. Marked virilization occurs in the severe form of the defect and may be as severe as in those patients with a 21-hydroxylase deficiency. In the late-onset form, mild virilization occurs in prepubertal and postpubertal patients.

The diagnosis of 11β-hydroxylase deficiency can be confirmed by finding increased plasma levels of 11-deoxycortisol and 11-DOC. Urinary levels of 17-ketosteroids and 17-hydroxycorticoids are increased. **The treatment with glucocorticoids is identical to that of patients with 21-hydroxylase deficiency.**

The least common enzyme deficiency responsible for a virilizing form of CAH is 3β-hydroxysteroid dehydrogenase. This deficiency affects the early steps in steroid biosynthesis in both adrenals and gonads, resulting in inability to convert 3β-hydroxysteroids to 3-ketosteroids. As a result, the severe form leads to impaired synthesis of aldosterone, cortisol, and sex steroids. Affected females exhibit mild clitoromegaly and labial fusion accompanied by symptoms of aldosterone and cortisol deficiency.

Two homologous genes have been identified for 3β-hydroxysteroid dehydrogenase, both of which contain four exons (Merke et al, 1998). A number of mutations giving rise to the syndrome have been described. This defect has an autosomal recessive inheritance pattern and is heterogeneous in its biochemical and clinical appearance. A non–salt-losing form and mild- and late-onset forms have been described, although the nonclassic form appears to be exceedingly rare.

The diagnosis of 3β-hydroxysteroid dehydrogenase is based on finding increased serum levels of 17-hydroxypregnenolone and dehydroepiandrosterone (DHEA). The pelvic ultrasound evaluation, confirming presence of müllerian tissue, would be supportive. Treatment is similar to that of patients with 21-hydroxylase deficiency.

Currently, one of the most exciting aspects of CAH is the capability of diagnosing and treating the disorder prenatally. **Prenatal diagnosis of CAH in the at-risk fetus was initially made by a measurement of amniotic fluid for 17-hydroxyprogesterone at 16 to 17 weeks' gestation** (Laue and Rennert, 1995). Currently, the diagnosis is made during the first trimester by HLA genotyping or by DNA analysis of genes within the HLA complex in cells obtained by chorionic villus sampling at 9 to 11 weeks' gestation (Hughes, 2002). **Treatment of the mother with dexamethasone, which crosses the placenta, suppresses fetal secretion of ACTH, thereby preventing virilization of the genitalia.** However, treatment should be instituted as soon as pregnancy is confirmed, and no later than 9 weeks after the last menstrual period, before initial development of the external genitalia (Nimkarn and New, 2007). There are certain complexities to this form of management. The diagnosis of CAH in the fetus may be determined on chorionic villous cells or on cells from amniotic fluid for families in which a prior member was affected. **Therefore, it is not possible to confirm the diagnosis before therapy is initiated.** Because virilization is not a concern with the male fetus and three of four female fetuses at risk are unaffected, given the autosomal recessive pattern of inheritance, seven of eight fetuses may be treated unnecessarily. Therefore, one goal in therapy has been earlier diagnosis to avoid unnecessary treatment. A promising approach that may allow the prenatal diagnosis of CAH as early as 6 weeks' gestation is polymerase chain reaction analysis of free fetal DNA, from circulating trophoblastic cells, in the maternal circulation.

A number of series have established the effectiveness of prenatal treatment for CAH with dexamethasone in 85% of cases (Migeon, 1990; Pang et al, 1990; Speiser et al, 1990). In some neonates there is no evidence of masculinization, suggesting totally successful therapy. In another group there is milder masculinization than that noted in an affected sibling. Although compliance and timing of initiation of treatment have been variable from series to series, this heterogeneity of response to therapy raises intriguing questions about the mechanisms involved in virilization of the CAH fetus. In addition, prenatal treatment with dexamethasone has raised ethical concerns. **Although there is no arguing its ability to prevent androgen effects on the genitalia and potentially the brain of affected females, the long-term effects of dexamethasone on unaffected fetuses undergoing treatment**

prenatally remain largely unknown. A study by Meyer-Bahlburg and colleagues (2004a) demonstrated no cognitive or developmental motor impairment to have resulted from prenatal treatment of CAH fetuses, but others have suggested potential deleterious effects on verbal working memory (Hirvikoski et al, 2007). Miller (1999) and others have advocated the use of prenatal treatment for CAH only as an experimental therapy in large centers and under institutional review board scrutiny. The importance of long-term follow-up of these neonates has been emphasized (Speiser, 1999).

Hughes (2002) and others have emphasized the close correlation in CAH of genotype and phenotype, which has a number of practical implications. Molecular biologists can now predict not only the risk of a couple having an affected child but also the likely clinical form of the disease. Therefore, genotypes of severe mutations would motivate prenatal treatment, whereas genotypes of less severe mutations would not. In addition, less severe genotypes in the newborn would allow for modification of corticosteroid treatment to minimize side effects.

The treatment of affected children with hydrocortisone in childhood and adolescence achieves a number of goals, as noted by Bongiovanni and Root (1963): "to supply the deficient hormone; to suppress pituitary ACTH secretion and hence adrenal androgens and clinical virilization; to forestall abnormally rapid somatic growth and osseous advance; to permit normal gonadal development; and to correct salt-water loss or hypertension in the complicated forms." The required dose of glucocorticoid may be predicted by genotype, as noted by Hughes (2002), but should be adjusted for the individual patient based on bone age, linear growth, 24-hour excretion of ketosteroids, and clinical evidence of glucocorticoid deficiency or excess (Grumbach and Conte, 1998). The effectiveness of therapy may be assessed by measuring morning plasma 17-hydroxyprogesterone levels. Those children with the salt-losing form of the disease require increased salt intake and mineralocorticoid treatment in addition to hydrocortisone therapy. After control of electrolytes and blood pressure has been achieved in the acute setting, maintenance therapy with fludrocortisone should be instituted (Laue and Rennert, 1995; Grumbach and Conte, 1998). The administration of hydrocortisone and, when required, fludrocortisone (0.05-0.3 mg/day) is continued indefinitely in all patients (American Association of Pediatrics, 2000). Typically, patients are instructed to triple their oral dose of hydrocortisone during physically stressful events such as surgery or infection.

In the majority of children (who will not have been diagnosed and treated prenatally), it is appropriate to perform feminizing genitoplasty at 3 to 6 months of age, when a well-established course of medical therapy has been instituted, the risks of anesthesia have become minimal, and the child has grown large enough to make the procedure technically feasible (Passerini-Glazel, 1990). **Long-term fertility in males and feminization, menstruation, and fertility in females can be anticipated in the well-treated patient.** Indeed, this potential in even the most masculinized female CAH patient has provided support for feminizing genitoplasty in virtually all 46,XX CAH patients.

An important area of recent research has been the potential imprinting of the brain by elevated prenatal androgen levels. A number of recent studies confirm that prenatal hyperandrogenization is associated with masculinization of gender-related behavior but not masculinization of gender identity. Meyer-Bahlburg and associates (Dessens et al, 2005; Meyer-Bahlburg et al, 2004b, 2008) noted a close correlation between hormonal abnormalities as a function of severity of enzyme deficiency with sexual orientation (homosexuality, bisexuality rates). Furthermore, Berenbaum and colleagues (2003, 2004) noted that in females with CAH and virilized genitalia psychological development is not compromised in those who are reared as females and receive good medical care. Meyer-Bahlburg and associates (2004a) noted in 46,XX CAH girls that marked masculinization of gender-related behavior in prenatally hyperandrogenized CAH girls was not associated with masculinization of gender identity. Therefore, the psychosexual evidence to date supports maintaining female gender in masculinized CAH patients diagnosed in infancy. Indeed, proper psychological support should be a component of long-term follow-up.

In an interesting new finding, both male and female patients with classic CAH have been noted on magnetic resonance imaging to have smaller amygdala volumes than controls, and altered amygdala function. The amygdala, regulated by glucocorticoids, is important in processing emotion (Ernst et al, 2007).

An intriguing area of surgical innovation in the management of CAH has been the experimental use of "prophylactic" adrenalectomy for selected patients. This approach is based on the premise that in certain patients it is more difficult to maintain adrenal suppression than to prevent adrenal crises. Clinically, these patients are the salt losers and extremely virilized females. For those with this most severe form of 21-hydroxylase deficiency, adequate suppression of adrenal production has required significant degrees of hypercortisolism, associated with poor growth, obesity, and infertility (in 40%). For the 25% of CAH patients who completely lack 21-hydroxylase enzyme activity and therefore produce neither cortisol nor aldosterone, adrenalectomy may be a practical approach (VanWyk et al, 1996). In general, these patients may be identified genotypically as homozygotes or compound heterozygotes for "null alleles" of the *CYP21* gene (VanWyk et al, 1996). In a series of 18 patients with long-term follow-up, VanWyk and Ritzen (2003) noted bilateral adrenalectomy to be safe and effective in managing severe forms of CAH in which patients repeatedly escaped adrenal suppression. Most of these patients reported a better quality of life after bilateral adrenalectomy. In a recent series bilateral adrenalectomy proved more successful for those patients pursing fertility rather than control of obesity and hyperandrogenism (Ogilvie et al, 2006).

Although these patients are rendered addisonian by this surgery, those with the most severe form of CAH would have a poor intrinsic adrenal response to metabolic stress (Gunther et al, 1997). One theoretical disadvantage of this approach is that if gene therapy were to one day allow functional *CYP21* genes to be introduced into adrenal cortical tissue, adrenalectomized patients would not be candidates for such therapy (VanWyk et al, 1996).

46,XX DSD (Masculinized Female) Secondary to Maternal Androgens and Progestins and Maternal Tumors

The masculinization of a female fetus as a result of maternal administration of synthetic progestational agents or androgens is a rare occurrence; lessons have been learned from prior unfortunate experiences. Historically, progestational agents were used to prevent threatened abortion. In one large series, masculinization occurred in 2% of female infants whose mothers were treated with progestins during pregnancy (Ishizura et al, 1962). In addition, danazol, a testosterone derivative used to treat endometriosis, has been associated with virilization of the female fetus. **The degree to which any androgen or progestational agent affects female fetal development is a function of the strength of the agent, its maternal dosage, and timing and duration of administration** (Bongiovanni and McFadden, 1960).

Very rarely, a maternal ovarian or adrenal tumor has virilizing effects on a female fetus. More typically, such a tumor has virilizing effects on the mother but no apparent effect on the fetus. Ovarian tumors that have resulted in masculinization of the female fetus include arrhenoblastoma, hilar cell tumor, lipoid cell tumor, ovarian stromal cell tumor, luteoma of pregnancy, and Krukenberg tumor (Calaf et al, 1994).

Rarer still are maternal adrenal tumors (adrenocortical carcinoma and adenoma), which have masculinizing effects on the female fetus.

Aromatase deficiency represents an even rarer cause of transplacental transport of excess androgens to the fetus. The cytochrome P450 aromatase enzyme catalyzes the conversion of androgens to estrogens. Normally, weak androgens produced by the fetal adrenal gland are converted to estrogens by placental aromatase and pass to the maternal circulation. Mutations of the *CYP19* aromatase gene can result in profound virilization of the female fetus and mother during pregnancy. Although maternal virilization resolves postnatally, it recurs in subsequent pregnancies.

In any case of exogenous androgen effect on a female fetus, normal endocrine status is recognized postnatally and management is confined to external genital reconstruction, as required.

46,XY DSD (Undermasculinized Male)

The term *46,XY DSD (undermasculinized male)* refers to 46,XY individuals with differentiated testes who exhibit varying degrees of feminization phenotypically. Impaired male differentiation in these patients is secondary to inadequate secretion of testosterone by the testes at the necessary period in development, inability of target tissue to respond to androgen appropriately, or impaired production or action of MIS.

Leydig Cell Aplasia (Luteinizing Hormone Receptor Abnormality)

Leydig cell aplasia as a cause of undermasculinization of the male was first reported by Berthezene and colleagues in 1976. **In its pure form, this rare disorder is characterized by a normal 46,XY male karyotype associated with a normal-appearing female phenotype. Typically, testes are palpable in the inguinal canals or labia majora.** On investigation, there are no müllerian structures and the vagina is short. A low testosterone level is noted in conjunction with an elevated LH concentration. **The absence of a rise in serum testosterone level after hCG stimulation is characteristic of this disorder** (Brown et al, 1978). Physiologically, this disorder represents a spectrum between absent Leydig cells and Leydig cells with abnormal LH receptor (David et al, 1984). Because a number of inactivating mutations have been found in the LH receptor gene, a correlation can be made between the phenotype of patients with Leydig cell hypoplasia and the activity of their LH receptor alleles (Richter-Unruh et al, 2004). It is transmitted as an autosomal recessive trait expressed only in males. Incomplete forms of the syndrome occur, with the mildest form being expressed as primary hypogonadism with normal male external genitalia (Lee et al, 1982).

The clinical diagnosis of Leydig cell aplasia, or LH receptor abnormality, is typically made as a result of sexual infantilism and the absence of development of secondary sexual characteristics or the discovery of palpable gonads in the inguinal canal or labia on physical examination (Arnholt et al, 1985). The differential diagnosis includes androgen insensitivity syndrome or a terminal defect in androgen synthesis. The histology of the abnormal testes demonstrates absence of Leydig cells in intratubular spaces with normal Sertoli cells.

Disorders of Testosterone Biosynthesis

A defect in any of the five enzymes required for the conversion of cholesterol to testosterone can cause incomplete (or absent) virilization of the male fetus during embryogenesis. The first three enzymes (cholesterol side chain cleavage, 3β-hydroxysteroid dehydrogenase, and 17β-hydroxylase) are present in both adrenals and testes. **Therefore, their deficiency results in impaired synthesis of glucocorticoids and mineralocorticoids in addition to testosterone.** For all five enzyme deficiencies, the pattern of inheritance is autosomal recessive.

StAR (Cholesterol Side Chain Cleavage Enzyme) Deficiency. The first step in gonadal and adrenal steroidogenesis is conversion of cholesterol to pregnenolone, which is mediated by a single cholesterol side chain cleavage enzyme known as 450SCC (previously known as 20-22 desmolase). A defect in this enzyme, first described by Prader and Gurtner in 1955, was believed to result in the rare condition congenital lipoid adrenal hyperplasia, so named because the adrenal glands became large and lipid laden. **However, more recent evidence suggests that a defect in cholesterol transport rather than a defective enzyme is etiologically responsible** (Saenger, 1997). The steroidogenic acute regulatory protein (StAR) stimulates cholesterol transport from the outer to the inner mitochondrial membrane (site of the cholesterol side chain cleavage complex). This appears to be the rate-limiting step in acute steroid synthesis.

StAR mutations are found in various ethnic groups but are most commonly reported in patients of Japanese, Korean, and Palestinian origin (Bhangoo et al, 2005). Affected 46,XY individuals have female or ambiguous external genitalia with a blind-ending vaginal pouch; intra-abdominal, inguinal, or labial testes; and absence of müllerian structures, consistent with functioning Sertoli cells (Hauffa et al, 1985). Wolffian ducts are present but rudimentary. Infants often present in the first few weeks of life with severe adrenal insufficiency and salt wasting.

A diagnosis of StAR (cholesterol side chain cleavage enzyme) deficiency should be entertained in any neonate with nonvirilized female external genitalia and evidence of cortisol and aldosterone deficiency with hyponatremia, hyperkalemia, and metabolic acidosis. Abdominal computed tomography demonstrates large, lipid-laden adrenal glands.

Management is similar to that for 21-hydroxylase deficiency. To date, all surviving 46,XY patients with this disorder have been raised as females and have undergone gonadectomy (Laue and Rennart, 1995). Because testosterone production was never significant, brain imprinting is not a factor in gender assignment.

Cytochrome P450 Oxidoreductase Deficiency. Cytochrome P450 oxidoreductase (POR) deficiency has been recently added to the causes of both 46XY and 46XX DSD. POR is a cofactor to all microsomal P450 enzymes, including 17-hydroxylase, 17,20-lyase, 21-hydroxylase, and aromatase. The condition emerged as a distinct entity through the realization that apparent combined deficiency of 17-hydroxylase and 21-hydroxylase enzymes is a single disorder due to lack of POR, a membrane-bound flavoprotein that plays a central role in electron transfer from NADPH to P450 enzymes. It was originally characterized in patients with Antley-Bixler syndrome (a skeletal dysplasia syndrome) in whom some had ambiguous genitalia and abnormal steroidogenesis.

Subsequently, it has become clear that POR deficiency can cause DSD unassociated with skeletal dysplasia and characteristics of Antley-Bixler syndrome (Hughes, 2008).

3β-Hydroxysteroid Dehydrogenase Deficiency. 3β-Hydroxysteroid dehydrogenase catalyzes the 3β-hydroxysteroids (pregnenolone, 17-hydroxypregnenolone, and DHEA) to the three ketosteroids, progesterone, 17-hydroxyprogesterone, and androstenedione. A congenital deficiency of 3β-hydroxysteroid dehydrogenase was first described by Bongiovanni in 1962.

Affected individuals present with various degrees of incomplete masculinization resulting from a block in testosterone biosynthesis and with salt-wasting adrenal insufficiency resulting from impaired synthesis of aldosterone and cortisol. The lack of salt-retaining hormone and cortisol results in a salt-losing crisis soon after birth. However, partial deficiencies associated with severe salt wasting occur, consistent with genetic heterogeneity. Two isoenzymes, type I and type II 3β-hydroxysteroid dehydrogenase, are involved in steroid biosynthesis. These enzymes are encoded by two genes, *HSD3B1* and *HSD3B2,* localized to chromosome 1 at locus p11-p13 (Chang et al, 1993). Classical 3β-hydroxysteroid dehydrogenase deficiency results from inactivating mutations, 37 of which have been identified, in the *HSD3B2* gene (Welzel et al, 2008).

Males with this deficiency usually exhibit incomplete virilization of the external genitalia, with a small phallus, hypospadias with labioscrotal fusion, a urogenital sinus, and a blind-ending vaginal pouch. Testes are often scrotal, and wolffian ducts develop normally. As with other defects in testosterone biosynthesis, in which normal Sertoli cell function is preserved, müllerian structures are absent.

The diagnosis should be considered in 46,XY males with ambiguous genitalia and signs of adrenal insufficiency. Endocrine study demonstrating increased levels of 3β-hydroxysteroids confirms the diagnosis.

Management of 3β-hydroxysteroid dehydrogenase is similar to that for patients with 21-hydroxylase deficiency.

17α-Hydroxylase Deficiency. 17α-Hydroxylase catalyzes the conversion of pregnenolone and progesterone to 17α-hydroxypregnenolone and 17-hydroxyprogesterone, respectively, in adrenal and gonadal steroidogenesis. The first case of male pseudohermaphroditism due to this enzyme deficiency was reported by New in 1970. The gene for this enzyme has been localized to chromosome 10 (Laue and Rennart, 1995).

Affected 46,XY individuals usually have female external genitalia with absent to slight masculinization. **A deficiency in 17α-hydroxylase activity impairs cortisol production, causing ACTH hypersecretion and resulting in increased levels of DOC, corticosterone, and 18-hydroxycorticosterone in the adrenals. These compounds with mineralocorticoid activity produce excess salt and water retention, hypertension, and hypokalemia.**

The phenotype of affected individuals varies from female with external genitalia with a blind-ending vaginal pouch to male with perineal hypospadias and chordee. The diagnosis should be considered in a undervirilized male with hypertension. Endocrine laboratory evaluation demonstrates elevated serum progesterone, DOC, corticosterone, 18-hydroxycorticosterone, and ACTH.

Therapy with glucocorticoid replacement brings blood pressure and hypokalemia back to normal by suppressing ACTH and hence adrenal cortical stimulation. Some patients have been raised as females with gonadectomy and estrogen replacement at puberty. In partial forms, typically with reasonable phallic size, patients may be raised as male with testosterone replacement at puberty. **Fertility has not been reported in patients with testosterone biosynthetic defects, and inadequate testosterone production makes androgen imprinting a less significant issue for these patients.** Therefore, the phenotype may dictate gender assignment.

17,20-Lyase Deficiency. The enzyme 17,20-lyase has been demonstrated to be related to 17α-hydroxylase in that the activities of both are linked to the same gene product on chromosome 10 (Laue and Rennart, 1995). However, in some patients with the genetic defect both biologic activities are absent, but with others only the 17,20-lyase function appears deficient. Zachmann and colleagues first described this clinical entity in 1972.

In cases in which the deficiency primarily involves 17,20-lyase, cortisol and ACTH secretion are normal. Aldosterone is secreted normally, and hypertension does not result. **However, impaired biosynthesis of testosterone in the 46,XY individual results typically in ambiguous rather than totally female genitalia at birth.** The deficient masculinization of the external genitalia can range from severe, resulting in a female gender assignment in the neonate, to mild, resulting only in hypospadias. At puberty, the secretion of testicular androgen remains low. Zachmann and colleagues (1982) have postulated that there are two types of 17,20-lyase deficiency—one that is partial and another that is a complete defect.

The diagnosis may be suspected in undervirilized males with absent müllerian derivatives and no defect in glucocorticoid or mineralocorticoid synthesis. At the time of expected pubertal development, the patients may present with failure to develop secondary sexual characteristics and elevated gonadotropin levels. The diagnosis may be made prepubertally using hCG and ACTH stimulation.

Management entails plastic reconstruction of the external genitalia and appropriate sex steroid replacement at puberty.

17β-Hydroxysteroid Oxidoreductase Deficiency. This last enzyme in the testosterone biosynthetic pathway catalyzes the conversion of androstenedione to testosterone, DHEA to androstenediol, and estrone to estradiol. Male undervirilization resulting from a deficiency in 17β-hydroxysteroid oxidoreductase was first described by Saez and associates in 1971.

Clinically, this is the most interesting enzymatic defect in testosterone biosynthesis in its similarities to 5α-reductase deficiency. At birth, affected individuals appear to have a normal female phenotype, without significant evidence of virilization. Therefore, a female gender assignment is usually made. However, these individuals have well-differentiated testes located intra-abdominally, inguinally, or in the labia and no müllerian structures. Surprisingly, wolffian ducts are normally developed, which may be secondary to the action of androstenedione or minimal amounts of testosterone produced during embryogenesis (Boehmer et al, 2001). **At puberty, there is phallic growth and progressive development of male secondary sexual characteristics.** These include increased muscle mass and development of pubic, axillary, and facial and body hair with male distribution. Gynecomastia may occur, and the testes may become palpable (Saez et al, 1972). In some cases, gender reassignment to male has been reported (Imperato-McGinley et al, 1979; Rosler and Kohn, 1983).

The late onset of virilization is related to the pubertal increase in gonadotropin production, which may partially overcome the block in testosterone biosynthesis.

There is a characteristic hormonal profile in this disorder. In the prepubertal patient, plasma androstenedione and estrone levels may not be increased. At puberty, androstenedione, the immediate precursor of testosterone, is increased to 10 to 15 times the normal plasma concentration (Virdis and Saenger, 1984). Earlier precursors are within normal levels. Plasma testosterone is in the low-normal range. Serum levels of LH and FSH are markedly elevated, typically four to six times normal.

As a result of biochemical characterization and molecular cloning, five different 17β-hydroxysteroid dehydrogenase isozymes have been identified to date. **The type III 17β-hydroxysteroid dehydrogenase isozyme, cloned by Andersson and colleagues** (1997), **catalyzes the biosynthesis of testosterone from androstenedione. A mutation involving the *HSD17B3* gene, mapped to chromosome 9q22, is responsible for male undervirilization.** The type III isozyme is apparently expressed early in utero and is responsible for testosterone biosynthesis during the critical period of sexual differentiation, based on the observation that male adults homozygous for 17β-hydroxysteroid dehydrogenase type III gene defects have ambiguous genitalia (Zhu et al, 1998).

The diagnosis is rarely made in the neonatal period. It may become apparent on discovery of a testis during a hernia repair in infancy or childhood. An hCG stimulation test resulting in an increased testosterone-to-androstenedione ratio would confirm the diagnosis and differentiate this condition from androgen insensitivity (Ahmed et al, 2000). **The primary management issue for patients with 17β-hydroxysteroid oxidoreductase deficiency has been gender assignment.** At this early stage, maintenance of the female sex of rearing with gonadectomy is usually elected. If the diagnosis is not made until puberty, when dramatic changes in virilization occur, certain families prefer a gender change to male. Cohen-Kettenis found gender role changes in 39% to 64% of 17β-hydroxysteroid oxidoreductase deficiency patients raised as female (Cohen-Kettenis, 2005). In an Arab cohort of 22 patients, Sobel and associates (2004) noted 7 to undergo spontaneous gender role reversal to male without parental consent or psychiatric intervention. Traditionally, this decision has been strongly culturally influenced.

If a female sex of rearing is elected, gonadectomy, plastic reconstruction of the genitalia as necessary, and estrogen replacement therapy at puberty are indicated. For the patient maintained in the male gender, orchidopexy and reconstruction of the external genitalia are required. This entails hypospadias repair and chordee correction, which can be quite successful. However, phallic size remains small and infertility is the rule. Some have suggested that childhood treatment with intramuscular testosterone may result in a larger phallus (Sobel and Imperato-McGinley, 2004). Usually endogenous androgen levels are adequate long term.

Two hypotheses have been proposed to explain the frequency of gender change from female to male with this enzyme deficiency, particularly among the cohort of Arab male pseudohermaphrodites with 17β-hydroxysteroid dehydrogenase type III deficiency. One entails the potential male imprinting of the brain in utero owing to the conversion of androstenedione to estrone; this theory is supported by studies in rats and rabbits demonstrating that administration of estrogen or androstenedione is capable of inducing male sexual behavior (Reddy et al, 1974). The second is the possibility that 17β-hydroxysteroid dehydrogenase activity is not deficient in the brain, its effect being mediated by the conversion of androstenedione to testosterone or estrogen (Imperato-McGinley et al, 1979).

Androgen Receptor and Postreceptor Defects

Disorders of androgen receptor function represent the most common definable cause of 46,XY DSD or the undervirilized male. These patients characteristically have a 46,XY karyotype and testes and present with a spectrum of phenotypic abnormalities that vary from complete external feminization (syndrome of complete androgen insensitivity), to ambiguous genitalia (partial androgen insensitivity), to the phenotypically infertile male. Although the clinical presentations vary according to the severity of the disorder, the pathophysiology is similar (Wiener et al, 1997).

Syndrome of Complete (Severe) Androgen Insensitivity. The syndrome of complete androgen insensitivity (previously known as testicular feminization) is characterized clinically by a 46,XY karyotype, bilateral testes, female-appearing external genitalia, and absence of müllerian derivatives. Wilkins first suggested in 1950 that the clinical features of this syndrome were the result of androgen resistance. This condition has an incidence of 1 in 20,000 to 1 in 60,000 males, and it is transmitted as an X-linked trait.

The androgen receptor regulates the transcription of other specific genes, once activated by testosterone or DHT. This results in new mRNA synthesis from the downstream genes and protein production. The androgen receptor has been mapped to the X chromosome at Xq11-12, spanning 90 kilobases and comprising eight exons (Brown et al, 1989; Hiort and Holterhus, 2003). Males have only one copy of this gene. Point mutations of the gene account for more than 90% of cases of androgen insensitivity (Quigley et al, 1995). **The identifiable molecular alterations of the androgen receptor gene cannot predict the resulting phenotype of the affected individual unless there is total loss of the receptor, which occurs in only 1% of all patients** (Quigley et al, 1995).

Patients with complete androgen insensitivity have a normal female phenotype with the exception of diminished axillary and pubic hair. Their breast development and body habitus are feminine in character, and their external genitalia are unequivocally female, although the vagina is short and blind ending. It had previously been believed that in-utero resistance to testosterone action prevented stabilization of the wolffian ducts. Hannema and associates (2004), however, have demonstrated wolffian duct derivatives in cases of complete androgen insensitivity. In 42% of patients, screening of the paratesticular area revealed well-developed epididymis and/or vasa deferentia. The mutations found in these patients entailed a single amino acid substitution in the androgen receptor ligand binding domain, rather than frameshift mutations, premature stop codons, or mutations in the DNA-binding domain, all of which were associated with absence of well-developed wolffian duct structures. These investigators suggest that mutant receptors with residual activity in vivo stimulate wolffian duct development. As a result, they should be classified as having *severe* rather than complete androgen insensitivity. Because the fetal testes secrete MIS, müllerian structures are absent. The testes may be found in the labia, inguinal canal, or abdomen.

These patients are rarely diagnosed in the neonatal period, unless a prenatal diagnosis is made on the basis of female phenotype and 46,XY karyotype on amniocentesis. With the increase in prenatal diagnostics, this is becoming a more common occurrence (Hughes and Patterson, 1994). More typically, however, the diagnosis is made as a result of primary amenorrhea or the finding of

a testis at inguinal herniorrhaphy. Fifty percent of patients with complete (severe) androgen insensitivity syndrome have an inguinal hernia (Conte and Grumbach, 1989). Conversely, 1% to 2% of apparently female infants with inguinal hernia are found to have a 46,XY karyotype and complete androgen insensitivity syndrome (Wiener et al, 1997; Barthold et al, 2000). Therefore, routine vaginoscopy to confirm the presence of a cervix or endoscopy through a hernia sac to identify an intra-abdominal testis at the time of inguinal herniorrhaphy in female patients is a prudent maneuver. Histologically, the testes exhibit incomplete or absent spermatogenesis, with normal or hyperplastic Leydig cells. They are comparable to immature, cryptorchid testes.

Endocrine evaluation in the neonatal period demonstrates normal male levels of testosterone, DHT, and gonadotropins. At puberty, gonadotropin levels rise, leading to increased levels of plasma estradiol, which results in feminization, including breast development.

Several types of mutant receptor abnormality that would account for this syndrome have been described, including (1) a decreased amount of apparently normal receptor; (2) absence of receptor binding; (3) a qualitatively abnormal receptor (thermolabile, or unstable); (4) other "receptor-positive" forms, including increased rate of dissociation of steroid receptor complex, defective upregulation of the androgen receptor, decreased affinity of ligand binding, and impaired nuclear retention of the ligand (Grumbach and Conte, 1998). In general, the severity of the defect in androgen receptor (quantity or quality) correlates with the phenotype. In addition, Hughes (2001) has noted the absence of coregulator proteins, without the absence of the androgen receptor, in cases of complete androgen insensitivity, suggesting that for androgen effects to be optimal an integrated array of transcriptional factors, coregulators, and ligands is required.

The diagnosis of complete (severe) androgen insensitivity may readily be made in the postpubertal patient on the basis of clinical and hormonal findings of amenorrhea, absence of pubic hair, or inguinal hernias containing testes. It is confirmed by a 46,XY karyotype and a normal male androgen and gonadotropin profile. Pelvic ultrasound examination confirms the absence of müllerian tissue, and a vaginal examination confirms a blind-ending vagina without a cervix.

In the prepubertal child, diagnosis is more difficult and requires an hCG stimulation test. Because of the time required for receptor binding quantification in genital skin, it is desirable to use PCR to characterize the androgen receptor gene in DNA obtained from a venous blood sample to detect a genetic marker for androgen insensitivity syndrome.

Management of complete (severe) androgen insensitivity relates primarily to the optimal timing of gonadectomy. Because the testes produce estradiol, which results in the appropriate changes for the female phenotype, it is considered by many preferable to leave the testes in situ until puberty is complete. Potential exceptions to the policy of delayed gonadectomy are palpable testes or testes associated with an inguinal hernia. One important caveat in deciding to leave the testes in situ is the need to confirm with absolute certainty that complete rather than partial androgen insensitivity exists by PCR characterization of the androgen receptor gene in venous blood DNA. If an incomplete form should exist, virilization at puberty could result (Batch et al, 1993). Another important consideration is the anticipated need to discuss with a postpubertal female the presence of testes that require removal, rather than doing so when the child is much younger and the psychosexual implications less charged.

A competing concern for retention of testicular tissue is the potential for malignant degeneration of the testes. In patients with complete androgen insensitivity who reach adulthood with a retained testis, the risk for development of a testis tumor—usually seminoma or gonadoblastoma—is thought to be 1% to 2%, only slightly higher than for a cryptorchid testis (Manuel et al, 1976; Muller and Skakkebaek, 1984). Before pubertal development the risk is extremely low, the youngest reported case of a germ cell tumor in an androgen insensitivity syndrome being in a 14-year old (Ahmed et al, 2000). Therefore, in general, delayed gonadectomy after puberty is believed to be safe (Cools et al, 2006).

After orchiectomy, cyclic estrogen/progestin therapy is begun. The majority of patients have successful treatment of their short vagina with progressive dilation (Ismail-Pratt et al, 2007). Some patients may benefit from vaginoplasty (Boehmer et al, 2001). **Currently, all studies of patients with complete androgen insensitivity support an unequivocal female gender identity, consistent with androgen resistance of brain tissue as well.** In one study, no statistical differences were found between the complete androgen insensitivity group and normal controls in any quality-of-life or gender-related behavior criterion (Hines et al, 2003). To date, there has been no report of a patient with complete androgen insensitivity raised as a female who needed gender reassignment to male (Meyer-Bahlburg, 1999). In any event, age-appropriate psychological counseling is an important component of management in the androgen insensitivity syndromes.

Syndrome of Partial Androgen Resistance. The syndrome of partial androgen resistance includes syndromes that were once thought to represent separate entities: Reifenstein, Gilbert-Dreyfus, Rosewater, and Lubs syndromes (Griffin, 1992). **These are X-linked disorders** of incomplete masculinization that represent a spectrum of phenotypic abnormalities. **The major finding is ambiguity of the external genitalia to varying degrees.** The partial form of androgen insensitivity may be expressed variably even within the same family. **The classic phenotype is that of a male with perineoscrotal hypospadias, cryptorchidism, rudimentary wolffian duct structures, gynecomastia, and infertility. However, the phenotypic spectrum can range from hypospadias and a pseudovagina to gynecomastia and azoospermia** (Wilson et al, 1974). The endocrine profile of partial androgen insensitivity syndrome is similar to that of the complete androgen insensitivity syndrome. At puberty, gynecomastia may develop. The phallus may enlarge slightly, but it remains small.

To date, over 500 mutations in the androgen receptor gene have been discovered. It has been well recognized in partial androgen insensitivity syndrome that these mutations produce a diversity of phenotypes between and within affected families, consistent with additional factors that modulate responsiveness to androgen. This seems consistent with prior studies in the 1980s on genital skin fibroblasts, demonstrating **two forms of receptor defect in the partial androgen insensitivity syndrome: (1) a reduced number of normally functioning androgen receptors and (2) a normal receptor number but decreased binding affinity** (Griffin and Durrant, 1982; Hughes, 2000).

The diagnosis of partial androgen insensitivity syndrome can be difficult. In the neonatal period, it may be made in the setting of a 46,XY karyotype, ambiguous external genitalia, and absent müllerian structures on pelvic ultrasound. Endocrine evaluation

confirms normal male levels of testosterone and gonadotropins, and a normal testosterone/DHT ratio. An hCG stimulation test and characterization of the androgen receptor gene in serum DNA by PCR should confirm the diagnosis. A family history consistent with X-linked inheritance of ambiguous genitalia is of great assistance. A course of androgen injections in early infancy is often used to assess androgen responsiveness, which can aid in gender assignment.

Management must be individualized depending on the degree of genital ambiguity. In patients assigned a female gender, gonadectomy and surgical reconstruction of the external genitalia are indicated; at puberty, estrogen/progestin replacement is instituted. Those individuals raised as males would require treatment of their cryptorchidism, reduction of gynecomastia, and genital reconstruction. Phallic size remains small, however, and the effects of supraphysiologic doses of testosterone have been disappointing (Migeon et al, 1994). The risk of gonadal tumor is somewhat higher than in complete androgen insensitivity syndrome (up to 5.5%), and there is an increased risk of male breast cancer with partial androgen insensitivity syndrome (Hughes, 2006). Of importance in considering gender assignment in patients with partial androgen insensitivity is the recognition that the receptor defect affecting the external genitalia appears to affect brain receptors for testosterone similarly. Unfortunately, because of the distinct phenotypic variability, even within families, gender assignment of patients with partial androgen insensitivity syndrome cannot be based on the specifically identified androgen receptor gene (Boehmer et al, 2001). The study by Melo and colleagues (2003) of 11 patients with partial androgen insensitivity syndrome (5 raised female, 6 raised male) demonstrated gender of rearing to be consistent with adult gender role. This suggests the possibility that in the setting of inadequate androgen imprinting of the fetal brain, sex of rearing may predominate in determination of gender identity. Unfortunately, this has not consistently proven to be the case.

Unfortunately, long-term outcome data in the management of patients with partial androgen insensitivity syndrome is limited. Migeon and colleagues' study (2002) of 14 patients with partial androgen insensitivity syndrome noted that 23% were dissatisfied with neonatal gender assignment irrespective of current status as male or female. Another study of 15 postpubertal males with partial androgen insensitivity syndrome documented major impairment in sexual function in all (Bouvattier et al, 2006). However, Mazur (2005) found that only 9% of patients with partial androgen insensitivity syndrome self-initiated a gender reassignment.

The current recommendation for partial androgen insensitivity syndrome is to allow virilization of the external genitalia to serve as a guide in gender assignment, in that this may be the best means of assessing androgen imprinting of the brain, for lack of a more precise marker (Sobel and Imperato-McGinley, 2004).

Mild Androgen Insensitivity Syndrome. A relatively new classification is that of mild androgen insensitivity syndrome discovered in the course of investigations for male factor infertility. Recent studies have demonstrated a variety of mutations, usually quite discrete within the androgen receptor gene, to account for the infertility (Hiort and Holterhus, 2003). Men with this syndrome may be normal phenotypically or have a history of mild hypospadias repair but are azoospermic or severely oligospermic. They have been found to have normal to elevated serum testosterone levels with normal to elevated LH levels. This suggests that infertility in otherwise normal males may be the clinical manifestation of partial androgen insensitivity, representing the far end of a variable phenotypic spectrum. To date, the pathophysiology of the abnormal spermatogenesis caused by androgen receptor mutations remains unknown (Hiort and Holterhus, 2003).

5α-Reductase Deficiency

The disorder of 5α-reductase deficiency is one of the most fascinating forms of male undervirilization. The clinical presentation of this enzyme disorder was actually predicted in 1972, before the description of such patients in 1974 by Walsh and Imperato-McGinley and their colleagues (Wilson, 1972; Imperato-McGinley et al, 1974; Walsh et al, 1974). Extensive characterization of the disease has been achieved since that time.

5α-Reductase is a microsomal enzyme that catalyzes the conversion of testosterone to DHT. The condition is transmitted in an autosomal recessive pattern, and only homozygous males are affected. Two 5α-reductase genes have been cloned; they encode different isoenzymes. The type 1 isoenzyme, encoded on chromosome 5, is expressed in low levels in the prostate and external genitalia. The type 2 isoenzyme is encoded on chromosome 2 and is expressed in high levels in the prostate and external genitalia (Thigpen et al, 1992b). **Male undervirilization due to 5α-reductase deficiency is secondary to mutations in the type 2 gene.** At least 40 mutations have been identified (Thigpen et al, 1992a; Imperato-McGinley, 2002). Identical mutations in individuals with widely different geographic and ethnic backgrounds support the concept of mutational "hot spots" on the gene.

Individuals with this disorder present as neonates with a 46,XY karyotype and a phenotype that may vary from penoscrotal hypospadias to, more commonly, markedly ambiguous genitalia. Typically, the phallus is quite small, appearing as a normal or enlarged clitoris (Fig. 133–22). A urogenital sinus is present, with convergence of vaginal and urethral channels, and there is labioscrotal fusion (Fig. 133–23). The vaginal pouch is short and blind ending. Testes and epididymides are located in the labia, inguinal canals, or abdomen; and the vasa terminate in the blind-ending vaginal pouch. At puberty, partial masculinization occurs with an increase in muscle mass, development of male body habitus, increase in phallic size, and onset of erections (Peterson et al, 1977). Sperm production and fertility in affected individuals have been reported (Imperato-McGinley et al, 1982; Zhu et al, 1998). Other secondary sexual characteristics, including enlargement of the prostate and hairline recession, do not develop.

On endocrine evaluation these individuals have elevated mean plasma testosterone but low DHT levels. After hCG stimulation, the testosterone-to-DHT ratio increases from the range of 3 to 25 in normal subjects to a range of 75 to 160 (Kupfer et al, 1992). Genital skin fibroblast cultures demonstrate diminished to absent 5α-reductase activity (Migeon et al, 1994). At puberty, virilization is presumed to occur because the androgen receptor binds markedly higher levels of testosterone at low affinity or because of the normal increase at puberty in the activity of the 5α-reductase type 1 isoform, resulting in sufficient DHT for virilization (MacLaughlin and Donahoe, 2004). Indeed, the enzyme abnormalities in this disorder have been shown to be biochemically heterogeneous, ranging from reduced affinity of the enzyme for testosterone and reduced affinity for nicotinamide adenine dinucleotide phosphate (NADPH) to altered pH activity profiles (Kupfer et al, 1992).

The phenotypic characteristics of this disorder have helped to clarify the roles of testosterone and DHT in normal development. **Although DHT appears to be critical for the development**

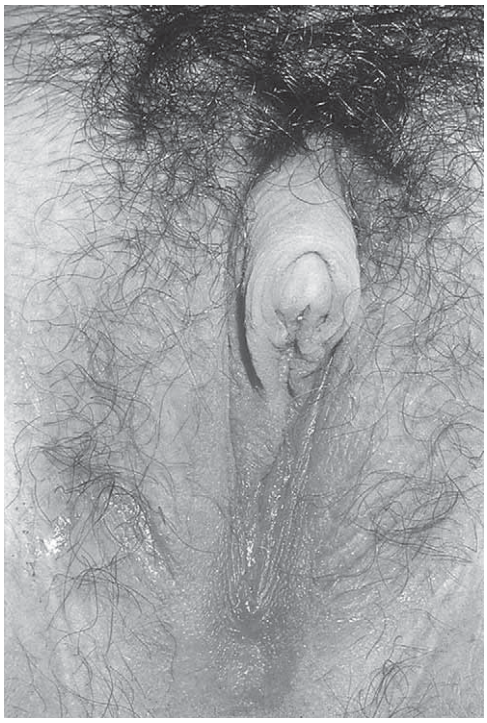

Figure 133–22. External genitalia of patient with 5α-reductase deficiency. Note clitoromegaly with marked labioscrotal fusion and small vaginal introitus. (From Diamond D. Intersex disorders: I and II. AUA Update Series, vol. IX, lessons 9 and 10. Houston: American Urological Association Office of Education; 1990.)

Figure 133–23. Intraoperative view of urogenital sinus in a patient with 5α-reductase deficiency; note enlarged clitoris, urogenital sinus with convergence of urethral and vaginal channels, and posterior labioscrotal fusion. (From Diamond D. Intersex disorders: I and II. AUA Update Series, vol. IX, lessons 9 and 10. Houston: American Urological Association Office of Education; 1990.)

of normal external genitalia in utero, testosterone alone appears sufficient for wolffian duct development.

Individuals in the pedigree studied by Imperato-McGinley and colleagues in the Dominican Republic underwent gender reversal at puberty and were known within the community as *guevedoces* ("penis at 12") (Imperato-McGinley et al, 1979). This strong tendency toward reversal of gender identity in 5α-reductase deficiency has been one of the most intriguing aspects of the disorder. It has lent support to the concept that testosterone exerts the primary male imprinting effect on the brain. However, the discovery that there are two isoenzymes for 5α-reductase, only type 2 being deficient in this syndrome, allows for the possibility that 5α-reductase type 1 has some impact on the brain (Thigpen et al, 1992b). As a result, with early diagnosis of 5α-reductase deficiency, a male gender assignment is generally favored, bearing in mind that the studies strongly supporting male gender identity in this disorder were performed in sociologically unique environments (Zhu et al, 1998). Cohen-Kettenis (2005) noted 56% to 63% of 5α-reductase deficiency patients to undergo gender reversal from female to male. The clinician must be open to familial cultural considerations regarding the value of male gender as well as the significance of penile size. In the setting of male gender assignment, cryptorchidism and hypospadias should be surgically corrected. Fertility is possible, particularly with the advent of intrauterine insemination (Katz et al, 1997). Exogenous DHT could be used at puberty in an attempt to promote phallic growth, but it would be likely to impair spermatogenesis. For some individuals, based primarily on extremely small phallic size, a female gender may be assigned. For these patients, gonadectomy should be performed as early as possible and certainly well before puberty to prevent virilization. Estrogen/progestin should be administered at the expected time of puberty. Vaginoplasty and clitoral reduction may be performed within the first year of life in those with a severe defect to provide for normal appearance of the external genitalia and to allay parental anxiety.

Persistent Müllerian Duct Syndrome

Persistent müllerian duct syndrome **(PMDS), or** ***hernia uteri inguinale,*** the term originally used by Nilson (1939), characteristically describes a group of **patients with a 46,XY karyotype and normal male external genitalia but internal müllerian duct structures. Typically, these phenotypic males have unilateral or bilateral undescended testes, bilateral fallopian tubes, a uterus, and an upper vagina draining into a prostatic utricle.** The condition is commonly diagnosed after müllerian tissue is encountered during inguinal herniorrhaphy or orchidopexy.

Clarnette and coworkers (1997) suggested three categories for patients with PMDS: (1) the majority (60% to 70%) with bilateral intra-abdominal testes in a position analogous to ovaries; (2) a smaller group (20% to 30%) in which one testis is found in a hernia sac or scrotum in association with a contralateral inguinal hernia (the classic presentation of hernia uteri inguinale); and (3) the smallest group (10%), in which both testes are located in the same hernia sac (as a result of transverse testicular ectopia) along with the fallopian tubes and uterus. Indeed, **PMDS is believed to be etiologically important in transverse testicular ectopia, occurring in 30% to 50% of cases** (Fujita, 1980).

The *MIS* gene was cloned in 1986 and localized on the short arm of chromosome 19 (Cates et al, 1986). It shows homology with the transforming growth factor-β super family of growth and

differentiation factors (Imbeaud et al, 1995). **PMDS is thought to be a heterogeneous disorder genetically in which some subjects have a defect in the gene for MIS located on chromosome 19p13 and others have a defect in the gene for its type II receptor located on chromosome 12q13** (MacLaughlin and Donahoe, 2004). The condition may occur sporadically or be inherited as an X-linked (or autosomal dominant, sex-limited) trait (Migeon et al, 1994).

The treatment of persistent müllerian duct syndrome is relatively straightforward, in that all patients are phenotypic males who require orchidopexy. The cases of adult patients with associated testis tumor (most commonly seminoma) probably reflect the increased risk of malignancy in intra-abdominal undescended testes. One treatment caveat relates to management of the rudimentary müllerian structures. **The vasa deferentia are in close proximity to the uterus and proximal vagina, and preservation of the necessary müllerian structures to avoid injury to the vasa is recommended to preserve fertility** (Sloan and Walsh, 1976). Although fertility has been reported with this syndrome, only recently has a case of malignancy in retained müllerian structures been reported (Berkmen, 1997; Shinmura et al, 2002).

Unclassified Forms: Mayer-Rokitansky-Küster-Hauser Syndrome

The Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome is a rare disorder entailing congenital absence of the uterus and vagina. It occurs in approximately 1 of every 4000 to 5000 female births. Patients with MRKH syndrome have a 46,XX karyotype and are normal-appearing females with normal secondary sex characteristics. The external genitalia appear normal, but only a shallow vaginal pouch is present. In the typical form of the syndrome there is symmetrical anatomy with absence of both vagina and uterus. Normal ovaries and fallopian tubes are present, and ovarian function is normal, but only symmetrical uterine remnants are found (Griffin et al, 1976). The recent report of a *WNT4* mutation in a woman with a phenotype resembling MRKH suggests the importance of this gene in müllerian duct formation (Biason-Lauber et al, 2004).

The most common clinical presentation for MRKH syndrome is primary amenorrhea, but patients may present with infertility or dyspareunia. **Upper urinary tract anomalies occur in approximately one third of patients and include renal agenesis, pelvic kidney, and horseshoe kidney.**

Atypical forms of MRKH syndrome have been described in up to 10% of cases, in which asymmetrical uterine remnants and/or aplasia of one or both fallopian tubes is discovered. As a result, endometrial tissue or variable development of the uterus with hematometra may be present, resulting in a clinical presentation with cyclical abdominal pain. **Urinary tract anomalies occur more commonly in patients with the atypical form of MRKH.** In a study of 100 patients with MRKH syndrome, 38 of 56 patients (68%) with the atypical form of the condition had upper urinary tract abnormalities. None of the 44 patients with the typical form of MRKH syndrome had an upper urinary tract anomaly (Strubbe et al, 1994). In addition, associated cardiac anomalies have been noted in 16% of MRKH patients (Pittock et al, 2005).

A radiologic evaluation with ultrasonography and magnetic resonance imaging may define müllerian anatomy accurately in MRKH and distinguish between typical and atypical forms of the disorder (Nussbaum-Blask et al, 1991; Reinhold et al, 1997).

Treatment entails creation of a neovagina, surgically or by means of dilation, to allow for sexual function (Ismail-Pratt et al, 2007). If present, a hemiuterus should be removed, whereas a midline uterine structure should be hormonally suppressed rather than connecting this structure to a reconstructed vagina.

EVALUATION AND MANAGEMENT OF THE NEWBORN WITH AMBIGUOUS GENITALIA

The evaluation and initial management of the neonate with ambiguous genitalia must be regarded as a medical and psychosocial emergency and be handled with great sensitivity toward the family. Ideally, a medical team including a pediatric urologist, an endocrinologist, and a psychiatrist or psychologist experienced in managing intersex patients should work closely with the family. **The team's goal should be to make a precise diagnosis of the disorder (which can be achieved in most cases) and, with the involvement of the parents, to assign a proper sex of rearing based on the diagnosis, the status of the child's anatomy, and the functional potential of the genitalia and reproductive tract.**

In obtaining the history, certain pieces of information may be particularly valuable. A history of infant death within the family might suggest the possibility of CAH, and infertility, amenorrhea, or hirsutism might also suggest possible familial patterns of intersex states. Certainly, maternal use of medications, in particular steroids or contraceptives, during the pregnancy is of great importance.

The critical finding on physical examination is the presence of one or two gonads. This finding effectively rules out overmasculinization of the female. Because ovaries do not descend, a distinctly palpable gonad along the pathway of descent is highly suggestive of a testis. Rarely, an ovotestis undergoes descent to the inguinal canal and may be suspected on the basis of asymmetry of tissue texture of the poles of the gonad. This suspicion may be further supported by ultrasound findings. **The patient with bilaterally impalpable testes or a unilaterally impalpable testis and hypospadias should be regarded as having a DSD until proven otherwise, whether or not the genitalia appear ambiguous.** Kaefer and associates (1999) studied the incidence of DSDs in patients with cryptorchidism and hypospadias and without ambiguous genitalia. **With a unilateral cryptorchid testis, the incidence of DSD was 30% overall—15% if the undescended testis was palpable and 50% if it was impalpable. In the setting of bilateral undescended testes and hypospadias, the incidence of DSD was quite similar—32% overall but only 16% if both gonads were palpable. If one of two undescended testes was impalpable, the incidence of DSD tripled to 47%, comparable to the rate in those with a unilateral, impalpable, cryptorchid testis.** In addition, posterior urethral meatal position was noted to be a strong predictor of DSD in this group of patients—65%, versus 5% to 8% with a midshaft to anteriorly located hypospadiac meatus (Kaefer et al, 1999).

In addition to gonadal examination, penile size should be assessed and an accurate measure of stretched penile length recorded. The mean stretched penile length in full-term males born in the United States is 3.5 cm (± 0.04) (Lee et al, 2006).

An additional important finding on physical examination is the presence of a uterus, which is noted as an anterior midline cordlike structure on rectal examination. **A more precise means of assessing müllerian anatomy is by pelvic ultrasonography, which may be performed immediately in the neonatal period.** In addition to defining müllerian anatomy and confirming the presence or absence of a uterus, the gonads and adrenals should be studied. Normal anatomy of an undescended gonad should be confirmed, and a cyst within the gonad, consistent with ovotestis, should be ruled out.

Within the immediate neonatal period, a karyotype should be obtained. Typically this requires 2 days to perform. Therefore, an attractive approach to obtain chromosomal data quickly is fluorescence in-situ hybridization, which rapidly identifies X and Y chromosomes. It is typically used to confirm the presence of a second X chromosome. The technique is much more rapid than karyotyping, producing results within a few hours.

Serum studies should be immediately sent to rule out a salt-wasting form of CAH. In addition to serum electrolytes, testosterone and DHT should be measured early. Migeon and colleagues (1994) emphasized that the androgen levels may drop quickly, necessitating early study. In addition, they suggested that serum 17-hydroxyprogesterone should not be measured until day 3 or 4 to rule out 21-hydroxylase deficiency, because the stress of delivery may result in physiologic elevation of this steroid precursor in the first 1 or 2 days of life.

In the absence of palpable testes, the presence or absence of testicular tissue should be determined by documentation of a markedly elevated LH, consistent with anorchia, or by means of an hCG stimulation test, which can demonstrate normally functioning testicular tissue (Jarow et al, 1986). In addition to ruling out anorchia, the study can enable diagnosis of 5α-reductase deficiency (by virtue of an increased ratio of testosterone to DHT) and can help distinguish between impaired testosterone synthesis (deficient response to hCG) and androgen insensitivity (normal response to hCG). Serum MIS measurement has been proposed as a reliable marker of the presence of testes (Hughes, 2002).

Key Points: Evaluation and Management of Intersex

- The team's goal should be to make a precise diagnosis of the intersex disorder (which can be achieved in most cases) and, with the involvement of the parents, to assign a proper sex of rearing based on the diagnosis, the status of the child's anatomy, and the functional potential of the genitalia and reproductive tract.
- The patient with bilaterally impalpable testes or a unilaterally impalpable testis and hypospadias should be regarded as having a DSD until proven otherwise, whether or not the genitalia appear ambiguous.

Based on physical examination (largely, gonadal palpability), the presence or absence of müllerian structures on ultrasonography, 17-hydroxyprogesterone concentration, and the karyotype, a reasonable differential diagnosis may be formulated (Fig. 133–24). A precise diagnosis can virtually always be achieved for the 46,XX DSD (overvirilized female) but in only 50% of 46,XY DSD undervirilized males (Lee et al, 2006). The presence of asymmetrical anatomy on examination and ultrasonography is an important observation and suggests mixed gonadal dysgenesis if the karyotype is XY and ovotesticular DSD if it is 46,XX (Fig. 133–25).

Laparotomy or laparoscopy and gonadal biopsy is usually the next definitive clinical step required when a firm diagnosis based

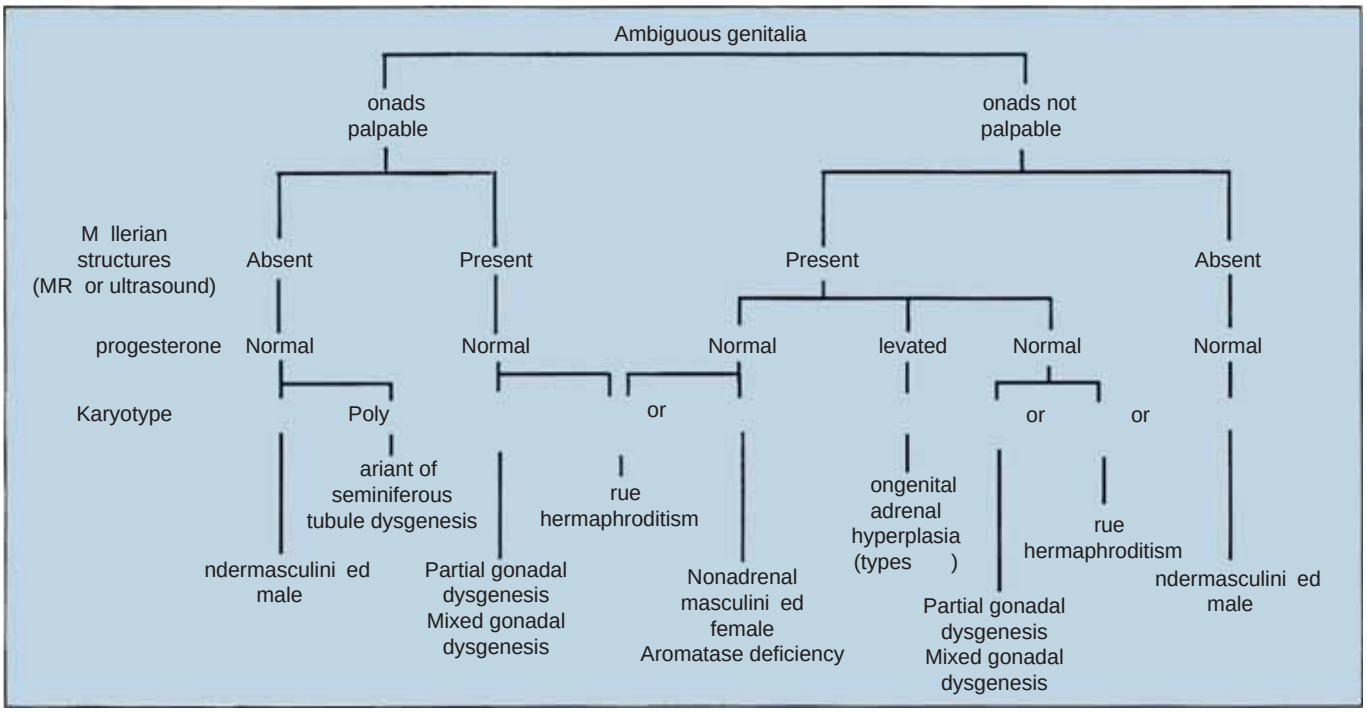

Figure 133–24. Diagnostic algorithm for a newborn with ambiguous genitalia based on gonadal palpability, presence or absence of müllerian structures, 17-hydroxyprogesterone concentration, and karyotype. (Modified from Grumbach MM, Conte FH. Disorders of sex differentiation. In: Wilson JD, Foster DW, editors. Williams textbook of endocrinology. Philadelphia: WB Saunders; 1998. p. 1401.)

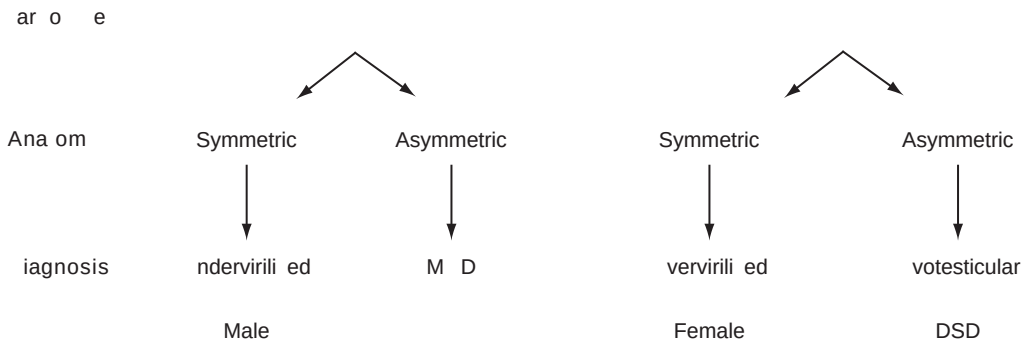

Figure 133–25. Likely diagnoses based on karyotype and anatomic symmetry. DSD, disorder of sex differentiation; MGD, mixed gonadal dysgenesis. (After Donahoe P.)

on the aforementioned data is impossible. **Laparotomy or laparoscopy in this setting remains a diagnostic maneuver; removal of gonads or reproductive organs should be deferred until the final pathology report is available and a gender has been assigned.** PCR characterization of the androgen receptor in venous blood DNA may define the precise genetic abnormality responsible for a given DSD, be it abnormal androgen receptor or an enzyme abnormality. These studies should be performed in specialized laboratories where normal values are well established.

Finally, anatomic definition of the urogenital sinus and ductal structures contributes to the correct diagnosis and is necessary before any surgical intervention. The urogenital sinus is well imaged by retrograde contrast injection, which also opacifies ductal structures, defines the entry of urethra and vagina into the sinus, and outlines the cervical impression within the vagina. Endoscopy can define these relationships further but is usually not necessary until surgical reconstruction becomes imminent.

Gender Assignment

After a definitive diagnosis has been reached, a thorough and candid discussion with the family regarding gender assignment should take place. **Issues related to the diagnosis-specific potential for normal sexual functioning and fertility and the risk of gonadal malignancy should be addressed.** Parents should understand that high-quality data regarding the long-term psychosocial outcomes of gender assignment for the majority of DSDs are lacking, although longitudinal studies are being pursued. Parental involvement in the decision-making process is essential. If the diagnosis of a DSD is made prenatally, it is important to present a plan of management to the parents or risk termination of the pregnancy (Nihoul-Fekete, 2004).

In the setting of a 46,XX karyotype and masculinized female, gender assignment is usually appropriately female. In CAH, cortisol suppresses the undesired androgen; and if maternal androgen is responsible for virilization, its discontinued stimulation is corrective. In both cases there are normal ovaries and müllerian ducts and a normal reproductive potential exists. **If the karyotype is 46,XY, the issue is a more complex one and includes factors such as penile length and evidence of androgen insensitivity.** For example, 46,XY patients with complete (severe) androgen insensitivity are appropriately assigned a female gender, whereas those with 5α-reductase deficiency may be more appropriately assigned a male gender. The most frequent abnormal karyotype is 45,X/46,XY mosaicism, which presents a variable phenotypic spectrum. The degree of masculinization of the external genitalia appears to vary with the amount of testicular tissue present, and gender assignment depends on the functional potential of the gonadal tissue, reproductive tracts, and genitalia. Some investigators have suggested deferring the issue of gender assignment until patients reach an age at which they may declare their own gender identity. Such an approach, although rational, is difficult to implement given cultural norms and not recommended in the consensus statement (Lee et al, 2006). As Elliott (1998) states, "We treat these children the way we do (as male or female) because this is the way we see the world; most importantly it is the way that the children, themselves, are taught to see the world."

Overall, it is well to remember in the management of ambiguous genitalia the parameters of optimal gender policy outlined by Meyer-Bahlburg (1998):

- **Reproductive potential (if attainable at all)**
- **Good sexual function**
- **Minimal medical procedures**
- **An overall gender-appropriate appearance**
- **A stable gender identity**
- **Psychosocial well-being**

Ultimately, management of patients with disorders of sexual differentiation remains a challenging and humbling process. On the one hand, physicians have at their disposal sophisticated molecular biologic techniques that have enabled them to identify genetic disorders responsible for the majority of DSDs. On the other hand, the mysteries of brain dimorphism in the setting of sexual ambiguity remain to be solved to optimize the long-term psychosocial outcome of gender assignment for the individual patient.

chapter 134

Surgical Management of Disorders of Sexual Differentiation, Cloacal Malformation, and Other Abnormalities of the Genitalia in Girls

Richard C. Rink, MD, FACS, FAAP • Martin Kaefer, MD, FAAP, FACS

Female Reproductive and Caudal Embryology
Structural Anomalies of the Female Internal Genitalia
Classification of Urogenital Sinus and Cloacal Anomalies
Surgical Reconstruction of Disorders of Sex Development and Urogenital Sinus
Surgical Reconstruction for Cloacal Malformations
Summary

As with all other organ systems, genital development in the female occurs in an orderly fashion through multiple complex steps that result in an anatomically and functionally normal child in the vast majority of cases. However, errors in development can occur, from minor, clinically insignificant disorders to severe abnormalities that are devastating to the child and parents. The abnormalities may affect the external genitalia alone or in combination with internal genital anomalies, and in some they may involve other organ systems. In this chapter normal urogenital and anorectal development is briefly described and then anomalies that arise when abnormal development occurs are discussed. Genital ambiguity is often the initial finding in these disorders. Only reconstruction along female lines is discussed; male reconstruction (i.e., hypospadias, chordee repair, and orchiopexy) is discussed in Chapters 130 and 132.

Genital reconstruction for disorders of sex development (DSD, formerly intersex) at this time is very controversial. Although significant advances in surgical techniques have occurred since Young's early work (1937), well-controlled studies with regard to not just cosmetic results but also functional and psychological results are almost nonexistent. Historically, reconstruction of DSD conditions has been surrounded by secrecy, and decisions have been made without scientific studies and often without the patient's knowledge. Questions regarding genital sensitivity, orgasmic potential, ability for intercourse without pain, gender identity, and psychological aspects in those undergoing early genital surgery currently exist. It is beyond the scope of this chapter to discuss all the pros and cons of this controversy, but it is clear that further studies are warranted.

The recently published "Consensus Statement on Management of Intersex Disorders" from a multispecialty international group has been beneficial, but many questions still remain unanswered (Hughes et al, 2006). It is strongly recommended that physicians honestly discuss with the parents of these children all aspects of care, including options, risks and benefits, and negative aspects of both observation and surgical therapy. Although early surgery has been the norm historically, the option of observation with psychological and peer support should be a realistic proposition (Creighton and Liao, 2004). A team of physicians, including a neonatologist, endocrinologist, geneticist, psychiatrist, psychologist, and pediatric urologist, should work with and for the parents in this decision making process. The formation of a gender assignment team has been shown to allow integrated care and more accurate diagnoses in children with DSD (Parisi et al, 2007). Current surgical techniques that are available should surgical therapy be chosen for a child with DSD are addressed in this chapter, but it must be known that absolute indications are rare (Schober, 2004). Other female genital anomalies not associated with genital ambiguity also are discussed.

FEMALE REPRODUCTIVE AND CAUDAL EMBRYOLOGY

A comprehensive description of genitourinary embryology can be found in Chapters 111 and 133. To foster a deeper understanding of the complex combination of anomalies that can occur in patients with vaginal and cloacal anomalies, a brief review of relevant embryologic events is presented.

The cloaca is an endoderm-lined primordial organ that is first apparent at the beginning of the second week of gestation (Grosfeld, 1996). This structure, which represents a confluence of the primitive hindgut (dorsally) and the allantois (ventrally) just before the fourth week of gestation, receives the mesonephric ductal system. The urorectal septum, which first appears during the fourth week of development, serves to separate the urogenital sinus (ventrally) from the anal canal (dorsally) (Moore and Persaud, 1995). The urorectal septum actually consists of two components. The first is the Tourneux fold, which develops along the coronal plane in the angle between the allantois and the hindgut and grows in a caudal fashion toward the cloacal membrane. As this septum nears the cloacal membrane, infoldings of the lateral walls of the cloaca form Rathke plicae, which coalesce in the coronal midline and form the urorectal septum caudally. By weeks 6 to 7 of development the urorectal septum has fused with the cloacal membrane and divided it into a ventral urogenital membrane and a dorsal anal membrane. The fibromuscular node of tissue that results from contact of the septum with the cloacal membrane serves as a critical insertion site for the perineal muscles and as the dividing point of the primitive cloacal sphincter complex into anterior (urogenital diaphragm) and posterior (external anal sphincter) components. The common ontogeny of these two sphincter complexes explains why the pudendal nerve supplies all of these muscles.

While the urorectal anlage is undergoing division, the developing mesonephric ducts, which have contacted the cloaca, enter the urogenital sinus near the müllerian tubercle (Churchill and Hardy, 1978). An offshoot of the mesonephric duct, the ureteric bud, extends cranially to induce development of the metanephric blastema. The terminal branch point of the ureteral bud from the mesonephric duct is later absorbed into the wall of the urogenital sinus. Proper incorporation of this complex results in the ureters opening at the lateral aspect of the trigone.

During this critical phase of cloacal development, paired müllerian ducts, which form from the coelomic epithelium, develop lateral to the mesonephric ducts and cross medially to fuse in the midline. The close proximity of these two ductal systems helps explain the common association of paramesonephric abnormalities and ipsilateral renal anomalies. The paired müllerian ducts then proceed caudally to join the urogenital sinus, where they produce an elevation called the müllerian tubercle. The caudal fusion of portions of these ducts normally leads to dissolution of the shared midline partition and the formation of a common uterovaginal canal, which as the name implies, gives rise to the uterus, cervix, and proximal two thirds of the vagina. Failure of septal regression can result in a number of possible müllerian duct abnormalities.

As first delineated by Koff in 1933, contact of the uterovaginal primordium with the urogenital sinus forms the müllerian tubercle, which in turn induces the formation of paired caudal endodermal outgrowths called sinovaginal bulbs. Evidence suggests that these outpouchings may in fact represent the terminal segments of the wolffian ducts (Bok and Drews, 1983). Regardless of origin, the cells within these sinovaginal bulbs then proliferate to form a cord of tissue that develops into a distal vaginal plate, which is later canalized in a caudal-to-cranial direction to form the distal aspect of the vagina (Fig. 134–1). The portion of the urogenital sinus distal to the müllerian tubercle subsequently undergoes exstrophy and everts to become the vestibule. As a result of this process, the urethra and vagina acquire separate openings in the vulva. The lumen of the vagina is separated from the cavity of the urogenital sinus by the hymen, an invagination of the posterior wall of the urogenital sinus. Rupture of the hymen should occur during the perinatal period.

Various cystic structures may form along the luminal aspect of the vagina. Remnants of the prostatic ductal system and the wolffian duct give rise to the paraurethral glands of Skene and Gardner, respectively. Outgrowths from the urogenital sinus form the greater vestibular glands of Bartholin, which are homologues of the bulbourethral glands in the male.

Key events in skeletal formation occur concurrently with cloacal division and proper formation of the mesonephric and paramesonephric ductal systems (Churchill and Hardy, 1978). The vertebrae develop in a craniocaudal direction, with the lower extremity limb buds developing from condensation of somites 25 through 29. These somites undergo critical differentiation from the fourth through the eighth weeks of development.

From the foregoing brief description of caudal embryology it should be evident that a disturbance in segmentation at the level of the caudal somites when the fetus is less than 10 mm in size (fourth to fifth weeks of human development) can affect many different organ systems. In 1960, Duhamel described the association of these "coincidentally" occurring congenital malformations

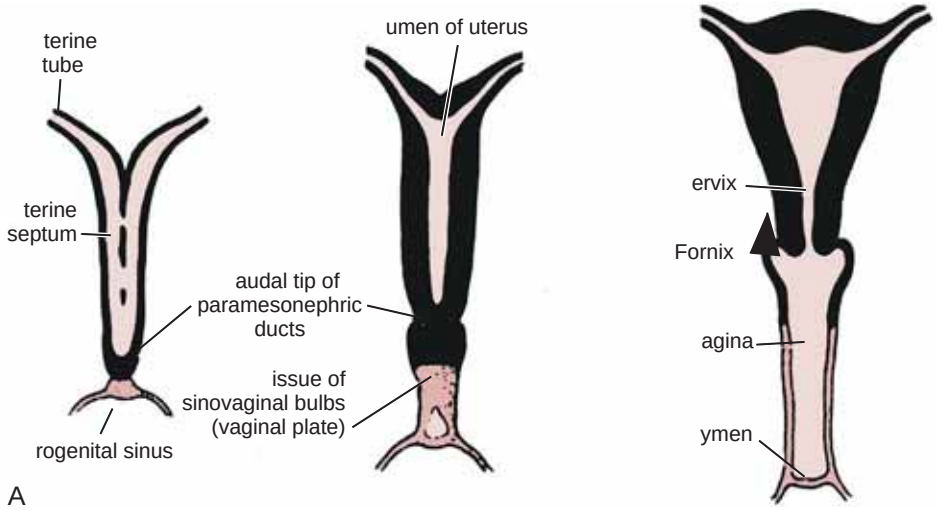

Figure 134–1. **A** to **C,** Formation of the vagina from the sinovaginal bulbs. (From Saler TW. Langman's medical embryology. 6th ed. Baltimore: Williams & Wilkins; 1990.)

and introduced the term *caudal regression syndrome* (Duhamel, 1961). Laboratory data with teratogens support the concept that a key event occurs between the fourth and fifth weeks of gestation that results in an error in the simultaneous development of the terminal bowel, kidney, bladder, paramesonephric ductal system, and lumbosacral spine (Mesrobian and Sessions, 1994). The actual inciting event remains unclear, although disordered mesodermal migration, reduced cellular proliferation, and premature apoptosis have all been proposed as potential mechanisms (Kallen and Winberg, 1974; Alles and Sulik, 1993). Elements of the caudal regression syndrome are seen with increased frequency in infants of diabetic mothers, but the exact mechanism is still in question (Deuchar, 1978; Lynch et al, 1995). Specific gene deletions in the homeobox region of the mammalian genome (the region critical for proper mammalian spatial orientation and segmentation) have been shown to result in a constellation of anatomic findings, as predicted by Duhamel (Warot et al, 1997). Because differentiation of the somites progresses in a cranial-to-caudal direction, it would follow that the most complex anomalies (higher anorectal malformations) would occur as a result of aberrations at an earlier stage of development. This also helps explain the greater association of severe upper urinary tract malformations, internal genital duct abnormalities, and spinal anomalies in these patients than in those with less severe cases of imperforate anus.

Mesodermal disturbances are not limited to the caudal somites. As seen in the VATER (*V*ertebral defects, *A*nal atresia, *T*racheoesophageal fistula with *E*sophageal atresia, and *R*adial and renal dysplasia) and MURCS (*MÜ*llerian duct aplasia, *R*enal aplasia, and *C*ervicothoracic *S*omite dysplasia) associations, mesodermally derived organs as cranial as the C1 vertebra and tracheoesophageal anlagen can be affected in association with congenital abnormalities of the mesonephric and paramesonephric ductal systems (Quan and Smith, 1973; Duncan et al, 1979).

Key Points: Embryology

- The close proximity of the mesonephric and paramesonephric ductal systems helps explain the common association of paramesonephric abnormalities and ipsilateral renal anomalies.
- The proximal part of the vagina forms from the paired müllerian ducts, whereas the distal portion forms from proliferating cells in the sinovaginal bulbs that later canalize.

STRUCTURAL ANOMALIES OF THE FEMALE INTERNAL GENITALIA

Anomalies of the female reproductive system can be grouped into three main categories: (1) those resulting from either hypoplasia or agenesis, (2) those caused by vertical fusion (canalization abnormalities resulting from abnormal contact of the müllerian structures with the urogenital sinus), and (3) those resulting from lateral fusion (duplication). The clinical manifestations, physical findings, evaluation, and subsequent therapy vary considerably among these groups. Radiographic imaging is of central importance in determining the correct diagnosis. Ultrasonography is helpful not only in identifying the genital anatomy but also in screening for associated upper urinary tract abnormalities (Rosenberg et al, 1986; Fernandez et al, 1996). Magnetic resonance imaging (MRI) is considered by many to be the "gold standard" for defining internal müllerian anatomy (Fedele et al, 1996; Russ et al, 1997; Lang et al, 1999). It is especially useful for determining the presence or absence of the cervix and the presence of functioning endometrium in complex anomalies. In complicated cases, additional information can be obtained by examination under anesthesia, vaginoscopy, hysteroscopy, and laparoscopy (Major et al, 1997). Obstructive anomalies typically require immediate intervention, but nonobstructive anomalies often do not require surgical intervention unless the patient has reached reproductive age and the condition affects intercourse or adversely affects fertility. Various systems have been proposed for the classification of these anomalies, with the system proposed by the American Society for Reproductive Medicine being the most inclusive (American Fertility Society, 1988).

Obstructive Genital Anomalies

Abnormalities of Vertical Fusion

Transverse Vaginal Septum. **Transverse vaginal septa are believed to arise from a failure in fusion or canalization (or both) of the urogenital sinus and müllerian ducts.** The estimated incidence of transverse vaginal septum is 1 in 70,000 females (Banerjee and Laufer, 1998). Many of the patients have amenorrhea and a distended upper vagina. **A complete transverse vaginal septum may be located at various levels in the vagina, but there is a higher frequency in the middle and upper third of the vagina.** In one large series the distribution was 46% in the upper vagina, 40% in the middle vagina, and 14% in the lower vagina (Fig. 134–2) (Lodi, 1951). The septa are usually less than 1 cm thick and frequently have a small central or eccentric perforation (Suidan and Azoury, 1979). Even in cases in which a perforation is present, significant obstruction and ascending infection can occur.

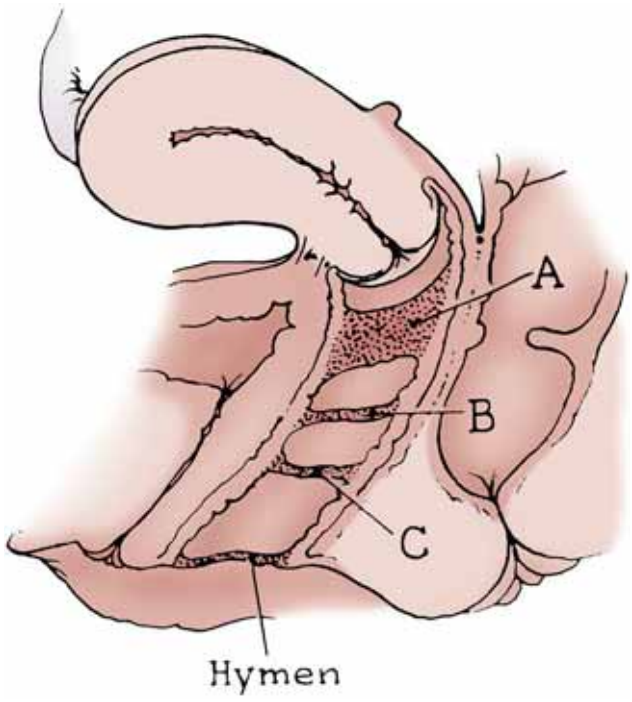

Figure 134–2. Transverse vaginal septum: A, high (upper vagina); B, middle; C, low. (From Yerkes EB, Rink RC. What urologists should know about pediatric gynecologic abnormalities. Contemp Urol 2002;14:12.)

Transperineal, transrectal, and abdominal ultrasonography and MRI may be beneficial in establishing the diagnosis and determining the location and thickness of a transverse vaginal septum (Ammann et al, 1983; Doyle, 1992; Meyer et al, 1995; Caloia et al, 1998; Fedele et al, 1999; Lang et al, 1999). MRI can help determine whether a cervix is present so that a high septum can be differentiated from congenital absence of the cervix. Failure to differentiate between these diagnoses can result in significant patient morbidity (Casey and Laufer, 1997).

Several surgical treatment modalities have been developed to treat congenital transverse vaginal septa. If the patient's pain from hematocolpos is manageable, surgery may be delayed with suppression of endometrial activity by a GnRH agonist or continuous oral contraceptives (Beyth et al, 2004). This may allow time for dilatation of the lower vaginal segment, potentially improving the ease of surgical repair. Techniques include simple incision (Brenne et al, 1965; Buttram, 1983), surgical excision of the septum followed by approximation of the corresponding portions of the transversely cut edges of the upper and lower mucosal membranes of the septum (Rock et al, 1982) and the use of Z-plasties involving vaginal mucosa (Wierrani et al, 2003). Vaginal stenosis at the site of resection is the most common complication (Joki-erkkila and Heinonen, 2003). The primary advantage of a Z-plasty is that as the suture line contracts the incision is more likely to take on a longitudinal rather than a transverse orientation. Placement of a vaginal mold subsequent to surgery has been reported to further reduce the risk of postoperative stenosis (Bijsterveldt and Willemsen, 2009). Characteristics of molds for transverse septa are different than those used after a McIndoe vaginoplasty (see later). Whereas a solid mold may be used after a vaginoplasty skin graft (because there is no uterus), the mold used after resection of a transverse septum is ideally hollow to allow egress of menstrual flow.

Vaginal Atresia (Distal Vagina). **Vaginal atresia occurs when the urogenital sinus fails to contribute to formation of the lower (distal) portion of the vagina. This condition differs from vaginal agenesis and testicular feminization in that the müllerian structures are not affected. As a result, the uterus, cervix, and upper portion of the vagina are normal.** A very shallow dimple caudal to the urethral opening may be appreciated on physical examination. Palpation of a distended vagina on rectal examination may help distinguish this condition from testicular feminization or vaginal agenesis. Radiographic evaluation in the form of ultrasonography or MRI, or both, is mandatory to adequately define the müllerian anatomy before intervention.

Surgical correction consists of a transverse incision at the level of the hymenal ring. Dissection is carried out through the fibrous area of the absent lower vagina until the upper vagina is reached. As in treatment of a transverse vaginal septum, distention of the vagina with retained menstrual blood products can prove extremely beneficial in that it acts as a tissue expander. After the obstruction is drained and the vaginal mucosa is identified, a pull-through procedure can be performed to bring the distended vagina down to the introitus. The distance to bridge between the vagina and the perineal surface can almost always be successfully managed with perineal skin flaps or simple mobilization of the vagina (or both). Ramenofsky and Raffensperger (1971) described a combined abdominoperineal approach that can be of help in exposing and anastomosing the distal vagina to the perineal skin.

Vaginal Agenesis (Müllerian Aplasia). Vaginal agenesis, which occurs at an incidence of approximately 1 in 5000 live female births, is congenital absence of the proximal portion of the vagina in an otherwise phenotypically (i.e., normal secondary sexual characteristics), chromosomally (i.e., 46,XX), and hormonally (i.e., normal levels of luteinizing hormone and follicle-stimulating hormone) intact female (Bryan and Nigro, 1949; Griffin et al, 1976). Although Realdus Columbus is credited by some authors as the first to describe a case of vaginal agenesis, Mayer was one of the first to report vaginal agenesis in stillborn children (Mayer, 1829; Lesavoy, 1985). In 1838, Rokitansky reported 19 adult autopsy cases of uterovaginal agenesis, including 3 with associated unilateral renal agenesis. In 1910, Küster recognized urologic associations, such as renal ectopy and agenesis, along with skeletal deformities. Hauser and Schreiner (1961) brought further attention to the frequent association of renal and skeletal anomalies in these patients and stressed the differences between patients with these findings and those with testicular feminization.

The Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome, as the entity of müllerian aplasia has come to be known, results from failure of the sinovaginal bulbs to develop and form the vaginal plate (Fig. 134–3). This may be caused by improper induction of the sinovaginal bulbs from the neighboring uterovaginal primordium. Chronologically, the uterovaginal canal develops at a point in embryogenesis during which other critical mesodermally derived organ systems are also forming, which in part explains the many associated findings. Müllerian aplasia has also been associated with maternal deficiency of galactose-1-phosphate uridyltransferase (Cramer et al, 1996). In contrast to vaginal atresia, the hymenal fringe is usually present along with a small vaginal pouch because they are both derived embryologically from the urogenital sinus.

Most patients with MRKH syndrome are initially evaluated by the physician after the expected age of menarche because of primary amenorrhea. This syndrome is in fact second only to gonadal dysgenesis as a cause of primary amenorrhea. A minority of patients have cyclic abdominal pain caused by retention of menstrual blood in the uterus. Physical examination reveals absence of the vagina. Inguinal hernia is less common in this disorder than in the testicular feminization syndrome (Schmid-Tannwald and Hauser, 1973). The karyotype is that of a normal 46,XX woman. Radiographic evaluation is indicated to more fully delineate remnant müllerian structures and search for associated anomalies involving the renal and skeletal systems.

Associated Findings. MRKH syndrome is associated with variable absence or hypoplasia of the cervix, uterus, and fallopian tubes. In approximately 10% of patients, a normal but obstructed uterus or a rudimentary uterus with functional endometrium is present (Murray and Gambrell, 1979; Singh and Devi, 1983; Bates and Wiser, 1985). In one of the largest single series to date, Salvatore and Lodovicci (1978) reported that of 91 patients with vaginal agenesis, almost 25% lacked a uterus, 55% had a solid rudimentary uterus, and the remaining 30% had other abnormalities of this organ. In addition, they demonstrated that although the fallopian tubes were normal in 32% of cases they were rudimentary in almost 50% and completely absent in 10%. Although occasionally cystic, the ovaries were almost always present and functional (Salvatore and Lodovicci, 1978). **It was subsequently recognized, based on the morphology of the retained müllerian structures, that MRKH syndrome could be divided into typical and atypical forms (Schmid-Tannwald and Hauser, 1977).**

In the typical form of MRKH syndrome (type A), the patient has symmetrical uterine remnants and normal fallopian tubes. The atypical form (type B) is characterized by asymmetrical uterine buds or abnormally developed fallopian tubes. This distinction is important

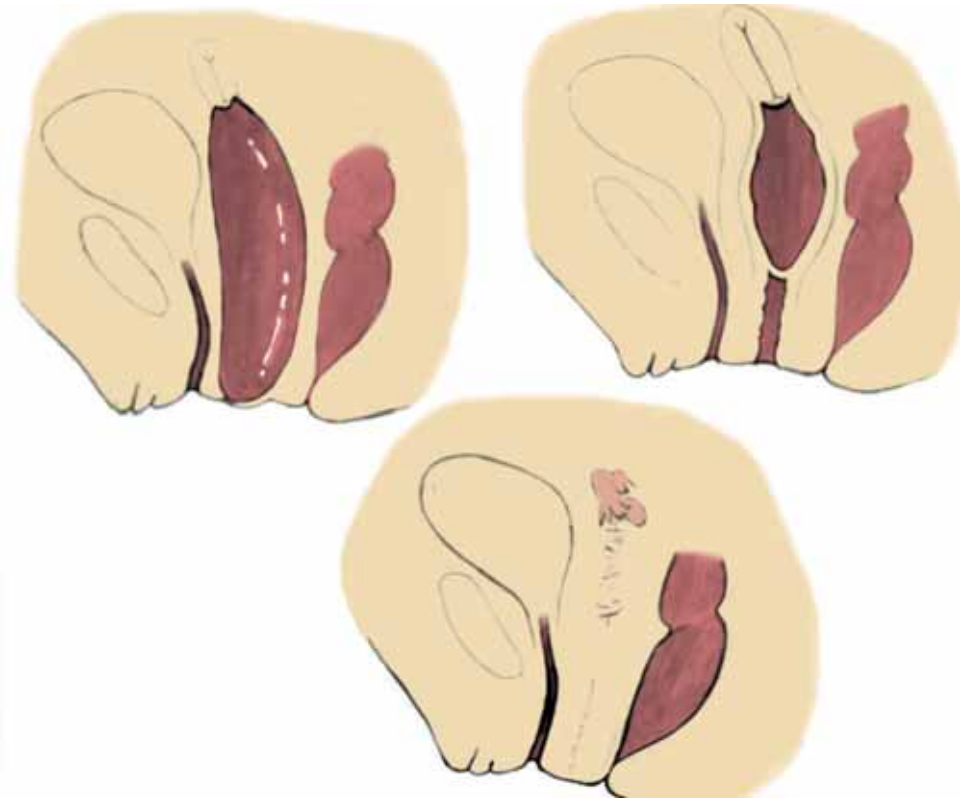

Figure 134–3. Forms of vaginal obstruction. *Upper left,* Imperforate hymen; *upper right,* transverse vaginal septum; *lower,* vaginal agenesis. (From Yerkes EB, Rink RC. What urologists should know about pediatric gynecologic abnormalities. Contemp Urol 2002;14:12.)

because the overwhelming majority of associated findings in other organ systems have been reported to be present with the atypical form whereas in the typical form these findings are usually absent (Strubbe et al, 1992, 1993).

The association between vaginal agenesis and developmental abnormalities of the kidney was first recognized by Rokitansky (1838). Approximately a third of patients are found to have abnormal renal findings on intravenous pyelography or ultrasound examination (Strubbe et al, 1993). Renal anomalies are present almost exclusively in patients with the atypical subtype of vaginal agenesis (type B). In Strubbe's series, 34 of 51 patients with type B anatomy had renal anomalies, but none of the 40 patients with type A (symmetrical) anatomy demonstrated such a deformity (Strubbe et al, 1993). A meta-analysis published by Griffin and associates (1976) demonstrated that the renal anomaly consists of either unilateral renal agenesis or ectopia of one or both kidneys in 74% of those affected. The close proximity of the mesonephric and paramesonephric structures during the early phase of fetal development is thought to be the reason for this frequent association of renal anomalies. Not surprisingly, the converse is also true: the incidence of associated genital abnormalities in female patients with renal anomalies ranges between 25% and 89% (Thompson and Lynn, 1966).

Associated congenital abnormalities of the skeletal system have been described in 10% to 20% of cases (Turunen, 1967; Willemsen, 1982; Strubbe et al, 1987). Congenital fusion (failure of segmentation) of the cervical vertebrae is known as the Klippel-Feil syndrome and occurs approximately once in 30,000 to 40,000 live births (Gunderson et al, 1967). An association between this abnormality of cervical somite development and vaginal agenesis was first recognized by Duncan (1977). He proposed the term *MURCS association* to describe the combination of *MÜ*llerian duct aplasia, *R*enal aplasia, and *C*ervicothoracic *S*omite dysplasia, which many believe is caused by a generalized disordered development of mesodermal differentiation during the fourth week of fetal life (Duncan et al, 1979). Strubbe demonstrated that the Klippel-Feil abnormality was found only in patients with the atypical form of MRKH syndrome (type B). Additional, albeit less common skeletal abnormalities include scoliosis and abnormalities of the hands and face (Willemsen, 1982; Fisher et al, 2000). Unlike müllerian anomalies that are associated with abnormal cloacal septation, vaginal agenesis is not associated with an increased incidence of

Key Points: Structural Anomalies of the Female Genitalia

- Anomalies of the female reproductive system can be grouped into three main categories, those resulting from (1) hypoplasia or agenesis, (2) vertical fusion, and (3) lateral fusion.
- Transverse vaginal septa are believed to arise from a failure in fusion or canalization (or both) of the urogenital sinus and müllerian ducts.
- Vaginal atresia occurs when the urogenital sinus fails to contribute to formation of the lower (distal) portion of the vagina.
- Vaginal agenesis is congenital absence of the proximal portion of the vagina in an otherwise phenotypically, chromosomally, and hormonally intact female.
- MRKH syndrome, as the entity of müllerian aplasia has come to be known, results from failure of the sinovaginal bulbs to develop and form the vaginal plate.

lumbosacral spinal disorders or occult spinal dysraphism (Gunderson et al, 1967).

Creation of a Skin Neovagina. Both nonoperative and operative treatment options exist for this anomaly. Regardless of the method used, it can be very helpful to have the patient speak with someone who has previously undergone treatment before treatment is initiated (Ingram, 1981). **The nonoperative approach, initially popularized by Frank** (1938), **involves gentle pressure of graduated hard dilators against the perineal surface to create a progressive invagination of the vaginal dimple.** Ingram (1981) modified this technique by using a bicycle seat mounted on a stool. The nonoperative approach has greatest success when a vaginal dimple or pouch is already present (Williams et al, 1984, 1985). Gargollo and colleagues (2009) recently reported their experience with 69 females (mean 17.5 years) with vaginal agenesis treated with progressive perineal dilation. Success, defined as the ability to achieve sexual intercourse, vaginal acceptance of the largest dilator without discomfort, or a vaginal length of 7 cm, was achieved in 88% of patients. The authors concluded that progressive perineal dilation should be offered as first-line therapy in adolescents with congenitally absent vagina.

Modifications of the Frank technique of perineal pressure have been developed that incorporate the surgical placement of tension sutures to aid in directing pressure from a Plexiglas dilator against the vaginal dimple (Vecchietti, 1979). The mold, often referred to as an "olive," has sutures attached to it that are guided in a cranial direction through the vesicorectal space into the perineal cavity and brought out through the abdominal wall (Vecchietti technique). Tension is progressively increased via the abdominal wall sutures until sufficient vaginal length has been achieved. To avoid a formal laparotomy, laparoscopic techniques have been described to assist in dissection of the tissue plane for the Vecchietti technique (Borruto, 1992; Gauwerky and Wallwiener, 1992; Fedele et al, 1996, 1999; Brucker et al, 2008). In Fedele and colleagues' more recent series, all patients were found to have healthy vaginal mucosa, with the average vaginal length being almost 8 cm at 3 months. This technique has had limited use by urologists.

If the Frank method has been unsuccessful or is not accepted as a reasonable option by the patient or parents, creation of a functional vagina can be achieved by one of several techniques (Abbé, 1898; McIndoe and Banister, 1938; Hendren and Atala, 1994). **The first landmark advance in vaginal reconstruction is attributed to Abbé in 1898. Abbé described dissecting a canal between the rectum and urethra and lining this area with split-thickness skin grafts. This method was later popularized by McIndoe, and the procedure that bears his name has gained wide acceptance in the United States** (McIndoe and Banister, 1938). Preoperative preparation consists of full mechanical and antibiotic bowel preparation. A split-thickness skin graft is taken from the buttocks (0.018 to 0.022 inch) and tubularized over a stent (Fig. 134–4). A transverse incision is made at the level of the perineal dimple, and the potential space between the urethra and the rectum is carefully dissected up to the level of the peritoneal reflection. The graft and mold are then inserted into the potential space, and the labia minora are sutured around the stent to prevent extrusion during the initial healing phase (McIndoe, 1950). Many types of vaginal stents have been used for this purpose, including packed gauze, wood covered with a condom, silicone foam, acrylic, various metals, and an inflatable vaginal stent (Concannon et al, 1993; Chen, 1994; Barutcu and Akguner, 1998). The Foley catheter is replaced by a suprapubic catheter, and postoperatively the patient

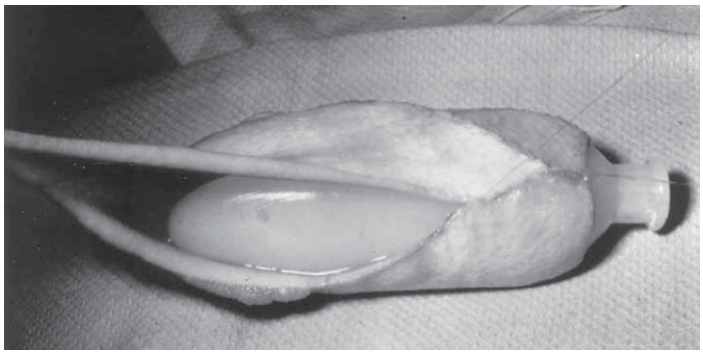

Figure 134–4. McIndoe skin vagina sewn over a vaginal stent.

is kept at strict bed rest for 1 full week. A high incidence of postoperative vaginal stenosis necessitates postoperative vaginal dilation (Ingram, 1981). Excellent patient satisfaction has been reported in most large series (Martinez-Mora et al, 1992; Strickland et al, 1993; Alessandrescu et al, 1996).

Other options for creation of a neovagina with local tissues include the use of full-thickness skin grafts from the buttocks or full-thickness skin flaps based on the labia majora. Those who champion the use of full-thickness skin grafts report a lower incidence of graft contracture than when split-thickness graft techniques are used (Sadove and Horton, 1988). The Williams vaginoplasty involves the creation of a vaginal pouch from the labia majora (Williams, 1964). The combination of this procedure and Frank-type dilation along the vaginal axis can provide a satisfactory result.

Many other surgical procedures have been developed for creation of a functional neovagina with various muscle flaps (e.g., pudendal thigh, rectus abdominis, buttock) (McCraw and Massey, 1976; Lilford et al, 1989; Dumanian and Donahoe, 1992; Wang and Hadley, 1993; Joseph, 1997). The pelvic peritoneum and human amnion are two other donor sites that have been used to create a neovagina (Davydov, 1977; Ashworth et al, 1986; Morton and Dewhurst, 1986; Tamaya and Imai, 1991; Marquis et al, 2008).

Creation of an Intestinal Neovagina. Baldwin first described the use of bowel for creation of the vagina in 1907. The procedure involved anastomosis of a U-shaped segment of sigmoid colon to the perineum with subsequent division of the intervening septum (Hensle and Dean, 1992). Additional experience with this technique was reported by Fall in 1940, but it did not gain widespread acceptance until the 1970s because of high patient morbidity and mortality (Fall, 1940; Pratt, 1972). Subsequent improvements in technique and postoperative care resulted in renewed enthusiasm for these techniques (Turner-Warwick and Kirby, 1990; Hendren and Atala, 1994; Hensle and Reiley, 1998; Tillem et al, 1998). Sigmoid, cecum, and small intestine have all been used successfully for the creation of a functional neovagina.

