Urinary continence usually relies on the integrity of the urethral sphincteric mechanism in females (analogous to the distal sphincter in men). Like the male distal mechanism, it is composed of a longitudinal intrinsic urethral smooth muscle and a larger extrinsic striated muscle component. This sphincter extends throughout the proximal two thirds of the urethra, being most developed in the middle one third of the urethra. **Therefore in women the majority of the urethra should be considered to be sphincter active.** Damage to the innervation of the urethral sphincter (in particular the pudendal nerve) by obstetric trauma reduces the effectiveness of this mechanism and predisposes to stress UI (Table 63–3).

The principles underlying normal sphincteric function are integrated interactions among a number of factors:

1. **Watertight apposition of the urethral lumen.** Four urethral wall factors promote continence: (1) wall tension or external compression, (2) inner wall softness, (3) a filler material beneath the mucosa that helps to deform the mucosal folds into apposition, and (4) a lining of mucus provides the stickiness that enables cooptation of these mucosal folds (Zinner et al, 1980). Histologic cross sections of the urethra show that the urethra is not simply a closed tube; rather, there are numerous mucosal folds, between which are potential spaces for urine leakage. In women, estrogen and a cushion effect of the submucosal vasculature have been suggested as ancillary factors (Raz et al, 1972; Tulloch, 1974).
2. **Compression of the wall around the lumen.** External compression of the urethral lumen is achieved by (1) smooth and striated muscle tone, (2) phasic contractions of the smooth and striated musculature, (3) elastic and viscoelastic properties of the extracellular matrix, (4) mechanical factors related to transmission of abdominal pressure, and (5) structural (anatomic) support of the posterior urethral wall.
3. **Structural support to keep the proximal urethra from moving during increases in pressure**
4. **A means of compensating for abdominal pressure changes (pressure transmission)**
5. **Neural control**

Conditions Causing Sphincter Abnormalities

The causes of sphincteric dysfunction are different in men and women.

In men, sphincter abnormalities are most commonly caused by anatomic disruption after prostate surgery or, less commonly, by trauma or neurologic abnormalities.

In women with stress incontinence it is likely that there is a degree of sphincter weakness in all cases. The sphincter abnormality will lie on a spectrum from a mild degree where the predominant pathophysiologic abnormality is urethral hypermobility (urethral support defect), to those where irrespective of the urethral support defect there is severe intrinsic sphincteric insufficiency (ISD). Urethral hypermobility and support defects in women are most commonly associated with pregnancy and vaginal delivery, pelvic surgery, and chronic abdominal straining (e.g., chronic constipation). In some cases, loss of support many be secondary to neurologic injury. In such cases, nerve injury (e.g., pudendal nerve) can lead to muscle atrophy and subsequent failure of the support mechanism.

Sphincter Abnormalities in Women

Labor and delivery have long been thought to be risk factors for stress incontinence, urogenital prolapse, and anal incontinence. Vaginal delivery may be associated with direct injury to the pelvic soft tissues, as well as partial denervation of the pelvic floor and thus may play a role in the etiology of stress urinary incontinence (SUI).

There are four major mechanisms by which vaginal delivery might lead to sphincteric damage and incontinence:

1. **Injury to connective tissue support by the mechanical process of vaginal delivery**
2. **Vascular damage to the pelvic structures as a result of compression by the fetus**
3. **Damage to the pelvic nerves or muscles or both as a result of trauma during parturition**
4. **Direct injury to the urinary tract during labor and delivery**

Vaginal delivery can cause partial denervation with consequent reinnervation in most first deliveries (Allen et al, 1990). A growing body of evidence indicates that **multiparity; forceps delivery; increased duration of the second stage of labor, partially related to epidural anesthesia; third-degree perineal tear; and high birth weight (>4000 g) are important factors leading to pudendal nerve injury**

(Snooks et al, 1986; Handa et al, 1996; Brown and Lumley, 1998; Rortveit et al, 2003). Snooks and colleagues (1984) studied the postpartum innervation of the external anal sphincter and found that the external anal sphincter and its innervation might be damaged by vaginal delivery but not by cesarean section. The abnormalities found were most marked in multiparas and correlated most strongly with a prolonged second stage of labor and forceps delivery.

Several conditions are associated with increased risk for ISD in women:

1. **Previous urethral or periurethral surgery** (e.g., anti-incontinence surgery, urethral diverticulectomy) may result in postoperative ISD from periurethral fibrosis, scarring, or denervation (Haab et al, 1996). Prevalence of ISD after two or more failed anti-incontinence operations was found to be as high as 75% (McGuire et al, 1980).
2. **Neurologic insult** may cause ISD. Sacral neurologic lesions have a variable effect on micturition, depending on the extent to which the neurologic injury affects the parasympathetic, sympathetic, and somatic systems (Gerstenberg et al, 1980; Blaivas and Barbalias, 1983; Wheeler et al, 1986; McGuire et al, 1988). In complete parasympathetic lesions, the bladder is areflexic and the patient is in urinary retention. When, in addition to a parasympathetic lesion, there is a sympathetic lesion, the proximal urethra loses its sphincteric function. Clinically, this results in incomplete bladder emptying, caused by the acontractile detrusor, and sphincteric incontinence, caused by the nonfunctioning proximal urethra (Gerstenberg et al, 1980; Blaivas and Barbalias, 1983). Somatic neurologic lesions affect pudendal afferent and efferent nerves (Blaivas, 1982). In addition to loss of perineal and perianal sensation, these lesions abolish the bulbocavernosus reflex and impair the ability to contract the urethral and anal sphincters voluntarily. Sacral neurologic lesions are caused by herniated disks, diabetic neuropathy, multiple sclerosis, and spinal cord tumors. They are also commonly encountered after extensive pelvic surgery such as abdominoperineal resection of the rectum and radical hysterectomy (Gerstenberg et al, 1980; Blaivas and Barbalias, 1983; Chang and Fan, 1983; McGuire et al, 1988).
3. **Pelvic radiation therapy** has been associated with damage to the mucosal seal coaptation of the urethra and local neurologic damage (Haab et al, 1996).

Sphincter Abnormalities in Men

Sphincter abnormalities in men are **caused by trauma or neurologic injury.** With **prostatectomy,** whether for benign disease or with radical prostatectomy, the distal urethral sphincter (particularly the rhabdosphincter) can be damaged by direct injury or injury to the nerve supply or supporting structures (Nitti, 2002). In some cases, there may be preexisting damage to the sphincter that cannot be accurately diagnosed preoperatively (Nitti, 2002). As in women (as noted earlier), **radiation** and **neurologic lesions** can cause sphincteric dysfunction. Finally, **pelvic trauma** or instrumentation that results in trauma to the distal urethral sphincter can result in incontinence, particularly when the PUS is absent or deficient.

Postprostatectomy incontinence, like any urinary incontinence, may be caused by bladder dysfunction, sphincter dysfunction, or a combination of both and may be associated with other lower urinary tract symptoms. Urodynamic investigations are helpful to rule out bladder outlet obstruction or significant bladder dysfunction. **Urodynamic studies have demonstrated that the sphincter incompetence occurs as the sole cause in more than two thirds of patients.** Isolated bladder dysfunction (detrusor overactivity, poor compliance, detrusor underactivity during voiding) is uncommon, occurring in less than 10% (Ficazzola and Nitti, 1998; Groutz et al, 2000). However, **sphincter and bladder dysfunction can coexist in at least one third of incontinent patients.**

Bladder dysfunction may occur de novo after prostatectomy, perhaps induced by bladder denervation; may be caused by outlet obstruction; or may be related to preexisting factors such as age. Impaired detrusor contractility and poor compliance resolved in the majority of patients within 8 months (Giannantoni et al, 2004). Decreased sphincter resistance may be due to tissue scarring in some cases and is reflected by a low urethral compliance; however, this parameter is difficult to measure (Groutz et al, 2000). Scarring may lead to an anastomotic stricture and is clinically suspected when both incontinence and decreased force of stream coexist. The preoperative length of the membranous urethra determined on magnetic resonance imaging (MRI) has been shown to be significantly related to time to postoperative continence. When urethral length was greater than 12 mm, 89% of the patients were continent at 1 year, versus 77% with 12 mm or less than this length (Coakley et al, 2002). Urodynamic studies revealed that a reduced functional urethral length was a predictive parameter of incontinence (Hammerer and Huland, 1997; Van Kampen et al, 1998; Wei et al, 2000). Different components of the urethra may also be involved. The urethral intrinsic component responsible for passive continence, as well as the extrinsic component responsible for active continence, may be involved as has been demonstrated in a study using urodynamic evaluation and alpha blockade (Pfister et al, 2002). This may explain passive incontinence despite a high voluntary urethral pressure or that measured during an active squeeze by the patient. Postoperative disruption of the innervation of the posterior urethra may also be involved and can affect both motor and sensory function (John et al, 2000; Bader et al, 2001).

Risk factors for incontinence after transurethral resection of the prostate (TURP) have not been clearly defined, probably because the incidence is so low. However, previous brachytherapy does predispose to post-TURP incontinence, as does significant bladder overactivity and preoperative urinary incontinence. Preoperative lower urinary tract symptoms including urgency incontinence and "overflow incontinence" may improve with de-obstruction secondary to extirpative surgery. **Whenever a functional abnormality of the bladder or sphincter abnormalities is suspected, preoperative urodynamic assessment is advised before TURP.**

UI occurring after radical prostatectomy (RP) is a significant problem. Although its rate has lessened in recent years primarily due to a better understanding of pathophysiology and improvements in surgical technique, its prevalence has increased due to the dramatic increase of laparoscopic and robotic-assisted laparoscopic radical prostatectomy as standard treatments for men with prostate cancer in developed countries (Hu et al, 2003, 2004) within the past decade. Based on the body of available data on postoperative continence, it would appear that **incontinence rates are similar between open and laparoscopic/robotic approaches.** Several studies have compared the techniques either prospectively in nonrandomized fashion (Anastasiadis et al, 2003; Jacobsen et al, 2007) retrospectively (Ahlering et al, 2004) or via limited meta-analysis (Rassweiler et al, 2003; Salomon et al, 2004),

and similar continence rates were found. Further prospective comparative studies with open surgery are necessary. Perineal prostatectomy is done by only a limited number of urologists but is still advocated for obese patients. The continence rate was reported as similar to the retropubic route (Weldon et al, 1997; Gray et al, 1999; Harris, 2003).

Data from large multicenter studies and prostate cancer databases suggest that **following RP, 1% to 40% of patients complain of persistent urinary incontinence. The incidence of postprostatectomy incontinence (PPI) depends on the definition of UI and the length of follow-up** (Olsson et al, 2001; Krupski et al, 2003; Rodriguez et al, 2006). Recent reports of large cohorts use definitions that include "total control/perfect continence," "occasional leakage but no pad," and "less than one pad." Because one third to one half of men who do not wear pads will have occasional leakage of urine, it is important to distinguish among those men who leak enough to require pad use and those who do not. It has been demonstrated that health-related quality of life is strongly correlated with the level of incontinence, and wearing a pad more significantly affects the quality of life than wearing no pad (Litwin et al, 2000). In addition, not all men who leak will elect to have further treatment. Most **large cohort studies indicate that between 6% and 9% of patients undergo subsequent surgical treatment for PPI following prostate cancer surgery** (Stanford et al, 2000; Begg et al, 2002; Steineck et al, 2002; Penson et al, 2005).

Reported risk factors for incontinence following radical prostatectomy include the following:

- Patient age at surgery
- Stage of disease
- Surgical technique including nerve sparing
- Preoperative bladder function and urinary continence status
- Prior radiation therapy
- Preoperative length of the membranous urethra
- Prior TURP
- Vascular comorbidities

Preoperative sphincteric insufficiency (demonstrated by either the preexisting clinical sign of SUI or the urodynamic finding of lower maximal urethral closure pressure) predicts postoperative SUI (Wei et al, 2000; Majoros et al, 2006). Preoperative bladder dysfunction can also contribute to postoperative incontinence. Preexisting abnormalities of detrusor function may predispose to leakage following surgery, especially neurogenic detrusor overactivity due to Parkinson disease, dementia, or spinal cord injury (Khan et al, 1991).

Advancing age as a risk factor is supported by several studies (Leandri et al 1992; Zincke at al, 1994; Eastham et al, 1996; Catalona et al, 1999; Horie et al, 1999; Moore et al, 2007). Others have found advancing age and the number of comorbidities to have a negative impact on the recovering time for continence during the first year after radical prostatectomy (Young et al, 2003). Rogers and colleagues demonstrated that age affected postoperative continence status following laparoscopic RRP. In those younger than 50 years old, 100% achieved 0 to 1 pad per day continence at 1 year, which decreased to 91% and 81% for those 50 to 59 years old and older than 60 years, respectively ($P < 0.01$) (Rogers et al, 2006). Strasser and colleagues (1998) hypothesized that age-related sphincteric changes may be responsible for the age-related increase in postoperative SUI and successfully demonstrated a progressive reduction in sphincter striated muscle cells with age.

Most large series have found no correlation between the stage of disease and incontinence rates (Eastham et al, 1996; Jonler et al, 1996; Lowe, 1996; Catalona et al, 1999; Pierorazio et al, 2007). However, in certain cases, the stage of disease may affect the surgical technique (i.e., nerve sparing) and incontinence rates may be higher, but this appears to be a reflection on surgical technique and not disease stage (Zincke et al, 1994).

Regarding surgical technique, the many parameters involved in continence have resulted in difficulties in understanding the benefit of certain technical points.

Bladder neck preservation has been reported to improve continence at 3 months (Lowe, 1996), but no difference was evident at 6 and 12 months (Poon et al, 2000; Srougi et al, 2001).

The role of nerve sparing on subsequent continence is debated. Nerve sparing has no significant impact according to Steiner and colleagues (1991), and Lepor and colleagues (2004) recently confirmed this. Others did find benefit (Wei et al, 2000). In particular, Nandipati and colleagues reported that in a cohort of 152 patients followed prospectively, bilateral nerve-sparing surgery was associated with a shorter time to regain continence, as well as improved long-term continence rates compared with non–nerve-sparing surgery. They additionally found that increased age was a risk factor for postprostatectomy incontinence (Nandipati et al, 2007). Burkhard and colleagues similarly demonstrated a positive effect of nerve-sparing surgery on postoperative continence. In a prospective cohort study of 536 patients, PPI developed in 1 of 75 (1.3%), 11 of 322 (3.4%), and 19 of 139 (13.7%) with attempted bilateral, attempted unilateral, and without attempted nerve sparing, respectively. Attempted nerve sparing was, in fact, the only statistically significant factor influencing urinary continence after RRP in this cohort (Burkhard et al, 2006).

PELVIC FLOOR SUPPORT MECHANISMS

Two major factors govern the predisposition of the human female to develop either stress UI or prolapse, or both.

1. After the evolutionary changes in pelvic floor anatomy resulting from the change from a four-limb to an upright two-limb posture; the pelvic floor has had to adapt from its mainly muscular utility (of moving the tail) in four-legged animals to a supportive function in the human. This has generated a decrease in reliance on muscle mass and an increase in the importance of connective tissue support mechanisms.
2. The human reproductive process consists of a relatively large fetus with a large bony cranium that must pass through the pelvic floor during labor and delivery.

Certainly, repeated episodes of vaginal traction can stretch, tear, or weaken urethral muscles and contribute to a chronically weakened urethra characterized by low VLPP or low urethral closure pressures. This is suggested to be typical of intrinsic sphincter deficiency (ISD). Clearly, however, there is no adequate categorization of ISD because most of the measures have limited sensitivity by virtue of their nature and inability to separate out the different components of urethral function. Electrophysiologic studies, MRI, and sonography can be used to quantify the morphologic and functional decline in striated sphincter tone, but analysis of the etiologic factors is difficult because the pathophysiology develops over many years. Successful operations can restore urethral position but probably do not reverse damage to urethral sphincter function, and there are still many question marks about whether this is ever possible.

The complex etiology of stress UI and pelvic organ prolapse and the long time period over which these complications and problems develop strongly supports the need for prospective studies taking account of both nature and nurture. This may allow the investigation of early timely interventions to prevent the further deterioration of their support tissues and urethral closure mechanisms.

From Dichotomy to Continuum between Hypermobility and Intrinsic Sphincter Deficiency

An integrated approach involving anatomy and physiology is essential to an improved understanding of pathophysiology. Clearly a continent bladder outlet in the females depends on multiple factors (resting tone, active contraction, external compression, pressure transmission, integrity of configuration), and the focal point appears to be the midpoint of the urethra. **In patients with stress incontinence there is clearly a spectrum between the two components of ISD and urethral hypermobility.** Clearly, some patients have primary sphincteric problems, whereas others have an adequately functioning sphincter but significant hypermobility. The majority lie somewhere between these two extremes.

In recent years there has been a gradual change from this dichotomic classification of stress incontinence: hypermobility or ISD. ISD alone is rare, and urethral hypermobility may occur commonly without significant ISD, but usually there is a combination of both in individual patients.

Figure 63–3 demonstrates the potential balance between the relative proportions of ISD and pelvic floor muscle weakness hypermobility seen in any individual patient.

This evolution in our understanding in part followed the development of the concept of Valsalva leak point pressure (VLPP) introduced by McGuire in 1995 and also from analysis of long-term results of incontinence surgery. Despite lacking standardization of recording methods, as well as lacking consensus on how to deal with any associated prolapse, low VLPP (inferior to 60 cm H_2O has been suggested) has been widely considered as an indicator of ISD. Reports in the literature vary considerably regarding the extent of correlation between VLPP and outcome. Similarly, urethral pressure profilometry has been extensively studied in this context but there is a similar lack of correlation both in terms of predictive value and outcome. For instance, a low-pressure urethra may not leak, whereas the high-pressure urethra may. Also, a number of studies have failed to show any correlation between postoperative UPP and outcome. Cystography, although an invasive technique requiring radiologic input, provides a reproducible and easily interpreted technique, which allows the relative contribution of both sphincteric weakness and hypermobility to be assessed (Blaivas and Olsson, 1988).

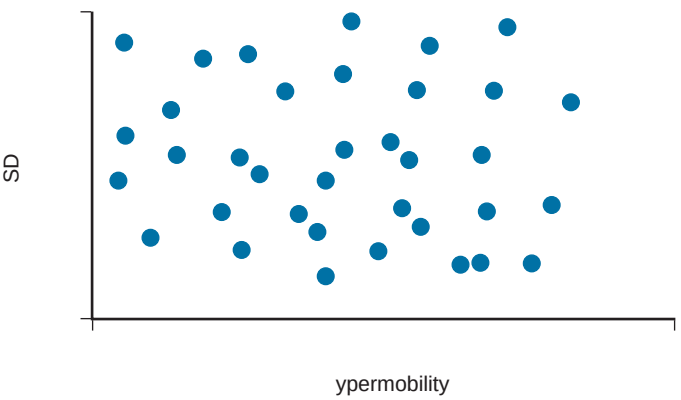

Figure 63–3. The potential balance between the relative proportions of intrinsic sphincter deficiency (ISD) and pelvic floor muscle weakness hypermobility seen in any individual patient.

Consequently, some degree of ISD may exist in many patients where hypermobility is believed to be the only cause of stress incontinence (Kayigil et al, 1999). This understanding supports the increasing use of suburethral slings to treat stress incontinence, whereas formerly this procedure was exclusively suggested for patients with recurrent stress incontinence or severe ISD (Chaikin et al, 1998). Clearly, vaginal support is an important factor in maintaining urinary continence, but in addition one needs to consider the importance of ISD, a discussion hampered by the lack of adequate techniques to evaluate ISD at present.

Urethral Support Mechanisms

The urethral support mechanism comprises all the structures extrinsic to the urethra that offer a supportive backplate on which the proximal urethra and midurethra lie.

The anatomic support is derived from the following:

1. **Fascial structures**

In recent years the important potential role of connective tissue in the overall physiologic function of the lower urinary tract and pelvic floor has been progressively recognized. The age-related weakening of connective tissues can influence both tissue and organ function, and it is likely that the increasing attention on connective tissue changes will provide a better understanding of pathophysiology, which hopefully will be useful in leading to the more effective management of stress UI and vaginal prolapse.

2. **Musculature**

Urethral hypermobility (increased mobility) is thought to be due to loss of the normal extrinsic support of the urethra by a weakness of both endopelvic fascia and pelvic floor muscles, usually initiated by childbirth but worsened by aging and alterations of hormone level. Stretching, tearing, and avulsion of the levator muscles results in the urogenital hiatus becoming longer and wider. This results in chronic anterior displacement of pelvic organs with loss of any organ support at rest and especially during straining. Stretching or tearing of the cardinal and utero-sacral ligaments may result in anterior displacement of the uterus at rest or during straining. This results in stretching of the vaginal wall and loss of the normal superior vaginal sulcus and vaginal folds.

The consequence of this is a rotational descent of the proximal urethra away from its retropubic position and the eventual development of SUI.

Certainly in lateral cystourethrograms, the main anatomic change is loss of the posterior urethra-vaginal angle with the urethra and trigone falling into the same plane (Jeffcoate and Roberts, 1952; Hodgkinson, 1953; Hodgkinson, 1970).

Consequently, radiographic studies cannot distinguish between lateral or central defects in vaginal wall support because they appear in the same sagittal plane. It is necessary to examine the patient to determine which defect is present and to what extent. Because the proximal urethra rotates out of the focal plane of ultrasonographic probes or MRI, coronal images of vaginal relaxation cannot provide adequate anatomic information during leakage.

Despite the extensive data about anatomic defects, it is difficult to correlate the influence of these defects, the vaginal position,

and the urethral closure mechanism. Not all women with stress incontinence have vaginal prolapse; clearly, prolapse repairs do not always cure the stress incontinence and, conversely, women who redevelop stress incontinence after an apparently successful operation do not always have a recurrence of prolapse (Wall et al, 1994).

In conclusion, **support and suspension of the pelvic organs is dependent on a healthy pelvic floor striated muscle, intact robust connective tissue, and their attachment to the bony frame of the pelvis.** A useful analogy to visualize these factors is to consider a ship lying moored in dock. One can consider the ligaments as the mooring ropes and the pelvic floor musculature as the water on which the ship sits. If the dock is emptied, the influence of the support of the water disappears, leaving all of the tension applied to the mooring robes, which will inevitably weaken and fracture (Fig. 63–4).

Berglas and Rubin (1953) showed that in the nulliparous patient, the lower one third of the vagina is oriented more vertically, while the upper two thirds deviate horizontally, thereby maintaining the vaginal axis in an almost horizontal position (Fig. 63–5A and B). This configuration is maintained by the posterior attachments of the cervix with the cardinal and utero-sacral ligaments and by the anterior position of the urogenital hiatus. During stressful maneuvers such as coughing or straining, the levator hiatus is shortened anteriorly by contraction of the pubococcygeus muscles (Fig. 63–5C). In the case of genital prolapse when the levator ani support is lost, the vaginal axis becomes more vertical, the urogenital hiatus broadens, and fascial supports are strained (Fig. 63–5D).

Analogy demonstrating the support provided by the **A,** pelvic floor (water) and ligaments (ropes) to the pelvic organs (ship). **B,** Consequences of a pelvic floor muscle weakness with increasing strain placed on ligamentous structures. **C,** Ligamentous damage as a consequence of loss of pelvic floor muscle weakness.

Connective Tissue

The **pubourethral ligament** attaches the midurethra to the inferior side of the pubic symphysis and prevents its downward rotational descent (Zacharin, 1963). It works in conjunction with the pubourethralis muscle, a subdivision of the levator ani muscle that forms a sling around the proximal urethra. Together they form the midurethral complex. In **particular it has been postulated that an elongation of the posterior pubourethral ligaments may be a significant contributory factor to the loss of urethral support seen in stress incontinence.** An important fascial support for the urethra is provided by the **urethro-pelvic ligament,** which attaches the urethra to the tendineus arc (Rovner et al, 1997).

In addition, the **endo-pelvic fascia/pubocervical fascia,** extending between the bladder and the vagina, suspends and attaches the vagina and cervix to the pelvic sidewall and to each arcus tendineus fascia pelvis, thereby offering posterior support to the bladder and bladder neck. It has two surfaces: the perivesical fascia on the vaginal side and the endo-pelvic fascia on the abdominal side. Its upper zone supports the bladder above the cervix, the middle zone supports the trigone, and the lower zone supports the bladder neck. Laxity of the fascia in each of the zones will result in uterine prolapse, cystocele, and urethrocele, respectively (DeLancey, 2001).

The **arcus tendineus fasciae pelvis** are tensile structures located bilaterally on either side of the urethra and vagina that act like the ropes of a suspension bridge and provide the necessary support needed to hang the urethra on the anterior vaginal wall. They originate as fibrous bands from the pubic bone and broaden out as aponeurotic structures moving dorsally to insert into the ischial spine (Fig. 63–6).

The **cardinal ligaments** and the more medially placed **utero-sacral ligaments** support the uterus and cervix; their relaxation results in uterine prolapse (Fig. 63–7).

Pelvic Floor Musculature

The pelvic floor musculature, represented by the **levator ani muscles,** carries the weight of the pelvic contents and prevents the abdominal pressure from stretching the ligamentous support structures. The levator ani includes the **puborectalis muscle,** which surrounds the rectum connecting the pubic bones anteriorly in a U-shaped configuration, the **pubococcygeus muscle,** which crosses from the pubis to the coccyx, and the **iliococcygeus muscle.** The last one arises laterally from the arcus tendineus levator ani and forms a horizontal sheet that spans the posterior opening of the pelvis, providing a shelf on which the pelvic organs lie. The urethra and vagina pass through an aperture in the levator musculature, the urogenital hiatus. The levator ani contains not only type I fibers providing resting tone but also type II (fast-twitch) fibers that, under stress, maintain the urethral closure and prevent stretching of the pelvic ligaments.

The constant muscle tone (Critchley et al, 1980) maintained by predominantly type I (slow-twitch) striated muscle fibers compresses the vagina and urethra anteriorly toward the pubic bone and keeps the hiatus closed (DeLancey and Hurd, 1998).

The pudendal nerve provides somatic innervation to the striated muscle of levator ani, as well as to the striated muscle within the external anal and urethral sphincters. The intrapelvic somatic

fibers travel along the anterior vaginal wall from the sacral segments S2 to S4 to provide asomatic nerve supply to the pelvic floor (Borirakchanyavat et al, 1997). Neuromuscular injuries have been proposed as an important factor in predisposing to pelvic floor dysfunction. Childbirth and age are the two major factors predisposing to pelvic floor denervation (Smith et al, 1989). Other factors include pelvic surgery (rectal and vaginal surgery with extensive pelvic dissection), radiotherapy, and congenital neurologic conditions such as spina bifida and muscular dystrophy (Fig. 63–8).

Current Theories Relating to the Maintenance of Continence

The traditional view has been that urethral support is critical to the maintenance of continence during increases in abdominal pressure. It was thought that loss of structural urethral support resulted in varying degrees of descent of the bladder neck and urethra, and it was thought that the resultant urethral hypermobility is the principal cause of SUI (Hodgkinson, 1953; Green, 1968; McGuire et al, 1976; Hodgkinson, 1978; Blaivas, 1988; Walters and Jackson, 1990). It was also thought that the normally supported bladder neck and proximal urethra sit in a high retropubic position and that increased intra-abdominal pressure is transmitted equally to both bladder and urethra. In cases of stress-induced urethral descent, the urethra attains a low, dependent position. Increased intra-abdominal pressure is then transmitted unequally to the urethra and bladder, and when bladder pressure exceeds urethral pressure, SUI ensues (McGuire and Herlihy, 1977; Constantinou and Govan, 1982; Westby et al, 1982; Constantinou, 1985; Bump et al, 1988; Rosenzweig et al, 1991). However, the fact that many women are totally continent despite clinical evidence of urethral hypermobility somewhat refutes that theory. This implies that the normal urethra remains closed even during stress-induced descent (Walters and Diaz, 1987).

The most commonly held view of the pathophysiology of stress incontinence secondary to urethral hypermobility is based on DeLancey's theory of urethral support, the so-called hammock theory (DeLancey, 1994). In anatomic specimens in which increases in abdominal pressure were simulated, he found that the urethra lies in a position where it can be compressed against a hammock-like musculofascial layer on which the bladder and urethra rest (DeLancey, 1994). **In this model, it is the stability of this supporting layer rather than the position of the urethra that determines stress continence.** Urethral support is supplied by connective tissue and muscle arranged to resist the downward pressure created by increases in abdominal pressure. The urethra is intimately connected to the anterior vaginal wall, and the connections of these two structures to the levator ani muscle complex and arcus tendineus fascia pelvis (ATFP) determine the stability of the urethra. The ATFP is a fibrous fascial band that stretches from the pubic bone anteriorly to the ischial spine. The fascial covering of the levator ani consists of two leaves: the endopelvic fascia (abdominal side) and the pubocervical fascia (vaginal side). The two leaves fuse laterally to attach on to the ATFP, creating a hammock of support under the urethra and bladder neck. **Normally, with rises in intra-abdominal pressure, the urethra is compressed against the supporting structures, which act like a backboard and prevent loss of urine** (DeLancey, 1997). When the supporting structures fail, there can be rotational descent of the bladder neck and proximal urethra during increases in abdominal pressure. If the urethra opens concomitantly, SUI ensues. If this supporting layer establishes its stability, although at a lower level, continence may still be preserved (DeLancey, 1996). **These findings have important clinical implications that support the contention that the primary goal of surgery for sphincteric incontinence in women is to provide a backboard against which the bladder neck and proximal urethra can be compressed during increases in abdominal pressure.** In fact, some of the most popular procedures for the treatment of stress incontinence do not change the position of the urethra or even correct mobility (Lo et al, 2001; Sarlos et al, 2003; Minaglia et al, 2005). An additional observation by DeLancey (1990) is that the medial portion of the levator ani muscle has a direct connection to the endopelvic fascia and the vaginal wall, and contraction of the levators contributes to stabilization of the urethra during sudden increases in abdominal pressure (e.g., a cough).

In a series of elegant MRI studies of the pelvic floor, stress incontinence was found to occur when there was unequal movement of the anterior and posterior walls of the bladder neck and proximal urethra during stress. With good anterior wall support and a lax posterior wall, the urethral lumen is literally pulled open as the posterior wall moves away from the anterior wall, resulting in incontinence (Yang et al, 1991; Yang et al, 1993; Mostwin et al, 1995). Conversely, one would expect less incontinence if there is similar laxity of the anterior wall.

Furthermore, ultrasound imaging of the bladder neck and proximal urethra, in both normal and stress-incontinent patients, demonstrated that opening (funneling) of the bladder neck was the common denominator underlying stress incontinence, not urethral hypermobility. Anterior support of the urethra is provided by the pubourethral ligaments, attaching the midurethra to the inferior aspect of the pubic bone. These work in conjunction with the pubourethralis muscle of the levator ani complex, which forms a sling around the proximal urethra and prevents rotational descent (Plzak and Staskin, 2002). Together, the two structures form the **midurethral complex,** which is now thought to play a significant role in the maintenance of stress continence along with the suburethral hammock described

earlier. According to Mostwin and colleagues (1995): **"It is the relative, not the absolute, position of the urethra with respect to the pubis that may contribute to urethral opening in stress incontinence. The length and strength of the suburethral complex may vary in patients. In those with shorter, stronger anterior fascial support, only a small loss of suburethral support may be sufficient to permit distraction (of the anterior and posterior urethral walls) during rotational descent."** In contrast to the explanation that proposes a pure transmitted pressure effect, the mechanism of shear force suggests that transmitted energy mechanically opens the proximal and middle urethra (Plzak and Staskin, 2002).

The exact point of continence in the urethra, if such a point exists, has been debated. For years it was thought to be the bladder neck; however, the work of Constantinou and Govan (1981) and Petros and Ulmstem (1990, 1998) **suggested that the midurethra supported anteriorly by the pubourethral ligaments is the most important zone of continence.** Constantinou and Govan (1981) showed that pressure change ratios in the urethra/bladder are highest at the midurethra in continent control patients and in postsurgical patients after endoscopic bladder neck suspension, whereas the high midurethral pressure is lost in women with stress incontinence. In 1990 Petros and Ulmstem published the **integral theory of stress and urge incontinence.** According to the theory, female stress incontinence and urgency incontinence have a common etiology. They proposed that support of the anterior vaginal wall is provided by three separate but synergistic mechanisms. The anterior pubococcygeus muscle lifts the anterior vaginal wall to compress the urethra; the bladder neck is closed by traction of the underlying vaginal wall in a backward and downward fashion; and the pelvic floor musculature, under voluntary control, draws the hammock upward, closing the bladder neck. Overall laxity of the anterior vaginal wall causes dissipation of all of these forces, resulting in stress incontinence. They further suggested that laxity of the anterior vaginal wall causes activation of stretch receptors in the bladder neck and proximal urethra that can trigger an inappropriate micturition reflex, resulting in detrusor overactivity. These theories are not mutually exclusive, and there is probably a least some truth in each. The fact that both bladder neck and midurethral slings have been shown to be successful in treating stress incontinence supports all these theories (Ulmsten et al, 1998; Olsson and Kroon, 1999; Nilsson and Kuuva, 2001; Rezapour and Ulmsten, 2001; Nilsson et al, 2004). Further reports of successful treatment of mixed incontinence with slings lend credence to the integral theory.

In 1980 **McGuire and colleagues first introduced the concept of intrinsic sphincteric deficiency** (ISD) when, in a retrospective analysis of the results of anti-incontinence surgery, they noted that some women who had undergone multiple retropubic operations had a deficient sphincteric mechanism characterized by an open bladder neck and proximal urethra at rest with minimal or no urethral descent during stress. They stated that ISD denotes an intrinsic malfunction of the urethral sphincter, regardless of its anatomic position. **Contemporary theories suggest that all patients with sphincteric incontinence have some degree of ISD.** Considerations that support this theory include the fact that the normal urethra is intended to remain closed no matter what the degree of stress or rotational descent. Furthermore, many women with urethral hypermobility remain continent (Versi et al, 1986). Finally, urethral hypermobility and ISD may (and often do) coexist in the same patient. Because urethral hypermobility and ISD often coexist, we believe that they do not necessarily define discrete classes of patients (Nitti and Combs, 1996; Fleischmann et al, 2003). Thus these parameters may be used to characterize incontinence but not necessarily classify patients. Classification systems have been devised to characterize stress incontinence by the presence or absence of urethral mobility, the degree of mobility, and the presence of rotational descent (Green, 1962; McGuire et al, 1976; Blaivas and Olsson, 1988). However, it is recommended **that rather than "classifying" stress incontinence, it makes more sense to simply characterize it by two parameters—the degree of urethral mobility and sphincter strength.**

EPIDEMIOLOGY OF URINARY INCONTINENCE AND PROLAPSE

The authors would like to acknowledge the major contribution made by the International Consultation on Incontinence Committee 1 on Epidemiology of Urinary and Faecal Incontinence and Pelvic Organ Prolapse (Milsom et al, 2009), on which the following section is based.

Background Terminology

Epidemiology is the scientific study of the distribution and determinants of disease in people. The epidemiology and natural history of UI vary greatly between the genders. Causes and risk factors are different. Therefore it is most practical to discuss the epidemiology of incontinence in men and women separately.

Prevalence is defined as the probability of experiencing a symptom or having a condition or a disease within a defined population and at a defined time point. The concept is important for establishing the distribution of the condition in the population and for projecting the need for health and medical services.

Incidence is defined as the probability of developing the condition under study during a defined time period. Incidence is usually reported for a 1-, 2-, or 5-year time interval.

When discussing the epidemiology and impact of incontinence, it is important to distinguish between its prevalence and incidence.

The relative risk (RR) estimates the magnitude of an association between exposure and a condition and indicates the likelihood of having the condition in the exposed group relative to those who are not exposed (e.g., do not have the risk factor). An RR of 1.0 indicates that the rates in the exposed and nonexposed groups are identical and thus that there is no association between the exposure and the condition in that specific dataset. A value greater than 1.0 indicates a positive association or an increased risk. An RR of 2.5 for UI indicates that there is a 2.5 times increased risk or that the persons in question are 250% more likely to have incontinence than those without the risk factor.

The odds ratio (OR) is the odds for having a risk factor in persons with a condition divided by the odds among those without the condition. An OR of 2.5 for UI may be interpreted as meaning that in this sample the odds in favor of having incontinence are 2.5 times higher among those with the risk factor than among those without.

For a condition with high prevalence, like UI or pelvic organ prolapse, OR and RR will not be identical, but in practice the results can be interpreted similarly. Results should always be given with a 95% confidence interval (CI).

Incontinence

UI is a common symptom that may affect women at all ages, and there is a wide range of severity and nature of symptoms. UI is not a life-threatening disease, but the symptoms may seriously influence the physical, psychologic, and social well-being of the affected individuals.

1. **Pregnancy, labor, and vaginal delivery** versus caesarean section are significant risk factors for later UI, but the strength of this association diminishes substantially with age (level 1 evidence).
2. Although several specific parturition factors such as **instrumental delivery and birth weight are risk factors for UI in the postpartum period, their association with UI in later life is weak or nonexistent,** suggesting that changes in birthing practices in developed countries are unlikely to affect UI in older age (level 2 evidence).
3. Additional evidence has now established **body mass** as important, modifiable risk factors for UI (level 1 evidence).
4. **Physical function** also appears to be an independent risk factor for UI in older women. Whether improvement in physical function leads to a reduction in UI remains to be established (level 2 evidence).
5. Evidence from two blinded, randomized controlled trials indicate **that oral estrogen, with or without progestogen,** is a significant risk factor for UI in women age 55 and older (level 1 evidence).
6. **Diabetes** is a risk factor for UI in most studies. Although diabetic neuropathy and/or vasculopathy are possible mechanisms by which diabetes could lead to UI, **no mechanism has been established, nor is it clear whether prevention or treatment of diabetes, separate from weight reduction, will reduce the risk of UI** (level 2 evidence).
7. **Menopause,** as generally defined, **does not appear to be an independent risk factor for stress UI** (level 2 evidence).
8. **Hysterectomy** remains a **possible risk factor** for later UI, but the evidence is inconsistent (level 2 evidence).
9. **Moderate to severe dementia** in older women is a **moderate to strong independent risk factor for UI** (level 2 evidence). Whether interventions to maintain or improve cognitive functioning also reduce UI has not been evaluated.
10. **Mild loss of cognitive function** in community-dwelling women, separated from physical function and other factors, **increases the risk of UI slightly,** if at all, but **may increase the impact of UI** (level 2 evidence).
11. Data from twin studies suggests that there is a **substantial genetic component** to UI (level 1 evidence).
12. Other potential risk factors including **smoking, diet, depression, constipation, UTIs, and exercise, although associated with UI, have not been established as etiologic risk factors** and are, in fact, difficult to study with observational data because of the potential for unmeasured confounding and questions of direction of the association (level 3 evidence).

General Comments

Virtually all epidemiologic studies rely on participant self-reporting of UI. Multiple studies have examined the association between self-reported incontinence and clinically demonstrable incontinence and by type of incontinence based on self-reported compared with type based on clinical diagnosis. Although self-reporting and clinical diagnosis are highly correlated, they are inherently different. Sandvik and colleagues (1995) validated diagnostic questions used in a survey against a final diagnosis made by a gynecologist after urodynamic evaluation. The percentage of stress-only incontinence increased from 51% to 77%, and mixed incontinence was reduced from 39% to 11% while the proportion with urgency-only UI remained virtually the same (10% vs. 12%). For public health purposes, self-report has the advantage of reflecting the woman's experience and allows further characterization of the incontinence by frequency and quantity of urine loss. Despite the uncertainty in determining the type of incontinence, the differences in the epidemiology of urgency and stress incontinence are potentially important given the presumed differences in underlying pathophysiology. Differences in the association of stress and urgency UI (based on self-report) with respect to age, race/ethnicity, and risk factors suggest that questionnaire-based determination of UI type is useful and should be included in all epidemiologic studies of UI (Thom, 1998).

Usually incontinence is defined by the episode frequency (e.g., one or more episodes in the past year or past month or typically leaking at least once a week or daily). **UI can also be defined by severity (a combination of frequency and quantity).** Probably the most widely used measure of severity is the Sandvik Severity index (Sandvik et al, 1993, 2000), which is calculated by multiplying the reported frequency (four levels) by the amount of leakage (three levels). **Incontinence can also be characterized by impact,** which is usually assessed either in terms of bothersomeness or by the degree to which it restricts a woman's activity (e.g., the Incontinence Impact Questionnaire) (Shumaker et al, 1994).

The vast majority of epidemiologic studies of female UI have been conducted in the United States, Canada, Europe, Australia, or Japan. A few additional studies have been reported from other Asian countries. Thus we know little about the prevalence, incidence, and risk factors for UI in Africa or other parts of the developing world.

Prevalence

Estimates of UI prevalence differ for a variety of reasons other than variation in true prevalence:

1. **Sampling frame.** Representative samples drawn from a large, usually geographically defined population (e.g., via random digit dialing) are thought to provide prevalence estimates that are the most generalizable.
2. **Response rates.** Even population-based studies can provide biased prevalence estimates due to poor response rates (Fultz and Herzog, 1993). Although the degree of bias is often unknown, as a general rule response rates above 80% are considered good and those between 60% and 80% are marginal.
3. **Threshold definition of UI.** Usually incontinence is defined by a threshold frequency (e.g., one or more episodes in the past year or past month, or typically leaking at least once a week or daily). Severity of degree of bother may also be used. The threshold chosen to define UI obviously affects the prevalence and incidence.

4. **Types of UI.** UI in women is typically classified as stress, urgency, or mixed. Prevalence estimates for each type of UI are sensitive to the wording of the questions and to definitions used.
5. **Survey methods.** Although there are few data comparing differences in prevalence based on method of ascertainment (Herzog and Fultz, 1990; Fultz and Herzog, 2000), variation in ascertainment (e.g., in-person interviews, phone interviews, mailed questionnaires, diaries) affects prevalence estimates for other socially sensitive conditions.
6. **Culture and language.** Although this area has not been investigated, it is likely that there are cultural differences in the perception of and terms used to describe UI that may affect prevalence estimates. Similarly, differences in language may lead to differences in ascertainment.

Prevalence in General Population of Adult Women

A review of 36 general population studies from 17 countries in the 2004 Third ICI edition (Hunskaar, 2005) found that the prevalence estimates for the most inclusive definitions of UI ("ever," "any," or "at least once in the past 12 months") ranged from 5% (Van Oyen and Van Oyen, 2002) to 69% (Swithinbank et al, 1999), **with most studies reporting a prevalence of any UI in the range of 25% to 45%. For daily incontinence, prevalence estimates typically range between 5% and 15% for middle-aged and older women** (Thomas et al, 1980; Yarnell et al, 1981; Holst and Wilson, 1988; Rekers et al, 1992; Lara and Nacey, 1994; Hannestad et al, 2000). Studies reported since 2004 have added important information on prevalence of incontinence in women younger than 30 and older than 80 years of age, particularly for prevalence of incontinence by type. These studies are consistent with previous studies reporting that **older women are more likely to have mixed and urgency incontinence** (Diokno et al, 1986; Molander et al, 1990; Roberts et al, 1998; Nuotio et al, 2003), whereas **young and middle-aged women generally report stress incontinence** (Hording et al, 1986; Holst and Wilson, 1988; Burgio et al, 1991; Samuelsson et al, 1997; Hannestad et al, 2000). **Overall, approximately half of all incontinent women are classified as stress incontinent. A smaller proportion are classified as mixed incontinent, and the smallest fraction as urgency incontinent.** A recent study that included the entire adult age range by Hannestad and colleagues (2000) demonstrated a fairly regular increase in prevalence of mixed incontinence across the age range and a decrease in prevalence of stress incontinence from the 40- to 49-year-old age group through the 60- to 69-year-old group.

Prevalence in Long-Term Care Facilities

Several studies have documented a **higher prevalence** of UI in women residing in long-term care facilities compared with community-dwelling women (Ouslander et al, 1982; Sgadari et al, 1997; Hunskaar et al, 1998; Aggazzotti et al, 2000; Saxer et al, 2008). Because UI is associated with dementia, limited mobility, and other comorbid conditions, **prevalence of UI is higher in facilities with residents requiring a higher level of care.** In addition to being more frequent, **UI in long-term care residents tends to be more severe, costly, and more burdensome on caregivers** compared with UI in the community (Ouslander and Schnelle, 1995).

Prevalence during Pregnancy and Postpartum

Studies of UI during pregnancy have reported **period prevalences of 32% to 64% for all UI and 40% to 59% for stress (including mixed) UI. Period prevalence is higher in parous than in nulliparous women** (Dimpfl et al, 1992; Marshall et al, 1998; Morkved and Bo, 1999; Hvidman et al, 2002), whereas new-onset UI (cumulative incidence) during pregnancy is higher in primigravida women (Marshall et al, 1998; Morkved and Bo, 1999; Hvidman et al, 2002). **Point prevalence of UI is low in the first trimester, rises rapidly in the second trimester, and increases further, though less rapidly, in the third trimester** (Marshall et al, 1998; Morkved and Bo, 1999). **Severity of incontinence appears to increase during pregnancy as well** (Burgio et al, 1996). Data recently reported from the Norwegian Mother and Child Cohort Study, a large (N = 43,279) population-based study, confirms these observations (Wesnes et al, 2007). In this study the prevalence of stress incontinence from before to during pregnancy rose from 9% to 31% in nulliparous women and from 24% to 42% in parous women. In contrast, mixed incontinence showed a similar rise in both groups (from 6% to 16% and from 8% to 20%, respectively). Urgency incontinence remained virtually unchanged in both groups at less than 5%.

Estimating the postpartum prevalence of UI is complex because in addition to differences in study design, method of ascertainment, and choices of definition of incontinence, prevalence may also depend on the number of previous births, type of delivery, and history of previous incontinence. **Nearly all postpartum UI is stress related.** Most studies did not provide information on the frequency of leakage or degree of bother. Overall, it appears that **any incontinence is reported by 15% to 30% of women during the postpartum year, weekly or greater incontinence is reported by 5% to 10%, and daily UI is reported by less than 5% of women.** Excluding women with UI before pregnancy reduced the prevalence of postpartum incontinence by 3% to 4% in the one study reporting separate prevalences for each group (Glazener et al, 2006). Studies that included women delivered by caesarean section and delivered vaginally consistently found **a lower prevalence in those delivered by caesarean section. Studies reporting prevalence in women delivered by elective caesarean section** and by caesarean section after initiation of labor showed a substantially lower prevalence of postpartum UI in the elective caesarean section group.

Prevalence in Different Racial and Ethnic Groups

Although most epidemiologic studies of UI have been conducted on Caucasian populations in the United States, Canada, and Europe, there are now a substantial number of studies in Asian countries (Herzog and Fultz, 1990; Dimpfl et al, 1992; Burgio et al, 1996; Marshall et al, 1998; Morkved and Bo, 1999; Hvidman et al, 2002; Jumadilova et al, 2005; Anger et al, 2006b; Glazener et al, 2006; Waetjen et al, 2007; Wesnes et al, 2007). Studies have also been conducted on racial/ethnic groups in the United States (Burgio et al, 1991; Fultz et al, 1999; Sampselle et al, 2002; Grodstein et al, 2003; Nygaard et al, 2003; Jackson et al, 2004; Anger et al, 2006a; Danforth et al, 2006; Thom et al, 2006; Waetjen

et al, 2007; Dooley et al, 2008; Fenner et al, 2008; Markland et al, 2008, 2009). Because of the substantial variation in prevalence of incontinence between studies, it is best to examine differences by race and ethnicity in the same study. Most striking is the **lower prevalence of stress UI in black and Asian compared with white women**. In most studies, blacks have half to a quarter the prevalence of stress UI compared with white women but the same or slightly higher prevalence of urgency UI and a slightly lower prevalence of mixed UI. Thus the difference in prevalence of UI between white and black women appears to be almost entirely the result of a markedly lower prevalence of stress UI symptoms in black women. In contrast, the lower prevalence of UI seen in Asian women compared with white women reflects a lower prevalence of both stress and urgency UI. The comparison of prevalences between Hispanic and non-Hispanic white women is complex in that some studies have found a lower prevalence of UI in Hispanic women while others have reported the prevalence to be higher in this group. This heterogeneity may be explained, at least in part, by differences in prevalence among a subpopulation of Hispanic women. Studies such as the SWAN study (Sampselle et al, 2002) that include Hispanic women who are primarily of Caribbean origin have reported lower UI prevalence, whereas those enrolling primarily Mexican-American women have reported higher UI prevalences (Thom et al, 2006; Daneshgari et al, 2008; Dooley et al, 2008). This relationship is further supported by the NHANES data reported by Anger and colleagues, which found prevalences of any UI to be 36% in Mexican-American women and 30% in other Hispanic women (Anger et al, 2006a; Daneshgari et al, 2008).

Key Points: Prevalence of Urinary Incontinence

- The estimated prevalence of UI in middle-aged and older women in the general population appears to be in the range of 30% to 60% (increasing with age). The prevalence of daily UI ranges from 5% to 15%, rising to more than 15% in women older than age 70 who are institutionalized. Some studies have found prevalences outside theses ranges, demonstrating that there remains a large variation in the estimated prevalence of UI in women, even after taking into account differences in definitions, ascertainment, and demographic characteristics. At least part of this variation is likely to be due to the sensitivity of the subject and subtle differences in the conduct of studies (level 1 evidence).
- Multiple observational studies have confirmed that white, non-Hispanic women have a substantially higher prevalence of stress UI than black or Asian women that is not explained by differences in known risk factors for UI (level 1 evidence).

Potential Risk Factors

Many epidemiologic studies have investigated potential risk factors for UI. The design of most of these studies has been cross sectional using prevalent UI. In cross-sectional studies, the temporal relationship between some potential risk factors such as diet, physical activity, medications, or body weight is ambiguous because the development of UI can lead to changes in behavior. Since 2004, several prospective studies have examined risk factors for incident UI that have allowed for evaluation of the temporal relationship. Associations in all observational studies are subject to potential confounding, necessitating multivariate analysis to estimate the independent association between risk factors and UI. The risk factors of estrogen use and body mass (obesity) have been examined in randomized, controlled trials. With the exception of age, the following risk factors are considered to be at least potentially modifiable.

Impact and Consequences

The impact of UI is typically assessed by degree of bother or by scales that measure the impact of incontinence on functional status and quality of life. A single question asking patients to report the degree of bother they experience from their incontinence provides an important dimension to characterizing UI in addition to frequency and amount of urine lost. Typically, **incontinence that is more severe, of longer duration, and is urgent or mixed is also more bothersome** (van der Vaart et al, 2002). Validated scales measure the impact of UI. One of the first scales, the Incontinence Impact Questionnaire (Shumaker et al, 1994), uses 30 items asking whether incontinence limits activities in four domains. Several other similar scales exist, some specific for urgency or stress incontinence or for overactive bladder (Shumaker et al, 1994; Uebersax et al, 1995; Jackson et al, 1996; Wagner et al, 1996; Kelleher et al, 1997; Brown et al, 1999; DuBeau et al, 1999). **In addition to severity of UI, interference with sexual activities and incontinence at night is associated with greater reported impact on quality of life** (Huang et al, 2006).

Incontinence has been identified as a **potential risk factor for falls and nursing home admissions.** In a prospective study of more than 6000 older women, women with weekly urgency, but not stress, incontinence were more likely to fall during the 3-year follow-up, adjusting for multiple other factors (adjusted OR = 1.3, 95% CI = 1.1 to 1.4) (Brown et al, 2000). Similarly, in a study of 472 long-term care residents in Germany, UI at baseline predicted falls over the next 12 months after adjusting for a variety of patient factors and comorbid conditions (Kron et al, 2003). UI was the second strongest predictor of falls (a history of falls being first). However, it is possible that both falls and UI are markers for frailty that cannot completely be adjusted for. Whether treatment of UI would reduce the number of falls has not been established.

UI has also been reported as a **risk factor for nursing home admissions even after adjusting for multiple comorbid conditions** (Thom et al, 1997a, 1997b). However, another study that also adjusted for additional measures of frailty including activities of daily living found that the association became weaker and nonsignificant (Holroyd-Leduc et al, 2004).

UI has substantial, well-documented economic consequences as well. Annual costs of UI are estimated to be more than $20 billion in direct costs (primarily costs of routine care including out-of-pocket costs) (Wilson et al, 2001), which is greater than the annual costs for breast, cervical, uterine, and ovarian cancer combined (Subak et al, 2006). There are also substantial indirect costs from work loss and missed volunteer work (Thom et al, 2005).

Treatment Seeking and Treatment

The proportion of women with any UI in the past 12 months who report having sought medical treatment ranges from 12% (Sampselle et al, 2002) **to 53%** (Mardon et al, 2006) **with about half the studies showing 25% to 30%** (Rekers et al, 1992; Hannestad et al, 2002; Hagglund et al, 2003; Hsieh et al, 2008). All studies that have examined treatment seeking by type of incontinence have found that **women with urgency or mixed incontinence are more likely to seek**

Key Points: Conditions Predisposing to Urinary Incontinence (Milsom et al, 2009)

- Age: Virtually all studies have found an increase of UI prevalence with age. As a result, while stress incontinence predominates in younger and middle-aged women, urgency and mixed incontinence are more common in older women.
- Pregnancy, parity, and parturition events: Stress UI is reported by most women at some time during pregnancy, usually in the third trimester, but is generally self-limited and resolves after delivery. The interpretation of this association is not clear. It may be that physiologic changes during pregnancy cause incontinence later in life, but it is also possible that the temporary physiologic changes during pregnancy may "uncover" women with a predisposition to incontinence who are destined to become incontinent later in life regardless of the effects of pregnancy. The vast majority of studies have found an association between parity and later UI.
- The effect of parturition on risk of incontinence is difficult to separate from the effect of pregnancy. Possible mechanisms by which vaginal birth could lead to incontinence include stretching damage to pudendal and other nerves and tearing of connective tissue, which reduces pelvic floor support for urethral competence.
- Obesity and body mass: Obesity is well established as a factor that can cause UI or contribute to the severity of the condition. It is believed that the added weight of obesity, like pregnancy, may bear down on pelvic tissues causing chronic strain, stretching, and weakening of the muscles, nerves, and other structures of the pelvic floor. Intervention studies for weight reduction have reported that loss of weight is associated with partial remission or complete resolution of UI. Thus there is strong evidence to support the causal role of excess weight in the development of UI.
- Hormones: Current evidence suggests that although oral estrogen as a risk factor for stress UI may be unexpected, it is likely to be important, at least in women age 55 and older.
- Diabetes: Many, though not all, cross-sectional studies have reported UI to be more common in women with type 2 diabetes than among women with normal glucose levels even after adjusting for common risk factors including age and obesity.
- Hysterectomy: Approximately 600,000 women have hysterectomies in the United States each year, usually for noncancerous conditions. There has been concern that hysterectomy may be associated with development of UI via damage to the pelvic nerves and pelvic supportive structures. On the basis of the available data, hysterectomy does not appear to increase the risk of UI in the short term.
- Urinary tract infections and lower urinary tract symptoms: Urinary tract infection (UTI) has long been considered to be a cause of transient UI. The role of UTIs with respect to the development of chronic UI is less clear. Without additional data, it is not possible to say if UTIs actually increase the risk of later UI, if UI increases the risk of being diagnosed with a UTI, or if both UI and UTIs are manifestations of a common underlying process.
- Impaired physical function: Functional impairments, particularly mobility limitations, a history of falls, arthritis, dizziness, the need to use a walking aid, and poor lower extremity strength, have been correlated with UI in many community-based and nursing home studies.
- Cognitive impairment: Research on UI in nursing home residents has consistently supported an association between UI and dementia. In studies using multivariate analyses, patients lacking mental orientation had a 3.6 times greater risk of being incontinent than those with normal mental status and the presence of dementia increased the odds of UI by 1.5 to 2.3.
- Depression: Although depression may predispose a woman to developing UI, it is also possible that UI leads to depression (e.g., by reducing a woman's social network); that depression and UI share one or more common neurochemical or hormonal pathways; or that women with depression are more likely than nondepressed women to be bothered by, and hence report, having incontinence.
- Menopause: Historically, menopause has been considered a risk factor for UI. However, establishing a relationship between menopause and UI has been difficult, probably in part because changes in endogenous hormone levels vary over a period of at least several years and only approximately correspond to amenorrhea or vasomotor symptoms used to define clinical menopause.
- Physical activity: Evaluating physical activity as a potential risk factor or protective factor for incontinence has been difficult. Incontinence, particularly stress UI, can be a barrier to exercise, which could lead to the spurious appearance of a protective effect of physical activity on UI. Alternatively, engaging in physical activity could "unmask" an existing propensity toward stress incontinence by increasing intra-abdominal pressure, resulting in physical activity being identified as a risk factor in the short term even if it is protective in the long term.
- Smoking, cough, and chronic lung disease: Conflicting data from cross-sectional studies and lack of association between smoking and incident UI in prospective studies suggest that smoking per se is probably not an independent risk factor for UI.
- Diet: Studying diet as a risk factor for UI is challenging. Although some dietary constituents such as coffee, alcohol, or carbonated beverages have been suspected as worsening UI, there is little reason to suspect other dietary constituents as causing, or protecting from, UI.
- Family history and genetics: Several family history studies have found a twofold to threefold greater prevalence of stress UI among first-degree relatives of women with stress UI compared with first-degree relatives of continent women.
- Ischemic heart disease: It is not clear if heart disease is an independent risk factor for UI.
- Other factors: Additional variables reported as associated with UI include constipation; fecal incontinence; genital prolapse; congestive heart failure; use of diuretics, benzodiazepines, and other drugs; and childhood enuresis.

treatment than women with stress incontinence (Hannestad et al, 2002; Danforth et al, 2006; Zhu et al, 2008). As expected, **the proportion of women seeking treatment is strongly associated with frequency, severity, and bothersomeness,** with several studies reporting proportions of 50% to 80% of women with daily, moderate to severe, or bothersome incontinence (Hannestad et al, 2002; Kinchen et al, 2003; Diokno et al, 2004; Gasquet et al, 2006).

Reasons given by people for not seeking help include not regarding incontinence as abnormal or serious, embarrassment, considering incontinence to be a normal part of aging, having low expectations of treatment, and thinking they should cope on their own. Other characteristics such as age, general health, or attitude toward health care may also play a role.

Key Points: Consequences of Urinary Incontinence

- Typically, incontinence that is more severe, of longer duration, and is urgency or mixed incontinence is more bothersome.
- In addition to severity of UI, interference with sexual activities and incontinence at night are associated with greater reported impact on quality of life.
- Incontinence has been identified as a potential risk factor for falls and nursing home admissions.
- UI has also been reported as a risk factor for nursing home admissions even after adjusting for multiple comorbid conditions.
- UI therefore has substantial, well-documented, economic consequences.
- The proportion of women with any UI in the past 12 months who report having sought medical treatment ranges from 12% to 53% with about half the studies showing 25% to 30%.
- Women with urgency or mixed incontinence are more likely to seek treatment than women with stress incontinence.
- The proportion of women seeking treatment is strongly associated with frequency, severity, and bothersomeness.

Urinary Incontinence in Men

General Comments

Prevalence

A systematic review of 21 studies reported a **prevalence of UI in older men ranging from 11% to 34%** (median = 17, pooled mean = 22%). In the same review, the **prevalence of daily UI in men ranged from 2% to 11%** (median = 4%, pooled mean = 5%) (Thom, 1998). A wide definition of UI, older age, inclusion of institutionalized men, and the use of self-reporting methods tend to result in higher prevalence rates (Koyama et al, 1998; Thom, 1998). The wide span of results may be explained by the variation in the population studied, the definition of incontinence used, and the methods used in the surveys.

For any definition of UI, there is a **steady increase in prevalence with increasing age.**

Incontinence Subtypes

Due to differences in pathologic anatomy and pathophysiology of UI in men and women, there is a different distribution in incontinence subtypes. Recent studies confirmed our previous reports of the **predominance of urgency incontinence (40% to 80%), followed by mixed forms of UI (10% to 30%) and stress incontinence (<10%)** (Herzog and Fultz, 1990).

The higher percentages of the urgency and mixed types of incontinence are more significant in studies involving older people. In fact, the increasing prevalence of any UI by age in men is largely due to the contribution of urgency incontinence rather than stress incontinence. One study demonstrated an increasing rate of urgency UI from 0.7% between ages 50 and 59 to 2.7% between 60 and 69 to 3.4% for respondents 70 years and older. Stress UI was steady at 0.5%, 0.5%, and 0.1% for these groups, respectively (Ueda et al, 2000). On the other hand, Maral and colleagues (2001) reported increasing prevalence of SUI with age: 0.9% between ages 35 and 44, 1.2% between ages 45 and 54, 3.8% between ages 55 and 64, and 4.9% at age 65 and older.

Most studies report a significant fraction of other/unclassified type of urinary incontinence. One study reported that a majority of men with UI had overflow and functional types of incontinence (Bortolotti et al, 2000), whereas another found constant dribbling in 7% of their respondents (Damian et al, 1998). **Terminal dribbling or postvoid dribbling is another type of leakage in men that is difficult to assign to the conventional subtypes of UI.** In an Australian survey, **12%** of respondents reported frequent terminal dribbling (Sladden et al, 2000).

Severity

When it comes to severity, the distribution in men follows that of the women. Estimates for severe UI in older women tend to be about twice as high as for older men (Herzog and Fultz, 1990).

Key Points: Urinary Incontinence in Men

- The epidemiology of UI in men has not been investigated to the same extent as for females. But it appears that **UI is at least twice as prevalent in women as compared with men.** There seems to be a more **steady increase in prevalence with increasing age than for women** (level 1 evidence).
- Most studies find a **predominance of urgency incontinence, followed by mixed forms of UI and stress incontinence the least.** Most studies have a large fraction of other/unclassified types (level 2 evidence).
- Literature on incidence and remission of male UI is still scarce.
- Few clear risk factors have been scientifically documented, but several medical correlates have been reported. **Established risk factors** predisposing men to UI include **increasing age, presence of lower urinary tract symptoms (LUTS), urinary tract infections, functional and cognitive impairment, neurologic disorders, and prostatectomy** (level 2 evidence).
- UI after radical prostatectomy is frequent, ranging from 2% to 57%. Rates steadily decline from the time of surgery and plateau at 1 to 2 years (level 1 evidence).
- Factors affecting **postprostatectomy UI** include the **age at surgery, type of prostatectomy, and the modifications in the technique involving nerve and bladder neck preservation** (level 2 evidence).

Race/Ethnicity

Few studies have looked at the impact of race or ethnicity on the prevalence of UI among men. A four-country study presented lower prevalences of reported UI among men from Korea (4%) and France (7%) than in men from Britain (14%) and Denmark (16%) (Boyle et al, 2003). On the other hand, unpublished data from the MESA study did not indicate differences in prevalence among white male respondents compared with African-American respondents.

Incidence and Remission

Literature on the incidence of male UI is scarce. The MESA study (Herzog and Fultz, 1990) found a 1-year incidence rate for men older than 60 years of 9% to 10%. In a population-based survey in the UK among men at least 40 years of age, the 1-year incidence of UI was noted to be 3.8% (McGrother et al, 2004). A review of a health organization database of males at least 65 years old revealed a UI incidence of 23.8 per 1000 person years. Malmsten (1997) analyzed the age of onset of UI for each age cohort. Mean starting age for all men was 63 years. The mean duration was about 8 to 10 years in the cohorts. Substantial remission rates for UI in males were noted by the MESA study, higher among men (27% to 32%) than women (11% to 13%) (Herzog and Fultz, 1990). A similarly high 1-year remission rate of 39.6% was noted among British males (McGrother et al, 2004). One possible explanation for the difference in the published incidence and remission rates in men compared with women is the predominance of urgency type incontinence among men and its close relation to overactive bladder with and without incontinence. Another factor is the close association among urgency UI and prostate gland disease, infections, or bowel dysfunction, all of which are relatively amenable to treatment or may improve even without treatment.

Potential Risk Factors for Urinary Incontinence

There is relatively little research concerning conditions and factors that may be associated with UI in men, and clear risk factors are poorly documented. However, a few available studies have identified potential risk factors, which are described next.

Age

As in women, **increasing age is correlated with increasing prevalence of UI.** Multivariate analysis in several studies has shown that age is an independent risk factor for incontinence (Muscatello et al, 2001; Boyle et al, 2003; Landi et al, 2003; Nelson and Furner, 2005; Diokno et al, 2007). Compared with women, however, there seems to be a steadier increase in prevalence in men with increasing age.

Lower Urinary Tract Symptoms and Infections

LUTS, like urgency, nocturia, a feeling of incomplete voiding, and reduced flow, are typically associated with UI (Diokno et al, 1986; Hunskaar, 1992; Schmidbauer et al, 2001). In one study, UI was reported by 15% of men without voiding symptoms, frequency, or urgency and by 34% of those with such symptoms (Diokno et al, 1986).

Studies have also reported that urinary tract infections and cystitis are strongly associated with male UI (Damian et al, 1998; Ueda et al, 2000), with an OR of 3.7 for UI in men reporting cystitis (Ueda et al, 2000) and an OR of 12.5 among men with recurrent infections (Bortolotti et al, 2000). It should be noted that reports indicating a positive association between UTI and incontinence involved men older than 60 years.

Functional and Cognitive Impairment, Physical Activity

Mobility problems such as use of a wheelchair or aids to walking, as well as diagnosed arthritis or rheumatism or having a fall during the past year, were **significantly greater among incontinent than continent men** (Diokno et al, 1990; Damian et al, 1998).

Neurologic Disorders

Many specific neurologic diseases may lead to UI (Resnick and Yalla, 1987). **Neurogenic detrusor overactivity** is seen commonly in meningo-myelocele patients and in spinal injuries, Parkinson disease, and multiple sclerosis. **Underactive bladder dysfunction** due to a cauda equina lesion or diabetes **might cause overflow or a paralyzed pelvic floor and hence stress incontinence.** Men who have suffered a stroke were at increased risk for incontinence with an OR of 7.1 (Ueda et al, 2000). A case control study of age-matched, long-term stroke male survivors with controls showed a higher prevalence of UI among stroke survivors compared with controls (17% vs. 9%). In addition, among UI sufferers, the stroke survivors were found to have higher frequency and more leakage than controls. In a study of 235 stroke patients, the occurrence of UI correlated with motor weakness (OR 5.4), visual defects (OR 4.8), and dysphagia (OR 4.0).

Prostatectomy

A well-known iatrogenic cause of male incontinence is prostatectomy, but the attributable risk for this factor in the population of men with UI is unknown. In a Norwegian survey of elderly men with UI, almost a third had undergone prostatectomy (Hunskaar, 1992).

In a cross-sectional study among men in Vienna, Schmidbauer and colleagues identified previous prostatectomy to be associated with UI (Schmidbauer et al, 2001).

TURP seems to be followed by an incidence of stress incontinence of about 1%. A randomized controlled trial comparing TURP, laser prostatectomy, and evaporization of the prostate for benign disease showed comparable incontinence rates immediately and up to 12 months postoperatively (van Melick et al, 2003).

Radical prostatectomy seems to induce UI at a much higher rate than TURP. The overall **prevalence of postradical prostatectomy incontinence ranges from 2% to nearly 60%.** This wide range may be explained by many factors including differences in study characteristics, population characteristics, study site, definition used, and timing of assessment of continence in relation to the surgery. The era of development of the procedure has also been found to be associated with the prevalence rates (Hu et al, 2003), as well as the various procedural modifications of the surgery (see later). **Postprostatectomy incontinence rates elicited from symptoms reported by patients are generally two to three times higher than those from physicians' observations.** Studies that have performed both assessments in the same population confirm this observation that **doctors underestimate postprostatectomy incontinence by as much as 75%** (Ojdeby et al, 1996; Donnellan et al, 1997; McKammon et al, 1997; Olsson et al, 2001).

Incontinence rates after prostatectomy seem to decline steadily with time and plateau 1 to 2 years after surgery (Lowe, 1996; Weldon et al, 1997; Goluboff et al, 1998; Horie et al, 1999; Walsh et al, 2000; Moinzadeh et al, 2003). This emphasizes the need for a long follow-up period to establish continence status postprostatectomy. An actuarial study among 647 postprostatectomy men estimated UI rate of 13% at 1 year and 7% at 2 years postsurgery (Saranchuk et al, 2005).

The **technique of radical prostatectomy** affects UI rates. Modifications associated with lower UI rates include the perineal approach (Bishoff et al, 1998; Gray et al, 1999) and preservation of neurovascular bundle (Eastham et al, 1996; Van Kampen et al, 1998; Wei et al, 2000). Bladder neck preservation affords earlier return to continence compared with bladder neck resection, but with similar UI rates after 1 year (Poon et al, 2000; Srougi et al, 2001). One study showed earlier recovery of UI after tennis racquet reconstruction and bladder neck preservation compared with bladder neck resection with puboprostatic ligament preservation, but with similar UI rates at 1 year (Lowe, 1996; Noh et al, 2003). However, continence status assessed more than 12 months after surgery showed even lower rates of UI after bladder neck preservation (11.6%) compared with resection (4.9%) in one study (Lowe, 1996). UI after laparoscopic procedures seems to be higher initially but approximates that of open techniques by 1 year (Jacobsen et al, 2007).

Older age at time of surgery has been found to be associated with a higher prevalence of postprostatectomy UI (Eastham et al, 1996; Goluboff et al, 1998; Van Kampen et al, 1998; Gray et al, 1999; Wei et al, 2000; Kundu et al, 2004). One study showed a doubled risk for every 10 years of age beginning at age 40 (Catalona et al, 1999). Another study suggested that rather than absolutely affecting final continence prevalence, elderly men need a longer time to achieve continence after surgery (Horie et al, 1999). Two studies found no relation between age at surgery and UI (Donnellan et al, 1997; Kao et al, 2000).

Other factors have been found to be associated with a higher prevalence of postprostatectomy UI, although not consistently. Such factors include prior TURP, preoperative lower urinary tract symptoms, obesity, clinical stage, prostate-specific antigen (PSA), prostate volume, and Gleason score (Eastham et al, 1996; Moul et al, 1998; Van Kampen et al, 1998; Kundu et al, 2004; Lee et al, 2006). A retrospective analysis of 156 patients who had undergone preoperative MRI of the prostate and were followed up postprostatectomy showed that time to return to continence was associated with the variation in the shape of the prostatic apex. The prostatic apex that does not overlap with the membranous urethra was found to be significantly associated with an early return of continence (Lee et al, 2006). The 5-year cohort study of the Prostate Cancer Outcomes Study found that among prostatectomy patients, race and ethnic differences were related to urinary incontinence, with African-Americans having better recovery compared with non-Hispanic whites and Hispanics (Johnson et al, 2004).

Adjuvant radiotherapy has not been found to affect postprostatectomy incontinence rates when assessed beyond 1 year (Formenti et al, 2000; Hofmann et al, 2003; Kundu et al, 2004).

Factors of Unclear Association with Urinary Incontinence in Men

A 9-year study of Janssen (2007) showed increasing rates of UI with increasing body mass index (BMI) among the older men and women. However, multivariate analysis failed to show increased BMI (overweight and obese levels) as an independent risk factor for the development of UI. In a study including a younger population in Australia, obesity was noted to be associated with UI with an OR of 3.2 (1.2 to 9.0) (Muscatello et al, 2001). In this study, however, being merely overweight was not associated with UI. Several studies in the older persons have shown an association between physical activity and UI among women that is not seen among men (Boyle et al, 2003; Kikuchi et al, 2007).

Key Points: Epidemiology of Male Incontinence

- Relatively little research concerning conditions and factors that may be associated with UI in men has been conducted, and clear risk factors are poorly documented.
- Increasing age is correlated with increasing prevalence of UI.
- LUTS, like urgency, nocturia, feeling of incomplete voiding, and reduced flow, are typically associated with UI.
- Many specific neurologic diseases may lead to UI.
- TURP seems to be followed by an incidence of stress incontinence of about 1%.
- The overall prevalence of postradical prostatectomy incontinence ranges from 2% to nearly 60%.
- Postprostatectomy incontinence rates elicited from symptoms reported by patients are generally two to three times higher than those from physicians' observations.
- Doctors underestimate postprostatectomy incontinence by as much as 75%.
- The technique of radical prostatectomy affects UI rates.
- Older age at time of surgery has been found to be associated with a higher prevalence of postprostatectomy.
- Other factors associated with a higher prevalence of postprostatectomy UI include prior TURP, preoperative lower urinary tract symptoms, obesity, clinical stage, PSA, prostate volume, and Gleason score.

EPIDEMIOLOGY OF OVERACTIVE BLADDER

The studies reported in the literature have used different populations and ways of selecting samples, and the definition of OAB has changed slightly after its initial description, although this was standardized after the 2002 ICS standardization report.

The prevalence of OAB in adult males varies from 10.2% to 17.4% and in females from 7.7% to 31.3%. Clearly different definitions, the different age groups studied and maybe cultural differences affect the rates (level 2 evidence). OAB_{wet} was less prevalent than OAB_{dry} except for one implausible-looking result. The response rate was quite low in many of these studies, and sometimes it was impossible to know the response rate (e.g., when quota sampling was used).

A common finding was that the **rates increased with age,** but this was not universal (level 2 evidence). Some studies found that after adjusting for state of health, the relationship with age went away, and some found that it only applied to OAB_{wet}. **Usually OAB was more prevalent in females, and this was much more pronounced for OAB_{wet}, which sometimes meant that OAB_{dry} was the same for males and females**. OAB was related to **general health problems** and in particular **diabetes.** It is likely to be related to urinary problems in childhood.

Key Points: Epidemiology of Overactive Bladder

- The prevalence of OAB in adult males varies from 10.2% to 17.4% and in females from 7.7% to 31.3%.
- Rates of OAB increase with age.
- OAB is more prevalent in females, particularly OAB_{wet} to the extent that the prevalence of OAB_{dry} can be the same for males and females.
- OAB is related to general health problems and in particular diabetes and probably urinary problems in childhood.

EPIDEMIOLOGY OF PELVIC ORGAN PROLAPSE

General Comments and Definitions

Pelvic organ prolapse (POP) refers to loss of support for uterus, bladder, colon, or rectum leading to prolapse of one or more of these organs into the vagina. The ICS Pelvic Organ Prolapse Quantification (POPQ) examination defines prolapse by measuring the descent of specific segments of the reproductive tract during Valsalva strain relative to a fixed point, the hymen. As noted earlier, the **POPQ system describes the anatomic findings of pelvic organ prolapse without consideration for symptoms and bother** perceived by the woman. Validation of this system has shown it to be highly reliable (Hall et al, 1996). The stages of prolapse severity are arbitrarily defined, and **there is no clear differentiation between normal anatomic variation and mild POP.** For research purposes there is consensus for use of the POPQ system until further evidence might clarify the distinction between normal variation and mild prolapse (Weber et al, 2001).

Determining POP on the basis of self-reported symptoms is difficult because of the lack of specificity and sensitivity of most symptoms attributed to pelvic organ prolapse (Ellerkmann et al, 2001) **and the fact that prolapse above the level of the hymenal ring is usually asymptomatic** (Lukacz et al, 2005). The only exception appears to be a sensation of bulging into the vagina, which is most strongly associated with prolapse at or below the hymeneal ring (Swift, 2000; Hendrix et al, 2002). A recent study of 110 women found that a question asking about a feeling of something bulging in or dropping out of their vagina had a sensitivity of 84% and a specificity of 94% for POP at or beyond the hymeneal ring on examination (Lukacz et al, 2005). Seeing prolapse would presumably be even more specific but is too uncommon to be useful as a definition.

Prevalence of PELVIC ORGAN PROLAPSE

The prevalence of POP based on a sensation of a mass bulging into the vagina was remarkably consistent, ranging between 5% and 10%. The study by Eva and colleagues (2003) reported a substantially higher prevalence included in the definition of POP, pelvic heaviness, or digital pressure on the perineum or in the vagina to aid with defecation. Reports from the Women's Health Initiative (WHI) Oestrogen Plus Progestin Trial and randomized controlled trial (Handa et al, 2004; Nygaard et al, 2004; Bradley et al, 2007), although not actually population based, recruited the women in the trial from the community rather than from women seeking gynecologic care and provided important information on the prevalence of POP based on pelvic examination. The prevalence of observed prolapse in women enrolled in the WHI trial is similar to the prevalence found in the population-based study that also used pelvic examination (Samuelsson et al, 1999), although the prevalence of each type of prolapse was higher in the WHI study (Hendrix et al, 2002). In both studies, **prolapse occurs most frequently in the anterior compartment, next most frequently in the posterior compartment, and least in the apical compartment.**

Two studies that examined prolapse by race found that black women had the lowest prevalence and Hispanic women the highest after controlling for multiple other factors in multivariate analysis (Hendrix et al, 2002; Rortveit et al, 2007). The study reported by Rortveit and colleagues (2007) based on symptoms found adjusted ORs of 0.4 (95% CI = 0.2 to 0.8) for black and 1.3 (95% CI = 0.8 to 2.2) for Hispanic women, with white women as the referent group. Hendrix and colleagues (2002) reported adjusted ORs of 0.6 (95% CI = 0.5 to 0.8) for black and 1.2 (95% CI = 1.0 to 1.5) for Hispanic women compared with white women for POP based on genital examination.

Key Points: Epidemiology of Pelvic Organ Prolapse

- Most studies have used a cross-sectional design and there are limited longitudinal data to suggest a causal relationship between symptoms of obstructed defecation and pelvic organ prolapse or vice versa.
- Posterior vaginal wall prolapse and perineal descent are the compartment-specific defects most clearly associated with symptoms of obstructive defecation.
- A number of studies suggest that hysterectomy and other pelvic surgery may increase the risk for pelvic organ prolapse (level 2 evidence).
- Hysterectomy due to pelvic organ prolapse and other pelvic floor surgery are the strongest predictors of secondary pelvic floor surgery (level 2 evidence).
- SUI and pelvic organ prolapse have familial transmission patterns mediated by either genetic or environmental factors (level 2 evidence).
- SUI is more common in Caucasian women and pelvic organ prolapse in Caucasian and Hispanic women when compared with African-American women (level 2 evidence).
- Twin studies suggest that heritability contributes to the liability of developing pelvic floor disorders, but environmental effects are substantial.
- Childbirth is associated with an increased risk for pelvic organ prolapse later in life. Current evidence also suggests that increasing number of childbirths increases the risk (level 2 evidence).
- It remains undecided if caesarean section prevents the development of pelvic organ prolapse but most studies indicate that caesarean is associated with a decreased risk for subsequent pelvic floor morbidity in comparison to giving vaginal birth (level 2 evidence).
- There is a dearth in the understanding of how specific obstetrical events and the process of labor and delivery affect the risk for pelvic organ prolapse.
- Lifestyle factors and socio-economic indices appear to be associated with the risk for pelvic organ prolapse.
- A number of somatic diseases and conditions have been linked to the occurrence of prolapse, but the cause-effect relationship is undetermined.

Incidence

Only two studies that reported the incidence of new POP could be located. Both studies were done on subgroups of women enrolled in the WHI Oestrogen Plus Progestin Trial. The first study of 412 women enrolled at the University of California, Davis site used a standardized pelvic examination repeated every 2 years over 8 years (Handa et al, 2004). The incidence of new cystocele, rectocele, and uterine prolapse was 9%, 6%, and 2%, respectively. Annual rates of remission from grade 1 (prolapse to above introitus) were relatively common for each type of POP (24%, 22%, and 48%, respectively) but less common from grade 2 or 3 (prolapse to or beyond introitus) (9%, 3%, and 0%, respectively). In a second study of 259 women, postmenopausal women with a uterus were examined using the POP-Q at baseline and annually for 3 years. POP was defined as prolapse to or beyond the hymeneal ring. The incidence of new POP was 26% at 1 year and 40% at 3 years, with remission rates of 21% at 1 year and 19% at 3 years (Bradley et al, 2007).

Several studies have reported the annual incidence of surgery for POP in the United States and at least one in the United Kingdom. A longitudinal study of more than 17,000 women in the United Kingdom, age 25 to 39 at baseline, reported an annual rate of prolapse surgery of 0.16% (Mant et al, 1997). This rate is consistent with the rate of approximately 0.2% per year reported in the United States (Brown et al, 2002; Boyles et al, 2003). One U.S. study reported an annual incidence rising with age from 0.05% in women age 30 to 39 to 0.5% in women age 70 to 79 with an estimated lifetime cumulative risk of surgery from prolapse of 7% to 11% (Olsen et al, 1997). A recent U.S. study reported similar surgical rates: 0.07% for women age 18 to 39, 0.24% for women age 40 to 59, and 0.31% for women age 60 to 79 (Shah et al, 2008). Surgical rates drop substantially after age 80 (Olsen et al, 1997; Shah et al, 2008). Estimating rates of prolapse surgery has the advantage of use of hospital discharge data on procedures, which is highly accurate for the procedure performed but less accurate for the indications for the procedures, particularly when a procedure may have more than one indication.

Management
Incontinence Treatment Overview
Pelvic Prolapse Treatment Overview

DEFINITION AND IMPACT OF PELVIC FLOOR DISORDERS

Pelvic floor disorders (PFDs), which include urinary incontinence, fecal incontinence, and pelvic organ prolapse (POP), pose a prevalent worldwide health concern. (For the purposes of this chapter, "incontinence" will refer to *urinary* leakage unless otherwise specified.) **On the basis of 2001-2004 data from the National Health and Nutrition Examination Survey (NHANES), an overall prevalence of incontinence of 49.6% in 4229 women older than age 20 was reported. Of those who reported incontinence, 49.8%, 15.9%, and 34.3% reported pure stress urinary incontinence (SUI), pure urgency incontinence (UI), and mixed incontinence, respectively** (Dooley et al, 2008). Interestingly, there appears to be a racial disparity with regard to pure SUI and pure UI with the odds of pure SUI being at least 2.5-fold higher in white and Mexican-American women than black women (Dooley et al, 2008; Fenner et al, 2008). The NHANES data from 2004-2005 showed that 23.7% of 1961 women described at least one PFD, and the proportion of women who reported a PFD increased with increasing age and body mass index (BMI) (Nygaard et al, 2008).

The overall prevalence of incontinence in community-dwelling men is 17% and varies with age, race, and socioeconomic status (Abrams et al, 2005; Anger et al, 2006). NHANES data revealed an 11% prevalence in those aged 60 to 64 and 31% in men 85 years or older. Daily incontinence occurs in 42% and weekly incontinence in 24%, with only 22% of those who leaked weekly seeking medical care for the problem (Harris et al, 2007). **Unlike in women, there is a prevalence of urgency incontinence (40% to 80%) as compared with mixed incontinence (10% to 30%) or pure SUI (<10%) in men.** Overall prevalence is higher in African-American men (21%) than in white men (16%).

Risk factors for development of POP include advanced age, increased parity (vaginal childbirth), genetic predisposition (Twiss et al, 2007), **estrogen deficiency, compromised pelvic floor muscle strength, and smoking** (Miedel et al, 2009; Samuelsson et al, 2000). Interestingly, recent studies indicate that current or past use of exogenous hormones in the form of oral contraception or hormone replacement therapy may paradoxically serve as a risk factor for the development of urinary incontinence (Samuelsson et al, 2000; Townsend et al, 2009). **In men, comorbidities, poor general health, cognitive impairment, stroke, radiation, urinary tract infections, prostate diseases, and diabetes are all associated with incontinence** (Shamliyan et al, 2009).

One questionnaire study of 4103 women, conducted in a large managed health care plan, found the prevalence of POP to be 6% (Lawrence et al, 2008). This and other studies have evaluated and found a high co-occurrence of PFDs. Lawrence and colleagues (2008) reported a co-occurrence of at least one additional PFD in approximately 80% of women with SUI or overactive bladder (OAB), 69% of women with POP, and 48% of women with anal incontinence. On the basis of the 2005-2006 NHANES data, Nygaard and colleagues (2008) found that the weighted prevalence of at least one PFD was 23.7%, increasing incrementally with age and parity. Although the prevalence of at least one PFD was 9.7% and 49.7% in women between ages 20 and 39 and those aged 80 or older, respectively, the prevalence was 12.8%, 18.4%, 24.6%, and 32.4% for those who had zero, one, two, and three or more deliveries, respectively. De Boer and colleagues (2010) reported a higher prevalence of OAB in patients with POP than in those without POP, although there was no relationship noted to exist between the grade and stage of POP and the presence of OAB symptoms. Wu and colleagues (2009) used U.S. Census Bureau population projections to forecast the change in PFD prevalence in women between 2010 and 2050. The current estimate of 28.1 million women with at least one PFD in 2010 is projected to increase substantially to 43.8 million in 2050.

The impact of PFDs is far-reaching, carrying a significant potential to affect patient quality of life (QoL), notwithstanding the psychologic burden it produces. Additionally, incontinence creates

a tremendous cost to the individual and to society. Hu and colleagues (2004) estimated that the evaluation and management of incontinence and productivity lost due to the condition resulted in a $19.5 billion (year 2000 dollars) cost to society, although sensitivity analysis suggested a potential cost range of between $9.32 and $28 billion. Contemporary numbers might predictably be higher in 2009, although Hu's most recent analysis demonstrated a 26% cost decrease compared with the 1995 report, which estimated $26.29 billion. The decrease was speculated to be due to various factors including decreased hospital stays and adjusted methods of assessing nursing home stays, routine care product use, and prevalence data. Other reports have demonstrated that medical expenditures for incontinence in the female Medicare population nearly doubled between 1992 and 1998, due primarily to increased outpatient expenditure from 9.1% to 27.3% of total Medicare costs in approximately the same time frame (Thom et al, 2005; Anger et al, 2006).

As a result of increasing awareness of the societal impact of PFDs in addition to the growing emphasis on maximizing QoL in our aging population, tremendous research efforts are under way to improve our understanding of the pathophysiology of these disorders, thereby improving both diagnostic and therapeutic techniques. The importance of evidence-based medicine and meticulous follow-up of patients is driving improvement in the science on which advancements in this subspecialty of urology are being made.

DIAGNOSTIC EVALUATION

General Considerations

A recent upsurge in research efforts has resulted in the emergence of new diagnostic and therapeutic techniques to address PFDs. As QoL impact has become a focus, many current research efforts include detailed QoL assessment and attempts to quantify and assess the relationship between PFDs and their effects on QoL. Correlating the bother caused by a given PFD with the risk of available therapies is an important consideration.

The type of incontinence affecting an individual must be defined and quantified in order to guide proper treatment planning. Transient or unrelated conditions that can cause leakage should be identified before proceeding with definitive therapy. Table 64–1 contains a mnemonic of transient causes of incontinence (Resnick, 1984). Table 64–2 lists current International Continence Society (ICS) nomenclature and definitions for types of incontinence (Abrams et al, 2002, 2009b). The terminology continues to adjust to reflect the evolving understanding of the condition. The importance of this flexibility has been realized and acknowledged by leaders in the subspecialty of pelvic floor medicine (Chapple, 2009).

Table 64–1.

Causes of Transient Incontinence (DIAPPERS)

Delerium
Infection (urinary tract infection)
Atrophic vaginitis/urethritis
Psychologic (e.g., severe depression, neurosis)
Pharmacologic
Excess urine production
Restricted mobility
Stool impaction

From Resnick NM. Urinary incontinence in the elderly. Med Grand Rounds 1984;3:281–90.

The classification of POP is categorized according to the affected compartment. Simply put, anterior compartment prolapse (cystocele) generally involves descent of the bladder toward the vaginal lumen, posterior prolapse (rectocele) involves the rectum compressing the posterior vaginal wall into the vagina, and apical prolapse is associated with descent of the uterus (uterine procidentia) and/or the bowel (enterocele) at the top of the vagina. Several grading systems exist to quantify the severity of POP and are discussed later and illustrated in Figure 64–1.

Regarding incontinence specifically, the substantiation of a proper diagnosis requires direct observation of urinary leakage by the clinician (Nitti and Blaivas, 2007). It is the belief of many experts that no patient should undergo invasive or irreversible therapies without definitive establishment of the cause of their incontinence. Complete and extensive evaluation can facilitate accurate diagnosis of PFDs to promote optimal treatment planning and counseling of patients.

HISTORY

A careful history should always be obtained from the patient. However, several studies have indicated that patient history alone is not completely accurate as the

Table 64–2.

Standard International Continence Society Terminology of Lower Urinary Tract Symptoms Pertaining to Continence

TERMINOLOGY	DESCRIPTION
Urinary incontinence	The complaint of any involuntary leakage of urine
Enuresis	Any involuntary loss of urine (should be specified if it is nocturnal)
Urgency	The complaint of a sudden compelling desire to pass urine that is difficult to defer
Urgency incontinence	The complaint of involuntary leakage accompanied by or immediately preceded by urgency
Stress urinary incontinence	The complaint of involuntary leakage on effort or exertion, or on sneezing or coughing
Mixed incontinence	The complaint of involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing
Continuous urinary incontinence	The complaint of continuous leakage
Other types of urinary incontinence	Situational incontinence (e.g., during sexual intercourse or giggle incontinence)
Dependent continence	Situation in which the individual would suffer a recurrence of incontinence if management was withdrawn
Contained incontinence	Situation in which incontinence is controlled by being contained in an absorbent product or collecting device (previously "social continence")
Overactive bladder	Urgency with or without urgency incontinence usually with increased daytime frequency and nocturia

Data from Abrams P, Cardozo L, Fall M, et al. The standardisation of terminology of lower urinary tract function: report from the Standardisation Sub-Committee of the International Continence Society. Neurourol Urodyn 2002;21:167–78 (reprinted in Urology 2003;61:37–49).

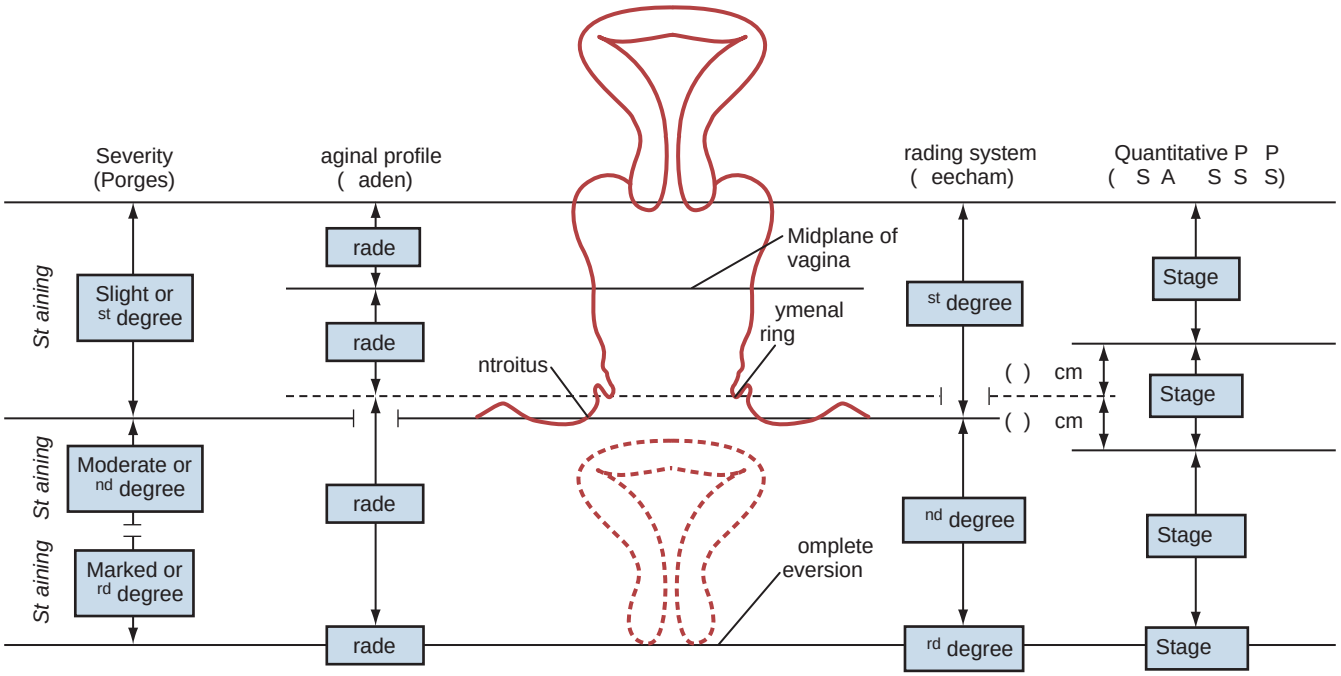

Figure 64–1. Visual comparison of systems used to quantify pelvic organ prolapse (From Theofrastous JP, Swift SE. The clinical evaluation of pelvic floor dysfunction. Obstet Gynecol Clin North Am 1998;25:783–804.)

Key Points: General Considerations

- Pelvic floor disorders (PFDs) are a prevalent worldwide health concern.
- Careful history and physical examination are integral in the proper evaluation of patients with PFDs.
- Supplementary evaluation including urinalysis, postvoid residual, urodynamics, endoscopy, and radiologic imaging can be helpful in arriving at a complete and accurate diagnosis.
- A variety of surgical and nonsurgical treatment options are available for treatment of urinary incontinence and pelvic organ prolapse.

sole determinant of incontinence type (Summitt et al, 1992; Jensen et al, 1994). Bates and colleagues (1973) are credited with the dictum, "The bladder is an unreliable witness," which has been corroborated by many investigators in various forms. **Accordingly, all available information including that which is obtained by supplementary examinations should be integrated into the diagnosis.**

History of Present Illness

A thorough history is imperative in the evaluation of incontinence. Several queries should be included in a continence and pelvic floor history in order to best portray the patient's symptoms (Holroyd-Leduc et al, 2008). **The incontinence should first be characterized subjectively.** Does the leakage occur (1) with physical activity? (2) with a sense of urgency? or (3) without sensory awareness? If the nature of the incontinence is mixed, does one component cause more bother or occur more frequently than the other? **Second, the leakage should be quantified if possible.** Appraisal of the degree of leakage before therapy can be helpful during postoperative assessment of treatment impact. For the purposes of routine outpatient assessment, this quantification can be achieved on the basis of the number of pads used per day or the frequency of clothing changes due to urinary leakage. In the setting of research or an academic practice, more stringent and objective measures such as pad weight testing are often used (see "Supplemental Evaluation" later). **Third, the voiding pattern should be defined.** What is the frequency of urination during the day? During the night? Are there any obstructive symptoms? Does the patient feel as though he or she empties the bladder completely? Is the stream strong or does it "trickle"? Does the stream fluctuate during the void? Is it necessary to push or strain or change posture to void or empty the bladder? **Fourth, establishment of the duration of symptoms and any inciting events that contributed to the onset of leakage is important.** Did the leakage follow a pregnancy or a vaginal delivery? How long ago? Did the leakage start after a strain, a fall, or trauma? Has the patient undergone pelvic or back surgery? In males, has there been any prostate or urethral surgery for benign or malignant disease? Has there been any lower urinary tract instrumentation? Are there any accompanying neurologic symptoms such as numbness or tingling in the extremities, blurry/double vision, balance or coordination changes, or tremor? **Finally, it is helpful to determine the impact that the leakage has on the patient's daily life and activities.** Does the incontinence limit the individual's activity? Has the patient changed his or her lifestyle due to the threat of leakage?

Regarding pelvic prolapse specifically, important questions focus on whether or not the patient is aware of any prolapse and what, if any, symptomatology and bother the prolapse may be causing. Does the patient feel that anything is falling down out of place in the vagina? Does she need to reduce the prolapse for comfort? Or empty her bladder completely? Or facilitate evacuation of her bowels?

Past medical and surgical histories are vital to the assessment of incontinence insofar as medical conditions and surgeries can affect urinary tract function. Childhood and adult urologic history

should be obtained, as should a neurologic history. **Neurologic conditions** such as Parkinson disease, multiple sclerosis, stroke, spinal cord injury, back surgery, and myelodysplasia can have a considerable impact on lower urinary tract (LUT) function. **Medical diagnoses** such as diabetes mellitus and dementia can affect continence. Similarly, a history of **radiation therapy** or neurologic or urologic **trauma** can affect LUT function, specifically with regard to outlet resistance and/or bladder contractility, stability, and compliance. Although outlet resistance may be compromised by trauma or LUT surgery, urethral strictures related to trauma or neurologic dysfunction that abnormally increase outlet resistance during voiding can cause obstruction and secondary symptoms related to the obstruction.

In women the **gynecologic and obstetric history** including gravity, parity, and hormonal status is important. Determination of whether the patient is premenopausal, perimenopausal, or postmenopausal, and whether or not she has used any exogenous hormones such as oral contraceptives or local or systemic hormone replacement therapy can be helpful in her overall assessment. As mentioned earlier, although beneficial effects of local hormone replacement therapy are well-established, there have been reports that exogenous hormone therapy can actually increase the risk of SUI (Townsend et al, 2009).

Clearly, **previous pelvic surgery** can affect LUT function. Anti-incontinence surgery, POP repair, and hysterectomy can contribute to a variety of urinary symptoms in women. Similarly, a history of prostate surgery can give rise to voiding or leakage complaints in men. Abdominoperineal resection can result in neurologic injury that can affect the function of either the bladder or the sphincter (Petrelli et al, 1993), and back surgery can cause a variety of symptoms dependent on the level affected.

Medications

An accurate assessment of medications is critical, particularly in the elderly patient population in whom polypharmacy is common. Many agents can affect urine production, LUT function, and mental status, all of which can have an impact on continence. Special attention should focus on agents that can affect bladder/sphincteric function. Table 64–3 categorizes some commonly used classes of medications by mechanism of action and potential effect on the LUT.

Other

As **genetics** can influence connective tissue integrity, it stands to reason that there may be a potential hereditary role in continence and POP (Twiss et al, 2007). Therefore inquiry about family history of POP may be helpful. Additionally, a thorough review of systems may reveal symptoms that suggest other conditions that could affect pelvic floor function.

Male incontinence, also a prevalent health issue, should be assessed in much the same way as female incontinence, although specific consideration of the impact of the anatomy specific to the male should be considered. **Benign prostatic hyperplasia,** the evaluation of which is covered in detail in Chapter 92, can cause secondary urgency and urgency incontinence in addition to more "typical" obstructive symptoms such as a decreased force of stream, urinary hesitancy, intermittency, and incomplete bladder emptying. **Prostate surgery for benign or malignant disease** can contribute to SUI. With this in mind, full assessment of male LUT symptoms (LUTS) should be performed to facilitate proper treatment planning.

Table 64–3.

Pharmacologic Agents That Can Affect the Lower Urinary Tract

PHARMACOLOGIC EFFECTS	POTENTIAL EFFECTS ON URINARY TRACT
Sympathomimetics	Can increase outlet resistance and exacerbate obstructive symptoms/overactive bladder symptoms Can decrease detrusor contractility and precipitate retention
Sympatholytics	Can decrease outlet resistance and exacerbate stress incontinence
Anticholinergics	Can contribute to urinary retention, particularly in patients with outlet obstruction
Diuretics	Do not affect bladder directly, but because of increased urine production, can aggravate incontinence problems

Key Points: Evaluation—History

- A thorough history is essential in the diagnostic evaluation of patients with PFDs.
- Queries specific to the character, severity, duration, and quantity of incontinence and other symptoms related to pelvic floor function should be presented.
- Attention should be paid to the impact of PFD symptoms on QoL.
- When appropriate, the clinician should present questions specific to the female with potential pelvic organ prolapse and the male with potential prostate issues.
- Queries regarding past medical and surgical history, obstetric and gynecologic history, radiation therapy, trauma, and medications may provide important information.

PHYSICAL EXAMINATION

The general appearance of a patient including details such as age, gait, stature, and fragility can provide important information regarding performance status, neurologic status, and other factors that may direct proper treatment planning. Similarly, an abdominal examination evaluating for incisions, hernias, organomegaly or bladder distention, and habitus is important, particularly if any abdominal surgery may be considered.

Per Medicare coding guidelines (Centers for Medicare/Medicaid, 1997), **a female pelvic examination includes at least 7 of the 11 bullet items listed in** Table 64–4**.** The external genitalia should be evaluated with regard to general appearance, estrogen status, lesions, and labial size and adhesions. **Estrogen status** can be evaluated on the basis of the presence or absence of a urethral caruncle, urethral prolapse, and/or labial adhesions, all of which, if present, may indicate estrogen deficiency. Likewise, attention to the overall tissue appearance and color is important. Hormonally deficient vaginal tissue has a pale, flat, dry appearance with no rugae, as opposed to the healthy, pink rugae of well-estrogenized tissue.

Urethral position and mobility should be assessed at rest and with straining and coughing. The **Q-tip test** was developed to objectify the evaluation of urethral mobility (Bergman and Bhatia, 1987; Walters and Diaz, 1987). The discomfort caused

Table 64–4.

Components of a Focused Pelvic Examination

- Inspection and palpation of breasts (e.g., masses or lumps, tenderness, symmetry nipple discharge)
- Digital rectal examination including sphincter tone, presence of hemorrhoids, rectal masses

Pelvic examination (with or without specimen collection for smears and cultures) including:

- External genitalia (e.g., general appearance, hair distribution, lesions)
- Urethral meatus (e.g., size, location, lesions, prolapse)
- Urethra (e.g., masses, tenderness, scarring)
- Bladder (e.g., fullness, masses, tenderness)
- Vagina (e.g., general appearance, estrogen effect, discharge, lesions, pelvic support, cystocele, rectocele)
- Cervix (e.g., general appearance, lesions, discharge)
- Uterus (e.g., size, contour, positions, mobility, tenderness, consistency, descent or support)
- Adnexa/parametria (e.g., masses, tenderness, organomegaly, nodularity)
- Anus and perineum

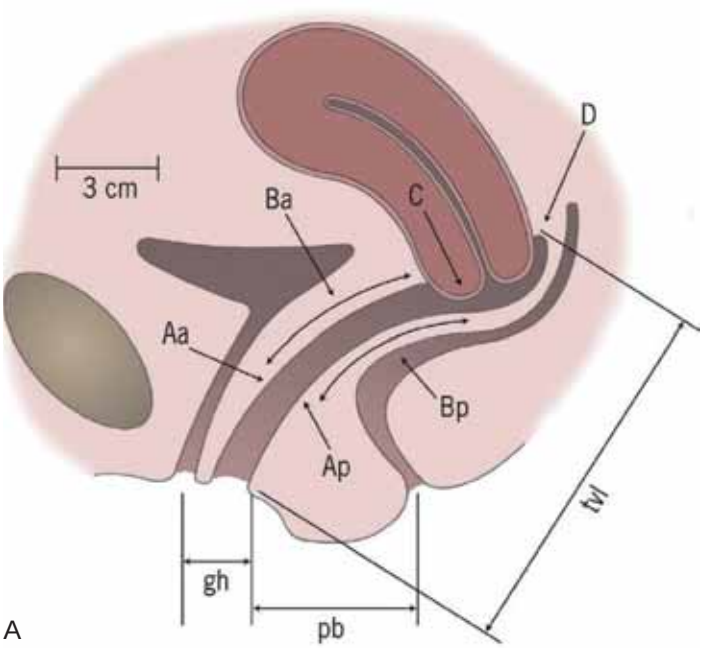
At press time, 7 of 11 bullet points listed above are required to be considered a complete female genitourinary examination. However, other organ systems/body areas not limited to the genitourinary system may be included in a report to accomplish the requirements of various levels of examination.

Data from Centers for Medicare/Medicaid (CMS): Single organ system examination—Genitourinary: 1997 Documentation Guidelines for Evaluation and Management (E/M) Services, jointly approved by the American Medical Association and HCFA with revisions November, 1997.

to the patient during insertion of the Q-tip can be minimized with the use of intraurethral lidocaine jelly. The Q-tip is inserted into the bladder through the urethra, and the angle that the Q-tip moves from horizontal to its final position with straining is measured. Hypermobility is defined as a Q-tip angle of greater than 30 degrees from horizontal.

Assessment of prolapse should ideally be performed in both the lithotomy and standing positions, the latter facilitated by having the patient stand with one foot elevated on a short stool. Each compartment—the anterior, posterior, and apical (uterus/cervix or vaginal cuff)—should be evaluated methodically and the perineal body assessed for laxity. A complete systematic examination is performed using two posterior blades of a split Grave speculum with and without straining. First, one blade is used to retract the posterior wall to facilitate anterior compartment examination. The blade is then repositioned to retract anteriorly for examination of the posterior compartment. Finally, both blades are inserted simultaneously, one anteriorly and one posteriorly, to isolate the vaginal apex and facilitate examination of the cervical or cuff support. The posterior blade is slowly withdrawn to examine the posterior wall. Next, with the posterior blade in place, the patient is asked to strain. Foreshortening of the posterior wall causes expulsion of the blade and suggests a compromise in the level I support (Delancey, 1992) (cardinal-uterosacral ligament complex) of the vault; if the blade remains in place, this could represent an isolated rectocele or enterocele without vault prolapse. Evaluation for occult SUI should be performed with the anterior wall supported. SUI can be masked if significant prolapse "kinks" the urethra and outlet.

Several classification systems are used to quantify POP, the most widely used of which are the **Baden-Walker classification** (Baden et al, 1968) and the **Pelvic Organ Prolapse Quantification system,** known as the "POP-Q" (Bump et al, 1996). The



A

Point	Description	Range of values
Aa	Anterior vaginal wall cm proximal to the hymen	cm to cm
a	Most distal position of remaining upper anterior vaginal wall	cm to tvl
	Most distal edge of cervix or vaginal cuff scar	
D	Posterior fornix (N A if post hysterectomy)	
Ap	Posterior vaginal wall cm proximal to the hymen	cm to cm
p	Most distal position of remaining upper posterior vaginal wall	cm to tvl
gh (genital hiatus)	Measured from middle of external urethral meatus to posterior midline hymen	
pb (perineal body)	Measured from posterior margin of gh to middle of anal opening	
tvl (total vaginal length)	Depth of vagina when point D or is reduced to normal position	

Figure 64–2. **A,** Landmarks for the POP-Q system. **B,** POP-Q Points of Reference. (**A,** From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. Am J Obstet Gynecol 1996;175:10–7.)

two systems are juxtaposed in Figure 64–1. **In the POP-Q system, which was created in an effort to provide objectivity to POP quantification, nine specific points of measurement are obtained in relation to the hymenal ring as illustrated in** Figure 64–2A and B. Six vaginal points labeled Aa, Ba, C, D, Ap, and Bp are measured during Valsalva maneuver. Points above the hymen are considered negative and points below the hymen are positive. The genital hiatus (gh) represents the size of the vaginal opening, and the perineal body (pb) represents the distance between the vagina and the anus. The total vaginal

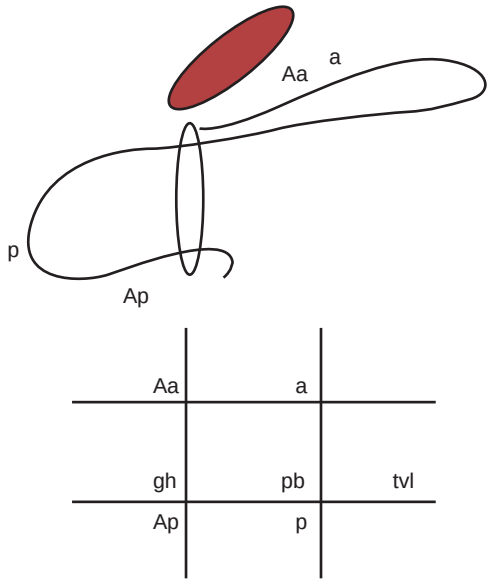


Figure 64–3. Line drawing example of posterior support defect. The anterior compartment is well supported. The leading point of the prolapse is point Bp (+5), which is 5 cm beyond the hymen. Total vaginal length is 8 cm, and point C (–6), the cuff position, has descended 2 cm. (From Bump RC, Mattiasson A, Bo K, et al. The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. Am J Obstet Gynecol 1996;175:10–7.)

Table 64–5.

POP-Q Staging Criteria

STAGE	CRITERIA
0	Aa, Ap, Ba, Bp at –3 cm *and* C or D ≤ –(tvl – 2) cm
I	Stage 0 criteria not met and leading edge < –1 cm
II	Leading edge ≥ –1 cm but ≤ +1 cm
III	Leading edge > +1 cm but < +(tvl – 2) cm
IV	Leading edge ≥ +(tvl – 2) cm

length (tvl) is measured by reducing the prolapse and measuring the depth of the vagina. Table 64–5 contains the **POP-Q staging criteria,** a simplified presentation of the POP-Q system, and Figure 64–3 illustrates an example of the application of the system.

A **neurologic examination** is important in any patient with a known or suspected neurologic condition. Attention to the patient's gait, speech, cognitive status, facial symmetry, sensation in the lower extremities, perineal and perianal regions, lower extremity motor strength, and vaginal and pelvic floor strength can provide helpful information. Mobility and cognitive status can play a role in urinary continence insofar as both can affect a patient's ability to reach the facilities in a timely fashion. The **bulbocavernosus reflex (BCR),** which is representative of sacral nerve root levels 2-4 (S2-4), is present in 70% of normal females and 100% of normal males. The BCR is considered positive when squeezing of the glans penis or clitoris results in anal and pelvic floor contraction that can be detected visually or by rectal examination. Alternatively, applying traction to an indwelling Foley catheter to pull the balloon against bladder neck should also precipitate a BCR.

A **digital rectal examination (DRE)** is important in men to assess the prostate for size, nodularity, or tenderness. In the female, the DRE can facilitate assessment of the rectovaginal septum. Demonstration of a rectocele can be facilitated via anterior pressure applied by a finger placed in the rectum. Anal sphincter tone, which is a reflection of the function at S2-4, is particularly important in neurologic patients with PFD. Patients are asked to voluntarily tighten the pelvic floor as if attempting to stop the flow of urine midstream. Laxity in the rectal sphincter tone may suggest a possible neurologic defect, but it may also be due to patient lack of understanding regarding how to voluntarily control the specific muscle groups necessary for contraction.

In men, genitourinary examination as it pertains to voiding function should also include evaluation of the penis for meatal stenosis and, particularly in the post-prostatectomy patient, visible urinary leakage with coughing and straining. Examination for leakage is ideally performed with the patient in the standing position.

Key Points: Evaluation—Physical Examination

- A properly performed physical examination is imperative in the evaluation of patients with PFDs.
- The Centers for Medicare/Medicaid require specific elements of both male and female genitourinary examination in order to meet coding guidelines (see Table 64–4).
- Assessment of pelvic organ prolapse (POP) should ideally be performed in both the supine and standing positions.
- Several classification and quantification systems are available for assessment of POP, the most widely used of which (Baden-Walker and POP-Q) are illustrated in Figures 64–1 and 64–2.
- A neurologic examination and rectal examination should be performed in appropriate patients in order to obtain complete clinical information important in the assessment of lower urinary tract and pelvic floor function.

SUPPLEMENTAL EVALUATION

A variety of measures are available to supplement the history and physical examination in patients with PFDs. Instruments exist to quantify symptoms, their effects on QoL, and the degree of bother experienced by patients with PFDs. **Most experts concur that a urinalysis and postvoid residual measurement should be considered in the majority of patients undergoing evaluation for incontinence. However, beyond this, there are no universally agreed-upon guidelines regarding the roles of other studies, such as endoscopy, urodynamics (UDS), and various modalities of radiographic imaging.** In circumstances in which further investigation is considered, the value and accuracy (sensitivity and specificity) of the information provided by the given assessment method should be considered in relation to the cost and morbidity of the examination.

Symptom Quantification Instruments

Voiding Diaries

Instruments such as voiding diaries, questionnaires, and pad tests have been developed to aid in the quantification of urinary loss, both symptomatically and volumetrically. **Voiding diaries can provide both diagnostic and therapeutic advantages. The use of diaries often helps patients realize their**

pattern of urination and is more accurate than recall (Larsson et al, 1984; McCormack et al, 1992; Siltberg et al, 1997). **Furthermore, the diary can provide patients with insights into those behaviors that can be altered to decrease urinary frequency** (Burgio, 2004).

Several studies have demonstrated the adjunctive role that diaries can have in the diagnosis and management of incontinence. Diaries can be helpful over routine subjective history because patient recall is often not as accurate as a formal voiding diary in ascertaining urinary frequency. In a retrospective review of 601 patients who underwent sling surgery and completed bladder diaries, only 47% were accurate about their daytime frequency; 51% overestimated their diurnal frequency, and this overestimation was exaggerated in those who reported voiding more than 10 times a day (Stav et al, 2009). Overestimation rates were similar between patients with and without overactive bladder (OAB) symptoms. Interestingly, 93% of women in this study were accurate about their nighttime frequency. In another study of women with UI, it was noted that the overestimation of incontinence episode frequency occurred more often in those patients who were more bothered by their incontinence. Conversely, Ku and colleagues (2004) found a poor correlation between subjective nocturnal frequency and that noted by 164 patients on their frequency volume charts. Wyman and colleagues (1987) similarly showed a higher correlation of diary-reported frequency in the daytime versus the night.

Martin and colleagues (2006) performed a meta-analysis of 121/6099 papers that compared two or more diagnostic techniques for incontinence and showed that diaries are most cost-effective when used in conjunction with history, particularly in patients undergoing treatment for detrusor overactivity (DO). It should be noted, however, that diaries should not substitute for more formal studies in select patients. One study that retrospectively assessed the Larsson frequency/volume chart as compared with the cystometrogram in 216 patients demonstrated the sensitivity and specificity of the chart with regard to DO to be 52% and 70%, respectively, and with regard to SUI, 66% and 65%, respectively (Tincello and Richmond, 1998). For daily clinical practice, 24-hour diaries should suffice to obtain valuable clinical information regarding LUT function; in academic studies, longer diaries may be requested, but this should be balanced with the well-established knowledge that the more complex a given instrument is (i.e., the more data requested), the lower patient compliance will be in completing it (Groutz et al, 2000).

Questionnaires and Quality of Life Instruments

Questionnaires can provide a helpful complement to the patient history and patient-reported outcomes (PROs). A plethora of instruments to evaluate symptoms, degree of bother, and QoL in patients with incontinence and PFDs have been developed in an effort to provide optimal assessment of outcomes and to eliminate the confounding issue of physician bias; many have been validated. Table 64–6 contains validated questionnaires highly recommended by the International Consultation on Incontinence (ICI). One such instrument, the modular ICIQ, was developed by the ICI in an effort to collaboratively develop a universally applicable instrument that could be used internationally to assess pelvic floor function in both clinical practice and research settings (Abrams et al, 2005) and has accordingly been translated in 38 languages. The short form of the ICI questionnaire (ICIQ-SF) has been shown to correlate nicely with both the 1-hour (Franco et al, 2008) and 24-hour (Karantanis et al, 2004) pad test for evaluation of the severity of SUI. Another comparison of the 24-hour pad test, the ICIQ-SF, the International Prostate Symptom Score (IPSS), and the Postoperative Patient Global Impression of Improvement (PGI-I) score in 26 men following perineal sling placement confirmed the construct validity of these instruments (Twiss et al, 2007). There was a strong correlation demonstrated between the ICIQ-SF and PGI-I scores and the percentage reduction in 24-hour pad weight. Appendices 1 to 6 on the Expert Consult website contain the ICIQ-MLUTS (male LUTS), ICIQ-FLUTS (female LUTS), ICIQ-SF (short form), ICIQ-OAB (overactive bladder), ICIQ-VS (vaginal symptoms), and the recently developed ICIQ-B (bowel). At the time of this writing, additional modules covering QoL, sexual function, pediatric LUTS, neurogenic LUTS, nocturia, and bowel function are available or are in development and are or will be available through the ICI (2010).

A study examining the incontinence- and nonincontinence-related pelvic floor symptoms evaluated by two widely used symptom tools, the UDI-6 and the ICIQ-UI, demonstrated that both symptom questionnaires were sound and correlated with each other and independently with the QoL scores, as measured by the IIQ-7 and IQOL (van de Vaart et al, 2010). This study also uncovered the interesting finding that the delay in time to consultation with a physician was associated with greater bother, emphasizing the importance of heightened awareness of PFDs in the female patient population.

In Martin's meta-analysis, two studies showed a high sensitivity (0.82 to 0.92) of question 3 in the Urogenital Distress Inventory for SUI; the specificity was 0.51 to 0.69 (Martin et al, 2006). In this study, history alone had a pooled sensitivity of 0.92 (95% CI) and a specificity of 0.56 for the diagnosis of SUI and a sensitivity of 0.61 and specificity or 0.87 for the diagnosis of DO. **It should be borne in mind, however, that for higher-risk interventions such as surgery, the most accurate testing available remains multichannel UDS studies.**

Pad Tests

Pad tests are generally used for academic purposes. **The ICS recommends both a three-day bladder diary and pad weight test as proper measures for symptom quantification in incontinence research** (Lose et al, 2001). However, although pad tests can be helpful in quantifying leakage, they are tedious and cumbersome for the patients. Moreover, they do not provide information that is necessary for daily routine clinical practice. **The Fourth ICI Committee on initial assessment did not recommend pad tests as part of the initial evaluation in the incontinent patient** (Staskin, 2009). **From an *academic* standpoint, however, many investigators advocate for pad tests in clinical trials because pad tests can provide objective, precise information for assessment of actual volume of urine lost over an established period of time.**

According to the Third ICI, greater than 1.3 g of urine loss is considered a "positive" 24-hour pad test (Tubaro, 2005), **whereas others consider up to 8 g of urine loss in 24 hours to be normal** (Lose et al, 1989). Vaginal secretions should also be taken into consideration, although the volume attributable to normal vaginal secretions may be as low as 0.3 g in 24 hours (Karantanis et al, 2003). O'Sullivan et al (2004) evaluated 110 women with incontinence with two 1-hour pad tests and 7 consecutive days of 24-hour pad tests. The severity of the leakage

Table 64–6.

Instruments Highly Recommended by the International Consultation on Incontinence (Fourth ICI) for Urinary Incontinence, Overactive Bladder (OAB), Lower Urinary Tract Symptoms (LUTS), and Pelvic Organ Prolapse Patient Reported Outcomes (PRO)

QUESTIONNAIRE	POPULATION	PURPOSE OF INSTRUMENT
Health-Related Quality of Life (HRQOL)		
BFLUTS (Bristol Female Lower Urinary Tract Symptoms Questionnaire) aka ICIQ-FLUTS (Jackson et al, 1996)	Women, incontinence	To assess female LUTS, particularly incontinence, measure impact on QOL and evaluate treatment outcome
DAN-PSS-1 (Danish Prostatic Symptom Score) (Hansen et al, 1995)	Men, BPH	To evaluate males with LUTS suggestive of uncomplicated BPH
ICIQ-UI-SF (ICIQ Urinary Incontinence Short Form) (Avery et al, 2004)	Men and women, urinary symptoms	To assess symptoms and impact of urinary incontinence in clinical practice and research
ICSmale (ICIQ-MLUTS) (Donovan et al, 1996)	Men with LUTS and possible BPH	To provide evaluation of occurrence and bothersomeness of LUTS and their impact on the lives of men with BPH
ICS-QoL (Donovan et al, 1997)	Men with LUTs and possible BPH	To assess impact of LUTS on the lives of men with LUTS
IIQ (Incontinence Impact Questionnaire (Wyman et al, 1988)	Women, UI, SUI	To assess impact of incontinence on HRQOL, primarily in patients with SUI
IIQ-7 (IIQ-short form) (Uebersax et al, 1995)	Women, UI, SUI	To assess impact of urinary incontinence on HRQOL
I-QOL (ICIQ-Uiqol) (Urinary incontinence-specific QoL instrument) (Wagner et al, 1996)	Women, UI	To assess AOL of women with urinary incontinence
KHQ (King's Health Questionnaire) (ICIQ-LUTSqol) (Kelleher et al, 1997)	Men and women, OAB	To assess the impact of LUTS on HRQOL
N-QoL (ICIQ-Nqol; Nocturia QOL) (Abraham et al, 2004)	Men and women	To assess the impact of nocturia on QOL
OABq-SF (Coyne et al, 2002)	Men and women, OAB	Shortened version of OAB-q to evaluate both continence and incontinence symptoms of OAB and their impact on QOL
OAB-q (ICIQ-OABqol) (Coyne et al, 2002)	Men and women with OAB wet and OAB dry	To evaluate both OAB-wet and OAB-dry symptoms and their impact on HRQOL
PRAFAB (Protection, Amount Frequency, Adjustment, Body image) (Hendriks et al, 2007)	Women, UI	To evaluate treatment effects for UI in women
UISS (Urinary incontinence severity score) (Stach-Lempinen et al, 2001)	Women, UI	To assess symptom severity and impact of urinary incontinence on everyday life
Urolife (BPH-QoL9) (Lukacs et al, 1997)	Men, BPH	To assess the impact of BPH and its treatment on the QOL of patients
Screeners		
B-SAQ (Bladder-Self-Assessment Questionnaire) (Basra et al, 2007)	Women	Screening tool for the presence of bothersome LUTS in women
LUSQ (Leicester Urinary Symptom Questionnaire) (Shaw et al, 2002)	Men and women, LUTS	Condition-specific screener of storage LUTS (urgency, frequency, nocturia, and incontinence)
OAB-SS (OAB Symptom Score) (Blaivas et al, 2007)	Men and women, LUTS with and without OAB	7-item tool to measure overall symptom severity due to the 4 index symptoms of OAB
OAB-V8 (OAB Awareness Tool) (Coyne et al, 2005)	Men and women, OAB	8-item screening tool for use in primary care setting to identify patients who may have OAB
QUID (Questionnaire for Urinary Incontinence Diagnosis) (Bradley et al, 2005)	Women, UI and SUI	6-item tool to diagnose SUI and UI
Symptom Bother		
PPBC (Patient Perception of Bladder Condition) (Coyne et al, 2006)	Men and women	To assess patients' subjective impression of their current urinary problems. Developed as a global assessment of bladder condition
UDI-6 (Urogenital Distress Inventory-6/short form) (Uebersax et al, 1995)	Women	To assess LUTS bother, including incontinence, in women
Urgency		
IUSS (Indevus Urgency Severity) (Nixon et al, 2005)	OAB with urgency incontinence, men and women	To quantify the level of urgency associated with each toilet void as measured during standard voiding diaries
POP Symptoms and QOL		
PFDI (Pelvic Floor Distress Inventory) (Barber et al, 2001)	Women	To quantify the symptoms caused by pelvic prolapse
PFIQ (Pelvic Floor Impact Questionnaire) (Barber et al, 2001)	Women	To quantify the effects of pelvic prolapse on quality of life

BPH, benign prostatic hypertrophy; HRQOL, health-related QOL; ICIQ, International Consultation on Incontinence Questionnaire; ICS, International Continence Society; MLUTS/FLUTS, male/female lower urinary tract symptoms; OAB, overactive bladder; QoL, quality of life; SF, short form; SUI, stress urinary incontinence; UI, urgency incontinence.

Data from Staskin DR. In: Patient-Reported Outcome Assessment. Fourth International Consultation on Incontinence, report of Committee 5, part 5B. 2009. p. 363–412.

was analyzed in relation to UDS parameters, age, parity, and pelvic floor muscle strength, showing increased severity with increasing age and parity and in those women who demonstrated DO. The authors proposed that 24-hour loss of 1.3 to 20 g, 21 to 74 g, and greater than 75 g signifies "mild," "moderate," and "severe" incontinence, respectively. Another study of 144 randomly selected Danish women who underwent 24-hour pad testing revealed a similar loss of urine in the self-reported continent and incontinent groups, or 3.1 and 3.3 g, respectively (Ryhammer et al, 1998).

It is generally agreed that the 24-hour pad test is a clinically more useful tool than the 1-hour pad test (Lose et al, 1989; Matharu et al, 2004); in fact, the test-retest reliability and the predictive value of the 1-hour test in the diagnosis of female incontinence has been shown to be poor (Lose et al, 1986; Lose et al, 1988; Simons et al, 2001; Constantini et al, 2008). Others have advocated the opposite extreme, suggesting that a 20-minute pad test with a standardized bladder volume of 250 mL instilled into the bladder via catheterization had superior sensitivity as compared with the 1-hour test conducted via the ICS standardized method of pad testing (Wu et al, 2006). The ICS method, described in 1988, requires the patient to drink 500 mL of sodium-free liquid in 15 minutes followed by a 30-minute resting period before proceeding with the recommended physical activity (Abrams et al, 1988). One potential concern about this method is the lack of standardization of bladder volume.

Parenthetically, pad use per day (PPD) obtained via patient history is a measure frequently used to quantify urine loss, but one study demonstrated that this is an unreliable measure of incontinence (Dylewski et al, 2007). A retrospective chart review of 145 males and 116 females who underwent artificial urinary sphincter placement and sling surgery, respectively, and who had completed a self-reported pad-use query was performed, and the patients were asked to bring three pads into their clinic visit: one dry "reference" pad and the incontinence pads used for the 24-hour periods preceding and including the day of their visit. The pads were quantified and weighed to determine the grams of urine per pad (GPP). All patients also underwent a 24-hour pad weight test. Only a weak correlation was found between reported pad usage and the 24-hour pad weight, with pad usage measuring only 38% of the variability of incontinence volume. Additionally, although the PPD decreased, the GPP increased with increasing age.

Dye Testing

Dye testing can be helpful to verify that the leakage represents urine versus another fluid such as vaginal discharge or peritoneal fluid and to substantiate the diagnosis of urinary tract fistulae. **Oral phenazopyridine** 200 mg three times a day colors the urine orange, and this simple test can confirm that the leaking fluid is indeed urine. Diagnosis of a vesicovaginal or urethrovaginal fistula can be supported by blue or orange staining of an intravaginal tampon following **intravesical instillation of methylene blue or phenazopyridine hydrochloride (Pyridium) dissolved in sterile water or saline.** In the case of a suspected *ureter*ovaginal fistula, **intravesical methylene blue with concurrent oral Pyridium** can elucidate the fistula location on the basis of the staining pattern on the vaginal tampon. Orange staining suggests a ureteral communication, whereas blue staining connotes a bladder communication (Raghavaiah, 1974). The clinician must keep in mind that simultaneous vesicovaginal and ureterovaginal fistulae can occur.

Key Points: Supplementary Evaluation

- It has been demonstrated that patient subjective history alone often does not reflect an accurate or complete picture of their symptomatology complex.
- Several instruments designed to facilitate symptom quantification have been developed and include tools such as voiding diaries, symptom and QoL questionnaires, and pad tests.
- Voiding diaries can be both diagnostic and therapeutic because they can provide patients with insights into behaviors that may be contributing to their voiding symptoms.
- Pad tests may be helpful, particularly in the academic setting, to quantify incontinence symptoms. Loss of up to 8 g of urine in 24 hours may be considered normal, although the International Consultation on Incontinence (ICI) considers loss of greater than 1.3 g to be a positive 24-hour test.
- Validated questionnaires are available to assess symptoms and quality of life in patients with PFDs.

Urinalysis

It is generally agreed that urinalysis plays a fundamental role in the evaluation of the incontinent patient or the patient with lower urinary tract symptoms (LUTS) (Abrams et al, 2009a). The urinalysis provides information such as the presence of hematuria, pyuria, glucosuria, or proteinuria that can be indicative of conditions that can cause *secondary* incontinence. As indicated by the screening dipstick analysis, a microanalysis and/or culture should be performed that may provide guidance regarding further testing or therapy for conditions related to or independent of urinary incontinence.

Postvoid Residual

The volume of urine left in the bladder following routine voiding is termed the postvoid residual (PVR) and should be evaluated in all incontinent patients (Tubaro, 2005; Gormley, 2007). This simple test, which can be performed via in-and-out catheterization or using noninvasive transabdominal ultrasonography, evaluates the bladder's emptying ability and can be helpful in the diagnosis of overflow incontinence. **It is also essential to establish baseline bladder emptying, particularly in stress incontinent patients who may be considered for an anti-incontinence procedure or patients with urinary urgency who may be candidates for therapies aimed at decreasing bladder contractility.**

A number of studies have demonstrated that ultrasound is comparable to catheterization in evaluating the PVR, although **there are no officially established volumes that define normal or impaired emptying.** The Agency for Healthcare Policy and Research (AHCPR) suggests that PVR less than 50 mL represents adequate emptying and PVR greater than 200 mL represents inadequate emptying (U.S. Department of Health and Human Services, 1992). There is no consensus recommendation regarding the significance of PVR between 50 and 200 mL. In one study, Gehrich and colleagues (2007) enrolled 96 healthy women who presented for routine "well-women" checkups. Exclusion criteria included urinary incontinence more than twice a week, urinary retention, neurologic disease, or symptomatic POP. The mean and median PVRs were 19 mL (0 to 145 mL) and 24 ± 29 mL. Fifteen percent

had PVR greater than 50 mL, and 95% had PVR less than 100 mL. Another study compared PVR measurements obtained by 3-D bladder scan versus catheterization in 170 women who were undergoing evaluation for SUI but who had never undergone previous pelvic surgery (Tseng et al, 2008). In addition, 35.5% had PVR greater than 50 mL and 15.9% had PVR greater than 100 mL. Ultrasound offered a sensitivity of 64.7% and a specificity of 94.3% in detecting PVR greater than 100 mL. Although several studies support the accuracy of the bladder scan (Al-Shaikh et al, 2009), some suggest that certain sonographic devices may provide more accurate information than others (Ghani et al, 2008).

Cystoscopy

Endoscopic examination of the bladder is important as a means to evaluate for intravesical or intraurethral pathology that may be contributing to the patient's symptomatology. Bladder tumors, bladder stones, cystitis, and intravesical or intraurethral foreign bodies such as mesh or suture can contribute to irritative voiding symptoms, recurrent urinary tract infections (UTIs), and incontinence. Patients with a history of previous pelvic floor reconstructive surgery should be evaluated for eroded materials into the LUT. The ureteral orifices should be identified and evaluated for morphology, position, number, and efflux. The bladder mucosa is examined for trabeculation (which can be indicative of bladder outlet obstruction [BOO] and/or overactivity) and estrogen status, and the urethra is assessed for foreign bodies, stricture, diverticulum or fistula, and position.

The role of preoperative cystourethroscopy has been addressed by few authors. Anger and colleagues (2007) analyzed Medicare claims data to assess the effects of preoperative cystoscopy and UDS studies on sling outcomes. The data of a random 5% sample of Medicare beneficiaries during an established 18-month period were used to assess the likelihood of undergoing postoperative studies in those who did and did not undergo the same studies preoperatively. Although patients who underwent preoperative cystoscopy were less likely to undergo postoperative cystoscopy (23.4% vs. 35.2%, $P < 0.0001$) or UDS (19.3% vs. 34%, $P < 0.0001$), there were no significant differences in complications or repeat incontinence procedures between the groups. However, Cundiff and Bent (1996) reported that cystoscopy changed the diagnosis and management in 6 of 84 women (7%) who underwent both cystoscopy and UDS for evaluation of LUT dysfunction. Findings included transitional cell carcinoma, cystitis glandularis, intravesical suture, and a urethral diverticulum.

Although the use of routine cystoscopy in the evaluation of the "index" stress urinary incontinence patient is controversial, it should be performed in patients who present with urinary urgency, hematuria, or other irritative symptoms, particularly if they have previously undergone a previous anti-incontinence procedure, pelvic radiation, or pelvic prolapse repair.

Urodynamics

Similar to cystourethroscopy, the routine use of UDS is the subject of much debate; however, one should strongly consider UDS in patients who have failed previous pelvic floor reconstruction or who complain of mixed incontinence, urinary urgency, or obstructive symptoms, and in those who have elevated PVRs or neurologic disease. The benefit of UDS in these situations is to establish baseline bladder capacity, compliance, sensation, stability, and sphincter function before further surgical or therapeutic manipulation. A comprehensive review of UDS is presented in Chapter 62.

LUT function can be simply categorized into storage and emptying. Each of these categories is affected by the bladder (detrusor) and the outlet. **Two main questions should be considered in the evaluation of the incontinent patient: (1) Is the problem at hand a storage issue, an emptying issue, or a combination of the two? *and* (2) Is the etiology of the first question due to a detrusor issue, an outlet issue, or a combination of both?**

"Eyeball UDS" is a simple economically favorable alternative to full multichannel UDS that can be helpful in selected patients. The study can determine bladder sensation, compliance, stability, and capacity, as well as outlet competence and PVR. Following voiding, the patient is placed in the lithotomy position and a Foley catheter is placed and the PVR measured. A 60-mL catheter tip syringe with the barrel removed is placed into the end of the catheter. With the syringe held upright, the bladder is filled with sterile fluid through the syringe. The height of the meniscus above the bladder represents the intravesical pressure. The volumes at first sensation, sensation to void, and strong sensation are recorded. During the filling phase, the meniscus in the syringe is observed for a rise and fall that may represent bladder overactivity or a consistent gradual rise that suggests compromised detrusor compliance. The catheter is removed, and a cough stress test is performed by observing the urethra for incontinence during coughing and straining.

Multichannel UDS offers an extensive evaluation of LUT function. This degree of accuracy is important in a variety of circumstances including when conservative treatment methods fail, when the diagnosis is unclear or when previous diagnostic procedures are inconclusive, in patients with clinical pictures complicated by radiation therapy, neurologic disease, or prior failed pelvic floor reconstruction or anti-incontinence surgery, or when patients describe symptoms that cannot be confirmed by the clinician. A complete UDS study evaluates the ***filling/storage phase*** by filling cystometrogram and the ***voiding/emptying phase*** by uroflowmetry.

Catheters are placed into the bladder and the rectum. The bladder catheter measures the actual pressure within the bladder, termed the *vesical pressure* (Pves). The rectal catheter measures the abdominal pressure (Pabd). The detrusor pressure (Pdet) is a calculated value (Pves – Pabd) that represents the pressure created by the detrusor independent of the influences of intra-abdominal pressure. During the filling phase, the Pdet is expected to remain low and stable to allow for low-pressure bladder filling. Poorly compliant bladders will show a gradual steady rise in the Pdet as the bladder volume increases. Detrusor overactivity is manifest by intermittent and unpredictable rises in the Pdet. During the voiding phase, the Pdet may rise as the urine flows. Many women normally void with virtually no rise in Pdet. High Pdet with low flow during voiding suggests BOO. Inability to produce a flow with no Pdet, particularly when accompanied by abdominal straining (represented by an undulant Pabd), may indicate an atonic or hypotonic detrusor.

Electromyogram (EMG) and fluoroscopic imaging ("videourodynamics," VURDS) are helpful adjuncts to the UDS study in selected patients and are covered in detail in Chapter 62. EMG activity is reflective of the activity of the striated muscles of the urethral and anal sphincters and the perineal musculature and can be measured using either surface electrodes or needle electrodes. Although the latter provides more accurate

readings, the discomfort caused to the patient and the expertise required for the technique render it far less popular than surface electrodes. The coordination of the EMG and detrusor activity is most helpful during the voiding phase, when failure to relax the pelvic floor can be indicative of pathology. Similarly, recruitment of activity should be noted with BCR and increased abdominal pressure, such as occurs during coughing. VURDS can be useful in the demonstration of anatomy in the upright position, and because the bladder and outlet are visualized "real time," VURDS can confirm incontinence in patients in whom the diagnosis is difficult and can provide an accurate measure of leak point pressure. It is also helpful to assess the bladder outlet in patients in whom detrusor-sphincter dyssynergia or primary bladder neck obstruction is suspected. Patients can be evaluated for vesicoureteral reflux (VUR). Assessment of detrusor pressures in the face of reflux can provide important information that would be missed without video-imaging.

Recent attention has been placed on scientifically establishing the role and clinical value of UDS. The worth of a test is not solely in its diagnostic accuracy but also in the improvement of the outcomes of subsequent interventions. UDS is frequently used in the evaluation of patients with PFDs. Suboptimal outcomes of anti-incontinence procedures are generally attributed to intrinsic sphincter deficiency (ISD), DO, or baseline dysfunctional voiding. The deliberation regarding the merit of these theories and the ability of UDS to accurately establish these conditions continues. In a study of 655 women with positive stress tests, 10% did not demonstrate urodynamic-SUI (UDS-SUI) (Nager et al, 2007). A meta-analysis based on a Medline search of the literature between 1975 and 1998 suggested that UDS has a positive predictive value (PPV) of only 56% and 79% for pure SUI and SUI with other abnormalities, respectively, while a positive cough test has PPVs for the same of 55% and 91%, respectively (Harvey and Versi, 2001). The Urinary Incontinence Treatment Network (UITN) reported that UDS did not predict postoperative voiding dysfunction or the risk for need of postoperative surgical intervention (Lemack et al, 2008). In another retrospective study in women who underwent retropubic midurethral sling placement for treatment of mixed incontinence, the median opening detrusor pressure was higher in women with postoperative DO than in those with normal postoperative UDS (Panayi et al, 2009).

Much of the literature to date has been limited by the retrospective design and small cohorts of the available studies. The UITN found that the success of anti-incontinence surgery in patients who demonstrated UDS-SUI was nearly twice that of those with non-UDS-SUI (type 0 SUI), although this trend did not reach statistical significance (Nager et al, 2008). Similarly, although the study by Anger and colleagues (2007) did not definitively establish an effect of preoperative UDS specifically on sling outcomes, there was a clear demonstration of a twofold (significant) increased likelihood of undergoing postoperative UDS studies in those patients who did not undergo the study preoperatively as compared with those who did.

With healthcare reform increasingly at the forefront of discussion, cost-effectiveness continues to be a subject of great debate. On the basis of decision-analytic (hypothetical) models, one group deemed UDS not cost-effective relative to the basic office evaluation (Weber and Walters, 2000; Weber et al, 2002). However, one must remain mindful that UDS provides information, not only about the overall diagnosis but also regarding important subtle findings that may direct the clinician in treatment planning and counseling (Summitt et al, 1992; Patel and Chapple, 2008). Although it has been suggested that UDS may not be necessary or useful in straightforward, non-neurologic patients who would be considered for initial conservative management (Colli et al, 2003; NICE, 2006), others have shown that up to 20% of patients with presumed pure SUI may have UDS findings that might alter their treatment or outcomes (Digesu et al, 2009).

Reproducibility of UDS studies, as well as the interpretation of the examination, has been questioned by several studies (Van de Beek et al, 1997; Gupta et al, 2004; Zimmern et al, 2006; Gacci et al, 2007). Others have demonstrated that intraobserver (interpretation repeated by the same individual) interpretation is superior to interobserver (same study read by two different individuals) interpretation for both pressure-flow analyses (Digesu et al, 2003) and filling/voiding studies (Whiteside et al, 2006). Still others have demonstrated no difference in interobserver and intraobserver interpretation, but that live interpretation of a study provides different readings than post hoc interpretation, suggesting that intangible experiential factors may play a role in the interpretation of UDS studies (Smith et al, 2009).

Approximately 40% of patients with POP describe SUI symptoms (Grody, 1998), **and UDS-SUI is demonstrated in 70% to 75% of prolapse patients** (Roovers and Oelke, 2007). **Occult SUI unmasked by reduction of prolapse is reported to be present in 36% to 80%** (Richardson et al, 1983; Bergman et al, 1988; Chaikin et al, 2000), and **11% to 50% of clinically continent patients will develop de novo SUI following repair of high-grade prolapse** (Bergman et al, 1988; Borstad and Rud, 1989; Gallantine and Cespedes, 2001). Women who demonstrated preoperative UDS-SUI before sacrocolpopexy were more likely to develop postoperative SUI irrespective of whether they received a concomitant Burch colposuspension (Visco et al, 2008). Conversely, following a retrospective review of the records of 76 patients who underwent POP repair, Roovers and colleagues (2007) reported that no UDS parameters predicted postoperative incontinence. In an effort to determine the need for prophylactic sling placement in patients undergoing surgery for high-grade POP, Ballert and colleagues (2009) followed a UDS protocol designed to address the urethra in a standardized fashion. They concluded that in patients who did not subjectively describe or urodynamically demonstrate SUI preoperatively, the risk of intervention due to BOO following sling placement was equivalent to the risk of intervention for SUI in patients who did not receive a sling.

In select patients, particularly those with OAB symptoms and/or known neurogenic bladder, UDS can be helpful in determining the risk of progression to upper tract deterioration. DO, poor compliance, detrusor–external sphincter dyssynergia (DESD), high detrusor storage pressures, VUR, and BOO all represent potential risk factors or the development of upper tract disease, particularly in those patients with sustained Pdet greater than 40 cm H_20 (McGuire et al, 1981; Blaivas and Barbalias, 1984; Ghoniem et al, 1989, 1990).

Although multichannel UDS remains the most accurate tool with which to evaluate LUT function, it is clear that multiinstitutional randomized prospective studies are of dire importance in addressing many of the unanswered questions regarding the role and contribution of UDS. The accuracy of the study and impact of the findings on treatment outcomes must be established.

Radiographic Imaging

Voiding Cystourethrogram

Standard imaging studies are not necessary in the initial evaluation of women with uncomplicated incontinence

Key Points: Evaluation—Urodynamics

- Urodynamics (UDS) is the most accurate tool available for the assessment of LUT function and provides information regarding urine storage and emptying as they are affected by the bladder and the bladder outlet.
- Although the use of routine UDS for straightforward incontinence is a subject of debate, UDS should be strongly considered before intervention in patients who have a complex clinical picture due to failed previous treatment or surgery, mixed incontinence, obstructive symptoms, neurologic disease, or other medical conditions that may contribute to the LUT function such as diabetes mellitus, pelvic prolapse, or history of radiation therapy.
- "Eyeball UDS" may provide a rough picture of the bladder capacity, sensation, stability, compliance, and outlet resistance when formal UDS is not available.
- Multichannel UDS offers extensive evaluation of LUT function. It involves direct measurement of bladder and intra-abdominal pressure (Pves and Pabd, respectively) and a calculated assessment of detrusor pressure independent of abdominal pressure (Pdet). Pves – Pabd = Pdet.
- Fluoroscopic imaging provides useful adjunctive information such as the position and status of the bladder base and bladder neck, the presence of vesicoureteral reflux, and direct visualization of urinary leakage under real-time circumstances. Video imaging should be considered when the diagnosis cannot be made with certainty without simultaneous understanding of the anatomy in conjunction with the functional findings.

(Artibani et al, 2002; Artibani and Cerruto, 2005). However, **upper and lower urinary tract imaging in patients in whom renal damage or pelvic pathology are suspected should be performed. Voiding cystourethrogram** (VCUG) is optional in patients with recurrent UTIs but can be helpful in the diagnosis of a urethral diverticulum or VUR. VCUG can provide valuable information regarding the contour of the bladder, the presence of VUR, the position of the bladder base with and without straining with the patient in an upright posture, and the position and configuration of the bladder neck during voiding. VCUG can also provide visualization of subtle leakage with coughing or Valsalva maneuver that may be difficult to detect with direct examination.

Ultrasound

Upper tract imaging is recommended in patients with neurogenic detrusor dysfunction considered to be at high risk for renal damage, chronic urinary retention, suspected extraurethral incontinence, and untreated severe POP. The latter group may develop upper tract obstruction and hydroureteronephrosis related to ureteral "kinking" due to the prolapse. **Ultrasonography** provides a noninvasive sensitive and specific method of assessing the upper tracts for hydronephrosis. Ultrasonic imaging of the bladder neck for urinary leakage and descent during stress has also been used to diagnose SUI with documented pooled sensitivity and specificity rates in the range of 0.84 to 0.89 and 0.82 to 0.89, respectively (Martin et al, 2006).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) has been proposed as an ideal method by which to evaluate the anatomy of the bladder neck and urethra with good correlation with functional studies (Macura, 2006; Macura and Genadry, 2008; Macura et al, 2006). MRI has also been advocated for evaluation of pelvic floor relaxation and POP (Boyadzhyan et al, 2008), particularly in patients undergoing evaluation for complex multicompartmental pelvic floor reconstruction (Macura, 2006; Boyadzhyan et al, 2008), and has been shown to identify changes related to the uterosacral ligaments before and following surgical repair of prolapse (Martin et al, 2006). MRI may also be helpful in identifying those patients in whom a urethral diverticulum may be present. Although urethral diverticula can cause symptoms of urinary leakage, pelvic pain, obstructive voiding symptoms, recurrent urinary tract infections, dyspareunia, and a multitude of nonspecific symptoms, up to 20% of diverticula may be completely asymptomatic (Rovner, 2007). In patients with complaints of SUI who are found to have a urethral diverticulum, a simultaneous anti-incontinence surgery can be offered, in which case proper radiographic imaging such as that which can be obtained with MRI can provide anatomic information germane to optimal surgical planning.

High-resolution MRI allows detailed visualization of the urethra, external sphincter, and supporting structures. Magnetic resonance evaluation focusing specifically on the muscle volume of the sphincter, defects in the sphincteric musculature, funneling of the bladder neck, asymmetry of the pubococcygeus muscle or urethral supporting ligaments, increase in the size of the retropubic space or urethrovesical angle, and abnormal vaginal shape may be helpful in the diagnosis of SUI due to ISD or urethral hypermobility (Macura, 2006). To facilitate assessment of POP using MRI, the HMO (H-line, M-line, organ prolapse) system was developed (Pannu et al, 2000).

Evaluation is performed using rapid half-Fourier T2-weighted images in the midsagittal plane during maximal patient straining. Three fixed points are in the HMO system: **A**, the inferior margin of the pubic symphysis, **B**, the posterior levator plate, and **C**, the junction between the first and second coccygeal segments. Two fixed reference points include the pubococcygeal line ***(PCL)***, drawn between points A and C, and point B. ***Line H***, drawn between A and B, represents the anterior-posterior hiatal dimension. ***Line M***, which is the shortest distance between point B and the PCL, represents the degree of pelvic descent. The ***O component*** comprises the shortest distance between the H line and the most caudal aspect of the evaluated organ during Valsalva maneuver. Prolapse is graded on the basis of the organ location relative to the H-line in centimeters.

Dynamic MRI can provide integral information in the preoperative assessment of POP, particularly in patients in whom the pelvic examination is difficult and inconclusive. The sensitivity, specificity, and positive predictive value (PPV) of MRI for cystoceles has been reported to be 70% to 100%, 83% to 100%, and 97% to 100%, respectively; 42% to 100%, 54% to 81%, and 33% to 60%, respectively, for vaginal vault prolapse; 87% to 100%, 80% to 83%, and 75% to 91%, respectively, for enteroceles; 83%, 100%, and 100%, respectively, for uterine prolapse, and 87%, 72%, and 66%, respectively, for rectoceles (Gousse et al, 2000; Deval et al, 2003). Other authors have found that dynamic MRI does not correlate well with clinical findings in patients with middle compartment (i.e., apical) prolapse, and much of the literature suggests that the study should be used only as an adjunct to clarify anatomy in complex cases (Cortes et al, 2004) or under investigational circumstances (Tubaro, 2005). Similarly, many authors agree that the posterior compartment is not as easily visualized on dynamic MRI. A study using intrarectal air during MRI did not demonstrate any value of dynamic MRI for

evaluation for rectoceles over videoproctography, the latter of which was more sensitive in identifying rectoceles (Matsuoka et al, 2001). For optimal visualization of rectoceles, intrarectal gel is used to provide hyperintensity on T2-weighted images (Macura 2006; Boyadzhyan et al, 2008; Law and Fielding, 2008).

MANAGEMENT

Incontinence Treatment Overview

The approach to treatment of incontinence is contingent on a clear understanding of the etiology and pathophysiology underlying the patient's symptoms. The clinician must first determine whether the cause of the symptomatology complex is a bladder or an outlet problem or, not uncommonly, a combination of both. Therapeutic options should be considered with the goal of providing an individualized patient-directed treatment plan on the basis of the patient goals and risk-benefit and cost-benefit ratios.

Management of incontinence can be categorized into nonsurgical and surgical options. Underlying causes such as UTI, BOO, bladder stones, foreign body, or bladder tumor should be identified and addressed first. Table 61–3 in Chapter 61 provides an overview of the treatment options available for the management of incontinence; a detailed review of the various therapeutic options is presented in Chapters 68 through 79.

Treatment of incontinence must be tailored to the patient's needs, goals, and expectations and requires proper counseling on the part of the clinician. Some patients may be satisfied with protective garments and/or urine collection devices such as indwelling or condom catheters or barriers such as urethral plugs or external occlusion devices. Intervention for patients with urgency incontinence may range from behavioral and dietary modification to biofeedback or pharmacotherapy. Sacral neuromodulation, off-label botulinum toxin A detrusor injection, and enteric augmentation of the bladder may be considered in patients with refractory symptoms.

Similarly, patients with SUI may benefit variably from conservative measures using pelvic floor muscle exercises, biofeedback, electrical stimulation, and pharmacotherapy. Urethral bulking injection therapy can provide an intermediate option between nonsurgical and surgical therapies, but surgery remains the mainstay of treatment for SUI. Although needle suspensions remain only as a point of historic discussion, retropubic suspensions have persisted as a reasonable treatment option for SUI. However, slings, using a variety of materials, insertion approaches, and anchoring techniques, have effectively become the standard of care for women with SUI. Injection therapy has not proven a particularly viable option for the treatment of male SUI (which occurs most commonly following prostatectomy for treatment of adenocarcinoma of the prostate), and follow-up of the outcomes with male slings is still early. The artificial urinary sphincter (AUS) remains the prevailing treatment option for postprostatectomy incontinence. The AUS has rarely been used for treatment of SUI in women. In the fortunately rare cases of complete urethral devastation, bladder neck closure or urinary diversion can be considered.

PELVIC PROLAPSE TREATMENT OVERVIEW

New techniques have been explored to improve on the traditional pelvic floor reconstructive approaches that depend on the inherently compromised tissues of the POP patient. The use of synthetic and biologic graft materials to improve the integrity and durability of POP repairs have become popularized over the past decade. Novel anatomic approaches and "kits" have been developed and have resulted in a dramatic increase in the number of clinicians participating in pelvic floor reconstruction.

The goal of POP repair is to restore the normal anatomy and function of the vagina and the lower urinary and GI tracts. The decision regarding whether to proceed with a transvaginal or a transabdominal approach is dependent on which of the three compartments is affected, the degree of prolapse, and patient and surgeon preference. Apical prolapse involving the uterus typically results in a hysterectomy, although uterine-sparing techniques can be performed. Posthysterectomy apical prolapse can be addressed transvaginally with a uterosacral ligament suspension or a sacrospinous ligament fixation. Several contemporary devices that aim to facilitate high prolapse reduction have been introduced. Nevertheless, the sacrocolpopexy, a transabdominal approach that can be performed either open or minimally invasively using laparoscopy or robotic assistance, remains the gold standard repair for apical prolapse. A Y-shaped mesh typically composed of polypropylene is attached to the apex of the vagina and bridged to the sacrum to return the vagina to its normal axis.

New techniques of pelvic floor reconstruction continue to emerge parallel with increasing efforts to understand pelvic floor anatomy and function. A comprehensive overview of current surgical management of pelvic prolapse is presented in Chapter 72.

CONCLUSION

The ultimate goal of pelvic floor reconstruction is to restore the normal anatomy and function of the vagina, bladder, and surrounding structures. Proper evaluation of the pelvic floor anatomy and function should theoretically maximize the probability of favorable outcomes. Additionally, with a growing emphasis on QoL-enrichment and a simultaneously increasing cost of health care, economically sound and durable treatments are the aspiration. Accordingly, efforts to develop methods by which to measure symptoms and evaluate outcomes continue. New techniques designed to provide robust, minimally invasive options to achieve this objective have been developed, and as our appreciation of the pelvic floor continues to advance, further approaches will undoubtedly arise.

Neuromuscular Dysfunction of the Lower Urinary Tract

Alan J. Wein, MD, PhD (Hon), FACS ● Roger R. Dmochowski, MD, FACS

Objectives
General Patterns of Neuropathic Lower Urinary Tract Dysfunction
Disease at or above the Brainstem
Diseases Primarily Involving the Spinal Cord
Disease Distal to the Spinal Cord
Miscellaneous Neurologic Diseases Causing Voiding Dysfunction
Miscellaneous Conditions Definitely, Probably, or Possibly Related to Neuromuscular Dysfunction
Treatment of Neurogenic Lower Urinary Tract Dysfunction: Overview

OBJECTIVES

This chapter begins with a summary of the abnormalities of the micturition cycle produced by different types of neuromuscular disease, injury, or dysfunction. The source material for the central and peripheral factors involved in the physiology and pharmacology of lower urinary tract function (and dysfunction) are thoroughly discussed in Chapter 60. Most chronic voiding dysfunctions secondary to neurologic disease or injury are logical, meaning that they can be inferred from a knowledge of the normal physiology and pharmacology and the type(s) and location(s) of the pathologic process(es). Certain secondary factors that can modify the type of voiding dysfunction seen and that, once established, can cause persistence of a filling/storage or voiding/emptying abnormality, even after the initial precipitating factor or factors have disappeared or been corrected, are considered. The specific types of voiding dysfunction that occur secondary to the most common categories of neuromuscular disease, injury, or dysfunction are then described in detail. Ideally, in any such discussion, the expected states of the following parameters should be described (see Chapter 61 for specific definitions of terms):

- Detrusor activity (normal, overactive, areflexic, impaired contractility)
- Detrusor compliance (normal, decreased, increased)
- Smooth sphincter activity (synergic, dyssynergic)
- Striated sphincter activity (synergic, dyssynergic, bradykinetic, impaired voluntary control, fixed tone)
- Sensation (normal, absent, impaired)

In Table 65–1 an attempt has been made to summarize many of these dysfunctions on the basis of the most common type of abnormal pattern that results from a given disease or injury, insofar as the parameters just listed are concerned. This abbreviated classification is not meant to be all inclusive but simply to indicate that, for the most part, an individual with a specific neurologic abnormality, and voiding dysfunction because of it, will, in general, have the type of dysfunction shown.

The chapter concludes with a general consideration of the principles that should guide the selection of therapy(ies) for the dysfunctions considered. The individual therapies, and potential consequences thereof, are discussed in great detail in other chapters. The types and management of voiding dysfunction in the pediatric age group are specifically covered in Chapters 127 and 128.

As an apology to others in the field whose works have not been specifically cited or not cited as frequently as they could have been, please note that citations have generally not been chosen, except where noted, because of initial publication or original thinking on a particular subject but primarily because of their review or informational content.

GENERAL PATTERNS OF NEUROPATHIC LOWER URINARY TRACT DYSFUNCTION

Discrete neurologic lesions generally affect the filling/storage and emptying/voiding phases of lower urinary tract function in a relatively consistent fashion. This fashion is dependent on (1) the area(s) of the nervous system affected; (2) the physiologic function(s) and the contents and location of the area(s) affected; and (3) whether the lesion or process is destructive, inflammatory, or irritative. The acute dysfunction produced may differ, for a variety of reasons, from the chronic one.

Plasticity

When used in the context of the nervous system and the structures it innervates, **plasticity refers to the inherent capacity to undergo structural and functional modification.** These induced changes can be reflected on a number of levels: (1) structural, (2) metabolic, and (3) neurologic. In addition, the neurologic changes can then be reflected on a number of levels: (1)

Table 65–1.

Most Common Patterns of Voiding Dysfunction Seen with Various Types of Neurologic Disease or Injury*

DISORDER	DETRUSOR ACTIVITY	COMPLIANCE	SMOOTH SPHINCTER	STRIATED SPHINCTER	OTHER
Cerebrovascular accident	O	N	S ±VC	S	There may be decreased sensation of lower urinary tract events.
Brain tumor	O	N	S	S	There may be decreased sensation of lower urinary tract events.
Cerebral palsy	O	N	S	S D (25% of those with detrusor overactivity) ±VC	
Parkinson disease	O I	N	S	S Bradykinesia	
Multiple system atrophy	O	N	O	S	Striated sphincter may exhibit denervation.
	I	†			
Multiple sclerosis	O	N	S	S D (30%-65%)	Dyssynergia figures refer to percentage of those with detrusor activity.
Spinal cord injury					
Suprasacral	O	N	S	D	Smooth sphincter may be dyssynergic if lesion is above T7.
Sacral	A	N † (may develop)	CNR O (may develop)	F	
Autonomic hyperreflexia	O	N	D	D	
Myelodysplasia	A	N	O	F	Findings vary widely in different series. Striated sphincter commonly shows some evidence of denervation.
		O	† (may develop)		
Tabes, pernicious anemia	I	N	S	S	Primary problem is loss of sensation. Detrusor may become decompensated secondary to overdistention.
	A	‡			
Disk disease	A	N	CNR	S	Striated sphincter may show evidence of denervation and fixed tone.
Radical pelvic surgery	I	†	O	F	
	A	N			
Diabetes	I	N	S	S	Sensory loss contributes, but there is a motor neuropathy as well.
	A O	‡			

Compliance: N, normal; †, decreased; ‡, increased.
Detrusor activity: A, areflexia ; I, impaired; O, overactive.
Smooth sphincter: CNR, competent, nonrelaxing; D, dyssynergic; O, open, incompetent at rest; S, synergic.
Striated sphincter: D, dyssynergic; F, fixed tone; S, synergic; ±VC, voluntary control may be impaired.
*See chapter content for percentages of patients with dysfunction.

Key Point: Lesions above the Brainstem

- Neurologic lesions above the brainstem (with rare exceptions) that affect micturition generally result in involuntary bladder contractions with coordinated sphincter function (smooth and striated sphincter synergy). Sensation and voluntary striated sphincter function are generally preserved, but sensation may be deficient or delayed. Detrusor areflexia may, however, occur, either initially or as a permanent dysfunction. Urinary incontinence may occur due to the detrusor overactivity.

Key Point: Complete Spinal Cord Lesions from Spinal Cord Level T6 to S2

- Patients with complete lesions of the spinal cord between spinal cord level T6 and S2, after they recover from spinal shock, generally exhibit involuntary bladder contractions without sensation, smooth sphincter synergy, but striated sphincter dyssynergia. Those with lesions above spinal cord level T6 may experience, in addition, smooth sphincter dyssynergia and autonomic hyperreflexia (see later). Incontinence may occur due to detrusor overactivity, but the outlet obstruction can also cause urinary retention and overflow incontinence.

Key Point: Trauma or Disease below Spinal Cord Level S2

- Patients with significant spinal cord or nerve root trauma or disease below spinal cord level S2 generally do not manifest involuntary bladder contractions per se. Detrusor areflexia is initially the rule after spinal shock, and, depending on the type and extent of neurologic injury, various forms of decreased compliance during filling (usually due to bladder wall fibrosis) may occur. An open smooth sphincter area may result, but whether this is caused by sympathetic or parasympathetic decentralization/defunctionalization (or both or neither) has never been determined. Various types of striated sphincter dysfunction may occur, but commonly the area retains a residual resting sphincter tone (not the same as dyssynergia) and is not under voluntary control.

Key Point: Interruption of the Peripheral Reflex Arc

- The dysfunctions that occur with interruption of the peripheral reflex arc may be similar to those of distal spinal cord or nerve root injury. Detrusor areflexia often develops, low compliance may result, the smooth sphincter area may be relatively incompetent, and the striated sphincter area may exhibit fixed residual tone not amenable to voluntary relaxation. True peripheral neuropathy can be motor or sensory, with the usual expected sequelae, at least initially.

morphologic, (2) neurochemical, (3) electrical, and (4) organizational. Each of these changes can be studied at a variety of different levels, from investigating the end product (e.g., the clinical manifestations) to the initial molecular correlates and the factors that induce or affect them. The chronic clinical manifestations that we associate with a particular voiding dysfunction may, in fact, be the ultimate results of the phenomena that fall under the rubric "plasticity." To a certain point, the changes may be reversible. After a certain point the changes may not be reversible, and thus **plasticity may account for the persistence of clinical symptoms after the initial stimulus for dysfunction has been removed or corrected.** Perhaps the most obvious changes that occur as a result of plasticity are (1) chronic changes in neural organization of the micturition reflex that occur after complete spinal cord transaction above the level of S2 and (2) the changes in peripheral neural organization that occur after damage to or transection of the peripheral parasympathetic innervation of the lower urinary tract. Specific details are contained in the relevant sections of this chapter.

What may be less obvious as a phenomenon related to plasticity are many of the changes that occur subsequent to bladder outlet obstruction. The most obvious changes that occur are those related to muscle and collagen content. However, these are themselves initiated by molecular events that ultimately cause increased contractile protein synthesis and hypertrophic bladder tissue growth (Levin et al, 1995). The initial stimulus might be stretched from overdistention (Cheng et al, 1999) or ischemia, likewise from distention (Chen et al, 1996). Compensation of the bladder smooth muscle cells to initially overcome the increased demand associated with obstruction is associated with alterations in the expression and function of many proteins involved in excitation/contraction coupling and active force generation of bladder smooth muscle (Chacko et al, 1999). Although urodynamic studies reflect obstruction, satisfactory emptying is generally preserved. Changes in the composition of the extracellular matrix occur as well, presumably also caused by an initial stretch stimulus. The ratio of type 3 collagen to type 1 collagen increases, and the localization of type 3 collagen changes as well (within and around some muscle bundle) (Macarak and Howard, 1999). The increase in connective tissue could be related to an increase in certain growth factors emanating from the smooth muscle or to a decrease in the activity of certain metabolic pathways contributing to the breakdown of various forms of collagen (Borer et al, 1999). Ischemia, which itself can be caused by obstruction or atherosclerosis, has also been hypothesized to contribute to remodeling of the extracellular matrix and fibrosis (Azadzoi et al, 1999; Mostwin et al, 2005).

Bladder outlet obstruction has also been postulated to be associated with partial denervation, owing to damage to the intrinsic innervation of the bladder smooth muscle from a combination of pressure and ischemia (Turner and Brading, 1997; Mostwin et al, 2005). With all of these potential adverse changes occurring, it seems almost miraculous that the bladder can maintain its function, but it does for variable periods of time under different circumstances. However, there does come a point when the ability to fill/store and empty is adversely affected, but not necessarily to the same extent. Filling/storage changes seem related primarily to (1) changes in the extracellular matrix, leading to decreased compliance; and (2) to the appearance of phasic bladder overactivity. This overactivity could be myogenic in origin (caused by partial denervation—see Turner and Brading, 1997), or it could be neurogenic and related to another facet of plasticity. Afferent neuroplasticity mediated by nerve growth factors occurs experimentally in response to bladder outlet obstruction, a phenomenon that is inhibited by autoimmunization against nerve growth factor (Steers et al, 1996). The ability to empty can be adversely affected by factors related to neurogenic or myogenic mechanisms. The myogenic mechanisms could include a reversal of the compensatory changes that initially occur (see Chacko et al, 1999) or a breakdown of the structure and function of the proteins that enable the smooth muscle cells to take up, store, and release calcium, affecting the calcium activation of the contractile apparatus (Zderic et al, 1998; Chacko et al, 1999).

Furthermore, these neurogenic changes associated with outflow obstruction may alter the neurotransmitter milieu of the lower urinary tract. In a model of fetal sheep bladder outlet obstruction, ligation of the urachus at midgestation in fetal sheep for 1 month resulted in a shifting of muscarinic, purinergic, and nitrergic mechanisms normally present during fetal development and growth. With outflow obstruction, bladder hypocontractility was induced and contractile forces decreased during stimulated conditions, consistent with denervation and the possibility of atropine resistance. Normal urothelial exerted negative inotropic effects (nitric oxide mediated) were also lost after obstruction. Additionally, loss of compliance resulted in reduced elasticity in the obstructed bladders, consistent with denervation (Thiruchelvam et al, 2003). Other evidence exists suggesting that bladder outlet obstruction alters the milieu of the lower urinary tract. Mirone and coworkers (2007) summarized changes related to bladder outlet obstruction on the ultrastructure of the bladder in prior animal models. These changes include alterations in the cytoskeleton and contractile protein matrix of the bladder, increasing expression of several growth factors and COX-2, swelling and structural destruction of the detrusor mitochondria, augmented extracellular matrix deposition with significant increase of the

type III/I collagen ratio, downregulation of matrix metalloproteinases, and upregulation of tissue inhibitors of metalloproteinases, increased afferent neural activity from epithelial cells due to higher density of mechanosensitive epithelial sodium channels, and activation of normal cell and unmyelinated C fibers. All of these factors appear to be related to bladder dysfunction associated with obstruction.

At this time, one cannot reverse certain precipitating factors for the initiation of voiding dysfunction such as spinal cord transection and peripheral nerve injury.

Thus the fact that the changes resulting from the neuroplasticity induced by these insults are permanent is not surprising. However, **there are instances in which the initiating "cause" of a particular voiding dysfunction can be removed and yet the symptoms do not entirely disappear. This may be another instance in which neuroplasticity is a major factor.** For instance, irritative voiding symptoms fail to disappear in a certain percent of patients with outlet obstruction who undergo surgical correction. Chai and colleagues (1998) found an increased incidence of a positive ice water test in patients with bladder outlet obstruction, indicating the presence of a primitive reflex circuitry capable of mediating an abnormal micturition reflex. Because the ice water test is mediated by C-afferent fibers, the findings support the hypothesis that bladder outlet obstruction is associated with afferent neuroplasticity, detectable in this case by ice water cystometry. Furthermore, persistence of this afferent neural plasticity after relief of the obstruction could account for at least a proportion of the symptomatic treatment failures after urodynamically successful outlet reduction.

Vizzard (1999, 2000a, 2000b, 2000c, 2000d; Qiao and Vizzard, 2004) has written prolifically about various aspects of neuroplasticity, specifically on the occurrence and potential role of such changes in altered lower urinary tract dysfunction after spinal cord injury (SCI) and irritant-induced cystitis. Changes in spinal cord protein expression from retrogradely transported bladder neurotrophic factors could play a role in the neurochemical, electrophysiologic, and organizational properties of the lower urinary tract seen in both of these conditions and could account, in the latter case, for persistence of symptomatic and/or urodynamic abnormalities after the irritating stimulus is removed (e.g., in patients with interstitial cystitis). Those especially interested in this area should consult Vizzard's articles and associated references.

DISEASE AT OR ABOVE THE BRAINSTEM

Cerebrovascular Disease

Cerebrovascular Accident (Stroke)

Cerebrovascular accident (CVA) is a common cause of death and one of the most common causes of disability in the United States and Europe. CVA is the most devastating manifestation of cerebrovascular disease, with an **annual incidence in the United States that has been variably cited as approximately 550,000** (Blaivas et al, 1998a) **and 83 to 160 per 100,000** (Blaivas and Chancellor, 1995a). Approximately one third are fatal, and another third require long-term nursing care (Marinkovic and Badlani, 2001). The prevalence of stroke in persons older than 65 years has been cited as approximately 60 in 1000, and in persons older than 75, 95 per 1000 (Khan et al, 1990). Wyndaele and colleagues (2005) estimate that 1 in 200 individuals will suffer from a CVA. Although CVA is the third leading cause of death in the United States (Marinkovic and Badlani, 2001), approximately 75% of stroke victims survive (Blaivas et al, 1998a) and, of these, only 10% are unimpaired, 40% have a mild residual, 40% have a significant disability, and 10% require institutionalization (Arunable and Badlani, 1993). Thrombosis, occlusion, and hemorrhage are the most common causes of stroke, leading to ischemia and infarction of variably sized areas in the brain, usually around the internal capsule. Marinkovic and Badlani (2001) cite evidence that arterial occlusion is found in 80% of patients.

After the initial acute episode, urinary retention from detrusor areflexia may occur. The neurophysiology of this "cerebral shock" is unclear. After a variable degree of recovery from the neurologic lesion, a fixed deficit may become apparent over a few weeks or months. **The most common long-term expression of lower urinary tract dysfunction after CVA is phasic detrusor overactivity** (Wein and Barrett, 1988; Khan et al, 1990; Fowler, 1999; Wyndaele et al, 2005). **Sensation is variable but is classically described as generally intact, and thus the patient has urgency and frequency with detrusor overactivity. The appropriate response is to try to inhibit the involuntary bladder contraction by forceful voluntary contraction of the striated sphincter. If this can be accomplished, only urgency and frequency result; if not, urgency with incontinence results.**

The exact acute and chronic incidence of any voiding dysfunction after CVA, and specifically of incontinence, is not readily discernable. **The cited prevalence of urinary incontinence on hospital admission for stroke ranges from 32% to 79%, on discharge from 25% to 28%, and some months later, from 12% to 19%** (Brittain et al, 1998). Sakakibara and colleagues (1999), based on their own experience and that of others, estimate that some voiding dysfunction occurs in 20% to 50% of patients with focal brain lesions from tumor and CVA. They cite nocturnal frequency as the most common manifestation, affecting 36% of their patients. Urgency incontinence occurred in 29%, "voiding difficulty" in 25%, urgency without incontinence in 25%, diurnal frequency in 13%, and enuresis in 6%. Acute retention occurred in only 6%. Fowler (1999) cites studies showing that the presence of urinary incontinence within 7 days of a stroke is a more powerful prognostic indicator for poor survival and functional dependence than a depressed level of consciousness. Urinary incontinence at admission was found by Garibella (2003) to have a hazard ratio of 2.8 as a predictor of stroke death at 3 months. Stroke patients who were incontinent had an increased risk of infectious complications and were malnourished, possible confounders of the increased death risk. Patel and colleagues (2001) reported that urinary incontinence was associated with age older than 75 years, dysphagia, visual field defect, and motor weakness. Certain specific types of strokes also appear to be associated with unusual forms of incontinence. Lenticulo-capsular strokes have been noted to be associated with incontinence. Fifty-two percent of patients with strokes in this area of the brain demonstrated poststroke emotional incontinence, which was not related to other aspects of stroke or gender (Kim, 2002). Lesions centrally located in the globus pallidus, especially dorsally located, were more prone to be associated with an emotional incontinence. This area of the brain is noted to have high density of serotonergic fibers, which has been attributed as an explanation as to why this occurs.

Previous descriptions of the voiding dysfunction after CVA have all cited the preponderance of detrusor overactivity with coordinated sphincter activity

(Kolominsky-Rabas et al, 2003; Wyndaele et al, 2005). **It is difficult to reconcile this with the relatively high incontinence rate that occurs, even considering the probability that a percentage of these patients had an incontinence problem before the CVA.** Tsuchida and colleagues (1983) and Khan and colleagues (1990) made early significant contributions in this area by correlating the urodynamic and computed tomographic (CT) pictures after CVA. They reported that patients with lesions in only the basal ganglia or thalamus have normal sphincter function. This means that when an impending involuntary contraction or its onset was sensed, these patients could voluntarily contract the striated sphincter and abort or considerably lessen the effect of an abnormal micturition reflex. The majority of patients with involvement of the cerebral cortex or internal capsule or both were unable to forcefully contract the striated sphincter under these circumstances. Although the authors and others have called this problem "uninhibited relaxation of the sphincter" (Marinkovic and Badlani, 2001), it really is not, but certainly the term does imply that a profound abnormality exists in these patients in the cerebral to corticospinal circuitry that is necessary for voluntary control of the striated sphincter.

Griffiths (2004) has summarized the evidence, obtained by electrical stimulation, positron emission tomography (PET), and functional magnetic resonance imaging (fMRI), implicating Barrington nucleus, the so-called M region, as responsible for coordinated striated sphincter relaxation followed by detrusor contraction (i.e., normal voiding). He summarizes evidence that a second region in the pons—the L region—may be responsible for maintaining striated sphincter tone between voids, although the evidence for this is less convincing. Griffiths (1998), studying the results of single-proton emission computer tomography (SPECT) in a group of geriatric patients with established urinary incontinence, found urge incontinence in approximately 50%; and, in half of these there was reduced sensation of bladder filling, more so in men than in women. True urgency incontinence with reduced bladder sensation was associated with global underperfusion of the cerebral cortex, especially the frontal areas, especially on the right. **Thus there are two possible mechanisms for the incontinence associated with involuntary bladder contractions in patients who have sustained a CVA: (1) impaired striated sphincter control and (2) lack of appreciation of bladder filling and impending bladder contraction.**

Smooth sphincter activity is generally unaffected (synergic) by CVA. Some authors describe striated sphincter dyssynergia in 5% to 21% of patients with brain disease and voiding dysfunction (Sakakibara et al, 1999). This is incompatible with accepted neural circuitry. The authors of this chapter agree with those who believe that **true detrusor–striated sphincter dyssynergia does not occur in this situation. Pseudodyssynergia may indeed occur** during urodynamic testing of these patients (Wein and Barrett, 1982). This refers to an electromyographic (EMG) sphincter "flare" during filling cystometry that is secondary to attempted inhibition of an involuntary bladder contraction by voluntary contraction of the striated sphincter. The guarding reflex is generally intact (Siroky and Krane, 1982).

Detrusor hypocontractility or areflexia may persist after CVA. The exact incidence of areflexia as a cause of chronic voiding symptoms after CVA is uncertain. In our patient population, this is rare, but some estimates place it as high as 20% (Arunable and Badlani, 1993). In a group of incontinent male stroke patients, Linsenmeyer and Zorowitz (1992) found 35% had involuntary bladder contractions with urodynamic evidence of bladder outlet obstruction and 6% had detrusor areflexia. In women in this group, 13% had involuntary contraction with a large residual urine volume and 19% had areflexia. **Poor flow rates and high residual urine volumes in a male with pre-CVA symptoms of prostatism generally indicate prostatic obstruction, but a full urodynamic evaluation is advisable before committing a patient to mechanical outlet reduction, primarily to exclude detrusor overactivity with impaired contractility as a cause of symptoms.**

Key Point: Lower Urinary Tract Dysfunction after CVA

- In the **functional system of classification** (see Chapter 66), the most common type of voiding dysfunction after stroke would then be characterized as a failure to store secondary to bladder overactivity, specifically involuntary bladder contractions. In the **ICS Classification System,** the dysfunction would most likely be classified as overactive neurogenic detrusor function, normal sensation, low capacity, normal compliance, and normal urethral closure function during storage; during voiding the description would be normal detrusor activity and normal urethral function assuming that no anatomic obstruction existed. Treatment, in the absence of coexisting significant bladder obstruction or significantly impaired contractility, is directed at decreasing bladder contractility and increasing bladder capacity (see Tables 61–3 and 61–4).

Other important modifying factors should be considered in the case of these patients. This is generally a problem of the elderly, some of whom have preexistent lower urinary tract pathologic processes. Previously, the problems may have been manageable, but the additional difficulty may make the situation intolerable. As Andrews (1994) notes, other aspects of the brain damage can affect general rehabilitation and control of the lower urinary tract dysfunction. These may include cognitive impairment, dysphasia, inappropriate and aggressive behavior, impaired mobility, and low motivation. Finally, the entire voiding dysfunction may be adversely affected by treatment regimens that concentrate on detrusor overactivity alone (e.g., anticholinergic or antispasmodic therapy). Many such patients are depressed, and confusion and disorientation often result, which compounds the problem. Vigorous pharmacologic therapy of detrusor overactivity with agents that cross the blood-brain barrier and inhibit M_1 receptor function may make these associated problems of mentation worse.

The underlying basic mechanisms of bladder overactivity after CVA remain unclear. Experimental models of middle cerebral artery occlusion have been described, most recently followed by reperfusion to simulate the clinical condition (Pehrson et al, 2003). Shimizu and colleagues (2003) described the development of a rat model involving an electrolytic lesion of the right basal forebrain. Following at least middle cerebral artery occlusion, the overactivity seems to involve glutaminergic, dopaminergic, and γ-aminobutyric acid (GABA)-ergic innervations (Kanie et al, 2000; Yokoyama et al, 2002). In addition, Fu and colleagues (2004) have shown upregulation of proinflammatory cytokines and neuronal nitric oxide synthetase gene in the spinal cord and bladder. Such findings raise interesting theoretic possibilities for pharmacologic management other than or in addition to antimuscarinic therapy.

Brainstem Stroke

Sakakibara and colleagues (1996b) studied 39 patients with brainstem stroke. Nineteen of these had voiding symptoms. The major problems were nocturnal frequency and voiding difficulty in six, urinary retention in eight, and urinary incontinence in three. Problems were more common after damage from bleeding than from infarction. Symptoms did not occur in those with strictly midbrain lesions but occurred in 18% of patients with medullary stroke and in 35% of patients with pontine lesions. Eleven patients were symptomatic and underwent urodynamic study. Detrusor overactivity was found in 8 of the 11 and low compliance in 1. What was interpreted as striated sphincter dyssynergia was reported in 5 of the 11 patients, and what was called uninhibited sphincter relaxation occurred in 3. The authors concluded that lesions of the dorsolateral pons involving the pontine reticular nucleus, reticular formation, and the locus coeruleus were mainly responsible for the micturition disturbances in patients with brainstem lesions and that these findings corroborated the presence of a pontine micturition center in humans, corresponding to the pontine storage and micturition centers reported in animal studies.

Dementia

Dementia is a poorly understood disease complex involving atrophy and the loss of gray and white matter of the brain, particularly of the frontal lobes. Problems result with memory and the performance of tasks requiring intellectual mentation. Associated conditions include widespread vascular disease, Alzheimer disease, Pick disease, Jakob-Creutzfeldt disease, syphilis, heat trauma, and encephalitis. Alzheimer disease is the principal cause of dementia in the elderly (Wyndaele et al, 2005, 2009). **When voiding dysfunction occurs, the result is generally incontinence. It is difficult to ascertain whether the pathophysiology and considerations are similar to those in the stroke patient or whether the incontinence reflects a situation in which the individual has simply lost the awareness of the desirability of voluntary urinary control.** Even if the person has voluntary sphincter control, such individuals may void when and where they please, because mentation fails to dictate why they should not. Such activity may be caused by detrusor overactivity or an otherwise normal, but inappropriately timed, micturition reflex. An accurate estimate of the prevalence of dementia-associated incontinence is confounded by the difficulty in distinguishing this from age-related changes in the bladder and from other concomitant diseases, as pointed out by Wyndaele and colleagues (2005, 2009), who cite figures of 30% to 100%. Treatment is obviously difficult without a desire for improvement. Additionally, therapy that inhibits muscarinic brain receptors may be contraindicated in Alzheimer disease if current theories about its etiology are valid (cortical cholinergic loss).

Traumatic Brain Injury

Traumatic brain injury has been cited as the most common form of severe neurologic impairment as a result of trauma (Blaivas and Chancellor, 1995a). **When voiding dysfunction occurs, there may be an initial period of detrusor areflexia. With lesions above the pontine micturition center, involuntary bladder contractions are the most frequent manifestation of chronic lower urinary tract dysfunction. Coordinated sphincter function is the rule. In patients who have more isolated brainstem injuries with involvement below the pontine micturition center, detrusor striated sphincter dyssynergia may occur in addition.**

Chua and colleagues (2003) assessed 66 males and 18 females within 6 weeks of acute traumatic brain injury. Sixty-two percent of patients had urinary incontinence on admission with retention (defined as >100 mL), noted in 9.5%. Sixty-two percent required either indwelling catheters or external collecting devices for urinary maintenance. Urinary incontinence was associated with poor functional status and bilateral lesions, whereas urinary retention was more commonly noted in patients with comorbid diabetes mellitus or fecal impaction. After rehabilitation, 36% remained incontinent (Chua et al, 2003).

Brain Tumor

Both primary and metastatic brain tumors have been reported to be associated with disturbances of bladder function. When dysfunction results, it is related to the localized area involved rather than to the tumor type. **The areas that are most frequently involved with associated micturition dysfunction are the superior aspects of the frontal lobe** (Blaivas, 1985). **When voiding dysfunction occurs, it generally consists of detrusor overactivity and urinary incontinence.** These individuals may have a markedly diminished awareness of all lower urinary tract events and, if so, are totally unable to even attempt suppression of the micturition reflex. **Smooth and striated sphincter activity is generally synergic.** Pseudodyssynergia may occur during urodynamic testing. Fowler (1999) has reviewed the literature on frontal lobe lesions and bladder control. She cites instances of resection of a tumor relieving the micturition symptoms for a period of time, raising the question of whether the phenomenon of tumor-associated bladder overactivity was a positive one (activating some system) rather than a negative one (releasing a system from control). **Urinary retention has also been described** in patients with space-occupying lesions of the frontal cortex, in the absence of other associated neurologic deficits (Lang et al, 1996). Posterior fossa tumors may be associated with voiding dysfunction (32% to 70%, based on references cited by Fowler, 1999). Retention or difficulty voiding is the rule, with incontinence being rarely reported.

Cerebellar Ataxia

This group of diseases involves pathologic degeneration of the nervous system generally involving the cerebellum, but with a possible extension to the brainstem, spinal cord, and dorsal nerve roots (Leach et al, 1982). Poor coordination, depressed deep tendon reflexes, dysarthria, dysmetria, and choreiform movements result because of the cerebellar involvement. **Voiding dysfunction is generally manifested by incontinence, usually associated with detrusor overactivity and sphincter synergia. Retention or high residual urine volume may occur as well. Poor emptying, when present, is most commonly caused by detrusor areflexia, but it may be associated with detrusor–striated sphincter dyssynergia, presumably secondary to spinal cord involvement.** Sakakibara and colleagues (1998b) reported micturitional symptoms in 184 patients with spinocerebellar degeneration. Twenty-nine (15.8%) showed stress urinary incontinence. Although 20 of these 29 also had detrusor overactivity and/or low compliance and/or residual urine, 9 had none of these findings. The authors

speculate that in some such patients, spinal lesions affecting Onuf nucleus and consequently pudendal nerve function were responsible.

Normal-Pressure Hydrocephalus

This is a disease of progressive dementia and ataxia occurring in patients with normal cerebrospinal fluid pressure and distended cerebral ventricles but with no passage of air over the cerebral convexities by pneumoencephalography (Blaivas, 1985). When voiding dysfunction occurs, it is generally incontinence secondary to detrusor overactivity with sphincter synergia.

Cerebral Palsy

Cerebral palsy (CP) is the name applied to a nonprogressive injury of the brain in the prenatal or perinatal or postnatal period (generally during the first year of life, but some say up to 3 years) that produces neuromuscular disability and/or specific symptom complexes of cerebral dysfunction. The etiology is generally infection or a period of hypoxia. Affected children exhibit delayed gross motor development, abnormal motor performance, altered muscle tone, abnormal posture, and exaggerated reflexes. **Most children and adults with only CP have urinary control and what seems to be normal filling/storage and normal emptying.** The actual incidence of voiding dysfunction is somewhat vague because the few available series report findings predominantly in those who present with voiding symptoms. Andrews (1994) estimates that a third or more of children with CP are so affected. Roijen and colleagues (2001) surveyed children and adolescents from six rehabilitation centers and cited the prevalence of "primary urinary incontinence" as 23.5%. The most important factors influencing the occurrence of incontinence were spastic tetraplegia and low intellectual capacity. Wyndaele and colleagues (2005, 2009) cite the occurrence of lower urinary tract dysfunction as 36%. When an adult with CP presents with an acute or subacute change in voiding status, however, it is most likely unrelated to CP.

Reid and Borzyskowski (1993) described findings in 27 patients, aged 3 to 20 years, referred for voiding dysfunction. Incontinence (74%), frequency (56%), and urgency (37%) were the most common presenting symptoms, and detrusor overactivity was the most common urodynamic abnormality (87% of those undergoing urodynamics), with 25% of these exhibiting apparent striated sphincter dyssynergia. Mayo (1992) reported on 33 CP patients referred for evaluation, of whom 10 were older than 20 years. Difficulty urinating was the predominant symptom in about half the patients, but half of these also had overactivity and urgency when the bladder was full. The cause of the difficulty in voluntarily initiating micturition was thought to be a problem with relaxing the pelvic floor and not true striated sphincter dyssynergia. Incontinence was the major presenting symptom in the other half, associated in 14 of 16 with detrusor overactivity; all exhibited normal voiding otherwise. Decreased sensation was reported in 17 of 23 patients younger than 20 years of age and in 4 of 10 older than 20. The more serious manifestations such as retention were found only in the adults, prompting the author to suggest that difficulty urinating may progress in adulthood.

Reid and Borzyskowski (1993) note that incontinence can be significantly improved in most CP patients and that, in their experience, intellectual delay is not a barrier to successful management. However, one special problem that is encountered in some of these individuals that makes their management difficult is a severe degree of mental retardation, such that any evaluation or treatment that requires cooperation is virtually impossible. With such individuals, sometimes the best that one can do is to check the upper tracts with renal ultrasonography, measure serum creatinine levels, and obtain an estimate of postvoid residual urine, either by catheterization or ultrasound, and proceed accordingly. **In those individuals with CP who exhibit significant dysfunction, the type of damage that one would suspect from the most common urodynamic abnormalities seems to be localized anatomically above the brainstem. This is commonly reflected by phasic detrusor overactivity and coordinated sphincters. However, spinal cord damage can occur,** and perhaps this accounts for those individuals with CP who seem to have evidence of striated sphincter dyssynergia or of a more distal type of neural axis lesion.

Parkinson Disease

Parkinson disease (PD) is a neurodegenerative disorder of unknown cause that affects primarily the dopaminergic neurons of the substantia nigra but also heterogeneous populations of neurons elsewhere (Lang and Lozano, 1998). The most important site of pathology is the substantia nigra pars compacta, the origin of the dopaminergic nigrostriatal tract to the caudate nucleus and putamen. **Dopamine deficiency in the nigrostriatal pathway accounts for most of the classic clinical motor features of PD.** The classic major signs of PD consist of tremor, skeletal rigidity, and bradykinesia, a symptom complex often referred to as *parkinsonism*. Positron-emission tomography (PET) has shown alteration in brain activation in response to bladder filling in PD. PET revealed changes in nine patients in brain activation associated with detrusor overactivity, specifically in the periaqueductal gray, the supplementary motor area, the cerebellar vermis, the insula, putamen, and thalamus. The most prominent degree of increased activation was noted in the cerebellum, with no change in pons during detrusor overactivity (Kitta et al, 2006).

The role of alterations in dopaminergic receptor subtypes has been assessed in animal models of PD. D-2 agonists and D-1 antagonists appear to result in a reduction of bladder capacity in these models. Brusa and colleagues (2006) studied a group of 87 patients with mild PD who were evaluated by symptomatic change and urodynamics after administration of selective dopaminergic agents. Agents resulting in acute central D-2 stimulation result in bladder capacity and worsened detrusor overactivity, as compared with peripheral dopaminergic antagonists (Brusa et al, 2006). There are causes of parkinsonism other than PD, and in an excellent review, Lang and Lozano (1998) discuss clinical distinguishing features of these other causes of parkinsonism from PD. These other causes consist of (1) multiple system atrophy (MSA: includes striatonigral degeneration, sporadic olivopontocerebellar atrophy, and Shy-Drager syndrome); (2) progressive supranuclear palsy; (3) cortical-basal ganglionic degeneration; (4) so-called vascular parkinsonism; and (5) dementia with Lewy bodies. **The combination of asymmetry of symptoms and signs, the presence of a resting tremor, and a good response to levodopa best differentiates PD from parkinsonism produced by other causes, although none of these is individually specific for PD.** Wyndaele and colleagues (2005) endorse additional criteria for distinguishing lower urinary tract symptoms caused by MSA from those caused by PD. The following suggest MSA: (1) urinary symptoms precede or present with parkinsonism; (2) urinary incontinence; (3) significant postvoid residual; (4) initial erectile failure; and (5) abnormal striated sphincter electromyogram. Five percent of patients initially diagnosed with PD are

found to have Parkinson's Plus Syndromes. These syndromes are characterized by early dementia and/or falls, symmetric symptoms such as a wide-based gait, normal eye movements, autonomic dysfunction, and marked disability. These variants tend to have a worse prognosis than does idiopathic PD. Urinary function is not well described in this subgroup of patients (Nutt and Wooten, 2005).

The "gold standard" for the diagnosis of PD is the neuropathologic examination. In addition to the characteristic pattern of the loss of selected populations of neurons, there is the presence of degenerating ubiquitin-positive neuronal processes or neurites (Lewy neurites) found in all affected brainstem regions. The Lewy body is an intracytoplasmic eosinophilic hyaline inclusion consistently observed in selectively vulnerable neuronal populations, although these are not specific to PD, being found in small numbers in other neurodegenerative disorders. PD affects both sexes roughly equally. The prevalence is cited as 0.3% of the general population and 3% of people older than 65 years (Lang and Lozano, 1998).

Voiding dysfunction occurs in 35% to 70% of patients with PD (Berger et al, 1990; Sotolongo and Chancellor, 1993; Blaivas et al, 1998a; Wein and Rovner, 1999; Wyndaele et al, 2005, 2009). Preexisting detrusor or outlet abnormalities may be present, and the symptomatology may be affected by various types of treatment for the primary disease. **When voiding dysfunction occurs, symptoms generally (50% to 75%) consist of urgency, frequency, nocturia, and urge incontinence.** The remainder of patients have "obstructive" symptoms or a combination. **The most common urodynamic finding is detrusor overactivity.** The pathophysiology of detrusor overactivity most widely proposed (Fowler, 1999) is that the basal ganglia normally have an inhibitory effect on the micturition reflex, which is abolished by the cell loss in the substantia nigra. Whether the dopamine D_1 or D_2 receptor (or both) are primarily responsible does not seem to have been settled as yet. It has been suggested that loss of inhibitory D_1-like receptors causes detrusor overactivity, allowing D_2 receptors to facilitate micturition (Andersson and Wein, 2004). **The smooth sphincter is synergic. There is some confusion regarding EMG interpretation.** Sporadic involuntary activity in the striated sphincter during involuntary bladder contraction has been reported in up to 60% of patients; however, this does not cause obstruction and cannot be termed *true* dyssynergia, which generally does not occur. **Pseudodyssynergia may occur, as well as a delay in striated sphincter relaxation (bradykinesia) at the onset of voluntary micturition, both of which can be urodynamically misinterpreted as true dyssynergia. Impaired detrusor contractility may also occur, either in the form of low amplitude or poorly sustained contractions or a combination. Detrusor areflexia is relatively uncommon in PD.**

It should be recognized, however, that **many cases of "PD" in the older literature may actually have been MSA, and citations regarding symptoms and urodynamic findings may not therefore be accurate.** A good and important example of this is the inference from the publication by Staskin and colleagues (1988) that transurethral prostatectomy (TURP) in the patient with PD is associated with a high incidence of urinary incontinence (because of poor striated sphincter control). Retrospective interpretation (Fowler, 1999, 2001; Wyndaele et al, 2005) has shown that these were patients with MSA and not PD and that **TURP should not be contraindicated in patients with PD because external sphincter acontractility is extremely rare** in such patients. However, one must be cautious with such patients, and a complete urodynamic or video-urodynamic evaluation is advisable. Poorly sustained bladder contractions, sometimes with slow sphincter relaxation, should make one less optimistic regarding the results of outlet reduction in the male. PD has been shown to impact voiding dysfunction in postradical prostatectomy patients. Routh and colleagues (2006) noted that in a study of retrospective evaluation of 20 patients with PD who had undergone radical prostatectomy that de novo incontinence rate was 24% and was of a minimal nature on the basis of pad utilization. However, the conclusion of the study was that advanced evaluation preoperatively including urodynamic or video-urodynamic evaluation would seem advisable for purposes of counseling given the higher rates of incontinence in this particular population.

Christmas and colleagues (1988) demonstrated that subcutaneous administration of a dopamine receptor agonist (apomorphine) can reliably and rapidly reverse parkinsonian "off" periods (periods of worsening symptoms mainly caused by the timing of previous medication doses and the unpredictable nature of motor fluctuations). By repeating video-urodynamic studies during the motor improvement after administration of apomorphine, bladder outlet obstruction secondary to benign prostatic hyperplasia (BPH) may be able to be distinguished from voiding dysfunction secondary to PD. The authors also point out that apomorphine might be useful in such patients who have severe off-phase voiding dysfunction (e.g., those with disabling nocturnal frequency and incontinence). **Voiding dysfunction secondary to PD defies "routine" classification within any system. It is most manifest by storage failure secondary to bladder overactivity, but detailed urodynamic evaluation is mandatory before any but the simplest and most reversible therapy.** The therapeutic menus (see Tables 66–3 and 66–4) are perfectly applicable, but the disease itself may impose certain limitations on the use of certain treatments (e.g., limited mobility for rapid toilet access, hand control insufficient for clean intermittent catheterization [CIC]).

Animal models of PD have been developed, using injections of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine or 6-hydroxydopamine into the nigrostriatal pathway (Yoshimura et al, 2003; Andersson and Wein, 2004; Wyndaele et al, 2005).

Subthalamic nucleus deep brain stimulation has been shown to be effective for motor symptoms and dyskinesias in patients with moderate to severe PD. Clinical studies have shown that this type of stimulation improves urinary function in these patients by ameliorating bladder sensation and also improving functional bladder capacity. Herzog and colleagues (2006) studied 11 patients undergoing deep brain stimulation with positron emission tomography assessments of regional cerebral blood flow. Subjects were studied with urodynamics both with stimulation on and stimulation off. At urodynamic capacity, significant increases in anterior cingulate regional blood flow were noted. They were increased when deep brain stimulation was off. At bladder capacity, there was also an increase in lateral frontal cortical blood flow with stimulation off. These results were felt to be indicative of deep brain stimulation improvement of bladder function by the modulation of afferent bladder information to cortical and subcortical areas (Herzog et al, 2006).

Multiple System Atrophy

Multiple system atrophy is a progressive neurodegenerative disease of unknown etiology. The symptoms encompass parkinsonism and cerebellar, autonomic (including urinary and erectile

problems), and pyramidal cortical dysfunction in a multitude of combinations. The clinical features and the differentiation from PD are nicely described in a consensus statement by Gilman and colleagues (1999). These investigators advocate a designation of MSA-P if parkinsonian features predominate and one of MSA-C if cerebellar features predominate. Older names such as "striatonigral degeneration," "sporadic olivopontocerebellar atrophy," and "Shy-Drager syndrome" (Wein, 2002a) should be discarded in favor of these.

The neurologic lesions of MSA consist of cell loss and gliosis in widespread areas, much more so than with PD, and this more diffuse nature of cell loss probably explains why bladder symptoms may occur earlier than in PD and be more severe and why erection may be affected as well (Kirby et al, 1986; Beck et al, 1994; Chandiramani et al, 1997). Affected areas have been identified in the cerebellum, substantia nigra, globus pallidus, caudate, putamen, inferior olives, intermediolateral columns of the spinal cord, and Onuf nucleus. Males and females are equally affected, with the onset in middle age. MSA is generally progressive and associated with a poor prognosis.

Shy-Drager syndrome has been described in the past as characterized clinically by orthostatic hypotension, anhidrosis, and varying degrees of cerebellar and parkinsonian dysfunction. Voiding and erectile dysfunction are common. Some consider this as late-stage MSA (Chandiramani et al, 1997).

Chandiramani and colleagues (1997) **compared the clinical features of 52 patients with probable MSA and 41 patients with PD.** Of patients with MSA, 60% had their urinary symptoms precede or present with their symptoms of parkinsonism. Of patients with PD, 94% had been diagnosed for several years before the onset of urinary symptoms. In patients with MSA, urinary incontinence was a significant complaint in 73%, whereas 19% had only frequency and urgency without incontinence. Sixty-six percent of the patients with MSA had a significant postvoid residual volume (100 to 450 mL). In patients with PD, frequency and urgency were the predominant symptoms in 85%, whereas incontinence was the primary complaint in 15%. In only 5 of 32 patients with PD in whom residual urine volume was measured was it significant. Eleven men with MSA underwent TURP. Nine of these had deterioration of their urinary incontinence afterward. All three women with MSA were incontinent after pelvic floor repair. Five men with PD underwent prostatectomy, and three reported a good result. Ninety-three percent of the men with MSA questioned about erectile function reported erectile failure, and in 13 of 27 of these the erectile dysfunction preceded the diagnosis of MSA. Seven of the 21 men with PD had erectile failure, but in all these men the diagnosis of erectile dysfunction followed the diagnosis of PD by 1 to 4 years. Fowler (2001) lists the clinical urogenital criteria favoring a diagnosis of MSA as (1) urinary symptoms precede or present with parkinsonism; (2) male erectile dysfunction precedes or presents with parkinsonism; (3) urinary incontinence; (4) significant postvoid residual; and (5) worsening lower urinary tract dysfunction after urologic surgery.

The initial urinary symptoms of MSA are urgency, frequency, and urgency incontinence, occurring up to 4 years before the diagnosis is made, as does erectile failure. **Detrusor overactivity is frequently found, as one would expect from the central nervous system areas affected, but decreased compliance may occur, reflecting distal spinal involvement of the locations of the cell bodies of autonomic neurons innervating the lower urinary tract. As the disease progresses, difficulty in initiating and maintaining voiding may occur, probably from pontine and sacral cord lesions, and this is generally associated with a poor prognosis. Cystourethrography or videourodynamic studies may reveal an open bladder neck (intrinsic sphincter deficiency), and many patients exhibit evidence of striated sphincter denervation on motor unit electromyography. The smooth and striated sphincter abnormalities predispose women to sphincteric incontinence and make prostatectomy hazardous in men.** Berger and coworkers (1990) described a useful urodynamic differentiation of what was termed Shy-Drager syndrome (probable late stage MSA) from PD. Parkinsonian patients with voiding dysfunction generally have detrusor overactivity and normal compliance. An open bladder neck was seen only in patients with "Shy-Drager syndrome," excluding those patients with PD who have had a prostatectomy. EMG evidence of striated sphincter denervation was seen much more commonly in those diagnosed as having Shy-Drager syndrome.

The treatment of significant voiding dysfunction caused by MSA is difficult and seldom satisfactory. Treatment of detrusor overactivity during filling may worsen problems initiating voluntary micturition or worsen impaired contractility during emptying. Patients generally have sphincteric insufficiency, so an outlet-reducing procedure is rarely indicated. Drug treatment for sphincteric incontinence may further worsen emptying problems. Generally, the goal in these patients is to facilitate storage, and CIC would often be desirable. Unfortunately, patients with advanced disease often are not candidates for CIC.

DISEASES PRIMARILY INVOLVING THE SPINAL CORD

Multiple Sclerosis

Multiple sclerosis (MS) is primarily a disease of young and middle-aged adults with a twofold predilection for women. Litwiller and colleagues (1999) detailed current prevalence rates for MS as 1/1000 Americans, 2/1000 northern Europeans, and 20 to 40/100,000 first-degree relatives of patients with MS. **The disease is believed to be immune mediated and is characterized by neural demyelination, generally characterized by axonal sparing, in the brain and spinal cord** (Noseworthy et al, 2000). This demyelination causes impairment of saltatory conduction and of conduction velocity in axonal pathways, resulting in various neurologic abnormalities that are subject to exacerbation and remission. Lesions, known as plaques, range from 1 mm to 4 cm and are scattered throughout the white matter of the nervous system (Chancellor and Blaivas, 1993). **The demyelinating process most commonly involves the lateral corticospinal (pyramidal) and reticulospinal columns of the cervical spinal cord,** and it is thus not surprising that voiding dysfunction and sphincter dysfunction are so common. Autopsy studies have revealed almost constant evidence of demyelination in the cervical spinal cord, but involvement of the lumbar and sacral cord occurs in approximately 40% and 18%, respectively (Blaivas and Kaplan, 1988). Lesions may also occur in the optic nerve and in the cerebral cortex and midbrain, the latter accounting for the intellectual deterioration and/or euphoria that may be seen as well (Kirby, 1994; Noseworthy et al, 2000), ultimately in up to 43% to 65% of patients (Litwiller et al, 1999). A rat model for a demyelinating disease resembling MS has been described using myelin basic protein as an antigen for inducing experimental allergic encephalomyelitis (Mizusawa et al, 2000).

The incidence of voiding dysfunction in MS is related to the disability status. Of patients with MS, **50% to 90% complain of voiding symptoms at some time; the prevalence of incontinence is cited as 37% to 72%** (Wyndaele et al, 2005). Litwiller and colleagues (1999), in their excellent review article, cite symptoms of frequency or urgency in 31% to 85% of patients in various series, with corresponding percentages of incontinence as 37% to 72% and of obstructive symptoms with urinary retention in 2% to 52%. Lower urinary tract involvement may constitute the sole initial complaint or be part of the presenting symptom complex in up to 15% of patients, usually in the form of acute urinary retention of "unknown" etiology or as an acute onset of urgency and frequency, secondary to overactivity (Wyndaele et al, 2005).

Detrusor overactivity is the most common urodynamic abnormality detected, occurring in 34% to 99% of cases in reported series (Blaivas and Kaplan, 1988; Chancellor and Blaivas, 1993; Sirls et al, 1994; Litwiller et al, 1999). **Of the patients with overactivity, 30% to 65% have coexistent striated sphincter dyssynergia. Impaired detrusor contractility or areflexia may also exist; estimates of prevalence range from 12% to 38%** (Wyndaele et al, 2005), **a phenomenon that can considerably complicate treatment efforts.** Other estimates suggest that 62% of patients with MS have neurogenic detrusor overactivity with bladder outlet obstruction, 25% have neurogenic detrusor overactivity with detrusor sphincter dyssynergia, 20% have detrusor under activity, and 10% have no initial abnormal urodynamic findings. The variability and potential multiplicity of lesions associated with MS, however, prohibit accurate diagnosis on the basis of urodynamics alone (Ukkonen et al, 2004). Bladder dysfunction associated with MS, as compared with women with non-neurogenic detrusor activity, has been shown to demonstrate significant differences. The amplitude of the first overactive contraction is greater in patients with MS as compared with those patients with idiopathic detrusor overactivity, as is the maximal detrusor contraction. The threshold volume at which detrusor overactivity occurs in patients with neurogenic detrusor overactivity, however, is somewhat higher than in those patients with idiopathic detrusor overactivity, which may be related to residual volume and which is noted in patients with detrusor overactivity. Using threshold values for prediction of type of voiding dysfunction, 30 cm of H_2O and above was predictive of patients having neurogenic detrusor activity as compared with those who have non-neurogenic detrusor overactivity. These differences in neurogenic detrusor overactivity urodynamic findings may be representative of direct neurogenic influences on the detrusor muscle from abnormal bladder interpolation and/or signaling as compared with non-neurogenic patients (Lemack, 2006).

Generally, **the smooth sphincter is synergic.** Chancellor and Blaivas (1993) reviewed urodynamic findings in multiple series of patients with MS and voiding dysfunction and summarized the incidence of three basic patterns: (1) detrusor overactivity, striated sphincter synergia 26% to 50% (average 38%); (2) detrusor overactivity, striated sphincter dyssynergia 24% to 46% (average, 29%); and (3) detrusor areflexia 19% to 40% (average, 26%). Litwiller and colleagues (1999) tabularized 22 references, reporting approximately the same ranges. It is also possible to see relative degrees of sphincteric flaccidity caused by MS, a phenomenon cited as occurring in less than 15% of patients (Litwiller et al, 1999); this finding could predispose and contribute to sphincteric incontinence. De Ridder and colleagues (1998) reported weakness of pelvic floor contraction in nearly all 30 women they studied with MS. Spasticity of the pelvic floor was present in all patients with striated sphincter dyssynergia but in none with detrusor overactivity alone.

Because sensation is frequently intact in these patients, one must be careful to distinguish urodynamic pseudodyssynergia from true striated sphincter dyssynergia. Blaivas and colleagues (1981) subcategorized true striated sphincter dyssynergia in patients with MS and identified some varieties that are more worrisome than others. For instance, in a female with MS, a brief period of striated sphincter dyssynergia during detrusor contraction but one that does not result in excessive intravesical pressure during voiding, substantial residual urine volume, or secondary detrusor hypertrophy may be relatively inconsequential, whereas those varieties that are more sustained—resulting in high bladder pressures of long duration—are most associated with urologic complications. Giannantoni and colleagues (1998) reviewed 116 of their patients and likewise concluded that there was a significant relationship between the maximum amplitude of the involuntary bladder contractions and upper urinary tract deterioration. Chancellor and Blaivas (1993) emphasized what they believed were **the most important parameters predisposing patients with MS to significant urologic complications: (1) striated sphincter dyssynergia in men; (2) high detrusor filling pressure (>40 cm H_2O); and (3) an indwelling catheter. Interestingly, however, Wyndaele's committee** (Wyndaele et al, 2005) **concluded that progressive neurologic disease, MS included, rarely causes upper urinary tract damage, even when, in MS, severe spasticity and disability exist. The reason for this is unknown, but they believe that the situation and concerns with respect to this are unlike those for SCI.**

Key Point: Multiple Sclerosis

- The most common functional classification applicable to patients with voiding dysfunction secondary to MS would thus be storage failure secondary to detrusor overactivity. This is commonly complicated by striated sphincter dyssynergia, with varying effects on the ability to empty completely at acceptable pressures. Other abnormalities and other combined deficits, are obviously possible, however. Once the dysfunction is broadly characterized, the treatment options should be obvious from the therapeutic menus (see Tables 61–3 and 61–4).

Aggressive and anticipatory medical management can obviate most significant complications. Sirls and colleagues (1994) reported that only 7% (the author calculated 10.4%) of their patients required surgical intervention because of failure of aggressive medical management and that none developed hydronephrosis on such therapy. The regimens used were (1) drugs to decrease detrusor overactivity plus CIC (57%); (2) such drugs alone (13%); (3) CIC alone (15%); and (4) behavioral therapy. **A significant proportion of patients with MS with and without new symptoms will develop changes in their detrusor compliance and urodynamic pattern** (Ciancio et al, 2001). **Caution should therefore be exercised in recommending irreversible therapeutic options.** No factors appear to be predictive of upper tract changes in MS. In a 4-year follow-up of multiple sclerosis patients, 113 patients were evaluated, of whom 66 patients

had both urodynamic and renal ultrasound testing. Sixteen percent (11 patients) had abnormal ultrasound findings. The most significant finding was minor caliectasis, which was of no clinical significance. Neither creatinine nor urodynamic findings were associated with the abnormal renal ultrasound findings (Lemack et al, 2005). Surgical intervention for multiple sclerosis appears to be diminishing with improved pharmacologic management and the realization of the alternating neurologic picture of lower urinary dysfunction associated with MS (Ukkonen et al, 2004).

No consensus on optimal bladder management has identified for multiple sclerosis, and most commonly, management is predicated on symptomatic and urodynamic findings. According to consensus agreement, De Ridder and colleagues (2005) concluded that in early multiple sclerosis, anticholinergics and intermittent catheterization were considered to be cornerstones of therapy. For advanced MS (with an EDSS > 7), specific guidelines remain lacking. In general, crédé voiding or Valsalva voiding are contraindicated, especially in the presence of detrusor sphincter dyssynergia. They further recommended that indwelling catheters be reserved for patients for whom all other possible treatments have failed. In the approximately 30% of patients with MS using indwelling urinary catheters, the suprapubic route is the preferred route in both men and women. This form of management is considered reasonable for that subpopulation, as long as long-term follow-up is continued (De Ridder et al, 2005).

Spinal Cord Injury

Epidemiology, Morbidity, General Concepts

SCI may occur as a consequence of acts of violence, fracture, or dislocation of the spinal column secondary to motor vehicle, diving accidents or falls, vascular injuries or repair, infection, disk prolapse, or sudden or severe hyperextension from other causes. Altered lower urinary tract and sexual function frequently occur secondary to SCI and significantly affect quality of life; SCI patients are at risk urologically for urinary tract infection, sepsis, upper and lower urinary tract deterioration, upper and lower urinary tract calculi, autonomic hyperreflexia (dysreflexia), skin complications, and depression (which can complicate their urologic management). Failure to properly address the lower urinary tract dysfunction can lead to significant morbidity and mortality. There is great variation in urologic practice regarding initial evaluation, follow-up, and surveillance among spinal injury units (Bycroft et al, 2004), a problem that Boone (2004) properly attributes to a lack of evidence-based decision making.

Complete anatomic transection of the spinal cord is rare, and the degree of neurologic deficit varies with the level and severity of the injury. **Spinal column (bone) segments are numbered by the vertebral level, and these have a different relationship to the spinal cord segmental level at different locations. One must be careful to specify cord or column level when discussing SCI. The sacral spinal cord begins at about spinal column level T12 to L1. The spinal cord terminates in the cauda equina at approximately the spinal column level of L2.** Multiple level injuries may occur, and, even with a single initial injury, cord damage may not be confined to a single cord segment and may extend cephalad, caudad, or both.

Stover and Fine (1987) reviewed the epidemiology and other general aspects of SCI. The annual rate was reported as 30 to 32 new SCIs per million persons at risk in the United States; the prevalence was approximately 906 per million. This coincides roughly with the estimate by DeVivo (1997) of approximately 10,000 new cases of SCI in the United States yearly and an estimate of 12,000 per year by Rabchevsky and Smith (2001). DeVivo (1997) reported the most common mechanisms of injury, as collected by the National Spinal Cord Injury Statistical Center, as motor vehicle accidents (35.9%), violence (29.5%), falls (20.3%), and sports-related injuries (7.3%). Males account for 71% to 80% of patients with SCI. The average age at injury is 31.5 years. Children comprise 3% to 5% of all patients with SCI (Generao et al, 2004). Stover and Fine (1987) reported that neurologically incomplete quadriplegics constituted the largest group of SCI patients at the time of hospital admission (28%), followed by complete paraplegics (26%), complete quadriplegics (24%), and incomplete paraplegics (18%). This seems to have changed little during the 1990s. The majority occur at or above the T12 spinal column (vertebral) level.

Although earlier data (Hackler, 1977) **indicated that renal disease was the major cause of death, at least in the paraplegic patient, a retrospective study of more than 5000 patients who sustained SCI between 1973 and 1980 revealed that the leading causes of death at that time were pneumonia, septicemia, heart disease, accidents, and suicide** (Stover and Fine, 1987; Soden et al, 2000). These figures seemingly indicate a distinct improvement in the urologic care of these patients. Impaired mobility is commonly noted in the spinal cord–injured patient and may substantially affect urinary habit and incontinence (Biering-Sorensen et al, 2004). Urologic phenomena also figure prominently in chronic SCI. Within 10 years after SCI, approximately 7% of patients with spinal cord will develop an initial kidney stone with the greatest risk occurring during the first 3 months after injury. Ninety-eight percent of these stones will be apatite or struvite in composition. There appear to be two time frames for stone formation in this population, one being the acute phase associated with immobilization and immobilization hypercalciuria. The other is a more chronic phase stone formation period, usually associated with chronic catheter management years after injury and predominately involving the lower tract (Post and Noreau, 2005).

Controlled and coordinated lower urinary tract function depends on an intact neural axis. Bladder contractility and the occurrence of reflex contractions depend on an intact sacral spinal cord and its afferent and efferent connections (see Chapter 61).

An impressive amount of literature is continuously building on the neurobiology of the spinal cord and its acute and chronic alteration after SCI. These topics are not specifically considered in

Key Point: Spinal Cord Injury

- Generally, complete spinal cord lesions above the sacral spinal cord, but below the area of the sympathetic outflow, result in detrusor overactivity, absent sensation below the level of the lesion, smooth sphincter synergia, and striated sphincter dyssynergia. Lesions at or above the spinal cord level of T7 or T8 (the spinal column level of T6) may result in smooth sphincter dyssynergia as well. However, although the correlation between neurologic and urodynamic findings is good, it is not perfect, and a neurologic examination is no substitute for a urodynamic evaluation in these patients when one is determining risk factors and treatment (see later).

detail here, nor are the ramifications of this information relative to potential improvement of spinal cord function after injury by stem cell implant or reinnervation. Earlier reviews can be found by Olson (1997), Fawcett (1998), and Kakulas (1999); later ones were presented by Rabchevsky and Smith (2001) (this also includes a discussion of pathophysiology and experimental models), Cao and colleagues (2002) (stem cell repair), Fawcett (2002) (repair of SCI), Rossi and Cattaneo (2002) (stem cell therapy), Mitsui and colleagues (2003) (stem cell repair), Kakulas (2004) (neuropathology and natural history of the spinal cord changes), and Livshits and colleagues (2004) (reinnervation). Sexual and reproductive dysfunction in the patient with SCI is a topic that deserves much attention in the overall rehabilitation plan. Pertinent general and specific concepts of sexual and reproductive dysfunction and their normalization in this special group of patients can be found in Chapters 23, 27 (male), and 30 (female). Other excellent reviews on the specifics of sexual function in SCI can be found by Bennett and colleagues (1988), Stone and MacDermott (1989), Smith and Bodner (1993), and Biering-Sorensen and Sonksen (2001), and on infertility by Linsenmeyer and Perkash (1991), Rajaskaran and Monga (1999), and Rutkowski and colleagues (1999).

Spinal Shock

After a significant SCI, a period of decreased excitability of spinal cord segments at and below the level of the lesion occurs, referred to as "spinal shock." There is **absent somatic reflex activity and flaccid muscle paralysis below this level.** Although classic teaching refers to generalized areflexia below the level of the lesion for days to months, Thomas and O'Flynn (1994) confirm that the most peripheral somatic reflexes of the sacral cord segments (the anal and bulbocavernosus reflexes) may never disappear or, if they do, may return within minutes or hours of the injury. However, functions proximal to the level of the injury may be depressed as well (Atkinson and Atkinson, 1996). Although the course of spinal shock is well known, the actual phenomenon remains poorly understood, with little or no basic research evident recently.

Spinal shock includes a suppression of autonomic activity, as well as somatic activity, and the bladder is acontractile and areflexic. Radiologically, the bladder has a smooth contour with no evidence of trabeculation. The bladder neck is generally closed and competent unless there has been prior surgery or in some cases of thoracolumbar and presumably sympathetic injury (Sullivan and Yalla, 1992). **The smooth sphincter mechanism seems to be functional. Some EMG activity may be recorded from the striated sphincter, and the maximum urethral closure pressure is lower than normal but still maintained at the level of the external sphincter zone; however, the normal guarding reflex (striated sphincter response during filling) is absent and there is no voluntary control** (Fam and Yalla, 1988). Because sphincter tone exists, urinary incontinence generally does not result unless there is gross overdistention with overflow. In evolving lesions, every attempt should be made to preserve as low a bladder storage pressure as possible and to avoid any measures that might impair this. Urinary retention is the rule, and catheterization is necessary to circumvent this problem. Although virtually all would agree that CIC is an excellent method of management during this period and advocate its use, Lloyd and colleagues (1986) reported their own experience and cite that of others that indicate no differences in outcome when a small-bore Foley catheter or suprapubic tube is used at this stage.

If the distal spinal cord is intact but is simply isolated from higher centers, there is generally a return of reflex detrusor contractility. At first, such reflex activity is poorly sustained and produces only low-pressure changes, but the strength and duration of such involuntary contractions increase, producing involuntary voiding, usually with incomplete bladder emptying. This return of reflex bladder activity is generally manifested by involuntary voiding between catheterizations and occurs along with the recovery of lower extremity deep tendon reflexes. Spinal shock generally lasts 6 to 12 weeks in complete suprasacral spinal cord lesions but may last up to 1 or 2 years. It may last a shorter period of time in incomplete suprasacral lesions and only a few days in some patients.

Suprasacral Spinal Cord Injury

There is no unanimous agreement on the neurobiology of the development of reflex bladder contraction in response to bladder distention after suprasacral SCI. de Groat and colleagues (1997) have studied this phenomenon and related events extensively in cats and listed four potential mechanisms for the recovery of such micturition and the development of C-fiber afferent evoked bladder reflexes (see also the description by Yoshimura and Chancellor in Chapter 60): (1) elimination of bulbospinal inhibitory pathways; (2) strengthening of existing synapses or formation of new synaptic connections from axonal sprouting in the spinal cord; (3) changes in synthesis, release, or actions of neurotransmitters, and (4) alterations in afferent input (afferent axonal sprouting) from peripheral organs. Recent reports of specific alterations in animal models are summarized by Morrison and colleagues (2005) as (1) increased sensitivity of C-fiber afferents, possibly involving nerve growth factor; (2) enlargement of dorsal root ganglion cells; (3) increased electrical excitability of afferents associated with a shift in expression of sodium channels from a high-threshold tetrodotoxin-resistant type to a low-threshold tetrodotoxin-sensitive type. Other findings possibly related to the development of lower urinary tract dysfunction after SCI have been reported as (1) increased concentrations of glutamate, glycine, and taurine (Smith et al, 2002); (2) disruption of bladder epithelium barrier function (Apodaca et al, 2003); (3) change from low affinity M_1 to high affinity M_3 receptors at prejunctional cholinergic nerve endings (Somogyi et al, 2003); (4) increased release of adenosine triphosphate from bladder urothelium (Khera et al, 2004); (5) increased spinal cord nerve growth factor (Seki et al, 2004); and (6) alterations in smooth muscle myosin heavy chain gene expression (Wilson et al, 2005). Recently, in murine models of acute SCI, nicotinic or purinergic receptor mechanisms have been shown to be the primary mechanism for ATP release as atropine has been shown to be only partially effective in stimulating ATP release (predominantly a muscarinic receptor phenomenon in the absence of injury).These findings further indicate a change in receptor-mediated bladder activity associated with SCI (Salas et al, 2007).

The characteristic pattern that results when a patient has a complete lesion above the sacral spinal cord is detrusor overactivity, smooth sphincter synergia (with lesions below the sympathetic outflow), and striated sphincter dyssynergia (Sullivan and Yalla, 1992; Thomas and O'Flynn, 1994; Chancellor and Blaivas, 1995b). **Neurologic examination shows spasticity of skeletal muscle distal to the lesion, hyperreflexic deep tendon reflexes, and abnormal plantar responses. There is impairment of superficial and deep sensation.** Figures 65–1 to 65–3 typify the cystourethrographic and urodynamic patterns. The guarding

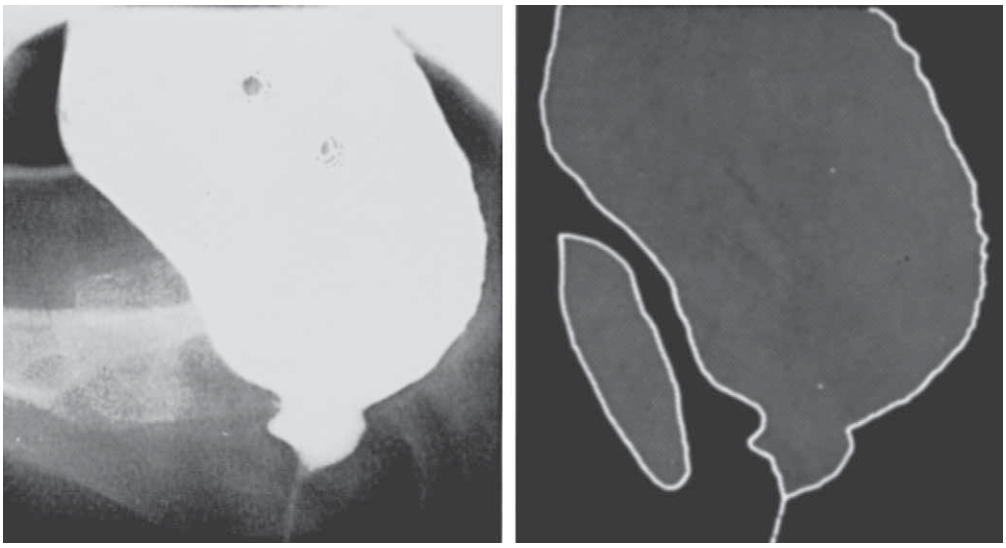

Figure 65–1. Cystourethrogram in a 19-year-old woman with detrusor–striated sphincter dyssynergia secondary to a complete spinal cord injury at vertebral level T11. Image was taken during an involuntary bladder contraction with exaggerated bladder neck opening caused by the obstruction below. (From Nordling J, Olesen KP. Basic urographic and cystourethrographic patterns. In: Pollack HM, editor. Clinical urography. Philadelphia: WB Saunders; 1990, p. 1953.)

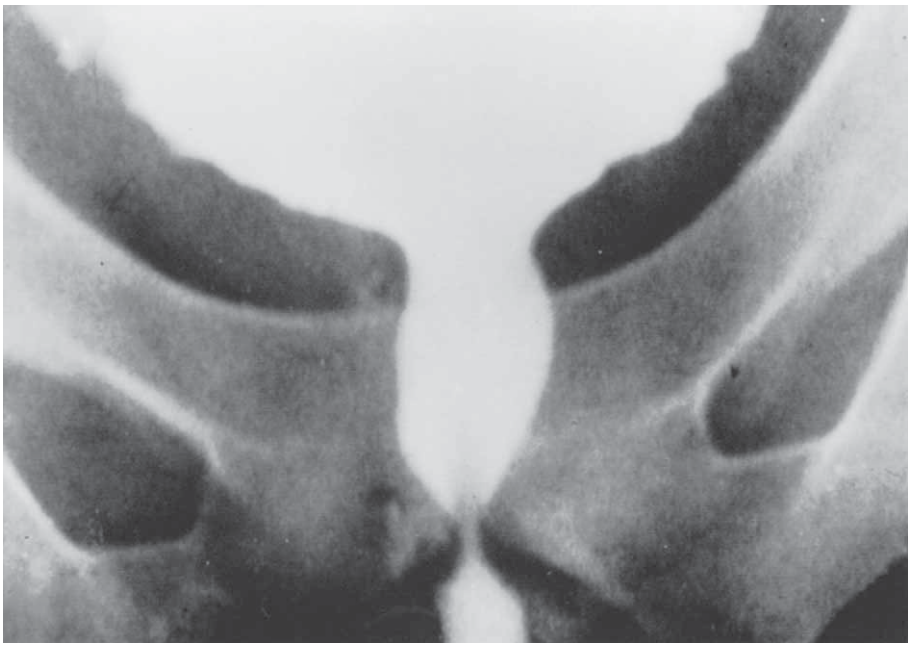

Figure 65–2. Typical cystourethrographic configuration of a synergic smooth sphincter and a dyssynergic striated sphincter in a man during a bladder contraction. (From Nanninga JB: Radiological appearances following surgery for neuromuscular diseases affecting the urinary tract. In: Pollack HM, editor. Clinical urography. Philadelphia: WB Saunders; 1990, p. 2003.)

reflex is absent or weak in most patients with a complete suprasacral SCI. In incomplete lesions the reflex is often preserved but variable (Morrison et al, 2005).

The striated sphincter dyssynergia causes a functional obstruction with poor emptying and high detrusor pressure. In an effort to subclassify detrusor sphincter dyssynergia, Karsenty and colleagues (2005) retrospectively evaluated videourodynamic recordings of patients with complete SCI with untreated neurogenic overactive bladder and detrusor sphincter dyssynergia. They identified two time periods within the tracings, with Delay A being defined as that period between the onset of external urethral sphincter (EUS) pressure increase and the subsequent onset of bladder pressure increase. Delay B was defined as the period between the onset of urethral sphincter pressure increase and the moment at which bladder pressure increase reached a level of 10 cm H_2O or greater above the baseline value. The recordings of 20 patients were assessed, with the Delay A timeframe found to be significant in 16 of 20 patients, with a meantime for delay of 2.2 seconds. There was a positive association between this delay and the completeness of the SCI and the presence of continuous DSD on electromyogram. Delay B was positive in all patients with a mean delay time of 7.6 seconds. The authors concluded that EUS contraction starts before the onset of bladder contraction in most patients with coexistent SCI and detrusor sphincter dyssynergia. **Occasionally, incomplete bladder emptying may result from what seems to be a poorly sustained or absent detrusor contraction.** This seems to occur more commonly in lesions close to the conus medullaris than with more cephalad lesions. This may result from a second occult lesion or may be caused by locally functioning reflex arcs, which result in detrusor inhibition from strong striated pelvic floor muscle contraction, or to a loss of higher

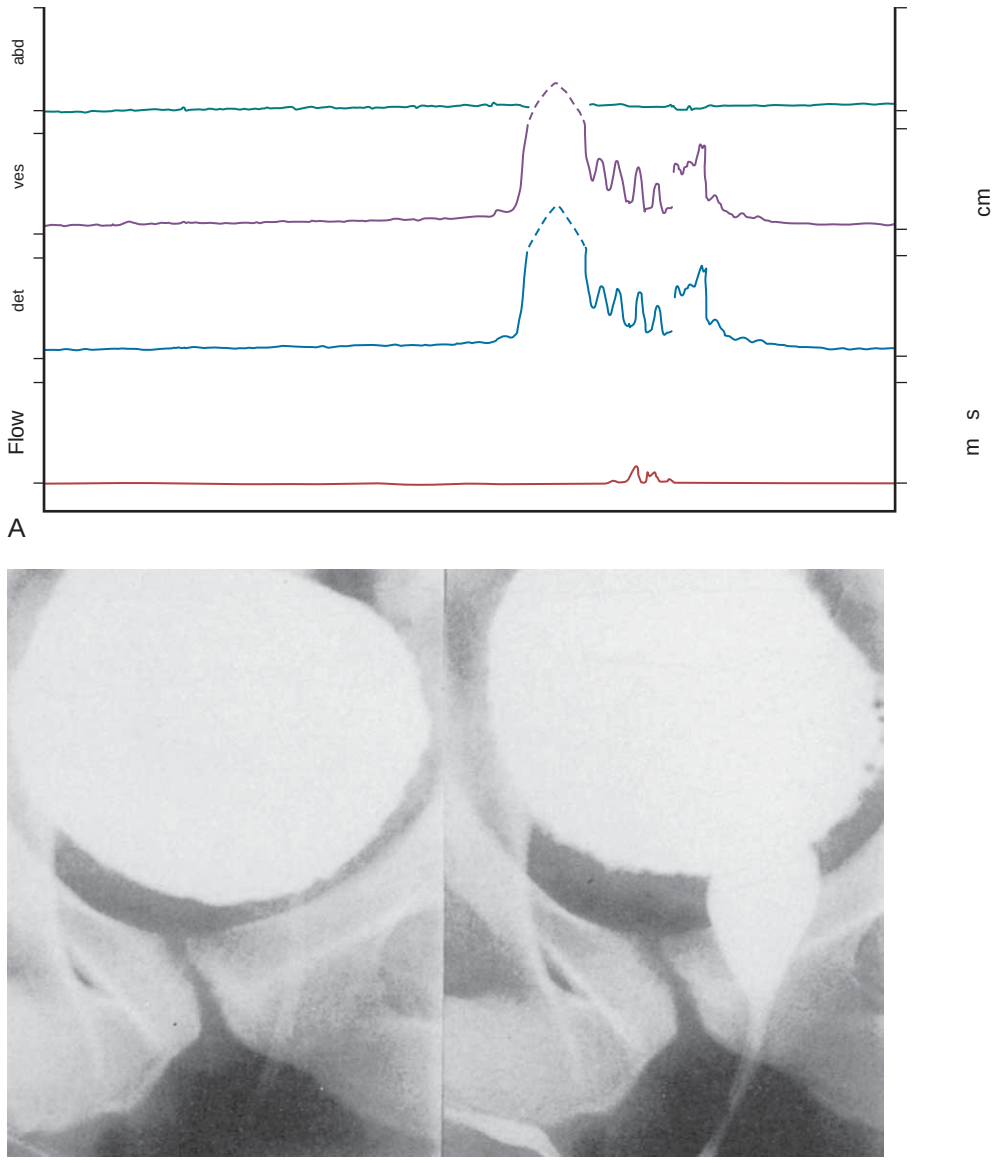

Figure 65–3. Video images in **B** at corresponding points of the urodynamic tracings in **A**. Detrusor hyperreflexia (P_{det} 150 cm H_2O), synergic bladder neck, dyssynergic striated sphincter. The *asterisk* represents a range change from a scale of 0 to 100 cm H_2O. (From Lawrence WT, Thomas DC. Urodynamic techniques in the neurologic patient. In: O'Reilly PH, George NJR, Weiss RM, editors. Diagnostic techniques in urology. Philadelphia: WB Saunders; 1990. p. 360.)

center–mediated detrusor facilitation, which normally occurs after the initial increase in pressure during a bladder contraction (Thomas and O'Flynn, 1994). Once reflex voiding is established, it can be initiated or reinforced by the stimulation of certain dermatomes, as by tapping the suprapubic area. The urodynamic and upper tract consequences of the striated sphincter dyssynergia vary with severity (generally worse in complete lesions than in incomplete ones), duration (continuous contraction during detrusor activity is worse than intermittent contraction), and anatomy (male is worse than female) (Linsenmeyer et al, 1998).

