Burnstock's observation (1999) that ATP has a role in mechanosensory transduction by the epithelial lining of hollow viscus organs such as bladder has been followed up by Sun and colleagues (2001). Stretched epithelial cells lining hollow organs release ATP, which acts on purinergic nociceptive receptors on subepithelial sensory nerve terminals. ATP levels were significantly elevated in the urine of PBS/IC patients, and the stretch-activated release of ATP was augmented in IC urothelium.

Neurogenic inflammation may be the cause of some cases of BPS or may be the result of other initiating etiologic events. It is not incompatible with the central role of the mast cell or with the leaky epithelium theory. It conceivably could result in the appearance of autoimmune phenomena or result from an episode of infection. The central nervous system may also be implicated in dysregulation of the pelvic floor, resulting in chronic pelvic pain and contributing to IC (Zermann et al, 1999) and perhaps in the rare cases of IC that chronologically seem to relate to trauma or pelvic surgery (Zermann et al, 1998). It is an etiologic theory that provides fertile ground for new treatment possibilities.

Key Points: Neurogenic Inflammation

- Numerous studies indicate increased sympathetic activity in BPS/IC. Activation of sensory pain fibers is known to trigger neurogenic inflammation through release of neuropeptides such as substance P, neurokinin A, and calcitonin gene–related protein.
- Neurogenic inflammation may be the cause of some cases of BPS/IC. Chronic neuropathic pain may continue after the resolution of tissue damage and persist on the basis of a maladaptive mechanism.

Pelvic Organ Cross-Sensitization

Clinical observations of viscerovisceral referred pain in patients with gastrointestinal and genitourinary disorders suggest an overlap of neurohumoral mechanisms underlying both bowel and urinary bladder dysfunctions. Close proximity of visceral organs within the abdominal cavity complicates identification of the exact source of chronic pelvic pain, where it originates, and how it relocates with time. Cross-sensitization among pelvic structures may contribute to chronic pelvic pain of unknown etiology and involves convergent neural pathways of noxious stimulus transmission from two or more organs. **Inflammation, nerve injury, ischemia, peripheral hyperalgesia, metabolic disorders, and other pathologic conditions can dramatically alter the function of directly affected pelvic structures as well as organs located next to a damaged domain** (Malykhina, 2007). It has been demonstrated in a rat model that acute colitis can sensitize lumbosacral spinal neurons receiving input from the urinary bladder (Qin et al, 2008). Acute colitis and acute cystitis in the rat model can each cross-sensitize the bladder and colon, respectively (Pezzone et al, 2005).

It is thought that chronic widespread pain in chronic fatigue syndrome and fibromyalgia (disorders associated with BPS/IC in many patients) can be a consequence of central sensitization. Central sensitization is an increased central neuronal responsiveness and causes hyperalgesia, allodynia, and referred pain and hyperalgesia across multiple spinal segments, leading to chronic widespread pain. Triggers include windup or temporal summation, dysregulated descending inhibitory pathways, and upregulated facilitatory modulation. Windup or temporal summation is the result of repetitive noxious stimuli, leading to an increase in electrical discharges in the dorsal horn. Inhibitory modulation can be impaired by abnormalities in the central nervous system, and the facilitatory pain pathways can be stimulated by certain behavioral and cognitive factors (Meeus and Nijs, 2007).

It is possible that a combination of central sensitization and pelvic cross talk may account for the association of BPS/IC with bowel symptoms in some patients and the use of dietary alterations for managing the severity of BPS symptoms. Relatively minor gut stimuli, which otherwise cause no symptoms, could exacerbate established, bladder-driven pelvic pain, because even slight increases of inputs from a second site like the gut might lead to a sum of inputs that is considerably elevated above a threshold necessary to induce pain (Rudick et al, 2007; Klumpp and Rudick, 2008). Central pain amplification might also account for the increased startle responses described in female BPS/IC patients in the context of a threat of abdominal pain (Twiss et al, 2009).

Key Points: Sensitization of Neural Pathways

- Cross-sensitization among pelvic structures may contribute to chronic pelvic pain syndromes.
- Neural pathways from two or more organs, one or both of which are carrying noxious stimuli transmissions, may converge. Theoretically this could lead to alteration of the function of not only the directly affected pelvic structures but also organs located nearby.

Nitric Oxide Metabolism

Regulation of urinary NOS activity has been proposed to be of importance for immunologic responses in BPS. The oral administration of L-arginine, the substrate for nitric oxide production (Moncada and Higgs, 1993) has been shown to increase nitric oxide–related enzymes and metabolites in the urine of patients with BPS (Smith et al, 1996). It has been reported that differences in nitric oxide evaporation between ulcerative and nonulcerative BPS allows for subtyping of cases meeting the NIDDK criteria. This could potentially replace cystoscopy as a tool for identifying ulcerative BPS/IC (Logadottir et al, 2004). Increased levels of endogenously formed nitric oxide correspond to increased iNOS in mRNA expression and protein levels in BPS patients. iNOS has been found to be localized to the urothelium and has also been found in macrophages in the bladder mucosa. Whether high levels of endogenously formed nitric oxide are a part of the pathogenesis in BPS/IC and whether it has a protective or damaging role remain to be elucidated (Koskela et al, 2008).

Urine Abnormalities

Current theories of pathogenesis generally involve access of a component of urine to the interstices of the bladder wall, resulting in an inflammatory response induced by toxic, allergic, or immunologic means. The substance in the urine may be a naturally occurring one—a substance that acts as an initiator only in particularly susceptible individuals—or may act like a true toxin, gaining access to the urine by a variety of mechanisms or metabolic pathways (Wein and Broderick, 1994). Clemmensen and colleagues (1988) noted that 8 of 11 IC patients had positive skin reactions to patch tests with their own urine. Immediate reactions were not observed, and the histology suggested a toxic rather than an allergic reaction. Lynes and associates (1990b) were unable to find a urinary myotropic substance unique to IC patients. The San Diego group found IC urine to result in higher cell death of cultured transitional cells than normal urine, suggesting a toxic compound in the urine of some IC patients (Parsons and Stein, 1990). They identified heat-labile, cationic components of low molecular weight that bind to heparin and that when separated from the bulk of urinary wastes are cytotoxic to urothelial cells as well as underlying smooth muscle cells (Parsons et al, 2000). They reported a 12% increase in 72-kD stress protein in cells treated with urine from IC patients compared with controls (Ito et al, 1998).

Others have not been able to demonstrate in-vitro cytotoxicity (Beier-Holgersen et al, 1994) or immunohistochemical changes in the nociceptive centers in the spinal cord or bladder wall when IC urine was compared with control urine (Baykara et al, 2003). Efforts to induce an IC-like picture in the rabbit bladder from exposure to urine of IC patients have failed to demonstrate conclusive changes (Perzin et al, 1991; Ruggieri et al, 1993; Kohn et al, 1998). Increased levels of soluble mediators associated with activation of sensory neurons and/or mast cells have been found in the urine of both IC and bladder cancer patients (Okragly et al, 1999).

Circumstantial evidence for the toxicity of IC urine is suggested by the failure of substitution cystoplasty and continent diversions in some of these patients because of the development of pain or contraction of the bowel segment over time (Nielsen et al, 1990; Baskin and Tanagho, 1992; Trinka et al, 1993; Lotenfoe et al, 1995) and the histologic findings similar to IC found to occur in

bowel used to augment the small-capacity IC bladder (Singh and Thomas, 1996; McGuire et al, 1973). Intestinal mucosa in contact with urine undergoes progressive changes as long as 3 years after surgery, and the significance of the histologic IC-like changes has been questioned (MacDermott et al, 1990; Davidsson et al, 1996).

The Role of Genetics in BPS

Warren and colleagues (2001) report findings from a small cohort of twins that demonstrated a greater concordance of BPS among monozygotic than among dizygotic twins. This finding suggested that there could be a genetic susceptibility to BPS. A later study by the same research group (Warren et al, 2004) suggested that adult female first-degree relatives of patients with BPS may have a prevalence of IC 17 times that found in the general population. This coupled with the previously reported twin data suggests, but does not prove, a genetic component adds to the susceptibility for BPS.

The report by Weissman and associates (2004) of the increased frequency of BPS in patients and their first-degree relatives with panic disorder and other seemingly disparate disorders has suggested that there is a familial syndrome consisting of BPS and other disorders of possible autonomic or neuromuscular dysfunction. More recent studies by the same group (Talati et al, 2008) from a case-control study suggested that this syndrome might include other anxiety disorders as well and that families with and without this collection of symptoms were genetically distinguishable on chromosome 13.

Gene expression profiles in cultured IC cells have been investigated and compared with controls (Erickson et al, 2008a). Few differences were appreciated, indicating that rather than being genetically based the abnormal urothelium in BPS/IC may be due to post-translational changes and/or to the bladder environment. It has been suggested that epigenetic reprogramming mechanisms in the bladder may provide an explanation for uroepithelial, mast cell, and nerve cell abnormalities in BPS/IC, as well as propagation of this altered state in the absence of the signal that may have triggered it (Elgavish, 2009). Viewing medically unexplained symptoms from the perspective of underlying developmental influences involving epigenetic modulation of gene expression that affect function of a variety of organs based on familial predispositions rather than from the traditional viewpoint of isolated organ-originating diseases may open up new areas of investigation for this class of "functional" disorders (Buffington, 2009).

Other Potential Causes

Various other etiologic theories have been proposed (Ratliff et al, 1994), but none has received much scientific support. Voiding almost hourly, always having to be aware of how far the nearest restroom facilities are, and suffering constant pain would be expected to lead to psychological stress. However, could there be individual differences in the propensity to develop IC that result from a dysregulation of anxiety and mood (Nesse, 1999; Bodden-Heidrich, 2004)? **There are no data currently to suggest that stress *initiates* the chronic syndrome of BPS/IC, although it certainly can increase symptom severity** (Lutgendorf et al, 2000). Cats restricted to indoor living are five times more likely to have urinary problems as cats allowed outdoors (Buffington, 2002). Female patients with PBS/IC have been shown to have increased heart rate at baseline and throughout a laboratory mental stress challenge but did not demonstrate greater autonomic reactivity to stress (Lutgendorf et al, 2004). Until stress can be shown to produce PBS/IC de novo in humans, it is just as reasonable to speculate that the stress is a result of the syndrome as a primary cause of it.

Speculation that abnormalities in or obstruction of lymphatics or vascular structures is causative has never been borne out. The fact that some of these patients have had a hysterectomy probably relates more to the attempt of the physician to treat chronic pelvic pain than a postsurgical change causing the IC syndrome (Chung, 2004).

The knowledge that there is at least a 5:1 female-to-male preponderance immediately makes the role of the hormonal milieu potentially important (Bjorling and Wang, 2001). Paradoxically, it is known that estrogens can control hematuria in hemorrhagic cystitis, perhaps by decreasing the fragility of the mucosal microvasculature of the bladder (Liu et al, 1990). Estradiol augments while the estrogen receptor blocker tamoxifen inhibits mast cell secretion (Vliagoftis et al, 1992). Bladder mast cells express high-affinity estrogen receptors, and there is a higher number of such cells present in patients with IC compared with controls. Although this may help explain why IC is so common in women, the hormonal role can only account for the propensity of IC to occur in females and not be the ultimate etiology.

Pelvic floor dysfunction has been associated with PBS/IC for many years (Schmidt and Vapnek, 1991), and uncontrolled trials suggest that treatment of this disorder can be effective in ameliorating symptoms (Lilius et al, 1973; Doggweiler-Wiygul et al, 2001, 2002; Holzberg et al, 2001; Weiss, 2001; Oyama et al, 2004). Speculation that abnormalities of the pelvic floor muscular function may contribute to the cause of some cases of CPPS in men are well accepted (Segura et al, 1979; Schmidt and Vapnek, 1991; Zermann et al, 1999) and a similar case might be made for patients with PBS/IC, although scientific support for a direct etiologic relationship is lacking.

One can understand the complexity of BPS/IC by looking at the myriad theories of etiology and the associated disorders that have been described. Complex functional disorders with patterns of comorbidity, where there is overlap of what had once been regarded as independent syndromes, appear to fall outside the biomedical framework. It has been said that they "fully escape the profession's divided and divisive grip. By their mere existence, they challenge the medical community's view of the body, their understanding of what it is to be human and question whether present approaches to obtaining knowledge are adequate for helping people who suffer" (Kirkengen and Ulvestad, 2007).

Key Points: Etiology

- Both stress and pelvic floor dysfunction can contribute to BPS symptom severity and may be targets for treatment. Whether they can be contributing initiators of the syndrome complex is unclear at this time. The 5:1 female preponderance suggests hormonal involvement in etiology.

PATHOLOGY

Please see the Expert Consult website for more discussion of this topic.

Key Points: Pathology

- The role of histopathology is primarily to exclude other possible diagnoses that might be responsible for the symptoms.
- There is no histology pathognomonic of BPS, and one cannot make the diagnosis on pathology alone in the absence of the cardinal symptoms.
- Completely normal-appearing bladder biopsy specimens in symptomatic patients are not uncommon.

DIAGNOSIS

BPS/IC can be considered a functional pain disorder (Mayer and Bushnell, 2009) and one of the chronic visceral pain syndromes, affecting the urogenital and rectal area, many of which are well described but poorly understood (Wesselmann et al, 1997; Wesselmann, 2001). These include vulvodynia, orchialgia, penile pain, perineal pain, and rectal pain. In men, many of the entities have now been included in the rubric of CPPS and can be difficult to distinguish from BPS/IC (Hakenberg and Wirth, 2002; Forrest and Schmidt, 2004). The diagnosis of BPS/IC is by its very nature based on the definition. In the past this was by default the symptom criteria enumerated by the NIDDK (Hanno et al, 1999a; Hanno et al, 1999b) (see Table 12–2). **It has now morphed largely into a diagnosis of chronic pain, pressure, or discomfort associated with the bladder, usually accompanied by urinary frequency in the absence of any identifiable cause** (Hanno et al, 2005a, 2005b). Diagnostic approaches vary widely, and **general agreement on a diagnostic algorithm remains a future goal** (Chai, 2002; Nordling, 2004; Nordling et al, 2004). A current algorithm is illustrated in Figure 12–9. The disorder can be very difficult to diagnose until symptoms become well established, unless one has a high level of suspicion (Porru et al, 2004). **Frequency and pelvic pain of long duration perceived to be related to the bladder unrelated to other known causes establishes a working diagnosis.** It is often difficult for patients to distinguish between sensations of pain, pressure, discomfort, and urgency. **Ask a patient why he or she voids hourly, and it is usually because of discomfort rather than convenience.** Heavy reliance on other aspects of the NIDDK research criteria will result in underdiagnosing more than half of the cases (Hanno et al, 1999b). **IC symptom scales** (O'Leary et al, 1997; Goin et al, 1998; Moldwin and Kushner, 2004), **such as the American Urological Association's symptom score for BPH, are designed to evaluate the severity of symptomatology and monitor disease progression or regression with or without treatment. They have not been validated as diagnostic criteria.**

One must rule out infection and less common conditions including but not limited to carcinoma (Utz and Zincke, 1974; Tissot et al, 2004), eosinophilic cystitis (Hellstrom et al, 1979; Sidh et al, 1980; Littleton et al, 1982; Aubert et al, 1983; Abramov et al, 2004), **malakoplakia, schistosomiasis, scleroderma** (Batra and Hanno, 1997), **and detrusor endometriosis** (Sircus et al, 1988; Price et al, 1996). In men younger than the age of 50, video-urodynamics are useful to rule out voiding dysfunction resulting from vesical neck obstruction, "pseudo" dyssynergia, or impaired contractility (Kaplan et al, 1996). Musculoskeletal dysfunction may also play a role in causation or increasing symptom severity and should be looked for in the diagnostic phase of evaluation (Prendergast and Weiss, 2003). Reports of successful treatment of IC symptoms by laparoscopic adhesiolysis (Chen et al, 1997) or urethral diverticulum excision (Daneshgari et al, 1999) give credence to the fact that IC is a diagnosis of exclusion. Many drugs including cyclophosphamide, aspirin, nonsteroidal anti-inflammatory agents, and allopurinol have caused a nonbacterial cystitis that resolves with drug withdrawal (Bramble and Morley 1997; Gheyi et al, 1999).

Various gynecologic problems can mimic the pain of IC (Kohli et al,1997). The pelvic congestion syndrome, a condition of the reproductive years and equally prevalent among parous and nulliparous women, is manifest by shifting location of pain, deep dyspareunia and postcoital pain, and exacerbation of pain after prolonged standing (Stones, 2003). Similar symptoms can be seen in BPS/IC. Other gynecologic disorders can include pelvic

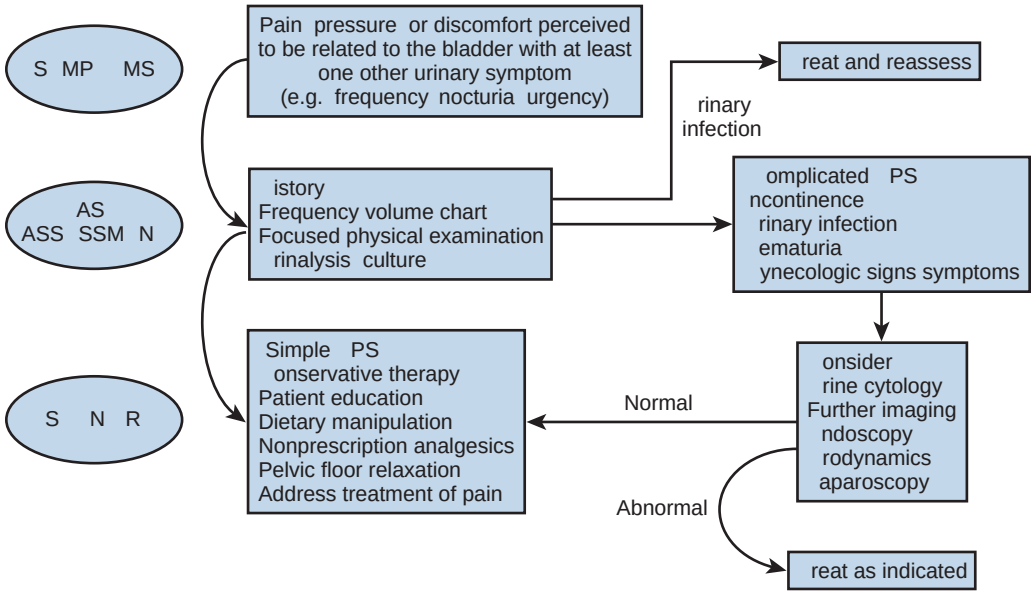

Figure 12–9. Diagnostic algorithm for bladder pain syndrome (BPS).

tumors, vaginal atrophy, vulvodynia, vestibulitis, pelvic relaxation, pelvic adhesive disease, levator ani myalgia, and undiagnosed chronic pelvic pain (Myers and Aguilar, 2002). Pelvic surgery is more common in women with a diagnosis of BPS/IC than in a control population as studied by Ingber and associates (2008). In this series the diagnosis of BPS/IC occurred 1 to 5 years after hysterectomy in most patients, suggesting that pelvic surgery may be performed for pain related to undiagnosed BPS.

Endometriosis can be a cause of pelvic pain (Evans et al, 2007), an idea largely based on findings of two randomized, placebo-controlled studies of laser laparoscopy (Sutton et al, 1995, 1997; Abbott et al, 2004). Nevertheless, it is disconcerting that any claim linking endometriosis with pain fails to account for the common experience that identical lesions can be found in symptomatic and asymptomatic women (Vercellini, 1997). Between 2% and 43% of asymptomatic women are found to have endometriosis (Moen and Stokstad, 2002). Furthermore, there does not appear to be any risk for patients with asymptomatic mild endometriosis to develop symptoms even after more than 10 years (Moen and Stokstad, 2002). Although 70% to 90% of women with chronic pelvic pain have endometriosis, this does not definitively establish causation (Gambone et al, 2002). For these reasons, laparoscopy, which is not considered essential before initiating hormonal treatment of endometriosis (Ling, 1999; Howard, 2003b), should not be considered a part of any routine evaluation of BPS/IC unless an experienced practitioner believes it is likely to benefit the patient.

A presumptive diagnosis can be made merely by ruling out known causes of frequency and pain/urgency in a patient with compatible chronic symptoms (Table 12–8). Often this will involve a complete history, physical examination, appropriate cultures, and local cystoscopy. **In the absence of microhematuria the value of cytology is questionable** (Duldulao et al, 1997) **but something we still consider important, especially if bladder carcinoma in-situ is a serious possibility, as in patients older than 40 and those with a smoking history.** The report of a large series of BPS/IC patients indicating that 1% actually had transitional cell carcinoma and that four of the six cancer patients did not have microhematuria, provides evidence for the justification of local cystoscopic examination (Tissot et al, 2004).

It must be recognized that one may sacrifice a certain level of confidence in the diagnosis without the supporting evidence that can be furnished by additional studies. In a long-term illness such as IC, many patients and physicians ultimately want to base a diagnosis and treatment plan on the most complete data set possible (Rovner and Wein, 1999). **A more thorough evaluation for IC would also include a urodynamic evaluation and cystoscopy under anesthesia with hydrodistention of the bladder** (Hanno et al, 1990; Hanno, 1994b). **Bladder biopsy is indicated only if necessary to rule out other disorders that might be suggested by the cystoscopic appearance. Cystoscopy under anesthesia with bladder distention has been important in the identification of a Hunner lesion.** Experimental data suggest that measurement of increased nitric oxide levels in the bladder can also accurately identify those with ulcerative disease (Logadottir et al, 2004). The diagnosis is generally subject to more rigorous testing in Europe (Fall et al, 2008) than in North America, where symptoms in the absence of other obvious causes seems to be the gold standard (Nordling 2004; Nordling et al, 2004; Hanno et al, 2005a). Japanese guidelines are described in Table 12–9.

Although sensations reported during cystometric bladder filling are subjective, they have a normal pattern and may be helpful in

Table 12–8.

International Consultation on Incontinence 2009: Diagnosis of Bladder Pain Syndrome

History

A general thorough medical history should emphasize:

1. Previous pelvic surgery
2. Previous urinary tract infection
3. Bladder history and urologic diseases
4. Location of pelvic pain and relationship to bladder filling/emptying
5. Characteristics, onset, correlation of pain with other events
6. Previous pelvic irradiation
7. Autoimmune diseases
8. Associated syndromes (irritable bowel, fibromyalgia, chronic fatigue)

Physical Examination

The physical examination should emphasize:

1. Standing: kyphosis, scars, hernia
2. Supine: abduction/adduction of hips, hyperesthetic areas
3. Females: Vaginal examination with pain mapping of vulvar region, vaginal palpation for tenderness of the bladder, urethra, levator and adductor muscles of the pelvic floor
4. Males: digital rectal examination with pain mapping of the scrotal-anal region and palpation of tenderness of the bladder, prostate, levator and adductor muscles of the pelvic floor and scrotal contents

Laboratory Testing

1. Urinalysis
2. Urine culture
3. Urine cytology in risk groups

Symptom Evaluation

1. Voiding diary
2. O'Leary-Sant Symptom and Problem Score
3. Visual analog scale for pain in the last 24 hours

Urodynamics (optional)

Cystoscopy with or without hydrodistention under anesthesia (optional)

Bladder biopsy (optional)

From Hanno P, Lin AT, Nordling J, et al. Bladder pain syndrome. In: Abrams P, Cardozo L, Khoury S, Wein A, editors. Incontinence. Paris: Health Publication Ltd.; 2009. p. 1459–518.

Recommended Tests for Diagnosis of Interstitial Cystitis

MANDATORY	RECOMMENDED	OPTIONAL
Clinical history	Urine culture	Ultrasonography
Physical examination	Urine cytology	Urodynamic study
Urinalysis	Symptom scores	Radiographic examination
	Quality of life scores	Potassium test
	Frequency-volume chart	Biopsy
	Residual urine measurement	
	Prostate specific antigen	
	Cystoscopy	
	Hydrodistention

distinguishing a bladder pathologic process (Wyndaele, 1998). Many dispute the need for urodynamic study (Cameron and Gajewski, 2009), but Siroky (1994) and Kim and colleagues (2009b) argue that not only can it help to assess bladder compliance and sensation and reproduce the patient's symptoms during bladder filling but also it can help to rule out detrusor overactivity. Women with pain on filling can be indistinguishable from those with detrusor overactivity in their perception of bladder fullness (Creighton et al, 1991). **One should be wary of diagnosing IC in patients with discrete, involuntary bladder contractions whose symptoms respond to antimuscarinic therapy. The two problems coexist in 15% to 19% of patients** (Gajewski and Awad, 1997; Kirkemo et al, 1997), **but the pathophysiology is possibly very different.** Patients who respond to anticholinergic medication tend not to respond to standard therapy for IC (Perez-Marrero et al, 1987). If involuntary contractions are noted and the patient's symptoms of frequency and pain continue despite treatment for overactive bladder, one is on firmer ground in considering a diagnosis of IC. Complex cases may benefit from full video-urodynamic studies (Carlson et al, 2001).

Cystometry in conscious IC patients generally demonstrates normal function, the exception being decreased bladder capacity and hypersensitivity. Pain on bladder filling that reproduces the patient's symptoms is very suggestive of IC. **Bladder compliance in patients with IC is normal, because hypersensitivity would prevent the bladder from filling to the point of noncompliance** (Siroky, 1994; Rovner and Wein, 1999). The possible addition of including a second cystometrogram after instillation of intravesical lidocaine to help to determine if pain is bladder related is a provocative one worth further study (Teichman et al, 1997). It is not uncommon to find evidence of outlet obstruction in BPS/IC, presumably related to associated pelvic floor dysfunction (Cameron and Gajewski, 2009).

Long before it was considered a diagnostic tool, cystoscopy with hydrodistention of the bladder was used as a therapeutic modality for IC (Bumpus, 1930). **When done under anesthesia this procedure allows for sufficient distention of the bladder to afford visualization of either glomerulations or Hunner ulcers** (Figs. 12–10 and 12–11). **After filling to 80 cm H_2O for 1 to 2 minutes, the bladder is drained and refilled. The terminal portion of the effluent is often tinged with blood. Reinspection will reveal the pinpoint petechial hemorrhages that develop throughout the bladder after distention and are not usually seen after examination without anesthesia** (Nigro and Wein, 1997).

Glomerulations are not specific for IC (Erickson, 1995; Waxman et al, 1998), and only when seen in conjunction with the clinical criteria of pain and frequency can the finding of glomerulations be viewed as potentially significant. **Glomerulations can be seen after radiation therapy, in patients with carcinoma, after exposure to toxic chemicals or chemotherapeutic agents, and often in patients on dialysis or after urinary diversion when the bladder has not filled for prolonged periods.** They have been reported in the majority of men with **prostate pain syndromes,** begging the question as to whether CPPS in men is closely linked with IC (Berger et al, 1998). They are observed in 20% of men undergoing transurethral prostatectomy for lower urinary tract symptoms (Furuya et al, 2007). We have speculated that they may simply reflect the response of the bladder to distention after a prolonged period of chronic underfilling because of sensory urgency rather than result from a primary pathologic process. Although the presence of a Hunner ulcer has been associated with pain and urinary urgency, neither the findings of bloody irrigating fluid nor

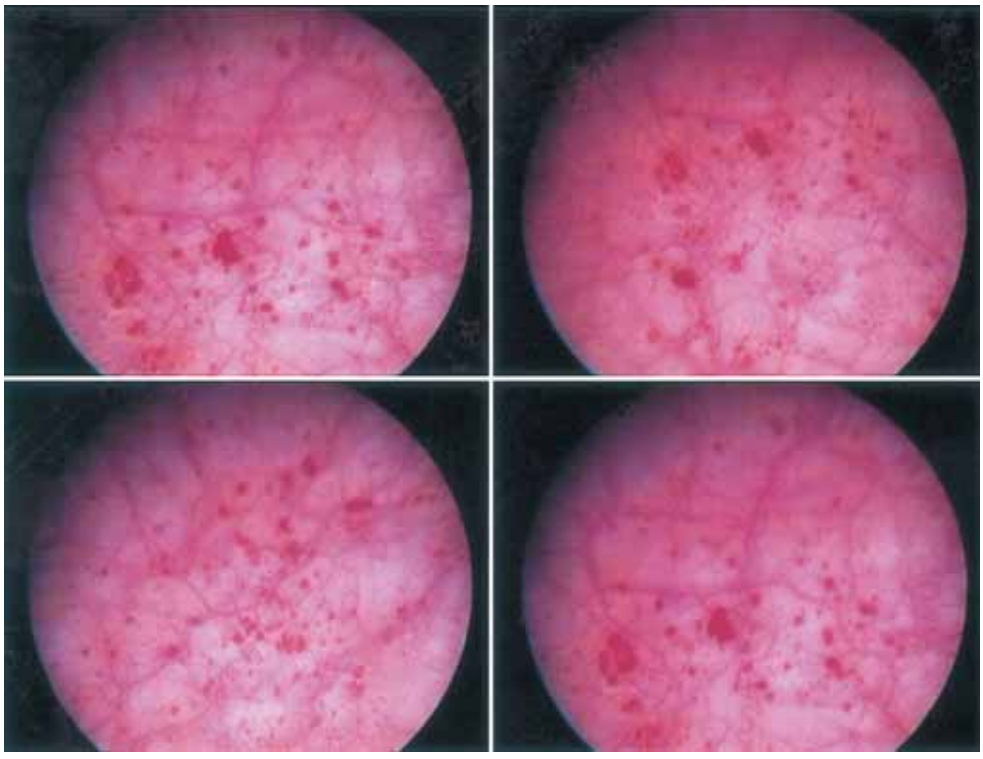

Figure 12–10. Typical appearance of glomerulations after bladder distention in a patient with nonulcerative bladder pain syndrome.

Figure 12–11. Typical appearance of a Hunner lesion in a patient with bladder pain syndrome before bladder distention.

glomerulations are strongly associated with any particular symptom in patients in the IC database (Messing et al, 1997).

Further confusion arises when the patient demonstrates the symptoms of IC but the cystoscopic findings under anesthesia are completely normal. This occurred in 8.7% of patients undergoing cystoscopy with hydrodistention of the bladder entered into the IC database (Messing et al, 1997). Awad and colleagues recognized this entity soon after the NIDDK research criteria had been described. They reported on a series of patients in whom the symptomatology, urodynamic evaluation, histology, and response to therapy were identical to that of IC and in whom findings on cystoscopy with hydrodistention of the bladder were normal. It was termed *idiopathic reduced bladder storage* (Awad et al, 1992). Clinical, urodynamic, and cystoscopic data strongly suggest that the presence of glomerulations is not selecting out a meaningful difference in patients with symptoms of BPS/IC (Al Hadithi et al, 2002). **The presence of glomerulations on cystoscopy under anesthesia meeting the NIDDK criteria may identify a group of patients with worse daytime frequency and nocturia and lower bladder capacity under anesthesia but does not have any relationship to biopsy findings, bladder pain, or urgency** (Erickson et al, 2005).

The Search for a Marker

What is the value of a "diagnostic test" in what is essentially a clinical syndrome defined by a symptom-complex? If a patient has chronic pain associated with the bladder usually accompanied by urinary frequency with no discernible cause, BPS/IC is diagnosed. In essence, once well-characterized pathologic entities are ruled out, the patient makes the diagnosis by relating symptoms; much like a patient with impotence makes that diagnosis. Testing for impotence may give clues as to etiology but impotence cannot be ruled out in a patient who cannot function sexually by doing a test!

This is not to say that establishment of a valid diagnostic marker would not be a major advance in our understanding of IC. Just as with phenotyping, it will be important largely to the extent that it can predict prognosis in a given group of patients, predict response to therapy in a given group of patients, and/or distinguish between BPS/IC and another possible cause of the symptom-complex that has been diagnosed. Ultimately, marker identification may enable us to stratify patients with the symptom-complex in such a way that treatments will be specific to the specific etiology (disease) the patient has. As various causes are identifiable, the diagnosis of BPS may itself become a rarity, much as what has happened to "acute urethral syndrome" (Stamm et al, 1980).

In just such an effort, numerous investigators have looked at the mast cell as a possible diagnostic marker for IC. The current standard involves detrusor muscle biopsy specimens examined with tryptase staining of 3-µm thick sections, with every seventh section used for quantification (Larsen et al, 2008). The finding of 27 mast cells/mm^3 is considered indicative of mastocytosis. The results in the past have been very contradictory; and at this time, in terms of the use of mast cell criteria in diagnosis, the issue remains moot (Kastrup et al, 1983; Feltis et al, 1987; Holm-Bentzen et al, 1987c; Lynes et al, 1987; Hanno et al, 1990; Christmas and Rode, 1991; Moore et al, 1992; Dundore et al, 1996; Hofmeister et al, 1997). Methylhistamine, a histamine metabolite found in the urine and thought to reflect mast cell activation was not associated with symptom scores, response to bladder distention, cystoscopic findings, or bladder biopsy features, including mast cell determination by tryptase staining (Erickson et al, 2004).

Attempts have been made to look at other markers (Erickson, 2001), including eosinophil cationic protein (Lose et al, 1987), GAG excretion (Hurst et al, 1993), and urinary histamine and methylhistamine (El Mansoury et al, 1994). Proposals for measuring smooth muscle isoactin expression (Rivas et al,1997) and urinary levels of neurotrophin-3, nerve growth factor, glial cell line–derived neurotrophic factor, and tryptase (Okragly et al, 1999) have been suggested. Low levels of GP51, a urinary glycoprotein with a molecular weight of 5 kD have been documented in IC patients compared with normal controls and patients with other urinary tract diseases (Byrne et al, 1999). Cell cultures (Elgavish et al, 1997) have been proposed as a screening technique.

The measurement of elevated nitric oxide levels in air instilled and incubated in the bladder has been proposed for office screening (Lundberg et al, 1996; Ehren et al, 1999). Increased levels of endogenously formed nitric oxide in patients with IC correspond to increased iNOS mRNA expression and protein levels in these patients. Furthermore, iNOS was found to be localized to the urothelium but it was also found in macrophages in the bladder mucosa (Koskela et al, 2008). The simple technique allows for discrimination of ulcer from nonulcer disease (Logadottir et al, 2004) and may provide an objective measure of treatment response (Hosseini et al, 2004).

The urine APF identified by Keay and colleagues (see earlier) may prove to be an accurate marker of BPS/IC if it can be confirmed by other centers and become a biochemical rather than biologic assay. **It appears to have the highest sensitivity and specificity of the variety of possible markers tested** and fits nicely into an etiologic schema (Keay et al, 2001; Erickson et al, 2002). It has also been shown to differentiate men with PBS/IC symptoms from controls and differentiate men with bladder-associated pain and irritative voiding symptoms from those with pelvic/perineal pain alone and other nonspecific findings compatible with the CPPS in men (CPPS III), previously referred to as "nonbacterial prostatitis" (Keay et al, 2004a). This question as to whether CPPS and BPS/IC are two different disorders will

doubtless be the subject of future research and is an integral question that the NIDDK is hoping to answer with current research (see www.mappnetwork.org).

Much work in markers is ongoing. Uroplakin III-delta 4 is a potential marker for identifying nonulcerative IC (Zeng et al, 2007). Most recently, the feasibility of diagnosing IC in humans and domestic cats from the spectra of dried serum films (DSFs) using infrared microspectroscopy has been reported (Rubio-Diaz et al, 2009).

Potassium Chloride Test

Parsons has championed an intravesical KCl challenge, comparing the sensory nerve provocative ability of sodium versus potassium using a 0.4-M KCl solution. Pain and provocation of symptoms constitutes a positive test. **Whether the results indicate abnormal epithelial permeability in the subgroup of positive patients or hypersensitivity of the sensory nerves is unclear.** Normal bladder epithelium can never be absolutely tight, and there is always some leak, however small (Hohlbrugger, 1997). The concentration of potassium used is 400 mEq/L, far exceeding the physiologic urinary concentrations of 20 to 80 mEq/L depending on dietary intake (Vander, 1995). Healthy controls can distinguish KCl from sodium chloride, although they do not experience severe pain (Roberto et al, 1997). **The hope is that this test may stratify patients into those who will respond to certain treatments (perhaps those designed to fortify the GAG layer), but to date this information is lacking** (Teichman and Nielsen-Omeis, 1999).

Used as a diagnostic test for IC, the KCl test is not valid (Chambers et al, 1999). The gold standard in defining BPS/IC for research purposes has been the NIDDK criteria. These criteria are recognized to constitute a set of patients that virtually all researchers can agree have PBS/IC, although they are far too restrictive to be used in clinical practice (Hanno et al, 1999b). Thus, this group of patients should virtually all be positive if the KCl test is to have the sensitivity needed to aid in diagnosis. **Up to 25% of patients meeting the NIDDK criteria will have a negative KCl test** (Parsons et al, 1998). **In the group it should perform the best in it is lacking in sensitivity.**

When we look at the specificity side of the equation, in the universe of unselected persons, recent studies reported a 36% false-positive rate in asymptomatic men (Yilmaz et al, 2004) and a 33% positive rate in a fixed population of Turkish textile workers (Sahinkanat et al, 2008). In the patient population with confounding conditions for which we would want help in sorting out BPS/IC from other disorders, 25% of patients with overactive bladder test positive and virtually all patients with irritative symptoms from radiation cystitis and urinary tract infection test positive (Parsons et al, 1994b, 1998). The results with CP/CPPS in men are variable, but 50% to 84% of men have been reported to test positive (Parsons and Albo, 2002; Yilmaz et al, 2004; Parsons et al, 2005). In women with pelvic pain the results are similar (Parsons et al, 2002b); and based on these findings, Parsons and colleagues (2002a) have expressed the view that BPS/IC may affect over 20% of the female population of the United States. Another way to interpret the findings would be that the KCl test is very nonspecific, missing a significant number of BPS/IC patients and overdiagnosing much of the population.

Prospective and retrospective studies looking at the KCl test for diagnosis in patients presenting with symptoms of BPS/IC have found no benefit of the test in comparison with standard techniques of diagnosis (Chambers et al, 1999; Gregoire et al, 2002; Kuo, 2003), **nor is it useful in monitoring results of treatment** (Sairanen et al, 2007). The development of a painless modification of the KCl test (Daha et al, 2003) using cystometric capacity and a 0.2-M solution may improve acceptability among patients, but further research is needed to determine what place, if any, this test will have in the diagnostic or treatment algorithm.

Confusable Diseases (Differential Diagnosis)

The diagnosis of BPS can be made on the basis of exclusion of confusable diseases and confirmed by the recognition of the presence of the specific combination of symptoms and signs of BPS. If the main urinary symptoms are not explained by a single diagnosis, the presence of a second diagnosis is possible. One must remember that BPS may occur together with confusable diseases such as chronic or remitting urinary infections or endometriosis. Table 12–10 summarizes confusable diseases related to BPS and their mode of exclusion based on aforementioned diagnostic proposals and procedures as outlined by the ESSIC group (van de Merwe et al, 2008).

Key Points: Diagnosis

- Bladder pain syndrome remains a diagnosis of exclusion in patients who meet the symptomatic criteria for diagnosis after confusable disorders have been ruled out.
- Cystoscopy with bladder distention under anesthesia aids in the diagnosis of a Hunner lesion but is not considered a prerequisite for beginning treatment.
- Cystoscopy and upper tract imaging are mandatory in patients with hematuria who have not been previously evaluated for this finding.
- Urodynamics are optional and generally reserved for complex cases.

CLASSIFICATION

IC was originally described as bladder disease with severe inflammation of the bladder wall described by Hunner (1915) as an ulcer. The lesion is, however, not an ulcer but a vulnus (weakness, vulnerability) that can ulcerate on distention, and the name of the bladder lesion has consequently been changed to *Hunner lesion* (van de Merwe et al, 2008). The finding of a Hunner lesion could therefore originally be regarded as a diagnostic criterion for IC. Messing and Stamey introduced glomerulations as another typical finding for IC, and this was included in the NIDDK criteria (Wein et al, 1990). Fall and associates (1987) proposed that patients with Hunner lesion (classic IC) and patients with glomerulations (nonulcerative type) represented two different subtypes with different clinical pictures, different outcomes, and different responses to treatment (Peeker and Fall, 2002), meaning that patients fulfilling the NIDDK criteria represent at least two different patient populations. Moreover, up to 60% of patients clinically believed to have BPS by experienced clinicians do not fulfill the NIDDK criteria (Hanno et al, 1999b) and whether these patients are comparable to the patients fulfilling the NIDDK criteria is unknown. Finally, Japanese urologists consider that "interstitial cystitis" should be

Table 12–10.

Confusable Diseases for Bladder Pain Syndrome

CONFUSABLE DISEASE	EXCLUDED OR DIAGNOSED BY
Carcinoma and carcinoma in situ	Cystoscopy and biopsy
Infection with:	
Common intestinal bacteria	Routine bacterial culture
Chlamydia trachomatis, Ureaplasma urealyticum, Mycoplasma hominis, Mycoplasma genitalium, Corynebacterium urealyticum, Candida species, *Mycobacterium tuberculosis*	Special cultures Dipstick; if "sterile" pyuria culture for *M. tuberculosis*
Herpes simplex and human papillomavirus	Physical examination
Radiation	Medical history
Chemotherapy, including immunotherapy with cyclophosphamide	Medical history
Anti-inflammatory therapy with tiaprofenic acid	Medical history
Bladder neck obstruction and neurogenic outlet obstruction	Uroflowmetry and ultrasonography
Bladder stone	Imaging or cystoscopy
Lower ureteral stone	Medical history and/or hematuria; upper urinary tract imaging (CT or IVP)
Urethral diverticulum	Medical history and physical examination
Urogenital prolapse	Medical history and physical examination
Endometriosis	Medical history and physical examination
Vaginal candidiasis	Medical history and physical examination
Cervical, uterine, and ovarian cancer	Physical examination
Incomplete bladder emptying (retention)	Postvoid residual urine volume measured by ultrasound evaluation
Overactive bladder	Medical history and urodynamics
Prostate cancer	Physical examination and PSA test
Benign prostatic obstruction	Uroflowmetry and pressure-flow studies
Chronic bacterial prostatitis	Medical history, physical examination, culture
Chronic nonbacterial prostatitis	Medical history, physical examination, culture
Pudendal nerve entrapment	Medical history, physical examination; nerve block may prove diagnosis
Pelvic floor muscle–related pain	Medical history, physical examination

CT, computed tomography; IVP, intravenous pyelogram; PSA, prostate-specific antigen.

From van de Merwe JP, Nordling J, Bouchelouche P, et al. Diagnostic criteria, classification, and nomenclature for painful bladder syndrome/interstitial cystitis: an ESSIC proposal. Eur Urol 2008;53:60–7.

preserved as a disease name reserved for patients with urinary symptoms and cystoscopic findings of glomerulations or Hunner lesion as outlined in the NIDDK criteria (Homma, 2008).

In an attempt to unite these different philosophies into a coherent schema, the **ESSIC proposed a classification of BPS based on findings during cystoscopy with hydrodistention and morphologic findings in bladder biopsy specimens** (van de Merwe et al, 2008) (see Table 12–4). The classification includes groups not having had cystoscopy with hydrodistention (group X) as well as groups not having had morphologic investigation of bladder biopsy specimens (group XX). By using this classification future research will be able to identify if findings of glomerulations and/or Hunner lesion as well as morphologic changes in bladder biopsy specimens do have significant importance for disease prognosis and/or treatment outcome.

TREATMENT

Conservative Therapies

Once the diagnosis has been made one must decide whether to institute therapy or employ a policy of conservative "*watchful waiting*." **If the patient has not had an empirical course of *antibiotics* for his or her symptoms by the time the PBS/IC diagnosis is made, such a trial is reasonable.** Doxycycline has been reported efficacious in a Swiss study (Burkhard et al, 2004). Further attempts to alleviate symptoms with antibiotics are unlikely to be worthwhile and are not recommended in the absence of positive cultures. **Stress reduction, exercise, warm tub baths, and efforts by the patient to maintain a normal lifestyle all contribute to overall quality of life** (Whitmore, 1994). In a controlled study of 45 PBS/IC patients and 31 healthy controls, higher levels of stress were related to greater pain and urgency in patients with IC but not in the control group (Rothrock et al, 2001). Maladaptive strategies for coping with stress may impact adversely on symptoms (Rothrock et al, 2003). **Biofeedback, soft tissue massage, and other physical therapies may aid in muscle relaxation of the pelvic floor** (Mendelowitz and Moldwin, 1997; Meadows, 1999; Holzberg et al, 2001; Lukban et al, 2001; Markwell, 2001). This is a reasonable intervention given the association of pelvic floor dysfunction and BPS/IC (Peters et al, 2007a), and an NIDDK trial is now in its final phases and should provide further information on efficacy of physical therapy. A preliminary NIDDK trial demonstrated the feasibility of such a study and strongly suggested the efficacy of physical therapy when compared with global therapeutic massage (National Institutes of Health, 2008a, 2008b; FitzGerald et al, 2009).

Mendelowitz and Moldwin (1997) had a 69% success rate in 16 patients treated with electromyographic biofeedback, but treatment response did not correlate to changes in muscle identification and the placebo effect may have been considerable. Acupuncture has been used for PBS/IC and many other chronic pain syndromes. There is limited evidence that it is more effective

than nontreatment for chronic pain, and inconclusive evidence that acupuncture is more effective than placebo, sham acupuncture, or standard care (Ezzo et al, 2000). In general, results with acupuncture for PBS/IC have been disappointing (Geirsson et al, 1993).

Diet

Elaborate dietary restrictions are unsupported by any literature, but many patients do find their symptoms are adversely affected by specific foods and would do well to avoid them (Koziol et al, 1993; Koziol, 1994). **Often this includes caffeine, alcohol, artificial sweeteners, hot pepper, and beverages that might acidify the urine such as cranberry juice** (Shorter et al, 2007). **Anecdotal association of IC with many foods has spawned the recommendation of various "IC diets" with little in the way of objective, scientific basis** (Table 12–11). The only placebo-controlled dietary study, although small, failed to demonstrate a relationship between diet and symptoms (Fisher et al, 1993). Bade and colleagues found that IC patients tend to have a healthier diet than the general population but could discern no rationale for dietary or fluid intake change other than decreasing caffeine intake (Bade et al, 1997b). Nguan and coworkers (2005) performed a prospective, double-blind, crossover study consisting of crossover instillations of urine at physiologic pH (5.0) and neutral buffered pH (7.5). There was no statistically significant difference in subjective pain scores, suggesting that adjusting urine pH with diet or dietary supplements may have little influence on symptomatology. Orange and grapefruit juices, rich in potassium and citrate, tend to increase urinary pH (Wabner and Pak, 1993) but are avoided by many IC patients based on "IC diet" recommendations. Urinary alkalinization may be worth trying, but supporting studies are lacking. Some patients have had benefit with calcium glycerophosphate, an over-the-counter food acid–reducing agent (Hill et al, 2008), but supporting controlled trials are lacking.

A large NIH study in which patients with newly diagnosed BPS/IC were treated with a focus on four targeted areas: (1) how to control or manage their symptoms, (2) controlling fluid intake, (3) changing diet which may improve symptoms, and (4) bladder training/urge suppression. A behavioral approach to stress and pain management was also used to help patients learn skills to reduce stress in their lives. Forty-five percent of 135 patients randomized to this approach without additional medication were

Table 12–11.

Interstitial Cystitis Association Recommendations of Foods to Avoid

Milk/Dairy Products	**Beverages**
Aged cheeses	Alcoholic beverages including beer and wine
Sour cream	Carbonated drinks
Yogurt	Coffee
Chocolate	Tea
Vegetables	Fruit juices
Fava beans	Seasonings
Lima beans	Mayonnaise
Onions	Ketchup
Tofu	Mustard
Soybeans	Salsa
Tomatoes	Spicy foods (Chinese, Mexican, Indian, Thai)
Fruits	Soy sauce
Apples	Miso
Apricots	Salad dressing
Avocados	Vinegar
Bananas	**Preservatives and Additives**
Cantaloupes	Benzyl alcohol
Citrus fruits	Citric acid
Cranberries	Monosodium glutamate
Grapes	Artificial sweeteners
Nectarines	Preservatives
Peaches	Artificial ingredients
Pineapples	Food coloring
Plums	**Miscellaneous**
Pomegranates	Tobacco
Rhubarb	Caffeine
Strawberries	Diet pills
Juices from above fruits	Junk foods
Carbohydrates and Grains	Recreational drugs
Rye bread	Allergy medications with ephedrine or pseudoephedrine
Sourdough bread	Certain vitamins
Meats and Fish	
Aged, canned, cured processed, smoked meats and fish	
Nuts

moderately or markedly improved at the 12-week end point (Foster et al, 2010).

Unfortunately, education and self-help are often not sufficient, and most patients will require one or more of a variety of therapies.

Oral Therapies

Some oral medications that have been used for treatment of BPS are listed in Table 12–12 and discussed in the following sections.

Amitriptyline

Amitriptyline, a tricyclic antidepressant, has become a staple of oral treatment for BPS/IC. The tricyclic antidepressants possess varying degrees of at **least three major pharmacologic actions:** (1) they have central and peripheral anticholinergic actions at some but not all sites, (2) they block the active transport system in the presynaptic nerve ending that is responsible for the reuptake of the released amine neurotransmitters serotonin and norepinephrine, and (3) they are sedatives, an action that occurs presumably on a central basis but perhaps is related to their antihistaminic properties. Amitriptyline, in fact, is one of the most potent tricyclic antidepressants in terms of blocking H_1-histaminergic receptors (Baldessarini, 1985). There is also evidence that they desensitize α_2-adrenergic receptors on central noradrenergic neurons. Paradoxically they also have been shown to block α-adrenergic receptors and serotonin receptors. Theoretically tricyclic agents have actions that might tend to stimulate predominantly β-adrenergic receptors in bladder body smooth musculature, an action that would further facilitate urine storage by decreasing the excitability of smooth muscle in that area (Barrett and Wein, 1987).

Hanno and Wein (1987) first reported a therapeutic response in IC after noting a "serendipitous" response to amitriptyline in one of their patients concurrently being treated for depression. The following year a similar report appeared relating a response to desipramine hydrochloride (Renshaw, 1988). Reasoning that a drug used successfully at relatively low dosages for many types of chronic pain syndromes, which would also have anticholinergic properties, β-adrenergic bladder effects, sedative characteristics, and strong H_1-antihistaminic activity would seem to be ideal for IC, Hanno and associates (1989) performed the first clinical trial with promising results. A subsequent follow-up study (Hanno, 1994a) reported that in 28 of 43 patients who could tolerate therapy for at least a 3-week trial at a dosage of 25 mg at bedtime gradually increasing to 75 mg at bedtime over 2 weeks, 18 had total remission of symptoms with a mean follow-up of 14.4 months, 5 dropped out because of side effects, and 5 derived no clinical benefit. Benefits were apparent within 4 weeks. All patients had failed hydrodistention and intravesical DMSO therapy. **Sedation was the main side effect.** Kirkemo and colleagues (1990) treated 30 patients and had a 90% subjective improvement rate at 8 weeks. Both studies noted that patients with bladder capacities over 450 to 600 mL under anesthesia seemed to have the best results. Another uncontrolled study of 11 patients with urinary frequency and pelvic pain (Pranikoff and Constantino, 1998) related success in 9 of the patients, with 5 reporting complete resolution of symptoms and 4 significant relief. Two patients could not tolerate the medication. In a 4-month intent-to-treat placebo-controlled double-blind trial of 50 patients, 63% on amitriptyline at doses of 25 to 75 mg (dose as tolerated) at bedtime reported good or excellent satisfaction versus 4% on placebo (van Ophoven et al, 2004a). At 19-month follow-up there was little tachyphylaxis

From Hanno P, Lin AT, Nordling J, et al. Bladder pain syndrome. In: Abrams P, Cardozo L, Khoury S, Wein A, editors. Incontinence. Paris: Health Publication Ltd.; 2009. p. 1459–518.

and good response rates were observed in the entire spectrum of BPS/IC symptoms (van Ophoven and Hertle, 2005).

The large, double-blind, randomized controlled trial by the NIDDK comparing education and behavioral modification with and without oral amitriptyline showed a 55% response to the study arm that included both medication and conservative therapy compared with a 45% response to education and behavioral therapy alone (Foster et al, 2010). The difference was not statistically significant. However, **if only patients who could tolerate 25 mg or more of medication or placebo are included the success compared with conservative therapy alone was 73% compared with 53% at 12 weeks.** Frequently, O'Leary-Sant symptom and problem scores also showed significant improvement. **Thus, on an intent-to-treat basis there was not significant benefit from amitriptyline, but in the 62% of patients who could tolerate the relatively low doses of drug the benefits appear substantial. Patients should be cautioned about fatigue, constipation, dry mouth, increased appetite, and dizziness.** Slowly titrating the dose on a weekly basis, beginning at 10 mg at bedtime and increasing by 10 mg weekly to a maximum tolerated dose of 50 mg at bedtime seems to minimize side effects.

Amitriptyline has proven analgesic efficacy with a **median preferred dose of 50 mg in a range of 25 to 150 mg/day.** This range is lower than traditional doses for depression of 150 to 300 mg. The speed of onset of effect is much faster (1 to 7 days) than reported in depression, and the analgesic effect is distinct from any effect on mood (McQuay and Moore, 1997). Tricyclic antidepressants are contraindicated in patients with long QT syndrome or significant conduction system disease (bifascicular or trifascicular block) after recent myocardial infarction (within 6 months), unstable angina, congestive heart failure, frequent premature ventricular contractions, or a history of sustained ventricular arrhythmias. They should be used with caution in patients with orthostatic hypotension (Low and Dotson, 1998). Doses greater than 100 mg are associated with increased relative risk of sudden cardiac death (Ray et al, 2004).

Other Antidepressants

Other tricyclic antidepressants that have been used for BPS. One trial employed the combination of doxepin and piroxicam, a cyclooxygenase-2 inhibitor. Twenty-six of 32 patients (81%) experienced remission of symptoms (Wammack et al, 2002). Another study reported satisfactory outcome with desipramine (Renshaw, 1988). The safety and efficacy of duloxetine, a serotonin and norepinephrine reuptake inhibitor, for BPS/IC was assessed in an observational study with 48 women (van Ophoven and Hertle, 2007). Patients were prospectively treated for 2 months following an uptitration protocol to the target dose of 40 mg duloxetine twice daily. Five patients were identified as responders, and 17 patients dropped out due to side effects, including nausea in all 17 patients. No severe adverse events were reported. In the 5 responders, the 40-mg twice-daily dose was required to see efficacy. Overall, duloxetine did not result in clinically meaningful improvement of symptoms.

Antihistamines

The use of antihistamines goes back to the late 1950s and stems from work by Simmons (1961), who postulated that the local release of histamine may be responsible for, or accompany, the development of, IC. He reported on 6 patients treated with pyribenzamine. The results were far from dramatic, with only half of the patients showing some response. The therapy is notable for this disease in that it was very logically conceived. It has been Theoharides who has spearheaded mast cell research in this field and been a major modern proponent of antihistamine therapy (Theoharides, 1994). He has used the unique piperazine H_1-receptor antagonist hydroxyzine, a first-generation antihistamine (Simons 2004), which can block neuronal activation of mast cells (Minogiannis et al, 1998). In 40 patients treated with 25 mg at bedtime increasing over 2 weeks (if sedation was not a problem) to 50 mg at night and 25 mg in the morning, virtually every symptom evaluated improved by 30%. Only 3 patients had absolutely no response. As with many IC drug reports, these responses were evaluated subjectively and without being blinded or placebo controlled. A subsequent study suggested improved efficacy in patients with documented allergies and/or evidence of bladder mast cell activation (Theoharides and Sant 1997a, 1997b). **No significant response to hydroxyzine was found in an NIDDK placebo-controlled trial** (Sant et al, 2003).

Why an H_2 antagonist would be effective is unclear, but uncontrolled studies show improvement of symptoms in two thirds of patients taking cimetidine in divided doses totaling 600 mg (Seshadri et al, 1994; Lewi, 1996). It proved effective in a double-blind, placebo-controlled trial (Thilagarajah et al, 2001), but histologic studies show the bladder mucosa to be unchanged before and after treatment and the mechanism of any efficacy remains unexplained (Dasgupta et al, 2001). Cimetidine is a common treatment in the United Kingdom, where over a third of patients reported having used it (Tincello and Walker, 2005).

Pentosan Polysulfate

Parson's suggestion that a defect in the epithelial permeability barrier, the GAG layer, contributes to the pathogenesis of IC has led to an attempt to correct such a defect with the synthetic sulfated polysaccharide sodium pentosan polysulfate (PPS), a heparin analogue available in an oral formulation, 3% to 6% of which is excreted into the urine (Barrington and Stephenson, 1997). It is sold under the trade name Elmiron. **Studies have been contradictory.**

Fritjofsson and coworkers (1987) treated 87 patients in an open multicenter trial in Sweden and Finland. Bladder volume with and without anesthesia was unchanged. Relief of pain was complete in 35% and partial in 23% of patients. Daytime frequency decreased from 16.5 to 13, and nocturia decreased from 4.5 to 3.5. Mean voided volumes increased by almost a tablespoon in the nonulcer group. Holm-Bentzen and associates (1987a) studied 115 patients in a double-blind, placebo-controlled trial. Symptoms, urodynamic parameters, cystoscopic appearance, and mast cell counts were unchanged after 4 months. Bladder capacity under anesthesia increased significantly in the group with mastocytosis, but this had no bearing on symptoms or awake capacity.

Parsons and colleagues (1983) had a more encouraging initial experience, and subsequently the results of two placebo-controlled multicenter trials in the United States were published (Mulholland et al, 1990; Parsons et al, 1993). In the initial study, overall improvement of greater than 25% was reported by 28% of the PPS-treated group versus 13% in the placebo group. In the later study the respective figures were 32% on drug versus 16% on placebo. Average voided volume on PPS increased by 20 mL. No other objective improvements were documented. An NIDDK 2 × 2 factorial study to evaluate PPS and hydroxyzine looked at each drug used alone and in combination and compared results with a placebo group (Sant et al, 2003). Patients were treated for 6 months. No statistically significant response to either medication

was documented. No significant trend was seen in the PPS treatment groups (34%) compared with non-PPS groups (18%). Of the 29 patients on PPS alone, 28% had global response (the primary end point) of moderately or markedly improved versus 13% on placebo, a number remarkably similar to the results in the 3-month pivotal trials, although not reaching statistical significance in the 6-month study. A subsequent industry-sponsored trial showed no dose-related efficacy response in the range of 300 to 900 mg/day, but adverse events *were* dose related (Nickel et al, 2001). Another 6-month trial that compared PPS with cyclosporine yielded a 19% response rate for PPS compared with 75% global response to cyclosporine (Sairanen et al, 2005a).

Long-term experience with PPS is consistent with efficacy in a subset of patients that may drop below 30% of those initially treated (Jepsen et al, 1998). **Tachyphylaxis seems to be uncommon in responders. Adverse events with PPS occurred in less than 4% of patients at the dose of 100 mg three times daily** (Hanno, 1997) **and include reversible alopecia, diarrhea, nausea, and rash. Rare bleeding problems have been reported** (Rice et al, 1998). It promotes cellular proliferation in vitro in the MCF-7 breast cancer cell line, and caution has been suggested in prescribing it in groups at high-risk for breast cancer and premenopausal females (Zaslau et al, 2004). **A 3- to 6-month treatment trial is generally required to see symptom improvement.** In a small trial, PPS has shown efficacy when administered intravesically (Bade et al, 1997a). It may be of value in the management of radiation cystitis (Parsons, 1986; Hampson and Woodhouse, 1994) and cyclophosphamide cystitis (Toren and Norman, 2005), but its value in the treatment of BPS/IC seems marginal.

Immunosuppressant Drugs

Cyclosporine. Cyclosporine, a widely used immunosuppressive drug in organ transplantation, was the subject of a novel BPS trial (Forsell et al, 1996). Eleven patients received cyclosporine for 3 to 6 months at an initial dose of 2.5 to 5 mg/kg/day and a maintenance dose of 1.5 to 3 mg/kg/day. Micturition frequency decreased, and mean and maximum voided volumes increased significantly. Bladder pain decreased or disappeared in 10 patients. After cessation of treatment, symptoms recurred in the majority of patients.

In a longer-term follow-up study, 20 of 23 refractory IC patients on cyclosporine therapy followed for a mean of 60.8 months became free of bladder pain. Bladder capacity more than doubled. Eleven patients subsequently stopped therapy; and in 9 the symptoms recurred within months but responded to reinitiating cyclosporine (Sairanen et al, 2004). Sairanen and colleagues (2005b) further found that cyclosporine was far superior to sodium PPS in all clinical outcome parameters measured at 6 months. Patients who responded to cyclosporine had a significant reduction of urinary levels of EGF (Sairanen et al, 2008).

Suplatast Tosylate. Suplatast tosylate is an immunoregulator that selectively suppresses IgE production and eosinophilia via suppression of helper T cells that produce interleukin-4 and interleukin-5. It is used in Japan to treat allergic disorders, including asthma, atopic dermatitis, and rhinitis. Ueda and colleagues (2000) reported a small study in 14 women with IC. Treatment for 1 year resulted in a significantly increased bladder capacity and decreased urinary urgency, frequency, and lower abdominal pain in 10 women. Concomitant changes occurred in blood and urine markers, suggesting an immune system response. Larger, multicenter, randomized controlled trials in the United States and Japan have not led to the governmental approval of the BPS/IC indication or the introduction of the drug into the United States.

Azathioprine and Chloroquine Derivatives. In a single report in 1976, Oravisto and Alfthan (1976) used azathioprine or chloroquine derivatives for BPS patients not responding to other treatments. About 50% patients responded.

Mycophenolate Mofetil. In an aborted multicenter randomized placebo-controlled NIDDK trial, mycophenolate mofetil (Cellcept 1 to 2 g/day in divided doses) failed to show efficacy in the treatment of symptoms of refractory BPS/IC (National Institutes of Health, 2007). The trial, which included 59 patients randomized 2:1 to the active arm, was halted when the U.S Food and Drug Administration issued a new black box warning for the drug (*miscarriage and congenital malformations have been associated with its use*), and **an interim analysis showed no benefit.**

Miscellaneous Agents

L-Arginine. Foster and colleagues (1997) were the original proponents of L-arginine in the therapy of IC. Eight patients with IC were given 500 mg of L-arginine three times daily. After 1 month, urinary NOS activity increased eightfold and 7 of the 8 patients noticed improvement in symptoms. An open-label study of 11 patients showed improvement in all 10 of the patients who remained on L-arginine for 6 months (Smith et al, 1997).

An open-label study of 9 women in Sweden failed to find any change in symptom scores or in nitric oxide production in the bladder (Ehren et al, 1998). A placebo-controlled randomized trial of 53 BPS/IC patients could find no difference on an intent-to-treat analysis between drug and placebo-treated patients (Korting et al, 1999). A smaller randomized placebo-controlled crossover trial of 16 BPS patients found no clinically significant improvement with L-arginine and concluded that it could not be recommended for IC treatment (Cartledge et al, 2000).

The body of evidence does not support the use of L-arginine for the relief of symptoms of IC.

Quercitin. Quercetin, a bioflavonoid available in many over-the-counter products, may have the anti-inflammatory effects of other members of this class of compounds found in fruits, vegetables, and some spices. Katske and coworkers (2001) administered 500 mg twice daily to 22 BPS patients for 4 weeks. All but 1 patient had some improvement in the O'Leary-Sant symptom and problem scores as well as in a global assessment score. Further studies are necessary to determine efficacy.

Antibiotics. Warren and associates (2000) randomized 50 patients to receive 18 weeks of placebo or antibiotics including rifampin plus a sequence of doxycycline, erythromycin, metronidazole, clindamycin, amoxicillin, and ciprofloxacin for 3 weeks each. Intent-to-treat analysis demonstrated that 12 of 25 patients in the antibiotic and 6 of 25 patients in the placebo group reported overall improvement while 10 and 5, respectively, noticed improvement in pain and urgency. The study was complicated by the fact that 16 of the patients in the antibiotic group underwent new BPS therapy during the study as did 13 of the placebo patients. There was no statistical significance reached. What was statistically significant were adverse events in 80% of participants who received antibiotic compared with 40% in the placebo group. Nausea and/or vomiting and diarrhea were the predominant side effects. Most patients on antibiotics correctly guessed what treatment arm they were in, and those who guessed correctly were significantly more likely to note improvement after the study. No duration in improvement after completion of the trial of antibiotics was reported.

Burkhard and colleagues (2004) recorded a 71% success in 103 women presenting with a history of urinary urgency and frequency and chronic urethral and/or pelvic pain often associated

with dyspareunia and/or a history of recurrent urinary tract infection. This was a large, inclusive group and one that is probably broader than the BPS we are focusing on. Nevertheless, they recommended empirical doxycycline in this group. The overwhelming majority of BPS patients have been treated with empirical antibiotics before diagnosis.

At this time there is no evidence to suggest that antibiotics have a place in the therapy for BPS in the absence of a culture-documented infection (Maskell, 1995). **Nevertheless, it would not be unreasonable to treat patients with *one* empirical course of antibiotic if they have never been on an antibiotic for their urinary symptoms.**

Methotrexate. Low-dose oral methotrexate significantly improved bladder pain in 4 of 9 women with BPS but did not change urinary frequency, maximum voided volume, or mean voided volume (Moran et al, 1999). No placebo-controlled randomized trial has been done with this agent.

Montelukast. Mast cell triggering releases two types of proinflammatory mediators, including granule stored preformed types such as heparin and histamine and newly synthesized prostaglandins and leukotriene B_4 and C_4. Classic antagonists, such as montelukast, zafirlukast, and pranlukast, block cysteinyl leukotriene-1 receptors. In a pilot study (Bouchelouche et al, 2001b), 10 women with IC and detrusor mastocytosis received 10 mg of montelukast daily for 3 months. Frequency, nocturia, and pain improved dramatically in 8 of the patients. Further study would seem to be warranted, especially in patients with detrusor mastocytosis, which is defined as more than 28/mm^2.

Nifedipine. The calcium channel antagonist nifedipine inhibits smooth muscle contraction and cell-mediated immunity. In a pilot study (Fleischmann, 1994), 30 mg of an extended-release preparation was administered to 10 female patients and titrated to 60 mg daily in 4 of the patients who did not get symptom relief. Within 4 months 5 patients showed at least a 50% decrease in symptom scores and 3 of the 5 were asymptomatic. No further studies have been reported.

Misoprostol. The oral prostaglandin analogue misoprostol was studied in 25 patients at a dose of 600 µg/day (Kelly et al, 1998). At 3 months 14 patients were significantly improved, and at 6 months 12 patients still had a response. A cytoprotective action in the urinary bladder was postulated.

Analgesics

The long-term, appropriate use of pain medications forms an integral part of the treatment of a chronic pain condition such as IC. Most patients can be helped markedly with medical pain management using pain medications commonly used for chronic neuropathic pain syndromes, including antidepressants, anticonvulsants, and opioids (Wesselmann et al, 1997). Many nonopioid analgesics including acetaminophen and the nonsteroidal anti-inflammatory drugs (NSAIDs) and even antispasmodic agents (Rummans, 1994) have a place in therapy along with agents designed to specifically treat the disorder itself.

Studies on the use of analgesics for BPS are sparse, and the majority of data is inferred from non-BPS types of pain and expert opinion. Health care professionals should ask about pain, and the patient's self-report should be the primary source of assessment. Clinicians should assess pain with easily administered rating scales and should document the efficacy of pain relief at regular intervals after starting or changing treatment.

Unlike opioids, with increasing doses acetaminophen, aspirin, and the other NSAIDs all reach a ceiling for their maximum analgesic effect (Drugs for pain, 1998). Gabapentin, introduced in 1994 as an anticonvulsant, has found efficacy in neuropathic pain disorders including diabetic neuropathy (Backonja et al, 1998) and postherpetic neuralgia (Rowbotham et al, 1998). It demonstrates synergism with morphine in neuropathic pain (Gilron et al, 2005). It may give some benefit in chronic pelvic pain syndromes and BPS/IC (Sasaki et al, 2001). Pregabalin is also reported to be effective for neuropathic pain and the pain of fibromyalgia (Freynhagen et al, 2005; Arnold et al, 2008).

With the results of major surgery anything but certain, the use of long-term opioid therapy in the patient who has failed more conservative therapies also may be considered (Table 12–13). Opiates are seldom the first choice of analgesics in chronic pain states, but they should not be withheld if less powerful analgesics have failed (Portenoy et al, 1997; Bennett, 1999). This is a difficult decision that requires much thought and discussion between patient and urologist, and involvement of a pain specialist is indicated. A single practitioner has to take responsibility for pain treatment and write all prescriptions for pain medications (Brookoff, 1997). Opioids are effective for most forms of moderate and severe pain and have no ceiling effect other than that imposed by adverse effects. The common side effects include sedation, nausea, mild confusion, and pruritus. These are generally transient and

Table 12–13.

General Guidelines for the Use of Opioids in Chronic/Nonacute Urogenital Pain

1. All other reasonable treatments must have been tried and failed.
2. The decision to instigate long-term opioid therapy should be made by an appropriately trained specialist in consultation with another physician (preferably the patient's family doctor).
3. When there is a history or suspicion of drug abuse a psychiatrist or psychologist with an interest in pain management and drug addiction should be involved.
4. The dose required needs to be calculated by careful titration.
5. The patient should be made aware (and possibly give written consent):
   a. That opioids are strong drugs and associated with addiction and dependency
   b. The opioids will normally only be prescribed from one source
   c. The drugs will be prescribed for fixed periods of time and a new prescription will not be available until the end of that period
   d. The patient will be subjected to spot urine and possibly blood checks to ensure that the drug is being taken as prescribed and that non-prescribed drugs are not being taken
   e. Inappropriate aggressive behavior associated with demanding the drug will not be accepted
   f. Hospital specialist review will normally occur at least once a year
   g. The patient may be requested to attend a psychiatric/psychology review
   h. Failure to comply with the above may result in the patient being referred to a drug dependency agency and the use of therapeutic analgesic opioids being stopped.
6. Morphine is the first-line drug, unless there are contraindications to morphine or special indications for another drug. The drug should be prescribed in a slow release/modified release form. Short-acting preparations are undesirable and should be avoided when possible. Parenteral dosing is undesirable and should be avoided when possible.

Modified from Fall M, Baranowski A, Elneil S et al. Guidelines on chronic pelvic pain. In: European Association of Urology; 2008. p. 1–99. www.uroweb.org/professional-resources/guidelines/.

easily managed. Respiratory depression is extremely rare if they are used as prescribed. Constipation is common, and a mild laxative is generally necessary. The major impediment to the proper use of these drugs when they are prescribed for long-term nonmalignant pain is the fear of addiction. Studies suggest the risk is low (Gourlay, 1994). The long-acting narcotic formulations that result in steady levels of drug over many hours are preferable.

Chronic pain patients often receive inadequate doses of short-acting pain medications, which put them on cycles of short-term relief, anxiety, and pain. It leads to doctor shopping and to drug-seeking behavior confused by physicians with drug addiction. Although physical dependence to opioids will be unavoidable, physical addiction, a chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user and the continued use despite that harm, is rare. Chronic opioid therapy can be considered in carefully selected patients. It is best administered in a pain clinic setting, requiring frequent reassessment by both patient and physician (Portenoy and Foley, 1986).

Intravesical Therapy for BPS: Assessments According to Oxford System

INTRAVESICAL AGENT	LEVEL OF EVIDENCE	GRADE OF RECOMMENDATION
DMSO	2	B
Heparin	3	C
Hyaluronic acid	1	D
Chondroitin sulfate	4	D
Pentosan polysulfate	4	D
Capsaicin/resiniferatoxin	1	–A (ineffective)
Bacillus Calmette-Guérin (BCG)	1	–A (ineffective
Oxybutynin	4	D
Lidocaine	2	C
Botulinum toxin	4	D

From Hanno P, Lin AT, Nordling J, et al. Bladder pain syndrome. In: Abrams P, Cardozo L, Khoury S, Wein A, editors. Incontinence. Paris: Health Publication Ltd.; 2009. p. 1459–518.

Key Points: Oral Therapies

- Few of the oral therapies commonly used for the treatment of BPS have unequivocal evidence of efficacy in large, multicenter, randomized controlled clinical trials.
- There is little evidence that any change the natural history of the disease, although many seem effective in individual patients.

Intravesical and Intradetrusor Therapies

Assessments according to the Oxford System for intravesical therapy for BPS are shown in Table 12–14.

Silver Nitrate

Although the evidence base for treating BPS/IC using intravesical preparations is limited and the potential for meta-analysis reduced by variation in the outcome measures used (Dawson and Jamison, 2007), intravesical lavage with one of a variety of preparations has remained a mainstay of treatment in the therapeutic armamentarium of BPS. Perhaps the oldest of the intravesical therapies is silver nitrate. The use of silver nitrate has been attributed to Mercier (cited in Pool and Rives, 1944), who reported in 1855 that excellent results with bladder instillations had been obtained in patients suffering from symptoms compatible with IC. Dodson (1926) advocated the use of solutions of silver nitrate in increasing strengths as the treatment of choice for this condition. Pool and Rives (1944) reported on 74 patients with IC treated with intravesical silver nitrate. The treatment was carried out as follows:

A urethral catheter is inserted and the contents of the bladder are evacuated. The bladder is then irrigated with a saturated solution of boric acid. Then 30 to 60 mL of a 1:5000 solution of silver nitrate is instilled into the bladder and permitted to remain there for 3 or 4 minutes if it does not cause intolerable irritation. At the end of this period the solution is permitted to run out through the catheter, which is then withdrawn. The patient usually experiences some dysuria and vesical irritability for 2 or 3 hours. Treatments are repeated every other day. At subsequent treatments the concentration of silver nitrate in the solution is increased to 1:2500, 1:1000, 1:750, 1:500, 1:400, 1:200, and finally 1:100. If at any time the reaction is too severe, the concentration is increased more slowly (Pool and Rives, 1944).

Although the initial treatments are performed with the patient under general anesthesia, later treatments are given on an outpatient basis. Ureteral reflux would be a contraindication, and it goes without saying that bladder biopsy would be contraindicated just before instillation for fear of extravasation. Twenty-three years later, Pool (1967) wrote that he still considered this treatment regimen the most efficacious form of treatment. He reported excellent results in 70% of patients with a mean response of 7.6 months. Burford and Burford (1958) reported a 14% cure rate and 79% improved figure. DeJuana and Everett (1977) had a 50% response rate in 102 patients.

Although **silver nitrate is rarely used in the current treatment of BPS,** an animal study showing that intravesical administration of nanocrystalline silver (1%) decreased urine histamine, bladder TNF-α, and mast cell activation in an experimental inflammation model without any toxic effect may restimulate interest in silver compounds (Boucher et al, 2008).

Clorpactin

O'Connor (1955) reported the use of intravesical Clorpactin WCS 90. Clorpactin is a generic term for closely related, highly reactive chemical compositions having a modified derivative of hypochlorous acid in a buffered base. Its activity depends on the liberation of hypochlorous acid and its resulting oxidizing effects, wetting and penetrating properties, and detergency. Wishard treated 20 patients with 0.2% Clorpactin gently lavaged in the bladder for 3 to 5 minutes without anesthesia, of whom 14 reported subjective improvement (Wishard et al, 1957). Murnaghan and coworkers (1970) noted improvement in 14 of 17 patients, although 10 required further treatment during the average 2-year follow-up. Most commonly the treatments are given as described by Messing and Stamey (1978), using 0.4% solution administered at 10 cm H_2O under anesthesia. Multiple instillations can be given, with a 1-month pause after the first 2 instillations to await a therapeutic response. The success rate of these researchers was 72%, with average 6-month duration of response. La Rock and Sant (1995) noted a 50% to 55% meaningful improvement rate occurring within 4 to 6 weeks of treatment. A case of ureteral fibrosis complicating the treatment prompted the recommendation that vesicoureteral reflux be considered a contraindication to the procedure

(Messing and Freiha, 1979). Our method of Clorpactin delivery is as follows:

Reflux is excluded with a cystogram. Under anesthesia the bladder is distended for 2 minutes at 60 to 80 cm H_2O and emptied. The perineum is shielded with a moistened towel. A solution of 0.4% freshly prepared Clorpactin (4 g in 1000 mL of sterile water) is instilled by gravity drainage (the Foley catheter held 10 cm above the level of the bladder) in 150- to 200-mL aliquots for a dwell time of 2 to 3 minutes and drained by gravity. This continues until the entire 1000-mL solution has been used. The bladder and introitus are then irrigated with normal saline, and the catheter is removed.

Dimethyl Sulfoxide

A mainstay of the treatment of BPS is the intravesical instillation of 50% DMSO (Sant, 1987). DMSO is a product of the wood pulp industry and a derivative of lignin. It has exceptional solvent properties and is freely miscible with water, lipids, and organic agents. Pharmacologic properties include membrane penetration, enhanced drug absorption, anti-inflammatory, analgesic, collagen dissolution, muscle relaxant, and mast cell histamine release. In-vitro effects on bladder function belie its positive effects in vivo (Freedman et al, 1989), where histamine release has not been demonstrated after treatment (Stout et al, 1995). It has been suggested that DMSO actually desensitizes nociceptive pathways in the lower urinary tract (Birder et al, 1997). Tests for DMSO for treatment of human illness began in the 1960s in the areas of musculoskeletal inflammation and the cutaneous manifestations of scleroderma.

Stewart and colleagues (1968) are credited for popularizing intravesical DMSO for BPS/IC. In the mid 1960s they applied it to the skin over the suprapubic area in a group of patients whose condition was refractory to conventional forms of therapy. Results were poor, but intravesical delivery of 50 mL of a 50% solution instilled for 15 minutes by catheter and repeated at intervals of 2 to 4 weeks showed positive effects in 6 of 8 patients lasting 2 to 12 months. The lack of side effects, other than a garlic-like odor on the breath, and of the need for inpatient administration were significant breakthroughs over previous treatments. Further reports by this group confirmed safety and efficacy (Stewart et al, 1971, 1972; Stewart and Shirley, 1976; Shirley et al, 1978) with symptom-free intervals of 1 to 3 months in 73% of patients. Ek and associates (1978) reported a 70% success rate but found most patients ultimately required re-treatment or further therapy with other modalities. Prospective series of Fowler (1981) and Barker and associates (1987) revealed symptomatic success rates of greater than 80%, although relapse was not uncommon. Fowler noted only minimal improvements in functional bladder capacity and attributed the beneficial effects of DMSO to a direct effect on the sensory nerves of the bladder. Perez-Marrero and associates (1988) compared DMSO with saline and showed a 93% objective improvement and 53% subjective improvement compared with 35% and 18%, respectively, for saline. Patients with bladder instability do not respond (Emerson and Feltis, 1986).

With its ease of administration (Biggers, 1986), **low morbidity, and reasonable symptomatic results, DMSO certainly merits its place as a useful treatment for BPS/IC.** In-vivo studies on rat bladder strips exposed to various concentrations of DMSO for 7 minutes showed absence of electrical field stimulation contraction at a 40% concentration and diminished compliance at 30% concentration (Melchior et al, 2003). Concentrations of 25% or less had negligible effects in this model. How it relates to use of DMSO in humans is unknown. A rare case of eosinophilic cystitis has been reported after DMSO instillation (Abramov et al, 2004).

Glycosaminoglycans

Exogenous GAGs have been shown to be effective in providing an epithelial permeability barrier in bladders in which the epithelium has been injured with protamine (Nickel et al, 1998). **Heparin,** which can mimic the activity of the bladder's own mucopolysaccharide lining (Hanno et al, 1978), has anti-inflammatory effects as well as actions that inhibit fibroblast proliferation, angiogenesis, and smooth muscle cell proliferation. Because of its numerous effects the possibility that heparin could be used for therapeutic reasons other than the control of coagulation has been the subject of much inquiry and speculation (Lane and Adams, 1993). Weaver and associates (1963) first reported intravesical heparin for IC treatment. Given intravesically there is virtually no systemic absorption, even in an inflamed bladder (Caulfield et al, 1995). Although uncontrolled studies suggested some beneficial effect for subcutaneous administration (Lose et al, 1983, 1985), the obvious risks of anticoagulation and osteoporosis have prevented this form of administration from undergoing further trials and general usage. Ten thousand units can be administered intravesically in sterile water either alone or with DMSO at varying intervals, with good results being reported (Perez-Marrero et al, 1993; Parsons et al, 1994a). Kuo (2001) reported 50% or more improvement in the International Prostate Symptom Score in 29 of 40 women with IC treated with 25,000 units intravesically twice weekly for 3 months.

Parsons (2000) has used daily intravesical doses of 40,000 units of heparin in 20-mL sterile water administered by the patient daily and held for 30 to 60 minutes. "Reasonable improvement of symptoms" can be expected between 6 months and 2 years after starting therapy. Adding alkalinized lidocaine to the heparin instillation provides better pain relief (Parsons, 2005). These encouraging outcomes must be kept in perspective, given that they are unproven by any placebo-controlled trial. The addition of 8 mL of 2% lidocaine and 4 mL of 8.4% sodium bicarbonate may improve results (Welk and Teichman, 2008). In fact, a combination of 200 mg of lidocaine with 8.4% sodium bicarbonate (10 mL total solution) *without* heparin showed a 30% response rate 3 days after completion of daily intravesical administration for 5 days and was statistically superior to a placebo cocktail (Nickel et al, 2009b).

Another GAG analogue, **pentosan polysulfate (PPS),** administered intravesically at 300 mg twice weekly in 50 mL of normal saline, showed some modest benefit in a small trial (Bade et al, 1997a). A 41-patient trial comparing oral PPS with oral and intravesical administration showed that the 24% reduction in O'Leary-Sant scores with oral therapy alone rose to a 46% reduction in the group that also received intravesical PPS (Davis et al, 2008).

The nonsulfated GAG, **hyaluronic acid,** has also been used intravesically. Trials using 40 mg dissolved in 40 mL of normal saline weekly for 4 to 6 weeks and then monthly treatments thereafter have had response rates varying from 71% (Morales et al, 1996) to 30% (Porru et al, 1997). In the summer of 2003, Bioniche Life Science (Interstitial Cystitis Association, 2003), and in the spring of 2004 Seikagaku Corporation, reported double-blind, placebo-controlled, multicenter clinical studies of their hyaluronic acid preparations (40 mg or 200 mg/mL, respectively), and neither showed significant efficacy of sodium hyaluronate compared with placebo. These negative studies have not been published in peer-reviewed literature. Neither preparation has been approved for use for BPS/IC in the United States. An Austrian open-label study showed 13 of 27 patients with BPS and a positive potassium test

responded to intravesical hyaluronic acid, 40 mg, given weekly for 10 weeks, although initial nonresponders at 5 weeks also were treated with intravesical PPS 200 mg thrice weekly for the remaining 5 weeks (Daha et al, 2008). The best results for hyaluronic acid come from Riedl and colleagues (2008), who studied 126 patients with a positive modified potassium test who could hold the solution for 2 hours, using 40 mg weekly for a minimum 10 weeks. Eight-four percent had significant improvement. Treatment-resistant cases have been managed with a combination of sequential bladder distention under anesthesia accompanied by a hyaluronic acid instillation every 1 to 3 months depending on response, with a 74% success rate in 23 patients (Ahmad et al, 2008). **Although used in Europe and Canada, the efficacy of hyaluronic acid for BPS/IC remains unproven in controlled and blinded trials** (Iavazzo et al, 2007).

Hurst (2003) has shown by immunohistochemistry a deficit of chondroitin sulfate from the luminal bladder surface in IC patients. Small uncontrolled studies using intravesical **chondroitin sulfate** have shown success rates of 33% (Steinhoff et al, 2002) to 50% (Sorensen, 2003). A multicenter, open-label study using 2% solution of sodium chondroitin sulfate weekly for 6 weeks and then monthly for 4 months had a 60% response rate with no safety issues (Nickel et al, 2009a). A large open-label experience using the device for all forms of "chronic cystitis" concluded that it was effective in improving urgency, voided volumes, and nocturia and well-tolerated when administered weekly for a maximum of eight instillations (Nordling and van Ophoven, 2008). The GAGs can be combined for instillation (Cervigni et al, 2008).

Other Intravesical Therapies

Doxorubicin (Khanna and Loose, 1990) and the mast cell stabilizer **cromolyn sodium** (Edwards et al, 1986; Kennelly and Konnak, 1995) have been tried in pilot trials with the promising results we come to expect in such studies. Follow-up studies are lacking, and these drugs have not become a part of the intravesical pharmacopeia.

The use of intravesical **bacillus Calmette-Guérin (BCG)** for IC was first reported by Zeidman and colleagues (1994). A subsequent randomized, prospective, double-blind, placebo controlled trial of 30 patients treated weekly for 6 weeks and followed for a mean of 8 months noted a 60% response rate compared with a 27% placebo response (Peters et al, 1997). Surprisingly, BCG was tolerated as well as placebo. Even more surprisingly, 8 of 9 BCG responders continued to have an excellent response in all parameters measured at 27 months of follow-up (Peters et al, 1998). It is unclear how BCG achieved this result, but immunologic and/or anti-inflammatory mechanisms have been postulated (Peters et al, 1999). A double-blind crossover Swedish study comparing DMSO to BCG failed to substantiate the efficacy of BCG (Peeker et al, 2000c).

A large multicenter randomized controlled trial by NIDDK comparing BCG with placebo found a 12% response rate for placebo compared with a 21% response for BCG. Placebo responders in the trial had the same durability of response (up to 68 weeks) as the BCG responders (Propert et al, 2008). In a follow-up open-label phase of the trial the response rate was 18% in both the group originally randomized to BCG and the group initially randomized to placebo, indicating a second course of therapy does not improve response rate (Propert et al, 2007). The small response rate in the randomized controlled trial failed to reach statistical significance at the $P = .05$ level, and this large study of 265 patients suggests that **BCG has no place in the treatment of moderate to severe BPS/IC** (Mayer et al, 2005). Although the BCG safety profile was considered acceptable in the NIDDK trial, adverse events were not uncommon and rare hypersensitivity reactions to intravesical BCG can occur (Parker et al, 2004). Although small, uncontrolled trials showing efficacy of BCG have been reported (Aghamir et al, 2007; El-Bahnasy et al, 2009), the NIDDK trial dampened enthusiasm for this treatment modality.

Efforts to bring new therapies directly to the bladder continue to be the focus of investigators. Oxybutynin has shown efficacy in preliminary studies when administered intravesically at doses of 10 mg dissolved in saline (Bade et al, 2000; Barbalias et al, 2000). Electromotive drug administration, the active transport of ionized drugs by the application of an electric current, using lidocaine and dexamethasone, has shown a 25% success rate up to 6 months after instillation (Rosamilia et al, 1997). A similar trial using repeated instillations noted success rates of 60% with a mean duration of 6.6 months (Riedl et al, 1997). **Capsaicin,** the main pungent ingredient in hot peppers of the genus *Capsicum,* is a specific neurotoxin that desensitizes C fiber afferent neurons. **Resiniferatoxin (RTX),** an ultrapotent analogue of capsaicin appears to have similar effects with less of the acute pain and irritation associated with capsaicin application. Both compounds have been tested intravesically for the relief of bladder instability and hyperreflexia (Chancellor and de Groat, 1999). Clinical trials for the use of these compounds in bladder pain and urgency/frequency could show this to be a new and viable treatment modality in the future, but **current data on efficacy in BPS are lacking** (Cruz et al, 1997; Lazzeri et al, 1996, 2000). A phase 2 safety and proof of concept multicenter, placebo-controlled trial conducted by ICOS Corporation (Bothell, WA, USA) found no significant efficacy of a single intravesical administration RTX compared with placebo, although no safety issues were identified (Payne et al, 2005). Studies using other concentrations and multiple administrations may be worthwhile (Peng and Kuo, 2007).

Key Points: Intravesical Therapies

- The potential for high efficacy combined with safety and low side effect profile that is gained by applying a treatment directly to the bladder lining has made research into new methods of intravesical therapy a high priority of researchers and pharmaceutical companies.
- Patients in whom pain and other symptoms are not related directly to a pathologic process of the bladder would not be expected to respond well to this type of organ-directed therapy.

Intradetrusor Therapies

The therapeutic value of **botulinum toxin type A (Botox)** stems partially from its ability to temporarily inhibit acetylcholine release and cause flaccid paralysis in a dose-related manner. It can correct focal dystonia when injected into a muscle. In recent years there has been increasing evidence that Botox might also have analgesic properties (Rajkumar and Conn, 2004). Initially this was thought to be due to relief of muscle spasm. However, botulinum has been shown to reduce peripheral sensitization by inhibiting the release of several neuronal signaling markers, including glutamate and substance P, and reducing c-*FOS* gene expression. It may affect the sensory feedback loop to the central nervous system by decreased input from the muscle tissue, possibly by inhibiting acetylcholine release from gamma motor neurons innervating intrafusal fibers of the muscle spindle (Rosales et al, 1996). It

inhibits the release of sensory neurotransmitters from isolated bladder preparations in rat bladder models of both acute injury and chronic inflammation (Lucioni et al, 2008). Botox has been used effectively for years in different conditions with muscular hypercontractions. Intravesical Botox administration blocks the acetic acid–induced calcitonin gene–related peptide release from afferent nerve terminals in the bladder mucosal layer in rats (Chuang et al, 2004). In an animal model of bladder permeability barrier disruption, intravesical Botox minimized bladder irritability and restored afferent neural responses to baseline levels (Vemulakonda et al, 2005). These results support clinical trials of Botox for the treatment of BPS/IC and other types of visceral pain (Chancellor and Yoshimura, 2004).

A multi-institutional case series using Botox or Dysport intravesical injections in 13 patients with refractory BPS/IC reported improvement in 9 patients. Improvements in symptoms lasted a mean of 3.72 months (mean, 1 to 8 months). No systemic complications were observed, although 2 patients had a diminished flow with some need to strain to void (Smith et al, 2004). Rackley and colleagues (2005) at the Cleveland Clinic reported no change in objective or subjective outcome measures in a series of 10 BPS/IC patients in whom the trigone was spared in the injection technique. A 1-year follow-up in 15 patients treated with 200 units Botox in 20 mL of normal saline showed that the success rate fell from 86.6% at 3 months to 26.6% at 5 months and was 0 at 12 months (Giannantoni et al, 2008). Bladder biopsy specimens 2 weeks after Botox intradetrusor injection show nerve growth factor production levels fall to those of controls in patients who respond (Liu et al, 2009). It is hypothesized that treatment-refractory patients may have developed antibodies after initial botulinum injection (Schulte-Baukloh, 2008). **At this time Botox can be recommended for BPS/IC use only in the context of carefully controlled clinical trials** (Cruz and Dinis, 2007; Del Popolo, 2008; Apostolidis et al, 2009).

Submucosal injection of 10 mL of 40 mg/mL triamcinolone acetonide injected in 0.5-mL aliquots was used for the treatment of Hunner lesions in 30 patients (Cox et al, 2009). Seventy percent of patients were very much improved, and duration of improvement was estimated to be 7 to 12 months.

Neuromodulation

Because it is a chronic pain syndrome it is reasonable to consider therapeutic options that directly interface with the nervous system in the treatment of PBS/IC. This approach is further supported by the association of pelvic floor dysfunction with pelvic pain syndromes (Zermann et al, 1999).

Pain diversion by **transcutaneous electrical nerve stimulation (TENS)** is routine in a variety of painful conditions (Fall, 1987). Fall and colleagues (1980) were the first to use electrical stimulation in IC, reporting on 14 women treated successfully with long-term intravaginal or TENS. Subsequently McGuire and coworkers (1983) noted improvement in 5 of 6 patients treated with electrical stimulation.

The primary intention in applying peripheral electrical nerve stimulation in IC is to relieve pain by stimulating myelinated afferents in order to activate segmental inhibitory circuits. As a secondary effect, urinary frequency may also be reduced. In the most complete review of the subject to date (Fall and Lindstrom, 1994) 33 patients with ulcerative IC and 27 patients with nonulcerative IC were treated by means of suprapubic TENS. Electrodes were positioned 10 to 15 cm apart immediately above the pubic symphysis. High- or low-frequency (2-50 Hz) TENS was employed. If there was no effect with high frequency after 1 month, low frequency was used. Thirty to 120 minutes of TENS was prescribed daily. Pain improved more than frequency. Good results or remission were described in 26% of nonulcer patients and in a surprising 54% of patients with ulcerative disease. The authors caution that the experience is based on open studies, relatively few patients, and the knowledge of a significant placebo effect with peripheral pain stimulation.

Acupuncture has been used to treat frequency, urgency, and dysuria (Chang, 1988). Twenty-two of 26 patients treated at the Sp. 6 point had clinically symptomatic improvement. A study looking at both acupuncture and TENS in IC showed limited effects of both modalities (Geirsson et al, 1993). **Lumbar epidural blockade** is the subject of a positive recent case report (Pelaez et al, 2004) but in an earlier series resulted in only short-term (mean 15 days) pain relief in IC (Irwin et al, 1993). **Posterior tibial nerve stimulation** was successful in 60% of 37 patients with symptoms of bladder overactivity in an uncontrolled Dutch study (van Balken et al, 2001). An Australian double-blind placebo controlled study of transdermal posterior tibial nerve laser therapy showed no benefit in 56 patients when comparing active to placebo arms, but the placebo effect was remarkably strong, indicating the importance of such trials when evaluating invasive therapies (O'Reilly et al, 2004). A Chinese study of posterior tibial nerve stimulation twice weekly for 5 weeks in BPS/IC patients failed to show improvement in pain scores, and none of 18 patients thought the treatment had a significant effect (Zhao et al, 2008).

Direct sacral nerve stimulation has been explored in the treatment of IC and urgency/frequency and is referred to as **neuromodulation,** a technique whose urologic potential was developed through the basic and clinical research of Tanagho and Schmidt (Schmidt, 1993; Fandel and Tanagho, 2005). They and others have observed that patients who do best with this treatment modality are those who have identifiable pain *and* dysfunction in the pelvic muscles (Everaert et al, 2001; Siegel et al, 2001; Aboseif et al, 2002). Those patients reporting pelvic pain in the absence of demonstrable pelvic floor dysfunction and levator tenderness did poorly (Schmidt, 2001). As initially practiced, trial stimulation was performed with a percutaneous temporary electrode for a 3- to 4-day temporary stimulation period to access efficacy. The S_3 nerve is most frequently used. A wire electrode is inserted into the foramen and connected to an external pulse generator (Medtronic Inc., Minneapolis, MN, USA). If the trial is successful, the patient would be considered for implantation of a permanent neural prosthesis. More recently, a staged procedure has supplanted the traditional percutaneous approach, because the response to stimulation can be better assessed with more accurate lead placement and stability than through the more hit-or-miss percutaneous lead placement (Peters et al, 2003). Peters' test to implant rate increased from 52% to 94%. Other reports have noted a test to implant rate in the percutaneous technique from 76% in 33 PBS/IC patients (Whitmore et al, 2003) to 40% in 211 patients with refractory urge incontinence, urgency-frequency syndrome, and urinary retention (Scheepens et al, 2002b).

Neuromodulation has been shown to be effective in treating refractory urinary urge incontinence (Schmidt et al, 1999; Spinelli et al, 2001). Studies on therapeutic potential in BPS/IC followed (van Kerrebroeck, 1999). The University of Maryland group described decrease in antiproliferative activity and normalization of HB-EGF levels in patients with successful test stimulation (Chai et al, 2000a). Peters and coworkers (2003) reported success in two thirds of BPS/IC patients with sacral nerve stimulation; Global Response Assessment as determined by the patient correlated with

objective findings (Peters et al, 2008). In another study (Comiter, 2003) success was noted in 17 of 25 patients with test stimulation and they went on to permanent implantation of the Interstim device (Medtronics, St. Paul, MN). Thirteen of 15 who underwent staged implantation were permanently implanted versus 4 of 10 undergoing percutaneous test stimulation. With a mean follow-up of 14 months, in 16 of 17 patients the treatment was judged successful, giving an intent-to-treat success rate of 64%. Although sacral neuromodulation can decrease narcotic requirements significantly in refractory BPS/IC, the majority of patients taking chronic narcotics for pain will likely continue to use them for pain relief even after implantation (Peters and Konstandt, 2004). One center reported a long-term improvement rate of 45% for the urgency/frequency indication (Elhilali et al, 2005).

Unilateral stimulation should be performed before bilateral sacral stimulation is considered (Oerlemans and van Kerrebroeck, 2008). A bilateral test stimulation could be indicated when a unilateral test fails (Steinberg et al, 2007). The only prospective randomized crossover trial to compare the unilateral with bilateral sacral nerve stimulation found no significant differences comparing the results (Scheepens et al, 2002a). The presence of pain is a predictor of adverse events (White et al, 2009); and although sacral neuromodulation is effective in 56% of patients with urgency/frequency, when pain is the major complaint then caution is indicated. Surgical revision rates are 7% to 18% (van Kerrebroeck et al, 2007). When used for BPS symptoms, frequent reprogramming is often required (Maxwell et al, 2008).

Key Points: Neuromodulation

- The association of pelvic floor dysfunction with pelvic pain syndromes makes neuromodulation a rational therapeutic alternative.
- Patients with pelvic pain in the absence of demonstrable pelvic floor dysfunction and levator tenderness may not respond as well as those with urgency/frequency associated with pelvic floor dysfunction. Controlled trials of sacral nerve stimulation for bladder pain syndrome are needed.

Surgical Therapy

Hydrodistention

Hydrodistention of the bladder under anesthesia, while technically a surgical treatment, is often the first therapeutic modality employed, often as a part of the diagnostic evaluation. Because there have been no standard methods of distention (Turner and Stewart, 2005), results vary markedly. Frontz (1922) first suggested hydraulic overdistention of the bladder for IC, and Bumpus (1930) reported the first series 8 years later. Simple bladder filling at cystoscopy will give relief to some patients (Hald et al, 1986); others have reported an office-based procedure with intravesical lidocaine anesthesia using electromotive drug administration (Rose et al, 2005), whereas Dunn and associates (1977) reported on 25 patients whose bladders were distended under anesthesia to the level of the systolic blood pressure for up to 3 hours. Sixteen of the patients were symptom free with a mean follow-up of 14 months; 2 patients suffered bladder rupture. The bladder in IC patients can be very thin, and the possibility of perforation or rupture must always be kept in mind and discussed with the patient (Badenoch, 1971; Hamer et al, 1992). Prolonged distention probably has little or no benefit over a short-term distention measured in minutes (Taub and Stein, 1994; McCahy and Styles, 1995). Using epidural anesthesia and a balloon distention technique to the mean arterial pressure for 3 hours continuously, Glemain and colleagues (2002) reported good but transient efficacy in patients with a bladder capacity of greater than 150 mL on predistention cystometry. In their prospective series of 30 patients, 18 had maintained a therapeutic response at 6 months and 13 at 1 year of follow-up. Moderate hematuria was almost universal, worsening of symptoms occurred in 5% of patients, and low back and hypogastric pain were common sequelae. There was one bladder rupture, one episode of sepsis, and one episode of prolonged retention.

Our method is to perform an initial cystoscopic examination (which is generally unremarkable), obtain urine for cytology, and distend the bladder for 1 to 2 minutes at a pressure of 80 cm H_2O. The bladder is emptied and then refilled to look for glomerulations or ulceration. A therapeutic hydraulic distention follows for another 8 minutes. Biopsy, if indicated, is performed after the second distention. Therapeutic responses in patients with a bladder capacity under anesthesia of less than 600 mL showed 26% with an excellent and 29% with a fair result compared with 12% excellent and 43% with a fair result in patients with larger bladder capacities (Hanno and Wein, 1991). Most favorable responses were extremely brief, however, with the exceptional patient noting improvement for 6 months and thus being a candidate for repeat therapeutic distention.

Acute hydrodistention does not seem to result in any long-term bladder dysfunction (Kang et al, 1992; Lasanen et al, 1992). Any efficacy is probably related to damage to mucosal afferent nerve endings (Dunn et al, 1977). It has no benefits in patients with detrusor hyperreflexia or instability (Taub and Stein, 1994; McCahy and Styles, 1995). Over half of men with prostate pain and without bacteriuria may have glomerulations. Symptoms in this group have been reported to improve with hydrodistention (Berger et al, 1998). While many patients with IC have sensory urgency at awake capacities of less than 100 mL, hydrodistention under anesthesia seems to allow for "staging" of the disease, giving the clinician some idea of the capacity he or she has to work with conservative therapies. A capacity under anesthesia of under 200 mL would not bode well for the likelihood of success of medical therapy. Fortunately these cases are relatively rare.

Surgical Considerations

Please see the Expert Consult website for more discussion on this topic.

Assessing Treatment Results

The diversity of BPS/IC therapies underscores the lack of understanding about the treatment of this syndrome (Rovner et al, 2000). It has been not only a difficult condition to diagnose but also a difficult condition for which to assess therapeutic impact. **There is a 50% incidence of temporary remission unrelated to therapy, with a mean duration of 8 months** (Held et al, 1990). A somewhat surprising finding from the Interstitial Cystitis Database was that although there was initial improvement in symptoms partially due to regression to the mean (Sech et al, 1998) and the intervention effect there was no evidence of a long-term change in average symptom severity over the 4-year course of follow-up (Propert et al, 2000). In a chronic, devastating condition with primarily subjective symptomatology, no known cause, and no cure, patients are desperate and often seem to respond to any new therapy (Fig. 12–12). They are often victims of unorthodox health care providers with untested forms of therapy, some medical, some homeopathic, and some even surgical.

Key Points: Surgical Therapy

- Major surgery for bladder pain syndrome is a reasonable alternative for patients with severe symptoms who have failed standard attempts at treatment and when the disease course suggests that spontaneous remission of symptoms is unlikely.
- Patients with a small bladder capacity under anesthesia are less likely to respond to conservative attempts at therapy.
- Patients with a Hunner lesion may have the best results with major surgery.
- If one conceptualizes bladder pain syndrome as two disorders, one of pain and the other of frequency, it becomes easier for the patient and physician to rationalize the decision.
- Conduit urinary diversion can be relied on to resolve the frequency symptoms, and if the patient would consider this alone to make for a successful procedure there is reason to seriously consider this option.
- Diversion, and even cystectomy with diversion, cannot guarantee a pain-free result, and it is critical for the patient to factor this into the decision about this often irrevocable step.

The Placebo Conundrum

When possible, the results of randomized controlled studies should be used for decision making. Placebo, double-blind studies are optimal in this disorder for which there is no generally effective standard therapy.

Placebo effects influence patient outcomes after any treatment which the clinician and patients believe is effective, including surgery. Placebo effects plus disease natural history and regression to the mean can result in high rates of good outcomes, which may be misattributed to specific treatment effects (Gillespie et al, 1991; Gillespie, 1994; Turner et al, 1994; Propert et al, 2000). Unfortunately, **too few BPS treatments have been subjected to a placebo-controlled trial.** This is not to say that what seems effective is not, but rather that a high index of skepticism is healthy, even in treatments tested in controlled trials (Schulz et al, 1995).

Although in many diseases an argument can be made against using a true placebo control as opposed to an orthodox treatment of approved or accepted value (Rothman and Michels, 1994), a good case for true placebo comparison can readily be made for BPS. The vagaries of the natural history, the general lack of progression of symptom severity over time, and the fact that it is not life threatening mean that there is little to lose and much to gain by subjecting new treatments to the vigorous scrutiny of placebo control. Many patients who volunteer for such trials have already run the gamut of accepted (although generally unproved) therapies. It has long been recognized in protocols that use subjective criteria for assessment that "improvement" may be expected in up to 35% of placebo-treated patients (Benson and Epstein, 1976). Because the spontaneous remission rate (although temporary) for BPS is 11% (Oravisto and Alfthan, 1976) to 50% (Held et al, 1990), combined with the placebo improvement it can be difficult to prove efficacy.

Even in placebo-controlled trials it is reasonable to surmise that some degree of unblinding may occur as a result of somatic or psychological side effects of the active arm, impairing the validity of the trial results and giving the active arm a slight edge over

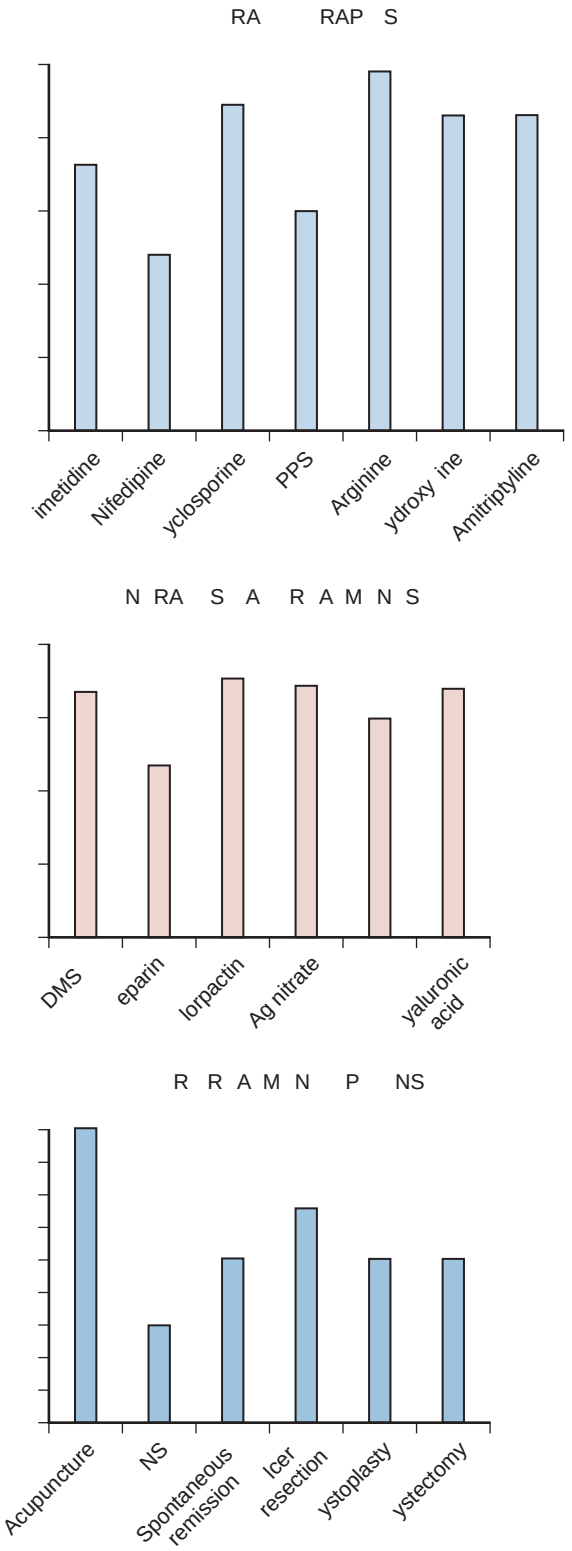

Figure 12–12. Selected reported treatment outcomes in uncontrolled studies in the bladder pain syndrome/interstitial cystitis literature: percentage of patients initially improved. Ag nitrate, silver nitrate; BCG, bacillus Calmette-Guérin; DMSO, dimethyl sulfoxide; PPS, sodium pentosan polysulfate; TENS, transcutaneous electrical nerve stimulation.

placebo (DuBeau et al, 2005; Rees et al, 2005). Failure to recognize unblinding can easily bias results of a study and has not been routinely measured in clinical trials (Desbiens, 2002). When occurring late in a study after one would expect onset of a therapeutic effect, unblinding could be the result of side effect profile or drug efficacy. Early in the trial it reflects poor placebo or study design. The degree of blinding needs to be ascertained throughout the trial. This is of specific concern in BPS and any disorder where primary outcomes may be subject to patient-specific psychological and physiologic factors.

The ethics and necessity of placebo-controlled trials have been questioned, especially in situations in which an effective treatment exists and also when delay in treatment has been shown to result in disease progression (Streiner, 1999; Anderson, 2006; Polman et al, 2008). However, there are methodologic concerns with equivalence and noninferiority active agent comparison trials (Streiner, 2007). These include an inability to determine if the treatments are equally good or equally bad, and the possibility that successive noninferiority trials can lead to a gradual decrease in treatment efficacy. Although the use of placebo-controlled trials raises ethical concerns when proven effective treatment exists for the condition under investigation, they are ethically justified, provided that stringent criteria for protecting research subjects are satisfied (Miller et al, 2004).

The value of placebo-controlled trials is aptly illustrated by the recent decisions by pharmaceutical manufacturers not to pursue FDA approval in the United States for seemingly promising intravesical therapies for BPS/IC (Morales et al, 1996; Chancellor and de Groat, 1999) after placebo-controlled trials failed to establish efficacy. These include low concentration hyaluronic acid (Bioniche, Canada), high concentration hyaluronic acid (SKK, Tokyo), and resiniferatoxin (ICOS, Bothell, WA, USA). Nalmefene, an initially promising oral therapy in the 1990s (Stone, 1994), also failed phase 3 trials (IVAX, Miami). Placebo trials are impractical in surgery and it can be difficult to evaluate surgical reports. The many older medications currently used off label might not meet success if tested in the stringent manner in which new molecular entities are tested. The expense of testing therapies currently used off label often requires dependence on the largesse of government agencies such as the NIH (Propert et al, 2002; Sant et al, 2003; Mayer et al, 2005).

Finally, when considering objective changes, the concept of statistical versus clinical significance is paramount. Investigators should, but rarely do, point out differences between statistical improvement and what they consider to be clinically significant improvement (Wein and Broderick, 1994). As Gertrude Stein reportedly stated, "A difference, to be a difference, must make a difference." An increase in bladder capacity of 30 mL may be statistically significant but clinically irrelevant. Number needed to treat and number needed to harm data (McQuay, 2003) may be particularly important in BPS/IC and typically have not been included in efficacy analysis.

Clinical Symptom Scales

There are three published BPS/IC symptom questionnaires: the University of Wisconsin IC Scale, the O'Leary-Sant IC Symptom Index and IC Problem Index, and the Pelvic Pain and Urgency/Frequency (PUF) Scale.

The University of Wisconsin IC Scale includes 7 PBS/IC symptom items (Table 12–15). **It has not been validated for identification or diagnosis of BPS/IC. It captures severity of symptom expression** (Keller et al, 1994; Goin et al, 1998). BPS/IC patients do not appear to indiscriminately report higher scores than controls for different somatic and general complaints (Porru et al, 2005). Unlike the other two instruments it addresses some quality-of-life issues, and this is an advantage when such issues are subject of investigation. Its most attractive aspects are its clinically apparent face validity and its ease of implementation.

The O'Leary-Sant indices (Table 12–16) are a **validated** questionnaire that was originally developed by focus groups, subjected to test-retest reliability analysis, and validated by administration to IC patients and asymptomatic controls (O'Leary et al, 1997; Lubeck et al, 2001). The questionnaire centers on 3 questions related to urgency/frequency and 1 on bladder-associated pain. It does not address generalized pelvic pain or symptomatology associated with sexual activity. This is not because these questions were not considered in the formulation of the questionnaire. Of 73 questions in the preliminary instrument covering domains of urinary symptoms, pain, sexual function, menstrual variability, and general health, only the 4 questions now in the instrument were needed to reliably and validly describe the illness experience of those with IC and distinguish these patients from those without the disorder (O'Leary and Sant, 1997).

Another instrument is the **PUF questionnaire** (Parsons et al, 2002a) (Table 12–17). It was specifically designed to include questions that directly reflect a wide variety of the symptoms experienced by patients who are affected by this disorder. One third of the questions address pelvic pain, including pain anywhere in the pelvis: the vagina, labia, lower abdomen, urethra, perineum, testes, penis, or scrotum. A large study utilizing the PUF questionnaire has concluded that up to 23% of American females have BPS/IC (Parsons et al, 2002a). This makes one wary as to the utility

7. Do you still have urgency after you go to the bathroom?	Never	Occasionally	Usually	Always			
8. a. If you have urgency, is it usually		Mild	Moderate	Severe			
b. Does your urgency bother you?	Never	Occasionally	Usually	Always			

Total Score (Symptom Score + Bother Score) Symptom Score (1, 2a, 4a, 5, 6a, 7, 8a) Bother Score (2b, 4b, 6b, 8b)
Total score ranges are from 1 to 35.

From Parsons CL, Dell J, Stanford EL, et al: Increased prevalence of interstitial cystitis: previously unrecognized urologic and gynecologic cases identified using a new symptom questionnaire and intravesical potassium sensitivity. Urology 2000;60:573–8.

and face-validity of the PUF (Ito et al, 2003). A total score of 10 to 14 equals a 74% likelihood of a positive potassium test (PST); 15 to 19 equals 76%; and 20+ equals 91%. To the extent that the PST is suspect, the reliability of PUF data comes into question. Question No. 4 of the PUF is problematic. Patients who are sexually active can gain up to 6 more points than those who are not, and patients who over time begin sexual activity because they are feeling better can actually accumulate a falsely elevated PUF score owing to this anomaly.

None of the questionnaires has been shown to be of value in diagnosis (Moldwin and Kushner, 2004), **although they may suggest who should be screened further for the syndrome** (Kushner and Moldwin, 2006). **The O'Leary-Sant and University of Wisconsin instruments correlate strongly in a large population of patients with BPS/IC** (Sirinian and Payne, 2001). **Both the O'Leary-Sant and University of Wisconsin questionnaires are responsive to change over time and thus good for following the natural history of the disorder and the results of treatment.**

Treatment outcome studies have also used the **Global Response Assessment** (GRA); a balanced patient self-report on overall response to therapy developed for NIDDK-sponsored multicenter therapeutic trials (Sant et al, 2003) (Table 12–18). A one-category change in GRA correlates with a 1.2-point change in the O'Leary-Sant indices and a 3.1-point change in the University of Wisconsin instrument (Propert et al, 2006).

PRINCIPLES OF MANAGEMENT

The information currently available in the literature does not lend itself to easily formulating a diagnostic or treatment guideline that would be universally accepted (Hanno and Dmochowski, 2009). Different groups of "experts" would undoubtedly create different "best practices." The compromise approach constructed by an experienced cross section of urologists and gynecologists from around the world at the International Consultation on Incontinence 2008 meeting in Paris seems reasonable and allows for significant latitude in individual practice and to account for patient preference (Hanno et al, 2009). It is outlined in Figures 12–13 and 12–14 and in Table 12–19.

Table 12–18.

Definition

Bladder Pain Syndrome (in the absence of a universally agreed definition, the European Society for the Study of Interstitial Cystitis—ESSIC definition is given along with a slight modification made at a recent international meeting held by the Society for Urodynamics and Female Urology—SUFU)

ESSIC: *Chronic pelvic pain, pressure or discomfort of greater than 6 months duration perceived to be related to the urinary bladder accompanied by at least one other urinary symptom like persistent urge to void or urinary frequency. Confusable diseases as the cause of the symptoms must be excluded.*

Consensus Definition from SUFU International Conference (Asia, Europe, North America) held in Miami, Florida February 2008: *An unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptom(s) of more than 6 weeks duration, in the absence of infection or other identifiable causes.*

Bladder Pain Syndrome (BPS)

NOMENCLATURE (see Fig. 12–13)

The scientific committee of the International Consultation voted to use the term "bladder pain syndrome" for the disorder that has been commonly referred to as interstitial cystitis (IC). The term painful bladder syndrome was dropped from the lexicon. The term IC implies an inflammation within the wall of the urinary bladder, involving gaps or spaces in the bladder tissue. This does not accurately describe the majority of patients with this syndrome. Painful Bladder Syndrome, as defined by the International Continence Society, is too restrictive for the clinical syndrome. Properly defined, the term Bladder Pain Syndrome appears to fit in well with the taxonomy of the International Association for the Study of Pain (IASP), and focuses on the actual symptom complex rather than what appears to be long-held misconception of the underlying pathology.

HISTORY/INITIAL ASSESSMENT

Males or females with pain, pressure, or discomfort that they perceive to be related to the bladder with at least one urinary symptom, such as frequency not obviously related to high fluid intake, or a persistent urge to void should be evaluated for possible bladder pain syndrome (see Fig. 12–9). The presence of commonly associated disorders including irritable bowel syndrome, chronic fatigue syndrome, and fibromyalgia in the presence of the cardinal symptoms also suggests the diagnosis. Abnormal gynecologic findings in women and well-characterized confusable diseases that may explain the symptoms must be ruled out.

The initial assessment consists of a frequency/volume chart, focused physical examination, urinalysis, and urine culture. Urine cytology and cystoscopy are recommended if clinically indicated. Patients with urinary infection should be treated and reassessed. Those with recurrent urinary infection, abnormal urinary cytology, and hematuria are evaluated with appropriate imaging and endoscopic procedures, and only if findings are unable to explain the symptoms, are they diagnosed with BPS.

INITIAL TREATMENT

Patient education, dietary manipulation, nonprescription analgesics, and pelvic floor relaxation techniques comprise the initial treatment of BPS. The treatment of pain needs to be addressed directly, and in some instances referral to an anesthesia/pain center can be an appropriate early step in conjunction with ongoing treatment of the syndrome. When conservative therapy fails or symptoms are severe and conservative management is unlikely to succeed, oral medication, intravesical treatment, or physical therapy can be prescribed. It is recommended to initiate a single form of therapy and observe results, adding another modality or substituting another modality as indicated by degree of response or lack of response to treatment. Excellence can be the enemy of good.

SECONDARY ASSESSMENT

If initial oral or intravesical therapy fails, or before beginning such therapy, it is reasonable to consider further evaluation which can include urodynamics, pelvic imaging, and cystoscopy with bladder distention and possible bladder biopsy under anesthesia (see Fig. 12–14). Findings of bladder overactivity suggest a trial of antimuscarinic therapy. Findings of a Hunner's lesion suggest therapy with transurethral resection or fulguration of the lesion. Distention itself can have therapeutic benefit in 30%-50% of patients, though benefits rarely persist for longer than a few months.

REFRACTORY BPS

Those patients with persistent, unacceptable symptoms despite oral and/or intravesical therapy are candidates for more aggressive modalities. Many of these are best administered within the context of a clinical trial if possible. These may include neuromodulation, intradetrusor botulinum toxin, or newly described pharmacologic management techniques. At this point, most patients will benefit from the expertise of an anesthesia pain clinic. The last step in treatment is usually some type of surgical intervention aimed at increasing the functional capacity of the bladder or diverting the urinary stream. Urinary diversion with or without cystectomy has been used as a last resort with good results in selected patients. Augmentation or substitution cystoplasty seems less effective and more prone to recurrence of chronic pain in small reported series.

Philosophy of Management

This author believes that, because of the natural history of the disorder, it is best to cautiously progress through a variety of treatments. Whereas the shotgun approach, starting newly diagnosed patients on a variety of simultaneous medications, seems to have many adherents, employing one treatment at a time makes the natural history of the disease itself an ally in the treatment process. One should encourage patients to maximize their activity and live as normal a life as possible, not becoming a prisoner of the condition. Although some activities or foods may aggravate symptoms, nothing has been shown to negatively affect the disease process itself. Therefore, patients should feel free to experiment and judge for themselves how to modify their lifestyle without the guilt that comes from feeling they have harmed themselves if symptoms flare. Dogmatic restriction and diet are to be avoided unless they are shown to improve symptoms in a particular patient.

In the near future, phenotyping of patients with BPS/IC may improve treatment outcomes but only time and future studies will determine if this is true (Baranowski et al, 2008). To answer the perennial question, "Can we, as health care providers, make evidence-based decisions for BPS/IC at this time?" the answer seems to be a qualified *sometimes* (Fall et al, 2008).

Overview of Other Sexually Associated Infections

Screening and detecting sexually transmitted infections (STIs) is a form of secondary prevention that interrupts further transmission as well as progression of the infection and its sequelae. Unfortunately, primary prevention, by means of education and safe sex practices, has not been enough to significantly curb the prevalence and high cost of STIs.

People at high risk of contracting STIs are young adults between the ages of 18 and 28. It is also important to bear in mind that STIs rank among the top five risks of international travelers, along with diarrhea, hepatitis, and motor vehicle accidents (Mawhorter, 1997).

The brunt of the STI burden, both in risk and consequence, falls on women. When exposed to STIs, women are more likely to become infected and are much more likely to be asymptomatic. STIs can cause pelvic inflammatory disease, with subsequent risks of chronic pain syndromes, ectopic pregnancy, and infertility. Unfortunately there is very little evidence that treatment will reverse the sequelae.

A urologist should have a high index of suspicion for underlying STI in women who present with recurrent urinary tract infections (UTIs) and in those who are symptomatic with sterile urine cultures. Up to 50% of women with signs of UTI during emergency department examination had subsequent positive cultures for STI (Berg et al, 1996). Physicians should maintain the same level of vigilance when treating women who have sex with women. Genital human papillomavirus (HPV) has been identified along with squamous intraepithelial lesions among lesbians and occurs among those who have not had sexual relations with men (Marrazzo et al, 1998).

Proctitis may occur in women and men who have anal sex. Causative organisms include *Neisseria gonorrhoeae, Chlamydia trachomatis, Treponema pallidum,* and herpes simplex virus (HSV). A discussion of human immunodeficiency virus (HIV) is beyond the scope of this chapter (see Chapter 14); however, **it is important to remember that STIs—especially the ulcerative types—facilitate the transmission and infection of HIV.** HSV type 2, in particular, may play a role in the transmission of HIV because it has been identified more frequently than other STIs among HIV-concordant couples. Increased risk of HIV concordance has also been observed among couples who both have *Mycoplasma genitalium* antibodies (Perez et al, 1998).

Evidence is available that has shown that the spermicide nonoxynol-9 is not preventive against STIs and that its frequent use may actually be detrimental by increasing the rate of genital ulceration and HIV transmission (Richardson, 2002).

It is imperative that the physician treating STIs make special efforts to be sure that his or her methods of diagnosis and treatment reflect the latest knowledge. To that end, the Centers for Disease Control and Prevention (CDC) periodically updates recommendations for STI treatment, which can be retrieved easily by checking the CDC website. Changes that occur in the interim will need to come from a review of current literature. The accurate diagnosis and treatment of a patient with an STI will allow the physician to treat not only the patient but also the sexual partner and possibly the couple's unborn children.

The most common STIs are discussed in this chapter and include HSV infection, chlamydial urethritis/cervicitis, lymphogranuloma venereum, syphilis, gonorrhea, chancroid, trichomoniasis, HPV infection, and scabies. Other sexually associated pathogens, which cause urethritis and vaginitides, are also discussed briefly.

EPIDEMIOLOGY AND TRENDS

It is estimated that more than 19 million new cases of STIs are reported each year and more than 65 million people are infected with incurable viral STIs (CDC, 2010b; American Social Health Association, 1998). Approximately two thirds of cases occur in adolescents and young adults. The most common STIs are HPV and HSV infections. **Of the top 10 nationally notifiable infectious diseases in the United States in 2008, 4 were STIs** (CDC, 2008). This does not include HPV and HSV infections because they are not reportable diseases.

The prevalence of infection with HPV in the United States is approximately 20 million, and the incidence is 6.2 million (Catea,

1999; Weinstock, 2004). At least 50% of sexually active men and women acquire genital HPV infection at some point in their lives. By age 50, at least 80% of women will have acquired genital HPV infection (STD Facts, 2005).