The day before surgery, the patient undergoes full mechanical and antibiotic cleansing of the alimentary tract. The procedure is performed with the patient supine, the legs spread, and the knees bent (frog-leg position). In an older child, Allen stirrups can be used. For a sigmoid vaginoplasty, the intra-abdominal portion of the procedure begins by first identifying an appropriate length of distal sigmoid with a blood supply that will comfortably reach the perineum (Figs. 134–5 and 134–6). The distal end of the proposed segment is then divided and anastomosed to the perineum (Fig. 134–7). An intervening segment of sigmoid (approximately 3 cm) is then excised to create a space between the oversewn proximal edge of the bowel vagina and the end of the sigmoid, which is

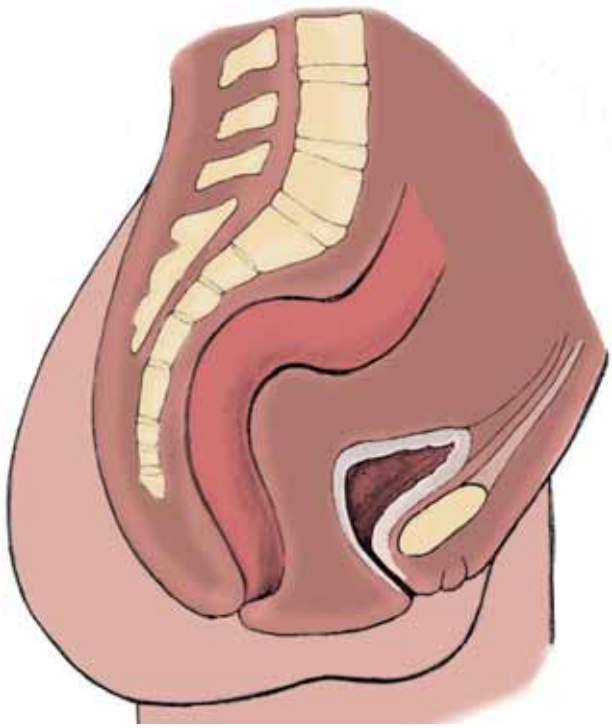

Figure 134–5. Vaginal agenesis.

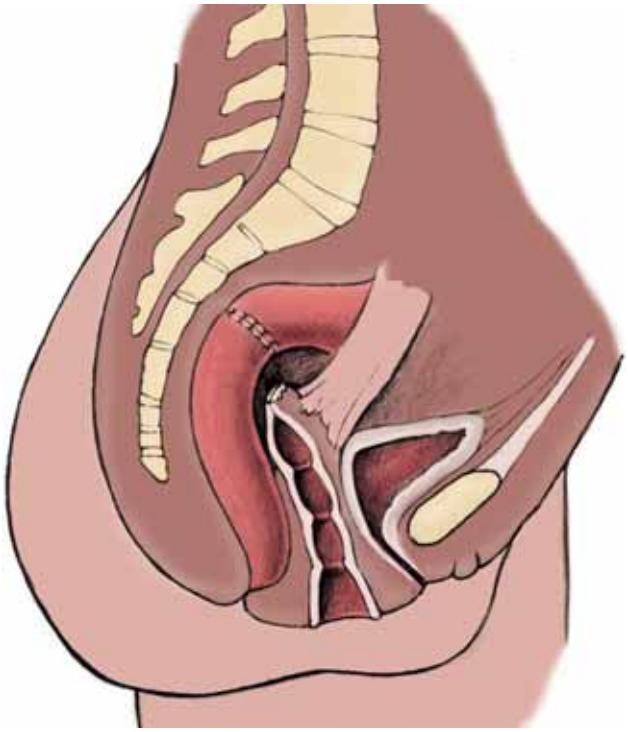

Figure 134–6. Bowel vagina: colonic segment sewn in place.

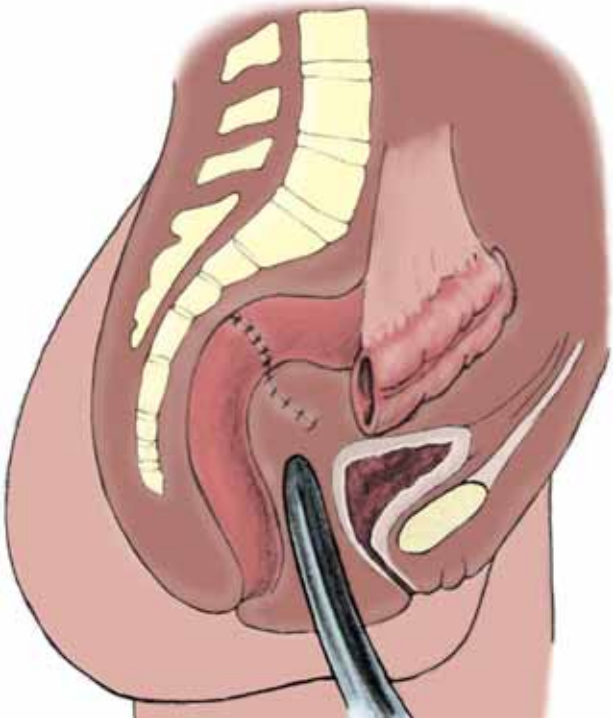

Figure 134–7. Bowel vagina: harvest of a colonic segment and creation of vaginal space.

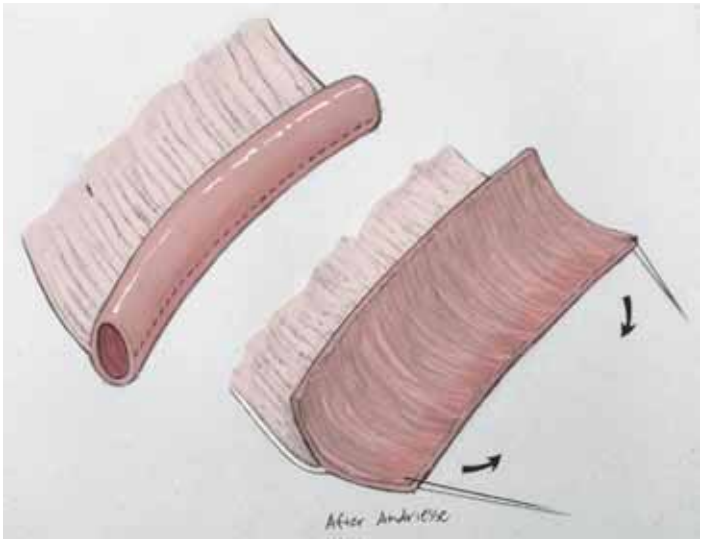

Figure 134–8. Bowel vagina: harvest of an ileal segment.

anastomosed to the rectum. This maneuver prevents an overlap of suture lines and thereby has the potential advantage of limiting the incidence of fistula formation. The bowel vagina is thereafter fixed to the posterior peritoneum to prevent prolapse. Gosalbez has recently described a modified Monti technique of bowel detubularization for vaginal replacement that can aid in allowing the segment to reach the perineum. By opening the colonic segment close to its mesentery along one side of the bowel and then retubularizing in a Heineke-Mikulicz fashion as described by Monti, the reconfigured segment allows for the mesentery to be located at the most cranial end of tube and allows the caudal end to extend more distally (Gosalbez, 2009).

Although the authors have had the most success with the sigmoid, a small-bowel segment may be chosen with a vascular pedicle that is of adequate length to reach the perineum. After isolating an appropriate length of ileum and reestablishing bowel continuity, the segment is detubularized and reconfigured in a conical arrangement to provide increased internal diameter (Figs. 134–8 and 134–9) (Hendren and Atala, 1994). The segment is then brought down to the perineum and sewn in place, as for a sigmoid

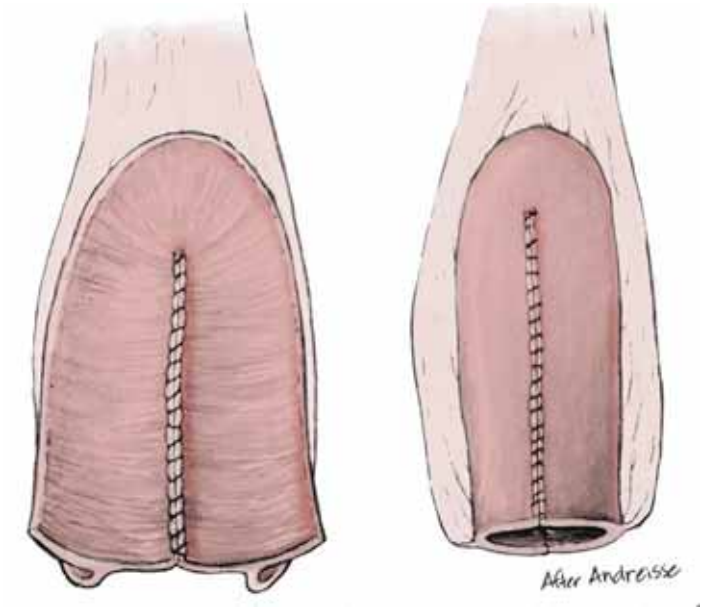

Figure 134–9. Bowel vagina: reconfiguration of the ileal segment to create a larger luminal diameter.

neovagina. To avoid a formal laparotomy, laparoscopically assisted techniques have been described for harvest and delivery of the bowel segment to the perineal location (Ota et al, 2000).

If there is a perineal dimple (i.e., the segment of vagina contributed by the urogenital sinus is present), the bowel segment should be anastomosed directly to it. When a direct perineal anastomosis is required, it is of critical importance to create a large enough space between the rectum and bladder to avoid compromise of the intestinal blood supply. Creation of such a space can be facilitated by the use of progressively larger Hegar dilators. Gentle passage of the intestinal segment into position is facilitated by placing the segment in a large lubricated Penrose drain before transfer to the perineum.

The functional results of bowel vaginoplasty have been excellent. Of the 65 patients reported by Hendren, 16 experienced mild eversion of the bowel segment, which in every case was amenable to simple trimming. Eight patients experienced mild stenosis that was later corrected by appropriate Z-plasties to increase the circumference of the mucocutaneous junction (Hendren and Atala, 1994). **Patient satisfaction is high, and the majority of patients who are old enough to engage in sexual relations are able to achieve adequate coitus** (Hensle and Reiley, 1998).

Stenosis has been reported more frequently after the use of ileum (Hensle and Dean, 1992). **This higher stenosis rate may be due not only to the more narrow ileal lumen but also to the limited mobility of the small bowel mesentery.** As a result, the authors and others believe that large intestine is the bowel segment of choice. Two specific indications for use of an ileal segment for bowel vaginoplasty are previous irradiation of the deep pelvis and the absence of large intestine (i.e., cloacal exstrophy). When ileum is used, various methods of reconfiguration can be used to increase the diameter (Hendren and Atala, 1994). Advantages of a bowel vagina over the McIndoe procedure include the lubricating properties of mucus (which may help facilitate intercourse) and the decreased incidence of postoperative contracture (and hence the reduced need for postoperative dilatation). Disadvantages include the frequent need to wear pads because of the chronic vaginal discharge. Daily douching may be necessary to evacuate the mucus. Finally, the potential transmission of blood-borne pathogens such as hepatitis and human immunodeficiency virus may be increased (in comparison to a squamous epithelium-lined vagina) because of the poor barrier effect of the gastrointestinal tract.

All patients undergoing creation of a functional vagina with perineal skin require annual examination because there have been reports of condylomata acuminata and squamous cell carcinoma involving grafts (Duckler, 1972; Rotmensch et al, 1983; Buscema et al, 1987). Annual examination of the bowel vagina is also indicated because adenocarcinoma has been identified after this procedure (Andryjowicz et al, 1985).

The optimal timing of surgery remains a source of debate. The majority of surgeons who favor the McIndoe procedure for construction of a neovagina believe that it is better to wait until adulthood to perform the procedure because a degree of maturity is required to consistently perform daily dilatations. Many surgeons who favor the use of bowel for neovaginal reconstruction do not believe that vaginoplasty should be deferred until the patient reaches adulthood. Hendren and Atala (1994) believe that delaying creation of a neovagina until adulthood may be psychologically traumatic to a young girl. The authors have based timing on the underlying diagnosis and need for a neovagina.

Special Considerations: Cervical Atresia. Cervical agenesis is an uncommon disorder that is associated with symptoms common to other obstructive entities of the female reproductive tract (i.e., primary amenorrhea, cyclic or chronic abdominal pain). **Failure to establish the correct diagnosis and thereby choose the appropriate method of surgical intervention can be fraught with disaster and possible patient mortality.** MRI is the most useful radiographic modality in establishing this diagnosis (Fig. 134–10). In many circumstances the patient is best served by hysterectomy with subsequent vaginal replacement by one of the previously described techniques (Rock et al, 1984; Cukier et al, 1986). Successful direct anastomosis of the neovagina to the uterine remnant has been reported. Deffarges and coworkers (2001), in describing their experience with uterovaginal anastomosis, reported a 40% pregnancy rate in patients attempting to conceive. Cerclage was performed in only one case. All deliveries were by cesarean section. **Although this procedure appears to be successful in the majority of cases, absence of the normal endocervical barrier can leave the patient predisposed to the development of life-threatening ascending infection** (Maciulla et al, 1978; Niver et al 1980; Casey and Laufer, 1997).

Key Points: Vaginal Replacement Surgery

- The McIndoe procedure (skin neovagina) is associated with a higher incidence of postoperative vaginal stenosis than a bowel neovagina.
- Vaginal stenosis after creation of an intestinal neovagina is more common with ileum than with large bowel.
- Vaginal reconstruction extending from the perineum to the uterus should be avoided in patients with cervical agenesis (because of the potential life-threatening complication of ascending bacterial infection).

In cases in which it has not been possible to successfully achieve continuity between the uterus and vagina, in-vitro fertilization plus transmyometrial embryo transfer has been performed, with

The *solid arrow* points to the most cranial portion of the perineal vaginal pit. The *dashed arrow* points to the most inferior aspect of the uterus, where no cervical impression can be appreciated.

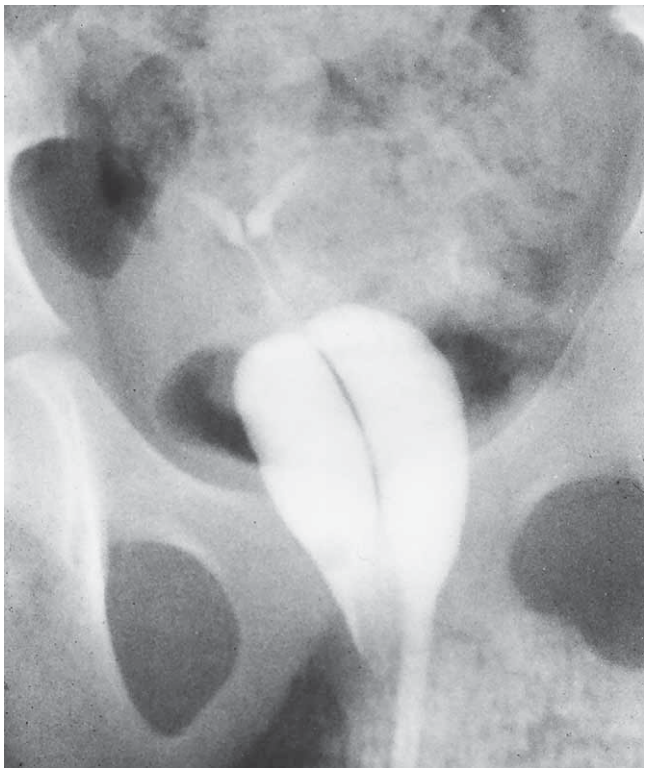

Figure 134–11. Genitogram of complete müllerian duplication (septated vagina and separate uteri).

subsequent delivery of a healthy fetus by cesarean section (Anttila et al, 1999; Lai et al, 2001). If this option is considered, hormonal blockade of the endometrium until the time at which the patient desires to initiate a pregnancy is indicated to minimize discomfort and reduce the incidence of endometriosis from retrograde menstrual flow in the fallopian tubes.

Abnormalities of Lateral Fusion

Most abnormalities of lateral fusion have no functional significance. With the exception of those with uterus didelphys and unilateral vaginal obstruction, most patients are asymptomatic. Although an exhaustive description of the defects of lateral fusion is beyond the scope of this chapter, some general comments can be made.

True duplication of the uterus is a rare event. This anomaly results from duplication of the müllerian ducts and subsequent doubling of the reproductive structures on one or both sides. The much more frequently encountered anomaly of uterine didelphys consists of two separate uterine cavities and cervices as a result of failed resorption of the common medial wall of the paired müllerian duct structures during development. Although up to 75% of patients also have a septate vagina, most have adequate reproductive outcomes and do not require surgical intervention. If later in life the patient experiences difficulty with intercourse, vaginal delivery, or the need to use two tampons, surgical excision of the vaginal septum should be undertaken. If only the most cranial portion of the septum remains, a bicornuate uterus will result. The vagina is typically normal, and surgical incision of the uterine septum is rarely indicated except in cases of recurrent pregnancy loss (DeCherney et al, 1986).

Duplication of the Uterus and Cervix with a Unilaterally Imperforate Vagina. **Although the majority of obstructive lesions are caused by abnormalities in vertical fusion, occasionally an obstructive process can be encountered in the context of an abnormality in lateral fusion** (Figs. 134–11 and 134–12). More than 50 cases of uterus didelphys with a unilateral imperforate vagina have been reported in the world's literature (Allan and Cowan, 1963; Burbige and Hensle, 1984). **As with other obstructive disorders, the patient may have cyclic or chronic abdominal pain. However, unlike other obstructive processes, duplication anomalies with unilateral obstruction do not result in primary amenorrhea.** On physical examination, a unilateral abdominopelvic mass that terminates in a bluish bulge in the lateral vaginal wall is often appreciated (Eisenberg et al, 1982). Abdominal ultrasonography and MRI are both excellent at defining the anatomy in a suspected case of unilateral noncommunicating uterine horn. Renal anomalies are frequently encountered on the side ipsilateral to the obstructed system, with renal agenesis being the most common (Eisenberg et al, 1982; Tridenti and Bruni, 1995). A prompt and accurate diagnosis is necessary to prevent injury to the genital organs as a result of chronic cryptomenorrhea and endometriosis. Treatment consists of wide incision of the vertical vaginal septum to release the entrapped menstrual blood.

Acquired Genital Obstructive Anomalies

Female Circumcision (Infibulation). Acquired vaginal obstruction may be secondary to a number of ritual female genital mutilation procedures that are widespread in many countries in Africa (stretching in a band from the Horn of Africa through Central Africa to parts of Nigeria), the Middle East, and Muslim populations of Indonesia and Malaysia (Toubia, 1994; Dorkenoo, 1996). Although similar procedures were prescribed to U.S. and British women during the 19th century for the treatment of ailments ranging from epilepsy to lesbianism, all forms of genital mutilation are now illegal in these Western countries. **Often referred**

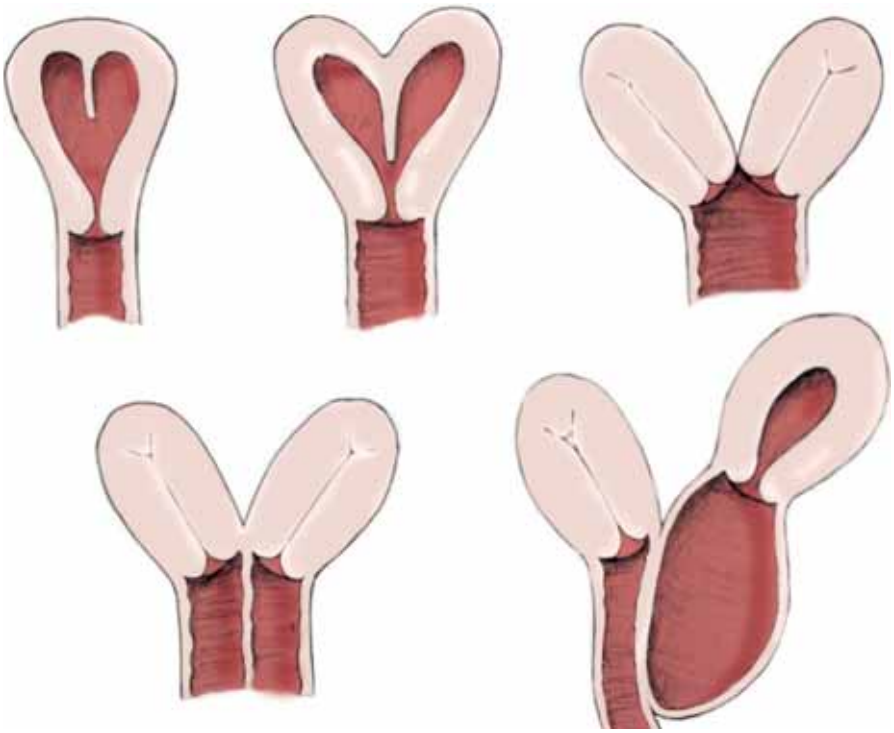

Figure 134–12. Fusion anomalies of the müllerian system. *Upper left to lower right,* Bicornuate uterus (partial), bicornuate uterus, uterine duplication, complete uterine and vaginal duplication, and duplication of the uterus and cervix with a unilateral imperforate vagina. (From Yerkes EB, Rink RC. What urologists should know about pediatric gynecologic abnormalities. Contemp Urol 2002;14:12.)

to as "female circumcision," the procedure continues to affect an estimated 80 to 110 million women worldwide (Toubia, 1994).

The age at which this procedure is performed ranges from birth to just before marriage. However, it is typically performed on preadolescent children between the ages of 4 and 10 years, most commonly at age 7 (American Medical Association, 1995). The procedure is usually performed without anesthesia in the context of a ceremony designating the rite of passage into adult society (American Medical Association, 1995). The extent of the mutilation varies according to ritual, but the practice predates Islam and is therefore not part of a religion (McCaffrey et al, 1995). In many countries the women have a deinfibulation procedure performed just before consummating the marriage.

The type of mutilation ranges from simple excision of the prepuce of the clitoris (termed *sunna*) to complete excision of all elements of the vulvar region (McCaffrey et al, 1995).

Toubia (1994) **classified the more extensive female genital mutilation procedures according to the amount of tissue destruction:**

Type I: Complete or partial removal of the clitoris.

Type II: Excision of the clitoris and a portion of the labia minora.

Type III: Excision of the entire clitoris and labia minora with incision of the labia majora along its medial aspect to create raw surfaces. The anterior two thirds of the labia majora are approximated to cover the urethra and introitus, with the lower third at the level of the posterior fourchette left for the passage of urine and menstrual fluid.

Type IV: Excision of the entire clitoris and labia minora with nearly complete approximation of the labia majora and only a pinhole opening left near the posterior fourchette for the passage of urine and menstrual fluid (Fig. 134–13).

Closing of the introitus, typically referred to as infibulation or pharaonic circumcision, is performed by a variety of means, including absorbable and nonabsorbable suture materials, thorns,

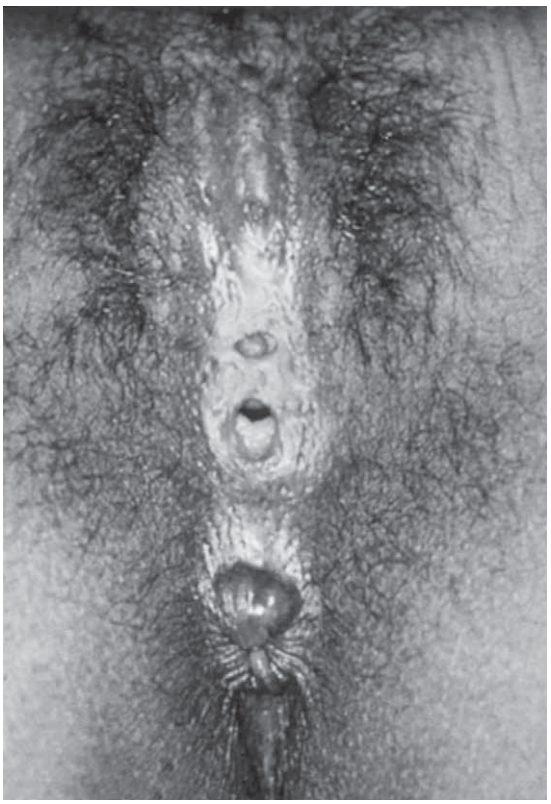

Figure 134–13. Female infibulation. Note the scarred labia majora with only a pinhole opening for the passage of menstrual fluid and urine. (From Gonzales ET, Bauer SB, editors. Pediatric urology practice. Philadelphia: Lippincott Williams & Wilkins; 1999. p. 599.)

and twigs. The child's legs are then bound for up to 40 days to ensure secondary healing in the ventral midline (McCaffrey et al, 1995).

The physical, psychological, and reproductive repercussions of these forms of genital mutilation are numerous and include immediate destruction and infection of local tissues (e.g., rectum, urethra). Long-term risks include chronic pain, recurrent urinary tract and vaginal infections, dysmenorrhea, dyspareunia, and apareunia. For individuals with the most narrowing, additional "surgeries" to revise the introital opening may be necessary for both intercourse and vaginal delivery (Aziz, 1980; Toubia, 1994).

Care of a patient who has undergone infibulation must be individualized, not only to provide functionality but also to respect the cultural and ritual desires of the woman. Educating the patient about the normal appearance of the external female genitalia is critical. Visual aids, including photographs or hand-drawn illustrations (or both) of the patient's anatomy and the planned revision, have been used as part of informed consent to avoid misunderstanding.

Nonobstructive Genital Anomalies (Interlabial Mass)

The differential diagnosis of an interlabial mass in a neonate and young child is broad and requires a thorough understanding of the diagnostic possibilities and a systematic evaluation. The age and racial background of the patient can help narrow the differential diagnosis, but physical examination remains the most useful tool for determining the specific pathology.

The physician must be sure to specifically reassure the girl that the examination will not be painful. With the child in the frog-leg position, the physician should note the size of the clitoris, the configuration of the hymen, the location of the urethra, and the character of the interlabial mass (e.g., smooth, lobulated, hemorrhagic). **To aid in visualization, the labia majora can be gently grasped and pulled caudally and laterally to enable funneling of the introitus and vagina (the so-called pull-down maneuver)** (Fig. 134–14). Determining the nature of a specific mass can be facilitated by establishing the location of expected anatomic landmarks. In certain circumstances, the relationship of the mass to the vagina and urethra can be improved by gentle placement of a lubricated cotton applicator posteriorly or placement of a small feeding tube within the suspected urethral orifice, or both. Although an otoscope, nasal speculum, or pediatric vaginal speculum can be useful in evaluating the vagina while the patient is awake, complaints of vaginal origin (i.e., vaginal discharge or bleeding) are often best investigated with a carefully performed examination and vaginoscopy under anesthesia. Renal-pelvic ultrasonography can be a useful adjunct in confirming or establishing the diagnosis in a few of these disorders.

Specific Lesions

Labial Adhesions. Labial adhesions, **also referred to as labial agglutination, and synechia vulvae are the most common interlabial abnormality identified in children, ranging in incidence from 0.6% to 1.8%** (Norbeck et al, 1993; Leung et al, 1993). **This condition occurs predominantly in the first 2 years of life, with a peak incidence between 13 and 23 months** (Fig. 134–15). Fusion of the labia minora

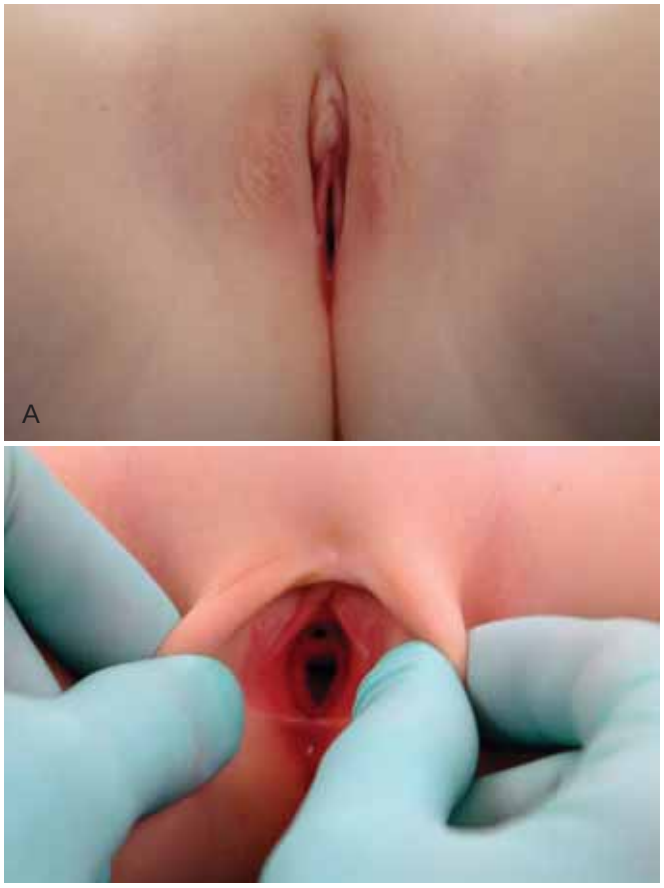

Figure 134–14. **A** and **B**, Photographs of the vaginal pull-down procedure. To aid in visualization of the female introitus, the labia majora are gently grasped and pulled caudally and laterally to enable funneling of the vagina.

Figure 134–15. Labial adhesions.

originates at the posterior fourchette and progresses for a variable distance toward the clitoris. It is important to differentiate this condition from the more serious entity of fusion of the labia majora, as is seen in certain DSDs. **It has been hypothesized that hypoestrogenism may play a role in adhesion of the labia minora.** Labial adhesions have not been reported in newborn children, presumably because of the protective effect of maternal estrogen (Leung et al, 1993). **However, the etiologic role of the hypoestrogenic state has been brought into question by a number of authors** (Caglar, 2007; Pulvino et al, 2008). Caglar (2007) measured circulating estradiol levels in 59 girls with labial adhesions and 60 control patients. He demonstrated no difference in the circulating level of estrogen in these two patient groups. Recently it has been shown that estradiol may enhance wound re-epithelialization by promoting heparin-binding epidermal growth factor production in keratinocytes (Kanda et al, 2005). **If there is a beneficial effect of topical estrogen it may be to promote healing after the adhesions have been separated. Nonhormonal factors may play an etiologic role in the formation of labial adhesions** (Papagianni and Stanhope, 2003). Local irritation and tissue trauma appear to be important inciting events in many cases. Adhesions can rarely be associated with sexual abuse; in such cases, additional physical findings are often noted, including hematoma and lacerations (McCann et al, 1988). Although labial adhesions are usually asymptomatic, urine pooling within the vagina may lead to postvoid dribbling and perineal irritation and may make it difficult to obtain an accurate urinalysis or perform radiographic procedures.

Most children with labial adhesions do not require treatment unless they are symptomatic. **With the rate of spontaneous resolution reported to be as high as 80% within 1 year, asymptomatic labial adhesions can comfortably be observed** (Pokorny, 1992). When necessary, treatment ranges from the topical application of various steroids to surgical division. The topical application of conjugated estrogens has been reported to be successful in separating adhesions in up to 90% of patients (Leung et al, 2005; Khanam et al, 1977). Concern over the possible side effects of breast budding and hyperpigmentation from prolonged use of conjugated estrogen led Myers and associates (2006) to treat a cohort of 19 prepubertal patients with topical betamethasone (0.05%). The authors reported success in 13 (68%) patients after administering one to three courses of twice-daily therapy for 4 to 6 weeks. It is important to have the family place the cream directly on the labia minora. In addition, it is helpful to have the family perform the pull-down procedure a few times a day to put light stress on the midline adhesions and hence facilitate their separation. If topical therapy is not successful, manual separation in the outpatient setting may be indicated. After the application of EMLA cream to the introitus, gentle pressure is applied to the thin connecting membrane with the use of a lubricated probe. Rarely, in cases in which the adhesions are extremely dense, surgical division is required. Although one group has recently advocated oversewing the separated edges with 7-0 chromic sutures (Nurzia et al, 2003), the authors have not found this to be necessary if the family is properly educated about keeping the labia separated (see Fig. 133–14) after the procedure. **Recurrence rates appear to be similar when comparing children who have undergone manual separation (16.7%) versus surgical separation (15.4%), emphasizing the importance of having families continue to separate the labia after separation has been achieved** (Muram, 1999).

Introital Cysts. Introital cysts in the newborn can represent one of three entities: paraurethral cysts (i.e., Skene duct cyst), remnants of the mesonephric ductal system (Gartner duct cyst), and a covered ectopic ureter. When the cyst is large and clearly emanating from the vaginal introitus, further investigation in the form of a renal-pelvic ultrasound evaluation is indicated to look for renal duplication.

Key Points: Nonobstructive Genital Anomalies

- Most children with labial adhesions do not require treatment unless they are symptomatic.
- Workup of a child with an introital (intralabial) mass that appears to be associated with the urethra should always include renal-pelvic ultrasonography.
- Urethral prolapse occurs most often in prepubertal black girls and in postmenopausal white women.

Paraurethral cysts in a neonate represent a dilatation of the periurethral glands, which are located just inside the urethral meatus (Fig. 134–16). These glands are homologues of the male prostatic glands and number between 6 and 30, with the two largest termed the *periurethral glands of Skene* (Skene, 1880; Gottesman and Sparkuhl, 1979). In a neonate the periurethral glands occasionally respond to maternal estrogen and secrete mucoid material, which can result in cyst formation. The main distinguishing feature of this condition is displacement of the urethral meatus by the mass and, consequently, an eccentric urinary

Figure 134–16. Paraurethral cyst. (From Yerkes EB, Rink RC. What urologists should know about pediatric gynecologic abnormalities. Contemp Urol 2002;14:12.)

stream. If the urethral meatus can be identified as being completely separate from the mass, radiographic evaluation is not needed to confirm the diagnosis (Nussbaum and Lebowitz, 1983). These cysts are frequently self-limited and often rupture spontaneously. If they are persistent, drainage by a small needle is easily achieved at the bedside.

Gartner duct cysts represent cystic remnants of the wolffian duct system and can be found along the anteromedial wall of the vagina (Pradhan and Tobon, 1986). A cystic structure related to a Gartner duct cyst is a *covered ectopic ureter* that enters into the vagina (Rosenfeld and Lis, 1993; Holmes et al, 1999). Embryologically, the ureter would not be expected to enter the vagina. However, an ectopically located ureter may end in a segment of the wolffian duct system, which in a female is represented by a Gartner duct cyst. In most instances this cystic structure spontaneously ruptures before delivery, thereby resulting in direct communication between the ectopic ureter and the vagina. However, if the surface epithelium fails to rupture, a covered, urine-filled cyst will exist within the vagina. Intraoperative injection of the cystic structure with radiographic contrast material may be beneficial in outlining the anatomy (Fig. 134–17). Incision of the cystic structure relieves the obstruction. As a general rule, the more ectopic the insertion of the ureter, the more dysplastic the segment that it drains will be. However, renal moieties that ectopically insert into the vagina may produce urine. Subsequent upper pole heminephrectomy may be indicated if the child has significant urine production from the segment (resulting in incontinence) or an infection develops after decompression.

Hymenal Disorders. ***Hymenal skin tags*** are virtually a normal finding and are rarely symptomatic (Figs. 134–18 and 134–19). When symptomatic (i.e., bleeding), they should be excised to ensure that they do not represent a malignancy and to provide symptomatic relief. Congenital abnormalities of the hymen are not uncommon and range from an imperforate hymen to one with numerous small microperforations.

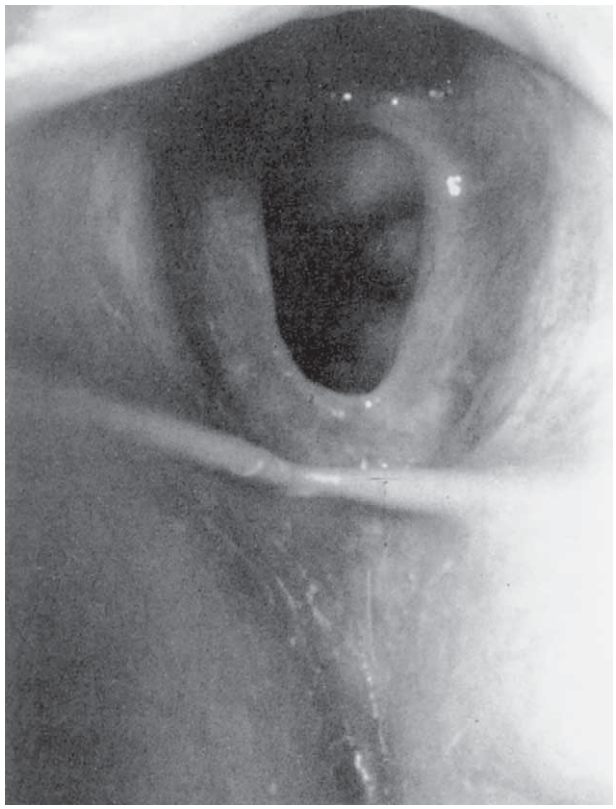

Figure 134–18. Normal hymenal ring. (From Emans SJ. Office evaluation of the child and adolescent. In: Emans SJ, Laufer MR, Goldstein DP, editors. Pediatric and adolescent gynecology. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 1998.)

Figure 134–22. Urethral prolapse. (From Yerkes EB, Rink RC. What urologists should know about pediatric gynecologic abnormalities. Contemp Urol 2002;14:12.)

Imperforate hymen is probably the most common congenital obstructive anomaly of the female reproductive tract. The diagnosis is most frequently made at birth by noting the presence of a bulge along the posterior aspect of the introitus, which represents retained fluid within the vagina, or by palpation of a suprapubic mass from a distended vagina (Fig. 134–20). The buildup of retained vaginal secretions in the neonatal period, which imparts a whitish appearance to the bulging hymenal membrane, is caused by maternal estradiol stimulation. If the diagnosis is made after the neonatal period, the mucus will often have been reabsorbed and a bulge in the hymenal membrane may no longer be evident. On occasion, the diagnosis is not made until the adolescent period, when the patient experiences amenorrhea and possibly cyclic abdominal pain. In these circumstances, a bluish bulging hymen may be observed on genital inspection and a mass will be appreciated on rectoabdominal palpation.

In newborns, repair by incision of the hymenal tissue at the bedside is performed in the transverse direction to avoid inadvertent extension of the incision anteriorly or posteriorly (which might injure the urethra or rectal structures). Simple aspiration of the vagina without a definite drainage procedure should be discouraged because incompletely evacuated material may be prone to ascending bacterial growth. In pubertal girls, general anesthesia with excision of excess hymenal tissue may be indicated (Fig. 134–21).

Acquired abnormalities of the hymenal ring usually result from sexual abuse. The associated finding of a hematoma, abrasion, or laceration in combination with hymenal transection should raise the possibility of this diagnosis. Proper examination under anesthesia and forensic swabbing of affected areas should be undertaken with the use of a standardized protocol.

Prolapsed Urethra. Urethral prolapse generally involves complete circumferential eversion of the urethral mucosa at the level of the external urethral meatus (Fig. 134–22) (Lowe et al, 1986). **This entity, which was first described by Solinger in 1732, occurs most often in prepubertal black girls and in postmenopausal white women** (Epstein and Strauss, 1937;

Richardson et al, 1982). Various causes that have been proposed for urethral prolapse include hypoestrogenism (Desai and Cohen, 1997), abnormal connections between the inner longitudinal and outer circular muscle layers of the distal urethra (Lowe et al, 1986), and episodic increases in intra-abdominal pressure (Lowe et al, 1986; Desai and Cohen, 1997; Valerie et al, 1999). The most common initial complaint is bleeding from the edematous and friable mucosa, which results in blood spotting on the underwear (Richardson et al, 1982; Chaouachi et al, 1989). Urethral prolapse is easily recognized as a doughnut-shaped mass with the urethral meatus at the center. If the diagnosis can be confirmed by passing a urethral catheter, radiographic evaluation is not indicated (Nussbaum and Lebowitz, 1983). Treatment options include observation, topical corticosteroids, and surgical excision (Redman, 1982; Fernandes et al, 1993). Sitz baths may be helpful. **Nonoperative treatment may lead to spontaneous reduction of the prolapse, but a recurrence rate of up to 67% has been noted** (Jerkins et al, 1984). Many methods of surgical repair have been described. Circumferential excision of the redundant mucosa with subsequent suturing of the normal urethra to the vestibule is the procedure of choice (Devine and Kessel, 1980). Other methods, including ligation over a transurethral catheter with subsequent sloughing and cryosurgery, should be discouraged (Owens and Morse, 1968; Klaus and Stein, 1973).

Prolapsed Ureterocele. An ectopic ureterocele is a cystic dilatation of the terminal portion of the ureter that occurs predominantly in white females (Mandell et al, 1980). Approximately 90% of ectopic ureteroceles are associated with the upper pole of a duplex collecting system. Although they normally remain positioned proximal to the bladder neck, some may prolapse through the urethra during micturition, almost always in infancy, and result in urinary retention and a relative urologic emergency (Gingell et al, 1971). **Depending on the length of time that the ureterocele has been prolapsed, it may vary in color from pink to dusky purple** (Fig. 134–23). **If a prolapsed ureterocele is in the differential diagnosis, bladder-renal ultrasonography should be performed to look for upper pole hydronephrosis in a duplicated collecting system** (Fig. 134–24).

Treatment of a prolapsed ureterocele consists of either needle decompression or incision and reduction and then placement of a urethral catheter. Although this can occasionally be achieved in the emergency department setting, abdominal straining by the infant may make this procedure difficult, and treatment under general anesthesia is often preferable.

Injection of radiographic contrast material into the ureterocele can be helpful in identifying the relevant anatomy.

Urethral Polyp. The pediatric equivalent of a urethral caruncle, namely, a urethral polyp, is a rare lesion that can be manifested as an intralabial mass (Fig. 134–25). The etiology of true lesions has not been completely elucidated, but in a young child they probably represent either hamartomatous growth or a response to inflammation.

The authors described two young girls with an interlabial mass. Histologic examination of each excised mass revealed a benign urethral polyp covered with transitional and squamous epithelium (Klee et al, 1993). Urethral polyps should be included in the differential diagnosis of an interlabial mass in young female patients.

Vaginal Rhabdomyosarcoma. Vaginal rhabdomyosarcoma is most often manifested as a grapelike cluster of tissue emanating from the posterior aspect of the vestibule (Fig. 134–26). The mean age of patients with primary vaginal tumors is younger than 2 years (Hays et al, 1988). Of all the female genital tract primary tumors, vaginal primary tumors appear to have the best prognosis. This excellent prognosis is thought to be a result of predominance of the embryonal cell type and relatively early detection because of symptoms of bleeding (Hays et al, 1988). Once a tissue diagnosis has been made by biopsy, proper staging with abdominal and pelvic computed tomography, chest radiography, and bone marrow biopsy is critical to optimal stratification of these patients into treatment protocols (Hays et al, 1985). Advances in

chemotherapy have led to a reduction in the role of surgery for this disease with each subsequent Intergroup Rhabdomyosarcoma Study (IRS) trial: IRS-I, 100%; IRS-II, 70%; IRS-III, 30%; and IRS-IV, 13% (Andrassy et al, 1999). After chemotherapy, local resection may be required, but unlike other malignancies of the vagina, wide excision of the involved organ has no role except for persistent or recurrent disease (Hensley, 2000).

CLASSIFICATION OF UROGENITAL SINUS AND CLOACAL ANOMALIES

Persistent urogenital sinus anomalies are one of the more complex problems that a pediatric urologist will face, and they occur in a spectrum. Evaluation and management must be meticulous.

In urogenital sinus anomalies there is a persistent communication of the vagina with the urinary tract. Communication of the vagina with the urinary tract may occur at any point from the urethral meatus to the bladder, but the majority occur within the mid to distal portion of the urethra. The two structures join and exit on the perineum as a single common urogenital sinus channel.

A persistent urogenital sinus is **seen in four entities.** Most commonly it occurs in **genital ambiguity states,** most frequently with congenital adrenal hyperplasia (CAH) (Fig. 134–27). It can also occur as a **pure urogenital sinus** with normal external genitalia (Fig. 134–28). In persistent **cloacal anomalies** there is the added complexity of rectal involvement, with all three systems—genital, urinary, and rectal—exiting as an isolated single perineal opening. More recently, **female exstrophy** has been thought to represent a form of persistent urogenital sinus (Adams, 2000).

Early descriptions of this confluence were based on previous medical training. Urologists described the vagina as entering the urethra, whereas gynecologists noted that the urethra entered the vaginal vestibule (Jones and Jones, 1954). Jaramillo and Lebowitz (1990) noted that on examination that the external cloacal orifice appears vaginal in nature in some but in others appears more like a normal urogenital orifice (Figs. 134–29 and 134–30). **Regardless of how the confluence of the urinary and genital tracts is described, the confluence location in relation to the bladder neck is a more critical factor in surgical management than the length of the common channel** (Rink et al, 2005a)

Key Point: Urogenital Sinus Anomalies—General

- Urogenital sinus anomalies are found in four entities: genital ambiguity states, pure urogenital sinus, persistent cloaca with rectal involvement, and female exstrophy.

Evaluation

Urogenital sinus abnormalities are most often seen in DSD states, most commonly in association with CAH, which has been noted to have an incidence as high as 1 in 500 in the nonclassic, mild form (Hughes, 1988). The most common enzymatic defect in CAH resulting in genital ambiguity is 21-hydroxylase deficiency, which occurs in approximately 1 in 15,000 to 16,000 persons (Spieser and White, 2003; Merke and Bornstein, 2005). Mutations in the 21-hydroxylase gene *(CYP21)* result in varying degrees of virilization corresponding to the type of mutation. CAH should be regarded as a spectrum disorder from mild anomalies to those with deep impact on life (Nordenskjold et al, 2008). Therefore, initial management must focus on making an accurate diagnosis to allow proper gender identification. Every effort should be made to establish the genetic

sex within 48 hours. Children with CAH require careful monitoring of fluid and electrolytes because 67% to 75% will have significant salt wasting (Spieser and White, 2003; Merke and Bornstein, 2005). Evaluation should include rapid karyotyping of cultured peripheral leukocytes, measurement of serum electrolyte levels, and determination of hormonal levels for CAH. All results are shared with the gender assignment team, which includes the parents, pediatric endocrinologist, pediatric urologist, neonatologist, geneticist, child psychiatrist, and often clergy. The child should not be named until sex assignment is complete (Rink and Adams, 1998).

Cloacal anomalies are a much more complex problem involving multiple organ systems, but fortunately they occur in only 1 in every 40,000 to 50,000 patients (Karlin et al, 1989). They are the most challenging of the anorectal malformations and make up 13.6% of this group (Fleming et al, 1986). These children have a very broad spectrum of findings on examination of the external genitalia. Some may have a prominent phallic structure and also initially require evaluation for a DSD.

History and Physical Examination

Many children with urogenital sinus abnormalities are now identified by antenatal ultrasonography, with the findings of fluid-filled pelvic structures (vagina and bladder) with indeterminant genitalia. However, the history and the physical examination remain extremely helpful in cases of genital ambiguity and can often lead to the diagnosis itself. It is critical to determine whether the mother ingested any medications during pregnancy, especially androgenic substances. A family history of early infant death or fluid and electrolyte abnormalities suggests CAH. Have other children had genital ambiguity or gender dysphoria at puberty? Notation should be made of any family members with abnormal pubertal development.

The physical examination can at times be very useful in determining the appropriate gender and in helping to identify other organ systems involved. A general evaluation of the child's overall health should be completed before focusing on the genital examination. Abnormal facies suggesting a syndrome should be noted. **Hypertension can occur in children with genital ambiguity secondary to CAH with 11β-hydroxylase deficiency.** Therefore, blood pressure should be documented. Evidence of dehydration may also lead to a diagnosis of CAH. On abdominal examination, a mass, particularly a suprapubic mass, may be present because of a distended bladder or hydrometrocolpos, or both. **Hydrometrocolpos is frequently an initial sign and is often the only early finding in pure urogenital sinus abnormalities.**

In cloacal anomalies, abdominal distention may be severe secondary to hydrometrocolpos and bladder and intestinal distention. Hydrometrocolpos was noted commonly in early series (Chappell and Bleloch, 1973; Klugo et al, 1974); its incidence ranged from 29% of Pena's patients (1989) to 63% of those reported by Bartholomew and Gonzales (1978). It is caused most commonly by preferential flow of urine into the vagina (or vaginas) with voiding and associated poor vaginal drainage. Maternal estrogen stimulation of the cervical glands results in mucus production, thereby further adding to the distention. Urine flow can occur into the rectum also. This distention has resulted in edematous, cyanotic legs and respiratory distress, as well as acidosis (Raffensberger, 1988).

The lower part of the back should be examined to identify any evidence of spinal cord abnormalities, which can be associated with urogenital sinus abnormalities and are very common with cloacal anomalies. Such abnormalities may take the form of a sacral dimple, hair patch, or area of abnormal pigmentation, but more commonly there is evidence of a bone abnormality, such as an abnormal buttock crease or flattened buttocks as a result of sacral agenesis.

Genital examination should note the size of the phallus and the consistency of the erectile bodies. Any degree of curvature should be documented. Huffman (1976) multiplied the width of the glans times the length of the phallus to determine the "clitoral index," which he noted should be less than 3.5 mm to be normal and was of concern when greater than 10 mm. The gonads should be sought, and, when found, their number, location, and consistency should be noted. If both gonads are descended, it is extremely unlikely that a 46,XX chromosome makeup will be found. The

labioscrotal folds should be examined for their relationship to the phallus and rectum, as well as for the degree of fusion. Increased pigmentation of the labioscrotal folds and areola may be seen in some cases of CAH as a result of increased levels of melanocyte-stimulating hormone.

In urogenital sinus anomalies the location of the anus should be noted. Although it is usually in the normal location, anterior displacement is not uncommon, and this bridges the gap to cloacal anomalies (see Fig. 134–29). A gentle rectal examination is helpful in identifying a cervix.

Examination of a child with a persistent cloaca deserves special mention. There is a single perineal orifice because the rectum also enters this common channel. The appearance of the external genitalia assumes a much wider spectrum, from a nearly normal female appearance to much more bizarre appearances such as genital transposition or a blank-appearing (doll-like) perineum (Fig. 134–31) (Hendren, 1989). In some instances there is an enlarged phallic structure that gives the genitalia an ambiguous appearance. The single perineal opening may exit what appears to be a normal vaginal introitus, or it may extend to the tip of a phallic structure. The authors, as well as others, have encountered children with a secondary accessory channel that exits the tip of the phallus (Hendren, 1989; Karlin et al, 1989; Krstic et al, 2001; Rink et al, 2005b).

Cloacal anomalies are associated with a high incidence of related anomalies in other organ systems. The authors found 14 of 23 patients with renal anomalies, including 6 with solitary kidneys, 4 with renal dysplasia, 2 with ureteropelvic junction obstruction, 1 with duplication, and 1 with cross-fused ectopia. There were also 2 with bladder duplications (Rink et al, 2005b). Sixty percent have some degree of septation of the vagina and uterus (Warne et al, 2003). Kay and Tank (1977) reported that 13% of patients with cloacal anomalies have cardiovascular abnormalities, 10% have central nervous system problems, and respiratory abnormalities are noted in 5%; vertebral, particularly sacral, anomalies are common. Many have the VACTERL association (*V*ertebral abnormalities, *A*nal atresia, *C*ardiac abnormalities, *T*racheoesophageal fistula and/or *E*sophageal atresia, *R*enal agenesis and dysplasia, and *L*imb defects), so tracheoesophageal fistula is often present (Hendren, 1986, 1988). Other gastrointestinal anomalies have been noted, including duodenal atresia and rectal duplication in 2% (Karlin et al, 1989).

Key Points: Urogenital Sinus Anomalies—Evaluation

- Key points of the history and physical examination are findings of a family history of sudden infant death, fluid and electrolyte abnormalities, hypertension, suprapubic mass, lower extremity cyanosis, palpable gonads, and hyperpigmentation, and number of perineal orifices.
- The level of the urethrovaginal confluence and the location of the rectum must be identified radiographically and endoscopically, with note made of their relationship to the bladder neck. Ultrasonography is mandatory to look for the uterus, ovaries, and kidneys.

Radiographic and Endoscopic Evaluation

Urogenital Sinus Abnormalities

Certain critical details of the anatomy, including the length of the common urogenital sinus, the location of the vaginal confluence and its proximity to the bladder neck, the size of the vagina and the number of vaginas, the presence of a cervix, and bladder and urethral anatomy, must be defined by radiographic and endoscopic evaluation. The authors believe that the location of the vagina in relation to the bladder neck is the critical issue in determining the type of surgery, and this distance is more important than the length of the common channel. Vaginal confluence with the urinary tract occurs in a continuum from the bladder to a nearly normal location in the perineum. **It is not simply "high" (proximal/suprasphincteric) or "low" (distal/infrasphincteric)** (Hendren and Crawford, 1969; Powell et al, 1995; Rink and Kaefer, 2002) (Fig. 134–32).

A new urogenital sinus classification that measures the exact distance of the common channel and the distance of the bladder neck to the vagina has been devised to help delineate the exact level of the confluence, as well as clitoral size and appearance of the external genitalia (Rink et al, 2005a).

Ultrasonography of the urinary tract and pelvis is mandatory. The location and normalcy of the kidneys, ovaries, and uterus should be defined. Any bladder or vaginal distention should be noted. A cerebriform appearance with enlargement of the adrenal glands is indicative of CAH (Brock et al, 1998).

Filling the entire bladder, urethra, vagina, and sinus with contrast (i.e., genitography) is critical in the anatomic evaluation of many children with a urogenital sinus (Figs. 134–33 and 134–34). Genitography is performed by placing a Foley catheter with the balloon occluding the perineal meatus and injecting a contrast agent. It is often helpful to pass a catheter into the bladder as for a voiding cystourethrogram. A cervical impression at the vaginal dome denotes normal female internal organs. MRI is of limited value in CAH but may be very helpful to define the anatomy in pure urogenital sinus anomalies or DSD conditions. In CAH patients,

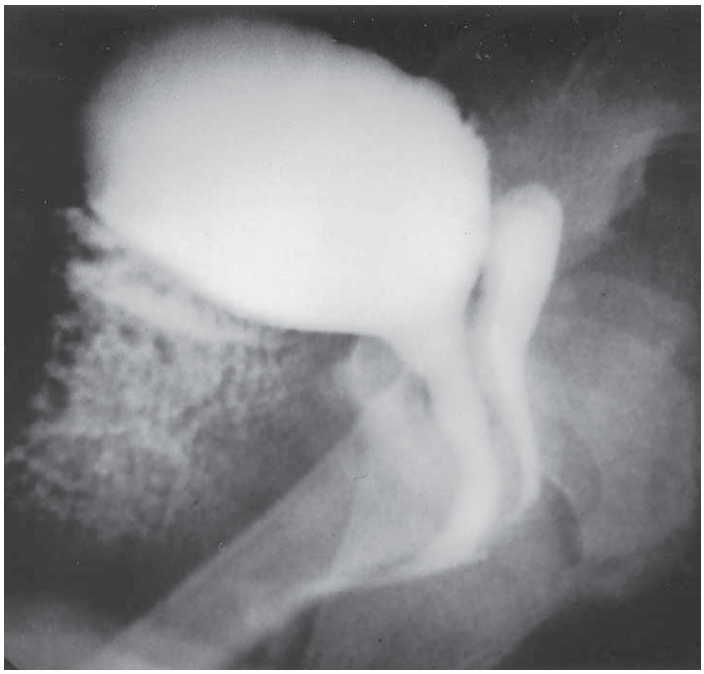

Figure 134–33. Genitography showing low confluence of the urethra and vagina.

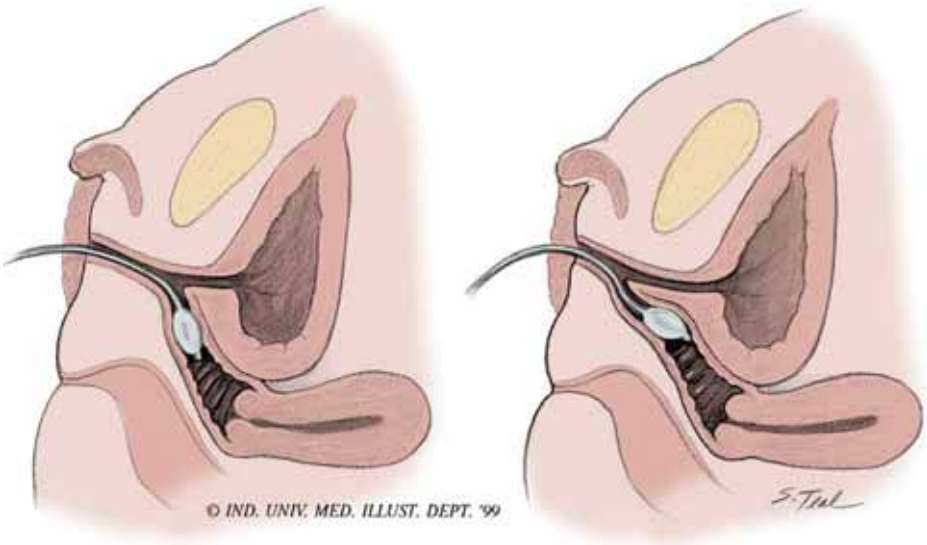

Figure 134–32. Fogarty catheter placed in the vagina in high confluence *(left)* and in low confluence *(right)*. (©1999, Indiana University Medical Illustration Department.)

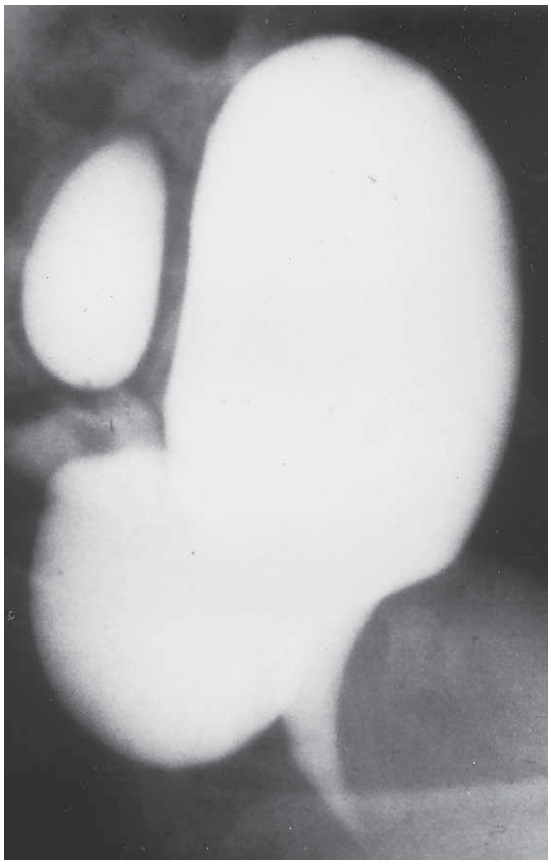

Figure 134–34. Genitography showing high confluence of the vagina entering near the bladder neck, with flow of contrast medium into the uterus.

Figure 134–35. Endoscopic view of confluence. The urethra is superior; the vagina is inferior.

the internal anatomy can nearly always be defined by an endoscopy at the time of reconstruction, making genitography less useful in this group (VanderBrink et al, 2010).

The most helpful diagnostic study in defining the anatomy for surgical reconstruction is endoscopy. In patients with CAH, endoscopy is usually performed at the time of reconstruction but may be necessary as a separate early procedure to help with gender identity in DSD cases or in those with complex pure urogenital sinus anomalies or if the vagina is not identified on genitography (Rink and Kaefer, 2002). In the latter situation, multiple punctuate openings in the proximal portion of the urethra may be observed (Donahoe and Gustafson, 1994). The authors have found it helpful to pass a ureteral catheter into the opening and evaluate the vagina fluoroscopically in this situation (Rink and Kaefer, 2002). Again, the exact location, size, and number of the vaginas should be recorded (Fig. 134–35). Hendren has noted a malelike external sphincter in severely masculinized children, with the vagina entering proximal to it in a verumontanum-like structure (Hendren and Crawford, 1969; Hendren and Atala, 1995). In the authors' initial experience, we thought this rarely if ever occurred (Adams and Rink, 1998), but more recently we have seen CAH children with a completely masculinized malelike urethra with an external sphincter and verumontanum-like structure.

Rarely, even with the evaluation described, some children with DSD require gonadal biopsy or evaluation of the internal genitalia, which has historically been done by laparotomy but in most cases can now be easily performed laparoscopically. Regardless of the means, it should be performed only when the findings would influence the gender of rearing (Rink and Adams, 1999). **If a biopsy is necessary, a deep incision should be made in the gonad because the ovarian component of ovotestes may completely surround the testicular component or be located at the poles** (Hensle and Kennedy, 1998; Schnitzer and Donahoe, 2001). Finally, scrotal skin biopsy may at times be helpful in males with incomplete androgen insensitivity, decreased 5α-reductase activity, or decreased dihydrotestosterone binding (Griffin and Wilson, 1989). Certainly all children with DSD should undergo chromosomal, endocrinologic and genetic evaluation. This is well described in Chapter 133.

Cloacal Anomalies

Evaluation for cloacal anomalies begins with antenatal ultrasound because there have now been several groups who have reported the prenatal diagnosis of persistent cloaca (Petrikovsky et al, 1988; Shalev et al, 1986; Cilento et al, 1994; Odibo et al, 1997; Adams and Rink, 1998; Cacciaguerra et al, 1998; Warne et al, 2002b). The diagnosis has been made as early as 19 weeks' gestation. **The finding of transient fetal ascites with bilobed or trilobed pelvic cystic structures, bilateral hydronephrosis, and decreased amniotic fluid is diagnostic** (Cacciaguerra et al, 1998; Warne et al, 2002a). The ascites is thought to develop via retrograde flow of urine into the uterus and out the fallopian tubes secondary to outlet obstruction from the distended vagina (Adams et al, 1998; Cacciaguerra et al, 1998).

Postnatal radiographic evaluation begins with a plain abdominal film (Jaramillo and Lebowitz, 1990). A pelvic mass may be obvious. Retrograde flow of urine and meconium, as described earlier, may result in the classic linear calcifications or calcified meconium. More granular calcifications may be noted along the course of the rectum as a result of urine flow into the rectum that yields calcified meconium (Jaramillo and Lebowitz, 1990).

Abdominal ultrasonography is very important to visualize not only the pelvic anatomy but also the kidneys because hydronephrosis is common (Hendren, 1998). Hydronephrosis is usually related to hydrocolpos, with the distended vagina compressing the bladder neck and resulting in varying degrees of bladder outlet obstruction (Hendren, 1998). Ureteral compression may also occur; however, the authors have seen hydronephrosis caused by primary obstructive megaureter in patients with cloacal anomaly.

Ultrasonography may also detect other renal anomalies. **Renal anomalies such as dysplasia, fusion anomalies, ectopia, ureteropelvic junction obstruction, and duplication have been seen in 33% to 83% of children with a persistent cloaca** (Kay and Tank, 1977; Warne et al, 2002b; Rink et al, 2005b).

As opposed to some urogenital sinus abnormalities in which genitography may be avoided, both genitography and endoscopy are mandatory to define the anatomy, which is even more complex with a cloacal anomaly.

The technique and goals of genitography and endoscopy are the same but must now include identification of the rectal as well as the vaginal confluence. The length of the urethra and its communication with the cloaca are important for reconstructive purposes. In Hendren's patients, the urinary communication to the cloaca was urethral in 77%, but in 23% there was virtually no urethra and the communication was noted at the bladder neck level (Jaramillo and Lebowitz, 1990). The vaginal anatomy is also much more complex and variable. In Hendren's report of 154 patients, 66 had one vagina, 68 had two vaginas, and the vagina was absent in 20 (Hendren, 1998). Vaginal duplication has been seen in nearly all of the authors' patient population (Rink and Yerkes, 2001) (Fig. 134–36). The duplication anatomy is also variable. Most authors have observed that the vaginas enter side by side with a single opening into the cloaca, but separate openings have been noted. The vaginas may be of different size, and one may enter the sidewall of the other. A cervix is usually seen at the top of each vagina. **The vaginal entrance into the cloaca again lies along a spectrum from the bladder to a location near the perineum.** Although the uterus is usually similar to the vagina (i.e., two vaginas with two uteri), the vagina may be absent with the uterus still present. Hall and associates (1985) found a bicornuate uterus, hypoplastic uterus, or uterus didelphys in 35% of their patients with persistent cloaca.

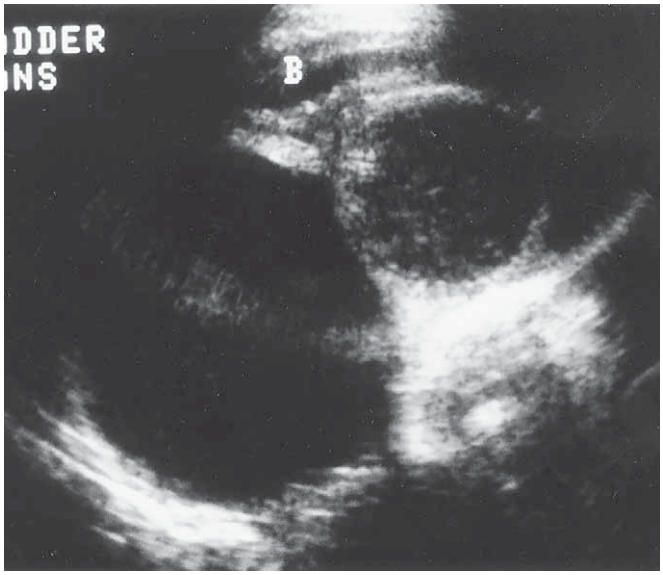

Figure 134–36. Pelvic ultrasonography in a patient with a cloaca. Duplicate fluid-filled vaginas are seen posterior to the decompressed bladder (B).

The rectal confluence is equally as complex, with the entrance in the authors' experience most commonly located just at the level of the vaginal confluence. This rectal opening may be broad, or it may have a long, narrow fistulous tract. It can even enter the vagina or bladder with no communication to the cloaca itself. The most common entrance in our experience is within the septum of a duplicated vagina, with all three joining the cloaca together (Rink and Kaefer, 2002). The rectal communication has been found to be vaginal in 68% and cloacal in 11%, with the remainder in other locations (Jaramillo and Lebowitz, 1990). The length and configuration of the common cloaca should also be noted because it has important surgical as well as anatomic implications. At times, the common channel is narrow and appears very much like a urethra; in other instances, the channel is much larger and redundant and appears more like a vagina. The urethral appearance was found in 48% of patients and the vaginal appearance in 52% (Jaramillo and Lebowitz, 1990). **The authors and others have noted that the urethral types result in higher outlet resistance and are more likely to lead to hydrocolpos** (Adams et al, 1998; Warne et al, 2002a).

The frequent presence of associated organ system abnormalities necessitates further radiographic evaluation. Echocardiography should always be performed. MRI is necessary for evaluating the lumbosacral spine and assessing the pelvic anatomy and musculature. Historically, it has been well recognized that sacral anomalies are common. Pena (1989) noted a normal sacrum in only 35% of his 54 patients, and Jaramillo and Lebowitz (1990) reported sacral agenesis in 40% of Hendren's 65 patients. De Filippo and associates (1999) found 10 of 21 patients with imperforate anus or cloaca to have an abnormality of the sacrum and spine. **With the use of MRI, spinal cord abnormalities have been more commonly detected, with an incidence as high as 43%** (Jaramillo and Lebowitz, 1990). Hendren (1998) found that a third of his patients had a tethered spinal cord. Skin stigmata in the lumbosacral region were absent in 8 of 10 patients with spinal cord tethering in Morimoto and colleagues' report (2003). MRI has also been very helpful in defining the level of the rectal atresia and in identifying the degree of sphincteric muscle development (Sato et al, 1988).

Because of the complexity of the anatomy and the frequency of hydrometrocolpos, a child with a cloacal anomaly often needs endoscopy early as a separate procedure to decompress the vagina and bladder and to define the anatomy. As a general rule, visualization of the vagina (or vaginas) is easily accomplished, but entry into the bladder can be very difficult and even impossible at times in a neonate because it is compressed very anteriorly by the distended vagina. The vagina should always first be emptied. Identification of the rectal fistula can also be difficult at times. Once it is located, mucus and fecal material should be irrigated from the colon, which can be done by irrigation through the scope in combination with irrigation through the mucous fistula of the divided colostomy. The length of the urethra to the vaginal and rectal confluence as well as the length of the common cloacal channel should be documented. The length of the common channel is helpful in cloacal patients in predicting fecal continence outcomes (Pena et al, 2004).

SURGICAL RECONSTRUCTION OF DISORDERS OF SEX DEVELOPMENT AND UROGENITAL SINUS

Initial Management, Timing, and Principles

The majority of children born with a urogenital sinus have genital ambiguity, and this should be initially evaluated by the gender assignment team. It is extremely important that the family be made aware of all controversies surrounding genital surgery. Certainly, most families, physicians, and surgeons have historically made the decision to proceed with early feminizing procedures to "normalize" the child and allow a positive psychosocial adjustment (Schober, 1998). This has been thought to relieve the parents' distress and improve their outlook toward their child, although there is limited evidence for this. The thought has been that raising a child with genital ambiguity would be extremely difficult (Thomas, 2004). Recently, a number of advocacy groups and physicians have begun to question this wisdom. Informed consent is impossible with an infant, and many believe that the decision for genital surgery is a right of the patient, not the parents. The ethical issues involving parents' rights and responsibilities to make decisions for their child remain unresolved (Lee and Witchel, 2002). Unfortunately, there are no data on the impact of raising a child with genital ambiguity (Rangecroft, 2002). Regardless of one's personal beliefs, all pros and cons of both surgery and observation must be presented to the parents without bias and certainly the option of observation with psychologic and peer support must be an option (Creighton and Liao, 2004).

At this time, excellent cosmetic results can be achieved by feminizing genitoplasty. However, it must be remembered that one's sexual identity is a result of many factors. It is known that the brain is the dominant organ in sexual orientation (Woodhouse, 2004). Schober (1999) has pointed out that little is known about how adults adjust to genitoplasty, nor are there any data in infants undergoing genitoplasty on what path they might have chosen had the opportunity been given to them as adults. It is clear that genital surgery does not "cure" a DSD. It is known that women with CAH are less satisfied with their genitalia than control subjects whether they had undergone an operation or not (Nordenskjold et al, 2008).

Unfortunately, a dilemma remains for DSD surgery because there is no absolute correct answer at this time. Information should never be withheld from the parents, and counseling should be provided. Parents must be informed of all risks and options and be made aware of the current state of knowledge. They should also be given access to advocacy groups regardless of the groups stance on surgery. There is then a changing of attitudes toward early reconstructive procedures particularly with regard to clitoral surgery (Lee et al, 2006).

For the purposes of the remaining description of surgical techniques, it is assumed that all parties (parents and medical team) agree that surgery is warranted.

Children born with a urogenital sinus associated with genital ambiguity usually have clitoral hypertrophy, fusion of the labia majora with absence of the labia minora, and a common urogenital sinus (Fig. 134–37). Furthermore, it has been shown that there is significant variability in what is considered normal clitoral, vaginal, and labial size (Lloyd et al, 2005). **Therefore, genital reconstruction involves three steps: (1) clitoroplasty, (2) labioplasty, and (3) vaginoplasty.**

Historically, clitoroplasty has been performed early in life, but this has again been challenged by DSD advocacy groups and physicians. In the mid 1900s there was not thought to be an optimal timing for reconstruction (Jones and Jones, 1954; Lattimer, 1961), but more recently, clitoral reconstruction has been carried out progressively earlier. Gross and colleagues in 1966 and Spence and Allen in 1973 noted that clitoral surgery can ideally be performed when the child is 1 year old. By the 1980s, clitoral surgery was

Figure 134–37. External appearance of genitalia in congenital adrenal hyperplasia. **A**, Moderately virilized with incomplete labioscrotal fusion. **B**, Moderately virilized with complete labioscrotal fusion. **C**, Severely virilized.

recommended as early as the first few months of life (Snyder et al, 1983). More recently, de Jong and Boemers (1995) reported surgical correction at 1 to 3 weeks of age. Parents are now less likely to choose surgery for minimal clitoral hypertrophy and the consensus document recommends surgery for only the more severe degrees of hypertrophy (Prader III-IV) (Lee and Witchel, 2002; Hughes et al, 2006).

The optimal timing for vaginoplasty likewise continues to be debated. Some have based the timing partly on the level of the vaginal confluence. A consensus statement on CAH from the Lawson-Wilkins Pediatric Endocrine Society and the European Society for Pediatric Endocrinology recommends surgery in the 2- to 6-month-old range for those with a high vaginal confluence, and surgery between 12 months and adolescence is not recommended (Consensus statement, 2002). **"There is inadequate evidence currently in relation to establishment of functional anatomy, to abandon the practice of early separation of the vagina and the urethra"** (Hughes et al, 2006).

Simultaneous performance of clitoroplasty, vaginoplasty, and labioplasty has been the standard practice for a child with a low (distal) vaginal confluence. Two separate schools of thought have been put forth for a high vaginal confluence. Some believe that the high rate of vaginal stenosis warrants delay of vaginal surgery until after puberty, which also avoids any need for vaginal dilatation (Sotiropoulos et al, 1976; Snyder et al, 1983; Alizai et al, 1999; Creighton et al, 2001; Rangecroft, 2002; Thomas, 2004). Others have found the incidence of vaginal stenosis to be higher in those who undergo surgery after puberty rather than during infancy (Eroglu et al, 2004). **The authors along with others believe that vaginoplasty, regardless of the vaginal location, is best combined with clitoroplasty and labioplasty in a single stage. This allows the surgeon flexibility in using redundant phallic skin for the reconstruction, which is compromised when the skin has previously been mobilized** (Mandell et al, 1988; Gonzalez and Fernandes, 1990; de Jong and Boemers, 1995; Hendren and Atala, 1995; Rink et al, 1997; Passerini-Glazel, 1998). Lean and colleagues (2007) found any plans for one-stage repair to give better results. **Furthermore, several authors have noted that maternal estrogen stimulation of the child's genitalia results in thicker vaginal tissue that is better vascularized, thus making it easier to perform early vaginal mobilization** (Passerini-Glazel, 1989; Donahoe and Gustafson, 1994; de Jong and Boemers, 1995; Rink and Adams, 1999; Farkas et al, 2001; Hensle and Bingham, 2002; Eroglu et al, 2004). Schober (2004) has noted that estrogen has a beneficial effect on the tissues, which may result in improved outcomes and making puberty the best opportunity for reconstruction.

Today, when performing clitoroplasty, every effort is made to not only provide excellent cosmesis but also retain normal clitoral innervation for optimal sexual gratification. Clitoral surgery has undergone significant evolution. Initial efforts were primarily directed at not just amputating the clitoris but also completely excising all clitoral tissue to avoid any later painful erection (Jones and Jones, 1954; Gross et al, 1966; Hendren and Crawford, 1969). Clitoral amputation was based on reports by both Hampson and Gulliver, who noted that the clitoris was not necessary for normal sexual response (Hampson, 1955). As recognition of the importance of the clitoris evolved, several ingenious clitoral recession techniques that preserved the innervation and all clitoral tissue were reported. Lattimer, in 1961, recessed the clitoris in subcutaneous fat and buried it beneath the skin. Kaplan (1967) reported an interesting technique of splitting the two corpora apart and performing closure in a transverse Heineke-Mikulicz fashion. Randolph and Hung (1970) and also Pellerin (1965) buried the corpora beneath the pubis. Efforts to preserve the glans based on a flap were attempted as early as the 1930s by Young, but the glans sloughed (Young, 1937). In 1961, Schmid was the first to report excising corporeal tissue yet preserving the neurovascular bundle with the glans intact. Kumar and coworkers (1974) later noted a similar technique proposed by Keifer the same year. Spence and Allen (1973) excised all of the clitoral shaft but left the glans intact to survive from the attached ventral urethral plate. **Virtually all techniques since have been based on Schmid's preservation of the neurovascular bundle** (Shaw, 1977; Barrett and Gonzales, 1980; Glassberg and Laungani, 1981; Mollard et al, 1981; Rajfer and Ehrlich, 1982). Although the glans often did well with these techniques, shrinkage and devascularization occurred at times. **Kogan and associates** (1983) **reported subtunical excision of the erectile tissue by incising laterally through Buck fascia to resect the erectile corpus cavernosa tissue.** Clitoroplasty techniques exhibited only minor technical advances until the recent demonstration of the neurovascular anatomy of the clitoris by Baskin and coworkers (1999). This work suggests that a ventral, rather than lateral, incision would preserve not only the main dorsal neurovascular bundle but also the neural branches that fan out laterally (Fig. 134–38). Currently, much research is under way to further evaluate clitoral neuroanatomy, as well as techniques to evaluate sexual sensitivity. And there have been two recent reports of preserving the Buck fascia with the neurovascular bundle and glans. The corporeal bodies are mobilized and disassembled and then placed in the labial fat. This allows the option of later use for reconstruction of the phallus should the patient choose a male gender identity (Pippi Salle et al, 2007).

Vaginoplasty techniques have similarly evolved, with all repairs based on a few landmark reports. **Almost every vaginal repair today uses a posteriorly based perineal flap proposed by Lattimer and originally described by Fortunoff and coworkers in 1964.** This wide-based Fortunoff flap has recently been modified to a more omega-shaped flap that has resulted in improved cosmesis (Jenak et al, 2001; Freitas-Filho et al, 2003). **In 1969, Hendren and Crawford reported a "pull-through" vaginoplasty for a high vaginal confluence.** Their efforts to establish the location of the vaginal confluence as the determining factor for the type of vaginoplasty remain the basis for all vaginoplasties today. Vaginal reconstruction techniques now generally take the form of one of four types. **(1) The cut-back vaginoplasty is rarely used and is appropriate for only simple labial fusion. (2) The flap vaginoplasty is applicable to a low (distal) vaginal confluence.** In this procedure, the posterior walls of the sinus and vagina are opened, but the anterior wall of the vagina is left intact. The posterior perineal flap fits into the opened vagina. **This procedure does not change the level of confluence; it simply widely opens the introitus and urogenital sinus** (Rink and Adams, 1998). Mild degrees of female hypospadias are common with this technique. The authors and others believe that a flap vaginoplasty should never be used for patients with a very high vaginal confluence because it may result in a short hypospadiac urethra, vaginal voiding, many infections, and even incontinence (Hendren and Atala, 1995; Rink and Adams, 1999). **(3) The pull-through vaginoplasty may be used for any level of confluence but is generally reserved for a very high confluence.** In this

The proximal preputial skin is plicated along its undersurface to create a "hooded" appearance to the segment of skin that will cover the glans. (© Indiana University Medical Illustration Department.)

procedure, the vagina is separated from the urogenital sinus, and the sinus is used to create a urethra. The mobilized vagina may reach the perineum, but in most cases skin flaps have been required. **(4) Complete vaginal replacement can be achieved by several techniques, but it is used only for a rudimentary or absent vagina.**

Labioplasty techniques also continue to evolve. In CAH and other DSD states, the labia minora are absent and the labia majora are superior to the new vaginal introitus. Labia minora are created by using the split phallic skin as described by Marberger (1975). Both the labia majora and labia minora should be moved inferiorly by YV-plasty to create a normal cosmetic appearance of the vagina now located between the labia (Hendren and Donahoe, 1980; Rink and Adams, 1998) (Fig. 134–39).

Regardless of the surgeon's personal bias toward reconstruction or its timing, a balanced presentation of all pros and cons of surgery versus no surgery is imperative. All current data should be made available to the parents and the risks associated with each path clearly defined. The ultimate decision is the parents', but it should be made as a participant of a team. In the following sections, the techniques described are applicable to either infants or adolescents.

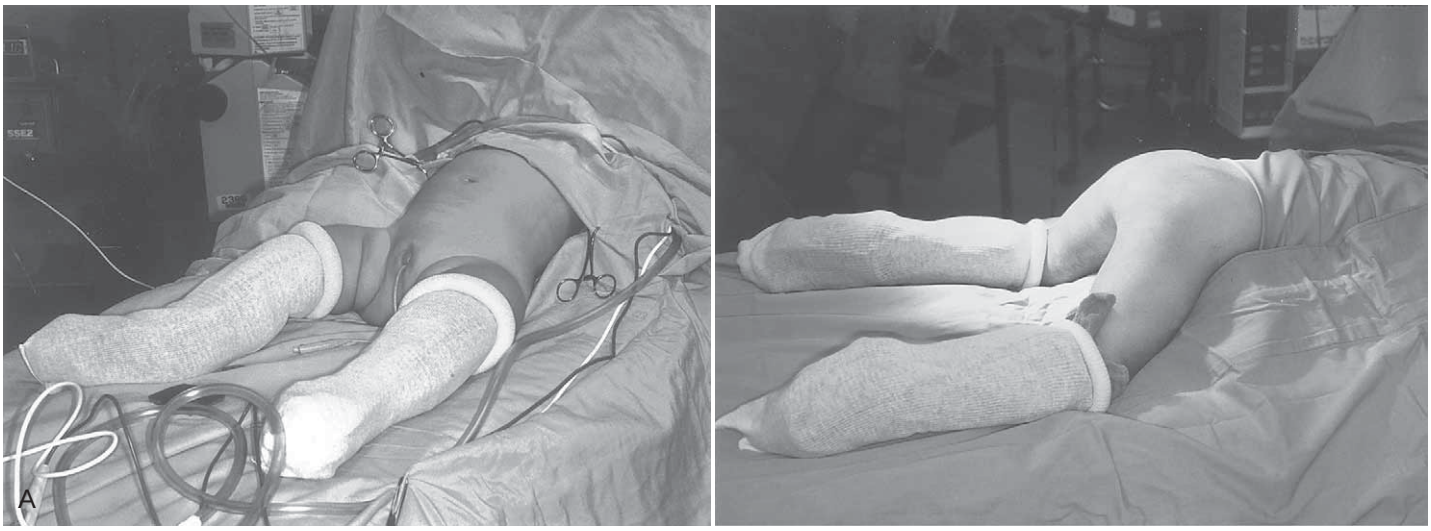

Figure 134–40. Total lower body preparation allows both supine (**A**) and prone (**B**) approaches. (From Rink RC, Adams MC. Feminizing genitoplasty: state of the art. World J Urol 1998;16:212.)

Current Operative Techniques for Female Disorders of Sex Development and Urogenital Sinus Repair

Preoperatively, it is important to ensure that the patient is metabolically stable, particularly a child with CAH. Most children with CAH only require an enema, but if there is an indication of a high confluence, complete bowel preparation with a polyethylene glycol-electrolyte solution (GoLYTELY) is warranted. All children receive preoperative broad-spectrum antibiotics. Children with CAH should undergo "stress dose" steroid replacement at the time of surgery. After general anesthesia, endoscopy is performed as described previously. **After passing a Fogarty catheter into the vagina, the balloon is inflated and the catheter is clamped and left indwelling. A Foley catheter is then anchored in the bladder.** Both are kept sterile, and the child is prepared with povidone-iodine. Many surgeons prefer to place the child in lithotomy position, but we have found that this position limits vision to only the surgeon, hinders teaching, and does not allow manipulation of the child if a posterior or abdominal approach is unexpectedly needed. All children undergo a complete lower body preparation from nipples to feet. The child's legs are wrapped, and the lower part of the body is passed through the aperture in the drapes; this facilitates access to the entire perineum and abdomen and further allows the child to be rotated either supine or prone during the procedure (Fig. 134–40). In the postpubertal patients, total body preparation may be difficult and necessitates the lithotomy position.

Key Points: Urogenital Sinus Anomalies—Reconstruction

- The three steps in surgical reconstruction are clitoroplasty, vaginoplasty, and labioplasty.
- Clitoroplasty is controversial. When performed, the glans and tunics with their neurovascular bundles must be preserved. Excision of erectile tissue, when performed, must be from the ventral aspect only.
- Vaginoplasties consist of four types: cutback (no longer used), "flap" for a low to midlevel confluence, "pull-through" for a high confluence, and vaginal replacement for a rudimentary or absent vagina. The timing of vaginoplasties is controversial.
- Labia minora are absent in urogenital sinus patients with genital ambiguity. They are reconstructed from phallic skin. The anteriorly located labia majora should be moved inferiorly.
- It is helpful to place a Fogarty catheter with the balloon inflated in the vagina. For a low confluence, an omega-shaped perineal flap provides better cosmesis. The flap is sewn into the posteriorly opened sinus, and this flap must reach to the more proximal normal-caliber vagina.
- For a high confluence, the vagina may require separation from the urinary tract at its confluence and is "pulled through" toward the perineum. The sinus opening is closed to create a urethra.

Low Vaginal Confluence—Clitoral Hypertrophy

The vast majority of children who undergo surgery for DSD or urogenital sinus conditions have a low vaginal confluence amenable to flap vaginoplasty. They usually have clitoral hypertrophy. Clitoroplasty and classic flap vaginoplasty are described. With the child in the supine position, a traction suture is placed through the glans and the proposed incisions are outlined with a skin scribe. Along these lines, 0.5% lidocaine with 1:200,000 epinephrine is injected subcutaneously for hemostasis. The proposed circumferential incision around the glans leaving the inner surface of the prepuce intact is drawn along with parallel longitudinal lines on either side of the ventral mucosal strip (urethral plate equivalent) extending around the meatus. A perineal omega-shaped flap with the apex near the meatus is outlined. A Y-incision line is drawn around the inferior aspect of each labia majora. The incision begins on the dorsal aspect of the clitoris and all inner preputial skin is left intact for later construction of a clitoral hood. This skin has been shown to be second only to the glans in sensitivity (Schober and Ransley, 2002). The clitoris is degloved while keeping the ventral "urethral plate" intact with the meatus. Dissection is carried out to the level of the bifurcation of the corporeal bodies and the pubis dorsally, and care should be taken to not injure any neurovascular tissue (see Fig. 134–38). It is important to recognize that the clitoral arterial supply branches

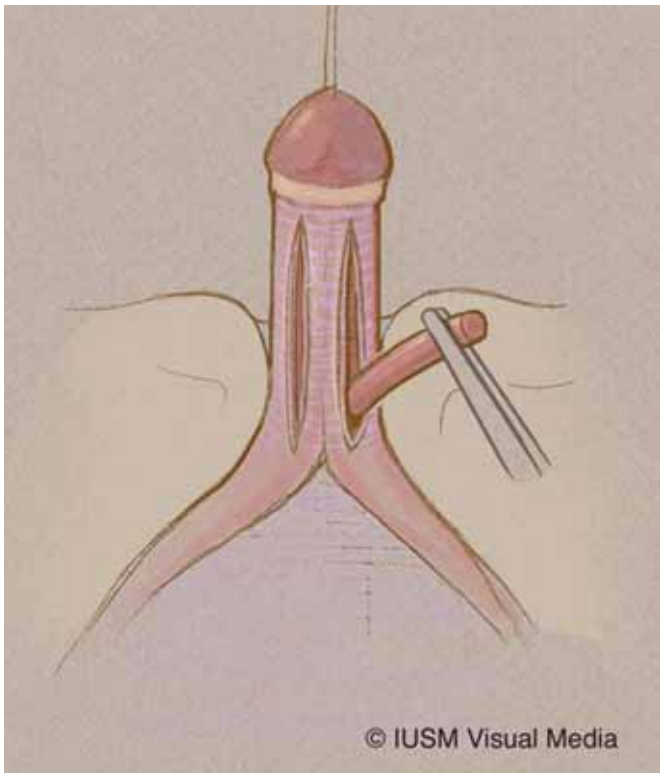

Figure 134–41. Proposed clitoral incisions. Note the ventral location. (© Indiana University Medical Illustration Department.)

from the internal pudendal artery from the Alcock canal near the ischial tuberosity. These arteries course ventrally and are on the medial aspect of the bifurcated corpora, where they then course dorsally along the phallic shaft (Schnitzer and Donahoe, 2001). The clitoral neural bundles ascend along the ischiopubic rami and meet as paired bundles that pass along the dorsal surface and then pass largely intact into the glans (Baskin et al, 1999; O'Connell et al, 2005). The authors' current clitoroplasty technique is described but regardless of technique, the just-described clitoral innervation must not be disturbed. A tourniquet is placed at the base of the clitoris. Longitudinal incisions are then made through the Buck fascia on the ventralmost aspect of each corporeal body (Fig. 134–41); the incisions extend from the glans to the bifurcation to expose the corpora cavernosa tissue, which is dissected (often teased) from the tunics. The tunics are left undisturbed, except for the ventral incision. **No tunical tissue is excised. The dorsal neurovascular bundle should not be mobilized or disturbed in any way.** The proximal ends of the erectile tissue only are suture ligated. Efforts to decrease the size of the glans are controversial and, if attempted, should be done with great caution. Studies of Juskiewenski and associates (1982) and Baskin and colleagues (1999) would suggest that any glans excision should be performed ventrally near the midline (similar to hypospadias glans wings). The glans is innervated by perforating branches entering at the dorsal junction of the glans and corpora (Baskin et al, 1999). Excision of glanular epithelium to conceal the glans is to be avoided because the sensory neuropeptides are located just beneath this layer. Remember there are no data to suggest that a large glans is detrimental to sexual function. The glans is now secured to the coronal stumps. In the authors' experience, a glans sewn to the pubis results in an abnormally high prominent position (Rink and Yerkes, 2001).

With clitoroplasty completed, the flap vaginoplasty is started. The previously outlined omega flap is incised, and the underlying fat is mobilized with the flap to expose the urogenital sinus. The flap must be made long enough to provide a tension-free anastomosis to the vagina and wide enough to provide a normal-caliber introitus without compromising the blood supply of the perineal body. The posterior wall of the sinus and vagina is now dissected free from the underlying rectum. This initial posterior step in separating the vagina from the rectum is the most difficult. With stay sutures in the meatus, the posterior wall of the sinus is opened in the midline and extended proximally into the posterior wall of the vagina. **The distal third of the vagina is usually narrowed; therefore, the posterior wall incision must be carried proximally until normal-caliber vagina is encountered.** Sutures are placed individually through the perineal flap and then through the split posterior wall of the vagina and tied.

The mobilized phallic skin is unfurled and divided longitudinally in the midline while stopping short of the base to allow a clitoral hood. This tissue at its base is incorporated with the preputial skin to create a clitoral hood. Labia minora are now created with this split preputial skin, which is moved inferiorly and anastomosed to the preserved ventral plate and the lateral vaginal wall. The proposed Y incisions are now made around the inferior aspect of each labia majora. The labia are mobilized and secured inferiorly alongside the vagina as a YV-plasty. The vaginal introitus should now reside between the labia minora and majora rather than appear as an isolated hole on the perineum.

High Vaginal Confluence—with or without Clitoral Hypertrophy

Most believe that complete separation of the vagina from the urogenital sinus with a "pull-through" vaginoplasty, as proposed by Hendren and Crawford (1969), **is the best solution to a high vaginal confluence.** Fortunately, this complex situation is found in only about 5% of patients with CAH (Dumanian and Donahoe, 1992). This high confluence is more commonly seen in pure urogenital sinus abnormalities. Although the concept of vaginal separation and pull-through was a major advance, the operation as originally described frequently resulted in an isolated vaginal opening that appeared to be separate from the remainder of the genitalia, and a mucosal lining was lacking (Passerini-Glazel, 1989). It was also technically difficult because of poor vision at the critical points (Rink et al, 1997). Several authors have addressed these issues. Passerini-Glazel (1989) used the mobilized sinus by dividing it dorsally; when tabularized with the phallic skin and folded back toward the vagina, it would create a more normal cosmetic result and provide excellent coverage in the area of the vaginal separation while helping to prevent a urethrovaginal fistula. He later used this as a flap to form the anterior vaginal wall rather than completely tubularizing it (Passerini-Glazel, 1994). Gonzalez and Fernandes (1990) used the preputial skin to construct the vaginal vestibule and anterior wall.

The critical and most technically demanding aspect of a pull-through vaginoplasty is separation of the anterior wall of the vagina from the urethra and bladder neck. There is no obvious plane of dissection, and great care must be taken to avoid injury to the urinary tract and its sphincteric mechanism. This area is also the most difficult to visualize, and poor exposure naturally leads to poor results, with the potential for a stricture, fistula, diverticulum, or retained distal vagina (Rink and Adams, 1998). Furthermore this is an area of significant nerve supply for the

vagina and urethra. Most surgeons have positioned the patient in the supine or lithotomy position. Several authors have reported means of improving exposure. Passerini-Glazel (1989, 1994) mobilized the vagina transtrigonally in difficult cases but has more recently reported that this approach is seldom necessary. Similarly, Di Benedetto and Rossi and their associates proposed an anterior sagittal transanorectal approach with a diverting colostomy (Di Benedetto et al, 1997; Rossi et al, 1998). Hendren and Atala (1995) reported lateral mobilization of the rectum in 1995 but have since stopped because of the difficulty of this maneuver. Rink and colleagues (1997) reported a midline posterior prone approach with retraction but not division of the rectum that provides excellent exposure for critical aspects of the pull-through vaginoplasty and is described here. Endoscopy with Fogarty and Foley catheter placement and total-body preparation are as described for a flap vaginoplasty. If the child has associated clitoral hypertrophy, the clitoroplasty is performed with the child supine as described earlier for a low confluence. The child is then rotated to the prone position. In a patient with a pure urogenital sinus, the procedure is started with the patient in the prone position.

The perineal omega-shaped flap incision is made as previously described, and then the flap is retracted posteriorly, with dissection now carried out in the midline between the posterior wall of the sinus/vagina and rectum. As dissection proceeds proximally, the rectum is easily retracted with a small Deaver retractor (Fig. 134–42) to expose the entire urogenital sinus without the need to divide the rectum. The entire length of the sinus may be divided in the midline posteriorly to the normal caliber of the vagina. The Deaver retractor is now placed in the vagina and with upward retraction easily exposes the anterior wall of the vagina at its confluence with the sinus. This allows dissection of the vagina from the urethra under direct vision (Fig. 134–43). The tissues are quite thin in this area, and one should always err on the side of the vagina. More proximally, the dissection becomes easier. Excellent vision is also provided for tubularization of the sinus to create a urethra, which is closed in two or three layers over a Foley catheter. The anterior wall of the vagina is now mobilized inferiorly, closer to the perineum. "Pull-through" vaginoplasty is often a misnomer because frequently the separated vagina will not reach the perineum. In this situation, skin flaps have been used to reach up to the vagina (rather than the vagina "pulled through" to the perineum). Preputial skin may be sewn to the spatulated anterior vagina, as described by Gonzalez and Fernandes (1990) (Fig. 134–44). When preputial skin is not available, a buttock flap or a laterally based skin flap can be used (Parrott and Woodard, 1991; Dumanian and Donahoe, 1992) (Fig. 134–45). The child is returned to the supine position, and the posterior perineal flap is anastomosed to the vagina as described for the flap vaginoplasty. The authors believe that skin flaps are best avoided because they are more likely to stenose and may be hair bearing. The use of urogenital tissue to create the flaps is more reliable, as in the Passerini-Glazel flap.

Labioplasty is now completed as described earlier. If a laterally based flap is required for the anterior wall, posterior relocation of the labia majora may be performed at a later stage.

In patients with a high confluence, particularly if multiple flaps have been used, the legs are bound together loosely postoperatively to prevent tension on the flaps.