The type of dyssynergia also appears to be associated with degree of injury and potential for progression of dysfunction. Schurch and colleagues (2005) evaluated 105 male patients with SCI to determine if neurologic examination could predict the type of detrusor sphincter dyssynergia present. A correlation was noted between type of dyssynergia and completeness of spinal cord lesion. More commonly, patients with incomplete sensory and motor lesions presented with type 1 DSD. Complete sensory and motor lesions were more commonly associated with either type 2 or type 3 detrusor sphincter dyssynergia. There was no correlation, however, noted between the type of DSD and the lesion level. At chronic follow-up DSD type was noted to evolve from type 2 or type 3 DSD in approximately a quarter of the studied patients, whereas 65% of patients remained stable with the same type of DSD at follow-up (Schurch et al, 2005).

Sacral Spinal Cord Injury

After the patient recovers from spinal shock, there **is generally a depression of deep tendon reflexes below the level of a complete lesion with varying degrees of flaccid paralysis. Sensation is generally absent below the lesion level. Detrusor areflexia with high or normal compliance is the common initial result, but decreased compliance may develop,** a change seen in some neurologic lesions at or

Key Point: Management of Patients with Suprasacral Spinal Cord Injury

- From a functional standpoint the voiding dysfunction most commonly seen in suprasacral SCI represents both a filling/storage and an emptying failure. Although the urodynamics are "safe" enough in some individuals to allow only periodic stimulation of bladder reflex activity, many will require some treatment. If bladder pressures are suitably low or if they can be made suitably low with nonsurgical or surgical management, the problem can be treated primarily as an emptying failure. CIC can be continued, when practical, as a safe and effective way of satisfying many of the treatment goals. Alternatively, sphincterotomy, stenting, or intrasphincteric injection of botulinum toxin can be used in males to lower the detrusor leak point to an acceptable level, thus treating the dysfunction primarily as one of emptying. The resultant storage failure can be obviated either by timed stimulation or with an external collecting device. In the dexterous SCI patient, the former approach using CIC is becoming predominant. Electrical stimulation of the anterior sacral roots with some form of deafferentation is also now a distinct reality (Creasey et al, 2001; Seif et al, 2004). As with all patients with neurologic impairment, a careful initial evaluation and periodic follow-up evaluation must be performed to identify and correct the following risk factors and potential complications: bladder overdistention, high-pressure storage, high detrusor leak point pressure, vesicoureteral reflux (VUR), stone formation (lower and upper tracts), and complicating infection, especially in association with reflux.

distal to the sacral spinal cord that most likely represents a complex response to neurologic decentralization probably involving reorganization and plasticity of neural pathways (Fam and Yalla, 1988; de Groat et al, 1997; Blaivas et al, 1998b). There is surprisingly little consensus on the evolution of the appearance or function of the bladder neck or smooth sphincter area after sacral spinal cord damage. **The classic outlet findings are described as a competent but nonrelaxing smooth sphincter and a striated sphincter that retains some fixed tone but is not under voluntary control. Closure pressures are decreased in both areas** (Sullivan and Yalla, 1992; Thomas and O'Flynn, 1994). However, the late appearance of the bladder neck may be "open" (Kaplan et al, 1991). Attempted voiding by straining or Credé's maneuver results in "obstruction" at the bladder neck (if closed) or at the distal sphincter area by fixed sphincter tone (Fam and Yalla, 1988; Thomas and O'Flynn, 1994). Figure 65–4 illustrates the typical cystourographic and urodynamic pictures of the late phases of such a complete lesion.

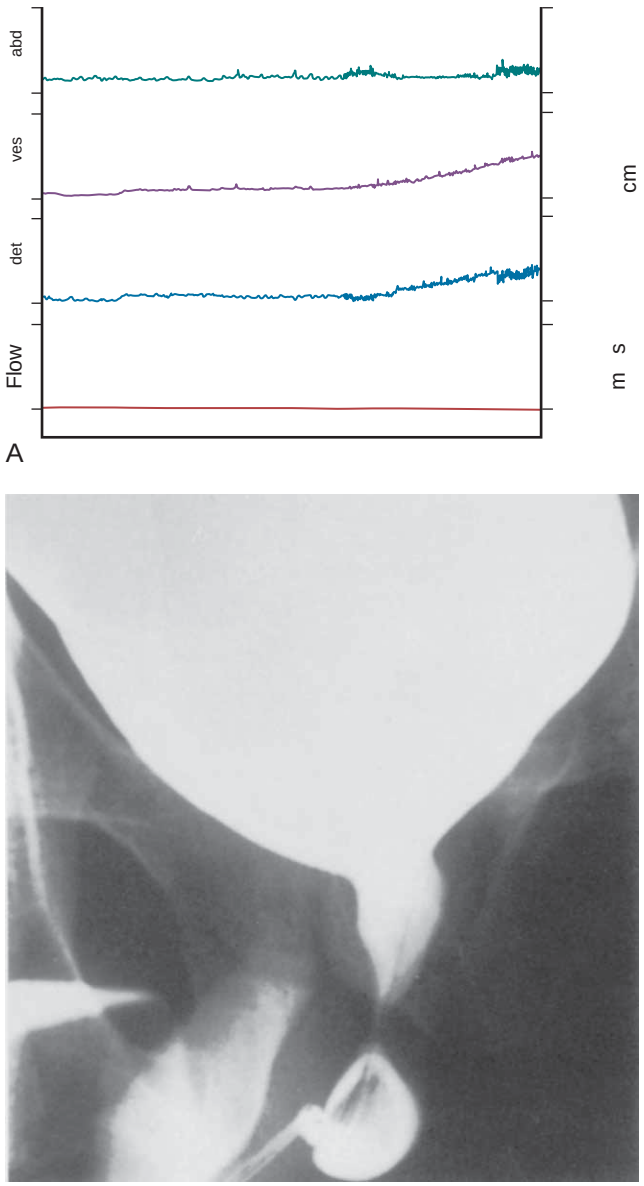

Figure 65–4. Simultaneous video **(B)** and urodynamic study **(A)** from a 28-year-old man whose bladder has been filled with 420 mL of contrast material. There is low compliance; the bladder neck is incompetent; and with straining the distal sphincter mechanism does not open—a pattern often seen in sacral spinal cord or efferent nerve root injury or disease. (From Lawrence WT, Thomas DC. Urodynamic techniques in the neurologic patient. In: O'Reilly PH, George NJR, Weiss RM, editors. Diagnostic techniques in urology. Philadelphia: WB Saunders; 1990, p. 362.)

Neurologic and Urodynamic Correlation

Although generally correct, the correlation between somatic neurologic findings and urodynamic findings in suprasacral and sacral SCI patients is not exact. A number of factors should be considered in this regard. First, whether a lesion is complete or incomplete is sometimes a matter of definition, and a complete lesion, somatically speaking, may not translate into a complete lesion autonomically and vice versa. Multiple injuries may actually exist at different levels, even though what is seen somatically may reflect a single level of injury. Even considering these situations, however, all such discrepancies are not explained. This is further demonstrated in patients with incomplete lesions. Patki and colleagues (2006) assessed a group of 43 men and 21 women with incomplete SCI (ASA grades D and E) during a 2-year period. In this group, 40 patients who were initially assessed as having a bladder not at risk for deterioration ultimately experienced deterioration requiring clean, intermittent catheterization. Conversely, 5 of 20 patients, who initially required clean intermittent catheterization, no longer required this with time. In chronic follow-up, 68% of patients continued to have abnormal urodynamic findings and 37% of patients required a

change in urologic management in the absence of perceptible change in neurologic status, indicating the potential of continued bladder changes in the absence of other detectable neurologic disease (Patki et al, 2006).

Key Point: Management of Patients with Sacral Cord Injury

- **Potential risk factors and complications are those previously described, with particular emphasis on storage pressure, which can result in silent upper tract decompensation and deterioration in the absence of VUR. The treatment of such a patient is generally directed toward producing or maintaining low-pressure storage while circumventing emptying failure with CIC when possible.** Pharmacologic and electrical stimulation may be useful in promoting emptying in certain circumstances (see Tables 66–3 and 66–4).

In a classic article, Blaivas (1982) **correlated clinical and urodynamic data from 550 patients with voiding dysfunction.** In 155 patients with complete and incomplete suprasacral neurologic lesions, physiologically normal voiding was reported in 41%. Detrusor–striated sphincter dyssynergia was demonstrated in 34%, and, surprisingly (and seemingly paradoxically), detrusor areflexia was noted in 25%. Other authors have noted detrusor areflexia with suprasacral SCI or disease, and the causes have been hypothesized as a coexistent distal spinal cord lesion or a disordered integration of afferent activity at the sacral root or cord level (Light et al, 1985; Beric and Light, 1992). Detrusor–striated sphincter dyssynergia was reported in 45% of 119 patients with suprasacral spinal cord lesions. None of 36 patients with supraspinal neurologic lesions had striated sphincter dyssynergia. **These data certainly support prior conclusions that (1) coordinated voiding is regulated by neurologic centers above the spinal cord and (2) a diagnosis of striated sphincter dyssynergia implies a neurologic lesion that interrupts the neural axis between the pontine-mesencephalic reticular formation and the sacral spinal cord.** All 27 patients with neurologic lesions above the pons and who were able to void did so synergistically—with relaxation of the striated sphincter preceding detrusor contraction. Twenty of these patients had detrusor overactivity, but 12 of these 20 had voluntary control of the striated sphincter, supporting a thesis of separate neural pathways governing voluntary control of the bladder and of the periurethral striated musculature. Most of these patients with detrusor overactivity secondary to lesions above the pons were able to voluntarily contract the striated sphincter, but without abolishing bladder contraction. This seems to indicate that the inhibition of bladder contraction by pudendal motor activity is not merely a simple sacral reflex but, rather, a complex neurologic event. Twenty-two of these patients had evidence of either sacral or infrasacral neurologic impairment of bladder function with suprasacral control of striated sphincter function or vice versa; this provides a clinical correlate to the separate anatomic locations of the parasympathetic motor nucleus and the pudendal nucleus in the sacral spinal cord (see Chapter 60).

A subsequent study from the same center analyzed the results of urodynamic evaluation in 489 consecutive patients with either congenital or acquired SCI or disease and correlated these with the diagnosed neurologic deficit (Kaplan et al, 1991). Although there was a general correlation between the neurologic level of injury and the expected vesicourethral function, it was neither absolute nor specific. Twenty of 117 cervical lesions exhibited detrusor areflexia; 42 of 156 lumbar lesions, detrusor–striated sphincter dyssynergia; and 26 of 84 sacral lesions, either detrusor overactivity or detrusor–striated sphincter dyssynergia. The patients were further classified on the basis of the integrity of the sacral dermatomes (intact sacral reflexes or not). This helps to explain some, but not all, of the apparent discrepancies. Of the patients with suprasacral cord lesions who had detrusor areflexia, 84% also had abnormal sacral cord signs (absent bulbocavernosus reflex, lax anal sphincter tone, or sphincter EMG abnormalities indicative of lower motor neuron degeneration). All suprasacral cord lesion patients who had no evidence of sacral cord involvement had either detrusor overactivity or detrusor striated sphincter dyssynergia.

Patients were also classified according to the three most common neurologic causes for their lesion: trauma, myelomeningocele, and spinal stenosis. Of the 284 trauma patients, all with thoracic cord lesions had either detrusor overactivity or detrusor striated dyssynergia and negative sacral cord signs. In contrast, in patients with traumatic lesions affecting other parts of the spinal cord, there was a wide distribution of both urodynamic and sacral cord sign findings. For example, of patients with traumatic lumbar cord injury, 38% had detrusor areflexia and positive sacral cord signs, 25% had detrusor–striated sphincter dyssynergia and negative sacral cord signs, 25% had detrusor overactivity and negative sacral cord signs, and 14% had either detrusor overactivity or detrusor–striated sphincter dyssynergia and negative sacral cord signs. Of 25 patients with lumbar myelomeningocele, 20 had either detrusor areflexia or detrusor–striated sphincter dyssynergia. All patients with lumbar myelomeningocele and detrusor areflexia had positive sacral cord signs. Of 48 patients with sacral myelomeningocele, 37 had detrusor areflexia and 35 had positive sacral cord signs. Of 54 patients with spinal stenosis, all those with cervical and thoracic cord lesions had either detrusor overactivity or detrusor–striated sphincter dyssynergia and negative sacral cord signs. Patients with a lumbar cord stenosis had no consistent pattern of detrusor activity or sacral cord signs. An open bladder neck at rest was found in 21 patients. All had either lumbar or sacral SCI. Sixteen of these had sacral cord lesions and detrusor areflexia. Decreased bladder compliance was noted in 54 patients, 41 of whom had sacral cord injury and 43 of whom had detrusor areflexia.

Koh et al (2006) reported urodynamic evaluation of five patients with myelomeningocele who underwent prenatal closure of the spinal dysraphism as compared with a large group of 88 patients who underwent postnatal closure. All five of the reported patients had lower lumbosacral lesions. They noted that there is no spontaneous electromyographic activity in the five prenatally intervened children as compared with only 39% identification in the postnatal group. Additionally, all five patients in the prenatal cohort exhibited detrusor overactivity as compared with 38% in the postnatal group. These findings were similar both at baseline and at 1 year. The finding of the complete innervation of the EUS suggested the need for close postnatal surveillance to exclude the possibility of tethering of the spinal cord and other events postsurgical intervention. The value of intervention in these patients has been noted in patients undergoing detethering. In a study of 120 children with myelomeningocele, Abrahamsson and colleagues (2007) identified 20 who underwent cord detethering at a

median age of 8 years. Preintervention and postintervention urodynamic evaluation was performed (median of 5 months preoperatively and a median of 12 months postoperatively). Of the 20 that underwent detethering in this group, 7 had improvement of their voiding dysfunction to a milder level of dysfunction with 1 experiencing deterioration. Six patients actually experienced deterioration of bladder dysfunction before detethering, all of whom returned to a less significant level postoperatively. Ten patients had no change in bladder function on urodynamics after intervention, one of whom actually deteriorated on urodynamic findings. The overall 35% improvement underscored the need for regular evaluation of bladder function in these children. Metcalfe and colleagues (2006) reported 36 patients who underwent sectioning of the filum terminale as management of tethered cord. They estimated 0.4% of pediatric clinic visits in the urology department resulted in neurosurgical referral for the potential exclusion of occult tethered cord. Symptoms included daytime incontinence in 83% of the patients and 47% with encopresis. Preintervention urodynamics showed a mean of a 55% reduction of expected bladder capacity in the affected patients. Clinical improvement was noted in 72% of patients undergoing intervention with 42% becoming clinically continent. Additionally, 88% of cases noted improvement in bowel symptomatology including 53% of patients noting improvement in encopresis after 3 months of surgery. Urodynamic improvement was likewise documented in 57% of patients on the basis of improved bladder capacity. No specific factors were identified that would improve surgical success on the basis of either urodynamic findings or symptomatic presentation. In yet another cohort of tethered cord patients (Guerra et al, 2006), 24 patients (10 male, 14 female) between the ages of 1 month and 12 years were treated for this condition. Diurnal incontinence was noted in 50% and constipation was noted in 42%. Incontinence resolved in all but 1 patient postoperatively with improvement in constipation in 4 of 10 patients with preoperative constipation. Forty-eight percent of children had resolution of urodynamic abnormalities postoperatively with 10 of 17 with detrusor overactivity normalizing and 7 remaining unchanged. Four patients with either diminished bladder capacity or low compliance did not improve postoperatively after intervention on urodynamics. Similarly, two of three patients with normal preoperative urodynamic evaluation developed detrusor overactivity and/or poor compliance postoperatively. They found there was no relationship between the level of conus on magnetic resonance imaging and predictive findings of urodynamics. The authors did raise concern regarding the potential for decompensation even after surgery.

Kessler and colleagues (2006) assessed 123 patients with myelomeningocele retrospectively on the basis of urodynamic patterns. The patients were classified into four categories: detrusor overactivity with overactive sphincter (43 patients), overactive detrusor and underactive or acontractile sphincter (37 patients), underactive acontractile detrusor with overactive spastic sphincter (8 patients), and underactive acontractile detrusor and underactive acontractile sphincter (35 patients). Patients were assessed for urinary incontinence and the need for adjunctive incontinence surgery between the four groups. At mean follow-up of 10 years, social continence was highest in groups one and three (86% and 87%, respectively) and lowest in groups two and four (57% and 74% respectively). There was statistical significance between interventions among the groups. The study concluded that initial urodynamics were useful in counseling families regarding the ultimate status of urinary incontinence in patients with myelomeningocele including rates of social continence.

Wyndaele (1997) correlated the neurologic and urodynamic data in 92 patients with SCI and came to the same general conclusion: **Although there was a general correlation between the neurologic level of injury and the expected vesicourethral function, it was neither absolute nor specific, especially in the group of patients with paraplegia resulting from spinal cord lesions at column level T10 to L2.** With reference to this latter group, Pesce and colleagues (1997) reported on 46 patients with complete SCIs from vertebral lesions between T11 and L2. Fifty percent of the patients had detrusor areflexia, and 50% had overactivity; 16 of the latter group also had striated sphincter dyssynergia. Of 22 patients with lesions above vertebral level L1, 8% showed areflexia and 14 showed overactivity, of whom 9 demonstrated sphincter dyssynergia. Of 9 patients with a lesion between T12 and L1, 3 showed detrusor areflexia and 6 overactivity, of whom 4 showed striated sphincter dyssynergia. Of 15 patients with a lesion at L1 or lower, 3% showed detrusor overactivity and striated sphincter dyssynergia.

Weld and Dmochowski (2000) agreed that the correlation between somatic neurologic findings or spinal imaging studies and urodynamic findings in patients with SCI is not exact, based on their review of 243 post-traumatic SCI patients who had complete spinal CT or MRI studies. It should be noted, however, that their correlation between level of injury and urodynamic findings was in fact better than those previously reported, most likely because of the more exact determination of the level of injury and the detection of multiple levels of injury, attributable to the precision of the radiologic imaging studies. Of 196 patients with suprasacral injuries, 94.9% demonstrated overactivity and/or striated sphincter dyssynergia, 41.8% had low bladder compliance (defined as 12.5 mL/cm H_2O), and 40.3% had detrusor leak point pressures greater than 40 cm H_2O. Of the 14 patients with sacral injuries, 85.7% demonstrated detrusor areflexia; 78.6%, low compliance; and 85.7%, high leak point pressures. Of 33 patients with combined suprasacral and sacral injuries, 68% demonstrated detrusor overactivity and/or detrusor dyssynergia; 27%, areflexia; 58%, low compliance; and 61%, high leak point pressures.

The degree and magnitude of SCI also impacts the overall management of these patients. Patki and colleagues (2006) assessed a group of 43 men and 21 women with incomplete SCI (ASA grades D and E) during a 2-year period. In this group, 40 patients who were initially assessed as having a bladder not at risk for deterioration ultimately experienced deterioration requiring clean, intermittent catheterization. Conversely, 5 of 20 patients, who initially required clean intermittent catheterization, no longer required this with time. In chronic follow-up, 68% of patients persisted with abnormal urodynamic findings, and 37% of patients required a change in urologic management in the absence of perceptible neurologic disease, indicating the potential of continued bladder changes in the absence of other detectable neurologic disease. Other factors such as underlying histology may also contribute to upper tract deterioration. Ozkan studied a group of patients undergoing augmentation for neurogenic detrusor overactivity, requiring augmentation cystoplasty. Patients underwent perioperative full-thickness bladder biopsies during the augmentation cystoplasty. A relationship between the degree of and severity of detrusor fibrosis was noted to be a significant risk factor of upper tract deterioration. Additionally, leak-point pressures of greater than 75 cm of water were also found to be consistent with upper tract deterioration (Ozkan et al, 2006).

All these data make the point, as cogently as possible, that **management of the urinary tract in such patients must be based on urodynamic principles and findings rather**

than inferences from the neurologic history and evaluation. Similarly, although the information regarding "classic" complete lesions is for the most part valid, one should not make neurologic conclusions solely on the basis of urodynamic findings.

Autonomic Hyperreflexia

First described by Guttmann and Whitteridge in 1947, autonomic hyperreflexia (autonomic dysreflexia) is a potentially fatal emergency unique to the SCI patient. Excellent sources of information include the reviews by Trop and Bennett (1991), Vaidyanathan and colleagues (1998), and Karlsson (1999). **Autonomic hyperreflexia represents an acute massive disordered autonomic (primarily sympathetic) response to specific stimuli in patients with SCI above the cord level of T6 to T8 (the sympathetic outflow).** It is more common in cervical (60%) than thoracic (20%) injuries. Onset after injury is variable (usually soon after spinal shock) but may be up to years after injury. Distal cord viability is a prerequisite.

Symptomatically, autonomic hyperreflexia is a **syndrome of exaggerated sympathetic activity in response to stimuli below the level of the lesion. The symptoms are pounding headache, hypertension, and flushing of the face and body above the level of the lesion with sweating. Bradycardia is a usual accompaniment, although tachycardia or arrhythmia may be present. Hypertension may be of varying severity,** from causing a mild headache before the occurrence of voiding to life-threatening cerebral hemorrhage or seizure. **The stimuli for this exaggerated response commonly arise from the bladder or rectum and generally involve distention, although other stimuli from these areas can be precipitating. Precipitation may be the result of simple lower urinary tract instrumentation, tube change, catheter obstruction, or clot retention; and, in such cases, the symptoms resolve quickly if the stimulus is withdrawn. Other causes or exacerbating factors may include other upper or lower urinary tract pathology (e.g., calculi), gastrointestinal pathology, long bone fracture, sexual activity, electrocoagulation, and decubiti.**

Striated sphincter dyssynergia invariably occurs, and smooth sphincter dyssynergia is generally a part of the syndrome as well, at least in males. The pathophysiology is that of a nociceptive stimulation via afferent impulses that ascend through the cord and elicit reflex motor outflow, causing arteriolar, pilomotor, and pelvic visceral spasm and sweating. Normally, the reflexes would be inhibited by secondary output from the medulla, but because of the SCI this does not occur below the lesion level. Vaidyanathan and colleagues (1998) emphasized that the SCI disrupts control of the sympathetic preganglionic neurons because bulbospinal input has been lost, and the remaining regulation is accomplished by spinal circuits consisting of dorsal root afferent and spinal interneurons. Karlsson (1999), however, points out that the underlying pathogenic mechanisms may not be as simple as they first appear. The amplitude of the blood pressure reaction indicates involvement of a large vascular bed, perhaps larger than that of the skin and skeletal muscle. It may be that the splanchnic vascular bed is involved as well, either from the standpoint of active vasoconstriction or simply from a lack of the ability to exhibit compensatory vasodilatation. Afferent and efferent plasticity in the sympathetic nervous system may also be involved.

Ideally, any endoscopic procedure in susceptible patients should be done under spinal anesthesia or carefully monitored general anesthesia. Acutely, the hemodynamic effects of this syndrome may be managed with β- and/or α-adrenergic blocking agents. Ganglionic blockers had previously been the mainstay of treatment (Wein, 2002a), but their usage has essentially been abandoned. Sublingual nifedipine had been reported to be capable of alleviating this syndrome when given during cystoscopy (10 to 20 mg) and of preventing it when given orally 30 minutes before cystoscopy (10 mg) (Dykstra et al, 1987). The rationale was that this presumably prevented smooth muscle contraction through its calcium antagonist properties and thereby prevented the increase in peripheral vascular resistance normally seen with sympathetic stimulation. The use of sublingual nifedipine, however, has been prohibited in the authors' particular medical center and doubtless in some others as well. It has been reported that the sublingual absorption of nifedipine is negligible and that the favorable therapeutic results obtained from such administration are probably caused by swallowing the drug (van Harten et al, 1987). These particular authors believe that if a fast onset of action of nifedipine is desired, the patient should be instructed to bite the capsule and swallow the contents with water, thereby rapidly achieving therapeutic plasma levels of the drug. Before electroejaculation, Steinberger and colleagues (1990) recommended oral prophylaxis with 20 mg of nifedipine, finding this markedly lowered pressure rises during treatment. Captopril, hydralazine, or diazoxide are still occasionally recommended but are less advantageous. Other rapidly acting agents have been reported to be beneficial. Many anesthesiologists recommend labetalol (Bycroft et al, 2005).

Chancellor and colleagues (1994) reported on the use of terazosin (a selective α_1-adrenergic blocker) for long-term management (3-month study) and prophylaxis. A nightly dose of 5 mg reduced severity, whereas erectile function and blood pressure were unchanged. Vaidyanathan and colleagues (1998) affirmed the success of the prophylactic use of terazosin. They treated 18 adults with tetraplegia and 3 with paraplegia with graduated increasing doses of the drug, ultimately varying from 1 to 10 mg daily, and reported complete subsidence of dysreflexic symptoms in all patients. Only one patient, a tetraplegic, required discontinuation of the drug because of persistent dizziness. Such prophylaxis may be particularly important in view of the fact that significant elevations in blood pressure can occur without other symptoms of autonomic hyperreflexia (Linsenmeyer et al, 1996). Similar salubrious results have also been reported with prazosin as prophylaxis for this condition (Bycroft et al, 2005).

Prophylaxis, however, does not eliminate the need for careful monitoring during provocative procedures. There are patients with severe dysreflexia that is intractable to oral prophylaxis and correction by urologic procedures. For these unfortunate individuals, a number of neurologic ablative procedures have been used—sympathectomy, sacral neurectomy, sacral rhizotomy, cordectomy, and dorsal root ganglionectomy (Trop and Bennett, 1991). Hohenfellner and colleagues (2001) advocate sacral bladder denervation by sacral rhizotomy as a moderately invasive, relatively low-risk procedure that, along with intermittent catheterization, produces good results in refractory patients.

Vesicoureteral Reflux

Surprisingly little is written about VUR in the SCI patient. The reported incidence varies between 17% and 25% of such patients (Thomas and Lucas, 1990) and is more common in those with

suprasacral SCI. Contributing factors include (1) elevated intravesical pressure during filling and emptying and (2) infection. Persistent reflux can lead to chronic renal damage and may be an important factor in the long-term survival of SCI patients. In the series of SCI patients reported by Hackler and colleagues (1965), persistent reflux was present in 60% of patients of those dying of renal disease. In patients with only transient reflux over a 5- to 15-year period, the urogram was normal in 83% and calyceal changes were only minimal. It should be noted, however, that high storage and voiding pressures without reflux can be responsible for renal damage (McGuire, 1984; Vega and Pascual, 2001). Ku and colleagues (2005) studied 179 men undergoing annual follow-up for SCI. The average duration of follow-up after injury was 29 years. The incidence of reflux in this group was 15.1%. Thirty-four percent of the patients were diagnosed with pyelonephritis at some point during their course of follow-up, and 24.6% developed renal stones. Thirty-two percent experienced upper tract deterioration as manifested by hydronephrosis. Upper tract degeneration was more prevalent in those managed with urethral catheters (51%) than in those managed with either spontaneous voiding or intermittent catheterization. Urethral catheter drainage was found to be inferior to all other forms of bladder drainage in terms of protection of the upper urinary tract, suggesting the inadvisability of urethral catheterization chronically in these patients (Ku et al, 2005).

The best initial treatment for reflux in a patient with voiding dysfunction secondary to neurologic disease or injury is to normalize lower urinary tract urodynamics as much as possible. Depending on the clinical circumstances, this may be by pharmacotherapy, urethral dilatation (in the myelomeningocele patient), neuromodulation, deafferentiation, augmentation cystoplasty, or sphincterotomy (Flood et al, 1994; Perkash et al, 1998). If this fails, the question of whether to operate on such patients for correction of the reflux or to correct the reflux while performing another procedure (e.g., augmentation cystoplasty) is not an easy one because correction of reflux in an often thickened bladder may not be an easy task.

Transureteroureterostomy for unilateral reflux is feasible, but even experienced urologists have had difficulties with ureteral calculi trapping, recurrent reflux, and obstruction at the vesicoureteral junction following such procedures in this difficult group of patients (Van Arsdalen and Hackler, 1983). Submucosal trigonal injection of bulking substances may add a new dimension to the treatment of this difficult problem.

One must remember the potential artifact that significant reflux can introduce into urodynamic studies. Measured bladder capacity appears artifactually large, and measured pressures at given inflow volumes may appear lower than after reflux correction. The apparent significance of detrusor overactivity may thus be underestimated.

Urinary Tract Infection

Urinary tract infection (UTI) is relatively common in patients with SCI. Fifty-seven percent of patients with SCI experience UTI or bacteriuria in the first year after initial hospitalization (Morton et al, 2002). Recurrent infections may be a manifestation of upper or lower tract calculi, symptomatic or silent pyelonephritis, or lower urinary tract dysfunction causing persistent residual urine. In conjunction with poor urodynamic function, UTI can lead to high morbidity, poor quality of life, and decreased life expectancy in patients with SCI (Sauerwein, 2002). The use of antibiotics in SCI patients remains a topic of discussion. **Virtually all who have written on the subject agree that bacteriuria should be treated only when signs or symptoms present, a consensus reached by the National Institute on Disability and Rehabilitation Research Group (1992)** (Penders et al, 2003). Biering-Sorensen and colleagues (2001) authored a nicely organized, well-written, and referenced article on the subject. They recommended the following: (1) treat bacteriuria only if symptomatic; (2) use antimicrobial agents, if possible, with little or no impact on normal flora; (3) treat at least 5 days; those with reinfection or relapse, treat 7 to 14 days; (4) repair structural and functional risk factors; (5) use prophylaxis only in those with recurrent UTI when no underlying cause can be found and especially if the upper tracts are dilated; (6) do not use antibiotics to prevent UTI in patients with an indwelling catheter. They regard the use of prophylactic antibiotics in patients on CIC as controversial.

Morton and colleagues (2002) concluded from a meta-analysis of 15 controlled trials that prophylactic antibiotics were not generally helpful but added that they could not exclude a clinically important effect, especially in those who had recurrent UTI that limited their functioning and well-being. Sauerwein (2002) recommends beginning antibiotic prophylaxis in patients on CIC and stopping after 1 year if there has been one or fewer UTIs. Some (Burns et al, 2001) believe that significant pyuria, defined as 8 to 10 or more white blood cells per high-power field, connotes tissue invasion and is an indication for antibiotic treatment. Evidence-based data in this area are sparse.

Spinal Cord Injury in Women

There are many aspects of management of the lower urinary tract affected by SCI that are specific to women (Yang and Cardenas, 2001). McColl (2002) summarized some of these. The problem of osteoporosis places women at a much increased risk of fracture. The symptoms of menopause (e.g., hot flashes) may be difficult to distinguish from those of autonomic dysreflexia. Incontinence and UTI become worse with age in women in the general population and particularly in those with SCI. Body composition of SCI women shows deficient protein and bone mass and excess fat, predisposing them to an increased incidence of fractures and the risk of skin breakdown. The incidence of SCI is highest among young men and older women. Psychologic outcomes (e.g., depression) have been shown to improve after 30 years' duration of disability. Women injured at a modal age of 60 are unlikely to enjoy this benefit.

Special difficulty in this category of patients is encountered because of the lack of an appropriate external collecting device. Suitable bladder reservoir function can usually be achieved either pharmacologically or surgically, and paraplegic women can generally master CIC. Although a few quadriplegic women can be trained to self-CIC, for the majority there is no practical alternative to indwelling catheterization (Lindan et al, 1987). McGuire and Savastano (1986) point out that indwelling catheter drainage on a long-term basis in women may not be, however, as is sometimes written, well tolerated because significant incontinence around the catheter and upper tract changes may develop.

For those SCI female patients who can assume CIC or who have around-the-clock medical or family care, creation of adequate bladder reservoir function is reasonable. For those not in this category, the alternatives are limited and difficult. Bennett and colleagues (1995) compared the incidence of major complications in a group of female SCI patients who were managed long term

by (1) CIC; (2) reflex voiding and incontinence padding; and (3) an indwelling catheter. There were 10 major complications in the 25 patients in group 2 and 58 in the 22 patients in group 3, compared with only 4 major complications in group 1. Singh and Thomas (1997) looked at the results of treatment in a group of female tetraplegics. Twenty-three of 27 patients with complete lesions wound up using an indwelling catheter, 3 underwent diversion, and in 1 patient the caregiver performed CIC. In 20 patients with incomplete lesions, all with poor functional recovery, 14 had permanent indwelling catheters, 3 were able to perform CIC, and 3 used reflex voiding by triggering. Of 37 patients with incomplete lesions with good functional recovery, only 3 required indwelling catheterization; 4 used CIC, and most were able to use reflex voiding by triggering. The authors noted also that 55% of the women with permanent catheters had bladder calculi, 35% had leakage around the catheter, and 33% had recurrent symptomatic infection. Although upper tract changes were seen in only 5%, it is obvious that the authors consider that, for the most part, female patients with voiding dysfunction secondary to cervical SCI who exhibit poor functional recovery represent urologic failures of management.

Spinal Cord Injury and Bladder Cancer

The development of carcinoma of the bladder in 6 of 59 patients with SCIs who had long-term indwelling catheters was reported by Kaufman and colleagues (1977). All were squamous cell lesions. Four of these patients had no obvious tumors visible at endoscopy, and the diagnosis was made by bladder biopsy. Five of these patients also had transitional cell elements in their tumor. Broecker and colleagues (1981) surveyed 81 consecutive SCI patients with an indwelling urinary catheter for more than 10 years. Although the investigators did not find frank carcinoma in any patients, they found squamous metaplasia of the bladder in 11 and leukoplakia in 1. Locke and colleagues (1985) noted two cases of squamous cell carcinoma of the bladder in 25 consecutive SCI patients catheterized for a minimum of 10 years. Bickel and colleagues (1991) reported eight cases of bladder cancer in SCI men, although the denominator was uncertain. Four of the men had been managed by indwelling catheterization for 7, 10, 14, and 19 years, respectively. All of these four men had transitional cell carcinoma, whereas in the other four, there were two cases of transitional and two of squamous cell carcinoma. In Chao and colleagues' series (1993), 6 patients developed bladder cancer, 3 of whom had indwelling catheters (of a total of 32) and 3 of whom (of 41) did not. Stonehill and colleagues (1996) retrospectively reviewed all bladder tumors in their SCI patients for 7 years and compared these with matched controls. They found 17 malignant and 2 benign bladder tumors. Indwelling catheters and a history of bladder calculi were statistically significant risk factors.

Hess and colleagues (2003) reported their own series and summarized one view of the literature regarding SCI and bladder cancer: (1) the relative risk in SCI patients is 16% to 28% greater than the general population; (2) the overall incidence is 2.3% to 10%; (3) there is a higher proportion of squamous cell than transitional cell carcinoma; (4) the prevalence peaks at an earlier age than in the general population; (5) diagnosis is made at a more advanced stage; (6) risk factors include chronic indwelling catheterization, bladder stones, and chronic UTI; (7) neither cystoscopy nor cytology is an entirely reliable diagnostic tool; and (8) those with multiple risk factors should have a more aggressive evaluation.

Tempering this are reports by Pannek (2002), who reviewed the data from 43,561 SCI patients in three countries and concluded the incidence of bladder cancer is comparable with that of the general population, but more than 60% of those affected presented initially with muscle invasive disease. Chronic indwelling catheters and persistent or recurrent UTI are suggested as the risk factors rather than the SCI itself. Subramonian and colleagues (2004) reported similar conclusions regarding age-standardized incidence of bladder cancer relative to the general population. Seventy-five percent of the affected patients in the series had indwelling catheters for 18 to 32 years.

The incidence of bladder cancer in MS patients with indwelling catheters is estimated at 0.29%, as compared with 0.004% in the general population of females and 0.018% in the population of males. The incidence of bladder cancer in SCI patients has been recorded to range from 0.27% to 9.6%; however, in larger series, the overall incidence is 0.27% to 0.37%. The natural history of bladder cancer is thought to be more highly aggressive in neurogenic patients and is responsible for 0.3% to 2.8% of known deaths in the SCI population.

Follow-Up

Linsenmeyer and Culkin (1999) reported the American Paraplegic Society (APS) Guidelines for urologic care of SCI. **Annual follow-up is recommended for the first 5 to 10 years after injury. If the patient is doing well, then follow-up every other year is advised. Upper and lower tract evaluation should be done initially and yearly for 5 to 10 years, then every other year.** Burns and colleagues (2001) recommended at least plain films and nuclear renal scans, with a decrease of more than 20% in renal plasma flow warranting further investigation. **Urodynamic evaluation was recommended by the APS at the same intervals as upper and lower tract screening. Cystoscopy was recommended annually in those with an indwelling catheter.**

Cervical Myelopathy

Cervical myelopathy is generally caused by compression, secondary to either spondylosis, ossification of the posterior longitudinal ligament, or cervical disk herniation (Sakakibara et al, 1995a; Mochida et al, 1996). Sakakibara and colleagues (1995a) studied 128 affected patients, of whom 95 had voiding symptoms, 61 had irritative symptoms, 71 had obstructive symptoms, and 25 had urinary incontinence. Urodynamic studies revealed involuntary bladder contractions in 61 patients and detrusor sphincter dyssynergia (DESD) in 22. Mochida and colleagues (1996), on the other hand, reported on 60 patients undergoing surgery for cervical myelopathy, 22 of whom (37%) were found to have neuropathic bladder dysfunction on urodynamic study. Of these, 9 (41%) were found to have detrusor overactivity but 13 (59%) were characterized as having an underactive detrusor. Because this is at odds with what one would expect with only cervical spinal cord pathology, it reinforces the need for urodynamic study to optimally guide therapy in patients with neurogenic bladder.

Acute Transverse Myelitis

Acute transverse myelitis is a rapidly developing condition with motor, sensory, and sphincter abnormalities, generally with a well-defined upper sensory limit and no signs of spinal cord compression or other neurologic disease (Kalita et al, 2002). It may result from a variety of mechanisms—parainfectious, autoimmune, vascular, or demyelinating (Ganeson and Borzyskowski, 2001). The condition usually stabilizes within 2 to 4 weeks, is not progressive

afterward, and is followed by variable recovery with some residual neurologic deficits. Although recovery is more variable, and the prognosis, in general, is more favorable, the development and nature of voiding dysfunction has been reported to be similar, level by level, to that of SCI (Sakakibara et al, 1995b). Kalita and colleagues (2002), however, reported on 18 patients with acute transverse myelitis whose 6-month outcome included persistent retention in 6 and storage symptoms in 10, of whom 5 had emptying problems as well; 2 patients had regained normal voiding. In the acute state, urodynamics showed an areflexic or contractile bladder in 10, detrusor overactivity with poor compliance in 2, and DESD in 3. Seventeen had presented in urinary retention. As in SCI, because the activity of the bladder and outlet during filling/storage and emptying/voiding does not always correspond to what they "should" be, based on the level of pathology, urodynamic studies are necessary to guide irreversible therapy.

Neurospinal Dysraphism

These topics are covered primarily in Chapters 127 and 128. However, certain considerations regarding the adult with these abnormalities should be mentioned. Spinal dysraphism refers to the malformation of the vertebral arches and, commonly, malformation of the neural tube. The term includes spina bifida occulta, which involves only a bony (vertebral) arch defect, and spina bifida cystica (aperta), which involves a bony defect and a neural tube (spinal cord) defect. The two primary subclasses of spina bifida cystica are myelomeningocele (the nerve roots or portions of the spinal cord have evaginated beyond the vertebral bodies) and meningoceles (contain only a herniated meningeal sac with no neural elements). If fatty tissue is present in the sac in either, the prefix "lipo-" is added (Churchill et al, 2001). **Myelomeningocele accounts for more than 90% of spina bifida cystica and is the most devastating condition in terms of sequelae. Of myelomeningoceles, 2% are cervical, 5% thoracic, 26% lumbar, 47% lumbosacral, and 20% sacral. The level(s) of the lesion correlates poorly with urodynamic findings** (Churchill et al, 2001). **Myelomeningocele occurs in approximately 1/1000 live births** (Wyndaele et al, 2005). **The incidence of lower urinary tract dysfunction is not absolutely documented, but most studies suggest an incidence of greater than 90%** (Wyndaele et al, 2005).

McGuire and Denil (1991) and Woodhouse (2005) point out that, secondary to progress in the overall care of children with myelodysplasia, urologic dysfunction often becomes a problem of the adolescent or adult with this disease. In McGuire and Denil's (1991) experience, **the "typical" myelodysplastic patient shows an areflexic bladder with an open bladder neck. The bladder generally fills until the resting residual fixed external sphincter pressure is reached, and then leakage occurs. Stress incontinence occurs also,** related to changes in intra-abdominal pressure. A small percentage (10% to 15%) of patients demonstrate detrusor striated sphincter dyssynergia, but these individuals show normal bladder neck function that, if detrusor reflex activity is controlled, is associated with continence. After puberty, most authors report that most myelodysplastic patients note an improvement in continence, but, at that age and after, they are less inclined than children to tolerate any degree of incontinence. In adult patients, the problems encountered in myelodysplastic children still exist but are often compounded by prior surgery, upper tract dysfunction, and one form of urinary diversion or another.

In adult females, the treatment strategy is generally to increase urethral sphincter efficiency without causing a major enough increase in urethral closing pressure that will result in a change in bladder compliance (McGuire and Denil, 1991). **Periurethral injection therapy to achieve continence may replace the pubovaginal sling and artificial sphincter in this circumstance. These authors also point out that continence in adult male myelodysplastic individuals follows the same general rules as in females, and injectable materials may give good results in this group as well. When the urethra is widely dilated and somewhat rigid, and neither procedure alone will provide sufficient coaptation, it may be possible to combine a "prostatic sling" with periurethral collagen injection. Dry individuals, of course, will be on intermittent self-catheterization.**

"Classic" may imply different urodynamic findings to different groups of clinicians. **Nowhere is the failure of a neurologic examination to predict urodynamic behavior more obvious than in patients with myelomeningocele.**

Van Gool and colleagues (2001) summarized the urodynamic findings in 188 children with myelomeningocele and categorized these into five groups. Seven percent had normal detrusor and sphincter activity; 11% had detrusor overactivity and an inactive sphincter; 45% had detrusor overactivity and an overactive sphincter; 23% had an inactive detrusor and inactive sphincter; and 14% had an inactive detrusor and an overactive sphincter. Sakakibara and colleagues (2003a) reported on urodynamic results in 16 adult patients with myelomeningocele. Detrusor overactivity was found in 38%, low compliance in 81%, impaired bladder sensation in 25%, DESD in 50%, low maximum urethral pressure in 56%, and silent sphincter electromyogram in 25%. Webster and colleagues (1986) urodynamically classified a large number of myelomeningocele patients as follows: 62% had detrusor overactivity, whereas 38% had detrusor areflexia, with 30 of 34 of these having low compliance with high terminal filling pressure. Striated sphincter behavior was characterized as follows: true detrusor–striated sphincter dyssynergia in 15%, an apparently innervated but fixed nonrelaxing sphincter in 15%, and some evidence of striated sphincter denervation in 69%.

It is clear, however, that whatever the pattern of voiding dysfunction in the adult, all authors would agree that a prime directive of therapy is still the avoidance of high storage pressures (McGuire and Denil, 1991; Persun et al, 1999; Woodhouse, 2005).

Voiding dysfunction secondary to occult spinal dysraphism may not present in childhood, and such patients may be referred as adults for symptoms as mundane as incontinence or recurrent urinary infection. Jakobsen and colleagues (1985) reported seven such patients ranging in age from 10 to 51 years. Delayed diagnosis of such voiding dysfunction was also reported by Yip and colleagues (1985). There was no characteristic abnormality, and the specific dysfunction is dependent on the level and extent of the neurologic injury.

The urologic rehabilitation of patients with spinal dysraphism relies primarily on medical management with the selective use of augmentation or urinary diversion after failure thereof. However, surgery does not necessarily yield superior results. In a review of 421 patients managed for spina bifida, 45% were medically treated, either with intermittent catheterization, spontaneous voiding, or no specific method utilized. Two-hundred and thirty patients were surgically treated. Overall incontinence episodes were higher in the surgical versus medical management group. These results may

have been reflective of the aggressiveness of management, as well as the severity of disease (Lemelle et al, 2006).

Recently, neural rerouting has been proposed as a potential option for some of these individuals. Ziao and colleagues have performed microanastomosis of the fifth lumbar ventral root to the third sacral ventral root in order to bypass low-level spina bifida injury. Initial improvements in bladder compliance and urinary incontinence were noted in patients and paralleled similar findings in spinal cord patients (Joseph, 2005).

Tethered cord syndrome (TCS) is defined as a stretch-induced functional disorder of the spinal cord with its caudal part anchored by inelastic structures. Vertical movement is restricted. The anchoring structures can include scar from prior surgery, fibrous or fibroadipose filum terminale, a bony septum, or tumor (Yamada et al, 2004a, 2004b). Adults with TCS can be divided into those with a prior history of spinal dysraphism with a previously stabilized neurologic status who present with subtle progression in adulthood and those without associated spinal dysraphism who present with new subtle neurologic symptoms (Yamada et al, 2004a, 2004b). **Symptoms can include back pain, leg weakness, foot deformity, scoliosis, sensory loss, and bowel or lower urinary tract dysfunction** (Phuong et al, 2002). **TCS is reported to occur in 3% to 15% of patients with myelomeningocele. There is no typical dysfunction in TCS, and treatment must be based on contemporary urodynamic evaluation.** Voiding dysfunction may not be present until the teenage years or later (Kaplan and Blaivas, 1988; Husmann, 1995). Giddens and colleagues (1999) point out that, whereas children often develop symptoms of tethered cord after growth spurts, in adults presenting symptomatology often follows activities that stretch the spine such as sports or motor vehicle accidents. In adults, urologic presentation can include irritative voiding symptoms, incontinence, or retention. These authors reported neurourologic and urodynamic findings in a group of adult patients. At presentation, urgency (67%) and urge incontinence (50%) were the most common findings. Pretreatment urodynamics in 18 patients revealed detrusor overactivity in 13 (72%), DESD in 4 (22%), decreased sensation in 4 (22%), decreased compliance in 3 (17%), and what was called a "hypocontractile" detrusor in 2 (11%). It is interesting that postoperative urodynamic findings were improved in only 4 patients (29%) and unchanged in 10 (71%). Steinbok and colleagues (2007) assessed eight children undergoing section of the filum inducing the tethered cord and compared them with seven children who had abnormal urodynamic findings and did not undergo filum release. Clinical improvement occurred in seven of the eight children at a mean follow-up of 3 years with improved urodynamics in four of seven children tested after surgery. These improvements were also associated with nonurologic functional improvements (motor leg function). At a mean follow-up of 3 years in the nonsurgical group, two patients had urologic improvement but three patients required surgical intervention and five had persistence of nonurologic symptoms. Section of the cord appeared to improve function as compared with conservative management (Steinbok et al, 2007).

Tabes Dorsalis, Pernicious Anemia

Although syphilitic myelopathy is disappearing as a major neurologic problem, involvement of the spinal cord dorsal columns and posterior sacral roots can result in a loss of bladder sensation and large residual urine volumes and therefore be a cause of "sensory neurogenic bladder" (see Chapter 61). Although this represents the "classic" tabetic bladder (Wheeler et al, 1986), Hattori and colleagues (1990) reported on some patients with only tabes as an obvious cause of their voiding dysfunction who had low compliance or detrusor overactivity. Another spinal cord cause of the classic "sensory bladder" is the now uncommon pernicious anemia that produced this disorder by virtue of subacute combined degeneration of the dorsolateral columns of the spinal cord.

Poliomyelitis

When seen, voiding dysfunction in polio is that of a typical "motor neurogenic bladder" (see Chapter 61) with urinary retention, detrusor areflexia, and intact sensation. The reported incidence of voiding dysfunction in patients with polio was described as ranging from 4% to 42% by Bors and Comarr (1971).

DISEASE DISTAL TO THE SPINAL CORD

Disk Disease

Goldman and Appell (2000a) nicely summarize the anatomic and neurologic considerations applicable to voiding dysfunction from lumbar disk disease. **In the adult, the sacral segments of the spinal cord are at the level of the L1 and L2 vertebral bodies.** In this distal end of the spinal cord, commonly called the ***conus medullaris,*** the spinal cord segments are named for the vertebral body at which the nerve roots exit the spinal canal. Thus although the sacral spinal cord segment is located at vertebral segment L1, its nerve roots run in the subarachnoid space posterior to the L2 to L5 vertebral bodies until reaching the S1 vertebral body, at which point they exit the canal. Thus all of the sacral nerves that originate at the L1 and L2 spinal column levels run posterior to the lumbar vertebral bodies until they reach their appropriate site of exit from the spinal canal. This group of nerve roots running at the distal end of the spinal cord is commonly referred to as the **cauda equina.**

Usually, disk prolapse is in a posterolateral direction, which does not affect the majority of the cauda equina. However, in 1% to 15% of the cases (Goldman and Appell, 2000a), central disk prolapse occurs and compression of the cauda equina may result. Thus disk prolapse anywhere in the lumbar spine could interfere with the parasympathetic and somatic innervation of the lower urinary tract, striated sphincter and other pelvic floor musculature, and afferent activity from the bladder and affected somatic segments to the spinal cord. **Most disk protrusions compress the spinal roots in the L4-L5 or L5-S1 vertebral interspaces. Voiding dysfunction may result and, when present, generally occurs with the usual clinical manifestations of low back pain radiating in a girdle-like fashion along the involved spinal root areas. Examination may reveal reflex and sensory loss consistent with nerve root compression. The most characteristic findings on physical examination are sensory loss in the perineum or perianal area (S2-S4 dermatomes), sensory loss on the lateral foot (S1-S2 dermatomes), or both.**

Goldman and Appell (2000a) also reviewed the literature on voiding dysfunction associated with lumbar disk disease. The incidence of such dysfunction in their review ranged from 27% to 92%. The true incidence is a bit difficult to ascertain because many reported series on this subject describe findings only in patients who present with voiding dysfunction. Bartolin and colleagues (1998) reported on findings in 114 patients with lumbar disk

protrusion who were prospectively studied. They found detrusor areflexia in 31 (27.2%) and normal detrusor activity in the remaining 83. **All 31 patients with detrusor areflexia reported difficulty voiding with straining. Patients with voiding dysfunction generally presented with these symptoms or in urinary retention. The most consistent urodynamic finding was that of a normally compliant areflexic bladder associated with normal innervation or findings of incomplete denervation of the perineal floor musculature.** In a later report, Bartolin and colleagues (2002) describe findings in 122 patients with lumbar disk protrusion. Detrusor areflexia was found in 32 (26%) and normal bladder urodynamic findings in 90 (74%). All with areflexia complained of difficulty voiding; 8 could not void at all, 14 had an interrupted flow, and 10 had a continuous but low flow. Occasionally, patients may show detrusor overactivity, attributed to irritation of the nerve roots (O'Flynn et al, 1992).

The detrusor areflexia associated with lumbar disk protrusion shows a lower incidence of decreased compliance than in the voiding dysfunction caused by myelomeningocele. Sandri and colleagues (1987) offered two possible explanations for this difference: (1) the effect of the disk represents a more incomplete lesion of the preganglionic parasympathetic fibers and (2) the lesion is more sensory than motor, implying that the decreased compliance seen with the type of neural lesion in myelomeningocele is primarily caused by injury of the preganglionic parasympathetic motor fibers to the bladder.

Laminectomy may not improve bladder function, and prelaminectomy urodynamic evaluation is therefore desirable because it may be difficult postoperatively in these cases to separate causation of voiding dysfunction owing to the disk sequelae from changes secondary to the surgery. Bartolin and colleagues (1999) reported on the results of surgery in a group of patients with lumbar disk protrusion. Of 27 patients with detrusor areflexia preoperatively, detrusor activity returned to normal in only 6. The patients were studied up to a year after surgery. Of the 71 patients with normal urodynamic findings preoperatively, 4 developed detrusor overactivity and 3 developed detrusor areflexia postoperatively. The medicolegal implications of a presurgical and postsurgical urodynamic evaluation are obvious.

***Cauda equina syndrome* is a term applied to the clinical picture of perineal sensory loss with loss of voluntary control of both anal and urethral sphincter and of sexual responsiveness.** This can occur not only secondary to disk disease (severe central posterior disk protrusion) but to other spinal canal pathologic processes as well. Yamanishi and colleagues (2003) place the incidence of cauda equina syndrome at 1% to 5% of all prolapsed lumbar disks. They reported on eight patients undergoing emergency corrective surgery for this entity. All had an acontractile detrusor with no bladder sensation, and four of seven had an inactive sphincter electromyogram. Follow-up urodynamics showed that all continued with an acontractile detrusor, three had normal EMG activity, and three had EMG activity but with denervation potentials in two and low activity in two.

Spinal Stenosis

Spinal stenosis is a term applied to any narrowing of the spinal canal, nerve root canals, or intervertebral foramina. It may be congenital, developmental, or acquired. Compression of the nerve roots or cord by such a problem may lead to neuronal damage, ischemia, or edema. **Spinal stenosis may occur without disk prolapse. Symptoms may range from those consequent to cervical spinal cord compression to a cauda equina syndrome, with corresponding urodynamic findings** (Smith and Woodside, 1988). Back and lower extremity pain, cramping, and paresthesias related to exercise and relieved by rest are the classic symptoms of lumbar stenosis caused by lumbar spondylosis and are believed to result from a sacral nerve root ischemia. The urodynamic findings are dependent on the level and the amount of spinal cord or nerve root damage. Deen and colleagues (1994) reported subjective improvement in more than 50% of such patients with bladder dysfunction who were treated by decompressive laminectomy. In cervical spondylitic spinal stenosis, detrusor overactivity or underactivity may occur, depending on whether the primary pathologic process affecting the micturition neural axis is compression of the inhibitory reticulospinal tracts or myelopathy in the posterior funiculus, which carries proprioceptive sensation (Tammela et al, 1992). Because there is no consistent pattern of dysfunction with any type of spinal stenosis, urodynamic studies again are the cornerstone of rational therapy. Podnar and colleagues (2006) assessed 65 cauda equina patients with neuro-urologic examination, electromyography, and urodynamics. Severe LUT dysfunction was noted in 14% of women and 15% of men, whereas moderate dysfunction was noted in 27% of men and 46% of women. Incomplete emptying was the most common symptom (>90%), and urinary incontinence was next with 56% of men and 71% of women. Reduced capacity was noted in 9% and 15%, respectively. Poor detrusor contractility was noted in 59% of men and 85% of women. Using multiple linear regression, perianal sensory loss and female gender had the most significant positive predictive value for urinary incontinence.

Radical Pelvic Surgery

Voiding dysfunction after pelvic plexus injury occurs most commonly after abdominoperineal resection and radical hysterectomy. The true incidence of neurogenic vesicourethral dysfunction after various types of pelvic surgery is unknown because there are few prospectively studied series of patients with preoperative and postoperative urodynamic evaluation. **The incidence has been estimated to range from 20% to 68% of patients after abdominoperineal resection, 16% to 80% after radical hysterectomy, 20% to 25% after anterior resection, and 10% to 20% after proctocolectomy** (Blaivas and Chancellor, 1995b). These are estimates drawn from past literature, and the current incidence is most likely significantly lower owing to the use of nerve-sparing techniques during these types of pelvic surgery. It has been estimated, however, that **in 15% to 20% of affected individuals, the voiding dysfunction is permanent** (McGuire, 1984; Mundy, 1984). The injury may occur consequent to denervation or neurologic decentralization, tethering of the nerves or encasement in scar, direct bladder or urethral trauma, or bladder devascularization. Adjuvant treatment such as chemotherapy or irradiation may play a role as well. The type of voiding dysfunction that occurs is dependent on the specific nerves involved, the degree of injury, and any pattern of reinnervation or altered innervation that results over time (see Chapter 60 and the previous section on neuroplasticity).

Literature on the effects of parasympathetic decentralization on neuromorphology and neuropharmacology of the lower urinary tract in many animal models is abundant (Wein and Barrett, 1988). Parasympathetic decentralization has been reported to lead to a marked increase in adrenergic innervation of the bladder in

some experimental models, with the resultant conversion of the usual β (relaxant) response of the bladder body in response to sympathetic stimulation to an α (contractile) effect (Sundin et al, 1977). Hanno and colleagues (1988) confirmed that, in the cat model, parasympathetic decentralization does result in adrenergic hyperinnervation of the detrusor but that pelvic plexus neurectomy alone or parasympathetic decentralization plus hypogastric neurectomy yields no detectable increase in adrenergic innervation. In their experimental model, decentralization did result in synaptic reorganization in bladder wall ganglia with new cholinergic excitatory inputs from the hypogastric nerves. Koyanagi was the first to call attention to what he referred to as supersensitivity of the urethra to α-adrenergic stimulation in a similar group of patients with neurologic decentralization of the lower urinary tract, implying a similar change in adrenergic receptor function in the urethra after parasympathetic decentralization (Koyanagi et al, 1988). Nordling and colleagues (1981) described a similar change in females after radical hysterectomy and ascribed this change to damage to the sympathetic innervation of the lower urinary tract.

When permanent voiding dysfunction occurs after radical pelvic surgery, the pattern is generally one of a failure of voluntary bladder contraction, or impaired bladder contractility, with obstruction by what seems urodynamically to be residual fixed striated sphincter tone, which is not subject to voluntarily induced relaxation. Often, the smooth sphincter area is open and nonfunctional. Whether this appearance of the bladder neck/proximal urethra is caused by parasympathetic damage or terminal sympathetic damage or whether it results from the hydrodynamic effects of obstruction at the level of the striated sphincter is debated and unknown. **Decreased compliance is common in these patients, and this, with the "obstruction" caused by fixed residual striated sphincter tone, results in both storage and emptying failure. These patients often experience leaking across the distal sphincter area and, in addition, are unable to empty the bladder because although intravesical pressure may be increased, there is nothing that approximates a true bladder contraction. The patient often presents with urinary incontinence that is characteristically most manifest with increases in intra-abdominal pressure.** This is usually most obvious in females because the prostatic bulk in males often masks an equivalent deficit in urethral closure function. Alternatively, patients may present with variable degrees of urinary retention.

Urodynamic studies may show decreased compliance, poor proximal urethral closure function, loss of voluntary control of the striated sphincter, and a positive bethanechol supersensitivity test, findings similar to those in Figure 65–4. **Upper tract risk factors are related to intravesical pressure and the detrusor leak point pressure, and the therapeutic goal is always low-pressure storage with periodic emptying. The temptation to perform a prostatectomy should be avoided unless a clear demonstration of outlet obstruction at this level is possible.** Otherwise, prostatectomy simply decreases urethral sphincter function and thereby may result in the occurrence or worsening of sphincteric urinary incontinence. **Most of these dysfunctions will be transient, and the temptation to "do something" other than perform CIC initially after surgery in these patients, especially in those with little or no preexistent history of voiding dysfunction, cannot be too strongly criticized.** Our general practice in such patients is to discharge them on CIC and then have them return for a full urodynamic evaluation at a later date. Six to 12 months may elapse before detrusor function returns to an acceptable level (Blaivas and Chancellor, 1995b). Many of the changes after radical pelvic surgery are similar to those seen in sacral cord injury or disease. Sislow and Mayo (1990), in an excellent study on decreased bladder compliance after decentralization, noted a higher prevalence of this finding in patients who had undergone radical pelvic surgery than in those who had sustained conus medullaris or cauda equina injury.

Finally, to answer questions as to whether some types of nonradical pelvic surgery such as simple hysterectomy are ultimately responsible for filling/storage or emptying abnormalities on the basis of neurologic damage, more series that include sophisticated preoperative and early and late postoperative urodynamic evaluation are necessary.

Herpesvirus Infections

Invasion of the sacral dorsal root ganglia and posterior nerve roots with herpes zoster virus may produce urinary retention and detrusor areflexia days to weeks after the other primary viral manifestations (Ryttov et al, 1985). Generally, painful cutaneous eruptions secondary to the virus are also present, but initially there may be just fever and malaise with perineal and thigh paresthesias and obstipation. **Urinary incontinence secondary to detrusor overactivity may also occur, but the pathophysiology is uncertain.** It may be related to nerve root irritation, inflammation of the meninges or spinal cord, or "zoster cystitis" (Broseta et al, 1993). Cystoscopy may reveal vesicles in the bladder mucosa similar to those seen on the skin. **Spontaneous resolution generally occurs in 1 to 2 months.** Broseta and colleagues (1993) reported on 57 patients with herpes zoster infection whose records were reviewed retrospectively. Fifteen (26%) of these patients showed urologic manifestations, but in only two of these did frank urinary retention occur. Three patients demonstrated urinary incontinence; urodynamically, all of those showed involuntary bladder contractions. Ten patients demonstrated irritative voiding symptoms with dysuria and frequency.

Chen and colleagues (2002) reported on the incidence of voiding dysfunction in 423 patients admitted with a diagnosis of herpes zoster. Seventeen (4%) had voiding dysfunction. Excluding those with cranial rather than spinal nerve involvement, the incidence was 8.8%; when only lumbosacral dermatome patients were considered, the figure rose to 28.6%. The authors subdivided the bladder disorders into three types. The most common is associated with a herpetic cystitis. Patients in this group may present with dysuria, frequency, retention, pyuria, or hematuria. Twelve of the 17 affected patients (71%) were in this group; they presented with dysuria and frequency or retention. The second type is neuritis associated, presumably affecting the sacral motor neurons. Four of the 17 (24%) were in this group and presented in urinary retention and with a "flaccid bladder." Myelitis-associated voiding dysfunction is the third type, associated with spinal cord involvement and presenting with detrusor overactivity. One of their patients was in this group. All patients regained a normal or "balanced bladder" within 8 weeks, and no major urologic sequelae were noted.

Urinary retention has also been reported to occur in association with anogenital herpes simplex virus infection. Caplan and colleagues (1977) reported 11 such patients with the typical clinical picture of herpes genitalis, all of whom

developed urinary retention 2 to 7 days after the genital eruption. Hemrika and colleagues (1986) reported three such patients, each of which showed pleocytosis of the cerebrospinal fluid, a finding that they believed was indicative of central nervous system involvement. They termed the coexistence of bilateral involvement of the sacral nerve roots of rapid onset accompanied by sphincteric incontinence with cerebrospinal fluid pleocytosis the ***Elsberg syndrome*** and tabulated 47 such cases reported before their article. Haanpaa and Paavonen (2004) added two cases, in which both patients had transient urinary retention but developed chronic neuropathic pain in the sacral area. The lower urinary tract dysfunction was transient, as with herpes zoster.

Diabetes Mellitus

Diabetes is the most common cause of peripheral neuropathy in Europe and North America. The exact prevalence of diabetes in the United States is somewhere between 1% and 6%, depending on whether one includes only diagnosed patients or diagnosed and undiagnosed patients and on what fasting blood glucose criteria one uses for inclusion (the higher estimate of prevalence represents a recent reduction in blood glucose criteria to 126 mg/dL) (Chancellor and Blaivas, 1995a; Goldman and Appell, 2000b). The clinical spectrum of voiding dysfunction thought to be caused by diabetes has been well reviewed by a number of authors, each of whom has cited the same historical articles up to their date of publication and added their personal experience at that time (Kaplan and Blaivas, 1988; Kaplan and Te, 1992; Beck et al, 1994; Chancellor and Blaivas, 1995a; Kaplan et al, 1995; Wein and Rovner, 1999; Goldman and Appell, 2000b). The exact incidence of voiding dysfunction caused by diabetes is, however, uncertain. Unselected patients generally do not complain of bladder symptoms. **If specifically questioned, anywhere from 5% to 59% of patients with diabetes report symptoms of voiding dysfunction.** However, the symptoms may or may not be caused by just the diabetes. In trying to come to conclusions regarding the incidence and types of voiding dysfunction specifically from diabetes, one has to carefully discriminate between articles that consider patients referred for voiding symptoms versus those that have evaluated unselected patients from a population known to have diabetes.

Current evidence points to both a sensory and a motor neuropathy as being involved in the pathogenesis, the motor aspect per se contributing to the impaired detrusor contractility. **The typically described classic urodynamic findings include impaired bladder sensation, increased cystometric capacity, decreased bladder contractility, impaired uroflow, and, later, increased residual urine volume.** The main differential diagnosis, at least in men, is generally bladder outlet obstruction because both conditions commonly produce a low flow rate. Pressure/flow urodynamic studies easily differentiate the two. **Smooth or striated sphincter dyssynergia is generally not seen in classic diabetic cystopathy,** but these diagnoses can easily be erroneously made on a poor or incomplete urodynamic study—voiding may involve abdominal straining, which will produce an interference EMG pattern (pseudodyssynergia), and abdominal straining alone will not open the bladder neck area.

Other articles have appeared, however, suggesting that this "classic" diabetic cystopathy may not be the predominant form of lower urinary tract dysfunction. Starer and Libow (1990) reported on a group of 23 elderly diabetic nursing home patients who presented with symptoms of urinary dysfunction. In these 19 women and 4 men, 61% had involuntary bladder contractions, 17% had voluntary contractions of decreased magnitude, 13% had normal detrusor contractility, and 9% were unable to initiate a detrusor contraction at all. Kaplan and colleagues (1995) reported on another group of patients with diabetes referred because of voiding symptoms. Fifty-five percent were found to have involuntary bladder contractions; 23%, impaired detrusor contractility; 10%, detrusor areflexia; and 11%, "indeterminate findings." In the 42 patients in this group with sacral cord neurologic signs, 50% had impaired detrusor contractility and 24% had detrusor areflexia. Chancellor and Blaivas (1995a) detailed the urodynamic findings in 43 diabetic patients at Chancellor's institution: 33% had involuntary bladder contractions with normal contractility; 23% had involuntary bladder contractions with impaired contractility but were able to void; 9% had impaired bladder contractility alone but were able to void; 23% had detrusor areflexia; and only 12% had a normal urodynamic study. Ueda and colleagues (1997) also found involuntary bladder contractions in a moderate percentage of diabetic patients (25%) but noted that all these patients had a history of cerebrovascular disease and that no patient had involuntary bladder contractions who did not have such a history. Although it is obvious that some (or even many) of the patients with diabetes who exhibited involuntary bladder contractions may have had factors other than diabetes to account for their bladder overactivity, the importance of urodynamic study in diabetic patients before the institution of therapy cannot be overemphasized.

A variety of animal models have been able to replicate the diabetic state; however, different models demonstrate different patterns of disease expression. Alloxan-induced diabetic rats demonstrated detrusor overactivity. Sucrose-fed rats demonstrated normal bladder contractions. Streptozotocin-induced diabetic rats demonstrate pyuria more commonly (raising the question of an inflammatory component). Therefore the type of model used should be considered when attempting to interpret experimental findings (Yoshimura et al, 2005).

Liu and Daneshgari (2005) concluded that bladders of diabetic and diuretic rats weighed more than control animals and that diabetes and diuresis caused a significant increase in overall fluid intake, urine output, and bladder size. An increased response after field stimulation was noted in both diabetic and diuretic conditions, and a reduced response to cholinergic activity was noted as compared with controls. The authors noted this finding indicated the possibility of neurogenically mediated bladder contraction in the diabetic rat (Liu and Daneshgari, 2005). Numerous articles

Key Point: Diabetes Mellitus

- Cai Frimodt-Moller (1976) coined the term *diabetic cystopathy* to describe the involvement of the lower urinary tract by this disease. The classic description of voiding dysfunction secondary to diabetes is that of a peripheral and autonomic neuropathy that first affects sensory afferent pathways, causing the insidious onset of impaired bladder sensation. As the classic description continues, a gradual increase in the time interval between voiding results, which may progress to the point at which the patient voids only once or twice a day without ever sensing any real urgency. If this continues, detrusor distention, overdistention, and decompensation ultimately occur. Detrusor contractility, therefore, is classically described as being decreased in the end-stage diabetic bladder.

describe potential pathophysiologic mechanisms that could account for the various types of voiding dysfunction seen in diabetes. Clark and Lee (1995) describe the basic mechanism of interference with physiologic mechanisms as increases in blood glucose increasing the intercellular accumulation of both glucose and its subsequent metabolic products. Hyperglycemia is then proposed to lead to microvascular and neurologic complications, the neurologic sequelae ultimately resulting in a loss of myelinated and unmyelinated fibers, wallerian degeneration, and blunted nerve fiber reproduction and function. The proposed mechanisms include increased accumulation of polyols (sorbitol) from glucose through the aldolase-reductase pathway, inhibiting both glomerular and neural synthesis of myoinositol. The decrease in myoinositol synthesis depresses phosphoinositide metabolism, decreasing Na^+,K^+-ATPase activity. Hyperglycemia also leads to the formation of advanced glycosylation end products, inhibition of the formation of which in animals has been shown to improve response to functional and structural abnormalities of peripheral nerves.

Nerve growth factor (NGF) and its primary receptor p75NTR expression have been shown to be altered in rodent diabetic models. Tong and Cheng (2005) evaluated NGF levels in streptozotocin-treated rats by means of ELISA expressions for MRNAs of NGF and its primary receptor. NGF levels were found to be significantly lower in streptozotocin-induced diabetic rats, as compared with controls for both NGF and its primary receptor. In a treatment group managed with insulin, with normal glycemia, NGF levels and expressions of NGF, MRNAs, and primary receptor MRNAs were normalized.

Another aspect of diabetic bladder dysfunction may occur at the organelle level. In rodent models, morphologic changes in chronic diabetes have also included mitochondrial abnormalities, especially in the urothelium. Increased collagen was noted to be deposited in capillary walls, with an interruption or extensive widening of the gap junctions between myocytes in the bladder muscularis. Reduced mitochondrial counts were noted in the urothelium and bladder muscle. Degenerated nerve fibers and myelin bodies were identified between myocytes with increased collagen, and mast cells inflammatory aggregates were noted in the stroma of diabetic rats as compared with nondiabetic controls. The duration of diabetes appeared to amplify these changes, and the authors concluded that diabetic changes were a time-dependent phenomenon (Rizk et al, 2006).

In addition to this overall hypothesis, there are tantalizing "chunks" of data from various investigators that may or may not prove to be involved in the pathogenesis of voiding dysfunction secondary to diabetes. In streptozotocin-induced diabetic rats, Hashitani and Suzuki (1996) report reduced spontaneous spike activity, failure of neuromuscular transmission, reduced potency of the smooth muscle sodium-potassium pump, and the development of a postjunctional, muscarinic supersensitivity, but without alteration of the adenosine triphosphate receptor sensitivity. Tong and colleagues (1999) reported an upregulation of M2 receptor protein in the bladder of streptozotocin-induced diabetic rats and an upregulation of M2 receptor protein in bladder body tissue (Tong and Juei-Tang, 2002). Presumably, this could be related to detrusor overactivity and conceivably account for a differential effect of various anticholinergic agents, depending on their receptor specificity. Mumtaz and colleagues (1999) reported an impairment of nitric oxide–mediated urethral smooth muscle relaxation in alloxan-induced diabetic rabbits along with a significant impairment of noradrenergic, noncholinergic, nerve-mediated relaxation in this area. They hypothesize that nitric oxide may be functionally inactive and/or unavailable in this type of diabetes, and this lack may contribute to non–BPH-related outlet obstruction in patients with long-term diabetes and to detrusor overactivity, although it is a bit unclear as to how changes in only the outlet might influence overactivity. Gupta and colleagues (1996) and Gupta and Wein (1999) suggested that diabetes diminishes sodium pump activity, thereby inhibiting agonist-induced contractions in bladder smooth muscle by an increase in intracellular sodium concentration, the latter acting to diminish calcium influx. In abstract form, Chacko's group (Su et al, 2004) has hypothesized a translocation of protein kinase C isoforms as being involved in decreased detrusor contractility in alloxan-induced diabetes in rabbits. Cardozo and colleagues (2002) reported enhancement of bladder contractions to substance P and des-Arg-BK in a streptozotocin model. Sasaki and colleagues (2002) described decreased nerve growth factor in bladder tissue and L6 to S1 dorsal root ganglia. In alloxan-induced diabetic animals, Khan and colleagues (2002) noted decreased apoptosis of bladder urothelial cells. In this same model, Su and colleagues (2004) reported increased myosin light chain phosphorylation and decreased sensitivity to activator calcium; Changolkar and colleagues (2005) reported decreased smooth muscle force associated with increased lipid peroxides and sorbitol and an overexpression of aldolase reductase and polyol pathway activation. Another interesting pathophysiologic explanation is that attributed to autoimmune phenomena. In a murine model, antibody-mediated bladder dysfunction in type 1 diabetes has been identified. In diabetic mice, anti–voltage-gated calcium channel antibodies induce urodynamic findings compatible with overactive bladder such as phasic detrusor contractions and also loss of bladder wall compliance. This autoimmune dysfunction was reversed by the administration of agonists for voltage-gated calcium channels. The possible reversibility of this phenomenon remains intriguing for early-stage treatment (Wan et al, 2007).

Early institution of timed voiding will avoid the proportion of the impaired detrusor contractility from chronic distention and detrusor decompensation. Experimental studies are currently directed at inhibiting the proposed mechanisms by which hyperglycemia produces neuropathy (Clark and Lee, 1995). Ayan and colleagues (1999) cite references showing that intensive therapy for diabetes can slow its progression and slow the development of abnormal autonomic tests. As a corollary, they showed on a short-term basis in alloxan-induced diabetic rabbits that insulin therapy prevented the urodynamic (increased bladder capacity and compliance) and histopathologic changes seen in a similar but non–insulin-treated group of animals. Insulin reversed most of the changes reported by Cardozo and colleagues (2002).

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is **an inflammatory demyelinating disorder of the peripheral somatic and autonomic nervous system** that may be life threatening. It is described as a recognizable clinical entity characterized by rapidly evolving symmetrical limb weakness, loss of tendon reflexes, absent or mild sensory signs, and variable autonomic dysfunctions (Hahn, 1998). It results from aberrant immune responses directed against peripheral nerve components (Hartung et al, 1995; Hahn, 1998). It is triggered by a preceding bacterial or viral infection, with the immune responses directed toward the infecting organisms cross-reacting with neural tissues. The immune reactions against Schwann cell surface membrane or myelin result in acute inflammatory demyelinating neuropathy (accounting for 85% of cases), whereas reactions against axonal membrane components cause

acute motor-sensory axonal neuropathy, accounting for 15% of cases. Two thirds of patients report an antecedent acute infectious illness, most commonly a respiratory tract infection or gastroenteritis, that has resolved by the time the neurologic symptoms begin. Several anecdotal case reports have linked GBS to vaccination by temporal association alone. About 75% of cases reach their nadir within 2 weeks and 94% within 4 weeks. After a brief plateau phase, improvement begins, with gradual resolution of paralysis over weeks to months. The outcome is generally favorable, but Hahn (1998) quotes a mortality rate of 5% to 8% despite the most aggressive management. **Autonomic neuropathy is a common complication.** Cardiac arrhythmia; hypertension and hypotension; and bowel, bladder, and sexual dysfunction may occur. **The prevalence of lower urinary tract dysfunction has been reported as ranging from 25% to more than 80%** (Wyndaele et al, 2005). Zochodne (1994) reviewed multiple series and reported a urinary retention rate of 11% to 30%. Sakakibara and colleagues (1997a) reported 7 of 28 patients with voiding dysfunction. Of these, three had transient urinary retention; two had urgency, nocturia, and urge incontinence; one had stress incontinence; and one had voiding difficulty, otherwise unexplained. Many of these patients will have an indwelling catheter to monitor output while in the intensive care unit. Otherwise, **their voiding dysfunction should be managed by reversible therapy** (e.g., CIC, anticholinergic therapy) while waiting and hoping for resolution.

MISCELLANEOUS NEUROLOGIC DISEASES CAUSING VOIDING DYSFUNCTION

Lyme Disease

The associated neurologic symptoms of Lyme disease (neuroborreliosis) fall broadly into three syndromes: (1) encephalopathy, (2) polyneuropathy, and (3) leukoencephalitis. The Lyme spirochete can also (rarely) invade the bladder itself. Chancellor and colleagues (1993) described seven patients who also had lower urinary tract dysfunction. Five had detrusor overactivity, none had dyssynergia, and two had detrusor areflexia. In two women, urinary retention was the presenting symptom of Lyme disease. Other subjective symptoms noted were urgency, frequency, nocturia, and urge incontinence. Follow-up at 6 months to 2 years after treatment revealed residual urgency and frequency in three patients.

Hereditary Spastic Paraplegia

Hereditary spastic paraplegia is a genetically transmitted disorder, generally autosomal dominant, less commonly autosomal recessive, and rarely sex linked. There is a pattern of central demyelination with axon loss and progressive lower extremity spasticity generally with muscle weakness. Bushman and colleagues (1993) reported three patients, two of whom had detrusor overactivity (one with striated sphincter dyssynergia), one who had significantly decreased compliance, and one who was urodynamically normal except for a high maximum urethral pressure of uncertain significance.

Jensen and colleagues (1998) reported the voiding characteristics of 11 patients with autosomal dominant pure spastic paraplegia linked to chromosome 2p21-p24. These were culled from six of eight families with the disorder, the authors commenting that lower urinary tract symptoms were present in 16 of 44 definitely affected family members. One patient had an indwelling catheter, and thus an accurate description of symptomatology was not possible. For the other patients, urinary urgency and frequency were the dominant complaints, with 6 of these 10 patients regularly experiencing urgency incontinence. Urodynamically, three patients showed detrusor overactivity, six demonstrated normal detrusor activity, and one demonstrated "hyporeflexia" with delayed first sensation. Satisfactory sphincter EMG recordings were obtained from seven patients, and all were normal. Postvoid residual urine volumes were raised in 8 of 10 patients. The bulbocavernosus reflex was absent in six patients and was truly normal in only one. The authors commented that the frequency of urinary symptoms in their patients (36%) correlated well with other reports in the literature. The authors proposed that the lower urinary tract symptoms (and bowel and sexual dysfunction) in patients with this disorder are caused by a combination of somatic and autonomic nervous system involvement, supporting a multisystem involvement.

Tropical Spastic Paraparesis

Tropical spastic paraparesis is primarily a spinal cord myelopathy caused by a retrovirus (human T-cell leukemia virus 1 [HTLV-1]) similar to HIV. Progressive lower limb weakness and back pain are typically the primary complaints, but voiding dysfunction occurs in up to 60% of those affected (Walton and Kaplan, 1993). Eardley and colleagues (1991) studied six such patients with voiding dysfunction. Two had detrusor areflexia, and three had overactivity, one of whom with dyssynergia. Walton and Kaplan (1993) found four of five consecutive patients had detrusor overactivity and striated sphincter dyssynergia, whereas one had overactivity and synergia. The type of voiding dysfunction depends on whether the damage is primarily to the descending spinal tracts, to the sacral nuclei, or to the sacral outflow. The disease must be distinguished from other myelopathic conditions associated with voiding dysfunction such as MS.

Acquired Immunodeficiency Syndrome

Infection with HIV can affect both the central and peripheral nervous systems, and so it is not unexpected that symptoms of lower urinary tract dysfunction occur, although there is some disagreement as to the overall prevalence of such symptoms in this population. Khan and colleagues (1992) were among the first to report on the types of voiding dysfunctions seen in patients with AIDS. They reported 11 such patients. Urinary retention occurred in six. On urodynamic evaluation, three had detrusor overactivity, four had detrusor areflexia, two had a hypocontractile detrusor, and two had outlet obstruction secondary to BPH. Hermieu and colleagues (1996) prospectively studied 39 patients with HIV infection and voiding symptoms. Clinical symptoms included frequency, urgency, and incontinence in 41% of patients, acute urinary retention in 28%, dysuria and frequency in 18%, and decreased flow in 13%. Seventeen of the patients had involuntary bladder contractions; of these, eight had striated sphincter dyssynergia or a lack of sphincter relaxation during micturition, five patients had detrusor areflexia, four patients had what was termed a "hypertonic urethra," three had "hypersensitivity," and five patients had a normal urodynamic evaluation. The authors characterized the voiding dysfunctions broadly as inability to void in 41% of the cases and frequency/urgency/incontinence in 41%. The authors comment that the appearance of neurogenic voiding disturbances

heralds a poor prognosis. Eighteen HIV-positive patients, 13 with AIDS, who presented with voiding dysfunction were urodynamically characterized by Kane and colleagues (1996). Chief presenting complaints were daytime frequency in eight patients; retention in three; nocturia in two; and having to strain to void, feeling incompletely empty, incontinence, split stream, and groin pain in one each. Five patients (28%) showed detrusor overactivity, five showed DESD, and one (6%) showed detrusor areflexia. The authors remarked that there was a correlation between cytomegalovirus infection, polyradiculopathy, and detrusor areflexia, a phenomenon reported by others as well. Other common causes of voiding dysfunction exist as well because four patients had outlet obstruction secondary to BPH and in one patient it was secondary to urethral stricture. In another study, Lima and colleagues (2002) evaluated a group of 26 men with HIV-induced bladder dysfunction. Eighty percent of those patients demonstrated detrusor overactivity, and 34% had detrusor-sphincter dyssynergia. These findings are indicative of the myopathy associated with HIV (Lima et al, 2002). Additionally, impaired micturition in the HIV complex may be due to infestations (cerebral toxoplasmosis or viral encephalitis), demyelination disorders, cytomegalovirus, polyradiculopathy, and AIDS-related dementia. Thirty to forty percent of patients with AIDS will develop neurologic involvement with 20% presenting initially with some neurologic symptom. In those patients presenting with urologic symptoms, an underlying neurologic cause is present in approximately 60% of those patients, and 90% of those patients will have already developed an AIDS-associated neoplasm or infestation. Detrusor-sphincter dyssynergia, poor bladder contractility, detrusor overactivity, and bladder outlet obstruction have all been reported in this population. AIDS-related neurogenic voiding dysfunction is associated with a poor outcome, with a mortality rate of approximately 40% within 8 months of development of urologic symptoms (Heyns and Fisher, 2005). How common are voiding problems overall in patients with HIV infection and AIDS? Gyrtrup and colleagues (1995) prospectively investigated voiding function in 77 men and 4 women with HIV infection or AIDS consecutively attending an outpatient clinic. Eight of these (10%) had moderate subjective voiding problems, whereas two (2%) had severe problems. The authors believed that in only 4% of patients did the nature of the disturbance warrant urodynamic examination and concluded that urinary voiding symptoms are only a modest problem overall in an HIV/AIDS population. They concluded that neuropathic bladder dysfunction is rare and occurs mostly in the late stages of the disease.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is an acute inflammatory demyelinating disorder of the central nervous system of unknown etiology. It is also sometimes known as *parainfectious* or *postinfectious encephalomyelitis*. The sites of lesions are multifocal and can include the cerebral white matter, cerebellum, brainstem, and spinal cord. The records of 11 patients with ADEM were reviewed and commented on by Sakakibara and colleagues (1996a). Nine patients had presented in urinary retention; the other two had urgency, frequency, nocturia, and difficulty voiding, one of whom had enuresis and urgency incontinence as well. The urodynamic findings are difficult to correlate with the presenting symptoms because in four of the patients the studies were done considerably after the onset of the disease. During the follow-up period, seven of the nine patients who originally had retention became able to urinate. Five had difficulty voiding, and four developed irritative symptoms. Six of the patients ultimately had a near-complete neurologic recovery, but voiding symptoms persisted in three. The authors concluded that the supranuclear and nuclear types of pelvic and pudendal nerve dysfunction were primarily responsible for the micturitional disturbances in patients with this disease and that voiding dysfunction was common in these patients.

Syringomyelia

Syringomyelia is a chronic disorder of the spinal cord characterized by dissociated sensory loss and brachial amyotrophy. It usually affects the cervical spinal cord but can extend caudally. Voiding dysfunction has been reported in 9% to 25% of patients. Fourteen patients with syringomyelia were studied urologically by Sakakibara and colleagues (1996d). Eleven of these had urinary symptoms: difficulty voiding in eight, retention in three, nocturnal and daytime frequency in three, incontinence in two, and urgency and enuresis in one. The urinary symptoms appeared from 2 months to 13 years after the initial neurologic symptoms. Urodynamic studies revealed detrusor overactivity in seven, detrusor-sphincter dyssynergia in four, detrusor areflexia in four, and "uninhibited sphincter relaxation" in two. It is interesting that motor unit EMG recordings disclosed findings compatible with denervation of the striated sphincter in five of six patients. The authors concluded that both supranuclear and nuclear types of peripheral autonomic and somatic nerve dysfunction are responsible for the voiding dysfunctions seen. It is also interesting that the micturitional status gradually improved in four of six patients after syringosubarachnoid shunts.

Schistosomal Myelopathy

In addition to causing voiding dysfunction secondary to bladder neck obstruction and impaired muscle contractility as a result of infiltration of the bladder smooth muscle itself, schistosomiasis can rarely cause spinal cord involvement, either as a granulomatous intrathecal mass or as an acute transverse myelitis (Razdan et al, 1997). Two such patients presented with urinary incontinence as their chief urologic complaint. Both had detrusor overactivity: one without dyssynergia and with minimal motor weakness and the other with striated sphincter dyssynergia and a T11 sensory level. It was believed that the findings in the former patient were characteristic of a partial spinal cord or cerebral lesion and that the second patient had a suprasacral transverse myelopathy. In the first patient, the urinary symptoms developed approximately 2 months after exposure and after the development of systemic symptoms; in the second case, symptoms developed some 5 years after the initial diagnosis. Gomes and colleagues (2002) reviewed the records of 14 patients with schistosomal myelopathy referred for voiding dysfunction. Of five patients with acute disease, three presented with retention and two had incontinence. Urodynamics were performed in three of these. Two (one in retention, one with hesitancy and incontinence) demonstrated detrusor areflexia, and one (in retention) showed detrusor overactivity and striated sphincter dyssynergia. Of the 9 chronic patients, 5 showed detrusor overactivity with dyssynergia, 1 with decreased compliance; 2 showed overactivity with synergic sphincters; and 25 showed detrusor areflexia, 1 with decreased compliance.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a disease in which there is widespread inflammatory change in the connective tissues and

small vessels of the skin and systemic organs, probably autoimmune in origin (Hahn cited by Sakakibara et al, 2003b). The prevalence of nervous system involvement is cited from 18% to 75%. Myelopathy occurs in 1% to 3% of SLE patients. Sakakibara and colleagues (2003b) reported on eight patients with SLE who presented with voiding dysfunction, six with voiding difficulty (two in retention) and four with urinary incontinence. Five exhibited decreased flow, three had increased residual urine, five had detrusor overactivity, five had impaired detrusor contractility, four had detrusor–striated sphincter dyssynergia, and two of four exhibited abnormal striated sphincter EMG potentials. Sensation was impaired in two patients. Although three patients had subacute encephalomyelopathy (one subacute myelopathy, four chronic myelopathy), the lower urinary tract dysfunction seemed related mainly to the myelopathy. Yu and colleagues (2003) studied 152 women with lupus. Urodynamics and an AUA-7 symptom index were administered and compared with 227 age-matched healthy women. A significantly higher percentage of women with SLE experienced emptying and storage dysfunction with higher symptom scores in the lupus group, as compared with the control group. There was a correlation between symptomatic presentation and Lupus index, but no correlation with disease duration. However, there was a significant relationship between symptom degree and magnitude of symptoms and central nervous system involvement in the lupus group. The lupus patients more commonly manifested a diminished cystometric capacity and a decreased flow rate.

Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy is a disabling syndrome characterized by severe pain with autonomic changes such as vasomotor disturbances. The condition usually follows a traumatic injury. The exact etiology and pathogenesis are unclear. The prevalence of voiding dysfunction in patients with reflex sympathetic dystrophy is unknown, but it must be more than a rare occurrence because Chancellor and colleagues (1996) were able to collect 20 consecutive patients with neurologically verified reflex sympathetic dystrophy who were referred for voiding symptoms, none of which existed before the initial trauma that induced the reflex sympathetic dystrophy. Seven of the patients presented with urinary retention, although some of these had had various types of surgery designed to treat the symptoms of the dystrophy. Five presented with urgency incontinence, one of whom also had stress incontinence. Six had urgency as a primary complaint, one had daytime frequency, and one had severe nocturia. Detrusor overactivity was demonstrated in eight patients, DESD in one, detrusor areflexia in eight, and hypersensitivity on filling in three. Because the authors excluded patients with acute development of voiding dysfunctions after back surgery and with herniated disks and included only those in whom voiding symptoms developed concurrently with progressive symptoms of reflex sympathetic dystrophy, one must conclude that significant lower urinary tract dysfunction can develop as a direct result of or an association with this problem, although the cause-and-effect relationship is unknown.

Other Conditions

A number of other conditions have been associated with voiding dysfunction, most of which have been reported as individual cases or small groups of cases. These are associated with neurologic symptoms typical of central and/or peripheral neural involvement. The interested reader is referred to relevant articles on amyloidosis (Sakamoto and Wheeler, 1997), adult polyglucosan body disease (Gray et al, 1988), Behçet disease (Theodorou et al, 1999; Saito and Miyagawa, 2000; Sakakibara et al, 2000), neurofibromatosis (Brownlee et al, 1998), spinal muscular atrophy (Von Gontard et al, 2001), Duchenne muscular dystrophy (MacLeod et al, 2003), and familial dysautonomia (Saini et al, 2003).

MISCELLANEOUS CONDITIONS DEFINITELY, PROBABLY, OR POSSIBLY RELATED TO NEUROMUSCULAR DYSFUNCTION

Detrusor Sphincter Dyssynergia

Dyssynergia refers to the kinesiologic disassociation of two groups of muscles that generally work in harmony. Sphincter dyssynergia refers to an involuntary contraction or lack of relaxation of either the striated sphincter (the striated muscle surrounding the proximal urethra and the striated muscle that forms a part of the urethra for a variable distance from the "urogenital diaphragm" to the bladder neck) or the smooth sphincter (the smooth muscle of the bladder neck and proximal urethra). **Detrusor sphincter dyssynergia,** unless specified otherwise, refers to dyssynergia of the striated sphincter and is sometimes abbreviated DSD or DESD. This is discussed in Chapter 61 and in the earlier parts of this chapter, especially in the section on SCI. It is discussed as a separate entity here as well to emphasize its importance in terms of recognition and proper management in patients with neurogenic voiding dysfunction.

True DESD should exist only in patients who have an abnormality in pathways between the sacral spinal cord and the brainstem pontine micturition center, generally caused by neurologic injury or disease (Blaivas, 1982; Rudy, 1993; Chancellor and Rivas, 1995; Wein and Rovner, 1999). The diagnosis of DESD should be suspected in any patient with a neurologic lesion in this area. Common causes include traumatic SCI, multiple sclerosis, and the various forms of transverse myelitis. Conversely, **in patients without such a lesion, this diagnosis should always be viewed with skepticism,** and, without such apparent pathology, such a patient deserves exhaustive study to exclude a neural diagnosis. One exception to this precept is in infants and children with dysfunctional voiding or the Hinman syndrome (see later).

Blaivas and colleagues (1981) have described three main types of DESD. In type 1, there is concomitant increase in both detrusor pressure and EMG activity; at the peak of the detrusor contraction, the sphincter suddenly relaxes and unobstructed voiding occurs. In type 2, there are sporadic contractions of the striated sphincter throughout the detrusor contraction. In type 3, there is a crescendo-decrescendo pattern of sphincter contraction that results in outlet obstruction throughout the entire detrusor contraction. Schurch and colleagues (2005) have correlated neurologic status and DESD type after SCI. Those with an incomplete sensory and motor lesion generally present with type 1 DESD; those with complete sensory and motor lesions present with type 2 and type 3. Weld and colleagues (2000) prefer to classify DESD as intermittent or continuous but note that in their experience the clinical significance of DESD type is not crucial because both types require urodynamic surveillance and expedient treatment to minimize complications. No significant association between type and level of injury was

found. Continuous DESD was more associated with complete injuries.

Sphincter EMG activity that increases simultaneously with intravesical or detrusor pressure does not always indicate true DESD, however. These other instances are referred to as pseudodyssynergia (Wein and Barrett, 1982), and such a misdiagnosis may be accompanied by adverse therapeutic consequences. **Common causes of pseudodyssynergia include (1) abdominal straining to either initiate or augment a bladder contraction or in response to discomfort and (2) attempted inhibition of a bladder contraction either because of its involuntary nature or because of discomfort.** Rudy (1993) has reported that pseudodyssynergia can reliably be differentiated from true DESD urodynamically by analyzing the patterns of detrusor and EMG activity, but others have not always found this to be the case.

Without proper treatment, more than 50% of men with DESD will develop significant complications such as VUR, upper tract deterioration, urolithiasis, urosepsis, and ureterovesical obstruction (Chancellor and Rivas, 1995). In women, these complications are much less common, probably because of the decreased detrusor pressures generated. Using Blaivas' categorization, type 1 DESD is generally managed with observation alone unless there is persistent reflux, hydronephrosis, or autonomic hyperreflexia. Types 2 and 3 are generally treated. In assessing success or failure of treatment, Kim and colleagues (1998) have used bladder leak point pressure greater than 40 cm H_2O as an indicator of the failure of at least sphincterotomy, because in their experience there was a significantly higher incidence of upper tract damage and persistent DESD in such patients. This most likely applies to other treatments as well. **Therapy for DESD is designed to either eliminate or significantly lessen the abnormal sphincter activity or to circumvent it. Oral medical therapy directed toward the striated sphincter has not enjoyed wide success, and the most common current approaches are (1) CIC (usually combined with therapy to control detrusor overactivity), (2) sphincterotomy, (3) stent placement across the sphincter, (4) injection of botulinum toxin into the sphincter, (5) continuous catheterization, and (6) urinary diversion.**

Experimental small animal models of DESD have been reported by Burnett and colleagues (1997) in mice with targeted deletion of the gene for neuronal nitric oxide synthase and by Cheng and colleagues (1997) by instillation of cold water into the urinary bladder of rats.

Dysfunctional Voiding

This subject is more extensively considered in Chapters 127-128 but is mentioned here because individuals with a history of unexplained lower urinary tract dysfunction symptomatology may not present to the urologist or be definitively diagnosed with this entity until adulthood. **This syndrome, also described by various authors as *non-neurogenic neurogenic bladder, occult voiding dysfunction, occult neuropathic bladder, learned voiding dysfunction,* and the *Hinman syndrome,* presents the unusual circumstance of what appears urodynamically to be involuntary obstruction at the striated sphincter level existing in the absence of demonstrable neurologic disease** (Hinman, 1986). It is difficult to prove urodynamically that an individual has this entity, and it should further be noted that the diagnoses in many of the patients reported have been made on the basis of only history, isolated flowmetry, isolated measurements of total intravesical pressure, and pelvic floor EMG activity (Wein and Barrett, 1988). I believe unequivocal demonstration of this entity requires pressure-flow-EMG evidence of bladder emptying occurring simultaneously with involuntary striated sphincter contraction in the absence of any element of abdominal straining, either in an attempt to augment bladder contraction or as a response to discomfort during urination. Such reports do exist and confirm the existence of this syndrome. The etiology is uncertain and may represent a persistent transitional phase in the development of micturitional control or persistence of a reaction phase to the stimulus of lower urinary tract discomfort during voiding, long after the initial problem that caused this has disappeared (Jorgensen et al, 1982).

Bladder Neck Dysfunction

Bladder neck dysfunction is defined here as **an incomplete opening of the bladder neck during voluntary or involuntary voiding.** It has also been referred to as *smooth sphincter dyssynergia, proximal urethral obstruction, primary bladder neck obstruction,* and *dysfunctional bladder neck*. **The term *smooth sphincter dyssynergia* or *proximal sphincter dyssynergia* is generally used when referring to this urodynamic finding in an individual with autonomic hyperreflexia.** In male patients with autonomic hyperreflexia, the neurologic pathophysiology is clear. **The term *bladder neck dysfunction* more often refers to a poorly understood non-neurogenic condition first described over a century ago but first fully characterized by** Turner-Warwick and colleagues in 1973**. The dysfunction is found almost exclusively in young and middle-aged men, and characteristically they complain of long-standing voiding/emptying (obstructive) and filling/storage (irritative) symptoms** (Webster et al, 1980; Norlen and Blaivas, 1986; Wein and Barrett, 1988; Trockman et al, 1996; Yamanishi et al, 1997). **These patients have often been seen by many urologists and have been diagnosed as having psychogenic voiding dysfunction because of a normal prostate on rectal examination, a negligible residual urine volume, and a normal endoscopic bladder appearance.** The differential diagnosis also includes anatomic bladder neck contracture, BPH, dysfunctional voiding, prostatitis/prostatosis, neurogenic dysfunction, and low pressure/low flow (see later). **Objective evidence of outlet obstruction in these patients is easily obtainable by urodynamic study. Once obstruction is diagnosed, it can be localized at the level of the bladder neck by video-urodynamic study, cystourethrography during a bladder contraction, or micturitional urethral profilometry** (see Chapter 62). The diagnosis may also be made indirectly by the urodynamic findings of outlet obstruction in the typical clinical situation in the absence of urethral stricture, prostatic enlargement, and striated sphincter dyssynergia. Involuntary bladder contractions or decreased compliance may occur. Noble and colleagues (1994) cite the incidence as 50%, but this seems high. Trockman and colleagues (1996) quote it as 34%.

The exact cause of this problem is unknown. Some have proposed that there is an abnormal arrangement of musculature in the bladder neck region, so coordinated detrusor contractions cause bladder neck narrowing instead of the normal funneling (Bates et al, 1975). The occurrence of this problem in young, anxious, and high-strung individuals and its partial relief by α-adrenergic blocking agents have prompted some to speculate that it may in some way be related to sympathetic hyperactivity.

When prostatic enlargement develops in individuals with this problem, a double obstruction results, to which Turner-Warwick (1984) **has applied the term *trapped prostate*.** The lobes of the prostate cannot expand the bladder neck and therefore expand into the urethra. A patient so affected generally has a lifelong history of voiding dysfunction that has gone relatively unnoticed because he has always accepted this as normal, and exacerbation of these symptoms occurs during a relatively short and early period of prostatic enlargement. Although α-adrenergic blocking agents provide improvement in some patients with bladder neck dysfunction, definitive relief in the male is best achieved by bladder neck incision. In patients with this and a trapped prostate, marked relief is generally effected by a "small" prostatic resection or ablation that includes the bladder neck or a transurethral incision of the bladder neck and prostate. Such patients often note afterward that they have "never" voided as well as after their treatment.

Bladder Outlet Obstruction in Women

The female counterpart of non-neurogenic bladder neck dysfunction in men does exist, although it is rare. **Bladder outlet obstruction in women in general is uncommon.** Dionko and colleagues (1984) were among the first to clearly define this entity in women on the basis of video-urodynamic studies. Nitti and colleagues (1999) evaluated the video-urodynamic studies of 261 of 331 women who underwent multichannel studies for non-neurogenic voiding dysfunction. **They defined *bladder outlet obstruction* as radiographic evidence of obstruction between the bladder neck and the distal urethra in the presence of a sustained detrusor contraction of any magnitude, which is usually associated with reduced or delayed urinary flow rate. Obstruction at the level of the bladder neck was diagnosed when the bladder neck was closed or narrowed during voiding. Obstruction of the urethra was diagnosed as a discrete area of narrowing, associated with proximal dilatation.** Strict pressure-flow criteria were not used to classify cases as obstructed or not obstructed. Using these criteria they found 76, or 23%, of their cases to be obstructed. Of those obstructed, only 16% (12 patients) were diagnosed as having primary bladder neck obstruction (the counterpart to non-neurogenic bladder neck dysfunction in the male). Thirty-three percent of the cases of obstruction were caused by dysfunctional voiding (see earlier for description), 28% by cystocele, 14% by obstruction created by prior incontinence surgery, 4% by urethral stricture, 3% by uterine prolapse, and 1% each by urethral diverticulum and rectocele. Groutz and colleagues (2000) reviewed their urodynamic database of 587 consecutive women referred for evaluation of voiding symptoms. **They defined obstruction as a persistent, low, noninvasive maximum flow rate less than 12 mL/sec on repeated study combined with a detrusor pressure at maximum measured flow rate of more than 20 cm H_2O in a pressure-flow study.** Only 38 women (6.5%) met these criteria of bladder outlet obstruction. Of those, only 8% (three women) were characterized as having primary bladder neck obstruction. Twenty-six percent (10 women) had obstruction on the basis of prior anti-incontinence surgery, 24% because of severe genital prolapse, 13% because of urethral stricture, 5% because of dysfunctional voiding, 5% because of true detrusor striated sphincter dyssynergia, and 3% because of urethral diverticulum. In 16%, there was no definable etiology. **Most authors would agree that surgical treatment of this problem in women should be approached with caution because sphincteric incontinence is a significant risk.** Smith and Appell (2006) commented on the importance of urodynamics in distinguishing dysfunctional voiding versus bladder neck dysfunction. They commented on the importance of evaluation inclusive of symptom assessment, uninstrumented uroflow patterns, simultaneous urodynamic and EMG assessment of voiding, as well as the addition of fluoroscopy to assess function of the bladder neck during voiding. They further stressed multidisciplinary therapy including pelvic floor therapy (biofeedback), behavioral modification, and the addition of pharmacotherapy. Neuromodulation may have a role in select patients, as well as rare surgical intervention for primary bladder neck dysfunction.

Low-Pressure/Low-Flow Voiding in Younger Men: Bashful Bladder

Low-pressure/low-flow voiding **can be the result of a number of causes, most notably a decompensating detrusor** (generally from bladder outlet obstruction—see Chapters 62 and 92) or as a part of the syndrome known as *detrusor hyperactivity with impaired contractility* (DHIC—see Chapters 62 and 76). **When this occurs in a young man, it is generally characterized by frequency, hesitancy, and a poor stream.** The entity is readily demonstrated on urodynamic assessment and with no coexisting endoscopic abnormality. **The patient usually notes marked hesitancy when attempting to initiate micturition in the presence of others,** and some have therefore described this condition as an "anxious bladder" or a "bashful bladder." The estimate of the incidence of this problem in younger male patients referred for urodynamic assessment varies between 6% (Barnes et al, 1985) and 19% (George and Slade, 1979).

Barnes and colleagues (1985) suggested that these men are psychologically unusual but in the direction of being obsessional rather than anxious. They suggest that these individuals have a lifelong tendency to overcontrol the process of micturition and are thus vulnerable to lower urinary tract symptoms under stress, and they recommend that a behavioral modification program be considered. Rosario and colleagues (2000) performed ambulatory urodynamic studies on 40 consecutive symptomatic men with a mean international prostate symptom score of 19 who were unable to "perform" during conventional video-urodynamic study. They concluded that a surgically correctable cause of the symptoms could be found in about 20% of men, but only in those older than 40 years. They believed therefore that the contribution of ambulatory urodynamic monitoring in such cases in men younger than 40 years was negligible. They also stated that they thought evidence from the literature suggested that a significant proportion of such nonobstructed cases would respond to drug therapy or behavioral therapy. The authors' experiences have been similar to those of others who have stated that, in the younger nonobstructed male with this condition, neither empirical pharmacologic treatment nor transurethral surgery has had any consistent beneficial effect.

Urinary Retention; the Fowler Syndrome in Young Women

Urinary retention is encountered fairly commonly by the urologist, especially in adult men secondary to anatomic obstruction from benign prostatic enlargement. Although unusual, urinary

retention in women is not rare. As in the male, **the potential causes are classically cited as neurologic, pharmacologic, anatomic, myopathic, functional, and psychogenic.** A particularly excellent review of the various causes of urinary retention in women along with an algorithm for evaluation and treatment has been published by Smith and colleagues (1999).

The Fowler syndrome (Fowler et al, 1988; Noble et al, 1994; Fowler, 1999, 2007; Swinn and Fowler, 2001) refers to **a syndrome of urinary retention in young women in the absence of overt neurologic disease. The typical history is that of a woman younger than 30 years of age who has found herself unable to void for a day or more with no urinary urgency but increasing lower abdominal discomfort. A bladder capacity of more than 1 L with no sensation of urgency is necessary for the diagnosis. There are no neurologic or laboratory features to support a diagnosis of any neurologic disease. MRI of the brain and the entire spinal cord is normal. On concentric needle electrode examination of the striated muscle of the urethral sphincter, however, Fowler and colleagues described a unique EMG abnormality.** This abnormal activity, localized to the urethral sphincter, consists of a type of activity that would be expected to cause inappropriate contraction of the muscle. Sphincter activity consists of two components: complex repetitive discharges and decelerating bursts. This abnormal activity impairs sphincter relaxation. These patients often have polycystic ovaries, raising the possibility that the activity is linked in some way to impaired muscle membrane stability, allowing direct spread of electrical impulses throughout the muscle, owing possibly to a hormonal abnormality; and thus the disorder may possibly be the manifestation of a focal, hormonally dependent "channelopathy." This would explain why the condition is seen only in premenopausal women. Efforts to treat this condition by hormonal manipulation, pharmacologic therapy, or injections of botulinum toxin have been unsuccessful. This condition is highly responsive to neuromodulation (success rate approaching 70%) even in women who have been in retention for many months or years.

Kavia and colleagues (2006) assessed a large group of women (247) for assessment of either complete (42%) or partial (58%) retention. Completeness was defined as inability to void whatsoever. These women had previously been diagnosed with abnormality of the striated urethral sphincter electromyogram (Fowler syndrome), which led to the referral. These women were assessed with a combination of urethral profilometry (71%), transvaginal ultrasonographic measurement of sphincter volume (57%), and sphincter electromyogram (39%). Those patients with complete retention showed a significant difference in sphincter volume between those who were EMG positive, as opposed to those who were EMG negative. The authors concluded that on the basis of this, the most common diagnosis for women referred for urinary retention was Fowler syndrome, which led to the potential use of neuromodulation for those patients.

The urodynamic problem is detrusor acontractility. The same EMG abnormality, however, is found sometimes in women with obstructed voiding. This type of EMG activity is not uncommon (Fitzgerald and colleagues [2000] cite an incidence of 8% in a series of women undergoing routine urodynamic and EMG studies), but its correlation with complete retention is relatively rare.

Neuromodulation has been advocated for Fowler syndrome (nonobstructive urinary retention in women). De Ridder and colleagues (2007) reported 62 women who underwent sacral nerve stimulation, 30 of whom had findings compatible with Fowler syndrome and 32 with idiopathic retention. Somatoform disorder was found in 26% of the Fowler's patients and 43.8% of the idiopathic group. Depression was also higher in the Fowler syndrome group (30% vs. 18.8%). Neither of these findings, however, had correlation with outcome. Nine patients with Fowler syndrome as compared with 19 without failed neuromodulation. The authors concluded that Fowler syndrome was actually a positive predictive factor for SNS response in patients with female urinary retention. They did advocate preimplant psychologic testing including the patient health questionnaire; however, there was no correlation with outcomes in this population.

Postoperative Urinary Retention

Postoperative urinary retention is a well-recognized but poorly understood event. Its incidence is generally quoted overall as 4% to 25%. It occurs more frequently after lower urinary tract, perineal, gynecologic, and anorectal surgery. In the placebo arms of four trials of α-adrenergic blocker prophylaxis after these types of surgery, the incidence of postoperative retention ranged from 18.8% to 57% (Velanovich, 1992). **Contributing factors, which are not mutually exclusive, include the following eight factors:**

1. Traumatic instrumentation
2. Bladder overdistention
3. Diminished awareness of bladder sensation
4. Decreased bladder contractility
5. Increased outlet resistance
6. Decreased micturition reflex activity
7. Nociceptive inhibitory reflex
8. Preexistent outlet pathology (e.g., BPH)

Anesthesia and analgesia can contribute to factors 2, 3, 4, and 6. The idea of a nociceptive inhibitory reflex, initiated by pain or discomfort, is an attractive one because a sympathetic efferent limb could directly affect factors 4, 5, and 6 (see Chapter 60).

Bladder decompression for 18 to 24 hours postoperatively decreased the incidence of retention in patients undergoing joint replacement surgery by 52% versus 27% (Michelson et al, 1988) and 65% versus 0% (Carpiniello et al, 1988), compared with CIC. The incidence of urinary infection with continuous catheterization was no different in the Michelson and colleagues' study (15% vs. 11%) and was less in the Carpiniello and colleagues' study (16% vs. 43%), in which straight catheterization was carried out in the recovery room as well. The avoidance of acute bladder overdistention to prevent postoperative urinary retention is supported by the experimental observation of a reduced bladder response to sacral neural stimulation during overdistention (>80% reduction) and, as well, after overdistention (19% reduction) (Bross et al, 1999).

α-Adrenergic blockade with phenoxybenzamine historically has seemed effective prophylactically in decreasing the incidence of postoperative retention. Velanovich (1992) performed a meta-analysis on the use of phenoxybenzamine (only randomized placebo-controlled studies) and concluded that this agent reduced the occurrence by 29.1%. In a retrospective review of colorectal patients treated with and without phenoxybenzamine, Goldman and colleagues (1988) found a 54.7% incidence of retention in patients not given this agent versus a 19.2% incidence in those who were. The regimen for those not catheterized preoperatively was 10 mg orally the evening before and 1 hour before surgery, 2 hours after, and 10 mg twice daily for 3 days. For those who were catheterized before the procedure, the regimen was 10 mg twice daily, initiated the day before catheter removal. The mechanism of action is uncertain. If an inhibitory nociceptive reflex is

initiated, and this is similar to the sympathetic reflex elicited by bladder filling (see Chapter 60), the mechanism is multifactorial. Alternatively, the drug may act only on the outlet to decrease resistance, which may be pathologically increased by anxiety, pain, and other factors related to surgery. Whether other α-adrenergic blockers are as effective is uncertain (Cataldo and Senagore, 1991).

Hyperthyroidism

Patients with thyrotoxicosis often present with symptoms caused by sympathetic overactivity and autonomic nervous system imbalance. Goswami and colleagues (1997) reported that 12 of 30 patients (40%) experienced the onset of voiding symptoms 1 to 6 months after the onset of the symptoms of thyrotoxicosis. Four of these patients had enuresis. Urodynamic studies were done in five patients; all had reduced flow rates, and four had a significant postvoid residual, three of whom had an enlarged bladder capacity and increased perineal EMG activity during voiding. The voiding dysfunction and urodynamic abnormalities resolved after resolution of the hyperthyroidism. The bladder symptoms were more common in females than in males. The authors hypothesize that increased β-adrenergic activity in thyrotoxicosis is responsible for a reduced flow rate and increased bladder capacity because of the inhibitory β-adrenergic activity on detrusor muscle contractility. Stoffer (1988) cited a much lower incidence of voiding dysfunction in thyrotoxicosis: a 7% prevalence of urgency and hesitancy and a 1% prevalence of enuresis.

Schizophrenia

Bonney and colleagues (1997) proposed that a significant subset of schizophrenic patients have involuntary bladder contractions secondary to brain pathology. In a previous study (Gupta et al, 1995), the same group demonstrated involuntary bladder contractions in 4 of 10 evaluable patients with schizophrenia who were referred for voiding dysfunction or incontinence. All of these patients had significant childhood incontinence, urge incontinence, bedwetting, and a small bladder capacity. In the later report (Bonney et al, 1997) the prevalence of urinary incontinence and related symptoms in a group of chronic schizophrenic patients was compared with a group of comparatively hospitalized patients with mood disorders. There was a significant difference in the prevalence of urge incontinence (34% vs. 17%) and bedwetting (46% vs. 20%). There were no significant differences in urinary urgency, overall voiding dysfunction, fecal incontinence, or sexual dysfunction. The hypothesis of a neurobiologic correlate between schizophrenic patients and the occurrence of involuntary bladder contractions in these patients is an intriguing one.

Gastroparesis

Gastroparesis is a condition characterized by symptoms from impaired transit of intraluminal gastric contents into the duodenum but in the absence of mechanical obstruction. It may be caused by diabetes, occur after gastric surgery, or be idiopathic. Goldman and Dmochowski (1997) characterized the voiding dysfunction of 17 patients with gastroparesis who were referred for voiding symptoms, 10 of whom had idiopathic gastroparesis and in 7 of whom the condition was secondary to diabetes. Seven patients had abnormal detrusor contraction and delayed sensation, five had poor detrusor function and normal sensation, three had normal detrusor function and poor sensation, and two had normal detrusor contraction and sensation. There was no difference between the occurrence of the dysfunctions in the two groups. Predominant symptoms were urinary frequency in 7 and difficulty emptying in 10. Patients with idiopathic gastroparesis were more likely to note difficulty emptying (70%), whereas those with diabetic gastroparesis were more likely to have urinary frequency (71%). The authors postulated an association between idiopathic gastroparesis and bladder dysfunction and proposed that a common autonomic neuropathic syndrome may account for the bladder dysfunction in both the idiopathic and the diabetic forms of this syndrome.

Myasthenia Gravis

Any neuromuscular disease that affects the tone of the smooth or striated muscle of the distal sphincter mechanism can predispose an individual patient to a greater chance of urinary incontinence after even a well-performed transurethral or open prostatectomy. Myasthenia gravis is an autoimmune disease caused by autoantibodies to acetylcholine nicotinic receptors. This leads to neuromuscular blockade and hence to weakness in a variety of striated muscle groups. The incidence of incontinence after prostatectomy is indeed greatly increased in patients with this disease (Greene et al, 1974; Khan and Bhola, 1989). Sandler and colleagues (1998), in addition, reviewed three cases of de novo voiding dysfunction in patients with myasthenia gravis (one woman with intrinsic sphincter deficiency, poor pelvic muscle contractility, and detrusor hyperreflexia; one male with detrusor hyporeflexia complaining of urgency and incontinence; and one young woman with an acontractile bladder) and added a personal report of a fourth patient with urinary retention from detrusor areflexia. They hypothesize that such autonomic dysfunction in a patient with myasthenia might indicate a unique subset with a worse prognosis.

Isaacs Syndrome

Isaacs syndrome is a rare neurologic disorder characterized by continuous muscle contraction, fasciculations, myokymia, excessive sweating, and elevated creatinine kinase level. It is shown to be secondary to antibodies possibly directed against potassium channels on peripheral nerves and is associated with peripheral neuropathy, autoimmune diseases, malignancies, and endocrine disorders. Tiguert and colleagues (1999) present a case with urinary retention associated with a picture of acute demyelinating neuropathy. Their patient was in painful urinary and fecal retention; the urinary retention was presumed to be caused by spasm of the periurethral striated sphincter, diagnosed by an inability to pass a catheter beyond this. Rectal sphincter spasm was also diagnosed. The condition was treated with plasmapheresis and pharmacologic agents to relax skeletal muscle. Suprapubic drainage was instituted. The condition subsided, and normal urinary function was ultimately restored.

Wernicke Encephalopathy

Wernicke encephalopathy is a rare but well-documented condition caused by a deficiency in thiamine (vitamin B_1) in both alcoholic and nonalcoholic populations. Pathologic lesions are characteristically distributed periventricularly at the levels of the third and fourth ventricles including the mammillary body, medial thalamic nucleus, hypothalamus, superior cerebellar vermis, periaqueductal gray matter, and midbrain tegmentum.

The two major clinical manifestations of thiamine deficiency involve the cardiovascular and neurologic systems. The latter manifests generally as peripheral neuropathy, the condition being known as Wernicke encephalopathy. The initial symptoms of the polyneuropathy range from simply burning feet to muscle weakness. Sakakibara and colleagues (1997b) report a case of a pregnant woman with multiple neurologic manifestations of central and peripheral neuropathy and with urge incontinence, manifested urodynamically by involuntary bladder contractions and a decreased bladder volume. **Resolution of the urinary symptoms occurred after thiamine replacement.** The authors hypothesize that lesions in the medial thalamic-hypothalamic area and periaqueductal gray matter were primarily responsible for the micturitional disturbance. Tjandra and Janknegt (1997) reported a case of a chronic alcoholic male with seemingly isolated erectile and voiding dysfunction, the latter consisting of complaints referable to emptying, correlated with flowmetry during a prolonged void with a peak flow rate of 6.4 mL/sec with an interrupted pattern, suggesting poor detrusor contractility. The erectile dysfunction was determined to be neurogenic. Both resolved with thiamine replacement.

Systemic Sclerosis (Scleroderma)

Scleroderma is a disease of the connective tissue characterized by thickening and fibrosis of the skin, abnormalities of the small arteries, and involvement of the gastrointestinal tract, heart, lung, and kidneys. The pathogenesis is unknown but thought to be caused by overexpression of the collagen gene DNA, contributing to excessive production of collagen in these patients. Lazzeri and colleagues (1995) report the urodynamic assessment and histologic evaluation of nine such women, of whom five had hesitancy; four, decreased stream; two, frequency and nocturia; and two, suprapubic pain. Four patients had detrusor areflexia, one of whom also had decreased compliance. Another patient with decreased stream also had decreased compliance. Three of the patients with areflexia demonstrated collagen accumulation on histologic examination of bladder biopsies. The authors review five literature reports of various aspects of lower urinary tract function and histology in patients with scleroderma but fail to find a consistent pattern in these. They hypothesize that in their patients the areflexia resulted from impaired neurologic modulation owing to the histologic changes in the detrusor tissue.

Minervini and colleagues (1998), conversely, carried out urodynamic and bladder morphologic evaluations in 23 female patients with systemic sclerosis, 9 of whom complained of urinary symptoms, and found urodynamic alterations in only 3 cases. They were unable to correlate voiding symptoms, urodynamic changes, and the degree of bladder wall fibrosis or visceral involvement. Evidence of autonomic nervous system dysfunction was found outside the urinary tract in 13 of these patients. The authors speculate that voiding dysfunction, when it occurs, could be caused by the fibrotic replacement of bladder smooth muscle, but they did not exclude some degree of autonomic dysfunction as well.

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome refers to a heterogeneous group of disorders characterized by inherited abnormalities of connective tissue. The main clinical manifestations are skin fragility, skin hyperextensibility, and joint mobility. More than 10 subtypes of the syndrome have been defined on the basis of clinical, genetic, and biochemical criteria. Bladder diverticula have been associated with this disorder, with operative repair characterized by an increased recurrence rate over that which would ordinarily be expected. Deveaud and colleagues (1999) reviewed the literature on this subject and reported on the intensive study of one such patient with a large left-sided diverticulum that did not empty, along with a greatly enlarged bladder capacity and residual urine. Simultaneously, they reported a second patient without Ehlers-Danlos syndrome who presented with a urinary tract infection and left pyelonephritis. This patient also reported decreased force of stream, and evaluation disclosed left VUR with a left (presumably congenital) periureteral diverticulum. The diverticulum enlarged with voiding, and the patient left a large postvoid residual. Both patients were treated surgically (successfully). The authors thought the tissue from the nonperiureteral diverticulum was more closely related to the pathophysiology of Ehlers-Danlos syndrome, noting the tissue from that diverticulum to be more compliant, and attributed this to changes in the extracellular matrix protein caused by the Ehlers-Danlos syndrome. Nonspecific joint hypermobility may also be associated with voiding dysfunction. Manning and colleagues (2003) prospectively evaluated 1000 women referred for urodynamic evaluation and noted benign joint hypermobility to be associated with increasing bowel dysfunction and a higher degree of urinary tract symptomatology. Also noted was a significant childhood history for both of these phenomena. Generalized joint hypermobility (GJH) has been associated with non-neurogenic bladder dysfunction in children. de Kort and colleagues (2003) reported 89 children with GJH and found that 19% of males, as compared to 4% of control, had constipation. Fecal soiling also occurred more commonly in the GJH group (34% vs. 18%). In girls, day and night urinary incontinence was more prevalent in the joint hypermobility group (38% and 14%, respectively), as compared with controls (13% and 2%). Urinary tract infections also tended to occur more commonly in joint hypermobility with 24% being noted, as compared with 11% in the control group. The generalized hypermobility is a mild form of a genetic, inheritable connective-tissue disease, which is related to Ehlers-Danlos syndrome, Marfan syndrome, and osteogenesis imperfecta. Hypermobility in these children has been reported in multiple organ systems. Additionally, an increased incidence of genitourinary prolapse in women with joint hypermobility has been attributed to connective tissue deficit.

Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant hereditary multiorgan disease characterized by myotonia and distal muscle atrophy, and in later stages by cataracts, endocrine disturbances, mental retardation or dementia, testicular atrophy and infertility, progressive frontal alopecia, and disturbances in cardiac conduction. Although myotonic activity has not been found in the sphincter or pelvic floor, many patients appear to have voiding complaints. Bernstein and colleagues (1992) reported on 10 patients, 8 of whom had urinary complaints by history (4 infrequent voiders, 1 with urge and stress incontinence, 1 with urge and urge incontinence, 1 with slight urgency without incontinence, and 1 with obstructive symptoms only in the morning). There were no characteristic urodynamic patterns observed, and urodynamic findings did not correlate particularly well with symptoms. Sakakibara and colleagues (1995b) also reported lower urinary tract symptoms in such patients, but the message seems to be that there is **no characteristic pattern of dysfunction,** and thus such patients

need to be characterized urodynamically before making any assumptions regarding therapy based on symptoms alone.

Corticobasalar Degeneration

Corticobasalar degeneration is a rare neurodegenerative disorder of the corticobasalar tracts in the cerebral cortex and basal ganglia, most likely in the supranuclear parasympathetic system. The disorder tends to have a unilateral predominance. Cortical, extrapyramidal, long-tract, and urinary symptoms are commonly noted in this disease process. Sakakibara and colleagues (2004b) assessed 10 patients with this disorder compared with 11 age-matched controls. As compared with controls, the degeneration patients had more common urinary symptoms (80% of study group). Urinary symptoms usually appeared within 1 to 3 years after onset of the disease and became more common with longer disease duration. Nocturnal frequency tended to be the initial urinary symptom, followed by incontinence, urgency, and frequency. Urodynamic findings included decreased bladder capacity, detrusor overactivity (most commonly), detrusor hypocontractility, and low compliance in individual patients. Detrusor sphincter dyssynergia was not noted (Sakakibara et al, 2004b).

SACRAL COCCYGEAL TERATOMA

Sacral coccygeal teratoma can produce significant neuro-urologic dysfunction and can be associated with upper tract deterioration due to high-grade reflux and abnormal bladder storage pressures. Öskan and colleagues identified 14 patients with sacral coccygeal teratoma, of whom detrusor overactivity was seen in 8, underactivity in 2. There was also abnormal urethral sphincteric activity in 54% of the patients, and 38% demonstrated sphincter dyssynergia. Eleven of 14 patients required clean intermittent catheter drainage for bladder emptying, and additionally, 5 required anticholinergics. Six patients had hydronephrosis, and seven had reflux (Ozkan et al, 2006).

Radiation

Vale and colleagues (1993) summarized their experience with the occurrence of voiding dysfunction after external-beam irradiation. **They describe an early radiation reaction most prominent at 4 to 6 weeks with an incidence as high as 70%. Symptoms are predominantly of the filling/storage type, and urodynamic studies have demonstrated reduced volume at first desire to void, reduced cystometric capacity, and reduced compliance. These parameters tend to return to pretreatment values by 6 months. Symptoms associated with later radiation effects are less common but may be progressive and intractable. Filling/storage symptoms predominate, and urodynamic studies, when positive, demonstrate reductions in first desire to void, maximum cystometric capacity, involuntary bladder contractions (in up to a third of patients), and an increase in maximum subtracted detrusor pressure during filling.** Historical explanations have concentrated on urothelial injury and ulceration with fibrosis. These authors attempted to develop an experimental model in rats. They found a biphasic reduction in compliance, the first reduction developing at 4 to 6 weeks after irradiation, followed by recovery. A second reduction phase in compliance started at 10 to 12 weeks and persisted. Interestingly, only half the irradiated bladders demonstrated fibrotic infiltration of muscle bundles, and there was no association between the presence of fibrosis and the magnitude of reduction and compliance. Mast cells were more abundant in irradiated bladders than in controls. Electron microscopic studies showed, in the irradiated bladders, the presence of areas displaying focal degeneration of smooth muscle cells, these cells showing disaggregation of filaments and in some cases cytoplasmic organelles free in the intracellular space. In scattered foci, selective degeneration of unmyelinated axon profiles was noted, ranging from marked to lesser degrees of axonal injury. The authors were thus unable to confirm a fibrosis-based hypothesis of postirradiation bladder dysfunction in their experimental model but did show other changes that could contribute to such dysfunction: neural degeneration and changes in the detrusor muscle itself.

Choo and colleagues (2002) reported on video-urodynamic parameters in 15 of 17 patients completing studies at baseline and at 3 and 18 months after external-beam irradiation for prostate cancer. Between baseline and 18 months there were no statistically significant changes in detrusor pressure, peak flow rate, voided volume, postvoid residual, compliance, occurrence of detrusor overactivity, or outlet obstruction. There was a mean reduction in bladder capacity of 100 mL in the supine position and 54 mL in the upright position. There was no change in self-assessed qualitative urologic function (International Prostate Symptom Score, Quality of Life Assessment Index, and urinary frequency). There were, however, individual patients who developed decreased compliance (four patients) and detrusor overactivity (two patients), urgency (five patients), and urgency incontinence (three patients).

Defunctionalized Bladder

The timing of bladder defunctionalization and the age on the individual at time of defunctionalization may be predictive of bladder functionality. In fetal sheep urinary diversion results in loss of overall bladder weight with marked connective tissue infiltration and loss of smooth muscle organization. Also, a reduced response to carbachol stimulation and increased response to field stimulation was noted in tissue from animals undergoing early diversion (Matsumoto et al, 2003).

The previously normal defunctionalized bladder will often show decreased capacity and involuntary bladder contractions and/or decreased compliance. Previously abnormal bladders will generally demonstrate their prior pathology, many times with these additional abnormalities. Rehabilitation of a defunctionalized bladder is certainly possible and should definitely be attempted by cycling with progressively increasing volumes. Serrano and colleagues (1996) considered this subject while evaluating the outcome of transplantation into five long-term defunctionalized bladders. Successful bladder rehabilitation was accomplished, and the transplantation was successful without bladder augmentation, although one patient required CIC. Normal compliance was inferred by the fact that there was no evidence of hydronephrosis after long-term allograft function up to 10 years. The authors recommend that transplantation can be accomplished into a previously defunctionalized bladder when a capacity greater than 100 mL and a voiding pressure less than 100 cm/H_2O are demonstrated during bladder rehabilitation.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is associated with mixed urinary symptoms. Davies and colleagues (2005) studied 19 women with congenital adrenal hyperplasia (16 of whom had

undergone childhood feminizing surgery). These were compared with age-matched controls. The CAH population had a higher incidence of urge incontinence (68%) and stress incontinence (47%) as compared with age-matched controls. The effects of congenital adrenal hyperplasia are uncertain and may be due to either the result of feminizing surgery (possible direct neuropraxia induced by surgery) or a primary affect of CAH (Davies et al, 2005).

Aging

Lower urinary tract symptoms and disorders are prevalent and bothersome in the elderly population. These problems are specifically and extensively considered in Chapter 76. When considering the effects of aging on the lower urinary tract, one cannot separate the effects of chronologic age itself from the various anatomic, neuromorphologic, neurophysiologic, neuropharmacologic, metabolic, and hormonal changes that coexist with aging, along with the effects of other coexisting disease processes. In addition to the material contained in Chapter 76, there is an excellent review of this area that was carried out by the Committee on Pathophysiology of the Urinary Bladder and Obstruction and Aging for the 4th International Consultation on BPH (Nordling et al, 2001).

Additionally, neurologic phenomena may masquerade as lower urinary tract symptoms associated with bladder outlet obstruction. These phenomena may include multiple cerebral infarctions, cervical spondylosis, and lumbar spondylosis. These findings were noted in the Olmsted County longitudinal study and are indicative of the need for urodynamics in older men with complex urinary symptoms (Woderich and Fowler, 2006).

Other Conditions

The effect of disordered function of other organs within the pelvis is also potentially contributory to lower urinary tract dysfunction. Some of this disordered function may arise due to altered afferent neurologic activity induced by other organ disorders. The potential for visceral "cross talk" has been proposed as an etiology for patients with lower urinary tract dysfunction including syndromes such as interstitial cystitis and irritable bowel syndrome. In a rodent, the short- and long-term effects of acid-induced colitis on bladder function have been assessed. Bladder detrusor muscle contractility and histology were evaluated, both acutely and subacutely after induction of chemical colitis. During the active phase (3 days postinjury), bladder muscle structure appeared histologically normal and without inflammation. However, some abnormalities in detrusor muscle contractility in response to electrical field stimulation were noted. During the subacute period and after recovery of colitis (15 and 30 days), bladder muscle contractility returned to control levels with no discernible histologic change. These reversible changes were postulated to result from altered afferent input from the colon, resulting in "field" type changes affecting the bladder (Noronha et al, 2007).

Parturition, Caesarean Section, and Simple Hysterectomy

No clear consensus yet exists as to the independent effects of child birth and hysterectomy on lower urinary tract function. A variety of explanations have been put forth regarding whether or not, in fact, lower urinary tract dysfunction is induced by these events and, if so, what the underlying pathophysiology may be.

In a multicenter Danish trial, patients undergoing hysterectomy (either total or subtotal) for benign uterine diseases were assessed. A total of 319 women were randomized to either total abdominal hysterectomy (158) or subtotal abdominal hysterectomy (161). At 1-year follow-up after intervention, urinary incontinence was less often noted in patients undergoing total abdominal hysterectomy. Both groups, however, did experience an increase in incomplete emptying requiring double voiding. Interestingly, both groups experienced an overall decrease in urinary incontinence frequency as compared with baseline (Gimbel et al, 2005).

No prospective trials, as yet, document the long-term follow-up relationship between urinary dysfunction and method of delivery, and no prospective clinical trials have been done to determine if caesarean section is protective against the development of incontinence. The debate regarding caesarean section as an alternative to spontaneous vaginal delivery and impact of each on the lower urinary tract also continues. The EPINCONT study assessed 15,307 women for the development of voiding dysfunction during longitudinal follow-up. The risk of urinary incontinence of all types was noted to be higher in women who had caesarean sections as compared with nulliparous women and those who had vaginal deliveries. However, the risk of moderate to severe incontinence was actually less in section patients than in patients who had had vaginal deliveries. Urgency incontinence was the only exception, being equal across all groups. The adjusted ratio for any incontinence in women after caesarean section was 1.5 versus 1.7 for women with vaginal deliveries. Stress incontinence appeared to be associated with mode of delivery (Rortveit, 2003a, 2003b).

McKinnie and colleagues (2005) studied 1004 women over an 18-month period to determine the relationship between urinary and fecal incontinence and type of delivery. In this study, pregnancy was identified as increasing the overall risk of urinary and fecal incontinence, and there was no apparent relationship to mode of delivery (McKinnie et al, 2005).

As of yet no agreement exists as to the putative causation of voiding dysfunction related to pregnancy and parturition. It would seem reasonable to believe that mass effect of the gravid uterus combined with peripheral nerve changes (neuropraxia related to stretch) may be contributory.

Any neurologic disease or injury can affect lower urinary tract function. Many have been mentioned in this chapter, but case reports and small series exist that document many others. The dysfunction produced by some is logically deducible on the basis of similarity to other neurologic lesions; for others the lower urinary tract dysfunctions are inconsistent and seemingly at odds with what would be predicted on the basis of neuroanatomic and neurophysiologic principles. For those who want to further pursue this subject, the following referenced list may be helpful:

Adrenoleukodystrophy (Silveri et al, 2004)
Adrenomyeloneuropathy (Sakakibara et al, 1998a)
Brown-Séquard syndrome (Sakakibara et al, 2001)
Central cord syndrome (Newey et al, 2000; Smith et al, 2000)
Incontinence in cystic fibrosis (Dodd and Langman, 2005)
Down syndrome (Handel et al, 2003)
Intramedullary epidermoid cyst (Ferrara et al, 2003)
Lambert-Eaton myasthenic syndrome (Satoh et al, 2001)
Machado-Joseph disease (Sakakibara et al, 2004a)
Pituitary adenomas and urinary symptoms (Yamamoto et al, 2005)
Sjögren syndrome (Kovacs et al, 2003)
Spinal cord tumors (Uchiyama et al, 2004)

TREATMENT OF NEUROGENIC LOWER URINARY TRACT DYSFUNCTION: OVERVIEW

In later chapters, the various therapies available for the treatment of lower urinary tract dysfunction are considered. Only a discrete number of such therapies are available, and these are easily categorized on a functional "menu" basis according to whether they are used primarily to assist urine filling/storage or voiding/emptying and according to whether their primary effect is on the bladder or on the outlet (see Tables 66–3 and 66–4).

The initial choice of a mode of management for a given problem is multifactorial. Although many of us who lecture and write about the management of neurogenic lower urinary tract dysfunction are associated primarily with one approach or another, **all would doubtless agree on certain goals of management for voiding dysfunction** (Table 65–2). The fact that these goals have remained relatively unchanged over the past few editions of this text attest to their general validity. As a corollary, absolute or relative indications for changing or augmenting a particular regimen exist, and, likewise, there is general agreement on these, although the relative importance of the indication for change might be disputed (Table 65–3). It should be remembered that the term *inadequate,* when applied to storage and emptying, applies not only to volumes (capacity, voided volume, residual) but also to unacceptably high detrusor pressures during either or both of the two phases of the micturition cycle. In the planning of goals of therapy and reasons for change, the concept of a "hostility score" such as that of Galloway (1989) is attractive. His hostility score includes five urodynamic characteristics—bladder compliance, overactivity, dyssynergia, outlet resistance, and VUR. Each is allocated a score of 0, 1, or 2. The best possible score is 0 and implies normal compliance, no inappropriate detrusor activity, a synergic sphincter, a low leak pressure, and no reflux.

The results of treatment of voiding dysfunction are rarely perfect, and they do not have to be. The goals are satisfaction and avoidance of adverse outcomes. A flexible approach must be adopted in choosing therapy that takes into account the individual wishes of each patient and family and the practicality of each proposed solution for that particular patient (Table 65–4). The therapeutic decisions are thus made with the patient and with the family. In every case, within the limits of practicality, the following should be discussed: reversibility, side effects that occur with some regularity, ultimate best and worst possible scenario, frequency and extent of follow-up, and alternate methods of management. Treatment should always begin with the simplest most reversible form(s) of therapy, proceeding gradually up the ladder of complexity, but with the knowledge that it is only the patient (and/or family) who is (are) empowered to say when "enough is enough." Again, avoidance of adverse outcomes and satisfaction are the primary goals. A combination of therapeutic maneuvers can sometimes be used to achieve a particular end, especially if these modalities act through different mechanisms and their side effects are not synergistic or additive. There are circumstances and locales in which health care resources and hospital bed use must also be considered.

New therapies continue to be proposed for those patients with neurogenic lower urinary tract dysfunction refractory to medical therapies. The use of dorsal penile or clitoral nerve stimulation for controlled neurogenic detrusor overactivity has been recently described. Hansen and colleagues (2005) studied a group of 16 patients (2 women and 14 men) with neurogenic detrusor overactivity and diminished bladder capacity associated with complete or incomplete SCI. After stimulation of the dorsal nerve, 13 of 16 were noted to have increased bladder capacity and improved storage pressures during stimulation. The average bladder capacity increase was 53% in the study group. Detrusor pressures were also modulated below those associated with ureterovesical reflux (Hansen et al, 2005).

Pudendal nerve stimulation has been used for improving neurogenic voiding dysfunction. Spinelli and colleagues treated 15 patients with neurogenic voiding dysfunction (varied causes). After pudendal stimulation, there was a significant decrease in incontinence episodes, with 8 of 15 patients becoming continent during stimulation, and two with improvement approximating 90%. Twelve of 15 ultimately progressed to permanent implantation. In the chronically implanted patients, maximal cystometric capacity was noted to significantly increase and maximum

Table 65–2.

Voiding Dysfunction: Goals of Management

Upper urinary tract preservation or improvement
Absence or control of infection
Adequate storage at low intravesical pressure
Adequate emptying at low intravesical pressure
Adequate control
No catheter or stoma
Social acceptability and adaptability
Vocational acceptability and adaptability

Table 65–3.

Reasons to Change or Augment a Given Regimen

Upper urinary tract deterioration
Recurrent sepsis or fever of urinary tract origin
Lower urinary tract deterioration
Inadequate storage
Inadequate emptying
Inadequate control
Unacceptable side effects
Skin changes secondary to incontinence or collecting device

Table 65–4.

Patient Factors to Consider in Choosing Therapy

Prognosis of underlying disease, especially if progressive or malignant
General health
Limiting factors: inability to perform certain tasks (e.g., hand dexterity, ability to transfer, body habitus)
Mental status
Motivation
Desire to remain catheter or appliance free
Desire to avoid surgery

detrusor pressure was also noted to decrease substantially. Neurophysiologic guidance was considered critical for adequate implantation (Spinelli et al, 2005).

Another form of neuromodulatory therapy for which more experience is being reported in SCI is anterior root stimulation. One of the largest experiences with sacral deafferentation and anterior root stimulator implantation was reported by Kutzenberger and colleagues (2005). Four-hundred and sixty-four paraplegic patients received this intervention, with most patients receiving the intradural approach. Four-hundred and forty of these patients were available for long-term follow-up with a mean of 6.6 years. Complete deafferentation was successful in 94% of the patients. Four-hundred and twenty patients used the sacral anterior root stimulator for voiding, and 401 used it for defecation. Overall, 364 (83%) of patients were continent. Urinary tract infections decreased from a mean of six to a mean of one, postoperatively, and kidney function remained stable in this population. Complications included cerebral spinal fluid leaks in six and infected implants in five. Additionally, later complications included device failure or cable failure in 35 patients. Interestingly, autonomic dysreflexia also disappeared or was resolved in most of these cases (Kutzenberger et al, 2005).

As a treatment of last resort, urinary diversion may provide significant functional improvement in addition to improved quality of life in selected patients with neurologic dysfunction. For patients with significant lower urinary tract dysfunction who are unable to catheterize, an alternative may also be urinary diversion. Stein and colleagues (2005) reported 24 patients undergoing Mainz pouch diversion. Urinary diversion was associated with stability of the upper tracts and daytime continence but with some nocturnal incontinence per stoma. Comparing this group with a separate group of patients undergoing bladder augmentation with suburethral fascial sling, all patients in the augmentation group had stability of the upper tracts and 8 of 10 were continent. Both alternatives were considered adequate for neurogenic voiding dysfunction (Stein et al, 2005).

Acknowledgment

The authors want to express their utmost appreciation to Rosemarie Larmer and Edna Johnson for their forbearance and expertise in assisting in the production of this chapter.

Pathophysiology and Etiology
Prevalence
Clinical Assessment
Initial Treatment
Urodynamic Evaluation
Management

The overactive bladder (OAB) is a prevalent problem, with considerable effects on the quality of life of affected individuals and substantial health economic costs. The condition is symptom based and defined by the International Continence Society (ICS) standardization committee as **urgency, with or without urgency incontinence, usually with frequency and nocturia, if there is no proven infection or other obvious pathology** (Abrams et al, 2002). A correction had to be put forward when it was realized that the term "urge incontinence" had been used in the original definition (Abrams et al, 2009). OAB is thus a syndrome in which several of the lower urinary tract symptoms (LUTS) relating to the storage of urine coexist, with urinary urgency as the essential parameter. Because urgency will frequently arise at comparatively small bladder volumes, patients tend to describe frequent voids with a low typical voided volume. Nocturia as a symptom is somewhat variable in OAB because the supine position and reduced physical exertion overnight seem to be less provocative in eliciting OAB. A difficulty with the ICS definition is that some patients may void preemptively (defensive voiding), passing urine before urgency arises; they will thus clearly have storage-phase LUTS yet lack the urgency symptom, which is the defining characteristic of OAB.

Urgency with at least one other symptom is essential to diagnose OAB. Thus urgency is the pivotal symptom, defined by the ICS as **the complaint of a sudden compelling desire to void that is difficult to defer**. However, there remains plenty of room for confusion. For example, a normal "urge to void" is not synonymous with abnormal urgency; the ICS therefore suggested that the term "desire to void" is more appropriate for describing normal filling sensation. Furthermore, there are grounds to consider including "for fear of leakage" alongside the sudden compelling desire to void that is difficult to defer—indeed this was included in earlier ICS definitions. Many OAB patients certainly feel as if they are going to leak, even if they say they never have, commonly expressing anxieties exemplified by, "When I want to go, I have to rush because I think I may wet myself."

In many OAB patients, urgency incontinence occurs, defined as involuntary leakage of urine, accompanied or immediately preceded by urgency (Abrams et al, 2002). This standardized definition abandoned the requirement that the leakage should be a "social or hygienic problem" to be called incontinence because considerable leakage can occur, which in some individuals may not be a problem to them, particularly in children and the elderly. In a prevalence survey, 69% of women had "any incontinence," but only 30% found this a "social or hygienic problem" (Swithinbank et al, 1999).

The symptom of "increased daytime frequency" is the complaint by the patient who considers that he or she voids too often by day. There is no minimum number of voids included in the standardized definition. **The symptom of nocturia is the complaint that the individual has to wake at night one or more times to void**. No agreement has been reached for individuals with differing sleep patterns such as night-shift workers.

Before the introduction of the standardized definitions, the use of several overlapping terms resulted in a confusing situation, hampering many aspects of research and management. The English-speaking world had adopted Patrick Bates' term *unstable bladder* to describe involuntary detrusor contractions seen during urodynamic studies as the bladder was filled, while the Scandinavians used the term *detrusor hyperreflexia*. To resolve the discrepancy, the ICS designated the term *unstable bladder* to be applied where there was no obvious cause for the contractions and *detrusor hyperreflexia* for patients whose involuntary contractions had a neurologic cause (Bates et al, 1980); ***overactive detrusor*** was used as the generic, overarching term. Nonetheless, the use of different terms in neurologic and non-neurologic patient groups became increasingly difficult. Firstly, several studies showed considerable overlap in the underlying mechanisms. In addition, explaining the terms to the patients and the wider medical profession highlighted the incongruity of the differing terminology. Furthermore, physicians had to be careful not to insult the sensibilities of the patient by inadvertently implying mental instability by using the word "unstable" in relation to bladder symptoms. "Overactive Bladder" was used as the title of a consensus conference, and a formal definition was proposed in 1999 (Abrams and Wein, 1999), culminating in the ICS definition used currently.

Crucially, the current definition of OAB is based on symptoms; in contrast, **detrusor overactivity (DO) is a urodynamic observation, characterized by involuntary detrusor contractions during the filling phase, which may be spontaneous or provoked** (Abrams et al, 2002). **OAB and DO are thus not interchangeable terms,** and the clinician must be specific in their use. Clinicians need to be clear on this among themselves and when discussing urgency with patients. All measures, for example "warning time" (between first sensation of urgency and eventual voiding), depend on the patients and the clinicians reaching a consensus as to the meaning of urgency. The

ICS terminology committee excluded "for fear of leakage" in the new definition of urgency, mainly because many OAB patients do not leak. Perhaps this was not entirely logical because patients can certainly feel as if they are going to leak, even if they have never actually done so. A couple of phrases are often used by patients:

- "When I've got to go, I've got to go."
- "When I want to go, I have to rush because I think I may wet myself."

Hence "fear of leakage" is an important concept to patients.

Key Points: OAB Terminology

- The International Continence Society updated its definitions for OAB and other lower urinary tract dysfunctions in 2002.
- OAB is a symptomatic diagnosis and is distinct from detrusor overactivity (DO), which is a urodynamic diagnosis.
- Other causes of similar symptoms must be excluded before diagnosing OAB.
- OAB is defined by the presence of urinary urgency with at least one other relevant symptom.
- "Fear of leakage" is not part of the ICS definition of urgency, but it is a concept that OAB patients feel is important.

PATHOPHYSIOLOGY AND ETIOLOGY

The reliance on urgency in defining OAB is a problem for investigation into its scientific basis because it complicates the development of reliable animal models, with which evaluation of subjective symptoms is not possible. Accordingly, research focus has particularly concentrated on abnormalities of afferent signaling and mechanisms underlying DO, the former as the presumed basis of urgency, the latter as it is likely to contribute in a large number of people with OAB. In addition, some hypothetical reasoning has been used to translate scientific observations into clinical reality.

Hypotheses of Detrusor Overactivity

Until recently, insight into the pathophysiologic basis of DO has generally focused on cellular mechanisms by which unregulated motor activity could arise. **The neurogenic hypothesis states that DO arises from generalized, nerve-mediated excitation of the detrusor muscle** (de Groat, 1997). There are several interdependent mechanisms by which this may arise. First, damage to the brain can induce DO by reducing suprapontine inhibition. Second, damage to axonal pathways in the spinal cord allows the expression of primitive spinal bladder reflexes. Third, synaptic plasticity leads to reorganization of sacral activity, with the emergence of new reflexes, which may be triggered by C-fiber bladder afferent neurons. Finally, sensitization of peripheral afferent terminals in the bladder can trigger DO.

The myogenic hypothesis suggests that overactive detrusor contractions result from a combination of an increased likelihood of spontaneous excitation within smooth muscle of the bladder and enhanced propagation of this activity to affect an excessive proportion of the bladder wall (Brading and Turner, 1994; Brading, 1997). Patchy denervation is a common observation in DO, regardless of etiology (German et al, 1995; Charlton et al, 1999; Drake et al, 2000; Mills et al, 2000). A smooth muscle cell deprived of its innervation shows an upregulation of surface membrane receptors and may have altered membrane potential, which increases the likelihood of spontaneous contraction in that cell. DO is also associated with characteristic changes in ultrastructure (Elbadawi et al, 1993; Haferkamp et al, 2003a, 2003b), which could facilitate the propagation of the contraction over a wider proportion of the body of the detrusor than normal. However, the observations in different models of DO and from clinical specimens do not uniformly describe these features.

Afferent Mechanisms in Overactive Bladder and Detrusor Overactivity

The afferent nerve endings are widely distributed in the bladder wall and are particularly dense in the connective tissue underneath the urothelium. In this location, they may be influenced by several cell types. **Urothelial cells possess sensory and signaling properties that allow them to respond to their chemical and physical environments and to communicate with subjacent structures** (Birder, 2001). **Suburothelial interstitial cells lie in close physical proximity to nerve fibers, suggesting a role in sensory transduction or regulation** (Wiseman et al, 2003). The number of impulses fired by an afferent ending at any level of distention can be varied physiologically; that is, the gain of the sensory nerve endings can be changed to vary the "afferent sensitivity." Thus the rate of firing in a particular afferent normally associated with a high vesical volume can occur at lower volumes if the afferent ending has been sensitized. Accordingly, the release of substances from the urothelium, as well as the direct interaction between afferent nerve endings and other cell types, may physiologically influence central reporting of the bladder state and could well contribute pathophysiologically. In theory, **OAB may arise if the level of sensory activity is inappropriately high for any given degree of bladder distention, resulting from pathologically sensitized or abnormally numerous afferent nerve endings.** The interaction among afferents, urothelium, and interstitial cells is thus interesting, in that modulating their interactions may result in amelioration of symptom severity. The expression of various receptors on urothelium and afferents, particularly members of the transient receptor potential (TRP) family, may thus be relevant in the development of future clinical management options. The sensory information is carried to the spinal cord by myelinated Aδ fibers and unmyelinated C fibers. As a general rule, **the Aδ fibers are regarded as responding to passive bladder distention and active detrusor contraction ("in series" mechanoreceptors** [Iggo, 1955]), **thus conveying information about bladder filling** (Janig and Morrison, 1986). **C fibers are regarded as responding primarily to chemical irritation of the bladder mucosa** (Habler et al, 1990) **or to thermal stimulus** (Fall et al, 1990). Accordingly, they may be less active in the physiologic state than the Aδ fibers. Nonetheless, there is almost certainly considerable overlap in the sensory information carried by the two types of afferent, and the C fibers may take on a more prominent role in the pathologic state.

Integrative Physiology of Overactive Bladder

The afferent, neurogenic, and myogenic mechanisms alluded to earlier are essentially based on physiology of individual cell types.

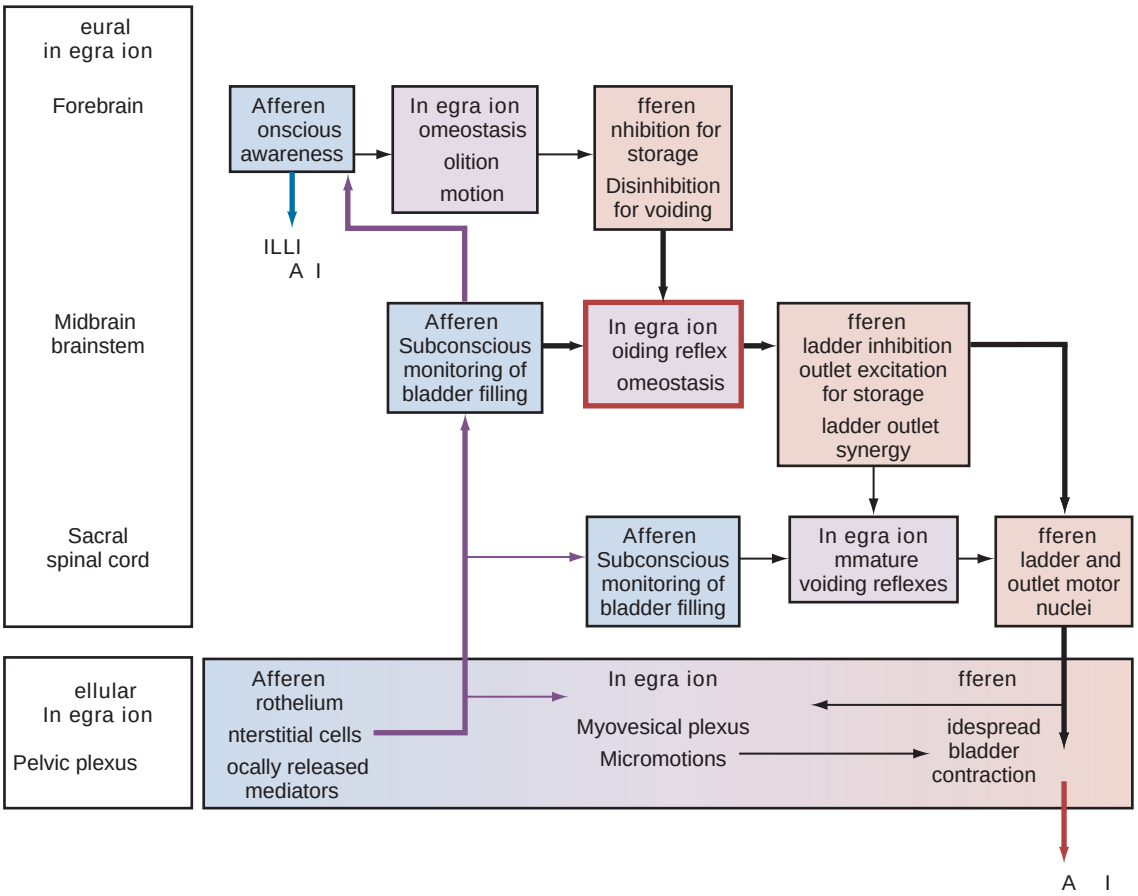

Figure 66–1. The integrative hypothesis of overactive bladder and detrusor overactivity. Neural circuits in the central nervous system and cellular interactions in the periphery integrate afferent input and modulatory influences, in a hierarchy of regulatory structures underpinning normal bladder function. Storage function is characterized by sensations of filling and desire to void at suitable volumes, whereas voiding function is characterized by volitional control and complete emptying. Lesions at various levels have seemingly similar effects because their effects are mediated by final common pathways of sensation and bladder contraction.

However, the complexity of lower urinary tract function is substantially increased by the potential interactions between differing cell types and their humoral/paracrine environments. The integrative properties determining the interaction between cell types is manifest in the neural circuits of the central nervous system, as well as the periphery (Fig. 66–1)—the latter working through networks (neural, interstitial cells) and by direct cell communication in the urothelium or muscle cell–to–muscle cell. The presence of interstitial cells in the bladder led to the proposal of a regulatory "myovesical plexus" comprising nerves (excitatory and inhibitory, peripheral and central) and interstitial cells loosely, akin to gut myenteric plexuses. The integrative hypothesis of OAB draws on the various contributory factors to understand the normal micturition cycle, OAB, and DO (Drake et al, 2001). Several observations can be understood by focusing on activity within the bladder wall itself:

1. Generation of normal and increased filling sensations in the absence of pressure change; the sensations of normal desire and strong desire to void arise in the absence of change in detrusor pressure. This could arise as a consequence of localized contractions (Drake et al, 2001), which are active in only a small part of the bladder wall, so they do not measurably affect intravesical pressure but result in small distortions that are detected by the afferent nerves. Such activity, termed "micromotions," is seen in various animal models and humans (Van Os-Bossagh et al, 2001; Drake et al, 2003a, 2003b; Gillespie et al, 2003; Drake et al, 2005). Exaggerated micromotions would then increase filling sensations pathologically, again without affecting pressure (i.e., OAB without DO). Local mediator release in inflammatory situations such as cystitis could cause temporary urgency sensations by increasing localized contractions.
2. Generation of DO; the myogenic hypothesis describes the abnormal propagation of localized excitation through direct muscle-to-muscle communication, which causes a substantial proportion of the bladder to contract synchronously as the basis of DO. In the integrative hypothesis, the possible routes of abnormal propagation extend to interstitial cell networks, innervation, and urothelium. The relative degree of local distortion and wider propagation will determine whether the individual patient manifests OAB, DO, or both together.
3. Completeness of bladder emptying; complete bladder emptying relies on sustaining detrusor contraction for a sufficient duration, and this could result from the myovesical plexus driving detrusor contraction during voiding (Drake, 2007). The hypothetical existence of feedback from bladder afferents into the myovesical plexus could ensure contraction is sustained for sufficient duration, and a lesion impairing this feedback would result in a postvoid residual (PVR).

The **crucial factors in the integrative hypothesis are the level of excitation and degree of propagation in the myovesical plexus structures of the bladder wall.** Both will be at low levels during normal bladder filling. Local excitability is high in OAB, whereas propagation alone is high in asymptomatic DO; both are increased where DO is symptomatic. Propagation is high in normal voiding (driven by efferent commands from the central nervous system [CNS]). Increased local excitation with impaired propagation could explain why patients have OAB and a PVR (detrusor hyperactivity with impaired contractility (Resnick and Yalla, 1987).

Central Nervous System

The development of functional brain imaging technology allows estimation of gross activity in specific brain areas and has been used to study bladder filling in normal and symptomatic individuals. Intriguing insights into contributions from various parts of the cerebral cortex such as the insula and the prefrontal cortex have resulted. Alterations in the regional brain activity of symptomatic individuals with OAB have been reported (Griffiths et al, 2007). Understanding brain responses to lower urinary tract activity through autonomic afferent processing networks, as is already under investigation for the gastrointestinal tract, will be crucial in the endeavor to develop improved clinical management options.

Etiology

Neurologic disease is associated with a high prevalence of LUT dysfunction, and this is to be anticipated given the fundamental regulatory influence of innervations on bladder and bladder outlet. Aging is associated with increased LUTS; this may be through the attritional effects on inhibitory innervation and brain function. Bladder outlet obstruction has long been considered an etiologic factor in generation of DO and OAB, but there is now some doubt as to whether this is correct.

Key Points: OAB Pathophysiology

- Normal lower urinary tract function derives from a complex interplay of cellular physiology and hierarchical neural control.
- DO may result from increased cellular excitability with abnormal propagation, arising within the detrusor muscle (myogenic), other cell types in the bladder (integrative), or the CNS (neurogenic).
- Altered afferent nerve function peripherally, or altered CNS processing, may underpin changes in urinary sensation.

PREVALENCE

Using the standardized ICS definition of OAB, the EPIC study reported the prevalence of OAB in four European countries and in Canada, reporting an **overall OAB prevalence of 11.8%, in the context of a prevalence of 64.3% for at least one LUTS** (Irwin et al, 2006). The EPIC study also catalogued multidimensional impact including effects on employment (Coyne et al, 2008; Irwin et al, 2009).

Older studies have to be interpreted according to the definitions they used for LUTS. One prevalence study (Milsom et al, 2001) reported prevalence of OAB symptoms that "occurred singly or in combination," estimating overall OAB prevalence at 16%. In the studied population, 9.2% had urgency, and this is perhaps closer to the true prevalence of OAB in the community.

The NOBLE study (Stewart et al, 2003) established the prevalence of OAB in more than 5000 community-dwelling individuals in the United States using a validated computer-assisted telephone interview. Men and women had the same prevalence of OAB overall (16.0% and 16.9%, respectively) as defined by the ICS. However, **men were shown to have a higher prevalence of "OAB dry"** (13.4% as opposed to 7.6% in women) and **women had a higher prevalence of "OAB wet"** (9.3% as opposed to 2.6% in men). **It is assumed that the difference in the prevalence of incontinence is due to the relative weakness of the bladder neck and urethral sphincter mechanism in women,** particularly in those who have had children. **In women the prevalence of "OAB wet" rose from 2.0% in the youngest group (ages 18 to 24) to 19.1% in those 65 to 74 years of age. Men, on the other hand, did not experience an increase in "OAB wet" until older: 8.22% for those 65 to 74 and 10.2% for those 75 years and older**.

In addition to simple prevalence, effect on quality of life needs to be evaluated. Both types of OAB have a significant impact on the patients' quality of life, as measured by generic quality of life instruments. It is not difficult to understand that being "OAB wet" has a profound impact. However, in some studies, the symptom of urgency was shown to have a greater effect on quality of life than incontinence (Coyne et al, 2004, 2008). EpiLUTS was an Internet-based survey of 30,000 people in the United States, United Kingdom, and Sweden documenting symptoms, symptom bother, and health-related quality of life. It derived a substantial amount of information about the impact of LUTS, individually and categorized as storage, voiding, and postmicturition including consequent anxiety and depression. It concluded that storage symptoms were significantly associated with greater impact (Sexton et al, 2009). Many studies in women have shown that urgency incontinence is more bothersome than stress incontinence. In some women, stress incontinence may occur several times a day and urgency incontinence only once or twice a week, but it is for the latter that the patient may demand treatment. This is probably because stress incontinence occurs more predictably and can usually be better contained by pads. OAB is a long-term condition, and ongoing quality of life impairment can be anticipated in many patients (Garnett et al, 2009).

Key Points: OAB Prevalence

- Overall prevalence of OAB in the EPIC study, using ICS standardized definitions, was 11.8%.
- Storage LUTS have a greater impact on health-related quality of life than other LUTS.
- Both genders have similar rates of OAB, but "OAB wet" is more prevalent in women and "OAB dry" is more prevalent in men.

CLINICAL ASSESSMENT

Patients with OAB may present to health care workers in various disciplines in either the community or the hospital service. It is vital that the doctor or nurse caring for such individuals is both

knowledgeable and sympathetic, taking into account the patient's psychosocial circumstances. OAB always requires management, and "cure" is not a realistic aspiration; appropriate expectations and honest explanation are therefore crucial. An appropriate initial assessment gives a presumptive diagnosis and thus the basis for empirical treatment. It should also establish the patient's desire for treatment and which therapies are open to consideration; for example, treatments likely to impair voiding contractility should not be employed if intermittent catheterization is unfeasible or indwelling catheterization will not be tolerated.

History should cover the following:

1. Presence or absence, incidence, severity, bother and effect on quality of life for each of the OAB symptoms including urgency incontinence. Other LUTS should also be assessed.
2. Presence or absence of dysuria and hematuria.
3. Nature and volume of fluid intake.
4. Whether occult neurologic disease could be present.
5. Obstetric and gynecologic history, previous surgery/radiotherapy, bowel symptoms, and drug history.
6. Other medical issues (e.g., closed-angle glaucoma and cognitive impairment can limit treatment options).

Focused physical examination requires abdominal and pelvic examination, as well as basic neurologic examination. Assessment of bladder emptying is necessary (most simply by palpating the lower abdomen, if the patient is slim). Urinalysis is important in all patients. The algorithms from the fourth International Consultation on Incontinence 2008 (Abrams et al, 2009) summarize the basic assessment necessary in the evaluation of lower urinary tract dysfunction in men, women, and the frail elderly (Fig. 66–2).

Instruments for Measuring Bladder Sensations and Storage Symptoms

Normal LUT sensations during cystometry are (1) first sensation of filling, (2) normal desire to void, and (3) strong desire to void (Wyndaele and De Wachter, 2002). Whether an individual with OAB also experiences normal sensations is not yet established but seems likely. Commonly, OAB patients have increased daytime frequency, but only a proportion of voids are associated with urgency. Tools for evaluating urgency thus have to deal with the subjective nature of the symptom, the habit of preemptive voiding at low bladder volumes, and the consequent increased frequency with low levels of urgency. A validation process is necessary to ensure tools employed are suitable for clinical or research use (Avery et al, 2004; Abrams et al, 2006).

The **urinary sensation scale** (Abrams et al, 2005) is as follows:

1. No urgency: "I felt no need to empty my bladder but did so for other reasons."
2. Mild urgency: "I could postpone voiding as long as needed without fear of wetting myself."
3. Moderate urgency: "I could postpone voiding for a short time without fear of wetting myself."
4. Severe urgency: "I could not postpone voiding but had to rush to the toilet in order not to wet myself."
5. Urgency incontinence: "I leaked before arriving at the toilet."

The **urgency percentage scale** (Cardozo et al, 2002) has three possible responses:

1. I am usually not able to hold urine.
2. I am usually able to hold urine until I reach the toilet if I go immediately.
3. I am usually able to finish what I am doing before going to the toilet.

The Indevus **"Urgency Severity Scale"** (Bowden et al, 2003), used in trials of trospium, has four responses:

0. None, no urgency
1. Mild, awareness of urgency but easily tolerated
2. Moderate, enough urgency/discomfort that it interferes with usual activities/tasks
3. Severe, extreme urgency/discomfort that abruptly stops all activities/tasks

A related strategy used an **"urgeometer"** (Oliver et al, 2003) in cystometry, asking patients sequentially to press a series of five buttons during bladder filling according to their degree of urgency:

0. None
1. Mild
2. Moderate
3. Strong
4. Desperate

However, the lower three of these scales do not explain to the patients how urgency is defined; thus **they are inappropriately named because they actually measure intensity of bladder sensation in differing parts of the sensation spectrum. Other measures such as "warning time"** (between first sensation of urgency and eventual voiding) also depend on the patients and clinicians reaching a consensus as to the meaning of *urgency* (Cardozo and Dixon, 2005).

Storage symptoms questionnaires are now available in a modular format, developed to address recommendations made by the International Consultation on Incontinence (Abrams et al, 2006), known as the *ICIQ*. The ICIQ has adopted several validated tools and developed new ones where necessary. The King's Health Questionnaire (Kelleher et al, 1997) and the OAB-q (Coyne et al, 2002) have been adopted as ICIQ modules.

Urgency assessment is a component of more generic LUTS assessment tools and may be of more practical use in clinical practice. For example, the "Patient Perception of Bladder Condition" is straightforward to administer and captures the clinical significance that patients attribute to their OAB (Coyne et al, 2008).

The frequency volume chart (FVC) (Abrams and Klevmark, 1996) remains the principal method of evaluating frequency and nocturia in an objective way. **In OAB, the pattern of voided volumes is characteristically erratic. On the FVC, frequency is defined as the number of voids recorded during waking hours including the last void before sleep and the first void after waking and rising in the morning** (Abrams et al, 2002). **Nocturia is the number of voids recorded during a night's sleep: each void is preceded and followed by sleep. The FVC is valuable in highlighting nocturnal urine output because nocturia due to nocturnal polyuria must be considered with other LUTS** as likely to mitigate against successful OAB management. The bladder diary additionally collects information on fluid intake and incontinence episodes.

Two symptom scales are undergoing evaluation in nonselected populations. The **bladder sensation scale,** for use with an FVC, is shown in Table 66–1. The **cystometry sensation scale,** for use during urodynamic study, is shown in Table 66–2. The approach of using complementary modalities of assessment in conjunction allows a more comprehensive baseline evaluation and is informative for evaluation of treatment response.

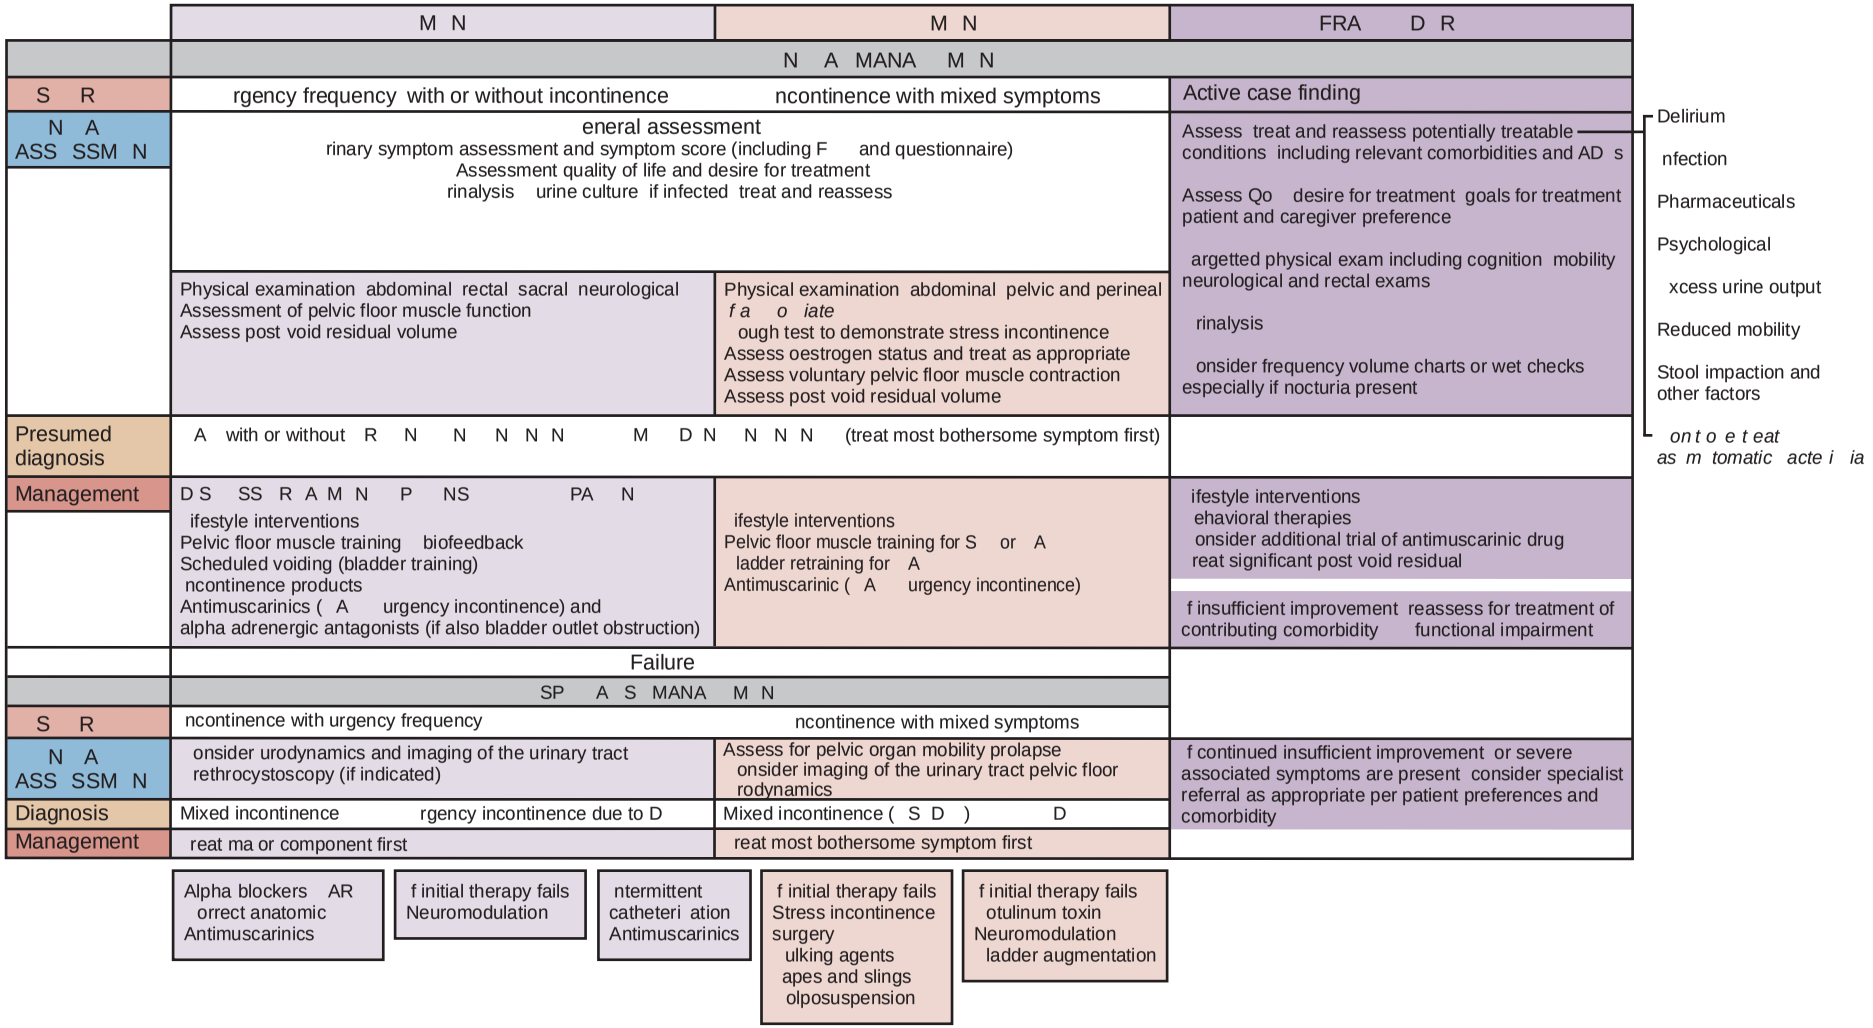

Figure 66–2. Overactive bladder in men, women, and the frail elderly; assessment and management, derived from the respective algorithms of the fourth International Consultation on Incontinence. (From Abrams P, Cardozo L, Khoury S, Wein A, editors. Incontinence. 4th ed. Plymouth [MA]: Health Publications; 2009.)

Table 66–1.

Bladder Sensation Scale

1. No sensation of needing to pass urine but passed urine for "social reasons" (e.g., just before going out, unsure where next toilet is); no urgency.
2. Normal desire to pass urine; no urgency.
3. Urgency but urgency passed away before had to visit bathroom; went later with normal desire to pass urine.
4. Urgency but managed to get to bathroom, still with urgency, yet did not leak urine.
5. Urgency and could not get to bathroom in time, so leaked urine.

Table 66–2.

Cystometry Sensation Scale

0. No bladder sensation: "I don't feel anything."
1. First sensation of filling: "I'm beginning to feel my bladder."
2. First desire to pass urine: "I feel like I want to pass urine."
3. Urgency is graded.
   Mild: "I think I can hold on."
   Moderate: "I don't know if I can hold on."
   Serious: "I have to go now or I will leak any moment."
4. Strong desire to pass urine: "I'm getting uncomfortable, I'd like to pass urine now."

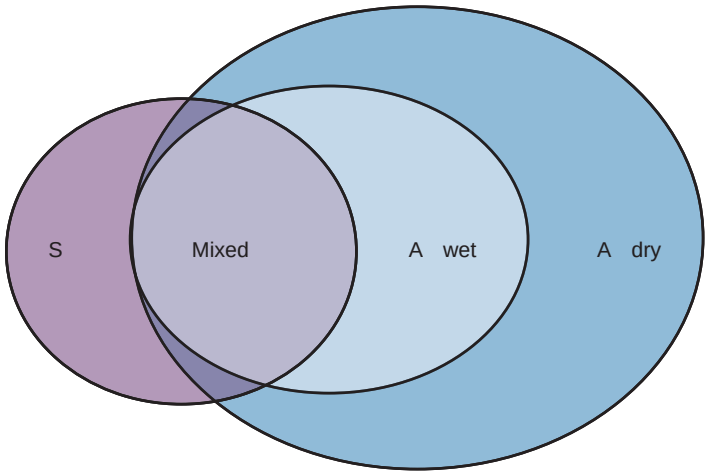

Figure 66–3. Incontinence in women may be stress urinary incontinence (SUI), mixed urinary incontinence (MUI), or urgency urinary incontinence ("OAB wet"). SUI can coexist with OAB dry, giving rise to mixed symptoms of stress incontinence and urgency.

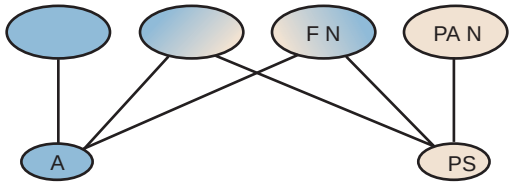

Figure 66–4. Overactive bladder (OAB) and bladder pain syndrome (BPS) both give rise to urgency (U), frequency (F), and nocturia (N); pain, but not urgency urinary incontinence (UUI), is seen in BPS.

Mixed Urinary Incontinence and Mixed Incontinence

OAB can coexist with stress urinary incontinence (SUI). Mixed urinary incontinence (MUI) is the **complaint of involuntary leakage associated with urgency and with exertion, effort, sneezing, or coughing** (Abrams et al, 2002). Figure 66–3 describes the relationships among SUI, MUI, and OAB in women. The group illustrated with SUI and "OAB dry" could be described as having "mixed symptoms" because they have key features of SUI and urgency symptoms, but their OAB is not associated with urgency incontinence, so they do not have MUI. In general, MUI is associated with more severe levels of leakage, although it is currently unclear which component, urgency or stress, is responsible: possibly either or both types will prove culpable. Mixed incontinence refers to the coexistence of urinary and fecal incontinence. Clarity of communication is necessary to ensure all parties are aware of the specific situation for each individual under consideration.

Distinguishing Overactive Bladder from Bladder Pain Syndrome

Urgency in the old ICS terminology included a comment as to the reason underpinning the need to pass urine related to "fear of leakage or pain." Pain aspects now fall into bladder pain syndrome (BPS), which constitutes a symptom complex clearly distinguished from OAB (Abrams et al, 2005; Hanno et al, 2008). BPS is defined **as the complaint of suprapubic pain related to bladder filling, accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other obvious pathology**. Figure 66–4 illustrates the relationship between OAB and BPS, and Figure 66–5 indicates the difference in bladder sensation/pain.

Differences that help to distinguish BPS include the painful nature of symptoms, the steady increase in pain with filling, the more consistent voided volumes compared with OAB, and the ability to defer voiding (albeit at the cost of greater pain). In BPS, suprapubic pain is usual and additional perineal (urethral/vaginal/penile) discomfort/pain can also occur (Fitzgerald et al, 2005); in OAB, urgency is typically felt in the perineum/base of penis or vagina/urethra.

Key Points: OAB Clinical Assessment

- A comprehensive clinical history and physical examination are essential in the assessment of OAB.
- Symptom assessment questionnaires provide valuable information for baseline assessment and follow-up of treatment response.
- The FVC/bladder diary is essential for assessing OAB and excluding additional problems such as polydipsia or nocturnal polyuria.
- Dipstick urinalysis is necessary to exclude hematuria or urinary tract infection.
- A significant postvoid residual volume must be considered when evaluating OAB.

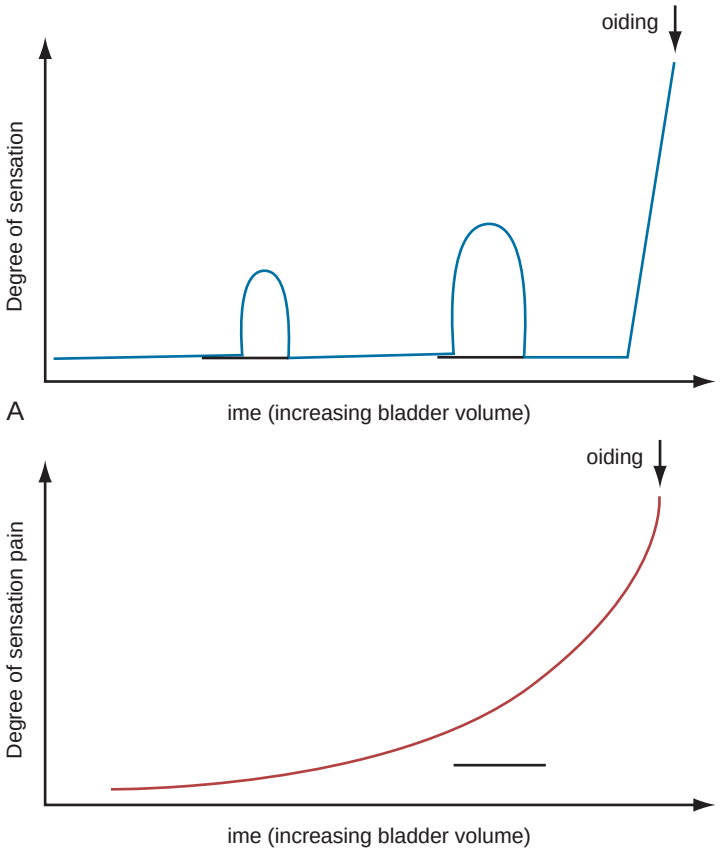

Figure 66–5. The differences in the development of bladder sensation in overactive bladder (OAB) and bladder pain syndrome (BPS). **A,** In OAB, phasic increases in urgency arise and recede as filling progresses, until severe urgency compels the patient to void or an urgency urinary incontinence (UUI) episode sets in. **B,** In BPS, pain increases throughout filling, accelerating as filling progresses.

INITIAL TREATMENT

Basic evaluation allows diagnosis of OAB and baseline severity assessment, at which point initial treatment can be instigated:

1. Lifestyle interventions; attention to the nature and volume of fluid intake, dietary irritants, and cessation of smoking foster a sense of engagement in their care for the patient.
2. Bladder training and pelvic floor muscle training help patients to reestablish inhibitory control over bladder storage and allow them to resist and abort urgency episodes.
3. Drug treatments should be employed once conservative approaches have been attempted. Antimuscarinic drugs are described in more detail in Chapter 68. Prescribers should warn the patient as to potential side effects including dry mouth, constipation, cognitive effects, visual impairment, and others. A range of agents and doses is available, and patients should be advised that the idiosyncratic nature of responses means that it may take some adjustment to find an optimum regimen.

In addition to the patient's perceptions regarding response, repeat measures using symptom assessment tools and the frequency volume chart are valuable in providing objective markers because subjective perceptions and recollections of LUTS are notoriously unreliable. Should these initial therapies fail both subjectively and objectively, and invasive treatment be contemplated by the patient and clinician, then urodynamic evaluation is usually desirable.

URODYNAMIC EVALUATION

It is common practice to employ conservative management and oral pharmacotherapy without a urodynamic diagnosis. Where the initial treatment is deemed inadequate and specialist referral is made, it is incumbent on the specialist clinician to ensure that conservative measures have been followed fully. Before urodynamic tests are requested, the reasons for "failure" of drug therapy should be explored:

1. Insufficient duration of prescription or poor patient compliance
2. Insufficient dose; individual patients absorb and metabolize drugs differently, so dose titration may be necessary to achieve a therapeutic level. Presence of dry mouth symptoms is a useful rule of thumb for deciding whether dose is adequate
3. Idiosyncrasy of response; some people appear to find better efficacy with certain agents
4. Adverse effects; some patients do have therapeutic improvement in symptoms but tolerate adverse effects poorly

For each circumstance, altered drug dose or agent may achieve sufficient improvement to obviate the need to consider more invasive investigation and treatment. Only when considerable efforts have been made should conservative therapy and antimuscarinic medications be considered unsuccessful.

Urodynamic evaluation should be considered where conservative and drug therapy fails adequately to manage OAB in a patient who is sufficiently healthy and is considering more invasive therapeutic interventions due to the impact of the symptoms on his or her quality of life. Whether to discontinue antimuscarinic drugs before the test can be argued either way; stopping the drugs gives the best chance of observing DO if present, while continuing them allows evaluation of the mechanism underlying residual refractory symptoms.

The primary aim of urodynamic studies is to reproduce the patient's symptoms and identify additional factors likely to influence management decisions. **The two main urodynamic diagnoses associated with OAB are DO and increased filling sensation.** Figure 66–6 shows the relationship between the symptom-based diagnosis of OAB and the urodynamic-based diagnosis of DO. It is worth emphasizing that DO may not be present in some patients with OAB, especially women (Hashim and Abrams, 2006), and that some patients with DO are asymptomatic (i.e., do not have OAB). OAB without DO could be a consequence of bladder wall micromotions, causing distortion that leads to sensations, but without affecting a sufficient proportion of the bladder wall to cause pressure change (Drake et al, 2005). **In some patients considered to have OAB on the basis of their symptoms, the ultimate diagnosis turns out to be urodynamic stress incontinence (USI),** perhaps because contact of urine with urethral receptors can trigger a reinforcement reflex. **Additional diagnoses relevant to management include bladder outlet obstruction and inefficient bladder emptying** because treatment measures aiming to improve bladder reservoir function may cause collateral problems with voiding, perhaps necessitating intermittent self-catheterization.

Ideally, the patient should be seated or standing for filling cystometry because OAB symptoms are usually experienced when

upright. However, where there is severe DO at low volumes, it may be difficult to ascertain if urinary stress incontinence (USI) is also present. In these patients, a second filling cycle in the supine position generally makes DO less overt (Al-Hayek et al, 2008), allowing more fluid to be instilled for determining whether USI is an additional diagnosis.

The urodynamic report must clearly state whether the patients' symptoms were reproduced completely, reproduced in part, or not reproduced to ensure that due caution is exercised in major treatment decisions where there is diagnostic uncertainty.

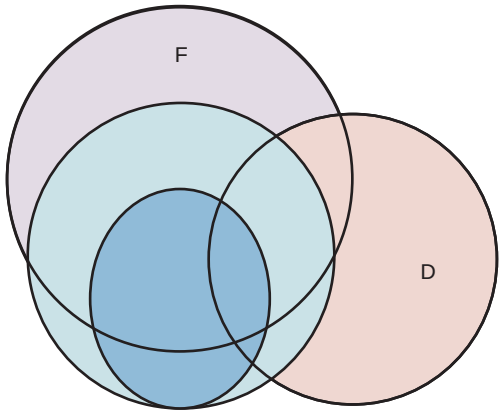

Figure 66–6. Correlation between the symptom-based diagnosis of overactive bladder (F, frequency; U, urgency; UUI, urgency urinary incontinence) and the urodynamic diagnosis of detrusor overactivity (DO). The correlation is best for urgency incontinence and least good for frequency (day and/or night).

Subclassification of Detrusor Overactivity and Technical Aspects of Urodynamics

The presence of a relevant neurologic condition distinguishes neurogenic DO from idiopathic DO, when there is no defined cause. Some clinicians feel that DO can arise as a consequence of BOO, but prevalence of DO is 60% in men who have had transurethral resection of the prostate previously (Thomas et al, 2005), despite the fact that they remain unobstructed. Accordingly, relief of BOO does not lead to permanent disappearance of DO. Although symptomatic improvement is seen in many of these men, it is probably less reliable than in men without DO.

DO has a variety of patterns on urodynamic traces. The ICS report describes two types:

1. **Phasic DO** has a characteristic waveform and may or may not lead to incontinence. It tends to be characterized by contractions of increasing amplitude as the bladder volume increases (Fig. 66–7) and is the characteristic pattern seen in most idiopathic DO.
2. **Terminal DO** is a single involuntary detrusor contraction occurring at cystometric capacity, which causes incontinence, often resulting in complete bladder emptying. It is most characteristically seen in the elderly person with "precipitant voiding" such as elderly patients who have suffered a cerebrovascular accident. Such patients appear to lose awareness of impending micturition and the ability to inhibit what turns out to be a voiding contraction.

Nonphasic changes in detrusor pressure before micturition should be regarded as changes in bladder compliance rather than as DO. Technical artifacts are easily introduced by moving a patient during urodynamics. Sometimes this change in pressure

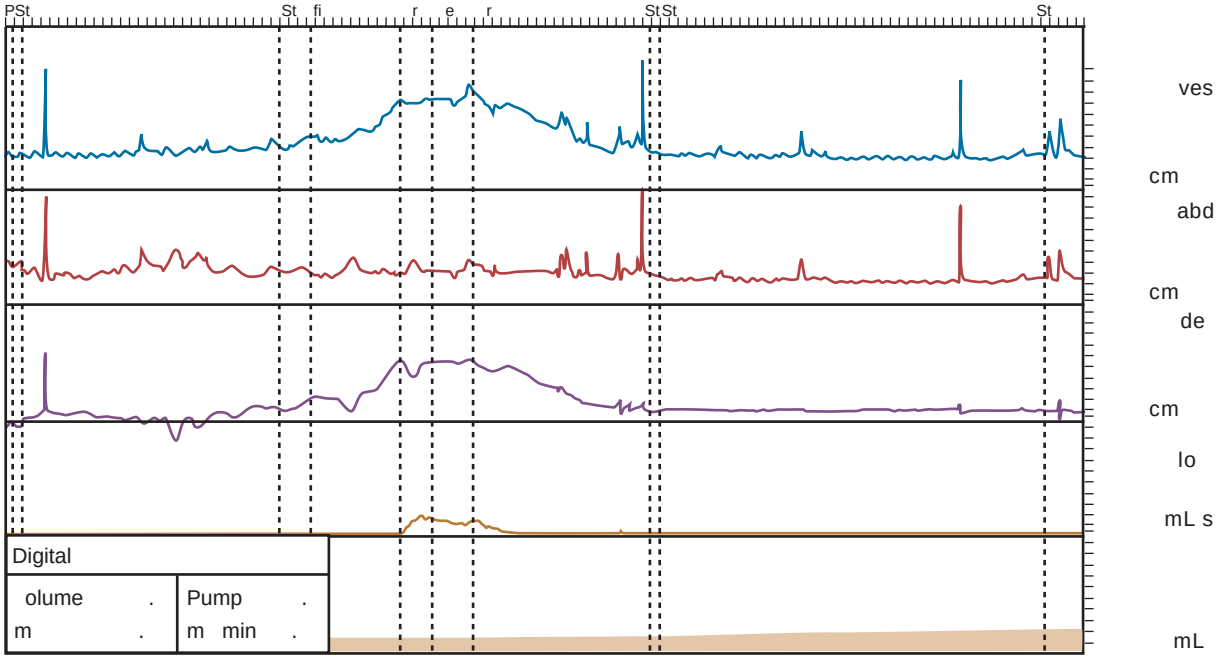

Figure 66–7. Detrusor overactivity trace. Bladder pressure is plotted in blue, rectal pressure in red, detrusor pressure in purple, flow in orange, and filling in light brown. This is a filling cystometry, so the presence of flow signifies incontinence. Incontinence in this individual is seen as a consequence of a phasic rise in detrusor pressure, at a comparatively low bladder volume.

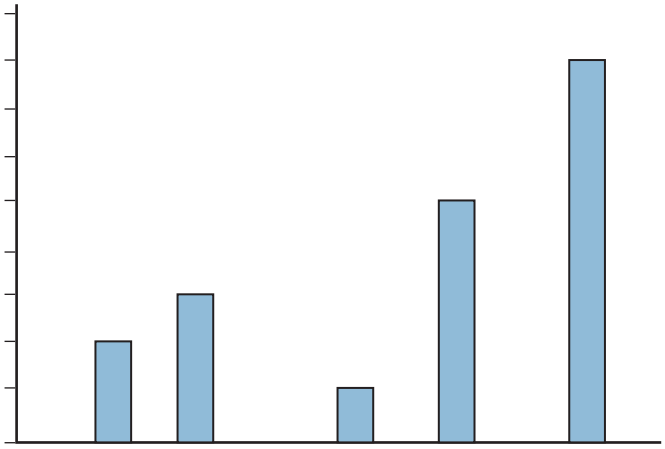

Figure 66–8. Detrusor overactivity (DO) index: a simple means of quantifying DO. It is calculated by summing the amplitude of the phasic DO contractions and dividing by the bladder volume. In this example, the DO index is (20 + 30 + 10 + 50 + 80)/300 = 0.63 cm H_2O/mL.

occurs if the patient is moved to the standing or sitting position, having had the bladder filled while supine.

If DO is not seen during filling, the investigator should attempt to use any provocations that the patient says lead to OAB symptoms such as the sound of running water. In some individuals, DO can be elicited by asking the patient to cough, but this must not be confused with stress urinary incontinence. Filling rate needs to be considered carefully; a short period of rapid filling can provoke the emergence of DO. However, fast filling can mask DO and cause low compliance, particularly in neurogenic DO.

There is no minimum value of amplitude below which a phasic detrusor contraction during filling does not constitute DO (Abrams et al, 2002). Earlier ICS reports (Bates et al, 1980) stated that, in order to diagnose "detrusor instability," the contraction should be at least 15 cm H_2O. However, it was later recognized that involuntary detrusor contractions of lower amplitude can cause significant symptoms, so the 1988 ICS report (Abrams et al, 1988) was altered accordingly. Measurement of the amplitude has been used as a way of describing the severity of DO (Abrams, 1984) (Fig. 66–8).

Ambulatory Urodynamics

The advent of ambulatory urodynamics has complicated the discussion because DO may be apparent in up to 60% of asymptomatic women (Heslington and Hilton, 1996). Does DO in these circumstances have any clinical relevance? It is not clear from the papers whether DO during ambulatory urodynamics in normal individuals is symptomatic or asymptomatic. If it were symptomatic, but this was a symptom the individual did not experience in everyday life, then the conclusion would be that the DO was artifactual, perhaps due to the presence of the pressure-measuring catheter "irritating" the bladder wall. Thus the requirements of good urodynamic practice to document the reproduction of a patient's symptoms are particularly pertinent in this context.

MANAGEMENT

The fourth International Consultation of Incontinence has produced a comprehensive review of the spectrum of incontinence management, using the International Consultation on Urological Diseases' adaptation of the AHCPR/ Oxford System of levels of evidence and grades of recommendation to evaluate the evidence from the scientific literature. The initial and specialized management algorithms for women show the care pathways for OAB and DO (Abrams et al, 2009) (see Fig. 66–2). Management of OAB is covered in detail elsewhere in this book. In brief, therapy for OAB can be divided into four classes of treatment:

1. Conservative management including weight loss, cessation of smoking, and dietary factors (decreased use of caffeine, decreased fluid intake, decreased alcohol intake, changes in food and drink). Lifestyle interventions include pelvic floor muscle training, to resist and occasionally to terminate overactivity when it arises, and bladder retraining, to encourage inhibitory influences on the lower urinary tract.
2. Pharmacotherapy; the antimuscarinics are the mainstay of treatment and can be given orally, transdermally, or intravesically. Other drug classes are in development, with β_3-adrenergic agonists currently in phase 3 trials. Vanilloid agonists, exemplified by capsaicin and resiniferatoxin, have been used in neurogenic DO; although not currently in use, analogous treatments may become available in the future.
3. Surgical therapy; sacral nerve stimulation, tibial nerve stimulation, intravesical botulinum injections, augmentation cystoplasty, and detrusor myectomy.

For intractable OAB, options are appliances, catheters (urethral or suprapubic), urethral closure, and urinary diversion.

Key Points: OAB Treatment

- Lifestyle interventions are the starting point in managing OAB including advice on fluid intake and bladder training.
- Antimuscarinic drugs may be used where symptoms remain bothersome, but due consideration of collateral effects is essential.
- Urodynamic studies are indicated in a patient with refractory symptoms who is willing to consider proceeding to more invasive treatment.
- The main urodynamic diagnoses in OAB are DO and increased filling sensation. Symptoms are not always reproduced in a urodynamic test.
- Management of refractory OAB is a challenging problem requiring specialist expertise.

Nocturia

Marcus Drake, DM, MA, FRCS (Urol)

Definitions and Terminology
Prevalence and Impact of Nocturia
Physiology and Pathophysiology
Clinical Assessment
Management

Nocturia is a common problem that presents to the urologist. It represents a considerable diagnostic and therapeutic challenge because failure to appreciate the extent of potential contributory factors predictably leads to poor treatment outcomes. Extensive knowledge of internal medicine and ready availability of multidisciplinary support are invaluable for achieving patient satisfaction. The clinician needs to apply a systematic approach in diagnosing underlying mechanisms so that treatments can be selected appropriately, avoiding untailored prescribing.

DEFINITIONS AND TERMINOLOGY

The term "nocturia" relates to passage of urine overnight. In common with other lower urinary tract symptoms (LUTS), the Standardisation Committee of the International Continence Society (ICS) has proposed definitions (Abrams et al, 2002) for general use to allow comparisons between studies, with a specific initiative for nocturia (Van Kerrebroeck, 2002; Van Kerrebroeck et al, 2002). Key terms are listed in Table 67–1. At its most basic, the symptom of **nocturia is the complaint that the individual has to wake at night one or more times to void.** There is no inclusion of degree of symptom bother in this definition, and many individuals will not regard nocturia on only one occasion per night as being of clinical significance. On the other hand, some people can be substantially bothered by nocturia once per night. Several reported studies disregarded nocturia if it was only a single episode per night; the outcomes have to be interpreted accordingly.

Defining "night-time" is contentious. In this context it does not specifically relate to the hours of dark, but rather to the hours of sleep. On this basis, shift workers who are active during the hours generally regarded as overnight can still manifest nocturia during their repose periods in daylight hours. For this specific group it is essential to ensure that frequency volume chart (FVC) documentation is explicit and unambiguous as to sleeping hours. Changing time zones (jet lag) also complicates interpretation, and it is best to allow recovery from jet lag before asking a patient to complete an FVC.

Nocturia frequency includes only those voids preceded and followed by sleep. Thus the first morning void after a night's sleep is counted toward daytime (diurnal) frequency rather than nocturia. An estimate of nocturnal functional bladder capacity is given by summing the volumes of all the nocturia episodes (nocturnal voided volume) and dividing the total by the nocturnal frequency. **The nocturnal urine production is given by adding the first morning void to the nocturnal voided volume. It is the nocturnal urine production that determines the diagnosis of nocturnal polyuria (NP). The ICS Standardisation Committee defined NP as nocturnal urine production exceeding 20% of 24-hour output in younger adults and 33% in older adults** (Abrams et al, 2002). In measuring nocturnal urine production, allowance has to be made for any significant delay between waking and the first morning void, particularly if there has been consumption of fluid in that time. Some studies have used alternative approaches (e.g., defining NP as a nocturnal diuresis of greater than or equal to 0.9 mL per minute overnight [Asplund et al, 1998], regarding "night" as time spent in bed). Alternatively, it has been defined as nocturnal urine volume exceeding 10 mL per kilogram, here referring to night as patient-reported sleeping time (Homma et al, 2000).

The **functional reservoir capacity of the lower urinary tract and the renal output volume it receives overnight can be linked using a nocturia index** (Ni) derived from a frequency volume chart (FVC) (Weiss et al, 1999). Ni in excess of 1.0 signifies that **nocturnal urine production exceeds the largest voided volume, such that it will be inevitable that the person has to get up at night to pass urine.**

Defining the reason people wake is intrinsically subjective and somewhat unreliable, particularly if the patient affected may not be certain in his or her own mind. The clinician should attempt to ascertain whether nocturia is the fundamental cause of sleep disturbance. Where sleep is disturbed for other reasons, voiding is a secondary issue, perhaps a habitual response or an action to assist subsequent return to sleep; sometimes this will not be clear from the history.

Nocturnal enuresis signifies voiding while remaining asleep, constituting part of the nocturnal voided volume. Nocturnal enuresis does not count as nocturia because the patient fails to wake when passing urine, but it clearly must be factored into any evaluation of LUTS and nocturnal urine production. Primary nocturnal enuresis in adults is a particularly difficult management challenge because the individual involved may have failed to establish cortical neuronal systems inter-relating toileting and arousal; once adulthood is reached, such links are unlikely to be acquired.

Key Points: Voided Volume and Frequency

- Nocturia is the number of voids recorded during a night's sleep: each void is preceded and followed by sleep.
- Nocturnal polyuria means overnight urine production exceeds 20% to 33% of total 24-hour volume and is age dependent.
- Polyuria in a 70-kg adult is diagnosed by a 24-hour voided volume in excess of 2.8 L (>40 mL/kg).
- If nocturnal urine production exceeds the largest voided volume (nocturia index >1), it will be inevitable that the person has to get up at night to pass urine.

Table 67–1.

Key Terms and Definitions

TERM	DEFINITION
Nocturia	The number of voids recorded during a night's sleep: each void is preceded and followed by sleep
Nocturnal urine volume	Total volume of urine passed during the night including the first morning void
Nocturnal polyuria	Nocturnal volume >20%-33% of total 24-hr volume (age dependent)
Polyuria	24-hour voided volume of >2.8 L in a 70-kg adult (>40 mL/kg)
Night	The period of time between going to bed with the intention of sleeping and waking with the intention of arising
Nighttime frequency	The number of voids recorded from the time the individual goes to bed with the intention of sleeping, to the time the individual wakes with the intention of rising
First morning void	The first void after waking with the intention of rising
Maximum voided volume	The largest single voided volume in a 24-hr period
Nocturnal enuresis	Voiding occurring during sleep

From Van Kerrebroeck P. Standardization of terminology in nocturia: commentary on the ICS report. BJU Int 2002;90(Suppl. 3):16–7.

PREVALENCE AND IMPACT OF NOCTURIA

Prevalence

Overall prevalence of nocturia for 5500 people in the Boston Area Community Health (BACH) study was 28.4%, affecting 25.2% of men and 31.3% of women (Fitzgerald et al, 2007). Prevalence of nocturia was 48.6% of men and 54.5% in the EPIC study in Europe and Canada, evaluating 19,000 adults with or without overactive bladder (OAB) (Irwin et al, 2006). In a subgroup analysis for men in the EPIC study, nocturia was the most prevalent LUTS (Irwin et al, 2009). In a European survey of nearly 3000 men aged 55 to 75 years in several primary care practices, nocturnal voiding frequency was zero in 20%, one in 45.8%, two in 20.8%, three in 7.1%, four 2.4%, and five or more in 2.6% (Gourova et al, 2006). In the hospital setting, prevalence of nocturia was 87% in a population of 700 women of mean age 59, with greater bother associated with higher number of nocturia episodes and with mixed incontinence (Lowenstein et al, 2007). Differences according to ethnicity are apparent, with an overall prevalence of 38.5% in blacks, 30.7% in Hispanics, and 23.2% in whites (Fitzgerald et al, 2007).

There is a clear impact of aging on prevalence of nocturia. Between the ages of 30 and 39 years old, nocturia prevalence is 19.9% and in those aged between 60 and 79 it is 41.2% (Fitzgerald et al, 2007). In people younger than the age of 40, nocturia is slightly more prevalent in women than men; above the age of 60, prevalence in the two genders is similar (Irwin et al, 2006). In general, younger people are more likely to manifest decreased nocturnal bladder capacity, whereas nocturnal urine overproduction increasingly accounts for nocturia as people age (Weiss et al, 2007). Presence of NP cannot be reliably predicted from daytime LUTS (Swithinbank et al, 2004).

Approaches to diagnosing NP (absolute, relative or functional) were compared in an epidemiologic study (Rembratt et al, 2002). In older patients showing at least two voids per night, 70% fulfilled all three diagnostic approaches. For those people with up to one void per night, 67% fulfilled at least one definition, but only 5% fulfilled all three definitions. Overall, the prevalence of NP in older nocturia patients was 45% to 100% when there were greater than or equal to two voids per night, 8% to 37% of people with up to one void per night, and 4% to 25% of people who did not void overnight.

Quality of Life and Wider Health Impact of Nocturia

The overall duration of sleep can be divided into specific stages according to various parameters including electro-encephalogram, muscle tone, respiration, heart rate, and eye movement. A **slow-wave sleep pattern, regarded as the restorative component of sleep, predominately occurs in the first part of the night. Thus early sleep disturbance may result in a more substantial impact on health and ability to carry out activities of daily living.** A series of potential causes of sleep disturbance was surveyed by the National Sleep Foundation "Sleep in America Poll" (Foley et al, 2004). These comprised nocturia, physical pain, caregiving, health concerns, cough, nighttime heartburn, headache, money problems, family problems, and uncomfortable bed. Nocturia was found to be the leading cause of sleep disturbance in older adults (aged 55 to 84) (Bliwise et al, 2009).

A high proportion of people with nocturia describe themselves as having impaired quality of life as a consequence. Nocturia is one of the main predictors of symptoms (Coyne et al, 2009a, 2009b) and drug treatment (Asplund et al, 2005) of anxiety and depression in people with LUTS. Increased nocturia severity was shown to increase absence from work for health reasons (Asplund et al, 2005). Nocturia impairs work productivity and activity in a nonlinear fashion (Kobelt et al, 2003). **Where nocturia of at least two voids per night is reported, impact on quality of life is more problematic at a population level** (Fiske et al, 2004; Yu et al, 2006), **becoming a major impact at three voids per night or more** (Tikkinen et al, 2010), **though this is subject to considerable individual variation.** Self-reported health status was impaired in people documented as having at least two voids per night in a Dutch population (van Dijk et al, 2002). Consequently, a greater proportion will seek medical input at this level of severity (Chen et al, 2007). In elderly residential care, falls are common at night and are frequently

reported to occur in relation to toilet visits. **The odds ratio of a fall is 1.84 where there are at least two voids per night, rising to 2.15 for more than three voids per night.** Observation of increasing prevalence of hip fracture as a consequence of nocturia has been documented (Asplund, 2006).

Key Points: Prevalence and Impact

- Overall prevalence of nocturia in the BACH study was 28.4%, affecting 25.2% of men and 31.3% of women.
- Aging affects the prevalence of nocturia; between the ages of 30 and 39 years prevalence is 19.9%, rising to 41.2% between 60 and 79.
- Younger people are more likely to manifest decreased nocturnal bladder capacity, whereas nocturnal urine overproduction increases with age.
- Slow-wave sleep is the restorative component of sleep, occurring mainly in the first part of the night.
- Overall, presence of nocturia of two or more episodes per night has a greater impact on quality of life, but there is considerable individual variation.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Influences determining urine output and storage are diverse, and the large range of potential mechanisms underlying nocturia is outlined in Table 67–2.

Table 67–2.

Nocturia Pathophysiology

Nocturnal Polyuria

1. Behavioral (e.g., excessive evening/nighttime fluid intake, polydipsia, drug-induced diuresis)
2. Global polyuria (e.g., poorly controlled diabetes mellitus, diabetes insipidus, DIDMOAD syndrome, panhypopituitarism)
3. Release of fluid and electrolyte sequestration (e.g., congestive heart failure, peripheral edema, venous stasis)
4. Obstructive sleep apnea
5. Renal tubular dysfunction (e.g., diuretic phase of acute tubular necrosis, nephrotic syndrome)
6. Hepatic failure
7. Hypoalbuminemia

Diminished Nocturnal Bladder Capacity and/or Global Bladder Capacity

1. Storage failure
   a) detrusor overactivity; *idiopathic or nocturnal detrusor overactivity, neurogenic bladder dysfunction*
   b) increased filling sensation; *overactive bladder*
2. Voiding failure leading to postvoid residual; *bladder outflow obstruction, reduced detrusor contractility, dysfunctional voiding, neurogenic bladder dysfunction*
3. Inflammatory or painful conditions of the urinary tract *(e.g., urinary tract or genital infection, bladder pain syndrome, bladder or ureteric calculi, malignancy)*

Sleep Impairment

1. Environmental
2. Anxiety disorders
3. Stimulants
4. Circadian disruption *(e.g., melatonin deficiency of aging)*

Regulation of Body Water Balance; Diuresis and Natriuresis

Tight regulation of total body water and electrolyte loads; relative distribution across the intracellular, extracellular, and intravascular compartments; and specific concentrations within each compartment are crucial homeostatic functions, regulated by hormonal and physical properties (Verbalis, 2006). Balance is achieved by interplay of diverse physiologic influences, in which renal regulation of glomerular filtration and tubular reabsorption play a foremost role, reflected in the composition and rate of production of urine. As a consequence, **the lower urinary tract, and hence LUTS, are subordinate to the greater physiologic needs of the organism as a whole.** Focusing on nocturia, without consideration of the pathophysiologic context, may prove counterproductive.

Aquaporins (Agre et al, 1998) **are a family of regulated channels with a key role in fluid and electrolyte balance.** For a recent review of renal aquaporins, read the work of Kwon and colleagues (2009). Various aquaporins are present in the kidney, with a major role attributed to aquaporin-2. **Key to rapid adjustment of fluid balance is the process of "trafficking," the short-term variation of aquaporin-2 channel density and function.** Changes in aquaporin-2 and aquaporin-3 can arise over periods of days, influenced by numerous factors. Some aquaporins have been identified in the urothelium of the bladder (Rubenwolf et al, 2008), where their roles have yet to be ascertained (reviewed in Khandelwal et al, 2009).

Arginine vasopressin is a key endocrine determinant of water retention, hence its alternative name of antidiuretic hormone (ADH). It modifies the structure of aquaporin-2 and causes increased insertion of aquaporin water channels at key locations in the nephron, consequently enhancing permeability for reabsorption of water. Human volunteers given ADH show an increase of body weight and a corresponding dilutional decrease in their serum sodium concentration, if not fluid restricted (Leaf et al, 1958). By extrapolation, retained water in the syndrome of inappropriate ADH secretion (SIADH) leads to increased body weight, hyponatremia, and blood pressure problems (Verbalis, 2006). Where there is chronic exposure to elevated levels of ADH, the phenomenon of "escape from antidiuresis" can occur as a result of desensitization of the renal tubules (Leaf et al, 1958), with downregulation of the aquaporin-2 channel (Verbalis, 2006). Accordingly, the **chronic nature of impaired fluid and electrolyte balance can lead to a refractory clinical situation unless the overall balance is corrected, and time allowed for recovery. Recognition that other hormones can also influence aquaporin-2 is more recent, including secretin** (Chu et al, 2009) **or oxytocin** (reviewed in (Cheng et al, 2009). These may yield alternative pharmaceutic strategies in the future (Bouley et al, 2008).

Natriuresis is the process of excretion of sodium in the urine and is a consideration in the clinical context (Matthiesen et al, 1996) that is often underestimated. The renin-angiotensin-aldosterone system makes major adjustments to the rates of renal sodium secretion, though at a comparatively slow rate. **Brain and atrial natriuretic peptides (BNP and ANP, respectively) cause net sodium excretion, whereas sodium is conserved by aldosterone. Natriuresis lowers the blood sodium concentration and lowers blood volume, as osmotic forces make water follow sodium into the urine.** Sympathetic innervation can make rapid adjustments to salt

balance. This may explain why global polyuria is common following renal transplantation, with a high prevalence of nocturnal polyuria (Mitsui et al, 2009). There are also intrarenal mechanisms including ATP influence on epithelial sodium channels (Wildman et al, 2009). Excess natriuresis can be caused by medullary cystic disease, Bartter syndrome, Gitelman syndrome, the diuretic phase of acute tubular necrosis, primary renal diseases affecting the renal tubules, and congenital adrenal hyperplasia.

Cardiac Impairment

Impaired cardiac function can result in accumulation of fluid in dependent parts of the body ("third-spacing"), which can then return to the circulating volume when the patient is recumbent. Older patients can demonstrate an increased body weight during the daytime, which is greater in patients with nocturia (mean daytime weight change 0.93 kg compared with 0.60 kg in asymptomatic patients) (Kaye, 2008). This led to a significant difference in overall urine volume passed overnight, along with significant differences in the sodium, potassium, and chloride output.

Ordinarily, blood pressure should reduce overnight ("dipping"). In hypertensive patients, dipping of the blood pressure overnight becomes less apparent, signifying an increased prevalence of cardiac disease and being associated with an increased risk of nocturia (Fitzgerald et al, 2007). Men with benign prostate enlargement (BPE) are significantly more likely to lose the overnight dip in blood pressure, particularly men with nocturia (Turgut et al, 2008). **Underlying pathophysiology of nocturia can be related to increased mean arterial blood pressure and blunted circadian variation in ADH** (Graugaard-Jensen et al, 2006).

Global Polyuria and Increased Fluid Intake

Urine output in excess of 40 mL per kilogram per 24 hours (equating to 2.8 L per 24 hours in a 70-kg adult) defines polyuria and is likely to lead to increased voiding frequency both day and night. The patient's fluid intake, either in the form of fluid drunk or free fluid in ingested food, will influence urine output. In many cases, patients deliberately increase their fluid intake volitionally. **Evaluation of sustained polyuria has to include consideration of whether there is excessive fluid intake (polydipsia); it is also important to consider whether the polydipsia is a cause of the polyuria or whether it is secondary to thirst induced by other pathologic causes of polyuria.** The best known medical examples of secondary polydipsia are poorly controlled diabetes mellitus and diabetes insipidus (DI), where thirst results from excessive fluid loss. Fluid loss in diabetes mellitus results from increased solute load (glucose) in the glomerular filtrate; **if polyuria is present in a seemingly well-controlled diabetic, breakthrough hyperglycemia and other causes of polyuria (e.g., impaired renal tubular function) should be considered**. DI can be a consequence of impaired ADH secretion (neurogenic/central DI) or impaired renal responsiveness to ADH (nephrogenic DI). DI can occur in conjunction with other problems such as panhypopituitarism, and it is part of DIDMOAD syndrome (DI, diabetes mellitus, optic atrophy, and deafness) (Barrett et al, 1995).

Nocturnal Polyuria

Ordinarily there is a circadian reduction in urine production overnight, which is largely regulated by endocrine or neural mechanisms but which is yet to be fully explained. This **circadian pattern relates to increased secretion of ADH during the hours of sleep** (Graugaard-Jensen et al, 2006), thus lower volumes of more concentrated urine (Asplund and Aberg, 1991). Loss of circadian reduction in overnight urine production is important clinically (Matthiesen et al, 1996). Plasma ADH levels may be pathologically undetectable during the night in elderly subjects with nocturia (Asplund and Aberg, 1991). Central nervous system lesions due to CVA can affect the hypothalamic-pituitary axis, causing a loss of ADH circadian rhythmicity (Ozawa et al, 1998). However, there remains a strong possibility of further underlying mechanisms yet to be elucidated.

Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) results from intermittent occlusion of the airway during sleep, leading to profound hypoxia, which is relieved by a gasping respiratory pattern. **The fluctuating hypoxia pattern impairs sleep patterns directly. In addition, the gasping intakes of breath substantially raise intrathoracic pressures. The increased right atrial transmural pressure resulting from hypoxia-induced pulmonary vasoconstriction leads to an elevation in ANP, which precipitates increased urine output** (Yalkut et al, 1996). Risk factors for OSA include morbid obesity, acromegaly, asthma, hypertension, adult onset diabetes mellitus, and craniofacial abnormalities. New-onset snoring in an older patient should prompt evaluating clinicians to consider overnight oximetry monitoring or polysomnographic sleep studies.

Increasing severity of OSA has been corresponded with nocturia (Fitzgerald et al, 2006), with reduction in nocturia episodes achieved by OSA treatment using continuous positive airway pressure. Elderly patients with severe sleep disordered breathing have a greater number of nocturia episodes (Endeshaw et al, 2004). The link between nocturia and OSA is sufficiently close that it has even been suggested that nocturia is as sensitive as snoring as a predictive symptom of OSA (Romero et al, 2010). OSA should be considered in any nocturia patient, even where OAB is clearly apparent in the daytime (Lowenstein et al, 2008).

Impaired Renal Function

Impaired renal tubular function leads to failure of reabsorption of glomerular filtrate and thus overall urine output rises. In a long-term cohort study to evaluate risk factors for end-stage renal disease, risk factors were identified as male gender, family history of renal disease, older age, proteinuria, diabetes mellitus, African-American race, higher blood pressure, higher body mass index, and higher creatinine level (Hsu, 2009). Proteinuria and excess weight were identified as the two greatest risk factors. In addition, self-reported history of nocturia was identified as a possible novel risk factor (Hsu, 2009). **Nocturia is an independent predictor of albuminuria, and this may underpin the value of the symptom as a predictor of chronic kidney disease,** as found by the PolNef Study (Krol et al, 2009). Numerous influences and conditions alter renal expression of aquaporins. For example, hypokalemia and hypercalcemia can lead to nephrogenic DI.

When polyuria is seen on the FVC, a water-deprivation test may be used to distinguish between DI and polydipsia. If the water deprivation test is abnormal, a renal concentrating capacity test can distinguish between central and nephrogenic DI by measuring urine osmolality a few hours after a dose of desmopressin under conditions of water restriction. If renal concentrating capacity is normal, any DI will be neurogenic/endocrine, for which desmopressin therapy is usually effective. Reduced concentrating capacity (urine osmolalities <550 mOsm/kg) signifies nephrogenic DI.

Multiple Medical Disorders

The treating clinician should not lose sight of the fact that nocturia represents a multifactorial problem (Tikkinen et al, 2009), extending substantially beyond the urinary tract. Particularly in elderly patients, the pathophysiology is complex (Wagg et al, 2005). A multivariate logistic regression analysis showed that nocturia in elderly men is significantly related to bladder/prostate cancer, cerebrovascular disease, treatment of voiding disorders, cardiovascular disease, hypertension, and moderate alcohol consumption (Gourova et al, 2006). Nocturia is an important nonmotor symptom in Parkinson disease; severity of neurological impairment is the main predictor, and nocturia ranks alongside urinary frequency as the greatest LUTS-derived adverse influence on quality of life. **Nocturia in Parkinson disease generally responds inadequately to dopamine-targeted treatment** (Kim et al, 2009; Sammour et al, 2009) **or antimuscarinics** (Sammour et al, 2009). In stroke patients, the most frequent bothersome LUTS is nocturia, with a prevalence of 53% (Tibaek et al, 2008).

Obesity is associated with nocturia (Shiri et al, 2008). Metabolic syndrome, defined as the presence of at least three of waist circumference greater than 102 cm; systolic blood pressure (BP) 130 mm Hg or greater or diastolic BP 85 or greater; high-density lipoprotein (HDL) cholesterol less than 40 mg/dL or lipid medication use; type 2 diabetes mellitus or increased blood sugar or diabetes medication use; or triglycerides greater than 150 mg/dL (Kupelian et al, 2006), is associated with an increased overall risk of nocturia (odds ratio 1.69) (Kupelian et al, 2009).

Medications

Drugs that can increase urine output include diuretics, selective serotonin reuptake inhibitors (SSRIs), calcium channel blockers, and tetracyclines. Lithium can cause nephrogenic DI in 40% of users (Grunfeld and Rossier, 2009).

Certain medications can be associated with insomnia, thereby causing additional sleep disturbance problems that may be correctable. Such agents include **central nervous system stimulants (e.g., dextroamphetamine and methylphenidate); antihypertensives (including alpha-adrenergic antagonists, beta blockers, methyldopa); respiratory medications (albuterol, theophylline); decongestants (phenylephrine, pseudoephedrine); hormones (corticosteroids, thyroid medications); psychotropics (atypical antidepressants, monoamine oxidase inhibitors, SSRIs); carbidopa; and phenytoin. In addition, chronic use of hypnotics and sedatives** to induce sleep can lead to tolerance and dependence. As a consequence, rebound insomnia and anxiety can arise when the medication is stopped (hypnotic-dependent insomnia).

Pregnancy

Pregnancy increases LUTS including nocturia, which is presumed to be a consequence of increased glomerular filtration rate and subsequent urine output. Symptoms tend to begin early in pregnancy, increasing with each trimester, with a high prevalence of nocturia by term (Aslan et al, 2003; FitzGerald and Graziano, 2007).

Impaired Lower Urinary Tract Reservoir Function

Urologic causes of low nocturnal and global bladder capacity include OAB, infravesical obstruction, idiopathic detrusor overactivity, neurogenic bladder, bladder inflammation (e.g., cystitis), and bladder pain syndrome (BPS). Bladder or ureteric calculi and neoplasms of the bladder, prostate, or urethra should also be considered.

Nocturia is an element in the definition of OAB (urgency, with or without urgency urinary incontinence, usually with frequency and nocturia in the absence of other causes of similar symptoms). The symptom of nocturia alone does not constitute a basis for diagnosing OAB. Indeed, lying recumbent reduces detrusor overactivity in many patients (Al-Hayek et al, 2008). Nonetheless, **the most prevalent combination of OAB symptoms is urgency with nocturia** (Irwin et al, 2008).

Nocturia is commonly reported in bladder pain syndrome. The original National Institute of Diabetes and Digestive and Kidney Diseases criteria of exclusion for diagnosing interstitial cystitis state that it should not be diagnosed if nocturia is absent (Hanno, 1994). In this context, waking is often caused by pain in the bladder. Because the cause of waking is the pain, rather than a desire to void, use of the term *nocturia* in this context is not consistent with the ICS standardized LUTS terminology, even though the pain may be reduced by voiding.

Insomnia

Insomnia can arise as a result of remarkably diverse causes. By definition, nocturia is preceded and followed by sleep. Thus complete failure to fall asleep or return to sleep will formally exclude nocturia. Nonetheless, more subtle sleep disruption can reflect failure of key sleep phases that underpin the restorative effects of a normal night's slumber. Thus specialist appraisal of a sleep may be necessary to detect whether fatigue reflects primary sleep disruption or whether the sleep disruption is secondary to nocturia.

CLINICAL ASSESSMENT

Patients are likely to present with either nocturia or fatigue-related symptoms. A practical aid for remembering key aspects in patient assessment is given in Figure 67–1 (Wein et al, 2002). Evaluation requires a focused history and physical examination to evaluate the following:

1. Sleep
2. Conditions that might account for excessive nocturnal urine output (cardiovascular, endocrine, neurologic, renal impairment)
3. LUTS and conditions impairing bladder capacity including OAB
4. Fluid intake and medication use

Key Points: Fluid and Electrolyte Balance

- Compartmental distribution of body water and electrolyte loads are homeostatic priorities.
- Short- and medium-term variation of renal aquaporin levels are important determinants of urine volume and composition.
- The antidiuretic hormone, arginine vasopressin, is the main endocrine regulator of aquaporin-2 expression.
- Natriuresis, net sodium loss in urine, is regulated by the renin-angiotensin-aldosterone system, brain- and atrial-natriuretic peptides, the sympathetic nervous system, intrarenal mechanisms, and other incompletely understood influences.
- Chronic fluid and electrolyte imbalance, as well as involvement of less well-recognized hormonal influences, can create a refractory clinical problem.
- Accumulated fluid in dependent parts of the body ("third-spacing") returns to the circulating volume when the patient is recumbent.
- Altered cardiovascular function in nocturia includes deficiency of the overnight dip in BP.
- Polyuria and polydipsia need careful evaluation to exclude underlying endocrine or renal dysfunction.
- Circadian reduction in nocturnal urine production is regulated by ADH and other influences.
- Obstructive sleep apnea causes natriuresis by release of atrial natriuretic peptide.
- Nocturia is an independent predictor of albuminuria, substantiating the high prevalence of nocturnal polyuria in renal tubular dysfunction.
- Patients with metabolic syndrome have a high prevalence of nocturia.
- Certain drugs influence nocturia directly by increasing urine production or indirectly by causing sleep disturbance.
- Lower urinary tract dysfunction including OAB can contribute to nocturia frequency by reducing bladder reservoir function.

The FVC is of particular importance to document the volume and time of each void, the time of retiring for sleep, and the time of rising, ideally over a 3- or 4-day period or longer if patient compliance allows (Matthiesen et al, 1999). On the basis of the FVC, the following observations should be considered: **diurnal or nocturnal frequency, global or nocturnal polyuria, reduced bladder capacity (overall or solely nocturnal), or a mixed disorder** (Weiss et al, 2008). Additional aspects included in a more comprehensive bladder diary could be nature and timing of fluid intake, LUTS such as urgency, potential contributory factors, sleep pattern, and confounding factors (e.g., staying in bed for a long time after waking). Nocturia due to diminished bladder capacity is of two types: **a global decrease in bladder capacity as expressed by reduced maximal voided volume or typical voided volume or decreased bladder capacity apparent primarily at nighttime.** Sleep duration is an independent factor for nocturia (Udo et al, 2009).

FVCs can be supplemented by quantifying symptom severity and bother using validated questionnaire-based symptom assessment tools. Nocturia can constitute the main assessment target (as in the nocturia quality of life "N-QoL" tool [Abraham et al, 2004]). Alternatively, nocturia may be an element in a global LUTS tool such as the International Prostate Symptom Score (IPSS) (Homma et al, 2002) or the ICI-Q (Abrams et al, 2006); this approach can reduce the ability to discern symptom severity and treatment response in situations where nocturia reflects systemic disease rather than being a dependent variable of LUTS.

MANAGEMENT

Management considerations are outlined in Table 67–3. **Individualized treatment plans are beneficial, and a tailored approach based on evaluation of risk factors is appropriate, integrating advice and specific instructions.** Objective data to corroborate subjective impressions is valuable; an FVC before and during treatment allows greater sensitivity when evaluating treatment response and facilitating self-management (Yap et al, 2009).

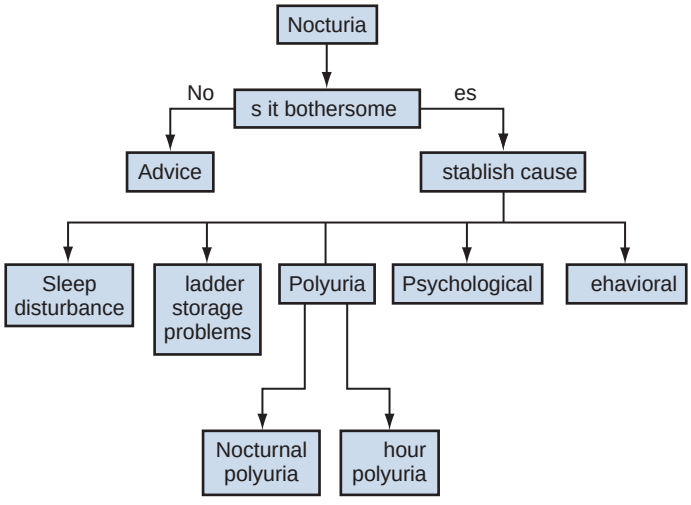

Figure 67–1. Key aspects of nocturia assessment. (From Wein A, Lose GR, Fonda D. Nocturia in men, women and the elderly: a practical approach. BJU Int 2002;90[Suppl. 3]:28–31.)

Table 67–3.

Key Considerations in Management of Nocturia

1. Health and lifestyle issues affecting sleep quality
2. Optimizing management of systemic conditions
   a) Optimizing management of known conditions likely to affect nocturnal urine output
   b) Identifying previously unrecognized conditions likely to affect nocturnal urine output
   c) Adjusting nature and timing of drugs used to treat otherwise-unrelated systemic conditions
3. Managing renal fluid and solute load
   a) Overall volume of oral intake
   b) Nature and timing of fluid and solute intake
   c) Endogenous fluid shifts
4. Increasing bladder reservoir capacity
   a) Reducing storage LUTS
   b) Improving bladder emptying in voiding dysfunction (bladder outlet obstruction, reduced detrusor contractility)
5. Hypnotics and restoration of circadian pattern
6. Pharmaceutic suppression of nocturnal renal output

Health and Lifestyle Issues Affecting Sleep Quality

In its wider context, nocturia is one of a range of interdependent sleep disturbances, such that attention has to be given to improving the sleep environment. In general, cognitive behavior therapy and relaxation techniques are preferred where there is comorbid insomnia (McCrae, 2009). Educating patients on consistent bedtimes, room temperature, noise, and lighting ("sleep hygiene") are appropriate. Gentle exercise leads to the deeper sleep, thence increasing the "arousal threshold bladder volume"—this also improves day-time urinary frequency and other health-related parameters (Sugaya et al, 2007). Several of the potential disturbances found in the Sleep in America Poll (Foley et al, 2004) may sometimes be correctable by simple measures (particularly physical pain, cough, headache, nighttime heartburn, headache, and uncomfortable bed), whereas some others (health concerns, money problems, family problems) should receive self-help coping measures and appropriate support. Depressive symptoms increase the incidence of nocturia (Hakkinen et al, 2008), so mental state needs to be considered.