In 2009, only 28 cases of chancroid were reported, down from 67 cases in 2002 (CDC, 2010b). Interestingly, 71% were reported from the three states of Tennessee, Wisconsin, and Texas. Overall, the rate of reported cases has declined 99% since 1987. *Haemophilus ducreyi* is difficult to culture, and therefore the infection could be underdiagnosed. Improved diagnostic testing by means of polymerase chain reaction (PCR) testing is now commercially available and may increase diagnostic capability.

The incidence of infection with *Chlamydia* has continued to rise since it became a notifiable disease in 1995. In 2009, over 1.2 million cases were reported to the CDC (CDC, 2010b). The reported number of cases of chlamydial infection was about four times greater than the reported cases of gonorrhea. It is probable that this incidence is at least in part secondary to improved diagnostic ability and growth and implementation of routine screening programs in women. Now that highly sensitive nucleic acid amplification tests (NAATs) for urine are available, the diagnosis of chlamydial infection is increasing in both symptomatic and asymptomatic men. From 2005 to 2009, the rate of chlamydial infection among men increased 37.6% compared with 20.3% among women.

The rate of gonorrhea was fairly stable from 1996-2006 at approximately 115 cases per 100,000 population, and then decreased from 2006-2009 to a rate of approximately 99.1 per 100,000 population in 2009 (CDC, 2009). The incidence rate is highest in persons aged 15 to 24 and is particularly high for non-Hispanic blacks (20 times higher than for non-Hispanic whites). Rates are particularly higher for non-Hispanic blacks (which is 20 times the rate for non-Hispanic whites) and for men who have sex with men (Fox et al, 2001; CDC, 2010b). There has also been a significant increase in quinolone-resistant *N. gonorrhoeae,* such that **fluoroquinolones are no longer recommended for treatment in the United States** (CDC, 2007).

The rate of syphilis increased yearly during 2001-2009, primarily among men (3.0 cases per 100,000 population in 2001 compared to 7.8 cases in 2009). The rate among women increased from 0.8 cases in 2004 to 1.4 cases in 2009 (CDC, 2010b). It has been proposed that this is secondary to outbreaks among males having sex with males in urban areas with high rates of coinfection with HIV and high-risk sexual behavior (CDC, 2004b). Rates continue to be particularly high in southern states and among African-Americans. There is no evidence that screening high-risk individuals, including those with HIV or other STIs, or the general population reduces morbidity or mortality from syphilis. However, it has been shown that screening pregnant women reduces the prevalence of congenital syphilis (Coles et al, 1998).

Expedited Partner Therapy

A common dilemma for physicians treating patients with an STI is how to expeditiously extend treatment to the partner to prevent complications from infection, such as pelvic inflammatory disease, and prevent the spread of disease. Expedited partner therapy (EPT) is the practice of treating the sexual partners of patients with STI by providing the patient with a prescription or medication to take to his or her partner without an intervening clinical evaluation or professional prevention counseling.

In the past, once an STI was reported to the health department the health department notified past and present sexual partners of the patient. However, the increased incidence of HIV and threats of bioterrorism are competing for health department resources and many departments now only notify partners of patients with HIV or syphilis (Erbelding and Zenilman, 2005). Patients are now requested to notify their own partners, who are then expected to go for evaluation and treatment themselves. The problems with this proposal are evident, and already this concept has been shown to be ineffective (Macke and Maher, 1999). Golden and colleagues (2003) reported their success implementing an expedited treatment plan for partners that did not require medical evaluation. This was a randomized controlled trial in which patients in the expedited treatment group were given a "partner packet" of therapy to deliver to the partner themselves or, if they were unwilling to do so, the partner was notified by the physician staff and the packet was delivered by mail or could be picked up at a participating pharmacy. Both the patients and partners in the expedited treatment group had better outcomes than the control group. Although this approach is sensible, effective, and progressive, legal and clinical barriers may unfortunately prevent the widespread acceptance of this approach.

In 2006 the CDC concluded that EPT has been shown to be at least equivalent to patient referral in preventing persistent or recurrent gonococcal or chlamydial infection in heterosexuals and released guidelines for the uses of EPT (CDC, 2006). The guidelines recommend that EPT should be implemented only when other management strategies are impractical or unsuccessful. All recipients should be encouraged to seek medical attention in addition to accepting therapy by EPT, through counseling of the index case, written materials, and/or personal counseling by a pharmacist or other personnel. However, EPT should not be used routinely in men who have sex with men because of a lack of data to confirm efficacy in this population and the high risk of comorbidity, especially with undiagnosed HIV. Similarly, EPT should not be used for partners of women with trichomoniasis because of the high risk of comorbidity with chlamydial or gonococcal infection or in the management of patients with infectious syphilis.

The CDC collaborated with the Center for Law and the Public's Health at Georgetown and Johns Hopkins Universities to assess the legal framework concerning EPT in all 50 states, the District of Columbia, and Puerto Rico. The objective of the research was to conceptualize and identify legal provisions that implicate a clinician's ability to execute EPT. As of January 2011, EPT is allowable in 27 states, potentially allowable in 15 states including the District of Columbia and Puerto Rico, and legally prohibited in 8 states. The results of the research, explanation, and up-to-date legal status for each state can be found at the CDC website (CDC, 2010; www.cdc.gov/std/ept/legal).

GENITAL ULCERS

Several sexually transmitted infections are clinically characterized by genital ulcers and most commonly include HSV infection or syphilis. Other STIs that may manifest with ulcer include chancroid and granuloma inguinale.

Although specificity for clinical diagnosis of genital ulcer disease is good (94% to 98%), sensitivity is quite low (31% to 35%) (DiCarlo and Martin, 1997). Inguinal lymph node findings did not contribute to diagnostic accuracy. Patients with genital, perianal, or anal ulcers should undergo a diagnostic evaluation for HSV and serologic testing for syphilis. Testing for *Haemophilus ducreyi* should be conducted in areas where chancroid is prevalent. Specifically, the CDC recommends (1) serology and either darkfield examination or direct immunofluorescence for *Treponema pallidum,* (2) culture or PCR test for HSV, and (3) serologic testing for

Table 13–1.

Genital Ulcer Disease

DISEASE	LESIONS	LYMPHADENOPATHY	SYSTEMIC SYMPTOMS
Primary syphilis	Painless, indurated, with a clean base, usually singular	Nontender, rubbery, nonsuppurative bilateral lymphadenopathy	None
Genital herpes	Painful vesicles, shallow, usually multiple	Tender, bilateral inguinal adenopathy	Present during primary infection
Chancroid	Tender papule, then painful, undermined purulent ulcer, single or multiple	Tender, regional, painful, suppurative nodes	None
Lymphogranuloma	Small, painless vesicle or papule progresses to an ulcer	Painful, matted, large nodes develop, with fistulous tracts	Present after genital lesion heals

Figure 13–2. Herpes simplex virus infection on the penis.

type-specific HSV antibody (CDC, 2010c). **One should bear in mind that patients may have more than one STI. Approximately 10% of patients with chancroid also have HSV infection or syphilis.** HIV testing should also be considered in the management of patients with confirmed STI. Clinical characteristics of sexually transmitted genital ulcers are summarized in Table 13–1. Other causes that are not sexually transmitted, such as Behçet syndrome, drug reaction, erythema multiforme, Crohn disease, lichen planus, amebiasis, trauma, and carcinoma, must also be considered. **Empirical treatment for the most likely cause based on history and physical examination should be initiated as laboratory test results are pending.** If ulcers do not respond to therapy or appear unusual, a biopsy should be performed.

HERPES SIMPLEX VIRUS INFECTION

Diagnosis. Genital herpes infection is common, afflicting more than 50 million people in the United States (Xu et al, 2006). It is caused by HSV type 2 (HSV-2) in 85% to 90% of cases and HSV type 1 (HSV-1) in 10% to 15% of cases. HSV-1 is responsible for common cold sores but can be transmitted via oral secretions during oral-genital sex. Silent infection is common and may account for more than 75% of viral transmission (Langenberg et al, 1999). Up to 80% of women with HSV-2 antibodies have no history of clinical infection (White and Wardropper, 1997). The incubation period ranges from 1 to 26 days but is usually short, approximately 4 days. Nongenital infection of HSV-1 during childhood may be protective to some extent against subsequent genital HSV-2 infection in adults. When exposed to HSV-2, women with negative HSV-1 antibodies had a 32% risk of infection per year whereas women with positive antibodies had a 10% risk of infection per year (Baker, 1997).

Primary infection manifests as painful ulcers of the genitalia or anus and bilateral painful inguinal adenopathy. The initial presentations for HSV-1 and HSV-2 are the same. A group of vesicles on an erythematous base that does not follow a neural distribution is pathognomonic (Figs. 11–1 to 11–3). The differential diagnosis includes other STIs, such as primary syphilis and chancroid, as well as noninfectious disorders such as Crohn disease, trauma,

Figure 13–3. Vulvovaginal herpes simplex virus infection.

contact dermatitis, erythema multiforme, Reiter syndrome, psoriasis, and lichen planus.

The initial infection is often associated with constitutional flulike symptoms. Sacral radiculomyelopathy is a rare manifestation of primary infection that has a greater association with primary anal HSV. Genital lesions, especially urethral lesions, may cause transient urinary retention in women. Recurrent episodes are usually less severe, involving only ulceration of the genital or anal area. Severe disease and complications of herpes include pneumonitis, disseminated infection, hepatitis, meningitis, and encephalitis. **Asymptomatic viral shedding can take place for up to 3 months after clinical presentation, thereby perpetuating the risk of transmission** (Baker, 1997).

The diagnosis of genital herpes should not be made on clinical suspicion alone because the classic presentation of the ulcer occurs in only a small percentage of patients. **Women especially may present with atypical lesions such as abrasions, fissures, or itching** (ACOG Practice Bulletin, 2004). Viral culture with subtyping has been the gold standard of diagnosis of herpes infection. Viral subtype should be determined in every patient because it is important for prognosis and counseling. Women with HSV-2 have an average of four recurrences within the first year, and women with HSV-1 have one recurrence in the first year. After the first year, HSV-1 rarely recurs whereas the rate of HSV-2 decreases but slowly (Bendedetti et al, 1994). Viral culture can generally isolate the virus in 5 days, is relatively inexpensive, and is highly specific. However, the sensitivity of viral culture ranges from 30% to 95%, depending on the stage of the lesion and whether it is the primary infection or a recurrence. Viral load is highest when the lesion is vesicular and during primary infection. Therefore, viral culture has the highest sensitivity at these times and declines sharply as the lesion heals.

There are currently three U.S. Food and Drug Administration (FDA)-approved type-specific antibody assays (HerpeSelect HSV-1 and HSV-2 ELISA, HerpeSelect HSV-1 and HSV-2 Immunoblot, and Captia ELISA). These tests identify antibodies to HSV glycoproteins G-1 and G-2, which evoke a type-specific antibody response (Wald and Ashley-Morrow, 2002). These tests may also be able to identify recently acquired versus established HSV infection based on antibody avidity (Morrow et al, 2004).

Antigen detection kits are available but cannot distinguish reliably between HSV-1 and HSV-2. PCR testing has been shown to be 1.5 to 4 times as sensitive as viral culture. Samples are easy to attain and more stable than samples for viral culture. PCR testing will most likely replace viral culture as its availability increases and cost decreases.

Table 13–2.

Recommended Oral Treatment for Genital Herpes Simplex Virus Infection

AGENT	FIRST CLINICAL EPISODE	EPISODIC THERAPY	SUPPRESSIVE THERAPY
Acyclovir	400 mg tid for 7-10 days *or* 200 mg five times a day for 7-10 days	400 mg tid for 5 days *or* 800 mg tid for 2 days *or* 800 mg bid for 5 days	400 mg bid
Famciclovir	250 mg bid for 7-10 days	125 mg bid for 5 days *or* 1000 mg bid for 1 day *or* 500 mg once, followed by 250 mg bid for 2 days	250 mg bid
Valacyclovir	1 g bid for 7-10 days	500 mg bid for 3 days *or* 1 g sid for 5 days	500 mg sid *or* 1 g sid

Adapted from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines 2010. MMWR 2010;59(RR-12):21–2.

Treatment. Antiviral therapies approved for treatment include those using oral acyclovir, valacyclovir, and famciclovir (Table 13–2). **Topical antiviral medications are not effective.** Recurrences can be treated with an episodic or suppressive approach. When used for episodic treatment, medication must be initiated during the prodrome or within 1 day of the onset of lesions. Daily suppressive therapy has been shown to prevent 80% of recurrences and is an option for patients who suffer from frequent recurrences. It has been shown to decrease the frequency and duration of recurrences as well as viral shedding and therefore reduce the rate of transmission. The safety and efficacy of daily suppressive therapy has been well documented.

CHANCROID

Diagnosis. Chancroid, caused by *Haemophilus ducreyi,* is the most common ulcerative STI worldwide but is rare in the United States. It affects men three times more often than women. The incubation period ranges from 1 to 21 days. It causes a painful, nonindurated ulcer on the penis or vulvovaginal area. The ulcer has a friable base covered with a gray or yellow purulent exudate and a shaggy border. It can spread laterally by apposition to inner thighs and buttocks, especially in women. **It is associated with inguinal adenopathy that is typically unilateral and tender with a tendency to become suppurative and fistulize** (Figs. 13–4 and 13–5). *H. ducreyi* is fastidious and difficult to culture. The special culture media is not widely available, and sensitivity of culture remains less than 80%. Gram stain of a specimen obtained from the undermined edge of the ulcer may be more helpful in identifying the short, fine, gram-negative streptobacilli, which are usually arranged in short, parallel chains. Recently, PCR assays have been shown to be a sensitive and specific means of detecting *H. ducreyi*. Although no PCR test is currently FDA approved, testing can be performed by commercial agencies. HIV and syphilis screening should be performed at the time of diagnosis and 3 months after treatment if initial results are negative.

Figure 13–4. Chancroid with regional adenopathy.

Figure 13–5. Chancroid lesion.

Treatment. Single-dose treatments consist of azithromycin, 1 g orally, or ceftriaxone, 250 mg intramuscularly. Alternative regimens include ciprofloxacin, 500 mg twice daily for 3 days, or erythromycin base, 500 mg by mouth three times daily for 7 days. However, antibiotic susceptibility varies geographically. Resistance has been reported to ciprofloxacin and erythromycin in some regions. Ciprofloxacin is contraindicated during pregnancy and lactation. Subjective improvement should be noted within 3 days, and ulcers generally heal completely in 7 to 14 days. Healing may be slower in uncircumcised men with ulcers below the foreskin and in patients with HIV (Schmid, 1999). Patients should be reexamined in 5 to 7 days. Sexual partners should be examined and treated if sexual relations were held within 2 weeks before or during the eruption of the ulcer. Symptomatic relief of inguinal tenderness can be provided by needle aspiration or incision and drainage of the buboes.

Figure 13–6. Syphilis with vulvar chancre.

SYPHILIS

Diagnosis. Syphilis is caused by the spirochete *Treponema pallidum*. Incubation periods range between 10 and 90 days. It is spread through contact with infectious lesions or body fluids. It can also be acquired in utero and through blood transfusion. Syphilis has been categorized into overlapping stages based on clinical signs and symptoms to guide diagnosis and treatment. Primary syphilis is characterized by a single painless, indurated ulcer occurring at the site of inoculation that appears about 3 weeks after inoculation and persists for 4 to 6 weeks (Figs. 13–6 and 13–7). The ulcer is typically found on the glans, corona, or perianal area on men and on the labial or anal area on women. It is often associated with bilateral, nontender inguinal or regional lymphadenopathy. Because the ulcer and adenopathy are painless and heal without treatment, primary syphilis often goes unnoticed.

Secondary syphilis usually begins 4 to 10 weeks after the appearance of the ulcer but may present as long as 24 months after the initial infection. Secondary syphilis manifests as mucocutaneous, constitutional, and parenchymal signs and symptoms (Figs. 13–8 and 13–9). Frequent early manifestations consist of maculopapular rash, which is commonly seen on the trunk and arms, and generalized nontender lymphadenopathy. After several days or weeks, a papular rash may accompany the primary rash. These papular lesions are associated with endarteritis and may therefore become necrotic and pustular. The distribution widens and commonly affects the palms and soles. **In the intertriginous areas these papules may enlarge and erode to produce condyloma lata, which are particularly infectious.** Less common manifestations of secondary syphilis include hepatitis and immune complex–induced glomerulonephritis (Goldmeier and Guallar, 2003).

Figure 13–7. Syphilis with penile chancre.

Figure 13–9. Secondary syphilis affecting the soles of the feet.

Figure 13–8. Secondary syphilis affecting the genitalia.

Approximately one third of untreated patients will develop tertiary syphilis. It is very rare in industrialized countries, except for occasional cases reported in HIV patients. **Syphilis is a systemic disease that can affect almost any organ or system, especially the cardiovascular, skeletal, and central nervous systems, and skin.** Neurosyphilis can occur at any stage. **Aortitis, meningitis, uveitis, optic neuritis, general paresis, tabes dorsalis, and gummas of the skin and skeleton are just some of the sequelae associated with tertiary syphilis.**

Latent syphilis is defined as seroreactivity with no clinical evidence of disease. Early latent syphilis is latent syphilis acquired within the past year. All other latent syphilis is either referred to as late latent syphilis or latent syphilis of unknown duration.

Darkfield microscopy and direct fluorescent antibody (DFA) tests can be performed on specimens obtained from primary or secondary lesions. Darkfield microscopy is not widely available, but DFA testing of a fixed smear from a lesion can be performed at many commercial laboratories. Nontreponemal serologic testing with rapid plasma reagin (RPR) or Venereal Disease Research Laboratory (VDRL) are the most common methods of screening suspected individuals. Sensitivity is 78% and 86% for RPR and VDRL, respectively, in primary syphilis, 100% for both in secondary syphilis, and over 95% in tertiary syphilis (Hart, 1986). The false-positive rate is 1% to 2% and may be secondary to a large variety of causes (Golden et al, 2003). **Therefore, all positive tests should be confirmed with treponemal testing using *T. pallidum* particle agglutination (TP-PA) or fluorescent treponemal antibody absorbed (FTA-ABS) testing.** HIV can cause false-negative results by both treponemal and nontreponemal methods (Hicks et al, 1987; Erbelding et al, 1997). Positive treponemal antibody tests usually remain positive for life and do

not correlate with disease activity. Nontreponemal antibody titers, RPR and VDRL, correlate with disease activity. These tests usually become negative 1 year after treatment. A low percentage of patients remain "serofast," never regaining a negative titer. A fourfold difference in titer is reflective of a clinically significant difference. A fourfold increase after therapy is indicative of ineffective therapy or reinfection (Johnson and Farnie, 1994). A fourfold decrease represents successful treatment. Following disease activity, the same test, either RPR or VDRL, should be performed at the same laboratory because the results are not interchangeable and may vary from laboratory to laboratory.

The U.S. Preventive Services Task Force recommends that pregnant women and people who are at higher risk for syphilis infection receive screening tests for the disease (Calonge, 2004). People at higher risk for syphilis include men who have sex with men and engage in high-risk sexual behavior, commercial sex workers, persons who exchange sex for drugs, and those in adult correctional facilities. The CDC recommends that HIV testing should be considered in the initial evaluation of all patients with syphilitic infection and that screening for hepatitis B and C, gonorrhea, and chlamydial infection also should be considered. The presence of chancres increases the risk of HIV acquisition twofold to fivefold (Greenblatt et al, 1988; Stamm et al, 1988).

Treatment. Benzathine penicillin G (2.4 million units intramuscularly as a single dose) remains the treatment of choice for adults with primary, secondary, or early latent syphilis. Other parenteral preparations or oral penicillin are not acceptable substitutes. The **Jarisch-Herxheimer reaction** is a reaction consisting of headache, myalgia, fever, tachycardia, and increased respiratory rate that occurs within the first 24 hours after treatment with penicillin. Patients should be warned about the reaction, and it is usually managed with bed rest and nonsteroidal anti-inflammatory agents. It may cause fetal distress and preterm labor in pregnant women. If the patient has penicillin allergy, doxycycline, 100 mg by mouth twice daily for 14 days, or tetracycline, 500 orally for 14 days, have been used as alternatives. Close follow-up of patents receiving alteratives to the recommended benzathine penicillin regimen is critical.

For late latent syphilis, latent syphilis of unknown duration, or tertiary syphilis with no evidence of neurosyphilis, benzathine penicillin, 2.4 million units intramuscular injection should be repeated weekly for a total of three doses (total dose of 7.2 million units) or doxycycline therapy extended for a total of 4 weeks. In pregnancy, the alternative regimens of doxycycline and tetracycline should not be used and desensitization to penicillin is recommended if the patient has a penicillin allergy. Small studies have shown that azithromycin or ceftriaxone may be potential alternatives for early syphilis, but insufficient data are available to make definitive recommendations (Augenbraun and Workowski, 1999; Gruber et al, 2000; Hook et al, 2002).

Neurosyphilis and syphilitic eye disease are treated with aqueous crystalline penicillin G, 3 to 4 million units intravenously every 4 hours for 10 to 14 days, or with procaine penicillin G, 2.4 million units intramuscularly once daily, plus probenecid, 500 mg orally four times daily, with both drugs given for 10 to 14 days. Probenecid cannot be used in patients with an allergy to sulfa. The CDC recommends consideration of treatment with benzathine penicillin, 2.4 million units intramuscularly once a week for 3 weeks after completion of the neurosyphilis treatment regimen, to provide total duration of therapy comparable to that of late syphilis.

Patients should be followed with nontreponemal antibody titers at 6 and 12 month. Patients with HIV should be followed at 3, 6, 9, 12, and 24 months. A fourfold decrease in antibody titer is usually reflective of cure. The rate of treatment failure ranges from 4% to 21% (Parkes et al, 2004). Patients with treatment failure should be re-treated, and cerebrospinal fluid should be examined to exclude neurosyphilis. Patients with neurosyphilis require repeat examination of cerebrospinal fluid 3 to 6 months after therapy and every 6 months afterward until normal results are achieved.

LYMPHOGRANULOMA VENEREUM

Diagnosis. Lymphogranuloma venereum is caused by *Chlamydia trachomatis* types L1, L2, and L3 and is extremely rare in the United States. It still persists in parts of Africa, Asia, South America, and the Caribbean (Mabey and Peeling, 2002). The incubation period ranges from 3 to 30 days. The initial manifestation of infection is usually a single, painless ulcer on the penis, anus, or vulvovaginal area that goes unnoticed. **Patients usually present with painful unilateral suppurative inguinal adenopathy and constitutional symptoms that occur 2 to 6 weeks after resolution of the ulcer** (Figs. 13–10 and 13–11). Women and homosexual men may present with proctocolitis and perirectal or deep iliac lymph node enlargement if the primary lesion

Figure 13–10. Lymphogranuloma venereum.

Figure 13–11. Lymphogranuloma venereum with inguinal adenopathy.

arises from the rectum or cervix. Significant tissue injury and scarring may occur, leading to labial fenestration, urethral destruction, anorectal fistulae, and elephantiasis of the penis, scrotum, or labia.

The diagnosis is mainly clinical and cultures are positive in only 30% to 50% of cases. Complement fixation or indirect fluorescence antibody titers can confirm diagnosis. A complement fixation titer greater than 64 is diagnostic of infection. Other causes of inguinal adenopathy should be excluded.

Treatment. Antibiotic therapy for 3 weeks is necessary, using either doxycycline, 100 mg twice daily, or erythromycin base, 500 mg four times daily. Doxycycline is contraindicated in pregnant and lactating women. Patients should be followed clinically until symptoms resolve. Sexual partners should be examined, tested for urethral or cervical infection, and treated if sexual relations occurred within 30 days of the onset of symptoms.

CHLAMYDIA TRACHOMATIS INFECTION

Diagnosis. Infection with *C. trachomatis* is the most common bacterial STI in the United States and the most common worldwide. In the United States it is most prevalent in sexually active adolescents and young adults. Virulent serotypes include D, E, F, G, H, I, J, and K. The incubation period ranges from 3 to 14 days.

The majority of both men and women are asymptomatic. Approximately 50% of men experience lower urinary tract symptoms attributed to urethritis, epididymitis, or prostatitis and may notice clear or white urethral discharge. ***C. trachomatis* is the most common cause of epididymitis in young men.** Approximately 75% of women are asymptomatic, and 40% with untreated infection will develop pelvic inflammatory disease (Rees, 1980). **The squamous cells of vaginal epithelium are relatively resistant to infection with *C. trachomatis,* but the columnar cells of the cervix are not. A mucopurulent endocervical discharge may be present.** Scarring of the fallopian tubes from chlamydial infection puts patients at risk for recurrent pelvic inflammatory disease with vaginal flora, ectopic pregnancy, pelvic pain, and infertility (Simms and Stephenson, 2000).

Chlamydia may also be transmitted to newborns during vaginal birth through exposure of the mother's infected cervix. Neonates may contract ocular, oropharyngeal, respiratory, urogenital, or rectal infection.

Selective screening has been shown to reduce the incidence of pelvic inflammatory disease (Scholes et al, 1996). Sexually active women should be screened annually until age 26. Older women should be screened if risk factors such as a new sexual partner are present. In women, screening may be accomplished by (1) a nucleic acid amplification test (NAAT) performed on an endocervical swab specimen, if a pelvic examination is acceptable; otherwise, an NAAT may be performed on urine; (2) an unamplified nucleic acid hybridization test, an enzyme immunoassay, or direct fluorescent antibody test performed on an endocervical swab specimen; or (3) culture performed on an endocervical swab specimen. In men, the options remain the same: using intraurethral samples or urine.

NAATs utilizing PCR assays for urine are a highly sensitive and noninvasive means of screening men and women for chlamydial infection. NAATs have doubled the detection rate for asymptomatic infections compared with culture and antigen tests (Black et al, 2002; Watson et al, 2002). **This method should not replace pelvic examination or endocervical culture in symptomatic women because antibiotic sensitivity cannot be determined.** Specimens for culture can be obtained from urethral or cervical swabs, urine, or prostatic fluid. However, NAAT remains an alternative in patients when culture is not possible due to logistics or noncompliance. Urine NAAT is only slightly less sensitive than endocervical swab and because of its noninvasive nature can be used in venues where pelvic examinations are not performed, such as schools and prisons (Black et al, 2002). NAATs may be used with urine or vaginal specimens but not oral or rectal samples. NAATs to test for cure should not be performed less than 3 weeks after treatment has been completed because dead organisms that may still be present will yield a false-positive test. NAATs are available that test for infection with both *Chlamydia* and *N. gonorrhoeae* from one sample; however, a positive result is nondiscriminatory between the two diseases and therefore further testing would be needed to determine which disease is present.

Treatment. Azithromycin, 1 g by mouth as a single dose, or doxycycline, 100 mg twice daily for 7 days, is the primary treatment and both are equally effective (Lau and Qureshi, 2002). Alternative therapies include erythromycin base, 500 mg four times daily, erythromycin ethylsuccinate, 800 mg four times daily, ofloxacin, 300 mg twice daily, or levofloxacin, 500 mg once daily for 7 days. Doxycycline, erythromycin estolate, and ofloxacin are contraindicated during pregnancy. Erythromycin base, erythromycin ethylsuccinate, and azithromycin are safe during pregnancy. Another alternative in pregnant women includes amoxicillin, 500 mg three times per day for 7 days. Partners should be examined, tested, and treated. Patients should refrain from sexual intercourse until both their and their partner's treatment is completed or 7 days after single-dose therapy. Reculture for cure is not needed for patients treated with doxycycline or a quinolone antibiotic. Reculture is recommended 3 weeks after treatment with erythromycin because cure rates are lower with this regimen, in pregnant women, or if the patient has persistent symptoms. However, patients with *Chlamydia* are at high risk for reinfection and should be rescreened 3 to 4 months after treatment.

All sexual partners who came in contact with the patient within 60 days of diagnosis or symptom onset should be evaluated, tested, and treated for both *N. gonorrhoeae* and *C. trachomatis*. If more than 60 days has passed, the most recent sexual partner should be evaluated and treated. Sexual activity should be avoided until both partners complete treatment and are symptom free.

GONORRHEA

Diagnosis. Gonorrhea is caused by the gram-negative diplococcus *Neisseria gonorrhoeae*. The incubation period ranges from 3 to 14 days. Risk of infection after one exposure is 10% in men and 40% in women. Men will usually experience lower urinary tract symptoms attributed to urethritis, epididymitis, proctitis, or prostatitis, with associated mucopurulent urethral discharge. Women are frequently asymptomatic but may have symptoms of vaginal and pelvic discomfort or dysuria. **As with *C. trachomatis* the vaginal epithelium is resistant to infection with *N. gonorrhoeae* but the cervix is not. A mucopurulent endocervical discharge may be present** (Table 13–3). Both symptomatic and asymptomatic infections can lead to pelvic inflammatory disease and its subsequent complications. Manifestations of gonococcal dissemination are rare today and include arthritis, dermatitis, meningitis, and endocarditis.

The U.S. Preventive Services Task Force recommends screenings for gonorrhea to those at increased risk for

Table 13–3.
Differential Diagnosis of Sexually Transmitted Infections in Women

	VAGINAL DISCHARGE	pH	WBC	MICROSCOPY	SYMPTOMS
Normal	White, thick, smooth	≤4.5	Absent	Lactobacilli	None
Candidiasis	White, thick, curdlike	≤4.5	Absent	Mycelia	Vulvar pruritus, external or superficial dysuria
Trichomoniasis	Frothy or purulent	≥4.5	Present	Mobile trichomonads present Amine odor	Vulvar erythema and edema, punctate strawberry lesions on cervix
Neisseria gonorrhoeae infection	None or mucopurulent discharge from cervicitis	≥4.5	Present	Gram-negative diplococci within or adjacent to polymorphonuclear leukocytes on Gram stain	Vaginal and pelvic discomfort, dysuria, most often asymptomatic
Chlamydia trachomatis infection	None or mucopurulent discharge from cervicitis	≥4.5	Present	Organisms not visualized	Vaginal and pelvic discomfort, dysuria, most often asymptomatic
Bacterial vaginosis	Thin, white homogeneous	≥4.5	Absent	Paucity of lactobacilli (75% of patients) Amine odor Clue cells	Fishy odor and increased vaginal discharge

infection, including women with previous gonorrhea infection or other STIs; women with new or multiple sex partners, inconsistent condom use, sex, and drug use; and women in certain demographic groups and those living in high-prevalence areas. Screening may be done by endocervical culture or can be performed with newer screening tests, including NAAT and nucleic acid hybridization tests using vaginal, urethral (men only), or urine specimens (U.S. Preventative Services Task Force, 2005; CDC, 2010b). In case of suspected or documented treatment failure, culture and sensitivity are important to monitor antibiotic susceptibility and resistance. Culture may be performed on urethral exudates if present. Patients found to have gonorrhea should be tested for other STIs, including chlamydia, syphilis, and HIV.

Treatment. The most highly recommended treatment for gonorrhea is ceftriaxone, 250 mg intramuscularly as a single dose. It produces high, sustained blood levels that result in cure in about 99% of uncomplicated cases at all anatomic sites, including the pharnyx, which often goes undiagnosed. If treatment with ceftriaxone is not possible, a single oral dose of cefixime (400 mg) is an acceptable alternative that provides a high cure rate for uncomplicated urogenital and anorectal infection but is less effective for pharyngeal infection. Other single-dose cephalosporins, including ceftizoxime 500 mg IM, cefoxitin 2 g IM with probenacid 1 g orally, and cefotaxime 500 mg IM, have been shown to be effective as alternative regimens for uncomplicated urogenital or anorectal infection but offer no advantage over the recommended regimens.

The CDC no longer recommends quinolones for the treatment of gonorrhea in the United States based on data indicating widespread resistance.

Spectinomycin (not available in the United States), 2 g intramuscularly, can be used as an alternative in patients allergic to cephalosporins and during pregnancy. In the United States, azithromycin 2 g orally can be considered for pregnant women who cannot tolerate cephalosporins. It is not considered effective for pharyngeal infection.

Patients with gonorrhea are often coinfected with *C. trachomatis*. **It has been recommended that patients undergo simultaneous dual treatment because the cost of treatment is less than that of chlamydial testing.** Single-dose regimens given in the office also ensure compliance in patients who may otherwise not be able to afford the medication, comply with treatment, or return for follow-up. Patients undergoing dual therapy for chlamydial infection should receive azithromycin, 1.0 g as a single dose, or doxycycline, 100 mg twice a day for 7 days (or other acceptable treatment regimen) in addition to one of the previously mentioned regimens for infection with *N. gonorrhoeae*.

All sexual partners who came in contact with the patient within 60 days of diagnosis or symptom onset should be evaluated, tested, and treated for both *N. gonorrhoeae* and *C. trachomatis*. If more than 60 days has passed, the most recent sexual partner should be evaluated and treated. Sexual activity should be avoided until both partners complete treatment and are symptom free.

TRICHOMONIASIS

Diagnosis. Trichomoniasis is one of the most common STIs, with approximately 174 million new cases reported worldwide each year and more than 8 million new cases reported yearly in North America (WHO, 1999). There is an increased incidence in developing countries and in women who have had multiple sexual partners. It is caused by the flagellated protozoan *Trichomonas vaginalis,* which can inhabit the vagina, urethra, Bartholin glands, Skene glands, and prostate. It does not infect the mouth, and rectal prevalence is low. The human is its only known host. The incubation period ranges from 4 to 28 days.

Trichomoniasis is typically asymptomatic in men but may produce short-lived symptoms of urethral discharge, dysuria, and urinary urgency. **Fifty percent of women are asymptomatic.** When present, clinical manifestations in women include the sudden onset of a frothy white or green, foul-smelling vaginal discharge, pruritus, and erythema. Other symptoms include dyspareunia, suprapubic discomfort, and urinary urgency. It has been associated with premature labor in pregnant women and with increased risk of HIV transmission (Cotch et al, 1997; Sorvillo et al, 1998).

Clinical examination in women may reveal a frothy discharge and the characteristic "strawberry vulva" or "strawberry cervix." However, clinical assessment alone is not specific enough for diagnosis. Typically, the vaginal discharge has an elevated pH. The motile protozoa, which are one to four times the size of polymorphonuclear cells, can also be seen on vaginal wet-mount smear or microscopic examination of urine. In men, the diagnosis can be made with urethral, urine, or semen culture or microscopic

examination of the urine (preferably voiding bottle No. 1). Standard culture, transport culture kits, enzyme immunoassay, nucleic acid amplification, and immunofluorescence techniques are also available for confirmatory testing. Nucleic acid amplification tests have the highest sensitivity for diagnosis in men (Nye et al, 2009).

Treatment. Infected individuals and their sexual partners should be treated to prevent recurrence of infection. Recommended regimens include a single oral 2.0 g dose of either metronidazole or tinidazole. The 2 g metronidazole regimen may be used during pregnancy; however, the safety of tinidazole in pregnancy has not been established. For nonpregnant treatment failures a longer course of metronidazole, 500 mg twice daily for 7 days, is recommended. The dosing regimens appear equally effective, but side effects, especially gastrointestinal side effects, are more common with the high-dose single therapy. Patients must abstain from alcohol consumption during therapy and for 24 hours after completion of metronidazole and for 72 hours after completion of tinidazole. Repeat testing at 5 to 7 days and 30 days should be performed if symptoms fail to resolve and treatment failure is suspected, and a course of metronidazole, 500 mg orally twice a day for 7 days, should be repeated, or 2 g oral treatment with tinidazole or metronidazole once daily for 5 days may be tried. Metronidazole gel for intravaginal application is available but is less than 50% as effective as oral treatment. Patients allergic to metronidazole should be desensitized. Clotrimazole and other agents have been tried as local intravaginal applications but have not been found to be effective (duBouchet et al, 1997).

Figure 13–12. Meatal wart caused by human papillomavirus.

GENITAL WARTS

Diagnosis. Genital warts (condylomata acuminata) are caused by HPV. HPV is a DNA-containing virus that is spread by direct skin-to-skin contact. Over 100 types of HPV exist, and over 30 types can infect the genital area. Risk factors for acquiring HPV include multiple sexual partners, early age at onset of sexual intercourse, and having a sexual partner with HPV. Most infections are subclinical and asymptomatic. It has been shown that 60% of a group of female college students followed by Papanicolaou smear every 6 months for 3 years were infected with HPV at some point. The median duration of HPV infection was 8 months, with only 9% remaining infected after 2 years (Ho et al, 1998).

External visible warts are typically caused by HPV types 6 and 11. Patients may be infected with more than one type of HPV. Genital warts may appear anywhere on the external genitalia (Figs. 13–12 to 13–14). It has been suggested that inoculation occurs at the site of genital microtrauma (Frydenberg and Malek, 1993). HPV has also been found on the cervix, vagina, urethra, anus, and mucous membranes such as the conjunctiva, mouth, and nasal passages. Intra-anal warts are contracted via receptive anal sex. However, perianal warts are contracted by skin-to-skin contact and not exclusively through receptive anal intercourse.

Types 6 and 11 HPV are low risk for conversion to invasive carcinoma of the external genitalia. Some other types present in the anogenital region. Types 16, 18, 31, 33, 35, 39, 45, and 51 have been associated with cervical dysplasia and neoplasm in women and squamous intraepithelial neoplasia in men (Syrjanen 1981; Adam et al, 2000; Kulasingam et al, 2002). Over 99% of cervical cancers and 84% of anal cancers are associated with HPV, most commonly HPV 16 and 18 (Frisch et al, 1997; Walboomers et al, 1999; Kulasingam et al, 2002). **Because HPV progresses rapidly in HIV-infected women, cervical cancer is considered one of the illnesses that defines the acquired**

Figure 13–13. Penile warts.

Figure 13–14. Vaginal condylomata caused by human papillomavirus.

immunodeficiency syndrome (AIDS). Smoking may increase the risk of dysplastic progression and malignancy in both men and women.

In women, HPV may be associated with nonspecific symptoms, such as vulvodynia or pruritus. Malodorous vaginal discharge may also be a presenting sign, and the high rate of coinfection with other STIs observed in this setting may be a contributing factor.

The diagnosis is usually made through the visualization or palpation of nontender papillomatous genital lesions. Acetowhitening with 3% to 5% acetic acid placed on a towel and wrapped around the genitalia may show subclinical, flat condylomata appearing as whitish areas; however, because it is not specific for HPV infection, it is not recommended as a routine screening procedure. When this method was used it was shown that 50% to 77% of steady male partners of women with HPV infection and/or cervical neoplasia had subclinical HPV infection (Schneider et al, 1988). Conversely, female partners of men with genital warts have a high incidence of HPV infection (Campion et al, 1985). The benefit of evaluating and treating asymptomatic sexual partners of women with genital warts or abnormal Papanicolaou smears remains unclear. Therefore, routine androscopy is not recommended. **Biopsies of genital warts are not routinely needed but should be undertaken in all instances of atypical, pigmented, indurated, fixed, or ulcerated warts.** In addition, biopsy should be performed if the lesions persist or worsen after treatment and in immunocompromised patients.

Treatment. The CDC currently recommends that patients with genital warts be informed that HPV and recurrence is common among sexually active persons, the incubation period can be long and variable, and duration of infection and methods of prevention are not definitively known. The choice of therapy for genital warts depends on several factors, including wart size, number, and location and patient and physician preference. Because genital warts spontaneously resolve with time, observation remains an option. Therapy can be patient applied or provider applied. Patient-applied therapies are less expensive and may be more effective than provider-applied therapy (Langley et al, 1999; Arican et al, 2004). Patients must be able to identify and access the lesion and be capable of carefully following the product instructions.

Recommended treatment choices for patient-applied therapy include podofilox 0.5% solution or gel, imiquimod 5% cream, or sinecatechins 15% ointment. Podofilox solution should be applied every 12 hours for 3 days, then off for 4 days with the option to repeat the treatment cycle four times. The total volume of solution used should not exceed 0.5 mL/day, and the total wart area should not be greater than 10 cm^2. It may be helpful to demonstrate the first application in the office. Imiquimod cream should be applied three times per week at bedtime for up to 16 weeks. The area should be thoroughly washed 6 to 10 hours after application. Imiquimod should not be used on vaginal lesions because it has been reported to cause chronic ulceration. Sinecatechin ointment (0.5 cm strand of ointment) should be applied three times daily using a finger to ensure a thin film of ointment until the wart completely clears, but no longer than 16 weeks. It should not be washed off after use. In addition, sinecathecin should not be used in immunocompromised persons, HIV-infected persons, or persons with genital herpes because the safety and efficacy in these populations has not been established. The safety of podofilox, imiquimod, and sinecatechin in pregnancy is unknown. Both imiquimod and sinecatechin may weaken condoms and vaginal diaphragms.

Options for provider-applied therapy include cryotherapy with liquid nitrogen, electrosurgery, laser therapy, podophyllin resin 10% to 25%, trichloroacetic acid (TCA) or bichloroacetic acid (BCA) 80% to 90%, or surgical excision. Surgical excision may be accomplished by electrocautery or sharply with a tangential incision. Bleeding can generally be controlled with electrocautery or silver nitrate application. Surgical therapies appear to be equally effective with regard to clearance rates (Wiley et al, 2002). The advantages of surgical excision are that large warts or large areas can be addressed at one time. Carbon dioxide laser therapy is an alternative option for treatment.

Podophyllin 10% to 25% in compound tincture of benzoin is applied once and washed thoroughly 1 to 4 hours after treatment. Treatment may be repeated weekly as needed. The total volume of solution used should not exceed 0.5 mL, and the total wart area treated should not be greater than 10 cm^2 per session. In addition, the area being treated should not contain any open wounds or lesions. Podophyllin is contraindicated during pregnancy. TCA and BCA should be carefully applied with a cotton-tipped applicator only to the warts at 1- to 2-week intervals. Patients will complain of a burning sensation, which should resolve in 2 to 5 minutes. Acid that does not react should be removed with baking soda or talc. TCA and BCA are not recommended for keratinized or large warts. TCA is not absorbed and may be used during pregnancy.

Women with genital warts or a history of exposure should seek prompt gynecologic evaluation of the vagina and cervix. In the past, extensive vulvar lesions were treated with 5-fluorouracil cream but it was reported to cause ulceration and acquired adenosis and its use is no longer recommended.

Large or extensive lesions surrounding the urethral meatus may herald the presence of urethral or bladder condylomata, warranting cystourethroscopy. Urethral or bladder lesions should be cystoscopically excised. Intraurethral 5%

5-fluorouracil cream used twice weekly may be useful. However, its use is limited by the great amount of inflammation produced. Cystoscopic evaluation should be considered with caution because of the risk of transmitting the infection beyond the urethra and into the bladder. Considerations might include many and proximal urethral condylomata or other factors that would heighten suspicion for intravesical papillomas. We try to avoid traversing the external sphincter when performing limited urethroscopic examinations for the diagnosis of urethral condyloma or for the treatment of more distal lesions. Frequent serial ultrasound examinations of the distended bladder have been used for long-term surveillance of patients to check for recurrence of urethral condylomata.

HPV Vaccine. Two virus-like particle vaccines for the prevention of HPV-associated conditions are availble. Gardasil (Merck and Co., Inc.) is a quadrivalent vaccine against HPV types 6, 11, 16, and 18 and is approved by the FDA for use in males and females for the prevention of HPV-associated conditions such as cervical cancer, cervical cancer precursors, anal cancer and associated precancerous lesions, and anogenital warts. Cervarix (GlaxoSmith-Kline, PLC.), a bivalent vaccine against HPV types 16 and 18, is approved for use in females for the prevention of cervical cancer and associated precancerous lesions.

Both vaccines demonstrate good efficacy against cervical cancer and high-grade cervical intraepithelial neoplasia caused by HPV 16 and HPV 18, if administered before the initial exposure to these HPV types (Harper et al, 2004; Villa et al, 2005; FUTURE II Study Group, 2007; Garland et al, 2007). In addition, the quadrivalent vaccine protects against condylomata acuminata caused by HPV 6 and 11 and vulvar and vaginal precancerous lesions (FUTURE II Study Group, 2007; Joura et al, 2007).

The Advisory Committee on Immunization Practices (ACIP) recommends vaccination with either vaccine for the prevention of cervicial cancer and precancers. The quadrivalent vaccination may also be used for prevention of genital warts and other HPV-associated conditions such as vulvar cancers and precancers. The vaccines are most effective when all doses are administered before sexual contact. Either vaccine is recommended for 11- and 12-year-old girls and for females aged 13 to 26 years who did not receive or complete the vaccine series when they were younger. Vaccination may begin at age 9 when appropriate. The quadrivalent vaccine can be used in males age 9 to 26 years old to prevent genital warts (CDC, 2010). The length of immunity has not been definitively determined, but in phase 2 follow-up studies both the quadrivalent and bivalent vaccines demonstrated high immunogenic levels for more than 5 years (Villa et al, 2006; Harper et al, 2008). Further research will determine how long immunity will last and if a booster dose will be needed. Vaccination provides less protection to those who have already been infected with one or more of the four vaccine HPV types; however, vaccination is still recommended for protection against the other vaccine subtypes. Unlike the CDC's guidelines, the American Cancer Society does not recommend universal vaccination among women aged 19 to 26 years because of a probable reduction in efficacy as the number of lifetime sexual partners rises (Saslow et al, 2007). It is important to inform girls and women that they should continue cervical Pap screening even if they have been vaccinated.

MOLLUSCUM CONTAGIOSUM

Diagnosis. Molluscum contagiosum virus (MCV) is a double-stranded DNA virus that belongs to the Poxviridae family and has worldwide geographic distribution. There are four known subtypes of MCV, but the subtype does not appear to influence disease presentation or course (Nakamura et al, 1995). MCV-1 is the most prevalent in the United States, whereas types 2 and 3 are more prevalent in Europe, Australia, and in HIV-infected patients (Thompson et al, 1990, 1992; Porter and Archard, 1992). The incubation period ranges from 14 to 50 days (Fenner et al, 2001). MCV may be transmitted by skin-to-skin contact, fomites, or self-inoculation. It was once believed to cause only a benign, self-limiting childhood syndrome but is now also considered an STI in adolescents and adults. In children, lesions usually occur in clusters on the face and neck, chest, back, and extremities. In adults and adolescents it is most commonly transmitted by sexual contact, and lesions most frequently appear in the genital and inguinal regions, the inner thighs, and perineum. It less commonly affects mucosal areas such as the conjunctiva and oral mucosa. In children it may spread by self-inoculation to the genital area.

MCV primarily infects the squamous epithelium and manifests as smooth, round, pearly papules that are 2 to 5 mm in diameter, with a subtle central umbilication (Figs. 13–15 and 13–16). The lesions may have an erythematous or hypopigmented halo at the base. The papules are typically asymptomatic but may be associated with an eczematous, pruritic reaction. Giant lesions, more than 5 mm, can occur and seem to be more common in immunocompromised patients. In immunocompetent persons the lesions usually spontaneously resolve within a few months

Figure 13–15. Molluscum contagiosum on abdomen.

Figure 13–16. Molluscum contagiosum affecting penis.

and usually by 1 year but may take up to 5 years (Gottlieb and Myskowski, 1994; Smith et al, 1999).

Diagnosis is usually made on clinical suspicion and may be incidental. If confirmation is necessary, hematoxylin and eosin staining of a biopsy specimen may be performed. The presence of acidophilic, hyaline-filled Henderson-Patterson bodies, also known as molluscum contagiosum bodies, are pathognomonic. A squash preparation with methylene blue will also reveal the molluscum contagiosum bodies. It is recommended that the patients be tested for other STIs such as gonorrhea, chlamydial infection, and syphilis and carefully examined for coexistent condylomata acuminata and pediculosis pubis (Waugh, 1998). Careful consideration should also be given to HIV testing in patients with extensive multisite lesions, especially those involving the head and neck, and in lesions with a poor response to treatment.

Treatment. In most cases, MCV is benign and self-limiting and therefore requires no treatment. If the patient desires or if spread is of particular concern, destructive therapy with cautery, curettage, or cryotherapy with liquid nitrogen are sound options. All of these methods cause discomfort and may result in scarring. Lidocaine/prilocaine cream applied in an occlusive manner before the procedure should assist with discomfort. A topical antibiotic preparation should be applied afterward to prevent secondary infection.

Other topical therapies such as TCA, cantharidin, tretinoin, and podophyllotoxin have been reported for the treatment of MCV (Smith and Skelton, 2002). None is approved by the U.S. FDA for this indication, and all may result in pain and inflammation, especially in the genital area. Immunotherapy with imiquimod cream, either 1% or 5%, applied to lesions three times daily has been shown to be effective and appears especially useful in patients infected with HIV (Syed et al, 1998; Liota et al, 2000). Small studies in HIV-infected patients with recalcitrant lesions have also reported success with 1% cidofovir cream (Calista, 2000; Torro et al, 2000). Currently cidofovir is commercially available only in an intravenous preparation.

SCABIES

Diagnosis. Scabies is caused by the mite *Sarcoptes scabiei*. In adults, scabies is usually sexually transmitted, but this is not the case in children. The incubation period ranges from 2 to 6 weeks. Wavy, elongated papules are characteristic of the mite burrow. Eruption with pruritus is caused by an immune reaction to the mites, their eggs, and their feces. Susceptible areas include the penile shaft and glands, areolae, finger webs, and auxiliary folds (Fig. 13–17). Confirming the diagnosis may require microscopic evidence of the mite or eggs, which is retrieved by scraping the burrow with a scalpel blade coated with mineral oil. It can also usually be demonstrated if a thin shaving of skin from a papule is removed and placed on a glass slide and digested with heat and 10% potassium hydroxide.

Norwegian scabies, also known as crusted scabies, is caused by the same mite but occurs in immunocompromised or debilitated persons. The parasite burden is much greater, resulting in many severe, deep, hyperkeratotic crusts that are characteristically less pruritic, most likely secondary to the host's immune compromise. The incubation period is shorter in patients with Norwegian scabies—usually less than 2 weeks (Kolar and Rapini, 1991).

Treatment. Permethrin cream (5%) should be applied to all areas of the body from the neck down and washed off 8 to 14 hours later. An alternative to permethrin cream is oral ivermectin, 200 µg/kg in a single dose, repeated 2 weeks later. Ivermectin therapy has been shown to be equally effective as permethrin cream and lindane lotion but is more expensive (Wendel and Rompalo, 2002). For intolerance to permethrin or ivermectin, or treatment failure, the alternative is lindane (1%) lotion or cream applied in a similar fashion and removed after 8 hours. If necessary, treatment may be repeated in 1 week. **Lindane should not be used after a bath and is contraindicated in children younger than 2 years of age, pregnant and lactating women, and patients with extensive dermatitis.** Serious adverse side effects from lindane include seizures and aplastic anemia. For young children or pregnant/lactating women, sulfur (3% to 6%) applied on 3 consecutive nights is an option. Sexual partners and close contacts should also be treated. Treatment of Norwegian scabies may require combined oral and topical therapy or repeated treatments. Lindane should be avoided in these patients because of their excessive dermatitis, which may lead to increased absorption.

Figure 13–17. Scabies affecting shaft of penis.

Clothing or bed linen that may have been contaminated should be washed and dried by machine on a hot cycle or dry cleaned and removed from body contact for at least 72 hours. It should be noted that itching may persist for 2 to 3 weeks after adequate therapy.

PEDICULOSIS PUBIS

Diagnosis. Pediculosis pubis infection (phthiriasis, pubic lice) is caused by infection with the human louse *Phthirus pubis*. This species of lice has a proclivity for the pubic area, but the nits and lice can be seen in other areas with hair, such as the axilla, eyelashes, or scalp hair. The saliva of the lice causes a maculopapular or urticarial reaction in sensitized people and results in intense itching of the affected area. The presence of eggs (nits) attached to the hair shaft near the skin surface or the actual presence of an imbedded louse in the hair follicle is diagnostic. These lice can often be seen with the naked eye or with low-power magnification.

Treatment. Recommended regimens include permethrin cream rinse (1%) or pyrethrins with piperonyl butoxide applied to affected areas of the body and washed off 10 minutes later. Alternative regimen in the case of patients who cannot tolerate the recommended regimens or for treatment failure, by patients with extensive dermatitis, include malathion 0.5% lotion applied for 8 to 12 hours and then washed off, or ivermectin 250 mcg/kg orally, repeated in 2 weeks. Although topical insecticidal preparations are

the preferred treatment, trimethoprim-sulfamethoxazole can eliminate infections (Hutchinson and Farquhar, 1982). Pediculosis of the eyelashes is treated by applying an occlusive ophthalmic ointment, such as sterile petrolatum, to the eyelid margins two times a day for 10 days. The medicated topical agents described above cannot be used on or near the eyes. Sexual partners within the past 30 days should also be treated. Clothing or bed linen that may have been contaminated should be washed and dried by machine on a hot cycle or dry cleaned and removed from body contact for at least 72 hours.

OVERVIEW OF OTHER SEXUALLY ASSOCIATED INFECTIONS

Mollicutes

Ureaplasma urealyticum, Mycoplasma hominis, and *Mycoplasma genitalium* are considered commensal organisms of the genital tract in both men and women. At least 60% of asymptomatic women have been shown to harbor *Ureaplasma* in their genital tract. **However, these organisms have also been implicated in cases of chronic prostatitis in men, urgency/frequency syndromes in women, and up to 40% of nongonococcal urethritis cases.** They have been isolated as the sole pathogen in symptomatic patients, who respond to antimicrobial therapy targeting these mollicutes. Women, especially young sexually active women, with urgency-frequency syndrome with or without dysuria who have repeatedly negative urine cultures may benefit from culture and subsequent treatment for *Mycoplasma* and *Ureaplasma*. Culturing for this organism should also be considered in men with symptoms previously attributed to prostatitis or in men with prior history of STI exposure or infection.

Mollicutes have complex nutritional requirements and will not grow on routine culture medium. They cannot be visualized well with Gram stain. Confirming the presence of the organism from cervical, urethral, or urine specimens requires the visualization of characteristic colonies on specialized agar and color changes of urea broth. The organisms are highly sensitive to drying and must be promptly placed in the proper medium and delivered to the laboratory. If cultures are positive, treatment is recommended with subsequent surveillance for improvement in symptoms. Sexual partners should be evaluated and treated and no sexual activity is advised for 2 weeks during treatment.

Historically this group of organisms was highly sensitive to tetracycline. Today, however, up to 30% of strains may be resistant, which may explain persistent symptoms in those patients treated empirically for nongonococcal urethritis or presumed *Chlamydia* infection. Most tetracycline-resistant strains remain sensitive to erythromycin. Currently, the initial recommended therapy is doxycycline, 100 mg twice daily for 2 weeks, or a single 1-g dose of azithromycin, which can be repeated after 10 to 14 days if needed. Other alternatives include erythromycin, 500 mg four times daily, or ofloxacin, 300 mg twice daily for 10 to 14 days. Sexual partners should be evaluated and treated as well as refrain from sexual activity for 2 weeks during treatment.

Bacterial Vaginosis

Diagnosis. Bacterial vaginosis is caused by the overgrowth of *Gardnerella vaginalis,* anaerobic organisms, and *Mycoplasma hominis* and inhibition of normal vaginal flora, particularly *Lactobacillus*. The cause of disruption in the microflora has not been elucidated. Bacterial vaginosis increases a woman's risk of contracting infection with HIV, is associated with increased complications in pregnancy, and may be involved in the pathogenesis of pelvic inflammatory disease.

Patients may complain of a malodorous vaginal discharge, particularly after sexual intercourse, and nonspecific low-grade genital discomfort. Risk factors for bacterial vaginosis include an increased number of sexual partners, douching, abnormal uterine bleeding, and contraceptive use.

To examine vaginal discharge, a wet mount is performed by adding 2 drops of normal saline to the vaginal discharge on one microscope slide and 2 drops of 10% potassium hydroxide to another sample on a second slide. The whiff test is performed immediately after adding the potassium hydroxide. A fishy odor secondary to the release of amines is suggestive of bacterial vaginosis. The slide is then examined under the microscope using low and high power. Clue cells are white blood cells with bacteria attached to the cell membrane. Three of four of the following factors must be met to confirm the diagnosis: (1) thin, white vaginal discharge that covers the vagina, (2) vaginal pH greater than 4.5, (3) clue cells, and (4) positive whiff test. Vaginal cultures are not helpful in this setting; however, a Gram stain of the vaginal discharge can identify the relative change in concentrations of normal bacterial flora. There are commercially available DNA probes and card tests that can be useful for office diagnosis. Routine operative prophylaxis with metronidazole before hysterectomy has been shown to reduce postoperative infectious complications.

Treatment. Recommended primary therapy includes metronidazole, 500 mg twice daily for 7 days; clindamycin cream, 2% (5 g) intravaginally at bedtime for 7 days; or metronidazole gel, 0.75% (5 g) intravaginally at bedtime for 5 days. Alternative regimens include clindamycin, 300 mg orally twice daily for 7 days; clindamycin ovules, 100 g intravaginally at bedtime for 3 days; tinidazole, 2 g orally once daily for 2 days; or tinidazole, 1 g orally once daily for 5 days. Clindamycin cream and ovules may weaken latex condoms and diaphragms. Factors that disrupt the normal vaginal flora, such as douching, should be avoided. Treatment of the sexual partner has not been shown to prevent recurrence in two randomized trials and is therefore not recommended (Vejtorp et al, 1988; Colli et al, 1997).

Vulvovaginal Candidiasis

Vaginitis caused by *Candida albicans* is the most common type seen in the clinical setting, but other species of *Candida* may also cause infection. The organism is present in the normal vagina and can also be found in the coronal sulcus of the penis. Sexual transmission with subsequent colonization and infection is possible. Predisposing factors for active infection include hormonal changes resulting from pregnancy or contraception, antibiotic use, systemic corticosteroids, or antimetabolites. Complicated vulvovaginal candidiasis is defined as recurrent, severe, non–*C. albicans* infections occurring in patients with altered immunity or pregnancy. Characteristically, thick, cheesy vaginal discharge is usually associated with vulvar irritation and itching. Patients may also experience vaginal discomfort, burning, dyspareunia, and external dysuria.

Diagnosis can be confirmed in a woman with signs and symptoms by findings of yeast or pseudohyphae on a wet preparation slide or Gram stain of the vaginal discharge. Often the yeast and pseudohyphae are seen better when 10% potassium hydroxide is used. The pH of the vaginal discharge should be normal

Key Points

- Bacterial STIs are decreasing in prevalence whereas the prevalence of viral STIs has increased significantly in recent years.
- The differential diagnosis for genital ulcers includes the following STIs: syphilis, chancroid, lymphogranuloma venereum, and herpes simplex virus. Other causes also include diseases not transmittable through sexual activity: Behçet syndrome, drug reaction, erythema multiforme, Crohn disease, lichen planus, amebiasis, trauma, and carcinoma.
- Sensitivity of diagnosis made solely on the appearance of genitourinary ulcers is 35% at best.
- Confirmatory testing made by cultures, PCR, or serologic studies is important for appropriate treatment and eradication of the disease in both patients and their partner(s).
- Empirical treatments for vaginitides should be done with caution because the differential diagnosis is quite extensive. Women with chronic lower urinary tract symptoms should be thoroughly examined to exclude the possibility of vaginal pathology and/or STIs.
- The physician treating STIs should make special efforts to be sure that his or her methods of diagnosis and treatment reflect the latest knowledge. The CDC periodically updates its website with recommendations for STI treatment, because this topic has rapidly changing epidemiologic characteristics and treatment trends based on newly resistant strains.

(<4.5). A vaginal culture may also be performed and is advised in patients with recurrent infections. Recurrent vulvovaginal candidiasis is defined as four or more episodes per year, and in 10% to 20% of patients *C. glabrata* and other candidal species are found.

Treatment. Over-the-counter antifungal vaginal creams, tablets, or suppositories of the topical azole class are generally effective, requiring 1- to 7-day regimens depending on the agent and dosage form. Over-the-counter treatment agents include butoconazole, clotrimazole, miconazole, and tioconazole. The vaginal preparations may weaken latex condoms. Prescription intravaginal agents include butoconazole, nystatin, and terconazole. An alternative to vaginal creams that is both effective and economical is fluconazole, 150 mg, as a single oral dose (Miller, 1997).

Recurring infections or complicated vulvovaginal candidiasis may require extended treatment of 14 days with vaginal preparations or oral fluconazole therapy repeated every 3 days (day 1, 4, and 7) for a total of three doses prior to starting an antifungal maintenance regimen. Patients suffering from recurrent candidal vulvovaginitis require further evaluation to exclude HIV infection, diabetes, or other immune-compromised states, although in most women no cause is found. These patients often do well with maintenance therapy, but 30% to 40% will have recurrence once maintenance therapy is stopped. Treatment of sexual partners is not suggested in general but may be considered in patients with recurrent infections.

HIV/AIDS Epidemiology
HIV Virology and Targets for Antiviral Therapy
Pathogenesis of HIV Infection
Tests to Diagnose and Monitor HIV Infection: What the Urologist Should Know
Urologic Manifestations of HIV Infection
Occupational Risks for HIV Infection in Urology
Antiretroviral Therapy

The acquired immunodeficiency syndrome (AIDS) is the most severe manifestation of infection with human immunodeficiency virus (HIV). **AIDS is defined by development of serious opportunistic infections, neoplasms, or other life-threatening conditions resulting from progressive immunosuppression caused by HIV infection.**

After AIDS was described in 1981 the number of cases increased rapidly (Steinbrook, 2004; World Health Organization, 2004). An estimated 30.6 million to 36.1 million people worldwide are living with HIV infection. More than 20 million have died of AIDS (Joint United Nations Program on HIV/AIDS, 2004; UNAIDS/WHO, 2008). In 2007 alone, 2.5 million people were infected and 2.1 million died of AIDS. Of all people 15 to 49 years of age worldwide, 1.1% are now infected with HIV (Steinbrook, 2004).

HIV/AIDS EPIDEMIOLOGY

In less than 15 years HIV infection reached pandemic proportions, with AIDS reported in over 190 countries (UNAIDS/WHO, 2008). The impact of HIV infection is much different in the developing world than in the industrialized world. **At one time AIDS was the leading cause of death among 25- to 44-year old men in Western European and North American cities and was the third most common cause of death among young women** (Carael et al, 2004; Steinbrook, 2004). **With effective antiretroviral therapy, deaths attributed to AIDS are declining rapidly.** Worldwide, AIDS-related deaths declined from 2.9 million to 2.1 million from 2004 to 2007 (UNAIDS/WHO, 2008).

In contrast, in many African cities AIDS represents the leading cause of death and of years of potential lost in men and the second most important cause of death in women. Life expectancy in the most affected sub-Saharan countries was reduced as much as 15 years by the year 2000, compared with projections of life expectancy in those not infected with HIV.

Worldwide Perspective

The three main modes of HIV transmission have changed little: unprotected intercourse, contact with blood, and transmission from mother to child. Direct blood contact, such as sharing drug-injection equipment, results in the most efficient transmission. Globally, "unprotected" sexual intercourse between men and women is the predominant mode of HIV transmission (World Health Organization, 2004).

The burden of HIV infection is greatest in the developing world (Steinbrook, 2004). Two thirds of HIV-infected persons are in Africa, where the epidemic exploded during the 1990s, and one fifth are in Asia, where the epidemic has been growing steadily (Steinbrook, 2004). Eight of nine countries with the most HIV-infected people are in sub-Saharan Africa. Estimates for India range from 2.2 to 7.6 million, and for China they are from 430,000 to 1.5 million. In comparison, an estimated 1.2 million people are living with HIV in the United States, 860,000 in the Russian Federation, and 680,000 in Brazil. Statistics highlight global disparities in availability of therapy. Overall, 1.6 million people died of AIDS in sub-Saharan Africa in 2007. By comparison, in Western and Central Europe, only 12,000 people died of AIDS in 2007 (Table 14–1) (Joint United Nations Program on HIV/AIDS, 2004; UNAIDS/WHO, 2007; Quinn, 2008).

Developed World Perspective

The prevalence of HIV has continued to rise in the United States with estimates as high as 1.2 million Americans living with HIV, nearly 75% of whom are adult men (Carael et al, 2004; Centers for Disease Control and Prevention, 2004; Steinbrook, 2004; Heyns et al, 2009). Early in the epidemic most infections occurred among men who have sex with men, but the incidence in this group leveled off by 1985-1987. However, HIV prevalence levels of 7% to 9% are still found among young homosexual and

Table 14–1.
The Global HIV-AIDS Epidemic at the End of 2007

REGION	NO. OF PEOPLE LIVING WITH HIV-AIDS	PREVALENCE OF HIV-AIDS AMONG ADULTS (%)	NO. OF NEW HIV INFECTIONS IN 2003	NO, OF DEATHS DUE TO AIDS IN 2003
TOTAL	33.2 million	0.8	2.5 million	2.1 million
Sub-Saharan Africa	22.5 million	5.0	1.7 million	1.6 million
South and Southeast Asia	4 million	0.3	340,000	270,000
Latin America	1.6 million	0.5	100,000	58,000
Eastern Europe and Central Asia	1.6 million	0.9	150,000	55,000
North America	1.3 million	0.6	46,000	21,000
East Asia	800,000	0.1	92,000	32,000
Western and Central Europe	760,000	0.3	31,000	12,000
North Africa and Middle East	380,000	0.3	35,000	25,000
Caribbean	230,000	1.0	17,000	11,000
Oceania	75,000	0.4	14,000	1,200

Data from UNAIDS/WHO. AIDS epidemic update. Geneva: UNAIDS/WHO; 2007.

bisexual men in cities such as San Francisco and New York. The largest decline in the proportion of AIDS cases in the United States has occurred among homosexual and bisexual men, whereas cases acquired by heterosexual transmission have increased. Despite antiretroviral therapy, blood screening, and treatment of sexually transmitted infections the number of infections has remained at a plateau of 40,000 new HIV infections per year in the United States over the past decade (Mayer and Safren, 2004).

The HIV prevalence among injecting drug users has been increasing steadily, but with large regional differences (Carael et al, 2004). Since the late 1980s on the U.S. west coast about 90% of people with AIDS are men who have sex with men, whereas on the northeastern coast most new HIV infections occurred among injecting drug users. Young adults belonging to ethnic minorities (including men who have sex with men) are at considerably greater risk of infection than they were 5 years ago. For example, African-Americans make up only 12% of the U.S. population but were affected in 47% of AIDS cases reported in 2000.

Table 14–2.
HIV Infection Risk Associated with Sexual Behaviors Compared with Blood Exposure

ROUTE/TYPE OF EXPOSURE	RISK OF INFECTION MEAN/RANGE (%)
Transfusion of contaminated blood	84-100
Intravenous drug use (needle sharing)	0.8
Receptive anal intercourse	0.3-0.8
Insertive anal intercourse	0.04-0.1
Occupational needlestick exposure	0.28-0.33
Insertive vaginal intercourse	0.03-0.09
Receptive vaginal intercourse	0.005-0.02
Insertive oral intercourse	0.003-0.008
Receptive oral intercourse	0.006-0.02

Data from Henderson et al, 1986; Kaplan and Heimer, 1994; Royce et al, 1997; Varghese et al, 2002; and Henderson, 2004.

Dynamics of the HIV Epidemic: Importance of Urologic Risk Factors

HIV epidemics may occur suddenly, reflecting circumstances that are not fully understood (Carael et al, 2004). For example, HIV seroprevalence among injecting drug users in Bangkok increased from zero in 1985-1986 to 16% in 1988 and 40% to 60% in 1992.

A number of the major risk factors are urologic (Table 14–2) (Carael et al, 2004). Early epidemiologic studies identified major risk factors, especially unprotected sexual intercourse with multiple partners or an infected partner, presence of sexually transmitted infections (STIs), or a history of STIs (Van de Perre et al, 1985; Kreiss et al, 1986; Cameron et al, 1989; Laga et al, 1994). More recent studies have highlighted sex differences in HIV transmission. For many monogamous women the main risk factor may be the sexual behavior of their steady partner (UNAIDS/WHO, 2008).

Variable Rates of Sexual Transmission

Multiple cofactors affect HIV transmission, which is why estimates vary on the relative risk for specific exposures (see Table 14–2) (Royce et al, 1997; Vernazza and Eron, 1997). The probability of HIV transmission associated with unprotected vaginal sexual intercourse is not constant from one contact to another: estimates range from 0.0005 to 0.002 per episode, in the absence of cofactors (Carael et al, 2004).

A recent meta-analysis of observational studies provided risk estimates for per sexual act transmission of HIV-1 among heterosexuals (Boily et al, 2009). The study included 43 publications, based on work in 25 different study populations. The pooled risk estimates suggest that female-to-male (0.04% per act [95% confidence interval [CI] 0.01-0.14]) and male-to-female (0.08% per act [95% CI 0.06-0.11]) HIV transmission rates are low in high-income countries. In contrast, much higher HIV transmission rates occur in low-income countries with female-to-male (0.38% per act [95% CI 0.13-1.10]) and male-to-female (0.30% per act [95% CI 0.14-0.63]) HIV transmission rates, even in the absence of commercial sex exposure. In multivariate analyses, transmission rates were influenced by gender, setting (high- vs. low-income countries), and antenatal HIV prevalence. As expected, the pooled risk estimate was higher for receptive anal intercourse (1.7% per act [95% CI 0.3-8.9]) and for the presence or history of genital ulcers in either couple member (5.3% per act [95% CI 1.4-19.5]).

Sexually Transmitted Infections

The presence of STIs suggests a marked risk of concurrent HIV. First, the modes of transmission of HIV and other STIs are similar.

Second, genital ulcers as well as nonulcerative STIs facilitate HIV transmission (Cameron et al, 1989). Ulcerative STIs, including herpes, syphilis, and chancroid, enhance susceptibility to HIV per sexual act. Nonulcerative STIs, including gonorrhea, chlamydial infections, and trichomoniasis, are independent risk factors for HIV, with relative risks of 2.7 to 3.5 (Laga et al, 1994). Because syphilis facilitates acquisition and transmission of HIV, recent outbreaks of syphilis among men who have sex with men in major U.S. cities and reported increases in sexual behavior have raised concerns about potential increases in HIV transmission (Centers for Disease Control and Prevention, 2004).

Several studies report conflicting results for aggressive diagnosis and treatment of STIs to limit HIV infection in high-risk populations. One study from Uganda employed syndromic management of STIs in an area where the epidemic was in its early stages with less than 1% of the adult population being infected at study inception. HIV incidence decreased in communities where the intervention was undertaken compared with control communities (Grosskurth et al, 1995). Different findings were reported in a study from Tanzania that employed periodic mass STI treatment of at-risk adults. This study found no decrease in HIV incidence (Wawer et al, 1999). In the later study the epidemic was more advanced with more than 16% of the adult population being infected at study inception. In addition there was a high rate of concomitant genital herpes that was not treated. Taken together, these findings suggest that efforts to decrease HIV spread through treating STIs should focus on specific treatment for individual patients, with aggressive diagnosis and treatment of STIs that are common in the community. The potential benefit of STI control programs may also prove greatest in areas of lower HIV prevalence. In communities where the epidemic is widespread, the likelihood of encountering a new partner who is HIV infected may be substantial, so the benefit of modifying a cofactor may be more limited (Mayer and Safren, 2004).

Antiretroviral Therapy and Genital Secretions

Only a small proportion of sexual exposures result in HIV transmission (Anderson and May, 1988). Transmission may occur by exposure to cell-free or cell-associated virus, and different factors may affect expression of virus concentrations in different body fluids (i.e., blood, semen, or cervicovaginal secretions) (Krieger et al, 1998; Chakraborty et al, 2001; Mayer and Safren, 2004). Although lower blood HIV levels are associated with lower transmission rates (Quinn et al, 2000), antiretroviral therapy may not make HIV-infected people noninfectious. In fact, sexual transmission of multidrug-resistant HIV has been well documented (Boden et al, 1999; Little et al, 1999). These observations underscore the need for HIV-infected patients to practice safer sex even if they are on therapy.

Circumcision Status

Three lines of evidence support the conclusion that circumcised men are at lower risk for HIV infection: biologic evidence, data from observational studies supported by meta-analyses, and the results of three randomized clinical trials supported by meta-analyses (Table 14–3) (Weiss et al, 2000).

The biologic mechanisms that could explain the increased risk of HIV among uncircumcised men include an increased rate of inflammatory conditions, susceptibility of the mucosal surface of the prepuce to trauma, and the longer survival of pathogens in the warm, moist subpreputial space. The inner foreskin is particularly susceptible to HIV infection owing to lack of keratinization and the high density of HIV target cells that are readily accessible (Patterson et al, 2002; Soilleux and Coleman, 2004; McCoombe and Short, 2006).

The hypothesis that male circumcision might protect against HIV infection was first suggested in 1986 (Fink, 1986). Subsequent support was provided by ecologic studies in areas with low prevalence of male circumcision and high HIV prevalence in sub-Saharan Africa in the late 1980s (Moses et al, 1999) and later across 118 developing countries (Drain et al, 2006). Further evidence comes from two systematic reviews of the observational study data comparing HIV infection rates in circumcised and uncircumcised men from the same populations (Weiss et al, 2000; Siegfried, 2005). One review was restricted to 27 studies from sub-Saharan Africa (Weiss et al, 2000), and the other was a global review including 37 studies (Siegfried, 2005). Circumcised men had substantially lower risk of HIV infection. Meta-analysis of the 15 studies that adjusted for potential confounders showed this reduction to be large and highly significant (adjusted risk ratio of 0.42, 95% CI 0.34-0.54) (Weiss et al, 2000). Subsequent studies have found similar large risk reductions among circumcised men (Weiss et al, 2008).

Although provocative, observational studies cannot prove causality. Three randomized clinical trials of adult male circumcision among consenting, healthy men in South Africa (Auvert et al, 2005), Kenya (Bailey et al, 2007), and Uganda (Gray et al, 2007) were started in 2002-2003. All three trials were stopped early after recommendations by independent data and safety monitoring boards when interim analyses found highly significant decreases in HIV infection risk among participants randomly assigned to circumcision.

The three trials enrolled a total of 10,908 uncircumcised, HIV-negative adult men. Participants were randomly assigned to circumcision or control arms and then observed for up to 2 years. Retention rates were high (86% to 92%). Subsequent meta-analysis using a random-effects model of the trial results, following the QUORUM statement recommendations, found no evidence of heterogeneity among the trials (Weiss et al, 2008). The overall risk ratio was 0.42 (95% CI 0.31-0.57), corresponding to a protective effect of 58% (95% CI 43%-69%), which was identical to that found in the observational studies (58%, 95% CI 46%-66%).

The true protection provided by male circumcision may be better estimated by an "as-treated" analysis, assigning outcomes according to the actual circumcision status of participants. All participants did not adhere to the study arm to which they were randomly assigned. Meta-analysis of the "as-treated" results of the three trials shows even stronger protection against HIV infection in the circumcision group (summary risk ratio of 0.35; 95% CI 0.24-0.54) (Weiss et al, 2008). Additional data have suggested that circumcision is both highly effective at reducing costs of HIV and AIDS and has a very low complication rate (Krieger et al, 2005, 2007; Gray et al, 2007). In summary, the positive findings in the male circumcision trials are in contrast to recent negative results with other HIV prevention interventions, including microbicides, the female diaphragm and gel, treatment to suppress genital herpes infections, and, most recently, an adenovirus-based HIV vaccine. **There is a need to provide safe male circumcision services for high-risk populations because this is one of few proven HIV prevention strategies.** In addition to other health benefits, male circumcision provides a much-needed addition to the limited HIV prevention armamentarium. Male circumcision is possibly the oldest and the most common surgical procedure. The evidence from biologic studies,

Table 14–3.

Evidence Table for Studies of Male Circumcision and HIV Infection Risk That Include Original Data, Systematic Reviews or Meta-Analysis, Expert Opinion, or Other Human Data (1999-2008)

STUDY TYPE	DESIGN	LEVEL OF EVIDENCE POSITIVE (FAVORING CIRCUMCISION) OR NEGATIVE	REFERENCE
Systematic reviews, meta-analyses and modeling	Meta-analysis of 29 published articles with serious technical flaws	4, Negative	Van Howe, 1999
	Meta-analysis of 33 diverse observational studies, stratifying by study type	2, Positive	O'Farrell and Egger, 2000
	Systemic review and meta-analysis of 27 studies	2, Positive	Weiss et al, 2000
	Systematic reviews	3, Positive	Siegfried et al, 2003; Siegfried, 2005
	Stochastic prevention trial simulator and RCT* data	2, Positive	Desai et al, 2006
	Dynamical simulation models using country level data	2, Positive	Williams et al, 2006
	Country-specific data from 118 developing countries evaluated with multivariate linear regression	2, Positive	Drain et al, 2006
	Individual-based stochastic model fitted to characteristics for urban African populations	3, Positive	Orroth et al, 2007
	Mathematical model parameterized RCT findings	3. Positive	Hallet et al, 2008
	Mathematical model simulated observed levels of HIV prevalence in sub-Saharan Africa	3, Positive	Londish and Murray, 2008
	Systematic review and meta-analysis of the three RCTs	1, Positive	Weiss et al, 2008
Randomized-controlled trials	3274 uncircumcised men randomized 1:1	1, Positive	Auvert et al, 2005
	2784 uncircumcised HIV-negative men randomized 1:1	1, Positive	Bailey et al, 2007
	4996 uncircumcised, HIV-negative men randomized 1:1	1, Positive	Gray et al, 2007
Nonrandomized cohort studies	Survey of 6821 men aged 15-59 years in rural Uganda	3, Positive	Kelly et al, 1999
	415 Ugandan couples in which one partner was HIV positive and one was initially HIV negative followed prospectively for up to 30 months	2, Positive	Quinn et al, 2000
	Prospective study of 2298 HIV-negative men attending sexually transmitted infection clinics in India	2, Positive	Reynolds et al, 2004
	150 Kenyan sex partners of women with genital symptoms	3, Positive	Meier et al, 2006
	Prospective cohort of 1378 men in rural Kenya followed for 2 years	2, Positive	Shaffer et al, 2007
	Respondent-driven sampling of 1154 black and 1091 Latino men who have sex with men in the United States	3, Negative	Millet et al, 2007
Case-control studies	Random population samples from two circumcising African populations compared with 2 noncircumcising populations (approximately 4000 men)	3, Positive	Auvert et al, 2001
	38 HIV-positive and 94 HIV-negative Kenyan men with genital ulcers	3, Positive	MacDonald et al, 2001
	Rural Uganda	3, Positive	Gray et al, 2004
	398 circumcised and 447 uncircumcised Kenyan men	3, Positive	Agot et al, 2004
	1277 sexually experienced men from 70 villages in South Africa	3, Positive	Jewkes et al, 2006
	Community-based study of 1418 women and 566 of their regular male partners in Tanzania	3, Positive	Kapiga et al, 2006
	Cross-sectional, population-based survey including 2941 Kenyan men	3, Positive	Johnson and Way, 2006
	Probability sample of homeless men aged in Kolkata, India	3, Positive	Talukdar et al, 2007
	Data from eight national surveys in sub-Saharan Africa	3, Positive	Mishra et al, 2007
	National probability sample of the general population in Slovenia	3, Negative	Klavs and Hamers, 2008
	Population-based study of Kenyan men	3, Positive	Foglia et al, 2008
	Cross-sectional nationally representative survey 10,227 women and 8298 men in Uganda	3, Positive	Mermin et al, 2008
Pertinent biologic studies	Immunologic and in-vivo infection of human foreskins	4, Positive	Patterson et al, 2002
	HIV-receptor studies of human foreskins	4, Positive	Soilleux and Coleman, 2004
	HIV-receptor studies of human foreskins	4, Positive	McCoombe and Short, 2006

observational studies, randomized controlled clinical trials, meta-analyses, and cost-effectiveness studies is conclusive; the challenges of implementation in high-risk populations must now be faced.

Gynecologic Factors

Female genital tract tissues vary in susceptibility to HIV infection. The stratified vaginal epithelium contains fewer cells with coreceptors that can bind HIV (Patterson et al, 1998). Thus, vaginal mucosa is less susceptible to HIV infection than the endocervix, which has a thinner, highly vascular layer, containing a much higher concentration of HIV-binding cells. Physiologic events that result in ectropion (i.e., increased exposure of the endocervix), such as the use of hormonal contraceptives or occult *Chlamydia trachomatis* infection, increase susceptibility to HIV (Mostad et al, 2000; Moscicki et al, 2001).

Specific Sexual Behaviors

Calculation of the precise risk for infection for each type of exposure is imprecise because many cofactors alter the amount of HIV in the genital tract (Mayer and Safren, 2004). Factors such as a source with a high plasma viral load (Quinn et al, 2000) or concomitant STI can greatly increase the average per-contact risk (Cohen et al, 1997; Wawer et al, 1999). Data used to generate per-contact risks are often based on cohort studies in which individuals recollect their risk during previous time intervals (often every 3 to 6 months). Recollections are often obtained about behaviors under the influence of drugs or alcohol.

Data from the developed world suggest that men are more likely to transmit HIV to their female partners (see Table 14–2) (Mayer and Safren, 2004). However, studies from Africa suggest that rates of male-to-female and female-to male transmission were similar (Quinn et al, 2000). Reasons for this apparent difference in the efficiency of female-to-male transmission may include different rates of male circumcision or the prevalence of other STIs. For anal intercourse the insertive partner is less likely to acquire HIV from an infected receptive partner than vice versa but there appear to be sufficient susceptible cells in the distal male urethra and foreskin such that an insertive partner is still at substantial risk. One study suggested that, on average, receptive anal intercourse was more than seven times as efficient at transmitting HIV as insertive anal intercourse (DeGruttola et al, 1989).

Oral intercourse, either fellatio or cunnilingus, is a much less efficient way to acquire HIV. However, case reports show that oral exposure to ejaculate may transmit HIV (Mayer and Safren, 2004). The efficiency of oral transmission is less than that of unprotected vaginal intercourse, in the realm of less than 1 per 1000 contacts. However, animal studies demonstrate that HIV can be transmitted orally via lymphoid tissue in the oropharynx. Although HIV has been identified in pre-ejaculatory secretions there are no reliable case reports of HIV transmission through exposure to pre-ejaculate without exposure to semen.

HIV VIROLOGY AND TARGETS FOR ANTIVIRAL THERAPY

The Virion

Although there are two HIV viruses, in this chapter the focus is on HIV-1 because there have been very few cases of HIV-2 in the developed world. HIV-2 is transmitted less readily than HIV-1 and the virus is less virulent. In this review, the term *HIV* refers to the clinical manifestations of infection caused by HIV-1.

HIV has a spherical shape with an outer envelope, variable surface projections, and an icosahedral capsid containing ribonucleoprotein complexed with a core shell (Fig. 14–1) (Liang and Wainberg, 2004). The HIV projections consist of envelope glycoproteins loosely associated with a lipid bilayer. Beneath the lipid layer the matrix protein covers the internal surface of the viral coat. The capsid protein constitutes the shell of the cone-shaped core, and the nucleocapsid protein forms part of a nucleoid structure that also consists of reverse transcriptase, integrase, and two copies of the single-stranded viral genomic RNA (Liang and Wainberg, 2004).

HIV Replication Cycle

The HIV replication cycle is diagrammed in Figure 14–2 (Liang and Wainberg, 2004).

Viral Attachment, Fusion, and Uncoating

HIV initially attaches to the CD4 receptor on susceptible host cells. High-affinity interactions occur between the viral envelope glycoprotein and a specific region of the CD4 molecule (Pollard and

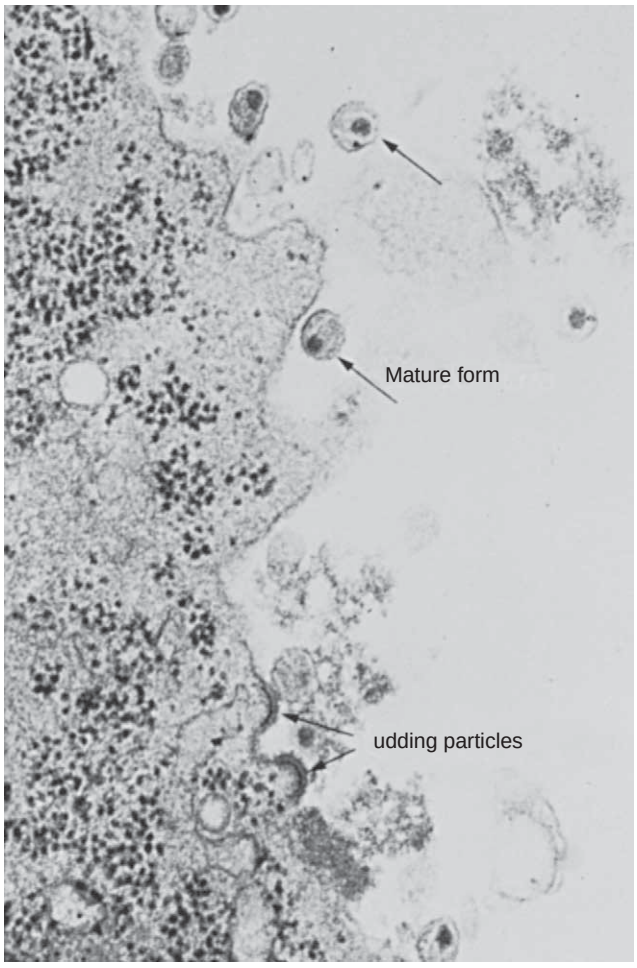

Figure 14–1. HIV virion. HIV has a spherical shape, an outer envelope, variable surface projections, and an icosahedral capsid containing ribonucleoprotein complexed with a core shell. (Electron micrograph courtesy of the Centers for Disease Control and Prevention.)

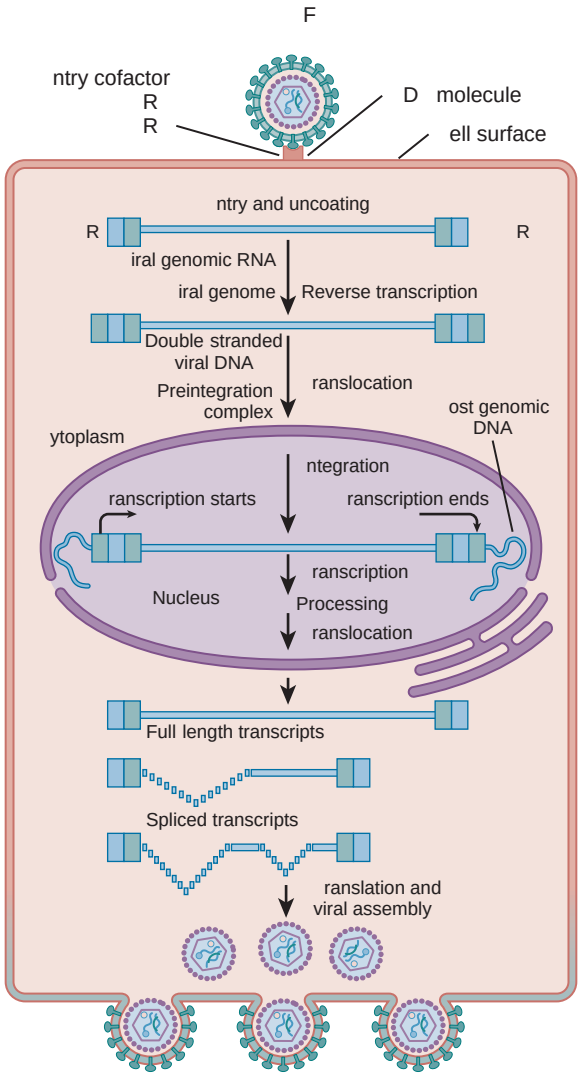

Figure 14–2. HIV replication cycle. The diagram illustrates the stages of HIV replication, including viral entry, uncoating, reverse transcription, integration, expression of proviral genome, viral assembly, and particle release. (From Liang C, Wainberg MA. Virology of HIV. In: Cohen J, Powderly WG, Berkley SF, et al, editors. Infectious diseases. vol. 2, 2nd ed. Edinburgh: Mosby; 2004. p. 1251–5.)

Malim, 1998) on the surface of immature T cells and mature CD4+ T-helper cells. In addition to CD4, a variety of coreceptors and host immune cell membrane proteins may promote HIV entry into target cells after the initial binding (Cocchi et al, 1996; Liang and Wainberg, 2004).

Efforts are underway to develop compounds that antagonize HIV entry into susceptible cells by interfering with either the CD4 receptor or the coreceptors. Cell entry probably occurs by fusion of viral and cell membranes mediated by the viral transmembrane protein. **Following fusion the virion is uncoated by a proteolytic event mediated by the virion-encoded protease. A number of protease inhibitors that inhibit this step have proven very effective antiretroviral agents.**

Reverse Transcription

After entry, viral RNA is converted into DNA, which is then integrated into host cell chromosomal DNA. This process of reverse transcription occurs within 4 to 6 hours of infection and takes place mainly in the cytoplasm catalyzed by virion-encoded reverse transcriptase. The final products of reverse transcription are double-stranded viral DNA molecules. This distinctive viral reverse transcription step has been the target of a number of effective antiretroviral agents.

Integration

The newly transcribed double-stranded DNAs are then transported into the nucleus where viral DNA is integrated into host cell chromosomal DNA, a process catalyzed by viral integrase. After integration, HIV proviral DNA remains permanently associated with the host genetic material for as long as the cell lives. The viral integrase is currently under active investigation as a potential target for antiretroviral therapy.

Viral Gene Expression, Packaging, and Assembly

HIV exploits the host cell transcription and translation machineries to generate its own gene products. The primary RNA transcripts of the provirus are made by host cell RNA polymerase II. Cellular activation and proliferation signals result in the binding of transcription factors to the long terminal repeat and lead to increased rates of initiation of transcription. Tat and Rev are two key virion-encoded proteins that upregulate viral gene expression and replication, whereas HIV accessory proteins, including Nef, Vif, Vpu, and Vpr, are crucial determinants of HIV virulence (Emerman and Malim, 1998). Host cellular ribosomes translate proviral mRNA into viral proteins (Liang and Wainberg, 2004). The HIV glycosaminoglycan proteins are the driving force for virus assembly.

Therapeutic Considerations

Viral reverse transcriptase and protease enzymes have been the main targets of anti-HIV therapy. Viral reverse transcriptase has an exceedingly high error rate (i.e., about one mutation/virus replication event) (Liang and Wainberg, 2004); thus mutants are constantly generated that have the potential for drug resistance. Drug resistance to HIV occurs when these mutations result in altered forms of HIV reverse transcriptase and protease that function yet are not inhibited by antiviral agents.

PATHOGENESIS OF HIV INFECTION

The prognosis and outcome of HIV infection changed dramatically with availability of highly active antiretroviral combination therapy (HAART). HAART has delayed the natural history and rate of progression, prolonging survival. However, initial optimism for immune reconstitution has been thwarted by information about HIV's pathogenic mechanisms and the limitations of HAART. It is now clear that eradication of the virus is not possible with available antiviral drugs.

Natural History of HIV Infection

The course of HIV infection is highly variable. In the absence of treatment the typical course occurs over 8 to 12 years. Three distinct phases have been defined: primary infection, chronic asymptomatic infection, and overt AIDS (Pierre-Alexandre and Pantaleo, 2004).

Primary HIV Infection

Primary HIV infection is a transient symptomatic illness of variable severity. This acute syndrome occurs in 40% to 90% of patients. Clinical signs and symptoms generally appear 2 to 4 weeks after infection. The clinical presentation may mimic acute

mononucleosis or other acute febrile illnesses, emphasizing the nonspecific nature of these symptoms and the difficulty of early diagnosis. The self-limited syndrome generally lasts less than 14 days.

Diagnosis of primary HIV infection depends on diagnostic testing. There are three laboratory characteristics: high plasma viremia often greater than 1 million HIV RNA copies/mL, a decrease in the blood CD4+ T-cell count, and large increase in the blood CD8+ T-cell count. Subsequently, a marked decline in plasma viremia coincides with resolution of the clinical syndrome (Kahn and Walker, 1998). This decrease in viral load also correlates with the appearance of the virus-specific immune responses, particularly HIV-specific cytotoxic T cells, indicating that immune responses downregulate virus replication (Pantaleo et al, 1994; Musey et al, 1997). Standard laboratory assays used to diagnose HIV infection are usually negative during acute infection.

Chronic Asymptomatic HIV Infection

Primary HIV infection is followed by a long phase of clinical latency, usually lasting around 10 years. During this phase patients have neither signs nor symptoms. Relatively stable HIV replication levels and CD4+ T-cell counts characterize this chronic phase.

This apparent clinical "stability" is deceptive. Although viral levels and the blood CD4 T-cell count are stable, this stability is only apparent in the blood. Virus replication and accumulation of extracellular virus trapped in the follicular dendritic cell network continue actively in the lymphoid tissue, where progressive anatomic and functional deterioration occurs, leading to impaired specific immune responses (Pantaleo et al, 1993, 1998). Eventually, immunologic deterioration is reflected by a rapid increase in viremia levels and a drop in CD4+ T-cell counts, resulting in transition to overt AIDS.

Overt AIDS

AIDS represents the end stage of HIV infection. This advanced stage of HIV disease is marked by low CD4+ T-cell counts (<2 to 300 cells/μL) and appearance of constitutional symptoms. This phase may be complicated by the development of AIDS-defining opportunistic infections or malignancies. **Without antiretroviral therapy, AIDS usually leads to death in 2 to 3 years.** The risk for death and opportunistic infections increases significantly with CD4+ T-cell counts less than 50 cells/μL.

Highly Variable Clinical Course

The clinical course of HIV infection is variable (Pierre-Alexandre and Pantaleo, 2004). Conceptually, patients may be classified in four categories: typical progressors, rapid progressors, slow progressors, or nonprogressors. **In 60% to 70% of HIV-infected patients the median time between infection and the development of AIDS is 10 to 11 years, in the absence of therapy. These infected persons are "typical progressors."** Their clinical course is described earlier.

Ten to 20 percent of HIV infections progress rapidly. These "rapid progressors" develop AIDS less than 5 years after infection. After primary infection these patients' plasma virus levels are often more than 10^5 HIV-1 RNA copies/mL and their CD4+ T-cell counts start to decrease much earlier and more rapidly. HIV-specific immune responses are either never detected or are lost rapidly after the transition from the acute to the chronic phase of infection.

At the other extreme, 5% to 15% of HIV-infected people are "slow progressors," remaining free of AIDS for more than 15 years in the absence of therapy. Their CD4+ T-cell counts remain stable, frequently greater than 500 cells/μL, and plasma HIV RNA levels are usually less than 10,000 copies/mL.

The slow progressors group includes a subgroup of long-term nonprogressors. About 1% of HIV-infected people appear to fall into this category. Long-term nonprogressors have documented HIV infections for at least 8 to 10 years without antiretroviral therapy and have no signs of disease progression (e.g., constant high CD4+ T-cell counts and either low [500 to 1000 HIV RNA copies/mL] or very low [<50 copies/mL] plasma virus levels).

Early Pathogenic Events Determine the Natural History

The most common route of HIV infection is sexual transmission at the genital mucosa (Royce et al, 1997). Animal models provide important insights into the early pathogenic events. After intravaginal infection of rhesus monkeys, tissue dendritic cells (i.e., Langerhans cells that reside in the lamina propria adjacent to the vaginal epithelium) are the first potential target cells of HIV (Spira et al, 1996). These dendritic cells constitute a complex and highly developed system of antigen-presenting cells that are able to prime naive T cells. The ability of dendritic cells to attract and prime naive T cells can be explained by expression of a type II membrane protein with an external mannose binding, C-type lectin domain, named DC-Sign (Steinman, 2000). It has been suggested that interaction between DC-Sign and the intracellular adhesion molecule-3 represents the initial contact between dendritic cells and resting T cells, a critical step for initiation of T-cell immune responses. Dendritic cells express high levels of specific chemokines that target naive rather than memory T cells (Cameron et al, 1996).

After encountering HIV below the vaginal epithelium, Langerhans cells either can be infected or can pick up HIV virions (Steinman, 2000). Thus DC-Sign–positive dendritic cells play the major role in the delivery of HIV to T cells, greatly amplifying the viral infection (Zhu et al, 1996). Subsequently dendritic cells migrate to the internal iliac lymph nodes where they target the T-cell areas and then present the viral antigens to activated virus-specific T cells. Therefore, dendritic cells play a key role, both in priming the initial HIV-specific immune response and in transporting HIV to the draining lymphoid tissue. Rapid recruitment and spreading of target cells (i.e., activated CD4+ T cells) confers a major advantage to HIV because these events occur before the appearance of virus-specific immune responses.

Within 2 days after infection, HIV can be detected in the draining lymphoid tissue. The virus then disseminates rapidly throughout the lymphoid system. Afterward, HIV enters the bloodstream, where viral replication can be detected in plasma 5 days after infection in the animal model. In humans the time from mucosal infection and initial plasma viremia varies, ranging from 4 to 11 days (Pierre-Alexandre and Pantaleo, 2004). The clinical importance of these observations is that the risk of infection is increased by conditions that decrease genital mucosal barriers, especially lesions caused by inflammatory or infectious diseases, such as cervicitis, urethritis, and genital ulcers.

Critical Role of Lymphoid Tissue in Primary HIV Infection

Events in the lymphoid tissue play a central role in HIV infection. During primary infection the peak number of virus-expressing cells in the lymph node occurs at the same time as the peak of plasma viremia or shortly precedes it (Brodie et al, 1999; Musey et al, 1999; Pierre-Alexandre and Pantaleo, 2004). With the

transition from primary to chronic infection there is a switch from individual virus-expressing cells to virus trapped by the follicular dendritic cell network of lymph node germinal centers. This trapped virus becomes the dominant form of virus in lymph nodes, and this event is associated with a dramatic decrease in the number of individual cells expressing viral RNA, reflecting the role of the host immune system in partially containing HIV infection (Pantaleo et al, 1998).

Virus Escape and Establishment of Chronic HIV Infection

Early in primary HIV infection, vigorous virus-specific immune responses may contribute to both control of the initial peak of virus replication and reduction in plasma viremia (Musey et al, 1997; Kahn and Walker, 1998; Pantaleo et al, 1993, 1998). **However, HIV-specific immune responses cannot control HIV or block the eventual progression to symptomatic disease.** HIV differs from other viruses by targeting a broad spectrum of effector components of the antiviral immune response very early after infection (during the primary phase) and by rendering these mechanisms ineffective or reshaping them (Soudeyns and Pantaleo, 1999).

HIV escapes the host immune response by both virologic and immunologic mechanisms. Virologic mechanisms include formation of a stable pool of latently infected CD4+ T cells containing HIV that is capable of replicating (Finzi et al, 1997; Wong et al, 1997), the genetic variability of HIV (Coffin, 1995), and trapping of infectious virions on the surface of follicular dendritic cells (Pantaleo et al, 1994; Chun et al, 1997; Wong et al, 1997). Initiation of HAART very early during primary HIV infection does have a significant impact on the size of this pool of CD4+ T cells. Decay of this pool of infected CD4+ T cells is very slow and not much influenced by the effective suppression of virus replication. This reservoir of replication-competent virus represents a major obstacle to HIV eradication and long-term control of virus replication (Chun et al, 1997; Finzi et al, 1997; Wong et al, 1997).

Genetic variability is another efficient mechanism by which HIV escapes the host immune response. During both primary and established chronic infection, rapid mutations ensure that the virus is able to escape both the humoral and the cell-mediated virus-specific immune responses.

HIV also reshapes antiviral mechanisms by trapping of the virus on the surface of follicular dendritic cells in lymphoid germinal centers. For most infections, formation of immune complexes and their attachment to the follicular dendritic cell network represent mechanisms leading to clearance of the pathogen and to maintenance of effective immune responses. However, with HIV infection these mechanisms lead to formation of a stable reservoir of infectious virions, representing a continuous source for infection of CD4+ T cells that ultimately results in the destruction of the lymphoid tissue (Musey et al, 1997).

HIV escapes from the immune response through multiple immunologic mechanisms that include deletion of HIV-specific CD4+ T-cell clones (Rosenberg et al, 1997), deletion of HIV-specific cytotoxic CD8+ T-cell clones, generation of virus escape mutants (Soudeyns and Pantaleo, 1999), egress of cytotoxic T cells from lymph nodes, impaired function of antigen-presenting cells (Soudeyns and Pantaleo, 1999), and interference with the humoral neutralizing response.

In summary, virus escape and establishment of chronic HIV infection reflect the ability of HIV to target the host's antiviral immune response and reshape it into a self-defense mechanism. Primary infection is critical in the pathogenesis of HIV infection because events that occur during this stage determine both the pattern and the rate of disease progression.

Virologic Set Point

During the transition from primary to chronic infection, HIV plasma RNA levels reach a virologic set point that predicts the rate of disease progression (Mellors et al, 1996). The virologic set point varies among HIV-infected individuals and tends to remain stable in the same person during the chronic phase. The virologic set point that a person attains is determined by both the mechanisms involved in the establishment of chronic infection and by host factors that can modulate the course of HIV disease. **The plasma RNA load is the most accurate predictor of disease progression** (Mellors et al, 1996). The higher the plasma viral RNA load, the greater is the risk of rapid progression to AIDS and death.

Prospects for HIV Eradication

Free HIV virions are eliminated with a half-life of 6 hours. In contrast, productively infected cells have a half-life of 1.6 days. It was hoped that HIV eradication was achievable within 2 to 3 years (Perelson et al, 1997). This goal could only be realized with complete and sustained suppression of HIV replication and if there were no pool of long-lived, latently infected cells to serve as a virus reservoir (Chun et al, 1997; Finzi et al, 1997; Wong et al, 1997).

Data from HIV-infected patients on long-term HAART significantly challenged these theories. There appears to be a pool of latent HIV–infected resting CD4+ T cells that persists in HIV-infected patients who adhered to HAART for up to 3 years (Chun et al, 1997; Finzi et al, 1997; Wong et al, 1997). This pool is composed of quiescent memory CD4+ T cells with a longer half-life than the original estimate of 1 to 4 weeks. More importantly, these cells contain replication-competent HIV proviral DNA. After activation these cells are able to support efficient viral replication.

The extent of this HIV reservoir is quantitatively limited, estimated between 50,000 and 5 million resting memory CD4+ T cells for the whole body. However, this pool of cells has a half-life of 3 to 6 months, dramatically increasing estimates of the potential time required for HIV eradication.

The reservoir of HIV-infected cells originates from productively infected cells during primary infection (Pierre-Alexandre and Pantaleo, 2004). Initiation of HAART as early as 10 days after the onset of symptoms of primary HIV infection rapidly controls plasma viremia but does not preclude generation of this viral reservoir. These observations emphasize the rapidity with which HIV viral reservoirs are established and the limited ability of HAART to interfere with this pathogenic process. This pool of HIV-infected cells represents a major obstacle to HIV eradication.

In addition to their role as a viral reservoir, HIV-infected, long-lived, resting memory CD4+ T cells possess the ability to support virus production, albeit at low levels. Patients on HAART with viral loads below detectable levels with usual clinical assays may still have viral replication detected by more sensitive tests (Pierre-Alexandre and Pantaleo, 2004). In these studies, 40% to 60% of patients still had low levels of viremia after 36 to 48 weeks of HAART.

Viral sanctuaries represent another potential source of residual HIV replication. **Sanctuaries are defined as cells and organs where the HIV can be sheltered or where HAART does not achieve therapeutic concentrations.**

Tissue sanctuaries include the lymphoid tissue, mucosa-associated lymphoid tissue, the genital organs, and the central nervous system, where the achievable concentrations of antiviral drugs (especially protease inhibitors) may be suboptimal. These sites may serve both as potential sources of low-level virus replication and as reservoirs of latently infected cells (Pierre-Alexandre and Pantaleo, 2004). Presence of viral sanctuaries, including the reproductive tract, with limited bioavailability of antiviral drugs further complicates the issue of HIV eradication. Current estimates are that it may take 5 to 10 years or more to eliminate HIV, considering a half-life of 4 months for the long-lived infected CD4+ cells and provided that effective and durable suppression of viral replication is achieved by HAART.

TESTS TO DIAGNOSE AND MONITOR HIV INFECTION: WHAT THE UROLOGIST SHOULD KNOW

HIV was first isolated in 1983, and the first diagnostic tests were marketed in 1985. Tests for diagnosis and monitoring of HIV infection have improved constantly (Kuritzkes, 2004; Reiss et al, 2004). Few areas in medicine have witnessed such rapid and widespread adaptation of molecular tools to everyday practice. Fortunately the many tests for diagnosis and monitoring HIV infection can be considered in three categories: diagnostic tests, viral load, and resistance assays.

Diagnostic Tests and Testing Algorithms

Assays have been developed to detect HIV antibodies in serum, whole blood, saliva, and urine (Kuritzkes, 2004). Most laboratories screen for anti-HIV-1 and anti-HIV-2 antibodies using an enzyme-linked immunosorbent assay (ELISA) based on antigens from viral lysates, recombinant or synthetic. Current third-generation HIV ELISAs have sensitivity and specificity approaching 100%. In contrast to earlier tests that only detected IgG antibodies these tests detect all classes of anti-HIV antibodies, substantially shortening the time to diagnosis after acute infection. A variety of rapid tests and "home tests" have also been developed.

Despite sensitivity of more than 99%, a reactive HIV ELISA has a relatively low positive predictive value in low-risk populations. Thus the current testing algorithm includes a confirmatory test to exclude false-positive results. The Western blot is most widely used for confirmation. Some laboratories prefer immunoblotting for confirmation because immunoblots are simpler to standardize and are more sensitive in cases of recent seroconversion (Kuritzkes, 2004).

Clinical Application

After acute infection, HIV RNA can be detected from day 12. HIV RNA assays (see later) **have a sensitivity of 100% in diagnosing acute infection but at the cost of lowered specificity (97%)** (Kuritzkes, 2004). **The first antibodies can generally be detected on day 21. However, development of a positive HIV antibody test can vary according to the patient and infecting strain. Beyond week 6 after infection antibodies are detectable in almost all patients** (Kuritzkes, 2004). Because reactivity by the Western blot test lags seroconversion by ELISA, a positive ELISA in a patient with a negative or evolving Western blot assay can provide evidence of recent infection.

Testing is a two-stage process. Samples positive by an initial screening assay are retested to exclude clerical or laboratory error, and then a confirmatory assay is performed on repeatedly reactive sera to verify that the antibodies are directed against HIV. Confirmation of a reactive ELISA by a positive Western blot establishes the diagnosis of HIV infection. A negative Western blot test suggests a false-positive ELISA or an acute infection.

Viral Load Monitoring

Assays to quantify HIV RNA, termed the *viral load,* led to our current understanding of HIV pathogenesis and helped establish complete suppression of HIV replication as the ultimate goal for antiretroviral therapy (Kuritzkes, 2004). These assays are now standard. Performance characteristics of the commercially available assays are similar. Current commercial assays have a lower limit of quantitation of 50 to 80 HIV RNA copies/mL.

Clinical Application

Plasma HIV RNA levels correlate with clinical stage (Kuritzkes, 2004). Patients with symptomatic HIV infection or AIDS have significantly higher virus loads than patients with asymptomatic infection. Plasma HIV RNA load is also a powerful predictor of the risk of disease progression and death at all stages of disease. Current guidelines recommend obtaining two plasma HIV RNA measurements to determine the baseline or "set point" virus load before initiating antiretroviral therapy.

After antiretroviral therapy the change in plasma HIV RNA provides important clinical information. Several large clinical trials showed significant correlations between the plasma HIV RNA reduction from baseline and the clinical benefit (Marschner et al, 1998). **The nadir in plasma HIV RNA levels is a marker for the duration of virus suppression** (Raboud et al, 1999). **The early response to treatment predicts long-term outcome. Conversely, increasing plasma HIV RNA level suggests treatment failure.**

Increasing plasma HIV RNA level is the harbinger of potential development of retroviral drug resistance (Reiss et al, 2004). This is not necessarily accompanied by an immediate decline in blood CD4+ lymphocyte numbers or by the development of clinical symptoms. Regular monitoring with plasma HIV RNA levels facilitates timely detection of drug-resistant HIV in patients on HAART.

HIV Drug-Resistance Assays

Various assays are available to assess drug resistance (Kuritzkes, 2004; Reiss et al, 2004). These assays can be considered as either genotypic or phenotypic assays. Genotypic assays evaluate HIV nucleotide sequences to detect critical drug-resistance mutations. Phenotypic assays estimate the concentration of antiviral drugs necessary to inhibit virus replication in vitro. Each approach has potential advantages and disadvantages. An important limitation is that both approaches measure characteristics of the predominant viral species but do not indicate the presence of minor species that may emerge as resistant variants during subsequent treatment.

Clinical Application

Clinical trials demonstrate the value of drug-resistance testing (Kuritzkes, 2004; Reiss et al, 2004). The risk of virologic failure during salvage therapy was reduced by 30% to 50% for each drug in the new regimen that was predicted to have activity

(De Gruttola et al, 2001; Kuritzkes, 2004). Drug-resistance remained an independent predictor of the likelihood of treatment failure even after controlling for treatment history.

Most experts recommend drug-resistance testing to guide the selection of salvage therapy for patients whose therapy is failing and in pregnant women (Hirsch et al, 2000). Resistance testing is also recommended for patients with acute HIV infection. Some experts also recommend that evidence for increasing transmission of drug-resistant HIV (Little et al, 2002) provides a rationale for testing of all patients before initiation of antiretroviral therapy where affordable (Kuritzkes, 2004).

UROLOGIC MANIFESTATIONS OF HIV INFECTION

Nonmalignant Conditions

The genitalia may be involved in either early or late stages of HIV infection (Kho et al, 2004).

Primary HIV Infection

Primary HIV infection may be characterized by an acute exanthem beginning 1 to 5 weeks after infection. Characteristic symptoms include fatigue, fever, and night sweats, accompanied by lymphadenopathy. The skin eruption consists of erythematous, round-to-oval macules and papules. The syndrome resolves with complete recovery.

Sexually Transmitted Infections

In many populations the pattern of HIV acquisition parallels that of STIs (Quinn et al, 1988). **Thus, testing for HIV is recommended in anyone with a diagnosed STI or at risk for STI** (Centers for Disease Control and Prevention, 2002). **Accurate diagnosis of STIs is of exceptional importance in individuals at high risk for HIV infection because presence of an STI increases the risk of both transmitting and acquiring HIV infection. These infections may have more atypical and prolonged clinical manifestations in people with HIV infection.**

Genital Herpesvirus. Herpes simplex virus (HSV) infection is common in HIV-infected persons (Centers for Disease Control and Prevention, 2002). In these populations HSV types 1 and 2 cause recurrent, severe, painful vesicles with an erythematous base. Untreated lesions may enlarge becoming confluent ulcerations that persist with secondary bacterial infection. Sometimes ulceration occurs without well-defined vesicles ever being noted (Kho et al, 2004). Specific diagnosis is established by viral culture, other diagnostic tests, or biopsy.

In patients with intact immune function the course of HSV is similar to that of other HSV-infected patients. Immunocompromised patients may have more prolonged and severe infections (Centers for Disease Control and Prevention, 2002). Episodic or suppressive therapy with oral antiviral agents is often beneficial (Table 14–4) (Centers for Disease Control and Prevention, 2002). Severe cases merit parenteral therapy with intravenously administered acyclovir (5 to 10 mg/kg every 8 hours) (Centers for Disease Control and Prevention, 2002).

HSV resistance should be suspected if lesions persist or recur despite antiviral therapy. Viral culture and resistance testing should be obtained if possible (Centers for Disease Control and Prevention, 2002). Patients with acyclovir-resistant HSV strains require alternative agents, such as foscarnet (40 mg/kg intravenously every 8 hours until clinical resolution) or topical cidofovir gel (1% applied to lesions daily for 5 days), which is a preparation that is not commercially available but must be compounded by a pharmacy.

Table 14–4.

Recommended Regimens for Treating Genital Herpes Virus Infections in HIV-Infected Patients

Episodic Treatment Regimens		
DRUG	DOSAGE	DURATION
Acyclovir	400 mg orally three times a day	5-10 days
Acyclovir	200 mg orally 5 times a day	5-10 days
Famciclovir	500 mg orally twice a day	5-10 days
Valacyclovir	1 g orally twice a day	5-10 days

Drug Suppressive Therapy	
DRUG	DOSAGE
Acyclovir	400-800 mg orally twice or three times a day
Famciclovir	500 mg orally twice a day
Valacyclovir	500 mg orally twice a day

From Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines 2002. MMWR Morb Mortal Wkly Rep 2002;5:1.

HSV infection increases HIV replication in persons infected with both viruses (Van de Perre et al, 2008). Studies have also shown that anti-HSV treatment with acyclovir reduced HIV in genital secretions among HIV- and HSV-coinfected persons (Dunne et al, 2008). Thus, it was disappointing that randomized clinical trials found that acyclovir as HSV suppressive therapy did not decrease the incidence of HIV infection in HSV-positive, high-risk HIV-negative women (Watson-Jones et al, 2008).

Human Papillomavirus. Warts can develop in unusual locations, such as on the lips, tongue, and oral mucosa in addition to the genitalia. Such lesions are treated using standard regimens (cryotherapy, podofilox, imiquimod, podophyllin resin, laser, or excisional surgery) (Centers for Disease Control and Prevention, 2002). However, in immunosuppressed patients genital lesions are resistant to treatment and these patients may be at higher risk for recurrence (Centers for Disease Control and Prevention, 2002).

In men, human papillomavirus (HPV) affects the penis, urethra, scrotum, perineal, and rectal mucosa as condylomata acuminata, which are usually recognized as soft sessile lesions with finger-like projections (Fig. 14–3). In women the spectrum of clinical disease is broad with vulvar, vaginal, and cervical condylomata. Other clinical presentations of HPV infection include bowenoid papulosis and epidermodysplasia verruciformis. Bowenoid papulosis presents as small, brown, flat papules affecting the perianal and genital areas. Epidermodysplasia verruciformis consists of a widespread eruption of pink-red, flat, wartlike lesions distributed mostly on sun-exposed skin (Berger et al, 1991).

HPV infection increases the risk for carcinoma, especially in HIV-infected hosts. These lesions include cervical intraepithelial neoplasia in women and squamous cell carcinoma in men. Whenever extensive warts develop the patient should be screened for HIV infection. Because there is an increased risk of anal cancer in HIV-infected homosexual men, screening for anal squamous intraepithelial neoplasia by cytology is recommended by some authorities. Until more data on the natural history of anal squamous intraepithelial neoplasia and the efficacy of treatment are available, routine screening is not recommended (Centers for

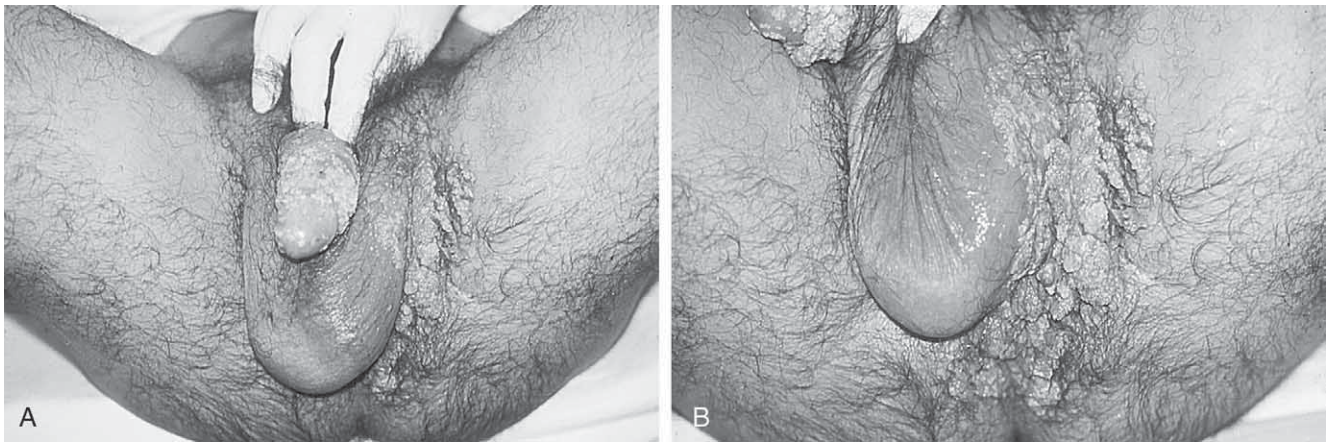

Figure 14–3. **A** and **B,** AIDS patient with five active urogenital viral infections. Extensive genital condylomata associated with areas of dysplasia and squamous intraepithelial neoplasia related to coinfection with human papillomavirus. Shedding of HIV, cytomegalovirus, and hepatitis B virus was documented in the patient's semen. Herpes simplex virus type 2 was cultured from active ulcers in the patient's inguinal crease.

Disease Control and Prevention, 2002). Differential diagnosis of atypical and/or extensive genital warts includes squamous cell carcinoma in-situ and squamous cell carcinoma. These cases are best diagnosed by biopsy. Treatment by various excisional procedures is often effective, but recurrence occurs frequently.

Syphilis. A high prevalence of syphilis is found in certain HIV-infected populations, particularly men who have sex with men (Quinn et al, 1988; Centers for Disease Control and Prevention, 2002). In HIV-infected patients, primary infection with *Treponema pallidum* presents as the typical chancre. Secondary syphilis may present in classic papulosquamous form with involvement of palms, soles, and mucous membranes, but unusual presentations are common, such as verrucous plaques, extensive oral ulcerations, keratoderma, deep cutaneous nodules, and widespread gummata (Kho et al, 2004). The disease may progress faster from secondary to tertiary syphilis in HIV-infected patients. Early central nervous system relapse also can be more common.

Unusual serologic responses have been observed among HIV-infected persons with syphilis, usually among persons with higher than expected titers. False-negative tests have also been reported (Centers for Disease Control and Prevention, 2002). Patients with clinical findings suggesting possible syphilis but with nonreactive or atypical serologic tests should have alternative diagnostic tests, such as biopsy of lesions, darkfield examination, or direct fluorescent antibody staining for diagnosis.

HIV-infected persons with early syphilis appear to be at increased risk for neurologic complications and higher risk for treatment failure with standard regimens. For primary and secondary syphilis in HIV-infected patients the current recommendation is intramuscular injection of benzathine penicillin G (2.4 million units). At least one dose is recommended and some authorities recommend three doses at weekly doses, as recommended for late syphilis. Careful follow-up is recommended with repeated serologic studies for at least 24 months after treatment.

Chancroid. In the United States, chancroid usually occurs in discrete outbreaks. Chancroid is a cofactor for HIV transmission. Definitive diagnosis requires culture of *Haemophilus ducreyi* on special culture. Although polymerase chain reaction–based tests are described, none is approved by the U.S. Food and Drug Administration. Probable diagnosis can be made if the patient has painful genital ulcers, no evidence of *Treponema pallidum* infection, and a negative test for HSV. The combination of a painful ulcer and tender inguinal adenopathy, symptoms occurring in one third of patients, suggests a diagnosis of chancroid. When accompanied by suppurative inguinal adenopathy these signs are almost pathognomonic.

Recommended regimens for chancroid in HIV-infected patients are either ciprofloxacin, 500 mg orally twice daily for 3 days, or erythromycin base, 500 mg orally three times daily for 7 days (Centers for Disease Control and Prevention, 2002). Alternative drugs are either azithromycin, 1 g orally as a single dose, or ceftriaxone, 250 mg as a single intramuscular dose. HIV-infected patients with chancroid should be monitored closely because, as a group, these patients are more likely to experience treatment failure and to have ulcers that heal more slowly. HIV-infected patients may require longer courses of therapy, and treatment failures can occur with any regimen.

Urethritis. As the first rheumatic disease reported in HIV-infected patients, Reiter syndrome, consisting of uveitis, urethritis, and arthritis often presents in incomplete form (Solomon et al, 1991). The link between Reiter syndrome and AIDS is poorly understood. The syndrome, particularly the urethral discharge, is usually refractory to antibiotic therapy.

Molluscum Contagiosum. Molluscum contagiosum is caused by a sexually transmitted poxvirus. This condition reportedly develops in 10% to 20% of AIDS patients (Kho et al, 2004). Characteristic lesions are umbilicated, dome-shaped, translucent 2- to 4-mm papules. Lesions can develop in any part of the body, especially the face and genital areas. In AIDS patients these lesions are widespread and may attain immense size (Izu et al, 1994). Most HIV-infected patients with extensive molluscum contagiosum have CD4+ counts less than 250 cells/mL. In such immunosuppressed patients the diagnosis of molluscum contagiosum should be confirmed by histologic examination because the clinical appearance may simulate more serious infections such as cutaneous pneumocystosis, histoplasmosis, *Penicillium marneffei* infection, cryptococcosis, or cutaneous mycobacterial infection. Molluscum contagiosum is treated with cryotherapy, electrodissection, curettage, or topical application of keratolytic preparations (Kho et al, 2004).

HIV-Related Genitourinary Tract Infections

The genitourinary tract may be involved as the site or sequelae of HIV-related opportunistic infections (Randazzo et al, 1986; Stamm et al, 1988; Miles et al, 1989; Shevchuk et al, 1989, 1999; Pudney and Anderson, 1991; Wilson et al, 1992; Buzelin et al, 1994;

Leibovitch and Goldwasser, 1994; Swartz et al, 1994; Trauzzi et al, 1994; Cespedes et al, 1995; Timmerman et al, 1995; Appel et al, 2004; Kuritzkes, 2004).

Renal Infections. There has been a rise in drug-resistant tuberculosis in the United States. Persons with or at risk for HIV infection appear to be at increased risk for active infection with drug-resistant strains of *Mycobacterium tuberculosis*. Persons coinfected with HIV and *M. tuberculosis* have a greater likelihood of developing clinical tuberculosis, including renal and other extrapulmonary disease, that may be more difficult to diagnose and to treat (Weiss et al, 1998).

Other renal infectious manifestations of AIDS include cytomegalovirus, *Aspergillus,* and *Toxoplasma* infections. Cytomegalovirus is a common opportunistic infection in immunocompromised patients. Renal infection is most commonly noted in widespread disease in association with acute tubular necrosis (Kwan and Lowe, 1995). Although it has been suggested that renal cytomegalovirus infection might facilitate the development of HIV-associated nephropathy (HIVAN), an autopsy study of 75 kidneys suggested that the two findings are unrelated (Nadasdy et al, 1992). Aspergillosis and toxoplasmosis are common opportunistic infections of the kidney. Both organisms are treated with systemic therapy. Serious infections such as abscesses require percutaneous drainage, open drainage, or nephrectomy.

Prostatitis. The prostate is the site for varied opportunistic infections in HIV-infected patients. In one study bacterial prostatitis was diagnosed in 17 (8%) of 209 men hospitalized for HIV (Leport et al, 1989). The clinical presentation varies based on the severity of the infection but includes fever, obstructive and irritative voiding symptoms, and a tender prostate on digital rectal examination with possible fluctuance. Superimposed urinary tract infections occurred in 22% of AIDS patients in one study (Kaplan et al, 1987). Diagnosis requires broad cultures including aerobes, anaerobes, fungi, and mycobacteria. Prostatic abscesses require open, transrectal or endoscopic drainage. Bacterial prostatitis requires prolonged courses of antibiotics with high levels of prostatic penetration. Fungal prostatitis is initially treated with two-agent therapy (amphotericin and flucytosine) or one of the newer antifungal drugs, with long-term suppression for persistent or recurrent infections.