Total and Partial Urogenital Mobilization

In 1997, Alberto Pena proposed a maneuver called ***total urogenital mobilization (TUM)*** as a means to repair the urogenital sinus component of a cloacal repair. **In this procedure the entire sinus is dissected circumferentially and mobilized toward the perineum.** Pena noted a decrease in operative time by 70%, a superior cosmetic result, and less risk of fistula, vaginal stenosis, or acquired vaginal atresia with TUM because vaginal separation is not usually required. Since Pena's original

description, TUM has been applied to several disorders, such as urogenital sinus, female exstrophy, and penile agenesis (Ludwikowski et al, 1999; Kropp and Cheng, 2000; Rink et al, 2006). Both Pena and Ludwikowski's group reported amputation of the mobilized sinus so that the vagina and urethra can be sewn flush to the perineum (Pena, 1997; Ludwikowski et al, 1999). **The authors have reported using the mobilized sinus to provide a mucosa-lined vestibule or a Passerini flap to cover the anterior vaginal wall when a pull-through procedure is performed** (Rink and Adams, 1999; Rink et al, 2006). Jenak and associates (2001) have since reported similar use of the mobilized sinus to create a mucosal vestibule, and Hamza and colleagues (2001) have noted that the sinus may be used as a Passerini-like flap. There have been two recent descriptions of use of the mobilized sinus to replace the posterior perineal-based skin flap with a sinus flap. In one, the sinus is split laterally and rotated posteriorly (Rink and Cain, 2002, Rink et al, 2006). In the other, the sinus is split in half longitudinally and the two halves are

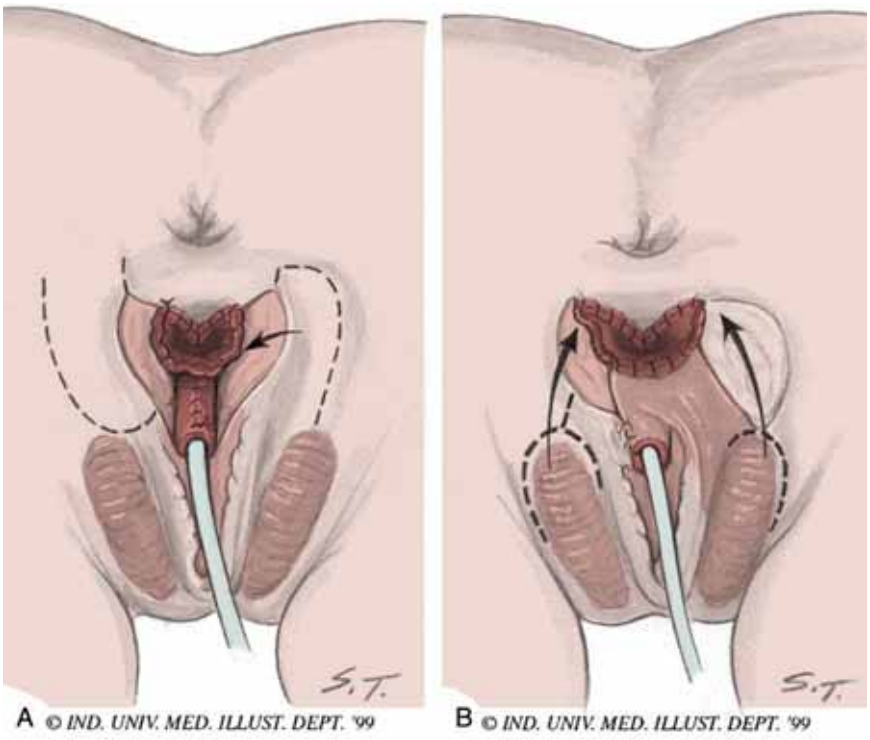

Figure 134–45. **A** and **B**, A buttocks- or labial-based flap may be used to create the anterior vaginal wall in a patient with a pure urogenital sinus. (©1999, Indiana University Medical Illustration Department.)

rotated inferiorly (Gosalbez et al, 2005). At the Riley Hospital for Children, the authors have incorporated urogenital mobilization techniques into nearly all of our urogenital sinus repairs. **It allows a midlevel confluence to reach the perineum without requiring vaginal separation. The highest-level confluences may still need a pull-through procedure with separation of the vagina and urethra,** but it is much more easily performed after the urogenital sinus has been mobilized.

TUM is often thought of as its own type of vaginoplasty but is, in fact, a technique to allow vaginoplasty that may result in the vagina being sewn flush to the perineum; however, a flap or pull-through vaginoplasty may still be required. Only rarely do the authors believe the vagina should be sewn flush to the perineum, owing to concerns of a circumferential anastomosis becoming stenotic. TUM is started, as previously described, with endoscopy to evaluate the anatomy, to note the level of the confluence, and to place a Fogarty catheter in the vagina and a Foley catheter in the bladder. A sponge is placed in the rectum, and the proposed incisions are outlined. Subcutaneous injection of 0.5% lidocaine with 1:200,000 epinephrine along the lines is carried out. Clitoroplasty is performed as previously described, with the meatus of the urogenital sinus and urethral plate being circumscribed with stay sutures to allow mobilization of the sinus from the corporeal bodies. This is initially carried out to just between the bifurcation of the corporeal bodies. The clitoroplasty is now completed as described earlier. The dissection is carried out in the midline posterior to the sinus until the peritoneal reflection is reached to allow access to the entire posterior wall of the vagina (Figs. 134–46 and 134–47). This circumferential mobilization is done directly on the urogenital sinus and continues proximally beneath the pubis. As the avascular ligaments from the pubis to the sinus are divided in this area, the entire urogenital sinus is felt to "give" and move toward the perineum (Fig. 134–48).

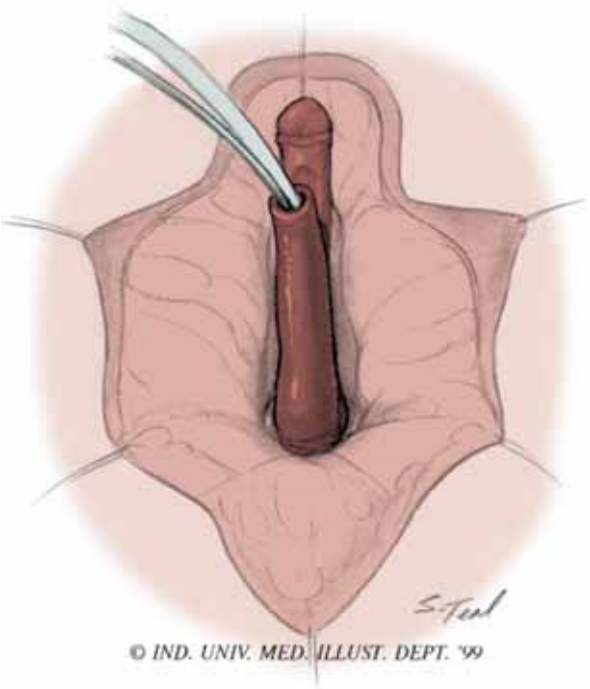

Figure 134–46. Skin mobilized with the sinus exposed. (©1999, Indiana University Medical Illustration Department.)

The Fogarty balloon is now easily palpable in the vagina. The posterior wall of the vagina is opened between stay sutures. If the vagina is now near the perineum, it may be sewn flush to the perineum, or an omega-shaped perineal flap may be placed into the spatulated posterior wall to augment the vaginal caliber. The authors prefer the latter. Rather than discard the mobilized sinus,

as previously reported, it is helpful to split the sinus ventrally and use it to provide a mucosa-lined vestibule (Fig. 134–49). If the vagina is still quite high, the anterior wall of the vagina should be separated from the urethra and bladder neck, as in the pull-through procedure (Pena, 1997; Rink and Kaefer, 2002; Rink et al, 2006). This is most easily performed with the child in the prone position to allow direct vision. The opening in the urethra is closed in two layers. The mobilized sinus in this situation is split anteriorly and then used as a Passerini-like flap to create the anterior vagina wall (Rink and Adams, 1999; Rink et al, 2006) (Fig. 134–50). The posterior perineal flap is approximated to the spatulated posterior vaginal wall. Labioplasty is performed as previously described. TUM has achieved great popularity, and reports to date reveal excellent cosmesis and continence. No long-term results are available.

Some have expressed concern regarding the proximal circumferential dissection because of the potential risk for sphincteric musculature or nerve injury. There is concern for resultant stress incontinence or foreshortening of the vagina. **To address these concerns, Rink and associates** (2005c; 2006) **proposed *partial urogenital mobilization* (PUM), a technique that starts with the same circumferential dissection but stops at the level of the pubourethral ligament** (Fig. 134–51). This still allows use of the mobilized sinus as described earlier to improve cosmesis, yet it avoids the aggressive retropubic and suprapubic dissection and is applicable to the majority of patients. If more mobilization is necessary for a very high vagina, TUM is easily carried out.

Key Points: Urogenital Mobilization

- TUM is a technique applicable to both urogenital sinus and cloacal anomalies. The entire sinus is dissected circumferentially to above the pubis to allow the confluence to move inferiorly to the perineum.
- With the TUM or PUM technique, the mobilized sinus tissue can be used to create a mucosa-lined vestibule or an anterior or posterior vaginal wall. This sinus tissue should not be discarded.
- PUM circumferentially mobilizes the sinus to the level of the pubourethral ligament but does not extend above this level.

Results of Urogenital Sinus and DSD Surgery

Only recently have we started to see more long-term surgical reports for DSD patients after feminizing genitoplasty. Most articles look at success as an adequately open vagina with a feminized appearance. Success should include normal erotic sensation, lubrication, sexual satisfaction, orgasm, and intercourse without discomfort. These latter factors are just beginning to be studied. **Cosmetic and early functional results have uniformly been reported to be good. Long-term outcomes are of more concern,** but in these studies it is often difficult to tell what procedures were done for what degree of severity of urogenital sinus, and none of the studies include data on the quality of endocrinologic control in these patients. Looking at what data are available, Jones and colleagues noted in 1976 that 25 of 84 patients undergoing vaginoplasty required a secondary procedure to provide a vaginal outlet satisfactory for intercourse; 5 of these 25 also required a third procedure. **The poor results were caused by failure to exteriorize the vagina initially or by scar formation. The distal vagina is always narrow. The normal caliber vagina must always be reached and exteriorized with current procedures.** Sotiropoulos and associates (1976) found that all patients undergoing prepubertal vaginoplasty required revision at puberty. Azziz and coworkers, in 1986, reported the results of attempted coitus in 42 women with CAH 23.6 years after vagina repair. Satisfactory coitus was noted in 62% (46% in salt wasters and 87% in those with the non–salt-losing form). There was a less favorable outcome when the initial procedure was performed before 1 year of age. Thirty secondary or tertiary procedures were needed to achieve the final results. These data are widely quoted, but almost all of these patients underwent a "cut-back" vaginoplasty initially ("incision of the urogenital sinus"), which is a procedure no longer used because it does not adequately open the vagina to the proximal normal caliber; specifically, the distal end of the vagina is narrowed and thus will be stenotic. Their revision involved the performance of a "flap" vaginoplasty, which currently would probably have been the initial procedure. In a series from Johns Hopkins Hospital, 28 patients (32% lost to follow-up) had adequate follow-up, 22 (78.6%) of whom needed further vaginal surgery (Bailez et al, 1992). The authors noted that if secondary surgery was needed for vaginal stenosis, success rates were high when the procedure was performed near puberty. This group also reported less favorable results in those younger than 1 year of age, with only 8 of 18 needing a secondary procedure requiring a flap. Nihoul-Fekete and colleagues (1982) noted that 30% of 43 CAH patients required secondary surgery. Hendren and Atala (1995), reporting on 16 patients with high vaginal confluence, noted that 6 of 9 adults had satisfactory coitus and 2 had vaginal stenosis.

More recently, Alizai and colleagues (1999) assessed 14 girls with CAH under anesthesia, 11 to 15 years old, who had undergone genitoplasty at a mean age of 2.5 years and noted that 13 of 14 required additional vaginal surgery. Stenosis was seen in 43% and persistent urogenital sinus with or without fibrosis in 50%. Minto and coworkers (2003) found that 39% of 28 patients required secondary surgery and a third procedure was required in 11%. Al-Bassam and Gado (2004) noted vaginal stenosis in 16% of their patients who underwent various types of vaginoplasties (43 vaginoplasties: 26 flap, 11 pull-though, 2 cutback, 3 sigmoid vaginal replacements). Nearly all underwent vaginal dilation. Vaginal stenosis was noted in 37% of CAH patients reported by Nordenskjold and colleagues (2008), whereas 15 of 50 noted painful intercourse. However, 24 of 41 vaginoplasties were cutbacks with 10 flaps and 7 combinations. Al-Bassam and Gado (2004) noted vaginal stenosis in 16% of their patients who underwent various types of vaginoplasties (43 vaginoplasties: 26 flap, 11 pull-through, 2 cutback, 3 sigmoid vaginal replacements). Nearly all underwent vaginal dilation. Vaginal stenosis was noted in 37% of Nordenskjold and colleagues' (2008) CAH operated patients with 15 of 50 noting painful intercourse. However 24 of the 41 vaginoplasties were cutbacks with 10 flaps and 7 combinations. It is tempting to assume that postpubertal vaginal surgery may result in better outcomes, but there are no data to support this assumption. Furthermore, Eroglu and associates (2004) actually noted less vaginal stenosis in those who underwent early single-stage repair (3.4%) than in those who underwent late vaginoplasty (42.8%). Lean and coworkers (2007) noted no difference whether the surgery was done before or after 2 years of age. In their series of 32 patients they noted good cosmesis in 72%, satisfactory in 22%, and poor in 6%. They believed that the planned one-stage operation gave better results than the planned multistage procedure, with only 2 of the former patients requiring further major surgery and 3 of 32 needing minor revisions. Al-Bassam and Gado (2004) also recommended a single-stage repair at 3 to 6 months of age.

It seems clear that a "single-stage" early vaginoplasty will probably require a secondary repair after puberty, but this should be expected because the orifice is likely to remain the size that was created given that there is no flow through the orifice in childhood. In the authors' experience, the secondary refinements are easily performed.

Surgical techniques to reduce clitoral size have dramatically improved and are now based on our current knowledge of clitoral neuroanatomy. Even though no long-term results are available for current techniques, some long-term results are now being reported for relatively modern techniques. Alizai and colleagues (1999) found clitoroplasty results to be unsatisfactory in 46%. **Gearhart and coworkers** (1995) **looked at pudendal evoked potentials after clitoroplasty and noted that modern clitoroplasties preserve nerve conduction in the dorsal neurovascular bundle.** Barrett and Gonzales (1980) found

intact sensation in all of their patients after clitoroplasty. Chase (1996) reported that even with normal evoked potentials there may be an absence of sensation and orgasm. The authors have not noted vascularization defects after modern clitoroplasty. It is clear that further long-term studies are necessary. Minto and coworkers (2003) found the clitoris to be cosmetically normal in 59% who had undergone clitoral surgery, but it was excessive in 20%, large in 7%, small in 7%, and absent in 7%. This group also reported that hot, cold, and vibratory sensation was markedly altered as recorded by a genitosensory analyzer. Sensation alone may be a poor indication of clitoral normality after surgery. Further studies to analyze the newest techniques are warranted. The erotic sensitivity and potential for orgasm should be studied. More recently, Nordenskjold and colleagues (2008) reviewed 62 CAH patients with 60 controls. Of the 49 who underwent clitoroplasty 16 had 1 operation, 14 had 2, 4 had 3, 4 had 4, and 11 had between 5 and 10 operative procedures. Twenty percent were not satisfied with their surgery. They thought there was decreased sensitivity. However, 50% of the nonoperated patients thought their clitoris was too large. There was no difference in the ability to achieve orgasm between the two groups. They noted that women with CAH were less satisfied with their genitalia whether operated or not.

The results of TUM and PUM are very early. These procedures are technically easier and the cosmetic results are superior, but whether the functional results are better is unknown. The potential for stress incontinence or denervation of the sphincteric mechanisms also is unknown. Most authors to date have not found continence to be altered by TUM (Rink and Adams, 1999; Hamza et al, 2001; Kryger and Gonzales, 2004; Rink and Leslie 2007). Until these results are available, this procedure should be used with caution.

Timing of vaginoplasty remains quite controversial. Although the few reported long-term studies suggest that delayed vaginoplasty may be preferable, most surgeons continue to recommend early surgery, particularly for the CAH group. Most would recommend delaying vaginoplasty for the patient with a small, very high confluence vagina. They argue that the available long-term studies are based on outdated techniques and that there are tremendous surgical advantages to a single-stage repair. Supporters of early vaginoplasty well recognize that secondary introitoplasty may be necessary, but this is usually accomplished easily. The argument, which will not be settled soon, contrasts two approaches, both of which usually result in two procedures: (1) a simple procedure in an infant (i.e., clitorolabioplasty) with a postpubertal extensive procedure (i.e., vaginoplasty) or (2) an extensive single-stage clitorolabiovaginoplasty in an infant with a simple introitoplasty in the postpubertal period.

Several studies have noted that the most important factor affecting results is whether there was a surgeon or surgical team with a special interest in feminizing genitoplasty procedures (Creighton et al, 2001; Lean et al, 2007; Nordenskjold et al, 2008). This suggests that supports for Centers of Excellence may be appropriate for the care of children with DSD.

Key Points: Urogenital Sinus Anomalies—Outcomes of Reconstruction

- It is clear that neonatal vaginoplasties will usually require a secondary procedure for stenosis after puberty (25% to 100%).
- Successful coitus is often reported, but further studies should note sexual satisfaction, lubrication, and erotic sensitivity, as well as nonpainful coitus.
- Current techniques of clitoroplasty seem unlikely to injure sensation, but newer studies question whether sensitivity is an adequate indication of clitoral function. Some studies note decreased sensation with newer techniques.

SURGICAL RECONSTRUCTION FOR CLOACAL MALFORMATIONS

Initial Management, Timing, and Principles

The initial management of cloacal anomaly involves stabilization because the child is often quite ill with abdominal distention that at times results in respiratory compromise. As with all other anomalies, its management has evolved. Historically, after decompression of the distended organs, it was common practice to perform a rectal pull-through procedure; genitourinary reconstruction followed at a later date, if at all (Okonkwo and Crocker, 1977). Hall and coworkers (1985) suggested that the vaginal surgery be done after puberty, when estrogen levels are higher. **Although it is tempting to perform a pull-through procedure only, it is now clear that this piecemeal repair of the cloaca is a disservice to the child and is absolutely contraindicated. It is optimal to repair all abnormalities (i.e., rectal, vaginal, and urethral) in a single stage** (Kay and Tank, 1977; Mollitt et al, 1981). **This allows the best exposure for the difficult rectal and vaginal separation.** Furthermore, the tissues have not been previously violated, and the rectum does not require remobilization. Hendren (1982, 1986) pointed out that rectal pull-through should never be done as a separate procedure. Of his 154 patients with cloacal anomaly, 60 were secondary cases, many of whom had undergone a previous pull-through procedure. Definitive repair in this situation often requires repeat rectal mobilization. Raffensberger (1988) proposed neonatal complete repair but later noted that this may not be appropriate. Levitt and Pena (2005) have stated that there are three pitfalls in the management of neonates with cloacae: (1) failure to recognize and manage hydrocolpos, (2) colostomy or vesicostomy problems, and (3) clinical misdiagnosis.

Surgical management now involves four basic steps: (1) decompression of the gastrointestinal tract, (2) decompression of the genitourinary tract, (3) correction of nephron-destructive or potentially lethal urinary anomalies, and (4) definitive repair of the cloaca.

Decompression of the Gastrointestinal Tract

Decompression of the gastrointestinal tract is done by colostomy. Although nearly all surgeons agree on the need for colostomy initially, the best anatomic location of the colostomy is debated. Hendren initially recommended a low-loop colostomy but more recently has performed a right transverse colon divided colostomy (Hendren, 1982, 1986, 1998). This change was prompted by difficulty in obtaining a bowel segment for vaginoplasty during the rectal pull-through procedure when a low colostomy has been performed. A divided transverse colostomy keeps the left colic blood supply intact (Hendren, 1992). Pena, as cited by Spitz and Coran (2006), preferred a descending colostomy because there was

less surface area for resorption of urine. A divided colostomy in the descending colon just after the colon takes off from its retroperitoneal attachment is now recommended by Levitt and Pena (2005). This procedure maintains the availability of enough distal colon for future pull-through, and prolapse is less likely to occur. However, Pena did recommend leaving a long segment of sigmoid to prevent a difficult pull-through requiring abdominal exploration. Levitt and Pena (2005) noted that 24 of 361 patients had a colostomy too low that interfered with the rectal pull-through. The authors have favored a proximal colostomy but have at times found clinically challenging acidosis caused by urine absorption through the colonic mucosa. Masuko and associates (2005) reported successful decompression of the colon by balloon catheter drainage with irrigation of the bowel three times a day. This avoided temporary colostomy and allowed a single-stage repair.

At the time of colostomy, endoscopy may be performed to more clearly define the anatomy and to aid in decompression of the urinary tract. In the authors' experience, as the cystoscope advances proximally through the cloacal channel, it tends to enter the vagina (or vaginas). In fact, entrance into the urethra/bladder can be extremely difficult in a neonate with a distended vagina because the vagina compressed the bladder to the anterior abdominal wall and obstructs the bladder neck. Drainage plus irrigation of the vagina (or vaginas) not only allows decompression and relief of abdominal distention but also may allow visualization of the bladder. Often, the rectal fistula is also difficult to locate; as noted previously, it is more often found within the septum of the duplicated vaginas but can enter at almost any location. With a combination of irrigation through the fistula and through the distal limb of the colostomy, the inspissated mucus and meconium can easily be cleared. It is often helpful to leave small feeding tubes in all channels and then obtain radiographic studies to further delineate the anatomy. In the authors' experience this is best done in the radiology suite with fluoroscopy.

Decompression of the Genitourinary Tract

Even after decompression of all structures draining into the cloaca, at times voiding continues into the vagina (or vaginas) or the rectum (or both) and results in rapid distention of these structures with subsequent poor urinary drainage, persistent hydronephrosis, abdominal distention, urinary infection, and hyperchloremic acidosis. This can generally be managed by intermittent catheterization. The catheter often enters the vagina rather than the bladder, but it still functions to drain and decompress the genitourinary tract (Hendren, 1992). If the desired decompression is not achieved, further maneuvers are required. The authors agree with Hendren that in a long urethra-like cloaca, catheterization can at times be difficult and a cut-back procedure (opening the cloaca) may be helpful to aid catheterization (Fig. 134–52). If this approach fails, further decompression can be achieved by either vesicostomy or vaginostomy (Kay and Tank, 1977). Levitt and Pena (2005, 2010) have found tube vaginostomy or vaginostomy to be helpful, but it is our belief that clean intermittent catheterization (CIC) or vesicostomy, or both, will usually keep the vagina adequately decompressed. Only when these maneuvers fail should vaginostomy be performed because it tethers the vagina to the abdominal wall and may make later pull-through or TUM difficult. It also necessitates an abdominal procedure. Levitt and Pena (2005) found that 25% of their cloaca patients had hydrocolpos but that in 59% of them it was either not identified or mismanaged. This resulted in significant morbidity from ureteral obstruction, urinary tract infection, acidosis, and failure to thrive. Adequate vaginal drainage resulted in resolution of these problems.

Figure 134–52. The urethra-like cloaca is opened, with a catheter in place; vesicostomy has also been performed.

Repair of Obstructive Urinary and Other Pathology

The third stage of care of a child with a cloacal anomaly is repair of any obstructive urinary tract pathologic process. Renal structural abnormalities have been identified in 60% to 83% of patients with persistent cloaca, some of which were obstructive (Warne et al, 2003; Rink et al, 2005b). In those with a common channel longer than 3 cm, 91% had urologic defects (Pena et al, 2004). At times, these anomalies are ignored early on while awaiting definitive cloacal repair, but this practice should be avoided. Obstructive lesions should be treated promptly. However, vesicoureteral reflux, which is quite common, can generally be managed medically if urinary infection is prevented. Other organ system anomalies (e.g., cardiac, spinal cord) should be fully evaluated. Some may require repair during this phase.

Definitive Repair of Cloacal Malformations

Definitive repair of a cloaca is usually carried out at 6 to 12 months of age, but obviously, the child must be well nourished and thriving to proceed with repair. In healthy thriving children, Pena and colleagues (2004) operate at 1 month of age. Definitive repair should never occur until the urinary tract has been evaluated and hydrocolpos has been ruled out. If endoscopy has not been performed previously, it may be

helpful as a separate procedure before the definitive repair. Defining the anatomy can be tedious, and it is helpful to thoroughly cleanse the distal colonic segment, which usually requires irrigation from the mucous fistula, as well as the distal limb of the colostomy. A standard GoLYTELY bowel preparation should also be done.

Operative Technique—Cloaca

The definitive repair begins with endoscopy to reacquaint the surgeon with the anatomy. The authors have also found it is helpful to place a Foley catheter in the bladder and different-colored Fogarty catheters in the vagina (or vaginas) and rectum. The catheters are kept sterile during preparation. As described previously for urogenital sinus repair, a complete lower body preparation with povidone-iodine is done circumferentially from the level of the nipples to the toes, and the legs are wrapped sterilely. Such preparation allows prone and supine positioning for perineal and abdominal surgery.

The definitive posterior sagittal anorectovaginourethroplasty (PSARVUP) is begun with the child in the prone position and the pelvis elevated on rolls to achieve a jackknife position. An electrical stimulator is used to determine the area of maximal contraction, which is marked with a skin scribe and with stay sutures for later rectal placement. The proposed locations of the perineal body and vagina are also marked (Fig. 134–53). The authors agree with Hendren that it is at times helpful to have a sound in the common cloacal channel, but the Foley and Fogarty catheters usually suffice. The entire dissection is done in the midline until mobilization of the rectum and vagina is begun. The most important advances of Pena's PSARVUP procedure are that it allows identification of the external sphincter and muscle complex of the rectum and provides excellent exposure for separation of the rectum and vagina (or vaginas) from the cloaca.

The initial incision extends from the tip of the coccyx in the midline to the posterior aspect of the cloacal orifice. Sutures mark the sphincteric muscular structures on either side as they are encountered. The authors have found it helpful in the past to open the common cloaca in the midline posteriorly to the level of the confluences to allow easy identification of the rectal and vaginal insertions. With TUM, this is less appropriate because it may limit the options for use of the sinus in the reconstruction as previously described for a urogenital sinus. When the rectal fistula is identified, it is opened posteriorly and multiple silk stay sutures are placed. These sutures are helpful in mobilizing the rectum away from the vagina (or vaginas). It is important to remember that the structures share a common wall initially and it is better to enter the vagina than either the rectum or urethra. Circumferential dissection of the rectum to well above the sacrum may be necessary. Separation of the peritoneum can be done from this position. Rarely, a child with a very high rectal confluence needs to be turned to the supine position for abdominal exploration to free the rectum more proximally. Levitt and Pena (2010) have noted abdominal surgery to be more likely when the common channel is greater than 3 cm in length. Once adequate rectal mobilization to allow a tension-free anastomosis to the perineal skin has been achieved, the rectal stay sutures are used to retract the rectum from the genitourinary structures.

In the classic PSARVUP procedure, the vagina is now separated from the sinus. This dissection is even more tedious and difficult than the rectal separation. With TUM (described later), which has now achieved widespread acceptance for cloacal repair, the vagina may not require separation. In classic vaginal separation, as noted earlier, it is an error to enter the urinary tract during vaginal mobilization. Side-by-side vaginal duplication is most common, and the midline septum has been incised with electrocautery during the initial endoscopy. Hendren (1998) noted that 66 patients had a single vagina, 68 had two, and 20 had none. The Fogarty catheter (or catheters) within the vagina is easily palpable, and the posterior aspect of the vagina is opened at the level of the confluence. Again, circumferential stay sutures are very helpful in

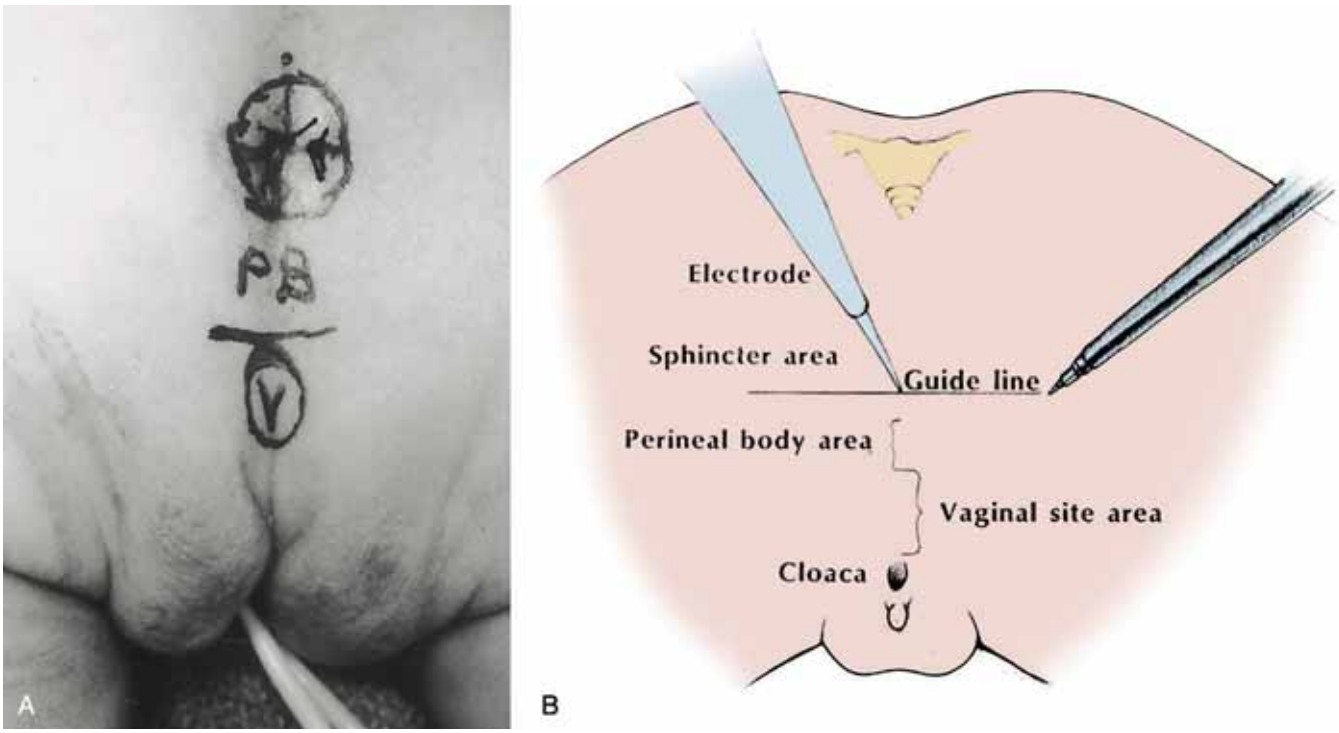

Figure 134–53. Cloaca: proposed location of the vagina (V) and perineal body (PB). Rectal location is identified by electrical stimulation.

separating the vagina from the urethra and bladder. A malleable retractor inserted into the opened posterior vaginal wall exposes the anterior wall confluence for separation. Sharp dissection is less likely to injure the urinary tract than cautery is. Making dissection even more difficult is the realization that frequently the vagina almost encircles the urethra. Failure to recognize this situation can result in injury to these structures. Use of the stay suture for traction aids in further mobilization of the vagina (or vaginas). The outer wall of the vagina appears white, and identification of this color is helpful. Great care should be taken to avoid devascularization of the vagina during mobilization. Usually, vaginal mobilization allows the vagina to be "pulled through" to a position near the perineum. If after significant mobilization it still does not reach the perineum, skin flaps can be used to reach the spatulated vagina. With an extremely high vagina or the rare vaginal agenesis, it may be necessary to interpose a bowel segment to reach the perineum, which obviously requires abdominal surgery. With a very dilated vagina, a vaginal flap or vaginal "switch" can be created to reach the perineum, although care must be taken to avoid devascularization and stenosis (Hendren, 1986; Pena, 1989; Pena et al, 2004).

Before the vagina is brought to the perineum, the openings in the common cloacal channel should be closed in two to three layers with absorbable suture to create a urethra. If the cloaca is large and resembles a vagina, it needs to be opened in its entirety and tailored over the Foley catheter. The vagina is then secured to the perineum. If there is any concern about vaginal injury, the vagina should be rotated to avoid overlapping suture lines (Hendren, 1992). The Foley catheter is left indwelling for 2 weeks.

Some surgeons have more recently noted that laparoscopic assisted PSARVUP can help in achieving a low dissection of the fistula and accurate placements of the rectal pull-through, while allowing excellent visualization of the pelvic structures (Tei et al, 2003).

The perineal body is now reconstructed, and the rectum is pulled through to the perineum. Pena (1989) stressed the importance of tailoring the widened rectum. The amount of tailoring differs in each patient. The muscles must meet posterior to the rectum. The rectum is placed in the center of the sphincteric muscle mass and anastomosed to the skin. Rectal dilation is begun gradually at 2 to 3 weeks after surgery, and the colostomy is closed in 3 months if all has healed well.

Once the urethral catheter has been removed, it is imperative to monitor the urinary tract and voiding dynamics closely because poor emptying secondary to a neuropathic component is seen in almost a third of patients. If any concern arises about the child's ability to empty, CIC should be started and continued until normal bladder dynamics are ensured. Failure to do so can ultimately result in urinary tract infection, hydronephrosis, and even loss of renal function.

Pena's TUM technique is now widely accepted for cloacal anomalies. It is a technically easier procedure that requires less time with less blood loss. The basic technique involves 360-degree mobilization of the entire urogenital sinus after the rectum has been separated. The technique at this point is not different from that described earlier for TUM for urogenital sinus abnormalities. The authors have found this technique to be extremely helpful. It makes the most difficult part of cloacal surgery, vaginal separation, much more easily performed when necessary. If the confluence is only 2 to 3 cm from the perineum, separation may not be even necessary. In those patients with a high vaginal confluence, separation may still be necessary, but it is much more easily accomplished (Rink et al, 1997). Concerns regarding continence have been raised, but to date the results have not been different than with standard repairs. Long-term results of the TUM procedure are needed.

Key Points: Cloacal Reconstruction

- Cloacal reconstruction involves four steps: (1) decompression of the gastrointestinal tract (colostomy), (2) decompression of the urinary tract (CIC, vesicostomy), (3) correction of associated organ systems anomalies, and (4) cloacal repair (PSARVUP).
- TUM is now commonly used for cloacal anomalies after the rectum is separated.
- The results of cloacal repairs are often based on the presence or absence of a normal spinal cord. CIC is frequently required, as is a bowel program, to achieve urinary and fecal continence.

Results of Cloacal Surgery

Cloacal anomalies are exceedingly challenging to repair. The anatomy is complex and differs from patient to patient. The surgeon must be prepared for a long, tedious procedure, must be imaginative, and must be willing to handle the tissues with great care. One might assume from this preface that the results would be dismal. On the contrary, most patients lead a productive life. We surgeons are indebted to Drs. W. Hardy Hendren and Alberto Pena for their pioneering work on children with cloacal anomalies, as well as their willingness to document their results.

Results have generally been reviewed in terms of urinary continence, fecal continence, and sexual capability; in the future, results should also focus on erotic sensitivity and fertility, pain-free intercourse, orgasm as well as quality of life. Early results from a urinary standpoint were dismal: Chappell and Bleloch (1973) reported that all 5 of their patients had some degree of incontinence postoperatively, and Bartholomew and Gonzales (1978) had 5 of 7 patients wet after reconstruction. **It is now clear that a high percentage of patients have a neuropathic component to their incontinence.** In 1999, De Filippo and colleagues reported urodynamic data on 26 patients with anorectal malformations (including 6 with cloacal anomalies). Twenty-one of the 26 had preoperative leak point pressures greater than 40 cm H_2O, and 15 had normal MRI of the spine. This means that even those not demonstrating a neurologic abnormality may have abnormally high outlet resistance, which adds to the risk for incontinence and upper tract changes. Of Hendren's 141 patients reported by De Filippo, 83 (59%) voided spontaneously with control, 40 (28%) required CIC, 4 (3%) had undergone urinary diversion, and 1 (0.7%) was continent with urinary diversion; only 5 (3.5%) were wet, and in 8 the results were too early to assess. Pena and coworkers (2004) reported a review of 339 patients operated on for cloacal anomalies, 193 of whom were evaluated for urinary continence. They found that spontaneous voiding was related to length of the common channel. Overall continence with spontaneous voiding occurred in 54%. Another 46% were dry with CIC (24% with a native urethra, 22% with a Mitrofanoff channel). However, when the common channel was less than 3 cm, 28% required CIC; if greater than 3 cm, 78% required CIC. Warne and associates (2002a) achieved 80% "social continence" but only 22% spontaneously voided, 12% performed CIC alone, and 46% required reconstructive urologic surgery to achieve continence (mean number of operations, 4.7). They likewise found that those with a common

Table 134–1.

Continence Rates after Cloacal Surgery

	VOIDING SPONTANEOUSLY	DRY WITH CIC ± CONTINENT RECTUM
Hendren, 1998	0.62	0.34
Pena et al, 2004	0.54	0.46
Warne et al, 2002a	0.22	0.58
Rink et al, 2005b	0.33	0.53

channel longer than 3 cm were less likely to void spontaneously (12% vs. 31%). In the authors' series, 86% were dry but only a third were continent with spontaneous voiding. The remainder required CIC with or without lower urinary reconstruction (Rink et al, 2005b) (Table 134–1). Warne and associates also noted that a good bladder neck, short common channel, normal sacrum, and two normal kidneys were all good prognostic signs for continence and spontaneous voiding. The authors are in agreement with Pena and Levitt (2003) that voiding abnormalities are generally related to a noncontractile bladder and warrant CIC, but Warne and associates (2002a) found hyperreflexia to be the predominant pattern in those with abnormal dynamics. It is important to note that 75% of their patients had an abnormal sacrum.

Fecal continence is directly related to neurologic status (Pena, 1989). **Hendren** (1992) **noted that certain factors bode well for continence: good perineal raphe, well-defined anal dimple, normal spine, normal MRI, and brisk muscle reflex.** In 105 patients, Hendren noted that 47 had normal bowel function, 27 required enemas, 7 had a colostomy, 7 had fecal soiling, and 4 with an anterior anus had normal control. Pena and coworkers (2004) reported that 60% of 156 patients have voluntary bowel movements but only 28% of them never soil. The 40% who are fecally incontinent remain "clean" with a bowel management program. The MACE (Malone Antegrade Continence Enema) appendicovesicostomy has been very helpful in preventing constipation and achieving fecal continence in those refractory to bowel management programs.

Although not a direct result of reparative surgery, renal outcomes are worrisome. Renal insufficiency was found in 50% of the patients treated at Great Ormond Street Children's Hospital, and 17% of the patients progressed to end-stage renal failure (Warne et al, 2002b). In the authors' series, 18% had an abnormally elevated serum creatinine level and in another 26% it was borderline (Rink et al, 2005b). Lifelong yearly urologic evaluation is warranted, and prompt recognition plus treatment of any obstructive pathologic process or urinary tract infections is imperative. Bladder dynamics must be evaluated and abnormalities addressed. Of 24 reported adult patients, 17 had coitus and 6 had borne children (including five deliveries by cesarean section and one vaginal delivery (Hendren 1998).

Leclair and associates (2007) reported on cloacal repair using the TUM technique. Urethral stenosis occurred in 2 of 22 patients and both required a Mitrofanoff catheterizable channel. One child developed a urethrovaginal fistula, and 3 had vaginal stenosis. Continence was noted in 15 of 17 patients older than 4 years of age. Seven voided spontaneously, and 8 emptied by CIC. Fecal continence was present in 12, with 9 having spontaneous bowel movements and 3 requiring MACE irrigations.

SUMMARY

Management of urogenital sinus and cloacal anomalies can be exceedingly complex. In those with disorders of sex differentiation, prompt but very careful evaluation by an expert multidisciplinary team is mandatory. Family support and education with openness and respect for the child and family are required. Differing cultural practices must also be respected and accepted. Confidentially must be maintained. Surgical reconstruction requires great care of tissues, meticulous attention to detail, and a lifelong commitment by the surgeon. These complex anomalies require an entire team of physicians and nurses dedicated to the care of these problems. Urogenital sinus and cloacal anomalies are very challenging reconstructive problems. Those at the more severe end of the spectrum should be handled only in centers with great expertise and experience.

Conclusions

Prior to 1990, nephrolithiasis was responsible for 1 in 1000 to 1 in 7600 hospital admissions annually throughout the United States (Nimkin et al, 1992). **In recent years, however, a dramatic increase in pediatric urolithiasis has been observed** (Srivastava and Alon, 2005). The authors would concur with this observation, especially among adolescents without known metabolic disturbances. It has been speculated that diets rich in sodium and carbohydrates may be contributing to the etiology of urolithiasis in this cohort of children.

The management of upper urinary tract calculi has evolved dramatically in both adults and children in the last two decades. Progress in the management of pediatric stone disease has been motivated by surgeons adopting and applying adult endourologic methods. The most important catalyst in the evolution of surgical advancement has been the expansion of minimally invasive surgery, in general, with development of smaller and more durable endoscopic equipment.

Since its introduction in the 1980s, extracorporeal shock wave lithotripsy (ESWL) has transformed the management of pediatric upper tract calculus disease and remains very useful today. Other modalities of treatment, including ureteroscopy, percutaneous nephrolithotomy (PCNL), and combination treatment protocols allow flexibility in management. However, a consensus has not been reached as to the most effective and safe technique for upper tract urolithiasis, especially considering ESWL versus ureteroscopy. Despite the lack of compelling scientific data comparing these treatment methods in children, ureteroscopy has emerged in many centers as the first-line of treatment.

Pediatric stone disease has always been more prevalent in underdeveloped countries. Of concern is the observation that pediatric stone disease is becoming more prevalent in the western hemisphere. Many pediatric patients with urolithiasis have metabolic abnormalities (Jayanthi et al, 1999). Therefore there has been an increased demand on pediatric urologists to manage both simple and complex urolithiasis in all pediatric age groups.

EVALUATION

Metabolic Workup

Often, a complete metabolic blood profile and a 24-hour urine collection are obtained once a stone is confirmed by imaging. Unfortunately, there are no accepted standard reference ranges for 24-hour urine analyses in the stone-forming pediatric population. Indeed, many pediatric urologists use adult standards to direct medical treatment, because specific reference ranges are not readily available or require additional complicated calculations. Regrettably, there are significant differences between the normal ranges of urine chemistries in children and adults (Battino et al, 2002; DeFoor et al, 2005a). In addition, conflicting reports exist as to the commonality of metabolic disturbances in the presence of calcium-based stones (Sternberg et al, 2005).

In the preliminary evaluation of pediatric stone disease, it is common to obtain 24-hour urine values for creatinine, sodium, calcium, oxalate, uric acid, and citrate. The very cumbersome nature of a 24-hour urine collection often limits its accuracy in the pediatric population. In light of this random urine spot sampling, ratios have been used. Urine calcium to urine creatine ratios (Uca:Ucr), for example, have been used with sensitivities and specificities up to 90% and 84%, respectively, in the evaluation of hypercalciuria, a known risk factor for urolithiasis (Mir and Serdaroglu, 2005). However, such a test is limited to one urinary metabolite and cannot be relied upon to monitor responses to various medical treatments. Furthermore, it is unreasonable to rely solely on urinary calcium excretion values as an indication of overall metabolic disturbances.

It has been suggested that measurement of urinary supersaturation products (calcium oxalate, urate) may help to improve identifying those children at risk for stone formation. DeFoor and colleagues (2006), for example, most recently determined that supersaturation levels of calcium oxalate, as well as calcium to

creatinine levels, were significantly higher in children with stones compared with controls. This difference, however, may have been reflective of differences found in urinary volumes. Lande and colleagues (2005) have demonstrated that low urine volumes in children often negate the benefit of pursuing urine supersaturation products in a stone workup. Such conflicting data often confuses clinicians as to what urinary evaluation to pursue in the workup and management of pediatric stone disease.

Stone disease in the pediatric population has genetic, anatomic, metabolic, and dietary causes. There are numerous genetic causes of hypercalciuric nephrolithiasis alone that contribute to pediatric stone disease (Stechman et al, 2009). In this regard, the medical treatment always accompanies the endourologic management. **To fully treat the pediatric stone patient, there must be a focus on prevention through diet and medication monitoring. For this reason, the pediatric nephrologist is a critical player in the management and surveillance of these children.** Details regarding the metabolic workup and medical treatment of pediatric stone disease are beyond the scope of this chapter. Numerous pediatric nephrology resources are available. Alon (2009), for example, provides an excellent pediatric nephrology review, including medication dosing by weight. The website Litholink (www.litholink.com) can provide valuable information to parents and pediatric urologists alike.

Imaging

Radiographic assessment of the child with calculus disease must be accurate, economic, and safe. **The goals include determination of stone location, size, density, and urinary tract anatomy.** Indications for assessment include acutely symptomatic children with a suspected calculus or children with known calculus disease requiring follow-up evaluation to either determine stone burden or recurrence. Radiographic evaluation is also important in children with abnormal urinary tract anatomy that may predispose to calculus formation, requiring eventual surgical management.

Radiographic imaging in children is similar to imaging in the adult patient. The workup begins when the diagnosis of a calculus is suspected, and the radiographic study is determined by factors such as acuity of presentation and the practices of the treating hospital. Many, if not most, children with renal colic present to an emergency room, and **unenhanced helical computed tomography (CT) has become the most accurate and efficient first choice in initial imaging.** Typically, thin-slice helical protocol is defined by narrow collimation (≤5 mm). CT is not only able to visualize the entire urinary tract for the tiniest calculus, but it has the potential of ruling out alternative diagnosis. Unenhanced helical CT of the abdomen and pelvis to evaluate urinary tract calculi was first described in 1995 and is the mainstay for calculus imaging in adolescents and adults, replacing more traditional studies, such as intravenous pyelography (IVP), a kidney-ureter-bladder (KUB) film, and ultrasonography (Smith et al, 1995). With increased usage and familiarity with the technique, its application has expanded into the pediatric population with similar advantages. These advantages include high sensitivity and specificity, ready availability and speed in assessment, and intravenous (IV) contrast is not necessary. Because children are at significant lifetime risk for recurrence of urolithiasis, judicious use is necessary to limit radiation exposure, particularly gonadal exposure, and concerns of potential increase risk of future malignancy.

CT is highly accurate in stone assessment, exceeding 96% sensitivity and specificity independent of the location of the calculus (Smith et al, 1996b; Hamm et al, 2001; Heneghan et al, 2003; Palmer et al, 2005). **CT is also helpful in demonstrating secondary signs of acute obstruction, such as hydroureteronephrosis, renal enlargement, and perinephric or periureteric stranding; however, the latter findings may be less obvious or absent in pediatric patients due to comparably less retroperitoneal fat** (Smith et al, 1996a; Smergel et al, 2001; Strouse et al, 2002)**.**

Progress has been made in developing unenhanced CT protocols that minimize the radiation dosage while not compromising diagnostic information (Heneghan et al, 2003; Cody et al, 2004; Singh et al, 2009). Experimental protocols using anthropomorphic pediatric phantoms have been used in a number of studies to determine specific organ doses, calculate effective dose, determine the lifetime attributable risk (LAR) for cancer incidence, and relative risk of cancer induction from a single scan under both standard- and low-dose modes (Brisse et al, 2009; Kim et al, 2010). Computer-simulated dose reduction has been useful in determining diagnostic thresholds in children. Compared with standard protocols, halving the dose to 40 mA for children weighing 50 kg or less does not significantly affect the diagnosis of pediatric renal stones (Karmazyn et al, 2009). Spielmann and colleagues (2002) found excellent detectability of calculi measuring 2 to 8 mm using much lower amperage, with an almost threefold decreased estimated radiation dose compared with standard protocols. **Perhaps most importantly, radiation exposure can also be reduced effectively by reducing the number of CT examinations performed for poor clinical indications, scanning only the anatomic region of interest, and not performing either unenhanced and contrast-enhanced scanning unless absolutely necessary** (Cohen, 2009).

Ultrasonography has a more limited role in the assessment of urolithiasis compared with CT but has the distinct advantage of no associated ionizing radiation. Therefore ultrasonography should be considered as a screening tool in the workup for nonemergent abdominal or flank pain. Ultrasonography, although useful in the evaluation of renal calculi or hydronephrosis, is technically limited for use in diagnosing a ureteral stone, with the possible exception of the very distal ureter or bladder. Especially in the *acute setting*, that is, symptomatic presentation with renal colic or hematuria, ultrasonography is less useful in detecting or directing management of urolithiasis. Palmer and colleagues (2005) demonstrated that ultrasonography was nondiagnostic in 41% of children compared with 5% using CT, and it failed to detect ureteral calculi in 62% of pediatric patients. Similar results have been reported in adults, confirming that ultrasonography is of limited value in the workup of urolithiasis (Fowler et al, 2002). Symptomatic children with a known history of renal urolithiasis, or children on observation protocols, may suffice with ultrasonography (US) and KUB alone, thereby limiting exposure to ionizing radiation. Additional support favoring US versus CT in the diagnosis of pediatric nephrolithiasis is also rooted in the ultimate clinical decision about how the child is to be treated. In a prospective study comparing CT and US, Passerotti and colleagues (2009) found that although CT was a more sensitive study in detecting stones in children, the difference in usefulness between the two radiologic techniques was not clinically significant.

Fluoroscopy has an important role in the real-time detection and management of urolithiasis in children, and the same important safety concerns exist regarding radiation exposure as with CT.

C-arm fluoroscopy is used during the surgical setting to assist in antegrade percutaneous access of the upper urinary tract and retrograde access of the lower urinary tract. Manipulation of endoscopic instruments in vivo often requires fluoroscopic monitoring. Fluoroscopy is also used during ESWL to assist in stone localization and monitor the effectiveness of treatment. Urologists must have a working understanding of the principles of fluoroscopy and be aware of the intraprocedure fluoroscopy time and energy settings to limit radiation exposure to both the pediatric patient and operative staff.

CONSERVATIVE MANAGEMENT

Conservative management of pediatric nephrolithiasis is considered first-line treatment, provided there is no evidence an obstructing stone is harboring an infection or a child is failing to thrive as the result of his or her stone disease. Clinical scenarios, including fever, anorexia greater than 24 hours, persistent nausea and vomiting, and/or pain refractory to conservative measures prompts endourologic intervention. In the instance of a stone in a solitary kidney, early intervention versus conservative treatment is favored. **In managing stone disease in the pediatric population, it is important to note that renal calculi less than 3 mm are likely to spontaneously pass, and stones greater than or equal to 4 mm in the distal ureter are likely to require endourologic treatment** (Van Savage et al, 2000). This information should be relayed to caregivers and parents. If a ureteral stent is placed acutely in children for the clinical circumstances described above, definitive endourologic therapy is delayed 2 to 4 weeks to allow for decompression, ureteric orifice dilation, resolution of edema, and proper treatment and clearance of any infection if need be.

There have been many studies in adults evaluating the efficacy of medical expulsive therapy to facilitate distal stone passage. Use of α antagonists, calcium channel blockers, and steroids has been shown to be effective. Based on efficacy demonstrated in the adult population (Porpiglia et al, 2004), α-receptor antagonists, such as tamsulosin, may be offered on an individualized basis as adjunctive therapy to facilitate ureteral expulsion in children. To date, however, there is a lack of published data capturing the pediatric population that prove the superiority of these agents versus standard pain medication. A Turkish study, for example, demonstrated that daily administration of 0.03 mg/kg of the α antagonist doxazosin versus an analgesic alone did not show superior expulsive results regarding distal ureteral stones up to 10 mm in children 2 to 14 years of age (Aydogdu et al, 2009).

MANAGEMENT OF UPPER URINARY TRACT CALCULI

Pediatric Considerations

Special considerations in the endourologic management of stone disease in children include preservation of renal development and function, prevention of radiation exposure, and minimizing the need for re-treatment. Despite advances in endourologic equipment and technique, controversy remains regarding the contribution of SWL to future development of diabetes or hypertension, and whether ureteric orifice dilation during ureteroscopy (URS) leads to ureteral stricture formation or development of vesicoureteral reflux. International consensus is lacking as to the most effective surgical management of pediatric stone disease due to lack of prospective randomized trials comparing treatment modalities and disparity in the access to emerging technologies. **Regardless of treatment modality, the presence of residual stone fragments is associated with adverse clinical outcomes** (Afshar et al, 2004), **and every attempt should be made to achieve a stone-free status.** The surgeon's experience is paramount to facilitate complete stone clearance and minimize re-treatment rates. The decision regarding the most efficacious primary treatment modality must be individualized per child based on age, anatomy, location, and composition of the stone burden.

Antibiotic Use

In line with the 2008 American Urologic Association's best practice statement on antibiotic prophylaxis, less than or equal to 24 hours of perioperative antibiotics are indicated in all patients undergoing upper tract instrumentation (Wolf et al, 2008). In children, appropriate agents include trimethoprim-sulfamethazole, first- and second-generation cephalosporins, and ampicillin in combination with an aminoglycoside. A urine culture is mandatory before all upper tract procedures to determine if the urine is sterile, and culture results are used to guide preoperative antibiotic therapy, particularly for percutaneous procedures, patients with high-grade obstruction, or patients with an indwelling stent (Wu and Docimo, 2004). In the authors' practice, children with a negative urine culture undergoing uncomplicated URS procedures receive perioperative cefazolin, and all children undergoing a percutaneous procedure or who have a preexisting ureteral stent/nephrostomy tube receive a fluoroquinolone or ampicillin/gentamicin. Use of postoperative antibiotics is controversial and is determined on an individual basis, especially with recent data demonstrating an increased risk of developing resistant bacterial strains with prolonged use of antibiotic prophylactic therapy (Conway et al, 2007).

SHOCK WAVE LITHOTRIPSY

The emergence of shock wave lithotripsy (SWL) revolutionized the minimally invasive treatment of adult urolithiasis during the early 1980s. Since the initial report on successful SWL use in children in 1986 (Newman et al, 1986), large series have reported complication, safety, and stone-free rates comparable to adult cohorts (Table 135–1) (Myers et al, 1995; Elsobky et al, 2000; Ather and Noor, 2003; Muslumanoglu et al, 2003; Rizvi et al, 2003; Aksoy et al, 2004; Raza et al, 2005; Demirkesen et al, 2006). When used as a primary treatment option for upper tract calculi, SWL efficacy ranges from 68% to 84% (Rizvi et al, 2003; Myers et al, 1995; DeFoor et al, 2005b). SWL has been a preferred treatment modality for uncomplicated renal and proximal calculi less than or equal to 15 mm in the pediatric population. In a contemporary series of 216 children (mean age 6.6 years) with a mean stone size of 14.9 mm and who were undergoing SWL with the Dornier HM3 lithotripter, Landau and colleagues (2009) reported a 3-month stone-free rate of 80%, demonstrating that efficacious stone-free rates can be achieved in appropriate candidates. **Complications rates are minimal and range in severity from hematuria and ecchymosis to obstruction with sepsis** (Farhat and Kropp, 2007).

Although well tolerated in children, current stone-free rates with SWL are difficult to interpret from the existing body of data due to discrepancies between studies regarding type of lithotriptor, number of shocks administered, and re-treatment rates. **Recent**

data suggest that stone-free rates in children with a history of urologic condition or urinary tract reconstruction are quite low (12.5%), and, with alternative surgical techniques available, children may be better served with URS or PCNL (Nelson et al, 2008). Despite encouraging results, SWL has not been approved by the Food and Drug Administration for use in children, although it is a widely accepted treatment modality.

Shock Wave Lithotripsy Technique in Children

General anesthesia is administered in a majority of smaller children to avoid both patient and stone motion and the need for repeated repositioning. With modern lithotriptors, intravenous sedation has been successfully employed in select older children (Aldridge et al, 2006). Bowel preparation is seldom used in order to avoid dehydration and electrolyte imbalance postoperatively. The number of shocks delivered and the kilovoltage used vary per lithotripter, but the current consensus is that low-power settings (17 to 22 kV) should be used to prevent stone migration during the procedure, with 3000 shock waves per session (<2000 in very young children) (Farhat and Kropp, 2007). A recent report assessed and compared the number and intensity of shock waves required for stone fragmentation in 44 children (mean age 5.9 years) and 562 adults (mean age 40.9 years). With an equivalent number of sessions (1.1 vs. 1.1), the mean number of shock waves (950 vs. 1262, $P < .001$) and the kV required (11.8 vs. 12.4, $P < .001$) were significantly reduced in the pediatric cohort (Kurien et al, 2009).

Whether or not to place a ureteral stent prior to ESWL in children remains controversial and is a matter of personal preference. It is currently unclear if placement of a ureteral stent prior to SWL facilitates fragment passage and improves stone-free outcomes. Although presenting rates are not consistent across series, **current relative indications include cases of solitary kidneys, staghorn calculi, large ureteral calculi, obstruction, or abnormal anatomy and are not based on total stone burden.** Ureteral catheters with retrograde opacification are occasionally employed by some to aid in the localization of radiolucent calculi.

Stone Size, Location, Composition, and Patient Age

Although early series focused primarily on the feasibility, safety, and efficacy of SWL in children, recent efforts have centered on identifying demographic, anatomic, and stone-related prognostic factors for treatment success. SWL is currently considered the primary treatment for upper tract calculi less than or equal to 15 mm in children (Farhat and Kropp, 2007), but evidence supporting this stone size cutoff is lacking. Ather and Noor (2003), for example, analyzed the correlation between stone size and clearance in 105 children younger than 14 years. They reported an overall stone-free rate of 95% after a mean of 1.7 SWL treatments, with 5% of patients requiring additional procedures as adjuncts to SWL. In this cohort, mean stone size in the treatment success group was 14 mm compared with 16 mm in the treatment failure group. By contrast, Elsobky and colleagues (2000) reported

a 91% stone-free rate versus 75% stone-free rate for a mean stone diameter less than 10 mm and greater than 10 mm, respectively. Recently, Shouman and colleagues (2009) reported on a series of 24 children with a mean stone size of 31 mm undergoing SWL with the Dornier DoLi S device. In 53 sessions requiring a mean number of 3489 shock waves per session, stone-free and complication rates were 83.3% and 25%, respectively. **Although it is possible to treat very large stone burdens with SWL, concerns include the necessity of more shock treatments, more frequent re-treatment sessions, and increased risk of postoperative obstruction.** Further study delineating a clear size cutoff for uncomplicated upper tract stone burden is required to effectively counsel parents regarding the most effective first-line therapy for renal calculi between 1 and 1.5 cm.

Renal anatomy and stone location has been the subject of recent interest. The subject of frequent debate in the adult population, the most effective management of lower pole calculi in children has yet to be determined. Stone-free rates from initial small retrospective SWL series range from 56% to 61% (Ozgur Tan et al, 2003; Onal et al, 2004) with re-treatment rates as high as 40% (Onal et al, 2004). **SWL failure and re-treatment rates were associated with increased mean stone burden** (Onal et al, 2004), **increased infundibular length** (Ozgur Tan et al, 2003), **and an infundibulopelvic angle greater than 45 degrees** (Ozgur Tan et al, 2003).

Staghorn calculi are uncommon in children and represent a management challenge. Although monotherapy success rates are low in adults, acceptable stone-free rates in children have been achieved with SWL. In 23 children with a mean stone burden of 1.6 cm who were stratified by age, Lottmann and colleagues (2001) reported an overall stone-free rate of 82.6%, with only one case of symptomatic obstruction. A ureteral stent was placed in 22% of children, and these authors reported an 88% stone-free rate in children less than 2 years old compared with 71% in children 6 to 11 years old. In 42 children with a mean stone burden of 3.2 cm and stratified by ureteral stent placement, Al-Busaidy and colleagues (2003) reported an overall stone-free rate of 79%. Although stent placement did not affect stone-free rates, they found that stent placement significantly reduced the major complication rate. **The superior success rates with SWL monotherapy in children compared with adults have been attributed to softer stone composition, smaller relative stone volume, increased ureteral compliance to accommodate stone fragments, and smaller body volume to facilitate shock transmission**.

SWL safety and efficacy have been demonstrated even in very young children. McLorie and colleagues (2003) treated 34 children younger than 3.5 years (mean age 23 months) and reported an 86% overall stone-free rate (66% after one treatment) without major complications. Treatment of proximal ureteral stones has achieved similar success rates compared with treatment of renal stones in most pediatric series, although ureteral stenting is more commonly employed to aid in stone localization and clearance (Myers et al, 1995). Treatment of mid- to distal ureteral calculi has historically been avoided in children due to difficulties with localization over the sacroiliac joint and concern regarding possible injury to developing reproductive systems. The greater and lesser sciatic foramen has been explored as a potential blast path to treat distal stones in children.

SWL success by stone composition is similar between the adult and pediatric populations. Cystine stones are uniquely challenging due to their durability and high recurrence rates. Although SWL monotherapy has demonstrated variable results in adults, there are few reports in the pediatric population. In a small recent series, Slavkovic and colleagues (2002) reported a 50% stone-free rate in 6 children with a cystine stone burden ranging from 0.2 to 2.5 cm. Although stone-free rates were low, fragmentation was achieved in 100% of patients, and the stone dissolution was achieved with medical therapy in the remaining children following SWL. Some authors have proposed that cystine stones formed within 2 years of therapy may be more easily fragmented with SWL and that stone number, and not diameter, may be more predictive of success (Farhat and Kropp, 2007).

Limitations and Concerns

In children, there is currently no consensus regarding the maximum size of residual stone fragments (RF) that are considered clinically significant, and as a result, there is no clear definition as to what constitutes "stone-free" status (Wu and Docimo, 2004; Farhat and Kropp, 2007). Although children have been shown to have a greater capacity to clear fragments than adults (Gofrit et al, 2001), the presence of RFs have been correlated with adverse clinical outcomes (Afshar et al, 2004). Afshar and colleagues (2004) followed 26 renal units with RFs less than or equal to 5 mm and reported that although 31% were asymptomatic with no fragment growth, 69% had adverse clinical outcomes, including RF growth or clinical symptoms. Patients with RF had a significant increase in adverse clinical outcome compared with stone-free subjects, and the presence of metabolic disorders was associated with RF growth (Afshar et al, 2004). For these reasons, metabolic evaluations are now routinely being performed in children with a history of calculi, and every attempt should be made to achieve stone-free status.

Although SWL is well tolerated in children with few complications, stone-free rates following single-session monotherapy can remain as low as 44% (Muslumanoglu et al, 2003). As a result, children are subjected to multiple treatments requiring general anesthesia (Aldridge et al, 2006). **The need for multiple treatment sessions is concerning, because the effects of shock waves on renal tissue are unclear. A growing body of evidence in adults indicates that shock waves result in renal vessel vasoconstriction and that renal tubular injury and subcapsular hematoma from cavitation and shear forces are dependent on the kilovoltage applied** (Lingeman et al, 2003). In a large series of 340 adult patients with a mean follow-up of 19 years post-SWL, (Krambeck and colleagues (2006) reported an increased risk of hypertension and diabetes mellitus related to bilateral treatment, number of administered shocks, and treatment intensity. Although these results are concerning, differences between pediatric and adult populations and limitations inherent to a questionnaire-based retrospective study make application of these data in children difficult.

Retrospective studies with limited follow-up in children have reported that SWL and PCNL do not cause renal morphologic or functional alteration as measured by glomerular flow rate (GFR) and serial dimercaptosuccinic acid (DMSA) functional studies (Wadhwa et al, 2007), but long-term data are unavailable to date. To eliminate confounding variables and fully address the risks of chronic renal damage from SWL, long-term prospective data in children are clearly required.

URETEROSCOPIC MANAGEMENT OF UPPER URINARY TRACT CALCULI

The indications for primary ureteroscopic management of upper tract calculi in children have significantly expanded. In

combination with new endourologic instrumentation and holmium:YAG lasers, access and treatment of calculus disease throughout the entire pediatric urinary tract is effective, safe, and readily available in the acute setting. Adoption of ureteroscopy in the treatment of pediatric upper tract calculus disease lagged behind the adult experience, because of concerns regarding large ureteroscope caliber size in children. However, evolving experience with ureteroscopy and recent large single-center retrospective series have demonstrated comparable stone-free and complication rates to SWL in children, validating its growing application in children.

Indications

Since the mid-1980s, with the acceptance of SWL as primary therapy for upper tract calculi less than 1.5 cm, ureteroscopy has been historically used for calculi found below the iliac crests and for upper tract calculi after SWL failure (Wu and Docimo, 2004). Ureteroscopy was not considered primary therapy for upper tract stones in children due to complications from ureteral ischemia, perforation, stricture formation, and development of vesicoureteral reflux as a result of dilation of small-caliber ureteric orifices.

With significant improvements in both the miniaturization and durability of endoscopic equipment and the acceptance of the holmium laser, ureteroscopy has become a more attractive option in young children. Early series using rigid ureteroscopy for distal stones reported stone-free rates ranging from 86% to 100% with minimal complications (Table 135–2) (Ritchey et al, 1988; Van Savage et al, 2000; Schuster et al, 2002; Rizvi et al, 2003; De Dominicis et al, 2005; Minevich et al, 2005; Tan et al, 2005). Children randomized to either ureteroscopy or SWL as primary therapy for distal ureteral stones were reported to have a significantly higher stone-free rate after one treatment (94% vs. 43%) for those treated with ureteroscopy (De Dominicis et al, 2005). Another group reported experience using 4.5-, 6-, and 8-Fr rigid ureteroscopy in treating proximal ureteral stones, with a mean age of 10.7 years. Ureteral dilation was not performed in any of the cases, and 100% of children were rendered stone free (Lesani and Palmer, 2006). **The results of these retrospective studies have begun to refute the notion that dilation of the pediatric ureter will result in vesicoureteral reflux or the development of ureteral strictures.** In a systematic review of the literature encompassing 221 pediatric ureteroscopies, Schuster and colleagues (2002) noted only two ureteral strictures and a low incidence of vesicoureteral reflux. Newer 4.5-Fr semirigid ureteroscopes, with working ports that accommodate 2.4-Fr endosurgical instrumentation, extend the versatility of managing distal ureteral calculi in most pediatric patients without predilation.

Standardization in the treatment of distal calculi in children has led a number of centers to expand ureteroscopy to the treatment of upper tract calculi (Table 135–2). Comparable stone-free rates approaching 100%, with complication rates similar to that of the adult population, have recently been reported (Minevich et al, 2005; Lesani and Palmer, 2006; Cannon et al, 2007; Corcoran et al, 2007; Smaldone et al, 2007). Smaldone and colleagues (2007)

reported a 91% stone-free rate with a mean follow-up of 10 months in a series of 100 children with a mean stone diameter of 8.3 mm, 52% of whom had upper tract calculi. Nine percent of these children underwent staged procedures. They reported a 4.2% perforation rate that was managed with ureteral stenting and one distal ureteral stricture requiring open neocystostomy. Corcoran and colleagues (2007) reviewed a cohort of 47 children (mean age 9.4 years) with upper tract calculi managed with flexible ureteroscopy and holmium laser lithotripsy. An 88% stone-free rate with a mean stone burden of 10.2 mm was reported, with 26% requiring staged procedures. **These authors concluded that because of improved ureteroscopic access to the pediatric upper tract, calculi up to 15 mm were as safely and effectively treated in children as in adults.** Even with outstanding pediatric ureteroscopic technology, pediatric ureters may require a period of stenting prior to embarking on endoscopic treatment. For example, a smaller-caliber ureter that is resistant to instrumentation may be passively dilated with an indwelling stent during 6 to 8 weeks (Fig. 135–1).

Adoption of techniques used in the adult population, most notably sequential coaxial and balloon dilation of the ureteric orifice and use of ureteral access sheaths, has further facilitated access to the pediatric urinary tract. Initially described in eight children by Singh and colleagues (2006), **ureteral access sheaths have been shown to facilitate repetitive upper tract access, reduce intrarenal pressures, decrease operative time, and improve stone-free rates in adults.** Access for the treatment of lower pole calculi is possible with use of ureteral access sheaths and the 6.9-Fr flexible ureteroscope, a stone location that would have previously required SWL or PCNL. Cannon and colleagues (2007) reported a 76% stone-free rate in 21 children with lower pole calculi and a mean stone diameter of 12.2 mm. After a mean of 11.4 months, no major complications were observed. **Therefore with the transition from SWL to ureteroscopy as a primary treatment modality at the authors' institution, current relative contraindications to ureteroscopic management include staghorn stones in recurrent stone formers more amenable to PCNL, anatomic anomalies making retrograde access difficult, and previous endoscopic failure.**

Equipment

Having an updated and well-stocked system that is familiar to the operative staff is vital to efficient management. It usually falls on the nursing staff to care for the delicate instruments and keep up on repairs so that the instruments are operational when needed; maintenance is often needed after 20 to 30 uses. A "basic" ureteroscopic kit is listed below; however, variation exists based on the manufacturer. An array of semirigid and flexible pediatric ureteroscopes, in additional to ureteral access sheaths, is available from numerous companies (Buscarini and Conlin, 2008). In general, semirigid ureteroscopes usually have a 2.4- to 3.5-Fr working port and flexible ureteroscopes a 1.8- to 3.5-Fr working port. With flexible ureteroscopes, distal tip deflection up to 270 degrees can facilitate access to most lower pole stones (Figs. 135–2 and 135–3). **However, smaller working areas and difficulties in exchanging instruments through the working element of a deflected ureteroscope may limit this treatment modality in some cases** (Fig. 135–4).

Ureteroscopes

6.9-Fr flexible ureteroscope
4.5- and 6.5-Fr semirigid ureteroscope

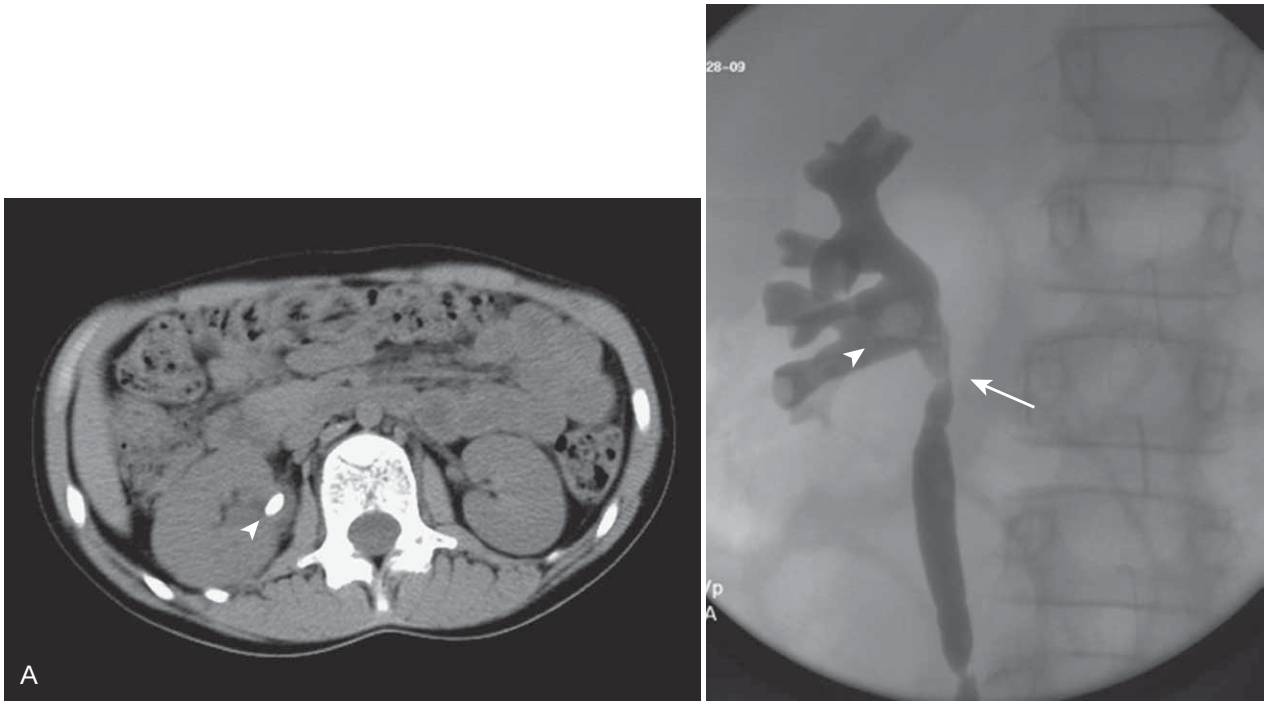

Figure 135–1. CT scan (**A**) and retrograde pyelogram (**B**) in a 10-year-old female with glucose transport deficiency demonstrating a 9-mm renal pelvic stone (*arrowheads*). Nephrolithiasis was secondary to profound hypocitruria and hypercalciuria. Primary ureteroscopy could not be accomplished because of a narrowed segment of proximal ureter (*arrow*). Following 8 weeks of ureteral accommodation with an indwelling stent, flexible ureteroscopy with laser lithotripsy and stone basketing was performed.

Figure 135–2. Pediatric semirigid self-dilating ureteroscopes may be used for rigid ureteroscopy in toddlers. A 4.5-Fr distal beak allows easier passage to facilitate dilation with the 6.5-Fr proximal component. (Photo provided by Richard Wolf; © Richard Wolf, all rights reserved.)

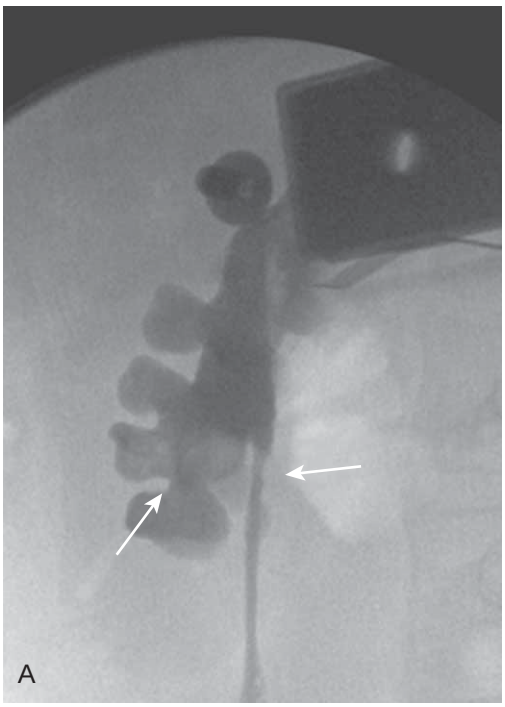
Endourologic Equipment

Guidewire array: 0.035 in Sensor GW, 0.018 to 0.025 in Glidewire (Terumo Interventional Systems, Somerset, NJ)
Basket devices: Zero-tip
8/10-Fr coaxial ureteral dilators
Ureteral access sheaths (9.5- and 11-Fr internal diameter)
Double-J ureteral stent array (3-, 4.8-, and 6-Fr internal diameter)

Ureteroscopic Technique in Children

All ureteroscopic procedures are performed under general anesthesia with paralysis to prevent patient movement and minimize the risk of ureteral perforation. When clinically appropriate, a urine culture should be confirmed prior to surgery. Following broad-spectrum antibiotic prophylaxis, patients are placed in the lithotomy position, and a rigid cystoscope (7.5, 11, or 18 Fr) is used to perform a retrograde pyelogram and to place a safety or working wire under fluoroscopic guidance. Initial ureteric orifice dilation

Figure 135–3. Flexible ureteroscopes offer thumb control (**A**) for biplanar 270-degree deflection (**B**). Working channels from 1.8 to 3.6 Fr can accommodate working elements such as a holmium:YAG laser fiber (**C**). (Photos provided by Richard Wolf; © Richard Wolf, all rights reserved.)



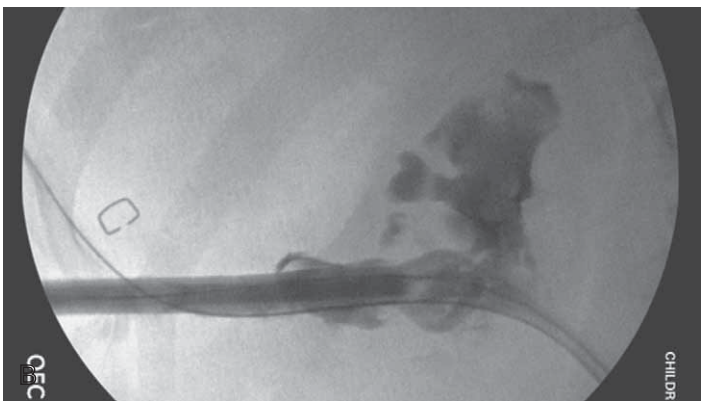


Figure 135–4. **A**, A 7-year-old boy with two separate 7- to 9-mm stones within lower pole calices (*left arrow*). A ureteroscopic approach was attempted, but a lower pole infundibular–ureteropelvic junction angle greater than 270 degrees (*right arrow*) limited ureteroscopic access and visibility. **B**, A percutaneous nephrolithotomy was subsequently performed, clearing all stones in one sitting.

is performed under C-arm fluoroscopic guidance with 8/10-Fr coaxial dilators in ureters that have not been prestented or when the rigid/flexible ureteroscope cannot easily be advanced. The authors generally do not use balloon dilation of the ureteric orifice due to less control and cognitive "feel" during active dilation, as well as concern for development of ureteral stricture from ischemia. If the authors encounter difficulty easily passing the 8/10 dilator, their preference is to place a stent and return for a second procedure rather than dilate more aggressively.

The decision to use a flexible (6.9-Fr) or semirigid (7.5-Fr) ureteroscope is determined on size and location of stone, anatomic factors, and individual surgeon preference. Rigid or semirigid ureteroscopy for ureteral calculi is routinely performed with a safety wire in place, while flexible ureteroscopy is performed with both a safety and working wire in place. Ureteral access sheaths (internal diameter of 9.5 Fr) are routinely used to facilitate flexible ureteroscopy, especially in cases of large proximal ureteral stones and heavy renal pelvis stone burdens. **Access sheaths may also serve to facilitate flexible ureteroscopy when altered anatomy or torturous ureters are encountered** (Fig. 135–5).

Irrigating fluid, which may be used under pressure, should be isotonic and at body temperature to avoid hypothermia and hyponatremia. Calculi are basket-extracted when feasible or fragmented using the holmium:YAG laser to

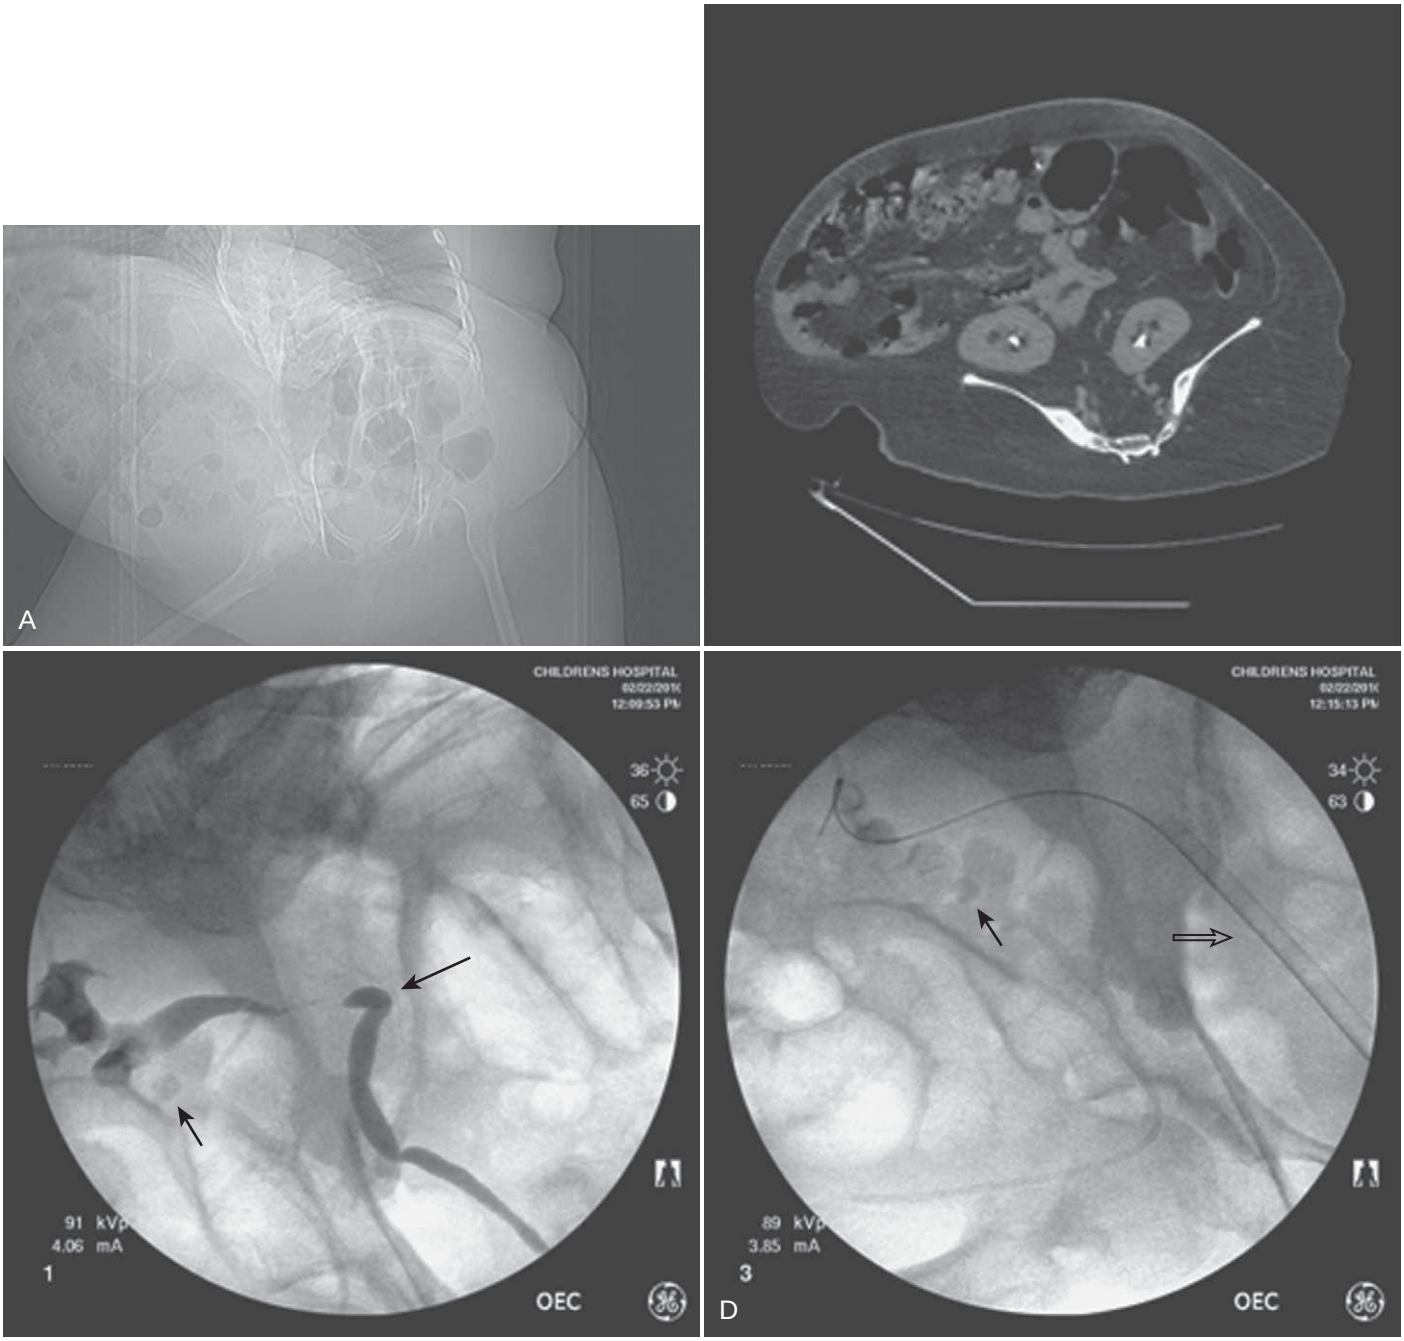

Figure 135–5. Altered anatomy in a 17-year-old male spina bifida patient who underwent a high thoracic myelomeningocele closure at birth (**A**). A computed tomography (CT) scan performed for a gross hematuria workup revealed bilateral nephrolithiasis in pelvic kidneys (**B**). The right retrograde pyelogram (**C**) demonstrated the lower pole stone (*short arrow*) and a torturous ureter almost taking a perpendicular course (*long arrow*). Placement of a ureteral access sheath (**D**) straightened the ureter (*white arrow*).

Continued

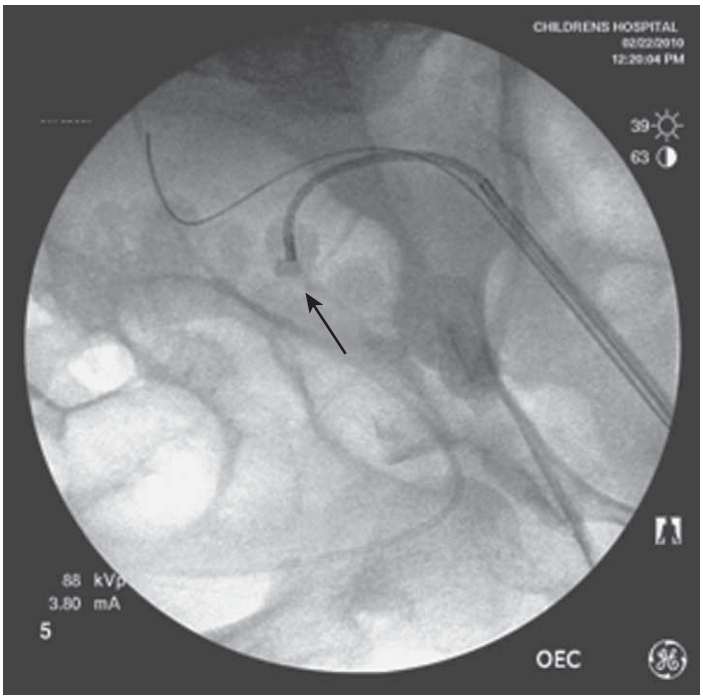

Figure 135–5, cont'd This allowed easier access to address the stone (*short arrow in* **D**) with a flexible ureteroscope (**E**).

facilitate removal. **The decision to place a ureteral stent postoperatively is made based on the duration of the procedure, number of passes with the ureteroscope, and degree of visible ureteral trauma or edema at the conclusion of the procedure.** If the child can tolerate leaving a urethral string in place for 3 days to 1 week, the patient's parents are asked to remove the stent at home; otherwise, the stent is removed under brief anesthetic after 7 days.

Limitations and Complications

As ureteroscopy is becoming more prominent in the pediatric endourologist's armamentarium, complications need to be anticipated and unanswered questions addressed. **The most common complications involve unrecognized ureteral injury, including mucosal flaps and tears, perforation, false passage, and partial to complete avulsion.** Mitigating the damage by early recognition and temporizing with immediate discontinuation of the procedure and passage of a ureteral stent may avoid complications related to shear force injury on the ureter, ischemic damage, and extravasation of irrigant or urine. Injury can occur during introduction of the ureteroscope or passage, either antegrade or retrograde, of instrumentation (guidewires, baskets, dilators), especially in the area of an impacted ureteral calculus. Attempting to withdraw a basket-entrapped calculus too large for the ureter to accommodate can result in any of the above-mentioned injuries. In postpubertal children with an adult body mass, ureteroscopic access is technically similar to the adult population. However, in the prepubertal child, whether or not to attempt primary treatment without ureteric orifice dilation, to perform dilation at the time of definitive therapy, or to place a stent and allow the ureter to passively dilate prior to definitive therapy remains in question. Herndon and colleagues (2006) performed semirigid ureteroscopy (4.5 and 6.5 Fr for distal ureteral calculi) in 29 children with a mean age of 11 years. With no ureter actively dilated and only 14% of children prestented, the ureter was accessed in 100% of cases for a stone-free rate of 96%. The authors can further validate this report with their own institutional experience using 6.9-Fr flexible and 4.5- and 6.5-Fr semirigid ureteroscopy; however, it is their preference to sequentially dilate with the 8/10 coaxial dilator even in very young children. If the authors encounter difficulties, a stent is placed rather than dilated more aggressively. This approach appears to minimize the immediate risks and potential long-term complications, particularly in the management of upper tract calculi; however, it increases the number of children who will require a second anesthetic and procedure to achieve stone-free status. Recent reports suggest that up to 40% of pediatric patients will require at least two procedures to treat upper tract calculi, suggesting that the likelihood of achieving a stone-free status after one ureteroscopic procedure may not be significantly better than with shock wave lithotripsy (Corcoran et al, 2007). Additional procedures were reported with more than half of the stones that were 6 mm or larger (Tanaka et al, 2008).

The necessity of placing a stent after ureteroscopy in all children has also been debated. Although, in large series, the tendency has been to leave a stent in place after ureteroscopic manipulation in a majority of children (Smaldone et al, 2007), several authors have reported no acute or long-term sequelae despite leaving a postoperative stent in less than 20% of cases (Herndon et al, 2006). In the authors' experience, the decision to place a postprocedural stent is made on an individual patient basis and is dependent on the surgeon's experience and degree of visible ureteral trauma at the conclusion of the procedure.

PERCUTANEOUS NEPHROLITHOTOMY

The safety and efficacy of percutaneous nephrolithotomy for large stone burdens have been well established in adults. Initially, urologists were reluctant to perform PCNL in children due to concerns regarding the use of large instruments in pediatric kidneys, parenchymal damage and the associated effects on renal function, radiation exposure with fluoroscopy, and the risks of major complications, including sepsis and bleeding. Another deterrent to performing PCNL in children was the potential resultant sequelae of hypothermia (i.e., coagulopathy) from prolonged exposure to irrigation. **With significantly accumulated experience, however, PCNL is currently being used as monotherapy and in combination with SWL (sandwich therapy) in children, achieving stone-free rates ranging from 68% to 100%** (Table 135–3) (Rizvi et al, 2003; Mahmud and Zaidi, 2004). **Although there is no current international consensus, relative indications for PCNL as the primary treatment modality in children include large upper tract stone burden (>1.5 cm), lower pole calculi greater than 1 cm, concurrent anatomic abnormality impairing urinary drainage and stone clearance, or known cystine or struvite composition** (Wu and Docimo, 2004; Farhat and Kropp, 2007).

The earliest pediatric PCNL series were performed using standard adult-sized instruments. In 1985, Woodside and colleagues (1985) first reported on a series of seven patients (ages 5 to 18 years old) who were rendered stone free without complications when using adult percutaneous techniques and equipment. Years later in 1997, Mor and colleagues (1997) also reported on using adult-sized instruments in their pediatric PCNL series. The use of PCNL in these early series was avoided in very small children (<5 years old) due to concerns regarding parenchymal damage. **In**

contrast to these concerns, multiple series subsequently used adult-sized instruments and reported high efficacy rates with acceptable complication rates even when the dilating tract size as high as 30 Fr (Salah et al, 2004; Samad et al, 2006; Bilen et al, 2007). **In fact, recent data have suggested that PCNL is possible in very young children using adult-sized equipment** (Nouralizadeh et al, 2009). Investigations regarding the risk of renal damage in pediatric patients treated with PCNL have revealed that there is no significant risk of renal functional loss. Mor and colleagues (1997) performed radioisotope scans on 10 children before and after PCNL and found no change in differential function and no evidence of significant scarring.

Despite early successes employing adult equipment, early efforts focused on developing technology to minimize percutaneous tract size without affecting PCNL efficacy. Jackman and colleagues (1998), developed a novel percutaneous access technique ("mini-perc") using an 13-Fr peel-away vascular access sheath and reported an 85% stone-free rate for 11 procedures in seven children with a mean age of 3.4 years and an average stone burden of 1.2 cm^2 (Fig. 135–6). With this technique, PCNL could now be performed in *preschool-aged children*. **The benefits of minimal tract dilation included increased maneuverability, decreased blood loss, and shorter hospital stay. However, theoretical limitations, including prolonged operative times and impaired visualization from bleeding, suggests that this technique may not be adequate for very large stone burdens.**

Recent advances in instrumentation, such as smaller nephroscopes (15- to 18-Fr) and more efficient energy sources for intracorporeal lithotripsy, including the holmium:YAG laser and smaller pneumatic lithoclast and ultrasound probes, have greatly facilitated percutaneous treatment techniques in pediatric patients (Fig. 135–7). As a result, PCNL has now replaced open surgery as the treatment of choice for large stone burdens in children of all ages.

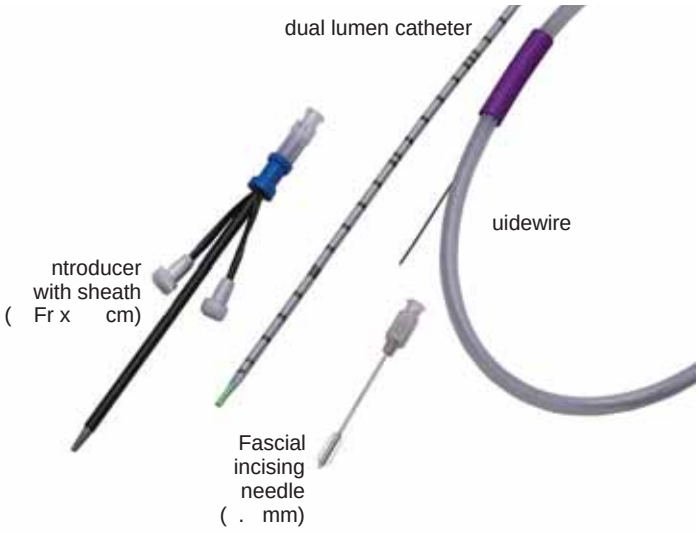

Figure 135–6. The "mini-perc" set uses an 11- to 13-Fr peel-away vascular access sheath to accommodate a ureteroscope or cystoscope, serving as a nephroscope, to perform percutaneous nephrolithotomy (PCNL) in children of preschool age.

Planning for PCNL in Children

Much planning is required prior to embarking on PCNL in children. Films must first be reviewed scrupulously to determine if the stone(s) is/are amenable to a percutaneous procedure. **Nephrocalcinosis in children, for example, may be confused with staghorn calculi; the etiology and treatment are very different** (Fig. 135–8). Infection is the most common causative agent in the formation of a staghorn calculus, and PCNL is a first-line therapy. The most frequent causes of nephrocalcinosis are hereditary tubulopathies and vitamin D intoxication (Ammenti et al, 2009). **Medullary sponge kidney is a**

renal malformation characterized by cystic anomalies of precalyceal ducts, which is frequently associated with nephrocalcinosis and stone formation (Gambaro et al, 2006). Nephrocalcinosis is most often not amenable to successful endourologic treatment(s) because calculi are intraparenchymal and thus outside the collecting system. Management is often medical and aimed at prevention of further nephrocalculi, a cause of worsening renal function.

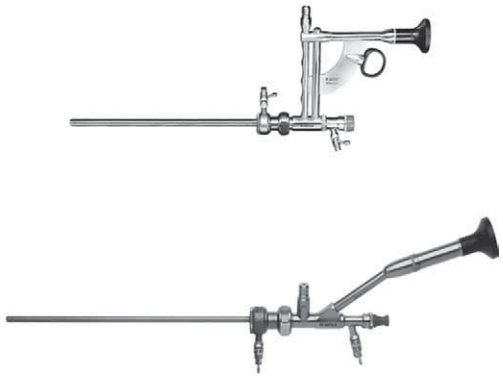

Figure 135–7. Smaller-caliber nephroscopes (15 to 18 Fr) with offset lenses have greatly facilitated standard percutaneous treatment techniques in pediatric patients. (From Wolf JS Jr, et al. Best practice policy statement on urologic surgery antimicrobial prophylaxis. J Urol 2008;179[4]:1379–90.)

The risks of the PCNL must be reviewed with the consenting parent or guardian. **It must be understood that a percutaneous procedure carries risks that are not limited to bleeding (requiring transfusion), delayed renal hemorrhage (requiring angioablation), sepsis, pneumothorax, hemothorax, urothorax, incomplete stone treatment, and injuries to organs adjacent to each respective kidney.**

Every attempt should be made to treat a urinary tract infection and/or minimize bacteriuria prior to the procedure. A urine culture, with antibiotic sensitivities, should be checked 3 weeks prior to the procedure. Any positive culture requires a full course of antibiotics and repeat culture to confirm sterility. Three to 5 days of prophylactic antibiotics is recommended prior to the procedure, even with a negative preoperative culture. Broad-spectrum IV antibiotics (i.e., ampicillin and gentamicin) should be given at the time of the procedure.