Optimizing Management of Systemic Conditions

Some of the underlying nonurologic diseases that can contribute to nocturia merit treatment priority because major morbidity can ensue if appropriate intervention is not instigated (Schneider et al, 2009). This requires optimizing management of known conditions and consideration that a patient could have undiagnosed conditions that might affect nocturnal urine output. The list includes cardiovascular disease, endocrine disorders, renal failure, and OSA. However, improvement in nocturia severity as a consequence of optimizing treatment cannot be relied on. For example, in elderly people with hypertension, addition of a thiazide for management of nocturia in people who are already using losartan provides no additional benefit (Kojima et al, 2008). Part of the optimization of treatment requires adjusting the nature and timing of certain drugs (particularly diuretics, SSRIs, calcium channel blockers, and lithium) used to treat otherwise unrelated systemic conditions, in liaison with the relevant physicians caring for that aspect of the patient's management.

Managing Renal Fluid and Solute Load

Evaluating overall volume of oral intake and understanding the nature and timing of fluid and solute intake are fundamental aspects of managing nocturia. Engaging the patient in their own management is a key factor in the likelihood of treatment success. Behavioral interventions to manage exogenous fluid intake include patient education, caffeine and alcohol reduction, and restriction of nighttime fluids. Evening fluid restriction appears to reduce nocturnal urine excretion by a comparatively small amount (Griffiths et al, 1993). In fact, a high proportion of people with nocturia, in excess of two voids per night, have already instigated evening fluid restrictions themselves (Asplund and Aberg, 1992).

Endogenous fluid shifts, the return of free water and solutes to the circulation from sequestration sites, also need to be considered. Lower limb elevation (so that ankles are above the level of the heart), sometimes combined with compression stockings to reduce gravity-induced third-spacing of fluid in the lower extremities, is often advised (Vaughan et al, 2009). However, clinical evidence to support their efficacy is limited. A peripheral edema score (grade 1: ankle edema; grade 2: edema of the tibial and pretibial region; grade 3: ascites; grade 4: extreme generalized edema (anasarca); upgrading for jugular vein distention) has been used to evaluate nocturia in men with heart failure (Siniorakis et al, 2008). The study proposed that edema within the prostate gland is an element underlying the symptomatology. Diuretics taken in the late afternoon or early evening conceivably will decrease third-spacing of fluid and appear to help nocturia (Reynard, 1998; Williams and Donaldson, 1998). Nocturia response to diuretic therapy is partly predicted by alterations in baseline ANP levels (Fujikawa et al, 2001). Combination therapy employing a diuretic with an α blocker can achieve some benefit in a subgroup of patients, particularly those with nocturnal polyuria (Cho et al, 2009).

Increasing Impaired Bladder Capacity

Storage LUTS and increased filling sensation counteract the reservoir function of the bladder. Voiding dysfunction must also be considered because the presence of a significant postvoid residual will impair reservoir function; instigating intermittent self catheterization at bedtime may help nocturia in this subgroup of patients.

For patients with OAB, antimuscarinic drugs appear to be a logical choice (Chapple et al, 2006; Nitti et al, 2006; Rackley et al, 2006; Brubaker and FitzGerald, 2007). Generally, evening administration of the drug is recommended, though timing of administration for individuals should consider relative bother impact of daytime and overnight LUTS. The presence of NP reduces the prospect of clinical success (Brubaker and FitzGerald, 2007). Furthermore, **reduction of nocturia frequency with these drugs is marginal relative to placebo** (Michel and de la Rosette, 2005), **and there is no significant difference compared with behavioral therapy** (Fitzgerald et al, 2008). **They are not currently licensed for nocturia as an isolated symptom**.

In men, α-adrenergic antagonists are sometimes beneficial (Paick et al, 2006), but NP does not generally improve with α blocker therapy alone (Koseoglu et al, 2006). Naftopidal has been used to treat men with nocturia who have not improved with tamsulosin; benefits were seen in men with nocturia of three or more times per night (Oh-oka, 2008). Celecoxib, a cyclooxygenase-2 inhibitor, can improve nocturnal frequency and IPSS in men with BPE (Falahatkar et al, 2008). Combination pharmaceutic therapy with α-adrenergic antagonists and 5α-reductase inhibitors can improve symptom severity, but changes beyond 1 year are of doubtful clinical significance (Johnson et al, 2007). In men with OAB and nocturia, combined treatment including antimuscarinic drugs can improve symptom severity (Kaplan et al, 2006). Combination treatment including a nonsedating hypnotic (zolpidem) leads to a subjective reduction in nocturia episodes in men with LUTS (Song and Ku, 2007). Chinese herbal medicines have been used with apparent improvement of nocturia in older men (Ogushi and Takahashi, 2007). Nocturia scores and quality of life can improve as a result of surgical treatment in men (Cai et al, 2006). Following TURP, nocturia improvement is more clearly apparent in men of a lower age and with a lower preoperative maximum flow rate (Seki et al, 2009). TURP can improve nocturia frequency and quality of life, hours of undisturbed sleep, and the longest sleep interval between voids (Margel et al, 2007). However,

in nocturia-predominant LUTS, the physician should fully investigate the pathophysiology underlying the nocturia, evaluate whether bladder outlet obstruction is actually present, and warn patients that improvement of nocturia with surgical intervention is not reliable and of uncertain longevity (Neal, 1997).

Hypnotics and Restoration of Circadian Pattern

Hypnotic sedatives administered to elicit sleep pharmaceutically can affect nocturia (Fujikawa et al, 2001). The benzodiazepine oxazepam reduced nocturia 63%, but with no effect on urine volume (Kaye, 2008). The benefits of sedative agents may be in improving return to sleep, rather than in improving nocturia frequency (Takami and Okada, 1993). Those patients taking in excess of 30 minutes to return to sleep after awakening can be prescribed a nonbenzodiazepine sedative hypnotic to take once per night after a first nocturia episode between 23.00 and 03.00 hours (Vaughan et al, 2009). These drugs can be associated with hangover sedation when rising the following morning.

The pineal gland hormone melatonin is secreted during nocturnal hours and is a major determinant of physiologic circadian rhythm. **This release is affected in some older patients with sleep impairment; exogenously administered melatonin can counteract some of the associated sleep impairment** (Garfinkel et al, 1995) **and is not associated with hangover sedation.** Melatonin in isolation has been used for treatment of nocturia in men with BPE, showing marginal changes in the overall study group but with more overt benefits in a small subgroup of patients in whom nocturnal frequency fell by more than one void per night (Drake et al, 2004). Effect of melatonin supplementation has been compared with the hypnotic agent rilmazafone in elderly patients; both groups showed reduction in the number of nocturnal voids (Sugaya et al, 2007).

Pharmaceutic Suppression of Nocturnal Renal Output

Desmopressin can achieve significant improvement in nocturia symptoms for the isolated symptom and when nocturia is a component of OAB. Desmopressin is increasingly used for management of nocturnal polyuria (van Kerrebroeck et al, 2007), and randomized double-blind trials have been reported in both men (Mattiasson et al, 2002) and women (Lose et al, 2003). Thirty-three percent of men and 46% of women showed at least a 50% reduction in the mean number of voids per night relative to baseline; a greater proportion of patients showed at least a 50% reduction in the number of nocturnal voids in longer-term use (Lose et al, 2004). **Dilutional hyponatremia occurs in 7.6% of patients** (Weatherall, 2004); **risk factors include age older than 65 years and low serum sodium at baseline** (Rembratt et al, 2006). **The serum sodium concentration should be checked within a few days of instigating treatment, and dose titration should be employed. In long-term use, sodium should be assessed at least every 6 months** (Bae et al, 2007). Desmopressin is licensed for management of nocturia in multiple sclerosis (MS); its influence on renal urine output is exerted in the 6-hour period following administration (Bosma et al, 2005). Its value is more likely to be clinically beneficial if maximal bladder capacity is adequate (Zahariou et al, 2008). Clinical response to vasopressin analogue treatment was not predicted by water-deprivation tests (Johnson et al, 2007). Cannabis extracts also appear to help nocturia in MS (Brady et al, 2004).

Nonsteroidal anti-inflammatory drugs including oral loxoprofen (Saito et al, 2005) and indomethacin suppositories (Al-Waili et al, 2005) have been administered at bed-time for the treatment of nocturia. The mechanism of action appears to be a reduction in nocturnal urine volume (Araki et al, 2008). It is not clear whether this approach risks any long-term effects on renal function.

Key Points: Assessment and Treatment

- The FVC is used to document key parameters determining diurnal or nocturnal frequency, global or nocturnal polyuria, reduced bladder capacity (overall or nocturnal), or a mixed disorder.
- Symptom assessment tools are used to capture subjective elements of nocturia.
- Individualized treatment plans based on evaluation of risk factors should integrate advice and specific instructions with directed interventions.
- Improved sleep environment, self-help, depression management, cognitive behavior therapy, relaxation techniques, and gentle exercise are used to manage comorbid insomnia.
- Major nonurologic diseases that can contribute to nocturia are prioritized in management.
- Volume, nature, and timing of fluid and solute intake can be adjusted, while endogenous fluid shifts also need to be considered.
- Storage and voiding dysfunction have to be managed to restore bladder reservoir function; intermittent self-catheterization, antimuscarinic drugs, and combination treatments can be considered.
- For nocturia-predominant LUTS in men, comprehensive evaluation is necessary before considering surgery to reduce the risk of a poor symptomatic outcome.
- The benefits of sedative agents may be in improving return to sleep, rather than nocturia frequency. Treatment with melatonin can counteract sleep impairment and reduces nocturia in some patients.
- Desmopressin can achieve significant improvement in nocturia symptoms for the isolated symptom, as well as when nocturia is a component of OAB. Dilutional hyponatremia occurs in 7.6% of patients.

Pharmacologic Management of Lower Urinary Tract Storage and Emptying Failure

Karl-Erik Andersson, MD, PhD ● Alan J. Wein, MD, PhD (Hon), FACS

Pharmacologic Therapy to Facilitate Bladder Filling and Urine Storage

Pharmacologic Therapy to Facilitate Bladder Emptying

The function of the lower urinary tract (LUT) is to effect efficient and low-pressure bladder filling, low-pressure urine storage with normal sensation and perfect continence, and periodic complete voluntary emptying, again at low pressure. The structures involved include the smooth musculature of the bladder and the bladder outlet and the striated muscle, both intrinsic (to the bladder outlet) and extrinsic (the striated musculature surrounding the bladder outlet and the striated musculature of the pelvic floor). These component structures are controlled by a complex interplay between the central and peripheral nervous systems and local regulatory factors. Pharmacologic alteration of LUT function can occur at any point along the afferent or efferent limb of this complex neuromuscular cascade, either by receptor activation/stimulation or blockade, by affecting the concentration of neurotransmitter at an activation site, or by stimulating or inhibiting signal transduction mechanisms (Andersson and Wein, 2004; Andersson et al, 2009; Birder et al, 2009; Fry et al, 2009; see also Chapter 60).

The focus of this chapter is the pharmacologic management of bladder filling/storage and bladder emptying/voiding dysfunction. The conceptual basis is that of the expanded functional classification seen in Table 61–5 and the division of therapies in the relatively simple-minded manner of those that facilitate urine storage/bladder filling and those that facilitate bladder emptying/voiding (see Tables 61–3 and 61–4). Although the principles expressed are generally applicable to all ages, specifics concerning usage in the elderly and pediatric age groups are considered in detail in Chapters 75, 126, and 127. Specific information regarding the pharmacologic management of LUT dysfunction secondary to obstruction by benign prostatic enlargement is considered in detail in Chapter 91, whereas drug therapy for the treatment of bladder and pelvic pain disorders is considered in detail in Chapters 11 and 12.

PHARMACOLOGIC THERAPY TO FACILITATE BLADDER FILLING AND URINE STORAGE

Inhibiting Bladder Contractility, Decreasing Sensory Input, Increasing Bladder Capacity

Bladder Contraction and Muscarinic Receptors

The major portion of the neurohumoral stimulus for physiologic bladder contraction is acetylcholine-induced stimulation of postganglionic parasympathetic muscarinic cholinergic receptor sites in the bladder (detrusor smooth muscle and possibly other sites) (see Chapter 60). Atropine and atropine-like agents will depress normal bladder contractions and involuntary bladder contractions of any cause (Andersson, 1988; 1993; Andersson and Wein, 2004). In patients with involuntary contractions, the volume to the first involuntary contraction will generally be increased, the amplitude of the contraction decreased, and the total bladder capacity increased (Jensen, 1981).

Previously, it has been stated (Wein, 1998) that bladder compliance in normal individuals and in those with neurogenic detrusor overactivity (NDO; Abrams et al, 2002), in whom the initial slope of the filling curve on cystometry is normal before the involuntary contraction, does not seem to be significantly altered by antimuscarinic agents and that the effect of pure antimuscarinics in those patients who exhibit only decreased compliance had not been well studied. Regarding the subject of bladder tone during filling, Andersson (1999a, 1999b, 2004; Andersson and Yoshida, 2003) has pointed out that, although it is widely accepted that there is normally no sacral parasympathetic outflow to the bladder during filling, antimuscarinic drugs increase, and anticholinesterase inhibitors decrease, bladder capacity. **Because antimuscarinic drugs do seem to affect the sensation of urgency during filling, this suggests an ongoing acetylcholine-mediated stimulation of detrusor tone** (see later). **If this is correct,**

agents inhibiting acetylcholine release or activity would be expected to contribute to bladder relaxation or the maintenance of low bladder tone during filling with a consequent decrease in filling/storage symptomatology unrelated to the occurrence of an involuntary contraction. Outlet resistance, at least as reflected by urethral pressure measurements, does not seem to be clinically affected.

Although the antimuscarinic agents usually produce significant clinical improvement in patients with involuntary contractions and associated symptoms, generally only partial inhibition results. In many animal models, atropine only partially antagonizes the response of the whole bladder to pelvic nerve stimulation and of bladder strips to field stimulation, although it does completely inhibit the response of bladder smooth muscle to exogenous cholinergic stimulation. This phenomenon, which is called ***atropine resistance,*** is secondary to release of a transmitter other than acetylcholine (see Andersson, 1993; Andersson et al, 1999c; Andersson and Wein, 2004; see also Chapter 60). Atropine resistance is the most common hypothesis invoked to explain the clinical difficulty in eradicating involuntary contractions with antimuscarinic agents alone, and it is also invoked to support the rationale of combined treatment of DO with agents that have different mechanisms of action (Andersson, 2006).

Andersson and Wein (2004) cite references stating that atropine resistance seems to be of little importance in normal human bladder muscle but point out that atropine-resistant (nonadrenergic, noncholinergic) contractions have been reported in human detrusor smooth muscle and in morphologically and/or functionally changed bladders in individuals with various types of voiding dysfunction. Thus, **the importance or nonimportance of an atropine-resistant component to detrusor contraction in the treatment of DO in humans remains to be established.**

Muscarinic Receptors

In the human bladder, where the mRNAs for all the five pharmacologically defined receptors, M_1 to M_5, have been demonstrated (Sigala et al, 2002; Abrams et al, 2006a; Giglio and Tobin, 2009), **there is a predominance of mRNAs encoding M_2 and M_3 receptors** (Yamaguchi et al, 1996; Sigala et al, 2002; Abrams et al, 2006a; Giglio and Tobin, 2009). This seems to be the case also in the animal species investigated (Hegde and Eglen, 1999; Chess-Williams, 2002; Andersson and Arner, 2004). **Both M_2 and M_3 receptors can be found on detrusor muscle cells, where M_2 receptors predominate at least 3:1 over M_3 receptors, but also in other bladder structures, which may be of importance for detrusor activation.** Thus, muscarinic receptors can be found on **urothelial cells, on suburothelial nerves, and on other suburothelial structures, such as interstitial cells** (Chess-Williams, 2002; Gillespie et al, 2003; Gillespie, 2004b; Mansfield et al, 2005; Bschleipfer et al, 2007; Giglio and Tobin, 2009).

In human as well as animal detrusor, the M_3 receptors are believed to be the most important for contraction (Andersson, 1993; Chess-Williams, 2002; Abrams et al, 2006a; Giglio and Tobin, 2009). No differences between genders could be demonstrated in rat and human bladders (Kories et al, 2003). **The functional role for the M_2 receptors has not been clarified,** and even in M_3 receptor knockout mice they seem responsible for less that 5% of the carbachol-mediated detrusor contraction (Matsui et al, 2000). Stimulation of M_2 receptors has been shown to oppose sympathetically (β-adrenoreceptor [β-AR]) mediated smooth muscle relaxation (Hegde et al, 1997). However, based on animal experiments, M_2 receptors have been suggested to directly contribute to contraction of the bladder in certain disease states (denervation, outflow obstruction). Experiments on human detrusor muscle by Stevens and associates (2007) could not confirm this; however, Pontari and colleagues (2004) analyzed bladder muscle specimens from patients with neurogenic bladder dysfunction to determine whether the muscarinic receptor subtype mediating contraction shifts from M_3 to the M_2 receptor subtype, as found in the denervated, hypertrophied rat bladder. They concluded that normal detrusor contraction is mediated by the M_3 receptor subtype whereas contractions can be mediated by the M_2 receptors in patients with neurogenic bladder dysfunction.

Muscarinic receptors are coupled to G proteins, but the signal transduction systems may vary. **Generally, M_1, M_3, and M_5 receptors are considered to couple preferentially to $G_{q/11}$, activating phosphoinositide hydrolysis, in turn leading to mobilization of intracellular calcium (Ca^{2+}). M_2 and M_4 receptors couple to pertussis toxin–sensitive $G_{i/o}$, resulting in inhibition of adenylate cyclase activity.** In the human detrusor, Schneider and coworkers (2004), confirming that the muscarinic receptor subtype mediating carbachol-induced contraction is the M_3 receptor, also demonstrated that the phospholipase-C inhibitor U73122 did not significantly affect carbachol-stimulated bladder contraction, despite blocking inositol 1,4,5-triphosphate generation. They concluded that carbachol-induced contraction of the human urinary bladder is mediated via M_3 receptors and largely depends on Ca^{2+} entry through nifedipine-sensitive channels and activation of the Rho-kinase pathway. Thus, **it may be that the main pathways for muscarinic receptor activation of the detrusor via M_3 receptors are Ca^{2+} influx via L-type Ca^{2+} channels and increased sensitivity to Ca^{2+} of the contractile machinery via inhibition of myosin light-chain phosphatase through activation of Rho-kinase.**

The signaling mechanisms for the M_2 receptors are less clear than those for M_3 receptors. As mentioned previously, **M_2 receptor stimulation may oppose sympathetically induced smooth muscle relaxation, mediated by β-ARs via inhibition of adenylyl cyclase** (Hegde et al, 1997). In agreement with this, Matsui and colleagues (2003) suggested, based on results obtained in M_2 receptor knockout mice, that a component of the contractile response to muscarinic agonists in smooth muscle involves an M_2 receptor–mediated inhibition of the relaxant effects of agents that increase cyclic adenosine monophosphate (cAMP) levels. M_2 receptor stimulation can also activate nonspecific cation channels and inhibit K_{ATP} channels through activation of protein kinase C (Bonev and Nelson, 1993; Kotlikoff et al, 1999).

Muscarinic receptors may also be located on the presynaptic nerve terminals and participate in the regulation of transmitter release. The inhibitory prejunctional muscarinic receptors have been classified as muscarinic M_2 in the rabbit (Tobin and Sjögren, 1995) and rat (Somogyi and de Groat, 1992) and as M_4 in the guinea pig (Alberts, 1995) and human bladder (D'Agostino et al, 2000). Prejunctional facilitatory muscarinic receptors appear to be of the M_1 subtype in the bladders of rats, rabbits (Somogyi and de Groat, 1992; Tobin and Sjögren, 1995, 1998), and humans (Somogyi and de Groat, 1999; Giglio and Tobin, 2009). The muscarinic facilitatory mechanism seems to be upregulated in overactive bladders from chronic spinal cord–transected rats. The facilitation in these preparations is primarily mediated by M_3 muscarinic receptors (Somogyi and de Groat, 1999).

The relative roles of the different presynaptic and postsynaptic receptor subtypes in normal and abnormal bladder function still require clarification, and thus speculation regarding optimal drug therapy based only on in-vitro receptor selectivity profiles represents, at the very least, a gross oversimplification of assumptions regarding the muscarinic regulation of bladder function. The muscarinic receptor functions may be changed in different urologic disorders, such as outflow obstruction, neurogenic bladders, DO without overt neurogenic cause, and diabetes (Andersson, 2000b). **However, it is not always clear what the changes mean in terms of changes in detrusor function.**

In general, **all drug therapy for LUT dysfunction is hindered by a concept that can be expressed in one word: "uroselectivity"** (Andersson, 1998). **The clinical utility of available antimuscarinic agents is limited by their lack of selectivity, which is responsible for the classic peripheral antimuscarinic side effects of dry mouth, constipation, blurred vision, and increase in heart rate and for the effects on cognitive functions.** Although M_3 receptor selective agents have the potential to eliminate some of these side effects, it would appear that the M_3 receptors in tissues of the LUT are identical to those elsewhere in the body (Caulfield and Birdsall, 1998). It may be speculated, however, that there is some heterogeneity among M_3 receptors, and this has prompted many pharmaceutical companies to continue to search for the "ideal" antimuscarinic agent to treat DO, one that would be relatively selective for muscarinic receptors involved in the regulation of bladder contraction. Receptor selectivity, however, is not the only basis on which a drug may be "uroselective." From a clinical standpoint it would seem particularly important to be able to describe in relative terms the ratio between a drug dose required for a desired therapeutic action and the dose producing side effects. A differential effect could be based not only on receptor selectivity but also on other known and as yet undefined physiologic, pharmacologic, or metabolic characteristics. Organ selectivity would thus seem to be the "holy grail" of such therapy. The same problematic set of concepts applies to virtually all drugs used for the treatment of LUT dysfunction.

Drugs Used for Treatment of Detrusor Overactivity/Overactive Bladder Symptomatology

The prevalence of the overactive bladder (OAB) syndrome varies with the criteria for diagnosis. According to Irwin and associates (2006), using the 2002 International Continence Society (ICS) definition, the overall prevalence (the EPIC study) was 11.8%. The rates were similar in men and women and increased with age. A similar study by Herschhorn and coworkers (2008) found the prevalence to be 13% in Canadian men and 14% in Canadian women. It appears that OAB/DO may be the result of several different mechanisms, both myogenic and neurologic (Morrison et al, 2002; Birder et al, 2009; Koebl et al, 2009). Most probably, both factors contribute to the genesis of the disease.

An abundance of drugs has been used for the treatment of OAB/DO. It should be stressed that in many trials on OAB/DO there has been such a high placebo response that meaningful differences between placebo and active drug cannot be demonstrated (Thüroff et al, 1998). However, drug effects in individual patients may be both distinct and useful.

The 4th International Consultation on Incontinence (ICI) (2008) **assessed drugs used for treatment of incontinence** (Andersson et al, 2009). **The assessment criteria** (Table 68–1) **were based on the Oxford guidelines, and the drugs included are given in** Table 68–2**.**

Antimuscarinic (Anticholinergic) Agents

Mechanism of Action. **For many years, antimuscarinic drugs have been the gold standard for treatment of OAB. Still, the way(s) by which they exert their beneficial effect has (have) not yet been established.**

Acetylcholine stimulates both muscarinic and nicotinic receptors. Antimuscarinic agents block selectively muscarinic receptors, and they are currently the mainstay of treatment of OAB/DO (Abrams and Andersson, 2007). The **traditional view** is that in OAB/DO the drugs act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by acetylcholine released from activated cholinergic (parasympathetic) nerves. Thereby, they decrease the ability of the bladder to contract. **However, antimuscarinic drugs act mainly during the storage phase, decreasing urgency and increasing bladder capacity; and during this phase there is normally no parasympathetic input to the LUT** (Morrison et al, 2002; Andersson, 2004). Furthermore, antimuscarinic agents are usually competitive antagonists. This implies that when there is a massive release of acetylcholine, as during micturition, the effects of the drugs should be decreased, otherwise the reduced ability of the detrusor to contract would eventually lead to urinary retention. Undeniably, high doses of antimuscarinic agents can produce urinary retention in humans, **but in the dose range used for beneficial effects in OAB/DO there is little evidence for a significant reduction of the voiding contraction** (Finney et al, 2006) (Fig. 68–1). There is indirect clinical evidence for release of acetylcholine during bladder filling in certain abnormal conditions. Smith and colleagues (1974) found that in patients with recent spinal cord injury, inhibition of acetylcholine breakdown by use of cholinesterase inhibitors could increase resting tone and induce rhythmic contractions in the bladder. Yossepowitch and coworkers (2001) inhibited acetylcholine breakdown with edrophonium in a series of patients with disturbed voiding or urinary incontinence. They found a significant change in sensation and decreased bladder capacity, induction or amplification of involuntary detrusor contractions, or significantly decreased detrusor compliance in 78% of the patients with the symptom pattern of OAB but in no patients without specific complaints suggesting DO. Thus, **during the storage phase,**

Table 68–1.

International Consultation on Incontinence (ICI) Assessments 2004, 2008: Oxford Guidelines (Modified)

Levels of Evidence

Level 1: Systematic reviews, meta-analyses, good quality randomized controlled clinical trials
Level 2: Randomized controlled trials, good quality prospective cohort studies
Level 3: Case-control studies, case series
Level 4: Expert opinion

Grades of Recommendation

Grade A: Based on level 1 evidence (highly recommended)
Grade B: Consistent level 2 or 3 evidence (recommended)
Grade C: Level 4 studies or "majority evidence"(optional)
Grade D: Evidence inconsistent/inconclusive (no recommendation possible)

Table 68–2.

Drugs Used in the Treatment of Detrusor Overactivity (ICI, 2008; Andersson et al, 2009)

ANTIMUSCARINIC DRUG	LEVEL OF EVIDENCE	GRADE OF RECOMMENDATION
Tolterodine	1	A

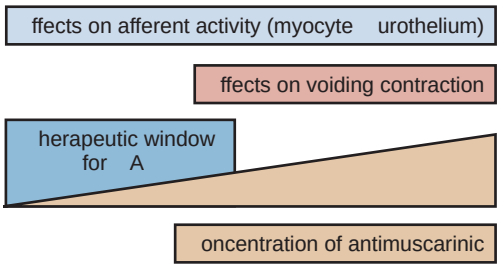

Figure 68–1. Rationale for use of antimuscarinic agents in overactive bladder (OAB).

acetylcholine may be released from both neuronal and non-neuronal sources (e.g., the urothelium/suburothelium) **and directly or indirectly (by increasing detrusor smooth muscle tone) excite afferent nerves in the suburothelium and within the detrusor. There is also good experimental evidence that antimuscarinic agents act during the storage phase by decreasing the activity in afferent nerves (both C and Aδ fibers) from the bladder** (De Laet et al, 2006; Iijima et al, 2007).

Muscarinic receptors are found on bladder urothelial cells where their density can be even higher than in detrusor muscle. The role of the urothelium in bladder activation has attracted much interest (Andersson, 2002a; de Groat, 2004; Birder and de Groat, 2007; Birder et al, 2009; Giglio and Tobin, 2009), but whether the muscarinic receptors on urothelial cells can influence micturition has not yet been established. Yoshida and colleagues (2004, 2006, 2008) found that there is basal acetylcholine release in the human bladder. This release was resistant to tetrodotoxin and much diminished when the urothelium was removed; thus, the released acetylcholine was probably of non-neuronal origin and, at least partly, generated by the urothelium. Thus, during the storage phase, acetylcholine and adenosine triphosphate (ATP) may be released from both neuronal and non-neuronal sources (e.g., the urothelium) and directly or indirectly (by increasing detrusor smooth muscle tone) excite afferent nerves in the suburothelium and within the detrusor. These mechanisms may be important in the pathophysiology of OAB and represent possible targets for antimuscarinic drugs.

Pharmacologic Properties. Generally, antimuscarinic agents can be divided into tertiary and quaternary amines (Guay, 2003; Abrams and Andersson, 2007). They differ with regard to lipophilicity, molecular charge, and even molecular size, with tertiary compounds generally having higher lipophilicity and molecular charge than quaternary agents. **Atropine, darifenacin, fesoterodine (and its active metabolite 5-hydroxymethyl-tolterodine), oxybutynin, propiverine, solifenacin, and tolterodine, are tertiary amines. They are generally well absorbed from the gastrointestinal tract and should theoretically be able to pass into the central nervous system (CNS),** dependent on their individual physicochemical properties. **High lipophilicity, small molecular size, and less charge will increase the possibilities to pass the blood-brain barrier, but for some of the drugs this is counteracted by active transport out of the CNS by P-glycoprotein. Quaternary ammonium compounds, such as propantheline and trospium, are not well absorbed, pass into the CNS to a limited extent, and have a low incidence of CNS side effects** (Guay, 2003). They still produce well-known peripheral antimuscarinic side effects, such as accommodation paralysis, constipation, increase in heart rate, and dryness of mouth.

Many antimuscarinic drugs are metabolized by the cytochrome P450 enzyme system to active and/or inactive metabolites (Guay, 2003). **The most commonly involved P450 enzymes are CYP2D6 and CYP3A4. The metabolic conversion creates a risk for drug-drug interactions, resulting in either reduced (enzyme induction) or increased (enzyme inhibition, substrate competition)**

plasma concentration/effect of the antimuscarinic and/or interacting drug. Antimuscarinic agents secreted by the renal tubules (e.g., trospium) may theoretically be able to interfere with the elimination of other drugs using this mechanism.

Antimuscarinic drugs are still the most widely used treatment for urgency and urgency incontinence (Andersson, 2004; Andersson et al, 2009). However, currently used drugs lack selectivity for the bladder, and effects on other organ systems (Table 68–3) may result in side effects that limit their usefulness. For example, all antimuscarinic drugs are contraindicated in patients with untreated narrow-angle glaucoma.

Theoretically, drugs with selectivity for the bladder could be obtained if the subtype(s) mediating bladder contraction, and those producing the main side effects of antimuscarinic drugs, were different. Unfortunately this does not seem to be the case. One way of avoiding many of the antimuscarinic side effects is to administer the drugs intravesically. However, this is practical only in a limited number of patients.

Clinical Efficacy. Several antimuscarinic drugs are and have been used for treatment of OAB/DO. For many of them documentation of effects is not based on randomized controlled trials (RCTs) satisfying currently required criteria, and some drugs can be considered as obsolete (e.g., emepronium). Information on these drugs is found elsewhere (Andersson, 1988; Andersson et al, 1999c).

The clinical relevance of efficacy of antimuscarinic drugs relative to placebo has been questioned. Herbison and associates (2003) stated in a widely discussed article: "Anticholinergics produce significant improvements in overactive bladder symptoms compared with placebo. The benefits are, however, of limited clinical significance." **Large meta-analyses of studies performed with the currently most widely used drugs** (Chapple et al, 2005, 2008a; Novara et al, 2008) **clearly show that antimuscarinic drugs are of significant clinical benefit.** Novara and colleagues (2008) reviewed 50 RCTs and 3 pooled analyses that they considered of good methodologic quality. They concluded that still more clinical studies are needed to decide which of the drugs should be used as first-, second-, or third-line treatment. Reviewing information from more than 12,000 references, Chapple and colleagues (2008a) based their conclusions ("antimuscarinics are efficacious, safe, and well tolerated treatments") on 73 RCTs selected for their meta-analysis. It was recommended that because the profiles of each drug and dosage differ that these factors should be considered in making treatment choices.

The consequence of this is that, in the authors' opinion, none of the antimuscarinic drugs in common clinical use (darifenacin, fesoterodine, oxybutynin, propiverine, solifenacin, tolterodine, or trospium) is ideal as a first-line treatment for *all* OAB/DO patients. Optimal treatment should be individualized, implying that the patient's comorbidities and concomitant medications, and the pharmacologic profiles of the different drugs, should be taken into consideration (Chapple et al, 2008a).

Behavioral therapy (see Chapter 69) **should always be used in conjunction with drug therapy for OAB/DO because most studies show the effects of the two combined are greater than the effect of either alone** (Burgio et al, 2000; Mattiasson et al, 2003; Klutke et al, 2009).

Tolerability and Safety. An extensive literature supports that antimuscarinic drugs for the treatment of OAB symptoms are generally well tolerated. The adverse effect profiles of the different drugs are determined by their organ and muscarinic receptor subtype selectivities and pharmacokinetic parameters. **The most commonly reported adverse effects are dry mouth, constipation, headache, and blurred vision.**

Among the more serious possibilities related to antimuscarinic use is **the potential risk of cardiac adverse effects,** particularly **increases in heart rate** and **QT prolongation and induction of polymorphic ventricular tachycardia** (torsades de pointes). **QT prolongation and its consequences are not related to blockade of muscarinic receptors but rather linked to inhibition of the hERG potassium (K^+) channel in the heart** (Roden, 2004). **Thus QT prolongation is not a class effect of antimuscarinic drugs.** In general the cardiovascular safety for antimuscarinic drugs seems to be good. However, **the potential of the different agents to increase heart rate or to prolong the QT time has not been extensively explored.** Differences between the drugs cannot be excluded, but risk assessments based on available evidence are not possible.

Another concern is that antimuscarinic drugs commonly used to treat OAB can be associated with CNS side effects, including cognitive dysfunction, memory impairment, dizziness, fatigue, and headache. With the exception of oxybutynin IR, CNS-related side effects are not commonly found when investigated. The potential to cause CNS-related adverse effects may differ between drugs, but in the absence of comparative trials, relative risk assessments are not possible.

Atropine Sulfate. Atropine (*dl*-hyoscyamine) is rarely used for treatment of OAB/DO because of its systemic side effects, which preclude its use as an oral treatment. However, in patients with neurogenic DO, intravesical atropine may be effective for increasing bladder capacity without causing any systemic adverse effects, as shown in open pilot trials (Ekström et al, 1992; Glickman et al, 1995; Deaney et al, 1998; Enskat et al, 2001; Fader et al, 2007). It appears that intravesical atropine may be as effective as intravesical oxybutynin in patients with neurogenic DO (Fader et al, 2007). The pharmacologically active antimuscarinic component of atropine is *l*-hyoscyamine. Although it is still used, few clinical studies are available to evaluate the antimuscarinic activity of *l*-hyoscyamine sulfate (Muskat et al, 1996). For assessment, see Table 68–2.

Table 68–3.

Muscarinic Receptors: Distribution and Function

REGION	SUBTYPE OF MUSCARINIC RECEPTOR	FUNCTION
Bladder	$M_2 > M_3$ (3:1)	M_3: mediates human detrusor contraction
Salivary glands, parotid gland	M_1, M_3	M_1: high viscosity lubrication M_3: salivation
Gastrointestinal tract	$M_2 > M_3$ (4:1)	M_3: stimulation of gastrointestinal motility
Brain	M_1 to M_5 (M_3 sparse)	Involved in higher cognitive processes such as learning and memory (mostly M_1)
Eye	M_1 to M_5 (M_3 predominates)	Controls iris sphincter contraction
Heart	M_2	Modulates pacemaker activity, atrioventricular conduction, and the force of contraction

Data from Abrams P, Andersson K-E, Buccafusco JJ, et al. Muscarinic receptors: their distribution and function in body systems, and the implications for treating overactive bladder. Br J Pharmacol 2006;148:565.

Propantheline Bromide. **Propantheline bromide (Pro-Banthine, others) is a quaternary ammonium compound,** nonselective for muscarinic receptor subtypes, that has a low (5% to 10%) and individually varying biologic availability. It is metabolized (metabolites inactive) and has a short plasma half-life (<2 hr) (Beermann et al, 1972). It is usually given in a dose of 15 to 30 mg four times daily, but, to obtain an optimal effect, individual titration of the dose is necessary and often higher dosages are required. Using this approach in 26 patients with DO, Blaivas and associates (1980) in an open study obtained a complete clinical response in all patients but one, who did not tolerate more than propantheline, 15 mg, four times daily. The range of dosages varied from 7.5 to 60 mg four times daily. In contrast, Thüroff and coworkers (1991) comparing the effects or oxybutynin 5 mg three times a day, propantheline 15 mg three times a day, and placebo in a randomized, double-blind, multicenter trial on the treatment of frequency, urgency, and incontinence related to DO (154 patients) found no differences between the placebo and propantheline groups. In another randomized comparative trial with crossover design (23 women with idiopathic DO), and with dose titration, Holmes and associates (1989) found no differences in efficacy between oxybutynin and propantheline. There is a surprising lack of evaluable data on the effectiveness of propantheline for the treatment of DO. The Agency for Health Care Policy and Research (AHCPR) Clinical Practice Guidelines (U.S. Department of Health and Human Services, 1992) lists five randomized controlled trials reviewed for propantheline, with 82% female patients. Percent cures (all figures refer to percent effect on drug minus percent effect on placebo) are listed as 0% to 5%, reduction in urgency incontinence as 0% to 53%, and percent side effects and percent dropouts as 0% to 50% and 0% to 9%, respectively. RCTs (n = 6) reviewed by Thüroff and associates (1998) confirmed a positive, but varying, response to the drug.

Although the effect of propantheline on OAB/DO has not been well documented in controlled trials satisfying standards of today, it can be considered effective and may, in individually titrated doses, be clinically useful (see Table 68–2). No new studies on the use of this drug for the treatment of OAB/DO seem to have been performed during the past decade.

Trospium Chloride. **Trospium is a quaternary ammonium compound with a biologic availability of less than 10%** (Fusgen and Hauri, 2000; Doroshyenko et al, 2005). The drug has a plasma half-life of approximately 20 hours and is mainly (60% of the dose absorbed) eliminated unchanged in the urine. The concentration obtained in urine seems to be enough to affect the mucosal signaling system in a rat model (Kim et al, 2006). Whether it contributes to the clinical efficacy of the drug remains to be established. Trospium is not metabolized by the cytochrome P450 enzyme system (Beckmann-Knopp et al, 1999; Doroshyenko et al, 2005). **It is expected to cross the blood-brain to a limited extent and seems to have no negative cognitive effects** (Fusgen and Hauri, 2000; Todorova et al, 2001; Wiedemann et al, 2002).

Trospium has no selectivity for muscarinic receptor subtypes. In isolated detrusor muscle it was more potent than oxybutynin and tolterodine to antagonize carbachol-induced contractions (Uckert et al, 2000).

Several RCTs have documented positive effects of trospium both in neurogenic (Stöhrer, et al, 1991; Madersbacher et al, 1995; Menarini et al, 2006) and non-neurogenic DO (Allousi et al, 1998; Cardozo et al, 2000; Jünemann and Al-Shukri, 2000; Halaska et al, 2003; Zinner et al, 2004a; Rudy et al, 2006; Staskin et al, 2007; Dmochowski et al, 2008). In a placebo-controlled, double-blind study on patients with neurogenic DO (Stöhrer et al, 1991) the drug was given twice daily in a dose of 20 mg over a 3-week period. It increased maximum cystometric capacity, decreased maximum detrusor pressure, and increased compliance in the treatment group, whereas no effects were noted in the placebo group. Side effects were few and comparable in both groups. In another RCT including patients with spinal cord injuries and neurogenic DO, trospium and oxybutynin were equally effective; however, trospium seemed to have fewer side effects (Madersbacher et al, 1995). The effect of trospium in urgency incontinence has been documented in several RCTs. Allousi and associates (1998) compared the effects of the drug with those of placebo in 309 patients in a urodynamic study of 3 weeks' duration. Trospium, 20 mg, was given twice daily. Significant increases were noted in volume at first involuntary contraction and in maximum bladder capacity. Cardozo and coworkers (2000) investigated 208 patients with DO who were treated with trospium, 20 mg twice daily, for 2 weeks. Also in this study, significant increases were found in mean volume at first unstable contraction (from 233 to 299 mL; placebo 254 to 255 mL) and in maximum bladder capacity (from 329 to 356 mL; placebo 345 to 335 mL) in the trospium-treated group. Trospium was well tolerated with similar frequency of adverse effects as in the placebo group. Jünemann and Al-Shukri (2000) compared trospium, 20 mg twice daily, with tolterodine, 2 mg twice daily, in a placebo-controlled double-blind study on 232 patients with urodynamically proven DO, urgency incontinence without demonstrable DO, or mixed incontinence. Trospium reduced the frequency of micturition, which was the primary end point, more than tolterodine and placebo and also reduced the number of incontinence episodes more than the comparators. Dry mouth was comparable in the trospium and tolterodine groups (7% and 9%, respectively). Halaska and colleagues (2003) studied the tolerability and efficacy of trospium chloride in doses of 20 mg twice daily for long-term therapy in patients with urgency syndrome. The trial comprised a total of 358 patients with urgency syndrome or urgency incontinence. After randomization in the ratio of 3:1, participants were treated continuously for 52 weeks with either trospium chloride (20 mg twice daily) or oxybutynin (5 mg twice daily). Urodynamic measurements were performed at the beginning and at 26 and 52 weeks to determine the maximum cystometric bladder capacity. Analysis of the micturition diary clearly indicated a reduction of the micturition frequency, incontinence frequency, and a reduction of the number of urgency episodes in both treatment groups. Mean maximum cystometric bladder capacity increased during treatment with trospium chloride by 92 mL after 26 weeks and 115 mL after 52 weeks ($P = .001$). Further comparison with oxybutynin did not reveal any statistically significant differences in urodynamic variables between the drugs. Adverse events occurred in 65% of the patients treated with trospium and 77% of those treated with oxybutynin. The main symptom encountered in both treatment groups was dryness of the mouth. An overall assessment for each of the drugs revealed a comparable efficacy level and a better benefit-risk ratio for trospium than for oxybutynin due to better tolerability. Zinner and coworkers (2004a) treated 523 patients with symptoms associated with OAB and urgency incontinence with trospium 20 mg twice daily or placebo in a 12-week, multicenter, parallel, double-blind, placebo-controlled trial. Dual primary end points were change in average number of toilet voids and change in urgency incontinent episodes per 24 hours. Secondary efficacy variables were change in average of volume per void, voiding urgency severity, urinations during day and night, time to onset of action, and change in

Incontinence Impact Questionnaire. By week 12, trospium significantly decreased average frequency of toilet voids per 24 hours (–2.37; placebo –1.29) and urgency incontinent episodes (–59%; placebo –44%). It significantly increased average volume per void (32 mL; placebo: 7.7 mL) and decreased average urgency severity and daytime frequency. All effects occurred by week 1, and all were sustained throughout the study. Nocturnal frequency decreased significantly by week 4 (–0.43; placebo: 0.17), and Incontinence Impact Questionnaire scores improved at week 12. Trospium was well tolerated. The most common side effects were dry mouth (21.8%; placebo 6.5%), constipation (9.5%; placebo 3.8%). and headache (6.5%; placebo 4.6%). In a large U.S. multicenter trial with the same design, and including 658 patients with OAB, Rudy and coworkers (2006) confirmed the data by Zinner and associates (2004a), both with respect to efficacy and adverse effects. An extended-release formulation of trospium allowing once-daily dosing (60 mg) has been introduced and its effects tested in controlled trials (Staskin et al, 2007; Dmochowski et al, 2008). These RCTs demonstrated similar efficacy as found with previous formulations.

The most frequent side effects were dry mouth (12.9%; placebo 4.6%) and constipation (7.5%; placebo 1.8%) (Dmochowski et al, 2008).

Intravesical application of trospium may be an interesting alternative. Fröhlich and colleagues (1998) performed a randomized, single-blind, placebo-controlled, monocenter clinical trial in 84 patients with urgency or urgency incontinence. Compared with placebo, intravesical trospium produced a significant increase in maximum bladder capacity and a decrease of detrusor pressure accompanied by an increase of residual urine. There was an improvement in uninhibited bladder contractions. No adverse events were reported. Interestingly, intravesical trospium does not seem to be absorbed (Walter et al, 1999), thus offering an opportunity for treatment with minimal systemic antimuscarinic effects.

Trospium is a well-documented alternative for treatment of OAB/DO and seems to be well tolerated.

Tolterodine Tartrate. **Tolterodine is a tertiary amine, rapidly absorbed and extensively metabolized by the cytochrome P450 system (CYP2D6). The major active 5-hydroxymethyl metabolite (5-HMT) has a similar pharmacologic profile as the mother compound** (Nilvebrant et al, 1997b) **and significantly contributes to the therapeutic effect of tolterodine** (Brynne et al, 1997, 1998). Both tolterodine and 5-HMT have plasma half-lives of 2 to 3 hours, but the effects on the bladder seem to be more long lasting than could be expected from the pharmacokinetic data. Urinary excretion of tolterodine accounted for less than 1.0% to 2.4% of the dose; 5% to 14% of 5-HMT is eliminated in the urine (Brynne et al, 1997). Whether the total antimuscarinic activity of unchanged tolterodine and 5-HMT excreted in urine is sufficient to exert any effect on the mucosal signaling mechanisms has not been established. However, the preliminary studies by Kim and coworkers (2006) and Chuang and colleagues (2008) do not support such an effect. The relatively low lipophilicity of tolterodine and even lesser one of 5-HMT implies **limited propensity to penetrate into the CNS,** which may explain a low incidence of cognitive side effects (Hills et al, 1998; Clemett et al, 2001; Salvatore et al, 2008). However, tolterodine may disturb sleep in subjects unable to form the even less lipophilic 5-HMT due to a low activity of CYP2D6 (Diefenbach et al, 2008).

Tolterodine has **no selectivity for muscarinic receptor subtypes** but is claimed to have functional selectivity for the bladder over the salivary glands (Stahl et al, 1995; Nilvebrant et al, 1996, 1997a, 1997c). In healthy volunteers, orally given tolterodine in a high dose (6.4 mg) had a powerful inhibitory effect on micturition and also reduced stimulated salivation 1 hour after administration of the drug (Stahl et al, 1995); however, 5 hours after administration, the effects on the urinary bladder were maintained whereas no significant effects on salivation could be demonstrated. Tolterodine is available as immediate-release (TOLT-IR; 1 or 2 mg; twice-daily dosing) and extended-release (TOLT-ER) forms (2 or 4 mg; once-daily dosing). The ER form seems to have advantages over the IR form in terms of both efficacy and tolerability (Van Kerrebroeck et al, 2001).

Several randomized, double-blind, placebo-controlled studies on patients with OAB/DO (both idiopathic and neurogenic DO) have documented a significant reduction in micturition frequency and number of incontinence episodes (Hills et al, 1998; Clemett et al, 2001; Salvatore et al, 2008). Comparative RCTs such as the OBJECT (Overactive Bladder: Judging Effective Control and Treatment) and the OPERA (Overactive Bladder; Performance of Extended Release Agents) studies have further supported its effectiveness. The OBJECT trial compared oxybutynin ER (OXY-ER) 10 mg once daily with TOLT-IR 2 mg twice daily (Appell et al, 2001) in a 12-week randomized, double-blind, parallel-group study including 378 patients with OAB. Participants had between 7 and 50 episodes of urgency incontinence per week and 10 or more voids in 24 hours. The outcome measures were the number of episodes of urgency incontinence, total incontinence, and micturition frequency at 12 weeks adjusted for baseline. At the end of the study, OXY-ER was found to be significantly more effective than TOLT-IR in each of the main outcome measures adjusted for baseline (see also later discussion on oxybutynin chloride). Dry mouth, the most common adverse event, was reported by 28% and 33% of participants taking OXY-ER and TOLT-IR, respectively. Rates of CNS and other adverse events were low and similar in both groups. The authors concluded that OXY-ER was more effective than TOLT-IR and that the rates of dry mouth and other adverse events were similar in both treatment groups. In the OPERA study (Diokno et al, 2003), OXY-ER at 10 mg/day or TOLT-ER at 4 mg/day was given for 12 weeks to women with 21 to 60 urgency incontinence episodes per week and an average of 10 or more voids per 24 hours. Episodes of incontinence episodes (primary end point), total (urgency and nonurgency) incontinence, and micturition were recorded in seven 24-hour urinary diaries at baseline and at weeks 2, 4, 8, and 12 and compared. Adverse events were also evaluated. Improvements in weekly urgency incontinence episodes were similar for the 790 women who received OXY-ER (n = 391) or TOLT-ER (n = 399). OXY-ER was significantly more effective than TOLT-ER in reducing micturition frequency, and 23.0% of women taking OXY-ER reported no episodes of urinary incontinence compared with 16.8% of women taking TOLT-ER. Dry mouth (usually mild) was more common with OXY-ER. Adverse events were generally mild and occurred at low rates, with both groups having similar discontinuation of treatment due to adverse events. The conclusions were that reductions in weekly urgency incontinence and total incontinence episodes were similar with the two drugs. Dry mouth was more common with OXY-ER, but tolerability was otherwise comparable, including adverse events involving the CNS.

In the ACET (Antimuscarinic Clinical Effectiveness Trial) (Sussman and Garely, 2002) study, which consisted of two trials, patients with OAB were randomized to 8 weeks of open-label treatment with either 2 mg or 4 mg of once-daily TOLT-ER (study 1) and to 5 mg or 10 mg of OXY-ER (study 2). A total of 1289 patients were included. Fewer patients prematurely withdrew from the trial

in the TOLT-ER 4-mg group (12%) than either the OXY-ER 5-mg (19%) or OXY-ER 10-mg groups (21%). More patients in the OXY-ER 10-mg group than the TOLT-ER 4-mg group withdrew because of poor tolerability (13% vs. 6%). After 8 weeks, 70% of patients in the TOLT-ER 4-mg group perceived an improved bladder condition, compared with 60% in the TOLT-ER 2-mg group, 59% in the OXY-ER 5-mg group and 60% in the OXY-ER 10-mg group. Dry mouth was dose dependent with both agents, although differences between doses reached statistical significance only in the oxybutynin trial (OXY-ER 5 mg vs. OXY-ER 10 mg; $P = .05$). Patients treated with TOLT-ER 4 mg reported a significantly lower severity of dry mouth compared with OXY-ER 10 mg. The conclusion that the findings suggest improved clinical efficacy of TOLT-ER (4 mg) over OXY-ER (10 mg) is weakened by the open-label design of the study.

Zinner and associates (2002) evaluated the efficacy, safety, and tolerability of TOLT-ER in older (≥65) and younger (<65) OAB patients in a 12-week RCT including 1015 patients with urgency incontinence and urinary frequency. Patients were randomized to treatment with TOLT-ER 4 mg once daily (n = 507) or placebo (n = 508) for 12 weeks. Efficacy, measured with micturition charts (incontinence episodes, micturitions, volume voided per micturition) and subjective patient assessments, safety, and tolerability end points were evaluated, relative to placebo. Compared with placebo, significant improvements in micturition chart variables with TOLT-ER showed no age-related differences. Dry mouth (of any severity) was the most common adverse event in both the TOLT-ER and placebo treatment study arms, irrespective of age (<65: TOLT-ER 22.7%, placebo 8.1%; ≥65: TOLT-ER 24.3%, placebo 7.2%). A few patients (<2%) experienced severe dry mouth. No CNS (cognitive functions were not specifically studied), visual, cardiac (per electrocardiogram), or laboratory safety concerns were noted in this study. Withdrawal rates due to adverse events on TOLT-ER 4 mg once daily were comparable in the two age cohorts (<65: 5.5%; ≥65: 5.1%).

The central symptom in the OAB syndrome is urgency. Freeman and coworkers (2003) presented a secondary analysis of a double-blind, placebo-controlled study evaluating the effect of once-daily TOLT-ER on urinary urgency in patients with OAB. Patients with urinary frequency (eight or more micturitions per 24 hours) and urgency incontinence (five or more episodes per week) were randomized to oral treatment with TOLT-ER 4 mg once daily (n = 398) or placebo (n = 374) for 12 weeks. Efficacy was assessed by use of patient perception evaluations. Of patients treated with TOLT-ER, 44% reported improved urgency symptoms (compared with 32% for placebo) and 62% reported improved bladder symptoms (placebo, 48%). The proportion of patients unable to hold urine on experiencing urgency was decreased by 58% with TOLT-ER, compared with 32% with placebo ($P < .001$). In the IMprovement in Patients: Assessing symptomatic Control with Tolterodine ER (IMPACT) study (Elinoff et al, 2006), the efficacy of TOLT-ER for patients' most bothersome OAB symptom was investigated in an open-label, primary care setting. Patients with OAB symptoms for more than 3 months received TOLT-ER (4 mg once daily) for 12 weeks. By week 12 there were significant reductions in the patients' most bothersome symptom—incontinence—urgency episodes, and nocturnal and daytime frequency. The most common adverse events were dry mouth (10%) and constipation (4%), and it was concluded that, in primary care practice, bothersome OAB symptoms can be effectively and safely treated with TOLT-ER, even in patients with comorbid conditions.

Various aspects of the efficacy and tolerability of tolterodine have been further documented in a number of RCTs (Dmochowski et al, 2007a, 2007b; Barucha et al, 2008; Choo et al, 2008; Coyne et al, 2008; Rogers et al, 2008; Rovner et al, 2008b; for further discussion see Chapple et al, 2008b; Novara et al, 2008). Importantly, the QTc effects of tolterodine were determined in a crossover-designed QT study of recommended (2 mg twice daily) and supratherapeutic (4 mg twice daily) doses of tolterodine, moxifloxacin (400 mg once daily), and placebo. No subject receiving tolterodine exceeded the clinically relevant thresholds of 500 msec absolute QTc or 60 msec change from baseline, and it was concluded that tolterodine does not have a clinically significant effect on QT interval (Malhotra et al, 2007). Olshansky and colleagues (2008) compared, in a randomized, placebo-controlled, double blind crossover study, the effects on heart rate of TOLT-ER 4 mg/day with those of darifenacin 15 mg/day and placebo in 162 healthy volunteers. They found that tolterodine, but not darifenacin and placebo, significantly increased mean heart rate per 24 hours. The treatment difference in adjusted mean change from baseline was +1.84 beats per minute ($P = .0004$) for tolterodine versus darifenacin and +1.42 beats per minute ($P < .001$) for tolterodine versus placebo. The proportion of subjects with an increase greater than 5 beats per minute was significantly greater in those receiving TOLT-ER (1 of 4) than with darifenacin (1 of 10). The clinical significance of this has yet to be established.

In a prospective, open study, Song and associates (2006) compared the effects of bladder training and/or tolterodine as first-line treatment in female patients with OAB. One hundred and thirty-nine female patients with OAB were randomized to treatment with bladder training, tolterodine (2 mg twice daily), or both for 12 weeks. All treatments were efficacious; however, combination therapy was the most effective. Mattiasson and colleagues (2003) compared the efficacy of tolterodine 2 mg twice daily plus simplified bladder training with tolterodine alone in patients with OAB in a multicenter single-blind study. At the end of the study the median percentage reduction in voiding frequency was greater with tolterodine plus bladder training than with tolterodine alone (33% vs. 25%; $P < .001$), whereas the median percentage increase in volume voided per void was 31% with tolterodine plus bladder training and 20% with tolterodine alone ($P < .001$). There was a median of 81% fewer incontinence episodes than at baseline with tolterodine alone, which was not significantly different from that with tolterodine plus bladder training (–87%). It was concluded that the effectiveness of tolterodine 2 mg twice daily can be augmented by a simplified bladder training regimen. However, Millard and colleagues (2004) investigated whether the combination of tolterodine plus a simple pelvic floor muscle exercise program would provide improved treatment benefits compared with tolterodine alone in 480 patients with OAB. Tolterodine therapy for 24 weeks resulted in significant improvement in urgency, frequency, and incontinence; however, no additional benefit was demonstrated for a simple pelvic floor muscle exercise program.

The beneficial effect of TOLT-ER in men with benign prostatic enlargement and LUTS, including OAB, has been well documented. Both as monotherapy, but particularly in combination with an α-adrenergic receptor (AR) antagonist, TOLT-ER was found effective (Kaplan et al, 2006; Höfner et al, 2007; Kaplan et al, 2008a; 2008b; Roehrborn et al, 2009; Rovner et al, 2008a). This effect was obtained irrespective of prostate size and was not associated with increased incidence of acute urinary retention (Roehrborn et al, 2009).

Tolterodine, in both the immediate- and extended-release forms, has a well-documented effect in OAB/DO.

Darifenacin Hydrobromide. Darifenacin is a tertiary amine with moderate lipophilicity, well absorbed from the

gastrointestinal tract after oral administration, and extensively metabolized in the liver by the cytochrome P450 isoforms CYP3A4 and CYP2D6, the latter saturating within the therapeutic range (Skerjanec 2006). UK-148,993, UK-73,689, and UK-88862 are the three main circulating darifenacin metabolites, of which only UK-148,993 is said to have significant antimuscarinic activity. However, available information suggests that various metabolites of darifenacin contribute little to its clinical effects (Michel and Hegde, 2006). The metabolism of darifenacin by CYP3A4 suggests that coadministration of a potent inhibitor of this enzyme (e.g., ketoconazole) may lead to an increase in the circulating concentration of darifenacin (Kerbusch et al, 2003). **Darifenacin is a relatively selective muscarinic M_3 receptor antagonist.** In vitro, it is selective for human cloned muscarinic M_3 receptors relative to M_1, M_2, M_4, or M_5 receptors. Theoretically, drugs with selectivity for the M_3 receptor can be expected to have clinical efficacy in OAB/DO with reduction of the adverse events related to the blockade of other muscarinic receptor subtypes (Andersson, 2002b). However, the clinical efficacy and adverse effects of a drug are dependent not only on its profile of receptor affinity but also on its pharmacokinetics and on the importance of muscarinic receptors for a given organ function.

Darifenacin has been developed as a controlled-release formulation, which allows once-daily dosing. Recommended dosages are 7.5 and 15 mg/day. The clinical effectiveness of the drug has been documented in several RCTs (Haab et al, 2004; Cardozo and Dixon 2005; Chapple et al, 2005, 2007a; Foote et al, 2005; Steers et al, 2005; Haab et al, 2006; Hill et al, 2006; Zinner et al, 2006; Abrams et al, 2008, Chancellor et al, 2008b; Dwyer et al, 2008; for reviews, see Guay, 2005; Zinner, 2007; Chapple et al, 2008; Novara et al, 2008). Haab and coworkers (2004) reported a multicenter, double-blind, placebo-controlled, parallel-group study that enrolled 561 patients (age 19 to 88; 85% female) with OAB symptoms for more than 6 months and included some patients with prior exposure to antimuscarinic agents. After washout and a 2-week placebo run-in, patients were randomized (1:4:2:3) to once-daily oral darifenacin controlled-release tablets: 3.75 mg (n = 53), 7.5 mg (n = 229) or 15 mg (n = 115) or matching placebo (n = 164) for 12 weeks. Patients recorded daily incontinence episodes, micturition frequency, bladder capacity (mean volume voided), frequency of urgency, severity of urgency, incontinence episodes resulting in change of clothing or pads, and nocturnal awakenings due to OAB using an electronic diary during weeks 2, 6, and 12 (directly preceding clinic visits). Tolerability data were evaluated from adverse event reports. Darifenacin 7.5 mg and 15 mg had a rapid onset of effect, with significant improvement compared with placebo being seen for most parameters at the first clinic visit (week 2). Darifenacin 7.5 mg and 15 mg were significantly superior to placebo for (median) improvements in micturition frequency (7.5 mg: –1.6; 15 mg: –1.7; placebo –0.8), frequency of urgency per day (–2.0; –2.0; –0.9), and number of incontinence episodes leading to a change in clothing or pads (–4.0; –4.7; –2.0). There was no significant reduction in nocturnal awakenings due to OAB. The most common adverse events were mild-to-moderate dry mouth and constipation with a CNS and cardiac safety profile comparable to that of placebo. No patients withdrew from the study as a result of dry mouth, and discontinuation related to constipation was rare (0.6% placebo vs. 0.9% darifenacin).

In a dose titration study on 395 OAB patients, darifenacin, allowing individualized dosing (7.5 or 15 mg), was found to be effective and well tolerated (Steers et al, 2005). A 2-year open-label extension study of these investigations (i.e., Haab et al, 2004; Steers et al, 2005) confirmed a favorable efficacy tolerability and safety profile (Haab et al, 2006). A review of the pooled darifenacin data from the three phase 3, multicenter, double-blind clinical trials in patients with OAB was reported by Chapple and coworkers (2005). After a 4-week washout/run-in period, 1059 adults (85% female) with symptoms of OAB (urgency incontinence, urgency and frequency) for at least 6 months were randomized to once-daily oral treatment with darifenacin: 7.5 mg (n = 337) or 15 mg (n = 334) or matching placebo (n = 388) for 12 weeks. Efficacy was evaluated using electronic patient diaries that recorded incontinence episodes (including those resulting in a change of clothing or pads), frequency and severity of urgency, micturition frequency, and bladder capacity (volume voided). Safety was evaluated by analysis of treatment-related adverse events, withdrawal rates, and laboratory tests. Relative to baseline, 12 weeks of treatment with darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week: 7.5 mg, –8.8 (–68.4%; placebo –54%, $P < .004$); 15 mg, –10.6 (–76.8%; placebo 58%, $P < .001$). Significant decreases in the frequency and severity of urgency, micturition frequency, and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although together these resulted in few discontinuations (7.5 mg, 0.6% of patients; 15 mg, 2.1%; placebo, 0.3%). The incidence of CNS and cardiovascular adverse events was comparable to that of placebo. The results were confirmed in other RCTs, including also a pooled analysis of three phase 3 studies in older patients (>65 years), showing that darifenacin (7.5 and 15 mg) had an excellent efficacy, tolerability, and safety profile (Foote et al, 2005; Zinner et al, 2005; Hill et al, 2006).

One of the most noticeable clinical effects of antimuscarinic agents is their ability to reduce urgency and allow patients to postpone micturition. A study was conducted to assess the effect of darifenacin on the "warning time" associated with urinary urgency. This was a multicenter, randomized, double-blind, placebo-controlled study consisting of 2 weeks' washout, 2 weeks' medication-free run-in, and a 2-week treatment phase (Cardozo and Dixon, 2005). Warning time was defined as the time from the first sensation of urgency to voluntary micturition or incontinence and was recorded via an electronic event recorder at baseline (visit 3) and study end (visit 4) during a 6-hour clinic-based monitoring period, with the subject instructed to delay micturition for as long as possible. During each monitoring period, up to three urgency-void cycles were recorded. Of the 72 subjects who entered the study, 67 had warning time data recorded at both baseline and study end and were included in the primary efficacy analysis (32 on darifenacin, 35 on placebo). Darifenacin treatment resulted in a significant ($P < .004$) increase in mean warning time with a median increase of 4.3 minutes compared with placebo (darifenacin group, from 4.4 to 1.8 minutes; placebo, from 7.0 to –1.0 minute). Overall, 47% of darifenacin-treated subjects compared with 20% receiving placebo achieved a 30% or more increase in mean warning time. There were methodologic problems associated with this study; it utilized a dose of 30 mg (higher than the dose recommended for clinical use), the treatment period was short, it was conducted in a clinic-centered environment, the methodology carried with it a significant potential training effect, and the placebo group had higher baseline values than the treatment group. In another warning time study (Zinner et al, 2006) with 445 OAB patients, darifenacin treatment (15 mg) resulted in

numerical increases in warning time; however, these were not significant compared with placebo.

Further studies have demonstrated that darifenacin treatment is associated with clinically relevant improvements on health-related quality of life in patients with OAB (Abrams et al, 2008), and such improvements were sustained as shown in a 2-year extension study (Dwyer et al, 2008). It was shown that the positive effects neither on micturition variables nor on health-related quality of life produced by darifenacin (7.5 and 15 mg) were further enhanced by a behavioral modification program including timed voiding, dietary modifications, and Kegel exercises (Chancellor et al, 2008b). Several studies have been devoted to study possible effect on cognition by darifenacin. Neither in healthy volunteers (19 to 44 years) and healthy subjects (>60 years) nor in volunteers 65 years or older could any effect of darifenacin (3.75 to 15 mg/day) be demonstrated compared with placebo (Kay and Wesnes, 2005; Lipton et al, 2005; Kay et al, 2006; Kay and Ebinger, 2008).

To study whether darifenacin had any effect on QT/QTc intervals, Serra and associates (2005) performed a 7-day, randomized, parallel-group study (n = 188) in healthy volunteers receiving once-daily darifenacin at steady-state therapeutic (15 mg) and supratherapeutic (75 mg) doses alongside control subjects receiving placebo or moxifloxacin (positive control, 400 mg) once daily. No significant increase in QTcF interval could be demonstrated compared with placebo. Mean changes from baseline at pharmacokinetic Tmax versus placebo were –0.4 and –2.2 msec in the darifenacin 15-mg and 75-mg groups, respectively, compared with +11.6 msec in the moxifloxacin group ($P < .01$). The conclusion was that darifenacin does not prolong the QT/QTc interval. Darifenacin 15 mg/day given to healthy volunteers did not change heart rate significantly compared with placebo (Olshansky et al, 2008).

Darifenacin has a well-documented effect in OAB/DO, and the adverse event profile seems acceptable.

Solifenacin Succinate. **Solifenacin is a tertiary amine and well absorbed from the gastrointestinal tract (absolute bioavailability 90%).** The mean terminal half-life is 45 to 68 hours (Kuipers et al, 2004; Smulders et al, 2004). **It undergoes hepatic metabolism involving the cytochrome P450 enzyme system (CYP3A4).** In subjects who received a single oral dose of 10 mg solifenacin on day 7 of a 20-day regimen of ketoconazole administration (200 mg) Cmax and AUC0-inf were increased by only approximately 40% and 56%, respectively (Swart et al, 2006). **Solifenacin has a modest selectivity for M_3 over M_2 receptors and a marginal selectivity over M_1 receptors** (Ikeda et al, 2002; Abrams and Andersson, 2007).

Two large-scale phase 2 trials with parallel designs, comprising men and women, were performed (Smith et al, 2002; Chapple et al, 2004a). The first dose-ranging study evaluated solifenacin (2.5 mg, 5 mg, 10 mg, and 20 mg) and tolterodine (2 mg twice daily) in a multinational placebo-controlled study of 225 patients with urodynamically confirmed DO (Chapple et al, 2004a). Patients received treatment for 4 weeks followed by 2 weeks of follow-up. Inclusion criteria for this and subsequent phase 3 studies of patients with OAB included at least eight micturitions per 24 hours and either one episode of incontinence or one episode of urgency daily as recorded in 3-day micturition diaries. Micturition frequency, the primary efficacy variable, was statistically significantly reduced in patients taking solifenacin 5 mg (–2.21), 10 mg (–2.47), and 20 mg (–2.75) but not in patients receiving placebo (–1.03) or tolterodine (–1.79). This effect was rapid, with most of the effect observed at the earliest assessment visit, 2 weeks after treatment initiation. In addition there were numerically greater reductions in episodes of urgency and incontinence when compared with placebo. Study discontinuations due to adverse events were similar across treatment groups, albeit highest in the 20-mg solifenacin group. Because the 5-mg and 10-mg doses caused lower rates of dry mouth than tolterodine, and superior efficacy outcomes relative to placebo, these dosing strengths were selected for further evaluation in large-scale phase 3 studies. The second dose-ranging study of solifenacin 2.5 mg to 20 mg was carried out in the United States (Smith et al, 2002). This trial included 261 evaluable men and women receiving solifenacin or placebo for 4 weeks followed by a 2-week follow-up period. Micturition frequency was statistically significantly reduced relative to placebo in patients receiving 10 mg and 20 mg solifenacin. The number of micturitions per 24 hours showed reductions by day 7 and continued to decrease through day 28; day 7 was the earliest time point tested. Efficacy was demonstrated at this time. The 5-mg, 10-mg, and 20-mg dosing groups experienced significant increases in volume voided; the 10-mg solifenacin dose was associated with significant reductions in episodes of incontinence.

In one of the early RCTs, a total of 1077 patients were randomized to 5 mg solifenacin, 10 mg solifenacin, tolterodine (2 mg twice daily), or placebo (Chapple et al, 2004b). This study was powered only to compare active treatments to placebo. Compared with placebo (–8%), mean micturitions per 24 hours were significantly reduced with solifenacin 10 mg (20%), solifenacin 5 mg (17%), and tolterodine (15%). Solifenacin was well tolerated, with few patients discontinuing treatment. Incidences of dry mouth were 4.9% with placebo, 14.0% with solifenacin 5 mg, 21.3% with solifenacin 10 mg, and 18.6% with tolterodine 2 mg given twice daily.

Cardozo and colleagues (2004b) randomized 911 patients to 12-week once-daily treatment with solifenacin 5 mg, solifenacin 10 mg, or placebo. The primary efficacy variable was change from baseline to study end point in mean number of micturitions per 24 hours. Secondary efficacy variables included changes from baseline in mean number of urgency, nocturia, and incontinence episodes per 24 hours and mean volume voided per micturition. Compared with changes obtained with placebo (–1.6), the number of micturitions per 24 hours was statistically significantly decreased with solifenacin 5 mg (–2.37) and 10 mg (–2.81). A statistically significant decrease was observed in the number of all incontinence episodes with both solifenacin doses (5 mg: –1.63, 61%; 10 mg: –1.57, 52%), but not with placebo (–1.25, 28%). Of patients reporting incontinence at baseline, 50% achieved continence after treatment with solifenacin (based on a 3-day micturition diary); placebo responses were not given. Episodes of nocturia were statistically significantly decreased in patients treated with solifenacin 10 mg versus placebo. Episodes of urgency and mean volume voided per micturition were statistically significantly reduced with solifenacin 5 mg and 10 mg. Treatment with solifenacin was well tolerated. Dry mouth, mostly mild in severity, was reported in 7.7% of patients receiving solifenacin 5 mg and 23% receiving solifenacin 10 mg (vs. 2.3% with placebo). A 40-week follow-up of these studies (i.e., Chapple et al, 2004b and Cardozo et al, 2004b) demonstrated that the favorable profile, both in terms of efficacy and tolerability, was maintained over the study period (Haab et al, 2005).

The STAR trial (Chapple et al, 2005, 2007b) was a prospective, double-blind, double-dummy, two-arm, parallel-group, 12-week study conducted to compare the efficacy and safety of solifenacin 5 or 10 mg and TOLT-ER 4 mg once daily in patients with OAB.

The primary effect variable was micturition frequency. After 4 weeks of treatment, patients had the option to request a dose increase but were dummied throughout, because approved product labeling only allowed an increase for those on solifenacin. The results showed that solifenacin, with a flexible dosing regimen, was "non-inferior" to tolterodine concerning the primary effect variable of micturition frequency. However, solifenacin showed significantly greater efficacy to tolterodine in decreasing urgency episodes (–2.85 vs. –2.42), incontinence (–1.60 vs. –0.83), urgency incontinence (–1.42 vs. –0.83), and pad usage (–1.72 vs. –1.19). More solifenacin-treated patients became continent by study end point (59% vs. 49%) and reported improvements in perception of bladder condition (1.51 vs. –1.33) assessments. However, this was accompanied by an adverse event incidence that was greater with solifenacin than with tolterodine. Dry mouth and constipation (mild + moderate + severe) were the most common (solifenacin 30% and 6.4%, tolterodine 23% and 2.5%). The majority of side effects were mild to moderate, and discontinuations were comparable and low (5.9 and 7.3%) in both groups.

A number of studies and reviews have further documented the effects of solifenacin (Cardozo et al, 2006; Chapple et al, 2006a, 2007b; Maniscalco et al, 2006; for further discussion see also Chapple et al, 2008; Novara et al, 2008). In a pooled analysis of four RCTs, Abrams and Swift (2005) demonstrated positive effects on urgency, frequency, and nocturia symptoms in OAB dry patients. In an analysis of four phase 3 clinical trials, Brubaker and FitzGerald (2007) confirmed a significant effect of solifenacin 5 and 10 mg on nocturia in patients with OAB (reductions of nocturia episodes with 5 mg: –0.6, $P < .025$; with 10 mg: –0.6, $P < .001$ vs. placebo: –0.4) but without nocturnal polyuria. Kelleher and colleagues (2006) and Staskin and Te (2006) presented data showing efficacy in patients with mixed incontinence. A pooled analysis of four studies confirmed the efficacy and tolerability of solifenacin 5 and 10 mg in elderly (>65 years) patients and also showed a high level of persistence in a 40-week extension trial (Wagg et al, 2006). Improvement of quality of life by solifenacin treatment has been documented in several studies (Kelleher et al, 2005; Garely et al, 2006). In female volunteers, aged 19 to 79 years, the effect of 10 mg and 30 mg solifenacin on the QT interval was evaluated at the time of peak solifenacin plasma concentration in a multiple-dose, randomized, double-blind, placebo- and positive-controlled (moxifloxacin 400 mg) trial. The QT interval prolonging effect appeared greater for the 30 mg (8 msec, 4, 13: 90% confidence interval [CI]) compared with the 10 mg (2 msec, –3, 6) dose of solifenacin. Although the effect of the highest solifenacin dose (three times the maximum therapeutic dose) studied did not appear as large as that of the positive control moxifloxacin at its therapeutic dose, the confidence intervals overlapped. This study was not designed to draw direct statistical conclusions between the drugs or the dose levels.

Michel and colleagues (2008) studied cardiovascular safety and overall tolerability of solifenacin in routine clinical use in a 12-week, open-label, post-marketing surveillance study. They concluded that "in real-life conditions, that is, with inclusion of large numbers of patients with cardiovascular comorbidities and taking comedications, therapeutically effective doses of solifenacin did not increase heart rate or blood pressure."

Solifenacin has a well-documented effect in OAB/DO, and the adverse event profile seems acceptable.

Fesoterodine Fumarate. **Fesoterodine functions as an orally active prodrug that is converted to the active metabolite 5-hydroxymethyltolterodine (5-HMT) by nonspecific esterases** (Michel, 2008; McKeage and Keating, 2009). **This compound, which is chemically identical to the 5-hydroxy metabolite of tolterodine, is** (like fesoterodine itself) **a non-subtype selective muscarinic receptor antagonist** (Ney et al, 2008). **All of the effects of fesoterodine in humans are thought to be mediated via 5-HMT,** because the parent compound remains undetectable on oral dosing. **5-HMT is metabolized in the liver, but a significant part of 5-HMT is excreted renally without additional metabolism.** Because the renal clearance of 5-HMT is about 250 mL/min, with more than 15% of the administered fesoterodine dose excreted as unchanged 5-HMT, this raises the possibility that 5-HMT also could work from the luminal side of the bladder (Michel, 2008).

Fesoterodine is indicated for use at doses of 4 and 8 mg once daily. In clinical studies, both doses of fesoterodine were consistently superior to placebo in improving the symptoms of OAB (Chapple et al, 2007c, 2008b; Nitti et al, 2007; McKeage and Keating, 2009), with 8 mg/day having significantly greater effects than 4 mg/day (Khullar et al, 2008). Analysis of pooled data on quality of life, using King's Health Questionnaire and ICI Questionnaire-Short Form, showed that both doses of the drug caused a significant improvement in quality of life. Compared with TOLT-ER (4 mg), fesoterodine (8 mg) had statistically significant advantages for improving incontinence episodes, severe urgency with incontinence, mean voided volumes, and number of continent days a week (Chapple et al, 2008b; Khullar et al, 2008). Adverse events were characteristic for an antimuscarinic drug, with dry mouth being the most frequently reported and rated as mild to moderate in most cases. In one phase 3 study it was seen in 7%, 16%, and 36% of patients receiving placebo and 4 and 8 mg/day fesoterodine, respectively (Nitti et al, 2007), whereas in the another phase 3 study the findings were 7.1%, 21.7%, and 33.8% in the same groups (16.9% for 4 mg/day TOLT-ER) (Chapple et al, 2007c). Kelleher and colleagues (2008) evaluated the effect of fesoterodine on health-related quality of life in patients with OAB syndrome. Pooled data from two randomized placebo-controlled phase 3 studies were analyzed. Eligible patients were randomized to placebo or fesoterodine 4 or 8 mg for 12 weeks; one trial also included TOLT-ER 4 mg. By the end of treatment, all active-treatment groups had significantly improved health-related quality of life compared with those on placebo. A study on possible effects on QT intervals has been performed (Michel, 2008). This included parallel groups of 64 to 68 subjects each who were treated for 3 days with 4 mg/day fesoterodine, the highly supratherapeutic dose of 28 mg/day fesoterodine, the active control moxifloxacin 400 mg/day, or placebo. Both the standard dose of 4 mg/day and the highly supratherapeutic dose of 28 mg/day did not provide any evidence of QT interval prolongation (e.g., QTc for 28 mg/day from 404.5 ± 16.7 to 400.1 ± 14.0 msec, delta: –5.0 ± 7.9 msec).

Fesoterodine has a well-documented beneficial effect in OAB (see Table 68–2), **and the adverse event profile seems acceptable.**

Drugs Acting at Membrane Channels

Calcium Antagonists. **Activation of detrusor muscle, both through muscarinic receptor and nonadrenergic, noncholinergic pathways, seems to require influx of extracellular Ca^{2+} through Ca^{2+} channels, as well as via mobilization of intracellular Ca^{2+}** (Andersson, 1993; Andersson and Arner, 2004). **The influx of extracellular Ca^{2+} can be blocked by Ca^{2+} antagonists, blocking L-type Ca^{2+} channels;** and, theoretically, this would be an attractive way of inhibiting DO. However, there have been few clinical studies of the effects of Ca^{2+} antagonists in patients with DO and the ones

that have been done suggest no beneficial effect. For example, Naglie and coworkers (2002) evaluated the efficacy of nimodipine for geriatric urgency incontinence in a randomized, double-blind, placebo-controlled crossover trial. Thirty milligrams of nimodipine was given twice daily for 3 weeks in older persons with DO and chronic urgency incontinence. A total of 86 participants with a mean age of 73.4 years were randomized. The primary outcome was the number of incontinent episodes, as measured by the self-completion of a 5-day voiding record. Secondary outcomes included the impact of urinary incontinence on quality of life measured with a modified incontinence impact questionnaire and symptoms, as measured by the American Urological Association (AUA) symptom score. In the 76 (88.4%) participants completing the study there was no significant difference in the number of incontinent episodes with nimodipine versus placebo. Scores on the incontinence impact questionnaire and the AUA symptom score were not significantly different with nimodipine versus placebo, and the authors concluded that treatment of geriatric urgency incontinence with 30 mg nimodipine twice daily was unsuccessful.

Available information does not suggest that systemic therapy with Ca^{2+} antagonists is an effective way to treat OAB/DO.

Potassium Channel Openers. **Opening of K^+ channels and subsequent efflux of K^+ will produce hyperpolarization of various smooth muscles, including the detrusor** (Andersson, 1992; Andersson and Arner, 2004). **This leads to a decrease in Ca^{2+} influx by reducing the opening probability of Ca^{2+} channels with subsequent relaxation or inhibition of contraction.** Theoretically, such drugs could be active during the filling phase of the bladder, abolishing bladder overactivity with no effect on normal bladder contraction. The K^+ channel openers, such as pinacidil and cromakalim, have been effective in animal models (Andersson, 1992; Andersson and Arner, 2004), but clinically the effects have not been encouraging. The first generation of openers of ATP-sensitive K^+ channels, such as cromakalim and pinacidil, were found to be more potent as inhibitors of vascular preparations than of detrusor muscle, and in clinical trials performed with these drugs no bladder effects have been found at doses already lowering blood pressure (Hedlund et al, 1991; Komersova et al, 1995). However, new drugs with K^+ ATP-sensitive channel opening properties have been described, which may be useful for the treatment of OAB (Andersson and Arner, 2004). Although K^+ channel openers are believed mainly to act directly on smooth muscle cells (Gopalakrishnan and Shieh, 2004), they may also at least in part affect bladder function by modulating the activity of afferent neurons (Tanaka et al, 2003).

Although the previous data demonstrate the potential of K^+ channel openers to inhibit nonvoiding detrusor contractions these channels are expressed not only in bladder but also, for example, in vascular smooth muscle. Therefore, K^+ channel openers **may also affect cardiovascular function** and in effective doses may considerably lower blood pressure (Howe et al, 1995; Shieh et al, 2007). Although some compounds of this class have a certain degree of selectivity for the bladder as compared with the cardiovascular system, it remains unclear whether the degree of selectivity offers a sufficiently large therapeutic window for clinical use. This consideration has led to a considerable hesitancy to study K^+ channel openers in patients with OAB. Nevertheless, one randomized, placebo-controlled clinical study on the K^+ ATP opener ZD0947 has been reported (Chapple et al, 2006b). Although ZD0947 at the chosen dose did not lower blood pressure or cause adverse events typical for a vasodilating drug, it failed to achieve superiority relative to placebo for the treatment of OAB symptoms. Therefore, **despite promising preclinical efficacy data, K^+ channel openers at present are not a therapeutic option and may never become one owing to a lack of selectivity for bladder over cardiovascular tissues.**

At present there is no evidence from RCTs to suggest that K^+ channel openers represent a treatment alternative.

Drugs with "Mixed" Actions

Some drugs used to block DO have been shown to have more than one mechanism of action. **They all have a more or less pronounced antimuscarinic effect and, in addition, an often poorly defined "direct" action on bladder muscle.** For several of these drugs the antimuscarinic effects can be demonstrated at much lower drug concentrations than the direct action, which may involve blockade of voltage-operated Ca^{2+} channels. **Most probably, the clinical effects of these drugs can be explained mainly by their antimuscarinic action.** Among the drugs with mixed actions was terodiline, which was withdrawn from the market because it was suspected to cause polymorphic ventricular tachycardia (torsades de pointes) in some patients (Connolly et al, 1991; Stewart et al, 1992).

Oxybutynin Chloride. **Oxybutynin is a tertiary amine that is well absorbed and undergoes extensive upper gastrointestinal and first-pass hepatic metabolism via the cytochrome P450 system (CYP3A4) into multiple metabolites. The primary metabolite, *N*-desethyloxybutynin (DEO), has pharmacologic properties similar to those of the parent compound** (Waldeck et al, 1997) **but occurs in much higher concentrations after oral administration** (Hughes et al, 1992). **It has been implicated as the major cause of the troublesome side effect of dry mouth** associated with the administration of oxybutynin. It seems reasonable to assume that the effect of oral oxybutynin to a large extent is exerted by the metabolite. The occurrence of an active metabolite may also explain the lack of correlation between plasma concentration of oxybutynin itself and side effects in geriatric patients reported by Ouslander and associates (1995). The plasma half-life of oxybutynin is approximately 2 hours, but with wide interindividual variation (Douchamps et al, 1988; Hughes et al, 1992).

Oxybutynin has several pharmacologic effects in vitro, some of which seem difficult to relate to its effectiveness in the treatment of DO. It has both an antimuscarinic and a direct muscle relaxant effect, and, in addition, local anesthetic actions. The latter effect may be of importance when the drug is administered intravesically but probably plays no role when it is given orally. In vitro, oxybutynin was **500 times weaker as a smooth muscle relaxant than as an antimuscarinic agent** (Kachur et al, 1988). Most probably, when given systemically, oxybutynin acts mainly as an antimuscarinic drug. Oxybutynin has a high affinity for muscarinic receptors in human bladder tissue and effectively blocks carbachol-induced contractions (Waldeck et al, 1997). The drug was shown to have **slightly higher affinity for muscarinic M_1 and M_3 receptors than for M_2 receptors** (Nilvebrant and Sparf, 1986; Norhona-Blob et al, 1991), **but the clinical significance of this is unclear.**

The immediate release (IR) form of oxybutynin (OXY-IR) is recognized for its efficacy, and most of the newer antimuscarinic agents have been compared with it once efficacy over placebo has been determined. In general, the new formulations of oxybutynin and other antimuscarinic agents offer patients efficacy roughly equivalent to that of OXY-IR and the advantage of the newer formulations lies in improved dosing schedules and side effect

profile (Appell et al, 2001; Dmochowski et al, 2002; Diokno et al, 2003). An extended-release oxybutynin (OXY-ER) once-daily oral formulation, an oxybutynin patch transdermal delivery system (OXY-TDS), and an oxybutynin gel are available. OXY-TDS offers a twice-weekly dosing regimen and the potential for improved patient compliance and tolerability. The gel requires once-daily application. Available formulations of oxybutynin were overviewed by McCrery and Appell (2006). Clinical use of the gel was first described by Staskin and coworkers (2009).

Immediate-Release Oxybutynin (OXY-IR). Several controlled studies have shown that OXY-IR is effective in controlling DO, including neurogenic DO (Yarker et al, 1995; Andersson and Chapple, 2001). The recommended oral dose of the IR form is 5 mg three times daily or four times daily, even if lower doses have been used. Thüroff and associates (1998) summarized 15 randomized controlled studies on a total of 476 patients treated with oxybutynin. The mean decrease in incontinence was recorded as 52%, and the mean reduction in frequency per 24 hours was 33% (data on placebo not presented). The overall "subjective improvement" rate was reported as 74% (range 61% to 100%). The mean percent of patients reporting an adverse effect was 70% (range 17% to 93%). Oxybutynin, 7.5 to 15 mg/day, significantly improved the quality of life of patients suffering from OAB in a large open multicenter trial. In this study, patient compliance was 97% and side effects, mainly dry mouth, were reported by only 8% (Amarenco et al, 1998). In nursing home residents (n = 75), Ouslander and colleagues (1995) found that oxybutynin did not add to the clinical effectiveness of prompted voiding in a placebo-controlled, double-blind, crossover trial. On the other hand, in another controlled trial in elderly subjects (n = 57), oxybutynin with bladder training was found to be superior to bladder training alone (Szonyi et al, 1995).

Several open studies in patients with spinal cord injuries have suggested that oxybutynin, given orally or intravesically, can be of therapeutic benefit (Kim et al, 1996; Szollar and Lee, 1996). The therapeutic effect of OXY-IR on DO is associated with a high incidence of side effects (up to 80% with oral administration). These are typically antimuscarinic in nature (dry mouth, constipation, drowsiness, blurred vision) and are often dose limiting (Baigrie et al, 1988; Jonville et al, 1992). The effects on the electrocardiogram of oxybutynin were studied in elderly patients with urinary incontinence (Hussain et al, 1996); no changes were found. It cannot be excluded that the commonly recommended dose of 5 mg three times a day is unnecessarily high in some patients and that a starting dose of 2.5 mg twice daily with following dose titration would reduce the number of adverse effects (Malone-Lee et al, 1992; Amarenco et al, 1998).

Extended-Release Oxybutynin (OXY-ER). This formulation was developed to decrease liver metabolite formation of desethyloxybutynin (DEO) with the presumption that it would result in decreased side effects, especially dry mouth, and improve patient compliance with remaining on oxybutynin therapy. The formulation utilizes an osmotic system to release the drug at a controlled rate over 24 hours distally primarily into the large intestine where absorption is not subject to first-pass metabolism in the liver. This reduction in metabolism is meant to improve the rate of dry mouth complaints when compared with OXY-IR. DEO is still formed through the hepatic cytochrome P450 enzymes, but clinical trials have indeed demonstrated improved dry mouth rates compared with OXY-IR (Appell et al, 2003). Salivary output studies have also been interesting. Two hours after administration of OXY-IR or TOLT-IR, salivary production decreased markedly and then gradually returned to normal. With OXY-ER, however, salivary output was maintained at predose levels throughout the day (Chancellor et al, 2001).

The effects of OXY-ER have been well documented (Siddiqui et al, 2004). In the OBJECT study (Appell et al, 2001) the efficacy and tolerability of 10 mg OXY-ER was compared with a twice-daily 2-mg dose of TOLT-IR. OXY-ER was statistically more effective than the TOLT-IR in weekly urgency incontinence episodes (OXY-ER from 25.6% to 6.1%; TOLT-IR 24.1% to 7.8%), total incontinence (OXY-ER from 28.6% to 7.1%; TOLT-IR 27.0% to 9.3%), and frequency (OXY-ER from 91.8% to 67.1%; TOLT-IR 91.6% to 71.5%), and both medications were equally well tolerated. The basic study was repeated as the OPERA study (Diokno et al, 2003) with the difference that this study was a direct comparison of the two extended-release forms, OXY-ER (10 mg) and TOLT-ER (4 mg); and the results were quite different. In this study there was no significant difference in efficacy for the primary end point of urgency incontinence; however, TOLT-ER had a statistically lower incidence of dry mouth. OXY-ER was only statistically better at 10 mg than TOLT-ER 4 mg in the reduction of the rate of urinary frequency. These studies made it clear that in comparative studies IR entities of one drug should not be compared with ER entities of the other. Greater reductions in urgency and total incontinence have been reported in patients treated in dose escalation studies with OXY-ER. In two randomized studies, the efficacy and tolerability of OXY-ER were compared with OXY-IR. In the 1999 study (Anderson et al, 1999), 105 patients with urgency or mixed incontinence were randomized to receive 5 to 30 mg OXY-ER once daily or 5 mg of OXY-IR one to four times a day. Dose titrations began at 5 mg, and the dose was increased every 4 to 7 days until one of three end points was achieved. These were (1) the patient reported no urgency incontinence during the final 2 days of the dosing period; (2) the maximum tolerable dose was reached; and (3) the maximum allowable dose (30 mg for OXY-ER or 20 mg for OXY-IR) was reached. The mean percentage reduction in weekly urgency and total incontinence episodes was statistically similar between OXY-ER and OXY-IR, but dry mouth was reported statistically more often with OXY-IR. In the 2000 study (Versi et al, 2000), 226 patients were randomized between OXY-ER and OXY-IR with weekly increments of 5 mg/day up to 20 mg/day. As in the 1999 study, OXY-ER again achieved a greater than 80% reduction in urgency and total incontinence episodes and a significant percentage of patients became dry. A negative aspect of these studies is that there were no naive patients included, as all patients were known responders to oxybutynin. Similar efficacy results have been achieved, however, with OXY-ER in a treatment-naive population (Gleason et al, 1999). In an RCT comparing different daily doses of oxybutynin (5, 10, and 15 mg), Corcos and colleagues (2006) found a significant dose-response relationship for both urgency incontinence episodes and dry mouth. The greatest satisfaction was with 15 mg oxybutynin/day.

Transdermal Oxybutynin (OXY-TDS). Transdermal delivery also alters oxybutynin metabolism reducing DEO production to an even greater extent than OXY-ER. A study (Davila et al, 2001) comparing OXY-TDS with OXY-IR demonstrated a statistically equivalent reduction in daily incontinence episodes (from 7.3 to 2.3: 66% for OXY-TDS, and 7.4 to 2.6: 72% for OXY-IR) but much less dry mouth (38% for OXY-TDS and 94% for OXY-IR). In another study (Dmochowski et al, 2002), the 3.9-mg daily dose patch significantly (vs. placebo) reduced the mean number of daily incontinence episodes (from 4.7 to 1.9; placebo from 5.0 to 2.9), while reducing average daily urinary frequency confirmed by an increased average voided volume (from 165 to 198 mL; placebo from 175 to 182 mL). Furthermore, the dry mouth rate was similar

to that of placebo (7% vs. 8.3%). In a third study (Dmochowski et al, 2003b), OXY-TDS was compared not only with placebo but also with TOLT-ER. Both drugs equivalently and significantly reduced daily incontinence episodes and increased the average voided volume, but TOLT-ER was associated with a significantly higher rate of antimuscarinic adverse events. **The primary adverse event for OXY-TDS was application site reaction pruritus in 14% and erythema in 8.3%** with nearly 9% feeling that the reactions were severe enough to withdraw from the study, despite the lack of systemic problems.

The pharmacokinetics and adverse effect dynamics of OXY-TDS (3.9 mg/day) and OXY-ER (10 mg/day) were compared in healthy subjects in a randomized, two-way crossover study (Appell et al, 2003). Multiple blood and saliva samples were collected, and pharmacokinetic parameters and total salivary output were assessed. OXY-TDS administration resulted in greater systemic availability and minimal metabolism to DEO compared with OXY-ER, which resulted in greater salivary output in OXY-TDS patients and less dry mouth symptomatology than when taking OXY-ER. Dmochowski and coworkers (2005) analyzing the combined results of two RCTs concluded that OXY-TDS was shown to be efficacious and well tolerated. The most common systemic side effect was dry mouth (7.0% vs. placebo 5.3%). Application-site erythema occurred in 7% and pruritus in 16.1%. Also Cartwright and Cardozo (2007), reviewing published and presented data, concluded that OXY-TDS has a good balance between efficacy and tolerability with a rate of systemic antimuscarinic side effects lower than that with oral antimuscarinic agents; however, this benefit was offset by the rate of local skin reaction. Sahai and associates (2008) largely confirmed these conclusions.

Oxybutynin Gel. Oxybutynin topical gel was introduced in 2009 as a transdermal formulation applied once daily to the abdomen, thigh, shoulder, or upper arm area (Staskin et al, 2009). The 1-g application dose delivers approximately 4 mg of drug to the circulation with stable plasma concentration. Staskin and associates (2009) reported a randomized controlled double-blind trial of patients (89% women) with urgency-predominant urinary incontinence. The mean number of urgency-predominant urinary incontinence episodes on a 3-day voiding diary was reduced by 3 episodes per day versus 2.5 in the placebo study arm ($P < .0001$). Urinary frequency was decreased by 2.7 episodes per day versus 2.0 episodes ($P = .0017$), and voided volume increased by 21 mL versus 3.8 mL ($P = .0018$). Dry mouth was reported in 6.9% of the treatment group versus 2.8% in the placebo group. Skin reaction at the application site occurred in 4.5% of the treatment group versus 1% in the placebo arm. It was believed that the **improved skin tolerability over the transdermal patch** system was secondary to a lack of adhesive and of skin occlusion. Person-to-person transference via skin contact is a risk but largely eliminated if clothing is worn over the application site.

Other Administration Forms. Rectal administration (Collas and Malone-Lee, 1997; Winkler and Sand, 1998) was reported to have fewer adverse effects than the conventional tablets. Administered intravesically, oxybutynin has in several studies been demonstrated to increase bladder capacity and produce clinical improvement with few side effects, both in neurogenic and in other types of DO, and both in children and adults (Weese et al, 1993; Lose and Norgaard, 2001; Fader et al, 2007; George et al, 2007; Guerra et al, 2008), although adverse effects may occur (Kasabian et al, 1994; Palmer et al, 1997). **Intravesical administration** of oxybutynin is a conceptually attractive form of drug delivery, especially for patients who already perform clean intermittent catheterization (CIC). However, a specific intravesical formulation is not available, and, currently, the oral formulation, either liquid or crushed tablet in solution, is delivered by periodic insertion through a catheter. There does appear to be some systemic absorption of oxybutynin placed intravesically. Plasma oxybutynin but not DEO levels were measured after intravesical and oral administration by Madersbacher and Jilg (1991). It is still not entirely clear what portion of the effects of the drug are due to local versus absorbed parent drug and primary metabolite. Certainly this is a circumstance in which the non-antimuscarinic actions of oxybutynin (see earlier) might be relevant.

Effects on Cognition. Several studies have documented the possibility that oxybutynin may have negative effects on cognitive functions, particularly in the elderly population but also in children (see Kay et al, 2006; Klausner al Steers, 2007; Kay and Ebinger, 2008). This factor should be taken into consideration when prescribing the drug.

Oxybutynin has a well-documented efficacy in the treatment of OAB/DO (see Table 68–2). **Despite the adverse effect profile, it is still an established therapeutic option.**

Dicyclomine. Dicyclomine (Bentyl) has attributed to it both a direct relaxant effect on smooth muscle and an antimuscarinic action (Downie et al, 1977). An oral dose of 20 mg three times a day in adults was reported to increase bladder capacity in patients with neurogenic DO (Fischer et al, 1978). Beck and associates (1976) compared the use of 10 mg of dicyclomine, 15 mg of propantheline, and placebo three times a day in patients with DO. The reported cure or improved rates, respectively, were 62%, 73%, and 20%. Awad and coworkers (1977) reported that 20 mg of dicyclomine three times a day caused resolution or significant improvement in 24 of 27 patients with involuntary bladder contractions.

Even if published experiences of the effect of dicyclomine on DO are favorable, the drug is not widely used, and controlled clinical trials documenting its efficacy and side effects are scarce.

Propiverine Hydrochloride. Several aspects of the preclinical, pharmacokinetic, and clinical effects of propiverine have been reviewed by Madersbacher and Murz (2001). **The drug is rapidly absorbed (Tmax 2 hr), but has a high first-pass metabolism, and its biologic availability is about 50%.** Propiverine is an inducer of hepatic cytochrome P450 enzymes in rats in doses about 100 times above the therapeutic doses in man (Walter et al, 2003).

Several active metabolites are formed that quantitatively and qualitatively differ from the mother compound (Haustein et al, 1988; Muller et al, 1993; Wuest et al, 2006; Sugiyama et al, 2008; Zhu et al, 2008). Most probably these metabolites contribute to the clinical effects of the drug, but their individual contributions have not been clarified (Michel and Hegde, 2006). The half-life of propiverine is 11 to 14 hours. An extended-release preparation was shown to be effective (Jünemann et al, 2006; May et al, 2008).

Propiverine has combined antimuscarinic and Ca^{2+} antagonistic actions (Haruno, 1992; Tokuno et al, 1993). The importance of the Ca^{2+} antagonistic component for the drug's clinical effects has not been established. Propiverine has **no selectivity for muscarinic receptor subtypes.** The drug is not available in the United States.

Propiverine has been shown to have beneficial effects in patients with DO in several investigations. Thüroff and coworkers (1998) collected nine randomized studies on a total of 230 patients and found a 17% reduction in micturitions per 24 hours, a 64-mL increase in bladder capacity, and a 77% (range 33% to 80%) subjective improvement. Side effects were found in 14% (range 8%

to 42%). In patients with neurogenic DO, controlled clinical trials have demonstrated propiverine's superiority over placebo (Stöhrer et al, 1999). Propiverine also increased bladder capacity and decreased maximum detrusor contractions. Controlled trials comparing propiverine, flavoxate, and placebo (Wehnert et al, 1989) and propiverine, oxybutynin, and placebo (Wehnert et al, 1992; Madersbacher et al, 1999) have confirmed the efficacy of propiverine and suggested that the drug may have equal efficacy and fewer side effects than oxybutynin. In a comparative RCT including 131 patients with neurogenic DO, propiverine and oxybutynin were compared (Stöhrer et al, 2007). The drugs were found to be equally effective in increasing bladder capacity and lowering bladder pressure. Propiverine caused a significantly lower frequency of dry mouth than oxybutynin. Also in children and adolescents with neurogenic DO, propiverine was found to be effective (Grigoleit et al, 2006; Schulte-Baukloh et al, 2006), with a low incidence rate of adverse events: less than 1.5% (Grigoleit et al, 2006).

Madersbacher and colleagues (1999) compared the tolerability and efficacy of propiverine (15 mg three times daily), oxybutynin (5 mg twice daily), and placebo in 366 patients with urgency and urgency incontinence in a randomized, double-blind placebo-controlled clinical trial. Urodynamic efficacy of propiverine was judged similar to that of oxybutynin, but the incidence of dry mouth and the severity of dry mouth were judged less with propiverine than with oxybutynin. Dorschner and coworkers (2000) investigated in a double-blind, multicenter, placebo-controlled randomized study the efficacy and cardiac safety of propiverine in 98 elderly patients (mean age 68 years) suffering from urgency, urgency incontinence, or mixed urgency stress urinary incontinence (SUI). After a 2-week placebo run-in period the patients received propiverine (15 mg three times daily) or placebo (three times daily) for 4 weeks. Propiverine caused a significant reduction of the micturition frequency (from 8.7 to 6.5) and a significant decrease in episodes of incontinence (from 0.9 to 0.3 per day). The incidence of adverse events was very low (2% dryness of the mouth under propiverine—2 of 49 patients). Resting and ambulatory electrocardiograms indicated no significant changes.

In a randomized, double-blind multicenter clinical trial, patients with idiopathic DO were treated with 15 mg propiverine twice daily or 2 mg TOLT-IR twice daily over a period of 28 days (Jünemann et al, 2005). The maximum cystometric capacity was determined at baseline and after 4 weeks of therapy. The difference of both values was used as the primary end point.

Secondary end points were voided volume per micturition, evaluation of efficacy (by the investigator), tolerability, postvoid residual urine, and quality of life. It was found that the mean maximum cystometric capacity increased significantly ($P < .01$) in both groups. The volume at first urgency and the frequency/volume chart parameters also showed relevant improvements during treatment. The most common adverse event, dry mouth, occurred in 20 patients in the propiverine group and in 19 patients in the tolterodine group. The scores for the quality of life improved comparably in both groups. Abrams and associates (2006b) compared the effects of propiverine and oxybutynin on ambulatory urodynamic monitoring parameters, safety, and tolerability in OAB patients. Patients (n = 77) received two of the following treatments during two 2-week periods: propiverine 20 mg once daily, propiverine 15 mg three times daily, oxybutynin 5 mg three times daily, and placebo. They found that oxybutynin 15 mg was more effective than propiverine 20 mg in reducing symptomatic and asymptomatic involuntary detrusor contractions in ambulatory patients. Oxybutynin had a higher rate of dry mouth, and propiverine had a more pronounced effect on gastrointestinal, cardiovascular, and visual function.

A randomized, double-blind, placebo-controlled trial with parallel-group design in children aged 5 to 10 years was performed by Marschall-Kehrel and coworkers (2009). Of 171 randomized children, 87 were treated with propiverine and 84 with placebo. Decrease in voiding frequency per day was the primary efficacy parameter; secondary end points included voided volume and incontinence episodes. There was a significant decrease in voiding frequency episodes for propiverine versus placebo. Superiority could also be demonstrated for voided volume and incontinence episodes per day. Propiverine was well tolerated: 23% of side effects were reported for propiverine and 20% for placebo.

Yamaguchi and colleagues (2007) performed a multicenter, 12-week, double-blind phase III trial in Japanese men and women with OAB (1593 patients were randomized and 1584 were treated), comparing solifenacin 5 or 10 mg, propiverine 20 mg, and placebo. Changes at end point in number of voids per 24 hours, urgency, incontinence, urgency incontinence and nocturia episodes, volume voided/void, restoration of continence, and quality of life were examined. It was found that at end point there were greater reductions in mean (SD) voids per 24 hours with all drug regimens than with placebo. All active treatments improved the volume voided and quality of life versus placebo; solifenacin 10 mg reduced nocturia episodes and significantly improved urgency episodes and volume voided versus propiverine 20 mg, and solifenacin 5 mg caused less dry mouth. Solifenacin 10 mg caused more dry mouth and constipation than propiverine 20 mg.

Propiverine has a documented beneficial effect in the treatment of OAB/DO (see Table 68–2) **and seems to have an acceptable side effect profile.**

Flavoxate Hydrochloride. Flavoxate is well absorbed, and oral bioavailability appeared to be close to 100% (Guay, 2003). The drug is extensively metabolized, and plasma half-life was found to be 3.5 hours (Sheu et al, 2001). Its main metabolite (3-methylflavone-8-carboxylic acid [MFCA]) has been shown to have low pharmacologic activity (Cazzulani et al, 1988; Caine et al, 1991). The main mechanism of flavoxate's effect on smooth muscle has not been established. The drug has been found to possess a moderate Ca^{2+} antagonistic activity, to have the ability to inhibit phosphodiesterase (PDE), and to have local anesthetic properties; no antimuscarinic effect was found (Guarneri et al, 1994). Uckert and associates (2000) found that in strips of human bladder the potency of flavoxate to reverse contraction induced by muscarinic receptor stimulation and by electrical field stimulation was comparable. Tomoda and coworkers (2005) studied the effects of flavoxate on K^+-induced tension using strips prepared from human urinary bladder and also investigated the effects of flavoxate on voltage-dependent nifedipine-sensitive Ba^{2+} currents (i.e., L-type Ca^{2+} currents) in single freshly dispersed human detrusor smooth muscle myocytes by use of whole-cell patch-clamp techniques. They found that flavoxate caused a concentration-dependent reduction of the K^+-induced contraction of the bladder strips and that in the human detrusor myocytes, flavoxate inhibited the peak amplitude of voltage-dependent, nifedipine-sensitive inward Ba^{2+} currents in a voltage- and concentration-dependent manner. They concluded that flavoxate caused muscle relaxation through the inhibition of L-type Ca^{2+} channels in the human detrusor.

It has been suggested that pertussis toxin-sensitive G proteins in the brain are involved in the flavoxate-induced suppression of the micturition reflex, since intracerebroventricularly or

intrathecally administered flavoxate abolished isovolumetric rhythmic bladder contractions in anesthetized rats (Oka et al, 1996).

The clinical effects of flavoxate in patients with DO and frequency, urgency, and incontinence have been studied in both open and controlled investigations, but with varying rates of success (Ruffmann, 1988). Stanton (1973) compared emepronium and flavoxate in a double-blind, crossover study of patients with detrusor instability and reported improvement rates of 83% and 66% after flavoxate or emepronium, respectively, both administered as 200 mg three times daily. In another double-blind, crossover study comparing flavoxate 1200 mg/day with that of oxybutynin 15 mg daily in 41 women with idiopathic motor or sensory urgency and utilizing both clinical and urodynamic criteria, Milani and associates (1993) found both drugs effective. No difference in efficacy was found between them, but flavoxate had fewer and milder side effects. Other investigators, comparing the effects flavoxate with those of placebo, have not been able to show any beneficial effect of flavoxate at dosages up to 400 mg three times daily (Briggs et al, 1980; Chapple et al, 1990; Dahm et al, 1995).

In general, few side effects have been reported during treatment with flavoxate. On the other hand its efficacy, compared with other therapeutic alternatives, is not well documented. No RCTs seem to have been performed with flavoxate during the past decade.

α-Adrenergic Receptor Antagonists

Even if it is well known that α_1-AR antagonists can ameliorate lower urinary tract symptoms (LUTS) in men with benign prostatic enlargement (Andersson et al, 2002) **there are no controlled clinical trials showing that they are an effective alternative in the treatment of OAB/DO in this patient category.** In an open-label study, Arnold (2001) evaluated the clinical and pressure-flow effects of tamsulosin 0.4 mg once daily in patients with LUTS caused by benign prostatic obstruction. He found that tamsulosin produced a significant decrease in detrusor pressure, an increase in flow rate, and a symptomatic improvement. In a study in which tamsulosin was given alone, or together with tolterodine, to male patients with LUTS, monotherapy with the drug was not effective (Kaplan et al, 2006). An RCT, comprising 364 women with OAB, revealed no effect of tamsulosin versus placebo (Robinson et al, 2007). On the other hand, voiding symptoms in women with functional outflow obstruction, or LUTS, were reported as successfully treated with an α_1-AR antagonist (Kessler et al, 2006; Low et al, 2008).

α_1-AR antagonists have been used to treat patients with neurogenic DO (Abrams et al, 2003); however, the success has been moderate. Thus there is no convincing evidence that α_1-AR antagonists are effective in patients with storage symptoms. Although α_1-AR antagonists may be effective in selected cases, convincing effects documented in RCTs are lacking (see Table 68–2). **In women, these drugs may produce or aggravate SUI** (Dwyer and Teele, 1992).

β-Adrenergic Receptor Agonists. In isolated human bladder, nonsubtype selective β-AR agonists such as isoprenaline have a pronounced inhibitory effect, and administration of such drugs can increase bladder capacity in humans (Andersson, 1993). However, the β-ARs of the human bladder were shown to have functional characteristics typical of neither β_1- nor β_2-ARs, because they could be blocked by propranolol but not by practolol or metoprolol (β_1) or butoxamine (β_2) (Nergardh et al, 1977; Larsen, 1979). On the other hand, early receptor binding studies using subtype selective ligands suggested that the β-ARs of the human detrusor are primarily of β_2 subtype (Andersson, 1993), and favorable effects on DO were reported in open studies with selective β_2-AR agonists such as terbutaline (Lindholm and Lose, 1986). In a double-blind investigation clenbuterol 0.01 mg three times daily was shown to have a good therapeutic effect in 15 of 20 women with DO (Gruneberger, 1984). Other investigators, however, have not been able to show that β-AR agonists represent an effective therapeutic principle in elderly patients with DO (Castleden and Morgan, 1980) or in young patients with myelodysplasia and DO (Naglo et al, 1981).

However, **three subtypes (β_1, β_2, and β_3) have been identified in the detrusor of most species, including humans** (Andersson and Arner, 2004; Michel and Vrydag, 2006). Also the human urothelium contains all three receptor subtypes (Otsuka et al, 2008). Studies, using real-time polymerase chain reaction, have revealed a **predominant expression of β_3-AR mRNA** in human detrusor muscle (Nomiya and Yamaguchi, 2003; Michel and Vrydag, 2006); and the functional evidence for an important role in both normal and neurogenic bladders is convincing (Fujimura et al, 1999; Igawa et al, 1999, 2001; Takeda et al, 1999; Morita et al, 2000; Biers et al, 2006; Michel and Vrydag, 2006; Badawi et al, 2007; Leon et al, 2008). **The human detrusor also contains β_2-ARs, and most probably both receptors are involved in the physiologic effects (relaxation) of norepinephrine in this structure** (Andersson and Arner 2004; Michel and Vrydag, 2006).

The generally accepted mechanism by which β-ARs induce detrusor relaxation in most species is activation of adenylyl cyclase with the subsequent formation of cAMP. However, there is evidence suggesting that, in the bladder, K^+ channels, particularly BK_{Ca} channels, may be more important in β-AR–mediated relaxation than cAMP (Hudman et al, 2000; Frazier et al, 2005; Uchida et al, 2005; Frazier et al, 2008).

Because β-ARs are present in the urothelium, their possible role in bladder relaxation has been investigated (Murakami et al, 2007; Otsuka et al, 2008). Murakami and coworkers (2007) found that the relaxation responses of the detrusor were not influenced by the urothelium. However, isoprenaline was more potent at inhibiting carbachol contractions in the presence of the urothelium than in its absence. It was suggested that this might reflect the release of an inhibitory factor from the urothelium. Further support for this hypothesis was given by Otsuka and associates (2008). However, to what extent a urothelial signaling pathway contributes in vitro and in vivo to the relaxant effects of β-AR agonists in general, and β_3-AR agonists specifically, remains to be elucidated.

The in-vivo effects of β_3-AR agonists on bladder function have been studied in several animal models. It has been shown that compared with other agents (including antimuscarinic drugs), β_3-AR agonists increase bladder capacity with no change in micturition pressure and the residual volume (Fujimura et al, 1999; Woods et al, 2001; Kaidoh et al, 2002). For example, Hicks and associates (2007) studied the effects of the selective β_3-AR agonist GW427353 in the anesthetized dog and found that the drug evoked an increase in bladder capacity under conditions of acid-evoked bladder hyperactivity, without affecting voiding.

A number of β_3-AR selective agonists are currently being evaluated as potential treatment for OAB in humans, including GW427353 (solabegron) and YM178 (Colli et al, 2007). Takasu and associates (2007) found that the selective β_3-AR agonist YM178 mediated muscle relaxation of human bladder strips. Chapple and coworkers (2008c) reported the results of a controlled clinical trial

with this drug in patients with OAB. Tolterodine and placebo served as controls. The primary efficacy analysis showed a statistically significant reduction in mean micturition frequency, compared with placebo (–2.19 vs. –1.18). With respect to secondary variables YM178 (100 mg) was significantly superior to placebo concerning mean volume voided per micturition (26 vs. 11 mL), mean number of incontinence episodes (–2.17 vs. –1.01), and urgency episodes per 24 hour (–2.30 vs. –1.03). The drug was well tolerated, and the most commonly reported side effects were headache and gastrointestinal adverse effects. The results of this proof of concept study showed that **the principle of β_3-AR agonism may be useful for treatment of patients with OAB** (see Table 68–2). However, to show that this class of drugs offers a viable therapeutic alternative or complement to current treatment of LUTS/OAB requires further well-designed RCTs.

Phosphodiesterase Inhibitors

Drugs stimulating the generation of cAMP are known to relax smooth muscles, including the detrusor (Andersson, 1999b; Andersson and Arner, 2004). I**t is also well established that drugs acting through the nitric oxide/cyclic guanosine monophosphate (NO/cGMP) system can relax the smooth muscle of the bladder outflow region** (Andersson and Arner, 2004). Use of PDE inhibitors to enhance the presumed cAMP- and cGMP-mediated relaxation of LUT smooth muscles (detrusor prostate, urethra) should then be a logical approach (Andersson et al, 2007). There are presently 11 families of PDEs, some of which preferentially hydrolyze either cAMP or cGMP (Andersson et al, 2007).

As a basis for PDE inhibitor treatment of LUTS, Truss and colleagues (2001) investigated human bladder tissue, revealing mRNA for PDE1, PDE2, PDE4, and PDE5; **most of these PDEs preferably inhibit the breakdown of cAMP.** In vitro, human detrusor muscle responded poorly to sodium nitroprusside and to agents acting via the cGMP system (Truss et al, 2001). However, significant relaxation of human detrusor muscle, paralleled by increases in cyclic nucleotide levels, was induced by papaverine, vinpocetine (a low affinity inhibitor of PDE1), and forskolin (stimulating the generation of cAMP), suggesting that the cAMP pathway and PDE1 may be important in regulation of detrusor smooth muscle tone. Significant dose-dependent relaxations were also induced by human cAMP analogues (Truss et al, 2001). With these studies as a background, Truss and colleagues (2000) presented preliminary clinical data with vinpocetine in patients with urgency/urgency incontinence or low compliance bladders and not responding to standard antimuscarinic therapy. This initial open pilot study suggested a possible role for vinpocetine in the treatment of OAB. However, the results of a larger RCT in patients with DO showed that vinpocetine showed statistically significant results only for one parameter (Truss et al, 2001). Studies with other PDE1 inhibitors than vinpocetine (which may not be an optimal drug for elucidating the principle) do not seem to have been performed.

PDE4 (which also preferably hydrolyzes cAMP) has been implicated in the control of bladder smooth muscle tone. PDE4 inhibitors reduced the in-vitro contractile response of guinea pig (Longhurst et al, 1997) and rat (Nishiguchi et al, 2007; Kaiho et al, 2008) bladder strips and also suppressed rhythmic bladder contractions of the isolated guinea pig bladder (Gillespie, 2004a). Previous experiences with selective PDE4 inhibitors showed emesis to be a dose-limiting effect (Giembycz, 2005). If this side action can be avoided, PDE4 inhibition seems to be a promising approach.

NO has been demonstrated to be an important inhibitory neurotransmitter in the smooth muscle of the urethra, and its relaxant effect is associated with increased levels of cGMP (Andersson and Wein, 2004). However, few investigations have addressed the cAMP- and cGMP-mediated signal transduction pathways and its key enzymes in the mammalian urethra. Morita and associates (1994) examined the effects of isoproterenol, prostaglandin E_1 and E_2, and sodium nitroprusside on the contractile force and tissue content of cAMP and cGMP in the rabbit urethra. They concluded that both cyclic nucleotides can produce relaxation of the urethra. Werkström and associates (2006) characterized the distribution of PDE5, cGMP, and PKG1 in female pig and human urethra and evaluated the effect of pharmacologic inhibition of PDE5 in isolated smooth muscle preparations. After stimulation with the NO donor, DETA NONO-ate, the cGMP-immunoreactivity in urethral and vascular smooth muscles increased. There was a wide distribution of cGMP- and vimentin-positive interstitial cells between pig urethral smooth muscle bundles. PDE5 immunoreactivity could be demonstrated within the urethral and vascular smooth muscle cells but also in vascular endothelial cells that expressed cGMP immunoreactivity. Nerve-induced relaxations of urethral preparations were enhanced at low concentrations of sildenafil, vardenafil, and tadalafil, whereas there were direct smooth muscle relaxant actions of the PDE5 inhibitors at high concentrations.

The distribution of PDEs in the male urethral structures does not seem to have been studied.

The observation that patients treated for erectile dysfunction with PDE5 inhibitors had an improvement of their LUTS has sparked a new interest in using these drugs also for treatment of LUTS and OAB. After the report in an open study (Sairam et al, 2002) that treatment with sildenafil appeared to improve urinary symptom scores in men with erectile dysfunction and LUTS, this observation has been confirmed in several well-designed and conducted RCTs (McVary et al, 2007a, 2007b; Stief et al, 2008).

McVary and colleagues (2007a) evaluated the effects of sildenafil (50 to 100 mg daily for 12 weeks) on erectile dysfunction and LUTS in men 45 years or older who scored 25 or less on the erectile function domain of the International Index of Erectile Function (IIEF) and 12 or greater on the International Prostate Symptom Score (IPSS). In 189 men receiving sildenafil, significant improvements were observed in IPPS (–6.32 vs. –1.93, $P < .0001$), Benign Prostatic Hyperplasia Impact Index (–2.0 vs. –0.9, $P < .0001$), mean IPSS quality of life score (–0.97 vs. –0.29, $P < .0001$) and total Self-Esteem and Relationship questionnaire scores (24.6 vs. 4.3, $P < .0001$). Interestingly there was no difference in urinary flow between the groups ($P = .08$). Significantly more sildenafil versus placebo-treated patients were satisfied with treatment (71.2 vs. 41.7, $P < .0001$). Sildenafil was well tolerated.

In an RCT, treatment with tadalafil once daily, in addition to improving erectile function in men with LUTS, was demonstrated to produce a clinically meaningful and statistically significant symptomatic improvement of LUTS (McVary et al, 2007b). In another RCT, vardenafil given twice daily for 8 weeks to men with erectile dysfunction and LUTS was shown to significantly improve LUTS, erectile function, and quality of life (Stief et al, 2008).

The mechanism behind the beneficial effect of the PDE inhibitors on LUTS/OAB and their site(s) of action largely remain to be elucidated. If the site of action were the smooth muscles of the outflow region (and the effect relaxation), an increase in flow rate should be expected. In none of the trials referred to, such an effect was found. However, there are several other structures in the LUT that may be involved, including those in the urothelial signaling

pathway (urothelium, interstitial cells, and suburothelial afferent nerves).

PDE5 inhibitors have a documented effect in men with LUTS/OAB (see Table 68–2). The place of PDE5 inhibitors in the treatment of OAB/DO remains to be established. Specifically, there seems to be no published information on the effects of these drugs in women with OAB/DO.

Antidepressants

Many clinicians believe that tricyclic antidepressants, particularly **imipramine** (Tofranil, others), are useful agents for facilitating urine storage, both by decreasing bladder contractility and by increasing outlet resistance (Wein, 1995a, 1995b). These agents have been the subject of a voluminous amount of highly sophisticated pharmacologic investigation to determine the mechanisms of action responsible for their varied effects (Maggi et al, 1989b; Richelson, 1994; Baldessarini, 2006). Most data have been accumulated as a result of trying to explain the antidepressant properties of these agents and are thus primarily from CNS tissue. The results, conclusions, and speculations inferred from the data are extremely interesting, but it should be emphasized that it is essentially unknown whether they apply to or have relevance for the LUT.

Tricyclic antidepressants possess varying degrees of at least three major pharmacologic actions: (1) they have central and peripheral antimuscarinic effects at some, but not all, sites; (2) they block the active transport system in the presynaptic nerve ending that is responsible for the reuptake of the released amine neurotransmitters norepinephrine and serotonin; and (3) they are sedatives, an action that occurs presumably on a central basis but is perhaps related to antihistaminic properties (at H_1 receptors, although they also antagonize H_2 receptors to some extent). There is also evidence that they desensitize at least some α_2- and some β-AR agonists. Paradoxically, they also have been shown to block some α-AR agonists and 5-hydroxytryptamine type 1 receptors.

Imipramine. As indicated earlier, imipramine has complex pharmacologic effects, and its mode of action in OAB/DO has not been established (Hunsballe and Djurhuus, 2001). **Even if it is generally considered that imipramine is a useful drug in the treatment of OAB/DO, no good quality RCTs that can document this have been retrieved.**

It has been known for a long time that imipramine can have favorable effects in the treatment of nocturnal enuresis in children with a success rate of 10% to 70% in controlled trials (Hunsballe and Djurhuus, 2001; Glazener et al, 2003).

The risks (see later) and benefits of imipramine in the treatment of voiding disorders do not seem to have been assessed. Very few studies have been performed during the past decade (Hunsballe and Djurhuus, 2001). No good quality RCTs have documented that the drug is effective in the treatment DO. However, a beneficial effect has been documented in the treatment of nocturnal enuresis.

Doxepine. Doxepine is another tricyclic antidepressant that was found to be more potent, using in-vitro rabbit bladder strips, than other tricyclic compounds with respect to antimuscarinic and musculotropic relaxant activity (Levin and Wein, 1984). Lose and associates (1989), in a randomized, double-blind crossover study of females with involuntary bladder contractions, and either frequency, urgency, or urgency incontinence, found that this agent caused a significant decrease in urine loss (pad weighing test) and in the cystometric parameters of first sensation and maximum bladder capacity. The dosage of doxepin used was either a single 50-mg bedtime dose or this dose plus an additional 25 mg in the morning. The number of daytime incontinence episodes decreased in both doxepin and placebo groups, and the difference was not statistically significant. Doxepine treatment was preferred by 14 patients, whereas 2 preferred placebo. Three patients had no preference. Of the 14 patients who stated a preference for doxepine, 12 claimed that they became continent during treatment whereas 2 claimed improvement; the 2 patients who preferred placebo claimed improvement. The AHCPR Guidelines combine results for imipramine and doxepine, citing only three randomized controlled trials, with an unknown percent of female patients. Percent cures (all figures refer to percent drug effect minus percent effect on placebo) are listed as 31%, percent reduction in urgency incontinence as 20% to 77%, and percent side effects as 0% to 70% (U.S. Department of Health and Human Services, 1992).

Duloxetine. Duloxetine is a serotonin-norepinephrine reuptake inhibitor that has been shown to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function (Thor et al, 1995; Katofiasc et al, 2002). **Bladder capacity was also increased in this model,** both effects mediated centrally through both motor efferent and sensory afferent modulation (Fraser et al, 2003). The effects of duloxetine were studied in a placebo-controlled study comprising 306 women (aged 21 to 84 years) with OAB, randomly treated with placebo (153) or duloxetine (80 mg/day for 4 weeks, which was increased to 120 mg/day for 8 weeks (Steers et al, 2007). The primary efficacy analysis compared the treatment effects on mean change from baseline to end point in the mean number of voiding episodes per 24 hours. Patients randomized to duloxetine had significant improvements over those randomized to placebo for decreases in voiding and incontinence episodes (–1.81 vs. –0.62, for increases in the daytime voiding intervals (29 vs. 7 minutes), and for improvements in Incontinence Quality of Life scores at both doses of duloxetine. Urodynamic studies showed no significant increases in maximum cystometric capacity or in the volume threshold for DO. The most common treatment-emergent adverse events with duloxetine (nausea 31%, placebo 4.6%; dry mouth 16%, placebo 1.3%; dizziness 14%, placebo 0.7%; constipation 14%, placebo 3.3%; insomnia 13%, placebo 1.3%; and fatigue 11%, placebo 2.0%) were the same as those reported by women with SUI (see later) and were significantly more common with duloxetine than placebo. Also in females with mixed incontinence, improvement of the OAB component has been demonstrated (Bent et al, 2008; Schagen van Leeuwen et al, 2008). For assessment, see Table 68–2.

When used in the generally larger doses employed for antidepressant effects **the most frequent side effects of the tricyclic antidepressants are those attributable to their systemic antimuscarinic activity** (Richelson, 1994; Baldessarini, 2006). Allergic phenomena, including rash, hepatic dysfunction, obstructive jaundice, and agranulocytosis may also occur but rarely. CNS side effects may include weakness, fatigue, parkinsonian effect, a fine tremor noted most in the upper extremities, a manic or schizophrenic picture, and sedation, probably from an antihistaminic effect. Postural hypotension may also be seen, presumably on the basis of selective blockade (a paradoxical effect) of α_1-AR agonists in some vascular smooth muscle. Tricyclic antidepressants can also cause excess sweating of obscure etiology and a delay of orgasm or orgasmic impotence, the cause of which likewise is unclear. They can also produce arrhythmias and interact in deleterious ways with other drugs, and so caution must be

observed in their use in patients with cardiac disease (Baldessarini, 2006). Whether cardiotoxicity will prove to be a legitimate concern in patients receiving the smaller doses (than for treatment of depression) for LUT dysfunction remains to be seen but is a potential matter of concern. Consultation with a patient's internist or cardiologist is always helpful before instituting such therapy in questionable situations. It is well established that **therapeutic doses of tricyclic antidepressants, including imipramine, may cause serious toxic effects on the cardiovascular system** (orthostatic hypotension, ventricular arrhythmias). Imipramine prolongs QTc intervals and has an antiarrhythmic (and proarrhythmic) effect similar to that of quinidine (Bigger et al, 1977; Giardina et al, 1979). Children seem particularly sensitive to the cardiotoxic action of tricyclic antidepressants (Baldessarini, 2006).

With respect to the potential cardiovascular risks of antidepressant medication, two additional points need to be made. First of all, it may be depression itself that is associated with an increased risk of myocardial infarction, cardiovascular disease, and all-cause mortality (see references in Cohen et al, 2000). Although treatments for depression, including antidepressive medications, are certainly a potential factor underlying this association, the separation from disease association and treatment association is difficult at best. The second point relates to whether there is a difference in this regard between the use of tricyclic antidepressants and selective serotonin reuptake inhibitors. Data presented by Cohen and coworkers (2000) suggest with respect to long-term adverse cardiovascular outcome there is an association between the use of tricyclic antidepressants but not selective serotonin reuptake inhibitors, a conclusion that differs from earlier data that indicated no significant differences in the safety or efficacy of these two groups of agents (AHCPR Report, cited by Cohen et al, 2000). As a closing statement on this subject, it should be noted that data in the literature refer to therapeutic doses of these medications for depression and not the smaller (in comparison) doses of imipramine used for the treatment of voiding dysfunction.

The use of imipramine is contraindicated in patients receiving monoamine oxidase inhibitors, because severe CNS toxicity can be precipitated, including hyperpyrexia, seizures, and coma. Some potential side effects of the antidepressants may be especially significant for the elderly, specifically weakness, fatigue, and postural hypotension. Psychotropic drugs in general have been shown to increase the risk of falls and hip fractures in the elderly (Liu et al, 1998). If imipramine or any of the tricyclic antidepressants is to be prescribed for the treatment of voiding dysfunction, the patient should be thoroughly informed of the fact that this is not the usual indication for this drug and that potential side effects exist. Reports of significant side effects (severe abdominal distress, nausea, vomiting, headache, lethargy, and irritability) after abrupt cessation of high doses of imipramine in children would suggest that the drug should be discontinued gradually, especially in patients receiving high doses.

Cyclooxygenase Inhibitors

Human bladder mucosa has the ability to synthesize eicosanoids (Jeremy et al, 1987), and these agents can be liberated from bladder muscle and mucosa in response to different types of trauma (Downie and Karmazyn, 1984; Leslie et al, 1984). Even if prostaglandins cause contraction of human detrusor (Andersson, 1993) **it is still unclear whether prostaglandins contribute to the pathogenesis of DO. More important than direct effects on the bladder muscle may be sensitization of sensory afferent nerves, increasing the afferent input produced by a given degree of bladder filling.** Involuntary bladder contractions can then be triggered at a small bladder volume. If this is an important mechanism, treatment with prostaglandin synthesis inhibitors could be expected to be effective. However, **clinical evidence for this is scarce.**

Cardozo and colleagues (1980) performed a double-blind controlled study of 30 women with DO using the prostaglandin synthesis inhibitor flurbiprofen at a dosage of 50 mg three times daily. The drug was shown to have favorable effects, although it did not completely abolish DO. There was a high incidence of side effects (43%) including nausea, vomiting, headache, and gastrointestinal symptoms. Palmer (1983) studied the effects of flurbiprofen 50 mg four times daily versus placebo in a double-blind, crossover trial in 37 patients with idiopathic DO (27% of the patients did not complete the trial). Active treatment significantly increased maximum contractile pressure, decreased the number of voids, and decreased the number of urgent voids compared with baseline. Indomethacin 50 to 100 mg/day was reported to give symptomatic relief in patients with DO, compared with bromocriptine in a randomized, single-blind, crossover study (Cardozo and Stanton, 1980). The incidence of side effects was high, occurring in 19 of 32 patients. However, no patient had to stop treatment because of side effects.

The few controlled clinical trials on the effects of prostaglandin synthesis inhibitors in the treatment of DO, and the limited number of drugs tested, make it difficult to evaluate their therapeutic value (see Table 68–2). **No new RCTs on the effects of COX inhibitors in OAB/DO patients seem to have been published during the past decade.**

Dimethyl Sulfoxide

Dimethyl sulfoxide (DMSO) is a relatively simple, naturally occurring organic compound that has been used as an industrial solvent for many years. It has multiple pharmacologic actions (membrane penetrant, anti-inflammatory, local analgesic, bacteriostatic, diuretic, cholinesterase inhibitor, collagen solvent, vasodilator) and has been used for the treatment of arthritis and other musculoskeletal disorders, generally in a 70% solution. The formulation for human intravesical use is a 50% solution. Sant (1987) has summarized the pharmacology and clinical use of DMSO and has tabulated "good to excellent" results in 50% to 90% of collected series of patients treated with intravesical instillation for interstitial cystitis. **However, DMSO has not been shown to be useful in the treatment of neurogenic or idiopathic DO or in any patients with urgency/frequency but without interstitial cystitis.** The subject of interstitial cystitis and its treatment is considered in Chapter 12.

Polysynaptic Inhibitors

Baclofen (Lioresal) is discussed primarily along with agents that decrease outlet resistance secondary to striated sphincter dyssynergia. Baclofen is a γ-aminobutyric acid type B ($GABA_B$) receptor agonist that depresses monosynaptic and polysynaptic motoneurons and interneurons in the spinal cord (Andersson et al, 1999, 2000a). It has also been shown capable of depressing neurogenic DO secondary to a spinal cord lesion (Kiesswetter and Schober, 1975). Taylor and Bates (1979), in a double-blind crossover study, reported it to be very effective also in decreasing daytime and night-time urinary frequency and incontinence in patients with idiopathic DO. Cystometric changes were not recorded, however, and considerable improvement was also obtained in the placebo

group. Effective intrathecal use of baclofen for treatment of neurogenic DO was reported by Kums and Delhaas (1991), Steers and associates (1992), and Bushman and colleagues (1993). Little on this subject has appeared during the past decade.

Toxins

Vanilloids. By means of **capsaicin,** a subpopulation of primary afferent neurons innervating the bladder and urethra, the "capsaicin-sensitive nerves," has been identified. It is believed that capsaicin exerts its effects by acting on specific "vanilloid" receptors on these nerves (Szallasi, 1994). Capsaicin exerts a biphasic effect: initial excitation is followed by a long-lasting blockade, **which renders sensitive primary afferents (C fibers) resistant to activation by natural stimuli. In sufficiently high concentrations, capsaicin is believed to cause "desensitization" initially by releasing and emptying the stores of neuropeptides and then by blocking further release** (Maggi, 1993). **Resiniferatoxin** (RTX) is an analogue of capsaicin, approximately **1000 times more potent for desensitization than capsaicin** (Ishizuka et al, 1995a) **but only a few hundred times more potent for excitation** (Szallasi and Blumberg, 1999). **Possibly, both capsaicin and RTX can have effects on Aδ fibers.** It is also possible that capsaicin at high concentrations (mM) has additional, nonspecific effects (Kuo, 1997).

The rationale for intravesical instillations of vanilloids is based on the involvement of C fibers in the pathophysiology of conditions such as bladder hypersensitivity and neurogenic DO. In the healthy human bladder C fibers carry the response to noxious stimuli, but they are not implicated in the normal voiding reflex. After spinal cord injury major neuroplasticity appears within bladder afferents in several mammalian species, including humans. C-fiber bladder afferents proliferate within the suburothelium and become sensitive to bladder distention. Those changes lead to the emergence of a new C-fiber–mediated voiding reflex, which is strongly involved in spinal neurogenic DO. Improvement of this condition by defunctionalization of C-fiber bladder afferents with intravesical vanilloids has been widely demonstrated in humans and animals.

Cystometric evidence that capsaicin-sensitive nerves may modulate the afferent branch of the micturition reflex in humans was originally presented by Maggi and colleagues (1989a), who instilled capsaicin (0.1 to 10 μM) intravesically in five patients with hypersensitivity disorders with attenuation of their symptoms a few days after administration. Intravesical capsaicin, given in considerably higher concentrations (1 to 2 mM) than those administered by Maggi and colleagues (1989a), has since been used with success in neurologic disorders such as multiple sclerosis or traumatic chronic spinal lesions (Fowler et al, 1992b, 1994; Geirsson et al, 1995; DeRidder et al, 1997; for more discussion see de Seze et al, 1999; DeRidder and Baert, 2000; Andersson et al, 2002, 2009; Cruz, 2004; de Seze et al, 2004). Side effects of intravesical capsaicin include discomfort and a burning sensation at the pubic/urethral level during instillation, an effect that can be overcome by prior instillation of lidocaine, which does not interfere with the beneficial effects of capsaicin (Chandiramani et al, 1996). No premalignant or malignant changes in the bladder have been found in biopsy specimens of patients who had repeated capsaicin instillations for up to 5 years (Dasgupta et al, 1998).

The beneficial effect of **RTX** has been demonstrated in several studies (see Andersson 2002a, 2009; Kim et al, 2003; Kuo et al, 2003; de Seze et al, 2004; Giannantoni et al, 2004; Watanabe, 2004).

de Seze and associates (2004) compared the efficacy and tolerability of nonalcohol capsaicin (1 mM) versus RTX (100 nM) in 10% alcohol in a randomized, double-blind, parallel-group study in 39 spinal cord–injured adult patients with neurogenic DO (hyperreflexia). Efficacy (voiding chart and cystomanometry) and tolerability were evaluated during a 3-month follow-up. On day 30, clinical and urodynamic improvement was found in 78% and 83% of patients with capsaicin versus 80% and 60% with RTX, respectively, without a significant difference between the two treated groups. The benefit remained in two thirds of the two groups on day 90. There were no significant differences in regard to the incidence, nature, or duration of side effects in capsaicin- versus RTX-treated patients. The data suggested that capsaicin and RTX are equally efficient for relieving the clinical and urodynamic symptoms of neurogenic DO and that glucidic capsaicin is as well tolerated as ethanolic RTX.

Available information (including data from RCTs) suggests that **both capsaicin and RTX may have useful effects in the treatment of neurogenic DO. There may be beneficial effects also in non-neurogenic DO in selected cases refractory to antimuscarinic treatment, but further RCT-based documentation is desired.** RTX is an interesting alternative to capsaicin, but the drug is currently not in clinical development owing to formulation problems.

Neither capsaicin nor RTX is approved in the United States for clinical use. It is obvious, however, that the intravesical use of such agents has the potential to significantly contribute to the treatment of DO in patients with neurogenic and other types of LUT dysfunction. Various techniques of administration of intravesical capsaicin and RTX differ slightly among experienced users and are described in detail in the articles by Chancellor and de Groat (1999), Fowler (2000), and DeRidder and Baert (2000).

Botulinum Neurotoxin (BoNT). **BoNT** is produced by *Clostridium botulinum*. **Of the seven subtypes of BoNT, subtype A (BoNT/A) is the most relevant clinically.** Most of the intravesical experience reported on BoNT/A deals with Botox. However, BoNT/A toxin is also available under the trade names of Dysport and Xeomin. Bladder experience with the latter was, however, never reported. Available information indicates that Botox is roughly three times more potent than Dysport (Cruz and Silva, 2004; Nitti et al, 2006). However, this relation has never been clearly defined. Therefore in a bladder setting these equivalents should be approached with caution (for clinical reviews, see Nitti et al, 2006; Patel et al, 2006; Cruz and Dinis, 2007; Karsenty et al, 2008). In addition to subtype A, recent reports have investigated the detrusor injection of BoNT subtype B (Neurobloc, Miobloc). BoNT was shown to exert a prolonged local effect when injected directly into skeletal muscles, and the effects are dose dependent and reversible.

BoNT consists of a heavy and a light chain linked by a disulfide bond. In the synaptic cleft the toxin binds to synaptic vesicle protein or SV2 (Dong et al, 2006) through its heavy chain and is internalized by the nerve terminal. On cleavage, the light chain is released in the cytosol, where it impedes binding of neurotransmitter-containing synaptic vesicles to the plasma membrane. This is achieved through the *N*-ethylmaleimide-sensitive factor attachment protein (SNARE) complex made up of synaptosome-associated protein 25 kD (SNAP 25), synaptobrevin (vesicle-associated membrane protein [VAMP]), and syntaxin. BoNT/A cleaves SNAP 25 rendering the SNARE complex inactive (Humeau et al, 2000; Chancellor et al, 2008a). Subtype B acts preferentially through the inactivation of VAMP (Humeau et al, 2000).

The rationale for using BoNT to treat human DO is based on the assumption that effects of the toxin on skeletal muscle would be replicated in bladder smooth muscle (Schurch et al, 2000a, 2000b) **and that detrusor muscle paralysis would reduce the symptoms of OAB** (Duthie et al, 2007). **BoNT has been developed as a second-line treatment option (after failure of, or intolerance to, appropriate antimuscarinic therapy) for patients with NDO with urinary incontinence or other neurogenic OAB symptoms and who are able and willing to perform CIC.**

The first report of the application of BoNT/A in NDO appeared in 2000 (Schurch et al, 2000b). Injection of BoNT/A 200 to 300 units at 20 to 30 detrusor muscle sites restored continence in 17 of 19 patients (89.5%) with severe neurogenic DO and incontinence secondary to traumatic spinal cord injury at the 6-week follow-up. No side effects were reported, mean reflex volume and mean maximum cystometric bladder capacity increased significantly from baseline, and there was a significant decrease in mean maximum detrusor pressure. Since then, the efficacy of BoNT/A injection into the detrusor muscle in adult patients with NDO refractory to, and/or intolerant of, antimuscarinic agents has been confirmed in a number of studies, which have been the subject of systematic review (Karsenty et al, 2008; Apostolidis et al, 2009; see also Andersson et al, 2009). The analysis by Karsenty and colleagues (2008) evaluated 18 trials with Botox, involving a total of 698 patients, of whom 83% had NDO with urinary incontinence. Significant benefits were seen in clinical variables (micturition frequency and number of incontinence episodes) as well as urodynamic variables (maximum detrusor pressure, maximum cystometric capacity). Complete continence was achieved in 40% to 80% of patients. Efficacy has also been demonstrated in spinal cord–injured patients with detrusor–striated sphincter dyssynergia (Dykstra et al, 1990, 1998; Schurch et al, 1996). A significant response to BoNT/A is seen as early as 1 week after treatment; however, maximum effects were seen between 1 and 4 weeks. **The efficacy of BoNT/A appears to persist for at least 3 to 4 months and up to 1 year but does decline over time** (Grosse et al, 2005), meaning that **repeat injections are required for continued therapeutic effect.** Repeat injections have been shown to be effective and well tolerated (Grosse et al, 2005; Karsenty et al, 2006; Giannantoni et al, 2009), and there is **no reported evidence of a reduction in response** over time, after two to nine repeat injections. The beneficial clinical and urologic effects of BoNT/A in adults with NDO are accompanied by improvement in patients' quality of life (Kalsi et al, 2006; Schurch et al, 2007).

BoNT/A is generally well tolerated. Data from a systematic review of the role of BoNT/A in NDO indicated that the most frequent adverse events are injection site pain, procedure-related urinary tract infection, and mild hematuria (Karsenty et al, 2008). A potential adverse effect resulting from the use of BoNT in patients not using CIC is an increase in postvoid residual volume that may result in de novo CIC (6% to 88% of patients), with associated impact on quality of life (Karsenty et al, 2008; Shaban et al, 2008). Systemic side effects, although rare, could be very disabling for patients with spinal cord injury (De Laet et al, 2005).

Important factors to consider in relation to the risk of adverse events during urologic use of BoNT/A are the drug dosage, the formulation used, and the injection technique. Available data indicate that Dysport may be associated with a higher risk of side effects related to drug migration (e.g., muscle weakness) than Botox (Dmochowski and Sand, 2007). The doses typically evaluated in clinical trials in urologic indications differ between the commercially available formulations of BoNT/A. Additionally, systemic adverse reactions, including respiratory compromise and death, have been reported after the use of BoNT/A and BoNT/B for both U.S. Food and Drug Administration (FDA) approved and unapproved uses (Dmochowski and Sand, 2007). The most serious cases involved treatment of children for cerebral palsy–associated limb spasticity, and the FDA is currently reviewing safety data relating to marketed BoNT products.

Accumulating evidence indicates that BoNT/A may be a useful option for treating children with NDO and urinary incontinence and whose disorders are refractory to antimuscarinic therapy. A systematic review on the use of BoNT/A (Botox) in children with NDO identified six small (10 to 26 patients) prospective studies primarily involving children with myelomeningocele (Game et al, 2009). BoNT/A treatment resulted in a reduction in urinary incontinence of 40% to 80%, and between 65% and 87% of patients became completely continent between CIC. In addition, all studies showed a significant impact of treatment on urodynamic variables, including maximum detrusor pressure and maximum cystometric capacity. Improvement was observed within 2 weeks of BoNT/A injection and persisted for up to 6 months. The amount of Botox injected ranged from 5 to 12 units/kg, with a maximum dose of 360 units. Repeat administration of BoNT/A was associated with similar therapeutic effects to the first dose. Available data therefore indicate that BoNT/A may have the ability to prevent or delay the need for surgery in children with NDO, but further studies with the appropriate design and with a longer follow-up are required to confirm this. The safety profile in children has not been established, and there is a need for studies that evaluate the effect of long-term, repeated administration on the bladder wall. Although the value of BoNT for the treatment of NDO is now recognized in European and U.S. consensus reports (Naumann et al, 2008; Apostolides et al, 2009), at the time of this writing, the only approval for BoNT/A in a urologic indication is for Botox for the treatment of OAB in Brazil. On the whole, studies on BoNT/A are small (<50 patients), short term, and are largely restricted to patients with spinal cord injury or multiple sclerosis. Indeed, several questions remain unanswered. These include the optimal dose and frequency of administration to balance efficacy with safety, the most appropriate method and location of administration, and how to identify patients who would benefit the most. Considerable systematic research is still required to answer these questions. Large phase 3 registration studies are being conducted to support the registration of this treatment for NDO, including the optimal dose recommendation.

There are limited data on the use of **botulinum toxin B (BoNT/B)** for incontinence, particularly in patients with NDO. In the only two published trials on the use of BoNT/B in urologic indications, the vast majority of patients had non-neurogenic OAB (Dykstra et al, 2003a, 2003b; Ghei et al, 2005). Data on the use of BoNT/B in patients with NDO come primarily from three case reports (Dykstra et al, 2003b; Pistolesi et al, 2004; Reitz and Schurch, 2004). In one report, BoNT/B 5000 units was injected into 10 different areas of the bladder wall in a patient with multiple sclerosis whose disease was refractory to oral and topical antimuscarinic agents. The patient reported a positive response within 24 hours and had no adverse effects. The beneficial effects of BoNT/B began to decline after 4 months, and a repeat BoNT/B dose of 7500 units was given that also provided therapeutic benefit for 4 months (Dykstra et al, 2003b). BoNT/A and BoNT/B interfere with different presynaptic proteins, meaning that a primary nonresponse to the type A toxin does not necessarily imply a

non-response to the type B toxin. Indeed, data from the other two case reports indicate that BoNT/B may have a place for the management of patients with NDO resistant to therapy with the type A toxin. However, the duration of effect was only 4 to 6 weeks (Pistolesi et al, 2004; Reitz and Schurch, 2004). There are no data on the use of BoNT/B in children.

Estrogens for Urgency Urinary Incontinence and Overactive Bladder Symptoms

Estrogen has been used to treat postmenopausal urgency and urgency incontinence for many years, but there have been **few controlled trials to confirm that it is of benefit** (Hextall, 2000; for assessment, see Table 68–2). A double-blind multicenter study of 64 postmenopausal women with "urgency syndrome" failed to show efficacy (Cardozo et al, 1993). All women underwent pretreatment urodynamic investigation to ensure that they had either "sensory urgency" or DO. They were randomized to treatment with oral estriol 3 mg daily or placebo for 3 months. Compliance with therapy was confirmed by a significant improvement in the maturation index of vaginal epithelial cells in the active but not the placebo group. Estriol produced subjective and objective improvements in urinary symptoms but was not significantly better than placebo.

Another recent RCT from the same group using 25 mg estradiol implants confirmed the previous findings (Rufford et al, 2003) and additionally found a high complication rate in the estradiol-treated patients (i.e., vaginal bleeding).

Evidence from Recent Large Clinical Trials. The **HERS study** included 763 postmenopausal women younger than the age of 80 years with coronary heart disease and intact uteri (Grady et al, 2001). It was designed to evaluate the use of estrogen in secondary prevention of cardiac events. In a secondary analysis, 1525 participants who reported at least one episode of incontinence per week at baseline were included. Participants were randomly assigned to 0.625 mg of conjugated estrogens plus 2.5 mg of medroxyprogesterone acetate in one tablet (n = 768) or placebo (n = 757) and were followed for a mean of 4.1 years. Severity of incontinence was classified as improved, unchanged, or worsened. The results showed that incontinence improved in 26% of the women assigned to placebo compared with 21% assigned to hormones whereas 27% of the placebo worsened compared with 39% of the hormone group ($P = .001$). This difference was evident by 4 months of treatment, for both urgency incontinence and SUI. The number of incontinent episodes per week increased an average of 0.7 in the hormone group and decreased by 0.1 in the placebo group ($P < .001$). The authors concluded that **daily oral estrogen plus progesterone therapy was associated with worsening urinary incontinence in older postmenopausal women with weekly incontinence and did not recommend this therapy for treatment of incontinence.** However, it is possible that the progestogen component may have had an influence on the results of this study.

The **Women's Health Initiative (WHI)** was a multicenter double-blind, placebo-controlled RCT of menopausal hormone therapy in 27,347 postmenopausal women aged 50 to 79 years enrolled between 1992 and 1998 for whom urinary incontinence symptoms were known in 23,296 participants at baseline and 1 year. The women were randomized based on hysterectomy status to active treatment or placebo. Those with a uterus were given 0.625 mg/day of conjugated equine estrogen (CEE) plus 2.5 mg/day of medroxyprogesterone acetate (CEE+MPA), whereas those who had undergone hysterectomy received estrogen alone (CEE). **At 1 year hormone therapy was shown to increase the incidence of all types of urinary incontinence among women who were continent at baseline.** The risk was highest for SUI, with results as follows: CEE+MPA: relative risk [RR] 1.7, 95% CI 1.61 to 2.18; CEE alone: RR 2.15, 95% CI 1.77 to 2.62; followed by mixed urinary incontinence CEE+MPA: RR 1.49, 95% CI 1.10 to 2.01. Results for CEE alone were RR 1.79 and 95% CI 1.26 to 2.53. The combination of CEE and MPA had no significant effect on developing urgency urinary incontinence: RR 1.15, 95% CI 0.99 to 1.34; but CEE alone increased the risk: RR 1.32, 95% CI 1.10 to 1.58. **For those women experiencing urinary incontinence at baseline, frequency worsened in both active groups:** CEE+MPA: RR 1.38, 95% CI 1.28 to 1.49; CEE alone: RR 1.47, 95% CI 1.35 to 1.61. Quantity of urinary incontinence worsened at 1 year in both active groups: CEE+MPA: RR 1.20, 95% CI 1.06 to 1.76; CEE alone: RR 1.59, 95% CI 1.39 to 1.82. Those women receiving hormone therapy were more likely to report that urinary incontinence limited their daily activities: CEE+MPA: RR 1.18, 95% CI 1.06 to 1.32; CEE alone: RR 1.29, 95% CI 1.15 to 1.45 at 1 year. Thus based on this secondary analysis of data from a huge study, **conjugated equine estrogen alone or in combination with medroxyprogesterone acetate was shown to increase the risk of urinary incontinence among continent women and worsen urinary incontinence among symptomatic women after 1 year of therapy.**

The **Nurses Health Study** (Grodstein et al, 2004) was a biennial postal questionnaire starting in 1976. In 1996, 39,436 postmenopausal women aged 50 to 75 years who reported no urinary leakage at the start of the study were followed-up for 4 years to identify incident cases of urinary incontinence: 5060 cases of occasional and 2495 cases of frequent incontinence were identified. The risk of developing urinary incontinence was increased among postmenopausal women taking hormones compared with women who had never taken hormones, respectively (oral estrogen: RR 1.54, 95% CI 1.44, 1.65; transdermal estrogen: RR1.68, 95% CI 1.41, 2.00; oral estrogen with progestin: RR 1.34, 95% CI 1.24, 1.44; transdermal estrogen with progestin: RR 1.46, 95% CI 1.16, 1.84). After cessation of hormone therapy there was a decreased risk of incontinence such that 10 years after stopping hormones the risk was identical in women who had and who never had taken hormone therapy.

Conclusions. Estrogen has an important physiologic effect on the female LUT and its deficiency is an etiologic factor in the pathogenesis of a number of conditions. However, the use of estrogen either alone or in combination with progestogen has yielded poor results. The current **level 1 evidence against the use of estrogens for the treatment of urinary incontinence comes from studies powered to assess their benefit in the prevention of cardiovascular events and therefore the secondary analyses have been based only on self-reported symptoms of urinary leakage without any objective data.** Despite this, **all of these large randomized controlled trials show a worsening of preexisting urinary incontinence (both stress and urgency) and an increased new incidence of urinary incontinence with both estrogen and estrogen plus progesterone.** However, the majority of patients in all of these studies were taking combined equine estrogen and this may not be representative of all estrogens taken by all routes of administration.

In a systematic review of the effects of estrogens for symptoms suggestive of an OAB, the conclusion was that estrogen therapy may be effective in alleviating OAB symptoms and that local administration may be the most beneficial route of administration (Cardozo et al, 2004c). It is quite possible that the reason for this

is that the symptoms of urinary urgency, frequency, and urgency incontinence may be a manifestation of urogenital atrophy in older postmenopausal women rather than a direct effect on the LUT (Robinson and Cardozo, 2003). Although there is good evidence that the symptoms and cytologic changes of urogenital atrophy may be reversed by low dose (local) vaginal estrogen therapy there is **currently no evidence that estrogens with or without progestogens should be used in the treatment of urinary incontinence.** Of interest would be studies looking at (1) the role of prophylactic versus therapeutic estrogen and (2) a double-blind study of transvaginal estrogen in various but low doses.

Concerns about the use of estrogen are summarized by Loose and Stancel (2006). **Unopposed estrogen for hormone treatment in postmenopausal women increases the risk of endometrial carcinoma by 5 to 15 fold, but this increased risk can be prevented if a progestin is coadministered with the estrogen, and this is now standard practice. In the WHI study** (see earlier), **an estrogen-progestin combination increased the total risk of breast cancer by 24%, translating into an absolute increase in attributable cases of disease of 6 per 1000 women requiring 3 or more years of treatment. In women without a uterus who received estrogen alone, the relative risk of breast cancer was actually decreased by 23%,** and the decrease only narrowly missed reaching statistical significance. **It appears to be the progestin component that plays a major role in the increased risk of breast cancer.** Estrogens increase cholesterol levels in bile and cause a relative twofold to threefold increase in gallbladder disease. The HERS study and the WHI study indicate that combination estrogen-progestin does not protect against coronary heart disease, but the specific populations studied and the specific preparations utilized may prohibit generalization of these conclusions to other preparations, doses, and patient populations. It is clear, however, that the **risk of thromboembolic disease is clearly elevated in women taking oral estrogen, both healthy women and women with preexisting cardiovascular disease. In the WHI study the estrogen-progestin combination was associated with an increase in eight cases of stroke per 10,000 women and a similar increase in pulmonary embolism.** Loose and Stancel (2006) also mention as possibilities altered cognition, changes in carbohydrate and lipid metabolism, hypertension, nausea, migraine, and changes in mood.

Future Possibilities

Peripherally Acting Drugs. A few new peripheral targets suitable for treatment have been identified and are under evaluation.

Vitamin D_3 Receptor Analogues. Rat and human bladders were shown to express receptors for vitamin D (Crescioli et al, 2005), which makes it conceivable that the bladder may also be a target for vitamin D. Analogues of vitamin D_3 have also been shown to inhibit benign prostatic hyperplasia (BPH) cell proliferation and to counteract the mitogenic activity of potent growth factors for BPH cells (Crescioli et al, 2002, 2003, 2004). Experiments in rats with bladder outflow obstruction (Schröder et al, 2006) showed that one of the analogues, BXL-628, at nonhypercalcemic doses, did not prevent bladder hypertrophy but reduced the decrease in contractility of the bladder smooth muscle that occurred with increasing bladder weight (Schröder et al, 2006). The mechanism of action for the effects has not been clarified. However, elocalcitol was shown to have an inhibitory effect on the RhoA/Rho kinase pathway (Morelli et al, 2007). Upregulation of this pathway has been associated with bladder changes associated with diabetes, outflow obstruction, and DO (Peters et al, 2006; Christ and Andersson, 2007). The effect of elocalcitol on prostate volume was evaluated in patients with BPH, and it was found that BXL628 was able to arrest prostate growth within 12 weeks in men aged 50 years or older with prostatic volume of 40 mL or more (Colli et al, 2006). In an RCT enrolling 120 female patients with OAB, in which the primary end point was an increase in the mean volume voided, a significant increase versus placebo (22% vs. 11%) was demonstrated (Colli et al, 2007). **Whether vitamin D receptor agonism (monotherapy or in combination) will be a useful alternative for the treatment of LUTS/OAB requires further RCTs.**

Centrally Acting Drugs. Many parts of the brain seem to be activated during storage and voiding (see, Griffiths 2007; Fowler et al, 2008; Griffiths and Tadic, 2008), and there is increasing interest in drugs modulating the micturition reflex by a central action (Andersson and Pehrson, 2003). Several drugs used for pain treatment also affect micturition, with morphine and some antiepileptic drugs being a few examples. However, CNS mechanisms have so far not been preferred targets for drugs aimed to treat OAB, because selective actions may be difficult to obtain. Holstege (2005), reviewing some of the CNS mechanisms involved in micturition, including the periaqueductal gray matter and the pontine micturition center, suggested that the problem in OAB or urgency incontinence is at the level of the periaqueductal gray matter or pontine micturition center and their connections, and possible treatments for this condition, should target the micturition pathways at that level.

Gonadotropin-Releasing Hormone Antagonists. The beneficial effects of the 5α-reductase inhibitors finasteride and dutasteride in the treatment of male LUTS are well documented. The efficacy of other hormonal treatments, for example, antiandrogens or gonadotropin-releasing hormone (GNRH; also known as luteinizing hormone-releasing hormone [LHRH]) agonists is either poor or at the expense of unacceptable side effects such as medical castration associated with hot flushes, decrease of potency and libido, and negative effects on bone density and cardiac health after long-term androgen ablation (Schroeder et al, 1986; Peters et al, 1987; Bosch et al, 1989; Eri and Tveter, 1993). With LHRH antagonists, submaximal, noncastrating blockade of the androgen testosterone and consequently of dihydrotestosterone can be achieved, thus avoiding medical castration.

Debruyne and coworkers (2008) demonstrated in a phase 2 RCT that the LHRH antagonist cetrorelix given subcutaneously weekly for 20 weeks to 140 men with LUTS (IPSS ≥ 13, peak urinary flow rates 5 to 13 mL/sec) rapidly caused a significant improvement in the mean IPSS: the peak decrease was –5.4 to –5.9 versus –2.8 for placebo. All dosage regimens tested were well tolerated, and the authors concluded that the drug offered a safe and effective treatment of male LUTS. **Further studies are needed to assess whether this therapeutic principle is a useful addition to the current treatment alternatives.**

Gabapentin. Gabapentin is one of the new first-generation antiepileptic drugs that expanded its use into a broad range of neurologic and psychiatric disorders (Striano and Striano, 2008). It was originally **designed as an anticonvulsant γ-aminobutyric acid (GABA) mimetic capable of crossing the blood-brain barrier** (Maneuf et al, 2003). The effects of gabapentin, however, do not appear to be mediated through interaction with GABA receptors, and its mechanism of action remains controversial (Maneuf et al, 2003). It has been suggested that it acts by binding to a subunit of the $\alpha_2\delta$ unit of voltage-dependent Ca^{2+} channels

(Gee et al, 1996; Striano and Striano, 2008). Gabapentin is also widely used not only for seizures and neuropathic pain but also for many other indications, such as anxiety and sleep disorders, because of its apparent lack of toxicity.

Carbone and coworkers (2006) reported on the effect of gabapentin on neurogenic DO. They found a positive effect on symptoms and significant improvement in urodynamic parameters and suggested that the effects of the drug should be explored in further controlled studies in both neurogenic and non-neurogenic DO. Kim and colleagues (2004) studied the effects of gabapentin in patients with OAB and nocturia not responding to antimuscarinic agents. They found that 14 of 31 patients experienced improvement of their symptoms with orally administered gabapentin. The drug was generally well tolerated, and the authors suggested that it can be considered in selective patients when conventional modalities have failed. It is possible that gabapentin and other $\alpha_2\delta$ ligands (e.g., pregabalin and analogues) will offer new therapeutic alternatives.

Tramadol. Tramadol is a well-known analgesic drug (Grond and Sablotzski, 2004). By itself it is a weak μ-receptor agonist, but it is metabolized to several different compounds, some of them almost as effective as morphine at the μ receptor. However, the drug (metabolites) also inhibits serotonin (5-HT) and norepinephrine reuptake (Grond and Sablotzski, 2004). This profile is of particular interest because both μ-receptor agonism and amine reuptake inhibition may be useful principles for treatment of LUTS/OAB/DO, as shown in a placebo-controlled study with duloxetine (Steers et al, 2008).

In rats, tramadol abolished experimentally induced DO caused by cerebral infarction (Pehrson et al, 2003). Tramadol also inhibited DO induced by apomorphine in rats (Pehrson and Andersson, 2003), a crude model of bladder dysfunction in Parkinson disease. Singh and associates (2008) gave tramadol epidurally and found the drug to increase bladder capacity and compliance and to delay filling sensations without adverse effects on voiding. Safarinejad and Hosseini (2006) evaluated in a double-blind, placebo-controlled randomized study the efficacy and safety of tramadol in patients with idiopathic DO. A total of 76 patients 18 years or older were given 100 mg tramadol in sustained-release form every 12 hours for 12 weeks. Clinical evaluation was performed at baseline and every 2 weeks during treatment. Tramadol significantly ($P < .01$) reduced the number of incontinence periods per 24 hours from 3.2 ± 3.3 to 1.6 ± 2.8 and induced improvements in urodynamic parameters. The main adverse event was nausea. It was concluded that, in patients with non-neurogenic DO, tramadol provided beneficial clinical and urodynamic effects. Even if tramadol may not be the best suitable drug for treatment of LUTS/OAB the study suggests efficacy for modulation of micturition via the μ receptor.

NK1-Receptor Antagonists. The main endogenous tachykinins substance P (SP), neurokinin A (NKA), and neurokinin B (NKB) and their preferred receptors NK1, NK2, and NK3, respectively, have been demonstrated in various CNS regions, including those involved in micturition control (Lecci and Maggi, 2001; Covenas et al, 2003; Saffroy et al, 2003). NK1 receptor–expressing neurons in the dorsal horn of the spinal cord may play an important role in DO, and tachykinin involvement via NK1 receptors in the micturition reflex induced by bladder filling has been demonstrated (Ishizuka et al, 1994) in normal and, more clearly, rats with bladder hypertrophy secondary to bladder outlet obstruction. Capsaicin-induced DO was reduced by blocking NK1 receptor–expressing neurons in the spinal cord, using intrathecally administered substance P/saponin conjugate (Seki et al, 2005). Furthermore, blockade of spinal NK1 receptor could suppress detrusor activity induced by dopamine receptor (levodopa) stimulation (Ishizuka et al, 1995b).

In conscious rats undergoing continuous cystometry, antagonists of both NK1 and NK2 receptors inhibited micturition, decreasing micturition pressure and increasing bladder capacity at low doses and inducing dribbling incontinence at high doses. This was most conspicuous in animals with outflow obstruction (Gu et al, 2000). Intracerebroventricular administration of NK1 and NK2 receptor antagonists to awake rats suppressed detrusor activity induced by dopamine receptor (levodopa) stimulation (Ishizuka et al, 2000). Taken together, available information suggests that spinal and supraspinal NK1 and NK2 receptors may be involved in micturition control.

Aprepitant, an NK-1 receptor antagonist used for treatment of chemotherapy-induced nausea and vomiting (Massaro and Lenz, 2005), was reported to improve symptoms of OAB in postmenopausal women with a history of urgency incontinence or mixed incontinence (with predominantly urgency urinary incontinence), as shown in a well-designed pilot RCT (Green et al, 2006). The primary end point was percent change from baseline in average daily micturitions assessed by a voiding diary. Secondary end points included average daily total urinary incontinence and urgency incontinence episodes and urgency episodes. Aprepitant significantly ($P < .003$) decreased the average daily number of micturitions (–1.3 ± 1.9) compared with placebo (–0.4 ± 1.7) at 8 weeks. The average daily number of urgency episodes was also significantly ($P < .047$) reduced (–23.2 ± 32%) compared with placebo (–9.3 ± 40%) and so were the average daily number of urgency incontinence and total urinary incontinence episodes, although the difference was not statistically significant. The large standard errors and the low placebo results are atypical for OAB trials. Aprepitant was generally well tolerated, and the incidence of side effects, including dry mouth, was low. The results of this initial proof of concept study suggest that NK-1 receptor antagonism holds promise as a potential treatment approach for OAB.

Drug Treatment of Overactivity in Augmented or Intestinal Neobladders

With regard to the subject of overactivity in bowel augmented or intestinal neobladders, Andersson and associates (1992) reviewed this subject and its pharmacologic treatment. They noted a few instances of positive results with drugs given systematically, but locally applied agents were believed to offer more promise. Pure antimuscarinic agents had produced few good results, either locally or systemically. Oxybutynin had shown some good results with local therapy but poor results with systemic therapy. The α- and β-AR agonists had shown little or no effects. Other possibilities mentioned included opioid agonists (diphenoxylate and loperamide), Ca^{2+} antagonists, K^+ channel openers, and nitric oxide donors. Apostolidis and colleagues (2007) reported a case of successful treatment with BoNT-A after failed augmentation ileocystoplasty.

Increasing Outlet Resistance

Many factors seem to be involved in the pathogenesis of SUI: urethral support, vesical neck function, and function of the nerves and musculature of the bladder, urethra, and pelvic floor (DeLancey, 1997; Mostwin et al, 2005). Anatomic factors cannot be treated pharmacologically. However, **women with SUI have lower resting urethral pressures than age-matched continent women** (Henriksson et al, 1979; Hilton and Stanton,

1983), **and because it seems likely that there is a reduced urethral closure pressure in most women with SUI it seems logical to increase urethral pressure to improve the condition.**

Factors that may contribute to urethral closure include tone of urethral smooth and striated muscle and the passive properties of the urethral lamina propria, in particular its vasculature. The relative contribution to intraurethral pressure of these factors is still subject to debate. However, there is ample pharmacologic evidence that a substantial part of urethral tone is mediated through stimulation of α-ARs in the urethral smooth muscle by released norepinephrine (Andersson, 1993; Andersson and Wein, 2004). A contributing factor to SUI, mainly in elderly women with lack of estrogen, may be lack of mucosal function. **The pharmacologic treatment of SUI aims at increasing intraurethral closure forces by increasing the tone in the urethral smooth and striated muscles. Several drugs may contribute to such an increase** (Andersson, 1988; Zinner et al, 2004b), **but relative lack of efficacy and/or side effects have limited their clinical use** (Table 68–4).

α-Adrenergic Receptor Agonists

Several drugs with agonistic effects on α-ARs have been used in the treatment of SUI (Table 68–5). However, **ephedrine** and norephedrine (**phenylpropanolamine** [PPA]) seem to have been the most widely used (Andersson et al, 2002). The original Agency for Healthcare Policy and Research Guidelines (1992) reported eight RCTs with PPA 50 mg twice daily for SUI in women. Percent cures (all figures refer to percent effect on drug minus percent effect on placebo) were listed as 0% to 14%, percent reduction in continence as 19% to 60%, and percent side effects and percent dropouts as 5% to 33% and 0% to 4.3%, respectively. The most recent Cochrane review on the subject (Alhasso et al, 2005) assessed RCTs or quasi-RCTs in adults with SUI that included an adrenergic agonist drug in at least one arm of the trial. There were no controlled studies reported on the use of such drugs in men. Twenty-two eligible trials were identified, 11 of which were crossover trials, which included 1099 women, 673 of whom received an adrenergic drug (PPA in 11, midrodrine in 2, norepinephrine in 3, clenbuterol in 3, terbutaline in 1, eskornade in 1, and RO 115-1240 in 1). The authors concluded "there was weak evidence to suggest that use of an adrenergic agonist was better than placebo treatment." The limited evidence suggested that such drugs were better than placebo in reducing the number of pad changes and incontinence episodes and in improving subjective symptoms. There was not enough evidence to evaluate the merits of an adrenergic agonist compared with estrogen, whether used alone or in combination. Regarding adverse events, the review reported similar numbers with adrenergic, placebo, or alternative drug treatment. Over 25% of subjects reported such effects, but when these consisted of effects due to adrenergic stimulation they caused discontinuation in only 4% of the total.

The date of the most recent amendment to this review is listed as May 15, 2007; no new trials were identified at that time. The update of 2005 (Alhasso et al, 2005) included seven new RCTs over the 2003 report, cited in the last consultation. The final statement on "what's new" reads, **"The conclusions still provide limited support for the use of adrenergics but side effects may cause dropout, and some side effects may be dangerous.** Further trials are needed."

Ephedrine and PPA lack selectivity for urethral α-ARs and can increase blood pressure and cause sleep disturbances, headache, tremor, and palpitations (Andersson et al, 2002). Kernan and coworkers (2000) reported **the risk of hemorrhagic stroke to be 16 times higher in women younger than 50 years of age who had been taking PPA as an appetite suppressant** (statistically significant) and 3 times higher in women who had been taking the drug for less than 24 hours as a cold remedy (not statistically significant). There was no increased risk in men. **PPA has been removed from the market in the United States.**

Numerous case reports of adverse reactions due to ephedra alkaloids exist, and some (Bent et al, 2003) had suggested that sale of these compounds as a dietary supplement be restricted or banned. In December 2003 the U.S. FDA decreed such a ban, a move that has survived legal appeal.

Midodrine and methoxamine stimulate α_1-ARs with some degree of selectivity. According to the RCTs available, the effectiveness of these drugs is moderate and the clinical usefulness seems to be limited by adverse effects (Weil et al, 1998; Radley et al, 2001; Alhasso et al, 2003).

Attempts continue to develop agonists with relative selectivity for the human urethra. Musselman and associates (2004) reported on a phase 2 randomized crossover study with Ro

Dantrolene	4	C

NR, not recommended.

115-1240, a peripheral active selective $\alpha_{1A/1L}$ adrenergic receptor partial agonist (Blue et al, 2004) in 37 women with mild to moderate SUI. A moderate, positive effect was demonstrated, but side effects have apparently curtailed further development of the drug.

β-Adrenergic Receptor Antagonists

The theoretical basis for the use of β-AR antagonists in the treatment of SUI is that blockade of urethral β-ARs may enhance the effects of norepinephrine on urethral α-ARs. Propranolol has been reported to have beneficial effects in the treatment of SUI (Gleason et al, 1974; Kaisary, 1984) **but there are no RCTs supporting such an action.** In Gleason and colleagues' (1974) study the beneficial effects become manifest only after 4 to 10 weeks of treatment—a phenomenon difficult to explain. Donker and Van der Sluis (1976) reported that β blockade did not change the urethral pressure profile in normal women. Although suggested as an alternative to α-AR agonists in patients with SUI and hypertension, these agents may have major potential cardiac and pulmonary side effects of their own, related to their therapeutic β-AR blockade.

β-Adrenergic Receptor Agonists

β-AR stimulation is generally conceded to decrease urethral pressure (Andersson, 1993), but **β_2-AR agonists have been reported to increase the contractility of some fast-contracting striated muscle fibers and suppress that of slow-contracting fibers of others** (Fellenius et al, 1980). **Some β-AR agonists also stimulate skeletal muscle hypertrophy—in fast-twitch more so than slow-twitch fibers** (Kim et al, 1992). **Clenbuterol** has been reported to potentiate the field stimulation–induced contraction in rabbit isolated periurethral muscle preparations, an action that is suppressed by propranolol and greater than that produced by isoproterenol (Kishimoto et al, 1991). These authors were the first to report an increase in urethral pressure with clinical use of clenbuterol and to speculate on its potential for the treatment of SUI. Yamanishi and associates (1994) reported an inotropic effect of clenbuterol and terbutaline on the fatigued striated urethral sphincter of dogs that was abolished by β-AR blockade.

Yasuda and coworkers (1993) described the results of a double-blind placebo-controlled trial with clenbuterol agent in 165 women with SUI. Positive statistical significance was achieved for subjective evaluation of incontinence frequency, pad usage per day, and overall global assessment. Pad weight decreased from 11.7 ± 17.9 g to 6.0 ± 12.3 g for drug and from 18.3 ± 29.0 g to 12.6 ± 24.7 g for placebo, raising questions about the comparability of the two groups. The "significant" increase in maximum urethral closure pressure was from 46.0 ± 18.2 cm H_2O to 49.3 ± 19.1 cm H_2O, versus a change of –1.5 cm H_2O in the placebo group. Fifty-six of 77 patients in the clenbuterol group reported some degree of improvement versus 48 of 88 in the placebo group. The positive effects were suggested to be a result of an action on urethral striated muscle and/or the pelvic floor muscles. Ishiko and associates (2000) investigated the effects of clenbuterol on 61 female patients with SUI in a 12-week randomized study, comparing drug therapy to pelvic floor exercises. The frequency and volume of SUI and the patient's own impression were used as the basis for the assessment of efficacy. The improvement of incontinence was 76.9%, 52.6%, and 89.5% in the respective groups. In an open study, Noguchi and colleagues (1997) reported positive results with clenbuterol (20 mg twice daily for 1 month) in 9 of 14 patients with mild to moderate SUI after radical prostatectomy. No subsequent published reports have appeared. **Further well-designed RCTs documenting the effects of clenbuterol are needed to adequately assess its potential as a treatment for SUI.**

Serotonin-Norepinephrine Uptake Inhibitors

Imipramine. Imipramine, among several other pharmacologic effects, inhibits the reuptake of norepinephrine and serotonin in adrenergic nerve endings. In the urethra this can be **expected to enhance the contractile effects of norepinephrine on urethral smooth muscle.** Gilja and colleagues (1984) reported in an open study on 30 women with SUI that imipramine 75 mg daily produced subjective continence in 21 patients and increased mean maximum urethral closure pressure from 34 to 48 mm Hg. A 35% cure rate was reported by pad test and, in an additional 25%, a 50% or more improvement.

Lin and coworkers (1999) assessed the efficacy of imipramine (25 mg imipramine three times a day for 3 months) as a treatment of genuine SUI in 40 women. A 20-minute pad test, uroflowmetry, filling and voiding cystometry, and stress urethral pressure profile were performed before and after treatment. The efficacy of "successful treatment" was 60% (95% CI 11.8 to 75.2). **There are no RCTs on the effects of imipramine on SUI.** No subsequent published reports have appeared.

Duloxetine. As mentioned previously, duloxetine is a serotonin-norepinephrine reuptake inhibitor that has been shown **to significantly increase sphincteric muscle activity during the filling/storage phase of micturition in the cat acetic acid model of irritated bladder function** (Thor et al, 1995; Katofiasc et al, 2002). The sphincteric effects were reversed by α_1-adrenergic (prazosin) and 5-HT_2 serotonergic (LY 53857) antagonism, whereas the bladder effects were mediated by temporal prolongation of the actions of serotonin and norepinephrine in the synaptic cleft (Fraser et al, 2003). Duloxetine is lipophilic, well absorbed, and extensively metabolized (CYP2D6). Its plasma half-life is approximately 12 hours (Sharma et al, 2000).

There are many studies, including RCTs, documenting the effects of duloxetine in SUI (Norton et al, 2002; Dmochowski et al, 2003a; Cardozo et al, 2004a; Millard et al, 2004; Van Kerrebroeck et al, 2004; Ghoneim et al, 2005; Kinchen et al, 2005; Hurley et al, 2006; Castro-Diaz et al, 2007; Bump, 2008). A Cochrane review of the effects of duloxetine for SUI in women is available, the last substantive amendment listed as May 25, 2005 (Mariappan et al, 2005). Fifteen reports were deemed eligible for analysis, nine primary studies, and six additional reports related to one or two of the primary references. An additional analysis "performed under the auspices of the Cochrane Incontinence Group" was performed on just the nine primary trials comparing duloxetine and placebo and published separately (Mariappan et al, 2007). The results can be summarized as follows. **Subjective "cure" in the duloxetine 80 mg daily (40 mg twice daily) group was higher than in the placebo group** (10.8% vs. 7.7%, overall RR = 1.42; 95% CI, 1.02 to 1.98; $P = .04$). The **estimated absolute size of effect was about 3 more patients cured of every 100 treated. Objective cure data, available from only one trial, showed no clear drug/placebo difference. Duloxetine showed greater improvement in Incontinence Quality of Life score (weighted mean difference for 80 mg:** 4.5; 95% CI 2.83 to 6.18, $P < .00001$). **Patient global impression of improvement (PGI-I) data also favored the drug** (RR for better health status 1.24, 95% CI 1.14 to 1.36; $P < .00001$). Adverse effects in six trials were analyzed. These were reported by 71% of drug subjects and 59% of those allocated to placebo. **Nausea was the most common adverse event,**

and the incidence ranged from 23% to 25% and was the main reason for discontinuation. **Other side effects reported were vomiting, constipation, dry mouth, fatigue, dizziness, and insomnia** for an overall RR of 1.30 (95% CI 1.23 to 1.37). Across these six trials 17% in the drug group and 4% in the placebo study arms withdrew. In the 2007 article the authors conclude by saying that **further research is needed as to whether management policies incorporating duloxetine are clinically effective and cost effective compared with other current minimally invasive and more invasive approaches in patients with varying severity of SUI and that "longer term experience is now a priority to determine whether there is sustained efficacy during and after duloxetine use and to rule out complications."** Hashim and Abrams (2006) suggested that to reduce the risk of nausea that therapy start with a dose of 20 mg twice daily for 2 weeks and then to increase to the recommended 40 mg twice-daily dosage.

Duloxetine is **licensed at 40 mg twice daily for the treatment of SUI in the European Union** (European Medicines Agency, 2005) for women with moderate to severe SUI (defined as 14 or more episodes per week). It was **withdrawn from the U.S. FDA consideration process for the treatment of SUI but is approved for the treatment of major depressive disorder (20 to 30 mg twice daily initially, 60 mg once-daily maintenance), diabetic peripheral neuropathic pain (60 mg once daily), and generalized anxiety disorder (60 mg once daily). The product information contains a "black box" warning of "increased risk of suicidal thinking and behavior in children, adolescents, and young adults taking antidepressants for major depressive disorder and other psychiatric disorders,"** noting also that "depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide" (Prescribing Information, revised December 2007, Eli Lilly and Company, Indianapolis, IN). Other warnings and precautions in the U.S. product information for psychiatric indications, not SUI, include hepatotoxicity (not to be used in patients with substantial alcohol use or chronic liver disease), orthostatic hypotension, serotonin syndrome (general statement regarding selective serotonin reuptake inhibitors, abrupt discontinuation (may result in dizziness, paresthesias, irritability, and headache), inhibitors of CYP1H2 or thioridazine (do not administer concomitantly), potent inhibitors of CYP2D6 (may increase concentration), and others.

Male Stress Urinary Incontinence

Although a problem of significant magnitude, especially after total prostatectomy for cancer, the pharmacologic treatment of male SUI is an area that has received relatively little attention. Tsakiris and coworkers (2008) searched for articles on this subject published between 1966 and June 2007 and did a generalized database search in addition. Nine trials were identified using α-AR agonists, β_2 antagonists, or serotonin-norepinephrine reuptake inhibitors. Only one of these included a comparison arm (Filocamo et al, 2007), 40 mg twice daily duloxetine plus pelvic floor exercises versus pelvic floor exercises with placebo. The results suggested a positive effect of drug but were a bit confusing. Of those patients completing the 4-month trial (92/112), 78% of the drug-treated patients versus 52% of those in the placebo group were dry. However, 1 month after the end of the study the corresponding figures were 46% versus 73%, a shift still observed 2 months later. The authors of the review article suggest further larger and well-designed studies on duloxetine for this potential usage.

Estrogens for Stress Incontinence

Estrogen-sensitive tissues of the bladder, urethra, and pelvic floor are all potentially important in maintaining the continence mechanism in women. For women to remain continent during increases in intra-abdominal pressure the urethral pressure must exceed the intravesical pressure at all times except during micturition. **There are four estrogen-sensitive functional layers that could play a part in the maintenance of a positive urethral pressure and closure mechanism: (1) the epithelium, including the mucosal seal mechanism; (2) the vasculature; (3) the connective tissue component; and (4) the muscular components,** including the smooth muscle of the bladder neck and urethra and the striated muscle, which is both intrinsic to the urethra and extrinsic (a part of the pelvic floor striated musculature). If estrogen did have a positive effect on SUI it could be by means of an effect on any or all of the structures (Andersson et al, 2009).

The role of estrogen in the treatment of SUI has been controversial, even though there are a number of reported studies (see Hextall, 2000). Some have given promising results, but this may be because they were observational, not randomized, blinded, or controlled. The situation is further complicated by the fact that a number of different types of estrogen have been used with varying doses, routes of administration, and durations of treatment. Fantl and coworkers (1996) treated 83 hypoestrogenic women with urodynamic evidence of genuine SUI and/or detrusor instability with conjugated equine estrogens 0.625 mg and medroxyprogesterone 10 mg cyclically for 3 months. Controls received placebo tablets. At the end of the study period the clinical and quality of life variables had not changed significantly in either group. Jackson and associates (1999) treated 67 postmenopausal women with genuine SUI or mixed incontinence with estradiol valerate 2 mg or placebo daily for 6 months. There was no significant change in objective outcome measures.

There have been two meta-analyses performed that have helped to clarify the situation further. In the first, a report by the Hormones and Urogenital Therapy (HUT) committee, the use of estrogens to treat all causes of incontinence in postmenopausal women was examined (Fantl et al, 1994). Of 166 articles identified, which were published in English between 1969 and 1992, only 6 were controlled trials and 17 uncontrolled series. The results showed that there was a significant subjective improvement for all patients and those with genuine SUI. However, assessment of the objective parameters revealed that there was no change in the volume of urine lost. Maximum urethral closure pressure did increase significantly, but this result was influenced by only one study showing a large effect. In the second meta-analysis, Sultana and Walters (1990) reviewed 8 controlled and 14 uncontrolled prospective trials and included all types of estrogen treatment. They also found that estrogen therapy was not an efficacious treatment of SUI but may be useful for the often associated symptoms of urgency and frequency. **Estrogen when given alone therefore does not appear to be an effective treatment for SUI.** However, several studies have shown that it may have a role in combination with other therapies (for combination with α-AR agonists, see earlier). In a randomized trial, Ishiko and coworkers (2001) compared the effects of the combination of pelvic floor exercise and estriol (1 mg/day) in 66 patients with postmenopausal SUI. Efficacy was evaluated every 3 months based on stress scores obtained from a questionnaire. They found a significant decrease in stress score in mild and moderate SUI patients in both groups 3 months after the start of therapy and concluded

that combination therapy with estriol plus pelvic floor exercise was effective and capable of serving as first-line treatment for mild SUI.

These conclusions still seem valid. Thus **reviews of recent literature agree on the fact that "estrogen therapy has little effect in the management of urodynamic SUI"** (Al-Badr et al, 2003; Robinson and Cardozo, 2003a, 2003b).

Circumventing the Problem

Vasopressin Analogues: Desmopressin

Desmopressin (1-desamino-8-D-arginine vasopressin; DDAVP) is a **synthetic vasopressin analogue with a pronounced antidiuretic effect but practically lacking vasopressor actions** (Andersson et al, 1988; Vande Walle et al, 2006). It is now widely used as **a treatment for primary nocturnal enuresis** (Nevéus et al, 1999; Glazener and Evans, 2002; Andersson et al, 2009). Studies have shown that one of the factors that can contribute to nocturnal enuresis in children, and probably in adults, is lack of a normal nocturnal increase in plasma vasopressin, which results in high nocturnal urine production (Rittig et al, 1989; Matthiesen et al, 1996; Nørgaard et al, 1997; Hjalmas, 1999). By decreasing the nocturnal production of urine, beneficial effects may be obtained in enuresis and nocturia. However, the drug may also have stimulatory effects on the CNS, as found in rats (DiMichele et al, 1996). Several, controlled, double-blind investigations have shown intranasal administration of desmopressin to be effective in the treatment of nocturnal enuresis in children (Nevéus et al, 1999; Glazener and Evans, 2002; Andersson et al, 2009). The dose used in most studies has been 20 µg intranasally at bedtime. However, the drug is orally active, even if the bioavailability is low (less than 1% compared with 2% to 10% after intranasal administration), and its efficacy in primary nocturnal enuresis in children and adolescents has been documented in randomized, double-blind, placebo-controlled studies (Janknegt et al, 1997; Skoog et al, 1997; Andersson et al, 2009).

Positive effects of desmopressin on nocturia in adults have been documented (Månsson et al, 1980; Hilton and Stanton, 1982; Asplund and Aberg, 1993; Asplund et al, 1999; Chancellor et al, 1999; Andersson et al, 2009). Nocturnal frequency and enuresis due to idiopathic DO responded favorably to intranasal desmopressin therapy even when previous treatment with "antispasmodics" had been unsuccessful (Hilton and Stanton, 1982). Also in patients with multiple sclerosis, desmopressin was shown in controlled studies to reduce nocturia and micturition frequency (Hilton et al, 1983; Kinn and Larsson 1990; Eckford et al, 1994; Fredrikson et al, 1996; Ferreira and Letwin, 1998; Andersson et al, 2009). In multiple sclerosis, effects on daytime frequency also have been documented (Hoverd and Fowler, 1998). Furthermore, desmopressin was shown to be successful in treating nocturnal enuresis in patients with spina bifida with diurnal incontinence (Horowitz et al, 1997).

Oral desmopressin also has proved to be effective in the treatment of nocturia. In a randomized double-blind study, Mattiasson and colleagues (2002) investigated the efficacy and safety of oral desmopressin in the treatment of nocturia in men. A 3-week dose-titration phase established the optimum desmopressin dose (0.1, 0.2, or 0.4 mg); and, after a 1-week "washout" period, patients who responded in the dose-titration period were randomized to receive the optimal dose of desmopressin or placebo in a double-blind design for 3 weeks. In all, 151 patients entered the double-blind period (86 treated with desmopressin, 65 with placebo). In the desmopressin group, 28 (34%) patients and in the placebo group, 2 (3%) patients had significantly fewer than half the number of nocturnal voids relative to baseline; the mean number of nocturnal voids decreased from 3.0 to 1.7 and from 3.2 to 2.7, respectively, reflecting a mean decrease of 43% and 12%. The mean duration of the first sleep period increased by 59% (from 2.7 to 4.5 hours) in the desmopressin group, compared with an increase of 21% (from 2.5 to 2.9 hours) in the placebo group. The mean nocturnal diuresis decreased by 36% (from 1.5 to 0.9 mL/min) in the desmopressin group and by 6% (from 1.7 to 1.5 mL/min) in the placebo group. The mean ratio of night per 24-hour urine volume decreased by 23% and 1%, and the mean ratio of night/day urine volume decreased by 27% and increased by 3% for the desmopressin and placebo groups, respectively. In the double-blind treatment period, similar numbers of patients had adverse events: 15 (17%) patients in the desmopressin and 16 (25%) patients in the placebo group. Most adverse events were mild. Serum sodium levels were less than 130 mmol/L in 10 (4%) patients, and this occurred during dose titration. The authors concluded that orally administered desmopressin is an effective and well-tolerated treatment for nocturia in men.

Lose and associates (2003) found similar results in women. In the double-blind phase of their study, 144 patients were randomly assigned to groups (desmopressin, n = 72; placebo, n = 72). For desmopressin, 33 (46%) patients had a 50% or greater reduction in nocturnal voids against baseline levels compared with 5 (7%) patients receiving placebo. The mean number of nocturnal voids, duration of sleep until the first nocturnal void, nocturnal diuresis, and ratios of nocturnal per 24 hours and nocturnal per daytime urine volumes changed significantly in favor of desmopressin versus placebo. In the dose-titration phase, headache (22%), nausea (8%), and hyponatremia (6%) were reported.

Robinson and colleagues (2004) introduced antidiuresis as a new concept in managing female daytime urinary incontinence. In a multicenter, multinational, randomized, double-blind, placebo-controlled, crossover exploratory study of women (aged 18 to 80 years) complaining of severe daytime urinary incontinence, 60 received study medication (safety population) and 57 completed the study. The primary efficacy end point was the number of periods with no leakage for 4 hours after dosing. There was a higher mean incidence of periods with no leakage in the first 4 hours on desmopressin, at 62 (35)%, than on placebo, at 48 (40)%, and during the first 8 hours, at 55 (37)% versus 40 (41)%. There was also a higher frequency of dry days on desmopressin than on placebo; 36% of patients had no leakage on virtually all treatment days (6 or 7) for 4 hours after dosing. The time from dosing to first incontinence episode was longer on desmopressin, at 6.3 (2.5) hours versus 5.2 (3.3) hours whereas the volume leaked per incontinence episode was lower on desmopressin than placebo. The total volume voided was consistently lower on desmopressin, at 1180 (58) mL versus 1375 (57) mL, over the 24-hour period after administration. There were no serious or severe adverse events reported, and it was concluded that desmopressin is an effective and safe treatment in women with daytime urinary incontinence.

Even if side effects are uncommon during desmopressin treatment there is a risk of water retention and hyponatremia (Robson et al, 1996; Schwab and Ruder, 1997). In elderly patients it was recommended that the serum sodium concentration should be measured before and after a few days of treatment (Rembratt et al, 2003). **Currently there are no predictive factors about who may be at increased risk of developing hyponatremia** (Andersson et al, 2009). However,

to reduce the risk of hyponatremia it is recommended that patients older than age 79 years or with a 24-hour urine volume more than 28 mL/kg should not be given desmopressin (Rembratt et al, 2006). In those older than age 65 years, serum sodium levels should be checked at baseline and at 3 days and 7 days after beginning treatment or changing dose. **It is probably good medical practice that these serum sodium measurements are also applied to those younger than 65 years of age, as well as checking sodium levels at 3 weeks after treatment or change of dose because there is the potential for levels of sodium to mean change within a 3-week period** (Callreus et al, 2005). One study showed that hyponatremia can develop after 6 months of administration, although this is not clinically significant (Bae et al, 2007), and therefore serum sodium levels may be checked at 6 months after administration and then every 6 months thereafter. Long-term use of desmopressin does not seem to affect baseline antidiuretic hormone secretion (Bae et al, 2007). The fluid intake will need to be limited to a minimum from 1 hour before the dose until 8 hours afterward, and there needs to be periodic blood pressure and weight measurements to monitor for fluid overload.

Desmopressin is a well-documented therapeutic alternative in pediatric nocturnal enuresis and also is effective in adults with nocturia of polyuric origin. Whether it will be an alternative for managing daytime OAB symptomatology, including urgency, frequency, and urinary incontinence, requires further documentation.

Diuretics

Another circumventive pharmacologic approach is to give a rapid-acting loop diuretic 4 to 6 hours before bedtime. This, of course, assumes the nocturia is not caused by obstructive uropathy. A randomized, double-blind crossover study on this approach using bumetanide in a group of 14 general practice patients was reported by Pedersen and Johansen (1988). Control nocturia episodes per week averaged 17.5; with placebo this decreased to 12 (!) and with drug to 8. Bumetanide was preferred to placebo by 11 of 14 patients.

PHARMACOLOGIC THERAPY TO FACILITATE BLADDER EMPTYING

Increasing Intravesical Pressure/Bladder Contractility

Parasympathomimetic Agents

Because a major portion of the final common pathway in physiologic bladder contraction is stimulation of parasympathetic postganglionic muscarinic cholinergic receptor sites, agents that imitate the actions of acetylcholine might be expected to be effective in treating patients who cannot empty their bladder because of inadequate bladder contractility. Acetylcholine, which is a quaternary amine, cannot be used for therapeutic purposes because of its action at both muscarinic and nicotinic receptors; it is rapidly hydrolyzed by acetylcholinesterase and by butyrylcholinesterase (Brown and Taylor, 2006). Many acetylcholine-like drugs exist, but only bethanechol chloride exhibits a relatively selective in-vitro action on the urinary bladder and gut with little or no nicotinic action (Brown and Taylor, 2006). **Bethanechol is cholinesterase resistant and causes an in-vitro contraction of smooth muscle from all areas of the bladder** (see Chapter 60).

Bethanechol, or agents similar to it, has historically been recommended for the treatment of postoperative or postpartum urinary retention, but only if the patient is awake and alert and if there is no outlet obstruction. The recommended dose has been 5 to 10 mg subcutaneously. For more than 50 years, bethanechol has been recommended for the treatment of the atonic or hypotonic bladder and has been reported as effective in achieving "rehabilitation" of the chronically atonic or hypotonic detrusor (Sonda et al, 1979). This drug has also been reported to stimulate or facilitate the development of reflex bladder contractions in patients in spinal shock secondary to suprasacral spinal cord injury (Perkash, 1975).

Although bethanechol has been reported to increase gastrointestinal motility and has been used in the treatment of gastroesophageal reflux, and although anecdotal success in specific patients with voiding dysfunction seems to occur, **there is little or no evidence to support its success in facilitating bladder emptying in a series of patients in whom the drug was the only variable** (Finkbeiner, 1985; Barendrecht et al, 2007). In one set of trials a pharmacologically active subcutaneous dose (5 mg) did not demonstrate significant changes in flow parameters or residual urine volume in (1) a group of women with a residual urine volume greater than or equal to 20% of bladder capacity but no evidence of neurologic disease or outlet obstruction; (2) a group of 27 "normal" women of approximately the same age; or (3) a group of patients with a positive bethanechol supersensitivity test (Wein et al, 1980a, 1980b). This dose did increase cystometric filling pressure and also decreased bladder capacity threshold, findings previously described by others (Sonda et al, 1979). Short-term studies in which the drug was the only variable have generally failed to demonstrate significant efficacy in terms of flow and residual urine volume data (Barrett, 1981). Farrell and colleagues (1990) conducted a double-blind randomized trial that looked at the effects of two catheter management protocols and the effect of bethanechol on postoperative retention after gynecologic incontinence surgery and concluded that bethanechol was not helpful in this setting. Although bethanechol is capable of eliciting an increase in bladder smooth muscle tension, as would be expected from in-vitro studies, its ability to stimulate or facilitate a coordinated and sustained physiologic-like bladder contraction in patients with voiding dysfunction has been unimpressive (Finkbeiner, 1985; Andersson, 1988).

It is difficult to find reproducible urodynamic data that support recommendations for the use of bethanechol in any specific category of patients. Most, if not all, "long-term" reports in such patients are neither prospective nor double blind and do not exclude the effects of other simultaneous regimens (e.g., treatment of urinary infection, bladder decompression, timed emptying, or other types of treatment affecting the bladder or outlet), an important observation to consider when reporting such drug studies. Whether repeated doses of bethanechol or any cholinergic agonist can achieve a clinical effect that a single dose cannot is speculative, as are suggestions that bethanechol has a different mode of action or effect on atonic or decompensated bladder muscle than on normal tissue.

Bethanechol, administered subcutaneously, does cause an increased awareness of a distended bladder (Downie, 1984). This could facilitate more frequent emptying at lower volumes and thereby help to avoid overdistention, but, it would seem, only in a bladder that is capable of a contraction. O'Donnell and Hawkins (1993) administered 5 mg of bethanechol subcutaneously to 10 neurologically intact males and made the following cystometric observations: bladder volume at first desire to void

decreased (220 mL to 85 mL), maximum bladder capacity decreased (380 mL to 160 mL), first desire to void occurred at a higher pressure (5 cm H_2O vs. 28 cm H_2O), and compliance was reduced. They concluded that bethanechol affects the ability of the bladder to accommodate volume. Patients were comfortable at a resting bladder pressure of 20 cm H_2O (uncommon in their population), and the pressures at maximum bladder capacity were considerably higher than commonly seen under normal conditions. This suggested to them that either bladder pressure alone is not a significant factor in the perception of a sensation of first desire to void or that bethanechol somehow alters the threshold at which perception of desire to void occurs (because these patients showed a tolerance for increased intravesical pressure before first desire to void and at maximum bladder capacity). De Wachter and Wyndaele (2001) determined the bladder electrical threshold in healthy volunteers receiving 5 mg bethanechol subcutaneously. They found a marked decrease in the volume at which various filling sensations occurred and that the electrical threshold decreased after drug administration. De Wachter and coworkers (2003) treated 18 women with impaired detrusor contraction with subcutaneous bethanechol (5 mg four times daily) for 10 days. At the end of treatment, 61% of the patients voided without a postvoid residual volume. These investigators also found that in these women the sensation of filling and the electrical sensitivity were significantly increased compared with before treatment. The authors suggested that patients likely to respond to bethanechol can be identified by determination of the bladder electrical perception threshold.

Riedl and colleagues (2000) performed a clinical study in 45 patients with detrusor areflexia. They were tested with electromotive administration of intravesical bethanechol. Bethanechol 25 mg given orally once daily were then prescribed for 15 patients and voiding control was assessed after 6 weeks of therapy. A mean pressure increase of 34 cm H_2O during the electromotive administration of bethanechol was found in 24 of 26 patients with areflexia and neurologic disease compared with only 3 cm H_2O in 3 of 11 with a history of chronic bladder dilatation. Oral bethanechol restored spontaneous voiding in 9 of 11 patients who had had a positive response to the electromotive administration of bethanechol, whereas all 4 without a pressure increase during the electromotive administration of bethanechol did not void spontaneously. Riedl and coworkers (2000) concluded that electromotive administration of intravesical bethanechol can identify patients with an atonic bladder and adequate residual detrusor muscle function who are candidates for restorative measures, such as oral bethanechol and intravesical electrostimulation. Those who do not respond to the electromotive administration of bethanechol do not benefit from oral bethanechol and are candidates for catheterization.

No agreement exists as to whether cholinergic stimulation produces an increase in urethral resistance (Wein et al, 1980a, 1980b). It would appear that pharmacologically active doses do, in fact, increase urethral closure pressure, at least in patients with neurogenic DO (Sporer et al, 1978). This would of course tend to inhibit bladder emptying. As to whether cholinergic agonists can be combined with agents to decrease outlet resistance to facilitate emptying and achieve an additive or synergistic effect, the authors' own experience with such therapy, using even 200 mg (50 mg four times a day) of oral bethanechol daily, has been extremely disappointing. Certainly, most clinicians would agree that a total divided daily dose of 50 to 100 mg rarely affects any urodynamic parameter at all. In a prospective, single-blind randomized study comprising 119 patients with underactive detrusor, Yamanishi and colleagues (2004) studied the effect of combination of a cholinergic drug (bethanechol 60 mg/day or distigmine 15 mg/day) and an α-AR antagonist (urapidil 60 mg/day). The effectiveness of each therapy was assessed 4 weeks after initialization of the therapy using the IPSS. The IPSS results remained unchanged after the cholinergic therapy but were significantly lower after the α-AR antagonist treatment and the combination therapy. With regard to the total IPSS, there were significant differences between the cholinergic and the α-AR antagonist groups and also between the cholinergic and combination groups, in favor of the latter. The average and maximum flow rates did not increase significantly after monotherapy with either the cholinergic drug or the α-AR antagonist, but they significantly increased after combination therapy compared with baseline values. Postvoid residual volume did not decrease significantly after the cholinergic drug therapy but decreased significantly after the α-AR antagonist and the combination therapies. The authors concluded that combination therapy with a cholinergic drug and an α-AR antagonist appeared to be more useful than monotherapy for the treatment of an underactive detrusor.

The question of whether bethanechol may be efficacious in a particular patient can be answered by a brief urodynamically controlled trial in which institution of therapy is the only variable. In the laboratory, a functioning micturition reflex is an absolute requirement for the production of a sustained bladder contraction by a subcutaneous injection of the drug (Downie, 1984). **Patients with incomplete lower motor neuron lesions constitute the most reasonable group for a trial of bethanechol** (Awad, 1985), although subcutaneous administration may be required. **It is generally agreed that, at least in a "denervated" bladder, an oral dose of 200 mg is required to produce the same urodynamic effects as a subcutaneous dose of 5 mg** (Diokno and Lapides, 1977).

The **potential side effects of cholinomimetic drugs** include flushing, nausea, vomiting, diarrhea, gastrointestinal cramps, bronchospasm, headache, salivation, sweating, and difficulty with visual accommodation (Brown and Taylor, 2006). Intramuscular and intravenous use can precipitate acute and severe side effects, resulting in an acute circulatory failure and cardiac arrest and are therefore prohibited. Contraindications to the use of this general category of drug include bronchial asthma, peptic ulcer, bowel obstruction, enteritis, recent gastrointestinal surgery, cardiac arrhythmia, hyperthyroidism, and any type of bladder outlet obstruction.

One potential avenue of increasing bladder contractility is cholinergic enhancement or augmentation. Such an action might be useful alone or in combination with a parasympathomimetic agent. **Metoclopramide** is a dopamine receptor antagonist with cholinergic properties (Pasricha et al, 2006). It has a central antiemetic effect in the chemoreceptor trigger zone and peripherally increases the tone of the lower esophageal sphincter, promoting gastric emptying. Its effects seem to be related to its ability to antagonize the inhibitory action of dopamine, to augment acetylcholine release, and to sensitize the muscarinic receptors of gastrointestinal smooth muscle. Some data in the dog suggest that this agent can increase detrusor contractility (Mitchell and Venable, 1985), but there are no controlled studies documenting a useful clinical effect in the treatment of detrusor underactivity.

Cisapride is a substituted piperidinyl benzamide with a number of different pharmacologic activities, including a possible direct stimulation of smooth muscle (Pasricha, 2006). Until

recently it was commonly used as a prokinetic agent, particularly for gastroesophageal reflux and gastroparesis. It was also suggested that it could improve bladder contractility (Carone et al, 1993; Binnie et al, 1988; Steele et al, 2001). However, there was never any particularly convincing data that the drug improved voiding function, and it is no longer available in the United States because of its potential to induce serious and occasional cardiac arrhythmias (Smalley et al, 2000; Pasricha, 2006). The concept, however, of cholinergic enhancement or augmentation remains attractive but awaits the development of a bladder selective compound.

Prostaglandins

The reported use of prostaglandins to facilitate emptying is based on hypotheses that these substances contribute to the maintenance of bladder tone and bladder contractile activity (see Chapter 60 and Andersson, 1993; Zderic et al, 1995; Andersson, 1999a, 1999b, 1999c; Andersson and Wein, 2004, for a complete discussion). **Prostaglandins and thromboxane A_2 (TXA_2) have been shown to be present in human bladder in the following quantitative order: $PGE_2 > PGE_1 > PGF_{2\alpha} > TXA_2$; isolated detrusor muscle is contracted by $PGF_{2\alpha}$, PGE_1, PGE_2, and TXA_2** (see references in Andersson and Wein, 2004). **Prostanoids are synthesized locally in both bladder muscle and mucosa, with synthesis being initiated by various physiologic stimuli such as detrusor muscle stretch, mucosal injury, and neural stimulation; by ATP; and by mediators of inflammation** (Andersson and Wein, 2004). Prostanoids may affect bladder activity directly by effects on the smooth muscle or indirectly through effects on neurotransmission. **Possible roles mentioned by** Andersson (2000a) **include (1) neuromodulators of efferent and afferent neurotransmission; (2) sensitization or perhaps (3) activation of certain sensory nerves; and (4) potentiation of acetylcholine release from cholinergic nerve terminals through prejunctional prostanoid receptors. PGE_2 seems to cause a net decrease in urethral smooth muscle tone; $PGF_{2\alpha}$ causes an increase.**

Bultitude and colleagues (1976) first reported that instillation of 0.5 mg PGE_2 into the bladders of females with varying degrees of urinary retention resulted in acute emptying and in improvement of longer-term emptying (several months) in two thirds of the patients studied (n = 22). Desmond and associates (1980) reported results with intravesical use of 1.5 mg of this agent (diluted with 20 mL of 0.2% neomycin solution) in patients whose bladders exhibited no contractile activity or in whom bladder contractility was relatively impaired. Twenty of 36 patients showed a strongly positive immediate response, and 6 showed a weakly positive one. Fourteen patients were reported to show prolonged beneficial effects, all but 1 of whom had shown a strongly positive immediate response. Stratification of the data revealed that an intact sacral reflex arc was a prerequisite for any type of positive response. Tammela and coworkers (1987) reported that one intravesical administration of 10 mg of $PGF_{2\alpha}$ facilitated voiding in women who were in retention 3 days after surgery for SUI. The drug was administered in 50 mL of saline solution as a single dose and retained for 2 hours. However, in these "successfully" treated patients, the average maximum flow rate was 10.6 mL/sec with a mean residual urine volume of 107 mL, and the authors stated that "bladder emptying deteriorated in most patients on the day after treatment." Koonings and colleagues (1990) reported that daily intravesical $PGF_{2\alpha}$ and intravaginal PGE_2 reduced the number of days required for catheterization after SUI surgery when compared with a control group receiving intravesical saline solution.

Others, however, have reported negative results. Grignaffini and Bazzani (1998) reported on instillation of 1.5 mg of PGE_2 in 50 mL of saline solution into the bladder of 50 patients on their fourth day after vaginal hysterectomy and cystourethropexy, with a control group of 60 patients. The results are presented in an interesting fashion. After catheter removal, following the PGE_2 or control treatment, 58% of the PGE_2-treated group voided spontaneously as compared with 48.3% of the control group. This difference was not significant. Thus, 42% of the treated group and 51.7% of the control group were in retention. Of those who were in retention, the number who were in retention for fewer than 3 days was greater in the PGE_2 group (32%) versus the control group (25%), and this was statistically significant. Likewise, the number who remained in urinary retention for 3 days or longer after the initial treatment was 10% in the PGE_2-treated group versus 26.7% in the control group. Stanton and colleagues (1979) and Delaere and associates (1981) reported on success utilizing intravesical PGE_2 in doses similar to those reported earlier; Delaere and associates (1981) similarly reported no success using $PGF_{2\alpha}$ in a group of women with emptying difficulties of various causes. Wagner and coworkers (1985) used PGE_2 in doses of 0.75 to 2.25 mg and reported no effect on urinary retention in a group of patients after anterior colporrhaphy.

In a prospective randomized double-blind study, Hindley and colleagues (2004) tested the hypothesis that the combination of intravesical PGE_2 and oral bethanechol are additive or synergistic in improving bladder emptying. Nineteen patients with detrusor underactivity (17 men and 2 women) were eligible and randomized to one of two treatments. One group (9 patients) received once-weekly intravesical PGE_2 (1.5 mg in 20 mL 0.9% saline) plus bethanechol 50 mg four times daily for a total of 6 weeks. A second group of 10 patients received a once-weekly instillation of saline together with placebo tablets, again for 6 weeks. Although there was evidence of a pharmacologic effect, bethanechol and PGE_2 had a limited therapeutic effect compared with placebo. The authors did not recommend this treatment as routine but suggested that it may be considered for the occasional treatment of a patient with detrusor underactivity.

There has been little recent activity in this area, a fact that generally means that clinicians have lost interest or that the initial optimistic results have not been confirmed. **Prostaglandins have a relatively short half-life, and it is difficult to understand how any effects after a single application can last up to several months. If such does occur, it must be the result of a "triggering effect" on some as yet unknown physiologic or metabolic mechanism. Because of the number of conflicting positive and negative reports with various intravesical preparations, double-blind, placebo-controlled studies would obviously be helpful to see whether there are circumstances in which prostaglandin use can reproducibly facilitate emptying or treat postoperative retention.** Potential systemic side effects of prostaglandin use include vomiting, diarrhea, pyrexia, hypertension, and hypotension (Campbell and Halushka, 1996).

Blockers of Inhibition

de Groat and coworkers (see Chapter 60; de Groat et al, 1993; Zderic et al, 1995) have demonstrated a sympathetic reflex during bladder filling that, at least in the cat, promotes urine storage partly by exerting an α-AR–mediated inhibitory effect on pelvic parasympathetic ganglionic transmission. Some have suggested that α-AR blockade, in addition to decreasing outlet resistance, may, in fact, facilitate transmission through these ganglia and

thereby enhance bladder contractility. On this basis, Raz and Smith (1976) were the first to advocate a trial of an α-AR blocking agent for the treatment of nonobstructive urinary retention. A complete discussion of postoperative retention, including the use of α-AR antagonists for its treatment, is presented elsewhere (see Chapter 65).

Opioid Receptor Antagonists

Endogenous opioids have been hypothesized to exert a tonic inhibitory effect on the micturition reflex at various levels (see Chapter 60) (Zderic et al, 1995), and agents such as opioid receptor antagonists therefore may offer possibilities for stimulating reflex bladder activity.

Thor and associates (1983) were able to stimulate a micturition contraction with naloxone, an opioid receptor antagonist, in unanesthetized chronic spinal cord–injured cats. The effects, however, were transient, and tachyphylaxis developed. Vaidyanathan and associates (1981) reported that an intravenous injection of 0.4 mg of naloxone enhanced detrusor reflex activity in five of seven patients with neuropathic bladder dysfunction caused by incomplete suprasacral spinal cord lesions. The maximum effect occurred within 1 to 2 minutes after intravenous injection and was gone by 5 minutes. Murray and Feneley (1982) reported that the same dose of naloxone caused, in a group of patients with idiopathic DO, an increase in detrusor pressure at zero volume and at first desire to void, a decrease in the maximum cystometric capacity, and a worsening of the degree of instability. Galeano and coworkers (1986) reported that although naloxone increased bladder contractility in the cat with chronic spinal cord injury, it also aggravated striated sphincter dyssynergia and spasticity—a potential problem in the treatment of emptying failure. Wheeler and colleagues (1987) noted no significant cystometric changes in a group of 15 spinal cord–injured patients after intravenous administration of naloxone, whereas 11 showed decreased perineal electromyographic (EMG) activity. **Although an intriguing area, the concept of reversing an inhibitory opioid influence to stimulate reflex bladder activity is of little practical use at present.**

Decreasing Outlet Resistance

At a Site of Anatomic Obstruction

This topic includes the treatment of bladder outlet obstruction secondary to benign prostatic enlargement, and a full discussion is appropriately found in Chapters 92 and 93.

At the Level of the Smooth Sphincter

α-Adrenergic Receptor Antagonists. Whether one believes that there is significant innervation of the bladder and proximal urethral smooth musculature by postganglionic fibers of the sympathetic nervous system, one must acknowledge the existence of α- and β-AR sites. **The smooth muscle of the bladder base and proximal urethra contains predominantly α-ARs, although β-ARs are present. The bladder body contains both varieties of adrenergic receptors, with the β-ARs (β_3) variety being more common** (see Chapter 60) (Zderic et al, 1995; Andersson, 2000a). **The human LUT contains more α_2 than α_1 ARs, but adrenergically induced prostatic smooth muscle contraction and human LUT smooth muscle contraction are mediated largely, if not exclusively, by α_1 ARs.** There are at least three subtypes of α_1 ARs, designated α_{1A}, α_{1B}, and α_{1D}. **Adrenergically induced smooth muscle contraction in the human LUT is mediated largely by the α_{1A}** (and in the detrusor α_{1D}) subtype (Docherty, 1998; Harada and Fujimura, 2000; Michel et al, 2000; Schwinn, 2000; Andersson and Wein, 2004; Andersson and Gratzke, 2007). In addition to the three cloned α_1 ARs, there is a possible fourth, α_{1L}, although the α_{1L}-AR is probably a variant of the α_{1A}. There is a tremendous amount of information and controversy in the literature regarding the selectivity of certain α-AR blocking agents for these respective receptor subtypes. Conclusions are drawn regarding "the best" α_1-AR antagonist for the treatment of at least BPH on the basis of in-vitro and in-vivo pharmacologic selectivity, but many authors note that this does not necessarily translate into functional selectivity in a given patient (Andersson, 2002c; Djavan et al, 2004). The various α-AR antagonists are dealt with in more detail in Chapter 60 (see also Andersson, 2007).

Krane and Olsson (1973) **were among the first to promote the concept of a physiologic internal sphincter partially controlled by tonic sympathetic stimulation of contraction-mediating α-ARs in the smooth musculature of the bladder neck and proximal urethra. Furthermore, they hypothesized that some obstructions at this level during bladder contraction are a result of inadequate opening of the bladder neck and/or of an inadequate decrease in resistance in the area of the proximal urethra. They also theorized and presented evidence that α-AR blockade could be useful in promoting bladder emptying in such a patient with an adequate detrusor contraction but without anatomic obstruction or detrusor–striated sphincter dyssynergia.** They and many others (see Wein and Barrett, 1988) have confirmed the usefulness of α-AR blockade in the treatment of what is now usually referred to as smooth sphincter or bladder neck dyssynergia or dysfunction. Successful results, usually defined as an increase in flow rate, a decrease in residual urine, and an improvement in upper tract appearance (where pathologic), could often be correlated with an objective decrease in urethral profile closure pressure.

One would expect success with such therapy to be most evident in patients without detrusor–striated sphincter dyssynergia, as reported by Hachen (1980). Mobley (1976), however, reported a startling 86% subjective success rate in 21 patients with a reflex neurogenic bladder, with a corresponding success rate of 66% in what was called "flaccid" and 57% of what was called "autonomous" neurogenic bladder dysfunction, with success being defined as postvoid residual urine volume consistently less than 100 mL. Scott and Morrow (1978), on the other hand, noted excellent results with phenoxybenzamine therapy in 9 of 10 patients with a flaccid bladder and a flaccid external sphincter and in a single patient with an upper motor neuron bladder with intact sympathetic innervation, but in only 8 of 21 patients with hyperreflexia and autonomic dysreflexia, and in none of 6 patients with an upper motor neuron bladder and sympathetic denervation (lesion between T10 and L2).

Although most would agree that α-AR blocking agents exert their favorable effects on voiding dysfunction by affecting the smooth muscle of the bladder neck and proximal urethra, **information in the literature suggests that they may decrease striated sphincter tone as well;** and other information suggests that they may exert some of their effects on at least the filling/storage symptoms of voiding dysfunction by decreasing bladder contractility (see previous discussion). Much of the confusion relative to whether α-AR blocking agents have a direct (as opposed to indirect) inhibitory effect on the striated sphincter relates to the interpretation of clinical observations and

experimental data referable to their effect on urethral pressure in the region of the urogenital diaphragm and on EMG activity in the periurethral striated muscle of this area. One cannot tell by pressure tracings alone whether decreased resistance in this area of the urethra is secondary to a decrease in smooth or striated muscle activity. Nanninga and associates (1977) found that the EMG activity of the external sphincter decreased after phentolamine administration in three paraplegic patients and attributed this effect to a direct inhibition of sympathetic action on the striated sphincter. Nordling and associates (1981) demonstrated that clonidine and phenoxybenzamine (both of which pass the blood-brain barrier) also decreased urethral pressure in this area and yet had no effect on EMG activity. They concluded (1) that the effect of phentolamine was from smooth muscle relaxation alone; (2) that the effect of clonidine, and possibly phenoxybenzamine, was elicited mostly through centrally induced changes in striated urethral sphincter tonus; and (3) that these agents also had an effect on the smooth muscle component of urethral pressure. None of the three drugs, however, affected the reflex rise in either urethral pressure or EMG activity seen during bladder filling, and none decreased the urethral pressure or EMG activity response to voluntary contraction of the pelvic floor striated musculature. Gajewski and colleagues (1984) concluded that α-AR blockers do not influence the pudendal nerve dependent urethral response in the cat through a peripheral action but that at least prazosin can significantly inhibit this response at a central level. Thind and associates (1992) reported on the effects of prazosin on static urethral sphincter function in 10 healthy females. They found a reduction—predominantly in the midurethral area—and hypothesized that the response was caused by a decrease in both smooth and striated sphincter activity, the latter as a result of a reduced somatomotor output from the CNS. Clinically, Chancellor and coworkers (1994) reported that terazosin, a selective α_1-AR antagonist, had little or no effect on striated sphincter function in spinal cord–injured patients and had no effect on functional obstruction caused by sphincter dyssynergia in these patients.

α-AR blocking agents have also been used to treat both bladder and outlet abnormalities in patients with so-called autonomous bladders—such as those with myelodysplasia, sacral spinal cord or infrasacral neural injury, and voiding dysfunction after radical pelvic surgery (Wein and Barrett, 1988). Decreased bladder compliance is a common clinical problem in such patients, and this, along with a fixed urethral sphincter tone, results in the paradoxical occurrence of both storage and emptying failure.

Phenoxybenzamine. This was the α-AR antagonist originally used for the treatment of voiding dysfunction (see Te, 2002). Phenoxybenzamine has **blocking properties at both α_1- and α_2-AR sites.** The initial adult dosage of this agent is 10 mg/day, and the usual daily dose for voiding dysfunction is 10 to 20 mg. **After discontinuation, the effects of administration may persist for days, because the drug irreversibly inactivates α-ARs** and the duration of effect depends on the rate of receptor synthesis (Hoffman and Lefkowitz, 1996). Side effects affect approximately 30% of patients (Kirby, 1999) and include orthostatic hypotension, reflex tachycardia, nasal congestion, diarrhea, miosis, sedation, nausea, and vomiting (secondary to local irritation). It has mutagenic activity in the Ames test, and repeated administration to animals can cause peritoneal sarcomas and lung tumors (Westfall and Westfall, 2006). Although this agent has been in clinical use for some 35 years without clinically apparent oncologic associations, one must now consider the potential medicolegal ramifications of long-term therapy, especially in younger persons. A reassessment of the use of phenoxybenzamine for treatment of urinary tract disorders was made by Te (2002).

Prazosin. **Prazosin was the first potent selective α_1-AR antagonist** (see Westfall and Westfall, 2006) used to lower outlet resistance (Andersson et al, 1981). The duration of action is 4 to 6 hours; therapy is generally begun in daily divided doses of 2 to 3 mg. The dose may be very gradually increased to a maximum of 20 mg daily, although seldom has anyone used more than 9 to 10 mg daily for voiding dysfunction. The potential side effects of prazosin are consequent to its α_1-AR blockade. Occasionally there occurs a "first-dose phenomenon," a symptom complex of faintness, dizziness, palpitation, and, infrequently, syncope, thought to be caused by acute postural hypotension. The incidence of this can be minimized by restricting the initial dose of the drug to 1 mg and administering this at bedtime. Other side effects associated with chronic prazosin therapy are generally mild and rarely necessitate withdrawal of the drug.

Terazosin and Doxazosin. Terazosin and doxazosin are two highly selective postsynaptic α_1-AR antagonists. They are readily absorbed with high bioavailability and a long plasma half-life, enabling their activity to be maintained over 24 hours after a single oral dose. Both of these agents have been evaluated with respect to their efficacy in patients with LUTS and decreased flow rates presumed secondary to BPH. Their efficacy in decreasing symptoms and raising flow rates has been shown to be superior to placebo and similar to that of prazosin (Kirby, 1999). Their safety profiles have been well documented as a result of their widespread use over several years for the treatment of hypertension. Side effects are related to peripheral vasodilatation (postural hypotension), and both drugs have to be started at a low dose and titrated to obtain an optimum balance between efficacy and tolerability. Dizziness and weakness are sometimes observed, and these are presumed secondary to CNS actions. These drugs are marketed for the treatment of hypertension as well as LUTS presumed secondary to BPH.

Alfuzosin and Tamsulosin. **Alfuzosin and tamsulosin, both highly selective α_1-AR blockers, have appeared and are marketed solely for the treatment of BPH because of some reports suggesting preferential action on prostatic rather than vascular smooth muscle** (Kirby, 1999; Djavan et al, 2004). **Marketing claims aside, whether there is any difference in the efficacy/side effect profiles of these individual agents remains a topic of controversy.** Both are able to be administered once daily and without titration. **Available data suggest that retrograde ejaculation and rhinitis are more common with tamsulosin, whereas dizziness and asthenia are more common with terazosin and doxazosin** (Djavan et al, 2004).

Silodosin. Silodosin is a novel highly selective α_{1A}-AR antagonist (Yoshida et al, 2007). Clinical data (Kawabe et al, 2006) showed that silodosin showed significant improvement in LUTS associated with BPH, as well as in quality of life. The improvements were observed in both voiding and storage symptoms. Long-term study revealed that the efficacy and safety was sustained for 1 year. The most common adverse event in the silodosin group was abnormal ejaculation, which occurred in 22% of cases (Kawabe et al, 2006). Adverse events associated with lowering of blood pressure were low.

Summary. Agents with α-AR blocking properties at various levels of neural organization have been used in patients with very varied types of voiding dysfunction—functional outlet obstruction, urinary retention, decreased compliance, and DO. The authors' own experience would suggest that a trial of such an agent is

certainly worthwhile, because the effect or noneffect will become obvious in a matter of days and any pharmacologic side effects are, of course, reversible. However, our results with such therapy for non–BPH-related voiding dysfunction have been somewhat less spectacular than those of at least some other investigators.

Nitric Oxide. In the future there may be other pharmacologic mechanisms that are explored to produce relaxation in the smooth muscle of the bladder neck, urethra, or prostatic stroma. **Nitric oxide is a neurotransmitter capable of producing smooth muscle relaxation, at least in the female rabbit urethra, pig urethra, and human bladder neck** (Andersson and Persson, 1993; Andersson and Wein, 2004). A selective nitrergic action on bladder neck and urethral smooth muscle is an interesting theoretical possibility, and Mumtaz and coworkers (2000) suggest that a topical intraurethral nitric oxide donor could induce urethral smooth muscle relaxation without affecting bladder smooth muscle function and that this is a possible clinical avenue of exploration. Mamas and associates (2001, 2003) hypothesized that augmentation of external sphincter nitric oxide could be an effective pharmacologic therapy for detrusor–striated sphincter dyssynergia. In a functional urodynamic study, Reitz and coworkers (2004a) assessed the effect of the nitric oxide donor isosorbide dinitrate on the external urethral sphincter. Magnetic stimulation of the sacral roots was performed in eight healthy males to evoke reproducible contractions of the external urethral sphincter. Sublingual administration of isosorbide dinitrate (10 mg) could significantly reduce the resting pressure of the external urethral sphincter for at least 1 hour. The maximum contractile strength measured as the maximum urethral closure pressure during single pulse and continuous magnetic stimulation of the sacral roots also decreased significantly. Nitric oxide did not induce a significantly faster fatigue of the external urethral sphincter during continuous magnetic stimulation of the sacral roots. The authors suggested that nitric oxide donors could offer a new pharmacologic approach to treat urinary retention due to an overactive or nonrelaxing external urethral sphincter. In a later study on 12 male spinal cord–injured patients presenting with neurogenic DO and detrusor–striated sphincter dyssynergia, Reitz and coworkers (2004b) found that nitric oxide significantly reduced external urethral sphincter pressures at rest ($P < .05$) and during dyssynergic contraction ($P < .05$) while bladder pressures at rest and during contraction as well as the reflex volume remained unchanged. In patients who used suprapubic tapping for bladder emptying the mean post-triggering residual volume was significantly reduced ($P < .05$). Their conclusion based on their findings was that nitric oxide donors could offer a potential pharmacologic option to treat detrusor–striated sphincter dyssynergia in spinal cord–injured patients.

At the Level of the Striated Sphincter

There is no class of pharmacologic agents that will selectively relax the striated musculature of the pelvic floor. Three different types of drugs have been used to treat voiding dysfunction secondary to outlet obstruction at the level of the striated sphincter: the benzodiazepines, dantrolene, and baclofen. The benzodiazepines are classified as antianxiety agents (Baldessarini, 2006) and as sedative/hypnotics, muscle relaxants, and anticonvulsants (Charney et al, 2006). Dantrolene and baclofen are characterized as antispasticity agents (Standaert and Young, 2006; Taylor, 2006). Baclofen and diazepam exert their actions predominantly within the CNS, whereas dantrolene acts directly on skeletal muscle. Unfortunately **there is no completely satisfactory form of therapy for alleviation of skeletal muscle spasticity.** Although these drugs are capable of providing variable relief in given circumstances, their efficacy is far from complete; and troublesome muscle weakness, adverse effects on gait, and a variety of other side effects minimize their overall usefulness as treatments of spasticity (Standaert and Young, 2006; Taylor, 2006).

GABA and glycine have been identified as major inhibitory transmitters in the CNS (Andersson and Wein, 2004; Bloom, 2006). GABA is the most widely distributed inhibitory neurotransmitter in the mammalian CNS. GABA receptors have been divided into three types. The $GABA_A$ receptor directly gates a chloride ionophore and has modulatory binding sites for benzodiazepines, barbiturates, neurosteroids, and ethanol (Bloom, 2006). The $GABA_B$ or metabotropic receptor couples to Ca^{2+} and K^+ channels by means of G proteins and second messenger systems. It inhibits adenylate cyclase, activates K^+ channels, and reduces Ca^{2+} conductance. The $GABA_B$ receptor is activated by baclofen and is resistant to drugs that modulate $GABA_A$ receptors. There is a third type of GABA receptor, the $GABA_C$, that is less widely distributed than the A and B subtypes (Bloom, 2006). GABA appears to mediate the inhibitory actions of local interneurons in the brain and presynaptic inhibition within the spinal cord (Bloom, 2006). Glycine receptors are prominent in the brain stem and spinal cord and have many features analogous to the $GABA_A$ receptor.

Benzodiazepines. Benzodiazepines potentiate the action of GABA by promoting GABA binding to the $GABA_A$ receptor (Baldessarini, 2006; Charney, 2006). Benzodiazepines are extensively used for the treatment of anxiety and related disorders (Baldessarini, 2006), although pharmacologically they can also be classified as centrally acting muscle relaxants. The generalized anxiety disorder that is responsive to pharmacotherapy with these agents is characterized by unrealistic and/or excessive anxiety and worry about life circumstances (Shader and Greenblatt, 1993). Specific symptoms can be related to motor tension, autonomic hyperactivity (frequent urination can be a manifestation of this, as well as nausea, vomiting, diarrhea, and abdominal distress), and excessive vigilance. Other common uses have included treatment of insomnia, stress-related disorders, muscle spasm, and epilepsy and as preoperative sedation (Lader, 1987). Side effects include nonspecific CNS depression—manifested as sedation, lethargy, drowsiness, a feeling of slowing of thought processes, ataxia, and decreased ability to acquire or store information (Shader and Greenblatt, 1993; Baldessarini, 2006). Some believe that any muscle relaxation effect in clinically utilized doses is caused by the CNS depressant effects and cite a lack of clinical studies showing any advantages of these agents over placebo or aspirin in this regard (Baldessarini, 2006; Charney et al, 2006). Effective total daily doses of diazepam, the most widely used agent of this group, range from 4 to 40 mg. Other benzodiazepine anxiolytic agents include chlordiazepoxide, clorazepate, prazepam, halazepam, clonazepam, lorazepam, oxazepam, and alprazolam.

Few references are available that provide evaluable data on the use of any of the benzodiazepines in the treatment of functional obstruction at the level of the striated sphincter. Opinions, however, are commonly expressed, at least in regard to diazepam. The authors have not found the recommended oral doses of diazepam to be effective in controlling the classic type of detrusor–striated sphincter dyssynergia secondary to neurologic disease. If the etiology of incomplete emptying in a neurologically normal patient is obscure, and the patient has what appears to be inadequate relaxation of the pelvic floor striated musculature urodynamically (e.g., dysfunctional voiding, occult neuropathic bladder, the Hinman syndrome), a trial of such

an agent may be worthwhile. The rationale for use is either that of relaxation of the pelvic floor striated musculature during bladder contraction or that of such relaxation removing an inhibitory stimulus to reflex bladder activity. Improvement under such circumstances may simply be caused, however, by the antianxiety effect of the drug, or by the intensive explanation, encouragement, and modified biofeedback therapy that usually accompanies such treatment in these patients.

Baclofen. **Baclofen depresses monosynaptic and polysynaptic excitation of motor neurons and interneurons in the spinal cord by activating $GABA_B$ receptors** (Standaert and Young, 2006). Baclofen's primary site of action is in the spinal cord, but it is also reported to have activity at more rostral sites in the CNS. Baclofen has been found useful in the treatment of skeletal spasticity from a variety of causes (especially amyotrophic lateral sclerosis) (Standaert and Young, 2006). Determination of the optimal dose in an individual patient requires careful titration. Treatment is started at an initial dose of 5 mg twice daily, and the dose is increased every 3 days up to a maximum daily dose of 20 mg four times a day. With reference to voiding dysfunction, Hachen and Krucker (1977) found a daily oral dose of 75 mg ineffective in patients with striated sphincter dyssynergia from traumatic paraplegia, whereas they found a daily intravenous dose of 20 mg highly effective. Florante and colleagues (1980) reported that 73% of their patients with voiding dysfunction secondary to acute and chronic spinal cord injury showed lower striated sphincter responses and decreased residual urine volumes after baclofen treatment, but only with an average daily oral dose of 120 mg. Potential side effects of baclofen include drowsiness, insomnia, rash, pruritus, dizziness, and weakness. This drug may impair a person's ability to walk or stand and is not recommended for the management of spasticity caused by cerebral lesions or disease. Sudden withdrawal has been shown to provoke hallucinations, anxiety, and tachycardia; hallucinations during treatment, which have been responsive to reductions in dosage, have also been reported (Roy and Wakefield, 1986).