Epididymitis and Orchitis. The most common intrascrotal pathology in AIDS is testicular atrophy secondary to endocrine imbalances, febrile episodes, malnutrition, toxic effects of therapeutic agents, and testicular infections (Leibovitch and Goldwasser, 1994). Autopsy studies have demonstrated opportunistic testicular infection in up to 39% of AIDS patients (De Paepe et al, 1990). One study (Shevchuk et al, 1989) of 80 autopsies in AIDS patients demonstrated that 2 of 11 cases with systemic toxoplasmosis involved the testes, 4 of 48 cases of systemic cytomegalovirus infection involved the prostate whereas 1 involved the testes, and 1 of 27 cases of systemic candidiasis involved the prostate. Most patients' testes exhibited marked spermatogenic arrest, germ cell degeneration, peritubular fibrosis, and Leydig cell depletion, nonspecific findings that likely reflect severe systemic disease (Shevchuk et al, 1999). Other immunocompromised patients develop symptomatic genitourinary tract infections with both common and unusual organisms, for example, epididymitis caused by *Candida* (Swartz et al, 1994) or cytomegalovirus (Randazzo et al, 1986). Patients may be less likely to respond to medical therapy and to require surgery (Coburn, 1998).

Clinically, scrotal infections usually present as epididymo-orchitis. Relapse is common and may result in persistent symptoms or fulminant infection with abscess formation. Treatment requires initial antibiotic treatment followed by long-term maintenance suppression. The differential diagnosis of epididymitis or orchitis that does not respond to conventional therapy includes fungal, mycobacterial, and other opportunistic infections, in addition to testicular tumors (see later).

Impetigo, Abscesses, Cellulitis, Lymphadenitis, and Necrotizing Fasciitis. Impetigo, usually caused by *Staphylococcus aureus*, occurs in the inguinal area as in other common sites (the face, shoulders, and axilla). Typically the infection begins with painful red macules, progressing to pustules that rupture producing a characteristic honey-colored crust (Kho et al, 2004). Soft tissue and deep-seated infections, including cellulitis, abscesses, and necrotizing fasciitis may develop in HIV-infected patients.

Necrotizing fasciitis of the genitalia, also known as Fournier gangrene, has a propensity to occur in immunocompromised hosts (Corman et al, 1999). This aggressive, progressive, necrotizing fasciitis has been documented as the presenting finding in previously undiagnosed AIDS patients (McKay and Waters, 1994). Treatment depends on rapid diagnosis, wide surgical debridement, hemodynamic support, and prolonged antibiotic therapy. Diverting colostomy and partial or complete scrotectomy may prove necessary during operative debridement.

Voiding Dysfunction

Because HIV infection affects both the central and peripheral nervous systems, voiding dysfunction is common in patients with advanced infection (Hermieu et al, 1996). Urinary retention is the most common voiding dysfunction (54%) seen by urologists, although detrusor hyperreflexia (27%) and outflow obstruction (18%) have been documented during urodynamic evaluation of AIDS patients with voiding symptoms (Travers and Huybers, 1987; Kane et al, 1996). **Standard pharmacologic measures are preferred for patients with mild dysfunction, and routine urodynamic investigation has proven to be of low yield** (Gyrtrup et al, 1995). In our experience, voiding complaints often reflect the degree of systemic impairment; such symptoms often improve substantially after effective antiretroviral therapy. For patients in urinary retention, intermittent catheterization is the treatment of choice. When the patient lacks sufficient manual dexterity, indwelling urethral or suprapubic catheterization is employed.

Urolithiasis

Urinary calculi have been associated with several treatments of HIV infection. **The strongest association is with protease inhibitors, especially indinavir** (Daudon and Jungers, 2004). Kidney and ureteral stones occur in 2% to 3% of patients taking indinavir (Lerner et al, 1998; Katner et al, 2002), but rates as high as 12% to 24% have been reported (Hermieu et al, 1999; Reiter et al, 1999; Meraviglia et al, 2002). Renal secretion appears to increase urinary supersaturation with formation of indinavir urinary crystals, especially with indinavir dosages of more than 600 mg (Vella and Floridia, 2004). **The stones are nonopaque and may be associated with minimal findings on noncontrast CT examination** (Gentle et al, 1997; Blake et al, 1998; Schwartz et al, 1999).

The authors' experience is consistent with recommendations for conservative treatment in most cases, consisting of hydration, analgesics, and temporary cessation of indinavir (Hermieu et al, 1999; Kohan et al, 1999). Indications for intervention include persistent fever, intractable pain, inability to tolerate oral hydration, or obstruction of a solitary kidney. Indinavir crystals develop at pH 7.0 and can be dissolved when the pH is lowered to 4.0.

This suggests that short-term urinary acidification may be valuable for stone dissolution (Kalaitzis et al, 2002). After resolution of the acute symptoms and passage of the stone, indinavir therapy can be restarted with aggressive oral hydration (Clayman, 1998). Urinary calculi have also been associated with use of other protease inhibitors, such as nelfinavir (Engeler et al, 2002) and saquinavir (Green et al, 1998).

HIV-infected patients on protease inhibitors also form stones that do not contain protease inhibitors. One study of 24 HIV-infected patients with urinary calculi found that only 3 (29%) of 14 on indinavir had indinavir-containing stones (Nadler et al, 2003). Of 10 patients evaluated, 8 had metabolic abnormalities. Thus metabolic evaluation may help prevent future stone episodes while avoiding the need to alter antiretroviral regimens in most patients.

Sulfadiazine therapy for toxoplasmosis has also been associated with obstructive nephropathy (Farina et al, 1995; Colebunders et al, 1999; Crespo et al, 2000). The obstructing calculi often appear radiolucent. Initial therapy should include hydration, discontinuation of the sulfadiazine, and urinary alkalinization (Crespo et al, 2000). Invasive interventions should be reserved for patients who fail such medical management (Colebunders et al, 1999).

HIV-Associated Nephropathy

AIDS-related renal failure was first reported in the 1980s and has now become known as HIV-associated nephropathy (HIVAN) (Rao et al, 1984). **This glomerular disease has emerged as a significant medical renal disease in HIV-infected patients. The high prevalence and severity of HIVAN among certain populations has made this diagnosis almost synonymous with HIV-associated chronic kidney disease** (Appel et al, 2004; Winston et al, 2008). More recently the clinical course of HIVAN has been substantially improved by the widespread use of HAART (Lucas et al, 2004). Nonetheless, HIVAN remains a significant cause of morbidity and mortality among infected individuals.

Epidemiology. HIVAN has been reported more often on the U.S. east coast than the west coast. In urban east coast populations the prevalence of HIVAN approached 90% in nephrotic HIV-infected patients compared with 2% in San Francisco, where most patients were white homosexuals (Appel et al, 2004; Ross and Klotman, 2004).

HIVAN occurs more frequently among HIV-infected black patients, with a black-to-white ratio of 12:1, and represents the third leading cause of end-stage renal disease among 20- to 64-year-old blacks (following only diabetes and hypertension). Blacks also appear to have more severe renal disease with heavier proteinuria, higher rate of the nephrotic syndrome, and greater renal insufficiency. Intravenous drug use has been the most common risk factor associated with HIVAN, but the disease has been seen in all HIV risk groups (Appel et al, 2004). There is no relationship between HIVAN and patient age, duration of HIV infection, or types of opportunistic infections or malignancies (Appel et al, 2004). The prevalence of HIVAN is reported to be 3.5% in HIV-infected clinic patients and 6.9% in autopsy series of HIV-infected patients (Shahinian et al, 2000). As expected, hypertension and diabetes mellitus remain the most common risk factors for the development of chronic kidney disease, leading to a 10-fold increased risk of chronic kidney disease and accounting for more than 70% of cases of end-stage renal disease. Data from the Multicenter AIDS Cohort Study suggest that HIV-infected individuals are four times more likely to have diabetes compared with control subjects. Thus the association between HIV, HIVAN, and chronic kidney disease is complex (Brown et al, 2005; Winston et al, 2008).

Clinical Presentation. **HIVAN usually occurs in patients with low CD4 counts, but overt AIDS is not a prerequisite** (Appel et al, 2004). **HIVAN typically presents as nephrotic range proteinuria and renal insufficiency** (Appel et al, 2004). Other characteristics typical of the nephrotic syndrome are common in some series, including edema, hypoalbuminemia, hypercholesterolemia, and hypertension. Patients may also present with sub–nephrotic-range proteinuria and urinary sediment findings of microhematuria and sterile pyuria. Renal ultrasound evaluation shows echogenic kidneys with preserved or enlarged size despite severe renal insufficiency (Appel et al, 2004).

Pathology and Pathogenesis. Diagnosis of HIVAN is based on a renal biopsy specimen showing characteristic focal segmental glomerulosclerosis with collapsing features and related mesangiopathies (Appel et al, 2004). Patients with HIVAN have a higher percentage of glomerular collapse, less hyalinosis, and greater visceral cell swelling than patients with classic, idiopathic focal segmental glomerulosclerosis or heroin nephropathy.

There are conflicting data on the potential for direct HIV infection of renal glomerular cells in vivo, but HIV appears to be able to infect glomerular endothelial cells and to a lesser degree mesangial cells in vitro (Marras et al, 2002; Appel et al, 2004). HIV replication may not be necessary for development of HIVAN, and it is likely that a viral gene product or indirect effects on host cytokine production are involved in the pathogenesis.

Course and Treatment. During the early years of the epidemic HIVAN was characterized by rapid progression to end-stage renal disease (Appel et al, 2004). There was an almost universal requirement for dialysis within 1 year of diagnosis (Appel et al, 2004).

With the introduction of HAART the rise in new cases of end-stage renal disease due to HIVAN slowed markedly (Kirchner, 2002; Appel et al, 2004). There are reports of patients with biopsy-documented or presumed HIVAN who experienced dramatic resolution of nephrotic syndrome and improved glomerular filtration rate on therapy (Appel et al, 2004). **Antiretroviral therapy also appears to delay progression of HIVAN to end-stage renal disease. Thus antiretroviral therapy is recommended for patients with early histologic lesions and milder proteinuria without renal deterioration. Antiretroviral drugs need to be selected with caution given their propensity to cause or potentate nephrotic syndrome and must be dose adjusted in cases of renal insufficiency** (Winston et al, 2008). Other therapies that have been recommended include angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, and immunosuppressive therapy in selected patients (Appel et al, 2004).

Abnormal Urinalysis

Abnormalities on urinalysis are relatively common in HIV-infected persons. These findings include hematuria, pyuria, bacteriuria, and proteinuria. One study suggests that hematuria occurs in 25% of HIV-infected persons (Cespedes et al, 1995). Although hematuria may be related to many causes, genitourinary tumors appear to be uncommon, particularly in young men. Thus, complete urologic evaluation may safely be omitted in young men with asymptomatic microscopic hematuria (Cespedes et al, 1995). In contrast, the authors have seen a number of HIV-infected patients with urologic malignancies, including bladder, renal, and other tumors, presenting with hematuria. These observations suggest that complete investigation is indicated in older patients and

those with significant hematuria. Proteinuria is also common in certain populations of HIV-infected patients (see earlier).

Neoplasms

Many neoplasms occur in HIV-infected patients (Kho et al, 2004; Tirelli and Vaccher, 2004). Vascular and lymphoreticular neoplasms have been associated most strongly with HIV infection, particularly Kaposi sarcoma (KS) and non-Hodgkin lymphoma (NHL) (Cadogan and Dalgleish, 2008). The risks of KS and NHL are increased 1000- and 100-fold, respectively, among HIV-infected patients compared with the general population (Tirelli and Vaccher, 2004). KS, primary central nervous system lymphoma, systemic intermediate/high-grade B-cell NHL, and invasive cervical cancer have been designated as AIDS-defining illnesses. Other malignancies reported to be associated with HIV infection include Hodgkin disease, high-grade anal epithelial lesions, nonmelanomatous skin cancer, myeloma, and lung and testicular carcinoma (International Collaboration on HIV and Cancer, 2000; Tirelli and Vaccher, 2004). HAART radically changed the clinical spectrum of HIV infection in industrialized countries. During the mid 1990s, rates of opportunistic infections, KS, primary central nervous system lymphoma, and NHL decreased significantly (International Collaboration on HIV and Cancer, 2000; Grulich et al, 2001).

Kaposi Sarcoma

KS is the most common vascular neoplasm and a significant cause of morbidity and mortality in certain HIV-infected populations (Cockerell, 1996).

Classification and Clinical Presentation. KS is classified into classic and epidemic forms. The classic form was first described in 1827 (Kho et al, 2004) and occurs mainly in elderly Mediterranean men, black equatorial Africans, and patients with lymphoma or immune deficiencies. In contrast, epidemic KS is associated with AIDS.

KS ranges from an indolent to an aggressive disease with substantial morbidity and mortality. **Typical patients present with disseminated skin lesions, often with lymph node and visceral involvement** (Tirelli and Vaccher, 2004). Any skin area may be involved, including the genitalia. Three types of skin lesions are described: macule or patch, plaque, and nodule (Kho et al, 2004). Typical macules are oriented along skin cleavage lines and may be mistaken for blushes, purpura, or nevi. With time the lesions darken and develop into raised, firm, indurated, purplish plaques reflecting the presence of abundant blood vessels, extravasated erythrocytes, and siderophages. Some lesions may ulcerate. Nodular lesions are dome-shaped elevated lesions that are usually purple. On palpation they are firm and may be ulcerated.

Epidemiology. KS incidence rates started to decline in the late 1980s and then dramatically lessened with the introduction of HAART in the mid 1990s (International Collaboration on HIV and Cancer, 2000; Grulich et al, 2001; Tirelli and Vaccher, 2004). Meta-analysis of 47,936 HIV-infected individuals from North America, Europe, and Australia found that the KS rate ratio for 1997-1999 versus 1992-1996 was 0.3 (International Collaboration on HIV and Cancer, 2000). The risk of KS among male homosexuals is more than 100,000-fold higher than other HIV-infected populations (Tirelli and Vaccher, 2004).

A new herpesvirus, called KS-associated herpesvirus or human herpesvirus 8 (Chang et al, 1994), **is essential for all forms of KS.** KS-associated herpesvirus transmission correlates with a history of STIs and number of male sexual partners. Coinfection with HIV and KS-associated herpesvirus increases the risk of developing KS 10,000-fold compared with KS-associated herpesvirus infection alone. The probability of developing KS after coinfection with both KS-associated herpesvirus and HIV approaches 50% over 10 years (Chang et al, 1994).

Pathology and Pathogenesis. KS is an proliferative disease characterized by angiogenesis, endothelial spindle cell growth (KS cells), inflammatory cell infiltration, and edema (Tirelli and Vaccher, 2004). These lesions reflect immune dysregulation characterized by CD8+ T-cell activation, production of T-helper-1 cytokines, and angiogenic factors. This process induces generalized activation of endothelial cells.

Diagnosis and Management. An experienced observer can often make a presumptive diagnosis but skin biopsy is necessary to confirm the diagnosis of KS.

No specific therapy is curative (Tirelli and Vaccher, 2004). Treatment needs to be individualized, based on the patient's clinical and immunologic status. HAART results in clinical improvement of KS lesions and prolongation of time to treatment failure (Lebbe et al, 1998; Levine and Tulpule, 2001). Numerous anecdotal reports document KS regression on HAART alone. Anti-KS activity of HAART appears to reflect immune system reconstitution and, to a lesser extent, suppression of HIV replication. HIV protease inhibitors are also potent antiangiogenic molecules that may affect KS pathogenesis (Sgadari et al, 2002).

Localized, cutaneous KS lesions can be treated using radiation, laser, cryotherapy, or intralesional injections of antineoplastic drugs (Levine and Tulpule, 2001). Cytotoxic chemotherapy is indicated for patients who do not respond to HAART and patients with life-threatening or visceral disease. A wide variety of drugs, including *Vinca* alkaloids (vincristine, vinblastine), bleomycin, and doxorubicin individually and in combination have produced tumor regression in 21% to 59% of patients, with lower rates for monotherapy. Paclitaxel is the newest systemic agent approved for use in the patient in whom KS has relapsed (Levine and Tulpule, 2001). Corticosteroid therapy should be avoided because they induce development of KS and may worsen preexisting KS lesions.

Prognosis for HIV-infected patients with KS depends primarily on their immune status and, secondarily, on the clinical stage of the KS lesions. Median survival of patients with CD4+ T-cell counts greater than or equal to 150/μL and early-stage disease is 35 months. Patients with CD4+ T-cell counts less than 150/μL have poor median survival (13 months for early-stage disease and 12 months for advanced-stage disease, respectively) (Levine and Tulpule, 2001).

Non-Hodgkin Lymphoma

A number of lymphoreticular malignancies of both B and T cells develop in HIV-infected patients. Most are based in the lymph nodes and reticuloendothelial system. The genital skin and genitourinary organs may be involved primarily or secondarily (Mearini et al, 2002; Kho et al, 2004; Tirelli and Vaccher, 2004). Patients usually present with advanced disease associated with a short median survival time. NHL is the most common lymphoreticular neoplasm.

Epidemiology and Clinical Presentation. NHL incidence decreased significantly after the introduction of HAART (Tirelli and Vaccher, 2004). Systemic NHL incidence decreased less than KS and later than the other AIDS-defining illnesses. Consequently, lymphoma has become the most common AIDS-associated cancer among patients receiving HAART (International Collaboration on HIV and Cancer, 2000; Grulich et al, 2001; Tirelli and Vaccher, 2004).

HIV-infected patients characteristically have widespread disease at presentation (Tirelli and Vaccher, 2004). They frequently have

systemic symptoms, including fever, night sweats, and weight loss of more than 10%. At diagnosis of NHL, approximately 75% of HIV-infected patients have advanced disease with frequent involvement of extranodal sites. Any body site may be affected, including the genitourinary tract.

Diagnosis and Treatment. NHL should be diagnosed by histologic examination of an incisional or excisional biopsy specimen. Treatment consists of the usual therapy for systemic lymphoma. Optimal therapy has not been defined, and whether intensive or conservative chemotherapy regimens are indicated remains controversial. Prognosis for HIV-infected patients with lymphoma is poor, with a median survival of 5 to 10 months after diagnosis (Tirelli and Vaccher, 2004).

Squamous Genital Cancers: Role of Human Papillomavirus

HIV infection is associated with HPV-related anogenital neoplasms (Tirelli and Vaccher, 2004). **These lesions include cancers and precancerous lesions of the cervix, vulva, anus, and penis.** The risk of all HPV-associated cancers and their in-situ precursor lesions in both women and men is elevated across all HIV exposure categories (Tirelli and Vaccher, 2004). Risk factors include multiple sexual partners, cigarette smoking, and STIs, particularly HPV infection.

HPV sequences are found in more than 99% of cervical squamous cell carcinomas and in most anal cancers, with HPV type 16 present in 50% and types 18, 31, and 45 present in another 30%. High-grade intraepithelial precursor lesions have comparable rates of similar HPV types. HPV-associated oncogenesis results from upregulated expression of viral-encoded transforming proteins, particularly E6 and E7. These proteins interact with and inactivate the host cell tumor suppressor gene products, including retinoblastoma and TP53. This results in upregulated cell cycle progression, deficient DNA repair, and, eventually, malignant transformation (Tirelli and Vaccher, 2004). The degree of HIV-related immunosuppression corresponds with the occurrence and severity of these anogenital tumors.

Testicular Cancer

There may be an increased incidence of germ cell and non–germ cell testicular tumors associated with HIV infection (Wilkinson and Carroll, 1990; Wilson et al, 1992; Kwan and Lowe, 1995). Retrospective review of 3000 patients enrolled in an HIV clinic found a 50 times greater rate of testicular neoplasms than in the general population (Wilson et al, 1992). Compared with HIV-uninfected patients there is a greater risk of tumor bilaterality and a greater risk of high-grade testicular lymphoma (Armenakas et al, 1992). **More recent data suggest that the increased risk of testicular germ cell tumors is more modest, whereby HIV-infected men are approximately two times more likely to develop seminoma (Standardized Incidence Ratio 1.9, 95% CI 1.6-2.2) but not more likely to develop nonseminomatous tumors** (Goedert et al, 2007).

The therapeutic dilemma is that all accepted treatments for testicular neoplasms, except surveillance, cause additional immune suppression. Furthermore, patients with advanced HIV/AIDS often tolerate radiation and chemotherapy poorly. This may require major modifications of standard treatment protocols, resulting in decreased effectiveness. Despite these limitations, most experts recommend that HIV-infected patients with testicular neoplasms should receive standard treatment, as indicated by the tumor histology and stage (Wilkinson and Carroll, 1990).

OCCUPATIONAL RISKS FOR HIV INFECTION IN UROLOGY

For reasons that are not completely understood, occupational HIV infection remains relatively uncommon (Henderson, 2004b).

Epidemiology

The Centers for Disease Control and Prevention has recorded only 57 instances of documented occupational HIV infection. For each case the worker sustained an occupational exposure, had a negative baseline serum sample, and then developed serologic evidence of HIV infection. In addition there have been 138 instances of probable or possible occupational HIV infection among U.S. health care workers (Centers for Disease Control and Prevention, 2004). Of adults with AIDS, 5.1% have occurred in health care workers, including 122 surgeons. Approximately 60 cases of "possible or probable" occupational infection have been reported from outside the United States (Henderson, 2004b). There were no documented cases of occupationally acquired AIDS/HIV infection among surgeons and 6 possible cases of occupational transmission among surgeons.

Risks Associated with Specific Exposures

Of the 57 health care workers who seroconverted following occupational exposures 48 (84%) had percutaneous (puncture/cut injury) exposures; 5 (9%) had mucocutaneous (mucous membrane and/or skin) exposures; 2 (4%) had both percutaneous and mucocutaneous exposure; and 2 (4%) had an unknown route of exposure. Forty-nine health care workers were exposed to HIV-infected blood, 3 to concentrated virus in a laboratory, 1 to visibly bloody fluid, and 4 to an unspecified fluid (Centers for Disease Control and Prevention, 2004).

Many occupational cases of HIV transmission share common features. Most are percutaneous exposures, especially injection needlestick injuries. All clinical cases occurred after exposure to blood or grossly blood-stained fluids from HIV-infected patients. As yet, no case has been documented following a needlestick injury with a solid surgical needle (Henderson, 2004b).

A retrospective, case-control study from the United States, France, and the United Kingdom identified **five risk factors for occupational infection: deep as compared with superficial exposure** ($P < .0001$), **blood visible on the device causing the exposure** ($P = .0014$), **placement of the device in a source-patient's vein or artery** ($P = .0028$), death of **the source-patient within 60 days of the exposure** ($P = .0011$), **and no postexposure chemoprophylaxis with zidovudine** ($P = .0026$) (Cardo et al, 1997). The first four factors are likely related to an increased inoculum.

The importance of an inoculum effect is supported by other data. Transfusion of a unit of blood from an HIV-infected donor is associated with virtually 100% risk for infection (Ward et al, 1987). The depth of a percutaneous exposure was an independent risk factor for occupational HIV infection (Cardo et al, 1997). In addition, all needlestick exposures associated with occupational transmission have been caused by hollow-bore needles (i.e., injection as compared with suturing needles), which contain more blood than solid needles.

Table 14–5.
Risk for HIV Infection Associated with Occupational Exposure

TYPE OF EXPOSURE	PERCUTANEOUS	MUCOUS MEMBRANE
No. of longitudinal studies	27	21
No. of exposures	6807	2761
No. of documented infections	21	0/1
Infection rate per exposure	0.031%	0-0.11%

From Henderson DK: Preventing occupational infection with HIV in the health care environment. In Cohen J, Powderly WG, Berkley SF, et al, editors. Infectious diseases. 2nd ed, vol. 22. Edinburgh: Mosby; 2004. p. 1217–22.

Combining available data, health care workers have sustained more than 6800 percutaneous exposures to sharp devices contaminated with blood or other blood-stained body fluids from HIV-infected patients (Ippolito et al, 1999; Henderson, 2004b). Twenty-one occupational HIV infections were documented, resulting in a risk of transmission per injury of 0.31% (Table 14–5). Thus, 1 in 324 parenteral exposures resulted in occupational HIV infection.

Other exposures represent a lower risk for infection. In rare circumstances, mucous membrane or cutaneous exposures may produce occupational infection (Chamberland et al, 1995). To date, more than 2700 exposures have been followed prospectively, with only one seroconversion (Ippolito et al, 1993). Thus, a maximum risk estimate for HIV infection is 0.11% per mucous membrane exposure. Occupational exposures other than percutaneous and mucous membrane exposures are even less likely to result in infection. Prospective studies (Friedland et al, 1990; Gershon et al, 1990) that include hundreds of person-years of follow-up have not identified a single instance of HIV transmission. Although exposures to other fluids are likely to be associated with some occupational risk, this risk is below measurable limits.

Interventions to Decrease Occupational Risk

Adherence to current guidelines might prevent one third of parenteral occupational exposures (Marcus, 1988). Universal Precautions are based on the principle that health care workers should treat blood and blood-stained body fluids from all patients as potentially infectious (Centers for Disease Control and Prevention, 1988). The CDC also recommends Standard Precautions, focusing on the bidirectional spread of organisms to and from patients and health care providers. The recommendations emphasize that blood and blood-containing body fluids represent risks to health care workers and that health care workers should use barriers and take precautions to prevent occupational exposures. These recommendations are effective. For example, the act of piercing a latex glove with a needle covered with blood may reduce the blood inoculum by as much as 50% (Henderson, 2004b).

Once exposure to HIV has occurred, the exposed site should be allowed to bleed freely and first aid should be administered. The wound should be cleansed and decontaminated as soon as patient safety permits. Wounds should be washed with soap and water and then irrigated with sterile saline, a disinfectant, or other suitable solution.

Postexposure Prophylaxis

Data support postexposure chemoprophylaxis to reduce the risk of occupational HIV transmission. Postexposure prophylaxis has proven effective in animal models (Henderson and Gerberding, 1989; Henderson, 2004a). The case-control study described earlier found that zidovudine chemoprophylaxis was associated with an 80% reduction in the risk for occupational infection (Cardo et al, 1997).

Current recommendations include a three-drug regimen for the most severe occupational exposures (i.e., zidovudine, lamivudine, and one of four additional agents) and a two-drug regimen for lesser exposures (i.e., zidovudine plus lamivudine or one of two other alternative two-drug regimens) (Centers for Disease Control and Prevention, 2001). If the source patient is (or recently has been) receiving antiretroviral therapy, some authorities recommended use of alternative regimens (Henderson, 2004a).

There are two major problems with antiretroviral prophylaxis following occupational exposure to HIV. First, these drugs have substantial toxicity. Data on healthy individuals, especially for the newer agents, are extremely limited (Henderson, 2004a). Studies of antiretroviral prophylaxis after occupational HIV exposures in health care workers have demonstrated substantial side effects, often limiting completion of the regimen. Recently, use of nevirapine has been contraindicated because of the risk of severe liver toxicity, including hepatic failure. Virtually all marketed antiretroviral agents have potential for carcinogenicity, teratogenicity, and mutagenicity. Second, there have been documented failures of antiretroviral prophylaxis. Cases of zidovudine chemoprophylaxis failure (eight of which have clinical relevance) have appeared in the literature (Henderson, 2004a). Thus, the potential risks and benefits of post-exposure prophylaxis must be considered on a case-by-case basis.

ANTIRETROVIRAL THERAPY

A diagram of antiretroviral therapy in HIV infection is presented in Figure 14–4 (Vella and Floridia, 2004).

Suppression of HIV replication is associated with a significant delay in the progression to AIDS and increased survival. Thus, the goal of antiretroviral treatment should be to obtain maximal and sustained suppression of HIV replication (Vella and Floridia, 2004).

The main tools for monitoring antiretroviral treatment are the plasma HIV RNA level and CD4+ T-cell count (O'Brien et al, 1996). **Previously untreated patients should reach undetectable plasma HIV RNA levels within 4 to 6 months accompanied by a concomitant rise in CD4+ counts. In this context "undetectable plasma HIV RNA level" does not mean eradication of the virus at other sites (lymphoid tissues, central nervous system, or genital tract)** (Perelson et al, 1997). Eradication of HIV from these viral reservoirs and sanctuaries is not yet a realistic goal.

From Monotherapy to Highly Active Antiretroviral Therapy (HAART)

In 1987 zidovudine, the first effective antiretroviral drug and prototype of the nucleoside reverse transcriptase inhibitors (NRTIs), was introduced. Zidovudine monotherapy remained the mainstay of treatment until it became evident that benefit was limited (Concorde, 1994). Clinical trials demonstrated that two-drug

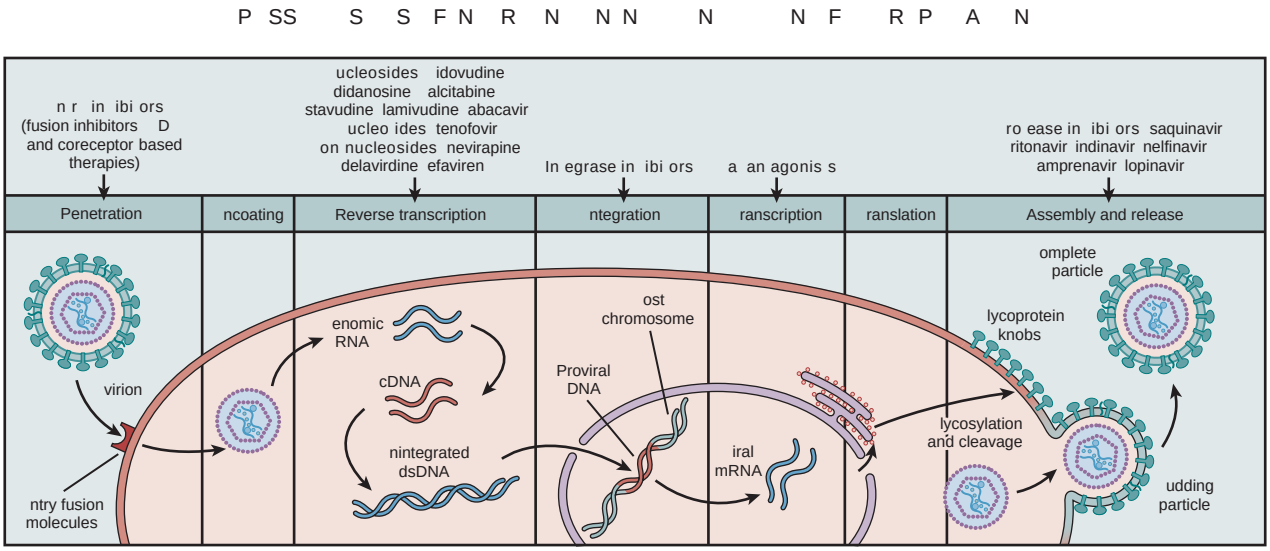

Figure 14–4. Antiretroviral therapy for HIV infection. Diagram illustrating potential sites of action for drug therapy. (From Vella S, Florida M. HIV therapy: antiviral therapy. In: Cohen J, Powderly SF, Berkley SF, et al, editors. Infectious diseases. 2nd ed, vol. 2. Edinburgh: Mosby; 2004. p. 1387–98).

regimens induced a more profound and prolonged effect on viral load, CD4+ T-cell counts, delayed clinical progression, and increased patient survival (Hammer et al, 1996; Deeks et al, 1997). In 1995 protease inhibitors became available. Combined with NRTIs, protease inhibitors produced a further reduction of HIV replication, often to undetectable levels (Deeks et al, 1997). Non-nucleoside reverse transcriptase inhibitors (NNRTIs), introduced after 1996, also proved highly effective. Availability of a rapidly increasing number of drugs and the evolving information has made HIV treatment extremely complex. The objective of antiretroviral therapy is to prevent disease progression and prolong survival while maintaining quality of life. Long-term nonprogression will be achieved by reducing plasma viral load below 50 copies/mL on a long-term basis. Combinations of antiretroviral agents with minimal or no overlapping toxicity and demonstrated antiviral additive to synergistic effect is recommended to maximize the antiviral response (Montaner et al, 2004). Current recommendations from the International AIDS Society-USA Panel note that the initial treatment regimen must be individualized but should generally include a protease inhibitor (efavirenz) plus two NRTIs (tenofovir/emtricitabine or abacavir/lamivudine) (Hammer et al, 2008).

Available Drugs

The optimal treatment of HIV infection is a potent combination of drugs, termed highly active antiretroviral therapy (HAART). Most HAART regimens are based on a dual nucleoside "backbone" plus an NNRTI or a protease inhibitor (with the option of adding low-dose ritonavir to another protease inhibitor for pharmacoenhancement.) Three-nucleoside regimens including abacavir are increasingly used because these regimens are easy to administer and are dual-class sparing (i.e., allow deferred use of protease inhibitors and NNRTIs).

Currently antiretroviral drugs include 7 NRTIs (zidovudine, didanosine, zalcitabine, stavudine, lamivudine, emtricitabine, and abacavir), 1 NRTI (tenofovir disoproxil fumarate), 3 NNRTIs (nevirapine, delavirdine, and efavirenz), and 10 HIV protease inhibitors (saquinavir, ritonavir, indinavir, nelfinavir, amprenavir, fosamprenavir, tipranavir, darunavir, atazanavir, and lopinavir). Other drugs have recently been approved by the U.S. Food and Drug Administration for treating HIV. These drugs may prove particularly useful in cases of viral resistance to standard regimens and include a fusion inhibitor (enfuviritide), an entry inhibitor (maraviroc), and an HIV integrase strand transfer inhibitor (raltegravir) (Table 14–6) (He et al, 2008; Hicks and Gulick, 2009; Hunt and Romanelli, 2009).

Nucleoside Reverse Transcriptase Inhibitors and Non-Nucleoside Reverse Transcriptase Inhibitors

NRTIs act through at least two mechanisms. First, as "chain terminators," they block viral DNA elongation, stopping addition of further nucleosides. This mechanism depends on intracellular phosphorylation of NRTIs to the corresponding triphosphates. Second, they act by competition/binding of the reverse transcriptase; NNRTIs act only through this mechanism and not as "chain terminators."

Protease Inhibitors

Protease inhibitors act by binding to the catalytic site of HIV aspartic protease. This enzyme is critical for post-translational processing of the polyprotein products into the functional core proteins and viral enzymes. By inhibiting this step, protease inhibitors release immature, noninfectious viral particles. However, unlike the NRTIs, which provide no protection in established HIV infection, protease inhibitors are also active in chronically infected cells. Protease inhibitors are combined with NRTIs or with other protease inhibitors, taking advantage of a boosting effect on drug concentrations that occurs when protease inhibitors are administered together.

Significant Urologic Side Effects

Of the NRTIs, zalcitabine is associated with peripheral neuropathy and painful penile ulcers. Of the protease inhibitors, ritonavir should be used with caution among patients at high risk of bleeding. Indinavir is a potent protease inhibitor that has been associated with urolithiasis (see earlier). In addition to drug-specific adverse events, long-term use HAART has highlighted a number

Table 14–6.

Antiviral Drugs Available for HAART Combination Regimens

CLASS	DRUG	TRADE NAME
Nucleoside reverse transcriptase inhibitors (NRTIs)	Zidovudine (AZT)	Retrovir*†
	Didanosine (ddI)	Videx
	Zalcitabine (ddC)	Hivid
	Lamivudine (3TC)	Epivir*†
	Stavudine (d4T)	Zerit
	Abacavir (ABC)	Ziagen†
	Emtricitabine (FTC)	Emtriva‡
Nucleotide reverse transcriptase inhibitors	Tenofovir	Viread
Non-nucleoside reverse transcriptase inhibitors (NNRTIs)	Delaviridine (DLV)	Rescriptor
	Nevirapine (NVP)	Viramune
	Efavirenz (EFV)	Sustiva
Protease inhibitors	Saquinavir (SAQ)	Invirase
	Ritonavir (RTV)	Norvir
	Nelfinavir (NFV)	Viracept
	Indinavir (IDV)	Crixivan
	Amprenavir (APV)	Agenerase
	Fosamprenavir (FOS-APV)	Lexiva
	Lopinavir (LPV)	Kaletra§
	Tipranavir (TPV)	Aptivus
	Darunavir	Prezista
	Atazanavir (ATV)	Reyataz
Fusion inhibitors	Enfuviritide (T-20)	Fuzeon
Entry inhibitors	Maraviroc	Selzentry
HIV integrase strand transfer inhibitors	Raltegravir	Isentress

*Also available as Combivir (300 mg AZT + 150 mg 3TC).
†Also available as Trizivir (300 mg AZT + 150 mg 3TC + 300 mg ABV).
‡Also available as Truvada (300 mg FTC + 200 mg tenofovir).
§Only available as Kaletra (133.3 mg lopinavir +33.3 mg ritonavir).
From Vella S, Floridia M. HIV therapy: antiviral therapy. In: Cohen J, Powderly WG, Berkley SF, et al, editors. Infectious diseases. 2nd ed, vol. 2. Edinburgh: Mosby; 2004. p. 1387–98.

of previously unrecognized adverse events. Some appear to be associated with a specific class of drugs, such as mitochondrial toxicity and lactic acidosis with NRTIs or hypoglycemia with protease inhibitors. Fat distribution changes (commonly described as lipodystrophy) represent a major clinical event. This syndrome presents as atrophic changes (peripheral fat loss involving face and limbs resembling Cushing disease), hypertrophic changes (visceral or dorsocervical fat accumulation, breast enlargement), or both.

New Investigational Agents

Even with potent, multidrug regimens, virologic failure is frequent. This may depend on various factors, including low adherence, drug-resistant HIV strains, low drug levels in the plasma or tissues, and other undetermined factors. Targeted strategies are being developed to improve treatment efficacy, including development of new drugs with improved formulation and administration schedules, increased potency, and reduced toxicity. A number of agents in each of the available drug classes as well as drugs with novel mechanisms of action are being developed. Desirable characteristics of this new generation of drugs include easier administration schedule, perfected pharmacokinetics, potency, tolerability, and the ability to inhibit HIV viruses that are resistant to the existing agents.

Evolving HIV Treatment Strategies

Growing appreciation of the difficulties of taking antiretroviral therapy on a long-term basis, the adverse effects of many regimens, and their negative impact on quality of life have led to reevaluation of this early intervention strategy. Because "eradication" of HIV is not on the horizon, the goal of therapy must now be redirected toward the long-term management of a chronic infection (Vella and Floridia, 2004).

The decision to start treatment is now based first on the patient's disease stage, because it is clear that a symptomatic patient should be treated. For an asymptomatic patient, the decision is often driven by the CD4+ lymphocyte count and the plasma HIV RNA level (Montaner et al, 2004). **The CD4+ T lymphocyte count can be regarded as an immediate predictor of prognosis, whereas the plasma HIV RNA level indicates the level of actual HIV replication.** Other elements include the patient's commitment to therapy and knowledge of the limitations of current regimens.

Despite the effectiveness of HAART the optimal time to initiate therapy remains unclear. Although current antiviral therapies have proven ability to suppress viral load and improve immune system function, several questions remain. Specific concerns remain about early initiation of HAART and patient compliance, drug toxicities, drug resistance, and the marked costs associated with prolonged therapy (Wilkin and Gulick, 2008). Despite the absence of randomized clinical trials, several large cohort studies have demonstrated decreased AIDS-related morbidity and mortality when HAART is started early in the course of infection, when CD4 cell counts are higher. Recent data from the ART Cohort Collaboration suggest that individuals in whom therapy is initiated with a CD4 count of 200 to 350 cells/μL have a 5-year mortality rate that is 40% higher than those in whom therapy is started with counts greater than 350 cells/μL (May et al, 2007). The rationale for early therapy is augmented by studies suggesting decreased rates of non–AIDS-defining conditions, such as cancers, neuropathy, and anemia when antiviral medications are initiated at these higher CD4 levels. Fear that early therapy may increase costs of HIV treatment prompted multiple studies of the cost-effectiveness of early antiviral treatment, with sensitivity analyses using varying CD4 count levels. These studies suggest that early treatment is cost effective and offers significant improvements in quality-adjusted life years (Wilkin and Gulick, 2008).

Strategies on the Horizon

In addition to a plethora of new antiretroviral agents targeting the HIV replication cycle there are a number of strategies under active investigation to prevent HIV infection or to improve therapy. Two promising approaches are development of immune-based strategies and vaccines.

Immune-Based Strategies That May Be Combined with HAART. Because eradication of HIV with HAART probably cannot be achieved in less than 50 to 60 years (Montaner et al, 2004) the possibility of adding additional treatment to ensure immune restoration holds considerable appeal (Pollard and Onorato, 2004). Various strategies are under investigation to both enhance HIV-specific immune responses and to stimulate the general immune responses, such as therapeutic vaccination, structured treatment interruption, transfer of HIV-specific cell populations to enhance cell-mediated immunity, and transfer of pooled immune sera from donors who have HIV infection or of monoclonal antibodies directed against HIV. Such strategies may be of particular value for treating patients with later-stage infection, whose high levels of

viremia and previous exposure to therapy place them at greatest risk of developing resistance to therapeutic agents (Pollard and Onorato, 2004).

Vaccines to Prevent HIV Infection. Considerable efforts are being expended to develop an effective vaccine to prevent HIV infection (Rosenberg et al, 1997; Amara et al, 2001; Shiver et al, 2002; Fast et al, 2004). HIV represents a formidable challenge. Its immune evasion mechanisms include molecular tricks to avoid neutralization by antibody, downregulation of immune functions, direct destruction of the CD4 T cells that support both antibody and effector T-cell responses, and a very rapid mutation rate that gives rise to virus strains lacking the antigenic sites to which effective immune responses are directed.

Nevertheless, several lines of evidence suggest that vaccines may prove effective in preventing HIV infection or in preventing progression to AIDS (Fast et al, 2004). First, HIV infection occurs after only a small fraction of all exposures, suggesting that a modest immune defense might be effective. Second, the natural history of HIV infection is that after an initial phase of rapid viral replication immune responses may control HIV replication and slow its pathogenic effects for many years. Third, in primate models some vaccines can prevent infection or slow viral replication and disease progression. Immunization that induces mucosal responses is particularly effective against mucosal challenges, as would occur with sexual exposure (Amara et al, 2001; Shiver et al, 2002). A number of vaccines have been tested and, lacking credible immunogenicity data, abandoned. Several more promising vaccines have recently entered trials or are expected to do so soon.

Cutaneous Diseases of the External Genitalia

Richard Edward Link, MD, PhD

Introduction to Basic Dermatology
Dermatologic Therapy
Allergic Dermatitis
Papulosquamous Disorders
Vesicobullous Disorders
Noninfectious Ulcers
Infections and Infestations
Neoplastic Conditions
Benign Cutaneous Disorders Specific to the Male Genitalia
Common Miscellaneous Cutaneous Disorders

The diagnosis and treatment of cutaneous diseases of the external genitalia remains an important element of urologic practice. Often overlooked during formal urology residency training, this topic lies at the interface of three specialties: urology, infectious disease, and dermatology.

INTRODUCTION TO BASIC DERMATOLOGY

Dermatology is the clinical discipline focused on the biology and pathology of the skin. The diagnosis of skin disease depends critically on the history and physical examination, with laboratory testing often relegated to a peripheral and confirmatory role. In many cases, visual inspection alone will suffice to narrow the diagnosis significantly.

The skin is divided into three layers: the epidermis, dermis, and subcutaneous tissue. The epidermis, composed of stratified squamous epithelium, can vary in thickness from 0.05 mm to 1.5 mm, depending on location. The dermis, composed of collagen, elastin, and reticular fibers, can be divided into two layers: the thin superficial layer (papillary dermis) and thicker deeper layer (reticular dermis).

Literally hundreds of cutaneous diseases exist involving the external genitalia. In addition, within each disease there may be significant variation in appearance and symptoms as the process evolves. For this reason, a methodical and systematic approach is essential to reach a rational diagnosis. The dermatologic history should focus on the duration, rate of onset, location, symptoms, family history, allergies, occupation, and previous treatment of the condition (Habif, 2004). Common symptoms include pruritus (itching), burning, and pain.

The physical examination should address the distribution of primary and secondary skin lesions. **It is important to perform a thorough skin survey and not focus solely on the area of affected genital skin.** Most skin conditions begin with a characteristic primary lesion that is an important key to diagnosis. Precise description of this lesion includes documenting its color (red, brown, black, yellow, blue, or green) and morphology (macule, papule, plaque, nodule, pustule, vesicle, bulla, or wheal; Table 15–1) (Habif, 2004). Because of the mucosal nature of genital skin, papular and macular lesions may present as erosions in this area (Margolis, 2002). Secondary skin lesions develop as the skin condition evolves or are caused by scratching or superinfection. A secondary lesion should also be classified morphologically as a scale, crust, erosion, ulcer, atrophy, or scar (Table 15–2).

Once gross morphology is determined, laboratory testing may serve to confirm the diagnosis. To identify cutaneous fungi such as dermatophytes and *Candida* species, potassium hydroxide (KOH) or periodic acid–Schiff (PAS) staining may be applied to scraped or touched skin specimens. KOH dissolves keratin, leaving fungal hyphal walls prominently visible under the microscope. Likewise, Tzanck preparations may aid in identifying viral agents such as herpes simplex, varicella zoster, and molluscum contagiosum.

For difficult cases or those in which malignancy is suspected, skin biopsy may be indicated. A variety of techniques exists for this purpose, including curettage, punch, shave, incisional, and complete excisional biopsies. For small scrotal or phallic shaft lesions, these techniques can often be performed in the office setting under local anesthesia. For larger lesions or those involving the glans penis or urethral meatus, biopsy in the operating room is recommended.

DERMATOLOGIC THERAPY

Medical therapy for dermatologic conditions consists of a broad range of topical and systemic compounds.

For systemic therapy, useful drug classes include antibiotics, antifungals, antivirals, anti-inflammatories, and antipruritics. Less commonly used agents, including chemotherapeutic drugs (e.g., methotrexate, cyclophosphamide),

Table 15–1.

Primary Cutaneous Lesions

PRIMARY LESION	DESCRIPTION
Flat	
Macule	A circumscribed, **flat** discoloration that may be brown, blue, red, or hypopigmented
Elevated Solid	
Papule	An **elevated, solid** lesion up to 0.5 cm in diameter of variable color. Papules may become confluent to become plaques
Nodule	A circumscribed, **elevated solid** lesion >0.5 cm in diameter
Plaque	A circumscribed, **elevated**, superficial, **solid** lesion >0.5 cm in diameter
Fluid-Filled	
Vesicle	A circumscribed **collection of free fluid** up to 0.5 cm in diameter
Bulla	A circumscribed **collection of free fluid** >0.5 cm in diameter
Pustule	A circumscribed collection of leukocytes and free fluid (**pus**)
Wheal (hive)	A firm **erythematous plaque** resulting from **infiltration** of the dermis with fluid (may be transient)

From Habif TP. Clinical dermatology: a color guide to diagnosis and therapy. Edinburgh: Mosby; 2004.

Table 15–2.

Secondary Cutaneous Lesions

SECONDARY LESION	DESCRIPTION
Scale	Excess dead epidermal cells that are produced by abnormal keratinization and shedding
Crust	A collection of dried serum and cellular debris (a scab)
Erosion	A focal loss of epidermis. Erosions do not penetrate below the dermoepidermal junction and heal without scarring
Ulcer	A focal loss of epidermis and dermis which heals with scarring
Fissure	A linear loss of epidermis and dermis with sharply defined, vertical walls
Atrophy	A depression in the skin resulting from thinning of the epidermis or dermis
Scar	An abnormal formation of connective tissue implying dermal damage

immunosuppressants (e.g., azathioprine, cyclosporine, tacrolimus), and hydroxyurea, will be covered under specific disease entities.

A lack of familiarity with cutaneous diseases affecting the genitalia may lower the threshold that leads urologists to prescribe systemic antibiotics for these conditions. Unfortunately, these agents carry significant greater risks than topical preparations, including promotion of resistant organisms, interaction with other medications, and disruption of the normal bowel and vaginal flora. Similar caveats apply to systemic antifungal agents such as ketoconazole and fluconazole. Superficial dermatophytes, such as those causing tinea cruris, generally respond well to topical antifungal preparations. **Systemic antifungals are indicated for local infection with an extensive area of skin involved, disseminated mycoses with skin involvement, infection involving the hair follicles, or fungal infections in immunocompromised individuals** (Lesher and McConnell, 2003). In some cases, even in immunocompetent individuals, systemic antifungals are necessary to treat infections resistant to local therapy (Lesher, 1999).

Systemic anti-inflammatory agents, particularly the glucocorticosteroids (GCS), deserve additional attention. Oral GCS are absorbed in the jejunum, with peak plasma concentrations occurring in 30 to 90 minutes (Lester, 1989). Despite short plasma half-lives of 1 to 5 hours, the duration of effect of GCS lasts between 8 and 48 hours, depending on the agent (Nesbitt, 2003). These drugs have **widespread** anti-inflammatory effects. They release neutrophils from bone marrow but inhibit their movement to sites of inflammation in tissue. They also impair both T-cell activation and antigen presentation by dendritic cells (Nesbitt, 2003). **For short-term (≤3 weeks) treatment of dermatologic conditions such as allergic contact dermatitis** (Feldman, 1992), **a single morning dose of GCS is given to minimize suppression of the hypothalamic-pituitary-adrenal axis** (Myles, 1971). Prednisone is generally the GCS of choice due to its low cost, intermediate duration of action, and variety of dosage forms, although methylprednisolone may be substituted to reduce mineralocorticoid effects (Wolverton, 2001). **Longer-term treatment with systemic GCS may lead to a wide variety of adverse effects, including osteoporosis, cataract formation, hypertension, obesity, immunosuppression, and psychiatric changes** (Nesbitt, 2003).

Topical preparations are the mainstay of therapy for a wide range of cutaneous diseases affecting the genitalia. Urologists tend to be less familiar with the use of these medications than dermatologists. **Topical medications can be broken down into five general classes: emollients, anti-inflammatories, antibiotics, antifungals, and chemotherapeutic agents.**

Topical preparations have both active ingredients and a vehicle, which determines the rate at which the active ingredients are absorbed by the skin. Emollients restore water and lipids to the epidermis and are useful for dry skin diseases. Emollients should be applied to moist skin for maximal effect, such as after bathing. Preparations containing urea (e.g., Carmol, vanodine) or lactic acid (Lac-Hydrin, AmLactin) may be particularly potent hydrating agents (Habif, 2004).

Topical corticosteroids are potent anti-inflammatory agents available in a myriad of preparations and strengths. A detailed review of the use and dosing of topical corticosteroids is beyond the scope of this chapter, and the reader is directed to several excellent dermatology textbooks for more detail (Habif, 2004). **It is important to recognize that even topical corticosteroids can have significant adverse effects, from both systemic and local absorption. Local effects include epidermal atrophy, dermal changes (telangiectasias, hypopigmentation), allergic reactions, and alteration in the usual course of skin infections and infestations** (Burry, 1973). In most cases, atrophy is a reversible process that can be expected to resolve over the course of several months (Sneddon, 1976). Atrophy is particularly troublesome if corticosteroids are applied under the foreskin, which can serve as an occlusive "dressing" and enhance penetration of the drug (Fig. 15–1) (Goldman and Kitzmiller, 1973).

A variety of physical modalities have also been applied to treat dermatologic problems, including ultraviolet light therapy,

photodynamic therapy, laser therapy, and cryosurgery. Ultraviolet light therapy with UVB has been used to treat psoriasis, atopic dermatitis, and seborrheic dermatitis (Honigsmann and Schwarz, 2003). Psoralens, when combined with long-wave UVA radiation (PUVA therapy), generate a phototoxic effect beneficial for treating psoriasis (Honigsmann, 2001; Stern, 2007), vitiligo (Honigsmann and Schwarz, 2003), atopic dermatitis (Morison, 1992), and lichen planus (Honigsmann and Schwarz, 2003). Photodynamic therapy (PDT) involves the use of cytotoxic oxygen radicals generated from photoactivated molecules to achieve a therapeutic response (Tope and Shaffer, 2003; Braathen et al, 2007). PDT is a new arena of dermatologic therapy and holds promise for treating a variety of inflammatory and malignant skin conditions. Laser and cryosurgery play a relatively small role in the management of genital lesions, although the CO_2 laser has been used effectively to manage genital condyloma acuminata.

ALLERGIC DERMATITIS

Allergic or "eczematous" dermatitis consists of a group of allergy-mediated processes leading to pruritic skin lesions (Table 15–3).

Atopic Dermatitis (Eczema)

Atopic dermatitis (AD) is a chronic relapsing dermatitis with a predilection for skin flexures that is associated with intense pruritus and damage to the epidermis (Williams, 2005). **The characteristic lesions are erythematous papules and thin plaques with secondary excoriations** (Fig. 15–2) (Kang et al, 2003). In general, the lesions do not have a precise border as is common for papulosquamous disorders (Margolis, 2002). Although any age can be affected, 90% of AD patients manifest their condition before the age of 5 years (Rajka, 1989). AD is associated with susceptibility to irritants and proteins as well as the tendency to develop asthma and allergic rhinitis.

The genetic susceptibility to AD has been extensively explored. In a study of 372 AD patients, 73% had a positive family history for atopy. Likewise, twin concordance studies have demonstrated a risk of 0.86 for monozygotic twins to have AD as compared with only 0.21 for dizygotic twins. These findings have spurred an intense search for genes involved in atopy and AD (Wollenberg and Bieber, 2000), although, to date no single gene serves as a unique marker for the disease (Kang et al, 2003).

Intense pruritus is the hallmark of AD, and controlling the patient's urge to scratch is critical for successful treatment (Przybilla et al, 1994). Itching is often worse during evening hours and can be exacerbated by sweat or wool clothing

(Kang et al, 2003). Scratching of lesions may contribute to the clinical complications of AD, including superinfection with *Staphylococcus aureus* species (Ogawa et al, 1994). There is growing evidence that bacterial toxins may serve as superantigens that drive an inflammatory cascade sustaining AD (Skov and Baadsgaard, 2000; Skov et al, 2000).

Clinically, there is no pathognomonic laboratory test, biopsy result, or single clinical feature that allows the definitive diagnosis of AD. The association with a personal or family history of atopy is a critical clue to the diagnosis (Kang et al, 2003). For patients presenting with genital findings, extragenital involvement is commonplace.

A variety of "trigger factors" have been implicated in the exacerbation of AD, including chemicals, detergents, and household dust mites. Removal of these factors from the environment may be beneficial on an individualized basis. Dust mite exposure, in particular, has received significant attention in the literature. Although several studies have demonstrated modest improvement in AD with mite reduction (Kubota et al, 1992; Tan et al, 1996), others report that reduction is associated with no significant clinical benefit (Colloff et al, 1989; Gutgesell et al, 2001).

Treatments for AD include gentle cleaning with nonalkali soaps and the frequent use of emollients. Evaporation of liquid from the skin may trigger AD (Kang et al, 2003); thus very frequent bathing is not encouraged. Soaking may be helpful during episodes of bacterial super-infection but should be discontinued once the infection has resolved (Margolis, 2002). Topical corticosteroids may be needed to control pruritus but should only be used for short courses with a rapid taper to avoid local complications of skin atrophy and pigment changes. Topical macrolide immunomodulatory agents such as tacrolimus and pimecrolimus have shown efficacy in the treatment of AD (Meagher, et al, 2002; Nghiem et al, 2002; Luger and Paul, 2007; Leung et al, 2009), and may decrease the need for corticosteroids during long-term therapy (Zuberbier et al, 2007). Antihistamines such as diphenhydramine may be helpful in breaking the "itch-scratch cycle" in AD, particularly when given before bedtime (Kang et al, 2003). Oral antistaphylococcal drugs have not been shown to significantly improve AD in a recent randomized, double-blind trial (Ewing et al, 1998). Systemic treatment with corticosteroids, cyclosporine, methotrexate, or azathioprine may be indicated rarely for severe, widely disseminated cases (Cooper, 1993; Salek et al, 1993).

Contact Dermatitis

Contact dermatitis can be broken down into two distinct entities: irritant contact dermatitis (ICD) and allergic contact dermatitis (ACD). Although the mechanisms differ significantly, the clinical presentation of ICD and ACD may be similar. Most notably, the affected area is usually sharply limited to an area of skin exposure to an allergen or irritating chemical. The primary mode of treatment is to identify and reduce exposure to the offending agent.

ICD results from a direct cytotoxic effect of an irritant chemical touching the skin and is responsible for approximately 80% of contact dermatitis cases (Marks et al, 2002). Examples of offending agents include soaps, solvents, metal salts, and acid- or alkali-containing compounds. Occupational ICD is a serious public health problem and contributes to costs on the scale of $1 billion annually in the United States (Cohen, 2000). The clinical manifestations of ICD depend on the identity of the irritating substance as well as the duration of contact, concentration, temperature, pH, and location of exposure. Acute ICD, such as might be result from an occupational accident, generally peaks within minutes to hours after exposure and then begins to heal. Symptoms of burning, stinging, and soreness may be accompanied by erythema, edema, bullae, or frank necrosis in a sharply defined area corresponding to the exposed skin (Cohen and Bassiri-Tehrani, 2003). There are also a variety of subacute forms of ICD that result from repeated subthreshold skin insults. Pruritus is much more common in these more chronic conditions and the skin lesions are less well demarcated. The mainstay of treatment for ICD lies in avoiding skin contact with the causative irritants through the use of protective clothing, safe occupational practices, and the use of skin barriers such as ointments or emollients (Berndt et al, 2000).

In contrast, allergic contact dermatitis (ACD) represents a local type IV hypersensitivity reaction to a skin allergen to which an individual has been previously sensitized. The typical appearance is a well-demarcated pruritic eruption, which may manifest blistering or weeping in the acute phase or the development of scaly plaques more chronically (Mowad and Marks, 2003). In 2003 and 2009, the North American Contact Dermatitis Group (NACDG) reported a long list of common allergens implicated in ACD based on patch testing results (Zug et al, 2009). Patch testing is a simple technique of exposing an area of skin to a variety of potential allergens in a grid template (Fig. 15–3). Generally performed by dermatologists, patch testing can help to confirm the diagnosis of ACD and the allergen involved. The most common sensitizing allergen identified by the NACDG was nickel sulfate (Zug et al, 2009), which is a common component of costume jewelry and belt buckles (Fig. 15–4). Although traditionally a cause of earlobe dermatitis from pierced earrings, nickel sensitivity may be a potential cause of genital ACD due to the increasing prevalence of genital piercing. Other important allergens include textile dyes, topical antibiotics, perfumes, and topical corticosteroids. Oral

Figure 15–3. An example of patch testing with a positive response to nickel. (From Bolognia JL, Jorizzo JL, Rapini RP. Dermatology. Edinburgh: Mosby; 2003. p. 233.)

antihistamines may be helpful for the symptomatic control of ACD in combination with removal of the inciting allergen.

Erythema Multiforme and Stephens-Johnson Syndrome

Erythema multiforme (EM) is a generalized skin disease that may involve the genitalia. **EM can be subdivided into minor and major forms.**

EM minor was first described in 1860 by an Austrian dermatologist, Ferdinand von Hebra (von Hebra, 1860). **It is an acute, self-limited skin disease characterized by the abrupt onset of symmetrical fixed red papules that may evolve into target lesions** (Weston, 1996). EM is a clinical rather than a histologic diagnosis. Papules and target lesions are usually grouped and can be present anywhere on the body, including the genitalia (Fig. 15–5A). There is also a predilection for involvement of the oral mucous membranes.

The majority of cases of EM minor are precipitated by herpesvirus type I and II (Schofield et al, 1993; Nikkels and Pierard, 2002), **with herpetic lesions usually preceding the development of target lesions by 10 to 14 days** (Lemak et al, 1986). Although continuous suppressive acyclovir may prevent EM episodes in patients with herpes infection (Tatnall et al, 1995), administration of the drug after development of target lesions is of no benefit (Huff, 1988). The natural history of EM minor is spontaneous resolution after several weeks without sequelae (Schofield et al, 1993), although recurrences are common (Huff and Weston, 1989). Oral antihistamines may provide symptomatic relief. For immunosuppressed patients, the time course of

Edinburgh: WB Saunders; 2009. p. 147.)

EM minor outbreaks may be longer, and the frequency of recurrence may be greater (Schofield et al, 1993).

The major form of EM has been called Stevens-Johnson syndrome (SJS) in the past, although there remains some controversy as to whether EM major and SJS are distinct entities (Bachot and Roujeau, 2003; Williams and Conklin, 2005). SJS is a much more serious illness than EM minor with features similar to extensive skin burns (Parrillo, 2007). In its more severe forms, SJS may mimic life-threatening toxic epidermal necrolysis. Admission to the intensive care unit or burn unit may significantly reduce morbidity and mortality in this condition (Wolf et al, 2005). **Most patients with SJS have a prodromal upper respiratory illness (fever, cough, rhinitis, sore throat, and headache) that progresses after 1 to 14 days to the abrupt development of red macules with blister formation and areas of epidermal necrosis. Genital involvement includes erythema and erosions of the labia** (Fig. 15–6), **penis, and perianal region.**

A vast array of inciting factors has been implicated in the development of SJS, with drug exposures being the most commonly

Figure 15–6. Labial erosions in a case of Stevens-Johnson syndrome. (From Bolognia JL, Jorizzo JL, Rapini RP. Dermatology. Edinburgh: Mosby; 2003. p. 319.)

identified. Nonsteroidal anti-inflammatory agents are the most frequent offending agents followed by sulfonamides, tetracycline, penicillin, doxycycline, and anticonvulsants (Chan et al, 1990). In contrast to EM minor, there is rarely an association with an infectious agent (Weston, 2003). **SJS generally has a protracted course of 4 to 6 weeks and may have a mortality rate approaching 30%. Severe scarring of denuded skin may result in a range of complications including joint contractures, vaginal stenosis, urethral meatal stenosis, and anal strictures** (Brice et al, 1990; Weston, 2003). Treatment involves immediate removal of the offending drug and supportive care similar to the management of severe burns. There is currently no strong evidence for any specific therapy for SJS (Weston, 2003), and the role of systemic corticosteroids in treating SJS remains controversial (Rasmussen, 1976; Tripathi et al, 2000; Weston, 2003).

PAPULOSQUAMOUS DISORDERS

Papulosquamous disorders are a disparate group of diseases that share a common primary lesion: scaly papules and plaques (Table 15–4).

Psoriasis

Psoriasis is a common disease affecting up to 2% of the population (Christophers, 2001; Nestle et al, 2009). For patients with a predisposition, which is likely polygenic in nature, triggering factors such as trauma, infection, psychological stress, or new medications can elicit a flare up in the psoriatic phenotype. One third of affected patients have a family history of psoriasis (Melski and Stern, 1981; Hensler and Christophers, 1985; Margolis, 2002).

The characteristic lesion is a sharply demarcated erythematous plaque with silvery-white scales (van de Kerkhof, 2003). Its pattern can be limited to the elbows or knees,

or distributed over the entire surface of the skin. Although psoriasis can appear at any age, two peaks of onset have been identified: 20 to 30 and 50 to 60 years of age. Patients complain of a significant impairment in their quality of life due to pruritus and the cosmetic impact of these visible plaques.

Psoriatic involvement of the genitalia is relatively common, although usually within the context of a generalized cutaneous disorder. **Patients may present with concerns for malignancy or sexually transmitted infection when psoriatic lesions are present on the genitals.** The presence of characteristic lesions on the elbows, knees, buttocks, nails, scalp, and umbilicus may help direct the diagnosis (Fig. 15–7A) (Margolis, 2002). When lesions are present in the inguinal folds and intergluteal cleft, scaling may be absent (so-called "inverse psoriasis") (Goldman, 2000). When evaluating nonscaling erythematous plaques in the inguinal folds, the diagnosis of fungal involvement (i.e., tinea or *Candida*) should be considered. In circumcised men, psoriatic plaques are often present on the glans and corona, whereas in uncircumcised men, lesions are commonly hidden under the preputial skin (Buechner, 2002). In some cases, however, psoriasis involves the entire penis and scrotum (Fig. 15–8).

Psoriasis is a chronic disease with a relapsing and remitting course. A variety of topical and systemic therapies have been developed and applied to this difficult problem. However, despite these therapies, as many as 40% of psoriasis sufferers express frustration with the ineffectiveness of current treatments (Krueger et al, 2001). **For genital psoriasis, the mainstay of therapy is the use of low-potency topical corticosteroid creams for short courses.** Examples include a preparation of 3% liquor carbonis detergens in 1% hydrocortisone cream (Fisher and Margesson, 1998). These preparations should not be used continuously for more than 2 weeks on thin genital skin or in areas occluded by skin folds (Margolis, 2002). Other topical therapies for psoriasis include vitamin D_3 analogues, dithranol, and retinoids, although these agents may be too irritating for genital skin application. Photochemotherapy combining an ingested psoralen with ultraviolet radiation (PUVA) has been used extensively to treat psoriasis (Stern, 2007). However, a dose-dependent increase in the risk of genital squamous cell carcinoma has been associated with high-dose PUVA therapy for psoriasis elsewhere on the body (Stern, 1990; Stern et al, 2002). Genital shielding during PUVA therapy is strongly recommended; therefore this modality is contraindicated for treating psoriatic lesions localized to genital skin.

For patients with extensive psoriasis, systemic therapy with methotrexate, cyclosporine, or retinoids may be appropriate. Experimental therapies that have shown promise in treating psoriasis include the 308-nm excimer laser (Gerber et al, 2003), vitamin D receptor ligands (Bos and Spuls, 2008), and antibodies or antisense oligonucleotides against T-lymphocyte surface molecules (Gottlieb et al, 2000a, 2000b), tumor necrosis factor (Chaudhari et al, 2001; Bos and Spuls, 2008), or intracellular adhesion molecules (Gottlieb et al, 2000a, 2000b).

Figure 15–7. Psoriasis. **A,** Silver scales on an erythematous base. **B,** Alternating neutrophils and parakeratosis in the stratum corneum of plaque psoriasis (sandwich sign). Edinburgh: WB Saunders; 2009. p. 152.)

Reiter Syndrome

This is a syndrome composed of urethritis, arthritis, ocular findings, oral ulcers, and skin lesions. The skin findings, particularly when present on the genitalia, may be mistaken for psoriatic lesions (Fig. 15–9). Reiter syndrome is more common in men than in women and is rarely diagnosed in children. **It is generally preceded by an episode of either urethritis (*Chlamydia, Gonococcus*) or gastrointestinal infection (*Yersinia, Salmonella, Shigella, Campylobacter, Neisseria,* or *Ureaplasma* species) and is more common in HIV-positive patients** (Rahman et al, 1992; Margolis, 2002; Wu and Schwartz, 2008). **There is a strong genetic association with the HLA-B27 haplotype.** Whether cross reactivity between bacterial antigens and HLA-B27 leads to autoimmunity in Reiter syndrome remains controversial (Ringrose, 1999; Yu and Kuipers, 2003).

Conjunctivitis is the most common ocular manifestation, although iritis, uveitis, glaucoma, and keratitis may occur. Polyarthritis and sacroiliitis are the most common orthopedic complaints and may lead to chronic disability in a small minority of cases (van de Kerkhof, 2003). Psoriasiform skin lesions present on

Figure 15–8. Psoriasis involving the entire penis and scrotum. (From Bolognia JL, Jorizzo JL, Rapini RP. Dermatology. Edinburgh: Mosby; 2003. p. 130.)

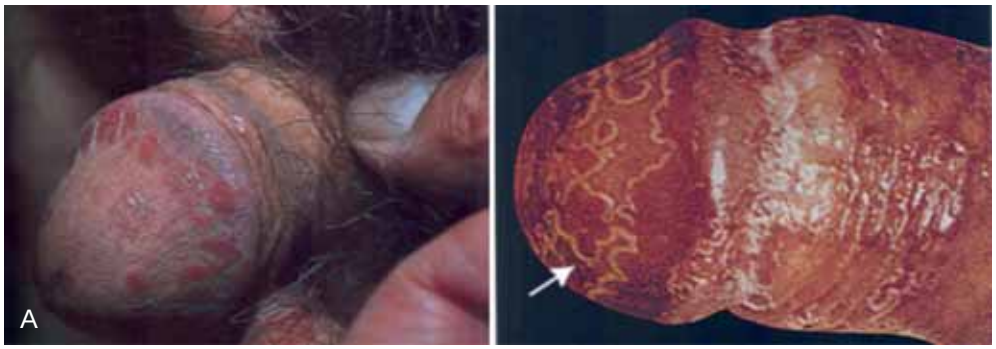

Figure 15–9. Comparison of psoriasis (**A**) and Reiter syndrome (**B;** *balanitis circinata*) involving the glans penis. Note the highly characteristic coalescence of lesions in this case of Reiter syndrome forming a wavy pattern (*white arrow*). (From Habif TP. Clinical dermatology. Edinburgh: Mosby; 2004. p. 217.)

Figure 15–10. Erosive psoriasiform lesions of the glans penis (Reiter syndrome; *balanitis circinata*) may also lack the wavy pattern, making them difficult to differentiate from genital psoriasis. (From Callen JP, Greer DE, Hood AF, Paller AS. Color atlas of dermatology. Philadelphia: WB Saunders; 1993. p. 160.)

the penis are referred to as *balanitis circinata* (Fig. 15–10). **These lesions may be difficult to differentiate from psoriasis, and histologic analysis of biopsy specimens cannot consistently differentiate the two conditions** (Margolis, 2002). The course of Reiter syndrome involving the genitalia is usually self-limited, lasting a few weeks to months. Lesions may respond to topical corticosteroids, and systemic therapy is rarely required.

Lichen Planus

Lichen planus (LP), the prototype of the lichenoid dermatoses, is an idiopathic inflammatory disease of the skin and mucous membranes. The characteristic "lichenoid tissue reaction" is characterized by epidermal basal cell damage that is associated with a massive infiltration of mononuclear cells in the papillary dermis (Shiohara and Kano, 2003). Cutaneous LP may affect up to 1% of the adult population (Boyd and Neldner, 1991), and oral lesions may be present in as many as 4% (Scully et al, 1998). The pathogenesis of LP appears to be related to an autoimmune reaction against basal keratinocytes that express altered self-antigens on their surfaces (Morhenn, 1986).

The primary lesion of LP is a small, polygonal-shaped, violaceous, flat-topped papule. These lesions may be widely separated or coalesce into larger plaques, which may ulcerate, particularly on mucosal surfaces. LP commonly involves the flexor surfaces of the extremities, the trunk, the lumbosacral area, the oral mucosa, and the glans penis (Margolis, 2002). **On the genitalia, the clinical presentation of LP can be quite variable and includes isolated or grouped papules, a white reticular pattern, or an annular (ringlike) arrangement with or without ulceration** (Fig. 15–11). In some cases, the lesions appear to form linear patterns related to skin trauma (the so-called Koebner phenomenon; also seen with psoriasis). The differential diagnosis of LP includes squamous cell carcinoma, Bowen disease, Zoon balanitis, psoriasis, secondary syphilis, and lupus erythematosus, and biopsy may be necessary to establish the diagnosis, particularly when the lesions are ulcerated (Shiohara and Kano, 2003). Lichenoid reactions can also occur in response to ingested drugs and contact allergens, and a careful search for potential offending agents is appropriate.

The natural history of LP is benign, and the spontaneous resolution of cutaneous lesions has been observed in up to two thirds of cases after one year (Shiohara and Kano, 2003), **although the oral form may persist significantly longer** (Mignogna et al, 2000). Although bothersome pruritus is common with LP, asymptomatic lesions on the genitalia do not require treatment. The primary modality of treatment for symptomatic cutaneous LP is topical corticosteroids, with the caveats mentioned previously about their use on genital skin. There also appears to be a role for topical calcineurin inhibitors in the management of LP (Luger and Paul, 2007). For severe cases, systemic corticosteroids (15 to 20 mg per day; 2- to 6-week course [Boyd and Neldner, 1991]) have been shown to shorten the clearance time of LP lesions from 29 to 18 weeks (Cribier et al, 1998). Other systemic therapies for severe LP include cyclosporine, tacrolimus, griseofulvin, metronidazole, and acitretin (Ho et al, 1990; Boyd and Neldner, 1991; Cribier et al, 1998; Buyuk and Kavala, 2000; Madan and Griffiths, 2007), although randomized trials demonstrating efficacy are generally lacking.

Lichen Nitidus

Lichen nitidus (LN) is an unusual inflammatory eruption characterized by tiny, discrete, flesh-colored papules arranged in large clusters. Although there is some debate whether LN may represent a variant of LP (Aram, 1988), the two entities are histologically distinct. LN has a dense, well-circumscribed, lymphohistiocytic infiltrate closely apposed to the epidermis (Shiohara and Kano, 2003). Commonly involved sites include the flexor aspects of the upper extremities, the genitals, trunk, and dorsal aspects of the hands. Nail involvement is common. Similar to LP, the natural history of LN is one of spontaneous resolution, with the majority of patients (69%) manifesting disease for less than one year (Lapins et al, 1978). Patients should be reassured that these genital lesions are not infectious and should resolve with time. For symptomatic pruritus, genital lesions usually respond to topical corticosteroids and oral antihistamines (Shiohara and Kano, 2003).

Lichen Sclerosus

Lichen sclerosus et atrophicus (LS) is a chronic inflammatory disease with a predilection for the external genitalia. LS is 6 to 10 times more prevalent in women than in men, generally presenting around the time of menopause (Wojnarowska and Cooper, 2003). For patients with genital LS, 15% to 20% have extragenital disease (Powell and Wojnarowska, 1999). LS is a scarring disorder characterized by tissue pallor, loss of architecture, and hyperkeratosis (Fig. 15–12). It tends to affect older men (>60 years of age) (Ledwig and Weigand, 1989) and can be associated with pain during voiding or erection (Margolis, 2002). The glans penis and foreskin are usually affected, and the perianal involvement common in women is usually absent. Preputial scarring from LS can lead to phimosis, and circumcision is usually curative, although recurrence in the circumcision scar may occur. The late stage of this

Figure 15–11. Lichen planus. Various presentations of lichen planus on the male genitalia. **A** and **B,** Both individual and grouped purple papules on the penile shaft; some oriented in a linear pattern. **C,** A white reticular pattern sometimes seen in lichen planus. **D,** An annular (ring-like) arrangement with a shiny surface. **E,** Histologically, lichen planus is characterized by destruction of the basal layer, a sawtooth rete ridge pattern, the presence of Civatte bodies, and dermal melanocytes, and the absence of parakeratosis or eosinophils. (**A,** From Korting GW: Practical dermatology of the genital region. Philadelphia: WB Saunders; 1981. p. 29; **B** to **D,** from du Vivier A: Atlas of clinical dermatology. London: Churchill Livingstone; 2002. p. 100); **E,** from Elston DM, Ferringer T. Dermatopathology. Edinburgh: WB Saunders; 2009. p. 137.)

disease is called *balanitis xerotica obliterans*, which can involve the penile urethra and result in troublesome urethral stricture disease.

Despite the similarities in name, LS shares little in common with LP and LN other than pruritus and a predilection for the genital region. **Another critical distinction is that LS has been associated with squamous cell carcinoma of the penis, particularly those variants not associated with human papillomavirus, and may represent a premalignant condition** (Velazquez and Cubilla, 2003; Bleeker et al, 2009). LS has specific histologic features, including basal cell vacuolation, epidermal atrophy, dermal edema, collagen homogenization, and focal perivascular infiltrate of the papillary dermis, and plugging of the ostia of follicular and eccrine structures (Margolis, 2002). Biopsy is worthwhile both to confirm the diagnosis and exclude malignant change (Powell and Wojnarowska, 1999).

From a management standpoint, long-term follow-up of patients with LS is important due to the association with squamous cell carcinoma. The application of potent topical steroids (such as clobetasol propionate 0.05%) for long courses (3 months) is well established as a treatment for LS in women and may both improve symptoms and reverse the disease process (Dalziel et al, 1991) This regimen is contrary to the usual policy of avoiding long courses of steroid application to genital skin. The efficacy of similar approaches has not been confirmed in adult men, although benefits have been demonstrated in the pediatric age group (Kiss et al, 2001). A recent European, multicenter, phase II trial also

Figure 15–12. **A** to **C,** Lichen sclerosis et atrophicus (balanitis xerotica obliterans) of the penis. supported the safety and efficacy of topical tacrolimus in the treatment of long standing LS (Hengge et al, 2006).

Fixed Drug Eruption

A fixed drug eruption occurs in response to oral medications, usually 1 to 2 weeks after the first exposure, and commonly involves the lips, face, hands, feet, and genitalia (Fig. 15–13). After subsequent re-exposure to the drug, the reaction presents in the exact same location, usually within 24 hours (hence the term "fixed"). The most common medications causing this reaction are sulfonamides, nonsteroidal anti-inflammatory agents, barbiturates, tetracyclines, carbamazepine, phenolphthalein, salicylates, oral contraceptives, and salicylates (Kauppinen and Stubb, 1985; Stubb et al, 1989; Thankappan and Zachariah, 1991).

When present on the penile shaft or glans, these lesions are usually solitary inflammatory plaques, which may be erosive and painful (Margolis, 2002). On the genitalia, the differential diagnosis includes herpes simplex infection or an insect bite. Removing the offending agent usually results in resolution of the lesion, although postinflammatory brown pigmentation may remain.

Seborrheic Dermatitis

This is a common skin disease characterized by the presence of sharply demarcated pink-yellow to red-brown plaques with a flaky scale. It shares a variety of features in common with eczematous dermatitis and could easily be grouped in that category. Common dandruff is a mild form of seborrheic dermatitis (SD) localized to the scalp. It has a predilection for areas rich in sebaceous glands and is generally present only during the first few months of life or post-puberty, when sebaceous glands are active. Common areas affected include the scalp, eyebrows, nasolabial folds, ears, and chest although the anus, penis, and pubic areas may also be involved (Margolis, 2002). Circumcision may be somewhat protective against the development of SD. In one study of 357 patients, the risk of developing penile SD was 2.5 times greater in the uncircumcised state (Mallon et al, 2000).

Adult SD has a chronic relapsing course (Webster, 1991). **This condition is particularly common in patients with Parkinson disease, and up to 83% of AIDS patients may manifest SD** (Froschl et al, 1990; Gupta and Bluhm, 2004). SD may involve a significant proportion of the body surface area, particularly in immunosuppressed individuals. **Extensive and/or severe SD should raise concerns for possible underlying HIV infection** (Fritsch and Reider, 2003). SD may be pruritic, and differentiation from psoriasis may occasionally be problematic. Unlike psoriasis, however, SD rarely involves the nails and tends to have a thinner associated scale.

Controversy concerning the etiology of SD revolves around a possible autoimmune response to a component of normal skin flora, the yeast *Malassezia furfur* (*Pityrosporum ovale*). Although *M. furfur* can be isolated from the lesions of SD, the number of organisms is only about twice that observed in normal control skin (Nenoff et al, 2001). Likewise, severely SD-affected HIV patients do not harbor more organisms than HIV patients without

Figure 15–13. Edinburgh: WB Saunders; 2009. p. 149.)

manifestations of SD (Pechere et al, 1999). Another factor potentially linked to SD is an elevated level of triglycerides and cholesterol at the skin surface (Fritsch and Reider, 2003).

Creams containing topical antifungals (i.e., ketoconazole) are the mainstay of SD treatment on the body and have a 75% to 90% response rate (Faergemann, 2000; Fritsch and Reider, 2003). For hair-bearing areas, "antidandruff" shampoos containing zinc, salicylic acid, selenium sulfide, tar, ciclopirox olamine, or ketoconazole are effective (Margolis, 2002; Squire and Goode, 2002). Because of the relapsing nature of SD, treatment often must be repetitive. Low-potency topical corticosteroids may play a role during the initial treatment of severe cases but should not be the primary mode of treatment for this chronic condition due to local steroid side effects.

VESICOBULLOUS DISORDERS

Vesicobullous disorders are uncommon conditions often characterized by autoimmune damage to the epidermis or basement membrane (Table 15–5). On the genitalia, the rupture of blisters and bullae may leave behind erosions (Margolis, 2002).

Pemphigus Vulgaris

Pemphigus is a family of autoimmune blistering diseases characterized by intraepidermal blisters due to the loss of keratinocyte cell–cell adhesion (Martel and Joly, 2001). These blisters are located in the deep epidermis close to the basal cell layer. The proposed immunopathology includes the development of autoantibodies directed against keratinocyte cell surface markers and desmosomes (Amagai et al, 1996; Zhou et al, 1997; Joly et al, 2000).

Almost all pemphigus patients will have painful oral mucosal erosions, and over half will have cutaneous blisters that may involve the genitalia. Characteristic oral lesions are, therefore, an important clue to the diagnosis (Fig. 15–14). The cutaneous blisters are thin-walled and easily broken, leaving behind a painful erosion. The loss of epidermal cohesion seen in pemphigus leads to the characteristic

Figure 15–14. Characteristic painful oral mucosal erosions in pemphigus vulgaris. (From Bolognia JL, Jorizzo JL, Rapini RP. Dermatology. Edinburgh: Mosby; 2003. p. 455.)

Asboe-Hansen sign: spreading of fluid under the adjacent normal-appearing skin away from the direction of pressure on the blister (Amagai, 2003). In severe cases, without appropriate treatment, pemphigus may be fatal due to the loss of the epidermal barrier function of large areas of affected skin. Treatment for pemphigus usually depends on systemic corticosteroids, although minimization of steroid dose is an important goal to limit side effects. The addition of immunosuppressive agents such as azathioprine and cyclophosphamide may be beneficial due to their corticosteroid-sparing effect (Amagai, 2003).

Bullous Pemphigoid

Bullous pemphigoid (BP) is a subepidermal blistering disease that is more common in men and generally afflicts patients older than 60 years of age (Rzany and Weller, 2001). There is enrichment for specific HLA class II alleles in BP patients as compared with normal controls (Delgado et al, 1996), supporting an autoimmune mechanism of pathogenesis. In BP, autoantibodies against specific proteins involved in cell–cell adhesion (BP180, BP230) are present. These proteins are components of hemidesmosomes, structures that mediate epidermal–stromal adhesion. Binding of autoantibodies to these structures leads to complement activation and a cascade of events resulting in tissue damage, epidermal–dermal separation and blister formation (Kitajima et al, 1994; Lin et al, 1997).

Clinically, the presentation of BP can be highly variable. It generally begins with a non-bullous phase characterized by severe itching and nonspecific skin findings. As the disease progresses to the bullous phase, vesicles and blisters appear on normal skin or areas containing confluent erythematous plaques. The blisters are tense, tend to form on flexor surfaces, and may involve the inner thighs and genitalia (Fig. 15–15A). Mucous membranes may also be involved, although less commonly than in pemphigus. **The diagnosis is made by a combination of clinical, histologic, and, often most importantly, immunohistochemical features such as the deposition of IgG antibodies along the basement membrane** (Fig. 15–15B) (De Jong et al, 1996). Treatment of BP is similar to that described for pemphigus, with systemic corticosteroids and immunosuppressants playing primary roles (Kirtschig and Khumalo, 2004). For treatment-resistant cases, intravenous immunoglobulin or plasmapheresis may be beneficial (Hatano et al, 2003; Lee et al, 2003; Ruetter and Luger, 2004; Wetter et al, 2005).

Dermatitis Herpetiformis and Linear IgA Bullous Dermatosis

Both of these entities are blistering autoimmune skin diseases associated with the deposition of IgA antibodies at the basement membrane.

Dermatitis herpetiformis (DH) is a cutaneous manifestation of celiac disease and is generally associated with gluten sensitivity (Karpati, 2004). It is most commonly found in people of Northern European origin. There is a close association of DH with certain HLA class II DQ2 alleles (DQA1*0501, DQB1*02) (Reunala, 1998). Pruritic plaques, papules, and vesicles in a symmetrical distribution characterize DH. These vesicles may form "herpetiform" groups on an erythematous base. Patients may also complain of pain and burning over the lesions. Diagnosis can be confirmed by biopsy and direct immunofluorescence, which shows a granular pattern of IgA deposition at the basement membrane. Treatment includes the use of dapsone and a strict gluten-restricted diet (Frodin et al, 1981; Andersson and Mobacken, 1992).

Linear IgA bullous dermatosis (LABD), in contrast, is not associated with celiac disease. As the name implies, a linear pattern of antibody deposition at the basement membrane is found on immunohistochemistry testing in LABD (Fig. 15–16). Characteristic clinical features include vesicles and bullae arranged in a combination of circumferential and linear orientations. Treatment with either sulfapyridine or dapsone is usually effective in controlling LABD, and long-term spontaneous remission rates of 30% to 60% have been described (Wojnarowska et al, 1988).

Hailey-Hailey Disease

Hailey-Hailey disease (HH) is an autosomal-dominant blistering dermatosis that usually develops within the second or third decade of life (Burge, 1992). **It has a predilection for the intertriginous areas, including the groin and perianal region** (Fig. 15–17). In women, disease in the inframammary folds is common, although vulvar disease is unusual (Wieselthier and Pincus, 1993). Symptoms include an unfortunate combination of pruritus, pain, and a foul odor. As heat and sweat exacerbate the condition, HH tends to worsen during the summer months (Burge, 1992). Skin findings include confluent areas of vesicles and fragile blisters, which form due to aberrant keratinocyte cell adhesion. Lesions may be confined to the axilla or groin, and superinfection with yeast or bacteria may compound the problem. Histologic examination may be helpful in differentiating HH from impetigo, pemphigus, intertrigo, and Darier disease (Margolis, 2002). **Treatment includes wearing lightweight, breathable clothing to avoid friction and sweating. Lesions may respond to topical or intralesional corticosteroids, with the caveats mentioned previously about the use of these agents on intertriginous skin. For disease resistant to medical therapy, wide excision and skin grafting have been effective, as have local ablative techniques such as dermabrasion and laser vaporization** (Hamm et al, 1994; Christian and Moy, 1999; Hohl et al, 2003).

NONINFECTIOUS ULCERS

Genital ulcers can be a result of both infectious and noninfectious causes (Table 15–6).

Aphthous Ulcers and Behçet Disease

Aphthous ulcers are small, painful erosions that commonly involve the oral cavity but can occasionally be present on the genitalia. **When oral and genital aphthous ulcers are coexistent, the clinician should consider the diagnosis of Behçet disease (BD).** BD is a generalized relapsing and remitting, ulcerative, mucocutaneous disease that probably involves a genetic predisposition and an autoimmune mode of pathogenesis (Sakane, 1997; Mendes et al, 2009). Oxidative stress related to overproduction of superoxide radicals by neutrophils has also been implicated in the development of this condition (Freitas et al, 1998; Najim et al, 2007). BD has a high prevalence in Turkey (80 per 100,000) and Japan (10 per 100,000) but is quite rare in

the United States (0.12 per 100,000) (Arbesfeld and Kurban, 1988). Affected individuals may also suffer from epididymitis, thrombophlebitis, aneurysms, and gastrointestinal, neurologic, and arthritic problems (Koc et al, 1992; Tuzun et al, 1997; Cetinel et al, 1998; Krause et al, 1999; Aykutlu et al, 2002; Margolis, 2002).

Mucocutaneous lesions of the oral cavity and genitalia (Fig. 15–18) **and ocular involvement (uveitis) form a triad of clinical features in BD. The genital lesions are larger and generally more painful than the oral lesions.** Optic involvement occurs in 90% of cases and may lead to blindness (Moschella, 2003). The Behçet's International Study Group has defined the diagnosis as recurrent oral ulceration plus any two of the following: recurrent genital ulceration, eye lesions, cutaneous lesions, and skin sensitivity to needle puncture (pathergy test) ("Criteria for diagnosis of Behçet's disease. International Study Group for Behçet's Disease," 1990). Other causes for genital ulceration, however, including aphthous ulcers, syphilis, herpes simplex, and chancroid must be considered before a diagnosis of BD is made (Margolis, 2002). The clinical course of BD is protean, and randomized controlled trials in support of specific therapy are currently limited (Kaklamani and Kaklamanis, 2001). A wide range of topical and systemic agents has been applied to treat BD with variable success, including corticosteroids, dapsone, colchicine, and immunosuppressants (Kose et al, 2009).

Pyoderma Gangrenosum

Pyoderma gangrenosum (PG) is an ulcerative skin disease associated with systemic illnesses including inflammatory bowel disease, arthritis, collagen vascular disease, and myeloproliferative disorders (Moschella, 2003). **It most commonly affects women between the second and fifth decade of life and likely has an autoimmune pathogenesis, given its association with other autoimmune diseases.** Between 20% and 50% of cases, however, are idiopathic.

The classic morphologic presentation of PG is painful cutaneous and mucous membrane ulceration, often with extensive loss of tissue and a purulent base (Fig. 15–19). Although unusual, PG can involve the penis, scrotum, vulva, and peristomal sites (Cairns et al, 1994). As with BD, no specific diagnostic laboratory test or histopathologic feature is pathognomonic for PG, although a history of underlying systemic disease may raise suspicion. Treatment includes a combination of local and systemic corticosteroid therapy with or without adjunctive immunosuppressants (i.e., cyclosporine) (Chow and Ho, 1996).

Traumatic Causes

Cutaneous lesions of the genitalia, including ulceration, can be caused by local trauma, which should be included in the differential diagnosis. **This can be either accidental ("innocent**

Figure 15–18. Scrotal (**A**), perianal (**B**), and (**C**) oral ulcers seen in Behçet disease. (**A,** From du Vivier A. Atlas of clinical dermatology. trauma") or self-inflicted ("factitial dermatitis"). Accidental injuries may be a result of trauma during sexual practices, ornamentation (i.e., piercing) or unusual hygiene practices (i.e., cleaning) (Margolis, 2002). **Factitial dermatitis is a psychocutaneous disorder in which the individual self-inflicts cutaneous lesions usually for an unconscious motive.** An association between factitial dermatitis and borderline personality disorder appears to exist (Koblenzer, 2000). Other disorders to be considered include Munchausen syndrome by proxy and malingering, if secondary gain issues exist.

INFECTIONS AND INFESTATIONS

Sexually Transmitted Infections

Sexually transmitted infections with genital cutaneous manifestations include lymphogranuloma venereum, granuloma inguinale, herpes simplex, chancroid, molluscum contagiosum, human papillomavirus, and syphilis (Fig. 15–20). These conditions are covered in detail in Chapter 13.

Balanitis and Balanoposthitis

Balanitis is an inflammatory disorder of the glans penis. When the process involves the preputial skin in uncircumcised men it is termed balanoposthitis. In children, bacterial infections are the predominant cause. In adult men, the cause may be intertrigo, irritant contact dermatitis, local trauma, or candidal and bacterial infections (Fig. 15–21). Treatment includes removal of irritating agents, improved hygiene, topical antibiotics, and antifungals and, occasionally, short courses of low-potency topical corticosteroids (Margolis, 2002). When treatment fails, the differential should include neoplastic diseases, Zoon balanitis, psoriasis, and alternative infectious agents such as papillomavirus (Wikstrom et al, 1994). Balanoposthitis tends to occur in patients with phimosis, and circumcision may be curative in select recurrent cases.

Cellulitis and Erysipelas

Cellulitis is an infection of the deep dermis and subcutaneous tissues most commonly caused by gram-positive organisms (*S. pyogenes* and *S. aureus*) (Lewis, 1998). In immunocompetent individuals, organisms usually gain entry to the site of infection through a break in the skin barrier. In immunocompromised patients, a blood-borne route of infection is more common. Systemic signs of illness include fever, chills, and general malaise. Local signs include erythema (rubor), warmth (calor), pain (dolor), and swelling (tumor) at the site with indistinct borders (Fig. 15–22). Treatment includes systemic antibiotics with activity against *S. pyogenes* and *S. aureus* species. In cases associated with diabetes, mixed flora may be present and antibiotic coverage should be broadened. Marking the zone of cellulitis at the onset of therapy is an important step to allow progression and resolution of cellulites to be monitored during therapy.

Erysipelas is a superficial bacterial skin infection limited to the dermis with lymphatic involvement. It is commonly a disease at the extremes of age and often involves the face. In contrast to the cutaneous lesion of cellulitis, erysipelas generally has a raised and distinct border at the interface with normal skin. The causative organism is usually *S. pyogenes*.

Fournier Gangrene (Necrotizing Fasciitis of the Perineum)

Fournier gangrene (FG) is a potentially life-threatening progressive infection of the perineum and genitalia (Morpurgo and Galandiuk, 2002). In the genital region, most cases of FG are caused by mixed bacterial flora, which include gram-positive, gram-negative, and anaerobic bacteria. Risk factors for developing FG include alcoholism, diabetes, malnutrition, advanced age, and peripheral vascular disease. However, group A streptococcal necrotizing fasciitis can occur in healthy immunocompetent individuals.

The hallmark of FG is a rapid progression from the signs and symptoms of cellulitis to blister formation and foul-smelling necrotic lesions (Fig. 15–23). **Infection may spread along fascial planes, and hence the exterior skin findings may represent only a small proportion of the underlying infected and necrotic tissue. The diagnosis of FG is a surgical emergency as progression from genitalia to perineum to abdominal wall may occur extremely rapidly (often within hours). The exclusion of FG, therefore, should be a priority during every consultation for soft tissue infection of the genitalia.** Pain out of proportion to the visible extent of infection should raise suspicion for FG. The skin may also have a grayish cast or fetid odor uncharacteristic of uncomplicated genital cellulitis. Imaging of the genitalia with

Figure 15–22. Penoscrotal cellulitis. (From Korting GW. Practical dermatology of the genital region. Philadelphia: WB Saunders; 1981. p. 37.)

Figure 15–23. Fournier gangrene of the scrotum. **A,** Surface appearance of scrotum and perineum showing area of frank necrosis. **B,** Extent of soft tissue debridement required to achieve margins of viable tissue. Note that the testes within their tunica vaginalis compartment are spared.

plain radiographs or computed tomography (Amendola et al, 1994) may demonstrate gas bubbles within the tissue, although the delay associated with imaging should not delay surgical intervention in obvious cases.

Treatment involves a combination of broad-spectrum antibiotics and extensive surgical debridement to margins of healthy bleeding tissue. These patients will often require a second-look operation after 24 to 48 hours to exclude further disease progression (Gurdal et al, 2003). During surgical debridement for scrotal FG, the testicles and other structures within the tunica vaginalis can almost always be spared, although loss of tissue in the abdominal wall may be extensive due to bacterial spread along fascial planes. The indications for adjunctive hyperbaric oxygen therapy in FG remain controversial, although several groups have reported favorable results (Dahm et al, 2000; Eke, 2000; Jallali et al, 2005). There may also be a potential benefit to the use of vacuum-assisted closure devices in FG (Czymek et al, 2009). However, despite aggressive modern management, the mortality of FG may be as high as 16% to 40% (Dahm et al, 2000; Eke, 2000; Blume et al, 2003; Yeniyol et al, 2004; Sorensen et al, 2009).

Folliculitus

Folliculitis is a common disorder characterized by perifollicular pustules on an erythematous base (Kelly, 2003). It occurs most frequently in heavily hair-bearing areas such as the scalp, beard, axilla, groin, and buttocks, and can be exacerbated by local trauma from shaving, rubbing, or clothing irritation (Margolis, 2002). Patients may complain of pruritus or pain over the area or symptoms may be absent. Cultures are generally negative, although a variety of infectious organisms have been associated with folliculitis, including *S. aureus*, *Pseudomonas* sp., fungi, and herpes simplex virus. Folliculitis has also been associated with the use of contaminated hot tubs and swimming pools, with the offending organism usually *Pseudomonas aeruginosa* (Fig. 15–24) (Gregory and Schaffner, 1987; Rolston and Bodey, 1992). Treatment for folliculitis includes good hygiene, removal of offending irritants, and appropriate topical or systemic antiviral, antibiotic, or antifungal agents.

Figure 15–24. Pseudomonal folliculitis caused by the use of a hot tub. (From Bolognia JL, Jorizzo JL, Rapini RP. Dermatology. Edinburgh: Mosby; 2003. p. 554.)

Furunculosis

Both furuncles and abscesses are walled-off collections of pus. **Although abscesses can occur anywhere on the body, a furuncle is by definition associated with a hair follicle.** Furuncles tend to occur in areas prone to minor trauma, including the groin and buttocks (Fig. 15–25). *S. aureus* is the most common causative organism, although anaerobes may be present. Risk factors include diabetes mellitus, obesity, poor hygiene, and immunosuppression (Brook and Finegold, 1981). Warm compresses may be beneficial, and larger lesions may require incision and drainage as for any abscess. When there is associated cellulitis, a systemic antibiotic with activity against staphylococci should be given.

Figure 15–25. A large furuncle located on the buttocks. (From Habif TP. Clinical dermatology. Edinburgh: Mosby; 2004. p. 284.)

Hidradenitis Suppurativa (Acne Inversa)

Hidradenitis suppurativa (HS) is a chronic disease of apocrine gland-bearing skin with a predilection for the axillae and anogenital regions (Kelly, 2003; Alikhan et al, 2009). **It generally begins after puberty and a familial form with an autosomal-dominant pattern of inheritance has been described** (Von Der Werth et al, 2000). Originally believed to be a disease of apocrine glands, HS is now thought to be an epithelial disorder of hair follicles (Jansen et al, 2001). Although superinfection of HS lesions may occur, bacterial infection does not appear to be the primary initiator. During the pathogenesis of HS, hair follicles become plugged and swollen. **Rupture of follicular contents (including bacteria and keratin) into the surrounding dermis initiates a marked**

Figure 15–26. Hidradenitis suppurativa. **A,** Characteristic painful papules and draining sinus tracts. **B,** Histology shows follicular plugging and connection to a dilated apocrine duct. (**A,** From du Vivier A. Atlas of clinical dermatology. London: Churchill Livingstone; 2002. p. 712; **B,** from Bolognia JL, Jorizzo JL, Rapini RP. Dermatology. St. Louis: Elsevier; 2008. Figure 39.13.)

inflammatory response with the formation of abscesses and sinus tracts (Slade et al, 2003).

The clinical features of HS include painful inflammatory nodules and sterile abscesses developing in the axillae, groin, perianal, and inframammary areas (Fig. 15–26) (Kelly, 2003). Over time, draining sinus tracts and hypertrophic scars develop. Serious complications of HS can occur, including hypoproteinemia, secondary amyloidosis, the development of fistulae to the urethra (Gronau and Pannek, 2002); bladder, peritoneum, and rectum (Nadgir et al, 2001); and squamous cell carcinoma in areas of heavy scarring (Altunay et al, 2002; Rosenzweig et al, 2005).

Treatment of HS includes improvement in hygiene, weight reduction, and efforts to minimize friction and moisture in affected areas (i.e., loose undergarments, absorbent powder) (Kelly, 2003). Topical clindamycin or the combination of oral clindamycin and oral rifampicin may be beneficial in some patients (Gener et al, 2009). In a double-blind randomized trial, systemic therapy with tetracycline was no more effective than topical clindamycin in HS (Jemec and Wendelboe, 1998). Systemic corticosteroids may improve HS, but relapse is the rule after cessation of therapy (Slade et al, 2003). Lithium may exacerbate HS or limit its response to conventional medical therapy (Gupta et al, 1995). Although recurrent incision and drainage of HS lesions is discouraged, wide excision and skin grafting has been effective (Rompel and Petres, 2000; Bocchini et al, 2003). A variety of new approaches, including the use of the CO_2 and Nd:YAG lasers to treat HS, are under investigation (Lapins et al, 1994; Madan et al, 2008; Tierney et al, 2009).

Corynebacterial Infection (Trichomycosis Axillaris and Erythrasma)

Trichomycosis axillaris (TA) is a superficial bacterial infection of axillary and pubic hair caused by *Corynebacteria*. Yellow, red, or black nodules are visible on the hair shafts (Fig. 15–27), and there is frequently a characteristic odor (Blume et al, 2003). There is an association with hyperhidrosis (Margolis, 2002). The differential diagnosis includes infestation with pediculosis pubis or fungal infection (piedra) (Avram et al, 1987), although examination with magnification can generally distinguish TA from these conditions. Shaving can provide immediate improvement, and antibacterial soaps may prevent further infection (Blume et al, 2003). For pubic TA, clindamycin gel, bacitracin, and oral erythromycin have also proven effective (Bargman, 1984; Blume et al, 2003).

Erythrasma is a *Corynebacterium minutissimum* infection of the skin that results in sharply bordered, red-brown, scaling eruptions in moist areas including the groin and axilla. These lesions may be pruritic or asymptomatic and may be confused with dermatophyte infection (tinea cruris) (Sindhuphak et al, 1985). Under a Wood light, the lesions show a characteristic bright coral-red fluorescence (see Fig. 15–27) (Halprin, 1967). Effective treatments include antibacterial soaps, topical aluminum chloride, topical clindamycin, miconazole cream, and oral erythromycin (Holdiness, 2002).

Ecthyma Gangrenosum

Ecthyma gangrenosum (EG) is a rare cutaneous manifestation of pseudomonal septicemia that presents most commonly on the anogenital area in debilitated or immunosuppressed patients. The lesions of EG are tender, grouped, erythematous macules that may progress to form bullae or rupture to produce a gangrenous ulcer (Fig. 15–28) (Blume et al, 2003). On histologic examination, necrotizing vasculitis and gram-negative organisms are present. The differential diagnosis includes pyoderma gangrenosum, necrotizing vasculitis, cryoglobulinemia, and septic emboli containing other organisms, including *Candida, Aspergillus, Citrobacter, Escherichia coli, Aeromonas hydrophila,* and *Fusarium* (Altwegg and Geiss, 1989; Martino et al, 1994; Gucluer et al, 1999; Reich et al, 2004). Consistent with the underlying sepsis, EG carries a poor prognosis, and immediate treatment with intravenous antipseudomonal antibiotics is indicated. Wound debridement may also be necessary (Collini et al, 1986).

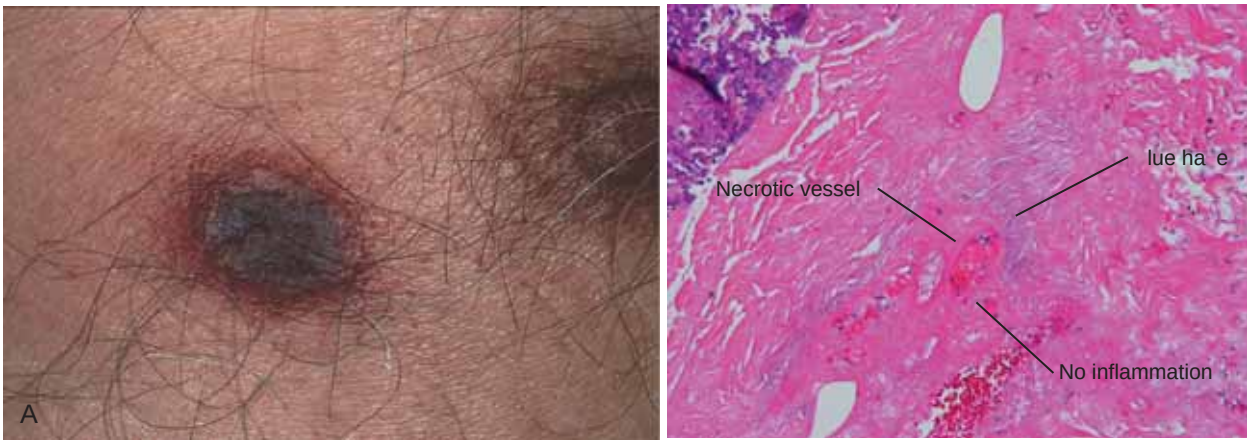

Figure 15–28. Ecthyma gangrenosum. **A,** Involvement on the chest wall. Note the necrotic center and erythematous border around the lesion. **B,** Histologically, ecthyma gangrenosum is characterized by necrotic vessels surrounded by a "blue haze" of organisms. (**A,** From Bolognia JL, Jorizzo JL, Rapini RP. Dermatology. Edinburgh, Mosby, 2003. p. 1132; **B,** from Elston DM, Ferringer T. Dermatopathology. Edinburgh, WB Saunders, 2009. p. 263.)

Figure 15–29. Candidal intertrigo with erythema, areas of tissue maceration and satellite lesions. (From Callen JP, Greer DE, Hood AF, Paller AS. Color atlas of dermatology. Philadelphia: WB Saunders; 1993. p. 318.)

Candidal Intertrigo

Fungal infection of macerated skin folds can occur with candidal species and involve the finger webs and intertriginous areas. Affected pruritic skin is reddened, and there may be characteristic satellite lesions present (Fig. 15–29). The differential diagnosis includes dermatophyte infection (tinea cruris), pemphigoid, psoriasis, seborrheic dermatitis, and contact dermatitis (Margolis, 2002). Fungal forms can be seen in scraped skin preparations after treatment with KOH, and culture is usually unnecessary. Topical treatment with imidazoles for at least 2 weeks is usually necessary for intertrigo, and occasionally oral antifungals are required (Cullin, 1977). Maneuvers to decrease moisture and skin maceration, such as the use of drying powders and loose clothing, may also help prevent relapse.

Dermatophyte Infection

Dermatophytes are fungi of three genera (*Trichophyton, Microsporum, Epidermophyton)* that have the propensity to invade and grow within keratinized tissues such as the skin, hair, and nails. These fungi produce keratinases that break down keratin and facilitate invasion (Viani et al, 2001). In addition, mannans in the cell wall of some dermatophytes have immunoinhibitory effects (Dahl, 1994).

Tinea cruris is the term given to dermatophyte infection of the groin and genital area and is commonly known as "jock itch." More common in males than females, this condition is favored by hot, humid environments and concomitant dermatophyte infection of the feet (*tinea pedis)*. Obesity may also be a significant risk factor (Scheinfeld, 2004). The inner thighs and inguinal region are the most commonly affected areas, and the scrotum and penis are usually spared in men. **Significant scrotal involvement should raise suspicion for cutaneous candidiasis as an alternative diagnosis** (Sobera and Elewski, 2003). Characteristic lesions in tinea cruris are sharply demarcated with a raised erythematous border (Fig. 15–30) and may be intensely pruritic. A variety of disorders can mimic dermatophytes infection, including seborrheic dermatitis, psoriasis, contact dermatitis, and erythrasma. The diagnosis of fungal infection can be confirmed with skin scrapings and a KOH preparation.

Good hygienic practices can be beneficial in preventing recurrent disease, including wearing loose clothing, cleaning of contaminated garments, weight reduction, and the use of topical powders to keep the intertriginous areas dry (Sobera and Elewski, 2003). Topical antifungal preparations are the primary agents for treatment, with the powdered forms having the added benefit of drying moist areas. **Care should be taken to treat only active disease and not the postinflammatory hyperpigmentation that can occur with recurrent chronic dermatophyte infection** (Margolis, 2002). Systemic antifungals are rarely necessary to treat groin infection with dermatophytes.

Infestation

Pediculosis pubis and scabies (*Sarcoptes scabiei*) are the most common infestations involving the genital region.

Infestation with the crab louse (*Phthirus pubis)* causes pediculosis pubis, a pruritic disorder of the genitalia that may coexist with other sexually transmitted infections (Opaneye et al, 1993; Varela et al, 2003). In one study of adolescent males, patients with pediculosis pubis had a more than twofold-higher risk of concomitant gonorrhea or chlamydial infection than normal controls (Pierzchalski et al, 2002). Louse infestation is not limited to the genitals and may involve other hair-bearing areas such as the eyelashes, beard, and axillae (Meinking, 1999). The diagnosis is confirmed by identification of crab lice attached to hairs (Fig. 15–31), often with associated perifollicular erythema. **Transmission of pediculosis pubis is usually through sexual contact, although contaminated clothing, bedding, and towels have also been implicated in some cases** (Meinking, 1999). **The standard treatment is application of 5% permethrin cream overnight to all affected hair-bearing areas with a repeat application one week later** (Meinking et al, 2003). Note that the second application of permethrin is important, as the rate of treatment success with a single application may be as low as 57% (Kalter et al, 1987). For rare cases refractory to topical therapy, or those involving the eyelashes (*tinea palpebrum*), the addition of oral ivermectin may be curative (Burkhart and Burkhart, 2000).

Another important infestation involving the genitalia is scabies, caused by the female itch mite *Sarcoptes scabiei*. **Scabies is a worldwide problem, and factors such as overcrowding, delayed treatment of primary cases, and poor public awareness encourage spread** (Meinking et al, 2003). Transmission is common between close contacts and family members (Burkhart et al, 2000). The number of mites living on an immunocompetent host is usually small (<100) (Arlian et al, 1988), although far greater numbers may be recovered in cases of immunosuppression (so-called "crusted scabies"). The incubation period before symptoms develop after infestation can vary from days to months in duration.

Severe pruritus is the hallmark of scabies, often accentuated at night or after bathing (Meinking et al, 2003). In both sexes, the genital areas are commonly affected. Small

Edinburgh: WB Saunders; 2009. p. 275.)

Figure 15–31. Pediculosis pubis. Several crab lice are visible. (From du Vivier A. Atlas of clinical dermatology. London: Churchill Livingstone; 2002. p. 338.)

erythematous papules are present and excoriations with secondary bacterial infection may occur (Fig. 15–32). **Thin, gray or white burrows may be visible and are pathognomonic for scabies infestation.** In the absence of visible burrows, a broad differential must be considered, including atopic dermatitis, pyoderma, psoriasis, and other insect bites. As with pediculosis pubis, the treatment of choice for scabies is 5% permethrin cream applied to the entire body overnight with a second application 1 week later. An alternative scabicide, lindane, is not favored due to both central nervous system (CNS) toxicity in children and a rising rate of resistance among mites (Purvis and Tyring, 1991; Elgart, 1996; Boix et al, 1997). Oral ivermectin is an alternative regimen that has been successfully used to treat scabies (Chouela et al, 2002; Heukelbach et al, 2004; Karthikeyan, 2005). **Note that pruritus may persist for several weeks despite successful treatment and that intimate contacts should also be treated to prevent reinfestation.**

NEOPLASTIC CONDITIONS

Squamous Cell Carcinoma In Situ

Squamous cell carcinoma in situ (SCCis) is a full-thickness intraepidermal carcinoma (Miller and Moresi, 2003). Bowen originally described this condition in 1912, hence the term "Bowen disease" (Bowen, 1912). On extragenital sites, there is a strong association between SCCis and ultraviolet light exposure (Reizner et al, 1994). **Commonly presenting in the seventh decade of life with a slight female predominance** (Hemminki and Dong, 2000; Arlette, 2003), **SCCis usually has an indolent clinical course and rarely progresses to invasive disease. When it occurs on mucosal surfaces of the male genitalia, most notably the glans penis of uncircumcised men, this entity is referred to as erythroplasia of Queyrat** (Fig. 15–33). In that location, coinfection with human papilloma virus types 8, 16, 39, and 51 has been identified (Wieland et al, 2000). Other risk factors for SCCis include ionizing radiation, immunosuppression, thermal injury, arsenic exposure, chronic dermatoses, and lichen sclerosis of the glans penis (Euvrard et al, 1995; Nasca et al, 1999; Powell et al, 2001; Centeno et al, 2002; Arlette, 2003).

Figure 15–32. Scabies. **A,** A papular eruption with characteristic burrows visible (*arrow*). **B** and **C,** Classic established genital scabies with eroded papules on the glans penis and scrotum. (**A,** From du Vivier A. Atlas of clinical dermatology. London: Churchill Livingstone; 2002. p. 332; **B** and **C,** from Habif TP. Clinical dermatology. Edinburgh: Mosby; 2004. p. 501.)

Figure 15–33. Erythroplasia of Queyrat. Squamous cell carcinoma involving the glans penis. (From Callen JP, Greer DE, Hood AF, Paller AS. Color atlas of dermatology. Philadelphia: WB Saunders; 1993. p. 330.)

SCCis lesions are sharply demarcated, solitary, pink to red, scaly plaques that may be confused with basal cell carcinoma, eczema, or psoriasis. When localized to the penile shaft, SCCis may have a more thickened, verrucoid appearance. Although usually asymptomatic, these lesions may also be pruritic or painful. The diagnosis is confirmed by histologic evaluation, and several areas should be sampled to exclude the presence of dermal invasion (Margolis, 2002).

Primary treatment of SCCis involves either surgical excision or tissue ablation. For accessible areas, such as the scrotum, simple excision with a 5-mm margin is favored (Bissada, 1992; Margolis, 2002). For areas where tissue preservation is more critical, Mohs microsurgery, laser therapy and cryoablation may have a role (Sonnex et al, 1982b; van Bezooijen et al, 2001; Leibovitch et al, 2005). Topical treatment with either 5-fluorouracil or imiquimod has also proven effective for management of selected cases of SCCis involving the genitalia (Gerber, 1994; Arlette, 2003; Micali et al, 2003).

Figure 15–34. Bowenoid papulosis. **A,** Involvement of the penile shaft. Note multiple brown verrucous papules on the penile shaft. **B,** Characteristic full thickness atypia, which may be mistaken for Bowen disease. (**A,** From Habif TP. Clinical dermatology. Edinburgh: Mosby; 2004. p. 343; **B,** from Elston DM, Ferringer T. Dermatopathology. Edinburgh: WB Saunders; 2009. p. 293.)

Bowenoid Papulosis

Bowenoid apulosis (BP) is an uncommon condition found on the penis and vulva of sexually-active adults, with a peak incidence in the third decade (Schwartz and Janniger, 1991). **It histologically resembles Bowen disease, except that the abnormal keratinocytes are spread discontinuously throughout the epidermis** (Margolis, 2002). Typical lesions are multiple small erythematous papules that may coalesce to form plaques with a verrucous surface similar to a genital wart (Fig. 15–34). There is a clear association with HPV type 16. **Female partners of men with BP have an increased risk of cervical neoplasia and should have close cervical follow-up** (Rosemberg et al, 1991). In men, however, BP generally has a benign course and spontaneous regression may occur (Eisen et al, 1983; Giam and Ong, 1986). Therefore conservative local therapy with observation, topical agents (5-fluorouracil or imiquimod), or ablative measures (electrodissection, cryotherapy, laser therapy) is usually appropriate (Margolis, 2002).

Squamous Cell Carcinoma

Invasive squamous cell carcinoma involving the genitalia (Fig. 15–35) is covered in detail in Chapter 83.

Verrucous Carcinoma (Buschke-Lowenstein Tumor)

Verrucous carcinoma (VC) is a locally aggressive, exophytic, low-grade variant of squamous cell carcinoma that has little metastatic potential (Habif, 2004). **The Buschke-Lowenstein tumor is a VC of the anogenital mucosal surface and may represent up to 24% of all penile tumors** (Schwartz, 1995). It most commonly occurs in uncircumcised men on the glans or prepuce, although similar lesions can be found on the vulva, vagina cervix, or anus. VC has been associated with human papilloma virus types 6 and 11 infection, but not with the more classically oncogenic types 16 and 18 (Yasunaga et al, 1993; Chan et al, 1994; Margolis, 2002; Ahmed et al, 2006).

VC lesions have a warty appearance and are often large and fungating when presenting on the genitalia (Fig. 15–36). Aside from genital sites, these lesions can also present within the oral and nasal cavities and plantar surfaces of the feet. They are slow-growing and locally destructive, often extending deeply into underlying tissue. Treatment is preferably by local excision. **Primary radiotherapy is relatively contraindicated due to the potential for anaplastic transformation with a subsequent increase in metastatic potential** (Stehman et al, 1980; Andersen and Sorensen, 1988; Fukunaga et al, 1994; Vandeweyer et al, 2001).

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is the most common cutaneous neoplasm, arising most often on areas of chronically sun-exposed skin such as the head and neck. Genital BCC has also been described as a rare entity, most commonly involving the scrotal skin in the male and vulva in the female (Nahass et al, 1992; Benedet et al, 1997; Esquivias Gomez et al, 1999; Kinoshita et al, 2005). Several subtypes of BCC have been defined including nodular, superficial, micronodular, and infiltrating. The nodular variant accounts for 60% of all BCCs and presents as a pearly, skin-toned papule or plaque, often with telangiectasias overlying the tumor (Fig. 15–37) (Miller and Moresi, 2003). These lesions may ulcerate and have a very low metastatic potential. Treatment is by local excision.

Kaposi Sarcoma

Kaposi sarcoma (KS) is a disease of endothelial cell origin. Whether KS is a neoplastic or hyperplastic process remains controversial, and evidence exists both for and against clonal expansion (Rabkin et al, 1997; Gill et al, 1998). Prior to the onset of the AIDS epidemic, KS was considered a chronic disease afflicting elderly men of Jewish, Mediterranean, or Eastern European descent ("classic KS") (Safai, 1987). However, infection with HIV-1 has increased the incidence of KS by more than 7000-fold (Miles, 1994; Margolis, 2002). KS generally affects HIV-infected patients with advanced immune impairment (CD4+ T-cell counts of <500 cells/mm) (Tappero et al, 1993). Approximately 40% of homosexual men with AIDS have developed KS as compared with less than 5% in other risk groups (Rogers et al, 1987; North et al, 2003). There is also a clear association between infection with human herpesvirus 8 and the development of KS (Boshoff and Weiss, 1997; Weiss et al, 1998).

Classic KS in immunocompetent individuals presents as slowly growing blue-red–pigmented macules on the

lower extremities. Although oral and gastrointestinal lesions may occur, the genitalia are seldom involved. This is in contrast to AIDS, ("epidemic KS") in which a solitary genital lesion may be the first manifestation of KS (Lowe et al, 1989). **The clinical features of KS in AIDS patients are diverse, ranging from a single lesion to disseminated cutaneous and visceral disease** (Fig. 15–38). Lesions may coalesce to cover large areas of skin and may result in lymphatic or venous blockage leading to local edema (Margolis, 2002). When these lesions involve the glans penis, they can cause obstruction at the urethral meatus or fossa navicularis (Swierzewski et al, 1993).

Treatment must be tailored to the individual clinical case and complete cure may be an unrealistic goal. For solitary lesions, local therapy such as surgical excision, laser treatment, cryotherapy, or intralesional injection of chemotherapeutic agents (i.e., vinblastine) may be beneficial (Chun et al, 1999; Schwartz, 2004; Heyns and Fisher, 2005). For extensive locoregional disease, radiotherapy (15 to 30 Gy) has an objective response rate of >90% (Kirova et al, 1998; Cattelan et al, 2002). For widely disseminated KS, systemic chemotherapy with vincristine, doxorubicin, and bleomycin is the treatment of choice (Aversa et al, 1999).

Figure 15–37. Basal cell carcinoma involving the vulva. (From du Vivier A. Atlas of clinical dermatology. London: Churchill Livingstone; 2002. p. 688.)

Pseudoepitheliomatous, Keratotic, and Micaceous Balanitis

Pseudoepitheliomatous, keratotic, and micaceous balanitis (PEKMB) is a rare entity characterized by the development of a thick, hyperkeratotic plaque on the glans penis of older men (Fig. 15–39). The term *micaceous* refers to the white, scaly appearance of the lesions (Child et al, 2000). PEKMB was originally thought to be a purely benign process, although several case reports have documented the presence of concurrent verrucous carcinoma associated with this lesion (Child et al, 2000). There remains controversy as to whether PEKMB is a premalignant condition (Read and Abell, 1981; Beljaards et al, 1987; Jenkins and Jakubovic, 1988). Histologic examination is essential to exclude the presence of squamous cell carcinoma and verrucous carcinoma (Margolis, 2002). PEKMB is characterized on histology by a hyperplastic epidermis with ridges extending deeply into the dermis (Jenkins and Jakubovic, 1988). These lesions should be treated locally either by surgical excision or ablative techniques, and close

Figure 15–38. Kaposi sarcoma. Classic macular lesions seen on the back (**A**) and glans penis (**B**). (**A,** From Callen JP, Greer DE, Hood AF, Paller AS. Color atlas of dermatology. Philadelphia: WB Saunders; 1993. p. 220; **B**, from du Vivier A. Atlas of clinical dermatology. London: Churchill Livingstone; 2002. p. 716.)

Figure 15–39. Pseudoepitheliomatous, keratotic and micaceous balanitis. The glans becomes covered with mica (asbestos-like) scales and horny crusts. (From du Vivier A. Atlas of clinical dermatology. London: Churchill Livingstone; 2002. p. 717.)

follow-up is essential (Read and Abell, 1981; Bargman, 1985). There are also anecdotal reports of successful treatment using topical 5-fluorouracil cream (Bargman, 1985; Krunic et al, 1996).

Melanoma

Malignant melanoma is a neoplasm arising from melanocytes. The incidence of melanoma has risen 3% to 7% over the past several decades (Nestle and Kerl, 2003). Risk factors for development of the disease include family history, certain genetic markers, fair skin, and ultraviolet radiation exposure. Primary melanoma of the male genitalia is an uncommon entity with only approximately 100 cases reported in the literature (Sanchez-Ortiz et al, 2005), and melanoma of the male urethra is even rarer (Oliva et al, 2000).

Genital melanoma usually presents as a pigmented macule or papule with an irregular border, although unpigmented lesions and ulceration may also be present (Margolis, 2002). **Early diagnosis is critical because local treatment of superficial lesions with wide local excision or partial penectomy can provide excellent disease control** (Stillwell et al, 1988; Sanchez-Ortiz et al, 2005). **In contrast, patients with biopsy-proven metastatic disease have a universally poor prognosis despite aggressive surgical management and multiagent cytotoxic chemotherapy.**

Extramammary Paget Disease

Extramammary Paget disease (EPD) is an uncommon intraepithelial adenocarcinoma of sites bearing apocrine glands (Zollo and Zeitouni, 2000). The majority of patients with EPD are elderly white females, and involvement of the male penis and scrotum is exceedingly rare (Park et al, 2001; van Randenborgh et al, 2002; Yang et al, 2005). The vulva is the most commonly involved genital site in women, followed by the perianal region in men (Wojnarowska and Cooper, 2003). **There is an important association between EPD and another underlying malignancy in 10% to 30% of cases** (Payne and Wells, 1994, Ng et al, 2001; Margolis, 2002). **In the male, associations between urethral, bladder, rectal, and apocrine malignancies with EPD have been described** (Hayes et al, 1997; Salamanca et al, 2004). It is critical, therefore, to perform a systematic evaluation for underlying carcinoma in cases of EPD.

The lesion in EPD is usually an erythematous plaque with a sharp border between normal and involved skin (Fig. 15–40). It may be asymptomatic, pruritic, or associated with burning pain. The diagnosis is confirmed histologically by the presence of vacuolated Paget cells in the epidermis, which stain for glandular cytokeratins, epithelial membrane antigen, and carcinoembryonic antigen (Wojnarowska and Cooper, 2003). Treatment generally involves surgical excision or Mohs micrographic surgery, although radiotherapy and topical imiquimod or 5-fluorouracil have also been used successfully (Sillman et al, 1985; Bewley et al, 1994; Brown et al, 2000; Brown et al, 2002; Guerrieri and Back, 2002; Moreno-Arias et al, 2003; Qian et al, 2003; Lee et al, 2009).

Cutaneous T-Cell Lymphoma

Cutaneous T-cell lymphoma (CTCL) represents a group of related neoplasms derived from T cells that home to the skin. It includes a variety of conditions including mycosis fungoides, Sezary syndrome, lymphoid papulosis, and pagetoid reticulosis (Willemze, 2003). There is an increased risk of CTCL associated with HIV infection (Biggar et al, 2001). Although these disorders may involve the genitalia of both sexes, extragenital disease is usually also present. CTCL accounts for the majority of primary cutaneous lymphomas, with B-cell–derived lymphomas accounting for only 20% to 25% (Willemze et al, 1997; Willemze et al, 2005). Definitive diagnosis depends on biopsy histopathology.