All percutaneous procedures are performed using general anesthesia. **A warm operating room, warmed isotonic irrigation solution, short operative times (not to exceed 1.5 hours), proper draping, and monitoring of body**

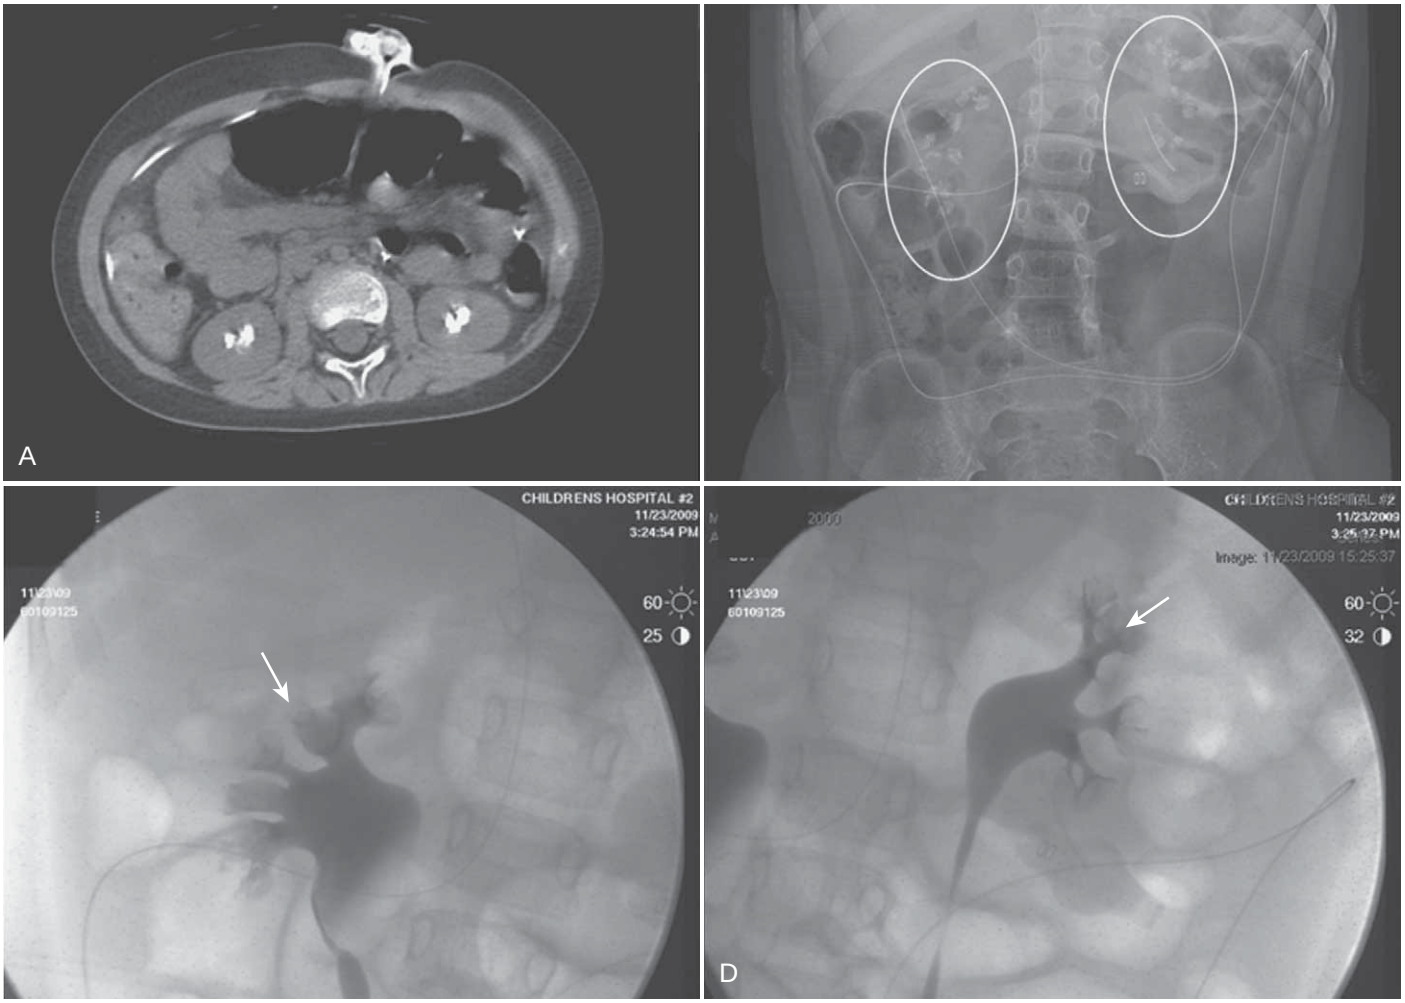

Figure 135–8. A 9-year-old boy with cerebral palsy and gross hematuria. CT scan demonstrated bilateral nephrolithiasis (**A**) thought to be staghorn calculi. Plain radiograph (**B**) and bilateral retrograde pyelograms (**C** and **D**) correlate to show nephrocalcinosis (*white circles* and *white arrows*, respectively) reflective of medullary sponge kidney disease. Subsequent metabolic workup revealed renal tubular acidosis (RTA) with hypercalciuria.

temperature should decrease the incidence of hypothermia and hyponatremia. After induction of anesthesia with the patient in the lithotomy position, a retrograde pyelogram is performed to outline the collecting system, and an occlusive balloon or a 5-Fr open-ended ureteral catheter is left in situ to opacify the collecting system during percutaneous access. The patient is then repositioned in the prone position with the torso elevated at 30 degrees from the table surface with a towel roll (Farhat and Kropp, 2007).

Circumstances that require special consideration involve children with spinal cord injuries and congenital anomalies such as spina bifida. In these patients, positioning can be a challenge due to existing spinal hardware and limb contracture (Fig. 135–9) (Ost and Lee, 2006a). Patients who have had prior spinal surgery consisting of vertebral fusion or Harrington rod placement will have restricted spinal mobility, spinal curvature, and/or atrophic or contracted extremities (Fig. 135–10). **As the result of scoliosis, lordosis, and/or kyphosis, renal anatomy is altered.**

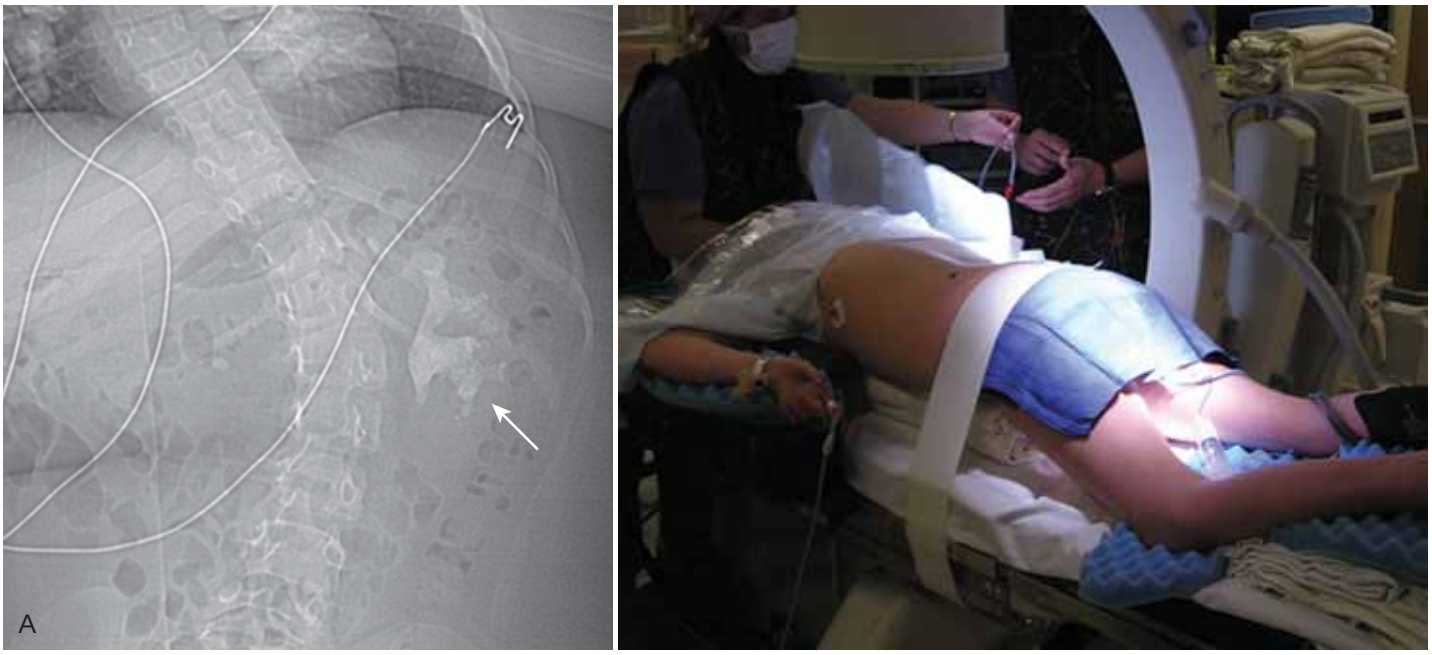

Figure 135–9. **A**, Severe scoliosis and complete staghorn calculus (*arrow*) in a 10-year-old partial quadriplegic. **B**, Spinal curvature and limb contractures (*left arm*) prevented optimal prone positioning. Care is taken to pad all joints in the prone position.

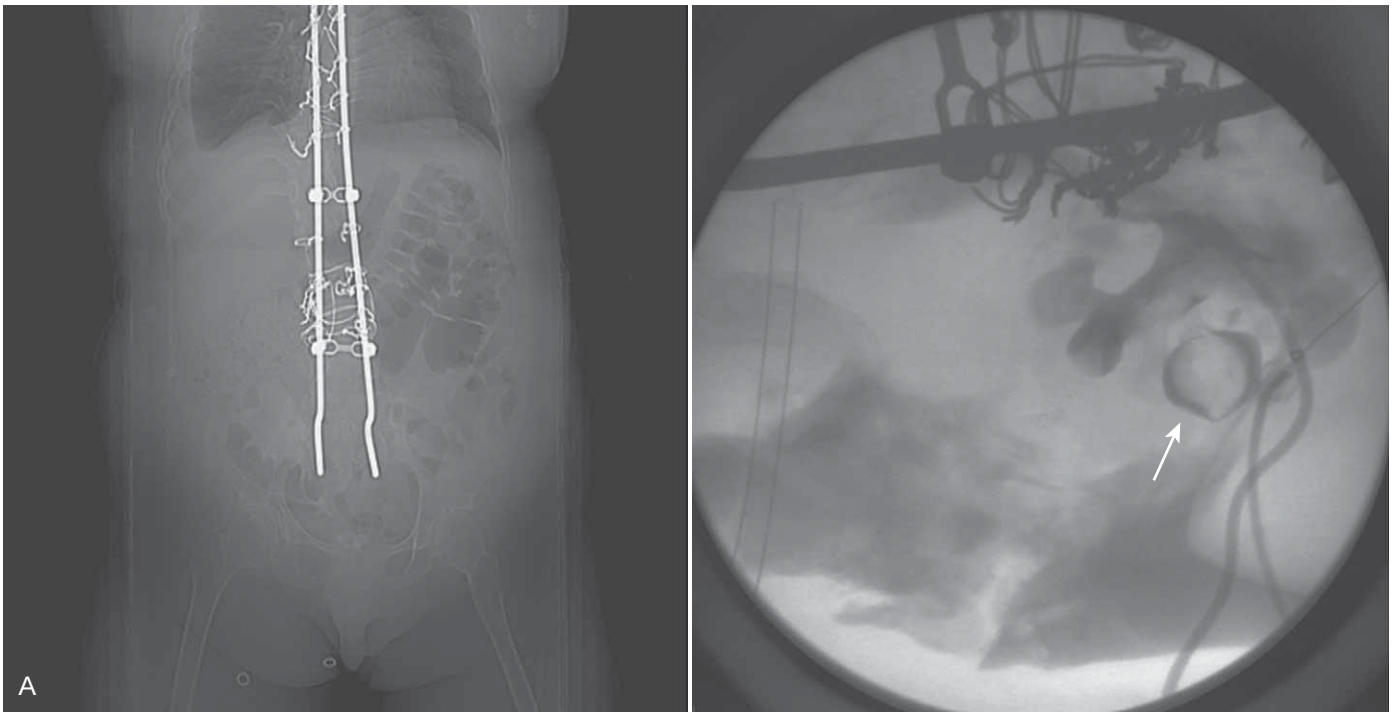

Figure 135–10. **A**, Harrington spinal rods in a 16-year-old spina bifida patient. **B**, Prone view of right collecting system showing midpole caliceal stone as filling defect (*arrow*). Hardware has obscured the proximal ureter and impeded access to this calyx when the C-arm was in the 30-degree position.

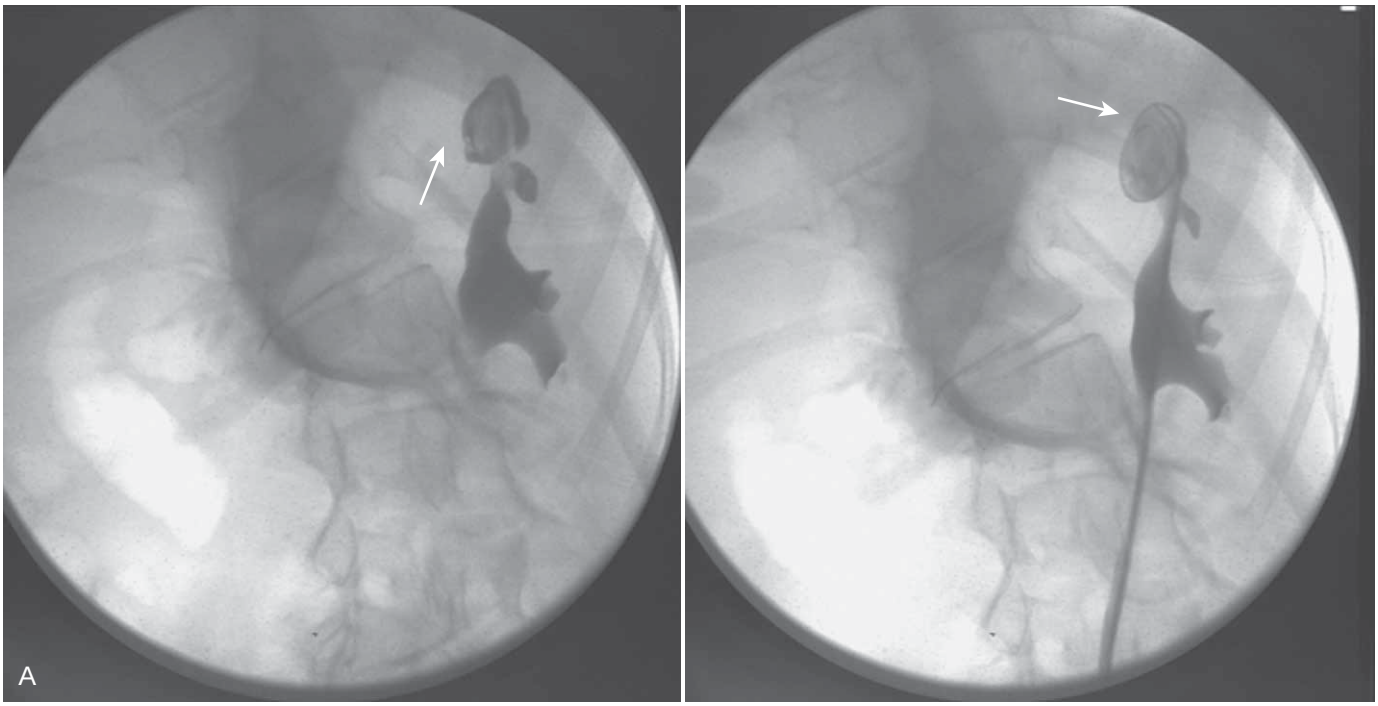

Figure 135–11. **A**, A14-year-old male with spina bifida and scoliosis with a left upper pole partial staghorn calculus (*arrow*). **B**, Altered spinal anatomy had deflected renal anatomy cephalad (*arrow*). Intercostal access between the 10th and 11th rib increases the risk of pneumothorax considerably.

Consequently, the risk of injuries to adjacent organs (i.e., pneumothorax) during percutaneous procedures increases. Assessing the degree of mobility in the trunk and extremities is crucial in planning for PCNL in these patients (Fig. 135–11). These patients must be placed in the most comfortable position possible without excessive contortion or flexion of the joints. Special attention must be paid to latex precautions in the myelomeningocele population, and, as in all cases, proper padding of pressure points is mandatory.

Percutaneous Nephrolithotomy Technique in Children

After selection of the desired calyx, a 16- or 18-gauge spinal needle is placed with the assistance of fluoroscopy in the 30-degree position. When fluoroscopy is used, the collecting system is opacified through an open-ended ureteral catheter that has been inserted cystoscopically prior to positioning in the prone position. Alternatively, ultrasound guidance can be used to puncture the calyx of choice. The ideal tract is one that provides the shortest and most direct access to the stone. For complex calculi occupying multiple calices, including the lower pole, a supracostal posterior access is preferred to provide visualization of the superior calyx and pelvis, access to the pelvis and ureter, and straight access to the inferior calices, allowing easier manipulation of the working instruments and minimizing torque on the collecting system (El-Nahas et al, 2008). Following initial puncture, to avoid trauma, no attempt should be made to redirect the needle while it is located within the cortex of the kidney. With the C-arm in the 90-degree plane, the depth and medial extension of the needle is checked. After access is confirmed with urine or irrigation return, a flexible guidewire is placed into the collecting system through the needle and directed down the ureter into the bladder. A small skin incision is made with a No. 11 scalpel and 8- and 10-Fr coaxial dilators are passed over the guidewire into the collecting system. Once in place, an Amplatz Super Stiff guidewire (AGA Medical, Plymouth, MN) is placed as a working wire.

Tract dilation can be performed by several techniques. Serial dilation with Amplatz dilators over working wires and subsequent sheath placement under fluoroscopic guidance is the most common technique employed. For smaller children and lower stone burdens, an 11- to 13-Fr peel-away sheath (Docimo Mini-Perc, Cook Urological, Spencer, IN) and trocar are passed over the wire and through the calyx under fluoroscopic guidance. For balloon dilation, either the Bard X-Force or NephroMax High-Pressure Nephrostomy Balloon Catheter (Bard Medical, Covington, GA; Boston Scientific, Natick, MA) may be used. Either will facilitate dilation of a 30-Fr tract at a pressure of 17 atmospheres. This technique permits dilation and sheath placement in a single step, thereby minimizing potential parenchymal trauma and bleeding from sequential dilation with rigid dilators. Although the decision to proceed with mini-perc or dilation is individualized based on the child's age, anatomy, and stone burden, familiarity with all of the above techniques facilitates complete access with minimal morbidity (Fig. 135–12A and B).

Once access is obtained, nephroscopy and nephrolithotomy can be performed with a variety of energy sources for stone fragmentation. The outer diameter of nephroscopes range from 15 to 26 Fr, and a 15-Fr flexible nephroscope with a 6-Fr working channel has also been developed. In addition, 7- and 8-Fr offset cystoscopes with 5-Fr working ports and 7- to 9-Fr flexible ureteroscopes can be used through an 11-Fr access sheath with enough clearance to allow low pressure irrigation (Wu and Docimo, 2004). Energy sources currently used include ultrasonic lithotripsy, electrohydraulic lithotripsy (EHL), and the holmium laser, although individual preference is determined by availability

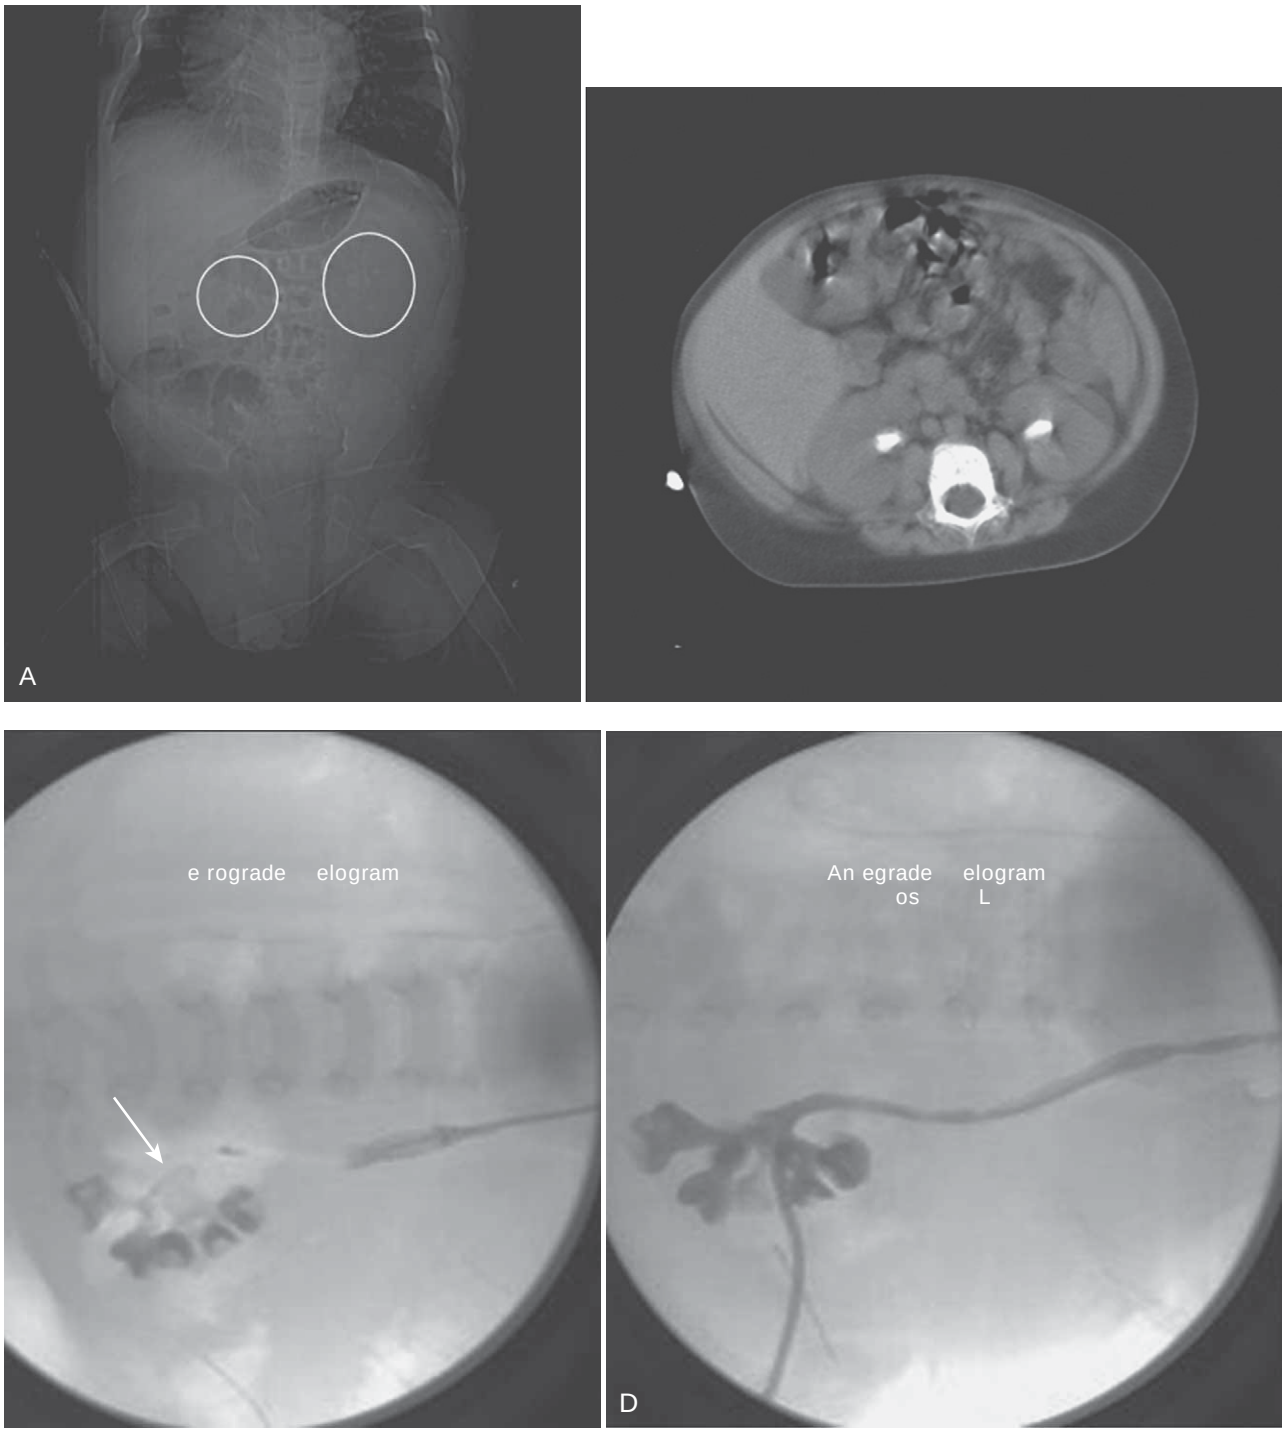

Figure 135–12. A 22-month-old boy with intractable diarrhea of infancy from tufting enteropathy who awaited a small bowel transplant. His risks for nephrolithiasis included total parenteral nutrition dependency, osteomalacia, chronic dehydration, hypocitruria, and hyperoxaluria. **A**, A kidney-ureter-bladder film demonstrated mildly radiopaque stones, and a subsequent CT scan (**B**) confirmed bilateral staghorn calculi. **C**, Prone view of left retrograde pyelogram of child in **A**, demonstrating staghorn calculi as a filling defect (*arrow*). A "mini-perc" technique was used to address his stones. **D**, Prone view of the antegrade nephrostogram through a 6-Fr nephrostomy tube demonstrating "stone-free" status.

and the surgeon's experience. Postoperative stenting and/or placement of a nephrostomy tube are both patient and surgeon dependent and vary between series. Similar to adult procedures, tubeless PCNL has theoretical advantages, including decreased postoperative pain and a short hospital stay, but currently, data is limited in the pediatric population (Khairy Salem et al, 2007).

Percutaneous Nephrolithotomy Outcomes

Recent large retrospective series of PCNL monotherapy have demonstrated high efficacy rates approaching 90% (see Table 135–3) (Zeren et al, 2002; Desai et al, 2004; Bilen et al, 2007). In 56 children (mean age 9.1 years) with a mean stone

burden of 337.5 mm^2, Desai and colleagues (2004) reported a stone-free rate of 89.8% using EHL through a 14-Fr nephroscope and a 20- to 24-Fr sheath. Of these, 61% required multiple tracts, and 45% were staged procedures. Findings demonstrated that the number and size of tracts were significantly associated with postoperative hemoglobin decrease (mean 1.9 g/dL) and an overall transfusion rate of 14%. In 52 children with a mean age of 7.9 years and a mean stone burden of 282 mm^2, Zeren and colleagues (2002) reported an 87% stone-free rate using US and EHL for fragmentation and tract dilation from 18 to 30 Fr. Complications included postoperative fever (30%) and the need for transfusion (24%). **Transfusion was associated with operative time, sheath size, and stone burden.** In 135 children of mean age 8.9 years with a mean stone burden of 507 mm^2, Salah and colleagues (2004) reported a 98.5% stone-free rate using US through a 26-Fr nephroscope. Complications were low (8% urine leak rate and 0.7% transfusion rate), with only one patient requiring a second procedure. In a recent series of 46 children with a mean stone burden of 332 mm^2, Bilen and colleagues (2007) reported an 88% stone-free rate using EHL, US, and the holmium laser. When stratified by tract size (14, 20, and 24 Fr), efficacy rates were similar in all groups, but there were no complications or transfusions in the 14-Fr tract group.

In an effort to reduce the number of tracts and associated morbidity, some centers have chosen to follow primary PCNL with adjunctive SWL therapy to clear residual stone fragments. In a small series of 29 children with a mean age of 3.8 years and a mean stone burden of 2.4 cm, Mahmud and Zaidi (2004) reported a 60% stone-free rate after PCNL monotherapy using EHL through a 17-Fr angled nephroscope. Only one tract was used in all patients, and after SWL sandwich therapy, the stone-free rate increased to 100%. In a larger series of 169 children with a mean stone burden of 3.1 cm, Samad and colleagues (2006) reported a 59% monotherapy stone-free rate with 96% of cases performed through a single tract. Approximately one third (34.5%) of primary failures were treated with SWL; the cumulative stone-free rate in all patients was 93.8% with a 3.6% transfusion rate. When stratified by age, anatomy, bilaterality, and renal function, stone-free outcomes were equivalent in all groups. The decision to follow PCNL with SWL is related to operator experience with percutaneous technique and available technology. **It is the authors' preference to perform a second-look nephroscopy through the original tract to ensure stone-free status during the initial hospital admission, rather than progress to SWL sandwich therapy.** Endoscopic surveillance during the initial procedure can determine the need for second-look nephroscopy without relying on additional imaging and the associated risks of radiation exposure (Roth et al, 2009). With continued improvement in technology and technique, the indications for PCNL in children will continue to increase. Given the technically challenging nature of PCNL, the surgeon's experience is paramount in developing individualized treatment plans to optimize efficacy with minimal morbidity.

LAPAROSCOPIC AND ROBOTIC-ASSISTED PYELOLITHOTOMY

Treatment of large stone burdens in children is technically challenging, often requiring multiple procedures. Laparoscopy and robotic-assisted laparoscopy have been used successfully in adults for treatment of calculi during the concomitant treatment of ureteropelvic junction obstruction and in the primary treatment of staghorn calculi. Small series using these techniques in children have only recently been described. In eight children (mean age 4 years) with a mean stone burden of 2.9 cm and who underwent transperitoneal laparoscopic pyelolithotomy, Casale and colleagues (2004) reported a 100% success rate, a mean hospital stay of 2.15 days, and a mean operative time of 1.6 hours with no major complications. In the first report of robotic-assisted laparoscopic pyelolithotomy, Lee and colleagues (2007) described their experience in five patients, four with cystine staghorn calculi refractory to PCNL and SWL and one with calcium oxalate calculi and concurrent ureteropelvic junction obstruction. Of these cases, four were completed robotically, with one patient having a residual 6-mm lower pole stone and one patient requiring conversion to an open procedure. Mean operative time in this series was 315 minutes, mean estimated blood loss was less than 20 cc, and the mean hospital length of stay was 3.8 days. These early experiences demonstrate that laparoscopic pyelolithotomy is feasible, safe, and efficacious as an alternative to open pyelolithotomy in children and warrants further study. However, due to their demanding technical nature, these procedures will likely be limited to endourologic management failures in academic centers with abundant expertise in laparoscopic and robotic pediatric surgery. The indications for use of these technologies are also limited to particularly complex and large stone burden patients.

PERCUTANEOUS CYSTOLITHOTRIPSY FOR BLADDER STONES

Bladder stones are more often found in children from developing countries and are thought to be related endemically to malnutrition. It is thought that diets low in animal protein and phosphorous (breast milk as opposed to cow's milk), in addition to vitamin A deficiency, are contributory (Kancha and Anasuya, 1992). **Bladder stones from children in these developing countries are most often composed of ammonium acid urate**. In contrast, among children from industrialized nations, bladder stones are most often found in those with spinal cord injuries or congenital abnormalities such as spina bifida. Very often, these children have undergone augmentation cystoplasty and/or manage their bladders by clean intermittent catheterization. **It has been reported that up to 50% of children with reconstructed bladders will develop a bladder stone(s) in their lifetime** (Palmer et al, 1993). **Urinary stasis, bacterial colonization or infection with urea-splitting organisms, retained mucus, and foreign bodies can all contribute to the formation of bladder stones, the majority of which are struvite.**

Open cystolithotomy has been the traditional modality to treat bladder stones. Transurethral cystolithotripsy is an alternative, although not ideal in the pediatric population. In children, a smaller-caliber urethra limits effective treatment of large bladder stone burdens. Percutaneous cystolithotripsy, however, is now used worldwide with the advantage of shorter hospital stays, smaller scars, and less indwelling catheter time postoperatively (Al-Marhoon et al, 2009). Presently, percutaneous cystolithotripsy is the preferred method to treat bladder stones that have formed in reconstructed bladders (Paez et al, 2007). In developing countries as well, percutaneous lithotripsy has become the first-line treatment modality to address bladder stones in bladders that have not been augmented. Salah and colleagues (2005) reported on their experience with cystolithotripsy in 155 children from Pakistan and Yemen with a mean age of 4.5 years and average bladder

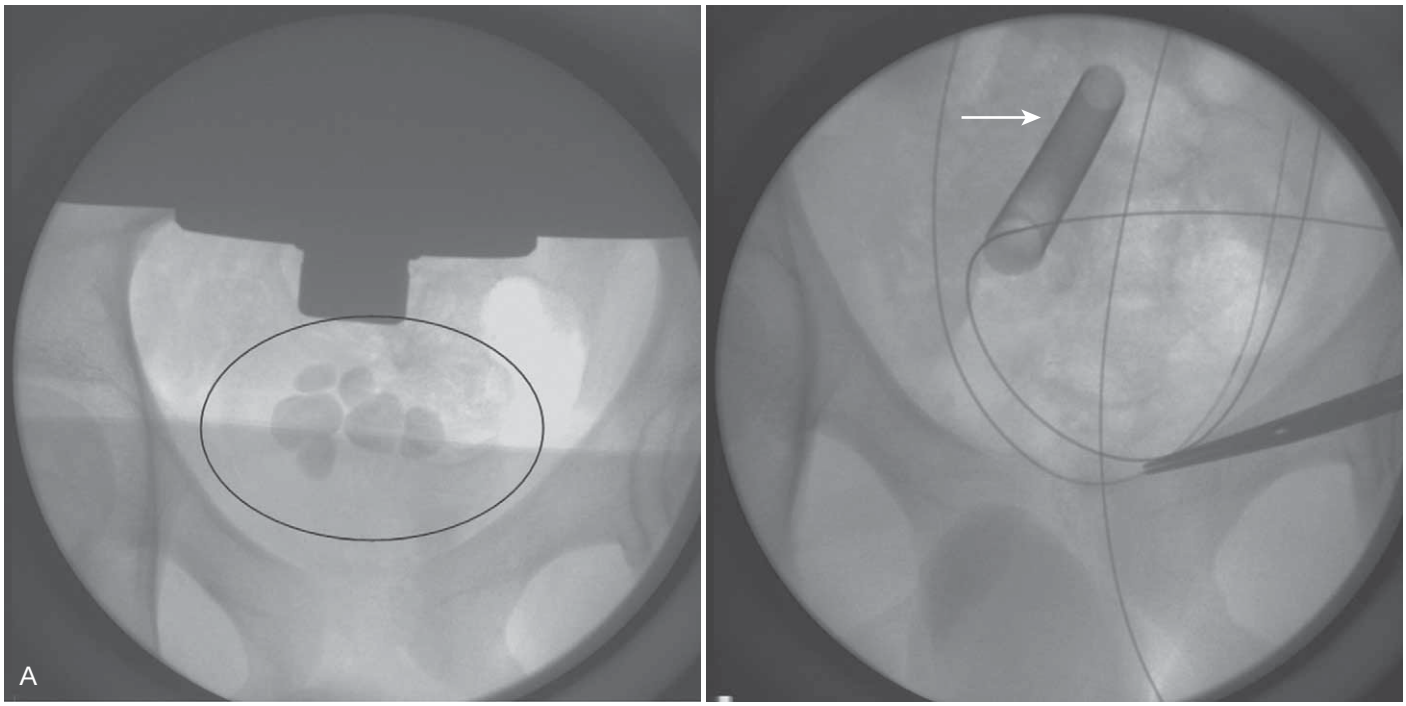

Figure 135–13. A 12-year-old male with spina bifida with an augmented bladder (ilealcystoplasty) found to have multiple sizeable bladder stones (**A**) on a workup for recurrent *Proteus mirabilis* infections. **B**, Percutaneous cystolithotripsy with an ultrasonic lithotripter was performed through a 30-Fr access sheath (*arrow*), clearing all stones from the augmented bladder.

stone burden of 2.3 cm (range 0.7 to 4 cm). All children were treated safely and successfully using a 26-Fr nephroscope through a 30-Fr sheath placed through a 1-cm suprapubic incision.

Percutaneous cystolithotripsy has also been used effectively in infants less than 1 year old to clear bladder stones. Gan and colleagues (2010), reported on their experience using a 16-Fr peel-away sheath with a ureteroscope to treat bladder stones with an average size of 1.4 cm in 15 boys with a mean age of 8.2 months.

Percutaneous cystolithotripsy in children may be performed under ultrasound or fluoroscopic guidance and is most often an outpatient procedure. With either modality, the bladder is first filled to capacity with water or contrast, respectively. The child is placed in the Trendelenburg position to minimize the risk of bowel injury during access and tract dilation/formation. An 18-gauge needle is placed into the distended bladder midline, 1 to 2 fingerbreadths above the pubic bone. Once proper placement is confirmed with return of fluid, a wire is passed through the needle into the bladder. A tract may then be established reflective of stone diameter and the child's size. Most often, a tract is established with a balloon dilator to accompany a 30-Fr sheath. Amplatz dilators may also be used. A 26-Fr nephroscope is used to extract stones less than 1 cm using a rigid stone forceps, or an ultrasonic lithotripter may be used to fragment stones greater than 1 cm. At the conclusion of the percutaneous cystolithotripsy procedure, a Foley catheter is left per urethra or per continent catheterizable stoma for 1 week. The rectus fascia defect is closed with a 2-0 Vicryl suture (Fig. 135–13).

DETERMINATION OF STONE-FREE STATUS

As the surgical management of pediatric stone disease evolves, the lack of a consistent definition of "stone free" following definitive therapy is an issue that remains unaddressed. Although controversial, in select adult patients, all stone fragments can be considered clinically significant and can lead to stone recurrence (Krambeck et al, 2008). Likewise, the presence of residual stone fragments in children has been associated with poor outcomes (Afshar et al, 2004), and any size stone fragment in a young stone former may result in the need for repeat surgical procedures. However, these fragments often are not detected on US or KUB, thus necessitating reliance on CT imaging in select children.

Balancing the risks of radiation exposure for post-treatment stone detection and the risks of anesthesia for secondary procedures is a challenging dilemma for contemporary pediatric endourologists. Newer, high-speed helical CT scanners reduce radiation exposure and rarely require intravenous sedation. In addition, maximizing intraoperative fragment detection by direct visualization in URS and PCNL and continued development of high-resolution real-time fluoroscopy may result in less reliance on postoperative imaging and decreased need for second-look nephroscopy/URS, SWL, or sandwich therapy (Ost and Smith, 2006b). Until the risks of radiation exposure in children are more clearly defined, surveillance in these children will be individualized based on age, anatomy, stone burden, and underlying metabolic abnormalities.

CONCLUSIONS

Evolution of techniques and miniaturization of instruments have changed the management of pediatric stone disease. However, despite encouraging results, concern remains regarding the safety of endourologic treatment in smaller patients and its subsequent effects on the developing kidney. Although SWL is still considered first-line therapy for upper tract calculi less than 1.5 cm, evidence is accumulating that ureteroscopy with laser lithotripsy and stone basketing may be more efficacious in treating upper tract stone

disease in children. Although PCNL remains the most effective technique for large upper tract stone burdens, there are now reports of laparoscopic and robotic-assisted laparoscopic pyelolithotomy in major pediatric academic centers with extensive laparoscopic and robotic experience. Prospective studies designed to determine "the preferred" endourologic approach to upper tract calculi in children would be helpful, albeit difficult to conduct. In this regard, the individual surgeon's experience and comfort level will weigh heavily in choosing a treatment modality. Pediatric urologists' familiarity with percutaneous renal access and the full spectrum of endourologic equipment and techniques will continue to facilitate efficacious minimally invasive approaches for the entire pediatric urinary tract.

Urologic Considerations in Pediatric Renal Transplantation

Craig A. Peters, MD, FACS, FAAP

Pretransplant Assessment
Pretransplant Preparation
Transplantation
Complications
Summary

The child requiring renal replacement will more often than not be a boy with an obstructive uropathy. The challenge for the pediatric urologist is to ensure that the damage done to the native kidneys will not be repeated with the transplanted kidney. These patients are some of the most complex children to care for, mostly in developing a therapeutic plan to provide for **several goals: (1) normal urinary drainage from the kidney into a reservoir, (2) a urinary reservoir that permits low-pressure storage for a socially acceptable time, (3) volitional emptying of the reservoir with continence, (4) absence of infection, and (5) all with the fewest surgical procedures and patient trauma.** These goals are achievable, but it must be clear that until they are assured, renal transplantation should be deferred, or a plan to achieve these goals with assurance of patient/family compliance must be in place.

Patient and family understanding and compliance are essential for successful urologic management of the child with an abnormal urinary tract and end-stage renal disease (ESRD). The integration of the entire care team in this preparation is also critical and demands a close working relationship between the urology team, the pediatric nephrologist, and transplant team. The urologist must have a basic understanding of the needs and constraints of the nephrologists and transplant surgeons, if they are not performing the entire transplant. The ureteral implantation can be performed by the urologist or the transplant surgeons, but this should be dependent upon the state of the bladder and the comfort level of the surgical teams with the particular aspects of the surgery and their postoperative management, including any complications.

PRETRANSPLANT ASSESSMENT

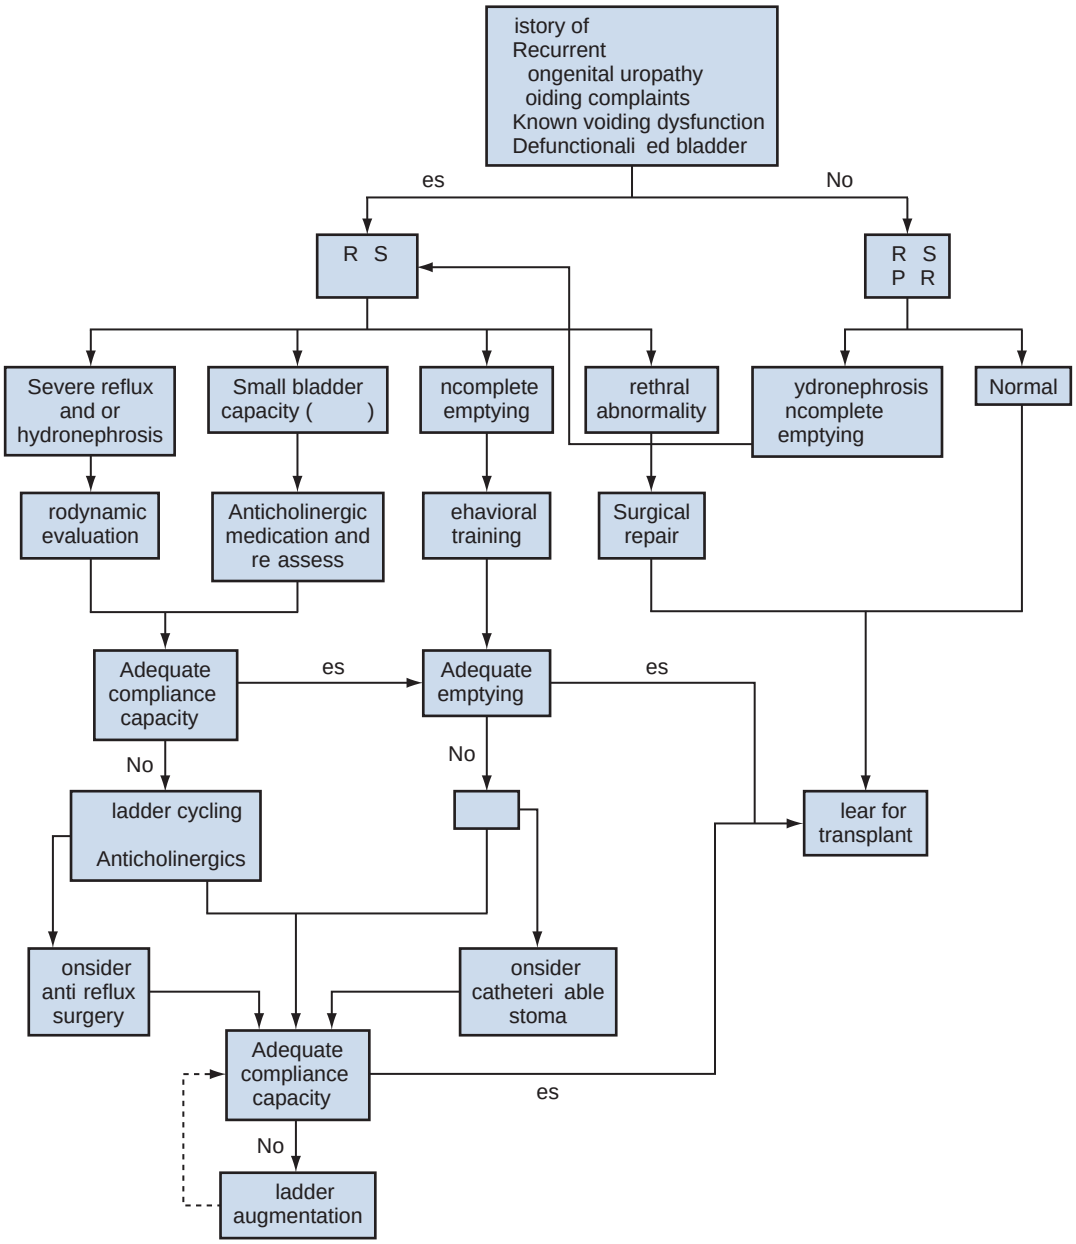
Screening

A large fraction of children in need of renal replacement will have some type of uropathy—either congenital obstruction, vesicoureteral reflux, or neuropathic bladder dysfunction (North American Pediatric Renal Transplant Cooperative Study [NAPRTCS], 2008). Younger boys will typically have obstructive uropathy, including posterior urethral valves, while the reflux and neuropathic bladder patients will be older, including young adults. Some children will have uncharacterized ESRD, and it is reasonable to have all children screened for urologic issues prior to transplant. A detailed history, renal ultrasonogram, and postvoid residual urine determined by ultrasonography (US) can effectively rule out most significant uropathies. A routine voiding cystourethrogram (VCUG) is not necessary, unless there is a history of a specific urologic disease, febrile or recurrent urinary tract infection (UTI), the presence of hydronephrosis, or clinically abnormal voiding (Ramirez et al, 2001) (Fig. 136–1).

Focused Assessment

The child with a known urologic abnormality will require a pretransplant assessment directed by the underlying condition and the status of the bladder and kidneys. In most, a VCUG will be useful to permit an assessment of voiding function, the state of the urethra, and the presence of reflux. When bladder dynamics are abnormal based on the VCUG or a renal US, consideration for urodynamic evaluation is appropriate. **The indications for urodynamic testing to assess bladder capacity, compliance, and emptying, as well as sphincter function, includes a known neuropathic bladder abnormality, prior severe posterior urethral valves and any child with ongoing voiding dysfunction, hydronephrosis, or recurrent UTI** (Burns et al, 1992; Zermann et al, 2003). The principle goal of the urodynamic testing is to determine the need for further therapy for bladder function. This might include medical therapy with anticholinergics, the use of intermittent catheterization, and the potential need for bladder augmentation in severe cases.

Urodynamics will also provide insight into bladder emptying function, which will be critical to prevent infection. Of course, if medical therapy for a noncompliant bladder is needed, this may impair bladder emptying and necessitate clean intermittent catheterization (CIC) to permit effective emptying. In the sensate child or in some with neuropathic bladders, the creation of a continent catheterizable stoma may be the ideal way to facilitate effective CIC. These decisions should be made and executed pretransplant. Urodynamic evaluation will often be a regular monitoring



f patient is anuric and has no urologic history no further testing is essential if there is a history of neurogenic bladder posterior urethral valves or complex urologic condition consideration of bladder cycling and anticholinergics is appropriate.

Figure 136–1. Algorithm for evaluation and management of the bladder in patients in preparation for renal transplantation. The key element is the history of urologic conditions or symptoms. CIC, clean intermittent catheterization; PVR, postvoid residual (volume); RUS, renal ultrasonogram; UTI, urinary tract infection; VCUG, voiding cystourethrogram.

evaluation in these children and a critical element in ongoing optimization of bladder function. It will often be necessary to repeat the study to ensure that the therapeutic intervention has been effective and that the bladder is prepared for the transplant.

PRETRANSPLANT PREPARATION

Bladder Preparation

General Issues

The most common bladder abnormality associated with ESRD is the low-capacity, hypertonic bladder with poor compliance. This is the typical picture with posterior urethral valves (PUV), but it is important to recognize that these bladders continue to evolve and may progress to a pattern of insufficient contractility to empty at all (Peters et al, 1990; Nguyen and Peters, 1999). They may still be hypertonic and pose ongoing renal risk and will require CIC in most cases. Hypertonicity is the most dangerous dynamic pattern, as it will create an obstructive condition for the kidneys, even in the absence of reflux. Bladder dysfunction can increase graft loss (Herthelius and Oborn, 2007).

Hypertonicity

The hypertonic bladder is managed with medication as a first-line therapy, typically with anticholinergics, and with augmentation

Key Points: Urologic Evaluation and Management

- The goals are (1) normal drainage from the kidney into a reservoir, (2) a urinary reservoir that permits low-pressure storage for a socially acceptable time, (3) volitional emptying of the reservoir with continence, (4) absence of infection, and (5) the fewest surgical procedures and patient trauma.
- A large fraction of children in need of renal replacement will have some type of uropathy—either congenital obstruction, vesicoureteral reflux, or neuropathic bladder dysfunction.
- Pretransplant assessment should be directed by the underlying condition and the status of the bladder and kidneys.
- Urodynamic testing aims to assess bladder capacity, compliance, and emptying, as well as sphincter function.
- Indications for urodynamics include a known neuropathic bladder, prior severe posterior urethral valves, and any child with ongoing voiding dysfunction, hydronephrosis, or recurrent UTI.

as the second-line therapy (Lopez Pereira et al, 2000). Medical management requires diligence on the part of the family and follow-up that regularly assesses the response to therapy. It will usually require a combination of anticholinergics and CIC, although some children with PUV can learn to void by the Valsalva maneuver. It should never be assumed that they will be able to do so; they must demonstrate this by repeated low postvoid residual volumes on catheterization.

Anticholinergic therapy is best titrated with increasing doses and watching for a change in catheterized volumes, wetting, and hydronephrosis. Urodynamic evaluation can more precisely define the efficacy. Often medical therapy is introduced at the same time as CIC, although this is not essential. Compliance with CIC is often an excellent test of later patient/family compliance with the stringent requirements of renal transplant. If a family is unable to manage with CIC, their ability to manage the medical care of a transplant must be questioned.

The goal of therapy is for the child to be able to hold to capacity expected for age at low pressure, that is, less than 30 cm H_2O. We have had some success at teaching parents with children on CIC to measure the opening pressures at catheterization by estimating the height of the water column in the catheter. This may be a more natural measurement, although the strict correlation with outcomes has not been defined.

Volume

Bladder capacity is another element of normal function and is the basis for both safe storage as well as social continence. As above, capacity can be improved with anticholinergic medication but may ultimately require bladder augmentation. There is a clear shift away from augmentation in all patients, and there have been prior reports that augmentation is not needed in renal transplant (Alfrey et al, 1997b; Salvatierra et al, 1999). However, there remains a role for this approach in children with complex uropathies with ESRD. Current indications would include nonsalvageable bladder (exstrophy, tumor, severe end-stage neuropathic bladder) and failure of medical and CIC therapy to achieve low-pressure storage for up to 3 hours. If pressures are safe for 1 hour only and they exceed 40 cm H_2O the rest of the time, despite aggressive medical and catheterization therapy, consideration for augmentation is important.

There is no evidence or logic that bladder augmentation, itself, increases the risk of transplant failure, despite some reports (Alfrey et al, 1997b), **and, indeed, it has permitted many effective transplants into very abnormal bladders** (Sheldon et al, 1994; Taghizadeh et al, 2007). There is no single approach that is ideal, although gastric augmentation gained popularity for ESRD children in the late 1980s and early 1990s. It offers the benefit of secreting acid in a patient who is typically acidotic, and it can limit infection and has a lower rate of bladder stones. Gastric augments have, however, been linked with severe complications, particularly in the pre-transplant anuric group, due to gastric juice injury of the native bladder segment and due to the fairly common hematuria-dysuria syndrome (Reinberg et al, 1992; Nguyen et al, 1993). Recent reports of malignancy, particularly in the transplant group, are worrisome but are too anecdotal yet to change practices (Castellan et al, 2007; Husmann and Rathbun, 2008). Caution and monitoring are essential. Composite gastric augmenting patches are useful and may have less morbidity. Ileum and sigmoid are all useful and may be more appropriate in some patients, depending upon anatomy, prior surgery, and preferences for continent catheterizable stomas.

The augmented patch rarely will create an issue with the transplant, but the fact of the pedicle presence and its anatomic orientation should be recognized by the transplant team. Similarly, **continent stomas should be placed in a location that avoids conflicting with the anticipated transplant incision(s), and stomas nearly always may be positioned medial to the incision(s).** Again, recognition of the location and presence of the mesentery for the stoma is important.

The infant receiving a transplant may have an aortic anastomosis to the renal vessels, which will create a potential need to mobilize the mesentery of the augment or stoma. Coordination between the reconstructive and transplant teams is essential.

Infections

Many children with complex reconstruction of the urinary tract will have a history of recurrent UTI. This may be associated with intermittent catheterization. This is a potential hazard for the transplant, and pyelonephritis of the graft is certainly associated with graft loss (Dunn et al, 1987; Hanevold et al, 1987; Neuhaus et al, 1997; Howie et al, 2002; Herthelius and Oborn, 2007). The underlying etiology of the infection is most likely due to inadequate emptying of the reservoir, either by catheterization or voiding. This needs to be assessed and addressed in advance of the renal transplant. Strategies include double and triple voiding to avoid using CIC, or, if CIC has already been instituted, to ensure adequate emptying or to teach proper methods to ensure emptying.

Persistent UTI in the face of appropriate technique for CIC suggests either an anatomic abnormality that has not been detected or may be chronic colonization. The latter will sometimes respond to long-term antibiotic courses, using agents including the fluoroquinolones and cephalosporins. The etiology and specific therapy for this situation is uncertain. Anatomic abnormalities, such as diverticula, may require more specific imaging studies but may be amenable to surgical cure, including a bladder diverticulum or nondraining ureteral stump. This, however, is uncommon.

Clean Intermittent Catheterization

The use of CIC in managing the abnormal bladder has been a truly revolutionary lifesaver in the last 4 decades. Although it may be a major challenge to initiate, once started it is

nearly always well accepted. Careful preparation, teaching, support, and follow-up are critically important for long-term success.

The importance and principles of CIC must be well understood by the care providers and carefully communicated to the family, including all possible caregivers. The recognition that this is a means by which to reduce infection and attain both safe bladder storage and control over voiding is very important, and yet it may not be readily apparent on first pass.

The frequency of CIC must be determined by measuring approximate urine outputs, as well as storage pressures, based on urodynamic assessment or by home catheterization opening-pressure measurements. This permits an estimate of safe pressure–volume relationships for day-to-day life. Avoiding regular excesses of these volumes, and therefore high pressures, will facilitate healthy kidney function. The typical frequency is between 3 and 4 hours. Pressures should not exceed 40 cm H_2O for any prolonged period of time.

Initiating CIC in preparation for transplantation serves an assessment purpose as well. For families where follow-through may be imperfect, it can be useful to use CIC to determine their commitment and ability to follow complex medical care plans. If CIC cannot be instituted pretransplant to manage an abnormal bladder, there is no reason to believe this ability will suddenly appear post-transplant. **The response to CIC can predict the ability to manage the necessary transplant medication and care regimen as well.** The committed and understanding family will manage well, and this will serve to demonstrate their readiness for transplant.

Key Points: Pretransplant Preparation

- The most common bladder abnormality associated with ESRD is a low-capacity, hypertonic bladder with poor compliance.
- There is no evidence that bladder augmentation increases the risk of transplant.
- Recurrent pyelonephritis is a potential hazard for the transplant and is associated with graft loss.
- Initiating CIC in preparation for transplantation serves an assessment purpose as well as facilitating bladder emptying.
- Bladder refunctionalization is often best accomplished by bladder cycling to increase capacity, determine bladder wall compliance, and assess the family's ability to perform CIC.

Defunctionalized Bladder

Neuropathic Bladder

The defunctionalized neurogenic bladder is becoming scarce due to better management but will occasionally present clinically in a transplant patient who has not had ongoing urologic care (Firlit, 1976; Serrano et al, 1996). **It is impossible to know without testing what the potential function of the bladder may be. It is also important to recognize that the bladder that has been defunctionalized will take some time to reach its maximal functional potential. This is often best accomplished by bladder cycling to increase capacity, determine bladder wall compliance, and assess the family's ability to perform CIC.**

Some have advocated simply implanting the transplant ureter into the bladder and anticipating normal function (Salvatierra et al, 1999). Although this may occur on rare occasions, it is a highly risky approach to the chronically defunctionalized bladder.

Cycling the defunctionalized bladder is best accomplished using a progressive program of catheterization with instillation of increasing volumes of saline, with a set dwell time, and then with catheter drainage (Alam and Sheldon, 2008). The amounts will be determined empirically based on initial tolerated volumes and should increase at regular intervals, usually 10 to 15 cc per day. The response to these instillations will give useful clues as to the utility of the bladder to serve as a reservoir and in its ability to empty spontaneously. Adjunctive anticholinergic medications are often necessary to increase bladder capacity and compliance.

The defunctionalized neurogenic bladder will almost certainly require intermittent catheterization for emptying. It is therefore reasonable to introduce this, as such, to the family. In the rare instance where the child can learn to empty satisfactorily, CIC may no longer be needed. This is a major step and requires a careful study of voiding diaries, postvoid testing, and assessment of the upper renal tracts.

The target volume is anticipated capacity for age based on any of the available formulas (Koff, 1983; Kaefer et al, 1997). This may not be reached immediately, but if volumes increase steadily without significant leakage, further expansion is likely. Although storage capacity is important, compliance is equally critical, and this must be assessed formally with urodynamics. The patient should be cleared for transplant only if capacity and compliance parameters near normal can be reached. Aggressive medical management is also important in this determination. If adequate storage and compliance cannot be attained, consideration for augmentation must be entertained. This should be performed prior to transplant, unless there are pressing contraindicating reasons.

Non-Neuropathic Bladder

The defunctionalized bladder associated with renal insufficiency is often due to posterior urethral valves or vesicoureteral reflux. These bladders may be more often salvaged to ultimately permit spontaneous voiding but should initially be approached as would the defunctionalized neurogenic bladder, and it should be assumed that CIC will be needed long term. The critical factor will be the storage capacity, and progressive cycling as described above can provide that assessment. At the same time, children can be asked to attempt to void after holding the instilled saline for a period of 15 or 20 minutes. A postvoid catheterization then determines the postvoid residual volume.

The ability to empty spontaneously will also impact the decision regarding the need for a continent catheterizable stoma. This is more critical in boys with normal sensation who may be very resistant to urethral catheterization. The period of pretransplant CIC will permit assessment of both voiding ability and tolerance of urethral CIC. These decisions are best made concurrently with other reconstructive choices to permit an integrated strategy and a single surgical procedure if possible.

The Decision to Augment

Although the use of bladder augmentation is declining due to concerns regarding metabolic, infectious, and neoplastic complications, enterocystoplasty remains the most effective means to provide normal bladder storage

function in both neurogenic and postobstructive bladder dysfunction (Barnett et al, 1987; Sheldon et al, 1994; Hatch et al, 2001; Nahas et al, 2002; DeFoor et al, 2003; Capizzi et al, 2004; Mendizabal et al, 2005; Rigamonti et al, 2005; Aki et al, 2006). To lose a renal graft due to the same processes that contributed to native renal demise is unacceptable. The potential complications of augmentation must also be clearly recognized and anticipated, although some reports have presented extreme examples that are not the author's experience (Alfrey et al, 1997a). A strategy of aggressive intermittent catheterization with medical management becomes the best approach to identify those patients in whom augmentation is the only real option for successful renal transplantation. It is difficult to determine a meaningful incidence of the need for augmentation, because the effort expended by both family and health-care team varies as much as the underlying pathology. With early aggressive bladder management, the need for augmentation in both neurogenic and obstructive bladder dysfunction has been declining. When bladder reconstruction using engineered tissues becomes more widely available, this will be a particularly valuable use.

Broad indications for augmentation prior to transplantation would be the inability to develop capacity greater than 75% of expected for age with pressures less than 30 cm H_2O, using catheterization that is no more frequent than every 3 hours, and using maximal anticholinergic medications. Tolerance to medication will obviously be an important element of these criteria. These thresholds are rules of thumb without strong clinical data to support them. Exceptions can be found where bladder capacity improves markedly after transplant, perhaps due to the effects of uremia, but they should serve as guidelines for determining when to augment prior to transplantation.

The availability of a dilated ureter to permit ureterocystoplasty (Kim et al, 1996; Kurzrock et al, 2002) should be explored, although results have been mixed. It is preferable to perform enterocystoplasty in this context, and efforts should be made to preserve the ureter, when possible, for this use or for a continent catheterizable channel.

Cutaneous Stomas

The defunctionalized bladder may be associated with a variety of urinary diversions, including ileal and colon conduits as well as ureterostomies. In the past, transplantation has been performed with the ureters draining into the diversion. This is rarely appropriate today. A functioning ileal loop diversion in the setting where augmentation is determined to be necessary can be used as the augmenting patch with bladder refunctionalization, even if the patient is anuric. If augmentation is not needed, based on CIC cycling, and the patient continues to make urine and the native kidney will not be removed, the native ureter should be implanted to refunctionalize the bladder, and the loop should be discarded. If there is uncertainty regarding the need for augmentation, the loop may be preserved and be available for augmentation after transplant, if essential.

Reconstruction Strategies

In the setting where bladder reconstruction will be needed, several factors must be considered in anticipation of the ultimate renal transplant. These considerations reflect the type of dialysis, either hemo- or peritoneal, likely placement of the graft, timing relative to both initiation of dialysis (if not already begun) and transplantation, the need for bowel surgery and the native kidneys. Consideration of these factors will permit a more coordinated and efficient reconstruction.

Dialysis Issues

If a patient is already on peritoneal dialysis (PD), any intraperitoneal surgery will likely require temporary transition to hemodialysis. Limiting this to one procedure is valuable. At times, this can be linked with placement of a PD catheter, but if bowel surgery is needed, this may increase the risk of infectious complications.

If the patient is not yet on dialysis but is approaching the need, there may be some consideration for initiating dialysis prior to reconstruction to improve the overall medical status of the child. This can promote more rapid wound healing and fewer complications. At the same time, this will impact the child on PD as noted, and for those on hemodialysis, there is a risk of fistula injury during surgery due to low flow states as well as direct pressure.

Graft Placement

Consideration should be made for the likely location of the graft. In the very small child in whom the graft will be placed intraperitoneally on the aorta, careful movement of any mesenteric pedicles away from the midline is advisable, as well as trying to avoid a transureteroureterostomy (TUU). A psoas hitch for ureteral reimplantation of the native kidney, if it is to be salvaged, can make iliac graft placement on that side difficult. There may be no feasible alternatives, and, in such cases, careful documentation of the procedure is essential.

Timing

In general, any major urologic reconstruction should be undertaken well before the anticipated transplantation (Taghizadeh et al, 2007). Minor ureteral surgery may be considered at the time of transplantation, but this is unusual. Following enterocystoplasty or continent diversion, at least 6 weeks is needed for healing, and 3 months would be preferable. Unilateral native nephrectomy is reasonable at the time of transplantation but only in older children. Operative time in the infant may have more of a negative impact on graft function, and it seems imprudent to add this extra risk.

Enterocystoplasty

Enterocystoplasty in the setting of a dialysis patient or a child approaching ESRD is feasible and, when needed, can be successfully accomplished in a manner similar to that for any other child (Sheldon et al, 1994; Taghizadeh et al, 2007). The selection of bowel segments and reconstructive strategy should be based on the functional anatomy and needs of the individual child. These include factors such as the need for a continent catheterizable stoma, the availability of native bladder tissue, the status of the bladder neck and continence mechanism, and bowel function. **If continent diversion is needed due to an unsalvageable bladder, there is no reason to defer this until after transplant.** The often-quoted contraindication to continent diversion of renal impairment is not applicable in these patients. They will need medical management of the metabolic effects of the diversion, but they require aggressive metabolic management at baseline. In some cases, by improving bladder

dynamics and limiting infection, the progression to end-stage may be delayed.

The use of gastric segments was considered particularly appropriate for the child approaching end-stage failure and can still be useful in selected cases (Burns et al, 1992; DeFoor et al, 2003). Due to the various complications of gastrocystoplasty, however, this approach has been used much less. The benefit of acid excretion for the child with chronic kidney disease (CKD) can be helpful, but these children are also at risk for complex metabolic derangements with alkalosis. For the anuric child, the presence of gastric secretions in the empty bladder can lead to erosion and even perforation (Reinberg et al, 1992). Care must be taken in those children to use proton pump inhibitors and to irrigate with bicarbonate solutions until urine output is restored.

Native Nephrectomy

The decision regarding native nephrectomy must be made with a multidisciplinary team involving the nephrologist and urologist as well as the family. There is controversy in this regard, and although, in general, it is preferable to leave the native kidneys, **there are several situations where removal pretransplant is necessary. These include malignant hypertension, profound nephrotic syndrome with malnutrition due to protein losses** (Kim et al, 1992)**, recurrent upper tract infection, and massive reflux.** The latter may be more relative, but with stasis and possible infection in an immunosuppressed child, removal is preferable and less risky. The utility of leaving a native kidney that produces some urine is that it makes dialysis more manageable with less fluid restrictions. This can facilitate nutritional support in the younger child. This must be balanced against the possible risks of infection and hypertension, as well as graft function.

In the infant undergoing renal transplantation, native nephrectomy is strongly recommended by some groups to enhance graft survival based on improving blood flow to the graft. Any shunting of blood from the graft in a small child whose cardiac output may be a small fraction of the adult from whom the graft came may potentially impair early graft function.

In a child for whom native nephrectomy is to be performed, the principle contributing factor is whether PD is being performed. If so, laparoscopic transperitoneal removal will require temporary hemodialysis. Some have performed immediate PD, but the risks of leakage with possible infection would argue against this practice. Retroperitoneoscopic nephrectomy can be performed with immediate PD (Gundeti et al, 2007), but leaks may still be encountered. If the kidneys are small, then this is the optimal approach. For large kidneys in children on PD, posterior open nephrectomy may be the overall optimal approach.

If PD is not being performed, then any type of nephrectomy is acceptable. The incidence of postoperative adhesions is limited and is unlikely to affect the efficacy of PD. There is the potential impact on the ultimate transplant procedure when the distal ureter is to be removed, because this will cause adhesions in the area of the iliac vessels. However, if there is significant reflux or obstruction and a dilated ureter, total removal may be the best course to limit the risk of infection. Renal embolization has been reported as an alternative to surgical nephrectomy (Capozza et al, 2007).

Dealing with the Native Kidneys

Avoiding Removal

In the absence of specific indications for nephrectomy, leaving the native kidneys offers the advantage of having a potential source of water excretion if the graft fails. Although this can be helpful in managing nutrition and lifestyle, it should not become a rigid goal if there are reasons to remove the kidneys. Their ultimate utility may be very limited, particularly after a period of graft function, because they often will regress in size and urine output.

Limiting Risk of Infection

Urinary infection in the setting of an immunosuppressed child with a renal graft is damaging to both child and graft. Preventing infection in the child with known urologic concerns is therefore a priority that should be acted upon proactively rather than purely in response to an infection. The damage from one infection may be critical to that child. Situations in which active prevention of infection may be useful include high-grade reflux and persistent hydronephrosis with or without reflux, particularly when intermittent catheterization is needed. These patients are frequently colonized with bacteria and may be more susceptible to UTI. The nondilated, nonrefluxing native kidney is unlikely to be subject to infection and can generally be maintained in the absence of other indications for removal.

Ureteral Preservation

When nephrectomy is to be performed, ureteral preservation should be considered. If the ureter is normal, it should always be left to limit surgical dissection near the iliac vessels and to have an option for proximal transplant-to-native ureteroureterostomy for distal ureteral stenosis (Kockelbergh et al, 1993). If bladder function is abnormal and intermittent catheterization may be needed, preserving the ureter for use as a continent stoma is advisable. This is best performed pretransplant. Creation of the continent stoma at the time of transplant is an option.

Combining Nephrectomy and Transplantation

Native kidneys may be removed at the time of the renal transplantation, but this is generally avoided to limit surgical complexity and time. It may be appropriate for a single native kidney, which may be swiftly removed through the transplant incision. In the absence of specific justification, however, this strategy is generally to be avoided.

TRANSPLANTATION

The technical elements of the vascular component of the transplantation are described in Chapter 43 and are appropriate to children. One exception may be transplantation into the infant where the vascular anastomoses are performed on the aorta. This usually is performed with anticoagulation, which may impact bladder surgery. More care with hemostasis is needed. For the pediatric urologist who is not performing the vascular anastomosis, the ureteral anastomosis becomes the focus of attention, as well as of complications.

Ureteral Anastomosis

Options

As with ureteroneocystostomy for vesicoureteral reflux (VUR), there are intravesical and extravesical techniques

Key Points: Pretransplant Reconstruction

- The ability to empty spontaneously will also impact the decision regarding the need for a continent catheterizable stoma.
- Indications for augmentation prior to transplantation include (1) capacity less than 75% of that expected for age, (2) pressures greater than 30 cm H_2O, (3) being catheterized every 3 hours, and (4) maximal anticholinergic medications.
- For patients on peritoneal dialysis, intraperitoneal surgery will likely require temporary transition to hemodialysis.
- In general, any major urologic reconstruction should be undertaken well before anticipated transplantation.
- Native nephrectomy is indicated for (1) malignant hypertension, (2) profound nephrotic syndrome with malnutrition, (3) recurrent upper tract infection, and (4) massive reflux.

for the transplant ureteral anastomosis. In general, the author has performed an antirefluxing anastomosis in all cases, although it is clear that this is not essential. Although careful screening can identify patients with bladder dysfunction, and therefore those at risk for graft reflux, the method to prevent reflux is simple, effective, and has minimal morbidity.

Extravesical ureteroneocystostomy is the preferred ureteral anastomosis. After the vascular anastomoses have been performed and hemostasis achieved, the bladder is partially filled with saline or a dilute antibiotic solution. The anterolateral aspect is cleared, and traction sutures are placed to mobilize the lateral aspect upward and to provide tension on the vesical wall. The ureter is sized to ensure it will reach. The detrusor is incised to the level of the mucosa for a length of about 3 to 3.5 cm in a horizontal direction. Flaps of detrusor are elevated away from the mucosa, and a small disc of mucosa is excised at the distal aspect of the trough. The bladder will drain and the traction sutures keep the trough in position. The ureter is trimmed loosely to length and spatulated for 4 to 5 mm. An interrupted, mucosa-to-mucosa anastomosis is performed using a fine absorbable suture; a monofilament is preferred. The detrusor flaps are then brought over the ureter. No advancement stitch is used, but two stitches are placed through the detrusor and the adventitia of the terminal ureter to prevent eversion of the ureter. The detrusor is closed with interrupted absorbable suture.

If the bladder wall is particularly abnormal and thick, a longer tunnel is developed and the flaps are dissected back a bit further to provide a more robust antireflux tunnel and limit the risk of obstruction, because these are typically abnormally functioning bladders. Implanting the graft ureter into an augmented bladder poses further challenges, and it is preferable to perform the ureteroneocystostomy into the detrusor. On occasion, this has necessitated an intravesical approach through the augment to reach the detrusor, which may be impossible to mobilize effectively otherwise. If there is no detrusor available, anastomosis into a colonic or gastric segment is preferred. It would always be advisable to perform a nonrefluxing ureteroneocystostomy in these settings, because these patients are inevitably on intermittent catheterization and often colonized with bacteria.

The author no longer performs a routine open ureteroneocystostomy for transplant, but a modified Leadbetter-Politano procedure is an effective method. It does introduce a large cystotomy and bladder spasms. In the unusual setting in which this is considered appropriate, there is no specific need for stenting beyond the indications as described below.

Transplant-to-native ureteroureterostomy is performed routinely for pediatric renal transplantation in a few institutions. The results have been reported as acceptable (Lapointe et al, 2001; Gurkan et al, 2006), but this does not seem to be a common option, and, of course, depends upon the availability of a normal, nonrefluxing native ureter. This option is available as a salvage procedure in the setting of distal ureteral stenosis.

Stenting

The role of routine ureteral stenting in pediatric transplant is debated, but there are no data to demonstrate its routine utility (French et al, 2001; Simpson et al, 2006; Dharnidharka et al, 2008). It has not been the routine approach for the author, but there are situations in which ureteral stenting is appropriate. This would be a difficult implant, particularly in an abnormal bladder, or in a very damaged graft ureter. If a stent is to be used, a short double-J ureteral stent is placed and generally removed after 4 weeks. This obviously requires a cystoscopy. We have not used extraction strings for those children undergoing stented transplants.

Key Points: Transplant Ureteroneocystostomy

- Extravesical ureteroneocystostomy is the preferred ureteral anastomosis.
- Transplant-to-native ureteroureterostomy is an effective option.
- There are no data to support routine ureteral stenting at the time of transplantation.

COMPLICATIONS

This section deals with the urologic complications of pediatric renal transplantation. Those related to the graft directly, including vascular and rejection issues, are dealt with in Chapter 43. Table 136–1 presents a summary of recent reports of urologic complications in pediatric renal transplantation. The unique analysis of Khositseth and colleagues (2007), comparing the incidence of urologic complications in transplant recipients with a history of obstructive uropathy or reflux to those without that history, shows the increased risk of all urologic complications in patients with a prior history of uropathy. Special vigilance and a lower threshold for intervention are appropriate in this population.

Urine Leaks

Urine leaks are typically identified in the early postoperative period with increasing fluid from the wound drains. The fluid creatinine level can determine if this is a urine leak as opposed to lymphatic drainage. At first presentation, it is critical to assess all urinary drainage tubes, particularly the Foley catheter. If the catheter has been removed, it is often best to replace it. A transplant ultrasonogram is performed to determine

Table 136–1.

if there is hydronephrosis, although its absence does not rule out obstruction. If present, distal ureteral obstruction should be suspected, and consideration for a percutaneous nephrostomy should be entertained. The level of the leak must then be determined, and either a MAG3 scan (assuming adequate graft function) or a CT scan can be effective. A cystogram may be useful to identify a bladder leak from the site of the anastomosis.

The indications for intervention are clinically based, and if the leak is limited, an observational approach is reasonable. The author has seen leaks associated with massive urine outputs in smaller children simply due to a small bladder catheter. If a larger catheter may be placed, this may facilitate resolution. If there is significant urine leak and limited bladder drainage, exploration may be needed.

Exploration is to identify the cause and location of the leak and provide for repair. If the leak is bladder based, simple repair and drainage is effective, but if the leak is due to distal ureteral necrosis, some means of ureteral replacement is needed. Native ureter, either ipsilateral or even contralateral, may be useful if available. A psoas hitch or bladder flap may be needed if the native ureter is not present. These strategies are similar to those used for ureteral strictures. Careful stenting and drainage are essential (Fig. 136–2).

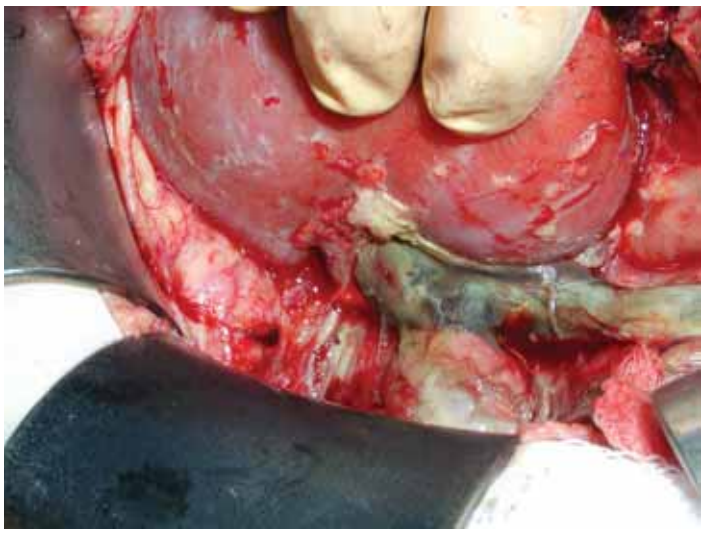

Figure 136–2. Ischemic loss of the entire renal pelvis and ureter in a cadaveric renal graft in a patient with a gastrocystoplasty. This patient presented with urine leak after a period of acute tubular necrosis. The graft was salvaged with an augment bladder flap to the lower calyces of the graft.

Infection

Urinary infection is a long-term and often delayed complication that largely reflects the status of bladder function, although this link is not proven (Herthelius and Oborn, 2007). Routine assessment of bladder emptying, hydronephrosis, and, occasionally, use of a voiding cystourethrogram will usually identify the cause. If the patient is on CIC and no specific correctable cause is present, a strategy of prevention by prophylactic antibiotics and bladder irrigation may be effective. Aggressive management of bladder dysfunction, which should have been identified pretransplant, is essential to preserve graft function. If VUR is present into the graft and infection with fever and altered renal function is present, correction of the reflux is warranted. Reflux in the absence of infection with normal bladder function may be observed with caution.

Reflux

Vesicoureteral reflux into the transplant is entirely distinct from routine reflux into an otherwise normal renal unit based upon the facts that this is a reimplanted ureter, that the risk to renal function of an episode of pyelonephritis is greater in a transplant, and that the patient is immunosuppressed (DeFoor et al, 2003; Coulthard and Keir, 2006). Routine evaluation for reflux after renal transplant has been the author's practice, even though not all cases were treated with surgery. Identification of this potential risk factor is useful for clinical decision making and ongoing risk assessment. If febrile UTIs occurred, the presence of transplant reflux justifies surgical correction with an open ureteral reimplantation (Hanevold et al, 1987). The risk of pyelonephritis in the graft is significant (Neuhaus et al, 1997; Ranchin et al, 2000; Barrero et al, 2007) and increases the potential for graft loss (Herthelius and Oborn, 2007) (Fig. 136–3). Identification of simultaneous bladder dysfunction is equally important (Casale et al, 2005), although this may not be correctable. In the setting of intermittent catheterization, any reflux should be corrected, because these bladders will be chronically colonized. Reflux in the absence of infection and bladder dysfunction may be observed, and attempts may be made to improve any suggestion of bladder dysfunction. There are no data to suggest that low-grade sterile VUR into a renal graft is harmful in children. Close observation

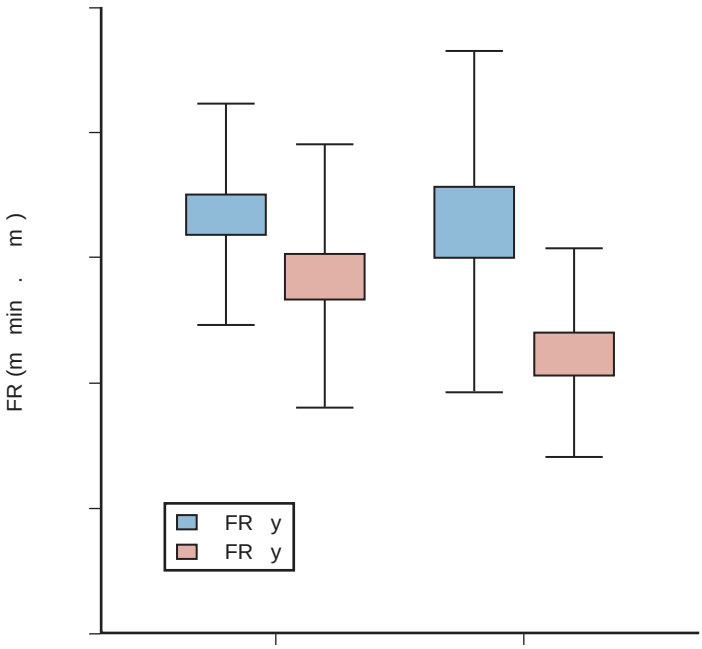

Figure 136–3. Graft function, measured as glomerular flow rate (GFR), at 1 and 4 years in children with less than or equal to one and greater than or equal to two urinary tract infections (UTI). (From Herthelius M, Oborn H. Urinary tract infections and bladder dysfunction after renal transplantation in children. J Urol 2007;177:1883–6.)

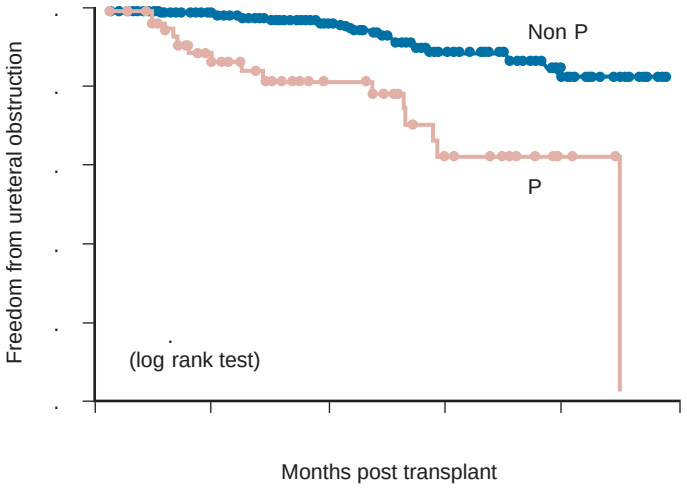

Figure 136–4. Obstruction-free survival in pediatric renal transplant patients with and without a history of posterior urethral valves (PUV). (From Smith KM, Windsperger A, Alanee S, et al. Risk factors and treatment success for ureteral obstruction after pediatric renal transplantation. J Urol 2010;183:317–22.)

for possible infection or deteriorating bladder function is warranted.

Surgical management of reflux into a transplanted ureter is never routine. The role of endoscopic therapy is limited, and the few reports available suggest limited benefit, with resolution rates of 50% to 80% (Kitchens et al, 2006; Williams et al, 2008). This may be an option for asymptomatic reflux, but in the face of an episode of febrile UTI, the most certain definitive intervention is justified. There are few data as to the relative efficacy of intravesical compared with extravesical methods (Krishnan et al, 2006), but the author's preference is intravesical, often using extravesical mobilization. A transtrigonal technique is effective if the contralateral native ureter can be avoided. Otherwise, an advancement or Politano-Leadbetter technique may be used. Ureteral stenting is advisable.

Hydronephrosis/Obstruction

A frequent urologic complication in pediatric renal transplant is hydronephrosis, and intervention for ureteral obstruction may be needed in as many as 8% of transplants (Shokeir et al, 2005; Smith et al, 2010). The presence of hydronephrosis necessitates careful evaluation and selective management to tailor appropriate treatment to the individual. The transplant kidney appears to be one of the rare situations in which obstruction may not be associated with hydronephrosis. This is uncommon and not well documented but can occur empirically. More commonly, obstruction is heralded by increasing renal dysfunction with a rising creatinine. Hydronephrosis is identified on ultrasonography or delayed drainage on MAG3 renal scan. More than half of obstructions in a recent series occurred within the first 100 days post-transplant (Smith et al, 2010). In the setting of normal prior bladder function, this pattern indicates ureteral obstruction until proven otherwise. If bladder dysfunction is known to be present, then both factors must be evaluated and managed, because obstruction is more frequent in patients with bladder dysfunction, particularly posterior urethral valves (Smith et al, 2010) (Fig. 136–4).

In the setting of a rising creatinine and hydronephrosis, obstruction and rejection may be intermingled. If the hydronephrosis is mild and there are other signs of rejection, the most efficient first step is biopsy. If there is no clinical suggestion of rejection, ureteral stenting, with or without a biopsy, is the best first step. Diagnostic studies for obstruction in the transplant setting are not clearly reliable given the associated risks, and the author has adopted the approach of stenting to assess the impact on renal function. It has been in this setting, albeit rarely, that an acutely failing transplant with minimal or no hydronephrosis and with no evidence of rejection has been stented with subsequent improvement in function. The more common situation is with moderate hydronephrosis and a rising creatinine with some rejection on biopsy. If the graft is not failing rapidly, initial medical treatment of the rejection is justified, with stenting being reserved for lack of improvement. Whether obstruction increases the risk of rejection is unproven but empirically suggested. In that light, having a low threshold for stenting, which can provide a definitive diagnosis of functionally significant obstruction, is essential.

The etiology of ureteral obstruction is usually in the distal ureter with stenosis at the reimplantation site, but it may be anywhere along the ureter. In a recent analysis, neither the method of ureteral implant nor use of stents was a contributing factor to obstruction. Bladder abnormalities, particularly due to posterior urethral valves, however, were a risk factor of post-transplant obstruction (Smith et al, 2010). Compression from a lymphocele or adenopathy from post-transplant lymphoproliferative disease (PTLD) are also possible causes (Dharnidharka et al, 2001; Buell et al, 2006). Definitive therapy is determined by the most likely etiology. Focal ureteral narrowing on retrograde imaging may be effectively treated with balloon dilation and

stenting for 4 to 6 weeks. Recognizing the risk posed to the graft due to obstruction, open definitive repair should not be delayed excessively (Smith et al, 2010). These procedures are never simple and may entail complex reconstruction using native ureter or bladder flaps (Kockelbergh et al, 1993). Avoiding use of nonurothelial segments, such as appendix, is advisable, although any of these methods may be needed. All of the principles of reoperative reconstruction must be adhered to in order to preserve well-vascularized functional tissues.

Bladder Dysfunction

Bladder dysfunction may produce infection but may also create an obstructive process that impairs renal graft function (Herthelius and Oborn, 2006, 2007; Van der Weide et al, 2006; Nahas et al, 2008). Discriminating this from ureteral obstruction may not be simple, and, on occasion, has necessitated sequential diagnostic drainage steps. If a bladder catheter can be placed easily, then continued drainage for 1 to 2 weeks with reassessment of creatinine can usually identify bladder dysfunction as the cause of graft dysfunction if the creatinine declines. If not, then combined stent and bladder drainage, followed by a recheck of the creatinine, is needed. It should be recognized that elements of bladder and ureteral dysfunction may contribute to graft failure. Both may need to be addressed. Treating bladder dysfunction involves measures to increase compliance, using anticholinergics as well as instituting or enhancing an intermittent catheterization program. Bladder augmentation may also be needed, although only after aggressive medical management has been tried. When intermittent catheterization per urethra is difficult, creation of a continent stoma may be needed. Identification of these potential risks to graft function is best accomplished prior to the transplant whenever possible.

Stones

Nephrolithiasis in a pediatric renal transplant is uncommon, occurring in up to 5% of patients (Khositseth et al, 2004), but potentially dangerous for long-term graft survival. With appropriate management, stones were not seen to increase the risk of graft loss, but were associated with more UTIs (Khositseth et al, 2004). There is a high incidence of bladder stones, approaching 50%, and several stones were due to retained suture material in the bladder (Lipke et al, 2004). Detection of an asymptomatic stone on routine surveillance should prompt attempts at removal as well as a search for cause. Stones associated with renal graft dysfunction due to obstruction or infection should be managed with urgent intervention to assure drainage and prompt removal. All conventional means of stone management are appropriate in a renal graft but should be modulated by recognition of the potential balance of risk to the graft as well as the relative efficacy of the various modalities. Selection of the modality that will have the highest likelihood of success with a single intervention is likely to be the best option in the long term, even if this incurs more complexity. A lower pole stone may be best managed with a percutaneous approach or ureteroscopic removal rather than ESWL, given the lower success of clearance of lower pole stones. These decisions should be individualized based upon clinical presentation, location and size of the stone(s), and renal functional status.

SUMMARY

Preparation and management of the pediatric transplant patient, particularly with an underlying urologic condition, requires a thorough understanding of the patterns of bladder dysfunction and clear strategies for evaluation and treatment prior to transplant. Anticipating the needs and constraints of the transplant procedure and being involved in appropriate cases permits a smoother procedure and ongoing continuity of care by the pediatric urologist. Post-transplant monitoring should be aggressively expectant in order to identify pathologic processes before they have damaged renal graft function irreversibly. This takes a high index of suspicion and a clear sense of the patient at risk for these processes. A multidisciplinary collaboration of the pediatric nephrologist, urologist, and the transplant surgical team is critical to maximizing patient and graft survival.

Key Points: Complications

- Common urologic complications for pediatric renal transplant include ureteral stenosis (6%), urinary leaks (3%), stones (2%), and clinically significant reflux (2%).
- Urine leaks are typically identified in the early postoperative period with increasing fluid from the wound drains.
- Urinary infection is a long-term and often delayed complication that largely reflects the status of bladder function.
- Vesicoureteral reflux into the transplant is entirely distinct from routine reflux, because the risk to renal function of acute pyelonephritis is greater.
- In the setting of a rising creatinine level and hydronephrosis, obstruction and rejection may be intermingled.
- The etiology of ureteral obstruction is usually in the distal ureter with stenosis at the reimplantation site.
- Bladder dysfunction may produce infection but may also create an obstructive process that impairs renal graft function.
- Nephrolithiasis is uncommon, but may occur in up to 5% of patients.

Neuroblastoma
Genitourinary Rhabdomyosarcoma
Wilms Tumor
Other Renal Tumors
Testicular Tumors

NEUROBLASTOMA

Neuroblastoma is the most common extracranial solid tumor of childhood. Regrettably over half of the children present with metastatic disease. Neuroblastoma is known to arise from cells of the neural crest that form the adrenal medulla and sympathetic ganglia. Tumors may occur anywhere along the sympathetic chain within the neck, thorax, retroperitoneum, or pelvis, or in the adrenal gland. Seventy-five percent arise in the retroperitoneum, 50% in the adrenal, and 25% in the paravertebral ganglia. The variety of locations where these tumors arise and the spectrum of their differentiation results in a wide range of clinical presentations and behaviors (Brodeur, 1991). These tumors can undergo spontaneous regression (Brodeur, 1991), differentiate to benign neoplasms, or exhibit extremely malignant behavior.

Epidemiology and Genetics

Incidence

Neuroblastoma accounts for 8% to 10% of all childhood cancers. In the United States, the annual incidence is 10 cases per 1 million live births. It is the most common malignant tumor of infancy. A recent review of 3666 children enrolled in the cooperative group trials of the Pediatric Oncology Group and the Children's Cancer Group showed a median age at diagnosis of 19 months (Brodeur and Maris, 2006). Thirty-six percent were infants, 89% were younger than 5 years, and 98% were diagnosed by 10 years of age.

Genetics

There have been a number of familial cases reported, which are postulated to represent an autosomal dominant pattern of inheritance (Knudson and Strong, 1972a; Robertson et al, 1991). Although the median age at diagnosis of neuroblastoma is 19 months, in familial cases it is 9 months (Kushner et al, 1986). At least 20% of patients with familial neuroblastoma have bilateral adrenal or multifocal primary tumors, which are quite unusual in spontaneous cases. The risk for development of neuroblastoma in a sibling or offspring of a patient with neuroblastoma is less than 6% (Kushner et al, 1986). Linkage analysis in seven families with two or more first-degree relatives affected with neuroblastoma identified a single interval at chromosome 16p12-13 with consistent linkage (Maris et al, 2002). This suggests that a hereditary neuroblastoma predisposition gene may be located at this site and may explain the familial cases.

Constitutional Chromosome Abnormalities

Numerous karyotypic abnormalities have been found in neuroblastoma, and these are recognized to have prognostic significance. These changes occur in the form of chromosomal deletions, translocations, and cytogenetic evidence of gene amplification. Aneuploidy of the tumor DNA occurs in a significant number of cases and is a favorable prognostic indicator, whereas **amplification of the N-*MYC* oncogene seen in roughly 20% of primary tumors is an adverse prognostic indicator** (Look et al, 1991; Muraji et al, 1993). These findings have been so striking that neuroblastoma was the first tumor in which the intensity of chemotherapy for a patient was determined not only by the stage and histology of the tumor but by its "biologic markers," which were primarily chromosomal (Matthay et al, 1998).

Deletion of the short arm of chromosome 1 (1p) is found in 25% to 35% of neuroblastomas and is an adverse prognostic marker (Brodeur et al, 1992; Caron et al, 1996). The deletions are of various lengths, but, in a series of eight cases, a consensus deletion included the segment 1p36.1-2, suggesting that genetic information related to neuroblastoma tumorigenesis is located in that segment, although the involved genes have not been identified despite intensive investigation (Weith et al, 1989; Maris et al 2007). There have been reports of constitutional abnormalities involving the short arm of chromosome 1 (Laureys et al, 1990). Recently, it has been demonstrated that loss of heterozygosity (LOH) at 1p36 and Unb11q is independently associated with a worse outcome in patients with neuroblastoma (Attiyeh et al, 2005). (Unbalanced LOH implies LOH at markers on 11q with retention of 11p material, in contrast with "whole-chromosome" 11 LOH, where there is LOH at every marker along the chromosome.) Of note, while the 1p deletions are seen in conjunction

with advanced stage and N-*MYC* amplification, the 11q deletions are rarely seen in tumors with N-*MYC* amplification, but are associated with other high-risk features (Spitz et al, 2006). In future trials of the Children's Oncology Group (COG), treatment duration will be established by tumor 1p and 11q allelic status. An additional genetic abnormality, gain of one to three copies of 17q, often the result of translocation with chromosomes 1 or 11, has been demonstrated to correlate with more aggressive tumors (Bown et al, 1999). The break points vary, but the addition of a region from 17q22-qter is common suggesting that genes replicated in this region provide an advantage (Schleiermacher et al, 2004). In multivariate analysis, gain of 17q was the most powerful prognostic factor, followed by the presence of stage 4 disease and deletion of 1p.

Embryology and Spontaneous Regression

In 1963, Beckwith and Perrin coined the term in-situ neuroblastoma for small nodules of neuroblasts found incidentally within the adrenal gland that are histologically indistinguishable from neuroblastoma (Beckwith and Perrin, 1963). In-situ neuroblastoma was found during postmortem examination in 1 of 224 infants younger than 3 months. This represents an incidence of approximately 40 to 45 times greater than that of clinical tumors, suggesting that these small tumors regress spontaneously in most cases. Studies have shown subsequently that these neuroblastic nodules are found in all fetuses studied and generally regress (Ikeda et al, 1981). Neuroblastoma identified by prenatal ultrasonography (US) has also been shown to have a clinically favorable course (Ho et al, 1993).

The concept of in-situ neuroblastoma has been used to support the argument that many neuroblastomas arise and regress spontaneously. This concept has been further supported by population-based studies in Quebec province and in Japan, where prospective screening of infants for neuroblastoma has been performed based on urinary catecholamine excretion. An increased number of children were identified with low-stage neuroblastoma, a higher frequency than present clinically, but there was no decrease in the incidence of advanced-stage tumors seen at an older age (Hayashi et al, 1995; Woods et al, 1996). Evaluation of adrenal tumors resected in the neonatal period, whether cystic or solid, showed that in most the "biologic markers" were favorable (Kozakewich et al, 1998). The highly favorable outcome of infants diagnosed with neuroblastoma in the population screening studies first led to attempts at expectant observation. These trials demonstrated a high rate of spontaneous resolution (Yamamoto et al, 1998; Yoneda et al, 2001). Spontaneous regression of these perinatally identified lesions has also been demonstrated radiographically (Holgerson et al, 1996). A current prospective study by the Children's Oncology Group is evaluating infants with adrenal masses identified in the perinatal or neonatal period. Expectant observation for infants with small lesions with favorable catecholamine ratios is encouraged. These lesions are then followed closely by serial ultrasound evaluations. The goal of this protocol is to document that expectant observation in these small stage I lesions in infants is safe and appropriate, as has been suggested by smaller retrospective studies.