Drug delivery often frustrates adequate pharmacologic treatment, and baclofen is a good example of this. GABA's hydrophilic properties prevent its crossing the blood-brain barrier in sufficient amounts to make it therapeutically useful. For oral use, the more lipophilic analogue baclofen was developed. However, its passage through the barrier is likewise limited, and it has proved to be a generally insufficient drug when given orally to treat severe somatic spasticity and micturition disorders secondary to neurogenic dysfunction (Kums and Delhaas, 1991).

Intrathecal infusion bypasses the blood-brain barrier; cerebrospinal fluid levels 10 times higher than those reached with oral administration are achieved with infusion amounts 100 times less than those taken orally (Penn et al, 1989). Direct administration into the subarachnoid space by an implanted infusion pump showed initially promising results for not only skeletal spasticity but also striated sphincter dyssynergia and DO.

Nanninga and colleagues (1989) reported on such administration to seven patients with intractable spasticity. All patients experienced a general decrease in spasticity, and the amount of striated sphincter activity during bladder contraction decreased; six showed an increase in bladder capacity. Four previously incontinent patients were able to stay dry with CIC. The action on DO is not unexpected, given its spinal cord mechanism of action, and this inhibition of bladder contractility when administered intrathecally may in fact prove to be its most important benefit. Laubser and associates (1991) studied nine spinal cord–injured patients with refractory spasticity using an external pump to initially test the response. Eight showed objective improvement in functional abilities; three of the seven studied urodynamically showed an increase in bladder capacity. Kums and Delhaas (1991) reported on nine paraplegic or quadriplegic males (secondary to trauma or multiple sclerosis) with intractable muscle spasticity treated with intrathecal baclofen. After a successful test period through an external catheter, a drug delivery system was implanted and connected to a spinal catheter. Doses per 24 hours ranged from 74 to 840 μg. Patients were studied before and 4 to 6 weeks after initiation of therapy. Mean residual urine volume fell from 224 to 110 mL ($P = .01$), mean urodynamic bladder capacity rose from 162 to 263 mL ($P = .005$), and pelvic floor spasm decreased at both baseline and at maximum bladder capacity ($P < .005$ and $< .025$, respectively). Three subjects became continent. Additionally, CIC was no longer complicated by adductor spasm. Bushman and associates (1993) reported an increase in bladder storage in three individuals with hereditary spastic paraplegia treated with intrathecal baclofen. Tolerance to intrathecal baclofen with a requirement for increasing doses may prove to be a problem with long-term chronic use, and studies are under way to investigate this. Vaidyanathan and colleagues (2004) reported a case with insidious development of autonomic dysreflexia and hydronephrosis due to dyssynergic voiding after discontinuation of intrathecal baclofen therapy. They recommended that in spinal cord–injured patients, in whom intrathecal baclofen therapy is terminated, close monitoring of the urologic status is needed.

Dantrolene

Dantrolene exerts its effects by a direct peripheral action on skeletal muscle (Standaert and Young, 2006; Taylor, 2006). **It is thought to inhibit the excitation-induced release of Ca^{2+} ions from the sarcoplasmic reticulum of striated muscle fibers,** thereby inhibiting excitation-contraction coupling and diminishing the mechanical force of contraction. The blockade of Ca^{2+} release is not complete, however, and contraction is not completely abolished. It reduces reflex more than voluntary contraction, probably because of a preferential action on fast-type, as compared with slow-type, skeletal muscle fibers. It has been shown to have therapeutic benefits for chronic spasticity associated with CNS disorders.

The drug has been reported to improve voiding function in some patients with classic detrusor–striated sphincter dyssynergia and was initially reported as being very successful in doing so (Murdock et al, 1976). Therapy in adults is recommended to begin at a dose of 25 mg daily, and this is gradually increased by increments of 25 mg every 4 to 7 days to a maximum oral dose of 400 mg given in four divided doses. Hackler and coworkers (1980) achieved improvement in voiding function in approximately half of their patients treated with dantrolene but found that such improvement required oral doses of 600 mg daily. Although no inhibitory effect on bladder smooth muscle seems to occur (Harris and Benson, 1980), the generalized weakness that dantrolene can induce is often significant enough to compromise its therapeutic effects. Other potential side effects include euphoria, dizziness, diarrhea, and hepatotoxicity. Fatal hepatitis has been reported in 0.1% to 0.2% of patients treated with the drug for 60 days or longer, and symptomatic hepatitis may occur in 0.5% of patients on treatment for more than 60 days, whereas chemical abnormalities of liver function are noted in up to 1%. The risk of hepatic injury is twofold greater in females (Ward et al, 1986).

One agreed-on use of dantrolene is to acutely manage malignant hyperthermia, a rare hereditary syndrome characterized by vigorous contraction of skeletal muscle precipitated by

excess release of Ca^{2+} from the sarcoplasmic reticulum, generally in response to neuromuscular blocking agents or inhalational anesthetics. Almost all hospital pharmacies stock parenteral dantrolene for this purpose. **Virtually no one currently uses dantrolene for the treatment of voiding dysfunction.**

Botulinum Toxin

As mentioned previously, BoNT is an inhibitor of the release of acetylcholine and other transmitters at the neuromuscular junction of somatic nerves in striated muscle and of autonomic nerves in smooth muscle (Simpson, 2004). It is interesting that it produces enough weakness of the muscle to prevent or considerably ameliorate spasm or involuntary contraction but not to completely block voluntary control, a phenomenon hypothesized to occur because more active neuromuscular junctions are more likely than less active junctions to be blocked by the effect of the drug (Hallett, 1999). **Its urologic use for the treatment of detrusor–striated sphincter dyssynergia** was first reported by Dykstra and colleagues (Dykstra and Sidi, 1990; Dykstra et al, 1998). Injections were performed weekly for 3 weeks, achieving a duration of effect averaging 2 months. The only side effects reported in these articles were transitory limb paresis and transitory exacerbation of autonomic hyperreflexia. Fowler and coworkers (1992a) used BoNT in six women with difficult voiding/urinary retention secondary to what is now called the Fowler syndrome (manifested by abnormal myotonus-like EMG activity in the striated urethral sphincter). Although no patient had improved voiding characteristics (a fact attributed to the type of repetitive discharge activity), three women did develop transient SUI, a positive effect of sorts, indicating that the sphincter muscle had indeed been weakened. Petit and associations (1998) reported on the endoscopic injection of BoNT, 150 IU, into the striated urethral sphincter, using a four-point injection technique (the medication was diluted to 4 mL with saline solution). Seventeen patients with spin cord injury or spinal cord disease were treated, and evaluation 1 month after treatment disclosed the following positive results: (1) a decrease in postvoid residual by an average of 176 mL; (2) a decrease in bladder pressure during an emptying contraction by an average of 19 cm H_2O; and (3) a decrease in urethral pressure during an emptying bladder contraction by an average of 24 cm H_2O. The authors judged voiding to be improved in 10 patients. Side effects included the new appearance of SUI in 2 patients and exacerbation of preexisting incontinence in 3 patients. The duration of the effect was variable, but no less than 2 to 3 months. There were no adverse effects on striated muscle elsewhere. The authors concluded that BoNT was a promising treatment for striated sphincter dyssynergia in certain patients refractory to CIC or surgery. Gallien and associates (1998) injected BoNT transperineally in five men with traumatic quadriplegia and striated sphincter dyssynergia. Using a total initial dose of 100 units, divided into four injections of 25 units each, the authors noted what they called improved bladder function in all patients, with a significant decrease in residual urine volume (however, on examining the figures, the mean reduction was only 14 mL, with one of the patients requiring a second set of injections). The maximum urethral closure pressure on average did not change, the maximum detrusor pressure during an emptying episode decreased 5 cm H_2O, and the functional detrusor capacity increased by an average of 89 mL. Urinary catheterization was able to be stopped in two patients, and autonomic hyperreflexia dramatically decreased in intensity in four patients. The time to improvement was 10 to 21 days, and the duration was 3 to 5 months. No patient had significant side effects. Wheeler and associates (1998) reported on three men with spinal cord injury, all with emptying problems related to striated sphincter dyssynergia. The sphincter was injected transperineally with BoNT, using EMG control for localization. Two of the patients reported excellent results. Schurch and associates (1996) used both transurethral and transperineal injections in 24 male spinal cord–injured patients with voiding dysfunction secondary to striated sphincter dyssynergia. They judged that in 21 of these patients, striated sphincter dyssynergia was significantly improved with a concomitant decrease in postvoid residual urine volume in "most cases." Nine of 24 patients had a decreased postvoid residual volume from 450 to 50 mL; in 7 patients, the residual urine volumes were less than 50 mL to begin with and remained unchanged; and in 8 patients, the postvoid residual urine volumes were high and remained unchanged. The authors commented that transurethral injections appeared to be more effective, at least in reductions in maximum urethral closure pressure, than did transperineal injections. They noted no side effects. de Seze and colleagues (2002) performed a double-blind lidocaine-controlled study in 13 patients with spinal cord disease and detrusor–striated sphincter dyssynergia and demonstrated the superiority of BoNT compared with lidocaine in improving clinical symptoms and increased urethral pressure.

There are several reviews summarizing the uses of BoNT injection (Cruz and Silva, 2004; Rackley and Abdelmalak, 2004; Reitz et al, 2004; Smith and Chancellor, 2004; Ghei et al, 2005; Sahai et al, 2005; Dmochowski and Sand, 2007; Karsenty et al, 2008; Andersson et al, 2009). A potential side effect is the spread to nearby muscles, particularly when high volumes of BoNT are injected. Distant effects can also occur, but distant weakness or generalized weakness, owing to the toxins spreading in the blood, is very rare. BoNT should be used only under close supervision in patients with already disturbed neuromuscular transmission or during treatment with aminoglycosides.

Theoretically, any agent that promotes striated sphincter relaxation in a uroselective manner could be used to decrease outlet resistance and facilitate voiding dysfunction. Yoshiyama and associates (2000) describe the intravenous use of α-bungarotoxin as improving voiding in spinal cord–injured rats. The drug is a toxin extracted from the venom of a Formosan snake; it selectively blocks nicotinic receptors without influencing transmission in autonomic ganglia. Although a long way from clinical use, nicotinic receptors in the striated sphincter have been shown to be a potential target for drug therapy for striated sphincter dyssynergia.

Practical Approach to Treatment
Conclusion

GENERAL CONSIDERATIONS

Impact of Urinary Incontinence

Urinary incontinence (UI) affects people in all strata of society—the young and the old, male and female, rich and poor, all ethnic and racial backgrounds—although women and older individuals bear a disproportionate share of the burden. The impact is enormous. The most recent comprehensive accounting estimated the total annual direct and indirect costs for UI in the United States alone to be $19.5 billion (in year 2000 dollars; Hu et al, 2004). **In a 2000 report to Congress, the National Institutes of Health (NIH) estimated the direct cost of UI at $12.5 billion, a figure comparable to other important diseases such as Alzheimer disease, chronic obstructive pulmonary disease, and human immunodeficiency virus infection/acquired immunodeficiency syndrome** (Table 69–1). **Although medical insurance covers some expenses, patients with UI bear a considerable percentage of the overall disease costs for protective pads, laundry, and other expenses not covered by individual insurance plans.** The median out-of-pocket costs to women with weekly or more UI were $186/year (2005 dollars), but those with severe UI spent $372/year and those with very severe UI spent $1148/year (Subak et al, 2007). These costs appear to be increasing rapidly; Medicare expenditures on women with UI increased 57%, adjusted for inflation, between 1992 and 1998 (Anger et al, 2006). As summarized in the Third International Consultation on Incontinence (ICI) Economics Committee (Hu et al, 2005) the consequences of UI lead to serious morbidity, including falls and fractures; urinary tract infections; skin breakdown, including pressure ulcers; and admission to nursing homes. Logically, the presence of lower urinary tract symptoms, including overactive bladder (OAB)/UI symptoms, was found to be associated with approximately 50% increased emergency department visits, hospitalizations, and medical provider visits (Kannan et al, 2009). Despite these figures, and despite markedly increased efforts to inform the public about UI in the past decades, the majority of patients suffer quietly; in one study, fewer than one third of women with bothersome UI in a prepaid health care plan had been diagnosed in the prior 5 years and few had been treated (Kinchen et al, 2007).

The Urologic Diseases in America project has published detailed analyses of expenditures by the U.S. health care system for UI in both men (Stothers et al, 2005) and women (Thom et al, 2005). Among the more interesting findings was a dramatic increase in Medicare expenditures for women from $128.1 to $234.4 million between 1992 and 1998, despite decreasing hospitalizations and length of stay. In men, the prevalence of incontinence was estimated at 17% for those older than 60 years of age (any incontinence over the past 12 months) and the annual expenditures for privately insured male adults with UI were $7702 compared with $3204 for a man without UI. Demographic trends producing increasing numbers of elderly individuals will make this problem a critical challenge to urologists for the coming decades. Those interested in further information are referred to the report of the Epidemiology Committee of the Fourth ICI (Milsom et al, 2009) which provides excellent summaries of prevalence, incidence, remission, and risk factors.

The impact of UI cannot be measured in dollars alone. A "social cancer," UI impacts every facet—social, physical, sexual, psychological, and medical—of human life at work and at home. Numerous reports continue to document the serious impact of UI and overactive bladder (OAB) on quality of life using high-quality methodology (Coyne et al, 2003, 2004; Avery et al, 2004; Hajjar, 2004). Incontinent patients are more likely to have poor self-esteem, feeling shame and guilt, which may keep them from working effectively and partaking in social activities. UI is strongly associated with depression and vice versa

Table 69–1.

Cost of Illness and National Institutes of Health Support

DISEASE/CONDITION	YEAR OF COST DATA	TOTAL COST (IN BILLIONS $)	POPULATION	FY 1999 NIH SPENDING (IN MILLIONS $)
Asthma	1997	100.0	Total	140.4
Alzheimer disease and other dementias	1996	14.0	Older than 65	406.5
Cerebrovascular disease (stroke)	1998	43.3	Total	186.0
Chronic obstructive pulmonary disease	1998	37.3	Total	997.0
Diabetes	1997	98.2	Total	457.6
HIV infections/AIDS	1999	28.9	Total	1792.7
Incontinence	1995	26.3	Older than 65	6.9

(Steers and Lee, 2001), although the nature of this relationship is not established. Stress urinary incontinence (SUI) restricts the physical activity of patients, many of whom are otherwise healthy young women. The long-term deleterious effects of exercise reduction on health are unclear but may be important. **Urgency urinary incontinence (UUI) affects quality of life even more than SUI because of its unpredictable nature.** It may lead to loss of sleep as well as the limitations just mentioned. Sexual activity and interpersonal relationships suffer due to UI. Despite this, many and perhaps most individuals still do not seek help for UI for a variety of reasons, including misguided perceptions that UI is a normal consequence of aging and that there is no effective treatment (Shaw, 2001). **Even more importantly, expenditures for UI research are a small fraction of that spent on other conditions; NIH-funded UI research is less than 2% than that for stroke or Alzheimer disease** (see Table 69–1).

Rationale for Conservative Therapies

This "silent" epidemic was brought to national attention with the 1988 NIH consensus conference (Consensus Conference, 1989) followed by the publication of the first Agency for Health Care Policy and Research (AHCPR) practice guideline on UI in adults in 1992 (Urinary Incontinence Guideline Panel, 1992). Two of the principal recommendations of the guideline relate directly to improving the recognition of UI and validating it as an important medical problem:

- "The guideline calls for vigorous efforts to educate health care professionals about this condition so that they are sufficiently knowledgeable to diagnose and treat it."
- "It recommends that the public be advised to report incontinence problems once they occur and be informed that incontinence is not inevitable or shameful but is a treatable or at least manageable condition."

A third recommendation of the 1992 AHCPR guideline applies directly to the focus of this chapter:

- "The guideline recommends that surgery, except in very specific cases, should be considered only after behavioral and pharmacologic interventions have been tried."

The rationale for a conservative approach is clear. UI is not an inexorably progressive disease. A moderate delay in surgical therapy does not make such treatment more difficult. As will be amply documented, "conservative" therapies are effective, well tolerated, and safe. In addition, they are preferred by many patients. In the fifth National Association for Continence (NAFC) survey of 130,000 members, 52% of men and 48% of women ranked conservative therapies in general as "most helpful" (NAFC, 1999). Because the impact of UI varies greatly from patient to patient, the patient's feelings and goals must be taken into consideration in treatment planning. Thus, it is generally appropriate that the least invasive treatment that takes into account patient preferences and offers a reasonable chance for success be used first.

Description: What Is "Conservative," Who Is it for?

Traditionally, treatments that are totally reversible have been considered "conservative." Depending on the reviewer, this may or may not include drugs. However, given the data just presented regarding the costs associated with UI, a more considered assessment is in order. It can no longer be acceptable to call all nonpharmacologic, nonsurgical therapy "conservative" and recommend that such treatments routinely be employed as initial therapy. "Conservative" therapies must be held to the same standards as pharmacologic and surgical treatments. Effectiveness and safety must be determined in the context of patient satisfaction—it does little good to identify a treatment as safe and effective if patients are ultimately not satisfied and go on to "second line" treatments. Ultimately, the clinician and patient need to know the long-term outcomes for continence, adverse events, and cost-effectiveness to develop appropriate treatment algorithms. Ultimately, specific patient factors should be identified that will help predict the likelihood of response to a given therapy. Only then will the precious resources spent on UI be used most effectively.

To this end, levels of evidence and grades of recommendation are used whenever possible and conclusions drawn from systematic literature reviews and the ICI are highlighted. The AHCPR has used specified evidence levels to justify recommendations for the investigation and treatment of a variety of conditions, and the Oxford Centre for Evidence Based Medicine produced a widely accepted adaptation of the work of the AHCPR (Oxford Centre, 2001). The highest level of evidence (level 1) is based on systematic reviews and/or randomized controlled trials. The highest grade of recommendation (grade A) stems from consistent level 1 evidence. When possible these terms are used in the chapter, although there is a great need for further high-quality research and there is a notable lack of long-term follow-up of treatment effect for almost all of the therapies discussed.

Overview

The challenge to the urologist is to understand all of the treatments for UI, to be able to assess the patient efficiently yet thoroughly, and then to construct an appropriate treatment plan with the patient, taking into account the problem and the goals of the

individual patient. A review is presented of the basic nonsurgical tools used in treating UI—behavioral therapy, pelvic floor muscle training and biofeedback, external devices, and peripheral electrical and magnetic stimulation. Pharmacologic therapy is discussed in Chapter 68, surgical and injection therapy in Chapters 71 to 74, and neuromodulation in Chapter 70. The detailed evaluation of the incontinent patient is discussed in Chapter 64. Although it is important to rule out serious underlying or associated conditions, invasive testing is rarely required before initiating treatment with the measures discussed here. The focus here is on only that part of the evaluation that directly relates to treatment planning. It is generally sufficient to have a working diagnosis classifying the patient as having stress, urgency, or mixed UI. Patients with symptoms of OAB (the generic term for urgency and frequency with or without UI) are treated in the same manner as those with UUI. Practical algorithms are presented that provide a rational means of applying these varied treatments to an individual patient.

Key Points: General Considerations

- The consequences of UI lead to serious morbidity, including falls and fractures, urinary tract infections, skin breakdown including pressure ulcers, and admission to nursing homes.
- UI is not an inexorably progressive disease. Conservative therapies are effective, well tolerated, safe, and preferred by many patients. Thus it is generally appropriate that the least invasive treatment that takes into account patient preferences and offers a reasonable chance for success be used first.
- Although it is important to rule out serious underlying or associated conditions, invasive testing is rarely required before initiating treatment with conservative measures.

THE TOOLS OF CONSERVATIVE THERAPY

Behavioral Therapy

Behavioral therapy describes a group of treatments grounded in the concept that the incontinent patient can be educated about his or her condition and develop strategies to minimize or eliminate UI. It is sometimes erroneously reduced to the combination of fluid restriction and timed voiding but is actually a far richer therapy. In fact, one of the main problems with the term *behavioral therapy* is that it has been used so differently by various practitioners that its meaning has become diluted and vague. There is no one standard protocol or "best" methodology. The shared aims of behavioral therapy are illustrated in Figure 69–1 (Payne, 2000). Although various practitioners may have different emphasis, the different treatment approaches are unified by education about normal urinary tract function. The individual elements of behavioral therapies discussed here are centered on basic educational techniques such as operant learning, which is intended to model activity so as to reproduce normal behavior, in this case urinary continence (Palmer, 2004). All of the individual techniques discussed fall into this category, although pelvic floor muscle training is both a behavioral therapy (education about anatomy and function of the muscles, learning to use the muscles properly to control lower urinary tract function) and a physical therapy (strengthening the muscles to improve function). In any case, education binds the various techniques together and plays the central role in behavioral therapy.

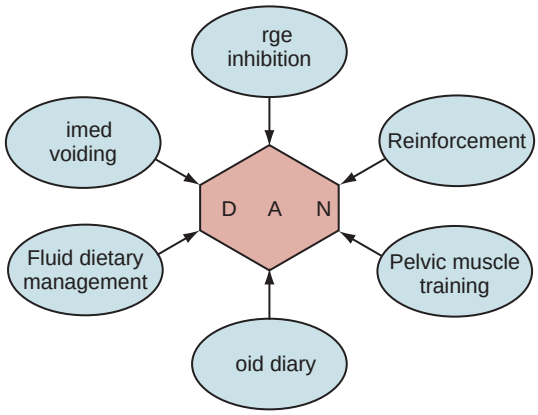

Figure 69–1. Behavioral therapy has many different components, all of which center on patient education. Education leads to understanding of normal lower urinary tract function and the patient's ability to self-regulate those functions.

Pelvic Floor Education

In a pure form of behavioral therapy there would simply be education about the normal anatomy of the pelvic floor musculature and the function of these muscles in maintaining continence. Pelvic muscle exercises could be explained along with the use of repeated rapid contractions ("quick flicks") to inhibit urgency by activating the spinal reflex pathway. However, the literature also includes sophisticated biofeedback techniques and treatment by physiotherapists in many trials of behavioral therapy. In most of these cases the purpose of the treatment is aimed at improving muscle strength and control; therefore the detailed discussion of this approach is included in the section on pelvic floor rehabilitation (see later).

Bladder Training/Timed Voiding

The term ***scheduled voiding*** is the generic term preferred for describing voiding regimens used for home-dwelling cognitively intact patients as opposed to ***prompted voiding*** **or** ***toileting***, terms properly applied to institutionalized or otherwise dependent patients. The most commonly used technique for patients with OAB and UUI is **"bladder training" ("bladder drill," "bladder retraining").** Bladder training starts a patient voiding on a fixed time interval schedule with the intention that, most of the time, the patient will urinate before experiencing urgency and UI. The interval is gradually increased with clinical improvement. Early practitioners of bladder training first established the effectiveness of intensive inpatient bladder training temporarily supplemented by medications (Frewen, 1978). Next, outpatient treatment was proven to be effective (Elder and Stephenson, 1980; Frewen, 1980). Finally, the durability of response, with 85% initial and 48% three-year response rates was reported (Holmes et al, 1983). **Bladder training should always be combined with urge inhibition techniques and is often combined with anticholinergic medical therapy,** particularly for more severe cases and for patients with neurogenic bladder. In contrast, **"timed voiding"** involves having a patient void on a fixed schedule, typically every 2 to 3 hours, and is intended to normalize frequency in a patient with infrequent voiding and/or diminished bladder sensation. This technique can be employed for patients with SUI with the idea that leakage will be less if the bladder is less full when physical stress occurs. It can also be used in a variety of patients with UUI who have a good bladder capacity (the classic example is that of patients with diabetic neurogenic

bladder; they do not have proper bladder sensation and thus delay voiding inappropriately).

Although there is no evidence as to the optimal program of bladder training, a common approach is to start at a safe interval based on the patient's bladder diary and increase the interval by 15 to 30 minutes as the patient achieves continence. The ultimate goal is a comfortable interval between voids with continence—a "retraining" of the bladder. Wilson and colleagues (2005) concluded that if no improvement is made after 3 weeks "the patient should be reevaluated and other treatment options considered." **The ICI authors acknowledge that the quantity of evidence is low but still make a grade A recommendation that "bladder training is recommended as a first line treatment of UI in women"** (Hay-Smith et al, 2009). Medical therapy is commonly employed initially, and there are rather limited studies comparing bladder training to anticholinergic medications for detrusor overactivity and UUI. One study demonstrated superior results with the combination of behavioral therapy and anorectal biofeedback in comparison to anticholinergic medication alone (oxybutynin chloride in titrated dosing) in a group of patients with urge and mixed UI (Burgio et al, 1998). Subsequent work by Burgio and colleagues (2000) confirms the clear truth that **behavioral and drug therapy are complementary, not competitive treatments;** the primary value of this research is to underscore the value of the behavioral component in the treatment plan. Logically, all patients should have behavioral therapy with medications used on an individualized basis. **The ICI committee** (Hay-Smith et al, 2009) **found level 2 evidence that the effect of bladder training may be enhanced by drug therapy and that, for women already taking an antimuscarinic drug, there was no additional benefit from adding brief written instructions on bladder training.**

Smoking

Aside from being a major risk factor for bladder cancer, smoking has been proposed as a risk factor for SUI by increasing coughing episodes and for OAB through bladder irritation from nicotine and toxins excreted in the urine. However, to date, epidemiologic studies of tobacco use have produced inconsistent findings. In women, some studies suggest that smoking increases the risk of UI, or at least severe UI, but others demonstrate no increased risk. A 1-year longitudinal study of 6424 women older than 40 years of age found that current smokers were at higher risk for both SUI and OAB than those who had never smoked, although statistical significance was seen only for OAB (Table 69–2). Former smokers had intermediate risk (Dallosso et al, 2004a). The same group also published a longitudinal study of 4887 men showing no association between smoking and OAB symptoms (Dallosso et al, 2004b). Another population-based study suggested that the risk of UI is limited to subjects with a history of more than 15 pack-years or current consumption of more than 20 cigarettes a day (Hannestad et al, 2003). One group of researchers found that smoking was associated with the severity of UI in women seeking surgical treatment (Richter et al, 2005). **As of yet there have been no adequate studies of smoking cessation on prevention or treatment of UI symptoms, and the ICI committee could make no evidence-based recommendation** (Hay-Smith et al, 2009). Despite these conflicting results, smoking cessation can logically be recommended as a general health measure, to reduce the risk of bladder cancer, and for those smokers with SUI particularly related to coughing. More research, particularly on the effectiveness of smoking cessation in treating UI and on the relationship between smoking and OAB, would be welcomed.

Table 69–2.

Risk Factors for Stress Urinary Incontinence and Overactive Bladder (Multivariate Analysis)

	Overactive Bladder		Stress Urinary Incontinence	
	RR	CI	RR	CI
Smoking vs. Never Smoked				
Former smoker	1.24	0.97-1.44	—	—
Current smoker	1.44	1.05-1.63	—	—
Obesity vs. Acceptable Weight				
Underweight	0.69	0.38-1.26	0.82	0.46-1.44
Overweight	1.25	0.94-1.67	1.24	0.93-1.63
Obese	1.74	1.22-2.12	1.46	1.07-1.99

RR, relative risk; CI, confidence interval.

Caffeine

Caffeine is well known as a nervous system stimulant and has demonstrable effects on detrusor muscle in vivo and in vivo, promoting detrusor overactivity. In one study of community-dwelling elderly women subjects who decreased caffeine and increased fluid intake, increased voiding volumes and fewer accidents were experienced (Tomlinson et al, 1999). High caffeine intake (>400 mg/day average) also correlated with urodynamic detrusor overactivity compared with stress-incontinent women (<200 mg/day average) (Arya et al, 2000). Caffeine has thus been postulated to be a cause of OAB symptoms, and **caffeine reduction has been advised for OAB patients.** Epidemiologic data are less clear. Reports usually break down consumption by type of beverage rather than actual caffeine consumption as is typically found in smaller studies of dietary intervention. Such small studies have typically shown a correlation between caffeine reduction and reduction of UI (Tomlinson et al, 1999; Bryant et al, 2002). Although larger studies would be helpful, it seems appropriate to recommend restriction, particularly in those patients with very high intake of caffeine. The ICI committee concluded that, "while large cross-sectional surveys indicate no association (level 3 evidence), small clinical trials do suggest that decreasing caffeine intake improves continence (level of evidence 2)" (Hay-Smith et al, 2009).

Fluid Management

Fluid restriction has been advocated in the treatment of both SUI and OAB. The rationale is that abdominal leak pressures appear to be volume dependent; therefore, physical stress occurring at lower bladder volumes both will be less likely to cause UI and will be associated with lower volume loss when leakage does occur. Similarly, OAB is believed to be a volume-driven phenomenon and slower filling promotes bladder compliance and lower pressures. This concept appears to be well accepted, as manifest by a recent U.S. study in which 38% of incontinent women had tried limiting fluids compared with 21% who tried Kegel exercises and 6% using prescription medications (Diokno et al, 2004a). On the other hand, extreme fluid restriction produces concentrated urine, which has been postulated to be a bladder irritant, leading to detrusor overactivity as well as constipation, which can negatively affect bladder function. Indeed, there is conflict regarding fluid management, with some investigators showing improvement with fluid reduction (Swithinbank et al, 2005) and others finding that increasing fluid intake improved UI (Dowd et al, 1996). Hashim and Abrams (2008) studied this controversy using

a crossover trial in which patients with OAB were instructed to first decrease fluid intake 25% to 50% below baseline and then to increase intake 25% to 50% above the baseline (or the reverse). A significant improvement in continence was noted with decreasing fluids (and increased UI was noted with increasing fluids). **It certainly seems reasonable to obtain a baseline frequency-volume chart and advise those patients with normal to increased fluid intake to try moderately restricting fluid intake. Any potential benefit must be balanced against possible problems with bladder infections and constipation.**

The types of fluid intake may also be significant; caffeinated beverages, acidic juices, and alcohol have been suggested to be bladder irritants. Caffeine was discussed earlier. Tea consumption correlated with UI in the EPINCONT study, but alcohol and coffee consumption did not (Hannestad et al, 2003). Although it is possible that caffeine is not the critical component, there is no clear hypothesis as to why tea (which has less caffeine than coffee) would be a relevant dietary factor but not coffee. Unless confirmed in other studies this may turn out to be a statistical aberration. In a population of Chinese women, alcohol consumption correlated with SUI but not UUI (Song et al, 2005), but other studies have shown no link between alcohol use and UI symptoms. Epidemiologic data support a link between consumption of carbonated beverages with both SUI and OAB (Dallosso et al, 2003) with level 2 to 3 evidence. Data on the effects of other beverages are scarce.

Other Dietary Management

A variety of different dietary maneuvers have been recommended for incontinent patients, including avoidance of alcohol, carbonated beverages, acid foods, salt, and others. A detailed study examining dietary factors noted an association between intake of vegetables with lower risk of OAB and intake of fruit with lower risk of SUI (Dallosso et al, 2003). These observations have yet to be reproduced in other populations. A follow-up report (Dallosso et al, 2004a) examined details of the diet in relationship to SUI and found that "intakes of total fat, saturated fatty acids and monounsaturated fatty acids were associated with an increased risk of SUI onset one year later. Of the micronutrients studied, zinc and vitamin B_{12} were positively associated with SUI onset." Because these observations are not hypothesis driven, confirmation is mandated before any recommendation can be given. No similar connection was identified with alcohol consumption in the same or other studies, and one study actually suggested a lower risk of OAB in men who were beer drinkers (Dallosso et al, 2004b). Once again, **the best advice for incontinent patients would seem to be to follow established guidelines for overall health with moderation in alcohol use and adequate intake of fruits and vegetables.**

Obesity/Weight Reduction

In no area of behavioral therapy has there been more advancement than in the recent work delineating **obesity as a serious, modifiable, and indeed reversible cause of UI.** There has long been an assumption that obesity is linked to UI, particularly SUI, by straining and potentially damaging the supportive structures of the bladder and pelvic organs. However, until recently little has been known about the true risk of obesity or about the effectiveness of weight loss as a therapy for UI.

Epidemiologic data provide persuasive support for a causal association between obesity and UI. The Nurses' Health Study identified 6,790 women with incident UI over a 2-year period among 35,754 women initially reporting no UI (Townsend et al, 2008a). There were highly significant trends of increasing risk of UI with increasing BMI and waist circumference (P for trend < .001 for both). The same research group showed that not only was obesity a risk for UI but also that weight gain was an independent risk for incident UI (Townsend et al, 2007). Gaining 5 to 10 kg after age 18 increased the risk of developing weekly UI by 44% (OR 1.44, CI 1.05 to 1.97) compared with women who maintained their weight within 2 kg—regardless of the initial weight! Gaining 30 kg increased the risk fourfold. The relationship between obesity, weight gain, and incident UI held for both SUI and UUI. Another powerful study from the United Kingdom followed 1201 women from their birth in 1946 annually from 48 to 54 years (Mishra et al, 2008). At the age of 20, 26, 36, and 43, body mass index (BMI) was positively associated with stress symptoms and severe UI in midlife and there appeared to be a cumulative effect. These relationships existed even after accounting for the effects of aging, childhood enuresis, childbirth characteristics, menopause, educational attainment, and smoking status. Interestingly, these researchers found that BMI was not significantly associated with symptoms of UUI. Finally, in a 1-year longitudinal study of 6424 women older than 40 years of age there was a strong correlation between BMI and the risk of both OAB and SUI (Dallosso et al, 2003) (see Table 69–2). Work in other populations consistently confirms the relationship between obesity and UI (Thom et al, 1997; Brown et al, 1999; Fornell et al, 2004; Larrieu et al, 2004; Melville et al, 2005b). The work in this field provides consistent findings describing a linear relationship between obesity and UI that cumulatively produce conclusive evidence for obesity as an important modifiable risk factor for UI.

More importantly, it is now clear that weight loss is an effective treatment for UI. A prospective randomized controlled trial (RCT) studied 338 overweight and obese women at two centers in the United States (Subak et al, 2009). All had BMI greater than 25 (mean 36) and at least 10 UI episodes per week (>75% with mixed UI). Subjects were randomized to an intensive 6-month weight loss program that included diet, exercise, and behavior modification (226 patients) or to a structured education program (112 patients). Weight loss was moderate (–8 kg vs. –1.6 kg), yet statistically significant decreases were found for all UI (–47% vs. –28%) and SUI (–58% vs. –33%). There was a trend to reduction in UUI (–42% vs. –14%, $P = .14$). More patients rated themselves to be moderately or very satisfied with the change in UI (75.8% vs. 46.8%, $P < .001$). These strong results were mirrored in a 2-year open-label trial in the United Kingdom of 64 obese women who were offered a commercially run program of diet and exercise (Rosemary Conley Diet and Fitness Clubs) aiming for weight loss of 5% to 10% over 6 months (Auwad et al, 2008) and by the initial pilot RCT by Subak and colleagues (2005). The high value of bariatric surgery for morbidly obese patients with UI has been clearly documented in four different case series, all showing dramatic reduction in UI episodes (Burgio et al, 2007; Kuruba et al, 2007; Maher et al, 2008, Laungani et al, 2009) (Table 69–3).

In summary, **it is clear that obesity is a cause for UI and weight loss is an effective treatment that also provides many other health benefits.** Weight loss should be first-line therapy for obese patients with UI, particularly SUI. More research is needed as to the role of obesity and weight loss in patients who are only overweight (BMI 25 to 30) and into the intriguing but less well defined relationship with UUI.

Urge Inhibition

Urgency is the predominant symptom for most patients with OAB and UUI. In many cases, UI has become a reflex as the patient has

Table 69–3.

The Value of Bariatric Surgery for Morbidly Obese Patients with Urinary Incontinence

CITATION	POPULATION	FOLLOW-UP	MEAN WEIGHT LOSS	ANY UI	ANY SUI	UUI
Kuruba et al, 2007	44 women/1 man	≥6 mo	64% of excess body weight	50% resolution/95% improved		
Maher et al, 2008	Unknown number, 80.5% female	1 yr	66% of excess body weight		87.7%	
Burgio et al, 2007	101 women	12 mo	18.8 ± 4.5 kg/m^2	66.7%-37%	59.8%-31.5%	35.9%-15.2%
Laungani et al, 2009	58 women	12 mo	66% of excess body weight	64% resolved/92% improved		

developed dysfunctional behavior in response to urgency. It is important to break the cycle of rushing to the toilet in response to urgency. The patient is instructed to stop, sit if possible, and use pelvic muscle contractions, distraction, or other techniques until urgency passes. There are no data on use of this practice as an isolated therapy, but it is a critical part of the overall treatment of patients with OAB; patients who learn to delay or overcome urgency may eventually be cured of their condition.

Other Lifestyle Issues

As summarized by Wilson and associates (2005), "there are many other lifestyle interventions suggested either by health care professionals or the lay press for the treatment of UI, including reducing emotional stress, wearing non-restrictive clothing, utilizing a bedside commode, decreasing lower extremity edema, treating allergies and coughs, wearing cotton underwear, and increasing sexual activity. These interventions are, however, all anecdotal in nature."

It has been shown (level 2 evidence) that stress-induced urine loss can be reduced by positional changes, that is, having a woman cross her legs with coughing, although this was only examined in the acute urodynamic testing situation (Norton and Baker, 1994). **The ICI panel** (Hay-Smith et al, 2009) **concluded that constipation and chronic straining may be a risk factor for the development of UI (level 3 evidence) but that there were no data on the effect of intervention.**

There is inadequate knowledge about the relationship of strenuous activity, sports, and work. It has long been known that low-grade SUI is common in female college athletes (Nygaard et al, 1994). However, the long-term clinical significance of this is unknown. Because women are universally advised to restrict activity after surgical treatment for SUI one might assume that the effect of postoperative activity on outcome had been investigated, but there are actually no useful data. One study has examined the association between physical activity and risk of developing UI by analysis of data from incident cases of UI in the Nurses' Health Study of women aged 54-79 years (Danforth et al, 2007). The authors found that increasing levels of total physical activity (which was mainly walking) were significantly associated with a reduced risk of UI and SUI although not with UUI (Table 69–4). The same researchers examined the dataset to explore the relationship for younger women, age 37 to 54 (Townsend et al, 2008b). They again found that activity was inversely correlated with incident UI and that the protective effect of exercise appeared to be present for both SUI and UUI. Accounting for the independent effect of BMI attenuated the findings, but exercise remained a significant independent factor. Although it is possible that these data may not apply to women engaged in very high level, chronic, strenuous activity, the important lesson is that good health habits clearly correlate with a lower risk of UI.

Table 69–4.

Physical Activity and Urinary Incontinence

	Any Incontinence	
	Cases*	OR† (95% CI)
Physical Activity (MET-hr/wk)

*Incontinence cases were defined as leaking urine at least once per week.
†Odds ratios were adjusted for age, race or ethnicity, body mass index, parity, cigarette smoking, and postmenopausal hormone therapy.
‡Walking analyses were controlled for total activity.
MET, metabolic equivalent task; OR, odds ratio; CI, confidence interval.
From Danforth KN, Shah AD, Townsend MK, et al. Physical activity and urinary incontinence among healthy, older women. Obstet Gynecol 2007;109(3):721–7.

The **ICI committee concluded** that "strenuous exercise is likely to unmask the symptoms of SUI during the provocation. There is currently no evidence that strenuous activity causes the condition of UI" and **"there is good prospective cohort information suggesting that moderate exercise decreases the incidence of UI in middle aged and older women"** (level of evidence II) (Hay-Smith et al, 2009).

Other Health Issues

Increasing attention has been paid to the relationship between **diabetes** and UI. Data from the Nurses' Health Study and the Nurses' Health Study II were examined to study associations between diabetes and UI type in 71,650 women (Danforth et al, 2009). Incident UI cases were identified over a 2-year period. The incidence of at least weekly UI was 5.3% among women without type 2 diabetes and 8.7% among women with diabetes (adjusted odds ratio 1.2; 95% CI 1.0 to 1.3; $P = .01$). This increase appeared largely explained by significantly greater odds of UUI (OR 1.4; 95% CI 1.0 to 1.9; $P = .03$). A cross-sectional mail survey of community dwelling women screened women for pelvic floor disorders while diabetes status and other risk factors were obtained from medical record review. Of 3,962 women, 393 (10%) had diabetes. Among women with diabetes, being obese was associated with SUI and

OAB (Lawrence et al, 2007). This finding was supported by analysis of an RCT comparing treatment of diabetics with UI using oral hypoglycemics (metformin) versus lifestyle intervention (weight loss and exercise) (Brown et al, 2006). The researchers found that the prevalence of UI was lower in women randomized to lifestyle intervention than those on medication or placebo.

There is a strong relationship between UI and **depression.** In one study, patients with UI were almost three times more likely to have major depression than those without (6.1% vs. 2.2%) and patients with UI and depression had significantly greater decrements in quality of life and functional status than those with UI alone (Melville et al, 2005a).

A specific investigation into comorbidities and UI was undertaken by a research group in the United Kingdom who note, "The bladder forms part of a sensitive and complex system of the body that operates largely autonomously but remains under voluntary control. As such, it is vulnerable to general disease processes related to ageing. Thus, associations with poor health and obesity could represent pathogenic as well as functional involvement of the bladder." (McGrother et al, 2006). They used a postal survey of a random sampling of over 19,000 community dwelling women older than 40 years of age with 1-year follow-up surveys. There were strong correlations between poorer health and increased prevalence of both SUI and OAB. There are many interesting findings but one of the most important is that **"OAB was independently predicted by poor health ... The association with old age, although consistent with other studies, disappeared after controlling for a full range of specific comorbidities, suggesting that the condition is age related rather than age dependent."**

CONCEPT OF "THERAPEUTIC PACKAGE"

It is, of course, logical and appropriate that these various behavioral treatments be used together in a therapeutic package. They are inherently complementary, are completely reversible, and lack significant adverse effects. They also can be (and typically are) combined with the pelvic floor rehabilitation techniques discussed later. Patients who are motivated to avoid surgical or pharmacologic interventions will be inclined to seek out such treatments; the problem remains as to the most efficient way to deliver therapy to the average patient.

Such an approach showed utility in an RCT in which patients were randomized to receive a package of behavioral therapy including individualized counseling about fluid and caffeine intake, quick pelvic floor muscle contraction, voiding frequency, and management of constipation or placed on a waiting list (Kincade et al, 2007). This design provides a good starting point for use in many patients with UI. In addition, Diokno and colleagues (2004b) demonstrated that two simple group sessions were effective in preventing UI. The trial randomized 359 continent women older than age 55 years who were recruited and observed for 1 year. The treatment group received a single 2-hour group session teaching pelvic floor muscle training (PFMT) and bladder training as well as an audiotape on PFMT for reinforcement; the control group was not treated. There was one follow-up office visit with a nurse specialist in 2 to 4 weeks. At the end of 1 year, 56% of the treatment group reported the same or better continence compared with only 41% of controls; 37% of the treatment group reported "absolute continence" compared with 28% of the controls. Several other studies using various combinations of therapies led the ICI group (Wilson et al, 2005) to a **level A recommendation that "women with stress, urge, or mixed incontinence should be offered a conservative management program as first line therapy for UI" while acknowledging that there were inadequate data to define the optimal treatment package and that most of the data comes from trials in older women.**

Key Points: The Tools of Conservative Therapy: Behavioral Therapy

- Behavioral therapy describes a group of treatments grounded in the concept that the incontinent patient can be educated about his or her condition and develop strategies to minimize or eliminate UI. There is no one standard protocol or "best" methodology. The different treatment approaches are unified by education about normal urinary tract function.
- Bladder training starts a patient voiding on a fixed time interval schedule with the intention that the patient will urinate before experiencing urgency and UI. It can be used with or without medical therapy. There is a grade A recommendation that "bladder training is recommended as a first line treatment of UI in women."
- There have been no adequate studies of smoking cessation on prevention or treatment of UI symptoms.
- There is level 2 evidence suggesting that decreasing caffeine intake improves continence.
- One prospective study showed improvement in UI with fluid restriction; the potential benefit must be balanced against possible problems with bladder infections and constipation.
- Epidemiologic data support a link between consumption of carbonated beverages with UI, with level 2 to 3 evidence.
- Epidemiologic studies provide consistent findings describing a linear relationship between obesity and UI that cumulatively provide strong evidence for obesity as an important modifiable risk factor for UI.
- There is level 1 evidence that weight improves continence, and the effect appears to be on both SUI and UUI symptoms. Weight loss should be first-line therapy for obese patients with UI, particularly SUI. However, effect of weight loss for the overweight population (BMI 25 to 30) is less clear.
- There is level 2 evidence that moderate exercise decreases the incidence of UI in middle-aged and older women.
- Although the prevalence of OAB/UUI increases with age it appears that this is due to comorbid conditions and not aging itself.
- Although acknowledging that the optimal treatment package is unknown, combinations of conservative therapies are logical and appropriate, leading to a level A recommendation that "women with stress, urge, or mixed incontinence should be offered a conservative management program as first line therapy for UI."

PELVIC FLOOR REHABILITATION

The term *pelvic floor rehabilitation* should be applied to any treatment intended to increase the strength, bulk, and function of the pelvic floor/levator muscles. Muscle rehabilitation can be achieved through a variety of tools, which

can be classified as "basic" or "advanced," depending on the cost and complexity of the therapy. **Basic treatments (Kegel exercises, vaginal cones, and simple home perineometry) are used in the home setting, require no or inexpensive equipment, and can be administered by a relatively unskilled therapist. Advanced treatments are used in an office setting, are administered by a trained therapist, and/or require more sophisticated equipment.**

Pelvic Floor Muscle Training

Pelvic floor exercises (PFE) or "Kegels" have been advocated in the treatment of UI since the 1950s (Kegel 1948a, 1948b, 1956). Dr. Kegel taught his patients to forcefully contract the pelvic muscles to treat and prevent postpartum UI. Unfortunately, **half of patients are unable to perform a proper contraction with simple instructions** (Bump et al, 1991), **and up to one fourth will actually promote UI with their efforts.** Indiscriminant recommendation of this therapy to all incontinent patients has created a negative bias that PFE are just "something to do" before pharmacologic or definitive surgical treatment. It should also be acknowledged that Dr. Kegel routinely employed a perineometer with his patients in one of the first documented uses of biofeedback in medicine. This implies that Kegel exercises alone should not be considered the standard treatment for pelvic floor rehabilitation.

Currently, ***PFMT* is the currently accepted term,** replacing *Kegels* and *PFE*. It is defined as "any program of repeated voluntary pelvic floor muscle contractions taught by a health care professional" (Wilson et al, 2005) and is advocated for both prevention and treatment of UI. "Training" is preferred over "exercises" to emphasize the importance of a regimen of repeated exercise over time. **The therapy is intended to improve the function of the pelvic floor muscles; whether this happens primarily by increasing the strength, power, and speed and/or improving the timing and coordination of a contraction is not known. Much more is known about the clinical effectiveness of the therapy than the exact physiologic changes that produce the outcomes.** With repeated exercise a muscle will develop improved responsiveness that may lead to a faster and/or stronger contraction before any increase in actual bulk. Over longer periods of time the muscle fibers will progressively hypertrophy, producing increased bulk. The ICI committee (Hay-Smith et al, 2009) points out that (1) an increase in strength occurs before visible hypertrophy, (2) early improved strength results from neural adaptation, and (3) hypertrophy begins only after a minimum of 8 weeks and may continue for some years. In any case, muscle bulk is clearly not a prerequisite for improved continence with PFMT, and many studies have failed to show a correlation between improved strength and improved continence.

Although a huge number of studies have investigated PFMT it is challenging to draw clear conclusions for a variety of reasons:

1. Treatment regimens vary widely.
   a. Type of exercises
   b. Number and frequency of exercises
   c. Initial confirmation of correct technique
   d. Use of various forms of biofeedback in teaching
2. Patient types are often widely mixed.
   a. Type of UI
   b. Severity of UI
   c. Temporal relationship of therapy to childbearing (or prostate surgery in males)
3. Outcome measures vary.
   a. Self-reported versus objective
   b. "Cure" versus "improved"
4. Duration of effect is not well defined.

When possible these issues are addressed in the following discussion. The interested reader is strongly encouraged to study the comprehensive review performed by the ICI committee (Hay-Smith et al, 2009).

It is difficult to analyze the literature on PFMT because training is commonly combined with other modalities. The combination can range from general advice about management of UI, specific strategies such as bladder diaries/timed voiding, and biofeedback training. **It is important to realize how differently PFMT is applied in research trials and in European practice compared with standard U.S. clinical practice.** The definition of PFMT clearly states that it is "taught by a health care professional." In clinical trials this is always the case; the instructor is typically a skilled physiotherapist who may apply a variety of techniques to promote learning as needed by an individual patient. In U.S. clinical practice a patient is often given only verbal instruction. In more ideal cases the patient will have written instruction after an initial assessment including a pelvic examination and assessment of and instruction in pelvic muscle contraction. Regular follow-up is not an option in most health care settings owing to poor or absent reimbursement. This divergence in care means that results obtained in research trials may be difficult or impossible to obtain in standard clinical practice and that the difference between stand-alone PFMT and PFMT with adjunctive treatments may be much greater in U.S. clinical practice than in research studies. The following discussion of PFMT results is based on the published literature; it remains a challenge for the clinician to translate these somewhat idealized results into clinical practice.

Does PFMT Prevent Urinary Incontinence in Childbearing Women?

PFMT has been used to prevent UI in pregnant women, because pregnancy and vaginal birth are strong risk factors for UI. Three prospective RCTs have investigated this question (Sampselle et al, 1998; Reilly et al, 2002; Mørkved et al, 2003), producing a **grade A recommendation that primiparous women "should be offered a supervised and intensive strengthening antepartum PFMT programme to prevent post-partum UI"** (Hay-Smith et al, 2009). In all three trials the PFMT group had less postpartum UI; and in one study (Reilly et al, 2002), the effect was still present at 4 years postpartum, although only 100 of 268 patients were available for follow-up. There was no evidence supporting the utility of PFMT in pregnant, previously continent, multiparous women. The **evidence reviewed by the ICI group for postpartum PFMT was less compelling, but it was concluded that the evidence also supports a grade C recommendation for supervised intensive PFMT for women after delivery utilizing instruments or delivery of a large infant** (≥4000 g) (Hay-Smith et al, 2009).

Is PFMT an Effective Treatment for Urinary Incontinence and Which Patients Are Good Candidates?

The most important question is whether PFMT is effective in the management of established UI and, if so, how to most effectively apply the therapy to the large population of incontinent women. Seventeen RCTs comparing PFMT to no intervention, placebo, sham, or control in childbearing women were summarized by

Hay-Smith and colleagues (2009) and are based on the findings of a Cochrane review (Dumoulin et al, 2008). Although the magnitude and duration of the expected effect is not well defined, the overwhelming majority of the trials showed effectiveness of PFMT, leading to a **grade A recommendation that "PFMT should be offered, as first line therapy, to all women with stress, urge or mixed incontinence."** This recommendation is, of course, based on the combination of demonstrable effectiveness with essentially no risk to the patient. It does not mandate that all patients undertake a formal course of PFMT before surgical treatment. **However, there are as yet no studies that adequately define patient groups who are unlikely to respond to PFMT** based on clinical factors such as age, obesity, and so on. In most cases, studies have been too small to examine such predictive factors and there may well be a role for individualized therapeutic recommendations if proper studies could be done. A single trial investigating PFMT for UI in pregnancy did not show efficacy (Woldringh et al, 2007), but this has been criticized owing to lack of specificity about the intervention. The ICI committee specifically points out the need for a large scale, pragmatic trial of PFMT with detailed reporting of long-term (>5 years) follow-up (Hay-Smith et al, 2009). The authors also describe what they believe are the key components of an effective program: (1) it is based on sound principles (specificity, overload, and progression), (2) correct contraction is confirmed before training, and (3) women are supported to maintain treatment adherence (level of evidence 4).

The quality of the data for men with postprostatectomy UI is less robust with too many single-center, underpowered trials. Research has focused on use of pelvic floor therapies to hasten return of continence. **A systematic review of the literature concluded that although training may hasten return of continence after surgery it does not affect long-term outcome** (MacDonald et al, 2007). Others have found that there is no difference between routine preoperative and postoperative PFMT (Filocamo et al, 2005). In contrast, one RCT found that significantly more men were completely continent 1 year after prostatectomy when performing PFMT with a physiotherapist than without (Overgard et al, 2008). When PFMT is used for established postprostatectomy UI, the results similarly do not establish long-term benefit of therapy, with or without biofeedback. Interested readers are referred to a Cochrane review on the subject (Hunter et al, 2004).

Within these overarching categories it is likely that specific patient subgroups are more or less likely to benefit from PFMT (and probably other conservative techniques). However, studies have not been designed to specifically identify such groups and subgroup analysis of relatively small trials is fraught with error. In one retrospective series of 447 women with SUI, 49% of patients were "successfully treated." Success appeared to be more likely in patients with milder degrees of UI (not using pads: 67% success; not having daily UI: 63% success; no leakage at first cough: 60% success). Independent risk factors for failure included two or more leaks per day, presence of leakage at first cough, and use of antidepressant/anxiolytic medications (Cammu et al, 2004). Burgio (2004) argues that PFMT is equally effective in treating UI with stress, urge, and mixed UI, whereas Goode (2004) commented that there are as yet no reliable predictors of treatment outcomes.

Other Benefits of PFMT

A small pilot study demonstrated effectiveness of PFMT in symptoms of prolapse and in objective prolapse stage for women with symptomatic stage I or II prolapse (Hagen et al, 2009). If confirmed in larger studies with long-term follow-up this could have a major impact on women's health.

Implementing PFMT in Clinical Practice

If PFMT is to be accepted as standard therapy, one must also define how to implement training in clinical practice. Many articles have evaluated different regimens and use of ancillary tools, but in many cases quality is lacking. In evaluating the literature it is important to ensure that groups being compared are truly equivalent in all parameters other than that being tested. Key elements include the usual demographic characteristics, the degree of supervision (expertise and contact time), the intensity of the exercise program (number, frequency, and duration of contractions), use of ancillary tools, and, of course, the length of the program and follow-up. **The ICI group** (Hay-Smith et al, 2009) **concluded that:**

1. **Clinicians should provide the most intensive heath care professional–led PFMT program that is possible within service constraints because programs taught and supervised by health care professionals are superior to self-directed programs.**
2. **No PFMT regimen has been proven most effective; treatments should be based on the exercise physiology literature.**
3. **There is no demonstrable benefit of adding clinic or home biofeedback to a PFMT program.**

A representative strengthening program for PFMT used by the author suggests:

1. **Sets of 8 to 12 near-maximal contractions are recommended.**
2. **Each contraction is held 6 to 8 seconds with an equivalent rest period.**
3. **At the end of each set a series of 5 to 10 rapid contractions are performed.**
4. **The exercises are repeated five times per day, every other day.**

In addition to the strengthening program **the author recommends use of the "knack" maneuver to promote timing of the contraction coincident to coughing for SUI patients** (Miller et al, 2001, 2008) **and "quick flicks," which are short, rapid contractions intended to inhibit urgency for those with OAB symptoms.**

Long-Term Results of PFMT

The need to practice PFMT is probably lifelong, and patients should be counseled to integrate exercise into their normal routines. Bo and colleagues (2005) reported a 15-year follow-up of a randomized trial between intensive exercise therapy and home exercises in women with SUI. Ninety percent of the subjects were located and responded to a questionnaire. Half of the women in both groups eventually underwent surgical treatment. It is clear that exercises were not continued (28% exercise at least weekly and 36% never exercise). Although most women in both groups were satisfied with their current condition, "the marked benefit of intensive PFMT seen short-term was not maintained 15 years later." The author suggests that training one to two times a week at high intensity is enough to maintain muscle strength. A second group was able to query 79 of 123 women with SUI or mixed UI initially treated with PFMT after 8 years. Again, less than 10% continued training throughout the interval (Kondo et al, 2007). Yet 39% of the group considered the treatment to be successful (>50% improvement). On the other hand, Cammu and

colleagues (2000) found that 16 of 24 patients (67%) originally satisfied with PFMT remained so after 10 years and only 2 of 24 (8%) went on to surgical therapy. They attributed sustained improvement to patients' use of a voluntary pelvic muscle contraction ("perineal lock" or "knack") before physical stress.

PFMT versus Other "Conservative" Modalities

PFMT has also been compared against other therapies, including various forms of vaginal cones, electrical stimulation, bladder training, and pharmacologic therapy. Again, most of the individual trials are relatively underpowered, often differ in the degree of therapist contact/supervision, and have a short follow-up. In addition there is always a selection bias because some women will not accept use of vaginal devices such as cones, biofeedback probes, or stimulators. **The following conclusions regarding first-line therapy came from the ICI committee** (Hay-Smith et al, 2009):

For women with SUI:

- PFMT is superior to electrical stimulation, particularly if PFMT is intensively supervised (grade B).
- PFMT is better than bladder training (grade B).
- PFMT has equivalent efficacy to duloxetine with fewer adverse effects (grade C).
- PFMT and surgery are both effective therapies but PFMT is better as a first-line treatment because it is less invasive (grade C).

For women with SUI or mixed UI:

- PFMT is better than vaginal cones (grade B).
- PFMT is better than phenylpropanolamine or clenbuterol because of the side effects with the medications (grade B).

For women with UUI or mixed UI:

- PFMT and bladder training are both effective first-line therapy (grade B).
- PFMT is superior to oxybutynin (grade B).

Although it is scientifically desirable to understand the relative value of each of these conservative treatments, the practical fact is that these are generally complementary tools. In particular, **bladder training and PFMT are useful for all types of UI and require no specialized equipment.** Wyman and colleagues (1998) found that adding PFMT to bladder training produced superior short-term results. Another clinical trial demonstrated the feasibility of using a booklet to provide an initial "package" therapy to be used without ongoing supervision (Goode et al, 2003). The standardized booklet was compared with one group receiving office behavioral training and another that used home vaginal electrical stimulation. Episodes of UI were reduced by 52.5%, 68.6%, and 71.9%, respectively. Although the booklet approach was inferior to the more intensive treatment, the results, including a statistically significant improvement in quality of life in all groups, suggest that **most cost-effective way to deliver therapy would be to begin with such a booklet, reserving office-based therapy requiring expert clinicians for those not satisfied with the initial results.**

Key Points: Pelvic Floor Rehabilitation: Pelvic Floor Muscle Training

- The term *pelvic floor rehabilitation* should be applied to any treatment intended to increase the strength, bulk, and function of the pelvic floor/levator muscles.
- Basic treatments are used in the home setting, require no or inexpensive equipment, and can be administered by a relatively unskilled therapist. Advanced treatments are used in an office setting with a trained therapist or require more sophisticated equipment.
- *Pelvic floor muscle training* (PFMT) is the currently accepted term, replacing *Kegels* and *pelvic floor exercises*. It is defined as "any program of repeated voluntary pelvic floor muscle contractions taught by a health care professional."
- Evidence supports the effectiveness of routine PFMT to prevent UI in primiparous women and for supervised intensive PFMT for all women after instrumental delivery or delivery of a large infant (grade C recommendation).
- The overwhelming majority of the trials showed effectiveness of PFMT in treating established UI, leading to a grade A recommendation that "PFMT should be offered, as first line therapy, to all women with stress, urge or mixed incontinence."
- No role has been established for pelvic floor rehabilitation in the treatment or prevention of postprostatectomy UI.
- Success with PFMT appears to be more likely in patients with milder degrees of UI. Independent risk factors for failure included two or more leaks per day, presence of leakage at first cough, and use of antidepressant/anxiolytic medications.
- The principles of a quality PFMT program include:
  1. Clinicians should provide the most intensive PFMT supervision that is possible within service constraints.
  2. No PFMT regimen has been proven most effective; treatments should be based on the exercise physiology literature.
  3. There is no demonstrable benefit of biofeedback over PFMT alone, although properly powered quality trials are probably warranted to study this issue further.
- A representative strengthening program for PFMT could include sets of 10 to 12 near-maximal contractions, with each contraction held 6 to 8 seconds with equivalent rest period and repeated three to five times per day, every other day.

Biofeedback

Biofeedback is any method of training a patient to control a bodily function by providing him or her with information about that function. In this case, the patient hopes to gain control of, and strengthen, the pelvic muscles. The tools range from inexpensive vaginal cones to office systems costing thousands of dollars. One must remember, however, that no study has ever demonstrated that a particular device is responsible for restoring continence. On the contrary **it is clear that the motivation of the patient and the experience and ability of the therapist are the critical factors for success** (Bo et al, 1990a). Published articles in the UI literature typically involve trained physical therapists specializing in UI and pelvic floor problems. In contrast, the biofeedback therapist in the "real world" setting is often a nurse or technician possessing only brief training in the subject. Finally, **biofeedback is only a tool, a teaching technique; real improvement in muscle strength and continence is dependent on the patient's work outside the office.** The bottom line with all of these pelvic floor therapies is that no piece of equipment is as important as the effort the patient puts into the program.

Palpation Only

Most of the literature on PFMT assumes at least initial basic evaluation and teaching by digital assessment of a pelvic floor muscle contraction during pelvic examination. This may or may not be performed at all follow-up visits. Although this is clearly an example of biofeedback, in the PFMT literature the term *biofeedback* is generally reserved for studies using sophisticated electronic or pressure devices to record pelvic floor activity.

Vaginal Cones

Sets of cones sold with varying numbers of cones ranging from 3 to 9, each of different weight, have been marketed for treatment of UI for many years (Fig. 69–2). The patient is instructed to insert a cone in the vagina above the levator muscles and hold it in for 15 to 20 minutes while in the erect position. **The concept is that the sensation of the cones slipping down or falling out of the vagina will provide biofeedback to the patient to learn to identify and contract the pelvic muscles.** Initially, the patient may only be able to hold the cone at rest for a short time but as she gains strength she will be able to retain the cone with normal activity. She then progresses to the next heaviest cone. This provides additional biofeedback and may encourage the patient to continue with therapy. It is unlikely that this is equivalent to the effect of a skilled therapist, but this approach offers convenience at a very low cost. There are many limitations in the use of cones. Many patients will not use any vaginal device, a substantial group will not even be able to retain the lightest cone, and some patients will retain the cones with use of thigh adductor muscles without proper levator contraction. They are obviously not useful for the incontinent male patient.

The clinical effectiveness of vaginal cones has been examined in a Cochrane systematic review (Herbison et al, 2004). The authors identified 15 studies involving 1126 women, of whom 466 received cones. However, the trials were small, many were published only as abstracts, and "the quality was hard to judge." Cones were believed to be better than no treatment but not clearly different from PFMT or electrical stimulation. Hay-Smith and colleagues (2009) concluded that there was grade B evidence that vaginal cones could be offered to women with SUI **"who can and are prepared to use them" but cones were inferior to PFMT (grade B). Cones were equally effective to electrical stimulation in four trials reviewed (grade B) and adding cones to PFMT does not appear to offer additional benefit.**

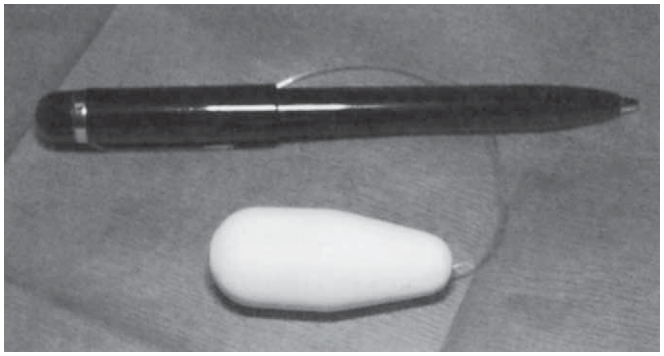

Figure 69–2. Small, weighted cones placed in the vagina provide biofeedback when the patient feels the cone slipping out and must tighten the pelvic floor muscles to retain it. They are typically sold in sets of five with progressively greater weight. (From Payne CK. Advances in nonsurgical treatment of urinary incontinence and overactive bladder. Campbell's Urology Update 1999;1[1]:6.)

Other Biofeedback Techniques

Most modern biofeedback units employ vaginal/anal sensors that display either pressure or electromyographic (EMG) activity on a computer screen for visual biofeedback (Fig. 69–3). In some cases, auditory biofeedback corresponding to the muscle contraction is provided, and this can be beneficial for those patients with visual limitations. Perineometers measure vaginal or anal squeeze pressure (as per Arnold Kegel), are available for about $100, and, in theory, might be more effective in teaching a patient to identify the proper muscles than vaginal cones. In practice, however, **pressure-based biofeedback has been criticized because abdominal pressure is also transmitted to the probe** (Bo et al, 1990b). A patient may perform a Valsalva maneuver, which is counterproductive, because the pelvic muscles are contracting. The devices are more expensive and have the same problems with patient acceptance as vaginal cones. **Pressure-based biofeedback has largely been supplanted by EMG systems,** which are more expensive ($250 to $400 and up). These reduce the problem with Valsalva maneuvers but **do not guarantee proper muscle isolation because they only register activity of one muscle group.** Devices used with vaginal sensors, rectal sensors, and perineal patches are available. Although many randomized controlled trials have been performed examining exercises with and without biofeedback, the results are mixed, and a recent review concluded, "The evidence for firm recommendations to include biofeedback in these conservative strategies is lacking, and further research is needed to clarify the role of biofeedback" (Weatherall, 2000). **The ICI review data presented earlier** (Hay-Smith et al, 2009) **concluded that there is no benefit to adding biofeedback to a good PFMT program.**

Peripheral Stimulation

Dissatisfaction with the time, effort, and expertise required for office-based biofeedback generates an interest in passive pelvic floor therapy. The two modalities used in this manner are peripheral electrical stimulation and magnetic stimulation.

Electrical Stimulation

There have been innumerable different devices used to assist and promote rehabilitation of the pelvic floor muscles. The type of stimulation varies by location, current type, waveform, and intensity. **High-frequency stimulation (50 to 200 Hz) generally has been used with vaginal or anal electrodes for SUI; the proposed mechanism of action is to directly stimulate the pelvic floor and urethral muscles thereby causing contractions.** Exactly how this improves continence—by changing muscle reaction or increasing bulk/strength—is not well documented in the literature. **Electrical stimulation can also be used to treat patients with urge or mixed UI.** Low-frequency stimulation **(5 to 20 Hz)** is typically employed, **intending to activate inhibitory bladder reflexes and reduce detrusor overactivity.** Although most devices employ vaginal or anal electrodes, the effect can also be achieved less invasively with peripheral stimulation using patch electrodes in the perianal or posterior tibial nerve distribution (McGuire et al, 1983; Hasan et al, 1996). Male patients may find this mode of therapy more acceptable than anal electrodes.

The advantage of this modality is that it is dependent only on patient compliance, not effort. The initial expense

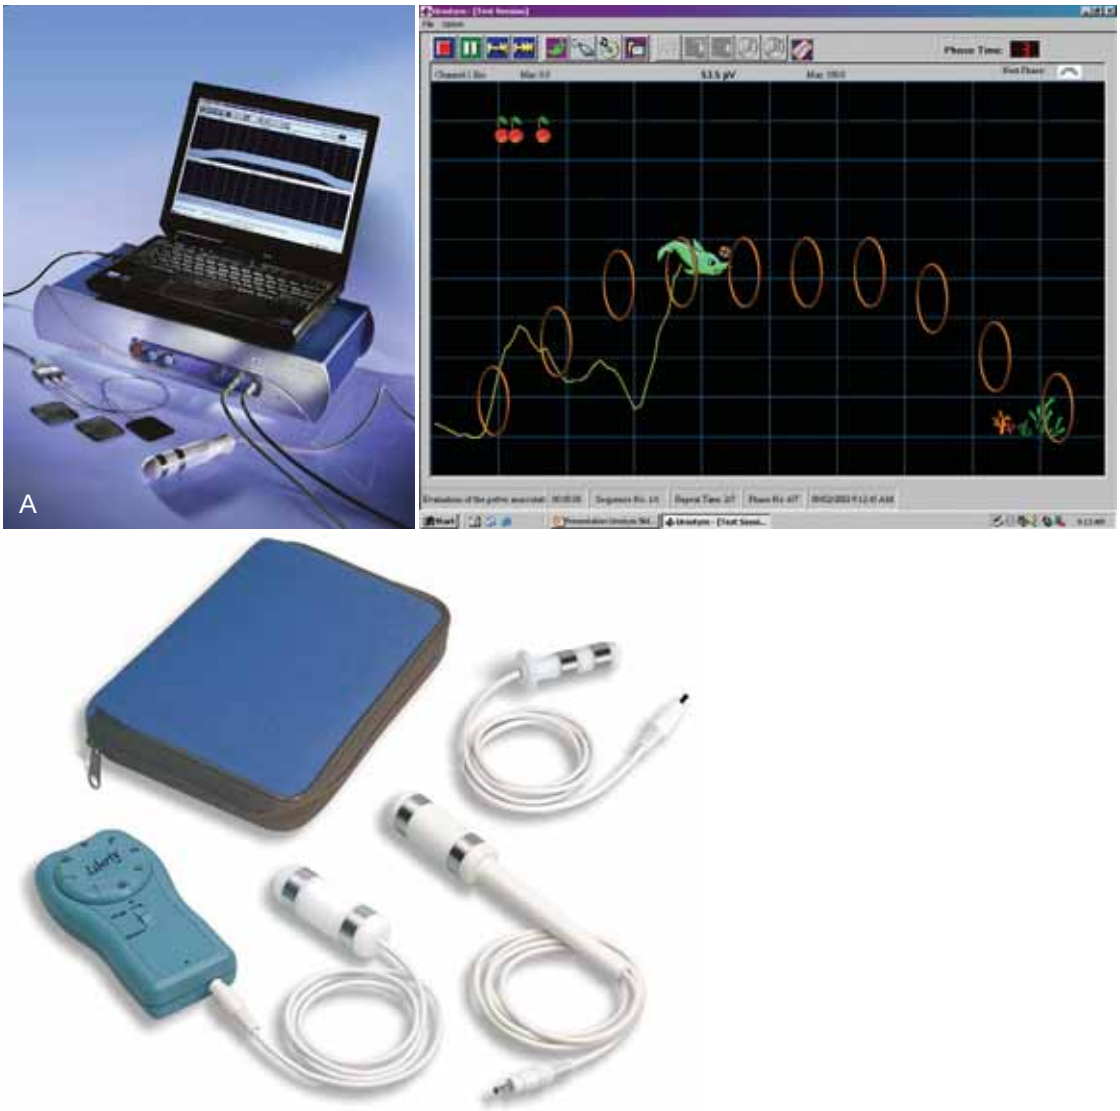

Figure 69–3. Tools for pelvic floor rehabilitation. **A,** Laptop-based office biofeedback system with probe and patches. **B,** Animated screen for pediatric biofeedback. **C,** Typical home electrical stimulation unit. (**A** and **B,** Courtesy of Laborie Corporation, Williston, VT; **C,** Courtesy of Utah Medical Products, Midvale, UT.)

($600 to $800) can be partially offset by home administration of treatments. Electrical stimulation can be combined with office biofeedback using the same probe on some systems.

Electrical stimulation has potentially wide applicability and reasonable cost. Unfortunately, the electrical stimulation literature is characterized by case series with small numbers of patients using different devices and widely varying treatment algorithms, few of which provide any follow-up after the initial assessment of response. In addition, the role of dual stimulation for mixed UI has not been adequately evaluated; this treatment would seem to be ideal for such patients using the high frequency for the sphincter and low frequency for the bladder. The various types of protocols for stimulation are well summarized by the ICI committee (Hay-Smith et al, 2009).

The most clinically useful data come from three RCTs using the EMPI product (EMPI Corporation, St. Paul, MN). One study including 121 women with UI found no significant changes in any of the clinical variables examined (frequency, incontinence, subjective improvement) even though active treatment produced an improvement in urodynamics for the subset with detrusor overactivity (Brubaker et al, 1997). In a second study investigating women with SUI, electrical stimulation was demonstrated to be significantly better than sham therapy. Patients were treated with home vaginal stimulation for 15 minutes twice per day for 12 weeks. Leakage episodes decreased from 3.1 to 1.8 (42%) per day, and pad use decreased from 6.2 to 4.1 (34%) per week in the treatment group; there were small, statistically insignificant increases in the placebo group. Importantly, the clinical improvement correlated with improvement in pelvic muscle strength on perineometry (10.6 mm Hg baseline and 15.2 mm Hg at the end of treatment compared with a small decrease in strength in the placebo group) (Sand et al, 1995). The final study examined the optimal treatment regimen; there was no difference in outcome between daily and every-other-day stimulation (Richardson et al, 1996). In a literature review of 361 cumulative patients with UUI, detrusor overactivity, and neurogenic detrusor overactivity, the overall results were 20% dry and another 37% significantly improved using a variety of definitions for outcome (Payne, 1996). **The ICI committee concluded that electrical stimulation might be better than no treatment for women with SUI**

or DO, that low-intensity home electrical stimulation may be superior to maximal stimulation in an office setting, and that adding electrical stimulation does not improve the outcome of a proper PFMT program (all grade C) (Hay-Smith et al, 2009).

The "new" treatment option for peripheral electrical stimulation is peripheral neuromodulation of the posterior tibial nerve using 34-gauge solid needles connected to an external stimulator (PTNS). The idea was initially developed and promoted by Stoller (Payne, 2002). The initial multicenter open-label trial found a 71% response in 53 patients with a variety of lower urinary tract disorders after 12 weekly treatments (Govier et al, 2001). In 2005 a small RCT showed no difference in response between three times per week and weekly treatment (Finazzi Agrò, 2005). The therapy was ultimately approved by the U.S. Food and Drug Administration (FDA) in 2007 as the Urgent PC (Uroplasty, Minnetonka, MN). Since then, further work has shown that the device has considerable promise in the treatment of OAB. Peters and colleagues (2009) compared PTNS with pharmacologic therapy with long-acting tolterodine 4 mg/day in 100 adults with OAB. The results were very similar with near-identical responses in reduction of frequency, nocturia, UUI, and urgency episodes. More subjects reported cure or improvement in OAB symptoms with PTNS than tolterodine (79.5% compared with 54.8%, $P = .01$). Constipation and dry mouth were significantly less common in the PTNS group, and local adverse effects from PTNS appear to have been minor. A follow-up manuscript reported the durability of PTNS at 1 year (MacDiarmid et al, 2010). Patients initially randomized to PTNS were offered an additional 9 months of therapy but could not use any supplemental anticholinergic medications. Treatments were given at the discretion of the patient and physician. There were 35 responders of the initial 44 patients randomized to PTNS. Thirty-three agreed to enter the continuation trial and 25 continued for 1 year (71% or 56% of those initially assigned to PTNS), and all but 1 continued to self classify as "cured or improved." Improvement in all voiding diary variables was sustained.

The ICI committee (Hay-Smith et al, 2009) was able to come to **several conclusions and recommendations about the use of peripheral electrical stimulation for UI:**

1. Home-based electrical stimulation is superior to no treatment for women with DO or SUI (grade C).
2. There was inadequate evidence to conclude that electrical stimulation was superior to sham therapy.
3. For women with SUI low-intensity home-based electrical stimulation daily for 6 months might be better than 16 sessions of maximal clinic-based electrical stimulation (grade C).
4. The addition of electrical stimulation to a biofeedback-assisted PFMT program does not appear to add benefit (grade C).
5. There was inadequate evidence to compare electrical stimulation to any alternative therapy.
6. Older women may respond to electrical stimulation as well as younger women and should not be excluded from studies of this therapy.

Magnetic Stimulation

One commercial device has been available in the United States to treat UI by extracorporeal magnetic stimulation since 1998. The NeoControl (Neotonus Corporation, Marietta, GA) device provides noninvasive, passive stimulation to the pelvic floor. The patient sits in the treatment chair, which emits electromagnetic waves focused on the expected area of the pelvic floor muscles. The recommended treatment session lasts 20 minutes and includes both high- and low-frequency stimulation, regardless of the type of UI. The low-frequency stimulus elicits a pulselike contraction of the levator muscles, whereas the higher frequency produces more of a tetanic contraction. There is some flexibility for the clinician to program the treatment, and the patient adjusts the intensity to comfort level. **The potential advantages of this therapy are as follows:**

- No internal probe—increased patient acceptance
- Patient can wear street clothes—convenience
- Operated by a technician with minimal training
- No supervision required

The disadvantage is that the twice-weekly treatments must be administered in the clinician's office, which is quite inconvenient for many patients in comparison to home electrical stimulation. The stimulation is nonspecific, and magnetic waves are not significantly attenuated by interaction with tissue. Thus, other muscles, nerves, and even the uterus could respond to stimulus, although most patients tolerate treatment well. Although magnetic stimulation is usually thought to act by improving pelvic floor muscle function, stimulation has been shown to suppress detrusor overactivity in the acute setting (McFarlane et al, 1997).

The initial case series suggested that magnetic stimulation might be effective for both SUI and UUI (Galloway et al, 1999; Yokoyama et al, 2004). Subsequent RCTs have had mixed results. Two sham-controlled trials have studied women with urodynamically proven SUI using the NeoControl device. Gilling and colleagues (2009) found that active treatment was not superior to sham therapy in 70 women treated three times per week for 6 weeks. Enrollment in another trial using twice-weekly treatment for 8 weeks was stopped early, having recruited only 48 of 60 patients, owing to poor results and a high dropout rate with adverse events in half of the subjects (Ismail et al, 2009). These results contrast to a case series of women with SUI treated with a similar device, most of whom had a sustained good response for 1 year but then suffered deterioration during the second year (Hoscan et al, 2008). Yet another device developed in Japan was studied in 39 patients with UUI who had failed PFMT (Suzuki et al, 2007). A double-blind crossover design with weekly treatment for 10 weeks was employed. The authors found improvement in UI episodes and urodynamic parameters with active treatment. These results were supported by a long-term follow-up of 48 women with OAB in which 26 of 27 subjects who were considered "cured" at 2 weeks continued to be improved at 24 months (Choe et al, 2007). Another trial using a different type of device (PULSEGEN by Power of Nature, Ft. Myers, FL) included 39 women with urge-predominant mixed UI (But et al, 2005) treated at 18.5 Hz. Those receiving active treatment had statistically significant improvements in several outcome variables, and symptoms improved in 42% with active therapy compared with 23% in the placebo-treatment group. However, this device is worn in a small pocket of specially designed underwear with stimulation used day and night for 2 months.

Thus, **the small trials performed to date suggest that extracorporeal magnetic stimulation is not effective for female SUI but may be useful for OAB/UUI.** The ICI committee (Hay-Smith et al, 2009) could only conclude that magnetic stimulation was "worthy of further investigation in women with UI." Several authors have suggested that the therapy might be best used with patients who are unable to perform a pelvic muscle contraction, but this has not been specifically studied. Very limited investigation into the durability of response in patients initially treated successfully suggests that the relapse rate is not

unreasonable; whether failures might respond to "booster" therapy is unknown. It is clear that larger-scale trials with pragmatic design are needed before the role of magnetic stimulation can be defined. The most important question is whether any of the advanced pelvic floor rehabilitation techniques provide more consistent or better durability of response than PFMT. Until such data exist, biofeedback, electrical stimulation, and electromagnetic therapy are all potential competitive treatment options to rehabilitate the pelvic floor when PFMT is insufficient.

Key Points: Biofeedback and Peripheral Stimulation

- Biofeedback is any method of training a patient to control a bodily function by providing him or her with information about that function. For UI, the patient hopes to gain control of, and strengthen, the pelvic muscles.
- The simplest form of biofeedback is direct palpation by a skilled therapist.
- Vaginal cones are inexpensive devices for home biofeedback. The evidence suggests that cones are better than no treatment but not clearly different from PFMT.
- More sophisticated office biofeedback machines may be useful for certain subgroups of patients but have not been proven to be superior to PFMT.
- High-frequency stimulation (50 to 200 Hz) has been used with vaginal or anal electrodes for SUI, and low-frequency stimulation (5 to 20 Hz) is employed to reduce OAB/UUI.
- There is a single trial showing PTNS to be superior to anticholinergic medication in the treatment of OAB with good durability at 1 year follow-up.
- Both electrical and magnetic stimulation are passive treatments that offer an opportunity to treat patients who may not be motivated to perform regular PFMT.

DEVICES

Vaginal Support (Pessaries) for Stress Urinary Incontinence

Vaginal support prostheses are among the oldest of medical devices. Although primarily used to treat pelvic organ prolapse, these products have been used to treat SUI and there has been an interest in developing devices specifically for SUI in recent years. Older devices, initially developed for lower-stage pelvic organ prolapse, such as the Smith and Hodge pessaries, have been used in treating SUI with limited clinical data as to their effectiveness (Bhatia et al, 1983; Bergman and Bhatia, 1984; Nygaard, 1995). The Incontinence Dish (Milex Corp., Chicago, IL) is another pessary commonly used in treating SUI; although there are no published clinical trials, a urodynamic investigation (Noblett et al, 2008) revealed that the mean Q-tip straining angle without and with the pessary, respectively, was 57.8 (+19.5) and 34.4 (+29.7), the maximum urethral closure pressure was significantly increased by 19.7 cm H_2O ($P < .001$), and 60% of the subjects did not experience any leaking with the device in place. In addition, any of the variety of devices that support the bladder neck have been used to estimate the response to surgical therapy in patients with mixed UI, although the predictive value of the trial is not established.

Advantages of vaginal support devices include:

- They are potentially applicable to the majority of the incontinent population (those with pure stress or mixed UI and urethral hypermobility).
- They do not require specific testing, such as urodynamics.
- They can be used "as needed" for predictable SUI (as can the other devices).
- They have mild side effects limited to occasional vaginitis and minor local discomfort.
- Some devices can be used to treat both pelvic prolapse and SUI.

Disadvantages of vaginal support devices include:

- They do not correct intrinsic sphincter deficiency and thus are not as likely to help patients without urethral hypermobility.
- They do not definitively treat potentially curable problems. If the problem worsens over time, the patient's health may make surgical therapy less attractive and, in rare cases, impossible.

The Introl bladder neck support prosthesis (Fig. 69–4) was the first device specifically approved for SUI in the United States, and it has subsequently been withdrawn from the market. The Introl was a simple device to mechanically support the hypermobile bladder neck. Clinical trials showed good objective relief of SUI without creating emptying difficulty (Davilla and Ostermann, 1994). One problem may have been relative difficulty in fitting because the Introl prosthesis had 25 sizes whereas traditional pessaries have about 10 sizes. There now appear to be three devices in use, but only one is currently available in the United States. All show promising results in small clinical trials.

The ConTIPI (Fig. 69–5) was developed and is sold in Israel. In contrast to other pessaries, it is disposable and intended for single-daily or as-needed use. It consists of a flexible core with the ends made of resin to provide anchoring. It is covered with a nylon mesh, and a string is attached to the cover for easy removal. This device has been tested in one prospective case series of women

Figure 69–7. The Uresta pessary (EastMed Inc., Halifax, Nova Scotia, Canada). (From www.uresta.com/sites/default/files/PPP%20Fitting%20Dec%208%2C%202009.pdf.)

with urodynamically proven SUI who were considered surgical candidates (Ziv et al, 2008). There was a 7-day "run in" followed by 28 days using the device. Eighty-five percent of the 60 women tested were considered responders, having achieved 70% or more reduction in home pad testing ($P = .01$). Improvements in overall quality of life, subjective perception of UI, and satisfaction with the device were observed. There were no changes in flow rates or residual urine, but 67% of subjects experienced some genital tract adverse event, including 25% with pain and 23% with spotting.

Another device, the "Contiform" (Fig. 69–6), is being used in Australia. It is intended for women with a main complaint of SUI but no pelvic organ prolapse. It comes in four sizes. Studies by Allen and associates (2008) showed that of 73 women invited to participate, 65 enrolled, 52 were successfully fitted (80% of those willing), and 37 completed the study protocol (71% of those fitted, 57% of those willing). At the end of 1 month, 20 (54%) of patients were dry after a 24-hour pad test. Only 8 of 37 (22%) chose to proceed with surgical therapy, whereas the rest were satisfied to continue using the device for a longer term. The patients had relatively mild SUI, with all having less than 25 g of urine loss on the baseline 24-hour pad test. This study points out one of the limitations of using pessaries; patients with prior surgery causing vaginal distortion or introital scarring may not be successfully fit, and those with an overly large genital hiatus may not retain a device.

The third device, the Uresta (Fig. 69–7), is marketed in the United States and Canada. It was studied in a small group of women with 1-year follow-up (Farrell et al, 2007). Thirty-two women started the trial, and 11 dropped out in the first 2 weeks. Among women successfully fitted at 2 weeks, 16 of 21 (76%, or 50% of the initial cohort) continued using their pessary at 1 year. Weekly UI episodes decreased from 20 to 4 ($P = .028$) and provocative pad test weight decreased from 20 to 9 g ($P = .06$).

Vaginal Support (Pessaries) for Prolapse (Overflow/Bladder Outlet Obstruction/ Urgency Urinary Incontinence)

Pessaries have been used for years as a treatment for pelvic organ prolapse and diseases of the uterus (Miller, 1991). In fact, most

devices used for SUI in the United States are pessaries primarily designed for pelvic organ prolapse. The Milex Corporation (Chicago, IL) and the Mentor Company (Santa Barbara, CA) offer a full range of pessaries for prolapse and have developed devices intended for SUI alone (Fig. 69–8) or that associated with pelvic organ prolapse (Fig. 69–9). These devices include a "knob" oriented anteriorly in the distal vagina at the level of the proximal urethra to improve closure. Such devices put pressure directly on the urethra and are thus more likely to be obstructive. This design could at least theoretically be useful for the patient with intrinsic sphincter deficiency because there is direct compression of the urethra. No direct comparison has ever been made between any of the various pessaries for any indication. **Pessaries used for prolapse only should be fitted with an empty bladder** for patient comfort. However, all **pessaries intended for use in SUI should be fitted with the bladder at a comfortable fullness.** The patient can then cough and strain to get an immediate assessment of effectiveness, and the patient should always urinate adequately before leaving the clinic because obstruction and retention can be a problem.

Vaginal pessaries have specific roles in diagnosis and treatment of lower urinary tract symptoms in at least three distinct situations:

1. Identification of "occult" SUI in a patient with cystocele
2. Identification/treatment of symptomatic prolapse causing OAB symptoms
3. Identification/treatment of symptomatic cystocele causing voiding symptoms and/or urinary retention

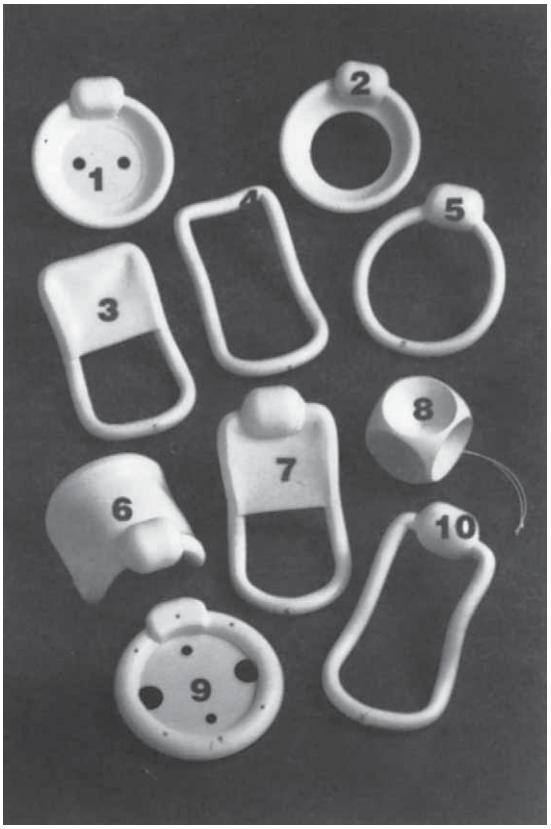

Figure 69–8. Pessaries available from Milex Corporation, Chicago. All provide varying anatomic support; those with "knobs" apply direct pressure to close the urethra to manage stress incontinence. 1, Incontinence dish with support; 2, Incontinence dish; 3, Hodge with support; 4, Hodge; 5, Incontinence ring; 6, Gehrung with knob; 7, Hodge with support and knob; 8, Cube; 9, Ring with support and knob; 10, Hodge with knob.

Prolapse, primarily from the anterior compartment, can impair voiding by mechanically obstructing the urethra through local pressure or by a kinking effect. This same mechanism could prevent clinical manifestations of SUI, and prolapse further diminishes SUI by dissipating abdominal pressure on the bladder neck and proximal urethra. Many authors have advocated using a vaginal pack or pessary test during preoperative evaluation before prolapse surgery (Fianu et al, 1985; Bergman et al, 1988; Ghoneim et al, 1994; Cross, 1998; Hextall et al, 1998; Chaikin et al, 2000; Klutke and Ramos, 2000). The use of a pessary or other means of prolapse reduction before surgery for apical prolapse was studied prospectively in the CARE trial (Colpopexy And urinary Reduction Efforts) by the NIH-sponsored Pelvic Floor Disorders Network. When clinically continent women were demonstrated to leak with stress with prolapse reduction during urodynamics they had a much worse result if no SUI procedure was performed (58% incontinent vs. 32% of those undergoing a Burch suspension) (Brubaker et al, 2003, 2008; Visco et al, 2008). Unfortunately, a negative stress test did not have a good predictive value because 38% of these patients had stress leakage after the prolapse repair. The pessary was the least specific of the five different methods of prolapse reduction tested (although a ring pessary was used that may not be suitable for higher grades of prolapse).

It thus seems reasonable to encourage prolapse patients considering surgery to undergo a trial of a pessary and evaluate the clinical response to the device. If OAB or other lower urinary tract symptoms resolve with the pessary, the patient may elect to use the device either temporarily until a convenient time for surgery or as a long-term solution. Similarly, if symptoms do not resolve after appropriate support with a pessary the patient should be counseled that the symptoms are more likely to persist even after successful repair of the anatomic defect. A pessary trial has an advantage over the packing tests during urodynamics in that the patient can be evaluated chronically and during day-to-day activities. However, **many patients with high-grade prolapse cannot retain any pessary and surgical decisions must be made using common sense, urodynamic data, and best clinical judgment.** If "de novo" SUI is uncovered, anti-UI surgery is clearly indicated. Even if no SUI is noticed with the pessary, consideration should be given to performing anti-UI surgery, providing the patient empties the bladder normally.

Urethral Meatal Occlusive Devices

At least three devices have been marketed for female SUI that were applied directly to the urethral meatus. The exact mechanism of action for these devices is not clear. The devices generally have a small reservoir or some absorptive capacity. They may create a "dam" to prevent leakage, work through absorption, or increase urethral closure by eliminating "pop off." The Capsure, Femassist, and Impress devices were approved for marketing, but all have been withdrawn from the market.

These were simple devices that could be more attractive to patients than a pad because they actually prevent leakage rather than simply absorbing the fluid. This would reduce odor and skin irritation. Good effectiveness was demonstrated for mild to moderate SUI, as detailed by Dmochowski (1998):

- Capsure: 84/100 completed 3 months, 48% dry/97% improved by pad test

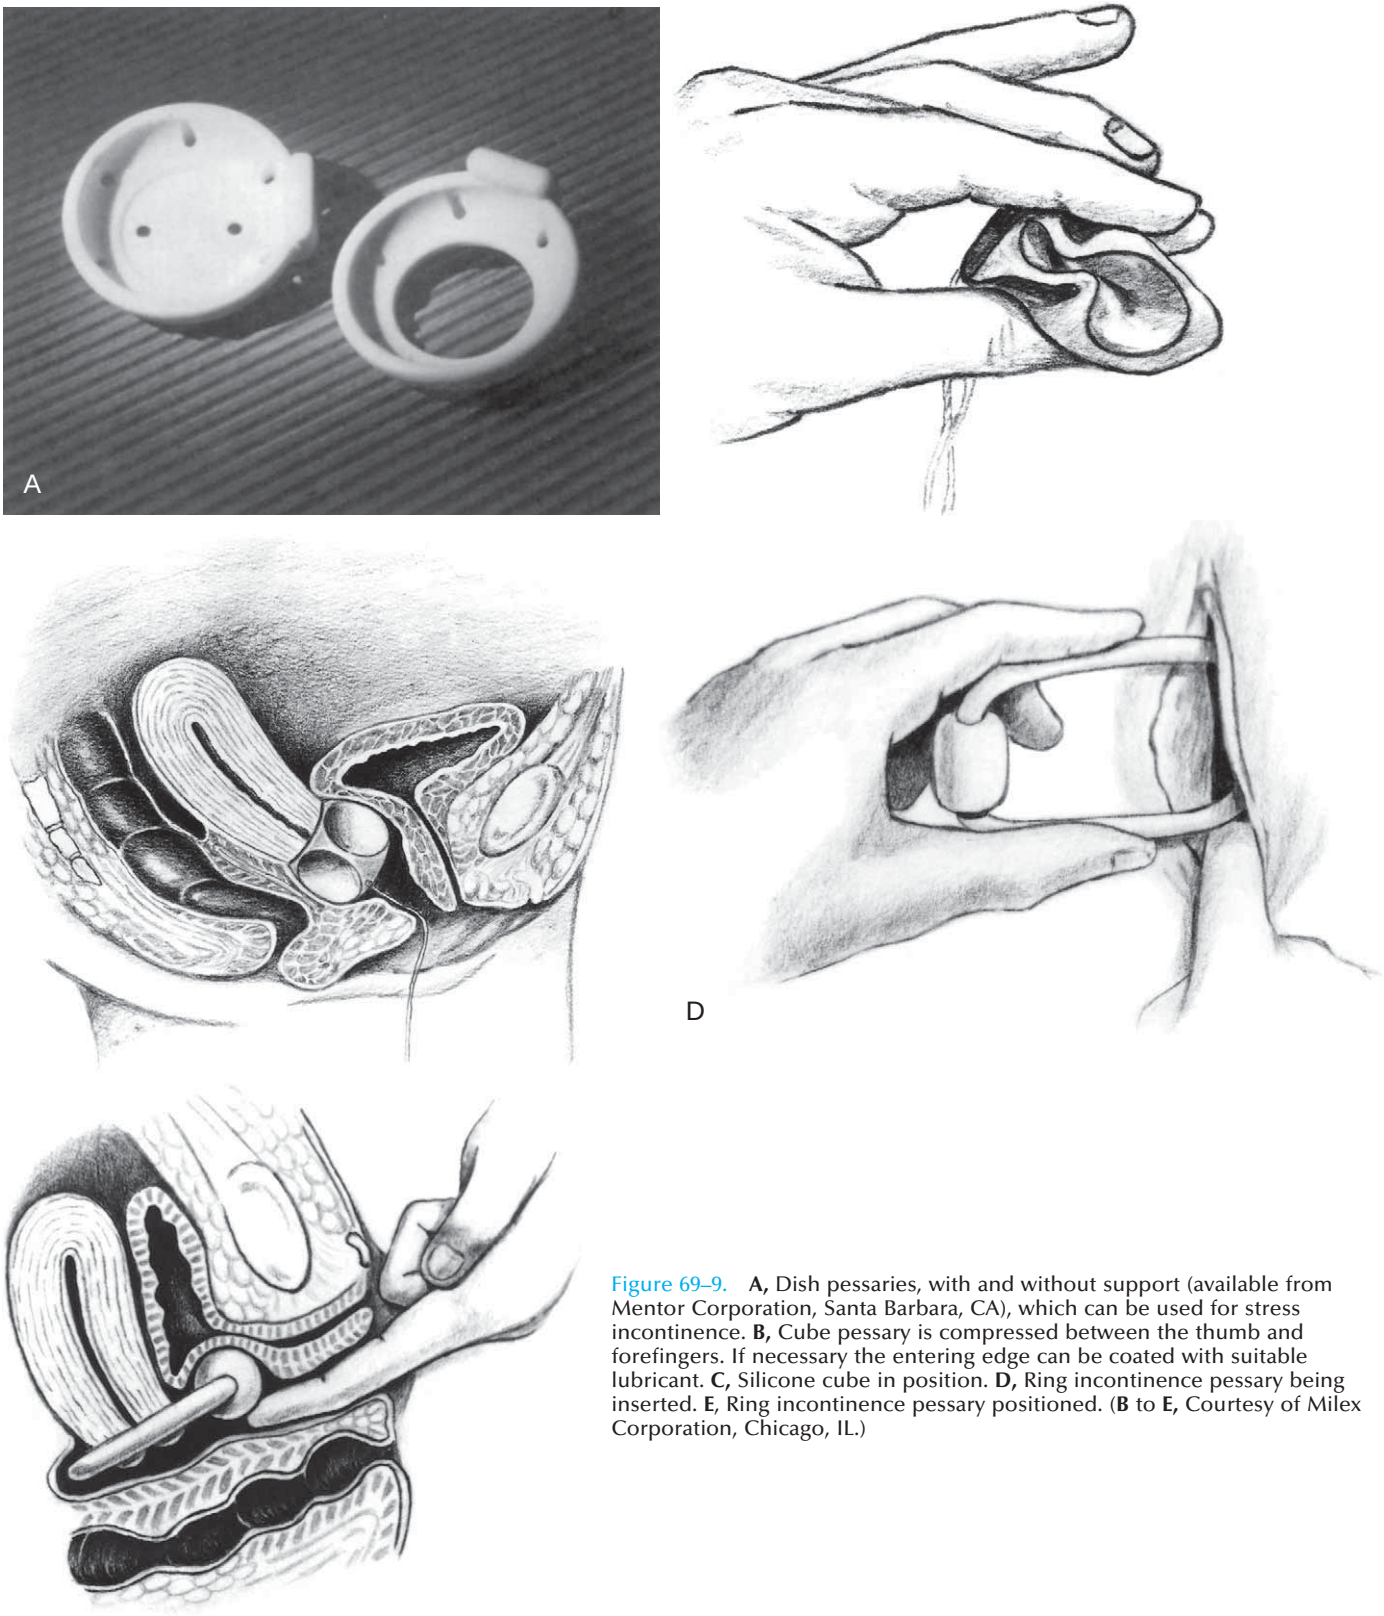

Figure 69–9. **A,** Dish pessaries, with and without support (available from Mentor Corporation, Santa Barbara, CA), which can be used for stress incontinence. **B,** Cube pessary is compressed between the thumb and forefingers. If necessary the entering edge can be coated with suitable lubricant. **C,** Silicone cube in position. **D,** Ring incontinence pessary being inserted. **E**, Ring incontinence pessary positioned. (**B** to **E,** Courtesy of Milex Corporation, Chicago, IL.)

- Femassist: 20/56 improved, 15 would use long term
- Impress: 17/19 cured/improved by a pad test

On the other hand, application was not uniformly easy and patients did not always have resources to help them get through initial problems in utilization. For some types of body habitus it was simply not possible to apply the device. The devices have a limited ability to oppose leakage and were not effective for severe stress leakage or any urge leakage. Finally, local tissue irritation was a minor but common problem. The future role for improved products in this area is unclear.

Urethral Inserts

Sometimes referred to as urethral stents or plugs, the urethral inserts for SUI passively occlude and/or coapt the urethra and must be removed for voiding. The first urethral insert to be approved for marketing by the U.S. FDA, the Reliance (UroMed, Inc., Needham, MA) (Fig. 69–10), has been withdrawn from the market. The second-generation FemSoft stent (Rochester Medical Corporation, Stewartville, MN) (Fig. 69–11) was FDA approved in 1997 and is currently available.

The multicenter study that led to the approval of the Reliance device enrolled 255 patients from eight centers. Of these, 135 completed at least 4 months with the device and were considered evaluable. The results were unquestionably good, with 80% of the subjects dry using the device and 95% improved (Staskin et al, 1998). At 1-year follow-up, the efficacy was maintained and there were significant but mostly minor complications, including urinary tract infection (30%), gross hematuria (24%), and local changes on cystoscopy (9%) (Miller and Bavendam, 1996). The device was also studied in a small comparative trial against a novel device, the NEAT, that never came to market. Both were effective against SUI with seemingly reasonable adverse events (Robinson et al, 2003).

In comparison, the one published study of the FemSoft insert was a 5-year, multicenter trial involving 150 women with mean follow-up of 15 months (Sirls et al, 2002). Pad testing and bladder diaries demonstrated efficacy. This device appears to be useful for a wide spectrum of the incontinent population, including those with urgency, low leak point pressure, failed surgery, and advanced age. In contrast, the Reliance was believed to be applicable only for pure SUI; if urgency was present it tended to be exacerbated by the device, resulting in loss of both urine and the device with an involuntary bladder contraction. Adverse events with the FemSoft were again common but not severe, including symptomatic urinary tract infection in 31.3%, mild trauma with insertion in 6.7%, hematuria in 3.3%, and migration in 1.3% of women.

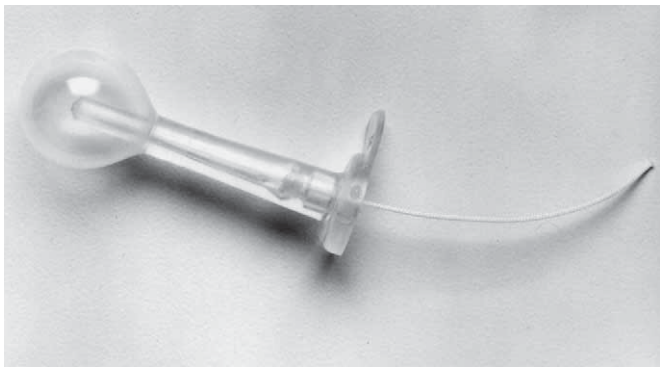

Figure 69–10. Reliance urethral insert. (Courtesy of Uromed Corporation, Needham, MA.)

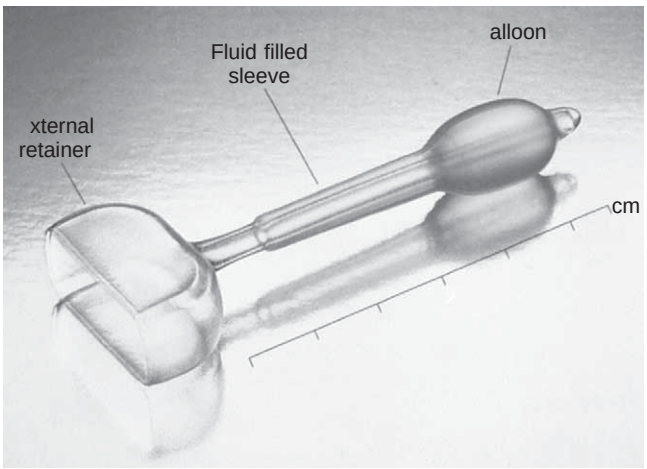

Figure 69–11. FemSoft urethral insert. (Courtesy of Rochester Medical Corporation, Stewartville, MN.)

Although urethral inserts are potentially applicable to almost all women with pure SUI and possibly some of those with mixed UI, it must be remembered that the device must be removed and replaced for each void. Despite the new soft, hydrophilic materials, only a small percentage of the SUI population seems to be willing to instrument the urethra to be dry. The highest patient acceptance seems to be among those with very predictable, episodic SUI, such as during sports or dancing. Such patients might use a device several times each week and have complete elimination of leakage. Many of these patients believe that their problem is too mild to undergo a surgical procedure but are happy to have this minimally invasive alternative.

Current practitioners and those who may design and market future devices might be informed by one study of women's knowledge of anatomy and their attitudes toward devices and genital touching. An Australian team questioned 104 consecutive women with UI using a 10-item questionnaire (Prashar et al, 2000). They found that only 30% of the women felt "quite comfortable" about the concept of touching their genitalia: this attitude was age dependent. Only 21% were quite willing to insert a continence device into their vagina: this attitude varied weakly with age but was significantly affected by previous tampon or diaphragm usage. Only 15% felt very comfortable about placing a continence device onto their urethra, but the likelihood of a positive response to this concept was not at all affected by age and was only slightly more common in previous tampon users. Thus older women are less likely to understand the anatomy of their genitalia or to be comfortable about the idea of exploring it, but age is no barrier to willingness to employ urethral or vaginal continence devices per se.

Urethral Stents

Urethral stents that allow for intermittent voiding through the device have been tested in both men and women with urinary retention/overflow UI. None has ever been approved in the United States. Most of the catheters that have been designed have internal motors that allow the patient to expel urine without removing the device, but one device, the ContiCath (ContiMed Corporation, Minneapolis, MN), works by allowing urine to pass around the catheter through three deep grooves. In contrast to the motorized stents, this device will be effective only for retention due to obstruction with intact detrusor function. In a preliminary trial (Corujo et al, 1999) 33 of 37 patients (90%) with a non-neuropathic cause and retention of 1 week or less were able to establish controlled voiding. The device was ineffective for neurogenic and chronic retention.

PRACTICAL APPROACH TO TREATMENT

General Issues—Patient Goals

Treatment of UI is more challenging and potentially more rewarding than many of the tasks facing the urologist because it requires

Key Points: Devices

- Bladder neck support devices are potentially applicable to the majority of the incontinent population (those with pure stress or mixed UI plus urethral hypermobility).
- Devices do not require specific testing such as urodynamics.
- Devices can be used "as needed" for predictable SUI.
- Supportive and occlusive devices have mild, reversible side effects limited to occasional vaginitis and minor local discomfort.
- Some supportive devices can be used to treat both pelvic prolapse and SUI.
- Devices do not definitively treat potentially curable problems. If the problem worsens over time, the patient's health may make surgical therapy less attractive and, in rare cases, impossible.
- Short-term trials using supportive devices can be a useful method to predict response to surgical therapy for prolapse and mixed UI.

a true partnership with the patient. **In most instances there is no one "best" treatment for the particular problem. Even when there is a superior treatment option, the nature of the disorder—not directly threatening to life and not necessarily progressive—not only allows but also mandates an individualized approach to therapy. The patient's personal goals should always be the prime concern.** A 40-year-old aerobics instructor may be highly motivated to be completely dry, whereas another woman might only want to attend church without fear of leakage; an incontinent man might be much more bothered by getting up three to four times at night than by daytime UI. Brubaker and Shull (2005) point out that it is "the patient's perspective that drives decisions about further treatment [in quality of life disorders]" in a review describing **the term *EGGS*, which has been coined to facilitate communication about patient-centered treatment outcomes. EGGS—Expectations, Goal setting, Goal achievement, and Satisfaction—describes a process in which the patient's point of view is explored to develop an individualized treatment plan.** This process is equally relevant for medical, surgical, and physical therapies; the importance of the patient perspective in surgical treatment has been demonstrated in prospective clinical trials. In a surgical series, **patient satisfaction was moderately correlated to goal achievement but was not related to objective cure of SUI or prolapse** (Elkadry et al, 2003), and goal achievement appeared to be durable at longer-term follow-up (Hullfish et al, 2004). Although less is known about expectations and goals as they relate to nonsurgical therapy, a clinician will do well to be aware of the patient's goals lest he or she lose the patient or find an unsatisfied customer. **The very nature of conservative therapies—safe, reversible, and effective—means that most patients will choose these options for first-line treatment. When the treatments are skillfully delivered, most patients will be very satisfied with the results.**

Treatment Planning—Data Collection

The clinician needs three primary pieces of information to develop a treatment plan for a given patient: the type of UI, the baseline voiding diary, and an assessment of anatomy with particular emphasis on pelvic floor muscle strength and function. In most cases a clinical diagnosis of stress, urge, or mixed UI is easily made but detailed evaluations are sometimes necessary before beginning treatment. **The voiding diary is important for four reasons.** First, **it is a reasonable substitute for cystometry, because the largest voided volume on a diary has been shown to correlate with the cystometric capacity** defined by urodynamic testing (Diokno et al, 1987). Given the high false-negative rate for cystometry and detrusor overactivity, determining a general sense of the bladder's capacity to store urine is at least as valuable as knowing whether involuntary contractions are present on cystometry. Second, **the voiding diary allows the clinician to objectively determine a "safe" voiding interval to begin a program of bladder training.** Third, **the "baseline" diary becomes the comparison for the clinician to objectively measure change with therapy.** Finally, **the process of keeping the voiding diary involves the patient in the treatment program,** starting the education essential to behavioral therapy. The assessment of baseline pelvic muscle strength is critical because that allows the clinician to intelligently prescribe pelvic floor rehabilitation therapy.

Pelvic floor rehabilitation has a unique role in UI therapy in that all types of UI can benefit and, potentially, be cured. Pelvic floor rehabilitation has long been identified as a treatment for SUI. It has been variously proposed that such treatments increase the resting tension, the contractile force, or the speed of recruitment of the voluntary sphincter. Such changes could increase resting urethral closure and improve the reflex closure that occurs with increases in abdominal pressure. Pelvic floor rehabilitation has been relatively overlooked in treating bladder-related UI. Pelvic floor therapy is theoretically valuable to the patient with OAB in three ways. First, the simple mechanics of voluntary sphincter closure oppose the unstable bladder contraction and prevent or minimize urine leakage. Second, there are inhibitory local reflexes between the pelvic floor muscles and the bladder. At least in theory, increased muscle tone and strength should decrease overactivity. Finally, many patients can use repeated quick, active contractions ("quick flicks") to inhibit an involuntary contraction once it starts. Thus, improved muscle function can improve continence for the patient with OAB through both passive and active mechanisms. Although pelvic floor therapy is of unquestioned value, it has not been properly appreciated, perhaps owing to confusion about the inappropriate use of the various tools described previously and improper referrals for therapy. A simple assessment of pelvic floor muscle function at physical examination may be useful in triaging patients with UI.

Patients are classified into three groups based on the assessment of pelvic floor muscle strength at baseline examination: (1) those with no or minimal ability to isolate and contract the levator muscles, (2) those who can isolate the correct muscles with poor strength, and (3) those with good pelvic floor muscle strength and isolation on the initial examination. There is no universally accepted objective method of evaluating pelvic muscle strength by digital vaginal examination. It is principally important that the clinician be internally consistent in his or her assessment. The author has used a convention proposed by Laycock (Tries and Eisman, 1995). A 6-point scale is used for contraction strength: 0, absent; 1, flicker; 2, weak; 3, moderate; 4,

good; 5, strong. A second score is given to indicate the endurance time in seconds. Romanzi and associates (1999) examined a similar system. Patients can have a maximum score of 9; a score less than 4 correlated with self-reported UI in a small test group. Scores correlated well (*r* values ~ 0.8) for both intra-rater and inter-rater observations. There was also a reasonable correlation to surface EMG determinations (*r* values ~ 0.5).

Regardless of which system a clinician chooses to score pelvic muscle strength, it is proposed that patients be stratified into three clinically relevant groups by the physical examination as described earlier. It is possible to assign treatment to patients in the three clinical groups by applying these basic principles. **It seems illogical to prescribe home exercises in the first group (inappropriate or absent baseline function), and anecdotal experience suggests that significant improvement is uncommon. These patients need some form of teaching/biofeedback (or passive stimulation) just to get started. Office-based training should be considered to be superior to other forms of biofeedback until proved otherwise.** Many of these patients are older and will not accept home therapy. The author's strategy has been to offer weekly office sessions and convert the patient to a home unit once there is consistent objective and subjective response. Alternatively, passive treatment with peripheral electrical stimulation or magnetic stimulation can be investigated.

The second group of patients demonstrate weak contractions but appropriate isolation and should be good candidates for some form of pelvic muscle rehabilitation; biofeedback has not yet been conclusively proved to be better than PFMT alone in this general population. The lesson learned from biofeedback in SUI is that results are primarily dependent on the motivation of the patient and the skill and enthusiasm of the therapist. The author recommends exercise therapy for most of these patients. They are given written instructions and a follow-up office appointment with a nurse to review their progress. Home therapy with cones or simple EMG/pressure devices is a practical option that is generally well accepted by patients who have a basic knowledge and comfort about their bodies. Definitive clinical trials focusing on this patient population would be welcome.

In the final category (strong baseline pelvic contraction) the value of pelvic floor "rehabilitation" is unclear. If these patients have significant UI there is generally severe urethral incompetence and/or severe bladder dysfunction; and they require more aggressive treatment. The author's general practice is to instruct the patient in "quick flicks" to inhibit urgency and offer vaginal cones to motivated patients. With these patients the onus is on the clinician to demonstrate effectiveness of more complex and expensive treatment.

Treatment of Female Stress Urinary Incontinence

The two principal treatments of pure female SUI are pelvic floor rehabilitation and surgery. These options have been compared in three trials with similar results. Klaskov and coworkers (1986) randomized 50 consecutive women with SUI to immediate surgery versus five weekly visits with a physical therapist, without complex biofeedback. Ten of 24 (42%) patients treated initially with pelvic floor therapy were satisfied and declined surgery after the training program. Tapp and associates (1989) followed 81 consecutive patients with SUI who were randomized to three groups: PFE, PFE plus electrical stimulation, or immediate surgery. The group treated with pelvic floor therapy again had a 43% satisfaction rate (19/44), although only 4 (9%) were cured of UI. Finally, in a group of 39 women awaiting surgery for SUI, 30 completed 1 month of therapy using vaginal cones for home biofeedback. Seventy percent were considered cured or improved, 11 of 30 chose surgery, and thus 49% of the initial group avoided an operation (Peattie et al, 1988). **It thus seems proper to counsel women who might appropriately choose surgery that although surgery is the single most effective treatment for SUI there is a 40% to 50% chance that they can avoid an operation and be satisfied with the outcome by going through PFMT.**

In practice, it seems that one could do better than simply giving the same advice to all patients. **Certain patients might logically benefit from immediate surgery. These would include those who have significant associated prolapse (beyond the hymenal ring) that may be corrected at the same time, those who are highly motivated to be completely dry or who have high levels of physical stress due to lifestyle or occupation, those with relatively severe SUI, and especially those with good pelvic floor function on initial examination (group 3 mentioned earlier).** On the other hand, patients with poorer pelvic floor function might reasonably be expected to have better odds of improvement than those cited earlier; thus a trial of pelvic floor therapy should be strongly encouraged. Those with weak muscles and good isolation may benefit from home pelvic muscle exercises alone, but those with absent voluntary contractions or poor isolation probably absolutely require a therapist or are best treated by immediate use of one of the advanced techniques: biofeedback or pelvic floor stimulation. Even those patients who eventually go on to surgery may be pleased with progress and may have better surgical outcomes because they will be better able to manage postoperative irritative bladder symptoms.

Surgery and pelvic floor therapy are the leading treatments of SUI because they are potentially curative. However, some patients will prefer other options for a variety of reasons. **The devices mentioned previously are particularly attractive to the patient who really only needs "PRN therapy," that is, a patient whose leakage is infrequent but predictable and bothersome.** An example would be a patient who only leaks during twice-a-week exercise classes or sports. She may feel that surgery would be too much treatment for such a problem but is not really satisfied with protective pads. Similarly, a patient may really prefer surgery but for personal or financial reasons may need to delay definitive treatment. The devices can provide good palliation of symptoms during the interim. Devices are also, of course, indicated for the nonsurgical patient with severe comorbidities. It is simply uncommon that a patient is too ill to undergo one of the minimally invasive operations yet still is active enough to have significant SUI. When such a patient has significant hypermobility, a vaginal support device may be used. Patients without hypermobility can usually be treated with periurethral injection therapy.

Finally, the role of behavioral therapy in SUI should not be overlooked. Fantyl and associates (1991) demonstrated more than 50% improvement in leakage episodes and volume of urine lost with their program, getting essentially equal results in patients with both SUI and UUI. This is enough improvement to satisfy many patients.

Overactive Bladder and Detrusor-Related Incontinence

Successful treatment of the patient with OAB mandates a complete understanding of the pathophysiology. **Although anticholinergic medications are quite effective for most patients with OAB, medical therapy should not be a reflexive initial treatment and should rarely be used in isolation.** Abnormal bladder activity is often central to the problem, but it is inappropriate to focus only on the bladder. Dysfunctional behaviors and physical limitations strongly impact and can be the primary cause of OAB symptoms. The patient with OAB with UI almost always has poor pelvic floor muscle function (or the symptoms would be limited to urge frequency without UI). Thus, most patients can benefit from multimodality therapy (Fig. 69–12).

Once underlying causes for OAB have been ruled out in the initial history, physical examination, and testing as required, treatment planning should begin with a review of the voiding diary and the patient's behaviors. The diary reveals the maximum functional bladder capacity, which gives a strong indication as to the severity of the underlying bladder dysfunction. A low functional capacity (<150 to 200 mL) typically correlates with more severe bladder dysfunction, whereas a good functional capacity (>300 mL) indicates better potential bladder function. The clinician may find an unusually large fluid intake to be a factor aggravating the symptoms. **A timed voiding regimen is prescribed based on a time interval determined by the patient's baseline diary. Usually a patient is instructed to void at the longest consistently dry interval. When the patient becomes dry, the interval is increased by 15 to 30 minutes per week until a normal voiding pattern is established.** Some patients will benefit from use of a watch with a timing alarm for prompted voiding. Finally, the patient's response to urge should be reviewed. Inappropriate behaviors such as running to the bathroom must be replaced by proper urge inhibition techniques.

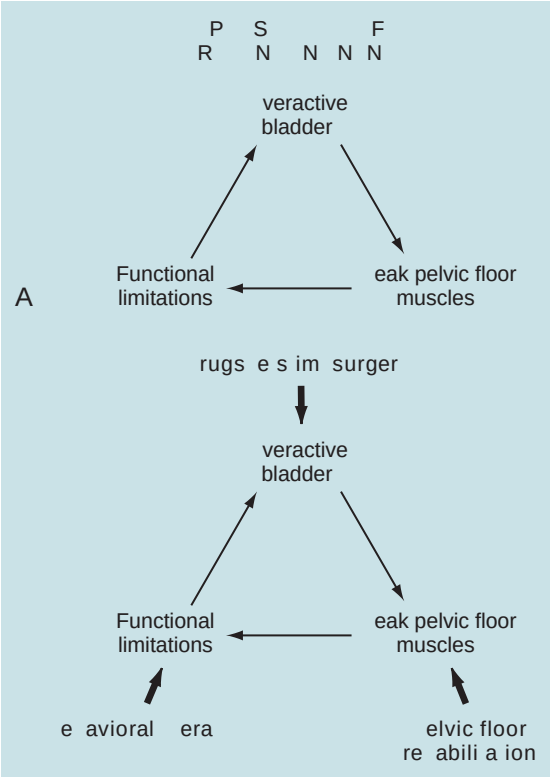

Figure 69–12. **A,** The clinical manifestation of urgency incontinence is caused not only by bladder overactivity but also by poor pelvic floor muscle function, functional limitations, and dysfunctional behaviors. **B,** Multimodality treatment is the most effective approach to managing urgency incontinence because each area can be addressed.

One of the key methods of urge inhibition is use of the pelvic muscle contraction and particularly "quick flicks" of short rapid contractions. The advantage of quick contractions is that the muscles are less likely to fatigue. If the patient can inhibit the urge for about 30 seconds it is likely to pass. Few incontinent patients can hold a maximal contraction that long; therefore, they leak when the muscles fatigue. Some therapists recommend teaching the patient to practice half-strength contractions for the same reason. In any case, pelvic floor therapy will be the appropriate second step for the vast majority of OAB patients who have suboptimal muscle function. The same classification system discussed in the context of SUI is also useful for triage of patients with OAB.

The key question in the treatment of OAB is when to introduce pharmacologic therapy. Unfortunately, most patients have been given drugs as first-line therapy without supplementing treatment with behavioral and pelvic floor therapy. This approach has the tandem problems of exposing many patients to expense and side effects unnecessarily. More importantly, drug therapy is rarely curative alone, whereas the other conservative measures can cure many patients, especially those who start with a reasonable bladder capacity and no underlying neurologic abnormality. Although the **newer medications have greatly improved patient acceptance of medical therapy, it still seems appropriate to use drugs selectively and with an eye toward ultimately rehabilitating the bladder and titrating the patient off of medicine.** Early use of medication is particularly indicated for patients with a low maximal voided volume on the diary, patients with underlying neurologic disease, and patients who seem uninterested or unable to participate in behavioral techniques. **Medications are relatively contraindicated in patients with a very large bladder capacity, medical reasons to avoid anticholinergics, the very old, and the very young.** Some clinicians prefer to start anticholinergic therapy on all patients (along with behavioral techniques) as in the original British bladder training protocols (Frewen, 1978; Holmes et al, 1983). This is reasonable because it improves the odds of the patient making an immediate improvement. However, whether drugs are used on all patients or selectively, consideration should be given to the ultimate goal of bladder retraining. Patients who become completely continent with good capacity on the voiding diary probably have approximately a 50% chance of being able to go off medication and stay dry in long-term follow-up (Holmes et al, 1983). Titration off medication should be suggested after 3 to 6 months when drug therapy is successful.

Refractory Overactive Bladder

In a small group of patients, OAB will prove to be refractory to the basic methods described previously. **These patients should have further evaluation with sophisticated urodynamic testing and cystoscopy to carefully define the nature of the lower urinary tract dysfunction and to rule out**

other causes for the symptoms. The patient who truly has refractory detrusor overactivity can be tried on combination medical therapy with a standard anticholinergic plus imipramine. When satisfactory continence is not achieved at the maximal tolerable medical therapy, the remaining options have been sacral neuromodulation or surgical reconstruction (e.g., augmentation, diversion).

Advances with botulinum neurotoxin type A (BoNT/A) injection therapy for detrusor overactivity challenge this algorithm. Although not yet FDA approved for use in the urinary system the drug is commonly used "off label." Treatments are performed cystoscopically, typically injecting 200 units divided into 20 sites around the bladder. The procedure can be performed on an outpatient basis under local anesthesia or sedation. BoNT/A injections have been proven effective for refractory neurogenic detrusor overactivity in one well-designed randomized controlled trial (Schurch et al, 2005). Fifty-nine patients with multiple sclerosis or spinal cord injury were randomized to receive injections with 200 units of BoNT/A, 300 units of BoNT/A, or a placebo. Dramatic improvements in bladder capacity and continence were seen in both active treatment arms compared with placebo. The gains were maintained for 24 weeks of follow-up. A small prospective randomized trial demonstrated similar results in idiopathic detrusor overactivity (Sahai et al, 2007). **More research is needed to define the optimal dose, mode of injection, the length of response, and most importantly the risk for urinary retention and catheterization for those patients who void normally before treatment.**

When comparing neuromodulation to BoNT/A injections, the most obvious difference is that the neuromodulation data are almost exclusively from the non-neurogenic population in contradistinction to the neurogenic patients treated with injections. The second key factor is that neuromodulation is FDA approved for UUI, urge-frequency syndrome, and idiopathic urinary retention. **BoNT/A injections are not currently FDA approved for any application in the urinary tract.** Nevertheless, some patients may prefer a trial of BoNT/A injections, and it would seem reasonable to offer this therapy to a well-informed patient. The advantages of BoNT/A include a lower initial cost, a somewhat simpler procedure, and elimination of the permanent implant (the implant precludes performing magnetic resonance imaging and can complicate travel). The disadvantages of BoNT/A include the need for repeated injections indefinitely over time. Long-term response to neuromodulation is somewhat better established than BoNT/A, but a great deal of research is needed in both areas and a head-to-head study would greatly advance this field.

The Problem of Mixed Incontinence

Mixed UI presents a special challenge to the clinician. These patients have typically been approached by offering a trial of anticholinergic medication first and then operating on those whose disorder does not adequately respond. There are certainly clues that can be used to define the primary component of the UI in at least some of the patients and develop more individualized treatment strategies.

The history can be helpful; the primary problem in mixed UI is often that component (the stress or the urge) that occurred first chronologically. The voiding diary can provide important clues. When OAB is the predominant problem the void volumes should be small both day and night. In contradistinction, if there are small daytime voids with little or no nocturia and a large first morning void the urgency symptoms tend to be a manifestation of SUI, perhaps stimulated as a few drops of urine leak into the proximal urethra with activity and trigger a sense of urgency. Pelvic organ prolapse can have a similar effect. When SUI is suspected to be the primary component, a short-term trial of one of the vaginal support devices may clarify the picture. If the symptoms are relieved by the device the patient may decide to continue using it or feel more confident that surgical intervention will be successful. **A pessary trial is doubly important before correcting pelvic organ prolapse (with or without UI). Elevation of a cystocele will unmask occult sphincteric incompetence in approximately 50% of patients who are continent with the prolapse.** If an ambulatory trial of a pessary is not performed, then a pessary or vaginal packing may be used during preoperative urodynamic testing as discussed in the pessary section previously. The urethral stent/plug devices are relatively contraindicated in

Key Points: Practical Approach to Treatment

- The patient's personal goals should always be a prime concern. Patient satisfaction was moderately correlated to goal achievement but was not related to objective cure of SUI or prolapse in prospective studies.
- Three primary pieces of information are required to develop a treatment plan for a patient with UI: the type of UI, the baseline voiding diary, and an assessment of anatomy with particular emphasis on pelvic floor muscle strength and function. In most cases, a clinical diagnosis of stress, urge, or mixed UI is easily made but detailed evaluations are sometimes necessary before beginning treatment.
- The largest voided volume on a diary correlates with the cystometric capacity defined by urodynamic testing.
- Patients are classified into three groups based on the assessment of pelvic floor muscle strength at baseline examination: (1) those with no or minimal ability to isolate and contract the levator muscles, (2) those who can isolate the correct muscles with poor strength, and (3) those with good pelvic floor muscle strength and isolation on the initial examination.
- Those with no voluntary pelvic muscle contraction should be offered biofeedback training and/or passive stimulation.
- Those with strong, coordinated muscle contractions will probably require medical or surgical therapy.
- Although surgery is the single most effective treatment for SUI there is a 40% to 50% chance that women can avoid an operation and be satisfied with the outcome by going through PFMT.
- Early surgical intervention is more appropriate for patients with significant associated prolapse (beyond the hymenal ring) that may be corrected at the same time, those who are highly motivated to be completely dry or who have high levels of physical stress due to lifestyle or occupation, those with relatively severe SUI, and especially those with good pelvic floor function on initial examination.
- Most OAB patients can benefit from multimodality therapy including bladder training, PFMT, and medical therapy.
- When OAB symptoms are cured, a trial of titration off medication is warranted.
- After appropriate evaluation, sacral neuromodulation, botulinum toxin injections, and surgical reconstruction/diversion are options for refractory OAB.

this patient population because clinical experience suggests that they typically aggravate the underlying urge and become totally ineffective.

The patient with mixed UI can usually benefit from each form of conservative treatment: behavioral, pelvic floor, and medical therapies. When medications are prescribed, it is particularly important to obtain voiding records before and during treatment. A patient who is not satisfied with treatment may be shown to have the same number of leaks but a significant improvement in bladder capacity. This would again argue for success with surgical therapy for residual SUI symptoms. Pelvic floor rehabilitation is probably the most important treatment in this patient group, and there may be a special role for electrical stimulation because, at least theoretically, stimulation may specifically improve both urethral and bladder function. The patient uses low- and high-frequency stimulation on alternate days. Any of the other therapies can be combined with stimulation.

CONCLUSION

Urinary incontinence is a pervasive and increasing problem throughout all segments of our society that produces a severe impact on our health care system and patients' quality of life. The incontinence specialist of the 21st century must be familiar with all types of therapies: conservative/behavioral treatments, medical therapy, and surgical options. There is a great need for quality research that compares various treatment options to determine the initial effectiveness and durability, the adverse effects, and the advantages for specific groups of patients. In the meantime, the therapist must be able to match treatment to the problems and goals of individual patients. Nonsurgical treatments are unquestionably effective and are preferred by many patients. Mastering of all types of therapies will keep the urologist the recognized expert in incontinence. Ignoring nonsurgical therapies will pass the mantle, and the surgery, to other providers.

Electrical Stimulation and Neuromodulation in Storage and Emptying Failure

Sandip P. Vasavada, MD ● Raymond Robert Rackley, MD

History of Electrical Stimulation
Neurophysiology of Electrical Stimulation for Storage and Emptying Disorders
Electrical Stimulation for Storage Disorders
Electrical Stimulation for Emptying Disorders
Future Research and Conclusions

For the past century, the development of electrical neurostimulation and neuromodulation to alter physiologic processes responsible for lower urinary tract symptoms and dysfunctions has largely been the result of important landmark discoveries in the clinical application of electricity and in the understanding of neuromuscular physiology. **In neurostimulation the use of electrical stimuli on nerves and muscles has mainly been developed to achieve immediate clinical responses in neurogenic conditions of pelvic organ dysfunction; in neuromodulation the application of electrical stimuli to nerves has been developed to alter neurotransmission processes in non-neurogenic and neurogenic conditions.** In this chapter the focus is on reviewing the application (Table 70–1) and clinical outcomes of neurostimulation and neuromodulation therapies for pelvic organ dysfunction with respect to the development of our knowledge of pelvic neuromuscular physiology and its role in translational innovations.

HISTORY OF ELECTRICAL STIMULATION

Although the field of electrical stimulation of nerves to achieve muscle contractions was not truly realized until the early 1800s, its roots can be traced into the 1700s, when inadvertent electrical impulses were found to generate strong muscle convulsions (Galvani, 1786; Bell, 1811). Magendie (1822) **was one of the first to conduct physiologic investigations of the spinal nerve roots, documenting in young dogs that transection of the posterior (dorsal) segments resulted in a lack of sensation but persistence of motor function, whereas anterior (ventral) root transection yielded preservation of sensation yet abolishment of motor function.** These important findings created the foundation for our understanding of basic neurophysiology of micturition and led to further discoveries on bladder function in the setting of selective rhizotomy of both the pelvic and hypogastric nerves (Giannuzzi, 1863; Langley, 1895). Ultimately, Saxtorph in 1878 used these principles to directly stimulate the bladder in patients with urinary retention via a metal transurethral catheter (Madersbacher, 1999). His early findings allowed others to develop enthusiasm for direct stimulation of the bladder through both transurethral and direct detrusor routes (see section on direct stimulation).

Because Saxtorph had significant influence on the idea that direct bladder stimulation may lead to bladder contractility, McGuire used some of these same principles to perform direct bladder stimulation in dogs (Boyce et al, 1964). He concluded that multiple pairs of electrodes were required to achieve a more uniform pressure rise within the bladder during the stimulated contraction. Research continued throughout the late 1900s and moved toward development of new electrodes (Susset and Boctor, 1967) and differing wire configurations (Timm and Bradley, 1969; Tscholl et al, 1971).

Direct pelvic nerve stimulation and pelvic floor muscle stimulation were not well-known or well-studied concepts until the mid 1900s because emphasis was clearly on different areas of direct stimulation (i.e., bladder). Dees (1965) studied the bladder contraction state after stimulation to the pelvic nerve. He achieved contraction of both the detrusor muscle and urethral sphincter in a cat model and produced pain and hind leg contraction as well. Others demonstrated similar findings of nonspecific contraction of the bladder and pelvic floor and other areas with direct pelvic nerve stimulation and ultimately realized that direct pelvic nerve stimulation may not be suitable for treatment of bladder dysfunction (Burghele et al, 1962; Hald et al, 1966; Holmquist and Olin, 1968). It appears that direct pelvic nerve stimulation elicits pudendal nerve activity such that outlet resistance is increased, as is pain, through simultaneous hypogastric nerve stimulation. Thus, with the limited-potential clinical utility of the pelvic nerve for stimulation, efforts focused on the pelvic floor muscles, spinal cord, and sacral roots. Caldwell first reported experience with pelvic floor muscle stimulation with the goal of improving fecal continence and later urinary incontinence (Caldwell, 1963;

Table 70–1.

Potential Applications of Electrical Stimulation in the Treatment of Voiding Dysfunction

PURPOSE	SITES OF STIMULATION	MECHANISM
Facilitate Filling-Storage		
Inhibit detrusor contractility	V, A, SP, PT	Neuromodulation
Increase bladder capacity	CP, SR, IV	
Decrease urgency and frequency		
Decrease nociception	V, A, SP, SR	Neuromodulation
Increase outlet resistance	V, A, SR	Direct stimulation (efferent nerves or roots)
Facilitate Emptying		
Stimulate detrusor contraction (spinal cord–injured patient)	SAR	Direct stimulation (efferent nerves or roots)
Restore micturition reflex (idiopathic retention)	SR, IV	Neuromodulation

A, anal; CP, common peroneal; IV, intravesical; PT, posterior tibial; SAR, sacral anterior (ventral) roots; SP, suprapubic; SR, sacral roots; V, vaginal.

Table 70–2.

Sacral Nerve Responses

SACRAL NERVE	MOTOR AND SENSORY RESPONSE
S2	*Motor:* Plantarflexion of the entire foot with lateral rotation and clamp movement of the anal sphincter *Sensory:* Sensations in the leg and buttock
S3	*Motor:* Dorsiflexion of the great toe and bellows reflex (anal wink) *Sensory:* Paresthesias or sensation of pulling in the rectum, scrotum, or vagina
S4	*Motor:* Bellows reflex only *Sensory:* Sensation of pulling in the rectum only

Caldwell et al, 1965). Subsequently, interest increased and efforts toward external stimulation were described by anal, vaginal pessary, and direct vaginal stimulation (Hopkinson and Lightwood, 1967; Alexander and Rowan, 1968; Erlandson et al, 1977; Fall et al, 1977).

Spinal cord stimulation, by attempting to directly activate the micturition center, was thought to be a promising avenue of therapy (Nashold et al, 1971; Jonas et al, 1975; Jonas and Tanagho, 1975). **Still, as in pelvic nerve stimulation, voiding was initiated; however, simultaneous sphincter activity precluded proper emptying.** The subsequent series of developments pursued therapy for incomplete emptying by affecting not only bladder stimulation but, in some way, sphincter relaxation as well.

In 1972, Brindley began experimentation of sacral root stimulation that led to implantation of sacral anterior root stimulators in paraplegic patients with urinary incontinence (Brindley, 1972, 1974, 1977). **Evolving data showed that, for optimal bladder emptying to be achieved, sacral anterior root stimulation with posterior rhizotomies of S2, S3, and S4 would be required** (Sauerwein, 1990). **The posterior rhizotomy would decrease the reflex activity of the detrusor and improve bladder compliance.** Tanagho and coworkers then began further examining the sacral roots and their individual contributions to bladder and outlet function. In 1982, Tanagho and Schmidt presented initial experience in sacral root stimulation in paraplegic dogs. In this initial study they realized the design of a spiral electrode to minimize nerve damage and fixed the lead wire to the sacral lamina, thereby preventing tension on the electrode itself. They ultimately attained good bladder contraction in these dogs, with minimal sphincteric response. From these initial good results, Tanagho and coworkers then began human trials and characterized the sacral root stimulation patterns and the corresponding muscle responses (Table 70–2). **In the course of the neurostimulation developments these researchers realized that sphincteric contraction abolished detrusor activity, and the role of the pudendal nerve and its modulation of bladder capacity began to evolve** (Tanagho and Schmidt, 1988; Schmidt, 1989). Thus, neuromodulation was introduced as a concept by which activation of the sacral roots may, in fact, modulate external sphincter function and in turn inhibit detrusor activity as a normal reflex. These early discoveries created the platform for the current and future concepts and technologies that are used for neurostimulation and neuromodulation.

NEUROPHYSIOLOGY OF ELECTRICAL STIMULATION FOR STORAGE AND EMPTYING DISORDERS

The exact mechanisms of how neuromodulation works are not completely understood, but several plausible theories with testable hypotheses are under investigation. Most are founded on the basic neurophysiologic mechanisms that result in the normal storage and emptying functions of the bladder. Although there is an expanding amount of information on our knowledge of micturition neurophysiology as discussed in this chapter, in this section the specifics of the micturition pathway in relation to neuromodulation are addressed.

Normal detrusor function appears to be a sacral balance under suprasacral influences of the sympathetic and parasympathetic nervous systems in their respective abilities to maintain continence. The sympathetic tone, for the most part, is dominant for the majority of time and thus provides continence or storage of urine; the parasympathetic nervous system allows detrusor contractions for emptying of the bladder. Thus, the micturition reflex pathway is activated by initial bladder afferent excitation that then results in a bladder efferent excitation leading to a detrusor muscle contraction. The acquired and unique ability to void volitionally is due to either negative feedback (inhibition of voiding) or positive feedforward (induction of voiding) influences of supraspinal inputs from the pontine micturition center on this sacral micturition reflex pathway. Any loss of either central supraspinal inhibitory influences or increased sensitization of bladder afferent signaling can lead to unmasking of involuntary voiding. As such, this has been proven only in animals and, by deference, relates then to humans. There may be primitive reflexes that reside within the spinal cord that can be "awakened" by somatic and afferent nerve stimulation and may have something to do with the mechanism of action of neuromodulation (de Groat, 1975, 1976; de Groat and Ryall, 1968a, 1968b).

Bladder afferent nerve signaling sends information about pain and bladder fullness to the brain that will in turn initiate the micturition reflex. Bladder overactivity may be in part mediated by the loss of voluntary control of the voiding reflex and, furthermore, emergence of primitive voiding reflexes. In certain states of neurologic or inflammatory disease of the bladder, the previously silent C fibers may emerge and trigger the micturition reflex. Accordingly, blockade of this pathway by electrical neuromodulation, similar to pharmacologic blockade by capsaicin (a C-fiber blocker), may suppress detrusor overactivity (Maggi and Meli, 1988; Chen et al, 1993).

Reflexes That Promote Bladder Storage

Two important reflexes may play an important role in modulation of bladder function: the guarding reflex and the bladder afferent loop reflex. Both reflexes promote urine storage (guarding reflex under somatic influence and bladder loop reflex under sympathetic tone). The guarding reflex guards or prevents urine loss from times of cough or other physical stress that would normally trigger a micturition episode. Suprapontine input from the brain turns off the guarding reflex during micturition to allow efficient and complete emptying. The bladder afferent reflex works through sacral interneurons that then activate storage through pudendal nerve efferent pathways directed toward the urethral sphincter. As such, the activity has truly been realized only in cats but has been postulated to exist in humans and to function the same. Similar to the guarding reflex, **the bladder afferent reflex promotes continence during periods of bladder filling and is quiet during micturition** (Fig. 70–1).

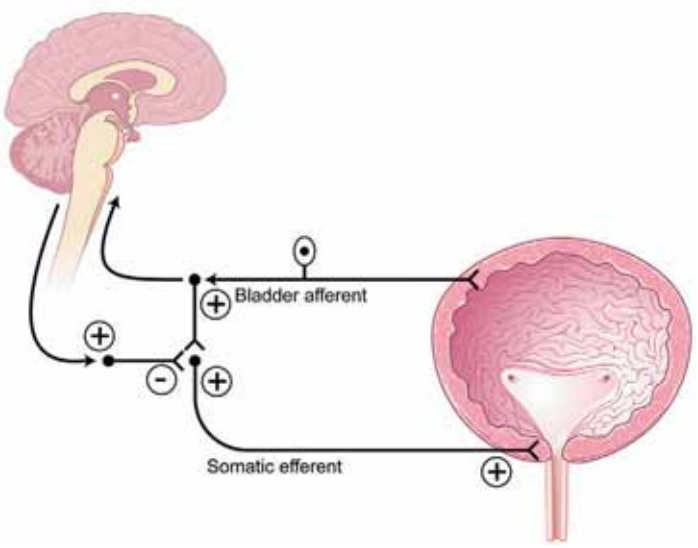

Figure 70–1. The guarding reflex promotes continence and allows the outlet to contract the urinary sphincter during periods of stress (e.g., cough). The brain can turn this reflex off during voiding. (Modified from Leng WW, Chancellor MB. How sacral nerve stimulation neuromodulation works. Urol Clin North Am 2005;32:11–8.)

Reflexes That Promote Bladder Emptying

Signals from the bladder that may modulate the need to void with fullness, pain, pressure, or stretch may elicit bladder afferent activity through the Aδ or even C fibers. These bladder afferent nerve fibers then synapse with both parasympathetic efferents (bladder-bladder reflex) and parasympathetic urethral efferents (bladder-urethral) reflex. The urge to void may then be translated as an initial activity (inhibitory) of the bladder-urethral reflex to allow the pressure in the urethral outlet to drop immediately before a bladder contraction ensues and simultaneously permit the bladder-bladder reflex to allow a smooth bladder contraction to occur as the reflex is maintained throughout the entire void (de Groat, 1978; de Groat et al, 1981, 1996).

Putative Mechanism of Action of Sacral Neuromodulation

Although our knowledge of how neuromodulation works is evolving, two main theories exist: (1) direct activation of efferent fibers to the striated urethral sphincter reflexively causes detrusor relaxation and (2) selective activation of afferent fibers causes inhibition at spinal and supraspinal levels. **Accumulating evidence suggests that activation of somatic sacral afferent inflow at the sacral root level that in turn affects the storage and emptying reflexes in the bladder and central nervous system accounts for the positive effects of neuromodulation on both storage and emptying functions of the bladder** (Yoshimura and de Groat, 1992, 1997; Leng and Chancellor, 2005). Malaguti and coworkers (2003), using detection of somatosensory evoked potentials during sacral neuromodulation, concluded that sacral neuromodulation therapy works by sacral afferent activity and concomitant activation of the somatosensory cortex. Because sacral neuromodulation has been clinically proven for both storage (urgency/frequency and urgency urinary incontinence) and emptying (nonobstructive urinary retention) dysfunctions of the bladder, isolating the mechanism of action to the micturition reflex pathway of sacral afferent and efferent pathways alone is challenging. However, by understanding the reflexes that influence the promotion of urine storage or emptying of the sacral micturition reflex pathway one begins to realize how neuromodulation may affect these reflexes and elicit symptomatic and functional improvement of voiding function (Fowler et al, 2000). Animal models of sacral neuromodulation for detrusor overactivity are now being developed and may shed more light on how this technology achieves its benefits (Riazimand and Mense, 2004; Vignes et al, 2009)

Putative Mechanism of Action of Sacral Neuromodulation in Overactive Bladder

The bladder storage and emptying reflexes are modulated by several centers in the brain and may be altered by neurologic injury that effectively unmasks involuntary bladder contractions. Thus, sacral neuromodulation of these primitive reflexes may restore normal micturition (de Groat, 1976). Animal data exist to support the fact that somatic afferent input to the spinal cord can affect the guarding and bladder-bladder reflexes (de Groat, 1978; Chen et al, 1993). It is believed that suppression of interneuronal transmission in the bladder reflex pathway may be how sacral neuromodulation affects detrusor overactivity (de Groat, 1976;

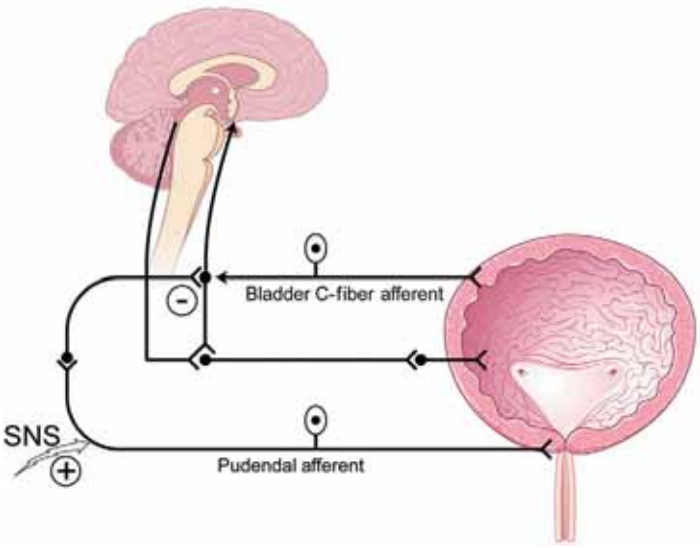

Figure 70–2. Pudendal nerve afferent firing can modulate and accordingly inhibit the bladder micturition reflex. SNS, sacral nerve stimulation. (Modified from Leng WW, Chancellor MB. How sacral nerve stimulation neuromodulation works. Urol Clin North Am 2005;32:11–8.)

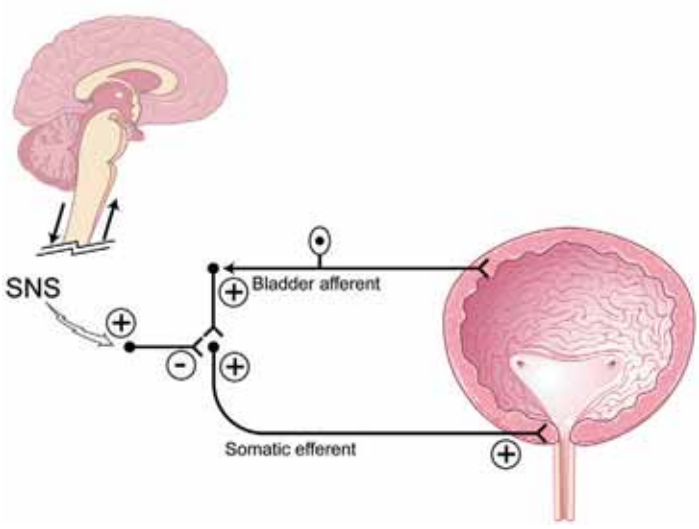

Figure 70–3. In neurologic disease the supraspinal circuitry is "disconnected" and therefore cannot turn off the spinal guarding reflex, and thus retention occurs. Sacral neuromodulation (SNS) can restore the normal voluntary pattern of micturition by inhibition of the spinal guarding reflex. (Modified from Leng WW, Chancellor MB. How sacral nerve stimulation neuromodulation works. Urol Clin North Am 2005;32:11–8.)

Kruse and de Groat, 1993; Leng and Chancellor, 2005). **The inhibition by electrical neuromodulation may, in part, modulate the sensory outflow from the bladder through the ascending pathways to the pontine micturition center, thereby preventing involuntary contractions by modulating the micturition reflex circuit but allowing voluntary voiding to occur** (Fig. 70–2). The preservation of voluntary voiding may be due to selective avoidance of normal sensory ascending outflow pathways of the bladder from Aδ fibers to the pontine micturition center as well as initiation of the descending pathways from the pontine micturition center to sacral efferent outflow pathways. Therefore, as is seen in clinical practice, sacral neuromodulation may affect and improve the abnormal bladder sensations, involuntary voids, and detrusor contractions but still maintain normal bladder sensations and voluntary voiding patterns.

Putative Mechanism of Action of Sacral Neuromodulation in Urinary Retention

Sphincteric activity can be turned off by brain pathways to allow efficient and complete bladder emptying. **If the suprasacral pathways are altered, the guarding and urethral reflexes still exist and cannot be turned off. This may cause retention, as in the spinal cord–injured patient who in turn has detrusor-sphincter dyssynergia resulting in urinary retention. Thus, inhibition of the guarding reflexes may allow urinary retention states to be improved** (Fig. 70–3). Originally for urinary retention due to functional outlet obstruction, sacral neuromodulation was thought to directly turn off excitatory flow to the urethral outlet and facilitate bladder emptying. This may be an efferent effect of the primary afferent mechanism of sacral neuromodulation as reported by Dasgupta and colleagues (2005), who described novel neuroimaging evidence for the existence of abnormal interaction between the brainstem and cortical centers in women with urinary retention due to Fowler syndrome or overactive sphincteric activity. The direct therapeutic effect of sacral neuromodulation in patients with sphincter overactivity or functional outlet obstruction appears to be in the afferent restoration of a normal pattern of midbrain activity and decreased cortical activity leading to inhibition of the guarding reflexes.

ELECTRICAL STIMULATION FOR STORAGE DISORDERS

Criteria for Selection of Patients

Because many lower urinary tract symptoms and dysfunctions are secondary to a neuromuscular etiology, a thorough history and physical examination will often reveal the nature (acute vs. chronic) and help classify the cause (neurogenic, anatomic, postsurgical, functional, inflammatory, or idiopathic). In addition to the unique evaluation of pelvic floor muscle dysfunction (Siegel, 2005), a urinalysis is routinely performed; urine cytology should be considered in patients who present with refractory symptoms of dysuria, urgency, or frequency of urination, because carcinoma in situ and bladder tumors may present as irritative bladder symptoms without hematuria. Further assessment of the bladder function, urodynamic studies including cystometrography, pressure-flow studies, and electromyography of sphincters and pelvic floor muscles are performed on a selected basis, because most non-neurogenic assessments are completed routinely with the use of a voiding diary and a focused physical examination of the pelvis. Electromyography is recommended in suspected cases of neurogenic bladder dysfunction, detrusor-sphincter dyssynergia, or Fowler syndrome and may be considered for evaluation of inappropriate pelvic floor muscle behavior (Dasgupta and Fowler, 2003). As of now, urodynamics have not yielded adequate predictive factors that allow enhanced

selection for patients undergoing sacral neuromodulation (Groenendijk et al, 2007). **The characteristics of neurogenic bladders, as seen in patients with multiple sclerosis and spinal cord injury, can change with time and disease progression. Therefore, reevaluation with urodynamics and assessment of the upper urinary tracts may be needed when symptoms change despite active medical intervention.**

Cystourethroscopy may yield information helpful in making a diagnosis. Anatomic lesions such as urethral stricture, bladder neck fibrosis, trabeculation, and bladder lesions have been found even in women with bladder outlet obstruction. Baseline upper tract imaging is performed in patients with neurologic disease or, if indicated, by physical or baseline studies or a patient's history.

Sacral neuromodulation is frequently attempted in patients in whom traditional conservative measures (e.g., bladder retraining, pelvic floor biofeedback, and medications) have failed and before more invasive surgical procedures (e.g., enterocystoplasty and urinary diversion). **Despite all the studies done to date there are no defined preclinical factors, such as urodynamic findings, that can predict which patients will or will not respond to sacral neuromodulation.**

Although most patients are considered candidates for neurostimulation and neuromodulation therapies when more conservative treatment has failed **there are some clinical considerations for excluding patients from this therapy. These include significant anatomic abnormalities in the spine or sacrum that may present challenges to gaining access; mental incapacitation of patients who cannot manage their device or judge the clinical outcome; physical limitations that prevent the patient from achieving normal pelvic organ function, such as functional urinary incontinence; and noncompliance of the patient.**

Relative contraindications for patients who may be considering or who have an implantable electrical stimulation device are magnetic resonance imaging (MRI) and pregnancy. Magnetic fields produce currents in neuroelectrodes, and there is some concern that the magnetic field from MRI may damage the pulse generator, as discussed later. Many radiologists are reluctant to provide MRI services for patients with implantable electrical stimulation devices despite the anecdotal evidence that no adverse event has occurred when MRI has inadvertently or purposefully been done for emergent reasons or in small trials (Hassouna and Elkelini, 2005). For patients who have InterStim devices in place (see later), the authors advocate removal of the device in preparation for elective MRI based on current manufacturer recommendations. After the MRI procedure, a new neuroelectrode and generator may be placed. Anecdotal reports of patients safely undergoing the study (MRI) with the InterStim implant in place have occurred, but patients should have the devices turned off in anticipation. Because of the potential for teratogenicity or abortion from the effect of electrical stimulation, electrical stimulation has been considered contraindicated in pregnant women with various voiding dysfunctions. However, whether electrical stimulation can cause abortion or malformation is not known. Wang and Hassouna (1999) reported no adverse effects of electrical stimulation on pregnant rats and that termination of pregnancy is not advised for prospective mothers when electrical stimulation has been performed unknowingly in early pregnancy. Women with electrical stimulation devices for pelvic health conditions who become pregnant may simply turn off their devices during pregnancy.

Electrical Stimulation of the Bladder

Transurethral electrical bladder stimulation (TEBS) has been pursued not only for initiating sensory awareness of bladder filling and stimulating detrusor contractility (see later section) **but also for increasing bladder capacity at low pressure in pediatric patients with myelomeningocele** (Kaplan et al, 1989; Decter et al, 1994). The authors in these two cited references carried on an interesting point-counterpoint discussion in publications regarding the practical benefit of TEBS (Kaplan, 2000; Decter, 2000), which remains controversial.

Both authors seem to be saying the same thing with respect to results but attach a totally different significance to the practical implications of the results. Kaplan (2000) points out that when the procedure was initiated the goal was to provide children with neurogenic bladder dysfunction, mostly secondary to spina bifida, enough sensation to detect a filling or full bladder and to have them synergistically void or catheterize in a timely manner. As the results of treatment have been evaluated over the years, the real benefit of this program, to Kaplan at least, was the potential to increase bladder capacity while maintaining or decreasing end-filling bladder pressure (in essence, improving compliance). Decter (2000) gives what seems to be a reasonable summation of the largest multi-institutional report of this therapy involving 568 patients who underwent TEBS at 11 institutions, only 335 of whom had adequate pretreatment and post-treatment urodynamics for evaluation. Bladder capacity increased by 20% or more in 56% of the 335 patients, whereas pressure at bladder capacity decreased by 25% or more in 16% of those in whom the bladder capacity increased. Decter (2000) calculated that only 30 of 335 patients had both a 20% or more increase in bladder capacity and a 25% decrease in compliance. He reports his experience with 25 patients during a 4-year period as showing that bladder capacity increased more than 20% (values referred to a comparison to age-adjusted bladder capacity) and end-filling bladder pressures showed clinically significant decreases in 29% of patients. Putting this in perspective, he believes "the practical benefits our patients derive seem limited…the urodynamic improvements we achieved after stimulation did not materially alter daily voiding routine (i.e., clean intermittent catheterization) of these children." Pugach and associates (2000) also reported the results of TEBS in a group of pediatric patients; only 7 of 44 (16%) had safe storage pressures with continence after treatment. There exist limited new data since 2000 on this treatment modality probably owing to other better potential nerve targets.

Sacral Rhizotomy

In most cases, **bilateral anterior and posterior sacral rhizotomy or conusectomy converts a overactive detrusor to an areflexic one.** This alone may be inappropriate therapy because it also adversely affects the rectum, anal and urethral sphincters, sexual function, and the lower extremities. In an attempt to leave sphincter and sexual function intact, **selective motor nerve section was originally introduced as a treatment to increase bladder capacity by abolishing only the motor supply responsible for involuntary contractions.** The initial use of this procedure followed the observation that the third anterior (ventral) sacral root provided the dominant motor innervation of the human bladder. **To enhance the clinical response and to minimize side effects, differential sacral rhizotomy should always be preceded by stimulation**

and blockade of the individual sacral roots with cystometric and sphincterometric control.

Although technique refinements, such as percutaneous radiofrequency selective sacral rhizotomy and cryoneurolysis, have occurred, **there is still controversy about the role of anterior rhizotomy procedures within a treatment plan for detrusor overactivity.** Torrens (1985) summarized successful results in collected groups of patients that ranged from 48% for idiopathic overactivity to 81% for patients classified as having a "paraplegic bladder." However, as he astutely pointed out, the definition of success varies from one series and from one patient to another. When these procedures are used, they should certainly be preceded by urodynamics and urologic evaluation of the effects of selective nerve blocks before performance, especially in patients without fixed neurologic disease or injury. Even then, **unintended effects on pelvic and lower extremity sensory or motor functions may occur with disastrous medical and legal sequelae.**

Both Tanagho and Schmidt (Tanagho and Schmidt, 1988; Tanagho et al, 1989) **and Brindley** (Brindley and Rushton, 1990) **have popularized the concept of sensory deafferentation by dorsal or posterior rhizotomy to increase bladder capacity as part of their overall plan to simultaneously rehabilitate storage and emptying problems in patients with significant spinal cord injury or disease. These are patients in whom electrical stimulation also was used to alleviate emptying deficits** (see section on emptying disorders). McGuire and Savastano (1984) **also mentioned dorsal root ganglionectomy alone in such patients to increase bladder capacity.**

Gasparini and colleagues (1992) reported durability of the deafferentation response to selective dorsal sacral rhizotomy up to 64 months after section. The technique involves selecting nerve roots whose intraoperative stimulation provokes an adequate detrusor response. The dorsal and ventral components of these roots are then separated and the dorsal root or roots severed. An increase in bladder capacity of 259 to 377 mL was noted in 16 of 17 patients studied (24 in the original series), with an increase in the volume to the first contraction of 99 to 270 mL. Fourteen patients were cured of incontinence, and 2 improved; the technique failed in 1 patient. Of seven potent men, two experienced a decrease in erectile frequency but were still able to achieve penetration. Bowel and sphincter function were unaffected. Koldewijn and associates (1994) reported on the effects of intradural bilateral posterior root rhizotomies from S2 to S5 with implantation of an anterior root stimulator in a group of patients with suprasacral spinal cord injury. All showed persistent detrusor areflexia afterward, although 2 required subsequent secondary rhizotomy at the level of the conus. A majority showed decreased bladder compliance up to 5 days postoperatively, followed by a rapid increase thereafter.

Brindley (1994) **summarized the advantages of bilateral posterior sacral rhizotomy in treatment of voiding dysfunction after spinal cord injury as abolishing reflex incontinence, improving compliance, and abolishing striated sphincter dyssynergia without altering resting tone. Partial or selective procedures are considered only in such patients who retain some sensation or have excellent reflex erections.** Madersbacher (2000) comments that posterior sacral rhizotomy for sacral deafferentation of the bladder is best achieved by the intradural approach, which has the advantage that, in this location, motor and sensory fibers can easily be separated, whereas distal to the spinal ganglion, motor and sensory fibers are intermingled and a clear separation is no longer possible. If an intradural procedure is not possible, he believes that a deafferentation at the level of the conus medullaris is preferable to an extradural sacral approach. He mentions that he has treated 65 tetraplegic or paraplegic patients with post–spinal cord injury reflex urinary incontinence who were resistant to all other means of conservative treatment. Incontinence was abolished in 90% of these patients.

Sacral Neuromodulation

Neuromodulation is an innovative treatment of lower urinary tract symptoms and dysfunctions of bladder storage secondary to neuromuscular causes. In addition to the application of evolving technologies for sacral neuromodulation therapy, expanding clinical indications such as neurogenic detrusor overactivity, post–sling-related voiding dysfunction, interstitial cystitis, pelvic pain, pediatric voiding dysfunction, and bowel disorders as well as novel forms of transcutaneous and implantable neuromodulation devices for different nerve roots are under investigation.

Technique

Sacral nerve stimulation (SNS) by the InterStim (Medtronic, Minneapolis, MN) procedure is performed in two stages: stage I, a clinical trial of a temporary or permanent lead for external stimulation; and stage II, implantation of a subcutaneous implantable pulse generator (IPG). Each stage can be performed with monitored anesthesia care supplemented by local anesthesia. During the initial introduction of sacral neuromodulation therapy, patients underwent a percutaneous nerve evaluation by the placement of a unilateral percutaneous lead in the S3 foramen with use of local injectable anesthesia. The lead was connected to an external pulse generator and worn by the patient for several days. A large number of false-negative results with therapy are attributed to improper lead placement and migration. Whereas some physicians still prefer to perform the first stage by a percutaneous nerve evaluation approach, most have adopted a permanent tined lead placement for the first stage in an attempt to avoid the issues related to high false-negative results with the first stage and high false-positive results with the second stage. Changes in lower urinary tract symptoms and postvoid residuals are recorded in a detailed bladder diary. If improvement is minimal or absent, revision or bilateral percutaneous lead placement may be attempted. If more than 50% improvement in symptoms of urgency/frequency or urgency urinary incontinence is attained, a permanent IPG is implanted. The length of the trial with the external pulse generator may vary slightly from patient to patient, by the indication, and by the surgeon's practice preference. In patients with urgency/frequency and urgency urinary incontinence, a 1- to 2-week trial is generally adequate. For retention, a longer trial of 3 to 4 weeks or more may be necessary before a desired clinical response is obtained.

Previous lead placement required a more time-consuming surgical dissection of the layers above the sacral foramen and unreliable lead fixation with anchors. Recent technical advances have made implantation of the percutaneous lead easier and less prone to migration. Spinelli and colleagues (2003) were the first to present the advantages of the tined lead that used a percutaneous approach for placement and fixation (Fig. 70–4). Subsequent large-scale clinical experience worldwide confirms that the tined lead is less prone to migration and has decreased false-negative results with the screening trial. Furthermore, the false-positive rate of the screening trial is reduced when placement of a permanent lead

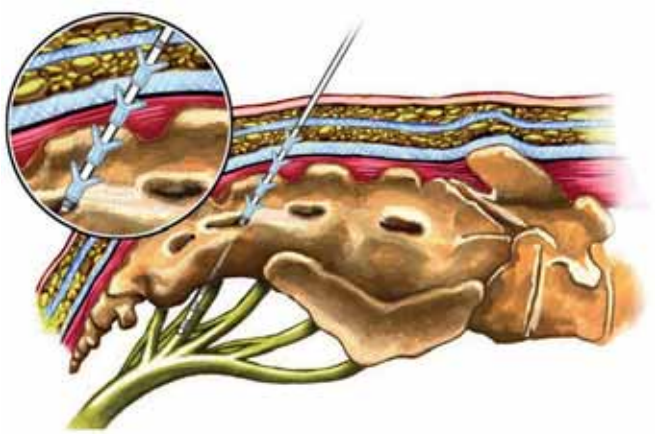

Figure 70–4. The tined lead is introduced typically into the S3 nerve foramen. The "tines" allow the lead to be fixed into the fascial layers above the sacrum. This lead has a quadripolar configuration (four contact points). (Courtesy of Medtronic, Minneapolis, MN.)

with reliable fixation during the screening trial ensures that the same location of stimulation is achieved when the IPG is implanted. With a percutaneous nerve evaluation or similar temporary lead electrode during the screening trial, a different clinical outcome may occur when the permanent lead is placed at the time of the IPG implantation.

For the first stage of the procedure, preoperative intravenous antibiotics are given before the procedure and aseptic techniques of foreign body implants are implemented. The patient is placed in the prone position, and the buttocks are held apart by wide tape retraction so that the anus is visible during test stimulation. The anus and tape are prepared in a sterile fashion and then covered with a separate plastic drape until visualization is needed during the procedure. The sterile drape covering the feet must be folded back such that the feet can be visualized during the procedure as well.

The location of the S3 foramen is approximated by measuring 9 cm cephalad to the dropoff of the sacrum and 1 to 2 cm lateral to the midline on either side. Alternatively, the site may also be localized by palpating the cephalad portions of the sciatic notches bilaterally and drawing a connecting line that intersects the midline of the sacrum; one fingerbreadth on either side of the midline of the sacrum at this intersection will define the location of the S3 foramen (Fig. 70–5). The foramen needle is then inserted into the S3 foramen. The pelvic plexus and pudendal nerve run alongside the pelvis, and therefore the needle should be placed just inside the ventral foramen. The position of the needle is confirmed by fluoroscopy. The nerve is tested for the appropriate motor response, which is dorsiflexion of the great toe and bellows contraction of the perineal area, which represents contraction of the levator muscles (bellows reflex). Simultaneous sensory responses determined at the time of lead placement help optimize positioning. Although this is controversial, if one can localize the stimulation at the time of lead positioning to the vagina-rectum juncture in females and perineoscrotal area in males this is proper localization of the device. The foramen needle stylet is then removed and replaced with the introducer sheath. The distal aspect of the lead consists of four electrodes numbered 0 through 3. The lead is placed into the introducer sheath as directed to expose the electrodes. Typically, electrodes are positioned such that electrodes 2 and 3 straddle the ventral surface of the sacrum

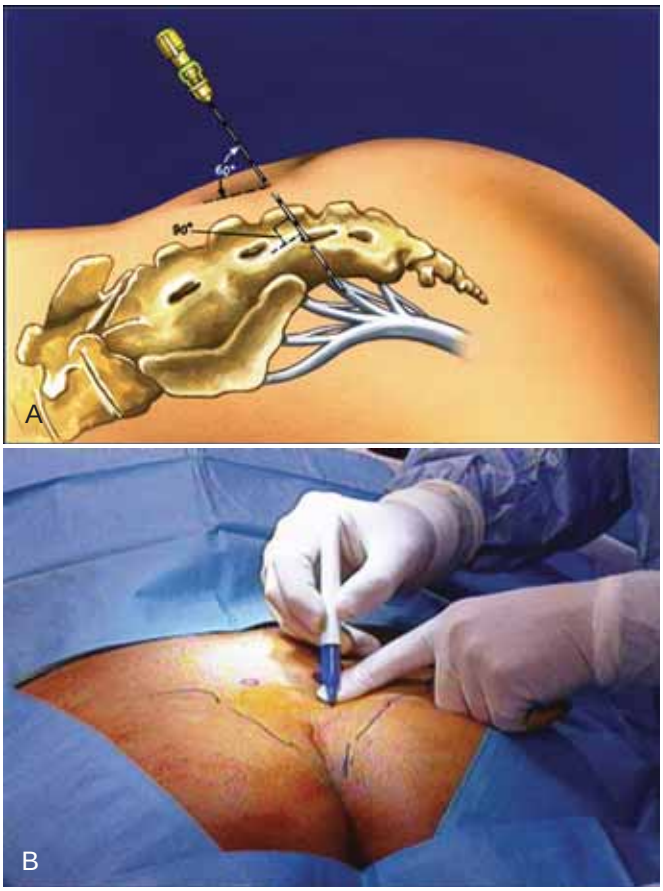

Figure 70–5. **A,** The percutaneous test stimulation is performed in an outpatient setting. A small lead wire is placed into S3 and connected to an external stimulator for 1 week to administer stimulation to the nerve roots. **B,** Measurement of the S3 nerve foramen is typically 9 cm to the coccyx and 11 cm to the anal verge. One measures 1 to 2 cm lateral to this mark to find the rough site of the S3 nerve foramen. The "cross hair" technique can be used to find the midline fluoroscopically and the lower aspect of the sacroiliac joints laterally to find the S3 nerve foramen as well. (Courtesy of Medtronic, Minneapolis, MN.)

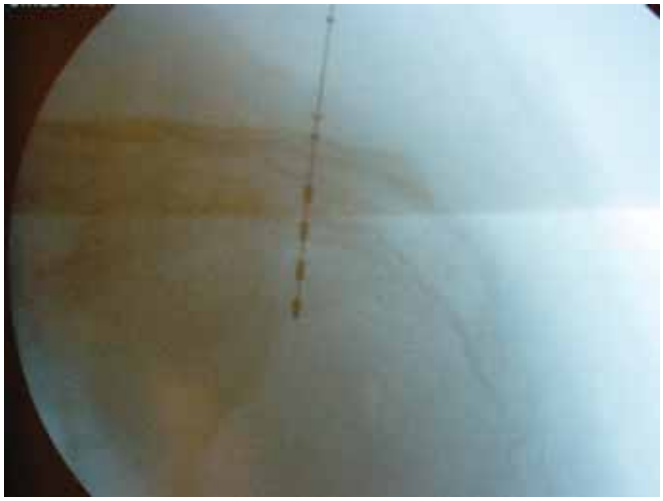

Figure 70–6. Fluoroscopy is used to confirm lead placement, typically with the lead configurations to obtain optimal muscle (bellows response and ipsilateral toe contractions) and sensory (vaginal, penile, or scrotal "pulsating" feeling) responses. The lead may then be deployed.

(Fig. 70–6). Test stimulation is repeated on each electrode, and the responses are observed. An S3 response should be noted on at least two of the electrodes (see Table 70–2). Once the surgeon is satisfied with the position, the sheath is removed, releasing the tines that anchor the lead. A sensory response, sensation of stimulation in the perineum, is not needed to confirm proper placement if the correct S3 motor response is observed. However, when a motor response is absent, raising the conscious level of the patient during the procedure and detecting the correct sensory response will confirm proper localization, and a clinical response may still be obtained during the screening trial period despite the absence of the motor response.

A 3- to 4-cm incision into the subcutaneous tissues in the upper lateral buttock is made below the beltline or below the level of the ischial wings for connecting the permanent lead to the percutaneous extension lead wire. If the screening trial is successful, this connection site will be the site of implantation for the IPG. With use of the tunneling device provided in the commercial kit, the permanent lead is transferred to the medial aspect of the lateral buttock incision. The lead is then connected to the extension wire, and the tunneling device is used again to transpose the extension wire from the medial aspect of the incision to an exit point on the contralateral side of the back. This transfer and long tunnel reduce the occurrence of infection from the percutaneous exit site of the wire. The extension wire is connected to the external pulse generator. Patients are able to resume their normal activities immediately but are advised to limit excessive movement-related activities, such as high-impact exercises, for the duration of the trial period.

The external generator can be flexibly programmed for the duration of the intended trial while the patient records symptoms and bladder function in a voiding diary. If there is more than 50% improvement in the symptoms or voiding function, a stage II procedure is performed.

A stage II procedure entails placement of the IPG. No fluoroscopy is required during stage II when a permanent neuroelectrode has been placed for the stage I procedure; however, if a percutaneous nerve evaluation was performed for stage I, fluoroscopic confirmation of the neuroelectrode placement is advised. The patient may be placed in the prone position or a lateral position with the site of the previous lateral incision for the lead connections placed upward (Fig. 70–7). The lateral position may improve ventilation during sedation. The previous buttock incision overlying the lead connections is opened, the percutaneous extension wire is removed, and the extension lead is secured to the permanent lead and subsequently to the IPG. A pocket is made in the subcutaneous tissue that is large enough to avoid tension on closure and at a depth to provide a covering layer of subcutaneous tissue anterior to the pulse generator to prevent erosion.

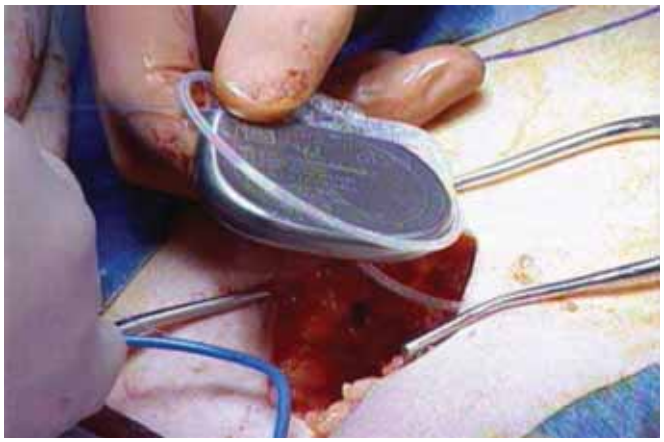

Figure 70–7. A 3- to 4-cm counterincision in the upper gluteal crease is made for a deep subcutaneous pocket to allow implantation of the implantable pulse generator.

Outcomes

Urinary urgency, frequency, and urgency incontinence have a significant impact on medical health and quality of life. Neuromodulation offers an alternative to patients who may be considering irreversible surgical options when pelvic floor muscle reeducation and pharmacologic therapy have failed. Outcomes of SNS for the indications of idiopathic urgency/frequency and urgency urinary incontinence are derived from only two studies that have randomized patients to active or delayed therapy as well as reports from numerous prospective and retrospective reviews of case series and registry databases.

Schmidt and coworkers (1999) reported on SNS therapy in 76 patients with refractory urgency urinary incontinence from 16 centers worldwide randomized to active or delayed therapy (control group) during the study period of 6 months. Of the 34 patients receiving active SNS therapy compared with the delayed group, 16 (47%) were completely dry and an additional 10 (29%) demonstrated more than 50% reduction in incontinence episodes. Complications were IPG site pain in 16%, implant infections in 19%, and lead migration in 7%.

In a similar study design, Hassouna and colleagues (2000) reported the outcomes of SNS on refractory urgency/frequency conditions in 51 patients randomized from 12 centers during an initial 6-month period that was extended to 2 years. Outcomes at 6 months in the active SNS group showed improvement in the number of daily voids (16.9 ± 9.7 to 9.3 ± 5.1), volume voided (118 ± 74 mL to 226 ± 124 mL), degree of urgency (rank score of 2.2 ± 0.6 to 1.6 ± 0.9), and SF-36 quality of life measures. At 6 months after implantation, stimulators in the active group were turned off and urinary symptoms returned to baseline values. After reactivation of SNS, sustained efficacy was documented at 12 and 24 months.

Limited but conformational results of the earlier randomized trials have been obtained from prospective series (Shaker and Hassouna, 1998; Siegel et al, 2000; Janknegt et al, 2001) and registry studies (Spinelli et al, 2001; Hedlund et al, 2002) evaluating efficacy, safety, and quality of life measures. The results for the registration trial that led to approval by the U.S. Food and Drug Administration (FDA) for SNS (Pettit et al, 2002) reveal that 37 of 62 patients (60%) with refractory urgency/frequency or urgency urinary incontinence achieved an improvement of 50% or more in their condition. van Kerrebroeck and coworkers (2007) have reported on a 5-year prospective worldwide series for patients with the InterStim device for varying indications and for the urgency/frequency and urgency urinary incontinence populations, and good success was achieved in all groups. Of note is that the analysis was of patients including those in the initial registration trial who then "crossed over" to the prospective 5-year trial. This study, unfortunately, was influenced by several patients who did not attend all follow-up visits and, therefore, had missing data points, a problem reflective of this challenging subgroup. Outcomes data were based on "last observation carried forward," which is of concern for not being statistically optimal, but nonetheless these are still the longest-term data this technology has available.

Special Populations

With the success of neuromodulatory therapies for refractory detrusor overactivity and urinary retention it should be no surprise that indications are expanding. Despite the fact that there is no true FDA-approved indication for neuromodulation in select populations, these groups all have some component of the indicated symptom-complex that includes urgency, frequency, urgency urinary incontinence, or urinary retention. The current expansion of indications for neuromodulation has developed into areas of neurogenic bladder (Parkinson disease, multiple sclerosis, spinal cord injury), interstitial cystitis (painful bladder syndrome), pelvic pain, fecal incontinence and bowel disorders, and pediatric voiding dysfunction.

Neurogenic Bladder. Patients with neurogenic bladder may have several urodynamic events that lead to their symptomatic voiding dysfunction. This may include neurogenic detrusor overactivity, detrusor-sphincter dyssynergia, and flaccid areflexia. Whereas neuromodulation has not been well examined in cases of obvious areflexia (possibly because of the need for some end-organ response for neuromodulation to have any benefit), it has been studied in small subgroups of patients with detrusor overactivity and possibly detrusor–external sphincter dyssynergia, although few published reports exist.

Because the spectrum of neurologic diseases with potential bladder **manifestations is wide, one must be cognizant of a few important relative contraindications before contemplating current neuromodulatory therapies, as follows: significant bone abnormalities in the spine or sacrum that may present challenges to gaining access; mental incapacity of patients, who cannot manage the device; physical limitations that prevent voiding (functional incontinence); future need of MRI; and noncompliance.**

Multiple Sclerosis. **Multiple sclerosis (MS) is a chronic demyelinating disease of the central and peripheral nervous system that can cause a variety of voiding dysfunction scenarios including neurogenic detrusor overactivity, detrusor-sphincter dyssynergy, areflexia, and combinations of these.** Because many patients have been refractory to standard therapies, neuromodulation or neurostimulation (to be addressed later in the section on neurostimulation for retention) may be considered a part of their treatment options. In an appropriately selected patient with MS, neuromodulation truly has some promise because it may balance the function of the bladder itself as well as that of the outlet (two of the main components of MS-related voiding dysfunction). This may be considered off-label use of neuromodulation because it is not approved specifically for MS-related voiding dysfunction, but approval may be based on symptoms such as urgency, frequency, or often urgency urinary incontinence and even nonobstructive urinary retention.

No prospective randomized trials exist on the use of neuromodulation in management of MS-related bladder dysfunction. Small series with encouraging results in patients with MS demonstrate that neuromodulation may have a role in treatment of MS-related voiding dysfunction (Bosch and Groen, 1996; Wallace et al, 2007). It appears that the best candidates are ones with mild, nonprogressive MS, with few functional issues, who also have detrusor overactivity or even retention but not areflexia. One of the major issues that arises in the patient with MS in particular is the potential change in the disease state that may be potentiated by neuromodulation. Although this may be theoretical, it was one of the factors cited by the FDA in the original sacral neuromodulation trials and precluded MS patients from being enrolled (Hassouna et al, 2000).

A secondary issue that may arise if a patient with MS is implanted with the lead and IPG system is the potential need for MRI in the future. One should maintain close contact with the patient's neurologist as to the decision to place a neuromodulatory device to prevent any future need for MRI or selection of a patient in an active phase of disease who requires routine MRI. **The main concern with MRI and implantable stimulator or pacemaker-type devices is that heating of the leads has been demonstrated in vivo and in vitro** (Roguin et al, 2004; Martin, 2005). Whereas some question the clinical significance of the small temperature changes with the leads, the potential exists to elicit nerve damage with heating of the lead, and the magnetic field may change the generator itself (Gimbel and Kanal, 2004). At present, it is contraindicated to perform MRI of a patient with an implantable neurostimulator system.

Spinal Cord Injury. Many specialists who treat neurogenic disorders due to spinal cord injury realize that a patient may present with a variety of clinical and urodynamic findings. Many patients have neurogenic detrusor areflexic situations, but perhaps more often and sometimes more challenging is the subset who may be incontinent from neurogenic detrusor overactivity with or without concomitant sphincteric dyssynergy. Furthermore, the adverse sequelae of treated or untreated spinal cord injury may include infections, urolithiasis, reflux, or obstruction. The goal, then, is not only to prevent these adverse events but also to ensure a bladder that functions well, empties at a low pressure to protect the upper tracts, and maintains a good capacity and continence. **Whereas it is implied that an intact reflex arc should be in place for neuromodulation to work, this has not been proved in clinical studies. Basic science data suggest that at least some communication should exist between sacral outflow and the pontine micturition center to allow processing for the reflexes that may be inhibited by the brain** (de Groat et al, 1981). Thus, a patient with a complete spinal cord lesion may not have the same potential benefit from neuromodulation as does one with an incomplete lesion. Again, this fact has yet to be proved clinically in patients. Shaker and colleagues (2000) described their observations in a group of female rats that developed bladder overactivity 3 weeks after spinal cord transection, associated with an increase in neuropeptide content of the dorsal root ganglion of L6. The spinal cord transections were at level T10. Electrostimulation of S1 was carried out and abolished overactivity while still attaining the rise in neuropeptide content in the L6 dorsal root ganglion. This suggested that blockade of C-fiber afferent pathways may have been one of the mechanisms of action of neuromodulation of the sacral root. In addition, they believed the time course of the reduction in neuropeptide content may explain the long-term changes that occur with chronic neuromodulation and the time needed for detrusor overactivity to return toward baseline after neuromodulation is initiated.

From a clinical perspective, few studies exist in neurogenic patients alone for whom sacral neuromodulation was performed. Andrews and Reynard (2003) described a T8 paraplegic with residual urinary urgency and urgency urinary incontinence who underwent percutaneous tibial nerve stimulation (see later section in this chapter) for his problem. This patient experienced an almost twofold increase in bladder capacity; this was repeated, and again, increased cystometric capacity was demonstrated on follow-up. Patients with incomplete spinal cord injury may respond in a

similar fashion to the remainder of the population, with fairly high success rates in motivated individuals (Lombardi and Del Popolo, 2010).

It is clear that this is an emerging area of interest in current techniques, and some have postulated a role for selective stimulation in neurogenic patients as a means to achieve better results. Future research will clearly need to be done in this challenging subset of patients.

Voiding Dysfunction after Prior Sling or Anti-Incontinence Surgery. It is well known that patients may develop urinary retention or some form of voiding dysfunction after vaginal sling surgery or other forms of surgical management for urinary incontinence. Whereas the mainstay of therapy is to surgically "undo" the operation, many patients who have been obstructed for some period of time may manifest long-term voiding difficulty. This problem may vary from urgency, frequency, to urgency urinary incontinence or to continued problems with retention and incomplete emptying despite adequate urethrolysis. This patient population (when refractory symptoms continue) may be ideally suited to the placement of a sacral neuromodulation device (Starkman et al, 2008). After implantation, patients had improved quality of life scores, improved urgency and frequency scores, with diminished urgency urinary incontinence in a small retrospective series.

Interstitial Cystitis (Painful Bladder Syndrome). Chronic pelvic pain and interstitial cystitis are challenging and frustrating conditions for both the physician and the patient. Therapeutic options are limited and frequently ineffective. Whereas neuromodulation therapy in patients with interstitial cystitis has typically been reserved for patients considering major surgery (e.g., cystectomy and urinary diversion) when behavioral and pharmacologic therapies have failed, more innovative consideration has been given to earlier application of this therapy before chronic neuroplastic changes become irreversible.

Interstitial cystitis is not a true FDA-approved indication for neuromodulation; however, the symptom-complex of urinary urgency and frequency is well within the standard approved criteria. **It may be realized that neuromodulation for interstitial cystitis may be best in combination with other therapies, because interstitial cystitis is thought to require a multimodal approach and neuromodulation should be considered only one part of the multimodal therapy.**

Comiter (2003) performed a prospective evaluation of 25 patients with refractory interstitial cystitis. Seventeen of the 25 patients demonstrated more than 50% improvement in average pain score and voiding symptoms and therefore qualified for permanent IPG placement. At a mean of 14 months of follow-up, improvements were seen in frequency, nocturia, and mean voided volume. Average pain scores decreased from 5.8 to 1.6 on a 10-point scale, and Interstitial Cystitis Symptom Index (ICSI) and Problem Index (ICPI) scores decreased significantly. Furthermore, 94% of patients implanted had a sustained improvement in symptoms. Similar findings were noted by Whitmore and associates (2003) in 33 patients who had statistically improved parameters in frequency, pain, average voided volume, and maximum voided volume as well as ICSI and ICPI scores.

Peters and colleagues (2003) retrospectively evaluated 21 patients with refractory interstitial cystitis with pelvic pain who underwent permanent implantation of the IPG. The patients were contacted by mail and asked to respond to a questionnaire that addressed the use of narcotic pain medication. There was an average decrease in morphine dose-equivalents after implantation of 36%. In addition, subjects were asked to rate their pelvic pain complaints on a 7-point scale. Most patients reported a moderate to marked improvement in pain after sacral neuromodulation. Approximately one fourth of the patients were able to discontinue narcotics completely, and patients overall were satisfied with this form of therapy compared with previous ones.

Chai and coworkers (2000) have reported that perhaps some of the effects of neuromodulation in patients with interstitial cystitis may be due to changes in antiproliferative factor. His group has shown that levels of antiproliferative factor and epidermal growth factor were elevated in the urine of patients with interstitial cystitis and that these levels subsequently normalized after a short trial of sacral neuromodulation.

Chronic Pelvic Pain. Pelvic pain, much like interstitial cystitis, has been investigated with therapy like neuromodulation; again, this affects a challenging subset of patients who no other treatments seem to benefit. Bemelmans (1999) described the mechanism in pain inhibition as involving the gate control mechanism at the spinal segmental level. At this point, large somatic sensory fibers inhibit the activity in small Aδ or unmyelinated C fibers via sacral segmental interneurons or perhaps supraspinally by way of the spinobulbospinal reflex system. The hypothesis is that sacral root stimulation for the treatment of many disorders may result from decreasing pelvic floor spasticity.

Multimodal therapy is likely to be of benefit; however, results may not be optimal in all cases. **Spinal cord stimulation at higher centers has been used by pain therapists and with moderate success; however, trial design and consistent entry criteria are debated** (Feler, 2003; Mailis-Gagnon et al, 2004). Small series have looked at more selective stimulation, primarily at sacral roots. Aboseif and colleagues (2002) examined the effect of sacral neuromodulation on pelvic floor dysfunction in 41 of 64 patients thought to have chronic pelvic or perineal pain. Patients with chronic pelvic pain had decreased pain scores on average (5.8 to 3.7) after neuromodulation based on validated pain scales. Siegel and associates (2001) examined patients with intractable pelvic or genitourinary pain in the absence of neurologic or pelvic disease. Sacral neuromodulation did benefit patients, and they described a decrease in severity of pain and quality of life improvements. Bilateral caudal sacral stimulation may yield almost 40% improvement in pain scores in patients with mixed symptoms of voiding dysfunction and pelvic pain (Zabihi et al, 2008). Still, some form of placebo effect is likely to exist and is challenging to control in these small series.

Pediatric Voiding Dysfunction. Children often experience voiding dysfunction in fairly high rates and may in fact have refractory bladder problems that require advanced management schemes. **Neuromodulation has been considered in this population because of the variety of lower tract dysfunctions that pediatric patients may have, including overactive bladder, urinary retention, and non-neurogenic neurogenic bladder (the Hinman bladder syndrome).** Because neuromodulation truly represents a minimally invasive option for refractory management, it follows that this may be an approach to be used in pediatric lower urinary tract dysfunction. **Still, sacral neuromodulation is not approved by the FDA for use in pediatric patients, perhaps owing to lack of data on what the sacral lead would do with concomitant growth of the spinal cord, nerve roots, and foramina. Accordingly, efforts in the past have been centered on alternative means of delivering electrical stimulation to the bladder and pelvic floor in these patients.** Few studies exist of pediatric patients and sacral neuromodulation. Guys and coworkers (2004) prospectively examined 21 patients aged 5 to 21

years with sacral neuromodulation in the setting of neurologic disease consisting predominantly of spina bifida. The neuromodulation implant group had improved compliance and bladder capacity at 6 and 9 months but not at 12 months. Of the 21 patients, 9 improved their intestinal transit times and 1 patient had complete disappearance of urinary incontinence. No patients in the control group experience an improvement of their condition. McGee and associates (2009) described the use of an incisionless first- and second-stage sacral neuromodulation procedure with fairly high success rates in pediatric patients with dysfunctional elimination syndromes and had minimal complications.

Transcutaneous electrical nerve stimulation (TENS) has been used in pediatrics because it is noninvasive. One usually places a patch electrode on both sides of the S3 nerve foramen, and it is connected to a pulse generator and amplifier. Hoebeke and associates (2001) reported on this use in 41 children. In this case series, patients had urodynamically proven detrusor overactivity, and anticholinergic therapy had failed in all. Patients had daily therapy with the patch electrodes placed at S3, and stimulation was delivered at 2 Hz. A 76% response rate was observed, and this was due in part to increase in bladder capacity and reduction in urgency urinary incontinence and urgency symptoms. Of 41 patients, 21 (51%) were definitively cured; the remainder experienced relapse in the ensuing 1 year of follow-up. Bower and colleagues (1998) reported a similar fairly high success rate with 17 children treated with S3 transcutaneous stimulation and demonstrated dryness in 73.3% of patients and improved urgency and bladder capacity based on visual analog scales and voiding diaries. A more recent study by Malm-Buatsi and associates (2007) also showed continued benefit in patients when 8 of 12 (75%) subjects received statistically significant benefits when therapy was completed. Although this technology seems to have fairly good success there has been no trial in a randomized prospective controlled fashion that may increase its acceptance.

Posterior tibial nerve stimulation (PTNS), much like TENS, has been studied in pediatric patients because of its lack of invasiveness. DeGennaro and colleagues (2004) reported on PTNS in children in a subset of patients with refractory non-neurogenic voiding dysfunction; 80% of patients had symptom improvement and 44% were totally dry, and 62.5% had improvement in bladder capacity. Furthermore, 71% had improvement in urinary retention symptoms. No patients had significant problems from the therapy, and it was overall thought to be both safe and well tolerated. Hoebeke and associates (2002), in a pilot study of PTNS, demonstrated similar success with 32 children. Of the 28 children with urgency before therapy, the urgency disappeared after therapy in 7 and improved in 10. Of the 23 children with daytime incontinence before treatment, 4 became dry after stimulation, and in 12 patients the incontinence decreased. Of the 19 patients who reported abnormal voiding frequency of either less than 4 or more than 8 voids per day, 16 of 19 achieved a normal frequency of 4 to 6 voids daily.

Fecal Incontinence and Bowel Disorders. **Sacral neuromodulation was investigated for bowel disorders on the basis of some of the early experience in bladder patients who exhibited treatment benefits with regard to the bowel symptoms** (Pettit et al, 2002). The use of sacral neuromodulation in bowel disorders is being actively examined, but it is not yet approved for use in the United States. **There exist two major areas of interest with regard to neuromodulation and bowel disorders: fecal incontinence and constipation.**

Fecal Incontinence. Several studies have been done to examine the utility of sacral neuromodulation in fecal incontinence (Kenefick et al, 2002a, 2002b; Uludag et al, 2002; Melenhorst et al, 2007). It appears that patients with a variety of causes of the fecal incontinence seem to have benefited from sacral neuromodulation therapy in this setting. The Cleveland Clinic scoring system allows comparisons to be made with regard to outcome measures including incontinent episodes (solid, liquid, and flatus), pad use, and lifestyle changes. **Several studies have used this scoring system, and all have shown improvements in these assessed parameters** (Matzel et al, 2003; Jarrett et al, 2004). **Sacral stimulation has been shown to be more effective than medical management based on randomized controlled trials for fecal incontinence** (Tjandra et al, 2008). **The mean incontinent (fecal) episodes decreased from 9.5 per week to 3.1 ($P < .001$), and perfect continence was gained in 47.2%. Similar improvements were demonstrated in quality of life parameters. The exact prognostic indicators for success have yet to be defined, particularly as they relate to etiology of the fecal incontinence (sphincter defect, neurologic, functional). The use of sacral neuromodulation is currently being investigated by the FDA for use in fecal incontinence.**

Constipation. *Constipation* as such is a broad term, with the definition being in evolution. It is thought to be representative of difficult evacuation of feces and infrequent or inadequate defecation. Other refinements to the definition may include bowel frequency of fewer than three stools per week. The ROME II criteria categorize constipation into subtypes, including constipation-predominant irritable bowel syndrome, functional constipation, and pelvic floor dyssynergia (Drossman and Corazziari, 2000). Sacral neuromodulation has been examined in this regard and has had favorable results on the basis of some of the criteria listed for improvement. Ganio and associates (2001) described 16 patients who underwent permanent implantation of sacral leads for constipation whereby they had more than 50% decrease in difficulty emptying the rectum and more than 80% improvement in the Cleveland Clinic constipation score that persisted during the course of 1 year of follow-up. Other series (Kenefick et al, 2002a, 2002b) have shown similar improvements, although in smaller numbers. Still, with the small series available, it is difficult to make any meaningful analyses. The more important parameters, perhaps, in this setting relate to quality of life; these have been assessed with SF-36 questionnaires and have proved to be beneficial at least in Kenefick and associates' study. **All of these results suggest, at least, that there is some benefit of sacral neuromodulation in refractory constipation cases. Further study is warranted to assess prognostic factors to better decide on future candidates for this therapy.**

Bilateral Stimulation and Neuromodulation

The current technique for sacral neuromodulation involves a unilateral lead at the S3 nerve foramen to achieve results in cases of urgency, frequency, urgency urinary incontinence, and idiopathic nonobstructive urinary retention. **Bilateral stimulation has been suggested as an alternative, particularly in failed unilateral lead placements, for potential salvage or added benefit as the bladder receives bilateral innervation** (van Kerrebroeck et al, 2005). The initial consideration of bilateral stimulation was based on animal studies

demonstrating that bilateral stimulation yielded a more profound effect on bladder inhibition than did unilateral stimulation (Schultz-Lampel et al, 1998a, 1998b). An animal model of unilateral versus bilateral stimulation has suggested that bilateral stimulation may be more effective overall (based on reduction of detrusor overactive contractions) than unilateral stimulation (Kaufmann, 2008).

There has been only one prospective clinical study to demonstrate the differences in unilateral versus bilateral stimulation (Scheepens et al, 2002). This study was a prospective randomized crossover design in which all patients underwent unilateral as well as bilateral test stimulations to assess the benefits of bilateral stimulation. Both unilateral and bilateral test stimulation was continued for 72 hours, and the patients were randomly assigned to start with unilateral or bilateral stimulation. No significant difference was found in the unilateral versus bilateral group with regard to urgency urinary incontinence, frequency, or severity of leakage in the overactive bladder group, although overall results were impressive in both categories. The retention group had better parameters of emptying (volume per void) in bilateral compared with unilateral stimulation. Still, the numbers were too small in the retention group for adequate conclusions to be made. **It appears that the data as presented, at least from a clinical perspective, do not suggest a large role for routine bilateral stimulation for most patients.** Perhaps there will be subgroups that may benefit more than others (e.g., retention patients), but larger-scale studies with good methodology as shown in the Scheepens study will be required. Still, if one could increase the overall success rates of patients undergoing sacral neuromodulation, one could ultimately help more patients. Accordingly, Pham and colleagues (2008) examined 124 patients undergoing stage I sacral neuromodulation and stratified patients into unilateral and bilateral groups, retrospectively. Successful stage 1 trials were noted in 58% of unilateral patients and 76% of bilateral patients. An important component that still needs to be evaluated is whether it is cost effective to "routinely" place bilateral leads in the setting of most unilateral lead success rates approaching 70% and 80%.

Selective Nerve Stimulation

Pudendal Nerve

Because the bladder afferent reflex works through sacral interneurons that then activate storage through pudendal nerve efferent pathways directed toward the urethral sphincter, the pudendal nerve is a logical target for developing neuromodulation therapies. The earliest attempts to manipulate this reflex through electrical stimulation were based on direct pelvic floor muscle stimulation by Caldwell (1963, 1965) and others with the development of the first implantable and external pelvic floor stimulators, anal plug stimulator (Hopkinson and Lightwood, 1966, 1967), and intravaginal pessary stimulation (Alexander and Rowan, 1968; Erlandson et al, 1977; Fall et al, 1977; Fall, 1985). To deliver optimal stimulation to the nerve directly, selective pudendal nerve stimulation was introduced by Vodusek and coworkers (1986) and shown to have an inhibitory effect on the micturition reflex.

Neurophysiologic studies reveal that SNS works for bladder storage disorders by a similar inhibition of the micturition reflex as a result of electrical stimulation of sensory afferent fibers, in particular by depolarization of Aα and Aγ somatomotor fibers that affect the pelvic floor and external sphincter and thus inhibit detrusor activity (Hohenfellner et al, 1992). Because many of the sensory afferent nerve fibers contained in the sacral spinal nerves originate in the pudendal nerve, the pudendal nerve afferents are important targets for neuromodulating the inhibitory reflex on the micturition reflex (Peng et al, 2008; Woock et al, 2008; Yoo et al, 2008). Furthermore, high-frequency electrical stimulation of this nerve may achieve blockade of external sphincter contractions leading to sphincter relaxation (Gaunt and Prochazka, 2009). Direct pudendal nerve neuromodulation stimulates more pudendal afferents than SNS provides and may do so without the side effects of off-target stimulation of leg and buttock muscles. Thus, techniques for direct pudendal nerve stimulation at alternative locations to the sacral foramen are being developed. Spinelli and associates (2005) modified existing sacral neuromodulation technology and adapted it to pudendal nerve stimulation and realized the need for more sensitive neurophysiologic guidance to better guide stimulation to the pudendal nerve target. Trials using different techniques and devices are under way for selective pudendal nerve stimulation within the ischial rectal fossa and the pure sensory afferent branch of the pudendal nerve at the level of the symphysis bone referred to as the dorsal genital nerve.

The Bion device (Boston Scientific, Natick, MA) is a minimally invasive implantable mini-stimulator with an integrated electrode for nerve neuromodulation. Early feasibility trial results of the Bion device placed at the level of the pudendal nerve exiting the Alcock canal indicate that a considerable reduction in the degree of detrusor overactivity incontinence can be obtained in refractory cases, including those cases of failed SNS neuromodulation (Bosch, 2005). Clinical trials of the rechargeable Bion device were halted in the United States and Europe.

External Periurethral Nerve

A relatively new way to stimulate the bladder has been investigated and is now underway with clinical trials in the use of external periurethral neuromodulation (Nissenkorn et al, 2004, 2005). This device basically entailed placement of a lead and generator apparatus in the periurethral location while the generator was in the lower abdomen subcutaneous space. The lead then stimulated the sphincter apparatus and nerves associated with this structure presumably. Whereas their early results are fairly impressive, the device may help both urgency and stress urinary incontinence (16 patients with stress urinary incontinence were treated and 9 were dry during electrostimulation and the remainder had a 74% reduction in pad weights). The exact positioning of the electrodes seems to be in the area proximate to the external urethral sphincter, thereby allowing for direct access to afferent nerve fibers (Whiteside et al, 2009). How this therapy benefits patients will be interesting because it has many potential uses, including stress and urgency urinary incontinence, pain syndromes, and neuromuscular disorders of the pelvic outlet.

Dorsal Genital Nerve

The dorsal genital nerves (dorsal nerve of the penis in males, clitoral nerve in females) are the terminal and most superficial branches of the pudendal nerve found at the level of the symphysis pubis. The nerves are afferent nerves that carry sensory information from the glans of the penis or clitoris. Proximally, the dorsal genital nerves form a component of the pudendal nerve and then the sacral spinal roots. As a pure sensory afferent nerve branch of the pudendal nerve, the dorsal genital nerve contributes to the pudendal-pelvic nerve reflex that has been proposed as a mechanism of bladder inhibition. Whereas squeezing the glans penis or manipulation of the clitoris is clinically known to help

suppress bladder contractions as observed in behaviors of voiding avoidance, direct electrical stimulation of these organs does not produce a significant effect on the micturition reflex as measured by urodynamics during the storage phase (Yalla et al, 1978; Kondo et al, 1982). However, direct dorsal genital nerve electrical stimulation in experimental and clinical studies appears promising in producing an inhibition of the micturition reflex.

Results in laboratory animals and in persons with spinal cord injury have demonstrated that electrical stimulation of the dorsal genital nerves inhibits bladder contractions (Craggs and McFarlane, 1999). In anesthetized cats (Sundin et al, 1974; Jiang and Lindstrom, 1999) and in unanesthetized chronic spinal cord–injured cats, reflex bladder contractions could be inhibited by stimulation of the genital nerves (Walter et al, 1993). Conditioning stimulation of afferents in the dorsal clitoral nerves has also been shown to suppress reflex bladder contractions in anesthetized cats (Jiang and Lindstrom, 1999). Similarly, recent work in anesthetized cats has shown that low-amplitude electrical stimulation of the S1 dorsal root (which in the cat carries the dorsal genital afferents) inhibits or abolishes ongoing reflex bladder contractions (Jezernik et al, 2001), resulting in significantly shorter bladder contractions. The micturition reflex can be activated and inhibited by stimulation of these dorsal penile afferent fibers in animal models (Woock et al, 2008).

Stimulation of the dorsal penile nerve has been tested in humans to control incontinence in individuals with spinal cord injury and increase bladder volume and reduce bladder overactivity (Wheeler et al, 1992, 1994). Penile nerve stimulation was painless with no side effects, was effective for inhibiting detrusor overactivity, and may be adaptable for chronic home use as an alternative to current therapy (Wheeler et al, 1992). Similar experiments have shown that stimulation of the dorsal nerve of the penis abolishes reflexive bladder contractions and increases bladder capacity in persons with spinal cord injury (Lee and Creasey, 2002). These results demonstrate that electrical stimulation of the dorsal genital nerves can abolish detrusor overactivity and increase bladder capacity in individuals with neurogenic detrusor overactivity due to spinal injury. Feasibility trials with this approach have been completed and demonstrate in a small series that 81% of patients experienced a 50% or greater improvement in urgency and 47% reported a 50% or greater reduction in incontinence episodes (Goldman et al, 2008). This approach seems to have further advantages in being minimally invasive, office based, and without the need for fluoroscopy or prone positioning.

Posterior Tibial Nerve

The posterior tibial nerve is a mixed sensory and motor nerve containing fibers originating from spinal roots L4 through S3 that modulate the somatic and autonomic nerves to the pelvic floor muscles, bladder, and urinary sphincter. On the basis of translational findings of the traditional Chinese practice of using acupuncture points over the common peroneal or posterior tibial nerve to inhibit bladder activity, McGuire and associates (1983) used transcutaneous stimulation of the common peroneal or posterior tibial nerve for inhibition of detrusor overactivity. PTNS (Urgent PC, CystoMedix, Anoka, MN) as approved by the FDA currently consists of weekly 30-minute stimulation treatments provided by insertion of a small-gauge stimulating needle approximately 5 cm cephalad from the medial malleolus and just posterior to the margin of the tibia with the grounding electrode pad placed on the medial surface of the calcaneus (Govier et al, 2001; Cooperberg and Stoller, 2005).

Clinical trials of PTNS have been performed in detrusor overactive conditions with and without pelvic pain (Klingler et al, 2000; van Balken et al, 2003; Vandoninck et al, 2003; Congregado Ruiz et al, 2004; Zhao et al, 2008) and urinary retention (van Balken et al, 2001; Vandoninck et al, 2003). Although clinical trials have produced variable results, PTNS is minimally invasive, demonstrates efficacy, and is easily applicable and well tolerated in all the lower urinary tract conditions studied. Recent urodynamic outcomes have been shown in an MS subpopulation and improvements during PTNS have been demonstrated, including increases in mean first involuntary detrusor contractions and mean cystometric capacity (Kabay et al, 2008). One major limitation of PTNS is that there does appear to be the need for chronic treatment that may be better derived from an implantable subcutaneous stimulation device (van Balken et al, 2003) and even continuous stimulation (Oliver et al, 2003). Perhaps the use of a sham control can help us better understand the potential clinical benefits of this therapy in the long run. A novel sham has been developed, and widespread study of PTNS with use of a sham control may help determine outcomes and eliminate placebo rates (Peters et al, 2009).

Transcutaneous Electrical Stimulation

Other methods of electrical stimulation have been used that seem to occupy a place midway between anal, vaginal, or perineal stimulation and sacral root stimulation. TENS devices have been used to limited degrees to achieve better tolerability to bladder filling and may have some efficacy in postponing voiding. Fall and associates (1980) described TENS use suprapubically in patients with interstitial cystitis, and subsequent studies have been done to gain wider use of this modality (Lindstrom et al, 1983; Fall and Lindstrom, 1991). The exact stimulation parameters are not agreed on because different frequencies have been used; 2 Hz may stimulate pudendal afferents, whereas 50 Hz may stimulate striated paraurethral musculature. Similarly, low-frequency TENS may have some use in abolishing detrusor contractility (Bower et al, 1998). As such, this technology is easy to do and apply, but it may be required for extended periods to gain treatment benefits. S2 or S3 TENS may make some sense, because direct stimulation transcutaneously of this area may yield better results than suprapubic stimulation. Positive results have been demonstrated on the basis of urodynamic data, with improved bladder capacity, delay in first urge to void, and reduced detrusor instability (Bower et al, 2001; Hoebeke et al, 2001). For adequate maintenance of the benefits of this therapy it must also be continued for longer durations. McGuire and associates (1983) described 16 patients with involuntary bladder contractions of varying etiology who were treated with common peroneal or posterior tibial nerve patch electrode stimulation: 12 patients initially were dry, 3 were improved, and 1 was "possibly improved." Vereecker and colleagues (1984), however, were unable to suppress hyperactivity by this method in patients with suprasacral spinal cord injury or disease. Okada and associates (1998) reported a positive experience with transcutaneous stimulation of the thigh muscle in 19 patients with detrusor overactivity; the maximal cystometric capacity was increased by 57% in 11 of 19 patients.

Noninvasive magnetic stimulation of the sacral roots will also inhibit bladder contractions and cause effects that will persist for short times beyond the period of stimulation. This type of stimulation at present cannot be applied for prolonged periods and is currently unsuitable for long-term treatment, although it

may be helpful for preliminary assessment of candidates for chronic sacral root neuromodulation. The extracorporeal magnetic stimulation provided by the "chair" has been used clinically for potential use in overactive bladder, stress incontinence, and pelvic pain (Galloway et al, 2000). No other prospective data on this technology are available for overactive bladder and, furthermore, the exact mechanism of action, if effective, remains to be explained, namely, magnetic, nerve root or peripheral nerve, or intramural nerve stimulation.

Complications and Troubleshooting of Sacral Neuromodulation

With the widespread adoption of sacral neuromodulation, an increasing need has developed to understand complications of this therapy and to learn how to troubleshoot the devices when responses change. It appears that the introduction of the tined lead concept has changed the frequency and profile of the complications that were once only technology related while keeping the patient-related complications at the same frequency.

Published Series

The SNS study group has published several reports on the efficacy and safety of the procedure for individual indications (Siegel et al, 2000). The complications were pooled from the different studies on the basis of the fact that the protocols, devices, efficacy results, and safety profiles were identical. The studies recruited 581 patients, 219 of whom underwent implantation of the InterStim system. The complications were divided into percutaneous test stimulation–related and postimplant-related problems. Of the 914 test stimulation procedures done on the 581 patients, 181 adverse events occurred in 166 of these procedures (18.2% of the 914 procedures). **Most complications were related to lead migration (108 events, 11.8% of procedures). Technical problems and pain represented 2.6% and 2.1% of the adverse events, respectively. For the 219 patients who underwent implantation of the InterStim system (lead and generator), pain at the neurostimulator site was the most commonly observed adverse effect at 12 months (15.3%). Surgical revision of the implanted neurostimulator or lead system was performed in 33.3% of cases (73 of 219 patients) to resolve an adverse event. This included relocation of the neurostimulator because of pain at the subcutaneous pocket site and revision of the lead for suspected migration. Explant of the system was performed in 10.5% for lack of efficacy. One should consider the fact that, at the time, the generator was implanted in the lower abdomen.**

Everaert and associates (2004) reported specifically on the complications with SNS. This was a retrospective study of 53 patients who had undergone implantation of the quadripolar electrode (Medtronic InterStim, model 3886 or 3080) and subcutaneous pulse generator in the abdominal site (Medtronic Itrel 2 IPG) between 1994 and 1998. Device-related pain was the most frequent problem and occurred equally in all implantation sites (sacral, flank, and abdominal). This occurred in 18 of the 53 patients (34%) and was more frequent in patients with dysuria and retention or perineal pain. Pain responded to physiotherapy in 8 patients, and no explantation was done for pain reasons. Current-related complications occurred in 11%. They performed 15 revisions in 12 patients. Revisions for prosthesis-related pain (n = 3) and for late failures (n = 6) were not successful. Similar series have been published by White and associates (2009) and show relatively low rates (30%) of adverse events and may have been predicted by trauma, body mass index and enrollment into a pain clinic, and history of adverse events.

A review (Hijaz and Vasavada, 2005) of the tined lead approach was performed at the Cleveland Clinic from June 2002 to June 2004 when 167 patients underwent sacral neuromodulation for indications of refractory overactive bladder, idiopathic and neurogenic urinary retention, and interstitial cystitis. In this cohort, 180 stage I operations used the tined lead approach. After 2 to 4 weeks of test stimulation, 130 (72.2%) patients proceeded to stage II implantation of the IPG.

Stage I complications can lead to explantation or revision of the tined lead. The reasons for either fall under response related, mechanical, or infection related. In this series, 50 tined leads were explanted (27.8%). The majority of lead explantations were performed for unsatisfactory or poor clinical response (46 of 50; 92%). The rest of the explantations were done for infection (4 of 50; 8%). Explantation for response reasons is not truly considered a complication as much as it is an integral part of the procedure. Stage I revisions totaled 22 of the 180 operations (12.2%). Revisions were done for marginal response (13 of 22), frayed subcutaneous extension wire (6 of 22), lead infection (3 of 22), and improper localization of stimulus (1 of 22). Eleven (50%) of the revisions proceeded to stage II generator implantation. When the revision was done for a marginal response (13 of 22), the response was ultimately clinically satisfactory in 5 of 13 (38.5%), and patients proceeded to generator implantation. Typically, when the patient reported a marginal or equivocal response during the test stimulation in the absence of infection or mechanical problems, a lead revision was offered with intraoperative sensory testing. Because 38.5% of these revisions eventually were successful and patients proceeded to stage II, this is an option to keep in mind in motivated patients with equivocal response.

As in stage I, stage II complications can be divided into explantation (generator and lead) or revision. Explantation was performed in 16 of 130 (12.3%). Explantations were done for infection and failure to maintain response in 56.3% and 43.7%, respectively. Revisions were done for infection, mechanical (generator related), and response causes. The revision rate of stage II in this series was 20% (26 of 130).

When infection at the generator site is diagnosed, the best management is explantation of the whole system.

Response-related complications necessitating revision are more common (18 of 26). The algorithm for management of a patient who presents with a decreased or absent response after a successful interval is outlined in Figure 70–8.

The outlined algorithm includes testing of impedances (Fig. 70–9). **Impedance describes the resistance to the flow of electrons through a circuit. Impedance or resistance is an integral part of any functioning circuit. However, if there is too much resistance, no current will flow (open). If there is too little resistance, excessive current flow results in diminished battery longevity (short). The electrical circuit that we are referring to starts at the neurostimulator's circuitry and goes through the connectors to the extension wires, through the extension connector to the lead wires, through the lead's electrodes to the patient's tissue, and back either through another electrode and up the same path to the circuitry (bipolar) or to the neurostimulator case and into the circuitry (unipolar).**

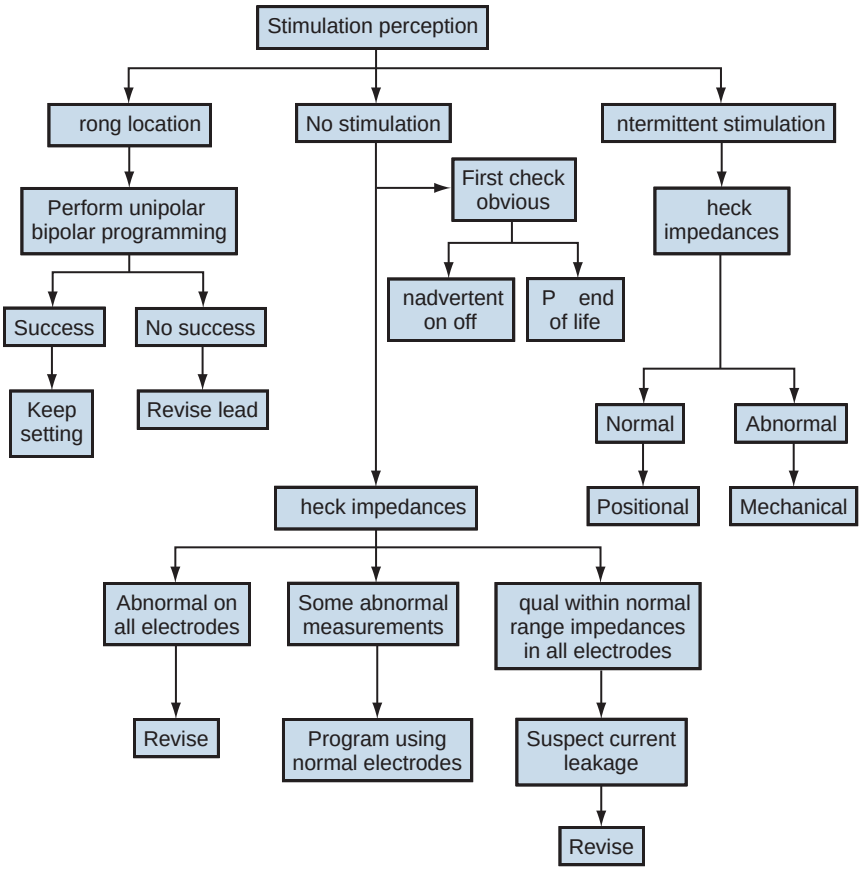

Figure 70–8. Diagnostic algorithm and troubleshooting for recurrent symptoms. IPG, implantable pulse generator.

If the circuit is broken somehow, electrons cannot flow. **This is called an open circuit, and impedance measurements are high.** Open circuits can be caused by a fractured lead or extension wires and loose connections. Patients generally feel no stimulation if an open circuit is present. In measurement of impedances by the programmer, **unipolar measurements are most useful for identifying open circuits** because they take one lead wire measurement at a time, immediately identifying which connection or wire has the problem.

Short circuits, which are reflected in **low impedance measurements,** can be caused by body fluid intrusion into the connectors or crushed wires that are touching each other. The electrons will always follow the path of least resistance. Patients may or may not feel stimulation, or stimulation may not be present in the correct area (i.e., the generator site) or may vary in strength (i.e., a surging sensation). In measurement of impedances by the programmer, **bipolar measurements are most useful for identifying shorts between two wires.**

Therefore, impedance measurement is used as a troubleshooting tool to check the integrity of the system when a patient presents with a sudden or gradual disappearance of stimulation. Many measurements fall within the 400- to 1500-ohm range. High levels (>4000 ohms) identify open circuits, and low levels (<50 ohms) identify short circuits. Medtronic (manufacturer of the InterStim) recommends performing the impedance measurements at the time of closure of the incision, at the first programming session, to get a baseline measurement and at any time a problem is suspected. These measurements will identify which electrodes, if any, are intact and allow the programmer to proceed with programming of only those with acceptable impedance measurements. If all electrode measurements read above 4000 ohms, a revision may be necessary.

The intraoperative algorithm for management of impedance problems includes initial testing of impedances (see Fig. 70–9). First, the tined lead is disconnected from the extension to the IPG and then dried. The connection may be irrigated with sterile water, and then the connection is dried with the 3-Fr ENT suction device before it is reconnected again. At this stage the impedances are repeated. If they normalize, the revision can be concluded at this stage. If impedances continue to be abnormal, one can evaluate or change the 10-cm extension and retest impedances. If they continue to be abnormal, the lead is revised. It has been the authors' experience that the connections to the IPG and the IPG itself seldom have anything to do with abnormal impedance values.

Troubleshooting Algorithm

After successful completion of stage II, a number of events can occur, and the treating physician should develop an algorithm to handle these events in a timely and efficient manner. These events with their probable causes and the troubleshooting algorithm are covered in this section.

Pocket (IPG Site) Discomfort. The probable causes of this symptom are pocket related or output related. Pocket-related causes of discomfort include infection, pocket location (waistline), pocket dimension (too tight, too loose), seroma, and erosion. Output-related causes include sensitivity to unipolar stimulation if this mode is used or current leak. To troubleshoot this problem the evaluating specialist is advised to do the following (Fig. 70–10):

1. Turn off the device and ask the patient if the discomfort is still present to differentiate pocket-related from output-related causes.

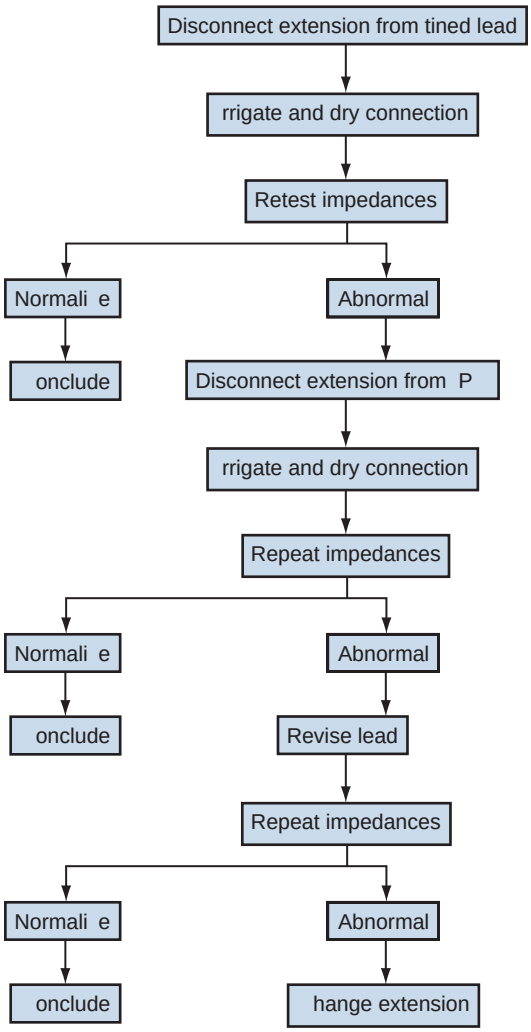

Figure 70–9. Intraoperative algorithm for impedance problem management. IPG, implantable pulse generator.

2. If the discomfort persists, the cause is not related to the device output. In the absence of clinical signs of infection, pocket-related causes such as pocket size, seroma, and erosion must be considered.
3. If the discomfort disappears, device output is probably causing discomfort. If the stimulation program is unipolar, switch to bipolar and see whether that eliminates discomfort. Some patients are sensitive to the unipolar mode of stimulation, because the positive pole is the neurostimulator itself. Another possibility is leakage of fluid into the connector. This somehow creates a short circuit whereby the current from the device now follows this fluid pathway out to the patient's tissue. Most patients report this as a burning sensation. Even though current is following this fluid out to the patient's tissue, some of the current may also be getting to the electrodes as well, so some patients feel both burning in the pocket and stimulation in the perineum. One can try reprogramming around this by using different electrode combinations. If reprogramming is unsuccessful, the patient is asked if the "burning" sensation is tolerable (it will not harm the patient's tissues); if it is not tolerable, a revision may be necessary to dry out the connection sites.

Recurrent Symptoms. When the patient presents with recurrent symptoms, evaluation of the stimulation perception is necessary.

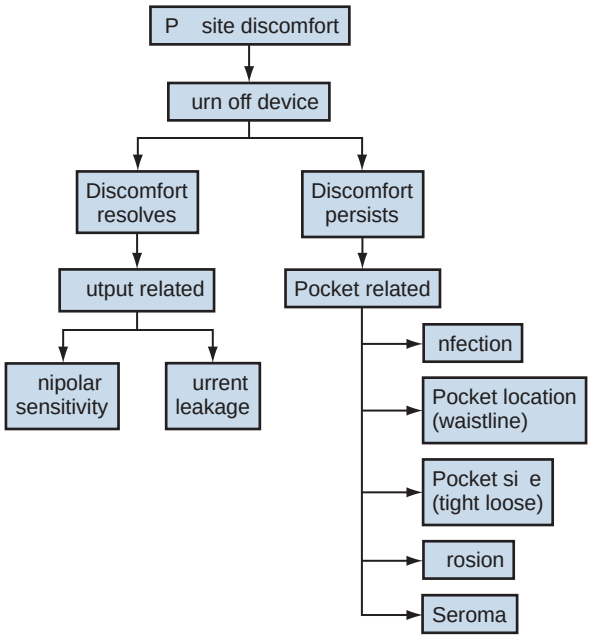

Figure 70–10. Troubleshooting algorithm for implantable pulse generator site discomfort.

The possibilities are that the patient perceives the stimulation in a wrong location compared with baseline, has no stimulation, or has intermittent stimulation.

Wrong Location. If the patient reports that the stimulation location or pattern has changed, it is best to go back to each unipolar setting and "map" out where the patient feels the stimulation. The device is set to 0–, case+ and the patient is asked where she or he feels the sensation; next it is set to 1–, case+ and the patient again is asked about the sensation; next it is set to 2–, case+ and finally to 3–, case+. If these combinations do not confirm the target area, the next step is to start programming bipolar combinations. When those are exhausted, sometimes increasing the pulse width widens the stimulation area. If the programming possibilities are exhausted, then revision for lead repositioning or relocation to the other side may be necessary.

No Stimulation. The obvious is checked first. The device parameters must be set high enough, an inadvertent on-off is checked (set magnet switch off to avoid inadvertent magnet activations), and whether the IPG is nearing the end of its life is checked. Next impedance readings are performed, paying close attention to unipolar impedances. These impedances measure one lead wire with the case, so it is easy to isolate a problem. Using unipolar impedances, it is possible to tell which lead wires are still intact and which ones are not, as mentioned previously. Programming of the electrodes is then continued with acceptable impedance measurements. Bipolar measurements are checked to rule out short circuits as well (very low impedance measurements). If programming around the malfunctioning lead does not restore the stimulation, the patient will often need to undergo revision.

Intermittent Stimulation. Again, inadvertent on-off is checked. Intermittent stimulation can be caused by either a loose connection or positional sensitivity. If a loose connection is suspected, palpating the connection site and re-creating the intermittency is a good clue as to where the problem lies. Taking impedances while the patient reports the stimulation intermittently determines whether the problem is positional (acceptable impedances are still present) or mechanical (when the patient feels stimulation go off,

the impedances are high). With positional sensitivity, the lead position shifts when a patient moves in a certain direction (for instance, the patient reports that the stimulation goes away on standing). The lead position may have moved farther from the nerve during standing, and the amplitude may just need to be increased. Intermittent stimulation represents a challenging dilemma to troubleshoot.

ELECTRICAL STIMULATION FOR EMPTYING DISORDERS

There exists strong evidence to suggest that neuromodulation works through supraspinal pathways (see the section on neurophysiology of electrical stimulation). The question of how it works for refractory detrusor overactivity as well as for urinary retention is based on changes in supraspinal pathways and perhaps the guarding reflex. It is important to understand that before neuromodulation, neurostimulation was applied in different forms to achieve bladder emptying. Still, neurostimulation has a role today in management of disorders of bladder emptying and has evolved through many different versions before its current techniques.

Electrical Stimulation Directly to the Bladder or Spinal Cord

Clinical trials of direct electrical stimulation of the bladder to facilitate emptying originated in 1940 but have met with only partial success and intermittent enthusiasm since then (Wein and Barrett, 1988). **Direct electrical stimulation was most effective in patients with hypotonic and areflexic bladders.** Initial success, defined as low postvoid residual urine volume with sterile urine, was achieved in only 50% to 60% of patients, and **secondary failure often supervened, usually related to fibrosis, electrode malfunction, bladder erosion, or other equipment malfunction. The spread of current to other pelvic structures with a stimulus threshold lower than that of the bladder often resulted in abdominal, pelvic, and perineal pain; a desire to defecate or defecation; contraction of the pelvic and leg muscles; and erection and ejaculation in male patients. It was also noted that the increase in intravesical pressure was generally not coordinated with bladder neck opening or with pelvic floor relaxation and that other measures to accomplish these ends could be necessary.** Direct electrical stimulation of the sacral spinal cord was also performed as an attempt to take advantage of the remaining motor pathways to initiate micturition. Although some short-term success was noted, many of the side effects seen with direct bladder stimulation occurred as well because the stimulus applied in this way was also unphysiologic. **Enthusiasm for both of these approaches has waned considerably, and resurrection seems unlikely.**

Electrical Stimulation to the Nerve Roots

For the past 25 to 30 years, Brindley (1993) and the Tanagho group (Tanagho and Schmidt, 1988; Tanagho et al, 1989) have pursued neurostimulation for the treatment of voiding dysfunction. The use of electrical stimulation for storage disorders and pelvic floor dysfunction has been covered. **The focus of this section is on the use of anterior root electrical stimulation to facilitate emptying.**

The Brindley device is the one most commonly used. Prerequisites for such use are described by Madersbacher and Fischer (Fischer et al, 1993) **as (1) intact neural pathways between the sacral cord nuclei of the pelvic nerve and the bladder and (2) a bladder that is capable of contracting. The chief applications are in patients with inefficient or nonreflex micturition after spinal cord injury. Simultaneous bladder and striated sphincter stimulation is obviated by sacral posterior rhizotomy, usually complete, which eliminates reflex incontinence and improves low bladder compliance,** if it is present (Brindley, 1994). The stimulation sequences and parameters themselves and their neurophysiologic consequences lead to less striated sphincter dyssynergia, even without posterior rhizotomy, than is seen in reflex micturition in a spinal cord–injured patient. Complete sacral deafferentation is usually performed, however, with the exception listed by Brindley as those patients who have genital sensation or useful reflex erections. **Electrodes are applied intradurally** to S2, S3, and S4 nerve roots, but the pairs can be activated independently (Fig. 70–11). **The detrusor is usually innervated primarily by S3 and to a smaller extent by S2 or S4. Rectal stimulation is by means of all three roots equally. Erectile stimulation is chiefly by S2 with a small contribution from S3 and none from S4.** Micturition, defecation, and erection programs are possible, with stimulus patterns set specifically for each patient (Brindley, 1994). The ventral sacral roots, however, carry both parasympathetic fibers to the bladder and somatic fibers to the striated sphincter. Ventral root stimulation therefore occasionally results in detrusor–striated sphincter dyssynergia.