CTCL generally presents with pruritus, which must be differentiated from a variety of benign dermatoses including psoriasis, eczema, superficial fungal infections, and drug reactions. Patients may subsequently develop hematologic involvement (Sezary syndrome) and cutaneous plaques, erosions, ulcers, or frank skin tumors (Fig. 15–41) (Margolis, 2002). CTCL is a chronic condition that may progress over many years. Topical treatments include corticosteroids, nitrogen mustard, and carmustine with complete remission rates of approximately 60% (Vonderheid et al, 1989; Zackheim et al, 1998). Other treatments include radiotherapy, phytotherapy (PUVA), and systemic treatment with chemotherapy, interferons, or retinoids (Hoppe et al, 1990; Olsen and Bunn, 1995; Diederen et al, 2003; Querfeld et al, 2005).

BENIGN CUTANEOUS DISORDERS SPECIFIC TO THE MALE GENITALIA

Angiokeratoma of Fordyce

Angiokeratomas of Fordyce (AF) are vascular ectasias of dermal blood vessels, which may be visible on the penis and scrotum of adult men (Bechara et al, 2002). These lesions appear as 1- to 2-mm red or purple papules (Fig. 15–42A), and there may be associated generalized scrotal redness (Miller and James, 2002). This is usually a benign condition without systemic manifestations, although it may rarely be a source of troublesome scrotal bleeding (Taniguchi et al, 1994; Hoekx and Wyndaele, 1998). Similar lesions can be observed in Fabry disease (Fig. 15–42B), which is a rare glycogen storage deficiency. Although treatment is usually unnecessary for AF, several authors have reported success using erbium:YAG, Nd:YAG, KTP, and argon laser photocoagulation in select cases (Occella et al, 1995; Bechara et al, 2004; Ozdemir et al, 2009).

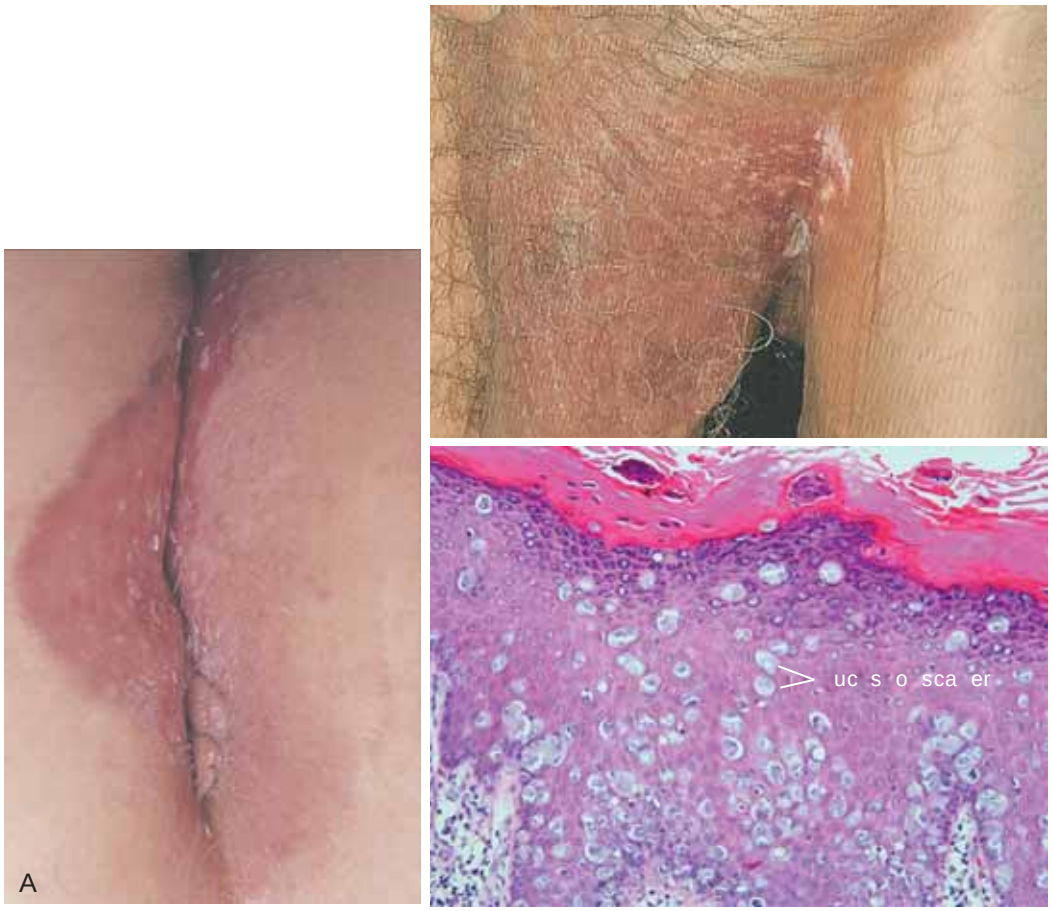

Figure 15–40. Extramammary Paget disease involving (**A**) the vulva and (**B**) base of scrotum. Note the well-demarcated border between the lesion and normal adjacent skin. **C,** Tumor cells distributed throughout the epidermis ("buckshot scatter"). (**A,** From Habif TP. Clinical dermatology. Edinburgh: Mosby; 2004. p. 764; **B,** from Bolognia JL, Jorizzo JL, Rapini RP: Dermatology. Edinburgh: Mosby; 2003. p. 1108; **C,** from Elston DM, Ferringer T. Dermatopathology. Edinburgh: WB Saunders; 2009. p. 66.)

Pearly Penile Papules

Pearly penile papules (PPP) are white, dome-shaped, closely spaced small papules located on the glans penis (see Fig. 15–42). They are often arranged circumferentially at the corona. PPP are very common lesions found in up to 14% to 48% of young postpubertal adults, particularly if the penis is not circumcised (Rehbein, 1977; Khoo and Cheong, 1995; Sonnex and Dockerty, 1999). **Although PPP may occasionally be misdiagnosed as condyloma, the available evidence does not support a role for human papilloma virus in causing PPP, and no association with cervical intraepithelial neoplasia in female partners has been demonstrated** (Hogewoning et al, 2003). Patients should be reassured that this is a benign condition that does not usually require treatment. If treatment is desired due to cosmetic concerns, local destruction with either the CO_2 laser or cryotherapy has been applied successfully (Ocampo-Candiani and Cueva-Rodriguez, 1996; Lane et al, 2002). **Histologically, these lesions are angiofibromas similar to the lesions seen on the face in tuberous sclerosis.**

Zoon Balanitis

Zoon balanitis, also called plasma cell balanitis, occurs in uncircumcised men from the third decade onward (Pastar et al, 2004). Smooth, moist, erythematous, well-circumscribed plaques on the glans penis characterize the disease (see Fig. 15–42). Shallow erosions may also be present (Yoganathan et al, 1994), and the lesions can be quite large (up to 2 cm in diameter) (Margolis, 2002). Squamous cell carcinoma and extramammary Paget disease should be excluded, often by biopsy. Circumcision appears to be proof against development of the disease and can be performed to cure the majority of cases (Sonnex et al, 1982a; Ferrandiz and Ribera, 1984). For patients averse to circumcision, topical corticosteroids may provide symptomatic relief, and topical tacrolimus and laser therapy may also have a role (Baldwin and Geronemus, 1989; Tang et al, 2001; Albertini et al, 2002; Retamar et al, 2003; Wojnarowska and Cooper, 2003; Rallis et al, 2007).

Sclerosing Lymphangitis

Nonvenereal sclerosing lymphangitis is a rare penile lesion consisting of an indurated, slightly tender cord involving the coronal sulcus and adjacent penile skin (Gharpuray and Tolat, 1991; Rosen and Hwong, 2003). It is usually flesh-colored but may occasionally be red. A mechanism related to thrombosis of lymphatic vessels has been proposed. There is an association with vigorous sexual activity and resolution usually occurs within several weeks (Sieunarine, 1987; Margolis, 2002).

Median Raphe Cyst

Median raphe cysts occur in young men on the ventral aspect of the penis, most commonly near the glans (Stone, 2003). Although

Figure 15–41. Mycosis fungoides (a cutaneous T-cell lymphoma) involving the buttocks. **A,** Limited plaque stage. **B,** A more advanced case with plaques, patches, and tumors present. (From Bolognia JL, Jorizzo JL, Rapini RP. Dermatology. Edinburgh: Mosby; 2003. p. 1926, 1927.)

these cysts are believed to develop from aberrant urethral epithelium, they do not communicate with the urethra (Asarch et al, 1979). Treatment is by surgical removal.

Ectopic Sebaceous Glands

Ectopic sebaceous glands on the penile shaft may be visible as pin-sized popular lesions that may be mistaken for verruca (see Fig. 15–42) (Margolis and Wein, 2002).

COMMON MISCELLANEOUS CUTANEOUS DISORDERS

Skin Tag

Skin tags (acrochordons, fibroepithelial polyps) are soft, skin-colored, pedunculated lesions that can be present anywhere on the body. Although usually asymptomatic, these lesions may be painful secondary to local trauma or torsion and infarction in rare cases. These are common lesions and up to 50% of all individuals may have at least one skin tag (Banik and Lubach, 1987). **It is important to distinguish these lesions from the hamartomatous skin lesions (multiple fibrofolliculomas) associated with Birt-Hogg-Dube syndrome, which are histologically distinct from common skin tags** (De la Torre et al, 1999).

Epidermoid Cysts

Epidermoid or epidermal-inclusion cysts (EC) are the most common cutaneous cysts, and these lesions can be found anywhere on the body, including the genitalia. They are particularly common on the scrotum (Fig. 15–43). **The term "sebaceous cyst" should be avoided because the contents of these cysts are not derived from a sebaceous origin** (Stone, 2003). Although not painful at baseline, rupture of the cyst wall can lead to a severe inflammatory reaction that is extremely painful. Definitive treatment requires surgical excision of the entire cyst wall to prevent cyst recurrence. Inflamed or superinfected epidermoid cysts may require incision and drainage, and antibiotic therapy if there is adjacent cellulitis. Dystrophic calcification of scrotal epidermoid cysts may be a cause of scrotal calcinosis (Dare and Axelsen, 1988; Michl et al, 1994).

Seborrheic Keratosis

Seborrheic keratoses are very common brown macules, plaques, and papules affecting individuals over 30 years of age and that increase in frequency with advancing age. They are most common on the face, neck, and trunk, although any body site except the palms, soles, and mucous membranes may be affected. The degree of pigmentation can vary significantly, and darker lesions may be confused with melanoma or warts (Pierson et al, 2003). **These lesions have a waxy, "stuck-on" appearance** (see Fig. 15–43), **and patients may note that they drop off spontaneously and regrow** (Margolis, 2002). Treatment by shave excision or destruction with liquid nitrogen is usually performed for cosmetic reasons. **An abrupt increase in the size and number of multiple seborrheic keratoses has been termed Leser-Trelat syndrome and has been implicated as a cutaneous marker of internal malignancy** (Chiba et al, 1996; Heaphy et al, 2000; Vielhauer et al, 2000; Ginarte et al, 2001).

Lentigo Simplex

Lentigo simplex is a condition characterized by the presence of brown-pigmented macules unrelated to sunlight exposure (see Fig. 15–43). These lesions can be found anywhere on the body, including the mucous membranes and nail beds. In the genital area (genital lentiginosis), these lesions present commonly on the labia, vaginal introitus, perineum, and glans penis (penile melanosis). The lesions of lentigo simplex are usually smaller than those seen in melanocytic nevi. Although usually benign, the lesions of lentigo simplex may deserve biopsy evaluation in cases with atypical shape or coloration. **Finally, the combination of multiple pigmented lesions associated with intestinal polyposis should raise suspicion for Peutz-Jeghers syndrome.**

Mole (Nevus)

A mole, or nevus of the skin, is composed of slightly altered melanocytes called "nevus cells" arranged in a cluster. The location of the cluster determines the type of nevus. Junctional nevi are located between the epidermis and dermis and are usually flat, tan to black in coloration, small (<5 mm), and sharply bordered (Margolis, 2002). Intradermal nevi have clusters within the dermis and are usually small (<5 mm) and lighter in coloration with sharp borders. Compound nevi have clusters in both locations and are usually darker and raised, as for a papule (see Fig. 15–43). As for

any pigmented lesion, irregularity in coloration or border and rapid change over time are indications for excisional biopsy.

Dermatofibroma

Dermatofibromas are small hyperpigmented nodules that occur most commonly on the lower extremities and occasionally on the genitalia. Pinching of these lesions causes a downward movement of the tumor (the so-called "dimple sign") (Kamino and Pui, 2003). These are benign lesions with a characteristic histologic pattern of spindle-shaped fibroblasts and myofibroblasts arranged in fascicles. Treatment by surgical excision is usually unnecessary and may leave a scar that is cosmetically inferior to the original lesion (Kamino and Pui, 2003).

Neurofibroma

Neurofibromas are common tumors composed of neuromesenchymal tissue with residual nerve axons. They can be present anywhere on the body including the labia and scrotum (Yoshimura et al, 1990; Singh et al, 1992; Mishra et al, 2002; Kantarci et al, 2005). They are usually skin-colored, soft or rubbery, nodular lesions, which may be pedunculated. **Digital pressure on the lesion causes invagination or so-called "button-holing"** (Habif, 2004). These can be solitary lesions or multiple, which should raise suspicion for neurofibromatosis or von Recklinghausen disease.

Capillary Hemangioma

Capillary hemangiomas are proliferations of blood vessels that are either present at birth or develop rapidly during the neonatal period. These lesions can involve the anogenital region and lead to bleeding or cause obstruction of the urethra, vagina, or anus (Sharma et al, 1981; Roberts and Devine, 1983). The majority will involute during childhood or early adolescence (Margolis, 2002).

Vitiligo

Vitiligo is an acquired disorder of skin depigmentation that affects 0.5% to 2% of the population (Ortonne, 2003). It may present at any age and the pathogenesis of vitiligo remains a topic of intense research effort. Large patches of skin become completely amelanotic, appearing white although the tissue is otherwise normal. The borders with unaffected skin are usually sharp and well defined. This condition is particularly noticeable in darker skinned individuals and on body sites that are normally hyperpigmented. Vitiligo limited to the genitalia has been observed in less than 0.3% of the male population (Moss and Stevenson, 1981). Lesions have a tendency to enlarge circumferentially over time and may develop at sites of local trauma (Koebner phenomenon). Genital vitiligo must be differentiated from lichen sclerosis and postinflammatory hypopigmentation (Margolis, 2002). Treatments include repigmentation with topical cosmetics, ultraviolet light exposure, PUVA therapy, and skin grafting.

Key Points

- The diagnosis of cutaneous diseases of the external genitalia depends critically on a thorough history and physical examination. Extragenital findings may provide the key to diagnosis. The urologist should perform a thorough skin survey and not focus solely on the area of affected genital skin.
- The side effects of topical corticosteroids are significant, both from systemic absorption and locally. Adverse effects may be worsened if these agents are applied under the foreskin, which may serve as an occlusive dressing. In general, when applied to genital skin, only low-potency topical corticosteroids should be used for short treatment courses.
- Cutaneous disorders of the external genitalia can be broken down into the general categories of allergic, papulosquamous, vesicobullous, ulcerative, infectious, neoplastic, and miscellaneous diseases.
- Histopathologic analysis of biopsy specimens plays an important role in differentiating cutaneous diseases with similar clinical features and in excluding malignancy.
- Local treatment modalities, including the use of laser energy, photodynamic therapy, ultraviolet radiation, and cryotherapy are being applied successfully to a variety of genital cutaneous disorders and offer an alternative to surgical excision in some cases.

Genitourinary Tuberculosis

Parasitic Diseases of the Genitourinary System

Other Parasitic Diseases of the Genitourinary Tract

GENITOURINARY TUBERCULOSIS

Tuberculosis has been one of the great imitators of all time, and only a few years ago was thought to be a disease of the past. Tuberculosis (TB) is a deadly infectious disease with a rising incidence worldwide. The urologist's awareness of the clinical features of genitourinary (GU) TB is necessary to effectively treat patients with this disease. A review of the literature will reveal that the clinical features and pathology of genitourinary tuberculosis described in the earlier part of the 20th century has remained essentially valid to date. Current research focuses on epidemiology of the new resurgence of the disease, as well as rapid diagnostic modalities and new treatment regimens to combat multidrug-resistant TB.

History

Akhenaton, a Pharaoh of the eighteenth dynasty of Egypt, and his wife Nefertiti both are believed to have died from tuberculosis, and evidence indicates that hospitals for tuberculosis existed in Egypt as early as 1500 BCE (Madkour, 2003). Signs of the disease have also been found in the spines of Egyptian mummies dating between 3000 and 2400 BCE (Zink et al, 2003).

Tuberculosis became known as "the consumption" during the 1700s in Europe when infections reached epidemic proportions, causing one fourth of the deaths in England (Daniel, 2000). The bacillus causing tuberculosis, *Mycobacterium tuberculosis,* was identified and described on March 24, 1882 by Robert Koch. He demonstrated that *Mycobacterium* was the single cause of tuberculosis in all of its forms. His conclusion was based on the observations that *Mycobacterium* was found in all cases of the disease, could be prepared as a pure culture, and the original infection could be reproduced in an inoculated animal, from which it could be cultured again (Koch, 1882). These observations lead to postulates that have become known as the "Koch postulates," and they form the basis for the study of all infectious diseases. March 24th has become "World Tuberculosis Day."

Epidemiology

Incidence

The World Health Organization (WHO) estimates that 9.27 million new cases of TB occurred in 2007, compared with 9.24 million new cases (140 per 100,000) in 2006. An estimated 1.37 million (14.8%) of the cases in 2007 were HIV-positive (World Health Organization and Global Tuberculosis Programme, 2008).

In the United States, the incidence of TB showed a resurgent peak in 1992 after having continually declined until 1985, coinciding with the emergence of HIV-AIDS. In 2008, 12,904 cases were reported (4.2 cases per 100,000), representing a decline of 2.9% compared with 2007.

The trend of the declining annual case rate has slowed, from an annual average decline of 5.6% for 1993 through 2002 to an annual average decline of 2.6% for 2003 through 2008.

Genitourinary TB

Extrapulmonary sites account for 10% of tuberculosis cases. Genitourinary TB accounts for 30% to 40% of all extrapulmonary TB, second only to lymphonodal affection (Eastwood et al, 2001). In developed countries, urogenital tuberculosis occurs in 2% to 10% of cases of pulmonary tuberculosis, while in developing countries it occurs in as many as 15% to 20% of cases.

Transmission and Development of Disease

Controversy existed as early as the latter part of the 19th century as to whether pulmonary tuberculosis spread to the genitourinary tract by bacterial retrograde ascent or hematogenous dissemination. In 1885, injection of the renal artery with TB bacillus was shown to produce renal tuberculosis in the kidney of an experimental animal. Ekehorn, in 1908, postulated that TB bacilli lodged in renal glomeruli flourished into renal infection. These suspicions were confirmed in 1949 by Medlar and associates, proving that

renal cortical TB was a "metastatic" infection spread by the hematogenous route (Medlar et al, 1949).

The kidney, epididymis in men, and fallopian tubes in women are the primary landing sites for hematogenous spread of TB. The prostate is also considered one of the sites for hematogenous spread, though its involvement with TB bacilli in urine is more common. Other genitourinary organs are involved by direct, endoluminal, or lymphatic spread from these sites.

Immunology and Pathogenesis

In the lung, inhaled tubercle bacilli implant in the respiratory bronchioles and alveoli. The interaction between bacterial virulence and host immunity determines whether an infection is established or aborted (Dannenberg, 1993). If infection occurs, the mycobacteria slowly divide within alveolar macrophages. Two to 12 weeks often ensue before mycobacterial numbers are sufficient to mount a clinically detectable cellular immune response (Dannenberg, 1994).

The interval before the development of cellular immunity is when tubercle bacilli spread through the lymphatics to the hilar lymph nodes and ultimately through the bloodstream to seed distant organs. Mycobacteria deposited in the upper lung zones, kidneys, bones, and brain find such environments favorable, and bacterial multiplication may occur before specific cellular immunity can limit bacterial activity.

In the presence of intact cell-mediated immunity, macrophages, T lymphocytes, B lymphocytes, and fibroblasts aggregate to form a granuloma, with lymphocytes surrounding the infected macrophages and organisms localized in the center of the granuloma. This pathognomonic lesion prevents dissemination of the mycobacteria. Immune cells communicate through cytokines within the milieu of the granuloma. T lymphocytes secrete interferon gamma, which induces intracellular killing of mycobacteria within infected macrophages (Kaufmann, 2002). An antibody response against *M. tuberculosis* has been demonstrated but does not appear to be protective (Abebe and Bjune, 2009). Tubercle bacilli often remain viable within the tubercle, become dormant, and finally result in a latent infection.

The risk of reactivation of dormant TB foci increases with diabetes mellitus and diseases associated with immunosuppression, e.g., HIV infection and malignancies, as well as by use of corticosteroids, chemotherapy, and other immunosuppressive drugs.

Pathologic Features

Kidney

The kidneys are the primary site of hematogenous spread of TB. Mycobacteria lodge in the renal capillaries causing microscopic foci near the glomeruli bilaterally, the cortex being favored due to its greater blood supply and higher oxygen tension (Pasternak, 2001). An initial acute inflammatory response ensues, resulting in polymorphonuclear leukocytes infiltration. Over the following 3 to 6 weeks cell-mediated immunity developing in macrophages may inhibit the *M. tuberculosis* by containing the bacterial replication and halting the disease in the renal cortex, leading to the formation of dormant TB foci.

Upon activation of the disease, a chronic inflammatory process arises with the subsequent development of characteristic granulomata, tubercles consisting of multinucleated Langhans giant cells, lymphocytes, and fibroblasts. Central caseous necrosis builds up within the tubercles, and neighboring tuberculous foci coalesce to form confluent areas of caseation. With progression of the disease, inflammatory changes extend into the renal tubules and medulla with further tubercle formation and caseous necrosis. Renal papilla involvement results in sloughing and caseous material gaining access to the collecting system by calyceal ulceration (Medlar, 1926). Renal tuberculosis often becomes clinically evident at this stage. Extensive fibrosis accompanying healing tubercles results in cicatricial complications, such as calyceal infundibular narrowing, ureteropelvic junction scarring, and disfiguration leading to segmental or generalized hydronephrosis respectively, and adds an obstructive element to the ongoing renal damage (Medlar, 1926).

Adrenal

Adrenal tuberculosis is seen in less than 6% of active TB cases. The lesion may be unilateral, but is usually bilateral. Tuberculosis causes necrosis of the adrenal gland, which manifests as Addison disease. Primary caseous tuberculosis of the adrenals is probably the most common lesion seen. The glands are enlarged, surrounded by a thickened capsule, and have irregular nodular surfaces with infrequent calcifications. Caseous cavitary destruction is found upon section. As a result, up to 56% of patients with adrenal TB will have a subnormal cortisol response to corticotrophin stimulation (Hawken et al, 1996).

Ureter

Tuberculosis of the ureter is almost always a direct extension of TB of the kidney. The passage of caseous material rich in mycobacteria leads to tubercle formation within the ureteric mucosa. This usually affects the lower ureter, commonly the ureterovesical junction, less commonly the middle and upper ureter (Shin et al, 2002). Tubercle formation is soon followed by ulceration of the mucosa and subsequent fibrosis and scarring, leading to ureteric stricture disease and obstruction. Lesions extending into the ureteric wall will also initiate a dense fibrosis on the ureteric serosa, leading to encasement of the ureter and angulation by contracted cicatricial bands (Johnson, 1911).

Bladder

Tuberculosis of the bladder occurs secondary to TB of the kidney. The bladder urothelium is very resistant to infection by TB bacilli. Urine of renal tuberculosis patients may contain mycobacteria for years prior to the involvement of the bladder. The most common sites affected by TB are the areas surrounding the ureteric orifices and the trigone. The urothelium is initially swollen and inflamed, following the formation of tubercles within the bladder mucosa. The ureteric orifice may be completely obscured by the swollen mucosa. In modern times the progression to the stage of mucosal ulceration is rare. However, if it does occur, the coalescence of tubercles will lead to larger areas of caseated mucosa, the top of which ulcerates leading to the formation of a classical undermined tuberculous ulcer with "worm-eaten" ragged edges (Johnson, 1911).

Epididymis, Vas, and Testis

Tubercle bacilli reach the epididymis by hematogenous spread. The disease initially affects the more vascular globus minor. Tubercles form within the epididymal epithelium eliciting a chronic inflammatory reaction that subsequently leads to fibrous narrowing and possible obliteration of the lumen. With disease progression, large caseous foci may form leading to a nodular epididymis. These lesions may become adherent to the overlying skin and ulcerate through giving the classic picture of a tuberculous sinus that is typically located on the posterior surface of the scrotum. Spread of the infection along the lumen, with the flow of

secretion, will lead to affection of the vas deferens in a similar pattern. The classical finding is that of a beaded vas as a result of tubercles eventually inducing dense fibrosis.

Tuberculosis of the testis is secondary to that of the epididymis and is due to direct extension of the disease. Tubercles form within the seminiferous tubular epithelium as well as in the connective tissue septa of the testis. As a result the affected testicular tissue is eventually replaced by caseous material and fibrosis. Such lesions may be clinically difficult to distinguish from a testicular tumor.

Prostate and Seminal Vesicles

The prostate is rarely affected, it is however one of the sites of hematogenous spread of TB. The lesions are often incidentally found on TUR specimens. In cases where progression occurs, caseous destruction of prostatic tissue ensues that may be significant enough to cause a noticeable reduction in semen volume (Marconi et al, 2009). Densely fibrotic nodules may form and are indistinguishable from cancer.

Tuberculosis of the seminal vesicle is rarely seen in modern times. The bacilli can reach the seminal vesicles through the vas deferens in cases of tuberculosis of the testis or epididymis, or through the urethra and ejaculatory duct because of tuberculosis of the kidneys, bladder, or prostate. Caseous masses develop in the walls, and the lumen may be filled caseation.

Penis and Urethra

Tuberculosis of the penis in adults is very rare and is secondary to infection of the kidney and bladder. It starts as a chronic process, by the formation of infected granulation tissue, which gradually infiltrates the glanular and cavernous tissues and may invade the whole thickness of the penis. As the infection progresses, isolated pea-sized masses can be felt in the cavernous bodies and urethra, and in some cases directly under the skin. On pathologic section, these lesions are found to be masses of caseous tubercles.

One rare presentation is an ulcerative lesion of the glans. This *primary* infection can be acquired by sexual relations with partners having genital or perineal tuberculous lesions (Angus et al, 2001). Several cases of primary TB of the penis were reported in young Jewish boys following circumcision. Hemorrhage was stopped by sucking the penis with the mouth. Rabbis with open pulmonary TB transmitted the infection through infected sputum. Urethral tuberculosis is rare, often only seen at the meatus. Small miliary tubercles are seen over the surface and throughout the urethra. Late cases may have advanced fibrotic strictures.

Clinical Manifestations

In the words of Chang: "the kidney is an inarticulate organ; its vocal cords are the bladder" (Chang, 1976). Tuberculosis can often mimic a wide range of nonspecific urologic symptoms. It is thus, no wonder that many cases of genitourinary TB are easily overlooked. A high index of clinical suspicion of TB is required to further investigate cases of unexplained symptoms in the urinary tract. This is especially important when there is a failure to respond to initial treatments given for lower urinary tract symptoms or when urinalysis and routine culture reveal "sterile pyuria." The fact that 18 out of 25 physicians with renal TB presented only after cavitary lesions developed is a measure of how silently the destructive process occurs (Lattimer, 1965).

Genitourinary TB is more commonly seen in men (male : female ratio of 2 : 1), usually presenting in the fourth decade of life. Lower urinary tract symptoms are the most common presentation, with over 50% of patients presenting with storage symptoms. Hematuria and loin pain are the presentation in one third of cases (Figueiredo et al, 2008). Passage of caseous material, necrotic renal papillary tissue, clots, or stones account for renal colic in 10% of patients (Simon et al, 1977). Less than 20% of cases will present with constitutional symptoms of fever, anorexia, weight loss, and night sweats. The presence of these symptoms, however, can alert to the presence of active TB elsewhere in the body (Simon et al, 1977).

Physical examination is often of limited value in the diagnostic process, because physical signs develop late in the disease. The most common physical finding is an abnormal scrotal exam in about half the patients (Figueiredo et al, 2008). Epididymal hardening, modularity, or scrotal fistulae are among the signs seen. A chronic renal fistula tract, often with a history of prior renal surgery is another late physical sign. Enlarged, firm seminal vesicles, or prostatic nodules on rectal examination, though nonspecific, should arouse suspicion in clinically suggestive cases. It remains a fact that up to 25% of patients will present only with sterile pyuria and 13% might have gross or microscopic hematuria as their only presentation (Wise and Shteynshlyuger, 2008). Functional loss of the affected kidney can be present in up to 25% of cases, and renal failure is present in 7.4% of cases (Figueiredo et al, 2008). Genitourinary TB may be diagnosed during a workup for infertility as a cause of epididymal and vasal obstruction (Paick et al, 2000). TB should be considered in all cases of recurrent hemospermia. Adrenal tuberculosis may present with an addisonian type of clinical picture.

Diagnosis

Urinalysis and Culture

Historically, the diagnosis of genitourinary TB has relied on the identification of *Mycobacterium tuberculosis* in the urine. Unlike sputum examination, Ziehl-Neelsen staining of concentrated urine samples for acid-fast bacilli is often negative. Of note, a large majority of patients with genitourinary TB have "sterile pyuria," often accompanied by hematuria and proteinuria, whereas up to 20% may have superimposed bacterial infection (Gow and Barbosa, 1984).

Urine cultures are carried out on standard solid media optimized for mycobacterial growth, namely egg-based (Löwenstein-Jensen) or agar-based (e.g., Middlebrook 7H10) media. Optimizing factors include aniline dyes, such as malachite green, that inhibit growth of bacterial contaminants. Agar-based media are transparent and facilitate earlier visualization of micro-colonies by approximately 1 week. Intermittent release of the organism in urine makes multiple sampling necessary. Three to five early-morning urine samples should be cultured soon after collection rather than 24-hour samples, because exposure to urine acidity for prolonged periods retards mycobacterial growth (American Thoracic Society [ATS] and Centers for Disease Control and Prevention [CDC], 2000; Sommers, 1979). One other caveat is that chronic renal lesions may no longer discharge tuberculous material in urine due to dense fibrosis that is a barrier to the collecting system. In such cases diagnostic methods other than urine testing must be applied. Notably, cultures optimized for mycobacterial growth will favor the growth of mycobacterial contaminants as well as TB. Species identification is done using growing colonies tested with DNA strip assays. These provide rapid confirmation of pathogenic *Mycobacterium* TB in culture (Piersimoni et al, 2002).

Urine cultures are sensitive in 80% to 90% of cases and have a specificity of nearly 100% (Sorlozano et al, 2009). However, they

may take up to 6 weeks to yield clinically reliable results. Radiometric detection of mycobacterial activity in liquid culture media allows a more rapid diagnosis. Inoculation of specimens in broth with radiolabelled ^{14}C-palmitate results in liberation of $^{14}CO_2$ by mycobacterial metabolism, which is then detected by a radiometric analyzer. Mycobacterial detection and drug sensitivity testing using this method is possible as early as 7 to 14 days after inoculation (Watterson and Drobniewski, 2000; Sorlozano et al, 2009). One of the most popular systems using this principle is the BACTEC 460TB (Becton, Dickinson, Franklin Lakes, NJ). Nonradiometric methods using advanced fluorometric technology to detect O_2 consumption also yield rapid detection of mycobacteria without the use of radiation. One example of this detection method is the mycobacterial growth indicator tube (MGIT; Becton, Dickinson; Watterson and Drobniewski, 2000).

Antibiotic sensitivity testing (AST) is also done using traditional and rapid culture methods.

Purified Protein Derivative–Tuberculin Test—Mantoux Test

Charles Mantoux, a French physician who developed on the work of Koch, described this test in 1907. Purified protein derivative (PPD) tuberculin is a precipitate of non–species-specific molecules obtained from glycerol extracted filtrates of sterilized, concentrated cultures of tubercle bacilli. In the United States, a standard dose of 5 tuberculin units (0.1 mL) is injected intradermal (between the layers of dermis) into the volar or dorsal surface of the forearm and read 48 to 72 hours later. T-cell–mediated delayed-type hypersensitivity reaction to this intradermal antigen is the principle of the test. Antigen stimulation of memory cells leads to cytokine release that induces induration via local vasodilatation, fibrin deposition, and recruitment of other inflammatory cells into the area. These begin to accumulate within 24 hours and reach their peak after 48 to 72 hours, hence the timing of test interpretation. Patients who have been exposed to TB are expected to mount an immune response to PPD (Daniel, 1980).

Tuberculin test is nondiagnostic, and is of value only if positive. Three distinct cut points for positivity have been defined to optimize sensitivity and specificity for the test in different patient populations. The test must be interpreted in light of the recommendations in Table 16–1.

It is important to note that prior vaccination with bacillus Calmette-Guérin (BCG) may lead to a false-positive tuberculin test. Interestingly, a PPD skin test done before initiation of BCG therapy for superficial bladder cancer converted from negative to positive in 68% of patients (Bilen et al, 2003).

Nucleic Acid Amplification (NAA) Testing—PCR

Nucleic acid amplification tests (NAAT), such as the polymerase chain reaction (PCR) and other methods for amplifying DNA and RNA, facilitate rapid detection of microorganisms, particularly those difficult to culture. The high sensitivity of PCR is particularly useful in non-pulmonary tuberculosis where discharge of the organism is sporadic and present in small amounts (Manjunath et al, 1991). Multiple sampling is also necessary for this method. The PCR test has been extensively studied and has shown reliably high sensitivity, specificity, and rapid results. In various studies, data show sensitivity ranging from 87% to 95% (usually >90%) and specificity from 92% to 99.8% (usually >95%) as compared to culture. Staining for acid-fast bacilli, bladder biopsies, and intravenous pyelography (IVP) examinations all yielded inferior results (Hemal et al, 2000b; Moussa et al, 2000). Numerous commercial tests and kits are available with near-equivalent quality.

Table 16–1.

Interpretation of Tuberculin Test: ATS and CDC Guidelines

- *Five millimeters or more* of induration is considered positive in persons with the highest likelihood of developing active disease. These include patients with HIV infection, organ transplants, and immunosuppression (equivalent to taking more than 15 mg/day of prednisone for at least one month), as well as those having close contact with persons having active tuberculosis cases or radiographic findings consistent with old tuberculosis.
- *Ten millimeters or more* of induration is considered positive in those who do not meet the preceding criteria but who are at high risk for tuberculosis. These include HIV-negative injection drug users; residents and employees of high-risk congregate settings, such as prisons, nursing homes, health care facilities, residential facilities for persons with HIV/AIDS, drug treatment centers, and homeless shelters; laboratory personnel dealing with mycobacterial samples; recent (<5 years) immigrants from countries where tuberculosis is prevalent; persons with high-risk medical conditions, including silicosis, diabetes, chronic renal failure, leukemias and lymphomas, carcinoma of the head or neck and lung, more than 10% loss of ideal body weight, gastrectomy, and jejunoileal bypass; children under 4 years of age; infants, children, and adolescents exposed to high-risk adults; those with a recent (within 2 years) conversion of their skin test result; and any other locally identified high-prevalence population.
- Fifteen millimeters or more of induration is considered positive in anyone.

From American Thoracic Society and Centers for Disease Control and Prevention. Diagnostic standards and classification of tuberculosis in adults and children. Am J Respir Crit Care Med 2000;161(4 Pt. 1):1376–95.

Some caveats exist in the interpretation of NAAT results, because they are best used in conjunction with clinical judgment and TB cultures. Urine is known to have naturally occurring enzyme inhibitors in up to 10% of cases, which suppress the enzymatic reactions of DNA/RNA amplification (van Vollenhoven et al, 1996). This may result in false-negative tests (Moussa et al, 2000). It is thus important to corroborate with the laboratory that appropriate measures have been done to confirm a PCR result as negative rather than an inhibited reaction, especially in clinically suspicious cases. Moreover, NAA tests can amplify nucleic acids from dead organisms, thus yielding positive results even after effective chemotherapy. Thus they should be used for diagnosis only and not as a follow-up to treatment (ATS and CDC, 2000).

Rapid molecular testing for drug resistance is available by detecting resistance mutations in three *Mycobacterium* TB genes. Results are available in 1 to 2 days (Barnard et al, 2008).

Radiography and Endoscopy

A wide spectrum of imaging findings has been described. Though each finding is nonspecific, multiple findings are common and are collectively suggestive of tuberculosis.

Plain Radiograph

Plain radiographic findings in genitourinary tuberculosis may be seen in the GU tract, surrounding tissues, and up to 50% of patients may show positive findings on chest radiograph. Disparity in renal size on plain films may indicate early increase in size of the affected kidney due to caseous lesions or a shrunken fibrotic kidney of autonephrectomy. Calcifications are seen in 30% to 50%

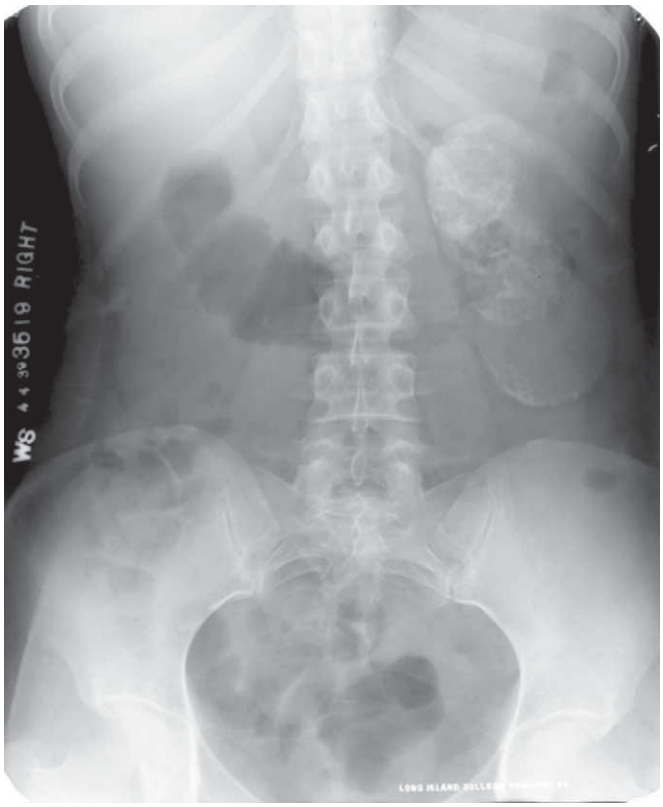

Figure 16–1. Kidney-ureter-bladder radiographic view in a patient with left renal tuberculosis with associated calcifications.

Figure 16–2. Occluded calyx.

of cases (Roylance et al, 1970). Focal calcifications occur within the caseating lesions (Fig. 16–1). A characteristic diffuse, uniform, extensive parenchymal, putty-like calcification, forming a lobar cast of the kidney is seen with autonephrectomy (Muttarak et al, 2005). Calculi may also be seen in the collecting system or ureter secondary to stricture formation. Ureteral calcifications are rare and are characteristically intraluminal as opposed to the mural calcifications of schistosomiasis. Bladder wall calcifications are not very common except in late cases of bladder contraction. Calcifications of the prostate and seminal vesicles are seen in 10% of cases (Burrill et al, 2007).

Plain film findings suggestive of tuberculosis may be seen in surrounding tissues such as erosions of the vertebral bodies or calcifications in a cold abscess of the psoas muscle (Burrill et al, 2007).

Intravenous Urography (IVU)

The majority of cases will show positive findings on excretory urography, the most common findings being hydrocalycosis, hydronephrosis, or hydroureter due to stricture formation (Wang et al, 2003). Early signs include the moth-eaten appearance of calyceal erosion and papillary irregularity. These signs are best seen on early excretory films, because they are often masked by increasing density of the contrast on later films of the IVU. Cavitary lesions communicating with the collecting system are characteristic of TB. These lesions eventually enlarge as parenchymal destruction ensues, and a picture similar to chronic pyelonephritis may be seen. Fibrotic distortion of the collecting system and ureter is also seen. Calyceal obliteration and amputation, hydrocalycosis, segmental or total hydronephrosis, and a shriveled reduced-capacity renal pelvis may all be signs of renal tuberculosis (Figs. 16–2 and 16–3). Scarring and angulation of the ureteropelvic

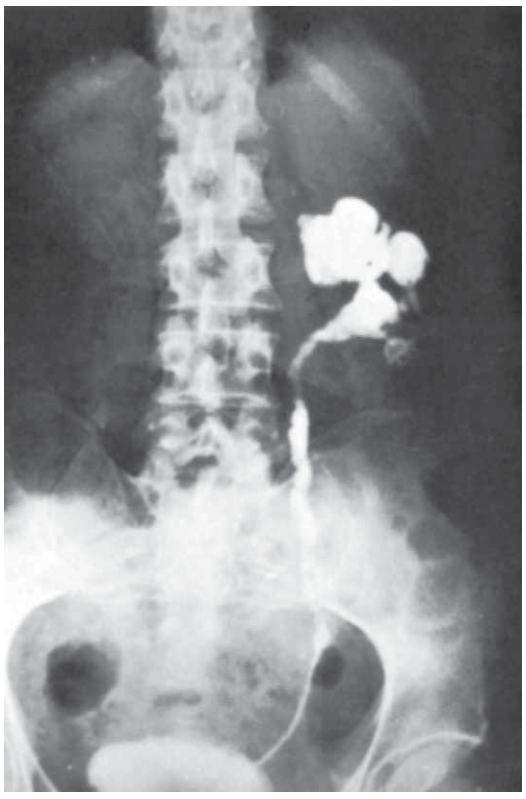

Figure 16–3. Severe calyceal and parenchymal destruction.

Figure 16–4. Stricture at the distal left ureter.

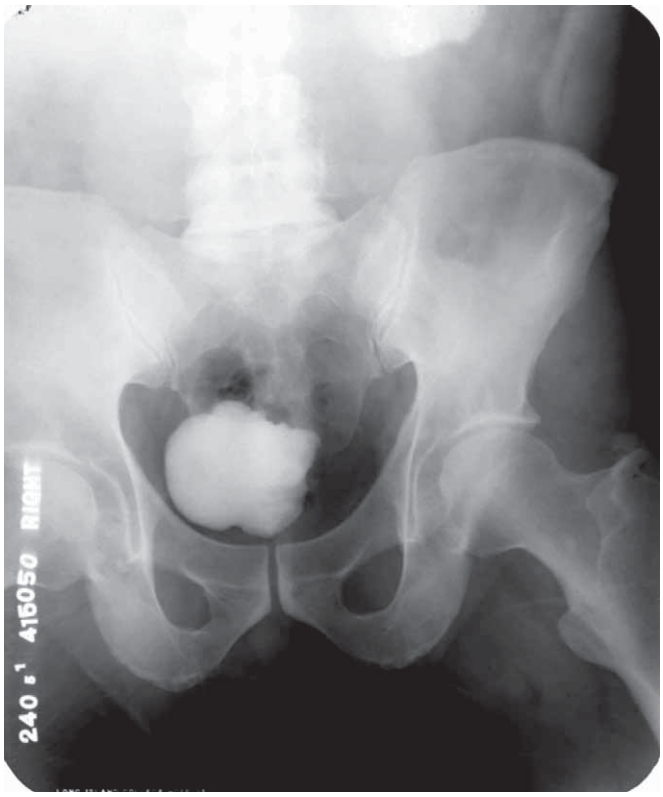

Figure 16–5. The cystogram portion of an intravenous pyelogram in a patient with left renal tuberculosis. Note the contracted left side of the bladder that is secondary to fibrosis from the tuberculosis.

junction (UPJ) may also occur, the so-called "Kerr's kink" (Matos et al, 2005). Ultimately diminished or absent function and extensive calcification may be seen with autonephrectomy. If nonvisualized on IVU, the kidney is best evaluated by computed tomography (CT) or ultrasonography.

Tuberculosis of the ureter is commonly seen as a rigid, straightened "pipe-stem" ureter. A beaded, corkscrew appearance is sometimes also seen. Ureterovesical junction obstruction is caused by tuberculous cystitis or strictures of the distal third of the ureter (Fig. 16–4). Secondary stone formation on top of this stricture is an occasional finding. The cystogram films may show a small contracted bladder due to excessive fibrosis (Fig. 16–5). Of note, although IVU is being phased out by CT-urography in many developed countries (Stacul et al, 2008), IVU continues to be a reliable imaging modality for genitourinary TB in most parts of the world.

Computed Tomography

The most common findings on contrast-enhanced CT include renal parenchymal masses and scarring, thick urinary tract walls (ureter and bladder) and extraurinary tubercular manifestations particularly in miliary TB (Wang et al, 2003). Coalescence of caseating granulomata may lead to a renal mass (tuberculoma), which must be differentiated from renal cell carcinoma. CT allows for evaluation of renal function, grading of hydronephrosis and parenchymal scarring (Fig. 16–6). CT is most sensitive in detecting renal calcifications (Premkumar, et al, 1987). Most CT findings are in themselves nonspecific, and the collective interpretation of multiple findings in conjunction with the clinical picture is the best option in decision making (Wang et al, 2003).

CT is also helpful in the diagnosis of adrenal tuberculosis, which may appear as bilaterally enlarged glands with areas of necrosis (caseation) early in the disease. Dotlike calcifications and atrophy of the adrenal gland are common late findings (Wang, et al, 1998).

Tuberculosis of the prostate or seminal vesicles may lead to calcification, caseation, and necrosis causing hypoattenuation or cavity formation that can be visualized on contrast-enhanced CT scan of the pelvis. However, in the absence of calcification,

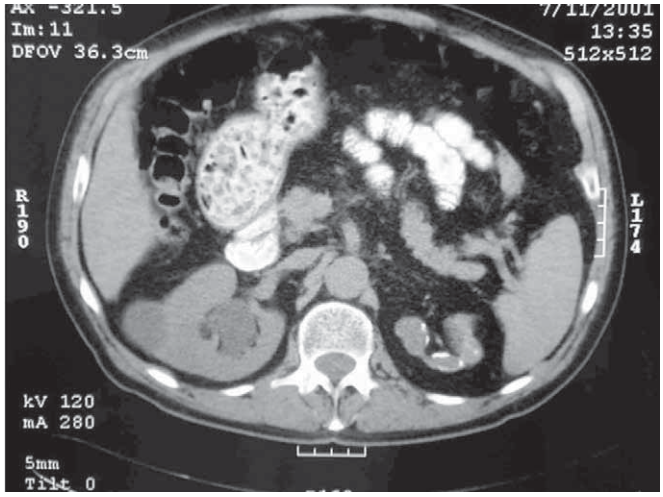

Figure 16–6. CT after oral contrast medium in a patient with bilateral tuberculosis. The right kidney is hydronephrotic secondary to infundibular stenosis but has retained good function. The left kidney is an end-stage nonfunctioning atrophic kidney with calcification.

tuberculous prostatic lesions may mimic a pyogenic abscess or carcinoma, especially that prostate-specific antigen (PSA) may be elevated in one third of cases (Lee et al, 2001). Needle biopsy may be needed in these cases.

Ultrasonography

Ultrasonography has a limited role in diagnosis because it provides nonspecific findings. However, it may be used to follow up cases

presenting with hydronephrosis during the course of treatment; fibrotic scarring during healing may lead to worsening of hydronephrosis, thus requiring surgical attention. Ultrasonography is useful in the demonstration of epididymal and testicular lesions. Transrectal ultrasonography may also show seminal vesicular and prostatic lesions. All findings are nonspecific and should be interpreted in light of the clinical picture.

Retrograde Pyelogram and Antegrade Pyelogram

Diagnosis using contrast studies by directly injecting a contrast medium, whether using endoscopy or percutaneous puncture, have largely been superseded by noninvasive imaging techniques such as CT urography and magnetic resonance imaging (MRI). The value of these modalities lies in the ability to obtain a urine sample from the upper tract, particularly where it is important to identify the affected side (as in surgical planning). Percutaneous puncture is particularly useful in cases where fibrosis has sealed the affected side, such that organisms are no longer discharged in urine. A ureteric stent or nephrostomy tube may be placed, at that time, to bypass a stricture or drain infected material in a septic patient.

Cystoscopy and Ureteroscopy

Endoscopy plays a limited role in the diagnosis of TB. Despite direct visualization of lesions, there are no pathognomonic findings that are specific for tuberculosis. Ulcerative lesions may mimic malignancy. A "golf-hole" ureteric orifice is suggestive of tuberculosis, and, when found, upper tract imaging or endoscopy should be obtained (Fig. 16–7). A positive urine culture or stain for acid-fast bacilli obviates the need for a biopsy, especially because it is diagnostic in only 18% to 45% of cases (Wong et al, 1984; Hemal et al, 2000b). However, a biopsy should be done when in doubt of malignancy.

Treatment

Successful treatment of genitourinary tuberculosis relies on the early diagnosis and the prompt initiation of an adequate drug regimen. Prior to successful antituberculous chemotherapy extirpative surgery was the initial form of treatment. Currently surgical treatment is reserved for advanced cases, often to correct the obstructive effects of fibrosis and scarring rather than the removal of infected tissues. Thus the balanced medical-surgical approach is ideally aimed at the preservation of renal (organ) function and eradication of mycobacteria. Despite standardized regimens and surgical indications, treatment must also be individualized; "No disease process is as atypical as a typical tuberculous process" (Cooper and Robinson, 1972).

Medical Therapy

On November 20, 1944, streptomycin was administered for the first time to a critically ill TB patient. His advanced disease was clearly arrested, and mycobacteria disappeared from his sputum. A succession of antimycobacterial agents rapidly appeared in the years that followed.

The principle underlying medical treatment is the effective eradication of the slowly dividing mycobacteria from tissues and urine. To understand the basis for modern-day multidrug regimens for tuberculosis, it is important to contemplate the following dilemma: Mycobacteria exist in several different environments in genitourinary tract TB. The largest population is the more actively dividing extracellular mycobacteria that exist within cavitary lesions, often at a neutral or alkaline pH. Another population exists in the intracellular acidic environment within macrophages. A smaller population of slowly dividing organisms can be found enclosed within caseous material at a neutral pH or freely in the acidic pH of urine (Dutt and Stead, 1982). The differential ability of various antimycobacterial drugs to penetrate tissues, inherent effects on the tubercle bacillus (bactericidal vs. bacteriostatic), and their levels of activity in the wide range of pH required to manage genitourinary TB (as discussed under the individual drugs below), dictates the use of a multidrug regimen. This is in addition to the standard principle of lowering the emergence of drug-resistant strains.

Genitourinary TB can safely be managed with short-course chemotherapy (Dutt et al, 1986; Small and Fujiwara, 2001). This treatment is effective because there are fewer organisms in genitourinary lesions; isonicotinic acid hydrazide (isoniazid, INH) and rifampicin have good penetration of lesions at lethal concentrations; and isoniazid, rifampicin, and pyrazinamide attain high concentrations in urine (Gow and Barbosa, 1984).

Classically, antimycobacterial regimens rely on a first line of drugs, namely, rifampicin, INH, pyrazinamide, and ethambutol. A second line of drugs is reserved for cases that fail to respond to first-line therapy or in drug-resistant cases. Finally, it is important to acknowledge the rising incidence of multidrug resistant (MDR-TB) and extensively drug resistant TB (XDRTB) infections, and the resultant implications for the drug regimens used (Johnston et al, 2009).

A standard treatment regimen for tuberculosis requires 6 months of therapy. The first 2 months involve three to four drugs: Rifampicin, isoniazid, and pyrazinamide are administered daily; ethambutol is added if drug resistance to isoniazid is suspected. An additional 4 months of rifampicin and isoniazid daily, twice per week, or three times per week are used (Small and Fujiwara, 2001). The intensive 2-month, three-drug regimen targets rapid multipliers, and the prolonged 4-month, two-drug regimen eradicates slow, sporadic multipliers and persistent bacteria. Directly observed therapy is often best to ensure patient compliance and completion of treatment.

It is important to obtain adequate specimens for culture and susceptibility testing before treatment is initiated. Ethambutol can be stopped if lack of resistance is demonstrated. Baseline measurements of hepatic enzymes, bilirubin, and creatinine, and a complete blood count with a platelet count, should be performed. During treatment, all patients should be monitored for adverse effects on a monthly basis. Routine follow-up of liver enzymes is important to detect hepatotoxicity of rifampicin. If pyrazinamide is used, uric acid levels should be measured, and if ethambutol is given, visual acuity and red-green color perception should be monitored (Small and Fujiwara, 2001) (Tables 16–2 and 16–3).

Antituberculous Drugs

Isoniazid

Isoniazid (INH) acts by inhibition of cell wall lipid synthesis, depletion of nucleic acid pools, and metabolic depression in mycobacteria (Timmins and Deretic, 2006). It penetrates caseous material and is active within the macrophages. INH is rapidly and completely absorbed orally; this may be slowed by food. It is widely distributed in the body, and tissue levels are similar to serum levels. Seventy percent of all administered INH is excreted by the kidneys, most in an inactive form. Dose modification in renal failure is usually not necessary but is recommended

Table 16–2.

First-Line Antituberculous Drugs

DRUG/FORMULATION	ADULT DOSAGE (DAILY)*	ADULT DOSAGE (INTERMITTENT)†	MAIN ADVERSE EFFECTS
Isoniazid (INH)‡ 100, 300 mg tabs 50 mg/5 mL syrup 100 mg/mL injection	5 mg/kg (max 300 mg) PO, IM, IV	15 mg/kg (max 300 mg) 2-3 times/week	Hepatic toxicity, peripheral neuropathy
Rifampin (Rifadin, Rimactane) 150, 300 mg caps 600 mg injection powder	10 mg/kg (max 600 mg) PO, IV	10 mg/kg (max 600 mg) 2-3 times/week	Hepatic toxicity, flulike syndrome, pruritus, drug interactions
Rifabutin§ (Mycobutin) 150 mg caps	5 mg/kg (max 300 mg) PO	5 mg/kg (max 300 mg) 2-3 times/week	Hepatic toxicity, flulike syndrome, uveitis, neutropenia, drug interactions
Rifapentine (Priftin) 150 mg tabs		10 mg/kg/wk PO (max 600 mg) continuation phase only	Similar to rifampin
Pyrazinamide 500 mg tabs	20-25 mg/kg PO	30-50 mg/kg 2-3 times/week (max 4 g); 3 times/week (max 3 g)	Arthralgias, hepatic toxicity, pruritus, rash, hyperuricemia, gastrointestinal upset
Ethambutol¶ (Myambutol) 100, 400 mg tabs	15-25 mg/kg PO	20-50 mg/kg 2-3 times/week (max 4 g); 3 times/week (max 2.4 g)	Decreased red-green color discrimination, decreased visual acuity, optic neuritis

*5 times/week regimen may be done with direct observed therapy.
†Intermittent therapy is started after a few weeks or months of daily treatment.
‡Pyridoxine, 25 to 50 mg, should be given to prevent neuropathy in malnourished or pregnant patients and those with HIV infection, alcoholism, or diabetes.
§For use with amprenavir, fosamprenavir, nelfinavir, or indinavir, the rifabutin dose is 150 mg/day or 300 mg two to three times a week. For use with atazanavir, ritonavir alone or combined with other protease inhibitors, and lopinavir/ritonavir, the rifabutin dose is further decreased to 150 mg every other day or three times weekly. For use with efavirenz, the rifabutin dose is increased to 450 to 600 mg/day or 600 mg two to three times weekly. Not recommended with saquinavir alone or delavirdine.
¶Some clinicians use 25 mg/kg/day during the first 1 or 2 months, or longer if organism is isoniazid resistant. Decrease dosage if renal function diminished.
From The Medical Letter. Drugs for tuberculosis. Treat Guidel Med Lett 2009;7(86):75–82; quiz 2 (after p. 82).

Table 16–3.

Some Second-Line Antituberculous Drugs

DRUG/FORMULATION	ADULT DOSAGE (DAILY)	MAIN ADVERSE EFFECTS
Streptomycin*	15 mg/kg IM, IV (max 1 g)	Vestibular and auditory toxicity, renal damage
Capreomycin (Capastat)	15 mg/kg IM, IV (max 1 g)	Auditory and vestibular toxicity, renal damage, electrolyte imbalance
Kanamycin (Kantrex and others)	15 mg/kg IM, IV (max 1 g)	Auditory toxicity, renal damage
Amikacin (Amikin)	15 mg/kg IM, IV (max 1 g)	Auditory toxicity, renal damage
Cycloserine† (Seromycin and others)	10-15 mg/kg in two doses (max 500 mg bid) PO	Psychiatric symptoms, seizures
Ethionamide (Trecator-SC)	15-20 mg/kg in two doses (max 500 mg bid) PO	Gastrointestinal and hepatic toxicity, hypothyroidism
Levofloxacin (Levaquin)	500-1000 mg PO, IV	Nausea, abdominal pain, restlessness, confusion, rash dysglycemia
Moxifloxacin (Avelox)	400 mg PO, IV	Nausea, abdominal pain, restlessness, confusion, rash dysglycemia
Aminosalicylic acid (PAS; Paser)	8-12 g in 2-3 doses PO	Gastrointestinal disturbance

*Streptomycin is generally given 5 to 7 times per week (15 mg/kg, or a maximum of 1 g per dose) for an initial 2- to 12-week period and then, if needed, two to three times per week (20 to 30 mg/kg, or a maximum of 1.5 g per dose). For patients >59 years old, dosage is reduced to 10 mg/kg/day (max 750 mg/day). Dosage should be decreased if renal function is diminished.
†Some authorities recommend pyridoxine, 50 mg, for every 250 mg of cycloserine to decrease the incidence of adverse neurologic effects.
From The Medical Letter. Drugs for tuberculosis. Treat Guidel Med Lett 2009;7(86):75–82; quiz 2 (after p. 82).

in hepatic failure, especially in persons who are slow hepatic acetylators.

INH is associated with hepatic toxicity in 10% to 20% of patients, usually in the form of asymptomatic elevations of transaminase levels. This occurs after 6 to 8 weeks of therapy and may normalize with continued INH treatment. Baseline liver function tests should be obtained, and INH should be stopped if the aminotransferase level triples or if symptoms suggestive of hepatitis develop (fatigue, nausea, anorexia), because severe hepatic necrosis has been reported. Peripheral neuropathy due to INH can be prevented by supplementation with pyridoxine (vitamin B_6) 20 to 50 mg/day. INH is an inhibitor of the hepatic cytochrome P-450

system; thus it increases serum levels of anticonvulsants, warfarin, benzodiazepines, haloperidol, theophylline, tacrolimus, and ketoconazole.

Rifampicin

Rifampicin acts by inhibiting the β-subunit–dependent DNA-directed RNA polymerase of mycobacteria, leading to suppression of DNA synthesis (Sousa et al, 2008). The drug is lipid soluble, enters macrophages, and is excreted in the urine.

Hepatotoxicity is the major adverse reaction to rifampicin. Liver failure requires a moderate reduction in dosage, but full doses can be given with renal insufficiency. Rifampicin decreases serum levels of digoxin, verapamil, diltiazem, warfarin, sulfonylureas, progestins, theophylline, diazepam, corticosteroids, and several other drugs.

Streptomycin

Streptomycin is an aminoglycoside and binds to the S12 protein of the 30S unit of the bacterial ribosome, interfering with bacterial protein synthesis. It penetrates the walls of tuberculous abscesses at lethal concentrations, even in caseous material, and is active mainly against extracellular tubercle bacilli because its penetration into cells is poor. High concentrations are obtained in the urine. Isolates resistant to streptomycin are not resistant to other aminoglycosides. It must be given intramuscularly because it is very poorly absorbed orally. Streptomycin is ototoxic, causing vertigo and hearing loss. It is also nephrotoxic. Toxicity is dose related, and the risk is increased in the elderly; dose adjustment according to renal function is necessary.

Pyrazinamide

Pyrazinamide is a derivative of nicotinamide. Its target and mechanism of action are not fully known. Being highly active at pH 5.5 makes it suitable for genitourinary tuberculosis. It is readily taken up by macrophages and is active in the acidic intracellular milieu against mycobacteria within lysosomes. Gastrointestinal disturbances, hepatotoxicity (in 1% to 5% of patients), arthralgias, and hyperuricemia are some of its side effects.

Ethambutol

Ethambutol halts mycobacterial cell wall synthesis by inhibition of arabinosyl transferases. It is active against *M. tuberculosis* strains resistant to INH and other commonly used antituberculous drugs. It is well absorbed after oral administration. Up to 80% is excreted in the urine as active unchanged drug; dosage should be reduced in renal failure. Ethambutol rarely causes retrobulbar neuritis and should be discontinued if ocular changes occur. Changes in visual acuity and red-green color perception are early findings, and these parameters should be tested at baseline and monthly therafter.

Corticosteroids

Steroids have a limited role in management of genitourinary TB. The general rational behind their use is lowering the host immune response that is responsible for the tissue destruction and subsequent scarring. In cases of severe acute tuberculous cystitis, steroids may reduce mucosal inflammation and improve symptoms. Of note, higher doses of oral steroids are needed because rifampicin will increase their hepatic metabolism.

Multidrug-Resistant TB

Drug-resistant tuberculosis is defined as *M. tuberculosis* that is resistant to one of the first-line antituberculosis drugs (isoniazid, rifampin, pyrazinamide, or ethambutol).

Multidrug-resistant tuberculosis (MDR-TB) refers to *M. tuberculosis* that is resistant to at least isoniazid *and* rifampin, and possibly additional chemotherapeutic agents.

Extensively drug-resistant tuberculosis (XDR-TB) refers to *M. tuberculosis* that is resistant to at least isoniazid and rifampin, and is additionally resistant to fluoroquinolones and either aminoglycosides (amikacin, kanamycin) or capreomycin, or both (Centers for Disease Control and Prevention [CDC], 2007). Typical MDR-tuberculosis regimens can consist of up to five drugs, used for a minimum of 18 months after culture conversion to negative. XDR tuberculosis requires individualized treatment based on drug-susceptibility testing of the particular organism (Rich and World Health Organization, 2006). Drug regimens combining linezolid with other companion drugs selected according to individual drug history, and tailored to the susceptibility results of each isolate, are currently being evaluated (Schecter et al, 2010).

Surgical Therapy

About 55% of patients with genitourinary TB will require surgical intervention. This rate is lower in areas where the disease is diagnosed early, while still asymptomatic. In developing countries, where the disease is diagnosed in late stages, often after examination of nephrectomy specimens, this rate maybe as high as 95% (Figueiredo et al, 2008). The role of surgery has changed in the era of effective antitubercular treatment. Surgical intervention compliments medical treatment in preservation and restoration of organ function. Ablative surgery is performed less commonly and should be considered carefully. The earlier diagnosis and chemotherapy have allowed reconstructive procedures to be performed more commonly today, even in advanced cases. Currently, more than half of surgeries performed for TB are reconstructive (Gupta et al, 2006). Moreover, surgical treatment is best carried out after an initial 3 to 6 weeks of medical treatment. This interval allows intense inflammatory changes to resolve and lesions to stabilize, permitting a better assessment of the extent of destruction, and hence doing the appropriate procedure. In the setting of obstruction and deteriorated kidney function, initiation of medical treatment can temporize definitive surgical intervention until renal function recovers, provided that measures are taken to relieve the obstruction (e.g., ureteric stenting or percutaneous nephrostomy).

Indications for surgical management follow broad lines: procedures to relieve obstruction and drain infected material, definitive local treatment, upper urinary tract reconstruction, lower urinary tract reconstruction, and surgery for genital TB.

Procedures to Relieve Obstruction

The prompt relief of obstruction is emergently required in cases of uremia or sepsis. Bilateral hydronephrosis or unilateral hydronephrosis of a solitary or functionally solitary kidney is often the cause of renal failure. Early ureteral stenting or percutaneous nephrostomy (PCN) for tuberculous ureteral strictures have been demonstrated to decrease the loss of renal function and increase the opportunity for later reconstructive surgery (Shin et al, 2002). In such cases, temporary and immediate drainage of hydronephrosis, preferably by retrograde ureteric stenting if possible, is required. An indwelling double J stent can be left until the patient's condition is optimized. Retrograde placement is successful in 41% of cases (Ramanathan et al, 1998). When this is not technically feasible, percutaneous puncture of the hydronephrotic kidney is done to pass an antegrade stent. If that also fails, a percutaneous tube is left until definitive management is done. In cases of

segmental hydronephrosis, more than one PCN may be required to achieve adequate drainage (Carl and Stark, 1997). It is important to understand that PCN placement must be followed by correcting the cause of obstruction. A tuberculous cutaneous fistula invariably develops if the PCN is simply removed. If the renal unit is deemed unsalvageable or shows no function, a nephrectomy is inevitable to prevent this complication. One pitfall to avoid during stent placement is the use of high-contrast injection pressures, because this may lead to possible dissemination of infection (Salem, 2008).

Nephrectomy

Upfront (primary) nephrectomy to remove an infected kidney or debride caseous tissue is no longer the preferred line of treatment of genitourinary TB in the era of modern antitubercular chemotherapy. Today, the decision for a nephrectomy is based upon the extent of renal parenchymal destruction and, more importantly, the function of the kidney (Ramanathan et al, 1998). The indications for nephrectomy have thus been reduced to the excision of a renal unit that is nonfunctioning despite adequate drainage and medical treatment (Gupta et al, 2006). Other indications include extensive parenchymal destruction involving the whole kidney associated with hypertension (Flechner and Gow, 1980). Coexisting renal carcinoma also mandates nephrectomy. The current paradigm implies that chemotherapy is sufficient to render lesions free of mycobacteria even in nonfunctioning kidneys. However, removal of a calcified nonfunctioning kidney may be curative in patients with persistent symptoms (predominantly those of cystitis), because up to 50% of cases may still discharge mycobacteria in urine despite adequate chemotherapy (Fischer and Flamm, 1990).

A standard lumbar incision provides adequate exposure sufficient to carry out the dissection and control of the kidney. Every effort should be taken to avoid inadvertent entry into the peritoneal or pleural cavities. It is often possible to preserve the adrenal gland. In rare cases, the perinephric fat may appear to have tubercles or caseous cavities. These should not be dissected from the kidney and should be removed with the specimen. Dense fibrosis, due to healing of such lesions after chemotherapy, is more commonly encountered in the perirenal tissues or surrounding the renal pedicle. Control of the renal artery and vein, separately, may be difficult in these cases, and the pedicle may be controlled in toto by suture ligation. Routine removal of the ureter is not necessary. Retroperitoneoscopic nephrectomy has been attempted successfully for tuberculous kidneys (Hemal et al, 2000a).

Partial Nephrectomy

Partial nephrectomy is permissible only where parenchymal destruction is clearly localized, such as a calcified polar cavitary lesion or localized lesions that progress to calcification despite 6 weeks of adequate chemotherapy. Early localized lesions are adequately managed by medical treatment. It is prudent to ensure that no obstruction is present at the level of the renal pelvis or ureter to avoid tuberculous fistula formation.

Ureteropelvic and Ureteral Surgery

Strictures of the UPJ and ureter may be temporarily stented, as mentioned above, to allow improvement of renal function, after which a definitive decision on the appropriate management of the stricture is made. Upper and midureteric strictures are rare and may be amenable to endourologic treatment. Lower ureteric strictures are the commonest form and will often require surgical intervention. Additionally, the length of a stricture, whether it is passable or not, and renal function are important factors to be considered.

Endoscopic Management. Several options are available for the endourologic management of ureteric strictures. Tuberculous ureteric strictures are characterized by mucosal ischemia and dense fibrosis. Hence, success rates of endoscopic management of strictures due to other etiologies may not necessarily apply to TB strictures. Generally, short, passable strictures, with good renal function yield the best endoscopic outcome.

Strictures forming during medical treatment and managed by early stenting (double J placement) have been shown to stabilize and require no further treatment (Shin et al, 2002). Balloon dilatation by retrograde or antegrade access has been described for TB strictures of the ureter, UPJ, and calyceal infundibula (Murphy et al, 1982; Kim et al, 1993). A stent is left after dilatation. Due to high failure rates, repeated procedures are needed.

Follow-up of all cases of ureteric strictures by imaging (ultrasonography or IVU), especially those managed endoscopically, is needed because some strictures will worsen during the healing process due to fibrosis and cicatrization. Corticosteroids may be added if deterioration is detected. Consequently, up to 72% of cases will show relief of obstruction (Horne and Tulloch, 1975), and stent placement, if still needed, is often possible at this time. Failure to respond or progression after 6 weeks is an indication for definitive management.

Surgical Options. Long, complex strictures require surgical repair. It must be kept in mind that due to loss of elasticity, fibrosis, and reduced vascularity, mobilization of structures may be difficult, and thus the surgeon should be open to alternative options.

Repair of the ureteropelvic junction scarring is more challenging in TB cases than for congenital stenosis. The choice of procedure largely depends on the degree of scarring and contraction of the pelvis. Dismembered pyeloplasty is feasible for extrarenal pelvis with short segment scarring. Nondismembered (flap) pyeloplasty is preferred for longer strictures, but may not be feasible due to excessive scarring of the pelvis. When anatomic reconstruction is not possible, ureterocalicostomy (ureter to the lower pole calyx) is an option. It is important to cover the exposed lower pole parenchyma (using preserved capsule or omentum) to avoid fibrosis and constriction around the anastomosis (Carl and Stark, 1997).

Upper and middle ureteric strictures can be managed by excision of the diseased segment and, with adequate mobilization, a primary tension-free ureteroureterostomy can be performed if endourologic management has failed. Alternatively, lysis of adhesions and intubation (Davis intubated ureterotomy) may be done.

Lower ureter strictures requiring surgery are best managed by complete excision of the entire affected ureteric segment back to healthy ureteric mucosa having good blood supply. Affection of the bladder around the ureteric orifice is also common, and the area of anastomosis must also be healthy. The main focus then becomes to bridge the resultant gap with a tension-free, well-vascularized anastomotic technique. An array of ureteroneocystostomy procedures exist to bring the bladder closer to the ureteric end. Salient points are discussed briefly here; surgical details can be found under ureteroneocystostomy. Simple mobilization of the lateral attachments of the bladder on the contralateral side, accompanied by dividing the superior vesical artery, may provide 2 to 3 cm of length to bridge a small gap. In patients with good bladder capacity, a psoas hitch may also be performed. The genitofemoral and femoral nerves are close in the vicinity, and care must be taken to avoid their injury when placing these sutures. A well-performed psoas hitch can bridge a gap of up to 5 cm.

Constructing a Boari flap is another method of bridging a longer gap of up to 10 cm, and may also be performed in combination with a psoas hitch. It is important to note that a poorly executed Boari flap can compromise bladder capacity. In addition, small or contracted fibrotic bladders of tuberculous cystitis may not have sufficient wall area to allow flap creation. Finally, ileal interposition (ileal ureteric replacement) can be done in cases of multiple or recurrent strictures, where the native ureter is no longer an adequate conduit.

Bladder Surgery

Augmentation cystoplasty and bladder substitution are options in the management of the tuberculous contracted bladder. A capacity of less than 100 mL is commonly the indication to augment. Extremely contracted bladders (thimble bladders of 20 mL capacity) are best managed by orthotopic bladder substitution (Hemal and Aron, 1999). Various bowel segments have been used, and the general rules of incorporating the bowel into the urinary tract apply, such as thoroughly evaluating renal functions, reconfiguring a low pressure reservoir (de Figueiredo et al, 2006), patient education, and long-term follow-up.

Prostate and Urethra

Bladder neck contracture or severe granulomatous prostatitis is best managed endoscopically by transurethral incision of the contracture or resection of the prostate. A tuberculous prostatic abscess can be managed by transurethral drainage or aspiration with ultrasound guidance.

Urethral strictures may also be managed endoscopically and will often require repeated procedures. Tuberculous urethral fistulae are best managed by initiation of medical therapy and suprapubic bladder drainage. Delayed reconstruction is preferred.

Drainage of a seminal vesicle TB cavity into the bladder by cold knife incision has been reported (Dewani et al, 2006).

Genital TB

Surgery is considered only for established male genital tuberculosis when symptoms have failed to respond to chemotherapy and for nonresolving caseating abscesses. Surgical options involve excision of the diseased tissue. Involvement of the epididymis without clear affection of the testis is often the case, and every effort should be made to perform an epididymectomy rather than excision of the testis. Preserving testicular blood supply is important during the tedious dissection of the epididymis. Initiating dissection at the globus minor after ligation of the vas facilitates excision. If testicular involvement is evident, a scrotal orchiectomy is done. Involvement of the vas deferens by TB is usually distal to the external ring and ligation of at the level of the ring is possible and sufficient.

Management of Genitourinary TB in Special Situations

Pregnancy and Lactation

Females of the childbearing age should be advised to avoid pregnancy while on antituberculous treatment. If the diagnosis is discovered during pregnancy, prompt treatment is initiated because risks to the fetus from TB outweigh the risk of adverse drug effects. Pregnancy is allowed to continue, and a drug regimen consisting of isoniazid, ethambutol, and rifampicin, in addition to pyridoxine supplements, is started and should continue for 9 months.

During lactation, pyridoxine should be given while on isoniazid because this drug is significantly excreted in breast milk. Ethambutol is sparsely excreted in milk, and risk of ocular toxicity is rare.

HIV Infection

Patients diagnosed with TB should be tested for HIV infection. HIV-positive individuals with recent contact with a TB case should receive empiric treatment of latent TB, regardless of screening test results. Patients on maintenance treatment for active TB should be placed on daily or three times a week regimens rather than weekly regimens to avoid the emergence of drug-resistant strains, particularly in patients with CD4 counts <100 cells/mm^3 (Nettles et al, 2004). Treatment should continue for a minimum of 9 months. Drug interactions with components of a highly active antiretroviral (HAART) regimen should be taken into consideration. Rifampicin may decrease the serum levels of HAART drugs to possibly ineffective levels. Dose increases may be needed to compensate for this effect.

Renal Transplant Recipients

Tuberculosis should be considered in the differential evaluation of a recipient with unexplained fever and constitutional manifestations. The risk is highest in recipients born in or who live in endemic areas, and the peak incidence occurs during the first year after transplantation (el-Agroudy et al, 2003). Urinary tract involvement occurs in up to 50% of cases. PPD skin testing may be falsely negative in 70% of cases due to anergy. A repeat test after one week may increase the diagnostic yield by 10%. Thus PCR analysis, or DNA probing, of urine is the recommended method of detection. Rejection may also complicate the presentation of allograft tuberculosis.

PPD-positive patients in pretransplantation evaluation should receive isoniazid prophylaxis for at least 6 months. Four drug regimens are used for treatment, which typically lasts for 18 months. Rifampicin induces the hepatic P-450 microsomal enzyme and may substantially decrease serum levels of cyclosporine, tacrolimus, and prednisolone below therapeutic levels, necessitating dose increases and frequent monitoring of serum drug levels. Rifampicin-free regimens have also been used (Khaira et al, 2009).

Renal Failure

Renal failure patients, particularly those on chronic dialysis, have a markedly increased risk for TB. Early diagnosis prevents a high mortality associated with this presentation (Hussein et al, 2003). Most antitubercular drugs need dose adjustments in the presence of various degrees of renal failure and in patients on hemodialysis and chronic ambulatory peritoneal dialysis. Reference should be made to dosing methods (interval increase or dose reduction) and clearance on dialysis of each drug.

PARASITIC DISEASES OF THE GENITOURINARY SYSTEM

Parasitic diseases remain a significant health problem, especially in resource-poor countries. The human urogenital tract is typically only affected by a few species of parasites (Richens, 2004; Kehinde, 2008). This chapter will discuss in detail *Schistosoma haematobium*, a blood trematode that causes severe genitourinary tract disease, and the filarial helminth infections of the generas *Wuchereria*, *Brugia*, and *Onchocerca*, which may result in hydrocele, chyluria, funiculoepididymitis, and genital elephentiatis. Involvement of the genitourinary tract by other parasites (except sexually

transmitted protozoa) is either subordinate to systemic manifestations or rare.

Billions of people harbor parasites, yet symptomatic infections are substantially less common. Parasitic infection does not always result in parasitic disease, depending on the intensity and duration of infection, as well as the contributing sequelae of inflammatory responses to the presence of parasites and/or their biologic products.

Increasing international travel, globalization of the economy, and jet travel increasingly results in uncommon and tropical diseases presenting in the offices of physicians far from endemic areas. The most important requirement for recognition of parasitic infections is awareness, based on knowledge of common clinical presentations, pathogenesis, and geographic distribution of parasitic diseases. The importance of careful history-taking should include questions of recent and remote travel. Additional probing can assist in establishing the likelihood of specific parasitic infections. Helpful cogent information on parasitic infections is available from the Centers for Disease Control and Prevention at www.dpd.cdc.gov/dpdx/. One of the best available resources for current knowledge on available drug therapies for parasitic infections is available from The Medical Letter (2010) (www.themedicalletter.com).

Urinary Schistosomiasis

History

Schistosomiasis is a chronic infection caused by the digentic parasitic trematodes of the genus *Schistosoma*. Human infection begins with free-swimming cercariae penetrating the skin and eventual development of the adult male and female worms. The threadlike female schistosome lies within a cleft in the body of the male worm, remaining in a state of permanent copulo for many years. The paired adult worms reside in the venous plexuses of the abdominal viscera. *S. mansoni* and *S. japonicum* reside in the mesenteric veins, leading to gastrointestinal and/or hepatic disease, while *S. haematobium* dwells principally in the perivesical venous plexus, resulting in urinary schistosomiasis.

Urinary schistosomiasis has been a scourge of the Middle East and Africa for millennia and remains a major cause of morbidity and mortality in these areas. Egyptian physicians of the twelfth dynasty (1900 BC) recognized hematuria as the cardinal sign and symptom of this disease. Theodore Bilharz, a German pathologist working in Cairo in 1852, first described worm pairs in mesenteric veins at autopsy and linked these to eggs found in human excreta.

Biology and Life Cycle

The life cycle of *S. haematobium* is outlined in Fig. 16–8 (King, 2006). The male and female worm pair and attach to the blood vessel endothelia, producing and depositing 200 to 500 eggs per day. The estimated common life span of 3 to 6 years (Butterworth et al, 1988) means a single worm pair can produce 250,000 to 600,000 eggs. Rare cases of long-lived worm pairs, of up to 30 years, are capable of inducing greater pathology (De Gentile et al, 1988).

According to experimental data, the majority of eggs microembolize in the microvasculature of the lungs, liver, and other sites (Cheever and Anderson, 1971), while 20% of the eggs cross into the lumina of the hollow viscera near the adult pair. Hence, for *S. haematobium* the eggs are predominantly excreted in the urine with some finding their way into the feces. The eggs entrapped in tissue become calcified and accumulate in the viscera at a rate of 90 to 100 per worm pair per day (Cheever et al, 1977). These eggs are destroyed by the host gramulomitis immune response which may result in clinical morbidity and possible mortality.

S. haematobium eggs measure 80 to 150 μm, are ovoid, and have a small spine at their terminal end. This differentiates them from the laterally spined *S. mansoni* eggs. *S. chyponecum* has a tiny lateral spine. The only other schistosome that is pathogenic for humans and has a terminally spined egg, *S. interculotum*, is rarely seen outside limited foci in the Republic of Congo, Gabon, and Cameroon (WHO, 1993). Diagnostic terminally spined eggs can be found in the urine, feces, or human tissue especially intestinal or bladder wall biopsy. Due to the ongoing nature of infection and egg production, all egg stages are seen during active infection. Once the infection is treated, only degenerated or calcified eggs can be found.

If viable eggs are placed in fresh water, the miracidia emerge as short-lived ciliated larvae that swim to seek intermediate snail hosts. For *S. haematobium* snails of the *Bulinus* species (Ross et al, 2002) can perpetuate the life cycle. The miracidia migrate through tissues and then transform into successive generations of sporocysts. An amplification cascade finds each miracidium developing into a sporocyst, which produces 20 to 40 daughter sporocysts, which each in turn produce 200 to 400 cercariae. The cercariae escape the daughter sporocyst, migrate to the snail surface, and emerge into the surrounding fresh water. This enormous asexual multiplication from a single miracidium to 10^5 cercariae compensates for the attrition during aquatic parts of the life cycle. The cercariae must penetrate unbroken skin of appropriate hosts within a few hours or they die. For *S. haematobium*, the developmental process from cercarial body to schistosomulum to adult pair may require 80 to 110 days.

Epidemiology

Of the 200 million persons afflicted with schistosomiasis, 80 to 90 million are infected with *S. haematobium* (Mahmoud and Abdel Wahab, 1990; WHO, 1998, 2002; Engels et al, 2002), and as many as 10 to 40 million have obstructive uropathy or other complications secondary to this parasitic disease. Transmission of *S. haematobium* occurs in many countries in the Middle East and in most of the African continent. In Southwest Asia, the disease is found in Southern Yemen, Yemen, Saudi Arabia, Lebanon, Syria, Turkey, Iraq, and Iran (WHO, 1998).

Clinical and autopsy studies have demonstrated a correlation between the prevalence of infection and its intensity with levels of egg excretion or tissue egg burden (Smith et al, 1974b). The tissue egg burden is related to the severity of the disease and to the frequency of complications. Autopsy studies have shown that severe urinary pathology is uncommon when the frequency of infection in a population is less than 30%, but increases linearly after this threshold is exceeded (Cheever et al, 1978).

Pathogenesis and Pathology

Schistosomal disease results directly from the granulomatous host response to schistosome eggs (Phillips and Colley, 1978; Cheever et al, 1985; Waine and McManus, 1997). During ongoing human infections all stages of granulomas are simultaneously present; whereas, in treated or burned-out infection the granulomas are uniform (Cheever et al, 1985). Four factors contribute to this spectrum of significant disease related to *S. haematobium*: intensity, duration, activity, and focality. These factors also determine the morbidity, mortality, and treatment of urinary schistosomiasis.

Though *S. haematobium* adult worm pairs are widely distributed in the pelvic venous plexuses, egg-laying occurs mainly in the lower urinary tract, the site of pathologic manifestations (Cheever

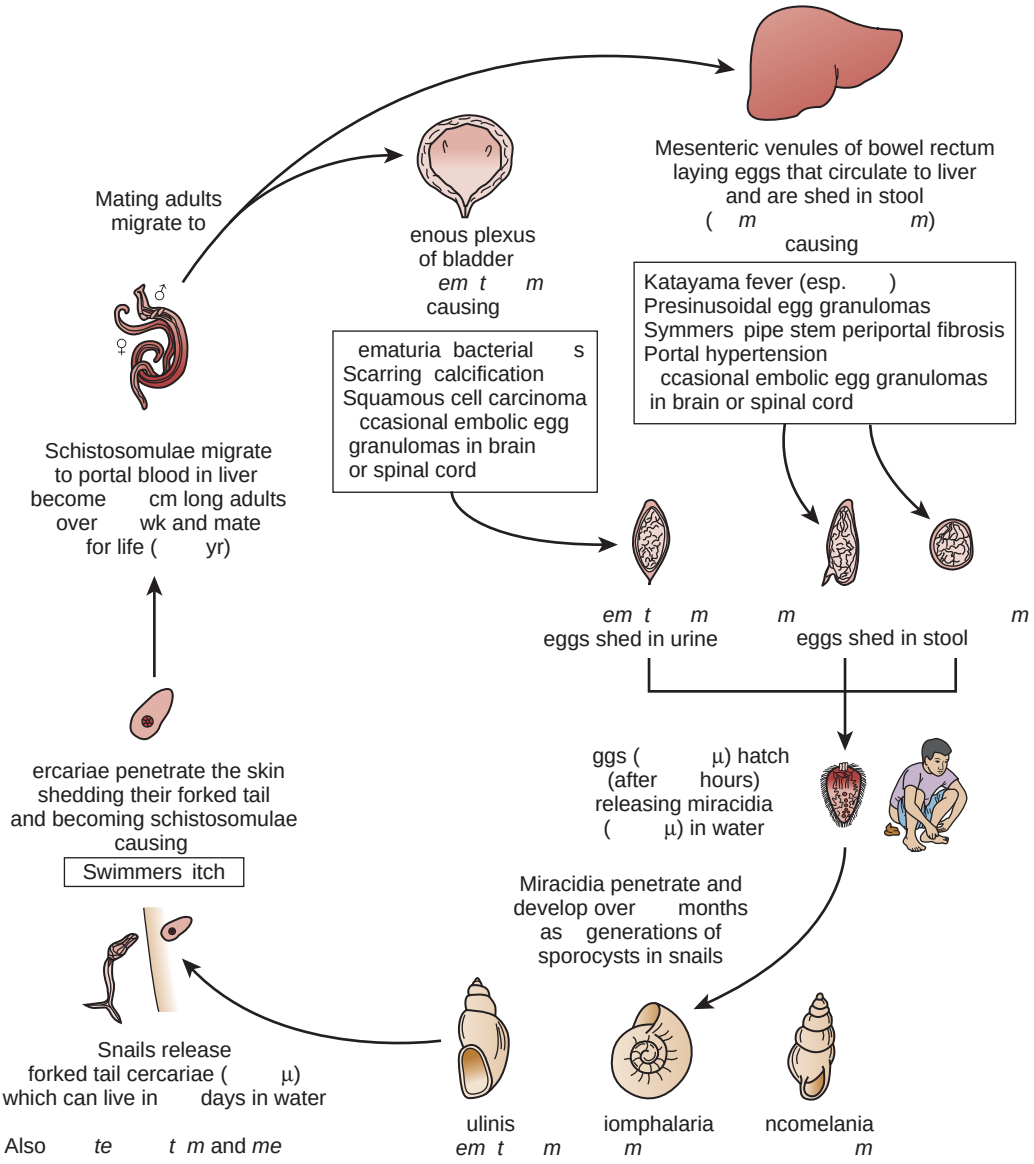

Figure 16–8. Life cycle of a schistosome. UTIs, urinary tract infections. (From King CH. Schistosomiasis. In: Guerrant RL, Walker DH, Weller PF, editors. Tropical infectious diseases, principals, pathogens, and practice. 2nd ed. Philadelphia: Elsevier Churchill Livingstone; 2006. p. 1341–8.)

et al, 1977). It is typical to see composite granulomas in tissue rather than a small single granuloma, because *S. haematobium* eggs are deposited in groups more often than singly. Even though *S. mansoni* may lay eggs in the lower urinary tract, no lesions have been ascribed solely to *S. mansoni* (Cheever et al, 1978).

The immune response to *S. haematobium* is complex and multifaceted. The embolized eggs induce a vigorous eosinophilic and granulomatous immune response. Significant cellular and humoral host responses develop (Phillips and Colley, 1978; Butterworth, 1993; Mwatha et al, 1998; De Jesus et al, 2002; Pearce and MacDonald, 2002; Leutscher et al, 2005). These immune responses partially abrogate (but do not eliminate) subsequent reinfection in human hosts (Hagan et al, 1985, 1987, 1991; Woolhouse et al, 1991). Areas of the world endemic for schistosomiasis often have very high rates of HIV coinfection. Egg excretion in HIV-seronegative persons is significantly higher than HIV-seropositive individuals, though circulating schistosomal antigen levels are similar (Karanja et al, 1997). These observations are compatible with the hypothesis that the transit of schistosome eggs through the tissue is facilitated by a competent immune system.

Microscopic examination of tissue shows polypoid patches consisting of scattered and massed composite granulomas separated by edematous granulation tissue diffusely infiltrated by eosinophils, lymphocytes, and plasma cells. On gross examination, the areas of granulomatous inflammation result in large, bulky, hyperemic, and polypoid masses projecting into the lumen (Fig. 16–9). In the active stage of disease, schistosomiasis is characterized by multiple large inflammatory polyps related to the heavy localized egg burden (Smith et al, 1977c). In the endemic areas, these polypoid patches occur mainly in children through their early teens. However, up to 60% of urinary bladder polypoid lesions in patients with schistosomiasis result from conditions other than schistosomiasis, such as polypoid cystitis (Smith et al, 1974a).

Inactive urinary schistosomiasis, occurs after adult worms have died, and is characterized by the absence of viable eggs in tissue or urine and the presence of "sandy patches"—relatively flat, tan

Figure 16–9. Intravenous urogram in an Egyptian boy shows scalloping of the bladder and right lower ureter by schistosomal polypoid lesions.

mucosal lesions of various depth, with somewhat ill-defined borders (Fig. 16–10). These patches are formed as the inflammation associated with active egg-laying wanes. The remaining entrapped eggs are destroyed or calcified and the tissues undergo fibrotic reaction, which is the histologic characterization of the sandy-patch lesions. Urinary excretion of dead or calcified eggs is rare. However, the bladder may contain a sufficient number of calcified eggs to result in a thin outline of the bladder on plain radiographs.

The clinical pathology of chronic schistosomiasis is often the development of obstructive uropathy. There are two components to schistosomal obstructive uropathy: obstruction and its effect on the proximal ureter. Schistosomal obstructive uropathy is usually asymmetric (Smith et al, 1974a). The location of the obstruction varies from the urethral meatus (1%), interstitial ureter (10% to 30%), juxtavesical ureter (20% to 60%), lower third of the ureter (15% to 50%), or a contiguous combination of these areas (30% to 60%) (Gelfand, 1948; Smith et al, 1977b; Al-Shukri and Alwan, 1983). Three types of hydroureter are associated with obstructive schistosomiasis: segmental (i.e., cylindrical or fusiform), tonic, and atonic (Smith et al, 1977b). Approximately 25% of obstructive uropathy cases involve segmental ureteral dilation, with 80% of those cases occurring in the lower ureter. The dilations occur above areas of concentric ureteral muscular obliteration associated with fibrosis and sandy patches. It is rare for segmental lesions to cause significant hydronephrosis. Up to 30% of obstructive uropathy is due to tonic hydroureter. This is characterized by dilated, tortuous, thick-walled, and trabeculated ureters with marked ureteral muscular hypertrophy and decreased peristaltic action. Typically, the entire ureter proximal to an obstructive lesion is involved, creating a functional stenosis. This is usually accompanied by significant hydronephrosis, which is reversible if the obstruction is relieved (Smith et al, 1977b). Atonic hydroureters are found in the remaining patients with schistosomal obstructive uropathy. This form is characterized by markedly dilated, very tortuous, thin-walled ureters, without peristalsis and associated with atrophic fibrotic ureteral muscle.

Hydroureter usually precedes hydronephrosis (Lehman et al, 1973; Smith et al, 1974a, 1977b; Cheever et al, 1978). Left untreated, schistosomal hydronephrosis advances from progressive renal pelvic dilation to medullary atrophy to near total medullary effacement before cortical atrophy ensues (Smith et al, 1974a, 1977b). This specific pathophysiology explains the abrogation of tubular function (especially maximal urine concentration) before compromise of glomerular function (Lehman et al, 1971, 1973).

Bladder cancer is the final pathologic sequela of schistosomiasis. Linkage between urinary schistosomiasis and the development of bladder cancer has been postulated since the end of the nineteenth century. Bladder cancer in the setting of *S. haematobium* has an early onset (40 to 50 years) and a high frequency of squamous cell carcinomas (60% to 90%), with 5% to 15% adenocarcinomas (Cheever, 1978; Lucas, 1982; Al-Shukri et al, 1987; Thomas et al, 1990; Bedwani et al, 1998). More than 40% of schistosomiasis-associated squamous cell carcinomas of the bladder are well-differentiated or verrucous carcinomas that are exophytic and carry an overall good prognosis. Tumors are found on the posterior wall about 50% of the time and on the lateral wall roughly 30% of the time. Exophytic tumors constitute about two thirds of schistosomal bladder cancers, while one third are ulcerative endophytic tumors. Mass schistosomiasis treatment campaigns in Egypt are associated with an overall reduction of all bladder cancers (27.6% to 11.7%) and a shift to more transitional cell carcinoma from squamous cell carcinoma (Gouda et al, 2007). Although less frequent transitional cell carcinomas of the bladder are associated with *S. haematobium* infection (Michaud, 2007), some epidemiologists feel the relatively high rate of smoking in this region may increase the risk of bladder cancer. Notably, however, some unselected autopsy series from the same regions have shown similar frequencies of bladder cancers in patients without schistosomiasis (Smith et al, 1977a; Cheever et al, 1978).

Clinical Manifestations

Acute Schistosomiasis. Acute schistosomiasis is also referred to as Katayama fever, rarely found among endemic populations. First coined about *S. japonicum* infection, it refers to a first, and presumably heavy, exposure of a noninfected individual that leads to fever, lymphadenopathy, splenomegaly, eosinophilia, urticaria, and other manifestations of a serum sickness–like disease (Doherty et al, 1996; De Jesus et al, 2002). This presentation is relatively rare in *S. haematobium* and more common in *S. japonicum,* which is probably the result of the significantly greater egg fecundity of *S. japonicum*. Acute schistosomiasis generally occurs 3 to 9 weeks after infection, coinciding with the onset of egg-laying, but may be delayed for up to 4 months (Young et al, 1986). Of note, this symptomatic phase often precedes the occurrence of eggs in the urine. Hematuria is the first sign of established *S. haematobium* infection, often appearing 10 to 12 weeks after infection (Kehinde et al, 2008).

Acute schistosomiasis is rarely associated with atopic egg-laying because worms meander toward the pelvic venous plexuses and become delayed or lost. These ectopic eggs incite an intense granulomatous inflammatory reaction in aberrant sites such as the skin (Edington et al, 1975), epididymis (Elem et al, 1989), or spinal cord or nerve roots or both (Pitella, 1997).

Chronic Schistosomiasis. Chronic schistosomiasis is far more common than acute disease and has several different clinical

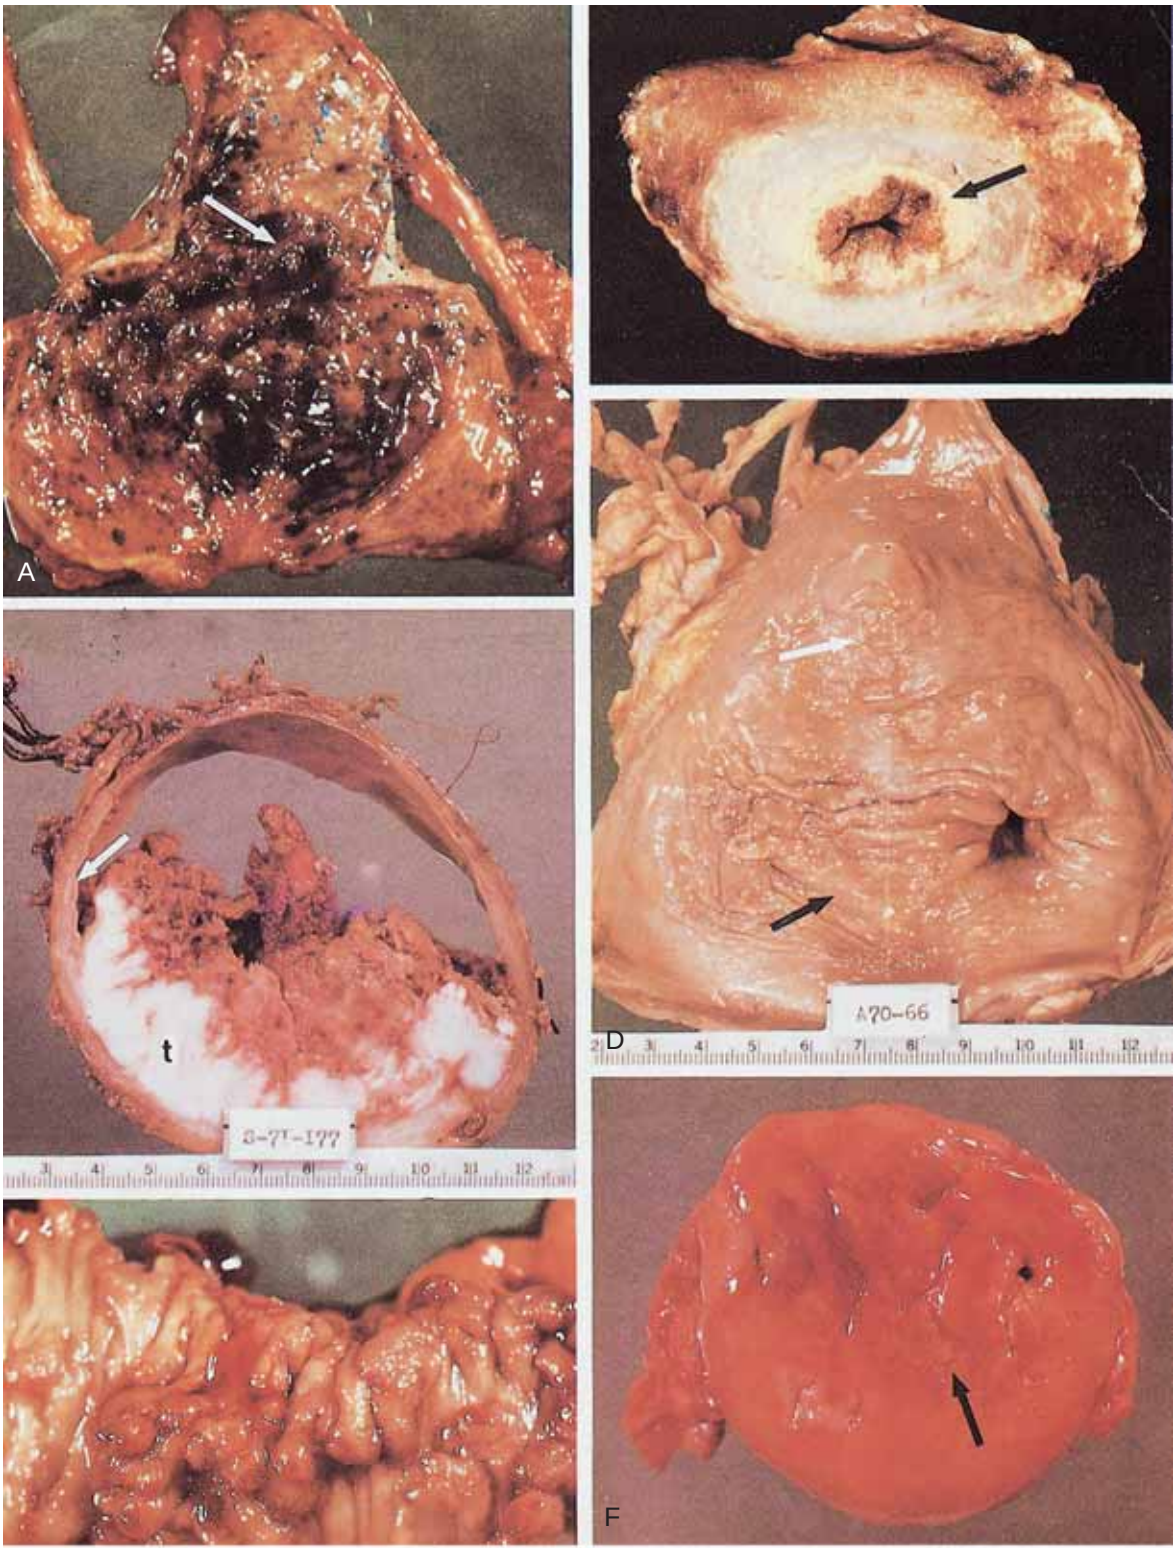

Figure 16–10. Macroscopic appearance of human urinary schistosomiasis. **A,** Urinary bladder opened with an anterior Y incision. The posterior and apical walls have many erythematous, granular, sessile, and pedunculated polyps *(arrow),* characteristic of the early active stage of urinary schistosomiasis. **B,** Coronal section through the apex of a formalin-fixed urinary bladder. The lamina propria has been expanded and is replaced by a yellow-tan, finely granular, sandy patch *(arrow),* which is characteristic of chronic inactive foci. Small sandy patches are sprinkled through the fibrotic, atrophic detrusor muscle, even in perivesical fat. The more superficial erythematous portion of the lamina propria contains some viable eggs with granulomatous response (chronic active stage of urinary schistosomiasis). **C,** Coronal section through the middle of a urinary bladder after formalin inflation and fixation. The lamina propria *(arrow)* has been replaced by a concentric sandy patch, most prominent at the margin of the exophytic, moderately differentiated squamous cell carcinoma. The bladder wall is attenuated except for the tumor (*t*). No evidence of recent oviposition was found in the lower urinary tract (chronic inactive stage of urinary schistosomiasis, usually found with the bilharzial bladder cancer syndrome). **D,** Urinary bladder opened with anterior Y incision shows several features of severe chronic inactive urinary schistosomiasis. The entire lamina propria has been replaced by a sandy patch. Foci of epidermization are seen at or near the *white arrow*. The left ureteral orifice *(right)* is markedly dilated (the so-called golf-hole ureter of schistosomal uropathy). The right ureteral orifice *(point of black arrow)* is markedly stenotic. **E,** Rectosigmoid colon with polyposis. Numerous sessile and pedunculated polyps are seen. Many are erythematous, indicative of active oviposition with granuloma formation. Some have necrotic hemorrhagic tips. **F,** Mucosal surface of partial cystectomy specimen (4- to 5-cm ellipse) from a patient with the chronic inactive stage of the disease. There is a stellate chronic schistosomal ulcer. Despite the inactivity of the disease, these ulcers may bleed profusely. Pale mucoid flecks at the margin of the ulcer *(arrow)* are areas of adenoid (goblet cell) metaplasia.

manifestations. The prepatent period, between penetration of the cercariae and onset of egg deposition in the tissues, is usually 2 to 3 months but may last more than 7 months (Young et al, 1986). The most typical presentation of active schistosomiasis is hematuria with terminal dysuria. This hematuria can be sufficient to induce anemia (Wilkins et al, 1985). Some patients develop early polypoid lesions of the bladder that result in urethral or ureteral obstruction or develop heavy bleeding, enough to produce clot retention. Because water contact is essentially universal, active schistosomiasis usually begins in childhood. In some cultures, hematuria in males may be seen as a sign of puberty. In this active infection stage, eggs are deposited in the tissues, traverse the bladder or rectosigmoid mucosa, and are excreted in the urine (or less commonly in the feces). This provides an opportunity for diagnosis.

S. haematobium egg burdens of the seminal vesicles and the ejaculatory ducts are high, and either blood and schistosome eggs or both may appear in the ejaculate before they appear in the urine. Patients with involvement of these genitourinary structures often present with scrotal pain or a testicular mass. Egg burdens of the uterus, vagina, and testes are lower than those of the epididymis, ovaries, and fallopian tubes (Cheever et al, 1977, 1978; Helling-Giese et al, 1996).

S. haematobium causes genital disease in 30% of infected women (Poggensee and Feldmeier, 2001; Kjetland et al, 2005). Schistosomal cervicitis and vaginitis may be asymptomatic or have clinical manifestations similar to cervicitis and vaginitis due to other causes (Williams, 1967). A routine Papanicolaou smear may reveal diagnostic eggs of *S. haematobium* infection. Similar to other ulcerating sexually transmitted infections, schistosomal lesions of the vagina and cervix may predispose patients to the acquisition of HIV infection (Feldmeier et al, 1994). Histologic evaluation of the placenta and amniotic fluid at term has shown schistosome eggs in these structures, but there are no documented reports of fetal schistosomiasis.

Over time, a late, chronic, active stage develops when egg burdens in the tissue are at their highest. Clinically constant, deep lower abdominal and pelvic pain with associated urinary urgency, frequency, and incontinence are noted with the "schistosomal contracted bladder" (Duvie, 1986). Anatomically, the trigone appears normal or minimally hyperemic and edematous, while the detrusor muscle is indurated and thickened, along with the entire bladder wall. The bladder lumen is reduced to as little as 50 mL of functional capacity.

After some years, the active infection enters a more quiescent period, in which egg deposition and excretion continue at a lower rate and symptoms are diminished. Over 30% of light infections "resolve" spontaneously in some endemic areas (Rutasitara and Chimbe, 1985). The painful presentations of acute schistosomiasis are typically absent at this point. However, silent obstructive uropathy may develop throughout this phase as fibrosis replaces polypoid lesions and the bladder and ureters undergo irreversible damage. A slow, insidious evolution may result in enormous hydroureters and hydronephrosis with few symptoms.

Patients finally enter a chronic inactive phase, in which viable eggs are no longer detected in urine or tissues. Signs and symptoms at this stage are caused by sequelae and complications of the immune reaction to the eggs rather than the schistosomal infection itself. Unfortunately, among patients with schistosomal obstructive uropathy, 40% to 60% present to urologists at this stage of their disease (Smith and Christie, 1986). In heavily endemic areas, it is common to find nonfunctioning kidneys in patients who are otherwise apparently well. About 50% of patients will develop chronic or acute bacterial urinary tract infection complications superimposed on their schistosomal obstructive uropathy. The bacterial organisms associated with schistosomiasis are the same organisms that cause infections in patients without schistosomiasis. Some series have noted an association of chronic or recurring urinary tract infections caused by *Salmonella* species, often associated with intermittent bacteremia in some patients with urinary schistosomiasis (King, 2001). *Salmonella* organisms reside in the apical invaginations of the schistosome tegument, where they are protected from host defenses and antibiotics. Awareness of this association can lead to treatment of both conditions with good response. Antibiotics alone do not fully resolve this process.

Another manifestation of schistosomal disease is the development of bladder ulcers, which are usually of two types (Smith et al, 1977a). Acute schistosomal ulcers will rarely present in the active stage, when a necrotic polyp sloughs into the urine. The more common chronic schistosomal ulcer is a late sequela of heavy infection. This lesion is associated with a constant "burning" micturition and intense pelvic and suprapubic pain. Over 90% of these patients have a history of previous urinary schistosomiasis, 20% have histories of previous sequelae and complications, and 10% have had previous surgical intervention for urinary schistosomiasis. Gross hematuria and gross pyuria are found in more than half of these patients.

Diagnosis

The presence of terminally spined eggs in the urinary sediment is diagnostic of active *S. haematobium* infection. The eggs of *S. mansoni* and *S. japonicum* have a lateral spine. Eggs may also be seen in the rectal stool samples examined for ova and parasites. If eggs are not found in the urine or stool, a rectal biopsy should be attempted before a bladder biopsy, because eggs are nearly as common in the rectum mucosa and the risk of a urinary tract infection is avoided. A squash preparation of the biopsy specimen between glass slides is better than histopathologic analysis, because it is more sensitive and allows determination of egg viability. Ova are excreted in the urine in proportion to the viable worm burden in the lower urinary tract tissues (Smith et al, 1974b; Smith and Christie, 1986). The intensity of the current infection in its early stages can be estimated by the examination of urine and quantitative urinary egg count. This also has some prognostic significance. Moderate to heavy infections will reveal eggs in almost all routine examinations of the urinary sediment, although lighter infections may require filtration or concentration of the urine (Mott, 1983). *S. haematobium* egg excretion peaks between 10 AM and 2 PM. Interestingly, this circadian phenomenon reverses in night-shift workers without the variation induced by athletic activity or water loading (McMahon, 1976).

Serology tests of the blood that combine a FAST-ELISA followed by Western blot analysis are available at the CDC (Wilson et al, 1995; Al-Sherbiny et al, 1999). In cases where the diagnosis is highly suspected but eggs are not present, the serologic tests can be useful, but do not distinguish between acute and chronic disease. Antibody titers can remain positive even after curative treatment. Although serologic testing is a valuable diagnostic and epidemiologic tool, finding eggs is the gold standard for diagnosis of active infection. Chronic inactive urinary schistosomiasis is characterized by the lack of egg secretion even in patients with severe clinical sequelae. When tissue biopsies are taken, up to 10^6 eggs/g of tissue have been found (Smith et al, 1974b). Real-time

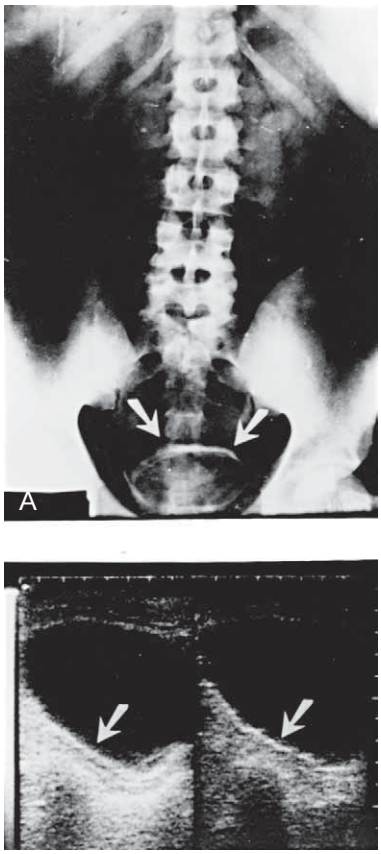

Figure 16–11. Bladder calcification in a 30-year-old Egyptian farmer. **A,** Plain x-ray film of the abdomen shows a rim of calcification surrounding the urinary bladder *(arrows)*. **B,** Abdominal ultrasound study shows a bright line surrounding the bladder with a definite dark rim behind it *(arrows)*. (**A** and **B,** Courtesy of G. Thomas Strickland, MD. From Abdel-Wahab MF, Ramzy I, Esmat G, et al. Ultrasonography for detecting *Schistosoma haematobium* urinary tract complications: comparison with radiographic procedures. J Urol 1992;148:346.)

PCR of the urine is in developmental testing, and may hold some promise in the future. Specificity of nearly 100% is better than sensitivity of 89% in studies, consistent with other nucleic acid–based diagnostic assays (Obeng et al, 2008). Radiography is an important diagnostic tool in the evaluation of sequelae and complications of urinary schistosomiasis. A plain radiograph of the abdomen may reveal calcifications in the urinary tract. The classic presentation of a calcified bladder, which may even look like a fetal head in the pelvis, is pathognomonic of chronic urinary schistosomiasis (Fig. 16–11). The seminal vesicles, prostate, posterior urethra, distal ureters, and, in rare instances, the colon may also show calcified lesions. The earliest radiographic changes appear to be striations in the ureters and renal pelvis (Hugosson, 1987). Ureteral calcification is typically mural, and the ureter is dilated. This differs from the calcification seen in tuberculosis, which forms a cast of a nondilated ureter.

Hydroureter, hydronephrosis, nonfunctioning kidney, ureteral stenosis, and bladder and ureteral filling defects caused by polypoid lesions are readily observed on a standard intravenous urogram. Similar lesions can also be seen with ultrasonography. In the presence of severe obstructive uropathy, delayed films are often needed to discern distended ureters and kidneys. Postvoid films may indicate bladder neck obstruction with retention. Fluoroscopy can differentiate tonic and atonic ureters (Abdel-Halim et al, 1985) and identify nonstenotic, immotile ureters. Computer tomography (CT) scans have the advantage of being able to detect both obstructive uropathy and calcified lesions in the urinary tract and colon (Jorulf and Linstedt, 1985), giving them advantage over the intravenous urogram. MRI scanning has been tried but so far has not shown significant enhanced diagnostic ability to warrant the additional expense (Kohono et al, 2008).

Another useful imaging modality is vesicocystourethrography. It indicates the presence of vesicoureteral reflux, which occurs in 25% of infected ureters. Abdominal ultrasound is a useful method to detect focal thickening of the bladder wall and polypoid lesions of the urinary tract. It also detects hydroureter, hydronephrosis, and heavily calcified patches (Medhat et al, 1997).

Treatment

Medical Management. The development of safe and effective antischistosomal drugs has dramatically changed the management of schistosome infections (WHO, 1993; Richter, 2003; Berhe et al, 2008). All patients with schistosomiasis should be treated regardless of the intensity or apparent activity of their infection. Praziquantel is the drug of choice for all schistosoma species (The Medical Letter, 2010). It is active against all clinical forms and stages of the disease after the first 3 to 4 weeks of infection, because it works better in the presence of antibodies against schistosomal organisms. Praziquantel interferes with the ion transport in the schistosome tegument, resulting in calcium and sodium fluxes, metabolic alterations, and sudden contraction of the parasite's musculature. Cure rates for *S. haematobium* infections are 73% to 100% (Mott et al, 1985; Leutscher et al, 2008). The drug also has activity against most other flukes and tapeworms, which is a great advantage in the developing world. The current recommendation is 2 oral doses of 20 mg/kg (or a single 40 mg/kg dose) in 1 day for *S. haematobium* (The Medical Letter, 2010). Praziquantel is extremely well tolerated, with occasional gastrointestinal complaints noted as the more common side effects. Headache, dizziness, and fever have occasionally been reported. The lack of serious side effects has made it an excellent agent of choice in mass chemotherapy campaigns (King et al, 1990).

Surgical Management. The efficacy and ease of current drug therapy for schistosomiasis, together with the possible reversibility of disease (Berhe et al, 2008) provides rationale for medical therapy trials prior to elective surgical approaches for genital urinary disease associated with schistosomal infection (Cioli et al, 1995). In general, surgery is reserved for complications that have not responded to adequate medical treatment within a reasonable follow-up time, or for those settings where immediate surgical intervention is necessary. Obstructive neuropathy is the most common chronic condition requiring surgery with severe bladder hemorrhage, the most common cause for urgent surgical intervention.

Significant prostatitis and hypertrophy are uncommon in schistosomiasis. There is no evidence of bladder outlet obstruction in *S. haematobium* infections in multiple autopsy studies (Smith et al, 1974a; Cheever et al, 1977, 1978). However, clinical studies consistently report cystoscopic (Fam, 1964), urodynamic (Sabha and Nilsson, 1988), and postvoid residual urine, which are evidence of functional bladder outlet obstruction that occasionally requires surgical intervention in patients with severe inactive urinary schistosomiasis (Abdel-Halim, 1984). Due to scrotal pain, induration, and enlargement associated with schistosomal

epididymitis, surgery is often performed for the suspicion of a testicular tumor.

As previously discussed, schistosomal disease of the urinary bladder leads to a spectrum of clinical outcomes, including schistosomal polyposis, sandy patches, contracted bladder, schistosomal ulceration, urothelial hyperplasia, metaplasia, dysplasia, and bladder cancer. In particular instances, such as the chronically contracted bladder, surgical intervention is indicated and takes the form of vesical denervation, urinary diversion, ileocystoplasty, or hydrodistention. Any treatment, however, must be done in conjunction with medical chemotherapy. Chronic deep bladder ulcers may necessitate a partial cystectomy, because fulguration rarely produces either symptomatic relief or healing of the ulcer. Urothelial hyperplasia is strongly associated with severe urinary schistosomiasis, whereas urothelial metaplasia and dysplasia commonly accompany schistosomal bladder cancer (Khafagy et al, 1972). Treatment of bladder cancer secondary to schistosomiasis is usually surgical and discussed elsewhere in this textbook.

The most common sequelae of urinary schistosomiasis result from ureteral involvement causing obstructive uropathy (Lehman et al, 1973; Smith et al, 1974a; Cheever et al, 1978; Smith and Christie, 1986). Hydroureter and hydronephrosis are related to the intensity of *S. haematobium* infection. **Because ureteral obstruction seen during active schistosomiasis is most often caused by concentric or hemiconcentric polypoid lesions that "girdle" the ureteral muscle in the intramural and adjacent extravesical ureter, it responds well to medical management alone.** Complete resolution of deteriorated renal function occurs within 1 to 2 months of antischistosomal chemotherapy when obstruction is caused by active disease (Lehman et al, 1973). One study reported that chemotherapy not only reverses schistosomal obstructive uropathy but also prevents it, even in persons who continue to become reinfected (Subramanian et al, 1999). In late chronic active and inactive urinary schistosomiasis, on the other hand, anatomic obstruction is more prominent.

Anatomic ureteral stenosis, with or without calculi, has been identified in up to 80% of obstructions (Lehman et al, 1973; Smith et al, 1977b; Al-Shukri and Alwan, 1983; El-Nahas et al, 2003). **Therefore when there is residual ureteral stenosis after successful chemotherapy it is usually amenable to surgical intervention. Depending on the extent and location of the stricture, procedures involving excision or dilatation have been used.** Balloon dilatation has reportedly proved effective with anatomic stenosis (Jacobsson et al, 1987), but mechanical dilatation is frequently followed by repeat stenosis (Wishahi, 1987). When the ureteral meatus, intermural ureter, ureterovesical junction, or lower ureter is involved, a variety of plastic operations to reconstruct a functional valve are available. Most of these procedures are variants of the Leadbetter-Politano operation (Politano and Leadbetter, 1958; Leadbetter and Leadbetter, 1961). Although highly effective for some patients (Smith et al, 1977b; Al-Shukri and Alwan, 1983), other authors have noted restenosis (Umerah, 1981).

In long or multisegmental lesions, excision of the affected portion leaves an inadequate residual ureter for reimplantation; in these cases, surgeons have successfully employed the Boari-Ockerblad bladder flap, Boari-Küss flap, ileal conduit, suprapubic intravesical ureterostomy, and ureteroileocystostomy, taking care to have an isoperistaltic direction of the ileal segment (Abdel-Halim, 1980, 1984; Al-Shukri and Alwan, 1983; Abu-Aisha et al, 1985). Isolated meatal stenosis may be amenable to simple meatoplasty (Al-Shukri and Alwan, 1983). When a ureter is hopelessly obstructed, long-term nephrostomy drainage or creation of an ileal ureter can provide relief.

Prognosis

Tens of millions of people are infected with *S. haematobium,* but **most have mild infections, and good prognosis. However, the morbidity and mortality of schistosomiasis are determined by the overall intensity of infection.** No mortality was observed in areas in which the prevalence of schistosomiasis and frequency and severity of schistosomal obstructive uropathy were low (Nigeria). Yet when Egypt had a prevalence of 50%, attributable mortality approached 10% (Smith et al, 1974a; Cheever et al, 1978). **Among patients with severe disease, mortality reached 50% in 2 to 5 years** (Lehman et al, 1970).

Patients who die of schistosomal obstructive uropathy (bilateral end-stage hydronephrosis) are usually in their 20s, have early-stage disease, and have heavy total egg burdens. Patients who develop the complications of pyelonephritis and urothelial cancer are usually older than age 40, consistent with time- and intensity-linked pathology (Christie et al, 1986; Smith and Christie, 1986).

The prognosis for persons with demonstrable urinary tract lesions has dramatically improved with praziquantel therapy. In children with obstructive polyps, the uropathy usually completely resolves within 2 to 6 weeks of treatment. For patients with chronic obstructive uropathy due to sandy patches and fibrosis, the prognosis is less clear. Some individuals tolerate advanced obstructive uropathy with little, if any, deterioration in renal function. **Schistosomal obstructive uropathy, urolithiasis, bladder outlet obstruction, and bacterial cystitis all predispose to pyelonephritis.** Bacterial superinfection is a serious prognostic event and should be treated as vigorously and as soon as possible. Furthermore, for **those who develop a bladder malignancy, their prognosis is dependent on the aggressiveness of their tumor.**

Prevention and Control

Travelers in endemic areas should be advised of the hazard of infected fresh water streams, rivers, ponds, and lakes and should avoid contact with such water. Boiling water kills the cercariae. Measures of control in endemic areas have utilized several approaches: destruction of the snail host, elimination of urine and fecal contamination of water, and reduction of contact with infected water (WHO, 1993). In many endemic areas, such measures are expensive, unfeasible, or poorly tolerated by the local population. Therefore mass therapy by drugs has been emphasized, and all major control campaigns today include drug treatment as a major component, often age-directed or annual or both (King et al, 1991; Engels et al, 2002; WHO, 2002). Vaccines to prevent disease or to reduce infection are not currently available (Pearce, 2003).

Genital Filariasis

In broad terms, filarial diseases are classified as lymphatic and nonlymphatic. *Wuchereria bancrofti* accounts for 90% of the cases of human lymphatic filariasis, notably widespread throughout tropical regions of the world. This human parasite has no animal reservoir. *Brugia malayi* and *B. timori* cause human lymphatic filariasis in the Far East, but also have primate and feline reservoirs. Nonlymphatic filariasis is caused by *Onchocerca volvulus*, *Loa loa* or

Mansonella perstans. *O. volvulus*, the agent of river blindness, is found predominantly in Africa with small scattered foci in South and Central America. Although dermatitis, keratitis, and chorioretinitis are the common features of *O. volvulus* infection (Freedman, 2006); subcutaneous nodules and massive inguinal lymphadenopathy may result in "hanging groin" and scrotal elephantiasis.

Very rarely, *Loa loa* or *M. perstans* have been isolated from ovarian follicular fluid and associated with infertility (Chang et al, 2008; Bazi et al, 2006).

Lymphatic Filariasis

The symptoms of bancroftian and brugian filariasis range from acute lymphatic inflammation characterized by fever, localized lymphangitis, and transitory lymphadenopathy to chronic lymphatic dilation with hydrocele, elephantiasis of the limbs, and chyluria (Ottesen, 1989; Dreyer et al, 2000). Lymphatic filariasis affects 120 million people living in 73 countries, with India accounting for 40% of the global infections (Ramaiah et al, 2000).

Biology and Life Cycle. The lymphatic filariae are elongated (100 × 0.3 mm for female and 40 × 0.1 mm for male *W. bancrofti*) nematodes. **Their cycle proceeds from human to mosquito and back.** The most common urban vectors of *W. bancrofti* are the ubiquitous *Culex pipiens* complex, but filariae have adapted to a wide variety of mosquitoes in different areas. Only small portions of mosquito bites (1%) are infective, even in hyperendemic areas. Typically, obstructive lymphatic disease occurs in people repeatedly infected over many years.

Female mosquitoes ingest microfilariae with their blood meals. These rapidly become infective larvae and go to the mosquitoes' salivary glands. The infective larvae are then deposited on the skin during the next mosquito feeding. Although unable to traverse unbroken skin, the infective larvae can enter the bite site or can cross the normal conjunctiva or buccal mucosa (Ah et al, 1974; Sullivan and Chernin, 1976). **The adult filaria then migrates to and lives in the larger lymphatic vessels. *W. bancrofti* adults have a predilection for periaortic, iliac, inguinal, and intrascrotal lymph vessels, whereas *B. malayi* prefers inguinal and more distal lymphangioles.**

Most of the mature *Wuchereria* female is composed of the uterus, which contains all stages, from eggs to mature microfilariae. Microfilaria discharge into the blood is regulated by a feedback system that maintains a constant level of microfilaremia. There is, however, no constant relationship between the number of worms and the level of microfilaremia. Indeed, microfilaremia is found in only 30% to 40% of all infections. The timing of peak microfilaremia in each endemic focus corresponds to the peak feeding period of local mosquito vectors.

Pathology and Pathogenesis. Epidemiologic findings and animal experiments clearly indicate that host reactions to microfilariae differ from those to adult worms. Although pathologic and clinical features differ between patients from endemic and from nonendemic areas, significant humoral and cellular immune responses develop in both groups (Steel et al, 1996). Filaria-specific IgE titers rise, and IgE-eosinophil–mediated killing of microfilariae has been noted in vitro. However, patients from endemic regions manifest IgG_4-blocking antibodies and antigen-specific suppressor T cells. The extent of immune down regulation correlates with an absence of pathologic sequelae and the presence of microfilaremia (Piessens, 1982; Davis, 1989; Ottesen, 1989).

Early Infection. **Lesions of established infection do not remit, but either persist actively or result in significant scarring and lymphatic obstruction. Lesions may appear at the worms' nesting areas (funiculoepididymitis, orchitis, filarial lymphangitis, filarial abscess), in their lymphatic distribution (e.g., hydrocele, lymphadenitis, genital edema), or both.** Dying or dead adult filariae are often detected in surgically excised tissue, which suggests that worm death provokes the inflammatory response.