Pathology

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma display a histologic spectrum of maturation and differentiation (Fig. 137–1). A grading classification of neuroblastoma, introduced in 1984 by Shimada and subsequently modified by him and others as the International Neuroblastoma Pathology Classification in 1999, has helped to define risk-based subtypes of ganglioneuroblastoma and neuroblastoma (Shimada et al, 1984, 1999a, 1999b). This revised system has been demonstrated to add independent prognostic information beyond the contribution of age that is contained in the system (Sano et al, 2006). Ganglioneuroma is a histologically benign, fully differentiated counterpart of neuroblastoma. It is unclear whether ganglioneuroma arises de novo or by maturation of a preexisting neuroblastoma or ganglioneuroblastoma. Metastatic lesions from neuroblastoma have been observed to develop the histology of mature ganglioneuroma, supporting the latter theory (Hayes et al, 1989).

The Shimada classification is an age-linked histopathologic classification. One of its important aspects is determining whether the tumor is stroma poor or stroma rich. Patients with stroma-poor

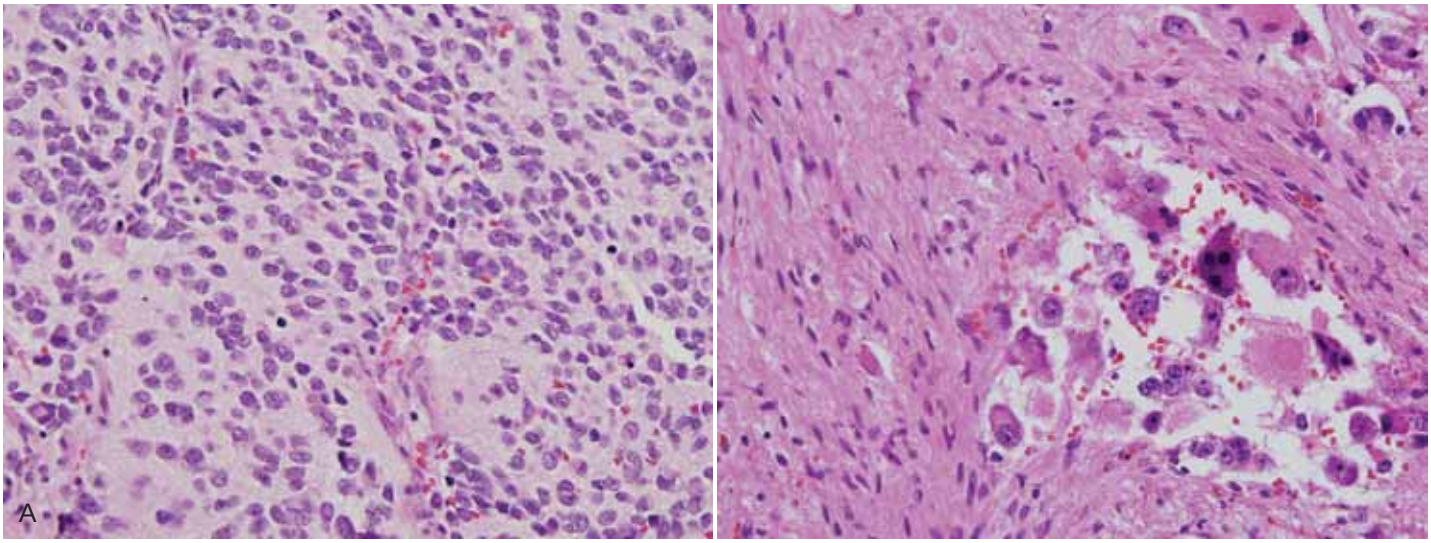

Figure 137–1. **A,** Poorly differentiated neuroblastoma with a minimal-to-moderate amount of neuropil. **B,** Ganglioneuroblastoma with more than 50% of surface area occupied by Schwannian stroma on left. Lobule contains ganglion cells, immature ganglion cells and poorly differentiated neuroblasts; only minimal neuropil is present within lobule. (Courtesy of Dr. Harry Kozakewich.)

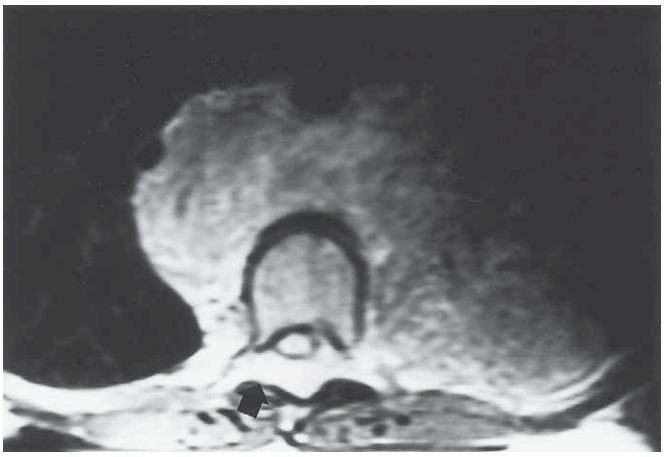

Figure 137–2. MRI of child with thoracic ganglioneuroma extending into the spinal canal *(arrow)*.

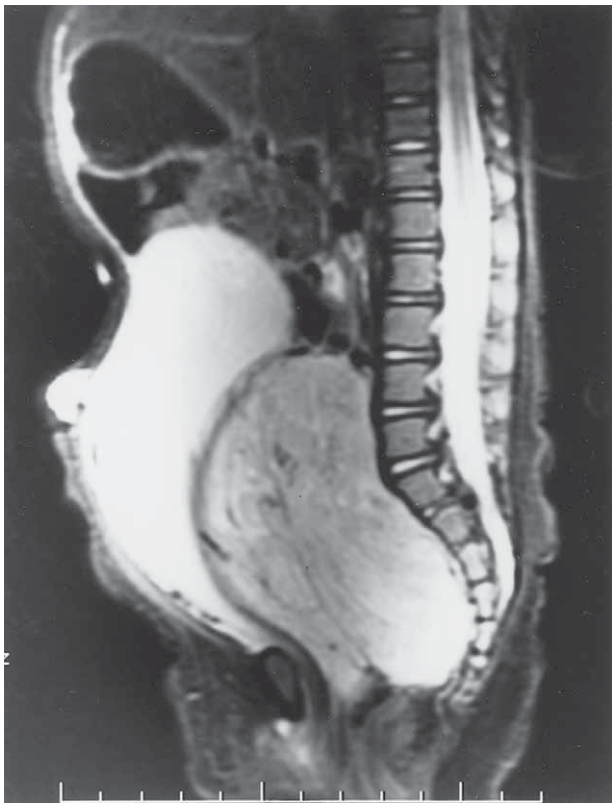

Figure 137–3. MRI demonstrating compression of bowel and bladder by a pelvic neuroblastoma.

tumors with unfavorable histopathologic features have a very poor prognosis (less than 10% survival) (Shimada et al, 1984). Stroma-rich tumors can be separated into three subgroups: nodular, intermixed, and well differentiated. Tumors in the latter two categories more closely resemble ganglioneuroblastoma or immature ganglioneuroma and carry a higher rate of survival. The stroma-poor tumors can be divided into favorable and unfavorable subgroups based on the patient's age at diagnosis, the degree of histologic maturation, and the mitotic rate. When compared with other clinical features, these histologic patterns were independently predictive of outcome (Shimada et al, 1984).

In contrast to neuroblastomas, ganglioneuromas are most often diagnosed in older children and are usually located in the posterior mediastinum and retroperitoneum, with only a small number arising in the adrenal glands (Enzinger and Weiss, 1988). Ganglioneuromas often grow to a very large size before they cause symptoms as a result of compression of adjacent structures or extension into the spinal canal (Benjamin et al, 1972) (Fig. 137–2).

Clinical Presentation and Pattern of Spread

The clinical manifestations of neuroblastoma vary widely. Most children present with abdominal pain or a palpable mass, but others are identified due to manifestations of their metastatic disease, including bone or joint pain and periorbital ecchymosis. Thoracic lesions may produce respiratory symptoms of cough or dyspnea. Direct extension of the tumor into the spinal canal may produce neurologic deficits as a result of cord compression.

Most primary tumors arise within the abdomen (65%); the frequency of adrenal tumors is slightly higher in children than in infants. Physical examination often reveals a fixed, hard abdominal mass. Pelvic neuroblastoma arising from the organ of Zuckerkandl accounts for 4% of tumors (Haase et al, 1995). Extrinsic compression of the bowel and bladder can produce symptoms of urinary retention and constipation (Fig. 137–3).

Metastases are present in 70% of patients with neuroblastoma at diagnosis and can be responsible for a variety of the clinical signs and symptoms at presentation. A number of unique paraneoplastic syndromes have been associated with both localized and disseminated neuroblastoma. Symptoms produced by catecholamine release may mimic those seen in pheochromocytoma: paroxysmal hypertension, palpitations, flushing, and headache. Secretion of vasoactive intestinal peptide (VIP) by the tumor can produce severe watery diarrhea and hypokalemia (Cooney et al, 1982). Another unusual presentation of neuroblastoma is acute myoclonic encephalopathy, in which patients develop myoclonus, rapid multidirectional eye movements (opsoclonus), and ataxia. It is thought to result from an interaction of antibodies produced against the neuroblastoma to normal neural tissues (Farrelly et al, 1984; Connolly et al, 1997). Although this syndrome is associated with a favorable outcome from an oncologic perspective (Altman and Baehner, 1976), prolonged neurologic impairment, including learning disabilities and developmental delay, is the rule in 70% to 80% of these children, and symptomatic therapy is often required (Russo et al, 1997; Rudnick et al 2001; Mitchel et al 2002). Adrenocorticotropic hormone (ACTH) or steroids are the basis of most therapy, but other treatments include high-dose intravenous gammaglobulin and cyclophosphamide. A current protocol of the Children's Oncology Group is evaluating the efficacy of intravenous gamma globulin and corticosteroids in the treatment of these children.

Diagnosis

Laboratory Evaluation

When sensitive techniques are used, increased levels of urinary metabolites of catecholamines, vanillylmandelic acid (VMA) and homovanillic acid (HVA), are found in 90% to 95% of patients (Williams and Greer, 1963). Therapy with various modalities produces a reduction in catecholamine metabolite excretion in most patients (Gerson and Koop, 1974). These metabolites can be monitored to detect tumor relapse and response to therapy.

Anemia is noted in children with widespread bone marrow involvement. Studies suggest that marrow biopsies add substantially to the detection of marrow involvement by tumor, compared with marrow aspirates alone (Franklin and Pritchard, 1983). It is recommended that two marrow aspirates and two biopsies be performed. In the future, neuroblastoma-specific immunocytology of marrow aspirates may obviate the need for marrow biopsies in most patients (Hsiao et al, 1990).

Imaging

Imaging studies play an important role in the evaluation of a child with neuroblastoma. **Plain radiographs may demonstrate a calcified abdominal or posterior mediastinal mass.** Computed tomography (CT) and magnetic resonance imaging (MRI) provide more information about the local extent of the primary tumors. Invasion of the renal parenchyma is not common, but it can be detected radiographically by CT (Albregts et al, 1994). MRI has advantages over CT in the evaluation of intraspinal tumor extension (see Fig. 137–2) and in demonstrating the relationship between the major vessels and the tumor (Azizkhan and Haase, 1993) (Fig. 137–4). **The finding of intratumoral calcifications, vascular encasement, or both on preoperative computed tomography may help distinguish neuroblastoma from Wilms tumor** (Dickson et al, 2008). Current Children's Oncology Group protocols require both a radionuclide bone scan and meta-iodobenzylguanidine (MIBG) scans for staging, but no longer require the classic skeletal survey. MIBG scans use ^{131}I-MIBG (Geatti et al, 1985), which is taken up by the adrenergic secretory vesicles of the tumor cells in both primary and metastatic sites. MIBG scintigraphy can determine the extent of disease and detect tumor recurrence after completion of therapy (Geatti et al, 1985). Recently, ^{131}I-MIBG has been shown to be more sensitive than either ^{131}I-MIBG or bone scans in detecting tumor relapse (Kushner et al, 2009). Osseous metastatic lesions occur most commonly in the long bones and skull.

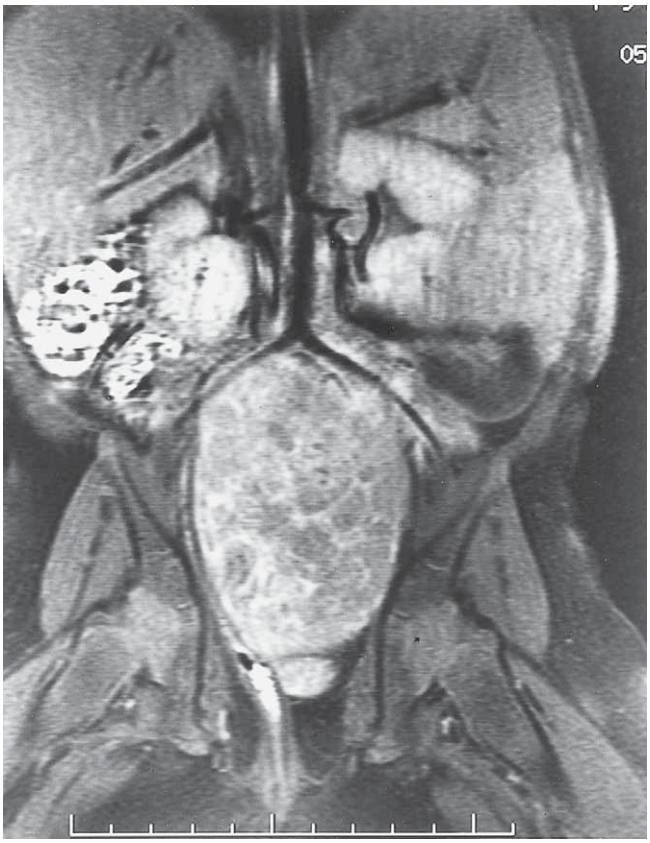

Figure 137–4. MRI of pelvic neuroblastoma. The bifurcation of the aorta and iliac vessels are well delineated, showing the relationship to the mass.

Screening

Mass population screening for neuroblastoma has been widely used in Japan for more than 20 years (Nishi et al, 1987). The goal of screening programs is to detect disease at an earlier stage and to decrease the number of older children with advanced-stage disease, thereby improving survival. In fact, the children diagnosed as a result of screening studies have had almost uniformly favorable survival (>97%) (Suita, 2002). An increased number of infants younger than 1 year of age have been diagnosed through the mass screening program (Ishimoto et al, 1990), and most of these patients have lower-stage tumors (Sawada, 1992). Before mass screening started, 20% of neuroblastoma cases were diagnosed before 1 year of age, compared with 55% after its implementation. However, the number of children older than 1 year of age diagnosed with advanced-stage disease has not decreased. These results suggested that the aggressive advanced-stage tumors in older children did not arise from the low-risk tumors seen in the infants less than 1 year of age.

There are biologic differences between tumors diagnosed by screening and those detected clinically (Hayashi et al, 1992). In one review of 48 cases discovered by screening, no tumors were observed to have amplified N-*MYC* oncogene expression (Ishimoto et al, 1991), and in a second review of 20 infants, only one who did poorly had amplification (Hase et al, 2002). Furthermore, 80% had a diploid chromosome pattern, which is also associated with a favorable prognosis. On follow-up, all 48 patients were still alive without tumor. In another series of 357 patients whose tumors were diagnosed by mass screening, the overall survival rate was 97% (Sawada, 1992). Given the favorable biologic characteristics of tumors discovered by screening, it is possible that many would spontaneously resolve without therapy, particularly given the increased incidence of neuroblastomas seen in the screened population.

Two large prospective population based studies were conducted in the Province of Quebec and in Germany. These studies demonstrated that urine screening at various ages was successful in identification of neuroblastoma, but there was no decrease in the occurrence of neuroblastoma in older children and its subsequent mortality (Schilling et al, 2002; Woods et al, 2002).

Staging

Staging of neuroblastoma is an important aspect of management. **The stage of the disease is a significant prognostic variable that determines adjuvant therapy.** The International Neuroblastoma Staging System (INSS) is based on clinical, radiographic, and surgical evaluation of children with neuroblastoma (Brodeur et al, 1993) (Table 137–1). Earlier staging systems provided generally comparable results in terms of distinguishing low-stage, good-prognosis disease from high-stage, poor-prognosis disease. Use of a uniform international system, however, makes comparison of results from various studies much easier to compare. The biggest differences arise when the various systems are applied to those with intermediate-stage disease. It is in this cohort of children where use of the Risk Group Classification, which

combines pathologic findings, stage, and several of the biologic markers, best defines the child's risk for progressive disease (Table 137–2) (Katzenstein and Cohn, 1998). Although the classification appears complex, it provides the most accurate assessment of how intense the chemotherapy and radiotherapy must be to cure the child.

Table 137–1.

International Neuroblastoma Staging System

STAGE	DEFINITION
1	Localized tumor with complete gross excision, with or without microscopic residual disease; representative ipsilateral lymph nodes negative for tumor microscopically (nodes attached to and removed with the primary tumor may be positive).
2A	Localized tumor with incomplete gross excision; representative ipsilateral nonadherent lymph nodes negative for tumor microscopically.
2B	Localized tumor with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumor; enlarged contralateral lymph nodes must be negative microscopically.
3	Unresectable unilateral tumor infiltrating across the midline,* with or without regional lymph node involvement; or localized unilateral tumor with contralateral regional lymph node involvement; or midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement.
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs.
4S	Localized primary tumor (as defined for stage 1, 2A, or 2B), with dissemination limited to skin, liver, and/or bone marrow (less than 10% tumor) in infants less than 1 year of age.

*The midline is defined as the vertebral column. Tumors originating on one side and crossing the midline must infiltrate to or beyond the opposite side of the vertebral column.

A recent effort has been made to identify, preoperatively, those tumors that are resectable without significant surgical risks. The Localized Neuroblastoma European Study Group (LNESG) defined the radiographic criteria associated with higher surgical morbidity. They validated that their presence was associated with a lower rate of complete resection and a greater risk of surgical complications (Cecchetto et al, 2005). This finding has been confirmed by others (Simon et al, 2008).

Prognostic Factors

Many variables affect the prognosis of neuroblastoma. In addition to the clinical features, there are now many biologic studies that can be used to stratify patients for treatment.

Clinical Variables

Age remains an important indicator of outcome, as originally reported by Breslow (Breslow and McCann, 1971). **Children age 1 year or younger have a better survival than older children** (Nitschke et al, 1988). **This may be attributed to more favorable biologic parameters in tumors diagnosed at this age.** Recent retrospective reviews have suggested that age is a truly more of a "continuous" prognostic variable and that a cutoff of 460 days maximized the outcome difference between the younger and older patients (London et al, 2005). Teenagers and adults with neuroblastoma have a particularly indolent and relentless disease (Gaspar et al, 2003; Kushner et al, 2003). **The *site of origin* is of significance, with better survival noted for nonadrenal primary tumors** (Haase et al, 1995). Most children with thoracic neuroblastoma present at a younger age with localized disease and have improved survival even when corrected for age and stage (Adams et al, 1993). Tumors at this site are less likely to have N-*MYC* amplification and more likely to have a DNA index greater than 1.0, both favorable prognostic indicators (Morris et al, 1995).

Stage of the disease is a powerful independent prognostic indicator. Virtually all stage I patients with complete resection of the primary tumor survive. Stage II patients also have a favorable survival prospect, even though there may be incomplete excision (Matthay et al,

Table 137–2.

Risk Group Classification

RISK GROUP	INSS	AGE (DAYS)	N-*MYC*	DNA INDEX	SHIMADA HISTOPATHOLOGY
Low	1	Any	Any	Any	Any
	2A, 2B	<365	Any	Any	Any
	2A, 2B	≥365	Nonamplified	Any	Any
	2A, 2B	≥365	Amplified	Any	Favorable
	4S	<365	Nonamplified	>1.0	Favorable
Intermediate	3	<365	Nonamplified	Any	Any
	3	≥365	Nonamplified	Any	Favorable
	4	<365	Nonamplified	Any	Any
	4S	<365	Nonamplified	1.0	Favorable
	4S	<365	Nonamplified	Any	Unfavorable
High	2A, 2B	≥365	Amplified	Any	Unfavorable
	3	<365	Amplified	Any	Any
	3	≥365	Nonamplified	Any	Unfavorable
	3	≥365	Amplified	Any	Any
	4	<365	Amplified	Any	Any
	4	≥365	Any	Any	Any
	4S	<365	Amplified	Any	Any

INSS, International Neuroblastoma Staging System.

1989). Children with advanced regional disease, stages III or I, fare less well and require more intensive treatment. The proportion of patients presenting with localized, regional, or metastatic disease is age dependent (Nitschke et al, 1988). The overall prognosis for stages I, II, or IV-S has a survival range of 75% and 90%, whereas those children with stage IV disease have a 2-year disease-free survival range of 19% to 30% despite intensive therapy, including bone marrow transplantation. The outcome for infants younger than 1 year of age is substantially better than for older patients with the same stage of disease.

Stage IV-S (S meaning special) is a distinct category referring to infants with small primary tumors and liver, skin, and bone marrow metastases without radiographic evidence of bone metastases. It was first proposed by Evans and colleagues in 1971. This group of patients has a good prognosis, with overall survival ranging from 80% to 88%. The INSS criteria later restricted this stage to children with less than 10% bone marrow involvement (Brodeur et al, 1993). This stage accounts for 7% to 10% of all cases of neuroblastoma. Many of these tumors undergo spontaneous regression (Evans et al 1987; Haas et al, 1990). In general, the tumors in children with stage IV-S neuroblastoma have favorable prognostic findings not typically seen in children with stage IV disease (Hachitanda et al, 1991; Nickerson et al, 2000). Poor outcome in stage IV-S patients is associated with elevated serum neuron-specific enolase (>100 nmol/mL), ferritin (>280 ng/mL), urinary dopamine levels (>2500 nmol/mmol creatinine), as well as N-*MYC* amplication and chromosome 1p deletion (Schleiermacher et al, 2003). Most deaths in this group are in infants under 2 months of age with extensive abdominal involvement and with respiratory compromise or disseminated intravascular coagulation (Nickerson et al, 2000).

Biologic Variables

The presence of homogeneously staining regions and double-minute chromosomes was noted in approximately one third of neuroblastoma tumors. These abnormalities are cytogenic manifestations of gene amplification, and it was subsequently found that the N-*MYC* oncogene was mapped to these regions. The association of N-*MYC* amplification with the pathogenesis of neuroblastoma is unclear, but N-*MYC* amplification is almost always present at the time of diagnosis (Brodeur, 1991). **Seeger and colleagues** (1985, 1988) **showed that N-*MYC* amplification is associated with rapid tumor progression and a poor prognosis. Amplification is found in 5% to 10% of patients with low-stage or stage IV-S** (Hachitanda et al, 1991) **but in 30% to 40% of those with advanced-stage disease** (Brodeur and Fong, 1989; Brodeur, 1990). **The poor prognosis associated with N-*MYC* amplification is independent of patient age or stage of disease at presentation** (Iehara et al, 2006). However, not all patients with a poor outcome have N-*MYC* amplification. Many advanced-stage tumors lack N-*MYC* at diagnosis, and recurrence or progression of disease develops in most of these patients.

DNA content of tumor cells and ploidy number has been reported to have prognostic value in patients with neuroblastoma (Cohn et al, 1990). Studies of DNA content measured by flow cytometry showed that a "hyperdiploid" karyotype (or increased DNA content) was associated with a favorable outcome (Look et al, 1984; Kusafuka et al, 1994). DNA diploidy and tetraploidy were associated with decreased survival. A recent review of 2660 children with localized neuroblastoma registered with the International Neuroblastoma Risk Group database evaluated tumor ploidy in children with N-*MYC*–amplified tumors (Bagatell et al, 2009). They reported an improved prognosis in children with hyperdiploid tumors compared to diploid tumors. This could be used to identify children for reduction in therapy.

Deletions of the short arm of chromosome 1 have been found in 70% to 80% of the near-diploid tumors that have been karyotyped (Brodeur and Fong, 1989; Brodeur, 1990). Preliminary studies suggest a correlation between 1p deletion and poor survival (Brodeur and Fong, 1989; Hayashi et al, 1989). Because there is an association between N-*MYC* amplification and 1p deletion, it remains to be determined whether this finding has independent prognostic significance.

Children currently treated on protocols of the COG are assigned to a risk group that is determined by age, stage of disease, N-*MYC* status, histologic grade, and DNA ploidy (Katzenstein et al, 1998) (see Table 137–2). Other factors that have been demonstrated to have prognostic significance, although they are often associated with these genetic abnormalities, include expression of the gene encoding the high-affinity nerve growth factor receptor (termed *TRKA* proto-oncogene) and the low-affinity nerve growth factor receptor (Tanaka et al, 1995). Both are favorable prognostic predictors and are inversely related to amplification of N-*MYC* oncogene (Nakagawara et al, 1993). Lack of expression of CD44 glycoprotein on the tumor cell surface and increased levels of serum ferritin, serum neuron-specific enolase, and serum lactate dehydrogenase are all adverse prognostic factors (Chan et al, 1991; Silber et al, 1991). They have not, however, been shown by multivariate analysis to be independently predictive from age, stage, ploidy, and N-*MYC* status. Telomere length has also been described as a significant prognostic parameter, and in a cohort of high-risk patients, it was the sole significant parameter that identified a group of patients with a favorable prognosis (Ohali et al, 2006).

Treatment

The treatment modalities primarily used in the management of neuroblastoma are surgery, chemotherapy, and radiation therapy. The role of each in individual patients varies depending on tumor stage, age, and biologic prognostic factors. These can be used to stratify patients into favorable and unfavorable categories by risk group (see Table 137–2).

Surgery

The goals of surgery are to establish the diagnosis, stage the tumor, excise the tumor (if localized), and provide tissue for biologic studies. Resectability of the primary tumor should take into consideration tumor location, mobility, relationship to major vessels, and overall prognosis of the patient. Neoadjuvant chemotherapy, given the efficacy of modern agents, is very successful in reducing the size of primary tumors. Sacrifice of vital structures to achieve resection at diagnosis should be avoided, particularly in young children in whom prognosis is excellent.

Low-Risk Disease (Stages I, II, and IV-S). Children with stage I neuroblastoma have a disease-free survival rate of greater than 90% with surgical excision alone (O'Neill et al, 1985; Nitschke et al, 1988; DeBernardi et al, 1995). **Chemotherapy is indicated only in the event of recurrence unless the child has N-*MYC* amplification and unfavorable histology.** The Pediatric Oncology Group reviewed 101 children with localized neuroblastoma who had complete gross excision of the primary tumor (Nitschke et al, 1988). Nine patients experienced relapse, but six were salvaged with chemotherapy.

Radiation therapy has no role in this subset of patients. With current use of the risk factor grading, those children with recurrence in the past may be identified now as the small number with adverse biologic markers. In a comparable study from the Children's Cancer Group, 374 stage I and II patients were treated primarily by resection (Perez et al, 2000). Event-free survival (EFS) and overall survival (OS) for stage I patients were 93% ± 3% and 99% ± 1%, respectively, compared with 81% ± 4% and 98% ± 2% for stage II patients, respectively. Supplemental treatment was required in only 10% of stage I and 20% of stage II patients, and excellent overall survival was achieved in the stage II patients. N-*MYC* amplification, unfavorable histology, age greater than 2 years, and positive lymph nodes predicted a lower overall survival.

Radical resection resulting in removal of normal organs, particularly the kidney, is not justified in this group of patients. Radiation of the local tumor bed has been advocated for treatment of residual disease in stage II cases. However, a review of 156 patients with stage II neuroblastoma found a 90%, 6-year, progression-free survival rate regardless of whether radiation therapy was used (Matthay et al, 1989). Therefore radiation should be reserved for those patients who fail to respond to either primary or secondary chemotherapy. In stage III disease, or in stage II with extensive tumor around the kidney and renal vessels, preoperative treatment with chemotherapy significantly decreases the risk of nephrectomy as a result of resection of the tumor (Shamberger et al, 1998) (Fig. 137–5).

The generally favorable behavior of IV-S disease has been explained with the understanding of biologic markers. The vast majority of these infants have tumors with entirely favorable markers, explaining their favorable behavior. However, a small percentage of these patients have adverse markers, and it is these children who have progressive disease that often is fatal. Resection of the primary is not mandatory (Nickerson et al, 1985; Evans et al, 1987). Although excellent survival has been reported after surgery (Martinez et al, 1992), information regarding histologic prognostic factors was not available for all of these patients. In a review of 110 infants with stage IV-S disease, the entire cohort had an estimated 3-year survival rate of 85% ± 4% (Katzenstein et al, 1998). This rate was significantly decreased to 68% ± 12% for infants whose tumors were diploid; to 44% ± 33% for those with N-*MYC* amplification; and to 33% ± 19% for those with unfavorable histology. Of note, there was no statistical difference in survival rate for infants who underwent complete resection of their primary tumor compared with those who had partial resection or only biopsy (Katzenstein et al, 1998; Nickerson et al, 2000; von Schweinitz et al, 2002). Patients with extensive metastatic disease and N-*MYC* amplification represent a high-risk group (Martinez et al, 1992). These patients should be considered for a more aggressive treatment with multimodal therapy, according to the risk group classification (see Table 137–2) (Schleiermacher et al, 2003). Those with favorable biologic markers and no symptoms can be followed with supportive care and limited chemotherapy, and hepatic radiation to infants with significant symptoms. Intensive chemotherapy is reserved for those with adverse markers, although these infants do poorly even with therapy.

High-Risk Disease (Stages III and IV). There is debate regarding the extent of surgical resection that is required for stage III lesions. A report from the Children's Cancer Group of 58 patients with stage III disease found that 8 of 12 patients with initial complete excision, and 12 of 14 with subsequent resection of the primary tumor, were long-term survivors (Haase et al, 1989). This result contrasts with only 9 of 32 survivors among patients in whom complete tumor excision could not be accomplished. Significant morbidity was reported in association with the surgical procedures, including 21 major complications. The Italian Cooperative Group for Neuroblastoma found that complete resection after chemotherapy of extensive unresectable neuroblastoma was associated with improved survival, compared with partial resection only (Garaventa et al, 1993). Similar results have been noted by others (LeTourneau et al, 1985; O'Neill et al, 1985; Powis et al, 1996). It has been suggested by some that even children with stage III disease do not need cytotoxic therapy if the biologic marker N-*MYC* amplification is not present (Kushner et al, 1996). These results are not widely accepted, however, and confirmatory studies are required before this policy can be widely adopted.

Figure 137–5. MRI before and after chemotherapy, showing marked reduction in size of right suprarenal neuroblastoma. **A,** Before chemotherapy. **B,** After chemotherapy.

Children with bulky pelvic tumors generally do quite well even with limited residual disease (LeClair et al, 2004). Extensive surgery at this site has been associated with long-term neurologic sequelae; thus the extent of resection must be balanced against this morbidity (Cruccetti et al, 2000).

There is conflicting evidence for the role of extensive resection in stage IV disease between studies that support (LeTourneau et al, 1985; Haase et al, 1991; Tsuchida et al, 1992; LaQuaglia et al, 1994; Chamberlain et al, 1995; DeCou et al, 1995; Yokoyama et al, 1995; Kuroda et al, 2003; Adkins et al, 2004; LaQuaglia et al, 2004; Koh et al, 2005; McGregor et al, 2005) and those that refute that approach (Sitarz et al, 1983; Matsumura et al, 1988; Adams et al, 1993; Losty et al, 1993; Kiely, 1994; Kaneko et al, 1997; Castel et al, 2002; von Schweinitz et al, 2002). In a retrospective review, Kiely (1994) compared the results of radical tumor resection with those of more conventional surgery in patients with stage III and IV disease. Kiely found no difference in survival between 46 patients treated with radical surgical procedures and 34 patients treated with more conventional surgery. Shorter and colleagues (1995) also did not find any evidence that the extent of surgical resection had an impact on the survival of stage IV patients. In these nonrandomized studies, it has been difficult to determine whether improved survival in those with complete resection has been due to the more favorable intrinsic biology of the tumor allowing resection or truly due to the completeness of resection.

As the intensity of the therapy increases, including the use of autologous bone marrow transplantation and control of distant metastasis, the impact of maximal local control may become apparent. The combination of gross total resection and external beam irradiation has achieved local control in 84% to 90% of children (Wolden et al, 2000; Kushner et al, 2001). In another series of reports, intensive chemotherapy followed by double autologous bone marrow transplantation, aggressive surgical resection, and radiotherapy has achieved an overall survival of 56% and a local recurrence rate of only 2.6% (Marcus et al, 2003; von Allmen et al, 2005).

Usually the safest approach for advanced tumors is to defer resection until after initial chemotherapy (Berthold et al, 1989; Shamberger et al, 1991; Shochat, 1992; LaQuaglia et al, 1994; Black et al, 1996). **The tumors are smaller and firmer, with less risk of rupture and hemorrhage following chemotherapy, resulting in a decreased rate of complications, particularly nephrectomy** (Shamberger et al, 1998) (see Fig. 137–5). One specific complication that is encountered after resection of extensive tumor surrounding the celiac axis and the superior mesenteric artery is diarrhea (Kiely, 1994). It is thought to result from resection of the autonomic nerves to the gut found anterior to the aorta at the base of the superior mesenteric artery and the celiac axis (Rees et al, 1998). Preoperative chemotherapy does appear to increase the proportion of children able to achieve a complete resection (Adkins et al, 2004).

Surgery usually is performed 13 to 18 weeks after initiation of chemotherapy, allowing three to four courses of treatment (Azizkhan and Haase, 1993). Some tumors remain inoperable even after chemotherapy.

Infants under 1 year of age with extensive local disease or stage IV disease comprise a special subset of patients. They have historically fared much better than children greater than 1 year of age with comparable disease, but not as well as infants with stage IV-S disease. It is now recognized that the biologic markers can be used to identify which infants have high-risk disease and require intensive therapy and which will have intermediate-risk disease requiring less intensive therapy.

In a large cohort (134 infants), N-*MYC* amplification, serum ferritin, Shimada histopathologic classification, and bone marrow involvement by immunocytology were analyzed. Although each factor had prognostic significance by univariate analysis, only N-*MYC* was significant by multivariate analysis; the EFS for infants without N-*MYC* amplification was 93% ± 4% versus 10% ± 7% in those with amplification despite intensive therapy (Schmidt et al, 2000).

Recent trials in Europe evaluated these infants without N-*MYC* amplification and achieved excellent survival (OS of 97.6% at 2 years) without chemotherapy in those with primaries extending across the midline or a positive skeletal survey (DeBernardi et al, 2009). Infants with overt metastases to the skeleton, lung, and central nervous system (CNS) were treated with a minimum of four chemotherapy courses and achieved a 2-year OS of 95.6%.

Chemotherapy

A variety of multiagent treatment regimens have been developed to treat high-risk patients with neuroblastoma. The goal of this treatment intensification is better disease control. Although initial response rates are improving, with a prolonged time to progression of disease, relapse continues to be a major problem, and the 4-year overall survival rate in stage IV disease is 20% (Ikeda et al, 1989; Haase et al, 1991).

The dose intensification of chemotherapy needed for local tumor control results in significant myelosuppression, limiting the amount of therapy that can be given. This has prompted the use of autologous bone marrow transplantation after sublethal chemotherapy or total-body irradiation. The use of marrow-ablative chemoradiotherapy followed by autologous marrow reinfusion has resulted in complete remission in up to 50% of patients with recurrent stage IV disease (Moss et al, 1987; Seeger et al, 1991; Dinndorf et al, 1992; Mugishima et al, 1994; Matthay et al, 1995; Grupp et al, 2000). However, a significant problem is the risk for late relapse. The randomized clinical trial of the German Society of Paediatric Oncology and Hematology of high-risk neuroblastoma showed improved event-free survival at 3 years with myeloablative therapy and autologous stem cell rescue compared with maintenance chemotherapy (Berthold et al, 2005). These results were similar to those of the COG study (Matthay et al, 1999). Regrettably, the overall survival rates were not statistically different in either study at initial report. A recent update of the latter study reveals that the 5-year OS of the patients receiving the autologous bone marrow transplant was improved (Matthay et al, 2009).

The presence of bulky disease results in increased failure. Tumor debulking with surgery or radiation therapy is warranted before autologous bone marrow transplantation. There are many questions yet to be resolved about this modality of treatment. Toxicity of bone marrow transplantation can be lethal, and the long-term complications in patients with successful transplantation are unknown. However, these risks are acceptable given that long-term survival is difficult to achieve without such aggressive therapy.

New agents in phase I and II trials for relapsed neuroblastoma include temozolomide, irinotecan, and topotecan (Kushner et al, 2006; Rubie et al, 2006; Simon et al, 2007). As efficacy is established, they will be advanced into clinical trials for high-risk tumors with a goal to improve the overall outcome.

New Innovative Biologic Therapies

Because increasing the intensity of chemotherapy appears to have reached its limit with the use of double autologous bone

marrow transplantation, other routes of treatment must be identified. The use of biologic modifiers is being investigated (Villablanca et al, 1995). 13-cis-Retinoic acid produces differentiation of neuroblastoma in cell cultures. It was given for a 6-month period after cytotoxic therapy in children with advanced-stage disease and significantly decreased the frequency of relapse (Matthay et al, 1999). Long-term follow up has shown that the 5-year OS is improved with the use of 13-cis-retinoic acid in these children after transplant or intensive chemotherapy (Matthay et al, 2009). Other avenues of treatment in current phase I and phase II trials include vaccine and antibody therapy against the GD2 cell surface marker occurring in neuroblastoma. A new synthetic retinoid, fenretinide, which has produced apoptosis rather than differentiation in neuroblastoma cell lines, is also in early clinical trials.

Inhibition of angiogenesis is another appealing avenue of therapy in this very vascular tumor, particularly once there is minimal residual disease. Antiangiogenic therapy has proved successful in animal models, but has not yet been used clinically.

Another modality in the treatment of metastatic neuroblastoma is the use of ^{131}I-MIBG (Hutchinson et al, 1992). The finding that both the primary tumor and metastatic areas take up this radiotracer suggested the possibility that therapeutic doses can be delivered to the tumor. Preliminary analysis indicates that objective responses do occur in terms of reduction of tumor volume, even in previously heavily treated patients (Howard et al, 2005; Matthay et al, 2007). Significant myelosuppression is seen with dose escalation, however, and stem cell support is required.

Radiotherapy

Radiotherapy is effective for local control in neuroblastoma and risk of local relapse can be correlated with the biologic markers. Although irradiation has not provided a benefit in low-stage tumors, it has increased local control in children with advanced stage IV or bulky stage III tumors (Matthay et al, 1989; Castleberry 1991; Evans et al, 1996). A randomized control trial to evaluate the efficacy of local control between radiotherapy alone and surgery has not been performed. Doses of external beam irradiation used have ranged between 15 and 30 Gy, depending on the patient's age, location, and extent of residual disease.

Intraoperative radiation therapy has been used for patients with unresectable disease. This technique has the advantage of delivering a higher dose of radiation to the operative field while sparing normal adjacent tissues (Leavey et al, 1997). Although its use has been promoted, it has not been convincingly demonstrated to improve control when compared with external beam irradiation (Haas-Kogan et al, 2000).

Spinal Cord Compression

Extension of tumor into the spinal canal produces symptoms of spinal cord compression in up to 5% of patients presenting with neuroblastoma (DeBernardi et al, 2001), while up to 13% of patients have radiographic evidence of extension into the spinal canal (Plantaz et al, 1996). These children have been treated by decompressive laminectomy, radiotherapy, or chemotherapy. Neurologic outcome has been similar by all modalities and, regrettably, patients presenting with severe motor deficits generally recover little function (DeBernardi et al, 2001; Katzenstein et al, 2001). Because of the delayed complications of scoliosis after laminectomy, current recommendations are to initiate treatment with chemotherapy and reserve laminectomy for children with progressive neurologic deterioration (Katzenstein et al, 2001). Radiotherapy is now generally avoided, because of its adverse effect on growth of the spine.

Key Points: Neuroblastoma

- Neuroblastoma is the most common extracranial solid neoplasm in children.
- Children 1 year old or younger have a better survival rate than older children. This may be attributed to more favorable biologic parameters in tumors diagnosed at this age.
- Complete surgical resection is curative for low-stage disease.
- N-*MYC* amplification, found in 20% of patients with primary tumors, is associated with tumor progression. This poor prognosis is independent of patient age and tumor stage.

GENITOURINARY RHABDOMYOSARCOMA

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma in infants and children, with nearly 350 new cases in the United States each year. It is the third most common solid tumor in children after neuroblastoma and Wilms tumor. **Fifteen to 20 percent of all RMS arise from the genitourinary system** (Maurer et al, 1988; Crist et al, 2001). **The most common genitourinary sites are the prostate, bladder, and paratesticular; the vagina and uterus are relatively unusual sites. Survival rates vary with site; certain sites such as the vagina and paratesticular have a better prognosis than bladder/prostate primaries** (Rodary et al, 1988; Crist et al, 1990; Martelli et al, 1999; Arndt et al, 2001; Wiener et al, 2001; Ferrari et al, 2002; Meza et al, 2006). There is a bimodal age distribution with a peak incidence in the first 2 years of life and again at adolescence, but two thirds of cases occur in children under 6 years of age (LaQuaglia et al, 1994). The botryoid variants arising from the bladder and vagina are seen almost exclusively in young children.

Etiology, Epidemiology, and Genetics

Subgroups of children with a genetic predisposition to the development of RMS have been identified. The Li-Fraumeni syndrome associates childhood sarcomas with mothers who have an excess of premenopausal breast cancer and with siblings who have an increased risk of cancer (Li and Fraumeni, 1969). A mutation of the *TP53* tumor suppressor gene was found in the tumors in all patients with this syndrome (Malkin et al, 1990). An increased incidence of RMS has been found in association with neurofibromatosis (Sung et al, 2004).

The two major histologic subtypes of RMS, embryonal and alveolar, have been noted to have distinct cytogenetic abnormalities. Alveolar RMS is associated with a translocation between chromosomes 1 or 2 and 13, resulting in the formation of a chimeric protein (Parham, 1994). PAX3, a DNA-binding protein on chromosome 2, or PAX7, a DNA-binding protein and on chromosome 1, is fused to the FKHR gene on chromosome 13 (Anderson et al, 2001). About 25% of cases lack these translocations. These genes may be involved in the pathogenesis of alveolar rhabdomyosarcoma and are prognostic factors as well. Expression of PAX3-FKHR is an adverse prognostic factor for children presenting with metastatic alveolar RMS (Sorensen et al, 2002). In addition, patients with the t(1;13) translocation, *PAX7-FKHR* fusion, are often younger and have a better prognosis than do their counterparts with the t(2;13), *PAX3-FKHR* fusion abnormality (Kelly et al, 1997; Anderson et al, 2001; Sorensen et al, 2002).

Embryonal RMS demonstrates loss of heterozygosity (LOH) on chromosome 11p15.5 at a different location than the *WT2* gene implicated in the development of some Wilms tumors (Douglass et al, 1987; Scrable et al, 1990). This region is the location of the *IGF-2* gene. IGF-2 overexpression has been documented in alveolar and embryonal rhabdomyosarcoma (Leiroth et al, 1995). IGF-2 is a growth factor that can stimulate the growth of RMS tumor cells, and antibodies directed against IGF-2 can inhibit tumor growth (El-Badry et al, 1990). Amplification of the transcription factor N-*MYC* has been noted in neuroblastoma and in RMS (Williamson et al, 2005). Overexpression of N-*MYC* was associated with an adverse outcome in alveolar RMS.

Pathology and Patterns of Spread

The Intergroup Rhabdomyosarcoma Study Group (IRSG) has developed a pathology classification recognizing three major histologic groups that have prognostic significance (Asmar et al, 1994). ***Embryonal* RMS is the most common subtype of RMS and accounts for most of the genitourinary tumors** (Maurer et al, 1977; Newton et al, 1988). **This may occur in solid form arising in muscle groups, such as the trunk and extremities, or as the so-called sarcoma botryoides, a polypoid variety that occurs in hollow organs or body cavities, such as the bladder or vagina.** Embryonal RMS may have variable cell types with small, round cells with hyperchromatic nuclei and large, polygonal-shaped cells with abundant eosinophilic cytoplasm (Fig. 137–6). **There is a spindle cell, or leiomyomatous, variant seen frequently in the paratesticular region. The botryoid and spindle cell variants of embryonal RMS are associated with an excellent survival. The second most common form is *alveolar*, comprising 15% to 20% of cases. Alveolar RMS occurs more commonly in the trunk and extremities than in genitourinary sites and has a worse prognosis than embryonal tumors** (Hays et al, 1983; Newton et al, 1988; Crist et al, 2001; Stevens et al, 2005). **Alveolar RMS also has a higher rate of local recurrence and spread to regional lymph nodes, bone marrow, and distant sites.** The third category consists of *undifferentiated* tumors that also fare poorly.

The diagnosis of rhabdomyosarcoma can occasionally be difficult with conventional histologic techniques. In such cases, histology may be complemented by other studies, including electron microscopy, cytogenetics, DNA flow cytometry, and immunochemistry (Shapiro et al, 1991; Davicioni et al, 2009). Immunohistochemical staining has been shown to be an effective adjunct for the diagnosis of alveolar RMS (Dias et al, 2000). Genes of the MyoD family are important in the differentiation of skeletal muscle (Parham, 1994). MyoD is important in the switch from proliferation to differentiation, and loss of this control and excess proliferation could lead to RMS (Sebire and Malone, 2003). Fetal myoblasts express MyoD and myogenin, another myogenic regulatory gene, whereas adult myoblasts do not. MyoD and myogenin are expressed in RMS and is believed to represent failure of differentiation. **Myogenin has been proven to be a useful marker of alveolar RMS. Alveolar RMS demonstrates high levels of staining, whereas embyronal RMS is either negative or has a low level of staining** (Dias et al, 2000). **Diffuse myogenin expression by immunohistochemistry has been shown to be predictive of decreased survival independent of tumor stage, site or histology** (Heerema-McKenney et al, 2008).

Clinical Grouping and Staging

Tumor stage at diagnosis is most predictive of clinical outcome, because patients with localized disease have a better prognosis (Lawrence et al, 1987). The likelihood of regional lymph node extension varies with site of the primary tumor, approaching 50% for older boys with paratesticular tumors. The most common site of metastatic spread of RMS is the lungs. The clinical group staging system was developed by the IRSG in 1972 (Table 137–3). One of the difficulties inherent in this system is that the group is dependent to a large extent on the completeness of surgical excision. As the treatment of RMS has evolved, more patients undergo biopsy only at the initial surgical procedure, leaving gross residual disease. This results in the shifting of more patients from group I to group III. Biologically equivalent tumors could end up in different categories, depending on the aggressiveness of the initial surgical resection.

Table 137–3.

Intergroup Rhabdomyosarcoma Study Group Clinical Grouping Classification

Group I	Localized disease completely resected Confined to organ of origin Contiguous involvement
Group II	Total gross resection with evidence of regional spread Microscopic residual Positive nodes but no microscopic residual Positive nodes but microscopic residual in nodes or margins
Group III	Incomplete resection with gross residual disease After biopsy only After gross or major resection of the primary (>50%)
Group IV	Distant metastasis at diagnosis (lung, liver, bones, bone marrow, brain, and nonregional nodes) Positive cytology in cerebrospinal fluid, pleural or peritoneal fluid, or implants on pleural or peritoneal surfaces are regarded as stage IV

A site-specific TNM staging system was devised by the IRSG for IRS-IV (Table 137–4) (Lawrence et al, 1997). The TNM system segregates patients by favorable and unfavorable sites. Favorable GU sites include the paratesticular and the vulvar-vaginal-uterine ones. Unfavorable GU sites are the bladder and prostate. Presence of distant metastases at diagnosis, involved regional lymph nodes, and large primary tumors (>5 cm) at unfavorable sites are relatively unfavorable prognostic signs (Lawrence et al, 1997). A recent report has suggested that tumor size should be correlated with body surface area (Ferrari et al, 2009). They found that for a given tumor size, the mortality increased from the larger to the smaller body surface area.

IRS-V and current COG rhabdomyosarcoma studies group patients into low-, intermediate-, and high-risk groups. This system combines both the clinical grouping and TNM systems. The system attempts to group patients based on the various prognostic variables known to predict outcome in patients with RMS (Table 137–5). Age is also an independent prognostic factor in children with RMS (Joshi et al, 2004; Meza et al, 2006; Oberlin et al, 2008). **Patients less than 1 year of age and greater than 10 years enrolled in IRS-III and IRS-IV had decreased survival. This poor prognosis persisted after adjustment for other known prognostic factors.**

The preoperative studies needed for determining the extent of disease include chest CT, CT, or MRI of the primary site, and regional lymph nodes, a bone scan, and bone marrow aspiration and/or biopsy.

Table 137–4.

Intergroup Rhabdomyosarcoma Study Group Pretreatment TGNM Clinical Staging Based on Clinical, Radiographic, Laboratory Examination, and Histology of Biopsy

Stage 1: Favorable site, nonmetastatic
Stage 2: Unfavorable, small, negative nodes, nonmetastatic
Stage 3: Unfavorable, big or positive nodes, nonmetastatic
Stage 4: Any site, metastatic

Tumor

T1: Confined to site of origin
T2: Fixation to surrounding tissues
≤5 cm
>5 cm

Histology

G1: Favorable histology (embryonal, botyroid, spindle-cell)
G2: Unfavorable histology (alveolar, undifferentiated)

Regional Lymph Nodes

N0: Regional lymph nodes not clinically involved
N1: Regional lymph nodes clinically involved

Metastases

M0: No distant metastases
M1: Metastases present

Treatment

General Principles

The treatment of RMS has evolved from radical surgical excision. Once it was demonstrated that most patients would survive the disease, investigators explored the use of primary chemotherapy and radiation therapy to avoid exenterative surgery employed for genitourinary RMS (Ortega, 1979; Voute et al, 1981). A major aim of IRS-II (1978 to 1984) and International Society of Paediatric Oncology/Société Internationale D'Oncologie Pédiatrique (SIOP) RMS-75 (1975 to 1984) was preservation of a functional lower urinary tract (Raney et al, 1990). Unfortunately, primary chemotherapy with vincristine, dactinomycin, and cyclophosphamide (VAC) did not obviate the need for radical surgery or radiation therapy for patients with pelvic RMS. The 3-year survival was the same for IRS-II as for IRS-I (Maurer et al, 1993). In IRS-III

Table 137–5.

Rhabdomyosarcoma Risk Groups Based on Prognosis

PROGNOSIS	STAGE	GROUP	SITE	SIZE	AGE	HISTOLOGY	METASTASIS	NODES
Excellent	1	I	Favorable*	a or b†	<21	EMB	M0	N0‡
	1	II	Favorable	a or b	<21	EMB	M0	N0
	1	III	Orbit only	a or b	<21	EMB	M0	N0
	2	I	Unfavorable	a	<21	EMB	M0	N0 or NX
Very good	1	II	Favorable	a or b	<21	EMB	M0	N1
	1	III	Orbit only	a or b	<21	EMB	M0	N1
	1	III	Favorable (excluding orbit)	a or b	<21	EMB	M0	N0 or N1 or NX
	2	II	Unfavorable	a	<21	EMB	M0	N0 or NX
	3	I or II	Unfavorable	a	<21	EMB	M0	N1
	3	I or II	Unfavorable	b	<21	EMB	M0	N0 or N1 or NX
Good	2	III	Unfavorable	a	<21	EMB	M0	N0 or NX
	3	III	Unfavorable	a	<21	EMB	M0	N1
	3	III	Unfavorable	a	<21	EMB	M0	N0 or N1 or NX
	1, 2, or 3	I, II, or III	Favorable or unfavorable	a or b	<21	ALV	M0	N0 or N1 or NX
	4	I, II, III, or IV	Favorable or unfavorable	a or b	<10	EMB	M1	N0 or N1
Poor	4	IV	Favorable or unfavorable	a or b	±10	EMB	M1	N0 or N1
	4	IV	Favorable or unfavorable	a or b	<21	ALV	M1	N0 or N1

*Favorable = orbit/eyelid, head, and neck (excluding parameningeal), genitourinary (not bladder or prostate); unfavorable = bladder, prostate, extremity, parameningeal, trunk, retroperitoneal, pelvis.
†a = tumor size ≤5 cm in diameter; b = tumor size >5 cm in diameter.
‡N0 = regional nodes clinically not involved; N1 = regional nodes clinically involved; NX = node status unknown.
ALV, alveolar rhabdomyosarcoma (RMS), or ectomesenchymoma with alveolar RMS; EMB, embryonal, botryoid, or spindle-cell rhabdomyosarcoma or ectomesenchymoma with embryonal rhabdomyosarcoma.

(1984 to 1991), intensification of therapy using a risk-based study design significantly improved overall treatment outcomes. This required more intensive chemotherapy for stage III tumors, but selected patients were able to receive decreased therapy (Crist et al, 1995).

In IRS-IV (1991 to 1997), patients were stratified for treatment based on site, size, and stage. The role of hyperfractionated radiation therapy and the use of ifosfamide and etoposide was examined. The relapse-free survival (RFS) for patients with embryonal RMS was improved on IRS-IV in comparison with IRS-III (Crist et al, 2001). This was predominantly for stage II/III, group I/II patients (93% versus 76%, $P < .001$). There was no difference in survival rates between patients treated with hyperfractionated or conventional radiation therapy. A review of the tumor response to initial induction chemotherapy at 8 weeks imaging was performed (Burke et al, 2007). The response rate for group III patients was 77% but had no influence on failure-free survival.

IRS-V (1997 to 2007) conducted several studies on children with RMS. Patients with low-risk embryonal/botryoid tumors were treated with the D9602 protocol. In this study, low-stage GU tumors (most bladder/prostate primaries would be excluded because primary complete resection is not done) received vincristine and dactinomycin (VA) for 45 weeks. X-ray therapy (XRT) was not given for stage I tumors. Children with vaginal primaries were reassessed with imaging after chemotherapy was initiated. Endoscopy with biopsy was done at week 28. If no viable tumor was found, chemotherapy alone was continued. Those with viable tumor had resection, if feasible, and XRT only given to those patients with positive margins. If the tumor was not resectable, XRT was given. The results did not show any difference in outcomes from similar patients treated on IRS-III and IRS-IV (Walterhouse et al, 2006).

Intermediate-risk patients were treated with the D9803 protocol. Most patients with bladder/prostate RMS were included in this study. This study evaluated the use of VAC, alternating that regimen with one substituting topetecan for dactinomycin. This regimen did not result in improved outcome compared with IRS-IV (Arndt et al, 2007).

The current COG study for low-risk patients with embryonal/botryoid/spindle cell rhabdomyosarcoma, ARST0331, opened in 2004. This study is evaluating reducing the duration of chemotherapy to 22 weeks for low-stage favorable-site tumors. Shortened duration of chemotherapy has been used by both SIOP and the German Cooperative Soft Tissue Sarcoma Study with good results (Ferrari et al, 2002; Stewart et al, 2003). The initial treatment will consist of VAC followed by VA. The study for intermediate-risk patients is ARST0531. This study will evaluate the role of XRT given at week 4 versus week 10 of treatment. The role of irenotecan will also be addressed.

In the SIOP MMT84 study, radiotherapy was omitted for patients who achieved a complete remission with chemotherapy (Flamant et al, 1998). Unfortunately, this resulted in reduced overall survival compared with IRS-III and IV, largely due to increased local relapse.

The SIOP MMT 89 protocol for treatment of RMS tried to limit the use of radiation therapy (Stevens et al, 2005). They also used tumor response to chemotherapy to stratify patients for therapy. There was a lower 5-year event-free survival (EFS) (64%) in patients who did not receive XRT as part of the initial therapy, but overall survival is comparable to patients receiving XRT. IRS-IV also reported a greater incidence of local recurrences when XRT was omitted (Arndt et al, 2004).

A number of advances have been made by these cooperative group studies, including identification of prognostic factors, for instance, histology, site, biology, and extent of disease (Lawrence et al, 1987; Rodary et al, 1991); reduction or elimination of radiation therapy for special groups or sites (Flamant et al, 1998); reduced need for radical surgery, leading to increased bladder salvage from 25% to 60% (Hays et al, 1993; Arndt et al, 2004; Stevens et al, 2005); and elimination of "routine" lymphadenectomy for some patients with localized paratesticular RMS (Crist et al, 2001; Ferrari et al, 2002). These advances, as they relate to specific genitourinary tumors, are addressed in more detail below.

Specific Sites

Bladder and Prostate Tumors. **Urinary obstruction is a frequent clinical presentation of RMS of the bladder or prostate** (Meir et al, 2004) (Fig. 137–7). **Signs and symptoms include urinary frequency, stranguria, acute urinary retention, and hematuria.** On physical examination, an abdominal mass from either tumor or a distended bladder is often present. Tumors of the bladder usually occur as a botryoid form and grow intraluminally, usually at or near the trigone (Hays, 1982) (Fig. 137–8). Prostatic RMS tends to present as a solid mass rather than the botryoid form seen in the bladder. Determining the actual site of origin can be difficult. Imaging studies show

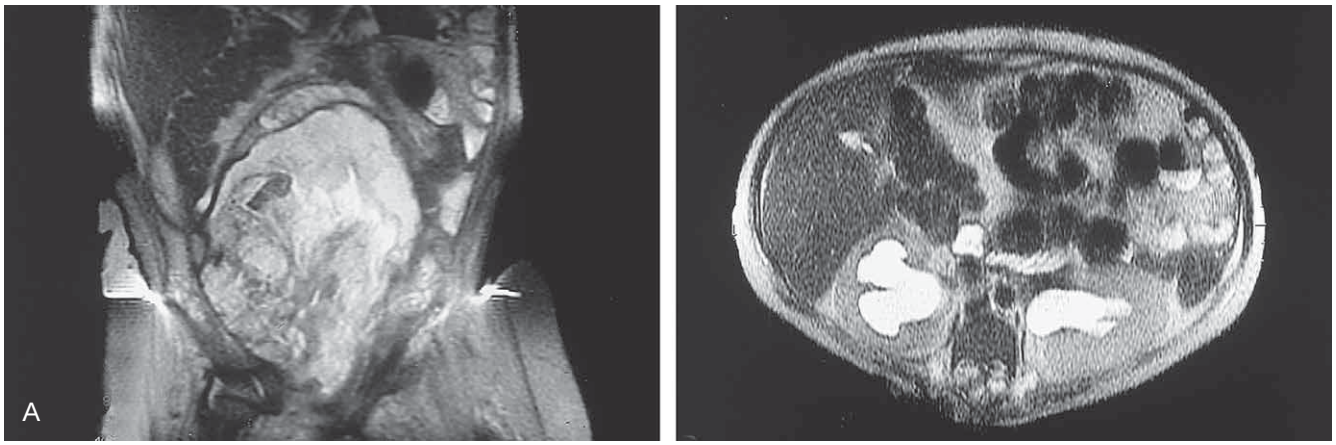

Figure 137–7. MRI of a large prostatic rhabdomyosarcoma extending into the upper abdomen (**A**) with bilateral hydroureteronephrosis (**B**).

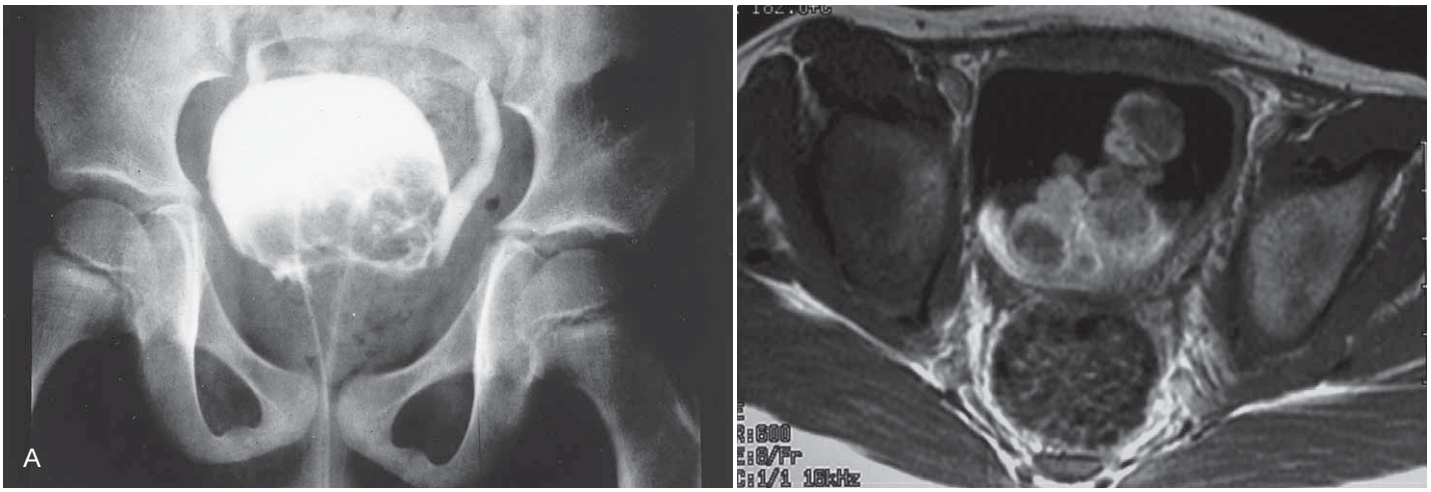

Figure 137–8. **A,** Excretory urogram demonstrating filling defects in the bladder from a botryoid rhabdomyosarcoma. **B,** MRI of botryoid type sarcoma of the bladder. (**A,** Courtesy of Dr. Stanford Goldman.)

filling defects within the bladder or elevation of the bladder base in prostatic RMS. CT/MR can delineate the extent of tumor as well as evaluate the pelvic and retroperitoneal nodes. Cystoscopic evaluation establishes the diagnosis, and transurethral biopsy specimens can be obtained.

As noted above, the treatment of bladder/prostate RMS has become focused on preserving an intact bladder. Most of these tumors arise from the trigonal area or prostate and are not amenable to local or partial resection. Only a small percentage of children with bladder RMS affecting the dome or sides of the bladder distant from the trigone are amenable to partial cystectomy as primary treatment. However, even patients with bulky bladder/prostate RMS can be considered for bladder sparing after multimodal treatment. The IRSG approach is to use both chemotherapy and radiation prior to surgical resection, with the exception of those children amenable to partial cystectomy at diagnosis. Although conservative surgical therapy for bladder/prostate tumors has not been as successful as for vaginal primaries, the bladder salvage rate has increased (Hays et al, 1990; Hays, 1993). With the intensification of treatment for pelvic RMS in IRS-III, 60% of patients retained a functional bladder at 4 years from diagnosis, and overall survival exceeded 85% (Hays, 1995). One concern about a bladder-sparing approach is residual disease after partial cystectomy. Among 22 patients undergoing conservative surgery as primary surgery, there were five cases of local relapse and one of distant relapse (Hays et al, 1990). All patients who relapsed died.

In IRS-IV, there were 88 patients with bladder/prostate primaries, including 17 patients undergoing partial cystectomy as the initial surgical procedure (Arndt et al, 2004). **Most patients had surgery after completion of XRT. Event-free survival at a mean of 6.1 years follow-up was 77%. Overall, the bladder was retained in 55 patients. However, only 36 patients (40%) had no relapse and a normally functioning intact bladder at last follow-up. The reason for the less favorable results, compared with those reported for IRS-III, was attributed to longer follow-up and stricter definition of normal bladder function.** Bladder function was determined by questionnaire, but this was completed in only 65% of patients with a retained bladder. Only one child had undergone urodynamic evaluation. A recent report pooled data on 164 bladder/prostate patients treated on IRS-IV, SIOP MMT-84 and 89, and the German and Italian cooperative groups (Walterhouse et al, 2006). About half the patients had no bladder surgery, and 30% underwent partial cystectomy. They reported that 30% of patients had some urinary incontinence, and half had a history of urinary tract infection. However, it is possible that the incidence of late urinary complications would be underreported in a retrospective chart review.

More objective evaluation of bladder function with urodynamics after multimodal treatment of pelvic RMS has been reported (Yeung et al, 1994). Yeung and colleagues evaluated 11 children treated for pelvic RMS. After a mean follow-up of 6.6 years, the four unirradiated children had normal bladder function. All seven of the children who had undergone irradiation had a markedly reduced functional bladder capacity and abnormal voiding patterns.

Several reports have expressed concern regarding the routine use of radiation therapy prior to surgery for bladder/prostate RMS (Fisch et al, 1995; Meguerian et al, 1998; El-Sherbiny et al, 2000; Filipas et al, 2004). Although radiation is important to prevent local treatment failure, radiation can affect bladder function in children with retained bladders and make subsequent reconstructive procedures more difficult. Merguerian and colleagues (1998) treated 10 patients with group III bladder/prostate RMS. Radiation therapy was reserved only for patients with residual or metastatic disease. They reported a survival rate of 80% among their group III patients, and only four patients received XRT. El-Sherbiny and colleagues (2000) have described a risk-based approach to the treatment of pelvic RMS. The response of the tumor to chemotherapy is used to stratify patients into low-risk patients with a complete or partial response, and high-risk patients with a minimal response to chemotherapy. The latter group undergoes exenterative surgery without any attempt at bladder salvage. The low-risk group had an 85.7%, 5-year, disease-free survival. Low-risk patients were only given radiation for relapse. The Mainz group also recommends assessment of response of the primary tumor to chemotherapy after 7 to 9 weeks (Filipas et al, 2004). If there is less than a one-third reduction in tumor volume, radiation is given before surgery. Patients who have a good response and undergo complete resection do not receive XRT. Filipas and colleagues (2004) believe

this approach provides more complete tumor resection with excellent cure rates. Quality of life can be maintained for patients requiring exenterative surgery with use of continent urinary diversion techniques.

Another approach has been proposed by Martelli and colleagues (2009). They have used conservative surgical resection followed by brachytherapy postoperatively for residual disease in bladder/prostate RMS. Twenty-six boys with a residual mass, postchemotherapy, were managed with either partial prostatectomy and/or cystectomy. Only one child had a cystectomy. Martelli and colleagues (2009) reported only one local relapse. At a median follow-up of 4 years, continence was present in 16 of 18 evaluable patients.

There is a subset of patients with bladder RMS who have a better prognosis. Leuschner and colleagues (2001) found a 92% 10-year survival in patients with botyroid subtype of RMS. Patients with a diffuse endophytic intramural growth had a 68% 10-year survival. Prostatic RMS is associated with a poorer prognosis, and these tumors do not have the botryoid type of growth pattern (Crist et al, 2001; Stevens et al, 2005). Prostatectomy without cystectomy has been performed in selected patients with persistent disease or local relapse (Hays, 1993; Lobe et al, 1996; Meguerian et al, 1998). However, local relapses have occurred in 40% of these patients.

Assessing complete response to therapy after chemotherapy can present challenges. Completeness of surgical resection may be difficult to determine by frozen section. Some patients will have mature rhabdomyoblasts identified on post-treatment biopsy. Several reports of small numbers of patients have suggested that these patients can be safely observed with a low risk for recurrence (Atra et al, 1994; Heyn et al, 1997; Ortega et al, 2000; Smith et al, 2002; Arndt et al, 2006). There is a report of two deaths occurring in patients with mature tumors post-therapy (Leuschner et al, 2001). Also concerning is the finding by Godzinski and colleagues (1994) of a 51% relapse rate in RMS confirmed to have a complete remission by imaging and biopsy. Follow-up of patients with apparent complete remission should include serial imaging, endoscopy, and biopsy if indicated.

Patients undergoing cystectomy will require diversion. Most authors advocate an initial non-refluxing colon conduit followed by later continent reconstruction after completion of therapy (Duel et al, 1996). Other authors have advocated combining continent reconstruction at the time of extirpative surgery (Lander et al, 1992; Meguerian et al, 1998; Rigamonti et al, 2006). There are several concerns regarding early reconstruction. Frozen section may be unreliable in excluding residual disease (Meguerian et al, 1998). Treatment of a subsequent local recurrence could adversely affect reservoir function. Early reconstruction should only be performed if it is certain that no further local therapy will be required (Hensle and Chang, 2000). Enterocystoplasty may be necessary in some patients with contracted bladders from radiation therapy (Hicks et al, 1993; Yeung et al, 1994).

Paratesticular Rhabdomyosarcoma. Among primary genitourinary tumors, 7% to 10% are located in the paratesticular area (Wiener et al, 1994). The peak age of presentation is between 1 and 5 years of age. Paratesticular RMS arises in the distal portion of the spermatic cord and may invade the testis or surrounding tissues. Paratesticular RMS is usually detected earlier than other genitourinary tumors. Presentation is often a unilateral painless scrotal swelling or mass that is usually distinct from the testis. Ultrasonography can confirm the solid nature of the lesion. **At diagnosis, 60% to 80% of paratesticular tumors are stage I, compared with 13% of RMS overall** (Wiener et al, 1994; Wiener et al, 2001; Ferrari et al, 2002). **More than 90% of paratesticular RMS are embryonal in histology and have a good prognosis. Patients with paratesticular RMS with alveolar histology do have a better prognosis than alveolar RMS found at other sites** (Ferrari et al, 2004).

Radical inguinal orchiectomy is recommended for initial treatment. If the tumor is removed through a prior transcrotal procedure, the risk of local recurrence and nonregional lymph node spread is increased. If cord elements remain after a transcrotal procedure, an inguinal exploration with removal of the remaining spermatic cord and a partial hemiscrotectomy, including the prior scrotal incision, is performed (Dall'Igna et al, 2003).

Before effective chemotherapy, surgery alone produced a 50%, 2-year, relapse-free survival (Sutow et al, 1970). With current multimodal treatment, survival rates of 90% are expected (Wiener et al, 1994, 2001; Ferrari et al, 2002; Stewart et al, 2003). An imaging evaluation is performed at diagnosis to detect or exclude metastasis. Extension to retroperitoneal lymph nodes occurs in up to 20% of patients. CT is most frequently used to evaluate the retroperitoneum to identify nodal metastases (Raney et al, 1987). When enlarged nodes are found on CT, 65% to 94% are confirmed as positive by pathology (Wiener et al, 1994; Ferrari et al, 2002). The converse is not always true. A review of 121 IRS-III patients with paratesticular RMS found a 14% false-negative rate of CT (Wiener et al, 1994). More recent studies have noted better accuracy of CT in identifying node-negative patients (Ferrari et al, 2002). Of 72 patients with negative imaging undergoing routine surgical staging, only one patient had positive lymph nodes identified on pathology.

The role of retroperitoneal lymph node dissection (RPLND) in paratesticular RMS has evolved (Olive et al, 1984; Goldfarb et al, 1994; Wiener et al, 1994, 2001; Ferrari et al, 2002). There can be significant morbidity associated with the surgery. Heyn and colleagues (1992) reported a 10% incidence of intestinal obstruction, 8% ejaculatory dysfunction, and edema of the lower extremities in 5% of patients who had undergone RPLND for paratesticular RMS. However, most of these patients underwent bilateral node dissection. A modified unilateral node dissection is appropriate for staging and, with the addition of nerve-sparing techniques, may avoid some of the reported morbidity of node dissection (LaQuaglia et al, 1989; Donohue et al, 1990).

SIOP first suggested elimination of routine RPLND. A cohort of 46 children with completely excised tumors and negative CT or lymphangiogram was managed with intensive chemotherapy alone (Olive-Sommelet, 1989). However, it should be noted that most of the children did receive doxorubicin (DOX) or ifosfamide, which have potential for adverse late effects.

During IRS-III, 121 children with paratesticular RMS were reported who underwent RPLND. The overall 5-year survival for the 98 patients with clinically negative nodes was 96%, and fewer than 10% of patients received doxorubicin or alkylating agents. Patients found to have positive lymph nodes on pathologic evaluation were given radiation to the retroperitoneum, due to the increased risk for relapse (Wiener et al, 1994). In IRS-IV, children with clinically negative nodes were treated primarily with chemotherapy. This resulted in a higher percentage of group I patients in comparison with IRS-III, 82% versus 68% (Wiener et al, 2001) However, adolescents were at higher risk of retroperitoneal relapse than were children less than 10 years of age, and their RFS and OS were worse. Adolescents with group I tumors on IRS-IV had a 68% RFS. This compares with a 100% survival of adolescents with group II tumors who received radiotherapy and intensified

chemotherapy. **The current COG protocols recommend that children 10 years of age and older should have ipsilateral RPLND as part of their routine staging prior to chemotherapy.** Patients with positive lymph nodes require intensified chemotherapy as well as nodal irradiation (Wiener, 2001).

The Italian and German cooperative group treated 106 low-risk patients with chemotherapy only, avoiding RPLND (Ferrari et al, 2002). Low-risk patients were defined as favorable histology, T1N0M0, and clinical group 1. Since 1988, these patients only received vincristine (VCR) and dactinomycin (AMD). The five-year survival was 99.1%. This study did also note a higher rate of retroperitoneal relapse in adolescents. SIOP treated low-risk patients with chemotherapy only in the MMT 84 and 89 studies (Stewart et al, 2003). Of 156 clinical stage I patients, 14 developed relapse. Patient age greater than 10 years and primary tumor size greater than 5 cm were identified as predictors for relapse. The larger tumors occur more often in adolescents, suggesting a delayed presentation.

Vaginal, Vulvar, and Uterine Rhabdomyosarcoma. Vaginal and vulvar RMS generally present in the first few years of life, with vaginal bleeding, discharge, or a vaginal mass. The clinical presentation can be quite striking, if there is prolapse of the mass from the vaginal introitus (Fig. 137–9). Uterine RMS may present in two ways—as a tumor originating from the cervix with vaginal bleeding or mass or as a tumor originating in the uterine body and presenting as an abdominal mass. The diagnosis is made by vaginoscopy and biopsy of the lesion. The vaginal lesions usually arise from the anterior vaginal wall in the area of the embryonic vesicovaginal septum (urogenital sinus). Vaginal tumors may invade the vesicovaginal septum or bladder wall because of their proximity. Cystoscopy is warranted during initial evaluation and at intervals during follow-up (Andrassy et al, 1994).

Figure 137–9. Mass protruding from the vaginal introitus in a young girl with vaginal rhabdomyosarcoma.

Vaginal and uterine lesions generally have embryonal or botryoid embryonal histology and have an excellent prognosis (Andrassy et al, 1994; Corpron et al, 1995; Martelli et al, 1999; Arndt et al, 2001). Vulvar lesions may have alveolar histology, but because most are localized, they also have a good prognosis. In addition to biopsy, staging requires a search for metastases, including pelvic examination and CT scans of the pelvis, abdomen, and chest and examination of the bone marrow, cystoscopy, and vaginoscopy.

Anterior pelvic exenteration was frequently employed to treat these patients in the past. With the development of effective chemotherapy, attempts to preserve the vagina and uterus have become a priority. Definitive surgery is delayed until after an initial course of therapy (Hays et al, 1988; Andrassy et al, 1994; Corpron et al, 1995; Martelli et al, 1999; Arndt et al, 2001). Once an adequate response is demonstrated, repeat biopsies are performed. If there is persistence of disease, delayed tumor resection is performed. This may consist of partial vaginectomy or vaginectomy with hysterectomy. In IRS-III, 24 patients with vaginal primaries were treated with a primary chemotherapy protocol. At subsequent surgery, seven patients underwent partial or complete vaginectomy. Six of these seven patients had no viable tumor in the resected specimen, and one had maturing rhabdomyoblasts. The presence of mature rhabdomyoblasts due to differentiation of chemotherapy may not signify persistent active cancer (see discussion above) (Heyn et al, 1997; Ortega et al, 2000; Smith et al, 2002; Arndt et al, 2006).

Older studies reported that uterine RMS occurs in a distinct group of patients who present at an older age and have less response to treatment and thus poorer prognosis than those with vaginal RMS (Hays et al, 1981, 1985). However, more recent reports suggest that patients with uterine RMS were of the same age group, mean age 5.5 years, as the vaginal RMS patients (Arndt et al, 2001).

During IRS-IV (1988 to 1996), the rate of hysterectomy was only 26% compared with 48% in IRS-I and -II (Arndt et al, 2001). Greater than 50% of patients did receive XRT for local tumor control in IRS-IV. This probably reflects the attempt to achieve a complete response without surgery. Only 3 of 21 patients (13%) underwent surgical resection after primary chemotherapy. Age at diagnosis of 1 to 9 years, botryoid histology, and localized disease were predictive of a good prognosis (Andrassy et al, 1999; Arndt et al, 2001).

SIOP also uses initial chemotherapy for vaginal RMS. Only 12% of their patients treated on MMT84 and MMT 89 required hysterectomy. XRT was used in 11 girls, but seven received intracavitary brachytherapy. Eleven girls did not require any local therapy, surgery, or XRT after chemotherapy (Martelli et al, 1999).

Treatment of pelvic RMS in females can result in significant late complications. Most of the complications are due to the use of XRT, but late complications of chemotherapy are also noted. Spunt and colleagues (2005) reported on 26 females treated for pelvic RMS who were free of disease for 5 years. Fourteen patients required surgery for treatment of complications related to treatment of the RMS. This included vaginal dilation/reconstruction to correct stenosis, procedures to relieve ureteral obstruction, intestinal stricture dilation or repair, and fistula repair. Twenty of the 28 patients had endocrine late effects; ovarian failure was the most common complication. Late urinary complications included ureteral obstruction, cystectomy, neurogenic bladder, and urethral stricture. Magne and colleagues (2008) reported on

the late effects in 39 girls treated for vaginal and vulvar RMS. For patients treated after 1990, they noted a 20% incidence of vaginal stenosis. Brachytherapy was employed in these patients, and the authors attribute the low complication rate to the judicious use of brachytherapy.

Key Points: Rhabdomyosarcoma

- Embryonal RMS is the most common subtype of genitourinary RMS. It can present as sarcoma botryoides, a polypoid variety that occurs in hollow organs or body cavities, such as the bladder or vagina.
- Sixty to 80 percent of paratesticular RMS is stage I at diagnosis. Patients older than 10 years have a higher risk for retroperitoneal relapse and should undergo staging with ipsilateral retroperitoneal lymph node dissection (RPLND) before chemotherapy.
- An organ-sparing approach is preferred for bladder and genital RMS. Vaginal and uterine primaries are associated with a good prognosis.

WILMS TUMOR

Wilms tumor, or nephroblastoma, is the most common primary malignant renal tumor of childhood. This embryonal tumor develops from remnants of immature kidney. Athough an excellent outcome is now expected for most children, there are subgroups of high-risk patients for whom more effective treatment is needed. Treatment of patients with nephroblastoma has been extensively investigated in a number of large randomized clinical trials in North America and Europe. Current management now emphasizes reducing the morbidity of treatment for low-risk patients by reserving more intensive treatment for those high-risk patients for whom survival remains poor. This section will outline current recommendations for treatment and review the latest developments in the biology of Wilms tumor.

Epidemiology

Wilms tumor accounts for 6% to 7% of all childhood cancers. In children less than 15 years of age, the annual incidence rate is about 7 to 10 cases per million (Breslow et al, 1993; Bernstein et al, 1999). More than 80% of cases are diagnosed before 5 years of age, with a median age of 3.5 years. Nevertheless, older children and, occasionally, even adults can be affected (Arrigo et al, 1990; Kalapurakal et al, 2004a). The median age at diagnosis is lower in children with bilateral Wilms tumor (Breslow et al, 1993). Wilms tumor presents at an earlier age among males with both unilateral and bilateral tumors.

In North America, Wilms tumor is slightly more frequent in females than in males. With regard to ethnicity, the incidence of Wilms tumor is lower in East Asian populations and higher in black populations compared with the incidence reported for North American and European whites (Breslow et al, 1994; Fukuzawa et al, 2004). However, the approximately three- to fourfold ratio of the maximum-to-minimum rate worldwide is substantially less than the ratios of 10 to 20 typically observed for adult epithelial tumors. The fact that such variations exist more closely associated with race than geography suggests that environmental risk factors likely play a minor etiologic role, certainly in comparison with adult epithelial cancers (Breslow et al, 1993). Several epidemiologic studies have investigated occupational, environmental, and lifestyle factors as risk factors for Wilms tumor. Although some studies have suggested that a number of parental exposures might be associated with an increased risk of Wilms tumor, very few have been found conclusively associated (Breslow et al, 1993).

Biology

Children with Wilms tumor have been extensively studied to determine the role of genetic alterations in tumor development. It is now recognized that the majority of Wilms tumors arise from somatic mutations restricted to tumor tissue, and a much smaller percentage originate from germline mutations (Ruteshouser et al, 2008). It is apparent that several genetic events result in Wilms tumorigenesis and that the Knudson two-hit model of cancer formation does not explain most cases (Knudson and Strong, 1972b). Approximately 10% of children with Wilms tumor have congenital anomalies and syndromes, 5% to 10% of tumors are bilateral/multicentric, and 1% to 2% are familial. These subsets of patients are the ones in whom the most thorough evaluation for genetic abnormalities has been conducted (Table 137–6).

WT1

WT1 was the first Wilms tumor gene to be identified. **The identification and subsequent cloning of *WT1* resulted from cytogenetic observations of gross deletions at chromosome 11p13 in patients with the WAGR (*Wilms tumor, *Aniridia, *Genital anomalies, mental *R*etardation) syndrome.** These children were shown to have heterozygous germline deletions at 11p13 (Riccardi et al, 1978). Subsequent molecular analysis of the DNA mapping of this specific region led to the identification of the *WT1* in 1990 (Bonetta et al, 1990; Call et al, 1990). Aniridia, found in 1.1% of Wilms tumor patients, is caused by an abnormality of the *PAX6* gene located adjacent to the *WT1*

Table 137–6.

Syndromes Associated with Development of Wilms Tumor

SYNDROME	GENES	LOCUS	WILMS TUMOR RISK
WAGR	*WT1*	11p13	50%
Denys-Drash	*WT1*	11p13	50%
Frasier	*WT1*	11p13	5%-10%
Beckwith-Wiedemann	*WT2*	IGF-2, H19, p57, Klp2	5%-10%
Familial Wilms tumor	*FWT1*	17q21	30%
	FWT2	19q13	
Perlman	Unknown		>20%
Mosaic variegated aneuploidy	*BUB1B*	15q15	>20%
Fanconi anemia D1	*BRCA2*	13q12.3	>20%
Simpson-Golabi-Behmel	*GPC3*	Xq26	10% (in males)
Li-Fraumeni	*TP53*	17p13	Low
Neurofibromatosis	*NF1*	17q11	Low
Sotos	*NSD1*	5q35	Low
Trisomy 18	Unknown	18	Low
Bloom	*BLM*	15q26	Low

gene. Aniridia patients with visibile (microscopic) chromosomal deletions that include *WT1* were noted to be prone to the development of Wilms tumor (Muto et al, 2002). Fluorescence in-situ hybridization (FISH) analysis of aniridia patients has been used to identify submicroscopic deletions of *WT1* and is also a useful predictor of Wilms tumor development (van Heyningen et al, 2007). Wilms tumor will develop in approximately 40% to 70% of aniridia patients with deletions of *WT1*. Conversely, aniridia patients with normal *WT1* do not develop Wilms tumor (Grenskov et al, 2001; van Heyningen et al, 2007).

The *WT1* gene is important for normal kidney and gonadal development. *WT1* encodes a zinc-finger transcription factor that is expressed in the kidney, gonads, spleen, and mesothelium (Pritchard-Jones, 1990, Dressler GR, 1995). *WT1* is necessary for ureteric bud outgrowth and is also important in nephrogenesis. Targeted mutation of the *Wt1* gene in mice results in failure of kidney and gonadal development (Kreidberg et al, 1997). **The Denys-Drash syndrome (DDS) is the specific association of male pseudohermaphroditism, renal mesangial sclerosis, and nephroblastoma** (Drash et al, 1970). The syndrome is caused by point mutations in the zinc-finger DNA binding region of *WT1* (Coppes et al, 1993). More than 90% of DDS patients harbor germline point mutations in only one *WT1* allele (Pelletier et al, 1991; Coppes et al, 1992). Therefore the *WT1* mutation acts dominantly with respect to genitourinary abnormalities. The fact that the phenotype resulting from these heterozygous mutations is far more severe than that resulting from constitutional deletion of one *WT1* allele (i.e., WAGR patients), suggests that the Denys-Drash mutations do not result in inactivation of the WT1 protein but rather in the production of a dysfunctional WT1 protein. It is postulated that this abnormally expressed protein alters regulation of transcription and urogenital development. The majority of these patients progress to end-stage renal disease. Nephropathy usually presents early in life and renal biopsy demonstrates mesangial sclerosis. Some *WT1* mutations can lead to an incomplete DDS phenotype, with varying degrees of genitourinary anomalies, renal pathologies, and penetrance of Wilms tumor (McTaggart et al, 2001). Although XY individuals have been reported most often, the DDS has been reported in genotypic/phenotypic females. WAGR and DDS patients are more likely to have bilateral tumors and are diagnosed at a younger age (Breslow et al, 2003).

This risk for renal insufficiency in DDS is shared by children with WAGR, both being diseases associated with a *WT1* mutation. **WAGR patients have an increased risk of renal failure if they survive into puberty** (Breslow et al, 2000, 2005). Recent studies of nontumoral renal tissue in children with WAGR and DDS have demonstrated smaller glomerular diameters than in controls (Dahan et al, 2007). This suggests a specific defect of WT1 function during renal development that leads to susequent deterioration in renal function with age.

WT1 was orginally considered to be a classic tumor suppressor gene, and the loss of both copies or mutations of this gene would lead to Wilms tumor development (Rauscher, 1993). Although this may be the case for some tumors, only 20% of patients with Wilms tumor have a mutation in the germline or in tumor tissue (Diller et al, 1998; Ruteshouser et al, 2008). Genitourinary anomalies (renal fusion anomalies, cryptorchidism, hypospadias) are present in 4.5% of patients with Wilms tumor (Breslow et al, 1993). Patients with genitourinary anomalies have an increased risk for carrying a constitutional *WT1* mutation (Diller et al, 1998). The incidence of *WT1* mutations in patients with Wilms tumor not associated with any genitourinary abnormality is approximately 2% (Little et al, 2004). Although there is no distinguishing phenotype for these patients, they do have an earlier age of onset and a stromal predominant histology. *WT1* is involved in regulation of other genes, many of which are involved in cell growth, differentiation, and apoptosis (Lee and Haber, 2001). It remains unclear which of these are most important for tumorigenesis. The WNT/β-catenin signaling pathway is likely involved, because activating mutations of the β-catenin gene (*CTNNB1*) are found in more than half of the Wilms tumors with the *WT1* mutation (Li et al, 2004).

WT2

There are a number of syndromes with overgrowth features at risk for the development of Wilms tumor, including hemihypertrophy, which may occur alone or as part of the Beckwith-Wiedemann syndrome (BWS), Perlman, Sotos, and the Simpson-Golabi-Behmel syndromes (Perlman et al, 1975; Neri et al, 1998). BWS is characterized by excess growth at the cellular, organ (macroglossia, nephromegaly, hepatomegaly), or body segment (hemihypertrophy) levels (Beckwith, 1969, Wiedemann, 1983). Most cases of BWS are sporadic, but up to 15% exhibit heritable characteristics with apparent autosomal dominant inheritance. **The risk of nephroblastoma in children with BWS and hemihypertrophy is estimated to be 4% to 10%, with 21% of children presenting with bilateral disease** (Beckwith, 1996; Debaun and Tucker, 1998; Porteus et al, 2000). Adrenocortical neoplasms and hepatoblastoma also occur with increased frequency in BWS. Children with BWS found to have nephromegaly (kidneys greater than or equal to the 95th percentile of age-adjusted renal length) are at the greatest risk for the development of Wilms tumor (Debaun et al, 1998). More recently, investigators have been able to correlate genetic changes to identify which BWS patients are at risk for Wilms tumor development (DeBaun et al, 2002; Bliek et al, 2004). The mean age at diagnosis of Wilms tumor in BWS and hemihypertrophy patients is similar to that of the general Wilms tumor population (Breslow et al, 1993). Vaughan and colleagues reported a 100% survival among BWS patients with Wilms tumors and noted that all had favorable histology (Vaughan et al, 1995).

A second Wilms tumor gene, *WT2,* was identified at the 11p15 locus due to the finding of loss of heterozygosity (LOH) at this site (Koufos et al, 1989; Mannens et al, 1990). **The *WT2* gene has been linked to the BWS** (Koufos et al, 1989). The WT2 locus has been extensively studied and a number of genes have been identified including *H19* and *IGF-2* (Bjornson et al, 2007). The latter genes are of importance in the epigenetic theory of cancer etiology. Epigenetic changes are modifications of the genome that do not involve a change in DNA sequence (Feinberg, 2004). *IGF-2* encodes an embryonal growth factor that is normally expressed solely from the paternal allele. The overexpression of IGF-2 can arise through duplication of the paternal allele or through abnormal expression from the maternal allele called loss of imprinting (LOI). Because *IGF-2* induces cell growth, increased expression of this imprinted gene could conceivably contribute to the development of both Wilms tumor and BWS. Loss of imprinting (LOI) of *IGF-2* was first identified in Wilms tumor and is overexpressed in a number of malignancies (Rainier et al, 1993; Feinberg, 2004). It is speculated that Wilms tumors that occur at a later age are the result of these epigenetic changes, such as LOI for *IGF-2* (Ravenel et al, 2001).

Ravenel and colleagues (2001) correlated LOI for *IGF-2* and LOH of *WT1* with pathologic findings and age in patients with Wilms

tumor. They found LOI of *IGF-2* in 9 of 10 (90%) Wilms tumors classified as having a pathologic subtype associated with a later stage of renal development, from perilobar nephrogenic rests (PLNR), and in only 1 of 15 (6.7%) Wilms tumors with a pathologic subtype associated with an earlier stage of renal development, from intralobar nephrogenic rests (ILNR). Remarkably, all 9 (100%) of the tumors that showed LOH of 11p were ILNR-like. Furthermore, none of 12 PLNR-like tumors showed LOH of 11p. This is consistent with an earlier observation that tumors with ILNRs are associated with LOH (Grundy et al, 1996). (See discussion below on nephrogenic rests.) Children whose Wilms tumors displayed LOI of *IGF-2* were statistically significantly older at diagnosis (median of 65 months) than children whose tumors displayed normal imprinting.

WTX

Recently, a previously uncharacterized tumor suppressor gene, otherwise known as the *W*ilms *T*umor gene on the *X* chromosome, or *WTX* at Xq11.1, was found to be inactivated in up to one third of Wilms tumors (Rivera et al, 2007). *WTX* is inactivated by a monoallelic, or "single-hit" event rather than by the classical biallelic inactivation of autosomal tumor suppressor genes. It targets the single X chromosome in males and the active X chromosome in females with tumors, and it occurs at comparable frequencies in males and females alike. Initially, it was reported that tumors caused by *WTX* mutations lack *WT1* mutations. Subsequently, it has been observed that *WTX* mutations occur with equivalent frequency in tumors with or without mutations in *WT1* and *CTNNB1* (Ruteshouser et al, 2008). *WTX,* similar to *WT1,* appears to play a role in the WNT/β-catenin signaling pathway. Mutations in *WT1, WTX,* and *CTNNB1* provide the genetic basis for about one third of Wilms tumors.

Familial Wilms Tumor

As noted above, 1% to 2% of Wilms tumor patients have a family history of Wilms tumor (Green et al, 1982; Ruteshouser and Huff, 2004). Familial cases have an earlier age of onset and an increased frequency of bilateral disease. Two familial Wilms tumor genes have been localized (Ruteshouser and Huff, 2004). *FWT1* is located at 17q12-q21 and *FWT2* at 19q13.4 (Rahman et al, 1996; McDonald et al, 1998). Penetrance of these genes appears to be moderate, and these genes do not follow the typical tumor suppressor gene pattern of loss of heterozygosity (Strong, 2003).

Other Chromosomal Abnormalities

Mutations of the tumor suppressor gene *TP53* are frequently encountered genetic events in human cancer (Hollstein et al, 1991). Studies of *TP53* mutations in Wilms tumor have shown an increased frequency in patients with anaplastic histology (Bardeesy et al, 1994). They also have been correlated with advanced-stage disease (Malkin et al, 1994; Sredni et al, 2001), but indexing of *TP53* expression has not been shown to be an independent prognostic factor (Skotnicka-Klonowicz et al, 2001).

Loss of the long arm of chromosome 16 has been found in approximately 20% of Wilms tumors (Maw et al, 1992), suggesting the presence of a gene at 16q involved in the biology of Wilms tumor. Similarly, loss of the short arm of chromosome 1p has been found in approximately 10% of cases (Grundy et al, 1994). **LOH at 1p and 16q are associated with an increased risk of tumor relapse and death** (Grundy et al, 1994, 2005; Wittman et al, 2007). However, the prognostic significance of these features has been questioned (Bown et al, 2002). Confirming the utility of LOH of 16q and 1p to predict outcome was one of the major objectives of the fifth National Wilms Tumor Study (NWTS) (see discussion below). LOH of chromosome 11q is noted in approximately 20% of tumors. LOH of 11q is 3 to 4 times more frequent in anaplastic tumors (Wittman et al, 2007). There is a correlation with tumor recurrence and death, but only for tumors that lost the entire long arm of chromosome 11.

Screening

Screening with serial renal ultrasonography has been recommended in children at high risk for development of Wilms tumor. Review of most studies suggests 3 to 4 months is the appropriate screening interval. Tumors detected by screening will generally be a lower stage (Green et al, 1993; Choyke et al, 1999). No studies, to date, have demonstrated that early detection has improved patient survival. Early detection can provide an opportunity for nephron-sparing surgery, because these children are at an increased risk for bilateral disease. The smaller tumors found on screening studies are more amenable to renal-sparing surgery (Fig. 137–10). The Wilms Tumor Surveillance Working Group from the United Kingdom recommended conducting screening when a condition has a WT incidence of greater than 5% (see Table 137–6) (Scott et al, 2006). Screening of the contralateral kidney following nephrectomy for unilateral Wilms tumor is also recommended (D'Angio et al, 1993). Infants less than 12 months of age found to have nephrogenic rests in the resected kidney are at the greatest risk for metachronous tumors (Coppes et al, 1999). Ultrasound surveillance is performed from time of diagnosis until 5 years of age, with a frequency of every 3 to 4 months. Those who have BWS, Simpson-Golabi-Behmel, and familial Wilms histories should continue to 7 years (Scott et al, 2006). CT or MRI should be performed if US demonstrates a suspicious lesion. Nonmalignant renal lesions, such as renal cysts, do occur at an increased rate in children with BWS, and recognition of these is important to avoid unnecessary nephrectomy when new lesions are identified on screening ultrasonography (Borer et al, 1999; Choyke et al, 1999).

An association between Wilms tumor and horseshoe kidney has been noted. A review of National Wilms Tumor Study Group (NWTSG) patients found that there was a sevenfold increased risk of developing a Wilms tumor in patients with a horseshoe kidney (Mesrobian et al, 1985). The diagnosis of horseshoe kidney can be missed on preoperative imaging due to the location of the tumor (Neville et al, 2002). Wilms tumor has been reported in patients with multicystic dysplastic kidney, but there is not sufficient evidence that this occurs at an incidence greater than for children with two normal kidneys (Narchi, 2005). There is an increased risk of müllerian duct anomalies in girls with Wilms tumor (Byrne and Nicholson, 2002). Approximately 10% of girls will have abnormalities, such as duplication of the cervix or uterus, or bicornuate uterus.