The current Brindley stimulator uses the principle of *post-stimulus voiding*, a term first introduced by Jonas and Tanagho (1975) **to obviate this. Relaxation time of the striated sphincter after a stimulus train is shorter than the relaxation time of the detrusor smooth muscle. When interrupted pulse trains are used, voiding is achieved between the pulse trains because of the sustained high intravesical pressure.** This concept and other methods that are available to overcome the stimulation-induced sphincter dyssynergia and allow low-pressure emptying are nicely reviewed by Rijkhoff and colleagues (1997). **Post-stimulus voiding has a few shortcomings, described in this article as follows: voiding occurs in spurts at above-normal bladder pressures; when the stimulus parameters are not properly adjusted the detrusor pressures can become too high, putting the upper tracts at risk; and movement of the lower limbs occurs during stimulation because the nerve roots also contain fibers innervating leg musculature, and this movement can be cumbersome for the patient.**

Brindley (1994) carefully reviewed the experience in the first 500 patients treated with his prosthesis with a total follow-up, at that time, of 2033.5 years. Of the total, 2 patients were lost to follow-up and 21 had died. Of the deaths, two were from septicemia (one definitely unrelated to the implant and the specifics of the other unmentioned) and one from related renal failure; the causes of five were unknown. Ninety-five reoperations were required for repair, six stimulators were removed (four infected), and two were awaiting repair. In 45 patients the stimulator was believed to be intact but not used for various reasons. In all others the stimulators were in use (411 for micturition and in most for defecation and in 13 for defecation alone) and the users were

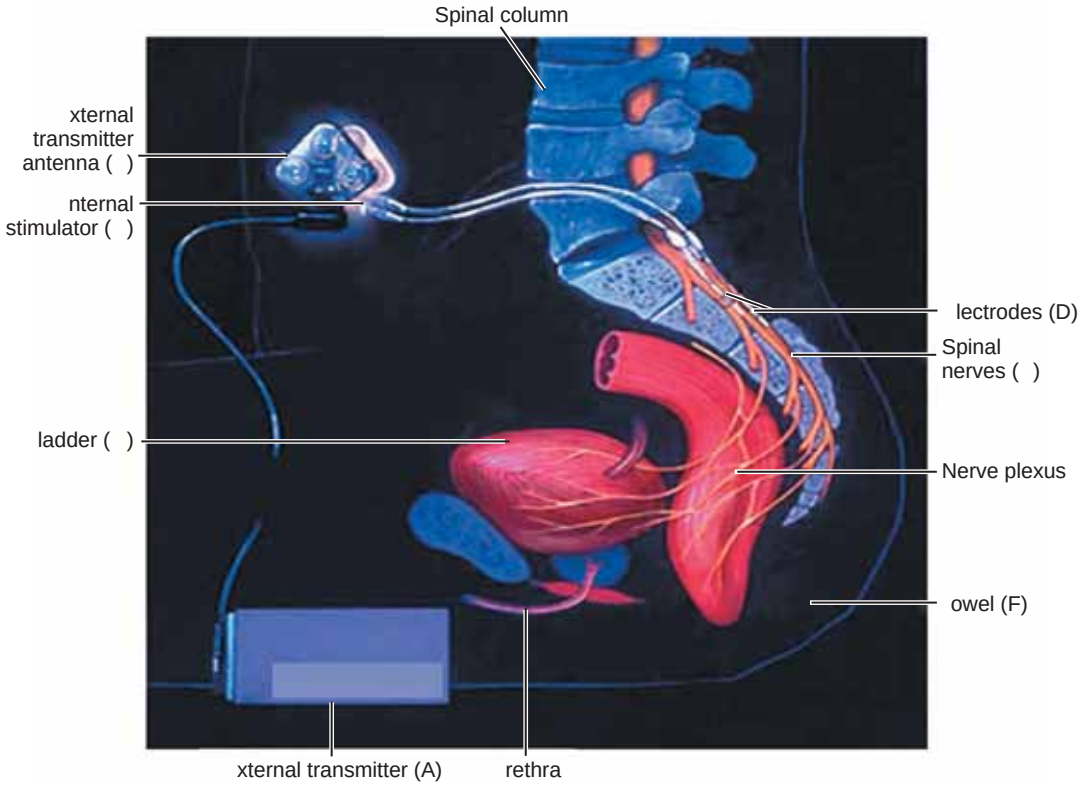

Figure 70–11. Brindley-Finetech system for sacral root stimulation. (Courtesy of NDI Medical, Cleveland, OH.)

believed to be "pleased." Upper tract deterioration was reported in only 2 of 365 patients with full deafferentation and in 10 of 135 with incomplete or no deafferentation. Two of these 10 had impaired renal function, and 1 died of this condition.

van Kerrebroeck and associates (1997) reported the results of use of the Finetech-Brindley stimulator in 52 patients. These patients were selected by screening 226 patients; complete posterior sacral root rhizotomies were performed in all. Thirty-seven of the patients had 6 months of follow-up; in these patients, complete daytime continence was achieved in 73% and night-time continence in 86%. There were significant increases in bladder capacity and bladder compliance, and residual urine was reduced significantly. Complications included cerebrospinal fluid leaks, which resolved spontaneously in 23 patients; nerve damage that resolved in 1 patient; and one implant failure caused by a cable fracture, which was successfully repaired. Sauerwein and colleagues (1999) reported in abstract form the results of sacral deafferentation and implantation of an anterior sacral root stimulator in 294 patients with spinal cord injury. Bladder spasticity was relieved in all. In 50%, micturition was achieved by stimulating S4 and S5 sacral ventral roots; in the remaining cases, it was achieved by stimulating the S2 and S3 roots. **Variations in surgical approaches designed to achieve stimulation of only bladder contraction are described by** Dahms and associates (2000), **who also summarize overall success rates for sacral ventral root stimulation in spinal cord–injured patients at about 75%. Recent laparoscopic access techniques have minimized the invasiveness of this procedure and may have a role in the future in this select group of patients** (Possover, 2009).

Extradural stimulation has been used by the Tanagho group (Tanagho and Schmidt, 1988; Schmidt, 1989; Tanagho et al, 1989) in the treatment of 19 patients with serious and refractory neuropathic voiding disorders. Extensive dorsal rhizotomy was performed, and a stimulator was implanted on the ventral component of S3 or S4 with selective peripheral neurotomy (Tanagho et al, 1989). In eight patients (42%), complete success was achieved with reservoir function, continence, and low-pressure/low residual voiding with electrical stimulation. Ten patients qualified as achieving partial success, regaining reservoir function and obtaining continence.

Electrical stimulation of the ventral sacral roots with some techniques to reduce detrusor hyperactivity and obviate striated sphincter dyssynergia has become an accepted treatment modality for lower urinary tract dysfunction in spinal cord–injured patients. Although more detailed follow-up is necessary, and further evolution will doubtless occur, these techniques have achieved remarkable improvements and success rates, which now seem to have stabilized at a high level.

Transurethral Electrical Bladder Stimulation

Intravesical electrotherapy is an old technique that has been resurrected with some interesting and promising results. The use of this technique to increase bladder capacity and to increase compliance has previously been discussed. This section deals with **the use of TEBS to facilitate bladder emptying by establishing conscious control of the initiation and completion of a micturition reflex.** Fischer and colleagues (1993) describe their concept of the basis for this use as follows. **In patients with incomplete central or peripheral nerve lesions—**and only these patients are suitable for this method—**at least some nerve pathways between the bladder and the cerebral centers**

are preserved but are too weak to be efficient under normal circumstances. TEBS in this situation is hypothesized to activate specific mechanoreceptors in the bladder wall. With depolarization of these receptors, activation of the intramural motor system is said to occur, resulting in small local muscle contractions that further depolarize the receptor cells. As soon as this local motor reaction reaches a certain strength, "vegetative afferentation" begins, meaning that stimuli travel along afferent pathways to the corresponding cerebral structures with the occurrence of sensation. This, in time, reinforces efferent pathways, and their stimuli create centrally induced and more coordinated and stronger detrusor contractions. Ebner and coworkers (1992) **simply conceptualize the mechanism as involving an artificial activation of the normal micturition reflex and further suggest that repeated activation of this pathway may "upgrade" its performance during voluntary micturition.**

Children with congenital neurogenic bladder dysfunction who have never experienced the urge to void require a biofeedback system to realize the nature and meaning of this new sensation induced by TEBS. This exteroceptive stimulation is also important for other groups of patients because it signals detrusor contractions and whether, and to what degree, voluntary detrusor control is or has become possible and, by demonstrating progress, serves as positive feedback.

This technique involves direct intraluminal monopolar electrical stimulation with a special catheter equipped with a stimulation electrode. Saline solution is used as the current-leading fluid medium in the bladder. Exteroceptive reinforcement is achieved by visual recording of detrusor contractions on a water manometer connected to the stimulation catheter. An intensive bladder training program has to be combined with TEBS and must be highly individualized. **Only patients with an incomplete spinal cord lesion and with receptors still capable of reactivity and with a detrusor still capable of contractility will benefit from this technique. The achievement of conscious control requires, in addition, an intact cortex.**

Fischer and colleagues (1993) have used this technique in patients with incomplete spinal cord injury and other incomplete central or peripheral lesions of bladder innervation, in pediatric patients with congenital neurogenic lower urinary tract dysfunction, and in patients, especially children, with non-neurogenic dysfunction voiding. Only patients with preserved pain sensation in sacral dermatomes S2 through S4 improved with this technique. The technique is time consuming because stimulation must be performed on a daily basis for weeks and months, with an individual treatment time of about 90 minutes. Kaplan and Richards (1988) reported on such therapy in myelodysplastic children, performing the treatment for 60 minutes (during a 90-minute catheterization), 3 to 5 days a week for 15 to 30 daily sessions. Of 62 patients evaluated, 42 completed at least one series of treatment. "Success" was defined differently for infants than for older children. For infants, success implied a decrease in filling pressure, an increase in the quality of bladder contraction, and a decrease in residual urine. For older children, this type of result implied a heightened awareness of detrusor contractions before and during a contraction, maintenance of low-pressure filling, effectively emptying detrusor contractions with low residual urine, and either a conscious urinary control or timely enough sensory input to allow clean intermittent catheterization for continence. Of children who initially had some detrusor contraction on initial evaluation, 80% were said to have achieved some or all of the success parameters. Of those with no initial detrusor activity, 33% achieved some success.

Other reports have been less optimistic. Lyne and Bellinger (1993) **reported the results of TEBS treatment of 17 patients with neurologic dysfunction, 10 with myelomeningocele, and 2 with lipomeningocele. Ultimately, all patients showed detrusor contraction during therapy (12 did so initially), but results related to increased bladder capacity and improved continence were disappointing. Five patients showed minor positive changes in continence. After completion of therapy in 12 patients who had serial cystometry, 5 experienced an increase in capacity (14% to 158%) and 4 a decrease (7% to 37%).** Decter and associates (1994) used TEBS in 25 patients with neurogenic voiding dysfunction. TEBS was correlated with an increase from 18 to 24 in the number of patients who manifested contraction on stimulation and from 3 to 12 in the number who sensed contraction during stimulation. However, cystometry showed a more than 20% increase in the age-adjusted bladder capacity in only 6 of 18 patients with serial studies and clinically significant improvements in end-filling pressures in 5 of these. A telephone questionnaire revealed that 10 of 18 patients or parents perceived an improvement in bladder function, but the authors stated that "the limited urodynamic benefits our patients achieved have not materially altered the daily voiding regimen and, because of these factors, we are not enrolling any new patients in our…program." **This technique is certainly controversial.** Some question the theoretical basis and the definitions of "success" applied to patients treated. **Currently, even** Kaplan (2000) **does not seem enthusiastic about the use of this technique to attain the goal of volitional voiding, and** Decter (2000), **as previously pointed out, stated that, in his opinion, TEBS is a modality with limited clinical efficacy for facilitation of filling-storage and emptying.**

Sacral Neuromodulation of Emptying Disorders

Sacral neuromodulation has been successful in patients with idiopathic nonobstructive retention, in patients with retention secondary to deafferentation of the bladder after hysterectomy, and in patients with Fowler syndrome (Dasgupta et al, 2004; De Ridder et al, 2007). Patient factors predictive of success have been sought, and increasing numbers of reports are differentiating results of sacral neurostimulation in urinary retention based on the functional disorders causing the condition, detrusor acontractility, and functional outlet obstruction. Bross and coworkers (2003) evaluated the predictive ability of the carbachol test and concomitant diseases in patients with an acontractile bladder. Whereas 33% of patients had a successful bilateral percutaneous nerve evaluation, a positive carbachol test result was not predictive of success. Goh and Diokno (2007) in a retrospective study of patients implanted for nonobstructive urinary retention found a statistically significant difference in predicting success of test stimulation for patients with a preimplantation ability to void (>50 mL) versus non-voiders. Further evidence of the predictive role of detrusor function was reported by Bertapelle and colleagues (2008) in developing a detrusor contractility test using urodynamics in conjunction with sacral neurostimulation in urinary retention as an exclusion criteria for sacral neurostimulation; this test appears to be a reliable tool to rule out detrusor acontractility due to irreversible bladder

myopathy or complete neurogenic lesion and to predict success of permanent sacral neuromodulation.

A large, prospective, randomized multicenter trial to evaluate the efficacy of SNS for urinary retention was performed by Jonas and colleagues (2001). After a percutaneous nerve evaluation period of 3 to 7 days, 68 patients (38% of those evaluated) with chronic urinary retention qualified for permanent implantation. Patients were randomly assigned to the treatment or control group, in which treatment was delayed for 6 months. Successful results were initially achieved in 83% of patients who received the implant, with 69% able to discontinue intermittent catheterization completely. At 18 months, 71% of patients available for follow-up had sustained improvement. These results have been corroborated by others with longer follow-up (Datta et al, 2008; White et al, 2008).

Aboseif and coworkers (2002) **evaluated the efficacy and change in quality of life in patients with idiopathic, chronic, nonobstructive functional urinary retention. Thirty-two patients with idiopathic retention requiring intermittent catheterization underwent percutaneous nerve evaluation. Permanent implants were placed in 20 patients (17 women) who showed more than 50% improvement in symptoms.** Eighteen patients were subsequently able to void and no longer required intermittent catheterization; one patient required bilateral SNS implants. Average voided volumes increased from 48 to 198 mL, and postvoid residual volume decreased from 315 to 60 mL. Eighteen patients reported more than 50% improvement in quality of life, although the questionnaire used in the study was not described. Significant score improvements in the Beck Depression Inventory and SF-36 after sacral root neuromodulation for retention have been demonstrated by Shaker and Hassouna (1998). **Overall success rates of the percutaneous nerve evaluation range from 33.3% to 100%** (Koldewijn et al, 1994; Scheepens et al, 2002; Spinelli et al, 2003). Improvement in patients with retention may not be as rapid as in patients undergoing sacral root stimulation for other reasons. A percutaneous nerve evaluation period of at least 2 to 3 weeks and a permanent implant lead evaluation of 4 weeks or more have generally been recommended. **Furthermore, bilateral or caudal SNS for urinary retention may be considered initially or for unilateral SNS trial failures, although this technique is performed infrequently and is less studied to date** (van Kerrebroeck et al, 2005; Maher et al, 2007; Pham et al, 2008).

FUTURE RESEARCH AND CONCLUSIONS

During the past century, neurostimulation and neuromodulation that originated in the 19th century have been clinically adopted. Advances in electrical innovations and our understanding of neurophysiology have provided important discoveries for the care of people with neuromuscular causes of their pelvic organ dysfunctions. To date, influencing these dysfunctions at the level of the sacral roots appears to have stood the test of time and has become generalizable to physicians worldwide. At the start of our next century of using this expanding therapy, we will need to urgently focus on developing the supportive clinical research needed to drive further innovations and acceptance of wider clinical indications and applications. Long-term surveillance studies and randomized clinical trials to compare different techniques and nerve locations and to evaluate placebo effects are critically needed, as are more studies to elucidate modes of action to improve stimulation applications, selection of patients, and therapeutic results.

The introduction of new stimulation methods as well as application of these methods to different nerve locations will continue to provide improved treatment alternatives. In addition, these innovations will provide the ability to further develop testable hypotheses of more basic questions on electrical neurostimulation, neuromodulation, and neurophysiology of the autonomic, somatic, and central pathways that regulate pelvic organ function. Such questions need to address the observed lack of neural plasticity-induced changes with long-term neuromodulation and neurostimulation despite acute cellular changes identified in nerve signaling molecules secondary to magnetic and electrical field changes.

In their present form, neurostimulation and neuromodulation work acutely through continuous electrical activity without inducing long-term neuroplastic changes. Therefore, future technologies are likely to provide closed-loop conditional stimulation, much in the same manner as "on-demand" cardiac pacemakers and defibrillators do, as a means to obtain better efficacy without additional adverse electric field effects. The development of change from the present open-loop stimulation to closed-loop conditional stimulation will necessitate innovations in neurosensing of pathologic neuromuscular events of the pelvis that will lead to on-demand therapeutic electrical activity. These innovations will in turn have a profound effect on our diagnostic ability to predict clinical responses to neurostimulation and neuromodulation as we seek to maximize our benefit-risk and benefit-cost ratios in patient care.

Key Points: Electrical Stimulation

- Neuromodulation is a field clearly in its infancy.
- Current techniques of sacral neuromodulation are indicated for treatment of refractory urgency/frequency, urgency urinary incontinence, and nonobstructive urinary retention.
- Sacral neuromodulation has yielded successful stage I to stage II conversion rates based on 50% symptom improvement in more than 60% of patients for urgency/frequency and urgency urinary incontinence.
- The exact best nerves to stimulate have yet to be realized, but data seem to be focusing on more selective nerve stimulation, particularly in complex subgroups such as patients with neurogenic bladders. Focused research on risk factor analysis of who is the best candidate for therapy will be beneficial to selection criteria.
- Transurethral electrical stimulation has fallen out of favor for the most part.
- Transcutaneous electrical stimulation, although demonstrating good efficacy, seems to have a more limited role because of the constant need to administer the therapy but its minimal invasiveness may allow a resurgence in interest in this therapy.
- Expanding indications for neuromodulation are likely to dominate the literature in the coming years as comfort with neuromodulation increases and more challenging subgroups are addressed.

Laparoscopic Retropubic Suspension
Complications of Retropubic Repairs
Comparisons Between Incontinence Procedures

Continence in the woman results from a complex interplay of anatomic and physiologic properties of the lower urinary tract (bladder, urethra and sphincter, and pelvic floor) acting under the coordinating control of an intact central and peripheral nervous system. The role of the pelvic floor is to provide support to both the bladder and urethra and to facilitate normal abdominal pressure transmission to the proximal urethra, thereby maintaining continence.

Stress incontinence is a symptom, a sign, and a clinical diagnosis; the clinical symptom is that of involuntary loss of urine associated with increased intra-abdominal pressure, such as occurs during coughing and sneezing. The International Continence Society (ICS) defines *urodynamic stress incontinence* as the involuntary loss of urine during increased intra-abdominal pressure during filling cystometry, in the absence of detrusor (bladder wall muscle) contraction (Abrams et al, 2002). Thus, urodynamic evaluation is a prerequisite for the diagnosis of urodynamic stress incontinence. Therefore, in discussing stress incontinence, this review refers to women with stress urinary incontinence (SUI) diagnosed on the basis of symptoms alone or urodynamically proven, so-called urodynamic stress incontinence.

Treatment options for SUI include conservative techniques and both pharmacologic and surgical interventions. Surgical procedures to treat SUI generally aim to improve the support to the urethrovesical junction and to correct deficient urethral closure. There is a contemporary lack of consensus, however, regarding the precise mechanism by which continence is achieved in the "normal asymptomatic female" and therefore not surprisingly in how "normality" is restored by surgical manipulation. Anti-incontinence surgery is generally used to address the failure of normal anatomic support of the bladder neck and proximal urethra and intrinsic sphincter deficiency. **Anti-incontinence surgery does not necessarily work by restoring the same mechanism of continence that was present before the onset of incontinence. Rather, it works by a compensatory approach, creating a new mechanism of continence** (Jarvis, 1994a).

THERAPEUTIC OPTIONS

The surgeon's preference, coexisting problems, and anatomic features of the patient and her general health condition influence the choice of procedure. Numerous surgical methods have been described, but they essentially fall into seven categories (Table 71–1).

This wide variety of treatment options for stress incontinence indicates the lack of a clear consensus as to which procedure is the most effective. Several groups have reviewed the literature, often using systematic and methodical analyses of well-designed randomized controlled trials (Jarvis, 1994b; Black and Downs, 1996; Fantl et al, 1996; Leach et al, 1997; Moehrer et al, 2002, 2003; Lapitan et al, 2003). **Most of these reviews, however, are hampered by the quality of the existing evidence base, and these reviews are based on studies of mixed quality with little standardization of the points in** Table 71-2.

A review of existing literature on confounding variables affecting outcome of therapy (Smith et al, 2005) concluded the following:

1. **Age may not be a contraindication to colposuspension,** with equivalent success rates in the elderly at long-term follow-up (Gillon and Stanton, 1984; Tamussino et al, 1999), although others reported less success with increasing age (Langer et al, 2001; Chilaka et al, 2002). Smith and associates (2009), from their review of the literature, concluded that the affect of age on outcomes is poorly undefined. The affect of aging on the lower urinary tract includes a higher rate of detrusor overactivity, as well as

Outcome measures and follow-up

urgency incontinence and intrinsic sphincteric deficiency. In addition, older patients are more likely to have had prior interventions and may, therefore, have a higher rate of periurethral fibrosis and/or other abnormalities in the area tissues surrounding the lower urinary tract. The presence of multiple comorbidities may also affect overall surgical outcome, including creating the possibility for increased complications and prolonged postoperative course.

2. The influence of the level of postoperative activity has been inadequately studied, so that no recommendations can be made (Smith et al, 2009).
3. There is level 4 evidence that medical comorbidity may have an impact on surgical outcomes, depending on the outcomes selected. There is level 3 evidence that psychologic factors have an impact on subjective and objective outcomes in different ways (Smith et al, 2005).
4. Obesity as a confounding variable is the subject of conflicting evidence in the literature and has not been studied in a prospective fashion. Obesity has been studied only retrospectively in case series as a risk factor for success or morbidity in stress incontinence surgery (level 4 evidence). There are no prospective, randomized trials that suggest superiority of one surgical technique over another in the obese population. Some studies have suggested increased failure rates in obese patients undergoing retropubic colposuspension (Brieger and Korda, 1992; Alcalay et al, 1995). Conversely, in a retrospective study of 198 women undergoing anti-incontinence surgery, cure rates were markedly better in those undergoing Burch colposuspension (Zivkovic et al, 1999).
5. **Surgery for recurrent stress incontinence has a lower success rate.** One study has reported that Burch colposuspension has an 81% success rate after one previous surgical procedure has failed, but this drops to 25% after two previous repairs and to 0% after three previous operations (Petrou and Frank, 2001). Other series report excellent results for colposuspension carried out after prior failed surgery. Maher and colleagues (1999) and Cardozo and associates (1999) have shown good objective (72% and 79%) and subjective (89% and 80%) success rates with repeated colposuspension at a mean follow-up of 9 months. Nitahara and coworkers (1999) reported a 69% subjective success at a mean follow-up of 6.9 years.
6. Berglund and associates (1996) reported that the duration of symptoms is a predictor of outcome, with a better response in those with a shorter history, which as a finding was independent of type of approach (e.g., vaginal versus retropubic). Ward and Hilton (2002), in a randomized comparison of colposuspension and tension-free vaginal tape, found no significant impact of symptom severity on outcomes for either procedure. Tamussino and coworkers (1999), in a review of 327 women assessed a minimum of 5 years postoperatively, noted that women with moderate or severe incontinence fared worse than those with milder symptoms. In their series, only Burch colposuspension was unaffected by the severity of preoperative symptoms.
7. It has been reported that as many as 23% of women undergoing urodynamics have mixed urodynamic stress incontinence and detrusor overactivity (Clarke, 1997). In a retrospective cohort study, Colombo and associates (1996b) compared 44 women with mixed incontinence with a matched group with urodynamic stress incontinence. The cure rate was 95% in the latter group compared with 75% in the former. Other studies report a less favorable outcome of 24% to 43% in those with detrusor overactivity combined with stress incontinence (Stanton et al, 1978; Milani et al, 1985; Lose et al, 1988). Smith and associates (2009) conclude that **surgery for urodynamic stress incontinence should not be considered contraindicated in women with mixed symptoms of SUI and overactive bladder syndrome or mixed urodynamic findings of urodynamic stress incontinence and detrusor overactivity (grade B).** All patients undergoing surgery for SUI should be appropriately counseled to allow realistic expectations of outcome; this is particularly important in those with mixed symptoms or mixed urodynamic incontinence (grade B).
8. The International Consultation on Incontinence (ICI), although allowing the fact that there is no consensus on the definition of intrinsic sphincter deficiency, concluded that there are limited evidence-based data to support that intrinsic sphincter deficiency influences either the outcomes of surgery or the type of surgical treatment (Smith et al, 2005, 2009). It would appear that a low leak point pressure is less predictive of outcome when compared with the presence or absence of urethral hypermobility (Smith et al, 2009).

CHOICE OF SURGICAL TECHNIQUE

Two types of stress incontinence have been suggested: one associated with a hypermobile but otherwise healthy urethra, a manifestation of weakened support of the proximal urethra, and one arising from a deficiency of the urethral sphincter mechanism itself, thereby compromising the ability of the urethra to act as a watertight outlet. **Hypermobility of the bladder neck and proximal urethra results from a weakening or loss of their supporting elements (ligaments, fasciae, and muscles), which in turn may be a consequence of aging, hormonal changes, childbirth, and prior surgery. It seems likely that the majority of women with SUI will also have an element of intrinsic sphincteric weakness with a variable degree of loss of the normal anatomic support of the bladder neck and proximal urethra,**

resulting in hypermobility. The compelling observation that one can cite for this is that a normal asymptomatic individual will not leak however much she strains.

Differentiating Relative Contributions of Hypermobility and Intrinsic Sphincter Deficiency

The influence of urethral function defined by leak point pressure or maximum urethral closure pressure (MUCP) is difficult to define on account of the large variation in outcome measures employed. Furthermore, other variables such as urethral mobility are often not controlled. Intrinsic sphincteric deficiency (ISD) is usually defined as a leak point pressure of less than 60 or MUCP of less than 20. A standardized test is not available to differentiate the relative contributions of intrinsic sphincter deficiency and hypermobility; therefore few studies have been able to accurately separate their individual contributions to the development of incontinence (Chapple et al, 2005). Retropubic procedures act to restore the bladder neck and proximal urethra to a fixed, retropubic position and are used when hypermobility is believed to be an important factor in the development of that woman's stress incontinence. This may facilitate the function of a marginally compromised intrinsic urethral sphincter mechanism, but if significant intrinsic sphincter deficiency is present it is likely that SUI will persist despite efficient surgical repositioning of the bladder neck and proximal urethra; at present this hypothesis remains unproven. In such circumstances then a sling procedure (particularly a "snug" fascial sling) or an artificial sphincter is most likely to be the therapy of choice.

In the normal continent woman, the bladder neck and proximal urethra are supported in a retropubic position, with the bladder base being dependent. Increases in intra-abdominal pressure are transmitted to both the bladder and the proximal urethra such that the pressure difference between the two is unchanged, promoting continence (Einhorning, 1961). A valvular effect at the bladder neck created by the transmission of abdominal pressure to the dependent bladder base may also be operative here (Penson and Raz, 1996). Furthermore, with proper bladder neck support, reflex contraction of the pelvic floor muscles during Valsalva maneuvers and coughing acts as a backboard for urethral compression (Staskin et al, 1985).

Surgical Procedures

Retropubic surgical procedures, usually chosen as surgical therapy for patients with SUI in which there is a significant component of hypermobility, are discussed here.

Open retropubic colposuspension is the surgical approach of lifting the tissues near the bladder neck and proximal urethra into the area of the pelvis behind the anterior pubic bones. When it is an open procedure the approach is through an incision over the lower abdomen. There are four variations of open retropubic colposuspension: Marshall-Marchetti-Krantz (MMK), Burch, vaginoobturator shelf (VOS), and paravaginal.

The term *colposuspension* was originally used to denote suspension of the urethra by the vaginal wall; however, by common usage, it now generally includes the paraurethral fascia and sometimes only this without the vagina. Retropubic colposuspension urethral repositioning can be achieved by three distinctly different procedures; these are all based on a similar underlying principle but in a spectrum in relation to the degree of the support/elevation they achieve, and their outcomes differ somewhat in the longer term.

The Burch colposuspension (Fig. 71–1A) is the elevation of the anterior vaginal wall and paravesical tissues toward the iliopectineal line of the pelvic sidewall with use of two to four sutures on either side (Burch, 1961). The VOS repair (see Fig. 71–1B) aims to anchor the vagina to the internal obturator fascia and is a modification of a combination of the Burch and paravaginal defect repair, with placement of the sutures laterally anchored to the internal obturator fascia rather than hitching the vagina up to the iliopectineal line (Turner-Warwick, 1986), although a more recent modification does, where appropriate, insert sutures into both the internal obturator and iliopectineal line (see Fig. 71–1C). The paravaginal defect repair (see Fig. 71–1D) aims to close a presumed fascial weakness laterally at the site of attachment of the pelvic fascia to internal obturator fascia (Richardson et al, 1976). The MMK procedure (see Fig. 71–1E) is the suspension of the vesicourethral junction (bladder neck) toward the periosteum of the symphysis pubis (Marshall et al, 1949) and was thought to act by buttressing the paraurethral area and bringing the vesicourethral junction into a more elevated "intra-abdominal" position.

The Degree of Urethral Elevation

The extent of the urethral elevation achieved by both the Burch (see Fig. 71–1A) and the VOS suspensions (see Fig. 71–1B and C) is higher than the arcus tendineus anchorage of the paravaginal defect repair (see Fig. 71–1D).

The Configuration of the Suspensions

A particular advantage of the horizontal urethral elevation achieved by both the VOS and the paravaginal repair suspensions is the significantly less susceptibility to tension on the urethra and to obstructive problems than with the V-shaped configuration of the Burch suspension (see Fig. 71–1A).

Tissue Approximation

Both the VOS and the paravaginal repair suspensions are anchored by tissue-approximating sutures; thus, unlike the Burch colposuspension, neither the VOS nor the paravaginal repair suspension is suture dependent in the longer term once the initial healing is complete because there is direct tissue adhesion. The VOS anchorage and suspension is significantly more robust than that of the paravaginal defect repair; the elevation it achieves can be further augmented by additionally including the iliopectineal ligament in the upper sutures (see Fig. 71–1C).

Laparoscopic colposuspension is the most popular of the laparoscopic incontinence procedures that were first introduced in the early 1990s (Vancaillie and Schuessler, 1991) with the premise that as minimally invasive procedures they would benefit patients by avoiding the major incision of conventional open surgery and shorten the time for a return to normal activity. As in open colposuspension, sutures are inserted into the paravaginal tissues on either side of the bladder neck and then attached to the iliopectineal ligaments on the same side. There are, however, technical variations in surgery with respect to the laparoscopic approach (transperitoneal into the abdominal cavity or extraperitoneal) and in the number and types of sutures, the site of anchor, and the use of mesh and staples (Jarvis et al, 1999).

ASSESSING OUTCOMES OF THERAPY

Before the best procedure can be determined, several issues regarding outcome reporting need to be addressed.

Duration of Follow-up

It is recognized that prolonged follow-up is required to assess the true benefit of an incontinence procedure. **Short-term follow-up should be considered to have begun in all studies after participants have reached 1 year of follow-up** (Abrams et al, 2005). In the short term (2 years), most procedures are successful and success rates between procedures are similar (Leach et al, 1997). However, with longer follow-up (>5 years), failures become manifest and the true benefit of the better procedures is realized. Most studies report outcomes after short-term follow-up, and thus results must be interpreted with caution.

The Issue of Intrinsic Sphincter Deficiency

There is no consistency in the existing literature database to support the likelihood that intrinsic sphincter deficiency can influence either the outcomes or the type of surgical treatment. The main problem is that there is no consensus on the meaning of intrinsic sphincter deficiency and how to diagnose it (Smith et al, 2005, 2009). Nevertheless it is likely in the author's view (unsubstantiated by any unequivocal evidence) that mild degrees of intrinsic sphincter

deficiency coexist with hypermobility in most cases. In a situation in which intrinsic sphincter deficiency is the predominant problem, then a repositioning procedure such as a colposuspension is less likely to be successful than a tight fascial sling or artificial sphincter.

The Definition of Cure

The definition of cure varies between studies. Some authors report cure of SUI only, whereas others define cure as complete continence postoperatively, implying the absence of urgency incontinence as well. The assessment of cure may vary. Some authors report subjective cure based on patient history, questionnaire, bladder diary, or medical chart review; others use more objective measures, such as pad tests, stress tests, and urodynamics.

Finally, one must question whether the goal of complete continence is reasonable, given that the condition of SUI is generally a degenerative one and corrective surgery does not replace the defective components. As well, **even in normal healthy women, urinary continence is a spectrum of dryness; approximately 40% of nulliparous 30- to 49-year-olds experience some degree of incontinence with exercise** (Nygaard et al, 1990). It seems unreasonable to expect surgery for a degenerative condition to achieve results that are better than the nondegenerative state.

The Patient's versus the Physician's Perspective

A patient's satisfaction with treatment is often based on the difference between her expectations and her experiences (Sofaer and Firminger, 2005). Thus, fulfillment of positive expectations is a key element of a patient's satisfaction (Sitzia and Wood, 1997). Because expectations vary widely, satisfaction is not a standard concept. Consequently, treatment plans must be tailored to meet a nonstandard goal. An integral step in achieving this goal is the development of a patient-physician partnership that promotes the negotiation of realistic expectations.

Logically, agreement of patient and physician with respect to treatment plan and goals should improve outcomes. When a diagnosis has been made, asking patients what they already know about the condition may give clues to expectations for treatment. The "ask-tell-ask" method may be employed to mend the gaps between the physician's and the patient's expectations. The physician explains the proposed treatment plan and expectations for the outcome, then encourages the patient to ask questions. The physician provides the information requested and invites questions again, continuing the process until a mutual understanding of treatments and expectations is reached (Barrier et al, 2003). This approach may prevent "surprises" such as unexpected pain of treatment, adverse events of medication, and prolonged recovery time. Elkadry and associates (2003) emphasized this point by demonstrating a significant association between feeling unprepared for surgery and the patient's dissatisfaction after pelvic reconstruction. The same investigators also reported that achievement of patient-defined goals was more predictive of a patient's satisfaction than were objective measures of surgical success.

Clearly, one or more high-quality validated symptom and quality of life instruments should be chosen at the outset of a clinical trial representing the patient's viewpoint, accurately defining baseline symptoms as well as any other areas in which treatment may be beneficial and assessing the objective severity and subjective impact of both.

Whereas many, including the author, think that urodynamic studies are helpful in defining the underlying pathophysiologic process in cases with incontinence, they have not been proved to have adequate sensitivity, specificity, or predictive value (Chapple et al, 2005). **The ICI meeting concluded that although urodynamic studies, such as frequency-volume charts and pad tests, are useful there is inadequate evidence to justify pressure-flow studies for routine testing as either entry criteria or outcome measures in clinical trials. It was recommended that most large-scale clinical trials enroll subjects by using carefully defined symptom-driven criteria when the treatment will be given on an empirical basis** (Abrams et al, 2005).

INDICATIONS FOR RETROPUBIC REPAIR

The treatment of SUI in women must be tailored to the individual patient. Once evaluation has identified contributing factors, a trial of conservative therapy should be pursued and surgery considered for patients who fail to respond to these conservative measures. Careful assessment of the patient is essential in making an accurate diagnosis (Fig. 71–2).

The selection of technique is largely based on the surgeon's preference and prior experience; bladder base and urethral hypermobility may be surgically corrected by either a vaginal or a retropubic approach. Although it has been suggested that a retropubic colposuspension should be considered in patients who frequently generate high intra-abdominal pressure (e.g., those with chronic cough from obstructive pulmonary disease and women in strenuous occupations) (Appell, 1993), it could also be argued that these patients may be better served by a pubovaginal sling as well.

Specific Indications

A retropubic approach for the correction of anatomic SUI is indicated (1) for a patient undergoing a laparotomy for concomitant abdominal surgery that cannot be performed vaginally and (2) where there is limited vaginal access.

Potential Contraindications

If there is a history of prior failed incontinence procedures the existence of significant sphincteric deficiency must be suspected, even if hypermobility exists, and consideration given to performing a pubovaginal sling, although retropubic colposuspensions may be successful in this scenario as well (Cardozo et al, 1999; Maher et al, 1999; Nitahara et al, 1999).

In the author's view, when SUI exists solely due to intrinsic sphincter deficiency (i.e., a fixed, nonfunctional proximal urethra with intrinsic urethral sphincter dysfunction), a retropubic suspension procedure is less likely to be successful because there is no hypermobility to correct and the patient is better served by a pubovaginal sling, collagen injections, or an artificial sphincter (Bergman et al, 1989b). This represents a personal view that is at variance with the ICI's conclusion statement on the role of urethral occlusive forces, which reads as follows: "It would appear that a low leak point pressure is less predictive of outcome on this

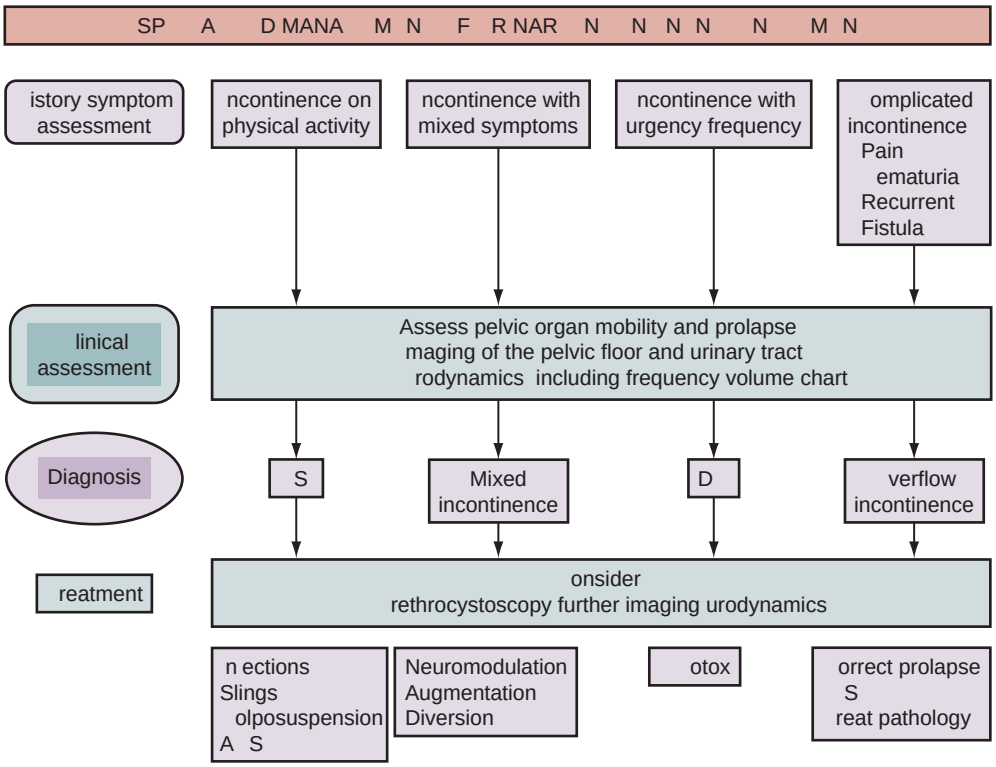

Figure 71–2. Algorithm for the specialized management of stress urinary incontinence (after the Third International Consultation on Incontinence, Monaco [Abrams et al, 2005]). USI, urodynamic stress incontinence; DO, detrusor overactivity; AUS, artificial urinary sphincter; CISC, clean intermittent self-catheterization.

data when compared to the presence or absence of urethral hypermobility" (Smith et al, 2009).

In cases with a pan–pelvic floor weakness, a colposuspension should not be used in isolation but should be part of a comprehensive approach to the pelvic floor and combined as appropriate with other alternative pelvic floor repair procedures. A retropubic colposuspension does not always adequately correct the associated vaginal prolapse that frequently coexists with bladder neck hypermobility. Although lateral defect cystocele and enterocele lend themselves to retropubic repair, a central defect cystocele, rectocele, and introital deficiency do not.

A retropubic colposuspension is contraindicated **when there is an inadequate vaginal length or mobility of the vaginal tissues, for example, after prior vaginal surgery or radiotherapy or such as that after a prior vaginal incontinence procedure** (Appell, 1993). The lysis of retropubic adhesions can be performed adequately and safely by a vaginal approach in conjunction with a needle suspension procedure or pubovaginal sling.

Vaginal versus Retropubic Surgery

From a review of the literature there is clearly a difference in the success rate of vaginal versus retropubic surgery alone with respect to correction of stress incontinence. An anterior colporrhaphy can certainly be efficacious for the correction of prolapse, with a reported efficacy in randomized controlled studies of 42% and 57% in the management of cystoceles (Sand et al, 2001; Weber et al, 2001). For the treatment of both a cystocele and SUI, an anterior colporrhaphy should be combined with a sling procedure. Goldberg and colleagues (2001), in a case-control series, demonstrated that in women with a cystocele and SUI the addition of a pubovaginal sling to an anterior colporrhaphy significantly decreased the recurrence rate from 42% in the control group to 19% in the anterior colporrhaphy group.

Glazener and Cooper (2001) reviewed the literature on randomized or quasi-randomized trials that included anterior vaginal repair for the treatment of urinary incontinence. Nine trials were identified that included 333 women having an anterior vaginal repair and 599 who received comparison interventions. They concluded that anterior vaginal repair was less effective than open abdominal retropubic suspension on the basis of patient-reported cure rates in eight trials both in the medium term (failure rate within 1 to 5 years after anterior repair, 97 of 259 [38%] versus 57 of 327 [17%]; relative risk [RR], 2.29; 95% confidence interval [CI], 1.7 to 3.08) and in the long term (after 5 years, 49 of 128 [38%] versus 31 of 145 [21%]; RR, 2.02; 95% CI, 1.36 to 3.01). There was evidence from three of these trials that this was reflected in a need for more repeated operations for incontinence (25 of 107 [23%] vs. 4 of 164 [2%]; RR, 8.87; 95% CI, 3.28 to 23.94). These findings held irrespective of the coexistence of prolapse (pelvic relaxation), although fewer women had a prolapse after anterior repair (RR, 0.24; 95% CI, 0.12 to 0.47) and later prolapse operation appeared to be equally common after either a vaginal (3%) or an abdominal (4%) operation.

Long-term follow-up beyond the first year is available in only three randomized controlled trials (Bergman et al, 1989a; Liapis et al, 1996; Colombo et al, 2000). There is a low morbidity with vaginal repair, but long-term success rates decrease with time to the extent that a 63% cure rate at 1 year fell to 37% at 5 years of follow-up (Bergman and Elia, 1995).

It can be concluded that with short-term follow-up vaginal and open retropubic suspension procedures have

similar success rates in the treatment of stress incontinence. However, with longer follow-up (and with the exception of the pubovaginal sling and loose midurethral tapes (see later) **patients who have retropubic procedures fare better than those undergoing vaginal repairs.**

The recommendation from the ICI committee (Smith et al, 2009) **is that anterior colporrhaphy should not be used in the management of SUI alone (grade A).**

GENERAL TECHNICAL ISSUES

Retropubic Dissection

In open retropubic suspension procedures good access to the retropubic space is crucial. This is best performed with the patient in the supine position with the legs abducted, in either a low or a modified dorsal lithotomy position with the use of stirrups, allowing access to the vagina during the procedure and a perineal-abdominal progression. A urethral Foley catheter is inserted; the catheter balloon is used for subsequent identification of the urethra and bladder neck, and, indeed, it is invaluable in allowing palpation of the edges of the bladder by appropriate manipulation. A Pfannenstiel or lower midline abdominal incision is made, separating the rectus muscles in the midline and sweeping the anterior peritoneal reflection off the bladder. It is essential to optimize the access to the retropubic space, and if a Pfannenstiel skin incision is made it is advisable to use the suprapubic V-shaped modification described by Turner-Warwick and colleagues (1974). Likewise, whatever incision is made, extra valuable access to the retropubic space is obtained by extending the division of the rectus muscles down to the pubic bone and elevating the aponeurotic insertion of the rectus muscle off the upper border of the pubic bone.

The retropubic space is then developed by teasing away the retropubic fat and underlying retropubic veins from the back of the pubic bone. The bladder neck, anterior vaginal wall, and urethra are then easy to identify, often facilitated by the presence of the Foley balloon. In patients who have had previous retropubic surgery, the dissection is performed sharply and it is important to take down all old retropubic adhesions, particularly in the presence of a prior failed repair. If difficulty is encountered in the identification of the bladder neck, the bladder may be partially filled or even opened to identify its limits and an examining finger in the vagina is invaluable in aiding the dissection (Symmonds, 1972; Gleason et al, 1976).

It is important to identify the lateral limits of the bladder as it reflects off the vaginal wall because only in this manner can one avoid inadvertent suturing of the bladder itself. Dissection over the bladder neck and urethra in the midline is to be avoided so as not to damage the intrinsic musculature. The lateral bladder wall may be "rolled off" medially and cephalad from the vaginal wall with a mounted swab and by use of countertraction with a finger in the vagina. In the author's experience it is necessary to incise the endopelvic fascia. Occasional venous bleeding from the large vaginal veins is controlled by suture ligature, although it often resolves with tying of elevating sutures. To aid in the identification of the lateral margin of the bladder it is helpful to displace the balloon of the Foley catheter into the lateral recess, where it easily can be palpated through the bladder wall.

Suture Material

Absorbable sutures were used in the original descriptions of the MMK procedure (chromic catgut), Burch colposuspension (chromic catgut), and VOS procedure (polyglycolic acid or polydioxanone), whereas the original paravaginal repair used nonabsorbable sutures (silicon-coated Dacron). Fibrosis during subsequent healing is likely to be the most important factor in providing continued fixation of the perivaginal fascia to the suspension sites (Tanagho, 1996); nevertheless, some surgeons believe that a nonabsorbable suture material is better because of the risk of suture dissolution before the development of adequate fibrosis (Penson and Raz, 1996). Clearly, the choice of suspension suture material is a personal choice, but erosion of nonabsorbent sutures into the lumen of the bladder is a not uncommon complication and a not uncommon source of medical litigation (Woo et al, 1995).

Bladder Drainage

Some degree of immediate postoperative voiding difficulty can be expected after retropubic suspensions (Lose et al, 1987; Colombo et al, 1996a). Immediately postoperatively, bladder drainage may take the form of a urethral or a suprapubic catheter, generally based on the surgeon's preference. A voiding trial is usually performed around the fifth day postoperatively. However, there is some evidence that a suprapubic catheter may be advantageous with respect to a lower incidence of asymptomatic and febrile urinary tract infection and earlier resumption of normal bladder function (Andersen et al, 1985; Bergman et al, 1987). In addition, the use of a suprapubic tube is generally more comfortable, allows the patient to participate in catheter management, and avoids the need for clean intermittent self-catheterization. Catheterization can be discontinued when efficient voiding has resumed, which is usually indicated by a postvoid residual urine volume either less than 100 mL or less than 30% of the functional bladder volume.

Drains

A tube drain may be placed in the retropubic space when there is concern about ongoing bleeding from perivaginal veins that may prove difficult to control with suture and electrocautery. Often, tying the suspension sutures is sufficient to stop this bleeding; but when the bleeding persists, drainage of the retropubic space is indicated. The drain is generally removed on the first to third day, when minimal output is noted.

MARSHALL-MARCHETTI-KRANTZ PROCEDURE

Technique

Marshall, Marchetti, and Krantz in 1949 described a retropubic approach for the elevation and fixation of the anterolateral aspect of the urethra to the posterior aspect of the pubic symphysis and the adjacent periosteum. Technically, the original description of the MMK procedure reported a double suture bite of the paraurethral tissue included with the vaginal wall; this may be generically entitled a cystourethropexy. In 1949, Marshall and coworkers described their retropubic vesicourethral suspension in 50 patients; 38 of the patients had symptoms of SUI, 25 of whom had failed prior gynecologic operations for urinary incontinence. A simple suprapubic procedure was described by which the vesical outlet was suspended to the pubis (Marshall et al, 1949). In the original description, three pairs of sutures (taking double bites of tissue) were placed on each side of the urethra, incorporating full-thickness vaginal wall (excluding mucosa) and lateral urethral wall

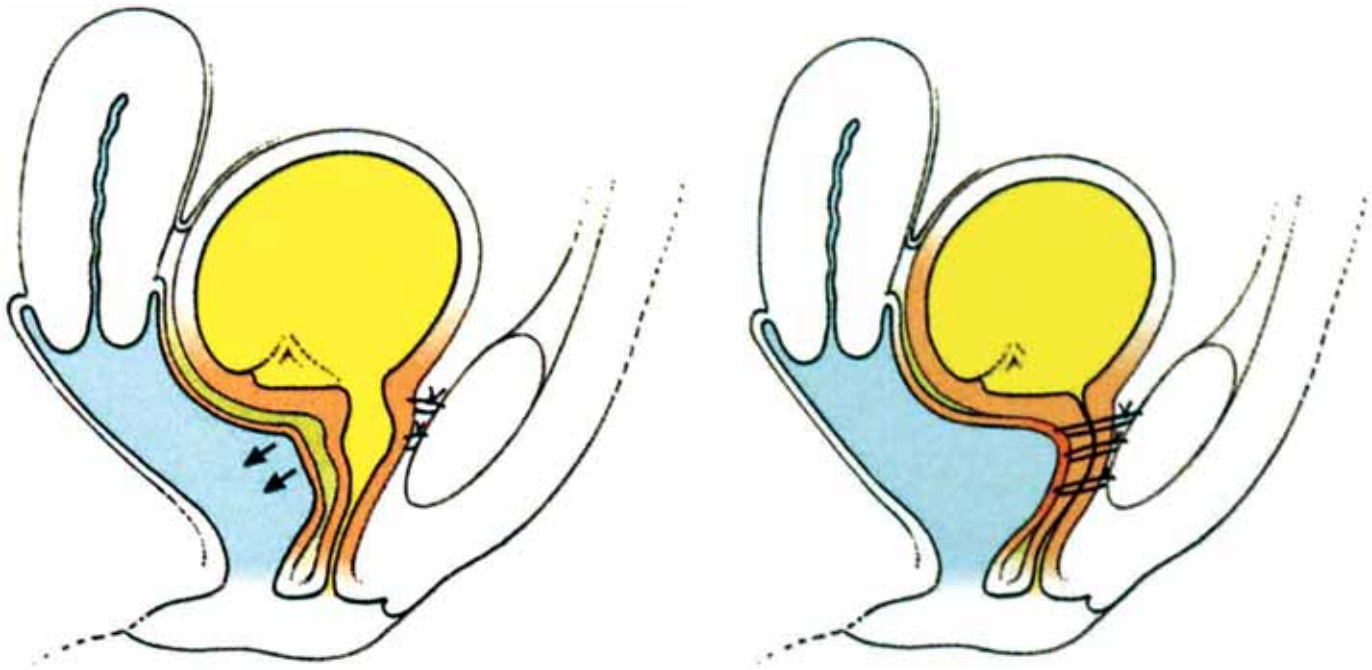

Figure 71–3. **A,** Potential risk of tethering the urethra with the Marshall-Marchetti-Krantz (MMK) procedure, influencing the function of the urethral sphincter mechanism. **B,** Potential risk of obstruction of the urethra with the paraurethral sutures of the MMK procedure.

(excluding mucosa) (Marshall et al, 1949). Marchetti (1949) then modified the procedure to omit the tissue bite through the urethral wall because of concern about urethral injury. Apart from modifications in suture number and material over the years, the procedure remains the same today.

Cystourethropexy was often used as a secondary procedure for the resolution of persistent leaking after an anterior colporrhaphy. A cystourethropexy does not support the posterior wall of the urethra unless the sutures include the paraurethral vaginal wall, nor does it positively reduce an anterior vaginal wall prolapse in the same way that the true retropubic colposuspension procedures do. If there is a significant urinary residual after colporrhaphy with associated laxity of the anterior vagina wall, then with the descent, this applies traction to the posterior aspect of the bladder neck and tends to "tent" it open because the anterior aspect is tethered by sutures to the back of the pubis (see Fig. 71–1E). Sutures are placed on either side of the urethra (avoiding the urethral wall), taking bites through the paraurethral fascia and anterior vaginal wall (excluding mucosa). The most proximal sutures are placed at the level of the bladder neck. Each suture is then passed into an appropriate site in the cartilaginous portion of the symphysis (Fig. 71–3). However, the main technical problem relating to the MMK procedure is the difficulty of obtaining an adequately robust anchorage of the anterior wall of the urethra and the paraurethral fascia to the symphysis and the periosteum of the pubis where the suture bites are relatively insecure. As shown in Figure 71–3 these sutures can potentially either distort the bladder neck and impair sphincter function (see Fig. 71–3A) or obstruct the bladder neck (see Fig. 71–3B). All sutures are inserted; and while an assistant elevates the anterior vaginal wall, each suture is individually tied, starting with the more distal pair. The proximal, or bladder neck, suture frequently needs to be passed through the insertion of the rectus abdominis. Additional sutures may or may not be placed between the anterior bladder wall and the rectus muscles to pull the bladder farther anteriorly.

Results

Krantz described a personal series of 3861 cases with a follow-up of up to 31 years and a 96% subjective cure rate (Smith et al, 2005). Short- and medium-term results with the MMK procedure have been good. Mainprize and Drutz (1988) reviewed 58 articles (predominantly retrospective) published between 1951 and 1988 for treatment outcomes in 3238 cases. The cure rate, mostly based on subjective criteria, was 88%, with an improvement rate of 91%. Jarvis's meta-analysis of studies in the literature (1994b) noted subjective continence in 88.2% (range, 72% to 100%) of 2460 patients with 1- to 72-month follow-up and objective continence in 89.6% (range, 71% to 100%) of 384 patients with 3- to 12-month follow-up. Whether the procedure was being done primarily or secondarily affected the outcome, with subjective continence in 92% if it was done primarily versus 84.5% if it was done secondarily. Longer-term data are limited in amount. McDuffie (1981) reported 75% success at 15 years. More recently, Clemens and coworkers (1998) noted subjective cure or improvement (SUI and urgency urinary incontinence) in only 41% of patients with a mean follow-up of 17 years, and Czaplicki and colleagues (1998) noted decreasing continence rates from 77% at 1 year to 57% at 5 years to 28% at 10 years, with a mean duration of continence of 78.5 months. There are significant limitations to the data since most series are retrospective, with preoperative assessment based mainly on the history and physical examination and few studies using objective data as outcome measures.

Complications occur in up to 21% of cases (Mainprize and Drutz, 1988), and the placement of sutures through the pubic symphysis incurs the risk of osteitis pubis, a potentially devastating complication of the MMK procedure that has been reported in 0.9% to 3.2% of patients (Lee at al, 1979; Mainprize and Drutz, 1988; Zorzos and Paterson, 1996). Patients usually present 1 to 8 weeks postoperatively with acute pubic pain radiating to the inner thighs, aggravated by moving. Physical examination reveals tenderness over the pubic symphysis, and radiography demonstrates

haziness to the borders of the pubic symphysis and possibly lytic changes. Treatment is with bed rest, analgesics, and possibly corticosteroids (Lee at al, 1979). Other specific complications of the MMK procedure have included the occasional erosion of nonabsorbable cystourethropexy sutures into the bladder lumen with stone formation. Also, the positioning of sutures in the endopelvic fascia close to the bladder neck can result in a significant outlet obstruction.

Whereas the MMK procedure produces a cure rate similar to that of colposuspension, the complication of osteitis pubis means that there is little to support its use as an alternative to other colposuspension procedures. Indeed the ICI committee (Smith et al, 2009) **concluded that although short-term results indicate comparable cure rates to colposuspension there is limited evidence that the longer-term outcome is poorer after MMK (level 1) and declines further over time (level 3). There is no evidence to support the continued use of MMK over colposuspension.**

The recommendation from the ICI committee (Smith et al, 2009) **is that the MMK procedure is not advised for the treatment of SUI (grade A).**

BURCH COLPOSUSPENSION

Technique

Burch's original description of the colposuspension in 1961 followed his original procedure, which was essentially a paravaginal repair attaching the paravaginal fascia to the white line of the pelvis, the arcus tendineus. The Burch colposuspension was a novel approach to restore the urethrovesical junction to a retropubic location by approximating the periurethral fascia to the tough bands of fibrous tissue running along the superior aspect of the pubic bone (Cooper [iliopectineal] ligament) with three pairs of sutures. The original Burch retropubic colposuspension is appropriate only if the patient has adequate vaginal mobility and capacity to allow the lateral vaginal fornices to be elevated toward and approximated to the Cooper ligament on either side. This technique has been modified. Tanagho's modification (1978) approximated the vaginal wall to the lateral pelvic wall, with the sutures holding the anterior vaginal wall to the Cooper ligament, being tied loosely so that two fingers could be placed between the symphysis and urethra. This achieved broad support for the urethra and bladder neck and potentially minimized the risk of postoperative voiding dysfunction. A more recent modification (Shull and Baden, 1989; Turner-Warwick and Chapple, 2002) involves a hybrid approach whereby the vaginal tissues are approximated to the internal obturator fascia with an anchoring bite to the iliopectineal ligament (see VOS repair later).

Suture placement is facilitated by the elevation of the dissected anterolateral vaginal wall into the field by the surgeon's fingers inserted in the vagina (Fig. 71–4). The bladder is retracted to the opposite side with a mounted swab. Two to four sutures are placed on each side, each suture taking a good bite of fascia and vaginal wall, with care taken not to pass through the vaginal mucosa. Some recommend taking double bites of tissue to lessen the risk of suture pull-through (Jarvis, 1994a). The most distal suture is at the level of the bladder neck and placed no closer than 2 cm lateral to it, although some place distal sutures at the midurethral level (Tanagho, 1978). The suspension suture bites of the paraurethral fascia should not be positioned too close to the bladder neck and the urethra, as they are in the cystourethropexy procedures (MMK), because the unwanted effect of lateral traction-tension created by their anchorage to the iliopectineal ligaments may tether the sphincteric occlusive effect on the urethra or create a degree of obstructed voiding. Subsequent sutures are placed proximal to the level of the bladder neck, at about 1-cm intervals. The sutures are then placed into corresponding sites in the Cooper ligament, the emphasis being on a mediolateral direction for the sutures. The exact mechanism of continence of the Burch colposuspension is still unknown. Burch (1968) thought it to be secondary to elevation and stabilization of the bladder neck and urethra. In support of the suggestion regarding suture placement, Digesu and colleagues (2004) reviewed magnetic resonance imaging findings before and 1 year after open Burch colposuspension in 28 women to see if this would explain the mechanism. In the 86% who were cured the distance between the levator ani muscle and bladder neck was significantly shorter than in those whose treatment failed. Their suggestion is that insertion of sutures in a medial-lateral direction as opposed to an anteroposterior direction may better appose the levator ani muscle and bladder neck. The highly vascular vaginal wall may bleed profusely during suture placement, and large vaginal veins often need to be oversewn, but most bleeding ceases once the sutures are tied and the vagina is suspended. To facilitate tying of the sutures, the assistant elevates the appropriate portion of the vaginal wall as each suture is tied, beginning with the more distal pair.

No attempt should be made to tie the sutures tightly. Often, the vaginal wall does not approximate to the Cooper ligaments, and free suture material is seen between the vagina and the ligaments. The principle is to approximate the vaginal wall to the lateral pelvic wall, where it will heal and promote adhesion formation (Tanagho, 1978; Shull and Baden, 1989; Turner-Warwick and Chapple, 2002), **thereby creating a broad support for the urethra and bladder neck.**

Results

As in the MMK procedure, short- and medium-term outcomes with the Burch colposuspension have been good. In Jarvis's meta-analysis (1994b), subjective continence was achieved in 91% (range, 63% to 97%) of more than 1300 patients with 3 to 72 months of follow-up and objective continence in 84% of more than 1700 patients with 1 to 60 months of follow-up. Lapitan and associates (2003) reviewed 33 trials involving a total of 2403 women who underwent open colposuspension and found an overall cure rate between 68.9% to 88.0%, with a 1-year cure rate of 85% to 90%. This decreased to 70% at 5 years. Although there may be a decline in the cure rate of only 15% to 20% beyond 5 years, Alcalay and colleagues (1995) noted a subjective and objective SUI cure rate of 69% with a mean follow-up of 13.8 years. Baessler and Stanton (2004) examined the impact of surgery on coital incontinence. Of the 30 women available for postoperative evaluation, 73% preoperatively had incontinence with penetration, 10% with orgasm only, and 17% with both. Postoperatively, 70% were cured of their coital incontinence. Moreover, in those who were subjectively cured of their stress incontinence, 87% were also cured of their coital incontinence.

Unlike with the MMK procedure, the good results with the Burch colposuspension appear to be durable with longer follow-up. Lapitan and associates (2003) **reached the conclusion from a review of two trials comparing the Burch colposuspension and the MMK procedure that the Burch technique results in higher cure rates. Thus,**

it should be regarded as the *standard* open retropubic colposuspension procedure.

Open colposuspension is as effective as any other procedure in primary or secondary surgery at curing SUI with proven long-term success (level 1 evidence, grade A recommendation) (Smith et al, 2005).

Prophylactic Colposuspension

In 2006, the Colpopexy and Urinary Reduction Efforts trial demonstrated that the postoperative risk of stress incontinence in stress-continent women undergoing open abdominal sacrocolpopexy could be substantially reduced by the addition of a Burch colposuspension (Brubaker et al, 2006). Initial results at 3 months after the procedure demonstrated reduction of de novo stress incontinence from 44% in the untreated group to 24% in the Burch group, without increased rates of voiding dysfunction or urgency symptoms. Subsequent 1- and 2-year outcomes from this trial showed continued benefit in patients who received the concomitant Burch colposuspension (Burgio et al, 2007; Brubaker et al, 2008).

Reoperative Surgery

Poorer results are likely to occur when the procedure is performed secondarily. Scarring and fibrosis from previous surgery can prevent adequate suspension in some cases, and suture cut-through is more likely. Furthermore, after failed surgery, patients may often have coexisting sphincteric weakness that places them at greater risk of recurrence after colposuspension (Bowen et al, 1989; Koonings et al, 1990).

Nevertheless, Maher and colleagues (1999) and Cardozo and associates (1999) have both shown good objective (72% and 79%) and subjective (89% and 80%) success with repeated colposuspension at a mean follow-up of 9 months. Nitahara and coworkers (1999) reported a 69% subjective success at a mean follow-up of 6.9 years. Urgency incontinence and sphincteric weakness are the main causes of failure and dissatisfaction. Urgency incontinence accounted for 63% (12 of 19) of failures; the remaining 7 with persistent stress incontinence in Nitahara's series demonstrated sphincteric deficiency with mean Valsalva leak point pressures of 65 cm H_2O. The low-pressure urethra has often been quoted as an adverse risk factor for colposuspension (Haab et al, 1996; Bowen et al, 1989; Koonings et al, 1990), but this topic also remains controversial. Several authors have studied the urethral pressure profilometry changes after colposuspension and have noted a statistically significant increase in the postoperative pressure transmission ratio but minimal changes in the postoperative MUCP, functional urethral length, and continence area (Faysal et al, 1981; Weil et al, 1984; Feyersiel et al, 1994). Although a low-pressure urethra (MUCP ≤ 20 cm H_2O) is considered a contraindication to the Burch procedure, a modification of the standard Burch operation has had some success in managing SUI associated with the low-pressure urethra. Bergman and colleagues (1989c) combined a standard Burch procedure with the Ball procedure (Ball, 1963) whereby, before the Cooper ligament suspension is performed, two or three sutures are used to plicate the anterior urethral wall at the level of the proximal and middle urethra. They retrospectively noted greater success with this technique than with a standard Burch procedure for the low-pressure urethra, and this was comparable to the success obtained with a standard Burch procedure in patients with a normal-pressure urethra (MUCP > 20 cm H_2O). With longer follow-up, the Ball-Burch procedure continued to yield better results than the standard Burch procedure in patients with a low-pressure urethra, with a documented 5-year cure rate of SUI of 84% (Bergman et al, 1991; Elia and Bergman,

1995). However, there are no randomized studies addressing the issue, and whether these results can be extrapolated for the use of this technique in patients with intrinsic sphincter deficiency is debatable.

As with any major abdominal or pelvic surgical procedure, intraoperative and perioperative complications that may occur after a retropubic suspension include bleeding, injury to genitourinary organs (bladder, urethra, ureter), pulmonary atelectasis and infection, wound infection or dehiscence, abscess formation, and venous thrombosis or embolism. Other complications more specific to retropubic suspension procedures include postoperative voiding difficulty, detrusor overactivity, and vaginal prolapse. These are discussed in more detail along with other reported complications in a later section in this chapter.

The recommendations from the ICI committee (Smith et al, 2009) **are as follows: Open retropubic colposuspension can be recommended as an effective treatment for primary SUI, which has longevity (grade A). Although open colposuspension has to a large extent been superseded by the less invasive midurethral tapes, it should still be considered for those women in whom an open abdominal procedure is required concurrently with surgery for SUI (grade D).**

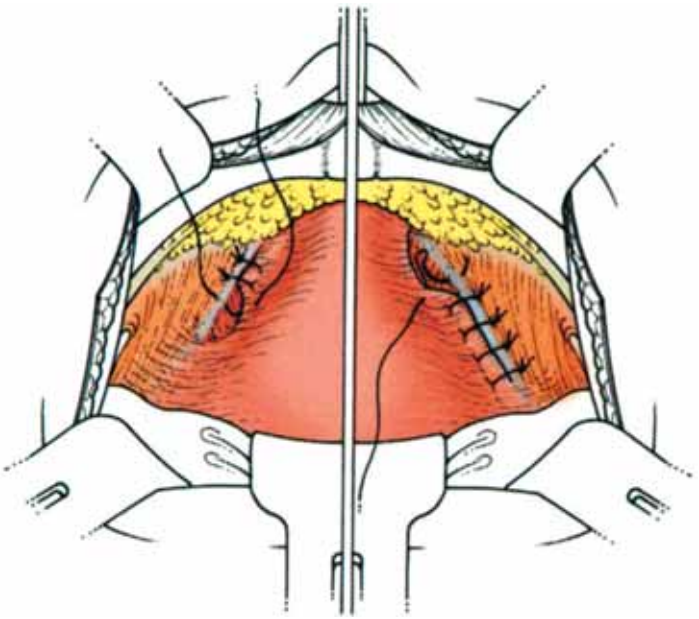

Figure 71–5. A paravaginal repair procedure.

PARAVAGINAL REPAIR

Technique

The origins of the paravaginal repair date to White (1912), who described the importance of the "white line" of the pelvis (arcus tendineus) as an integral structure supporting the proximal urethra and bladder base to the pelvic wall and the development of paravaginal fascial tears predisposing to cystocele formation. He performed the paravaginal repair by a vaginal approach but envisioned that it would be easier if it was performed abdominally (White, 1912). Later, in his original description, Burch (1961) attached the vaginal wall to the arcus tendineus in seven patients, only to realize that the attachment may not be secure, prompting him to use the Cooper ligament as an attachment site. In the 1970s, Richardson and coworkers (1976) reintroduced the concept of a lateral defect cystourethrocele as an etiologic factor in the genesis of SUI and popularized the paravaginal repair as a technique for management.

The patient is placed in a low lithotomy position, just as for the MMK procedure and Burch colposuspension. If there are retropubic adhesions resulting from prior surgery they are sharply incised; the dissection is facilitated by placement of two fingers of the surgeon's left hand in the vagina. The bladder and urethra are not mobilized from the vaginal attachments. Richardson and colleagues (1981) describe an extensive reattachment of the lateral vaginal sulcus with its overlying fascia to the arcus tendineus fasciae pelvis from the back of the lower edge of the symphysis pubis to the ischial spine, using six to eight sutures placed at 1-cm intervals. The vaginal wall in the region of the bladder neck is identified, and these interrupted sutures are placed at approximately 1-cm intervals through the paravaginal fascia and vaginal wall (excluding vaginal mucosa) beginning at the urethrovesical junction. The sutures are then passed through the adjacent obturator fascia and underlying muscle at the site of the arcus tendineus fascia (Fig. 71–5). If the arcus is not visible, the obturator foramen may be used as a landmark. It is situated 1.5 to 2 cm above the white line.

The end point that should be achieved is the reestablishment of the urethral axis in an anatomic position, easily allowing three fingerbreadths between the pubic symphysis and the proximal urethra but providing secure fixation and preventing rotational descent. Consequently, it has been reported that postoperative voiding difficulties are uncommon (Richardson et al, 1981).

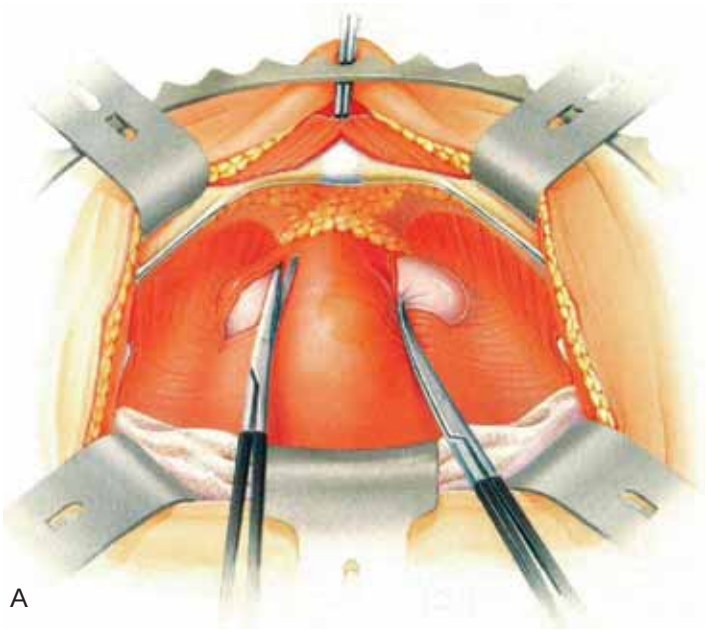
Results

Few reports on the use of this technique have been published. With variable follow-up, cure rates greater than 90% have been reported for the paravaginal repair (Richardson et al, 1981; Shull and Baden, 1989). There is only a single randomized comparison of colposuspension with paravaginal repair including 36 patients who were randomly allocated to treatment by either colposuspension or paravaginal repair with nonabsorbable suture material. At 6 months of follow-up there was an objective cure rate of 100% for those undergoing colposuspension and 72% for those undergoing paravaginal repair (Colombo et al, 1996a).

Small series have reported on vaginal approach paravaginal repairs (Scotti et al, 1998; Mallipeddi et al, 2001). In particular, Mallipeddi and colleagues observed 45 patients (21 with SUI) after this approach for a mean of 1.6 years, and 57% had persistent stress incontinence; their conclusion was that this technique had limited applicability for SUI. **It can be concluded that there is level 1/2 evidence that abdominal paravaginal repair is less effective than colposuspension. There are limited data (level 3/4) on laparoscopic and vaginal paravaginal repairs, but interpretation of these data is hampered by the small numbers of patients, the short follow-up, and a combination of this procedure with other types of incontinence procedures** (Smith et al, 2005).

There is limited evidence (level 2) that abdominal paravaginal defect repair is less effective than open colposuspension (Smith et al, 2009).

The recommendation from the ICI committee (Smith et al, 2009) **is that paravaginal defect repair is not recommended for the treatment of SUI alone (grade A).**



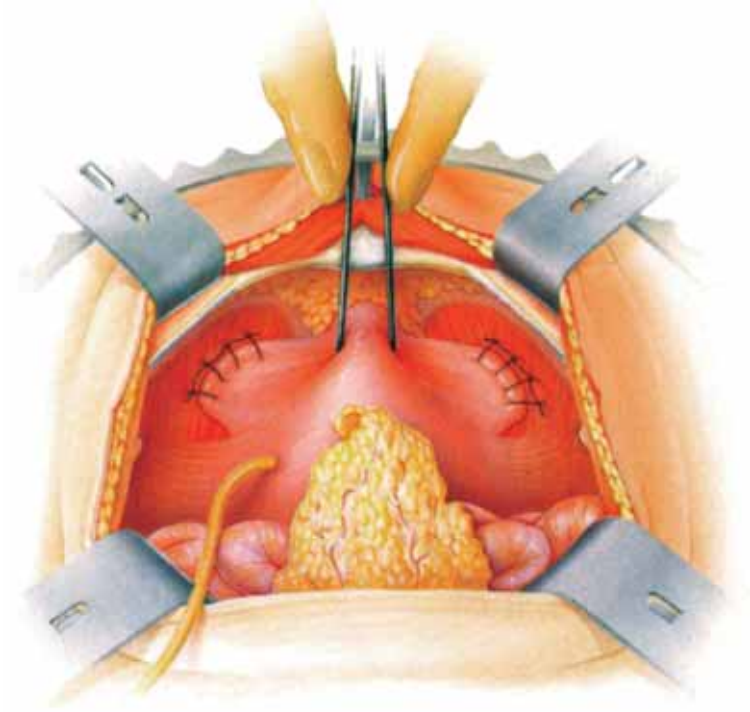


Figure 71–6. **A,** Mobilizing the tissues. The tissues should be stripped by blunt dissection with a mounted swab or the edge of a pair of scissors; only occasionally is sharp dissection necessary, provided the stripping action starts far laterally adjacent to the pubic bone. **B,** Completed vagino-obturator shelf procedure.

VAGINO-OBTURATOR SHELF REPAIR

Technique

Turner-Warwick (1986; Turner-Warwick and Chapple, 2002) reported his variant of the paravaginal repair, which he called the vagino-obturator shelf (VOS) repair. The premise for this is that there should be no restriction to the intrinsic sphincteric function of the urethra by fixation or paraurethral tethering, and there should be no urethral compression (Turner-Warwick and Kirby, 1993).

Just as for other retropubic suspension procedures (Fig. 71–6), the anterior wall of the lower segment of the bladder wall is exposed and the position of the bladder neck is identified by gentle traction on a balloon catheter in the urethra. The surgeon's forefinger in the vagina elevates its anterior wall and the overlying endopelvic fascia on either side of the urethra. Lateral displacement of the catheter balloon with the finger in the vagina facilitates the identification of the inferolateral margin of the bladder, lateral to the bladder neck; and its separation from the paraurethral endopelvic fascia is achieved by simple blunt dissection with a sponge or scissor-tip retraction. This naturally exposes the surface of the obturator muscle and the arcus tendineus origin of the levator muscles deep in the sulcus below this, the site of suture placement in the paravaginal repair (which is well below the vaginal anchorage point in the VOS procedure). The obturator nerves lie superolaterally; their canals run high up in a groove under the superior pubic ramus so that once they are identified,

injury to them can be avoided. The full thickness of the vagina and its overlying layer of endopelvic fascia are elevated by the surgeon's finger in the vagina and are approximated to the internal obturator muscle and anchored to the bulk of this with absorbable 0 or 1 sutures mounted on robust 35- to 40-mm half-circle needles. Slight flexion of the fingertip tents the vaginal wall and facilitates the full-thickness insertion of these suture bites through it, thus avoiding inclusion of the surgical glove. Three or four successive sutures are inserted. For knot security these are best tied continuously, head to tail, as they are inserted, rather than separating them individually. Each tied suture bite facilitates the insertion of the next (unlike in the Burch procedure, in which the sutures are not tied until they have all been inserted). A similar obturator suspension of the elevated protrusion of the vagina and its overlying endopelvic fascia is achieved on the opposite side. Some additional elevation of the lateral anchorage of the VOS by the inclusion of a bite of the iliopectineal ligament within the suture bite approximating the vagina to the obturator muscle (like a Burch procedure) may be used to reinforce the repair (Shull and Baden, 1989). This modification is one the author favors and represents a hybrid with the Burch procedure, facilitating reattachment of the pubocervical fascia to the arcus tendineus fasciae pelvis, tissue apposition to the lateral pelvic wall, and nonobstructive elevation of the urethra and urethrovesical junction. In addition, obliteration of the pouch of Douglas (culdoplasty) may be needed to prevent enterocele (Shull and Baden, 1989; Turner-Warwick and Kirby, 1993).

Results

There are limited data available for the VOS repair, which has had reported cure rates of 60% to 86%, depending on whether the procedure was performed primarily or secondarily (Turner-Warwick, 1986; German et al, 1994). German and colleagues (1994) reported that the VOS procedure is less likely to be successful in those patients who had undergone previous surgery.

Ultimately, as with all such reconstructive surgery, the surgeon should select the correct procedure for the individual patient. Although the VOS, which is a synthesis of the principles of the paravaginal repair and the Burch colposuspension, is of interest, further clinical results are necessary before definitive conclusions can be drawn.

LAPAROSCOPIC RETROPUBIC SUSPENSION

Laparoscopic techniques for retropubic suspension were introduced by Vancaillie and Schuessler in 1991. They essentially performed an MMK urethropexy laparoscopically and, since that time, laparoscopic techniques have been applied to both the Burch procedure and the paravaginal repair. Subsequent modifications to the suspension suturing techniques have been introduced, including the use of mesh (Ou et al, 1993), staples (Lyons, 1994), and fibrin sealant (Kiilholma et al, 1995), but all adhere to the same principles of their open counterparts. Proposed advantages to the laparoscopic approach include improved intraoperative visualization, less postoperative pain, shorter hospitalization, and quicker recovery times (Liu, 1993). Disadvantages include greater technical difficulty with resultant longer operating times and higher operating costs (Paraiso et al, 1999).

The procedure may be performed extraperitoneally or transperitoneally, and each approach has its proponents. Although the extraperitoneal technique may be associated with shorter operating times, easier dissection, and fewer bladder injuries (Frankel and Kantipong, 1993; Raboy et al, 1995), the transperitoneal approach provides a larger operating space and the ability to perform concomitant intraperitoneal procedures and apical prolapse repair (Paraiso et al, 1999). The specifics of the different procedures are beyond the scope of this chapter.

Short- and medium-term outcomes with the laparoscopic retropubic suspensions have become available. In their review of 13 studies of laparoscopic retropubic suspensions, Paraiso and colleagues (1999) found cure rates to range from 69% to 100% with follow-up of 1 to 36 months. This is comparable to outcomes of the open procedures as already noted. Both retrospective (Polascik et al, 1995) and randomized, prospective comparisons (Summitt et al, 2000) between open and laparoscopic techniques have demonstrated similar short-term success. However, with longer follow-up, laparoscopic retropubic suspensions appear to fail more frequently. McDougall's group (1999) retrospectively noted only 30% cure of SUI and 50% cure or improvement by a laparoscopic Burch procedure with 45 months of follow-up, and this was no different from the results with a Raz procedure.

Five trials summarized in a Cochrane review have compared laparoscopic with open colposuspension (Burton, 1997, 1999; Su et al, 1997; Carey et al, 2000; Summitt et al, 2000; Fatthy et al, 2001; Moehrer et al, 2002). All had different lengths of follow-up: 6 months (Carey et al, 2000); 1 year (Su et al, 1997; Summitt et al, 2000); 6 and 18 months (Fatthy et al, 2001); and 6 months, 1 year, 3 years, and 5 years (Burton, 1997, 1999). Outcome data for 6 months to 18 months were therefore available for all studies. Longer-term data are currently available only for Burton's study. The ability to synthesize data was also limited by the variable tests and definitions used to measure subjective and objective outcomes across the trials (Moehrer et al, 2003). Moehrer and colleagues, in their meta-analysis, noted that a total of 233 women received a laparoscopic and 254 women an open colposuspension, and the confidence intervals are generally all wide as a consequence. Four trials comparing laparoscopic with open colposuspension were otherwise of good quality (Burton, 1997, 1999; Carey et al, 2000; Summitt et al, 2000; Fatthy et al, 2001). Burton's study had the potentially confounding factors of use of absorbable sutures and of the surgeons having performed only a relatively small number of laparoscopic colposuspensions (<20) before beginning the trial. These factors may have influenced his results, in particular since there is believed to be a definite albeit relatively steep learning curve associated with laparoscopic colposuspensions. The fifth trial had methodologic problems with corrupted randomization and confounding factors of performance of additional surgery in some patients and the use of a different number of sutures for laparoscopic (one suture) and open (three sutures) colposuspension (Su et al, 1997). The number of sutures used appears to have a significant influence on the cure rate, with more sutures resulting in a significantly higher success rate. Persson and Wolner-Hanssen (2000) compared different numbers of paravaginal sutures and found a significantly higher objective 1-year cure rate (dry on "ultrashort" pad test) for women randomized to two sutures compared with one suture, with a cure rate of 83% for two sutures and 58% for one suture. Only one trial currently has data beyond 18 months of follow-up (Burton, 1997, 1999). This suggested poorer long-term results after laparoscopic surgery. This finding should be interpreted cautiously, however, because there are concerns that the surgeon's laparoscopic performance may have been suboptimal because he had performed few laparoscopic colposuspensions when the trial started. Data from other larger trials with

multiple operators are now needed to assess whether this is a real effect. All the other trials had data up to a maximum of 18 months. These show some inconsistencies. Outcome assessed by the women participating (arguably the most important outcome) appeared equally good in the two groups. Urodynamic investigations were used to assess cure objectively in all five studies. Overall, there was a significantly higher success rate after open colposuspension (RR, 0.89; 95% CI, 0.82 to 0.98) equivalent to an absolute difference of an additional 9% risk of failure after laparoscopic surgery. No significant differences between the two groups were observed for postoperative urgency, voiding dysfunction, or de novo detrusor overactivity. A trend was shown toward a higher complication rate, less postoperative pain, shorter hospital stay, and more rapid return to normal function for laparoscopic colposuspension. The operating time tended to be longer, the intraoperative blood loss less, and the duration of catheterization shorter for laparoscopic compared with open colposuspension (Moehrer et al, 2003).

In a previous review of laparoscopic colposuspension, Paraiso and colleagues (1999) noted major intraoperative and short-term complications in up to 25% of cases, with bladder injury being the most common complication and declining with experience; ureteric injury has also been reported (Aslan and Woo, 1997). The use of mesh and tacks or staples may be complicated by foreign body erosion (Arunkalaivanan and Arunkalaivanan, 2002; Kenton et al, 2002), and in a randomized study (Ankardal et al, 2004) it was reported that the use of sutures was superior to the laparoscopic mesh and staple technique.

A previous Cochrane review (Moehrer et al, 2002) was dependent on small trials, recruiting a total of 487 women between them, with mostly only medium-term follow-up data (18 months) and limited evidence from other small studies and concluded that laparoscopic colposuspension had the benefit of a more rapid recovery but might have a higher complication rate and be more expensive and possibly less effective in the long term than open colposuspension. This highlighted the need for further well-designed clinical studies.

Carey and colleagues (2006) have reported a randomized trial that recruited 200 women during 1997 and 1998, with 2-year follow-up available for 83% of participants and longer-term subjective data from a similar proportion. The primary outcome measure was objective cure (absence of urodynamic stress incontinence) at 6 months, powered to detect a difference of 20% between the two study arms. Secondary measures included patient satisfaction, quality of life and general well-being, and complications. In the same year Kitchener and coworkers (2006) reported the results of the COLPO trial, which recruited 291 women between 1999 and 2001, with a 2-year follow-up rate of more than 80%. The primary outcomes were objective (dry pad test) and subjective (symptom report) cure at 24 months. Secondary outcomes included recovery time, complications, and a formal cost-benefit analysis. The trial was powered to show noninferiority of laparoscopic colposuspension to open colposuspension, assuming a cure rate of 80% for the open procedure. Both studies were well designed, well conducted, and clearly reported.

Carey and coworkers found no difference in urodynamic cure rate, incidence of detrusor overactivity, or patient satisfaction at 6 months, with an overall objective cure rate of 75%. Detrusor overactivity occurred in 12% of women; 66% of women were urodynamically "normal." If the raw data are converted to percentage scores, there was 89% satisfaction with the treatment outcomes and 88% satisfaction with the care received. The overall satisfaction was 87%. At 24 months after surgery there were no significant differences between the two treatment groups with respect to reporting SUI, urgency, and urgency incontinence and a satisfaction score of greater than or equal to 80. Across both treatment groups, by 24 months after surgery, 66% of women reported no SUI, 38% reported no urgency, 47% reported no urgency incontinence, and 64% reported a satisfaction score of greater than or equal to 80. Although follow-up information was only available on approximately 80% of all subjects by 24 months, a sensitivity analysis was performed assuming that all women who did not complete the 24-month follow-up had either occasional or frequent SUI. With these assumptions, cure rates decreased to 61% for open colposuspension and 50% for laparoscopic colposuspension. There was no significant difference between the two groups treatment groups, even when adjusted for surgeon experience (P = .08). The study population was contacted by telephone for further follow-up at a mean of 3.7 years (range 3 to 5 years) after surgery. This follow-up was undertaken at a single point in time. A total of 164 women were contacted, 88 of whom underwent open colposuspension and 76 of whom underwent laparoscopic colposuspension. There were no significant differences between the two treatment groups at 3 to 5 years after surgery and the findings were similar to the 24-month data. Mean operating time was approximately twice as long for laparoscopic colposuspension, but surgeon's estimates of blood loss and patient's estimates of immediate postoperative pain at rest were significantly less after the laparoscopic procedure with a return to normal activities, on average, 5 days earlier (P = .01).

Kitchener and colleagues also found no difference in the objective cure rate (79% for laparoscopic vs. 70% for open) or subjective cure rate (55% vs. 54%) between the study arms, again showing the now well-recognized mismatch between objective and subjective outcomes. The intention-to-treat analysis indicated no significant difference in cure rates between open and laparoscopic surgery. The study was slightly underpowered based on the sample size calculations, but the analyses clearly demonstrated that laparoscopic colposuspension is not inferior to open colposuspension. The complication rate was low in both arms, with more bowel and bladder injuries in the laparoscopic arm and more wound infections in the open arm. Each demonstrated comparable improvements in generic quality-of-life scores. Other points of note include the careful selection of surgeons who had experience of both open and laparoscopic surgery and interestingly as contrasted to the Carey study contrary to the previously held beliefs of laparoscopic surgery is that it would be associated with longer operating times, less postoperative pain, and shorter hospital stay. For hospital stay there was only a small advantage for laparoscopic surgery, with a median stay of 5 days compared with 6 days for open surgery. The operating times were fairly similar in terms of "knife to skin" to completion of surgery, there being a median time of 65 and 51 minutes for laparoscopic and open surgery, respectively, but postoperative pain was significantly less in the laparoscopic surgery group. But there were no differences in time of return to work identified in this study. Complications of surgery were low generally, with a higher bladder injury rates in the laparoscopic procedure and a higher wound infection with open surgery as would be expected. The impact of these differences was analyzed in a cost-benefit analysis accompanying this study that suggested that a greater quality-adjusted life year total is achieved in the laparoscopic arm at both 6 and 24 months, suggesting that laparoscopic surgery may confer an additional benefit of well-being (Manca et al, 2006). But the additional costs of laparoscopic surgery were only recouped after 24 months of follow-up, thus highlighting the need to address long-term outcomes in any surgical study.

The last major publication in this field was a meta-analysis of all of the comparative studies published between 1995 and 2006 of laparoscopic versus open colposuspension (Tan et al, 2007). End points evaluated were operative outcomes and subjective/objective cure. A random-effect model was used and sensitivity analysis performed to account for bias in patient selection. Sixteen studies matched the selection criteria, reporting on 1807 patients, of whom 861 (47.6%) underwent laparoscopic and 946 (52.4%) underwent open colposuspension. Length of hospital stay and return to normal life were significantly reduced after laparoscopic surgery. These findings remained consistent on sensitivity analysis. Bladder injuries occurred more often in the laparoscopic group, but only with marginal statistical significance. Comparable bladder injury rates were found when studies were matched for quality, year, and randomized trials. Cure rates were similar between the two procedures at 2 years follow-up.

The current evidence would suggest that in adequately experienced hands there is no difference in overall safety and efficacy between laparoscopic and open colposuspension. Clearly another concern is how generalizable the data are on laparoscopic colposuspension because the majority of reported studies are from expert laparoscopists or surgeons working in specialized units. The evidence base on both laparoscopic and open colposuspension is limited by relatively short-term follow-up (robust data are needed out to 5 years) and the tendency toward small numbers, and poor methodology limits the interpretation of most studies with the exception of those reported by Carey and coworkers (2006) and Kitchener and colleagues (2006). Laparoscopic colposuspension shows comparable subjective outcome, but poorer objective outcome than both open colposuspension and tension-free vaginal tape procedure in the short to medium term; longer term outcomes are unknown (level 2). It may not be good value for money when compared with open colposuspension in the short term (i.e., first 6 months after surgery), but it could be a cost-effective alternative over 24 months (level 1); other comparisons, however, suggest that minimally invasive midurethral tape procedures may be dominant in health economic terms.

Recommendations from the ICI committee (Smith et al, 2009) **include the following:**

- **Laparoscopic colposuspension is not recommended for the routine surgical treatment of SUI in women (grade A).**
- **Laparoscopic colposuspension might be considered for the treatment of SUI in women who also require concurrent laparoscopic surgery for other reasons (grade D).**
- **Laparoscopic colposuspension should be performed only by surgeons with specific training, expertise, and appropriate workload in laparoscopic surgery and in the assessment and management of urinary incontinence in women (grade D).**

COMPLICATIONS OF RETROPUBIC REPAIRS

As with any major abdominal or pelvic surgical procedure, intraoperative and perioperative complications that may occur after a retropubic suspension include bleeding, injury to genitourinary organs (bladder, urethra, ureter), pulmonary atelectasis and infection, wound infection or dehiscence, abscess formation, and venous thrombosis or embolism. Other common complications more specific to retropubic suspension procedures include postoperative voiding difficulty, detrusor overactivity, and vaginal prolapse. Potentially, it is overcorrection of the urethrovesical angle that may be a major contributory factor in the development of the long-term complications of de novo urgency, voiding dysfunction, and enterocele formation.

Nevertheless, the reported incidence of these problems is relatively low. In their meta-analysis, Leach and associates (1997) noted a 3% to 8% transfusion rate for retropubic suspensions and no significant difference in the overall medical and surgical complication rates between retropubic suspensions, needle suspensions, anterior colporrhaphy, and pubovaginal slings. Mainprize and Drutz (1988), in their review of the MMK procedure literature (2712 patients), noted an overall complication rate of 21%, with wound complications and urinary infections making up the majority (5.5% and 3.9%, respectively). Direct surgical injury to the urinary tract occurred in only 1.6%, and genitourinary tract fistulas occurred in 0.3%. Ureteral obstruction has been reported rarely after Burch colposuspension, and it usually results from ureteral kinking after elevation of the vagina and bladder base, although direct suture ligation of the ureter can occur (Applegate et al, 1987). If it is identified intraoperatively, it is best remedied by removal of the offending ligature and temporary placement of a ureteral stent. The so-called post-colposuspension syndrome, which has been described as pain in one or both groins at the site of suspension, has been noted in up to 12% of patients after a Burch procedure (Galloway et al, 1987). More recently, Demirci and colleagues (2001, 2002) reported the occurrence of groin or suprapubic pain in 15 of 220 women (6.8%) after Burch colposuspension with a follow-up of 4.5 years.

Postoperative Voiding Difficulty

Postoperative voiding difficulty after any type of retropubic suspension is not uncommon, and undoubtedly its occurrence is more likely if there is preexisting detrusor dysfunction or denervation resulting from extensive perivesical dissection. In most cases, however, it is the result of overcorrection of the urethral axis from inappropriately placed or excessively tightened sutures. If the sutures are placed too medially, they may also transfix the urethra or distort it.

Preoperatively, at-risk patients may be identified by their history of prior voiding dysfunction or episodes of urinary retention. These women should be carefully counseled preoperatively about the potential for postoperative voiding difficulty and the possible need for self-catheterization intermittently. Their incontinence should be of sufficient magnitude that its correction offsets the risk of the need for self-catheterization.

Women with postcystourethropexy voiding problems who have obstruction often do not exhibit the classic urodynamic features of obstruction. However, the history of postoperative voiding symptoms and associated new-onset bladder storage symptoms and a finding of a retropubically angulated and fixed urethra generally indicate that obstruction does exist (Carr and Webster, 1997). In such cases, revision of the retropubic suspension by releasing the urethra into a more anatomic position resolves voiding symptoms in up to 90% of cases (Webster and Kreder, 1990; Nitti and Raz, 1994; Carr and Webster, 1997).

The meta-analysis by Leach and coworkers (1997) **noted that the risk of temporary urinary retention lasting more than 4 weeks postoperatively is 5% for all retropubic suspensions, and the risk for permanent retention is estimated to be less than 5%. These risks are not**

significantly different from those for needle suspensions or pubovaginal slings. Mainprize and Drutz's review of the literature (1988) yielded a 3.6% incidence of postoperative voiding problems after an MMK procedure, whereas the Burch procedure literature reports an incidence of postoperative voiding disorders ranging from 3% to 32% (Hilton and Stanton, 1983; Galloway et al, 1987; Eriksen et al, 1990; Alcalay et al, 1995; Colombo et al, 1996a). In more recent literature, voiding dysfunction may be persistent, as noted in 3.5% of a series of 310 women with a mean follow-up of 36 months (Viereck et al, 2004). Nonpersistent voiding dysfunction has been reported in 12.5% (6% to 37.2%) after primary surgery (Smith et al, 2005). After colposuspension conducted as a secondary procedure, Bidmead and associates (2001) reported voiding difficulties requiring intermittent self-catheterization in 6% of cases.

Because the paravaginal repair aims to restore normal anatomy there is theoretically little chance of overcorrection of the urethral axis, which should translate into a lower risk of postoperative obstruction. In Richardson and coworkers' study (1981), 80% of patients were able to void immediately after paravaginal repair, and "all patients had satisfactory bladder function at the time of discharge." However, temporary voiding difficulty has been noted in up to 17% of patients after a VOS procedure (German et al, 1994), and chronic (>2 years) voiding difficulty has been noted in up to 11% of patients after the paravaginal repair (Colombo et al, 1996a).

All patients should be counseled before surgery about the potential need for intermittent self-catheterization.

Bladder Overactivity

Bladder overactivity commonly accompanies anatomic SUI, and its incidence preoperatively has been reported to be as high as 30% in patients undergoing either first correction or repeated operations (McGuire, 1981). **Provided it is considered as a diagnosis, urodynamic evaluation is performed to show whether detrusor overactivity is present, an attempt at treatment of the related overactive bladder symptoms has been made (with or without success), and the patient has been advised that the presence of detrusor overactivity will increase the risk of continuing storage symptoms postoperatively, then preoperative bladder overactivity does not contraindicate a retropubic suspension procedure, provided that anatomic SUI has also been demonstrated.** In the majority of cases, the bladder overactivity symptoms resolve after surgical repair (McGuire, 1988). Leach and coworkers' meta-analysis (1997) found the risk of urgency after a retropubic suspension to be 66% if urgency and detrusor overactivity were present preoperatively, 36% if there was urgency but no documented overactivity preoperatively, and only 11% if there was neither urgency nor overactivity preoperatively. There was no significant difference in the incidence of postoperative urgency between retropubic suspensions, needle suspensions, and pubovaginal slings. Postoperative urgency was noted in only 0.9% of MMK procedures in Mainprize and Drutz's meta-analysis of 15 series (1988), although Parnell and associates (1982) reported that 28.5% of their patients developed postoperative storage symptoms. Jarvis's meta-analysis (1994b) of Burch procedures found the incidence of de novo bladder overactivity to be 3.4% to 18%. More recently, Smith and colleagues (2005) quoted a figure for postoperative detrusor overactivity of 6.6% for colposuspension (range, 1.0% to 16.6%), whereas the incidence of postoperative urgency or of urgency incontinence after the paravaginal/VOS repair has been reported to be 0% to 6% (Shull and Baden, 1989; German et al, 1994; Colombo et al, 1996a).

For those patients in whom postoperative storage symptoms persist, proven to be associated with detrusor overactivity and intractable to management with anticholinergic therapy and behavioral modification, surgical techniques including intravesical botulinum toxin therapy, neuromodulation, augmentation cystoplasty, or detrusor myectomy may be indicated.

Bladder storage symptoms arising de novo after retropubic suspension may be associated with bladder outlet obstruction. This premise is supported by the frequent coexistence of these symptoms with impaired voiding after suspension procedures and confirmed by the finding that urethrolysis, by freeing the urethra from an obstructed position, often resolves both storage and voiding symptoms (Raz, 1981; Webster and Kreder, 1990).

Vaginal Prolapse

Retropubic suspensions alter vaginal and bladder base anatomy, and thus postoperative vaginal prolapse is a potential complication. Genitourinary prolapse has been reported as a sequel to Burch colposuspension in 22.1% of women (range, 9.5% to 38.2%) by Smith and colleagues (2005) in their review of the literature. **The Burch colposuspension, because of lateral vaginal elevation, may aggravate posterior vaginal wall weakness, predisposing to enterocele.** The incidence varies between 3% and 17% (Burch, 1961, 1968; Galloway et al, 1987; Wiskind et al, 1992); **because of this, prophylactic obliteration of the cul-de-sac of Douglas is sometimes considered in performing retropubic suspensions** (Shull and Baden, 1989; Turner-Warwick and Kirby, 1993). However, simultaneous hysterectomy is not recommended prophylactically because it does not enhance the outcome of a retropubic suspension and should be performed only if there is concomitant uterine disease (Milani et al, 1985; Langer et al, 1988). Although the Burch colposuspension and paravaginal/VOS repair both correct lateral defect cystourethroceles, recurrent cystourethroceles were noted in 11% and 39% of Burch colposuspensions and paravaginal repairs, respectively (Colombo et al, 1996a). In Mainprize and Drutz's review (1988), postoperative cystocele was noted in only 0.4% of patients after an MMK procedure.

Wiskind and coworkers (1992) noted that 27% of patients who had undergone a Burch colposuspension developed prolapse requiring surgery: rectocele in 22%, enterocele in 11%, uterine prolapse in 13%, and cystocele in 2%. More recently, it has been suggested that most women are asymptomatic, and less than 5% have been reported to request further surgery (Smith et al, 2005). Ward and Hilton (2004) reported that 4.8% of women needed a posterior repair, whereas Kwon and associates (2003) reported that 4.7% required subsequent pelvic reconstruction.

Auwad and colleagues (2006) have reported the findings of the first prospective study to determine the prevalence of pelvic organ prolapse (POP) after colposuspension and to investigate possible preoperative and operative risk factors. Seventy-seven women who underwent colposuspension between 1996 and 1997 were investigated. POP was assessed before colposuspension using the pelvic organ prolapse quantification (POP-Q) system (Bump et al, 1988). Women were reassessed at 1 and at 7 to 8 years (or when referred with symptomatic POP). By 7 to 8 years, of the 77 women, 29 (38%) had developed symptomatic prolapse, 29 (38%)

had asymptomatic prolapse, 7 (9%) had no symptoms and no prolapse, and 12 (15%) could not be assessed. POP at 1 year was significantly associated with the presence of posterior vaginal descent before colposuspension (odds ratio 3.07, 95% CI 1.10 to 8.60, $P = .03$). No potentially predisposing variable reached statistical significance by 8 years after colposuspension. The results add support to the view that there is an association between colposuspension and the development of symptomatic POP (requiring surgery).

Because retropubic suspensions are unable to correct central defect cystoceles, patients must be carefully examined preoperatively to exclude their presence and must be counseled if undergoing a colposuspension of the high risk of needing further surgery in the long term. Particularly those in whom a weakness of the posterior compartment is identified preoperatively and with a past history of hysterectomy might be at increased risk.

COMPARISONS BETWEEN INCONTINENCE PROCEDURES

Retropubic Repair versus Needle Suspension and Anterior Repair

Three articles that reviewed the literature on incontinence procedures all found retropubic suspensions to be more effective than either needle suspensions or anterior colporrhaphies (Jarvis, 1994b; Black and Downs, 1996; Leach et al, 1997). Cure rates were approximately 85% for the retropubic suspensions compared with 50% to 70% for the needle suspensions and anterior colporrhaphies. Results were more durable for the retropubic suspensions and better if the procedure was primary.

Overall therefore there is now high-level evidence that indicates that needle suspension procedures are as effective as anterior colporrhaphy but less effective than colposuspension even in the short-term (level 1). Long-term studies indicate lack of longevity even of the initial modest results; long-term complications remain a concern (level 3) (Smith et al, 2009).

The recommendation from the ICI committee (Smith et al, 2009) **is that endoscopic and nonendoscopic bladder neck needle suspension procedures, with and without bone anchors, are not recommended for the treatment of SUI (grade A).**

Retropubic Repair versus Pubovaginal Sling

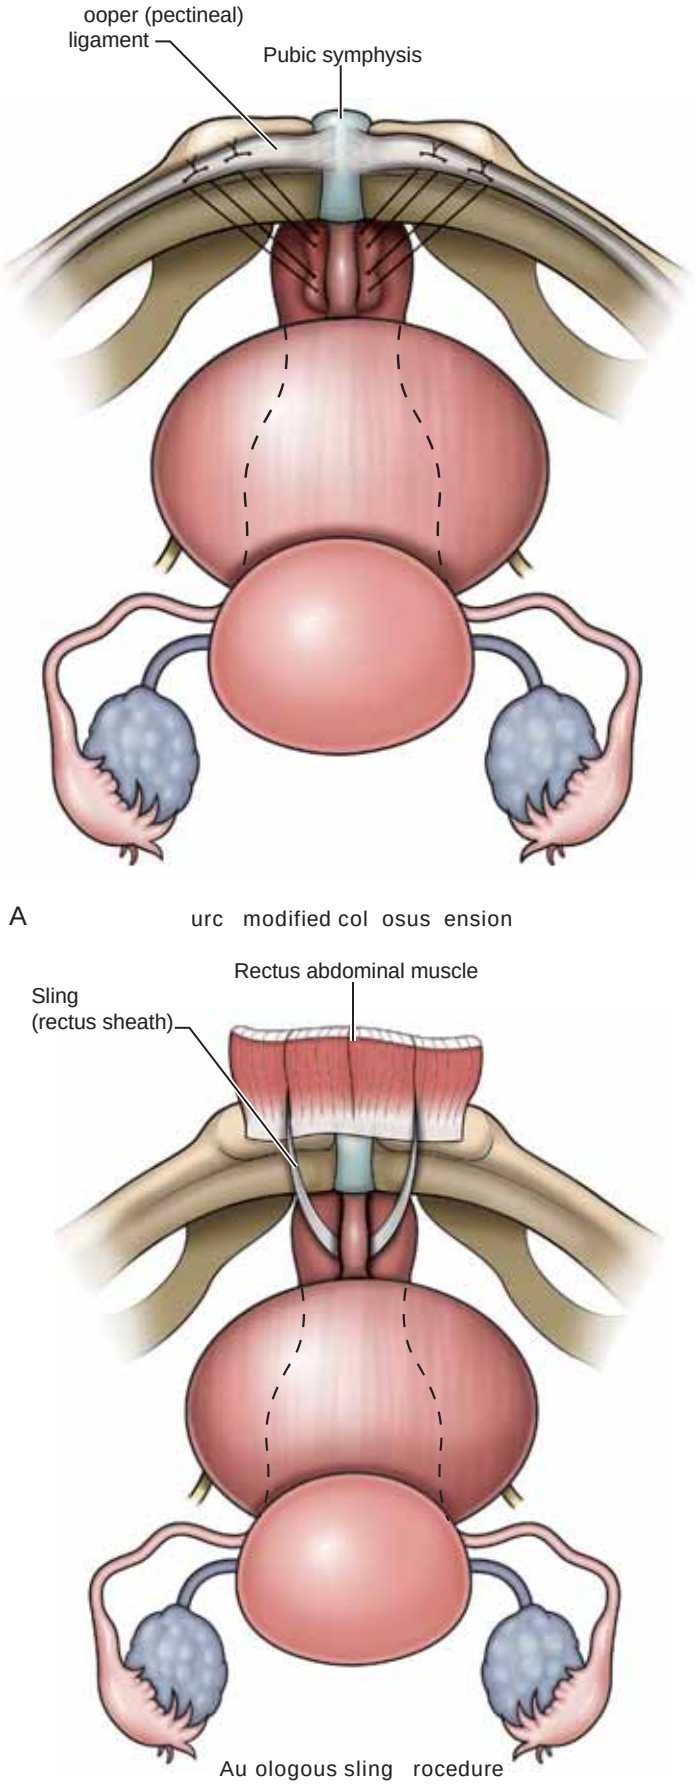
Most studies in the historical literature have not demonstrated a significant difference in cure rates between retropubic suspensions (generally a Burch colposuspension) and pubovaginal slings (Jarvis, 1994b; Black and Downs, 1996; Leach et al, 1997). However, often, selection bias exists in that the pubovaginal sling is generally reserved for patients with multiple prior failed incontinence procedures and with less prolapse, and the presence of presumed intrinsic sphincter deficiency (a fixed urethra with periurethral fibrosis) is often used in clinical practice as a contraindication to a retropubic suspension. In an interesting randomized study in patients with a prior failed incontinence procedure (anterior repair) but without a low-pressure urethra (i.e., MUCP > 20 cm H_2O), Enzelsberger's group (1996) found no significant difference in cure (subjective or objective) at 32 to 48 months between the Burch colposuspension and the Lyodura sling. However, they noted significantly more postoperative voiding difficulty with the pubovaginal sling (13% vs. 3%) and more vaginal prolapse (enterocele or rectocele) with the Burch colposuspension (13% vs. 3%).

A recent high-quality multicenter randomized clinical trial in women with stress incontinence compared the Burch colposuspension with a pubovaginal sling using autologous rectus fascia (Aldo et al, 2007). Women were eligible for the study if they had predominant symptoms associated with the condition, a positive stress test, and urethral hypermobility. The primary outcomes were success in terms of overall urinary incontinence measures, which required a negative pad test, no urinary incontinence (as recorded in a 3-day diary), a negative cough and Valsalva stress test, no self-reported symptoms, no re-treatment for the condition, and success in terms of specific measures of stress incontinence as well as an assessment of postoperative urgency incontinence, voiding dysfunction, and adverse events. A noteworthy aspect of the study was the careful approach to standardization (using the recommendations from the standardization committees of the ICI with regard to clinical terms, urodynamic nomenclature, and methods of evaluation of patients across all sites. Key elements of the two surgical procedures were standardized among all participating surgeons and included the use of preoperative antibiotics, skin-incision length, number and type of Burch sutures, fascial-sling length and width, and cystoscopic evaluation of the bladder. A criticism that can be leveled at the study is the choice of technique for the Burch colposuspension with very medial paraurethral sutures. The techniques utilized are demonstrated in Figure 71–7.

Because these procedures are frequently performed in conjunction with surgery for pelvic prolapse, abdominal and vaginal approaches for both pelvic prolapse repair and hysterectomy were permitted; however, surgeons were required to declare before randomization which concomitant procedures would be performed.

A total of 655 women were randomly assigned to study groups: 326 to undergo the sling procedure and 329 to undergo the Burch procedure; 520 women (79%) completed the outcome assessment. At 24 months, success rates were higher for women who underwent the sling procedure than for those who underwent the Burch procedure, for both the overall category of success (47% vs. 38%, $P = .01$) and the category specific to stress incontinence (66% vs. 49%, $P < .001$). There was no significant difference between the sling and Burch groups in the percentage of patients who had serious adverse events (13% and 10%, respectively; $P = .20$). However, more women who underwent the sling procedure had adverse events than in the Burch group, with 415 events among 206 women in the sling group as compared with 305 events among 156 women in the Burch group. This difference was due primarily to urinary tract infections; 157 women in the sling group (48%) had 305 events and 105 women in the Burch group (32%) had 203 events. When urinary tract infections were excluded, the rates of adverse events were similar in the two groups.

The distribution of time to return to normal voiding differed significantly between the two groups ($P < .001$). Voiding dysfunction was more common in the sling group than in the Burch group (14% vs. 2%, $P < .001$). Consequently, surgical procedures to reduce voiding symptoms or improve urinary retention were performed exclusively in the sling group, in which 19 patients underwent 20 such procedures (63% vs. 47%, $P < .001$). Treatment



satisfaction rates for the 480 subjects who answered the satisfaction question at 24 months were significantly higher in the sling group than in the Burch group (86% vs. 78%, $P = .02$).

A further analysis of this study focused on sexual activity as assessed by the Pelvic Organ Prolapse/Urinary Incontinence Sexual Questionnaire (PISQ-12) among those sexually active at baseline and 2 years after surgery (Brubaker et al, 2009). This report demonstrated that sexual function improves after successful surgery and does not differ between the Burch and sling operations.

It therefore can be reliably concluded that in specialist centers working in a standardized fashion, the autologous fascial sling results in a higher rate of successful treatment of stress incontinence but also greater morbidity than the Burch colposuspension.

Burch Colposuspension versus Marshall-Marchetti-Krantz Procedure versus Paravaginal Repair

Comparisons between the MMK and the Burch procedures have generally yielded similar results. Jarvis, in his meta-analysis of the literature (1994b), noted that overall continence rates were 89.6% and 83.9% for the MMK and the Burch procedures, respectively. When he looked at the effect of prior incontinence surgery, the continence rates were 92.1% and 94% when there was no prior surgery and 84.5% and 84% when there was a history of prior incontinence surgery for the MMK and Burch procedures, respectively. Similarly, Black and Downs (1996), in reviewing five studies (one randomized) that directly compared the MMK procedure with the Burch procedure, found that there was no significant difference in cure rates between the two procedures, although the Burch procedure generally yielded better results. However, they pointed out that overall the studies were of poor quality with small sample sizes.

Two randomized studies that assessed urethral sphincteric function by urethral pressure profilometry had conflicting results. Quadri's group (1999) compared the MMK procedure with the Burch procedure in women with a hypermobile, low-pressure urethra (MUCP ≤ 20 cm H_2O) and noted significantly higher subjective and objective 1-year cure rates with the MMK procedure. They used urethroscopy to facilitate MMK suture placement. On the other hand, Colombo's group (1994) excluded women with a low-pressure urethra (MUCP < 30 cm H_2O) and performed a cystotomy to facilitate MMK suture placement. With 2- to 7-year follow-up (mean, 3 years), they noted higher subjective and objective cure rates with the Burch procedure, although these were not statistically significant. In addition, significantly more MMK patients had persistent postoperative voiding difficulties (28% vs. 8%).

Figure 71–7. **A,** In the Burch colposuspension, sutures are placed in the anterior vaginal wall at the level of the bladder neck and proximal urethra and sutured to the iliopectineal ligament. **B,** In the autologous sling procedure a strip of rectus fascia is harvested and permanent sutures placed at both ends. The sling is positioned beneath the urethra via a vaginal incision. The two ends of the sling are then secured to the anterior abdominal wall, either together or to the rectus fascia. (Modified from Aldo ME, Richter HE, Brubaker L, et al. Burch colposuspension versus fascial sling to reduce urinary stress incontinence. N Engl J Med 2007;356:2143–55.)

The literature on the paravaginal repair is sparse. The only randomized study that compared the Burch procedure with a paravaginal repair found significantly greater subjective and objective cure with the Burch procedure (Colombo et al, 1996a). Until large, randomized studies with prolonged follow-up are available, the issue of which is the best procedure will remain unresolved.

Tension-Free Vaginal Tape Procedure versus Colposuspension

Since its introduction in 1996 by Ulmsten and colleagues, the tension-free vaginal tape (TVT) procedure has gained widespread acceptance for treatment of SUI, given its low morbidity, short-term success rates, and ability to be performed as an outpatient procedure under local or regional anesthesia. The 7-year objective and subjective success rate for TVT is 81% (Nilsson et al, 2004). More recently in reviewing this series, 77% of the initial cohort of 90 women and 89% of those alive and capable of cooperating were assessed 11.5 years after the TVT operation. Ninety percent of the women had both a negative stress test and a negative pad test and were considered to be objectively cured. Subjective cure by patients' global impression was found in 77%, 20% being improved and only 3% regarding the operation as a failure. No late-onset adverse effects of the operation were found, and no case of tape erosion was seen (Nilsson et al, 2008).

There have been a number of well-designed, prospective, randomized trials comparing the Burch colposuspension (two open and two laparoscopic) with TVT.

Liapis and coworkers (2002) reported a prospective randomized comparative study of Burch colposuspension (n = 35) and TVT (n = 36). They concluded that at 2-year follow-up the TVT and Burch procedures were equally effective with an objective pad test cure rate of 84% and 86%, respectively. TVT had a shorter operative time and entailed less postoperative pain with a faster return to normal activity.

Ward and Hilton (2004) published a 2-year follow-up of their landmark prospective randomized trial comparing TVT and open Burch colposuspension. At 2 years, 74% of the initial TVT and 69% of the open colposuspension patients completed the evaluation. The objective cure rates for the TVT (81%) and colposuspension (80%) were not significantly different. However, if the missing patients were evaluated by the last observation carried forward analysis, the cure rates would favor TVT (78% vs. 68%). It is interesting that the subjective cure rates differ from the objective rates dramatically, with only 43% and 37% reporting subjective cure of stress incontinence after TVT and colposuspension, respectively. At 2 years the colposuspension group still had significantly lower scores on mental and emotional health. The incidences of enterocele and vault prolapse were higher in the colposuspension group, requiring significantly more prolapse surgery. Likewise, the number of patients still requiring intermittent catheterization was higher in the colposuspension group. The intraoperative complications were higher in the TVT group, whereas the postoperative complications were higher in the colposuspension group. The authors' conclusion at 2 years, because of patients lost to follow-up, is unchanged from their conclusion at 6 months, namely, that TVT may be better than, worse than, or the same as colposuspension.

A Cochrane review of open colposuspension examined a total of seven trials comparing TVT with open colposuspension (Lapitan et al, 2005), although the trial by Ward and Hilton noted earlier dominated the analysis. The review concluded that TVT and open colposuspension were equally effective but that TVT carried an increased risk of complications, particularly bladder perforation. A further cost-benefit analysis based on the Ward and Hilton study showed that TVT was a cost-effective alternative to colposuspension, largely based on shorter hospital stay and rapid return to work (Manca et al, 2003).

In a further report from the Ward and Hilton study, 98 of those who had TVT and 79 of those having colposuspension returned for 5-year follow up; 72 in the TVT group and 49 in the colposuspension group had full subjective and objective data (Ward et al, 2008). The primary outcome in this analysis was a negative 1-hour pad test and this was not significantly different between the two groups, being recorded in 58/72 (81%) women in the TVT group and 44/49 (90%) in the colposuspension group ($P = .21$, Fisher's exact test) at 5 years. Significantly, more women in the colposuspension group (11 [7.5%]) underwent surgery for prolapse during the follow-up period than those in the TVT group (3 [1.8%]). Tape-related complications were seen in six women. In the first year, one tape was divided for obstructed voiding; there was one suprapubic extrusion and one vaginal erosion. Two further vaginal erosions were detected at 5-year follow-up; and, in addition, one woman was found to have tape within the bladder at cystoscopy after complaining of symptoms of overactive bladder. There were no reported suture-related complications in the colposuspension group.

The effect of both procedures on cure of incontinence and improvement in quality of life appears from this follow-up of a proportion of the originally treated patients to be maintained in the long term out to 5 years (Ward et al, 2008), **with 81% of the women who had undergone TVT and 90% who had undergone colposuspension as satisfied or very satisfied with the results of their surgery at 5 years. The key messages in terms of adverse events are that vault and posterior vaginal wall prolapse are seen more commonly after colposuspension and that late tape erosion may occur several years after surgery.**

Persson and coworkers (2002) were one of the first groups to compare TVT and laparoscopic Burch colposuspension. At 1-year follow-up there was no difference between objective and subjective cure rates. Valpas and associates (2004) conducted a prospective randomized trial comparing TVT and laparoscopic mesh colposuspension at 1-year follow-up. The objective cure rate (negative stress test, 86% vs. 57%), satisfaction, and quality of life were statistically better for the TVT group.

Paraiso and colleagues (2004) prospectively randomized 72 patients into laparoscopic Burch colposuspension and TVT at a mean follow-up of 20 months, but only 17 and 16 patients were available in the laparoscopic and TVT groups, respectively. Whereas objective and subjective cure rates were significantly higher in the TVT group, satisfaction of patients was equal in each group and no difference was reported in voiding dysfunction, urgency, or symptomatic pelvic prolapse. All these laparoscopic studies require longer follow-up with greater power to demonstrate a persistent difference between TVT and Burch colposuspension.

A meta-analysis of the literature has been reported by Novara and colleagues (2007) in which they combined the results of open and laparoscopic colposuspension. To date, nine RCTs compared TVT to Burch colposuspension as primary treatment for SUI (Liapis et al, 2002; Persson et al, 2002; Ward et al, 2002, 2004; Ustun et al, 2003; Paraiso et al, 2004; Valpas et al, 2004; Bai et al, 2005; El-Barky et al, 2005). A further study compared the suprapubic arc sling to laparoscopic Burch colposuspension (Foote et al, 2006). TVT was followed by significantly higher continence rates compared with Burch colposuspension, considering success rates

evaluated according to any definition of continence (OR = 0.58; 95% CI = 0.42 to 0.79; $P = .0007$), presence of negative stress test (OR = 0.38; 95% CI = 0.25 to 0.57; $P < .0001$), and negative pad test (OR = 0.59; 95% CI = 0.41 to 0.85; $P = .005$).

A recent study has contrasted direct health care costs of treatment of SUI in Sweden to four different procedures: (1) open Burch colposuspension (OBC), (2) laparoscopic colposuspension with sutures (LCS), (3) laparoscopic colposuspension with mesh and staples (LCM), and (4) tension-free vaginal tape (TVT) (Ankardal et al, 2007). A model was constructed representing a hospital with standardized surgical equipment, staff, and average unit costs in 2003 euros. The time used for anesthesia and surgery was calculated. Clinical data were collected from three different sources: a multicenter, randomized, prospective study comparing OBC with LCM with 1-year follow-up; a three-armed, prospective study in which women were randomized to either OBC, LCM, or LCS with 1-year follow-up; and a descriptive study reporting results of TVT with 5-year follow-up. Data collected from the studies and hospital cost data were put into the model to create the different cost elements. The total cost per individual, showed a lower cost for TVT compared with the other alternatives. The direct costs for a TVT were only 56% of the costs for an OBC ($P < .001$) and 59% of the costs for an LCS ($P < .001$). Thus, when using a model and comparing health care costs for surgical treatment of female SUI in Sweden, the TVT procedure generated a lower direct cost than both open and laparoscopic colposuspension.

The shift in practice pattern away from Burch colposuspension for the treatment of SUI to midurethral slings as the primary treatment of SUI shows one of the difficulties in conducting surgical randomized controlled trials, especially when the field has changed as quickly as it has in recent years in the treatment of urinary incontinence. A recent survey of urogynecology fellows found that the average third-year fellow had performed 257 midurethral sling procedures and only 13 Burch procedures (LeBrun et al, 2008). It would be interesting to determine if a surgeon's experience with Burch colposuspension is correlated with outcomes. Indeed, the outcomes reported in the existing literature base are likely to be very different to those seen in many clinicians' clinical

Key Points

- Anti-incontinence surgery does not necessarily work by restoring the same mechanism of continence that was present before the onset of incontinence. It works by a compensatory approach.
- The surgeon's preference, coexisting problems, and anatomic features of the patient and her general health condition influence the choice of procedure.
- There is lack of a clear consensus as to which surgical procedure for stress incontinence is most effective, but contemporary practice is shifting to the "loose" urethral sling being the most widely used and having largely replaced the colposuspension.
- A number of variables may influence surgical outcome: age, postoperative activity, medical comorbidity, obesity, duration of symptoms, coexistence of detrusor overactivity, prior surgery, and intrinsic sphincter deficiency.
- There is no consensus on how to differentiate the relative contributions of hypermobility and sphincteric weakness.
- There remains no consensus on how to assess the outcomes of surgery, but this requires careful assessment with adequate follow-up and use of simple objective measures as well as taking particular account of patient-perceived outcomes.
- During short-term follow-up, vaginal and open retropubic suspension procedures have similar success rates. With longer follow-up (and with the exception of the pubovaginal sling), patients who have retropubic procedures fare better.
- With the MMK procedure, placement of sutures through the pubic symphysis incurs the risk of osteitis pubis in 0.9% to 3.2% of patients.
- The Burch colposuspension is as effective as any other procedure in primary or secondary surgery at curing SUI, with proven long-term success. Thus, it should be regarded as the *standard* open retropubic procedure for incontinence.
- Abdominal paravaginal repair is less effective than other forms of colposuspension.
- As with any major abdominal or pelvic surgical procedure, intraoperative and perioperative complications that may occur after a retropubic suspension include bleeding, injury to genitourinary organs (bladder, urethra, ureter), pulmonary atelectasis and infection, wound infection or dehiscence, abscess formation, and venous thrombosis or embolism. Other common complications more specific to retropubic suspension procedures include postoperative voiding difficulty, detrusor overactivity, and vaginal prolapse.
- The risk of temporary urinary retention lasting more than 4 weeks postoperatively is 5% for all retropubic suspensions. The risk of permanent retention is estimated to be less than 5%. These risks are not significantly different from those of needle suspensions or pubovaginal slings.
- All patients should be counseled before surgery about the potential need for intermittent self-catheterization.
- Because retropubic suspensions are unable to correct central defect cystoceles, patients must be carefully examined preoperatively to exclude their presence. The Burch colposuspension, because of lateral vaginal elevation, may aggravate posterior vaginal wall weakness, predisposing to enterocele.
- Retropubic suspensions are more effective than either needle suspensions or anterior colporrhaphies.
- Laparoscopic colposuspension is not recommended as a routine surgical procedure and when performed should only be carried out by a surgeon skilled in laparoscopic surgery.
- Most studies in the literature have not demonstrated a significant difference in cure rates between retropubic suspensions (generally a Burch colposuspension) and pubovaginal slings.
- Comparisons between the MMK procedure and the Burch procedure have generally yielded similar results.
- The literature on the paravaginal repair is sparse. The only randomized study that compared the Burch colposuspension with a paravaginal repair found significantly greater subjective and objective cure rates with the Burch colposuspension.
- At this time, the TVT procedure appears to be at least equivalent to the Burch colposuspension and in general is probably better.

practices in which this has become a rare operation and where many have had very limited experience of performing the procedure during their training over the past decade.

At this time the TVT appears to be an equivalent operation to the open or laparoscopic Burch colposuspension. A recent meta-analysis (Novara et al, 2007) **suggested superiority for the TVT, but this combined open and laparoscopic procedures and studies of variable quality. It is likely that greater reliability should be placed on single high-quality comparative studies** (Ward et al, 2004, 2008). **The TVT has now largely supplanted the colposuspension in contemporary practice. An open colposuspension should still be considered as a surgical option in patients undergoing open surgery and still has a role when there is associated prolapse. The laparoscopic colposuspension has been shown in the short term to have some advantages over open colposuspension in experienced hands but as a procedure has largely been supplanted by the TVT in contemporary practice.**

Vaginal and Abdominal Reconstructive Surgery for Pelvic Organ Prolapse

Jack Christian Winters, MD ● Joanna Maya Togami, MD ● Christopher J. Chermansky, MD

Surgical Anatomy of the Pelvic Floor
Site-Specific Defects by Compartment (Identification)
Preparing the Patient for Prolapse Surgery
Biologic and Synthetic Materials in Prolapse Surgery
Surgical Management of Pelvic Organ Prolapse

Surgical treatment of pelvic organ prolapse (POP) is one of the most challenging problems faced by surgeons who perform procedures to correct disorders of the pelvic floor. The cause is usually multifactorial, and the clinical presentation and the impact on a patient's quality of life may vary considerably. Surgical correction is aimed at addressing defects in the supporting structures, which requires a comprehensive understanding of pelvic floor anatomy and function. Pelvic floor defects have been traditionally named for the prolapsing visceral organs; however, it is important to conceptualize that these disorders have less to do with the prolapsing organs and more to do with compartmental defects in the supportive tissues. Just as any hernia represents a defect in the fascia, POP represents herniations or descensus of the bladder, rectum, bowel, uterus, and urethra through defects in the pelvic floor connective tissues. Procedures must be tailored to the patient's unique presenting factors, such as comorbidities and concomitant pathology of the pelvic floor, as well as patient goals and expectations in surgical restoration of pelvic organ support. The aim of this chapter is to provide a practical overview of the surgical anatomy and discuss the vaginal and open abdominal techniques for the treatment of POP.

Pelvic organ defects occur as compartmental defects of vaginal support. Patients may present with any combination of compartmental defects, and multiple defects are very common. **The aims of surgical management include restoration of normal vaginal anatomy while maintaining visceral and sexual function.** It is critical to understand the patient's goals and expectations of treatment to ensure that the prescribed treatment will meet these goals. This is the art of tailoring the appropriate treatment for each individual surgical patient.

SURGICAL ANATOMY OF THE PELVIC FLOOR

Anatomy

Supporting Structures

Bony Scaffolding. The bones of the pelvis provide the scaffold on which the soft tissue supports (muscles, ligaments, and fascia) are anchored. They include paired innominate or hip bones on either side of the sacrum, which comprise the pelvic girdle. The innominate bones are further divided into the ileum, the ischium, and the pubis. The ischial spine provides attachment for the arcus tendineus fasciae pelvis (ATFP), the sacrospinous ligament, and the coccygeus muscle (Fig. 72–1). The obturator foramen is formed by the superior pubic ramus above, the pubic body and inferior ramus medially, and the anterior border of the ischial body below (Newell, 2005) (Fig. 72–2).

Muscular Supports of the Pelvic Floor. The pelvic floor comprises all of the soft tissues that essentially hold the pelvic viscera in place at the base of the bony pelvis and the levator ani muscle complex. The pelvic floor is a three-dimensional structure that functions as a unit (Hurt, 2000). The pelvic diaphragm is composed of the striated pubococcygeus, iliococcygeus, and coccygeus (Fig. 72–3). The levator ani muscles are composed of the pubococcygeus and iliococcygeus. The coccygeus is also termed the ischiococcygeus and is attached to the lateral margins of the coccyx and fifth sacral segment (Mundy, 2005). It is attached laterally to the ischial spine. The iliococcygeus is attached to the ischial spine, the arcus tendineus levator ani laterally and posteriorly, the tip of

the sacrum, and the coccyx. The pubococcygeus is attached to the back of the pubis, and it courses lateral to the urethra (in males it is the puboure thralis, and in females, because it forms a sling around the vagina, it is the pubovaginalis). In both men and women, fibers of the pubococcygeus attach to the perineal body (Mundy, 2005). The pubococcygeus compresses the visceral canals, which cross the pelvic floor. The puborectalis portion of the pubococcygeus helps to create the anorectal angle. Contraction of the puborectalis causes the rectoanal junction to move toward the pubic symphysis, which is critical in maintaining fecal continence (Rogers, 2003). **Although the muscles are referred to separately, like other structures of the pelvic floor the boundaries are often difficult to delineate and they perform similar physiologic functions** (Mundy, 2005). The posterior levator ani group (iliococcygeus and coccygeus) fuses in the midline and attaches to the coccyx. The complex formed by this fusion is the levator plate, which serves as a supporting structure for the upper vagina and cervix, This serves not only to stabilize the upper vagina in a horizontal plane but also to provide a protective mechanism preventing downward forces onto the perineal body (Wall and Menafee, 2002).

Beneath the pelvic diaphragm is the diamond-shaped urogenital diaphragm (Fig. 72–4). The boundaries are the pubic symphysis anteriorly, the tip of the coccyx posteriorly and laterally, and the ischiopubic rami on either side. It can be further divided anteriorly and posteriorly by imagining a line between each ischial tuberosity. This results in the urogenital triangle anteriorly and the anorectal triangle posteriorly. The deep transversus perinei muscle, also referred to as the perineal membrane, is contained by the urogenital triangle, in which the urethra and vagina traverse. In contrast to the perineal membrane in males, which is a sheetlike structure, the perineal membrane in females is a three-dimensional structure that has two regions, dorsal and ventral (DeLancey, 1999; Stein and DeLancey, 2008) (Fig. 72–5). The dorsal region is attached to the perineal body and the lateral wall of the vagina via the ischiopubic rami. The ventral region is part of a solid

three-dimensional mass that is contiguous with the paraurethral and paravaginal connective tissues. This portion contains the compressor urethrae and urethrovaginal sphincter muscles of the distal urethra (Stein and DeLancey, 2008).

The anorectal triangle contains the external anal sphincter, which attaches to the anococcygeal ligament and fuses to the superficial transverse perinei muscle. External to the urogenital triangle are the external genital muscles, bulbospongiosus, ischiospongiosus, and superficial transversus perinei. The hymen is located just inside the labia minora and is the fixed point of reference recommended by the International Continence Society Committee on Standardisation of Terminology, Subcommittee on Pelvic Organ Prolapse and Pelvic Floor Dysfunction to grade prolapse (Bump et al, 1996). This is in contrast to the term *introitus,* which is ill defined.

The urogenital hiatus is the opening within the levator ani muscle through which the urethra and vagina pass. Because the rectum is attached directly to the muscles at this level it is not within the urogenital hiatus. The hiatus is supported anteriorly by the pubic bones and levator ani muscles and posteriorly by the perineal body and external anal sphincter (Ashton-Miller and DeLancey, 2007). The urogenital hiatus elongates and descends with POP.

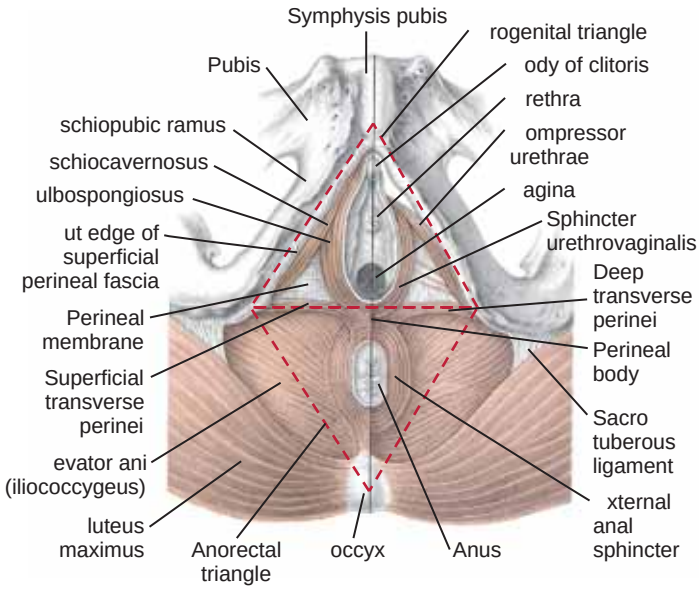

Figure 72–4. Muscles of the female perineum. The cut edge on the right side is the cut edge of the superficial fascia that has been removed. The left side depicts the deep perineal muscles (seen without the superficial perineal muscles and overlying fascia. (From Mundy A. True pelvis, pelvic floor and perineum. In: Standrinak W, editor. Gray's anatomy: the anatomical basis of clinical practice. 39th ed. New York: Elsevier; 2005.)

Endopelvic Fascia and Connective Tissue Supports. The endopelvic fascia is a network of fibromuscular tissue located between the peritoneum and the levator muscles. It surrounds and attaches the bladder, uterus, vagina, and rectum to the pelvic walls, thereby stabilizing the pelvic viscera. The endopelvic fascia is one continuous unit; however, distinct areas are named separately. The parametrium (broad, cardinal, and uterosacral ligaments) attaches the uterus and upper vagina to the pelvic sidewall. The paracolpium (the arcus tendineum levator ani and the ATFP) attaches the vagina to the pelvic sidewalls. In his landmark article, DeLancey (1992) described the supports of the vagina and conceptually divided them into three parts according to the region of vaginal support (Fig. 72–6). The structures supporting the uterus and the cephalad 2 to 3 cm of the vagina comprise level I support, and these fibers originate from the greater sciatic foramen, the sacroiliac region, and the lateral sacrum. The fibers are primarily vertical in their orientation and are the longest fibers of the endopelvic fascia, thereby suspending the uterus and upper vagina, and comprise the cardinal/uterosacral ligament complex. Level II support is at the mid vagina. These fibers are shorter than level I support but longer than those at level III. The orientation of the attaching fibers is lateral, and they are more dense than the cardinal/uterosacral ligament complex. The endopelvic fascia splits at this level to encompass the bladder and urethra such that the abdominal leaf is still named the endopelvic fascia and the vaginal leaf is the pubocervical and periurethral fascia. Posteriorly, the endopelvic fascia, which attaches laterally to the superior fascia of the levator ani muscles, is the rectovaginal fascia. Level III support of the vagina starts at the introitus and extends 2 to 3 cm above the

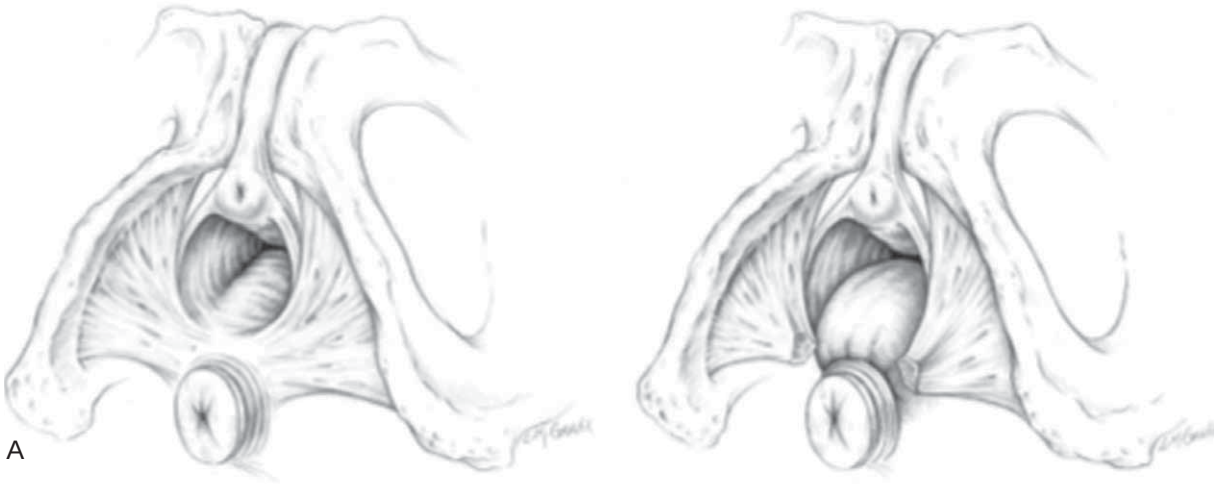

Figure 72–5. **A** and **B,** Perineal membrane. The two halves of this triangular sheet of fibromuscular connective tissue form a central tendon referred to as the perineal body. (From DeLancey JO. Structural anatomy of the posterior pelvic compartment as it relates to rectocele. Am J Obstet Gynecol 1999;180:815–23.)

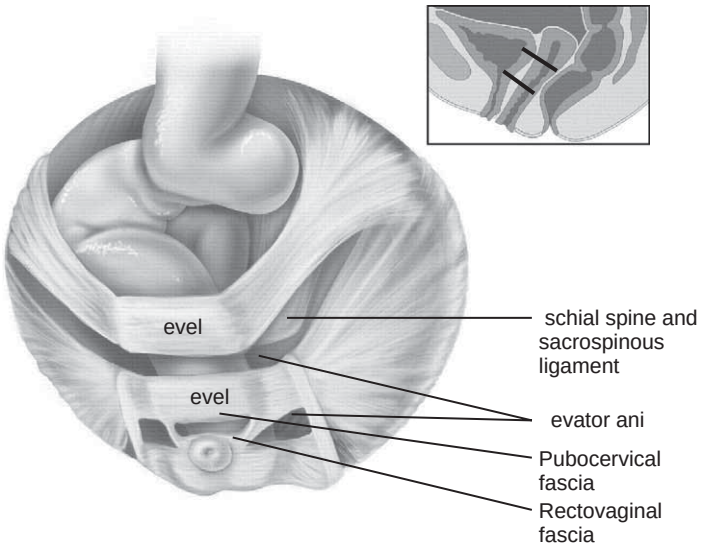

Figure 72–6. Vaginal and visceral supportive structures as defined by DeLancey. The fibers of level I support are oriented vertically and suspend the uterus and upper vagina. Level II support is more horizontal in its orientation and attached to the mid vagina. Distally, level III support fuses directly into the support structures. (From DeLancey JO. Anatomic aspects of vaginal eversion after hysterectomy. Am J Obstet Gynecol 1992;166:1717–28.)

hymenal ring. In this most distal location there is no intervening paracolpium and the vagina is fused directly to the urethra and is embedded in the connective tissue of the perineal membrane (urogenital diaphragm). Laterally it blends into the medial margins of the levator ani muscles, and posteriorly it blends into the perineal body.

The endopelvic fascia is a composite of tissues of fibers embedded in a matrix. The variability of this tissue matrix may lead to its inherent weakness and inconsistency in reconstructive surgery. In fact, fresh strips of pubocervical fascia have been shown to shorten 15% to 20% of its length (Richardson, and DeLancey, 2000). Thus, these tissues are supportive and contractile. Histologically, this tissue is unlike abdominal wall fascia or the fascial coverings of other muscles such that they lack the organization of the fascial coverings of the skeletal muscle.

Support by Compartment

Anterior Compartment Supports. Because the urethra is fused to the anterior vaginal wall for much of its length, the supporting structures of the urethra and distal anterior vagina are one in the same. The major components are the endopelvic fascia (periurethral and pubocervical fascia), ATFP, and the levator ani muscles (Ashton-Miller and DeLancey, 2007). At this level the endopelvic fascia surrounds the vagina and attaches to the ATFP bilaterally. Each ATFP is attached to the pubic bone anteriorly and to the ischial spine dorsally. This structure appears as a band closer to the pubic bone, and as it courses toward the ischial spine it fans out into a broad aponeurotic structure. Laterally it merges with the levator ani muscles at the confluence of the iliococcygeus and obturator internus.

Apical (Middle) Compartment Supports. This support is provided by the cardinal/uterosacral ligament complex, which are level I supports as described by DeLancey (1992). They originate from fibers of the pelvic sidewall and extend to the area around the greater sciatic foramen and extend to the second, third, and fourth sacral segments. From there they fan out as they attach to the cervix and the upper vagina. The medial edge of this complex is the area of the uterosacral ligaments. The uterosacral ligaments are visible and palpable with traction of the cervix or the cuff of the vagina after hysterectomy. The fibers encircle the cervix and in aggregate are called the pericervical ring.

Posterior Compartment Supports. The rectovaginal fascia is also sometimes referred to as Denonvilliers fascia in the female (Richardson and DeLancey, 2000). It has more dense strands of elastin and less smooth muscle compared with the pubocervical fascia. It is stabilized in the upper vagina by the cardinal/uterosacral ligament complex, because it is contiguous with this structure. The uterosacral ligament inserts into the rectovaginal fascia just below the attachment to the posterior cervix. Because the rectovaginal fascia is connected to the sacrum and the perineal body it provides continuous posterior support.

The perineal body is a condensation of fibromuscular tissue and collagen that is located in the midline between the vagina and the anus. It serves as a point of fixation for the rectovaginal fascia, the levator ani muscles, the transverse perinei muscles, and the external anal sphincter (Rosenblum et al, 2005).

Pathophysiology of Pelvic Organ Prolapse: Surgical Correlation

The levator ani muscles comprise both type I and type II fibers. Type I muscle fibers are slow twitch and provide sustained tonicity of the pelvic floor. This function serves a crucial role in providing dynamic pelvic floor support, thus taking the mechanical stress off of the endopelvic connective tissue attachments. Type II fibers consists of fast-twitch fibers that are mainly responsible for the reflex contractions of the pelvic floor associated with sudden increases in intra-abdominal pressure. Thus, the levator ani muscle complex fulfills multiple functions. First, the tonic contraction of the pubococcygeus muscle narrows the genital hiatus. Second, contraction of the pelvic floor leads to the elongation and elevation of the pelvic organs facilitating urinary and fecal continence. Additionally, posterior levator ani tonicity elevates the upper vagina and stabilizes it into a horizontal plane near the hollow of the sacrum (Fig. 72–7) (Wall and Menafee, 2002). Direct muscular damage, neuromuscular dysfunction, and inherent tissue defects may predispose to a dysfunction of the levator ani musculature. As a result, the burden of support shifts mostly to the endopelvic connective tissues. As these structures weaken, various “breaks” occur that lead to vaginal support defects.

It is most useful to define defects by compartment while keeping in mind that many patients present with multicompartmental defects. Additionally, some patients will present with several defects within the same compartment.

SITE-SPECIFIC DEFECTS BY COMPARTMENT (IDENTIFICATION) (Table 72–1)

Anterior Compartment

Within the anterior compartment two types of defects can lead to cystoceles. The central cystocele results from attenuation or separation of the pubocervical fascia, resulting in a protrusion of anterior compartment structures through this defect. This protrusion results in the classic appearance of a loss of the rugae or vaginal

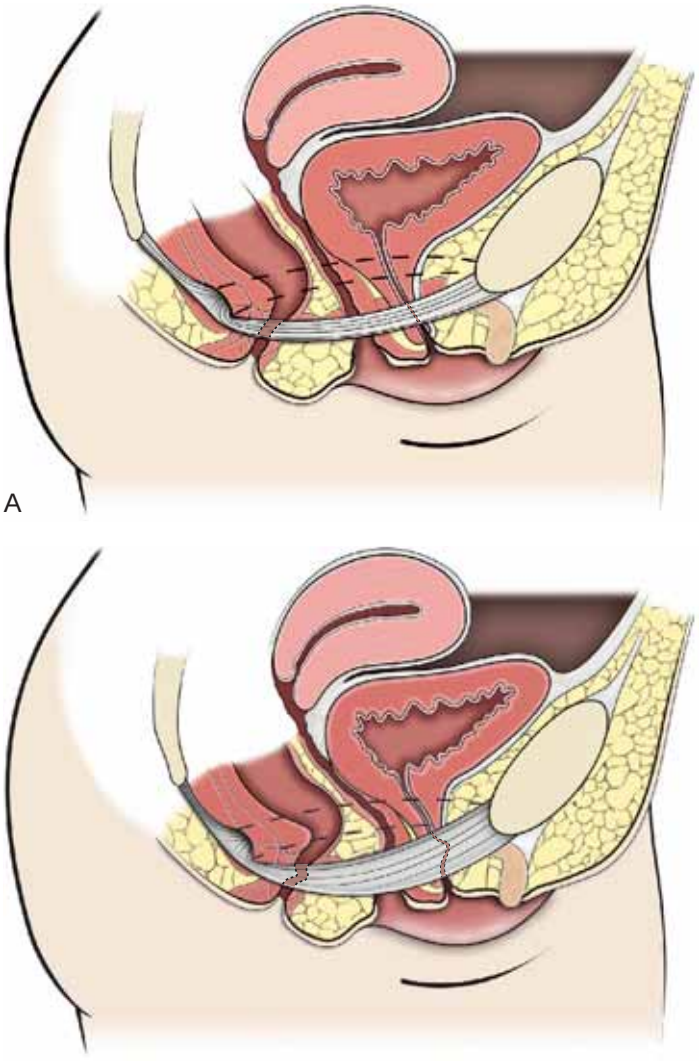

Figure 72–7. Function of the levator ani. The tonic contraction of the pubococcygeus muscle narrows the genital hiatus and leads to elongation and elevation of the pelvic organs, facilitating continence (**A** at rest; **B** contracted). The posterior levator ani elevate the upper vagina and stabilize it on the levator plate, which provides a supportive role to the perineal body. (From Wall LL, Menefee S. Incontinence, prolapse and disorders of the pelvic floor. In: Berek JS, editor. Novak's textbook of gynecology. 13th ed. Philadelphia: Lippincott Williams & Wilkins; 2002, with permission.)

folds of the anterior vaginal wall. Detachment of the pubocervical fascia and the pubourethral ligaments to the ATFP results in a lateral cystocele and can also involve the urethra. This usually results in a preservation of the rugal folds of the vaginal wall and a "rotational" prolapse of the anterior wall (Fig. 72–8). Urethroceles, which are distal anterior compartment defects, usually result in urethral hypermobility (Weber and Walter, 1997).

Apical Compartment

Apical compartment defects involve a disruption in the uterosacral/cardinal ligament complex. This defect may lead to prolapse of the uterus, the vaginal cuff after hysterectomy, and the peritoneum cul-de-sac with or without bowel (enterocele). Enteroceles

Table 72–1.

Compartmental Anatomy: POP-Q Sites and Organ Involvement

COMPARTMENT	POP-Q SITE	PROLAPSED ORGAN	VAGINAL WALL SITE
Anterior	Aa	Urethra (urethrocele)	Distal anterior vaginal wall
	Ab	Bladder (cystocele)	Proximal and distal anterior vaginal wall
Middle	C	Cervix	Cervix
	D	Small bowel (enterocele)	Uterosacral scar
Posterior	Ap	Small bowel (enterocele)	Proximal posterior vaginal wall
	Bp	Rectum (rectocele)	Proximal and distal posterior vaginal wall
		Perineal body	Perineal body

are most commonly associated with apical or high posterior compartment defects; however, enteroceles may rarely occur anteriorly. Enteroceles can occur with or without vaginal vault prolapse. Complete vaginal vault prolapse contains enteroceles in 75% of patients. Waters (1956) described four types of enteroceles by etiology: congenital, pulsion, traction, and iatrogenic. Congenital enteroceles occur either from the failure of the peritoneum to fuse with the perineal body or from reopening of previously fused structures. Pulsion defects occur with increased intra-abdominal pressures, and traction enteroceles occur by a pulling of the vaginal epithelium from other prolapsing organs. Iatrogenic enteroceles are created when a surgical procedure is performed that alters the normal vaginal axis or when the pubocervical fascia and the rectovaginal septum are not reapproximated after hysterectomy (Wiskind et al, 1992).

Uterine prolapse occurs with loss of support of the cardinal and uterosacral ligaments. The broad ligaments also provide uterine support and are located above insertion of the cardinal uterosacral ligaments. They are located within the leaves of the anterior and posterior peritoneum. Within this fused structure are the fallopian tubes and the round and ovarian ligaments along with their blood supply (Rosenblum et al, 2005). It is difficult to differentiate other prolapsing organs with loss of apical support high in the vagina. As such, careful dissection is often needed to identify other prolapsing organs with uterine prolapse. **This reinforces the concept that the endopelvic fascia is best considered as a contiguous unit that can fail together. Consequently, the bladder, small bowel, and rectum are often found prolapsing with the uterus.**

Vaginal vault prolapse can occur after hysterectomy if support of the vault is not reconstituted by suspending it to the cardinal/uterosacral ligament complex. Incidence of vaginal vault prolapse after hysterectomy has been reported to be as high as 18.2%, and it can contribute to prolapse in other compartments (Richter, 1982). Because of the redundancy of the support by the endopelvic fascia, failure to reattach the suspensory component does not lead to immediate vaginal eversion after hysterectomy (DeLancey, 1992). Complex vaginal eversion is vaginal eversion associated with cystocele, rectocele, or both (DeLancey, 1992). Complex vaginal eversion has been reported as high as 67% of vault prolapse (Morley and DeLancey, 1988). In this group of patients, 7% had apical prolapse and cystocele, 30% had apical prolapse

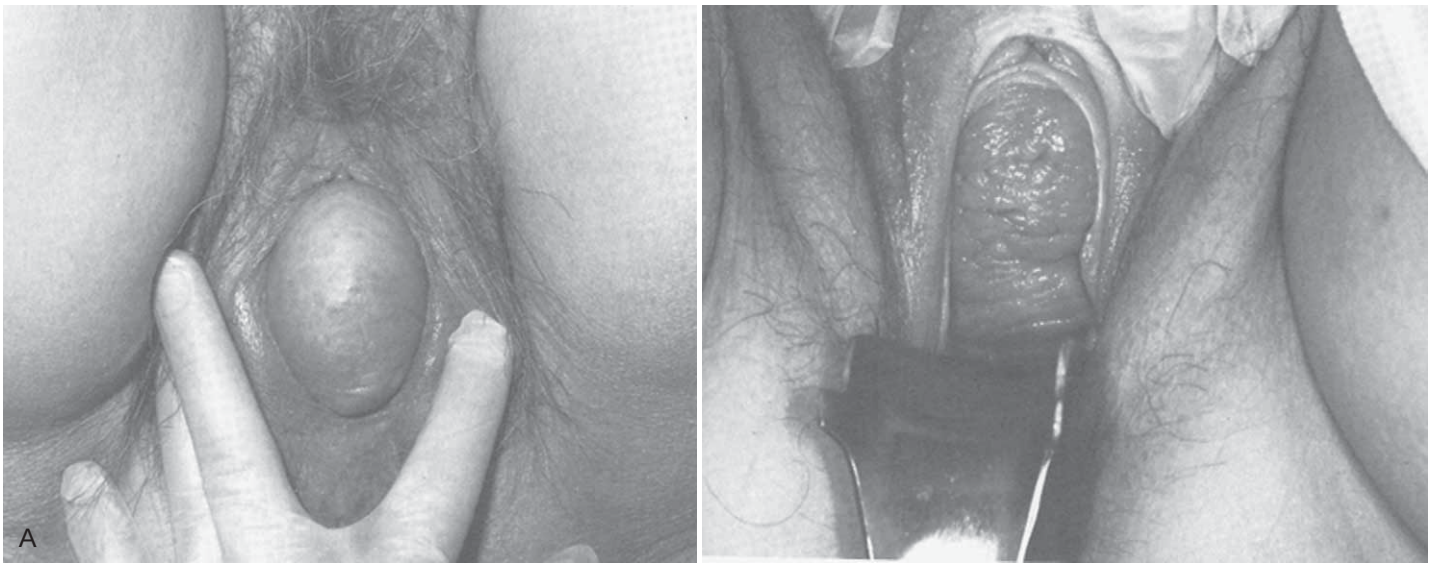

Figure 72–8. **A** and **B,** Cystoceles. (From DeLancey JO. Relation of prolapse syndromes to symptoms. In: Kursh E, McGuire E, editors. Female urology. Philadelphia: JB Lippincott; 1994.)

with rectocele, and 30% had prolapse with both cystocele and rectocele.

Posterior Compartment

The posterior vaginal compartment comprises the peritoneum of the cul-de-sac, the rectum, and the perineum. Defects in the rectovaginal fascia either in the form of attenuated fascia or site-specific tears will result in herniation of the rectum and sometimes the small bowel into the vagina. Rectoceles may be divided into low, midvaginal, or high depending on the location of loss of support, and it may present as a combination of defects. Richardson was the first to describe site-specific defects of the rectovaginal fascia in 1993 (Fig. 72–9). Defects in the cardinal/uterosacral ligament complex can result in high rectoceles and can involve enteroceles. Enteroceles are estimated to be present in 0.1% to 16% of women undergoing surgery for POP (Chou et al, 2000). Loss of support in the mid vagina from the lateral attachments to the arcus tendineus fascia rectovaginalis will result in a bulging in the midportion of the posterior compartment. The perineal body is suspended from the sacrum by the contiguous support of the uterosacral ligaments and rectovaginal septum. Any break in this support system will lead to a hypermobile perineal body that descends with increases in intra-abdominal pressures (Richardson, 1993). Separation of the perineal body at the level of the rectovaginal fascia results in perineal descent or a low rectocele. The rectocele will be visible just inside the hymen posteriorly (Fig. 72–10). If perineal body detachment is left untreated at the time of rectocele repair, a perineal rectocele can occur in which the rectum bulges into the perineal body, termed a *perineal rectocele* (Richardson, 1995).

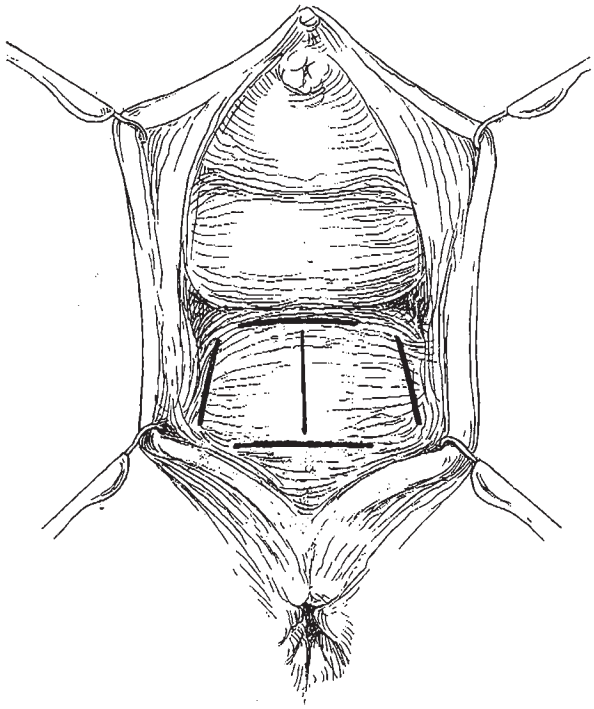

Figure 72–9. Locations where breaks in the rectovaginal septum have been observed in patients with posterior defects. (From Richardson AC. The rectovaginal septum revisited: its relationship to rectocele and its importance in rectocele repair. Clin Obstet Gynecol 1993;36:976–83.)

PREPARING THE PATIENT FOR PROLAPSE SURGERY

Because pelvic organ prolapse is, for the most part, a quality of life issue, consideration must be given to the grade of prolapse, patient's symptoms, and the degree to which the patient's quality of life is impaired (Novara and Artibani, 2005). In selecting surgical procedure(s), one must individualize management based on the unique clinical presentation of each patient, taking into account physiologic age, comorbidities, previous surgeries, and level of physical and sexual activity (Flynn and Webster, 2002). Once the decision has been made to proceed with surgery, it is imperative to recall that the best chance at restoring normal support and function is to reapproximate normal anatomy during

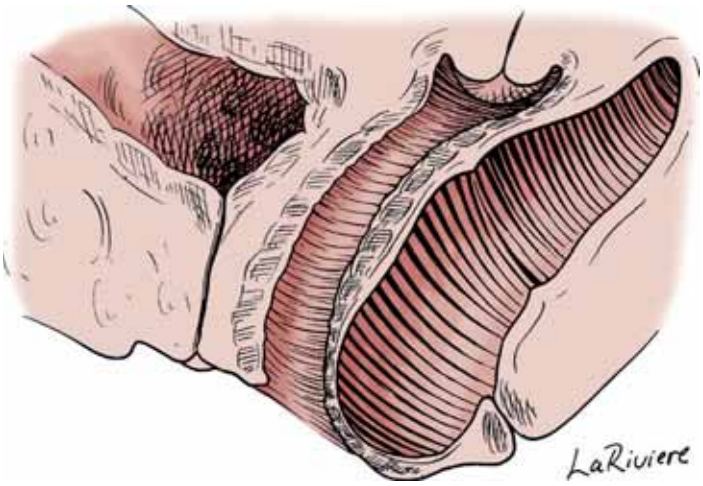

Figure 72–10. Large rectocele with perineal body defect. (From Nichols DH. Rectocele and perineal defect. In: Nichols DH, editor. Gynecologic and obstetric surgery. St. Louis: CV Mosby; 1993. p. 363–85.)

the first surgery (Rogers, 2003). After the first procedure, the normal anatomic planes will no longer be present, which may add to the difficulty and complexity of subsequent surgeries. Recurrence rates increase with each attempt to surgically correct the defect(s) (Birch, 2005; Maher et al, 2006). In addition, the surgeon who operates in the region of the pelvic floor must understand the anatomic alterations that result from each technique and how that surgery will affect the continuity and function of the endopelvic fascia and its related viscera (Rogers, 2003).

Repairs can be defined as restorative, compensatory, and obliterative (Van Rooyen and Cundiff, 2005). In patients whose comorbidities preclude prolonged surgery, obliterative procedures provide symptom relief with minimal morbidity. These procedures are contraindicated in patients who wish to remain sexually active. For those patients who have discrete defects in the fibromuscular layer of the endopelvic fascia, restorative repairs are an appropriate option. These repairs correct the defined defects in the native tissues by utilizing endogenous support structures. For patients whose native tissues are particularly weak or in those who have had failed surgeries, compensatory procedures have been used. These procedures involve placing a graft to reinforce the repair. Grafts are made of synthetic materials and biologic and autologous tissues.

In assessing tension of the repair at the time of surgery, the pelvic floor surgeon should recall that the muscles of the pelvic floor are relaxed under anesthesia (general or spinal). Postoperatively, these muscles will contract along with the endopelvic fascia due to its own contractile fibers. Furthermore, scarring and postmenopausal atrophy may also cause further narrowing (Segal and Karram, 2002). Although the etiology of postsurgical dyspareunia is not fully understood, these factors should be kept in mind when repairing the pelvic floor.

Pelvic floor reconstruction may be performed through a vaginal, open abdominal, laparoscopic approach or any combination of these techniques. Because POP is often mixed, surgery commonly involves a combination of repairs addressing any affected compartments. In addition, an anti-incontinence procedure may be performed at the same time. In comparing the vaginal approach with the abdominal approach there is a benefit with the vaginal approach in that complications and recovery time are less with the vaginal approach (Weber and Richter, 2005). The operative time is generally less with the vaginal approach, as is the hospital stay and recovery time (Morley and DeLancey, 1988; Shull, 1999). However, there is evidence that the abdominal approach is more durable compared with a vaginal technique (Benson et al, 1996). This fact should be considered in younger and more active patients.

Preoperative Counseling of Patient for Vaginal POP Surgery

Over the past decade the definition of success has been expanded to include patient satisfaction and symptom improvement in addition to objective measures. Patients' expectations and readiness to undergo surgery for POP have been shown to impact their satisfaction and how they perceive their improvement (Kenton et al, 2007). In the first article to examine patient-selected goals and surgical outcomes, Elkadry and coworkers (2003) found that patient satisfaction after surgery for POP correlated highly with achievement of self-described goals. In contrast, patient satisfaction correlated poorly with objective measures of surgical success. Dissatisfaction was highly associated with feeling unprepared for surgery. Furthermore, patients perceived the experience of routine postoperative events such as pain, hospital discharge with a catheter, constipation, urgency incontinence, and minor effects of anesthesia as surgical complications. These perceived complications were also associated with dissatisfaction. Additionally, they also demonstrated dissatisfaction despite high cure rates. **Thus, patient perception of perioperative events and bother from recurrent symptoms equate largely to postoperative dissatisfaction even in the presence of high objective cure rates. It is vitally important to recognize that the absence of symptoms influences patient satisfaction greater than the elimination of anatomic prolapse.** Kenton and associates (2007) evaluated patients with standardized counseling using a three-page handout on what to expect after surgery. Women who perceived they were fully prepared for surgery were more likely to be improved on the Patient Global Impression of Improvement (PGI-I) scale (Yalcin and Bump, 2003) and had lower postoperative scores on the Pelvic Organ Prolapse Distress Inventory (POPDI) (Barber et al, 2001) and Urogenital Distress Inventory (UDI) (Shumaker et al, 1994). Also, they found that objective measures of cure did not differ by preparedness. In conclusion, **the preoperative surgeon-patient interaction is a key time that can be used to improve postoperative patient satisfaction. Therefore it is recommended to complete a thorough consent about the surgery, alternatives to surgery, the purpose of planned surgery (what it can and cannot accomplish), the benefits of surgery (what symptoms can be improved), the risks, and complications. In addition, it is useful to review what to expect while the patient is in the hospital, what to expect at home, and strategies on coping with a catheter both in the hospital and at home if needed** (Kenton et al, 2007).

In 2001 the Agency for Healthcare Research and Quality (AHRQ) identified perioperative interventions to improve patient safety (Shojania et al, 2001). These include asking the patient to recall and restate what she was told during the informed consent process, administering appropriate antibiotic prophylaxis to prevent postoperative infections, and implementing prophylaxis to prevent venous thromboembolism in patients at risk.

The second most common source of nosocomial infections is infection at the surgical site (Bratzler and Houck, 2004). Current

guidelines by the Centers for Medicare and Medicaid Services recommend that prophylactic antibiotics be administered within 60 minutes of incision time and discontinued within 24 hours of surgery (Centers for Medicare and Medicaid Services, 2008). The antibiotic chosen should be active against the likely infectious organisms to be encountered during the surgery performed. Although the American College of Obstetricians and Gynecologists has provided recommendations for antibiotic prophylaxis in patients undergoing hysterectomy there are no current guidelines addressing prolapse operations without hysterectomy (ACOG, 2009). Most favor the use of prophylactic antibiotics in reconstructive vaginal surgery, especially in surgery involving synthetic and biologic grafts.

The risk of deep venous thrombosis (DVT) after major gynecologic surgery in patients not receiving prophylaxis is between 15% and 40% (Gutt et al, 2005). Risk factors include increasing age, previous venous thromboembolism, gynecologic malignancy surgery, and major pelvic reconstructive surgery. Waetjen and associates (2003) found that 42% of patients having surgery for POP were older than 60. The Centers for Medicare and Medicaid Services has endorsed a risk stratification presented by Geerts and colleagues (2004) that states that patients older than age 60 undergoing major surgery are at high risk for DVT. Without prophylaxis, high-risk patients have a 20% to 40% risk for calf DVT, a 2% to 4% risk for pulmonary embolism, and a 1% risk of fatal pulmonary embolism. They have recommended both anticoagulant-based and mechanical prophylaxis in patients at high risk for DVT. Specifically, heparin 5000 units three times a day and low-molecular-weight heparin with or without sequential compression devices are acceptable choices.

Patients with advanced POP and incomplete bladder emptying may be taught to perform clean intermittent catheterization (CIC) preoperatively in the event that complete bladder emptying becomes a problem postoperatively. **In postmenopausal women, local estrogen therapy with vaginal cream to treat atrophic vaginitis is started 6 weeks preoperatively.** The administration of unopposed low-dose vaginally administered estrogen has been shown to be both safe and effective (Robinson and Cardozo, 2003). Also, local estrogens may increase vascularity and facilitate healing (Cervigni, 1996). The use of yellowfin (Allen, Acton, MA) or comparable stirrups, careful positioning of the patient in a neutral anatomic position, and avoiding leaning on or into the patient will minimize the risk of neuropathy, specifically to the lateral peroneal nerves.

BIOLOGIC AND SYNTHETIC MATERIALS IN PROLAPSE SURGERY

Although there has been an increased use of interposition graft materials in the area of pelvic floor reconstruction there are little controlled data to recommend their use. Graft materials have been used in an effort to improve outcomes of transvaginal prolapse repairs. The risk factors for failure of prolapse surgery include age, vaginal parity, smoking, deficient tissue quality, conditions that impair wound healing (diabetes mellitus and corticosteroid use), and conditions that stress the repair (chronic constipation, chronic obstructive pulmonary disease, and obesity). **When examining the issue of failed prolapse surgery there are limitations. The definition of failure is not standardized, and many studies are short term, lacking controls. However, in spite of the limitations it is clear that failure of prolapse surgery is not uncommon.** Some patients with POP have specific deficiencies in their tissues, which may predispose them to failure with traditional restorative procedures. Abnormal type I to type III collagen ratios have been identified, leading to a less organized collagen matrix (Falconer et al, 1998). Normal collagen protects fibroblasts from apoptosis, whereas abnormal fibroblasts are not protective (He et al, 2002). Decreased numbers and impaired function of fibroblasts have also been cited (Poncet et al, 2005). Overexpression of matrix metalloproteinases that break down extracellular matrix proteins have been demonstrated in women with prolapse (Jackson et al, 1996). These factors imply that these affected tissues may be less likely to respond to the dynamic forces placed on the female pelvic floor (Chen et al, 2004). As a result of these potential tissue disorders and inherent tissue weakness, graft interposition has been utilized with increased frequency. Although there is level I evidence supporting the use of synthetic graft materials for abdominal sacrocolpopexy (Davila et al, 2005) there is little evidence regarding the most appropriate usage of transvaginal mesh in prolapse repairs.

Classification of Graft Materials

The ideal prosthetic implant would be biocompatible, chemically inert, noncarcinogenic, mechanically strong, and sterile, have minimal allergic or inflammatory reaction, and avoid shrinkage and mechanical stress (Birch, 2005). In addition, the ideal implant should be readily available and affordable. Grafts may be categorized as either synthetic or biologic, and both graft types are used in pelvic floor reconstruction. Synthetic graft materials are usually classified as absorbable or nonabsorbable (permanent). Permanent graft materials are usually classified by pore size (macroporous, microporous, submicroporous, and combined) and by material structure (monofilament or multifilament). Biologic grafts are classified by source—autologous or heterologous—and further categorized as allografts or xenografts (Fig. 72–11).

Basic Science: Graft-versus-Host Interaction

Graft incorporation of the tissues involves a foreign body response. Although many materials used for synthetic grafts are reported to be chemically and physically inert and nonimmunogenic (Davila

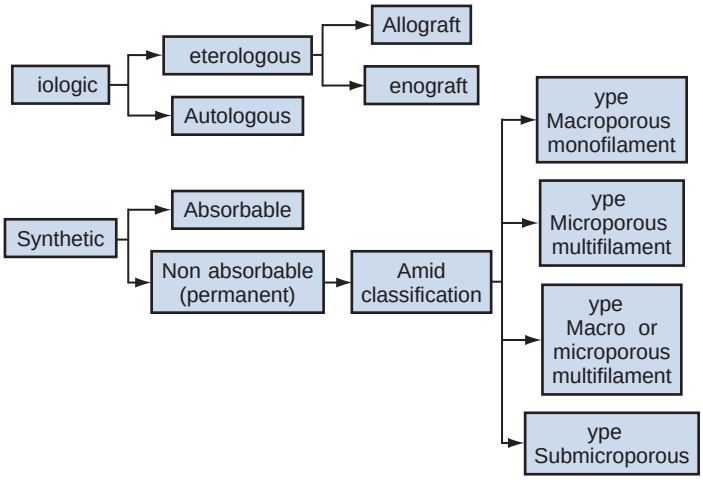

Figure 72–11. Classification of graft materials. (From Togami J, Krlin R, et al. Graft materials in prolapse surgery. AUA Update Series 2008;27[31]:294–303, with permission.)

et al, 2005; Deprest et al, 2006), none is biologically inert. Regardless of the material type, wound healing with a graft follows a stepwise cascade. Initially a biofilm is produced in response to tissue injury. Low-molecular-weight protein adsorption occurs quickly at the interface and does not require a cellular response. Complex proteins such as fibrinogen, immunoglobulins, and extracellular matrix proteins follow. If bacteria are incorporated into the biofilm at this point later wound healing can be affected (Deprest et al, 2006). These complex proteins undergo a conformational change to become more immunogenic, which leads to an inflammatory cascade by activating complement, binding antibodies, leukocytes, blood clotting, and fibrinolysis (Tang and Eaton, 1995). At this point the acute inflammatory response becomes chronic and granulation tissue forms. This involves fibroblasts, macrophages, giant cells, and, later, neovascularization and fibrosis. At this point the implant is mechanically stable. The amount of foreign body reaction is proportional to the surface area of the material exposed to the host. **The degree of response and amount of tissue ingrowth is determined by the nature of the material, its structure, and the amount implanted for biologic grafts** (Deprest et al, 2006). Ideally, host-tissue integration into the graft takes place, leading to long-term graft function after this biologic transformation. This illustrates an important concept in that the graft, biologic or synthetic, acts as a scaffold to provide a substrate to facilitate tissue ingrowth, rather than it functioning as a permanent mechanical support (Birch, 2005).

Once a graft has been implanted into the human host, one of four processes may occur: (1) rejection in which there is severe and chronic inflammatory reaction around the implant, (2) degeneration (the result is necrosis from in-situ exothermic polymerization by the host), (3) encapsulation (minimal foreign body response in which there is fibrosis around the graft), or (4) incorporation into the human host tissue (a response in which there are inflammatory cells and giant cells leading to ingrowth of host tissues into the graft) (Williams, 1973). **For long-term graft survival it appears that incorporation by the host through a process known as graft remodeling is necessary** (Fig. 72–12).

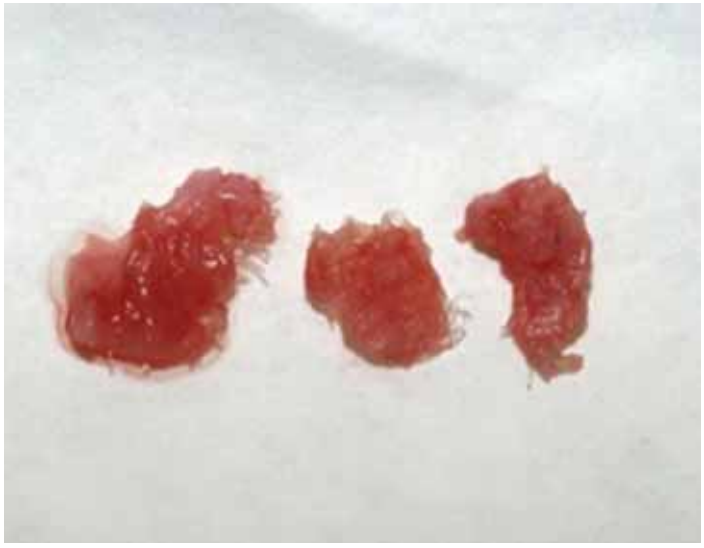

Figure 72–12. Host tissue ingrowth (process of graft remodeling) into polypropylene mesh. (From Woodruff A, Cole E, Scarpero H, et al. A histologic analysis of sling graft materials: a comparative study. Urology 2008;72:85–9, with permission.)

Pore size affects host fibroblast infiltration, flexibility, and mechanical integration of the graft (Klinge et al, 2002). Large pore size has been shown to facilitate this process by enhancing host tissue infiltration and reducing the amount of inflammatory reaction with increased fibroblast infiltration. The large pores become integrated in a loose network of perifilament granulomas filled with fat, which maintains elasticity. After ingrowth of host tissue, a process of transformation occurs to complete the process of remodeling. Solid products or products with small pores (< 50 μm) induce a foreign body reaction that fills the entire pore. This promotes the bridging of the filaments to each other, thereby predisposing to encapsulation (Beets et al, 1996).

Kaupp and colleagues (1979) described four histologic stages of the host to biologic graft implantation:

- Stage 1 occurs over the first 7 days. This is marked by intense inflammation around the graft, which induces capillary proliferation, formation of granular tissue, and presence of giant cells.
- Stage 2 encompasses the next 7 days. Granular tissues are still present, and foamy histiocytes appear. Giant cells may increase or decrease at this point.
- Stage 3 spans 21 and 28 days, when the acute inflammation dissipates with decreased capillaries. Foamy histiocytes and giant cells increase in number.
- Stage 4 happens after 28 days. Giant cells are present on the surface of the implant along with dense fibrotic tissue. This initiates the process of the host-graft interaction.

Once the entire graft is infiltrated with host tissue the transformation process is complete. If this remodeling process characterized by ingrowth and transformation occurs before the graft substrate dissolves, long-term viability of the implant may be ensured. Although synthetic mesh material is a permanent substrate, the principles of tissue incorporation are necessary to prevent infection, extrusion, or erosion. Extrusion is thought to be secondary to exposed graft, which is attributable to localized infection, inadequate closure of the wound, or poor tissue quality (decreased vascularity or thickness) (Birch, 2005). Erosion is thought to be a chronic process related to host inflammatory response at the tissue-graft interface.

Clinical Application of Graft Materials

Biologic Grafts

Because of concerns regarding potential complications associated with synthetic grafts, some authors have turned to biologic grafts to circumvent these complications (Togami et al, 2008). Biologic grafts are categorized as autologous (patient serves as the donor), heterologous (same species, different individual [cadaveric]), and xenogenic (obtained from other species, typically porcine). The advantages of biologic grafts include in-vivo tissue remodeling, histologic similarity, and decreased propensity to elicit local complications (Silva and Karram, 2005).

The donor sites for autologous grafts include rectus fascia, fascia lata, and vaginal epithelium, with the most common being rectus fascia and fascia lata. **Autologous grafts are ideal in that they are well incorporated, pose no threat of disease transmission, and have minimal risk of encapsulation or rejection.** The major drawback is the harvesting process, with increased morbidity, time, and potential for complications at the donor site. These factors are eliminated by using allografts and xenografts (Jarvis et al, 1985). Allografts are obtained from cadaveric donors and include dura mater, fascia lata, and dermis.

Cadaveric fascia lata and dermis are used most commonly. A major concern when utilizing biologic materials is the potential for disease transmission. Choe and Bell (2001) demonstrated intact DNA in freeze-dried/irradiated cadaveric fascia lata and freeze-dried cadaveric dermal allograft. Fitzgerald and associates (2000) also examined irradiated freeze-dried or solvent dehydrated cadaveric fascia lata and found that it retained the donor human leukocyte antigen (HLA) class I and II antigens. Although extensive steps are taken to prevent infection exposure, risk of prion and human immunodeficiency virus transmission is estimated to be 1 in 1.7 million (Buck et al, 1989). To date there have not been any reports of disease transmission from grafts used for POP.

The harvesting techniques of nonautologous biologic graft materials are standardized. In their review, Chen and colleagues (2007) described the process of allograft acquisition. Before allografts are harvested the donor undergoes serologic testing for hepatitis B and C, human immunodeficiency virus, and human T-lymphotropic virus type 1. Aseptic technique is used during harvest, and cultures are obtained at the time. The source animals for xenografts are specifically raised for medical purposes with production being strictly controlled by U.S. Food and Drug Administration (FDA) guidelines (Deprest et al, 2006). Materials available are derived from porcine subintestinal mucosa, porcine dermis, bovine dermis, and bovine pericardium, although the most commonly used are from porcine sources. These function as acellular collagen–based scaffolds to serve as a platform for host infiltration.

Allografts and xenografts must undergo tissue processing before implantation, and, unlike harvesting, there is a variance in the processing techniques of these materials. This variance may affect the biologic and biomechanical properties of the grafts. There is no consensus as to which method should be used to optimize tissue properties. In some cases, processing is carried out to affect the long-term effects of the tissue to decrease graft breakdown and increase host tissue ingrowth. Sterilization is achieved by freeze-drying, solvent dehydration, and/or gamma irradiation. Lemer and associates (1999) demonstrated that freeze-dried cadaveric fascia demonstrated the least desirable characteristics when compared with autologous rectus fascia, cadaveric dermis, and solvent dehydrated cadaveric fascia lata. The freeze-dried cadaveric fascia demonstrated a reduced maximum load to failure and stiffness. In addition there was greater variability in the tissue's strength and stiffness throughout its entire length.

Cross-linking is another processing technique that can affect graft performance. This is done to delay reabsorption by collagenases (Badylak et al, 2002). Several methods are used, including aldehyde cross-linking and hexamethylene di-isocyanate (HMDI). Aldehydes are cytotoxic in high concentrations and may increase concentrations of gelatinases, which may actually increase the rate of degradation (Jorge-Herrero et al, 2001). In addition, aldehydes may cause calcification of the grafts, adversely affecting their function. Studies performed in rats have shown no graft mineralization with HMDI cross-linked dermal implantation at 2 years in contrast to aldehydes (Oliver, 1987).

Local complications such as encapsulation may occur after the use of porcine dermis grafts (Cole et al, 2003). Graft fenestrations have been reported to enhance ingrowth and angiogenesis (Taylor et al, 2008). They may also decrease seroma formation and local complications. Porcine small intestine submucosa (Surgisis, Cook Medical, Bloomington, IN) is a non–cross-linked graft processed so that the complex extracellular matrix and natural growth factors are left intact (Cook Medical, 2007). There is histologic evidence that by 1 month the strength and histology of the graft is identical to native material and at 2 years it exceeds the strength of native tissue (Konstantinovic et al, 2005).

The lack of in-vivo data limits the study of many biologic and synthetic grafts. Naturally it would be of benefit to demonstrate how the biomechanical properties of these materials are altered or remodeled by the host. Several animal models have been used to study grafts and meshes. In the rabbit model a free or pedicle flap of autologous rectus fascia decreased 37% in length, 63% in width, and 53% in tensile strength after implantation for 12 weeks. Neovascularization, minimal inflammation, and fibrosis was noted only along the permanent suture used to secure the graft (Fokaefs et al, 1997). In a rabbit model, freeze-dried, irradiated cadaveric fascia lata had a 90% decrease in tensile strength 12 weeks after implantation (Walter et al, 2003). There was variability in tensile strength from lot to lot and from grafts taken from different areas in the same lot. In an extensive rabbit study examining six different graft materials, tensile strength and stiffness of human cadaveric fascia and porcine xenografts decreased by 60% to 89%. Polypropylene (Prolene) mesh and anterior rectus fascia had no change in tensile strength from baseline (Dora et al, 2004). When comparing a tension-free vaginal tape (TVT) (Ethicon, Somerville, NJ) polypropylene sling to a cadaveric fascia lata sling in the rat model there was an advantage for the polypropylene sling in the breakload and maximum average load compared with cadaveric fascia lata (Spiess et al, 2004). **There is a wide variation in the types of grafts available and tissue processing they undergo. It is unclear how this affects the performance of the grafts because there are little data comparing them.** Before implantation, dermal allografts, solvent dehydrated fascia lata, and synthetic mesh have equal or higher tensile strength compared with autologous fascia. In some studies, freeze-dried grafts have a decreased tensile strength compared with similar grafts that have been solvent dehydrated. After implantation, autologous fascia and synthetic mesh seem to retain more of their tensile strength compared with allografts or xenografts (Chen et al, 2007).

Synthetic Grafts

Synthetic mesh can be permanent or absorbable. Absorbable mesh has several desirable characteristics. It promotes postoperative fibroblast activity, has less infectious disease risk, is not rejected, and has not been reported to be harmful to the viscera. One disadvantage is that the resultant scar tissue may not be as strong as the native tissue it is reinforcing (Klinge et al, 2001). Classification of the synthetic meshes occurs by type of mesh (absorbable or nonabsorbable), pore size (macroporous or microporous), and filament type (monofilament or multifilament). Two types of absorbable meshes are available: polyglycolic acid (Dexon, Davis and Geck, American Cyanamid, Danbury, CT) and polyglactin 910 (Vicryl, Ethicon, Somerville, NJ). They differ in the duration in the tissues. Polyglactin 910 starts to hydrolyze by 21 days and loses its mechanical support by 30 days. Polyglycolic acid takes 90 days for absorption.

The most important characteristic of a synthetic mesh is its pore size. Meshes are divided into macroporous (>75 μm) or microporous (<10 μm). Pore size is important from an infectious standpoint because it allows cellular elements such as macrophages and granulocytes to enter the mesh construct. In addition, it is important for tissue ingrowth with fibroblasts, blood vessels, and collagen fibrils (Amid, 1997; Deprest et al, 2006; Dwyer, 2006) (Fig. 72–13). Most bacteria are less than 1 μm; granulocytes and macrophages are greater than 10 μm in diameter, but 75 μm is the key

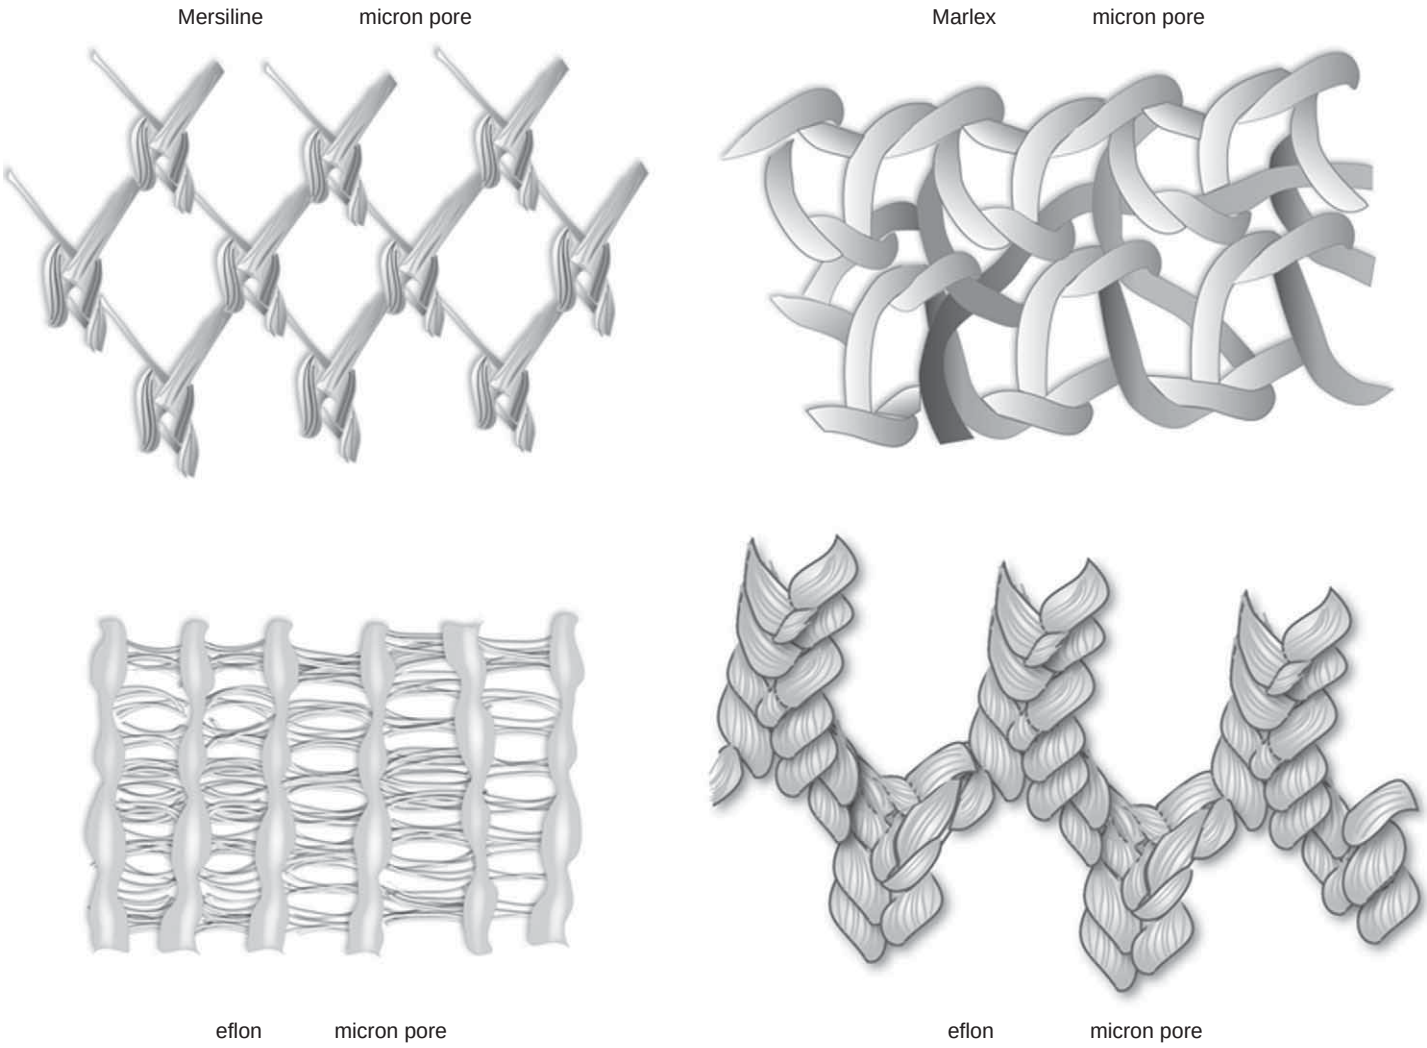

Figure 72–13. Synthetic graft pore and interstices: Note the multifilamentous nature of Mersilene, which may promote bacterial adherence. (From Togami J, Krlin R, et al. Graft materials in prolapse surgery. AUA Update Series 2008;27(31):294–303.)

size that allows the tissue ingrowth. Pore size also determines the flexural rigidity. The larger the pore size, the more flexible the mesh (Dietz et al, 2003). This property may impact local tissue trauma and erosive risk (Birch, 2005).

Synthetic mesh can be monofilament or multifilament. Multifilament synthetics may have pore sizes that allow them to be classified as macroporous; however, between the fibers the size is less than 10 µm, owing to the way they are either woven or knitted. The spaces are small enough to allow bacteria into confines less than 10 µm, which carries a greater theoretical risk than a monofilament mesh. The construct of the mesh affects pore size, and the interstitial distance is measured between the synthetic fibers (Fig. 72–14). Woven mesh has small pore size and interstices, whereas knitted materials are able to assume a macroporous configuration and are flexible with high tissue conformity.

Although there is no classification system specifically used for mesh in pelvic floor reconstruction, the Amid classification, which was originally used to describe mesh used in the treatment of abdominal wall hernias, is currently the standard (Amid, 1997).

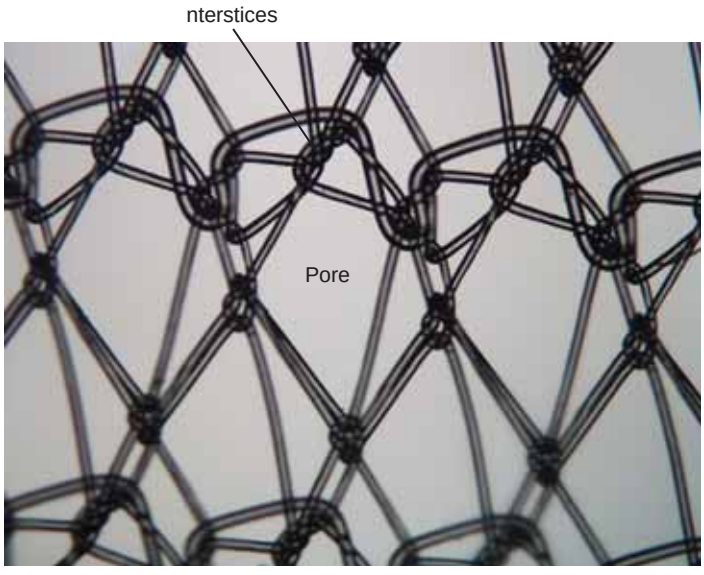

Figure 72–14. Polypropylene mesh depicting pore and interstices.

This classification emphasizes the importance of pore size and filament type (see Fig. 72–11).

Type I promotes host defenses and tissue infiltration. Type II and type III meshes result in a greater foreign body response and are associated with greater rates of erosion (Julian, 1996; Debodinance et al, 1999). **The most desirable synthetic for pelvic floor reconstruction are monofilament, macroporous mesh, most commonly polypropylene mesh.**

SURGICAL MANAGEMENT OF PELVIC ORGAN PROLAPSE (Table 72–2)

Anterior Compartment

Anterior Colporrhaphy

Kelly described his method of cystocele repair as a treatment for urinary incontinence in 1913. He emphasized the importance of repairing the pubocervical fascia with plication sutures to repair the central defect. This procedure eventually became known as the anterior colporrhaphy, and it corrects the central defect in the anterior compartment. However, **anterior compartment defects are commonly combined central and lateral defects. Thus, an isolated anterior colporrhaphy is not recommended except in rare circumstances.** In addition, the American Urological Association Female Stress Urinary Incontinence Clinical Guidelines Panel, in 1997, performed a meta-analysis and found that the failure rate of anterior colporrhaphy as a treatment for stress urinary incontinence (SUI) was close to 40% after 4 years of follow-up (Leach et al, 1997). **As such, anterior colporrhaphy is not recommended as treatment for SUI.**

Technique (Fig. 72–15)**.** After placement of the patient in the dorsal lithotomy position an indwelling urethral catheter is placed and the bladder is kept drained throughout the procedure. Hydrodissection may be utilized to facilitate the dissection. A midline incision is made in the anterior vaginal wall, extending from the vaginal apex to the bladder neck. The incision should not extend to the urethra when a simultaneous midurethral sling is performed. Optimally the sling should be placed through a separate, suburethral incision. However, when performing a pubovaginal sling, it is desirable to create one incision that extends to the distal urethra and facilitates more precise sling location. The vaginal epithelium is dissected off the pubocervical fascia, and the dissection should be carried out sufficiently to delineate the defect. Usually, the incision should extend as far laterally as possible. Allis clamps or a self-retaining ring retractor may be utilized to provide optimal exposure. The bladder is then reduced with a finger or instrument, and this facilitates exposure and reapproximation of the pubocervical tissues. Once these tissues are identified, interrupted 2-0 delayed absorbable plication sutures are then placed from the bladder neck to the apex. The plication sutures are then tied. Care must be taken to avoid excessively deep suture placement to avoid ureteral injury. If the pubocervical fascia is too attenuated, a piece of allograft or mesh can be placed under the vaginal wall on one side to strengthen the repair and prevent suture pull-through (Chesson et al, 1999). After completion of the colporrhaphy, cystoscopy is performed after the administration of indigo carmine or methylene blue to inspect the bladder for any iatrogenic injury and to visualize urine effluxing from each ureteral orifice. Finally, the vaginal wall is trimmed and closed with a 2-0 absorbable suture.

Results. In earlier studies, the reported cure rate of cystocele approached 95% (Table 72–3). In a large, retrospective study that

included 299 patients with anterior vaginal wall prolapse, Porges and Smilen (1994) reported a recurrence rate of only 3%, with a mean follow-up of 31 months. Recurrence was defined as only symptomatic descent for which further surgery was performed or recommended. Also, in a prospective, randomized trial between Burch colposuspension versus anterior colporrhaphy, Colombo and colleagues (2000) reported a recurrence rate again of only 3% in the 33 patients who underwent anterior colporrhaphy. The mean follow-up was 5 years. All of the patients in both groups underwent concomitant hysterectomy and uterosacral ligament fixation. **Recent series have reported recurrence rates for standard anterior colporrhaphy that approach 40%** (Table 72–4). Recurrence in these series included asymptomatic grade 2 or stage 2 anterior compartment prolapse. Sand and associates (2001) reported on 161 women randomized to either anterior colporrhaphy with polyglactin suture or anterior colporrhaphy with a free polyglactin mesh inlay, which was placed underneath the trigone after plicating the pubocervical fascia. After 1 year of follow-up, the women randomized to polyglactin mesh had a failure rate of 25% compared with the 43% failure rate in those women who underwent the plication with suture alone ($P = .02$). Weber and colleagues (2001) compared anterior colporrhaphy reinforced with polyglactin mesh to traditional plication without tension using polydioxanone suture and "ultralateral" plication using both polydioxanone suture and tension. In this study, 114 women with symptomatic cystoceles (mostly stages 2 and 3 on the pelvic organ prolapse quantification [POP-Q] system) were randomized between the three groups. With a mean follow-up of 23 months there was no significant difference in failure rate (defined as stage 2 or greater on the POP-Q) between the three groups. The failure rate was 30% in those who underwent traditional plication, 46% in those who underwent ultralateral plication, and 42% in those who underwent traditional plication augmented with polyglactin mesh. Unfortunately, the study did not recruit enough women to achieve statistical power to detect differences between the groups. This is in contrast to an earlier paper by the same author that stated that anterior vaginal wall prolapse recurs after standard anterior colporrhaphy in 20% of patients (Weber and Walter, 1997). The Sand and Weber trials are not similar enough to do a meta-analysis. **Yet, the high recurrence rates observed with anterior colporrhaphy illustrates the main concern regarding the durability of this procedure in most women with moderate- or high-grade anterior compartment defects. The most likely contributing factor is the concomitant presence of other compartmental defects.**

Complications. Reported complications from anterior colporrhaphy include de novo SUI (if the patient had SUI masked by a high-grade cystocele), de novo detrusor overactivity, postoperative urinary retention, incomplete bladder emptying, significant bleeding of more than 350 mL, wound infection, bladder or ureteral injuries, vaginal shortening, and dyspareunia. De novo detrusor overactivity can occur in 5% to 7% of patients after standard colporrhaphy (Raz et al, 1991). Yet, preexisting detrusor overactivity has been reported to resolve in up to 63% of patients after surgical repair of pelvic organ prolapsed (Nguyen and Bhattia, 2001).

Table 72–4.

Results of Anterior Compartment (AC) Repair with Graft

TECHNIQUE	STUDY	NO. PATIENTS	MEAN FOLLOW-UP (mo)	SUCCESS RATE	EVALUATION	COMPLICATIONS
Polyglactin 910 mesh	Weber et al, 2001	114	23	AC alone 70% AC + mesh 58%	POP-Q, reported symptoms, visual analog scale	Hemorrhage, vaginal mesh extrusion
	Sand et al, 2001	161	12	AC alone 57% AC + mesh 75%	Baden-Walker classification	Urinary retention (post sling)
Polypropylene mesh	Nicita, 1998	44	13.9	93%	SEAPI QMM scale	Vaginal mesh extrusion and dyspareunia in one patient
	de Tayrac et al, 2002	48	18	97.9%	POP-Q	Vaginal mesh extrusion and dyspareunia
	de Tayrac et al, 2005	87	24	91.6%	POP-Q	Vaginal mesh extrusion and dyspareunia
	Hiltunen et al, 2007	202	12	AC alone 61% AC + mesh 93%	POP-Q and questionnaire	Vaginal mesh extrusion and dyspareunia
	Rodriguez et al, 2005	98	Not reported	85%	POP-Q, UDI-6, validated global QOL question	De novo SUI and de novo UUI
Cadaveric fascia	Groutz et al, 2001	21	20	100%	Baden-Walker classification, 24-hour pad test	Persistent SUI
	Gandhi et al, 2005	154	12	AC alone 71% AC + fascia 79%	POP-Q, Likert questionnaire	Excessive bleeding

POP-Q, Pelvic Organ Prolapse Quantification System; QOL, quality of life; SUI, stress urinary incontinence; UDI-6, Urogenital Distress Inventory, Short Form; UUI, urgency urinary incontinence.

Urinary retention usually happens in cases during which an anti-incontinence procedure is performed. In most instances, the retention resolves after a brief period of CIC. If the retention persists and the patient had a concomitant anti-incontinence procedure, urethrolysis is often required. When impaired bladder emptying is due to preexisting hypocontractility, the patient may require chronic CIC or neuromodulation.

Bleeding during anterior colporrhaphy is usually due to both the high vascularity of the vagina and to the venous complex beneath the inferior pubic bone. **During transvaginal anterior colporrhaphy, problematic bleeding can occur if the dissection is carried out in the wrong plane. During anterior colporrhaphy, the vaginal wall should be dissected off of the pubocervical fascia directly on its white shiny surface.** In patients undergoing repeat anterior colporrhaphy, scarring will often obscure the correct dissection plane. As such, these patients are at higher risk for bleeding.

Bladder or ureteral injuries are rare during standard anterior colporrhaphy. **Bladder injuries can occur when perforation into the retropubic space occurs. Ensuring bladder drainage before perforating the endopelvic fascia may reduce this.** Should an inadvertent bladder injury occur, a two-layer closure should be performed with absorbable suture. If the patient has a history of pelvic irradiation or if the repair quality seems tenuous, a labial fat pad interposition should be considered to prevent vesicovaginal fistula formation (Kreder, 1993). **Cystoscopy after the administration of indigo carmine should be routinely performed with every anterior colporrhaphy.** If blue-stained urine is not seen effluxing from either ureteral orifice, ureteral catheterization should be considered before taking down the plication sutures. In some cases the ureter is patent and an alternative reason will explain the lack of efflux. Appropriate steps must be taken to ensure ureteral patency if the ureter cannot be catheterized. This may include taking down the repair.

Procedures for Lateral and Combined Defects

Vaginal Paravaginal Repair. In his first description of a vaginal paravaginal repair, George White (1909) described a cystocele repair that involved suturing the lateral sulci of the vagina to the white line of the pelvic fascia. White believed that the cause of a cystocele was weakness of the lateral vaginal attachments to the ATFP. As Kelly's anterior colporrhaphy became the primary technique of cystocele repair for the next 70 years, White's concept fell into disfavor. In 1976, Richardson and coworkers (1976) reintroduced the paravaginal defect repair, but they described the technique using an abdominal approach. Regardless of the approach the goal of a paravaginal repair is to repair a lateral compartment defect by reattaching the pubocervical fascia to the ATFP. A vaginal

paravaginal repair may be combined with anterior colporrhaphy in patients with combined lateral and central defects.

Technique (Fig. 72-16)**.** A midline anterior vertical incision is made through the vaginal epithelium from the bladder neck to the vaginal apex. After the vaginal epithelium is sharply dissected off the attenuated pubocervical fascia and bladder the dissection is carried laterally to the pelvic sidewall. Blunt dissection can be used to facilitate this. Access to the pelvic sidewall is achieved by either continued lateral dissection or perforation of the endopelvic fascia. On entry into the retropubic space, palpation is utilized to identify the ATFP as it courses from the ischial spine to the inferior aspect of the pubic ramus. Deep, lighted retractors may be useful to facilitate exposure. With the bladder retracted medially, five to seven interrupted nonabsorbable sutures are placed at 1-cm intervals through the ATFP. A Capio Suture Capturing Device (Boston Scientific, Natick, MA) may expedite placement of these sutures. These sutures are then passed through the lateral edge of the detached pubocervical fascia. No sutures should be tied until all are placed on either one side or both sides (if bilateral defects). At this point, if indicated, central defect plication sutures may be placed to complete a combined repair. As with anterior colporrhaphy, cystoscopy must be performed to confirm ureteral patency and the absence of intravesical sutures. The vaginal wall is trimmed and closed with a 2-0 absorbable suture. Vaginal packing is placed.

Results (see Table 72–4)**.** Shull and colleagues (1994) reported that 41 patients (73%) had no cystocele recurrence with vaginal paravaginal repair after a mean follow-up of 1.6 years. Of the 15 recurrences, only 4 developed to or through the hymen, and in these the prolapse was less than what was noted preoperatively. Elkins and associates (2000) reported an 8% lateral cystocele recurrence rate and a 22% central cystocele recurrence rate 0.5 to 3 years after vaginal paravaginal repair in 25 patients with grade 3 or greater anterior wall vaginal prolapse. Midline central defects were common, leading surgeons to perform joint repairs with an anterior colporrhaphy. Young and coworkers (2001) retrospectively evaluated 100 patients with symptomatic grade 2 to 4 combined central and lateral cystoceles. All 100 patients underwent both vaginal paravaginal repair and concomitant anterior colporrhaphy. With a mean follow-up of 11 months, the lateral cystocele recurrence rate was only 2% and the central cystocele recurrence rate was 22%. Mallipeddi and colleagues (2001) reported a 3% central cystocele recurrence 20 months after vaginal paravaginal repair in 35 patients with grades 2 to 4 anterior vaginal wall prolapse. Of the 21 patients with concomitant SUI, 12 (57%) had persistent SUI after the paravaginal repair. **The paravaginal repair, like standard anterior colporrhaphy, is ineffective in the treatment of SUI.** Finally, there are no studies comparing paravaginal defect repair with or without midline anterior repair to standard anterior colporrhaphy alone.

Although complications after vaginal paravaginal repair are infrequent, they are significant. Young and associates (2001) reported 21 major complications, including three major intraoperative hemorrhagic complications. Two patients developed lower extremity neuropathy, one of whom was in the lithotomy position for a prolonged period of time. Elkins and associates (2000) reported a transfusion rate of 12%. Mallipeddi and coworkers (2001) reported 2 patients with vaginal abscesses that required drainage, 1 patient with retropubic hematoma who required reexploration, and 1 patient with bilateral ureteric obstruction that resolved after takedown of the repair and suture replacement.

The vaginal paravaginal repair as described is technically more challenging than the standard anterior colporrhaphy. Complication rates are higher and usually more serious. In addition, the conventional vaginal paravaginal repair relies on suture placement through weakened pubocervical fascia. To compensate for these factors, most surgeons describe transvaginal correction of lateral defects using placement of grafts, which are attached to the pelvic sidewalls bilaterally.

Anterior Compartment Repairs Utilizing Grafts

Technique. The incision and dissection into the retropubic space are performed in a similar manner as for the vaginal paravaginal repair. Once access to the pelvic sidewall is achieved, the bladder is retracted medially, and 2 to 3 sutures (permanent or delayed absorbable) are placed into the ATFP and/or obturator internus fascia, which will serve as adequate lateral fixation for the graft. A Capio Suture Capturing Device (Boston Scientific, Natick, MA) may expedite placement of these sutures (Fig. 72–17). Before fashioning the graft it is useful to estimate the distance between the proximal and distal ipsilateral sutures and the distance between the sutures on each side. These measurements serve to determine the dimensions of the graft material, which is trimmed to size. At this point, central plication sutures may be placed. The previously placed pelvic sidewall sutures are then brought out to the corresponding locations on the graft. The sutures are then tied, securing the graft to the pelvic sidewall. It is useful to leave the sutures long until after cystoscopy confirms patency of the ureters. The vaginal wall is trimmed and closed with a 2-0 absorbable suture. Vaginal packing is placed at the end of the case.

Results

POLYPROPYLENE MESH (see Table 72–4). Nicita (1998) described the use of polypropylene mesh for the treatment of anterior vaginal wall prolapsed. He sutured the mesh to the anterior aspect of the ATFP on each side using 3-0 polypropylene sutures. With 2 years of follow-up, only 3 of the 44 patients (7%) had prolapse recurrence. The only patient who developed dyspareunia had vaginal mesh extrusion (exposure), and this was managed with mesh trimming and vaginal closure.

de Tayrac and associates, in 2002, described placement of polypropylene mesh (Gynemesh; Ethicon, Somerville, NJ) into the retropubic space in a tension-free fashion without suture fixation. The lateral extensions of the mesh were placed in contact with the ATFP and anchored with a transobturator approach. A total of 48 women with grade 3 and 4 cystoceles underwent this procedure. After a mean follow-up of 18 months the authors reported an anatomic success rate of 97.9%. Vaginal mesh extrusion was noted in 8.3%. In a subsequent series with 87 women and with 24 months of follow-up, de Tayrac and associates again (2005) used GyneMesh and found that 77 women (91.6%) were cured of their symptomatic anterior vaginal wall prolapse, defined as POP-Q stage 0 or 1. Of the 7 patients with recurrent cystoceles, 5 were asymptomatic. Vaginal mesh extrusion was again noted in 8.3%, and the de novo dyspareunia rate was 16.7%.

In a randomized controlled trial of 202 women with anterior vaginal wall prolapse, Hiltunen and coworkers (2007) compared anterior colporrhaphy (n = 97) to the same procedure reinforced with low-weight polypropylene mesh (n = 105). After 1 year of follow-up the addition of the polypropylene mesh to the anterior repair did statistically decrease the risk of recurrent stage 2 or greater anterior prolapse. **Recurrence was noted in 7 of 104 women in the mesh group versus 37 of 96 women in the group with no graft ($P < .001$). However, there was no statistically significant difference in symptomatic outcomes (pelvic pressure, vaginal bulging, or difficulty with bladder emptying) between the groups.**

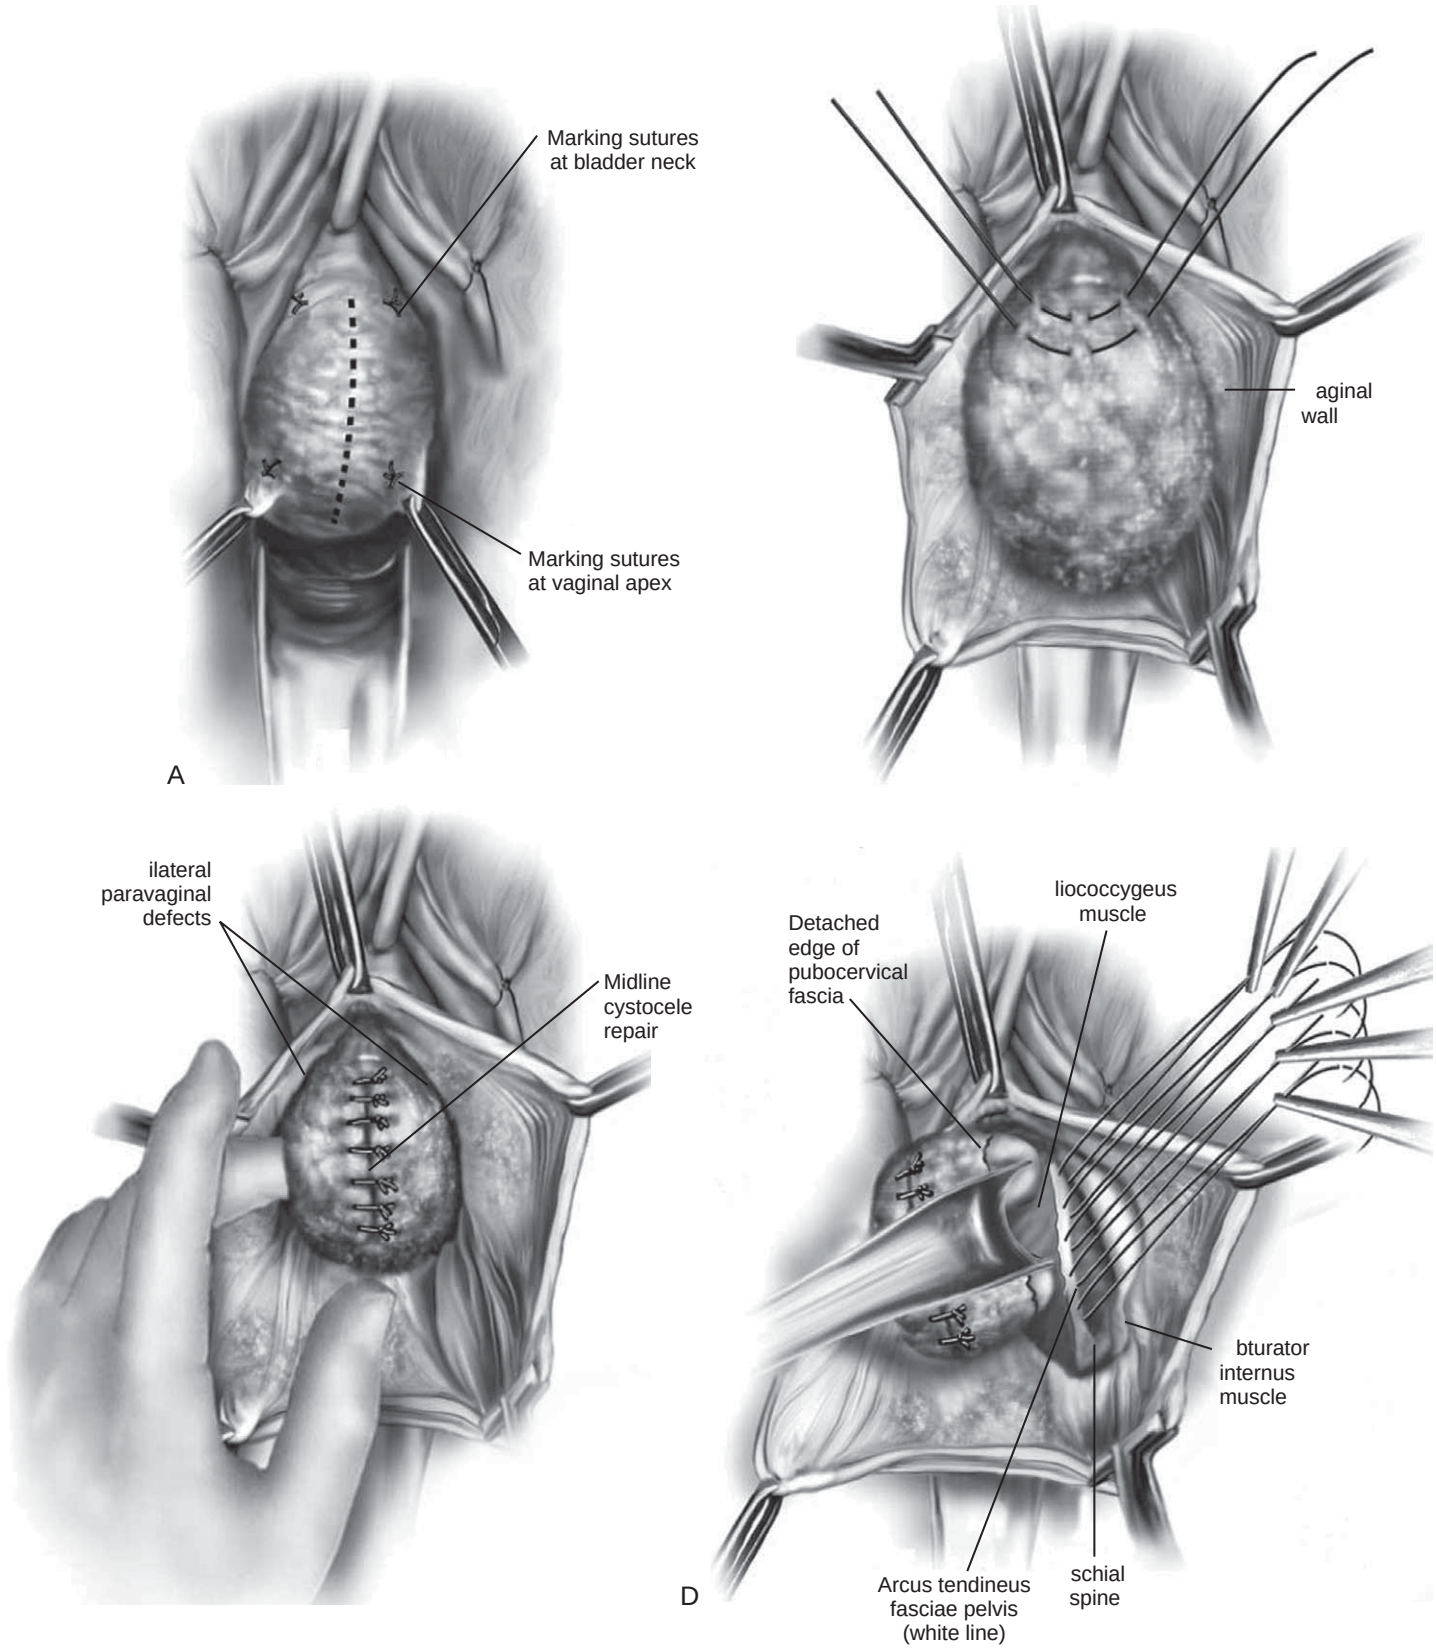

Figure 72–16. Vaginal paravaginal repair. **A,** Unopened anterior vaginal wall with marking sutures placed at anatomic level of bladder neck and vaginal apex. **B,** Anterior vaginal wall opened via a midline incision. Sutures placed for midline cystocele repair. **C,** Midline cystocele repair completed. Bilateral paravaginal defects identified. **D,** Bladder retracted medially to expose lateral pelvic sidewall. Permanent sutures have been passed through the white line.

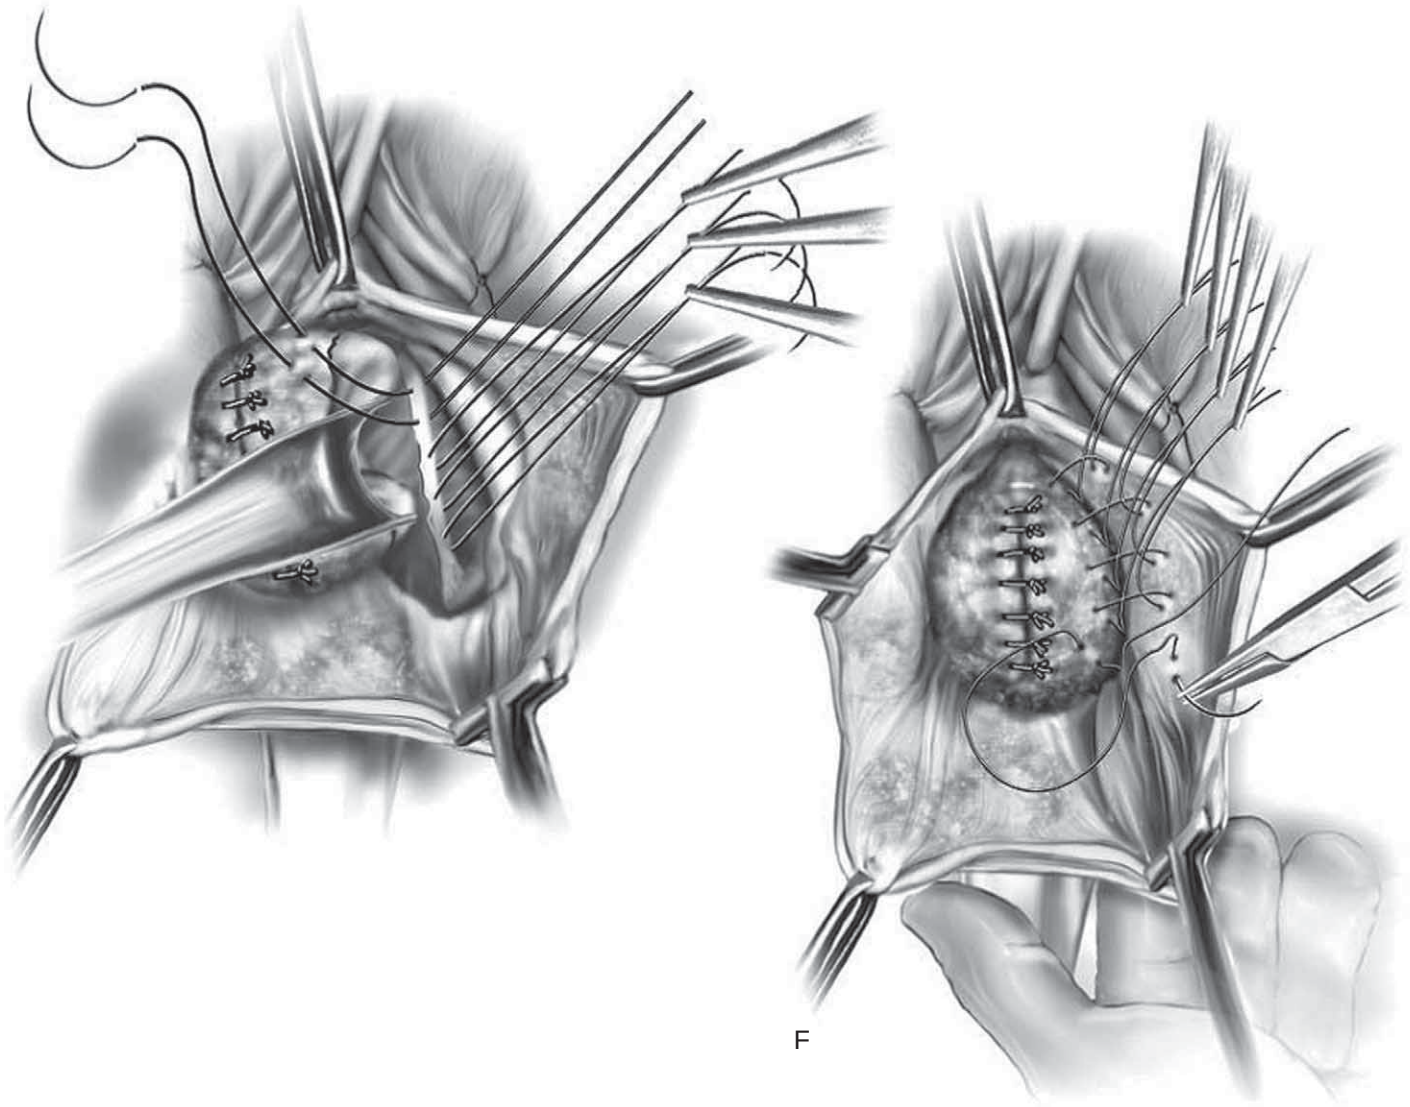

Figure 72–16, cont'd. **E,** Top two sutures have been passed through detached edge of pubocervical fascia. **F,** Three-point closure is completed with all sutures passed through the pubocervical fascia and inside wall of the vagina. (From Mallipeddi PK, Steele AC, Kohli N, et al. Anatomic and functional outcome of vaginal paravaginal repair in the correction of anterior vaginal wall prolapse. Int Urogynecol J 2001;12: 83–88, with permission.)

Importantly, 18 patients in the mesh group (17.3%) had vaginal extrusion of the mesh, although only 4 of the 18 patients were symptomatic and none required total removal of the mesh.

In a prospective study of 98 patients with stage 3 and 4 cystoceles using the POP-Q, Rodriguez and associates (2005) attached a 5 × 5-cm piece of polypropylene mesh to the obturator internus fascia using 2-0 polyglactin suture to repair the paravaginal defect (Fig. 72–18). This mesh was placed after repair of the central defect with horizontal mattress sutures of 3-0 polyglactin. All patients underwent a distal urethral polypropylene sling regardless of any SUI symptoms. They reported an 85% anatomic success rate, defined as stage 0 or 1. No patient experienced urinary retention. Three patients who did not report SUI before the procedure developed mild de novo SUI after the procedure. Overall quality of life due to genitourinary symptoms improved from 4.7 (unhappy) to 1 (pleased) ($P < .005$).

CADAVERIC FASCIA (see Table 72–4). Groutz and colleagues (2001) prospectively enrolled 21 women with grade 3 or 4 anterior vaginal wall prolapse to cystocele repair using solvent dehydrated cadaveric fascia lata (Fig. 72–19). The graft was anchored transversally between the bilateral arcus tendineus and the cardinal and uterosacral ligaments. Also, 19 of the 21 women underwent concomitant pubovaginal sling for either symptomatic or occult SUI. After a mean follow-up 20 months, none of the patients developed a recurrent cystocele. In addition, no patient developed new-onset dyspareunia, pelvic pain, or postoperative vaginal stenosis.

Gandhi and colleagues (2005) published a prospective randomized controlled trial comparing ultralateral anterior colporrhaphy with 0 polyglactin suture (n = 78) to the same colporrhaphy reinforced with cadaveric fascia lata (n = 76) in women with grade 2 or greater anterior vaginal wall prolapse. Previous surgery did not preclude participation. Although there was a trend toward improved anatomic outcome with graft use, the addition of the

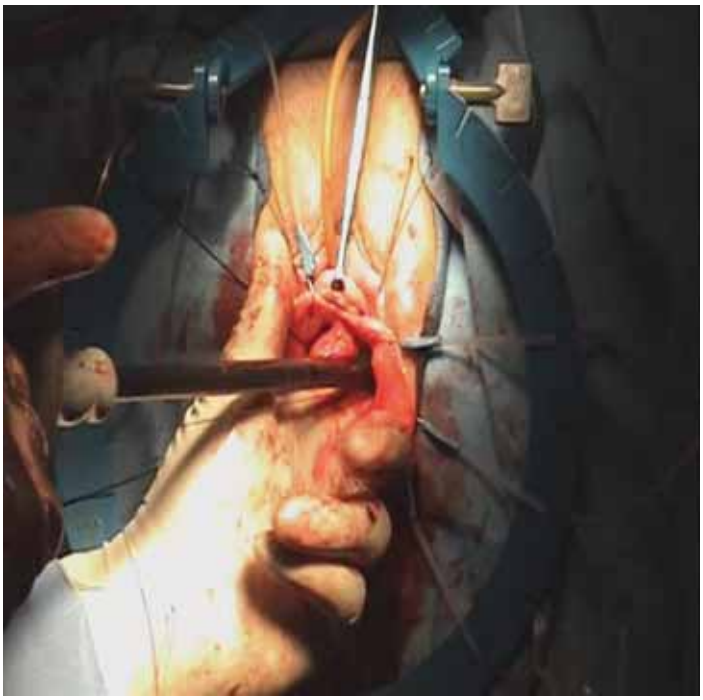

Figure 72–17. Capio needle driver utilized to facilitate suture placement in the arcus tendineus fascia pelvis. (Photograph courtesy of Victor Nitti.)

Figure 72–18. Anterior compartment repair with polypropylene mesh graft. Polypropylene mesh is anchored to the uterosacral ligament at the bladder base, laterally to the obturator fascia and distally to the bladder neck using 2-0 polyglactin suture. (From Rogriguez LR, Bukkapatnam R, Shah SM, et al. Transvaginal paravaginal repair of high-grade cystocele central and lateral defects with concomitant suburethral sling: report of early results, outcomes, and patient satisfaction with a new technique. Urology 2005;66[Suppl. 5A]:57–65.)

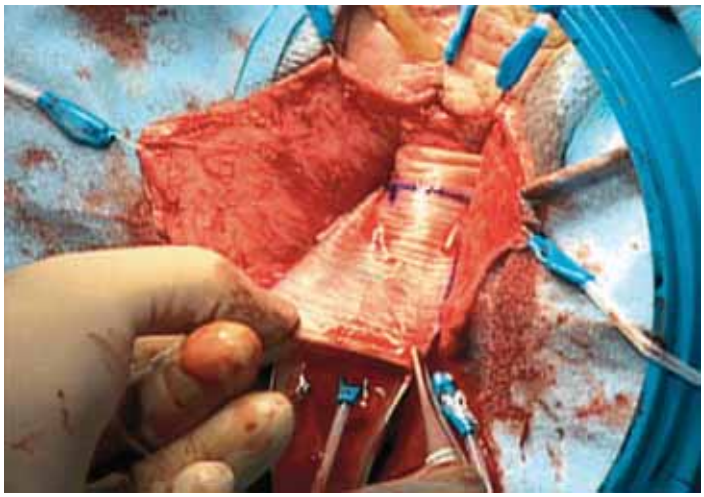

Figure 72–19. Anterior compartment repair with cadaveric fascia graft. Cadaveric fascia patch was tailored appropriately. Typically a 5- × 7-cm patch is more than adequate. (From Groutz A, Chaikin DC, Theusen E, et al. Use of cadaveric solvent-dehydrated fascia lata for cystocele repair—preliminary results. Urology 2001:58:179–83.)

fascia lata patch to the anterior repair did not statistically decrease the risk of recurrent grade 2 or greater anterior vaginal wall prolapse ($P = .23$). Of the 39 total patients with recurrent prolapse, 26 (67%) were asymptomatic. Interestingly, concomitant transvaginal Cooper ligament sling procedures were associated with a decrease in recurrent grade 2 anterior vaginal wall prolapse ($P < .0001$).

Kobashi and coworkers (2000) first described the cadaveric prolapse repair and sling procedure (CaPS) as combined treatment of both symptomatic cystocele and SUI. The procedure is performed transvaginally using a 6 × 8-cm piece of cadaveric fascia lata and bone anchors. In a noncomparative study of 251 patients with a mean follow-up of 2 years after CaPS, Frederick and Leach (2005) noted a symptomatic cystocele recurrence rate of 7%. Because the cured/dry rate for SUI was 56%, with most of the failures occurring beyond 1 year, the authors questioned the long-term efficacy of the sling portion of the CaPS.

Cadaveric dermis was evaluated by Chung and colleagues (2002) in 19 patients with combined SUI and symptomatic grade 3 cystocele. The proximal portion of the 3 × 7-cm graft was sutured to the uterosacral/cardinal ligament complex to repair the central cystocele defect, and the distal portion of the allograft was used as the sling. Patients with lateral and paravaginal defects were excluded. The mean follow-up was 28 months. One patient developed a graft infection and underwent graft removal. Of the remaining 18 patients, 16 patients had no cystocele recurrence. Seventeen of the 18 patients (94%) were cured of their SUI, including 10 patients who had prior incontinence surgery. Clemons and coworkers (2003) described a vaginal paravaginal repair using cadaveric dermis in 33 women with recurrent stage 2 or with primary or recurrent POP-Q stage 3 or 4 cystoceles. The 3 × 7-cm graft was positioned over the bladder base and secured to the ATFP with four sutures of 2-0 braided permanent polyester bilaterally. The mean follow-up was 18 months. Objectively, 13 patients (41%) had recurrent stage 2 cystoceles; however, only 1 patient (3%) had a symptomatic recurrence. All of the objective failures were failures of point Aa on the POP-Q, implying that the anterior vaginal wall was well supported proximally but not distally. Eight

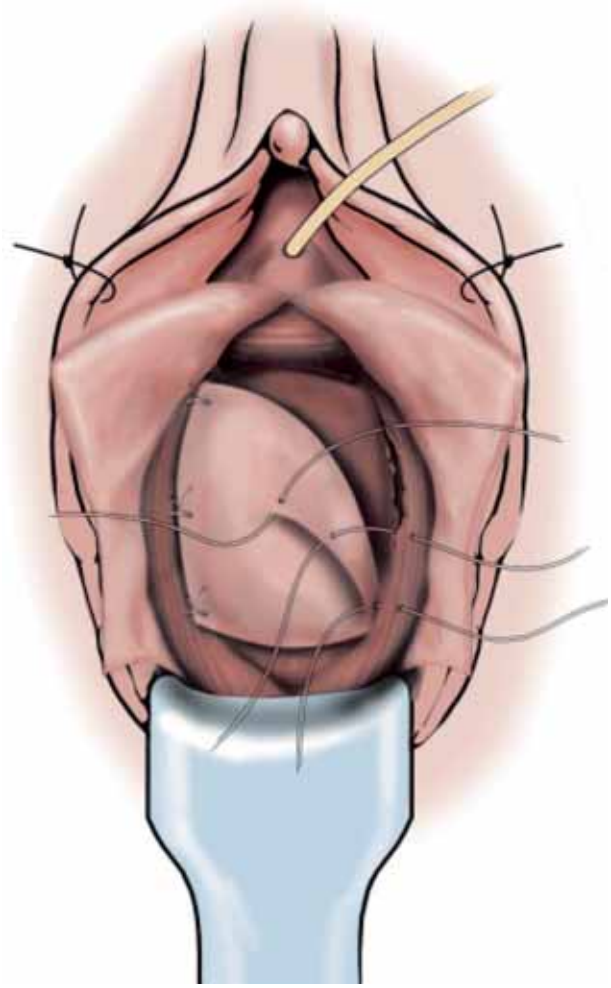

Figure 72–20. Anterior compartment repair with porcine dermis graft. Three pairs of delayed absorbable sutures are inserted into the arcus tendineus fasciae pelvis and into the porcine dermis patch. (From Gomelsky A, Rudy DC, Dmochowski RR. Porcine dermis interposition graft for repair of high grade anterior compartment defects with or without concomitant pelvic organ procedures. J Urol 2004;171:1581–4.)

women underwent a concurrent TVT sling, and the TVT sling did not prevent objective failure.

PORCINE DERMIS (see Table 72–4). The majority of clinical experience in the use of xenografts for pelvic organ prolapse has been with porcine dermis. Pelvicol (CR Bard, Murray Hill, NJ) is acellular cross-linked porcine dermis (Chen et al, 2007). Gomelsky and associates (2004) reported favorable, durable outcomes using a 6 × 8-cm piece of porcine dermis sutured laterally to the ATFP to correct high-grade cystoceles (Fig. 72–20). In a retrospective review of 70 patients, 61 patients (87%) had no cystocele recurrence after a mean follow-up of 24 months. Of the 9 patients (13%) with recurrent cystoceles, none was symptomatic. One patient had superficial vaginal wound separation, which was treated with conservative measures.

Meschia and colleagues (2007) published a prospective randomized controlled trial comparing anterior colporrhaphy with 0 polyglactin suture (n = 103) to the same colporrhaphy reinforced with a 4 × 7-cm piece of Pelvicol (n = 98) in women with stage 2 or greater anterior vaginal wall prolapse as defined on the POP-Q. After 1 year of follow-up, the women randomized to receive the Pelvicol graft experience graft failure 7% of the time, compared with the 19% failure rate in those women who underwent the anterior colporrhaphy with suture plication alone (P = .019). One patient who received the Pelvicol graft had vaginal extrusion of the mesh 1 month after surgery. Finally, there were no differences between the two groups in the incidence of postoperative dyspareunia.

In a recent retrospective study, Handel and associates (2007) compared two different grafts (polypropylene mesh and porcine dermis) to traditional anterior colporrhaphy with suture alone. In a nonrandomized comparison, 119 patients underwent cystocele repair using one of the three techniques. Traditional anterior colporrhaphy was performed in 18 patients, colporrhaphy reinforced with a 3 × 7-cm piece of polypropylene mesh was performed in 25 patients, and colporrhaphy reinforced with a 3 × 7-cm piece of porcine dermis was performed in 56 patients. For patients undergoing repair with a graft, it was anchored to the levator fascia bilaterally and to the uterosacral/cardinal ligament complex. With a mean follow-up of 13.5 months there was no significant difference in failure rate (defined as grade 2 or greater on the Baden-Walker classification) between the three groups. Unfortunately, the study was not powered adequately because there was no sample size justification among the groups.