Figure 16–12. Huge hydrocele and scrotal elephantiasis. (Courtesy of Dr. B.H. Kean. From Zaiman H. A pictorial presentation of parasites, Valley City, ND.)

The lesions vary from nodular inflammation, simulating neoplasm, to suppuration, simulating acute bacterial disease. Histologically, nodular lesions show massive granulomas around cuticular fragments or necrotic filaria. **Tissue eosinophilia is a useful diagnostic hint but may be absent.** The most acute subcutaneous filarial lesions simulate fluctuant abscesses with bacteriologically sterile but purulent exudate that surrounds a dying worm (O'Connor and Hulse, 1935).

Episodic filarial inflammation eventually abates, leaving obliterated lymphatics surrounded by poorly organized scar tissue. A palpable mass or indurated cord may develop. The consequences of lymphatic obstruction vary with the location of the obstruction, but the common feature is the accumulation of lymphedema or hydrocele fluid associated with lymphoid infiltrates.

Late Infection. The complications of late infection include huge hydroceles and scrotal and penile elephantiasis (Fig. 16–12). **Lymphangiographic studies reveal that the initial obliteration of lymphatic vessels is bypassed by collateral formation. As these collaterals become progressively obstructed, lymph dilatation follows.** Lymphangiograms in late filariasis show poorly draining networks of communicating lymph vessels extending through lymphedematous tissues into superficial dermal layers (Kanetkar et al, 1966).

Patients demonstrating chyluria and filarial hydrocele rarely experience bacterial super-infection. In contrast, elephantiasis and lymphedematous scrotum are often superinfected (Olszewski et al, 1997). Further supporting the role of infection in classic elephantiasis is noted by the ability to prevent this manifestation when patients with lymphedema are instructed to use antiseptic soap on a regular basis and treated with antibiotics (Maher and Ottesen,

2000). Bacterial superinfections are thus considered an additional contributing factor to the development of sequelae from filarial infection (Dreyer et al, 2000).

Serial autopsy studies of men show that the tail of the epididymis and the lower spermatic cord are the most constant locations of worms (Galindo et al, 1962). Correspondingly, funiculoepididymitis and hydrocele are the most common consequences of bancroftian filariasis. Assuming that heavy infections saturate the preferred habitat and compel adult filariae to spread centrifugally to increasingly distant sites, saturation of inguinal lymphatic trunks (yielding scrotal edema) initiates encroachment into femoral lymphatics (causing elephantiasis of lower extremities) and proximally to renal lymphangioles (producing lymph varices whose intrapelvic rupture causes chyluria).

Clinical Manifestations. Clinical lymphatic filariasis manifests as one of four forms:

Asymptomatic Infection. Persons in endemic areas may have positive serology or skin test reactivity to filarial antigens but no microfilaremia and no clinical evidence of filariasis. Asymptomatic microfilaremia may occur in patients with downregulated effector immune responses (Ottesen, 1989). Such individuals probably developed tolerance to filarial antigens in utero (Weil et al, 1983). In addition, generation of elevated levels of interleukin-12 has been noted in individuals with chronic microfilaremia (King et al, 1995).

Filarial Fevers. Patients with "filarial fever" sustain episodic fevers, lymphangitis-lymphadenitis, funiculoepididymitis, transient edema, and small acute hydroceles. **They are typically amicrofilaremic.** Patients with endemic filarial fever usually inexorably progress due to ongoing reinfection and persistent inflammatory reaction. Expatriates who may experience parasite-related fevers will abate after repatriation and treatment.

Chronic Filariasis. Early established filariasis progresses to the late chronic stage with a series of **progressive lesions: funiculoepididymitis, hydrocele, orchitis, scrotal and penile elephantiasis, lymph scrotum, and chyluria. These do not resolve with treatment, reflective of the chronic tissue changes induced by earlier inflammatory reaction. This pathology alters local lymph fluid drainage** (Fan et al, 1995).

Funiculoepididymitis. Most symptomatic cases of filarial funiculoepididymitis appear before patients' fourth decade. The attack may be isolated, with remission, or may be repetitive and progressive. Pain radiating to the testis and simulating ureteral colic may accompany the systemic symptoms.

Palpable cordlike swelling may mimic an intrascrotal tumor or torsion of the cord and be accompanied by hydrocele or soft tissue edema. Eosinophilia is common because of the persistent tissue migratory nature of this parasitic infection. Varicocele, or thrombosis of the pampiniform plexus, may complicate inflammation, increasing pain and swelling. Bacterial superinfection of acute filarial corditis, is a rare but often lethal complication, with exquisite pain and septic thrombophlebitis as a contributing cause.

Mild cases may involute spontaneously, but, in an endemic setting, they more often point to future recurrences or the development of chronic lymphedema or both (Kazura et al, 1995). The disease frequently simulates malignancy, and many patients ultimately undergo operations including orchiectomy. Even in severe filarial funiculitis, the spermatic cord is usually intact and patent. Sterility and orchitis due to filariasis are rare.

Hydrocele. In endemic areas, differentiation of filarial from idiopathic hydrocele is difficult on either clinical or laboratory grounds. Microfilariae or adult worms are rarely detected in the hydrocele fluid, but a milky or sediment-rich hydrocele fluid suggests a filarial origin. Hydrocele accompanied by nodules in the cord or epididymis and a history of travel to or residence in an endemic area suggests filariasis. Discovery of a thick, fibrous tunica, especially with cholesterol or calcium deposits, should also suggest a diagnosis of filariasis. Tunical calcification is very rare in idiopathic hydrocele.

Scrotal and Penile Elephantiasis. Mild scrotal edema is not unusual during early infection or with established hydrocele. Penile edema, on the other hand, is unusual, and the monstrous elephantine enlargements of the scrotum or penis depicted in textbooks occur largely in populations without access to medical care. Elephantiasis of the limbs poses the differential diagnosis between filarial and other causes, but genital elephantiasis is rarely due to other causes, such as malignancy.

Chyluria. Chyluria occurs with or without microfilaremia, usually in young adults. It occurs earlier in the natural history of filariasis than does genital elephantiasis. Dying worms provoke lymphatic obstruction with proximal lymphangiolar dilatation. Rupture of a lymphatic varix into the urinary collecting system has been demonstrated by lymphangiography. Chyluria may initially alarm patients but often is disregarded and may result in severe protein loss, leading to hypoalbuminemia and anasarca. Chyluria is usually intermittent and may spontaneously remit with bed rest.

Tropical Pulmonary Eosinophilia. Tropical pulmonary eosinophilia occurs in patients with an allergic response to microfilarial antigens; such patients are amicrofilaremic (Ong and Doyle, 1998). This syndrome is characterized by marked, sustained peripheral eosinophilia, only temporarily affected by corticosteroids but responsive to antifilarial drugs. There is an absence of classic filarial lesions, such as lymphedema or funiculoepididymitis. However, the presence of lymphadenopathy that can be marked enough to mimic lymphoma and symptomatic pulmonary infiltrates suggests asthma (Danaraj et al, 1966). Patients develop very high levels of filaria-specific IgE and pulmonary reticulonodular densities on chest radiographs that reveal an eosinophilic interstitial pneumonitis on biopsy. The frequency of this syndrome varies markedly between endemic foci and is most common in southern India and Singapore.

Diagnosis. Careful history-taking and physical examination are paramount in suggesting a filarial lymphedema. TB, *S. haematobium*, and gonorrhea may also produce funiculoepididymitis. Idiopathic hydrocele with or without varicocele or hernia is common in tropical and nontropical areas. However, hydrocele occurs at an earlier age and in greater frequency in areas of endemic filariasis (Jachowski et al, 1962).

The histologic finding of adult worms is a diagnostically definitive but insensitive technique. The presence of microfilariae in peripheral blood, chylous urine, or hydrocele fluid is also diagnostic. Blood samples must be taken when peak microfilaremia occurs (e.g., midnight in the case of nocturnal periodic *W. bancrofti*). Peripheral blood is best examined by the thick-drop technique with Giemsa stain. It is important to remember that filaremia may be absent in both early and late filariasis, after treatment with a microfilaricide, and in tropical pulmonary eosinophilia. Immunoassays for measuring antibody and circulating antigens, as well as molecular biologic assays for detecting parasite DNA, have been developed (McCarthy, 1996; Harnett et al, 1998; Mishra, 2005).

Direct ultrasonographic observation of adult filariae has been reported in lymph vessels of microfilaremic and otherwise asymptomatic patients, made possible by energetic movements of the

worms ("filarial dance sign") (Amaral et al, 1994; Chaubal et al, 2003). Lymphangiography may distinguish filariasis from other causes of lymphatic obstruction, especially in conditions with reduced numbers and competence of lymph vessels. Plain radiographs may reveal calcified worms, which are diagnostic.

Treatment and Prevention. There is continual development of new control strategies and treatment programs for filariasis. The new methodology of control leverages the benefits of mass treatment programs and individual patient treatment to dramatically reduce transmission (Ottesen et al, 1997). Four drugs are now used singly or in various combinations and doses: diethylcarbamazine (DEC), ivermectin, albendazole, and doxycycline (Shenoy et al, 1999; Taylor et al, 1999; Mand et al, 2009). DEC has been used for over 50 years and is predominantly effective against adult worms. Ivermectin has efficacy against microfilaremia, but is relatively ineffective against adult parasites. The objective of therapy is to kill adult worms and abolish microfilaremia. Unfortunately, patients may have prominent immune reactions to the enhanced antigenic exposure associated with dying filariae, the severity directly proportional to the magnitude of the microfilaremia. Patients with high microfilarial counts should start with lower doses when DEC is used for the first several days to minimize these reactions. Some treatment protocols include premedication with corticosteroids or antihistamines to reduce the inflammatory symptoms. Additional treatment-related effects, including fever, headache, nausea, vomiting, and arthralgias, may occur in the first few days of treatment.

Ivermectin is used in a single dose of 200 to 400 μg/kg. The microfilaricidal effect is comparable to that of DEC. There is no effect on adult filariae. In contrast, albendazole kills both adults and microfilariae in lymphatic disease (Ottesen et al, 1999; Bookaire et al, 2002; Gardon et al, 2002). These medications are the cornerstone of mass treatment programs; they successfully interrupt transmission by reducing the microfilariae available for the arthropod vectors in endemic areas.

The recognition that all human pathogenic filariae harbor the bacterial endosymbiont (*Wolbachia* spp.) has led to trials of doxycycline, which kills the filarial by killing the *Wolbachia*. Subsequent use of the three classic antifilarial agents may still have a role in full eradication (Coulibaly et al, 2009; Mand et al, 2009). Three-week doxycycline therapy for *W. bancrofti* cases followed by a single dose of DEC has been shown to reduce or resolve lymphatic pathology in GU filariasis (Mand et al, 2009).

Use of elastic stockings and elevation of extremities are important adjunctive measures in reducing lymphedema. Meticulous skin care and aggressive treatment of secondary infections may halt or even reverse the lymphedema and prevent the development of elephantiasis (Ottesen et al, 1997). Abdominal binders have been used to increase intra-abdominal pressure in an effort to stop chyluria but are controversial because they may increase chyluria in some patients (Ahrens, 1970). Finally, diagnostic retrograde lymphangiography curatively sclerose lymphatic fistulas in 48% of patients (Gandhi, 1976). Thus **surgical correction is unnecessary in many of these cases, and operative intervention is challenging because the varices are hard to identify and eliminate.**

Genital elephantiasis is rarely amenable to surgery. Additionally, procedures such as lymphadenectomy may further compromise lymph drainage and exacerbate complications. There are, however, a few instances when surgical intervention is necessary to treat the complication of filariasis. For example, patients with filarial funiculoepididymitis should first undergo a thorough workup for malignant, filarial, and bacterial causes of their symptoms. Then, appropriate antibiotics should be prescribed for bacterial disease, and treatment of the filariasis may require surgical decompression or excision of filarial nodules, preserving the testis and cord. When funiculoepididymitis is recurrent, painful, and deforming or complicated by blood vessel involvement, more radical surgery is warranted. Next, for the treatment of large or symptomatic hydroceles, hydrocelectomy is indicated. Excision of the intact hydrocele sac is the treatment of choice; an alternative method is inversion with partial excision (Jachowski et al, 1962). Small hydroceles that do not enlarge can be ignored. Finally, a variety of procedures have been devised to remove redundant tissue and to reconstruct the scrotum or vulva.

For prevention of disease, DEC has been used as a prophylactic drug, given as an annual dose of 6 mg/kg. Trials with prophylactic ivermectin have had similar beneficial effects. Major control methods, however, depend on the use of residual insecticides, domestic mosquito netting, and the reduction of mosquito breeding sites.

Onchocerciasis

Onchocerca volvulus is the agent of river blindness and of severe, debilitating, chronic dermatitis. Onchocerciasis is **common throughout tropical Africa, and endemic foci also exist in Central and South America.** This filaria differs sharply from *Brugia* and *Wuchereria:* (1) It is transmitted by black flies of the *Simulium* species; (2) adult worms inhabit subcutaneous tissue and cause palpable fibrous nodules in which they are encapsulated; and (3) microfilariae travel through the dermis (and the eye) but are not in the peripheral blood. Diagnosis and estimation of infection intensity are made by microscopic examination of skin snips immersed in normal saline solution for 20 to 30 minutes under a coverslip on a slide, or with Giemsa stain. Serologic and antigen detection tests have also been developed (Vincent et al, 2000; Pischke et al, 2002).

In late stages, onchocerca infection may produce "hanging groin" or scrotal elephantiasis. Histology demonstrates atrophy and fibrosis of the inguinal lymph nodes with subcutaneous edema and fibrosis superimposed on the typical onchocercal dermatitis (Connor et al, 1970). In addition, onchocerciasis is occasionally accompanied by giant inguinal lymphadenopathy, which can also produce "hanging groin."

A single oral dose of ivermectin (150 μg/kg) repeated every 2 to 6 months until the patient is asymptomatic (resolution of pruritis and rash) has proved to be a successful onchocercal microfilaricide with few side effects (Greene et al, 1985; The Medical Letter, 2010). **DEC should not be used for treatment of this disease,** because of the severe allergic immune responses to microfilariae dying in the skin and other sites (the Mazzotti reaction). Ivermectin distribution has been successfully used for curbing *O. volvulus* transmission in an international campaign against African river blindness under the auspices of the WHO (Dull and Meredith, 1998). An advance with potential therapeutic implications is the demonstration that a 6-week course of doxycycline renders the female worm sterile by reducing the symbiotic *Wolbachia* endobacteria (Hoerauf, 2003).

OTHER PARASITIC DISEASES OF THE GENITOURINARY TRACT

This section describes parasitic infections that are rare, or in which urogenital manifestations are overshadowed by diseases and other organs. They are, nonetheless, occasionally clinically important

for individual patients. The organisms involved include the intestinal helminth *Enterobius;* the larval tapeworm of hydatid disease, *Echinococcus; Entamoeba histolytica; Gnathostomiasis; Trichomonas vaginalis; Plasmodium falciparum; Strongyloides stercoralis;* and, very rarely, locally inoculated fly larvae.

Enterobiasis

The common **intestinal pinworm *Enterobius vermicularis,* which is ubiquitous worldwide,** occasionally migrates from its nocturnal swarming site, the anus, upward into the vagina, reaching the peritoneal cavity through the uterus and fallopian tubes. In that unnatural habitat, worm movement and egg-laying may continue, producing inflammation of the pelvic peritoneum with pain, fever, simulated acute appendicitis, or other lesions. Dead worms and eggs incite granulomas and adhesions. Careful searching for enterobiasis eggs in vaginal secretions may properly diagnose a persistent vaginal discharge that was originally thought to be caused by more typical organisms. Treatment of pelvic enterobiasis is with pyrantel pamoate, mebendazole, or albendazole (The Medical Letter, 2010).

Hydatid Disease

No part of the human anatomy is invulnerable to hydatid cysts, but renal hydatids occur in only about 2% of cases (Musacchio and Mitchell, 1966; Kehinde et al, 2008). **The hydatid is the larval form of *Echinococcus granulosus,* whose definitive host is the dog, and whose principal intermediate host is the sheep.** The major endemic loci of hydatid disease are sheep-herding areas, such as Australia, Argentina, Greece, Spain, and the Middle East. In addition, feral life cycles lead to sporadic human cases in sites without sheep. Echinococcal cysts of other species are found in Alaska, Siberia, parts of Europe *(Echinococcus multilocularis)* (Rausch, 1967), and Central America *(Echinococcus vogeli)* (D'Alessandro, 1979). In each instance, humans acquire the cysts by accidentally eating eggs excreted in the feces of dogs or alternative feral hosts.

In the kidney and other sites, hydatid cysts evolve by slow, asymptomatic, concentric growth over years and may invoke pressure symptoms or flank pain, depending on their location and size. Cysts can reach over 20 cm in diameter (Fig. 16–13). A host fibrous shell with scant inflammatory reaction envelops the cyst. They often enlarge 1 to 2 cm per year.

The most common urologic presentation is of chronic dull flank or lower back discomfort from cystic pressure (Gogus et al, 2003). The cysts seldom affect renal function. Diagnosis can be made by plain film radiography, ultrasonography, or CT, which shows a thick-walled, fluid-filled spherical cyst, often with a calcific cyst wall (Horchani et al, 2001; Turgut et al, 2009). Serologic testing (available through state laboratories or the CDC) has proved useful but has a sensitivity of only 60% to 90%. **Albendazole, 400 mg twice daily for 1 to 6 months, is the recommended medical therapy. Some patients may require surgical excision of their cysts because of the size or location of the lesions** (Handa and Harjai, 2005). **Praziquantel and albendazole have been recommended preoperatively for 7 to 10 days to minimize or prevent secondary seeding by daughter cysts if they accidentally contaminate the operative field** (The Medical Letter, 2010). Spillage of cystic products into the peritoneum or the bloodstream may result in metastatic infection. Rupture of cysts may result in systemic anaphylaxis.

Figure 16–13. Echinococcosis of the human kidney.

Amebiasis

***E. histolytica* is a rare cause of renal abscess** (Brandt and Perez Tamayo, 1970). Liver abscesses invariably accompany the abscess. The right kidney is more frequently involved. Hematuria may be a prominent manifestation, especially if the abscess induces renal vein thrombosis. Medical therapy (metronidazole or tinidazole) must be promptly instituted (The Medical Letter, 2010). Surgery, if necessary, should be delayed until drug therapy has been initiated; otherwise, disastrous spread of amebic infection is likely (Grigsby, 1969). Good reviews on the pathology (Brandt and Perez Tamayo, 1970), surgery (Grigsby, 1969), and medical management of amoebiasis (Ravdin and Stauffer, 2005) are available.

Gnathostomiasis

Gnathostomiasis is a food-borne zoonotic nematode. *Gnathostoma spinigerum* is the most common species to infect humans. Disease is acquired by consumption of infected fish when eaten raw or undercooked. Humans represent an accidental host, which means the parasite is unable to reach full maturity. It wanders through tissues resulting in local symptoms, depending on location, and typically a very predominant eosinophilia (often greater than 50%) (McCarthy and Moore, 2000). While the disease typically has superficial subcutaneous manifestations, deeper visceral tissues may be involved. Very rare genitourinary cases have been reported (Rusnak and Lucey, 1993).

Serologic assays have been developed with sensitivity and specificity of 93% and 98%, respectively, but are not readily available.

The definitive treatment is surgical excision when possible. Albendazole is a safe and well-tolerated medical treatment that is often successful (Kraivichian et al, 1992).

Trichomoniasis

Trichomonas vaginalis is a flagellate protozoal organism, commonly found in the secretions of inflamed genital surfaces, such as the vagina or the preputial skin or the urethral mucosa (Kehinde, et al, 2008). Infection from this parasite is most commonly transmitted through intimate sexual contact and may involve the Cowper or Skeen glands. In women, the prevalence of trichomoniasis is estimated to be 3% to 48% in various studies (Sena et al, 2007). Vaginitis is the most frequent manifestation; however, it has been associated with preterm delivery in pregnant women (Cotch et al, 1997). The majority of male partners of women with trichomoniasis are infected even when the men are asymptomatic. Men may experience urethritis, epididymitis, prostatitis, and infertility, probably through infection of the seminal vesicles.

Diagnosis can be relatively straightforward if secretions are examined under a microscope and the highly active motile flagellum is visualized. However, the sensitivity of this diagnostic step is limited. Newer nucleic acid amplification tests have been developed with sensitivities ranging from 85% to 100% (Kaydos et al, 2002).

Malaria

Plasmodium falciparum is a protozoal parasite that causes severe malaria. The urogenital manifestation is through the phenomenon of black water fever due to hemoglobinuria (Kehinde et al, 2008). This is a rare manifestation involving a complement-mediated immune reaction found in patients who have resided 2 to 3 months in endemic areas, and who have also been treated with inadequate doses of antimalarial medication. The treatment includes appropriate full-course doses of effective antimalarials together with supportive medical care if the hemoglobinuria has resulted in acute renal tubular necrosis.

Strongyloidiasis

Strongyloides stercoralis is the fourth most important intestinal nematode infection in the world, with distribution throughout the tropical and temperate world. The parasite has the capacity for autoreinfection, which perpetuates infection for decades after exposure (Siddiqui et al, 2006). Typically, *S. stercoralis* infection produces an asymptomatic chronic upper gastrointestinal infection. However, in immunocompromised individuals, especially those receiving corticosteroids, strongyloides hyperinfection can develop with dissemination of the larvae to extraintestinal organs with mortality rates as high as 85%. Genitourinary infection is extremely rare and is usually an indication of disseminated disease. Motile larvae are rarely visible on urinalysis (Rifaat et al, 1973). The migrating worms carry gram-negative bacteria on their coat, which may result in bacteremia or infection of the genitourinary system if the parasites accidentally migrate to the genitourinary organs.

Diagnosis is usually best accomplished with blood serology, although the high sensitivity decreases in the face of immunosuppression. The organism exists as worms and larvae in typically low numbers, making direct observation challenging. The high numbers seen in disseminated infection can increase this sensitivity. Ivermectin represents the treatment of choice at a dose of 200 μg/kg daily for 2 days in normal hosts. Longer courses of treatment may be necessary in patients with disseminated disease. Of note, thiabendazole, the historical drug of choice, should no longer be used due to its prominent gastrointestinal and neuropsychologic side effects. Albendazole has some activity but a lower cure rate than ivermectin (The Medical Letter, 2010).

Key Points

- The symptoms of bancroftian and brugian filariasis range from acute lymphatic inflammation characterized by fever, localized lymphangitis, and transitory lymphadenopathy to chronic lymphatic dilatation with hydrocele, elephantiasis of the limbs, and chyluria.
- Schistosomiasis and filariasis parasites can survive in a host for up to 10 years. *Strongyloides* species can survive for many decades. A careful social history is essential to determine exposure, thus leading to thoughtful diagnostic testing and helping to understand if such infections may explain the presenting GU symptoms.
- When schistosomiasis is diagnosed during active infection (before scarring), treatment with praziquantel may reverse significant GU changes caused by infection and inflammatory reaction to the parasite.
- For schistosomiasis, although serologic testing is a valuable diagnostic and epidemiologic tool, finding eggs is the gold standard for diagnosis of active infection. If not found in urine or stool, tissue biopsy of the bladder or rectum may reveal eggs and aid in diagnosis.
- To minimize the risk of seeding new metastatic infection in the case of spillage of cyst contents, praziquantel or albendazole have been recommended for 7 to 10 days before any procedure on an echinococcal cyst.

Molecular Immunology

The immune system was initially described as the collection of cells, tissues, and molecules that provide resistance to infections. However, we now know it is essential for the maintenance of health and for combating a broad range of diseases. Various immune mechanisms are involved in urologic disorders including infections of the urinary tract, urologic cancers, the rejection of transplanted organs, the transfusion of blood products, and abnormalities of male reproduction. The immune response, once a set of clinical observations, has now been traced to unique cell populations, their secretory and membrane products, and the very intracellular machinery unlocking these responses. This has come about due to rapid advances in molecular immunology, including the development of monoclonal antibodies, the ability to clone cell populations, recombinant gene technology, and the ability to place genes into (transfect) or eliminate them from (knockout) animals. Nevertheless, the immune response remains identified by a set of unique characteristics that help explain its utility and adaptability against many different foreign invaders. **These include (1) the ability to identify self from nonself, (2) specificity, (3) memory, and (4) rapid amplification.** What we describe today as the immune system represents the interplay between two separate biologic responses, those that are **innate** and those that are acquired, or **adaptive.** In this chapter we will describe the nuts and bolts of the immune response and how they interact in various states of disease. This will often be presented in the context of an invading microbe and how it engenders immunity.

Immune mechanisms rely upon the interactions between diverse cell populations, which at any point in time are in various stages of differentiation. In contemporary terms immunity can be divided into two separate responses. **Cell-mediated immune responses describe those primarily directed by cell-to-cell contact, and humoral immune responses describe those primarily due to the production of antibody (immunoglobulin).** In fact, most responses involve both cellular and humoral events, which are mediated by several different types of immune competent cells. Although the small lymphocyte is the backbone of the immune response, several other bone marrow–derived cells are needed for a mature immune response. **These cells "talk" to each other and their surroundings through receptors that they express on their surface, and through cytokines, which are small peptides that they secrete locally** (Clark and Ledbetter, 1994). The receptors are usually glycoproteins that extend from the cell surface as single chains or double chains called dimers, which are often designated alpha and beta. A nomenclature has developed to describe these markers, at international workshops, comparing several monoclonal antibodies from different laboratories. When a cluster of monoclonals are found to react with the same surface polypeptide, it is designated with a CD number (cluster of differentiation). The number of CD specificities on leukocytes is now in the hundreds, and Table 17–1 provides the ones more commonly associated with immune responses. **A cell surface receptor bound by its ligand will often trigger downstream intracellular events, thereby activating the cell to either produce specific cytokines, express other surface markers required for immune interactions, or enter cell cycle progression and proliferation.** Many of the small peptide cytokines that directly influence immune responses will be described further in this chapter, and are represented in Table 17–2.

INNATE IMMUNITY

The innate immune responses are constitutive and do not improve on repeated contact with the same offending agent. An invading microbe first encounters innate immune responses. **Innate**

Table 17–1.

Some of the Major Cell Surface CD (Cluster of Differentiation) Markers

CD NO.	CELLULAR ASSOCIATION	MEMBRANE COMPONENT/LIGAND
CD2	T cells, NK cells	Receptor for LFA3 (CD58), sheep RBC rosettes
CD3	T cells	Component of T-cell receptor, signal transduction
CD4	Helper T cells	Receptor for MHC class II and HIV virus
CD5	T cells, thymocytes	Signaling molecule, binds CD72
CD8	Cytotoxic T cells	Receptor for MHC class I
CD11a	Leukocytes	Adhesion binds ICAMs (CD50, 54, and 102)
CD16	PMN, NK, macrophages	Fcγ receptor, phagocytosis, and ADCC
CD18	All leukocytes	Integrin beta chain
CD19	B cells	Pan–B-cell marker
CD20	B cells	Role in B-cell activation
CD25	Activated T and B cells, macrophages	IL-2 receptor, also called Tac
CD28	T cells	Costimulator ligand for B7.1 (CD80) and B7.2 (CD86)
CD40	B cells, APCs	Receptor for CD40 ligand (CD154), B-cell costimulator
CD44	Leukocytes	Proteoglycan binding receptor,
CD45	Leukocytes	Leukocyte common antigen, tyrosine phosphatase
CD45RO	Activated and memory T and B cell subset, monocytes, macrophages	Isoform of CD45, CD45RO memory cells; high MW CD45RA naive cells; low MW
CD52	T and B cells, some monocytes, macrophages	CAMPATH-1, unknown function
CD54	Dendritic, macrophages, B cells	Leukocyte adhesion, also called ICAM-1
CD55	Most cells	Decay accelerating factor (DAF), binds C3b
CD56	NK, few T cells	Adhesion
CD58	Broad	Binds CD2 (called LFA-3)
CD62L	B and T cells, monocytes, PMN	L-Selectin, endothelial adhesion, homing of naive T cells to lymph nodes
CD69	Activated leukocytes	Activation inducer molecule (AIM), signal transduction
CD71	Erythroid cells	Transferrin receptor, iron uptake
CD80	Dendritic, macrophages, B cells	Ligand for CD28, also B7.1, T-cell costimulator
CD86	Dendritic, macrophages, B cells	Ligand for CD28 and CD152 (CTLA-4), also B7.2 T-cell costimulator
CD152	Activated T cells	Also called CTLA-4; negative regulation of costimulation; binds CD80 (B7.1) and CD86 (B7.2)
CD154	Activated CD4+ T cells	CD40 ligand, activates B cells

AM, adhesion molecules; MW, molecular weight; NK cells, natural killer cells; PMN, polymorphonuclear leukocytes; RBC, red blood cells.

Table 17–2.

Representative Cytokines

CYTOKINE	CELLULAR SOURCE	MAJOR ACTIVITIES
IL-1	MØ, EC, keratinocytes	Upregulation of AM expression, stimulation of CK production, activation of MØ and T cells
IL-2	T cells	Activation of NK cells, T-cell growth factor
IL-4	Type 2 CD4+ and CD8+ T cells	T-cell growth factor, B-cell growth factor, Ig class switching to IgE
IL-5	Type 2 CD4+ and CD8+ T cells	Stimulation of eosinophil development
IL-6	Type 2 CD4+ T cells, MØ	Stimulation of acute phase proteins, activation of lymphocytes
IL-7	Stromal cells bone marrow	Stimulates survival and expansion of immature T and B cells
IL-10	Th2 and Th3 T cells, MØ	Immunosuppression
IL-12	MØ, DC	Stimulation of IFN-γ production
IL-13	Type 2 CD4+ T cells	Allergic inflammation, upregulation of VCAM-1 expression
IL-15	Fibroblasts, EC, DC	CD8+ T-cell growth factor
IL-17	CD4+ T Cells	Promotes inflammatory responses; may trigger autoimmunity
TNF-α	T cells, NK cells, MØ	Upregulation of AM expression, stimulation of CK production, inflammation
TNF-β	Type 1 CD4+ and CD8+ T cells	MØ activation, cytolysis
IFN-γ	Type 1 CD4+ and CD8+ T cells, NK cells	MØ activation, upregulation of AM expression, production of T-cell chemoattractants, inhibition of Th2 cells
GM-CSF	T cells, NK cells, B cells, MØ	Stimulation of MØ and granulocyte development
TGF-β	T cells, B cells, mast cells, MØ	Immunosuppression

AM, adhesion molecules; CK, chemokines; DC, dendritic cells; EC, endothelial cells; MØ, macrophages; NK cells, natural killer cells.

defense mechanisms represent nonspecific barriers to invaders, which rely primarily on physical barriers, phagocytic cells, natural killer cells, complement, acute phase proteins, lysozyme, the interferons, and defensins. Innate immunity also underlies most inflammatory responses; these are initially triggered by macrophages, polymorphonuclear leukocytes, and mast cells through their germline-encoded innate immune receptors (Janeway and Medzhitov, 2002).

Barrier Function

The body's first line of defense includes mechanical, chemical, and biologic barriers that lie external to the basement membrane of the skin and mucous membranes of the respiratory, alimentary, and urinary tract. The epithelial surface of tissues exposed to the environment provides a barrier to infection. This is most clearly demonstrated by the increased susceptibility to infection at sites where the epithelial barrier is breached, such as occurs in open wounds. In addition, the epithelial cells protecting the internal portion of the body produce mucus that prevents microbial adherence to the epithelium. Hairs and cilia serve to filter and sweep out microbes. The strong periodic flushing of the urinary tract helps to limit bacterial ascension to the kidneys. Cells composing most areas of the epithelial barrier also produce small, positively charged antibacterial peptides called **defensins.**

Defensins

Defensins are small cysteine-rich peptides of 18 to 45 amino acids that are found in both vertebrates and invertebrates (Klotman and Chang, 2006). They are active against bacteria, fungi, and both enveloped and nonenveloped viruses. Cells of the immune system contain these peptides to assist in killing phagocytized bacteria—for example, in neutrophilic granulocytes and almost all epithelial cells. Most defensins function by binding to microbial cell membranes, and once embedded, forming porelike membrane defects. These defects allow the efflux of essential ions and nutrients, resulting in microbial death.

Phagocytosis

Phagocytosis is a nonspecific innate response of circulating neutrophils and macrophages that actively ingest microbes and secrete antimicrobial toxins. Phagocytosis also includes reticuloendothelial cells such as Kupffer cells in the liver and bronchial alveolar macrophages. **The macrophage advances pseudopodia over the microbe, which is internalized into a phagocytic vacuole that fuses with a lysosomal vacuole.** This fusion vacuole results in the degradation of the microbe or particle as digestive enzymes are released. Killing is mediated by reactive oxygen intermediates and hydrogen peroxide (Underhill and Ozinsky, 2002).

Opsonization

The term opsonization describes the process of tagging microbes with macromolecules, or "opsonins," that promotes their elimination by phagocytosis. **Opsonins can be complement fragments (C3b) or antibodies such as IgG, which can be recognized by surface receptors on neutrophils and macrophages.** When antibodies bind to a microbe, their Fc regions project outward and can engage the high-affinity receptor for the Fc regions of γ chains called FcγR1 (CD64), which is expressed on neutrophils and macrophages. The engagement of antibody Fc tails to these receptors will trigger the intracellular machinery that begins phagocytosis, because FcγR1 contains various signaling chains that are necessary for activation.

Granulocytes

The polymorphonuclear leukocyte (PMN) shares a common stem cell precursor with the other formed blood elements, and is the predominant cell type, comprising 60% to 75% of the circulating white blood cells. The name derives from its multilobed nucleus, and the cytoplasm is filled with granules. The granules are often lysosomal and contain the enzymes necessary to digest engulfed microorganisms. Based on the histologic appearance of the granules, they are identified as neutrophils, eosinophils, or basophils, and are about 16 to 18 microns in diameter. **The PMNs are phagocytic and can be attracted to a local site by chemotactic factors such as complement C5a.** The eosin-staining granules of eosinophils contain cationic peptides that are toxic to surrounding tissues. The number of eosinophils increases during allergic reactions and during parasitic infestations. Basophil granules stain with basic dyes and contain heparin, histamine, and proteases. Surface receptors bind IgE with high affinity**. Binding of antigens to the surface IgE on basophils cause them to degranulate, resulting in immediate (type I) hypersensitivity. When basophils are fixed in the tissues they are called mast cells.**

Monocytes and Macrophages

Bone marrow–derived mononuclear phagocytic cells circulate in the blood for 1 to 2 days, and then migrate and attach to tissues where they mature and become macrophages**. They usually occupy perivascular areas and can be called Kupffer cells in the liver, alveolar macrophages in the lung, and histiocytes in connective tissue, brain microglia, or kidney glomerular mesangial cells.** They are relatively large, 15 to 25 microns, and have abundant lysosomes and digestive enzymes required for phagocytosis. These cells have a variety of cell surface receptors that enable them to bind to carbohydrates and protein molecules, such as immunoglobulins (Fc receptor) and complement (CR 1 and 3). Mononuclear phagocytes also secrete a rich array of cytokines, such as tumor necrosis factor alpha (TNF-α), IL-1, IL-6, prostaglandins, and some complement proteins. Activated macrophages can also express cell surface major histocompatibility complex (MHC) class I and II molecules, which play an important role in antigen presentation.

Natural Killer Cells

These are large granular lymphocytes that can destroy various nucleated cells including tumors and virus-infected cells. They are an important component of innate immunity and do not require prior contact with antigen, nor are they MHC-restricted. NK cells release cytotoxic factors such as perforin, serine proteases called granzymes, and tumor necrosis factor beta (TNF-β). They can also trigger apoptosis in their targets. Interferons seem to augment their activity. They also participate in antibody-dependent cell-mediated cytotoxicity (ADCC), by the binding of their cell surface Fc receptor (CD16) to the Fc portion of antibody-coated cells. The precise lineage of NK cells is not known. Characterized by the presence of CD16 and CD56, and the absence of CD3, they have IL-2 receptors and respond to exogenous IL-2. Although their

T-cell receptor (TCR) genes are not rearranged, they seem to be related to T cells (Yokoyama et al, 2004).

Toll-Like Receptors

Toll receptors were originally identified as transmembrane receptors required for the establishment of polarity in the developing *Drosophila* embryo, but also were shown to be essential in protecting flies from infection. The mammalian counterpart, a family of 10 structurally similar proteins has been identified and named Toll-like receptors (TLRs 1 to 10). Most tissues express at least one TLR, but phagocytes, in particular, show abundant expression of all known TLRs. The mRNA of TLRs has been found in monocytes and macrophages, dendritic cells, mast cells, B cells, and epithelial cells of the respiratory and intestinal tract. Different TLRs respond to different products of microbes, but all of the TLRs activate similar signaling mechanisms, resulting in cellular responses that are central to innate immunity. The TLRs can be present on the cell surface, where they recognize the extracellular products of microbes, and other TLRs are actually part of intracellular endosomes where microbes are ingested. Once TLRs are engaged, they activate transcriptional factors that signal the expression of genes that encode various enzymes, proteins, and cytokines that focus on the antimicrobial functions of phagocytes and dendritic cells (see Immunity to Infections).

Pattern Receptors

Various components of innate immunity recognize structures that are shared by many microbes but are not present on host cells. Examples are bacterial lipopolysaccharide (endotoxin), terminal mannose residues typical of bacterial but not mammalian glycoproteins, double-stranded RNA (viral), and certain unmethylated oligonucleotides seen in microbial DNA**. The receptors that recognize these shared but different structures are referred to as pattern recognition receptors. Many pattern receptors have evolved to recognize structures that are essential for the survival and infectivity of the microbes.** The receptors of innate immune system are encoded in the germline, have a predetermined specificity, and have evolved as a protective mechanism against invading microbes. Thus all macrophages may recognize one microbial pattern receptor. The innate immune system does not react against "self" because the inherent specificity of its receptors are coded for microbial structures, and there are regulatory molecules that control reactions. Thus the innate immune system responds the same way to repeat encounters with a microbe. This is in distinct contrast to the adaptive immune system, which is produced by somatic recombination of genes.

Complement

A major component of innate immunity is the collection of about 20 soluble proteins referred to as complement. Complement, once activated, can directly lyse invading bacteria or viruses, and several of its components are important in the regulation of immune responsiveness (Carroll, 2004). **Complement activation results in a cascade phenomenon where the product of one reaction is the enzyme catalyst of the next.** Each component is described by the letter "C" and a number, more closely reflecting the sequence of discovery rather than sequence of action. The split components are designated with an a or b. The most critical component is C3, which has a molecular weight of about

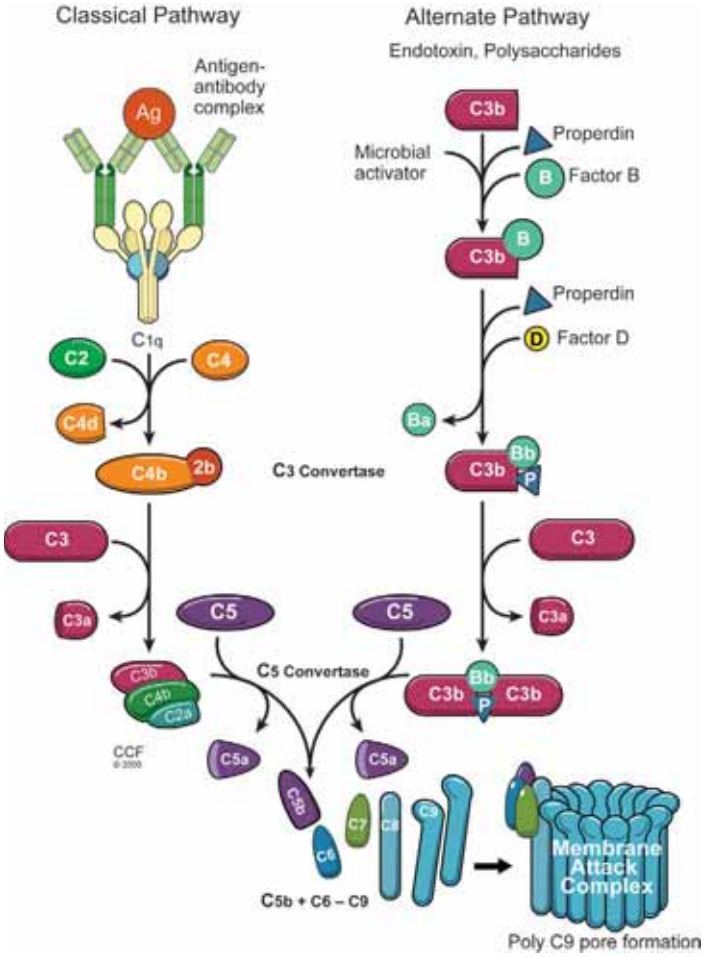

Figure 17–1. The classical and alternative complement pathways. Each component protein labeled "C" acts as an enzyme catalyst for a subsequent product in a ever-expanding cascade. The process can be initiated when an antigen-antibody complex fixes the first component C1q to the cell surface. Alternatively, the cascade can be initiated by microbial products and properdin that can directly activate C3. In addition to forming the membrane attack complex, complement fragments C3b can function as opsonins, and C3a and C5a function as anaphylatoxins. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

195 kD. Once complement proteins and a target substance interact, a C3 convertase is activated, which splits C3 into C3a and C3b fragments (Fig. 17–1). The C3b bound to the target becomes a component of the convertase for C5. The union of C5b with C6-C9 generates the membrane attack complex (MAC), which integrates with the lipid bilayer of the target cell. The MAC produces cell membrane lesions that permit loss of potassium and ingress of salt and water leading to hypotonic lysis (Walport, 2001).

Complement plays an important role in the elimination of microbes and invaders during both innate and adaptive immune responses. Three important mechanisms can be identified. **(1) Opsonization and phagocytosis:** Not all C3b produced becomes a component of the C5 convertase. Some binds directly to the cell membrane and coats microbes, acting as an **opsonin** for phagocytes such as neutrophils and macrophages that have receptors for C3b. **(2) Complement-mediated cytolysis**: C3b bound directly to a microbe can trigger late complement components and formation of the MAC, leading to osmotic lysis. **(3) Augmentation of inflammation:** Fragments C3a and C5a serve as powerful **anaphylatoxins** that degranulate mast cells

with the release of histamine, which enhances vascular permeability and smooth muscle contraction. The C5a fragment is also a chemoattractant for PMNs and macrophages, which are recruited and activated at inflammatory sites.

Multiple substances may trigger the complement system, which has two pathways of activation. **The classical pathway is a mechanism to activate C3 using the serum proteins C1, C4, and C2. The process is initiated when an antigen-antibody complex fixes the first component C1q, which results in the cascade C1qrs, 4, 2, 3, 5, 6, 7, 8, 9 to produce lysis**. Complement fixation requires one IgM or several IgG antibody molecules. **The alternative pathway is non–antibody dependent, and does not require C1, C4, and C2 to initiate the process.** It is dependent upon bacterial products such as endotoxin and microbial polysaccharides and a serum globulin called **properdin,** which activates C3 directly. An alternative C3 convertase is formed that triggers the sequence leading to cell lysis. The complement system is regulated by endogenous inhibitors that protect the host from continuous activation. These complement regulatory proteins, such as decay accelerating factor (DAF), membrane cofactor protein (MCP, CD46), and CD59, are glycoproteins found on erythrocytes, platelets, neutrophils, and on selected mucosal epithelial and endothelial cells. For example, the membrane protein DAF disrupts the binding of factor B to C3b, or the binding of C4b2a to C3b, which terminates both the classical and alternate activation pathways. MCP serves as a necessary cofactor for the proteolysis of C3b into inactive fragments.

Recently, complement activity has become an important target for immune responses to transplanted organs. The human gene for DAF has been transfected into pigs in an attempt to control complement activation during a pig-to-primate xenograft rejection model. In addition, the complement protein split product C4d has been proposed as a reliable marker for antibody-mediated rejection of renal allografts. Antibody-mediated activation of the classical complement pathway leads to the formation of C4d, which covalently binds to the endothelial surface of the kidney peritubular capillaries, thus leaving an imprint of antibody activity that persists for days to weeks (Collins, 1999). C4d-staining in the kidney correlates with the presence of circulating donor-specific antibody in the recipient.

ADAPTIVE IMMUNITY

Specifically acquired, or **adaptive,** responses result from repeated exposure to invading microbes, and rely primarily on large populations of lymphocytes, each with its own individual (clonal) specificity for an invader. **In addition, the clonal expansion of specific lymphocyte populations after first contact with a foreign molecule confers memory and the ability to elicit a more vigorous response upon subsequent exposure to the same foreign molecule.**

Unlike innate immune pattern receptors, which are encoded in the germline, the adaptive immune system is produced by somatic recombination of genes during maturation, which can generate many more structurally different receptors on lymphocytes such as antibodies and T-cell receptors. This provides for more **diversity** of adaptive responses that are capable of recognizing many more chemically distinct structures. **It is estimated that the entire lymphocyte population can recognize more than a billion different antigens, while innate immune receptors recognize less than a thousand microbial patterns.** Adaptive responses are purged of self-reacting lymphocytes during their first encounter with self-antigens.

Lymphoid Organs and the Lymphatic System

Although descriptions of immune responses are often presented as individual events, in vivo they take place within the organized architecture of lymphoid tissue. **Bone marrow stem cells differentiate into immunocompetent T and B cells in the primary lymphoid organs, and then colonize the secondary lymphoid tissues where the immune responses take place.** The primary lymphoid organs are the thymus, responsible for the selection and education of T cells, and the bone marrow, responsible for the education of B cells. Secondary or peripheral lymphoid tissue includes the spleen, lymph nodes, and unencapsulated tissues lining the alimentary, respiratory, and urogenital tracts (Drayton, 2006). B lymphocytes seed the secondary lymphoid tissues where they form follicles. **The spleen filters the blood, the lymph nodes drain local body tissues, and the unencapsulated tissues associated with mucosal surfaces can secrete IgA antibodies.** The lymphoid tissues communicate through a network of lymphoid ducts that drain all the viscera and return through the thoracic duct to the circulation (Fig. 17–2). This communication is maintained by populations of

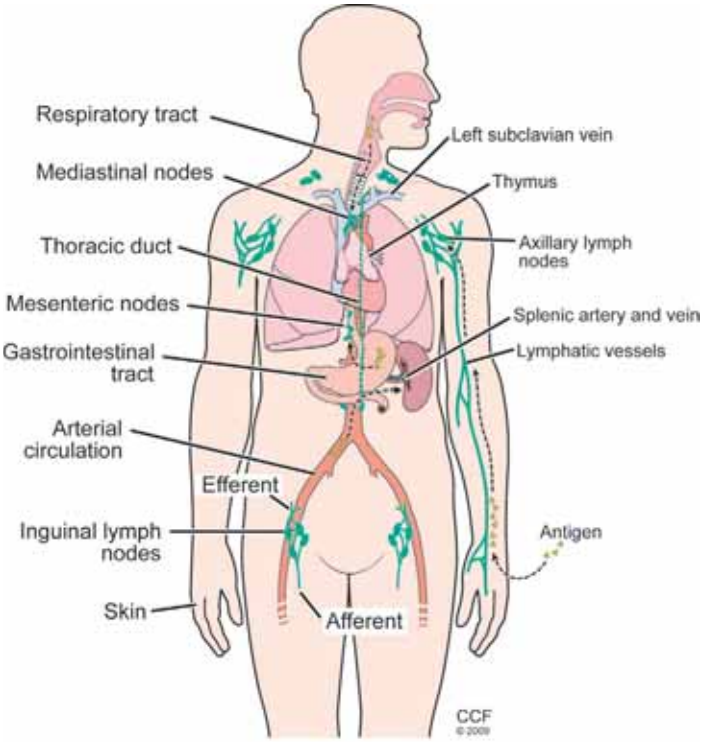

Figure 17–2. The lymphatic system. A major function of the lymphatic system is to collect antigens from their portals of entry and deliver them to lymph nodes where they first interact with immunoresponsive cells of the host. Numerous lymphatic capillaries in the periphery absorb and drain interstitial fluid (lymph) that flows into convergent, ever-larger, central lymphatic vessels. Ultimately the large central thoracic duct drains into the superior vena cava returning the lymph to the circulation. Lymph nodes are interposed along lymphatic vessels and act as filters that sample the lymph at numerous points before it reaches the circulation. The course of antigens (Δ) entering in the periphery or the gastrointestinal tract are followed. Lymphatic vessels that carry lymph into a lymph node are referred to as afferent, and those that drain lymph from the node are called efferent. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

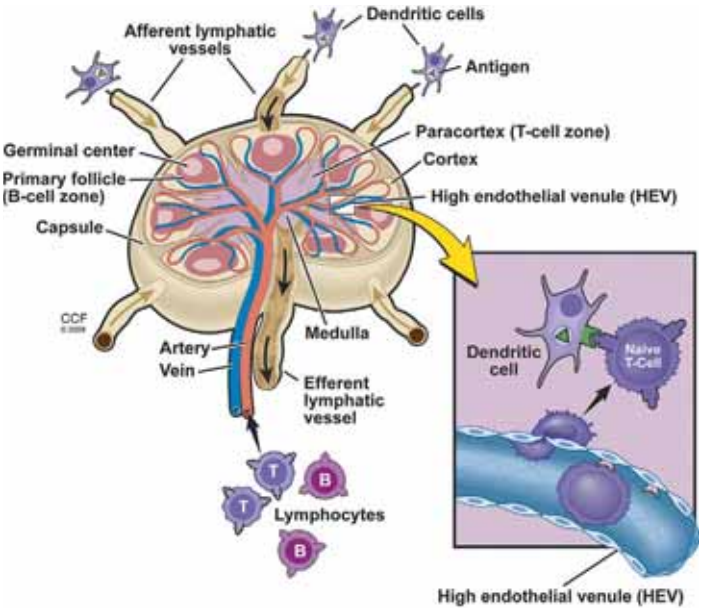

Figure 17–3. Representative morphology of a lymph node. Lymph nodes reside in the periphery connected by lymphatic channels. Each has its own arterial and venous circulation. Afferent lymphatic vessels carry lymph fluid into the node, and efferent lymphatic vessels carry lymph fluid out of the node, eventually reaching the circulation through the thoracic duct. The node is organized into a cortex and medulla. The T lymphocytes aggregate into the paracortical areas and the B lymphocytes form follicles with germinal centers in the periphery of the node. Naive lymphocytes first encounter antigen displayed by dendritic cells in the lymph nodes. Once activated, lymphocytes exit through the efferent lymphatic vessels. Specialized high endothelia venules form a gate for lymphocyte entry into the node. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

recirculating lymphocytes, which can travel from the blood into the spleen, lymph nodes, and peripheral tissues, and return. **This traffic, or recirculation, of lymphocytes between the peripheral tissues, lymph nodes, and bloodstream enables the immune system to function as a single organ.** Antigen-responsive cells can be recruited to peripheral sites for initial activation, and memory cells can be disseminated to these sites to amplify ongoing responses.

The lymph nodes, located along lymphatic channels throughout the body, are the primary nexus where naive immunocompetent cells meet a foreign antigen (Fig. 17–3). Fluid draining from various epithelial cells, tissues, and organs (called lymph), is collected through lymph channels and funneled to lymph nodes through their afferent lymphatic vessels. The assorted antigen-presenting cells (APC) residing in the nodes can then sample the various antigens, particles, and microbes present in the lymph fluid. In addition, dendritic cells can directly transport digested antigenic particles through lymph fluid to the nodes. Naive T and B lymphocytes enter the nodes through the arterial circulation and migrate through specialized high endothelial venules (HEVs) to reside in the node where they encounter antigens. The lymph nodes are organized into various compartments that concentrate the different lymphocyte subsets. T cells migrate to the paracortical areas of the nodes where they encounter antigens that are displayed by dendritic cells. The B cells form follicles at the periphery of the nodes that often contain germinal centers in which rapid B-cell maturation and proliferation occurs. Once activated, lymphocytes exit the lymph nodes through efferent lymph channels to reach the circulation and migrate to the periphery at sites of inflammation and infection.

Cellular immune traffic is also highly organized and restricted, with certain cell populations directed to specific sites. For example, lymphoblasts and memory cells display tissue-restricted migration to extralymphoid sites such as the skin or mucosal surfaces, while lymphocytes, neutrophils, and monocytes, target and migrate to sites of inflammation in response to local mediators. Such directed movement of immune cells is termed homing, and results from the interaction of various homing receptors that recognize their complementary ligands on the surface of specialized vascular endothelium in selected tissues (Salmi and Jalkanen, 1997). Much of this directional trafficking is orchestrated by two families of G protein–coupled receptors: chemokine receptors and sphingosine-1-phosphate (S1P) receptors (Cyster, 2005). For example, in the spleen, lymphocytes enter the lymphoid area (white pulp) from the arterioles, pass to the sinusoids of the erythroid area (red pulp), and leave by the splenic vein.

Dendritic Cells

Dendritic cells originate in the bone marrow but are dispersed and populate the epithelium of common sites of entry for microbes, such as the respiratory and gastrointestinal tracts and the skin. In the skin, epidermal dendritic cells are called Langerhans cells. They are also dispersed throughout most solid organs. They are characterized by thin membranous projections, which are helpful for capture of large protein antigens. **Dendritic cells are commonly referred to as "professional antigen-presenting cells (APCs)," because they display antigens and provide activating signals to T and B lymphocytes.** Dendritic cells not only capture antigens, but also transport them to peripheral lymphoid tissues where they encounter lymphocytes. During their migration to lymph nodes, dendritic cells mature by increased synthesis and expression of MHC and surface costimulatory molecules needed for T-cell activation (Villadangos and Schnorrer, 2007). In addition, dendritic cells play a central role in the differentiation of naive T cells into their various subsets.

Lymphocytes: T and B Cells

T lymphocytes originate in the bone marrow and migrate to the thymus where they undergo a complex process of maturation. Mature T cells are responsible for cell-mediated cytotoxicity, providing help to antibody-producing B cells, delayed-type hypersensitivity, and play specific roles in immune regulation. Stem cells first enter the outer cortical thymus and mature as they pass to the thymic medulla. During this migration, the critically important surface T-cell receptor (TCR) genes are rearranged, and the CD3, CD4, and CD8 surface molecules appear (Starr et al, 2003). **During maturation CD4–CD8– (double-negative) T cells develop into CD4+CD8+ (double-positive) T cells, and then become single-positive CD4–CD8+ (cytotoxic/suppressor) or CD4+CD8– (helper/inducer) T-cell precursors. Each retains the pan–T-cell CD3 marker, which is a signal-transducing component of the TCR.** Thymic T-cell maturation also involves the critical initial process of self-recognition, which is a consequence of the interaction between maturing T cells and the surrounding thymic cortical epithelium. This leads to the selection of those T cells that are to be saved. **Negative selection** occurs when CD4+CD8+ TCR+ thymocytes recognize self-peptide–MHC complexes on thymic epithelium with high avidity, which leads to apoptosis or deletion of these clones. The

majority of cortical thymocytes are killed during the selection process, thus preventing the development of autoimmune T cells. During **positive selection** CD4+CD8+ TCR+ thymocytes recognize self-peptide–MHC complexes on thymic epithelial cells with low avidity. This saves them from programmed cell death. **The resulting T-cell populations are self-MHC restricted and tolerant to self-antigens, but are capable of reacting to foreign antigens.** Cells leaving the thymus migrate to the peripheral lymphoid organs and seed the T-dependent regions of lymph nodes, spleen, and lymphoid follicles (Przylepa et al, 1998).

B lymphocytes are responsible for the production of immunoglobulin or antibody. They are so named because they mature in hindgut lymphoid tissue called the bursa of Fabricius in birds. In mammals the bone marrow serves as their point of origin and maturation. Immature B cells express immunoglobulin in their cytoplasm, and mature B cells express immunoglobulin on their cell surface. **Cell surface immunoglobulin, both IgD and IgM, serves as the antigen receptor on B cells. Each B cell has about 10^5 identical antibody molecules on its surface. Once activated by antigen bound to its surface antibody, B cells mature to become plasma cells, which secrete the specific antibody. That is, a single B cell produces only one antibody specificity that recognizes only one antigenic determinant (epitope).** B cells also express receptors for the Fc portion of antibody (FcR), which serves to concentrate antigen-antibody complexes on their cell surface. In addition, B cells also express receptors for the third component of complement (C3R). Plasma cells develop from B cells and are large, ellipsoid in shape with an eccentric nucleus, and about 15 to 20 microns in diameter. They are factories for antibody production, although they do not express surface antibody, complement receptors, or CD19 and CD20.

Trafficking of Naive T Cells

Rather than remain passively in the lymphoid tissues, naive or antigen inexperienced T cells circulate through the secondary lymphoid tissues using the lymphatic and blood vessels (Picker and Butcher, 1992). From the blood vessels, T cells enter secondary lymphoid tissues using specialized carbohydrate binding proteins termed selectins. Naive T cells express high levels of L-selectin (CD62L) that mediates binding to its ligand, peripheral lymph node vascular addressin (PNAd). PNAd is expressed by specialized postcapillary venules, called high endothelial venules (HEV), draining the lymphoid node. CD62L-PNAd engagement ceases the circulation of the T cells, allowing the T cells to traverse the HEV barrier and enter the cortical areas of the lymph node. The cortical areas of lymphoid tissues are rich in professional antigen-presenting cells such as macrophages and dendritic cells (see Fig. 17–3). As the naive T cells percolate through this area the T-cell receptors on each cell can survey the surface of these APCs for recognition of the specific peptide-MHC ligand, leading to cellular activation. This restricted circulation of naive T cells optimizes the chance of T-cell encounters with dendritic cells presenting the specific ligand, and is critical for efficient immune surveillance in light of the low number of T cells specific for any particular antigen-MHC complex (approximately 1 in every 10^5 to 10^6 cells). Unless the T cell encounters the appropriate activating complex presented by an antigen-presenting cell, the naive T cells exit the lymph node through the efferent lymphatics and are eventually carried into the thoracic duct. The thoracic duct drains into the blood vessels, and the pattern of naive T-cell circulation through the secondary lymphoid tissues continues.

MOLECULES OF THE ADAPTIVE IMMUNE SYSTEM

Major Histocompatibility Complex

The MHC describes a region of genes, located on chromosome 6 in man, that encodes proteins responsible for the rejection of tissue between different species or members of the same species. More importantly, these cell surface proteins serve as identity markers on cells interacting with T lymphocytes carrying out specific immune functions. The cell surface MHC markers are called human leukocyte antigens (HLA), because they were first identified on white blood cells. There are two major types of HLA antigens termed class I and class II. Interestingly, a heterogeneous group of protein products that track with the MHC termed class III have immune-related functions and include some complement proteins and tumor necrosis factors. **Virtually all nucleated cells express HLA class I antigens, while class II antigens are primarily found on B cells, monocytes, macrophages, and antigen-presenting cells.** Many other cells can express class II antigen once activated, such as renal tubular epithelium during kidney allograft rejection. Interferon is a cytokine that can upregulate different cells to express class II antigens during activation. **Each individual inherits two class I and one class II antigen(s) from each parent, so six HLA antigens constitute an individual's tissue type (three from each parent).** The HLA molecules are polymorphic, based on multiple alleles (alternative genes at each locus) with over 150 now serologically defined. Therefore it is very unusual if two unrelated individuals have the same tissue type of six HLA antigens.

Both class I and II molecules are dimers with an α and a β chain (Fig. 17–4). The class I alpha chain has three domains of amino

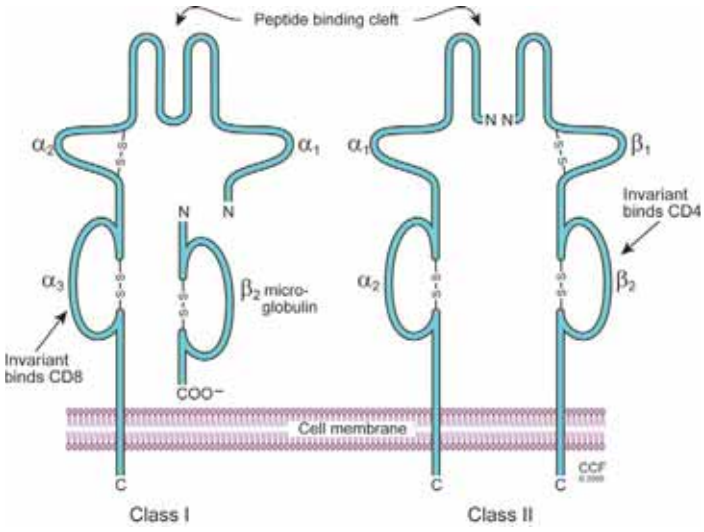

Figure 17–4. Schematic diagram of major histocompatibility complex (MHC) class I and class II molecules. Both are cell surface glycoprotein dimers with the carboxyl terminus directed towards the plasma membrane. Class I molecules (left) have an alpha chain with three domains and an invariant beta chain with a solitary domain. Class II molecules (right) have two alpha- and two beta-chain domains. Both molecules have polymorphic Ig-like regions that extend off the cell surface and form a cleft in which small peptides can bind. A peptide residing in an MHC molecule cleft provides signal 1 to the receptor of a naive T cell during activation. The nonpolymorphic Ig-like domains of MHC molecules contain binding sites for the T-cell molecules CD4 and CD8. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

acids and a constant β chain called β-2 microglobulin, which is the same in all class I molecules and does not insert into the cell membrane (Bjorkman, 1987). The class II molecules have two domains for each chain, and both chains insert into the cell membrane. **The alpha-1 and -2 domains of class I molecules and the alpha-1 and beta-1 domains of the class II molecules form a unique antigen peptide–binding cleft that cradles the antigen and is essential for antigen presentation.** Analysis of peptides eluted from the binding groove of MHC class I molecules revealed that a maximum of 8 to 10 amino acids will fit, while the groove for the MHC class II molecule is larger and allows a peptide of 12 to 28 amino acids in length. The β-2 microglobulin domain of the class I and the alpha-2 and beta-2 domains of the class II molecules are fairly invariant, so the diversity of the different HLA antigen molecules resides in the domains that define the peptide-binding groove.

T-Cell Receptor

The TCR is that cell surface structure responsible for the initial steps in T-cell activation upon encounter with antigen. The TCR comprises at least seven receptor subunits whose production is encoded by six separate genes that are precisely assembled (Davis and Bjorkman, 1988). The TCR is composed of the clonotypic α and β chains that are responsible for antigen binding and are noncovalently associated with the invariant CD3-γ, -δ, -ε, and TCR ζ chains. The cytoplasmic tails of the CD3 and TCR ζ chains contain a critical amino acid sequence known as the immunoreceptor tyrosine–based activation motif (ITAM) that includes two tyrosine residues. The CD3 chains contain one ITAM, while the TCR ζ chain contains three ITAM sequences (Fig. 17–5). **CD3 is commonly called the pan–T-cell marker, present on all T cells. There are generally two types of TCRs named TCR1 and TCR2. The TCR1 consists of a γδ heterodimer, appears first in ontogeny, and represents about 5% of circulating T cells in an adult. The TCR2, representing 95% of peripheral blood T cells, has an αβ heterodimer. Each of the two polypeptides comprising each receptor has a constant and a variable region (similar to immunoglobulin). Antigen recognition takes place at the variable αβ heterodimer, resembling an antibody Fab antigen–binding fragment.** The relatively invariant transmembrane CD3 complex transmits the signal to the cell interior. Reminiscent of the diversity of antibody molecules produced by rearrangements of variability, diversity, and joining genes, the TCRs can likewise identify a large number of antigenic specificities, estimated to be 10^{10} to 10^{12} epitopes (Davis et al, 1998). The affinity of TCR binding to APCs is rather weak, which is why additional adhesion molecules are required to strengthen the interaction.

B-Cell Receptor

The functional B-cell receptors are the IgD and IgM immunoglobulin molecules on the surface of B cells. These antibodies are anchored to the B-cell plasma membrane by the C-terminal ends of their heavy chains. The surface antibodies provide antigen specificity through the variable regions of both heavy and light chains, which face outward from the cell surface. The variable regions usually have three hypervariable or complementarity-determining regions (CDRs) that make direct contact with antigens. The CDRs form a loop structure that is complementary to the three-dimensional structure of the antigen. The antigen

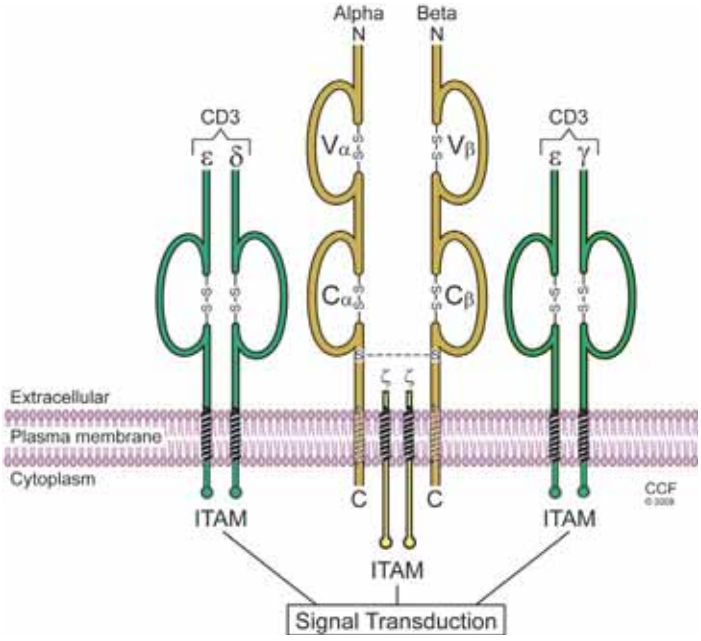

Figure 17–5. Schematic diagram of the T-cell receptor (TCR). The receptor is a complex of two main glycoprotein alpha and beta chains (defining an αβ TCR) noncovalently linked to the CD3 proteins (γ, δ, ε) and the ζ chain. As in other Ig superfamily products disulfide bonds form domains and the carboxyl terminus of each chain is inserted into the plasma membrane. The amino terminus extracellular domains are variable in amino acid sequence, and form the site of recognition of MHC-peptide complexes. The CD3 and ζ chains have intracytoplasmic ends (○) with signaling functions termed immunoreceptor tyrosine based activation motifs (ITAMs). The phosphorylation of the tyrosines in ITAMs represent the initial intracellular signaling events induced by TCR interaction with antigen. receptors of B cells can recognize a wide variety of macromolecules, such as proteins, polysaccharides, lipids, and nucleic acids. This broad specificity of B cells gives antibodies a wide net to recognize microbes and toxins in their native form. However, very large proteins are not able to bind B-cell receptors, and a full B-cell response requires help from CD4+ T cells. B cells can ingest protein antigens, which are processed and displayed as peptides with MHC molecules for recognition by helper T cells.

LYMPHOCYTE ACTIVATION

Presentation of Antigen

An essential requirement of immunity is that the system cannot be continuously triggered by self-antigens. As described previously, an early process of selection of T cells during maturation in the thymus deletes many offending clones, and selects those for future antigen response by utilizing MHC restriction. **The TCR2 T cells bearing αβ receptors only respond when the antigen-presenting cells express the same MHC molecules as the host from which the T cells were derived (the MHC molecules that first primed the T cell).** The types of responses are also controlled by the specificity of the MHC antigens on the APCs themselves. **Those T cells bearing CD8 that are programmed to be cytotoxic require APCs to present antigen in the context of MHC class I molecules, while those helper T cells expressing CD4 require antigen to be**

associated with MHC class II molecules on the APC for activation (Micelli and Parnes, 1993).

An additional layer of control is also imbedded in this system. Antigen must be processed into smaller pieces, linear 8 to 20 amino acid sequences, so it can fit precisely into a groove created by the outermost domains of the class I and class II MHC molecules (Germain, 1994). The result is that the T cell must recognize both MHC and peptide in a particular arrangement for antigen-specific activation to take place (Madden, 1995). **Antigen processing necessitates the conversion of native proteins to peptide-MHC complexes. This involves uptake by the cell, proteolysis, and additional mechanisms for the repackaging and transport of the MHC-peptide complex to the cell surface**. In general, peptides associated with MHC class I are derived from proteins synthesized within the cell on cytosolic ribosomes, such as viral and oncogenic products, whereas those peptides associated with MHC class II molecules often originate from extracellular fluids, such as bacterial products and toxins, and are taken up by receptor-mediated endocytosis.

Antigen-Presenting Cells

An antigen-presenting cell (APC) is a cell that can process a protein antigen, breaking it into peptides and then presenting it in conjunction with MHC molecules on the cell surface, where it may interact with appropriate T-cell receptors. Macrophages, monocytes, some B cells, Langerhans cells of the skin, dendritic reticulum cells, and vascular endothelium can process and present antigen. **The most efficient are the dendritic cells, which have a characteristic starfish shape and line the epithelial layer of exposed surfaces.** Once mature, they travel to the periphery to pick up antigen, then process and present it to naive T cells in the lymphoid tissues. These cells ingest proteins and split them into small peptides in endosomes. The peptides are then transported to the cell surface and assembled in the peptide-binding groove on the MHC molecules for presentation (Trombetta and Melman, 2005). **The peptides presented by APCs must be assembled with self-MHC molecules, forming the basis of MHC restriction in the immune response.** CD4+ T cells will recognize antigens only in the context of self-MHC class II molecules on the surface of the APCs. Again, cells that can initiate an immune response, such as dendritic cells, macrophages and some B cells, are often referred to as "professional APCs."

Three Signals

T cells become activated when the TCR engages an antigen for which it is specific; however, the TCR must "see" the antigen peptide presented in the groove of an MHC molecule on an APC. The interaction of one TCR and a peptide-MHC is of surprisingly low affinity and must be stabilized by an appropriate coreceptor–CD4 for MHC class II and CD8 for MHC class I molecules (Fig. 17–6). This initial step is called **signal 1.** Although triggering by signal 1 is necessary, it is not sufficient for T-cell activation alone. In fact, stimulation by signal 1 alone leads to a state of anergy, whereby the T cell becomes unresponsive to antigen. **Activation requires costimulation by proteins on the APC that engage specific receptors on the T-cell surface, referred to as signal 2.** The major APC molecules providing signal 2 are B7.1 (CD80) and B7.2 (CD86), but a number of other accessory molecules may support or enhance costimulation, such as CD2 engaging LFA-3 (CD58) and

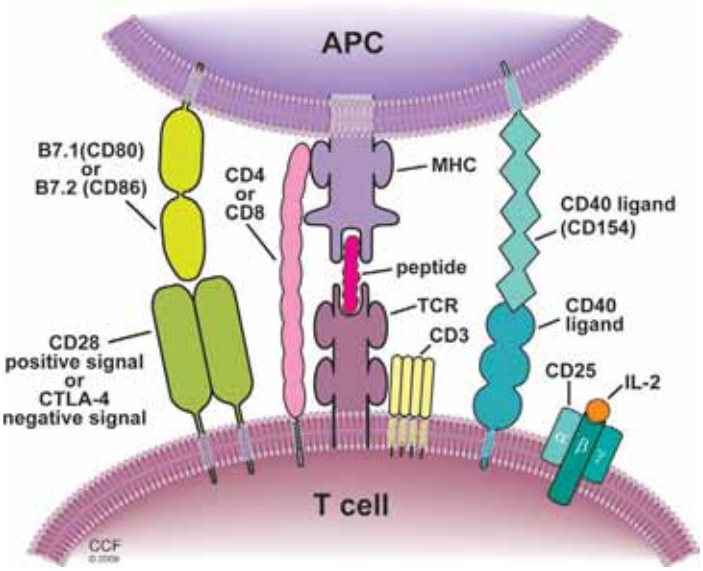

Figure 17–6. The immune synapse: T-cell activation requires three signals. Activation is initiated at the cell surface between an antigen-presenting cell (APC) and a T cell bearing a T-cell receptor (TCR). Signal 1 is delivered by an APC by a major histocompatibility complex (MHC) molecule with bound peptide to a tight-fitting TCR. This interaction is stabilized by a T-cell CD4 during presentation by MHC class II molecules, and stabilized by CD8 for presentation by MHC class I molecules. Activation will not proceed without the delivery of a second signal, which is required for further intracellular signal transduction. The second signal may be delivered by one of several glycoproteins, such as B7 (CD 80/86) and CD40, to their T-cell ligands CD28 and CD40 ligand (CD 154), respectively. The necessary signal 3 is delivered by interleukin-2 (IL-2) and other cytokines (IL-15) to their respective receptors. This leads to activation of various cyclins and the target of rapamycin, resulting in T-cell proliferation. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

LFA-1 engaging ICAM. These molecules engage the T-cell surface glycoprotein CD28, and when combined with signal 1, leads to activation of calcium-calcineurin phosphatase, mitogen-activated protein (MAP) kinase, and protein kinase C pathways, which in turn initiate transcription (Dustin, 2005) (see Signal Transduction). **Completion of activation requires the delivery of growth factors (interleukin [IL]-2 and -15), using phosphoinositide-3-kinase (PI-3K) and the target of rapamycin (mTOR) pathways, referred to as signal 3, thus initiating the cell cycle.**

Recognition of Alloantigen

The MHC was originally defined by its ability to provoke and sustain the rejection of organs and tissues between members of the same species (the allograft response). This response can be very rapid and intense, because individuals have a very high frequency of potentially alloreactive T cells. **As previously described, only a small fraction of T cells are specific for a single peptide, yet more than 10% of the T-cell population can react with alloantigens. Why is this so? Alloantigens create a unique potential for T-cell activation, because they serve both as immunogens as well as participants in the activation of the immune response in the host.** When an allograft kidney, heart, or liver is transplanted into a recipient, it brings an array of tissue-bound cell-surface class I and II MHC antigens that are foreign to the host. In addition,

the grafted organs transport large numbers of "passenger leukocytes" that can be both adherent to the blood vessels as well as within the interstitial tissues. As a "passenger leukocyte" the mononuclear dendritic cell is particularly suited to augment the alloimmune response, because it functions as an APC and can traffic from the graft to recipient secondary lymphoid tissues to interact with immune-competent cells. **Remember that the requirements for T-cell activation are dependent on both the presentation of peptide-MHC complexes and the costimulatory signals provided by professional APCs.**

The immune response is provided by two distinct pathways for allograft recognition (Gould and Auchincloss, 1999). In the **direct recognition** pathway, recipient T cells engage peptide-MHC molecules expressed on allogeneic cells. **The direct pathway is mainly responsible for the initiation of acute cellular rejection of allografts, and evidence suggests that passenger leukocytes (dendritic cells) play a key role.** These donor APCs must express both MHC class II and the appropriate costimulatory molecules, because the depletion of either will prevent an immune response from taking place. The peptides sitting in the MHC groove may be derived from endogenous proteins of either the donor or the recipient. Thus the foreign MHC molecules presented to the recipient can be a myriad of alloantigens, including the allogeneic MHC molecule itself plus the many different peptides derived from endogenous proteins. There is also evidence that recipient T cells can recognize allo-MHC molecules that are empty, with no peptide in the binding groove. These observations help explain why so many recipient T cells can become alloreactive and rapidly destroy a graft.

The immune response is also provided an indirect recognition pathway for alloantigens, whereby T cells recognize processed alloantigens presented by recipient APCs in association with self-MHC class II molecules. Mechanistically, this pathway requires the uptake and processing of the donor MHC molecules (to form peptide fragments) by the APCs of the recipient. **The evidence for such an indirect pathway comes from observations that rejection can take place even if donor and recipient share most, if not all, MHC antigens.** During indirect pathway recognition, recipient APCs migrate to the graft and take up soluble donor MHC molecules for processing. The actual T-cell activation occurs in recipient secondary lymphoid tissues, similar to activation in the direct pathway. Because the indirect pathway results in T cells that are self-MHC–restricted, their numbers are much smaller than those produced from direct pathway recognition, which predominates during the initiation of acute allograft rejection. However, the direct route becomes less important with time as the number of donor APCs diminish by senescence. The ready supply of recipient APCs involved in the indirect pathway is never depleted and can continuously process and present donor antigens. **For this reason, indirect recognition is thought to be more closely linked to chronic rejection of an allograft.**

Lymphocyte Precursor Frequency

The magnitude of the responses produced by various subsets of lymphocytes is closely related to the absolute number of precursor cells capable of responding. Thus the frequency of precursor cells can determine the robustness of an antigen-specific response in culture. Simply counting cells with a particular marker (i.e., CD4) may over- or underestimate the number of cells able to perform the function associated with cells bearing that marker. So, a technique called limiting dilution analysis (LDA) is used to measure the abundance of cells able to perform a particular function. The particular function can be CD4+ helper-cell proliferation measured by ^{3}H-thymidine incorporation, or CD8+ CTL lytic activity of chromium-labeled targets. The LDA procedure involves setting up cell cultures with graded dilutions of cell suspensions (peripheral blood lymphocytes) to be tested. If the quantity of active cells in the suspension is so high that each culture is positive for the specificity being tested, then all the cultures will be positive. If the concentration of cells is very low, then only rarely will a positive culture be found. Between these extremes, the response can be quantified as a function of cell dose. The analysis follows a Poisson distribution in that the dilution at which 37% of the aliquots give negative responses will contain one precursor cell per aliquot. From this concentration one can calculate the precursor frequency for the original cell suspension (Lefkovits and Waldmann, 1979).

Regulation of T-Cell Activation

Until they are activated through TCR-mediated engagement of a specific antigen-MHC complex on professional APCs, T cells are immunologically quiescent and do not express immune functions. **Activation of specific T cells and the generation of an immune response require transport of antigenic components to the lymphoid tissue. For the induction of most T-cell–mediated immune responses, the critical antigen-presenting cell is the dendritic cell, which is interspersed throughout peripheral tissues (Shortman and Naik, 2007).** As situated in the peripheral tissues, dendritic cells exist in an immature state and must be activated to perform the immune functions of antigen processing, presentation, and trafficking to the lymphoid tissue.

The immune system has evolved with highly regulated components to control the activation of dendritic cells and the transport of antigenic material to the lymphoid tissue. **Tissue trauma and/or the deposition of antigenic material in peripheral tissues, such as from a microbial infection, vaccination, or an organ allograft, induces a local inflammatory response. This inflammation is initiated by the production of TNF-α and IL-1 in response to tissue trauma and/or recognition of microbial products (Tracey and Cerami, 1994). Microbial products such as flagellin, unmethylated CpG of DNA, lipopolysaccharide, or single- or double-stranded RNA are potent activators of cells through innate pattern recognition and Toll-like receptors. In addition, endogenous stress molecules released by a variety of cells during tissue injury include HMGB1, heparin sulfate, and hyaluronan fragments bind to TLR2 and TLR4 to activate cells.** An important consequence of this response is that inflammation is stimulatory for antigen capture, processing, and transport to the lymphoid tissues. **Interstitial dendritic cells are activated by TNF-α to become phagocytic cells and ingest pieces of foreign material and tissue debris. The ingested material is processed or degraded within specialized intracellular compartments, and peptides and glycolipids are presented as complexes in association with class I or class II MHC–encoded proteins. TNF-α produced during tissue inflammation also stimulates the dendritic cells to downregulate the expression of molecules retaining or tethering dendritic cells in parenchymal tissues, and to upregulate expression of receptors for chemoattractant cytokines, or chemokines, that direct trafficking of the dendritic cells through the afferent lymphatic vessels**

and into the T-cell rich areas of lymphoid tissues draining the tissue site (Saeki et al, 1999).

Following trafficking to the lymphoid tissue, dendritic cells presenting peptide-MHC complexes secrete proteins that attract naive T cells to survey or sample the dendritic cell surface. **During antigen presentation in the lymphoid tissues, T cells expressing receptors with specificity for peptides presented in association with class II MHC molecules (i.e., CD4+ T cells) and/or T cells with specificity for peptides presented in association with class I MHC molecules (i.e., CD8+ T cells) are stimulated to develop into effector cells (Germain and Margulies, 1993).** In addition to TCR engagement of peptide-MHC complexes, activation of naive T cells to functional activity requires other receptor–ligand interactions (Schwartz, 1992). This costimulation is provided by several complementary sets of molecules. During the initial period of T-cell priming, TCR engagement of peptide–class II MHC complexes on the dendritic cell stimulates the CD4+ T cell to express the ligand CD154, which binds to a costimulatory molecule, CD40, constitutively expressed by dendritic cells. Engagement of this ligand–receptor pair stimulates the dendritic cell to upregulate expression of the CD80/B7-1 and/or CD86/B7-2 costimulatory molecules that bind to a constitutively expressed molecule, CD28, on the T-cell surface.

CD8+ T cells do not express CD154 during peptide–class I MHC interaction for the generation of many immune responses. However, other costimulatory molecules, such as 4-BB1, have been identified for CD8+ T cells, and these molecules may in some circumstances substitute for the absence of CD154 expression. Similar to the activation of CD4+ T cells, most CD8+ T-cell responses are dependent on B7-mediated costimulation during priming. **It is also important to note that the generation of many CD8+ T cell–mediated responses requires provision of CD4+ T-cell helper signals. The CD4+ T-cells help is not provided through production of cytokines for antigen-specific CD8+ T-cell growth but through delivery of signals to the antigen-presenting dendritic cells that "license" the dendritic cell to activate the CD8+ T cell.** CD40–CD154 interactions appear to be important signaling components in dendritic cell licensing to activate CD8+ T cells, and CD4+ T-cell help can be replaced by agonist anti-CD40 antibodies. CD4+ T-cell helper–dependent CD8+ T-cell responses include most CD8+ T-cell responses to viruses and to solid organ allografts, whereas CD4+ T cell–independent responses include CD8+ T-cell responses to skin allografts and to contact allergens.

During T-cell priming by dendritic cells in the lymphoid tissues, many regulated events occur that promote the optimal development of T cell–mediated immune responses. These events include (1) the expression of growth factor receptors on the T cell, (2) the production of appropriate growth factors, (3) the expression of molecules which direct trafficking of the primed T cells to inflammatory sites, (4) the production of effector molecules mediating the immune response following the arrival of T cells at the peripheral site of inflammation, and (5) the interaction with cells expressing the target peptide-MHC complex.

ACTIVATION OF B CELLS

Antibody Production

Although the thrust of this chapter focuses on cell-mediated immunity, a brief description of antibody structure follows. Antibodies are glycoprotein molecules of the globulin fraction, produced by plasma cells in response to stimulation with an immunogen. They are also called immunoglobulins and constitute 1% to 2% of the total serum proteins. The term antigen is used to describe a molecule capable of being recognized by an antibody or a T-cell receptor. **The immunoglobulin molecule consists of two identical heavy (H) and two light (L) chains held together by disulfide bonds** (Fig. 17–7). There are five antibody classes termed isotypes, so named by their different heavy chains and designated IgM, IgG, IgA, IgD, and IgE. Two types of light chains, kappa and lambda, are present in all five antibody classes, although only one is present in a specific molecule. **The basic structure is Y shaped with a hinge region rich in proline, stabilized by the disulfide bridges and noncovalent forces. Both H and L chains have constant amino acid sequences at their carboxy terminus and variable sequences at their amino terminus** (Alzari et al, 1988).

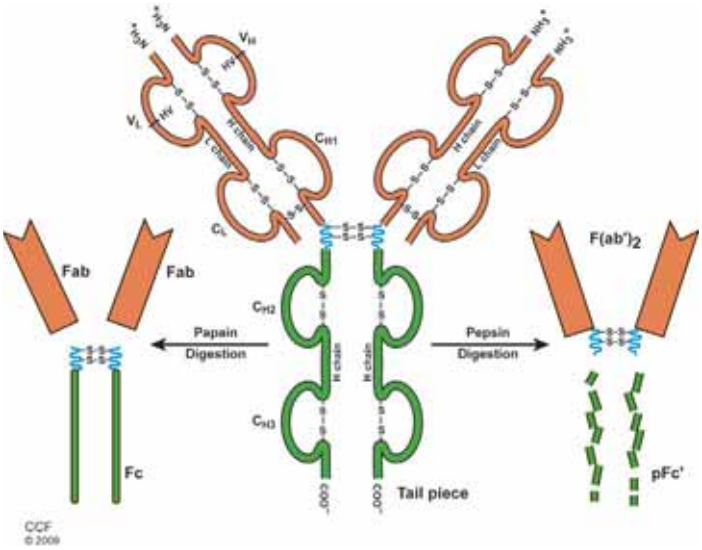

Figure 17–7. Schematic diagram of a typical IgG antibody molecule. Antibodies are dimers of two identical amino acid chains joined by disulfide bonds. These bonds provide the alignment of the two heavy and light chains and the formation of domains. The domains at the carboxyl-terminal ends are generally uniform or constant in sequence. The domains at the amino-terminal ends are variable and unique for each antibody molecule. There are usually three constant domains in heavy chains (C_H) and one in light chains (C_L). The antigen binding sites are formed by the juxtaposition of variable light chain (V_L) and variable heavy chain (V_H) domains. Enzymatic digestion with pepsin results in a divalent antigen binding fragment termed $F(ab')_2$. Digestion with papain results in three functional fragments; two (Fab) that bind antigen, and an Fc that identifies the different antibody isotypes. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

Much has been learned about antibody structure and binding after digestion experiments using the proteolytic enzymes papain and pepsin (see Fig. 17–7). Digestion with papain yields two Fab (antibody binding) and one Fc (crystallizable) fragment(s). Each Fab fragment has one antibody-binding site. The Fc fragment does not bind antibody, but is responsible for fixation to complement and attachment of the molecule to the cell surface. Digestion with pepsin cleaves the molecule toward the carboxyl-terminal side of the disulfide bonds, resulting in a single $F(ab')_2$ fragment with two antigen-binding sites and a functionless heavy chain segment. **These experiments confirmed that specific antigen binding occurs at the Y limb of the molecule, and that**

the nonspecific functions of each antibody isotype reside in the Fc end (Harris et al, 1999).

Each antibody H and L chain also conforms to several domains of 110 amino acid residues that form loops linked by disulfide bonds. In a typical IgG molecule, an H chain will have four domains, and an L chain two domains. Three of the H chain domains and one of the L chain domains are usually invariable in amino acid sequences and are called the constant regions. **The amino terminus domain on the H and L chains contains unique sequences for each molecule and is called the variable region. Several sites within the variable region are even more unique and are referred to as hypervariable. These hypervariable sequences govern both the conformation and specificity of the antigen-binding site of an antibody molecule.** The part of the hypervariable regions on the antibody that contacts the antigen is called the **paratope,** and the part of the antigen that is in contact with the **paratope** is called the **epitope.** Today, the nomenclature complementarity-determining region (CDR), rather than paratope, is more commonly used to describe these amino acid sequences. Both the variable and constant regions of each antibody molecule are encoded by specific gene sequences. The term **idiotype** is used to describe the unique antigen-binding site of each antibody molecule formed by a unique clone of lymphocytes.

Monoclonal Antibodies

The in vivo antibody response to an antigen is polyclonal in that many different antibody molecules are generated that will bind to the antigen. Each antibody originates from a specific clone of plasma cells, and binds to a different antigenic determinant or epitope. **Monoclonal antibodies are synthesized from a single clone of cells. The identical copies produced contain only one class of H chain and one type of L chain.** They are produced by fusing antigen-primed splenic B cells with an immortal myeloma cell line to create a hybridoma (Kohler and Milstein, 1975). Polyethylene glycol is used to effect the cell fusion. The antibody-producing B cell provides the specificity, and the myeloma cell provides the immortality to the hybridoma, which can generate large quantities of the monoclonal antibody. For clinical practice, murine-derived monoclonal antibodies can be engineered by "humanizing" the sequences of the constant regions of the light and heavy chains or with recombinant technology actually fusing human constant regions to murine variable regions to create a "chimeric" antibody. This is done to minimize undesired reactions of the human host to the murine sequences, which may trigger inflammatory responses such as fever, chills, nausea, vomiting, joint pains, hypotension, tremors, seizures, or visual disturbances.

Allogeneic B-Cell Activity

B cells often require the help of CD4+ T cells to proliferate and differentiate into plasma cells that synthesize and secrete specific antibody (Parker, 1993). This is especially true when B cells encounter alloantigens from an organ transplant. After B-cell immunoglobulin receptors react with donor protein antigens, the antigens are endocytosed, processed, and transported to the cell surface for presentation to resting T cells, only in the context of MHC class II molecules on the B-cell surface. The helper CD4+ T-cell TCR is engaged and stabilized by its CD4 molecule, which leads to T-cell activation and secretion of lymphokines including IL-2 (see Fig. 17–6). These lymphokines promote B-cell growth and differentiation into plasma cells that secrete specific antibodies. **B-cell activation also requires the presence of a second costimulatory signal to complete the process. In this case, a marker on the B-cell surface, CD40, must be engaged by its ligand CD40L on the surface of the helper T cell** (Foy et al, 1996)**. T cells are also required for isotype switching that occurs during some immune responses** (Stavnezer, 1996). Plasma cells often secrete IgM antibodies after primary antigen exposure. Secondary responses (after reexposure to the same antigen) usually results in the production of IgG or IgA antibodies by B cells with the same antibody-binding variable regions.

It should be emphasized that B and T cells usually recognize different antigens and/or different epitopes on the same antigen. **B cells usually recognize native proteins, peptides, or denatured proteins through their surface immunoglobulin receptors, whereas T cells are more complex in their recognition system in that smaller peptides are only recognized when processed and presented to T cells by APCs in context of MHC class I or II molecules.** However, B cells can recognize certain antigens without T-cell help. These so-called **T cell–independent antigens** are large macromolecules with repeating segments, such as bacterial polysaccharides and lipopolysaccharides that can cross-link many B-cell receptors. These antigens can bypass the second costimulatory signal (CD40), elicit a weaker response with poor memory, and usually cause only a polyclonal IgM response. **T cell–dependent antigens** are smaller and more complex, and elicit a more specific antibody response with durable memory. All antibody classes can be generated, but this process remains dependent upon the delivery of two signals for T-cell help.

CELL SIGNAL TRANSDUCTION

The response of cells to external stimuli, typically through surface receptors, results in the conversion of that signal into intracellular biochemical events, which ultimately leads to the expression of a variety of genes that are critical for cell function and growth.

TCR-Signaling Proximal Events

Activation of T cells is dependent on the signaling events transmitted by the TCR to the cytoplasm and the nucleus (Fig. 17–8)**. The initial intracellular signaling events, after lymphocyte detection of specific antigen, begin with the CD3 molecules (CD3ε, γ, and δ) and their corresponding motifs termed ITAMs (immunoreceptor tyrosine-based activation motifs), which are phosphorylated following TCR ligation** (van Leeuwen and Samelson, 1999; Kane et al, 2000; Myung et al, 2000; Smith-Garvin et al, 2009). Phosphorylation of ITAMs is mediated by two Src family kinases: Lck, which constitutively associates with CD8 and CD4 molecules, and Fyn, which interacts with the cytoplasmic domains of the CD3ε and ζ chain after receptor engagement. The phosphotyrosines produced by tyrosine kinases form binding sites for protein domains referred to as SH2 domains (Src homology 2 domains) that are present in a number of signaling molecules. The interaction of SH2 domains with the phosphotyrosines provides an important way to recruit signaling proteins to the activated receptors. TCR signaling can also be negatively regulated by the protein tyrosine kinase Csk, which alters the phosphorylation status of the Src kinases. The kinase domain of the Src kinase contains two tyrosine residues, where one provides an activation signal while the other inactivates the

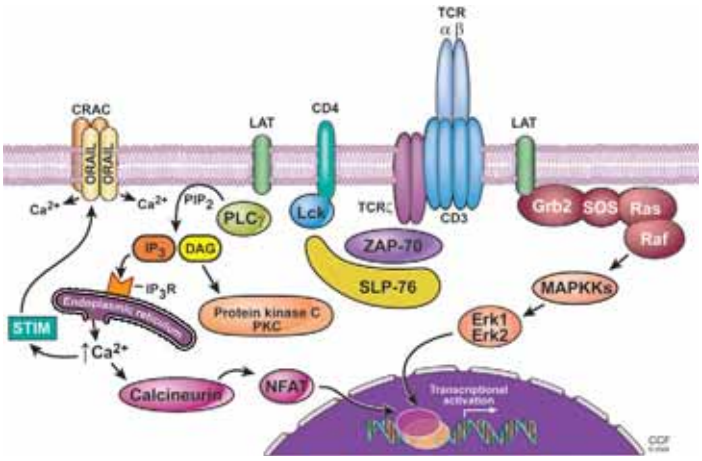

Figure 17–8. Signaling pathway induced by the T-cell receptor (TCR). The binding of antigen to the α/β chains of the TCR causes activation of Lck, which in turn results in the phosphorylation of TCR ζ and the recruitment and activation of another tyrosine kinase ZAP-70. This kinase phosphorylates the adaptor molecules LAT and SLP-76 that are the backbone of a complex that interacts with and orients different effector molecules, allowing activation of multiple signaling pathways. LAT then recruits PLCγ to the membrane where it cleaves its substrate PIP_2 into IP_3 and diaclyglycerol (DAG). IP_3 stimulates Ca^{2+}-permeable ion channel receptors (IP_3R) causing a release of Ca^{2+} into the cytosol from ER storage sites raising the intracellular levels of Ca^{2+}. The depletion in ER Ca^{2+} induces an influx of extracellular Ca^{2+} by the activation Ca^{2+} release-activated Ca^{2+} (CRAC) channels. The pore-forming units of the channel were determined to be a transmembrane molecule termed Orail. These events are regulated by stromal interaction molecule (STIM). The increase in Ca^{2+} activates the phosphatase calcineurin, which dephosphorylates the transcription factor NFAT allowing it to migrate to the nucleus. DAG release leads to the activation of protein kinase-C (PKC). Phosphorylated LAT also binds Grb2 that recruits the guanine-nucleotide exchange factor SOS that activates RAS. Activated Ras then recruits Raf-1 to the membrane where it is activated. Raf-1 then phosphorylates and activates MAPK kinases (MAPKKs), which initiates the activation of other kinases (Erk-1 and Erk-2) in this pathway. The end result is the activation of a number of transcription factors that initiate gene expression. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

enzyme. In resting cells, the Csk kinase phosphorylates the inhibitory tyrosine that maintains the Src enzymes in an inactive state. The negative effect of Csk on Src kinase function can be reversed by the protein tyrosine phosphatase CD45, which is involved in receptor signaling in T cells. This involves the removal of the phosphate group from the inhibitory tyrosine residue of the Src kinase.

The most effective activation of the TCR requires interaction with the coreceptor molecules CD4 and CD8, which serves to bring Lck in close proximity to the cytoplasmic domains of the TCR complex (van Leeuwen and Samelson, 1999; Kane et al, 2000; Myung et al, 2000). Once activated, Lck phosphorylates the tyrosine residues in the ITAMS of the CD3 and TCR ζ chains, which then provide the docking site for the tyrosine kinase ZAP-70. After recruitment to the TCR, ZAP-70 becomes activated as a result of its phosphorylation on multiple tyrosine residues by either Lck or Fyn kinases. Activated ZAP-70 then leads to the activation of the adaptor molecule LAT (linker of activation in T cells) and SLP-76. LAT is a transmembrane protein expressed in T cells and NK cells. It is a critical SH2 domain–binding protein involved in transmitting the signal from the membrane to downstream targets. LAT is essential for coupling the TCR to the PLC-γ1–Ca^{2+} and the Ras signaling pathways. SLP-76 is another adaptor protein that is also important for efficient TCR-induced tyrosine phosphorylation of PLC-γ1, inositol phosphate accumulation, Ca^{2+} mobilization, and Ras activation. **Thus the proximal signaling complex composed of the adaptor molecules along with a growing number of effector molecules is responsible for promoting the TCR–phosphotyrosine kinase (PTK) signal into multiple distal signaling pathways** (Smith-Garvin et al, 2009).

Activation of Intracellular Calcium and Protein Kinase C (PKC)

Phosphorylation of the enzyme phospholipase C–γ (PLC-γ) is a critical event in transmitting the activation signal from the membrane downstream (Myung et al, 2000). After TCR ligation, PLC-γ is present in the proximal signaling complex bound to SLP-76 and LAT where it is phosphorylated, an event that is dependent on several kinases (Lck, ZAP-70, Itk, and a Tec kinase family member, Rlk). The activated PLC-γ then hydrolyzes membrane-bound phospholipid phosphatidylinositol bisphosphate (PIP_2) into two active components, inositol triphosphate (IP_3) and diacylglycerol (DAG).

IP_3 stimulates Ca^{2+}-permeable ion channel receptors (IP_3R), resulting in the release of Ca^{2+} into the cytosol from storage sites within the endoplasmic reticulum (Oh-hora and Rao, 2008) which raises the intracellular levels of Ca^{2+}. The reduction in endoplasmic reticulum (ER) Ca^{2+} stimulates a sustained influx of extracellular Ca^{2+} via the activation of plasma membrane Ca^{2+} release–activated Ca^{2+} (CRAC) channels. Recent studies have identified the sensor for the depletion of ER Ca^{2+} stores and the activator of CRAC as an ER transmembrane protein referred to as stromal interaction molecule (STIM) (Roos et al, 2005). **Elevated μCa^{2+} results in the activation of multiple transcription factors along with various signaling molecules. This includes the Ca^{2+} enzyme calcineurin, a cytosolic serine/threonine protein phosphatase that regulates the activation of an important family of transcription factors, termed NFAT (nuclear factor of activated T cells).**

NFAT transduces Ca^{2+} signals not only in T lymphocytes but also in B cells, NK cells, monocytes, and nonhematopoietic cells, including those of the cardiac and nervous system (Zhu and McKeon, 2000). Four separate genes are present that encode different NFATs: NFAT1/p, NFAT2.c, NFAT3, and NFAT4. **NFAT, along with other transcription factors, play a critical role in T-cell activation and clonal expansion through their activation of the interleukin-2 gene.** The inactive form of NFAT is retained in the cytoplasm, unable to translocate to the nucleus because its nuclear localization sequence (NLS) is phosphorylated on serine/threonine. Calcineurin is composed of a catalytic subunit and a regulator subunit and is activated by the recruitment of Ca^{2+}-bound calmodulin. The association of calmodulin with calcineurin alters the structure of catalytic subunit, leading to activation of its phosphatase activity. Calcineurin then dephosphorylates the NLS of NFAT, allowing the transcription factor to translocate into the nucleus.

NFAT is important for T-cell activation; and because of its role in the regulation of critical genes in this process (e.g., IL-2, proto-oncogenes c-*myc* and cytokine receptors), it is a target for immune suppression in the allotransplant setting (Matsuda and Koyasu, 2000). **The immunosuppressive drugs cyclosporine and tacrolimus function by blocking the NFAT pathway.** Cyclosporine is a small, cyclic, fungus-derived peptide that is immunosuppressive once it has formed a complex with its

cytoplasmic receptor, cyclophilin, a ubiquitous cytosolic protein. The activity of tacrolimus also is dependent on binding to its receptor, FK-binding protein 12 (FKBP12). **The active complexes, cyclosporine/cyclophilin and tacrolimus/FKBP12, are known to block NFAT nuclear translocation by binding to the catalytic subunit of calcineurin and inhibiting its phosphatase activity.** The major inhibitory activity of cyclosporine and tacrolimus is thought to be their suppression of the growth factor IL-2. **Actually, the induction of IL-2 gene expression along with other T-cell activation genes involves stimulation of NFAT/AP-1 transcription factors and Ras signaling while NFAT activity in the absence of AP-1 stimulation induces a gene expression pattern that promotes T-cell anergy** (Macian et al, 2002)**.**

The cleavage of the PIP_2 by the PLC-γ enzyme also results in the formation of diacylglyerol (DAG), which remains attached to the inner surface of the plasma membrane (Myung et al, 2000). **DAG is involved in the activation of protein kinase C (PKC), a serine/threonine protein kinase that regulates the nuclear translocation of various transcription factors, including NFκB.** Recent studies have detailed how PKC activation leads to nuclear import of NFκB via the phosphorylation of a multiple protein complex (Matsumoto et al, 2005). PKC can be further activated by the increase in Ca^{2+} resulting from the release of IP_3. Beside activation of the PKC pathway, TCR-induction of DAG leads to activation of the Ras pathway.

Ras Pathway

Activation of the TCR-associated tyrosine kinases involves the small guanosine triphosphate (GTP)-binding protein Ras (Ebinu et al, 2000; Genot and Cantrell, 2000). **Ras proteins are proto-oncogenes that were initially discovered because of their effect on tumor cell growth, but it is now known that Ras plays an important role in lymphocyte activation.** Ras is involved in the activation the AP-1 family of transcription factors, which are composed of heterodimers of the oncogenes *fos* and *jun*. It also regulates other transcription factors such as NFAT, Elk-1, and the serum response factor (SRF). Ras also mediates TCR signals important to thymocyte and B-cell development. Defects in the activation of Ras have been linked to the development of T-cell anergy. Ras is a guanine-nucleotide binding protein that rapidly cycles from an inactive guanosine diphosphate (GDP) form to an active GTP-bound state. Ras activation is enhanced by two different proteins (SOS and RasGRP) and is suppressed by GTPase-activating proteins (Smith-Garvin et al, 2009). The activation of Ras induces a cascade of protein kinases referred to as the mitogen-activated protein kinases (MAP kinase). One of the best characterized Ras effector pathways is mediated by the MAP kinase Raf-1. Activation through the TCR results in the tyrosine phosphorylation of LAT that binds to Grb2 and recruits the guanine-nucleotide exchange factor SOS that activates the G protein, Ras. Activated Ras recruits Raf-1 to the plasma membrane, where Raf-1 is activated. Raf-1 then phosphorylates and activates the kinase MAPKKS, which then activates the MAPKs Erk1 and Erk2. These events ultimately lead to the activation of a variety of transcription factors.

Actin and Cytoskeletal Changes

The interaction between TCR and APCs results in the rearrangement of the actin cytoskeletal compartment that leads to polarization and activation of T cells with a reduction in cellular motility. As part of this process, there is movement of the microtubular organizing center toward the site of contact between T-cells and APC (Jacobelli et al, 2004). **At this contact site, an organized structure develops that is referred to as the immunologic synapase (IS)** (Monks et al, 1998; Smith-Garvin et al, 2009) **and is composed of two concentric regions, the central and peripheral supramolecular activation clusters (cSMAC and pSMAC).** Although much remains to be determined, it is thought that the start of TCR signaling is in the peripheral microclusters containing the TCR and associated signaling molecules (LAT, SLP-76, and Ca^{2+}). The cSMAC is thought to be the site of TCR signaling prolongation and, ultimately, degradation (Varma et al, 2006). TCR signaling is also important for the activation of integrins that are receptors responsible for cell–cell and cell–matrix adhesions. Relevant integrins include leukocyte function–associated antigen-1 (LFA-1) and very late antigen–4 (VLA-4) that bind their respective ligands intercellular adhesion molecule (ICAM) and vascular cell adhesion molecule (VCAM) (Menasche et al, 2007). A critical regulator of these interactions is the small GTPase Ras-proximity-1 (Rap1) molecule, because mutations in Rap-1–initiated integrin interaction is associated with leukocyte adhesion deficiency syndrome.

B-Cell Signaling

The receptor on B cells that recognizes antigen and transmits signal to the nucleus for gene expression is composed of a cell surface immunoglobulin containing heavy and light chains with variable regions (Janeway and Medzhitov, 2002). The immunoglobulin molecule is linked to two proteins (Iga and Igb) that consist of a single amino-terminal Ig-like domain and a transmembrane domain linked to a cytoplasmic tail. Iga and Igb are involved in signaling and contain one ITAM each. The Src kinases Fyn, Blk, and Lyn are associated with the B-cell receptor and are responsible for the phosphorylation of the ITAM after antigen engagement. The phosphatase CD45 is likely involved in removing inhibitory phosphates from the Src kinases and thus allowing their activation. Signaling, by the immunoglobulin receptors, is facilitated by coreceptor molecules that include CD19, CD21, and CD81. CD21 is a receptor for complement fragments that can recognize complement associated with antigen bound to the immunoglobulin receptor. These complexes cross-link CD21, which then induces phosphorylation of the cytoplasmic tail of CD19, allowing other Src kinases to bind and thus enhance receptor signaling. The next protein tyrosine kinase involved in the B-cell pathway is Syk, which induces the activation of phospholipase C-γ, leading to an increase in Ca^{2+} levels and activation of PKC. The tyrosine kinases are also responsible for activating the Ras pathway. Activation of these various pathways leads to induction of transcription factors that initiate gene expression required for B-cell proliferation and effector function.

JAK/STAT Signaling Pathway

The Janus family of kinases (Jak kinases) and the STAT (signal transducers and activators of transcription) proteins constitute one of the main signaling pathways that regulate cytokine gene expression (Schindler, 1999; Imada and Leonard, 2000). In mammals there are four Jak kinases, Jak1, Jak2, Jak3, and Tyk2, which are constitutively associated with many different cytokine receptors. However, different cytokine receptors are regulated by select kinases. For example, 1 and Tyk2

are required for IFN-γ/β signaling, whereas IFN-γ is dependent on Jak1 and Jak2. On the other hand, cytokines whose receptors share γc (IL-2, IL-4, IL-7, IL-9, and IL-15) use Jak1 and Jak3, except IL-13, which uses Jak1, Jak2, and Tyk2. Cytokines whose receptors share βc (IL-3, IL-5, and granulocyte-macrophage colony-stimulating factor [GM-CSF]) use 2. Ligand binding causes dimerization of receptor chains, leading to activation of the Jaks and phosphorylation of the receptors that provide docking sites for the STAT proteins. The recruited STATs are phosphorylated by the Jaks and then translocate to the nucleus, where they initiate transcription. Seven different STAT proteins have been identified. Differences in the SH2 domains of the different STAT proteins determine their selectivity to various cytokine receptors.

The biologic importance of different Jaks and STATs has been revealed by deficiencies in these proteins in both humans and animal models (Imada and Leonard, 2000). **Mutations in Jak3 have resulted in patients having severe combined immunodeficiency (SCID), which is similar to X-linked SCID, which occurs because of a mutation in the common cytokine receptor γ chain. Jak3 activation is necessary for normal development and survival of T and B cells but not for dendritic cells (DCs)** (Yamaoka et al, 2005; Ross et al, 2007). Most mice deficient in Jak1 die perinatally and have defects in lymphoid development, except that Jak1 is not necessary for late stages of thymocyte maturation (Roberts et al, 2004; Ross et al, 2007). On the other hand, Jak2-deficient mice result in embryonic lethality due to loss of erythropoiesis, but Jak2 is not required for survival and function of lymphoid progenitors. Mice deficient in Tyk2 demonstrated only a reduced response to IFN-α/β and IL12. STAT1-deficient mice demonstrate a significant defect in IFN-dependent antiviral and antimicrobial immune responses. Although STAT2 KO mice develop normally, they are susceptible to viral infections. STAT4-deficient mice confirm that STAT4 is only activated by IL-12, because T cells from these mice were unresponsive to IL-12 and were defective in Th1 development. As expected, the STAT4-deficient mice showed an increase in IL-1/IL-10–producing Th2 cells. It has also been noted that STAT6-deficient mice are impaired in the development of a Th2 immune response as predicted, because IL-4 and IL-13 activate STAT6. Although there are no apparent immune deficits in either STAT5a–/– or STAT5b–/– mice, double KO mice exhibited severe impairment in T-cell function (Moriggl et al, 1999).

T-CELL MATURATION TO EFFECTOR FUNCTION

Clonal Expansion of Specific T Cells

Because the frequency of naive T cells for a particular peptide–self-MHC complex is very low (e.g., 1 in 10^5 to 10^6 T cells), the pool of reactive T cells needs to be expanded during priming in order to mount an effective immune response. **Most naive or quiescent T cells constitutively express the common cytokine receptor γ chain that is a component of the receptor for many cytokines, including IL-2, IL-4, IL-7, IL-9, and IL-15** (Leonard, 1996). The common γ chain is the target defect in X-linked severe combined immunodeficiency. In addition to the common γ chain, most naive T cells constitutively express the IL-2 receptor β chain. The combination of the β and γ chains form a receptor complex with low affinity for IL-2. **TCR engagement of a specific ligand, with delivery of costimulation during CD4+ T-cell priming, induces the expression of the IL-2 receptor α chain (called CD25) on the T cells. In combination, the α, β, and γ chains constitute the high-affinity IL-2 binding receptor.** TCR engagement plus costimulation also stimulates the CD4+ T cells to produce IL-2, which binds to the high-affinity IL-2 receptor and stimulates clonal proliferation of the CD4+ T cells in an autocrine manner (Fig. 17–9). This series of events results in rapid expansion of the reactive CD4+ T-cell pool. In many immune responses, activation of naive CD8+ T cells does not induce expression of the IL-2 receptor α chain. **Although CD8+ T-cell expansion can be promoted in vitro during culture with IL-2, a different growth factor, IL-15, appears to be critical for naive CD8+ T-cell proliferation during antigen priming in vivo** (Kennedy et al, 2000). **For expansion of reactive CD8+ T cells, TCR engagement of peptide–class I MHC complexes stimulates the upregulated expression of the α chain of the IL-15 receptor**. Rather than T cells, IL-15 is produced by a number of nonlymphoid cells, including fibroblasts, epithelial cells, and dendritic cells.

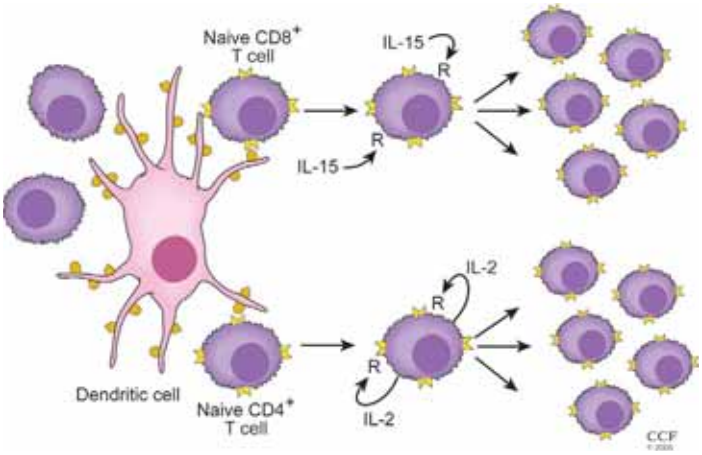

Figure 17–9. Activation of naive CD4+ and/or CD8+ T cells by dendritic cells results in proliferation of the reactive T-cell clones. Following emigration from the peripheral tissues to lymphoid tissues, dendritic cells presenting foreign peptides in the context of class I and/or class II major histocompatibility complex (MHC) molecules activate CD8+ and CD4+ T cells bearing receptors with specificity for the peptide-MHC complex. This activation includes the upregulation of growth factor receptor components that increase the affinity of the growth factor receptor. In addition to the expression of CD25 and high-affinity interleukin-2 (IL) receptors, activated CD4+ T cells produce IL-2, which is used in an autocrine manner to drive clonal proliferation of the activated CD4+ T cell. During activation, CD8+ T cells are stimulated to express the α chain of the IL-15 receptor that forms the high-affinity receptor for this growth factor. In contrast to IL-2–mediated expansion of CD4+ T cells, IL-15 is not produced by the CD8+ T cell but is produced by the dendritic cell and stromal cells in the lymphoid tissue. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

It is also important to note that maintenance of specific numbers of T cells occurs through homeostatic mechanisms that control the levels of the proliferative cytokine IL-7. This cytokine maintains the viability of naive, unstimulated T cells in the secondary lymphoid organs (the spleen, lymph nodes, and Peyer patches). The introduction of naive T cells into a lymphopenic environment results in the rapid proliferation of T cells (homeostatic proliferation), and their differentiation into effector and memory T cells. Homeostatic proliferation requires TCR engagement of MHC molecules and IL-7, or other proliferative cytokines. Because homeostatic proliferation

requires MHC stimulation of T cells, the importance of homeostatic proliferation arises in expansion of donor-reactive T cells in cases of intentional lymphodepletion for bone marrow or solid organ transplantation. Such conditioning can be achieved clinically with monoclonal or polyclonal anti–T-cell antibodies such as muromonab-CD3, alemtuzumab, or thymoglobulin.

Following initial priming and expansion of the peptide-MHC–reactive T-cell pool, T cells develop into cells with effector function. **Effector T cells mediate and regulate immune responses through two activities: cytokine production and expression of cytolytic function.** These effector functions are then expressed by antigen-primed T cells following interaction with target cells expressing the specific peptide-MHC ligand in peripheral tissues during elicitation of the immune response.

Cytokine-Producing T-Cell Phenotypes

During antigen priming CD4+ T cells develop into: (1) cells producing type 1 cytokines (e.g., Th1 cells), (2) cells producing type 2 cytokines (e.g., Th2 cells), (3) cells producing IL-17 and IL-21 (Th17 cells), or (4) cells that express regulatory function (O'Garra, 1998; Korn et al, 2009). **Type 1 cytokines include IFN-γ and TNF-β (also called lymphotoxin) and are critical components of cell-mediated immune responses, particularly responses to intracellular parasites and tuberculin delayed-type hypersensitivity** (see Table 17–2). The prototypic type 1 cytokine IFN-γ induces a number of proinflammatory events, including stimulating increased class I and class II MHC expression, stimulating production of intracellular molecules required for antigen processing and presentation, and stimulating macrophage proinflammatory activities such as superoxide and nitric oxide (NO) production, which render macrophages engulfing bacteria competent to kill the bacteria. These inflammatory functions are also important components of many organ-specific autoimmune diseases. **Type 2 cytokines include IL-4, IL-5, IL-6, IL-9, and IL-10 and are critical components of allergic responses and immune responses to extracellular parasites such as helminths.** These activities include the stimulation of eosinophil and mast cell growth and function, including the release of histamine and other molecules involved in allergic responses. IL-4 is also an important stimulus of B-cell growth. **IL-17 and IL-21 are important cytokines amplifying inflammation by inducing the recruitment and activation of innate immune cells, particularly neutrophils. Recent studies have also documented the critical role of IL-17 in the elicitation of autoimmune disease.**

The type 1 and type 2 cytokines also influence the isotype of antibody produced by B cells during an immune response. In general, the type 1 cytokines direct antibody responses to those fixing complement and participating in cell-mediated immune responses, such as opsonization, that are critical for protection against intracellular pathogens. In contrast, type 2 cytokines stimulate IgE production and other antibodies involved in allergic reactions. Obviously, the phenotype of T-cell cytokine production will have an important impact on the course of immune responses to infectious agents, as well as the sequelae of the response.

The most important factor influencing the development of CD4+ T cells to a particular functional phenotype is the cytokine environment present during priming by the antigen-presenting cell (Fig. 17–10). This polarization can occur within 48 hours of initial priming by dendritic cells.

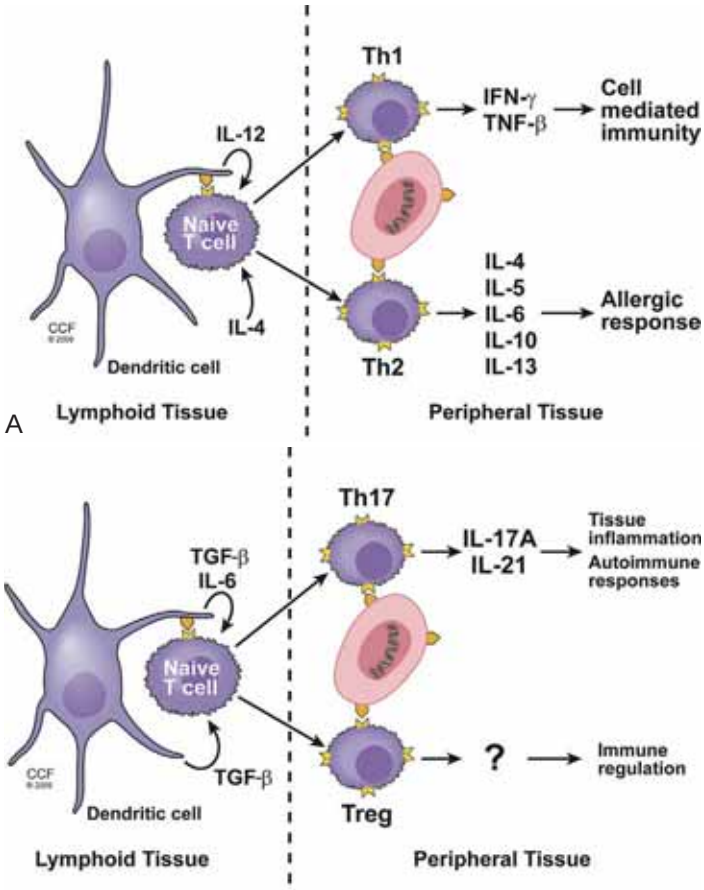

Figure 17–10. The cytokine environment during peptide–class II major histocompatibility complex (MHC) priming influences skewing of CD4+ T-cell development to Th1, Th2, Th17 or Treg cells. Following emigration from the peripheral tissues to lymphoid tissues, dendritic cells presenting foreign peptide in the context of class II MHC molecules activate specific CD4+ T cells to develop into immune effector T cells. **A,** The production of interleukin-12 (IL-12) by the dendritic cell or the presence of IL-12 during CD4+ T-cell priming skews the CD4+ T cells to develop into Th1 cells. Upon encounter with the specific peptide–class II MHC complex in the periphery, the Th1 cells are activated to produce type 1 cytokines, such as interferon-γ (IFN-γ) or tumor necrosis factor-β (TNF-β), during the elicitation of the immune response. The presence of IL-4 in the priming environment skews the CD4+ T cells to develop into Th2 cells. Upon encounter with the specific peptide–class II MHC complex in the periphery, the Th2 cells are activated to produce type 2 cytokines, such as IL-4, IL-5, or IL-13, that promote allergic-type immune responses. **B,** Similarly, the presence of both transforming growth factor-β (TGF-β) and IL-6 in the priming environment skews antigen-reactive CD4+ T cells to develop into Th17 cells, and upon encounter with the antigen in the periphery these T cells are activated to produce IL-17A and IL-21, cytokines that mediate inflammation by recruiting and activating neutrophils, as well as playing key roles in the elicitation of responses in autoimmune disease. When TGF-β is present in the absence of IL-6 in the priming environment, CD4 T cells develop into T-regulatory cells. Many different effector mechanisms have been ascribed to the functions of Tregs to mediate regulation of immune responses. Production of the cytokine IL-12 by antigen-presenting dendritic cells is a critical factor in guiding CD4+ T-cell development to the type 1 cytokine-producing phenotype (Gately et al, 1998). IL-12 is a 75-kD disulfide-linked dimer of p35 and p40 subunits. Many cells constitutively produce the p35 subunit, whereas production of the p40 subunit is restricted

to macrophages and dendritic cells. Induction of p40 expression and IL-12 heterodimer production by these cells is stimulated by microbial or endogenous stress products binding to TLR and/or by CD40 ligation during interaction with T cells. In the absence of IL-12 and in the presence of IL-4, CD4+ T-cell development is guided to the type 2 cytokine–producing phenotype. The source of this IL-4 during priming of the Th2 cells is not clear but may be provided by cells that express at least some properties of NK cells and some properties of T cells, thus classified as NK T cells. The development of CD4+ T cells to Th17 cells during antigen priming occurs in the presence of TGF-β and IL-6. In addition, the p19/p35 heterodimer, IL-23, stabilizes the phenotype and function of the IL-17/IL-21–producing cells. Finally, the presence of TGF-β and IL-2 in a priming environment in which there is no IL-6 can promote CD4+ T-cell development to CD4+CD25+FoxP3+ T-regulatory cells. The skewed development of CD4+ T cells to a specific functional phenotype occurs through the induced expression of specific transcription factors. IL-12 stimulates T-cell production of the transcription factor T-Bet which promotes IFN-γ production during Th1 development, whereas IL-4 stimulates production of the transcription factors c-Maf and GATA-3, which promote IL-4 production. The combination of TGF-β and IL-5 leads to the activation of ROR_{gt}, the transcription factor required for differentiation to Th17 cells. Other factors may also influence CD4+ T-cell development–the antigen dose and the type of costimulation provided during priming.

An important facet of the immune system is that type 1 and type 2 cytokines are counter-regulatory (Sher and Coffman, 1992). **IFN-γ inhibits IL-4 production, as well as the development of CD4+ T cells to the type 2 or Th17 cytokine–producing phenotypes. Similarly IL-4 inhibits the development of CD4+ T cells to IFN-γ cytokine–producing cells.** During T-cell cytokine–dendritic cell interactions, many cytokine-mediated regulatory events occur. For example, the presence of IL-12 induces the production of IFN-γ that, in turn, stimulates increased expression of the inducible IL-12 β2 receptor component. Alternatively, the presence of IL-4 downregulates the expression of the β2 receptor subunit and the T-cell development is skewed to the type 2 cytokine-producing phenotype. **In addition to the Th1 and Th2 populations of cytokine-producing T cells, a novel population of CD4+ T cells that produce IL-10, and TGF-β has been identified in some experimental systems and in humans** (Groux et al, 1997). **These cytokines, and therefore these T cells, have potent down-regulatory activities for Th1- and Th2-mediated responses.**

Antigen priming of CD8+ T cells in vivo usually induces IFN-γ–producing cells. In contrast to CD4+ T cells, CD8+ T-cell development to IFN-γ–producing cells is not dependent on the presence of IL-12 during priming. In vitro, development of CD8+ T cells to type 1 versus type 2 production can be promoted during antigen stimulation in the presence of IL-12 or IL-4, respectively. CD8+ T cells producing IL-4 and IL-5 have been isolated from patients with the tuberculoid form of leprosy or AIDS, which may indicate that the induction of type 2–producing CD8+ T cells in vivo is limited to certain disease states.