Pathology

Pathologists have made important contributions to the study of both the clinical behavior and biology of Wilms tumor (Beckwith and Palmer, 1978; Beckwith, 1983; Weeks et al, 1987; Zuppan et al, 1991; Schmidt and Beckwith, 1995; Ravenel et al, 2001; Vujanic et al, 2002). Wilms tumor is characterized by tremendous histologic diversity, and classification of childhood tumors can be difficult. As noted in the discussion above, correlation of the

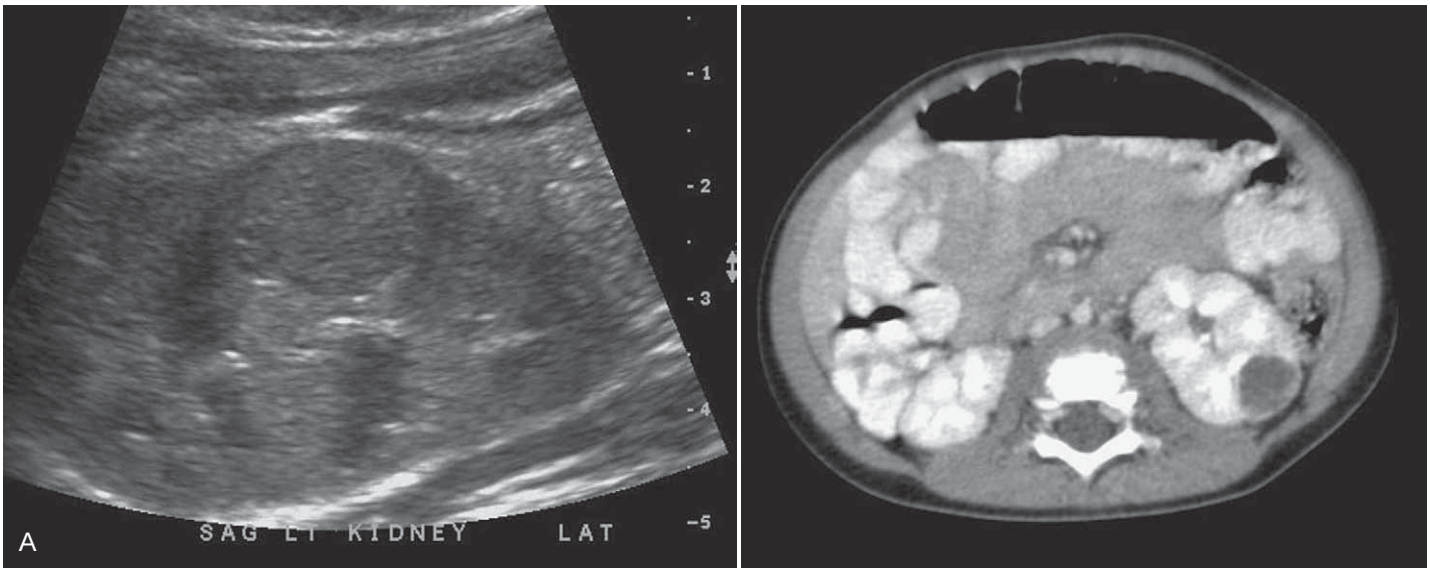

Figure 137–10. Small renal tumor found on serial screening. **A,** Ultrasonogram shows solid lesion just pushing out from the cortex. **B,** CT demonstrates that lesion is amenable to renal-sparing surgery.

pathologic findings with genetic events are improving our understanding of the development of Wilms tumor.

Favorable-Histology Wilms Tumor

Wilms tumor usually compresses the adjacent normal renal parenchyma, forming a pseudocapsule composed of compressed, atrophic renal tissues. This intrarenal pseudocapsule can be helpful in distinguishing Wilms tumor from nephrogenic rests and other renal tumors. The texture of the tumors varies, depending on the predominant histologic pattern. Many are soft and friable with necrotic or hemorrhagic areas frequently noted. This consistency increases the risk of intraoperative tumor rupture. Most Wilms tumors are unicentric, but 12% are multicentric unilateral tumors (Breslow et al, 1988a). Extrarenal Wilms tumor arising in the retroperitoneum and elsewhere are rare and are thought to arise from displaced metanephric elements or mesonephric remnants. Derived from primitive metanephric blastema, Wilms tumor is characterized by tremendous histologic diversity (Beckwith and Palmer, 1978). In addition to expressing a variety of cell types found in a normal developing kidney, Wilms tumor often contains tissues such as skeletal muscle, cartilage, and squamous epithelium. These heterotopic cell types likely reflect the primitive developmental potential of metanephric blastema that is not expressed in normal nephrogenesis. **The "classical" Wilms tumor is characterized by islands of compact undifferentiated *blastema* and the presence of variable *epithelial* differentiation in the form of embryonic tubules, rosettes, and glomeruloid structures separated by a significant *stromal* component** (Fig. 137–11). The proportion of each of these components varies from infrequent to abundant within and among individual tumors. Some Wilms tumors, however, are not triphasic but present only biphasic or even monomorphous patterns, and the latter can present diagnostic difficulties (Schmidt and Beckwith, 1995). **Wilms tumors with predominantly epithelial differentiation have a low degree of aggressiveness, and the majority are stage I tumors (Beckwith et al, 1996). However, these tumors may be more resistant to therapy, if they present as advanced-stage disease.**

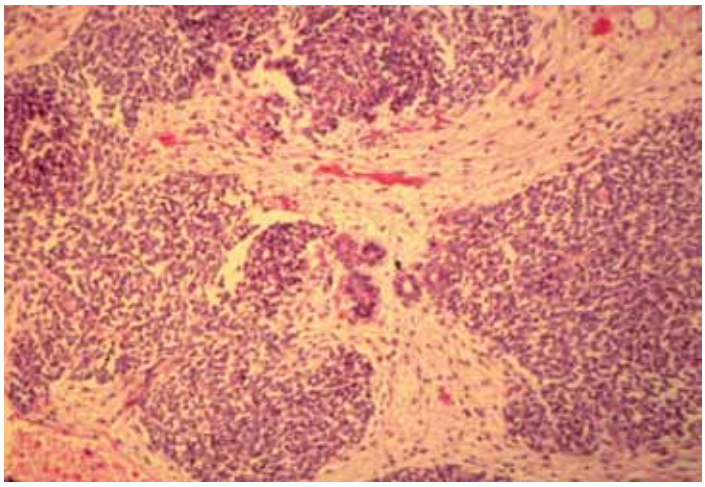

Figure 137–11. Typical Wilms tumor with blastemal, epithelial, and stromal components.

Anaplastic Wilms Tumor

Identification of tumors with unfavorable histologic features, such as anaplasia, was an important milestone accomplished by the inclusion of the central pathologic review of the National Wilms Tumor Study Group protocols (Beckwith and Palmer 1978; Bonadio et al, 1985; Zuppan et al, 1988). It has allowed progressive use of adjuvant therapies in the sequential studies based on the risk and response of the various pathologic tumor types. Anaplasia is characterized by the presence of three abnormalities: nuclear enlargement to three or more times the diameter of the adjacent cells, hyperchromasia of enlarged nuclei, and abnormal mitotic figures. Anaplasia is rarely seen in tumors of patients younger than 2 years at diagnosis (incidence about 2%), but its presence increases to a relatively stable incidence of about 13% in those older than 5 years (Bonadio et al, 1985). **Anaplasia is associated with resistance to chemotherapy.** This is evidenced by the similar incidence of anaplasia (5%) in the NWTSG and SIOP studies (Vujanic

et al, 1999). **The presence of anaplasia has clearly been demonstrated to carry a poor prognosis, even when the tumor is apparently confined to the kidney in stage I** (Dome et al, 2006). Anaplasia has been further divided into focal and diffuse patterns, to reflect further the different prognosis of anaplasia that is present throughout the kidney or in an extrarenal location (Faria et al, 1996).

Nephrogenic Rests

More than one third of kidneys resected for Wilms tumor contain precursor lesions, known as nephrogenic rests (NR) (Beckwith et al, 1990; Beckwith, 1993). Nephrogenic rests have a varied natural history, and most do not form Wilms tumor. A rest can undergo maturation, sclerosis, involution, or complete disappearance. Nephrogenic rests have also been detected in 1% of kidneys in infants on postmortem exam, a much higher incidence than that of Wilms tumor. Hence, most apparently undergo involution (Beckwith, 1998).

NRs can be separated into two fundamentally distinct categories: *perilobar nephrogenic rests* (PLNRs) and *intralobar nephrogenic rests* (ILNRs) (Beckwith et al, 1990). These two types of NRs are distinguished by their location within the renal lobe (Fig. 137–12). Relative position within the lobe is a direct reflection of the chronology of the embryologic development of the kidney. **PLNRs are found only in the lobar periphery, which is elaborated late in embryogenesis, while ILNRs are found anywhere within the lobe, as well as the renal sinus and the wall of the pelvicalyceal system.** Therefore ILNRs are generally believed to be the result of earlier gestational aberrations (Beckwith et al, 1998). ILNRs are commonly stroma rich and intermingle with the adjacent renal parenchyma. PLNR are usually subcortical, sharply demarcated, and contain predominantly blastema and tubules. Of particular interest is the observation that PLNRs are usually found in children with BWS, linked to the 11p15 Wilms locus, while ILNRs are typically seen in children with aniridia, WAGR, and DDS or other features associated with *WT1* (Table 137–7). The age at diagnosis is lower for Wilms tumor associated with *WT1* mutations, and those arising in association with ILNR. These tumors have a stromal-predominant histology with varying degrees of rhabdomyogenesis (Fukuzawa et al, 2008).

Multiple rests in one kidney usually implies that NRs are present in the other kidney (Beckwith, 1990). **Children less than 12 months of age who are diagnosed with Wilms tumor and also have NRs, in particular PLNRs, have a markedly increased risk of developing contralateral disease and require frequent and regular surveillance for several years** (Coppes et al, 1999). Surveillance is also recommended for those diagnosed after 12 months of age who have NRs (D'Angio et al, 1993). The occurrence of metachronous Wilms tumor in patients previously treated with conventional chemotherapeutic regimens suggests that nephrogenic rests are not always eradicated.

NRs display a spectrum of appearances. Hyperplastic NRs can produce a renal mass that can be mistaken for a small Wilms tumor (Beckwith, 1998). Incisional biopsy of a hyperplastic rest is of little value in distinguishing this lesion from a Wilms tumor, unless the interface between the rest and normal kidney is included. Wilms tumor will have a pseudocapsule at the interface with the normal parenchyma compressing the normal elements. The appearance of the lesion can provide some help in distinguishing between NR and Wilms tumor. The Wilms tumor will have a spherical shape, while hyperplasic rests will retain the appearance of the orginal rest and be more elliptical or lenticular in shape. MRI may be of some value in distinguishing between the two lesions, but this needs to be confirmed prospectively in large numbers of patients (Rohrschneider et al, 1998; Hoffer, 2005).

Nephroblastomatosis refers to the presence of multiple nephrogenic rests. Diffuse overgrowth of PLNRs may produce a thick rind that enlarges the kidney but preserves its original shape (Fig. 137–13). Patients with nephroblastomatosis are prone to Wilms tumor development, and

bilateral lesions are common. Perlman and colleagues (2005) have reviewed 52 cases of diffuse hyperplastic perilobar nephrogenic rests reported to the NWTSG pathology center. Wilms tumor developed in 23 patients at a median of 30 months. Of children receiving adjuvant therapy at diagnosis, 17 of 33 (52%) developed a Wilms tumor. There was an increased incidence of anaplasia noted in tumors that developed following chemotherapy in patients with nephroblastomatosis (Perlman et al, 2005).

Preoperative Evaluation and Staging

A palpable smooth abdominal mass is present on physical examination in over 90% of children. A family member or primary care provider often discovers the mass incidentally. Abdominal pain, gross hematuria, and fever are less frequent findings at diagnosis. Rupture of the tumor with hemorrhage into the free peritoneal cavity can result in the occasional presentation of an acute abdomen.

Compression or invasion of adjacent structures may result in an atypical presentation. Extension of Wilms tumor into the renal vein and inferior vena cava (IVC) can cause a varicocele, hepatomegaly due to hepatic vein obstruction, ascites, and congestive heart failure. Such symptoms are found in less than 10% of patients with intracaval or atrial tumor extension (Ritchey et al, 1988, 1990; Shamberger et al, 2001). Occasionally, children with Wilms tumor have symptoms secondary to the production of bioactive substances by the tumor (Coppes, 1993). Hypertension is common at diagnosis and has been attributed to elevated plasma renin levels (Maas et al, 2007). This will usually resolve shortly after removal of the tumor. During the physical exam, it is important to assess for signs of associated Wilms tumor syndromes, such as aniridia, hemihypertrophy, and genitourinary anomalies.

Emergent operation is not necessary unless there is evidence of active bleeding or tumor rupture. Laboratory evaluation should include a complete peripheral blood count, renal and liver function tests, serum calcium, and urinalysis. Acquired von Willebrand disease has been found in 8% of newly diagnosed Wilms tumor patients (Coppes, 1993).

Imaging

A precise histologic diagnosis cannot be obtained on the preoperative imaging studies. All of the solid renal tumors of childhood have some common radiographic features, including renal cell carcinoma (Broecker, 1991; Miniati et al, 2008). **In the SIOP-9 study, 5.4% of patients in whom preoperative chemotherapy for Wilms tumor was commenced prior to diagnostic biopsy, were found to have renal malignanices other than Wilms tumor or benign renal conditions upon nephrectomy** (Tournade et al, 2001). In the United Kingdom Children's Cancer Study Group (UKCCSG), 12% of renal tumors clinically and radiologically consistent with Wilms tumor were found to have some other diagnosis on biopsy (Vujanic et al, 2003). Other clinical parameters can provide some clues to the diagnosis. The development of a renal tumor in a child known to have aniridia, hemihypertrophy, or other syndromes associated with an increased incidence of nephroblastoma is most likely to be a Wilms tumor. Bilateral or multicentric tumors are more typical of Wilms tumor, but renal lymphoma can present in this fashion. Congenital mesoblastic nephroma (CMN) is the most likely diagnosis in a neonate with a renal mass. However, favorable-histology (FH) Wilms tumor and rhabdoid tumor of the kidney can also present in the first few months of life (Ritchey et al, 1995a; LeClair et al, 2005). The renal origin of the mass is usually apparent on CT, but can be mistaken for neuroblastoma.

The clinical presentation, for instance, as abdominal pain with tumor rupture, can create confusion regarding the preoperative diagnosis. In 2.5% of NWTS-3 patients, there was an erroneous diagnosis prior to surgical exploration (Ritchey et al, 1992). Most of these children did not have any preoperative imaging studies performed, and this group of patients had an increased incidence of surgical complications. This emphasizes that defining the exact histology is not as important as establishing that the child has a solid renal tumor, allowing the surgeon to plan for a major cancer operation. Another important role of imaging is to confirm that the contralateral kidney is functioning prior to performing a nephrectomy.

Ultrasonography is the first study performed in most children with an abdominal mass. This will demonstrate the solid nature of the lesion. Doppler ultrasonography is particularly helpful in excluding intracaval tumor extension that occurs in 4% of Wilms tumor patients (Ritchey et al, 1988; Shamberger et al, 2001). Magnetic resonance imaging (MRI) is the study of choice if extension of tumor into the IVC cannot be excluded by ultrasonography (Fig. 137–14) (Schenk JP et al, 2008). CT and MRI can further define the extent of the lesion (Fig. 137–15) (Hoffer, 2005; Schenk JP et al, 2008); however, the role of imaging studies in staging of the renal tumor continues to be defined. If the preoperative imaging could accurately detect local extension of tumor beyond the renal capsule or into regional lymph nodes, it would obviate concerns regarding staging in patients treated with preoperative therapy. The local tumor burden (e.g., regional lymph node involvement) determines the intensity of the chemotherapy regimen and whether a child receives abdominal irradiation. Regional adenopathy can be identified on CT/MRI, but enlarged retroperitoneal benign lymph nodes are common in children, and correlation between pathologic findings and lymph node evaluation at surgical exploration in Wilms tumor patients have found significant false-positive and false-negative error rates (Othersen et al, 1990). It should not be expected that CT/MRI would have greater accuracy than visual inspection. Positron emission

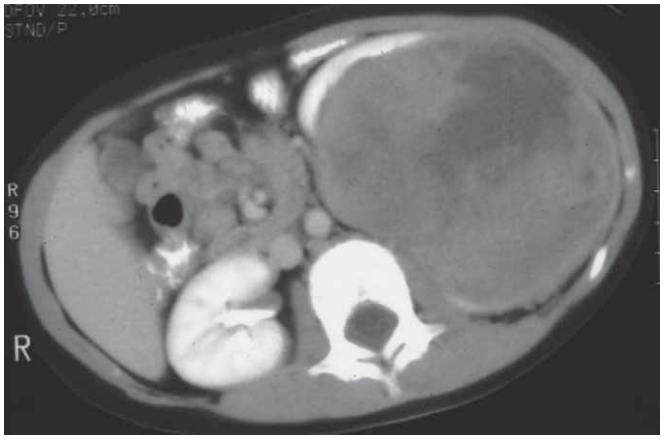

Figure 137–15. CT scan of a left Wilms tumor with a small rim of functioning renal parenchyma.

tomography (PET) has not been shown to have any advantages over conventional imaging modalities in preoperative assessment of Wilms tumor (Misch et al, 2008). Detection of extrarenal tumor extension into the perirenal fat and into adjacent structures is also problematic. Apparent extension of the tumor into adjacent structures is usually the result of compression and not frank invasion (Ng et al, 1991). Therefore determination of inoperability must be made at surgical exploration.

Exploration of the contralateral kidney had long been advised before proceeding with nephrectomy to identify lesions missed on preoperative imaging. However, frequent failure to perform contralateral exploration before nephrectomy was reported in a quality assurance review of NWTS-5 patients (Ehrlich et al, 2005). A review of NWTS-4 patients with bilateral Wilms tumor found that 7% of lesions were missed preoperatively (Ritchey et al, 1995b). Most of the missed contralateral lesions were managed with biopsy alone, yet extended follow-up of the children has not demonstrated any relapses (Ritchey et al, 2005). **The conclusion was that routine exploration is not necessary provided preoperative imaging with thin slices on multidetector helical CT scanners or MRI is performed.**

The lung is the most common site of distant metastasis in children with Wilms tumor. CT of the chest is recommended before surgery. The clinical significance of lung nodules detected on CT scan alone is controversial (Meisel et al, 1999; Owens et al, 2002). CT will clearly detect more lesions than chest x-ray (CXR), but not all of these lesions represent metastases (Ehrlich et al, 2006). Some reports have suggested that treatment of such patients with dactinomycin and vincristine is sufficient without the need for doxorubicin or pulmonary radiation. Others have found an increased risk of pulmonary relapse if more intensive treatment is not given (Owens et al, 2002).

Clear cell sarcoma of the kidney (CCSK) and renal cell carcinoma have a propensity to metastasize to the skeleton (D'Angio et al, 1993; Indolfi et al, 2003). Skeletal surveys and bone scans are both recommended after the histologic diagnosis is confirmed (Feusner et al, 1990). Cranial CT or MRI is performed on all children with CCSK or with rhabdoid tumor of the kidney (RTK), because both are associated with intracranial metastases (Weeks et al, 1989; Indolfi et al, 2003).

Table 137–8.

Staging System of the Children's Oncology Group

Stage I	Tumor confined to the kidney and completely resected. The renal capsule is intact and the tumor was not ruptured prior to removal. No renal sinus extension. There is no residual tumor.
Stage II	Extracapuslar penetration, but is completely resected. Renal sinus extension or extrarenal vessels may contain tumor thrombus or be infiltrated by tumor.
Stage III	Residual nonhematogenous tumor confined to the abdomen: lymph node involvement, any tumor spillage, peritoneal implants, tumor beyond surgical margin either grossly or microscopically, or tumor not completely removed
Stage IV	Hematogenous metastases to lung, liver, bone, brain, etc.
Stage V	Bilateral renal involvement at diagnosis.

Staging

The most important determinants of outcome in children with Wilms tumor are the histopathology and tumor stage. Accurate staging of Wilms tumor allows treatment results to be evaluated and enables universal comparisons of outcomes. The current staging system used by the Children's Oncology Group (Table 137–8) is based primarily on the surgical and histopathologic findings. Examination for extension through the capsule, residual disease, vascular involvement, and lymph node involvement are essential to properly assess the extent of the tumor at presentation.

Stage I tumors are limited to the kidney and completely resected. However, evidence for tumor extension can be subtle. Tumor invasion of blood and lymphatic vessels in the renal sinus is the first sign of spread outside the kidney in stage II tumors (Weeks et al, 1987). Penetration through the renal capsule is the next most common finding of extrarenal spread. Clear demonstration of tumor cells in the perirenal fat is required to document capsular penetration. **Any tumor spill is now a criterion for stage III designation, due to the increased risk for local tumor recurrence** (Shamberger et al, 1999). For NWTS-5, the distribution by stage for patients with FH tumors was stage I, 24.9%; stage II, 29.9%; stage III, 30.6%; and stage IV, 14.5%. Patients with anaplastic tumors are more likely to present with stage III to IV disease than those with FH tumors (Dome et al, 2006).

Prognostic Factors

As the treatment regimens for children with Wilms tumor have become more effective, the ability of retrospectively determined prognostic factors to predict outcomes is diminished. Traditional staging factors, such as tumor size, histology, and lymph node metastases, relied upon in the past to predict risk for tumor progression or relapse, are now less able to stratify FH patients for treatment. Clinical cancer trials are now evaluating biologic factors that may predict tumor behavior.

Chromosomal Abnormalities. As noted above, **LOH for a portion of chromosome 16q and/or 1p has been noted in 20% of Wilms tumors. This is associated with an increased risk for relapse** (Grundy et al, 1994, 2005; Wittman et al, 2007). **This difference in outcome is independent of histology and stage.** NWTS-5 patients with stage I-II FH tumors with LOH of either 1p or 16q had an increased risk of relapse and death in comparison with patients lacking LOH at either locus (Grundy et al, 2005). The risks of relapse and death for patients with stage III to IV FH tumors were increased only with LOH for both regions. These results have been incorporated into the current COG renal tumor protocols. Children whose tumors demonstrate LOH for these chromosomal regions will receive an intensification of treatment.

Another potential marker is telomerase, a reverse transcriptase that maintains chromosome ends, compensating for the loss of DNA that occurs in replication. High telomerase activity has been found to be an unfavorable prognostic feature for several types of cancers. A case cohort study involving 291 patients confirmed the correlation between telomerase RNA expression and recurrence, and this was independent of tumor stage in multivariate analysis (Dome et al, 2005). Future studies will seek to evaluate how telomerase expression may be used in conjunction with other prognostic markers, such as LOH at 1p and 16q, to stratify patients into risk-appropriate treatment groups.

DNA Content. The proliferative rate of tumor cells can be estimated by the measurement of DNA content. Aneuploidy occurs more frequently in anplastic histology tumors, but findings in FH tumors are inconclusive. The correlation between cellular DNA content and prognosis was examined in the NWTS-5 cohort. A DNA index greater than 1.5 was strongly associated with anaplastic histology and predictive of poor outcome. However, DNA content was not predictive of outcome when stratified by histology and stage (Ehrlich, 2007).

Cytokines. The growth of solid tumors is critically dependent on the induction of neovascularity by angiogenic cytokines. Vascular endothelial growth factor (VEGF) is an angiogenic cytokine detected with increased frequency and quantity in experimental and clinical specimens of Wilms tumor (Kayton et al, 1999; Karth et al, 2000). In experimental animals, lung metastases were far more likely to occur in animals with VEGF positive tumors. Anti-VEGF therapy has been shown to suppress tumor growth in mice and can prevent development of metastases (Rowe et al, 2000; Frischer et al, 2004). Antiangiogenesis treatment would appear to be a promising adjunctive future treatment for patients with Wilms tumor.

Treatment

Surgical Considerations

The initial therapy for most children with Wilms tumor is radical nephrectomy. Nephrectomy should be done by a transperitoneal approach. The surgeon is responsible for determining tumor extent. Accurate staging is essential for the subsequent determination of the need for radiation therapy and the appropriate chemotherapy regimen. Thorough exploration of the abdominal cavity is necessary to exclude local tumor extension, liver and nodal metastases, or peritoneal seeding. Exploration of the contralateral kidney is no longer mandated prior to nephrectomy if the preoperative CT or MRI demonstrates a normal kidney (Ritchey et al, 2005). The renal vein and IVC are palpated to exclude intravascular tumor extension prior to vessel ligation. Wilms tumor extends into the inferior vena cava in approximately 6% of cases and may be clinically asymptomatic in more than 50% (Ritchey et al, 1988; Shamberger et al, 2001). **Selective sampling of suspicious nodes is an essential component of local tumor staging. Formal retroperitoneal lymph node dissection is not recommended** (Othersen et al, 1990; Shamberger et al, 1999). Extensive lymph node dissection, particularly above the renal hilum, can result in chylous ascites (Weiser et al, 2003).

The other major responsibility when performing a nephrectomy for Wilms tumor is complete removal of the tumor without contamination of the operative field. Gentle handling of the tumor throughout the procedure is mandatory to avoid tumor spillage, because these patients have a sixfold increase in local abdominal relapse (Shamberger et al, 1999). **Shamberger and colleagues** (1999) **identified risk factors for local tumor recurrence as tumor spillage, unfavorable histology, incomplete tumor removal, and absence of any lymph node sampling**. **The 2-year survival after abdominal recurrence was 43%, emphasizing the importance of the surgeon in performing careful and complete tumor resection.**

Removing a large renal tumor in a small child is associated with some morbidity. NWTS-4 patients undergoing primary nephrectomy had an 11% incidence of surgical complications (Ritchey et al, 1999). The most common complications encountered are hemorrhage and small bowel obstruction (Ritchey et al, 1992, 1993a, 1999). SIOP investigators have reported a lower rate of complications when nephrectomy is performed after preoperative chemotherapy (Godzinski et al, 1998).

Cooperative Group Trials

The finding in the 1960s that dactinomycin (AMD) and vincristine (VCR) were effective agents for treating Wilms tumor radically altered the approach to management of children with this disease (Farber, 1966; Sutow, 1967). Multiple randomized clinical trials have been conducted by the NWTSG, SIOP, and the United Kingdom Children's Cancer Study Group (UKCCSG) to determine the appropriate role for each of the therapeutic modalities available. The NWTSG has now been incorporated with several other groups to form the COG. Patients are stratified into different treatment groups based on stage and pathology. The goals of these trials are to decrease the intensity of therapy for most patients in an effort to prevent late sequelae of treatment while maintaining excellent overall survival. Conduct and design of the trials is becoming longer and more complex given that the survival for patients with all stages of FH Wilms tumor now exceeds 90%.

National Wilms Tumor Study Group (NWTSG) and Children's Oncology Group (COG). The NWTSG was formed in 1969 to study Wilms tumor. The early NWTSG studies, NWTS-1 (1969 to 1973) and NWTS-2 (1974 to 1978), showed that the combination of VCR and AMD was more effective than the use of either drug

alone. The addition of doxorubicin (DOX) was found to improve survival for stage III and IV patients, and postoperative flank irradiation was unnecessary for stage I patients (D'Angio et al, 1976, 1981). **A major achievement of the early trials was identification of prognostic factors that allowed stratification of patients into high-risk and low-risk treatment groups. Patients with positive lymph nodes and diffuse tumor spill were found to be at increased risk of abdominal relapse and therefore considered stage III and given postoperative irradiation. One of the most important findings was the identification of the unfavorable histologic features that have a very adverse impact on survival.**

NWTS-3 (1979 to 1986) demonstrated that stage I-II patients could be treated with 18 weeks of AMD and VCR without irradiation (D'Angio et al, 1989). For stage III FH patients, 10.8 Gy of abdominal irradiation was shown to be as effective as 20 Gy in preventing abdominal relapse if DOX was added to VCR and AMD. NWTS-4 (1987 to 1994) proved that treatment durations of 6 months produced comparable outcomes to 15 months of therapy for patients with stages II-IV/FH tumors (Green et al, 1998). A recent analysis was done comparing the impact of postoperative irradiation on flank recurrence and survival (Breslow et al, 2006). This review found that although radiation did decrease the incidence of flank recurrence, there was no survival advantage. This was attributed to a lower postrecurrence mortality in unirradiated patients.

NWTS-5 (1995 to 2003) was a single arm therapeutic trial. One of the major aims of the trial was to confirm the utility of LOH for chromosomes 16q and 1p to predict increased risk of tumor relapse and death (Grundy et al, 2005). Another objective was to evaluate the efficacy of treatment regimens for anaplastic histology Wilms tumor. Stage I patients were treated with AMD and VCR, but this resulted in a low 4-year EFS of 69.5% (Dome et al, 2006). A new intensified chemotherapy regimen used for patients with stage II to IV diffuse anaplasia did not result in an improved survival.

In NWTS-5, children less than 2 years of age with stage I FH tumors and weighing less than 550 g did not receive chemotherapy after nephrectomy. This portion of the study was closed when the number of tumor relapses exceeded the limit allowed by the design of the study (Green et al, 2001a). A recent long-term review of this cohort was done comparing the outcomes to similar patients treated with postoperative AMD and VCR (Shamberger et al, 2009). The 5-year EFS for surgery alone was 84%, but the 5-year OS was the same. These results suggest that such an approach should continue to be evaluated in future trials. There is a trade-off between more intensive therapy and its potential long-term sequelae required for the 16% of children who relapse versus the avoidance of any postoperative chemotherapy in the majority.

A uniform approach for the treatment of tumor relapse was used in NWTS-5. These results were recently published (Green et al, 2007). For children whose intial treatment was AMD and VCR only, there was an overall 81% survival at 4 years. Children who relapsed after intial treatment with AMD, VCR, DOX, and radiation did not fare as well, with an overall 48% survival at 4 years (Malagolowkin et al, 2008). The NWTSG merged with several other oncology groups to form the COG. Table 137–9 lists the current COG renal tumor protocols and their major objectives.

Table 137–9.

Summary of Current Children's Oncology Group Renal Tumor Studies

AREN 0532

1. Very low-risk patients (stage I FH tumors <550 g with age <2 years) will be treated by nephrectomy alone. The goal is to achieve a 4-year EFS of greater than or equal to 85% and 4-year OS greater than or equal to 95%.
2. Patients with stage III FH Wilms tumor without LOH of 1p *and* 16q will be treated with vincristine, dactinomycin , and doxorubicin (regimen DD-4A), and radiotherapy. The goal is to achieve a 4-year EFS of greater than or equal to 85% and 4-year OS greater than or equal to 95%.
3. Patients with stage I and II FH Wilms tumor with LOH of 1p *and* 16q will be treated with vincristine, dactinomycin, and doxorubicin (regimen DD-4A) but not radiotherapy. The goal is to improve the current 4-year EFS.

AREN 0533

1. Patients with stage IV FH Wilms tumor will be treated with vincristine, dactinomycin, and doxorubicin (regimen DD-4A). Those that have complete resolution of the pulmonary lesions after 6 weeks will not receive radiation therapy. The goal is to achieve a 4-year EFS of 85% without whole lung irradiation.
2. Patients with stage IV FH Wilms tumor who do not have resolution of pulmonary metastases after 6 weeks of therapy will receive cyclophosphamide and etoposide in addition to regimen DD-4A. The goal is to achieve a 4-year EFS of 85%.
3. Patients with stage III or IV FH Wilms tumor with loss of LOH for chromosomes 1p *and* 16q will receive cyclophosphamide and etoposide in addition to regimen DD-4A. The goal is to improve the 4-year EFS to 75%.

AREN 0321

1. Patients with stage I diffuse anaplasia and stage I-III focal anaplasia Wilms tumor will be treated with vincristine, dactinomycin, and doxorubicin (regimen DD-4A) and radiotherapy.
2. Patients with stage I CCSK will be treated with vincristine, dactinomycin, and doxorubicin (Regimen DD-4A) but not radiotherapy.
3. Patients with stage IV focal anaplasia, diffuse anaplasia stage II-III Wilms tumor, stage IV CCSK, and stage I-IV malignant rhabdoid tumor of the kidney will be treated with new chemotherapy protocols to try and improve survival.

AREN O534

1. Patients with bilateral Wilms tumor will be given 6-12 weeks of vincristine, dactinomycin, and doxorubicin. Surgery is to be performed no later than week 12. The goal is to improve the 4-year EFS to 73%.
2. Patients with diffuse hyperplastic perilobar nephrogenic rests (DHPLNR) will be treated with 18 weeks of vincristine and dactinomycin. The goal is to evaluate the efficacy of chemotherapy in preserving renal units in children with and preventing Wilms tumor development.
3. Patients with unilateral tumors and aniridia, Beckwith-Wiedemann syndrome (BWS), hemihypertrophy, or other overgrowth syndromes will receive prenephrectomy chemotherapy for 6 weeks with vincristine and dactinomycin. The goal is to facilitate partial nephrectomy in 25% of children.

AMD, dactinomycin; CPM, cyclophosphamide; DOX, doxorubicin; EFS, event-free survival; FH, favorable histology; OS, overall survival; VCR, vincristine.

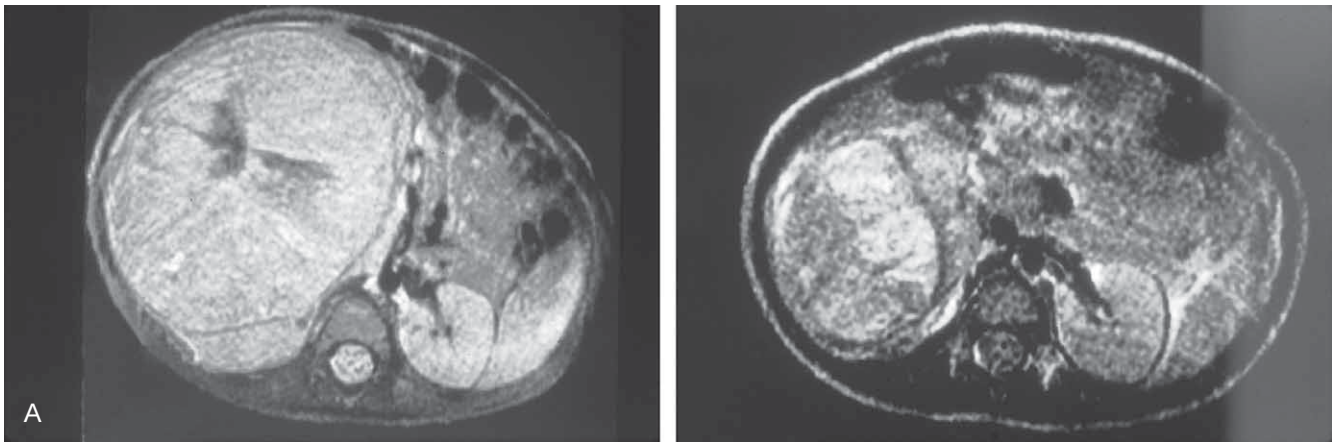

Figure 137–16. **A,** MRI of a Wilms tumor that was pretreated with chemotherapy. **B,** After 6 weeks of chemotherapy, the tumor is much smaller in size.

Wilms tumor occasionally occurs in adults. Earlier reports suggested that the outcome for adults with Wilms tumor was poor and that they require more intensive therapy (Byrd et al, 1982, Arrigo et al, 1990). Recent reviews of adult patients with FH Wilms tumor registered on NWTS-4 and -5 and SIOP 93-01 found improved survival compared with earlier reports (Kalapurakal et al, 2004a; Reinhard et al, 2004a). The recommendation is that adult patients receive stage-appropriate combined modality therapy.

International Society of Pediatric Oncology (SIOP). In the randomized clinical trials conducted by SIOP, preoperative therapy is given before surgery. This approach usually results in tumor shrinkage (Fig. 137–16), reducing the risk of intraoperative rupture or spillage (Lemerle et al, 1976). A greater number of patients have "post-chemotherapy stage I" tumors due to disappearance of micrometastases after neoadjuvant therapy. This was thought to be a significant advantage in terms of decreasing morbidity of treatment, particularly the late effects of radiotherapy.

Early SIOP studies evaluated prenephrectomy XRT (Lemerle et al, 1976). **SIOP-5 (1976 to 1980) showed that 4 weeks of AMD and VCR was as effective as prenephrectomy XRT in avoiding surgical tumor rupture and increasing the proportion of patients with low-stage disease** (Lemerle et al, 1983). **SIOP-6, (1980 to 1987), demonstrated that patients with "postchemotherapy stage I" disease can safely be treated with 18 weeks of AMD and VCR** (Tournade et al, 1993). **However, patients with "postchemotherapy stage II" tumors and negative lymph nodes were found to have a higher rate of abdominal relapse if postoperative irradiation was omitted** (Tournade et al, 1993). An anthracycline was subsequently added for treatment of these children. SIOP-6 confirmed the need for a three-drug chemotherapy regimen following nephrectomy for patients with "postchemotherapy stage II" lymph node–positive and stage III tumors. SIOP-9 (1987 to 1993), demonstrated that the relapse rate for stage II patients with negative lymph nodes without radiation therapy was reduced with epirubicin (Tournade et al, 2001). This study also demonstrated that treatment with VCR and AMD for 4 weeks versus 8 weeks had comparable rates of stage distribution and tumor shrinkage in patients with stage I to III disease. The majority of tumor shrinkage was noted in the first 4 weeks of therapy. Radiotherapy was limited to patients with stage II node-positive and III disease, resulting in 18% of patients being irradiated (Graf et al, 2000). There were 59 children with stage I to IV tumors who had complete tumor necrosis induced by chemotherapy, and 98% of these children had no evidence of disease at 5 years (Boccon-Gibod et al, 2000).

The latest SIOP study on Wilms tumor, SIOP 93-01 (1993 to 2000), evaluated a reduction in postoperative therapy for patients with stage I intermediate-risk and anaplastic Wilms tumor (deKraker et al, 2004; Reinhard et al, 2004b). Patients were randomized to receive either 4 or 18 weeks of postoperative chemotherapy with AMD and VCR. Two-year event-free survival (EFS) was 91.4% after 4 weeks and 88.8% after 18 weeks of therapy, demonstrating that survival can be maintained while shortening the duration of postnephrectomy therapy.

An interesting finding of the SIOP studies is the assessment of the tumor response after preoperative chemotherapy in terms of tumor volume and histology. The relative proportions of histologic subtypes of WT differ following preoperative chemotherapy when compared with those reported following primary surgical resection (Weirich et al, 2001). **Stromal and epithelial predominant tumors are found more often after chemotherapy. These histologic subtypes may demonstrate a poor clinical response to therapy but have an excellent prognosis if the tumor is completely excised.** The proportion of blastema-predominant tumors is decreased after chemotherapy, indicating some response of this tumor type to the preoperative chemotherapy. **However, patients with blastema-predominant tumors after chemotherapy have a high relapse rate** (Reinhard et al, 2004b). Tumor progression during therapy occurred in 5% of patients enrolled in SIOP 93-01 (Ora et al, 2007). These patients were documented to have decreased overall survival.

SIOP now classifies tumors with complete tumor necrosis following preoperative chemotherapy as "low risk." Children with stage I "low-risk" tumors following post-chemotherapy nephrectomy receive no further chemotherapy (Boccon-Gibod et al, 2000). Tumors with diffuse anaplasia and blastemal predominance after chemotherapy are classified as "high risk," and these children are treated with an intensified postoperative chemotherapy regimen. SIOP "intermediate-risk" tumors comprise all other histologies. The ongoing SIOP 2001 study treats patients with stage I "intermediate-risk tumors" with AMD and VCR. The most important study question of this trial is whether patients with stage II and III "intermediate-risk" tumors can be safely treated without

an anthracycline. Data from SIOP 93-01 has suggested that surival was not adversely affected when nonviable tumor was identified in the renal sinus and/or perirenal fat after preoperative chemotherapy (Vujanic et al, 2009).

United Kingdom Children's Cancer Study Group. The UKCCSG trials use prenephrectomy chemotherapy but, unlike SIOP, they perform biopsy prior to treatment (Pritchard et al, 1995; Mitchell et al, 2000; Pritchard-Jones et al, 2003). This is done to avoid giving chemotherapy for benign conditions, which acccount for 1% of lesions thought to be Wilms tumor on imaging studies (Tournade et al, 2001). The other reason to perform biopsy is to avoid giving inappropiate chemotherapy to non-Wilms tumors. The UKW3 trial noted a 12% incidence of non-Wilms tumors in patients with the typical features of Wilms tumor on imaging study (Vujanic et al, 2003). The UKW1 and UKW2 studies evaluated the single agent vincristine for treatment of stage I FH tumors (Pritchard et al, 1995; Mitchell et al, 2000). The overall survival of 96% compares well with two-drug chemotherapy, but age greater than 4 years was considered an adverse prognostic factor (Pritchard-Jones et al, 2003).

The UKW3 trial randomly assigned patients to either immediate surgery or to 6 weeks preoperative chemotherapy and then delayed surgery (Mitchell et al, 2006). Event-free and overall survival at 5 years was similar in the two groups. Around 20% of survivors avoided treatment with doxorubicin or radiotherapy, due to favorable stage distribution after preoperative therapy. They concluded, like the SIOP group, that all children with nonmetastatic Wilms tumor should receive chemotherapy prior to tumor resection.

Preoperative Chemotherapy (COG Recommendations)

On the COG renal tumor protocols, treatment is dependent on surgical and pathologic staging following immediate nephrectomy. There are, however, some situations where preoperative chemotherapy is recommended. These include children for whom renal-sparing surgery is planned (Blute et al, 1987), tumors are inoperable at surgical exploration (Ritchey et al, 1994), and there is tumor extension into IVC above the hepatic veins (Ritchey et al, 1993b; Shamberger et al, 2001; Szavay et al, 2004). The latter two conditions are associated with an increased risk for surgical complications if primary nephrectomy is undertaken (Ritchey et al, 1992).

Inoperable Tumors. **The surgeon must make the determination that a tumor is inoperable. This decision should not be based on preoperative imaging studies, which can overestimate local tumor extension.** As noted above, not all renal masses in children represent Wilms tumor (Vujanic et al, 2003; Reinhard et al, 2004a, 2004b). **If the tumor is found to be unresectable, pretreatment with chemotherapy almost always reduces the bulk of the tumor and renders it resectable** (Ritchey et al, 1994; Grundy et al, 2004) (Fig. 137–16). **Patients who are staged by imaging studies alone and recieve preoperative chemotherapy before nephrectomy are also at risk for understaging** (Tournade et al, 1993). **A patient determined to have an inoperable tumor should be considered stage III and treated accordingly** (Ritchey et al, 1994).

Repeat imaging is performed after 6 weeks of chemotherapy. Experience in SIOP has shown that the majority of reduction in tumor volume occurs in the first 4 weeks (Tournade et al, 2001). After there has been adequate shrinkage of the tumor, definitive resection can generally be completed. A clinically good response (by imaging) is usually associated with a pathologically good response in terms of regressive histologic changes (Zuppan et al, 1991; Weirich et al, 2001). The converse is not always true. The distribution of histologic subtypes is different following preoperative chemotherapy compared with primary surgery, with differentiation of the tumor occurring after chemotherapy. Stromal and epithelial predominant tumors are found more often after treatment with preoperative chemotherapy. These histologic subtypes may demonstrate a poor clinical response to therapy but have an excellent prognosis if the tumor is completely excised. Patients with progressive disease have a poor prognosis, and these patients will require treatment with a different chemotherapeutic regimen (Ritchey et al, 1994; Ora et al, 2007).

Bilateral Wilms Tumors. **Synchronous bilateral Wilms tumors occur in 5% to 7% of children with Wilms tumor** (Blute et al, 1987; Coppes et al; 1989; Montgomery et al, 1991). **Children with bilateral tumors should not undergo initial radical nephrectomy. These children should receive preoperative chemotherapy with the goal of tumor shrinkage and renal-sparing surgery** (Blute et al, 1987; Coppes et al, 1989; Kumar et al, 1998). Preservation of renal tissue is important to decrease the incidence of renal failure, which approaches 15% at 15 years post-treatment in patients with bilateral Wilms tumor (Ritchey et al, 1996; Breslow et al, 2005). The most common etiology for renal failure was the need for bilateral nephrectomy for persistent or recurrent tumor in the remaining kidney after initial nephrectomy. Nephrectomy can be avoided in the majority of patients if a careful protocol is followed and the surgery is performed by surgeons experienced in renal-sparing techniques (Davidoff et al, 2008).

The current COG protocol for patients with BWT recommends 6 weeks of chemotherapy prior to surgery. Biopsy is not needed if the radiographic picture is consistent with Wilms tumor. Tumor response is assessed after 6 weeks with CT or MRI to determine the reduction in tumor volume and feasibility of partial resection. Patients with tumors amenable to renal-sparing procedures can proceed with surgery. Imaging cannot, however, predict the histology of the tumor based on changes in volume of the tumor after chemotherapy (Weirich et al, 2001; Olsen et al, 2004). **Tumors not responding to therapy require bilateral open biopsy to determine histology. Open biopsies are recommended, because they are more accurate than percutaneous needle biopsies when assessing for anaplasia** (Hamilton et al, 2006). **Failure to achieve a reduction in volume is likely due to tumor differentiation** (Fig. 137–17) (Weirich et al, 2001; Anderson et al, 2002; Shamberger et al, 2006). Differentiated tumors may show a poor clinical response to therapy, but have an excellent prognosis if the tumor is completely excised. If renal sparing surgery is not feasible, additional chemotherapy is then given based on the biopsy findings, but all patients should proceed to surgical resection within 12 weeks of starting therapy. Continuing treatment beyond 12 weeks will not likely provide any additional reduction in tumor burden.

At the time of second-look surgery, partial nephrectomy or wedge excision of the tumor is preferred, with an attempt to achieve negative margins. The kidney with the lower tumor burden is addressed first. Tumor enucleation may be considered in lieu of a formal partial nephrectomy. This is often needed for large centrally located tumors where removal of a margin of renal tissue would compromise the vascular supply to the kidney (Cozzi et al, 1996; Horwitz et al, 1996). The concern is that enucleation will be more likely to result in positive surgical

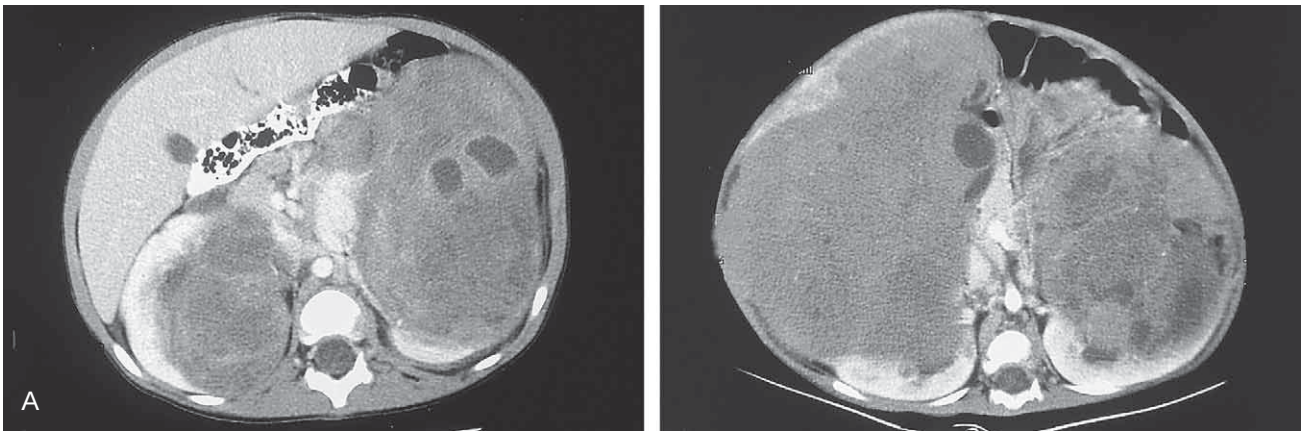

Figure 137–17. Patient with bilateral tumors who was treated with chemotherapy. **A,** CT before treatment. **B,** CT after 6 months of chemotherapy, showing an increase in the size of the tumors. Bilateral partial nephrectomies were performed, revealing mature tumor elements with rhabdomyoblastic differentiation.

margins. For FH tumors, adjuvant therapy may still provide for a good outcome (Cozzi et al, 1996; Horwitz et al, 1996; Davidoff et al, 2008). However, if there is anaplasia in the resected specimen, a positive margin will adversely affect survival and require additional resection. Even when large bilateral masses remain after initial chemotherapy, a high percentage of children can be successfully managed with renal-sparing surgery (Davidoff et al, 2008). It is easy to underestimate the amount of renal parenchyma that can be salvaged due to compression by the tumor; therefore nephron-sparing surgery should be entertained in all patients.

Radical nephrectomy may be needed in a kidney with extensive tumor involvement. Bilateral nephrectomies and dialysis are rarely required when the tumors fail to respond to chemotherapy and radiation therapy. This is the most common cause of renal failure in patients with bilateral Wilms tumor (Ritchey et al, 1996). Fortunately, anephric patients can still be administered chemotherapy with some modifications (Feusner et al, 2008). The recommended interval between successful completion of treatment of the Wilms tumor and renal transplantation varies (Penn, 1979; Kist-van Holthe et al, 2005). Some advocate a waiting period of 2 years to ensure that the patient does not develop metastatic disease; others have found that a 1-year interval is sufficient. Patients who develop renal failure after renal-sparing surgery should have removal of the remaining renal tissue prior to transplant to prevent tumor recurrence after starting immunosuppression (Kubiak et al, 2004).

All patients treated for bilateral Wilms tumor require close long-term follow-up. SIOP investigators have noted that late relapses have occurred in patients with BWT more than 4 years post-treatment and recommended long-term follow-up (Coppes et al, 1989). These patients should also have frequent assessment of renal function, urine protein, and blood pressure.

Partial Nephrectomy for Unilateral Tumors. Several centers have explored the role of parenchymal-sparing procedures in children with unilateral Wilms tumors (McLorie et al, 1991; Cozzi et al, 1996; Moorman-Voestermans et al, 1998; Haecker et al, 2003; Linni et al, 2003; Zani et al, 2005). The primary motivation for this approach is concern about late occurrence of renal dysfunction after unilateral nephrectomy. **However, the incidence of renal failure following nephrectomy for most children with unilateral Wilms tumor is low, 0.6% at 20 years post-treatment** (Breslow et al, 2005). **The risk of renal failure is higher for patients with genitourinary anomalies, DDS, and WAGR.** As noted above, this is due to mutation of *WT1,* which is necessary for normal renal development.

Most Wilms tumors are too large at diagnosis to allow partial nephrectomy. After preoperative chemotherapy, partial nephrectomy can be performed in 10% to 15% of patients. Only the occasional child with Wilms tumor will present with a lesion small enough to allow partial nephrectomy at diagnosis, for instance, tumors detected due to screening studies for Beckwith-Wiedemann syndrome and aniridia (see Fig. 137–10). As noted above, there are concerns regarding staging after chemotherapy, requiring some patients to receive added therapy to prevent local recurrence. Another concern is the increased risk for local recurrence after partial nephrectomy (Horwitz et al, 1996; Haeker et al, 2003). Patients who develop intra-abdominal relapse have a markedly decreased survival (Shamberger et al, 1999).

The COG has proposed a renal-sparing protocol for select patients with unilateral Wilms tumors. These include patients known to be at risk for bilateral disease or those at increased risk for renal failure. These patients will be managed with a strict surgical protocol to minimize risk for residual disease (Cozzi et al, 2004). The lesion should be completely excised with a margin of normal renal parenchyma. These patients should not undergo partial nephrectomy if the tumor cannot be removed as a stage I entity. Patients with high-risk histologic patterns, such as anaplasia or persistent blastema-predominant tumor after chemotherapy, should be treated with complete nephrectomy because these tumors have resistance to chemotherapy.

Late Effects of Treatment

Numerous organ systems are subject to the late sequelae of anticancer therapy. Clinicians must be aware of the spectrum of problems that face children as they grow into adulthood. Musculoskeletal problems, such as scoliosis, were significant in children receiving irradiation in the early NWTS trials (Evans et al, 1991). Hogeboom aand colleagues (2001) studied the impact of treatment on stature in Wilms tumor patients. The authors noted that reductions in stature directly correlated to total radiation

dose and age at treatment but concluded that currently recommended radiation doses should not result in clinically significant height deficits.

Gonadal radiation can produce hypogonadism and temporary azospermia in boys (Kinsella et al, 1989). The severity of damage is dependent on the radiation dose. The Leydig cells are more radioresistant than the germ cells, but higher doses can produce damage resulting in inadequate production of testosterone. This can result in delayed sexual maturation. Chemotherapeutic agents can also adversely affect testicular function (Mustieles et al, 1995). A 12% incidence of ovarian failure was found in girls receiving abdominal XRT (Stillman et al, 1987). Abdominal XRT also increases the risk for adverse pregnancy outcomes (Li et al, 1987; Green et al, 2002). The offspring of irradiated female patients are at risk for low birth weights, premature birth, and congenital malformations. Radiation portals that include the pelvis and doses exceeding 20 Gy increase the risk of miscarriage (Kalapurakal et al, 2004b).

An increased incidence of second malignant neoplasms has been noted in children treated for Wilms tumor. There is a 1% cumulative incidence at 10 years postdiagnosis and a rising incidence thereafter (Breslow et al, 1988b; Taylor et al, 2008). One of the greatest risk factors is prior irradiation, and most tumors occur in the radiation field (Breslow et al, 1988b; Bassal et al, 2006; Taylor et al, 2008).

In recent years, there has been increasing concern regarding the risk of congestive heart failure in children who receive treatment with anthracyclines such as DOX (Green et al, 2001b). In addition to the acute cardiotoxicity, cardiac failure can develop many years after treatment (Steinherz et al, 1991). In a preliminary review of patients entered on NWTS-1, -2, -3, and -4, the frequency of congestive heart failure was 4.4% among DOX-treated patients who received this drug as part of their initial chemotherapy regimen (Green et al, 2001b). The risk was increased if the patient received whole lung or left flank irradiation.

OTHER RENAL TUMORS

Clear Cell Sarcoma of the Kidney

Clear cell sarcoma of the kidney (CCSK) accounts for 3% of renal tumors reported to the NWTSG. The tumor derives its name from the clear cytoplasm of the predominant cell type (Schmidt and Beckwith, 1995). **Important predictors of improved survival are lower stage, younger age at diagnosis, treatment with doxorubicin, and absence of tumor necrosis** (Argani et al, 2000). **The addition of doxorubicin improved both overall survival and relapse-free survival** (D'Angio et al, 1989; Argani et al, 2000; Seibel et al, 2004). Patients with stage I tumors (using the current criteria of absence of renal sinus invasion) had a 98% survival rate. Unlike anaplastic Wilms tumor, even stage I CCSK lesions are associated with increased rates of relapse and require postoperative irradiation. Long-term follow-up of CCSK patients is needed because 30% of relapses occurred more than 3 years after diagnosis, and some as late as 10 years. Unlike Wilms tumor, **CCSK is associated with bone and brain metastases.** Bilateral involvement has thus far not been reported, nor has the presence of Wilms tumor–associated congenital anomalies such as aniridia or hemihypertrophy. Patients with CCSK were treated on NWTS-5 with a regimen combining VCR, DOX, cyclophosphamide, and etoposide in an attempt to further improve the survival of this high-risk group, but results of that trial are pending.

Rhabdoid Tumor of the Kidney

Rhabdoid tumor of the kidney (RTK) is the most aggressive and lethal childhood renal tumor, which accounts for 2% of renal tumors registered to the NWTSG. RTK is now considered a sarcoma of the kidney, and the cell of origin is unknown (D'Angio et al, 1989). The tumor derives its name from the resemblance to rhabdomyoblasts, but the tumor is not derived from myogenic cells. RTK and CCSK both occur in renal and extrarenal locations, suggesting an origin from a non–organ-specific mesenchymal cell. Cytogenetic studies have shown that there may be a common genetic basis for renal and extrarenal rhabdoid tumors. Deletions and somatic mutations in the *INI1* gene on chromosome 22 in the region of 22q11 predispose to the development of this tumor (Biegel et al, 1999). Germline mutations of *INI1* have been identified in renal rhabdoid tumors. Staining for the products of the *INI1* gene can be useful because rhabdoid tumor of the kidney is consistently negative (Hoot et al, 2004).

Typical clinical features include early age of diagnosis (median age less than 16 months), advanced stage, resistance to chemotherapy, and high mortality (Amar et al, 2001; Tomlinson et al, 2005). Younger age at diagnosis is an adverse prognostic factor. **RTK is distinguished by its propensity to metastasize to the brain** (D'Angio et al, 1993). In addition, RTK is associated with second primary tumors in the brain, including cerebellar medulloblastomas, pineoblastomas, neuroblastomas, and subependymal giant cell astrocytomas (Bonnin et al, 1984).

Congenital Mesoblastic Nephroma

Congenital mesoblastic nephroma (CMN) is the most common renal tumor in infants, with a mean age at diagnosis of 3.5 months (Howell et al, 1982; van den Heuvel-Eibrink et al, 2008). **This is the most common renal tumor diagnosed on antenatal ultrasonography** (LeClair et al, 2005). Congenital mesoblastic nephroma is a very firm tumor on gross examination, and the cut surface has the yellowish-gray trabeculated appearance of a leiomyoma. There are three histolgic subtypes: classical, cellular, and mixed (showing areas of both classical and cellular). The classical subtype, characterized by interlacing sheets of bland spindle cells, resembles infantile fibromatosis. The cellular variant, with a solid sheetlike growth pattern and frequent mitoses, is virtually identical histologically to congenital fibrosarcoma (Beckwith, 1986; Joshi et al, 1986; Gormley et al, 1989). Both tumors have a similar translocation that fuses the *ETV6* (*TEL*) gene from 12p13 with the 15q25 neurotrophin-3 receptor gene, *NTRK3* (Argani et al, 1998). In CMN, tumor induction is postulated to occur at a time when the multipotent blastema is predominately stromagenic (Snyder et al, 1981; Tomlinson et al, 1992). *WT1* is not expressed in CMN (Tomlinson et al, 1992).

The most important aspect of CMN is the usually excellent outcome with radical surgery only (Howell et al, 1982). The tumor can extend into the hilar or perirenal soft tissue, therefore complete surgical resection is important (Beckwith, 1986). Local recurrence and metastasis can occur particularly with the cellular variant of CMN (Joshi et al, 1986; Gormley et al, 1989; Fitchey et al, 2003). The risk of recurrence is thought to be less in children less than 3 months of age at diagnosis, but metastases have been reported in a few infants (Heidelberger et al, 1993). Neither chemotherapy nor radiation therapy is routinely

recommended (Howell et al, 1982), but consideration for adjuvant treatment should be given to patients with cellular variants that are incompletely resected (Gormley et al, 1989). There are reports demonstrating response of both inoperable and recurrent tumors to chemotherapy (Loeb et al, 2002; McCahon et al, 2003).

Solitary Multilocular Cyst and Cystic Partially Differentiated Nephroblastoma

Solitary multilocular cyst, or multilocular cystic nephroma, is an uncommon, benign renal tumor. Fifty percent of multilocular cysts are found in young children, usually boys. The second peak incidence occurs in young adult women (Eble and Bonsib, 1998; Luithle et al, 2007). Although the majority of cases of multilocular cystic renal disease have been unilateral, there are rare reports of bilateral cases (Ferrer and McKenna, 1994). The gross appearance of the tumor is its most distinguishing feature. The cut surfaces reveal a well-encapsulated multilocular tumor composed of varying-sized cysts compressing the surrounding renal parenchyma. This tumor is distinguished by the finding of only mature cell types within the septa of the cyst wall. Multilocular cystic nephroma is cured by nephrectomy, but recurrence has occurred following incomplete excision by partial nephrectomy. If partial nephrectomy is considered, frozen section is indicated to exclude cystic, partially differentiated nephroblastoma (CPDN), or clear cell sarcoma, which can occasionally have a similar appearance.

Another entity reported in the literature with similar features is cystic partially differentiated nephroblastoma. The majority of these lesions occur in the first 2 years of life (Joshi and Beckwith, 1989; Blakely et al, 2003; Luithle et al, 2007). Eble and Bonsib (1998) recommend that multilocular cystic nephroma and cystic partially differentiated nephroblastoma be considered the same entity. They are indistinguishable radiographically. Histologic examination reveals that blastemal cells or nephrogenic rests may be found in the septa of both tumors. Surgery is curative in almost all patients with recurrence, the result of incomplete resection (Eble and Bonsib, 1998; Blakely et al, 2003). In a review of 21 children with CPDN reported to the NWTSG, there was 100% survival. Eight were treated with surgery alone (Blakely et al, 2003). Thirteen patients received postoperative chemotherapy, including two patients with stage II disease.

Metanephric Adenofibroma

Another tumor with prominent stromal features that can resemble CMN is metanephric adenofibroma (Arroyo et al, 2000). The epithelial component of these tumors can range from inactive metanephric adenoma to Wilms tumor. Other lesions contain areas morphologically identical to papillary renal cell carcinoma. This uncommon entity may be derived from ILNR (Arroyo et al, 2000). Metanephric adenofibromas with a composite Wilms tumor component occur at a young age (mean of 12 months), similar to other ILNR-related Wilms tumors that develop in patients with DDS and aniridia. None of these tumors have recurred after nephrectomy, but all have been treated with Wilms tumor chemotherapy.

Renal Cell Carcinoma

Renal cell carcinoma is the most common renal malignancy in the second decade of life. Only 5% of renal cell carcinomas occur in children (Hartman et al, 1982; Broecker, 1991). An abdominal mass is the most common presentation, but hematuria is more common than in Wilms tumor (Broecker, 1991). Imaging studies cannot differentiate renal cell carcinoma from other solid renal tumors. **There is a higher incidence of papillary renal cell carcinoma in children** (Carcao et al, 1998; Renshaw et al, 1999). **These tumors, typically seen in adolescence or young adults, are genetically unique in that they have chromosome translocations involving a common breakpoint in the *TFE* gene located at Xp11.2** (Bruder et al, 2004). These tumors differ from adult RCC in that immunoreactivity for epithelial markers is reduced or absent.

Another type of RCC more often seen in children is renal medullary carcinoma found in patients with sickle cell hemoglobinopathy (Swartz et al, 2002). The median age at presentation is 13 years, but can be found in much younger children. It is a highly lethal tumor.

Complete tumor resection is the most important determinant of outcome in RCC. Raney and colleagues found that all children with stage I lesions survived, and others have reported 64% to 80% survival for stage I and II tumors (Dehner et al, 1970; Castellanos et al, 1974; Raney et al, 1983; Aronson et al, 1996). Partial nephrectomy has been used in pediatric patients with RCC, but outcome data are limited (Cook et al, 2006). Younger age at diagnosis is a favorable prognostic factor (Raney et al, 1983). Regional lymph node involvement does not portend the same poor prognosis as adult renal cell carcinoma (Geller and Dome, 2004). Like renal cell carcinoma in adults, these tumors are not responsive to chemotherapy or radiation therapy.

Angiomyolipoma

Renal angiomyolipoma is a hamartomatous lesion that is only rarely seen in childhood. There is a clear association with the tuberous sclerosis complex (TSC), and presentation is more often bilateral in these patients (Blute et al, 1988; Ewalt et al, 1998). **The renal lesions of the TSC include angiomyolipoma, simple cysts, polycystic kidney disease, and renal cell carcinoma. Angiomyolipoma develops in up to 80% of patients with the TSC** (Ewalt et al, 1998). Two genes have been identified in the TSC on chromosome 9 (*TSC1*) and chromosome 16 (*TSC2*) (Povey et al, 1994). It has been postulated that these genes act as tumor suppressor genes and that the LOH of *TSC1* or *TSC2* may explain the progressive growth pattern of renal lesions seen in these patients (Henske, 2004).

The incidence of angiomyolipoma increases with age. Ewalt and colleagues (1998) reported on 60 patients with the TSC who were followed with periodic ultrasonograms. The average age at which a normal ultrasonogram became abnormal was 7.2 years. Angiomyolipomas were found in 45 children. Growth of the lesion was observed in 28 children. Girls were more likely to have an increase in the size of the lesion. All patients with lesions greater than 4 cm in diameter were postpubertal. Annual ultrasonograms are recommended after puberty. **Children with growing lesions** (Fig. 137–18) **can be managed with embolization or partial nephrectomy before they become symptomatic with bleeding** (Lee et al, 1998; Williams et al, 2006). **The risk of serious bleeding appears to correlate with a diameter of greater than 4 cm** (Blute et al, 1988; Dickinson et al, 1998; Steiner et al, 1993). Nephron-sparing approaches are recommended in children with the TSC, due to the presence of multiple, bilateral lesions and the risk of developing of new lesions.

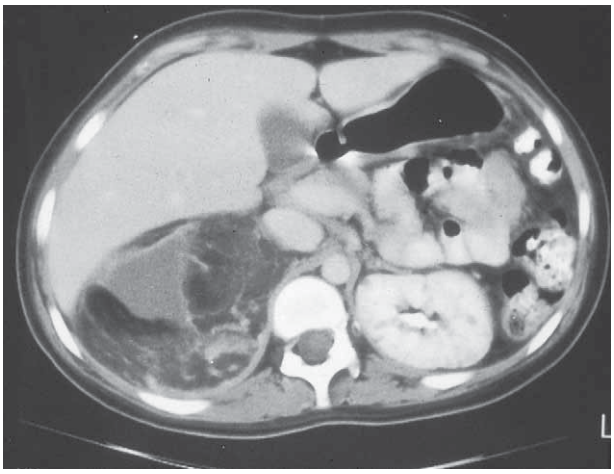

Figure 137–18. Angiomyolipoma of the right kidney in a patient with tuberous sclerosis.

Key Points: Renal Tumors

- Deletions of *WT1*, located on chromosome 11p, are found in patients with aniridia and Wilms tumor. Mutations of *WT1* occur in DDS. *WT1* is important for normal renal and gonadal development.
- LOH for chromosomes 1p and 16q is associated with an increased risk for relapse and death in Wilms tumor patients.
- Local recurrence is increased in Wilms tumor patients with local tumor spillage, and this is not classifed stage III disease. The 2-year survival rate after local recurrence is 43%.
- Congenital mesoblastic nephroma (CMN) is the most common renal tumor in infants.

TESTICULAR TUMORS

Testicular tumors account for 1% to 2% of all pediatric solid tumors, with an annual incidence of 1:100,000 for boys less than 15 years of age in the United States (Young et al, 1986). **Benign lesions represent a greater percentage of cases in children than in adults.** The American Academy of Pediatrics prepubertal testis tumor registry reported that benign tumors accounted for 38% of cases (Ross et al, 2002). Several large series have reported a higher percentage of benign lesions, suggesting that these entities were under-reported to the tumor registry (Metcalfe et al, 2003; Shukla et al, 2004). **One multicenter report found that 74% of primary testis tumors in prepubertal children were benign** (Pohl et al, 2004). The incidence of childhood testicular tumors peaks at age 2 years (Li and Fraumeni, 1972; Haas and Schmidt, 1995), tapers after age 4 years, but then begins to rise again at puberty. Testis tumors are more common in whites during infancy and rare in black and Asiatic children (Walsh et al, 2008).

Etiology and Genetics

A variety of chromosomal abnormalities have been identified in both adolescent and adult germ cell tumors (GCT). Benign teratomas in children less than 4 years old usually demonstrate no abnormalities (Bussey et al, 1999). The testicular GCTs of adolescents had abnormalities resembling those found in adult testicular GCT, including loss of chromosomes 11, 13, and 18, and gain of chromosomes 7, 8, and the X chromosome (Bussey et al, 1999). The most frequent chromosomal abnormality is the isochromosome of 12p or i(12p), characteristically composed of two copies of 12p. The i(12p) is found in intratubular germ cell neoplasia, implying that this genetic event occurs early. Endodermal sinus tumors have been noted to have a deletion of the short arm of chromosome 1, specifically 1p36 in 805 to 100% of cases (Perlman et al, 1996; Zahn et al, 2006).

Although the etiology of testicular cancer is unknown, a number of etiologic factors have been evaluated. There has been an increasing incidence of testicular cancer in the past few decades among adult men (McKiernan et al, 1999), but this has not been documented in prepubertal boys (Walsh et al, 2008). It is suggested that early or prolonged exposure to some carcinogenic stimuli might be implicated. **Patients with disorders of sex development (DSD) have an increased incidence of gonadal tumors. Patients with hypovirilization and gonadal dysgenesis are at the highest risk. The risk of tumor formation in gonadal dysgenesis is increased if there is a Y chromosome present, with the incidence of tumor development approximately 10% by age 20 years.** The presence of a well-defined part of the Y chromosome (the GBY region) is a prerequisite for tumor formation, with the gene for the testis-specific protein on the Y chromosome (*TSPY*) being a likely candidate gene (Lau et al, 2000; Hersmus et al, 2008). **Intratubular germ cell neoplasia has been noted in 6% of children with DSD, with a higher incidence after puberty** (Ramani et al, 1993). No cases of carcinoma in situ were found before puberty in a large series of patients with complete androgen insensitivity (Hannema et al, 2006).

The link between cryptorchidism and germ cell tumors of the testis is well known, but these are quite rare in childhood (Kay, 1993). Cortes and colleagues (2004) found testicular neoplasia in 7 of 182 (3.8%) children with abdominal undescended testes, abnormal external genitalia, or abnormal karyotype, but none in 1281 children without these characteristics. Neoplasia was found most often in bilateral cryptorchidism. The relative risk of cancer increases with age at orchidopexy, with the greatest risk after puberty (Pettersson et al, 2007).

Pathology

Non–germ cell and germ cell tumors arise from the celomic epithelium and primordial germ cells, respectively. It is postulated that the totipotent germ cells can evolve into seminona or embryonal carcinoma. Embryonal carcinoma is capable of differentiating into embryonic structures, such as mature or immature teratomas and extraembryonic structures (e.g., endodermal sinus tumors and choriocarcinoma). Seminoma or dysgerminoma is a primitive germ cell neoplasm that lacks the capacity for further differentiation. These tumors are unusual in childhood, except when related to gonadal dysgenesis.

Yolk sac tumor (YST) is known by a number of other eponyms, including endodermal sinus tumor, embryonal adenocarcinoma, infantile adenocarcinoma of the testis, orchidoblastoma, and Teilum tumor. It is the most common malignant testis tumor in infants and young boys. Grossly, the tumor is firm and yellow-white on cross section, and hemorrhage is unusual. The microscopic appearance shows a mixture of epithelial and mesenchymal

cells in a characteristic organoid pattern. The tumor cells produce the characteristic stages seen in the morphogenesis of extraembryonic membranes (yolk sac and allantoic mesoderm of the placenta). **The characteristic histologic finding in yolk sac tumors is Schiller-Duval bodies** (Wold et al, 1984). The latter are similar to the endodermal sinuses seen in the rat placenta. Eosinophilic cytoplasmic inclusions are common, and specialized staining techniques demonstrate the presence of α-fetoprotein (AFP).

Teratoma is a germ cell tumor composed of elements of more than one germ cell layer: endoderm, ectoderm, and mesoderm. Teratomas are classified as mature teratoma, immature teratoma, and malignant teratoma. Mature teratomas generally appear well encapsulated on gross examination. There are multiple cysts present, but consistency on cross section varies with the amount of solid tissue present between the cysts. The microscopic appearance varies with the relative amounts of tissue derived from the different germ layers and the degree of maturation (Mostofi and Price, 1973). Cartilage, bone, mucous glands, or muscle may be evident.

Epidermoid cysts occur within the testicular parenchyma and are filled with keratinous debris. Microscopically, well-differentiated stratified squamous epithelium lines the cysts. It is proposed that epidermoid cysts represent a monodermal teratoma (Ulbright, 2005). Intratubular germ cell neoplasia has not been found in the testis parenchyma adjacent to epidermoid cysts (Manivel et al, 1989).

Immature teratomas have a gross appearance similar to that of mature teratomas, but they contain various immature tissues. The latter is usually neuroepithelium, but immature elements representative of other germ cell layers may be found (Heifetz et al, 1998). A grading system for teratomas has been developed (Gonzalez-Crussi, 1982). The incidence of foci of yolk sac tumor increases with the grade of the teratoma, and these patients frequently had elevation of serum AFP preoperatively (Heifetz et al, 1998).

Leydig, Sertoli, and granulosa cells have a common embryologic origin from a mesenchymal stem cell. Pathologic diagnosis can be difficult due to incomplete differentiation (Goswitz et al, 1996). Leydig cell tumors appear well encapsulated with compression of the adjacent testicular tissue. They appear yellow to brown on cross section, reflecting the steroid production by the tumor. Microscopic appearance is similar to that of adrenal rests. The pattern is that of closely packed esosinophilic cells with a granular cytoplasm. **The pathognomonic histologic feature of Leydig cell tumor, Reinke crystals, is present in only about 40% of tumors** (Mostofi and Price, 1973). **Increased mitotic figures or other features suggestive of malignancy are absent in prepubertal Leydig cell tumors.** A review of 30 cases of Leydig cell tumors identified the following features associated with tumors that metastasized: increased mitotic activity, DNA aneuploidy, infiltrative margins, and angiolymphatic invasion (Cheville et al, 1998). Metastasizing tumors also had higher MIB-1, a cell proliferation marker, activity. None of the prepubertal patients had developed metastatic disease.

Sertoli cell tumors are solid, usually without hemorrhage or necrosis. On cross section, they are white to yellow and lobulated in appearance. On microscopic examination, there are large polygonal cells with eosinophilic cytoplasm. Large cell sertoli cell tumors can be confused with Leydig cell tumors, because both are characterized by cells with abundant eosinophilic cytoplasm (Goswitz et al, 1996). The tumors of the adrenogenital syndrome are also another confusing entity in the differential diagnosis (Srikath et al, 1992). Histology does not correlate with outcome, because Sertoli cell tumors often have features of high mitotic rates, nuclear pleomorphism, and increased cellularity.

Gonadoblastomas are small benign tumors found in patients with gonadal dysgenesis, including those who have at least a portion of the Y chromosome (Scully, 1970). They are bilateral in up to one third of cases. The tumors are composed of large germ cells similar to seminoma, sex cord derivatives resembling immature granulosa and Sertoli cells, and occasionally stromal elements.

Carcinoma In Situ

Carcinoma in situ (CIS) or intratubular germ cell neoplasia, is commonly found in adult patients with testicular cancer and is a precursor to the development of invasive germ cell tumor (Skakkebaek, 1975). CIS has been detected in adolescent cases of germ cell tumor (Jorgensen et al, 1995) but has not been identified in children with YST of the testis. The seminiferous tubules adjacent to germ cell tumors in prepubertal children frequently contain cells with enlarged nuclei and clear cytoplasm. However, staining for markers of CIS—placental alkaline phosphatase, and c-*KIT*—in seminiferous tubules adjacent to the germ cell tumor was negative in 28 prepubertal testes (Hawkins et al, 1998). CIS is also frequently detected in patients with androgen-insensitivity disorders and dysgenetic gonads (Muller et al, 1985; Ramani et al, 1993). OCT3/4 has been shown to be a sensitive and specific marker for CIS in the adult male, but its role in prepubertal or DSD patients remains to be defined (Looijenga, 2009).

There is an association between cryptorchidism and the development of CIS. The incidence of CIS is 1.7% in adults who have previously undergone orchidopexy (Giwercman et al, 1989). **Identification of CIS is more difficult in the prepubertal patient.** Biopsies at the time of orchidopexy in prepubertal children have only rarely demonstrated CIS (Hadziselimovic et al, 1984). Giwercman and colleagues (1988) recommend repeat biopsy after puberty in prepubertal patients with CIS.

Diagnosis and Staging

A painless testicular mass is the most common presentation of a child with a testicular tumor. Disorders that must be excluded are epididymitis, hydrocele, hernia, and spermatic cord torsion. The latter can present as a painless mass in the neonate, with little scrotal wall inflammation if the event occurred prenatally. Acute abdominal pain can be the presenting symptom, with torsion of an abdominal undescended testicle containing a tumor. Some patients with hormonally active tumors may have small intratesticular lesions that are not palpable on physical examination.

Testicular ultrasonography is routinely performed in the evaluation of testicular masses in children. Color Doppler ultrasonography has been reported to be more effective than gray-scale ultrasonography in detecting intratesticular neoplasms in the pediatric population (Luker and Siegel, 1994). **There are no sonographic features that can reliably distinguish benign and malignant tumors, but the finding of anechoic cystic lesions can suggest a benign lesion, such as a simple cyst, cystic dysplasia, teratoma, or cystic granulosa cell tumor. The ultrasound findings of epidermoid cyst are also unique** (Fig. 137–19). There is a heterogeneous intratesticular mass with concentric rings of alternating

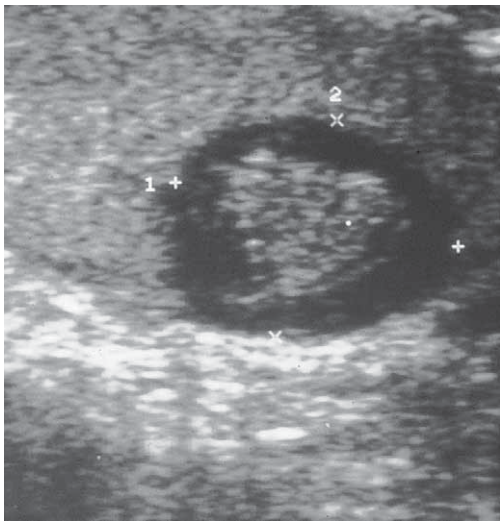

Figure 137–19. Testicular ultrasonogram demonstrating cystic lesion that proved to be an epidermoid cyst of the testicle. The patient underwent a testis-sparing procedure.

hypo- and hyperechoic layers that give rise to an "onion-skin appearance." This corresponds to the multiple layers of keratin debris within the lesion. The mass is surrounded by a hypoechoic or echogenic rim and the absence of flow on color Doppler ultrasonography (Langer et al, 1999). Ultrasonography can also assess if there is enough normal testis parenchyma remaining to warrant salvage. If a child is identified with a cystic lesion on ultrasonography and serum AFP is normal, the surgeon can plan for a testicular-sparing procedure (Rushton et al, 1990; Grunert et al, 1992; Valla et al, 2001; Metcalfe et al, 2003; Shukla et al, 2004). MRI may detect small functioning Leydig cell tumors not evident on ultrasonography (Kaufman et al, 1990).

In addition to ultrasonography, measurement of serum AFP can help identify tumors amenable to a testis-sparing procedure. AFP is a single–polypeptide chain amino acid produced by the fetal yolk sac, liver and gastrointestinal tract. YSTs invariably produce AFP, and all AFP-positive tumors are considered to contain yolk sac elements (Huddart et al, 1990). Teratomas and other benign lesions are associated with normal AFP levels. AFP has a half-life of approximately 5 days, and degradation curves are followed after orchiectomy to assess for residual or recurrent disease. **It is important to note that AFP levels may be elevated levels in infant boys and do not always represent the presence of a malignant tumor or persistent disease after orchiectomy for YST. Normal adult reference laboratory values for AFP cannot be used in young children, because AFP synthesis continues after birth** (Wu et al, 1981; Lahdenne et al, 1991, Brewer and Tank, 1993). **Normal adult levels (<10 mg/mL) are not reached until 8 months of age** (Wu et al, 1981). Human chorionic gonadotropin-β (β-hCG) is a glycoprotein produced by embryonal carcinoma and mixed teratomas. The normal value for β-hCG is less than 5 IU/L. The half-life of β-hCG is approximately 24 hours. β-hCG is rarely elevated in preadolescent tumors.

The current staging system used by the Children's Oncology Group is listed in Table 137–10. Staging is based on both tumor markers and pathologic findings. AFP levels are determined at diagnosis and monitored after radical inguinal orchiectomy to determine if there is an appropriate half-life decline. CT of the retroperitoneum and chest are obtained to exclude metastatic lesions. CT imaging of the retroperitoneum can identify most patients who have lymph node metastases, but there is a 15% to 20% false-negative rate (Pizzocara et al, 1987; Wiener et al, 1994).

Table 137–10.

Children's Oncology Group Staging System for Testicular Germ Cell Tumors

STAGE	EXTENT OF DISEASE
I	Tumor is limited to the testis, completely resected by high inguinal orchiectomy. No clinical, radiographic, or histologic evidence of disease beyond the testes. If scrotal orchiectomy has been performed, all margins are negative after resection of proximal cord structures to the level of the internal inguinal ring. Tumor markers are negative after appropriate half-life decline. Patients with normal or unknown tumor markers at diagnosis must have a negative ipsilateral retroperitoneal node sampling to confirm stage I disease, if radiographic studies demonstrate lymph nodes greater than 2 cm.
II	Microscopic residual disease is present in the scrotum or high in spermatic cord (<5 cm from proximal end). Tumor markers remain elevated after appropriate half-life interval. Tumor rupture or scrotal biopsy prior to complete orchiectomy.
III	Retroperitoneal lymph node involvement. Lymph nodes greater than 4 cm by CT are considered metastases. Lymph nodes greater than 2 cm and less than 4 cm need biopsy to document nodal metastases.
IV	Distant metastatic deposits.

Germ Cell Tumors

Mature Teratoma

Teratoma accounts for more than 40% of testis tumors in prepubertal children (Metcalfe et al, 2003; Pohl et al, 2004; Shukla et al, 2004). **Prepubertal mature teratomas have a benign clinical course that contrasts with the clinical behavior of teratomas in adults who have the propensity to metastasize** (Mostofi and Price, 1973; Grady et al, 1997; Gobel et al, 1998). As noted above, the presumptive diagnosis of teratoma can often be made on ultrasound examination. Other cystic lesions of the testis must be considered in the differential diagnosis. Teratoma appears more as complex hypoechoic areas surrounded by highly echogenic signals (Krone and Carroll, 1985).

Testicular teratomas are currently managed with testis-sparing procedures rather than radical orchiectomy (Altadonna et al, 1988; Rushton et al, 1990; Valla et al, 2001; Metcalfe et al, 2003; Shukla et al, 2004). There have been no recurrences reported to date. Frozen sections should be obtained intraoperatively and can reliably distinguish benign from malignant lesions (Valla, 2001; Elert et al, 2002). A detailed review of 21 cases of prepubertal teratoma at the Armed Forces Institute of Pathology did not reveal evidence of multifocal disease or carcinoma in situ of the adjacent testis (Rushton et al, 1990). Preoperative ultrasonography can underestimate the volume of normal testis parenchyma, due to compression by the tumor against the capsule (Patel et al, 2007).

Testis-sparing surgery should be done through an inguinal incision with vascular control of the cord. An incision is made in

the tunica albuginea, and the mass is enucleated. Teratomas generally shell out easily due to the pseudocapsule around the lesion. The tumor is sent for frozen section and the tunica closed. The patient is not awakened until the results of frozen section are available.

Epidermoid Cyst

Epidermoid cysts account for 15% of pediatric testicular tumors (Valla et al, 2001; Pohl et al, 2004). This monodermal teratoma follows a benign clinical course. Due to the lack of associated intratubular germ cell neoplasia in the surrounding testis, testis-sparing surgery has been advocated both in children and adults (Manivel et al, 1989; Ross et al, 1993; Pohl et al, 2004). AFP levels are normal, and the diagnosis of epidermoid cyst can be suggested by ultrasonography. Frozen section diagnosis has been shown to be reliable in distinguishing this lesion (Valla, 2001; Elert et al, 2002). Epidermoid cyst can be differentiated from mature teratoma by the lack of chromosome 12p abnormalities (Cheng et al, 2006).

Immature Teratomas

A less common tumor of the testis is an immature teratoma. The most common extracranial site is in the ovary, with only 10% occurring in the testes. Immature teratomas have often been considered to be malignant tumors, but in children they appear to be benign unless they have foci of malignant cells. Because most patients with recurrent tumor can be salvaged with platinum-based chemotherapy, observation alone is recommended for completely resected immature teratoma (Gobel et al, 1998; Marina et al, 1998; Mann et al, 2000). Unlike other sites, the testicular immature teratomas have a low risk for relapse (Gobel et al, 1998). Incomplete resection of the tumor is a risk factor for relapse, but testis tumors are more amenable to complete resection than other sites (Lo Curto et al, 2007). Recurrence of immature teratomas after resection occurs almost exclusively in patients with elevated AFP or foci of yolk sac tumor in the initial resection specimens. Recurrent tumors typically are yolk sac tumors.

Yolk Sac Tumor

YST is the second most common prepubertal testicular tumor of germ cell origin (Metcalfe et al, 2003; Shukla et al, 2004). This tumor occurs primarily in children younger than age 2 years. The clinical behavior of YST varies considerably from embryonal carcinoma seen in adults, despite the histologic similarities. The most common site of distant metastases is the lung, and metastasis to the retroperitoneal lymph nodes occurs in 4% to 6% of children with YST (Bracken et al, 1978; Brosman, 1979)**. More than 90% of prepubertal children present with stage I disease** (Haas et al, 1999).

The initial treatment for YST is radical inguinal orchiectomy. This treatment is curative in most children. Routine RPLND and/or adjuvant chemotherapy are not indicated (Mann et al, 1989; Haas and Schmidt, 1995; Haas et al, 1999). Staging of the patient with tumor markers and imaging studies is performed as outlined above.

Clinical stage I patients do not receive additional adjuvant treatment after radical orchiectomy. Chest x-ray, CT, or MRI of the retroperitoneum is recommended monthly ×3, every 3 months ×1, and then every 6 months. This surveillance is continued until the patient is 36 months post-treatment. Tumor markers and physical examination are performed at more frequent intervals. Approximately 90% of YSTs produce positive serum levels of AFP. Scrotal orchiectomy with negative margins can be treated as stage I, but the proximal cord structures should be resected to the level of the internal ring (Rogers et al, 2004).

Patients who have undergone prior scrotal biopsy are considered stage II (Rogers et al, 2004). A completion orchiectomy with removal of all cord structures is performed. This approach has proven to be of benefit in adult patients with gross contamination during removal of germ cell tumors (Giguere et al, 1988; Capelouto et al, 1995). Hemiscrotectomy is not required. All patients undergo abdominal CT to examine for retroperitoneal lymphadenopathy. Patients with enlarged lymph nodes should undergo lymph node sampling or biopsy. Patients who have persistent elevation of AFP and retroperitoneal adenopathy are presumed to have metastatic disease. These patients can be treated as stage III.

Combination chemotherapy using platinum-based therapy—cisplatin, etoposide, and bleomycin (PEB)—has been used in pediatric patients with advanced germ cell tumors (Ablin et al, 1991). Two intergroup studies for the treatment of localized and advanced germ cell tumors in children conducted by the Children's Cancer Group and the Pediatric Oncology Group were recently published (Cushing et al, 2004; Rogers et al, 2004). The 6-year event-free survival (EFS) and overall survival (OS) of children with stage II testicular tumors was 100%. For stage III disease, age less than 15 years was associated with better 6-year EFS, 100% versus 83.3%, but both groups had a 100% OS. Patients less than 15 years of age with stage IV disease also had an improved 6-year EFS and OS, 94.4% and 100% versus 84% and 84%, respectively. The histology of tumors in patients less than 15 years was pure yolk sac tumor in 83% of patients, whereas 80% of older patients had mixed germ cell tumor.

A number of patients experience significant ototoxicity with the cisplatin-based chemotherapy regimens, and nephrotoxicity is also common (Pinkerton et al, 1990; Cushing et al, 2004). The UKCCSG used carboplatin instead of cisplatin in their second germ cell study, GCII (Mann et al, 2000). This trial was restricted to patients less than 16 years of age. The 5-year EFS for testicular germ cell tumors was 100%, with decreased toxicity compared with the PEB regimen.

Persistent retroperitoneal masses postchemotherapy are uncommon (Uehling and Phillips, 1994; Kuo et al, 1999). However, children with clinically evident retroperitoneal disease or elevation of tumor markers after chemotherapy undergo surgery at 12 weeks to establish a histologic diagnosis. Patients with persistent viable tumor are then switched to another treatment regimen. Those patients who develop relapse after initial treatment of a stage I tumor should also undergo biopsy for histologic confirmation.

Gonadal Stromal Tumors

Gonadal sex-cord stromal tumors are the most common nongerminal testicular tumors in children (Cortez and Kaplan, 1993; Goswitz et al, 1996; Valla, 2001; Pohl et al, 2004). These benign non–germ cell tumors are more common in children than adults. They arise from a common mesenchymal stem cell that can differentiate toward Leydig cells, Sertoli cells, granulosa cells, or a combination of these. An interesting feature of these tumors is the ability to secrete hormones.

Leydig Cell Tumors

Leydig cell tumor is the most common of the sex cord tumors, with a peak incidence at age 4 to 5 years. Leydig cells produce testosterone, and production of the hormone by the tumor can produce precocious puberty (Urban et al, 1978). This can lead to

accelerated skeletal and muscle development and penile growth that does not resolve after treatment (Mengel and Knorr, 1983). Other hormones produced by Leydig cell tumors include corticosteroids, progesterone, and estrogens.

The differential diagnosis of precocious puberty includes pituitary lesions, Leydig cell hyperplasia, large cell Sertoli cell tumors, and hyperplastic testicular nodules that develop in boys with poorly controlled congenital adrenal hyperplasia (CAH) (Wilson and Netzloff, 1983; Cunnah et al, 1989; Srikath et al, 1992; Walker et al, 1997). Pituitary lesions can be excluded by the finding of an increased serum testosterone with prepubertal LH and FSH levels. Children with Leydig cell hyperplasia have normal levels of urinary 17-ketosteroids. Testicular nodules in CAH patients tend to occur bilaterally, but there have been reports of bilateral Leydig cell tumors (Bokemeyer et al, 1993). A family history of CAH is helpful in making the diagnosis. The hyperplastic nodules that develop in CAH resemble Leydig cells histologically but behave biochemically like adrenal cortical cells. Urinary ketosteroids are elevated in patients with 21-hydroxylase deficiency, and serum levels of 17-hydroxy progesterone are elevated. Regression of the hyperplastic nodules in the testis is usually seen after glucocorticoid replacement (Srikath et al, 1992; Walker et al, 1997). Persistent nodules may result from fibrosis or calcification.

Inguinal orchiectomy has been used most often for Leydig cell tumors. Testis-sparing surgery and enucleation of the tumor has now been reported in a number of children (Konrad and Schoenle, 1999; Valla, 2001; Henderson et al, 2006). There is a report of one patient developing local recurrence (Wegner et al, 1997). Malignancy has not been reported in Leydig cell tumors in children (Brosman, 1979).

Sertoli Cell Tumor

Sertoli cell tumor is the next most common gonadal stromal tumor in children (Young et al, 1998). This tumor presents at an earlier age than Leydig cell tumors with the usual presentation of a painless testicular mass. These tumors are not as metabolically active as Leydig cell tumors, but gynecomastia has been reported (Gabrilove et al, 1980). There are limited series of patients with Sertoli cells tumors occurring in children (Gabrilove et al, 1980; Goswitz et al, 1996; Thomas et al, 2001). Most recommend observation in infants because metastases are rare (Kolon and Hochman, 1997). The vast majority of patients have been managed with orchiectomy, but testis-sparing procedures have been performed in prepubertal children (Sugita et al, 1999; Nonomura et al, 2001; Valla, 2001). Examination of the retroperitoneum is warranted to exclude retroperitoneal spread (Rosvoll and Woodward, 1968). Large cell Sertoli cell tumors have been noted with increased frequency in patients with Peutz-Jeghers syndrome and the Carney complex (Chang et al, 1998).

Gonadoblastoma

Gonadoblastomas are the most common tumors found in association with disorders of sex differentiation. They occur in dysgenetic gonads and are associated with the presence of a Y chromosome in the karyotype (Manuel et al, 1976). Recent evidence suggests that gonadoblastomas originate from surviving OCT3/4-positive germ cells in areas of undifferentiated gonadal tissue within the dysgenetic gonad (Cools et al, 2006). **Children with mixed gonadal dysgenesis have a 25% risk of tumor formation** (Schellas, 1974), **and the incidence increases with age** (Manuel et al, 1976). **The germ cell component of gonadoblastoma is prone to malignant degeneration into seminoma and nonseminomatous tumors. All streak gonads in patients with gonadal dysgenesis should be removed** (Aarskog, 1970). Patients with gonadal dysgenesis raised as females should have the gonads removed at diagnosis (Olsen et al, 1988; Gourlay et al, 1994). Early gonadectomy is advocated because tumors have been reported in children under age 5 years (Olsen et al, 1988; Gourlay et al, 1994). In mixed gonadal dysgenesis patients reared as males, all streak gonads and undescended testes should be removed. Scrotal testes can be preserved because they are less prone to tumor development. It has been suggested that gonadal biopsy and histologic examination for CIS in children with gonadal dysgenesis can identify those at risk for development of malignant germ cell tumors (Muller et al, 1985). However, recognition of CIS in prepubertal gonadal biopsies can be difficult, and a negative biopsy does not preclude the later development of a germ cell tumor.

Other Lesions

Leukemia and lymphoma are the most common malignancies to spread to the testicle in children. Children with acute lymphoblastic leukemia who have bulky disease at diagnosis have been reported to have up to a 20% incidence of testicular relapse (Askin et al, 1981). A recent report found no relapses after systemic chemotherapy and a 4% relapse rate after total-body irradiation with a testicular boost (Quaranta et al, 2004). Routine testicular biopsy after treatment is no longer recommended (Trigg et al, 2000). Positive testis biopsies early in remission identify patients at a slightly higher risk for adverse events, but do not impact on survival. Follicular lymphoma may occur as a primary tumor of the testis (Finn et al, 1999). The prognosis is favorable if the tumor is localized. Testicular involvement occurs in 4% of boys with Burkitt lymphoma and may be the initial clinical presentation (Lamm and Kaplan, 1974).

Testicular cystic dysplasia is a rare benign lesion in boys that has been reported with increasing frequency (Noh et al, 1999; Toffolutti et al, 1999). It is distinguished by the presence of multiple small irregular cysts localized in the rete testis. Renal agenesis or multicystic renal dysplasia has been noted in more than half the reported cases. A proposed etiology is a defective connection between the efferent ductules, originating from the metanephros, and the rete testis tubules, originating from the gonad. Management options include testis-sparing surgery and nonoperative treatment (Noh et al, 1999; Eberli et al, 2002). If the latter approach is used, follow-up with serial testicular ultrasonography is advised.

Testicular microlithiasis has been reported in association with testicular tumors but is present in more than 5% of healthy young men. It has been noted less often in children, and recommendations have been made for noninvasive ultrasound follow-up until adult age (Furness et al, 1998; Dell'Acqua, et al; 1999; Leenen and Riebel, 2002). Patients in whom there is an increased risk for cancer are infertile men with atrophic testes and microlithiasis and patients with known testis cancer and microlithiasis in the contralateral testis (Holm et al, 2003; Hoei-Hansen et al, 2005). Routine screening ultrasound studies are not warranted for asymptomatic patients without known risk factors for testicular cancer (Rashid et al, 2004; Dagash et al, 2007; Jaganathan et al, 2007). Routine testicular self-examination is all that is needed in the asymptomatic patient. The role of serial scrotal ultrasonogrphy in men with increased risk (history of undescended testis, infertility) is unclear, given the high survival rate of testicular cancer.

Key Points: Testis Tumors

- YST is the second most common testicular tumor in children. More than 90% of patients have stage I disease and do not require adjuvant chemotherapy. Monitoring serum AFP levels can detect tumor relapse.
- Patients with disorders of sexual development have an increased risk of gonadal tumors. Those with hypovirilization and gonadal dysgenesis are at greatest risk.
- Prepubertal patients with testis teratoma can be managed with a testis-sparing approach. Recognition of these tumors is feasible with testicular ultrasonography.

GENERAL COMMENTS ON PEDIATRIC RENAL TRAUMA

The Pediatric Kidney: Traumatic Renal Injuries and Congenital Renal Anomalies

The pediatric kidney is believed to be more susceptible to trauma, due to a decrease in the physical renal protective mechanisms found in childhood. Specifically, in contrast with the adult, the pediatric kidney is protected by an immature, more pliable thoracic cage, weaker abdominal musculature, less perirenal fat, and it sits in a lower abdominal position. Whether the incidence of renal injury following blunt abdominal trauma is truly increased in the pediatric versus the adult patient population is controversial, with statistical evaluations revealing mixed results, and the question remains in play (Brown et al, 1998; Chopra et al, 2002; McAleer et al, 2002a; Heyns, 2004).

What is known however is that preexisting renal abnormalities (i.e., ureteropelvic junction [UPJ] obstruction, hydroureteronephrosis, horseshoe kidney) are three- to fivefold more common in pediatric patients undergoing a screening CT scan for trauma than in the adult population (Brown et al, 1998; Chopra et al, 2002; McAleer et al, 2002a; Heyns, 2004).

Classically, patients with a preexisting congenital renal abnormality present with a history of hematuria disproportionate to the severity of trauma. Although it has been hypothesized that a preexisting congenital genitourinary anomaly would be associated with a higher stage of renal injury, this has not been documented to be true, with the majority of the patients still sustaining only renal contusions or minor renal fracture (Al-Qudah and Santucci, 2006; Chopra et al, 2002; McAleer et al, 2002a).