Complications. **Vaginal exposure (extrusion) has been reported in anterior compartment prolapse repair with most materials.** Rates from 0% to 13% have been reported in recent series with synthetic grafts (Sand et al, 2001; Weber et al, 2001; Dwyer and O'Reilly, 2004; de Tayrac et al, 2005; Milani et al, 2005; Rodriguez et al, 2005) and are less common with biologic grafts. Dyspareunia has been reported by 3.1% to 19% of patients with anterior colporrhaphy (Dwyer and O'Reilly, 2004; Yan et al, 2004; Milani et al, 2005).

Other Procedures to Correct Anterior Compartment Defects

Six-Corner Needle Suspension. Raz and colleagues (1989) originally described the four-corner needle suspension in 1989 for women with SUI due to urethral hypermobility and mild to moderate lateral cystocele defect. With a mean follow-up of 24 months, they reported a 94% subjective correction of SUI and a 98% correction of cystocele on physical examination. The procedure did not include anterior colporrhaphy. The technique was modified to a six-corner suspension in 1996 by Albo and associates to treat larger-grade cystoceles.

Technique (Fig. 72–21)**.** The technique begins by making two parallel, oblique incisions from the bladder neck to the proximal vagina. Alternatively, this can also be accomplished through a midline incision. The dissection is then carried lateral to expose the pubocervical fascia. The endopelvic fascia is perforated, and the retropubic space is entered. Three sets of size 1 polypropylene suture are placed on each side. Each suture incorporates multiple passes through the tissue. The proximal sutures are placed through the cardinal ligament and vaginal wall to support the bladder base. The middle and distal sutures are placed to support the bladder neck and proximal urethra, respectively. Next, a small suprapubic incision is made, and the double-pronged ligature carrier is passed under direct fingertip control through the retropubic space, exiting in the vaginal incision. All six sutures are transferred individually to the suprapubic incision. After the administration of intravenous indigo carmine, cystoscopy is performed to confirm both ureteral patency and the absence of suture in either the bladder or urethra. The polypropylene sutures are then lifted to ensure anatomic reduction of the cystocele. The vaginal incision is closed with a running 2-0 polyglactin suture. Finally, the polypropylene

suspension sutures are tied sequentially to themselves and to the corresponding one from the opposite side. **It is important to tie the polypropylene suspension sutures without tension to avoid postoperative urinary retention.** The suprapubic site is irrigated with povidone-iodine solution, and the wound is closed with 4-0 polyglactin.

Results (see Table 72–4)**.** For larger cystoceles with a central defect, Raz and colleagues (1991) combined anterior colporrhaphy with his four-corner needle suspension. Of the 46 patients who underwent the repair, 5 (11%) had prolapse recurrence with a mean follow-up of 2.8 years. Miyazaki and colleagues (1994) noted a prolapse recurrence rate of 59% in the 22 patients they followed for 3.5 to 4 years after four-corner needle suspension. In a prospective study of 47 patients, Dmochowski and associates (1997) noted that 27 patients (57%) had grade 1 or 2 cystoceles after a four-corner needle suspension with a mean follow-up of 37 months. Recurrent prolapse symptoms were noted in 12 of these 27 patients. Safir and associates (1999) described the four-defect repair of grade 4 cystoceles, whereby a vaginal wall sling and anterior colporrhaphy reinforced with polyglactin mesh are added to the traditional Raz four-corner needle suspension. With a mean follow-up of 21 months, 92% of the 112 patients had excellent objective and subjective results for cystocele repair. Of the patients with preoperative SUI, 90% had excellent or good subjective results.

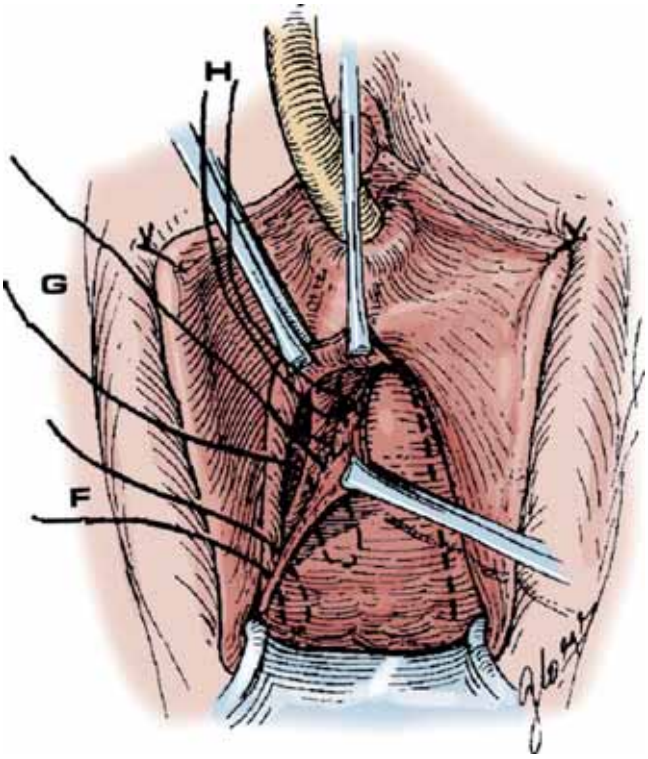

Figure 72–21. Six-corner bladder neck suspension with size 1 polypropylene sutures placed at the level of the vaginal cuff (F), bladder neck (G), and distal urethra (H). (From Albo M, Dupont MC, Raz S. Transvaginal correction of pelvic prolapse. J Endourol 1996;10:231–9.)

Complications. Complications of four- and six-corner suspensions include bladder or urethral injury with suture passage, ureteral obstruction, and injury or entrapment of the genital branch of the genitofemoral or ilioinguinal nerve.

A number of needle suspension reports have demonstrated high failure rates utilizing the six-corner repair in the treatment of anterior compartment defects. Perhaps, suture displacement through weakened tissue contributes to these failures. Although not commonly utilized at present, these procedures were influential in exposing urologists to the technique of endopelvic fascia perforation and access into the retropubic space, which is a useful adjunct to many commonly performed procedures utilized today in the correction of POP.

Abdominal Paravaginal Repair. ***Technique*** (Fig. 72–22)**.** Positioning and preparation of the patient to allow abdominal and vaginal access initiate the repair. The bladder is drained. The retropubic space is entered through either a low midline or transverse incision. Additionally, this may be accomplished laparoscopically. The bladder neck, symphysis pubis, endopelvic fascia, ATFP, and obturator fascia should all be clearly identified. The normal site of normal vaginal attachment on the pelvic side wall from the interior aspect of the superior pubic ramus to the ischial spine is then identified. The surgeon's nondominant hand is placed into the vagina and used to elevate the lateral superior vaginal sulcus to its site of normal attachment along the course of the ATFP. With the bladder retracted medially, four to six interrupted nonabsorbable sutures are placed at 1-cm intervals through the ATFP extending from the ischial spine to the pubic bone. These sutures are then placed in the appropriate location in the lateral wall of the vagina. Care is taken to avoid paravaginal veins, which commonly course through this area. Elevating the vagina to its normal

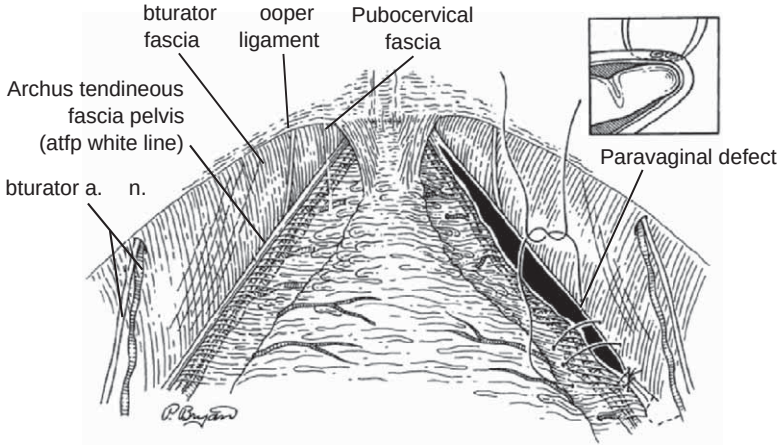

Figure 72–22. Abdominal paravaginal repair. Paravaginal defect repair as viewed from the retropubic space: approximation of the pubocervical fascia medially to the arcus tendineus fasciae pelvis laterally with 2-0 braided nonabsorbable suture. Note the vertical orientation of the vaginal vessels in relation to the transverse orientation of the bladder vessels. *Inset* shows suture being passed beneath the vaginal vessels to ensure generous purchase of pubocervical fascia and control of hemostasis. (From Bruce RG, El-Galley R, Galloway NT. Paravaginal defect repair in the treatment of female stress urinary incontinence and cystocele. Urology 1999;54:647–51.)

anatomic position to localize suture placement site may facilitate vaginal suture placement. After the sutures are tied, cystoscopy must be performed to confirm ureteral patency and the absence of intravesical sutures. The incision is closed and the catheter is left indwelling.

Results (see Table 72–4)**.** Richardson and coworkers (1976) popularized the abdominal paravaginal defect repair. In a retrospective study of 233 patients with follow-up spanning 2 to 8 years, they reported an anatomic cure of 95%. Of these patients, 53 (23%) had previously undergone one or more successful anterior vaginal wall prolapse repairs. No patient required transfusion. Eighty-eight percent of the women with preoperative SUI were cured after abdominal paravaginal repair (Richardson et al, 1981).

Other authors published the results of case series that demonstrated similar encouraging results with SUI cure rates of 85% to 97% after abdominal paravaginal repair (Baden and Walker, 1987; Shull and Baden, 1989). **However, recent evidence over the past 15 years suggests that abdominal paravaginal defect repair is not as effective as either the Burch colposuspension or suburethral sling for the treatment of SUI.** In 1996, Colombo and coworkers (2000) published the results of a randomized trial comparing paravaginal defect repair to Burch colposuspension for the treatment of SUI in 18 patients. With a mean follow-up of 2.2 years, the objective (urodynamic) cure rates were 100% for Burch colposuspension and 61% for abdominal paravaginal defect repair. Colombo and coworkers found that the Burch colposuspension increased the functional urethral length and pressure transmission ratio in the proximal urethra whereas the abdominal paravaginal repair did not. Bruce and associates (1999) examined the abdominal paravaginal defect repair (PVdR) in the treatment of women with both lateral cystocele and symptomatic SUI. In this retrospective cohort of 52 patients, half underwent abdominal PVdR and half underwent abdominal PVdR with pubovaginal sling using rectus muscle. All the patients who underwent concomitant sling had intrinsic sphincter deficiency. With a mean follow-up of 17 months, 4 patients (8%) had recurrent cystocele, 3 patients developed vault prolapse, and 1 patient developed an enterocele. Thus, the overall prolapse cure rate was 85%. Finally, the overall cure rate for SUI was 72% in the group that underwent PVdR alone and 85% in the group that underwent PVdR and pubovaginal sling.

Anterior Compartment Repair with Sling. In patients with high-grade anterior compartment prolapse the descent may create urethral kinking and urethral compression (Gallentine and Cespades, 2001) (Fig. 72–23). This may predispose a patient to develop SUI after prolapse correction. Documenting the presence of SUI in patients with the prolapse reduced is helpful in the preoperative management of women with high-grade anterior compartment prolapse. **SUI occurring in presumably continent women after prolapse correction is known as occult SUI. It is essential for women with high-grade prolapse to undergo an evaluation with the prolapse reduced to identify if they are at risk for occult SUI.** In two prospective studies POP repair in clinically continent women was shown to result in postoperative SUI in 11% to 22% (Stanton et al, 1982; Borstad and Rud, 1989).

To diagnose occult SUI, the prolapse may be reduced with vaginal packing, rectal swabs, a speculum blade, or pessary. Ghoniem and coworkers (1994) used a vaginal pack (formed from two rolled 4 × 4-inch gauze pads) to reduce large cystoceles and found occult SUI in 69% of the women. They found that the vaginal pack provided superior visualization of the vesicourethral angle during fluoroscopic urodynamics. Gallentine and Cespades (2001) used gauze packing and a speculum blade to reduce high-stage POP and found occult SUI in at least 50% of the women with high-grade anterior compartment prolapse. Using a fitted vaginal pessary, Chaikin and coworkers (2000) detected occult SUI in 58% of the women. They also noted that none of the women had urethral obstruction after pessary placement.

There are multiple techniques used to reduce prolapse, and these methods are not standardized. This has led to variance in the reported incidence of occult SUI (Haessler et al, 2005). Veronikis and associates (1997) compared prolapse reduction with rectal swabs, Gellhorn pessary, and a Graves speculum blade. Because prolapse reduction with rectal swabs revealed a significantly lower midurethral closure pressure, these authors concluded that the rectal swabs were superior. **Sensitivity and specificity data are lacking with all of the methods used to reduce POP. As such, no method for prolapse reduction has been proven to be superior.**

Performing a concomitant sling at the time of anterior vaginal wall prolapse repair in women without symptoms of SUI or occult SUI remains controversial. Twiss and colleagues (2007) recommended a simultaneous anti-incontinence procedure at the time of high-grade POP repair because they contend there is no correlation between the preoperative position of the urethra utilizing any

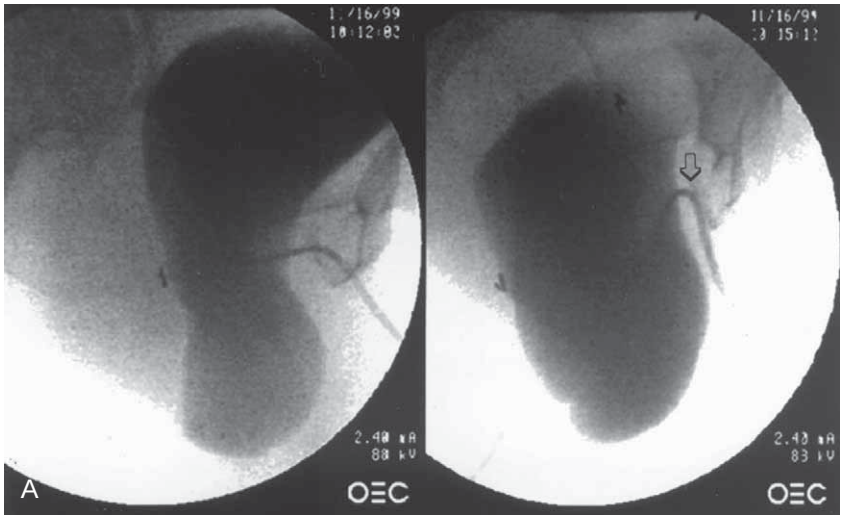

Figure 72–23. Urethral kinking caused by large cystocele. Fluorourodynamic study shows a large cystocele before **(A)** and after **(B)** Valsalva maneuver was performed. The urethra *(arrow)* clearly can be seen to "kink off" during the Valsalva maneuver. The patient did demonstrate severe SUI after prolapse reduction. (From Gallentine ML, Cespedes RD. Occult stress urinary incontinence and the effect of vaginal vault prolapsed on abdominal leak point pressures. Urology 2001;57:40–4.)

method of cystocele reduction and the ultimate position of the urethra after surgery. Thus they believe that the diagnosis of occult SUI is inconsistent and not reproducible. Consequently, occult SUI could be missed. It has also been reported that a concomitant suburethral sling may contribute to the long-term success of anterior compartment repairs. Goldberg and associates (2001) demonstrated a 55% reduction in postoperative cystocele recurrence in patients who underwent suburethral sling at the time of prolapse repair. Also, Cross and coworkers (1997) reported that the support created by the simultaneous placement of a pubovaginal sling in grade 3 and 4 cystoceles was improved. It remains an important distinction that the protection from recurrent anterior compartment defects has only been described for bladder neck slings, which are not the most commonly performed midurethral sling procedures.

Liang and associates (2004) prospectively evaluated 49 patients with severe POP and occult urinary incontinence. POP repair alone was performed in 17 patients with occult SUI, and POP repair with simultaneous TVT was performed in 32 patients. They found that the addition of a prophylactic TVT to the prolapse repair significantly decreased postoperative objective and subjective SUI rates. Yet, in this series some patients with occult SUI did not undergo sling. Of the 30 patients without occult SUI preoperatively, none had SUI postoperatively. Also, complication rates were higher in the group undergoing concomitant sling.

The Colpopexy and Urinary Reduction Efforts trial is the only large, randomized, controlled trial evaluating a simultaneous anti-incontinence procedure with POP repair (Brubaker et al, 2006). The investigators evaluated 322 patients with stage 2 to 4 POP who underwent abdominal sacrocolpopexy, of whom 157 were randomized to concomitant Burch colposuspension and 165 were randomized to abdominal sacrocolpopexy alone. The addition of a Burch colposuspension to abdominal sacrocolpopexy decreased postoperative SUI from 44.1% to 23.6% at 3 months postoperatively. In a subsequent study examining 2-year outcomes in the same group of patients, the authors found that 32% of patients who underwent concomitant Burch colposuspension were incontinent versus 45% of patients who underwent abdominal sacrocolpopexy alone (Brubaker et al, 2008). Approximately a third of the women after a Burch colposuspension still had SUI. Thus the major implication of this work is that women undergoing colpopexy should have an anti-incontinence procedure. However, these data cannot be generalized to women who undergo transvaginal POP repair or anti-incontinence procedures other than Burch colposuspension.

Most authors who have examined this issue have reported that the majority of women without occult SUI or symptoms of SUI do not leak after prolapse surgery. Chaikin and colleagues (2000) reported that all (100%) of their patients without occult SUI did not leak after prolapse. They concluded that the decision to perform a concomitant prophylactic anti-incontinence procedure should be tailored to individual urodynamic findings. Ballert and associates (2009) reported that 22 of 24 women (91.7%) without symptomatic or occult SUI did not leak after repair of stage 2 to 4 POP. They also found that the risk of intervention due to obstruction after receiving a midurethral sling was 8.5%. Therefore, the risk of intervention due to sling obstruction was equal to the risk of intervention due to SUI when no clinical, urodynamic, or occult SUI was present and no midurethral sling was placed. Because the need to intervene for complications resulting from a midurethral sling equaled the risk of having to perform a secondary sling, the necessity for secondary surgery in women without SUI after repair of anterior vaginal wall prolapse is not decreased.

In summary, there is no standardized terminology or accurate testing for occult SUI. In addition, there are no controlled studies proving that continent women (no clinical, urodynamic, or occult SUI) develop postoperative SUI. **However, it is clear that all women with advanced stage anterior compartment prolapse should be screened for the presence of SUI with the prolapse reduced and consideration should be given to a concomitant anti-incontinence procedure. All women with preoperative symptoms of SUI, occult SUI, or urodynamically proven SUI should undergo a simultaneous anti-incontinence procedure. The risks and benefits of a prophylactic anti-incontinence procedure on continent women should be reviewed with each patient because the current literature supports selective use of an anti-incontinence procedure at the time of POP repair.**

Apical Vaginal Compartment

Middle compartment defects involve the vaginal apex. The organs involved in defects of the middle compartment include the uterus, bowel or omentum, and, depending on the size, bladder and rectum. **The apex remains the cornerstone of vaginal support, and failure to ensure apical support at the time of prolapse correction will undoubtedly increase the risk of recurrence exponentially.**

McCall (1957) highlighted this importance when he described his technique of posterior culdoplasty. This technique closed the peritoneal cul-de-sac posteriorly, thereby preventing enterocele formation, and emphasized the importance of apical fixation. In this landmark paper, he described the following technique:

> The posterior culdoplasty is a simple procedure which obliterates the redundant cul-de-sac of Douglas by a series of continuous sutures so as to suspend it by the uterosacral ligaments which then are brought together in the midline…The first suture picks up the left uterosacral ligament about 2 cm above its cut edge. Several bites of redundant sac are then taken at 1-2 cm intervals until the right uterosacral ligament is reached and picked up…Three external through-and-through sutures of this type are usually inserted, each one higher than the last, so as to be placed through the uterosacral ligaments at intervals between the internal sutures. The highest of these is placed just at the top of the newly supported vagina. It is this suture, which brings the new vaginal vault to the highest possible level thus insuring that the vagina will be as long as possible in each instance. The internal sutures are now tied and the previously herniated cul-de-sac obliterated into a firm, shelflike structure. The external sutures are then tied and the vaginal mucosa snugged against this shelf.

Apical Vaginal Prolapse Repairs

The uterosacral vault suspension preserves the orientation of the vaginal axis in its natural position, thus potentially preventing recurrence of prolapse in other segments (Silva et al, 2006). Several authors have reported that the uterosacral ligaments break at specific points rather than an attenuation of the uterosacral/cardinal ligament complex, thus allowing for a more site-specific repair (Jenkins, 1997; Barber et al, 2000; Shull et al, 2000). These findings are in contrast to a histologic assessment of the uterosacral ligaments, which calls into question the integrity of this structure for long-term apical support (Cole et al, 2006).

Surgical Anatomy of the Uterosacral Ligaments. The ligament is attached broadly to S1 to S3 and variably to S4 (Buller et al, 2001) (Figs. 72–24 and 72–25). It proceeds in a fanlike manner anterolaterally to the cervical os and also onto the proximal portion of the posterior vagina. The ligament can be divided into sacral, intermediate, and cervical portions. Beneath the sacral portion of the ligament runs the superior gluteal vein. Although there is great variability in the location of the ureter relative to the spine (Karram

et al, 2001), the ureter has been reported to be near the anterior margin of the uterosacral ligament near the cervix. As the ureter courses distally, the distance between the uterosacral ligament and ureter decreases from 4 cm near the sacrum to 0.9 cm near the cervix (Buller et al, 2001). Because of the fibrous tissues of the ureteral sheath, the ureter is subject to kinking from traction caused by sutures placed in the adjacent tissue (Dwyer and Fatton, 2008). If sutures are placed close to the sacrum there is a risk of entrapping fibers of the sacral plexus trunk of S1 to S4 (Siddique et al, 2006; Wieslander et al, 2007). This can result in buttock pain, which radiates to the posterior thigh and popliteal fossa. **Placing sutures in the intermediate portion of the uterosacral ligament appears to be the optimal site because there are fewer structures to be potentially affected and it provides a stable point of fixation. There is a decreased chance of traction affecting the ureter at this point, because it is further away from the ureter and its sheath.**

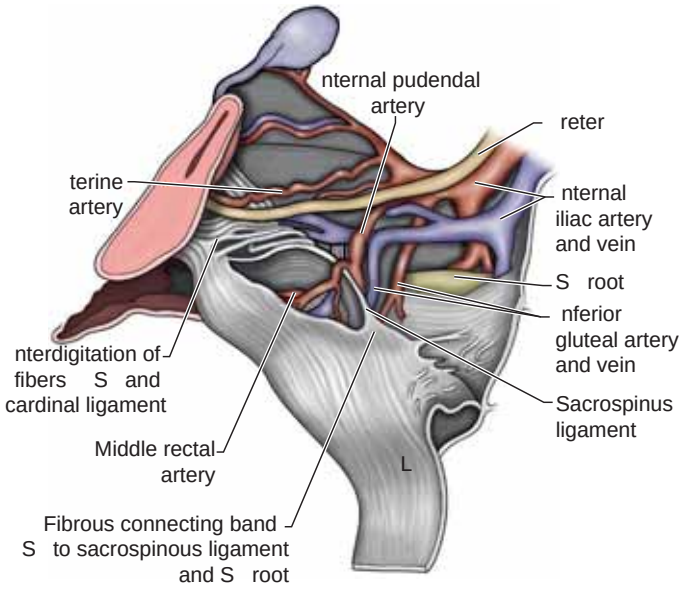

Figure 72–24. Right hemipelvis: sagittal view. The uterosacral ligament (USL) has been reflected to show subjacent anatomy. (From Buller JL, Thompson JR, Cundiff GW, et al. Uterosacral ligament: description of anatomic relationships to optimize surgical safety. Obstet Gynecol 2001;97:873–9.)

Placing the sutures from lateral to medial will also minimize accidentally catching either the ureter or its attachments in the stitch (Shull et al, 2000). The intermediate segment can be located 1 cm posterior along the palpable uterosacral ligament at the level of the ischial spine with the uterosacral ligament placed on tension (Buller et al, 2001). An advantage of suspension to the uterosacral ligament is that it minimizes injury to the pudendal and gluteal vessels relative to sacrospinous ligament fixation (Barber et al, 2000).

Technique

HIGH UTEROSACRAL VAGINAL VAULT SUSPENSION. This procedure starts intraperitoneally (Karram et al, 2001). After hysterectomy the apex is identified on the vaginal cuff at the 3- and 9-o'clock positions, which represent the attachments of the cardinal and uterosacral ligaments (Shull et al, 1993). It is useful to place stay sutures at these dimples before incision. The vaginal epithelium is dissected away from the peritoneum of the hernia sac. Once the dissection has mobilized the hernia sac from the epithelium to the neck of the sac, it is entered and the sac excised (Fig. 72–26). Laparotomy pads are placed to pack the bowel away. Ischial spines can then be palpated transperitoneally. The uterosacral ligaments will be located posteriorly and medially to the ischial spines. By placing traction to the stay sutures or by placing an Allis clamp at the 5- and 7-o'clock positions of the apex the uterosacral ligament will tent and two to four nonabsorbable sutures can be placed through the uterosacral/cardinal ligament complex (Fig. 72–27). The ureters should be located lateral to the uterosacral ligaments; however, it should be noted that depending on the degree of the prolapse there can be significant variability in their location relative to the edge of the uterosacral ligament (Silva and Karram, 2006). If there is any question as to their location, temporary stents may be placed to facilitate their palpation. In placing the needles through the uterosacral ligaments it is important to pass them lateral to medial, exiting away from the ureter to avoid inadvertent inclusion into the tie (Shull et al, 2000). To ensure the proper depth, the suture should be passed at the level of the ischial spines. Subsequent sutures are placed proximal to the last. If an anterior colporrhaphy or sling is planned it may be done at this point. Suspensory sutures in the uterosacral ligaments are then placed in the most apical portions of the pubocervical and rectovaginal fascia. The highest sutures are then sewn to the most medial portions of the pubocervical and rectovaginal fascia. The more distal sutures are placed most laterally in the pubocervical and rectovaginal fascia and passed out of the vaginal epithelium on each side

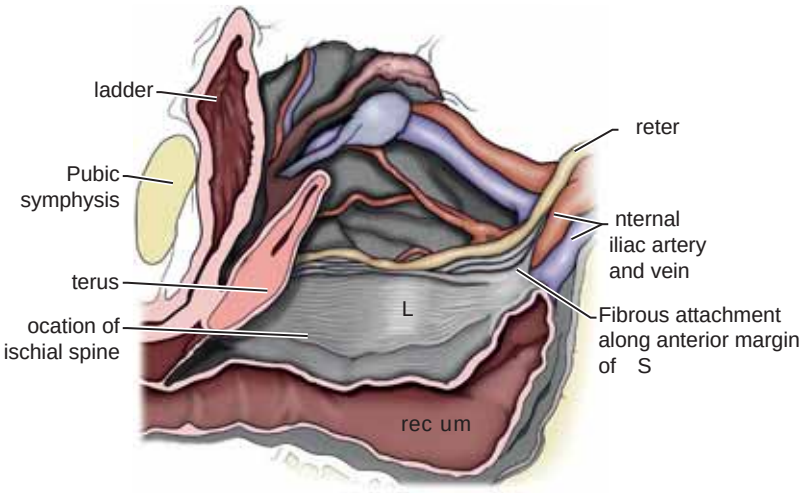

Figure 72–25. Right hemipelvis sagittal view. The peritoneum has been removed and the uterosacral ligament (USL) was left intact to show the proximity of the ureter in this specimen. (From Buller JL, Thompson JR, Cundiff GW, et al. Uterosacral ligament: description of anatomic relationships to optimize surgical safety. Obstet Gynecol 2001;97:873–9, with permission.)

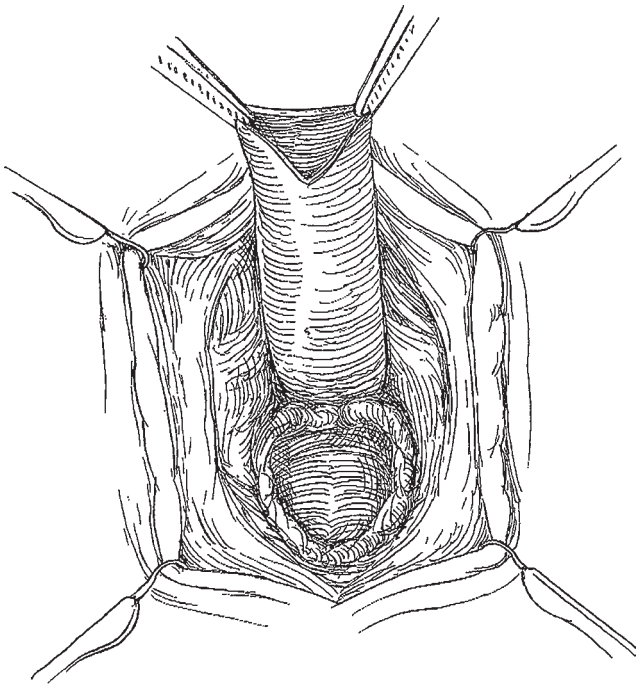

Figure 72–26. Vaginal enterocele repair. Enterocele sac is identified and opened to reduce its contents. It is then tied in a purse-string suture and the excess is excised. Before closure of the enterocele sac the peritoneal cavity is entered to access the uterosacral ligament. (From Cespedes RD, Winters CW. Colpocleisis for the treatment of severe vaginal vault prolapse. In: Vasavada SP, Appell RA, Sand PK, Raz S, editors. Female urology, urogynecology, and voiding dysfunction. Boca Raton [FL]: Taylor & Francis; 2005.)

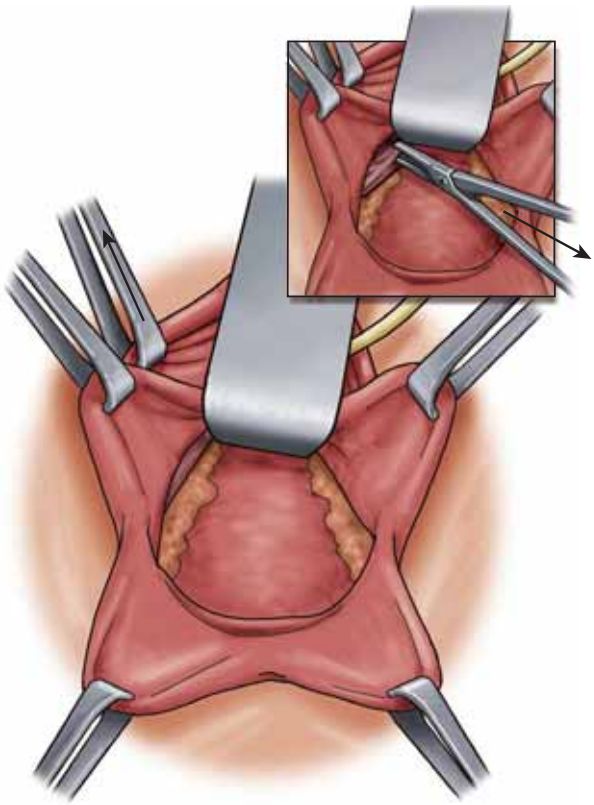

Figure 72–27. To identify the uterosacral ligament, an Allis clamp is placed on the vaginal epithelium at the right apex and pulled straight upward. Placing the right uterosacral ligament on tension aids in visualizing this structure within the pelvis. *Inset,* A long Allis clamp is used to grasp the right uterosacral ligament. (From Walters M, Muir T. Surgical treatment of vaginal apex prolapse. In: Vasavada SP, Appell RA, Sand PK, Raz S, editors. Female urology, urogynecology, and voiding dysfunction. Boca Raton [FL]: Taylor & Francis; 2005.)

(Fig. 72–28). Cystoscopy with indigo carmine is an essential step after this procedure to confirm ureteral patency and should be performed before trimming the suture because this will facilitate identification of the sutures if they need to be removed due to obstruction. If no efflux of urine is seen the sutures should be removed starting with the most lateral suture of the ipsilateral side. In addition, it is important to perform the cystoscopy after the suture is tied, not just placed (Yazdany and Bhatia, 2008). After ureteral patency is ensured, it is useful to close the vaginal cuff at least one third of the length of the incision before tying down the uterosacral sutures to avoid the difficulty of placing the closing sutures high in the vagina once it is suspended. As one ties these suspending sutures, the rectovaginal fascia and pubocervical fascia are brought together at the uterosacral/cardinal ligament complex, thus resuspending the apex of the vagina and closing the cul-de-sac (Fig. 72–29).

An extraperitoneal approach has also been described (Dwyer and Fatton, 2008). A midline incision is made, depending on concomitant prolapse. The vaginal epithelium is then dissected away from the endopelvic fascia, and the enterocele sac is identified and dissected free of the vault. Dissection is continued laterally until the uterosacral/cardinal ligament complex is identified posterior and medial to the ischial spine. Palpation to tent the uterosacral/cardinal ligament complex is facilitated by placing tension on the vagina. Use of the Breisky-Navratil retractor to retract the bladder and ureters anteriorly has prevented ureteral obstruction through traction or injury (Fatton et al, 2009). Once the ligaments are identified, the sutures are placed in a similar fashion to the intraperitoneal approach. Cystoscopy and vaginal closure are performed as described previously.

ABDOMINAL APPROACH TO THE UTEROSACRAL LIGAMENTS. The uterosacral ligaments may be accessed transabdominally (Lowenstein et al, 2009). This technique begins by elevating the uterus at the time of abdominal hysterectomy. Three permanent sutures are placed in each of the uterosacral ligaments proximal and medial to the ischial spine. They are numbered in the manner described by Shull and colleagues (2000) (Fig. 72–30). Once the hysterectomy has been performed and the cuff has been closed, the sutures are placed sequentially through the anterior and posterior leaves of the endopelvic fascia. By reapproximating the anterior and posterior muscularis of the vagina, any potential enterocele defects are closed and the cuff is elevated toward the sacrum, re-creating the normal vaginal axis. Cystoscopy is performed after tying the sutures, which are left uncut until efflux of urine is demonstrated. If no urine is seen, the most lateral ipsilateral suture is removed and subsequent sutures are taken down in sequence.

Results (Table 72–5)**.** Jenkins (1997) reported his experience in 50 patients who underwent vaginal vault suspension to the uterosacral ligaments, 33 of whom underwent concomitant vaginal hysterectomy. There was no recurrence of vault prolapse; however, 2 patients had asymptomatic cystoceles. Three had erosion of the suture (monofilament) into the vagina. Although not sexually active, 1 patient who had vaginal narrowing complained of tightness of the bladder and vagina. Three had de novo dyspareunia, with resolution in 2 by 6 months. Barber and associates (2000)

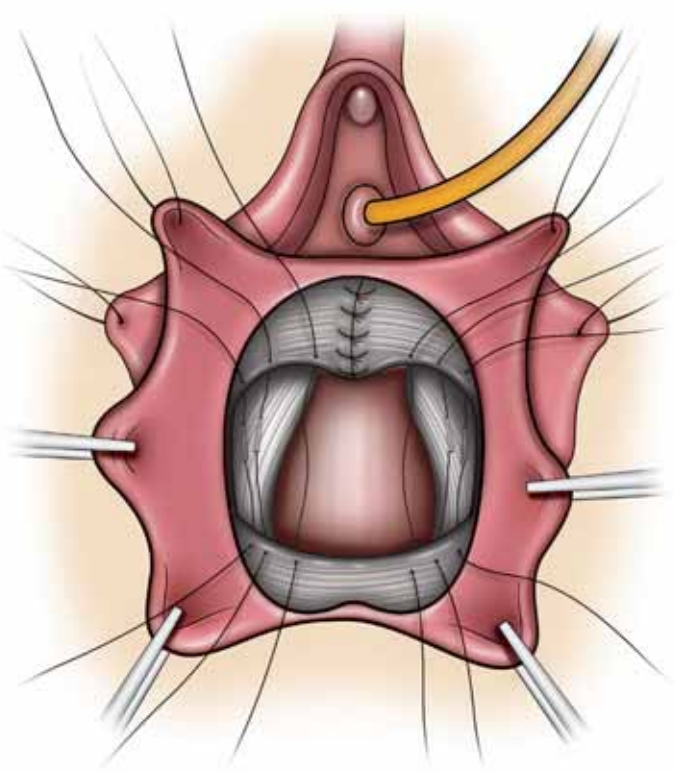

Figure 72–28. High uterosacral ligament vaginal vault suspension. Three sutures are placed from lateral to medial in each uterosacral ligament. The sutures are brought through the vaginal muscularis anteriorly (pubocervical fascia) and posteriorly (rectovaginal fascia). (From Walters M, Muir T. Surgical treatment of vaginal apex prolapse. In: Vasavada SP, Appell RA, Sand PK, Raz S, editors. Female urology, urogynecology, and voiding dysfunction. Boca Raton [FL]: Taylor & Francis; 2005, with permission.)

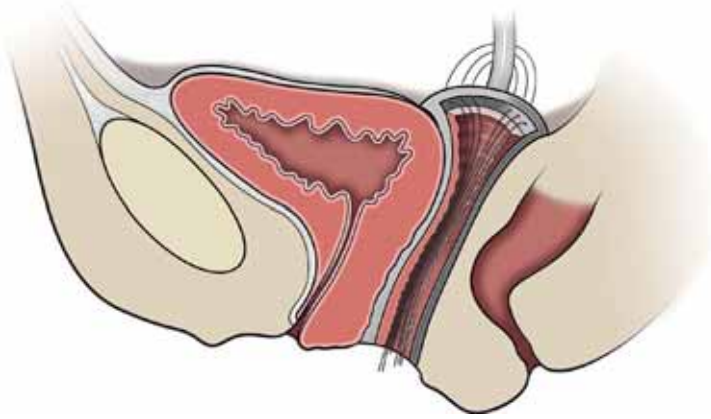

Figure 72–29. Completed uterosacral vaginal vault suspension with anterior colporrhaphy. (From Walters M, Muir T. Surgical treatment of vaginal apex prolapse. In: Vasavada SP, Appell RA, Sand PK, Raz S, editors. Female urology, urogynecology, and voiding dysfunction. Boca Raton [FL]: Taylor & Francis; 2005, with permission.)

reported on 46 women who underwent site-specific repair of the endopelvic fascia defects with suspension of the vaginal cuff to the proximal uterosacral ligaments. At a median follow-up of 15.5 months, 67% had POP-Q stage 1 or less prolapse of any compartment, and 95% had correction of apical prolapse. Voiding dysfunction was noted to improve from 59% to 7%. Eleven percent of patients were noted to have entrapment of the ureter, which was recognized intraoperatively. Two had to undergo ureteral reimplantation, which was performed at the time of the original surgery. This emphasizes the need for intraoperative cystoscopy to identify ureteral injury. Shull and colleagues (2000) reported a large series of patients who underwent uterosacral ligament suspension. Of 289 patients who were observed over time, a majority (87%) had no recurrence of support defect at any site on any postoperative examination. Only 5% of the patients had grade 2 prolapse or greater. The most common site was the anterior compartment in which 10 patients had grade 2 or 3 defects. One patient required ureteroneocystostomy. Two patients required removal of suspensory sutures. Karram and coworkers (2001) reported on 202 patients who underwent vaginal vault suspension. Of interest, uterosacral ligament suspension could not be performed in six patients because the enterocele sac could not be identified or exposure of the cul-de-sac could not be carried out. These patients underwent sacrospinous ligament fixation. Ninety-nine percent had a successful vaginal vault suspension. Ten women had recurrent grade 2 prolapse at other sites. Wheeler and associates (2007) reported patient satisfaction of 89% in 35 patients. No ureteral injuries were noted, and none of the patients required operation for recurrent prolapse, urinary incontinence, or urinary tract injury. Amundsen and associates (2003) reported on a retrospective analysis of 33 patients who underwent bilateral uterosacral ligament suspension with concomitant pubovaginal sling and site-specific endopelvic fascial repair. Vaginal prolapse symptoms resolved in 82%, and SUI improved in 82%. No dyspareunia was reported postoperatively. Eighty-three percent of women who needed to perform vaginal or perineal splinting ceased to do so postoperatively. POP-Q measurements improved significantly ($P < .05$) for all sites. Although these investigators noted a decrease in total vaginal length of 0.9 cm there was no corresponding loss of sexual function. Silva and Karram (2006) evaluated 5-year anatomic and functional outcomes of high uterosacral vaginal vault suspension. Apical recurrence occurred in 2 of 78 patients. Seven patients had de novo postoperative dyspareunia. Short-form Incontinence Impact Questionnaire/Urinary Distress Inventory scores indicated improvement in all three domains of irritative, obstructive, stress, and overall symptoms compared with preoperative scores. Rare complications such as blood transfusion (1% to 3%), bowel injury (0% to 0.6%), and pelvic infection (0.6%) have all been reported after the uterosacral ligament suspension (Shull et al, 2000; Karram et al, 2001; Amundsen et al, 2003).

Fatton and colleagues (2009) examined their results performing an extraperitoneal bilateral uterosacral vaginal vault suspension over 2 years. Some of the patients in this series also had mesh reinforcement both anteriorly (47.1%) and posteriorly (53.7%). Recurrence at the apex was noted in 4.6% of patients. Mesh exposure occurred and was diagnosed within 6 months in the majority of the patients. Their results are similar to that reported for an intraperitoneal approach.

Sacrospinous Ligament Fixation

The sacrospinous ligament fixation was first described by Richter in 1942 but was not widely utilized until Nichols reported on the technique forty years later (Nichols, 1982). The sacrospinous ligament fixation has been shown to be an effective method to correct apical prolapsed (Cruikshank and Muniz, 2003). This technique is appealing because of its retroperitoneal approach and consistency as a strong structure on which to anchor the apex. Access to the spine was originally achieved from the posterior approach, although dissection from the anterior approach may also be

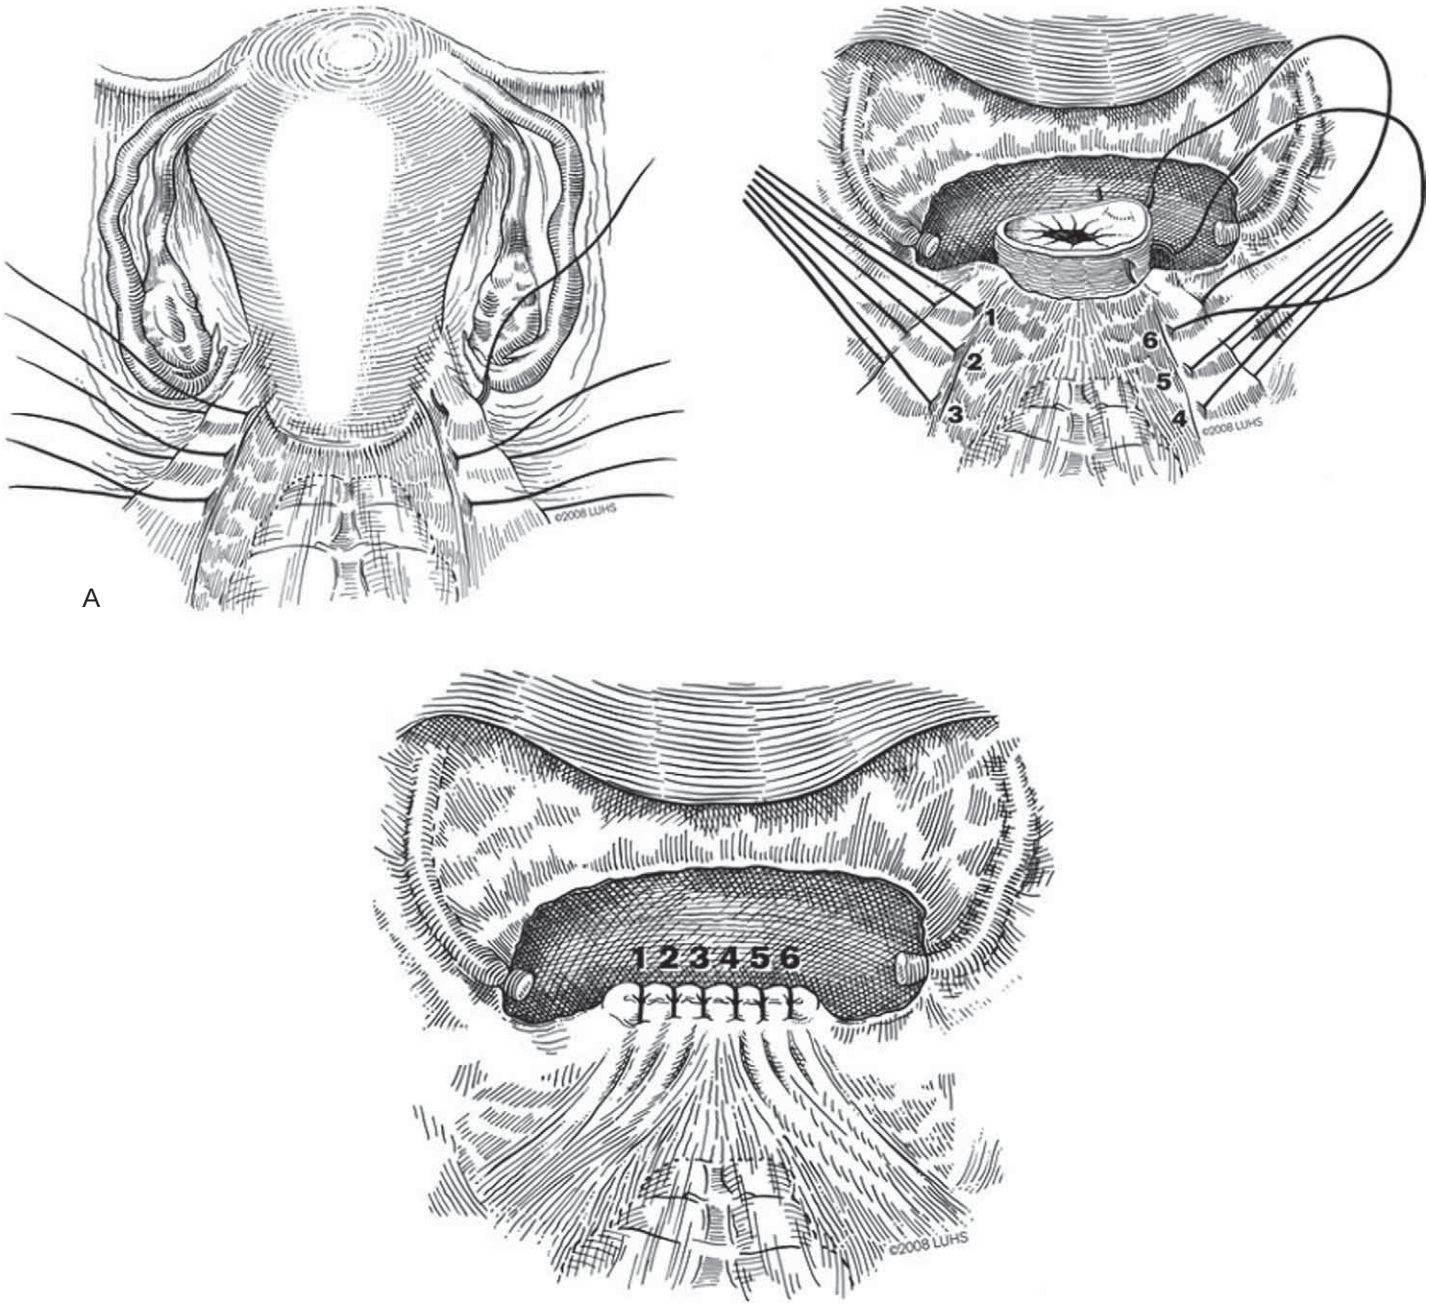

Figure 72–30. **A,** Three permanent sutures are placed in each of the uterosacral ligaments medial to the ischial spine. **B,** One end of each of the six sutures is placed serially across vaginal apex through the anterior endopelvic fascia and the other end is placed through the posterior endopelvic fascia. **C,** All sutures are tied to reapproximate the anterior and posterior vaginal muscularis, to close any potential enterocele defect, and to elevate the vaginal apex toward the sacrum. (© 2008 Loyola University Health System. Used with permission from Mary Pat Fitzgerald, MD.)

performed via the paravaginal space (Cespedes, 2000; Winkler et al, 2000). The advantages of sacrospinous ligament suspension are success rates comparable to abdominal procedures (Brown et al, 1989; Imparato et al, 1992), ability to repair concomitant pelvic floor defects, absence of a laparotomy (Morley and DeLancey, 1988), shorter hospital stay (Brown et al, 1989), preservation of vaginal length and function (Morley and DeLancey, 1988; Brown et al, 1989), and cost effectiveness (Brown et al, 1989). The structures at risk with this technique include the pudendal or inferior gluteal vessels and the sciatic or pudendal nerves. Pudendal nerve entrapment results in posterior buttocks pain, which may radiate down the back of the thigh. **A disadvantage of this approach is the alteration in vaginal axis, which results in apical displacement posteriorly and to the right side when unilateral fixation is used. This posterior displacement can result in anterior compartment recurrence even when an anterior repair is performed** (Morley and DeLancey, 1988; Shull et al, 1992; Sauer and Klutke, 1995).

Sacrospinous fixation may be performed unilaterally or bilaterally (Pohl and Frattarelli, 1997). With the unilateral suspension, right-sided placement is generally preferred. Technically, it is easier to place the sutures on the right ligament for a right-handed surgeon (Sauer and Klutke, 1995). Cespedes (2000) reported success using the bilateral anterior support and noted the advantage of

Table 72–5.

more midline location of the vaginal apex. Although bilateral placement has been advocated (Nichols, 1996), there is little to support the advantage of bilateral fixation over unilateral fixation when examining outcomes (Morley and DeLancey, 1988).

Surgical Anatomy of the Sacrospinous Ligament Fixation. The sacrospinous ligament is 7 to 8 cm in length (Morley and DeLancey, 1988). It extends from the ischial spine laterally, courses medially under the coccygeus muscle, and inserts into the sacrum. The pudendal nerves and vessels are in close proximity to the ligament just proximal to their course around the ischial spine (Fig. 72–31). Additionally, the hypogastric plexus of veins are located superiorly and the hemorrhoidal vessels are located medially to the sacrospinous ligament (Morley and DeLancey, 1988); thus retraction should be carried out carefully in these respective areas. To avoid the gluteal vessels, the suture should be placed into the ligament and not behind it (Kettel and Herbertson, 1989). Pudendal nerve entrapment may result in pain, which localizes to the buttocks or perineum. This may be avoided by placing sutures more medially about 1.5 cm from the ischial spine (Sauer and Klutke, 1995; Alevizon and Finan, 1996). **Thus, the optimal position of the suture placement is 1.5 to 2.0 cm medial to the ischial spine, directly into the sacrospinous ligament.** Placing it too far medially may risk failure of the repair because the sacrospinous ligament fans and thins as it inserts into the sacrum (Sauer and Klutke, 1995). In addition, there is a higher concentration of sacral nerves in this medial location. Barksdale and associates (1997) performed a cadaveric study to assess the histology of the sacrospinous ligament. Segments were taken near the ischial spine, including middle and sacral portions of the ligament. The highest concentration of nerves was found in the sacral portion of the ligament, with the lowest being near the spine. Although it was postulated that the nerves embedded in the sacrospinous ligament were a potential source of neuropathic pain, no clinical correlation could be made in this cadaveric study. Lantzsch and coworkers (2001) concluded that localization and depth of the suture can also influence the occurrence and intensity of sciatic neuralgia.

Technique. The procedure starts by marking the apex of the vagina. The vaginal apex is then reduced to the sacrospinous ligament(s) intended to be used. This site of attachment is then tagged for later fixation. A midline vaginal incision is fashioned, the location of which is largely dependent on the need for other compartmental repairs. The vaginal epithelium is separated from the rectovaginal septum posteriorly and/or pubocervical fascia anteriorly. If an anterior compartment repair will be performed, the sacrospinous ligament may be approached anteriorly, exposing the paravesical space. The tissue attachments overlying the spine and ligament are swept medially. Alternatively, if the posterior approach is used, one must enter the perirectal space by bluntly mobilizing the rectum medially. On entering the perirectal space the ischial spine is identified. With further dorsal and medial blunt dissection, the sacrospinous ligament is palpated. Blunt dissection is continued to ensure that the rectum is retracted medially, and the ligament is adequately exposed. At this point Heaney or Breisky-Navratil retractors are very useful to visualize the ligament and facilitate suture placement. Additionally, long lighted retractors can provide added visualization. The sacrospinous ligament is then palpated. The suture is placed approximately one to two fingerbreadths medial from the spine, to avoid damage to the structures in the Alcock canal. Several different methods have been used to fix the suture to the sacrospinous ligament. The Capio Suture Capturing Device (Boston Scientific, Natick, MA)

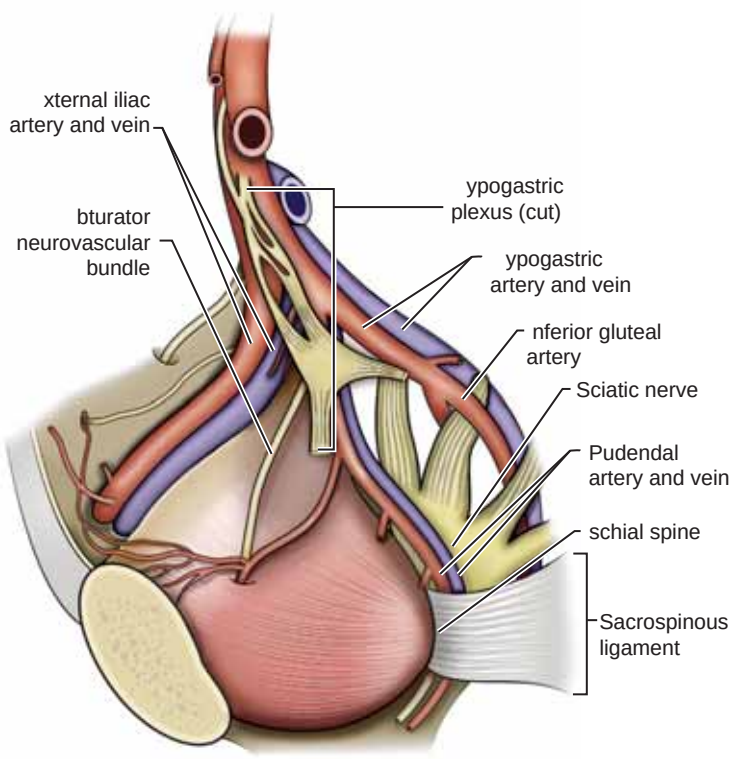

Figure 72–31. Anatomy of the sacral spinous ligament and surrounding structures. Note the close proximity of the pudendal vessels, hypogastric plexus, inferior gluteal vessels, and sciatic nerve. (From Walters M, Muir T. Surgical treatment of vaginal apex prolapse. In: Vasavada SP, Appell RA, Sand PK, Raz S, editors. Female urology, urogynecology, and voiding dysfunction. Boca Raton [FL]: Taylor & Francis; 2005, with permission.)

enables the suture to be placed by palpation. Alternatively, the Miya Hook (Cooper Surgical, Trumbull, CT) (Miyazaki, 1987), the Autosuture Endo Stitch Suturing Device (Covidien, Norwalk, CT) (Schlesinger, 1997), and Deschamps Ligature Carrier may be utilized to place the sutures under direct vision. Two sutures are most commonly placed. In cases of bilateral sacrospinous ligament fixation, one suture may be placed on each ligament. In the case of unilateral sacrospinous ligament fixation the placement of the sutures on the ligament 2 cm apart will prevent constriction of the vaginal apex. Additional repairs may be performed at this point. Following this, the previously placed sacrospinous ligament sutures are brought out of the vagina to the previously marked vaginal apex (Fig. 72–32). If a permanent suture is utilized for sacrospinous ligament fixation, a (pulley stitch) configuration, which ensures that the knot of the suture will remain internal, is needed. To create a pulley stitch, tying a knot onto the fibromuscular portion on the visceral side of the vagina creates a fixed point. The free end of the suture is then pulled, thus suspending the apex to the sacrospinous ligament, and this is then secured by tying a secure knot. Importantly, this resultant knot remains internal and is not within the vaginal canal. Closure of the vaginal wall halfway before tying down the sutures is useful because the suspended apex may be quite difficult to reach. The sutures should be tied such that the vaginal apex is firmly attached to the coccygeal/sacrospinous ligament complex with no intervening suture material bridging a gap (Morley and DeLancey, 1988; Sze and Karram, 1997). Palpation of the suture behind the vaginal cuff will ensure that the suture is tied securely. It is useful to leave the suture untrimmed until the cystoscopy is performed in case the suture needs to be removed. Once efflux has been ensured, the suture is trimmed and the remainder of the vaginal wall is closed.

Results (Table 72–6). Nichols (1982) reported outcomes of sacrospinous ligament fixation in 163 patients, some with "massive" vaginal eversion and procidentia, and had no recurrences of

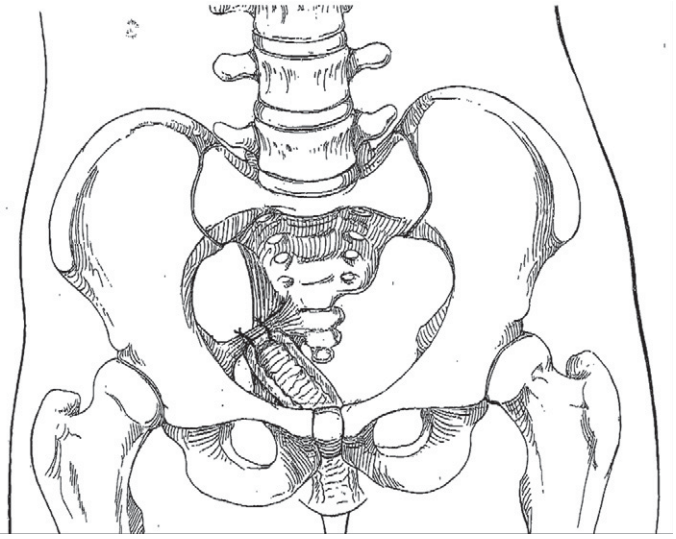

Figure 72–32. Sacral spinous ligament fixation. With a unilateral suspension, the vagina is deflected to the right side and caudally. (From Richter K, Albright W. Long-term results following fixation of the vagina on the sacrospinous ligament by the vaginal route [vaginaefixatio sacrospinalis vaginalis]. Am J Obstet Gynecol 1981;141:811–6, with permission.)

vaginal vault prolapse. Nine patients reported that the vagina was too narrow postoperatively. Richter and Albrich (1981) reported excellent patient satisfaction, although eight patients were reluctant to resume sexual relations because of a perceived narrowed vagina. Morley and DeLancey (1988) reported on 100 patients who underwent sacrospinous ligament fixation, 33 of whom underwent isolated apical treatment. Sixty-seven had concomitant prolapse repairs. Apical success was noted in 95.7%, 90.1%

globally, with four patients having prolapse in the anterior compartment. They noted that the long-term results were acceptable with minimal adverse effects.

Bilateral sacrospinous ligament suspension was compared with abdominal sacrocolpopexy in a prospective randomized study (Benson et al, 1996). Time to failure was shorter in the sacrospinous ligament suspension group compared with the abdominal sacrocolpopexy group (11 vs. 22 months) with the vaginal group having 12 cystoceles requiring reoperation versus 4 cystoceles in the abdominal group. Sauer and Klutke (1995) reported on 24 patients with a mean follow-up of 13.8 months. They had very little blood loss, and no transfusions were needed. Mild buttock pain was noted that resolved by 3 months. In 21 of 24 patients there was no recurrence of prolapse at the apex. One patient underwent repeat operation for a significant cystocele. Meschia and associates (1999) reported on 103 patients who underwent sacrospinous ligament fixation and found excellent results for the posterior and apical compartments but disappointing results for the anterior compartment, with 16% having grade 2 or greater prolapse.

The anterior compartment has been reported as a particularly vulnerable site for developing a defect after sacrospinous vaginal vault suspension. Recurrent cystoceles have been reported in 7.6% to 92% of patients postoperatively (Richter and Albrich, 1981; Morley and DeLancey, 1988; Pasley, 1995). This has been attributed to vaginal retroversion. This is noted not only postoperatively but intraoperatively, although many who develop anterior defects remain asymptomatic and do not undergo subsequent surgery to correct the anterior compartment defect (Paraiso et al, 1996).

Several authors have demonstrated the feasibility and efficacy of an anterior approach to the sacrospinous ligament vaginal vault suspension (Cespedes, 2000; Winkler et al, 2000). Winkler and coworkers (2000) reported that the anterior compartment recurrence rate after an anterior sacrospinous ligament fixation and anterior repair was 9%, in contrast to a 24% after sacrospinous ligament fixation with posterior repair. Cespedes (2000) reported on the bilateral anterior approach and noted no recurrences. Some of the theoretical advantages of the anterior approach include improved ability of the vagina to withstand increased intra-abdominal pressures (Pohl and Frattarelli, 1997) and less likelihood of rectal injury (Sauer and Klutke, 1995). Again, a low incidence of anterior compartment recurrence was noted (7%) (Cespedes, 2000).

Successful healing in the short term may predict long-term success of the sacrospinous ligament suspension. Shull and colleagues (1992) reported on 81 women undergoing sacrospinous ligament suspension, 72% of whom had undergone previous pelvic surgery. Those who showed absence of any compartment defect at the 6-week follow-up visit had a 3% likelihood of requiring additional reconstructive surgery within 2 to 5 years.

Complications. Cruikshank and Muniz (2003) reported 15% of patients experienced gluteal pain after sacrospinous ligament fixation on the ipsilateral side. Generally this pain resolves

spontaneously within 2 to 3 months when delayed absorbable sutures are used (Maher et al, 2001). Postoperative neuropathic pain can be managed with observation, and patients should be counseled that duration may be as long as 3 months (Sauer and Klutke, 1995). Injection of the nerve with local anesthetic has also been reported (Lantzsch et al, 2001). Rectal perforation has been reported, recognized at the time of surgery, and repaired primarily with no sequelae (Richter and Albrich, 1981; Sauer and Klutke, 1995). In addition, injury to the pudendal nerve and internal pudendal vessels may occur with medially placed sutures near the ischial spine.

Iliococcygeus Suspension

The iliococcygeus suspension has the advantage of maintaining the vagina in the normal axis and is useful in cases in which the uterosacral ligaments are insufficient for attachment or cannot be identified. In this technique the vaginal vault is attached to the fascia of the iliococcygeus muscle as the anchoring site in contrast to the uterosacral or sacrospinous ligaments.

Technique and Results. The approach is similar to the uterosacral and sacrospinous ligament fixation and is usually approached extraperitoneally. The fascia of the iliococcygeus muscle is identified lateral to the rectum and anterior to the ischial spine (Shull et al, 1993). The point of suture fixation is placed 1 cm distal to the ischial spine, near the insertion of the ATFP. This suture is then passed through the condensation of connective tissue at the apex of the vagina anteriorly through the pubocervical fascia and posteriorly through the rectovaginal fascia (Fig. 72–33). Another suture is placed on the contralateral side in a similar manner. It is recommended that bilateral suture fixation be performed to achieve optimal results. Once the sutures are tied securely the vagina will be suspended bilaterally. As in sacrospinous ligament fixation the sutures may be placed through an anterior or posterior approach. Special needle drivers and lighted retraction are useful to facilitate suture placement. In cases utilizing permanent suture a pulley stitch technique is applied tying the knot internally.

Shull and colleagues (1993) reported on bilateral attachment of the vaginal cuff to the iliococcygeus fascia in 42 patients. Eight patients experienced pelvic support loss postoperatively, 3 in the middle compartment, 2 in the posterior compartment, and 4 in the anterior compartment. Six patients had additional surgery. Meeks and associates (1994) reported an anatomic cure of 96% in 110 patients. Intraoperative complications included rectal and bladder laceration and hemorrhage requiring transfusion. Postoperative complications included vaginal cuff abscess, fever, and transient femoral neuropathy. Maher and coworkers (2001) reported a 53% cure rate in 50 patients, and 19% of the patients experienced buttock pain.

Abdominal Sacrocolpopexy

The abdominal sacrocolpopexy should be considered a treatment option in the following clinical scenarios: in a patient with a failed previous vaginal repair, in a patient with isolated apical prolapse and/or enterocele, and in a younger woman with an active lifestyle who desires to continue sexual intercourse. In these patients, **abdominal sacrocolpopexy is an excellent choice because it maximizes functional vaginal length and a near-normal vaginal axis.** As discussed earlier, other pelvic floor defects and occult SUI can be addressed at the same time. In addition to open surgery, robotic-assisted laparoscopic and pure laparoscopic approaches have all been described (Sundaram et al, 2004; Rozet et al, 2005; Daneshgari et al, 2006; Elliott et al, 2006). The principles of the operation remain the same regardless of the approach.

Technique. The critical elements of the operation include the use of permanent mesh (type I macroporous, monofilament) as graft material, secure fixation of the graft to the sacral promontory and vaginal cuff, and complete enterocele reduction and culdoplasty.

The patient is positioned in the low lithotomy position, providing both transvaginal and transabdominal access. A Pfannenstiel or low midline abdominal incision may be used. On entry into the peritoneal cavity it is important to achieve exposure of true

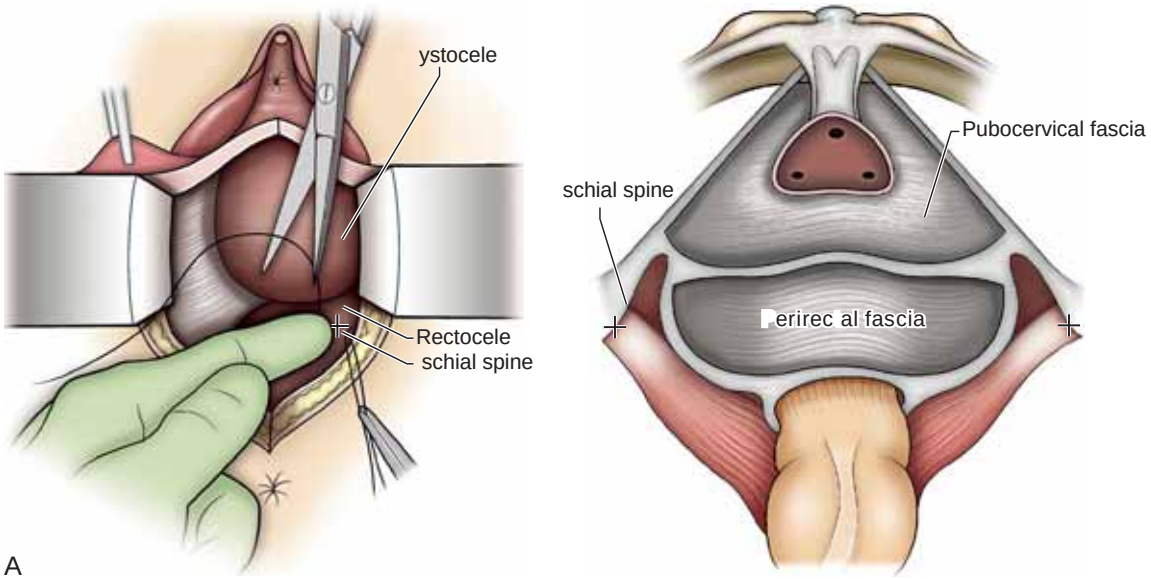

Figure 72–33. Iliococcygeus fascia suspension. **A,** With the surgeon's finger deflecting the rectum downward, the right iliococcygeus fascia sutures are placed. *Inset,* View of the dissected vagina. **B,** Abdominal view of the endopelvic fascia. Approximate location of the sutures is delineated by the + sign. (From Walters M, Muir T. Surgical treatment of vaginal apex prolapse. In: Vasavada SP, Appell RA, Sand PK, Raz S, editors. Female urology, urogynecology, and voiding dysfunction. Boca Raton [FL]: Taylor & Francis; 2005, with permission.)

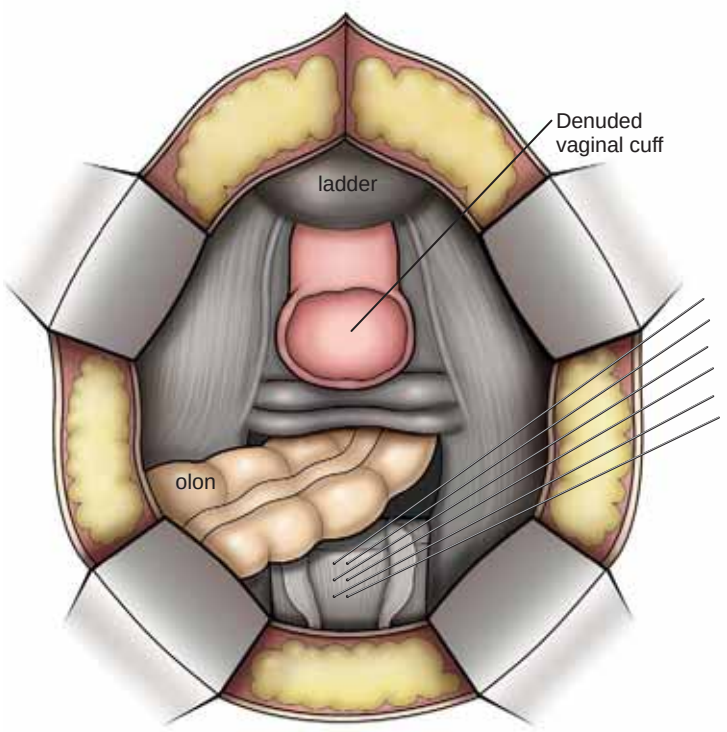

Figure 72–34. Abdominal sacral colpopexy. *A,* Incision in peritoneal cuff overlying the vagina, exposing the vaginal cuff. *B,* Two permanent sutures are placed in the sacral promontory to secure the graft material. Philadelphia: Lippincott Williams & Wilkins; 2009, with permission.)

pelvis by careful packing of the small intestine and sigmoid colon. This is accomplished by releasing all adhesions in the pelvis and packing the bowel above the level of the sacral promontory. An incision is made in the posterior peritoneum over the sacral promontory, extending inferiorly along the right lateral aspect of the rectum. Electrocautery is used when dividing the fatty tissue over the promontory. Careful dissection in this area is essential to avoid shearing of presacral veins because severe bleeding may occur. The middle sacral vein traverses over the promontory and should also be avoided. As the fatty tissue is dissected free, the anterior surface of the sacral promontory is visualized, usually by identification of the anterior longitudinal ligament. Two or three permanent sutures are placed into the sacral promontory. These sutures are safely tagged for later placement into the graft. Alternatively, commercially available tacking devices may be used for securing the graft to the sacral promontory (Fig. 72–34).

After placing an obturator in the vagina (large end-to-end anastomosis sizers are useful) the enterocele sac is identified and secured with an Allis clamp. If the enterocele is large, a Halban culdoplasty is performed by placing linear permanent (or delayed absorbable) sutures through the posterior peritoneum and on the outer surface of rectum up to the vaginal cuff (Geomini et al, 2001). Upward retraction of the sizer will assist in exposing the cul-de-sac. Usually four to six sutures are used to complete adequate cul-de-sac closure. This technique of closure (Fig. 72–35) is in contrast to that of the Moschowitz procedure, which involves purse-string closure and may predispose to ureteral angulation and obstruction.

The peritoneum over the vaginal cuff is incised, and the peritoneum is dissected off of the cuff of the vagina (see Fig. 72–35). A 2.0-cm wide segment of graft is sutured to the exposed vaginal cuff using six to eight sutures of permanent suture material (Fig. 72–36). Care is taken to identify the border of the bladder to avoid suturing the graft to the bladder. An obturator in the vagina is useful to facilitate suture placement and secure the mesh to the vagina. A polypropylene, macroporous, monofilament, nonabsorbable mesh is recommended. The graft is secured to the vagina by folding over the cuff of the vagina and allowing the long end of the graft to exit posteriorly and extend to the sacrum. (Alternatively, a T-shaped configuration of the graft may be created. The short arm of the T is placed on the top of the vagina, and the long arm of the T is secured to the lower end of the vagina.) Additionally, a long segment of posterior mesh may be attached to the perineal body, a procedure termed *colpoperineopexy* (Cundiff et al, 1997). At this step the central sutures from the culdoplasty are placed through the long arm of the mesh if desired.

The graft is then secured to the promontory. Care must be taken to avoid excessive tension. Placing the obturator all the way into the vagina but not pushing the vagina upward establishes the proper length of the graft. The graft is placed around the right lateral aspect of the rectum. A space of 2 fingerbreadths between the graft and the rectum prevents compression of the rectum over the graft (Fig. 72–37). The excessive length of the graft is trimmed after fixation to the sacrum. Lastly, the graft is positioned in the retroperitoneal space by closing the presacral peritoneum over the graft and covering the graft on the vagina with the superior edge of the peritoneum over the vagina. Procedures for SUI (if indicated) are then performed. The patient is then examined to determine if any ancillary prolapse repairs are needed.

Abdominal sacrocolpopexy maintains a functional vagina and restores maximum vaginal length and support. In a comparative study, vaginal length was longer after abdominal sacrocolpopexy compared with sacrospinous fixation (Given et al, 1993). A nonabsorbable monofilament synthetic mesh should be used during abdominal sacrocolpopexy. In a study by Culligan and coworkers (2005), patients undergoing abdominal sacrocolpopexy using either absorbable cadaveric fascia lata graft (Tutoplast) or nonabsorbable monofilament polypropylene were randomized. The objective failure rate for recurrence at any other vaginal site was 14 of 44 in the fascial group and 4 of 45 in the mesh group.

There are numerous reports by multiple authors that confirm the success of abdominal sacrocolpopexy.

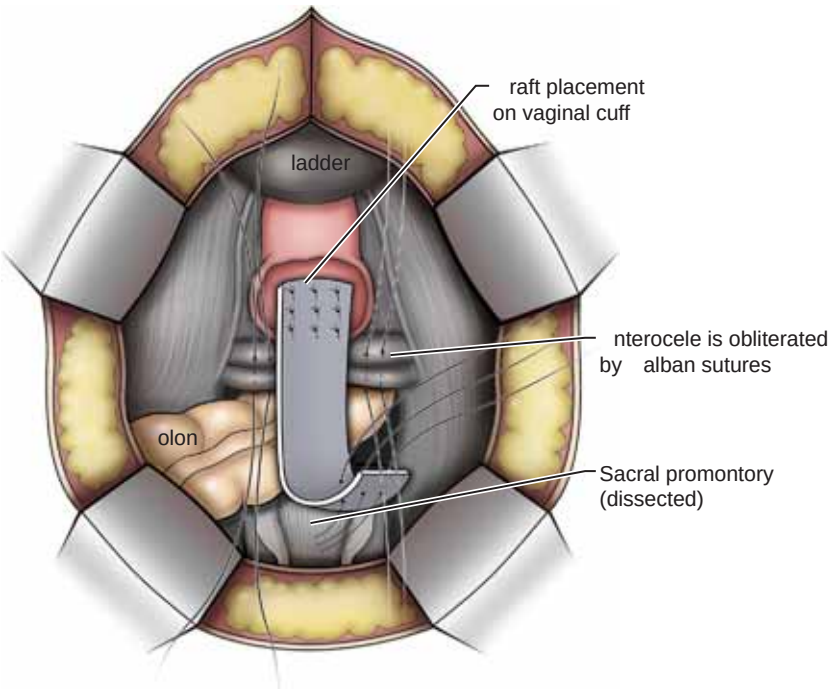

Figure 72–35. Abdominal sacral colpopexy: Synthetic graft material is sutured securely to vaginal cuff using multiple interrupted permanent sutures. The peritoneal cul-de-sac is closed using linearly placed sutures to obliterate this potential space. (From Winters J, Cespedes R, Vanlangendonck R. Abdominal sacrocolpopexy and abdominal enterocele repair in the treatment of vaginal vault prolapse. Urology 2000;56:55–63, with permission.)

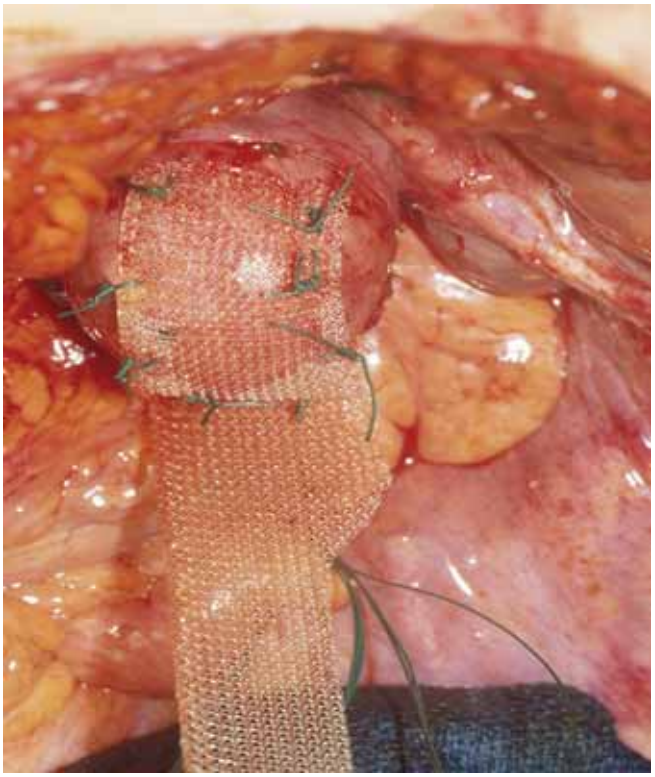

Figure 72–36. Abdominal sacral colpopexy: intraoperative view. Permanent mesh material sutured to vaginal cuff. End-to end anastomosis sizer was utilized to provide exposure of vaginal cuff. (From Scarpero H, Cespedes R, Winters J. Abdominal approach to the repair of vaginal vault prolapse. Tech Urol 2001;7:139–45, with permission.)

Multiple authors have reported success rates greater than 90% (Snyder and Krantz, 1991; Addison and Timmons, 1993; Webb et al, 1998; Menefee et al, 1999). There are several randomized, prospective trials comparing sacrospinous ligament fixation with abdominal sacrocolpopexy. In a comparative study between abdominal sacrocolpopexy versus vaginal repair, Benson and colleagues (1996) reported a lower success rate with vaginal repair, and an equivalent hospital stay between the two groups. Lo and Wang (1998) reported on their results of abdominal sacrocolpopexy versus sacrospinous ligament fixation at a duration of 2.1 years: 94.2% success in abdominal sacrocolpopexy compared with 80% in sacrospinous ligament fixation. Maher and coworkers (2001) reported on a comparative study between abdominal sacrocolpopexy and sacrospinous ligament fixation. At 2 years follow-up, symptoms and anatomic success were equivalent but asymptomatic failures to introitus and recurrent cystoceles were less after abdominal sacrocolpopexy. **Overall, vaginal (sacrospinous ligament fixation) procedures have a higher rate of recurrent anterior defects even when performed in the setting of a concomitant anterior repair (colporrhaphy)** (Holley et al, 1995). After an isolated abdominal repair of vaginal vault prolapse without addressing concomitant pelvic floor defects, recurrent distal defects such as cystocele and rectocele may occur up to a third of the time. This may predispose to decreased patient satisfaction and the possibility of secondary vaginal repair (Blanchard et al, 2006). Although most patients remain asymptomatic, secondary repair of these defects may be required (Blanchard et al, 2006). **It is important to counsel patients preoperatively about the possibility of distal anterior or posterior defects after abdominal sacrocolpopexy and the need for secondary vaginal repair, which can occur up to 20% of the time** (Blanchard et al, 2006).

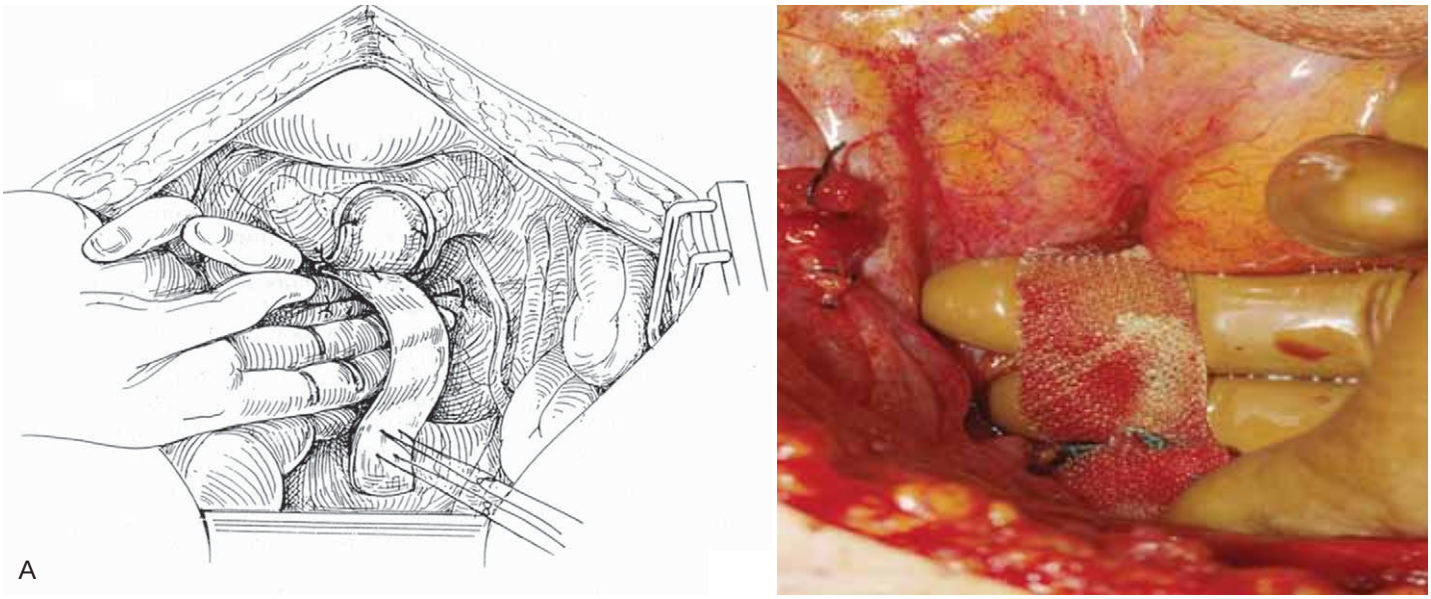

Figure 72–37. Abdominal sacral colpopexy. **A,** Graft is secured without tension to sacral promontory. **B,** Intraoperative view. (**A,** From Winters J, Cespedes R, Vanlangendonck R. Abdominal sacrocolpopexy and abdominal enterocele repair in the treatment of vaginal vault prolapse. Urology 2000;56:55–63, with permission; **B,** from Scarpero H, Cespedes R, Winters J. Abdominal approach to the repair of vaginal vault prolapse. Tech Urol 2001;7[2]:139–45.)

In a comprehensive review by Nygaard and coworkers (2004), intraoperative complications of sacrocolpopexy included hemorrhage or transfusion in 4.4%, cystotomy in 3.1%, enterotomy in 1.6%, and ureteral injury in 1.0%. Postoperative complications included urinary tract infection in 10.9%, wound infection in 4.6%, ileus in 3.6%, deep venous thrombosis or pulmonary embolism in 3.3%, and small bowel obstruction in 1.1%. The risk of significant bleeding has been reported from 1.6% to 4.4% and may be controlled with the use of stainless steel thumbtacks (Timmons et al, 1991). **Significant hemorrhage may occur from disruption of the presacral vessels, and the occurrence of this complication may be reduced when fixation of the graft is performed high on the sacral promontory.** The rate of reoperation for gastrointestinal complications is 1.2% (Whitehead et al, 2007). Vaginal exposure of mesh is heralded by persistent pain, discharge, or infections, and clinicians must be vigilant in follow-up (Karlovsky et al, 2005). In a recently reported meta-analysis, mesh erosion into the vagina is reported at 3.4% to 5.4% and may vary on the type of mesh used (Brizzolara and Pillai-Allen, 2003; Nygaard et al, 2004). **Erosions are more prevalent with Teflon or Gore-Tex materials and rare with macroporous, monofilament meshes.** Several authors have suggested that hysterectomy at the time of colpopexy increases the rate of mesh extrusion, although these findings are not uniform (Nygaard et al, 2004; Marinkovic, 2008) and no randomized trials address this issue (Nygaard et al, 2004). In 60 patients undergoing concomitant hysterectomy using a two-layer closure of the vaginal cuff followed by abdominal sacrocolpopexy with synthetic nonabsorbable monofilament mesh, the erosion rate was 0.8% compared with 0% in the 64 patients with a prior hysterectomy (Wu et al, 2006). In patients undergoing a combined operation, supracervical hysterectomy or a meticulous two-layer closure of the cuff should be performed to decrease the incidence of mesh erosion. **Surgeons must be aware that the concerns of mesh erosion after abdominal sacrocolpopexy are higher after hysterectomy.** Options in the management of eroded mesh after colpopexy may also include mesh excision with partial colpocleisis (Quiroz et al, 2008) and abdominal mesh excision.

Colpocleisis

Colpocleisis is an obliterative procedure used in the treatment of posthysterectomy vaginal vault prolapse or significant uterovaginal prolapse. In properly counseled, older patients who do not desire functional vaginal anatomy for sexual activity, colpocleisis may be an appropriate procedure. The total colpocleisis refers to removal of the vaginal epithelium to 0.5 to 2 cm from the urethral meatus with complete closure. A partial colpocleisis is used in cases of uterovaginal prolapse, and this procedure involves creating lateral channels to allow uterine drainage. Advantages of the colpocleisis procedures are shorter operative time, ability to use regional anesthesia or local anesthesia with sedation, minimal complications, and decreased recuperative time (Cespedes et al, 2001; FitzGerald et al, 2008). In those whose uterus is to be left in situ, preoperative evaluation should include a Papanicolaou smear, pelvic ultrasonography, and endometrial biopsy if indicated. Performance of hysterectomy at the time of colpocleisis eliminates the risk of developing cervical or endometrial cancer and eliminates the risk of developing pyometra, which is a serious complication of partial colpocleisis when the channels become obstructed (Shayya et al, 2009). However, most patients selected for colpocleisis are older with significant comorbidities that make a concomitant hysterectomy undesirable.

Technique

PARTIAL COLPOCLEISIS. The patient is placed in the standard lithotomy position. A Foley catheter is placed into the bladder. If an anti-incontinence procedure is needed, it may be performed first. The cervix is grasped with a tenaculum, and a rectangular segment of vaginal epithelium is marked anteriorly and posteriorly. The excision of the vaginal epithelium will extend 3 cm from the urethral meatus to 3 cm from the cervix (Cespedes et al, 2001).

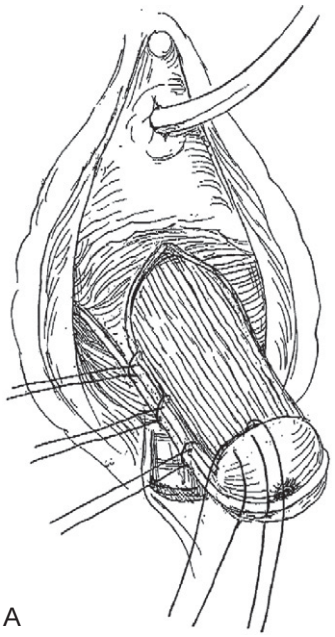
It is important to leave sufficient vaginal epithelium laterally to allow creation of the lateral channels to facilitate drainage. The epithelium is then excised. It is optional to place a 14-Fr red Robinson catheter along the vaginal sidewalls to assist in forming the channels. Then, starting at the leading edge of the prolapse, one places successive layers of 2-0 delayed absorbable sutures, which plicate and reduce the prolapse until the prolapsed tissues are above the levator plate (Fig. 72-38A). The sutures are placed in transverse rows consisting of linear sutures through the pubocervical fascia anteriorly and rectovaginal fascia posteriorly. As these sutures are tied, the apical prolapse is reduced proximally (see Fig. 72-38B). Successive rows of sutures are placed until the apical prolapse is completely reduced. A high perineorrhaphy is performed by removing a triangular segment of the vaginal epithelium. The fibromuscular tissues of the perineal body are approximated in the midline with absorbable sutures to narrow the introitus. The completed procedures are shown in Figure 72–39. Indigo carmine is administered and a cystoscopy is carried out to confirm ureteral patency.

TOTAL COLPOCLEISIS (Fig. 72–40). The technique differs from partial colpocleisis in that the lateral channels are not left in place, but, rather, the entire prolapsed vagina is denuded of its epithelium from the apex to 3 cm proximal to the urethral meatus. The dissection is carried laterally and continued to the posterior lateral sulcus. The prolapse sac is dissected away from the vaginal epithelium. Usually the enterocele reduces easily and no further treatment is necessary (Cespedes et al, 2001). At this point the colpocleisis is carried out starting at the leading edge of the prolapse. Purse-string sutures of 2-0 absorbable sutures are placed circumferentially around the prolapse (see Fig. 72–37A). As each progressive suture is tied, the prolapse is reduced proximally (see Fig. 72-37B). These progressive purse-string sutures are tied until the prolapse is adequately reduced. Alternatively, the prolapse may be reduced as described for the partial colpocleisis by placing transverse rows of interrupted sutures. As these rows are tied the prolapse is reduced proximally. Successive rows of sutures are placed until the prolapse is fully reduced. The remainder of the procedure is performed as described for the partial colpocleisis. After the prolapse is reduced the posterior vaginal wall and perineum are repaired. A high perineorrhaphy is important to narrow the introitus. Cystoscopy to ensure patency of the ureters is recommended. For both techniques, success depends on the amount of vaginal tissue sutured together. This creates a septum of support, which is enhanced by bringing the levator muscles together along with the perineorrhaphy.

Several authors have reported that it is unnecessary to open the enterocele sac if one is present, because the repair will close the potential space in which the bowel might protrude (DeLancey, 1997; Glavind and Kempf, 2005). If the enterocele sac cannot be reduced, then purse-string absorbable sutures incorporating the sac and the uterosacral remnants can be used to reduce the sac (Cespedes et al, 2001).

Results (Table 72–7)

TOTAL COLPOCLEISIS. DeLancey (1997) reported on 33 women who underwent colpocleisis over a 20-year period. In this study, opening of the enterocele sac was avoided. One patient had recurrence of a vaginal eversion and was treated with repeat colpocleisis and had a good response 1 year after the second colpocleisis. All but one patient expressly denied regret over the decision to have an operation that precludes the ability to have intercourse; however, one "accepted" her sexual inactivity. Many indicated relief of the discomfort associated with the prolapse and were positive about the outcome of the operation. Cespedes and



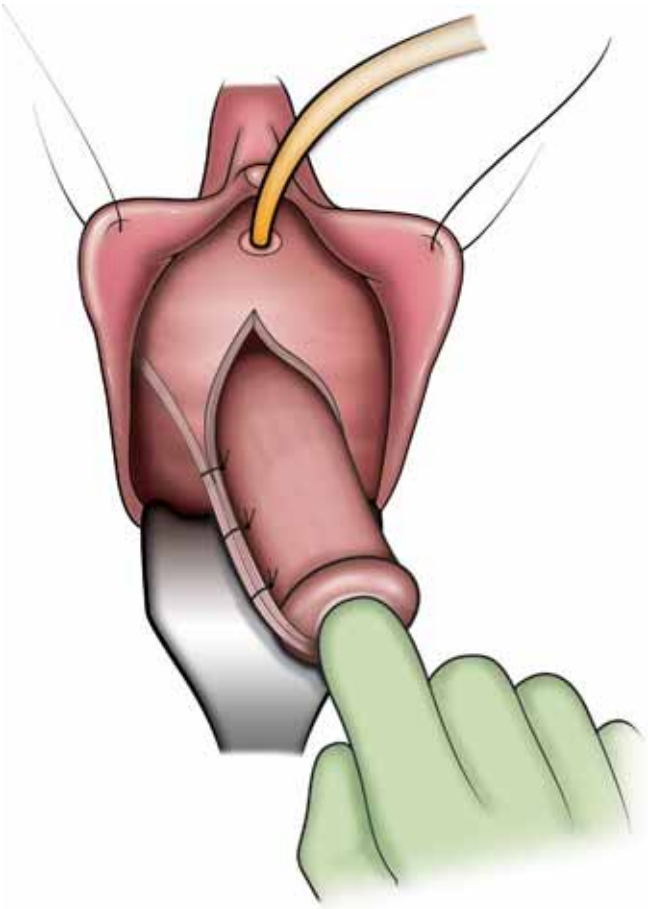


Figure 72–38. **A,** Partial colpocleisis is started by excising rectangular portions of the vaginal epithelium, leaving lateral channels. The cervix is then everted over a red Robinson catheter. **B,** The cervix is everted as the prolapse is reduced. (From Cespedes RD, Winters CW. Colpocleisis for the treatment of severe vaginal vault prolapse. In: Vasavada SP, Appell RA, Sand PK, Raz S, editors. Female urology, urogynecology, and voiding dysfunction. Boca Raton [FL]: Taylor & Francis; 2005, with permission.)

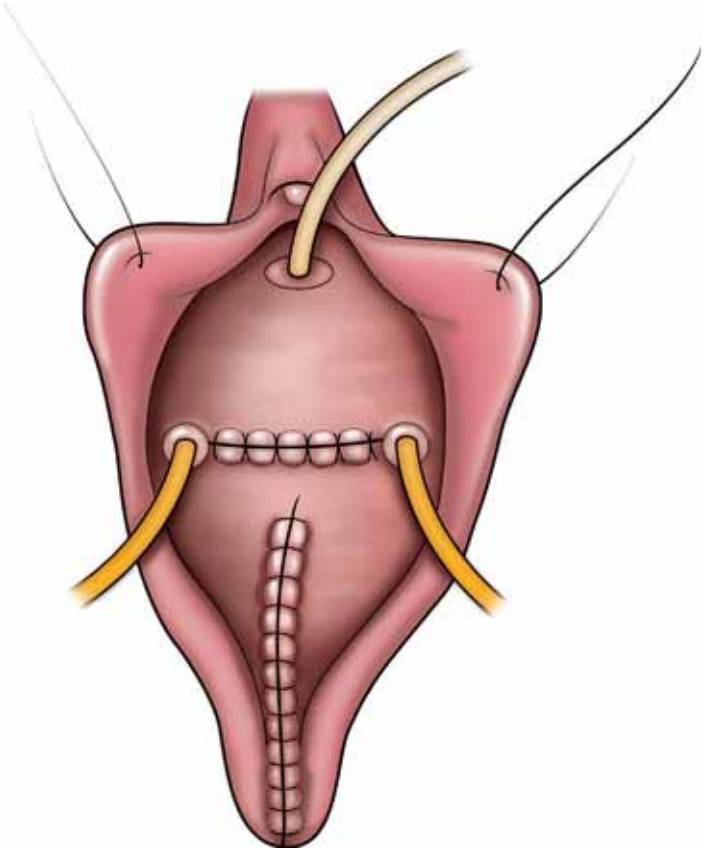

Figure 72–39. The partial colpocleisis is completed along with perineorrhaphy. (From Cespedes RD, Winters CW. Colpocleisis for the treatment of severe vaginal vault prolapse. In: Vasavada SP, Appell RA, Sand PK, Raz S, editors. Female urology, urogynecology, and voiding dysfunction. Boca Raton [FL]: Taylor & Francis; 2005, with permission.)

coworkers (2001) reported on 38 patients who underwent a mean of 24 months follow-up. There was no recurrent prolapse. Three patients who had a Kelly plication for incontinence had mild SUI, and two were treated successfully with collagen. All were satisfied with the procedure, and no complications were noted. von Pechmann and colleagues (2003) reported on a large study (92 patients) who underwent colpocleisis. Patients were followed by examination and telephone survey, which appraised satisfaction and regret. Regret over the loss of coital ability was expressed in 12.9% (eight patients). In a multicenter, prospective study designed to study the effect of colpocleisis on pelvic support, symptoms, quality of life, morbidity, and postoperative satisfaction, FitzGerald and associates (2006) reported on 152 patients with 1-year follow-up. Eighty-four percent stated they were either very satisfied or satisfied about the decision for vaginal closure. One patient was dissatisfied, and one was very dissatisfied. One patient underwent repeat colpocleisis for recurrence. Most patients did not experience worsening of their body image. Hoffman and coworkers (2003) reported favorably on vaginectomy or hysterovaginectomy in which the denuded tissues are brought together with serial purse-string sutures. They preferred this approach because of optimal exposure to the cul-de-sac and the ability to perform multicompartmental repair.

PARTIAL COLPOCLEISIS (see Table 72–7). Goldman and coworkers (1981) reported on 118 patients who underwent Le Fort colpocleisis. Good anatomic results were noted in 107 patients, with 101 reporting relief of symptoms. There were three recurrences but no patient underwent further operative therapy. Immediate postoperative complications were one pulmonary embolism, fever, and urinary tract infection. Langmade and Oliver (1986) reported on 102 patients. There were no recurrences and no de novo stress incontinence. Sixteen patients had transient postoperative urinary retention. No patient changed her mind regarding the ability to engage in sexual intercourse.

Table 72–7.

Results of Partial and Total Colpocleisis

AUTHOR	NO. PATIENTS	FOLLOW-UP (mo)	SUCCESS RATE	METHOD OF EVALUATION	COMPLICATIONS
Total Colpocleisis					
DeLancey, 1997	33	1-18 (examination) 36-88 (phone)	97% anatomic 97% did not regret loss of coital ability	Examination Structured telephone questionnaire	Postoperative pneumonia, UTI, worsening of CHF
Cespedes et al, 2001	38	3-52 mean 24	100%	Examination	None
von Pechmann et al, 2003	92	0-64 (examination) 13-161 (phone)	98% anatomic 90% phone survey	Examination Phone survey	One death (lung cancer) rectal prolapse, transfusion, ureteral occlusion, proctotomy, prolapse recurrence
Hoffman et al, 2003 (vaginectomy)	54	6-56	100%	Examination Phone survey	CVA, pulmonary edema, atrial fibrillation
Harmanli et al, 2003	41	5-65	100%	Examination Phone survey	Vesical injury, late rectal bleeding
Deval, 2005	30	7.7 (1-21 examination) 35 (13-161 phone)	100% anatomic 88% answered very satisfied or satisfied	Examination Phone survey	CHF, PE, UTI, 6.6% de novo stress incontinence
Partial Colpocleisis					
Goldman et al, 1981	118	12-180	91%	Examination	Fever, UTI, thrombophlebitis, PE, wound infection
Langmade and Oliver, 1986	102	35 (12-168)	100%	Examination	Urinary urgency, renal toxic reaction to the tobramycin, fever

CHF, congestive heart failure; CVA, cerebrovascular accident; PE, pulmonary embolism; UTI, urinary tract infection.

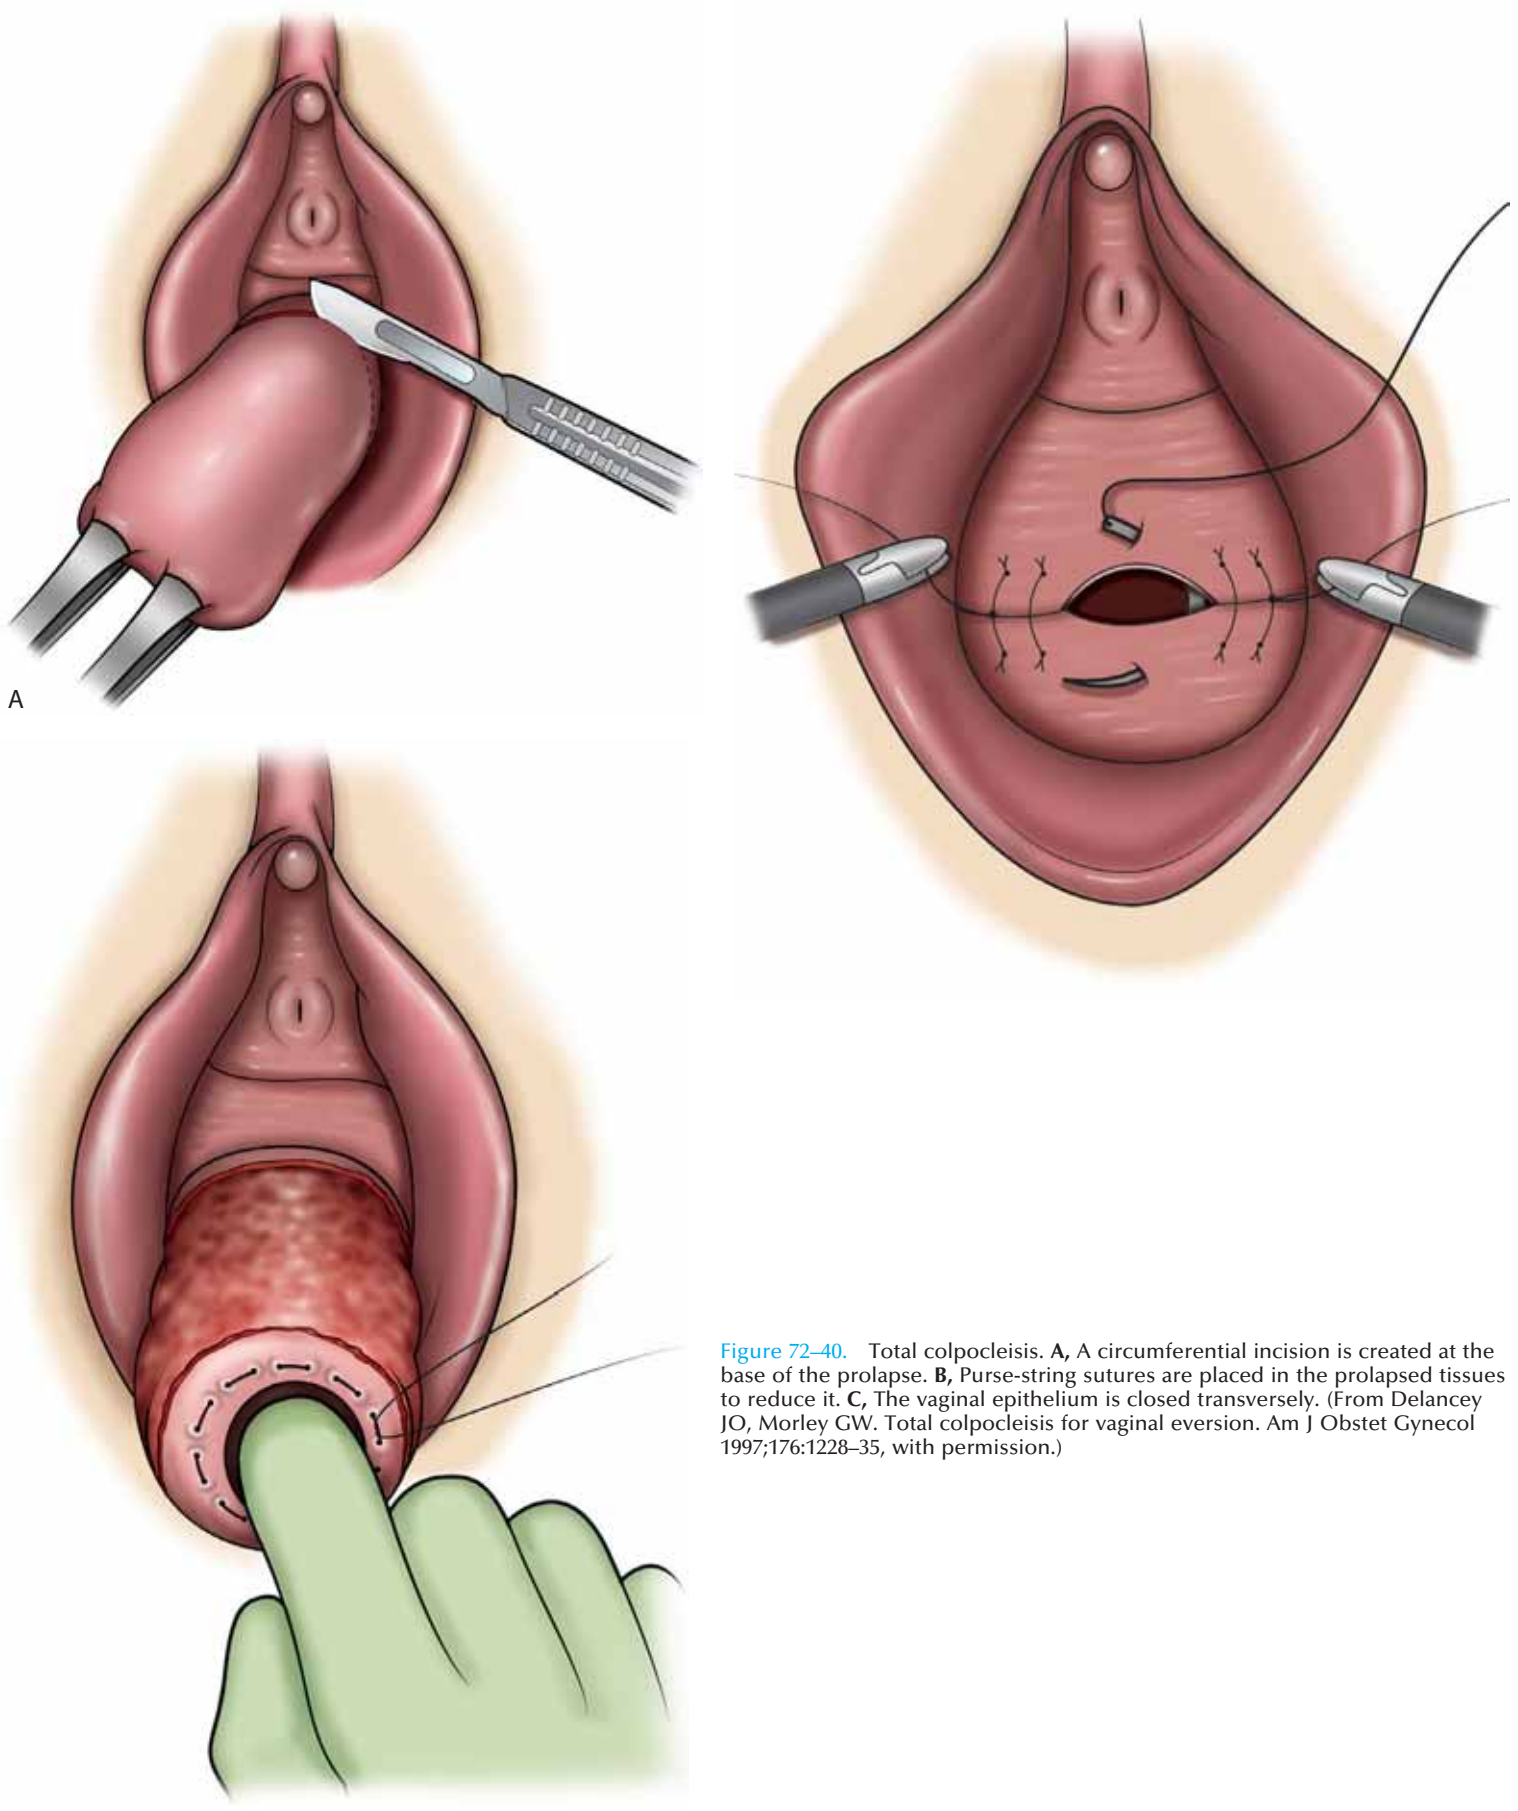

Figure 72–40. Total colpocleisis. **A,** A circumferential incision is created at the base of the prolapse. **B,** Purse-string sutures are placed in the prolapsed tissues to reduce it. **C,** The vaginal epithelium is closed transversely. (From Delancey JO, Morley GW. Total colpocleisis for vaginal eversion. Am J Obstet Gynecol 1997;176:1228–35, with permission.)

Urinary incontinence after colpectomy may occur and has been attributed to several mechanisms. The first, occult stress incontinence, is when correction of the urethral angulation will unmask preexisting stress incontinence. The other is from traction of the urethra when it is approximated with the posterior vaginal muscularis (FitzGerald et al, 2006). Thus it is recommended to modify the procedure so that the distal edge of the colpocleisis is at least 1.5 cm from the urethral meatus (FitzGerald et al, 2006). As with other prolapse cases, the recommendation of a concomitant anti-incontinence procedure in an asymptomatic patient is controversial and remains to be substantiated by prospective studies. **However, it is clear that these women may develop SUI postoperatively. Thus all women before undergoing colpocleisis should be screened for the presence of occult SUI, and anti-incontinence procedures should be done concomitantly in women with symptoms of SUI or occult SUI.** Additionally, in these frail, elderly patients there is a concern of urinary retention, which frequently is the result of impaired contractility and other perioperative factors. This may be more difficult to manage because these patients are more likely to be unable to perform intermittent catheterization. Thus these possibilities must be discussed with the patients in advance of surgery. Patients considered at significant risk for retention should be offered a suprapubic tube to assist in bladder management postoperatively.

Uterine Prolapse

Pelvic organ prolapse was the indication for 16.3% of all hysterectomies performed between 1988 and 1990. Although the majority of hysterectomies are performed transabdominally, the vaginal approach offers the advantages of less invasive surgery and the ability to repair concomitant pelvic floor defects (ACOG, 2009; Eilber et al, 2004).

The uterus is suspended in the pelvis by the cardinal/uterosacral ligament complex. The body of the uterus is enveloped between the two leaves of the broad ligament, which also surrounds the fallopian tube, round ligament, and ovarian ligament along with the uterine and ovarian vessels. The broad ligament does not provide significant support (Eilber et al, 2004). Therefore the defect prompting uterine prolapse is in the form of attenuated ligaments or specific breaks in the continuity of the cardinal/uterosacral ligament complex. Contraindications for the vaginal approach are endometriosis of unknown extent, obliteration of the cul-de-sac, large fibroids (size disproportion to the introitus), pelvic tumor, adnexal tumor, and malignancy of the uterus or ovaries (Eilber et al, 2005).

Transvaginal Hysterectomy

Technique. The patient is placed in the dorsal lithotomy position. A catheter is placed to drain the bladder. Retraction of the labia with a ring retractor and stays is useful. Two Lahey clamps are placed on the cervix. Care must be taken to place it on the most distal portion because the bladder may descend fairly low on the anterior vaginal wall. The incision is made full thickness through the vaginal epithelium around the cervix approximately 1 cm from the cervical os (Fig. 72–41). Because the posterior cul-de-sac is entered first, a U-shaped incision is made initially from the 3-o'clock position to the 6-o'clock position to the 9-o'clock position. The posterior peritoneal fold is exposed (Fig. 72–42). Applying traction to the tenaculum and using a right angle retractor to apply countertraction to the vagina facilitate this exposure. This maneuver will help to identify the correct plane, because the vagina will retract when the correct depth is reached. Once the posterior peritoneal fold is identified, it is opened sharply to enter

Figure 72–41. Circumferential incision through the vaginal epithelium is made at the level of the cervix. (From Rooney CM, Karram MM. Vaginal hysterectomy in the treatment of vaginal prolapse. In Raz S, Rodriguez LV, editors. Female urology. 3rd ed. Philadelphia: Elsevier Saunders; 2008.)

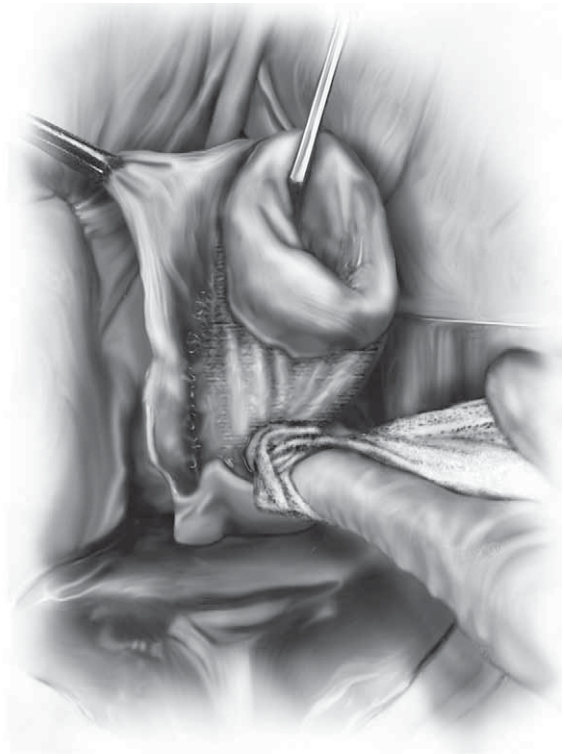

Figure 72–42. The vaginal epithelium is sharply dissected from the cervix revealing the posterior peritoneal fold. (From Rooney CM, Karram MM. Vaginal hysterectomy in the treatment of vaginal prolapse. In: Raz S, Rodriguez LV, editors. Female urology. 3rd ed. Philadelphia: Elsevier Saunders; 2008.)

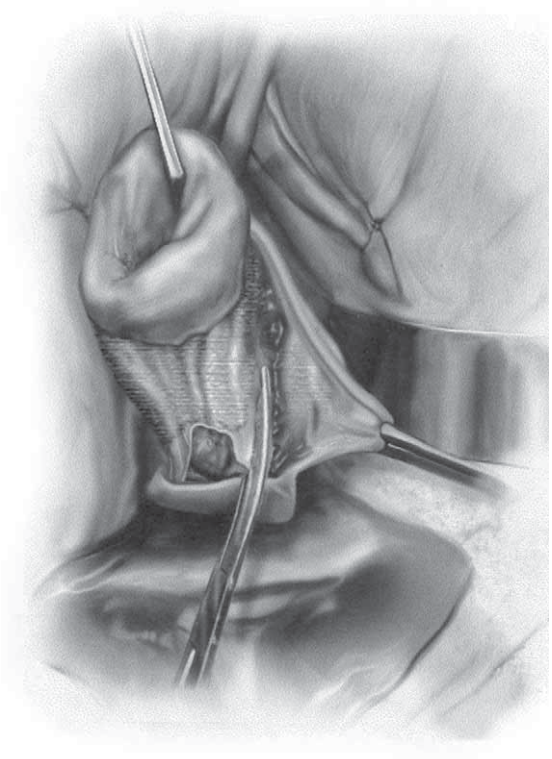

Figure 72–43. Clamping of the uterosacral ligaments. (From Rooney CM, Karram MM. Vaginal hysterectomy in the treatment of vaginal prolapse. In: Raz S, Rodriguez LV. Female urology. 3rd ed. Philadelphia: Elsevier Saunders; 2008.)

the cul-de-sac. Visualization of bowel and omentum will confirm correct entry into the peritoneal cavity. By entering the peritoneal cavity posteriorly, control of the uterosacral ligaments can be attained before the anterior dissection (Fig. 72–43). This prevents potential anterior bleeding from obscuring the posterior portion of the dissection and facilitates mobilization of the uterus when the uterosacral ligaments are divided. Countertraction and use of gauze will aid with separation of the peritoneum off of the posterior aspect of the uterus. Once the cul-de-sac is entered, the uterus and adnexa may be palpated to check for further pathology. A long, weighted vaginal speculum is placed with the beak into the abdominal cavity. The anterior dissection is now started. The circumferential incision is completed anteriorly. It is imperative to keep the dissection close to the uterus by placing the tips of the curved Metzenbaum scissors toward the cervix. The glistening white surface of the uterus confirms the correct plane of dissection. Traction on the cervix with countertraction applied with a right angle (Heaney) retractor will facilitate with the dissection of the vesicouterine space. The peritoneum is identified anteriorly and entered. Visualization of the bowel or omentum will confirm the location in the peritoneal cavity. Once the peritoneum has been entered anteriorly and posteriorly the ureters can be palpated to verify the location. The uterosacral ligament can then be shortened to facilitate suspension into the pelvis to restore the vaginal cuff once the uterus has been removed.

The cardinal and uterosacral ligaments are isolated with a large right-angle clamp and Phaneuf clamp, divided, and then suture ligated with delayed absorbable suture. First, the uterosacral ligament is identified. A small stump of tissue should be left rather than cutting flush with the clamp to facilitate later identification. This is done bilaterally. The pedicles should be tagged with a curved hemostat. The uterus will then descend. The cardinal ligament is then grasped by swinging the clamp laterally, which shortens the pedicle. It is not unusual to have an elongated cervix with prolapse, which will make visualization of the fundus of the uterus challenging. The uterine arteries are cross clamped, suture ligated, and then divided, being careful to leave enough of a stump so that the suture does not slip (Fig. 72–44). Including the peritoneum anteriorly and posteriorly will ensure the complete inclusion of the artery in the clamp. Next comes the broad ligament. If the ovaries and adnexa are to be left, the utero-ovarian ligament, fallopian tube, and round ligaments are visualized from anterior to posterior and are divided and ligated. The broad ligament is then clamped and divided bilaterally. All the pedicles are examined for hemostasis.

Vaginal vault suspension is crucial because the hysterectomy alone will not restore the anatomy of the vaginal vault. Two maneuvers are important to perform. The pubocervical fascia and the rectovaginal fascia are approximated to close the cul-de-sac and a culdoplasty is done. The culdoplasty should be performed first. This is started by placing a suture into the uterosacral ligaments and a suture at the corners of the vaginal cuff. These are not tied down until after the cuff is closed, because doing so will suspend the vaginal vault. Two purse-string sutures of 0 polyglactin are placed to close the cul-de-sac. These sutures will incorporate the pubocervical fascia, rectovaginal septum, cardinal/uterosacral ligament complex, broad ligaments, and perivesical fascia. The sutures are not placed too laterally on the pubocervical fascia because this can cause ureteral injury. The purse-string sutures are tagged and not tied down at this point. The vaginal cuff can then be closed in a continuous locking or interrupted fashion. The sutures from the uterosacral ligaments are brought to the midline, and then the purse-string sutures are tied. The suspension sutures are then tied, thus suspending the vaginal vault and restoring vaginal depth. At this point any other repair is performed, but extending the anterior or posterior incisions to the previously incised vaginal cuff (T colpotomy) should be avoided because this inherently weakens the repair (Fine and DeLancey, 2005). A cystoscopy is then performed before cutting the excess suture material.

Posterior Compartment Repair

Symptoms attributable to posterior compartment prolapse can be divided conceptually as herniation symptoms, defecatory dysfunction, and sexual dysfunction (Cundiff and Fenner, 2004). Herniation symptoms include vaginal bulging and bleeding of the epithelium from excoriation. Defecatory dysfunction includes stool trapping requiring vaginal splinting or manual digitations, defecatory urgency, and constipation. It is important to differentiate between outlet obstruction (including defects in the support of the posterior compartment, perineum, and rectum), motility disorders, and anismus (Cundiff and Fenner, 2004). Anismus is the failure of the puborectalis to relax during defecation. Motility disorders, which usually involve impaired transit of the rectum and anus, are treated with dietary modifications and medication. Anismus responds to biofeedback, and pelvic floor support defects are treated surgically. In combined disorders it is recommended that nonsurgical treatment for anismus or slow transit constipation (the most common disorder of motility) be treated before embarking on surgical intervention. Sexual dysfunction is thought to be secondary to dyspareunia, although decreased desire and

Figure 72–44. The uterine vessels are clamped and the vascular pedicle suture ligated. Care should be taken to leave enough of a stump to prevent the suture from slipping off the pedicle. (From Rooney CM, Karram MM. Vaginal hysterectomy in the treatment of vaginal prolapse. In Raz S, Rodriguez LV. Female urology. 3rd ed. Philadelphia: Elsevier Saunders; 2008.)

anorgasmia may also be contributing factors (Handa et al, 2004). There is conflicting evidence between the correlation both in sexual dysfunction and defecatory dysfunction and the degree of POP (Weber et al, 1998; Ellerkman et al, 2001; Fialkow et al, 2002; Jelovsek et al, 2005; Bradley et al, 2006).

Several authors have sought to identify patient factors that would predict who might benefit most from rectocele repair (Murthy et al, 1996; Watson et al, 1996). These include sensation of vaginal mass or bulge, need for digitalization to complete rectal evacuation, nonemptying or partial emptying on defecography, and presence of a large rectocele. Sensation of incomplete emptying and constipation are not specific to rectoceles and may be associated with other disorders, including irritable rectum and slow transit constipation. **Patients should be counseled that surgery may reduce the vaginal protrusion and decrease or eliminate the need for vaginal splinting; however, some patients may have persistence of constipation because motility disorders and anismus can coexist with prolapse.**

Rectoceles can be approached transanally or transvaginally. Nieminen and coworkers (2004) randomized 30 patients to rectovaginal fascia plication or transanal repair. Both approaches resulted in a high rate of symptom resolution (93% for the vaginal approach vs. 73% for the transanal approach). However, the vaginal approach had better objective findings and a lower rate of prolapse recurrence (7% vs. 66%). The traditional posterior colporrhaphy was devised in the 19th century to treat perineal tears, which occurred during vaginal delivery. The original description involved plicating the pubococcygeus muscles and the posterior vaginal wall and reconstruction of the perineal body, which was termed *posterior colpoperineorrhaphy* (Cundiff and Fenner, 2004). This creates a rigid inferior shelf, which reduced the herniation of the posterior wall and prevented descensus of the vaginal vault or uterus. In 1961, Francis and Jeffcoate (1961) reported a high incidence of dyspareunia after colporrhaphy with levator plication. In their series of 243 women, 50% developed postoperative dyspareunia. In addition, there is evidence to suggest that the traditional posterior colporrhaphy with levator plication may worsen defecatory symptoms. Khan and Stanton (1997) reported increased symptoms of fecal incontinence, constipation, incomplete evacuation, and dyspareunia postoperatively. **Because of the increase in dyspareunia postoperatively, plication of the levator ani muscles has largely been abandoned. Site-specific repairs and midline fascial plication without levator ani plication have emerged as the predominant surgical treatments of rectocele.**

Posterior Colporrhaphy

Technique (Fig. 72–45). The patient is placed in the dorsal lithotomy position. If a patient requires an anterior or middle compartment repair, it is performed first (Rovner and Ginsberg, 2001). The anterior wall can be retracted with a Heaney retractor to improve visualization. Hydrodissection may be accomplished by injecting saline or a local anesthetic. A midline incision is made on the posterior vaginal epithelium. For a high rectocele the incision may be as high as the vaginal vault; for smaller rectoceles the incision is started at the most caudal position. The rectovaginal fascia is separated from the vaginal epithelium with Metzenbaum scissors. The tips of the scissors should be pointed toward the vagina to avoid rectal injury. The dissection proceeds laterally until the pararectal attachments to the pelvic sidewall are visualized. In cases of large posterior defects, a purse-string suture of 2-0 or 3-0 absorbable suture may be placed at the base of the rectal herniation to reduce it. Additionally, this acts to bring the attenuated rectovaginal tissue together to aid in its reapproximation. The rectovaginal tissue is then plicated in the midline with either interrupted or continuous 2-0 absorbable suture. Care is taken to avoid excessively lateral placement of these sutures, because this may result in a painful "ridge" along the posterior vaginal wall. This is extended distally and incorporated into a perineal body reapproximation. The excess vaginal epithelium is trimmed, and the vaginal epithelium is closed with an absorbable suture. A perineorrhaphy may also be performed before the vaginal epithelium is closed.

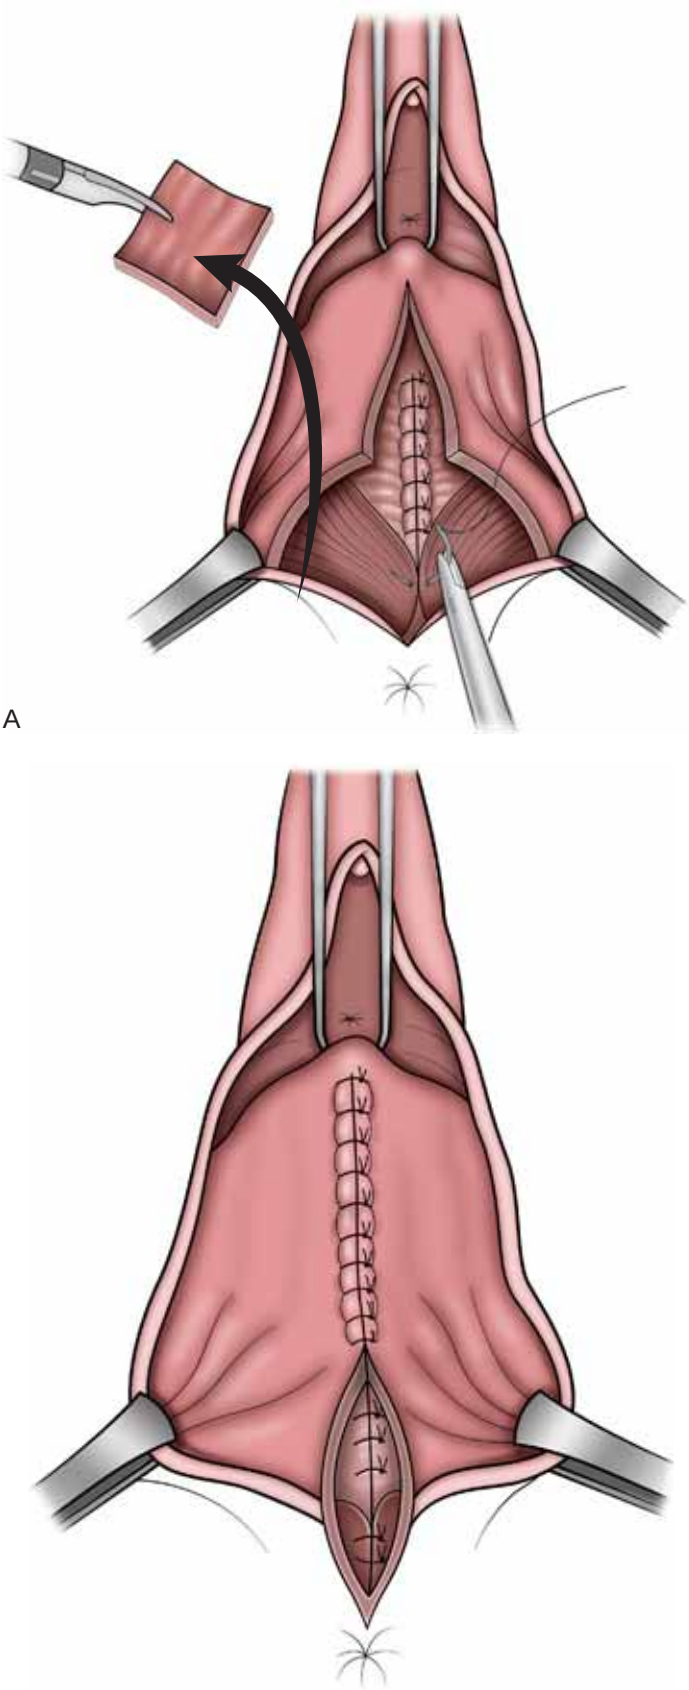

Figure 72–45. **A** and **B,** Technique of posterior colporrhaphy with rectovaginal tissue plication. From Ginsberg D. Treatment of vaginal wall prolapse. In: Goldman H, Vasabada S, editors. Female urology: a practical clinical guide. Totowa [NJ]: Humana Press; 2007. p. 281–96, with permission.)

SITE-SPECIFIC REPAIR. To minimize complications associated with posterior colporrhaphy, a site-specific defect repair was described. Richardson (1993) described discrete defects in the rectovaginal fascia found in both patients undergoing posterior colporrhaphy and cadaveric dissections. He found that the most common defect was the transverse configuration, separating the vaginal septum from the perineal body (Fig. 72–46). This essentially results in a separation of the rectovaginal tissues from the perineal body. The goal of the site-specific repair is to restore the anatomy by closing these discrete defects.

A midline incision is made on the posterior vaginal epithelium. For a high rectocele the incision may be as high as the vaginal vault; for smaller rectoceles the incision is started at the most caudal position. The rectovaginal fascia is separated through a virtually bloodless plane from the vaginal epithelium. The index finger of the nondominant hand is then inserted into the rectum to facilitate identification of the fascial defect. The defect is closed with absorbable interrupted sutures. The excess vaginal epithelium is trimmed, and the vaginal epithelium is closed with interrupted sutures.

PERINEORRHAPHY. A triangular incision at the mucocutaneous junction is removed (Rovner and Ginsberg, 2001). The triangular island of posterior vaginal wall is sharply removed from the pre-rectal levator fascia. Horizontal mattress sutures are used to approximate the attenuated perineal body fibromuscular tissue. Once these are brought together, the muscles of the urogenital diaphragm are reconstituted and support is restored to the central tendon. It is important that a smooth contour be created along the suture line, because ridges may cause dyspareunia. A vaginal packing soaked with the antibiotic solution or metronidazole gel is then placed.

Results (Table 72–8). Khan and Stanton (1997) reported on the anatomic and functional results of posterior repair utilizing levator plication. Both reported anatomic success; however, many patients complained of bowel symptoms and dyspareunia postoperatively. Because of these adverse events associated with levator plication, this technique has been largely abandoned.

Paraiso and associates (2006) randomized patients prospectively to posterior colporrhaphy (rectovaginal fascial plication), site-specific repair, or site-specific repair with porcine small intestinal submucosa graft. They found that posterior colporrhaphy and site-specific rectocele repair had similar functional and anatomic outcomes. The addition of the porcine-derived graft did not improve anatomic outcomes. Rates of dyspareunia did not differ when comparing all three groups. In a follow-up study of these same patients specifically looking at bowel symptoms, Gustilo-Ashby and coworkers (2007) found that anatomic cure was associated with a reduced risk of postoperative straining and sensation of incomplete bowel evacuation but not with other bowel symptoms. They found that bowel symptoms, including feeling of incomplete emptying, straining to defecate, splinting to defecate, and fecal incontinence improved significantly after rectocele repair. Abramov and associates (2005) retrospectively studied patients with advanced posterior vaginal prolapse and compared patients who underwent posterior repair to those who had site-specific repair. They found that the recurrence of posterior defects was higher in the site-specific group compared with the midline plication of the rectovaginal fascia (33% vs. 14% for second-degree repair and 11% vs. 4% for third-degree repair). In addition, recurrence of symptomatic rectocele was greater in the site-specific group (11% vs. 4%). Rates of de novo dyspareunia and postoperative bowel symptoms were the same in both groups. Maher and colleagues (2004) prospectively studied the efficacy of posterior

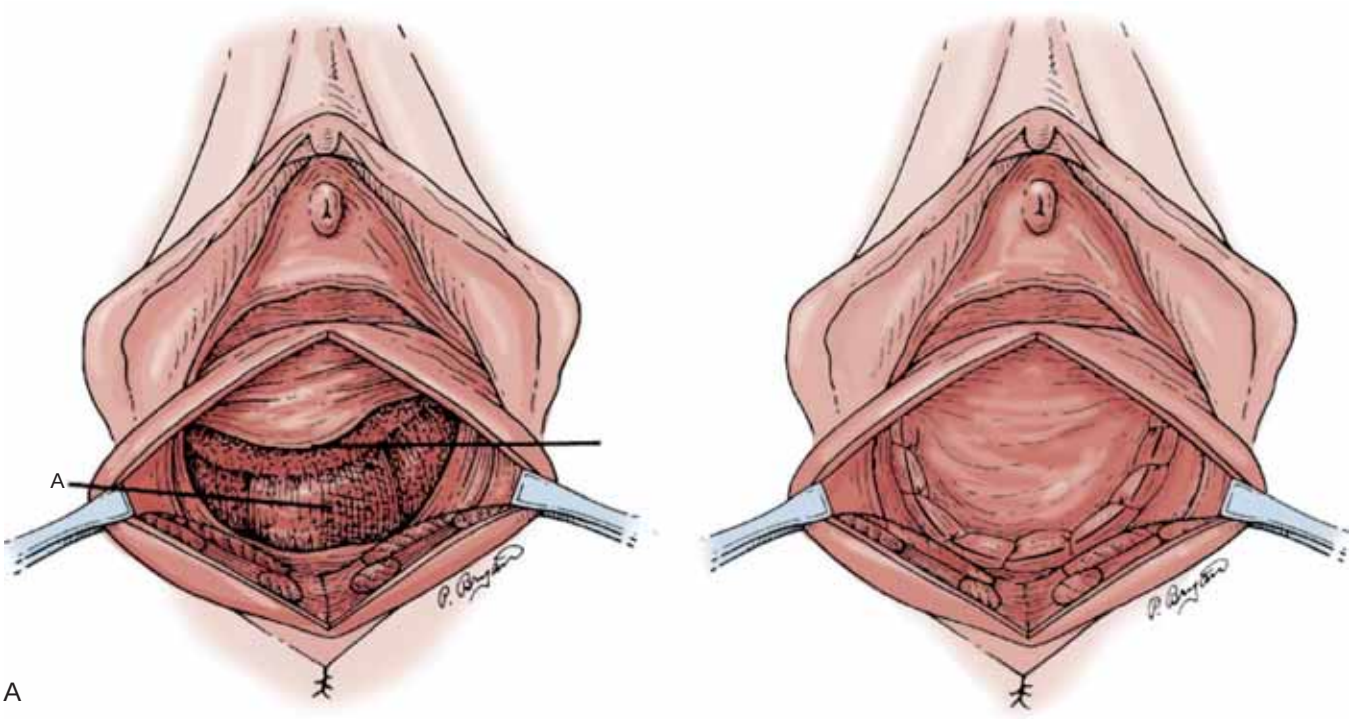

Figure 72–46. Site-specific rectocele repair. A low transverse defect is identified and repaired primarily. (From Richardson AC. The rectovaginal septum revisited: its relationship to rectocele and its importance in rectocele repair. Clin Obstet Gynecol 1993;36:976–83.)

POP-Q, Pelvic Organ Prolapse Quantification System; UTI, urinary tract infection.

repair with plication of the rectovaginal fascia and found that improved anatomic outcome correlated with improved functional outcomes. Eighty-seven percent of patients no longer experienced obstructed defecation postoperatively. Significant improvements were seen in awareness of prolapse, obstructed defecation, straining to defecate, hard stools, dyspareunia, and digitations. Dyspareunia decreased from 37% to 5%. Singh and associates (2003) reported a prospective study of 42 women evaluated for bowel, sexual, urinary, and prolapse symptoms as well as anatomic outcomes after fascial plication technique. At 6-week follow-up, 87% noted an improvement of bowel symptoms. At 18 months they estimated the relief of vaginal symptoms to be between 73% and 92%. Sixty-five percent had improvement of the defecatory symptoms and 38% had improvement of sexual discomfort. None of the patients reported de novo dyspareunia or bowel symptoms.

In contrast to the generalized repair of midline plication of the rectovaginal fascia, several authors have reported their experience with site-specific repair. Glavind and Madsen (2000) prospectively studied 67 patients who underwent a discrete repair. Of the 67 patients, 64 were found to have a discrete defect, which was repaired; and in 3 there was an attenuation of the tissue. At 3-month follow-up, 85% of those who reported bowel symptoms preoperatively reported resolution of symptoms. Two patients (3%) had de novo dyspareunia. Porter and colleagues (1999) examined anatomic, functional, and quality of life aspects of posterior colporrhaphy in a retrospective study. Improvement or cure was noted for pain or pressure, vaginal mass, splinting, and difficulty with defecation. Constipation did not significantly change. Preoperative dyspareunia improved in 73% patients, worsened in 19%, and occurred de novo in three patients. Emotional health improved, specifically thoughts of embarrassment and frustration. Kenton and coworkers (2007) reported on 66 patients who underwent site-specific repair; all patients had reattachment of the rectovaginal septum to the perineal body. Statistically significant symptom relief was noted in protrusion, manual evacuation, difficult defecation, and dyspareunia. Constipation was unchanged. Three patients developed de novo dyspareunia, and one had de novo constipation. At 1 year, 7 of 11 patients who used manual evacuation preoperatively returned to doing so. The authors commented that this may be due to a functional decompensation of the rectum that is not corrected surgically. Finally, Cundiff and colleagues (1998) reported on the anatomic and functional aspects of discrete fascial defect repair of the posterior compartment. At 12-month follow-up, 86% were noted to have stage 1 or less. Splinting was eliminated in 63% of patients who reported this symptom preoperatively. The mean satisfaction score was 8.6 (10 highest). **The mean improvement did not correlate to the anatomic correction but did correlate with alleviation of defecatory symptoms, stressing the importance of symptom relief being of priority to the patient over anatomic correction.**

Interposition Graft Repairs of the Posterior Compartment (Table 72–9)

Both synthetic mesh and biologic grafts have been used in posterior repairs, although data are lacking regarding routine use. Also, several authors caution against the use of synthetic materials in the posterior compartment, owing to the potential for dyspareunia and visceral erosion, and favor using biologic grafts (Chen et al, 2007). Kohli and Miklos (2003) reported anatomic outcomes on 43 patients who underwent a site-specific repair with cadaveric dermis: 30 were available for evaluation at an average of 12.9 months. The graft was fixed proximally to the vaginal apex, laterally to the levator ani muscles, and distally to the perineal body. They reported a 93% success rate using the POP-Q system. Kobashi and associates (2005) reported using cadaveric fascia lata in 73 patients. With a mean follow-up of 13.7 months, there was an 83% to 89% improvement in symptoms. Ninety percent of those examined had a grade 0 rectocele by the Baden-Walker classification. Dell and O'Kelley (2005) used Pelvisoft, a fenestrated, porcine dermal acellular matrix, and reported no wound complications. Despite these encouraging results, Altman and associates (2005) reported on 29 patients using collagen mesh for symptomatic rectocele. Twenty-three were available at 3-year follow up: 41% had recurrence of stage 2 or greater, and 12 of 23 patients reported incomplete rectal evacuation. They advocated further study before recommending the routine use of graft-augmented tissue repair.

A number of authors are utilizing permanent mesh materials via a posterior approach. By using permanent materials, multicompartmental repairs are more commonly performed extending from the sacrospinous ligament to the perineal body. de Tayrac and associates (2006) reported on 26 patients with 2-year follow up. Objective and subjective cure rates of 92.3% and 88%, respectively, were observed. Dwyer and O'Reilly (2004) used a technique attaching Atrium mesh to the sacrospinous ligament bilaterally to the perineal body. Fifty patients underwent posterior repair, 17 of whom had both anterior and posterior repair. No rectocele recurrence was seen at 13 months. Lim and associates (2005) reported using a composite polyglactin/polypropylene mesh (Vypro II, Ethicon, Somerville, NJ). In a descriptive study, 90 patients underwent interposition graft placement with no primary repair. Mesh was placed loosely. Success was noted in 27 of 31 (84%) at minimum 6-month follow-up. The 5 patients with recurrence of the rectocele did not have prolapse in other compartments. Mercer-Jones and coworkers (2004) reported 22 patients who underwent transperineal placement of either polyglactin/polypropylene or just polypropylene mesh: 77% reported moderate, good, or excellent results after mesh repair.

In the posterior compartment, graft extrusion rates of 1.3% to 12% have been reported (Kobashi et al, 2005; Lim et al, 2005; de Tayrac et al, 2006, 2007). Dyspareunia has also been reported with rates as high as 60% when using mesh posteriorly (Milani et al, 2005).

Vaginal Kits

There has been a rapid expansion of the use of vaginal kits in the treatment of pelvic organ prolapse. With the popularity of the transobturator approach of the midurethral sling it was not long before techniques involving the blind passage of trocars to the level of the sacrospinous ligament via the paravaginal space were developed. Although some have been marketed as single-compartment repairs, in actuality the presence of the mesh at the level of the vaginal apex with fixation turns a single-compartment repair into a multicompartmental repair, thus making comparisons to traditional prolapse repairs challenging. Lo and Wang (1998) reported on their results of abdominal sacrocolpopexy versus sacrospinous ligament fixation at a duration of 2.1 years. Success was noted in 94.2% of patients after abdominal sacrocolpopexy compared with 80% success after the sacrospinous ligament fixation.

Transvaginal Kits

Tension-free vaginal kits have been introduced to provide a graft augmented durable repair. The proposed advantages of kits are

Table 72–9.

"less invasive," standardization of technique, standardization of mesh, and the ability to repair multiple compartments through a vaginal approach. Currently, there are a number of vaginal prolapse repair kits on the market (Table 72–10), with Prolift (Ethicon, Johnson and Johnson, Somerville, NJ) and Apogee/Perigee (American Medical Systems, Minnetonka, MN) being most commonly utilized. Short-term cure rates of approximately 90% have been reported in several series (de Tayrac et al, 2007; Fatton et al, 2007; Gauruder-Burmester et al, 2007). These transvaginal kit procedures have gained widespread acceptance in light of little controlled, quality data that strongly support their use. Implanting surgeons must realize that these procedures are utilizing a significantly higher volume of mesh than conventional midurethral slings and that the trocars are passed deeply into the pelvic musculature. The potential for organ injury and hemorrhage are greater with these procedures. In addition, functional implications regarding these mesh procedures remain largely unknown. **Thus, pelvic surgeons must make an informed decision with the patient, which weighs the apparent advantage in anatomic efficacy, decreased invasiveness, and potential durability against the potential morbidity associated with mesh erosion and the possibility of more significant complications unique to these procedures.**

Technique. The anterior prolapse repair follows many of the same basic steps for all of the kit procedures. A midline incision is created in the anterior vaginal wall. Hydrodissection may facilitate a deep, full-thickness vaginal dissection. The full-thickness dissection is important to minimize the occurrence of vaginal exposure of mesh. The dissection progresses laterally to the level of the endopelvic fascia, which is entered by sharp or blunt dissection. The pelvic sidewalls are developed until the ischial spines and the ATFP are palpated. Stab incisions are made overlying the obturator foramen. The distal incisions are placed in the anteromedial edge of the obturator foramen at the level of the clitoris, and the proximal incisions are placed 2 cm below and 1 cm lateral to the distal incision. The trocars are utilized to position the arms of the mesh patch along the ATFP. The distal trocars are placed approximately 2 cm from the distal aspect of the pubic bone, and the proximal trocars are advanced along the ATFP, exiting 1 cm distal to the ischial spine. The proximal trocars in the Perigee system are different than the distal needles, which facilitate a deep passage of the proximal devices to the ischial spine. The mesh arms are utilized to position the mesh appropriately without tension. Sutures are used to fix the mesh both proximally at the level of the vaginal cuff (preferably with delayed absorbable or permanent sutures) and distally proximal to the bladder neck with

Table 72–10.

absorbable sutures. Prior to mesh placement, anterior colporrhaphy may be performed to correct a central defect if present. Cystoscopy is performed to confirm lower urinary tract integrity. Care is taken to confirm the absence of excessive tension on each of the mesh arms (Fig. 72–47). The vagina is then closed without trimming the vaginal wall to minimize the occurrence of vaginal mesh extrusion. A loosely interrupted vertical mattress closure may be used to create a virtual two-layer closure of the vaginal epithelium.

The posterior and apical approach to kit placement does vary between kit devices. The Prolift device utilizes proximal attachment through the sacrospinous ligament, whereas the Apogee device is fixed proximally 1 cm distal to the ischial spine. For all procedures, the dissection begins with a posterior vaginal incision, which is full thickness. The dissection proceeds laterally and proximally to expose the ischial spine (Apogee) and the sacrospinous ligament (Prolift). Two stab incisions are made 3 cm lateral and below the anus. With the surgeon's hand in the vagina retracting the rectum, the trocars are advanced through the ischiorectal fossa. The Prolift is brought through the sacrospinous ligament 3 cm medial to the ischial spine. The Apogee trocars exit 1 cm distal to the ischial spine. The mesh is trimmed so that it does not extend to within 1 cm of the perineal body. This avoids mesh complications in the perineum. The mesh is fixed laterally with absorbable sutures. The mesh is fixed with permanent or delayed absorbable suture proximally to the vaginal apex or posterior lip of the cervix. As with the anterior compartment, no trimming of the epithelium is recommended and closure is completed with absorbable suture.

There are new kits, which do not utilize trocars for mesh placement. The Pinnacle device (Boston Scientific, Nantucket, MA) uses a Capio Needle Driver System to pass the arms of the mesh through the sacrospinous ligament proximally and the ATFP and obturator internus fascia distally to provide anterior support. The mesh may also be deployed posteriorly using the Capio device as well. The Elevate (American Medical Systems, Minnetonka, MN) has a unique "tacking" device, which anchors the graft in the sacrospinous ligament as well as ATFP. There is a special tool that facilitates adjustment of mesh tension after the tacking mechanism is deployed. Both of these devices have not been in use very long and there are little meaningful data at this time.

Results. When evaluating the results of the vaginal kit procedures in the treatment of prolapse there are a paucity of peer review data to guide most appropriate usage. Much of the literature regarding kits include preliminary data in abstract form. The multicenter preliminary results of Prolift have been published by Fatton and associates (2007): 110 patients were observed for 3 months, and a 94.3% success rate was reported. Gauruder-Burmester and colleagues (2007) reported on a retrospective analysis of 121 women utilizing Apogee/Perigee. Success rates of 93% were achieved. Sanses and colleagues (2009) compared the outcomes of Prolift, uterosacral ligament suspension and abdominal sacrocolpopexy for the treatment of apical prolapse. Prolift, uterosacral ligament suspension, and abdominal sacrocolpopexy were performed for 206, 231, and 305 subjects, respectively. There was no difference in apical success after Prolift (98.8%) compared with uterosacral ligament suspension (99.1%) or abdominal sacrocolpopexy (99.3%) (both $P = 1.00$) 3 to 6 months after surgery. The average elevation of the vaginal apex was lower after Prolift

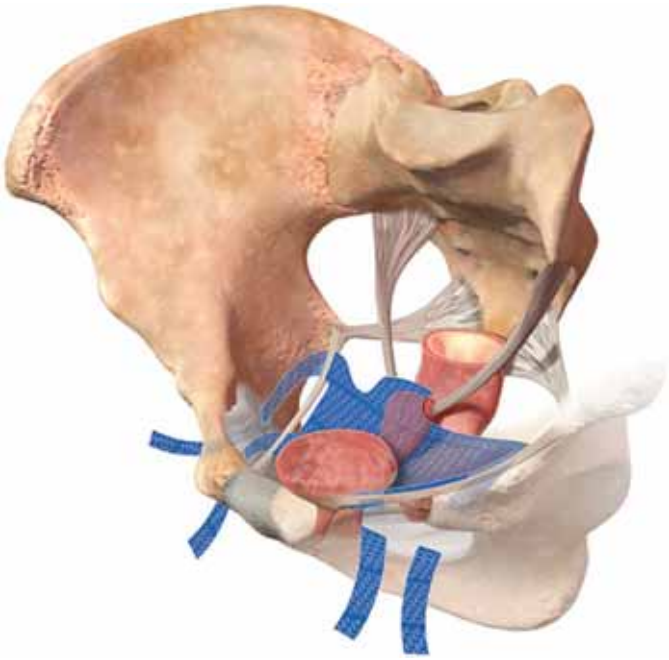

Figure 72–47. Transvaginal kit. Total Prolift device in place. (Courtesy of Ethicon, Inc.)

(–6.9 cm) than uterosacral ligament suspension (–8.05 cm) and abdominal sacrocolpopexy (–8.5 cm) (both $P < .001$) (Sanses et al, 2009). Feiner and associates (2009) performed a meta-analysis of the peer-reviewed literature and select peer-reviewed gynecologic abstracts to evaluate outcomes and complications after transvaginal synthetic apical suspension procedures. After the Apogee procedure, 525 women had a mean follow-up of 26 weeks (range 10 to 56 weeks). Mean objective success was 95% (range 81 to100). In the same meta-analysis, a posterior or total Prolift procedure was performed in 1295 women with mean follow-up time of 30 weeks (range 12 to 52 weeks), and the mean objective success rate was 87% (range 75% to 94%). Although these early data demonstrate successful outcomes, it is important to note that serious complications, some unique to these procedures, are being reported. These concerns have prompted comments regarding new procedures and materials for the treatment of incontinence and prolapse, warning that there are insufficient data supporting the routine use of these devices (Ostergaard, 2007). In light of this, it is incumbent on physicians to openly discuss these issues with patients.

Complications. Mesh complications are most commonly in the form of mesh exposure or "extrusion." Extrusion rates of approximately 10% can be expected (Gauruder-Burmester et al, 2007; Feiner et al, 2009). The exposures seem to occur more frequently on the anterior wall, and a concomitant hysterectomy significantly increases the risk (de Tayrac et al, 2007; Gauruder-Burmester et al, 2007). **Measures to minimize the occurrence of vaginal mesh exposure are minimizing excessive vaginal wall trimming and closing without tension. Some advocate closing with a vertical mattress technique to separate the graft from the wound** (de Tayrac et al, 2006). Symptoms of mesh extrusion include vaginal discharge, persistent bleeding, pain, dyspareunia, partner pain, dysuria, and recurrent urinary tract infections. Examination by palpation as well as visualization is important to detect this complication. While some patients can be managed with either observation or local treatment, many will require excision with primary vaginal closure (de Tayrac et al, 2006). Infected vaginal mesh can lead to sinus formation, abscess, and enterovaginal fistula formation. One case of necrotizing fasciitis with *Staphylococcus aureus* requiring extensive perineal debridement and colostomy has been reported after a kit procedure (Abdel-Fattah et al, 2008). Persistent groin pain has been reported after transobturator grafts and may signify an erosion or abscess of a transobturator graft (Mahajan et al, 2005; Rafii et al, 2006).

Unfortunately, significant lower urinary tract erosion into the bladder or urethra have also been reported, with significant consequences (Yamada et al, 2006). Altman and Falconer (2007) found the overall risk of serious complications of the Prolift procedure is 4.4%. The majority of serious complications were visceral perforations. Including transvaginal kits systems, the incidences of visceral (including urethra) injuries have been reported from 2.7% to 4.4% (Altman and Falconer, 2007; de Tayrac et al, 2007). The rates of bladder perforation vary between 0.9% and 2.8% (Altman and Falconer, 2007; de Tayrac et al, 2007; Fatton et al, 2007). Bladder perforation after retropubic midurethral slings is not uncommon and appears to be a benign event in the presence of adequate bladder drainage (Kuuva and Nilsson, 2002). The fate of bladder injury at the time of mesh prolapse repairs is much less certain. Two studies have reported on placement of mesh with single, small, uncomplicated bladder injuries (Fatton et al, 2007; Popovic et al, 2007). **If the bladder is injured, it is the opinion of the authors that the procedure should be completed without a mesh interposition of the anterior compartment, because placing mesh in the setting of a bladder laceration would prohibitively increase the risk of erosion.** Extensive erosions into the bladder requiring partial cystectomy have been reported (Abdel-Fattah et al, 2008). With urethral injury, the defect should be repaired primarily, and, again, mesh/graft placement should not be done.

Rectal perforation is reported in 0.7% to 2.8% of cases (Altman and Falconer, 2007; de Tayrac et al, 2007). If rectal injury is recognized intraoperatively, synthetic mesh should not be placed (Mercer-Jones et al, 2004; de Tayrac et al, 2006). Rectal erosion of synthetic mesh may require both rectal and vaginal excision (Hurtado et al, 2007). From these outcomes it is clear that **if the rectum is perforated a multilayer closure should be performed, povidone-iodine distention of the rectum should follow to ensure the integrity of the repair, and the procedure should be abandoned.**

The trocars are passed through the pelvic muscular complex both for anterior and posterior kit repairs. The trocars pass near the ischial spine, and significant intraoperative bleeding may occur. This would usually emanate from the pudendal neurovascular bundle, and embolization of the source of bleeding has been reported (Mokrzycki and Hampton, 2007). Also multiple authors have reported pelvic hematomas after transvaginal kit procedures (Ignjatovic and Stosic, 2007; LaSala and Schimpf, 2007; Abdel-Fattah et al, 2008). Abdel-Fattah and colleagues described vascular complications after Prolift and Apogee/Perigee procedures, including arterial injury requiring embolization. Perhaps blind passage of the trocars through the levator musculature poses a risk for these hemorrhagic complications. Hematomas have also been reported after these procedures (Ignjatovic and Stosic, 2007). Commonly, patients will present with unusually more pelvic pain than typically encountered. Computed tomography is an excellent method to detect hematomas. Thus, if excessive postoperative pain occurs after the procedure, one should consider an evaluation with computed tomography to detect a hematoma. If a hematoma is present, observation with serial hematocrit levels is the appropriate initial evaluation; however, surgical drainage may be required for expanding hematomas, decreasing hematocrits, refractory pain, or infection.

Local complications such as pelvic pain, defecatory pain, and dyspareunia have been reported after kit procedures (Altman and Falconer, 2007; de Tayrac et al, 2007). When examining these patients, one must carefully look for areas of impaired healing, banding or tenting of the mesh, "trigger points" that elicit pain, and signs of focal inflammation. If these abnormal areas are identified, release of the arms or site of mesh tension may alleviate these areas of discomfort. When performing the mesh release, one should excise as much offending mesh material as possible before vaginal closure. In cases of infection, granulomas, or persistent draining sinuses, all mesh involved in the infected areas must be removed. If no local incriminating factors are found, a period of conservative therapy consisting of physical therapy, trigger point injections, and other adjunctive techniques should be attempted first.

U.S. Food and Drug Administration Public Health Notification

A public health notification is an important message from the FDA for devices and radiologic health to the health care community (Schultz, 2008). This message describes a risk associated with the use of a medical device and provides recommendations to avoid or reduce the risk. In October 2008 the FDA released a public

health statement that "Serious Complications are Associated with Transvaginal Placement of Surgical Mesh in Repair of Pelvic Organ Prolapse and Stress Urinary Incontinence." This report was designed to alert health care practitioners of complications associated with transvaginal placement of surgical mesh to treat POP and SUI. This report cited that over 3 years the FDA received more than 1000 reports from nine surgical mesh manufacturers of complications that were associated with surgical mesh devices used to repair POP and SUI. These potential complications are outlined previously and in some cases lead to a significant decrease in quality of life due to discomfort and pain, including dyspareunia. As a result, a number of recommendations were made to physicians that include obtaining specialized training for each mesh placement technique and to inform patients that implantation of surgical mesh is permanent. As a result, some complications associated with the implanted mesh may require additional surgery that may or may not correct the complication. In addition it is recommended to inform patients about the potential for serious complications and their adverse effect on quality of life. Also, it is recommended that the physicians provide patients with a written copy of the patient labeling from the surgical mesh manufacturer, if available.

The impact of these recommendations or the evidence that these recommendations will improve outcomes is unknown. However, it is important for pelvic surgeons to be aware of the growing concerns regarding the potential for serious complications associated with the use of these materials. Patients must be informed of the indications for and benefits and risks of mesh placement before any surgical intervention, and surgeons must remain vigilant in assessing their own outcomes. It is only through well-designed and sufficiently powered randomized controlled trials that these questions will be answered.

Slings: Autologous, Biologic, Synthetic, and Midurethral

Roger R. Dmochowski, MD, FACS • Priya Padmanabhan, MD, MPH • Harriette Miles Scarpero, MD

Pubovaginal Slings

Midurethral Slings

Urethral slings are currently the procedure of choice for the surgical correction of female stress urinary incontinence (SUI). A variety of materials (autologous, allograft, and synthetic) and techniques have been pursued for sling placement. The concept of slings for urethral support was first introduced in 1907 by Von Giordano as a gracilis muscle graft wrapping around the urethra (Blaivas, 1994). German surgeons were using slings fashioned from muscle and fascia for slings in children at the turn of the century (Goebell, 1910). The rectus abdominis muscle and fascia were first used by Frangenheim in 1914 and then adapted by Millin for use in recurrent SUI (Frangenheim, 1914; Millin, 1948). It was Aldridge who first understood the abdominal relationship between muscles and urethra and showed that an increase in abdominal pressure caused simultaneous compression of the urethra. He used rectus fascial slings in conjunction with vaginal plastic operations (Aldridge, 1942). Jeffcoate (1953) used the Aldridge technique on 40 women and reported an 86% cure rate. It was **McGuire's use of the pubovaginal sling** (PVS) in patients who failed prior retropubic suspension and anterior colporrhaphy, with a cure rate of 91% that reintroduced this procedure (McGuire, 1978). **This is the modern description of the PVS, with placement at the bladder neck, in an effort to correct urethral hypermobility and modify the pressure transmission invoked by intra-abdominal pressure changes** (Blaivas and Olsson, 1988).

PUBOVAGINAL SLING

In addition to the correction of urethral hypermobility, the PVS (a sling at the bladder neck as distinct from a midurethral sling) is also **indicated for intrinsic sphincter deficiency (ISD) associated with urethral hypermobility, SUI presenting with concomitant cystoceles** (Cross et al, 1997; Serels et al, 1999), **and SUI associated with urethral diverticulum or urethral defects (e.g., urethrovaginal fistula) in which urethral reconstruction is required and in women with SUI and associated neurogenic conditions** (Austin et al, 2001). In neurogenic patients, such as those with myelodysplasia, a PVS is indicated for SUI that occurs between clean intermittent catheterizations (once a thorough urodynamic study [UDS] of compliance and bladder capacity is completed). A PVS is used during **reconstruction of proximal urethral loss secondary to trauma, or erosion (synthetic material or prolonged Foley catheter), or for interposition in repairs of urethrovaginal fistulae or urethral diverticula** (Gormley et al, 1994; McGuire and O'Connell, 1995; Blaivas and Heritz, 1996; Leng and McGuire, 1998). A PVS is also indicated for **recurrent SUI**, especially **after failed retropubic suspensions or prior midurethral sling placement** (Beck et al, 1988; Petrou and Frank, 2001). **The definition of ISD has evolved from a strict urodynamic criterion to a clinical diagnosis. In understanding surgical treatment it is essential to appreciate that all women with SUI have some component of ISD. The PVS is the gold standard for management of *all* forms of SUI.** The PVS has less morbidity than older retropubic suspensions and a better long-term outcome than needle suspensions and urethral collagen injections. Using female Medicare beneficiary records, Anger and colleagues (2009) identified patterns in the surgical treatment of women with SUI in the United States from 1992 to 2001. By 2001, the PVS became the dominant anti-incontinence procedure, corresponding with a steady decline in needle suspensions and anterior urethropexies (Anger et al, 2009).

Assessment of Intrinsic Sphincter Deficiency

The immobile urethra with poor intrinsic function has been classified as type III incontinence (Blaivas and Olsson, 1988) **but is more commonly referred to as ISD.** ISD is a complex condition with an imprecise definition and a large variability in measurement. The earliest measurements were by radiographic or endoscopic procedures, confirming an open proximal urethra and urethrovesical junction at rest (Blaivas and Olsson, 1988). Earlier methods for diagnosing ISD included the use of the supine stress test (empty and at capacity) (Lobel and Sand, 1996; Hsu et al, 1999), easy removal of inflated 8-Fr pediatric Foley balloon catheters as a positive office screening tool (Arya et al, 2001), color translabial sagittal ultrasonography for urethral vascularization measurement (Siracusano et al, 2002), ultrasound assessment of bladder neck funneling during straining (Huang and Yang, 2003), and translabial ultrasonography for measurement of the diameter of the urethra (Oliveira et al, 2006). In 2008, Oliveira and colleagues retrospectively reported lower opening detrusor pressure in stress incontinent women with ISD. Smith and Appell

(2008) tried to determine whether voiding flow rates in women with symptomatic vaginal prolapse could predict ISD. Flow rates did not predict ISD (Hosker, 2009).

ISD continues to be defined imprecisely by a low-pressure urethra based on urethral closure pressures and abdominal leak point pressures. **A maximum urethral closure pressure (MUCP) of 20 cm H_2O or less has been a determinant of ISD since McGuire's (1981) research on failed SUI procedures.** Although patients who experienced treatment failure were more likely to have an MUCP of 20 cm H_2O or less, McGuire was unable to determine whether closure pressure was the cause or effect of the failures. Therefore, Sand and associates (1987) performed UDS on 86 women undergoing modified Burch colposuspensions. The women were divided into two groups: one with an MUCP of 20 cm H_2O or less and one with an MUCP of more than 20 cm H_2O. The group with lower urethral closure pressures had a 54% failure rate, compared with 18% in the group with higher urethral closure pressures. Sand and associates concluded that a modified Burch colposuspension was not appropriate in patients younger than age 50 years with an MUCP of 20 cm H_2O or less. Also other authors have not used an MUCP of less than or equal to 20 cm H_2O to define ISD (Clemons and La Sala, 2007; Fritel et al, 2008). **Abdominal leak point pressure (ALPP) less than or equal to 60 cm H_2O has been used as a determinant of ISD since videourodynamic analysis by McGuire and colleagues** (1993). They found that women who leaked with low abdominal pressures (5 to 60 cm H_2O) were most seriously incontinent and 75% had ISD on videourodynamics (proximal urethral pressure <10 cm H_2O at 0.5 cm from the bladder neck or a nonfunctioning open sphincter with leakage). There was no correlation between ALPP and MUCP (Hosker, 2009). ISD is clinically relevant, but until the imprecision of diagnosis is addressed it cannot be utilized completely.

Anatomy and Mechanics

Female SUI is due to a combination of urethral hypermobility and ISD. The female urethra lies under the pubic symphysis, and the pubourethral ligaments suspend the anterior urethral wall to the pubic arch. **During Valsalva or other stress maneuvers the posterior wall of the urethra slides away from the anterior urethral wall and causes the bladder neck to open in cases of urethral hypermobility. The uneven pressure transmission combined with opening of the bladder neck (funneling) causes a loss of urine with stress maneuvers. ISD arises from defects within the urethra proper, so that the urethral sphincter is unable to coapt and generate enough resting urethral closing pressure to store urine in the bladder.** The female urethra is composed of four separate tissue layers that assist in keeping it closed. It is compression from the middle muscular coat that helps to maintain the resting urethral closure mechanism and the outer seromuscular layer that augments this closing pressure. In normal circumstances the resting urethral closing pressure of the internal sphincter exceeds the resting or Valsalva pressure exerted by the bladder. Additionally, the fast-twitch fibers of the external sphincter allow for the sudden voluntary guarding reflex and the slow-twitch fibers provide continuous passive control by the involuntary guarding reflex. In addition to these structures the integrity of the pelvic diaphragm is dependent on the levator ani for continence control. The urethropelvic ligament and pubocervical fascia also provide needed support to the bladder neck and undersurface of the bladder, respectively, to prevent SUI (Vasavada and Rackley, 2011).

The PVS is positioned at the bladder neck to provide urethral compression without obstruction during times of increased intra-abdominal pressure. The ultimate goal is to provide adequate urethral coaptation to increase urethral responsiveness to abdominal pressure. This must be balanced with the risks of ischemia, retention, and erosion from unnecessary tension. Aldridge's (1942) earliest anatomic descriptions had fascia attached at the medial aspect of the rectus limiting sling mobility and provided no method for avoiding excess tension, resulting in outlet obstruction. The sling was often too short to pass under the urethra. McGuire (1978) modified this technique with a strip of rectus fascia 1 × 12 cm in length, which remained attached laterally on one side. In this technique there was also no way to adjust the tension with one side attached. The modifications by Blaivas and Jacobs (1991) with a free graft of rectus fascia whose tension could be adjusted (by pulling up and tying the sutures at each end of the free graft) are the present concept of the PVS. This allows for a shorter fascial sling. The key to the length of the fascial sling is its method of providing support. It is the incorporation of the sling into the endopelvic fascia and subsequent fibrosis, and not entry into the retropubic space, that prevents SUI. The width (2 to 3 cm) of the PVS ensures that there is sufficient support to provide the needed urethral compression and a cross-sectional area adequate to avoid the formation of a narrow constricting band. The choice of material in PVS requires material longevity and durability to allow for a strong sling scaffolding. The material should be incorporated and remain intact, with limited tissue reaction.

Sling Materials

Various substances have been utilized for construction of a PVS—**autologous, allograft, xenograft, or synthetic materials.** The ideal material provides long-lasting suburethral support with minimal complications. Ideally, implanted material should be incorporated into the host with minimal tissue reaction. In reality, most materials promote organized fibrosis, reinforcing the sphincteric mechanism through improved suburethral support. Theoretically, a greater degree of fibrosis leads to better clinical results (Bidmead and Cardozo, 2000; Woodruff et al, 2008). Yet, inflammatory infiltration leads to rapid sling material degradation and possible tissue destruction with erosion (Bidmead and Cardozo, 2000). Although there is complete biocompatibility of the autologous sling and negligible urethral erosion, biologic and synthetic graft materials have been increasingly used to decrease operative time, morbidity, pain, and hospital stay (Niknejad et al, 2002). Outcomes of these materials are discussed later.

Autologous Materials

The most commonly used autologous materials include **rectus fascia and fascia lata.** Rectus fascia is harvested through a suprapubic Pfannenstiel incision. FitzGerald and associates (2000) reported that after sling placement, rectus fascial grafts undergo extensive remodeling with increased fibroblasts and connective tissue on biopsy specimens. Yet, histologic comparison of PVS grafts noted the **greatest degree of host fibroblast infiltration and neovascularization in autologous materials with minimal inflammatory or foreign body reaction.** The fascial graft changes were consistently intact with a small

amount of sling degradation at explantation up to 65 months after placement (Woodruff et al, 2008). The rectus fascia harvest site may be scarred and thickened after prior operations, but this does not compromise its utility for PVS placement. **The benefits of autologous tissue include the lack of tissue reaction and negligible urethral erosion** (Webster and Gerridzen, 2003). **Disadvantages include increased operative time and hospital stay, relative increase in postoperative pain, and suprapubic tissue seroma formation and hernia formation in a rectus fascial PVS** (Gomelsky et al, 2003).

Fascia lata is the other commonly utilized autologous material for a PVS. It is harvested from the thigh and has similar properties to rectus fascia (Beck et al, 1988; Latini et al, 2004). Methods for harvest are discussed in the section on operative procedure. Like rectus fascia, fascia lata is completely biocompatibility and is associated with minimal tissue reaction. The **recovery time may be less, and there is no risk of future abdominal hernia formation,** unlike rectus fascia. Yet, fascia lata **requires repositioning of the patient, increased operative time, and operating in an area unfamiliar to urologists** (Govier et al, 1997). Wheatcroft and colleagues (1997) reported 67% of their patients had pain on walking for 1 week after surgery. Latini and coworkers (2004) only reported 7% of patients with pain at incision site 1 week postoperatively after using a Crawford fascial stripper. Debility from a thigh hernia has also been reported.

Another autologous material, vaginal wall, has also been used. Raz and associates (1989) described use of in-situ vaginal wall for autologous sling material. This tissue may lack sufficient tensile strength, and there is a risk of epithelial inclusion cyst formation and possible vaginal shortening. Lack of retropubic space dissection may militate against overall efficacy of this procedural variety (Raz et al, 1989; Ghoniem and Hassouna, 1998; Loughlin, 1998; Appell, 2000).

Allograft Materials

Biologic and synthetic graft materials have been increasingly used to decrease operative time, morbidity, pain, and hospital stay. Cadaveric allografts have been used in many nonurologic surgical arenas (e.g., orthopedics, neurosurgery) and eventually adopted for SUI. Allograft slings are currently derived from either **cadaveric fascia lata or acellular human dermis.** After harvest the allografts are processed by solvent dehydration or by lyophilization (freeze-drying) to remove genetic material and to prevent the transmission of infectious agents. Secondary sterilization may also be achieved by gamma radiation (Gomelsky et al, 2003). Histologic analysis reveals cadaveric dermis to **have little host fibroblast infiltration and little neovascularity, particularly in central aspects of the graft.** Additionally, inconsistencies were found within the materials grossly, with specimens exhibiting **significant thinning and degradation of the graft, disrupting the sling scaffold** (Woodruff et al, 2008). **No specific allograft has shown a clinical advantage in use.** Acellular dermis rehydrates in 0.9% saline quicker than does cadaveric fascia lata (5 minutes vs. 15 to 30 minutes), but each type is pliable, easy to use, and available in a variety of sizes (Gomelsky et al, 2003).

Biomechanical studies have shown that solvent-dehydrated cadaveric fascia lata and acellular dermis have a higher maximal load failure compared with freeze-dried cadaveric fascia lata (Hinton et al, 1992; Lemer et al, 1999). Lemer and associates (1999) prospectively studied the maximum load failure and stiffness of rectus fascia versus freeze-dried fascia versus solvent-dehydrated fascia and cadaveric dermal grafts. The mean values for maximum load to failure, maximum load-graft width, and stiffness were all significantly lower for the freeze-dried fascia lata group compared with the autologous, solvent-dehydrated, and dermal graft groups. The authors believed that ice crystal formation characteristics of tissue freezing may disrupt the collagen matrices, yielding poor strength properties. Dermal grafts differ from fascial allografts because they are derived from skin that is processed to eliminate the epidermis and all immunogenic cellular elements. Dermal grafts provide a protein matrix that serves as a collagen scaffold for the host's own cellular matrix (Lemer et al, 1999).

Although biomaterials were thought to be a good choice for increased biocompatibility, lower risk of erosion, and lack of response to hormonal stimuli, allografts raise the concern of potential transfer of disease, including human immunodeficiency virus (HIV), hepatitis, and Creutzfeldt-Jacob prion infection. There has been one documented case of HIV transmission from a tissue transplant since the onset of screening in 1985. **The estimated risk of acquiring tissue from a properly screened donor infected with HIV is 1 in 1,667,600** (Gallantine and Cespedes, 2002). A few cases of Creutzfeld-Jakob disease (CJD) have been reported after transplantation of cadaveric dura or corneas; however, skin obtained from animals infected with prions has demonstrated no detectable infectious particles. Currently, **the theoretical risk of developing CJD from a non-neural allograft is 1 in 3.5 million.** No cases of hepatitis or CJD have ever been attributed to the use of processed cadaveric fascia or dermis (Amundsen et al, 2000b; Gallantine and Cespedes, 2002). Within the musculoskeletal tissue transplantation literature, two cases of hepatitis transmission have been reported. The first refers to one tissue donor (cancellous chips) who transmitted HIV, hepatitis B virus, and human T-lymphotrophic virus. These transmissions all occurred before the implementation of extensive donor screening for viruses and bacteria or the availability of validate serologic tests (or both) (Shutkin, 1954). In June 2002, the Centers for Disease Control and Prevention (CDC) reported a case of hepatitis C transmission from minimally processed, cryopreserved patellar tendon allograft. Donor screening was performed during the window period for hepatitis C virus (HCV). Retest of the donor sample with HCV RNA testing confirmed the donor as the source once the recipient reported HCV infection 1 year after transplantation (CDC, 2003; Vangsness, 2006). Despite the low risk of disease transmission, human DNA has been detected in various allograft materials (Choe and Bell, 2001; Hathaway and Choe, 2002). The clinical significance of this is unknown. The theoretical risk of developing hepatitis from allograft graft material is unknown.

Xenograft Materials

Xenografts have been utilized since the 1980s (Descurtins and Buchmann, 1982; Iosif, 1987) owing to their immediate accessibility and use without morbidity. Porcine and bovine xenografts have been used as sling material with decreasing popularity in recent years. The forms of xenograft available for use are **porcine dermis or small intestinal submucosa (SIS) and bovine pericardium.** Modern processing techniques using diisocyanate to remove genetic material have made porcine safer and more pliable, yet there is significant loss of tensile strength after implantation in a 12-week rabbit model (Dora et al, 2004). Histopathologic analysis has shown porcine SIS to contain growth factors that may reduce significant host-graft immunologic reaction and result

in less tissue scarring (Wiedemann and Otto, 2004). Although a majority of data support SIS as nonimmunogenic, animal studies by Thiel and colleagues (2005) suggest that an intense inflammatory reaction 30 to 90 days after subcutaneous implantation occurs. In a report by Kalota (2004), 6 of 18 (33%) patients experienced postoperative inflammation after a PVS procedure. Konig and coworkers (2004) reported a single case of postoperative inflammation with abscess formation. Ho and colleagues (2004) reported a similar reaction in 6 of 10 patients. All of the patients presented with pain and erythema at the abdominal incision, and 2 developed abscesses. Five of the 6 patients with inflammatory responses are currently dry. All were treated conservatively, except 1 patient who required abscess drainage. The etiology is unknown but is likely due to a foreign body reaction from the multilayered (8-ply) SIS material, a reactive manufacturing ingredient, or a tendency for suprapubic fat to produce an inflammatory reaction (John et al, 2008). Kubricht and colleagues (2001) have shown that **porcine SIS has less tensile strength than cadaveric fascia lata** (Kubricht et al, 2001). Bovine pericardium is available in a preparation either cross-linked with glutaraldehyde or as a non–cross-linked acellular matrix (Gomelsky et al, 2003). Histopathologic comparison of sling materials revealed xenograft (porcine dermis) to have **no host fibroblast infiltration, no inflammatory reaction, and no foreign body reaction. Xenograft had the highest propensity to encapsulate.** A capsule formed around the porcine dermis, isolating the graft from the periurethral tissue. The graft was described as appearing similar to its original appearance at time of implantation (Woodruff et al, 2008).

Synthetic Materials

In 1959, Francis Usher introduced the first synthetic biomaterial—polyethylene mesh—for use in hernia surgery. In the decades since there has been a transition to polypropylene and the introduction of additional synthetic materials (Amid, 1997). The first synthetic sling, made of nylon, was introduced in 1953 (Kraatz, 1953). The addition of synthetic material for use in PVS surgery brought **obvious advantages: unlimited supply of artificial graft material in endless sizes and shapes, consistency in quality, and elimination of harvest site and decreased associated operative time.** As compared with absorbable biomaterials, synthetic materials are **more uniform, more consistent, and more durable.** Additionally, **artificial graft materials are sterile, biocompatible, noncarcinogenic, and free of biomaterials** (Niknejad et al, 2002). On histopathologic comparison, **synthetic materials demonstrated the greatest amount of fibroblast ingrowth and tissue ingrowth into the specimen. There is no degradation or disruption of the graft, and the mesh is completely infiltrated by the viable host tissue.** Microscopically, the synthetic material **has large amounts of fibroblasts and foreign body reaction characterized by giant cells and occasional microcalcification.** This foreign body reaction is not visible grossly by graft disruption, and the graft was completely infiltrated by host tissue (Woodruff et al, 2008).

Artificial graft materials do have **potential drawbacks, including graft infection, genitourinary erosion, or vaginal extrusion.** The chemical and physical properties of each artificial material and patient characteristics determine how the sling is incorporated into the surrounding tissue and its susceptibility to infection, rejection, erosion, or extrusion. **The susceptibility to infection in multifilament fibers is proportional to the porosity and the pore size of the materials** (Amid, 1997; Niknejad et al, 2002). **Tightly woven mesh provides a safe harbor for small bacteria, excluding macrophages and polymorphonuclear leukocytes. Loosely woven mesh allows tissue ingrowth and neovascularization, without limiting cellular access.** Tissue bonding to the mesh strengthens and supports the repair. **A tightly woven and large-diameter filament mesh will tend to exhibit increased stiffness or decreased pliability, contributing to migration, extrusion, or erosion.** The classification by Amid (1997) used for synthetic materials in hernia surgery may be practically applied to urology as well (Table 73-1). The most frequently used materials are grouped into four types. Type I are totally macroporous prostheses (Atrium, Trelex, Marlex, Prolene) containing pores larger than 75 μm, which is the pore size for admission of macrophages, fibroblasts, blood vessels, and collagen fibers (White et al, 1981; Bobyn et al, 1982; White, 1988). Type II includes totally microporous prostheses (polytetrafluoroethylene [PTFE]: GORE-TEX, Surgical Membrane, and Dualmesh) containing pores less than 10 μm in at least one of their dimensions. Type III includes a macroporous prosthesis with multifilamentous or microporous components (PTFE: Teflon; braided Dacron mesh: Mersilene; braided polypropylene mesh: Surgipro; and perforate PTFE patch: MycroMesh). Lastly, type IV includes biomaterials with submicronic pore size (Silastic, Cellgard (polypropylene sheeting). Type IV is not appropriate for hernia surgery unless used in combination with type I (Amid, 1992). **The most commonly utilized synthetic material for a PVS is polypropylene mesh** (Table 73–2). **It is composed of loosely woven strands of synthetic material, with a pore size greater than 80 μm, permitting passage of macrophages that may allow better host tissue ingrowth compared with the smoother, more tightly woven counterparts** (Kobashi et al, 2005). This represents type I among the Amid classification. In fact, Amid (1997) concluded that the risk of infection and seroma formation was avoided by utilization of type I prostheses.

Historically, sling techniques have changed to limit the associated morbid complications. **Synthetic material is no longer utilized in a PVS graft to pull the bladder neck into a high retropubic position owing to high erosion rates** (see section on complications). **Instead, newer approaches position a sling at the midurethra** (see later) (Niknejad et al, 2002).

Table 73–1.

Amid Classification for Synthetic Materials

TYPE	DESCRIPTION	BRANDS
I	Pores >75 μm; macroporous	Atrium, Trelex, Marlex, Prolene
II	Pores <10 μm; microporous	PTFE: GORE-TEX, Surgical Membrane, Dualmesh
III	Macroporous with multifilamentous or microporous components	PTFE: Teflon, braided Dacron mesh (Mersilene), braided polypropylene mesh (Surgipro), perforated PTFE patch (MicroMesh)
IV	Submicronic pore size	Silastic, Cellcard (polypropylene sheeting)

PTFE, polytetrafluoroethylene.

Table 73–2.

Synthetic Sling Materials

TRADE NAME	COMPOSITION	DETAILS
Mersilene	Polyethylene terephthalatae	Multifilament fibers Very porous, becomes firmly embedded in native tissues
Teflon	Polytetrafluoroethylene (PTFE)	Multifilament
GORE-TEX	Expanded PTFE	Very flexible
Silastic	Silicone plus woven polyethylene terephthalate	Minimal tissue reaction, which facilitates removal or revision if necessary
ProteGen	Synthetic mesh impregnated with collagen matrix	Removed from market secondary to high rate of vaginal extrusion
Marlex, Prolene	Polypropylene	Monofilament with open-weave pattern

Adapted from Niknejad K, Plzak LS, Staskin DR, Loughlin KR. Autologous and synthetic urethral slings for female incontinence. Urol Clin North Am 2002; 29:597–611.

Key Points: Pubovaginal Sling Materials

- The construction of a PVS has utilized various materials: autologous (rectus fascia or fascia lata), allograft, xenograft, and synthetic.
- The ideal material is sterile, biocompatible, noncarcinogenic, and consistent in quality. The implanted material should be incorporated into the host with minimal tissue reaction and provide long-lasting suburethral support with minimal complications.
- Autologous materials remain the gold standard, associated with no tissue reaction and negligible urethral erosion.
- To decrease operative time, hospital stay, and postoperative stay, other biomaterials are utilized.
- Allografts raise concern for transfer of infection, whereas reportable cases are extremely rare. Additionally, the type of processing technique may disrupt the microstructure and affect strength properties.
- Xenografts have less tensile strength than allograft in situ and have the highest propensity to encapsulate.
- Synthetic materials have large inflammatory and foreign body reactions and are associated with high rates of graft infection and erosion, owing to their placement at the bladder neck. Synthetic materials are no longer used for a bladder neck PVS.

Operative Procedure

Preoperative and Preliminary Steps

Before performing a PVS, a thorough history and physical examination is performed. Key points in the history should include preoperative voiding status and symptoms. Specifically, the relationship between stress maneuvers (i.e., cough, sneeze, laugh, weight bearing, exercise) and related incontinence should be elucidated. It is important to identify preoperative storage symptoms, such as frequency, urgency, and urinary urgency incontinence (UUI), because these symptoms may not resolve after a sling procedure. A complete history of all prior vaginal and abdominal operations should include graft material placement, prior urethrolysis, and/or prolapse surgery. A history of prior irradiation is useful because this may compromise the quality of a rectus fascial graft. Physical examination should include an abdominal examination and complete pelvic examination to assess urethral hypermobility, quality of vaginal epithelium, extrusion of previously placed graft material, and prolapse. Cystocele and other forms of prolapse should be assessed, because they may lead to symptomatology and be a source of future obstruction. Special attention should be paid to the anterior vaginal compartment to determine if coexistent prolapse is present. The authors recommend UDS on all women undergoing surgical intervention for SUI, with or without simultaneous prolapse correction. UDS is recommended by the International Consultation on Incontinence (ICI) before undergoing surgical procedures to obtain a more accurate preoperative diagnosis (Griffiths et al, 2005). Knowing the urodynamic abnormalities responsible for urinary manifestations is essential to directing treatment at the underlying pathophysiology. The American Urological Association (AUA) recognizes uroflow, cystometry, leak point pressures, sphincter electromyography, and radiographic visualization as five modalities useful in understanding bladder storage and emptying. Implicitly, diagnosing impaired detrusor contractility or obstruction requires Pdet/uroflow, and cystometry is necessary for identifying detrusor overactivity (DO) (Rutman and Blaivas, 2007). A cough stress test may demonstrate SUI, but it provides no information regarding a patient's bladder storage and emptying characteristics. This information is essential for tailoring the appropriate treatment plan. "The bladder is an unreliable witness," because symptoms are not predictive of diagnosis. UDS may aid the clinician in detection of preoperative DO, preoperative abnormal voiding patterns (high postmicturition residual, obstructed flow), and de novo DO (Digesu et al, 2009). Cundiff and colleagues (1997) studied 535 incontinent women and concluded that pure symptoms identified less than half of the patients with urodynamic SUI, recommending UDS for all patients considering surgical intervention. UDS should be performed with and without a pessary if prolapse is present.

This procedure may be performed with the patient under spinal or general anesthesia, based on preference determined between the surgeon and anesthesiologist. A single perioperative dose of cefazolin or fluoroquinolone is given intravenously (as per Centers for Medicare and Medicaid Services recommendations). Bilateral lower extremity sequential compression devices (SCDs) are placed before administration of anesthesia. The patient is placed in the dorsal lithotomy position, and the abdomen (from umbilicus down) and vagina are prepped and draped in sterile fashion. A weighted speculum is placed in the vagina, and an 18-Fr Foley catheter is placed into the urethra and left in place with the bladder left to straight drainage. The patient should be placed in moderate Trendelenburg position, and the surgeon would benefit from a headlight for optimal visualization during vaginal dissection. A vaginal ring retractor is utilized initially for retracting the labia majora for ease with dissection and visualization.

In the case of fascia lata harvesting, the SCDs are placed below the patient's patella on the harvest side. The knee is elevated and supported with a 1-L bag of intravenous fluid or an appropriate cushion or pad. The involved extremity is internally rotated at the hip and secured to the table using 3-inch tape, below the operative site. The thigh is prepped and draped to expose the anterolateral aspect of the thigh from the greater trochanter to distal to the patella. The greater trochanter and lateral femoral condyle of the femur are identified and marked. These landmarks mark the

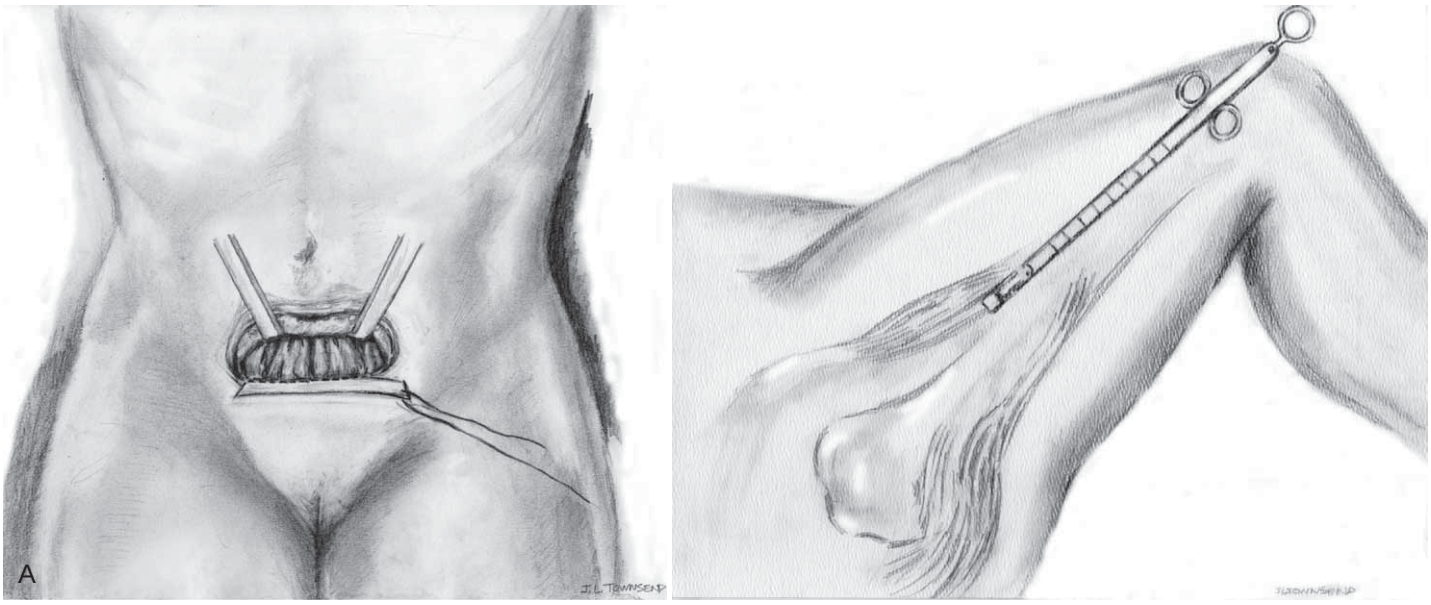

Figure 73–1. **A,** Rectus fascial graft harvest. **B,** Autologous fascia lata harvest.

proximal and distal attachments of the fascia lata (Dwyer and Kreder, 2008).

Graft Harvest

A 6- to 7-cm Pfannenstiel incision is made approximately 2 cm above the pubic symphysis and carried down to the rectus fascia. A 2-cm wide by 8-cm long graft is marked out in the rectus fascia. The premarked graft is harvested out of the rectus fascia. With the use of Allis clamps the edges of the free fascia are freed from the underlying rectus muscle with bovie cautery to aid in a tension-free closure (Fig. 73–1A). The fascia is closed with a running 1 polydioxanone (PDS) suture or other alternative suture. The graft is placed in 0.9% normal saline solution after harvest. On a sterile side table, the overlying fat and perifascial tissue are cleaned off of the graft. A size 1 polydioxanone suture is utilized (perpendicular to sling fibers) at each end of the sling to run across the full width of the sling and tied down. Sutures are left long, and the graft is placed in the 0.9% normal saline until needed.

For fascia lata harvest, a 3-cm longitudinal incision is marked beginning just above the patella over the iliotibial band (see Fig. 73-1B). Dissection is carried down to the level of the fascia lata, where two parallel incisions are made longitudinally in the fascia lata, 2 cm apart. The autologous fascia is bluntly lifted off the underlying muscle and clamped as far distally as possible with a right-angle clamp (3 to 4 cm) and transected, allowing one free end. The free end is secured with a 1-0 polypropylene, polydioxanone, or polyglactin suture, and the proximal fascia lata is lifted off the muscle belly with a thin, malleable retractor. The fascia lata is separated from both the adipose tissue and the muscle fibers by passing the retractor superficial and deep to the fascia lata. With the free distal end under tension, a Crawford fascial stripper is used to extend the fascial incision proximally and divide it before removal. Classically, the fascial strip was 20 × 2 cm in dimension; however, now shorter lengths (8 cm) are used (Karram and Bhatia, 1990). Another 1-0 polypropylene monofilament suture is secured to the other free end of the graft, and the graft is placed in 0.9% normal saline until needed. Immediate compression is applied to the thigh to constrict perforating vessels. The wound is irrigated and closed in three layers without closing the fascia lata. The area is carefully evaluated for bleeding arteries before closure. Once the thigh closure is complete, a compressive wrap is applied to the thigh and the SCD is replaced (to remain in place for the duration of the hospital stay). The compressive bandage should remain in place for 8 hours postoperatively, and the patient should be encouraged to ambulate early postoperatively (Dwyer and Kreder, 2008).

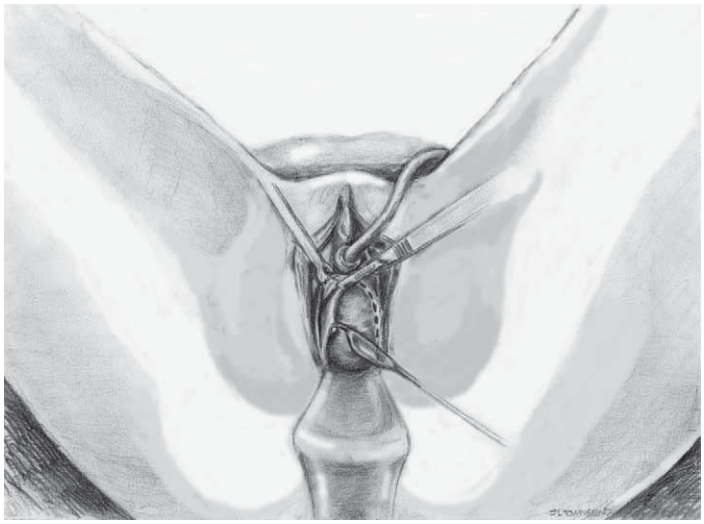

Figure 73–2. Inverted-U incision.

Vaginal Approach

Sterile 0.9% normal saline is injected into the vaginal epithelium, surrounding the urethra to provide hydrodistention and aid in tissue dissection. The authors prefer an inverted-U–shaped incision because it enables adequate exposure to the urethra and bladder and access to the endopelvic fascia and subsequent retropubic space (Fig. 73–2). The top of the incision is approximately 2 cm below the urethral meatus (easily visualized with assistance

of an Allis clamp placed immediately below the meatus), and the arms of U should extend to the level of the bladder neck (determined by Foley balloon location). A No. 15 blade knife is used to carry this incision down through the vaginal epithelium, with care to stay above the periurethral and pubocervical fascia (to avoid bleeding and injury to the urethra and bladder). With an Allis clamp and Metzenbaum scissors, thick vaginal epithelial flaps are created. The flaps are retracted with the help of the vaginal ring retractor. Once adequate lateral flaps have been created and the ischiopubic rami are easily palpated, it is appropriate to perforate the endopelvic fascia. It is imperative that the bladder is adequately drained before this maneuver and before later passage of Stamey needles or larger clamps to prevent inadvertent bladder perforation. With the tips of the Metzenbaum scissors pointed upward and to the ipsilateral shoulder, the endopelvic fascia is perforated by remaining directly medial and immediately under the ischiopubic ramus at the superior margin of dissection (Fig. 73–3). Perforation occurs in a superolateral direction, and the dissecting scissors are spread widely to aid in dissection. With the use of blunt finger dissection, the retropubic space is dissected bilaterally (Fig. 73–4). This dissection leads to the connection between the infrapubic and retropubic dissection planes. Simultaneous finger palpation from abdominal and vaginal incisions should be possible, while gently palpating the bladder medially. Aggressive medial mobilization should not be attempted because it may result in bladder injury. Hemostasis should be achieved with bipolar cautery. In the case of women who have undergone prior urethral suspension or sling, more aggressive dissection may be required. The dissection plane into the retropubic space should be immediately adjacent to the periosteum of the pubis, and the dissection should be performed only sharply to minimize risk of injury to the pelvic viscera.

Sling Placement and Fixation

Stamey needles or large clamps are passed from above, through the abdominal incision by careful guidance behind the pubis, and passage is in contact with the pubis throughout until brought out lateral to the bladder and through the vagina (Fig. 73–5). Alternatively, large surgical instruments such as Tonsil clamps may also be used (McGuire, 1978; Blaivas and Olsson, 1988). The bladder must be completely drained before passage of the Stamey needles to avoid inadvertent bladder injury. Cystoscopy should be performed with a 70-degree lens after passage of the needles to confirm the integrity of the bladder, by following the course of the needles (while an assistant moves them). Cystoscopy is not practiced consistently by all urologists after needle passage except when there is visible hematuria or another cause for suspicion (Niknejad et al, 2002; Seung-June et al, 2007). It is the authors' belief that this step eliminates the morbidity and reoperation required for passage of the sling through the bladder and that **cystoscopy is an essential step.** In the case of a small bladder injury or inadvertent passage of Stamey needles through the bladder, the needles are removed and passed again and the procedure is completed. Extravesical passage is confirmed. One ampule of indigo carmine is given at this point to confirm ureteral efflux during final cystoscopy for tensioning of sling. The Foley catheter is replaced. The ends of graft suture are passed through the Stamey needle eyelets. After marking the center of the graft with a clamp, the Stamey needles are removed and the ends of the suture are brought out through the abdominal incision and tagged with hemostat clamps (Figs. 73–6 and 73–7). The distal aspect of the graft is sutured to the periurethral tissue with two simple 4-0 polyglactin sutures. The vaginal incision is closed with a watertight, running 2-0 polyglactin suture after complete hemostasis is

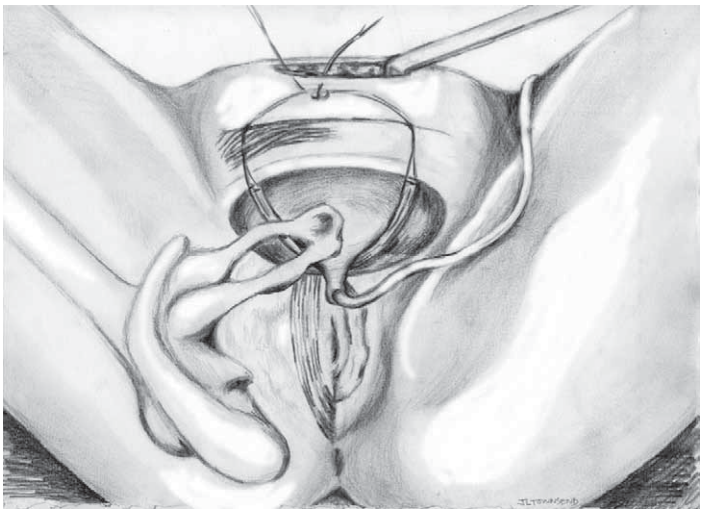

Figure 73–7. Tying and tensioning of sling.

achieved. Before final tensioning of the sling (see Fig. 73-7) the vagina should be closed and the weighted speculum removed to eliminate factors that can affect the final tension. The polydioxanone sutures are tied down above the rectus fascia (see Fig. 73–7) while cystoscopy with a 30-degree lens is performed to visualize adequate coaptation of the proximal urethra. There is approximately a two-fingerbreadth width between the rectus fascia and the sutures once tied down. The amount of tension may vary owing to the mobility of the urethra or desire to create permanent retention in an individual who will have permanent catheterization. The abdominal incision is closed with a subcuticular 4-0 polyglactin suture. The Foley catheter is left to straight drainage, and a vaginal pack moistened with conjugated estrogens is placed.

Postoperative Care

The vaginal packing is removed on postoperative day 1, and the patient is given a voiding trial once she is ambulating. If the patient voids adequately (after postvoid residual urine confirmation), she is discharged. If she is unable to urinate or has an elevated postvoid residual urine volume, she is discharged with a Foley catheter. She will return within 5 days for a repeat trial of voiding. Patients are instructed to avoid heavy lifting (>5 lb) and sexual intercourse for 6 weeks postoperatively. Sexual intercourse should be resumed only after a physical examination by the surgeon.

Outcomes

Autologous Pubovaginal Sling

Since McGuire's reintroduction of the autologous PVS in 1978 with 80% overall success rate, continence rates have been reproducibly satisfactory, even at long-term follow-up (Table 73–3). Earliest series (McGuire, 1987; Blaivas and Jacobs, 1991) with rectus fascial slings include a diverse and complex patient population, with patients having a history of pelvic irradiation, diabetes, spinal cord injury, and pelvic trauma. Poor or no urethral function was associated with 35% of cases (McGuire, 1987). Cure rates among these earliest series were similar (82%). A main cause of failure was urgency and UUI. A majority of the patients who required clean intermittent catheterization postoperatively had a neurogenic bladder and were counseled to expect urinary retention. Harvesting of rectus fascia appears a favored option over fascia lata for autologous material, likely owing to the urologist's greater comfort with abdominal anatomy. Yet, intermediate and long-term results of fascia lata PVS procedures (Beck et al, 1988; Govier et al, 1997) are comparable to those that use rectus fascia. Beck and colleagues (1988) noted that all three sling failures occurred within the first 22 cases performed and that 10 of the 13 overall failures were due to UUI. Five (3%) of the patients in this study population were extremely bothered by delayed voiding (mean interval of 59.6 days) and underwent a urethrolysis. Govier and associates (1997) administered an independent survey to assess outcomes, yielding worse outcomes than cure rates reported based on their chart review (70% vs. 87.5%, respectively). The vast majority of incontinence reported postoperatively was related to urgency. This patient satisfaction rate was similar to that noted by Brown and associates (2000) with questionnaire-based outcomes. In this group, all of the patients had thigh pain at 1 to 2 weeks and 11% described persistent thigh pain at 6 weeks. Latini and colleagues (2004) used the Crawford fascial stripper to obtain fascia lata. They reported 20% localized numbness at harvest site, 7% with harvest site pain 1 week postoperatively, 5% tendonitis in the harvest site leg, and 1 case of a harvest site hematoma requiring physical therapy. Yet, 83% of respondents indicated that the procedure had a positive effect on their life, 82% would recommend the surgery to a friend, and 83% would undergo the procedure again (Latini et al, 2004).

The rectus fascial autologous sling has been effective up to 7 years (Howden et al, 2006) postoperatively with low morbidity when performed by experienced surgeons. **Cure rates have ranged from 46% to 97%, although the measurement of outcomes is varied. Patient-derived cure rates are lower than physician-based or chart review–based outcomes.** There is no direct correlation between universally accepted objective and subjective measures of improvement or cure for anti-incontinence procedures (Padmanabhan and Nitti, 2006). The most commonly cited reason for failure relates to urgency symptoms. UUI at follow-up is a common reason for patient dissatisfaction. **Reported de novo or UUI rates are 2.0% to 20.8%** (Mason and Roach, 1996; Zaragoza, 1996; Haab et al, 1997;

Table 73–3.

*4 of 6 patients had neurogenic bladders planned on clean intermittent catheterization postoperatively.
†1 of 82 was a male patient and excluded.
AUR, acute urinary retention; DO, detrusor overactivity; FL, fascia lata; MUI, mixed urinary incontinence; NA, not available; R, rectus; SUI, stress urinary incontinence; UDS, urodynamic study; UUI, urgency urinary incontinence.

Chaikin et al, 1998; Cross et al, 1998; Hassouna an Ghoniem, 1999; Morgan et al, 2000; Groutz et al, 2001; Flynn and Yap, 2002; Albo et al, 2007; Mitsui et al, 2007; Onur et al, 2008). Zaragoza and colleagues (1996) report that their three failures had persistent leakage due to UUI (present preoperatively). One of these patients had previous pelvic irradiation and radiation cystitis, and 1 had additional UDS, confirming bladder instability and lack of urethral obstruction. The short-term complication of postoperative retention that occurred in 60% immediately postoperatively is highlighted. Urinary retention persisted in this group for a median of 6.5 days (1 day to 5 weeks) and resolved in 70% within 10 days. Mason and Roach (1996) confirmed the success of a modified rectus fascial sling (smaller graft, 4 × 2 cm) with intermediate follow-up. Twelve (19%) patients had urgency, and 10 (15.9%) had frank UUI. By 6 months these symptoms had resolved in all but 3 (4.8%), who remained on anticholinergic medication. Haab and associates (1997) provided results of long-term follow-up using a self-administered questionnaire to assess success rates and overall patient satisfaction. Among the 3 patients (7.5%) requiring permanent clean intermittent catheterization, 2 had known sacral arc denervation and were expected to have urinary retention. These investigators cited the main reason for failure as urgency symptoms in 62% of patients at follow-up, with 10% reporting de novo urgency. The low reported dry rate (46%) relates to the large preoperative mixed urinary incontinence (MUI) group (67%) as compared with their cure rate for SUI only (73%).

Cross and colleagues (1998) advocated the use of a PVS in conjunction with anterior colporrhaphy for repair of cystocele to treat both conditions effectively. Thirty-six patients (63%) had a PVS due to a grade III or IV broad-based cystocele and SUI. Thirty-three (92%) of these cystoceles were cured. These authors reported a 28% postoperative urgency/UUI rate with 19% de novo urgency/UUI. Yet only 3% had persistent UUI requiring treatment; 2.8% underwent further urethrolysis to resolve voiding difficulties. Hassouna and colleagues (1999) reported long-term outcomes of a modified rectus fascial PVS. The modified PVS is a modification of the free rectus fascial strip technique popularized by McGuire that includes fixation of the sling to the pubocervical and periurethral ligaments in a four-quadrant manner (Ghoniem, 1991). After the initial reported 95% success rate by Ghoniem, this study confirms a lower overall rate of 80.8%, when including assessment by a patient quality of life questionnaire. All 15 of the patients with documented failures had UUI or severe irritative symptoms. The additional quality of life assessment highlights the impact of UUI, frequency, nocturia, and pain on patient satisfaction.

Chaikin and Blaivas (1998) and Morgan and associates (2000) provide a long-term analysis of the efficacy and quality of life impact of an autologous PVS. Chaikin and Blaivas (1998) reported an SUI cure or improved rate of 92% but also compared instruments for measurement of incontinence (patient assessment, chart review, pad testing, and voiding diary entries). Seventy-five percent of the patients have "complex" SUI, which included "pipe stem urethra," urethral or vesicovaginal fistula, urethral diverticulum, grade 3 or 4 cystocele, or neurogenic bladder. Concern is raised over the PVS converting an incompetent bladder neck into an obstructing system, with the finding of 23% incidence of DO at 1 year, which increased to 41% at 10 years. The failure rate due to UUI (de novo plus persistent) is similar to that reported by Cross and coworkers (1998) of 22%. Morgan and associates (2000) reported an 85% cure rate at 5 years, yet to achieve this level of cure 14 patients (5.7%) had secondary procedures. This included six collagen injections, three repeat PVS procedures, and five urethrolyses. Eighty percent of these 5 patients had a subsequent return to normal voiding. Chaikin and Blaivas (1998) and Morgan and associates (2000) together demonstrate that when SUI is resolved for more than 1 year after an autologous PVS procedure, the long-term (5 to 10 year) risk of recurrent SUI is low.

Groutz and associates (2001) reported outcomes based on whether the PVS was the primary (57%) or secondary anti-incontinence procedure (43%). The latter group had undergone 1 to 3 prior unsuccessful anti-incontinence procedures for recurrent incontinence. The cure rate was significantly higher in patients with primary incontinence than those with recurrent incontinence (74% vs. 59%, $P = .006$). Yet there were no surgical failures

in either group. All of the patients were either cured or improved based on their outcome score, incorporating 24-hour voiding diary, 24-hour pad test, and patient satisfaction. Richter and associates (2001) assessed long-term effects based on a telephone quality of life survey. This study reports high patient satisfaction, whereas 11.8% of the subjects required regular intermittent self-catheterization; 5.8% had to adopt adaptive positions to facilitate voiding. All of the obstructed patients were satisfied due to freedom from urinary incontinence and did not elect urethrolysis. This may relate to an emphasis of preoperative counseling in conveying the possibility of long-term voiding dysfunction after a PVS procedure. Chou and colleagues (2003) provided long-term outcomes for the effectiveness of an autologous PVS in management of MUI. The population included 48.5% with simple SUI and 51.5% with MUI. On univariate analysis of MUI, the higher number of urgency or UUI episodes preoperatively, the more likely it was that the PVS would fail. Yet, women with SUI and concurrent UUI or DO have a successful PVS outcome at a rate comparable to that in women with simple SUI (97% vs. 93%, respectively, $P = .33$). DO in 26% of those with MUI did not predict a poor outcome. This is contrary to their earlier observations (Chaikin and Blaivas, 1998).

The SiSTER trial (Albo et al, 2007), **a multicenter, randomized clinical trial, compared the rectus fascial autologous sling to the Burch colposuspension. The two primary outcomes were composite measures of success in terms of overall urinary incontinence measures (no self-reported symptoms of incontinence, increase of less than 15 g in pad weight during a 24-hour pad test, and no medical or surgical treatment for incontinence) and of SUI measures (no self-reported symptoms of SUI and negative stress test), specifically. Whereas success rates were higher for the PVS (47% vs. 38%, $P = .01$), voiding symptoms were also higher: urinary tract infections (UTIs) (48% vs. 32%), difficulty voiding (14% vs. 2%, $P < .001$), and postoperative UUI (27% vs. 20%, $P = .04$). All of the surgical procedures for bladder outlet obstruction (19 of 20) were performed in the sling group.**

Mitsui and associates (2007) analyzed the risk factors for postoperative voiding difficulty. Patients with a postvoid residual urine volume greater than 100 mL ($P = .05$) or $\dot{Q}$max of less than or equal to 20 mL/s ($P = .09$) in preoperative urodynamics were more likely to require prolonged intermittent self-catheterization. In this group, 28% needed prolonged intermittent self-catheterization (range 4 to 40 months). There have been heterogeneous outcomes in regard to risk factors for postoperative voiding difficulty. This may relate to differences in surgeon skill or surgical method. **Although postoperative urgency and UUI are strongly related to failure, there are no preoperative risk factors that consistently predict outcomes after a PVS operation** (Mitsui et al, 2007).

Petrou and Frank (2001) **retrospectively reviewed the safety and efficacy of a repeat PVS for recurrent SUI among 14 women and concluded that repeat PVS is a reasonable treatment option.** The original surgeries included autologous PVS (3 patients), cadaveric bone–anchored PVS (3 patients), cadaveric bone–anchored suburethral sling (5 patients), and a vaginal patch sling (3 patients). Postoperative complications included a pelvic abscess related to a prior cadaveric sling and osteomyelitis pubis related to the prior bone anchored sling. One (7%) of the patients developed long-term urinary retention and is on intermittent bladder catheterization; 86% of the patients considered themselves cured or improved.

Value of Autologous Pubovaginal Sling in Urethral Reconstruction. Urethral and bladder neck reconstruction for fistulae and diverticula requires restoration of both anatomy and function. An autologous PVS serves an important role in these reconstructions. Anatomic damage refers to tissue loss and can range from a urethrovaginal fistula to absence of the urethra or vesical neck. The causes of damage include protracted obstetric delivery, antiincontinence procedures, urethral diverticulectomy or other sequelae of urethral diverticulum, aggressive transurethral resection of the bladder neck, long-term indwelling urethral catheter, pelvic trauma, tumors, and irradiation (Blaivas and Jacobs, 1991). The goals of surgical repair are to restore function and anatomy while fashioning an unobstructed urethra and maintaining continence (Blaivas and Heritz, 1996).

Swiertzewski and McGuire (1993) reviewed the records of 14 women who underwent urethral diverticulectomy during a 3-year period. Only 8 (57%) had symptoms of SUI, confirmed on urodynamics in 7. All 7 women were cured with a diverticulectomy and autologous PVS. One patient demonstrated DO. These investigators concluded that the presence of a urethral diverticulum did not compromise the outcomes of the PVS. Chancellor and coworkers (1994) performed a PVS procedure in 14 women with destroyed urethras secondary to long-term indwelling Foley catheter management of neurogenic bladder dysfunction. Greater tension was applied to the sling suspension to achieve urethral closure. Ten patients had simultaneous intestinal augmentations or diversions, 2 had concurrent suprapubic tube placement, and 2 had adequate bladder capacity and compliance and only had PVS performed. All of the patients achieved continence. The PVS is a simpler addition and avoids the risk of fistula formation associated with bladder neck closure, which has historically been used in this population. Blaivas and Heritz (1996) performed a retrospective study of 49 women who underwent a one-stage urethral reconstruction at up to 11-year follow-up. Forty-one of these women had a concomitant PVS placed for management of preoperative SUI. Only 1 patient experienced obstruction and DO after PVS placement, requiring incision and subsequently is continent. Three of 5 women who had Pereyra repairs for SUI required secondary PVS and are also now continent.

Faerber (1998) reported on 16 women who had simultaneous PVS and diverticulum repairs after UDS. All were either significantly improved (12%) or cured (88%), and only 2 patients developed de novo urgency. The average time for achieving adequate bladder emptying after repair was 5 weeks. For the initial 2 weeks, a Foley catheter is usually in place for urethral healing. Rovner and Wein (2003) reported on the circumferential urethral diverticulum repair among 9 patients who received either end-to-end urethroplasties or dorsal urethroplasties. Based on preoperative SUI status or evidence of open bladder neck on preoperative cystography, 8 patients were recommended to have a concurrent PVS procedure performed. All patients had a rectus fascial PVS sling placed, except 1 who requested a porcine PVS and 1 who refused to have PVS repair. All patients were continent postoperatively, except the patient who refused the PVS procedure and developed de novo SUI. Flisser and Blaivas (2003) evaluated the results of 74 women with urethral pathologic processes that required vaginal flap reconstructions. A majority of the women had required reconstruction for a diverticulum or urethral fistula secondary to iatrogenic causes. Fifty-six of these women had a concomitant PVS placed. Eighty-seven percent (54 women) considered themselves cured postoperatively. Three of 4 patients who had persistent SUI had failed a modified Pereyra procedure but were cured at reoperation. One patient was

continent after operative revision of the PVS for obstruction and significant UUI.

Allograft

The autologous fascial PVS remains a gold standard with efficacious and durable outcomes, but, owing to the morbidity of graft procurement, cadaveric allograft slings were introduced. This was to provide decreased morbidity, reduce operative time, and minimize pain (Table 73–4). There are limited outcome data owing to questions surrounding efficacy and durability. Early literature used cadaveric frozen or freeze-dried fascia lata with a variety of fixation methods, including suture fixation and bone anchors (Handa et al, 1996; Wright et al, 1998; FitzGerald et al, 1999; Brown and Govier, 2000; Carbone et al, 2001; Flynn and Yap, 2002; O'Reilly and Govier, 2002; Walsh et al, 2002; Amundsen et al, 2003; Richter et al, 2003; Almeida et al, 2004; Howden et al, 2006). Experience has shown that tissue processing techniques can have deleterious effects on cadaveric sling outcome (Nazemi et al, 2008). Lemer and associates (1999) found differences in both tissue integrity and durability between freeze-dried fascia and solvent-dehydrated fascia. They theorized that ice crystal formation characteristics of tissue freezing may disrupt the collagen matrices, yielding poor strength properties. **Failure rates for frozen or freeze-dried grafts range from 6.0% to 37.6%** (Handa et al, 1996; Wright et al, 1998; FitzGerald et al, 1999; Brown and Govier, 2000; Carbone et al, 2001; Flynn and Yap, 2002; O'Reilly and Govier, 2002; Walsh et al, 2002; Amundsen et al, 2003; Richter et al, 2003; Almeida et al, 2004; Howden et al, 2006).

Handa and associates (1996) reported on some of the earliest short-term outcomes for cadaveric fascia lata, with promising cure rates. Two of their patients (12%) developed abdominal wound infections, which resolved with local care, including drainage.

*Questionnaire results are significant ($P = .04$ and $P = .03$), indicating patients with preoperative MUI have increased risk of postoperative dissatisfaction.
†Represents 5/25 allograft suburethral slings.
CAPS, cadaveric sling placement and prolapsed repair; CATS, cadaveric sling placement; MUI, mixed urinary incontinence; NA, not available; SUI, stress urinary incontinence; UDS, urodynamic study; UUI, urgency urinary incontinence.

They reported de novo urgency in 36% of the cases, whereas DO resolved in one of four cases. Two of the 3 patients who had SUI recurrence were continent after a synthetic midurethral sling. FitzGerald and associates (1999) reported on 35 patients undergoing cadaveric fascia lata sling placement with a high failure rate of 17%. Symptom recurrence was seen very early (1 week to 5 months). Histopathologic analyses of the retrieved material indicated ongoing processes in the failed graft: disorganized remodeling, areas of graft degeneration, and evidence of immune reaction. These findings led them to conclude that freeze-dried, irradiated donor fascia lata grafts should not be used for urogynecologic procedures due to the high material failure rate.

Three studies (Amundsen et al, 2000b; Walsh et al; 2002; Richter et al, 2003) documented good results without significant adverse outcomes using freeze-dried fascia lata. Amundsen and associates (2000b) utilized questionnaires and pad testing to assess incontinence outcomes in a complex population (80% having had prior pelvic surgery and 49% having had at least 1 prior anti-incontinence procedure). Sixty-five percent of the group had MUI preoperatively, with 41% of them having resolution of UUI; 15% developed de novo UUI, and no erosions were present. In 1 patient who underwent reoperation for a failed sling the fascia lata was found completely intact. The sling was torn from its nonabsorbable suture material, similar to a previously reported case (Chaikin and Blaivas, 1998; Amundsen et al, 2000b). Walsh and colleagues (2002) prospectively evaluated 31 women with promising short-term follow-up. There was complete resolution of SUI in 94% at both 4 months and 1 year. There was also a reduction in the incidence and severity of urgency and UUI after surgery, reflected in the declining use of anticholinergic surgery from before to 4 months and 1 year postoperatively (55% to 32% to 26%). Richter and colleagues (2003) conducted a prospective long-term study using validated questionnaires for a follow-up of 48 months. Difficulty emptying the bladder was described by 58.2% of patients at 12 month follow-up, with 34.2% describing it as slight. By 48 months, 50% of patients continue to have difficulty emptying their bladders. Patients reported a 90.2% satisfaction rate at 12-month follow-up and continued to be satisfied at 48-month follow-up (85.7%).

Two groups documented high failure rates with freeze-dried allograft (Carbone et al, 2001; O'Reilly and Govier, 2002). Carbone and associates (2001) used cadaveric fascia with titanium bone anchors for placement bilaterally in pubic bones. They reported a 38% failure rate and 17% reoperation rate at short-term follow-up of 11 months. Average time to reoperation was 9 months (3 to 15 months). Intraoperative findings at reoperation revealed the titanium anchors to be in position, the polypropylene sutures to be intact, and retropubic fibrosis and scarring of the urethropelvic ligament suggesting appropriate placement of the sling. All of the allogenic fascia appeared to be fragmented, attenuated, or simply absent. These authors have subsequently abandoned the use of cadaveric fascia allografts in all the PVS procedures at their institution. O'Reilly and Govier (2002) reported high intermediate failure rates in 121 women. Eight patients had recurrent SUI at a mean of 6.5 months (4 to 13 months); 7 of the 8 women had previous incontinence surgery and had multiple comorbidities, including neurologic disease, diabetes, previous pelvic irradiation, and previous pelvic surgery. Based on these results and findings by Lemer and associates (1999), this group discontinued use of fresh frozen grafts and switched to solvent dehydrated cadaveric fascia and dermal grafts.

Some studies support the efficacy of solvent-dehydrated fascial slings (Frederick and Leach, 2005; Onur and Singla, 2005; Pianezza et al, 2007; Nazemi et al, 2008), yet previous reported failures coupled with the consistent success and rapid adoption of synthetic midurethral slings has led to abandonment of all types of cadaveric allograft at most centers. Thus there are few data to assess long-term outcomes and define sling outcomes after solvent dehydration techniques (Nazemi et al, 2008).

Huang and colleagues (2001) were the earliest to report unfavorable experiences using solvent-dehydrated allograft in 18 women at short-term follow-up. They reported a 27.8% failure rate with full recurrence of incontinence and subsequently stopped using all allograft as a sling material. On reoperation with an autologous PVS for recurrent SUI the allograft remained only rudimentary and was very friable. Histologic examination of the retrieved allograft revealed wavy collagen fibers with loosely packed fibroblasts and focal areas of degeneration. Carey and Leach (2004) prospectively compared octogenarians and younger women undergoing treatment for incontinence with bone-anchored solvent-dehydrated cadaveric fascia lata. No statistically significant difference in outcome parameters was identified. The rates of de novo urgency were similar between the two groups, yet persistent urgency was greater among the octogenarians. Onur and associates (2005) reported 80% cure rates at 12-month follow-up. In 5 patients (20%) complete recrudescence of symptoms occurred within 6 months of surgery. Frederick and associates (2005) reported on prospective, intermediate-term results for cadaveric prolapse repair with bone-anchored sling (CaPS), with dry/cure rate and improvement rate of 56% and 82%, respectively. There was one case of osteitis pubis related to use of transvaginal bone anchor fixation that resolved with conservative management. Fifty-six percent of the failures occurred after 12 months of follow-up: 80% of these women were satisfied and 77% stated that they would undergo the CaPS procedure again. Using validated questionnaires (i.e., Urogenital Distress Inventory, Short Form [UDI-6]; Incontinent Impact Questionnaire [IIQ-7]), Pianezza and associates (2007) reported on similar levels of long-term patient satisfaction. Patients with preoperative MUI were at the greatest risk for postoperative dissatisfaction. Nazemi and associates (2008) described durable improvements in incontinence episodes, patient satisfaction, and validated quality of life end points when comparing a CaPS and CaTS (cadaveric sling placement alone) cohort. Yet there was a reduction in dry rates with extended follow-up (24 months, 48 months, and 60 months), especially in the CaTS group (23%, 18%, and 9% respectively); 4% of patients presented with sling extrusion and 4% required sling incision and urethrolysis.

Because of early and intermediate graft failure with cadaveric fascia lata, surgeons were prompted to use alternative materials: cadaveric dermal grafts. Crivellaro and associates (2004) presented their prospective series of patients treated with bone-anchored Repliform cadaveric human dermal allograft (LifeCell Corp., The Woodlands, TX) PVS. There was a 22% failure rate, yet based on patient report there was average incontinence improvement at 9 months of 85% and at 18 months of 80%. The 2 patients requiring long-term intermittent catheterization had neurogenic bladders. Owens and Winters (2004) assessed outcome and patient satisfaction with Duraderm allograft (C.R. Bard, Covington, GA). Initial results were promising, with a dry rate of 68% and improved rate of 24%. At intermediate follow-up only 32% of the patients were dry and 36% noted improvement. Two of the 8 patients who experienced graft failure underwent periurethral injections with significant improvement, and 1 is dry after an autologous sling procedure. Surgical reexploration revealed almost complete absence of graft material, without evidence of infection or excessive inflammatory response.

Six studies have compared the outcomes of women undergoing a PVS procedure using either autologous or cadaveric allograft fascia (Wright et al, 1998; Brown and Govier, 2000; Flynn and Yap, 2002; Almeida et al, 2004; Howden et al, 2006; Onur and Singla, 2008). Four groups found the outcomes comparable with equally high success rates and no negligible difference in complications. They concluded that allograft fascia lata may be used as an alternative to autologous fascia for PVS, to reduce operative time and decrease postoperative pain and disability (Wright et al, 1998; Brown and Govier, 2000, Flynn and Yap, 2002; Onur and Singla, 2008). With long-term follow-up, two groups noted superior continence outcomes in the autologous group (Almeida et al, 2004; Howden et al, 2006). Almeida and associates (2004) did not report adverse outcomes in either group. Howden and colleagues (2006) found recurrent symptoms occurred in a higher proportion in the cadaveric group (39.6%) compared with the autologous group (28.3%; P = .04). The reoperation rate was also higher for the allograft group (12.7% vs. 3.3%, P = .003).

Xenograft

A number of different sling materials are available and have been discussed. Because of the morbidity of autologous fascial harvest, high failure rates of allograft materials, and high erosion rate with synthetic PVS materials, xenografts are an attractive option. **They are associated with a low rate of infection, rejection, or extrusion, owing to their incorporation into host tissue** (Rutner et al, 2003). **Studies present in the literature utilize porcine dermis (Pelvicol), porcine SIS, and bovine dermis as xenografts for use in PVS surgery** (Arunkalaivanan and Barrington, 2003; Rutner et al, 2003; Abdel-Fattah et al, 2004;Wiedemann and Otto, 2004; Giri et al, 2006; Wilson et al, 2008) (Table 73–5). Rutner and colleagues (2003) were the first to describe the use of porcine SIS as a bone-anchored PVS in 152 patients with long-term follow-up. They reported cure rates comparable to those with the autologous sling. Among the 7 patients who experienced graft failure (4.6%), 5 had recurrent SUI within 3 months of surgery and the other 2 had recurrences at 9 and 11 months postoperatively. Two of the failures were related to the bone anchors. One patient had repeat porcine SIS PVS, with continued failure to relieve incontinence and 1 patient became dry after carbon bead bulking injections. One patient achieved continence after a urethrolysis 2 years postoperatively. At reoperation, grossly no evidence of the implanted SIS material was found. Biopsy specimens of the periurethral tissue revealed fibrous and muscular tissues with a few remnants of SIS. Wiedemann and Otto (2004) performed the first histopathologic examination of porcine SIS in a series of 15 women with SIS PVS. Three reoperations (20%) were necessary owing to recurrent SUI at a mean of 12.7 months. All 3 patients underwent reoperation with implantation of a polypropylene mesh and achieved immediate continence. Biopsy specimens from the SIS band under the vaginal mucosa revealed only focal residues of SIS without any evidence of tissue reaction. There was also no evidence of a significant immunologic or chronic inflammatory reaction. These authors concluded that the advanced incorporation of the implant would lend to good biocompatibility.

Arunkalaivanan and Barrington (2003) first reported on Pelvicol in a randomized, short-term trial comparing Pelvicol PVS with the tension-free vaginal tape (TVT) procedure. Questionnaire-based cure rates were comparable between the two: 85% in the TVT group and 89% in the Pelvicol implant group. Abdel-Fattah and associates (2004) presented the 3-year follow-up data for this prospective trial. Cure rates remained high and comparable between the two groups: 79.1% for the TVT group and 77.8% for the Pelvicol group. There was no statistical difference in regard to complication rates or postoperative pad score. Giri and colleagues (2006) compared the 3-year efficacy of Pelvicol with autologous rectus fascia in 101 consecutive, nonrandomized patients. Although porcine dermis reduced the associated surgical morbidity, there were significantly inferior long-term cure rates as compared with the autologous PVS. Treatment failure occurred by 9 months in the autologous group and by 24 months after the Pelvicol sling. Repeat UDS indicated SUI as the cause of treatment failure in 18 of 20 (90%) women treated with porcine dermis but only in 3 of 8 (6.5%) women after a rectus fascial sling. These authors concluded that Pelvicol should not be used as a substitute for rectus fascia.

Bovine dermis is the most recently reported material used for a xenograft PVS (Wilson et al, 2008). Women at high risk for sling failure (with advanced age, previous surgical failure, intrinsic sphincter deficiency) underwent either a bovine dermis or autologous rectus fascia PVS procedure with short-term follow-up. Global

Table 73–5.

Outcomes with Xenograft Pubovaginal Sling

STUDY	NO. PATIENTS	TYPE	AGE	PURE SUI	FOLLOW-UP (mo)	CURED/ IMPROVED/ FAILED	ASSESSMENT OF OUTCOME	DE NOVO URGENCY	PERSISTENT URINARY RETENTION
Rutner et al, 2003	152	Porcine SIS*	NA	75 (49%)	2.3 yr (4-48 mo)	93.4%/2%/4.6%	Subjective	5	0
Abdel-Fattah et al, 2004	74	Pelvicol†	53 (34-75)	NA	36 mo	77.8% (dry)/9.7%/12.5%)	Subjective; mail questionnaire	17.6%	0

Wilson et al, 2008	37	Xenform Matrix‡	67.7	NA	19.5 mo	83.8% SUI cure rate; 54.1 global cure rate	Cough test; questionnaire	NA	NA

*Porcine SIS is an acellular, collagen matrix of processed small intestine submucosa.
†Pelvicol is gamma sterilized, cross-linked porcine skin.
‡Xenform Matrix is acellular bovine dermis.
NA, not available; SUI, stress urinary incontinence.

cure rates and SUI cure rates were not statistically different between the two groups. Four women (8.3%) in the autologous group were reoperated with injections, repeat autologous PVS placement, and anterior colporrhaphy with interposition graft. Two women (5.4%) in the bovine dermis group underwent additional interventions: injections and a repeat autologous PVS placement. Biopsy specimens of the bovine dermis sling material during reoperation (for SUI recurrence at 3 months) revealed the sling was replaced by fibrosis, hemorrhage, and mild chronic inflammatory infiltrate, with no acellular component. Tissue breakdown, represented by intermittent areas of myxoid degeneration, was present and may indicate evidence of early graft failure.

Key Points: Pubovaginal Sling Outcomes and Urethral Reconstruction

- The autologous PVS is associated with cure rates of 46% to 97% with variable measurements of outcome utilized.
- De novo urgency and UUI rates are 2.0% to 20.8%.
- There are no risk factors that consistently predict the outcomes after a PVS. Only one study reports on the rate of cure with PVS for recurrent SUI (86%), and the PVS appears to be a valid and useful treatment option.
- Autologous PVS serves an important role for providing continence and robust tissue coverage in urethral reconstruction (urethral fistula, urethral diverticulum, destroyed urethra).
- Freeze-dried allograft is associated with higher failure rates (6.0% to 37.6%) and has been predominately replaced by solvent-dehydrated fascia.
- Pelvicol, SIS, and bovine dermis are the xenografts used in PVS surgery, with cure rates of 31% to 93.4%. In randomized trials, porcine dermis was associated with significantly inferior long-term cure rates compared with the autologous PVS (Arunkalaivanan and Barrington, 2003).