T Cell–Mediated Cytolysis of Target Cells

The development of CD8+ T cells with cytolytic function is a critical component of many immune responses to tumors, viruses, and other intracellular parasites. Cytolysis of infected target cells is an efficient mechanism for inhibiting the replication of intracellular parasites. **There are two major mechanisms used by CD8+ T cells to mediate cytolysis of cells expressing the target peptide–class I MHC complex** (Fig. 17–11)**. During priming in the lymphoid tissue, CD8+ T cells may develop into cells containing intracellular granules containing a protein called perforin, and a family of serine esterases of which granzyme B is the prototype enzyme** (Shi et al, 1997). Following TCR engagement of the specific peptide–class I MHC complex on a target cell the CD8+ T cell becomes activated to release these granules toward the target cell. The perforin monomers polymerize in the membrane of the target cell forming a pore. Granzyme B then enters the target cell and enzymatically activates intracellular caspases, such as caspase 10, leading to the induction of apoptosis. Perforin/granzyme B–mediated cytolysis is also an important function

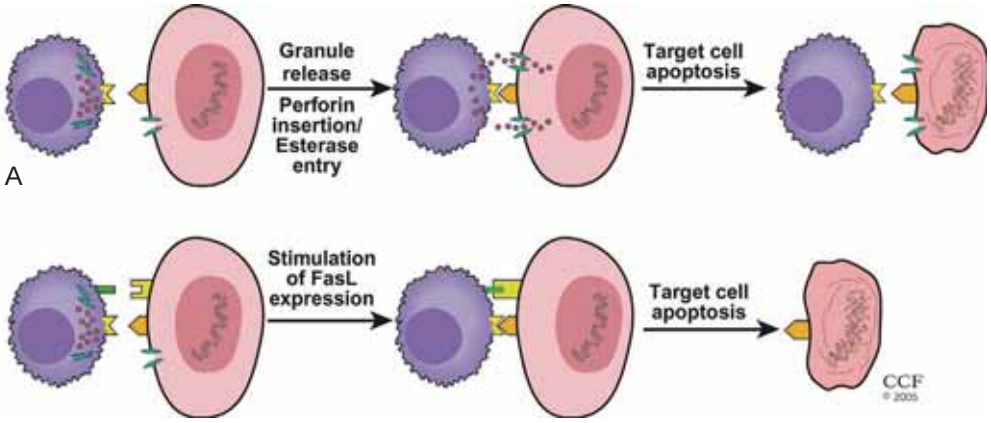

Figure 17–11. Two pathways used by CD8+ T cells to mediate cytolysis of target cells. Following priming by peptide–class I MHC complexes presented by dendritic cells in the lymphoid tissues, CD8+ T cells enter peripheral tissues and mediate cytolysis of target cells expressing the priming peptide–class I MHC complex. **A,** Following recognition of the target complex on target cells, the CD8+ T cell is activated to release cytotoxic granules containing perforin and serine esterases, such as granzymes A and B. The perforin monomers form a complex in the cell membrane of the target cell allowing the serine esterases to enter the target cell. The enzymes activate caspases, which promote apoptosis of the target cell. **B,** Following recognition of the target complex on target cells, the CD8+ T cell is activated to express FasL. The interaction of FasL with Fas on the surface of the target cell stimulates the induction of the apoptotic pathway and the death of the target cell. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

expressed by NK cells during innate immune responses and immune surveillance. Another lytic protein in T-cell and NK-cell granules, granulysin, is an important component of CD8+ T cell–mediated responses to intracellular microbial infections (Stenger et al, 1998). **The second major cytolytic mechanism is mediated through expression of Fas ligand (FasL), a member of the TNF family of proteins** (Sabelko-Downes and Russell, 2000). **FasL is induced on T cells following TCR recognition of the specific peptide-MHC complex. Engagement of FasL with the Fas receptor expressed by the target cell transduces apoptotic signaling resulting in target cell death.** Although cytolytic function has been primarily attributed to CD8+ T cells during immune responses, there is considerable evidence for CD4+ T-cell expression of perforin/granzyme B- and FasL-mediated lytic function, which may be an important component of immune responses to class II MHC–bearing target cells. Expression of mRNA encoding perforin and FasL is observed during rejection of renal allografts and is a reliable indicator of an ongoing acute rejection response.

Phenotypic Changes during TCR-Mediated Activation

In addition to alterations in immune function, priming induces many phenotypic changes in T cells. As discussed above, the expression of high-affinity receptors for growth factors is necessary for clonal expansion of reactive T cells and for their development to cells with immune effector function. An activation antigen, CD69, is expressed within hours of TCR engagement, and this expression disappears within 18 hours of its initial appearance. **Once T cells have been primed to the specific peptide-MHC complex, it is essential that they be able to get to sites in the peripheral tissue where an immune response is needed. During activation, T cells down modulate expression of CD62L, a receptor that facilitates T-cell entry into lymph nodes. Activation also stimulates T cells to express adhesion molecules and chemokine receptors that direct the cells to inflammation in the vascular endothelium.** Phenotypic analysis of circulating T cells is often used in diagnosis of ongoing immune responses, such as during an infection or autoimmune disease.

Memory Cells

During activation and clonal expansion of specific T cells, a portion of the pool develops into a population of memory T cells (Dutton et al, 1998). **In contrast to the effector T cells developing during the course of a primary immune response, the memory T-cell population is long-lived.** Memory cells survive even after an infection is eradicated or the inciting antigen is no longer present. This results in an increased frequency of reactive T cells, when compared with the original naive progenitor T cells. Whether memory T cells originate from specific precursor cells or from a set of long-lived primary effector T cells is still not clear and is under investigation in many laboratories. **Phenotypically, memory T cells express a high molecular-weight form of CD45, CD45RO, whereas naive T cells express the low molecular-weight form, CD45RA. Memory T cells have a lower threshold of activation and require less antigen-MHC complex to become activated. In addition, memory T cells use different costimulatory pathways than do naive T cells for activation, which may complicate the use of costimulatory blockade strategies to inhibit T cell–mediated responses in sensitized patients.** Following reencounter with a specific ligand, memory T cells will more quickly expand and develop to effector T cells than will naive T cells. In contrast to effector T cells generated during a primary immune response, memory T cells may also express multiple immune effector functions. It is also important to note that during differentiation to memory cells, some memory T cells express chemokine receptors and integrins, directing their trafficking to peripheral tissue such as the skin, gut, and lung, and they are termed effector memory T cells—those situated for rapid response in the peripheral tissue. In contrast, central memory cells are those that express receptors and integrins, directing their trafficking to secondary lymphoid tissues where antigens and antigen-presenting dendritic cells from the periphery drain.

Similar to T cells, naive B-cell activation results in the development of a memory B-cell pool. Subsequent activation of memory B lymphocytes results in more rapid generation of antibody responses than during primary antibody responses. **In contrast to memory T cells, the antibody produced by memory B cells is of increased affinity that is the result of somatic hypermutation of the V-region genes of the memory B cell** (Wagner and Neuberger, 1996). **Furthermore, the isotypes of antibody produced by memory B cells (e.g., IgG and IgA) are different from those produced during primary B-cell responses (e.g., primarily IgM with some IgG).** The purpose of vaccination is to induce populations of memory T and B cells so that upon infection with the microbial agent, a protective immune response is quickly mounted and consists of a broader range of protective effector mechanisms.

APOPTOSIS-PROGRAMMED CELL DEATH

Death Receptor Pathway

Apoptosis is a mechanism by which an organism deletes aged, damaged, and autoimmune cells, or cells that are no longer required in subsequent stages of differentiation (Ashkenazi and Dixit, 1998; Scaffidi et al, 1999). There are many stimuli that induce apoptosis and numerous intracellular pathways that lead from these to the final effector phase of the process. The proteins responsible for executing the suicide program, the caspases, are essentially common to all the stimuli and pathways and mediate the nuclear and cytoplasmic alterations characteristic of apoptotic cell death. **The specific roles of each member of the caspase cascade are gradually becoming defined. Caspase-8 and -10 are the initiator caspases that are involved in apoptosis mediated by the extrinsic pathway through the activation of different death receptors, Fas (CD95), TNFR (CD120a), and DR4 (TRIAL-R1) and DR5 (TRAIL-R2)** (Fig. 17–12). **Caspase-9 is the initiator for the intrinsic pathway (mitochondrial pathway). Caspases-3, -6 and -7 typically function to carry out the final steps of the committed apoptotic program** (Danial and Korsmeyer, 2004; Aslan and Thomas, 2009; MacFarlane, 2009).

The death receptor pathway is initiated by the Fas ligand (FasL/CD95-L) binding to Fas (CD95) or the ligand TRAIL (TNF-related apoptosis-inducing ligand) binding to cells that express one of two proapoptotic receptors, DR4 (TRIAL-R1) and DR5 (TRAIL-R2). These receptors

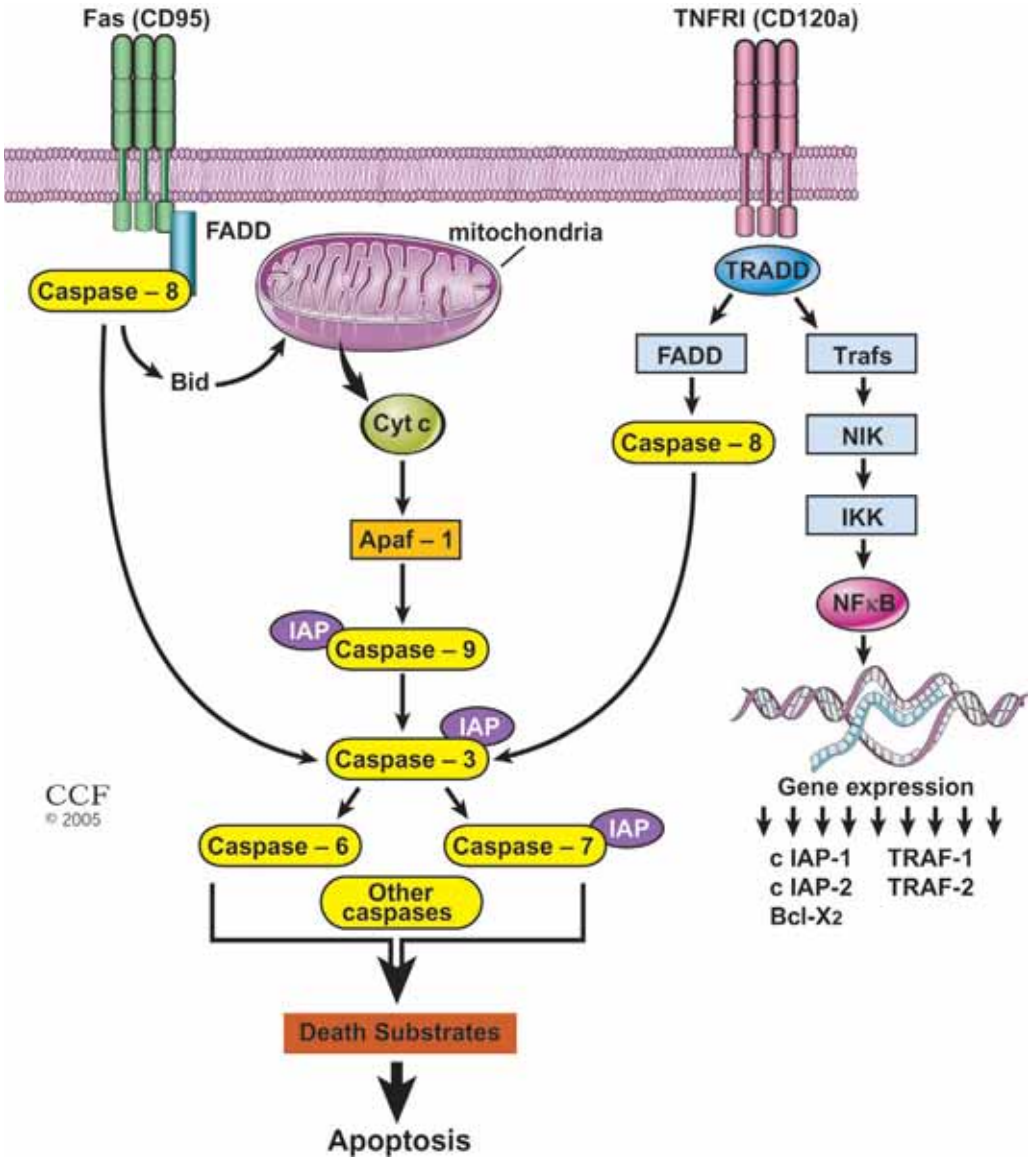

Figure 17–12. Scheme of Fas and TNFR1 activation leading to apoptosis. Ligation of Fas results in FADD binding to the death domains of the Fas receptor. FADD then recruits and activates caspase-8, which, in turn, activates downstream caspases in this pathway. Caspase-8 can also cleave Bid, which induces the release of cytochrome c from the mitochondria. Cytochrome c binding to Apaf-1 results in caspase-9 activation, which then initiates the caspase cascade to apoptosis. A similar extrinsic pathway is induced by the TNF-related apoptosis-inducing ligand (TRAIL/Apo2L) upon binding to its proapoptotic receptors DR4 (TRAIL-R1) and DR5 (TRAIL-R2) (not shown). TNFR1 ligation can also initiate the death pathway through the activation of caspase-8. It also activates the signaling pathway for the activation of the transcription factor NFκB. NFκB regulates the expression of a number of antiapoptotic genes (e.g., cIAP) some of which can bind to and inhibit the activity of caspases. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

contain a cytoplasmic sequence termed the death domain (Danial and Korsmeyer, 2004; MacFarlane, 2009). The death domains enable the death receptors to engage the cells' apoptosis machinery. Interaction between the Fas receptor (Apo-1/CD95) and its ligand is known to regulate several types of physiologic apoptosis. Fas-L is used by lymphocytes not only as a cytotoxic effector mechanism to induce apoptosis in Fas-expressing targets but also to diminish the immune response, once the targeted antigen has been eliminated. Fas/Fas-L–mediated induction of apoptosis is also an effective mechanism of T-cell homeostasis whereby self-reactive clones can be eliminated. Fas/Fas-L is also involved in killing of inflammatory cells at immune-privileged sites. **Oligomerization of Fas or DR4/DR5 as a consequence of ligand binding results in the recruitment of the Fas-associated death domain (FADD), thus forming a death-inducing signaling complex (DISC), which in turn activates caspase-8 and -10 triggering of apoptosis** (Danial and Korsmeyer, 2004; MacFarlane, 2009). Using selective inhibitors, a branched protease cascade was revealed in the Fas pathway, in which caspase-8 activates caspases-3 and -7, and caspase-3 activates caspase-6. Caspases-3 and -6 have specific roles in the nuclear changes accompanying apoptosis, whereas caspase-7 is responsible for the mitochondrial permeability transition and cytoplasmic shrinkage. **The formation of the DISC can be impaired by the protein c-FLIP, which is structurally similar to caspase-8 but is enzymatically inactive, and/or by decoy receptors (DcR3), which can bind ligand but do not signal apoptosis** (MacFarlane, 2009).

The engagement of TNFR1 by its ligand TNF activates the transcription factors NFκB and AP-1, leading to the induction of proinflammatory and immunomodulatory genes that are critical to the development of an immune response. **In contrast to Fas, TNF does not induce apoptosis by TNFR1 unless protein synthesis is blocked, suggesting that preexisting antiapoptotic genes can block the apoptotic pathway.**

The molecular events that modulate apoptosis vary depending on cell type. Cells that use the type 1 pathway can stimulate the initiator caspases directly to activate the executioner caspases, independent of the mitochondria. In contrast, type II cells have the initiator caspases that stimulate the executioner caspase, through Bcl-2 proteins such as the death agonist Bid (BH3-interacting–domain), which facilitates the release of cytochrome *c* through mitochondria membrane permeabilization (MMP).

Mitochondrial Pathway

In many apoptosis scenarios, changes in mitochondria play an integral role in the cell death process (Green and Reed, 1998). **Although the caspases can be characterized as the molecules that directly mediate apoptotic cell death, the Bcl-2 family of proteins regulates apoptosis at the mitochondrial level. The antiapoptotic members of this group (Bcl-2 and Bcl-X_L) buffer some of the signals that initiate the sequence to cell destruction, whereas others in the family (BAD, BAX) are proapoptotic** (Adams and Cory, 1998). The antiapoptotic and proapoptotic members act by differentially modulating cytochrome *c* release from mitochondria. Binding of cytochrome *c* to Apaf-1 causes a conformational change that results in the interaction of Apaf-1 with procaspase-9, and the ultimate activation of the latter to initiate a caspase cascade. Some proapoptotic members of the Bcl-2 family bind and destabilize the mitochondrial membrane directly, whereas others heterodimerize to and antagonize the anti-apoptotic membrane–spanning proteins. In addition to stabilizing the mitochondrial membrane to prevent cytochrome *c* release, Bcl-2 also acts cytoplasmically to inhibit activation of caspase-9. Overexpression of Bcl-2 and Bcl-X_L by gene transfer acts dominantly to prevent the activity of expressed proapoptotic Bcl family members. As mentioned above the mitochondria pathway can be induced after activation of the death receptors (Fas). The linkage between these pathways is the protein Bid, which is inactive in the cytosol but can be cleaved into an active form by caspase-8. The active fragment of Bid travels to the mitochondria and induces cytochrome *c* release, resulting in the activation of downstream effector caspases (Luo et al, 1998).

NFκB Regulation of Apoptosis

The importance of NFκB in host survival has been elucidated from studies using knockout mice having deletions of individual NFκB family members (Barkett and Gilmore, 1999). Cells deficient in RelA are much more sensitive to TNF-α–mediated apoptosis as compared with the wild type. This increased sensitivity to apoptosis is reversed by overexpression of RelA.

The increased susceptibility to apoptosis in NFκB defective cells probably results from the fact that NFκB regulates the expression of antiapoptotic genes (Deveraux and Reed, 1999). This includes TRAF-1 and TRAF-2, which associate with the cytoplasmic regions of TNFR family members. TRAF-2 interacts with downstream signal transducers that activate NFκB, while TRAF-1 is required for the recruitment of the NFκB-inducible cellular inhibitors of apoptosis proteins (cIAP-1 and cIAP-2). The cIAPs can directly bind and neutralize caspases-3, -7, and -9, and are thought to have other downstream antiapoptotic roles as signal transducers. Overexpression of TRAF-1, TRAF-2, cIAP-1, and cIAP-2 by transfection can together inhibit the apoptosis observed when NFκB activation is suppressed in TNF-sensitive cells. IEX-1L is another NFκB-dependent gene whose transfection into NFκB-defective mutants also provides protection against apoptosis in some systems.

Other antiapoptotic molecules with NFκB-dependent expression include Bcl-2, Bcl-X_L, and Bfl-1/A1 members of the Bcl family of proteins. Although some members of the family are proapoptotic, these molecules are known to protect against apoptosis induced by mediators of the mitochondrial permeability transition and also have been found to inhibit the activation of caspase-9.

LYMPHOCYTE TOLERANCE

The recombinatorial mechanisms generating receptors on T- and B-lymphocyte precursors result in the appearance of cells expressing receptors with reactivity to self-proteins. If allowed to mature and become activated in peripheral tissues, self-reactive lymphoid cells could cause considerable harm by mediating autoimmune disease. In addition to the generation of T- and B-cell clones with reactivity to a great number of different antigens, an essential feature of the immune system is the presence of mechanisms to remove or inactivate those cells with specificity for self-peptides. The development of autoimmune disease represents the failure of mechanisms maintaining nonresponsiveness or tolerance to self-proteins. Formally, tolerance may be defined as the inability of the immune system to react to a specific determinant following an initial encounter with that determinant. Thus the development of tolerance results in the absence of lymphocyte reactivity to receptor-reactive ligands that have been previously encountered by the immune system. The immune system has evolved with several mechanisms to circumvent the activation of antigen-reactive T and B lymphocytes. As will be briefly discussed below, mechanisms mediating tolerance to self-proteins may be manipulated in the design of strategies to induce tolerance to exogenous antigens such as alloantigens expressed by organ allografts.

Central Tolerance

An important mechanism mediating tolerance to self-proteins is the deletion of self-reactive T cells and B cells during maturation (see T and B cells). This mechanism is termed central tolerance. Maturation of T cells occurs in the thymus, and those cells that undergo a process termed positive selection are given signals to leave the thymus and seed the peripheral lymphoid tissues, whereas those with high reactivity for self are deleted or negatively selected (Sebzda et al, 1999). These selection processes begin when T-cell precursor cells originating from the fetal liver (in preborn and neonates) and the bone marrow traffic to the thymus. Three potential outcomes arise from these interactions. Those T cells expressing receptors that do not engage peptide-MHC complexes in the thymus undergo apoptosis due to the absence of survival signals delivered from the thymic cells. Those T cells expressing receptors with moderate reactivity to self-peptide–MHC complexes, presented by cortical epithelial cells in the thymus, receive signals to survive, and these are the cells that are positively selected to emigrate from the thymus and seed the peripheral lymphoid tissues to form the peripheral T-cell

repertoire. In contrast, those T cells expressing receptors with very high reactivity to complexes of self-peptides and class I or class II MHC molecules receive signals to undergo programmed cell death and are negatively selected or deleted from the repertoire. Recent studies have also identified a population of thymic medullary epithelial cells that express a set of peripheral tissue-specific antigens (TSA), including insulin, glutamic acid decarboxylase (GAD), and many other organ-specific proteins, under control of the *AIRE* (autoimmune regulator) gene and mediate the deletion of T cells with receptors specific for the TSA (Mathis and Benoist, 2009). The transcriptional activator AIRE was first identified and cloned from patients with autoimmune polyendocrinopathy-candidiases-ectodermal dystrophy (APECED). Rodent models have directly demonstrated that the deletion of AIRE and/or other defects in the deletion of self-reactive T cells results in the development of overt autoimmune disease.

Immature B-cell precursors expressing surface immunoglobulin receptors with reactivity to self-proteins are deleted during maturation in the bone marrow similar to the way T cells are negatively selected in the thymus (Nemazee, 2000). Deletion of self-reactive B cells in the bone marrow is dependent on cell-associated rather than soluble antigen.

Peripheral Tolerance

Negative selection does not result in deletion of all self-reactive T and B lymphocytes during maturation. One factor accounting for the incompleteness of this mechanism is that not all self peptides may be presented with MHC molecules by cells in the thymus. The escape of self-reactive T and B cells from the thymus and the bone marrow imparts the need for mechanisms to mediate tolerance of self-reactive lymphocyte clones in the periphery. Compensating for the incomplete deletion of self-reactive lymphocytes during maturation are mechanisms mediating deletion (e.g., clonal exhaustion and veto cell–mediated deletion) or inactivation (clonal anergy and active suppression) of peripheral T and B cells.

Peripheral Deletion of T Cells

Several mechanisms mediate deletion of antigen-specific T cells in the periphery. **Administration of large antigen doses stimulates the rapid proliferation of reactive T cells, but this is quickly followed by apoptosis of the reactive cells. This form of deletion due to "clonal exhaustion" has been shown experimentally in mouse models using virus infections and is thought to be operative in removing viral antigen-reactive CD8+ T cells during HIV infections** (Moskophidis et al, 1993). Clonal exhaustion is likely to occur in response to the large amount of self-proteins in the periphery, acting as a backup to remove self-reactive T cells that escaped negative selection during maturation in the thymus

An active mechanism of T-cell deletion in the periphery is mediated through stromal cells in the lymph nodes expressing AIRE (Gardner et al, 2008). Interestingly, the set of TSA expressed under the control of AIRE in the periphery is distinct from that expressed by thymic medullary epithelial cells.

Clonal Anergy

Clonal anergy of T cells is induced by TCR engagement of peptide-MHC complexes in the absence of costimulatory signals (Schwartz, 1997). In the two-signal model of naive T-cell activation, signal one (e.g., TCR-mediated stimulation) is delivered in the absence of signal two (e.g., B7/CD40–mediated costimulation). The major consequence of clonal anergy induction is the inability of the anergized T cell to produce IL-2 in response to subsequent encounters with the specific peptide-MHC ligand. Thus these T cells are unable to clonally expand and differentiate into effector cells. In at least some experimental model systems, T cells rendered anergic are able to proliferate when provided with exogenous growth factors such as IL-2, and their continued proliferation in the presence of growth factors promotes development to effector function such as IFN-γ production.

Clonal anergy of T cells can be induced by TCR engagement of specific antigen-MHCs presented by nonprofessional APCs that do not express costimulatory molecules; by resting professional APCs that do not express costimulatory molecules, by interaction with chemically fixed APCs, or by blocking-mediated costimulatory interactions, particularly CD28- and/or CD154-mediated costimulation. In some instances costimulation may also be delivered by other receptor ligand interactions during naive priming by professional antigen-presenting cells. Administration of antibodies to adhesion molecules, such as ICAM-1 and LFA-1, and to CD45RB during antigen priming induces clonal anergy of specific T cells. The ability to induce clonal anergy using these strategies emphasizes the importance of a highly regulated process of antigen capture, processing, and presentation by professional APCs having the ability to deliver the necessary costimulatory signals during T-cell priming. Anergy of B cells is also induced by antigen binding to surface immunoglobulins in the absence of costimulatory signals that are required for complete activation and development to antibody-producing cells.

Blockade of costimulation delivery during TCR interaction with peptide-MHC results in the alteration of many intracellular biochemical events observed during TCR-mediated activation of T lymphocytes. These events include absence of kinase activation (including the LCK and ZAP-70 kinases), absence of phosphorylation of CD3 components, and absence of activation of transcription factors including AP-1 and NF-AT. These intracellular signaling alterations suggest that the induction of clonal anergy is an active process. The ability of many immunosuppressants to block clonal anergy during naive T-cell interaction with peptide-MHC complexes in the absence of appropriate costimulation is consistent with clonal anergy induction as an active process.

In addition to the removal or inactivation of autoreactive lymphocytes through TCR engagement in the absence of costimulation, it is obvious that this feature of the immune system can be manipulated to induce tolerance and promote the survival of allografts or to ameliorate active autoimmune disease (Larsen et al, 1996). **The induction of clonal anergy by costimulation blockade forms the basis of several immunosuppressive strategies currently under investigation in clinical studies of transplantation and autoimmune disease. Many of these studies have used CTLA-Ig that binds to B7-1 and B7-2 molecules with high affinity and blocks interaction with CD28 expressed by T cells in combination with anti-CD154 monoclonal antibodies** (Leonard et al, 1996). Preclinical studies testing this approach have shown considerable promise in prolonging allografts in nonhuman primate models. In addition, strategies combining costimulatory blockade with injection of donor bone marrow at the time of allograft transplantation appear to be effective in inducing recipient tolerance to graft alloantigens.

Regulatory T Cells

An active mechanism of tolerance mediated by T cells with suppressive or downregulatory activities may also

be induced to inhibit immune responses to self- and exogenous antigens. The concept of T cells with suppressive or downregulatory function was originally conceived by Gershon in experiments using mouse models (Gershon, 1975). Mice primed with high doses of antigen were not only rendered unresponsive to subsequent challenges with the original antigen, but the tolerant state was transferable to naive animals by T cells from the tolerant animals. Treatment with nondepleting anti-CD4 monoclonal antibodies during antigen priming also induces a population of CD4+ T cells that can transfer tolerance to naive animals. **More recent studies have identified a population of CD25+ CD4+ T cells that inhibit the activation of peripheral T cells to self-antigens. Depletion or removal of these regulatory T cells promotes the development of autoimmune disease in animal models of colitis and diabetes** (Salomon et al, 2000). Similar populations of regulatory CD4+ T (also termed Th3 cells) have been identified in humans. The forkhead/winged helix transcription factor FOXP3 is required for the development of CD4+CD25+ regulatory T cells, and FOXP3 is currently used as a reliable marker of these cells. The immunosuppressive functions expressed by these regulatory T cells appear to be many and may be mediated at least in part through production of the immunosuppressive cytokines IL-10 and TGF-β, which may inhibit antigen-presenting cell function during T-cell priming. Other mechanisms expressed by these regulatory cells may be mediated through expression of FasL and deletion of antigen-presenting cells during effector T-cell priming. **An important consequence of tolerance mediated by regulatory T cells specifically is the ability to inhibit immune responses to an irrelevant antigen when that (irrelevant) antigen and the regulatory T cell–specific antigen are presented by the same APC. This form of so-called "linked immunosuppression" may be further manipulated in future strategies to inhibit responses to self- and allogeneic antigens.**

Tolerance in Human Organ Transplantation

Currently, patients transplanted with organs from MHC-mismatched donors to treat end-stage organ failure must take a potent immunosuppression regimen to prevent rejection of the graft. The immunosuppression currently used renders the recipient susceptible to infection, tumors, and renal fibrosis. The design and implementation of a strategy that would induce donor-specific tolerance would obviate the need for this immunosuppression and the accompanying side effects. Seminal experiments by Billingham, Brent, and Medawar using rodent models demonstrated that introduction of allogeneic cells during the development of the immune system generated tolerance to the donor alloantigens, first suggesting that the manipulation of recipients to become tolerant to alloantigens was possible (Billingham et al, 1953). **Based on this original premise, a nonmyeloablative conditioning regimen that includes a donor bone marrow infusion to induce a period of mixed chimerism has recently been used clinically in a small cohort of adult recipients of single HLA single-haplotype–mismatched kidney grafts to induce tolerance and allow complete withdrawal of immunosuppressive drugs** (Kawai et al, 2008). **Furthermore, recent studies have also demonstrated a time window after birth in which neonates can be transplanted with ABO-incompatible heart allografts and induce deletion of B cells producing antibodies to the ABO-incompatible carbohydrate moieties** (Fan et al, 2004).

ADHESION MOLECULES AND CONTROL OF LYMPHOCYTE TRAFFICKING

A critical feature of the immune system is the restriction imposed on the migration of T lymphocytes through lymphoid versus peripheral tissues, which is dependent on the stage of T-cell development or activation. Trafficking of naive T cells is restricted to primary lymphoid tissues. It is in these tissues that the chances of encountering dendritic cells presenting foreign peptide-MHC complexes are highest (see Trafficking of Naive T Cells). In contrast, T-cell activation results in the ability of the T cells to recognize and stop at sites of vascular inflammation. This allows the T cells to traverse the endothelium barrier and enter peripheral tissues where the effector functions of primed T cells may be needed during an immune response.

Upregulated Adhesion Molecule Expression

TCR engagement of a specific ligand in association with appropriate costimulation from professional APC leads to T-cell activation. Activation induces two phenotypic changes that alter the migration pattern of the T cell. First, the expression of the lymph node homing receptor CD62L is downregulated. This decreases the ability of the T cells to traffic into the lymph nodes and promotes T-cell circulation through the blood vessels. Second, expression of molecules that facilitate localization of antigen-primed T cells to inflammatory sites in the vascular endothelium is stimulated. T cells and other leukocytes travel through the circulation under extremely high shear forces. **The expression of these adhesion molecules is critical for mediating the arrest of the activated cells on the vascular endothelium under this high shear force and facilitates T-cell entry into the peripheral tissues** (Springer, 1994). Complementary sets of receptors on leukocytes and endothelial cells help mediate the arrest of activated T cells and other leukocytes at inflammatory foci on the vascular endothelium. These molecules include the selectins and their ligands, the addressins, and the integrins and their ligands, which are members of the Ig superfamily.

The principal adhesion molecules upregulated during cellular activation of leukocytes are the integrins, a family of noncovalently associated dimers composed of an α chain and a common β chain (Table 17–3). On T cells, antigen priming stimulates increased expression of CD11a, which associates with CD18 to form the integrin LFA-1 (leukocyte functional antigen–1) or $\alpha_L\beta_2$. T-cell activation also induces expression of the integrin VLA-4 (very late activation antigen–4) or $\alpha_4\beta_1$. **In addition to their adhesive functions, integrin ligation may deliver costimulatory signals during T-cell interaction with antigen-presenting cells** (Ni et al, 1999). **Integrins also bind to extracellular matrix proteins, and this engagement may augment T-cell effector function during the elicitation of an immune response.** Activation of leukocytes including T cells also upregulates expression of a proteoglycan binding

Table 17–3.
Representative Integrins

α/β CHAINS	COMMON NAME	CD DESIGNATION	LIGAND
αLβ2	LFA-1	CD11a/CD18	ICAM-1; ICAM-2; ICAM-3
αMβ2	MAC-1	CD11b/CD18	ICAM-1; Fibronectin
α4β1	VLA-4	CD49d/CD29	VCAM-1; Fibronectin
α5β1	VLA-5	CD49e/CD29	Fibronectin
α4β7	LPAM-1	CD107a	VCAM-1; MAdCAM-1

receptor, CD44. Macrophages and neutrophils also express LFA-1 as well as CD11b in association with CD18 ($\alpha_M\beta_2$), commonly called Mac-1.

In addition to integrins, T cells and other leukocytes express selectin binding molecules that direct cells to inflammatory sites in the vascular endothelium. **The P-selectin glycoprotein ligand (PSGL-1) is expressed by granulocytes and T lymphocytes and is the major ligand for P-selectin on endothelial cells** (Kansas, 1996). Expression of these ligands may also direct the T cells to distinct tissue sites. Activated T cells that are programmed to traffic to the skin also express cutaneous lymphoid antigen (CLA), which binds to E-selectin. In contrast, T cells trafficking to the gut mucosa are stimulated to express $\alpha_4\beta_7$ during priming.

Adhesion Molecule Expression on Endothelial Cells

Vascular endothelial cells normally express low levels of ligands for integrins and other adhesion molecules. **During tissue inflammation, endothelial cells are activated to produce several cytokines including TNF-α and IL-1** (Pober et al, 1986). **These cytokines stimulate the endothelial cells to express several classes of adhesion molecules.** Endothelial cells express two different selectins that facilitate the localization of activated T cells and other leukocytes to the vascular endothelium surface. P-selectin is preformed in specialized vacuoles called Weibel-Palade bodies, and surface expression is mobilized following activation of the endothelial cells. In contrast, endothelial cell activation initiates transcription and expression of E-selectin. During activation, endothelial cell expression of adhesion molecule members of the super-Ig family is also upregulated. These molecules include intercellular adhesion molecule (ICAM) -1 and very late cell adhesion molecule (VCAM) -1. Another member of this family, ICAM-2, is constitutively expressed on the endothelial cell surface and is not upregulated by proinflammatory cytokines such as TNF-α and IL-1 during inflammatory processes.

T-Cell–Endothelial Cell Interactions

The localization of T cells and other leukocytes in response to inflammation on the vascular endothelium is a highly regulated process (Ebnet et al, 1996). This localization begins with the regulated expression of adhesion molecules and their ligands on the leukocytes and endothelial cells. As the leukocytes are circulating through a vessel, engagement of selectins tether the cells and slow their movement to rolling along the endothelial surface (Fig. 17–13). **After cell movement is slowed by selectin-mediated tethering, the binding of integrins to Ig superfamily counter-receptors mediates the arrest of the T cells on the vascular endothelium. During this process, leukocyte engagement of cytokines produced by endothelial cells, including IL-8 and TARC, is required to trigger activation of the integrins**

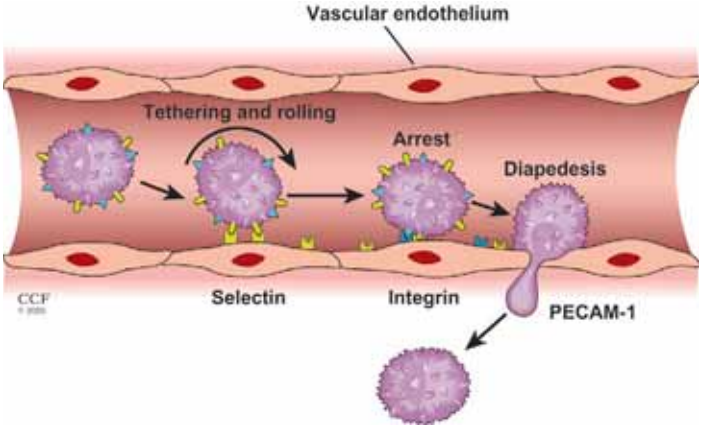

Figure 17–13. Localization of leukocytes to sites of vascular inflammation. During inflammation, vascular endothelial cells are activated to express adhesion molecules, such as selectins and ligands for integrins and several different chemokines. Under high shear forces, leukocytes in the circulation are slowed down by selectin-mediated tethering on the endothelium. As the leukocytes are rolling along the vascular endothelial surface, expressed integrins are activated by endothelial chemokines and the interaction of the integrins with their ligands results in leukocyte arrest. Through the homotypic interactions of platelet–endothelial cell adhesion molecule–1 (PECAM-1) on the leukocyte and endothelial cell surfaces, the leukocyte transmigrates across the vascular endothelial cell barrier. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2009-2011. All Rights Reserved.)

(Campbell et al, 1996). Binding of these cytokines through specific G protein–coupled receptors induces a conformational change to a high-affinity binding molecule and mediates arrest of the leukocytes on the vascular endothelium. As leukocyte movement is arrested, there is a considerable amount of "cross-talk" between the leukocyte and the endothelial cell. Activation of macrophages, neutrophils, and possibly other leukocytes at the endothelial cell surface stimulates the leukocytes to produce TNF-α, which provides continued stimulation to express increased levels of VCAM-1 and ICAM-1 on the endothelial cell surface. Furthermore, antigen-primed T-cell recognition of specific peptide-MHC complexes on the endothelial cell surface stimulates the T cells to express immune function such as cytokine production. T-cell production of IFN-γ stimulates endothelial cells to upregulate expression of MHC molecules and to produce chemoattractant cytokines, which amplifies T-cell recruitment and the immune response to localized areas in the endothelium.

Traversing the Endothelial Barrier

Following the arrest of the leukocyte on the vascular endothelium, the cell traverses the endothelial barrier into the peripheral tissue, a process termed diapedesis. Platelet–endothelial cell adhesion molecule–1 (PECAM, CD31) is expressed on endothelial cells and is concentrated at the cell junctions in a vessel (Muller and Randolph, 1999). This molecule is also expressed on the surface of leukocytes. A critical property of PECAM-1 is the ability to bind to another PECAM-1 molecule, a process called homophilic adhesion. During diapedesis, PECAM-1 on the leukocyte binds to a PECAM-1 molecule at an endothelial cell junction, and the leukocyte begins to traverse the endothelial barrier. In addition to these interactions, other molecules including CD99 and JAM (junctional adhesion molecule) are expressed by leukocytes and endothelial cells and coordinate with PECAM-1 interactions to guide the leukocyte

through the endothelium, and the leukocyte enters the peripheral tissue. Following TCR-mediated activation, the T cell expresses immune function such as cytokine production or target cell cytolysis.

Chemokines and Peripheral Tissue Recruitment of Leukocytes

Cytokines with chemoattractant properties, chemokines, are also critical in mediating localization and trafficking of leukocytes to tissue sites during physiologic processes, including inflammation and homeostasis (Rollins, 1997). Chemokines are a superfamily of small (<14 kD), heparin-binding proteins. More than 50 chemokine proteins have been identified and are grouped into four families based on a cysteine motif in the amino-terminal area of the protein (Table 17–4). The C-X-C chemokines, in which these cysteines are separated by a single amino acid, are attractant for neutrophils and include IL-8 and GROα. The CXC chemokines also include three members, IP-10 (IFN-γ–inducible protein), Mig (monokine induced by IFN-γ), and I-TAC (interferon-inducible T-cell alpha chemoattractant), which are chemoattractant for activated T cells. The C-C chemokines, in which the two cysteines are adjacent, are chemoattractant for a variety of leukocytes including monocytes, eosinophils, T lymphocytes, NK cells and dendritic cells. Representative C-C chemokines include MIP (macrophage inflammatory protein)-1α, MIP-1β, and monocyte chemoattractant protein–1 (MCP-1). The C family consists of a single cytokine, lymphotactin, which is chemotactic for NK cells and T cells. The C-X_3-C family also contains a single chemokine, fractalkine, which is on a membrane-bound mucin stalk and has adhesive and chemoattractant properties for IL-2–activated NK cells and CD8+ T cells.

Under appropriate stimulatory conditions, such as inflammation, virtually all cells produce specific chemokines. **Chemokine production is primarily regulated by the cytokine environment.** TNF-α and IL-1 induce many different cell types to produce neutrophil (e.g., IL-8 and GROα) and macrophage (e.g., MCP-1) chemoattractants. IFN-γ stimulates many different cells to produce the T-cell attractants IP-10, Mig, and ITAC. Cytokines including IL-4, IL-10, and IFN-γ inhibit production of specific chemokines during many processes.

Chemokines play a major role in tissue pathology by directing receptor-bearing leukocytes to tissue sites of inflammation. The hepta-transmembrane–spanning chemokine receptors are linked to G-coupled proteins, which transduce intracellular signals following ligand binding. Because chemokines bind to glycosaminoglycans on cell surfaces and to extracellular matrix proteins, leukocytes expressing the appropriate receptors likely bind chemokines as solid-phase (nonsoluble), proteins during infiltration into inflammatory tissue sites, and this solid-phase binding may be required to augment intracellular signaling. Some leukocyte populations constitutively express chemokine receptors, but cellular activation is required for expression of chemokine receptors on other types of cells. The expression of chemokine receptors such as CXCR3, the ligand for IP-10 and Mig, on T cells is induced by antigen priming and/or cytokines. There is considerable experimental and clinical evidence indicating that populations of CD4+ T cells producing type 1 (e.g., Th1 cells) versus type 2 (e.g., Th2 cells) cytokines express unique patterns of chemokine receptors (Bonecchi et al, 1999). TNF-α stimulates the expression of CCR7 on interstitial dendritic cells and directs their migration through the afferent lymphatics into the draining lymphoid tissue, where they prime peptide-MHC–specific T cells.

The critical role of chemokines during inflammatory processes has been clearly demonstrated in animal models where neutralization of specific chemokines results in inhibition of leukocyte infiltration and tissue pathology (Huffnagle et al, 1995; Koga et al, 1999). Chemokines are produced by all renal cell types and promote tubulointerstitial and glomerular pathology (Segerer et al, 2000). **In addition to leukocyte recruitment, many chemokines stimulate other proinflammatory activities, which may amplify the function of target leukocyte populations in vivo and intensify tissue inflammation.** These activities include the ability of specific chemokines to: (1) trigger the arrest of monocytes and T lymphocytes rolling on endothelial surfaces under physiologic shear conditions in an adhesion molecule–dependent manner; (2) stimulate increased integrin expression and cell adhesion; (3) stimulate the release of granules by neutrophils and granulocytes; and, (4) amplify CD8+ T cell and NK cell–mediated cytotoxicity. Each of these processes has a critical impact on the intensity and duration of inflammation and is likely to be augmented by specific chemokines.

Chemokines also play a crucial role in immune homeostasis (Cyster, 1999). For example, chemokines such as B lymphocyte chemoattractant (BLC) direct newly matured B lymphocytes to form follicles in the secondary lymphoid tissue. The localization of immature dendritic cells in peripheral tissues, where they will function as antigen-processing and -presenting cells during the initiation of immune responses, is also directed by specific chemokines.

Table 17–4.

Representative Chemokines and Receptors

FAMILY	CHEMOKINE	RECEPTOR	RESPONSIVE LEUKOCYTE POPULATIONS
CXC	IL-8	CXCR1, CXCR2	Neutrophils
	GROα	CXCR2	Neutrophils
	IP-10	CXCR3	Activated T cells
	MIG	CXCR3	Activated T cells
	SDF	CXCR4	Naive T cells, B cells, Dendritic cells, MØ
	BLC	CXCR5	B cells
CC	MIP-1α	CCR1, CCR5	T cells, NK cells, MØ
	MCP-1	CCR2, CCR10	MØ
	TARC	CCR4	T cells
	Eotaxin	CXCR3	Eosinophils
	RANTES	CCR1, CCR3, CCR5	T cells, MØ, NK cells
	MIP-3α	CCR6	Immature dendritic cells
	SLC	CCR7	Mature dendritic cells, T cells
C	Lymphotactin	XCR1	T cells, NK cells
CX_3C	Fractalkine	CX_3CR1	CD8+ T cells, NK cells

MØ, macrophages; NK cells, natural killer cells.

TUMOR IMMUNOLOGY

The concept that the immune system protects the host from cancer dates back to 1909, and was refined in the 1950s (Bhardwaj, 2007) when it was proposed that immune cells eliminate tumors by an "immune surveillance" mechanism. **This concept was challenged in the 1980s but has regained favor and has**

now been expanded based on additional findings. We now describe "cancer immunoediting" that encompasses three different phases (Dunn et al, 2004). The initial phase of editing involves immune cell elimination of tumor cells, supported by a greater incidence of tumor development in mice deficient in immune cells (RAG-2 mice deficient in T, B, and NK cells) or immune-related molecules (IFN-γ–deficient mice). In the second phase, there is modification of tumors by immune cells, leading to persistence and the establishment of an equilibrium between the tumor and the immune systems. In the third phase, the tumors escape the immune system by various mechanisms, resulting in tumor progression. Thus the challenge is to develop a greater understanding of each of these phases, which in turn should lead to more effective ways to stimulate potent T-cell antitumor immunity and, at the same time, define new approaches to modify or eliminate the mechanisms by which tumors can escape the immune system.

Role of T Cells

T lymphocytes are central to the generation of an effective tumor immune response (Cheever and Chen, 1997). In fact, most approaches to immunotherapy center on stimulating a potent T-cell response**.** The importance of T cells in tumor eradication is illustrated by the demonstration that adoptive transfer of tumor-reactive T cells into syngeneic murine tumor models, and in melanoma patients, can lead to the rejection of established tumors. Furthermore, the in-vivo deletion of T cells using antibodies to CD8 and, in some cases, to CD4, will eliminate antitumor activity normally induced by various forms of immunotherapy.

Activation of CD8+ T cells that recognize tumor-associated antigens (TAA) presented by MHC class I molecules and CD4+ T cells that respond to TAA presented by MHC class II molecules represents the most effective tumor immune response (Robbins and Kawakami, 1996). Dendritic cells present in tumors and draining lymph nodes are critical for the presentation of processed tumor antigen peptides to the T cells and their subsequent activation (Schuler and Steinman, 1997). Tumor cells are generally considered to be poor stimulators of T cells, owing in part to the lack of expression of MHC class II molecules and their variable expression of MHC class I molecules. After T-cell activation, tumor rejection is thought to occur by several mechanisms that may vary depending on the effectors generated and the sensitivity of the tumors (Kagi et al, 1996). Cytotoxic CD8+ T cells (CTL) destroy tumor cells by elaboration of cytoplasmic granules containing the pore-forming protein perforin, resulting in plasma membrane disruption, or by the upregulation of Fas ligand that can bind to Fas (on the tumors) to induce apoptosis. CD4+ T cells are important for the generation of memory CD8+ T-cell responses (Ossendorp et al, 1998; Janssen et al, 2003), which are typically the effector cells associated with tumor rejection (Matsui et al, 1999). However, antitumor CD4+ T effector cells also have the capacity to mediate the regression of MHC class I–loss tumors that are resistant to CD8+ CTLs (Surman et al, 2000). Additionally, the quality of antitumor CD4+ T-cell responses appears to be a prognostic indicator of disease progression and immunotherapeutic responsiveness. For example, renal cell carcinoma (RCC) patients whose tumor environment is biased towards a type 1 immune response have a more favorable prognosis (Kondo et al, 2006). **Moreover, the production of Th1 cytokines, such as IFN-γ, produced by both CD4+ and CD8+ T cells is known to be critical** (Brunda et al, 1995). Although IFN-γ production is necessary, it is not sufficient for tumor rejection. Other T1 cytokines, such as IL-2 and IL-12, are involved in antitumor response primarily through their ability to activate effector T cells and induce their clonal expansion (Burke, 1999). The secretion of select chemokines is also necessary for the recruitment of additional T cells and dendritic cells to the tumor site (Tannenbaum et al, 1998). In contrast, Th2 CD4+ T cells produce cytokines such as IL-4, IL-5, IL-6, and IL-10, which lead to a humoral immune response but are not typically targeted for cellular immunotherapy. The third subset of CD4+ T cells produce IL-17 and is a major effector cell in autoimmunity. **Although present in human and murine tumors, the role that Th17 cells play in tumor immunity is unclear because there are opposing data.** One study showed that in IL-17 deficient mice the growth of B16 melanoma and MB49 bladder carcinoma tumors was reduced, which was significantly enhanced, however, in IFN-γ knockout mice where IL-17 expression was increased within the tumor (Wang et al, 2009). Others, however, show that tumor growth and lung metastasis were increased in IL-17–deficient mice, which was associated with decreased expression of IFN-γ–producing NK cells and tumor-specific T cells (Kryczek et al, 2009). The latter findings suggest that the induction of IL-23/IL-6 and IL-17 pathways may not always lead to tumor progression. Thus further studies are needed to define the role of Th-17 T-effector cells in the tumor-bearing host.

Tumor Antigens

The initial gene encoding a human tumor associated antigen (TAA) recognized by MHC restricted T cells was the melanoma antigen-1 (MAGE-1) (van der Bruggen et al, 1991). **Subsequently over 300 TAAs have been identified along with their HLA class I and II restrictions** (Novellino et al, 2005). Peptide epitopes for a number of the TAAs have been identified, which can serve to stimulate T-cell immunity. Many of the TAAs that have been identified are expressed on melanomas, which is attributable to the ease with which it has been possible to isolate and detect MHC-restricted melanoma-specific T cells from this patient population. TAAs are expressed by a variety of different tumor types, including urologic tumors such as RCC and prostate. An updated peptide database for T cell–defined tumor antigens is available (van der Bruggen et al, 2001).

Four main groups of TAAs have been identified, and three of these represent shared antigens present on multiple tumor types. **One group is the shared tumor-specific antigens that are encoded by a family of genes that include *BAGE-1, MAGE-1, MAGE-2 LARGE-1, NY-ESO-1,* and *RAGE* (cancer-testis genes)** (Table 17–5). These antigens are expressed on a variety of human tumors but not by most normal tissues, with the exception of testis and placenta. **Their tumor expression includes melanomas, lung tumors, breast tumors, head and neck tumors, RCC, and bladder cancer** (Robbins and Kawakami, 1996; Bellone et al, 1999). **A second group of shared TAAs is the differentiation antigens, which are also expressed by normal tissue from which the tumor was derived** (van der Bruggen et al, 2001). These include antigens that are encoded by genes such as MART-1/MelanA (GP100 along with tyrosinase), a melanocyte lineage protein that is a key enzyme in pigment synthesis. Other differentiation antigens that are recognized by T cells include the gut carcinoma antigen CEA, (along with kallikrein 4 and PSA) expressed by prostate cancer, and NY-Br-1 (expressed on some breast cancers). These antigens are not tumor specific and some may result in an autoimmune response that can be mild in the case of tyrosinase or more severe in the

Table 17–5.
Human Tumor Antigens Recognized by T Cells

Oncogenic viral antigens	
E7, human papilloma virus	

case of CEA. **A third group of shared TAAs is represented by proteins that are overexpressed in the tumor compared to normal tissue.** Included in this group are BCLx, expressed on colon, breast, and melanoma tumors; CALCA expressed on thyroid tumors; and some lung carcinomas as well as G250 (CAIX), expressed on stomach; RCC; and liver tumors. HER2/NEU is another protein that is present in normal tissues at low levels but is overexpressed in some tumors, particularly breast and ovarian carcinomas. There are other antigens that have been identified that can serve as potential targets for immunotherapy. This includes MUC-1, a cell surface protein composed of multiple tandem repeats that can be recognized by T cells, which is directed against breast, ovarian, and pancreatic tumors. The risk of autoimmune responses is also possible with some of the antigens in this group. **The fourth group is composed of antigens that arise from point mutations in genes that are ubiquitously expressed.** These antigens are tumor specific and usually limited to a small subset of patients. **Because of their restricted expression, many of these may not be the best candidate antigens targeted for immunotherapy.** This group of TAAs includes BCL-ABL fusion protein, CDC-27, P53, K-RAS, and HSP70. Thus a significant number of human tumor antigens have been identified that are recognized by T cells and many are currently being evaluated for their ability to stimulate antitumor immune responses in mouse models and cancer patients.

RCCs have the potential to stimulate an immune response (Bukowski, 2000) **as evident by the isolation and expansion of CD4+ and CD8+ T-cell lines, along with clones from patients that produce IFN-γ and mediate lysis in response to autologous tumor cells.** RCCs express a number of TAAs that could serve as targets for immunotherapy. These include RAGE-1, HER2/NEU, G250, PRAME, PG75, MUC-1, and the receptor tyrosine kinase, EPHA2. There is considerable variation in the level of expression and percentage of cells expressing these antigens among renal tumors. For example, RAGE is expressed on 2% to 20% of renal cell carcinomas, whereas most renal cell carcinomas (75%) express carboxyl esterase. Recently, MAGE-6 was shown to be expressed on 30% of RCCs, whereas the receptor kinase EPHA2 was expressed on 90% of RCCs and is associated with a more aggressive phenotype (Tatsumi et al, 2002; Herrem et al, 2005). The demonstration of TAAs on RCCs is an important step toward developing vaccine strategies for this disease. **There are also a number of TAAs expressed on prostate cancers that can serve as potential targets for different immunotherapy approaches.** This includes prostate specific membrane antigen (PSMA), prostate stem cell antigen, MUC1, epidermal growth factor receptor, and urokinase plasminogen activator and its receptor (Mohebtash et al, 2009; Li et al, 2010).

Role of Innate Immunity

NK cells represent part of the host immune response against neoplastic cells (Basse et al, 2000). NK cells can recognize and destroy some tumors, particularly those of lymphoid origin, without any exogenous activation. However, the lysis of many freshly isolated solid tumors requires activation of these cells by IL-2; thus NK cells have been referred to as lymphokine-activated killer (LAK) cells. **The destruction of tumor target cells by NK cells does not involve MHC restriction, and, in fact, these cells are considered most effective against tumor cells that express low to no MHC class I antigens. Indeed, the ability of NK cells to kill tumor cells is regulated by several receptors with unique specificity for different MHC class I antigens, and are collectively referred to as killer–Ig-like receptors (KIR)** (Moretta, 2007). Although the interaction of different KIRs with their corresponding HLA–class I molecules is a major regulator of NK activation, the activation of these cells is dependent on activation receptors that recognize unique ligands on target cells (Moretta et al, 2004). Several receptors have been identified (NK-46, NKp30, and NKp44) and are referred to as natural cytotoxicity receptors (NCR). Usually the ligands recognized by the NCRs are not expressed by normal cells but are highly expressed by tumor cells and virally infected cells. **NK cells can also kill tumor targets by antibody-dependent cell-mediated cytotoxicity.** In this setting, there is redirected lysis because the specificity of tumor recognition resides in the variable region of the antibody. While the Fab portion of the antibody binds to its tumor antigen, the Fc portion of the immunoglobulin engages the Fc receptor on an NK cell, which in turn activates the cells lytic machinery. **The relevance of NK cells in defense against cancer cells has been demonstrated by evidence that the depletion of this population in some tumor models by anti-NK antibodies reduces or eliminates antitumor activity.**

Tumor Evasion of the Immune System

Although most solid tumors, including RCCs, express TAAs that can be recognized by T cells, the immune response that develops is insufficient to impair tumor progression (Finke, 2004). There is growing evidence to suggest that the absence of a strong antitumor response in vivo is partly attributable to the tumor promoting an immunosuppressive environment. Indeed**, it has been shown that T cells infiltrating many tumors are functionally**

impaired, as demonstrated by their diminished ability to proliferate in response to a variety of stimuli and their diminished cytotoxic activity. Dendritic cells within the tumor have been shown to be impaired in their antigen-presenting function, which may contribute to the immune dysfunction noted in the tumor microenvironment. **The immune dysfunction is not restricted to tumor infiltration of lymphocytes because tumor-specific CD4+ T cells in the peripheral blood of RCC and melanoma patients display a Th2 bias in response to dendritic cells pulsed with peptides to either MAGE-6 or EPHA2.** However, in patients who have no evidence of disease MAGE-6–specific and EPHA2-specific IFN-γ–producing T cells were predominant (Tatsumi et al, 2002; Tatsumi et al, 2003). Thus the tumor microenvironment may shift the balance from a Th1 cytokine response, which is known to be important for the rejection of tumors in animal models, to a Th2 cytokine response, which is primarily effective at promoting a humoral immune response. There is also evidence that increased apoptotic activity within T cells from cancer patients may also contribute to the immune dysfunction that could be mediated by Fas/FasL interaction or by other tumor products (Gastman et al, 2000; Das et al, 2008).

The following describes several different mechanisms that are thought to play important roles in tumor evasion of the immune system (Fig. 17–14). Most of these mechanisms are supported by substantial experimental data derived from murine tumor models and cancer patients.

Impaired Antigen Presentation

The recognition of tumor cells by T cells may be impaired because of defective antigen processing and presentation (Pawelec et al, 1997; Seliger et al, 1997). Reduced or loss of MHC class I and class II expression by tumors, including RCCs, has been well documented. In some tumors there is also decreased expression of transporter proteins associated with antigen processing (TAP proteins), as well as deficient levels of LMP proteosomal complexes. A reduction in mRNA and protein levels of these molecules appears more pronounced in RCC cells that have acquired metastatic potential, suggesting that the process of malignant transformation may include progressive loss of TAP and LMP. Increasing the levels of TAP in tumors, either by stimulation by IFN-γ or by transfection with TAP-1 cDNA, results in higher expression of MHC class I molecules on the tumor cell surface and enhanced tumor-specific, class I–restricted cytotoxic T-cell recognition.

Regulatory T Cells

Regulatory T cells (Tregs) are divided into two subsets, which include natural/intrinsic and adaptive/induced populations (Shevach, 2002; Fontenot and Rudensky, 2005). The natural subset, is characterized as CD4+, interleukin (IL)-2 receptor–α (CD25)+, FOXP3 (transcription factor)+, and is thought to be a distinct T-cell lineage originating from the thymus, representing 1% to 3% of CD4+ T cells in healthy individuals. This Treg subset is the most

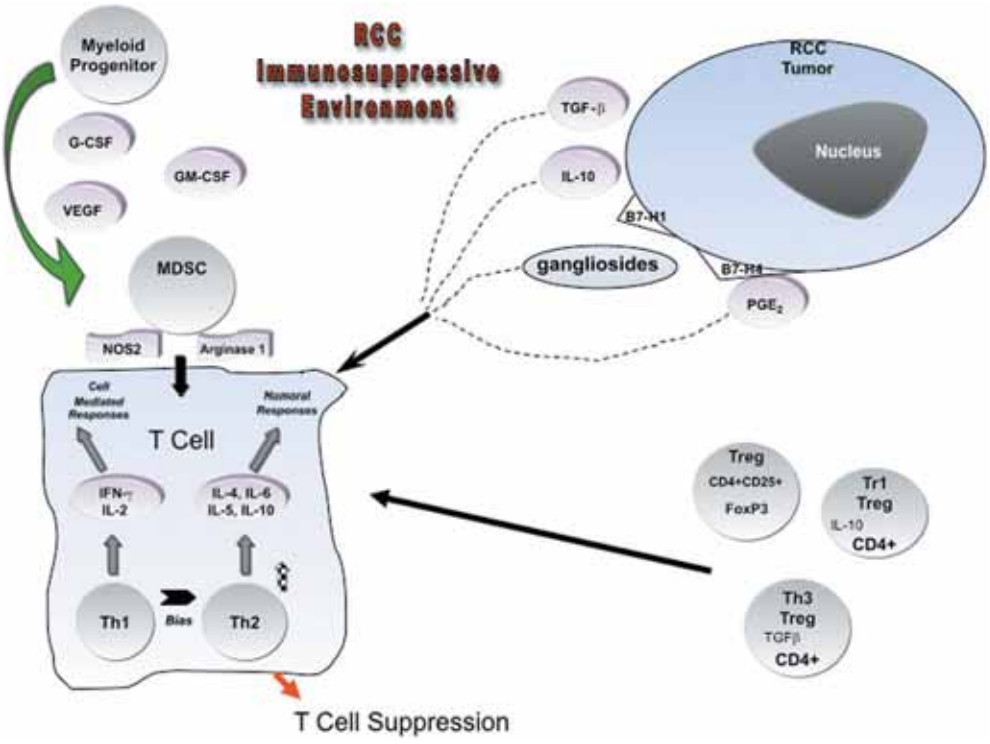

Figure 17–14. Scheme showing the mechanisms by which tumor cells can induce immune dysfunction in T cells. Tumor cells produce a variety of immunosuppressive products that include interleukin-10 (IL-10), gangliosides, transforming growth factor-β (TGF-β), and prostaglandins, which can directly suppress T-cell function. B7-H1 and B7-H4 ligands expressed on tumor cells, including renal cell carcinoma (RCC), can promote T-cell anergy or cell death by engaging its receptor PD-1 on T cells. Tumor cells can also indirectly suppress T-cell function by promoting the activation and expansion of T-regulator cells, and by producing cytokine (G-CSF, VEGF, GM-CSF) that can stimulate myeloid-derived suppressor cell (MDSC) accumulation. These suppressive cells and secreted products have the ability to inhibit the development of a type 1 T-cell response (interferon-γ [IFN-γ] production) that is critical for development of antitumor immunity. The tumor environment can, in some cases, increase a type 2 response resulting in a Th2 bias. NOS2, nitric oxide synthase 2; PGE_2, prostaglandin E_2.

characterized of the T-regulatory cells and has emerged as another mechanism that promotes immune suppression in a tumor-bearing host. This occurs by inhibiting the proliferation of CD4+ T-helper cells, as well as their ability to produce the cytokines IFN-γ and IL-2 (Curiel et al, 2004). It also appears that the cytokine IL-2 produced by T-helper cells may promote the growth of T-regulatory cells (Antony and Restifo, 2005). The adaptive subset is not characterized by a specific marker, but by the immunosuppressive cytokines they produce. The adaptive subset includes Tr1 Tregs that produce IL-10, while Th3 Tregs produce TGF-β. Adaptive Tregs appear to originate from naive T cells after interaction with dendritic cells (Shevach, 2002; Fontenot and Rudensky, 2005).

Tregs appear to preferentially migrate to and accumulate in tumors and ascites of cancer patients. The expression of Tregs in cancer patients may have a negative impact on clinical outcomes. For some tumor types, including ovarian, breast cancer, and hepatocellular carcinomas, the accumulation of Tregs (FOXP3+) in the tumor microenvironment correlates inversely with patient survival (Curiel et al, 2004; Bates et al, 2006; Kobayashi et al, 2007). In a study of ovarian cancer, an increase in Tregs was associated with inhibition of tumor-specific cytotoxic T-cell activity and cytokine production. Conversely, it appears that in follicular and Hodgkin lymphoma the increased numbers of Tregs (FOXP3+) can be correlated with improved patient survival (Alvaro et al, 2005; Carreras et al, 2006).

Metastatic RCC patients have a significant increase in Tregs (FOXP3+) in their peripheral blood (Cesana et al, 2006; Griffiths et al, 2007; Finke et al, 2008), which are able to inhibit T-effector cell proliferation. Furthermore, Griffith and colleagues found that increased Tregs (FOXP3+) numbers in the peripheral blood of metastatic RCC patients correlated with poor clinical outcomes. However, an analysis of RCC patients with localized disease (tumor tissue) found that the FOXP3– (Tr1) rather than the FOXP3+ subset of Tregs was significantly associated with poor outcomes and death from RCC (Siddiqui et al, 2007). Based on these findings, it is clear that additional studies are needed to define the role of Tregs in urologic cancers such as RCC.

Tregs are beginning to be examined as therapeutic targets. One study used DAB389IL-2, a recombinant IL-2–diphtheria toxin conjugate, to remove Tregs in cancer patients (including RCC) and the reduction of Tregs coincided with an augmented T-cell response to tumor antigens after vaccination. These findings suggest that Tregs in RCC patients are directly contributing to the immunosuppressive environment that is allowing tumor cells to thrive, and that they can be reduced in numbers by targeting the IL-2 receptor. It is also interesting to note that the tyrosine kinase inhibitor, sunitinib, used in the treatment of RCC can also cause some reduction in Tregs in RCC patients (Finke et al, 2008) and murine tumor models (Ozao-Choy et al, 2009).

Myeloid-Derived Suppressor Cells

Myeloid-derived suppressor cells (MDSC) represent a heterogeneous group of immature myeloid cells (monocytic/macrocytic, granulocytic, and dendritic) at various stages of maturation, which accumulate in tumor-bearing hosts as result of tumor-induced alterations in myelopoiesis. These cells suppress the antitumor T-cell response by several mechanisms such that their removal facilitates tumor rejection in mouse tumor models (Marigo et al, 2008; Gabrilovich and Nagaraj, 2009). They are broadly defined in mouse models as CD11b+Gr–1+ cells with T-cell suppressive function; and granulocytic (Ly6G+) and monocytic (Ly6G–) subsets have recently been reported (Marigo et al, 2008; Movahedi et al, 2008; Gabrilovich and Nagaraj, 2009). In the peripheral blood of cancer patients, MDSC that are immature (Lin–CD33+HLADR–), granulocytic (CD33+CD15+CD14–), and monocytic (CD33+CD14+HLADR–/dim) have all been reported (Almand et al, 2001; Zea et al, 2005; Hoechst et al, 2008; Marigo et al, 2008; Gabrilovich and Nagaraj, 2009). MDSC are not only implicated in immune dysfunction, but they have also been shown to directly promote tumor-dependent angiogenesis.

The suppressive mechanisms of MDSC may largely be grouped into L-arginine–dependent and –independent ones. MDSCs metabolize L-arginine by two main pathways: arginase 1 (ARG1) and/or nitric oxide synthase 2 (NOS2). ARG1 activation occurs in response to type 2 cytokines (IL-4, IL-13), IL-10, TGF-β, GM-CSF, and PGE_2 among others (Hesse et al, 2001). ARG1 upregulation leads to the depletion of environmental L-arginine, and consequently compromises TCR-mediated T-cell activation, proliferation, and cytokine production (Rodriguez et al, 2009). Arginine metabolism by upregulated levels of NOS2 in MDSC occurs in response to prostaglandin E_2, and inflammatory cytokines such as IFN-γ, TNF-α, or IL-1–α. Whereas L-arginine is depleted by arginase, NOS2 metabolizes arginine to produce superoxide and NO, which rapidly combine to form highly reactive peroxynitrites that disrupt downstream JAK/STAT proteins required for normal T-cell function (Marigo et al, 2008). In this regard, ARG1 and NOS2 pathways can actually operate in parallel and synergize to inhibit T-cell function.

Targeting MDSC in mouse tumor models to reverse T-cell suppression and promote antitumor immunity has been achieved by treating tumor-bearing mice with anti-Gr1 antibody (Marigo et al, 2008; Gabrilovich and Nagaraj, 2009). In cancer patients, treatment with all-trans-retinoic acid has been shown to improve T-cell response and also reduced MDSC levels (Mirza et al, 2006). Recently it was observed that sunitinib, which is front-line therapy for RCC, significantly reduced the number of MDSC and restored a Th1 T-cell response in the treated patients (Ko et al, 2009).

B7-H1– and B7-H4–Mediated Immune Suppression

The costimulatory molecule, B7-H1 (PD-L1) is a B7 family member that has been reported to provide either a positive or negative signal for the generation of T-effector function (Greenwald et al, 2005; Flies and Chen, 2007). Recent studies have implicated B7-H1 as a potent negative regulator of antitumor immunity (Greenwald et al, 2005; Flies and Chen, 2007). B7-H1 expression on tumors interacts with the corresponding receptor PD-1 (programmed death receptor–1, CD279) on T cells to enhance either apoptosis or decrease TCR-mediated proliferation and cytokine production. Similarly, B7-H1 expressed on activated T cells has been demonstrated to impair both T-cell function and survival. Consistent with these observations, in-vivo monoclonal antibody blockade of B7-H1 has been shown to potentiate antitumor responses in several murine cancer models, presumably by blocking the interaction of B7-H1 with its receptor (Dong et al, 2002; Iwai et al, 2002).

Constitutive expression of B7-H1 has been found in a number of human cancers, including melanoma glioblastoma along with carcinomas of the lung, ovary, colon, bladder, breast, cervix, and liver (Greenwald et al, 2005; Flies and Chen, 2007). B7-H1 is also expressed in both primary and metastatic renal cell carcinoma (RCC), and patients with tumors expressing high levels of B7-H1 were at significant risk for disease progression, cancer-specific death, and overall mortality (Thompson et al, 2004). Additionally, B7-H1 expression by clear cell RCC tumors (or infiltrating mononuclear cells) correlates with aggressive pathologic features,

including advanced tumor-node-metastasis stage, tumor size, higher nuclear grade, and coagulative necrosis (Thompson et al, 2004). B7-H1, along with other negative regulators of T-cell activation, may act in concert to thwart host antitumor immunity in patients with RCC and also other forms of malignancy. Thus tumor-associated B7-H1 has recently garnered attention as a potential inhibitor of host antitumor immunity. B7-H4 expression was also associated with adverse clinical and pathologic features (including lymphocytic infiltration), as well as an increased risk of death from RCC and disease progression after surgical removal of localized RCC (Kryczek et al, 2009).

Based on the all the available data, B7-H1 expressed by RCC tumor tissue and infiltrating lymphocytes may serve to facilitate tumor progression by inhibiting the generation of host anti-tumor T cell–mediated immunity. Thus blocking B7-H1 may be a relevant strategy for improving the development of an effective antitumor immune response in patients with metastatic RCC.

Immunosuppressive Cytokines

Several molecules with known immunosuppressive activity are present within the tumor microenvironment (see Fig. 17–14). These products may be secreted by the tumor cells themselves or by surrounding mononuclear inflammatory infiltrates (Pawelec et al, 1997). **Among the best-studied immunosuppressive molecules overexpressed in the tumor microenvironment is the Th2 cytokine IL-10** (Pawelec et al, 1997). **The primary inhibitory effect of this cytokine relates to downregulation of MHC class II expression on monocytes/dendritic cells, resulting in diminished antigen presentation.** The immunosuppressive properties of IL-10 may be partly attributable to its ability to inhibit activation of the transcription factor NFκB, which regulates a number of genes important to tumor immunity development. Although it is clear that IL-10 is immunosuppressive, its impact on the generation of an antitumor immune response is complex. In knockout mice deficient in IL-10, tumor growth is either reduced or prevented when compared with tumor growth in IL-10–producing mice. However, tumor cells genetically modified to overexpress IL-10 are found to be less tumorigenic than wild-type tumors (Halak et al, 1999).

TGF-β contributes to the suppression of tumor immunity (Pawelec et al, 1997). **TGF-β is produced by a variety of tumors, including RCC, and increased levels of this cytokine have been reported in the serum of patients with kidney tumors. TGF-β is a potent inhibitor of IL-2–dependent T-cell proliferation affecting both helper and cytotoxic lymphocyte populations.** TGF-β appears to suppress T-cell growth by blocking TCR- and IL-2R–mediated tyrosine phosphorylation, thereby impairing downstream signaling events central to the control of cell cycle progression.

Prostaglandin E_2 (PGE_2) is frequently present in the tumor bed and is known to regulate T-cell function (Menetrier-Caux et al, 1999; Ochoa et al, 2007). PGE_2 can block T-cell proliferation by several mechanisms, which include increasing the levels of the intracellular second messenger cyclic adenosine monophosphate, inhibiting the DNA-binding activity of NFκB, and blocking IL-2–dependent G1–S transition. PGE_2 can promote a Th2 response and MDSC accumulation. Prostaglandins may also adversely affect the function of NK cells.

Gangliosides Contribute to the Immune Suppression

Gangliosides are structurally diverse acidic glycosphingolipids present in the outer leaflet of the plasma membrane that are involved in cell–cell interactions and membrane receptor modulation (Deng et al, 2000). Importantly, they also act as inhibitors of the host immune response. Select gangliosides are increased in expression and shed into the tumor microenvironment. For example, in malignant melanomas and neuroblastomas, there is overexpression of GD3, GD2, and GM2 (Hakomori, 1996). Rapid progression of tumors and lower survival rates were related to higher GD2 levels in patients with neuroblastomas. Recent findings also show increased expression of GD1a, GM1, and GM2 in RCCs as compared with normal kidney tissue (Biswas et al, 2006). Gangliosides isolated from different tumor types, such as neuroblastoma, lymphoma, and melanoma, all can inhibit immune responses. **Gangliosides have been shown to interfere with proliferation, antigen presentation, cytotoxic effector function, and IL-2 and IFN-γ production by T cells, without affecting production of the Th2 cytokine IL-10.** Animal studies have shown that the administration of tumor-derived GM1b inhibits the in-vivo development of antitumor immunity (McKallip et al, 1999). Thus mediators within the tumor environment may diminish effective antitumor immunity through a number of mechanisms that result from select alterations in signal transduction pathways critical for normal T-cell activation. TNF-α can increase the expression of gangliosides on tumor cells, thereby enhancing ganglioside-mediated immune suppression.

IMMUNOTHERAPY

Adoptive Cell Therapy

The transfer of tumor-reactive T cells has been shown to protect animals from tumor challenges and to cause rejection of established tumors (Cheever and Chen, 1997). T-cell transfer has been used primarily for the treatment of metastatic melanoma. This has included the administration of tumor-infiltrating lymphocytes (TIL) that have been expanded ex vivo with IL-2 (Rosenberg et al, 1994). **Efficacy of adoptive T-cell therapy has been improved by lymphocyte depletion with cyclophosphamide and fludarabine, which allows the transferred T cells to undergo increased expansion in response to growth factors** (Dudley et al, 2002; Gattinoni et al, 2006). T cells expanded from draining lymph nodes of patients with renal cell carcinoma, and vaccinated with irradiated autologous tumor cells plus GM-CSF, have antitumor activity in a small subset of patients even in the absence of IL-2 administration (Plautz et al, 1999). New directions in adoptive T-cell therapy include the use of gene therapy where melanoma cancer patients' peripheral lymphocytes are transduced with high-affinity T-cell receptors recognizing shared tumor antigens (Johnson et al, 2009). Approaches to enhancing the survival and functionality of adoptively transferred T cells will likely include transfecting (or cotransfecting) the tumor-reactive T cells with genes encoding proteins such as costimulatory molecules, chemokine receptors, and antiapoptotic and survival molecules (Charo et al, 2005; Gattinoni et al, 2006).

Cytokines and Interferons

Some patients have benefited from cytokine therapy (Bukowski, 2000). **The use of natural and recombinant cytokines has been investigated over the past 2 decades, with IFN-α and IL-2 being the only agents appearing to at least reproducibly cause tumor regressions in 10% to 15% of patients**

with renal cell carcinoma. Responses to IFN-α occur most frequently in patients with pulmonary metastases and good performance status, where the median response duration is between 6 to 10 months (Bukowski, 2000). Randomized trials in metastatic disease comparing IFN-α with other therapeutic approaches do suggest IFN-α may enhance survival in patients with metastatic RCC, but the effect is only modest at best. IL-2 was approved for use in renal cell carcinoma by the U.S. Food and Drug Administration on the basis of demonstrated safety and efficacy in clinical studies. Use of high-dose IL-2 appears to cure a small percentage of highly selected patients (Klapper et al, 2008). However, toxicity, including hypotension, dyspnea, thrombocytopenia, malaise, and disorientation, associated with high-dose IL-2 treatment represents a serious obstacle to this single-agent therapy.

A number of studies have tested whether combining IL-2 with IFN-α would improve the therapeutic activity over either agent alone. This combination of cytokines caused only a modest increase in response rates, and no effects on survival were evident. Other combinations are currently being tested in phase I/II trials, and this includes IL-12 combined with IFN-γ and the triple combination of IL-2, GM-CSF, plus IFN-α. It is clear from these and other studies that a subset of individuals with metastatic renal cancer do respond favorably to cytokine therapy; however, they represent a minority of patients (<15% response rate).

Cancer Vaccines

Several different vaccine approaches are underway to stimulate the immune response in patients with existing tumors. **The injection of irradiated tumors genetically engineered to secrete various immunostimulatory cytokines, such as IL-2, IL-4, IFN-γ, IL-12, and GM-CSF, demonstrated some antitumor activity** (Sogn, 1998; Burke, 1999). Also, different chemokines (e.g., IP-10 and MIG) have been overexpressed in tumors as a means of attracting T cells, as well as APCs, into the tumor microenvironment. Many of the chemokines and cytokines secreted by the tumor cells decreased tumorigenicity, and some could protect animals from subsequent challenge with the parental tumor. The inhibition in tumor growth occurred through a variety of mechanisms, including, in some cases, the generation of an antitumor T-cell response. Although the transfer of this technology to cancer patients has been difficult, some clinical trials using gene-modified tumor cells have been used as vaccines. Thus far, technical problems that have hindered the use of gene therapy in cancer patients, include the low efficiency of transfections, the safety issues of infecting with retroviral vectors, and the development of antiviral responses to adenoviral constructs that may compromise the immune response generated to the tumor.

Synthetic peptides corresponding to defined TAAs (e.g., MART-1) have been used as vaccines in cancer patients with melanoma, lung carcinoma, pancreatic cancer, and prostate carcinomas (Robbins and Kawakami, 1996; Bellone et al, 1999). The defined peptides have been given in the absence and presence of adjuvants, or pulsed on autologous monocytes or dendritic cells. In some cases, vaccination with defined TAAs has led to induction of a TAA peptide–specific T-cell response in cancer patients. **After immunization, increases in peptide-specific CD8+ T cells from the peripheral blood and draining lymph nodes have been detected by their binding to MHC class I tetramer complexes containing the appropriate TAA peptide. Increases in antigen-specific cytokine-secreting T cells have been detected by the use of enzyme-linked immunosorbent spot (ELISPOT) assays. Unfortunately, there has been a poor correlation between induction of specific T cells and the clinical responses. A limitation to immunization with a single TAA is the potential to generate antigen-loss variants that are not recognized by the specific T cells. To minimize this problem, some studies are using combinations of peptides that should evoke a broader range of tumor-reactive T cells.** Another approach is to use tumor cell lysates that contain a wide variety of peptides for the pulsing of dendritic cells (DC). Indeed, antitumor responses have been seen in melanoma and renal cell carcinoma patients immunized with dendritic cells pulsed with whole tumor cell lysates. However, in many clinical trials, DC-based vaccines as monotherapy have had limited therapeutic success (Bhardwaj, 2007). Another approach for immunizing patients with multiple peptides has been to electrofuse the patients' own dendritic cells to tumors and thus generate dendritic cell–tumor hybrids for T-cell activation. This is currently being tested in renal cell carcinoma patients with metastatic disease (Avigan et al, 2007).

Different vaccine strategies are under investigation in patients with prostate cancer. One approach selectively targets the prostate-specific antigen (PSA) and is produced by ex-vivo exposure of dendritic cell precursors to PA2024, a recombinant fusion protein composed of the PAP target fused to granulocyte-macrophage colony-stimulating factor (GM-CSF) (termed Sipuleucel-T; Dendreon, Seattle, WA) (Ward and McNeel, 2007). Other vaccines that are in phase II/III clinical trials include immunization with two allogeneic prostate cancer cell lines transduced with the GM-CSF (termed GVAX; Cell Genesys, Hayward, CA) (Ward and McNeel, 2007) and Prostvac-VF (Cell Genesys), a vaccinia-plus fowlpox-based vector containing the transgenes for PSA and the multiple T-cell costimulatory molecules TRICOM (Madan et al, 2009). The real potential of these vaccines in prostate cancer are yet to be determined.

Combinational approaches to immunotherapy are now receiving significant attention. This includes combining vaccines with Toll-like receptor (TLR) agonists that include oligodeoxynucleotides containing one or more unmethylated CpG dinucleotides (CpG, ODN), which can activate B cells and plasmacytoid DC, and promote T-cell immunity (Bhardwaj, 2007). Another approach is to combine immunotherapy with tyrosine kinase inhibitors (TKI) such as sunitinib, which is front-line therapy for RCC. Sunitinib monotherapy in metastatic RCC patients has shown to significantly reduce the number of MDSC and Tregs while at the same time increasing the type 1 T-cell response (Finke et al, 2008; Ko et al, 2009). Similar findings have been reported in several murine tumor models, and one study showed that sunitinib would enhance the therapeutic activity of IL-12 and 4-1BB (Ozao-Choy et al, 2009).

Monoclonal Antibodies for Cancer Therapy

There is interest in monoclonal antibodies for the treatment of select tumors. Antibodies to CD20 have produced meaningful responses in a number of patients with B-cell lymphoma patients who were refractory to chemotherapy (Maloney et al, 1997). The Food and Drug Administration (FDA) has also approved an antibody to HER2/NEU for the treatment of patients with breast cancer. **Additional antibodies are being tested that can reduce immune suppression by targeting CTLA4, PD1 receptor, and B7-H1** (Iwai et al, 2002; Hodi et al, 2003).

IMMUNITY TO INFECTIONS

The immune system provides protection against the ubiquitous numbers of infectious microbes that surround us at all times. They can range in size from 10^{-4}-mm viruses to 10^{3}-mm worms. **The initial barrier to these pathogens is the skin and external body fluids described previously under innate immunity.** If penetration occurs, organisms can be killed by soluble factors such as lysozyme, which is an antibacterial enzyme present in the tears, saliva, and phagocytic cells that digests peptidoglycans in bacterial cell walls. **Neutrophils and macrophages provide phagocytosis, killing, and digestion of bacteria and fungi.** Killing is accomplished by digestive enzymes and by oxygen-free radicals and other reactive oxygen species generated by the nicotinamide adenosine diphosphate (NADPH) oxidase, and oxidized halides produced by myeloperoxidase. The oxidase pumps electrons into phagocytic vacuoles, which produces conditions conducive to microbial killing and digestion by enzymes released into vacuoles from the cytoplasmic granules (Soehnlein et al, 2008). **This process is greatly enhanced by the complement proteins that are not only cytotoxic but are attractants for phagocytic cells, and that facilitate inflammation and cell adhesion.** The combination of innate and adaptive immunity is required for complete eradication of the offending organisms (Janeway, 2002). However, the burden of invading microbes may be large and overwhelm immune mechanisms so that drainage or (surgical) removal, and the use of antimicrobial drugs to diminish replication, may be required for complete elimination of the invading organisms.

Bacterial Infections

Extracellular Bacteria Are Susceptible to Killing by Phagocytosis and Complement

Bacteria try to evade these mechanisms by surrounding themselves with capsules that do not readily adhere to phagocytic cells, by secreting exotoxins that can impede host responses, or by proliferating in relatively inaccessible locations. For example, some gram-positive bacteria have developed capsules that do not favor stable binding of the complement C3 convertase, or prevent the insertion of the lytic C5b-9 membrane attack complex. To overcome this, host antibodies can override some of these mechanisms by directly binding to bacterial exotoxins and "neutralizing" them. They can also bind to the encapsulated bacteria, which will permit ingestion by PMNs and macrophages. **These coated bacteria become "opsonized" as the Fc portion of the antibody permits binding to high-affinity receptors on phagocytes and also can fix complement.** In addition, secretory IgA (and some IgM) antibodies can afford protection in the tears, saliva, gut, vaginal mucosa, and lung by preventing bacterial adherence to these epithelial surfaces. Opsonized bacteria too large for phagocytosis can also be killed because the Fc portion of antibody can attract "killer" lymphocytes by the process called antibody-dependent cell-mediated cytotoxicity (ADCC).

Some bacteria, such as the bacilli that cause tuberculosis, leprosy, listeriosis, and brucellosis, try to escape the immune system by growing within macrophages (Schaible et al, 1997). They defy the innate killing mechanisms by blocking macrophage activation, scavenging oxygen radicals, or inhibiting lysosomal fusion with the phagocytic vacuole. These organisms develop strong lipid outer coats and can escape from the phagosome into the cytoplasm of the macrophage and there proliferate. **Clearance of these intracellular microbes is directly dependent upon T-cells, which in turn must activate the infected macrophages. Specifically primed T cells react with processed antigen derived from the intracellular bacteria in association with MHC class II antigens on the macrophage surface.** The subsequent T-cell release of lymphokines, such as INF-γ and other macrophage activating factors, up regulate the macrophage killing mechanisms. These include the formation of nitric oxide and other reactive oxygen intermediates within the macrophage.

Chronic Inflammation

The character of the immune response can change during persistent infections or when the immune response is ineffective or unable to clear the offending microbe. In these instances, the site of infection becomes dominated by macrophages in various stages of activation. These cells may fuse and appear as "giant cells" or line up in arrays called "epitheliod cells." Macrophages bearing bacterial antigens on their surface may actually become targets of cytotoxic T cells and be destroyed. Lymphocytes in various stages of activation will also be present. This combination of immune-activated cell types is also associated with proliferating fibroblasts and areas of necrosis. **This reaction represents an attempt by the body to wall off a site of persistent infection, and the site is referred to as a granuloma. Such a response can also arise from the persistence of undigested inorganic materials or antigen–antibody complexes.**

Viral Infections

Viruses are subject to the same mechanisms of immune clearance as other microbes but attempt to avoid the immune system by altering their surface antigens. **Minor changes in surface antigens due to point mutations in the viral genome is called antigenic drift, while major changes arising from exchanges of large portions of the viral genome with other viruses is called antigenic shift. Influenza viral epidemics often result from such antigenic shifts, which act like new infections and bypass host immune memory and recall.** Viruses can use certain host receptors (the CD4 molecule by HIV) to gain entry into the host cell. Altered viral epitopes can inhibit the triggering of the host T-cell receptors, block complement components, and prevent antigen processing by APCs. The viral genome may encode proteins similar to host cytokines and their receptors that subvert immune activation (Watts and Bertram, 2004). **As with bacterial infection, host antibody is essential for eliminating extracellular viral particles, and cell-mediated responses are necessary for those that are intracellular.** Antibodies can neutralize viruses by blocking their surface receptors, activating the classical complement pathway, and clumping or aggregating the viral particles for enhanced phagocytosis. These responses are especially effective when the virus has to travel in the bloodstream to reach its target, such as the poliovirus, which enters through the gut and travels to the nervous system. When the target organ is at the portal of entry, such as the gut or lung, rapid release of local interferon and recruitment of NK cells is essential for immune clearance.

Toll-Like Receptors and Microbial Killing

The first mammalian TLR identified, TLR4, was shown to induct the genes for several inflammatory cytokines and costimulatory molecules. Therefore it was anticipated that the TLRs might be

Table 17–6.
Toll-Like Receptors (TLRs) and Their Ligands

TLR FAMILY	LIGANDS (ORIGIN)
TLR1	Triacyl lipopeptides (bacteria, mycobacteria)
	Soluble factors (*Neisseria meningitides*)
TLR2	Lipoprotein/lipopeptides (a variety of pathogens)
	Peptidoglycan (gram-positive bacteria)
	Lipoteichoic acid (gram-positive bacteria)
	Lipoarabinomannan (mycobacteria)
	A phenol-soluble modulin (*Staphylococcus epidermidis*)
	Zymosan (fungi)
	HSP70 (host)
TLR3	Double-stranded RNA (virus)
TLR4	LPS (gram-negative bacteria)
	Taxol (plant)
	Fusion and envelope protein (RSV)
	HSP60 and HSP70 (*Chlamydia*, host)
	Type III domain A of fibronectin (host)
	Oligosaccharides of hyaluronic acid (host)
	Polysaccharide fragments of heparan sulfate (host)
	Fibrinogen (host)
TLR5	Flagellin (bacteria)
TLR6	Diacyl lipopeptides (mycoplasma)
TLR7	Synthetic compounds
TLR9	CpG DNA (bacteria)
TLR 8 and 10	??

involved in immune responses, especially in the activation of innate immunity (Takeda et al, 2003). TLR4 was then shown to be involved in the recognition of lipopolysaccharide (LPS), a major cell wall component of gram-negative bacteria. Subsequently, other members of the TLR family have been shown to be essential for the recognition of a wide range of microbial components (including double-stranded RNA), flagellin, taxol, fibrinogen, peptidoglycan, and various other viral and fungal envelope proteins and products (Table 17–6). TLRs also recognize some endogenous ligands such as heat-shock proteins. A wide variety of stressful conditions, such as heat shock, ultraviolet radiation, and viral and bacterial infection, induce the increased synthesis of heat-shock proteins, which can activate macrophages and dendritic cells to secrete proinflammatory cytokines and to express costimulatory molecules.

Expression of TLRs is modulated by a variety of factors such as microbial invasion, microbial components, cytokines (such as colony-stimulating factor 1), and macrophage migration inhibitory factor (MIF). Upon recognition of their cognate ligands, TLRs induce the expression of a variety of host defense genes. These include inflammatory cytokines and chemokines, interferons, antimicrobial peptides, costimulatory and MHC molecules, and other effectors necessary to arm the host cell against the invading pathogen (Zhang et al, 2007). The pathways that transduce TLR signals in mammals are highly homologous to that of the IL-1R family, and ultimately lead to the activation of two distinct signaling pathways, JNK and NFκB (Barton and Kagan, 2009). Once freed from inhibitors NFκB translocates into the nucleus and turns on transcription of target genes. Not surprisingly, NFκB is critical in the function and development of dendritic cells. Both TLR and IL-1R interact with an adaptor protein MyD88, which is critical to the production of inflammatory cytokines induced by the TLR family. Indeed, no activation of NFκB was observed in macrophages of MyD88-deficient mice, which were found to be susceptible to infection by *Staphylococcus aureus*.

Recognition of microbial components by TLRs triggers activation of not only innate immunity but also adaptive immunity, which is largely provided by dendritic cells. Immature dendritic cells residing in the periphery have a high capacity for endocytosis, which facilitates antigen uptake. They are activated by various microbial components to undergo maturation and express many of the TLRs. TLR-mediated recognition of microbial components by dendritic cells induces the expression of costimulatory molecules such as CD80/CD86, and production of inflammatory cytokines such as IL-12. Once matured, dendritic cells lose their capacity for endocytosis and migrate into the draining lymph nodes. Here they present microorganism-derived peptide antigens expressed on the cell surface with MHC class II antigen to naive T cells, thereby initiating an antigen-specific adaptive immune response. In addition to controlling the development of adaptive immunity, activation of TLRs appears to be directly involved in antimicrobial activity. TLR2 activation leads to nitric oxide–dependent and –independent killing of intracellular *Mycobacterium tuberculosis* in macrophages. TLR2 confers LPS- and lipoprotein-induced apoptosis of macrophages, indicating the possible involvement of TLRs in infection-induced cell death.

Passive and Acquired Immunity

Protection against a specific infection can be passively transferred from one individual to another by serum containing preformed antibodies. This type of passive immunity is generally short lived because the half-life of immunoglobulins is generally 1 to 2 weeks. Patients with immunodeficiency diseases may actually be sustained by regular treatments with pooled nonspecific human gamma globulin treatments. High-titer, pooled, specific antibodies to agents such as the cytomegalovirus can be given as prophylaxis or treatment of the viral infection. Equine globulin raised against diphtheria and tetanus toxin has also been effective, although globulin from nonhuman species tends to be more toxic and presents the risk of serum sickness. Passive immunity is also transferred from mother to child by the placental transfer of IgG during gestation and the intestinal absorption of secretory IgA in the mother's milk.

The most durable form of protection from infection results from active immunization. This can arise from an acquired infection that results in host immunity, or vaccination by intentional exposure to either killed or attenuated live organisms. **Attenuated organisms, which cause only a very mild form of the natural disease, yet retain the antigenic specificity of the organism, are most effective.** Attenuated organisms replicate, which provides for a larger dose, and the immune response is produced at the site of natural infection. The objective is to provide effective immunity by establishing adequate levels of antibody and a primed population of memory cells, which can rapidly expand upon rechallenge with the offending agent. To be most effective, successful immunization requires a combination of specific antibody, macrophage-activating cell-mediated immunity, and the generation of cytotoxic T-cells.

MOLECULAR IMMUNOLOGY

"Omics" Era of Biology

During the past decade the first version of the complete human genome has been sequenced and published (www.ornl.gov/scitechresources/Human_Genome/home.shtml), which has unlocked a remarkable potential for discoveries in human biology

and medicine. In parallel, recent advances in molecular biologic techniques have permitted the profiling of the global mRNA transcript, which encompasses the cell's transcription of activated genes that drive the subsequent events of protein translation, modification, and metabolism—creating the complex functions of any biologic system. **These emerging technologies have set the stage for the "omics" era of biology in which cellular events are described in terms of the transcriptome (mRNA transcripts), the proteome (proteins); the metabolome (metabolic products), and glycomics (carbohydrate modifications to proteins).** These technologies offer immense potential because they provide a global view of changes in gene expression in the tissue or organ studied. The changes can be profiled to differentiate normal or healthy states from diseased ones. This genome-wide approach can describe both the expression of known genes and mechanistic pathways, as well as the discovery of yet unknown genes and pathways. These newly identified genes and proteins may provide the key targets for future therapies. Such genomic profiling can also identify prognostic biomarkers to diagnose, classify, and guide the treatment of disease. Several clinical fields related to urology have begun to explore these technologies, which include oncology, immunology, and transplantation biology. The initial foray into these technologies has been the analysis of gene expression profiles using DNA microarrays.

Gene Chip

cDNA Arrays and Oligonucleotide Arrays

Although earlier estimates suggested that the linear sequence of 3 billion base pairs in human DNA encoded over 100,000 genes, the numbers have now been downsized by more than half. High-throughput technologies are now in place to identify most of the known genes that have been previously identified and annotated. **The basic principle involves the "spotting," on a glass support, of a nucleotide sequence that represents a particular gene (a probe) to which a complementary nucleotide sequence (a target) will hybridize according to molecular attraction (A-T and G-C). The probe is generally a piece of complementary DNA (cDNA) several hundred nucleotides in length that is generated as a polymerase chain reaction (PCR) product from a known cDNA library. More recently, machine-synthesized oligonucleotides of between 25- to 75-mer length have been used as probes. When thousands of these probes are spotted, they are described as a DNA microarray, or a DNA gene chip.** The target can come from any tissue or cell type of interest by first extracting its total RNA, then labeling the mRNA fraction with a fluorescent isotope. The relative amount of labeled target that hybridizes to the DNA on the chip provides a signal captured by a laser scanner, and the signal reflects the expression level of the corresponding gene. Using the current version of a commercially produced human DNA microarray (U133A Plus 2.0; Affymetrix, Santa Clara, CA), about 47,000 transcripts, representing 38,500 well-characterized genes, can be screened on one chip, now referred to as a whole genome-wide array. Such large data sets were originally generated from publicly available (on the Internet) gene sequence databases. Once such a large volume of raw data is generated, computerized bioinformatics is necessary to identify relationships. A commonly used technique is hierarchical clustering of up- or downregulated genes comparing experimental groups to controls.

Gene Expression Profiling in Urologic Oncology

Although costs and labor have been reduced with production efficiency, DNA microarray analysis remains expensive, labor intensive, and cumbersome. However, a number of initial experiences provide exciting future possibilities. **Gene expression profiling has the potential to significantly advance the diagnosis and classification, prognosis, and treatment of urologic cancers.** Creating gene lists from high-throughput microarrays can establish gene profiles of different tumor types. Such profiling has been used to distinguish the various histologic subtypes of renal cell carcinomas (RCCs), each with a unique molecular signature (Yang et al, 2006). For example, microarrays identified strong alpha-methylacyl coenzyme A racemase in 41/41 papillary RCCs, including 6 with metastases; while this gene was only weakly found in less than 15% of all other renal cancers tested (Tretiakova et al, 2004). Clear cell renal cancers commonly express glutathione-S-transferase alpha, while carbonic anhydrase II is upregulated in chromophobe renal cancers; neither enzyme is expressed in oncocytomas. For these reasons, it has been suggested that gene expression profiling may someday permit the use of renal biopsy to accurately diagnose radiographic renal masses such as oncocytomas from carcinomas (Rohan et al, 2006). In addition, DNA microarray analysis of benign prostatic hyperplasia (BPH) versus prostate adenocarcinoma has revealed 402 genes in BPH and 141 genes in cancer, which were up- or downregulated at least fivefold (Endo et al, 2009).

Some have proffered that gene expression profiling could help quantify the malignant potential of specific cancers. Two studies reported a 40-gene and a 45-gene cluster associated with poor cause-specific survival for clear cell RCC, and suggested that vascular cell adhesion molecule–1 may be a useful prognostic marker (Takahashi et al, 2001; Vaselli et al, 2003). Recently, data-mining with DNA microarray analysis of bladder cancer tissue and voided urine identified differential expression according to tumor grade. A more select cluster of eight genes was then used to demonstrate tumor progression (Mengual et al, 2009). However, such analysis is often retrospective and complex, as evidenced, in one study, by the lack of association of gene expression profiles for predicting metastases from penile cancer (Kroon et al, 2008). In future studies, the combination of genomics and proteomics may further refine the molecular analysis of specific tumors (Seliger et al, 2009). Lastly, gene expression profiling can also identify targets for therapeutic intervention. Topoisomerase II, identified as being highly upregulated in aggressive Wilms tumors, has also been found in renal medullary cancers, making it an early molecular target for therapeutic interventions.

Gene Expression Profiling in Transplantation

Another area explored with DNA microarray technology has been renal transplantation, in particular the gene profiles associated with allograft rejection and renal dysfunction. Using a spotted cDNA array consisting of about 12,440 selected genes created at Stanford University; 67 pediatric renal allograft biopsies were profiled. **Hierarchical clustering of gene expression demonstrated three patterns of acute rejection that also correlated with 2-year graft survival, and suggested a previously unknown correlation with genes linked to B cell–mediated immunity** (Sarwal et al, 2003). Two reports

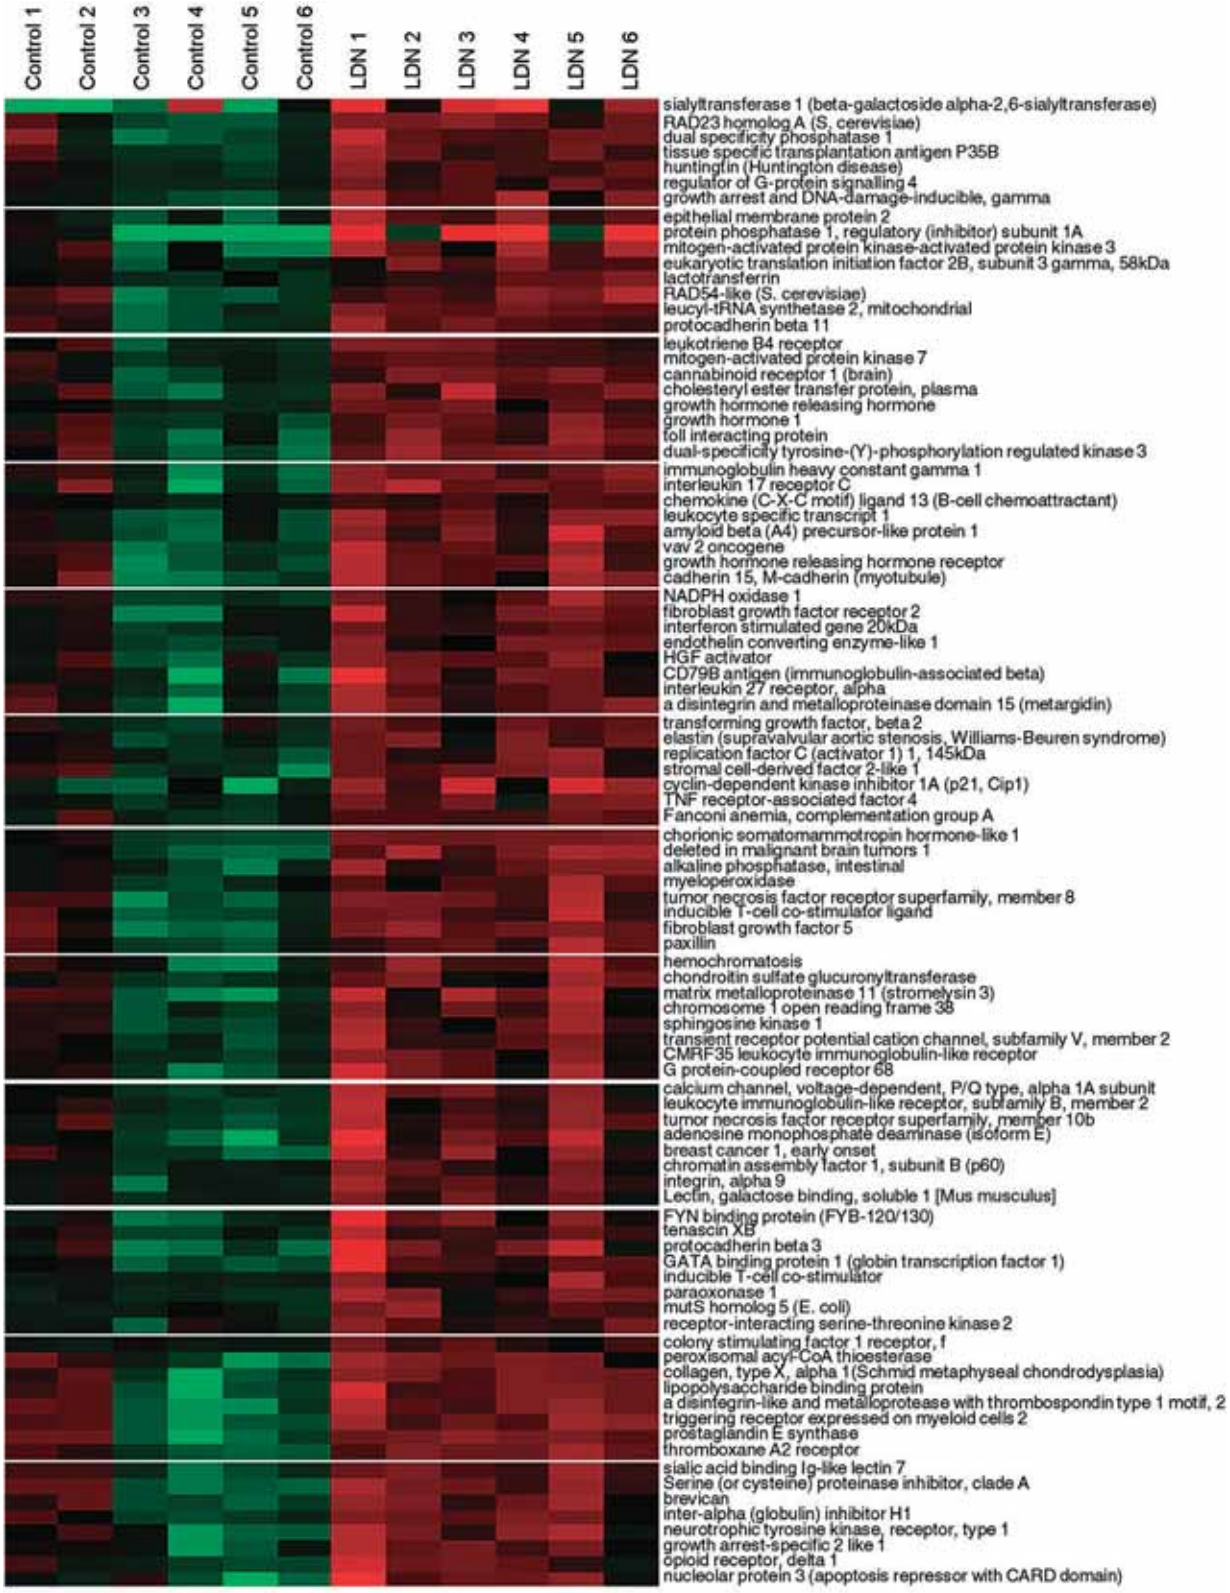

Figure 17–15. Heat map representing the relative signal intensities of a subset of 95 differentially expressed genes selected from a class comparison of the gene expression profiles between control and laparoscopic donor kidneys. Control biopsies were obtained prior from open nephrectomies prior to surgical manipulation. Genes were selected based on association with ischemia, tissue injury, and stress from a literature search using publicly available databases.

describe the use of high-density oligonucleotide arrays to define molecular signatures for transplant kidney biopsies, as well as peripheral blood lymphocytes (PBL). Affymetrix HG-U95Av2 GeneChips (over 22,600 genes) were used in four groups of transplant patients: normal donors, recipients with well-functioning kidneys, patients with acute rejection, and patients with renal dysfunction but no rejection. Distinct gene expression profiles were identified for both kidney biopsies and PBL that correlated and classified each of the four groups of patients (Flechner et al, 2004). **Interestingly, the genes upregulated in the PBL did not overlap with the biopsies associated with acute rejection, suggesting that the PBL and the transplanted kidney represent two distinct compartments regarding the immune mechanisms involved.** In another study, the same group compared the gene expression profiles from 2-year kidney biopsies in recipients treated with or without a calcineurin inhibitor (CNI) drug. The authors showed that the patients on the CNI-free immunosuppressive protocol had better renal function and a significantly diminished prevalence of chronic allograft nephropathy by histology. **Gene expression profiles of kidneys that were graded with higher Banff scores for chronic allograft nephropathy showed a marked upregulation of genes that were involved in immune//inflammation and tissue injury/remodeling and fibrosis** (Flechner et al, 2004). Another group has used DNA microarrays in an attempt to separate histologic grades of severity in the rejection of kidneys (Mueller et al, 2007). cDNA microarrays can also be used to study specific mechanisms of renal transplant physiology by comparing the gene expression profiles from laparoscopically removed donor kidneys (Kurian et al, 2005), and from the glomeruli and tubulointerstitium obtained by microdissection of biopsies from both deceased and live-donor kidneys (Kainz et al, 2004). One can see that several hours of pneumoperitoneum and laparoscopic surgery causes a specific signature of up- and down-regulated genes compared with controls (Fig. 17–15). **Such gene expression patterns can be used to identify which compartments in the kidney may be most susceptible to ischemia, and which biologic products may be targets to help minimize injury.** Lastly, hierarchical clustering of genes from a DNA microarray can be used to establish the state of degeneration or cyst formation in the end-stage kidney, such as those found with adult polycystic kidney diseases (Schieren et al, 2006).

Key Points

- The immune response is identified by unique characteristics that explain its utility and adaptability against numerous foreign invaders and substances. These include (1) the ability to identify self from non-self, (2) specificity, (3) memory, and (4) rapid amplification.
- Innate immune responses are constitutive and do not improve on repeated contact. Innate defense mechanisms represent nonspecific barriers to invaders, which rely primarily on physical barriers, phagocytic cells, natural killer cells, complement, acute phase proteins, lysozyme, interferons, defensins, and germline-encoded innate immune receptors.
- Adaptive or specifically acquired immune responses result from repeated exposure to invading microbes and rely primarily on large populations of lymphocytes, each with its own individual specificity. The clonal expansion of specific lymphocyte populations after first contact confers memory and the ability to elicit a more vigorous response upon subsequent exposure.
- T-cell activation requires costimulation. Initial engagement of the TCR with MHC-peptide on an antigen-presenting cell (signal 1) alone will result in anergy. Additional engagement with accessory molecules on the APC (signal 2) is necessary for further intracellular signal transduction leading to T-cell activation.

Stem Cells and Cancer

Despite decades of intensive biomedical research, cancer remains a significant cause of morbidity and mortality worldwide. In part, this is due to the complexity inherent in this disease, which is, in fact, not truly a single disease at all, but well over 100 separate subtypes, all grouped together under the single term, "cancer."

In the United States alone, cancer strikes over half a million victims annually and is currently the second leading cause of death, poised to become the leading cause of death in the near future, should recent trends continue. **Genitourinary (GU) malignancies comprise 28% (413,700) of all cancer cases in the United States (nonmelanoma skin cancers excluded) and 15% of all cancer deaths** (Jemal et al, 2009). However, significant advances in the diagnosis and treatment of certain GU cancers have been made. For example, the cure rate for testicular cancer now approaches 100% (Einhorn, 2002; Horwich et al, 2006). Unfortunately, this cancer is unusual in its responsiveness to therapy and is relatively uncommon. We have had less success with the more prevalent GU malignancies, such as prostate, bladder, and renal cancers—the second, eighth and tenth most common cancers, respectively. Encouragingly, however, mortality figures for these malignancies have shown a slow but steady decline over the past decade, and there is every reason to believe that these trends will continue and even accelerate in the future.

Much of our current understanding of cancer is the direct result of the molecular biology (Table 18-1) revolution that developed rapidly following the elucidation of the molecular structure of deoxyribonucleic acid (DNA) by Watson and Crick in 1953. In subsequent years, the field of molecular genetics has complemented and greatly expanded upon knowledge gleaned by other disciplines, such as biochemistry and cell biology, providing important insights, at the molecular level, regarding the abnormalities present in cancer cells. Thus a great deal is now known concerning the numerous molecular signaling pathways that provide both positive and negative regulatory signals that stringently control cell proliferation in normal cells, such that any losses in cell number are precisely counterbalanced by cell proliferation, thereby maintaining tissue and organ homeostasis. Renegade populations of autonomously proliferating cells represent a serious threat to survival of the organism, particularly to large, long-lived species such as ourselves; therefore, we have evolved multiple barriers to prevent such outbreaks from occurring. This means that incipient cancer cells must overcome several hurdles on the way to becoming fully malignant—a multistep process that takes many years or even decades to complete. Consequently, it has been recognized that **cancer cells need to acquire several key attributes in order to make the transition from a normal cell to a malignant tumor. These attributes include (1) genetic instability, (2) autonomous growth, (3) insensitivity to internal and external antiproliferative signals, (4) resistance to apoptosis and other forms of induced cell suicide, (5) unlimited cell division potential, (6) the ability to induce new blood vessel formation, a process termed angiogenesis, (7) locally invasive behavior, which uniquely distinguishes malignant from benign neoplasms, and (8) evasion of the immune system.** In addition, cancer cells need to cope with various cellular stresses that are byproducts of their abnormal physiology. **Finally, many cancers develop an additional, lethal attribute—the ability to leave the site of the primary tumor to colonize and thrive in distant organs or tissues as metastases** (Hanahan and Weinberg, 2000; Solimini et al, 2007; Luo et al, 2009).

This chapter outlines fundamental concepts of molecular genetics that are directly related to human cancer in general, with an emphasis on genitourinary malignancies in particular. Spurred by recent technological advances such as high-throughput DNA sequencing, genome-wide assessment of DNA polymorphisms and DNA copy number changes, as well as array-based gene expression profiling methods, our knowledge of the molecular genetics of cancer is rapidly expanding, providing new insights that are just beginning to be successfully exploited for use in novel diagnostic, prognostic, and therapeutic applications.

Table 18–1.

Molecular Biology: Glossary of Terms

Allele: An alternative form of a gene.
Amplification: Additional copies of a chromosomal sequence; these sequences may include genes and may be extrachromosomal or intrachromosomal.
Aneuploid: Deviation in chromosomal number from the usual diploid state (e.g., tetraploidy)
Annealing: The pairing of two single strands of complementary DNA sequences to form a double helix.
Alternative splicing: A mechanism by which variations in the incorporation of a gene's coding regions during mRNA maturation leads to the production of multiple related forms of a gene.
Base pair: The physical relationship between adenine/thymidine and guanine/cytosine within the double helix of DNA. Abbreviated as bp, it provides the unit of measurement for DNA. Each base pair is stabilized by hydrogen bonds.
cDNA: A segment of DNA complementary to an RNA sequence.
Centromere: An essential structural element of chromosomes consisting of repetitive, non-coding DNA to which the spindle microtubules attach during mitosis.
Chromosome: A distinct segment of linear DNA containing a large number of genes. In humans there are 23 such segments, each containing hundreds to thousands of genes.
Codon: Three sequential nucleotides in protein coding genes that specify a particular amino acid in the protein or a STOP translation signal.
Deletion: The removal of a segment of DNA, with rejoining of the ends.
Diploid: A set of chromosomes containing two complete copies of the organism's genomic DNA.
Dominant: Allele determining the phenotypic manifestation of a gene.
Endonuclease: An enzyme that cuts DNA or RNA within the nucleotide chain.
Epigenetic: Nongenetic information, such as methylation or acetylation of histone proteins that modifies gene expression.
Exon: A sequence of DNA that is represented with a complementary RNA sequence, also known as the coding sequence.
Expression vector: A vector designed to encode a particular DNA sequence or gene for transcription and translation into RNA or protein.
FISH: Fluorescence in situ hybridization. A technique in which a fluorescently-labeled nucleic acid probe is hybridized to its complementary target sequence in the genome, allowing localization and enumeration of the target.
Frameshift mutation: A deletion or insertion of DNA that shifts the normal codons into a different order for translation into protein.
Gene: A segment of DNA that contributes to the formation of a protein, including both the introns (noncoding regions) and the exons (coding regions), as well as the regulatory regions preceding and following the coding regions.
Genetic code: The correspondence between triplets of DNA or RNA (codons) and amino acids making up proteins.
Genotype: The genetic makeup of an organism as reflected in its DNA sequence.
Haplotype: A group of alleles in relative close proximity on a chromosome that are inherited together.
Hemizygote: Having only one copy of a gene owing, for example, to the loss of chromosomal material or an entire chromosome.
Heterozygote: Having two different copies (alleles) of a gene.
Homozygote: Having two identical copies (alleles) of a gene.
Hybridization: The physical pairing of complementary RNA and/or DNA sequences.
Intron: A segment of DNA that is transcribed but is removed by the splicing together of the exons on either side; part of the noncoding sequences of a gene.
Karyotype: A catalogue of all the chromosomes within a particular cell. Typically accomplished by isolation and staining of metaphase chromosomes.
Linkage: The tendency for genes in proximity to one another on a chromosome to be inherited together.
Locus: The position of a particular gene on a particular chromosome.
Loss of heterozygosity (LOH): Deletion or mutation of a gene creating a hemizygous state or, if the remaining allele is duplicated, a homozygous state. In cancers arising in cancer predisposition syndromes caused by an inherited gene mutation, the remaining wild-type allele is often lost by LOH.
Methylation: The addition of a methyl group to a molecule. Methylation of the nucleotide cytosine in the promoter regulatory region of a gene is often associated with decreased transcription of that gene.
Micro-RNA: (miRNA); small, single-stranded RNA molecules, 21 to 23 nucleotides in length, that function to negatively regulate transcribed genes for which they have sequence complementarity.
Mutation: Any change in the sequence of genomic DNA.
Northern blotting: A technique of transferring RNA from an agarose gel to a nitrocellulose filter for hybridization with a complementary DNA.
Oncogenes: Genes that encode for proteins that have the ability to transform normal cells into cancerous cells.
Phenotype: The appearance or function of an organism, reflecting the contributions of the genotype and the environment.
Ploidy: The number or copies of entire chromosome complements (genomes) within a cell; diploid has two copies, triploid has three copies, tetraploid has four copies, etc.
Point mutation: A change in a DNA sequence involving a single base pair.
Polymerase chain reaction (PCR): A technique using sequential temperature cycles favoring DNA denaturation, annealing of primer sequences, and primer extension with DNA polymerase to amplify a large number of copies of a particular sequence of DNA. This technique can be used to detect very small amounts of DNA by creating a huge number of identical copies.
Polymorphism: A difference in normal DNA sequence between individuals. It can be a repetitive element or a single nucleotide polymorphism (SNP).
Promoter: The region of DNA in a gene where RNA polymerase binds and gene transcription begins. This region is often the sequence of DNA 100 to 500 base pairs immediately before the initiation site of the protein coding portion of the gene.
Recessive: An allele that is not represented phenotypically in the presence of a dominant allele.
Reporter gene: A gene encoding for a new or foreign protein that can easily be detected. For example, the luciferase gene, encoding the light-producing proteins of the firefly, is introduced into cells that do not express this gene.

Continued

Table 18–1.

Molecular Biology: Glossary of Terms—cont'd

Restriction enzyme: An enzyme recognizing specific short sequences of DNA (e.g., 4 or 6 base pairs); these enzymes cut the DNA at a particular location.
Silent mutation: An alteration in a DNA sequence that does not change the protein product of the gene.
Small interfering RNA: (siRNA); small double-stranded RNA molecules, 20 to 25 nucleotides in length, that promote degradation of mRNA molecules to which they have complementarity, thus downregulating expression of the corresponding gene—often employed by researchers as a means of reducing expression of specific genes.
Southern blotting: A technique of transferring denatured DNA from an agarose gel to a nitrocellulose filter for hybridization with complementary DNA.
Splicing: The removal of introns (spliced out) and the connection of exons (spliced together) in mRNA.
Telomere: An essential structural element of chromosomes consisting of repetitive, noncoding DNA and associated telomere-specific binding proteins that cap and stabilize the chromosomal termini.
Transcription: Synthesis of RNA on a DNA template.
Transfection: The introduction of DNA sequences into a cell.
Transgenic animals: Animals created by the introduction of new DNA into the germ line (into the egg).
Translation: Synthesis of protein from the messenger RNA (mRNA) template.
Vector: A plasmid, bacteriophage, or virus that carries new DNA into a cell. Vectors are often designed to produce large amounts of protein encoded by the gene within the host cell.

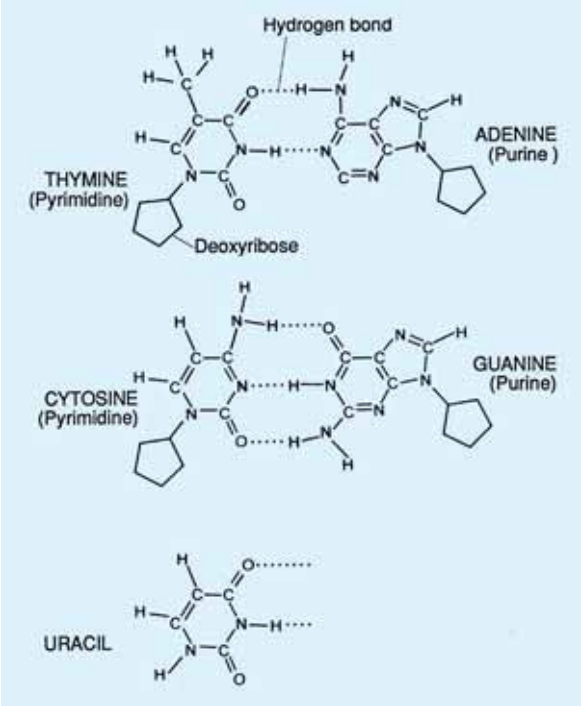

Figure 18–1. The nucleic acid alphabet consists of four bases: the purines adenine (A) and guanine (G), and the pyrimidines thymine (T) and cytosine (C). Uracil (U) is substituted for thymine in the case of RNA. The combination of a base and a sugar (deoxyribose) is referred to as a *nucleoside*.

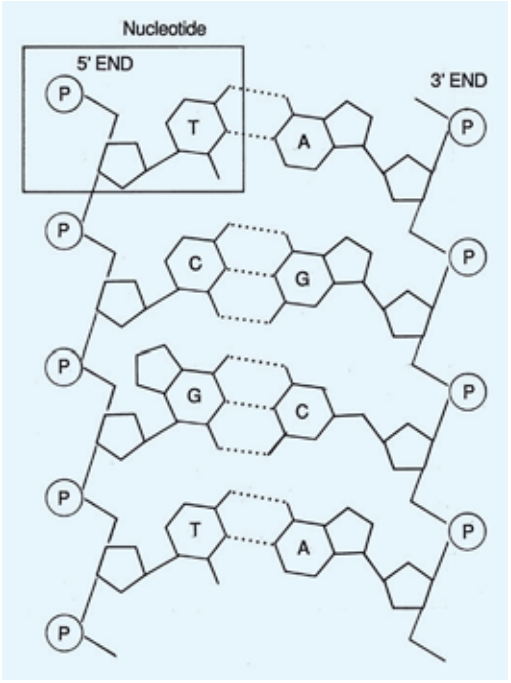

Figure 18–2. The combination of a sugar phosphate group and a base constitutes a *nucleotide*. The double helix is made from two polynucleotide chains, each of which consists of a series of 5'– to 3'–sugar phosphate links that form a backbone from which the bases protrude. The double helix maintains a constant width because purines always face pyrimidines in complementary A-T and G-C base pairs, respectively.

BASIC MOLECULAR GENETICS

DNA

The molecular characteristics of DNA were first described in 1953 (Watson and Crick, 1953). This molecule serves as the blueprint for determination of structure and function of all living organisms. **DNA is composed of three basic components: a pyrimidine or purine base, a sugar (2-deoxyribose), and a phosphate** (Fig. 18–1). The connection between repeating phosphates and sugars creates a helical chain. The DNA structure exists as a double helix in which one strand of bases is ordered in one direction and the other strand is ordered in the opposite direction. The two strands are held together by hydrogen bonds and are organized by complementary base pairing. The four bases that primarily comprise DNA are adenine, cytosine, guanine, and thymine. There is a fifth base that can be found in DNA known as 5-methylcytosine (5-mC). Uracil is substituted for thymine in ribonucleic acid (RNA). **Hydrogen bonding occurs specifically between the purine adenine (A) and the pyrimidine thymine (T) and between the purine guanine (G) and the pyrimidine cytosine (C)** (Fig. 18–2). **In the RNA molecule, adenine base pairs with uracil (U).**

During the process of replication, each strand of the DNA double helix acts as a template for generation of the new strand of DNA. The precise ordering of DNA base pairs results in a code

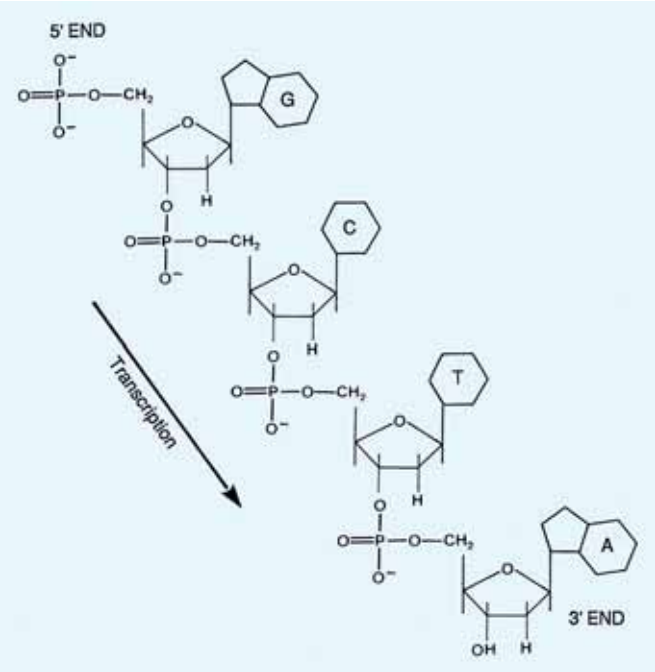

Figure 18–3. During transcription, a section of one DNA strand, or the other, is used as a template for the synthesis of messenger RNA. This synthesis always occurs in a 5′ to 3′ direction.

that will be processed to ultimately generate proteins responsible for a variety of cellular functions. Each single-stranded DNA molecule has two nonidentical ends referred to as the 5′ (5 prime) and 3′ (3 prime) termini. The 5′ and 3′ numbering refers to the carbon atoms in the deoxyribose sugar. The 5′ carbon of one deoxyribose is linked to the 3′ carbon of another deoxyribose by a phosphate group. Each strand will end with part of the sugar ring exposed based on these connections.

Transcription

During the process of transcription, linear DNA is converted to linear messenger RNA (mRNA). The process of translation consists of the conversion of linear mRNA to a linear set of amino acids that will eventually form a functional protein (Fig. 18–3). Transcription is the first step in converting DNA into protein. A single strand of RNA is copied from one of the strands of DNA. The sugar element in the RNA molecule is ribose and the pyrimidine uracil substitutes for thymine. RNA polymerase II is the enzyme that synthesizes the first copy of RNA, which is a complementary strand of the DNA template. This primary strand of RNA is called heterogeneous nuclear RNA (hnRNA) and contains coding sequences (exons) of DNA and noncoding sequences (introns).

The pre-mRNA molecule undergoes three major modifications: 5′ capping, 3′ polyadenylation, and RNA splicing. These processes occur in the nucleus before the RNA molecule is translated into protein. A guanine is added to the 5′ end of the molecule which results in the formation of a methylated cap (Perry, 1981). A long chain of approximately 200 adenine residues forms what is called a poly(A) tail that is added to the 3′ end of the mRNA and may provide stability to the molecule (Jackson and Standart, 1990). RNA splicing is a dynamic process that can result in the formation of different peptide sequences. A primary RNA transcript is converted into a mature mRNA prior to protein synthesis. **The process known as alternative RNA splicing is how a single gene can encode for multiple unique proteins by including or excluding certain exons in the mRNA transcript** (Sharp, 1987). The sequences contained within introns are not essential for protein synthesis; therefore introns are spliced out and exons are spliced together to generate the functional message known as mRNA. **Exons are sequences of DNA that have corresponding sequences in the mRNA, and introns are regions of DNA sequence that are not represented in mRNA** (Witkowski, 1988).