Trauma-Induced Hematuria: Pediatric versus Adult Patients

Two major clinical findings suggest the need to work up the genitourinary tract of an adult for a possible injury following trauma: Is there gross hematuria or is there microscopic hematuria (>50 red blood cells [RBC]/high-power field [HPF]) with shock (systolic pressure <90 mm Hg)? In adults, if physicians use only these two questions to decide who to screen for a traumatic genitourinary injury, they will find 98% of the clinically significant genitourinary (GU) injuries following blunt trauma and 90% of GU injuries associated with penetrating trauma (Mee et al, 1989; Heyns, 2004; Santucci et al, 2004a). Indeed, the yield in the adult population with just those two questions is significant, with 30% of the patients presenting with gross hematuria and 10% of the patients with microscopic hematuria associated with shock found to have a radiologically definable GU injury (Mee et al, 1989; Heyns, 2004; Santucci et al, 2004a). **In contrast, in children there is poor correlation relating the presence of hematuria to the presence of renal injuries. Indeed, some studies have found that two thirds of children sustaining a grade 2 or higher renal injury will have completely normal urinalysis** (Morey et al, 1996; Buckley and McAninch, 2004, 2006; Santucci et al, 2004a). **The correlation of hypotension to the**

extent of injury is also problematic, with the sympathetic tone in children being able to sustain a normal blood pressure despite significant blood loss. In fact, in children serial hemoglobin/hematocrit (Hb/Hct) values will demonstrate significant decreases before orthostatic hypotension develops (Quinlan and Gearhart, 1990). Notably, 90% of the pediatric patients with a clinically significant traumatic renal injury will have coexisting injuries to either the thoracic contents, intra-abdominal organs, or orthopedic (ribs, spine, pelvic, or femur) fractures (Levy et al, 1993; Buckley and McAninch, 2004; Heyns, 2004; Sahin et al, 2004; Santucci et al, 2004b). **In essence, in the pediatric patient presenting with a history of trauma, the clinical history combined with the presence of associated injuries becomes paramount in determining the need to assess for possible GU injuries** (Morey et al, 1996; Buckley and McAninch, 2004, 2006; Santucci et al, 2004a).

Indications for Imaging the Genitourinary Tract Following Trauma in the Pediatric Patient

Santucci and associates reviewed all of the published data regarding traumatic renal injuries in children. The outcome of this excellent review article found that the screening criteria outlined in Table 138–1 were highly reliable and cost effective (Mee and McAninch, 1989; Mee et al, 1989; Herschorn et al, 1991; Heyns, 2004; Santucci et al, 2004a, 2004b; Wu and Gaines, 2007).

RADIOGRAPHIC AND ENDOSCOPIC ASSESSMENT AND TREATMENT OF UPPER TRACT GENITOURINARY INJURIES

FAST: Focused Assessment with Sonography for Trauma

Because of its low cost, wide availability, and freedom from ionizing radiation, the use of ultrasonography (US) has become a major screening tool in pediatric level 1 trauma centers. Use of the FAST exam to detect renal injuries **has a reported specificity range of 95% to 100%, (the ability to diagnose true negatives—kidneys without a clinically significant traumatic injury). However, the sensitivity (the ability to diagnose true positives—kidneys with a clinically significant traumatic injury) is highly variable and extremely operator dependent, with published sensitivity results ranging widely from 22% to 85%** (McGahan et al, 1999; Jang et al, 2004; Sirlin et al, 2004; Suthers et al, 2004; Nural et al, 2005; Lee et al, 2007b; Bent et al, 2008). The clinical usefulness of a FAST scan is best when combined with serial physical examinations. If both the **FAST exam and serial physical examinations are within normal limits for 24 hours, the combination of these findings will virtually rule out the presence of significant renal and/or intra-abdominal injuries** (McGahan et al, 1999; Jang et al, 2004; Sirlin et al, 2004; Suthers et al, 2004; Nural et al, 2005; Lee et al, 2007b; Bent et al, 2008).

Table 138–1.

Indications for Radiographic Assessment of Pediatric Patient for Possible Genitourinary Injury

All penetrating abdominal/pelvic traumas
or
A history of blunt abdominal trauma that meets one of four following criteria:
1. A significant deceleration or high-velocity accident, fall from greater than 15 feet, or strike to the abdomen or flank with a foreign object, for instance, football helmet, baseball bat, among others
2. Significant trauma that has resulted in a fracture of the thoracic rib cage, spine, pelvis, or femur; bruising of the torso; or clinical signs of peritonitis
3. Gross hematuria
4. Microscopic hematuria (>50 RBC/HPF) associated with shock (systolic blood pressure <90 mm Hg)

HPF, high-power field; RBC, red blood cells.

Abdominal and Pelvic Computed Tomography and Single-Shot Intravenous Pyelography (IVP)

The patient's hemodynamic stability determines whether, when, and occasionally what type of imaging studies can be done. The most sensitive and specific radiologic test to rule out a genitourinary injury is a triphasic abdominal and pelvic computed tomography (CT) scan (precontrast study, followed by a CT study immediately after injection of contrast [1.5 to 2 mL/kg], and then a 10-minute delayed study). See Table 138–2 for the classification of renal trauma and Figures 138–1 through 138–5 for examples (Mee et al, 1989; Stein et al, 1994; Morey et al, 1996; Brown et al, 2001; Buckley and McAninch, 2004, 2006; Heyns, 2004; Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Lee et al, 2007b). **In the clinically labile patient, a single-phase CT scan with the study taken immediately following injection of contrast is the mainstay. This test is beneficial in**

Table 138–2.

Grading of Renal Injuries

GRADE OF RENAL INJURY	DESCRIPTION
1	Renal contusion or subcapsular hematoma
2	Nonexpanding perirenal hematoma, less than 1-cm parenchymal laceration, no urinary extravasation, all renal fragments viable
3	Nonexpanding perirenal hematoma, greater than 1-cm parenchymal laceration, no urinary extravasation, renal fragments may be viable or devitalized
4	Laceration extending into the collecting system with urinary extravasation, renal fragments maybe viable or devitalized *or* Injury to the main renal vasculature with contained hemorrhage
5	Completely shattered kidney; by definition, multiple major lacerations of greater than 1 cm associated with multiple devitalized fragments *or* Injury to the main renal vasculature with uncontrolled hemorrhage; renal hilar avulsion

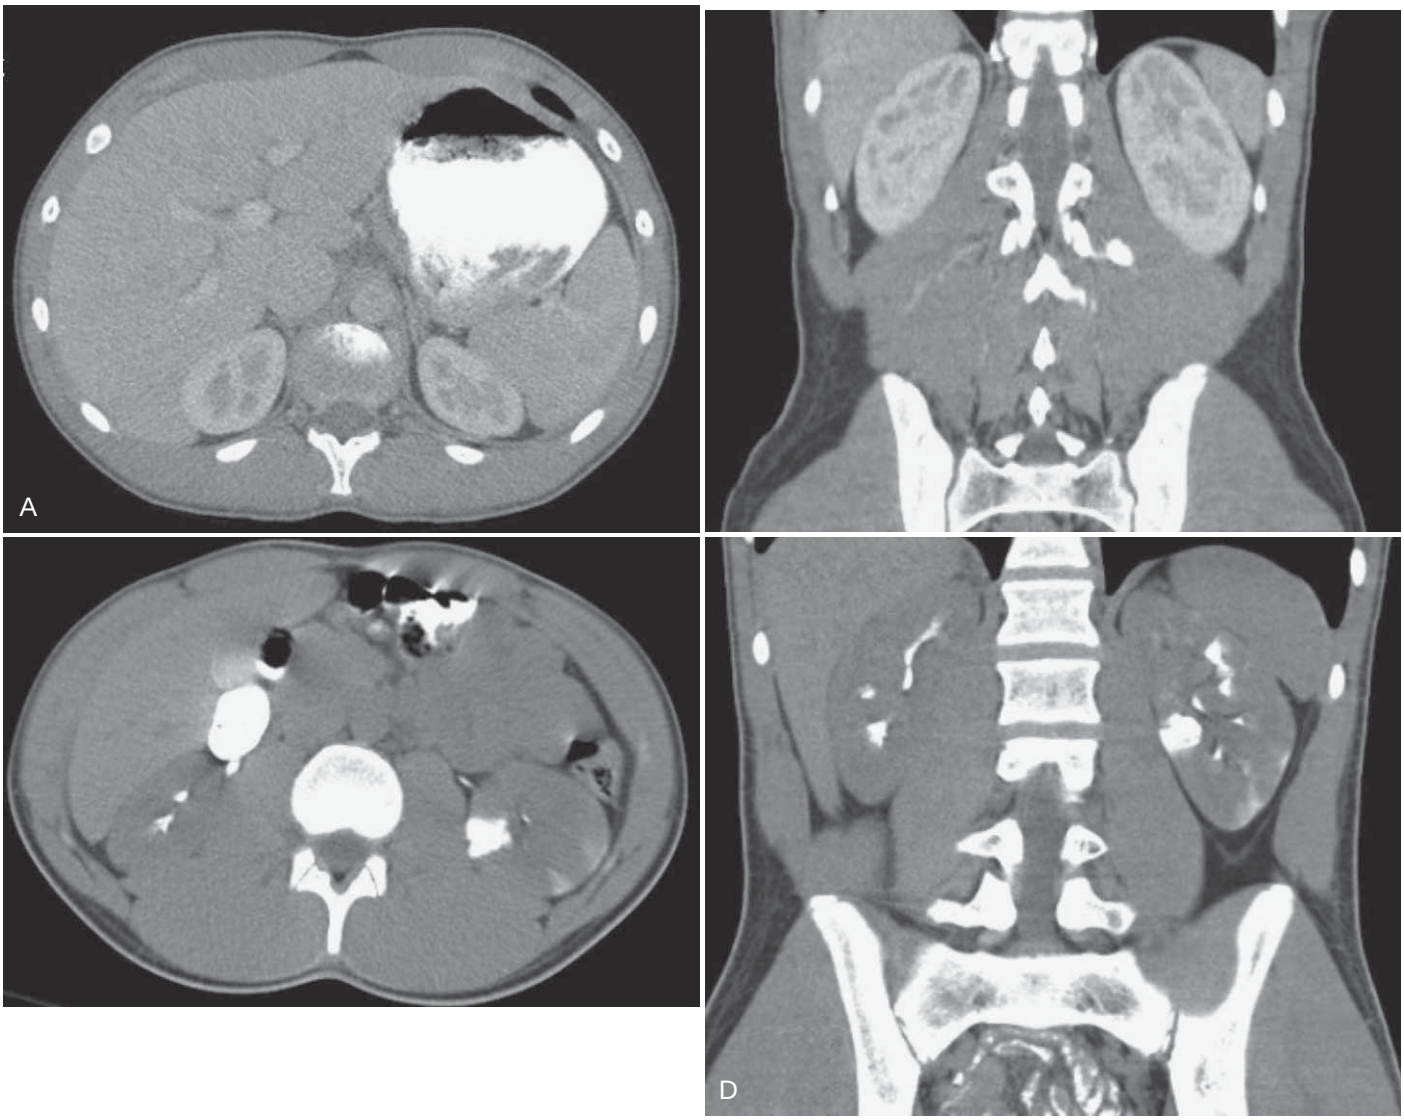

Figure 138–1. CT images, acute and delayed, with grade 1 renal trauma. **A,** Acute CT image of grade 1 renal trauma. Note normal-appearing parenchyma. **B,** Acute CT image coronal reconstruction of grade 1 renal trauma. **C,** Two-hour delayed CT of grade 1 renal trauma revealing renal contusion with delayed excretion of contrast in cortex of contused renal parenchyma. **D,** Two-hour delayed coronal reconstruction of CT grade 1 renal trauma revealing delayed excretion of contrast in cortex of contused renal parenchyma.

determining renal perfusion and the presence of major renal fractures; it will, however, be unable to accurately determine the presence of urinary extravasation and, in our experience, will miss the majority of the isolated ureteral injuries (Boone et al, 1993). In the unstable patient requiring emergent laparotomy, once the patient is stabilized in the operating room (OR), a one-shot IVP (2 mL/kg intravenous bolus of contrast) with the x-ray taken 10 to 15 minutes following injection may be beneficial if retroperitoneal exploration is considered. The authors would caution the reader regarding the quality of the single-shot IVP; this study is frequently a suboptimal examination with poor excretion/visualization of contrast, due to the patient's clinical status. The chief benefit of the single-shot IVP may be to detect a normally functioning contralateral kidney if unilateral nephrectomy is a consideration. As an alternative to the single-shot IVP, the patient can be stabilized and a delayed CT evaluation obtained. Definitive surgical repair of any GU injury is subsequently deferred for 12 to 24 hours (Azimuddin et al, 1997; Heyns, 2004).

Once the diagnosis of a traumatic renal injury is made, five possible complications can arise that may need to be addressed: (1) urinary extravasation, (2) an infected urinoma/perinephric abscess, (3) persistent or delayed renal hemorrhage, (4) hypertension, and (5) post-traumatic chronic pain syndrome.

Indications and Use of Arteriography: Management of Persistent/Delayed Hemorrhage and Persistent Urinoma

Approximately 25% of patients with a grade 3 to 4 renal trauma, managed in a nonoperative fashion, will develop persistent or secondary (delayed) hemorrhage (Wessells et al, 1997b; Dinkel et al, 2002; Goffette and Laterre, 2002; Kansas et al, 2004; Sofocleous et al, 2005, Al-Qudah and Santucci, 2006). Classically, delayed hemorrhage develops 5 to 14 days postinjury but may occur up to 1 month following the insult. Delayed hemorrhage usually arises from the development of arteriovenous

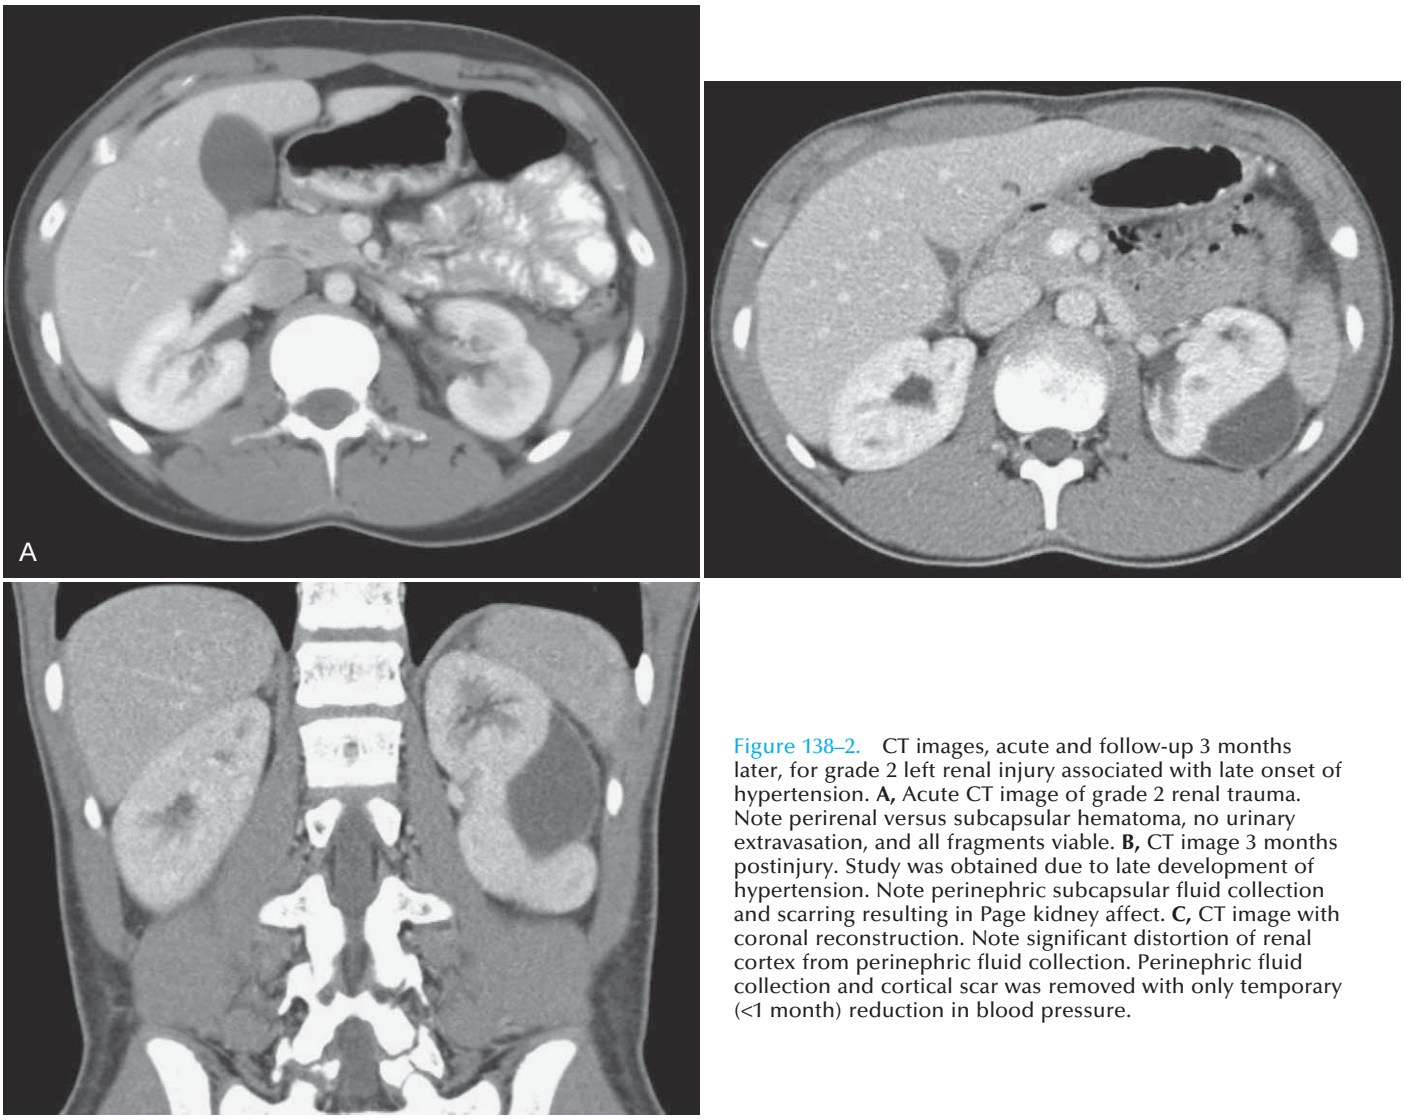

Figure 138–2. CT images, acute and follow-up 3 months later, for grade 2 left renal injury associated with late onset of hypertension. **A,** Acute CT image of grade 2 renal trauma. Note perirenal versus subcapsular hematoma, no urinary extravasation, and all fragments viable. **B,** CT image 3 months postinjury. Study was obtained due to late development of hypertension. Note perinephric subcapsular fluid collection and scarring resulting in Page kidney affect. **C,** CT image with coronal reconstruction. Note significant distortion of renal cortex from perinephric fluid collection. Perinephric fluid collection and cortical scar was removed with only temporary (<1 month) reduction in blood pressure.

fistulas or pseudoaneurysm malformations. In this scenario, the initial bleeding is tamponaded by the surrounding hematoma; as the hematoma resolves and liquefies recurrent bleeding develops. Unlike the arteriovenous fistulas noted after renal biopsy, where a spontaneous resolution rate of greater than 70% is found, the vast majority of arteriovenous fistulas occurring after renal trauma will not spontaneously resolve, with almost all cases of delayed hemorrhage secondary to trauma requiring active intervention (Heyns and Van Vollenhoven, 1992; Dinkel et al, 2002; Goffette and Laterre, 2002; Heyns, 2004; Sofocleous et al, 2005; Al-Qudah and Santucci, 2006; Breyer et al, 2008). **Superselective angiographic embolization of isolated renal artery branches for persistent or secondary hemorrhage has a success rate approaching 80%. The percentage of salvaged renal function postembolization varies depending upon the degree of the initial injury, but the median reported value is 30%. Surgery required following angiography is due to one of three problems: persistent or repetitive bleeding, postembolization abscess, or persistent urinary fistula from an isolated renal segment. Angiographic embolization is currently the preferred treatment method for persistent or delay bleeding with nonoperative management protocols. Surgical exploration is reserved for embolization failure** (Heyns and Van Vollenhoven, 1992; Dinkel et al, 2002; Goffette and Laterre, 2002; Heyns, 2004; Sofocleous et al, 2005; Al-Qudah and Santucci, 2006; Breyer et al, 2008).

Angiographic embolization will, on occasion, also be used to treat persistent urinary fistulas. In this scenario, a functional transected fragment of a grade 4 or 5 renal injury is completely separated from the renal collecting system, and a persistent urinary fistula/urinoma has developed despite management by double-J stent and percutaneous nephrostomy tube placement. In these rare patients, selective angiographic embolization will resolve the urinary fistula by necrosing the isolated functional renal fragment (Pinto and Chimeno, 1998; Heyns, 2004).

Postembolization syndrome is a well recognized and self-limiting condition manifested by pyrexia (up to 40° C), flank pain, and an adynamic ileus. Symptoms will usually resolve within 96 hours after the embolization. Unlike angioinfarction for renal tumors, where up to 60% of patients may develop postembolization syndrome, approximately 10% of patients following

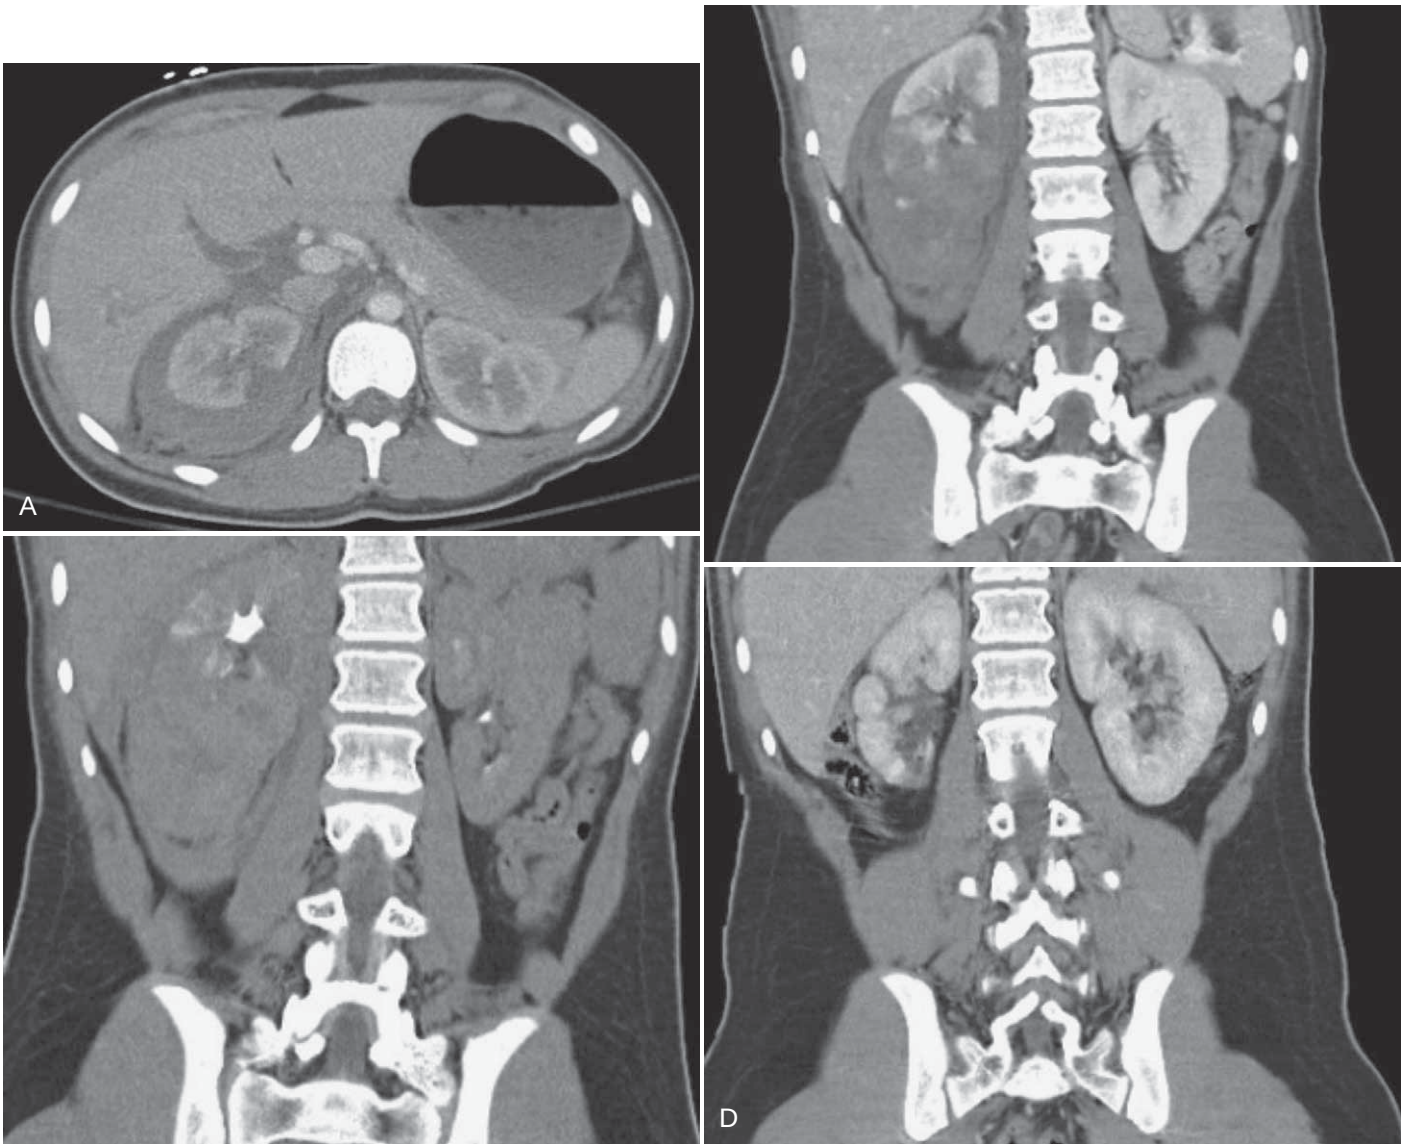

Figure 138–3. CT images of grade 3 right renal trauma—acute, delayed, and at 3-month follow-up. **A,** Acute CT image of grade 3 renal trauma showing greater than 1-cm laceration of midrenal pole, perinephric hematoma. **B,** Acute CT image coronal reconstruction of grade 3 renal trauma, with possible devitalization of the entire lower pole of the kidney. **C,** Two-hour delayed CT image coronal reconstruction of grade 3 renal trauma, with no urinary extravasation noted and lower pole with questionable devitalization versus contusion. **D,** CT image coronal reconstruction 3 months post-traumatic injury revealing parenchymal scarring at site of laceration with scarred but functional lower pole consistent with healed parenchyma following severe renal contusion. Scarring of lower pole was believed to have occurred with impoverished blood supply due to severe contusion.

angioinfarction after a traumatic injury develop this complication. The decrease in the frequency of this syndrome following trauma is believed to be secondary to fewer pyrogens being released from the already partially necrotic tissue (Oesterling et al, 1986; Kehagias et al, 1998; Kalman and Varenhorst, 1999; Heyns, 2004; Mitra et al, 2004; Sofocleous et al, 2005; Breyer et al, 2008). **The problem faced with persistent pyrexia following embolization is the need to rule out bacterial seeding of the necrotic tissue. It is therefore mandatory in the presence of a febrile response following embolization to obtain blood and urine cultures. Consideration for a repeat CT scan with possible aspiration, culture, and drainage of the hematoma/urinoma should be given if symptoms persist for greater than 96 hours** (Sofocleous et al, 2005; Breyer et al, 2008).

Indications and Use of Retrograde Pyelography, Percutaneous Nephrostomy, and Perinephric Drain Placement: Diagnosis of Ureteropelvic Junction Disruptions, Renal Pelvis Lacerations, and Management of Symptomatic Urinomas and Perinephric Abscesses

Two indications exist for the use of retrograde pyelography following renal trauma: (1) the need to diagnose a partial/total ureteral disruption or renal pelvic laceration and (2) the need to aid in the management of

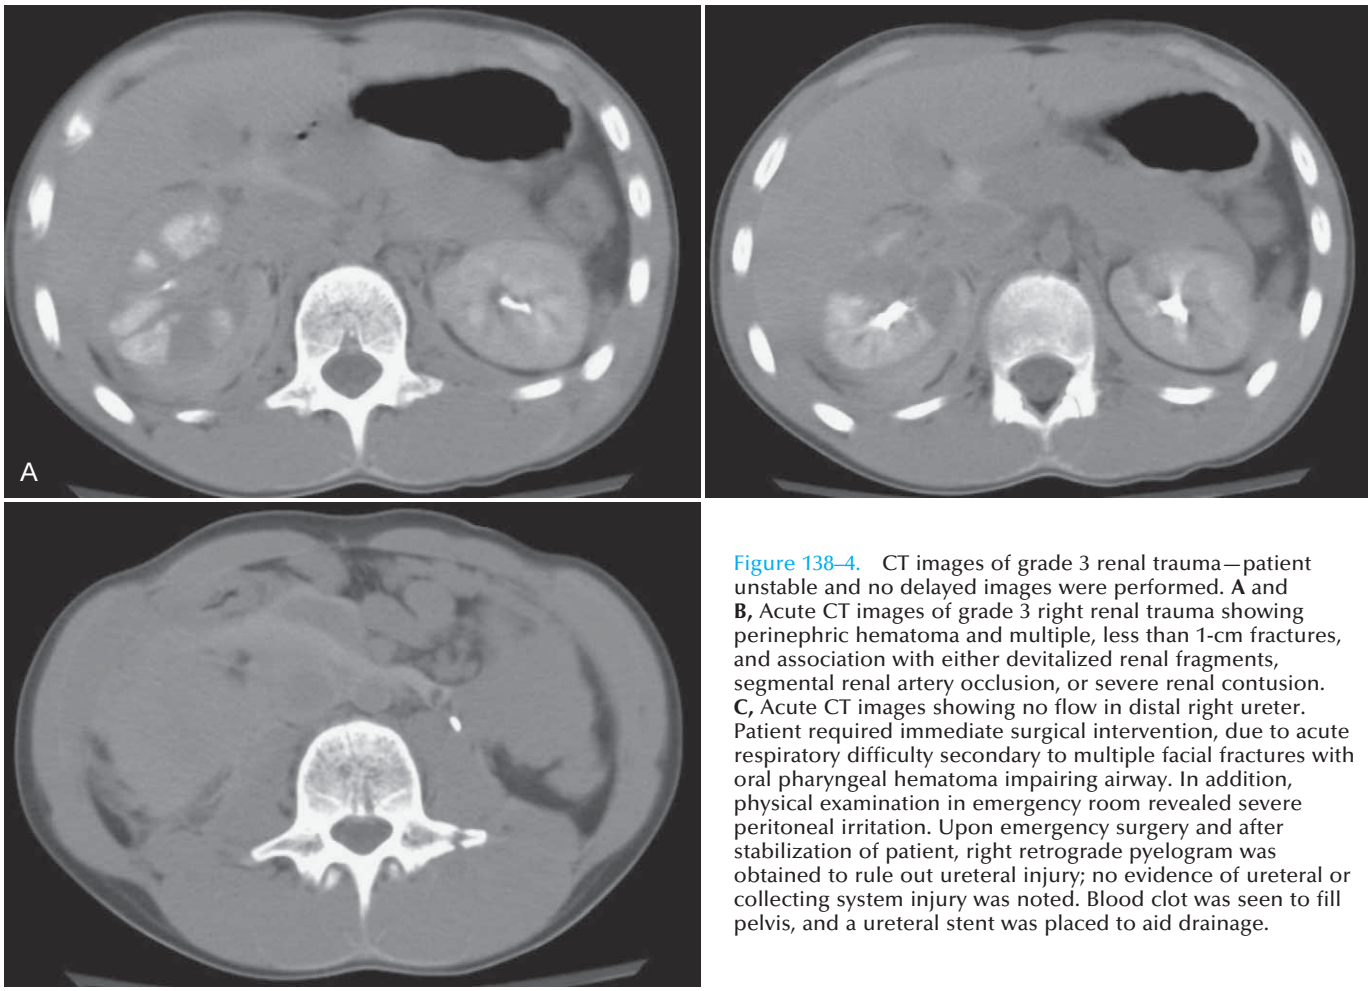

Figure 138–4. CT images of grade 3 renal trauma—patient unstable and no delayed images were performed. **A** and **B,** Acute CT images of grade 3 right renal trauma showing perinephric hematoma and multiple, less than 1-cm fractures, and association with either devitalized renal fragments, segmental renal artery occlusion, or severe renal contusion. **C,** Acute CT images showing no flow in distal right ureter. Patient required immediate surgical intervention, due to acute respiratory difficulty secondary to multiple facial fractures with oral pharyngeal hematoma impairing airway. In addition, physical examination in emergency room revealed severe peritoneal irritation. Upon emergency surgery and after stabilization of patient, right retrograde pyelogram was obtained to rule out ureteral injury; no evidence of ureteral or collecting system injury was noted. Blood clot was seen to fill pelvis, and a ureteral stent was placed to aid drainage.

a symptomatic urinoma (Boone et al, 1993; Kawashima et al, 1997; Heyns, 2004; Santucci et al, 2004b). Concern for a ureteral injury usually arises when a CT scan reveals urinary extravasation and no ipsilateral distal ureter is seen. In the presence of these CT findings, a retrograde pyelogram is mandatory. This study is performed to either confirm or refute the diagnosis of a ureteropelvic junction disruption or laceration of the renal pelvis, both of which require operative exploration and repair. If no evidence of these injuries is present we recommend a ureteral stent be placed following the retrograde pyelogram. This recommendation is based on prior studies revealing that patients with trauma-induced urinary extravasation who have absence of contrast in the ipsilateral distal ureter are at a higher risk for developing a symptomatic urinoma if left unstented (Boone et al, 1993; Kawashima et al, 1997; Chopra et al, 2002; McAleer et al, 2002b; Smith et al, 2003; Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Broghammer et al, 2006; Cannon et al, 2008).

The second consideration for intervention with cystoscopy and retrograde pyelography is the presence of a symptomatic urinoma. **Although most post-traumatic urinomas are asymptomatic and have a spontaneous resolution rate approaching 85%, urinomas will occasionally persist. Symptomatic urinomas will develop a classic triad of findings: ipsilateral flank pain, adynamic ileus, and a low-grade temperature.** Management of these patients is by endoscopic intervention, with cystoscopy, retrograde pyelography, placement of a ureteral stent, urethral catheter drainage, and intravenous antibiotics. When a ureteral stent is placed in conjunction with temporary placement of a urethral catheter, greater than 90% of the symptomatic urinomas will resolve (Al-Ali and Al-Hajaj, 2001; Alskikafi et al, 2006). Classically, the urethral catheter is removed 3 to 5 days after the patient's clinical symptoms have abated. Intravenous antibiotics are discontinued and prophylactic antibiotics initiated at the time of urethral catheter removal. The author removes the ureteral stent 4 to 6 weeks postinjury and will maintain oral prophylactic antibiotic coverage for 48 hours after stent removal. It should be noted that both percutaneous nephrostomy drainage and internal stenting are equally efficacious for the treatment of symptomatic urinomas (Husmann and Morris, 1991; Husmann et al, 1993b; Philpott et al, 2003; Bozeman et al, 2004; Heyns, 2004; Keller et al, 2004; Al-Qudah and Santucci, 2006). The advantage of an internal stent is that it prevents possible dislodgment of the drainage tube and the need for external drainage devices. The two major disadvantages of internal drainage are that both stent placement and removal, in the pediatric patient population, require general anesthesia. In addition, the small-size ureteral stents (4 to 5 Fr) placed in young children may become blocked with blood clots from the dissolving hematoma, resulting in persistence of the urinoma (Husmann and Morris, 1991; Husmann et al, 1993b).

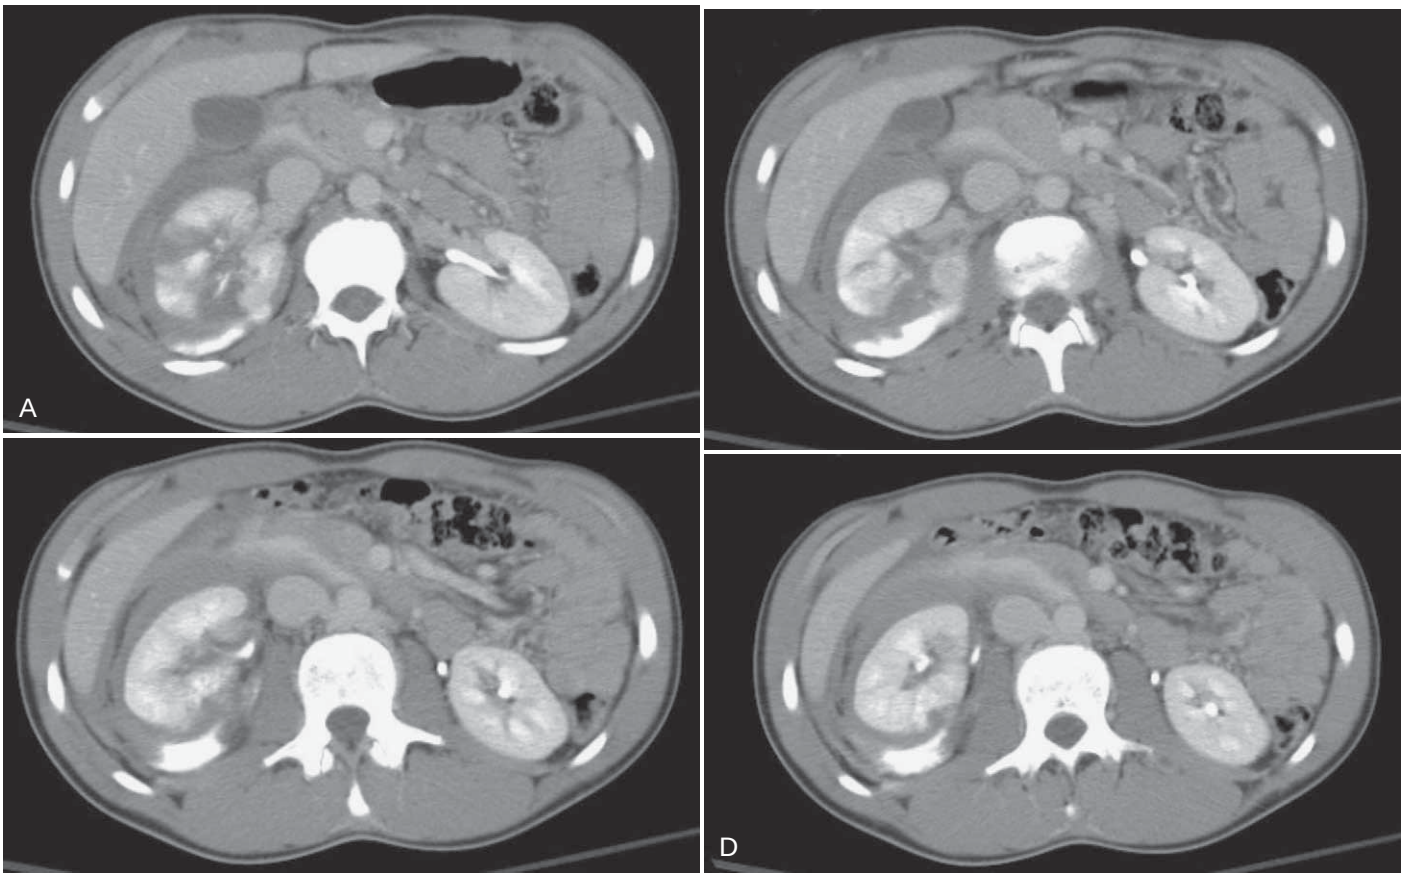

Figure 138–5. Acute and delayed images of grade 4 right renal injury. **A** and **B,** Acute CT image of grade 4 renal trauma with perinephric hematoma, severe (greater than 1 cm) fractures with devitalized renal segments, and urinary extravasation. **C** and **D,** 10-minute delayed CT revealing flow of contrast in ureter distal to injury, confirming patency of distal ureter. Patient was treated with observation only; no stent or drainage was necessary.

The development of a perinephric abscess postrenal injury is extremely rare, occurring in less than 1% of injuries following blunt renal injuries and in 5% of renal injuries caused by penetrating renal trauma. It is more commonly seen in patients when there is a confluence of injuries; specifically, a devitalizing grade 3 to 5 renal injury, in conjunction with either duodenal, pancreatic, or colonic injuries or, occasionally, in patients with large areas of traumatic soft tissue loss requiring frequent debridement. On rare occasions, a perinephric abscess may arise from seeding of a perinephric hematoma by an infected venous line or by ascending bacteria following bladder colonization (Husmann and Morris, 1991; Husmann et al, 1993b).

Symptoms of a perinephric abscess are intermittent febrile spikes, flank pain, persistent ileus, and elevated white count. These symptoms may exactly mimic those associated with an undrained symptomatic urinoma. In the absence of gas within the soft tissues, the differential diagnosis between a symptomatic urinoma and perinephric abscess may be very difficult. The author chooses to treat all patients with these findings for a symptomatic urinoma and will resort to additional percutaneous drainage of the perinephric fluid collection only if there is gas in the soft tissue at the time of initial diagnosis, or if the patient's febrile course persists after 72 hours of drainage through a ureteral stent and urethral catheter or nephrostomy tube (Husmann and Morris, 1991; Husmann et al, 1993b; Al-Qudah and Santucci, 2006).

Follow-up Radiographic Imaging after Renal Trauma: The ALARA Concept: As Low as Reasonably Achievable

Recommendations for follow-up renal imaging in the pediatric patient sustaining renal trauma has significantly changed over the past 5 years. This alteration is due to concerns regarding the future risk of radiation-induced malignancy (Brenner and Hall, 2007; Malcom et al, 2008; Shah and Platt, 2008; Eeg et al, 2009). **In the recent past, a repeat CT scan for all grade 3, 4, and 5 renal injuries was recommended during the acute healing phase, usually 3 to 5 days postinjury and again at 3 months.** The routine use of a CT scan 3 to 5 days post-trauma has been abandoned in an effort to decrease radiation exposure to children (Alskikafi et al, 2006; Malcom et al, 2008; Eeg et al, 2009). The principle that radiation exposure for diagnostic and follow-up purposes should be kept to a minimum is known as ALARA—as low as reasonably achievable. This concept currently permeates all of pediatric practice and has greatly impacted follow-up recommendations for post-traumatic injury. Presently, a CT scan is repeated in the acute post-traumatic phase only for patients who have symptoms; specifically, persistent or new onset of fever, persistent ileus, worsening flank pain, or persistent gross hematuria greater than 72 hours after the traumatic insult (Santucci et al,

2004b; Al-Qudah and Santucci, 2006; Buckley and McAninch, 2006; Bent et al, 2008; Malcom et al, 2008). Although some authors have advocated performing a screening ultrasonogram in this latter situation, with a CT scan used in the presence of abnormalities, the author and colleagues have frequently found the US study, in this situation, to be inconclusive, and it adds to the financial cost of patient evaluation and delays the inevitable CT scan. Based on our personal experience, we would preferentially recommend a CT scan for reevaluation if the clinical circumstances suggest reevaluation is necessary (Bent et al, 2008; Malcom et al, 2008; Eeg et al, 2009).

Currently no radiographic follow-up is recommended for grade 1 to 2 renal injuries, and renal ultrasonography at 3 months is recommended for grade 3 lacerations where all fragments are viable. There is controversy regarding radiologic follow-up for grade 3 renal lacerations associated with devitalized fragments, grade 4, and salvaged grade 5 renal injuries (Bent et al, 2008; Dunfee et al, 2008; Malcom et al, 2008; Eeg et al, 2009). **Although most authors recommend performing a repeat CT/magnetic resonance imaging (MRI) scan at 3 months, others advocate US, CT, or MRI be used only in the presence of abnormalities** (Eeg et al, 2009). **Our personal experience is that a renal US will inevitably be abnormal following high-grade renal injuries and will prompt additional evaluations. For cost-beneficial purposes, we will preferentially perform a CT evaluation, although consideration for a MRI study can be given in the older child when sedation/anesthesia would not be necessary.** The delayed study, 3 months postinjury, is done to document resolution of the urinary extravasation, assess the anatomy of the healed kidney, and rule out any occult complications (El-Sherbiny et al, 2004; Bent et al, 2008; Dunfee et al, 2008; Malcom et al, 2008; Eeg et al, 2009).

Serial dimercaptosuccinic acid (DMSA) scans obtained post-trauma have revealed that little, if any, renal parenchyma recovers function 1 week following injury; therefore nuclear renography obtained any time 1 week post-trauma results in a valid prognosis of renal function and can aid in the diagnosis of severe renal contusion versus a nonfunctional renal fragment following grade 3 and 4 injuries (see Fig. 138–3) (Wessells et al, 1997a; Moog et al, 2003). **Currently, renal scans are obtained in two circumstances: when there is concern for long-term renal prognosis or in the presence of post-trauma–induced hypertension** (Moog et al, 2003; Heyns, 2004). Classically, if the serum creatinine is normal, a differential renal function of greater than or equal to 30% demonstrates satisfactory ipsilateral renal function, which would prevent renal failure if the uninjured kidney is lost. In the presence of post-trauma–induced hypertension, mercaptoacetyltriglycine (mertiatide, MAG3) renography can be used to screen for trauma-induced renal vascular stenosis. Notably, the vast majority of patients with trauma-induced hypertension will have a kidney that has healed with a differential renal function of less than or equal to 20% (Wessells et al, 1997a; Moog et al, 2003; Heyns, 2004; Keller et al, 2004; Santucci et al, 2004b; Chedid et al, 2006) (Fig. 138–6).

MANAGEMENT OF RENAL TRAUMA

Multiple studies have stated that the nephrectomy rate in patients with traumatic renal injuries was higher with surgical exploration than with nonoperative management (Cass and Ireland, 1973; Cass et al, 1987; Kristjanson and Pederson, 1993; Hammer and Santucci, 2003; Keller et al, 2004; Broghammer et al, 2007). These papers suggested that hemorrhage from the severely injured kidney was held in check by a tamponade maintained by an intact Gerota fascia. Surgical exploration with disruption of the fascia resulted in uncontrollable renal bleeding and the need for emergent nephrectomy. Current studies reveal that this long-held hypothesis appears inaccurate. Specifically, with the enhanced

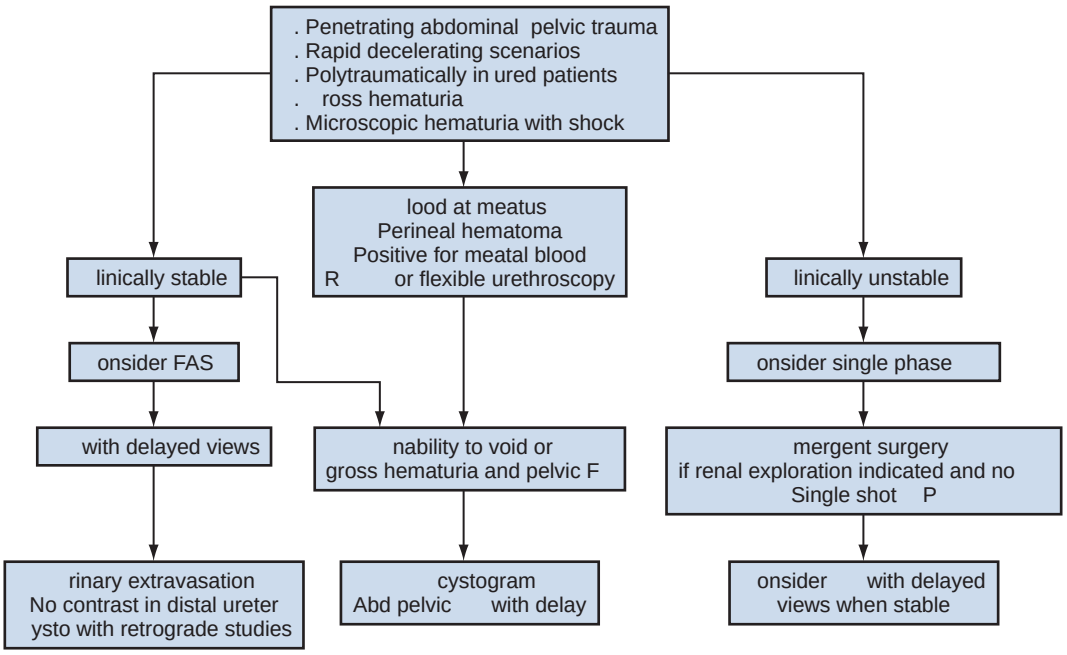

Figure 138–6. Abd, abdominal; CT, computed tomography; cysto, cystogram; FAST, focused assessment with sonography for trauma; FX, fracture; IVP, intravenous pyelography; RGUG, retrograde urethrogram.

Key Points: Radiographic and Endoscopic Assessment and Treatment of Pediatric Upper Tract Genitourinary Injuries

- Radiographic assessment of the GU tract for a possible injury should occur following all penetrating abdominal trauma, as well as blunt trauma victims who have one of four criteria: (1) a history of a significant deceleration or high-velocity injury, (2) significant trauma that has resulted in fractures of thoracic rib cage, spine, pelvis, or femur and bruising of the torso/perineum or signs of peritonitis, (3) gross hematuria, and (4) microscopic hematuria (>50 RBC/HPF) associated with shock (systolic blood pressure less than 90 mm Hg).
- A triphasic abdominal and pelvic CT scan is the most sensitive method for the diagnosis and classification of pediatric GU trauma.
- The two most likely GU injuries to be missed by a single-phase CT scan or single-shot IVP are urinomas and/or isolated ureteral injuries.
- Approximately 25% of patients with a grade 3 to 4 renal trauma, managed in a nonoperative fashion, will develop persistent or secondary (delayed) hemorrhage. Superselective angioinfarction of the bleeding vessel is the preferred method to manage this complication.
- Most post-traumatic urinomas are asymptomatic and will spontaneously resolve. Approximately 15% will be associated with continued flank pain, adynamic ileus, and/or low-grade temperature and require endoscopic or percutaneous management.
- Follow-up renal imaging is not recommended for grade 1 to 2 renal injuries and for grade 3 lacerations where all fragments are viable. Grade 3 renal lacerations associated with devitalized fragments, grade 4 and grade 5 renal injuries should have a repeat CT scan in the acute phase only if symptomatic; otherwise, a urinalysis and blood pressure check should be performed at 6 and 12 weeks postinjury and follow-up radiologic studies obtained at 12 weeks.

ability of the CT scan to accurately stage renal injuries and with the development and application of trauma-related severity scores, multiple current studies reveal that the need for emergent nephrectomy during renal exploration is not due to intractable hemorrhage incited by the renal exploration; rather, emergent nephrectomy is usually due to either the severity of the initial renal injury and/or was performed in patients who had severe intraoperative hemodynamic instability due to multiple coexisting injuries. Nephrectomy in this latter situation was performed for expediency to save the hypothermic, coagulopathic, and clinically unstable patient (Husmann et al, 1993b; Wessells et al, 1997b; Gonzalez et al, 1999; Santucci et al, 2001, 2004b; Santucci and McAninch, 2001; Bozeman et al, 2004; Davis et al, 2006; Wright et al, 2006; Broghammer et al, 2007; Shariat et al, 2007, 2008).

Although all authorities agree that a clinically stable patient with an isolated renal injury should be managed in a nonoperative fashion, considerable controversy exists regarding the management of grade 3 or higher renal injuries when intra-abdominal injuries that mandate surgical exploration are found. There are three schools of thought in this controversy: (1) Provided no absolute indications for renal exploration are present, all renal trauma should be observed (Altiman et al, 2000; Hammer and Santucci, 2003; Keller et al, 2004); (2) renal exploration and renorrhaphy of a grade 3 or higher renal injury should be carried out if a laparotomy was to be performed for a coexisting intra-abdominal injury (especially if the stomach, duodenum, pancreas, or colon was injured) (Corriere et al, 1991; Husmann et al, 1993b; Heyns, 2004; Santucci et al, 2004b); and (3) renal exploration can be excluded in patients with concurrent intra-abdominal injuries, provided the trauma surgeon separates the site of the enteric injury from the urinary tract by omentum or other alternative tissue and places perioperative drains. It is hypothesized that the separation of the two sites of injury and the placement of drains will prevent breakdown of enteric repairs caused by leaking urine and/or help prevent the development of urinary tract complications by removal of excess contaminating bacteria or pancreatic enzymes from the site of GU injury (Husmann et al, 1993b; Wessells and McAninch, 1996; Matthews et al, 1997; El Khader et al, 1998; Santucci et al, 2004b; Broghammer et al, 2007). **Due to the controversy, the major problem facing the urologist in the patient with traumatic renal injury is determining when to surgically intervene. The current recommendations on when to pursue operative intervention are based on three findings: the hemodynamic stability of the patient, an accurate radiographic staging of the renal trauma, and the presence of associated organ injury** (Table 138–3) (Husmann and Morris, 1991; Husmann et al, 1993b; Wessells et al, 1997b; Heyns, 2004; Santucci et al, 2004b; Buckley and McAninch, 2006).

Nonoperative Therapy for Renal Trauma

The ideal candidate for nonoperative management is the hemodynamically stable patient sustaining either blunt or penetrating trauma, with or without associated intra-abdominal injuries, and having a grade 1 to 2 renal injury. Genitourinary complications in this subset of patients are minimal (Wessells et al, 1997b; Heyns, 2004; Santucci et al, 2004b). **Patients who are hemodynamically stable with isolated grade 3, 4, and 5 renal injuries are also candidates for nonoperative treatment. Even identification of a large perinephric hematoma or urinoma is not an absolute contraindication for nonoperative management, provided the distal ureter is documented to be intact** (see Fig. 138–5). In patients with isolated grade 3 to 4 renal injuries, angiographic, endoscopic, or percutaneous intervention will be required in up to 55% of the patients. Intervention will be necessary for persistent or delayed bleeding in approximately 25%, symptomatic urinomas in approximately 25%, and surgical exploration to control complications not amenable to nonoperative techniques will develop in approximately 5%. In essence, conservative management of isolated grade 3 or 4 renal injuries will save approximately 95% of the patients by open surgical intervention (Husmann and Morris, 1991; Husmann et al, 1993b; El Khader et al, 1998; Bozeman et al, 2004; Buckley and McAninch, 2004, 2006; El-Sherbiny et al, 2004; Heyns, 2004; Santucci et al, 2004b; Broghammer et al, 2006, 2007; Henderson et al, 2007; Shariat et al, 2008).

Nonoperative therapy consists of bed rest, close monitoring of vital signs and urine output, serial abdominal examinations, serial hemoglobin/hematocrit determinations, and transfusion as indicated (Heyns, 2004; Santucci et al, 2004b). In patients with a renal injury secondary to penetrating trauma on a nonoperative protocol, intravenous broad-spectrum antibiotics are recommended,

Table 138–3.

Consensus Recommendations for Management of Renal Trauma

CLINICAL FINDINGS AND/OR GRADE OF RENAL INJURY	RECOMMENDED TREATMENT
Grade 1 or 2 renal injury irrespective of traumatic etiology*	Nonoperative
Isolated grade 3, 4, and hemodynamically stable grade 5 renal injuries	Nonoperative
Uncontrollable renal hemorrhage/ vascular instability (usually grade 4 vascular or grade 5 injuries)	Absolute requirement for surgical intervention
Persistent or delayed hemorrhage not responding to angiographic embolization	Absolute requirement for surgical intervention
Expanding pulsatile retroperitoneal mass found on surgical exploration for coexisting intra-abdominal injuries	Absolute requirement for surgical intervention (verify contralateral renal function prior to exploration)
Penetrating trauma, inadequate preoperative radiographic staging due to vascular instability of patient, retroperitoneal hemorrhage found on exploration	Retroperitoneal (renal) exploration recommended (verify contralateral renal function)
Blunt trauma, inadequate preoperative radiographic staging due to vascular instability of patient, retroperitoneal hemorrhage found on exploration	Retroperitoneal (renal) exploration recommended (verify contralateral renal function)
Blunt/penetrating trauma, radiographic screening studies reveal grade 3 with devitalized renal fragments, grade 4 or 5 renal injury, coexisting intra-abdominal injuries—especially, duodenum, pancreas, and colon	Retroperitoneal (renal) exploration with renorrhaphy and repair recommended

due to the risk of wound contamination. In renal injuries following blunt trauma, antibiotics may be considered if a large retroperitoneal hematoma, urinary extravasation, or extensive soft tissue injuries are present. The use of antibiotics following blunt trauma is advocated due to the presence of indwelling urethral catheters and/or multiple intravascular catheters or superficial dermatologic abrasions that could serve as a nidus for bacteremic colonization of the urine or blood and, hypothetically, result in an infected hematoma or urinoma (Husmann and Morris, 1991; Husmann et al, 1993b; Al-Qudah and Santucci, 2006; Buckley and McAninch, 2004, 2006; Heyns, 2004; Kansas et al, 2004; Santucci et al, 2004b).

Concerns regarding the risk of radiation exposure in children have lead the author and colleagues to refrain from the routine use of serial CT imaging in the acute post-traumatic phase. Currently, we recommend repeat CT scan only be obtained during this time span in patients who have a persistent fever, decreasing hematocrit, persistent gross hematuria/flank pain, or persistent ileus.

If the child becomes hemodynamically unstable or continues to have a decreasing hemoglobin/hematocrit despite transfusions, renal angiography with selective angioinfarction of the bleeding site is recommended. If the patient develops a symptomatic urinoma, consideration for endoscopic or percutaneous management of the urinoma will be needed. Ambulation is allowed as soon as gross hematuria has resolved; resumption of strenuous physical activity should be avoided for 6 weeks. At 6 weeks, a physical examination and urinalysis are obtained; if the physical examination is normal and hematuria has cleared, the patient is allowed to resume all activities. Patients are reevaluated again at 12 weeks with a repeat physical examination and urinalysis, in addition to a repeat radiographic evaluation for patients with a grade 3 renal injury with devitalized fragments, grade 4, and grade 5 injuries (Wessells et al, 1997b; Heyns, 2004; Kansas et al, 2004; Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Buckley and McAninch, 2006; Broghammer, 2007).

Operative Intervention for Renal Trauma

Absolute indications for renal exploration are hemodynamic instability due to a renal source, an expanding or pulsatile retroperitoneal hematoma, and inability to stop persistent or delayed hemorrhage by selective vascular embolization. Relative indications for exploration are a history of vascular instability resulting in an inability to obtain adequate preoperative radiographic evaluations, where surgical exploration for intra-abdominal injuries reveals a retroperitoneal hematoma. It is important to note that a single-shot IVP to verify contralateral renal function is required before renal exploration. Another relative indication for surgical exploration is the presence of coexisting intra-abdominal injuries associated with a grade 3 or higher renal injury (see Table 138–3) (Heyns, 2004; Santucci et al, 2004b). In this latter situation, the consensus opinion is that patients with a known grade 3 or higher renal injury undergoing exploratory laparotomy for multiorgan injury should undergo either renal exploration with renorrhaphy and the placement of retroperitoneal drains or separation of the urinary tract injury from adjacent enteric injuries by interposing omentum or other tissue with concurrent placement of adjacent drainage tubes. **Although the surgeon can choose between the two options noted above, he or she should be aware that the consensus opinion is that renal exploration and renorrhaphy are preferred** (Husmann et al, 1993b; Wessells et al, 1997b; Santucci and McAninch, 2001; Buckley and McAninch, 2004, 2006; Heyns, 2004; Santucci et al, 2004b).

Renal salvage by renorrhaphy or partial nephrectomy requires complete exposure of the injured kidney, debridement of nonviable tissue, suture ligation of bleeding arterial vessels, and repair of the collecting system injury. Defects in the renal parenchyma may be closed primarily with renal capsule. For larger defects, we prefer the placement of Gelfoam (Pfizer, New York, NY) and Surgicel (Ethicon, Somerville, NJ) packing into the parenchymal defect, with coverage or closure of the renal capsule defect using woven polyglycolic acid mesh. Alternatively, perinephric fat, omentum, or thrombin-soaked gel foam may be used to pack the parenchymal defect. Watertight closure of the collecting system is not always possible and may be inadvisable. If the renal pelvis or ureter is closed with excessive stretch, further devascularization, tissue sloughing, and delayed urinary leakage may occur. If a major violation of the urinary drainage system is present, placement of intraoperative ureteral stents or a nephrostomy tube should be considered. Adequate drainage of the perinephric area following repair is vital. In the presence of concurrent duodenal, pancreatic, and colonic injuries, interposition of omentum or peritoneum between the site of the major renal injury and the site of the coexisting intra-abdominal injury is strongly advised.

Nephrectomy should be considered in irreparable grade 4 to 5 renal injuries and in the hemodynamically unstable patient with multiorgan trauma. A nephrectomy in this latter situation may need to be performed to reduce operative time and help control bleeding in the hypothermic and coagulopathic patient (Heyns, 2004; Santucci et al, 2004b; Davis et al, 2006; Wright et al, 2006; Broghammer et al, 2007; Shariat et al, 2008).

Key Points: Renal Trauma

- The ability of the CT scan to accurately stage renal injuries, combined with the application of trauma-related severity scores, suggest that emergent nephrectomy at the time of surgical exploration is usually due to either surgical expediency in the unstable patient or preexisting vascular damage, but it is not the consequence of intractable hemorrhage incited by the renal exploration.
- Nonoperative management is preferred in the hemodynamically stable patient with a grade 1 or 2 renal injury, due to either blunt or penetrating trauma with or without associated intra-abdominal injuries. It is also the preferred treatment modality in isolated grade 3, 4, and 5 renal injuries.
- Identification of a urinoma is not a contraindication for nonoperative management, provided the distal ureter is documented to be intact.
- Absolute indications for renal exploration following trauma are (1) hemodynamic instability due to a renal bleeding, (2) an expanding or pulsatile retroperitoneal hematoma or, (3) inability to stop persistent or delayed hemorrhage by selective vascular embolization.
- There are two relative indications for renal exploration. The first is finding a retroperitoneal hematoma at the time of surgical exploration for intra-abdominal injuries in a patient with inadequate preoperative radiographic staging. A single-shot IVP to verify contralateral renal function is required before renal exploration. The second is CT-documented presence of a grade 3 or higher renal injury coexisting with intra-abdominal injuries that require abdominal exploration.

RENAL VASCULAR INJURIES

In terms of arterial renal blood flow, the kidney is an end organ; only rarely is collateral blood flow outside of the main renal arterial supply sufficient to maintain renal function. **In a patient sustaining renal arterial trauma, the clinical triad of hemodynamic instability, inadequate collateral blood flow, and warm ischemic time almost invariably results in the inability to salvage renal function** (Heyns, 2004; Santucci et al, 2004a). **Because of these conditions, no attempt to repair injuries to segmental renal vessels should be considered, and repair of the traumatically injured main renal artery is seldom, if ever, indicated when a normal contralateral kidney is present. In essence, reconstruction of the main renal artery following trauma is only a primary consideration in patients who are hemodynamically stable with an injury to a solitary kidney or in patients with bilateral renal arterial injuries** (Heyns, 2004; Santucci et al, 2004a). The infrequent exception to this rule is the presence of an incomplete arterial injury where perfusion to the kidney has been maintained by flow of blood through either the partially occluded main renal artery or through collateral vessels.

TRAUMA-INDUCED RENAL VASCULAR HYPERTENSION

The most common causes of post-traumatic renal hypertension are invariably rennin-mediated secondary to renal ischemia. Ischemia typically develops from one of four etiologies: a partial arterial stenosis, complete obstruction of a segmental or main renal artery with an intact peripheral blood supply, trauma-induced alteration in blood flow due to an arteriovenous malformation (AVM) or pseudoaneurism, or, on extremely rare occasions, compression of the renal parenchymal by hematoma/fibrosis/urinoma (Page kidney model). **The presence of hypertension immediately following the traumatic insult may be secondary to pain and resolve with observation. Persistent hypertension 30 days postinjury or hypertension developing within 3 months of the injury could be due to a trauma-induced renal source, and the diagnosis should be considered.** The incidence of trauma-induced hypertension after a grade 3 or higher renal injury is approximately 5% (Heyns, 2004; Santucci et al, 2004b; Al-Qudah and Santucci, 2006; Chedid et al, 2006; Henderson et al, 2007).

In patients with suspected traumatic hypertension, blood pressure is controlled with angiotensin-converting enzyme inhibitors. Also, evaluation with both nuclear renography, to determine differential renal function, and radiographic studies (MRI or CT angiography), to rule out an arteriovenous fistula or a pseudoaneurysm as the source of the hypertension, should be performed. Hypertension found to be related to a vascular malformation may be treated with angiographic embolization. If consideration for surgical intervention is entertained, renal vein renin sampling for split renin ratios should be considered. The latter is especially helpful in the presence of segmental renal scarring when partial nephrectomy is a consideration for surgical management. In this situation, hypertension proven to be related to segmental renal ischemia can be treated by partial nephrectomy. **The most common clinical finding in patients with post-traumatic hypertension is a small poorly functioning kidney (<20% function) associated with pan-nephric scarring; nephrectomy is the best surgical alternative** (Wessells et al, 1997b; Moog et al, 2003; Heyns, 2004; Keller et al, 2004; Santucci et al, 2004b; Chedid et al, 2006; Myrianthefs et al, 2007). Treatment of hypertension due to a subcapsular hematoma or fibrosis by decortication of the Page kidney has been published; however, the long-term results of this surgical treatment modality are extremely controversial (see Fig. 138–2) (Heyns, 2004; Santucci et al, 2004b; Myrianthefs et al, 2007).

TRAUMA-INDUCED CHRONIC FLANK PAIN FOLLOWING RENAL INJURY

Chronic flank pain developing post-traumatic renal injury is reported to occur in approximately 7% of patients following grade 3 or higher renal injuries. CT scans with delayed images and, occasionally, Lasix renograms are warranted. Findings of renal

Key Points: Renal Vascular Injuries and Trauma-Induced Renal Hypertension

- In renal arterial trauma, the clinical triad of hemodynamic instability, inadequate collateral blood flow, and warm ischemic time almost invariably results in inability to salvage renal function. Therefore repair of the traumatically injured main renal artery is seldom, if ever, indicated when a normal contralateral kidney is present.
- Hypertension secondary to renovascular trauma will usually develop within 36 months following the injury. If sustained hypertension does develop, evaluation with a DMSA scan, to determine differential renal function, and radiographic studies (MRI or CT angiography), to rule out development of an arteriovenous fistula as the source of the hypertension, should be performed. Hypertension found to be related to an arteriovenous malformation may be treated with angiographic embolization.
- The most common clinical finding in post-trauma–induced hypertension is a small poorly functioning kidney (<20% function) associated with pan-nephric scarring, with nephrectomy being the best treatment alternative.

Table 138–4.

Incidence of Pediatric Renal Injury Related to Mechanism of Injury

MECHANISM OF RENAL INJURY	PERCENTAGE OF RENAL INJURIES CAUSED BY BLUNT TRAUMA IN A PEDIATRIC POPULATION
Motor vehicle collision (including MV vs. pedestrian)	45%
Bicycle accidents (including dirt bikes and motor cross)	17%
Contact sports	12%
All-terrain vehicle accident	10%
Sports—miscellaneous (sledding, skiing, snowboarding, horseback riding, rollerblading, etc.)	7%
Falls	6%
Abuse/assault	3%

From Emmanuel et al, 1977; Amaral, 1997; Gerstenbluth et al, 2002; McAleer et al, 2002b; Johnson et al, 2005; Broghammer et al, 2006; Wu and Gaines, 2007.

lithiasis, UPJ obstruction, and persistent urinoma will occasionally be found. Unfortunately, the majority of patients will not have a clear etiology for their chronic pain syndrome. Treatment will usually involve pain management and, on rare occasions, nephrectomy. We would caution the surgeon that removal of the kidney does not necessarily correlate with resolution of the pain (Mogensen et al, 1980; Al-Qudah and Santucci, 2006).

RECOMMENDATIONS FOR ACTIVITIES IN PATIENTS WITH A SOLITARY KIDNEY

Th recommendations by the American Academy of Pediatrics are that all patients with a solitary kidney who desire to participate in contact sports should undergo individual physician assessment, with recommendations for participation based on the physician's findings. Most urologists are currently making their recommendations on the basis of the following facts. Contact sports are the third most common cause of renal injury in children (Table 138–4). The mean stage of traumatic renal injury occurring as a consequence of contact sports is lower than that of all other etiologic causes of traumatic renal injury in children. Specifically, the mean stage for renal injury following bicycle, motocross, and dirt bike accidents is 2.7 ± 1.0; all-terrain vehicle (ATV) accidents 2.4 ± 1.3; falls 2.4 ± 1.2; and motor vehicle collisions 2.1 ± 1.0 compared with the severity of injuries caused by contact and miscellaneous sports, which is 1.7 ± 1.0 (Fitness Committee on Sports Medicine and Fitness, 2001; Gerstenbluth et al, 2002; McAleer et al, 2002a; Johnson et al, 2005; Wu and Gaines, 2007). The facts as noted above have prompted most pediatric urologists to clear patients with one kidney for participation in organized contact sports, provided three baseline criteria are met: the remaining kidney has normal anatomy, it is in the normal anatomic position, and protective gear is worn. It has also resulted in the routine cautioning of parents and patients that the child with a solitary kidney should wear a seat belt or be restrained in a car seat at all times; ATV activities, motocross, and dirt bike racing are associated with increased risk for renal injury; and participation in these activities should be done with caution (Fitness Committee on Sports Medicine and Fitness, 2001; Gerstenbluth et al, 2002; McAleer et al, 2002a; Johnson et al, 2005; Wu and Gaines, 2007).

PREEXISTING HYDRONEPHROSIS AND URETEROPELVIC JUNCTION DISRUPTION

Disruption of the ureteropelvic junction is most commonly caused by acceleration-deceleration injuries, (falling from >15 feet) or by a sudden extreme hyperextension of the trunk (pedestrian-MVA, ejection injury associated with MVA). The mechanism of injury is hypothesized to be a sudden displacement of the more mobile kidney associated with a relatively fixed ureter, with force vectors from the traumatic impact interacting at the ureteropelvic junction (Boone et al, 1992; Chopra et al, 2002; McAleer et al, 2002a).

Although it has been reported that preexisting hydronephrosis or a congenital ureteropelvic junction obstruction renders the patient more susceptible to a UPJ disruption, this is controversial. The vast majority of patients with a history of trauma and preexisting UPJ or hydronephrosis will be found to have a renal contusion or grade 1 renal injury on evaluation (Fig. 138–7). If the initial CT scan reveals poor renal function secondary to a thinned cortex from the preexisting obstruction, we will usually place a percutaneous nephrostomy tube for 4 weeks and reassess function with a renal scan. Repair is recommended for patients with a differential renal function of greater than 20%.

When urinary extravasation is seen, rupture of the renal pelvis or a major laceration extending through a thinned renal cortex into the collecting system (grade 3 renal injury) is the most common finding, not a UPJ disruption (Boone et al, 1993; Hall and Carpinito, 1994; Gschwend et al, 1995; Kattan, 2001; Chopra et al, 2002; McAleer et al, 2002a; Smith et al, 2003; Ashebu et al, 2004). The majority of patients sustaining a UPJ disruption will present with vascular instability, requiring emergent laparotomy with the patient unable

to undergo preoperative imaging. Urinalysis on presentation will have some degree of hematuria in 70% of patients; however, 30% of patients with UPJ disruption will have a completely normal urinalysis. Emergent exploratory laparotomy for coexisting intra-abdominal injury is usually necessary, and exploration fails to reveal the presence of a retroperitoneal hematoma (Boone et al, 1993; Gschwend et al, 1995; Hall and Carpinito, 1994; Chopra et al, 2002; McAleer et al, 2002a; Smith et al, 2003; Ashebu et al, 2004; Al-Qudah and Santucci, 2006). Due to the frequent association of this injury with life-threatening trauma, the diagnosis of a ureteropelvic junction disruption is delayed for greater than 36 hours in more than 50% of patients (Boone et al, 1993; Kattan, 2001; Chopra et al, 2002; McAleer et al, 2002a; Al-Qudah and Santucci, 2006). Patients will eventually come to attention due to CT abnormalities found during the workup of persistent postoperative fever, chronic flank pain, continued ileus, or sepsis (Boone et al, 1993; Kattan, 2001; Chopra et al, 2002; McAleer et al, 2002a; Al-Qudah and Santucci, 2006). **Three classic findings on a triphasic CT scan are associated with UPJ disruption: (1) absence of parenchymal laceration, (2) medial extravasation of contrast in the perirenal and upper ureteral area, and (3) no visualization of the ipsilateral distal ureter** (Boone et al, 1993; Kawashima et al, 1997; Kattan, 2001; Chopra et al, 2002; McAleer et al, 2002a; Al-Qudah and Santucci, 2006).

Children with preexisting hydronephrosis secondary to congenital hydronephrosis or a UPJ obstruction almost invariably have the site of the injury being a major laceration through the thinned renal cortex (grade 3 renal injury) or laceration of the renal pelvis; rarely is disruption of the UPJ present. These patients should undergo a retrograde pyelogram to confirm continuity of the ureteropelvic junction and then can be safely managed with

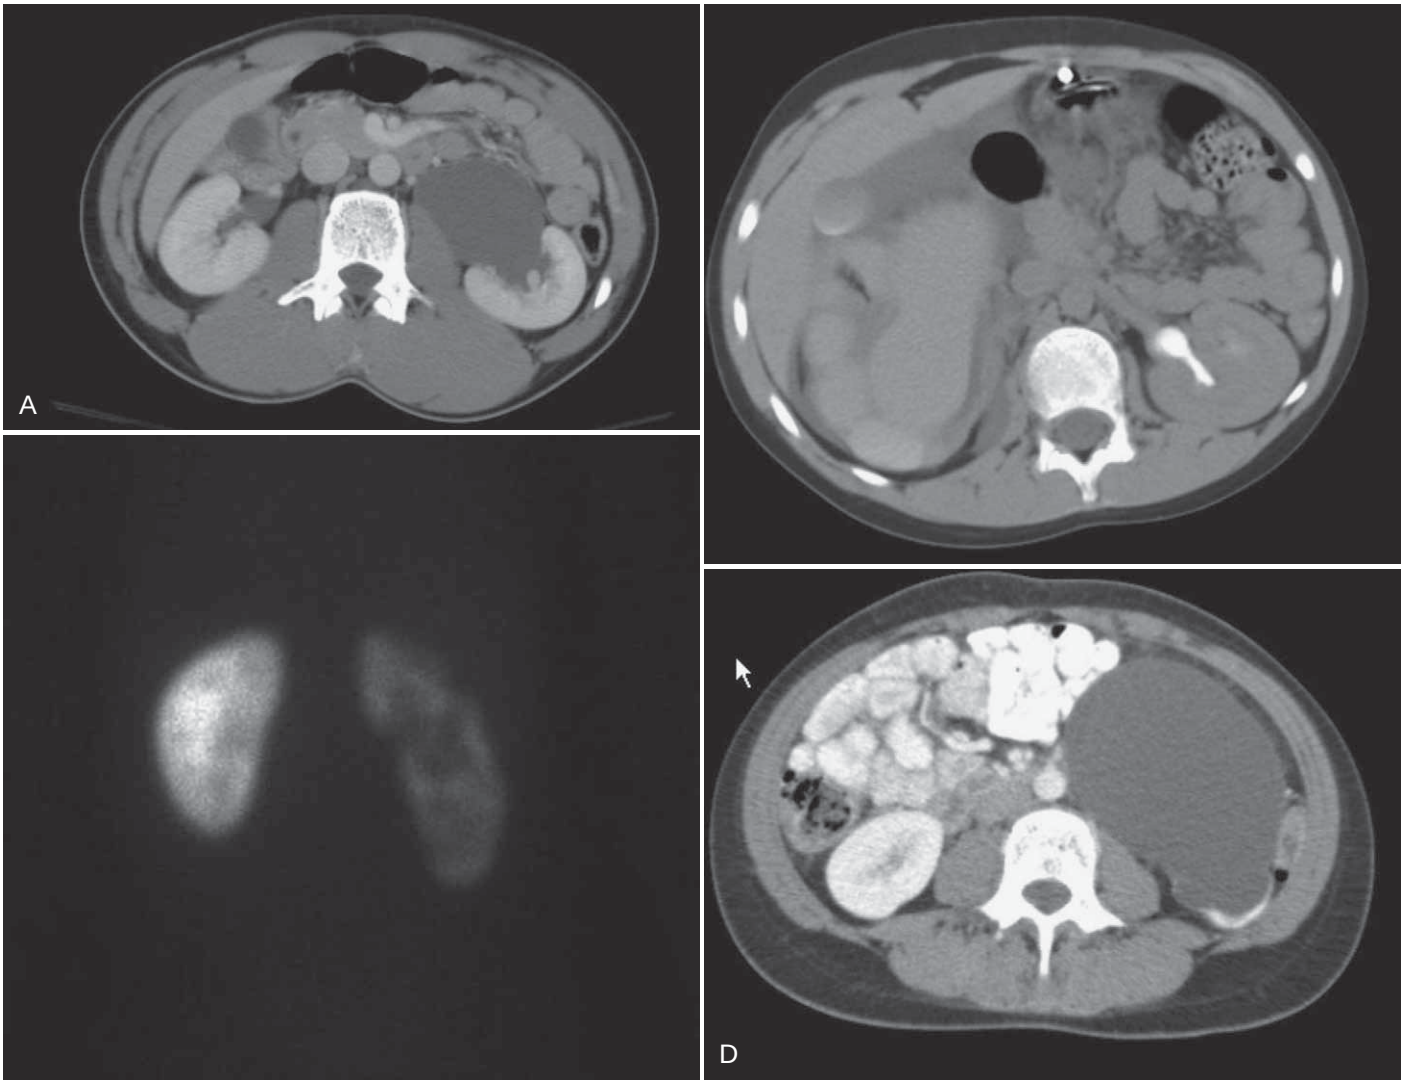

Figure 138–7. Spectrum of ureteropelvic junction (UPJ) obstructions presenting after renal trauma. **A,** A 16-year-old girl with gross hematuria and grade 1, left renal injury after low-speed (<10 mph) motor vehicle collision. **B,** A 14-year-old boy with gross hematuria after being struck in the right flank with a soccer ball. CT scan revealed grade 1 injury. Percutaneous nephrostomy was placed for 4 weeks with follow-up MAG3 scan as noted in **C**. **C,** MAG3 renal scan revealing 25% function of right kidney 4 weeks following percutaneous nephrostomy tube placement. UPJ repair was subsequently performed. **D,** A 14-year-old girl presented with gross hematuria after fall from a horse. Percutaneous nephrostomy was placed for 4 weeks, a DMSA renal scan showed less than 6% function at the end of 4 weeks, and a left nephrectomy was performed.

Continued

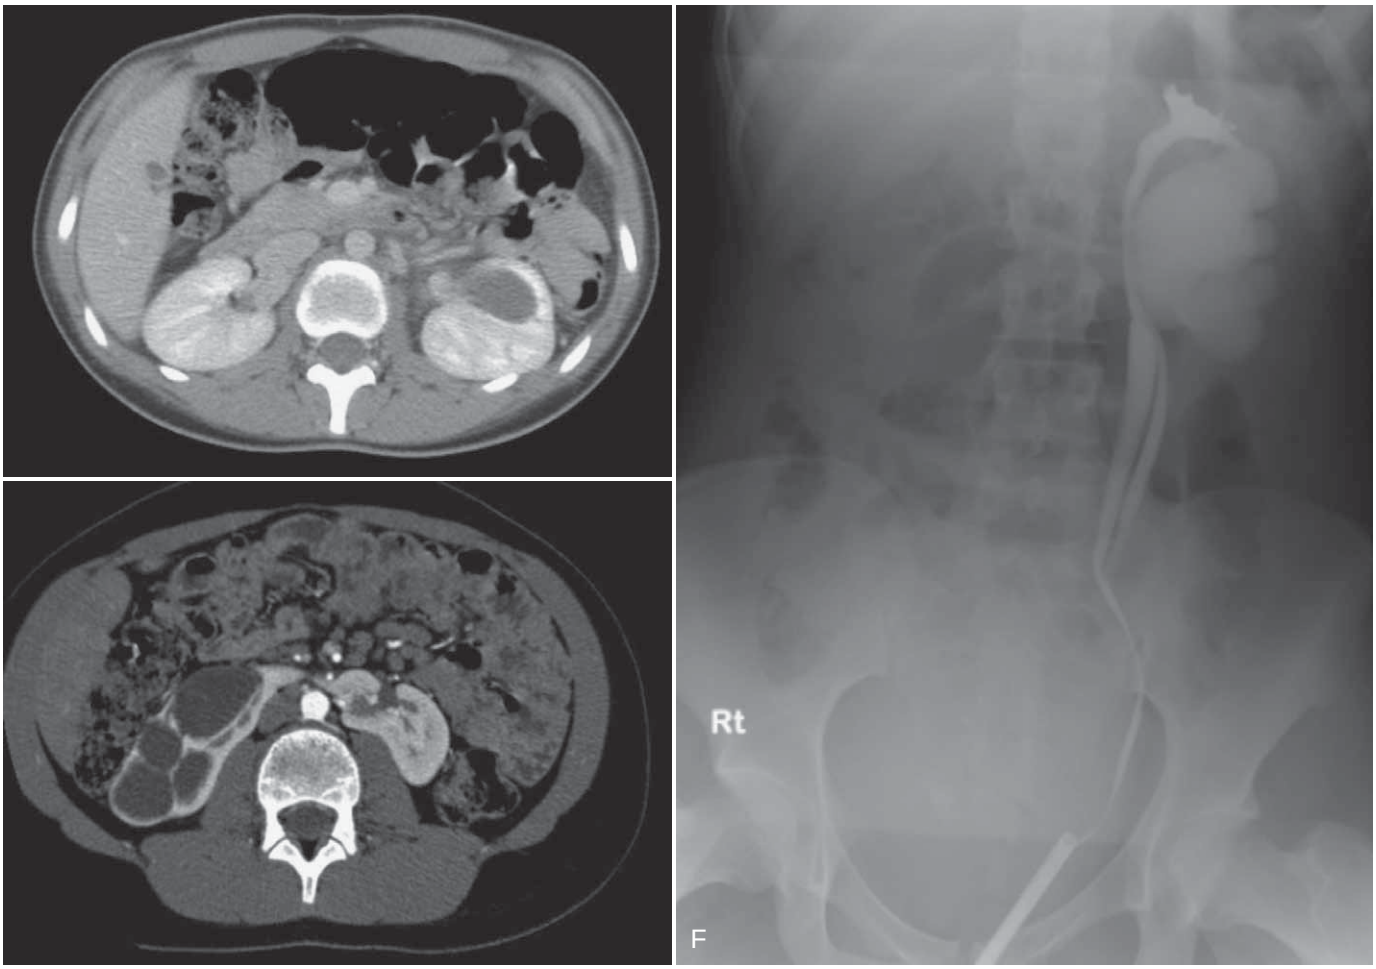

Figure 138–7, cont'd. **E,** A 15-year-old boy presented with gross hematuria following a fall while running cross country race; findings were suggestive of left lower pole UPJ obstruction. **F,** Left retrograde pyelogram confirmed incomplete left duplication with left lower pole UPJ obstruction. **G,** A 14-year-old male presented with gross hematuria following collision while playing hockey. CT scan revealed horseshoe kidney with severe right UPJ obstruction.

either a percutaneous nephrostomy or double-J stent placement, with delayed pyeloplasty performed following stabilization of the patient (Husmann and Morris, 1991; Matthews et al, 1997; McAleer et al, 2002a; Smith et al, 2003).

In patients with a disruption of the UPJ, a delayed diagnosis can reach up to 12 weeks postinjury and will significantly increase the risk of nephrectomy (Boone et al, 1993; Kattan, 2001; McAleer et al, 2002a; Smith et al, 2003; Kunkle et al, 2006). In the clinically stable patient, when the diagnosis is made within 5 days after the traumatic insult, we prefer to proceed to immediate surgical repair with debridement of any devitalized tissue, spatulation and re-anastomosis of the ureter over a stent, and placement of an intraoperative nephrostomy tube and retroperitoneal drain. Because the area of ureteral necrosis may extend for 2 to 3 cm, mobilization and downward displacement of the kidney may be necessary to obtain a tension-free anastomosis (Boone et al, 1993; Kattan, 2001; McAleer et al, 2002a; Smith et al, 2003). In patients with a delayed diagnosis of 6 or more days, we prefer to place a nephrostomy tube and allow the patient and injury to stabilize for 12 weeks. Differential renal function is then obtained using a DMSA renal scan, and the length of the ureteral injury is ascertained by a combined antegrade and retrograde pyelogram. The combination of remaining renal function and the length of the surgical defect allow the surgeon to make the proper surgical planning. Surgical alternatives in this situation include primary ureteroureterostomy, ileal ureter, autotransplantation, and nephrectomy. Notably, at the time of delayed repair there is usually significant technical difficulty in mobilization of the kidney, renal pelvis, and blood vessels; thus the option of nephrectomy should always be discussed and may become necessary (Boone et al, 1993; Kattan, 2001; Heyns, 2004; Santucci et al, 2004b; Kunkle et al, 2006).

URETERAL TRAUMA

External Trauma Resulting in Ureteral Injury

In children, external trauma causing ureteral injuries are rare, occurring in less than 4% of penetrating traumas and are reportable following blunt trauma (Velmahos and Degiannis, 1997; Velmahos and Demetriades, 2002; Hudolin and Hudolin, 2003; Kansas et al, 2004; Elliot and McAninch, 2006). Ureteral injuries will be found in conjunction with other intraperitoneal organ injuries in 90% of the patients and coexisting with renal or bladder

injuries in 10%. Due to the frequent presence of multiple organ injury, the mortality rate of a patient sustaining a ureteral injury from external trauma is in excess of 30% (Velmahos and Degiannis, 1997; Wessells et al, 1997b; Velmahos and Demetriades, 2002; Hudolin and Hudolin, 2003; Carver et al, 2004; Kansas et al, 2004; Elliot and McAninch, 2006).

Ureteral injuries associated with external trauma will lack the presence of hematuria in up to two thirds of the patients; the diagnosis is usually made by a triphasic CT study obtained to evaluate penetrating trauma and/or to rule out a GU injury following high-velocity deceleration or impact trauma (Velmahos and Degiannis, 1997; Wessells et al, 1997b; Medina et al, 1998; Velmahos and Demetriades, 2002; Hudolin and Hudolin, 2003; Carver et al, 2004; Kansas et al, 2004; Elliot and McAninch, 2006). **Gunshot wounds caused by a high-velocity missile (>350 m/second) deserve special mention. The kinetic energy of a high-velocity bullet creates a surrounding energy wave 30 to 40 times the missile diameter** (Al-Ali and Haddad, 1996; Perez-Brayfield et al, 2001; Hudolin and Hudolin, 2003; Carver et al, 2004; Santucci et al, 2004b). **In addition, the missile will frequently yaw or tumble during penetration, and the combination of blast injury and missile tumbling results in extensive damage to the surrounding tissues at a significant distance from its path. Of concern regarding high-velocity gunshot wounds to the torso is that radiographic and/or surgical evaluation at the time of the assault may not reveal the presence of a GU injury** (Al-Ali and Haddad, 1996; Medina et al, 1998; Brayfield et al, 2001; Hudolin and Hudolin, 2003; Carver et al, 2004; Perez-Santucci et al, 2004b; Kunkle et al, 2006). **In some patients with a high-velocity injury, the renal pelvis and/or ureter will appear intact or perhaps only slightly contused at the time of the radiographic examination and/or surgical exploration. As the high-velocity blast injury matures, necrosis of the ureter or portions of the renal pelvis may develop. The extent of the GU injury finally comes to attention as urinary extravasation develops due to delayed necrosis. Classically, blast injuries to the urinary drainage system present as an increase in urine output from surgically placed drains 3 to 5 days after the injury** (Al-Ali and Haddad, 1996; Medina et al, 1998; Perez-Brayfield et al, 2001; Hudolin and Hudolin, 2003; Santucci et al, 2004b; Carver et al, 2004; Kunkle et al, 2006).

Iatrogenic Ureteral Injuries Following Open, Laparoscopic, and Endoscopic Procedures

The most common iatrogenic ureteral injury in the pediatric population is following ureteroscopy; even these are rare events with ureteral perforations occurring in less than 2% of all prepubertal ureteroscopic procedures (Schuster et al, 2002; Wu and Docimo, 2004; Minevich et al, 2005). Ureteral perforation following ureteroscopy can almost invariably be managed with endoscopic intervention with ureteral stenting, with or without nephrostomy tube placement. Long-term results following endoscopic management are excellent (Schuster et al, 2002; Wu and Docimo, 2004; Minevich et al, 2005).

Traumatic ureteral injuries following laparoscopy or open surgical procedures are relatively common in adults following gynecologic and vascular surgery; however, literature reports of iatrogenic ureteral injuries following laparoscopic and open procedures in pediatric patients are extremely rare (Elliot and McAninch, 2006; Routh et al, 2009). The management of traumatic ureteral injuries revolves around the timing of diagnosis, with a delay in the diagnosis of greater than or equal to 6 days found in 50% to 60% of both pediatric and adult patients sustaining these types of injury (Elliot and McAninch, 2006; Routh et al, 2009).

If recognized at the time of surgery, surgical division of the ureter and/or partial ureteral excision should be managed based on the location and length of the ureteral injury. Options are ipsilateral ureteroureterostomy, ureteral reimplantation with or without a psoas hitch, trans-ureteroureterostomy (beware of placing the contralateral normal kidney at risk), or, on rare occasions, ureteral ligation placement of a nephrostomy tube and planned reconstruction in the next 48 to 72 hours. Ureteral contusions secondary to a high-velocity gunshot wound or inadvertent ligation of the ureter should be treated by removal of any offending clip or ligature and placement of a ureteral stent for 6 to 8 weeks. Long-term 1- to 2-year radiologic follow-up after removal of the stent or ureteral repair is necessary, because ureteral strictures or ureteral fistulae form over time (Al-Ali and Haddad, 1996; Ghali et al, 1999; Elliot and McAninch, 2006; Routh et al, 2009).

Patients diagnosed greater than or equal to 6 days after traumatic insult are usually managed by placement of a temporary percutaneous nephrostomy tube and/or ureteral stent and delayed definitive repair. **Notably, some authors have recommended management of all ureteral injuries diagnosed in a delayed fashion be with a percutaneous nephrostomy tube and stent placement** (Al-Ali and Haddad, 1996; Ghali et al, 1999). **Other authors have challenged this recommendation, noting that management of ureteral injuries with endoscopic methods alone has a complication rate of approximately 40%, usually with obliterative ureteral strictures; in comparison, delayed open repair has a complication rate of 10%** (Campbell et al, 1992; Selzman and Spirnak, 1996; Elliot and McAninch, 2006; Kunkle et al, 2006; Routh et al, 2009). We approach these patients using a combined approach, with an initial attempt to place a ureteral stent with or without a nephrostomy tube. If we successfully bridge the area of injury with a ureteral stent, we remove the stent 6 to 8 weeks following the traumatic insult and reassess the upper tract for developing hydronephrosis and renal function using ultrasonography and MAG3 diuretic renography 6 weeks later. If progressive hydronephrosis is noted, temporary drainage of the upper tract with nephrostomy tube is performed. Diagnostic radiographic studies to assess renal function and to assess the location and extent of stricture are subsequently performed a total of 12 weeks following stent removal. If we were unsuccessful in bridging the area of ureteral injury, we assess the patient approximately 12 weeks following the traumatic injury. Radiographic assessment at this time may employ a variety of modalities: antegrade and retrograde pyelography, nuclear renography to assess differential renal function, CT urography, and cystography.

The type of delayed ureteral repair to be used is based on the location and the extent of ureteral damage. Options include direct ureteral anastomosis to the renal pelvis, ureterocalycostomy, primary ureteroureterostomy, transureteroureterostomy, ureteral reimplantation with or without a psoas hitch, ileal ureter, autotransplantation, and, occasionally, nephrectomy. We would caution that the use of transureteroureterostomy places the contralateral uninjured kidney and ureter at risk. Based on this concern, we dislike transureteroureterostomy as a surgical

alternative in managing the difficult problems that arise following traumatic ureteral injuries (Elliot and McAninch, 2006; Routh et al, 2009).

Key Points: Traumatic Ureteropelvic Junction Disruption and Ureteral Injuries

- In patients sustaining a UPJ disruption, 30% will have a completely normal urinalysis.
- Due to the frequent association of traumatic UPJ disruption with life-threatening trauma, the diagnosis of this injury is delayed for greater than 36 hours in more than 50% of patients. Patients will eventually come to attention due to CT abnormalities found during the workup of persistent postoperative fever, chronic flank pain, continued ileus, or sepsis.
- Three classic findings on a triphasic CT scan are associated with UPJ disruption: (1) medial extravasation of contrast in the perirenal and upper ureteral area, (2) contrast extravasation in the absence of parenchymal lacerations, and (3) no visualization of the ipsilateral distal ureter.
- In the clinically stable patient, when the diagnosis of UPJ or ureteral disruption is made within 5 days after the traumatic insult, immediate surgical repair is the preferred treatment modality.
- In patients with a delayed diagnosis of UPJ or ureteral disruption made 6 or more days after the traumatic insult, placement of a nephrostomy tube, with or without a ureteral stent, with delayed repair at 12 weeks is preferred.
- The type of ureteral repair used is based on the location and extent of the ureteral injury.

BLADDER INJURIES

General Comments

The urinary bladder is well protected from external trauma by the bony confines of the pelvis. Due to the extensive pelvic protective mechanisms, when bladder injuries do occur, they are frequently associated with multiorgan trauma, with an average of three coexisting organ injuries and a mortality rate of 20% (Carroll and McAninch, 1984). Although it was once recommended that all patients with a history of blunt abdominal trauma presenting with either microscopic or gross hematuria should undergo bladder imaging, studies have revealed that this recommendation is associated with an extremely low yield for injury and is cost ineffective (Mokoena and Naidu, 1995; Cunningham et al, 1998; Iverson and Morey, 2001). **Absolute indications for bladder imaging following blunt abdominal trauma are currently limited to two indications: (1) the presence of gross hematuria coexisting with a pelvic fracture or (2) inability to void. Neither gross hematuria alone or pelvic fracture alone are absolute indications for screening** (Mokoena and Naidu, 1995; Cunningham et al, 1998; Iverson and Morey, 2001). Relative indications for bladder imaging following blunt abdominal trauma are urinary clot retention, perineal hematoma, and a history of a prior bladder augmentation. **Bladder imaging following penetrating trauma should be performed any time concern exists that the missile could have injured the bladder and/or if free abdominal fluid is found on the initial CT scan** (Cunningham et al, 1998).

Differences between Adults and Children in Traumatic Bladder Injuries: Lacerations through the Anterior Bladder Neck

Traumatic bladder lacerations in children are approximately two times more likely to extend through the bladder neck compared with the same injury in an adult (Husmann et al, 1990; Boone et al, 1992; Koraitim, 1997, 1999; Chapple, 2000; Ashley and Husmann, 2007; Routh and Husmann, 2007). The clinical importance of this fact is significant. Specifically, management of a bladder neck laceration with either a suprapubic tube alone and/or urethral catheter alone without coexisting repair of the bladder neck may result in the persistent extravasation of urine with the possible development of a pelvic urinoma/abscess, pelvic osteomyelitis, and an increased risk of permanent urinary incontinence (Husmann et al, 1990; Boone et al, 1992; Koraitim, 1997, 1999; Chapple, 2000; Ashley and Husmann, 2007; Routh and Husmann, 2007). The diagnosis of a bladder neck injury should be suspected any time extravasation of contrast is noted and a competent bladder neck cannot be documented with radiographic studies. **If concern for a bladder neck injury is present, the patient should undergo surgical exploration with opening of the bladder at the dome. Repair of the bladder neck should be by an intravesical approach with a multilayered closure. Great care should be given not to dislodge the pelvic hematoma to help prevent blood loss. The surgeon should be aware that anterior bladder neck lacerations are frequently associated with urethral injuries, and retrograde urethrography or cystoscopy to rule out this possibility should be considered. If a bladder neck laceration is repaired, a voiding urethrocystogram (VCUG) is necessary at the time of catheter removal to adequately visualize the bladder neck and confirm healing** (Husmann et al, 1990; Boone et al, 1992; Koraitim, 1997, 1999; Chapple, 2000; Ashley and Husmann, 2007; Routh and Husmann, 2007).