Complications

Erosion and Extrusion

The incidence of sling erosion is dependent on the composition of sling material. Synthetic slings erode 15 times more often into the urethra and extrude 14 times more often into the vagina than autologous, allograft and xenograft slings (Blaivas and Sandhu, 2004). This is based on a meta-analysis of peer-reviewed literature in 1997, citing a urethral erosion incidence of 0.02% and vaginal extrusion of 0.007% in 1515 patients who underwent synthetic slings. This is compared with a urethral erosion incidence of 0.003% and vaginal extrusion of 0.0001% in 1715 patients undergoing autologous and allograft slings (Leach et al, 1997). In subsequent studies, most erosions have been associated with synthetic slings, particularly woven polyester slings (Summit et al, 1992; Bent et al, 1993; Weinberger and Ostergard, 1995; Myers and LaSala, 1998; Kobashi et al, 1999; Duckett and Constantine, 2000; Clemens et al, 2000; Amundsen et al, 2003; Chen et al, 2010), but recently there are a few reported cases of autologous and allograft slings (Handa and Stone, 1999; Golomb et al, 2001; Amundsen et al, 2003; Bradley et al, 2003; Blaivas and Sandhu, 2004) (Table 73–6).

Most urethral erosions are diagnosed 1 to 18 months after the original surgery, with a mean presentation of approximately 9 months. **Presenting symptoms often include urinary retention, UUI, and MUI. Synthetic sling erosions are often also associated with vaginal discharge, vaginal pain/pressure, suprapubic pain, and recurrent UTIs. The etiology is multifactorial, including local tissue factors (i.e., postsurgical scarring, urethral atrophy, estrogen deficiency, and radiation-induced ischemia) or surgical techniques (i.e., excessive tension, dissection too near urethra, or perforation of urethra or bladder)** (Blaivas and Sandhu, 2004). Golomb and colleagues (2001) reported a rare case of autologous sling erosion into the midurethra after traumatic urethral catheterization for prolonged urinary retention.

Erosion of an autologous PVS is rare. There are only four cases of erosions documented in peer-reviewed literature. Handa and Stone (1999) and Golomb and colleagues (2001) reported on an individual case of an autologous sling eroding through the midurethra. Possible causative factors include misplacement or incorrect technique in sling passage or positioning, excessive tension, or traumatic urethral instrumentation after placement of a PVS (i.e., for retention, hematuria clot evacuation, surveillance cystoscopy). In both cases the eroded portion of the sling was excised and the urethra was closed (Handa and Stone, 1999; Golomb et al, 2001). Clemens and colleagues (2000) described two cases of bladder dome erosion by an autologous rectus fascial sling that presented as recurrent UTI, dysuria, and UUI. One of these patients presented with a bladder calculus on sling material that was visible on cystoscopy. The other woman presented with edema and suture at the dome. In both cases adequate cystoscopy with 30- and 70-degree lenses after Stamey needle passage may have avoided this. Both cases were successfully managed with endoscopic removal of stitches and treatment of the bladder stone. No further treatments were necessary (Clemens et al, 2000).

Eight cases of allograft erosion and extrusion were found within the literature between three groups (Clemens et al, 2000; Amundsen et al, 2003; Bradley et al, 2003). Among the three cases of vaginal extrusion (Clemens et al, 2000; Bradley et al, 2003) of an allograft PVS, patients commonly presented with vaginal bleeding, persistent SUI, and irritative voiding symptoms. All three cases were managed successfully with transvaginal exploration, partial sling removal, and closure of the vagina. The patients did not require reoperation or further treatment. **Management of autologous and allograft sling urethral erosion is usually done with incision or excision of that part of the sling that has eroded and simple closure of the urethra** (Blaivas and Sandhu, 2004). Rarely are additional coverage measures (i.e., Martius flap) required. **No cases of xenograft erosion or extrusion are present in the literature.**

Erosions and extrusion of a synthetic PVS were very common and associated with significant morbidity. Synthetic material is no longer utilized for bladder neck slings. In fact, the ProteGen sling (Boston Scientific, Natick, MA) was recalled in January 1999 because of the high erosion rates (Clemens et al, 2000). The other 60 cases of erosion and extrusion found within the literature are cases of synthetic PVS: ProteGen, Mersilene, silicone, GORE-TEX or polypropylene (Myers and LaSala, 1998; Kobashi et al, 1999; Clemens et al, 2000; Duckett and Constantine, 2000; Amundsen et al, 2003). Rates of rejection or erosion, usually requiring removal of the synthetic material historically, vary from 2.7% to 22% (Summit et al, 1992; Bent et al, 1993; Weinberger and Ostergard, 1995). **Most authors agree that erosions from synthetic slings require complete removal of the sling and all other foreign materials (sutures, bone anchors, screws) whenever present** (Blaivas and

*1 of 7 patients re-presented 3 months after excision with further vaginal erosion.
†7 of 12 patients (58%) with urethral or vaginal erosions experienced recurrent SUI after sling removal.
SUI, stress urinary incontinence.

Sandhu, 2004). Myers and LaSala (1998) reported on 7 patients with vaginal extrusion among 116 women with bladder neck Mersilene mesh slings. All of the cases presented within 4 to 12 weeks of initial operation and were managed with trimming of visible mesh, excision of granulation tissue, and re-covering of erosion. One of these 7 women presented with recurrent extrusion (Myers and LaSala, 1998). Of note, whereas follow-up of these 7 women was up to 37 months, many of the other 109 patients were likely also to have had subsequent erosions or extrusions. Kobashi and colleagues (1999) published the multi-institutional results of ProteGen sling (bovine collagen with bone anchors) erosions and extrusions in 34 women. The most common presenting complaints were delayed vaginal discharge in 21 (32%), vaginal pain or pressure in 21 (62%), suprapubic pain in 11 (32%), and recurrent UTI in 5 (15%). The synthetic sling was entirely removed. Attempt was additionally made to remove all bone anchors. One patient with residual pain after sling removal had a "hot area" at the bone anchor site revealed on bone scintigraphy (Kobashi et al, 1999). Duckett and Constantine (2000) came to a similar conclusion about silicone as sling material as other groups reported with the ProteGen sling. Among the initial 7 women who had a silicone PVS placed, 5 experienced silicone erosion and sinus formation. The study was terminated due to the high complication rates. Clemens and colleagues (2000) reported on complications associated with 10 cases of ProteGen and 1 case of GORE-TEX. This included four ProteGen extrusions, six ProteGen erosions with extrusions, and one GORE-TEX extrusion. All of the cases were managed with transvaginal removal of sling sutures and bone anchors wherever possible. Five of these 14 women had recurrent SUI, including 1 who opted to have an autologous sling placed at the time of ProteGen sling removal owing to persistent SUI after the initial surgery. Other symptoms resolved among all of the patients (Clemens et al, 2000). Amundsen and colleagues (2003) performed complete sling removal, urethral repair, and additional placement of a Martius flap in patients with two of the three synthetic erosions that occurred. They noted an intense inflammatory reaction with superimposed infection, leading to extensive urethral loss. This was thought to contribute to the significant recurrent SUI (ISD), requiring a PVS and collagen (Amundsen et al, 2003). **The incidence of recurrent SUI in contemporary series of urethral erosions after synthetic PVS placement is 74% to 100%, often necessitating a secondary PVS** (Kobashi et al, 1999; Clemens et al, 2000).

There are few studies concerning treatment of urethral erosions after a PVS procedure, success rates, and rates of continence. **Urethral reconstruction is successful a majority of the time, yet continence is achieved in only 17% to 56% of patients** (Clemens et al, 2000; Amundsen et al, 2003) **who had erosions secondary to a synthetic sling. When erosions were managed with concurrent placement of a new PVS, Flisser and Blaivas** (2003) **reported an 87% continence rate. Secondary procedures such as bulking agents and PVS surgery are successful in a majority of patients** (Blaivas and Sandhu, 2004). **However, if the bladder neck is involved with the erosion the authors have noted much lower overall continence rates, even with the use of concomitant autologous slings at the time of reconstruction.**

Key Points: Erosion and Extrusion

- The incidence of erosion is dependent on the sling material, with synthetic slings eroding 15 times more often into the urethra and 14 times more often into the vagina than other materials. For this reason the synthetic PVS is no longer used for support at the bladder neck.
- Synthetic sling erosion presents as vaginal discharge, pain, suprapubic pain, and recurrent UTIs and requires complete removal of the PVS.
- The incidence of recurrent SUI after synthetic PVS urethral erosion is 74% to 100%, often requiring a secondary PVS.
- Erosion with other materials has more association with urgency, UUI, and irritative voiding symptoms and requires excision of eroded portion of sling. Erosion of autologous PVS is rare.

Voiding Dysfunction Secondary to Bladder Outlet Obstruction

The voiding dysfunction that develops from iatrogenic outlet obstruction by a PVS is related to **obstruction, DO, or impaired detrusor contractility.** The incidence of voiding dysfunction after continence surgery varies widely in the literature, from 2.5% to 35% (Foster and McGuire, 1993; Carr and Webster, 1997; Cross et al, 1998; Chaliha and Stanton, 1999). The traditional PVS is known to have higher rates of voiding dysfunction than the Burch colposuspension (Stanton et al, 1983). A multi-institutional, randomized clinical trial (SiSTER) compared the autologous rectus fascia PVS procedure and the Burch colposuspension. Although success rates were higher for women who underwent the sling procedure there was significantly greater voiding dysfunction (63% vs. 47%, $P < .001$): UTIs, difficulty voiding, and postoperative UUI (Albo et al, 2007). A meta-analysis by the **AUA Stress Urinary Incontinence Clinical Guidelines Panel reported that the incidence of urinary retention more than 4 weeks after PVS placement was 8% and the risk of permanent retention "generally does not exceed 5%"** (Leach et al, 1997). In a series of 252 women at 4-year follow-up, Morgan and colleagues (2000) reported a prolonged **urinary retention rate of only 2.4%. Patients may present with complete urinary retention or obstructive voiding symptoms and less obvious irritative symptoms, including UUI** (Carr and Webster, 1997). **Obstruction may present as recurrent UTIs, prolonged suprapubic pain, and painful voiding,** even if emptying is completed. Nitti and colleagues (2002) found that 16% of patients who required PVS lysis did not have obstructive symptoms or retention. Some studies report **persistent postoperative UUI and urgency as presenting more commonly (8% to 25%) than frank retention** after a PVS (Cross et al, 1998). The risk of iatrogenic obstruction usually relates to technical factors (i.e., placement and tension of sutures or sling material). When there is an inadequately supported bladder neck/proximal urethra there is potential for continued SUI. When the sling is tied too tightly there is excessive elevation of the bladder neck toward the pubic bone, causing "hypersuspension" or overcorrection of the urethrovesical angle.

Preoperative voiding dysfunction affects a patient's ability to empty after anti-incontinence surgery. **Detrusor hypocontractility, a condition that is present preoperatively, may manifest symptomatically with even a "relative obstruction" when urethral resistance is increased by an anti-incontinence surgery.** During preoperative counseling these patients should be warned of the possibility of postoperative voiding dysfunction. Dysfunctional voiding or failure of relaxation of the external (striated) urethral sphincter may affect emptying after surgery (FitzGerald and Brubaker, 2001). A patient who habitually voids by abdominal straining may have difficulty emptying after incontinence surgery. Because of the variability of presenting symptoms after a PVS procedure it is important to ascertain the predominant symptom through a focused history. **The temporal relationship between anti-incontinence surgery and onset of persistent voiding symptoms is key.** For example, de novo urgency may actually exist as a result of urethral obstruction. On physical examination an abnormal urethral angulation, a foreshortened nonpliable vagina, or a nonmobile urethra may be noted. Hypersuspension is usually not evident on physical examination. The postvoid residual urine volume is very important in the evaluation of voiding dysfunction, although no clear cut-off values exist (Siddighi and Karram, 2007). **Cystoscopy is useful to rule out a bladder pathologic process, sling erosion, and a hypersuspended urethra. Videourodynamics are useful in selected cases at the physician's discretion. Most important remain the temporal relationship between the symptoms and the surgical procedure and the main criterion for a sling incision or urethrolysis.**

There are no well-established risk factors for patients who are likely to experience obstruction after anti-incontinence surgery. UDS has been used to investigate multiple factors to determine which may be predictive. Miller and associates (2003) noted that women undergoing an allograft PVS who voided with no or minimal detrusor pressure (19%) had a significantly increased risk of postoperative retention. In contrast, no patient with a detrusor contraction developed retention postoperatively. Weinberger and Ostergard (1995) studied 108 women undergoing synthetic PVS procedures and found that the absence of detrusor contractions predicted delayed returns to normal voiding. Valsalva voiding had no affect on the incidence of postoperative retention or voiding dysfunction in either of these studies. The association between low voiding detrusor pressures and Valsalva voiding with subsequent voiding dysfunction was not seen by others (McLennan et al, 1998). **UDS is useful in understanding voiding dynamics of incontinent women, yet low detrusor pressure or Valsalva voiding preoperatively should not exclude patients from having an anti-incontinence procedure.** Lemack and colleagues (2008) examined the preoperative and postoperative urodynamic data for patients enrolled in the SiSTER trial (prospective, randomized clinical trial comparing the PVS procedure with Burch colposuspension) to predict voiding dysfunction after surgery. UDS findings did not predict postoperative voiding dysfunction or the risk of surgical revision in the PVS group. Recently, there have been anecdotal data on correlation between preoperative postvoid residual urine volume and urodynamic $\dot{Q}$max with postoperative retention (Mitsui et al, 2007). **No study to date has shown a definitive relationship between preoperative urodynamic findings and risk of postoperative retention.**

A key factor in assessing voiding dysfunction is prolapse that was either uncorrected at the time of surgery or occurred postoperatively. **Prolapse of sufficient size may kink or angulate and externally compress the urethra.** Apical, anterior, and posterior prolapse must be ruled out as a cause of the urethral obstruction. Kobashi and colleagues reported on a technique of combined cystocele repair and PVS using a single piece of

cadaveric fascia. Although no patients required surgery for obstruction the follow-up was only 6 months and long-term data are lacking (Kobashi et al, 2000). There is a paucity of literature on the affects of concurrent PVS and prolapse repair on postoperative emptying and voiding symptoms. Barnes and associates (2002) reported on 38 women with grade 3 to 4 pelvic prolapse and occult SUI who underwent concurrent PVS with prolapse repair. No patient developed permanent urinary retention. Two (9.5%) of the women developed de novo UUI. Existing UUI resolved in 45%. These investigators concluded that concurrent surgery had little negative effect on postoperative bladder emptying. **Data are lacking on risk factors for voiding dysfunction after an anti-incontinence procedure performed with surgery for pelvic organ prolapse.**

Whereas transient urinary retention is common, most patients return to spontaneous voiding within the first 10 days (Zaragoza, 1996; Cross et al, 1998). **Obstruction after a PVS procedure may improve or resolve with time, which is the reason most physicians historically prefer waiting 3 months before considering surgical intervention.** Persistent voiding dysfunction is initially treated conservatively. This includes temporary catheter drainage, clean intermittent catheterization, timed voiding, double voiding, biofeedback, pelvic floor muscle training, and antimuscarinic agents, which are extremely effective in specific cases. Anecdotal evidence shows improvement in urethral obstruction with urethral dilation and downward traction. These results may vary from temporary relief to worsening of the urethral rigidity secondary to periurethral fibrosis (Zimmern et al, 1987; Beck et al, 1988). This, like resection or incision of the bladder neck, is likely to fail because the sling is extraluminal. Additionally, these procedures may be associated with damage to the sphincter or bladder neck, leading to worsened incontinence, in addition to postoperative fibrosis and bladder neck contracture (Ghoniem and Elgamasy, 1995). It is not the authors' practice to perform urethral dilation. When conservative measures fail, surgical intervention is indicated.

Surgical management of bladder outlet obstruction after a PVS procedure traditionally involves complete urethrolysis by a retropubic, transvaginal, or suprameatal approach, with success rates of 65% to 93% (Foster and McGuire, 1993; Carr and Webster, 1997; Cross et al, 1998; Goldman, 1999; Petrou et al, 1999). Most of these series include patients with obstruction after many different anti-incontinence procedures. Only two groups have stratified their results specifically for the PVS (Foster and McGuire, 1993; Petrou et al, 1999). Foster and McGuire (1993) reported that transvaginal urethrolysis was successful in 50% of PVS obstructions, which was less than both needle suspensions (75%) or retropubic urethropexy (63%). Their conclusion was that transvaginal lateral dissection is insufficient in relieving the direct suburethral compressive force of the sling. Petrou and coworkers (1999) reported on the suprameatal approach as superior to the transvaginal approach, allowing access and division of the lateral wings of the sling. Eight of 12 patients had successful results. In a series of 12 women, Petrou and Young (2002) reported resolution of obstruction in 10 patients with new-onset SUI (18% of women) after retropubic urethrolysis. Carr and Webster (1997) reported complete or significant resolution of symptoms in 86% of patients with retropubic urethrolysis. **Recurrent SUI after formal urethrolysis is reported as 0% to 19%** (Table 73–7).

Table 73–7.

Results of Therapy for Bladder Outlet Obstruction after Pubovaginal Sling (PVS) Surgery

STUDY	NO. PATIENTS	MANAGEMENT	TIME TO TREATMENT (MEAN)	SUCCESS RATE	RECURRENT SUI	REPEAT SURGERIES
Foster and McGuire, 1993	10	Transvaginal urethrolysis	25.9 mo (2-35)	50%	None	NA
Carr and Webster, 1997	51	Retropubic, vaginal, or infrapubic urethrolysis	15 mo (4-268)	86% (retropubic), 73% (vaginal), 25% (infrapubic)	13.7%	NA
Cross et al, 1998	15	Transvaginal urethrolysis	16 mo (3-36)	72%	1 patient	PVS 1 year after urethrolysis
Goldman et al, 1999	11	Transvaginal urethrolysis	14 mo (2-36)	84%	19%	NA
Petrou et al, 1999	12	Suprameatal transvaginal urethrolysis	1.5 yr (3 mo-6 yr	66.7%	None	NA
Defreitas and Herschorn, 2000	16	Lateral sling lysis	NA	94%	34%	NA
Amundsen et al, 2000	32	22 transvaginal urethrolysis 10 sling lysis	39 wk (5-150)	84% (not stratified by procedure)	12.5%	1 patient received collagen injections
Kusuda, 2001	5	Sling lysis	6 wk-2 yr	100%	None	NA
Nitti et al, 2002	19	Sling lysis	10.6 mo (3-72)	84%	17%	2 patients received collagen injections; 1 patient had repeat PVS
Goldman, 2003	14	Sling lysis	8.6 mo (3-26)	93%	21%	1 patient received polypropylene sling
Thiel et al, 2005	13 (2 lost to follow-up)	Sling lysis	65 days (36-235)	45% improved; 45% cured	7.7%	No repeat surgery

SUI, stress urinary incontinence.

Ghoniem and Elgamasy (1995) were the first to report on the successful use of sling incision and interposition of a free graft of vaginal wall for obstruction. **Sling incision has comparable success rates (84% to 100%) without the longer operative time and potential morbidity of a formal urethrolysis** (McLennan and Bent, 1997; Defreitas and Herschorn, 2000; Shenassa et al, 2000; Amundsen et al, 2000a; Kusuda, 2001; Nitti et al, 2002; Goldman, 2003; Thiel et al, 2005). Theoretically the interposition of autologous graft material between cut ends of the sling was to prevent recurrent incontinence. Others have found that this technique did not live up to this expectation. Shenassa and associates (2000) and McLennan and Bent (1997) used vaginal wall interposition in 12 and 4 women, respectively. The success rate was 92% and 100%, but SUI recurred in 25% in each series. Several small series have reported on successful sling incision without graft interposition. Kusuda and colleagues (2001) reported successful outcomes for 5 patients who underwent lateral sling incision. Defreitas and Herschorn (2000) had a 94% success rate in 16 women after lateral sling incision, with a 34% rate of recurrent SUI. Lateral incision is beneficial to avoid urethral injury in cases in which the sling is identified but the dissection plane between the urethra and sling is difficult. Amundsen and associates (2000a) used midline incision of a PVS in 10 of 32 patients, in whom the sling was easily identified. In the rest, a formal urethrolysis with entrance into the retropubic space was performed. The overall success rate was 84%, but the results were not stratified between sling incision and formal urethrolysis. In 9 of 12 of the obstructing autologous slings in this series the sling material could not be identified and was replaced by dense fibrosis. Nitti and colleagues (2002) reported on 19 women who underwent a PVS lysis for obstruction. The success rate was 84% and the recurrent SUI rate was 17%. Two of the 3 women who experienced failure of their procedures underwent subsequent successful retropubic urethrolysis. This allowed for complete release of all retropubic space scarring, which likely contributed to the failure of the suburethral sling release. Goldman (2003) performed simple sling incision in 14 women with iatrogenic urethral obstruction. This included 3 patients with a midurethral polypropylene mesh sling. Thirteen of 14 (93%) patients had complete or significant improvement of presenting complaints, and 1 (7%) required subsequent urethrolysis. Twenty-one percent (3 patients) developed recurrent SUI, with only 1 patient requiring treatment (repeat mesh midurethral sling). Long-term results after simple sling incision were reported on 13 women with catheter-dependent urinary retention after PVS surgery by Thiel and colleagues (2005). At 5-year follow-up, patients reported 45% cure and 45% improvement; 7.7% of the women noted recurrent SUI but chose to not pursue further therapy.

There are no preoperative or urodynamic parameters that predict success or failure of urethrolysis. Foster and McGuire (1993) found that patients with DO had a higher rate of failure but later studies contradicted this. Carr and Webster (1997) found the only parameter predictive of success was no prior urethrolysis. Nitti and Raz (1994) found that as the postvoid residual urine volume increased so did the failure. This has not been confirmed by others. Four of these women who failed to generate a contraction during UDS testing had successful urethrolysis. They also reported that UDS findings in patients whose procedures were considered failures after transvaginal urethrolysis failed to elucidate the reason for their continued voiding dysfunction. Because of the limitation of UDS in evaluation of these patients the temporal relationship of urethrolysis to the onset of symptoms is relied on as an indicator of obstruction. If a patient fails to resume voiding or improve significantly, then continued obstruction is suspected.

Failure of urethrolysis may be due to persistent or recurrent obstruction, DO, impaired detrusor contractility, or learned voiding dysfunction. Recurrent obstruction may result from periurethral fibrosis and scarring or intrinsic damage to the urethra that has occurred from the prior urethrolysis surgery. The most common reason is likely due to insufficient dissection and lysis of the urethra. Scarpero and colleagues (2003) reported on the value of repeat urethrolysis after failed urethrolysis in 24 women. Both transvaginal and retropubic approaches were chosen depending on the clinical situation. Obstruction was cured in 92%, but storage symptoms only resolved in 12%. Sixty-nine percent were improved and continued to require antimuscarinic therapy. SUI recurred in 18% of the women. This supports the use of repeat urethrolysis in the presence of initial failure or in cases in which the aggressiveness of the initial dissection is unknown. After an aggressive transvaginal urethrolysis, a retropubic urethrolysis may be considered (Scarpero et al, 2003).

Refractory storage symptoms after a urethrolysis are a challenging problem to treat. Overactive bladder symptoms are refractory in more than 50%, affecting patient satisfaction and quality of life. There are no predictors of outcome after urethrolysis, yet DO preoperatively may suggest an increased likelihood of refractory overactive bladder (Starkman et al, 2008b). **There are no established guidelines for management.** Twenty-five women with UUI after urogynecologic surgery (19 PVS, 3 retropubic suspension, and 3 transperitoneal vesicovaginal fistula repair; 4 required further urethrolysis) were retrospectively analyzed after sacral neuromodulation stimulation (SNS) therapy (Starkman et al, 2007). SNS was effective (80% reported > 50% improvement and 6 were continent), and there were no significant differences in response based on age, duration of symptoms, type of surgery, or urodynamic parameters. Starkman and associates (2007, 2008b) evaluated SNS in the management of 8 women who had at least one urethrolysis. Six patients had a favorable response during test stimulation and underwent implantation of a pulse generator. All 6 of the patients significantly improved, and the 2 who failed test stimulation perceived no change (Starkman et al, 2008b). In addition to antimuscarinic agents, SNS should be considered as an option for de novo or refractory urgency and UUI after urethrolysis.

Mixed Urinary Incontinence

The treatment of patients with mixed urgency and SUI is complicated and often involves a combination of anticholinergic therapy and surgery. Medical therapy for MUI is associated with significant resolution of the urgency component in only two thirds of patients (Nordling et al, 1979; Stephenson and Mundy, 1994). This therapy does not address the bladder outlet and would not be expected to achieve complete dryness. **Anti-incontinence surgery may cure or aggravate the urgency symptoms and lead to de novo urgency. This aspect of anti-incontinence surgery is unpredictable and a major cause of patient dissatisfaction.** Osman and associates (2003) evaluated outcomes of patients with stress and sensory UUI (no DO on UDS) compared with a control group of patients with pure SUI. Patients were divided between a Burch colposuspension study arm (Valsalva leak point pressure [VLPP] >90 cm H_2O) with 24 patients and a PVS study arm (VLPP < 90 cm H_2O) with 26 patients. Twelve PVS procedures and 8 Burch colposuspensions were performed among the SUI-only control subjects, using the same leak point parameters. The

Key Points: Voiding Dysfunction after a Pubovaginal Sling Procedure

- Obstruction, DO, and impaired detrusor contractility are the manifestations of voiding dysfunction from iatrogenic outlet obstruction by a PVS.
- The incidence of permanent retention is usually 5% or less (Leach et al, 1997). Persistent urgency incontinence and urgency (8% to 25%) are more common presenting symptoms in bladder outlet obstruction after a PVS than frank retention (Cross et al, 1998).
- The key to diagnosis is the temporal relationship between the anti-incontinence surgery and onset of voiding symptom. UDS is essential in these cases to diagnose and make an appropriate treatment plan.
- Transient urinary retention usually resolves within 10 days, and obstruction from a PVS may improve or resolve with time; therefore most surgical intervention is avoided until 3 months postoperatively.
- Reported success rates of surgical management of bladder outlet obstruction after a PVS procedure are 65% to 93%. There is a 0% to 19% recurrent SUI rate after urethrolysis. There are no preoperative variables that predict success or failure of urethrolysis. Overactive bladder symptoms are refractory in 50% of affected patients after urethrolysis and account for a significant portion of the reported failures.

incidence of persistent UUI was 12% among the PVS patients with MUI. Twenty percent of controls with PVS had de novo UUI. The incidence of residual urgency was not significantly higher than that of de novo urgency in those with genuine SUI. Chou and colleagues (2003) used a validated questionnaire, voiding diary, and pad testing to report outcomes of the PVS for MUI, compared with pure SUI. Among 98 patients, 46 (48.5%) had pure SUI and 52 (51.5%) had MUI (26% with DO). The cure/improved rates were 97% among the SUI group and 93% in the MUI cases ($P = .33$). Increasing episodes of urgency and UUI on preoperative voiding diary correlated directly with surgical failure, whereas voiding frequency was associated with cure. This frequent voiding may have been adapted by patients preoperatively to avoid incontinence. Stress-induced DO is unique and difficult to treat. It is thought that traction on the pelvic nerves when increased abdominal pressure is applied to weakened pelvic supportive tissue causes this form of DO (Serels et al, 2000). Records of 36 patients with Valsalva-induced DO were reviewed by Serels and associates. Seventy-five percent of patients had resolution of UUI, and 92% achieved cure. Leak point pressures did not correlate with outcome. **The presence of residual urgency is similar to de novo urgency after a PVS procedure. Increasing episodes of urgency and UUI may correlate with surgical failure. The PVS is an effective treatment option for stress-induced DO with cure rates similar to those of simple SUI.**

Fulford and colleagues (1999) were the first group to utilize videourodynamics in the assessment of how a PVS affects the urgency syndrome. Ninety-seven percent (83 of 85 women) were symptomatically cured of SUI but only 66 (78%) were satisfied with the surgical result, owing to persistence of urgency symptoms in 27. Among these 27 women, 9 (41%) had an open bladder neck at rest compared with 4 of 50 (8%) women without UUI ($P < .01$) postoperatively. The storage symptoms resolved in 69% (32 patients), almost all of whom had a closed bladder neck at rest. Yet the postoperative urgency symptoms were not significantly associated with any preoperative clinical or urodynamic variables. Schrepferman and associates (2000) attempted to predict urinary urgency resolution after a PVS procedure with preoperative videourodynamics. Seventy women with MUI were divided into two groups of sensory urgency (one or more episodes of subjective symptoms without DO) and motor urgency (one or more episodes of subjective urgency symptoms correlating with DO). DO was documented in 41 patients. They concluded that there was a significantly greater resolution of urinary urgency symptoms in those with low-pressure motor urgency than high-pressure motor urgency or sensory urgency. Overall, urgency resolution rate in patients with MUI was 51% in this study (Schrepferman et al, 2000). Stoffel and colleagues (2008) found no difference in preoperative videourodynamics between women with MUI and urodynamic DO and those without DO. MUI patients with DO had less improvement in UDI-6 scores than MUI patients without DO, despite similar reduction in pad use/day. **The presence of preoperative DO on UDS may relate to decreased quality of life and decreased urgency resolution rates after a PVS procedure. There are no data on consistent videourodynamic parameters that relate to outcomes of MUI after a PVS.**

Key Points: Pubovaginal Sling for Mixed Urinary Incontinence

- Treatment of these patients is complicated and involves a combination of anticholinergic therapy and surgery.
- The PVS is an effective treatment option for stress-induced DO with cure rates similar to those of PVS done for SUI only.
- The presence of preoperative DO may relate to decreased quality of life and decreased urgency resolution rates after a PVS procedure.
- There is no preoperative variable relating to outcomes of MUI after a PVS procedure.

Nonurologic Complications

Beyond discussion of voiding dysfunction and erosions after PVS placement, the AUA Female Stress Urinary Incontinence Clinical Guidelines Panel (1997) reported on surgical management of female SUI, which included summary data of published outcomes data on complications (Table 73-8). Although an extensive literature review was performed there was insufficient information to estimate the following complications: large bowel injury, peripheral nerve injury, and vascular injury. The literature available for UTI had variable definitions and bias. Due to death being a rare complication, the panel estimated a death rate of approximately 5 per 10,000 procedures, combining all SUI procedures (retropubic suspension, transvaginal suspensions, anterior repairs, and PVS surgeries).

Anger and associates (2007a) analyzed Medicare claims data and determined short-term complications after sling surgery among female beneficiaries aged 65 years and older. A total of 1356 sling procedures were performed between 1999 and 2001. In 3 months after the procedure, 12.5% women developed surgical or urologic complications and 33.6% were diagnosed with UTIs. At 1 year after the operation the following nonurologic complications were

Table 73–8.

American Urological Association Female Stress Urinary Incontinence Clinical Guidelines Panel Complication Summary

COMPLICATION	%
Postoperative urgency	
For patients with urgency and DO preoperatively	46 (24-68)
For patients with urgency and no DO preoperatively	34 (13-61)
For patients with no urgency but with DO preoperatively	20 (5-45)
For patients with no urgency and no DO preoperatively	7 (3-11)
Retention	
Longer than 4 weeks	8 (6-11)
Permanent	<5
Transfusion	4 (2-7)
General medical complications (significant/nonsignificant)	4 (2-5)/6 (3-10)
Subjective complications	6 (2-13)
Complications requiring surgery	3 (2-5)

DO, detrusor overactivity.

reported: bowel injury or obstruction (6.6%), cardiac (9.1%), thromboembolic (2.6%), pulmonary (15.3%), and other (22.1%). Multivariate analysis revealed that race, age, and comorbidity did significantly impact on both urologic and nonurologic complications. Nonwhite subjects were more likely to experience urologic and nonurologic postoperative complications. Women 65 to 69 years were significantly less likely to experience nonurologic complications or undergo treatment for outlet obstruction or re-treatment for incontinence than women older than 75 years.

MIDURETHRAL SLINGS

Since the inception of the PVS approximately a century ago, experimentation has continued with multiple types of slings composed of different materials using different suspension techniques. Materials used as sling constituents have included autografts, allografts, xenografts, and, more recently, synthetic variants. Methods of anchoring these slings have also undergone development and advancement; however, the ideal method of suspension remains to be completely defined. **Sling placement was classically described at the level of the bladder neck in an effort to correct urethral hypermobility and enhance pressure transmission invoked by intra-abdominal straining.**

However, competing theories arose initially as espoused by Zaccharin in the 1960s and DeLancey in the 1990s (Zaccharin, 1968; DeLancey, 1994). In these theories the importance of the pubourethral ligaments and their function in maintaining the integrity of urinary control **furthered the concept of the importance of the midurethral mechanism for preservation of urinary incontinence under stress circumstances. These findings further demonstrate the fact that hypermobility is a secondary finding noted in association with incontinence but not causative of the condition of effort-related urinary loss (SUI).** Studies performed by Asmussen and Ulmsten (1983) demonstrated the importance of the distal components of the urethra for preserving urethral closure during stress events. They demonstrated that **MUCP occurs at the level of the midurethra and this closure mechanism is associated with intrinsic urethral function in continent women.** Ingelman-Sundberg (1953) noted that the pubococcygeal muscles also played a role in the midurethral mechanism, inserting at the level of the midurethra just outside the vaginal epithelial wall, and propounded this anatomic finding as being important when considering methods to correct urinary incontinence. Westby and colleagues (1982) demonstrated that in continent women, midurethral closure is associated with the area of MUCPs on pressure evaluation of the urethra and considered this phenomenon to be due to the confluence of anatomic structures in that area.

Petros and Ulmsten (1993), **using these theories, proposed a unifying concept now known as the midurethra theory (previously the integral theory). They postulated that injury arising from surgery, parturition, aging, or hormonal deprivation led to weakening or damage of the pubourethral ligaments, impairing midurethral function and anterior urethral wall support, thus resulting in urinary incontinence. They theorized that this damage was not only a ligamentous injury but also a representation of weakening of the pubococcygeal muscles at the level of the midurethra.** It has been shown that weakness of soft tissue in this area and specifically connective tissue can contribute to urinary incontinence (Ulmsten et al, 1987). Ultrasound techniques provide greater understanding of the vesicourethral dynamics by giving a detailed view of the exact anatomic location of the midurethral sling. Lo and associates (2003) conducted early ultrasound studies to describe dynamic urethral kinking (or rotational urethral descent) as the morphologic feature (92% of the time) contributing to continence after a TVT procedure. Preoperative real-time imaging demonstrates the motion of anterior and posterior urethral walls in the same axis and vector, regardless of the urethral descent. Midurethral tape binding impedes the movement of the posterior urethra above the tape, directing its motion away from an inferior course in an anteroinferior or anterior direction. Inward movement of the posterior urethral wall results in urethral narrowing. Width, position, and appearance of slings on ultrasonography are similar: a V at rest, round angulation on Valsalva maneuver, and closed angulation at maximum retaining. It is closer angulation during a Valsalva maneuver that may be associated with postoperative voiding dysfunction (Dietz and Wilson, 2004; Masata et al, 2006; Chene et al, 2008; Kociszewski et al, 2008).

The Tension-Free Vaginal Tape Procedure

The TVT procedure was developed using the concepts of the integral theory. The provisions of this operation include **a minimally invasive approach, which would supplement the diminished midurethral mechanism and produce the ingrowth of new host tissues after implantation for purposes of further supplementing support introduced by the procedure.** As initially described, the procedure was performed with the patient under local anesthesia to allow ambulatory delivery of the intervention and enable intraoperative testing of the urethral compression.

Initially, several types of material were evaluated until the final material was chosen, **a synthetic polypropylene monofilament mesh with pore size under 150 μm. Also, this material allowed optimal migration of host inflammatory components (leukocytes and macrophages) into the**

mesh for purposes of infectious surveillance and host wound healing (imbibition and inosculation). It was found that this material was optimal for inciting fibrous tissue ingrowth. This type of mesh is known as a type 1 mesh and has previously been described in the general surgical literature as being favorable from the standpoints of its mechanical properties (stretch and elasticity) (Dietz et al, 2001, 2003). Efforts have been made to standardize the procedure by incorporating certain technical approaches and safety features for purposes of avoiding injury to surrounding structures. To date, more than 400,000 of these procedures have been performed worldwide.

The Procedure

The device consists of two specially curved 5-mm-diameter insertion needles that are attached to a 40-cm segment of polypropylene tape that is 11 mm wide. The tape is covered with a clear plastic sheath, which protects the tape from contamination and allows easy passage through host tissues. A rigid catheter guide is placed in the bladder with an 18-Fr Foley catheter to help deflect the bladder away from the locale of needle path insertion. An ergonomic handle is attached to the insertion needles for actual placement of the needles during the procedure. This handle is reusable and sterilizable.

The midurethra sling procedure (transvaginal tape) is performed with the patient in the dorsal lithotomy position with a significant degree of flexion (70 degrees or more) of the thighs. The patient has received parenteral sedation and then local anesthetics are placed in the region of insertion of the device (vaginal wall and retropubic space). Approximately 5 mL of local anesthetic is injected into the vaginal area as well as into the planned suprapubic insertion skin sites. For placement of retropubic local anesthesia, another 20 mL of local anesthetic agent is injected into the area along the posterior aspect of the pubic bone to the level of the urogenital diaphragm. Additional vaginal infiltration includes approximately 10 mL injected on either side of the urethra to the level of the urogenital diaphragm.

After appropriate anesthesia, two small suprapubic stab incisions are created just above the level of the symphysis pubis, approximately 2 cm lateral to the midline. A third midline vaginal incision approximately 1.5 cm wide is created approximately 1.5 cm from the external meatus of the urethra, between that structure and the bladder neck. After the vaginal incision is created, minimal dissection is performed using Metzenbaum scissors under the vaginal flaps on either side to elevate the vaginal epithelium from the underlying periurethral tissue to the level of the pubocervical fascia, which is not perforated. The TVT needle is then placed in the dissection tunnel immediately beneath the vaginal epithelium on one side of the urethra with the needle tip situated in close proximity to the lower rim of the pubic ramus. With the use of controlled pressure, the needle is elevated through the endopelvic fascia, into the space of Retzius, through the rectus muscles, and through the previously created suprapubic skin incision. During this maneuver the needle is kept in close contact with the intrapelvic surface of the pubic bone to avoid perforation of the lower urinary tract and also to avoid intraperitoneal entry. Tactile contact ensures direct apposition of metal to bone, as does slow graded pressure during needle advancement.

Simultaneous deflection of the lower urinary tract is accomplished during insertion using the catheter guide and catheter with the pelvic viscera deflected away from the side of needle insertion. The same maneuver is performed contralaterally so that each needle exits through the appropriate skin incision. Cystoscopy is performed to exclude needle penetration of the lower urinary tract. The use of a 70-degree lens is essential, as is complete distention of the bladder with irrigant to exclude subtle tangential injury. If perforation is noted, the needle is withdrawn and passed once more in the same area in an effort to avoid further perforation. Once cystoscopy has demonstrated no evidence of bladder injury, the tape is brought through the incisions and tension adjustment of the tape is performed. Tension adjustment is most commonly performed by inserting either a surgical instrument (clamp) or a metallic sound between the tape and urethra while the covering plastic sheath is removed from the field. The tape is set to tension such that with the bladder full to 300 mL of saline and the patient now aroused and asked to cough, no incontinence occurs during the stress maneuver. Redundant tape is then excised at the level of the suprapubic skin incisions, and all incisions are closed (Fig. 73–8).

The procedure may also be performed with the use of regional or general anesthesia according to the surgeon's preference. Outcome data support the incorporation of midurethral sling techniques with concomitant vaginal prolapse repairs.

Results

In reviewing the extensive results reporting for the midurethral sling, several caveats must be entertained. Outcomes are reported in varying fashions using different tools, lengths of follow-up, and overall definitions of success and failure. These factors should be kept in mind when attempting to cross-compare different groups and procedural nuances.

Initial results with the midurethral sling technique approximated 80% (author-defined) success rates (Ulmsten et al, 1996). A subsequent prospective multicenter trial that included 130 women with genuine SUI who were observed for 1 year revealed success rates of 91% (Ulmsten et al, 1998). Seven percent were considered improved, and only 2% were deemed failures. Complication rates were low, including one bladder perforation and one wound infection. Voiding dysfunction was also relatively low, with 1 patient experiencing retention for 12 days, which resolved spontaneously, and 3 patients with less than 3 days of voiding dysfunction (regarding catheterization), which the authors defined as a short-term voiding problem.

On the basis of these findings, further studies were then embarked upon. Nilsson and Kuuva (2001) evaluated 161 consecutive TVT operations in cases of which 28% had failed prior incontinence surgery, 11% had ISD, and 37% had MUI. At 16 months mean follow-up, the overall objective cure rate was 87%, with 7% significantly improved and another 5% considered failures. Bladder injury rate at the time of insertion was 3.7%, and 4.3% of women experienced short-term de novo voiding dysfunction. Urgency symptoms arising after surgery occurred in 3% of women, yet 80% of the women who had preoperative urgency symptoms had relief of those symptoms at their 16-month visit. No serious complications were noted.

Long-term results mirror the short-term experience with this procedure. Success rates ranging from 81% to 90% have been reported at more than 3 years. Ulmsten and associates (1999) reported an 86% success rate in 50 women at 3 years. Olsson and Kroon (1999) reported 90% success in 51 women at 3 years. Doo and colleagues (2006) evaluated long-term efficacy and safety of this procedure among 134 Korean women. The overall 5-year success rate was 94.9%, with an 86.6% patient satisfaction rate. Although success rates between 1 and 5 years were similar (97.7% and 94.9%), the cure rate decreased from 90.1% to 76.9%. Nilsson and coworkers reported success rates of 84.7% at 5 years (Nilsson

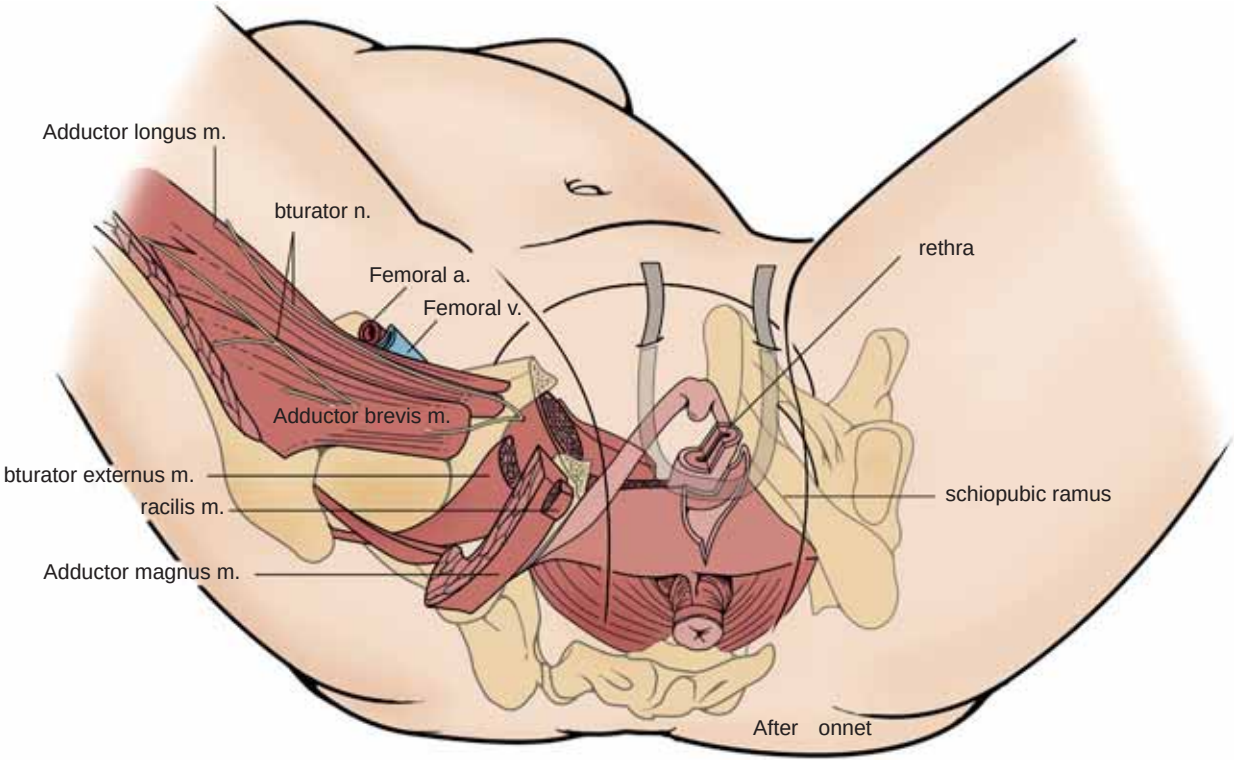

Figure 73–8. Midurethral sling as placed by the suprapubic approach (any technique).

et al, 2001) and 81.3% at 7 years (Nilsson et al, 2004) in a consistent cohort of 90 women. Liapis and colleagues (2008) prospectively assessed the efficacy of the TVT in 65 women: at 5-year follow-up the objective cure rate was 53% and failure rate was 9.4%, whereas at 7-year follow-up the objective cure rate was 80% and the failure rate 13.5%. Song and associates (2009) reported on the second longest follow-up (≥7 years) in 306 women with a cure rate of 84.6%; they reported on 6 patients who had complications from mesh exposure. As a continuation of their earlier work, Nilsson and coworkers (2008) provide the longest (11 years) prospective observational cohort study of 90 women with primary SUI. Ninety percent of these women were objectively cured, and 77% reported subjective cure. No late onset adverse effects or cases of tape erosion were seen. The Austrian Urogynecology Working Group published their data compiled within the Austrian central registry beginning in 1998 (Table 73–9). There were no serious complications and no mortality within the registry; 363 (45%) of those in the registry had a TVT in combination with other procedures (Tamussino et al, 2001). These long-term studies have all attempted to evaluate risk factors for declining effectiveness. **There does appear to be a tendency for higher failure rates to be associated with advancing age at the time of procedure and also with diminished urethral function (ISD).**

Twelve randomized clinical trials have compared the TVT with traditional incontinence procedures in published peer-reviewed journals. This includes five that compared TVT with open colposuspension (Ward and Hilton, 2002, 2004, 2008; Bai et al, 2005; El-Barky et al, 2005), four comparing TVT with laparoscopic colposuspension (Persson et al, 2002; Ustun et al, 2003; Paraiso et al, 2004; Valpas et al, 2004), two comparing TVT with a fascial sling (Bai et al, 2005; Wadie et al, 2005), and one that compared TVT with no treatment (Campeau et al, 2007) (Table 73–10).

From Tamussino K, Hanzal E, Kolle D, et al. The Austrian Tension-Free Vaginal Tape Registry. Int Urogynecol 2001;Suppl. 2:S28–9.

Among the TVT versus Burch comparisons, the trials by Ward and Hilton (2002, 2004, 2008) and Valpas and associates (2004) enrolled the greatest number of patients. The United Kingdom/Ireland cooperative group compared TVT with open colposuspension published data at short (Ward and Hilton, 2002), intermediate (Ward and Hilton, 2004), and long-term (Ward and Hilton, 2008) follow-up. At 6-month follow-up, 344 women were

PVS, pubovaginal sling.

randomized to TVT and Burch colposuspension study arms, with no significant difference in cure rates. Surgery with TVT was associated with more operative complications (i.e., bladder injury), yet colposuspension was associated with more postoperative complications and longer recovery (Ward and Hilton, 2002). At 2-year follow-up, 175 and 169 women were randomized to TVT and Burch colposuspension, respectively. A variety of outcome measures, including subjective and objective measures, were utilized. Overall cure rates noted in the study were lower than other reported cure rates, with 63% of TVT patients and 51% of colposuspension patients being cured. This is likely due to their strict definition of cure (1-hour pad test with change in weight <1 g) and failures including both dropouts and those lost to follow-up. There were significantly more patients in the colposuspension group needing intermittent self-catheterization (<0.0045) and surgery for pelvic organ prolapse (<0.0042) than in the TVT group (Ward and Hilton, 2004). At long-term follow-up (5 years) there were no difference in cure rates. Consistent with earlier studies, prolapse was seen more commonly in the Burch colposuspension group. Two tape extrusions (only one symptomatic) were found in the TVT group. Unlike reports of 27% de novo urgency and UUI in the literature (Jarvis, 1994) after colposuspension, this group reported less than 2% after TVT and less than 5% after colposuspension (Ward and Hilton, 2008). Ward and Hilton (2002) and El-Barky and colleagues (2005) found operation time, hospital stay, and time until return to normal activity significantly shorter in the TVT group. El-Barky and colleagues (2005) reported two bladder perforations in the TVT group (<0.05), whereas wound infections (<0.05) were more common among the Burch colposuspension patients. Bai and associates (2005) compared TVT with open colposuspension and fascial sling: at 3- and 6-month follow-up there were no differences in cure rates between the operations, but at 12 months the patients with a PVS had significantly higher cure rates (92.8%) than those who had the colposuspension (87.8%) or the TVT procedure (87.0%). Wadie and associates (2005) found PVS and TVT procedures to be equally effective. The TVT procedure is cost effective and superior in terms of impact on health care spending compared with open colposuspension (Manca et al, 2003).

Four randomized trials (Persson et al, 2002; Ustun et al, 2003; Paraiso et al, 2004; Valpas et al, 2004) have been performed comparing TVT with laparoscopic colposuspension. Valpas and associates (2004) and Persson and coworkers (2002) reported results at 12 months, and Paraiso and colleagues (2004) reported outcomes at 18 months. The results of the laparoscopic comparator trials revealed TVT cure rates in the range of 86% to 97%, with colposuspension rates ranging from 57% to 100%, depending on the reporting method. There was no apparent difference between procedures in the Persson and coworkers' trial, but Paraiso and colleagues and Valpas and associates noted significant differences in success in the two study groups. These trials noted no other apparent differences between techniques other than that the TVT group recovered more rapidly and had a lower need for subsequent urogenital prolapse procedures than the colposuspension group. Dean and colleagues (2006) reviewed seven randomized trials comparing TVT and laparoscopic colposuspension and found no statistically significant difference in reported subjective cure rates within 18 months. Yet the overall objective cure rate was significantly higher for TVT. Novara and colleagues (2008) performed a meta-analysis of 33 randomized controlled trials comparing tension-free midurethral slings with other anti-incontinence procedures. Complications were similar between TVT and Burch colposuspension, with the exception of bladder perforation (higher in TVT group) and reoperation rate (higher in the Burch colposuspension study arm). TVT and PVS procedures were found to be equally effective, with better cure rates than the Burch colposuspension (Novara et al, 2008).

Because of the success of the TVT operation, several modifications to the retropubic procedure and use of different tape materials arose. These retropubic modifications have not been evaluated

extensively. Only seven randomized studies exist comparing the TVT with different retropubic slings. Three trials compared the TVT with the suprapubic arc sling (SPARC), a polypropylene tape material approaching the midurethra from the abdominal incision (Tseng et al, 2005; Andonian et al, 2005; Lord et al, 2006). Tseng and associates (2005) found the TVT and SPARC to be equally effective. The SPARC group had a greater (12.9%) number of bladder perforations than the TVT group (0%). This was not statistically significant, but the authors believed it was clinically significant. Andonian and associates (2005) randomized 84 patients to either study arm and found no statistically significant difference between SPARC and TVT, in terms of objective cure rates at 12-month follow-up. Tape erosion, infected pelvic hematoma, and UTI were only found postoperatively in the SPARC group, yet there were no differences in other perioperative complications (bladder perforation, blood loss, hospital stay, urinary retention, postoperative analgesia). Lord and colleagues (2006) found the TVT group to have a lower rate of vaginal erosion (4.8% vs. 10.5%) and a statistically significantly higher subjective cure rate (87.1% vs. 76.5%) than the SPARC group. The SPARC was found to be more difficult to adjust correctly, and a statistically significant number of patients required loosening of the tape (P =.002). Campeau and colleagues (2007) compared elderly women who either had a TVT or had to wait 6 months for surgery, using quality of life questionnaires. The women who had the TVT procedure had a significantly higher quality of life (P < .0001), yet 22.6% experienced bladder perforation and 12.9% had urinary retention.

Arunkalaivanan and Barrington (2003) compared the TVT procedure with the use of allogenic acellular porcine collagen (Pelvicol) in a questionnaire-based study. They reported on both 12-month and 36-month results and found no difference in subjective cure rates. TVT was compared in three studies to the intravaginal sling (IVS), a multifilament, miniporous polypropylene tape material produced by Tyco that is passed similar to a SPARC. Rechberger and associates (2009) reported no differences in cure rates at 13-month follow-up of 50 patients per group. Complications were similar with the exception of postoperative acute urinary retention occurring significantly more commonly among the patients having the TVT procedure. Meschia and colleagues (2006) compared the TVT and IVS with intermediate follow-up and reported subjective cure rates of 80% (TVT) and 78% (IVS) and objective cure rates of 85% (TVT) and 72% (IVS). Eight (9%) of the IVS patients experienced vaginal erosion, with none found in the TVT group. The TVT was compared with the IVS and SPARC by Lim and associates (2005) in the SUSPEND trial. There was no significant difference between the cure rates: 87.9% (TVT) versus 81.5% (IVS) and 71.4% (SPARC). There was a significantly greater rate of tape extrusion in the SPARC group. Balakrishnan and coworkers (2007) followed a subgroup of IVS patients from the Lim and associates' (2005) group up to 30 months and found 13% with sling erosions, requiring removal of the sling. Of the 29 patients (47%) from this initial IVS group seen 12 to 34 months postoperatively, 24% experienced sling erosion with associated sinus formation, requiring sling removal. In Novara and colleagues' (2007) meta-analysis the TVT was found to be more efficacious than the IVS and SPARC.

Special Groups of Patients

Elderly. Although there is a large body of literature that demonstrates the efficacy and low morbidity associated with midurethral slings for SUI **there are few data evaluating the effect of advanced age on outcomes.** Aging affects the lower urinary tract both anatomically and functionally. The aging lower urinary tract has a higher rate of DO, UUI, and ISD. Emptying abnormalities related to impaired contractility are also more common in elderly persons. Older women are more likely to have had prior procedures for incontinence and therefore may have higher rates of urethral fixation. More severe vaginal atrophy related to longstanding lack of salubrious estrogen support of the vaginal tissues in the older woman could pose a greater risk of poor healing and erosion after vaginal incontinence surgery. Older patients are generally considered poorer surgical candidates because of medical comorbidities that could complicate the surgery, the surgical outcome, or the postoperative course. Prior studies and prevailing attitudes maintain that retropubic suspensions and vaginal procedures for SUI in elderly patients have variable rates of success (Gillon and Stanton, 1984; Schmidbauer et al, 1986; Couillard et al, 1994; Chilaka et al, 2002).

Few studies of relatively small numbers of patients examine the safety and efficacy of midurethral slings in older women. In all these studies, "old" is defined as 70 years of age and older. The most robust of the studies is a prospective comparison of 460 consecutive women who underwent TVT surgery (Gordon et al, 2005); 157 (34%) were elderly, and all women underwent UDS preoperatively and 3 months postoperatively. Outcome measures were compared between elderly and younger patients with follow-up of at least 12 months, and mean follow-up was 26 months. Preoperatively, a statistically significant greater prevalence of MUI was noted in the older (31%) versus younger (23%) patients. Concomitant pelvic organ prolapse surgery was undertaken in 84% of older patients and 67% of younger patients. The main outcome measures evaluated were perioperative morbidity, postoperative SUI, persistent or de novo UUI, and voiding dysfunction. Intraoperative complications were infrequent. The rates of blood loss were equal, and there were significantly fewer bladder perforations in the elderly patients. The incidence of postoperative fever, UTI, wound infection, and hematoma formation was similar in the two groups. Older patients did experience some age-related morbidities such as pulmonary embolism (2 patients), cardiac arrhythmia (2 patients), deep vein thrombosis (1 patient), and pneumonia (1 patient), whereas of the younger patients only 1 had a cardiac arrhythmia. Older women experienced no increased risk of urethral erosion or vaginal extrusion. The rates of postoperative voiding dysfunction necessitating catheterization for more than 1 week were low and similar between groups. Only 1 patient, an older woman, required urethrolysis. Rates of persistent SUI were uniformly low and no higher in the older women. Rates of UUI were similar between groups, but the **rate of de novo UUI was greater to a statistically significant degree in the older patients** (18% vs. 4%).

A similar rate of postoperative de novo urgency in elderly women undergoing TVT was documented in a smaller study of 76 women (Sevestre et al, 2003). One strength of this study is that a description of the degree of urethral hypermobility is given. Of these women, 53% had urethral hypermobility defined by a Q-tip test greater than 30 degrees, 28.9% had undergone prior incontinence procedures, and 4 (5.2%) showed UDS evidence of DO. At a mean follow-up of 24.6 months, 67% of the patients were cured, as determined by questionnaire and examination. Ten (13.7%) had persistent SUI, and all of these had negative Q-tip tests preoperatively; and 14 (18.4%) had UUI. Satisfaction with the procedure was 82%, and rates of dissatisfaction were higher in those with de novo UUI. For the older women with a negative Q-tip test, the cure rate was 71%, compared with 100% in women with a positive test. The rate of immediate urinary retention was 26.3%,

but only 1 patient had urinary retention for more than 1 week. One case of bladder perforation and one case of vaginal erosion were reported. Liapis and associates (2006) similarly correlated the degree of urethral hypermobility and outcomes after a TVT procedure among women aged 65 to 85 years. An overall cure rate of 76% was reported, with positive correlation to bladder neck mobility. Of patients in whom the angle of displacement on the Q-tip test was less than 30 degrees, 42% became continent, whereas 90% were continent among those with an angle greater than 30 degrees. Among those in whom the angle was less than 10 degrees, 80% remained incontinent.

The success rates and complications after colposuspension and TVT procedure were compared between women older than age 70 years and younger women (Pugsley et al, 2005). The cure rates were similar between the age groups. There was an increased incidence of UTI among the elderly women with Burch colposuspensions and the TVT patients. After the Burch colposuspension, women older than age 70 required more long-term self-catheterization. Among the elderly group with the TVT procedure, postoperative UDS was required more often for voiding dysfunction and eventual need for sling lysis was higher. Touloupidis and coworkers (2007) reported a cure rate of 96% among women with mean age 72.3 years; however, these authors were concerned by the rate of bladder perforation (5.8%) and de novo urgency (9.8%).

Overall, **cure rates at least in older women with urethral hypermobility are comparable to those in younger women.** Complication rates vary, with some studies citing a higher rate of age-related morbidities but no apparent increase in intraoperative complications. Jha and colleagues (2009) evaluated factors influencing outcome with the TVT procedure and found that age did not impact significantly on outcomes for SUI reduction or improvement in quality of life. **Postoperative voiding dysfunction or increased de novo urgency does seem to be a complication of greater incidence and significant impact in older women.** Postoperative urgency symptoms in as many as 60% of women older than 70 years have been reported (Allahdin et al, 2004), and 44% developed the symptom de novo. Bafghi and associates (2005) noted cure rates among patients younger than 70 years of 97.5% versus 78.5% among patients older than 70 years ($P = .001$). The satisfaction among the younger group was also higher, 92.6% and 66.7%, respectively. This difference was attributed to higher rates of de novo and persistent UUI in those older than age 75 years.

A sensation of impaired emptying postoperatively has also been reported (Sevestre et al, 2003). Furthermore, one study documented a 4-fold increase in the need for repeated UDS in older women after TVT surgery and an approximately 30-fold higher risk of further surgery to divide the tape.

Another important measure of the success of a TVT procedure in elderly patients is quality of life assessments. The outcome of TVT surgery was assessed prospectively in older women at a mean follow-up of 22 months by a validated health-related quality of life instrument, the King's Health Questionnaire (Walsh et al, 2004). The improvement in SUI was greater in the age group younger than 70, which is not clearly attributed to any preoperative factor. Rates of preoperative DO were 24% versus 9% in older and younger women, respectively. Older women had a history of prior surgery more often than younger women (67% vs. 28%) and lower leak point pressures, but no specific comment on their physical examination and degree of urethral hypermobility was made. Although the outcome for the TVT procedure was successful, the hospital course may be longer, as found by Walsh and colleagues (2004). The mean hospital stay in their series was 6 days, indicating that the postoperative morbidity in this age group was significant. The reasons for the longer hospital stays were not given in this study.

Hellberg and colleagues (2007) used a mailed questionnaire for 970 consecutive TVT procedures performed between 1995 and 2001 to compare outcomes between women older than 75 years and younger women at a mean follow-up of 5.7 years. The older women were significantly more often on hormone replacement therapy, had lower education, and had history of recurrent UTIs, previous vaginal repair, and previous incontinence surgery. The elderly patients more commonly had MUI and required longer hospitalization postoperative care. The unfavorable cure rates among the older women (55.7% vs. 79.7%, $P = .0001$) were due to higher failure rate for SUI, rather than for urgency symptoms.

Most recently, a multicenter, prospective randomized clinical trial was performed to compare TVT surgery versus no treatment in elderly women with SUI. Campeau and colleagues (2007) studied 69 women older than the age of 70 years who consented to be randomized to undergo immediate TVT surgery or wait for 6 months before submitting to the same surgery (control group). The main outcomes measured included the Incontinence-Quality of Life (I-QOL) Questionnaire, the Patient Satisfaction Questionnaire, and the Urinary Problems Self-Assessment Questionnaire. At 6 months after randomization the group of elderly women who underwent immediate TVT surgery had significant improvement in quality of life and patient satisfaction and fewer urinary complaints compared with the group of women waiting for the same surgery. Importantly, no age-related morbidity was observed in the immediate surgery group.

Obesity. **Whether obesity affects surgical outcome with the TVT procedure is controversial.** A few small studies have examined the safety and efficacy of TVT surgery in this population. In a prospective study of 242 women with genuine SUI, women were stratified into three groups on the basis of body mass index (BMI) (Mukherjee and Constantine, 2001). The cure rate in obese women was 90% versus 95% in women with a BMI of 25 to 29 and 85% in those with a BMI less than 25. No women experienced a wound infection, and there was no higher rate of retropubic hematoma in obese women. In addition, obese patients undergoing TVT surgery did not demonstrate a statistically significant difference in the incidence of voiding dysfunction: de novo urgency symptoms, UUI, or voiding disorders. Although few in number, studies with 6- to 12-month follow-up support equal efficacy and no difference in intraoperative or postoperative complication rate. No relation between obesity and the occurrence of bladder injury has been found (Lovatsis et al, 2003; Rafii et al, 2003). Skriapas and associates (2006) matched 31 women with BMI greater than 40 with 52 women with BMI less than 30 and reported on their 18.5 month follow-up after a TVT procedure. The continence rates among the morbidly obese group were not significantly different from those of the control group, 87% and 92% ($P = .103$), respectively. The early postoperative complications were significantly higher among the morbidly obese patients. Killingsworth and coworkers (2009) reported on 127 overweight to obese women and concluded that success rates, patient satisfaction, and complications were not significantly different with increasing BMI. Meschia and colleagues (2007) had similar findings to those of Mukherjee and Constantine (2001) and Killingsworth and coworkers (2009) with no differences in BMI of successes and failure, suggesting that the TVT procedure could be confidently used in overweight women. Muller and associates (2007) reviewed randomized and retrospective clinical trials in the

English TVT surgical literature from 1998 to 2006. Neither age older than 70 years nor morbid obesity was a risk factor for failure of the TVT procedure; however, there was an increase of de novo urgency among the elderly women and those with a BMI greater than 35.

Hellberg and colleagues (2007) conducted a questionnaire-based study, including 970 consecutive TVT procedures performed between 1995 and 2001 to compare outcomes between women with a BMI greater than 35 (n = 61) and those who had normal weight at a mean follow-up of 5.7 years. There was a sharp decline in long-term cure rates between women with a BMI less than 25 and those with a BMI greater than or equal to 35: 81.2% and 52.1%, respectively (P = .0005). The obese women were significantly older, had a higher parity, were less educated, and more often had diabetes and chronic bronchitis. The women with normal weight had higher mean postvoid residual urine volumes after surgery and required more adjustments of tape. The increased failure rate among the obese population was due to low cure rates of both stress and urgency components.

Despite the success of the TVT procedure in obese women there is a reported case of necrotizing surgical site infection after TVT placement in a 53-year-old obese woman (Connolly, 2004). Morbidly obese patients have a 44% increased risk of postoperative infectious morbidity (Forse et al, 1989). Obesity poses a greater risk for necrotizing fasciitis than diabetes in obstetric and gynecologic procedures (Gallup et al, 2002). Standard antibiotic prophylaxis and the time of surgery may need to be altered for the morbidly obese to provide adequate tissue levels, and infected tapes require complete removal. Obese women, like all women undergoing midurethral sling, should be counseled about the risk of infection.

Concomitant Pelvic Organ Prolapse. A large proportion of women with SUI have associated pelvic organ prolapse that requires concurrent treatment. Many studies have explored the outcomes of TVT with concomitant surgery. **The advantage of using a synthetic sling with concomitant surgery is that operative time is reduced sizably and blood loss from the TVT portion is usually minimal compared with autologous slings or retropubic suspensions. Some of the theoretical risks of midurethral slings with concomitant transvaginal surgery are that the increased dissection will increase exposure of the graft, leading to greater rates of infection, erosion, or vaginal extrusion, or that increased blood loss or anatomic distortion from the concomitant procedures could increase the rate of sling migration and postoperative voiding dysfunction or obstruction. These studies tend to be small and have short follow-up, but results suggest that the TVT procedure can be added to prolapse surgery with minimal morbidity.** Success rates in combined TVT and prolapse repair vary from 88% to 93% (Jomaa, 2001; Huang et al, 2003; Meltomaa et al, 2004). Even in questionnaire-based assessments 3 years after surgery the data do not show a statistical difference in the cure rate of SUI and incidence of urgency symptoms after TVT alone or in combination with other vaginal surgery (Meltomaa et al, 2004). Transient urinary retention occurred more often in patients undergoing concomitant vaginal surgery, but urethrolysis rates were low and not statistically different between groups. Interpretations of rates of postoperative urinary retention are limited by variation in the definition of retention, and therefore caution must be exercised when reviewing outcomes.

Gordon and colleagues (2005) examined TVT surgery as a prophylactic procedure for SUI in prolapse repairs. None of the patients had undergone prior incontinence surgery. With a mean follow-up of 14 months, no patient developed symptomatic SUI but 3 had a positive stress test urodynamically. Six of 9 patients with preoperative urgency had persistent symptoms, and 4 (13.3%) developed de novo urgency without evidence of obstruction. No woman had urinary retention lasting more than 2 weeks. Subsequent 5-year data from a prospective analysis of a large group of women undergoing TVT for occult SUI combined with transvaginal repair of second- or third-degree prolapse showed a low incidence of complications (Groutz et al, 2004). The authors reported that one case of bladder perforation was managed conservatively without consequence. Two patients experienced extended voiding difficulty requiring catheterization for more than 7 days, but urethrolysis was not necessary in any case. Three cases of vaginal erosion were documented. Two patients developed recurrent symptomatic SUI, and another 15 patients were found to have asymptomatic urodynamically confirmed SUI. Eight patients developed de novo UUI, and 72% of the 18 patients with preoperative UUI had postoperative persistent incontinence. Yuan and associates (2008) retrospectively reviewed results of 12 patients who underwent concurrent TVT and Prolift repair of prolapse. Thirty percent of the patients initially presenting with SUI had moderate to severe anterior prolapse. All patients had satisfactory results. The Cochrane Incontinence Group reviewed 22 randomized trials of surgical prolapse repair that included 2368 women. It was concluded that the addition of a TVT procedure to endopelvic fascial plication, Burch colposuspension, and abdominal sacrocolpopexy may reduce the incidence of postoperative SUI, but issues of cost and associated adverse effects were unclear (Maher et al, 2008).

Although **concurrent surgery does not appear to alter success of a TVT procedure,** whether concurrent surgery alters the time to efficient voiding or incidence of urinary retention has been examined separately in a retrospective study of 267 women (66% having concurrent prolapse repair) (Sokol et al, 2005). Without standard definitions of urinary retention, results are not comparable between studies. Sokol and associates (2005) noted that there was no significant difference in median days to voiding and rate of urinary retention based on prolapse repair status. Yet, increasing age, decreasing BMI, and postoperative UTI were independent predictors of time to adequate voiding. Only previous history of incontinence surgery was an independent predictor of urinary retention. No statistically significant difference in the rate of urethrolysis between TVT surgery alone and TVT with prolapse repair was found.

Unlike most other authors, Partoll (2002) claimed that urinary retention is far more common after combined procedures than with a TVT procedure alone. Results showed a 94% cure rate at 11 months and an alarming 43% rate of urinary retention after concurrent anterior or posterior repair. However, in her study, "urinary retention" was defined as not meeting the criteria for catheter removal on postoperative day 2. The expectation of voiding efficiently within 48 hours of surgery, rather than the more lenient expectations in other studies, probably accounts for the higher rate of retention found in her study. Using Medicare claims data on a 5% national random sample of female beneficiaries who underwent sling procedures, Anger reviewed 1356 cases. Of 1356 sling cases, 467 (34.4%) had concomitant prolapse repairs. Women who underwent prolapse repair at the time of the sling surgery were significantly more likely to be diagnosed with postoperative outlet obstruction (9.4% vs. 5.5%, $P < .007$) but less likely to undergo a repeat procedure for SUI or reoperation for prolapse within 1 year after sling surgery (Anger et al, 2008).

When TVT procedures are placed for only urodynamic or occult SUI at the time of prolapse repair, the risk of intervention due to obstruction is equal to the risk of intervention due to SUI when no clinical, urodynamic, or occult SUI is present and no TVT was placed (8.5% and 8.3%, respectively) (Ballert et al, 2009). Ballert and colleagues (2009) did report that the risk of intervention for SUI in patients with clinical SUI but no urodynamic or occult SUI and no midurethral sling was 30%.

TVT surgery performed with either transvaginal or laparoscopic-assisted vaginal hysterectomy and anterior/posterior colporrhaphy has been shown to have success rates similar to those in published series of a TVT procedure alone (Huang et al, 2005). Complication rates were also in accordance with other TVT surgical series, with 2% bladder perforation, 11% postoperative urgency, and 11% postoperative voiding difficulty. A study specifically looking at the complications and cure rates of TVT procedures performed with or without vaginal hysterectomy found that there was no overall difference (Darai et al, 2002). The TVT-hysterectomy group did have a trend toward more bladder perforation and lower postoperative urinary flow rates, but it was not statistically significant. Objective and subjective cures for this group were 92.5% and 75%, respectively, which was not significantly different from the TVT-alone group.

Anger and associates (2007b) evaluated the relationship between provider specialty and outcomes of sling surgery specifically related to concurrent prolapse management. Utilizing 1999 to 2000 Medicare data, they reported on 1063 slings performed by urologists and 246 by gynecologists. Urologists performed concomitant prolapse repairs in 29.1% of cases versus 55.7% among gynecologists ($P < .0001$). After a year, urologists were more likely to perform a repeat incontinence procedure (9.3% vs. 4.9%, $P = .024$) and prolapse repair (26.0% vs. 12.2%, $P < .0001$). Their findings suggest that urologists should identify and manage prolapse at the time of evaluation of urinary incontinence, to avoid the morbidity and cost of repeat surgery.

The design and methodology for the OPUS trial is presently being finalized. This will attempt to determine whether the use of a concomitant prophylactic anti-incontinence procedure may prevent development of SUI symptoms in women undergoing prolapse surgery and to evaluate the cost-effectiveness of this prophylactic approach. Ethical issues may arise because the protocol includes a sham incision in the control arm and patients may be reluctant to accept random assignment for invasive randomization (Wei et al, 2009).

Mixed Incontinence. **Evidence suggests that the TVT procedure has successful outcomes for women with MUI symptoms.** However, interpretation of these studies should be judicious because many outcomes were reported on the basis of symptoms only, with no UDS substantiation. **There are presently no randomized control trials evaluating the TVT placement for MUI symptoms.**

In a retrospective analysis of 112 consecutive women with genuine SUI and MUI the objective cure rate as measured by clinical and urodynamic examination was 89.3% at a mean follow-up of 25 months. Objective cure was defined as no evidence of SUI, a negative stress provocation test, and any urinary retention or residual volume greater than 150 mL. No difference was found in the objective cure rate between patients with genuine SUI and those with MUI. The overall subjective cure rate determined by the Contilife questionnaire was 66%. Subjective cure was lower than objective cure in both patients with genuine SUI and patients with MUI, 69.3% and 54.2%, respectively. The type of incontinence did not alter the incidence of postoperative voiding difficulty. Ten of the 24 patients with MUI had persistence of the urgency component (Jeffry et al, 2002).

Holmgren and colleagues (2005) evaluated the outcome of TVT surgery in women with SUI and MUI with mailed questionnaires 2 to 8 years postoperatively. This was a large cohort of 970 women, and the 78% response rate was remarkable. Five hundred eighty women with SUI and 112 women with UUI were eligible for analysis. However, UDS was not performed in these women preoperatively or postoperatively, and therefore categorization of their incontinence was based only on a positive stress test and a history of leakage immediately preceded by urgency. The questionnaire itself is not fully described in this article; therefore, it is not clear whether a validated instrument was used. Specific questions regarding SUI and UUI were posed, and respondents selected options including worsened, unchanged, improved, almost cured, and cured. For analysis, the women were grouped into cohorts by the number of years since they had undergone TVT surgery. The mean age of women with MUI was greater than the age of women with SUI (67 vs. 61.2), and this was a statistically significant difference. Adjustment for age was made in the analysis. In addition, women with MUI had a statistically significant higher BMI, rate of cesarean delivery, and prevalence of urinary frequency than those with SUI. More women with MUI had a history of irradiation for gynecologic malignancy. Although the numbers were small, irradiation may have had repercussions for bladder function that cannot be fully elucidated by questionnaire and could skew results. Sixty percent of women with MUI were cured up to 3 years after surgery, but outcome declined steadily thereafter. By 6 to 8 years postoperatively the cure rate in women with MUI was only 30%. Urgency and episodes of UUI increased with time after the TVT procedure. In the final analysis the lower rate of cure in the patients with MUI may be due to the other variables in this population, such as age, cesarean section, irradiation, and higher BMI. These differences in the populations confound the ability to assess outcome and highlight the limitations of this study design. Overall, despite the population variables, early outcomes of TVT surgery are good and equal in women with SUI and those with UUI. The diminishment of results over time needs to be confirmed by a prospective study (Holmgren et al, 2005).

In a similar Finnish study, 191 women who underwent TVT procedures were evaluated by examination or telephone interview for outcome at a mean follow-up of 17 months. Sixty-four (34%) of these women had preoperative stress-predominant MUI. None of the women had preoperative UDS; instead, the preoperative diagnosis was based on symptoms. Cure after the TVT surgery was judged as self-report of completely dry in any stress situation. At latest follow-up, 164 of the 187 patients were completely cured, for a cure rate of 87.7%. The cure rate in women with MUI was 69% compared with a cure rate of 97% in the women with pure SUI. This outcome difference was statistically significant. No difference in cure rate was found between women who had concomitant surgery or TVT surgery alone. Sixty percent of the women with MUI considered themselves improved from an UUI perspective as well. The lower cure rate in the MUI patients is not fully known. No description of the preoperative physical examination is given, and it is not known how many of them were among the 149 (78%) who had urethral hypermobility. The authors suggested that, on the basis of these results, preoperative UDS should be performed in women with MUI before anti-incontinence surgery (Laurikainen and Killholma, 2003).

Segal and colleagues (2004) evaluated 98 women after TVT placement explicitly to answer the question of what happens to

the UUI. The outcome of TVT surgery in women with mixed incontinence or significant SUI with associated frequency and urgency was assessed retrospectively by a variety of methods: subjectively by patients' symptoms, by the rate of anticholinergic use before and after TVT, and by before and after quality of life questionnaires. One strength of this study is that patients with concomitant surgery were excluded to minimize the confounding effect of other causes on UUI or frequency and urgency. Sixty-five women were identified as having UUI, and follow-up occurred at 3 months and 1 year. Several preoperative factors were looked at for risk of postoperative frequency, urgency, or UUI requiring anticholinergic agents. On the basis of preoperative subjective symptoms, the urgency component was found to be resolved in 63.1% after the TVT procedure. Two patients with complaints of UUI only but SUI identified on UDS had persistent UUI requiring anticholinergic drug treatment. Seventy-five patients had preoperative urinary frequency and urgency, which resolved in 57.3% after TVT surgery. Thirty (57.7%) of the 52 patients requiring anticholinergic agents preoperatively no longer needed medication after surgery. Only 4 (8.7%) patients needed anticholinergic agents for the first time after TVT surgery. Of all the variables assessed as possible risk factors for postoperative OAB requiring an anticholinergic agent, only a history of prior anti-incontinence surgery was statistically significant. Patients with prior surgery were eight times more likely to have postoperative OAB requiring anticholinergic therapy. Overall, the resolution of preoperative UUI was 63% and the resolution of preoperative urinary frequency and urgency was 57.3%. Resolution based on no longer needing anticholinergic medication postoperatively was 57.7%. TVT surgery resulted in statistically significant improvement in quality of life scores postoperatively in women with stress-predominant MUI and with SUI with urinary frequency and urgency (Segal et al, 2004).

Rezapour and Ulmsten (2001) reported their 5-year data on the efficacy and safety of TVT in women with MUI. In all of these women the urgency component was sensory, and no woman had urodynamic evidence of DO. Eighty women were evaluated, and results were reported in a retrospective fashion. All had undergone UDS preoperatively, and all were found to have SUI as well as motor detrusor contractions during filling. At follow-up, 85% were reported as cured and an additional 4% had improved symptoms on the basis of pad testing and symptom questionnaire. These investigators concluded that UDS was essential before surgery to analyze presenting symptoms. Only 1 patient had prolonged retention (6 weeks), but 8% were found to have small hematomas and 1 patient required exploration for bleeding.

Basu and Duckett (2007) reported on two case reports of women with DO and clinical SUI but no evidence of urodynamic SUI. In both cases the SUI and DO resolved with TVT placement and postoperative anticholinergic treatment. Yet, both women continued to have persistent urgency requiring prolonged anticholinergic therapy.

The short-term outcomes of TVT surgery and use of outside-in transobturator tape (TOT) and SPARC in women with MUI were reported by Paick and colleagues (2008). There was no significant difference in cure rates for SUI. Preoperative DO was an independent risk factor for treatment failure of the UUI component. Athanasiou and associates (2009) compared the efficacy of the TVT procedure and inside-out transobturator tape (TVT-O) for treatment of urinary incontinence in women with MUI and idiopathic DO. There were no subjective differences in outcome, yet women undergoing the TVT procedure were less likely to have persistent DO postoperatively.

Kulseng-Hanssen and colleagues (2008) evaluated results of TVT placement in 1113 women with MUI based on the patient's predominant bother, that is, SUI, UUI, or SUI and UUI equally. There were no differences in cure rates between the three groups. Patients with predominant SUI bother had significantly better results at 7 and 38 months than the other two groups, especially those complaining mainly of UUI. Eleven percent of women had an increase in UUI 38 months after the TVT procedure. The authors concluded that patients with predominant UUI have poorer results than those with predominant SUI. In a retrospective evaluation of long-term effects of TVT surgery on OAB and urodynamic SUI, Leron and colleagues (2009) noted 88.7% cure and 9% improvement with 62.2% improvement in OAB symptoms. There was no change in severity of symptoms in a third of the patients. De novo OAB symptoms developed in 6.2%. Using the AUA Symptom Index for measurement of outcomes, Ballert and coworkers (2008) found no difference in storage, voiding, or total score between patients with SUI and MUI or those undergoing TVT versus TVT-O placement. Sinha and associates (2008) used the Medical Epidemiology and Social Aspects of Ageing (MESA) and other outcome measures used by the British Society of Urogynaecology (BSUG) database for short-term evaluation of TVT in women with MUI. SUI and UUI were either cured or improved in 78% and 75% of women, respectively. The postoperative global impression of outcome noted great or moderate improvement in 75% of cases and reduction in mean MESA scores of 69% ($P < .001$).

Duckett and associates (2008) used perineal ultrasonography in 77 women with DO and urodynamic SUI to determine whether the position of a TVT has any effect on the resolution of irritative symptoms. They found that placement of the TVT on any part of the urethra is not more likely to resolve irritative bladder symptoms. Three studies have attempted to correlate preoperative variables with outcomes of TVT in women with MUI (Basu and Duckett, 2007; Gamble et al, 2008; Panayi et al, 2009). Duckett and Basu (2007) reported on correlation between preoperative pressure-flow studies and resolution of DO and OAB symptoms after a TVT procedure. Pressure-flow studies were compared before and after TVT surgery. Women whose $\dot{Q}$max decreased significantly after the TVT placement were more likely to have persistent OAB symptoms. The flow rate was significantly higher in women before the TVT placement, with an objective cure of DO after TVT placement than in those with persistent DO. Basu and Duckett believed that this supported an obstructive cause in women with persistent DO. Gamble and associates (2008) found that age, nocturia, maximum capacity, and choice of sling procedure (lowest rate of DO with TVT-O, followed by TVT, SPARC, and then bladder neck sling) impacted on the persistence of DO and UUI. Panayi and coworkers (2009) found higher median preoperative opening detrusor pressure in women with DO postoperatively (33 cm H_2O vs. 26 cm H_2O, $P < .05$).

Intrinsic Sphincteric Deficiency. In most evidence sources, ISD is defined urodynamically as a leak point pressure less than 60 cm H_2O or MUCPs less than 20 cm H_2O. However, several of these articles fail to describe the patients' physical examination or reveal whether any urethral hypermobility existed. **What is clear from the current literature is that success of midurethral slings is less in the patient with a fixed urethra and that low leak point pressures seem to portend a poorer outcome, but this may be due to lack of urethral mobility in the same patient.** Rezapour and associates (2001) published a prospective 4-year follow-up study of 49 women with ISD who underwent TVT surgery. Forty-one of these women had hypermobility of the urethra; the other 8 had immobile urethras.

Postoperatively, 36 (74%) of patients were cured, 12% were improved, and 7 patients (14%) experienced failure of the procedure. None of the women with fixed urethras was cured: 3 improved and in 5 the procedure failed. Other studies support lower cure rates of TVT surgery in women with low leak point pressures when rates of urethral hypermobility are not statistically different (Paick et al, 2004). **Urethral mobility before midurethral sling procedures has been shown to be predictive of success.** The more the proximal urethra moves during Valsalva maneuvers, the better the cure rate for incontinence (Fritel et al, 2002). Leak point pressures alone have not been shown to predict outcome after a midurethral sling (Gutierrez Banos et al, 2004; Rodriguez et al, 2004); therefore, low leak point pressures are not necessarily a contraindication to TVT surgery. Leak point pressures in the era of the midurethral sling should be correlated with the patient's physical examination and used to counsel patients about their risk for a reduced chance of success.

A deficient sphincter mechanism is an important risk factor for failure of conventional anti-incontinence procedures. It is difficult to evaluate the efficacy of surgical treatment for ISD because no universally accepted definition presently exists. A few studies have been performed to assess the clinical effectiveness of the TVT procedure in women with ISD (Ghezzi et al, 2006; O'Connor et al, 2006; Sang et al, 2007; Rechberger et al, 2009). In all of these studies, patients were included with urodynamic SUI from ISD, based on a VLPP less than 60 cm H_2O. Ghezzi and coworkers (2006) prospectively studied 35 patients and noted a 93.7% cure rate at 12.5 month follow-up. Two of the 3 patients who failed the procedure were noted to have a fixed urethra preoperatively. In a retrospective study, Song and colleagues (2009) compared the treatment outcome of the TVT procedure in patients with ISD (31 patients) and non-ISD (80 patients) SUI after 1-year follow-up. Whereas at the 1-month follow-up there was significant difference in cure rates between the ISD (87%) and non-ISD patients (100%), by 1 year after surgery there was no significant difference. Rechberger and associates (2009) conducted a prospective, randomized trial with a follow-up of 18 months comparing the clinical effectiveness of retropubic and transobturator midurethral slings. Although the efficacy of both techniques was comparable, the retropubic route was more efficient in the ISD group.

Mode of Anesthesia

In the original description of the midurethral sling, anesthesia was local so that the patient would be able to perform a cough as a method of adjusting sling tension intraoperatively. It was believed that this would minimize the incidence of obstruction; however there is conflicting information in the literature regarding whether the mode of anesthesia affects the incidence of intraoperative and postoperative complication. Two studies have failed to show a difference in the efficacy or safety of the TVT procedure performed with the use of local or spinal anesthesia (Wang and Chen, 2001; Adamiak et al, 2002). In a study of 103 women who underwent TVT procedures, a comparison of local and spinal anesthesia was made; 67 women underwent the procedure with local anesthesia and 36 underwent TVT with spinal anesthesia (Adamiak et al, 2002). In the postoperative evaluation there was no difference in the success rate of the TVT surgery performed; there was also no difference in the rate of complications between the groups. There was a difference in the patients' ability to perform a cough test effectively during the procedure because of spinal anesthesia, but this did not result in an increase in the rate of postoperative obstruction. It appears that tensioning the sling by cough stress test is not necessary. Lo and colleagues (2002b) demonstrated that vigorous manual pressure against the abdominal wall and intraoperative introital ultrasonography to set tension resulted in no obstruction in 45 patients at 1 year. No comparisons of tensioning techniques have been performed to the authors' knowledge, and many different methods are used. Outcomes in women who undergo TVT surgery in combination with a prolapse repair under general or spinal anesthesia are similar to those in women who undergo TVT surgery alone.

Key Points: Tension-Free Vaginal Tape Surgical Results in Special Populations

- The literature supports the use of midurethral slings in a variety of special populations of patients.
- Efficacy and safety of the TVT procedure are not compromised in the elderly, obese, those with recurrent incontinence, or those undergoing concomitant vaginal surgery.
- A few small studies suggest that concomitant vaginal surgery places a patient at higher risk for delayed return to normal voiding and urinary retention. However, limitations in the studies prevent comparison of the data.
- It is difficult to analyze the current sling data because of the lack of standard definitions of cure and improvement and lack of standard outcome measures. Absolute conclusions about the use of the TVT procedure in special populations should not be made until larger prospective multicenter studies can be performed.

Complications

Complications associated with the TVT procedure appear to be within the acceptable range for incontinence procedures. **Quality of life is affected not only by the outcome of the incontinence surgery from the standpoint of cure or improvement but also by the appearance of voiding difficulties, UTIs, and other adverse consequences of the surgical procedure itself.** The evidence appears to suggest that a minimally invasive procedure that is standardized can decrease rates of complications. **The Finnish TVT registry demonstrates a pronounced learning curve** for surgeons adopting this new technology (Kuuva and Nilsson, 2003). This registry is unique in that all TVT procedures are recorded in this database, and therefore the data are reflective of an entire national experience with a new procedure. A second registry is currently maintained in Austria and includes more than 3000 cases but it does not involve all surgeons in the country (Tamussino et al, 2001). Overall, the rate of complications associated with the TVT procedure is relatively low. **Bladder injury in the two national registries ranges from 2.7% to 3.8%. Voiding dysfunction is reported as approximately 7.6%, and wound healing problems are less than 1%.** Other studies have also reported complication rates in smaller but still significant groups of patients (Table 73–11).

The definition of voiding dysfunction in these studies varies; however, the common definition is the need for catheterization, with short-term catheterization usually being defined as 2 days. The highest voiding dysfunction rate (19.7%) was reported by Abouassaly and colleagues (2004) at 48 hours. The highest UTI rates were reported in the Austrian National Registry (17%) (Tamussino et al, 2001). However, in this registry the infection rate may be reflective of the operative tendency to leave indwelling catheters in the majority of cases. Bodelsson and associates (2002)

Table 73–11.

Complications as Reported by Recent Large Series (Two of Which Represent National Registries)*

STUDY	NO. PATIENTS	BLADDER INJURY	BLEEDING/ DEFECT HEALING	DE NOVO URGE HEMATOMA	UTI	VOIDING DIFFICULTY	WOUND INFECTION

*Definitions of some entities vary, and voiding dysfunction specifically is defined differently between trials.
NR, not reported; UTI, urinary tract infection.

found that the risk of bladder perforation was three times higher in patients undergoing regional versus local anesthesia.

When UUI and urgency symptoms are evaluated, patients with MUI experienced cure rates of approximately 80% with resolution in patients with urgency in 50% to 80% of cases. The appearance of de novo urgency occurs in 0.2% to 15% of patients without an apparent escalation of risk over time from the initial procedure. Long-term follow-up suggests approximately 6% of patients with de novo urgency postoperatively (Nilsson et al, 2001).

Intraoperative and postoperative bleeding are also variably defined, often by estimation of volume of blood loss. **Hemorrhage, however, is relatively rare.** Hemorrhage, defined as greater than 200 mL or postoperative hematoma, occurs in approximately 2% of patients and can usually be managed by observation or local compression. Flock and colleagues (2004) reported a rate of 4.1% of 249 patients experiencing hemorrhage of 300 mL or more and requiring surgical intervention.

Although rare, vaginal, urethral, and intravesical erosion of the midurethral sling polypropylene mesh is a particularly feared complication of the technique, largely because of advances in materials science. Tape erosion has been reported in the literature with an incidence of 0.3% to 23%, and currently there is no clear consensus on the management of this particular complication. Given the extensive experience with the TVT device, the majority of reported complications have been associated with this device; however, given the similarity between the various devices, it is reasonable to assume that these results will be noted with other types of midurethral slings (Clemens et al, 2000; Volkmer et al, 2003).

The incidence of TVT erosion in the reported literature is extremely low. Many attribute this phenomenon to the macroporous characteristics of the polypropylene mesh. These characteristics allow excellent incorporation of fibroblasts, macrophages, white blood cells, collagen, and neovascular tissue within the interstices of the tape. The excellent tissue ingrowth facilitates integration of the mesh with the surrounding host tissues and decreases tape encapsulation, all of which minimize the risk of an erosion complication. **The erosion rate reported in the literature for polypropylene mesh is 0.5% to 1.3%** (Meschia et al, 2001; Kuuva and Nilsson, 2002; Karram et al, 2003; Levin et al, 2004).

Voiding dysfunction after genitourinary erosion of synthetic midurethral slings has been reported. Starkman and associates retrospectively reviewed the voiding dysfunction in 19 patients with genitourinary erosion of polypropylene mesh slings after mesh excision. They reported on a total of 11 vaginal, 7 intravesical, and 5 urethral erosions. After surgery, only 4 patients (21%) achieved complete resolution of symptoms. Persistent voiding dysfunction was present in 15 patients (79%), including persistent or de novo pelvic pain, storage symptoms, and SUI. Ten patients were incontinent after surgery (4 had SUI, 2 had UUI, and 4 had MUI) (Starkman et al, 2006).

The Austrian Urogynecology Working Group reported no serious complications and no mortality within their registry (Tamussino et al, 2001) (see Table 73–9). Two percent were noted to have intraoperative bleeding, and 4% had bladder perforation. Among those reported to have bleeding, most were treated conservatively and only 0.8% required conversion or reoperation (Kolle et al, 2005).

Terminology. **The term *erosion* implies that the mesh has either entered the lower genitourinary tract (urethra or bladder) or has penetrated through the vaginal epithelium.** The latter circumstance may better be termed *exposure* or *extrusion* (*exposure* may be preferable because the underlying causative mechanism may not be identifiable) and may arise from either mechanical or wound-related variables. The actual mechanism of erosion is still poorly understood. There are a number of theoretical possibilities, including subclinical infection, poor tissue ingrowth into the sling, disturbed wound healing, rolling or twisting of the tape, and excessive friction between host tissue and the tape. Also, iatrogenic injury and surgeon technical error should be considered as factors in the etiology of erosive complications (Kobashi and Govier, 2003a, 2003b; Domingo et al, 2005). Biomechanical properties of the sling material play a major role in the incidence of complications related to tape erosion. Although various materials have been historically utilized for sling implants there has been a trend in the contemporary literature toward the use of macroporous polypropylene slings. The increased pore size allows excellent tissue ingrowth, promotes integration with the surrounding host tissues, and decreases encapsulation and infection (Dietz et al, 2001, 2003; Slack et al, 2005). Adherence to meticulous surgical technique and utilization of polypropylene tapes with favorable biomechanical properties may help the surgeon minimize this particular complication.

Vaginal Erosion. Vaginal tape erosion or extrusion is a rare complication after the TVT procedure (Fig. 73–9). **In three large studies the incidence was reported to be 1.1%, 1.3%, and 0.5%** (Meschia et al, 2001; Levin et al, 2004; Huang et al, 2005). Most cases present within a few weeks to a few months after the

midurethral sling procedure. One case of delayed vaginal erosion at 18 months has been reported (Sharma and Oligbo, 2004). **Symptoms of vaginal erosion include vaginal discharge (with variable constituents and different amounts of blood and inflammatory components), a palpable rough surface in the vagina, sexual discomfort (including partner related), pelvic pain, inguinal discomfort, and lower urinary tract symptoms** (LUTS) (urgency, frequency, persistent incontinence, hematuria). Symptoms are often nonspecific, and therefore a high index of suspicion is required. Careful vaginal examination usually identifies an area on the anterior vaginal wall with separated epithelial edges and exposed mesh. **The management of this complication is not standardized, and there are various reports claiming successful outcomes with observation, partial tape excision, complete tape excision, and reapproximation of the vaginal mucosa over the exposed tape** (Table 73–12).

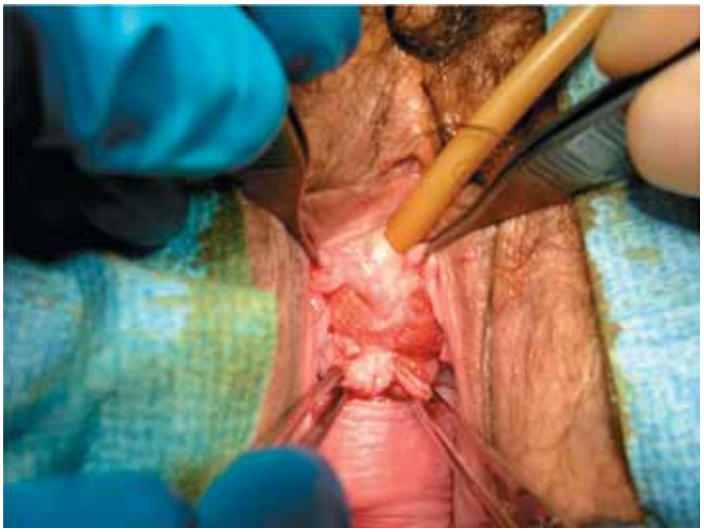

Figure 73–9. Vaginal mesh extrusion.

Historically, most authors have advocated removal of the exposed tape when a vaginal erosion occurs. Reports of conservative management in the literature are sparse. Kobashi and Govier (2003a) reported their experience managing 4 patients (3 SPARC and 1 TVT) with vaginal erosion in a conservative fashion. Two patients presented with persistent vaginal discharge and 2 were completely asymptomatic. All patients were observed with serial physical examinations, and all patients had spontaneous reepithelialization of the mesh at 3 months, which they attributed to the macroporous characteristics of the polypropylene mesh facilitating excellent tissue ingrowth. This is less likely with other synthetic materials such as GORE-TEX, polyester, and silicone, because epithelialization is not likely to occur (Leach et al, 1997; Kobashi et al, 1999).

In a review by Huang and associates (2005), six vaginal erosions and one bladder erosion after creation of polypropylene synthetic slings were initially expectantly managed. In 4 patients with vaginal mesh erosion of less than 1 cm, conservative management was initiated for a 3-month period. One of these patients was observed for 24 months without adverse sequelae. In contrast to the results seen by Kobashi and Govier (2003b), none of the patients in their series had vaginal epithelialization over the area of erosion. Therefore, all 6 patients underwent TVT excision in conjunction with excision of all fibrotic vaginal tissues. Symptoms resolved in all patients, and all patients were continent at their last follow-up. Although all patients ultimately required surgical intervention, the authors believed that a trial of conservative management in appropriately selected patients (i.e., erosion <1 cm) was reasonable; and if no epithelialization occurs at 3 months of follow-up the tape should be surgically removed. In a review of tape-related complications in a series of 200 patients, Tsivian and coworkers (2004) observed five vaginal tape erosions.

Table 73–12.

Vaginal Erosion and Management

STUDY	NO. PATIENTS	LOCATION OF EROSION	MANAGEMENT	REMOVAL	SYMPTOM RESOLUTION	CONTINENCE
Huang et al, 2005	6	6 vaginal	6 transvaginal	Partial	6 asymptomatic	6 dry
Tsivian et al, 2004	5	5 vaginal	4 vaginal; 1 observation	Partial	5 asymptomatic	4 dry; 1 dry repeat TVT
Karram et al, 2003	3	3 vaginal	1 vaginal excision; 1 vaginal advancement flap; 1 antibiotics	Partial	3 asymptomatic	2 dry; 1 SUI
Levin et al, 2004	4	4 vaginal	4 vaginal excision		NR	NR
Kuuva and Nilsson, 2002	10	10 vaginal	4 resutured; 2 tape partially removed; 3 observation; 1 unknown	Partial		10 dry
Meschia et al, 2001	2	2 vaginal	Resuture vaginal mucosa		Yes	2 dry
Volkmer et al, 2003	1	1 vaginal	Transvaginal tape excision	Partial	Yes	Recurrent SUI
Sharma and Oligbo, 2004	1	1 vaginal—delayed 18 mo	3 transvaginal tape excisions (same patient)	Partial	Yes	NA
Kobashi and Govier, 2003a	4	4 vaginal	Observation	NA	Yes	All 4 dry
Hammad et al, 2005	17	17 vaginal	Transvaginal tape excision	Partial	11 yes	NR
Starkman et al, 2006	11	11 vaginal	Transvaginal tape excision	Partial	Yes	
Giri et al, 2007	5	5 vaginal	Resuture vaginal mucosa	NA	Yes	NR
Ordorica et al, 2008	11	11 vaginal	Transvaginal tape excision	Complete	Yes	2 SUI
Lapouge et al, 2009	12	12 vaginal	Transvaginal tape excision	Partial	10 yes	4 dry
Al-Wadi et al, 2009	1	1 vaginal	Martius flap	NA	Yes	Dry

NA, not available; NR, not reported; SUI, stress urinary incontinence; TVT, tension-free vaginal tape.

Four patients required surgical excision of the exposed tape, and 1 asymptomatic patient was being observed conservatively without adverse outcomes. Four of the 5 patients were dry, and 1 with recurrent SUI was dry with repeated TVT surgery. Symptoms resolved in all patients after partial tape excision and judicious vaginal debridement. Furthermore, in a large series of 350 TVT procedures reported by Karram and colleagues (2003), three vaginal erosions were noted with 1 patient managed with local estrogen cream and antibiotics. This patient had done well without recurrence of symptoms or additional morbidity at last follow-up. In the same series, another patient underwent careful excision of the vaginal tissues with coverage of the tape with a vaginal advancement flap with satisfactory results. The third patient required partial excision of the exposed tape and redeveloped SUI. In all patients, symptoms related to the tape erosion resolved after management.

In the Finish nationwide review of 1455 TVT procedures, 10 patients were identified with vaginal polypropylene tape exposure. Three of these patients were managed without surgical intervention with good results and maintenance of continence (Kuuva and Nilsson, 2002). Four patients had the vaginal mucosa resutured over the exposed tape, and 2 patients required partial tape excision. One patient was lost to follow-up, and management was unknown at the time of their report. According to this national registry, continence was maintained in all patients, regardless of the management. Australasian data on erosions was presented by Hammad and associates (2005) that included 17 vaginal erosions. Thirty-five percent of the erosions were asymptomatic and identified by vaginal examination. Symptomatic patients complained of palpable tape and vaginal discharge, local pain, UTI, and dyspareunia. All vaginal erosions were managed with either partial or complete sling removal. Five (29%) of these patient with erosions had simultaneous anti-incontinence procedures. Data are unavailable on the other 12 patients.

Among 166 patients in whom TVT procedures performed, 5 (3%) developed vaginal extrusion between 4 and 40 months postoperatively (Giri et al, 2007). Patients complained of vaginal discharge, pain, bleeding, and dyspareunia. The eroded margin of vaginal mucosa was trimmed and closed over the tape. All of the patients were subsequently symptom free at 12-month follow-up. Ordorica and colleagues (2008) reported on 11 vaginal erosions after nonautologous sling (33 retropubic, 2 bone anchors, 3 TOT) placement. Involved sling and suture were excised. The bone anchors were unable to be removed. An autologous sling was placed in the same setting if the patient complained of SUI at presentation. Two patients had recurrent or persistent SUI, 2 had de novo urgency/frequency, and 1 developed osteitis pubis. Lapouge and colleagues (2009) described their management of 12 patients with vaginal erosions. Initially all patients were managed with partial transvaginal excision. Eight (67%) had no complaints after excision, and 50% of these were continent. Al-Wadi and associates (2009) presented a case report of a women with vaginal extrusion of mesh after a TVT procedure that was managed without excision of the exposed sling. After failure of conservative treatment, a Martius graft was used for coverage, with preservation of the exposed mesh and closure of the vagina. These authors believed that removal of sling material increased the patient's chance of recurrent incontinence. At 5-month follow-up the woman is asymptomatic and dry.

Chen and associates (2008) analyzed risk factors associated with vaginal erosion (6/239, 2.5%) after synthetic sling placement. Women with diabetes were 8.3 time more at risk of developing vaginal erosion after synthetic sling placement. The vaginal erosion-free rate during the 24-month follow-up decreased significantly in women with diabetes. There was also a 10.7% more vaginal erosion rate associated with type III multifilamentous polypropylene sling (intravaginal slingplasty) than with type I monofilament polypropylene sling (TVT and TVT-O, $P = .054$). These authors encourage counseling women with diabetes of the risk of erosion.

The sexual function of women after correction of erosion from a midurethral sling was determined using a validated questionnaire (Female Sexual Function Index [FSFI]) by Kuhn and coworkers (2009a, 2009b). Among 21 erosions, 3 healed with topical estrogen; and 18 larger defects required operative intervention. Initially, vaginal closure was attempted, but 2 patients had recurrent erosion. One patient had repeat vaginal closure, and the other had partial sling excision and vaginal closure. The results for the domains of desire, arousal, lubrication, satisfaction, and pain improved significantly. The results pertaining to orgasm remained unchanged.

Key Points: Tension-Free Vaginal Tape Procedure—Vaginal Erosion

- Conservative management seems to be a plausible option in well-selected patients who are relatively asymptomatic and have small-caliber erosions.
- Good results have also been observed in selected patients with vaginal advancement flaps and suture approximation of the debrided vaginal mucosa over the exposed tape (Meschia et al, 2001; Kuuva and Nilsson, 2002, 2003; Karram et al, 2003).
- Even with partial excision of the tape, continence is maintained in the majority of patients.
- Observation should never be considered when there is foreign body involvement of the urinary tract, as with urethral or intravesical erosion.
- Obviously, more data supporting specific management strategies are necessary before a given approach can be advocated for patients with this complication.
- The authors recommend initial judicious observation for small vaginal erosions (with use of topical estrogen cream when appropriate). Excision should be reserved for failure of conservative therapy or when local symptoms militate against observational management (i.e., bothersome dyspareunia).

Urethral Erosion. *Urethral erosion* is defined as presence of sling material within the urethral lumen (Fig. 73–10). **A review of the published literature by the AUA Stress Urinary Incontinence Clinical Guidelines Panel found 5 cases of urethral erosion after 1715 autologous fascial slings (0.003%) and 27 cases of urethral erosion after 1515 synthetic PVS procedures (0.02%)** (Leach et al, 1997). **The exact incidence of urethral erosion after the newer tension-free midurethral sling procedures is, as yet, undetermined. Factors thought to contribute to urethral erosion include compromised urethral blood supply** (i.e., radiation therapy or estrogen deficiency), **excessive sling tension, extensive dissection too close to the urethra with subsequent urethral devascularization, iatrogenic urethral injury (at time of device insertion), and traumatic catheterization/dilation. Furthermore, twisting or rolling of the tape**

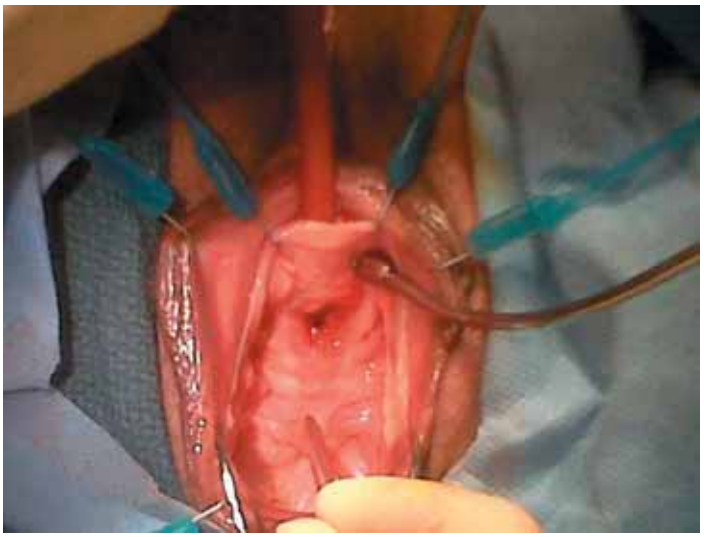

Figure 73–10. Urethral mesh erosion and urethrovaginal fistula.

can create a ridge that leads to pressure necrosis and erosion through the urethra (Dell and O'Kelley, 2005). Management of this complication is extremely challenging with the possibility of significant morbidity, because access to the tape is traditionally gained by incising the urethra, although endoscopic management has been attempted.

Presenting symptoms are varied. In almost all published cases, voiding dysfunction is predominant, with **typical symptoms including urgency, UUI, obstructive voiding, urinary retention, history of self-catheterization, urethral dilations, recurrent UTI, and persistent urinary incontinence** (Haferkamp et al, 2002; Madjar et al, 2002; Pit, 2002; Sweat et al, 2002; Lieb and Das, 2003; Vassallo et al, 2003; Glavind and Sander, 2004; McLennan, 2004; Tsivian et al, 2004; Wai et al, 2004). Diagnosis is often delayed in these patients for an extended period of time. In a review by Amundsen and associates (2003), the average time from placement of the initial PVS to diagnosis of urethral erosion was 9 months.

Diagnosis is made by confirming the presence of the tape within the urethral lumen during cystoscopy. Voiding cystourethrography has also been useful adjunctively by documenting a dilated proximal urethra related to high-grade obstruction caused by the eroded tape (Lieb and Das, 2003).

Management of urethral tape erosion has typically involved transvaginal urethrotomy and excision of the exposed tape. In selected cases an autologous fascial sling and Martius labial fat pad graft can be utilized at the discretion of the surgeon. Pit (2002) described two cases of urethral erosion. The urethra was incised, and the tape was cut at the level of the mucosa. The tape was then dissected on its medial edge toward the inferior ischiopubic ramus and cut bilaterally, which allowed the tape to be removed from the periurethral fascia. A Martius graft was placed over the urethra in one case, and a cadaveric fascia lata graft was used in the second case. A second TVT was then placed over the tissue bolsters without complication. In a review by Sweat and colleagues (2002), transvaginal tape excision was accomplished by identifying and dividing the tape in the midline, followed by sharp lateral dissection along the medial border of the tape, freeing the mesh from the urethra and bladder neck. The endopelvic fascia was perforated and the tape cut in the retropubic space. A Martius fat pad graft was interposed over the urethral closure in one case and an autologous fascial sling placed over the graft in both cases. Both patients improved symptomatically and were continent during postoperative follow-up. Glavind and coworkers (2004) reported a urethrovaginal fistula caused by urethral erosion of the polypropylene tape. Transvaginal tape excision failed to resolve the fistula, and the patient required two transabdominal fistula repairs until closure was achieved and symptom resolution occurred. Persistent SUI was managed by conservative means with satisfactory results. Sokol and Urban (2008) reported use of the internal urinary sphincter for covering the defect after sling resection. They believe this may reduce the risk of fistula formation and be a less morbid option than a Martius flap. Four other additional case reports reported excellent results utilizing a midline transvaginal approach with partial tape excision and closure of the urethra (Haferkamp et al, 2002; Madjar et al, 2002; Lieb and Das, 2003; Wai et al, 2004). The postoperative results reported by each of these investigators were excellent, with all patients achieving symptom resolution after surgical intervention. In 2 patients mild recurrent SUI was successfully managed with biofeedback (Glavind and Sander, 2004; Wai et al, 2004). In 2 patients continence was achieved by intraoperative fascial sling, and in 1 patient a postoperative fascial sling resulted in satisfactory continence (Vassallo et al, 2003; Wai et al, 2004).

Three cases without ideal outcomes utilizing transvaginal excision have been reported. Mesens and associates (2007) described a patient who had recurrence of her erosion paraurethrally 3 months after the initial transvaginal excision. Powers and colleagues (2006) describe two women who presented 1 and 3 years after TVT surgery with urethral erosion. Both patients had UUI and pain at presentation and underwent transvaginal excision. Both women had recurrence of SUI and 1 had persistence of her UUI.

In 2004, McLennan successfully managed a TVT urethral erosion endoscopically. Hysteroscopic scissors were used to transect the tape flush with the urethral mucosa. Catheter drainage was continued postoperatively for 72 hours. The patient remained symptom free and continent at 10 months of follow-up. In a case report by Wai and associates (2004), a combined endoscopic and transvaginal approach was used successfully to manage a difficult urethral erosion. Initially, the tape was cut in the midline transurethrally. Transvaginal periurethral dissection was performed, and the tape was identified and removed from the dense fibrous attachments. An accidental urethrotomy was noted and closed without difficulty. The theoretical advantage of this technique is that, with endoscopic transection of the tape, entry into the urethral lumen is unnecessary. Wijffels and coworkers (2009) utilized an endoscopic transurethral approach successfully in three cases of urethral erosion. The visible tape is grasped with forceps and cut while on traction with scissors. This is performed on both sides of the urethra. One patient had recurrent SUI and another had a TVT placed. Otherwise there were no complaints. A similar approach was used by Baracat and coworkers (2005) successfully for five urethral erosions.

Nine urethral erosions (0.6%) were reported in the Australasian data presented by Hammad and associates (2005). Thirty percent of these erosions presented more than 1 year after surgery, and 89% were symptomatic. Presenting symptoms included urinary retention, bleeding, and local pain. One case was discovered incidentally on cystoscopy. Unlike the reported vaginal erosions, 33% of the urethral erosions occurred when the polypropylene sling followed another anti-incontinence procedure. Four (44%) were managed conservatively (2 patients were too frail to undergo operative intervention). Five patients (56%) had transvaginal excision:

all were cured and dry. Velemir and colleagues (2008) presented a retrospective analysis of eight cases of urethral erosion that were managed with a combination of transvaginal and endoscopic approaches. One patient refused intervention. Two had transvaginal excision of mesh, with 1 developing recurrent SUI, although continent with Zuidex bulking injections followed by laparoscopic Burch colposuspension. One underwent a combined endoscopic and transvaginal excision of mesh but required later endoscopic removal of residual mesh; the patient was dry and asymptomatic following her second endoscopic mesh excision. Four patients were managed endoscopically. Three of the 4patients required repeat endoscopic attempts at mesh removal and urethral stone removal. Two patients had recurrent SUI and were treated with Zuidex bulking injections and a TVT-O procedure.

Key Points: Tension-Free Vaginal Tape Procedure—Urethral Erosion

- Overall, the incidence of urethral erosion is extremely low in the reported literature.
- As the number of synthetic midurethral slings continues to increase, physicians need to be aware of the potential complications, have a high index of suspicion, and be aware of the management options available to treat the patient.
- Conservative observational treatment is not an option for urethral tape erosion.
- The success of endoscopic tape transection needs to be duplicated by others before it can be considered first-line management of urethral erosion.
- Currently, transvaginal excision of the polypropylene mesh with closure of the urethrotomy should be considered the first line of management and is the authors' preferred method if significant surface area of the sling is present within the urethral lumen.
- If the repair is tenuous, a vascularized Martius fat pad graft can bolster the repair. Furthermore, an autologous fascial sling can be placed at the time of surgery or in a delayed fashion to treat recurrent SUI.

Intravesical Tape Erosion. The finding of synthetic mesh within the lumen of the urinary bladder is another particularly distressing complication (Fig. 73-11). This complication is also **exceedingly rare after the TVT procedure** with only case reports in the published literature. Bladder injury recognized at the time of cystoscopy is much more common, occurring with a frequency between 2% and 11% of cases (Nilsson et al, 2001). Recognition of this complication allows the surgeon to remove and reintroduce the trocar in a controlled fashion, with placement of the tape in the correct anatomic plane. The **vast majority of intravesical tape erosions are most likely due to unrecognized cystotomy and placement of the tape within the urinary bladder at the time of surgery. True erosion of the tape across the seromuscular wall of the bladder into the lumen is much less likely.** Thus, performing complete and thorough cystoscopic examination of the bladder with adequate hydrodistention is critical to minimize this complication. Occasionally the insertion trocar may telescope the vesical wall during insertion and may obscure intravesical entry.

Patients typically present after their TVT procedure with a variety of symptoms. A review of seven reported cases in the literature was included in a case report by Negoro and colleagues (2005). **Typical symptoms can include lower abdominal pain, intermittent gross hematuria, recurrent UTI, urgency, frequency, dysuria, and urinary incontinence.**

Figure 73–11. Cystoscopic view of intravesical retropubic sling erosion.

Diagnosis is made with a high index of suspicion by the clinician and cystoscopic examination confirming the presence of the tape within the lumen of the urinary bladder. Imaging including computed tomography and cystography may help in difficult cases but is not a substitute for cystoscopic examination. A review of intravesical polypropylene tape erosions is presented in Tables 73–13 and 73–14.

Management goals are aimed at removing the portion of polypropylene tape from the urinary tract and reconstructing the lower urinary tract. Observational treatment is not recommended because the tape often becomes encrusted, leading to stone formation, persistent lower urinary tract storage/voiding symptoms, recurrent UTI, and intermittent gross hematuria. Different techniques and surgical approaches have been advocated with varying levels of invasiveness, complexity, and success.

In a report by Negoro and colleagues (2005) a retropubic approach was used to resect the intravesical portion of the tape. The bladder was closed with absorbable suture, and catheter drainage was maintained postoperatively. The patient was symptom free and continent at 10-month follow-up. Volkmer and coworkers (2003), Sweat and associates (2002), and Huang and colleagues (2003) used a combined transvaginal and abdominal approach to remove the tape in its entirety. One patient had residual urgency and frequency treated with anticholinergic agents; the other patients had resolution of symptoms but recurrent SUI managed with collagen in one patient and pelvic floor muscle training and estrogen in the remaining two patients.

Ordorica and associates (2008) reported two vesical erosions after nonautologous sling placement. These were managed with either transvesical removal of mesh or a suprapubic extravesical approach. Lapouge and colleagues (2009) retrospectively reviewed five bladder erosions after TVT placement that were initially managed endoscopically. Two patients went on to need open

transvesical removal of residual sling material, owing to insufficient removal on endoscopy or recurrent symptoms. All 5 patients were dry after the last treatment. Oh and Ryu (2009) evaluated the efficacy of transurethral resection in 14 patients with intravesical mesh. The intravesical mesh was resected deep into the perivesical fat. The patients presented with dysuria, hematuria, pelvic pain, and urgency. Six patients presented with stone encasing the mesh. Thirteen (92.9%) had mesh completely removed during a mean follow-up of 18 months. One patient had recurrent bladder stones. One patient had mild SUI and UUI, which was controlled with anticholinergic agents; no further treatment for SUI was performed.

Jorion (2002) excised the tape endoscopically using an offset nephroscope transurethrally and a 5-mm laparoscopic trocar placed suprapubically. Laparoscopic grasping forceps were used to grasp the tape, and endoscopic shears excised the mesh flush with the bladder mucosa, allowing the tape to be easily removed. Cystoscopy at 1 month revealed healed mucosa, and the patient was continent and symptom free. In a separate report by Tsivian and coworkers (2004), the tape was cut endoscopically. Because of dense adhesions and adherent calculus the tape could not be extracted endoscopically. Therefore, a suprapubic approach was required to remove the stone and intravesical tape. Wyczolkowski and associates (2001) attempted to cut the tape endoscopically without success. Transabdominal exploration allowed the tape to be excised, and the cut ends were secured to the inguinal ligaments bilaterally. Holmum:yttrium-aluminum-garnet (YAG) laser excision of encrusted intravesical TVT has been successful in 15 cases (Baracat et al, 2005; Giri et al, 2005; Huwyler et al, 2008; Shrotri et al, 2010). Holmium laser destruction (vaporization) of visible tape has also been performed successfully in two cases (Hodroff et al, 2004; Lane et al, 2005). In two cases, patients presented with bladder stones that had formed on intravesical portions of TVT. Endoscopic lithotripsy of the calculi and transurethral resection of the TVT material was performed. Both patients demonstrated complete mucosal healing and remain asymptomatic and dry (Irer et al, 2005; Mahmoud and Wadie, 2007). There are three reported cases of successful laparoscopic removal of intravesical mesh after retropubic sling placement. In one of these cases a three-port intraperitoneal approach was used (Siow et al, 2005), and in the other two a three-port extraperitoneal approach was used (Rehman et al, 2008). All of the patients were free of symptoms and dry after the mesh removal.

It is unclear from the literature whether complete or partial tape excision is preferred. The authors routinely use the open cystotomy approach for complete tape

excision. This approach is necessitated by a large surface area of tape present in the vesical lumen or in the case of tape collocation near the bladder neck, trigone, or ureteral orifices. Only patients with complete tape removal had recurrent SUI; the patients with partial excision maintained continence postoperatively. The significance of this, given the small number of cases, is unclear, but it may imply that suburethral support is maintained when the midurethral portion of tape is left in situ. The endoscopic approach is intriguing because it is minimally invasive and with the addition of the laparoscopic trocar achieved a satisfactory outcome. This should be duplicated by others before it is universally adopted to treat patients with this particular complication.

Voiding Dysfunction. Voiding dysfunction is a well-recognized complication of suburethral sling procedures for SUI. Although it is difficult to quantify objectively, a review by the AUA guidelines panel concluded that the incidence of permanent urinary retention after suburethral slings does not exceed 5% (Leach et al, 1997). **Anti-incontinence surgery, regardless of the technique, has some effect on outlet resistance. As a result, clinical symptoms of urethral obstruction have not been eliminated by the TVT procedure with an incidence in the literature of 1.9% to 9.9%** (Klutke et al, 2001; Meschia et al, 2001; Kuuva and Nilsson, 2002, 2003; Volkmer et al, 2003; Levin et al, 2004; Long et al, 2004).

Despite the fact that TVT is described as a tension-free procedure there is controversy about whether tension or resistance is directed at the bladder outlet. In one study of 404 TVT procedures, UDS before and after surgery showed an increase in voiding time but no difference in flow rate, urethral closure pressure, or urethral functional length (Meschia et al, 2001). A study by Lo and colleagues (2001) showed no statistical difference in several UDS parameters ($\dot{Q}$avg, $\dot{Q}$max, postvoid residual urine volume, MUCP, and functional urethral length) in 82 patients before and after TVT. In another study, Wang and Chen (2001) looked at filling cystometry, uroflowmetry, and urethral pressure profile data before and after TVT and found the only statistically significant difference to be in resting MUCP. Several other studies have also shown

no statistical difference in UDS pressure flow variables after the TVT procedure (Wang, 2000; Wang and Chen, 2003a, 2003b; Lin et al, 2004).

In contrast, Gateau and associates (2003) analyzed UDS findings before and after TVT surgery in 112 patients and reported consistent decreases in $\dot{Q}$max, increased mean Pdet $\dot{Q}$max, increased mean urethral resistance, and elevated postvoid residual urine volume. They concluded from their data that TVT surgery leads to obstructive changes in the bladder outlet. Sander and colleagues (2002) evaluated the voiding phase before and 1 year after the TVT procedure. They found both subjective and objective changes in the voiding phase, with 78% of patients experiencing more difficult voiding and significant decreases in $\dot{Q}$max, corrected $\dot{Q}$max, and $\dot{Q}$avg . Postvoid residual urine volume was also significantly increased, although not greater than 25% capacity. Furthermore, in another study comparing the TVT procedure and Burch colposuspension, a significant decrease in the flow rate was observed after surgery (Atherton and Staton, 2000).

There are contemporary UDS data both supporting and refuting bladder outlet obstructive changes after the TVT procedure. The physician must therefore consider these issues when counseling patients with SUI before surgical intervention with TVT. It would be most helpful when selecting patients for the TVT procedure to identify preoperative factors predictive of voiding dysfunction and urinary retention after surgery. One study assessed differences in surgical outcome after TVT by subgrouping patients into two groups, those with dysfunctional voiding and those with normal voiding (Wang and Chen, 2003b). Dysfunctional voiding in this study was defined as having both a free $\dot{Q}$max of less than 12 mL/sec and a Pdet $\dot{Q}$max of greater than 20 cm H_2O as defined by Blaivas and Groutz (2000). Statistically significant differences in pressure-flow variables of free $\dot{Q}$max and Pdet $\dot{Q}$max between the two groups were observed, as well as a higher objective cure rate in the normal voiding group. In a separate study by Hong and colleagues (2003), 375 patients were analyzed to see which factors predicted urinary retention after the TVT procedure. Urinary retention, defined as the need to catheterize for 72 hours or longer after surgery, was identified in 32 patients. Twenty-eight patients resumed normal voiding within 3 months, and 4 patients required a TVT release procedure. Patients' age, parity, peak flow rate, and history of hysterectomy predicted urinary retention on univariate analysis, and only peak flow rate predicted urinary retention on multivariate analysis. Finally, a small study of 14 patients showed that low Pdet $\dot{Q}$max on the preoperative pressure-flow study correlated with elevated postvoid residual urine volume in 3 patients after a TVT procedure (Kawashima et al, 2004).

Urethral obstruction after suburethral sling surgery can arise in variety of ways. **Patients may complain of straining to void, incomplete emptying, urgency and frequency, hesitancy, UUI, elevated postvoid residual urine volume, recurrent UTI, and total urinary retention.** These symptoms usually cause patients bother and prompt evaluation and treatment after the initial surgical procedure.

The optimal evaluation for patients with postoperative voiding dysfunction is poorly defined in the literature. In a study by Carr and Webster (1997) there were no parameters (urodynamic, previous surgery, time from suspension to urethrolysis, and surgical approach) that predicted which patients would benefit from urethrolysis. The decision to perform urethrolysis was based on a clear temporal relationship between onset of symptoms and the surgical procedure. In a study by Petrou and coworkers (1999) there was no difference in urethrolysis outcomes with respect to patients with urodynamic obstruction versus those who had surgery based on clinical criteria. Under ideal circumstances, videourodynamics would differentiate patients with high-pressure, low-flow voiding consistent with obstruction and patients with detrusor hypocontractility. **At this time there does not appear to be enough evidence correlating urodynamic parameters with surgical outcomes. Therefore, UDS can be useful in selected cases at the physician's discretion; however, it appears that the temporal relationship correlating symptoms with an antecedent surgical procedure should be the primary criterion in selecting patients for urethrolysis and tape release procedures. Cystoscopy is useful to rule out bladder pathology, urethral tape erosion, and a hypersuspended bladder neck.**

In most cases, persistent postoperative voiding dysfunction is initially treated conservatively. Temporary catheter drainage, clean intermittent catheterization, timed voiding, biofeedback, pelvic floor muscle training, and selective medical therapy have all been successful to some degree in managing postoperative voiding dysfunction. Several reports have shown some benefit with urethral dilation (Hong et al, 2003; Mishra et al, 2005). **However, when these conservative measures fail, surgical intervention is usually indicated.** The urethrolysis literature is more mature and robust in the management of urethral obstruction secondary to traditional PVS surgery. A discussion of the results of surgical management of urethral obstruction after a TVT procedure follows (Table 73–15).

In a large review of 1175 TVT procedures, Rardin and colleagues (2002) found 23 (1.9%) women with persistent voiding dysfunction. Twenty patients had urinary retention or incomplete emptying, 3 patients had symptoms of refractory urgency and UUI, and 7 had both. Symptoms of incomplete bladder emptying usually arose in the immediate postoperative period, and LUTS arose in delayed fashion some weeks later. All patients were refractory to conservative regimens and underwent TVT release at a mean time of 17.3 weeks after the TVT procedure. Tape release was performed in the majority (17 patients), with mild urethrolysis in 2 patients and segmental tape excision (2 to 11 mm) in 4 patients. Relief of impaired bladder emptying was complete in 100%, and relief of urgency/UUI was complete in 30% and partial in 70%. Fourteen patients (61%) maintained their baseline continence, 6 (26%) were improved over baseline, and 3 (13%) had recurrent SUI.

Kuuva and Nilsson (2002, 2003) reviewed complications associated with the TVT procedure from the nationwide database in Finland. In their analysis of 1455 TVT procedures, 34 cases (2.3%) of urinary retention were reported and duration was recorded for 23 patients. A normal voiding pattern was resumed in 14 patients (2 days to 2 weeks), 2 patients (5 to 6 weeks), and 6 patients (within 24 hours) after surgery. One patient required that the tape be released by cutting it in the midline, and normal voiding resumed. In 111 cases the authors noted "minor" postoperative voiding difficulty (e.g., urgency, frequency) that resolved without intervention in the majority of patients. Thirteen cases were identified that lasted up to 4 months, and 2 of these patients required surgical transection of the tape to achieve a normal voiding pattern.

In another large review by Klutke and colleagues (2001), 17 of 600 patients (2.8%) required reoperation secondary to urinary retention and persistent obstructive symptoms. In their series, tape release was performed at a mean of 64 days after the TVT procedure. The tape was identified and either released with downward traction for 1 cm or cut in the midline. There was one urethral injury, which was repaired without sequelae. Symptoms resolved in all patients after tape release, all patients voided to

LUTS, lower urinary tract symptoms; NR, not reported; SUI, stress urinary incontinence; TVT, tension-free tape.

completion, and 16 patients remained continent. In a review by Long and associates (2004), 7 of 71 patients (9.9%) underwent lateral tape excision to treat patients with evidence of urethral obstruction. All patients had irritative symptoms or elevated amounts of residual urine and 6 patients voided with significant straining. Six of the patients had urodynamic obstruction (Pdet > 20 cm H_2O and $\dot{Q}max$ < 12 mL/sec) and 1 patient had low-pressure, low-flow voiding. Long and associates described a technique transecting the tape lateral to the midline on the right side of the periurethral fascia, leaving the tape in the shape of a J underneath the urethra. Symptoms resolved in 6 patients, and 5 patients were continent. Of note, in the 2 patients who had

recurrent SUI after transection of the tape, the tape was cut on postoperative day 4 in both cases. In the other cases the tape was cut after a minimum of 14 days after TVT. Therefore, on the basis of their experience, the authors recommended a minimum waiting period of 2 weeks before surgical intervention.

In a study reviewing outcomes and complications of 404 TVT procedures, Meschia and coworkers (2001) found 17 patients (4%) who had voiding difficulties defined as residual urine greater than 100 mL. At 1-month follow-up, 15 patients resumed normal voiding patterns and the remaining 2 patients required the tape to be cut in the midline to release tension; normal voiding was observed thereafter. A review by Volkmer and coworkers (2003) found 3 patients with permanent urinary retention after the TVT procedure. UDS revealed high-grade obstruction in each patient utilizing the Abrams-Griffiths nomogram. Two patients had the tape cut in the midline transvaginally, and 1 patient had segmental excision of the entire suburethral portion of the tape. All 3 patients were able to resume normal voiding without significant residual urine, and 2 of the 3 patients remained continent. In the patient with recurrent SUI the suburethral portion of the tape was excised and she underwent repeated TVT surgery to restore continence.

Levin and colleagues (2004) reviewed a series of 313 patients who underwent the TVT procedure. They identified 8 patients (2.5%) who had urinary retention with incomplete bladder emptying. Seven patients required temporary catheterization for a short period of time before resumption of normal voiding at a follow-up of 1 month. The remaining patient had persistent urinary retention 2 months after TVT surgery, and UDS showed obstruction on the pressure-flow study. Transvaginal urethrolysis with tape excision was performed, and the patient thereafter resumed complete bladder emptying with complete continence. Tsivian and associates (2004) found 8 of 12 patients who required repeated surgery after a TVT procedure to have urethral obstruction, with complaints ranging from severe urgency symptoms to straining to void. All patients had incomplete bladder emptying, and 5 patients had objective evidence of obstruction on pressure-flow UDS. All 8 women underwent corrective surgery with resolution of symptoms, and only 2 women suffered from recurrent SUI symptoms.

Karram and coworkers (2003) reviewed their series of TVT procedures looking at the incidence of postoperative complications. Seventeen women (4.9%) were performing clean intermittent self-catheterization beyond 7 days. Another 42 women with irritative LUTS were taking anticholinergic medications more than 6 weeks after surgery. Twenty-eight patients underwent urethral dilation, which provided symptom relief in 23; and 6 patients with persistent urinary retention had transvaginal takedown and incision of the tape. Normal voiding resumed in all 6 of these patients, although 2 experienced recurrent SUI.

Zubke and colleagues (2004) managed 3 patients with urethral obstruction after TVT with a novel surgical technique. They cut the tape in the midline with a transvaginal approach and sutured the edges of the tape to a Prolene mesh, thus lengthening the tape. All 3 patients were continent and resumed normal voiding after intervention. Mishra and colleagues performed urethral dilation on 3 of 52 cases who had retention 3 months after TVT. Two of the three patients voided effectively after urethral dilation. In this series the postoperative retention rate is significantly higher (23%) than published data. Although many practitioners report anecdotal success, no randomized trials exist in peer-reviewed literature. It is the authors' opinion that urethral dilation is of limited utility and if used too aggressively may be detrimental. There are concerns about the potentially traumatic nature of dilation, which could induce scarring of the urethra. Hammad and associates (2005) reported on their incidence and management of urinary retention in an Australasian cohort after 1459 midurethral slings (993 TVT, 466 SPARC). Postoperative retention occurred in 95 patients, but surgical intervention was only required in 33 patients. This included sling loosening, lysis, and urethrolysis. This study does not provide information on time to presentation of obstruction or of results after treatment of obstruction.

Sokol and coworkers (2005) described the management of obstruction after a TVT procedure with and without concurrent prolapsed repair. The median days to voiding (8 vs. 5 days) and rate of urinary retention were similar between patients with and without prolapse repair. Increasing age, decreasing BMI, and postoperative UTI were independent predictors of time to adequate voiding, whereas previous history of incontinence surgery was the only independent variable predictive of urinary retention. Sling loosening was reported by Nguyen (2005) within approximately 1 week after TVT placement. All patients had a suprapubic tube placed at time of initial TVT, which was removed once the patient was able to void at least 75% of total bladder volume on two consecutive occasions. All patients were continent after mobilization, and quality of life scores of the nonvoiders did not differ from those of voiders 1 year after surgery.

A nationwide analysis of obstruction after TVT surgery was performed by Finnish authors (Laurikainen and Killholma, 2006). A retrospective review of 9040 patients who received a TVT procedure was reviewed. Approximately 50% were cured with sling lysis and remained continent. Four (12%) continued to have retention after lysis. There was no difference in continence rate among patients based on interval between a TVT procedure and sling lysis. Repeat sling lysis and urethrolysis were options used in managing the refractory retention.

Gamé and colleagues (2006) presented results of 30 women requiring sling lysis with a single lateral incision over a 4-year period. Seventy percent were continent after intervention, and 2 women developed recurrent SUI. Glavind and Glavind (2007) evaluated different treatment options for managing prolonged voiding dysfunction after TVT placement (clean intermittent catheterization, sling loosening, and lysis). Seven percent of their initial cohort developed prolonged voiding difficulties. Five patients experienced loosening at between 1 and 3 weeks; 2 underwent sling lysis between 5 and 7 months, and 3 patients chose to perform extended clean intermittent catheterization. The sling loosening study arm was the only group who was subsequently continent. The authors concluded that voiding issues should be followed closely for the first 1 to 2 weeks and intervention should not be delayed if symptoms persist. The value of this study is limited by the large variability in time between presentation of symptoms after TVT and intervention. It clearly supports timely evaluation and intervention for obstruction or related symptoms.

Three studies attempted to relate preoperative or intraoperative variables to postoperative voiding dysfunction. Takacs and colleagues (2007) found that a poor quality intraoperative cough test predicted immediate postoperative retention. The quality of the cough test was determined by whether every cough produced urinary incontinence. This study is limited by subjective measurements of the cough test. The cough test is no longer commonly performed intraoperatively for setting sling tension. Shukla and colleagues (2007) found no significant predictive factors but described a trend toward long-term voiding difficulty after concurrent posterior vaginal repairs and in women with low preoperative flow rates. Vervest and colleagues (2007) performed a prospective

cohorts study in 703 women with a TVT procedure and reported the need for postoperative catheterization for more than 24 hours in 11% and sling lysis in 1.3% of patients. Using validated questionnaires, these authors found that the negative impact of abnormal voiding on TVT outcomes is greater than in those without voiding dysfunction. Yet, this impact decreased significantly after a TVT procedure, implying a considerable improvement in quality of life.

Key Points: Tension-Free Vaginal Tape Procedure—Voiding Dysfunction

- It appears that long-term urinary retention and obstructive voiding dysfunction are extremely rare after the TVT procedure.
- Although definitions of urinary retention and indications for management vary in the reported literature, most patients are initially managed conservatively. Anecdotal cases have shown modest benefit from urethral dilation.
- For patients with persistently elevated residual urine and bothersome symptoms refractory to conservative management, TVT release procedures consistently provide resolution of symptoms with maintenance of continence in the majority of patients.
- The authors recommend a waiting period of at least 4 weeks before any consideration of sling release. Sling release should be attempted through a small midline vaginal incision using minimal dissection.

Other Complications. A diverse group of complications have been reported with the midurethral sling, aside from those mentioned previously. These include vascular injury, bowel perforation, dyspareunia, pain (inguinal, suprapubic, pelvic), and infection-related complications. Death has also occurred after sling implant and been directly attributable to the procedure.

Wound-related complications include minor superficial cutaneous infections, pelvic abscesses, and UTI. A case of necrotizing fasciitis was reported in an obese, diabetic patient. This resolved after intensive resuscitation (Connolly, 2004). Interestingly, a review of necrotizing fasciitis in gynecologic surgery found that obesity (88%), hypertension (65%), and diabetes (47%) were all strong factors in the development of this infection after surgery (Gallup et al, 2002).

Serious complications such as vascular perforation or intestinal perforation remain relatively low. The rate of serious vascular complications in the Finnish registry was 0.07% (Kuuva and Nilson, 2002), and the Austrian registry reported a bowel perforation rate of 0.04% (Tamussino et al, 2001). In a systemic evaluation of the occurrence of postoperative retropubic hematoma formation, Flock and colleagues (2004) reported a rate of 4.1% among 249 consecutive cases, with only 4 patients with hematomas exceeding 300 mL and requiring surgical intervention.

Groin and suprapubic pain are potential problems after TVT placement. Thigh pain is usually associated with the transobturator approach (see later). A randomized controlled study from Finland (Laurikainen and Killhoma, 2006) reveals 16% of women in the transobturator (inside-to-outside) group had groin pain compared with only 1.5% of those in the TVT study arm. This groin pain persisted longer after the TVT-O than after the TVT (Daneshgari et al, 2008). Long and associates (2009) and Wang and colleagues (2009) both also found the TVT-O group to have significantly more postoperative groin and thigh pain. Duckett and Jain (2005) reviewed different strategies for managing groin pain after a TVT procedure or other similar midurethral slings in five women (1%). Initial conservative management was successful in most patients. Those with persistent or severe pain (four women) were given combination of corticosteroid and local anesthetic injections. Two women developed recurrent pain and had the TVT excised, with significant pain relief. Doo and associates (2006) noted persistent suprapubic pain in three (2.2%) women at 5-year follow-up after a TVT procedure.

Varying degrees of sexual impairment after TVT insertion (0% to 15%) have been associated with dyspareunia (Kuhn et al, 2009a). Among 20% prospectively evaluated who reported sexual impairment after TVT placement, 14.5% related this to dyspareunia (none preoperatively vs. eight postoperatively, $P < 0.01$) (Mazouni et al, 2004). Marszalek and colleagues (2007) performed a cross-sectional analysis and noted that the 14.3% deterioration in sexual function was significantly associated with de novo urgency, dyspareunia, and a sensation of incomplete emptying. The sexual satisfaction of the TVT and Burch colposuspension were compared (Demirkesen, 2008). Fifty-four percent expressed a negative change, of which the majority suffered from dyspareunia. The TVT procedure appeared to more adversely affect sexual satisfaction, but the difference was not significant. Kuhn and coworkers (2009a) reviewed the impact of sling removal for postoperative female de novo dyspareunia and found that pain improved significantly.

Review of the U.S. Food and Drug Administration safety database for complications reported to that agency is noted in Table 73–16. Catastrophic complications are rare but do occur and may result in mortality: 11 reported deaths exist in the database from 1998 to July 2009.

Key Points: Tension-Free Vaginal Tape Procedure—Voiding Dysfunction

- Clinical experience with the TVT operation suggests that it is beneficial in the management of SUI.
- In prospective trials, significant percentages of patients have been found to be cured or significantly improved compared with standard operations for the indication of SUI.
- There appears to be a relatively robust outcome expected from this procedure in patients with all types of incontinence, whether it be primary SUI or MUI, or in patients who have prior failed procedures or who are undergoing simultaneous pelvic prolapse surgery.
- Patients with ISD appear to have worse outcomes, although the absolute reported rates of cure and improvement are within the range of reported results experienced with other types of procedures.
- The risks of intraoperative and short-term postoperative complications are low, especially with trained physicians. There does appear to be a learning curve, which must be taken into account with new adopters and trainees. There do not appear to be any long-term adverse events.

Table 73–16.

Summary of All Significant Complications Reported to the U.S. Food and Drug Administration with the Midurethral Sling TVT: 1998-2009

Bladder erosion	50
Urethral erosion	51
Vaginal erosion	239
Bowel perforation	48
Major vascular	26
Blood loss >200 mL	36
Plastic sheath malfunction	51
Leg pain	44
Needle broken from mesh	154

This analysis is limited by reporting inaccuracies and the incomplete nature of adverse event reporting in common practice.

Transobturator Slings

Subsequent to the development of TVT it was recognized that transobturator tape (TOT) was a viable method for correction of SUI. Since Ulmsten's initial article in 1996 there has been extensive acceptance of the various midurethral sling technologies. In Europe, as of 2005, approximately 83.9% of all procedures are midurethral-type synthetic slings, of which 26.9% are with TOT (de Tayrac and Medelenat, 2004). Since the initial description of the TOT approach, numerous other similar TOT approaches have been noted.

The goal of the minimally invasive surgical procedure should be to provide acceptable long-term efficacy comparable to that of more standard methods as well as a relatively low incidence of long-term complications, again compared with these "gold standard" procedures. Retropubic midurethral slings have demonstrated robust outcomes in both primary and recurrent SUI as well as in women with MUI and in those with ISD. Delorme (2001) initially described the placement of synthetic polypropylene mesh using the TOT approach. The technique was described as being relatively facile and associated with fewer complications than retropubic approaches. It was also thought that the procedure did not require cystoscopy.

Much of the understanding of the function of the TOT slings arises from that which has evolved from TVT-type procedures. Perineal ultrasonography has been used to assess the function of the TVT in patients who undergo successful incontinence procedures. In those individuals, a functional kinking of the urethra during stress events is noted to occur when the tape is placed at the midurethra (Lo et al, 2004). In relatively long-term follow-up (3 years), 92% of patients had ultrasonic demonstration of tape at the midurethra and evidence of urethra kinking that caused the "urethral knee angle." Of these patients, 92% were continent. Of the patients who had tape location either at the posterior urethra or bladder neck, only three of five (60%) were continent, presumably because of lack of a fulcrum-like effect at the midurethra. These ultrasound studies appear to underscore the importance of the midurethral location and also the ability of the TOT to accomplish this localization (Lo et al, 2001, 2004).

Similarly, Minaglia and colleagues (2004), using a variant of the TOT (ObTape), showed no difference in resting urethral angulation after tape insertion. These authors, however, did notice that there was a statically significant difference preoperatively and postoperatively in urethral angle with straining. They also noted that most women had persistent urethral hypermobility after the procedure, and they concluded that correction of hypermobility was not necessary to achieve continence. Their results documented that 90.4% of patients with documented hypermobility were continent, whereas only 50% of the patients without hypermobility were continent. They concluded that a persistently positive Q-tip test was predictive of a successful outcome. They found that concomitant prolapse surgery or previous incontinence surgery had no effect on outcome.

Surgical Anatomy

For successful implantation of the TOT, an understanding of the surgical anatomy of the pelvic floor, including the surrounding neurovascular structures, pelvic and perineal anatomy, and the obturator foramen, is crucial to provide surgical success and minimize morbidity. Three reviews have demonstrated with cadaveric dissection the importance of landmarks and implantation technique for the success of the TOT procedure.

Bonnet and colleagues (2005) performed the "inside-out" TOT technique as described by de Leval (2003) in 13 cadavers to determine tape path and proximity to surrounding structures. Cadaveric dissection was extended from the femoral triangle medially through the obturator externus muscle and adductor longus to the inferior pubic ramus. The perineal space was then entered, and the pubic bone was sectioned to evaluate the relationship of the tape to various structures. Finally, the subfascial anterior perineum and pelvis were dissected to analyze the tape path fully. These authors demonstrated several significant points in their cadaveric dissection. They noted that the tape never penetrated the adductor longus muscle, thus being a safe distance from neurovascular structures. In approximately 70% of studied cases the implanted material did traverse the adductor magnus, adductor brevis, and gracilis muscles during its path into the pelvis.

At the level of the obturator foramen the tape was noted to traverse both the obturator externus and internus muscles as well as the obturator membrane. The relationship between the inserted tape and the obturator nerve showed that the closest proximity of the two was 22 mm with a distance as great as 30 mm (mean 26.2 ± 2 mm) at the level of the obturator foramen. The authors emphasized that an individual's thighs in hyperflexion and the rotational trajectory of the helical passer associated with this positioning ensured the separation of the insertion tool from the nerve during the actual implantation of the material. They also noted that regional vascular anatomy (anterior branch of the obturator) was protected from injury by the bony architecture of the inferior pubic ramus.

More medially, the tape entered the anterior compartment of the ischiorectal fascia, in the area of the levator ani membrane and obturator internus muscle. The tape remained outside the pelvic space and did not penetrate the levator ani muscular group. The tape remained above the perineal membrane at all times. The dorsal nerve of the clitoris was found to be consistently caudal to the perineal membrane and thus protected from injury during needle passage. These relationships were found to be consistently confirmed in each cadaveric specimen, and thus Bonnet and colleagues believed that these observations represented highly reproducible anatomic positioning and therefore concluded that the TOT technique is safe.

Delmas and associates (2003) utilized the "outside-in" approach on 10 female cadavers, again detailing the relevant pelvic anatomy in relationship to the tape insertion path. In this study, dissection demonstrated that the tape always consistently passed 4 cm opposite and caudal to the obturator canal, again confirming the

relative safety of neurovascular structures. They also demonstrated that the tape traverses a plane between the perineal and levator antimusculature but above the neurovascular pedicle of the pudendum. They also noted that in the pelvic component of their dissections, the tape courses medial to the obturator plexus. They concluded that tunneling passage anteriorly risks injury to the bladder and passage in the posterior dissection demonstrated a risk of vaginal perforation.

A third study by Whiteside and Walters (2004) further evaluated the obturator anatomy in relationship to tape insertion in six female cadavers. These authors found that the mesh, on average, passed 2.4 cm inferior and medial to the obturator canal and that both divisions of the obturator (anterior and posterior) were 3.4 and 2.8 cm, respectively, separated from the path of the insertion tool. They also noted that the insertion tool passed within, on average, 1.1 cm proximity to the medial branch of the obturator vessels. These authors concluded that a risk of injury does exist and that appropriate caution should be exercised.

Operative Technique

Operative technique varies with insertion method. Various procedures using similar insertion methods represent relatively similar technique (Fig. 73–12). Not only does implantation technique affect overall success of the sling, but also the type of mesh or tape implanted has a substantive effect on overall results. Mesh properties have been shown to have a significant effect on local inflammatory response and ingrowth of local fibrous tissues (collagen, neovascularity) and subsequent integration of these tapes into host tissues. These differences in properties are believed to affect the risk of erosion and subsequent infection and other vaginal and local complications. There are intrinsic differences between the various meshes that have been used for the TOT approach. The ObTape and UraTape meshes are polypropylene material but are small pore, knitted, and thermally bonded with an approximately 15-mm silicone component that is immediately suburethral in location after implantation. A second-generation obturator tape developed by the Mentor Corporation is known as the Aris TOT; it has a larger 200-µm pore size that allows improved tissue ingrowth with less encapsulation. The ObTryx, TVT-O, Monarc, I STOP, and Urotex-TO are large-pore open knit polypropylene meshes. A unique obturator mesh is the BioArc, which, like the suprapubic variety, has a biologic graft material that is sutured on either end to the polypropylene tape. The biologic material actually occupies a suburethral position (de Leval, 2003; Delorme et al, 2003) (Table 73–17; Fig. 73–13).

Transobturator Outside-In. The patient is placed in the dorsal lithotomy position with legs in hyperflexion (120 degrees). A small vertical vaginal incision is created as with the TVT procedure over the midurethra, and dissection is carried out laterally to the ischiopubic ramus. A puncture incision is made in the obturator foramen at the level of the clitoris in the leg using the tunneler; the obturator membrane is perforated, at which point resistance is noted by the operative surgeon. Using the nondominant index finger and identifying the landmarks of ramus and the obturator internus muscle, the surgeon turns the tunneler in a medial orientation and advances it on the tip of the index finger and brings it out through the vaginal incision. Inspection is carried out at this point to exclude inadvertent penetration of the vaginal fornix or associated urinary structures. The synthetic material is then attached to the tunneler and brought out through the inner thigh stab wound. The procedure is then repeated on the contralateral side. Tension is set on the tape by passing a clamp between the tape and urethra such that a surgical clamp can be passed easily between these two structures. Excess material is then cut at the

skin puncture site, and the incisions are closed according to the surgeon's preference.

This approach is used for the following devices: ObTape, UraTape, Aris TOT, Monarc, BioArc TO, Uretex-TO, ObTryx, I STOP.

Transobturator Inside-Out. The vaginal component of the procedure is essentially the same as in the outside-in technique. Stab incisions are created approximately 2 cm superior to the horizontal line level with the urethra and 2 cm lateral to the labial folds, which will be the exit point for the helical passer. Once the device is inserted through the urethra and the upper part of the ischiopubic ramus is reached with the device, the obturator membrane is perforated sharply with scissors. The introducer is then passed at a 45-degree angle relative to the midline sagittal plane until it reaches and perforates the obturator membrane. The open side of the introducer is passed out facing the surgeon. The more distal end of the tubing is then mounted on the spiral segment of the helical passer and slipped along the open gutter of the introducer. The passer is aligned parallel to the sagittal axis and rotated so that the tip of the tubing exits the inner thigh stab incision. The tubing is then removed from the passer until the first few centimeters of the tape become externalized, and the procedure is repeated on the contralateral side. All plastic covering sheaths are then removed simultaneously from the tape while maintaining no tension on the sling itself using the technique previously described.

Only one technique currently uses this method: TVT-O.

Results

Since the initial description by Delorme in 2001, continence rates have been reproducibly satisfactory although follow-up has, in general, been short (Table 73–18). Reported continence rates range from 80.5% to 96% on the basis of a variety of subjective (questionnaire and quality of life single-item assessment) and objective (cough stress test, uroflowmetry, physical examination) measures.

Efficacy

Efficacy analyses have included heterogeneous groups of patients, including those in whom prior procedures failed, those who had concomitant prolapse, and those with MUI. Delorme (2001) noted that 15.6% of his patients had ISD, and Mellier and colleagues (2004) diagnosed 28% of their patients with ISD. Despite these diverse populations of patients, relatively similar results were obtained. O'Connor was the first group to examine the early outcomes of the transobturator approach for SUI in women with a variable VLPP. Patients were divided into high (>60 cm H_2O) or low (<60 cm H_2O) VLPP groups. The odds of continued SUI after TVT-O were 12 times greater for women with VLPP less than 60 cm H_2O compared with those with VLPP greater than 60 cm H_2O (O'Connor et al, 2006). However, no preoperative predictors of outcomes using either clinical or urodynamic parameters were established to determine overall results of these procedures. Therefore, the effect of MUI and concomitant prolapse on surgical outcomes for this intervention are unknown. Prospective studies are needed to answer these questions.

Two nonrandomized studies have compared TOT with TVT procedures and have found no significant difference in postoperative voiding dysfunction, complications, or overall continence. There was a tendency toward more bladder injuries (10% vs. 0%) and hemorrhage (10% vs. 2%) with the suprapubic as compared with the TOT approach, but this did not reach statistical significance (de Tayrac et al, 2004; Mellier et al, 2004). Five prospective randomized studies have compared TOT with TVT procedures, ranging in follow-up from 6 to 31 months (Lee et al, 2007b; Porena et al; 2007; Zullo et al, 2007; Rinne et al, 2008; Schierlitz et al, 2008; Rechberger et al, 2009). Among two groups there were a significantly greater number of bladder perforations in patients with the retropubic approach over the TOT approach: 6.5% vs. 0% (Rechberger et al, 2009) and 7.3% vs. 0% (Schierlitz et al, 2008). Both of these groups also found the TVT to be more effective than the TOT in patients with ISD. Schierlitz and colleagues (2008) observed that at 6-month follow-up, 13% of the TOT procedure patients with ISD required further surgery whereas 0% of the TVT patients with ISD required reoperation for SUI (Schierlitz et al, 2008). Porena and associates noted that storage symptoms were significantly improved in the TOT group (still present in 24%) while persisting in 44% of the TVT group (Porena et al, 2007). **A few key points are consistent between these studies: these techniques were safe, there were no long-term complications in either group, cure rates were equal (with exception of ISD group), and patients were equally satisfied.**

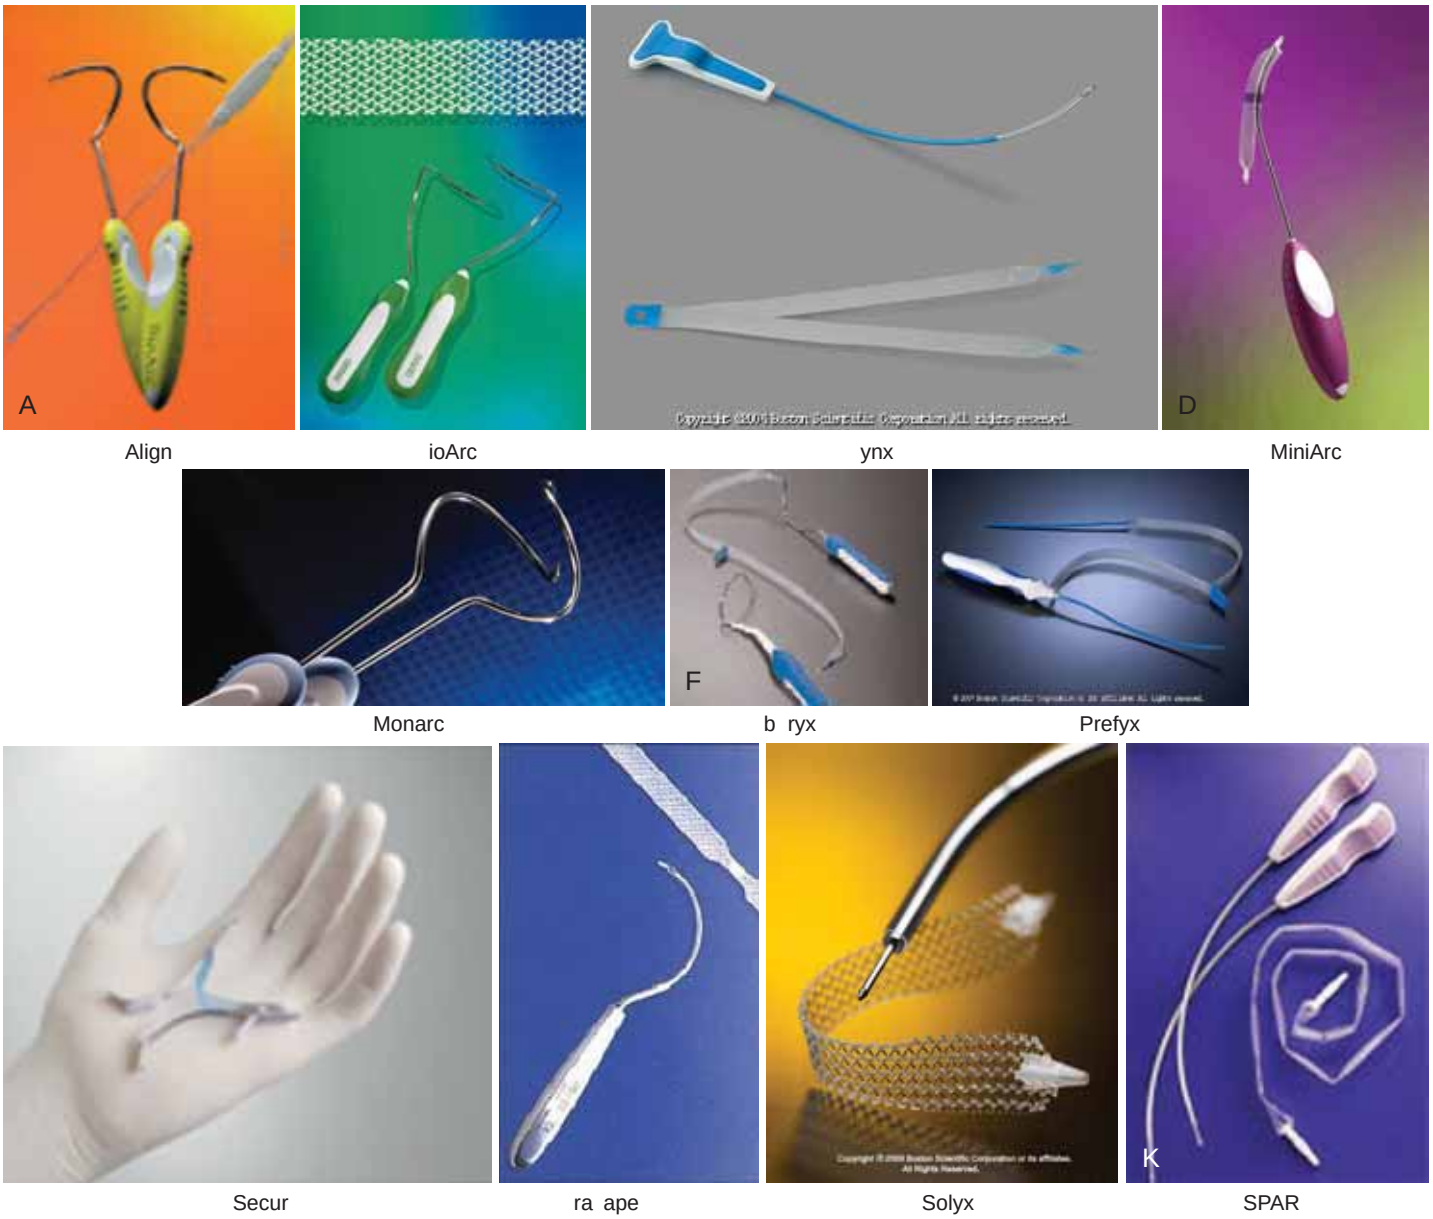

Figure 73–13. Midurethral devices.

Complications of the Transobturator Approach

Despite the minimally invasive nature of these procedures, perioperative and postoperative complications have been reported with a variety of techniques.

Bladder Injury. The anatomic variation between the inside-out (TVT-O) and outside-in (TOT) approaches has been compared, especially in regard to their association with adverse outcomes. Cadaver dissections after a TVT-O procedure noted the mean distance from the vaginal incision to the obturator membrane is 4.0 cm, and from the vaginal incision to the obturator neurovascular bundle is 6.75 cm. At the obturator membrane the closest point of the passer is only a mean distance of 2 cm from the obturator neurovascular bundle. This is the reason the curved passer is directed away from these structures and advanced. Also, an anterior branch of the obturator artery coursed medially along the exterior edge of the obturator foreman in 60% of the cadavers. They believed that this artery was protected by the exterior bony rim of the obturator foramen during an inside-out pass but could be potentially injured in an outside-in approach (Rogers et al, 2005).

Conflicting results have been reported by Zahn and associates (2007), who found that the inside-out method was significantly closer to the obturator canal. The greater proximity and distance from the ischiopubic ramus of the inside-out method was noted in all of their cadaveric dissections. Additional dissections revealed the deep external pudendal vascular structures coursing from superolateral to inferomedial over the obturator foramen, putting it at risk during the exit of an inside-out approach. No clinical correlations exist to date, suggesting that one approach is associated with a higher incidence of tunneler-related complications.

Bladder perforation appears to be the most common complication associated with any midurethral sling, with a 2% to 11% risk with the suprapubic approach. Although initial reports described the risk with the TOT approach as being negligible, the risk of bladder injury

ISD, intrinsic sphincter deficiency; MUCP, maximum urethral closure pressure; MUI, mixed urinary incontinence; NA, not available; NR, not reported; SUI, stress urinary incontinence.

is now identified as associated with this sling insertion technique (Table 73–19) (Olsson and Kroon, 1999; Kobashi and Govier, 2003b; de Tayrac et al, 2004).

Minaglia and colleagues (2004) reported three cases of intraoperative bladder injury while performing the TOT insertion method. They identified all injuries intraoperatively because of their utilization of cystoscopy as an adjunct to all insertion procedures. All injuries were managed with catheter placement for 1 week postoperatively, and these authors noted no complications after sling removal and reinsertion at that same setting. Parekh and associates (2006) reported a case of intravesical mesh erosion after TOT placement and cystocele repair. The patient did not have cystoscopy intraoperatively. She initially presented with mesh on the left side of the bladder and then 6 months later with sling material in the right side of the bladder. She had a successful transurethral, transvaginal, and suprapubic mesh resection.

A single case of bladder laceration was reported by Cindolo and Costa that was also managed intraoperatively (Cindolo et al, 2004; Costa et al, 2004). This apparently was a more extensive injury than just trocar perforation. The tunneler passage of the outside-in obturator approach has been shown to be associated with lower urinary tract injury. To date, no case of bladder injury when performing the TOT procedure by the inside-out approach has been reported using the TVT-O (Hermieu et al, 2003; Whiteside and Walters, 2004).

Table 73–19.

Complications Associated with Transobturator Tape Techniques

STUDY	NO. PATIENTS	ADVERSE EVENTS
Delorme et al, 2003	32	None reported
de Leval, 2003	107	One superficial vein thrombosis with abscess; ?(27/107) 15.9% transient thigh pain
Domingo et al, 2005	65	Nine vaginal mesh erosion
Costa et al, 2004	183	Three vaginal erosion; two urethral erosion; one bladder perforation; one vaginal perforation; two urethral perforation
de Tayrac et al, 2004	30	Six uncomplicated UTI; one obturator hematoma
Cindolo et al, 2004	80	One vaginal erosion with inguinal abscess
Mellier et al, 2004	94	2% intraoperative hemorrhage (300 mL); one urethral perforation
Queimadelos et al, 2004	47	None reported
Krauth et al, 2005	604 (140 with 1-yr follow-up)	0.3% vaginal erosion; 2.5%UTI; 0.5% bladder perforation; 0.33% vaginal perforation; 2.3% perineal pain
Giberti et al, 2007	118	6.4% vaginal erosion; one vaginal hematoma
Juma and Brito, 2007	117	3.84% vaginal erosion; 1.52% bladder perforation
Neuman, 2007	300	0.7% vaginal erosion; 1.3% dyspareunia
Al-Singary et al, 2007	24	1% perforated vaginal fornix; 12.5% vaginal erosion
Waltregny et al, 2008	102	1 vaginal laceration
Rechberger et al, 2009	197	2.5% vaginal erosion; 5.5% UTI; 5% urinary retention
Lee et al, 2009	105	4% dyspareunia

UTI, urinary tract infection.

Erosions, Extrusions, and Infectious Complications. Domingo and coworkers (2005) reported a relatively high incidence of vaginal erosion in their series using either the ObTape or UraTape. They attributed their erosion rate to the characteristics of the particular mesh that they utilized, with the reduced pore size and other mechanical properties of that particular material. They noted a slightly increased risk of erosion with the ObTape (15-mm silicone-coated portion)—19% versus 12% compared with the UraTape—and they believed that this was most likely due to reduction in pore size and higher degree of encapsulation. They also concluded that synthetic mesh with larger pore sizes facilitates vascular and tissue ingrowth, optimizing mesh incorporation. Tape erosion was usually managed by removal by the transvaginal approach alone or combined with the transobturator approach. They noted continence rates of 78% (despite tape removal in their series) (Domingo et al, 2005). Vaginal extrusions and erosions of up to 15% have been reported, often accompanied by obturator and ischiorectal abscesses, sinus formation, and voiding difficulty using the ObTape or UraTape (Babalola et al, 2005; Domingo et al, 2005; Deval et al, 2006; Robert et al, 2006; Al-Singary et al, 2007; Dobson et al, 2007; Giberti et al, 2007; Juma and Brito, 2007; Karsenty et al, 2007). Abscess and adductor myositis have been reported, manifesting as leg pain, difficulty ambulating, and cellulitis (Goldman, 2006; DeSouza et al, 2007; Karsenty et al, 2007; Leanza et al, 2008; Zumbé et al, 2008). Gamé and colleagues (2004) reported an infected obturator hematoma also requiring exploration and drainage. Tamussino and associates (2007) published data from the Austrian database, including 2543 transobturator cases, using 11 different tape systems. They reported greater number of complications than reported earlier in their TVT database. This included 120 intraoperative complications (4.7%), 85 cases of bleeding (3.3%), 10 vaginal perforations (0.4%), 10 bladder perforations (0.4%), and 2 urethral perforations. Bladder perforations occurred more frequently with the outside-in tape systems than the inside-out tape systems in their database. The ObTape is no longer available for construction due to the high erosion rates.

Newer, knitted polypropylene slings and many of the reports using the inside-out approach have lower incidence of erosions, extrusions, and infectious complications (Neuman, 2007; Waltregny et al, 2008; Lee et al, 2009; Rechberger et al, 2009). Neuman (2007) reported two patients with vaginal extrusion, which were repaired by covering the exposed mesh with surrounding vaginal mucosa successfully. Of the 197 women who had multifilament transobturator slings by Rechberger and associates (2009), 2.5% developed vaginal extrusions. These were all managed successfully with sling excision and closure of the vagina. Two groups reported no evidence of extrusion or erosion at 1 year (Lee et al, 2009) and 3-year (Waltregny et al, 2008) follow-up. Waltregny and associates (2008) experienced one intraoperative vaginal sulcus laceration, which was closed uneventfully. Lee and colleagues (2009) presents a modified canal TOT approach, creating a suburethral tunnel between two oblique lateral incisions in the anterior vaginal wall to decrease the incidence of vaginal extrusion through the classic single midline incision. The value of this needs to confirmed by a randomized control trial.

Voiding Dysfunction. **Postoperative voiding dysfunction has been noted to occur in 0% to 20.6% of patients after**

a TVT procedure (Pesschers et al, 2000). **The incidence after TOT procedures varies between 2.1% and 6.7%.** Although clinically there seems greater voiding dysfunction associated with a TVT than the TOT there is no significant difference in postoperative voiding dysfunction between the TVT and TOT in nonrandomized studies (Mansoor et al, 2003; de Tayrac et al, 2004). Urinary retention also appears to not be significantly different. **The rate of obstructive symptoms after the TOT midurethral sling varies between 1.5% and 15.6% of patients.** Tsivian and colleagues (2009) assessed the effect of concomitant vagina surgery on the outcomes of TOT placement. The group without concurrent vaginal surgery had no voiding dysfunction postoperatively, whereas 7 (11%) of the group who had additional pelvic surgery experienced voiding dysfunction. Three went on to require sling lysis for obstruction. After lysis, the continence rates were similar: 82.86% and 85.2%. Yang and associates (2009) identified morphologic features associated with functional impairment after a transobturator procedure. Among 98 women at a median follow-up of 22 months, 11 women had recurrent SUI, 22 had voiding dysfunction, and 12 had worsening or de novo urgency. A resting tape distance of less than 12 mm and urethral encroachment at rest were the variables predictive of postoperative voiding dysfunction. Bladder neck funneling was associated with postoperative urgency symptoms.

Urinary obstruction is usually transient and managed with short-term intermittent catheterization, although occasionally symptoms mandate tape release. Long-term retention after TVT is a rare complication (0.6% to 3.8%) and can be expected in the TOT population as well (deTayrac et al, 2004). Removal of the tape, in most cases, improves the patient's symptoms. There has been some anecdotal experience with downward displacement of the tape under local anesthesia to provide symptomatic relief in patients with persistent voiding dysfunction (Ozel et al, 2004). Nonetheless, the overall risk of postoperative voiding dysfunction after the TOT is relatively low.

Management of MUI by a TOT sling has been discussed by three groups (Botros et al, 2007; Paick et al, 2008; Tahseen and Reed, 2009). Botros and coworkers (2007) compared the resolution of DO, UUI, and de novo urgency between the Monarc (125), TVT (99), and SPARC (52) procedures. De novo urgency was significantly lower in the Monarc group (8% vs. 33% TVT and 17% SPARC, $P = .04$), yet rates of resolution of DO, UUI, and de novo DO did not differ between the three groups. Paick and associates (2008) performed 72 TVT, 22 SPARC, and 50 TOT procedures in women with MUI. There were no significant differences in SUI cure rates or general urinary incontinence cure rates between the three slings. The presence of DO during preoperative UDS was associated with a high treatment failure of UUI in all three groups. Tahseen and associates (2009) performed a TOT procedure in 58 women and found a 77% SUI cure rate and 19% SUI improvement rate. UUI was additionally cured in 43% and improved in 36% of women suffering from MUI. Twenty-one percent had persistent UUI.

Pain. Another bothersome complication, unique to the TOT approach, is that of postoperative leg pain. de Leval (2003) described 15.9% of patients with temporary groin pain that resolved after the second postoperative day. Similarly, Krauth and associates (2005) reported 14 cases (2.3%) of patients with postoperative perineal groin pain. They also noted it to be transient and responding to nonsteroidal anti-inflammatory agents in all but 1 case. They hypothesized that the cause of the pain was either subclinical hematoma or a transient neuropathic phenomenon. They recommended that persistent leg pain that does not respond to conservative measures should prompt an investigation to exclude the possibility of erosion. Roth (2007) managed three women with persistent groin pain 3 months postoperatively in a similar fashion. Combined corticosteroids and local anesthetic was effective for pain relief, and no side effects were noted from the treatment. One case of failed sling and vaginal extrusion was reported by Mahajan and associates (2006). This patient additionally reported severe groin pain, fevers, and chills 10 days postoperatively. The tape was easily removed through the vaginal erosion, and mesh cultures were positive for *Bacteroides fragilis*. Complete symptom resolution occurred within 1 week of tape removal. Wolter and colleagues published a case report on recalcitrant medial thigh pain after TOT midurethral sling placement; the patient ultimately required medial thigh/TOT exploration by orthopedic surgery and sling excision (Wolter et al, 2008).

Key Points: Transobturator Midurethral Slings

- The transobturator sling appears to have reproducible short-term continence results similar to those seen with the TVT procedure, yet seemingly less voiding dysfunction.
- It does appear to mimic the suprapubic approach by stabilizing the midurethra, recapitulating the "hammock" support that is thought to be responsible for continence. Major vascular and bowel complications have not been reported, but lower urinary tract injury does occur, and this experience underscores the necessity of cystoscopy as an adjunct to this technique.
- Initial retrospective comparisons with the TVT show no significant difference in efficacy outcomes between these techniques. Longer-term follow-up is necessary prospectively to evaluate these procedures.

Secondary or Salvage Procedure

There are limited data regarding the efficacy of midurethral slings as secondary surgery in women with recurrent incontinence. Five small studies with relatively short follow-up could be found addressing the issue (Azam et al, 2001; Rezapour and Ulmsten, 2001; Kuuva and Nilsson, 2002, 2003; Lo et al, 2002a; Rardin et al, 2002). Comparison of the studies is hampered by differences in the definitions used for *cure, improved,* and *failed*. The population of patients may be considered skewed by the inclusion of women in whom bulking agents failed. It is debatable whether women in whom bulking agents fail are the same as those in whom a surgical anti-incontinence procedure has failed. The methods of evaluating outcomes (objective, subjective, or both) also differ between studies. Despite these limitations between studies, cure rates of a midurethral sling after prior failed anti-incontinence surgery vary from 81% to 89.6%. Failure rates vary from 4.2% to 13%. In a review of these articles, several trends emerge: **the procedure can be performed in the same way as it is performed for primary genuine SUI. The complication rate is similar to that of TVT done for primary SUI, but risk of bladder perforation appears to be higher in women who have had one or more prior retropubic suspensions. The failure rate is higher in women with immobile urethras, as is the case in primary surgery.**

The longest follow-up of women who underwent TVT for recurrent incontinence is 4 years in a study by Rezapour and Ulmsten (2001). The 34 women studied had undergone 64 different

anti-incontinence surgeries. Any patient with significant prolapse, DO, or ISD defined as a MUCP of less than 20 cm H_2O was excluded. By physical examination, 24 women had a hypermobile urethra. Ten had a less mobile urethra, but none had a fixed urethra. The procedure was performed using the standard TVT technique, and only one bladder perforation occurred in a patient with a prior Marshall-Marchetti-Krantz urethroplasty. No significant complications were encountered. Twenty-eight (82%) were cured by objective and subjective parameters, 3 (9%) were improved based on failure to achieve more than 90% improvement in quality of life, and in 3 the procedure failed. Postoperative voiding dysfunction was negligible with no change in postvoid residual urine volume after 8 weeks. Long-term catheterization was not necessary in any patient. These results were durable up to 5 years.

The mechanism of failure in midurethral slings is typically misplacement of the suburethral tape or inadequate tension on the tape. There are a few reports of small numbers concerning recurrent incontinence after a midurethral sling in patients being treated with a repeat midurethral sling (Riachi et al, 2002; Villet et al, 2002; Lee et al, 2007a; Tsivian et al, 2007; Biggs et al, 2009). Reported cure rates of a midurethral sling after prior failed anti-incontinence surgery vary from 62.5% to 92.3%. **Cure rates are higher for retropubic slings than for the TOT approach for recurrent SUI.** Tsivian and associates (2007) found that in 12 patients with repeat midurethral sling the only procedure that failed was the TOT. Similarly, Lee and colleagues (2007a) found that the cure rate for the repeat TOT approach was 62.5% as compared with 92.3% for the repeat retropubic sling procedure. A possible explanation for this difference is the angle of the tape; specifically the retropubic sling has a U shape, which may be more supportive and obstructive than the TOT. Additionally, the outside-in approach to the TOT procedure may need wider dissection of the periurethral area, leading to future migration of the tape. Salvage procedures are performed on a portion of women who failed the initial midurethral sling due to underlying ISD or now have a fixed urethra from the initial surgery. This is consistent with the evidence of high success in retropubic slings for patients with a component of ISD.

Key Points: Midurethral Slings for Refractory Stress Urinary Incontinence

- A repeat midurethral synthetic sling for persistent or recurrent SUI is a viable option for select patients in whom the initial procedure has failed.
- Cure rates are higher for redo retropubic slings than the TOT approach, in a great part due to the higher number of patients with ISD.

New Technology: Single-Incision Transvaginal Slings

Surgical treatment of SUI has expanded to include a single-incision sling (TVT-S). This technology was first approved (Gynecare, TVT Secur) by the U.S. Food and Drug Administration in 2006 and has since included the AMS and MiniArc. There are little data available regarding the safety and efficacy of this new generation of slings. The ideal midurethral sling requires a short hospital stay, has rare and mild complications, provides a quick return to active life, and has high success rates.

Procedure

The device consists of a short 8 × 1.1-cm polypropylene laser-cut tape, the same material as a standard TVT, which is coated on both ends with an absorbable fleece material (Ethisorb). The absorbable material is made of polyglactin and polydioxanone. It is usually absorbable within 90 days, with polypropylene remaining intact to provide long-term fixation. A curved stainless steel inserter instrument and "release wire" is attached on both ends of the mesh. The implant may be placed under the midurethra and can be fixed in the "hammock" position (Fig. 73–14A) into the obturator internus muscle or in the U-shaped position (see Fig. 73–14B) into the connective tissue of the urogenital diaphragm behind the pubic bone (Meschia et al, 2009).

The procedure is performed with the patient in the dorsal lithotomy position (with sequential compression devices in place) with a significant degree of flexion (70 degrees or more) of the thighs. A Foley catheter is placed before the repair to ensure the bladder is fully decompressed before passage of the device. As heretofore described, the patient has received parenteral sedation, and approximately 5 mL of 0.9% normal saline is used to hydrodistend the anterior vagina. After the vaginal incision is created, minimal dissection is performed using Metzenbaum scissors under the vaginal flaps on either side to elevate the vaginal epithelium from the underlying periurethral tissue to the level of the pubocervical fascia, which is not perforated. One inserter of the device is placed in the right dissection tunnel immediately beneath the vaginal epithelium and advanced up to the ischiopubic bone and into the internal obturator muscle, where the tape edges are anchored by the needle holder. The left side is introduced in the same way, creating a hammock-shaped sling. The definitive sling tension is achieved when the tip of a hemostat is easily passed between the urethra and the sling. Before engaging the sling by pulling the release wire, the patient is given indigo carmine and undergoes cystoscopy with a 30-degree rigid cystoscope. This step is essential to avoid the future morbidity of repeat surgery for intravesical or urethral mesh. Efflux of both ureteral orifices is confirmed. At this point the release wires are pulled with an empty needle driver and the inserters are removed on each side with a twisting motion of the hand. The authors' experience suggests that the tension of the mini-slings should be tighter than in the classic TVT or TVT-O procedures to achieve the same result.

Anatomic Considerations

Like the TVT procedure, early attempts are being made at describing the anatomic localization and function of the TVT-S with cadaveric dissection and through ultrasound. Using 14 embalmed and 5 fresh frozen female bodies, Hubka and colleagues (2009) placed TVT-S inserters bilaterally. After dissection, they measured the distances from the obturator bundle (obturator nerve and vessels) and found that the mean distance of the TVT-S from the obturator bundle was 3.05 to 3.07 cm. Perforation of the fascia of obturator internus muscle occurred in 4.4% and they believed that injury to variable vessels could occur. The position of the TVT-S was not found to change with repositioning the legs. Ultrasound studies attempt to identify the dynamics behind the curative effects of the TVT-S. Martan and associates (2009) analyzed 85 patients after a TVT-S with perineal ultrasonography. Efficacy of the TVT-S was evaluated with cough test and validated questionnaire. Objectively, 62% had a negative cough test and 38% had persistent leakage. The TVT-S was noted to restrict urethral mobility, with a higher degree of obstruction associated with a higher

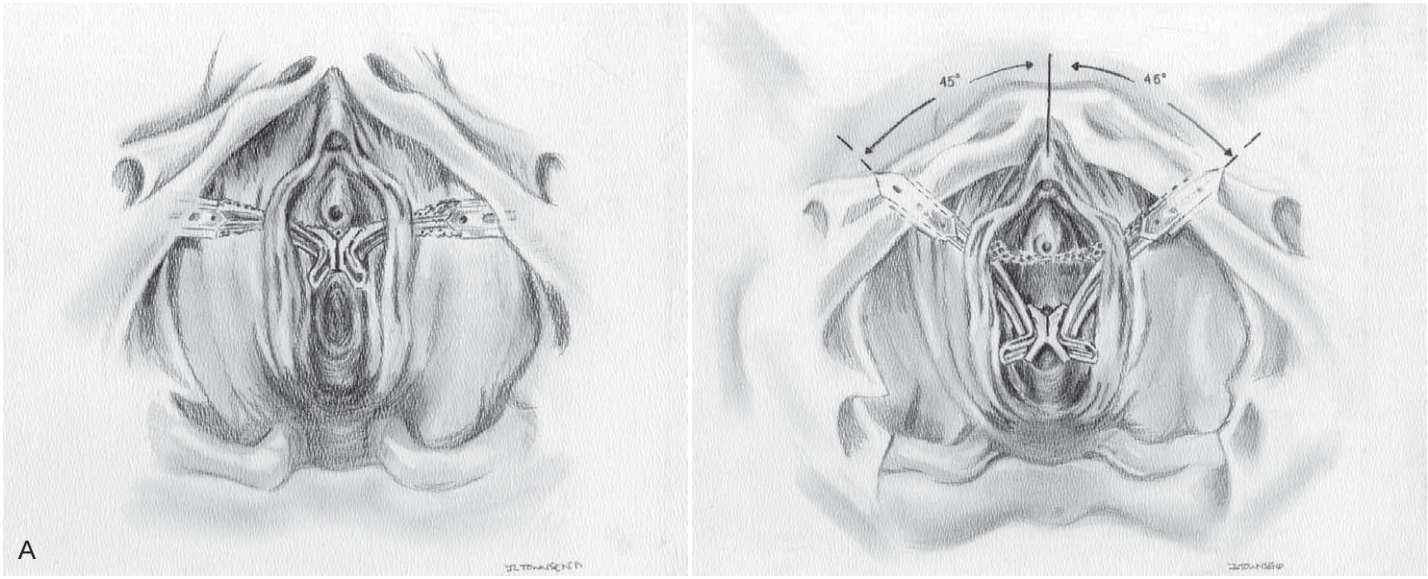

Figure 73–14. Midurethral sling as placed with single-incision approach. **A,** "Hammock." **B,** "U" position.

likelihood of cure. This restrictive effect was noted to weaken within the first 3 months after surgery.

Results

There are nine prospective, often multi-institutional trials with minimum of 1-year follow-up reviewing the results of TVT-S and MiniArc slings. Dmochowski and colleagues (2009) report on the largest ongoing registry at 29 sites in eight countries. Effectiveness was measured by standing cough test and Incontinence Quality of Life (I-QOL) instrument. Six hundred forty-two women were studied, with 64.5% having a hammock placement and 35.5% having the U placement of the TVT-S. Of these women, 65.3% had pure SUI and 34.7% had MUI, with predominately stress symptoms. Intraoperative complications noted included one bladder perforation (0.2%) and 3 cases of bleeding more than 200 mL (0.5%). Postoperatively, there was one reported case of retention (0.2%), 10 UTIs (1.6%), 6 cases of voiding dysfunction (0.9%), and 15 cases of de novo urgency (2.3%). There were 5 cases of mesh erosion (0.8%). Improvements in quality of life at 3 months were sustained at 12 months. Objective incontinence with cough test was 11% at 6 months and 12.5% at 12 months, giving an objective cure rate of 87.5%.

Pickens and colleagues (2009) presented their initial experience with 120 MiniArc cases at 13 month follow-up. Success was defined as using no pads, with subjective outcomes assessed with the IIQ-7 and UDI-6 questionnaires. Thirty-five percent had concurrent UUI. At 13 months, 94% had complete resolution of SUI whereas 6 patients reported significant improvement and 1 patient experienced a treatment failure. Twenty-four percent reported resolution of their UUI. Three patients (0.4%) had intraoperative bladder perforations. Two patients experienced retention postoperatively: in 1 it resolved, and the other patient had a urethrolysis due to persistent retention.

Krofta and coworkers (2009) analyzed the efficacy and complications among 73 women using a cough stress test and validated questionnaires. There were no major perioperative complications or cases of urinary retention reported. Two patients had UTIs (2.9%) and 4 had wound infections (5.8%) within the first week after surgery. Mesh erosion occurred in 4 patients (6%). Subjective outcomes were cure of 58.2%, 23.9% improvement, and 17.9% failure. Objective cure rate was 51.5%. A second anti-incontinence procedure was performed in 8 patients (six TVT procedures, two Burch colposuspensions). These authors believe that the TVT-S was less effective than the TVT or TVT-O.

In a prospective, multicenter study of 154 women with TVT-S, Debodinance and associates (2009) reported cure rates of 70.3%, improvement in 11%, and failure in 18.7% at 1 year follow-up. MUI occurred in 31.8%. Perioperative complications included five hemorrhages, one bladder injury, one vaginal wound, 21 cases of elevated postvoid residual urine volume, and 1 woman with persistent groin pain. Two patients returned with vaginal extrusion of mesh and 1 with a granuloma. Cure of urgency was reported by 61.1%, whereas 12.3% reported de novo urgency. The overall cure rate did not change between 2 months and 1 year.

Neuman and associates (2008) performed a prospective observational study of 100 consecutive women with "hammock-style" TVT-S. The perioperative and 12-month postoperative data were compared between the first 50 patients and the last 50 patients. The objective failure rate went down from 20% to 8% between the two groups with the tape being placed closer to the urethra. Four (8%) patients in the first group had vaginal perforation with the inserter. This was avoided in the second group by widening the submucosal tunnel. The tape extrusion rate decreased from 12% to 8% by making deeper submucosal tunnels. There was one case of a paravesical self-remitting hematoma. Otherwise, the authors reported no cases of bladder or urethral perforation, UTI, wound infection, or intraoperative bleeding. At 12-month follow-up the objective cure rates between the two groups were 88.6% and 93.5%. Oliveira and colleagues (2009) provide 15-month follow-up of 107 patients with TVT-S. Fifteen percent had MUI, with predominant SUI symptoms. Seventy-one percent reported being dry, and 14% improved. Six (5.6%) patients presented with de novo urgency, and one case of vaginal mesh extrusion was reported. There were no cases of bowel injury, bladder perforation, hematuria, excessive bleeding, or hematoma formation. Meschia and coworkers (2009) used multiple validated questionnaires and cough test to assess 91 women after placement of TVT-S at 1-year follow-up. Fifty-five patients had a TVT-S in the hammock position, and 40 patients had it in the U position. These researchers reported subjective and objective cure rates of 78% and 81%,

respectively. No bladder perforations were encountered. Two patients had intraoperative hemorrhage greater than 500 mL. Postoperative complications included 7 women with voiding difficulty (8%), 9 with recurrent UTIs (10%), 9 with de novo urgency (10%), and 2 with vaginal extrusions. Among the 20 with failed procedures, 8 patients went on to have a second anti-incontinence procedure (5 with retropubic TVT surgery, 2 with transobturator slings, 1 with a Reemex implant). Tartaglia and colleagues (2009) provide up to 18-month follow-up on 32 hammock-shaped TVT-S tapes. There were no surgical complications or reports of postoperative pain. One case of vaginal extrusion occurred. All 32 patients achieved continence based on quality of life assessment and physical examination. Jimenez and associates (2008) reported on their experience with both TVT-S and MiniArc slings in 41 patients with 1-year follow-up. The median follow-up in the TVT-S group was longer than the MiniArc group (328 days vs. 101 days). Only one bladder perforation was experienced in the TVT-S group. The reported cure rates were 80.4% in the TVT-S group and 90.2% in the MiniArc group. Ninety percent of the patients reported being satisfied at 3 months.

Four studies have compared mini-slings to standard midurethral slings (TVT or TVT-O). Using the TVT-WORLD observational registry, Tincello and colleagues (2009) compared 12-month outcomes of the TVT, TVT-O, and TVT-S procedures. The primary outcome measures are cough stress test and incontinence quality of life. The baseline characteristics, including proportions of MUI, were similar. TVT-S procedure patients returned to normal activities quicker than those who received either the TVT or TVT-O. Satisfaction rates were similar between the three groups. Objective cure rates were as follows: 90.6% TVT-S, 87.7% TVT, and 97.2% TVT-O. In regard to complications, all three techniques were similar.

Basu and Duckett (2009) performed a prospective, randomized control trial of the TVT versus the MiniArc in 70 women with 6-month follow-up. The MiniArc group had statistically lower subjective cure rates and urodynamic SUI cure rates than the TVT group: 63.3% vs. 100% and 45% vs. 93%, respectively. At 6-month follow-up, 50% of the MiniArc population had urodynamic SUI versus 7% of the TVT group. Two groups reported on randomized control trials of the TVT-O versus the TVT-S (Hinoul et al, 2009; Jarmi-Di et al, 2009). Jarmy-Di and associates (2009) observed the early postoperative results at 30 days. Two patients in the TVT-S group had temporary urinary retention, and 1 patient in the TVT-O group had leg pain. There were no UTIs or evidence of de novo urgency within this month period. No early mesh erosions were reported. Hinoul and associates (2009) performed a 12-month study of 135 randomized women (70 TVT-O and 65 TVT-S). Quality of life and subjective outcomes were reported using validated questionnaires. One bladder perforation occurred in the TVT-O group. The self-reported cure rates for the TVT-O were significantly higher than for the TVT-S (91.5% vs. 78.5%, $P = .02$), yet the TVT-S procedure was associated with less pain in the first week postoperatively. This pain difference disappeared within 2 weeks. Based on short-term follow-up, the single incision slings are a valuable addition, providing short hospital stays, quicker return to active life, and success rates equal to the TVT and TVT-O procedures. Their appeal is the single incision, avoidance of the retropubic space, and prevention of thigh pain. Most importantly, patients thus far appear to have reduced discomfort in the postoperative period. Long-term, comparative data collection is necessary to establish the efficacy and durability of these procedures.

Injection Therapy for Urinary Incontinence

Sender Herschorn, MDCM, FRCSC

History of Injectable Agents

Use of Injectable Agents in Female Stress Urinary Incontinence

Pathophysiology of Incontinence After Prostatectomy and Use of Injectable Agents for Male Stress Urinary Incontinence

Use of Injectable Agents for Incontinence After Urinary Diversion

HISTORY OF INJECTABLE AGENTS

The quest for injectable agents for stress urinary incontinence (SUI) started at the end of the 19th century when Gersuny (1900) from Vienna suggested periurethral paraffin injection for urethral compression. In 1914, Kelly and Dumm warned about the dangers of embolism after injection and pointed out that this treatment showed only temporary improvement of symptoms. In 1938, Murless first reported the injection of sodium morrhuate, a sclerosing agent synthesized from cod liver oil, into the anterior vaginal wall for treatment of SUI. Of the 20 patients treated, 17 were cured or improved for at least 12 months. Sloughing of a segment of the anterior vaginal wall was seen in 12 patients, and of these 75% were cured. Murless postulated that success was due to contraction of the resulting scar of the anterior vaginal wall. Quackels (1955) reported on the injection of paraffin for incontinence after prostatectomy in 1955; and Sachse (1963), based on previous reports, injected a mineral oil preparation, granugenol oil (Dondren), another sclerosing agent. He reported cures in 12 of 24 men after prostatectomy and 4 of 7 women. However, significant complications of pulmonary emboli and urethral sloughing were seen. With the last case report of distal ureteral stenosis after periurethral injection it was recommended not to use sclerosing agents for incontinence (Bubanz et al, 1980).

Polytetrafluoroethylene (Teflon) paste was first introduced by Berg (1973) and then popularized by Politano and colleagues (1973) in the 1970s. Shortliffe and coworkers (1989) published the first report on glutaraldehyde cross-linked collagen, and Cervigni and colleagues (1994) described the use of autologous fat in woman with SUI. More recently, newer synthetic materials have been described that theoretically should improve efficacy, durability, and safety.

The ideal injectable agent should be easily injectable and conserve its volume over time. It should also be biocompatible, nonantigenic, noncarcinogenic, and nonmigratory and cause little or no inflammatory reaction (Kershen and Atala, 1999) **or fibrotic ingrowth** (Dmochowski and Appell, 2000). **The components of the bulking agent should not separate or dissociate on injection, and if the agent contains microcrystalline or micropolymeric components they should be reasonably uniform spheres of particle sizes above 110 μm that are nonfragile and adhere to host tissue** (Dmochowski and Appell, 2000). **If the substance used is not successful it should not interfere with subsequent surgical intervention. To date, no substance has met all of these requirements.**

Over the past 15 years there has been an evolution of injectable agents and diverse types have been tested. Table 74–1 is a list of the agents that are discussed here. Most of the agents are bulking agents, but recently injection of autologous muscle stem cells for sphincter enhancement and implantable balloons that compress the urethra have been introduced.

USE OF INJECTABLE AGENTS IN FEMALE STRESS URINARY INCONTINENCE

Pathophysiology of Stress Urinary Incontinence and the Role of Injectable Agents

Please see the online edition of this chapter on the Expert Consult website for a discussion of this topic, along with Figures 74–1 and 74–2.

The goal of injectable agents is to augment or restore urethral mucosal coaptation and its "hermetic seal effect" contribution to the continence mechanism (Appell and Winters, 2007). It is generally thought that these agents improve intrinsic sphincter function, although the exact mechanism has not been defined (Smith et al, 2009). Bulking agents such as collagen have been reported (McGuire and Appell, 1994; Monga et al, 1995) to augment urethral mucosa and improve coaptation and intrinsic sphincter function, as evidenced by an increase in post-treatment abdominal leak point pressure (ALPP) (Herschorn et al, 1992; Richardson et al, 1995; Winters and Appell, 1995). Bulking agents do not generally obstruct voiding after the initial post-treatment period.

Table 74–1.

Types of Injectable Agents for Stress Urinary Incontinence

Biologic
BULKING
Currently used: Homologous: bovine collagen (Contigen), porcine collagen (Permacol)
No longer used: Autologous fat
FUNCTIONAL
Autologous muscle stem cells
Synthetic
Currently used: Carbon-coated zirconium beads (Durasphere), polydimethylsiloxane (Macroplastique), hyaluronic acid dextranomer (Deflux), polyacrylamide hydrogel (Bulkamid), calcium hydroxyapatite (Coaptite)
No longer used: Polytetrafluoroethylene (Teflon), ethylene vinyl alcohol (Tegress)
Balloons
Currently used: Adjustable balloons (ACT, ProACT)
No longer used: Microballoons (UroVive)

Monga and coworkers (1995) showed that successfully treated patients have an increased area and pressure transmission ratio in the first fourth of the urethra. They suggested that placement of the injectable agent at the bladder neck or proximal urethra prevents bladder neck opening under stress, although this is controversial. Proper placement of the injectable agent, possibly just below the bladder neck, rather than actual quantity (Khullar et al, 1997) of the agent improves intrinsic sphincter deficiency (ISD).

Patient Selection, Indications, and Contraindications

Injectable agents are one of the many treatment options for SUI. **Although initially it was thought that these agents would be most effective in patients with ISD alone, multiple reports have shown clinical efficacy in patients with hypermobility** (Herschorn et al, 1996; Steele et al, 2000; Bent et al, 2001). **Injectable agents may provide a rapid response for some patients and are an option for those who do not wish to undergo more invasive procedures. However, these patients must understand that efficacy and duration of these agents are inferior to surgery and follow-up injections may be required. Other possible indications include elderly patients, those with high anesthetic risk, or those willing to accept an improvement rather than cure of their SUI symptoms** (Appell et al, 2009).

Detrusor overactivity should be treated before injection because results may be compromised (Herschorn et al, 1996). Severe urethral scarring from radiation or surgery may affect mucosal pliability by preventing bulking and retention of the injectable agent in the urethra.

Contraindications include active urinary tract infection and hypersensitivity to the injectable material.

Patient History

Patients who may be candidates for injectable agents should undergo a diagnostic evaluation to confirm the diagnosis in a similar fashion to other SUI patients. A focused history to characterize the chief complaint including the frequency, severity, and degree of bother should be done. An assessment of other urinary symptoms should be completed, and the desire for treatment should be ascertained. Helpful tools include various validated Symptom and Quality of Life questionnaires and frequency-volume charts (Appell et al, 2009; Abrams et al, 2010).

Physical Examination

The physical examination should provide information about the cause of the lower urinary tract symptoms and suggest additional management options. The general examination should include an abdominal examination to evaluate the skin, surgical incisions, and the presence of any hernias or abdominal masses, including a full bladder.

Pelvic Examination

The patient is placed in the lithotomy position. The external genitalia should be examined for dermatologic lesions and inflammatory conditions. The internal genitalia should be examined for estrogen deficiency, urine or abnormal vaginal discharge, pelvic organ prolapse, and abnormal pelvic masses. The poorly estrogenized vaginal wall has a thinned epithelium with loss of transverse rugae, which are normally present in its lower two thirds (Fantl et al, 1994). The patient should be examined with a comfortably full bladder to assess stress leakage and, if necessary, with an empty bladder to assess other pelvic organ prolapse and masses.

Because incontinence (or pelvic organ prolapse) may not be evident, or its full extent demonstrated, in the dorsal lithotomy position, it has been recommended that the patient be examined in the semi-upright or even upright position (Walters and Karram, 1992). A systematic examination of the vaginal walls and perineum should also be done. (For details, see Chapter 64.)

Urethral mobility can be observed with the patient straining or by the Q-tip test (Crystle et al, 1971). The angles of deflection of the Q-tip at rest and with straining are measured with a goniometer. *Hypermobility* is defined as a maximum strain axis of more than 30 degrees from the horizontal. Urethral axis testing does not diagnose any form of incontinence because continent women may demonstrate rotational descent of the urethra (Fantl et al, 1986) and incontinent women may have no descent. Although urethral axis testing has been shown to be reproducible (Fantl et al, 1986), it has not been compared with other radiologic methods. However, it may be helpful in assessing the degree of hypermobility.

If the patient has a fixed nonmobile urethra, especially if there has been previous SUI surgery, and leaks with coughing and/or straining, most likely that patient has ISD as the predominant cause of the SUI. However, if hypermobility is present the relative contribution of the causes (ISD vs. anatomic support) cannot be ascertained clinically.

Additional Testing

The initial evaluation of urinary incontinence in women includes a history, physical examination, urinalysis, and measurement of postvoid residual urine (Abrams et al, 2010). The basic evaluation may be satisfactory for proceeding with treatment, including surgery, for patients with straightforward SUI associated with hypermobility with normal postvoid residual volume (Fantl et al,

1996). The indications for additional testing include an inability to make a definitive diagnosis based on symptoms and the initial evaluation, concomitant overactive bladder symptoms, prior lower urinary tract surgery (including failed anti-incontinence procedures), known or suspected neurologic disease affecting the bladder, a negative stress test, abnormal findings of urinalysis such as hematuria or pyuria, abnormal levels of postvoid residual urine, beyond hymen and symptomatic pelvic prolapse, and dysfunctional voiding (Appell et al, 2009). Additional testing can include pad testing and/or use of a voiding diary, urodynamic studies, cystoscopy, and imaging. The evaluation can be tailored to elucidate the patient's problem.

Urodynamic Studies. In the evaluation of the patient with SUI, urodynamic studies before interventional treatment are helpful in specific circumstances. These are to confirm the diagnosis if the symptoms are confusing or complex and other problems are suspected, such as detrusor overactivity, urethral obstruction or voiding dysfunction, low bladder compliance, and/or impaired or absent detrusor contractility (National Institute for Health and Clinical Excellence, 2006; Appell et al, 2009). Urodynamic studies have also been recommended if there has been previous surgery for SUI or anterior compartment prolapse (National Institute for Health and Clinical Excellence, 2006). There is controversy as to whether urodynamic studies are warranted in the straightforward or pure SUI patient with no previous surgery. The National Institute for Health and Clinical Excellence guidelines (2006), similar to the updated American Urological Association guidelines (Appell et al, 2009), did not recommend testing, whereas testing was recommended by the recent 4th International Consultation on Incontinence (Hosker et al, 2009). This was based largely on a report from Agur and coworkers (2009) that showed that only 5.2% of 6276 women in a urodynamic patient database had pure SUI and of those a fourth had other findings that could impact clinical decision making, such as detrusor overactivity, voiding dysfunction, and absence of SUI on testing.

Because injectable agents are indicated for the ISD component of SUI, can urodynamic studies assess ISD? Two measures of urethral function have been used: maximum urethral closure pressure (MUCP) and ALPP. An MUCP of less than or equal to 20 cm H_2O has been suggested as indicating clinically significant urethral weakness, but there is controversy regarding the diagnostic and predictive value of urethral pressure profilometry in characterizing ISD (Weber, 2001). **Similarly, an ALPP of less than or equal to 60 cm H_2O was identified as an indicator of severe ISD** (McGuire et al, 1993) **but many studies have not confirmed the test's value in quantifying the degree of ISD** (Koelbl et al, 2009). **Previously, ALPP measurements of initially less than or equal to 65 cm H_2O and then less than or equal to 100 cm H_2O were used as indicators of ISD to justify the use of injectable agents** (Appell and Winters, 2007). **However, because ISD may be present in many patients with SUI with or without urethral hypermobility** (Koelbl et al, 2009), **the specific value of either the MUCP or ALPP may be of little importance in the clinical decision about the use of injectable agents.** As with other patients with SUI who opt for interventional therapy, urodynamic studies are helpful for the reasons mentioned earlier.

Cystoscopy. Routine cystoscopy is not recommended for the evaluation of SUI. However, it is indicated for the evaluation of incontinent patients who have sterile hematuria or pyuria; urgency incontinence to rule out other pathologic processes (e.g., bladder tumor, interstitial cystitis); recurrent or iatrogenic incontinence when surgery is indicated or planned; vesicovaginal fistula or extraurethral incontinence (Tubaro et al, 2009); and when urodynamic studies fail to duplicate symptoms of incontinence (Fantl et al, 1996). Furthermore, **preinjection cystoscopy is helpful to make sure that there are no adverse factors or unexpected findings that may prevent or compromise the injection procedure such as extensive urethral scarring from previous surgery, irradiation, or trauma, foreign bodies, or urethral diverticula.**

Injection Techniques

The materials can be administered under local anesthesia with cystoscopic control as an outpatient procedure. Both the **periurethral** and **transurethral** methods have been done to implant the agent within the urethral wall, preferably into the submucosa or lamina propria. It is thought that the implant should be positioned at the bladder neck or proximal urethra. Different sites can be chosen such as the 3- and 9-o'clock or 4- and 8-o'clock positions. The needle size depends on the viscosity of the agent. Preoperative and postoperative antibiotics are frequently administered. The technique of injection is seen in Figures 74–3 and 74–4. Additional bilateral periurethral infiltration of 2 to 3 mL of 1% or 2% aqueous lidocaine injected lateral to the urethra may improve patient comfort. The goal with current injectable agents is to create mucosal apposition at the end of treatment.

Periurethral Technique

The patient is placed in the lithotomy position and prepared and draped in the usual sterile fashion. Topical 2% urethral lidocaine jelly is instilled into the meatus. Perimeatal blebs are raised with 1% or 2% aqueous lidocaine at the 3- and 9-o'clock or 4- and 8-o'clock positions 3 to 4 mm lateral to the urethral meatus with a 25-gauge needle. A 20-Fr urethroscope with a 30-degree telescope is inserted into the urethra. The periurethral needle is introduced and advanced parallel to the endoscope sheath until its position can be seen cystoscopically just below the bladder neck within the mucosa. The surgeon can hold the cystoscope in one hand and advance the needle with the other. Care must be taken to prevent the needle from getting too close to or entering the urethral lumen because rupture of the mucosa and extravasation will occur. Rocking the needle will confirm the position of the tip. If penetration of the mucosa occurs, the needle should be removed and repositioned. The substance is injected either unilaterally or bilaterally to create the appearance of "prostatic" lobes (Fig. 74–5). Transvaginal injection with the needle placed through the biopsy port of an ultrasound probe has also been described (Appell, 1996).

An 18-gauge "bent tip needle" has been designed for the periurethral approach for placement of carbon-coated zirconium spheres (Durasphere; Boston Scientific, Natick, MA) within the proper plane (Appell and Winters, 2007).

Transurethral Techniques

With Cystoscopic Monitoring. The implant can also be injected transurethrally through the cystoscope with specially designed injection needles or with other devices that do not necessitate cystoscopy. In this approach a 0-, 12-, or 30-degree lens may be used. Various cystoscope sheaths are available, but one with a flat rather than beaked end will prevent the needle from penetrating the urethra proximal to the view from the lens. Endoscopic instrument companies have an array of equipment designed for transurethral injections. The material can be injected through a

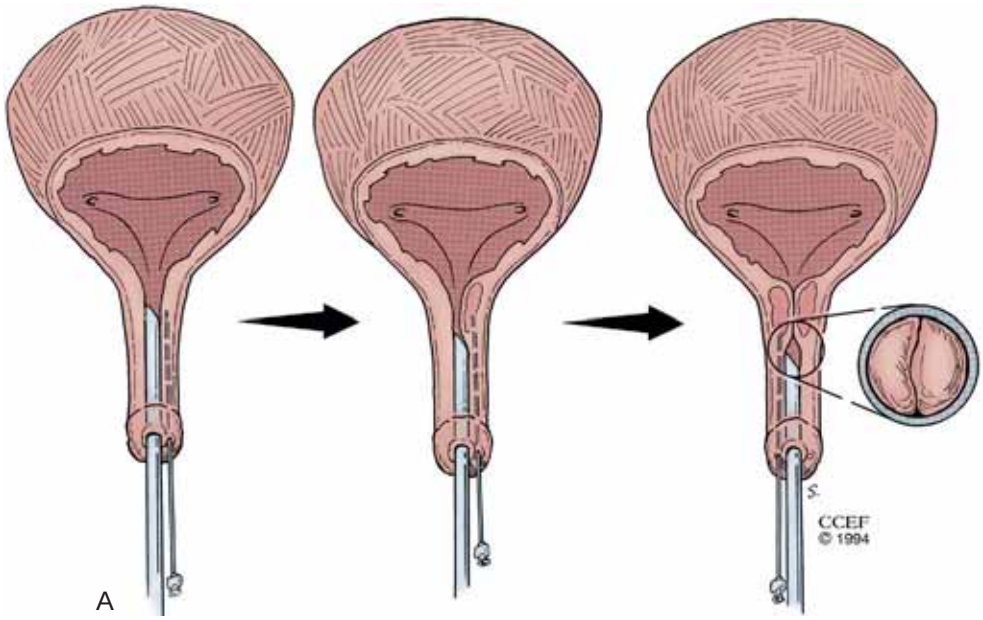

Figure 74–3. Periurethral collagen injection. The 20-Fr cystoscope with a 30-degree lens is positioned in the urethra while the substance is injected into the bladder neck region. **A,** Appearance of the urethra before treatment. **B,** Periurethral needle positioned in the proximal urethra below the bladder neck. **C,** Appearance of the urethra after injection. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 1994-2011. All Rights Reserved.)

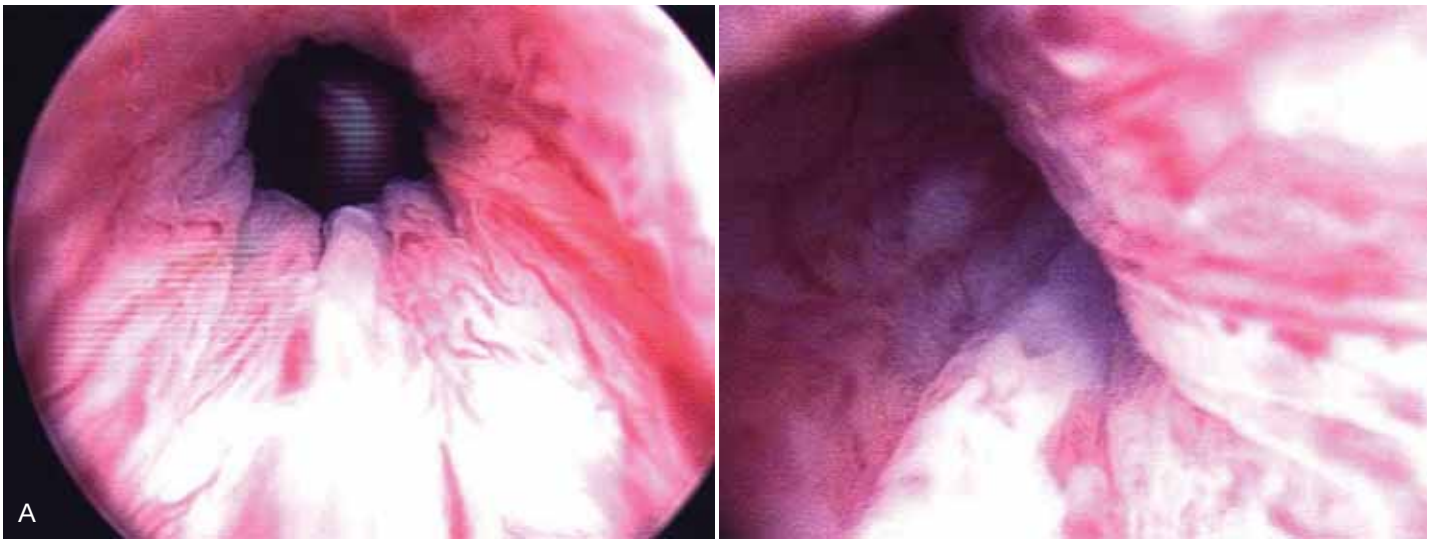

Figure 74–4. **A,** Cystoscopic view of the open bladder neck region before injection. **B,** Collagen has been injected via the periurethral route on the patient's left side. Note the intraluminal bulking effect of the bulking agent.

semi-rigid needle that is advanced through a working element or a flexible needle that is advanced by the surgeon. Both have 22-gauge tips that are about 1 cm long.

The patient is prepared in the same fashion as with the periurethral approach. Topical urethral lidocaine jelly as well as aqueous lidocaine injected periurethrally can be used. The injection needle is inserted into the urethra at a 30- to 45-degree angle and advanced proximally in the submucosal region under the surface of the mucosa. The point of penetration of the urethra has to be at a distance below the bladder neck of more than the length of the needle to prevent extravasation of the substance into the bladder. Injections can be given at the 3-, 6-, and 9-o'clock positions until mucosal apposition is achieved. The cystoscope should not be advanced through the bulked-up urethra and bladder neck to avoid compressing or causing extravasation of the injected material.

Because of its high viscosity, silicone microimplant (Macroplastique; Uroplasty, Inc, Minnetonka, MN) injections require the use of a ratcheted injection gun (Fig. 74–6A). The injection needle is 7 Fr with a 10-mm, 18-gauge needle tip.

The periurethral and transurethral approaches for collagen were compared first by Faerber and colleagues (1998), **who reported no significant difference in success rates and numbers of injections required in 24 patients with transurethral treatment versus 21 with a periurethral approach. However, significantly more collagen**

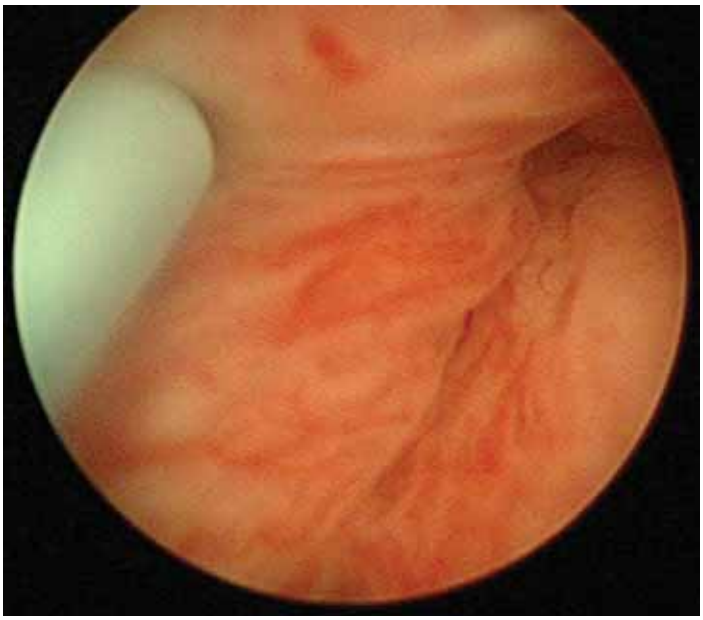

Figure 74–5. Appearance of urethra after injection of collagen with a transurethral needle that is seen on the left. Both sides of the urethra have been injected, giving the appearance of an occlusive prostate.

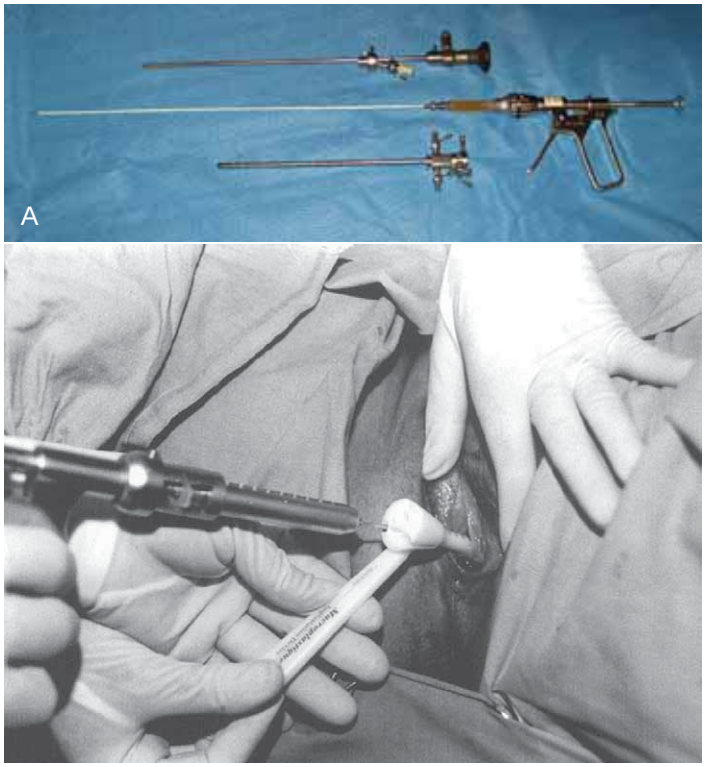

Figure 74–6. **A,** Silicone macroparticle injection gun. The injection needle is 7 Fr with a 10-mm, 18-gauge needle tip. **B,** The implantation procedure. The bulking agent is injected through the device using the injection gun and a rigid needle. (From Tamanini JT, D'Ancona CA, Netto NR Jr. Treatment of intrinsic sphincter deficiency using the Macroplastique Implantation System: two-year follow-up. J Endourol 2004;18[9]:906–11.)

was required for the periurethral approach. Schulz and coworkers (2004) **reported similar findings in 40 women randomly assigned to either technique. There was no difference in short-term success rate, but the 20 women assigned to the periurethral approach required more collagen than those assigned to the transurethral approach. The transurethral approach is now much more commonly reported than the periurethral approach.**

Without Cystoscopic Monitoring. A handheld device that allows the operator to inject Macroplastique transurethrally without cystoscopy was introduced by Henalla and colleagues (2000) in a multicenter trial of 40 patients (see Fig. 74–6B). Device efficacy and acceptability were rated highly by the surgeons at 92.5% and 95%, respectively, and at 3 months 74.3% of patients had a good outcome. Twelve-month outcomes in a cohort of 21 patients who had Macroplastique injections administered with this device were reported by Tamanini and coworkers (2003): 57.1% of patients considered themselves cured, 19% were improved, and 23.8% experienced failure. Outcomes at 2 years showed some deterioration in results, with 47% considered cured, 14.3% improved, and 38.1% failed (Tamanini et al, 2004).

A handheld Implacer device was designed to administer hyaluronic acid dextranomer (Zuidex), but it was withdrawn from the market with failure of the North American multicenter randomized trial to demonstrate noninferiority of Zuidex compared with collagen (Lightner et al, 2009).

Periprocedural Care

Although randomized trials have not been done, prophylactic antibiotics with a fluoroquinolone or trimethoprim-sulfamethoxazole (TMP-SMX) for 24 hours or less can be recommended (Wolf et al, 2008). An additional 2 to 3 days has also been suggested (Appell and Winters, 2007).

After the injection the patient is asked to cough or strain in the supine and then upright positions. If leakage still occurs, more agent may be given. If no leakage is seen the procedure may be terminated. The patient then voids and can be discharged. Urinary retention can be treated by insertion of a fine Foley catheter (12 to 14 Fr or smaller) overnight or intermittent catheterization. Although not specifically reported, an indwelling Foley catheter may cause molding of the agent and lead to early failure, so long-term catheterization should be avoided.

Reinjections

The minimum timing for reinjections varies and depends on the agent. Although collagen can be reinjected within 7 days, most clinicians wait 4 weeks or longer to assess response of the urethra and the need for reinjection (Appell and Winters, 2007). Macroplastique injections can be repeated after 12 weeks. Durasphere can be reinjected after a minimum of 7 days (Lightner et al, 2001) and calcium hydroxyapatite (Coaptite; Bioform Medical, San Mateo, CA) can be reinjected after 1 month or less (Mayer et al, 2007). Reinjection timing with other new agents, if known, is mentioned later in the chapter.

Pitfalls in Reported Study Results of Durability

A number of pitfalls in reporting of injectable studies can lead to inflated success rates. Because injectable agents

can be repeated if the patient is not a success or fails, authors should specify whether that time point is after all treatments have been completed or whether it is from baseline. If durability is reported after all injections are administered, then an accurate picture of duration of efficacy can be conveyed. A Kaplan-Meier curve of efficacy has been useful in showing what happens to patients' continence outcome over time (Herschorn and Radomski, 1997; Lightner et al, 2001). **Nevertheless, some studies report duration of results from initial treatment** (Richardson et al, 1995) **or do not specify it** (Monga et al, 1995). **This may overestimate success because failures are re-treated and can be counted as successes within the follow-up period. Another pitfall is reporting success rates on cohorts of patients followed for the long term rather than on all patients treated from the start** (Stenberg et al, 2003). **If the patients in whom the procedure failed or those lost to follow-up are not included in the denominator the success rate is higher.**

Outcome Assessment in Bulking Agent Clinical Trials by the U.S. Food and Drug Administration

The Stamey 0 to 3 Grading System (Stamey, 1979) (Table 74–2) for SUI has been recommended as the primary outcome measure by the FDA since the original U.S. collagen trial (McGuire and Appell, 1994). Although the scale is extensively used there is little evidence that it is as valid or reliable as other measures, such as voiding diaries, pad tests, and leak point measurements (Payne et al, 2009).

Systematic Reviews of Injectable Agents for Women with SUI

The *Cochrane Database of Systematic Reviews* published an update review of injectable agents in women in 2009 (Keegan et al, 2007). The authors reviewed 12 trials with 1318 women. They concluded that the trials were small and generally of moderate quality. Pending further evidence, injection therapy may represent a useful option for short-term symptomatic relief for women with comorbidity that precludes anesthesia. Two or three injections are likely to be required to achieve a satisfactory result.

Injection therapy was also reviewed at the Fourth International Consultation on Urinary Incontinence (Smith et al, 2009). **Evidence for the benefit of injectable agents was also considered to be limited and of short term. Greater symptomatic improvement was observed after surgery, which is of higher risk. There is no evidence for the superiority of any bulking agent over another (although new data on silicone microimplant injections may challenge this** [Ghoniem et al, 2009]**). There are also no available data comparing bulking agents with nonsurgical or minimal access surgical techniques. It was recommended that, if bulking agents are to be used, women should be made aware that repeat injections are likely to be required, that efficacy diminishes with time, and that this therapy is inferior to that of conventional surgical techniques. Women should also be aware of alternative minimally invasive procedures.**

Table 74–2.

Stamey Incontinence Grading System

Grade 0	Continent
Grade 1	Patient loses urine with sudden increases in abdominal pressure but not while supine
Grade 2	Patient loses urine with physical stress (walking; changing from a reclining to a standing position; sitting up in bed)
Grade 3	Patient with total incontinence; urine loss unrelated to physical activity and/or position

Key Points: Use of Injectable Agents in Female Stress Urinary Incontinence

- The ideal injectable agent that is biocompatible, nonantigenic, noncarcinogenic, and nonmigratory, causes little or no inflammatory reaction or fibrotic ingrowth, and retains efficacy over time has not yet been found.
- The goal of injectable agents is to augment or restore urethral mucosal coaptation and its "hermetic seal effect" contribution to the continence mechanism.
- Although initially it was thought that these agents would be most effective in patients with ISD alone, multiple reports have shown clinical efficacy in patients with hypermobility.
- Injectable agents may provide a rapid response for some patients and are an option for those who do not wish to undergo more invasive procedures. The efficacy and duration are inferior to surgery, and follow-up injections may be required. Other possible indications include elderly patients, those with high anesthetic risk, or those willing to accept an improvement rather than cure of their SUI symptoms.
- The workup includes history and physical examination. Urodynamic studies are helpful. Cystoscopy is helpful to rule out adverse factors such as scarring, foreign bodies, and diverticula that may prevent or compromise injections.
- Injectable agents are indicated for the ISD component of SUI. However, because ISD may be present in many patients with SUI with or without urethral hypermobility the specific value of either the MUCP or the ALPP may be of little importance in the clinical decision about the use of injectable agents.
- The results of periurethral and transurethral techniques are similar. Most reports are now about the transurethral technique.
- Periprocedural antibiotics for 24 hours or less can be recommended.

Currently Used Injectable Agents

Glutaraldehyde Cross-linked Bovine Collagen (Contigen)

Glutaraldehyde cross-linked collagen (Contigen; C.R. Bard, Covington, GA) is a highly purified suspension of bovine collagen in normal saline containing at least 95% type I collagen and 1% to 5% type III collagen (Remacle et al, 1990). This cross-linking makes the collagen resistant to the fibroblast-secreted collagenase. As a result of this, the collagen is only very slightly resorbed. The implant causes little inflammatory reaction or granuloma formation and is colonized by host fibroblasts and blood vessels. It is not known to migrate; however, it does degrade over time with

volume loss via absorption of the carrier medium (Kershen and Atala, 1999) and may be replaced by host collagen, to explain its persistence (Keefe et al, 1992). To decrease its antigenicity the collagen is prepared by selective hydrolysis of the nonhelicoidal amino- and carboxy-terminal groups (telopeptides) of the collagen molecule that are the antigenic parts of the molecule (Remacle and Declaye, 1988).

All patients must undergo a skin test into the volar aspect of the forearm 30 days before treatment. Approximately 3% of patients will have a positive skin test reaction, with 70% showing the reaction within 3 days, indicating a preexisting sensitivity to bovine dermal collagen through dietary exposure. The remaining 30% do not respond until later so a 4-week period is required (Keefe et al, 1992). A negative skin test does not preclude development of a hypersensitivity reaction to subsequent treatment and, although infrequently used, a second skin test has been recommended (Elson, 1989; Stothers and Goldenberg, 1998). Positive responders should be excluded.

Collagen can be injected transurethrally or periurethrally through a 22-gauge needle. It is supplied in syringes that contain about 3 mL of collagen. Ordinarily one to three syringes are used during each treatment.

Collagen is the standard against which all new injectable agents have been compared. The results of these trials are outlined in the following sections. C.R. Bard, Inc., has announced that Contigen will not be available after 2011.

Results. The most extensively reported injectable agent has been collagen (Table 74–3). It was first reported by Shortliffe and colleagues in 1989, and since then numerous reports of its efficacy, safety, ease of administration, and relative lack of morbidity have appeared. The author's original report, with short-term follow-up of 32 patients for 6 months (Herschorn et al, 1992), showed a cured and improved rate of 90.3%. Longer-term results of more than 1 to 2 years vary from 57%, cure and improved (Khullar et al, 1997), to 94% (Cross et al, 1998). Most patients need one to two treatment sessions with means of 5.6 to 15 mL of collagen. Winters

ISD, intrinsic sphincter deficiency.

and Appell (1995) reported a 50% rate of complete continence in a multicenter trial after 2 years. Corcos and Fournier (1999) reported 4-year follow-up with 40% improvement and 30% cure. The longest follow-up reported to date is from Gorton and coworkers (1999), who reported on 53 patients with at least 5 years after their last collagen injection: only 14 (26%) had persistent improvement, and of these 1 (2%) was completely dry. Because patients in any series are treated at different times and durations of follow-up vary, a Kaplan-Meier curve is useful to display the persistence of a good result (Herschorn and Radomski, 1997). Figure 74–7 shows that the probability of remaining dry after the last collagen injection was 72% at 1 year, 57% at 2 years, and 45% at 3 years. A similar deterioration over time was reported by Gorton and coworkers (1999).

Multiple factors that may influence outcome have been reported. Previous incontinence surgery was identified by Eckford and Abrams (1991) as a favorable factor but was not supported by others (Herschorn et al, 1996). Preoperative detrusor overactivity may be an adverse factor (Herschorn et al, 1996; Smith et al, 1997). The degree of mucosal coaptation after injection as judged on cystoscopy was not found to correlate with long-term improvement (Kim et al, 1997). Elia and Bergman (1996) used perineal ultrasonography to measure the location of the collagen deposit 3 months after the procedure. They reported that a positive outcome was more likely if collagen was located at a distance of 6 mm or less from the bladder neck. Defreitas and coworkers (2003) correlated a good outcome to circumferential distribution of collagen around the urethra. They did three-dimensional transvaginal ultrasonography in 46 patients at a median follow-up of 14 months and found that the 21 satisfied patients had a higher rate of circumferential distribution compared with the 25 unsatisfied patients. Kuhn and colleagues (2008) compared the site of injection (i.e., bladder neck versus midurethra) in a small randomized study. They found no difference in outcome between the two sites.

Collagen and Hypermobility. The use of collagen for patients with hypermobility has been reported extensively. Moore and colleagues (1995) included patients with hypermobility. Faerber (1996) treated elderly patients with type 1 abnormality. In the report by McGuire and Appell (1994) the results at more than 1 year in women with ISD were similar to those in women with hypermobility, although there were far more women with ISD. Monga and coworkers (1995) included patients with hypermobility and found that cure rates were not reduced for women with up to 2.5 cm of movement. In the author's series of 181 patients there was no significant difference in outcome in patients with or without hypermobility (Herschorn and Radomski, 1997). Corcos and Fournier (1999) found no difference between patients with and without bladder neck hypermobility in their 4-year follow-up on 40 patients. Steele and colleagues (2000) found that urethral mobility did not significantly affect the success rate. Furthermore, 4 of 6 patients with urethral hypermobility were dry at the 6-month follow-up examination, whereas among the 19 women without hypermobility only a 32% remained dry. Bent and colleagues (2001) reported a 44% cure/improvement rate for 12 months in a cohort of 90 women with SUI and hypermobility. **They concluded, as have others, that collagen injection therapy is appropriate for women with hypermobility.**

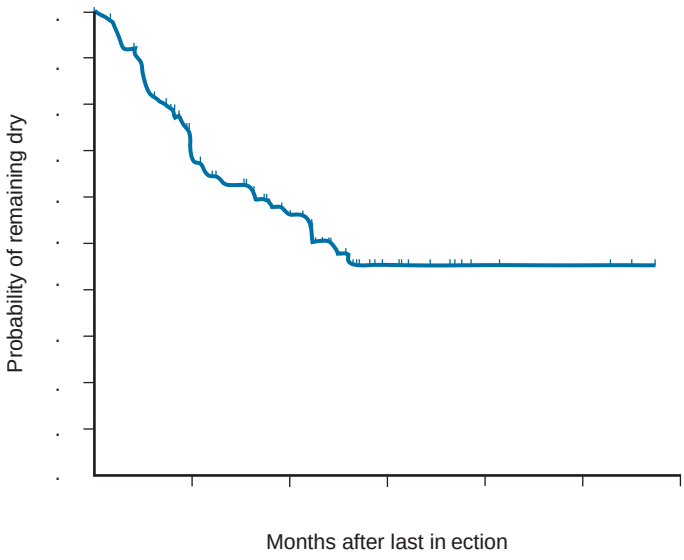

Figure 74–7. Durability: Kaplan-Meier curve showing durability of cure of incontinence after the last collagen injection in 78 patients. (From Herschorn S, Radomski SB. Collagen injections for genuine stress urinary incontinence: patient selection and durability. Int Urogynecol J Pelvic Floor Dysfunct 1997;8[1]:18–24.)

Collagen versus Surgery. Berman and Kreder (1997) found that after an average follow-up of 14.9 months after sling cystourethropexy 71.4% of the patients were continent versus 26.7% of patients with collagen after 21.3 months. They analyzed associated costs and concluded that surgery was more cost effective than collagen. In a multicenter prospective randomized trial, Corcos and colleagues (2005) reported a lower success rate of 53.1% in the collagen-treated patients versus 72.2% in the surgery group. However, general and disease-specific quality of life scores were similar, satisfaction was slightly higher in the surgery group, but complications were less frequent and severe with collagen. Corcos and colleagues concluded that collagen was a reasonable alternative to surgery. The follow-up was relatively short, and the study was done before the era of midurethral slings.

Complications. **Treatment-related morbidity has been minimal. Common complications include transient urinary retention, which ranges from 1% to 21%** (Herschorn et al, 1992; Winters and Appell, 1995; Appell and Winters, 2007) **and can be managed with intermittent catheterization or short-term use of a Foley catheter. Urinary tract infection occurs in 1% to 25% of patients** (Herschorn et al, 1992; Winters and Appell, 1995; Appell and Winters, 2007). **De novo detrusor overactivity was reported in 11 of 28 elderly women (39%) treated by** Khullar and coworkers (1997). Stothers and colleagues (1998) **reported de novo urgency with urgency incontinence in 43 of 337 patients (12.6%), 21% of whom did not respond to anticholinergic agents. Hematuria can occur in 2% of patients** (Appell and Winters, 2007). Extravasation resolves quickly with flushing away of the dilute collagen suspension and sealing over of the small needle site.

A rare complication is periurethral abscess formation (Sweat and Lightner, 1999). Another is a reaction in the previously negative skin test site after a urethral collagen injection (Stothers and Goldenberg, 1998). This occurred in 3 patients (1.9%) and was associated with arthralgias in 2. This reaction has been reported before in dermatology (Elson, 1989), and two negative pretreatment skin tests have been suggested to prevent it. The potential for hypersensitivity reactions is present because antibody production is stimulated by collagen injection (McClelland and Delustro, 1996).

Vesicovaginal fistula occurring after collagen injections for SUI in 2 women after cystectomy and neobladder was described by

Pruthi and colleagues (2000). Carlin and Klutke (2000) reported a urethrovaginal fistula in a woman whose warfarin was not completely reversed. She had a postinjection hematoma that ultimately fistulized to the vagina.