RNA Interference

Post-transcriptional gene regulation can occur by a mechanism involving the expression of noncoding RNAs that have the capability of binding to and degrading messenger RNAs. RNA interference (RNAi) was first discovered in *Caenorhabditis elegans,* but exists as a means of post-transcriptional regulation in a wide variety of organisms (Fire et al, 1998). RNAi are double-stranded RNAs that are transcribed from cellular genes or infecting pathogens. A double-stranded RNA species is reduced in size by a ribonuclease (RNAse) III–like enzyme, known as Dicer, into 21– to 23–base pair (bp) products with two-nucleotide 3′ overhangs known as small (or short) interfering RNA (siRNA) (Bernstein et al, 2001). These short RNA molecules are homologous to the gene that is being suppressed. The antisense strand of the siRNA is incorporated into a multicomponent nuclease called "RNA-induced silencing complex" (RISC) to destroy specific mRNAs (Gregory et al, 2005).

RNAi has been used to investigate gene function in the laboratory. Long micro-RNAs contain self-complementary regions resulting in the formation of hairpin loops that are cleaved by two RNAse III–like enzymes. The enzyme called Drosha cuts the long hairpin to generate a short hairpin RNA (shRNA) molecule. The shRNA is then processed by Dicer to produce double-stranded miRNA capable of binding target genes for destruction. Synthetic siRNA and shRNA species can be generated to target and knock-down specific gene expression. For example, this technique has been used to study the role of the androgen receptor (AR) in the progression of castrate-resistant prostate cancer. Expression of AR was knocked down using an shRNA in prostate cancer xenografts and cell lines, demonstrating that AR was necessary and sufficient for tumor growth, thereby implicating continued AR function as an essential component in both hormone-dependent and castrate-resistant prostate cancer (Chen et al, 2004).

Protein Translation

Translation of mRNA into protein occurs in the cytoplasm where ribosomes are located. The mRNA message is translated in segments of three adjacent nucleotides called a codon. Each codon is translated into one of 20 amino acids (Fig. 18–4). A total of 64 different codons can be generated from the four bases found in RNA. Due to redundancy, more than one codon can encode for a single amino acid (Fig. 18–5). Genetic mutations or alterations can have a profound effect on protein translation of mRNA. For example, a single base insertion or deletion results in a frame-shift mutation and often results in a nonfunctioning protein product. In contrast, a single base substitution may or may not result in a change in the amino acid sequence to alter protein function.

Two other forms of RNA are important for protein translation: transfer RNA (tRNA) and ribosomal RNA (rRNA). Transfer RNA is a small (75 to 85 bases long) adapter molecule that is covalently linked to a single

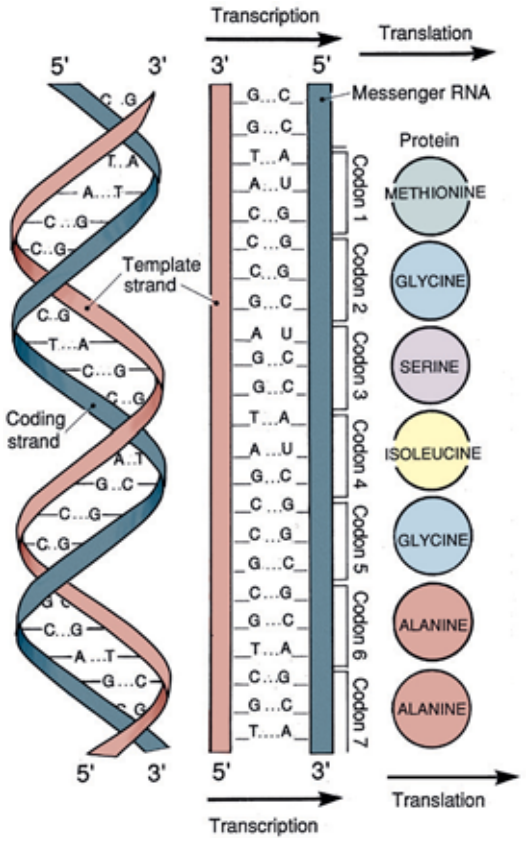

Figure 18–4. During transcription, the coding strand conveys its message through the template strand to make messenger RNA that is eventually translated into polypeptides by ribosomes. The relationship between a DNA sequence and the corresponding protein is called the *genetic code*, which is read in nucleotide triplets, or codons, specifying amino acids or protein translational start and stop signals. The code is degenerate, in that multiple codons may code for the same amino acid.

amino acid at one end and an anticodon in the middle of the chain. The anticodon is composed of three nucleotides that are complementary to the codon representing a particular amino acid. Ribosomal RNA comprises approximately 80% of the RNA within a cell and makes up part of the ribosome that is responsible for protein synthesis.

The three major stages of protein synthesis are: initiation, elongation, and termination. Initiation is frequently the rate-limiting step in translation (Merrick, 1992). During the process of initiation, the 40S ribosome binds to mRNA and forms an initiation complex that binds a tRNA with an amino acid attached. All new proteins start with methionine because the initiation codon is AUG. During elongation, amino acids are sequentially added to the peptide chain, and the ribosome moves along the mRNA chain similar to beads on a string. Elongation is the most rapid phase of protein synthesis. For any given mRNA transcript, multiple ribosomes can simultaneously move along the chain to generate new polypeptides (Rich et al, 1963). Termination is the last stage of protein synthesis and is signaled by one of three "stop" codons (Tate and Brown, 1992). The release factor is a cytoplasmic protein that binds to the stop codon and catalyzes the hydrolysis of the aminoacyl linkage that releases the carboxyl end of the polypeptide chain (Merrick, 1992). The ribosome releases from the mRNA and dissociates into two subunits after termination.

Chromosomes and Gene Structure

The long strands of DNA responsible for the genetic makeup of eukaryotic cells are organized together with specialized proteins to form chromosomes. Eukaryotic cells contain large linear chromosomes that are packaged by proteins into a condensed structure called chromatin. The chromatin structure varies depending upon the phase of the cell cycle. During interphase, euchromatin consists of DNA that is actively being expressed as protein. Heterochromatin is composed of inactive DNA that may serve a structural support role.

First base	Second base			hird base

Figure 18–5. RNA codon table. The 20 amino acids found in proteins are listed. All 64 possible 3-letter combinations of the RNA coding units U, C, A, and G are used to encode an amino acid or one of the 3 stop codons. Note: The codon AUG codes for methionine and also serves as an initiation site (the first AUG in the mRNA coding region where translation into protein is initiated).

Key Points: Basic Molecular Genetics

- The information contained in DNA is transcribed into RNA and then translated into protein.
- Transcription of RNA is tightly regulated and is tissue specific.
- A single gene can encode for multiple unique proteins by including or excluding certain exons in the mRNA transcript by alternative splicing.
- Post-transcriptional gene regulation can occur by a mechanism involving the expression of noncoding RNAs that have the capability of binding to and degrading messenger RNAs.

TUMOR SUPPRESSOR GENES AND ONCOGENES

Tumor Suppressor Genes

Tumor suppressor genes regulate cellular growth and play a critical role in the normal processes of the cell cycle. These genes are also important for DNA repair and cell signaling. The absence of tumor suppressor gene function may lead to dysregulation of normal growth control and malignancy. **Loss of function of both alleles of a tumor suppressor gene is typically required for carcinogenesis. This functional loss can occur by (1) homozygous deletion, (2) loss of one allele and mutational inactivation of the second allele, (3) mutational events involving both alleles, and (4) loss of one allele and inactivation of the second allele by DNA methylation.** Classic tumor suppressor genes discussed later in this chapter are the retinoblastoma gene (*RB*) and *TP53* (see The Cell Cycle).

The "two-hit" hypothesis was first proposed in cases of retinoblastoma, which required mutations in both alleles for disease manifestation (Knudson, 1971). This is because if just one allele is inactivated, the remaining allele could produce a sufficient amount of the correct protein to maintain the normal state (Fig. 18–6). **Specific types of mutations in certain genes, however, may not follow this two-hit rule and can function as dominant negative mutations that produce altered protein.** Mutant protein products have been reported to inhibit function of normal protein from unaltered alleles (Baker et al, 1990). Mutation of a single allele may result in haploinsufficiency, causing increased carcinogen susceptibility as in the case of the TP27Kip1 gene (Fero et al, 1998). Abnormally low levels of the TP27 protein were frequently observed in human cancers; however, homozygous inactivating mutations of the *TP27* gene were infrequent. Both *Tp27* nullizygous and *Tp27* heterozygous mice were predisposed to developing tumors when exposed to radiation or a chemical carcinogen. **The assumption that null mutations in tumor suppressor genes are recessive excludes genes that exhibit haploinsufficiency** (Fero et al, 1998).

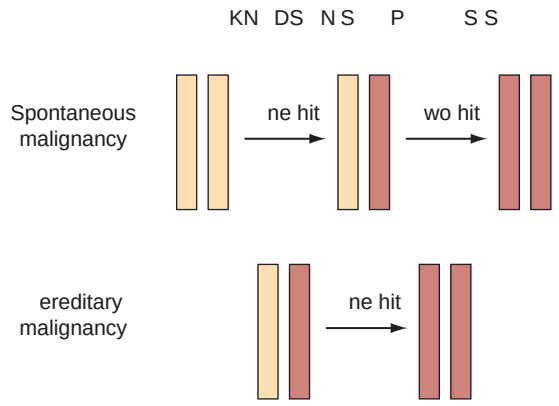

Figure 18–6. Knudson's hypothesis was that inactivation of the same gene was responsible for both sporadic and hereditary malignancies. Patients with sporadic tumors had two normal copies of the gene, and therefore the sporadic tumors required inactivation of both copies of the gene. Patients with hereditary tumor syndromes were born with only one functioning copy of the gene of interest, and therefore the hereditary tumors required inactivation of only one copy.

Oncogenes

Oncogenes are associated with cellular proliferation and are the mutated form of normal genes (proto-oncogene). A number of oncogenes were initially identified by their presence in retroviruses that were capable of inducing malignant transformation of normal cells (Martin, 1970). Two oncogenes that have been found to be overexpressed in a variety of cancers include c-*MYC* and c-*MET* (Wong et al, 1986; Bottaro et al, 1991). The proto-oncogene, c-*MYC*, encodes an early-response gene product that is a transcription factor responsible for regulating cellular proliferation. Amplification of c-*MYC* is a frequent event in prostate cancer and expression of c-*MYC* in human prostate epithelial cells has been associated with immortalization (Gil et al, 2005).

Hepatocyte growth factor acts through a receptor that is encoded by the proto-oncogene c-*MET* (Bottaro et al, 1991). Hepatocyte growth factor plays a role in normal development of the kidney, acts as a mitogen for renal tubular cells, and is capable of inducing tubulogenesis of renal cells in vitro (Montesano et al, 1991; Santos and Nigam, 1993). Increased expression of c-*MET* has been reported in renal cell carcinoma and is also more frequent in higher grade cancers (Pisters et al, 1997). Missense mutations of the *MET* proto-oncogene may also result in constitutive activation of the MET protein in tumors associated with hereditary renal cell carcinoma (Schmidt et al, 1997).

Mechanisms by which a proto-oncogene can be converted to an oncogene are by (1) mutation of the proto-oncogene resulting in an activated form of the gene, (2) gene amplification, and (3) chromosomal rearrangement. A mutation occurring within the coding sequence of a gene can lead to a continuous proliferation signal. The proto-oncogene *ERBB* encodes for the epidermal growth factor receptor (EGFR), and mutations of *ERBB* can result in overexpression of a receptor form that is constitutively active (Downward et al, 1984). Errors that occur during chromosomal replication may result in gene amplification and aneuploidy. An increase in gene copy number can produce an increased number of mRNA transcripts and overproduction of protein. For example, certain types of bladder cancer have been found to over-express c-*MYC* by this mechanism (Christoph et al, 1999). Immunohistochemical staining of bladder cancer specimens has demonstrated overexpression of c-MYC protein in more than half of papillary and invasive tumors (Schmitz-Drager et al, 1997). Finally, chromosomal rearrangements such as translocation events can result in the formation of an oncogene. This has been classically described in chronic myelogenous leukemia in which the Philadelphia chromosome is formed by reciprocal translocation between chromosome 9 and 22 (Nowell and Hungerford,

1960). A portion of the breakpoint cluster region (*BCR*) gene from chromosome 22 (region q11) is juxtaposed to the *ABL1* gene on chromosome 9 (region q34) to form a constitutively active *BCR-ABL* transcript.

Key Points: Tumor Suppressor Genes and Oncogenes

- Mutations in DNA can lead to changes in protein function or expression that increase the potential for cancer initiation, progression, or metastasis.
- Tumor suppressor genes regulate and control cellular growth. Oncogenes promote cell growth.
- Loss of tumor suppressor gene function can occur primarily by (1) homozygous deletion, (2) loss of one allele and mutational inactivation of the second allele, (3) mutational events involving both alleles and (4) loss of one allele and inactivation of the second allele by DNA methylation.
- Certain tumor suppressor genes do not follow the "two-hit" hypothesis and may be inactivated by dominant negative mutations or haploinsufficiency.
- Proto-oncogenes can be converted to oncogenes by (1) mutation of the proto-oncogene resulting in an activated form of the gene, (2) gene amplification, and (3) chromosomal rearrangement.

THE CELL CYCLE

Apart from development and growth, **cell division is tightly regulated such that the production of new cells precisely balances those lost during normal wear and tear, thus maintaining tissue and organ homeostasis.** Unlike single-celled eukaryotes, individual human cells are not allowed to make autonomous decisions regarding their proliferation. Rather, **a complex series of external growth inhibitory and growth stimulatory signals are integrated by the cell, resulting in either cell division or quiescence. Many activated oncogenes and inactivated tumor suppressor genes contribute to the deregulated growth phenotype of cancer cells by altering the balance between these signals such that proliferation is continuously favored.**

Quiescent cells are considered to be out of cycle, in a reversible state known as "G_0," which is the default state for most cells (Fig. 18–7). When signaled to proliferate, cells activate their **cell cycle** machinery, initiating **an orderly, unidirectional, series of events resulting in (1) accurate duplication of the cell's genome during the DNA synthetic phase (S phase), followed by (2) accurate segregation of each genomic complement to each of two resulting daughter cells, a process referred to as mitosis (M phase).** These two critical phases are **separated by two so-called "gap" phases (G_1 and G_2).** Throughout the cell cycle, which takes approximately 24 hours to complete, each sequential step is dependent upon completion of the prior step before progressing further (Hartwell et al, 1974). In addition, **checkpoint mechanisms closely monitor DNA integrity as well as certain critical cell cycle events. If problems are detected (e.g., DNA damage), the cell cycle will pause to allow repair** (Hartwell and Weinert, 1989). **If repair is not possible, normal cells often will commit cellular suicide through an active process termed apoptosis.** In addition to proliferative signaling networks, **many oncogenes and tumor suppressors exert their effects by interfering with cell cycle checkpoints and apoptotic pathways, allowing cancer cells to divide continuously and accumulate. Loss of the ability to respond appropriately to damaged DNA is particularly dangerous, because it fosters genetic instability, a key attribute of cancer cells. Loss of DNA damage checkpoint controls results in an increased mutation rate, accelerating the mutation of cancer-associated genes, thus contributing to carcinogenesis and disease progression** (Bartek et al, 1999).

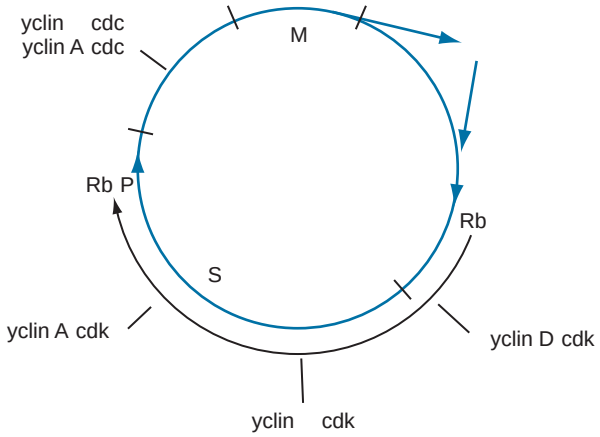

Figure 18–7. A schematic drawing of the cell cycle. Sequential activation of cyclin-CDK complexes is critical to the orderly progression of cell replication.

Cyclin-Dependent Kinases and Cyclins

The temporal sequence of events occurring throughout the cell cycle are effected by a highly conserved set of serine- and threonine-specific protein kinases termed cyclin-dependent kinases or CDKs for short (Meyerson et al, 1992). CDKs phosphorylate specific protein substrates involved in executing the phase-specific activities of the cell cycle. As their name implies, **the enzymatic activities of the CDKs are dependent upon a class of regulatory proteins called cyclins,** of which there are 12 known in mammals (Morgan, 1995). Cyclins, so named because the abundance of specific cyclins within the cell was found to be highly dynamic and tightly linked to specific phases of the cell cycle, physically associate with and activate CDK enzymatic activity (De Bondt et al, 1993; Jeffrey et al, 1995) (Fig. 18–7). Additionally, cyclins also assist in guiding CDK substrate specificity. Thus **depending largely on the transitory presence of particular cyclins, which are rate-limiting, specific cyclin/CDK complexes form and act during restricted periods within the cell cycle to initiate and regulate the events required during these precise phases, after which each cyclin is typically degraded by polyubiquitination of specific lysine residues that serve as the signal for proteosomal degradation, thereby inactivating its CDK partner** (Sherr, 1993; van den Heuvel and Harlow, 1993). The rapid, phase-specific destruction of cyclins also underlies the irreversible nature of the cell cycle. CDKs are also regulated by specific sites of phosphorylation on the CDKs themselves (Lundgren et al, 1991). For example, activation of the cyclin-dependent kinase CDK2 is dependent upon phosphorylation, by CDK-activating kinase (CAK), of threonine 160, which

moves a regulatory loop away from the CDK2 catalytic active site, thereby allowing access to substrate. In contrast, phosphorylation of tyrosine 15 on CDK2 (effected by kinases WEE1 or MIK1) acts to inhibit CDK2 enzymatic activity. In addition, removal of this inhibitory phosphate group can occur by the phosphatase CDC25 (Sebastian et al, 1993). Finally, a group of proteins termed cyclin-dependent kinase inhibitors (CDKIs) exist that can bind to and directly inhibit CDK activity or their activating phosphorylations (Peter and Herskowitz, 1994; Sherr and Roberts, 1995). Thus, although cyclins play major regulatory roles in orchestrating CDK activities, **CDKs are subject to additional levels of control** and, as might be expected, these processes are also commonly altered in cancer cells.

Cell Cycle Entry

Under normal conditions a cell will be induced to proliferate when the balance between growth-stimulatory signals received from its environment (e.g., soluble growth factors in the extracellular space) outweighs growth inhibitory signals (e.g., TGF-β). If the cell was in the G_0 state, it will proceed into **G_1, the first gap phase of the active cell cycle, during which sufficient macromolecules and organelles are synthesized to support cell replication.** Growth stimulatory signaling pathways (e.g., the RAS/RAF/MEK pathway) promote expression of the main G_1 cyclins, cyclin D and cyclin E, leading to their association with CDK4 and CDK6 kinases, thus activating these CDKs (Baldin et al, 1993; Winston and Pledger, 1993; Sherr et al, 1994). **Throughout early and mid-G_1, progress through the cell cycle remains sensitive to external signals, largely because persistent mitogenic stimulation is required for sustained expression of cyclin D** (Matsushime et al, 1991). Cyclin D is the main cyclin functioning early in G_1. Cyclin E is expressed later in G_1, peaking at the G_1S boundary, where its presence is required for S-phase entry (Dulic et al, 1992; Koff et al, 1992; Ohtsubo et al, 1995).

The Retinoblastoma Protein and the Restriction Point

Due to the dependence of cyclin D on the continued presence of mitogens and other favorable conditions (e.g., attachment to the substratum), the cell cycle remains responsive to external signals throughout early and mid-G_1 (Guadagno et al, 1993). However, **if the decision is made in late G_1 to continue on with cell division, then the subsequent phases of the cell cycle (S, G_2, and M) proceed in an autonomous fashion. This key point in time in late G_1, after which the cell cycle becomes insensitive to extracellular signals, is termed the restriction point (R point)** and is highly regulated (Pardee, 1974).

The retinoblastoma susceptibility protein, pRB, plays a central role in controlling the R point, and the inappropriate, continuous proliferation of cancer cells is largely due to a loss of R-point control, typically the result of functional inactivation of the RB pathway (Pardee, 1989). pRB is a member of a protein family termed pocket proteins that includes the closely related proteins TP107 and TP130. pRB is a substrate of G_1 cyclin/CDK complexes and its activity is critically dependent on its phosphorylation state (Buchkovich et al, 1989; Mittnacht et al, 1994; Sherr, 1994). **In nondividing cells, pRB is unphosphorylated and in this state pRB and the other pocket proteins physically associate with members of the E2F family of transcription factors, inhibiting their transcriptional activation of target genes required for cell cycle progression into S phase** (Lai et al, 1999b). In addition, pRB recruits proteins such as histone deacetylases (HDACs) to E2F target genes promoting the formation of repressive heterochromatin at these sites and pRB itself may play a role in maintaining this repressive chromatin state, further suppressing E2F target genes (Lai et al, 1999a, Gonzalo and Blasco, 2005). However, **during G_1, pRB becomes progressively phosphorylated, on 8 different sites, by cyclin D-CDK4/6 and cyclin E-CDK2 complexes, creating hyperphosphorylated pRB, causing its dissociation from E2F** (Fig. 18–8). The liberated E2F proteins, of which there are at least seven, heterodimerize with one of three DNA polymerase (DP) subunits (DP1-3) and activate transcription of target genes, including essential S-phase genes (e.g., DNA polymerase and S-phase cyclins) (Dyson, 1998). Notably, the cyclin E gene is an E2F target gene; thus once E2Fs become activated, a positive feedback loop is initiated, with further production of cyclin E reinforcing pRB hyperphosphorylation, which, in turn, frees additional E2F. In addition, activated E2F increases transcription of its own gene, thus providing another positive feedback loop. These autocatalytic cycles represent the molecular core of the R point. Beyond this point, pRB remains inactivated and the remaining cell cycle phases are unresponsive to either external mitogenic or antiproliferative signals. Once the cell cycle is complete, pRB returns to its unphosphorylated state, once more suppressing E2F until cell division is once again signaled (Ludlow et al, 1993).

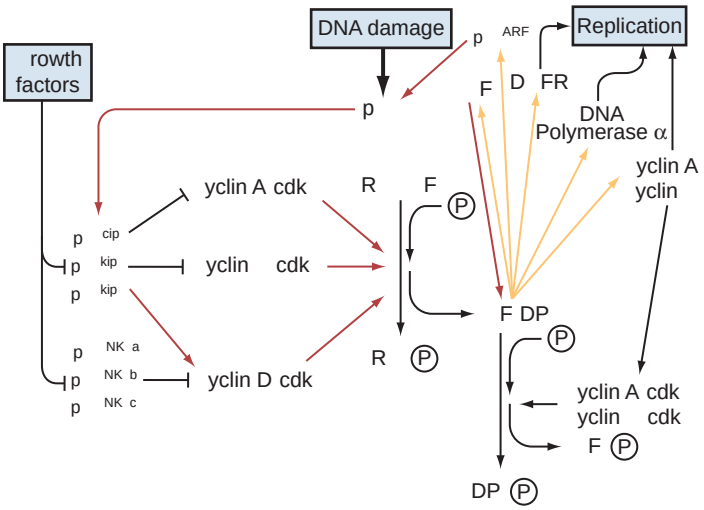

Figure 18–8. Schematic representation of the stimulatory and inhibitory cascade at the G_1S boundary. This finely tuned system takes advantage of multiple negative and positive feedback loops.

The *pRB* gene was initially characterized as the tumor suppressor gene responsible for disease susceptibility in familial retinoblastoma (thus the name) and, as is the case with many cancer predisposition genes, was also found to be compromised in sporadic retinoblastoma as well (Friend et al, 1986; Knudson, 1993). As outlined above, its central role as the gatekeeper of the R point in the cell cycle explains why pRB is also commonly altered in other cancers besides retinoblastoma. In fact, **it has been suggested that RB, or components of the regulatory pathway it is associated with (e.g., cyclins D and E, CDK4, E2F, TP16 and TP27), are likely to be altered in virtually all human cancers** (Sherr, 1996; Hanahan and Weinberg, 2000).

There are many ways, both direct and indirect, in which cancer cells inactivate pRB's function, including mutation or deletion of the *pRB* gene itself, silencing of the *pRB* gene by promoter DNA hypermethylation, overexpression of proteins such as cyclin D and E2F (in some cases due to increased copy number of the gene; gene amplification), as well as mutational inactivation, deletion, or promoter methylation of genes encoding specific CDK inhibitors (described below).

Retinoblastoma Protein and Genitourinary Malignancies

pRB gene mutations have been identified in approximately one third of bladder tumors (Horowitz et al, 1990), and reintroduction of the *pRB* gene into bladder carcinoma cell lines has been found to inhibit cell growth in vitro and tumor formation in vivo (Takahashi et al, 1991). Altered expression of pRB protein has been also identified in approximately one third of bladder carcinomas (Logothetis et al, 1992), and altered expression has been correlated with higher-stage disease and decreased patient survival (Cordon-Cardo et al, 1992).

Prostate carcinoma has not been as strongly linked to *pRB*. Although *pRB* mutations are present in 10% to 30% of prostate cancer specimens (Bookstein et al, 1990; Kubota et al, 1995), decreased expression is not consistently identified with high-risk patients or recurrent disease (Kibel and Isaacs, 2000). In other studies, no correlation was found between expression and grade or stage (Ittmann and Wieczorek, 1996), but Theodorescu and colleagues (1997), reported that low pRB protein expression correlated with decreased disease-specific survival in univariate and multivariate analysis.

Renal carcinoma has not been clearly linked to *pRB*. *pRB* is rarely inactivated in renal carcinoma cell lines or tumors (Ishikawa et al, 1991), and analysis of clinical specimens has not demonstrated a clear association between prognosis and *pRB* expression (Lipponen et al, 1995).

Cell Cycle Progression through S phase

During S phase, a normal cell replicates its diploid genome once and only once. S-phase genes are activated as a result of cyclin A replacing cyclin E to form cyclin A-CDK2 complexes in early S phase, and later by cyclin A associating with CDK1 forming cyclin A-CDK1 complexes in late S phase (Girard et al, 1991; Pagano et al, 1992). Upon completion of S phase, cyclin A-CDK2 phosphorylates E2F-DP heterodimers, thus terminating E2F's activity (Dynlacht et al, 1994). At the end of S phase, cyclin B replaces cyclin A, forming cyclin B-CDK1 complexes that move the cell into the second gap phase of the cell cycle, G_2, and on into mitosis (Pines and Hunter, 1989). It should be noted that the above description, although correct in outline, has been simplified. For example, there are actually multiple closely related cyclins within each cyclin class; thus there are actually three D-type cyclins (D1, D2, and D3), two E-type cyclins (E1 and E2), two A-type cyclins (A1 and A2), and two B-type cyclins (B1 and B2).

Mitosis

Although mitosis is the shortest of the cell cycle phases (lasting approximately 1 hour), it is one of the most complex and dramatic (Alberts, 2007). **During mitosis, the two genomic complements present following S phase are precisely partitioned into what will become two separate daughter cells.** The proper functioning of many of the proteins participating in mitosis depends upon phosphorylation of these substrates by cyclin B-CDK1. Early in mitosis, the chromosomes condense through the activity of condensin proteins. Each chromosome is tightly associated along its length with its corresponding S-phase copy, termed the sister chromatid, through cohesin proteins. When isolated and stained, these condensed metaphase chromosomes are used in karyotyping studies to look for numerical and structural chromosome aberrations. During this time also, two structures called centrosomes, which act as microtubule organizers, migrate to opposite poles of the nucleus and assemble spindle microtubules that radiate through the nucleus and attach to the condensed chromosomes at constriction sites termed centromeres, through complex protein matrices termed kinetochores. The nuclear envelope and supporting intermediate filament proteins, the nuclear lamins, dissociate in response to phosphorylation by cyclin B-CDK1. Balanced tension along the spindle microtubules causes all of the chromosomes to align along the cell midline, creating a hallmark stage of mitosis termed metaphase. Once all metaphase chromosomes are properly aligned, a protein complex termed the anaphase promoting complex (APC, not to be confused with the adenomatous polyposis coli gene, which is commonly mutated in colon cancer) is activated by cyclin B-CDK1. The APC, in turn, ubiquitinates a protein called securin, targeting it for destruction, which liberates separase protease from securin's inhibitory influence (Nasmyth et al, 2000). Once activated, separase functions to cleave the cohesin complexes, thus liberating the sister chromatids from one another, allowing microtubule-associated motors on the spindle microtubules to pull each diploid chromosome complement apart toward the centrosomes at opposite poles, a key mitotic event termed anaphase. One of the APC's substrates is cyclin B itself; thus by activating the APC, cyclin B initiates its own destruction (Deshaies, 1995). Lastly, two new nuclei are assembled around the two separated chromosome complements, which decondense, and two separate daughter cells are formed in a cell-splitting process termed cytokinesis.

Mitotic abnormalities are commonly seen in human cancers and were noted by David Hanseman in the late 1800s, soon after the discovery of chromosomes, and, in 1914, the eminent German biologist Theodor Boveri proposed that such abnormalities might underlie tumor formation (Harris, 2008).

Cyclin-Dependent Kinase Inhibitors

In addition to their dependence on cyclins and regulation by specific phosphorylations, CDK **activities are also subject to negative regulation by a set of seven proteins termed cyclin-dependent kinase inhibitors (CDKIs)**. CDKIs belong to either of two different classes: the CIP/KIP family, which includes the proteins TP21 (*CDKN1A*), TP27 (*CDKN1B*), and TP57 (*CDKN1C*); and the INK4 (*in*hibit CD*K4*) family, which includes TP15 (*INK4B*), TP16 (*INK4A*), TP18 (*INK4C*), and TP19 (*INK4D*). The CIP/KIP proteins are broadly acting, able to inhibit multiple cyclin-CDK complexes throughout the cell cycle (Clurman and Porter, 1998), while the members of the INK4 group are more restricted in their activities, inhibiting CDK4 and CDK6-containing complexes; thus they are critical regulators of the R point and the G_1S transition because they can block pRB phosphorylation (Fig. 18–8). **Increased expression and accumulation of CDKIs is used by the cell as a means of halting the cell cycle in response to various stresses.** For example, TP21 expression is

increased in response to DNA damage (el-Deiry et al, 1993). CDKIs function in nonstress situations as well. For example, TP27 levels are high in quiescent cells, and all of the CIP/KIP proteins appear to play some role in maintenance of the G_0 state in terminally differentiated cells (Halevy et al, 1995; Matsuoka et al, 1995). Interestingly, mice engineered with a homozygous deletion of the *TP27* gene grow more quickly, exhibit hyperplasia in multiple organs, and are cancer prone (Fero et al, 1996). In addition to increased expression in order to inhibit cell cycle progression, CDKIs can also be oppositely regulated by proteolytic degradation—for example, the targeted elimination of *TP27* upon mitogenic stimulation (Ohtsubo et al, 1995).

Among the *INK4* family, inactivating mutations and abnormal methylation of *TP15* and *TP16* have been strongly implicated in cancer in general (Kamb et al, 1994; Hirama and Koeffler, 1995) and specifically in genitourinary malignancies (Cairns et al, 1995; Herman et al, 1995). The best studied of the INK4 proteins is TP16. The gene was initially found mutated and deleted in a wide variety of tumors including bladder and kidney (Kamb et al, 1994). Subsequent analysis has demonstrated that **inactivation often occurs by DNA hypermethylation at the *TP16* promoter,** an alternative method of gene inactivation (Merlo et al, 1995). Interestingly, the same *CDKN2A* locus codes for an entirely different gene product, $TP14^{ARF}$, the coding sequence of which partially overlaps with the *TP16* coding sequence but uses a separate gene promoter and is translated using an alternate reading frame (Quelle et al, 1995). **TP14 modulates the TP53 tumor suppressor pathway, serving to stabilize TP53 protein** by inhibiting the ubiquitin ligase HDM2 (Mdm2 in the mouse) which normally tags TP53 for destruction. TP14 binds to HDM2 directly inhibiting it, as well as sequestering it in the nucleolus, a subcompartment within the cell nucleus (Honda and Yasuda, 1999; Llanos et al, 2001). In addition, TP14 can also bind to E2F transcription factors, inhibiting them and inducing their degradation (Rizos et al, 2007). The *TP15* gene lies just adjacent to the *TP16* gene on the short arm of chromosome 9 (9p21), and therefore was deleted in many of the same tumors and cell lines that lost *TP16* (Hannon and Beach, 1994). However, *TP15* does not appear to play as strong a role in tumorigenesis as *TP16* (Stone et al, 1995).

The *TP16* gene is frequently inactivated by deletion in bladder carcinomas (Cairns et al, 1995; Williamson et al, 1995). Importantly, despite its proximity, the *TP15* gene was ruled out as the primary tumor suppressor at this site because it was not within the deletion interval. A study by Orlow and colleagues (1999) found that deletion and methylation of the *TP16* gene occurred frequently in superficial bladder carcinoma, but only those deletions that affect both the *TP16* and *TP14*ARF genes correlated with a decrease in disease-free survival.

Mutational inactivation of *INK4* family members appears to be rare in prostate carcinoma. Komiya and associates (1995) identified a mutation of *TP16* in only 1% of clinical specimens. Park and associates (1997) examined primary prostate carcinomas for mutations in *TP16, TP15,* and *TP18* and identified one mutation in *TP16*. In contrast, inactivation of *TP16* by hypermethylation has been implicated in prostate cancer. Herman and associates (1996; 1995) demonstrated hypermethylation of *TP16* in 60% of prostate cancer cell lines, whereas *TP15* was rarely inactivated. However, these results are tempered by observations that *TP16* gene silencing by promoter hypermethylation often occurs during the establishment of cell lines.

Despite the critical role that CIP/KIP family members play in G_1S cell cycle arrest, they are rarely mutated in a wide variety of malignancies, including genitourinary tumors, and there are only rare reports of promoter hypermethylation (Shiohara et al, 1994; Kawamata et al, 1995). However, expression of this family of CDK inhibitors plays an important role in cancer in general (Catzavelos et al, 1997; Loda et al, 1997; Yatabe et al, 1998), and in genitourinary carcinomas in particular. Stein and associates (1998) found increased expression of *TP21* in 64% of bladder tumors and that increased expression was associated with decreased probability of tumor recurrence and improved patient survival. Decreased *TP27* expression has also been linked to increasing tumor grade, pathologic stage, and poor survival in bladder carcinoma (Del Pizzo et al, 1999).

The expression of *TP21* in prostate cancer has not demonstrated a clear correlation with advanced disease or poor outcome (Kibel and Isaacs, 2000). However, specific genetic polymorphisms in *TP21* and *TP27* have been associated with advanced disease (Kibel et al, 2003), and altered expression of *TP27* has been implicated in aggressive disease in multiple studies. Cordon-Cardo and colleagues (1998) examined radical prostatectomy specimens and found that absent or low *TP27* expression by immunohistochemistry was an independent risk factor for decreased disease-free survival by multivariate analysis. Cote and colleagues (1998) found that decreased *TP27* nuclear staining not only correlated with decreased disease-free survival but also overall survival in radical prostatectomy patients, while Freedland and colleagues (2003) found that *TP27*-positive cells in the prostate needle-biopsy specimen had a 2.5-fold increased risk of biochemical recurrence (prostate-specific antigen [PSA] relapse).

The relevance of TP27 to prostate cancer is also supported by studies of mouse models. For example, mice deficient in TP27 develop prostate hyperplasia, confirming the potential importance of this gene in prostate tissue homeostasis (Cordon-Cardo et al, 1998). More excitingly, studies have shown that mice deficient in both TP27 and Pten have a high incidence of prostate cancer (Di Cristofano et al, 2001).

Cell Cycle Checkpoints

Although beyond the R point the cell cycle functions autonomously, in a unidirectional manner, the cell is still capable of halting its progress at various points should adverse conditions arise. Thus **a number of so-called "checkpoints," first discovered in yeast, have been identified, the two primary ones being the G_1S, and G_2M checkpoints** (Weinert and Hartwell, 1988). These checkpoints are primarily **tasked with monitoring the completion of key events in the cell cycle, although genomic integrity is also closely monitored** (Hartwell et al, 1994). **Loss of checkpoint control can allow inappropriate cell division to occur and also facilitates genetic instability, two key contributors to cancer progression. Indeed, inherited mutations in several of the genes involved in cell cycle checkpoint control (e.g., *TP53* and *ATM*) cause familial cancer predisposition syndromes.**

The G_1S Checkpoint

As previously mentioned, the expression of cyclin D during G_1 is dependent upon the integration of both pro- and antiproliferative signals received from the extracellular environment (e.g., mitogens, nutrient and oxygen availability, etc.); thus the cell will not fully commit to division unless it receives a sustained signal to do so and conditions remain favorable (Matsushime et al, 1991).

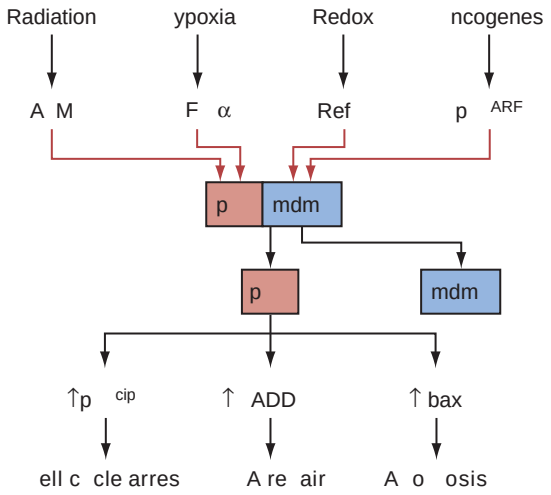

Figure 18–9. TP53 plays a central role in the cell's response to extracellular stimuli. Radiation, hypoxia, redox reactions, and oncogenes can all increase TP53 activity through different mechanisms. In response, the cell initially stops dividing and then attempts to repair the DNA damage. If it fails to repair the DNA, it undergoes apoptosis (programmed cell death). These functions are mediated through transcriptional activation of a variety of genes, some examples of which are indicated in the figure.

A critical contributor to the G_1S checkpoint is the TP53 protein. As discussed elsewhere in more detail, **the TP53 tumor suppressor is a pleiotropic transcription factor that receives signals from multiple types of cell stress and damage and, in response, activates genes that function variously in cell cycle arrest, DNA damage repair, and apoptosis (programmed cell death), thus highlighting the link between cell cycle arrest and DNA repair** (Elledge, 1996) (Fig. 18–9). DNA damage has obvious relevance for the G_1S checkpoint because a normal cell will not proceed to S phase if the genomic template DNA is damaged, thus **intact checkpoint controls represent important antitumor mechanisms acting to limit the proliferation of cells bearing potentially oncogenic mutations.** During the cellular response to damaged DNA, specific kinases are activated that phosphorylate the TP53 protein, thereby protecting it from HDM2 ubiquitin ligase–mediated degradation (Momand et al, 1992). The accumulated TP53 undergoes further modifications that serve to activate it and facilitate its translocation to the nucleus, where it induces various checkpoint and DNA repair proteins. TP53 target genes that facilitate the G_1S checkpoint include *TP21* and *14-3-3-sigma*, which cause cell cycle arrest by inactivating or sequestering G_1 CDK complexes (Giaccia and Kastan, 1998). **If the cell cannot arrest growth and/or repair the DNA damage, TP53 often induces apoptosis** (Levine, 1997).

S-Phase Arrest

Whereas S phase is not considered to have a checkpoint per se, such as those recognized during G_1S and G_2M, the cell does maintain the ability to arrest the cell and repair DNA damage through two mechanisms, both mediated through the ATM kinase. In response to genotoxic insults, CDC25A is ubiquitinated through an ATM-dependent cascade, resulting in a rapid decrease in CDC25A levels. Because CDC25 family members normally activate CDK2, the loss of CDC25A function maintains CDK2 in its inactive form, preventing its phosphorylation of substrates required for DNA synthesis. Inactive CDK2 prevents CDC45 from recruiting DNA polymerase. Thus this cascade pauses the cell in S phase, ostensibly to allow time for DNA repair (Bartek et al, 2004).

The second mechanism mediated by ATM in response to DNA damage is phosphorylation of DNA repair enzymes (see DNA Repair). These two parallel pathways further highlight the interaction between DNA repair and checkpoint control. It is not surprising that such S-phase control has been documented in response to DNA-damaging agents, because it is the last opportunity to repair DNA damage before replication (Falck et al, 2002; Pichierri and Rosselli, 2004). Notably, the cascade does not appear to be mediated by TP53 and therefore is an intriguing potential target for therapy in the future (Kastan and Bartek, 2004).

G_2M Checkpoint

The G_2M checkpoint is a second major point of control during cell division. Unlike the G_1S checkpoint, which responds to a variety of extracellular signals in addition to DNA damage, **the G_2M checkpoint appears to be similar to S-phase arrest and responds only to DNA damage. It therefore serves as an important monitor of DNA replication errors** (Weinert, 1997; Bartek et al, 1999).

DNA damage secondary to radiation is believed to induce G_2M arrest through ATM. ATM activates CHK1 and CHK2 kinases in response to DNA damage, and these, in turn, inactivate the CDC25 family proteins through phosphorylation, which causes 14-3-3-sigma to bind and sequester it (Hermeking et al, 1997; Sanchez et al, 1997). There are three CDC25 proteins, primarily functioning at the G_1M and S-phase checkpoints as outlined previously, whereas CDC25B and CDC25C primarily function at the G_2M checkpoint. CDC25B/C phosphorylation disallows their activation of CDC2, therefore inhibiting the cyclin B and cyclin A-CDC2 complexes (Mailand et al, 2002; Donzelli and Draetta, 2003).

It has become apparent that, at least in part, G_2M arrest may also be mediated by TP53 and the BRCA1 tumor suppressor (Bunz et al, 1998; Xu et al, 2001). Transcriptional upregulation of cell cycle inhibitors (e.g., TP21, GADD45, and 14-3-3-sigma) by TP53 helps maintains the cell in G_2M arrest (Nyberg et al, 2002). As a result, **it appears that TP53 mediates both G_1S and G_2M arrest, consistent with its critical role in preserving genomic integrity.**

Mitotic Arrest: Spindle Assembly Checkpoint

As detailed earlier, **one of the key events in mitosis is the proper attachment of each and every chromosome to the spindle microtubule apparatus.** It is critical that all chromosomes are attached before proceeding into anaphase where the chromosome complements are pulled apart. Failure of one or more chromosomes to attach leads to chromosome nondisjunction, wherein one daughter cell receives an extra copy of the chromosome, becoming trisomic for that chromosome, while the other receives one copy too few, becoming monosomic. Both cases are abnormal and fall under the category of aneuploidy, a nearly universal characteristic of human solid tumors. Gene expression patterns often correlate with gene copy number; thus the widespread change in gene dosage due to gains or losses of entire chromosomes can lead to profound imbalances in the expression

of hundreds or thousands of genes and, as such, it has been proposed that aneuploidy may be a major contributor to cancer initiation and progression (Duesberg et al, 1999; Duesberg, 2005). **The mitotic checkpoint (spindle assembly checkpoint) apparatus monitors chromosome attachment and receives a "not ready" signal from any unattached chromosomes, preventing activation of the APC complex, thus blocking the transition from metaphase to anaphase until all chromosomes are attached** (Chan et al, 1999; Holland and Cleveland, 2009). Although mutations have been identified in specific mitotic checkpoint genes, such as hBUBR1, in some cancers (Cahill et al, 1998), subsequent studies have shown these to be relatively rare (Wang et al, 2008b). Additional studies have found aberrant expression levels of mitotic checkpoint proteins, which may better explain the mitotic instability frequently observed in cancer cells (Yuan et al, 2006), including reports of reduced levels of the checkpoint proteins MAD1 and MAD2 in renal cell carcinoma (Pinto et al, 2007) and reduced MAD2 in testicular cancer (Fung et al, 2007).

Key Points: The Cell Cycle

- The cell cycle consists of an ordered, unidirectional series of events, the main goal of which is to replicate the cell's genome and partition one copy into each of two resulting daughter cells.
- The cell cycle is divided up into 4 phases; G_1, S, G_2, and M phase. The transition from G_1 into S is critically dependent on phosphorylation of the pRB tumor suppressor protein. Mutations in *pRB* are common in some urologic malignancies.
- Phase-specific phosphorylation of substrate proteins by cyclin-dependent kinases (CDK) orchestrate progression through the cell cycle.
- The activities of CDKs are dependent upon their association with specific cyclin proteins. Cyclins accumulate and are rapidly degraded in a phase-specific manner, thus assuring the proper sequencing and irreversibility of key events throughout the cell cycle.
- Primary points of cell cycle control are the G_1S and G_2M checkpoints. Checkpoints employ cyclin-dependent kinase inhibitor proteins (CDK1) to pause the cell cycle in response to a variety of stress signals, including DNA damage, cell–cell contact, cytokine release, and hypoxia.
- The TP53 tumor suppressor protein is a key player in cell cycle checkpoints, responding to DNA damage by signaling cell cycle arrest and repair of the damage. If the DNA damage cannot be repaired, TP53 may trigger cell death (apoptosis).
- *TP53* is the most commonly mutated gene in cancer and plays a prominent role in genitourinary malignancies.
- Defects in cell cycle checkpoints lead to unregulated cell proliferation and genetic instability.

DNA METHYLATION

The covalent modification of the C-5 position of cytosine is mediated by DNA (cytosine-5) methyltransferase, resulting in the formation of 5-methylcytosine. This enzymatic conversion is an epigenetic modification of DNA that occurs in vertebrates and is essential for normal embryonic development (Jones, 1986; Bird, 1992). Methylation of cytosine occurs primarily at the CpG palindrome in DNA. The presence of 5-methylcytosine at CpG dinucleotides has resulted in a significant depletion of this sequence from the genome during the course of vertebrate evolution (Schorderet and Gartler, 1992). This reduction in frequency of CpG dinucleotides in the genome is the result of spontaneous deamination of 5-methylcytosine to thymine (Rideout et al, 1990; Sved and Bird, 1990). Certain areas of the genome do not show a depletion of the CpG dinucleotide and contain the expected frequency of this sequence. These regions are referred to as CpG islands and comprise approximately 1% of vertebrate genomes, yet account for approximately 15% of the total number of CpG dinucleotides in DNA (Bird, 1986; Gardiner-Garden and Frommer, 1987). CpG islands are typically located upstream of many housekeeping and tissue-specific genes. Methylation of cytosines within CpG islands is believed to affect gene function by altering transcription (Cedar, 1988). Hypermethylation of CpG islands results in transcriptional downregulation, while hypomethylation of these regions may increase the potential for gene activity.

CpG islands located in the promoter regions of tumor suppressor genes are normally unmethylated. Abnormal methylation of these regions may result in a progressive reduction in gene expression, thus altering normal cellular growth control. Methylation of CpG islands may lead to decreased gene expression by mechanisms including: disruption of local chromatin structure, inhibition of transcription factor binding, or exclusion of transcriptional machinery from methylated promoter DNA (Bird and Wolffe, 1999). The epigenetic properties of methylation may therefore affect gene activity without altering the DNA sequence.

Changes in global levels and regional patterns of DNA methylation are among the earliest and most frequent events known to occur in human cancer (Jones and Baylin, 2002). Alterations in DNA methylation have a direct impact on mutational and epigenetic components that may contribute neoplastic transformation. **Three major pathways by which DNA methylation may result in genetic dysregulation in human caner include (1) inherent mutational effects of 5-methylcytosine, (2) epigenetic effects of promoter methylation on gene transcription, and (3) potential gene activation and induction of chromosomal instability by DNA hypomethylation** (Gonzalgo and Jones, 1997; Jones and Gonzalgo, 1997).

DNA Methylation and Prostate Cancer

Glutathione-S-transferases belong to a superfamily of enzymes responsible for detoxification of a wide range of xenobiotics. These enzymes catalyze the nucleophilic attack of reduced glutathione on electrophilic compounds. **Aberrant methylation of the CpG island at the glutathione-S-transferase Pi (*GSTP1*) locus is the most frequent somatic genome alteration reported in prostate cancer** (Lee et al, 1994; Jeronimo et al, 2001). Methylation of *GSTP1* has been detected in greater than 90% of prostate carcinomas and approximately 70% of prostatic intraepithelial neoplasin (PIN) lesions, but is not present in normal prostate tissue or benign prostatic hyperplasia (Lee et al, 1994). In normal prostate tissue, expression of *GSTP1* is limited to basal cells, but it can be upregulated in columnar epithelial cells exposed to oxidative stress. Increased levels of DNA methylation have also been associated with worse clinical outcomes in patients with prostate cancer (Maruyama et al, 2002).

The *RAS* association domain family protein 1, isoform A (*RASSF1A*) gene is located on chromosome 3p21. *RASSF1A* is a

tumor suppressor gene that is frequently altered in a variety of human cancers. Abnormal methylation of *RASSF1A* has been reported to occur in 60% to 70% of prostate carcinomas (Kuzmin et al, 2002). Loss of heterozygosity (LOH) of the 3p21 region is associated with methylation and silencing of the remaining *RASSF1A* allele during tumorigenesis. Methylation of *RASSF1A* has been observed more frequently in higher grade prostate cancers compared with less aggressive tumors (Liu et al, 2002).

Role of DNA Methylation in Bladder Cancer

The *TP53* tumor suppressor gene plays a critical role in a variety of growth regulatory mechanisms involving cell cycle, apoptotic, senescence, and angiogenic pathways (Smith et al, 2003). Mutations of the *TP53* gene are present in more than half of all human malignancies. Approximately 24% of point mutations in the *TP53* gene are C→T transitions located at CpG dinucleotides (Greenblatt et al, 1994). Many of the mutational hotspots found in the *TP53* gene occur at CpG dinucleotides that are methylated, thus implicating 5-methylcytosine as an endogenous mutagen in the genome (Rideout et al, 1990; Tornaletti and Pfeifer, 1995). Mutational inactivation of *TP53* is a frequent event in urothelial dysplasia, carcinoma in situ (CIS), and invasive bladder cancer (Spruck et al, 1994b).

The presence of DNA methylation at CpG dinucleotides within the *TP53* gene is associated with many mutational hotspots found within this gene. The contribution of DNA methylation to these mutational events is be variable depending upon the type of bladder cancer and the etiologic agent believed to be responsible for tumor formation (Jones et al, 1998). Urothelial carcinomas in Western countries and Japan have relatively few mutations at CpG sites, suggesting that DNA methylation may not play a major role in inducing these changes. In contrast, a higher frequency of mutations at CpG dinucleotides consistent with 5-methylcytosine deamination is observed in patients with squamous cell carcinoma, and urothelial carcinoma with a history of exposure to phenacetin or arsenic (Jones et al, 1998). Although the exact mechanisms responsible for variability of the *TP53* mutational spectra are not fully understood, these observations highlight the potential mutagenic effects of DNA methylation upon the genome and the contribution of methylation to *TP53* inactivation during bladder carcinogenesis.

TP16 Methylation in Bladder Cancer

The cyclin-dependent kinase inhibitor 2A (*TP16/CDKN2A/INK4a*) is a tumor suppressor gene found on chromosome 9p21. The protein product TP16 binds to cyclin-dependent kinases 4 and 6 and inhibits their interaction with cyclin D1, which normally mediates passage through G_1 phase of the cell cycle by phosphorylation of the protein product of the retinoblastoma gene (*RB*) (Serrano et al, 1993). Unphosphorylated RB exerts its cell cycle inhibitory effects through binding of regulatory proteins that normally stimulate genes required for cellular proliferation. Inactivation of the *TP16* may occur by a variety of mechanisms including deletion, mutation, and promoter methylation (Spruck et al, 1994a; Gonzalez-Zulueta et al, 1995; Herman et al, 1995). Mutation or deletion of one *TP16* allele and concurrent methylation of the remaining allele may result in loss of functional activity. Methylation of *TP16* has been observed in 27% to 60% of primary urothelial carcinomas (Chan et al, 2002; Chang et al, 2003). Epigenetic changes are among the earliest molecular events associated with transformation and may therefore precede morphologic alterations in cellular architecture.

The first detailed study investigating the effects of *TP16* promoter methylation on transcriptional activity was performed in bladder cancer cells (Gonzalgo et al, 1998). A reduction in *TP16* expression was associated with higher levels of methylation in the upstream promoter region. Methylation of specific CpG sites in the *TP16* promoter was shown to significantly down regulate transcriptional activity in a chloramphenicol acetyltransferase (CAT) assay (Gonzalgo et al, 1998). Administration of the demethylating agent 5-aza-2′-deoxycytidine (5-aza-CdR) was capable of reactivating *TP16* expression in bladder cancer cells that were previously shown to contain methylated alleles of the gene. Methylation in exon 2 of the *TP16* gene is also a frequent occurrence in a variety of cancers and is an excellent marker for transformation. Presence of methylation in this region of the *TP16* gene, however, does not affect *TP16* transcription in bladder cancer cells (Gonzalgo et al, 1998).

Hypermethylation of Genes in Bladder Cancer

The E-cadherin (*CDH1*) gene encodes a transmembrane glycoprotein that modulates calcium-dependent intercellular adhesion in epithelial tissues. Methylation of the CpG island located in the *CDH1* promoter is associated with decreased gene expression in high-grade urothelial carcinoma, including disease associated with carcinoma in situ (Graff et al, 1995; Horikawa et al, 2003). *CDH1* methylation has also been reported in histologically normal urothelium; however, many of these cases were from patients older than 70 years of age and may be related to a potential link between methylation and aging (Ahuja and Issa, 2000; Bornman et al, 2001). Lower levels of *CDH1* expression resulting from promoter hypermethylation may increase β-catenin/TCF activity and proliferation in urothelial carcinomas (Maruyama et al, 2002; Thievessen et al, 2003).

Methylation of *RASSF1A* has been reported in up to 97% of primary bladder tumors (Lee et al, 2001). High tumor grade, nonpapillary growth pattern, and muscle invasive disease are associated with *RASSF1A* promoter methylation in bladder cancer (Maruyama et al, 2001). Downregulation of *RASSF1A* expression in bladder cancer cell lines and primary tumors by aberrant promoter hypermethylation suggests that epigenetic inactivation of this gene may play an important role in bladder carcinogenesis.

Hypomethylation in Bladder Cancer

Global DNA hypomethylation and gene-specific hypermethylation are frequent events in tumorigenesis (Jones and Baylin, 2002). **Hypomethylation may result in genomic instability through alterations in chromatin structure, recombination between repetitive elements, or reexpression of retrotransposons** (Baylin et al, 2001). Methylation of CpG sites is normally maintained by the enzymatic activities of DNA methyltransferase 1 (DNMT1), while de novo methylation of CpG sites is mediated by DNA methyltransferases 3A and 3B (DNMT3A, DNMT3B) (Jones and Baylin, 2002). **One important role for methylation is genomic imprinting, which results in monoallelic gene expression without altering the genetic sequence.** Loss of imprinting (LOI) is a reduction in the methylation of the normally methylated allele, which can

lead to activation of the normally silent copy of a growth-promoting gene (Feinberg and Tycko, 2004). This phenomenon has been reported for the human insulin-like growth factor-2 gene (*IGF2*) in a variety of cancers (Woodson et al, 2004; Sakatani et al, 2005).

Methylation of long interspersed nuclear element (L1 LINE) sequences is reduced in bladder cancer cell lines and primary tumors compared with normal bladder mucosa (Jurgens et al, 1996). DNA methyltransferase expression, however, did not correlate with methylation status of cell lines, and methyltransferase activity was reduced in quiescent cells suggesting that aberrant expression of *DNMT1* does not account for the altered methylation patterns found in urothelial carcinoma (Jurgens et al, 1996). Decreased *DNMT1* expression and induction of *DNMT3A* and *DNMT3B* in bladder cancer has also been reported (Kimura et al, 2003). These data suggest that downregulation of *DNMT1* expression may be at least partly responsible for hypomethylation of repetitive elements in bladder cancer. Although the exact mechanisms underlying the dysregulation of methyltransferase activity during malignant transformation are not well defined, the enhanced cellular proliferation observed in bladder cancer does not appear to be accompanied by an appropriate increase in *DNMT1* expression. Dysregulation of this process in combination with other factors may determine the extent of DNA hypomethylation during cancer development.

Key Points: DNA Methylation

- Methylation occurs specifically at CpG dinucleotides in the genome. The presence of 5-methylcytosine in DNA can result in spontaneous deamination to thymine and formation of C→T transition mutations.
- DNA methylation can affect gene function by mutational events or epigenetic mechanisms. Methylation of CpG islands associated with the promoter region of genes may result in down-regulation of transcription and suppression of gene expression.
- Loss of methylation of normally methylated genes can lead to the potential for gene expression.

DNA DAMAGE AND REPAIR

Cancer is fundamentally a genetic disease. Alterations in numerous genes provide the malignant cell the means to activate cancer-associated pathways and inactivate tumor suppressive barriers, making possible the acquisition of the key set of attributes associated with the cancer phenotype. **The intrinsic accuracy of DNA polymerase coupled with associated error-correction mechanisms keeps the error rate during DNA replication to an astonishingly low estimated value of approximately three incorrect bases per cell division, this in a genome of over three billion bases! And yet, cancer causing changes occur in oncogenes and tumor suppressor genes by epigenetic, mutational, and copy number alterations.** Many of these genetic changes are thought to result from a variety of endogenous (e.g., mitochondrial respiratory byproducts) and exogenous (e.g., chemicals, radiation, etc.) DNA-damaging agents that constantly assault the genome (Ames and Gold, 1991, 1998). To counter these threats, our cells employ a plethora of defensive mechanisms, including free-radical scavengers such as alpha-tocopherol, vitamin C, carotenoids, bilirubin and urate, as well as protective enzymes such as superoxide dismutases, glutathione peroxidases, and glutathione transferases that serve to detoxify a wide range of carcinogens (Mates and Sanchez-Jimenez, 1999; Finkel and Holbrook, 2000). Loss of expression, due to promoter hypermethylation, of the glutathione-S-transferase Pi enzyme encoded by the *GSTP1* gene is observed in the vast majority of prostate cancer cases (Lee et al, 1994; Lin et al, 2001), and recent studies have found associations between genetic polymorphisms in GSTs and the risk of biochemical recurrence in prostate cancer patients (Nock et al, 2009). Epidemiologic and retrospective studies on prostate cancer risk have found a protective effect for selenium, which is used as a cofactor by glutathione peroxidases (Lowe and Frazee, 2006; Colli and Amling, 2009), raising hope that dietary intervention might be protective against prostate cancer. However, a recent large clinical trial showed no benefit for dietary supplementation with selenium (Hatfield and Gladyshev, 2009), and it now appears that selenium's observed protective effects may be limited to men with low selenium levels at baseline. Results from other clinical chemoprevention trials in prostate cancer have, unfortunately, been similarly disappointing (Gaziano et al, 2009).

Despite the presence of detoxification systems such as those just described, DNA damage routinely occurs. For example, it has been estimated that each cell's genome experiences on the order of 10,000 lesions per day from reactions with oxidative species alone (Ames et al, 1993). Other processes, such as spontaneous loss of individual DNA bases (depurination and depyrimidination), as well as spontaneous deamination of bases, also occur at appreciable rates. **Thus, in addition to damage prevention, the cell employs a host of DNA repair systems as well.** The set of pathways dealing with DNA damage recognition and repair is **referred to as the DNA damage response, or DDR,** and encompasses a plethora of genes whose protein products are involved in ensuring the fidelity of DNA replication. The DDR includes the replication machinery itself (with its associated proofreading capability), as well as the many components of specific DNA repair systems such as base-excision repair, nucleotide-excision repair, double-strand break repair, and mismatch repair described in detail below (Loeb, 1998; Schmutte and Fishel, 1999) (Fig. 18–10).

As previously mentioned, **the cell cycle and the DDR are closely integrated. In response to DNA damage, the first step is to arrest the cell cycle so that the DNA can be repaired. It is therefore not surprising that there is substantial overlap between the initiators of DNA repair and cell cycle arrest** (Kastan and Bartek, 2004). For example, ATM and ATR kinases are both activated in response to DNA damage, and both activate TP53, CHK1, and other proteins critical to cell cycle arrest (Bartek and Lukas, 2003). In addition, both recruit and activate various DNA repair factors, such as MRE11, BLM, NBS1, BRCA1, BRCA2, RAD51, FANCD2, and RPA to sites of damage (Zou and Elledge, 2003; Kitagawa et al, 2004).

Considering the number of genetic changes calculated to be required for cancer development, as well as the large number of changes actually observed in cancer cells, and also taking into account the extraordinarily low spontaneous mutation rates in normal human cells, Loeb and colleagues concluded that the spontaneous mutation rate is insufficient to explain the number of mutations observed in the majority of human cancers. Loeb hypothesized that early in the process of tumorigenesis

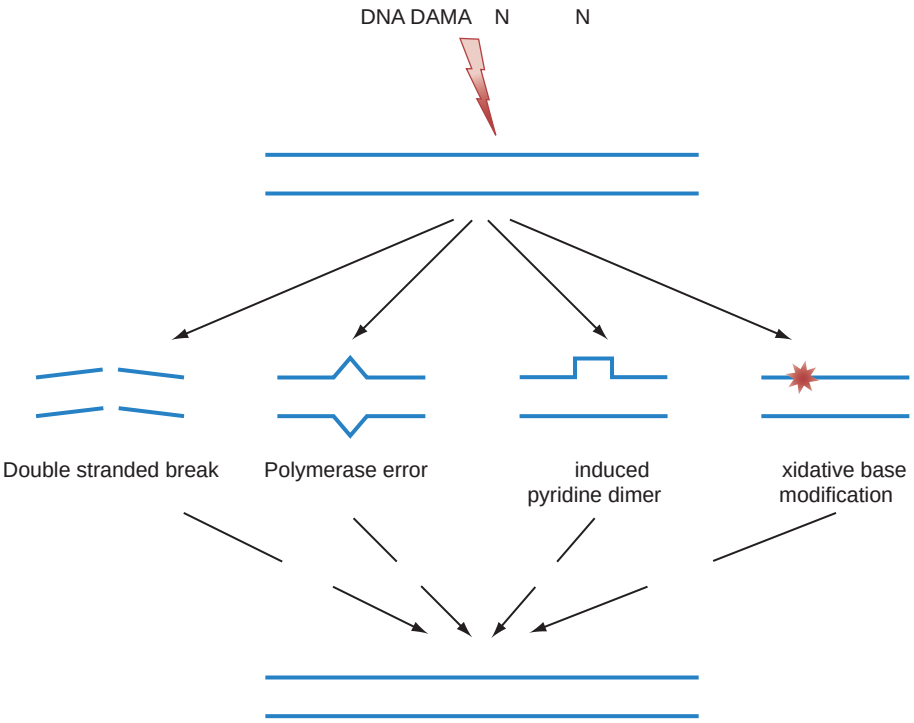

Figure 18–10. Schematic of different DNA damaging events and repair mechanisms.

preneoplastic cells might develop defects in one or more of the genes responsible for the fidelity of DNA replication (Loeb et al, 1974; Loeb, 1991; Cheng and Loeb, 1993). Such a defect would then lead to an increased mutation rate resulting in a so-called "mutator phenotype." This hypothesis gains further support from observations that most cells of proliferating tissues, such as epithelial tissues (the source of the vast majority of human cancers), are relatively short lived, being eliminated either by cell shedding or apoptosis. Thus the target population of cells at risk for becoming cancerous is far less than the total number of cells in the body, yet cancers are certainly not uncommon. In addition, cells with a "hypermutable" phenotype are often more difficult to treat because the selection pressure of therapy may rapidly select tumor cells with mutations conferring resistance (Tlsty et al, 1989).

The term mutator phenotype is generally used to refer to defects in the DNA replication and repair proteins, resulting in relatively small-scale errors in the DNA sequence, such as single base substitutions, deletions, and duplications. Despite (or perhaps because of?) the many potential targets for mutator genes, few such genes have been found to be consistently mutated in significant proportions of common human cancers, a notable exception being the mismatch repair pathway. Mismatch repair defects are the underlying cause of hereditary nonpolyposis colorectal cancer (HNPCC) (Aaltonen et al, 1993), and have also been reported in as many as 15% of sporadic colon cancers (Liu et al, 1995). There have been reports of mismatch repair defects (usually gauged by measuring instability in so-called microsatellite sequences) in cancers other than colon cancer (Eshleman and Markowitz, 1995), but, as yet, it remains to be determined to what extent mismatch repair defects contribute to the overall development of sporadic tumors. Indeed, the relevance of the postulated mutator phenotype itself, as originally outlined, remains a hotly debated topic, with authors such as Tomlinson and Bodmer 1999 arguing that clonal expansion and selection in the absence of any raised mutation rate are sufficient to account for the number of mutations observed in cancer cells (Tomlinson et al, 1996). Furthermore, other researchers have calculated higher basal spontaneous mutation rates than those which led Loeb to consider the need for a mutator phenotype (Simpson, 1997). It is intriguing however that **many recessively inherited cancer predisposition syndromes (e.g., xeroderma pigmentosum, Bloom syndrome, Werner syndrome, ataxia telangiectasia, hereditary breast and colon cancer syndromes, etc.) are caused by defects in genes involved with DNA maintenance and repair, thus strongly implicating hypermutability in cancer causation** (Modrich, 1994; Sancar et al, 1996; Patel et al, 1998).

Although defects in DNA repair genes in sporadic malignancies, including genitourinary tumors, have been identified, Loeb's concept of the mutator phenotype, as originally stated, has yet to be fully evaluated, and it currently appears that it may not be a major player in the development of the majority of common sporadic human cancers. **If, however, one broadens the mutator concept to include systems involved in *chromosomal* stability, then it may become widely applicable**. At any rate, **the current consensus is that genetic instability of *some* sort is required for cancer development.**

Nucleotide Excision Repair

NER is a major defense against DNA damage caused by ultraviolet (UV) radiation and chemical exposure. NER acts on a wide range of alterations that result in large local distortions in DNA, by recognizing distortions in the DNA helix, excising the damaged DNA, and replacing it with the correct sequence (Wood, 1997).

The study of three syndromes—xeroderma pigmentosum, Cockayne syndrome, and trichothiodystrophy—associated with inborn defects in proteins essential to NER has been critical to expanding our understanding of this pathway (Hoeijmakers,

2001). Patients with xeroderma pigmentosum, caused by defects in one of eight distinct genes, have a risk of skin cancer that approaches 100% by 20 years of age. The increased cancer risk is linked to exposure to ultraviolet radiation. That these patients are at such a profound risk for developing malignancies demonstrates the fundamental importance of NER in protecting DNA from cancer-causing mutations (Kraemer, 1997). In contrast, skin cells of patients with Cockayne syndrome and trichothiodystrophy are particularly sensitive to lesion-induced apoptosis. Intriguingly, the result is accelerated aging but no predisposition to cancer (Hoeijmakers, 2001).

NER requires at least a dozen proteins in humans, including: RPA, XPA-XPG, and TFIIH (Mu et al, 1997; Sancar et al, 2004). DNA damage that produces a substantial distortion in the DNA helix, such as UV-induced thymidine dimers, is recognized by XPA, which binds to the damaged DNA and recruits the other enzymes critical for DNA repair. XPA forms a complex with replication protein A (RPA) and then recruits the transcription complex TFIIH. This protein complex has helicase activity, which allows the complex to unwind the damaged DNA. A 24- to 32-bp segment of DNA is then excised by exonucleases, and the excised sequence is replaced by DNA polymerase delta or epsilon. The newly synthesized DNA is then ligated into place (Wood, 1997; Sancar et al, 2004). A special subtype of NER called transcription-coupled repair (TCR) focuses on the template strand of actively transcribed genes.

Base Excision Repair

The BER pathway repairs damage caused by a variety of events including spontaneous deamination of bases, radiation, oxidative stress, alkylating agents, or replication errors. In particular, the pathway is critical for repair of oxidative lesions caused by reactive oxygen species (ROS). Unlike NER, lesions recognized by BER do not tend to create major distortions in the DNA molecule. Because ROS are a normal byproduct of metabolism, loss of BER repair is particularly detrimental in the fidelity of DNA. ROS react with DNA to produce DNA base modifications, and the modified bases often mispair during DNA replication, resulting in mutations (Croteau and Bohr, 1997).

As the name implies, the initial step in BER is the removal of a base rather than a nucleotide. The key element of the repair is the recognition of the modified bases by one of several DNA glycosylases (Krokan et al, 1997). Many DNA glycosylases are nonspecific and remove several structurally different damaged bases while others have specific substrates. Each glycosylase identifies the damaged base, cleaves the N-glycosidic bond between the target base and the DNA deoxyribose backbone, thus releasing the damaged base, leaving an apurinic/apyrimidinic (AP) site (Wyatt et al, 1999; Bruner et al, 2000).

There are two forms of BER: short patch repair and long patch repair. In a short patch repair of one nucleotide, a 5′ endonuclease termed APE1 and the 3′ phosphodiesterase activity of polymerase-β excise the remaining base-free sugar, and then DNA polymerase-β fills in the single nucleotide gap (Beard and Wilson, 2000). Lastly, a DNA ligase (LIG3/XRCC1 complex) ligates the inserted nucleotide (Cappelli et al, 1997). An alternative BER mechanism is called long patch repair. This allows insertion of a 2- to 10-bp sequence beginning at the damaged nucleotide. It is most useful in cases in which the damaged moiety is refractory to polymerase-β excision (Gary et al, 1999). APE1 again makes a 5′ incision next to the damaged nucleotide, but, in this case, recruits DNA polymerase-δ or -ε, PCNA, and FEN1. A 2- to 10-bp patch is then synthesized, which displaces the damaged nucleotide, along with adjacent nucleotides, and then is ligated by LIG1 (Klungland and Lindahl, 1997; Levin et al, 1997).

Mouse models provide some insight into associations between components of the BER pathway and cancer risk. Whereas loss of some glycosylases can increase the risk of developing malignancies when exposed to mutagens (Elder et al, 1998), in general, loss of individual glycosylases does not cause an overt phenotype, probably due to overlapping function among the many glycosylases. On the other hand, core BER enzymes appear to be essential, because inactivation in knockout mice is embryonic lethal (Friedberg et al, 1998). In human cancers, mutations in the MUTYH glycosylase are associated with colorectal carcinoma. This glycosidase functions with OGG1 to correct A/G and A/C mismatches (Al-Tassan et al, 2002). Interestingly, polymorphic variants of OGG1 have been implicated in genitourinary malignancies (Xu et al, 2002b).

Mismatch Repair

MMR removes nucleotides mispaired by DNA polymerases and insertion/deletion loops (ranging from 1 to 10 or more bases) that result from slippage during replication of repetitive sequences or during recombination.

The MMR pathway functions primarily to reverse incorporation errors made by DNA polymerase. Defects in MMR compromise DNA replication fidelity by approximately two orders of magnitude, thus dramatically increasing mutation rates. Although DNA polymerases have the ability to identify and correct their own errors, some mistakes are not identified. Several of the proteins responsible for MMR (*MSH2, MSH3, MLH1, PMS1, PMS2, and MSH6*) have been identified through the study of the hereditary nonpolyposis colon cancer (HNPCC) syndrome, in which the adenoma-to-carcinoma transition is greatly accelerated. The MMR process has been elucidated in large part by studying the proteins responsible for MMR in bacteria (Modrich, 1997). MMR defects cause high rates of mutation in genes that contain microsatellite repeats within their coding sequences. For example, one study of colon cancer cell lines found mutated TGF-β receptors, which carry a run of 10 adenines in a row, in 9/11 cell lines examined (Carethers and Pham, 2000). TGF-β signaling is a major inhibitor of the cell cycle in epithelial cells, with signal transduction occurring from the TGF-β receptor to the nucleus through SMAD transcription factor proteins. **Activated TGF-β signaling can have multiple antiproliferative effects** including induction of TP15, TP21, and TP27 expression, as well as inhibition of CDK4 translation (Laiho et al, 1990; Ewen et al, 1993; Hannon and Beach, 1994; Koff et al, 1993). Cancer cells that abrogate this pathway become refractory to TGF-β's inhibitory effects.

Once an error has been detected, it is critical for the MMR proteins to distinguish the newly synthesized strand of DNA, that is, the strand that contains the error, from the original template strand. The mechanism for strand distinction has not been well elucidated in eukaryotes, but in *Escherichia coli* the parental strand is methylated, which allows identification of the daughter strand (Modrich, 1997).

The MMR proteins form heterodimers, each of which is responsible for detecting specific DNA replication errors. The MSH2/MSH3 heterodimer (MutSβ) mediates repair of insertions and deletions whereas the MSH2/MSH6 heterodimer (MutSα) recognizes single nucleotide mismatches in addition to insertions and deletions. Once the error has been detected, MutSα and MutSβcomplex with the MLH1/PMS2 heterodimer (MutLα) to direct the repair process. The newly synthesized strand containing the incorrect base(s) is degraded along with surrounding nucleotides. DNA

polymerase then replaces the degraded DNA using the parental strand as a template (Kolodner and Marsischky, 1999; Jiricny, 2000).

The MutSα and MutSβ complexes have also been found to play a role in cell cycle arrest (Meyers et al, 1997) and apoptosis (Tominaga et al, 1997). This is a further example of the integration that exists between cell cycle arrest, DNA repair, and apoptosis that is critical to protecting the fidelity of the DNA.

The critical role of MMR in protecting the cell from mutations that may lead to tumorigenesis is highlighted by their role in HNPCC, studies of sporadic tumors, and evidence from knockout mice. Inherited mutations in *MSH2, MLH1, PMS1, PMS2,* and *MSH6* have all been linked to an increased risk of malignancy (Fishel et al, 1993; Nicolaides et al, 1994; Papadopoulos et al, 1994; Wijnen et al, 1999). Genetic inactivation of MMR genes, particularly *MLH1,* is a frequent event in sporadic colon carcinoma (Veigl et al, 1998) and has been implicated in prostate (Boyer et al, 1995) and bladder carcinoma (Christensen et al, 1998). The finding that MMR knockout mice are cancer prone provides additional evidence that defects in MMR repair can contribute substantially to tumorigenesis (Friedberg et al, 1998).

Double-Stranded Break Repair

DNA double-strand breaks (DSBs) arise from a variety of causes including ionizing radiation or x-rays, free radicals, reactive chemical species, as well as during replication of DNA containing single-strand breaks. After DSB detection, a complex cascade of reactions is triggered that halts the cell cycle and recruits specific repair factors (Kastan and Bartek, 2004). **Double-stranded breaks have the potential to be the most disruptive form of DNA damage. If they are not repaired, the cell will oftentimes undergo apoptosis. This apoptotic response process to double-stranded DNA breaks is the basis of radiation therapy and many chemotherapeutic agents that function primarily by inducing double-strand breaks. Thus cancer cells that have abrogated this response may exhibit increased resistance to such therapies.** Incorrectly repaired DNA can lead to DNA mutations, deletions, and structural chromosomal rearrangements, which are nearly ubiquitous in human solid tumors. There are two DSB repair pathways: homologous recombination (HR) and nonhomologous end joining (NHEJ) (Sancar et al, 2004).

The ATM kinase is a key player in DSB repair (Berkovich et al, 2007). By mechanisms that are still unclear, DSBs are quickly recognized, leading to rapid ATM activation by phosphorylation. In turn, activated ATM phosphorylates and activates TP53 and kinases CHK1 and CHK2, which, among other things, act to halt cell cycle progression to allow DNA repair (Fig. 18–11). ATM also activates many genes involved in DSB repair, such as the histone H2A variant *H2AX* (Rogakou et al, 1998; Lukas et al, 2003), *NBS1, BRCA1,* and *SMC1* (Kitagawa et al, 2004). Phosphorylated H2AX (also known as gamma H2AX) binds at the breakpoint and also occupies a sizeable stretch of DNA (up to 30 Mbp) on either side of the break, where it serves to recruit other DDR factors creating so-called repair foci (Rogakou et al, 1999; Bassal and El-Osta, 2005). Activated NBS1-MRE11-RAD50 (MRN) complex can then bind to RAD52 and the broken chromosomal ends (Lobachev et al, 2004). RAD51, along with the breast cancer susceptibility gene products, BRCA1 and BRCA2, plus the BRCA1-associated–RING-domain 1 protein (BARD1) then participate in replicating the undamaged region from the sister chromosome template (Welcsh et al, 2000; Sancar et al, 2004). Homologous recombination involves the transfer of genetic information between sister chromatids. Essentially, **homologous repair allows the normal undamaged sister chromatid to act as a template to allow precise repair of a damaged segment of DNA** (Johnson et al, 1999). It should be noted that use of the sister chromatid is only an option following S phase into G_2, before mitosis has occurred.

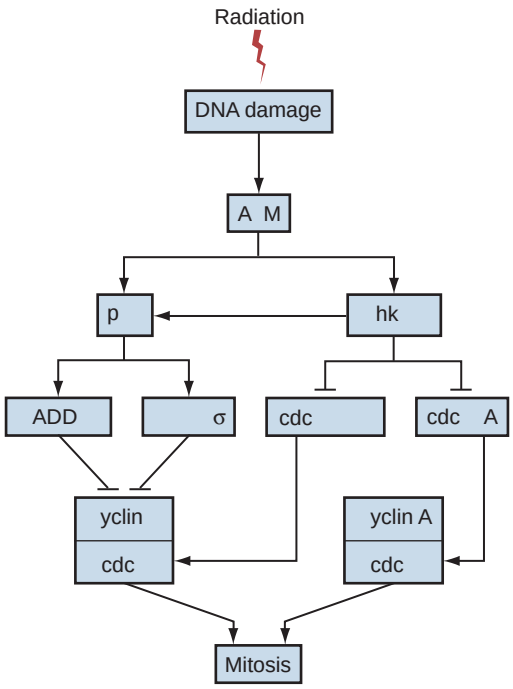

Figure 18–11. Schematic representation of the cascade at the G_2M checkpoint in response to genotoxic events such as radiation. Increased ATM kinase activity eventually leads to inhibition of cyclin B through TP53 and decreased stimulation of CDC2 through CHK1 and CHK2. This leads to cell cycle arrest.

NHEJ is the more extreme of the two DSB repair pathways. In this instance, broken ends are brought together and ligated, often with a loss of some nucleotides at the resulting joint. In addition, the potential exists for incorrectly joining broken DNA ends that were not originally juxtaposed in the genome, thus creating chromosomal rearrangements such as chromosomal translocations. The KU protein is a heterodimer consisting of KU70 and KU80 subunits that initiates NHEJ by binding to the broken ends of the DNA (Tuteja and Tuteja, 2000). KU complexes with DNA-dependent protein kinase (DNA-PK), and in doing so activates DNA-PK's kinase activity (Anderson, 1993). Active DNA-PK phosphorylates a large number of proteins involved in the repair process, including KU and also H2AX. Phosphorylated KU uses its helicase activity to unwind the damaged DNA and allows the ligase 4/XRCC4 heterodimer to repair the break (Tuteja and Tuteja, 2000).

Similar to other DNA repair mechanisms, defects in DSB repair have clearly been linked to cancer. *BRAC1* and *BRAC2* are associated with familial breast and ovarian cancer (Miki et al, 1994; Wooster et al, 1995). Patients with Nijmegen breakage syndrome have mutation in *NBS1* and are predisposed to leukemia, lymphoma, and breast carcinoma (Varon et al, 1998). Patients with mutations in *MRE11* are also predisposed to cancer (Stewart et al, 1999). These inherited cancer predisposition syndromes further highlight the existing link between genomic instability and cancer causation.

Key Points: DNA Damage and Repair

- DNA damage does not often lead to malignancy, because the cell possesses multiple repair mechanisms.
- Defects in DNA repair facilitate the accumulation of the mutations critical for tumor formation and progression.
- The cell cycle and the DDR are closely integrated. In response to DNA damage, the first step is to arrest the cell cycle so that the DNA can be repaired. TP53 plays a key role at this interface.
- Nucleotide excision repair (NER) is a major defense against DNA damage caused by ultraviolet radiation and chemical exposure.
- Base excision repair (BER) repairs damage caused by spontaneous deamination of bases, radiation, oxidative stress, alkylating agents, and replication errors.
- Mismatch repair (MMR) removes nucleotides mispaired by DNA polymerase.
- Double-stranded break repair (DSBR) is a major defense against DNA damage caused by ionizing radiation, free radicals, and chemicals.
- Many syndromes involving inherited defects in DNA repair exhibit marked increases in cancer susceptibility; strongly linking genomic instability and cancer.

CHROMOSOMAL ABNORMALITIES AND GENETIC INSTABILITY

Research by many different groups on several different tumor types has strongly implicated genetic instability as an important determinant of tumorigenesis, although the ultimate source of genetic instability in cancer is still not entirely clear (Loeb, 1991; Hartwell, 1992). As mentioned above, although certainly important in specific instances, such as inherited cancer susceptibility syndromes, deficiencies in genes involved in the replication, maintenance, and repair of DNA have not yet been shown to play a major direct role in the genesis of most sporadic human cancers. On the other hand, because there are so many proteins involved in these various pathways, it is conceivable that efforts such as the comprehensive cancer genome sequencing projects now underway may find that such defects are widespread. **Recent studies on a limited number of colon and breast cancers found that the genomes of each cancer do indeed have numerous mutations (90 mutant genes per tumor, on average) in gene coding sequences, although deciphering how many of these are truly oncogenic changes ("driver mutations") versus merely irrelevant secondary changes ("passenger mutations") remains a challenge** (Sjoblom et al, 2006).

Apart from the simple sequence alterations predicted to arise from the original mutator phenotype concept, *chromosomal* instability leads to gross changes in chromosome number and/or structure. The spectrum and severity of such chromosomal alterations may differ for different tumor types. For instance, **hematological malignancies often present with simple diploid or near-diploid karyotypes with only one or very few detectable, often balanced, chromosomal rearrangements** (see later). However, as a class these cancers only account for about 10% of all human cancers. **In stark contrast, the presence of large variations in chromosome numbers and complex structural rearrangements, as well as intratumoral variation in these aberrations, are hallmarks of most human solid tumors,** which represent the bulk of human malignancies. Important exceptions include certain tumors deficient in MMR. Thus Lengauer and colleagues (1997), observed an intriguing exclusivity between microsatellite instability (MIN) and chromosomal instability (CIN) in colorectal cancer cells. These authors proposed that while this finding supports the necessity of genetic instability in cancer, it may manifest itself in various forms.

In prostate cancer, as well as most human tumor types and transplantable tumor models, the extent of chromosomal abnormalities correlates with disease severity and aggressiveness, pointing to a role for these changes in cancer progression—running from pre-malignant lesions to localized primary tumors, and, finally, to metastatic disease to which patients typically succumb (Brothman et al, 1990; Lundgren et al, 1992; Sandberg, 1992; Isaacs et al, 1995; Bostwick et al, 1996).

The chromosomal changes seen in solid tumors can be broken down into two main classes: changes in the number of whole chromosomes and changes in chromosomal structure. Numerical chromosomal alterations can be further subdivided into changes in the numbers of specific individual chromosomes (aneusomies, e.g., monosomies and trisomies) and changes in the number of copies of the entire diploid set of chromosomes (ploidy changes, e.g., tetraploidy, octaploidy, etc.). Possible mechanisms responsible for such numerical changes include nondisjunction, endoreduplication (an abrupt doubling of the chromosome complement without cell division) cytokinesis defects, and cell fusion events. Likewise, structural changes can be subdivided into several distinct types of chromosomal aberrations as listed in Table 18–2. Over the years, painstaking dissection of chromosomal regions that are repeatedly found to undergo alteration in specific tumor types or subtypes has led to the discovery of hundreds of individual cancer-associated genes. Typically, genomic loci that are frequently lost tend to harbor tumor

Table 18–2.

Gross Chromosomal Abnormalities Frequently Observed in Cancer

Numerical Abnormalities
Aneuploidies
Abnormal numbers of whole chromosome complement (triploidy, tetraploidy, etc.)
Losses or gains of single chromosomes (monosomy, trisomy, etc.)
Structural Abnormalities
Rearrangements
Inversions
Translocations (either balanced or unbalanced)
Chromosomal fusions
End-to-end fusion = dicentric chromosome
Intrachromosomal fusion = ring chromosome
Deletions (from small segments up to entire chromosome arms)
Duplications, amplifications
Double minutes (often containing amplified sequences)
Isochromosomes (loss of one chromosomal arm, replaced by duplication of the remaining arm)
Complex (a variety of combinations of the above abnormalities)

suppressor genes, while those loci exhibiting copy number gains (e.g., gene amplification) point towards oncogenes (Snijders et al, 2005). Examples of genes frequently amplified in cancers include members of the *MYC*, *RAS*, *EGFR* and *FGF* gene families, as well as cell cycle regulatory genes such as *CCND1* (cyclin D gene), *CDK4* and *HDM2*. **Gene amplifications in cancer are usually seen either as multiple small extrachromosomal copies, called double minutes, or as amplified regions within chromosomes, so-called homogeneous staining regions or (HSRs)** (Cowell, 1982).

Specific Chromosomal Translocations Are Frequently Observed in Leukemias, Lymphomas, and Sarcomas

In contrast to numerical changes, the genesis of most structural changes requires that one or more DNA double-strand breaks occur. As outlined previously, normal cells are extremely intolerant of double-strand breaks, and if these are not resolved by HR or NHEJ repair processes, the cell typically commits suicide by apoptosis. Uncovering precisely what has gone wrong within the cancer cell that allows it to generate, as well as tolerate, such gross chromosomal changes is currently an intensive area of research.

As previously mentioned, cancer-associated chromosomal changes were recognized as early as the 1900s by Boveri, who proposed that such abnormalities might be involved in cancer causation. Much later, Klein put forth the idea that chromosomal rearrangements affect the expression of cancer-related genes located near the observed chromosomal breakpoints (Klein, 1981). This hypothesis has been validated over the ensuing years, in large part due to studies showing consistent chromosomal changes found in hematologic malignancies and soft tissue sarcomas, these studies eventually leading to the isolation and cloning of the resident genes involved (Nowell, 1994). A classic example of such a discovery is that involving the chromosomal translocation associated with chronic myelogenous leukemia (CML). An abnormal derivative chromosome, first identified by the karyotyping of metaphase chromosomes (the so-called "Philadelphia chromosome"), was found to be the result of a translocation between chromosomes 9 and 22, formally designated t(9;22)(q34;q11). This rearrangement brings together two genes, *BCR* and the *ABL* proto-oncogene, with the result that a chimeric fusion protein is expressed from the juxtaposition of these two genes (Rowley, 1990; Look, 1997). The net result is inappropriate functioning of the ABL tyrosine kinase portion of the chimeric protein product, which is an oncogenic event in the hematopoietic cell lineage giving rise to CML. A similar scenario is played out in greater than 50% of all leukemias and many lymphomas and sarcomas; involving a host of translocation partner genes. **In general, these involve the juxtaposition of known proto-oncogenes (often protein kinases or nuclear transcription factors) with other genes featuring strong tissue-specific promoters (such as an immunoglobulin or T-cell receptor locus), such that the oncogene is overexpressed or constitutively activated in the context of a fusion protein. Assaying for specific translocations has clinical utility in diagnosis, and in many cases they provide significant prognostic information as well, thus helping to guide treatment decisions** (Pui, 1995).

Specific Chromosomal Rearrangements in Genitourinary Malignancies

Recurrent Gene Rearrangements in Prostate Cancer

Although they are much less frequently observed in common adult solid tumors, recurrent translocations do occur, often amid the backdrop of a sea of numerical and structural abnormalities (Sandberg, 1985). **One of the most exciting recent findings in prostate cancer research has been the discovery of recurrent structural rearrangements in the majority of prostate cancer cases involving oncogenic ETS transcription factor family members.** The initial report by Tomlins and colleagues (2005), described the use a novel bioinformatic approach that led to the identification of recurrent gene fusions between the upstream regulatory region of the androgen-regulated gene *TMPRSS2* and *ERG*, an ETS family member previously known to be involved in Ewing sarcoma and various leukemias. These two genes reside 3 Mb apart on chromosome 21 (*TMPRSS2*, 21q22.3; *ERG* 21q22.2), and detailed molecular analysis revealed that in the majority of cases (approximately two thirds) the gene fusion occurs by deletion of the intervening sequence, with the remaining fusions due to more complex, translocation-type of rearrangements (Tomlins et al, 2005; Perner et al, 2007). In either case, **the net result is to place a known oncogenic transcription factor under the control of an androgen-regulated promoter, resulting in androgen-driven expression of the fusion transcript,** of which there are greater than 20 splice variants (Wang et al, 2008a). As expected, increased *ERG* transcription is positively correlated with presence of the gene fusion. In addition to splice variants, there are multiple forms of the genomic rearrangement, the most common one being a fusion between exon 1 of *TMPRSS2* to exon 4 of *ERG*. **These gene rearrangements can be readily detected, either by assaying for the presence of the fusion transcripts by real-time polymerase chain reaction (RT-PCR), or by assaying for the rearrangement directly by multiprobe, multi-color fluorescence in-situ hybridization (FISH), and such approaches are being evaluated for potential use in noninvasive diagnostic applications (e.g., in urine or blood).**

Since the publication of the initial report by Tomlins and colleagues (2005), several large retrospective studies have been preformed assessing these fusions in localized prostate cancers in PSA-screened cohorts. These studies confirmed the initial finding and found the prevalence of *TMPRSS2-ERG* fusion in prostate cancer to be in the range of 40% to 60%, making this one of the most common somatic genetic alteration in prostate cancer (Mehra et al, 2007; Nam et al, 2007; Perner et al, 2007; Tu et al, 2007; Wang et al, 2008a; Gopalan et al, 2009b; Mosquera et al, 2009). One intriguing exception is cancer originating in the transition zone of the prostate, which appears to completely lack *TMPRSS2-ERG* gene rearrangements (Guo et al, 2009).

As assessed by FISH in tissue sections, the *TMPRSS2-ERG* fusion has not been observed in benign prostate epithelial or stromal cells, although it has been reported to be present in high-grade prostatic intraepithelial neoplasia (HG-PIN), the presumptive precursor lesion for prostate adenocarcinoma, at frequencies between 15% to 20%, which is about one half the frequency observed in localized PSA-detected cancers (Cerveira et al, 2006; Perner et al, 2007; Mosquera et al, 2008; Han et al, 2009). This finding indicates that, at least in a subset of cases, the rearrangement may be an early event in prostate tumorigenesis. **With the important**

exceptions of transition zone cancers and HG-PIN, the prevalence and high degree of specificity of the *TMPRSS2-ERG* fusion for prostate cancer makes this a potentially useful biomarker for diagnosis and disease monitoring, one that could be used in conjunction with current markers such as serum PSA, which have limited specificity.

Apart from its promising potential as a diagnostic prostate cancer marker, it is as of yet unclear if additional clinical information might be provided by determining a patient's *TMPRSS2-ERG* gene fusion status. In 111 tissue specimens obtained by transurethral resection in a population-based Swedish cohort undergoing expectant management for prostate cancer, the presence of *TMPRSS2-ERG* rearrangement was found to be significantly associated with cancer-specific death, leading the authors to suggest that fusion positivity may mark a more aggressive form of the disease (Demichelis et al, 2007). Interestingly, the frequency of fusions detected in this cohort (≈15%) was significantly lower than the range reported for tissues obtained from radical prostatectomy in PSA-screened populations. In two other population-based studies, the frequency of fusion-positive cases ranged between 30% to 35%, higher than that found in the Demichelis study but still lower than that typically found in PSA-screened prostatectomy series, which average around 50% fusion-positivity (Attard et al, 2008a; Fitzgerald et al, 2008). Despite these intriguing reports, **the prognostic significance of fusion status in prostate cancer remains uncertain.** Thus while several studies have reported associations between *TMPRSS2-ERG* rearrangement and various indicators of disease aggressiveness, including higher stage, presence of metastases, and disease-specific mortality (Demichelis et al, 2007; Mehra et al, 2007; Nam et al, 2007; Perner et al, 2007; Rajput et al, 2007; Attard et al, 2008a; Cheville et al, 2008), other studies did not observe such associations (Yoshimoto et al, 2006; Lapointe et al, 2007; Tu et al, 2007; Dai et al, 2008; Rouzier et al, 2008; Albadine et al, 2009; Darnel et al, 2009; Gopalan et al, 2009b; Lotan et al, 2009). In addition, one study reported a link between gene fusion and *favorable* prognosis (Saramaki et al, 2008), and Petrovics and colleagues (2005) have reported that higher levels of *ERG* mRNA expression appeared to be associated positively with disease-free survival. The precise reasons for these conflicting results are not apparent. A number of variables differ between many of these studies, including the nature the study cohorts, sample sizes, methods of cancer detection, how the tissues were obtained, how the gene fusions were detected (e.g., PCR or FISH), length of patient follow-up, and the clinical end points assessed. Further research in this area is clearly warranted in order to better resolve these issues.

Following the report of *TMPRSS2-ERG* rearrangements, further study revealed additional gene fusions in prostate cancer. Thus the *TMPRSS2* gene can fuse to other ETS family member genes including *ETV1, ETV4,* and *ETV5* (Tomlins et al, 2005; Tomlins et al, 2006; Helgeson et al, 2008). These additional translocations are much rarer than the *TMPRSS2-ERG* rearrangement, which is estimated to represent greater than 90% of all fusions involving *ETS* genes in prostate cancer (Kumar-Sinha et al, 2008). In addition, fusions involving upstream fusion partners other than *TMPRSS2* have also been found, including the fusions *SLC45A3-ETV5, SLC45A3-ERG, SLC45A3-ELK4,* and *HNRPA2B1-ETV5*; however, these are also relatively rare (Mehra et al, 2007; Attard et al, 2008a; Attard et al, 2008b; Hermans et al, 2008; Maher et al, 2009; Rickman et al, 2009). **In total, greater than 70% of prostate cancers are now thought to harbor some form of recurrent gene fusion, and this number continues to increase as novel fusion partners are discovered.**

Recurrent Gene Rearrangements in Renal Cancer

Recently, a novel subtype of renal cell carcinoma (RCC), MITF/TFE family translocation carcinoma, was described that features chromosomal translocations involving one of two members of the micropthalmia transcription factor (MITF) family (Hemesath et al, 1994; Argani et al, 2005). The first involves the *TFE3* gene on chromosome Xp11.2, which translocates to one of several partner genes including *PRCC* (1q21), *ASPL* (17q25), *PSF* (1p34), *NONO* (Xq12; rearranged by inversion), and an unknown gene at 3q23 (Sidhar et al, 1996; Weterman et al, 1996; Argani et al, 2001a; Argani et al, 2001b; Argani et al, 2005; Argani and Ladanyi, 2005; Martignoni et al, 2009). These translocations place the *TFE3* gene under the control of strong promoters that then drive inappropriate expression of TFE3 (or a TFE3-containing fusion protein). In these cancers, TFE3 protein is readily detectable in the nucleus by immunohistochemical (IHC) staining with anti-TFE3 antibody, thus aiding in diagnosis. TFE3 renal cell carcinomas are primarily found in children and adolescents and account for the majority of pediatric RCC cases (Argani and Ladanyi, 2005). It has recently been reported that activation of the *MET* proto-oncogene may play a role with *TFE3* in these tumors (Tsuda et al, 2007), which is of interest because these tumors display papillary histological architecture, and mutations in the *MET* gene are the underlying cause of hereditary papillary renal cell carcinoma (Jeffers et al, 1997).

A second class of *MITF/TFE* family translocation carcinomas contain a specific translocation between the *TFEB* gene on 6p21 and the *ALPHA* gene on 11q12 (Argani et al, 2005). Like the *XP11* translocation RCCs, this entity is also most commonly found in children and adolescents and shares many other features with the *TFE3* translocation tumors. In addition to IHC staining for TFE3 and TFEB proteins, it was recently demonstrated that these tumors are also marked by staining for the protein cathepsin K, whose gene is a shared transcriptional target gene of these transcription factors (Martignoni et al, 2009). The use of such markers or PCR to detect these specific gene fusions may have clinical importance because, as the cathepsin K example shows, these tumors likely are controlled by a different transcriptional program than conventional RCC, thus therapeutic targets used against these cancers may not be effective against translocation RCCs.

Recurrent Gene Rearrangements in Testicular Cancer

In testicular germ cell tumors (TGCT), gain of the short arm of chromosome 12 is a nearly universal finding, with the notable exception of the rare spermatocytic seminoma subtype (Atkin and Baker, 1982; Rodriguez et al, 1993; Rosenberg et al, 1998; Verdorfer et al, 2004). In the majority of cases (≈80%), this occurs through a structural rearrangement producing an isochromosome 12p, that is, a version of chromosome 12 consisting of two p-arms and no q- (long) arm. In the remainder of cases 12p material is gained through more complex chromosomal rearrangements (Rosenberg et al, 2000; Ottesen et al, 2003; Looijenga et al, 2007). More detailed analyses have revealed amplification of specific regions on 12p, including the area 12p11-12p13. One common region of amplification at 12p11.2-12p12.1 contains 22 potential genes, including *KRAS*, a promising candidate TGCT gene, which also undergoes activating

mutations in TGCTs (Moul et al, 1992; Olie et al, 1995; Rodriguez et al, 2003; Zafarana et al, 2003; Goddard et al, 2007). An additional region of interest lies at 12p13.31, where the so-called "stem cell cluster region" resides. This region contains several stem cell–related genes including *CD9, EDR1, GDF3, SCNN1A, NANOG,* and *STELLAR,* which exhibit coordinate overexpression (Clark et al, 2004; Korkola et al, 2006).

Other Recurrent Structural Genomic Alterations in GU Malignancies

Apart from chromosomal translocations, which are primarily specific changes in the spatial organization of the genome, an overall derangement of the chromosomal complement is nearly universal in human cancer, particularly in carcinomas; cancers that originate from epithelial cells and represent the vast majority of adult GU malignancies. Such abnormalities are wide ranging, affecting the genome at multiple scales, including losses and gains of entire chromosomes or chromosomal arms, as well as deletions and amplifications of chromosomal regions both large and small. **These changes are generically referred to as copy number alterations (CNA) that, in addition to mutations, structural rearrangements, and epigenetic changes, are yet another reflection of the underlying genomic instability inherent in cancer cells and responsible for the large number of genetic changes required for malignant transformation.** This instability generates a great degree of genetic heterogeneity. For instance, when metaphase chromosomes of tumor cells are examined during karyotypic analysis, a bewildering array of chromosomal aberrations is typically observed, such that no two karyotypes within a given cancer cell population are exactly the same. However, within this seemingly random assortment of alterations, there are some changes that are seen in multiple different cells and multiple tumor samples, providing a strong indication that a gene (or genes) located in the region undergoing recurrent alteration is involved in the pathogenesis of the disease. Over the past several decades, using ever more sophisticated and higher-resolution molecular methods, many such changes have been cataloged and candidate cancer genes identified. Two general approaches are used here. In the first, inherited (germ-line) defects in genes that cause hereditary cancer predisposition syndromes are sought, often by performing genetic linkage analysis in affected and nonaffected family members in an attempt to find genetic loci that track in a mendelian fashion with disease status. Several familial cancer predisposition syndromes are now understood in significant detail, some featuring GU malignancies, others not (Tables 18–3 and 18–4). In the second approach, a variety of techniques are employed to discover disease-associated genes in sporadic cancers that lack a strong familial component (caused by somatic rather than germ-line genetic alterations). **The detection of copy number alterations in a particular gene (or region containing the gene), coupled with mutations in the other allele is persuasive evidence for that gene functioning as a disease-relevant oncogene**

Table 18–3.

Tumor Syndromes Associated with Genitourinary Malignancies

SYNDROME	TUMOR	CHROMOSOME(S)	GENE(S)	(FUNCTION)
Wilms' tumor	Wilms' tumor	11p13	*WT1*	(Transcriptional repressor)
Beckwith-Wiedemann	Wilms' tumor	11p15	*CDKN1C*	(Cell cycle regulator)
von-Hippel-Lindau	Clear cell renal carcinoma Pheochromocytoma	3p25	*VHL*	(Transcriptional elongation and ubiquitination)
Hereditary papillary renal cancer	Papillary renal carcinoma	7q31	*MET*	(Receptor tyrosine kinase)
Birt-Hogg-Dubé	Papillary renal carcinoma Oncocytoma	17p11.2	*FLCN*	(Unknown function)
Multiple endocrine neoplasia type II	Pheochromocytoma	10q11	*RET*	(Receptor tyrosine kinase)
Hereditary nonpolyposis colorectal cancer	Upper tract transitional cell carcinoma	2p22, 3p21.3, 2p18, 2q31-q33, 7p22, 14q24.3	*MSH2, MLH1, MSH6, PMS1, PMS2, MLH3*	(DNA mismatch repair)
Hereditary prostate cancer	Prostate cancer	1q24-25, 1p36, 1q42-43, 8p22-23, 17p11, 20q13, Xq27-28	*RNASEL, MSR1, ELAC2*	(Endoribonuclease, macrophage-specific receptor, cell cycle regulator)

Table 18–4.

Selected Tumor Syndromes Not Strongly Associated with Genitourinary Malignancies

SYNDROME	PRIMARY TUMOR	CHROMOSOME(S)	GENE(S)	(FUNCTION)
Familial retinoblastoma	Retinoblastoma	13q14	*pRB*	(Transcriptional regulation)
Li-Fraumeni	Sarcoma, breast carcinoma	17p13 22q12	*TP53* *hCHK2*	(Transcription factor, serine kinase)
Familial adenomatous polyposis	Colorectal carcinoma	5q21	*APC*	(Regulates β-catenin activity)
Familial breast carcinoma	Breast carcinoma	17q21, 13q12	*BRCA1, BRCA2*	(DNA double-strand break repair)
Cowden's disease	Breast carcinoma	10q23	*PTEN*	(Phosphatase; TPI3K antagonist)
Multiple endocrine neoplasia type I	Pancreatic islet cell carcinoma	11q13	*MEN1*	(Transcription factor)

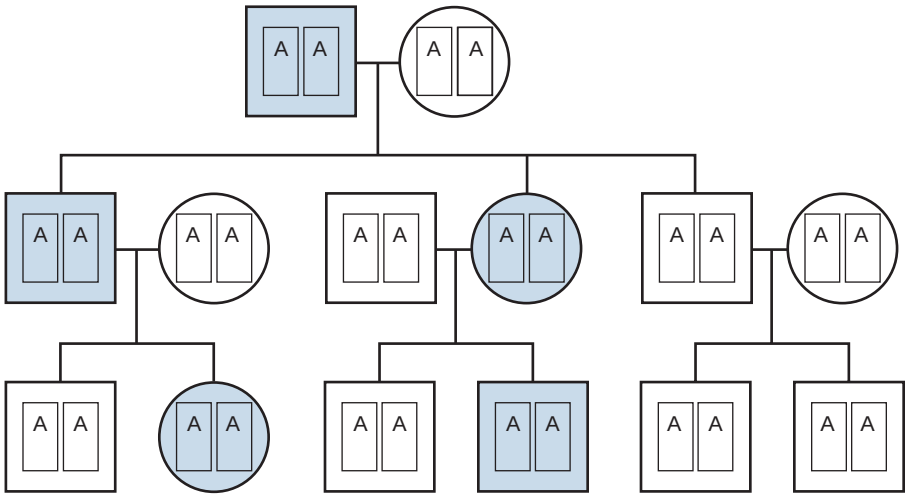

Figure 18–12. The familial tumor syndrome is passed from generation to generation. Genotyping demonstrates that the polymorphic marker A *(bold)* is passed also from generation to generation in concert with the phenotypic disease. Presumably, a gene responsible for the syndrome is located near marker A. Linkage analysis is complicated by incomplete penetrance (not all members of the family with the allele get the disease), phenocopies (family members who have sporadic disease), inability to get DNA from all family members, and the large number of markers being simultaneously analyzed.

(with activating mutations) or tumor suppressor gene (featuring inactivating mutations). In the case of cancer-related genes identified in hereditary predisposition syndromes, one hopes that alterations of genes discovered in familial forms of the disease are also relevant to their more common sporadic counterparts. In a number of instances, this has been found to be the case; for example, gene abnormalities linked to certain familial forms of kidney cancer are also involved in sporadic forms of the disease. In the following sections we describe some of the recurrent genetic changes identified in familial and sporadic forms of genitourinary malignancies.

Hereditary Prostate Cancer

Family history is one of the strongest prostate cancer risk factors (Steinberg et al, 1990), and criteria defining a hereditary form of the disease have been established (Carter et al, 1993). Twin studies have estimated a heritable risk for prostate cancer of approximately 50% (Page et al, 1997; Lichtenstein et al, 2000). Initial genome-wide searches in HPC families uncovered evidence for susceptibility loci on chromosome 1q, 4q, 5p, 7p, 13q, and Xq (Smith et al, 1996). The first strong candidate locus, *HPC1,* was localized to the region 1q24.25 (Gronberg et al, 1997) and a gene, *RNASEL*, was later identified at this locus (Carpten et al, 2002; Rokman et al, 2002). Although this linkage was replicated in some studies, it was not confirmed in others (Cooney et al, 1997; McIndoe et al, 1997; Eeles et al, 1998; Bergthorsson et al, 2000). Similarly, a failure to consistently confirm linkage has plagued other candidate HPC loci/genes as well, highlighting the difficulty in conducting such studies, because prostate cancer is a relatively common disease, HPC families are contaminated with sporadic cases ("phenocopies"). Furthermore, it has become apparent that familial prostate cancer lacks the type of high-risk susceptibility genes such as *BRCA1* or *BRCA2* that are clearly linked to hereditary forms of breast and ovarian cancers (Simard et al, 2003). Among other considerations, these facts underline the need for large, well-defined HPC cohorts, making genetic studies difficult to perform. Other candidate HPC susceptibility genes include *ELAC2* (*HPC2*), macrophage scavenger receptor-1 (*MSR-1*), and *PODXL* (Tavtigian et al, 2001; Xu et al, 2003; Nupponen et al, 2004; Casey et al, 2006). It is intriguing that two of the HPC candidates, *RNASEL* and *MSR-1* are both associated with functions of the immune response, as inflammation is currently considered a likely contributor to the pathogenesis of prostate cancer (De Marzo et al, 2007b).

Traditional linkage analysis is well suited to identifying highly penetrant genetic alterations (Fig. 18–12). **The overall low yield and irreproducibility seen in HPC linkage studies has led to the conclusion that rather than being caused by a few high-impact genes, HPC is likely, instead, to be dependent upon alterations in many genes, each of which has only a modest effect** (Easton et al, 2003; Schaid, 2004).

Sporadic Prostate Cancer

In sporadic prostate cancer, initial studies found recurrent changes involving losses of genetic material at 6q, 7q, 8p, 10q, 13q, 16q, 17p, 17q, and 18q; however, in most cases, the precise genes involved have yet to be identified (Karan et al, 2003). **Changes in chromosome 8, typically loss of the p-arm and gain of the q-arm, or portions of these arms, are the most frequently observed genetic alterations.** At least two to three separate regions are deleted on 8p, implying the existence of multiple tumor suppressor genes (TSG). **8p22 is commonly deleted, with frequencies of 32% to 65% reported in primary tumors and 65% to 100% in metastases. *MSR-1* lies in this region,** and sequence variants in *MSR-1* have been found to be associated with increased disease risk; however, mutations in *MSR-1* have not been reported in sporadic prostate cancers (Xu et al, 2002a; Nupponen et al, 2004; Wiklund et al, 2009). **Another promising candidate, *TSG* on 8p, is the prostate-restricted homeobox gene *NKX3.1* at 8p21** (He et al, 1997). Mice engineered with a loss of a single allele of *NKX3.1* develop prostate hyperplasia and PIN, an example of haploinsufficiency, wherein a phenotypic effect is observed due to the loss of a single allele (Bhatia-Gaur et al, 1999; Abdulkadir et al, 2002).

8q gain, often involving the entire chromosomal arm, is the most common chromosomal abnormality found in advanced prostate cancer (e.g., hormone-refractory lymph node metastases) and is correlated with disease progression and resistance to hormone deprivation or blockade (Alers et al, 2000; Isaacs, 2002; van Dekken et al, 2003). **The proto-oncogene c-*MYC* at 8q24 is a likely candidate gene on 8q,** but the observed gains are large and more work is required to properly assess this possibility. Elevated expression of another gene in

this region, *EIF3S3*, has been documented in cancer compared to benign prostatic hyperplasia (Savinainen et al, 2004). Mouse models lend support for a linkage to *MYC*, because transgenic mice with forced prostate-specific expression of human c-*MYC* develop PIN and invasive adenocarcinomas (Ellwood-Yen et al, 2003). Furthermore amplification at the c-*MYC* locus has been reported in some human prostate cancers and is associated with a poor prognosis (Jenkins et al, 1997; Sato et al, 1999).

Chromosome 7 abnormalities are also frequently observed in prostate cancer. Aneusomy of the entire chromosome (trisomy 7) has been reported in both PIN and cancer and has been associated with advanced stage and a poor prognosis (Arps et al, 1993; Macoska et al, 1993; Alcaraz et al, 1994; Zitzelsberger et al, 1994; Qian et al, 1995). Apart from whole chromosome gains, losses involving 7q31.1 have been documented, suggesting a tumor suppressor resides here (Takahashi et al, 1995; Zenklusen et al, 1994). A potential candidate TSG in this region is *CAV1*, which encodes caveolin, whose expression is reportedly decreased in cancer (Bender et al, 2000; Wiechen et al, 2001). On the other hand, positive IHC staining for caveolin has been associated with *poor* prognosis; thus its role in prostate cancer remains unclear (Yang et al, 1999; Tahir et al, 2001). Another attractive candidate gene in this region is *EZH2*, which codes for a histone methyl-transferase involved in gene silencing. In microarray analyses *EZH2* has been found to be overexpressed in prostate cancer metastases, and its expression in primary tumors is associated with disease (PSA) recurrence (Varambally et al, 2002; Rhodes et al, 2003; Lapointe et al, 2004).

Chromosome 10 also undergoes alteration in prostate cancer, with deletions observed at 10p11.2 and 10q23-q24 (Ittmann, 1996; Trybus et al, 1996). **The tumor suppressor gene *PTEN*, a TPI3 kinase antagonist, maps to this second region and has been linked to human prostate cancer in a number of studies** (Li et al, 1997a; Ayala et al, 2004). *PTEN* undergoes homozygous (both copies) deletion, loss of heterozygosity (LOH), promoter hypermethylation, and is also mutated in prostate cancer. **Overall, *PTEN* is more frequently altered in advanced disease** (reported rates of 60% to 100%) compared with primary tumors (Cairns et al, 1997; Pesche et al, 1998; Whang et al, 1998; Han et al, 2009; Sarker et al, 2009). Interestingly, the frequency of *PTEN* LOH greatly exceeds *PTEN* mutation; therefore it is suggested that another gene or genes may be targeted for deletion in this region of chromosome 10. One possibility is the *MXI1* gene, whose protein product binds to and antagonizes c-*MYC*. In the mouse, *Pten* deficiency exhibits synergy when combined with other mouse models of prostate cancer (Di Cristofano et al, 2001; Kim et al, 2002; Chen et al, 2006).

LOH on 13q has been reported in greater than 50% of prostate cases examined. Three separate regions of loss have been identified, containing the potential cancer genes *BRCA2*, *RB1*, *EDNRB,* and *KLF5* (Cooney et al, 1996b; Hyytinen et al, 1999; Chen et al, 2003). High rates of *pRB* loss (up to 80%) have been reported in advanced cancers (Cher et al, 1996); however, the *pRB* mutation rate is relatively low, and *pRB* expression is not well correlated with the gene dosage or disease status (Bookstein et al, 1990; Kubota et al, 1995; Ittmann and Wieczorek, 1996; Kibel and Isaacs, 2000). However, Theodorescu and colleagues (1997) reported that low RB protein expression was correlated with decreased disease-specific survival in univariate and multivariate analysis.

Losses on 16q have been observed with reported frequencies ranging from 30% to 56% of prostate cancer cases, being more commonly seen in advanced cancer and also associated with a poor prognosis (Carter et al, 1990; Bergerheim et al, 1991; Suzuki et al, 1996; Elo et al, 1997; Li et al, 1999). A common region of loss at 16q22-q24 contains two likely candidate genes, the *CDH1* gene at 16q22.1, coding for the calcium-dependent cell–cell adhesion protein E-cadherin (Morton et al, 1993; Umbas et al, 1994; Murant et al, 2000; Rubin et al, 2001), and the *ATBF1* gene at 16q22, coding for an AT-sequence–binding transcription factor (Sun et al, 2005). Loss of *CDH1* has been associated with metastatic prostate cancer; however, IHC staining studies have produced mixed results, and reports of mutation or LOH of E-cadherin are lacking. Therefore *CDH1* may not be the primary target of the 16q deletion. The *ATBF1* gene, on the other hand, has been reported to be mutated in 40% of prostate cancers (Sun et al, 2005).

Reports of LOH on 6q range from 30% to 50%, with a minimal region of loss at 6q14-q22, although no strong candidate gene has been identified in this region (Cooney et al, 1996a; Hyytinen et al, 2002).

Allelic losses of a region on 17p that includes the *TP53* gene have been documented, but are relatively infrequent in primary prostate cancer compared with more advanced disease (Brooks et al, 1996). This matches findings of mutational analyses where *TP53* mutations are rarely found in primary tumors but are reported in up to 40% of advanced disease (Visakorpi et al, 1992; Bookstein et al, 1993; Navone et al, 1993). A recurrent region of loss on 17q is located near the *BRCA1* gene at 17q21; however, the identified common area of loss does not include this critical tumor suppressor gene (Brothman et al, 1995; Williams et al, 1996).

Deletions on 18q are mainly observed in advanced prostate cancer, with a common region of deletion encompassing the known cancer-related genes *DCC*, *SMAD2,* and *SMAD4* (Ueda et al, 1997; Yin et al, 2001).

Loss of the cell cycle regulatory gene *CDKN2A* on 9p21, which encodes the cyclin-dependent kinase inhibitor TP16, has been reported in 20% of prostate cancers, and at twice this frequency in advanced disease (Cairns et al, 1995; Jarrard et al, 1997). As discussed previously, this locus also contains the *TP14* and *TP15* genes as well, making it difficult to pinpoint the exact target(s) of genetic loss in this region. Reduced expression and LOH of another CDKI gene, *CDKN1B* on 12p13.1-p12 which encodes the TP27 protein, are also found in prostate cancer and are associated with more advanced disease (Guo et al, 1997; Kibel et al, 1998; Yang et al, 1998).

One additional locus that has particular relevance for prostate cancer is the androgen receptor (AR) gene located on Xq12. **The region Xq11-q13 containing *AR* is amplified in up to 30% of cases of advanced disease failing hormonal ablation therapy, in stark contrast with untreated (hormonally naive) cases that do not show *AR* amplification** (Visakorpi et al, 1995; Linja and Visakorpi, 2004; Wang et al, 2004; Mellado et al, 2009). AR mutations, which often act to broaden the receptor's ligand specificity or otherwise provide a gain of function, occur in both advanced as well as lower stage cancer, although they are rarely found in cases untreated by androgen deprivation therapy (Newmark et al, 1992; Taplin et al, 1995; Tilley et al, 1996; Culig et al, 2001; Hara et al, 2003; Gottlieb et al, 2004). Even in the absence of gene amplification, AR protein levels have been seen elevated in prostate cancer (Latil et al, 2001; Linja et al, 2001), further emphasizing the importance of AR hyperactivation in this disease.

Subsequent studies using the comparative genomic hybridization (CGH) technique—in which competitive reactions between differentially labeled tumor-derived versus normal-derived

genomic DNA highlight regions lost or gained in the tumor sample—have largely confirmed and also extended the genomic alterations previously uncovered using LOH analysis. These CGH studies indicate that the number of different alterations is increased in advanced disease and that losses are more frequent than gains in early stages of the disease, with gains and genetic amplifications more commonly seen in advanced hormone-refractory disease (Visakorpi et al, 1995; Cher et al, 1996; Nupponen and Visakorpi, 2000). Recently, Sun and colleagues reviewed all published prostate cancer CGH studies (Sun et al, 2007). Overall, 13 regions were found to be altered in at least 10% of prostate cancer cases, with 8 regions showing deletion and 5 regions showing copy number gain. An additional 6 regions (3 with gains, 3 with losses) were found to be altered in greater than 10% of advanced cancers. In agreement with earlier studies, 8p was the most frequent region of genomic loss (with a peak at 8p21.3), being observed in one third of all cases and one half of advanced disease. Likewise, 8q was gained most often (bimodal peaks at 8q22.2 and 8q24.13), being observed in one quarter of all cases versus one half of cases with advanced disease (Sun et al, 2007). The other regions commonly lost, in decreasing order of frequency, included 13q21.q31, 6q14.1-q21, 16q13-q24.3, and 18q12.1-q23, while regions exhibiting gain included 7q11.21-q32.3, Xq11.1-q23, 17q24.1-q25.3, and 3q26.23-q33. Also, in keeping with the general observation that more aggressive and advanced cancers typically harbor more genetic abnormalities than their lower-grade and lower-stage counterparts, advanced prostate cancers displayed two- to three-fold more copy number alterations.

The application of modern high-resolution methods for assessing CNA, such as representational oligonucleotide microarray analysis (ROMA) and single nucleotide polymorphism (SNP) mapping arrays, will vastly improve our ability to detect CNA, particularly smaller alterations below the resolution limit of CGH, as well as aid in the identification of the resident oncogenes and tumor suppressor genes (Lucito et al, 2003; Sebat et al, 2004; Slater et al, 2005; Zhao et al, 2005; Liu et al, 2006).

Recently, high-density single nucleotide polymorphism (SNP) microarrays have been used in genome-wide–association studies (GWAS), high-resolution–association studies examining the relationship between common DNA sequence variants (SNPs) and cancer risk. Unlike the more traditional linkage analyses of the past, the new platform is amenable to very large cohorts and is better able to detect genetic variations with small to moderate effects on disease risk (Risch and Merikangas, 1996; Jorgenson and Witte, 2007). To date, several GWAS studies have been published on prostate cancer, resulting in the identification of 20 SNPs that are associated with the risk of developing prostate cancer (Amundadottir et al, 2006; Duggan et al, 2007; Gudmundsson et al, 2007; Haiman et al, 2007; Witte, 2007; Eeles et al, 2008; Gudmundsson et al, 2008; Thomas et al, 2008; Breyer et al, 2009; Yeager et al, 2009). Interestingly, most of the SNPs are not located in or even near genes previously shown to be involved in prostate cancer pathogenesis. Notably, three independent loci were identified on 8q24, all contained within a 1-Mb DNA segment; however, no genes have yet been identified to account for these risk alleles (Cheng et al, 2008). Although the *MYC* gene is in this vicinity, it is still 200 Kb away from the nearest SNP; thus its relevance, if any, remains uncertain. Importantly, unlike the loci identified in earlier linkage studies in HPC families, the risk alleles identified in these GWAS studies have been independently confirmed. As predicted, the risk attributable to each locus is small to modest, yet, due to the large cohorts studied, each association is highly statistically significant, and each has been shown to confer risk independent of the other loci; thus these risk alleles act in a fairly additive fashion (Kote-Jarai et al, 2008; Zheng et al, 2008; Witte, 2009). However, **although men in the top decile, in terms of number of combined risk alleles, have a two- to fourfold increased risk for prostate cancer compared with the bottom decile. The numbers of men harboring such large numbers of risk alleles is small; thus these SNPs are unlikely to have utility for population screening purposes.** An important facet to these studies is that so far none of these prostate cancer risk alleles appear to be associated specifically with risk for aggressive disease (Kader et al, 2009; Wiklund et al, 2009). This is unfortunate, because the lack of strong prognostic markers is a key shortcoming in the field that desperately needs to be resolved. **The current GWAS studies all used case-control designs; therefore it will likely require new case-case studies, comparing aggressive versus nonaggressive disease, to uncover new SNPs informative for disease aggressiveness. Recently identified SNPs are therefore thought to be more likely related to prostate cancer initiation rather than to progression. One alternative approach, which has had some early success in other cancers, is to use gene expression array data to develop "gene signatures" able to predict aggressive behavior** (Cheville et al, 2008; Mucci et al, 2008; Setlur et al, 2008).

Renal Cancer

Renal cell carcinoma (RCC) includes a spectrum of subtypes and can be subdivided into at least five different categories: clear cell RCC (ccRCC), which accounts for the majority (70% to 80%) of adult cases; papillary RCC, which accounts for most of the remaining 10% to 20%; chromophobe RCC; collecting duct RCC; and the MITF/TFE family translocation carcinomas described earlier. In addition, there are more than four inherited forms of RCC. **Importantly, the genes discovered to have germ-line mutations that cause these familial forms of the disease have also been found to play important roles in sporadic RCC as well** (Coleman, 2008).

Patients with von Hippel-Lindau syndrome are predisposed to a number of tumor types, notably ccRCC (Coleman, 2008). The finding of consistent losses of 3p in this disease led to the identification of the *VHL* gene located at 3p25-p26; the germ-line mutation causes VHL disease (Zbar et al, 1987; Tory et al, 1989; Latif et al, 1993; Stolle et al, 1998). **Once the *VHL* gene was identified, its status was assessed in sporadic (nonfamilial) RCC, where it was found to be mutated in over half of sporadic ccRCC cases** (Gnarra et al, 1994; Shuin et al, 1994). To date, over 300 different *VHL* mutations have been cataloged, and ccRCC cases not harboring *VHL* mutations often undergo LOH (deletion) or silencing of the gene by promoter hypermethylation. Thus, altogether, the vast majority of ccRCCs have compromised *VHL*. **The VHL protein normally functions as part of a multiprotein complex with elonginB, elonginC, CUL-2 (cullin-2), and RBX1 (ring box-1), which exhibits E3 ubiquitin ligase activity and targets subunits of the hypoxia-inducible factor-1 (HIF-1) transcription factor for ubiquitination and subsequent proteosomal destruction** (Kibel et al, 1995; Iliopoulos et al, 1996; Pause et al, 1997; Kamura et al, 1999; Kaelin, 2002). **HIF-1 functions as a master regulator of the cellular response to low oxygen levels.** Under normal conditions, specific proline amino acid residues in

the two HIF-1 subunits, HIF-1α and HIF-1β, are hydroxylated by the oxygen-dependent proline hydroxylase enzymes EGLN1-3. This oxygen-dependent modification signals HIF-1's ubiquitination, and thus HIF-1 is rapidly turned over (Maxwell et al, 1999; Bruick and McKnight, 2001; Ivan et al, 2001; Jaakkola et al, 2001). **Under conditions of oxygen deprivation (hypoxia) the prolyl hydroxylases fail to act; thus HIF-1 is spared and accumulates, allowing its translocation to the nucleus where it activates a number of target genes,** including the glucose transporter GLUT-1, the proangiogenic growth factors PDGF and ***VEGF,*** the chemokine CXCL-1 and its receptor CXCL-4, TGF-α, and the HGF receptor MET (Wykoff et al, 2001; Igarashi et al, 2002; Hu et al, 2003; Staller et al, 2003; Linehan et al, 2007). That the HIF-1 pathway is activated in ccRCCs is supported by the highly vascular nature of these tumors and that expression of HIF-1 target genes is found to be elevated. Thus **in ccRCCs, the loss of VHL function leads to a state of "pseudohypoxia" in which the cells respond as if they are being starved for oxygen.**

Several of the genes activated by HIF-1 have been singled out for therapeutic targeting, and positive results in clinical trials have led to Food and Drug Administration (FDA) approval of some of these agents (Linehan, 2002; Hansel and Rini, 2008). For example, the monoclonal anti-VEGF antibody bevacizumab, and the small molecule kinase inhibitors sunitinib and sorafenib, which inhibit both VEGF and PDGF, have all shown improvements in progression-free survival in clinical trials for metastatic RCC, leading to FDA approval in the latter two cases (Hansel and Rini, 2008).