Diagnosis of Bladder Injuries

The diagnosis of a traumatic bladder injury should be assessed by either standard or CT cystography. Either modality is accurate, provided adequate bladder distention occurs. **In a child, the amount instilled within the bladder should, at a minimum, be equal to one half of the estimated bladder capacity for age (60 cc at birth and 30 cc for each year thereafter); instillation of contrast can stop at the maximum of bladder capacity for age, a total of 300 cc or if a bladder contraction occurs.** We would discourage performing a CT cystogram by plugging the catheter and evaluating the bladder at the time of the initial CT scan. Frequently, the injured patient has oliguria secondary to hypovolemia, resulting in diminished urine output with inadequate filling of the bladder. In our experience, performance of a CT cystogram by plugging the catheter alone has led to missing the diagnosis of a traumatic bladder injury on multiple occasions (Husmann, 1996; Haas et al, 1999; Peng et al, 1999; Deck et al, 2001; Iverson and Morey, 2001).

Classification and Treatment of Traumatic Bladder Injuries

All patients with traumatic bladder lacerations, either extra- or intraperitoneal, should initially be treated with intravenous antibiotics, with oral antibiotic therapy continued for 48 hours following removal of bladder catheters. Extraperitoneal injuries are twice as common as intraperitoneal injuries and are almost invariably associated with a pelvic fracture. Classically, extraperitoneal bladder ruptures will have a star-burst appearance on radiographic studies. **In the presence of an extraperitoneal bladder injury, consideration for open surgical intervention should be given if a bony spicule is found to protrude into the bladder on CT evaluation or if concern for a bladder neck laceration is present** (Kotin and Koch, 1995; Husmann, 1996; Ashley and Husmann, 2007). **If these two complications are not present, management by an indwelling urethral catheter can be considered.** The age and size of the patient plays a major role in determining if the individual can be managed by an indwelling urethral catheter. In our experience, a small-caliber urinary catheter placed in young children will frequently be occluded by blood clots. Placement of a large-bore urethral catheter to allow better drainage is a concern in young boys, due to the possibility of producing a urethral stricture; therefore a large-caliber suprapubic tube should be placed (Kotin and Koch, 1995). Urinary drainage through the bladder catheter is maintained for 7 to 10 days, and a cystogram should be obtained to verify healing of the injury prior to catheter removal.

Intraperitoneal bladder injuries will initially appear as free fluid in the abdomen on a CT scan. Instillation of contrast in the bladder will result in extravasation of the contrast into the peritoneal cavity. Almost all intraperitoneal bladder ruptures occur at the dome of the bladder, the site of least support by the perivesical surrounding structures. Because these lacerations are usually large in size, the integrity of the bladder neck frequently cannot be assessed by radiographic means (Husmann, 1996). **In intraperitoneal bladder injuries, open surgical repair of the laceration is the recommended treatment modality. This allows the surgeon to reduce any herniating omentum or small bowel from the confines of the bladder and allows careful intravesical inspection of the bladder neck at time of surgical exploration.** In all patients, a perivesical drain is placed, and a large-bore urinary catheter is used to provide urinary drainage. In younger females and/or boys, persistent gross hematuria with clots may occlude small-caliber urethral catheters, and placement of a larger-bore suprapubic tube is usually merited. Urinary drainage for 7 to 10 days postinjury should be provided and a cystogram obtained prior to catheter removal.

Key Points: Traumatic Bladder Injuries

- Absolute indications for bladder imaging following blunt abdominal trauma are currently limited to two indications: (1) the presence of gross hematuria coexisting with a pelvic fracture or (2) complaints of inability to void.
- Bladder imaging following penetrating trauma should be performed any time concern exists that the missile could have injured the bladder and/or if free abdominal fluid is found on the initial CT scan.
- Traumatic bladder lacerations in children are approximately two times more likely to extend through the bladder neck compared with the same injury in the adult.
- Failure to repair a bladder neck injury may result in the persistent extravasation of urine, with the possible development of a pelvic urinoma/abscess, osteomyelitis, and increased risk of permanent urinary incontinence.
- Traumatic bladder injuries can be accurately diagnosed by either standard or computerized tomographic cystography, provided adequate bladder distention occurs. In a child, the amount instilled within the bladder should, at a minimum, be equal to one half of the estimated bladder capacity for age.
- In the presence of an extraperitoneal bladder injury, consideration for open surgical intervention should be given if a bony spicule is found to protrude into the bladder on CT evaluation or if concern for a bladder neck laceration is present. If these two complications are not present, management by an indwelling urethral catheter can be considered.
- In intraperitoneal bladder injuries, open surgical repair of the laceration is the recommended treatment modality. This allows the surgeon to reduce any herniating omentum or small bowel from the confines of the bladder and allows careful intravesical inspection of the bladder neck at time of surgical exploration.

URETHRAL INJURIES

Differences between Pediatric and Adult Patients in Urethral Injuries

Due to the immature pelvis and the relatively intra-abdominal position of the child's bladder, children with a posterior urethral injury will differ from adults with this injury in four ways. **First, a pelvic fracture is more likely to be unstable and associated with a severely and permanently displaced prostatic urethra. Second, the severe displacement of the prostate off the pelvic floor makes a complete posterior urethral disruption more common in boys than in men. Third, in children, concurrent bladder and urethral injuries may occur in up to 20% of the patients, with coexisting anterior longitudinal tears though the bladder neck and sphincteric complex being twofold more common in children compared with adults. Fourth, in prepubertal girls, pelvic fractures are four times more likely to be associated with a urethral injury than in adult women** (Husmann et al, 1990; Boone et al, 1992; Perry and Husmann, 1992; Koraitim, 1997, 1999, 2004; Chapple, 2000; Hemal et al, 2000; Ashley and Husmann, 2007; Routh and Husmann, 2007).

The clinical impact of these differences is noteworthy. Permanent displacement of the prostate off the pelvic floor results in an increased need for either a transpubic, trans-symphyseal, or combined transpubic and perineal dissection for urethral reconstruction compared with the adult patient population. Hypothetically, the severe displacement of the prostate off of the pelvic floor raises concern that erectile dysfunction will be more common in children sustaining a urethral injury than in adults (Boone et al, 1993; Koraitim, 1997; Chapple, 2000; Basiri et al, 2002). There is also apprehension that permanent urinary incontinence may be more likely in children following this injury, due to the increased risk

of combined injuries to the posterior urethra, bladder neck, and sphincteric complex (Husmann et al, 1990; Boone et al, 1992; Perry and Husmann, 1992; Hemal et al, 2000; Rosenstein and Alsikafi, 2006; Ashley and Husmann, 2007; Routh and Husmann, 2007).

Initial Presentation of Urethral Injury

Consideration for a urethral injury should arise any time a patient presents with a history of direct trauma to the penis, vagina, perineum, or pelvis. Radiographic or cystoscopic evaluations to rule out this injury are mandatory in the following circumstances: **(1) when the patient presents with the classic triad of perineal/penile hematoma, blood at the meatus/vaginal introitus, and inability to void; (2) when there is a pelvic fracture with one or more fractured pubic rami or symphyseal diastases; (3) when radiographic findings are suggestive of a bladder neck injury** (Chapple, 2000; Rosenstein and Alsikafi, 2006).

Association of Pelvic Fractures to Posterior Urethral Distraction Injuries

Approximately 5% of patients sustaining a pelvic fracture will have a urethral injury. **The risk of a urethral injury following a pelvic fracture is directly related to the number of pubic rami fractures present, the degree of separation of the pubic symphysis, and the presence of a concurrent diastasis of the sacroiliac joint. A Malgaigne fracture, that is, a pelvic fracture that has disruption of the ischiopubic rami coexisting with diastasis of the sacroiliac joint, has the highest risk of urethral injury** (Colapinto, 1980; Kricum, 1990; Koraitim, 1996, 1999, 2004; Kommu et al, 2007). In turn, the likelihood of a urethral injury following isolated pelvic fractures of the acetabulum, ilium, and sacrum that do not involving a fracture of a ramus or the separation of the pubic symphysis is essentially zero.

Diagnosis of Urethral Injuries

In males, a retrograde urethrogram (RGUG) is the diagnostic modality of choice to rule out the presence of a urethral injury. In the pre- and postpubertal female, findings suggestive of a urethral injury are frequently noted on a CT evaluation; however, we prefer to confirm the diagnosis by cystoscopy and vaginoscopy performed under general anesthesia (Husmann et al, 1990; Boone et al, 1992; Perry and Husmann, 1992; Venn et al, 1999; Rosenstein and Alsikafi, 2006).

When a urethral injury is found to coexist with a pelvic fracture, a concurrent rectal injury will be present in 15% of children. It used to be mandatory for a digital rectal examination (DRE) be performed in these children to assess for the presence of the concurrent rectal injury. Current studies, however, have revealed the DRE to be highly inaccurate for diagnosing either a displaced prostate or a rectal injury. The ability of the DRE to correctly diagnose the presence of these findings was less than 15%, with radiographic studies and endoscopy being far more specific and sensitive for such a diagnosis. The emergency medicine community has subsequently recommended that the DRE be abandoned in the evaluation of the traumatically injured patient under these circumstances (Shlamovitz et al, 2007a, 2007b). When a rectal injury is identified to coexist with a urethral disruption treatment with a temporary diverting colostomy, it is mandatory to prevent the disastrous consequences of pelvic abscess, pelvic osteomyelitis, and necrotizing fasciitis that can accompany an unrecognized rectal injury.

General Comments Regarding Repair of Urethral Injuries: Immediate, Delayed, and Late Urethroplasty

In the early phase of the injury, the most important potential urologic complication is infection induced by bacterial contamination of the pelvic/perineal hematoma and extravasated urine. **Immediate treatment of urethral injuries should include the administration of broad-spectrum antibiotics, assessment of the competence of the bladder neck, and the establishment of urinary drainage.** Repair of the urethral injury may be immediate (primary realignment or sutured primary end-to-end anastomosis, less than 2 days postinjury); delayed (primary realignment or sutured end-to-end anastomosis), occurring 2 to 14 days following injury; or late (any type of repair occurring 3 months or more after injury) (Boone et al, 1992; Perry and Husmann, 1992; Venn et al, 1999; Rosenstein and Alsikafi, 2006; Ashley and Husmann, 2007; Routh and Husmann, 2007).

Anterior Urethral Injuries

Anterior urethral injuries in children are usually iatrogenic, due to urethral instrumentation, circumcision, or injury occurring during the repair of a congenital anorectal malformation. If the anterior urethra was injured due to urethral instrumentation, acute management should be with antibiotic therapy, followed by establishment of urethral continuity with catheter drainage. Preferably, a urethral catheter is placed by either radiologic or endoscopic techniques and maintained for 5 to 21 days, depending on the extent of the injury (Maheswari and Shah, 2005; Kommu et al, 2007). If urethral continuity cannot be established, alternative treatments include temporary suprapubic tube placement or vesicostomy. If a urethral or suprapubic catheter is placed, a VCUG is obtained at the time of anticipated removal. If no persistent urethral injury is noted, in infants we obtain a follow-up RGUG after 3 months; alternatively, in a child who is potty trained, a flow rate with ultrasound residual urine is adequate for follow-up. If a permanent urethral stricture develops, we will usually defer definitive surgical repair until the child is either greater than 1 year of age, or, if the child is older than 1 year of age, wait at least 3 months from the time of the injury, that is, a late urethroplasty. The delay in the repair allows the stricture to clearly delineate the extent of the injury, allowing the physician to plan for the urethral reconstruction.

Three types of urethral injuries can result following a circumcision: meatal injury, loss of the distal urethra secondary to partial or complete glanular amputation, or the development of a urethrocutaneous fistula due to ischemic necrosis of the urethra (Gluckman et al, 1995; Baskin et al, 1997).

The latter injury usually occurs when the urethra was either crushed by a circumcision clamp or when a cautery or a suture ligature was used to stop bleeding from a vessel that was overlying the urethra (Baskin et al, 1997). Immediate repair of the acutely traumatized anterior urethra can be technically difficult. When the meatus is injured, a formal meatoplasty should be performed

to prevent meatal stenosis from developing. When the glans with distal urethra has been amputated, it may be reattached successfully using a direct spatulated suture anastomosis of the urethra and glans with urethral stenting, perioperative antibiotics, and a compressive dressing for immobilization of the glans. When a partial distal urethral injury has occurred without substantial glans loss, suture reapproximation of the meatus, that is, a meatoplasty, can be performed. After healing, a delayed repair using hypospadias techniques may be used if necessary. Urethrocutaneous fistulas are repaired using techniques similar to those used to close fistulas following a hypospadias repair; this surgery is usually delayed until the child is 6 to 9 months of age for technical reasons (Gluckman et al, 1995; Baskin et al, 1997).

We have had a number of children referred to us for repair of urethral injuries that occurred at the time of surgical correction of their congenital anorectal malformation. **In our experience, this injury is usually due to one of two causes: no urethral catheter was in situ at the time of the rectal repair or the urethral catheter had been placed into the rectum through the urethral-rectal fistula**. In these circumstances, the proximal penile or bulbar urethra is usually excised or partially avulsed at the time of rectal dissection. The injury is frequently identified when the child is unable to void following surgery or voids through the perineal wound. The importance of an appropriately placed urethral catheter at the time of anorectal repair cannot be understated. Initial placement of the catheter prior to repair of the anorectal malformation may be difficult, because the catheter hangs up at the site of the rectourethral fistula or inadvertently passes into the rectum. Placement of the catheter over a cystoscopically placed glidewire prior to the surgical repair of this congenital anomaly is frequently helpful. This allows easy identification of the urethra, and if the urethral catheter becomes exposed during the case, the problem is recognized immediately and can usually be primarily repaired, with rare long-term consequences (Spence, 1954; Williams and Grant, 1969; McLorie et al, 1998; Hong et al, 2002).

Assessment of Urethral Stricture Prior to Delayed Repair

At the time surgical reconstruction is considered, usually 3 months postinjury, a retrograde urethrogram, followed by a simultaneous RGUG and VCUG, are the first three studies performed. If a suprapubic catheter or vesicostomy has been performed, a static cystogram is also performed. A correctly performed RGUG will allow the physician to identify the location of the urethral stricture but may not allow the appropriate determination of stricture length, especially if an extremely tight bulbar or posterior urethral distraction injury is present. Proper interpretation of these three radiographic studies is essential for true estimation of the defect between the disrupted urethral ends. Without correct interpretation of the studies, the urethral defect may be underestimated (contrast filling of a urinoma cavity associated with an incompetent bladder neck) or overestimated (nonfilling of the normal urethra due to failure of the bladder neck to open with voiding). When contrast from the static cystogram is found in the posterior urethra, it arouses suspicion for a bladder neck injury and mandates further evaluation as outlined below. If the bladder neck is competent, we obtain a simultaneous RGUG and VCUG. Great care should be taken in interpreting these films. More often than not, the pediatric patient will be unable to void and will fail to open the bladder neck. This results in non-visualization of the proximal urethral segment and may cause a spurious estimation of a long distraction defect. **If the posterior urethra fills with contrast on the static cystogram, this could be due to either a poorly felt or described detrusor contraction or an incompetent bladder neck. Because of the significant impact the latter has on the surgical prognosis, if contrast is seen in the posterior urethra, a video urodynamic study (UDS) is necessary.** If the video UDS documents an incompetent bladder neck, or, if the patient was unable to open the bladder neck to allow visualization of the posterior urethra during VCUG, we perform a simultaneous flexible cystoscopy and urethroscopy. Occasionally, in children, the physician may need to use flexible ureteroscopes for this procedure. This examination allows the physician to confirm the anatomic detail of the bladder neck and allows determination of the extent of the urethral stricture. Specifically, we will obtain anteroposterior (AP) and oblique pelvic films with the flexible scopes placed at the distraction margins; this allows the physician to see the extent and orientation of the distraction injury. Alternatively, a pelvic MRI with three-dimensional reconstruction can be obtained to evaluate the prostatic urethral dislocation and distal bulbar urethral position. The latter radiographic study lacks the ability to evaluate bladder neck competence. If cystoscopy and video urodynamics demonstrate an incompetent bladder neck, we discuss with the patient and his or her family the options of urethral reconstruction with the possible result of chronic incontinence or, alternatively, the performance of a continent abdominal stoma, appendicovesicostomy as first-line therapy (Ashley and Husmann, 2007; Routh and Husmann, 2007) (Fig. 138–8). Also see the section Mitroffanoff Principle for Bladder Neck Incompetence Following Posterior Urethral Injuries.

Endoscopic Repair of the Urethral Injury: Immediate Endoscopic Realignment, Delayed Urethroplasty with Direct Internal Visual Urethrotomy, and Delayed Urethroplasty with "Cut to Light" Procedure

Immediate endoscopic realignment using guidewires and urethral catheters for either partial or complete anterior or posterior urethral disruptions have been recommended by some authors (Husmann et al, 1990, 1993a; Koch, 1995; Elliott and Barrett, 1997; Freitas Filho et al, 2003; Maheswari and Shah, 2005; Rosenstein and Alsikafi, 2006; Hadjzacharia et al, 2008). **We believe this technique is extremely reasonable for partial urethral injuries secondary to iatrogenic catheter–induced or endoscopically induced urethral injuries; however, in our hands endoscopic realignment for noniatrogenic urethral trauma has resulted in abysmal long-term results. Indeed, in our patient population, with noniatrogenic urethral trauma managed by this technique, intermittent catheterization or repeated serial visual internal urethrotomies to maintain urethral patency was necessary in greater than 90% of children during long-term follow-up** (Husmann et al, 1990, 1993a; Boone et al, 1992). **Due to our poor experience with urethral realignment in children with noniatrogenic traumatic urethral injuries, we have elected not to pursue this treatment modality in prepubertal patients.** In the postpubertal patient

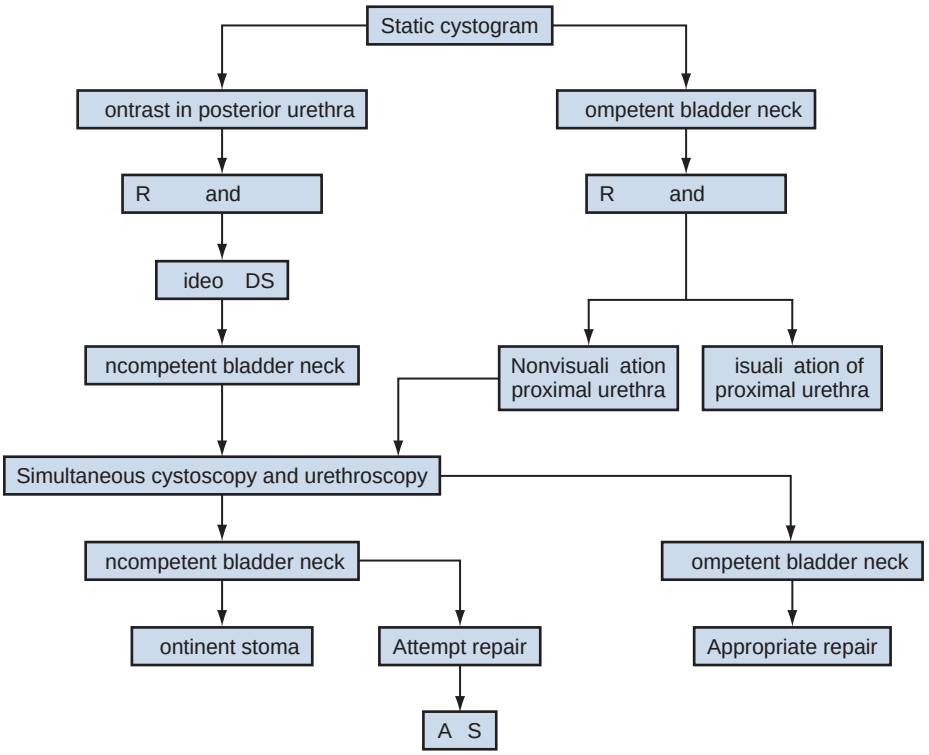

Figure 138–8. Workup of posterior urethral distraction injuries prior to delayed operative repair. AUS, artificial urethral sphincter; RGUG, retrograde urethrogram; UDS, urodynamic study; VCUG, voiding urethrocystogram.

who is clinically stable with a posterior urethral distraction injury and a competent bladder neck, we will make a limited attempt at endoscopic realignment. If the alignment cannot be established within 10 minutes, we abandon the procedure for placement of a suprapubic tube and a delayed repair. The time limitation is used in an attempt to limit the risk of bacterial colonization of the pelvic hematoma and possible consequence of osteomyelitis (Husmann et al, 1990, 1993a; Koch, 1995; Elliott and Barrett, 1997; Freitas Filho et al, 2003; Maheswari and Shah, 2005; Rosenstein and Alsikafi, 2006; Nerli et al, 2007; Hadjzacharia et al, 2008).

The "cut to light" procedure, or antegrade and retrograde urethroscopy with either endoscopic incision or laser ablation of the obliterative urethral stricture, received publicity in the late 1980s as a less invasive treatment for obliterative posterior urethral distraction injuries. Long-term follow-up has revealed a high recurrent stricture rate of greater than 90%, with urethral patency being maintained only by daily use of intermittent catheterization. This finding has led most authorities in the field to abandon this treatment method (Tollefson et al, 2007).

Endoscopic urethrotomy for short (less than 1 cm) nonobliterative trauma-induced bulbar and penile urethral strictures is commonly performed for pediatric urethral stricture disease. Unfortunately, follow-up on these patients in adulthood is limited. Short-term follow-up of 1 year frequently reveals success rates as high as 75% to 100%; however, follow-up intervals of greater than 5 years reveals success decreasing into the 20% to 35% range, with some studies suggesting that long-term success can be doubled by repeating the urethrotomy at least one time. **Repeating the urethrotomy more than one time does not appear to enhance its success and may, in fact, decrease the successful result of the eventual open urethral reconstruction** (Roehrborn and McConnell, 1994; Albers et al, 1996; Duel et al, 1998; Hsiao et al, 2003; Hafez et al, 2005; Husmann and Rathburn, 2006).

Anastomotic Urethroplasty

The principles of anastomotic urethral reconstruction include complete excision of the scar tissue and a widely spatulated anastomosis with a tension-free epithelial-to-epithelial approximation associated with viable urethral margins. **An anastomotic urethroplasty using either the perineal, transpubic, transsymphyseal, or combined approach has a reported success of greater than 90% in the pediatric patient population.** The excellent outcome of this procedure verifies that the end-to-end anastomotic urethroplasty is the procedure of choice for distraction urethral injuries in both children and adults (Cooperberg et al, 2007; Tollefson et al, 2007; El-Sheikh et al, 2008). A direct end-to-end anastomosis of up to 2 cm may be performed in most children. Gaps of 3 cm or more usually require partial or complete pubectomy or symphysiotomy with or without splitting the penile crura to accomplish the anastomosis (Boone et al, 1993; Chapple, 2000; Basiri et al, 2002; Koraitim, 2004; Park and McAninch, 2004; Cooperberg et al, 2007; El-Sheikh et al, 2008). As noted previously, because of the propensity of the child's prostatic urethra to be permanently displaced off the pelvic floor following a posterior urethral distraction injury, there will be a tendency for children to require either a partial pubectomy, symphysiotomy, or combined perineal and transpubic urethroplasty to complete the urethral reconstruction more often than would adults (Koraitim, 1997; Basiri et al, 2002; Koraitim, 2004; Park and McAninch, 2004).

Patch Urethroplasties: Flap versus Graft (One-, Two-, or Multistage Procedures)

Repair of traumatic urethral strictures of the bulbar, proximal, and penile urethra of greater than 3 to 4 cm in length in children is usually pursued using a one-stage flap procedure from the prepuce or penile shaft skin (Orandi procedure), or, if local skin is

unavailable, a dorsal graft urethroplasty using a free-skin graft or buccal mucosa (Schreiter and Noll, 1989; Barbagli et al, 2004; Park and McAninch, 2004; Schulte-Baukloh et al, 2004; Dubey et al, 2005). We prefer to do a single-stage repair by approximating at least one side of the urethra and using the flap or graft on the opposing wall. If the defect is large enough that the flap or graft must be used in a circumferential manner (tube), we will opt for a two- or multistage approach. The use of a staged reconstruction is based on the realization that recurrent strictures are more likely to occur when any flap or graft is used in a circumferential manner (tube) as a single-stage procedure (Al-Ali and Al-Hajaj, 2001; Andrich and Mundy, 2001; El-Sherbiny et al, 2002; Dubey et al, 2003; Kessler et al, 2003; Manzoni et al, 2004; Dubey et al, 2005; Husmann and Rathburn, 2006). Staging the operation by performing a classic two-stage Johannson urethroplasty or, preferentially, a multistaged preputial flap or buccal graft urethroplasty allows the surgeon to verify flap/graft survival and provide time for neovascularity and the assessment of the urethral plate for possible hair-bearing skin prior to urethral closure. In general, the length of the urethral stricture, the availability of well-vascularized excess adjacent skin, and the health of the donor bed determine if we use a one-, two- or multistage approach (Schreiter and Noll, 1989; Al-Ali and Al-Hajaj, 2001; Andrich and Mundy, 2001; El-Sherbiny et al, 2002; Dubey et al, 2003; Kessler et al, 2003; Manzoni et al, 2004; Schulte-Baukloh et al, 2004; Dubey et al, 2005; Husmann and Rathburn, 2006).

Female Urethral Injuries

Urethral injuries in females are invariably associated with an unstable pelvic fracture and are usually caused by a disruption of the pubic symphysis with a longitudinal laceration extending through the bladder neck and into the urethra, or by dislocation of a bony fragment that lacerates the urethra, resulting in distraction of the two severed margins. Female urethral injuries may be quite insidious in nature and are associated with concurrent vaginal laceration in 75% and concurrent rectal injuries in 30% (Perry and Husmann, 1992; Venn et al, 1999; Chapple, 2000; Hemal et al, 2000). **Blood at the vaginal introitus or the presence of a rectal injury in combination with a pelvic fracture should prompt the physician to consider a diagnosis of a female urethral injury.** Urethroscopy and vaginoscopy should be considered mandatory in these individuals. If the patient is clinically stable, immediate end-to-end urethroplasty for avulsion distraction injuries, primary bladder neck repair, and repair of the longitudinal lacerated urethra over a urethral catheter should be performed. Concurrent repair of vaginal and rectal injuries (with a diverting colostomy) should be performed when indicated. Preliminary diversion with a suprapubic cystostomy without any treatment of the urethra will invariably result in either a urethral stricture, urinary fistula, or both. Delayed repairs of these injuries using a two-stage approach involving preliminary suprapubic cystostomy followed by a definitive reconstruction is less successful. Delayed urethral repair and establishment of urinary continence by bladder neck reconstruction, sling, or artificial urinary sphincter placement frequently results in incontinence, urethral erosion with fistula formation, or proximal urethral obliteration. Indeed, the need for urinary diversion or a continent abdominal stoma to manage complications of the female bladder neck and urethral injuries occurs in up to 30% of female pediatric patients (Perry and Husmann, 1992; Venn et al, 1999; Chapple, 2000; Hemal et al, 2000; Castera et al, 2001; Huang et al, 2003; Koraitim, 2004; Ashley and Husmann, 2007; Routh and Husmann, 2007).

Mitroffanoff Principle for Bladder Neck Incompetence Following Posterior Urethral Injuries

In patients with bladder neck incompetence and concurrent urethral stricture disease, we have pursued two different treatment options. Initially, reconstruction of the bladder neck with re-establishment of urethral continuity is performed. If subsequent urinary incontinence persists, as it almost inevitably does, we proceed with placement of an artificial sphincter or bladder neck sling (Ashley and Husmann, 2007; Routh and Husmann, 2007). Alternatively, we may initially proceed with a continent catheterizable stoma using the Mitrofanoff principle, with no attempt to reestablish urethral continuity (Ashley and Husmann, 2007; Routh and Husmann, 2007). Indeed, personal experience with these two techniques has resulted in our preference for a continent stoma. Unfortunately, placement of an artificial urinary sphincter or sling around the bladder neck or urethra following bladder neck reconstruction and end-to-end urethroplasty is technically difficult and fraught with the risk of delayed urethral erosion (Ashley and Husmann, 2007).

Erectile Dysfunction and Urinary Incontinence Following Urethral Injuries

For decades it was argued that immediate repair of posterior urethral disruption injuries by primary urethral anastomosis and/or primary urethral realignment was directly associated with an increased incidence of erectile dysfunction and urinary incontinence. **Current studies have failed to reveal an association between the type of repair, (immediate vs. late) and the incidence of erectile dysfunction and urinary incontinence. At this time, it is believed that the severity of the primary injury and not the initial treatment modality chosen is the cause of these complications** (Husmann et al, 1990; Boone et al, 1992).

It should be noted that the incidence of erectile dysfunction is increased when total disruption of the urethra occurs and/or when the prostate is grossly dislocated, both of which are more common in children than in adults. The incidence of sexual dysfunction following this injury is correlated to the number of pubic rami fractured, the extent to which the pubic symphysis is distracted, and the length of the ensuing urethra stricture (Husmann et al, 1990; Boone et al, 1992; Koraitim, 1997, 1999; Chapple, 2000; Hemal et al, 2000). **Long-term follow-up of children sustaining a posterior urethral disruption revealed erectile dysfunction may occur in up to 70% of children when severe dislocation and injury to the apical prostatic urethra occurs, compared with a 30% incidence of erectile dysfunction when minimal dislocation of the pubic symphysis is present** (Boone et al, 1992). Whether repair by an anastomic urethroplasty increases the risk of erectile dysfunction is controversial (Kanishka et al, 2004). Patients complaining about erectile dysfunction should undergo diagnostic testing to outline the etiology of the dysfunction. Although the etiology is usually due to neurogenic causes, vasculogenic, combined neurogenic and vasculogenic, and even psychogenic etiologies have all been found

within this patient population, with therapy dictated by the diagnostic findings (Kanishka et al, 2004; Feng et al, 2008; Tal et al, 2008).

The etiology of urinary incontinence following urethral injuries is almost invariably related to the presence of a concurrent bladder neck/urethral injury or is a consequence of pelvic or pudendal nerve damage, resulting in denervation of the sphincteric complex (Husmann et al, 1990; Perry and Husmann, 1992; Koraitim, 1997; Chapple, 2000; Hemal et al, 2000; Ashley and Husmann, 2007; Kommu et al, 2007; Routh and Husmann, 2007).

Key Points: Traumatic Urethral Injuries

- A urethral injury should be ruled out in the following three circumstances: (1) if the classic triad of a perineal/penile hematoma, blood at the meatus/vaginal introitus and inability to void are present, (2) if a pelvic fracture is associated with one or more fractured pubic rami and/or symphysis diastases, and (3) if radiographic findings are suggestive of a bladder neck injury.
- In a young girl, with a pelvic fracture, if blood is noted at the vaginal introitus or if a concurrent rectal injury is present, urethral injury must be ruled out.
- Immediate treatment of urethral injuries should include the administration of broad-spectrum antibiotics, assessment of the competence of the bladder neck, and the establishment of urinary drainage.
- Short, less than 1 cm, nonobliterative bulbar and penile urethral strictures may be treated by a urethrotomy, with a success rate approaching 20% to 35%, repeating the urethrotomy more than once does not appear to enhance its success and may, in fact, decrease the success of an open urethral reconstruction.
- Following a posterior urethral injury, the incidence of erectile dysfunction and urinary incontinence is directly related to the severity of the primary injury, that is, the severity of the prostatic dislocation, the concurrent presence of a bladder neck injury, or the presence of trauma-induced pelvic or pudendal nerve damage; it is not the result of the initial treatment modality chosen.

PENILE INJURIES

Penile trauma in the pediatric patient population is most commonly iatrogenic and caused by circumcision. **If excess penile skin is excised during circumcision, the majority of patients can be treated by wet-to-dry dressings and antibiotic ointment. Healing by secondary intention usually results in an excellent cosmetic appearance. If the penis is totally degloved, the penile shaft skin, if salvaged, can be defatted and replaced on the penis as a full-thickness skin graft** (Gluckman et al, 1995; Baskin et al, 1997; El-Bahnasawy and El-Sherbiny, 2002).

Penile strangulation caused by a hair or thread is occasionally seen. In most cases it is hard to believe that this insult is purely accidental, and consideration for social service investigation for possible child abuse should be given. The human hair-tie will result in the gradual onset of ischemia, with little or no discomfort to the child. If seen early, the glans or distal penis will be edematous, erythematous, and ulcerated. The constricting hair or thread may not be noticeable without careful inspection. Removal of the constricting agent at this stage usually results in no long-term complications. Unfortunately, if the child presents in a delayed fashion or if the original diagnosis is missed, the hair may continue to cut through the penis, causing damage to the neurovascular bundle, corporeal bodies, and urethra. Injuries range from loss of glanular sensation to the development of a urethrocutaneous fistula, and, in the extreme form, partial or complete penile amputation (El-Bahnasawy and El-Sherbiny, 2002; Radhakrishnan et al, 2002).

Domestic animal attack is the most severe form of penile trauma usually seen in childhood. These penile injuries are usually associated with significant tissue destruction and fraught with complications due to bacterial contamination. Treatment requires verification of a current tetanus vaccination and absence of rabies in the offending animal. The patient is treated with the liberal use of antibiotics, wound cleansing, and debridement and repair or reattachment of the penis as the injury would direct (El-Bahnasawy and El-Sherbiny, 2002; Radhakrishnan et al, 2002).

Key Points: Traumatic Penile Injuries

- During a circumcision, excision of excess penile skin in the vast majority of patients can be treated by wet- to-dry dressings and antibiotic ointment, with healing by secondary intension resulting in excellent cosmetic appearance.
- If during the circumcision the penis is totally degloved, the penile shaft skin, if salvaged, can be defatted and replaced back onto the penis as a full-thickness skin graft.
- Penile strangulation caused by a hair is occasionally seen, and consideration for social service investigation for possible child abuse should be given.
- Domestic animal attack is the most severe form of penile trauma seen in childhood. Treatment requires verification of a current tetanus vaccination and absence of rabies in the offending pet. The patient is treated with the liberal use of antibiotics, wound cleansing, debridement, and repair or reattachment of the penis as the injury would direct.

SCROTAL, VULVAR, AND TESTICULAR TRAUMA

In the prepubertal and adolescent boy presenting with testicular/scrotal pain, the primary diagnosis should be testicular torsion until proven otherwise. Frequently, boys with testicular torsion will present with a trauma decoy, that is, a complaint of incidental scrotal trauma preceding the onset of testicular pain, with the patient's history masking the true diagnosis of torsion. If clinical examination cannot clarify the diagnosis, scrotal ultrasonography is essential; any finding consistent with testicular torsion, hematocele, or irregular testicular outline mandates surgical exploration to rule out the presence of a ruptured testis (Lee et al, 2007a).

In the pediatric patient, trauma to the scrotum or vulvar region is usually the result of athletic activities, an assault, or a fall. It is classically broken down into the two categories of penetrating or

blunt trauma. If the patient has sustained a penetrating scrotal or vulvar trauma, concern for associated injuries to the urethra and rectum exists (Husmann et al, 1993a; Lee et al, 2007a). A history of vaginal or rectal penetrating injuries; the presence of blood staining/bruising in the scrotal, labial, or perineal area; and hematuria or bloody rectal discharge should prompt further evaluations for coexisting urethral and rectal injuries. In some situations, scrotal ultrasonography, pelvic CT, or MRI maybe of significant benefit if the history is unclear, child abuse is suspected, and physical findings are worrisome. If sedation in the emergency room is inadequate in allowing the physician to perform a thorough physical examination of the genitalia, it may be necessary to bring the patient to the operative suite for general anesthesia. In all cases of penetrating trauma, a meticulous examination to determine the depth of penetration, along with cleansing and debridement of the wound, broad-spectrum antibiotics, and verification of an up-to-date tetanus immunization are employed.

Artificial urinary sphincter (AUS), 3467-3469
in bladder outlet compression/closure. *See Website*.
for male incontinence
complications of, 2302-2304
history and development of, 2291, 2292f
implantation technique for, 2296-2299, 2297f-2298f, 2299b
for bladder neck cuff placement, 2299
control pump placement in, 2298, 2298f
making connections in, 2298-2299
pressure-regulating balloon placement in, 2298-2299
for tandem-cuff placement, 2299, 2300f
for transcorporeal cuff placement, 2299, 2300f
for transscrotal placement, 2299, 2300f
indications for, 2295
long-term results of, 2304-2305
outcomes of, assessment of, 2295t
persistent incontinence after, evaluation of, 2294
in special circumstances, 2304
mechanical failure of, 2304
for stress incontinence in elderly, 2219
ARTs. *See* Assisted reproductive techniques (ARTs).
Ascites
benign, as contraindication for laparoscopy, 205
chylous, complicating laparoscopy, 249-250
posterior urethral valves and, 3394-3395
ASI stent, for benign prostatic hyperplasia, 2660
Ask-Upmark kidney, 3164, 3165f
Aspiration, testicular, percutaneous, 651
Aspirators, laparoscopic, 226
Aspirin, in antiplatelet therapy, interruption of, perioperative management of, 168-169
Assisted reproductive techniques (ARTs), 645-646
artificial insemination as, 645-646
in-vitro fertilization as, 646
Asthenospermia, 621
evaluation and treatment of, 635
Asthma, surgery and, in children, 3202
Atamestane, for benign prostatic hyperplasia, 2638
Ataxia, cerebellar, voiding dysfunction in, 1914-1915
Atheroembolism, renal, 1057-1058, 1057b
Atherosclerosis
erectile dysfunction and, 710-711
renal artery (ARAS), 1048-1050. *See also* Renovascular hypertension.
endovascular stenting for, patient selection for, 1058-1059, 1066f-1067f
percutaneous transluminal angioplasty for, 1073-1075, 1074f, 1074t-1075t
renovascular surgery for, 1576, 1576f
ATN. *See* Acute tubular necrosis (ATN).
Atopic dermatitis, of external genitalia, 438-439, 438f
Atrasentan, 2967
Atrial natriuretic peptide (ANP)
for acute kidney injury, 1204-1205
in renal hemodynamics, 1090
in renal vasoconstriction, 1028, 1028f
Atrophic urethritis/vaginitis, in geriatric incontinence, 2205-2207, 2206t
Atropine, in ureteral function, 1768-1769
Atropine sulfate, for detrusor overactivity/overactive bladder, 1970t, 1971
Audiovisual sexual stimulation, in erectile dysfunction evaluation, 734-735
Augmentation, bladder. *See* Bladder augmentation.
AUS. *See* Artificial urinary sphincter (AUS).
Autoaugmentation, bladder, 577, 577f. *See also Website*.
Autoimmune responses, as prostate cancer markers, 2759
Autoimmunity, in bladder pain syndrome/interstitial cystitis etiology, 369-371, 370b
Autoinflation, complicating penile prosthesis implantation, 788
Autologous chondrocytes, for incontinence, 2179
Autologous fat injections, for incontinence, 2178, 2178t
Autologous myoblasts, for incontinence, 2180
Autologous tumor vaccines, in renal cell carcinoma, 1464f, 1468
Autonomic hyperreflexia, in spinal cord injury, voiding dysfunction with, 1910t, 1926
Autonomic nervous system
evaluation of, in erectile dysfunction, 736
of retroperitoneum, 14-16, 15f-16f
Autonomic plexus, pelvic, 48, 49f-50f
Autoregulation, of glomerular filtration rate, 1026
Autosomal dominant (adult) polycystic kidney disease, 3170-3176, 3176b. *See also* Polycystic kidney disease, autosomal dominant (adult).
Autosomal recessive (infantile) polycystic kidney disease, 3167-3170, 3171b. *See also* Polycystic kidney disease, autosomal recessive (infantile).
Autotransplantation
with extracorporeal partial nephrectomy, 1588-1592, 1621
background of, 1588-1590
complications of, 1592
evaluation before, 1592
indications for, 1590-1592, 1590f-1591f
outcomes of, 1592
postoperative care for, 1592
preparation for, 1592
surgical procedure for, 1592, 1594f-1595f. *See Website*.
of kidney, for upper ureteral trauma, 1185
for ureteral stricture, 1162
Avitene Microfibrillar Collagen Hemostat, in laparoscopy, 222
Avulsion injury, ureteral, uteroscopic, 1407
management of, 1188
Axial resolution, of ultrasound image, 112
Axitinib
for clear cell renal cell carcinoma, 1487-1488, 1488t
for metastatic bladder cancer, 2373
Azathioprine, for bladder pain syndrome/interstitial cystitis, 387t, 389
Azoospermia
evaluation of, 620-628, 634-635, 634f
obstructive, 626, 635
treatment of, 634-635, 634f
Azotemia
in acute renal injury, 1193
in benign prostatic hyperplasia, 2603
with conduit urinary diversions, 2442
in ischemic nephropathy, 1059
postrenal, 1195
prerenal, 1194-1195, 1194t
in renovascular hypertension, 1058
Aztreonam, for urinary tract infections, 276t-279t, 279
Azygos vein, 13f

Clonidine suppression testing, for pheochromocytoma, 1708
Cloning, therapeutic, 570-571, 571f
in kidney regeneration, 587, 587f
Clopidogrel, in antiplatelet therapy, interruption of, perioperative management of, 168-169
Clorpactin, for bladder pain syndrome/interstitial cystitis, 391-392
Clostridium difficile colitis, antibiotic bowel preparation causing, 165
Clots. *See* Blood clots.
Clusterin, in apoptosis regulation in genitourinary cancer, 566
CMN. *See* Congenital mesoblastic nephroma (CMN).
Coagulopathy, uncorrected, renal calculi management in, 1373
Coccygeus muscle, 38, 40f, 43f
Cockcroft-Gault formula, for creatinine clearance, 1027
Coffee consumption, urothelial tumors associated with, 1517
Cognitive impairment
hormonal therapy for prostate cancer and, 2943
incontinence prevalence and, in men, 1892
Cohen cross trigonal technique, 3298-3299
Colchicine, for Peyronie's disease, 800
Colitis, pseudomembranous, antibiotic bowel preparation causing, 165
Collagen
bladder wall, 1795
bovine, glutaraldehyde cross-linked, injections of, for incontinence, 2173-2176, 2174t, 2175f
in paraurethral tissue, stress incontinence and, 1800
porcine dermal, injections of, for incontinence, 2179
for regenerative medicine, 574, 574f
Collagenase, intralesional, for Peyronie's disease, 801
Collecting devices, external, for bladder storage/emptying failure. *See Website*.
Collecting ducts
carcinoma of, 1432t, 1436
systemic therapy for, 1491
development of, 2979f
Collecting system, renal. *See* Renal collecting system.
Colles fascia, 33-34, 35f
Colon
anatomy of, 18
injury to, complicating percutaneous nephrostomy, 1352
reflection of, in laparoscopic nephrectomy, 1637-1638, 1637f-1638f
surgical anatomy of. *See Website*.
for urinary diversion, selection of. *See Website*.
Colon conduit, in conduit urinary diversion, 2438-2440
complications of, 2439-2440, 2441t
procedure for, 2439, 2439f-2440f
Colon pouch, right, for continent urinary diversion, 2465, 2474-2477, 2475f
Color, of urine, 85, 85t
Color Doppler ultrasonography, 116
Color flow Doppler with spectral display, 116
Colpocleisis
for apical vaginal prolapse repair, 2101-2105
partial
results of, 2103-2105, 2103t
technique of, 2101-2102, 2102f-2103f
total
results of, 2102-2103, 2103t
technique of, 2102, 2104f
partial, Latzko, 2236-2237
Colpoperineorrhaphy, posterior, 2107
Colporrhaphy
anterior
for female incontinence, retropubic suspension surgery vs., 2064
for pelvic organ prolapse, 2080-2082, 2080f, 2081t-2082t
posterior
for pelvic organ prolapse, 2107-2110
results of, 2108-2110, 2109t, 2111t
technique of, 2107-2110, 2108f
perineorrhaphy with, 2108
site-specific, 2108, 2109f

Colposuspension
in bladder outlet compression/closure. *See Website*.
Burch, 2049, 2050f, 2055-2058. *See also* Burch colposuspension.
configuration of suspensions in, 2049, 2050f
description of, 2049
for female incontinence, tension-free vaginal tape procedure vs., 2066-2068
laparoscopic, 2049
open retropubic, 2064-2068
tissue approximation in, 2049, 2050f
urethral elevation in, degree of, 2049, 2050f
Column of Bertin, 20, 20f
Combined genital and subjective arousal disorder, 826
Combined intracavernous injection and stimulation (CIS) test, for erectile dysfunction, 729-730
Complement, in innate immunity, 498-499, 498f
Compression, external, to improve bladder emptying, 2196-2197
Compression neurapraxia, complicating open renal surgery, 1623
Computed tomography angiography (CTA), in renovascular hypertension diagnosis, 1063
Computed tomography (CT), 128-132, 129f, 131f-132f
in acute focal bacterial nephritis, 299
in acute pyelonephritis, 297
in adrenal adenoma, 1721, 1722f
in adrenal carcinoma, 1716
in bladder cancer staging, 2358, 2358t
of bladder diverticulum, 2264, 2265f
dual energy, in stone composition determination, 1296
in emphysematous pyelonephritis, 300, 301f
in genitourinary tuberculosis, 473, 473f
in hematuria evaluation, 130-132, 135f
Hounsfield units in, 130
before laparoscopic/robotic surgery, 206
in malacoplakia, 311
in pediatric evaluation, 3082
in percutaneous renal ablative therapy, 1674-1676, 1675f
in perinephric abscess, 304, 305f
in predicting stone composition, 1366. *See also Website*.
preoperative, for partial nephrectomy, 1613, 1614f
in PSA rise investigation, 2923
in renal abscess, 302, 302f-303f
in renal cell carcinoma staging, 1442-1443, 1442f
in renal echinococcosis, 312
in renal injury staging, 1172, 1172f
in renal mass evaluation, 130, 134f-135f, 1416, 1416f-1417f
before renal surgery, 1559, 1559f-1560f
in retroperitoneal fibrosis, 1109, 1110f
in seminal vesicle evaluation, 1014-1015, 1014f
of simple renal cyst, 3189, 3189f
in stone composition determination, 1296
in tuberous sclerosis complex, 3178f, 3179
in ureteral trauma, 1179, 1179f
in ureteral trauma diagnosis, 1182-1183
of ureteropelvic junction obstruction, 1124f-1125f, 1131-1134
Computed tomography *(Continued)*
in ureterovaginal fistula diagnosis, 2243-2244, 2245f
of urinary calculus, 1290-1291, 1291f
in urinary tract infections, 274
in urinary tract obstruction diagnosis, 1103-1105
in urolithiasis evaluation, 130, 133f
in vesicoenteric fistula diagnosis, 2253-2254, 2253f
in vesicouterine fistula diagnosis, 2246, 2248f
in xanthogranulomatous pyelonephritis, 308-309
Computed tomography (CT) cystography, in bladder trauma, 2514-2515, 2515f. *See also Website*.
Computed tomography (CT) urography, in urothelial tumor diagnosis, 1523
Concentration product, 1260
Condom catheters
in geriatric incontinence management, 2218
Conduit, conversion of, to continent reservoir, in continent urinary diversion, 2473-2474
Condylomata acuminata, 411-413, 411f-412f
in HIV patients, 426-427, 427f
Congenital adrenal hyperplasia (CAH), 1714
male infertility and, 627
prenatal diagnosis of, 3057
sexual differentiation and, 3614-3618
surgery and, 3204
voiding dysfunction in, 1943-1944
Congenital anomalies, in pediatric evaluation, 3072-3075
Congenital bilateral absence of vas deferens, 641-642
Congenital cryptorchidism, 3560-3561
Congenital mesoblastic nephroma (CMN), 3060, 3723-3724
Congenital urethral fistula, 3551
Congenital urethral stricture, 3407
Congenital urinary obstruction. *See* Urinary tract obstruction, congenital.

Cystitis cystica, 2310-2311, 2310f
Cystitis glandularis, 2310f, 2318f
Cystoceles, 2072-2073, 2073t, 2074f
Cystography
in bladder trauma, 2514-2515, 2514f
static, 109-110, 110f
in ureterovaginal fistula, 2243-2244, 2243f
in vesicouterine fistula, 2246, 2247f
in vesicovaginal fistula, 2229-2230, 2229f
Cystolitholapaxy, for bladder calculi, 2526
Cystolithotomy, in bladder calculi, 2525-2526
Cystolithotripsy, percutaneous, for pediatric stone disease, 3682-3683
Cystometrogram (CMG), definition of, 1851, 1852f
Cystometrography, in benign prostatic hyperplasia, 2618
Cystometry, filling
in benign prostatic hyperplasia, 2618
bladder compliance during, 1877-1878
Cystometry Sensation Scale, 1951, 1953t
Cystoplasty. *See also* Bladder reconstruction.
augmentation, 3471-3491. *See Website.*
ileocystoplasty in, 3474-3475
intestinal segment management in, 3473
native bladder management in, 3473
cecocystoplasty, 3475-3477
gastrocystoplasty, 3478-3479
postoperative management for, 3479
reduction
to improve bladder emptying, 2197-2198
for prune-belly syndrome, 3319
sigmoid, 3477
Cystoprostatectomy, radical, robotic-assisted, 2400-2410. *See also* Laparoscopic radical cystoprostatectomy, robotic-assisted.
Cystoscopy
antibiotic prophylaxis for, 283
for bladder cancer, 2327
for bladder reconstruction, 3461
fluorescence, in bladder cancer, non–muscle-invasive, 2342, 2342f
in genitourinary tuberculosis, 474
before injection therapy for incontinence, 2170
in non–muscle-invasive bladder cancer surveillance, 2350-2351
in pelvic floor disorder evaluation, 1905
preoperative, for surgical repair of male incontinence, 2294
in pubovaginal sling placement and fixation, 2121-2122
before ureteroscopy, 201
in urothelial tumor diagnosis, 1523
in vesicoureteral reflux, 3277-3278
in vesicoureteral reflux surgery, 3294
for vesicouterine fistula, 2246, 2247f
for vesicovaginal fistula, 2228-2229, 2228f-2229f
Cystostomy, suprapubic
in anterior urethral injury, 2520
in posterior urethral injury, 2517. *See also Website.*

Cystourethrography, voiding, 110-111, 111f
in pelvic floor disorder evaluation, 1906-1907
in urinary tract infections, 274
Cystourethroscopy, 192-196
with continent urinary diversion, 195-196
equipment for, 193-194, 193f-194f, 196t
indications for, 192
patient preparation for, 194
special considerations for, 195-196
with suprapubic catheterization, 195
technique of, 194-195, 195f
in urethral diverticulum, 2278, 2279f
Cytochrome P450 oxidoreductase deficiency, 3619-3620
Cytokine(s)
in benign prostatic hyperplasia, 2576-2577, 2577f
immunosuppressive, in tumor immunology, 523
in immunotherapy, 523-524
representative, 496t
in septic shock, 313-314
T cell phenotypes producing, 510-511, 510f
Cytology
urine, in non–muscle-invasive bladder cancer surveillance, 2351
in urothelial tumor diagnosis, 1524
Cytomatrix, of prostate, 2540, 2540f
Cytomegalovirus (CMV), serologic testing for, before renal transplantation, 1229-1230
Cytometry, ploidy-flow, in urothelial tumors, 1522
Cytoreductive nephrectomy
for metastatic renal cell carcinoma, 1476-1477, 1478b
metastectomy and, 1610-1612, 1611t, 1612f
Cytoskeletal changes, in cell signal transduction, 508
Cytotoxic therapy, for renal cell carcinoma, resistance to, 1427

D

D-penicillamine, for cystinuria, 1318
da Vinci Robotic System, 226-227, 227f
in prostatectomy, 2830-2834
Dantrolene, to facilitate bladder emptying, 2001-2002
Dapoxetine, for premature ejaculation, 776-777, 777t
Darifenacin, in geriatric incontinence management, 2216-2217
Darifenacin hydrobromide, for detrusor overactivity/overactive bladder, 1970t, 1974-1976
Dartos fascia, 33-34, 35f, 56-57, 65f, 66
Dartos smooth muscle, 66, 67f
DAX1 gene, 3601
Death, from percutaneous nephrostomy, 1355
Death receptor pathway, of apoptosis, 512-514, 513f
Debridement
for Fournier gangrene, 325
of scrotal wall, in Fournier gangrene, 1002-1003, 1003f
Debulking nephrectomy, for metastatic renal cell carcinoma, 1476-1477
Decongestants, geriatric incontinence and, 2207
Deep venous thrombosis (DVT)
complicating laparoscopy, 248-249
Deep venous thrombosis *(Continued)*
with laparoscopic radical prostatectomy, 2846
Defensins, in innate immunity, 497
Definitive therapy, for prostate cancer
localized, 2771-2788. *See also* Prostate cancer, localized, definitive therapy for.
selective, active surveillance with
current results of, 2796-2799
watchful waiting vs., 2789-2790, 2790t
Deflux, in endoscopic correction of vesicoureteral reflux, 3306
Dehiscence
fascial, 176
wound, complicating open renal surgery, 1624
Dehydroepiandrosterone (DHEA), aging effects on, 816, 816t
Delirium, in geriatric incontinence, 2205, 2206t
Dementia, voiding dysfunction in, 1914
Dendritic cells, in adaptive immunity, 500
Denervation, of spermatic cord, microsurgical, 1011-1012, 1012f
Denonvilliers fascia, 51f, 60, 2838
Deoxyribonucleic acid. *See* DNA; DNA *entries*.
Dependent continence, definition of, 1897t
Depression
bladder pain syndrome/interstitial cystitis and, 365
incontinence in, 2009
in prostatitis, 332-333
Dermal graft inlays, in Peyronie's disease management, 805
maturation of, 807
Dermal grafts, 958
Dermatitis

basic, 436
definition of, 436
medical therapy in, 436-438
Dermatophyte infections, cutaneous, 456, 457f
DES. *See* Dysfunctional elimination syndrome (DES).
Desmopressin
in geriatric incontinence management, 2217-2218
in nocturia management, 1965
for primary nocturnal enuresis, 1994-1995
Detrusor leak point pressure (DLLP)
definition of, 1856
measurement of, 1855f, 1856-1857, 1857f
Detrusor muscle, 1787f. *See also* Bladder; Smooth muscle, bladder.
acontractile, definition of, 1840-1841, 1858
acontractility of, in Fowler syndrome, 1940
areflexia of, 1840-1841
after cerebrovascular accident, 1913
from herpesvirus infection, 1932
in lumbar disc disease, 1931
urodynamic classification of, 1841-1842, 1843t
cellular mechanics of, 1791-1794
Detrusor muscle *(Continued)*
in children, 3413-3414
compliance of. *See* Bladder compliance.
contractility of
decreased, benign prostatic hyperplasia and, 2582
impaired, in Parkinson disease, 1916
contraction of
muscarinic-receptor induced, 1814-1815, 1967-1968
sequence of, 1792, 1792t
discoordination in infancy, 3415-3416
excitation-contraction coupling in, 1792-1793
hyperactivity of, with impaired contractility, 1939
hypocontractility of, after cerebrovascular accident, 1913
interstitial cells of, 1793f, 1794
layers of, 53-54, 53f
muscarinic receptors in, 1968-1969
overactivity of. *See also* Overactive bladder (OAB).
afferent mechanisms in, 1948
aging and. *See Website*.
bladder distention therapy for, 2189-2190
from bladder outlet obstruction. *See Website*.
botulinum toxin injections for. *See Website*.
causes of, 1876t
definition of, 1875
in geriatric incontinence, 2208-2209
treatment of, 2214-2218, 2214t, 2215f
hypotheses of, 1948
idiopathic, 1876
in neuropathic bladder dysfunction, 1877
incontinence caused by, 1875
inflammation in. *See Website*.
mechanisms of, 1831-1832
in multiple system atrophy, 1917
neurogenic, 1840. *See also* Neurogenic bladder.
definition of, 1875-1876
mechanisms underlying. *See Website*.
spinal cord injury and. *See Website*.
neuroplasticity and, 1832
overactive bladder and
differentiation of, 1947-1948
integrative physiology of, 1948-1950, 1949f
in Parkinson disease, 1916
pathophysiology of, 1854-1855
phasic
definition of, 1875
urodynamic waveform in, 1955, 1955f
stress-induced, in urodynamic evaluation, 1857, 1857f
in suprasacral spinal cord injury, 1920-1921
terminal, 1955
definition of, 1875
treatment of, drugs for, 1969, 1970t
urodynamic evaluation of, 1854-1855, 1854f
in proximal urethra, 1787
relaxation of, parathyroid hormone-related peptide in, 1821-1822
tone of, 1794
underactivity of
definition of, 1840-1841, 1858
in geriatric incontinence, 2209

Detrusor muscle *(Continued)*
treatment of, 2214t, 2220-2221, 2220t-2221t
Detrusor overactivity index, 1956f
Detrusor pressure at voiding in, 3413-3414
Detrusor sphincter dyssynergia (DSD)

for specimen entrapment, 224-225
for stapling and clipping, 224, 224f, 225t
for suturing and tissue anastomosis, 222-223
for visualization, 218-220
for lower ureteral injuries, 1185
versus retroperitoneoscopy, 250
troubleshooting in, 234-250
ureteral injuries associated with, 1180-1181
Laparoscopic ureterocolicostomy, for ureteropelvic junction obstruction, 1139
Laparoscopic ureterolithotomy, 1379
Laparoscopic ureteroureterostomy, 3254
Lapatinib, for metastatic bladder cancer, 2373
Lapdisc, 216
Lapides classification, of voiding dysfunction, 1842-1845, 1843t
Laplace equation, 1771
bladder biomechanics and, 1788, 1788f
ureteral obstruction effects and, 1775
Lapra-Ty clips, 223
LapSac, 224-225
Larotaxel, for metastatic bladder cancer, 2371-2372, 2371t
Laser, in laparoscopy, 221
Laser ablation, for penile cancer, 911
Laser interstitial thermal therapy (LITT), 1681
Laser lithotripsy, 1383-1385. *See also* Lithotripsy, laser.
Laser therapy
for benign prostatic hyperplasia, 2671-2678
clinical results of, 2674-2678
contact laser in, 2673
clinical results of, 2676
with diode laser, 2671
with holmium:yttrium-aluminum-garnet laser, 2671
interstitial laser in, 2673
clinical results of, 2676-2677
methods of delivery in, 2671-2672
with neodymium:yttrium-aluminum-garnet laser, 2671
with potassium-titanyl-phosphate laser, 2671
clinical results of, 2678
side-firing laser in, 2672-2673
clinical results with, 2675-2676
types of laser used in, 2671
for bladder cancer, non–muscle-invasive, 2341
for penile cancer, 934-935
for urethral stricture, 973
Lateral fusion abnormalities, 3637
Lateral resolution, of ultrasound image, 112, 112f
Latissimus dorsi muscle, 7f, 10f
Laxative abuse, ammonium acid urate stones from, 1319-1320

Lazy bladder, 3419
Le Bag (ileocolonic) pouch, for orthotopic urinary diversion, 2495-2497, 2499f
Le Duc technique of small bowel anastomosis, 2428t, 2431, 2431f
Leadbetter and Clarke technique, of ureterocolonic anastomosis, 2427, 2427f, 2428t
Leak point pressures
  abdominal, measurement of, 1855-1857, 1856f

Male urogenital triangle, 63-64, 63f-64f
Malecot catheter, for percutaneous nephrostomy drainage, 1342-1343, 1343f
Malignancy. *See* Cancer; *specific neoplasm*.
Malignant fibrous histiocytoma, retroperitoneal, 1508-1509
Malignant hemangiopericytoma
renal, 1471
retroperitoneal, 1509
Malnutrition, perioperative care and, 163-164
Mannitol, for acute kidney injury, 1203-1204
Mansonella perstans, 486-487
Mantoux test, for genitourinary tuberculosis, 471, 471t
Marshall-Marchetti-Krantz procedure
in bladder outlet compression/closure. *See Website*.
for female incontinence, 2053-2055, 2054f
Burch colposuspension and paravaginal repair vs., 2065-2066
results of, 2054-2055
technique of, 2053-2054, 2054f
Martius flap, in vesicovaginal fistula repair, 2238-2240, 2239f
Massage
pelvic floor, for prostatitis, 347
perineal, for prostatitis, 347
prostatic, for prostatitis, 347
history of, 327
Mast cells, in bladder pain syndrome/interstitial cystitis
diagnostic role of, 383
etiologic role of, 371-372, 371f, 372b
Matrix calculi, surgical management of, 1360
Matrix metalloproteinases, in Peyronie's disease, 794-795
Matrix stones, 1282-1283
Mature teratoma, 3727-3728
Maximum voided volume, definition of, 1959t
Mayer-Rokitansky-Küster-Hauser syndrome (MRKH), 3625, 3632-3637
MCDK. *See* Multicystic dysplastic kidney (MCDK).
MCKD1 gene mutations, in medullary cystic disease, 3176
MCKD2 gene mutations, in medullary cystic disease, 3176
MDRD formula. *See* Modification of diet in renal disease (MDRD) formula.
MDV3100, 2939
Meares-Stamey four-glass test, for prostatitis, 337-338, 337f
Mechanical bowel preparation, for urologic surgery, 165-167
Mechanical index, 118
Medial fibroplasia, 1048t
of renal artery, 1048t, 1050-1051, 1051f, 1576, 1576f
Median raphe cyst, 463-464, 3550
Mediastinum, resection of, postchemotherapy, 889
Mediastinum testis, 67, 68f
Medical history, 79-80
in erectile dysfunction, 725-727
Medical Therapy of Prostatic Symptoms (MTOPS) Trial, of combination therapy for benign prostatic hyperplasia, 2639-2641
Medications. *See* Drug(s).
Medullary cystic disease
in chronic kidney disease, 1214
genetics of, 3176
with juvenile nephronophthisis, 3176-3177. *See also* Juvenile nephronophthisis/medullary cystic disease complex.
Medullary sponge kidney, 3191-3192, 3192b
characteristics of, 3191, 3191f
clinical features of, 3168t, 3191-3192
diagnosis of, 3192
stone formation in, 1285
treatment and prognosis of, 3192
Megacalycosis, 3155
Megacystis
congenital, 3380
vesicoureteral reflux and, 3286-3287
Megalourethra
prenatal diagnosis of, 3057
prune-belly syndrome and, 3312
Megaureters, 3215-3216
vesicoureteral reflux and, 3286-3287
Meiosis, in spermatogenesis, 602-603, 603t
Melanocortin-receptor agonists, for erectile dysfunction, 743
Melanocortins, in male sexual function, 700, 700t
Melanoma, penile, 929-930, 929f
Melatonin, aging effects on, 816-817, 816t
Membranoproliferative glomerulonephritis, 3010-3011
Membranous glomerulonephritis, 3010
Membranous urethra, 59-60, 60f
Memotherm stent, for benign prostatic hyperplasia, 2660
Mental health, measurement instruments for, 149
Mental retardation, in tuberous sclerosis complex, 3177
Mepartricin, for prostatitis, 346
α–Mercaptopropionylglycine, for cystinuria, 1318
Mesenchymal tumors, of prostate, 2733
Mesenteric artery
inferior, 11, 11f, 13t

Mesenteric vein, superior, 12f
Mesenterorenal bypass, 1586, 1587f
Mesentery, blood flow in, effects of pneumoperitoneum on, 232
Mesonephric duct, persistent, 3595
Mesonephros, 2975-2978, 2978f
Mesothelioma, of testicular adnexa, 869
Metabolic acidosis, 1044-1045
hyperchloremic, 1044t
Metabolic alkalosis, 1045-1046, 1045t
Metabolic syndrome
benign prostatic hyperplasia and, 2591
erectile dysfunction and, 718-719
hormonal therapy for prostate cancer and, 2943-2944
stone formation in, 1307
Metabolism
acid-base, effects of pneumoperitoneum on, 232-233
effects of conduit urinary diversion on, 2441-2447
effects of laparoscopic surgery on, 233-234
Metabolites, in prostate cancer biomarker research, 2762
Metaiodobenzylguanidine (MIBG) scintigraphy, in pheochromocytoma, 1706, 1707f
Metallic mesh stents, 187, 187f
Metanephric adenofibroma, 3724
Metanephrine testing, for pheochromocytoma, 1707-1708, 1734-1735
Metanephros
adenoma of, 1495-1496, 1495f-1496f, 1496b
development of, 2978-2980
transplantation of, into diseased kidney, 586
Metaplasia, urothelial, 1520-1521
Metastasis(es)
to adrenal glands, 1719-1720, 1720f
from penile cancer, 931

Metastasis(es) *(Continued)*
from prostate
bisphosphonates for, 2964
castration-resistant, 2957-2958
RANKL inhibitors for, 2964
risk of, 2925-2927
from renal cell carcinoma, resection of, 1477-1478, 1478b
from renal tumors, 1470t, 1472
from retroperitoneal tumors, 1515
Metastectomy, cytoreductive nephrectomy and, 1610-1612, 1611t, 1612f
Metformin, intravascular radiologic contrast medium and, 103
Methotrexate
for bladder pain syndrome/interstitial cystitis, 387t, 390
for metastatic urothelial tumors, 1552-1553
Methoxamine, for stress incontinence, 1991
7α-Methyl-19-nortestosterone, for androgen deficiency in aging male, 818
α-Methylacyl-CoA racemase, in prostate cancer, 2718
α-Methylacyl coenzyme racemase, in prostate cancer biomarker research, 2760
Methylene blue, in ureteral trauma diagnosis, 1182
Methylprednisolone, premedication with, to reduce contrast media reactions, 102-103, 103t
Metoclopramide, to facilitate bladder emptying, 1996
Metyrosine, for pheochromocytoma, preoperative, 1709
Michaelis-Gutmann bodies, in malacoplakia, 310
Microbial killing, in immunity to infections, 525-526
Microdeletions, Y-linked, infertility due to, 641, 641f
Microexplosive generator, for shockwave lithotripsy, 1389-1390
Micropapillary variant, of transitional cell carcinoma, upper urinary tract, 1521
Micropenis
causes of, 3547, 3547t
definition of, 3547
evaluation of, 3548
gender reassignment with, 3548
primary erectile dysfunction and, 720
MicroRNAs, in prostate cancer biomarker research, 2760
β-Microseminoprotein, in prostatic secretions, 2565-2566
Microwave hyperthermia, for prostatitis, 348
Microwave thermotherapy (MWT), 1681
Micturition. *See also* Voiding *entries, e.g.* Voiding urethrography.
central reflex pathways regulating. *See Website*.

Porcine dermal collagen injections, for incontinence, 2179
Ports, for laparoscopic surgery, removal of, in exiting abdomen, 228-229
Positioning, patient
  for laparoscopic radical prostatectomy, 2832
    complications with, 2846
  for laparoscopic retroperitoneal lymph node dissection for testicular tumors, 895, 895f
  for laparoscopic/robotic surgery, 206-207
  for percutaneous nephrostomy, 1329-1330, 1330f
  for surgery, 173-174, 173t
  for ureteroscopy, 201
Positioning, patient *(Continued)*
  for urethral distraction injury repair, 984, 985f
Positron emission tomography (PET), 127-128
  in adrenal mass evaluation, 1729
  in bladder cancer staging, 2358
  of brain, in ejaculation, 770-771
  ^{18}F-fluorodeoxyglucose
    in adrenal carcinoma, 1716
    in retroperitoneal fibrosis, 1109-1110
  for PSA rise investigation, 2924
  in renal cell carcinoma staging, 1443
Post-translational modifications, of androgen receptors, 2551f, 2552
Posterior culdoplasty, 2090
Posterior tibial nerve stimulation (PTNS)
  in bladder pain syndrome/interstitial cystitis, 394
  electrical, for bladder storage disorders, 2038
  for voiding dysfunction, in children, 2036
Postinfectious glomerulonephritis, 3011
Postmicturition dribble, definition of, 1873
Postpartum period, incontinence in, prevalence of, 1888
Posture stimulation test, in primary aldosteronism diagnosis, 1702
Postvoid dribbling
  in children, 3420
  patient history of, 76
Postvoid residual (PVR) urine
  in benign prostatic hyperplasia
    effects of medical therapy on, 2620
    preoperative, 2617-2618
  definition of, 1851
  in geriatric incontinence evaluation, 2212
  in pelvic floor disorder evaluation, 1904-1905
Potassium
  renal reabsorption of
    in cortical collecting tubule, 1037-1038
    in loop of Henle, 1035, 1035f
    in proximal convoluted tubules, 1033
  in resting membrane potential, 1756-1757, 1756f
  transport of, after urinary tract obstruction, 1094
Potassium aminobenzoate (Potaba), for Peyronie's disease, 800
Potassium channel openers
  bladder actions of, 1815t, 1826-1827
  to facilitate bladder filling/storage, 1970t, 1978
  ureteral function and, 1784
Potassium channels
  in detrusor smooth muscle, 1791-1792
  in penile smooth muscle relaxation, 706
Potassium chloride test, for bladder pain syndrome/interstitial cystitis, 384
Potassium citrate
  for cystinuria, 1317
  for enteric hyperoxaluria, 1315
  for gouty diathesis, 1317
  for hyperuricosuric calcium nephrolithiasis, 1313-1315
  for hypocitraturia in chronic diarrhea, 1316
  for hypocitraturic calcium nephrolithiasis, 1315-1316
  for hypomagnesiuric calcium nephrolithiasis, 1316-1317
Potassium-magnesium citrate, for hypomagnesiuric calcium nephrolithiasis, 1317

Potassium-titanyl-phosphate (KTP) laser, for benign prostatic hyperplasia, 2671
  clinical results of, 2678
Pouch perforation, complicating orthotopic urinary diversion, 2503
Power Doppler ultrasonography, 116
Prader-Willi syndrome, 638
Prazosin, to facilitate bladder emptying, 1999
Pre-massage and post-massage two-glass test, for prostatitis, 337-338, 338b, 338f
Precipitancy, urinary, definition of, 2210
Precursor cells, frequency of, in lymphocyte activation, 504
Prednisone, premedication with, to reduce contrast media reactions, 102-103, 103t
Pregabalin, for prostatitis, 346
Pregnancy
  adrenalectomy in, 1751
  after renal transplantation, 1232, 1251-1252, 1253t
  anatomic and physiologic changes during, 315-317
  bacteriuria in, 315-318. *See also* Bacteriuria, in pregnancy.

    estrogens for, 1993-1994

Stress incontinence *(Continued)*
hypermobility in, contribution of, 2049, 2116. *See also Website*.
intrinsic sphincter deficiency in, contribution of, 2049, 2116. *See also Website*.
pathophysiology of, role of injectable agents and, 2168-2169
retropubic suspension surgery for, 2047-2068. *See also* Retropubic suspension surgery, for female incontinence.
sling procedures for, 2115-2167. *See also* Sling procedures.
therapeutic options for, 2047-2048, 2048t
treatment of, conservative, 2022
urodynamic evaluation of, evidence-based review of, 1866-1867
genuine, 1838
hammock hypothesis of, 1799-1800, 1838, 1885. *See also Website*.
inducing urgency incontinence, 1807
injection therapy for, 2168-2185. *See also* Injection therapy, for incontinence.
male
pathophysiology of, postprostatectomy, injection therapy and, 2180-2184
pharmacologic treatment of, 1993
occult, in urodynamic evaluation, 1857
paraurethral tissue collagen and, 1800
pathophysiology of, 1838
hammock hypothesis of. *See Website*.
intrinsic sphincter deficiency and urethral hypermobility in. *See Website*.
role of injectable agents and. *See Website*.
sphincteric injection therapy for. *See Website*.
support mechanisms in, continuum of, 1882, 1882f
treatment of, pharmacologic, 1990-1994, 1991t
α-adrenergic receptor agonists in, 1991-1992
β-adrenergic receptor agonists in, 1992
β-adrenergic receptor antagonists in, 1992
serotonin-norepinephrine uptake inhibitors in, 1992-1993
urodynamic, definition of, 2047
vaginal pessaries for, 2016-2017, 2016f-2017f
Stress-Related Leak, Emptying Ability, Anatomy, Protection, Inhibition, Quality of Life, Mobility and Mental Status (SEAPI-QMM) Instrument, 150
Striated muscle, urethral, 1798-1799
Striated sphincter, decreasing outlet resistance at, to facilitate bladder emptying, 2000-2001, 2200-2203
Striated sphincter dyssynergia, 1841-1842. *See also* Detrusor sphincter dyssynergia (DSD).
in multiple sclerosis, 1918
in suprasacral spinal cord injury, 1920-1922, 1921f-1922f, 1924
Strickler technique, of ureterocolonic anastomosis, 2428, 2428f, 2428t
Stricture
complicating ureterointestinal anastomoses, 2434
intestinal, complicating intestinal anastomoses, 2423
Stricture *(Continued)*
ureteral, ureteroscopic, 1406-1407
urethral, congenital, 3407
Stroke, voiding dysfunction after, 1912-1913, 1913b
Stroma, bladder wall, 1795
Stromal cells, of prostate, 2540
in benign prostatic hyperplasia, 2570
epithelial cell interactions with, 2535f, 2548
in benign prostatic hyperplasia, 2574-2575
Stromal tumors, 867-868
Strongyloides stercoralis, 491
Strongyloidiasis, 491
Strontium 89, in prostate cancer, 2871
Struvite stones, 1300-1301, 1301b, 1302t, 1303f. *See also* Infection (struvite) stones.
Studer ileal bladder technique, of orthotopic urinary diversion, 2493, 2494f
Stuttering (intermittent) priapism, 749-750. *See also* Priapism, stuttering (intermittent).
Subadventitial fibroplasia, 1048t
of renal artery, 1576, 1577f
Subcapsular approach, for simple nephrectomy, 1573-1574, 1575f
Subcostal flank approach, to renal surgery, 1564t-1565t, 1565-1567, 1566f-1567f
Subcostal nerve, 16-17, 17f
Subcutaneous emphysema, with pneumoperitoneum, 236-237
Subcutaneous fasciae, of anterior abdominal wall, 33-34, 35f
Subjective sexual arousal disorder, 826
Substance P, bladder activity and, 1820
Succinylcholine, in intravenous general anesthesia, 171
SUI. *See* Stress incontinence (SUI).
Sunitinib
for clear cell renal cell carcinoma, 1486-1487, 1486t, 1487f
for metastatic bladder cancer, 2373
Superficial pouch
female, 68, 69f
male, 63-64
Superfocusing mechanism, of stone comminution, 1393
Superior lumbar triangle, for percutaneous access, 1337, 1337f
Suplatast tosylate, for bladder pain syndrome/interstitial cystitis, 387t, 389
Supracostal flank approach, to renal surgery, 1564t-1565t, 1567-1568, 1567f-1568f
Suprapubic catheterization, 182-183, 183f
cystourethroscopy with, 195
Suprapubic cystostomy
in anterior urethral injury, 2520
in posterior urethral injury, 2517. *See also Website*.
Suprapubic prostatectomy, 2699-2701. *See also* Prostatectomy, open, suprapubic.
Supraspinal mechanisms, in pontine micturition center, 1830-1831
Supravesical diversion. *See Website*.
Supravesical urinary diversion, for prune-belly syndrome, 3318
Surgery
anesthesia for, pediatric, 3200-3207
antimicrobial prophylaxis for, 3207
asthma and, pediatric, 3202
for bladder exstrophy, 3337-3355
for bladder-sphincteric dysfunction, 3427
congenital adrenal hyperplasia and, 3204
Surgery *(Continued)*
for erectile dysfunction, 746
evaluation before, 159
growth and, 3197-3199
hair removal for, 3208
for hypospadias, 3509-3523
intrauterine growth restriction and, 3197
Jehovah's witnesses and, 3204
maturation and, 3197-3199
in office, pediatric, 3083-3084
optimization of comorbid illness before, 162
perioperative fluids with, in children, 3199-3200
preparation for, 164-169. *See also* Preoperative period.
previous, patient history of, 79-80
for prune-belly syndrome, 3318-3321
psychological preparation for, in children, 3200-3201
risk evaluation for, 159-162, 160t
cardiac, 160, 160t
surgery-specific, 160-161
clinical markers in, 160
functional capacity in, 160, 161t
hepatobiliary, 161-162
pulmonary, 161
in spina bifida patients, 3203
testing before, 159
for ureteropelvic junction obstruction, 3217-3226
for vesicoureteral reflux, 3293-3294
Surgical history, in pediatric evaluation, 3075
Surgical site infections (SSIs)
antibiotic prophylaxis for, 164-165, 164t, 166t
classification of, 175
management of, 175-176
prophylaxis for, before open renal surgery, 1560-1561, 1563t
risk of, 164-165, 164t
urinary tract infections and, 3119-3120
Surgical wound, classification of, 164t
Surrogate end points, as outcomes measures, 144-145
Surveillance
active, for prostate cancer, 2793-2794
localized, 2772-2775
outcomes of, 2796-2798, 2797f, 2797t
patient selection for, imaging in, 2795-2796, 2796f
progression of men on, prediction of, 2798-2799
with selective delayed definitive therapy
current results of, 2796-2799
watchful waiting vs., 2789-2790, 2790t
for nonseminomatous germ cell tumors, clinical stage I, 881
Suspensory ligament, of clitoris, 60f, 62
Suture(s)/suturing
in hypospadias repair, 3507-3508
laparoscopic, instrumentation for, 222-223
materials for
properties of, 175t
in retropubic suspension surgery, 2053
methods of, 174-175
SWL. *See* Shockwave lithotripsy (SWL).
Swyer syndrome, 3611-3612
Sympathetic chain, of retroperitoneum, 14-16, 15f
Sympathetic dystrophy, reflex, voiding dysfunction in, 1937

Sympathetic nervous system
in ejaculation, 770
in lower urinary tract control, 1800-1801
in ureteral function, 1769
Sympathetic skin response, in erectile dysfunction, 736
Sympathomimetic drugs, intracavernous injections of, for priapism, 758-759
Syndrome of complete androgen insensitivity, 3621-3622
Syndrome of inappropriate antidiuretic hormone secretion (SIADH), 1039-1040, 1039t
Syndrome of partial androgen resistance, 3622-3623
Synthetic grafts, in pelvic organ prolapse surgery, 2078-2080
Syphilis, 406-408, 406f-407f
in HIV patients, 427
Syringomyelia, voiding dysfunction in, 1936
Systemic inflammatory response syndrome (SIRS), 313
bacteriology of, 314
clinical presentation of, 314
Systemic lupus erythematosus (SLE)
bladder pain syndrome/interstitial cystitis and, 366, 366f
chronic kidney disease in, 1212
voiding dysfunction in, 1936-1937
Systemic sclerosis, voiding dysfunction in, 1942

T

T cell(s)
activation of, regulation of, 504-505
in adaptive immunity, 500-501
naive, trafficking of, 501
CD4+. *See* CD4+ T cells.
CD8+. *See* CD8+ T cells.
clonal anergy of, 515
clonal expansion of, 509-510
cytolysis of target cells mediated by, 511-512, 511f
endothelial cell interactions with, 517, 517f
maturation of, to effector function, 509-512
memory, 512
peripheral deletion of, 515
phenotypes of, cytokine-producing, 510-511
regulatory, 515-516
in tumor immunology, 521-522
in tumor immunology, 519
tumor-reactive, in immunotherapy, 523
T-cell lymphoma, cutaneous, of genitalia, 462, 464f
T-cell receptors (TCRs), 502, 502f
activation mediated by, phenotypic changes during, 512
signaling events transmitted by, in cell signal transduction, 506-507, 507f
T pouch ileal neobladder technique, of orthotopic urinary diversion, 2494-2495, 2496f-2497f
Tabes dorsalis, voiding dysfunction in, 1930
Tachykinin receptors, 1820, 1820t
Tachykinins, 1820
Tacrolimus, toxicity of, acute kidney graft rejection differentiated from, 1247-1248, 1248t
Tadalafil
for erectile dysfunction, 741-742, 741t
to facilitate bladder filling/storage, 1970t, 1983
priapism risk and, 752-753
for stuttering priapism, 762
Taghaandan, penile fracture from, 2507
Takayasu arteritis, renal artery stenosis in, 1075
Takayasu disease, renovascular surgery for, 1578, 1579f
Tamm-Horsfall mucoprotein, secretion of, in loop of Henle, 1036
Tamm-Horsfall protein, as stone formation inhibitor, 1265
Tamoxifen
for Peyronie's disease, 800-801
for retroperitoneal fibrosis, 1111
Tamsulosin
for benign prostatic hyperplasia, 2628-2629, 2629t
to facilitate bladder emptying, 1999
in geriatric incontinence management, 2219
for prostatitis, 344-345
Tanner classification, 3537-3539
Target cells, cytolysis of, T cell-mediated, 511-512, 511f
Targeted embolization, before radiofrequency ablation, 1682
Targeted molecular agents. *See also specific agent, e.g.* Bevacizumab.
for metastatic renal cell carcinoma, 1468, 1469t, 1483-1490
mammalian target of rapamycin inhibitors as, 1488-1489
molecular basis for, 1482, 1483f
vascular endothelial growth factor antagonists as, 1482t-1484t, 1483-1488, 1484f-1487f, 1486t
combination and sequential therapy with, 1489-1490
TB. *See* Tuberculosis (TB).
TCRs. *See* T-cell receptors (TCRs).
TDS. *See* Testicular deficiency syndrome (TDS).
Tea, green, in prostate cancer chemoprevention, 2724
Technical process, in quality of health care, 144
Teflon paste, in vesicoureteral reflux correction, 3305-3306
Telomerase, 558-562
activity of
allowing unlimited replication, 560-561
as diagnostic marker, 561
restabilizing chromosomes, 560-561
in cancer, therapeutic targeting of, 562
in prostate cancer, 2718
in renal cell carcinoma, 1429
Telomeres, 558-562
chromosomal instabillity and, 558
length of, in prostate cancer, prognostic value of, 561-562
shortening of
in cancers and premalignant lesions, 559-560
as tumor suppressive mechanism, 558-559, 559f
TEMPE, for premature ejaculation, 778
Temperature, patient, perioperative, 172
Temsirolimus, for clear cell renal cell carcinoma, 1488-1489, 1489f
Tension-free vaginal tape procedure, 2136-2156. *See also* Vaginal tape procedure, tension-free.
Teratoma(s)
immature, 3728
mature, 3727-3728
sacral coccygeal, voiding dysfunction in, 1943-1944
testicular
histopathologic characteristics of, 841f, 842
resection of, 884-885
Teratospermia, evaluation and treatment of, 635
Terazosin
for benign prostatic hyperplasia, 2624-2625, 2624f, 2624t-2625t, 2626f-2627f
to facilitate bladder emptying, 1999
for prostatitis, 344-345
Terfenadine (Seldane), for Peyronie's disease, 800
Testicular adnexa tumors, 869-870, 869b
adenomatoid, 869
cystadenoma, 869
mesothelioma, 869
sarcoma, 869-870
Testicular artery, 8, 13t, 45f, 48f, 67-68
inferior, 68
injury to, complicating varicocelectomy, 685
Testicular cancer
demographics of, 873b
family/personal history of, germ cell tumors associated with, 837-838
gene rearrangements in, recurrent, 549-550
genetic alterations in, 557-558
germ cell tumors as, 837-867. *See also* Germ cell tumors (GCTs), testicular.
gonadoblastoma as, 868
granulosa cell tumor as, 868
in HIV/AIDS patients, 431
leukemic infiltration in, 868-869
metastases of, 869
staging of, TNM, 845t-846t
Testicular deficiency syndrome (TDS), 810, 810b. *See also* Androgen deficiency in aging male (ADAM).
clinical diagnosis of, 812-813
definition of, recommendations on, 820
screening questionnaires for, 813, 813t, 814f
treatment of, 817-820
testosterone in. *See also* Testosterone, for androgen deficiency in aging male.
Testicular germ cell tumors, 557-558, 3573-3574
Testicular hypertrophy, varicocele and, 3576-3578
Testicular injury, 2510-2512
diagnosis of, 2510-2511, 2511f
etiology of, 2510-2512
management of, 2511-2512, 2511f
outcome and complications of, 2512
Testicular regression, embryonic, 3613
Testicular tumor(s), 837-870
in children, 3725-3729
carcinoma in situ in, 3726
diagnosis of, 3726-3727
etiology of, 3725
genetics of, 3725
pathology of, 3725-3726
staging of, 3726-3727
classification of, WHO, 838t

Testicular tumor(s) *(Continued)*
germ cell. *See* Germ cell ltumors (GCTs), testicular.
laparoscopic retroperitoneal lymphadenectomy for, 893-900
Leydig cell, 867-868
malignant. *See* Testicular cancer.
non–germ cell, 867-869, 869b
primary, management of, 871-873
secondary, 868-869
Sertoli cell, 868
sex cord/stromal, 867-868
staging evaluation of, 873
surgery of, 871-892. *See also specific procedure, e.g.* Orchiectomy.
Testicular vein, thrombophlebitis of, ureteral obstruction from, 1118
Testis(es), 66, 67f
anatomy of, 67-68, 67f-68f
androgen production by, prostate growth and, 2541-2543, 2542f, 2542t
arterial supply to, 595-596, 595f, 604-605
aspiration of, percutaneous, 651
bell-clapper deformity of, 66
biopsy of, 650-652. *See also* Biopsy(ies), testicular.
blood supply to, 649, 649t, 1002t
cancer of. *See* Testicular cancer.
contralateral, biopsy of, 844
cytoarchitecture of, 596-601
descent of, 3557-3560
development of, 2976f-2977f, 3557-3558
embryology of, 3557-3560
end-stage, biopsy in, 633
examination of, 82-83
failure of, 634-635, 637-638
gross architecture of, 594-596, 595f
inflammation of, 353-354, 353t
injury to, 2510-2512. *See also* Testicular injury.
lymphoma of, 868
maldevelopment of, 3565-3566
in male reproductive physiology, 593
neoplasms of, 837-870. *See also* Testicular tumor(s).
nonpalpable, 3564-3565
pain in, patient history of, 74-75
palpable, 3564
in prune-belly syndrome, 3312-3313
regenerative medicine for, 584, 584f
retractile, 3560-3562
retractile, in adults, 686
surgery for germ cell tumor sparing, 844
transposition of, in vasovasostomy, 664, 665f
trauma to, in children, 3752-3753
tuberculosis of
pathologic features of, 470
surgery for, 479
tumors of, 837-870. *See also* Testicular tumor(s).
vanishing, 3560-3561, 3613
Testosterone
for androgen deficiency in aging male, 817-820
adverse effects of, 819-820
monitoring and, recommendations on, 822
age and, recommendations on, 822
body composition/strength effects of, 818
recommendations on, 821
bone mineral density effects of, 818
recommendations on, 821
Testosterone *(Continued)*
buccal and nasal delivery of, 817t, 818

  positron emission, 127-128. *See also* Positron emission tomography (PET).
Topical pharmacotherapy
  for erectile dysfunction, 745
  for Peyronie's disease, 801
Topiramate, in stone formation, 1283-1284, 1320
Total parenteral nutrition (TPN), perioperative, 163-164
Toxins, to facilitate bladder filling/storage, 1970t, 1986-1988
TP27, in prostate cancer, 2718
TP53, in apoptosis, 565
TP16 methylation, in bladder cancer, 542
TP53 protein, in urothelial tumors, 1522
Traction devices, penile, for Peyronie's disease, 802
Training programs, for laparoscopic/robotic surgery, 252
Tramadol
  for detrusor overactivity, 1990
  for premature ejaculation, 777, 777t
Transabdominal ultrasonography
  in male infertility evaluation, 629
  of pelvis, 120-122, 121f
  of prostate, 109-110, 122f
Transcatheter angiographic occlusion, for renal arteriovenous fistula, 1081
Transcolonic Goodwin technique, of ureterocolonic anastomosis, 2427-2428, 2428f
Transcorporeal artificial urinary sphincter, 2299, 2300f
Transcostal flank approach, to renal surgery, 1564t-1565t, 1568
Transcriptional activation domains, of androgen receptors, 2553-2554, 2553f, 2554t
Transcutaneous electrical nerve stimulation (TENS). *See also* Electrical stimulation.
  for bladder pain syndrome/interstitial cystitis, 394
  for bladder storage disorders, 2038-2039
  for voiding dysfunction, in children, 2036
Transdermal pharmacotherapy, for erectile dysfunction, 745
Transection, ureteral, surgical
  delayed recognition of, management of, 1186-1188
  immediate recognition of, management of, 1186
Transferrin, in prostatic secretions, 2567
Transforming growth factor-β (TGF-β)
  accumulation of, in Peyronie's disease, 794
  in immunotherapy, 523
Transforming growth factor (TGF), in benign prostatic hyperplasia, 2575-2576
Transfusions, in pediatric surgery, 3209
Transglomerular pressure, in glomerular filtration rate, 1025
Transglutaminases, in prostatic secretions, 2562-2563
Transient incontinence, causes of, 1897t
Transient receptor potential (TRP) channels
  in bladder inflammation, detrusor overactivity and. *See Website*.

general considerations on, 2450-2452
Mainz pouch I for, 2463f. *See also* Mainz pouch I, for continent urinary diversion.
operative technique variations in, 2473-2477
absorbable stapling techniques as, 2474
conduit conversion to continent reservoir as, 2473-2474
minimally invasive continent cutaneous diversion as, 2473
right colon pouch as, 2474-2477, 2475f
stapled sigmoid reservoir as, 2474-2475, 2476f
W-stapled reservoir as, 2475-2477, 2477f
patient preparation for, 2450-2451
patient selection for, 2450
postoperative care in, 2477
quality of life assessments in, 2473
rectal bladder for, 2453-2456. *See also* Rectal bladder, for continent urinary diversion.
ileal conduit, in laparoscopic radical cystoprostatectomy, 2408
incontinence after, injection therapy for, 2185
intestinal anastomoses in, 2414-2426. *See also* Intestinal anastomoses, in urinary diversion.
intestinal segments used in, 2411-2449
abdominal stoma and, 2423-2425
complications of, 2422t, 2425-2426
end, 2423
flush, 2423, 2425
loop end ileostomy as, 2423, 2425, 2425f
nipple "rosebud", 2424, 2424f
colon as, surgical anatomy of. *See Website*.
elongation of, complicating intestinal anastomoses, 2423, 2424f
motor activity in, 2448
neuromechanical aspects of, 2447-2448
preparation of, 2411-2414
antibiotic, 2413-2414, 2413t
diarrhea and pseudomembranous enterocolitis after, 2414
mechanical, 2412-2413, 2412t
selection of. *See Website*.
small bowel as, surgical anatomy of. *See Website*.
Urinary diversion *(Continued)*
stomach as, surgical anatomy of. *See Website*.
volume-pressure considerations in, 2447-2448, 2448f
in laparoscopic radical cystoprostatectomy
continent cutaneous, 2409
ileal conduit, 2408
orthotopic, 2409, 2409f
for lower urinary tract dysfunction, 1946
orthotopic, 2479-2506
adaptation of, to minimally invasive techniques, 2498-2499
antireflux mechanisms in, 2489-2490, 2501t
basic principles of, 2481, 2481b
bladder substitution in, 2489-2499
bowel segment selection for, 2489, 2491b
reflux prevention in, 2489-2490
complications of, 2501t, 2502-2503
continence mechanism in, 2486-2487
continence preservation for, during radical cystectomy, 2487-2489
evolution of, 2479-2481, 2480b, 2481f
follow-up for, 2502t, 2503, 2504b
general perioperative management of, 2490-2491
in laparoscopic radical cystoprostatectomy, 2409, 2409f
patient selection for, 2481-2486
cancer-related factors in, 2481-2484, 2484b
patient-related factors in, 2484-2486
quality of life after, 2504-2505, 2505b
results of, 2499-2505, 2501t, 2502b
continence in, 2499-2500, 2501t, 2502b
urinary retention in, 2500-2502, 2502b
surgical techniques of, 2491-2495
Camey II in, 2491, 2492f
ileal neobladder (Hautmann pouch) in, 2491-2492, 2492f
ileal reservoirs in, 2491
ileocolonic (Le Bag) pouch in, 2495-2497, 2499f
orthotopic Kock ileal reservoir ("hemi-Kock") in, 2492-2493, 2493f
orthotopic Mainz pouch (Mainz III) in, 2495, 2498f
right colon pouch in, 2497
serous-lined extramural tunnel in, 2494, 2495f
sigmoid pouch in, 2497-2498, 2500f
Studer ileal bladder in, 2493, 2494f
T pouch ileal neobladder in, 2494-2495, 2496f-2497f
postoperative, with hypospadias, 3508
renal deterioration after, 2435
renal function necessary for, 2435
suprapubic, in genital skin loss management, 2512
ureterointestinal anastomoses in, 2426-2435. *See also* Ureterointestinal anastomoses, in urinary diversion.
in vesicovaginal fistula management, 2242
Urinary fistula, 3408-3410. *See also* Fistula(e).
Urinary free cortisol evaluation
in adrenal mass assessment, 1732-1733
in Cushing syndrome diagnosis, 1694-1695
Urinary frequency, patient history of, 75
Urinary hesitancy, patient history of, 79-80
Urinary incontinence. *See* Incontinence.

Urinary intermittency, patient history of, 76
Urinary leukocyte esterase, in pediatric urinary tract infections, 3097
Urinary lithiasis, 1257-1323. *See also* Renal calculi; Ureteral calculi; Urinary calculi.
Urinary refunctionalization, 3500-3501
Urinary retention
  acute, in benign prostatic hyperplasia, 2603
    analytical epidemiology of, 2604-2605, 2605f-2607f, 2605t
    descriptive epidemiology of, 2603-2604, 2604t
    medical therapy for, 2652-2653, 2653f
    preventive, 2653
  after orthotopic urinary diversion, 2500-2502, 2502b
  complicating artificial urinary sphincter, 2302
  in Fowler syndrome, voiding dysfunction in, 1939-1940
  from herpesvirus infection, 1932-1933
  postoperative, voiding dysfunction in, 1940-1941
  sacral nerve neuromodulation in, mechanism of action of, 2029, 2029f
Urinary sensation sale, 1951
Urinary sphincter, artificial. *See* Artificial urinary sphincter (AUS).
Urinary toxicity, in radiation therapy for prostate cancer, 2868
Urinary tract
  anomalies in
    of ascent, 3135-3140
    of form and fusion, 3140-3149
    of number, 3123-3135
    of rotation, 3149-3150
  biomaterials used in, biofilm formation on, 190
  drainage of, 177-183. *See also* Drainage.
  evaluation of, for renal transplantation, 1231
  fistulae of, 2223-2261. *See also* Fistula(e).
  functional, 3458-3460
  imaging of
    computed tomography in, 128-132, 129f, 131f-135f
    intravenous urography in, 105, 106f
    loopography in, 108-109, 109f
    magnetic resonance imaging in, 132-138, 136f-138f, 137t
    nuclear scintigraphy in, 125-128, 126f-127f
    radiographic, 99. *See also* Radiography.
      plain abdominal, 105-107, 106f-107f
    retrograde pyelography in, 107-108, 108f
    retrograde urethrography in, 109, 110f
    static cystography in, 109-110, 110f
    ultrasonography in, 111-125. *See also* Ultrasonography.
    voiding cystourethrogram in, 110-111, 111f
  injury to, laparoscopic, 240, 245-246
  lower. *See* Lower urinary tract.
  natural defenses of, 267-268
  obstruction of. *See* Urinary tract obstruction.
  reconstruction of, in renal transplantation, 1242, 1243f-1244f
  schistosomiasis of, 480-486. *See also* Schistosomiasis.
  upper. *See* Upper urinary tract.
Urinary tract infections (UTIs), 257-326
  antimicrobials for
    adverse reactions, precautions, and contraindications for, 278t-279t
    aminoglycosides as, 277-279
    aminopenicillins as, 277
    aztreonam as, 279