Carbon-Coated Zirconium Beads (Durasphere)

Durasphere consists of nonabsorbable pyrolytic carbon-coated zirconium beads suspended in a water-based polysaccharide carrier gel of 2.8% β-glucan (Lightner et al, 2001). Pyrolytic carbon has been used in medical devices such as heart valves. The bead size ranges from 212 to 500 µm, which is larger than the threshold for particle size migration of 80 µm (Malizia et al, 1984). It is nonantigenic, and no skin testing is required. The agent can be delivered through an 18-gauge needle via the transurethral or periurethral approach with cystoscopic monitoring. It is more viscous than collagen, so greater pressure is required for delivery into the tissues.

As a result of reported difficulty in injecting the agent the beads were modified and made smaller. The bead sizes of Durasphere EXP now range from 90 to 212 µm, still larger than 80 µm threshold for migration.

Results. Published results with Durasphere are shown in Table 74–4. In the original multicenter randomized 235-patient clinical trial of Durasphere versus collagen, Lightner and colleagues (2001) reported a 12-month continence grade improvement rate of 76/115 (66.1%) in the Durasphere group versus 79/120 (65.8%) in the collagen group ($P = 1.000$). They also reported that at 1 year after their last treatment 49 of 61 (80.3%) in the Durasphere group versus 47 of 68 (69.1%) in the collagen group had a continence grade improvement ($P = .162$). Both injectable agents performed similarly. There was also no difference in number of injections or in results of a pad weight test. However, the injected initial and repeat injection volume of Durasphere was significantly less than those of collagen. It is notable that in the 12-month result after the last injection 45% (106/235) of the study patients were not accounted for.

In another randomized prospective trial of Durasphere versus collagen, Andersen (2002) reported 80% (20/25) of Durasphere patients versus 61.9% (13/21) of collagen patients had a continence grade improvement ($P = .205$) after a mean of 2.6 and 2.8 years, respectively, after initial treatment. This is similar to the study of Lightner and colleagues (2001).

In a series of 13 women, Pannek and colleagues (2001) reported a decline in success from 76.9% at 6 months to 33% at 12 months. In contrast to the study of Lightner and colleagues (2001) they demonstrated particle migration locally and to distant sites on follow-up plain radiographs. As a result of reported injection difficulties, Madjar and coworkers (2003) modified the technique by injecting local anesthetic into the mucosa to raise a circumferential bleb into which the Durasphere is injected. They reported results on 46/70 (65.7%) of patients. At a mean of 9.4 months, 65.2% of patients considered themselves to be cured or improved.

In a longer-term follow-up matched-cohort study, Chrouser and colleagues (2004) reported initial success of 63% in both groups. With longer follow-up of 24 and 36 months, Durasphere was effective in 33% and 21% whereas collagen was effective in 19% and 9%, respectively. The results were not significantly different. Sokol and coworkers (2008) tried to improve on the results of transurethral collagen by injecting additional periurethral Durasphere. However, they failed to show any benefit. After 6 months there was no difference in cure rates: 33.3% in the combined group versus 29.4% in the collagen alone group.

Overall, no study has shown a benefit over collagen.

Complications. In the multicenter randomized trial of Durasphere versus collagen the adverse event profiles were similar (Lightner et al, 2001). However, more women had significantly more post-treatment urgency and acute retention with Durasphere versus collagen: 24.7% and 16.9% versus 11.9% and 3.4%, respectively. Pelvic radiographs taken at 1 and 2 years after injection showed stability of the bulking agents at the injection site. Pannek and associates (2001) reported particle migration. This was attributed to the high pressure necessary to inject the viscous material with large particles, resulting in material displacement into vascular or lymphatic spaces (Appell et al, 2006). Durasphere EXP with its smaller particles may be less likely to lead to this.

Other reported adverse events include urethral mucosal prolapse (Ghoniem and Khater, 2006) and periurethral sterile abscess formation in 2.9% of a series of 135 patients (Madjar et al, 2006).

Silicone Microimplants (Macroplastique)

Silicone microimplants (Harriss et al, 1996) are solid polydimethylsiloxane (silicone rubber) particles suspended in a nonsilicone carrier gel that is absorbed by the reticuloendothelial system and excreted unchanged in the urine. Because 99% of the particles are between 100 µm and 450 µm in diameter, the likelihood of migration is low. Henly and coworkers (1995) demonstrated distant migration of small particles, less than 70 µm, but no migration of particles greater than 100 µm in diameter. Although there was a typical histiocytic and giant cell reaction within the injection site there was no granuloma formation in response to the larger particles. Because the substance is quite viscous it must be injected with an injection gun and a 16-gauge tip transurethral needle. The vials contain 2.5 mL of silicone microimplants.

Results. The results for silicone microimplants are shown in Table 74–5. Harriss and colleagues (1996) reported on 40 patients

Table 74–4.

followed for a minimum of 3 years, at which time 16 (40%) were dry, 7 (18%) were improved, and 17 (42%) reported failure of the treatment. Twelve of the 16 required one injection, and 4 needed two injections to become dry. Sheriff and coworkers (1997) reported an overall success of 48% in 34 patients after unsuccessful surgery for SUI, and Koelbl and colleagues (1998) reported a 60% success rate in 32 women after 12 months but noted a time-dependent decrease in success. Radley and coworkers (2001) reported a success rate of 61% (19.6% cured and 41.1% improved) in 60 women after a mean of 19 months. Barranger and coworkers (2000) in a group of 21 patients reported a dry rate of 19%, an improved rate of 38%, and a failure rate of 52% at a median follow-up of 31 months; interestingly, they did not observe a time-dependent decrease in results. Tamanini and coworkers (2003, 2004) reported 1- and 2-year results in 21 patients with the use of a handheld noncystoscopic injector system (see Fig. 74–6B). There was a decrease in continence outcome after 2 years. Plotti and colleagues (2009) reported 84% cure/improvement rates in a series of 24 women with de novo SUI after radical hysterectomy.

Recently Ghoniem and colleagues reported the results of a North American multicenter randomized trial of Macroplastique versus collagen (Ghoniem et al, 2009). **After 1 year, 61.5% (75/122) with Macroplastique and 48% (60/125) with collagen had an improvement of at least 1 Stamey grade. This indicated that Macroplastique was noninferior to collagen ($P < .001$). The proportion of the patients who were dry was higher in the Macroplastique group at 36.9% versus 24.8% ($P < .05$). However, there were no significant differences in pad weight testing, quality of life scale, or adverse events.** The same authors subsequently reported the 2-year results in the Macroplastique group (Ghoniem et al, 2010). Eighty-four percent of those who had a benefit at 12 months maintained that level of cure or improvement to 24 months. That means that of the original 122 patients 51.7% had a good outcome at 2 years.

Complications. Self-limited side effects of urinary tract infection, hematuria, dysuria, urgency, frequency, voiding difficulty, and urinary retention have been reported (Ghoniem et al, 2009). Rarely erosion of the injectable occurs. The lack of a granulomatous reaction and migration of the large silicone particles may provide some benefit over smaller-particle injectable agents such as polytetrafluoroethylene, although long-term data are not yet available. Despite the laboratory and clinical evidence of safety with the large particles, concerns still exist about the small silicone particle migration and long-term tissue response to the injection (Henly et al, 1995).

Calcium Hydroxyapatite (Coaptite)

Calcium hydroxyapatite (Coaptite; Bioform Medical, San Mateo, CA), which is a normal constituent of bone, can be manufactured into particles of a spherical mean diameter of 100 μm (75 to 125 μm) suspended in a carboxymethylcellulose gel carrier. This exogenous substance has been used in orthopedic and dental applications (Bucholz, 2002), as well as soft tissue augmentation of vocal cords (Belafsky and Postma, 2004), face (Tzikas, 2004), and the ureteral orifice for reflux (Mevorach et al, 2006). Animal experiments have demonstrated the safety and biocompatibility of this substance. It stimulates fibroblast infiltration when placed into soft tissue, which may explain its long-term bulking effect after degradation of the carrier gel (Mayer et al, 2007).

The implant is currently supplied in 1-mL syringes and can be injected via a transurethral approach though a 21-gauge needle.

Results. Mayer and colleagues (2001) reported initial results in 10 women with ISD and limited hypermobility. After 1 year, 7 reported substantial improvement, 2 improved, and 1 had no change. No significant complications were reported. In a randomized prospective trial of calcium hydroxyapatite compared with collagen, Mayer and coworkers (2007) reported results in 231 women. Up to 5 injections were performed in the first 6 months of the trial. At 12 months, 83 (63.4%) of 131 patients who had injections of calcium hydroxyapatite showed improvement of one Stamey grade or more versus 57 (57%) of 100 collagen patients ($P = .34$). There was no difference in cure (39% calcium hydroxyapatite vs. 37% collagen) and improvement (50% calcium hydroxyapatite vs. 46% collagen) rates. More patients who had had calcium hydroxyapatite injections required only one injection, and the total average injected volume was lower (4.0 mL vs. 6.6 mL, respectively; $P < .0001$).

Complications. Minor adverse events such as transient retention (41%), urinary tract infection, and urgency incontinence (5.7%) were reported (Mayer et al, 2007). Serious adverse events were vaginal wall erosion of the implant and dissection of the material

beneath the trigone. Because this agent has a greater particle density than collagen it is thought to have the potential to cause more local tissue pressure effects.

Autologous Fat

Autologous fat has been used for aesthetic and defect reconstruction since the 1980s (Billings and May, 1989). Although fat is biocompatible and readily available, 50% to 90% of the transferred adipose tissue graft may not survive (Horl et al, 1991). Graft survival depends on minimal handling, low suction pressure during liposuction, and the use of large-bore needles. Smaller grafts survive better than larger ones (Bircoll and Novack, 1987).

The procedure involves harvesting abdominal wall fat by liposuction either under local (Trockman and Leach, 1995) or general anesthesia (Su et al, 1998). The injection is usually carried out via the periurethral route with a 16- or 18-gauge needle. Postprocedural care may involve intermittent catheterization or even a suprapubic tube (Su et al, 1998).

Results. A number of reports of urethral fat injections have been published and appear in Table 74–6. Most of the series report short-term results with success apparently lower than that of other injectable agents, apart from the study of Su and colleagues (1998) with a follow-up of more than 12 months. Palma and coworkers (1997) showed that repeat injections improved the cure rate from 31% to 64%. Haab and colleagues (1997) reported a comparative study with collagen. After a mean of 7 months, 13% of the women with fat injection were cured versus 24% of the women with collagen injections. The subjective improvement rate was also higher with the collagen. Lee and colleagues (2001) reported a randomized double-blind study of autologous fat versus saline injection. At 3 months, 6 of 27 (22.2%) and 6 of 29 (20.7%) women were cured or improved in the fat and saline groups, respectively. In this study, periurethral fat injection did not appear to be more efficacious than placebo in treating SUI.

Since the publication of the randomized trial of Lee and colleagues (2001) **showing that fat was no more efficacious than saline, no further publications have appeared in the literature. Furthermore, the report of a death from fat embolism** (Currie et al, 1997) **most likely discouraged additional studies.** However, experimental work on the use of adipose-derived stem cells to help improve function after urethral injury has progressed in the rat model (Lin et al, 2010).

Complications. Reported complications are similar to other injectable agents with urinary infection, retention, hematuria, and extravasation. Additional problems with donor site, the abdominal wall, such as pain, hematomas, and infection may also be seen. Other noteworthy complications are urethral pseudolipoma (Palma et al, 1996) and fat embolism (Sweat and Lightner, 1999), one of which was fatal (Currie et al, 1997).

Key Points: Currently Used Injectable Agents for Female Stress Urinary Incontinence

- All patients must undergo a skin test into the volar aspect of the forearm 30 days before treatment with collagen.
- Results of collagen may be optimized if there is circumferential distribution of the injections in the proximal urethra.
- Complications of collagen are usually mild and may be self-limited. Common ones include transient retention, urinary infection, de novo urgency and urgency incontinence, and hematuria.
- In two separate randomized clinical trials versus collagen, both carbon-coated zirconium beads (Durasphere) and calcium hydroxyapatite (Coaptite) showed similar results to collagen after a 1-year follow-up.
- In a randomized clinical trial comparing silicone microimplants (Macroplastique) to collagen, silicone microimplants were shown to be noninferior to collagen after 1-year follow-up.

New Agents Undergoing Development

Polyacrylamide Hydrogel (Bulkamid)

Polyacrylamide hydrogel (PAHG) is a nontoxic, nonresorbable sterile aqueous gel consisting of 2.5% cross-linked polyacrylamide and 97.5% nonpyrogenic water. It is homogeneous, stable, and nonbiodegradable and has tissue-like viscosity and elasticity. It is being used in plastic surgery (Breiting et al, 2004) and ophthalmology (Lloyd et al, 2001).

Lose and coworkers (2006) reported 12-month results in a study with 25 women. The injection was delivered transurethrally with a 23-gauge needle. Four women were lost to follow-up. Eleven women (44%) underwent a second injection after 3 months because of lack of effect. Overall, 8 (32%) were dry and 9 (36%) experienced improvement. Minor adverse events included urinary tract infections (40%), transient retention (10%), urgency (8%), urgency incontinence (8%), and nocturia (4%). Multicenter randomized trials are underway in North America and Europe.

Table 74–6.
Results of Autologous Fat Injection

STUDY	NO. PATIENTS	FOLLOW-UP (mo)	Results		
			No. Dry (%)	No. Improved (%)	No. Failed (%)
Cervigni et al, 1994	11	22.6	6 (54.5)	2 (18)	3 (27.3)
Santarosa and Blaivas, 1994	12	11	7 (58)		5 (42)
Trockman and Leach, 1995	32	6	4 (12)	14 (44)	14 (44)
Haab et al, 1997	45	7	6 (13)	13 (29)	26 (58)
Su et al, 1998	26	Mean: 17.4 Range: 12-30	13 (50)	4 (15)	9 (35)
Palma et al, 1997	30	12	1 injection: 4/13 (34) 2 injections: 11/17 (67)		

Porcine Dermal Collagen

Porcine dermal collagen implants have been used in hernia repairs and pelvic floor reconstruction (Harper, 2001; Dench et al, 2006). This substance is maintained in its original three-dimensional form and is close to human dermis in architecture (Meyer et al, 1978). It is biocompatible, and patients do not have to be skin tested as for bovine collagen.

Bano and colleagues (2005) reported early results of a randomized trial of porcine dermal collagen versus Macroplastique. There were 25 patients in each arm. The porcine collagen was injected periurethrally in 21 patients. At 6 months, 15 (60%) of 25 in the collagen group were dry and 10 were unchanged or worse (40%). In the Macroplastique group, 9 (36%) were dry, 1 was improved (4%), and 14 (56%) were unchanged or worse. There were no significant differences between the groups. Minor complications of transient retention and urgency incontinence were seen in both groups and were similar.

Autologous Chondrocytes

A bulking agent composed of autologous chondrocytes has been used to treat children with vesicoureteral reflux (Diamond and Caldamone, 1999). Animal studies of the implant demonstrated stability and lack of migration over time (Atala et al, 1994; Cozzolino et al, 1999). The injectable material consists of autologous chondrocytes in a calcium alginate gel administered endoscopically through a 22-gauge needle. The chondrocytes obtained from biopsy of the external pinna of the patient's ear are expanded in tissue culture and combined with a carrier gel that degrades after injection.

Bent and coworkers (2001) reported 12-month results in 32 women after a single outpatient injection in a multicenter trial. Incontinence grading indicated 16 patients dry and 10 improved, for a total of 26 (81.3%). Side effects were minimal.

Implantable Balloons

To obviate the degradation and movement of injectable materials Yoo and coworkers (1997) developed a self-detachable implantable balloon system. The balloon is a silicone elastomer with a check valve that prevents escape of the solution that is injected at the time of implant. The filling solution is a biocompatible cross-linked hydrogel that maintains its volume within the silicone shell. The balloons are inserted into the submucosal area, usually periurethrally, with cystoscopic control.

Pycha and coworkers (1998) reported that 8 (42%) of 19 women were dry and 7 (36.8%) were improved after a mean of 14.4 months. The patients with hypermobility had a poor outcome. Mazouni and colleagues (2004) reported results in 45 women who were observed for a mean of 3 months. The overall success rate was 65%, with 24 dry and 2 improved. Complications included detrusor overactivity, balloon rupture on insertion, and balloon extrusion.

There have been no recent developments in the technology.

Adjustable Continence Therapy (ACT)

The Adjustable Continence Therapy (ACT) device (Uromedica, Plymouth, MN) consists of two inflatable silicone balloons attached to silicone tubing with a titanium and silicone port (Fig. 74–8). The procedure can be done under local, regional, or general anesthesia. The balloons are placed into the periurethral space at the bladder neck with introducer devices inserted through two 1-cm incisions in the labial sulci at the level of the vaginal introitus. The procedure is carried out under fluoroscopic guidance with a contrast-filled Foley balloon positioned at the bladder neck. After the correct position is ascertained the device balloons are inflated with 1.0 to 1.5 mL of an isotonic solution (sterile water and contrast material).The aim is to increase urethral resistance and support the bladder neck with the inflated balloons (Stecco et al, 2006). The ports are buried in the subcutaneous tissue of the labia to enable postoperative reinjection of the balloons if necessary (Kocjancic et al, 2008). Beginning at 6 weeks, additional fluid, usually with volumes of 2 mL, can be added to the balloons by injecting percutaneously through the port sites, if necessary. The technology was developed as an alternative to bulking agents that would not migrate (Kocjancic et al, 2008).

Kocjancic and coworkers (2008) implanted 49 patients, of whom 38 were observed for more than 1 year. Of these, 26 of 38 (68%) were dry, 6 of 38 (16%) were improved, and 6 of 38 (16%)

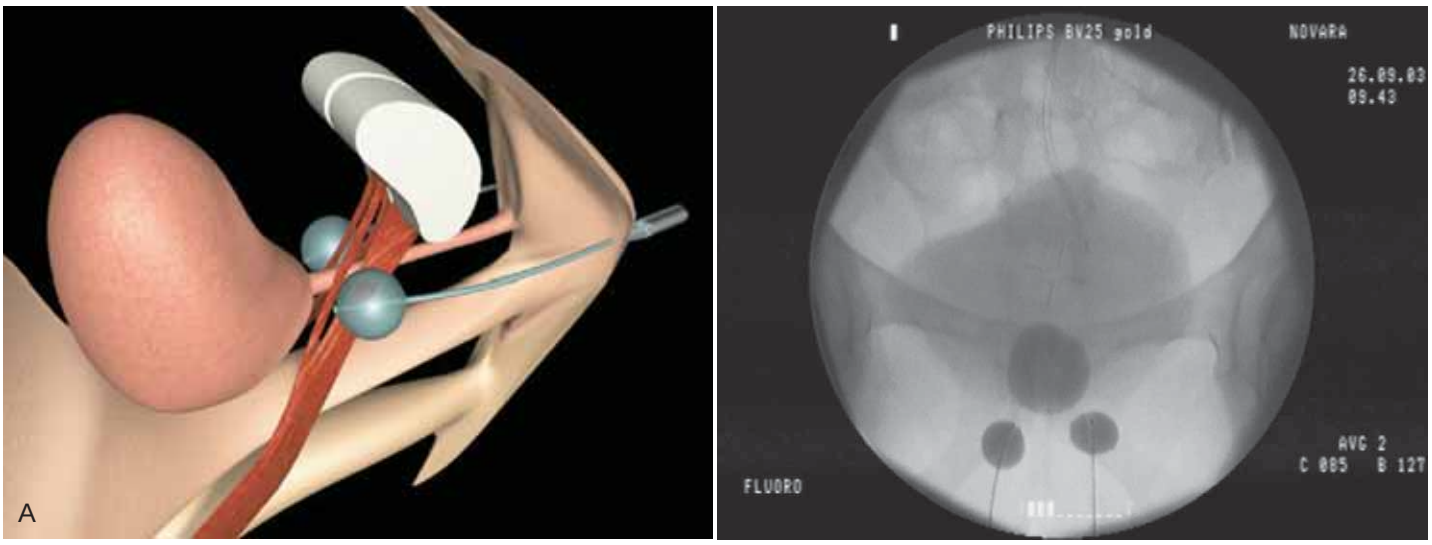

Figure 74–8. Illustration of Adjustable Continence Therapy balloon device for women. **A,** Schematic diagram showing percutaneous placement of the balloons on both sides of the bladder neck. **B,** Fluoroscopic picture showing contrast agent in the bladder, Foley catheter, and balloons. (From Aboseif SR, Franke EI, Nash SD, et al. The adjustable continence therapy system for recurrent female stress urinary incontinence: 1-year results of the North America Clinical Study Group. J Urol 2009;181[5]:2187–91.)

experienced failure. In 62%, one to five fluid additions were necessary throughout the follow-up period. Wachter and coworkers (2008) reported a series of 41 women: the dry rate was 44%, marked improvement was 15%, and 41% had slight improvement or no change; device adjustment was need in 70% of patients. Aboseif and coworkers (2009) reported a North American study consisting of 162 patients of whom 84% had undergone at least one unsuccessful surgical procedure for SUI. Of those observed for 1 year or more, 107 of 140 (76.4%) improved by one or more Stamey grades, 67 of 130 (52%) had less than 2 g of urine on pad weight testing, and 102 of 126 (81%) had a greater than 50% reduction in provocative pad weight. Within 9 months of implantation a mean of 2.3 balloon readjustments were required. Because volume adjustments were done during the follow-up periods in all series there were no data available on continence outcome long after cessation of fluid addition.

Complications. Complications have occurred in 24% (Aboseif et al, 2009) to 39% (Wachter et al, 2008) of patients, with most classified as mild to moderate. Common ones include port or balloon erosion (13%), balloon or port migration (8%), urinary retention (8%), and balloon failure (4%). Kocjancic and coworkers (2008) removed the device in 11 (22%) and then reimplanted it in all of them. Aboseif and coworkers (2009) reimplanted the device in half of the 28 (20% of the total) patients who required its removal, and Wachter and coworkers (2008) explanted 6 devices (15%) owing to nonresponse.

Overall, the procedure may be more suited to patients after surgical failures. Long-term durability still has to be established.

Autologous Myoblasts

Myoblasts, the mononuclear precursor cells of skeletal muscle, can differentiate into multinucleated muscle fibers capable of muscle contraction. They fuse to form myotubes, which stop dividing with maturation and can express protein for a prolonged period (Yokoyama et al, 2000). These cells can be harvested from skeletal muscle outside the urinary tract. The aim is to improve urinary sphincter function with urethral sphincter injections of these cells.

In a short-term feasibility animal study, Chancellor and coworkers (2000) injected mouse myoblasts into rat urethras and bladders. After 3 to 4 days the harvested organs showed viable cells with fusion of injected cells to form myotubes. The same group subsequently used adult rat muscle–derived allografts containing satellite cells and myoblasts and injected it into autologous animals and compared it with injected collagen. After 30 days there was almost no collagen but there was a large cell mass bulging into the urethral lumen (Yokoyama et al, 2001). Mitterberger and coworkers (2007) injected allograft myoblasts in a porcine model and demonstrated a 300% increase in urethral pressure values and survival of the injected cells with formation of myofibers.

Mitterberger and coworkers (2008) reported on 20 women with SUI who underwent transurethral ultrasound-guided injection of autologous fibroblast injection into the urethral submucosal and myoblast injection into the rhabdosphincter. The cells were cultured from skeletal muscle forearm biopsy specimens. Two years after therapy, 16 were cured, 2 were improved, and 2 were lost to follow-up. Apart from 1 patient with transient retention, no complications were encountered. Strasser and associates (2007), **from the same group in Innsbruck, Austria, published results of a randomized trial of autologous myoblast versus collagen injection, but the article was subsequently retracted by the *Lancet*** (Kleinert and Horton, 2008).

Carr and colleagues (2008) reported results in 8 women followed for a mean of 16 months after transurethral or periurethral injection of autologous skeletal thigh muscle–derived stem cells. Five of 8 improved with one reporting being dry. No serious adverse events were reported.

This technology looks promising and may provide advantages over bulking agents. No long-term data are available at present, and further studies are underway.

Agents That Are No Longer Used

The reader is referred to the electronic version of this edition on the Expert Consult website.

Key Points: New Agents Undergoing Development for Female Stress Urinary Incontinence

- Both biologic and synthetic agents are undergoing development.
- Adjustable volume silicone balloons are technically feasible, but no comparative studies have been done or long-term durability demonstrated.

PATHOPHYSIOLOGY OF INCONTINENCE AFTER PROSTATECTOMY AND USE OF INJECTABLE AGENTS FOR MALE STRESS URINARY INCONTINENCE

Incontinence after prostatectomy may be caused by bladder dysfunction, sphincter dysfunction, or a combination of the two. Urodynamic investigations are helpful to rule out bladder outlet obstruction or significant bladder dysfunction. In addition to incontinence symptoms, storage and voiding symptoms may be associated (Gray et al, 1999; Hollenbeck et al, 2002). **Urodynamic studies have demonstrated that sphincter incompetence occurs as the sole cause in more than two thirds of patients whereas isolated bladder dysfunction (detrusor overactivity, poor compliance, detrusor underactivity during voiding) is uncommon, occurring in less than 10% of patients** (Ficazzola and Nitti, 1998; Groutz et al, 2000). **However, sphincter and bladder dysfunction can coexist in at least one third of incontinent patients.** Decreased sphincter resistance may be due to tissue scarring in some cases and is reflected by a low urethral compliance; however, this parameter is difficult to measure (Groutz et al, 2000). Scarring may lead to an anastomotic stricture evidenced by endoscopy or urethrography and is clinically suspected when incontinence and decreased force of stream coexist.

The preoperative length of the membranous urethra determined on magnetic resonance imaging has been shown to be related to time to postoperative continence (Coakley et al, 2002). Urodynamic studies have revealed that a reduced functional urethral length was predictive of incontinence (Hammerer and Huland, 1997; Van Kampen et al, 1998; Wei et al, 2000). The state of a patient's pelvic floor may also influence continence or return to continence after radical prostatectomy. Physiotherapy and

pelvic floor rehabilitation have been shown to improve or enhance continence (decreased time to final continence level) in the postoperative period in two randomized studies, but only if such measures are instituted before or immediately after catheter removal (Van Kampen et al, 2000; Parekh et al, 2003). Maximum difference between physiotherapy and no treatment is achieved at 3 months, with almost no difference at 12 months. A randomized study in which randomization occurred 6 weeks after surgery showed no difference in continence at 6 months (Wille et al, 2003).

Bulking agents are the most minimally invasive treatment for incontinence after prostatectomy after conservative measures have been tried. They work theoretically by adding bulk and increasing coaptation at the level of the bladder neck and proximal urethra. Several agents have been used, including bovine collagen (Contigen) and silicone microimplants (Macroplastique). All agents share the similar problems, including the need for multiple injections and treatment sessions, deterioration of effect over time, and low cure rates. It remains to be seen if improvements in outcomes can be achieved with alternative agents or if the concept of urethral bulking has achieved its maximum benefit with currently available agents (Herschorn et al, 2010). An alternative technology with implanted adjustable volume balloons (ProACT) will be discussed.

Workup

Basic evaluation includes history, physical examination, urinalysis, and measurement of postvoid residual urine. A frequency-volume chart (Griffiths et al, 1993) or bladder diary is also helpful. A pad test quantifies the severity of incontinence. The 24-hour home test is the most accurate pad test for quantification and diagnosis and the most reproducible (Mouritsen et al, 1989). The 1-hour pad test is widely used because it is more easily done and standardized. The amount of postvoid residual urine is a good estimation of voiding efficiency (Diokno et al, 1988; Starer and Libow, 1988).

Blood tests (blood urea nitrogen, creatinine, glucose) are recommended if compromised renal function is suspected or documented (Fantl et al, 1996).

Uroflowmetry is also helpful to assess voiding function.

Cystourethroscopy is done to verify integrity of the urethral wall, bladder neck, and the status of the bladder (e.g., trabeculation, stones, diverticula). Injectable agents are not effective with scarred supramembranous urethras because the tissues cannot expand with the agent. The status of the urethra should be assessed preoperatively.

Invasive urodynamic studies are useful to assess bladder and urethral function before interventional therapy (Herschorn et al, 2010). Detrusor overactivity or decreased bladder compliance demonstrated on multichannel testing may be contributing to symptoms and may merit alternative treatment. Sphincter weakness can be documented by the Valsalva (McGuire et al, 1993) or cough (Schick, 1985) abdominal leak point pressure, but its reproducibility has been studied in women and not men. **Although ALPP may be helpful, it has been shown to be a poor predictor of incontinence severity after radical prostatectomy** (Twiss et al, 2005). **Furthermore, in male patients, ALPP measurement may be better via a rectal catheter because a urethral catheter may occlude a scarred urethra** (Flood et al, 1996). **Although definite evidence supporting the predictive value of urodynamic studies is lacking, they are still recommended before interventional treatment** (Hosker et al, 2009).

Injection Techniques

Retrograde Injection

The patient is placed in the lithotomy position, and the surgical field is prepared in the usual sterile fashion (Fig. 74–9A). The procedure can be performed with local, regional, or general anesthesia. If local anesthesia is employed, 2% topical urethral lidocaine jelly can be inserted 10 minutes before instrumentation. In some patients, preoperative sedation may also be of benefit. A 20- or 22-Fr cystoscopic sheath is employed using a 0- or 30-degree lens. Collagen is provided in a 3.0-mL Luer-Lok syringe containing 2.5 mL of injectable material. The syringe attaches to a 5-Fr injection catheter containing a 1.5-cm 20-gauge needle at the tip. Most injections are done transurethrally under cystoscopic vision.

After a prostatectomy the urethra is frequently scarred and not very pliable; thus, several needle insertions are frequently needed to deposit sufficient material to produce urethral coaptation. The injection is completed in up to four quadrants after localization of the appropriate level in the proximal urethra. The needle is advanced under the urethral mucosa with the beveled portion of the needle facing the urethral lumen to allow for layering of the material. The injectable material is then delivered, creating a bleb under the urethral mucosa that protrudes into the urethral lumen. This is performed in a circumferential manner in four quadrants, creating a bleb in each quadrant. After completion, the urethral mucosa should be completely coapted and creates the appearance of an obstructed urethra. Extrusion of the injectable agent into the urethral lumen as the needle is withdrawn may occur. This may be prevented in most cases by leaving the needle in place for at least 30 seconds after the injection is completed or by flushing the material with saline. The loss of additional material is diminished by preventing advancement of the cystoscope proximal to the injection sites. If material extravasation occurs in all quadrants during injection, the procedure should be terminated and rescheduled (Appell and Winters, 2007).

Antegrade Injection

Because of less than optimal results an alternative method of injecting collagen in men was introduced using a suprapubic antegrade approach. The antegrade approach has the advantage of direct visualization of the bladder neck and the injection of material into more supple, less scarred urethra (see Fig. 74–9B). The patient is placed in the lithotomy position, and flexible cystoscopy is carried out, simultaneously filling the bladder. A percutaneous suprapubic puncture allows placement of two guide wires into the bladder. The site is dilated to 16 Fr with Amplatz dilators. A sheath may be used, but commonly the cystoscope (flexible or rigid pediatric) can be advanced over one of the guide wires into the bladder. A small red rubber catheter or the flexible cystoscope can be used to assist in localization of the bladder neck. The needle is placed just under the urethral mucosa at the level of the bladder neck and advanced proximally, meaning it is pulled back toward the bladder. The bladder neck closes off completely as the material is injected. Injection stops after the bladder neck closes off, the two sides meeting in apposition near the midline. A small suprapubic tube can be placed to avoid the possible necessity of urethral catheterization.

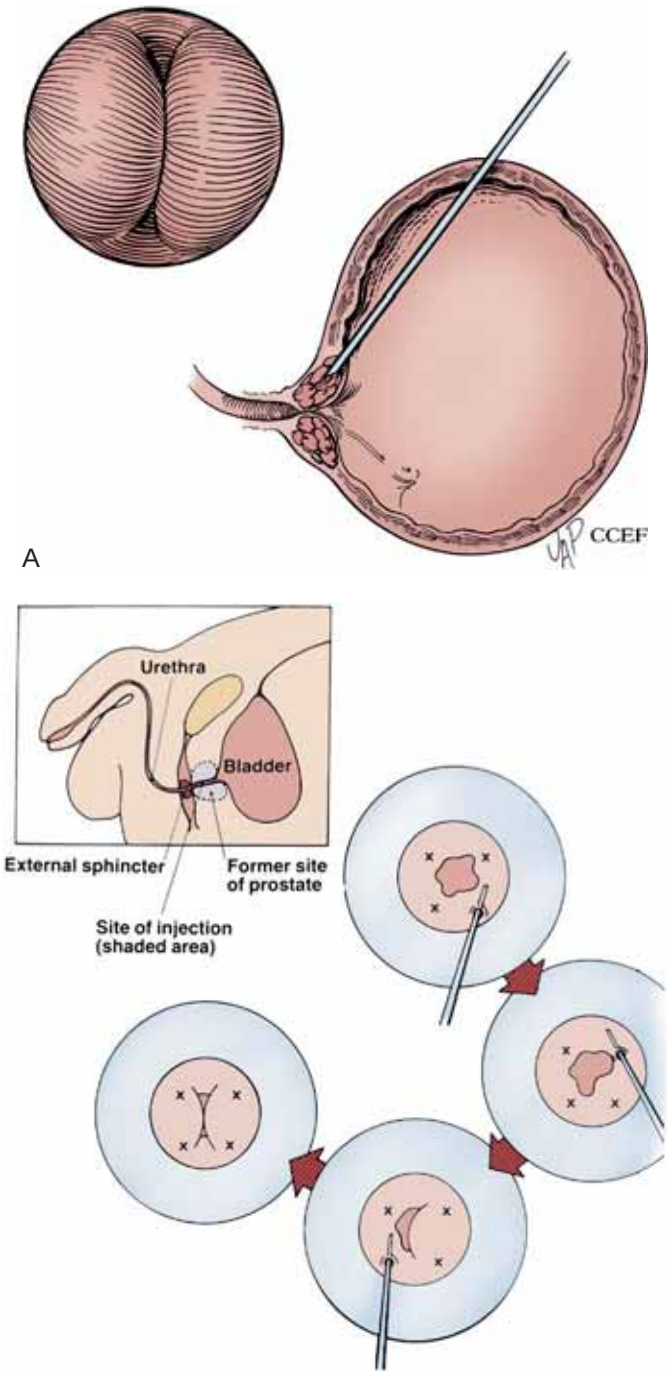

Figure 74–9. **A,** Retrograde urethral injection technique in men. Schematic representation of transurethral circumferential injection in a male after prostatectomy. **B,** Antegrade urethral technique injection in the male after radical prostatectomy. Periprocedural Care

Prophylactic antibiotics with a fluoroquinolone or trimethoprim-sulfamethoxazole for 24 hours or less can be recommended (Wolf et al, 2008). Therapy for an additional 2 to 3 days also has been suggested (Appell and Winters, 2007).

The patient then voids and can be discharged. Urinary retention can be treated by insertion of a fine Foley catheter (12 to 14 Fr or smaller) overnight or intermittent catheterization. Although not specifically reported, an indwelling Foley catheter may cause molding of the agent and lead to early failure; thus long-term catheterization should be avoided.

Reinjections

The same schedule applies as in female patients.

Currently Used Injectable Agents

Glutaraldehyde Cross-linked Bovine Collagen (Contigen)

Collagen has been injected transurethrally with cystoscopic monitoring into the supramembranous urethra. It has also been injected percutaneously through a suprapubic approach in an antegrade manner. The published results for both techniques are in Tables 74–7 and 74–8.

For collagen, "success rates" for incontinence after prostatectomy range from 36% to 69%, with 4% to 20% of patients reporting being dry (McGuire and Appell, 1994; Aboseif et al, 1996; Cummings et al, 1996; Sanchez-Ortiz et al, 1997; Smith et al, 1998; Cespedes et al, 1999; Klutke et al, 1999; Tiguert et al, 1999). Unfortunately, the end points in most of these studies are subjectively based, making comparisons difficult; however, it is clear that cure rates (total dryness) are low, and multiple injections are required to achieve modest rates of subjective improvement. There is no advantage of delivery technique (retrograde vs. antegrade). Several authors have identified factors that negatively affect results, including extensive scarring or stricture formation, previous irradiation, and high-grade SUI and low ALPP (Aboseif et al, 1996; Sanchez-Ortiz et al, 1997; Smith et al, 1998; Cespedes et al, 1999). One study reported more favorable results for collagen in treating incontinence after transurethral prostatectomy as opposed to radical prostatectomy (35.2% "social continence" vs. 62.5%) (Smith et al, 1998). Westney and coworkers (2005) reported long-term results in 322 men observed for a mean of 40.1 months. Overall, 55 patients (17%) were dry for a mean of 11.1 months and required 3.8 injections with a total volume of 29.3 mL. In those who experienced any improvement the mean duration of response was 6.3 months. They concluded that collagen was of some benefit but that the duration of response was limited.

Collagen injection does not adversely affect outcomes of artificial sphincter implantation and does not increase the complication rate (Gomes et al, 2000), nor does collagen injection adversely affect the outcome of the bone-anchored male sling (Comiter, 2002; Onur and Singla, 2006). The cost efficacy of injections remains to be determined.

Complications. In addition to those reported in the section in females, worsening of incontinence symptoms may occur in 1.5% of patients (Westney et al, 2005).

Silicone Microimplants (Macroplastique)

Initial success has been demonstrated with silicone microimplants, but results deteriorate over time. Bugel and coworkers (1999) treated 15 patients. They noted rapid deterioration after initial improvements with success rates of 40%, 71%, 33%, and 26% at 1, 3, 6, and 12 months, respectively. They also noted that a urethral closure pressure of at least 30 cm H_2O was essential for success. Kylmala and colleagues (2003) studied 50 patients with mild to moderate SUI (average 48 mL on 1-hour pad test), with 12% achieving short-term continence after one injection and an additional 20%, 18%, and 10% achieving continence with two,

three, and four injections, respectively. Follow-up, however, was limited to 3 months. In a series of 14 men with spinal injuries and SUI, Hamid and associates (2003) reported that 5 (36%) were dry, 3 (21%) improved, and 6 (43%) experienced failure after a mean follow-up of 35 months.

In a randomized trial of the Artificial Urinary Sphincter (AUS) versus Macroplastique injection in patients with minimal SUI (the vast majority had SUI after surgery for benign prostatic hyperplasia, with greater than a third of the cohort suffering from SUI after radical retropubic prostatectomy), Imamoglu and colleagues (2005) demonstrated no difference in success with AUS versus Macroplastique in men with mild incontinence. However, in patients with more severe incontinence, the AUS was superior and minimal improvement was seen after transurethral implantation of Macroplastique.

Complications. Side effects in men are similar to those reported in women.

Adjustable Balloons (ProACT)

The adjustable balloon procedure is based on the concept of passive compression utilizing balloons located on either side of the urethra. Balloons may be progressively inflated until there is optimal coaptation, thereby achieving continence. The biomaterial name ACT (Adjustable Continence Therapy) was originally developed for female SUI and subsequently was applied to male incontinence. The male ProACT device (Uromedica, Plymouth, MN) was first reported in 2000 (Hubner, 2000).

The device consists of a silicone elastomer balloon attached to an injectable titanium port with a silicone tube (Fig. 74–10). A balloon is implanted on either side of the urethra, either under the bladder neck for post–radical prostatectomy incontinence or under the verumontanum for incontinence after transurethral resection of the prostate. The ports are positioned subcutaneously in the scrotum, allowing simple access for percutaneous adjustment of the balloon volume. The implantation is performed under general or spinal anesthesia through a short perineal incision. A trocar covered with a U-shaped sheath is inserted up to the site of implantation and then the balloon is pushed along inside the sheath. Fluoroscopic and urethroscopic guidance is used for the procedure. Transrectal ultrasound-guided implantation (Gregori et al, 2006, 2010) is a possible option. The balloons are filled with 2 mL of isotonic sterile water and contrast medium during the initial procedure. After approximately 1 month, the balloons are refilled with 1 mL of this solution at each period (maximum filling is 8 mL) until continence is achieved. The adjustments of the filling are volume limited and are carried out step by step to obtain a pseudocapsule surrounding the balloons to minimize the risk of urethral erosion or migration.

Results from seven studies are shown in Table 74–9. Of 170 patients reported by Hubner and Schlarp (2005) and Lebret and colleagues (2008), one third became pad free. In other studies 70% of patients utilized no pad or just 1 pad daily (Hubner and Schlarp, 2005; Trigo-Rocha et al, 2006; Cansino Alcaide et al, 2007; Lebret et al, 2008). Mean procedure time of 35 minutes was reported. Along with this improvement in pad use there were parallel improvements in Incontinence-Quality of Life questionnaire (I-QOL) score (Hubner and Schlarp, 2005; Trigo-Rocha et al, 2006; Lebret et al, 2008). The mean number of postoperative adjustments of the balloon was 3 to 5, with some patients requiring up to 15.

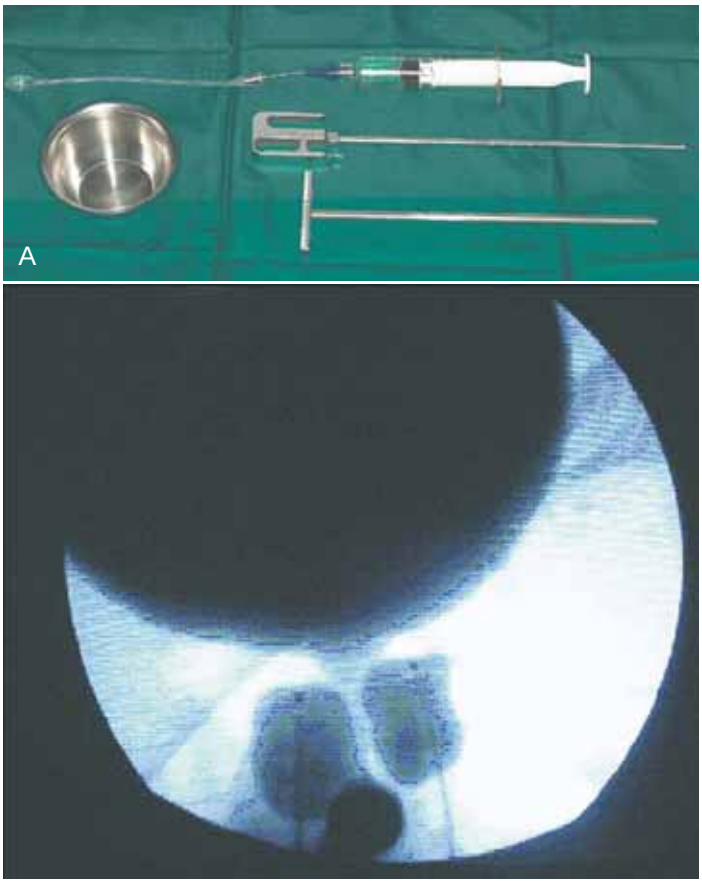

Figure 74–10. Illustration of Adjustable Continence Therapy balloon device for men. **A,** Balloon, trocar, and U-shaped insertion device are shown. Syringe with contrast agent is connected to balloon port. **B,** Fluoroscopic picture showing contrast agent in the bladder and urethra with balloons near the bladder neck. (From Trigo-Rocha F, Gomes CM, Pompeo AC, et al. Prospective study evaluating efficacy and safety of Adjustable Continence Therapy [ProACT] for post radical prostatectomy urinary incontinence. Urology 2006;67[5]:965–69.)

In a simultaneously treated cohort study from two centers, Crivellaro and colleagues (2008) reported no difference in outcome of the adjustable balloons versus the bone-anchored male sling. At a mean follow-up of 19 months after use of adjustable balloons, 30 of 44 men (68%) were dry and 7 (16%) were improved versus 23 of 36 (64%) and 8 (22%) after a bone-anchored male sling procedure, respectively, after a mean of 33 months ($P > .05$).

Complications. The most common perioperative complication is urethral or bladder perforation, necessitating termination of the implant on the perforated side. However, contralateral implantation was not adversely affected, and repeat ipsilateral implantation was invariably achieved after healing of the urethral or bladder wall. Lebret and colleagues (2008) reported a perforation rate of 10% and Hubner and Schlarp (2007) reported a rate of 18% early in their series but a lower urethral perforation rate in more recent cases, illustrating a relatively short learning curve for optimal balloon placement near the urethral/bladder wall. Temporary urinary retention was reported at 5% (Hubner and Schlarp, 2007). Voiding was restored by removing fluid from the balloon.

Device explantation is related to balloon failure, infection, erosion, or migration. The explantation rate ranged from 11% to 58% (Hubner and Schlarp, 2005, 2007; Trigo-Rocha et al, 2006; Cansino Alcaide et al, 2007; Lebret et al, 2008) but decreased with experience (Hubner and Schlarp, 2007). Device removal is straightforward, because a deflated balloon can be explanted transperineally. Reported risk factors for failure and complications were prior external beam radiation therapy (Lebret et al, 2008; Gregori et al, 2010) and severe preoperative incontinence (Gregori et al, 2010). Kocjancic and colleagues (2007) reported a continence rate of 67% in nonirradiated patients compared with 36% in irradiated patients.

Conclusion. The adjustable balloon (ProACT) technique appears to be a feasible procedure to improve continence in the short and medium term. Appropriate candidates include those with mild to moderate leakage and no previous radiation. **The benefit of an adjustable system should be weighed against the need for multiple sessions to refill the balloons and with reported rate of perioperative and postoperative complications necessitating removal.**

The technology appears to have better results than injectable agents in men. Longer follow-up is needed before definitive comparison to male sling or artificial sphincter can be made (Herschorn et al, 2010). The device is not commercially available in the United States.

Key Points: Use of Injectable Agents in Male Stress Urinary Incontinence

- The workup includes history and physical examination, urinalysis, uroflowmetry, and assessment of postvoid residual urine. Urodynamic studies are helpful. Cystoscopy is done to verify the status of the urethra because scarring may prevent the tissues from expanding with the bulking agent.
- Both transurethral retrograde and percutaneous antegrade techniques are feasible with no differences in outcome reported.
- Commonly reported injectable agents have included collagen and silicone microimplants. All agents show initial good results, the need for multiple treatment sessions, and deterioration of outcome over time.
- Implanted adjustable silicone balloons appear to be a feasible technique. However, randomized trials have yet to be done and long-term durability is still to be demonstrated.

USE OF INJECTABLE AGENTS FOR INCONTINENCE AFTER URINARY DIVERSION

There are very few reports in the literature about the use of injectable agents after urinary diversion. Izes and colleagues (1997) demonstrated in a canine study that collagen injected circumferentially into the lumen of the ileocecal valve can increase the leak point pressure for up to 1 month after injection. Subsequently, Smith and colleagues (1998) reported results of collagen in four women and two men with leaking Indiana pouches. They injected a mean of 16 mL circumferentially into the ileocecal junction to obtain visual closure of the bowel lumen. After a mean follow-up of 26 months 5 of the 6 patients remained dry.

Use of injectable agents has been reported in women after construction of a neobladder. Tchetgen and colleagues (2001) reported on 3 patients with SUI after cystectomy and orthotopic neobladder. An average of two injections was given with a cure in 1, improvement in 1, and no change in 1. Wilson and colleagues (2004) administered transurethral collagen to 11 patients and pyrolytic carbon-coated zirconium beads to 1 patient with SUI after cystectomy and construction of a neobladder. After a mean of 22.5 months 2 patients (16.7%) were dry although continued to have urinary frequency. Four patients (33.3%) were improved, and 6 were unchanged. These researchers concluded that the treatment response was not optimal nor durable.

New-onset vesicovaginal fistula has been reported in 2 patients after collagen injection for SUI after cystectomy and construction of a neobladder (Pruthi et al, 2000). Both patients underwent transvaginal fistula repair with pubovaginal sling procedures.

To date, the success of injectable agents for these clinical circumstances is limited.

Other Therapies for Storage and Emptying Failure

R. Duane Cespedes, MD ● Jason L. Gerboc, DO

Methods to Improve Bladder Filling/Urine Storage
Decreasing Spasticity and Increasing Cystometric Capacity
Increasing Outlet Resistance
Lower Urinary Tract Reconstruction, Diversion, and Bladder Substitution
Catheterization
Urinary Collection Devices and Continence Products
Methods to Improve Bladder Emptying
Decreasing Outlet Resistance at a Site of Anatomic Obstruction
Decreasing Outlet Resistance at the Level of the Striated Sphincter
Summary

The etiologies of voiding dysfunction are diverse and may occur as a result of neurologic, inflammatory, or infectious disorders. Other factors such as surgical or nonsurgical trauma and aging are also important causes. Obstruction continues to occupy a central role in the development of emptying failure and, when present chronically, may lead to poor bladder compliance and the failure to store. For both filling/storage and emptying disorders, dysfunction may originate primarily from the bladder, sphincter, or a combination of both. The majority of patients with voiding dysfunction will respond favorably to standard therapy (discussed elsewhere in this book). The treatment of complex cases should be individually tailored and may entail a combination of techniques, especially if approached through different mechanisms. Tables 61–3 and 61–4, list the numerous strategies devised to meet this goal, a testament to the complex management of voiding dysfunction. Additional treatments that have been developed for the management of storage and emptying failure are discussed in this chapter. Some of the topics are covered in other areas of this text but require special mention, while other topics are covered nowhere else in this edition. While some of these approaches offer promising results and are deserving of continued follow-up, others have been mentioned for historic reference only.

METHODS TO IMPROVE BLADDER FILLING/URINE STORAGE

Symptoms of urinary frequency, urgency, and/or incontinence are among the most common manifestations of storage failure. These symptoms can be tremendously bothersome and significantly decrease the patient's quality of life. When severe, many patients will limit their activities and social functions in order to avoid embarrassment from their disorders. **Volume accommodation with low pressure, continence, and the absence of involuntary bladder contractions are the goals of management.** Treatment is often targeted at decreasing sensory input during filling, inhibition of bladder contractility, and increasing outlet resistance. The following sections discuss methods to facilitate urine storage and promote bladder filling by different means.

DECREASING SPASTICITY AND INCREASING CYSTOMETRIC CAPACITY

Lower Urinary Tract Denervation, Decentralization, and Neuromodulation

Altering the innervation of the urinary tract is the focus of several strategies for the management of storage failure and is the central mechanism for procedures that vary from sacral rhizotomy to intravesical botulinum toxin. In addition, interventions may involve different levels of the nervous system, such as the spinal cord, nerve roots, or peripheral nerves. Of note, noncentral denervation proximal to the postganglionic neuron is properly termed "decentralization" and because the bladder is innervated by a short-neuron system, almost all denervation procedures outside the central nervous system that we will describe are properly referred to as decentralization. **In general, more central procedures would appear more suitable for patients with spinal cord injury (SCI) or neurogenic detrusor overactivity, and although central denervation is theoretically very effective, it may also have a potentially wider range**

of unintended consequences. Peripheral decentralization is more selective for the bladder and more suitable for idiopathic detrusor overactivity, as other structures innervated by the sacral nerves remain neurologically intact (Madersbacher, 2000). There would seem to be only a small role for most of the procedures discussed in this section, because conservative measures are often sufficient in significantly improving or alleviating storage symptoms in most patients. Although favorable results have been reported with denervation techniques, some of these procedures have been accompanied by significant adverse outcomes that have limited their usefulness. **One significant problem with central denervation and decentralization is that neuroplasticity often results in a variable restoration of neurologic function, with an even less desirable result than was present originally in many cases** (Madersbacher, 2000). This section will focus on surgical techniques of bladder denervation, both central and peripheral. Sacral neuromodulation is covered in Chapter 70.

Central (Subarachnoid) Block

These procedures, comprise chemical rhizolysis, sacral rhizotomy, and conusectomy, selective anterior sacral rhizotomy, and dorsal rhizotomy are seldom used today and are discussed fully on the Expert Consult website.

Peripheral, Perivesical, and Intravesical Bladder Denervation

Transvaginal Denervation

A number of procedures fall into the category of attempts to achieve a peripheral denervation. The exact nature of these denervations is unclear and may involve interruption of sensory, motor, or both types of innervation. **As evident from neuroanatomic considerations, at best, such attempts achieve primarily neurologic decentralization and, at most, partial peripheral denervation.** Although many authors report relatively high success rates for these procedures, it is unclear why they are not used more frequently. Because they are primarily used for detrusor overactivity, it is likely that many clinicians use nonsurgical methods first and are often successful in managing detrusor overactivity with fewer side effects. Also, because these procedures are uncommonly performed, many clinicians are unfamiliar with how to perform the procedure, and the success rate is likely much lower than when performed by clinicians who commonly perform these procedures. Lastly, many clinicians have begun to use neuromodulation or botulinum toxin injections to treat refractory overactive bladder, leaving the role of transvaginal denervation in question.

Regarding the literature on transvaginal denervation, in many articles, there is little description of what "success" actually means. In addition, there are few studies with long-term follow-up, and "postoperative assessment" often means a few months of follow-up. A comprehensive summary of the surgical treatment of detrusor overactivity by peripheral denervation was reported by Mundy in 1985; however, many reports have been published since that time.

Transvaginal partial denervation of the bladder was originally described by Ingelman-Sunberg in 1959. The original procedure, which was an extensive denervation, was used mostly for the treatment of refractory urge-urinary incontinence, and in the originator's hands, success rates of up to 80% were achieved. Mundy (1985) reported that other investigators found success in 50% to 65% of cases, and Torrens (1985) noted that "the technique has not found favor with other workers."

More recently, Cespedes and associates (1996) described McGuire's modification (limited lateral vaginal dissections) of the Ingelman-Sundberg procedure in 25 women with urinary urgency incontinence and detrusor overactivity who had failed behavioral and medical therapy (Fig. 75–1). Transvaginal local anesthesia was used as a test to determine which patients would benefit from the procedure, with significant improvement of urgency symptoms considered a positive test. Twenty-five patients were found to have a positive test; the number of patients unsuccessfully tested was not reported. Sixteen (64%) of these patients were cured of urgency incontinence at a mean follow-up of 14.8 months. Of the 16 patients cured, 9 patients required one medication, and 2 required two medications. Madersbacher (2000) comments that a follow-up period of 15 months is too short to determine long-term effects.

Long-term follow-up was reported by Westney and associates (2002), who retrospectively reviewed 28 patients with refractory urgency incontinence, having undergone the modified procedure with a mean follow-up of 44.1 months. Of these, 68% were cured (54%) or improved (14%). Based on these results and the prior series, the authors concluded that the modified Ingelman-Sundberg procedure is an efficacious, minimally invasive option for this difficult-to-treat patient population.

Bladder Transection and Peripheral Chemical Neurolysis

These procedures are seldom used today and are fully discussed on the Expert Consult website.

Acupuncture

The use of acupuncture as a therapeutic treatment modality is described in Chinese medical texts as early as 300 BC. Acupuncture is a form of somatic sensory stimulation using a variety of procedures that involve stimulation of specific anatomical locations by insertion of thin, solid, metallic needles into the skin. In the classic forms of acupuncture, needles are stimulated manually to achieve the desired effects. In more modern forms of acupuncture, heat or electrical stimulation may be provided by the addition of an energy source or be performed needleless, as in laser acupuncture. Indeed, McGuire and coworkers' (1983) developed transcutaneous posterior tibial nerve stimulation for bladder inhibition that was based on the acupuncture points. The use of acupuncture has been described for a number of urologic symptoms, including urinary urgency, frequency, incontinence, nonobstructive urinary retention, enuresis, and neurogenic detrusor overactivity. Acupuncture is generally a well-tolerated procedure, and although side effects are generally uncommon and minimal in nature, treatment may occasionally result in localized pain, hematoma, infection, and even organ puncture. Several treatment sessions are usually required.

There has been much interest in determining the mechanism by which acupuncture exerts its beneficial effects. According to traditional Chinese medicine, concepts such as the meridian system, circulation of Qi, and other related theories remain difficult to define and characterize. Sato (1997) has shown somatovisceral reflexes evoked from somatic afferent stimulation may induce either excitatory or inhibitory changes in bladder function and sphincter activity**. Bergström and associates** (2000)

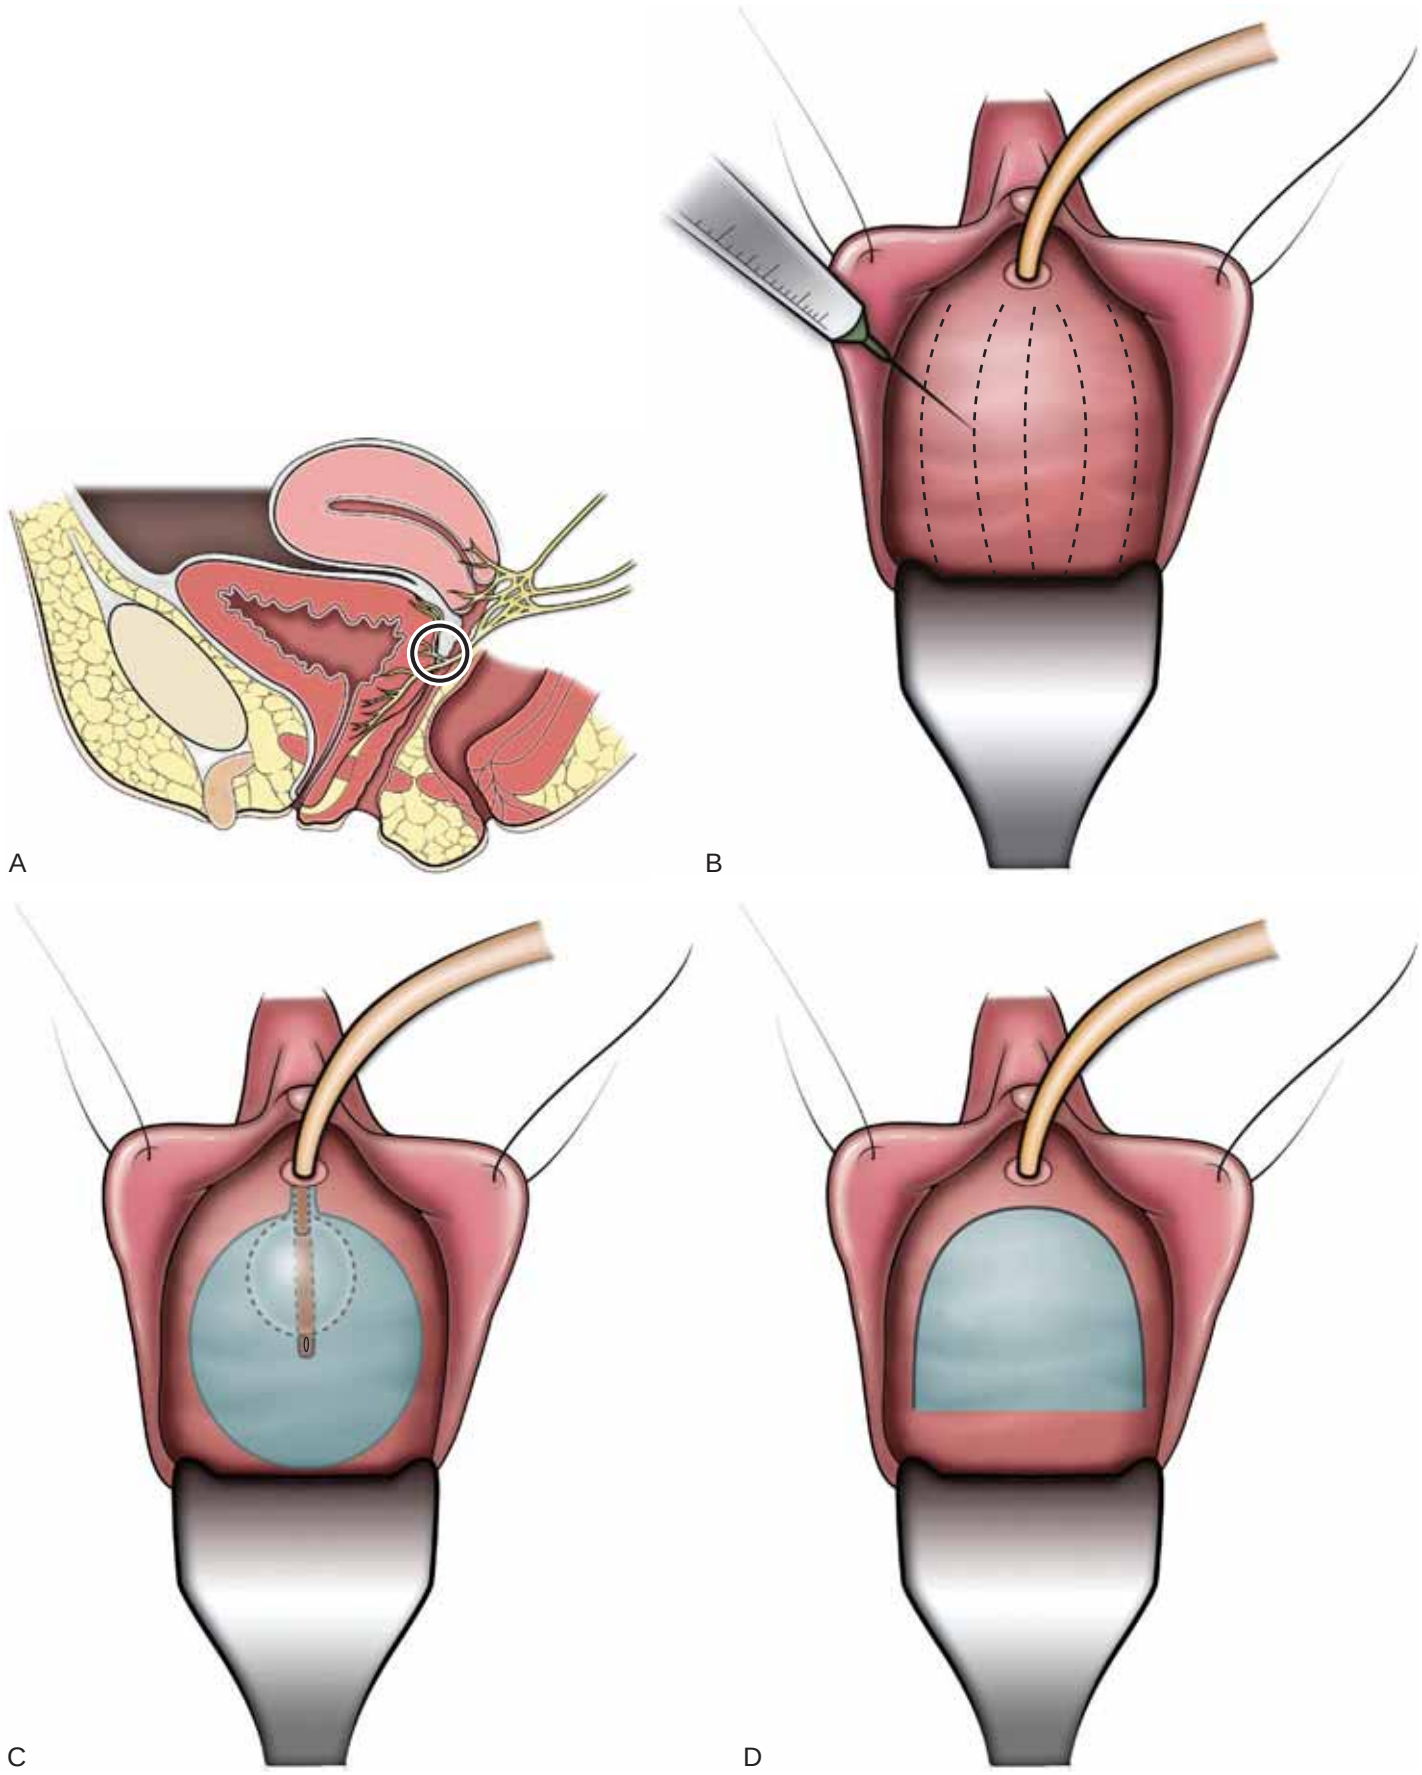

Figure 75–1. Terminal pelvic nerve branches enter the bladder near the trigone. **A**, To assess preoperatively in clinic whether the patient would benefit from the procedure, local anesthetic (0.25% bupivacaine) is injected subtrigonally to block the nerves which would be denervated by the operative procedure. **B**, Normal saline is injected submucosally to facilitate dissection of the vaginal mucosa off the bladder. **C**, Position of the trigone outlined by a catheter balloon inflated to 30 mL. **D**, Inverted-"U" vaginal incision is made.

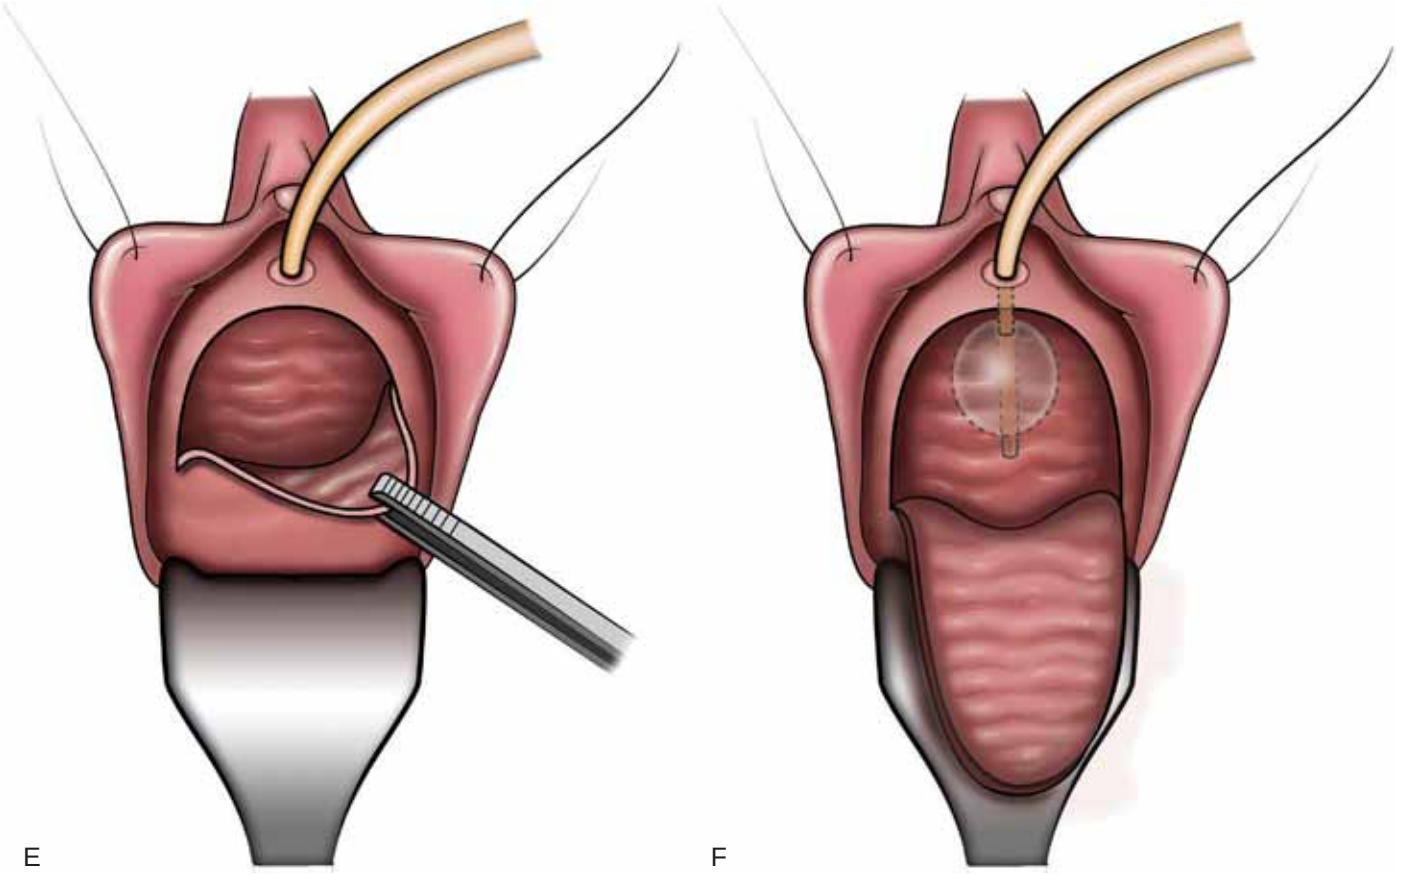

Figure 75–1, cont'd. **E**, Dissection of the vaginal mucosa and deeper tissues off the underlying bladder. **F**, Completed dissection.

hypothesized any one or a combination of (1) endorphinergic effects at the sacral spinal cord level or above, (2) inhibitory somatovisceral reflexes, and (3) increase in peripheral circulation as possible mechanisms of action. The true nature of how acupuncture exerts its beneficial effects remains incompletely understood.

Bergström and associates (2000) reported on the results of classic acupuncture performed twice weekly in a group of 15 elderly women with urgency or mixed incontinence. In this open, uncontrolled study, subjective assessments of improvement and objective measurements in the form of grams of leakage over 48 hours were encouraging, not only at the end of the study but also after 1 and 3 months. More recently, Emmons and Otto (2005) compared acupuncture versus placebo acupuncture in the treatment of women with overactive bladder and urinary urgency incontinence. The number of incontinent episodes decreased by 59% in the treatment group compared with 40% in the placebo group. The treatment group had a significant improvement in bladder capacity, urgency, frequency, and quality-of-life scores compared with the placebo group.

Many studies have been performed to determine the efficacy of acupuncture; however, the level of evidence continues to be limited secondary to difficulties in performing adequate placebo controlled, double-blind studies. In addition, acupuncture requires extensive training, is performed by few clinicians, and few teachers exist. Overall, the importance of acupuncture may not just be in learning or performing the procedure; it may be more important to learn the mechanisms by which it achieves these results, in order to develop easier and less invasive methods of achieving the same (or better) clinical results.

Bladder Distention Therapy

Initially described by Helmstein in 1972 for the treatment of patients with bladder carcinoma, this treatment modality has undergone several modifications. Bladder overdistention, most familiar for its use in the treatment of interstitial cystitis (see Chapter 12), has also been used for other diverse indications, including nocturnal enuresis, irritative symptoms following radiation or BCG, and for patients with overactive bladder.

No standard technique has been clearly defined for this procedure and, as such, several variations exist. Bladder distention may be performed under regional or general anesthesia. The bladder is then distended by either a balloon catheter or more commonly by saline infused cystoscopically or through a urethral catheter. **The ideal pressure and duration needed to distend the bladder has not been well defined. Dunn and colleagues** (1974) **described prolonged bladder distention of several hours at a pressure equal to the patients' systolic blood pressure.** At this pressure, therapeutic benefit is thought to derive from ischemic changes induced in submucosal afferent nerve endings and stretch receptors (Dunn et al, 1977). In a primarily interstitial cystitis population, Hanno and Wein (1991) described distending the bladder to 80 cm H_2O for several minutes with good results. **Bladder rupture, historically as high as 5%**

to 10%, is the most significant complication after bladder distention therapy. Other possible complications include hematuria, back pain, and urinary retention.

Ramsden and colleagues (1976) reported good to excellent results in the treatment of patients with detrusor overactivity, while most others have reported inferior results with this treatment modality. In this same patient population, Jorgensen and coworkers (1985) reported a success rate of only 1 in 15 (6%) patients. In a retrospective review by Taub and Stein (1994), 8 of 22 (36%) of patients with frequency and urgency of various etiologies had subjective improvement, while no patient with detrusor overactivity improved. They also demonstrated that short duration distention therapy (15 to 30 minutes) was as efficacious as prolonged therapy (6 hours). Lloyd and colleagues (1992) reported that only 6 of 29 women with severe irritative symptoms, including 6 patients with interstitial cystitis and none with neurogenic detrusor overactivity, had a good response to treatment. In a study of 26 women with frequency and urgency, Liapis and associates (2001) found a statistically significant increase in bladder capacity after treatment; however, only 4 (15%) had any improvement in symptoms beyond 9 months. **Although largely regarded as an ineffective procedure in patients with storage failure secondary to neurogenic detrusor overactivity, bladder overdistention may provide substantial, but usually temporary, improvement to some patients with non-neurogenic storage symptoms who have failed medical therapy.**

Key Points: Storage Failure Due to Bladder Overactivity, Decreased Compliance, or Hypersensitivity

- Adequate capacity, low detrusor storage pressures, continence, and the absence of involuntary bladder contractions are the goals of managing storage failure.
- To obtain optimal results, complex cases of voiding dysfunction may best be managed by a combination of techniques approached through different mechanisms.
- Central denervation appears to be more suitable for patients with SCI or neurogenic detrusor overactivity but may cause a wide range of unintended side effects.
- Peripheral denervation is relatively bladder selective and more suitable for detrusor instability, with fewer neurologic side effects than more centrally based procedures.
- Denervation may be achieved by sectioning anterior (motor), posterior (sensory) or both sacral roots, converting an overactive bladder into an areflexic one.
- Significant side effects may develop following rhizotomy and may affect bladder, bowel, sphincter, sexual, and motor/sensory elements of the lower extremities.
- To enhance clinical efficacy, differential sacral rhizotomy is typically preceded by stimulation and blockade of the individual sacral roots with cystometric and sphincterometric control.
- The anterior S3 nerve root is the dominant motor innervation of the human bladder.
- Afferent stimulation from dorsal nerve roots is important in generating detrusor contractions. Interruption of the afferent reflex arc by complete transection of all dorsal roots (sacral or sensory deafferentation) abolishes detrusor overactivity.
- Complete dorsal rhizotomy of the S2 through S5 nerve roots abolishes reflex erections, reflex ejaculation, and sacral sensation, and it can reduce reflex defecation.
- The Ingelman-Sundberg procedure and its modifications involve transvaginal partial denervation of the bladder and may benefit patients with refractory urge urinary incontinence.
- It is unclear whether bladder transection, encompassing complete circumferential division of the full thickness of the bladder wall just above the ureteric orifices, is a viable procedure.
- The use of acupuncture has been described for a number of urologic symptoms, including urinary urgency, frequency, incontinence, nonobstructive urinary retention, enuresis, and neurogenic detrusor overactivity.
- The somatic afferent stimulation generated by acupuncture is believed to evoke somatovisceral reflexes that may induce an either excitatory or inhibitory change in bladder function and sphincter activity. Other theories regarding the mechanism of action of acupuncture include endorphinergic effects at the sacral spinal cord level or above and an increase in peripheral circulation.
- Bladder overdistention has been used to treat irritative lower urinary tract symptoms of various etiologies. The most significant complication of bladder distention therapy is bladder rupture. Generally regarded as ineffective for neurogenic detrusor overactivity, distention therapy may provide substantial, albeit temporary, improvements in patients with non-neurogenic–related storage symptoms.

INCREASING OUTLET RESISTANCE

See the Expert Consult website for a discussion of this topic, as well as Figures 75–2 and 75–3.

Key Points: Storage Failure Due to Sphincter Underactivity

- Urethral compression devices are primarily used to treat patients with pure sphincteric incontinence, most commonly postprostatectomy incontinence (PPI). Normal bladder capacity and storage pressures are a relative requirement. Pressure-related injuries may occur with these devices and may be more prevalent in patients with impaired sensation or cognition.
- Injectables treat stress incontinence by increasing the abdominal leak point pressure. Patients with intrinsic sphincter deficiency (ISD) are the best candidates for injectables.
- Most male patients undergoing injection therapy for mild PPI require four to five injections with reinjections every 6 to 12 months to maintain dryness.
- Severe vaginal vault prolapse may cause occult urinary incontinence, defined as stress incontinence, which only occurs with reduction of the prolapse.
- The artificial urinary sphincter (AUS) is very effective in preventing incontinence and may be used in adults or children of both sexes. Caution should be exercised in patients with neurogenic bladder, because renal deterioration may occur if high bladder pressures develop due to poor compliance.

- The main indication for bladder outlet closure is urethral destruction secondary to prolonged catheter drainage in patients with neurogenic bladder.
- Bladder outlet reconstruction may involve tightening, lengthening, or reconstructing the urethral segment to improve the sphincteric mechanism and continence.
- Skeletal muscle transposition and injection of allogenic muscle-derived progenitor cells represent two methods by which functional sphincteric reconstruction may be performed. Further study is required to determine the role of these treatment modalities.
- These topics, many of which are covered elsewhere in the text, are fully discussed on the Expert Consult website.

LOWER URINARY TRACT RECONSTRUCTION, DIVERSION, AND BLADDER SUBSTITUTION

See the Expert Consult website for a discussion of the topic.

Key Points: Lower Urinary Tract Reconstruction, Diversion, and Bladder Substitution

- Bladder augmentation offers the best chance to construct a "normal" urinary system, but the ability to void without catheterization is not guaranteed; therefore, only patients who have the ability and motivation to perform CIC should be considered for this procedure.
- Although bladder augmentation is invasive, it is generally very effective, with significant improvement reported in up to 90% of patients with neurogenic lower urinary tract dysfunction or limited-capacity bladders due to other causes.
- Results are less favorable and of shorter duration following the autoaugmentation procedure than with conventional enterocystoplasty. Autoaugmentation is less morbid and may benefit patients who require avoidance of intestinal segments.
- Supravesical diversion may serve as treatment for both storage and emptying disorders. Indications for diversion may include progressive, medically refractory hydronephrosis; recurrent urosepsis; or intractable storage or emptying failure when CIC is impossible.
- The incontinent ileovesicostomy is an excellent method for managing patients with neurogenic bladder who are unable to perform CIC independently. Complications of long-term indwelling catheters are avoided, and the native antireflux and urethral sphincteric mechanisms are maintained.
- The ileal conduit is the most recognized and commonly performed form of urinary diversion.
- Despite advances in the development of the tissue-engineered and artificial bladder, we are still far from achieving an adequate bladder replacement.
- A more extensive discussion of these topics can be found on the Expert Consult website.

CATHETERIZATION

Catheterization, in its many forms, is an effective method of bladder emptying, and is a useful adjunct when efforts to increase intravesical pressure and/or decrease outlet resistance have been unsuccessful. In addition, for those patients who have filling/storage failure caused by bladder overactivity and/or sphincteric incontinence, catheterization may also be used if the dysfunction can be converted solely or primarily to one of emptying by nonsurgical or surgical means (Wein and Barrett, 1988). The common goals, irrespective of the mode of catheterization, are to provide low-pressure storage, preserve continence, avoid renal deterioration, minimize complications, and maintain quality of life.

Indwelling urethral catheters are generally used for short-term bladder drainage, and careful use of a small-bore catheter for a short time is unlikely to adversely affect the ultimate outcome, especially if used in the initial bladder management in SCI (Lloyd et al, 1986). Long-term bladder drainage may be obtained by intermittent catheterization, or by an indwelling suprapubic or urethral catheter. Historically, the most appropriate form of bladder drainage in patients requiring prolonged bladder management has been debated. Most studies evaluating the different forms of long-term bladder management have been retrospective and in patients with SCI, because they represent the majority of patients requiring long-term catheterization. **The main area of controversy concerns whether long-term indwelling catheterization in neurologically impaired patients is associated with an inferior outcome compared to clean intermittent catheterization, specifically regarding urinary tract complications or quality of life.**

Although CIC is currently the preferred management for patients requiring prolonged bladder drainage, it is a recent innovation. Intermittent catheterization was first introduced as a sterile procedure in 1949 by Guttman and, at the time, challenged the beliefs of most urologists (Guttman, 1949; Guttman and Frankel, 1966). It was not until Lapides and colleagues (1972) introduced the concept of clean intermittent catheterization that widespread usage became more common. **As the popularity of CIC grew, long-term indwelling catheterization was condemned, based on both infectious risks and a perceived increased risk of other urologic complications.** Jacobs and Kaufman (1978) reported that there were more renal and other urologic complications with long-term (>10 years) catheterization use than with short-term use. Hackler (1982) also reported accelerated renal deterioration in patients with SCI managed with long-term suprapubic catheterization. McGuire and Savastano (1984) reported a poorer outcome in women with an indwelling urethral catheter than in those on CIC after 2 to 12 years. Of 13 in the catheter group, 54% had adverse changes on intravenous pyelography, as opposed to 0% in the CIC group. Other urologic complications were also more frequent and severe in the catheter group.

Conversely, more recent investigations have suggested the complications from chronic indwelling catheters may be lower than previously thought. Sekar and coworkers (1997) reported on the effect of different bladder management methods in 1114 patients with SCI using total and individual kidney-effective renal plasma flow as the primary outcome measure. Follow-up was relatively long with 51.3% followed 0 to 3 years, 40% at least 5 years, and 20% for at least 10 years. Unfortunately, many issues, such as unclear methods of urinary management at discharge, incomplete data on approximately 200 patients, and the fact that most men who were discharged using CIC later changed to condom catheter drainage, weaken the authors' conclusions that there was very little change in renal function over time in patients using different bladder management methods. Dewire and associates (1992)

reviewed the course of 32 quadriplegic patients managed with, and 25 without, an indwelling catheter. The groups were roughly comparable, and follow-up was for 10 years or longer. The incidences of upper and lower urinary tract complications and renal deterioration were not significantly different. Chao and coworkers (1993) did a similar review on 32 patients with SCI with an indwelling urethral (14 patients) or suprapubic catheter (18 patients) versus 41 patients without. Follow-up was 20 years or longer. Although the catheterized group had a higher prevalence of upper tract scarring and caliectasis, no significant differences were found in other indices of renal function or in the prevalence of other urologic complications. Jackson and DeVivo (1992) reported on the results of indwelling catheterization in 108 women (with SCI) followed for 2 to 5 years (56 women), 6 to 9 years (31 women), and 10 or more years (21 women) after injury. Compared with the male population, the majority being managed by condom drainage, there was no difference in upper or lower tract complications. MacDiarmid and colleagues (1995) reported on suprapubic catheterization in 44 patients with SCI, with follow-up ranging from 12 to 150 months (mean, 58 months). They reported that no patient had renal deterioration or vesicoureteral reflux and that the incidences of incontinence, infection, and calculi were acceptable. Eleven percent of the patients had leakage, 100% had bacteriuria, 41% developed bladder calculi, and 7% developed renal calculi. Thirty-six percent of patients developed episodes of catheter blockage, and gross hematuria resulting in hospitalization occurred in 5%.

Upper tract and infectious complications often occur regardless of whether intermittent or indwelling catheterization is used. Although bacteruria is common in all forms of bladder catheterization, symptomatic infection is not. **The presence of asymptomatic bacteruria does not usually require treatment and should be distinguished from an invasive, symptomatic urinary tract infection (UTI). Treatment of asymptomatic bacteruria has not proven beneficial, and the use of continuous prophylactic antibiotics is rarely indicated (Gribble and Puterman, 1993).** Nevertheless, infectious complications are the most common complications associated with prolonged catheterization, and procedures such as frequent catheter changes should be considered to reduce these complications (Weld and Dmochowski, 2000; Wyndaele, 2002). Much interest has recently been generated with catheter-associated infections in hospitalized patients. Under new rules by the Centers of Medicare and Medicaid Services, hospitals will not be compensated for catheter-associated UTIs, causing many hospitals to intensify their efforts in implementing preventive measures (Saint et al, 2009). For more information regarding bacteruria and catheter-associated UTI see Chapter 10.

More recent studies have shown the superiority of CIC over long-term indwelling catheter drainage. Weld and Dmochowski (2000) reported a retrospective review of 316 patients with SCI with a mean follow-up of 18.3 years. Bladder management methods included chronic urethral catheterization in 114 patients, CIC in 92, spontaneous voiding in 74, and suprapubic catheterization in 36. Complications were recorded in terms of infectious complications (epididymitis and pyelonephritis), renal and bladder calculi, urethral complications (stricture and periurethral abscess), and radiographic abnormalities (vesicoureteral reflux and abnormal urographic findings). Overall, there were 398 complications recorded, of which 236 developed in 61 patients (53.5%) on chronic urethral catheterization, 48 in 16 patients (44.4%) on suprapubic catheterization, 57 in 24 patients (32.4%) who voided spontaneously, and 57 in 25 patients (27.2%) on CIC. Separate bar graphs for each type of complication seem to confirm the overall superiority of CIC as the least problematic long-term form of bladder management (Fig. 75–4).

The exact etiology of upper tract deterioration in patients with long-term indwelling catheters is unclear, because the bladder should be well drained by a catheter; however, it is likely related to chronic "occult" or subclinical detrusor overactivity in the face of sphincteric dyssynergy providing a functional obstruction. Regardless of the etiology, it is clinically heralded by the development of poor detrusor compliance demonstrated on urodynamic studies. Weld and colleagues (2000) reported the effects of CIC versus indwelling urethral catheterization on bladder compliance in patients with SCI. Logistical regression analysis of compliance versus bladder management and interval because injury revealed that CIC and spontaneous voiding were associated more with normal compliance than indwelling urethral catheterization. **Poor compliance was statistically associated with vesicoureteral reflux, radiographic upper tract abnormalities, clinical pyelonephritis, and upper tract calculi** (Fig. 75–5). Jamil and associates (1999) reported on ambulatory urodynamics in 30 patients with SCI whose bladders were managed with an indwelling urethral catheter. They found that freely draining indwelling catheters did not guarantee consistently low intravesical pressure. Eleven of 30 patients demonstrated intermittent detrusor contractions causing intravesical pressure increases greater than 40 cm H_2O for up to 4.5 minutes. These patients had used an indwelling catheter for a mean of 14.3 years (range, 4 to 36 years). Renal scarring was observed in 9 patients, and, of these, 6 were in the group with the abnormal bladder contractions, whereas only 5 of 21 patients with normal kidneys had such pressure rises. **The clinical correlate emphasized by the authors was their belief that maintenance of a compliant bladder and suppression of high-pressure contractions in chronically catheterized patients may play a role in the prevention of renal deterioration.** Kim (1997) demonstrated in a retrospective analysis that anticholinergic medications can reduce the incidence of hydronephrosis, improve bladder compliance, as well as decrease leak point pressures in patients with chronic catheters. The role of anticholinergics with various forms of prolonged bladder management and in the prevention of upper tract complications has not yet been clarified (Feifer, 2008).

There is certainly some controversy about the classic teaching that long-term continuous bladder catheterization in patients with neurogenic bladder dysfunction should be avoided at all costs. There are clearly some situations in which such management is desirable and necessary. Most of the studies that purport to compare methods of management regarding lower and upper tract complications are often flawed and prevent total acceptance of their conclusions. In the absence of a prospective, randomized study or acceptable retrospective data, patient and family comfort, convenience, and quality of life must be strongly considered in the decision of which method of catheterization will be employed. Regardless of which method is used, **periodic upper and lower tract evaluation using renal ultrasonography and cystoscopy should be considered in all patients who require prolonged bladder management.** Lastly, the use of urodynamics to monitor the bladder in neurologically impaired individuals is controversial. **At a minimum, we believe that urodynamics should be**

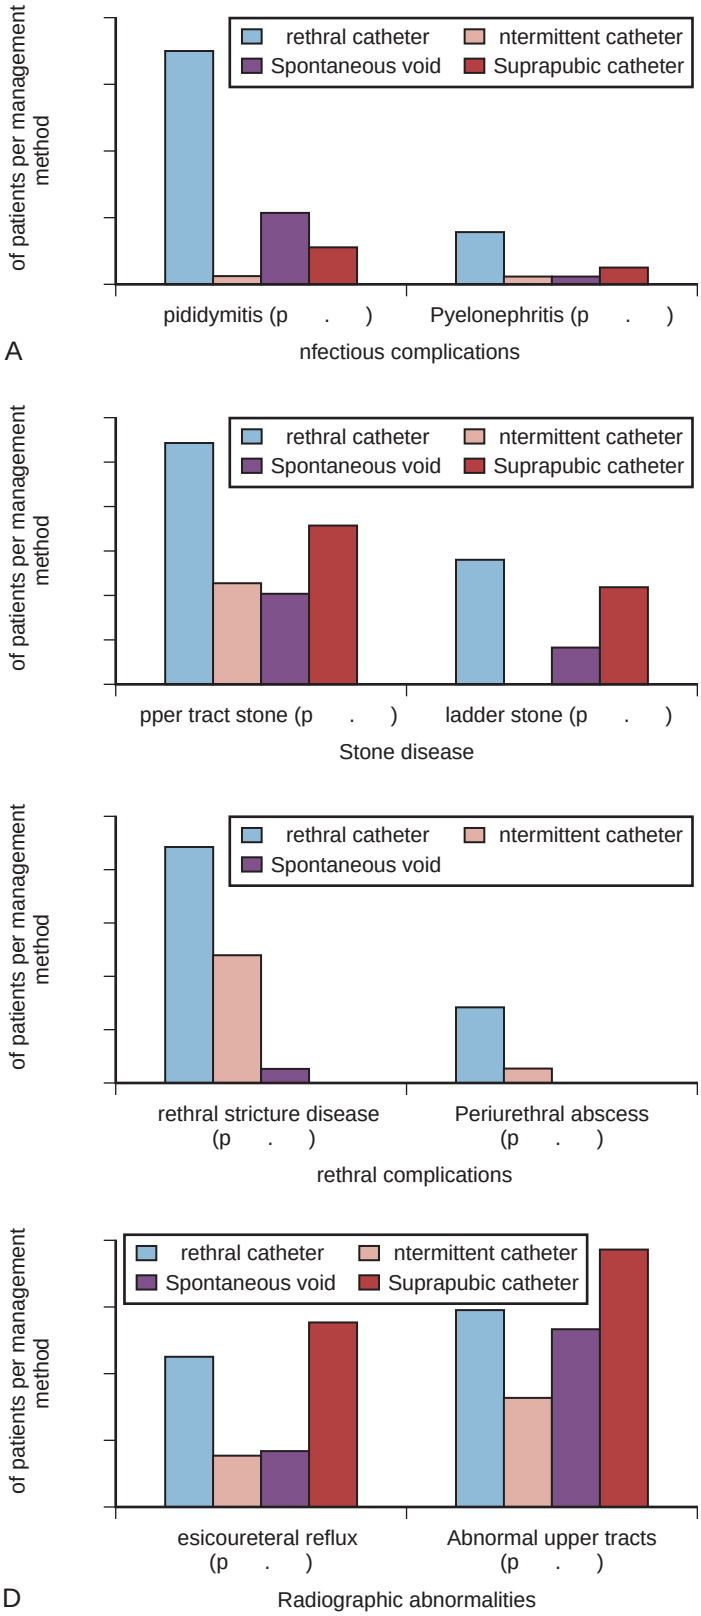

Figure 75–4. Complications related to specific bladder management methods: infectious **(A);** stone disease **(B);** urethral **(C);** radiographic abnormalities **(D).** (Modified from Weld KJ, Dmochowski RR. Effect of bladder management on urological complications in spinal cord injured patients. J Urol 2000;163:768–72.)

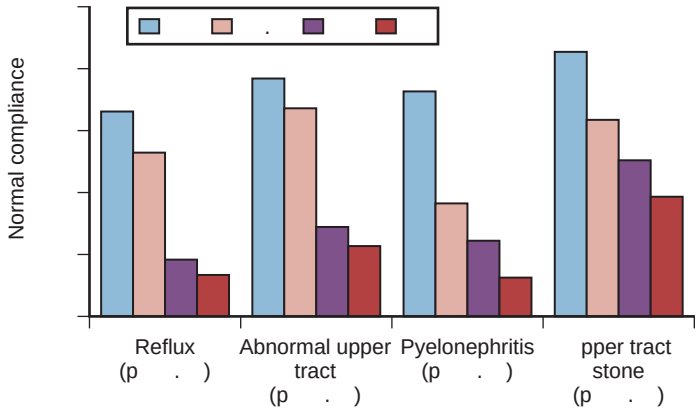

Figure 75–5. Incidence of patients with upper tract complications who had normal bladder compliance at various threshold values. (From Weld KJ, Graney MJ, Dmochowski RR. Differences in bladder compliance with time and associations of bladder management with compliance in spinal cord injured patients. J Urol 2000;163:1228–33.)

performed after the initial neurologic injury is stable and whenever any significant changes in continence or voiding function occur. The initial urodynamics is useful to direct early bladder management, while subsequent urodynamics evaluations are performed to determine if lower urinary tract changes, such as the development of dyssynergia, have occurred.

Clean Intermittent Catheterization (CIC)

CIC has proved to be the most effective and practical means of attaining a catheter-free state in the majority of patients with acute spinal cord lesions. CIC has revolutionized the treatment of difficult cases of neuromuscular dysfunction of the lower urinary tract by providing a safe and effective method that preserves the independence of the patient to empty the lower urinary tract in cases in which continence has been achieved pharmacologically or surgically, producing total or partial urinary retention. **For example, without CIC, the successful outcomes achieved using augmentation cystoplasty or continent urinary diversion would have never been achieved. CIC is based on a theory proposed by Lapides that high intravesical pressure or bladder overdistention is primarily responsible for the development of UTI, not the bacteruria itself.** Theoretically, reduced blood flow to the bladder can lead to increased host susceptibility to bacterial invasion and UTI. Bacteria introduced by CIC would be neutralized by the host, and relatively sterile urine would be maintained as long as bladder distention and high intraluminal pressures were avoided. The long-term efficacy and safety of such a program has been demonstrated by Lapides and others (Weld and Dmochowski, 2000).

Whereas indwelling catheter drainage requires little input from the patient, **a cooperative, well-motivated patient or family is a requirement for CIC.** The patient must have adequate hand control, or a family member must be willing to perform the catheterization. In addition, **there must be adequate urethral exposure.** Graham (1989) reported on the factors required to successfully develop a catheterization program

for patients with functional limitations, which commonly exists in patients with neurogenic bladder dysfunction. It is advantageous to have a dedicated nurse who instructs the patients and families in the catheterization regimen; provides them with understandable written instructions to refresh their memory regarding technique, precautions, and danger signals; and provides continuing support for patients and families who call with questions or problems regarding their regimen. Many patients are initially reluctant to perform any procedure on their own genitalia. Patients need a thorough explanation of the advantages of CIC along with assurances that it is simple and that it will not tie them to their houses or to an absolute time schedule. Additionally, proper selection of equipment for the patient's intelligence and financial level will increase patient acceptance of and compliance with a self-catheterization program. Patients who are reticent initially are continually amazed by the ease with which such a regimen is established. Successful CIC is intimately associated with patient compliance, and therefore patients should be monitored periodically to ensure catheterization is performed properly. Of note, **CIC should be used cautiously in patients known to have autonomic dysreflexia.**

Intermittent catheterization may be performed by clean, aseptic, or sterile techniques (Hudson and Murahata, 2005). Clean intermittent catheterization often includes reusing a catheter several times before disposal. It is washed, generally with soap and water, and allowed to air dry prior to storage. When reusing catheters, some have advocated boiling or microwaving for sterilization (Douglas et al, 1990). **In April 2008, in an attempt to decrease the incidence of UTIs in patients performing intermittent catheterization, Medicare policy regarding intermittent catheterization changed. Any patient requiring intermittent catheterization may obtain up to 200 sterile catheters per month for one-time use.** This change in policy has negated the need for reusing catheters in most patients, but it still may be necessary in patients without insurance coverage or other financial limitations. **For adult patients, catheterization is typically performed at a minimum of every 4 to 6 hours to minimize bacterial dwell time. CIC may need to be more frequent if large volumes of fluid are ingested. In most cases, catheterizations should be timed to maintain bladder volumes below the normal 400- to 500-mL capacity** to minimize bladder wall pressure. Even smaller volumes may be required if they have poor detrusor compliance. Catheter choice is variable, but a 12- to 16-Fr soft catheter may be used for males and short (6-inch "female") 12- to 16-Fr catheters for females. Note that rigid catheters have the potential to injure the urethra in insensate males because they may not "make the bend" at the prostate, causing a false passage such that CIC may be quite difficult or impossible. Larger catheters may be required in patients with a prior bowel augmentation or those who require bladder irrigation. In men, hydrophilic coated catheters have been found to reduce the incidence of UTI and hematuria and have higher patient satisfaction rates than conventional plastic catheters (Vapnek et al, 2003; De Ridder et al, 2005). Patients with recurrent UTIs, despite the use of single-use sterile catheters, may obtain sterile catheter kits for sterile intermittent catheterization (IC). Anticholinergic medication should be considered when urine leakage occurs between catheterization intervals or if high storage pressures develop. Wyndaele (2002) reported that trauma from catheterization occurs frequently, but effects are usually not long standing, and urethral stricture and false passages are more common the longer that CIC is employed.

Continuous Catheterization

Long-term indwelling catheters should be considered when anatomical, functional, or familial limitations prohibit performance of intermittent catheterization. Continuous catheterization may also be indicated in patients with complications from persistent incontinence or autonomic dysreflexia, despite therapy or when a small bladder capacity prohibits effective CIC. Long-term catheterization may be accomplished by either a urethral or suprapubic catheter. The basics of urethral catheterization, including the technique of suprapubic tube (SPT) insertion are covered in Chapter 7.

In males, the benefits of an indwelling SPT over urethral catheterization include a lower incidence of epididymitis and urethral stricture disease (Weld and Dmochowski, 2000) **and preserved sexual function** (Rutkowski et al, 1995) (see Fig. 75–4). Overall, suprapubic catheters have been associated with high rates of patient satisfaction. Barnes and associates (1993) concluded that long-term suprapubic catheters were well tolerated by patients with neuropathic bladders. Based on the replies of 32 patients who expressed an opinion, 84% were satisfied; however, the follow-up was short (mean 23 months), and in 2 of 12 patients assessable at over 2 years, creatinine levels increased. Other problems occurred, including recurrent catheter blockage in 38%, recurrent symptomatic urinary infections in 23%, and displaced catheters requiring reinsertion in the operating room in 15%. Urethral leakage occurred in 8 of 14 females with a suprapubic catheter alone and in 6 of 16 males. **Patients using a suprapubic catheter must be warned that urinary incontinence may commence or worsen in the setting of sphincteric incontinence or reflex detrusor overactivity, because active opening of the sphincteric unit will occur in the absence of dyssynergia.** Sheriff and associates (1998) discussed the clinical outcome in a satisfaction survey of 185 patients with neuropathic bladder dysfunction treated with long-term suprapubic catheterization (follow-up, 3 to 68 months; mean, 24 months). The authors reported an 82% satisfaction rate; however, the main reason for this procedure was failed CIC from poor hand function. In addition, only 103 of the 185 patients filled out the satisfaction questionnaire, and only 8 patients had a suprapubic catheter for longer than 2 years. Complications in this group included 5 patients with a small-bowel injury during insertion, 2 developing significant hemorrhage, 2 requiring catheter repositioning, 1 requiring reinsertion because of dislodgement, 8 with persistent incontinence, and 18% with recurrent catheter blockage. Bacteriuria existed in 98% of the patients, but recurrent symptomatic infection occurred in only 4%. More recently, Ahluwalia and colleagues (2006) reported a satisfaction rating of 71% among 219 patients having indwelling suprapubic catheters for greater than 50 months.

A controversial issue, common to all long-term indwelling catheters, is the development of bladder cancer. **The long-term risk of carcinoma in the SCI patient with a chronic catheter has been estimated to be 8% to 10%** (Locke et al, 1985; Delnay et al, 1999). Kaufman and colleagues (1977) were among the first to recognize that patients with SCI and chronic indwelling catheters had an increased incidence of bladder cancer, particularly squamous cell carcinoma (SCC). Several others have reported similar findings (Chao et al, 1993; Stonehill et al, 1996). Since this report, the association between chronic indwelling catheterization and the development of bladder carcinoma has been debated. **No associations with intermittent**

catheterization have been identified. Chronic inflammation is the most likely causative factor and may be caused by the indwelling catheter itself, bladder calculi, and/or recurrent infections. It is not clear whether earlier treatment of these conditions or better follow-up will lessen the risk for bladder carcinoma. A mechanism for the development of bladder carcinoma secondary to long-term inflammation was described by Wall and colleagues (2001). **According to their report, inducible nitric oxide synthase expressed by inflammatory macrophages in areas of chronic inflammation may lead to the formation of potentially carcinogenic nitrosamines in the bladder.** For more on the development of carcinoma and the associations with spinal cord injury and chronic catheterization, see Chapter 65.

When SCC is identified in SCI patients, it is often advanced and commonly fatal; however, routine screening cystoscopy for SCI patients at risk is controversial. **Although some authors suggest that screening cystoscopy conveys a survival advantage by identifying bladder cancer at an earlier stage** (Navon et al, 1997), **others have found no advantage for screening** (Yang and Clowers, 1999; Hamid et al, 2003). Cytology, although commonly obtained, is not useful for detecting squamous cell carcinoma (Bejany et al, 1987). Additionally, SCC may not always be cystoscopically detectable (Kaufman et al, 1977). For this reason, routine random biopsies have been advocated by some (Stonehill et al, 1996). **Despite the lack of data in non-SCI patients, most urologists recommend all patients with chronic catheters undergo annual screening, generally starting after 8 years** (Stonehill et al, 1996). **Gross hematuria has been reported by several investigators as the most common presenting symptom for patients eventually diagnosed with bladder cancer** (Hess et al, 2003). Despite the disparate opinions regarding screening, certainly all would agree that patients with new-onset gross hematuria should be evaluated with upper tract imaging, urinary cytology, cystoscopy, and perhaps random biopsies. **Other patients to consider for close surveillance should include patients with known risk factors for the development of carcinoma, such as recurrent UTIs or recurrent bladder stones.**

Key Points: Catheterization

- Catheterization is an effective tool in promoting bladder emptying and may also assist patients with filling/storage failure due to overactivity and/or sphincteric incontinence, especially if the bladder can be converted solely or primarily into a storage organ using either medical or surgical means.
- Whether long-term indwelling catheterization is inferior to clean intermittent catheterization remains a main area of controversy, specifically regarding urinary tract complications and quality of life.
- Asymptomatic bacteruria is common in catheterized patients and does not require treatment unless the patient becomes symptomatic.
- Periodic surveillance should be considered in patients with chronic catheters, because elevated bladder pressures, poor bladder compliance, and upper tract deterioration may develop despite seemingly adequate bladder drainage by CIC or an indwelling catheter.
- Maintenance of low intravesical pressure and avoidance of bladder overdistention is essential to successful CIC.
- The most common complications associated with catheter use include infectious (epididymitis, periurethral abscess, pyelonephritis), renal and bladder calculi, urethral stricture, and vesicoureteral reflux.
- The exact etiology of upper tract deterioration in patients with long-term indwelling catheters is unclear; however, it is likely related to chronic "occult" or subclinical detrusor overactivity in the face of sphincteric dyssynergy providing a functional obstruction.
- Poor compliance is associated with vesicoureteral reflux, radiographic upper tract abnormalities, clinical pyelonephritis, and upper tract calculi.
- In patients with SCI, urodynamics should be performed after the initial neurologic injury is stable and whenever any significant changes in continence or voiding function occur. Periodic upper and lower tract evaluation using renal ultrasonography and cystoscopy should also be considered in all patients who require prolonged bladder management.
- CIC should be used cautiously in patients known to have autonomic dysreflexia.
- Intermittent catheterization may be performed by clean, aseptic, or sterile techniques.
- Any patient requiring intermittent catheterization may obtain up to 200 sterile catheters per month for one-time use.
- In most patients, catheterizations should be timed to maintain bladder volumes below the normal 400- to 500-mL capacity.
- Long-term indwelling catheters should be considered when anatomical, functional, or familial limitations prohibit performance on intermittent catheterization.
- In males, the benefits of an indwelling SPT over urethral catheterization include a lower incidence of epididymitis and urethral stricture disease with preservation of sexual function.
- The long-term risk of carcinoma in the SCI patient with a chronic catheter has been estimated to be 8% to 10%. This association has not been identified in patients performing intermittent catheterization.
- The development of gross hematuria in patients with a chronic indwelling catheter should prompt further evaluation, including upper tract imaging, urine cytology, cystoscopy, and consideration of bladder biopsy.

URINARY COLLECTION DEVICES AND CONTINENCE PRODUCTS

See the Expert Consult website for a discussion of the topic.

Key Points: Urinary Collection Devices and Continence Products

- There currently is no external collection device that performs effectively or reliably for female patients.
- The most common male external collection device is the condom catheter. Patients often perceive condom catheters as more comfortable than indwelling catheters; however, many find the device unacceptable due to its visibility and potential for foul odors.
- Condom catheters may be associated with pressure-related injuries, especially when used by patients with impaired sensation or cognition.
- Condom catheters and absorbent products are associated with a lower incidence of complications than indwelling catheters, but higher complication rates than if no devices or products are used at all.
- A patient's satisfaction with absorbent products may be influenced by several factors, such as the shape or contour of the pad, their capacity and speed of absorbency, amount of core fluff, fit, and comfort when dry or wet.
- Selection of an absorbent product is often a matter of trial and error and often based on personal opinion, manufacturer's claims, convenience of the caregiver, or cost of the product, rather than any evidence-based guidance.
- Incontinence-associated dermatitis (IAD) is defined as inflammation of the surface of the skin with redness, edema, and in some cases bullae. IAD predominately occurs in skin folds and may promote candidiasis or bacterial skin infections.
- A complete discussion of these topics can be found on the Expert Consult website.

METHODS TO IMPROVE BLADDER EMPTYING

Low flow rates and elevated residual volumes are often signs of a bladder that fails to empty. Symptoms are less specific in identifying the underlying abnormality but may include incomplete emptying, straining to urinate, and decreased force of stream. Patients with emptying failure are prone to bladder stones, UTI, and urinary retention and, if not addressed, may lead to renal deterioration. **Methods to improve bladder emptying consist of two main strategies: increasing intravesical pressure and decreasing outlet resistance. Unfortunately, management of poor detrusor contractility is limited and has not been overwhelmingly successful,** obliging most patients to rely on chronic catheterization. Attempts to alter the contractility of the bladder through pharmacotherapy or electrical stimulation have also been described and are detailed in Chapters 68 and 70, respectively.

Conversely, **methods of decreasing outlet resistance due to obstruction are more straightforward, more successful,** and are thoroughly discussed in several chapters. Pharmacologic measures have been used to decrease outlet resistance both at sites of anatomic and sphincteric obstruction and are reviewed in Chapters 92 and 68. Chapter 36 outlines the management of urethral stricture disease; prostatic obstruction is discussed in Chapters 93 and 94. For patients with intractable emptying failure and inability to catheterize, urinary diversion may be considered (see earlier discussion in this chapter). In the following sections, we discuss further management options to improve bladder emptying. Some of these modalities are well known and established, while others are less familiar.

Increasing Intravesical Pressure or Facilitating Bladder Contractility

External Compression (Credé) and Valsalva Maneuver

The Credé maneuver (manual compression of the bladder) is most effective in patients with decreased bladder tone who can generate an intravesical pressure greater than 50 cm H_2O and have decreased bladder outlet resistance (Wein and Barrett, 1988). The technique of voiding by the openhanded Credé method involves placement of the thumbs of each hand over the area of the anterior superior iliac spines and the digits over the suprapubic area, with slight overlap at the fingertips. The slightly overlapped digits are pressed into the lower abdomen and when they are located behind the symphysis, are pressed downward to compress the fundus of the bladder. For some patients, this maneuver can be accomplished more efficiently by using a closed fist of one hand or using a rolled-up towel. Straining as the Credé maneuver is applied is generally counterproductive because this increases intra-abdominal pressure and causes bulging of the abdominal wall, which then tends to lift the compressing hands off the fundus of the bladder. If the guarding reflex arc is intact, this may also produce a striated sphincter contraction. The Credé maneuver is much easier in a patient with a lax, lean abdominal wall than in one with a taut or obese one, and it is more readily performed in a child than an adult.

A similar increase in intravesical pressure may be achieved by abdominal straining (Valsalva maneuver). The proper technique involves sitting and letting the abdomen protrude forward on the thighs. During straining in this position, hugging of the knees and legs may be advantageous to prevent any bulging of the abdomen. To increase intravesical pressure in this manner requires voluntary control of the abdominal wall and diaphragmatic muscles.

"Voiding" by the Credé or Valsalva maneuver is generally discouraged, because it is nonphysiologic and is resisted by the same forces that normally resist stress incontinence. Reflex sphincteric opening of the bladder outlet does not occur with external compression maneuvers of any kind, and, in many cases, an increase in outlet resistance may occur reflexively. If adequate emptying does not occur in the properly selected patient, other types of therapy to decrease outlet resistance may be considered; however, these treatments may adversely affect urinary continence.

The best chance of success with this mode of therapy (some would say it should never be used) is in the patient with an areflexic bladder and some degree of outlet denervation. This is most commonly seen in the patient with an autonomous neurogenic bladder (Lapides classification), T11 through L2 spinal cord injury where the sympathetic nervous supply is damaged, or after outlet resistance is decreased surgically or by botulinum toxin injection. Most of these patients already

have stress incontinence, and the Credé or Valsalva maneuver simply helps the patient overcome outlet resistance to empty the bladder at a convenient time. These techniques may also be useful to decompress a neobladder when the outlet resistance is low either by volitional sphincteric relaxation or when surgically induced.

Vesicoureteral reflux is a relative contraindication to external compression or the Valsalva maneuver, especially in patients capable of generating a high intravesical pressure. The most flagrant misuse of this form of management is in the patient with a neurogenic bladder and poor detrusor compliance, because the increased storage pressures can cause upper tract deterioration with minimal filling. External compression or Valsalva maneuvers will only further aggravate this already dangerous situation.

Even when the patient has a flaccid bladder and/or low detrusor leak point pressures, close follow-up and periodic evaluation are necessary to avoid upper tract deterioration. Chang and colleagues (2000) reported the long-term urologic complications and residual volumes of 74 SCI patients with flaccid bladders who routinely performed the Credé maneuver as their primary form of bladder management for more than 20 years. Residual urine volume was greater than 100 ml in 93% of patients, and 50% were greater than 300 ml. The authors also reported that 59.5% developed ureteral dilation, 35.1% developed hydronephrosis, and 16.2% suffered renal deterioration. Males were significantly more likely to develop these complications than females, probably due to increased outlet resistance. Other complications included recurrent UTIs, pyuria, urinary lithiasis, epididymo-orchitis, genital-rectal prolapse, and hemorrhoids (Chang et al, 2000; Wyndaele, 2008).

Promotion or Initiation of Reflex Contractions

In patients with SCI and an intact sacral spinal cord, voiding can be elicited by exploiting existing spinal reflexes. The sacral micturition reflex occurs when tension receptors within the bladder wall are stimulated by bladder filling and activate sensory afferent neurons. Motor efferents from the spinal cord respond by generating a reflexive bladder contraction and, when of adequate magnitude, will result in voiding. Bladder contractions obtained in this manner are often involuntary and sporadic. In some cases, patients with SCI may be able to trigger this reflex voluntarily by manual stimulation of areas within the sacral or lumbar dermatomes**. According to the classic reference by Glahn** (1974), **the most effective method of initiating a reflex contraction is rhythmic suprapubic manual pressure (seven or eight pushes every 3 seconds). Quick repetitive stimulation in this manner is thought to produce a summation effect on the tension receptors in the bladder wall, resulting in activation of the bladder reflex arc.** Ideally, the elicited contraction would be of sufficient magnitude and duration to empty the bladder. **Other commonly used maneuvers to induce reflex detrusor contractions include pulling the skin or hair of the pubis, scrotum, or thigh; squeezing the clitoris; or by digital rectal stimulation** (Wein and Barrett, 1988). Patients able to void in such a way are encouraged to find their own optimal trigger points and position for urination. If induced emptying can be carried out frequently enough to keep bladder volume and pressure below the threshold for activation of the involuntary micturition reflex, and below pressures that might cause upper tract deterioration, incontinence can be controlled, similar to timed voiding in normal individuals. Reflex voiding is dependent on the ability to stimulate detrusor contractions and may be most suitable for patients with SCI or conditions characterized by detrusor overactivity. To void reflexively, patients require manual dexterity and the ability to transfer to a commode, or at least the ability to use and maintain an external collecting device. For this reason, reflex voiding may not be suitable for many female patients. Surgical procedures to reduce outlet resistance should be considered if significant obstruction or sphincter dyssynergia are present. Complications with this voiding technique are most often related to the use of external collection devices or from the development of high-pressure storage resulting in upper tract deterioration. To ensure compliance, periodic surveillance should be performed with consideration of regular urodynamic evaluation.

Some clinicians believe that the micturition reflex can be "trained" by maintaining a copious fluid intake and periodically clamping and unclamping an indwelling catheter or by CIC at regular intervals. This cyclic pattern of filling and emptying may promote storage and emptying in a more physiologic manner, focuses attention on the urinary tract, and ensures an adequate fluid intake. It is true that balanced lower urinary tract function can be achieved using this program (Opitz, 1984; Menon and Tan, 1992), but whether this is a cause-and-effect relationship is unknown and difficult to prove.

One fascinating set of experiments that relates to the concept of establishing or promoting a reflex pathway for micturition is that reported by Xiao and de Groat (1999). They created a skin-to–central nervous system to bladder reflex pathway in cats by intradural microanastomosis of the left L7 ventral root to the S1 ventral root, leaving the L7 dorsal root intact to conduct cutaneous afferent signals. A detrusor contraction, without striated sphincter dyssynergia, could be initiated by scratching the skin or by percutaneous electrical stimulation in the L7 dermatome. The pathway was found to be mediated by cholinergic transmission at both ganglionic and peripheral levels. **The importance of this experimental model is that somatic motor axons were able to innervate parasympathetic bladder ganglion cells and therefore transfer somatic reflex activity to the lower urinary tract**. Xiao and colleagues (2003) reported on the first human clinical trial, in which 15 males with neurogenic overactivity and detrusor–external sphincter dyssynergia (DESD) secondary to complete suprasacral SCI underwent a ventral root microanastomosis between the L5 and the S2 and/or S3 ventral root. With a mean follow-up of 3 years, recovery in bladder storage and emptying function was reported in 10 (67%) patients. Average residual urine decreased from 332 cc to 31 cc with resolution of UTIs and overflow incontinence. Postoperative urodynamics demonstrated the resolution of detrusor overactivity and DESD to near-normal storage pressures, with synergic voiding and without DESD. Improvement in bowel function was also noted. Xiao and colleagues (2005) subsequently reported on 20 children with neurogenic bladder from spina bifida, among whom 17 of 20 (71.4%) demonstrated urodynamic improvements after surgery. Partial loss of L4 or L5 motor function, ranging from slight muscular weakness to visible foot drop, was reported in 5 of 20 patients. Xiao (2006) recently reviewed the initial human trials to date, and although encouraging results have been reported, experiences from other centers are needed to confirm these findings.

Reduction Cystoplasty

Myogenic decompensation of the bladder with excessive urinary capacity and chronic urinary retention may be idiopathic, of neurologic origin, the result of an infravesical obstruction, or exist as one of the components of the prune belly syndrome (Eagle-Barrett

syndrome). **The simplicity of partial cystectomy to reduce bladder capacity and, theoretically, restore contractility has often enticed surgeons to perform this procedure; however, if urodynamic evaluation after prolonged Foley catheter drainage shows no spontaneous detrusor contractions, this procedure is unlikely to be successful. If contractility is proven, surgical reduction is certainly an option in the appropriate patient.** Some of the techniques that have been used in the past include fundus invagination (Stewart, 1966), transection and removal of the upper "free" part of the bladder (Klarskov et al, 1988), a detrusor wrap (Hanna, 1982), or detrusor duplication (Zoedler, 1964). Kinn (1985) reported on 10 patients with various etiologies and was successful in reducing the bladder capacity, reducing residual urine volume, and reducing frequency of urinary infection, but found no improvement of detrusor contractility after reduction cystoplasty. Similar results were obtained by Klarskov and colleagues (1988), who reported on 11 patients, with only 3 being subjectively cured, one proceeding to supravesical diversion, and 5 using CIC. **Although patients with acontractile bladders generally do poorly, encouraging results have been attained in patients with hypocontractile detrusor function** (Kinn, 1985; Klarskov et al, 1988). Kinn (1985) recommended that a radical incision of the bladder neck also be performed in men undergoing these procedures to reduce outlet resistance. Bukowski and Perlmutter (1994) reported on the long-term outcome of reduction cystoplasty in 11 boys with prune belly syndrome. They found that short-term reductions in bladder volume may have initially contributed to the decreased incidence of urinary infections, but bladder capacity and residual volumes tended to increase over time. **Overall, reduction cystoplasty has not been definitively proven to yield long-term success in most patients, and its use remains debatable.** When compared to properly performed CIC alone, reduction cystoplasty is unlikely to add much to the patient's quality of life and should be used in only select patients.

Bladder Myoplasty

Patients with impaired or absent detrusor contractility have few dependable treatment options, except for continuous or clean intermittent catheterization. **Although neurostimulator implantation has achieved modest success in patients with idiopathic detrusor hypotonicity, it has not shown significant benefit in neurogenic conditions where the bladder is unable to generate a contraction.** To address this particularly difficult situation, several investigators have focused on attempting to restore bladder contractility through correction of the myogenic component of the disorder. Restoration of myogenic deficits by the transfer of an innervated, striated free muscle flap has been used successfully in reconstructive efforts involving other areas of the body, such as the heart (Blanc et al, 1993; Ninkovic et al, 2003). The augmentation of detrusor function with a skeletal muscle flap and cellular tissue engineering using injectable myoblasts represent the two current methodologies that have evolved.

In an animal feasibility study, Chancellor and associates (1994c) were among the first to report successful restoration of voluntary emptying of the bladder using a wrap of skeletal muscle. To augment the noncontractile detrusor, a segment of neurovascularly intact rectus muscle was wrapped around the bladder. Further experience was reported by Stenzl and colleagues (1998), when three patients managed with chronic catheterization for bladder acontractility were treated with a microneurovascular free transfer of autologous latissimus dorsi muscle. Short-term follow-up revealed peak flow rates of 18 to 26 mL/sec and residual urine volumes of 0 to 90 mL. In this procedure, the main neural and vascular supply to the latissimus dorsi was anastomosed to the lowermost motor branch of the intercostal nerve and to the inferior epigastric vessels supplying the rectus abdominis muscle. The transferred muscle was wrapped around the bladder with longitudinal tension and a slightly spiral configuration, ultimately covering about 75% of the mobilized bladder and leaving only the area of the trigone and the lateral pedicles uncovered. Patients were instructed to empty their bladders by actively contracting the lower abdominal musculature. Similarly, Stenzl and colleagues (2003) reported on 20 patients with bladder acontractility, with a mean follow-up of 44 months, and found that 14 of 20 (70%) were able to void spontaneously within 4 months, 4 more were able to void spontaneously after a bladder neck incision, while 2 had minimal improvement. Available urodynamic parameters revealed mean voided volumes of 447 mL (range, 250 to 728 mL), mean postvoid residual volumes of 38 mL (range, 0 to 100 mL), and mean maximum detrusor pressures of 72 cm H_2O (range, 5 to 218 cm H_2O). **Recently, equally impressive results were reported in a multicenter trial of latissimus dorsi detrusor myoplasty by Gakis and associates** (2009). **In 24 patients with a mean follow-up of 46 months, 16 of 24 (67%) regained spontaneous micturition without the need for CIC, while 3 were able to reduce the frequency of CIC.**

Key Points: Increasing Intravesical Pressure or Facilitating Detrusor Contractility

- Methods to improve bladder emptying consist of two main strategies: increasing intravesical pressure and/or decreasing outlet resistance.
- Management of poor detrusor contractility is limited and has few dependable treatment options other than continuous or clean intermittent catheterization.
- The Credé maneuver is most effective in patients with decreased bladder tone who can generate an intravesical pressure greater than 50 cm H_2O and have decreased bladder outlet resistance.
- Both the Credé and Valsalva maneuvers may elevate intravesical pressure sufficiently to cause upper tract deterioration, especially if performed in the setting of poor detrusor compliance.
- In SCI patients with an intact sacral spinal cord, reflex voiding can be initiated through activation of the sacral micturition reflex. Voiding can be elicited by pulling the skin or hair of the pubis, scrotum, or thigh; squeezing the clitoris; or by digital rectal stimulation.
- Reflex voiding is dependent on the ability to stimulate detrusor contractions and may be most suitable for patients with SCI or conditions characterized by neurogenic detrusor overactivity.
- Reduction cystoplasty has not been definitively proven to yield long-term success, and its use remains debatable.
- Bladder myoplasty including augmentation of detrusor function with a skeletal muscle flap or injectable myoblasts has been successfully performed in a few specialized centers but requires further study.

Both Von Heyden and colleagues (1998) and Van Savage and associates (2000) reported early studies with electrically stimulated detrusor myoplasty in dogs. Von Heyden and colleagues described anastomosing the thoracodorsal nerve to the obturator nerve and the vascular supply to the external iliac vessels. The graft was then stimulated by electrodes connected to the anastomosed neural supply and with direct muscle stimulation. Van Savage and associates described detrusor myoplasty with rectus muscle with the addition of stimulation being achieved with electrodes inserted into the muscle near the nerve entrance. Good results were reported initially with acute stimulation generating bladder pressures adequate for bladder emptying. Unfortunately, in a study of chronic contractile dysfunction, although detrusor compliance and flap viability were maintained, bladder emptying was not (Van Savage et al, 2002).

Yokoyama and coworkers (2000) reported on myoblast-mediated ex-vivo gene transfer to improve contractility. **The authors demonstrated successful long-term survival of the injected myoblasts in the bladder, with preliminary histochemical evidence that these skeletal myoblasts can differentiate to smooth muscle.** Further research in this area will be needed to determine whether tissue engineering using cellular myoplasty can improve impaired bladder contractility. For further discussion of the role of myoblast injection therapy for urologic disorders, including treatment of detrusor failure and stress urinary incontinence, see Chapter 19.

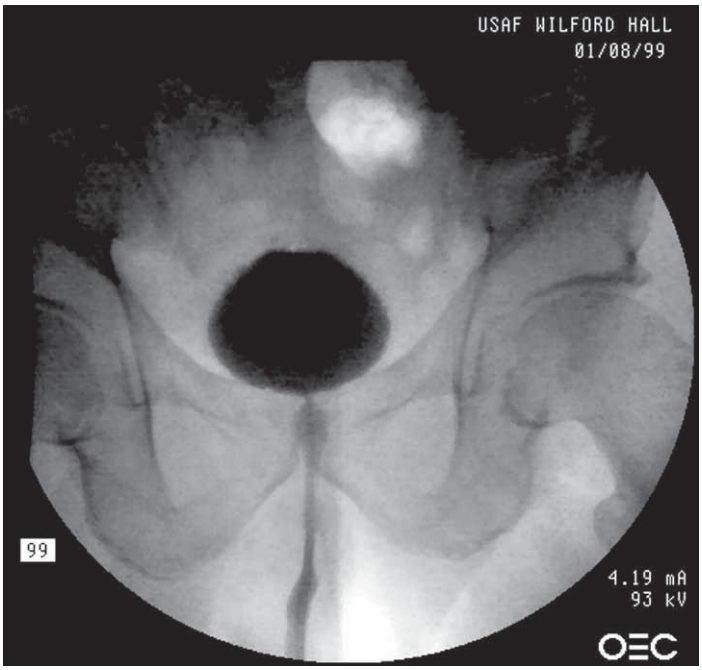

Figure 75–6. During urodynamics in a young male with severe lower urinary tract symptoms, a primary bladder neck obstruction was found. The bladder neck obstruction was accentuated by having the patient tighten his voluntary sphincter during voiding.

DECREASING OUTLET RESISTANCE AT A SITE OF ANATOMIC OBSTRUCTION

Transurethral Resection or Incision of the Bladder Neck

The first transurethral bladder neck resection for neurogenic lower urinary tract dysfunction was performed by Emmett in 1937 (Wein and Barrett, 1988). Originally, the procedure had two main indications: a hypocontractile (or atonic bladder) and anatomic (or functional) obstruction at the level of the bladder neck and/or proximal urethra that prevented emptying despite abdominal straining or a sustained detrusor contraction. It was also used in areflexic bladder patients with sacral spinal cord lesions who could not adequately empty by straining or Credé maneuver; however, this simply created progressively severe stress incontinence. In these instances, other alternatives for improving bladder emptying should be sought first (Wein et al, 1976).

The most common modern indication for transurethral resection (TURBN) or incision (TUIBN) of the bladder neck is a urodynamic-confirmed anatomic or functional obstruction at the bladder neck or proximal urethra. **Primary bladder neck obstruction (PBNO) is a videourodynamically diagnosed condition, characterized by high-pressure, low-flow voiding, with radiographic evidence of obstruction at the bladder neck, without striated sphincter contraction or distal obstruction** (Padmanabhan and Nitti, 2007) (Fig. 75–6). Alternatively, the diagnosis can be made by a micturitional urethral profile (McGuire et al, 1984). The true prevalence and etiology of PBNO is unknown. The highest reported incidence is in younger males with severe lower urinary tract symptoms (LUTS) and ranges from 33% to 54% in this population (Huckabay and Nitti, 2005). Much lower incidences have been reported for females (4.6% to 8.7%). For more on bladder neck dysfunction refer to Chapter 65.

Currently, the preferred technique is incision of the bladder neck at the 5-o'clock and/or 7-o'clock positions. A single full-thickness incision is extended from 1 cm distal to each ureteral orifice and continued through the bladder neck and prostatic fossa to just proximal to the verumontanum. The incision is deepened until no ridge is visible at the bladder neck, and fat is visualized through the capsular fibers (Huckabay and Nitti, 2005). Other techniques include a limited resection of the dorsal tissue from the 3-o'clock to the 9-o'clock position and a resection limited to the posterior lip. In women, incisions may be performed at the same anatomic location as in men and extended from just inside the vesical neck through the proximal third of the urethra (Blaivas et al, 2004). Overly aggressive technique should be avoided in females, because of the risk of stress incontinence.

In this predominately young male population, one of the most significant concerns with bladder neck incision or resection is the development of retrograde ejaculation. A reduction in the incidence of retrograde ejaculation has been reported with the performance of a unilateral TUIBN (Kaplan et al, 1994; Kochakarn et al, 2003). Earlier studies reported the incidence of diminished ejaculate volume ranging from 10% (Turner-Warwick, 1984) to as high as 50% (Norlen and Blaivas, 1986). More recently, a 27% incidence was reported with bilateral incisions (Trockman et al, 1996), while antegrade ejaculation was preserved in all patients who underwent a unilateral incision (Kaplan et al, 1994).

Significant improvements in symptom relief and maximum flow rate have been reported with these techniques (Huckabay and Nitti, 2005). Norlen and Blaivis (1986) reported subjective improvement in 18 men with PBNO, with an increase in Q_{max} from 9.1 mL/sec to 26.1 mL/sec. Kaplan and colleagues (1994) performed a unilateral incision in 31 men, 30 of 31 had subjective improvement and a mean increase in Q_{max} from 9.2 to 15.6 mL/sec. Peng

and Kuo (2005) reported their experience with TUIBN in 11 women with urodynamically confirmed bladder neck obstruction. After a mean follow-up of 10 months, significant urodynamic improvements were reported in Q_{max} (3.8 to 12.0 mL/sec), residual urine (355.5 to 84.5 mL), and voiding pressure (86.5 to 59.1 cm H_2O). A similar study of 11 women with PBNO was reported by Goldman and Zimmern (2006). Ten had improvement or resolution of symptoms, and one developed mild SUI postoperatively.

YV-Plasty of the Bladder Neck

The objective of the YV-plasty is to reduce bladder outlet resistance by revision of the anterior bladder neck; however, this technique is now rarely performed. Bladder neck resection or incision performed endoscopically is now the preferred procedure and is capable of achieving the same objectives as the YV-plasty but with less morbidity. It would only seem appropriate to consider this method when a concurrent open procedure is already required for a concomitant urologic disorder. Significant incontinence may result following this procedure and, at times, was the intended consequence, especially when it was performed radically or in the setting of a refractory, poorly emptying bladder. Due to the infrequency and short-lived use of this procedure, the efficacy of YV-plasty and incidence of postoperative complications have not been reported.

DECREASING OUTLET RESISTANCE AT THE LEVEL OF THE STRIATED SPHINCTER

Detrusor sphincter dyssynergia (DSD) is the most common cause of neurogenic sphincteric obstruction and is most often managed by intermittent catheterization. Avoidance of high intravesical pressure through appropriate bladder drainage protects the upper tracts, decreases provocation of autonomic dysreflexia, and lessens the risk for other complications such as UTI and stones. **If improperly treated, complications from DSD will occur in greater than 50% of men** (Chancellor and Rivas, 1995; Ku, 2006). For patients who are unwilling or unable to self-catheterize, the most effective treatment option is controversial. Historically, external sphincterotomy served as the primary surgical intervention for DSD, resulting in significant short-term improvement in bladder emptying in 70% to 90% of cases (Wein et al, 1976). Failure rates as high as 40% to 50%, however, have left the long-term efficacy of sphincterotomy in question (Santiago, 1993; Vapnek et al, 1994; Yang and Mayo, 1995). With favorable results being reported for less invasive alternatives such as laser sphincterotomy and urethral stenting, the role of traditional sphincterotomy continues to be debated. Sphincteric injection of botulinum toxin has also gained interest as an alternative to sphincterotomy. Other pharmacologic alternatives, including the use of Botox are discussed in Chapter 68.

Surgical Sphincterotomy

Therapeutic destruction of the external urethral sphincter was initially performed in 1936, but the first large clinical series was not reported until 1958 by Ross and colleagues (Wein and Barrett, 1988). **Several techniques have been described; however, the 12-o'clock sphincterotomy, as originally proposed by Madersbacher and Scott** (1975), **remains the procedure of choice for a number of reasons.** The anatomy of the striated sphincter is such that its main bulk is anteromedial. With the blood supply primarily lateral, a 12-o'clock incision is least likely to cause hemorrhage, with reported rates of 5% to 20%. The rate of postoperative erectile dysfunction with this incision is approximately 5% compared with a 5% to 30% incidence with a 3-o'clock and 9-o'clock technique. Significant urinary extravasation has also been reported. Sphincterotomy can be performed using a knife electrode, resection with a loop electrode, or laser ablation. The incision must extend from the level of the verumontanum at least to the bulbomembranous junction. Gradual deepening of the incision allows good visual control and minimizes the chance of significant hemorrhage and extravasation. An external collecting device is usually necessary postoperatively, precluding usage in females. Vapnek and associates (1994) reported that conversion to suprapubic bladder drainage was most commonly attributed to difficulty with the collection device. Continuous sphincteric incontinence or severe stress incontinence is uncommon, unless the urethra or bladder neck has been compromised by prior surgery or preexisting pathology. Noll and colleagues (1995) reported that laser sphincterotomy seems to have an advantage over conventional diathermy procedures, after finding that only 15.1% of laser-treated patients required resphincterotomy compared with 30% of those treated with a conventional procedure. Further advantages of laser sphincterotomy were reported by Perkash (1996) with the finding of less bleeding following procedures performed in this manner.

When early failure occurs, it is generally attributable to an inadequate surgical procedure (either not deep enough or not extensive enough), inadequate detrusor function, and bladder neck or prostatic obstruction. Late failure may occur because of fibrosis somewhere along the extent of the sphincterotomy, a change in detrusor function, the development of prostatic obstruction, or a change in neurologic status such that smooth sphincter dyssynergia develops (Lockhart and Pow-Sang, 1989). **Yang and Mayo** (1995) **defined failure as (1) the presence of large postvoid residual urine volumes associated with urinary tract infections, (2) autonomic hyperreflexia symptomatology associated with bladder overdistention or high voiding pressures, and/or (3) progressive upper tract deterioration from persistent reflux or poor bladder emptying.**

Failure rates following sphincterotomy have been reported to be as high as 40% to 50% in some series (Santiago, 1993; Vapnek et al, 1994; Yang and Mayo, 1995). In addition, the incidence of failure increases with time from the initial procedure (Vapnek et al, 1994; Yang and Mayo, 1995). In a more recently reported series, Pan and colleagues (2009) reported only a 32% primary success rate following external sphincterotomy, with eventual failure occurring in 57 of 84 (68%) patients at a mean of 42.7 months from the initial procedure. Of the 57 patients that failed, 30 underwent a repeat sphincterotomy with a mean response of 56 additional months. Kim and colleagues (1998) reported a significantly higher incidence of upper tract damage and persistent sphincter dyssynergia with detrusor leak point pressures of greater than 40 cm H_2O. Juma and associates (1995) considered detrusor leak point pressure as the most reliable urodynamic parameter to predict the risk of upper tract complications after sphincterotomy. The authors reported a 30% incidence of significant upper tract complications (half of which developed more than 2 years after sphincterotomy), in their series of 63 patients with a mean follow-up of 11 years. Lower urinary tract complications (recurrent infection, calculi, urethral diverticula, stricture,

bladder neck stenosis, and recurrent epididymitis) occurred in 48% of patients.

Urethral Stenting

The use of a urethral stent to bypass the striated sphincter was suggested by Shah and associates (1990). Chancellor and Rivas (1995) reported the initial multicenter North American data using the UroLume stent (American Medical Systems, Minnetonka, MN) in 153 patients at 15 centers. A significant decrease in detrusor leak pressure and residual urine volume was seen; however, 18% of patients required more than one procedure to adequately open the sphincter, hyperplasia within the lumen was seen in 42 patients (33.3%) at 3 months, and 10 devices were removed (7 for migration) and 7 were replaced. Bladder neck obstruction requiring treatment was seen in 13 patients (4 with α blockers, 7 with incision, 2 with CIC), and when removal was required (in 4) this was not a problem up to 12 months. Rivas and coworkers (1994) concluded that a stent prosthesis is as effective, easier, less morbid, and less expensive than a sphincterotomy.

Chancellor and colleagues (1999b) reported the long-term follow-up of the UroLume stent in for striated sphincter dyssynergia in a group of 160 men with SCI at 15 centers in North America. **Mean voiding pressure decreased from 75.1 cm H_2O to 37.4 cm H_2O at year 1 and was maintained for up to 5 years. Residual urine volume also decreased and was maintained for 5 years; however, the residual urine volume was not less than 105 mL in any group, and mean cystometric bladder capacity did not change. Symptoms of autonomic hyperreflexia after stent placement were reduced in 53 of 89 patients at 1 year and 37 of 72 at 2 years.** De novo detrusor overactivity developed in only 1 of 36 patients in the 1-year follow-up group and only 3 of 30 in the 2-year group. **One obvious advantage using a sphincteric stent is that it is potentially reversible.** Fifteen percent of patients (24 patients) required stent removal; another stent was implanted in 4 of these. Stent migration occurred in 12.4% of patients at 3 months after implantation and in 5% at 6 months, with correspondingly decreased percentages up to 4 and 5 years. Forty-seven patients (26.3%) were diagnosed with bladder neck obstruction after stent placement, and were managed by bladder neck incision in 20, α blockade in 10, CIC in 8, and watchful waiting in 9. The authors commented that in those patients who required stent removal, the procedure could be accomplished despite epithelialization but that a learning curve certainly exists before one becomes comfortable removing the stent.

Chancellor and colleagues reported a prospective, randomized, multicenter trial of sphincteric stent placement versus external sphincterotomy (Chancellor et al, 1999a). Fifty-seven men were randomized; the primary outcome indicator was maximum detrusor pressure. At 12 months, there was no significant difference; however, at 24 months, maximum detrusor pressure had decreased from 90.6 cm H_2O to 41.6 cm H_2O in the sphincterotomy group and from 101.9 cm H_2O to 71.6 cm H_2O in the stent group. Whether this is meaningful is uncertain. At 24 months, residual urine volume had decreased from 218 to 112 mL in the sphincterotomy group and from 164 to 132 mL in the stent group. Cystometric capacities did not appear to change up to 24 months. Bladder neck obstruction requiring treatment developed in 6 patients in each group. Six of the 31 stent patients required stent removal, all without difficulty.

The use of temporary urethral stents in 147 men with DSD was reported by Gamé and colleagues (2008). Patient satisfaction and treatment efficacy was assessed every 3 months postoperatively until a mean of 10 months after insertion. After the initial period of temporary stenting, patients who were subjectively satisfied with this treatment modality, who also had a significant decrease in urinary complications and in postvoid residual, went on to permanent urethral stenting, 70.7% in this case. Seven (4.7%) recovered enough neurologically to perform CIC upon removal of the temporary stent. The authors state that the use of temporary urethral stents allows identification of patients who are unlikely to benefit from permanent stent insertion.

The ideal patient and therapeutic role for urethral stenting remains controversial (Boone, 2009; Perkash, 2009). **The reversibility of this procedure is attractive to some; however, stent removal, when necessary, may be difficult. Complications include obstruction by urothelial ingrowth, stent encrustation, stricture, stent migration, and UTI.** Similar to sphincterotomy, a collection device is required with urethral stenting, precluding use in females.

An intraurethral sphincter prosthesis with a self-contained urinary pump has been developed for use in women with a hypocontractile or acontractile bladder ("inflow" intraurethral insert). Schurch and associates (1999) reported on the use of this device in 18 women with neurogenic voiding dysfunction and a hypocontractile bladder. Sixteen months after placement, only 6 of the women were still using the implant and were satisfied. In 10 patients, severe incontinence around the catheter or irritation necessitated removal. In 2 patients, the device was removed because the patients could not transfer to the toilet to empty their bladder. Fourteen of the devices had to be replaced early because of device dysfunction, and three external remote control units malfunctioned. At that time, the authors considered the device unsuitable for long-term use.

Madjar and colleagues (2000) reported on 92 women, having the device, who were followed for periods of longer than 1 year. Early removal of the device (<14 days) was required in 56.5% of patients, mostly because of local discomfort and urinary leakage. In an additional 20.6% of patients, the device was removed between 2 and 16 months after placement. Only 21 patients (22.8% of the original group) with the device still in place after more than 1 year (mean, 24.6 months) were being followed. In these patients, six device removals in 4 patients were required because of migration into the bladder, asymptomatic bacteriuria developed in 15 patients, and symptomatic urinary tract infections developed in 4 patients. The authors' conclusion that further studies are necessary to compare this treatment with CIC and other modalities seems justified.

Pharmacologic Sphincterotomy

Botulinum toxin is a protein neurotoxin produced by the bacterium *Clostridium botulinum*. Urologic use of botulinum toxin for the treatment of detrusor striated sphincter dyssynergia was first reported by Dykstra and colleagues (Dykstra and Sidi, 1990; Dykstra et al, 1998). Further experiences followed, with several reports of botulinum toxin usage in diverse groups with voiding dysfunction (Schurch et al 1996; Gallien et al, 1998; Petit et al, 1998). Fowler and coworkers (1992) injected botulinum toxin into six women with difficult voiding/urinary retention secondary to what is now called the Fowler syndrome (manifested by abnormal myotonus-like electromyographic activity in the striated urethral sphincter). Kuo (2003) reported periurethral injections of botulinum A toxin in 103 patients with lower urinary tract dysfunction

due to a number of different causes, including detrusor sphincter dyssynergia, dysfunctional voiding, nonrelaxing urethral sphincter, cauda equina lesion, peripheral neuropathy, and idiopathic detrusor underactivity. As the role of botulinum toxin in the treatment of sphincteric obstruction continues to evolve, its use remains uncommon and unclear. A more detailed discussion of the role of botulinum toxin in urologic practice is covered in Chapter 68.

Theoretically, any agent that promotes striated sphincter relaxation in a uroselective manner could be used to decrease outlet resistance and facilitate voiding dysfunction. Yoshiyama and associates (2000) reported improved voiding in rats with SCI by using intravenously administered α-bungarotoxin. This compound is a toxin, extracted from the venom of a Formosan snake, that selectively blocks nicotinic receptors without influencing transmission in autonomic ganglia. The nicotinic receptors in the striated sphincter have been shown to be a potential target for drug therapy for striated sphincter dyssynergia.

Urethral Overdilatation

Urethral overdilatation to 40 to 50 Fr in females can achieve the same objective as external sphincterotomy in males (see Wein and Barrett, 1988) but is rarely performed because of the lack of a suitable external collecting device. In young boys, a similar stretching of the posterior urethra can be performed using a perineal urethrostomy, obviating or postponing the need for a surgical sphincterotomy. Wang and associates (1989) reported the results of urethral dilatation, using sounds or balloon procedures, to 22 to 28 Fr in 11 myelodysplastic children with high intravesical pressures refractory to traditional forms of treatment. **After dilatation, the intravesical pressures decreased, and upper tract function and bladder compliance improved. There was no discernible effect on continence. These observations demonstrated that urethral dilation can decrease outlet resistance and improve compliance without deterioration in urinary control beyond preoperative conditions.**

Balloon dilatation of the external urethral sphincter was reported by Werbrouck and associates (1990). Using balloon dilatation to 90 Fr at 3 atm, Chancellor and colleagues (1994b) compared balloon dilatation (20 patients), sphincterotomy (15 patients), and stent placement (26 patients) in the treatment of striated sphincter dyssynergia. A significant decrease in detrusor leak point pressure and residual urine occurred in all three groups. Bladder capacity remained constant, renal function stabilized or improved, and autonomic hyperreflexia improved. Balloon dilatation and stent placement were associated with a significantly shorter surgery and hospitalization times and less blood loss. In the dilatation group, 3 patients developed recurrent obstruction (at 3, 8, and 12 months), 1 required transfusion, and 1 developed a 1-cm bulbar stricture. In the surgical sphincterotomy group, 2 patients required transfusion, 2 developed a stricture with obstruction, and 1 developed erectile dysfunction. In the stent group, 3 patients had migration requiring adjustment (1 had the stent replaced, 2 had a second overlapping stent), and 2 developed bladder neck obstruction requiring transurethral incision. McFarlane and colleagues (1997) reported on the use of balloon dilatation of the striated sphincter as an alternative to sphincterotomy in 14 patients followed for a mean of 55.5 months (8 to 68 months). Sphincter activity was initially abolished in all patients, and reflux, which was present in 1 patient, resolved. Long term, however, 62% failed within 1 year, and overall 85% failed. The authors concluded that this is an ineffective long-term treatment for striated sphincter dyssynergia in the majority of patients, thus recommending either surgical sphincterotomy or stenting as the surgical treatments of choice for this condition.

Pudendal Nerve Interruption

Relief of obstruction at the level of the striated sphincter can also be achieved by pudendal neurectomy, first described in 1899 by Rocket (see Wein and Barrett, 1988). This method is seldom used today due to potential undesirable effects, even after a unilateral nerve section. Bilateral nerve section results in an extremely high rate of impotence and may result in significant fecal and stress urinary incontinence. If this procedure is contemplated, the results

Key Points: Decreasing Outlet Resistance

- The most common indication for transurethral resection or incision of the bladder neck is a urodynamically confirmed anatomic or functional obstruction at the bladder neck or proximal urethra.
- Primary bladder neck obstruction (PBNO) is diagnosed videourodynamically and characterized by high-pressure, low-flow voiding, with radiographic evidence of obstruction at the bladder neck, without striated sphincter contraction or distal obstruction. Alternatively, PBNO may be diagnosed by micturitional urethral profiles.
- One of the most significant concerns with bladder neck incision or resection is the development of retrograde ejaculation, especially given the predominately younger-aged patient affected with this disorder.
- Given the less morbid and often successful use of endoscopic procedures, open YV-plasty of the bladder neck is only rarely performed and would only seem appropriate to consider when a concurrent open urologic procedure is already required.
- If improperly treated, complications from DSD will occur in greater than 50% of men.
- Early failure after sphincterotomy is often due to inadequate surgical technique, inadequate detrusor function, or obstruction at the level of the bladder neck or prostate.
- Late failure after sphincterotomy typically occurs when fibrosis develops at site of sphincterotomy, prostatic obstruction develops, or following changes in detrusor function or neurologic status.
- Urethral stenting offers a less invasive alternative to traditional sphincterotomy with the added advantage of being a reversible procedure. The ideal patient for this procedure continues to be debated. Complications of urethral stenting include stent migration, recurrent obstruction, stent encrustation, stricture, and UTI.
- Although successfully used, the role of botulinum toxin in the treatment of sphincteric obstruction still remains to be defined.
- Urethral overdilatation through the use of urethral sounds or balloon procedures may improve compliance and decrease outlet resistance; however, long-term success is unlikely.
- Pudendal nerve interruption is seldom performed today due to potential complications, including impotence and significant fecal and stress urinary incontinence.

of a block should precede the formal procedure, which should be performed only unilaterally. More recently, Changfeng and colleagues (2004) reported on the use of high-frequency electrical stimulation to provide a reversible pudendal nerve block in cats. The authors stated that the goal of this approach is to relax the external urethral sphincter only at the time of voiding, allowing normal function between voids to maintain continence. No human studies have been reported at this time.

SUMMARY

The possible etiologies of voiding and storage dysfunction are numerous and varied. Some conditions will require a complex treatment strategy including a combination of medications and diverse surgical procedures. It is important that we continue to advance our understanding of the complex pathophysiology of storage and voiding dysfunction to improve the quality of life of the patients under our care.

The Impact of Age on Incontinence
Causes of Transient Incontinence
Established Incontinence
Diagnostic Approach
Therapy
Summary

Urinary incontinence is a major problem for the elderly (Chang et al, 2008). **It afflicts 15% to 30% of older people living at home, one third of those in acute-care settings, and half of those in nursing homes** (Fantl et al, 1996; McGrother, 1998). It predisposes to perineal rashes, pressure ulcers, urinary tract infections, urosepsis, falls, and fractures (Fantl et al, 1996; Tromp et al, 1998; Brown et al, 2000; Parsons et al, 2009). It is associated with embarrassment, stigmatization, isolation, depression, anxiety, sexual dysfunction, and risk of institutionalization (Fantl et al, 1996; Farage et al, 2008; Angner et al, 2009). Also, it cost more than $26 billion to manage incontinence in America's elderly in 1995, the last time primary data was collected (Wagner and Hu, 1998). This amount exceeded the amount devoted to dialysis and coronary bypass surgery combined. Despite these considerations, geriatric incontinence remains neglected by patients and physicians alike.

Providers and older patients alike often neglect incontinence or dismiss it as a normal part of growing old (Branch et al, 1994; Mann et al, 2000; Chang et al, 2008; Lawhorne et al, 2008), but **it is abnormal at any age** (Resnick, 1988; Herzog and Fultz, 1990; Fantl et al, 1996). Although its prevalence increases, at no age does incontinence affect the majority of individuals**,** even over age 85 (Wetle et al, 1995). Moreover, its increased prevalence relates more to age-associated diseases and functional impairments than to age itself (Resnick et al, 1988; Herzog and Fultz, 1990; Resnick et al, 1995; Wetle et al, 1995). Regardless, **incontinence is usually treatable and often curable at all ages, even in frail elderly** (Ouslander and Schnelle, 1995; Resnick, 1995; Wagg and Malone-Lee, 1998; Weinberger et al, 1999)**, but the approach must differ significantly from that used in younger patients**.

THE IMPACT OF AGE ON INCONTINENCE

At any age, continence depends on not only the integrity of lower urinary tract function but also the presence of adequate mentation, mobility, motivation, and manual dexterity. Although incontinence in younger patients is rarely associated with deficits outside the urinary tract, such deficits occur commonly in older patients. It is crucial to detect them, both because they exacerbate and, occasionally, even cause incontinence in the elderly, and because design of an efficacious intervention requires that they be addressed.

In addition, **the lower urinary tract changes with age,** even in the absence of disease. Data from continent elderly are sparse and longitudinal data virtually nonexistent. However, it appears that although **bladder capacity does not change with age** (Pfisterer et al, 2006b), **bladder sensation, contractility, and the ability to postpone voiding decline in both sexes, while urethral length and maximum closure pressure, as well as striated muscle cells in the rhabdosphincter and urogenital diaphragm, probably decline with age in women** (Diokno et al, 1988; Resnick, 1988; Resnick et al, 1995; Strasser et al, 1999; Perucchini et al, 2002; Pfisterer et al, 2006a, 2006b; Trowbridge et al, 2007; Betschart et al, 2008). The prostate enlarges in most men, and appears to cause urodynamic obstruction in half (Resnick et al, 1995). **In both sexes, the prevalence of involuntary detrusor contractions increases, whereas the postvoid residual (PVR) volume probably increases but to no more than 50 to 100 mL** (Diokno et al, 1988; Resnick, 1988; Resnick et al, 1995; Bonde et al, 1996). In addition, **the elderly often excrete most of their fluid intake at night,** even in the absence of venous insufficiency, renal disease, heart failure, or prostatism (Miller, 2000; Morgan et al, 2000). **This fact, coupled with an age-associated increase in sleep disorders, leads to one to two episodes of nocturia in the majority of healthy elderly** (Miller, 2000; Morgan et al, 2000). Finally, **at the cellular level, detrusor smooth muscle develops a "dense band pattern" characterized by dense sarcolemmal bands with depleted caveolae** (Elbadawi et al, 1993a, 1993b, 1997a). This depletion may mediate the age-related decline in bladder contractility. **In addition, an "incomplete dysjunction pattern" develops,** characterized by scattered protrusion junctions, albeit not in chains; these changes may underlie the high prevalence of involuntary detrusor contractions (vide infra) (Resnick et al, 1995; Hailemariam et al, 1997; Elbadawi et al, 1997a).

None of these age-related changes causes incontinence, but they do predispose to it. This predisposition, coupled with the increased likelihood that an older person will encounter an

additional pathologic, physiologic, or pharmacologic insult, explains why the elderly are so likely to become incontinent. The implications are equally important. **The onset or exacerbation of incontinence in an older person is probably due to precipitant(s) *outside* the lower urinary tract that are amenable to medical intervention. Furthermore, *treatment of the precipitant(s) alone may be sufficient to restore continence, even if there is coexistent urinary tract dysfunction***. For instance, flare of hip arthritis in a woman with age-related detrusor overactivity may be sufficient to convert her urinary urgency into incontinence. Treatment of the arthritis, rather than the involuntary detrusor contractions, will not only restore continence but also lessen pain and improve mobility. These principles, depicted in Figures 76–1 and 76–2 (Resnick, 1996; Resnick and Marcantonio, 1997), provide the rationale in the older patient for adding a set of transient causes to the established lower urinary tract causes of incontinence. Because of their frequency, ready reversibility, and association with morbidity beyond incontinence, the transient causes are discussed first.

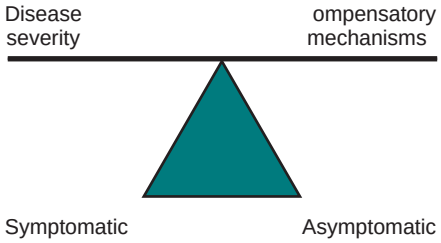

Figure 76–1. Incontinence results when the ability to compensate for bladder dysfunction is inadequate. For instance, in the intact older person, detrusor overactivity or sphincter weakness may not cause leakage if the patient is more attuned to bladder fullness, drinks less, voids more often, eliminates precipitants such as coughing, and stays close to a toilet. This explains how older patients may remain continent despite such abnormalities, and also suggests alternative therapeutic approaches independent of the urinary tract. (From Resnick NM. An 89-year-old woman with urinary incontinence. JAMA 1996;276:1832–40.)

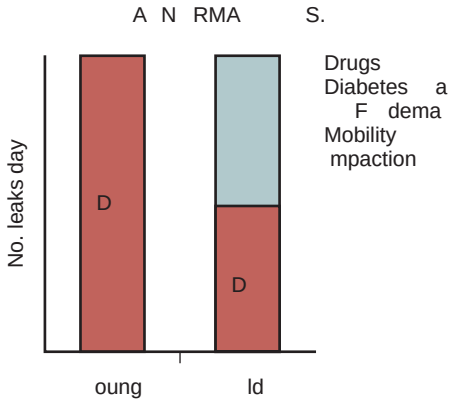

Figure 76–2. This graph shows why treatment of urinary incontinence (UI) in older adults has to differ and is often easier than in younger adults. Both of these patients with detrusor overactivity (DO) have the same frequency of leakage. However, in the younger patient with intact compensatory mechanisms, such leakage reflects solely the contribution of the DO. In the older adult, other comorbid conditions make it more difficult to appreciate bladder fullness, adjust fluid output, and reach the bathroom. Such conditions magnify the impact of DO and will be unaffected by bladder relaxant therapy. But addressing them will result in a marked improvement in the UI even without treatment of the DO and will make DO therapy, if still required, more effective. LUT, lower urinary tract. (From Resnick NM, Marcantonio ER. How should clinical care of the aged differ? Lancet 1997;350:1157–58.)

CAUSES OF TRANSIENT INCONTINENCE

Incontinence is transient in up to one third of community-dwelling elderly and in up to half of acutely hospitalized patients (Resnick, 1988; Herzog and Fultz, 1990). Although most of the transient causes lie outside the lower urinary tract, **three points warrant emphasis. First, the risk of transient incontinence is increased if, in addition to physiologic changes of the lower urinary tract, the older person also suffers from pathologic changes.** Anticholinergic agents are more likely to cause overflow incontinence in persons with a weak or obstructed bladder, while excess urine output is more likely to cause urge incontinence in persons with detrusor overactivity and/or impaired mobility (Fantl et al, 1990; Diokno et al, 1991). **Second, although termed "transient," these causes of incontinence may persist if left untreated and cannot be dismissed merely because incontinence is longstanding.** Third, similar to the situation for established causes (vide infra), identification of "the most common cause" is of little value. The likelihood of each cause depends on the individual, the clinical setting (community, acute hospital, nursing home), and referral pattern. Moreover, **geriatric incontinence is rarely due to just one of these causes.** Trying to disentangle which of the multiple abnormalities is "the" cause is more useful for metaphysics than for clinical practice.

The causes of transient incontinence can be recalled easily using the mnemonic "DIAPERS" (Table 76–1). In the setting of ***delirium*** (an acute and fluctuating confusional state due to virtually any drug or acute illness), incontinence is merely an associated symptom that abates once the underlying cause of confusion is identified and treated. The patient needs medical rather than bladder management (Resnick, 1988).

Symptomatic urinary tract ***infection*** causes transient incontinence when dysuria and urgency are so prominent that the older person is unable to reach the toilet before voiding. **Asymptomatic bacteriuria**, which is much more common in the elderly, **does not cause incontinence** (Brocklehurst et al, 1968; Resnick, 1988; Baldassare and Kaye, 1991; Ouslander et al, 1995). Because illness can present atypically in older patients, however, incontinence is occasionally the only atypical symptom of a urinary tract infection (UTI). Thus, if otherwise asymptomatic bacteriuria is found on initial evaluation, it should be treated and the result recorded in the patient's record to prevent future futile therapy.

Atrophic urethritis/vaginitis frequently causes lower urinary tract symptoms, including incontinence. Up to 80% of elderly women attending an incontinence clinic have atrophic vaginitis, characterized by vaginal mucosal atrophy, friability, erosions, and punctate hemorrhages (Robinson and Brocklehurst, 1984). Incontinence associated with this entity usually is associated with urgency and, occasionally, a sense of "scalding" dysuria that mimics a urinary tract infection, but both symptoms may be unimpressive. In demented individuals, atrophic vaginitis may present as agitation. Atrophic vaginitis also can exacerbate stress incontinence.

The importance of recognizing atrophic vaginitis is that it may respond to low-dose estrogen (Fantl et al, 1996;

Table 76–1.

Causes of Transient Incontinence

CAUSE	NOTES
Delirium/confusional state	Results from almost any underlying illness or medication; incontinence is secondary and abates once the cause of confusion has been corrected
Infection—Urinary (only *symptomatic*)	Causes incontinence, but the more common asymptomatic bacteriuria does not
Atrophic urethritis/vaginitis	Characterized by vaginal erosions, telangiectasia, petechiae, and friability; may cause or contribute to incontinence. Now controversial but may be worth a 3- to 6-month trial of estrogen, especially topical application (if not contraindicated by breast or uterine cancer)
Pharmaceuticals	Includes many prescribed and nonprescribed agents, because incontinence can be caused by diverse mechanisms (see Table 76–2)
Excess urine output	Results from large fluid intake, diuretic agents (including theophylline, caffeinated beverages, and alcohol), and metabolic disorders (e.g., hyperglycemia or hypercalcemia); nocturnal incontinence also may result from mobilization of peripheral edema (e.g., congestive heart failure [CHF], venous insufficiency, drug side effect)
Restricted mobility	Often results from overlooked, correctable conditions such as arthritis, pain, foot problem, postprandial hypotension, or fear of falling
Stool impaction	May cause both fecal and urinary incontinence that remit with disimpaction

Adapted from Resnick NM. Urinary incontinence in the elderly. Med Grand Rounds 1984;3:281–90.

Cardozo et al, 2004). Moreover, as for other causes of transient incontinence, treatment has additional benefits; in the case of atrophic urethritis, treatment ameliorates dyspareunia and reduces the frequency of recurrent cystitis (Resnick, 1988; Raz and Stamm, 1993; Cardozo et al, 1998; Eriksen, 1999).

Reports from two large-scale randomized prospective trials, however, have recently challenged long-standing assumptions about the benefits and risks of hormone therapy. The **Women's Health Initiative (WHI)** randomized more than 27,000 women, aged 50 to 79 years, to oral conjugated equine estrogen (CEE) 0.625 mg, with or without medroxyprogesterone (MPA) 2.5 mg (Hendrix et al, 2005). The **Heart and Estrogen/Progestin Replacement Study (HERS)** randomized nearly 2800 postmenopausal women of the same age to the same regimen (Grady et al, 2001). **Both studies found that hormone therapy was associated with worsening of pre-existing incontinence. WHI investigators also found that hormone therapy,** whether prescribed as CEE alone or with MPA, **was associated with increased incidence of new incontinence.** Because both studies also found that hormone therapy did not protect against heart disease, they advised against using hormone therapy for urinary incontinence.

In trying to apply the results of the WHI and HERS trials, several caveats should be noted. Postmenopausal hormone levels differ substantially, and in some individuals they are similar to levels seen in the follicular phase of premenopausal women (Kuchel et al, 2001). Tissue sensitivity also varies. Thus it is surprising that neither WHI nor HERS randomized or stratified results by the presence or absence of atrophic vaginitis, nor did investigators examine patients to determine whether the dose administered was sufficient to treat the condition if it was present. Dropout rates in WHI were also high: 42% in the combined hormone therapy group and 54% in the estrogen-alone group. In addition, incontinence data were based on self-report, which can be problematic in older adults, both for reproducibility and for determining the type of incontinence (Resnick et al, 1994; Kirschner-Hermanns et al, 1998). Urodynamic testing was not performed. Moreover, although drugs used to treat heart disease in such patients can cause or exacerbate incontinence (e.g., diuretics, α blockers, calcium channel blockers, and angiotensin-converting enzyme inhibitors (ACEI), their impact was not reported. Finally, other hormone doses, types, and routes of administration were not evaluated. For example, a recent randomized placebo-controlled study with ultralow-dose transdermal estrogen (0.014 mg) revealed no substantial effect on either the frequency of incontinence or the risk of developing at least weekly incontinence (Waetjen et al, 2005).

There is less evidence available from recent studies of nursing home patients, but limitations of sample size; selection bias; route, dose adequacy, and type of hormone used; and characterization and stratification by type of urinary infection (UI) all similarly preclude meaningful conclusions (DuBeau, 2001; Ouslander et al, 2001a).

The apparent lack of efficacy for conjugated equine estrogen demonstrated in these two studies, as well as the risks associated with long-term use of higher doses, must be balanced against the other benefits cited above—the lower doses and shorter duration of treatment advised for treatment of atrophic vaginitis, and the shorter life expectancy of many older women in whom the prevalence and severity of atrophic vaginitis are highest. Moreover, data from other randomized double-blind trials, which employed different estrogen preparations (estriol, estradiol, or quinestradol), demonstrated significant reduction in incontinence among nursing home residents (Judge, 1969) and postmenopausal women with sensory urge incontinence (Walter et al, 1978; Moehrer et al, 2003). Thus clinical judgment is warranted, and local administration of other types of estrogen may be best. Unfortunately, the use of vaginal estrogen has not yet been well-studied.

With adequate treatment, symptoms of atrophic vaginitis remit in a few days to several weeks, but the intracellular response takes longer (Semmens et al, 1985). The duration of therapy has not been well established (Pandit and Ouslander, 1997). One approach is to insert a ring containing estradiol. The advantage is that it is small and delivers the dose locally. Because it does not increase systemic estrogen concentrations, it is often considered for women with a past history of breast cancer. The disadvantage is that, despite its small size, it is not always feasible or well tolerated by frail older women, especially those with pronounced vaginal stenosis. Another option is to administer a low dose of estradiol orally or vaginally for 1 to 2 months and then taper it. Most patients probably can be weaned to a dose given as infrequently as 2 to 4 times per month. After 6 months, estrogen can be discontinued entirely in some patients, but recrudescence is common. Because the dose is low and given briefly, the carcinogenic effect is likely slight, if any. However, if long-term treatment is selected,

a progestin probably should be added if the patient has a uterus. **Hormone treatment (except for administration by a vaginal ring) is contraindicated for women with a history of breast cancer. For those without such a history, mammography should be performed prior to initiating hormone therapy.** There appears to be a slightly increased risk of breast cancer among women using oral estrogen daily for more than 5 years, but fortunately, such high-dose, frequent, and long-term therapy is rarely required.

Pharmaceuticals are one of the most common causes of geriatric incontinence, precipitating leakage by a variety of mechanisms (Table 76–2 and Tsakiris et al, 2008). Experts often cite dosages and serum levels below which side effects are uncommon. Unfortunately, such rules are of limited use in the elderly, because they are generally derived from studies of healthy younger persons who have no other diseases and take no other medications. Of note, many of these agents also are used in the treatment of incontinence, underscoring the fact that most medications are "double-edged swords" for the elderly.

Long-acting sedative/hypnotics, whose half-life can exceed 100 hours, are associated not only with incontinence (Landi et al, 2002) but also with falling, hip fractures, driving accidents, depression, and confusion. Alcohol causes similar problems, but, for a variety of reasons, physicians frequently fail to identify alcohol use by older people as a source of symptoms, including incontinence. Sequelae of alcohol abuse are often absent or attributed to other causes. In addition, because of age-related alterations in the pharmacokinetics and pharmacodynamics of alcohol disposal, as well as interactions with other commonly used drugs, as few as one or two drinks can pose a problem for older individuals.

Because **anticholinergic agents** are prescribed so often for the elderly, and are used even without prescription (e.g., sedating antihistamines used for allergies, coryza, and insomnia), it is important to ask about them. They cause or contribute to incontinence in several ways. In addition to provoking overt urinary retention, these agents often induce subclinical retention. The resultant decrease in available bladder capacity (i.e., total capacity minus residual) allows it to be reached more quickly, exacerbating incontinence due to DO, as well as that due to functional impairment. By increasing bladder capacity (and often residual volume), anticholinergic agents also may aggravate leakage due to stress incontinence by further increasing the challenge to the sphincter mechanism. Additionally, many of these drugs decrease mobility (e.g., antipsychotics that induce extrapyramidal stiffness) and precipitate confusion. Finally, several agents intensify the dry mouth that many elderly already suffer owing to an age-related decrease in salivary gland function; the resultant increased fluid intake contributes to incontinence. Attempts should be made to discontinue anticholinergic agents, or to substitute with ones having less anticholinergic effect (e.g., a selective serotonin uptake inhibitor [SSRI] for a tricyclic antidepressant; risperidone for chlorpromazine). Limited data suggest that bethanechol may be useful for nonobstructed patients whose urinary retention is associated with use of an anticholinergic that cannot be discontinued (Everett, 1975).

In men with asymptomatic prostatic obstruction, **α-adrenergic agonists** can provoke acute retention. Particularly problematic are **nonprescribed decongestants.** They often contain an (anticholinergic) antihistamine and are frequently taken with a nonprescribed hypnotic, all of which are also sedating antihistamines. Because older individuals often fail to mention nonprescribed agents to a physician, urinary retention due to use of a decongestant, nose drops, and a hypnotic may result in premature or even unnecessary prostatectomy.

By blocking receptors at the bladder neck, **α-adrenergic antagonists** (many antihypertensives) may induce stress

Table 76–2.

Commonly Used Medications That May Affect Continence

TYPE OF MEDICATION	EXAMPLES	POTENTIAL EFFECTS ON CONTINENCE
Sedatives/hypnotics	Long-acting benzodiazepines (e.g., diazepam, flurazepam)	Sedation, delirium, immobility
Alcohol		Polyuria, frequency, urgency, sedation, delirium, immobility
Anticholinergics	Dicyclomine, disopyramide, antihistamines (sedating ones only, e.g., Benadryl)	Urinary retention, overflow incontinence, delirium, impaction
Antipsychotics	Thioridazine, haloperidol	Anticholinergic actions, sedation, rigidity, immobility
Antidepressants *(tricyclics)*	Amitriptyline, desipramine; *not* SSRIs	Anticholinergic actions, sedation
Anti-Parkinsonians	Trihexyphenidyl, benztropine mesylate (*not* L-dopa or selegiline)	Anticholinergic actions, sedation
Narcotic analgesics	Opiates	Urinary retention, fecal impaction, sedation, delirium
α-Adrenergic antagonists	Prazosin, terazosin, doxazosin	Urethral relaxation may precipitate stress incontinence in women
α-Adrenergic agonists	Nasal decongestants	Urinary retention in men
Calcium channel blockers	All dihydropyridines*	Urinary retention; nocturnal diuresis due to fluid retention
Potent diuretics	Furosemide, bumetanide (***not*** thiazides)	Polyuria, frequency, urgency
NSAIDs	Indomethacin, COX-2 inhibitors	Nocturnal diuresis due to fluid retention
Thiazolidinediones	Rosiglitazone, pioglitazone	Nocturnal diuresis due to fluid retention
Anticonvulsants/analgesics	Gabapentin, pregabalin	Nocturnal diuresis due to fluid retention
Parkinson agents (some)	Pramipexole, ropinirole, amantadine	Nocturnal diuresis due to fluid retention
Angiotensin converting enzyme (ACE) inhibitors	Captopril, enalapril, lisinopril	Drug-induced cough can precipitate stress incontinence in women and in some men with prior prostatectomy
Vincristine		Urinary retention owing to neuropathy

*Examples include amlodipine (Norvasc), nifedipine, nicardipine, isradipine, felodipine, nimodipine.

COX-2, cyclooxygenase-2; NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

Adapted from Resnick NM. Geriatric medicine. In: Isselbacher KJ, Braunwald E, Wilson JD, Martin JB, Fauci AS, Kasper DJ, editors. Harrison's principles of internal medicine. New York: McGraw-Hill; 2004. p. 34.

incontinence in older women (Mathew et al, 1988; Marshall and Beevers, 1996) in whom urethral length and closure pressure decline with age. Because hypertension affects half of the elderly, use of these agents may increase. Before considering interventions for stress incontinence in such women, one should substitute an alternative agent and reevaluate the incontinence.

Calcium channel blockers also can cause incontinence. As smooth muscle relaxants, they may increase residual volume and may occasionally lead to overflow incontinence, particularly in obstructed men with coexisting detrusor weakness. The dihydropyridine class of these agents (e.g., nifedipine, amlodipine, nicardipine, isradipine, nimodipine) also can cause peripheral edema, which can exacerbate nocturnal polyuria and nocturnal incontinence.

Angiotensin-converting enzyme inhibitors (ACEI) are prescribed increasingly for age-associated conditions such as myocardial infarction, congestive heart failure, and hypertension. Because the risk of developing an ACEI-induced cough increases with age, these agents may exacerbate what otherwise would be minimal stress incontinence in older women.

A few reports impugn **cholinesterase inhibitors,** such as donepezil (Aricept) or rivastigmine, as a cause of urinary incontinence (Hashimoto et al, 2000; Starr, 2007). The association is plausible, because these agents block the breakdown of acetylcholine within the neuroeffector junctional cleft. However, the incontinence often ceases even if the drug is continued, the number of cases is small, and the descriptions and evaluations of these cases are sparse. In addition, prospective trials in which these agents were evaluated for their cognitive impact did not note an increase in incontinence. Nonetheless, the association has not been well-evaluated to date, and because incontinence may improve or resolve on decreasing the drug dose or discontinuation, such an association is worth keeping in mind.

Excess urine output commonly contributes to or even causes geriatric incontinence. Causes include excessive fluid intake; diuretics (including theophylline-containing fluids, lithium, and alcohol); metabolic abnormalities (e.g., hyperglycemia and hypercalcemia); and disorders associated with fluid overload, including congestive heart failure, peripheral venous insufficiency, hypoalbuminemia (especially in malnourished debilitated elderly), and drug-induced peripheral edema associated with an increasing array of medications, including nonsteroidal anti-inflammatory drugs (NSAIDs), dihydropyridine calcium channel blockers, thiazolidinediones ("glitazones"), pramipexole and ropinirol (for Parkinson disease), amantadine (for Parkinson disease and influenza), and β blockers. Fluid overload is a likely contributor when incontinence is associated with nocturia.

Restricted mobility commonly contributes to geriatric incontinence. It can result from numerous treatable conditions, including arthritis, hip deformity, deconditioning, postural or postprandial hypotension, claudication, spinal stenosis, heart failure, poor eyesight, fear of falling, stroke, foot problems, drug-induced disequilibrium or confusion, or being restrained in a bed or chair (Resnick, 2004). A careful search will often identify these or other correctable causes. If not, a urinal or bedside commode may still improve or resolve the incontinence.

Finally, **stool impaction** is implicated as a cause of urinary incontinence in up to 10% of older patients admitted to acute hospitals or referred to incontinence clinics (Resnick, 1988); the mechanism may involve stimulation of opioid receptors (Hellstrom and Sjoqvist, 1988). Patients present with urge or overflow incontinence and typically have associated fecal incontinence as well. Disimpaction restores continence.

These seven reversible causes of incontinence should be assiduously sought in every elderly patient. In one series of hospitalized elderly patients, when these causes were identified, continence was regained by most of those who became incontinent in the context of acute illness (Resnick, 1988). Regardless of their frequency, their identification is important in all settings because they are easily treatable and contribute to morbidity beyond incontinence.

Key Points: Transient Incontinence

- In the elderly, continence generally results *not* from normal lower urinary tract (LUT) function but *despite* abnormal LUT function. Thus the compensatory role of factors beyond the urinary tract is more important in older incontinent patients than in younger individuals.
- Because such compensatory factors are often impaired in older patients, owing to comorbidity and medication use, these factors should be identified and addressed in all incontinent older adults.
- Reversal of such factors can resolve or improve incontinence in many older patients and improve the efficacy of lower urinary tract therapy in the remainder.

ESTABLISHED INCONTINENCE

Lower Urinary Tract Causes

If incontinence persists after transient causes have been addressed, the lower urinary tract causes should be considered. These are similar to the causes in younger individuals, but there are several significant differences.

***Detrusor overactivity (DO) is* the most common type of lower urinary tract dysfunction in incontinent elderly of either sex** (Resnick, 1988; Resnick et al, 1989). DO has been associated with increased spontaneous activity of detrusor smooth muscle and with specific changes at the cellular level. Termed the "complete dysjunction pattern," these changes include widening of the intercellular space, reduction of normal (intermediate) muscle cell junctions, and emergence of novel "protrusion" junctions and "ultraclose abutments" connecting cells together in chains. These junctions and abutments may mediate a change in cell coupling from a mechanical to an electrical mechanism, which could facilitate propagation of heightened smooth muscle activity and provide the "final common pathway" by which such spontaneous cellular contractions result in involuntary contraction of the entire bladder (Elbadawi et al, 1993c, 1997a, 1997b; Hailemariam et al, 1997; Tse et al, 2000). However, this remains speculative to date. Other potential mechanisms are also being investigated, including, among others, the role of ischemia (Azadzoi et al, 2007), suburothelial myofibroblasts (Fry et al, 2007), and changes in central nervous system (CNS) structural and functional control mechanisms (Griffiths et al, 2007, 2009; Poggesi et al, 2008; Tadic et al, 2008; Kuchel et al, 2009).

A distinction is generally made between detrusor overactivity that is associated with a CNS lesion and that which is not. In older patients, the distinction is often unclear, because involuntary detrusor contractions may be due to normal aging, a past stroke (even if clinically unapparent), or urethral incompetence or

obstruction—even in a patient with Alzheimer disease. There is still no reliable way to determine the source of such contractions (Elbadawi et al, 2003). This obviously complicates treatment decisions. It also suggests that DO coexisting with urethral obstruction or stress incontinence is less likely to resolve postoperatively than in younger individuals without other reasons for detrusor overactivity (Resnick, 1988; Gormley et al, 1993).

Traditionally, detrusor overactivity has been thought to be the primary urinary tract cause of incontinence in demented patients. Although this is true, DO is also the most common cause in nondemented older patients; the three studies that examined it failed to find an association between cognitive status and DO (Castleden et al, 1981; Resnick et al, 1989; Dennis et al, 1991). This lack of association likely reflects the fact that, in the elderly, there are multiple causes of DO unrelated to dementia, including cervical disk disease or spondylosis, Parkinson disease, stroke, subclinical urethral obstruction or sphincter incompetence, and age itself. Moreover, demented patients also may be incontinent due to the transient causes discussed above. Thus it is no longer tenable to ascribe incontinence in demented individuals a priori to detrusor overactivity (Resnick, 1995).

Detrusor overactivity in the elderly exists as two physiologic subsets: one in which contractile function is preserved and one in which it is impaired (Resnick and Yalla, 1987; Yalla et al, 2007). **The latter condition is termed detrusor hyperactivity with impaired contractility (DHIC) and is likely the most common form of DO in the elderly** (Resnick et al, 1989; Elbadawi et al, 1993c). DHIC appears to represent the coexistence of DO and bladder weakness rather than a separate entity (Elbadawi et al, 1993c). Regardless of the cause, DHIC has several implications. First, because the bladder is weak, urinary retention develops commonly in these patients, and DHIC must be added to outlet obstruction and detrusor underactivity as a cause of retention. Second, even in the absence of retention, DHIC mimics virtually every other lower urinary tract cause of incontinence. For instance, if the involuntary detrusor contraction is triggered by or occurs coincident with a stress maneuver, and the weak contraction (often only 2 to 6 cm water) is not detected, DHIC will be misdiagnosed as stress incontinence or urethral instability (Resnick et al, 1996a); alternatively, because DHIC may be associated with urinary urgency, frequency, weak flow rate, elevated residual urine, and bladder trabeculation, in men it may mimic urethral obstruction (Resnick et al, 1996a). Third, bladder weakness often frustrates anticholinergic therapy of DHIC because urinary retention is induced so easily. Thus alternative therapeutic approaches are often required (see Therapy section).

Stress incontinence is the second most common cause of incontinence in older women. As in younger women, it is **usually associated with urethral hypermobility. A less common cause is intrinsic sphincter deficiency (ISD)** or type 3 stress incontinence (McGuire, 1981; Blaivas and Olsson, 1988). The prevalence of ISD may be lower than thought, however, because the diagnosis is often based solely on documenting a very low leak point or urethral closure pressure. Because urethral pressure decreases with age, even a closure pressure of less than 20 cm water does not establish the presence of ISD. Moreover, because urethral pressure normally decreases with detrusor contraction, leakage coinciding with low urethral pressure can be observed in patients with DHIC in whom the low pressure contraction is missed (Resnick et al, 1996a).

When it occurs, ISD is usually due to operative trauma. But a milder form also occurs in older women, resulting only from urethral atrophy superimposed on the age-related decline in urethral pressure. Instead of leaking, with any bladder volume, such women leak at higher amounts (e.g., >200 mL). ***Many become dry if bladder volume is kept below this level.***

A rare cause of stress incontinence in older women is "urethral instability," in which the sphincter paradoxically relaxes in the absence of apparent detrusor contraction (McGuire, 1978). However, most older women thought to have this condition actually have DHIC (Resnick et al, 1996a).

In men, stress incontinence is usually due to sphincter damage following radical prostatectomy. In both sexes, stress-associated leakage also can occur in association with urinary retention, but in this situation leakage is not due to outlet incompetence.

Incontinence in the setting of ***outlet obstruction*** is the second most common cause of incontinence in older men, although most obstructed men are not incontinent. When obstruction is associated with incontinence, it generally presents as urge incontinence owing to the associated DO; overflow incontinence owing to obstruction is uncommon. Especially in older adults, it is difficult to determine whether DO that occurs with obstruction is related to the obstruction or is simply coexistent owing to its increased prevalence with age, even in non-obstructed individuals. Nonetheless, DO is more common among obstructed patients, even older ones, (Resnick et al, 1995) and can cause incontinence. In most women, urethral elasticity decreases with age. In a small proportion of older women, this reduced elasticity may be compounded by fibrotic changes associated with atrophic vaginitis and can result in moderate urethral stenosis. Frank outlet obstruction, however, is as rare in older women as in younger women. When present, it is usually due to kinking associated with a large cystocele or to obstruction following bladder neck suspension. Rarely, bladder neck obstruction or a bladder calculus is the cause.

Detrusor underactivity is **usually idiopathic,** but more information on this condition is emerging (Taylor and Kuchel, 2006). In the absence of obstruction or overt neuropathy, detrusor underactivity is characterized at the cellular level by widespread degenerative changes of both muscle cells and axons, without accompanying regenerative changes (Elbadawi et al, 1993b; Hindley et al, 2002). **When it causes incontinence, detrusor underactivity is associated with overflow incontinence** (<10% of geriatric incontinence) (Diokno et al, 1988; Resnick, 1988; Resnick et al, 1989). Owing to the age-related decline in sphincter strength, however, the postvoid residual (PVR) volume in women with overflow incontinence is often lower than in younger women. **A mild degree of bladder weakness occurs quite commonly in older individuals. Although insufficient to cause incontinence, it can complicate treatment of other causes** (see Therapy section).

Causes Unrelated to the Lower Urinary Tract ("Functional" Incontinence)

"Functional" incontinence is often cited as a distinct type of geriatric incontinence and attributed to deficits of cognition and mobility. This concept is problematic for several reasons (Resnick and Marcantonio, 1997). First, "functional incontinence" implies that urinary tract function is normal, but studies of both institutionalized and ambulatory elderly reveal that normal urinary tract function is the exception even in continent subjects, and is rarely observed in the

incontinent elderly (Ouslander et al, 1986; Resnick, 1988; Resnick et al, 1989; Resnick et al, 1995). **Second, incontinence is not inevitable with either dementia or immobility.** We found that 17% of the most severely demented institutionalized residents (mean age 89) were continent and, if they could merely transfer from a bed to a chair, nearly *half* were *continent* (Resnick et al, 1988). **Third,** because functionally-impaired individuals are the most likely to suffer from factors causing transient incontinence (Resnick et al, 1988; DuBeau and Resnick, 1995; Skelly and Flint, 1995; Brandeis et al, 1997), **a diagnosis of functional incontinence may result in failure to detect reversible causes of incontinence. Finally, functionally-impaired individuals may still have obstruction or stress incontinence and benefit from targeted therapy** (Resnick, 1988; Resnick et al, 1989; Gormley et al, 1993; DuBeau and Resnick, 1995).

Nonetheless, the importance of functional impairment as a factor *contributing* to incontinence should not be underestimated, because incontinence is also affected by environmental demands, mentation, mobility, manual dexterity, medical factors, and motivation (Jenkins and Fultz, 2005; Cigolle et al, 2007; Kikuchi et al, 2007) Although lower urinary tract function is rarely normal in such individuals, these factors are important to keep in mind because small improvements in each may markedly ameliorate both incontinence and functional status. In fact, once one has excluded causes of transient incontinence and serious underlying lesions, addressing causes of functional impairment may obviate the need for further investigation.

Key Points: Established Incontinence

- Established causes of geriatric incontinence comprise those in the lower urinary tract and also those beyond it.
- Detrusor overactivity (DO) is the most common lower urinary tract cause of incontinence in older adults, even in the absence of cognitive impairment. Differentiating a neurogenic from a non-neurogenic etiology is generally not possible in older patients, nor is differentiating DO that is due to urethral obstruction or incompetence from DO that simply coexists with these abnormalities.
- In older patients, DO commonly coexists with detrusor weakness, a condition known as DHIC. Without careful evaluation, such patients may be misdiagnosed as having urethral incompetence or, especially in the setting of urinary retention, urethral obstruction. Urethral surgery may exacerbate the problem.
- Stress incontinence is the second most common cause of incontinence in older women. Although urethral hypermobility is the most common cause, it often coexists with an age-related impairment of sphincter function.
- Urethral obstruction can contribute to incontinence in many men but is as uncommon in older women as in younger women.
- Isolated detrusor weakness is a very uncommon cause of overflow incontinence.
- In addition to abnormalities of lower urinary tract function, impairment of cognitive and/or physical function can also contribute to established geriatric incontinence and occasionally even cause it.

DIAGNOSTIC APPROACH

Evaluation

The evaluation should **identify transient and established causes of incontinence, assess the patient's environment and available support, and detect uncommon but serious conditions that may underlie incontinence,** including lesions of the brain and spinal cord, carcinoma of the bladder or prostate, hydronephrosis, bladder calculi, detrusor-sphincter dyssynergia, and decreased bladder compliance. **Assessment must be tailored** to the patient's clinical status and goals, and **tempered by the realization that not all detected conditions can be cured, that simple interventions may be effective even in the absence of a diagnosis, and that for many elderly patients, diagnostic tests are themselves often interventions.** Because the evaluation generally requires a comprehensive approach, it should be conducted over more than one visit to ease the burden and obviate further evaluation in those who respond to simple measures.

History

In addition to the assessment outlined in Chapter 64, evaluation of the older patient should search for transient causes of incontinence (including nonprescribed medications) and functional impairment. It should be augmented by medical records, as well as input from caregivers. Functional assessment focuses on both basic activities of daily living (ADLs: i.e., transferring from a bed, walking, bathing, toileting, eating, and dressing) and more advanced "instrumental" activities of daily living (IADLs: i.e., shopping, cooking, driving, managing finances, using the telephone). The assessment is accomplished by using a questionnaire, which can be completed by the patient or caregiver prior to the evaluation, and by objective evaluation of the patient from the beginning of the encounter, noting affect, mobility, ability to sit and rise from a chair, ability to provide a coherent history, and amount of time and assistance required to dress and undress.

Of course, as for younger individuals, it also is important to characterize the voiding pattern and the type of incontinence. Although the clinical type of incontinence most often associated with detrusor overactivity (DO) is urge incontinence, **"urge" is neither a sensitive nor specific symptom; it is absent in 20% of older patients with detrusor overactivity, and the figure is higher in demented patients** (Resnick et al, 1989). **"Urge" is also reported commonly by patients with stress incontinence, outlet obstruction, and overflow incontinence.**

A better term for the symptom associated with DO is **"precipitancy,"** which can be defined in two ways. For patients with no warning of imminent urination ("reflex" or "unconscious" incontinence), the abrupt gush of urine in the absence of a stress maneuver can be termed **precipitant leakage,** and it is **almost invariably due to DO.** For those who do sense a warning, it is of less value to focus on the leakage, because the presence and volume of leakage in this situation depend on bladder volume, amount of warning, toilet accessibility, the patient's mobility, and whether the patient can overcome the relative sphincter relaxation accompanying detrusor contraction (Dyro and Yalla, 1986). Instead, **precipitancy** should be defined as the *abrupt sensation* that urination is imminent, *whatever the interval or amount of leakage that follows*; defined in these two ways, precipitancy is both a sensitive and specific symptom (Resnick, 1990).

Table 76–3.

Causes of Nocturia

Volume Related
Age-related
Excess intake/alcohol
Diuretic, caffeine, theophylline, lithium
Endocrine/metabolic
Diabetes mellitus/insipidus
Hypercalcemia
Peripheral edema
Congestive heart failure
Low albumin states
Peripheral vascular disease
Venous insufficiency
Drugs (e.g., NSAIDs [indomethacin, COX-2 inhibitors], nifedipine)
Sleep Related
Insomnia
Obstructive sleep apnea (causes polyuria as well)
Restless legs syndrome
Pain
Dyspnea
Depression
Drugs
Lower Urinary Tract–Related
Small bladder capacity
Detrusor overactivity
Prostate related
Overflow incontinence
Decreased bladder compliance
Sensory urgency

COX-2, cyclooxygenase; NSAIDs, nonsteroidal anti-inflammatory drugs.

Figure 76–3. Voiding diary of an incontinent 75-year-old man. Urodynamic evaluation excluded urethral obstruction and confirmed a diagnosis of detrusor hyperactivity with impaired contractility (DHIC). Note the 24-hour urine output of nearly 3 L, due to the belief that drinking 10 glasses of fluid/day was "good for my health." (He did not mention this until queried about the voiding record). Given the typical voided volume of 150 to 250 mL and a measured postvoid residual (PVR) of 150 mL, excess fluid intake was overwhelming his usual bladder capacity of 400 mL (150 + 250 mL). Although involuntary bladder contractions were present, the easily reversible volume component of the problem—combined with the risk of precipitating urinary retention with an anticholinergic agent—prompted treatment with volume restriction alone. After daily urinary output dropped to 1500 mL, frequency abated and incontinence resolved. (Adapted from DuBeau CE, Resnick NM. Evaluation of the causes and severity of geriatric incontinence: a critical appraisal. Urol Clin North Am 1991;18:243–56.)

Similar to the situation for urgency, other symptoms ascribed to DO also can be misleading in the older person unless explored carefully. **Urinary frequency (greater than seven diurnal voids) is common** (Brocklehurst et al, 1968; Diokno et al, 1986; Resnick, 1988), and may be due to voiding habit, preemptive urination to avoid leakage, overflow incontinence, sensory urgency, a stable but poorly compliant bladder, excessive urine production, depression, anxiety, or social reasons (Resnick, 1990). **Conversely, incontinent individuals may severely restrict their fluid intake so that even in the presence of DO they do not void frequently.** Thus the significance of urinary frequency, or its absence, can be determined only in the context of more information.

Nocturia also can be misleading unless it is first defined (e.g., two episodes may be normal for the individual who sleeps 10 hours but not for one who sleeps 4 hours) and then approached systematically (Table 76–3). The **three general reasons for nocturia—excessive urine output, sleep-related difficulties, and urinary tract dysfunction—can be differentiated by careful questioning and a voiding diary that includes voided volumes** (Fig. 76–3). The record of voided volumes is inspected to determine the available bladder capacity (the largest single voided volume) and then compares this capacity to the volume of each nighttime void. For instance, if the available bladder capacity is 400 mL and each of three nightly voids is approximately 400 mL, the nocturia is due to excessive production of urine at night. If the volume of most nightly voids is much smaller than bladder capacity, nocturia reflects either: (1) a sleep-related problem (the patient voids because she is awake anyway), or (2) a problem with the lower urinary tract. Similar to excess urine output, sleep-related nocturia may also be due to treatable causes, including age-related sleep disorders, pain (e.g., bursitis, arthritis), dyspnea, depression, caffeine, or a short-acting hypnotic (e.g., triazolam). Bladder-related causes of nocturia are displayed in the table. Whatever the cause, the nocturnal component of incontinence can generally be ameliorated.

The symptoms of "prostatism" also warrant comment. Owing to the high prevalence of medication use, nocturnal polyuria (Reynard et al, 1998), constipation, and DHIC, as well as the impairment of bladder contractility that accompanies aging, "prostatic" symptoms are even less specific in older men than in younger men (DuBeau and Resnick, 1991).

When asking about leakage with stress maneuvers, it is important to ensure that the absence of such leakage is not due to simply the lack of coughing or sneezing. For those without such precipitants, it is useful to inquire about instantaneous leakage with lifting or bending over to put on a shoe or stockings.

Finally, **patients or their caregivers should be asked which voiding symptom is most bothersome.** For example, although a woman may have both stress and urge incontinence,

the urge component may be her worst problem and should become the focus of evaluation and treatment. A man with "prostatism" may be most bothered by nocturia (DuBeau et al, 1995), which may be remedied without any consideration of his prostate (see Fig. 76–3). Failure to address symptom bother can lead to frustration for patient and provider alike.

Voiding Diary

One of the most helpful components of the history is the voiding diary. Kept by the patient or caregiver for 48 to 72 hours, the diary records the time of each void and incontinent episode. No attempt is made to alter voiding pattern or fluid intake. Many formats have been proposed; a sample is shown in Figure 76–3.

To record voided volumes at home, individuals use a measuring cup, coffee can, pickle jar, or other large-mouth container. **Information regarding the volume voided provides an index of functional bladder capacity and, together with the pattern of voiding and leakage, can suggest the cause of leakage.** For example, incontinence occurring only between 8 AM and noon may be caused by a morning diuretic. Incontinence that occurs at night in a demented man with congestive heart failure, but not during a 4-hour nap in his wheelchair, is likely due to neither dementia nor prostatic obstruction but to postural diuresis associated with his heart failure. A woman with volume-dependent stress incontinence may leak only on the way to void after a full night's sleep, when her bladder contains greater than 400 mL—more than it ever does during her continent waking hours. A patient with impaired mobility may become incontinent if polyuria develops.

The voiding diary should also guide therapy. For instance, in a patient with DO or prostatic obstruction, excess nocturnal excretion may result in nocturnal incontinence, which is more severe and troublesome than daytime leakage; successful therapy must address the excess excretion. By contrast, another patient with the same urinary tract dysfunction and excretion—but with the ability to hold more urine when asleep—might be bothered more by daytime leakage. Shifting nocturnal excretion to the daytime will *exacerbate* his problem.

Targeted Physical Examination

Similar to the history, the physical examination is essential to detect transient causes, comorbid disease, and functional impairment. In addition to the standard neurourologic examination, one should check for signs of neurologic diseases that are more common in older people, such as delirium, dementia, stroke, Parkinson disease, cord compression, and neuropathy (autonomic or peripheral), as well as for atrophic vaginitis and general medical illnesses, such as heart failure and peripheral edema. The rectal exam checks for fecal impaction, masses, sacral reflexes, symmetry of the gluteal creases, and prostate consistency and nodularity; as noted in Chapter 92, the palpated size of the prostate is unhelpful. Many neurologically unimpaired elderly patients are unable to volitionally contract the anal sphincter, but, if they can, it is evidence against a spinal cord lesion. The absence of the anal wink is not necessarily pathologic in the elderly, nor does its presence exclude an underactive detrusor (due to diabetic neuropathy, for example).

Stress Testing and PVR Measurement

Several caveats apply to performing the stress test and measuring the PVR in older patients. Stress testing is performed optimally when the bladder is full, and the patient is relaxed (check the gluteal folds to corroborate) and in as close to the upright position as possible. The cough or strain should be vigorous and *single*, so one can determine whether leakage coincides with the increase in abdominal pressure or follows it. Stress-related leakage may be missed if any of these conditions is not met. Delayed leakage typical of stress-induced DO should be differentiated from leakage typical of stress incontinence, which is instantaneous and ceases as soon as abdominal pressure declines. **To be useful diagnostically, leakage must replicate the symptom for which help is sought,** because many older women have incidental but not bothersome leakage of a few drops. The test should not be performed if the patient has an abrupt urge to void because this is usually due to an involuntary detrusor contraction that will lead to a falsely positive stress test. Falsely negative tests occur when the patient fails to cough vigorously or to relax the perineal muscles, the bladder is not full, or the test is performed in the upright position in a woman with a large cystocele (that kinks the urethra). If performed correctly, the stress test is reasonably sensitive and quite specific (>90%) (Hilton and Stanton, 1981; Diokno, 1990; Kong et al, 1990).

Following the stress test, the patient is asked to void into a receptacle, and the PVR is measured. If the stress test was negative, the history suggests stress incontinence, *and* the combined volume of the void and PVR is less than 200 mL, the bladder should be filled with sterile fluid so that the stress test can be repeated at an adequate volume. There is no need to repeat a correctly performed positive stress test. Neither is there a need to repeat it in a woman whose history is negative for stress-related leakage; the sensitivity of the history for stress incontinence, unlike its specificity, exceeds 90% (Diokno et al, 1987; Jensen et al, 1994), making the likelihood of stress incontinence rare in this situation.

Optimally, the PVR is measured by portable ultrasonography, and within 5 minutes of voiding. Measuring it after an intentional void is better than after an incontinent episode, because many patients are able to partially suppress the involuntary contraction during the episode, and more than the true PVR remains. In cognitively impaired patients this may not be possible. Nonetheless, because the resulting artifact will lead to a falsely elevated PVR, a low value is still useful. The PVR will also be spuriously high if measurement is delayed (especially if the patient's fluid intake was high or included caffeine), the patient was inhibited during voiding, or there is discomfort due to urethral inflammation or bladder infection. It will be spuriously low if the patient augmented voiding by straining (most important in women). If a catheter is used, the PVR will be spuriously low if the catheter is withdrawn too quickly or if the woman has a cystocele that allows urine to "puddle" beneath the reach of the catheter. Of note, relying on the ease of catheterization to establish the presence of obstruction can be misleading, because difficult catheter passage may be caused by urethral tortuosity, a "false passage," or catheter-induced spasm of the distal sphincter, although catheter passage may be easy even in obstructed men (Klarskov et al, 1987).

Two other tests should be mentioned. The Q-tip (cotton swab) test for pelvic floor laxity is of little value in determining the cause of a patient's leakage, and has a high false-negative rate in elderly women (DuBeau and Resnick, 1991). The Bonney (or Marshall) test is also of limited usefulness in the elderly, because vaginal stenosis is common and may lead to a false-positive result by precluding accurate finger placement. Furthermore, even if the test is performed correctly, a false positive result may occur if the first episode of leakage was due to a cough-induced detrusor contraction that, having emptied the bladder, does not recur during bladder base elevation.

Laboratory Investigation

(Resnick and Ouslander, 1990; DuBeau and Resnick, 1991; Fantl et al, 1996). **BUN, creatinine, urinalysis, urine culture, and PVR should be checked in all older patients. Serum sodium, calcium, and glucose should be measured in patients with confusion.** If the voiding record suggests polyuria, serum glucose and calcium (and albumin, to allow calculation of free calcium levels in sick or malnourished patients) should be determined. Sterile hematuria suggests partially/recently treated bacteriuria, malignancy, or calculus; tuberculosis should also be considered, because the elderly, particularly institutionalized residents, are an unappreciated reservoir of this infection (Stead, 1985). Finally, it is important to recognize when evaluating renal function that the **age-related decline in glomerular flow rate (GFR)—30% by the 8th decade—is not associated with an increase in creatinine because of a concomitant decrease in muscle mass; thus *normal creatinine levels do not imply a normal GFR*.**

Empiric Diagnostic Categorization

After transient and serious causes have been addressed, the optimal diagnostic strategy for persistent incontinence is unknown (Resnick and Ouslander, 1990; Fantl et al, 1996; Abrams et al, 2005; Fonda et al, 2005). "Bedside" cystometry has been proposed, but its utility is limited because it misses low-pressure contractions of DHIC; its feasibility and accuracy are low in frail elderly (Ouslander and Colling, 1992); and detected DO may be either incidental and unrelated to leakage, or due to urethral obstruction or incompetence and warrant different therapy. The following approach (Resnick, 1995), although still unproven, is relatively noninvasive, accurate, cost effective, and easily tolerated. A similar approach forms the basis for the Agency for Health Care Policy Research (AHCPR) Clinical Practice Guideline (Fantl et al, 1996), the International Consultation on Incontinence (Fonda et al, 2005), as well as the Minimum Data Set/Resident Assessment Instrument, which we designed and validated for use in all American nursing homes (Resnick et al, 1996b).

The **first step is to identify individuals with overflow incontinence** (e.g., PVR > 450 mL). **Because obstruction and underactive detrusor cannot be differentiated clinically** (Resnick et al, 1996b; DuBeau et al, 1998; Sonke et al, 2000), **further assessment is warranted for those in whom it would affect therapy, while catheterization should be used for the rest. For the remaining 90% to 95% of patients, the next step depends on their sex. In women, the differential diagnosis is generally between stress incontinence and DO, because obstruction is rare in the absence of previous bladder neck suspension or prolapsing cystocele.** If the contemplated intervention is nonoperative, the diagnosis usually can be established on clinical grounds alone, informed by the caveats mentioned earlier.

In men, stress incontinence is uncommon and, when present, results in a characteristic drip (similar to a "leaky faucet") that is exacerbated by standing or straining. Thus **the usual problem in men is differentiating unobstructed DO from obstruction. Uroflowmetry is helpful, but only if peak flow is normal (e.g., >12 mL/sec for voided volume of 200 mL); the age-related decrease in bladder contractility means that a normal *unstrained* flow rate, together with PVR <100 mL, effectively excludes clinically significant obstruction in an older man** (DuBeau et al, 1998). **The next step is to search for hydronephrosis in men whose PVR exceeds 200 mL and to decompress those in whom it is found** (DuBeau and Resnick, 1992). Further evaluation is also reasonable for men without hydronephrosis who are appropriate candidates and would be amenable to surgery if obstructed. For the rest, **it seems sensible to treat those with urge incontinence for presumed DO, provided they are compliant and can be taught signs of incipient urinary retention;** bladder relaxants probably should be avoided in those with significantly elevated PVR (e.g., ≥ 150 mL). A similar approach is advocated for cognitively impaired men who can be closely observed (e.g., institutionalized residents) (Resnick et al, 1996b). **Men without urge incontinence, those who fail empiric therapy, and those who are cognitively impaired and less supervised should be evaluated further if findings would affect therapy.**

Urodynamic Testing

Although its precise role in the elderly is unclear, **multichannel urodynamic evaluation is probably warranted when diagnostic uncertainty may affect therapy and when empiric therapy has failed and other approaches would be tried.** Because conditions that closely mimic obstruction and stress incontinence are so common in the elderly, including altered fluid excretion (Reynard et al, 1998), medication use, DH, and DHIC (Resnick et al, 1996a), urodynamic corroboration of the diagnosis is strongly recommended if surgery will be performed (Resnick et al, 1991; Fantl et al, 1996; Resnick and Baumann, 1997). Whatever its role, however, urodynamic evaluation of even frail elderly patients is reproducible, safe, and feasible (Resnick et al, 1987; Resnick et al, 1989).

Key Points: Diagnostic Approach

- The evaluation should identify contributing factors both within and beyond the lower urinary tract and determine their impact on the patient's symptoms.
- Because the range of contributing causes is broader in older adults, and because fluid excretion changes with age, the voiding diary is of particular importance in evaluating older incontinent patients.
- Laboratory testing should often include more than serum measures of renal function. In addition, it is important to recall that serum creatinine underestimates creatinine clearance owing to the age-related decline in muscle mass and creatine production.
- DHIC can mimic both urethral obstruction and stress incontinence.
- Urodynamic testing should be strongly considered if surgery is contemplated since DHIC can mimic both urethral obstruction and stress incontinence.

THERAPY

Similar to the diagnostic approach, treatment must be individualized, because factors outside the lower urinary tract so often affect therapeutic feasibility and efficacy. For instance, although both may have detrusor overactivity that can be managed successfully, a severely demented and bedfast woman must be treated differently from one who is ambulatory and cognitively intact. This

section and Table 76–4 outline several treatments for each condition and provide guidance for their use. It is assumed that serious underlying conditions, transient causes of incontinence, and functional impairments have already been addressed.

It cannot be overemphasized that **successful treatment of established incontinence, especially in the elderly, is usually multifactorial and requires addressing factors beyond the urinary tract.** Figure 76–4, based on empiric data, illustrates the many factors that determine whether DO in an older adult will be associated with incontinence and, if so, the frequency of the related leakage (Miller et al, 2002; Rosenberg et al, 2005).

Detrusor Overactivity

The initial approach to detrusor overactivity is to identify and treat its reversible causes. Unfortunately, many of its causes are not amenable to specific therapy or a cause may not be found, so treatment usually must be symptomatic. **Simple measures, such as adjusting the timing or amount of fluid**

Table 76–4.

Stepwise Approach to Treatment of Urinary Incontinence*

CONDITION	CLINICAL TYPE OF INCONTINENCE†	TREATMENT
Detrusor overactivity with normal contractility (DO)	Urge	1. Bladder retraining or prompted voiding regimens 2. ± Bladder relaxant medication, if needed and not contraindicated (see drug list below) 3. Indwelling catheterization alone is often unhelpful because detrusor "spasms" often increase, leading to leakage around the catheter 4. In selected cases, induce urinary retention pharmacologically and add intermittent or indwelling catheterization‡
Detrusor hyperactivity with impaired contractility (DHIC)	Urge§	1. If bladder empties adequately, behavioral methods (as above) ± bladder relaxant medication (low doses; especially feasible if sphincter incompetence coexists) 2. If residual urine ≥150 mL, augmented voiding techniques‖ or intermittent catheterization (± bladder relaxant medication). If neither feasible, undergarment or indwelling catheter‡ 3. In selected cases, induce urinary retention pharmacologically and add intermittent or indwelling catheterization‡
Stress incontinence	Stress	1. Conservative methods (weight loss if obese; treatment of cough or atrophic vaginitis; physical maneuvers to prevent leakage [e.g., tighten pelvic muscles before cough, cross legs]; occasionally, use of tampon or pessary is useful) 2. If leakage threshold ≥150 mL identified, adjust fluid excretion and voiding intervals appropriately 3. Pelvic muscle exercises ± biofeedback/weighted intravaginal "cones"; must continue indefinitely 4. Surgery (sling, artificial sphincter, periurethral bulking injections)
Urethral obstruction	Urge/overflow¶	1. Conservative methods (including adjustment of fluid excretion, bladder retraining/prompted voiding) if hydronephrosis, recurrent symptomatic UTI, and gross hematuria have been excluded 2. α-Adrenergic antagonist 3. Also consider adding a bladder relaxant if DO coexists, PVR is small, and surgery not desired/feasible; *monitor PVR!* 4. Finasteride, if not contraindicated and the patient either prefers it or is not a surgical candidate 5. Surgery (incision, prostatectomy) is an effective alternative before or after these steps
Underactive detrusor	Overflow	1. Decompress for at least several days (the larger the PVR, the longer should be the decompression [up to a month]) and then perform a voiding trial 2. Exclude urethral obstruction if this has not already been done 3. If cannot void or PVR remains large, try augmented voiding techniques‖ 4. ± α-Adrenergic antagonist, but only if some voiding possible; bethanechol *rarely* useful 5. If fails, or voiding is not possible, intermittent or indwelling catheterization‡

*These treatments should be initiated only after adequate toilet access has been ensured, contributing conditions have been treated (e.g., atrophic vaginitis, UTI, fecal impaction, heart failure), fluid management has been optimized, and unnecessary or exacerbating medications have been addressed. For additional details, see text.

†*Urge:* Leakage in the absence of stress maneuvers and urinary retention, usually preceded by *abrupt* onset of desire to void.
Stress: Leakage that coincides *instantaneously* with stress maneuvers, in the absence of urinary retention or detrusor contraction.
Overflow: Frequent leakage of small amounts associated with urinary retention.

‡UTI prophylaxis can be used for recurrent symptomatic UTIs, but only if catheter is not indwelling.

§May also mimic stress or overflow incontinence.

‖Augmented voiding techniques include Credé (application of suprapubic pressure) and Valsalva (straining) maneuvers, and "double" voiding. They should be performed only *after* voiding has begun.

¶Also can cause postvoid "dribbling" alone, which is treated conservatively (e.g., by sitting to void and allowing more time, "double voiding," and in men by gently "milking" the urethra after voiding).

PVR, Postvoid residual; UTI, urinary tract infection.

Adapted and updated in 2010 from Resnick NM. Voiding dysfunction and urinary incontinence. In: Beck JC, editor. Geriatric review syllabus. New York: American Geriatrics Society; 1991. p. 141–54.

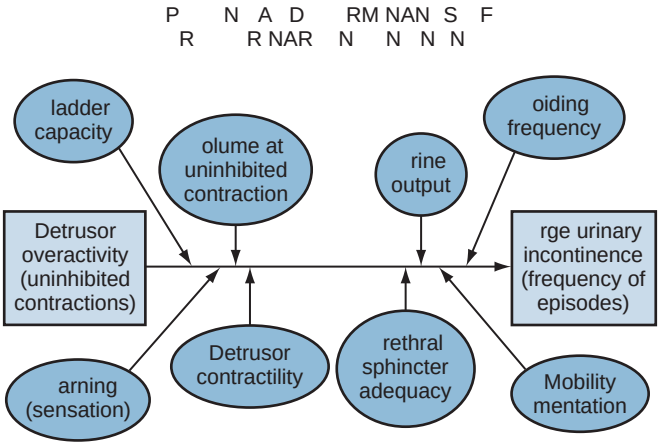

Figure 76–4. Factors that determine whether detrusor overactivity, found in nearly half of *continent* older adults, will be associated with urge incontinence and, if so, the frequency of the related leakage. (Data from Miller KL, DuBeau CE, Bergmann M, et al. Quest for a detrusor overactivity index. J Urol 2002;167:578–85; Rosenberg LJ, Griffiths DJ, Resnick NM. Factors that distinguish continent from incontinent older adults with detrusor overactivity. J Urol 2005;174:1868–72.)

excretion (see Fig. 76–3) **or providing a bedside commode or urinal are often successful. If not, the cornerstone of treatment is behavioral therapy, which can be effective and avoids drug side effects.** Some evidence suggests that it also may be more durable than drug therapy (Kafri et al, 2008). If the patient can cooperate, bladder training regimens will extend the voiding interval (Fantl et al, 1991; Burgio et al, 1998; Berghmans et al, 2000; Payne, 2000; Burgio et al, 2002). For instance, if the voiding record documents incontinence when the interval exceeds 3 hours, the patient is instructed to void every 2 hours and suppress urgency in between. Once dry, the patient can extend the interval by half an hour, and repeat the process until a satisfactory result or continence is achieved. Patients need not follow this regimen at night, because nighttime improvement parallels daytime success (Johnson et al, 2005). Biofeedback may be added (Berghmans et al, 2000), but its marginal benefit is unclear (Resnick, 1998; Burgio et al, 2002; Wilson et al, 2005; Shamliyan et al, 2008; Hartmann et al, 2009).

For cognitively impaired patients, "prompted voiding" is used (Fantl et al, 1996; Tannenbaum and DuBeau, 2004). Asked every 2 hours whether they need to void, patients are escorted to the toilet if the response is affirmative. Positive verbal reinforcement is employed, and negative comments are avoided. Prompted voiding reduces incontinence frequency in nursing homes by roughly 50%, and leakage can be virtually eliminated during daytime hours in one third of residents (Hu et al, 1989; Engel et al, 1990; Schnelle, 1990; Fink et al, 2008). The latter group can be identified within three days. When prompted *hourly* to void, they urinate into a toilet or commode more than two thirds of the time that they indicate the need to do so, or they become continent on more than 80% of checks. Response is maintained when the prompting interval is increased to two hours. Half of the remaining patients also improve with prompting, but they are still wet more than once during the daytime. For the quarter of patients who do not respond to prompting at baseline, little benefit is obtained by further prompting. Importantly, response does not correlate with the degree of dementia. In addition, these results were obtained without drugs, and urodynamic evaluations were not performed (Schnelle, 1990; Ouslander et al, 1995). Two additional studies found that adding oxybutynin or tolterodine improved results still further (Ouslander et al, 2001b; Fink et al, 2008).

The voiding record also can be helpful if it reveals that nocturnal incontinence correlates with nocturnal diuresis. If due to systolic congestive heart failure, it should improve with diuretic therapy. If due to obstructive sleep apnea, it may respond to continuous positive airway pressure (Guilleminault et al, 2004). If due to peripheral edema in the absence of heart failure and hypoalbuminemia (i.e., venous insufficiency), it should respond to pressure gradient stockings. If not associated with peripheral edema, it may respond to alteration of the pattern of fluid intake or to administration of a rapidly acting diuretic in the late afternoon or early evening (Pedersen and Johansen, 1988; Reynard et al, 1998). For patients with DHIC, whose voiding record and PVR suggest that involuntary detrusor contractions are provoked only at high bladder volume, augmented voiding techniques or catheterization at bedtime will remove the residual urine, thereby increasing functional bladder capacity and restoring both continence and sleep.

Drugs may augment behavioral intervention but do not supplant it, because they generally do not abolish involuntary detrusor contractions. Moreover, combining the two interventions generally improves outcome (Burgio et al, 2000; Mattiasson et al, 2003; Alhasso et al, 2006; Burgio et al, 2008). Timed toileting or bladder retraining in conjunction with a bladder relaxant is especially useful for older adults who have little warning before detrusor contraction (Wagg and Malone-Lee, 1998).

There are few data on comparative efficacy or toxicity of standard incontinence drugs in the elderly, but available **studies show similar efficacy for most agents,** except flavoxate, which fares poorly in controlled trials; (Fantl et al, 1996; Andersson et al, 2009a; Hartmann et al, 2009) no controlled data are available for hyoscyamine in any adult age group.

Data regarding use in the elderly are most extensive for oxybutynin and tolterodine. This includes dozens of trials that have included the elderly, several that have stratified results by age, and several that have focused exclusively on older adults, including patients who were frail and/or reside in nursing homes (Zinner et al, 2002; Ouslander, 2004; Sand et al, 2004; Sand et al, 2006; Lackner et al, 2008; Andersson et al, 2009a; DuBeau et al, 2009; Griebling et al, 2009; Hartmann et al, 2009). Such trials have established that these agents are likely as effective for improving incontinence and quality of life in older adults as they are in younger individuals and, especially in lower doses, as tolerable. **Thus oxybutynin and tolterodine should be considered first-line pharmacotherapy in this population.** As for any drug used in older adults, **therapy should start with a low dose that is increased slowly,** consistent with the agent's pharmacokinetics and pharmacodynamics in older patients. **Given the marked variability, however, dose escalation should continue until either a successful end point is reached or an intolerable side effect is encountered.** Experience suggests that for oxybutynin IR, most older adults will respond best to 2.5 mg 3 to 4 times daily; for oxybutynin ER, 5 to 15 mg is optimal. At larger doses, side effects increase much more than therapeutic response. Immediate release oxybutynin, which has a short half-life, can be employed prophylactically if incontinence occurs at predictable times. Intravesical instillation of these agents is also effective in younger patients, but the need for self-catheterization makes this strategy less useful in the elderly.

The only currently used agents that have been evaluated in the nursing home setting are the immediate release formulations of tolterodine (1 to 2 mg twice daily) and oxybutynin (2.5 mg 3 to 4 times daily). Both have been evaluated during daytime hours when staff is available (7 AM to 7 PM). Overall, the reported reduction in leakage frequency is roughly 25%; roughly one third of such patients experience a decrease of at least 33%, and about 10% become continent during that time period (Ouslander et al, 2001b; DuBeau et al, 2009).

Antimuscarinic agents used to treat UI can induce confusion in older adults, but the incidence is rare, both in trials and in practice, and the very small risk should not preclude prescribing them for older adults, even those who are frail and/or cognitively impaired. There is justifiable concern about prescribing anticholinergic drugs in the elderly. CNS levels of acetylcholine decline with age and decline still further in the presence of many diseases. Many drugs prescribed for the elderly have anticholinergic properties, and anticholinergic agents are one of the most common causes of delirium in this age group, especially among individuals with preexisting cognitive, sensory, affective, or functional impairment. In addition, all currently-available agents used for incontinence either require metabolism by the hepatic cytochrome P450 system and/or renal excretion. Each of these functions declines with age and can be further impaired by other drugs and diseases.

Theoretical arguments have been marshaled for using one antimuscarinic over another. These are largely based on the drug's characteristics, including muscarinic subtype affinity, lipophilicity, polarity, molecular size, protein binding, drug half-life, and active and passive transport across the blood-brain barrier. Also cited are experimental studies that observed a short-term impact on some components of detailed neuropsychological testing (Klausner and Steers, 2007; Kay and Ebinger, 2008), when continent volunteers were given doses of oxybutynin that are likely too high for older adults.

Yet understanding of the role and importance of CNS muscarinic subtypes in humans is still limited, and the blood brain barrier can be compromised by age and other drugs, as well as by a host of diseases that are common in the elderly, including diabetes, Alzheimer disease, stroke, Parkinson disease, and trauma (Klausner and Steers, 2007; Kay and Ebinger, 2008). The resulting permeability changes may dwarf the differences observed in experiments that involved younger and healthier elderly subjects. In addition, neuropsychologic impairments observed in older volunteers have generally been mild, and the subjects have been unaware of them, making it difficult to assess their relevance. Because the studies to date also have been short term, have been conducted in artificial conditions, and have used high doses of oxybutynin, it is impossible to know whether such effects would persist with chronic treatment. It is also worth noting that even darifenacin, which is widely marketed as being free of such effects, has been associated with significantly slowed reaction times in the Divided Attention Test (Kay et al, 2006), which could potentially predispose to problems in tasks that require such attention, such as driving and walking without falling.

Moreover, after decades of widespread use, evidence of clinical cognitive impairment still comprises only a handful of case reports, and clinical trials—which have involved relatively large numbers of older individuals—have observed only rare instances of drug-associated cognitive impairment (Tsao and Heilman, 2003; Andersson, 2004; Ouslander, 2004). For instance, analysis of the OPERA trial, which included approximately 120 patients over age 75 years, disclosed only 1 of 390 patients on oxybutynin 10 mg/day ER who reported confusion, and it was judged "mild" because it did not interfere with activities or require intervention; none of the 399 patients on tolterodine 4 mg LA reported confusion (Chu et al, 2005). Another study randomized 50 cognitively impaired nursing home residents, average age 89 years, to receive extended release oxybutynin 5 mg or placebo for 4 weeks. No changes were found in cognitive test performance, nor were there any cases of delirium. Another group of 48 nursing home residents responded well to tolterodine 1 to 2 mg administered twice daily in an 8-week trial. Side effects were minimal, and only 1 patient experienced worsening of baseline confusion (Ouslander et al, 2001b). In summary, the risk of drug-induced cognitive impairment appears to be real but small.

There is also a theoretical concern about prescribing an anticholinergic bladder relaxant to a patient taking a cholinesterase inhibitor. Fortunately, this has not proved to be a problem in clinical practice. Although a few case reports have appeared (Siegler and Reidenberg, 2004), neither a large observational nursing home study (Sink et al, 2008) nor a recent case series of 26 demented patients (Sakakibara et al, 2005) noted a deterioration in mental status when patients were also prescribed an antimuscarinic drug for incontinence. Furthermore, in some situations, the clinician and caregiver will decide that the positive impact on the incontinence warrants continuation of both agents regardless.

Finally, there is concern that an antimuscarinic-induced increase in heart rate may be dangerous. Apart from terodiline (which was withdrawn), however, there are no data to substantiate this concern at present, although the risk cannot yet be completely excluded. Among patients with established heart disease (who are generally not taking an anticholinergic agent), increased heart rates are associated with increased mortality. However, the risk in such patients likely reflects the extent of intrinsic heart disease and/or the drugs used to treat it. Heart rate increases induced by antimuscarinics are generally less than or equal to 5 beats/minute. An increase of this magnitude is of unknown significance and, to date, has not been associated with an increased mortality rate in antimuscarinic trials. Studies have also revealed little impact on the electrocardiogram (ECG) or Q-T interval (other than with terodiline). Moreover, because vagal influence on heart rate is substantially less in older adults than in younger adults, the likelihood of inducing an increased heart rate is less, especially because the appropriate dose of an antimuscarinic is also lower in the elderly.

Newer agents include darifenacin, solifenacin, trospium, and fesoterodine. Similar to the extended-release preparations of oxybutynin and tolterodine, and the newer preparations of oxybutynin (patch and gel), each is more convenient and better tolerated than the immediate release versions of oxybutynin and tolterodine. Not surprisingly, however, data for older people taking these drugs are still limited. To date, the only controlled trial of darifenacin in older adults focused on a relatively young (mean age 72 years) and fit group. Although the group randomized to placebo was younger than the darifenacin group (31% >75 years vs. 43%), urge incontinence improved similarly in both (Chapple et al, 2007). The only controlled data of solifenacin in older adults comprises a secondary analysis of pooled Phase 3 data, which revealed efficacy and safety similar to that seen among younger enrollees (Wagg et al, 2006); however, a higher rate of adverse effects was documented in a 12-week postmarketing surveillance study, especially among patients over age 80 years who were also taking multiple other medications (Michel et al, 2008). No controlled studies of fesoterodine or trospium have yet stratified the

results by age, despite marketing for the latter agent that emphasizes its theoretical advantage in older adults as being less likely to cross the blood-brain barrier. Regardless, each agent has theoretical benefits and drawbacks for older adults; Table 76–5 notes some of the relevant caveats.

Table 76–5.

Bladder Relaxant Medications Used to Treat Urge Incontinence*

MEDICATION CLASS, NAME, AND DOSAGE	COMMENTS
Anticholinergic Agents Oxybutynin IR 7.5-20 mg daily (2.5-5 mg PO tid-qid)† Oxybutynin XL 5-30 mg daily (given once daily) Oxybutynin patch twice weekly Oxybutynin gel Tolterodine 2 mg twice daily Tolterodine LA 4 mg daily Darifenacin (7.5-15 mg qd)‡ Solifenacin (5-10 mg qd)‡§ Trospium (20 mg daily to twice daily; XL now available)§‖ Fesoterodine	These agents are now the drugs of choice for older adults. Both oxybutynin and tolterodine have proved effective for older patients in controlled trials when used continuously; less controlled data are yet available for the other agents and still less for their efficacy, side effects, and drug interactions in frail older adults. Benefits of M3 selectivity remain theoretical. Concerns re: CNS side effects of oxybutynin and tolterodine emanate primarily from rare case reports and short-term, artificial experiments and likely are overstated. Immediate release oxybutynin has a rapid onset of action and can be tried prophylactically if incontinence occurs at predictable times.
Smooth Muscle Relaxant Flavoxate 300-800 mg daily (100-200 mg PO tid-qid)	Obsolete; has not proved effective in placebo-controlled trials
Tricyclic Antidepressants¶ Imipramine 25-100 mg daily (10-25 mg PO qd-qid) (Doxepin 25-75 mg daily [10-25 mg PO qd-tid])	Older controlled trial data support their use, but they are not first choice. May be helpful in women with coexistent stress incontinence. Orthostatic hypotension often precludes their use, but a tricyclic antidepressant may be preferred for a depressed incontinent patient without risk for orthostatic hypotension. Doxepin has more anticholinergic side effects than imipramine and can cause confusion.

*Each drug should be started at the lowest dose and increased slowly until encountering maximum benefit or intolerable side effects. The highest doses are generally not required and can cause problematic side effects for older patients.

†May also be applied intravesically in patients who can use intermittent catheterization.

‡Toxicity can occur with concurrent use of potent cytochrome P450 3A4 inhibitors (e.g., amiodarone).

§Dose reduction required for creatinine clearance ≤30 mL/min (e.g., in an 85-year-old woman with serum creatinine of 1.2 who weighs 50 kg).

‖Levels may be affected by other commonly used drugs in the elderly such as digoxin or metformin, which compete for renal tubular secretion.

¶May give as single daily dose of 25-100 mg after determining the optimal dose.

CNS, central nervous system; IR, immediate release; XL and LA, extended release.

Adapted and updated in 2005 from Resnick NM. Urinary incontinence. Lancet 1995;346:94–9.

Other agents, formerly advocated for older incontinent adults, are no longer advised. Specifically, there are no appropriate trials for hyoscyamine (Roxburgh et al, 2007; Andersson et al, 2009a) and, as the active ingredient in atropine, hyoscyamine has a substantial risk of inducing confusion in older adults. Flavoxate has been not been found effective despite several controlled trials (Roxburgh et al, 2007). Calcium channel blockers, drugs long thought to be theoretically preferable for the elderly, were finally studied in a controlled trial and found to be ineffective (Naglie et al, 2002). For the incontinent and depressed older patient, nortriptyline or imipramine may be considered (amitriptyline and doxepin should not be given to older patients) (Fantl et al, 1996), but because evidence of their efficacy falls short of modern standards, they should be used only if depression has not already responded to an SSRI, there is no evidence of orthostatic hypotension, and the patient can be monitored for orthostasis and falls.

Regardless of which antimuscarinic is used, urinary retention may develop. The PVR and urine output should be monitored, especially with DHIC, in which the detrusor is already weak. Subclinical urinary retention also may develop, reducing available bladder capacity and attenuating, or even reversing, the drug's benefit. Thus if incontinence worsens as the dose is increased, the PVR should be remeasured. **Another reason for drug failure is excess fluid ingestion engendered by anticholinergic-induced xerostomia.** For patients whose incontinence defies other remedies (such as those with DHIC), inducing urinary retention and using intermittent catheterization may be viable if catheterization is feasible.

Other remedies for urge incontinence, including electrical stimulation (see Chapter 70) **and selective nerve blocks, are successful in selected situations.** However, they have not been studied adequately in the elderly, and the limited preliminary data suggest that older patients may not fare as well (Amundsen and Webster, 2002; Amundsen et al, 2005; South et al, 2007; White et al, 2009). Trials of botulinum A toxin (BoNT) intradetrusor injection have included some older adults, but only a single study has focused on older patients (White et al, 2008). In that series, symptoms in 16 of the 21 patients over age 75 improved by at least 50%. However, incontinence was not specifically reported, and patients with PVR greater than 150 mL were excluded, as were those whose bladder failed to empty completely with a detrusor contraction on urodynamic testing. Moreover, a recent randomized clinical trial (RCT) of middle-aged women (Brubaker et al, 2008), mean age 65 years, found a much higher incidence of urinary retention and UTIs than previously reported. In 2009, the Food and Drug Administration (FDA) required a black-box warning for BoNT, owing to the risk of injected toxin migrating and causing paralysis, and even death. **Thus BoNT appears promising, but given the very limited experience in older adults, the significant number who have impaired detrusor contractility, the non-feasibility of intermittent catheterization in many older patients, the risk, and the numerous remaining questions regarding optimal patient selection, dose, dilution, and injection site, BoNT is still best viewed as investigational** (Brubaker et al, 2008; DuBeau et al, 2009; Hartmann et al, 2009).

Recent studies have suggested that desmopressin is relatively safe for older adults. However, these studies have generally been short term, have included very few subjects older than age 75, have included still fewer with comorbidity or diuretic use, and have sedulously screened and monitored all subjects. Moreover, they also have enrolled *only* patients who, during a prestudy

run-in period, tolerated treatment with desmopressin, responded well to it, and did not lower their serum sodium (Weatherall, 2004). Despite these precautions, hyponatremia still developed in up to 22% of patients. Serum sodium levels decreased to less than 130 mMol/L in one fifth of these patients, almost all of whom were more than 65 years old (Abrams et al, 2002; Weatherall, 2004; Rembratt et al, 2006). More recently, a longer-term study documented the risk of hyponatremia at 6 months, even among patients who did not develop it earlier (Bae et al, 2007). Additional concerns include the fact that many older persons do not develop warning symptoms of hyponatremia, as well as recent data suggesting that even short-term desmopressin therapy can increase calcium excretion and decrease potassium excretion (Chang et al, 2007). If substantiated in longer-term studies, this effect would be problematic for older patients in whom the prevalence of both osteoporosis and renal insufficiency is considerable. Moreover, **there is little evidence that vasopressin is effective for geriatric incontinence** (Dequecker, 1965; Asplund and Aberg, 1993; Cannon et al, 1999). Thus **the high prevalence of contraindications to its use (e.g., hyponatremia, renal insufficiency, heart failure [even subclinical]), the risk of inducing serious hyponatremia with fluid retention** (Cannon et al, 1999), **the potentially adverse impact on calcium and potassium excretion** (Chang et al, 2007), **and its lack of demonstrated efficacy all suggest that desmopressin should be used to treat urge incontinence in older adults with extreme caution, if at all.**

Adjunctive measures, such as pads and special undergarments, are invaluable if incontinence proves refractory. Many types are now available, allowing the recommendation to be tailored to the individual's problem (Fader et al, 2007; Fader et al, 2008; Cottenden et al, 2009). Most are included in an illustrated catalog (National Association for Continence (NAFC), PO Box 1019, Charleston, SC 29402; www.nafc.org). For bedridden individuals, a launderable bed pad may be preferable, while for those with a stroke, a diaper or pant that can be opened using the good hand may be preferred. For ambulatory patients with large gushes of incontinence, wood pulp–containing products can be superior to ones containing polymer gel, because the gel generally cannot absorb the large amount and rapid flow, while the wood-pulp product can be doubled up if necessary. Optimal products for men and women differ because of the location of the "target zone" of the urinary loss. Finally, the choice will be influenced by patient preference, cost, and the presence of fecal incontinence.

Condom catheters are helpful for men, but they are associated with skin breakdown, bacteriuria, and decreased motivation to become dry (Ouslander and Schnelle, 1995; Cottenden et al, 2009), and they are not feasible for the older man with a small or retracted penis. External collecting devices have been devised for institutionalized women, but whether they will adhere adequately in more active women remains to be determined. **Indwelling urethral catheters are not recommended for detrusor overactivity because they usually exacerbate it.** If they must be used (e.g., to allow healing of a pressure sore), a small catheter with a small balloon is preferable to avoid leakage around the catheter; such leakage almost invariably results from bladder contractions rather than from a catheter that is too small. Increasing catheter and balloon size only aggravates the problem and may result in urethral erosion and sphincter incompetence. If spasms persist, drugs such as oxybutynin can be tried. **More potent anticholinergic agents, such as belladonna suppositories, should be avoided in the elderly.**

Stress Incontinence

Urethral hypermobility, the most common cause of stress incontinence in older women, may be improved by **weight loss** if the patient is obese, (Brown et al, 2006; Hunskaar, 2008; Subak et al, 2009) **by postural maneuvers** (Norton and Baker, 1994), **by therapy of precipitating conditions such as atrophic vaginitis or cough** (e.g., due to an ACE inhibitor), **and by insertion of a pessary** (Suarez et al, 1991; Zeitlin and Lebherz, 1992; Donnelly et al, 2004; Cottenden et al, 2009). If the voiding diary reveals that leakage is volume dependent, it also may be improved by adjusting fluid excretion and voiding intervals to keep bladder volume below this threshold. However, if the threshold is less than 150 to 200 mL, this strategy, alone, is generally not sufficient.