The VHL/sporadic ccRCC example epitomizes the potential for translational application of cancer molecular genetics, beginning with studies on a familial cancer (then translated to the sporadic form of the disease), culminating in the rational design of therapeutic agents against revealed molecular targets having a positive impact in the clinic.

A second familial form of RCC is hereditary papillary renal carcinoma (HPRC), whose cause has been pinpointed to activation of the proto-oncogene tyrosine kinase c-MET, which is the cell surface receptor for the growth factor HGF (Jeffers et al, 1997). The *MET* gene is located at 7q31-q34, which is notable because the vast majority of sporadic papillary RCC cases show trisomy of chromosome 7 (Kovacs, 1993). In addition, activating mutations, typically affecting the tyrosine kinase domain and leading to a constitutively active receptor, have also been found in sporadic cases (Schmidt et al, 1997).

A third type of hereditary renal cell cancer predisposition is Birt Hogg Dube (BHD) syndrome. Individuals with BHD most commonly develop chromophobe RCC, but other forms, such as clear cell RCC, papillary RCC, and benign oncocytomas are also observed (Pavlovich et al, 2002; Pavlovich et al, 2005). The *BHD* gene underlying the disease is located at 17p11.12 and codes for the protein folliculin (Schmidt et al, 2001). A spectrum of disruptive mutations and gene deletions support a tumor suppressor gene function for folliculin (Khoo et al, 2002; Nickerson et al, 2002; Schmidt et al, 2005; Vocke et al, 2005); however, the precise function of this protein has not been elucidated, although evidence indicates it impacts both the ERK and AKT/mTOR signaling pathways (Baba et al, 2008).

A fourth familial RCC subtype, albeit rare, is hereditary leiomyomatosis RCC (HLRCC), featuring an aggressive form of papillary RCC (Kiuru and Launonen, 2004; Merino et al, 2007; Sudarshan et al, 2007). The cause of HLRCC has been traced to the fumarate hydratase gene at 1q42.3-q43, whose protein product acts to convert fumarate to malate in the Krebs cycle. Once again, the HIF-1 pathway is implicated in RCC tumorigenesis, because the resulting accumulation of fumarate acts as a competitive inhibitor of the prolyl hydroxylase *EGLIN1-3*, preventing modification of HIF-1 subunits, prolonging their half-lives, and leading to a pseudohypoxic state, as was the case for mutated VHL. In support of this pathogenetic scheme, increased expression of VEGF and a high microvessel density have been found in HLRCC tumors (Isaacs et al, 2005; Pollard et al, 2005).

Bladder Cancer

Although first degree relatives of patients with bladder cancer are at increased risk of developing the disease, high-risk families are very rare and lack clear mendelian inheritance patterns, precluding classical linkage analysis. Bladder cancer is therefore not considered a familial disease. Instead, it has been proposed that there likely exist many susceptibility genes with small to moderate effects on disease risk (Aben et al, 2006; Kiemeney, 2008). Recent attention has therefore turned to the use of GWAS, which are better suited to the discovery of low penetrance susceptibility loci. The first such studies have been published, and reported susceptibility loci include 8q24.21, near the *MYC* proto-oncogene; 3q28, associated with the *TP53* relative *TP63;* and at 5p15.33, which is near the *HTERT* gene coding for the cancer-associated telomere maintenance enzyme telomerase (Kiemeney et al, 2008; Kiemeney et al, 2009; Rafnar et al, 2009; Wang et al, 2009a). Notably, gain of 5p15.33 had previously been identified as being associated with bladder cancer progression (Yamamoto et al, 2007), and reduced or absent *TP63* expression has been associated with disease progression and poor prognosis (Urist et al, 2002; Koga et al, 2003). An additional GWAS, reported by Wu and colleagues found a missense variant in the prostate stem cell antigen (*PSCA*) gene to be associated with bladder cancer risk (Wu et al, 2009). This mutation is predicted to result in truncation of the first nine amino acids of the PSCA protein, and earlier studies reported that PSCA mRNA and protein levels are increased in bladder cancer compared with normal urothelium, with mRNA expression serving as an independent predictor of recurrence in superficial bladder cancer (Amara et al, 2001; Elsamman et al, 2006). The increased risk of bladder cancer engendered by these risk alleles uncovered by GWAS range from 16% to 22%, and further studies are currently underway.

The majority (75% to 85%) of bladder cancer and cancer-associated lesions seen in the clinic are of superficial type (stages pTa, pTis, pT1). Recurrences following therapy are frequent, requiring diligent surveillance by urine cytology and cystoscopy, resulting in frequent resections. In addition, the risk of progression is likewise high. Accurate assessment of risk for recurrence and progression to muscle-invasive disease are critical needs for which current predictive schemes based on histopathologic features are suboptimal. Hopefully, information at the molecular level will help improve current methods of risk stratification.

Much work has been done to identify genetic alterations in bladder cancer. In general, changes observed fall into two groups, those that are mostly unrelated to clinical subtype (e.g., changes in chromosome 9 and *RAS* mutations), and those that are related to specific grades and/or stages of the disease (e.g., *FGFR3* mutations in superficial pTa disease; *TP53* and *pRB* alterations in muscle-invasive disease) (Knowles, 2008).

Greater than half of urothelial cell carcinomas of all grades show chromosome 9 alterations; commonly these

are losses of the entire chromosome or entire chromosomal arms, while LOH events of more restricted regions are also seen, leading to the current consensus that there are multiple tumor suppressor genes located on both chromosomal arms (Tsai et al, 1990; Cairns et al, 1993; Linnenbach et al, 1993). In otherwise near-diploid tumors, complete loss of one copy (monosomy 9) is the only karyoptypic abnormality seen (Gibas et al, 1984; Fadl-Elmula et al, 2000). **The region at 9p21 containing the genes for the CDKI proteins TP15 and TP16, which suppress the pRB pathway, as well as harboring the TP53-stabilizing gene *TP14*^{ARF}, is a strong candidate for the bladder cancer *TSG* locus.** This region commonly undergoes LOH or homozygous deletion in bladder cancers, including low-grade and low-stage tumors (Devlin et al, 1994; Orlow et al, 1995; Williamson et al, 1995; Berggren et al, 2003), and mutations have been associated with high-grade disease and tumor progression (Orlow et al, 1999).

At least three different regions of loss have been mapped on 9q, and candidate bladder cancer TSGs have been proposed, including the patched gene (*PTCH*) at 9q22, which shows mutations and LOH in up to 40% of cancers (McGarvey et al, 1998; Aboulkassim et al, 2003); the region termed DBC1 at 9q32-q33, which exhibits deletion and silencing in approximately 50% of cases (Habuchi et al, 1998; Nishiyama et al, 1999); and 9q34, which exhibits LOH and contains the gene *TSC1* (tuberous sclerosis gene 1), a strong candidate bladder TSG due to finding *TSC1* mutations in conjunction with LOH (Hornigold et al, 1999; Adachi et al, 2003; Knowles et al, 2003). The *TSC1* gene encodes the protein hamartin, which is a phosphorylation target of AKT and functions in negative regulation of mTOR (mammalian target of rapamycin), a downstream target of the *PI3K* pathway, which is also dysregulated in bladder cancer by inactivation of the *PI3K* antagonist *PTEN*, as well as mutational activation of the TP110 catalytic subunit of PI3 kinase; *PIK3CA* (Cairns et al, 1998; Aveyard et al, 1999; Wang et al, 2000).

Noninvasive (superficial, pTa) papillary urothelial cell carcinoma (UCC) represents a major bladder cancer subgroup at diagnosis. Apart from changes involving chromosome 9, these tumors appear relatively stable with respect to chromosomal structural changes, with losses and gains reported for approximately a dozen different chromosomal locations, most in 20% or fewer of cases examined (Koed et al, 2005; Knowles, 2008). More subtle genetic alterations in oncogenes and tumor suppressor genes also occur with varying frequencies. As recently reviewed by Knowles (2008), activating mutations in the *RAS* family of proto-oncogenes (*H-, K-*, and *NRAS*) have been reported in up to 15% of cases, mutations in *PIK3CA* in 16% of cases, and amplification/overexpression of *CCND1* and *HDM2* have been reported in 10% to 20% and approximately 30% of cases, respectively.

In addition to oncogene activation, inactivation of several tumor suppressor genes by either deletion or promoter hypermethylation has been reported in superficial papillary UCC. These genes include several genes on chromosome 9 such as *CDKN2A* (*TP16*), affected in 30% to 60% of cases; *PTCH*, the *DBC1* locus, and *TSC1*, all reportedly affected in 60% of cases (Knowles, 2008).

The most frequently altered TSG in superficial Ta disease is the fibroblast growth factor receptor 3 (*FGFR3*), with mutation frequencies approaching 90% of cases reported (Cappellen et al, 1999; Billerey et al, 2001; Sibley et al, 2001; Tomlinson et al, 2007). The most common *FGFR3* mutation is a serine to cysteine mutation at amino acid 249 that has been shown to cause constitutive ligand-independent receptor activation due to induced receptor dimerization by intermolecular cys–cys disulfide bonding (Li et al, 2006). **The frequency of *FGFR3* mutations is much lower in higher-stage, invasive bladder cancers, and mutations are lacking in the superficial Tis stage (carcinoma in situ, CIS) that have a high propensity for recurrence and progression to invasive disease.** In addition, in Ta disease there is a strong inverse correlation between mutation and tumor grade (Billerey et al, 2001). The high preferential prevalence of *FGFR3* mutations in Ta disease suggests an association with low-risk bladder cancer (Tomlinson et al, 2007). In this respect, it is noteworthy that *FGFR3* mutations are also associated with benign tumors of the skin (seborrheic keratoses) (Logie et al, 2005; Hafner et al, 2006). In a recent prospective study, Hernandez and colleagues (2006) concluded that *FGFR3* mutations are associated with a subgroup of tumors having good prognosis, and Burger and colleagues (2008) reported *FGFR3* status is useful in risk stratification for patients with high-grade non–muscle-invasive UCC. Finally, there are indications that *FGFR3* mutations and *RAS* family mutations are mutually exclusive (Jebar et al, 2005; Logie et al, 2005; Hafner et al, 2006). These findings may be rationalized by considering that *FGFR3* itself is known to activate the *RAS/RAF/MEK/ERK* pathway (Choi et al, 2001). Likewise, reports of mutational exclusivity have been made regarding *FGFR3* and *TP53*, which is only mutated in about 5% of pTa cases, and is associated with higher-grade disease (Bakkar et al, 2003; Zieger et al, 2005). Interestingly, in pT1 disease, the frequency of *FGFR3* mutations is lower, *TP53* mutation frequency is higher, and, unlike pTa disease, these mutations are not necessarily mutually exclusive (Bakkar et al, 2003; van Rhijn et al, 2004; Tomlinson et al, 2007).

Although the frequency of chromosome 9 alterations and *RAS* family mutations are comparable across all grades and stages of bladder cancer, **muscle-invasive urothelial carcinomas (stage pT2 and higher) exhibit more genetic alterations (both qualitatively and quantitatively) than lower-stage disease in keeping with the general observation that more aggressive cancers tend to exhibit evidence of greater genetic instability than their less aggressive counterparts.** Invasive bladder tumors exhibit a wide range of copy number alterations across virtually every chromosome, although the gene targets of these changes are largely unknown at present (Koed et al, 2005). In a similar vein, Blaveri and colleagues (2005), used cluster analysis of array CGH (aCGH) data to successfully separate bladder tumors of differing stages and grades from one another. In addition, a quantitative measure of the fraction of genome altered (FGA) was shown to be inversely related to patient survival time in cases with muscle-invasive cancer. Ploidy, another reflection of genomic instability, has been found to be associated with progression from noninvasive to invasive bladder cancer (Holmang et al, 2001). Mutational inactivation of *TP53* is seen in greater than 40% of invasive pT2 tumors, in sharp contrast to the low mutational rate seen in pTa disease, where *TP53* mutation is associated with risk for progression (Fujimoto et al, 1992; Spruck et al, 1994b; Uchida et al, 1995; George et al, 2007). Likewise, inactivation of *RB,* either by LOH or through *TP16* inactivation, is common in invasive bladder cancer but is infrequent in pTa tumors (Cairns et al, 1991; Benedict et al, 1999; Chatterjee et al, 2004; Shariat et al, 2004). Loss of the region of 10q harboring the *PTEN* tumor suppressor gene is also more frequent in muscle-invasive bladder cancer than in lower stage pTa tumors (Cappellen et al, 1997; Kagan et al, 1998; Aveyard et al, 1999).

Genetic Alterations in Bladder Preneoplasia

Urothelial hyperplasias with flat or papillary histomorphology have been proposed as precursors of low-grade bladder cancers, although this concept is somewhat controversial (Chow et al, 2000). In support, Hartmann et al (1999) reported that, when present, genetic alterations (assayed at 9q21, 9q22, and 17p13) in hyperplasias were also found in superficial papillary tumors from the same patient. Genetic studies on hyperplasias have reported moderate to high frequencies of chromosome 9 alterations, whereas other genetic changes that are associated with aggressive forms of bladder cancer are reportedly infrequent (Chow et al, 2000). Dysplastic urothelial lesions have been found to have frequent changes in chromosome 9, frequent aneuploidy, and approximately half are *TP53*-mutated (Hartmann et al, 2002; Mallofre et al, 2003). The prevalence of changes seen in low-grade intraurothelial neoplasia was lower than that observed in high-grade (CIS) lesions (Hartmann et al, 2002). CIS lesions (pTis) are aggressive, high-grade precursor lesions, exhibiting high rates of recurrence and progression to invasive disease. In contrast to superficial papillary lesions, CIS exhibits frequent (50% to 70% range) genetic alterations (LOH) of 4q, 8p, 11p, 13q, and 14q, in addition to several other chromosomal alterations observed at lower but still significant frequencies (Rosin et al, 1995). CIS lesions may be subdivided into primary lesions that are isolated without associated cancer and cancer-associated secondary lesions. It has been reported that chromosome 9 changes are infrequent in primary lesions, whereas the majority of secondary lesions exhibit deletions on chromosome 9 (Spruck et al, 1994b; Billerey et al, 2001; Hartmann et al, 2002; Hopman et al, 2002).

As expected, given their aggressive nature, *FGFR3* mutation rates are low in CIS, while the *TP53* pathway shows frequent alterations. *TP53* mutation occurs in over half of CIS lesions and is correlated with strong nuclear TP53 staining by IHC (Hartmann et al, 2002; Hopman et al, 2002). Nuclear *TP53* expression in transitional cell carcinoma (TCC) has been associated with increased risk of recurrence and death, independent of tumor grade, stage, and lymph node status in TCC patients (Lipponen, 1993; Sarkis et al, 1993; Esrig et al, 1994).

Genetic Alterations in Normal and Benign Bladder Urothelium

Given the propensity of bladder cancer to recur, plus that it is often multifocal, there are proposals that genetic changes may occur in broad areas of the urothelium. Such a hypothesis concurs with the "field cancerization" concept (also known as "field effect"), first put forward by Slaughter and colleagues, in 1953, to help explain the multifocal nature and high local recurrence rates of cancers of the oral cavity, as well as the finding of histologically abnormal epithelium in areas adjacent to cancer. These authors proposed that multiple cancer foci arose within a wider field of abnormal epithelium that had been preconditioned by some prior carcinogenic insult(s), a process they termed field cancerization. Genetic changes have been detected in samples of histologically normal-appearing urothelium obtained from surgical samples from cancer patients. For example, Muto and colleagues (2000) found shared instances of LOH, as well as promoter hypermethylation of the *TP16* gene, between normal-appearing and tumor areas from the same case. Likewise, Stoehr and colleagues (2005) performed LOH analyses on a large number of cases in which normal-appearing epithelium was isolated by laser capture microdissection. These authors also reported cancer-associated genetic changes in the normal-appearing urothelium which, in some cases, matched the changes found in concurrent cancers in the same case. However, caution is warranted when assessing such results, given the possibility of contamination of the normal areas sampled by small multifocal cancer lesions or by pagetoid spread of tumor cells (Junker et al, 2003). On the other hand, a study by Obermann and colleagues (2004), using interphase FISH in tissue sections detected losses involving chromosome 9 in normal-appearing cells, that, from a technical standpoint, should be effective at excluding possible confounding microscopic foci of cancer cells.

Inverted papillomas of the urinary bladder are considered benign entities. In keeping with this, they exhibit infrequent LOH at cancer-associated chromosomal loci, as well as infrequent (less than 10%) mutations of *FGFR3* (Sung et al, 2006; Eiber et al, 2007). In contrast to inverted papillomas, papillary urothelial neoplasia of low malignant potential (PUN-LMP) exhibit high rates (85%) of *FGFR3* mutation (van Rhijn et al, 2002), a genetic alteration that is strongly associated with bladder tumors of low stage and low grade, as described above. However, a study by Cheng and colleagues (2004) found frequent LOH at several loci that typically undergo LOH in advanced (greater or equal to pT2).

Molecular Genetic-Based Assays for Bladder Cancer Detection and Surveillance

The large amount of data concerning common genetic alterations in bladder cancer has been exploited to aid in detecting the presence of bladder cancer. One widely used test termed Urovysion (Vysis/Abbott Molecular, Abbott Park, IL) is a multiplex, multicolor FISH-based assay that features a cocktail of four hybridization probes that assess the status of four chromosomes (Bubendorf et al, 2001; Halling, 2003). Probes specific for the centromeres of chromosomes 3, 7, and 17 provide information on cancer-associated gains of these chromosomes, while the fourth probe is specific for 9p21, which harbors the *TP14* and *TP16* genes that are often deleted in bladder cancers. This test, approved by the FDA in 2005, is used in conjunction with standard urine cytology in diagnosing suspected cases, as well as monitoring for local recurrence in patients previously diagnosed and treated (Halling et al, 2000; Hajdinjak, 2008). In addition, the test may have utility in monitoring response in patients with superficial bladder cancer treated with intravesical bacillus Calmette-Guérin (BCG) therapy (Kipp et al, 2005), and may also be useful in distinguishing inverted papillomas from urothelial carcinoma with inverted growth pattern (Jones et al, 2007).

Currently there are six FDA-approved urine-based molecular tests for bladder cancer focused on either genetic or immunochemical targets, and many other potential markers are under development (van Rhijn et al, 2005; Herman et al, 2008; Zwarthoff, 2008; Sullivan et al, 2009). **However, notably, although these new tests improve upon standard urine cytology, they do not supplant it.**

Finally, a recent study by Wang and colleagues (2009b), reported the development of a quantitative-PCR (Q-PCR) gene signature for predicting progression in cases of non–muscle-invasive bladder cancer.

Testicular Cancer

Testicular germ cell tumors (TGCT) are a fascinating set of malignancies possessing many unique features (Oosterhuis and Looijenga, 2005). These cancers appear to originate from totipotent stem cells, with evidence strongly supporting TGCT initiation in utero, whereby abnormal primordial germ cells (PGC), or gonocytes, are blocked in their differentiation, remaining dormant until puberty. This is supported by expression in TGCT of markers closely associated with PGC, including placental alkaline phosphatase (PLAP), the stem cell factor tyrosine kinase receptor c-KIT, and the transcription factors OCT3/4 and NANOG, which are involved in maintenance of pluripotency or "stemness." The presumptive common precursors to TGCT are the intratubular germ cell neoplasia unclassified (ITGCNU), which closely resemble PGC, sharing many of the same markers (PLAP, c-KIT, OCT3/4) (Skakkebaek et al, 1987). ITGCNU, also traditionally referred to as CIS (carcinoma in situ), although this nomenclature is technically inaccurate, have a very high rate of progression to invasive disease, estimated to be essentially 100% if allowed sufficient time (Linke et al, 2005).

TGCT are classified into two main categories: seminomas and the nonseminomas. A third type, the so-called spermatocytic seminomas, is extremely rare and will not be discussed here (Ulbright, 1993). **Like the TGCT precursor ITGCNU, seminomas closely resemble PGC/gonocytes, both morphologically as well as in their expression of molecular markers** (positive expression of PLAP, c-KIT, OCT3/4, NANOG, STELLAR, and SOX-17) (Sperger et al, 2003; de Jong et al, 2008). **Nonseminomatous TGCTs resemble embryonic and extra-embryonic tissues that have undergone varying extents of differentiation.** The non-seminomas include four subtypes. Embryonal carcinomas (EC) are similar, in many respects, to embryonic stem cells, or perhaps primitive ectoderm, and express *OCT3/4, NANOG,* and *STELLAR,* as well as *SOX-2* (Gopalan et al, 2009a). Extraembryonic differentiation is apparent in the yolk sac tumors (YST) and choriocarcinoma (CC), while somatic tissue differentiation is found in the teratomas.

Beside their unique pathogenesis, TGCT are also unique in their responsiveness to treatment modalities that induce DNA damage (e.g., ionizing radiation and cis–platin-based chemotherapy). Thus the vast majority of patients are currently curable, even those with advanced disseminated disease (Einhorn, 2002). This extreme sensitivity to DNA damage is thought to be related to the origins of TGCT (their normal stem cell counterparts are poised to undergo apoptosis in response to DNA damage), and the observation that **most TGCT maintain wild-type *TP53,* and apparently intact DDR** (Kersemaekers et al, 2002; Gorgoulis et al, 2005; Bartkova et al, 2007). Interestingly, responsiveness to therapy in TGCT is the inverse of that seen in most other cancers, that is, sensitivity decreases with increasing differentiation state, such that ITGCNU are eliminated with low-dose radiation while teratomas exhibit resistance to radiation and chemotherapy.

Family history is a strong risk factor for the development of TGCT, stronger than that found in most other cancers (Forman et al, 1992; Westergaard et al, 1996; Czene et al, 2002; Mai et al, 2010). Despite this, initial reports of an association between specific losses on Yq and risk of TGCT were not later confirmed (Krausz and Looijenga, 2008). Genetic polymorphisms in CAG-tract length, which codes for polyglutamine repeats in the androgen receptor, were assessed but were not found to be associated with disease risk (Rajpert-De Meyts et al, 2002; Giwercman et al, 2004; Garolla et al, 2005). Furthermore, **linkage and more recent GWAS analyses have not revealed evidence for major TGCT-related genetic loci, implying instead the existence of multiple loci having modest influence** (Lutke Holzik et al, 2005; Crockford et al, 2006; Rapley, 2007). **However, a very recent GWAS study by Kanetsky and colleagues reported that common genetic variants at 5q31.3 and in the *KITLG* gene region (c-KIT ligand, also known as stem cell factor or steel factor) on 12q22 are significantly associated with TGCT risk,** including both seminomas and nonseminomas (Kanetsky et al, 2009).

Spontaneous (as opposed to inherited) genetic alterations have been catalogued in TGCTs. Apart from aneuploidy, there are relatively few genetic changes or gene mutations found in TGCT, giving an overall picture of a relatively low level of genetic instability, which may be in large part due to the aforementioned intact DDR and predominately wild-type *TP53* status in these cancers (Bignell et al, 2006; Greenman et al, 2007). One recurrent, nearly universal genetic alteration in TGCT (excluding the rare spermatocytic seminomas) is the previously described gain of 12p that may involve the *KRAS* gene or genes such as *NANOG* and *STELLAR,* located in the stem cell cluster region at 12p13.31. Additional evidence for *KRAS* involvement in TGCT include reports of activating mutations in up to 40% of cases, as well as increases in expression in concert with increased gene copy number. Interestingly, *BRAF* mutations have also been identified in TGCT but are seen to be mutually exclusive to *KRAS* overexpression (McIntyre et al, 2005b; Sommerer et al, 2005).

Other changes that have been reported in sporadic TGCT include gains of material on chromosomes 1, 5, 7, and X; losses on 18 in both ITGCNU as well as invasive cancer; and losses from chromosomes 4 and 13, plus gain of 2p, which were more restricted to invasive cancers (Summersgill et al, 2001).

In seminomas, recurrent gains of 4q12, 16p13, and Xq22, plus losses of 3q29, 11q12.1, and 14q13.2 have been reported (Goddard et al, 2007). The c-*KIT* gene, whose protein product is a receptor tyrosine kinase also known as CD117, is located at 4q12, and c-*KIT* amplifications have been reported in 24% of seminomas and 17% of gene-specific amplifications, but these changes were lacking in nonseminomas and ITGCNU (McIntyre et al, 2005a). Also, mutations in c-*KIT* represent the most common somatic mutations found in seminomas (25% of cases), but are rarely found in nonseminomas (Forbes et al, 2006; Coffey et al, 2008). Despite the apparent lack of c-*KIT* gene amplifications in ITGCNU, activating mutations in c-*KIT* have been reported, and IHC staining is positive for this entity as well as seminomas, while it is not seen in nonseminomas or spermatocytic seminomas (Tian et al, 1999; Przygodzki et al, 2002; Looijenga et al, 2003; Kemmer et al, 2004; Goddard et al, 2007).

Gains of 17q11.2-q21 have been reported in TGCT, and this region contains the *ERBB2* receptor tyrosine kinase gene as well as the *GRB7* adaptor protein gene. *ERBB2* ties into the RAS pathway, while GRB7 binds to and likely regulates c-KIT, ERBB2, and RAS and is reportedly overexpressed in TGCT and their ITGCNU precursor (Kraggerud et al, 2002; Skotheim et al, 2003).

The above results create an emerging picture of derangement of growth stimulatory protein kinase signaling pathways in TGCT, including activations in the RAS and KIT pathways in most seminomas and nonseminomas (Kemmer et al, 2004; Sommerer et al, 2005). Activated AKT has also been observed concomitant with **both RAS and KIT activation of the PI3K/AKT pathway** (Kemmer et al, 2004). In addition, **the PI3K antagonist PTEN is reported to**

be frequently inactivated by either mutation or deletion in both seminomas and nonseminomas, further suggesting an important role for activated PI3K/AKT pathway in TGCT (Teng et al, 1997; Di Vizio et al, 2005).

Normal PGC undergo programmed erasure of DNA CpG methylation marks and thus a loss of imprinting. Recent IHC studies using an anti–5-methylcytosine antibody to assess global methylation status in situ have confirmed and extended prior reports focusing on specific loci. These new studies found very low to absent 5-methylcytosine in the vast majority of ITGCNU and seminoma compared to robust detection of 5-methylcytosine in nonseminomas (Peltomaki, 1991; Smiraglia et al, 2002; Zhang et al, 2005; Netto et al, 2008). These results are supportive of a model for TGCT pathogenesis in which ITGCNU is derived from retained abnormal PGC that have matured to the point of 5-methylcytosine erasure, but prior to the point in normal PGC development where epigenetic marks are reestablished by de novo DNA methylation. Notably, such observed changes in global methylation do not necessarily rule out the existence of hypermethylation at specific gene promoters. For instance, epigenetic silencing of specific genes, such as the tumor suppressor *RASSF1A*, has been reported in seminoma (Koul et al, 2002; Honorio et al, 2003).

Key Points: Chromosomal Abnormalities and Genetic Instability

- Large variations in chromosome numbers and complex structural rearrangements, as well as intratumoral heterogeneity in these aberrations, are hallmarks of most human solid tumors.
- The extent of chromosomal abnormalities typically correlates with disease severity and aggressiveness.
- Recurrent structural rearrangements occur in prostate (*ETS* family gene fusions), renal (*MITF/TFE* family translocation carcinomas), and testicular cancers (isochromosome 12p).
- Copy number alteration in a particular gene, coupled with changes in the other allele is strong evidence for that gene functioning as a disease-relevant oncogene or tumor suppressor gene.
- Genes discovered to have germ line mutations that cause familial forms of cancer may also be involved in the sporadic form of the disease (e.g., *VHL* in ccRCC).
- High-density single nucleotide polymorphism (SNP) microarrays have been used in genome-wide association studies (GWAS) to identify DNA sequence variants associated with cancer risk.

TELOMERES AND TELOMERASE

As we have seen, **cancer cells exhibit marked genetic, morphologic, and behavioral heterogeneity, a reflection of their underlying genetic instability. In addition, most cancers display a strong positive association with increasing age.** As discussed previously, it has been persuasively argued that an increase over the extremely low baseline mutation rate (a mutator phenotype) is needed for accrual of sufficient mutations to bring about malignant transformation (Loeb, 1991).

Cancer genomes exhibit clear evidence of instability; however, defective DNA maintenance and repair genes do not appear to be major contributors to the development of most sporadic cancers. Thus the source of the genetic instability involved in the majority of cancers has been unclear. This has been particularly true of chromosomal instability, a nearly ubiquitous feature of carcinomas. Although alterations in chromosome number may arise through defects in centrosomes or the mitotic spindle checkpoint, very little information exists regarding the origins of structural chromosomal abnormalities (Pihan et al, 2003; Roh et al, 2003). **An attractive candidate for the source of chromosomal instability in cancer is telomere dysfunction. Telomeres may provide a common link between genetic instability, cellular proliferation, and ageing** (Shay, 1997; DePinho, 2000).

Telomeres and Chromosomal Instability

Telomeres are structures composed of specialized repetitive DNA complexed with telomere-specific binding proteins, located at the ends of every human chromosome where they function to stabilize and protect the ends (Blackburn, 1991). Telomeric DNA is noncoding and consists of tandem repeats of the 6–base pair sequence TTAGGG (Moyzis et al, 1988; Meyne et al, 1989). In normal human cells, telomere lengths typically range from 6 to 12 kilobases per chromosome. **Telomeres that are too short are dysfunctional ("uncapped"), causing chromosomal destabilization** (Karlseder, 2003; Saldanha et al, 2003).

Importantly, telomeres are dynamic; shortening by approximately 100 base pairs each time a cell divides due to inability of DNA polymerases to completely replicate terminal DNA sequences (Harley et al, 1990; Lindsey et al, 1991). **Thus telomere length is inversely correlated with the number of times a cell has divided** (Hastie et al, 1990; Levy et al, 1992). Telomere shortening may also occur due to unrepaired single-strand breaks caused by oxidative damage to telomeric DNA (Kruk et al, 1995; von Zglinicki et al, 2000). Conversely, telomeres may be elongated through the action of the telomere synthetic enzyme telomerase or, uncommonly, by a poorly characterized telomerase-independent genetic recombination mechanism termed alternative lengthening of telomeres (ALT) (Greider and Blackburn, 1985; Reddel et al, 2001).

Chromosomes with short, dysfunctional telomeres are prone to fusion, leading to the formation of dicentric chromosomes that mis-segregate or break in mitosis during anaphase. The newly generated chromosomal breaks are themselves fusogenic, thus perpetuating a cycle of chromosome fusion and breakage (McClintock, 1941; Lo et al, 2002). In this way, critically short telomeres initiate chromosomal instability (Artandi et al, 2000; Feldser et al, 2003; Vukovic et al, 2007). **Numerous studies support the link between telomere dysfunction and chromosomal instability in human cancers.** For example, in head and neck tumors, chromosomes bearing severely short telomeres are associated with chromosomal fusions, rearrangements, anaphase bridges, and multipolar mitoses (Gisselsson et al, 2000).

Telomere Shortening Acts as a Tumor Suppressive Mechanism in Normal Cells

Normal cells closely monitor their telomere lengths. Moderate telomere shortening either signals entry into an irreversible cell cycle arrest termed replicative senescence, or initiates programmed

cell death—responses thought to have evolved as tumor suppressive barriers against abnormal clonal expansion and the development of excessive telomere shortening that would accompany further cell division, were it allowed to continue (Wright and Shay, 2001). Thus **progressive telomere shortening acts as a "mitotic clock," counting down cell divisions and signaling cell cycle exit once one or more telomeres reaches a threshold length** (Harley et al, 1990).

Forced expression of the enzyme telomerase in presenescent cells counteracts telomere shortening, thus preventing replicative senescence and endowing the cells with unlimited cell division potential or "immortalization" (Bodnar et al, 1998; Vaziri and Benchimol, 1998). In normal somatic human cells, telomerase activity is stringently repressed; thus telomere length will decrease in proliferating cells and can be used as a signal to halt further expansion. **Although the precise mechanism(s) by which short telomeres trigger senescence and apoptosis are still under study, evidence, to date, implicates the tumor suppressors TP53 and pRB as being involved in the response to shortened telomeres** (Vaziri and Benchimol, 1999). Importantly, abrogation of this telomere length checkpoint allows continued cell division and, in the absence of telomerase, severe telomere shortening beyond the minimum length required for proper telomere function, therefore causing telomere uncapping and chromosomal destabilization (Counter et al, 1992).

In summary, **telomere shortening presents two important barriers to incipient cancer cells. First, moderate shortening instigates the senescence cell cycle exit. Second, extreme telomere shortening causes chromosomal instability that, although it increases the mutation rate, will also tend to result in lethal genetic abnormalities** (Fig. 18–13).

Cancers and Premalignant Lesions Possess Abnormally Short Telomeres

The majority of human cancer tissues and cancer-derived cell lines examined to date have been found to contain abnormally short telomeres (Hastie et al, 1990; Mehle et al, 1996; Takagi et al, 1999; Furugori et al, 2000; Remes et al, 2000). For example, prostate carcinomas typically have shorter-than-normal telomeres. Using a Southern blot technique for bulk telomere length assessment, Koeneman and colleagues (1998) and Sommerfeld and colleagues (1996) observed telomere shortening in primary prostate cancer tissues compared with matched adjacent or nearby normal-appearing and benign proliferative hyperplasia (BPH) areas in radical prostatectomy specimens. Furthermore, results from direct telomere length assessment in archival tissue samples using FISH are also in agreement with the previous telomere length analyses, with shorter telomeres found in prostate cancer cells when compared with their normal epithelial cell counterparts within the same tissue samples (Meeker et al, 2002a).

When examined using high-resolution telomere-specific FISH, it has been found that **pre-malignant lesions, including those of bladder and prostate cancer, tend to have abnormally short telomeres** (van Heek et al, 2002; Meeker et al, 2004; Meeker and Argani, 2004; Hansel et al, 2006; Kawai et al, 2007). This finding indicates that **telomere loss occurs early in the disease process**, at the intraepithelial neoplasia (IEN) stage, **strongly implying a causal role for telomere shortening in carcinogenesis through the initiation of chromosomal instability** (O'Shaughnessy et al, 2002). In the prostate, the premalignant precursor is high-grade prostatic intraepithelial neoplasia (HGPIN) (Bostwick et al, 1996), the majority of which (93%) were found to harbor abnormally short telomeres by FISH (Meeker et al, 2002b). Notably, in this study,

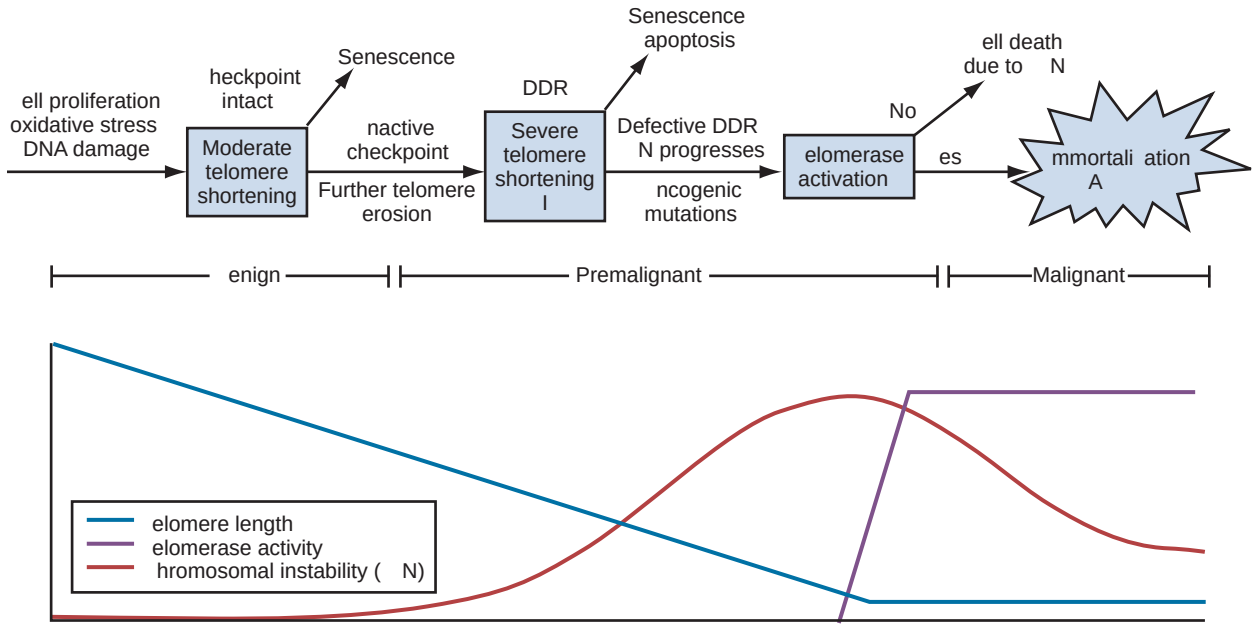

Figure 18–13. Contributions of telomere loss and telomerase activation to oncogenesis. Bypass of the normal telomere length-sensitive cell senescence checkpoint allows severe telomere loss that initiates chromosomal instability (CIN). Defective DNA damage response (DDR) allows CIN to continue, generating potentially oncogenic mutations but also producing intolerable levels of genomic damage. Transformed cells may proceed through this second barrier by activating telomerase, which stabilizes the telomeres and also provides an unlimited proliferative potential ("immortalization").

telomere shortening in HGPIN foci was restricted to the *luminal* secretory epithelial cells only, while the underlying basal epithelial cells and surrounding stromal cells displayed normal telomere lengths. In a separate independent study, Vukovic and colleagues (2003), reported significant shortening in 63% of HGPIN overall, with a higher rate of telomere shortening (80%) reported for foci situated near (within 2 mm) adenocarcinoma within the same tissue sample. When studying a cohort of men with a diagnosis exclusively of HGPIN (using prostate needle biopsies), Joshua and colleagues (2007), reported an association between short telomeres in the PIN lesions, or surrounding stromal cells, and eventual diagnosis of prostate cancer, as well as time to diagnosis.

The level of telomere shortening observed in PIN exceeds that which would normally elicit a cell cycle checkpoint response, thus implying that the telomere checkpoint tumor suppression system is defective in PIN lesions. Similar levels of telomere shortening have been correlated with markers of chromosomal instability in other organ systems (O'Sullivan et al, 2002; Meeker et al, 2002b; Meeker and Argani, 2004; Montgomery et al, 2004). One candidate element of an abrogated checkpoint response in PIN is 13-3-3-sigma. This protein is normally induced by *TP53* in response to DNA damage and leads to G_2M cell cycle arrest (Hermeking, 2003). Lodygin et al (2004), found the promoter of this gene to be hypermethylated in prostate cancer cell lines and 100% of primary prostate cancers assayed. Decreased 13-3-3-sigma protein expression was also seen in 91% of prostate cancers, while normal, atrophic, and BPH areas showed high levels of expression in both luminal and basal epithelial cells. Interestingly, 13-3-3-sigma protein expression levels were also low in the luminal cells of PIN lesions, whereas basal cells retained robust expression, matching the aforementioned pattern of telomere shortening seen in HGPIN (Lodygin et al, 2004). **Because the majority of PIN lesions are not thought to progress to invasive cancers, intact telomere-based replicative senescence or apoptosis checkpoints may represent a critical bottleneck restraining the outgrowth of most PIN lesions. Even if incipient cancer cells manage to abrogate these checkpoints, as described below, they would still need to activate telomerase to avoid intolerable levels of genetic instability and provide an immortalized phenotype.**

A consideration of telomere biology as outlined above leads to the conclusion that telomeres can play opposing roles in the development of cancer. On the one hand, telomere shortening places strict limits on the proliferative capacity of a given cell lineage, thus serving to prevent the expansion of potentially malignant (initiated) cells. This is supported by mouse models engineered with combinations of telomere dysfunction and cancer predisposition, where the overall tumor incidence is decreased in the short telomere background (Karlseder et al, 1999; Farazi et al, 2003; Wong et al, 2003). On the other hand, critically short telomeres can promote carcinogenesis by initiating chromosomal instability (Artandi et al, 2000; Feldser et al, 2003). In keeping with this, the frequency of *initiated* lesions is increased in the aforementioned combined mouse models, despite the decrease in overall tumor incidence (Karlseder et al, 1999; Farazi et al, 2003; Wong et al, 2003). The deciding factor in determining which of these opposing outcomes wins appears to be the status of the cellular checkpoint pathways that monitor telomere length. Thus, telomerase deficient mouse models support a tumor suppressive role for telomere shortening only if cellular checkpoints are intact; particularly the Tp53 tumor suppressor pathway. Research on mice doubly deficient for telomerase and Tp53 has revealed a key role for dysfunctional telomeres in the development of epithelial cancers in the setting of defective checkpoints, and tumors arising in such a background of short dysfunctional telomeres display the types of complex karyotypic abnormalities typically seen in human carcinomas but usually lacking in mouse models of human cancer (Artandi et al, 2000; O'Hagan et al, 2002).

The root cause of the telomere shortening that occurs during malignant transformation in humans is unknown. Because telomeres shorten during cell division, one possibility is that telomeres are progressively lost through normal division as cells are replaced during ageing. This would help explain the strong dependence of cancer on age (Hsing et al, 2000). On the other hand, in an organ such as the prostate, the normal rate of cell division is relatively low; thus it may be that other processes serve to accelerate cell turnover and/or telomere loss. One such process may be inflammation, a common histologic finding in the prostate that also increases with age (De Marzo et al, 2007a). Locally, the inflammatory response generates genotoxic chemical species such as oxy-radicals as part of the host defense mechanism against pathogens. Exposure to these chemicals causes co-lateral host cell killing leading to compensatory proliferation in order to replace the lost cells. Furthermore, oxidative stress itself is able to cause rapid loss of telomere DNA (von Zglinicki, 2002). Additionally, **chronic inflammation not only increases cell turnover and perhaps telomere loss, but the accompanying genotoxic stress may impair telomere-sensitive senescence/apoptosis checkpoints, as well as DNA damage-sensitive checkpoints, perhaps in cells whose genomic protection is already crippled**—for instance, due to epigenetic downregulation of glutathione-S-transferase Pi (Nakayama et al, 2003; Nelson et al, 2003).

Telomerase Activity Restabilizes Chromosomes and Allows Unlimited Replication

Although dysfunctional telomeres may help initiate cancer formation, if left unchecked continued telomere shortening in premalignant lesions and cancers would cause increasing levels of genetic instability ultimately becoming lethal to the tumor. Cancer cells overcome this problem by restabilizing their telomeres, primarily through activation of the enzyme telomerase, a specialized reverse transcriptase that adds back telomere DNA repeats to chromosome ends (Greider and Blackburn, 1987). Telomerase provides at least two critical functions to the tumor cell—namely, quelling chromosomal instability and supplying the capacity for unlimited replication ("immortalization") (Shay and Wright, 1996; Greider, 1998). Research has revealed that telomere length maintenance appears to be a necessary step for human cells to become malignant; confirming the long-held belief that cellular immortalization is a key attribute of cancer cells (Hahn et al, 1999; Elenbaas et al, 2001). Thus **at least 85% of human epithelial cancers have measurable telomerase activity** (Kim et al, 1994; Meeker and Coffey, 1997; Shay and Bacchetti, 1997). **In contrast to cancer cells, telomerase activity is stringently repressed in most normal human somatic cells, thus allowing telomere loss to act as the counting element of the tumor-suppressive mitotic clock** (telomere length checkpoint) (Shay, 1997; Harley, 2002). A subset of normal cells do express some telomerase, including activated lymphocytes; subpopulations of highly proliferative tissues, such as in the hematopoietic system

and testes; and proliferative zones in renewal tissues, such as the intestinal crypts and the basal layer of the skin and cervix, plus hormonally-responsive cells of the female breast and endometrium, as well as the prostate (Broccoli et al, 1995; Harle-Bachor and Boukamp, 1996; Hiyama et al, 1996; Meeker et al, 1996; Weng et al, 1996; Wright et al, 1996; Yasumoto et al, 1996; Kyo et al, 1997). Notably, the activity detected in these normal tissues is either transient or much weaker than that found in malignant tumors of the same tissue of origin.

Although telomerase activity appears to be the preferred way cancer cells stabilize their telomeres, approximately 15% of human cancer cases lack detectable telomerase activity. At least a subset of these, particularly certain tumors of mesenchymal origin, maintain their telomeres through a telomerase-independent pathway known as alternative lengthening of telomeres (ALT), the details of which are still being uncovered (Reddel, 2003).

Several studies have reported on telomerase activity in clinical prostate samples, with positivity ranging from 47% to 100%, whereas normal and BPH tissues taken from prostates without evidence of cancer are typically negative for telomerase activity (Kim et al, 1994; Sommerfeld et al, 1996; Engelhardt et al, 1997; Kallakury et al, 1997; Lin et al, 1997; Koeneman et al, 1998; Zhang et al, 1998; Wullich et al, 1999; Caldarera et al, 2000; Kamradt et al, 2003). Although two of these studies found a positive correlation between either the presence or level of telomerase activity and tumor grade, four other studies found no correlation with grade, stage, or preoperative PSA levels. However, the number of cases in many of these studies was small. Furthermore, the situation is complicated by the observation that a tumor initially lacking telomerase could conceivably acquire it at a later time.

Telomerase Activity as a Potential Diagnostic Marker

Although there are potential confounding factors when assaying telomerase activity (e.g., activity in activated lymphocytes, intratumoral heterogeneity of activity, etc.), the high prevalence and relatively strong activity found in prostate cancers compared with normal tissue, plus the very high sensitivity of the standard telomerase activity assay has led to evaluation of the telomerase activity assay as a potential diagnostic marker for prostate cancer. In the prostate, activity assays have been performed using prostate needle biopsy samples (Scates et al, 1997; Takahashi et al, 1997; Lin et al, 1998; Bertaccini et al, 1999; Muller, 1999; Wymenga et al, 2000; Chieco et al, 2001; Wang et al, 2001). In these studies, activity was detected in over half of all cancer cases (range 58% to 91%), with most reporting telomerase activity in greater than 80% of cases with cancer. In two of five studies that also tested normal prostate tissue, no activity was detected in normal tissue. However, the remaining three studies found activity in 11% to 17% of samples lacking prostate cancer. Likewise, two studies that included BPH tissues detected activity in 12% and 38% of cases, although, in the former, the activity seen was very weak, and cancer was later detected in these patients by repeat biopsy (Wymenga et al, 2000). This study also found a trend for increased activity levels in cancers of higher Gleason grade, although this did not reach statistical significance in this small study. Lin and colleagues (1998) and Wang et al (2001) also noted a positive correlation between either activity levels or telomerase detection rates and pathologic grade. Using a split biopsy approach, Lin and colleagues (1998), showed that differences in activity levels they observed were not simply due to different amounts of cancer in the needle biopsy samples. Similarly, using a touch preparation method, Chieco and colleagues (2001) found no association between activity detected and either area of cancer or extent of inflammation on the needle biopsy.

In addition to tissue biopsy samples, noninvasive detection of telomerase enzyme components and enzymatic activity has been attempted. Overall, the potential utility of aiding cancer diagnosis appears limited, primarily due to problems with both false-negative and false-positive results seen with the technically demanding assay. False-negative results may occur due to inactivation of the labile enzyme during isolation, while false-positive results may stem from the presence of inflammatory cells in the sample (Meeker and Coffey, 1997). One avenue showing some early promise is the detection of bladder cancer in voided urine and bladder washings. Bladder cancer diagnosis and surveillance is currently conducted by a combination of cystoscopy and urine cytology; however, cytology provides suboptimal sensitivity in low-grade disease. Detection of telomerase components by RT-PCR in urine provides some improvement in the sensitivity and specificity compared with urine cytology in bladder cancer detection, particularly in low-grade disease (Eissa et al, 2007). However, van Rhijn and colleagues (2005) recently reviewed the literature on urinary molecular markers for bladder cancer detection and concluded that other markers (e.g., microsatellites, FISH, and cytokeratin 20) outperform telomerase.

In an intriguing study, Wu and colleagues (2003) **found that shorter telomeres in peripheral blood leukocytes (PBL), as measured with telomere-specific Q-PCR, were associated with increased risk for a number of cancers, including bladder and renal cancer**. Similar associations between short telomeres and bladder cancer risk were observed when telomere lengths were measured in either buccal cells or PBL (Broberg et al, 2005; McGrath et al, 2007). **However, no association was observed between PBL telomere length and prostate cancer risk in a recent study** (Mirabello et al, 2009). Interestingly, a recent report by Svenson and colleagues found that patients with the longest PBL telomeres had a significantly worse prognosis compared with patients with shorter PBL telomeres (Svenson et al, 2009). The variations in the PBL telomere lengths measured in these studies are thought to be due to inherited interindividual differences in telomere lengths modified by changes occurring postnatally, perhaps due to diet and lifestyle factors. It is often assumed that telomere lengths obtained in PBL reflect those in other tissues throughout the body, although this remains to be rigorously shown.

Potential Prognostic Value of Telomere Length in Prostate Cancer

Telomere shortening has been found to be predictive of poor prognosis in several cancers including those of the lung, endometrium, breast, and neuroblastoma (Smith and Yeh, 1992; Hiyama et al, 1995a; Hiyama et al, 1995b; Griffith et al, 1999; Bisoffi et al, 2006). A potential link between telomere length and prostate cancer prognosis was first reported by Donaldson et al (1999), using a slot blot method devised by Bryant and colleagues (1997), which measures relative telomeric DNA content, a surrogate for telomere length. In this retrospective case-control study, both biochemical recurrence and overall survival were significantly correlated with tumor telomere content. Specifically, all seven prostatectomy patients, whose tumor telomeric DNA contents were less than that of control samples (placental DNA),

showed evidence of biochemical recurrence (elevated PSA) within 10 years after surgery (Donaldson et al, 1999). Of the nine patients with short tumor telomeres, seven died within 10 years, in contrast with 100% ten-year survival for patients with normal-to-long tumor telomeres. Additionally, these patients also showed no evidence of biochemical recurrence. Potential drawbacks of this study include a small sample size (18 cases; only seven of nine men in the short telomere category underwent surgery), and that it was not known whether the deaths observed were due specifically to prostate cancer. In a more recent retrospective study using 77 prostatectomy samples and a more sensitive chemiluminescent slot blot assay, Fordyce and colleagues (2002) reported that less-than-normal telomere content in primary prostate cancers was associated with recurrence, independent of patient age, grade (Gleason sum), and regional lymph node status (Fordyce et al, 2005). The magnitude of the relative hazard for disease recurrence associated with low telomere content (RH = 5.02) was on par with that of Gleason grade and nodal status. Interestingly, a positive correlation was found between telomere content of the tumor and that of the surrounding normal-appearing prostate tissue within the same prostatectomy samples. An association was also found between telomere content of these normal-appearing prostate tissues and 72-month recurrence-free survival. The authors postulated that telomere loss in morphologically normal tissue represent areas at heightened risk for genetic instability. This is reminiscent of the so-called "field effect" phenomenon that has long been discussed in the cancer literature (Crissman et al, 1993; Bostwick et al, 1998; Foster et al, 2000; Yuen et al, 2004). The authors further proposed that cancers arising in such areas may show greater genotypic and phenotypic heterogeneity, and thus be more prone to behave aggressively due to a greater level of chromosomal instability caused by short telomeres (Fordyce et al, 2005).

Telomerase-Based Opportunities for Therapy

Because the majority of human tumors rely on telomerase for immortalization and genomic stabilization, this enzyme is an attractive target for anticancer therapy. There are two overall strategic paradigms for therapeutic targeting of telomerase in cancer. The first involves taking advantage of the tumor's dependence on telomerase enzymatic activity for survival. This strategy includes approaches aimed at directly inhibiting telomerase enzymatic activity or blocking its expression. The second approach attempts to exploit the observation that the telomerase gene (*HTERT*) promoter is selectively active in cancer cells. For example, the telomerase promoter could be used to drive oncolytic virus or gene therapy vectors and thus limit their replication or expression to tumor cells. Also, immunotherapy could be directed against cells expressing HTERT protein.

Many of these approaches have undergone preclinical testing using prostate cancer cell lines and xenografts, and some are currently in early clinical trials. One point of concern with anti-telomerase therapies relates to their selectivity of action against tumor cells versus normal telomerase-positive cells, such as the stem cells of the hematopoietic system and those within tissues with high turnover rates. This is of particular importance for those approaches in which telomerase-positive cells are actively targeted for destruction, including immunotherapy, gene therapy, and oncolytic viral therapies. Encouragingly, work to date describing the treatment of human tumor xenografts in mice have, in general, not produced major toxicity in normal tissues.

Key Points: Telomeres and Telomerase

- Telomeres contain stretches of terminal, noncoding, repetitive DNA that cap the ends of each chromosome, thereby stabilizing them.
- Telomere DNA repeats are progressively lost as cells divide and as a result of oxidative DNA damage at the telomeres.
- Normal cells monitor their telomere lengths and permanently exit the cell cycle (cellular senescence) or commit suicide (apoptosis) in response to telomere shortening. This tumor-suppressive telomere length checkpoint involves *TP53* and *pRB*.
- Loss of telomere length checkpoints can lead to critical telomere shortening that initiates chromosomal instability, thus contributing to carcinogenesis.
- A majority of cancers and premalignant lesions have abnormally short telomeres.
- Most cancers express the enzyme telomerase, which restabilizes the telomeres and allows unlimited cell division potential ("immortalization"), thus telomerase represents an attractive therapeutic target.

APOPTOSIS

Apoptosis, also known as programmed cell death, is a tightly regulated process used by multicellular organisms to eliminate unwanted cells. For example, apoptosis is used in tissue remodeling during development, and in the immune system to eliminate self-reactive T cells (Kerr et al, 1972; Ashkenazi and Dixit, 1998). **Apoptosis contrasts sharply with necrosis, a nonprogrammed form of cell death** in which cells that are acutely injured (e.g., by physical trauma) swell and burst, abruptly releasing their contents, which act as potent inducers of the inflammatory response. **Apoptosis is a more orderly, energy-requiring process in which the dying cell's contents are degraded and neatly packaged into so-called apoptotic bodies, which are then engulfed by neighboring cells or macrophages, a process which does not elicit a strong inflammatory response** (Fadok et al, 1992).

Apoptosis and Cancer

Unlike unicellular organisms, cancer poses a risk to multicellular life forms; thus a variety of abnormalities linked to tumorigenesis can signal a cell to eliminate itself as a potential threat by apoptosis. For example, if a cell suffers DNA damage (potentially mutagenic), but fails to make repairs, it will be eliminated and replaced from the organism's pool of undamaged cells. **Depending on the location, environment, or extent of damage, apoptosis may even be the primary response to DNA damage** (Evan and Littlewood, 1998). Other potentially oncogenic abnormalities that can signal apoptosis include excessive *E2F* transcriptional activity, loss of cell contact to other cells and the basement membrane, hypoxia and activated oncogenes (e.g., c-*MYC*). Therefore, it is not surprising that aberrations of apoptosis can be detrimental, and that failure of dividing cells to initiate apoptosis contributes to cancer (Ashkenazi and Dixit, 1998).

Abnormalities in the apoptotic machinery have implications for malignancy beyond an individual cell's ability to respond appropriately to cell physiologic stresses such as DNA damage. First, **the apoptosis cascade is critical to the immune system's**

ability to eliminate cancer cells (Nagata, 1997). This has clear implications for both the organism's intrinsic immunosurveillance for malignancy and the tumor's response to extrinsic immunotherapy. Second, because cytotoxic cancer therapies depend in large part on inducing apoptosis, **defects in the apoptotic cascade can profoundly influence tumor responses to chemotherapy and radiotherapy** (Walton et al, 1993; Bostwick et al, 1998; Thornberry, 1998).

Apoptosis Is an Evolutionarily Conserved Process

Apoptosis is tightly regulated by an evolutionarily conserved system of positive and negative signals, the balance of which determines whether the cell will undergo apoptosis. These signals ultimately converge upon an important family of proteases named caspases ("cysteine proteases with aspartic acid specificity"), key components of the apoptotic machinery (Thornberry and Lazebnik, 1998). Caspases, of which there are at least 13, are **broadly categorized as either initiator caspases (e.g., caspases-8, -9, and -10) or executioner caspases (e.g., caspases-3, -6, and -7).** Caspases are synthesized as larger, inactive forms called procaspases, which **require specific proteolytic cleavage to become active proteases themselves.** Often a procaspase is activated by another caspase, setting in motion a sequential, amplifying, proteolytic cascade. **Initiator caspases begin the cascade that ultimately leads to activation of executioner caspases downstream. Once activated, the executioner caspases attack several intracellular protein targets.** One of the initial targets of executioner caspases is procaspase-8, activation of which serves to accelerate the apoptotic process by a positive feedback loop. Executioner caspases cleave antiapoptotic proteins, such as BCL-2 and BCL-X_L, which not only destroys their antiapoptotic function but actually releases proapoptotic carboxyl-terminal fragments, further stimulating cell death (Wolf and Green, 1999). Executioner caspases then target proteins critical to cell survival, from DNA to the extracellular matrix. Cleavage of DNA repair and replication proteins, such as DNA-PK_{cs} and replication factor C, leads to nuclear dysregulation. Nuclear structural proteins such as lamins NuMA and SAF-A are fragmented, contributing to dissolution of the nucleus and nuclear condensation, a hallmark of apoptosing cells. Proteolysis of cytoskeletal proteins, such as fodrin, keratin, and actin, leads to destruction of the internal structural integrity of the cell. Lastly, cleavage of proteins critical to cell–cell interaction, such as β-catenin and focal adhesion kinase (FAK), precipitates the specific and irreversible phenotypic changes associated with apoptosis (Orth et al, 1996; Wen et al, 1997; Wolf and Eastman, 1999). **The end result is a stereotypical death in which the cytoplasm shrinks, the cell membrane blebs, and the nuclear chromatin condenses. The entire apoptotic process can be completed in just 60 minutes** (Thornberry, 1998).

Intrinsic Apoptotic Pathway

Apoptosis can be initiated by two different routes: the intrinsic and the extrinsic apoptotic pathways (Fig. 18–14). **The intrinsic apoptotic pathway monitors conditions within the cell, responding to various forms of stress.** Proapoptotic signals may arise due to unrepaired DNA damage or from a lack of prosurvival signals transduced from cell-surface receptors, such as when cell–cell or cell–extracellular matrix (ECM) contact is disrupted or soluble factors such as hormones or growth factors are withdrawn.

The mitochondrion is the main site of the intrinsic pathway, including the conserved protein family BCL-2. BCL-2 family members include both pro- and antiapoptotic proteins. The proapoptotic group consists of at least a dozen members, including BAX, BAK, BOK, BIK, BAD, BID, and BIM. There are at least a half dozen antiapoptotic (prosurvival) BCL-2 family members, including BCL-2 itself, BCL-X_L, BCL-W, and MCL1 (Adams and Cory, 1998). All members contain one or

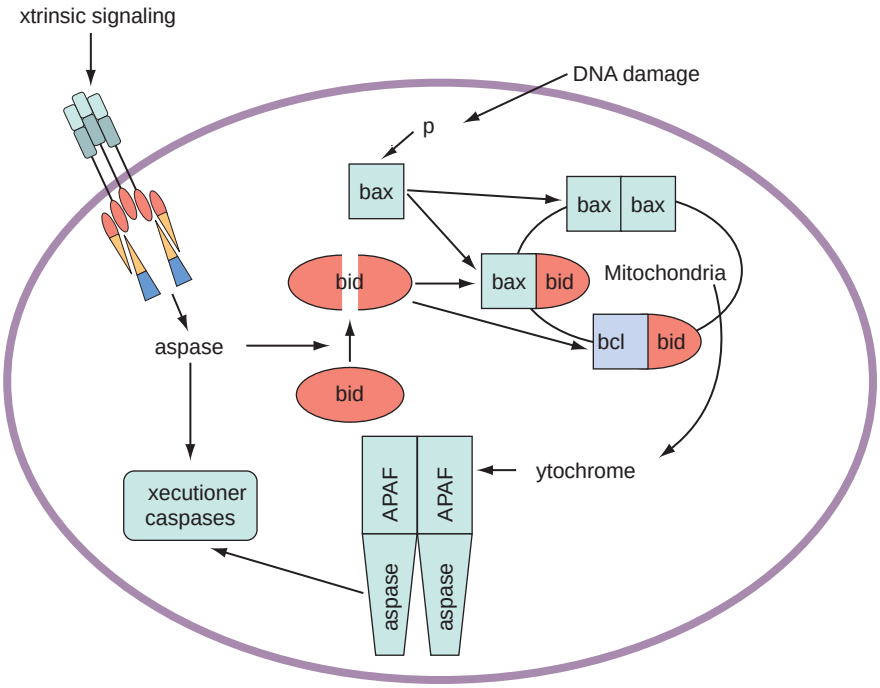

Figure 18–14. Cascade of extrinsic and intrinsic mechanisms of apoptosis. The extrinsic system depends on ligand-induced activation of executioner caspases, whereas the intrinsic system depends on the dimerization of BCL2 family members to alter mitochondrial membrane permeability.

more BCL-2 homology domains (BH1 to BH4) that allow members of the family to heterodimerize with each other. BCL-2 family members regulate each other's function through these BH domains (Chittenden et al, 1995; Cheng et al, 1996). Whereas each pro-apoptotic BCL-2 family member responds to different stimuli, **the principal mechanism by which they induce cell death is by increasing mitochondrial membrane permeability** (Kroemer and Reed, 2000). When apoptosis is signaled by the intrinsic pathway, the balance between BCL-2 family members shifts in favor of pro-apoptotic proteins that increase the permeability of the mitochondrial outer membrane, facilitating the release of cytochrome *c* from the intermembrane space into the cytoplasm (Jurgensmeier et al, 1998; Wolf and Eastman, 1999). **Once in the cytoplasm, cytochrome *c* molecules bind to APAF-1 proteins, forming a complex known as the apoptosome. The apoptosome activates caspase-9, one of the initiator caspases, thus beginning the caspase cascade as described above** (Li et al, 1997b).

Antiapoptotic BCL-2 family members block apoptosis by inhibiting the proapoptotic family members and, in doing so, decreasing mitochondrial permeability (see Fig. 18–14) (Li et al, 1997b; Srinivasula et al, 1998).

BAX is the best-studied proapoptotic BCL-2 family member. It is transcriptionally activated by TP53. Once activated, BAX dimerizes at the mitochondrial membrane. The dimer forms a channel that facilitates the release of cytochrome *c* from the mitochondria. BCL-2 is the best-studied antiapoptotic BCL-2 family member. It functions by binding to BAX and, in doing so, blocks BAX-induced mitochondrial permeability (Miyashita et al, 1994; Adams and Cory, 1998).

Other proapoptotic family members are activated by a variety of stimuli. Often they function not by inducing mitochondrial permeability directly but by activating or inhibiting other BCL-2 family members. The first example is BID. BID is regulated by initiator caspases. Cytosolic BID is activated by caspase-8 (see Fig. 18–14). This allows dimerization of BID with either BAX or BCL-2. This dimerization activates BAX activity and inhibits BCL-2. The net result is to tip the balance in favor of apoptosis (Li et al, 1998). Because BID is activated by caspases, it provides a link between the ligand-induced apoptotic machinery of the extrinsic pathway (described below) and BCL-2 family members.

A second example is BAD. BAD is not regulated by transcription or by cleavage but by AKT-dependent phosphorylation. In tumors with activation of the TPI3 kinase pathway, the resulting AKT activation leads to BAD phosphorylation, which is prosurvival. In contrast, removal of growth factors has been demonstrated to deactivate AKT, which leads to dephosphorylation of BAD. BAD can then bind to and inactive BCL-2, the net result being proapoptotic (Kroemer and Reed, 2000).

An additional level of regulation is provided by inhibitor of apoptosis proteins (IAPs), a family of proteins which act to prevent apoptosis by inhibiting specific caspase proteases, either directly or by inhibiting the conversion from the procaspase to the active form (Deveraux et al, 1998).

Extrinsic Apoptotic Pathway

In addition to the intrinsic pathway, a second pathway termed the extrinsic pathway mediates apoptosis following receipt of extracellular signals from cell surface receptors called "death receptors," such as the tumor necrosis factor receptor, TNFR1, and the FAS receptor (Fig. 18–15). These receptors belong to the tumor necrosis factor superfamily and contain a ligand-specific extracellular domain and an intracellular "death domain." The binding of extracellular signaling molecules to the receptor activates the receptor, which then signals through the death domain located on the cytoplasmic portion of the receptor. The death domain allows the receptor to bind to intracellular adaptor proteins that also contain a death domain (e.g., RIP, TRADD, FADD). In addition to their own death domain, the adaptor proteins have a death effector domain that allows the adaptor protein to bind to the caspase recruitment domain (CARD) of initiator caspases (Ashkenazi and Dixit, 1998). Once bound, the initiator caspases undergo self-cleavage and are then capable of activating effector caspases by the caspase cascade. (Li et al, 1998; Muzio, 1998).

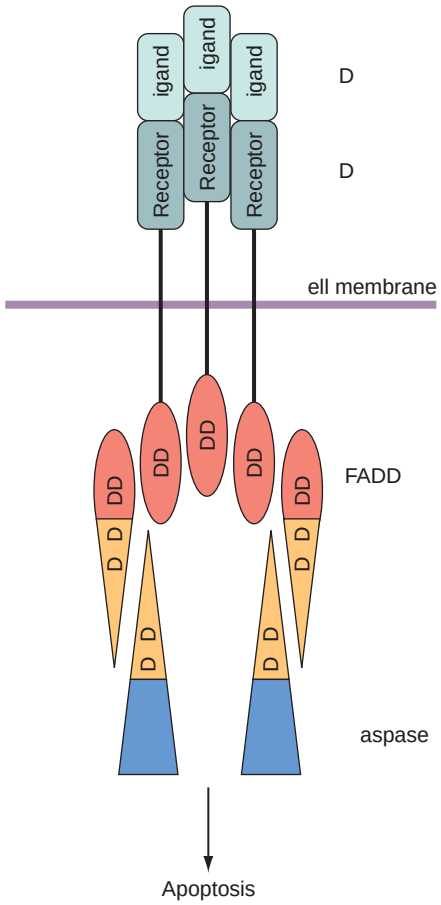

Figure 18–15. Example of death receptor–mediated activation of initiator caspases.

The best-characterized death receptor is CD95, or FAS, which appears to play an important role in cancer immunosurveillance (Ashkenazi and Dixit, 1998). The ligand CD95L (also known as FAS ligand or FASL) forms a trimer that binds three CD95 receptors (Nagata, 1997). The clustering of CD95 allows the adaptor protein FADD to bind to CD95 by their death domains (see Fig. 18–15). In turn, procaspase-8, or FLICE, binds to FADD by the death effector domain. Procaspase-8 oligomerization promotes autoactivation to active caspase-8 (Muzio, 1998). Other initiator procaspases, such as procaspase-10, are activated through similar mechanisms (Vincenz and Dixit, 1997). Negative regulatory molecules, such as FLIP, bind to FADD and, in doing so, inhibit procaspase-8 binding and therefore apoptosis (Irmler et al, 1997).

A second important death receptor is TRAIL (Mariani et al, 1997). In contrast to CD95L, which is predominantly expressed on activated T lymphocytes and natural killer cells (Nagata, 1997), TRAIL's receptors, DR4 and DR5, are expressed in many human tissues, including the prostate. Similar to CD95L-mediated apoptosis, TRAIL induces cell death through caspase activation. Again, negative regulatory elements, such as the decoy receptor TRID, play an important role in modifying the ligand's activity. TRID binds to TRAIL, but because it lacks a death domain, it is unable to bind adaptor proteins and therefore blocks the pathway (Pan et al, 1997).

The death receptor pathway does not appear to have a direct role in the etiology of cancer. Patients with hereditary defects in this system and knockout mice are both characterized by T-cell abnormalities and fatal autoimmune syndromes, but not hereditary tumor syndromes (Nagata, 1997). **However, the identification of ligand-dependent apoptosis receptors may have a profound impact on therapy. Most cancer therapies (i.e., chemotherapy and external-beam radiation therapy) depend on *TP53* to induce apoptosis in the cancer cell. Because *TP53* is mutated in over half of malignancies** (Hollstein et al, 1991), ***TP53*-independent pathways for apoptosis are of great clinical interest. Because the ligand-dependent apoptosis described earlier is independent of *TP53*, this makes these receptors and ligands attractive novel treatment targets.** Unfortunately, compounds that bind to the receptors are extremely toxic (Nagata, 1997). Hopefully, novel compounds will have improved toxicity profiles.

Role of TP53 in Apoptosis

In addition to the key roles played by the TP53 tumor suppressor in cell cycle arrest and DNA damage repair, TP53 can also induce apoptosis (May and May, 1999). TP53-induced apoptosis is mediated through the BCL-2 family by the intrinsic pathway, and dysregulation of this apoptotic pathway has direct relevance to the etiology of cancer. The mechanism by which TP53 induces cell cycle arrest or apoptosis is still not well understood, but in both cases recognition of physiologic cell stresses, such as DNA damage, triggers TP53 activation (Sabbatini et al, 1995; Attardi et al, 1996). TP53-induced apoptosis is mediated by transcriptional activation of genes that initiate the apoptotic cascade and inhibition of genes that block the cascade (Miyashita et al, 1994; Miyashita and Reed, 1995; Oda et al, 2000) TP53-induced apoptosis is dependent of the APAF-1/caspase-9 activation pathway (Soengas et al, 1999) (see Fig. 18–14). Whereas the BCL-2 family member BAX has been implicated as the primary factor responsible for TP53 induction of this cascade (Miyashita and Reed, 1995), BAX is not essential for TP53-dependent apoptosis (Knudson et al, 1995). It is possible that inhibition of BCL-2 (Miyashita et al, 1994) or upregulation of the proapoptotic BCL-2 family member noxa, may allow cells lacking BAX to still undergo TP53-dependent apoptosis (Oda et al, 2000).

Considering the role of TP53 in multiple tumor suppressive pathways (DNA damage response, cellular senescence, and apoptosis), it is not surprising that it is so frequently mutated in cancer.

Apoptosis and Genitourinary Malignancies

Because a tumor cell's inability to undergo apoptosis is a hallmark of malignancy, multiple groups have attempted to characterize the apoptotic response of genitourinary malignancies. Because cells undergoing apoptosis undergo a stereotypical death, global analysis of apoptosis is possible using assays designed to detect hallmarks of the apoptotic process, such as the fragmentation of DNA characteristic of the process, as well as assays designed to detect abnormalities in specific apoptotic proteins.

Global Defects in Apoptosis

Both high-grade prostatic intraepithelial neoplasia (HGPIN) and prostate carcinomas actually have significantly higher levels of apoptosis than normal prostatic epithelium. The level of apoptotic activity is relatively low compared with other malignancies and is balanced by increased replication. Importantly, many prostate cancer cells can be induced to undergo apoptosis in response to androgen withdrawal, which represents a front-line therapy for patients with advanced disease (Kyprianou et al, 1990; Isaacs, 1994; Tu et al, 1996; Denmeade and Isaacs, 1996). Unfortunately, clearly not all of a patient's cancer cells succumb, as recurrences inevitably arise. As the tumor progresses to androgen independence, it is unclear if the androgen-resistant cells have an increased or decreased rate of apoptosis, because studies have demonstrated both in hormone-refractory disease (Berges et al, 1995; Koivisto et al, 1997). The conflicting data may reflect both the tumor's dynamics and the effect of therapy. There is a clear survival advantage for the advanced cancer cell that can protect itself from apoptosis. However, **a rapidly growing, infiltrative, advanced tumor, which is outgrowing its blood supply and mutating its DNA, may have a high apoptotic rate despite protective mechanisms acquired by the tumor's cells.**

Studies of apoptosis in bladder carcinoma have demonstrated an association with aggressive, high-grade, advanced disease but not with decreased disease-free survival (Lipponen and Aaltomaa, 1994; King et al, 1996). External-beam radiation therapy has been associated with a modest improvement in survival for tumors with high apoptotic rates, possibly reflecting that effective external-beam radiation therapy requires an intact apoptotic mechanism (Rodel et al, 2000).

As previously mentioned, **most testicular germ cell tumors maintain intact DDR and wild-type *TP53* and thus display high cure rates in response to therapies inducing DNA damage** (Einhorn, 2002; Kersemaekers et al, 2002; Gorgoulis et al, 2005; Bartkova et al, 2007).

Individual members of the apoptotic machinery have been studied frequently. However, all these studies suffer from an inability to assay all elements of the apoptotic machinery simultaneously, and therefore to globally assess the tumor's ability to undergo programmed cell death.

***TP53* mutations and abnormalities in expression are among the most frequent in cancer and have been identified in prostate, bladder, and renal cancers** (Hollstein et al, 1991; Sidransky et al, 1991; Reiter et al, 1993). Abnormalities in *TP53* cause dysregulation of the cell cycle and DNA repair mechanisms in addition to apoptosis and are covered in more detail in the section The Cell Cycle.

BCL-2 family members have been studied in genitourinary malignancies. **Elevated levels of BCL-2 have been identified in the majority of hormone-refractory prostate tumors, reflecting the tumor's relative resistance to apoptosis in the advanced state** (McDonnell et al, 1992; Colombel et al, 1993). Both increased and decreased levels of BCL-2 have been identified in localized prostate tumors, and few studies have found a correlation with grade, stage, and progression (Byrne et al, 1997; Lipponen and Vesalainen, 1997; Theodorescu et al, 1997). Other

antiapoptotic members of the BCL-2 gene family, BCL-X_L and MCL1, may also be linked to prostate carcinoma (Krajewska et al, 1996). Analysis of bladder carcinoma has demonstrated similar results. BCL-2 levels are higher in more aggressive bladder carcinoma, but expression of BCL-2 had no effect on treatment outcome (King et al, 1996; Rodel et al, 2000). As noted earlier, phosphorylation of BAD by AKT can also tilt the scales toward cell survival, especially in concert with elevated levels of BCL-2. AKT activation is commonly seen in many urologic malignancies and can result from loss of the tumor suppressor *PTEN,* mutation and constitutive activation of TPI3 kinase, and/or activation of tyrosine kinase receptors such as HER2/NEU, EGFR, and the insulin-like growth factor receptor (IGFR).

Other BCL-2 family members have not been as well studied. Loss of BAX expression is apparently not a common mechanism for the development of prostate carcinoma (Krajewska et al, 1996; Johnson and Hamdy, 1998) but may play a role in progression of localized bladder carcinoma (Ye et al, 1998).

In summary, deficiencies in signal transduction pathways leading to apoptosis clearly play a role in the initiation and progression of malignancy. It is unclear if expression analysis of the apoptotic machinery will provide additional prognostic information other than that derived from traditional histochemical analysis. However, it is clear that effective chemotherapy and radiation therapy is, in large part, dependent on apoptosis. Additionally, in the future, the apoptotic machinery may be manipulated using novel ligands that bind to death receptors and promote *TP53*-independent cancer cell death.

Alternative Regulators of Apoptosis in Genitourinary Malignancies

In addition to the classic regulators of apoptosis, a number of other pathways for cell survival and death play key roles in urologic cancer. Some of these pathways are being actively explored as targets for cancer therapy. Miyake and colleagues (2000) mapped a detailed gene profile of prostate tumors treated with neoadjuvant hormonal ablation therapy to identify key regulators of cell death and survival after castration. In addition to BCL-2, which is upregulated in surviving cancer cells, they have also reported on clusterin and HSP27. **Clusterin, or TRPM2 (testosterone repressed prostate message–2), is upregulated, both in patient samples after hormone ablation as well as in the Shionogi and CWR-22 xenograft models of hormone-sensitive tumors. Although its precise function is not known, a large body of evidence suggests that clusterin is induced by stress and functions to stabilize the cell during periods of stress** (Miyake et al, 2000). In this model, clusterin is believed to act like heat shock proteins, whose role as a protein chaperone is also to stabilize client proteins. Clusterin is activated by heat shock protein–1 (HSP1). Functional evidence of clusterin's role comes from studies in which clusterin is either overexpressed or knocked down using antisense strategies. In the first scenario, clusterin expression promotes hormone-refractory cell growth and prevents androgen withdrawal–induced apoptosis. In the second scenario, treatment of hormone-refractory cells with antisense clusterin promotes apoptosis (July et al, 2002; Miyake et al, 2004; Gleave and Miyake, 2005). This same group of investigators has also reported that the heat shock protein HSP27 is also frequently overexpressed in hormone-refractory prostate cancers. Similar experiments using overexpression and antisense strategies have suggested that targeting HSP27 may influence the course of hormone-refractory cancers, in particular in combination with cytotoxic chemotherapies (Rocchi et al, 2004).

Another family of cellular signaling molecules that play a role in the regulation of cell survival and apoptosis is that of sphingolipids. Sphingolipids are one of three major constituents of the cell membrane, along with phospholipids and cholesterol. Sphingolipid generation is regulated by a large cast of enzymes—notably, the sphingomyelinases, ceramide synthase, and the ceramidases. Ceramide is produced from sphingomyelin by sphingomyelinase, and from sphinganine by ceramide synthase. Ceramidases, on the other hand, degrade ceramide and lead to formation of sphingosine and sphingosine-1-phosphate. Ceramide is a potent proapoptotic molecule that can promote apoptosis through the classical mitochondrial activation of caspases, or through a nonclassical caspase-independent form of apoptosis (Kolesnick and Fuks, 2003). Sphingosine-1-phosphate, in contrast, is a powerful antiapoptotic molecule that may modulate the degree of apoptosis, similar to a rheostat (Maceyka et al, 2002).

The importance of ceramide to genitourinary tumors is its role as a key modulator of radiation-induced tissue damage and apoptosis. As with clusterin and other heat shock proteins, ceramide appears to be a critical mediator of stress response in cells, in this case promoting apoptosis as opposed to cell survival. Studies supporting the role of ceramide in radiation-induced apoptosis are manifold, including studies demonstrating the direct cell death signal induced by exogenous treatment of cells with ceramide, studies of radiation response in mouse knockout models, and studies of radiation response in the presence and absence of inhibitors of sphingolipid metabolism. Hopefully, therapeutics that increase ceramide production and promote apoptosis can be developed. The role of sphingolipid-1-phosphate has also emerged from these studies, and recent work suggests that this molecule is a promising target for cancer therapy (Gulbins and Kolesnick, 2003; Kester and Kolesnick, 2003; Perry and Kolesnick, 2003).

STEM CELLS AND CANCER

Stem cells are found in multicellular organisms and are characterized by the ability of self-renewal through mitotic cell division and differentiation into a diverse range of specialized cell types. **Common properties of stem cells include the ability of self-renewal, generation of cellular progeny, localization within specialized niches, and the ability to give rise to all cell types within an organ.** Prostate stem cells are believed to be localized within the basal epithelium and give rise to a hierarchy of progenitor cells that may differentiate into secretory or neuroendocrine cells (Burger et al, 2005; Xin et al, 2005). Cancer stem cells are tumorigenic and possess characteristics associated with normal stem cells, including the ability to give rise to all cell types found in a particular cancer.

Recent studies suggest that neoplastic cells mimic normal tissue development and may arise from and are dependent on a small population of stem cells. **The cancer stem cell hypothesis argues that cancers arise from transformation of stem or progenitor cells that are capable of multilineage differentiation.** Cancer stem cells may account for only a small percentage of any tumor, but this small population of cells is critical for tumor survival. Initial evidence to support the cancer stem cell hypothesis is based on observations in leukemia, breast, and neurologic cancers. A CD44+/CD24low/– population of cells in primary breast tumors were specifically capable of tumor

Key Points: Apoptosis

- Apoptosis is a rapid, orderly, programmed form of cell death that is used by multicellular organisms to eliminate unwanted cells. Through this process, cells are preprogrammed to commit suicide in response to various internal and external signals.
- Apoptosis is believed to play an important role in tumor suppression because many of the signals that induce apoptosis arise from potentially tumorigenic cell stresses such as DNA damage.
- Cancer is characterized by interruptions in the normal process of apoptosis, resulting in inappropriate cell survival.
- Apoptosis is mediated by a conserved family of proteases known as caspases. *Initiator caspases* begin caspase proteolytic cascades that result in the activation of downstream *executioner caspases,* which, in turn, target several cellular proteins.
- Two main apoptotic pathways have been identified. In the *intrinsic pathway,* BCL-2 family members modulate the release of cytochrome *c* from mitochondria, which then participates in the activation of initiator caspases. The *extrinsic pathway* activates caspases in response to signals from extracellular "death receptors."
- In addition to its functions in cell cycle arrest and DNA repair, *TP53* also plays a key role in apoptosis.
- BCL-2 is a classic inhibitor of the mitochondrial pathway of apoptosis and is overexpressed in some genitourinary malignancies.
- Therapeutic response is often dependent upon the integrity of apoptotic pathways in cancer cells. Most TGCT retain intact DDR, wild-type *TP53*, and apoptotic responses, providing high cure rates with DNA-damaging agents.
- Novel agonists and antagonists of apoptosis, such as ceramide and clusterin, may be successfully controlled to combat cancer.

formation when engrafted into nude mice (Dontu et al, 2003). Similar reports about glioblastomas suggest that the putative stem cells are CD133 positive (Singh et al, 2003; Dirks, 2005).

The hedgehog (HH) signaling pathway is required for regeneration of prostate epithelium and has been implicated in transformation of prostate progenitor cells (Karhadkar et al, 2004). Elevated HH pathway activity has been shown to distinguish metastatic prostate cancer from localized disease. This pathway was activated in response to endogenous expression of HH ligands and was shown to be dependent upon expression of Smoothened which is an essential response component that is not expressed in benign prostate epithelial cells (Beachy et al, 2004; Karhadkar et al, 2004).

A tumor-initiating cell (T-IC) subpopulation has also been identified in human bladder cancer. This group of cells was found to express CD44+/CK5+/CK20– markers similar to normal bladder basal cells (Chan et al, 2009). The bladder T-IC subpopulation was also capable of forming xenografted tumors in vivo that recapitulated characteristics of the original tumor. Furthermore, CD47 was highly expressed in this group of cells, and blockade of CD47 resulted in macrophage engulfment of bladder cancer stem cells in vitro. This finding suggests a potential role for therapeutic targeting of CD47 and the T-IC subpopulation in bladder cancer (Chan et al, 2009).

Key Points: Cancer Stem Cells

- Stem cells are defined by their ability to differentiate along multiple lineages and their immortality.
- Cancer is believed to be a stem cell disease in which a small population of cancer stem cells maintains the larger tumor.
- The hedgehog signaling pathway is required for regeneration of prostate epithelium and has been implicated in transformation of prostate progenitor cells.
- Cancer may ultimately be eradicated by targeting only the cancer stem cell.

Regenerative Medicine in Urology: Stem Cells, Tissue Engineering, and Cloning

Anthony Atala, MD

Regenerative Medicine: Strategies for Tissue and Organ Reconstitution
Sources of Cells for Therapy
Biomaterials for Genitourinary Regenerative Medicine
Regenerative Medicine of Urologic Structures
Other Applications of Genitourinary Regenerative Medicine
Summary

"So the Lord God caused the man to fall into a deep sleep, and while he was asleep, He took part of the man's rib, and closed up the place with flesh. Then the Lord God made a woman from the part He had taken out of the man, and He brought her to the man."

—*Genesis 2:21*

Four medical firsts are described in the passage cited above: the use of anesthesia, surgery, cloning, and tissue engineering. Even three decades ago, the performance of two of these, tissue engineering and cloning, was not possible. The use of one body part for another or the exchange of parts from one person to another was mentioned in the medical literature even in antiquity and captured the imagination of many over time. The maintenance of organs in culture was a major area of inquiry in the early 1900s. Charles Lindbergh, the first pilot to successfully fly across the Atlantic in the 1920s, joined forces with Alexis Carrel, a Nobel Prize winner in the field of medicine, to investigate the potential of keeping organs alive ex vivo long-term (Carrel et al, 1935).

The field of urology was the earliest to gain from the advent of transplantation, with the kidney being the first entire organ to be replaced in a human, in 1955 (Guild et al, 1955). In the early 1960s, Joseph Murray, who later received the Nobel Prize for his work, performed a nonrelated kidney transplantation from a nongenetically identical patient into another. This transplant, which overcame the immunologic barrier, marked a new era in medical therapy and opened the door for use of transplantation as a means of therapy for different organ systems. However, lack of good immune suppression and the ability to monitor and control rejection, as well as a severe organ donor shortage, opened the door for other alternatives.

As times evolved, synthetic materials were introduced to replace or rebuild diseased tissues or parts in the human body. The advent of new manmade materials, such as tetrafluoroethylene (Teflon) and silicone, opened a new field that included a wide array of devices that could be applied for human use. Although these devices could provide for structural replacement, the functional component of the original tissue was not achieved.

Simultaneous with this development was an increased body of knowledge of the biologic sciences that included new techniques for cell harvesting, culture, and expansion. The areas of cell biology, molecular biology, and biochemistry were advancing rapidly. Studies of the extracellular matrix and its interaction with cells, and with growth factors and their ligands, led the way to a further understanding of cell and tissue growth and differentiation. The concept of cell transplantation took hold in the research arena, and culminated with the first human bone marrow cell transplant in the 1970s.

In the 1970s, a natural evolution occurred wherein researchers started to combine the field of devices and materials sciences with cell biology, in effect starting a new field called *tissue engineering*. As more scientists from different fields came together with the common goal of tissue replacement, the field of tissue engineering became more formally established. Tissue engineering was defined as "an interdisciplinary field which applies the principles of engineering and life sciences towards the development of biological substitutes that aim to maintain, restore or improve tissue function" (Atala et al, 2001). The first use of the term "tissue engineering" in the literature can be traced to a reference dealing with corneal tissue in 1985 (Wolter et al, 1985).

The field of stem cells also received a large boost with the discovery of mouse embryonic stem cells in the early 1980s (Martin,

1981). However, the field remained relatively dormant until the description of human embryonic stem cells in 1998 (Thomson et al, 1998). The description of these cells led to one of the most contested ongoing ethical debates in the field of medicine. Just a year later, in 1999, the world awoke to the startling media announcement of the creation of the first cloned mammal, a sheep named Dolly (Wilmut et al, 1997). Although cloning, or nuclear transfer, had been done in amphibians and other animal models for years, this accomplishment in a mammal showed once again that concepts believed to be scientifically prohibitive were indeed possible.

The fields of cell transplantation, tissue engineering, and nuclear transfer all had one unifying concept—the regeneration of living tissues and organs. Thus in 1999, William Haseltine, then the scientific founder and Chief Executive Officer of Human Genome Sciences, coined the term "regenerative medicine," in effect bringing all these areas under one defining field (Haseltine, 1999). Soon, the first online journal for the new field of tissue engineering, *Regenerative Medicine*, was formed, along with The Regenerative Medicine Society.

Organ transplantation remains a mainstay of treatment for patients with severely compromised organ function. Despite initiatives to increase the availability of transplant organs, however, the number of patients in need of treatment far exceeds the organ supply, and this shortfall is expected to worsen as the global population ages. One alternative treatment approach is regenerative medicine. In the last two decades, scientists have attempted to grow native and stem cells, engineer tissues, and design treatment modalities using regenerative medicine techniques for virtually every tissue of the human body. This chapter reviews some of the progress that has been achieved in the field of genitourinary regenerative medicine.

REGENERATIVE MEDICINE: STRATEGIES FOR TISSUE AND ORGAN RECONSTITUTION

Regenerative medicine follows the principles of cell transplantation, materials science, and engineering toward the development of biologic strategies that can restore and maintain normal function. Regenerative medicine strategies usually fall into one of three categories: cell-based therapies, the use of biomaterials (scaffolds) alone, wherein the body's natural ability to regenerate is used to orient or direct new tissue growth, or the use of scaffolds seeded with cells to create tissue substitutes.

SOURCES OF CELLS FOR THERAPY

Stem Cells

The cells used for regenerative medicine can be autologous or heterologous, and from either native or stem cell sources. In general, there are three broad categories of stem cells obtained from living tissue that are used for cell therapies. Embryonic stem cells are obtained through the aspiration of the inner cell mass of a blastocyst or, more recently, a single cell from this mass. Fetal and neonatal amniotic fluid and placenta may contain multipotent cells that may be useful in cell therapy applications. Adult stem cells, on the other hand, are usually isolated from organ or bone marrow biopsies. Stem cells are defined as having three important properties: the ability to self-renew, the ability to differentiate into a number of different cell types, and the ability to easily form clonal populations (populations of cells derived from a single stem cell). Many techniques for generating stem cells have been studied over the past few decades. Some of these techniques have yielded promising results, but others require further research. The main techniques are discussed in detail below, and their advantages and limitations are summarized in Table 19–1.

Embryonic Stem Cells

In 1981 pluripotent cells were found in the inner cell mass of the human embryo, and the term "human embryonic stem cell" was coined (Martin, 1981). These cells are able to differentiate into all cells of the human body, excluding placental cells (only cells from the morula are totipotent; that is, able to develop into all cells of the human body). These cells have great therapeutic potential, but their use is limited by both biological and ethical factors.

The political controversy surrounding stem cells began in 1998 with the creation of human embryonic stem (hES) cells derived from discarded embryos. hES were isolated from the inner cell mass of a blastocyst (an embryo 5 days postfertilization) using an immunosurgical technique. Given that some cells cannot be expanded ex vivo, ES cells could be an ideal resource for regenerative medicine because of their fundamental properties: the ability to self-renew indefinitely and the ability to differentiate into cells from all three embryonic germ layers. Skin and neurons have been

Table 19–1.

Summary of Alternate Methods for Generating Pluripotent Stem Cells

METHOD	ADVANTAGES	LIMITATIONS
Somatic cell nuclear transfer	Customized stem cells Has been shown to work in nonhuman primates	Requires oocytes Has not been shown to work in humans
Single cell embryo biopsy	Patient-specific to embryo Does not destroy or create embryos Has been done in humans	Allogeneic cell types Is not known if single cells are totipotent Requires coculturing with a previously established human embryonic stem cell line
Arrested embryos	Cells obtained from discarded embryos Has been done in humans	Allogeneic cell types Quality of cell lines might be questionable
Altered nuclear transfer	Customized stem cells	Ethical issues surround embryos with no potential Modified genome Has not been done with human cells
Reprogramming	Customized stem cells No embryos or oocytes needed Has been done with human cells	Retroviral transduction Oncogenes

formed, indicating ectodermal differentiation (Reubinoff et al, 2001; Schuldiner et al, 2001; Zhang et al, 2001). Blood, cardiac cells, cartilage, endothelial cells, and muscle have been formed, indicating mesodermal differentiation (Kaufman et al, 2001; Kehat et al, 2001; Levenberg et al, 2002). Pancreatic cells have been formed, indicating endodermal differentiation (Assady et al, 2001). In addition, as further evidence of their pluripotency, embryonic stem cells can form embryoid bodies, which are cell aggregations that contain all three embryonic germ layers while in culture, and can form teratomas in vivo (Itskovitz-Eldor et al, 2000). These cells have demonstrated longevity in culture and can maintain their undifferentiated state for at least 80 passages when grown using current published protocols (Reubinoff et al, 2000; Thomson et al, 1998).

However, in addition to the ethical dilemma surrounding the use of embryonic stem cells, their clinical application is limited because they represent an allogenic resource and thus have the potential to evoke an immune response. New stem cell technologies (such as somatic cell nuclear transfer and reprogramming) promise to overcome this limitation.

Single Cell Embryo Biopsy. Because a major objection to hES cell research for some persons is that it results in the destruction of embryos, a method of isolating these cells without destroying the embryo would be advantageous. In 2006, Chung and colleagues were the first authors to report the generation of mouse embryonic stem cell lines in this manner. Their method was based on a technique used to obtain a single cell embryo biopsy for preimplantation genetic diagnosis. Cells were taken from eight-cell blastomeres rather than from blastocysts. The cells differentiated into derivatives of all three embryonic germ layers in vitro, and as well as into teratomas in vivo. In addition, the mouse embryos that resulted from the biopsied blastomeres developed to term without a reduction in their developmental potential.

Obtaining Cells from Arrested Embryos. hES cell lines can also be derived from arrested embryos (Zhang et al, 2006a). During in vitro fertilization, only a small proportion of zygotes produced will develop successfully to the morula and blastocyst stages. Over half the embryos stop dividing (Hardy, 1993; Geber et al, 1999) and are, therefore, considered dead embryos (Landry et al, 2004). Such embryos have unequal or fragmented cells and blastomeres and are usually discarded. Not all the cells within these arrested embryos, however, are abnormal (Martinez et al, 2002; Zhang et al, 2006a), and these embryos might be a source of hES cells. More studies are needed to characterize the full proliferation and differentiation potential of embryonic stem cells derived from arrested embryos.

Altered Nuclear Transfer. Altered nuclear transfer is a variation of somatic cell nuclear transfer (SCNT) in which a genetically modified nucleus from a somatic cell is transferred into a human oocyte. This embryo, which contains a deliberate genetic defect, is capable of developing into a blastocyst, but the induced defect prevents the blastocyst from implanting in the uterus. This process has the potential to generate customized hES cells from the blastocyst stage (Hurlbut, 2005). Human embryos with this genetic defect might lack the capacity to develop into viable fetuses, as a result of their inability to implant, thus providing a source of stem cells without destroying viable embryos. Proof of concept was obtained in mice by Meissner and Jaenisch (2006) by using embryos lacking the *CDX2* homeobox gene.

The viability of human embryos lacking the *CDX2* gene is unclear, as is whether this mutation restricts human developmental potential into certain lineages. Although much research must be done before therapeutic strategies based on this technique could ever enter the clinic, at this time, hES cells derived from altered nuclear transfer can provide opportunities to study pluripotency in hES cells without the need for destruction of viable embryos. The exact effects of *CDX2* gene knockout on the development of human embryos are not well known. The effects of this gene however, have been thoroughly investigated in the gastric and intestinal epithelium (Benahmed et al, 2008; Vauhkonen et al, 2008).

Therapeutic Cloning (Somatic Cell Nuclear Transfer)

Somatic cell nuclear transfer, or therapeutic cloning, entails the removal of an oocyte nucleus in culture, followed by its replacement with a nucleus derived from a somatic cell obtained from a patient. Activation with chemicals or electricity stimulates cell division up to the blastocyst stage.

At this point, it is extremely important to differentiate between the two types of cloning that exist: reproductive cloning and therapeutic cloning. Both involve the insertion of donor deoxyribonucleic acid (DNA) into an enucleated oocyte to generate an embryo that has identical genetic material to its DNA source. However, the similarities end there. In reproductive cloning, the embryo is then implanted into the uterus of a pseudopregnant female to produce an infant that is a clone of the donor. A world-famous example of this type of cloning resulted in the birth of a sheep named Dolly in 1997 (Wilmut et al, 1997). However, there are many ethical concerns surrounding such practices, and as a result, reproductive cloning has been banned in most countries.

Although therapeutic cloning also produces an embryo that is genetically identical to the donor, this process is used to generate blastocysts that are explanted and grown in culture, rather than in utero. Embryonic stem cell lines can then be derived from these blastocysts, which are only allowed to grow to a 100-cell stage. At this time the inner cell mass is isolated and cultured, resulting in ES cells that are genetically identical to the patient. This process is detailed in Fig. 19–1. It has been shown that nuclear-transferred ES cells derived from fibroblasts, lymphocytes, and olfactory neurons are pluripotent and can generate live pups after injection into blastocysts. This shows that cells generated by SCNT have the same developmental potential as blastocysts that are fertilized and produced naturally (Hochedlinger et al, 2002; Eggan et al, 2004; Brambrink et al, 2006). In addition, the ES cells generated by SCNT are perfectly matched to the patient's immune system, and no immunosuppressants would be required to prevent rejection should these cells be used in regenerative medicine applications.

Although ES cells derived from SCNT contain the nuclear genome of the donor cells, mitochondrial DNA (mtDNA) contained in the oocyte could lead to immunogenicity after transplantation. To assess the histocompatibility of tissue generated using SCNT, Lanza and colleagues (2002b) microinjected the nucleus of a bovine skin fibroblast into an enucleated oocyte. Although the blastocyst was implanted (reproductive cloning), the purpose was to generate renal, cardiac and skeletal muscle cells, which were then harvested, expanded in vitro, and seeded onto biodegradable scaffolds. These scaffolds were then implanted into the donor steer from which the cells were cloned to determine if cells were histocompatible. Analysis revealed that cloned renal cells showed no evidence of T-cell response, suggesting that rejection will not necessarily occur in the presence of oocyte-derived mtDNA. This finding represents a step forward in overcoming the histocompatibility problem of stem cell therapy.

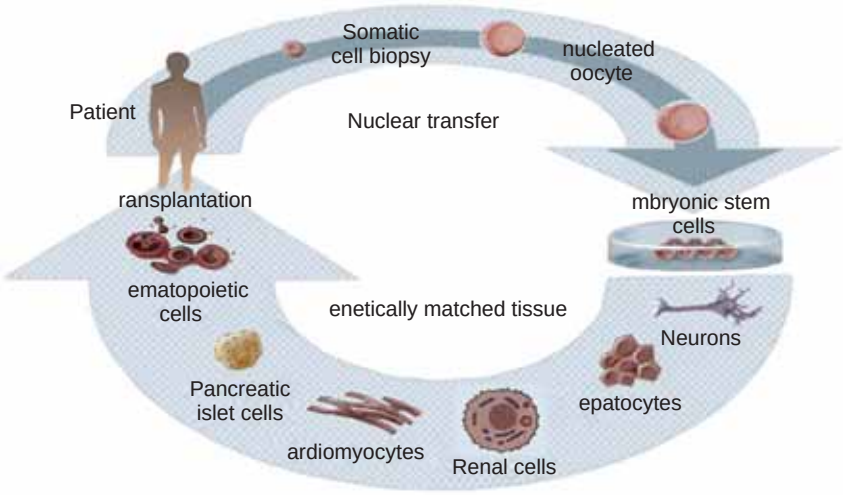

Figure 19–1. Therapeutic cloning strategy and its application to the engineering of tissues and organs.

Although promising, SCNT has certain limitations that require further improvement before its clinical application, in addition to the ethical considerations regarding the potential of the resulting embryos to develop into cloned embryos if implanted into a uterus. In addition, to date this technique has not been shown to work in humans. The initial failures and fraudulent reports of nuclear transfer in humans reduced enthusiasm for human applications (Simerly et al, 2003; Hwang et al, 2004; Hwang et al, 2005), although it was recently reported that nonhuman primate ES cell lines were generated by SCNT using nuclei from adult skin fibroblasts (Byrne et al, 2007; Mitalipov, 2007).

Before SCNT-derived ES cells can be used as clinical therapy, careful assessment of quality of the lines must be determined. For example, some cell lines generated by SCNT have contained chromosomal translocations, and it is not known whether these abnormalities originated from aneuploid embryos or if they occurred during ES cell isolation and culture. In addition, the low efficiency of SNCT (0.7%) and the inadequate supply of human oocytes further hinder the therapeutic potential of this technique. Still, these studies renew the hope that ES cell lines could one day be generated from human cells to produce patient-specific stem cells with the potential to cure many human diseases that are currently untreatable.

Reprogramming (Induced Pluripotent Stem Cells)

Recently, reports of the successful transformation of adult cells into pluripotent stem cells through a type of genetic "reprogramming" have been published. Reprogramming is a technique that involves de-differentiation of adult somatic cells to produce patient-specific pluripotent stem cells, eliminating the need to create embryos. Cells generated by reprogramming would be genetically identical to the somatic cells (and thus, the patient who donated these cells) and would not be rejected. Yamanaka's group was the first to discover that mouse embryonic fibroblasts (MEFs) and adult mouse fibroblasts could be reprogrammed into an "induced pluripotent state" (iPS) (Takahashi and Yamanaka, 2006). These iPS cells possessed the immortal growth characteristics of self-renewing ES cells—expressed genes specific for ES cells, and generated embryoid bodies in vitro and teratomas in vivo. When iPS cells were injected into mouse blastocysts, they contributed to a variety of cell types. However, although iPS cells selected in this way were pluripotent, they were not identical to ES cells. Unlike ES cells, chimeras made from iPS cells did not result in full-term pregnancies. Gene expression profiles of the iPS cells showed that they possessed a distinct gene expression signature that was different from that of ES cells. In addition, the epigenetic state of the iPS cells was somewhere between that found in somatic cells and that found in ES cells, suggesting that the reprogramming was incomplete.

These results were improved significantly by Wernig and colleagues in July 2007 (Wernig et al, 2007). In this study, DNA methylation, gene expression profiles, and the chromatin state of the reprogrammed cells were similar to those of ES cells. Teratomas induced by these cells contained differentiated cell types representing all three embryonic germ layers. Most importantly, the reprogrammed cells from this experiment were able to form viable chimeras and contribute to the germ line like ES cells, suggesting that these iPS cells were completely reprogrammed.

It has recently been shown that reprogramming of human cells is possible (Yu et al, 2007). Yamanaka's group generated human iPS cells that are similar to hES cells in terms of morphology, proliferation, gene expression, surface markers, and teratoma formation. These were generated via retroviral transduction of the stem cell markers *OCT4, SOX2, NANOG, and LIN28* (Takahashi et al, 2007). However, in both studies, the human iPS cells were similar but not identical to hES cells. Although reprogramming is an exciting phenomenon, our limited understanding of the mechanism underlying it currently limits the clinical applicability of the technique, but the future potential of reprogramming is quite exciting.

Amniotic Fluid– and Placenta-Derived Stem Cells

The amniotic fluid and placental membrane contain a heterogeneous population of cell types derived from the developing fetus (Priest et al, 1978; Polgar et al, 1989). Cells found in this heterogeneous population include mesenchymal stem cells (in 't Anker et al, 2003b; Tsai et al, 2004). In addition, the isolation of multipotent human and mouse amniotic fluid– and placenta-derived stem (AFPS) cells that are capable of extensive self-renewal and give rise to cells from all three germ layers was reported in 2007 (De Coppi et al, 2007a). AFPS cells represent approximately 1% of the cells found in the amniotic fluid and placenta. The undifferentiated stem cells expand extensively without a feeder cell layer and double every 36 hours. Unlike human embryonic stem cells, the AFPS cells do not form tumors in vivo. Lines maintained for over 250 population doublings retained long telomeres and a normal complement of chromosomes. AFPS cell lines can be induced to differentiate into cells representing each embryonic germ layer, including cells of adipogenic, osteogenic, myogenic,

endothelial, neural-like and hepatic lineages. In addition to the differentiated AFPS cells expressing lineage-specific markers, such cells can have specialized functions. Cells of the hepatic lineage secreted urea and α-fetoprotein, while osteogenic cells produced mineralized calcium. In this respect, they meet a commonly accepted criterion for multipotent stem cells, without implying that they can generate every adult tissue.

AFS cells represent a new class of stem cells with properties somewhere between those of embryonic and adult stem cell types. They are probably more agile than adult stem cells, but less so than embryonic stem cells. Unlike embryonic and induced pluripotent stem cells, however, AFPS cells do not form teratomas, and if preserved for self-use, avoid the problems of rejection. The cells could be obtained either from amniocentesis or chorionic villous sampling in the developing fetus, or from the placenta at the time of birth. They could be preserved for self-use, and used without rejection, or they could be banked. A bank of 100,000 specimens could potentially supply 99% of the U.S. population with a perfect genetic match for transplantation. Such a bank may be easier to create than with other cell sources, because there are approximately 4.5 million births per year in the United States.

Since the discovery of the AFPS cells, other groups have published on the potential of the cells to differentiate to other lineages, such as cartilage (Kolambkar et al, 2007), kidney (Perin et al, 2007), and lung (Warburton et al, 2008). Muscle differentiated AFPS cells were also noted to prevent compensatory bladder hypertrophy in a cryoinjured rodent bladder model (De Coppi et al, 2007b).

Adult Stem Cells

Adult stem cells, especially hematopoietic stem cells, are the best understood cell type in stem cell biology (Ballas et al, 2002). However, adult stem cell research remains an area of intense study, because their potential for therapy may be applicable to a myriad of degenerative disorders. Within the past decade, adult stem cell populations have been found in many adult tissues other than the bone marrow and the gastrointestinal tract, including the brain (Taupin, 2006), skin (Jensen et al, 2008; Jiao et al, 2008), and muscle (Crisan et al, 2008). **Many other types of adult stem cells have been identified in organs all over the body and are thought to serve as the primary repair entities for their corresponding organs** (Weiner, 2008) (Fig. 19–2). The discovery of such tissue-specific progenitors has opened up new avenues for research.

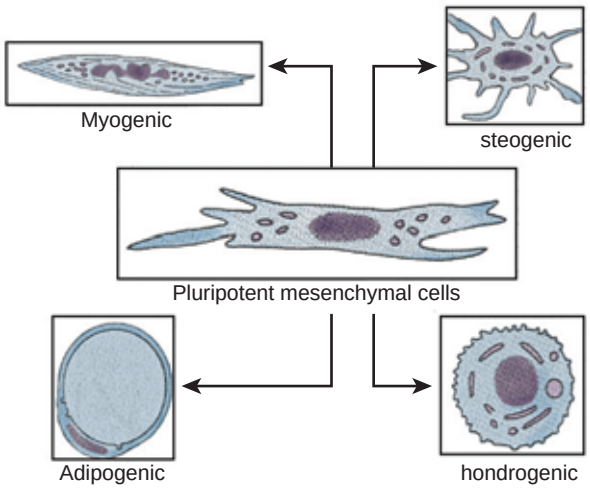

Figure 19–2. Schematic diagram of pluripotential stem cell lineages that can be derived from postnatal tissue.

A notable exception to the tissue specificity of adult stem cells is the mesenchymal stem cell, also known as the multipotent adult progenitor cell. This cell type is derived from bone marrow stroma (Devine, 2002; Jiang et al, 2002). Such cells can differentiate in vitro into numerous tissue types (Caplan, 2007; da Silva Meirelles et al, 2008) and can also differentiate developmentally if injected into a blastocyst. Multipotent adult progenitor cells can develop into a variety of tissues including neuronal (Duan et al, 2007), adipose (Crisan et al, 2008), muscle (Crisan et al, 2008; Luttun et al, 2006), liver (Ikeda et al, 2008; Mimeault et al, 2008), lungs (Nolen-Walston et al, 2008), spleen (in 't Anker et al, 2003a), and gut tissue (Jiang et al, 2002), but notably not bone marrow or gonads.

Research into adult stem cells has, however, progressed slowly, mainly because investigators have had great difficulty in maintaining adult nonmesenchymal stem cells in culture. Some cells, such as those of the liver, pancreas, and nerve, have very low proliferative capacity in vitro, and the functionality of some cell types is reduced after the cells are cultivated. Isolation of cells has also been problematic, because stem cells are present in extremely low numbers in adult tissue (Hristov et al, 2008; Mimeault et al, 2008). Although the clinical utility of adult stem cells is currently limited, great potential exists for future use of such cells in tissue-specific regenerative therapies. The advantage of adult stem cells is that they can be used in autologous therapies, thus avoiding any complications associated with immune rejection.

Native Targeted Progenitor Cells

In the past, one of the limitations of applying cell-based regenerative medicine techniques to organ replacement was the inherent difficulty of growing certain human cell types in large quantities. Native targeted progenitor cells, or native cells, are tissue specific unipotent cells derived from most organs. The advantage of these cells is that they are already programmed to become the cell type needed, without any extralineage differentiation. By noting the location of the progenitor cells, as well as by exploring the conditions that promote differentiation and/or self-renewal, it has been possible to overcome some of the obstacles that limit cell expansion in vitro. One example is the urothelial cell. Urothelial cells could be grown in the laboratory setting in the past, but only with limited success. It was believed that urothelial cells had a natural senescence that was hard to overcome. Several protocols have been developed over the last two decades that have improved urothelial growth and expansion (Cilento et al, 1994; Liebert et al, 1997; Scriven et al, 1997; Puthenveettil et al, 1999). A system of urothelial cell harvesting was developed that does not use any enzymes or serum and has a large expansion potential. Using these methods of cell culture, it is possible to expand an urothelial strain from a single specimen that initially covers a surface area of 1 cm^2 to one covering a surface area of 4202 m^2 (the equivalent area of one football field) within 8 weeks (Cilento et al, 1994).

An additional advantage in using native cells is that they can be obtained from the specific organ to be regenerated, expanded, and used in the same patient without rejection, in an autologous manner (Atala et al, 1992b, 1993b, 1993c, 1994, 1995b, 1997, 1998; Cilento et al, 1994; Yoo et al, 1997; Fauza et al, 1998a, 1998b; Machluf et al, 1998; Yoo et al, 1998b; Amiel et al, 1999; Kershen et al, 1999; Oberpenning et al, 1999; Park et al, 1999).

Bladder, ureter, and renal pelvis cells can equally be harvested, cultured, and expanded in a similar fashion (Fig. 19–3). Normal human bladder epithelial and muscle cells can be efficiently

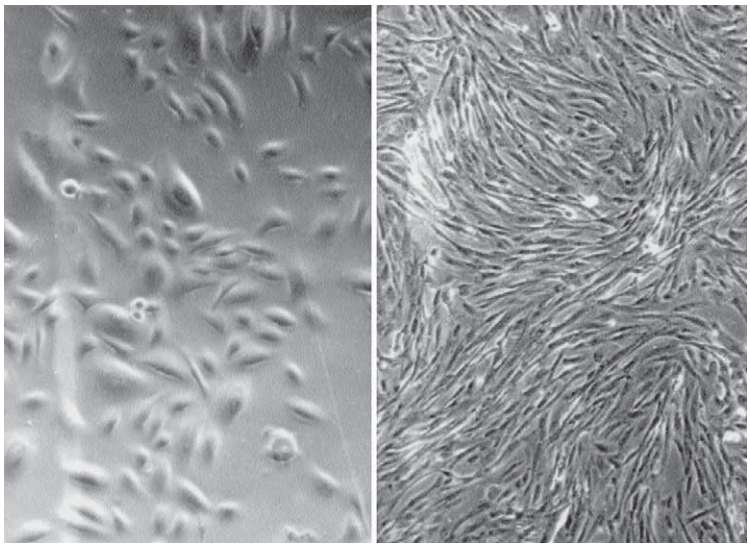

Figure 19–3. Urothelial *(left panel)* and bladder muscle *(right panel)* cells growing in vitro.

harvested from surgical material, extensively expanded in culture, and their differentiation characteristics, growth requirements, and other biologic properties can be studied (Liebert et al, 1991; Cilento et al, 1994; Tobin et al, 1994; Harriss, 1995; Freeman et al, 1997; Liebert et al, 1997; Fauza et al, 1998a, 1998b; Lobban et al, 1998; Solomon et al, 1998; Nguyen et al, 1999; Puthenveettil et al, 1999; Rackley et al, 1999). Major advances in cell culture techniques have been made within the past decade, and these techniques make the use of autologous cells possible for clinical application. However, even now, not all human cells can be grown or expanded in vitro. Liver, nerve, and pancreas are examples of human tissues where the technology is not yet advanced to the point where these cells can be grown and expanded.

When cells are used for tissue reconstitution, donor tissue is dissociated into individual cells that are either implanted directly into the host or expanded in culture, then attached to a support matrix or reimplanted after expansion. The implanted tissue can be heterologous, allogeneic, or autologous. Ideally, this approach allows lost tissue function to be restored or replaced in toto, and with limited complications (Atala, 1997). **Native cells and tissues are usually preferable for reconstruction.** In most cases, the replacement of lost or deficient tissues with functionally equivalent cells and tissues would improve the outcome for these patients. This goal may be attainable with the use of regenerative medicine techniques.

BIOMATERIALS FOR GENITOURINARY REGENERATIVE MEDICINE

Synthetic materials have been used widely for urologic reconstruction. **The most common type of synthetic prostheses for urologic applications is made of silicone.** Silicone prostheses have been used for the treatment of urinary incontinence with the artificial urinary sphincter and detachable balloon system, for treatment of vesicoureteral reflux with silicone microparticles, and for impotence with penile prostheses (Atala et al, 1992a; Riehmann et al, 1993; Levesque et al, 1996; Buckley et al, 1997). There has also been a major effort directed toward the construction of artificial bladders made with silicone. In some disease states, such as urinary incontinence or vesicoureteral reflux, artificial agents (Teflon paste, glass microparticles) have been used as injectable bulking substances; however, these substances are not entirely biocompatible (Atala, 1994).

For regenerative medicine purposes, there are clear advantages in using degradable, biocompatible materials that can function as cell delivery vehicles, and/or provide the structural parameters needed for tissue replacement. **Biomaterials in genitourinary regenerative medicine function as an artificial extracellular matrix (ECM) and elicit biologic and mechanical functions of native ECM found in tissues in the body.** Native ECM brings cells together into tissue, controls the tissue structure, and regulates the cell phenotype (Alberts et al, 1994). Biomaterials facilitate the localization and delivery of cells and/or bioactive factors (e.g., cell adhesion peptides, growth factors) to desired sites in the body; define a three-dimensional space for the formation of new tissues with appropriate structure; and guide the development of new tissues with appropriate function (Kim et al, 1998). Direct injection of cell suspensions without biomaterial matrices has been used in some cases (Ponder et al, 1991; Brittberg et al, 1994), but it is difficult to control the localization of transplanted cells. In addition, the majority of mammalian cell types is anchorage-dependent and will die if not provided with a cell-adhesion substrate.

Design and Selection of Biomaterials

The design and selection of the biomaterial is critical in the development of engineered genitourinary tissues. The biomaterial must be capable of controlling the structure and function of the engineered tissue in a predesigned manner by interacting with transplanted cells and/or host cells. Generally, the ideal biomaterial should be biocompatible, promote cellular interaction and tissue development, and possess proper mechanical and physical properties.

The selected biomaterial should be biodegradable and bioresorbable to support the reconstruction of a completely normal tissue without inflammation. Such behavior of the biomaterials avoids the risk of inflammatory or foreign-body responses that may be associated with the permanent presence of a foreign material in the body. The degradation rate and the concentration of degradation products in the tissues surrounding the implant must be at a tolerable level (Bergsma et al, 1995).

The biomaterials should provide an appropriate regulation of cell behavior (e.g., adhesion, proliferation, migration, differentiation) to promote the development of functional new tissue. Cell behavior in engineered tissues is regulated by multiple interactions with the microenvironment, including interactions with cell-adhesion ligands (Hynes, 1992) and with soluble growth factors (Deuel, 1997). Cell adhesion–promoting factors (e.g., arg-gly-asp [RGD]) can be presented by the biomaterial itself or incorporated into the biomaterial to control cell behavior through ligand-induced cell receptor signaling processes (Barrera et al, 1993; Cook et al, 1997). The biomaterials provide temporary mechanical support sufficient to withstand in vivo forces exerted by the surrounding tissue and maintain a potential space for tissue development. The mechanical support of the biomaterials should be maintained until the engineered tissue has sufficient mechanical integrity to support itself (Atala, 2007). This potentially can be achieved by an appropriate choice of mechanical and degradative properties of the biomaterials (Kim et al, 1998).

The biomaterials need to be processed into specific configurations. A large ratio of surface area to volume is often desirable to allow the delivery of a high density of cells. A high-porosity, interconnected pore structure with specific pore sizes promotes tissue ingrowth from the surrounding host tissue. Several techniques, such as electrospinning, have been developed that readily control porosity, pore size, and pore structure (Lee et al, 2007; Yoo et al, 2007; Choi et al, 2008; Lee et al, 2008a, 2008b, 2008c).

Types of Biomaterials

Generally, three classes of biomaterials have been used for engineering of genitourinary tissues: naturally derived materials, such as collagen and alginate; acellular tissue matrices, such as bladder submucosa and small-intestinal submucosa; and synthetic polymers, such as polyglycolic acid (PGA), polylactic acid (PLA), and poly(lactic-co-glycolic acid) (PLGA). These classes of biomaterials have been tested in regard to their biocompatibility with primary human urothelial and bladder muscle cells (Pariente et al, 2001). Naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition. Synthetic polymers can be produced reproducibly on a large scale with controlled properties of strength, degradation rate, and microstructure.

Collagen is the most abundant and ubiquitous structural protein in the body, and it may be readily purified from both animal and human tissues with an enzyme treatment and salt/acid extraction (Li, 1995). Collagen has long been known to exhibit minimal inflammatory and antigenic responses (Furthmayr et al, 1976), and it has been approved by the U.S. Food and Drug Administration (FDA) for many types of medical applications, including wound dressings and artificial skin (Cen et al, 2008). Intermolecular cross-linking reduces the degradation rate by making the collagen molecules less susceptible to an enzymatic attack. Intermolecular cross-linking can be accomplished by various physical (e.g., ultraviolet radiation, dehydrothermal treatment) or chemical (e.g., glutaraldehyde, formaldehyde, carbodiimides) techniques (Li, 1995). Collagen contains cell-adhesion domain sequences (e.g., RGD) that exhibit specific cellular interactions. This may help to retain the phenotype and activity of many types of cells, including fibroblasts (Silver et al, 1992) and chondrocytes (Sams et al, 1995). This material can be processed into a wide variety of structures such as sponges (Fig. 19–4, top) fibers, and films (Yannas et al, 1980a, 1980b; Cavallaro et al, 1994).

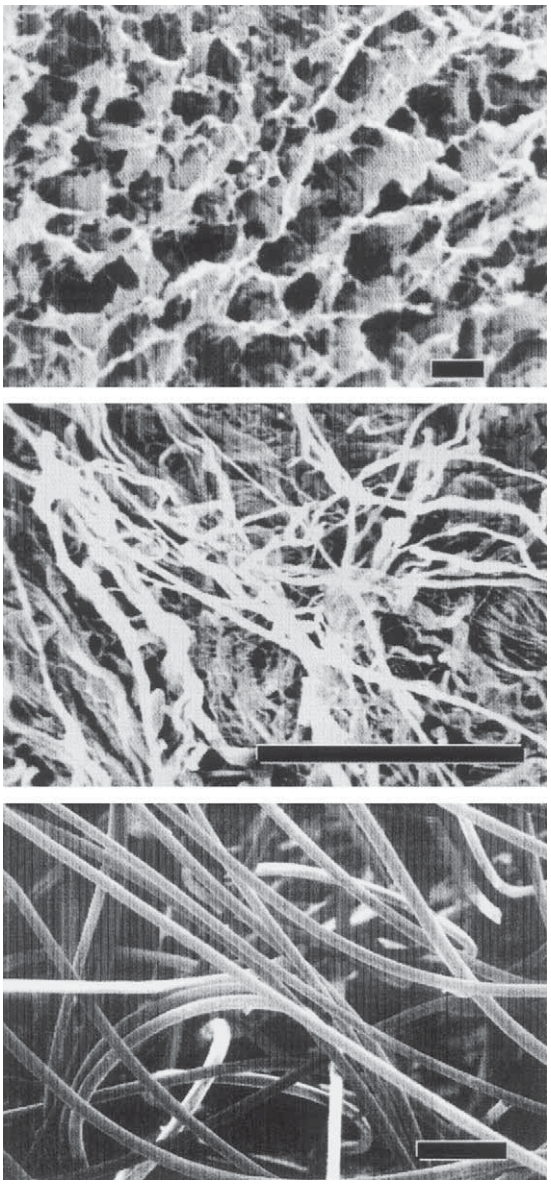

Figure 19–4. Scanning electron micrographs of biomaterials: collagen sponge *(top)*, acellular matrix prepared from pig bladder submucosa *(center)*, and polyglycolic acid fiber-based matrix *(bottom)*. (Size bars = 100 µm.)

Alginate, a polysaccharide isolated from seaweed, has been used as an injectable cell delivery vehicle (Smidsrod et al, 1990) and a cell immobilization matrix (Lim and Sun, 1980) owing to its gentle gelling properties in the presence of divalent ions such as calcium. Alginate is a family of copolymers of D-mannuronate and L-guluronate. The physical and mechanical properties of alginate gel are strongly correlated with the proportion and length of the polyguluronate block in the alginate chains (Smidsrod et al, 1990). Efforts have been made to synthesize biodegradable alginate hydrogels with mechanical properties that are controllable in a wide range by intermolecular covalent cross-linking and with cell-adhesion peptides coupled to their backbones (Rowley et al, 1999).

Recently, natural materials such as alginate and collagen have been used as "bio-inks" in a newly developed bioprinting technique based on inkjet technology (Boland et al, 2006; Campbell et al, 2007). Using this technology, these scaffold materials can be "printed" into a desired scaffold shape using a modified

inkjet printer. In addition, several groups have shown that living cells can also be printed using this technology (Laflamme et al, 2005; Nakamura et al, 2005). This exciting technique can be modified so that a three-dimensional construct containing a precise arrangement of cells, growth factors, and extracellular matrix material can be printed (Roth et al, 2004; Ilkhanizadeh et al, 2007; Xu et al, 2009). Such constructs may eventually be implanted into a host to serve as the backbone for a new tissue or organ.

Acellular tissue matrices are collagen-rich matrices prepared by removing cellular components from tissues (Fig. 19–4, center). The matrices are often prepared by mechanical and chemical manipulation of a segment of bladder tissue (Dahms et al, 1998; Piechota et al, 1998; Yoo et al, 1998b; Chen et al, 1999). The matrices slowly degrade after implantation and are replaced and remodeled by ECM proteins synthesized and secreted by transplanted or ingrowing cells. Acellular tissue matrices have been proved to support cell ingrowth and regeneration of genitourinary tissues, including urethra and bladder, with no evidence of immunogenic rejection (Probst et al, 1997; Chen et al, 1999). Because the structures of the proteins (e.g., collagen, elastin) in acellular matrices are well conserved and normally arranged, the mechanical properties of the acellular matrices are not significantly different from those of native bladder submucosa (Dahms et al, 1998).

Polyesters of naturally occurring α-hydroxy acids, including PGA, PLA, and PLGA, are widely used in regenerative medicine. These polymers have gained FDA approval for human use in a variety of applications, including sutures (Gilding, 1981). The degradation products of PGA, PLA, and PLGA are nontoxic, natural metabolites that are eventually eliminated from the body in the form of carbon dioxide and water (Gilding, 1981). Because these polymers are thermoplastics, they can easily be formed into a three-dimensional scaffold with a desired microstructure, gross shape, and dimension by various techniques, including molding, extrusion (Freed et al, 1994), solvent casting (Mikos et al, 1994), phase separation techniques, and gas foaming techniques (Harris et al, 1998). More recently, techniques such as electrospinning have been used to quickly create highly porous scaffolds in various conformations (Han et al, 2006; Choi et al, 2008; Lee et al, 2008a; Lee et al, 2008b).

Many applications in genitourinary regenerative medicine require a scaffold with high porosity and a high ratio of surface area to volume. This need has been addressed by processing biomaterials into configurations of fiber meshes (Fig. 19–4, bottom) and porous sponges using the techniques described previously. A drawback of the synthetic polymers is lack of biologic recognition. As an approach toward incorporating cell recognition domains into these materials, copolymers with amino acids have been synthesized (Barrera et al, 1993; Intveld et al, 1994; Cook et al, 1997). Other biodegradable synthetic polymers, including polyanhydrides and polyortho-esters), can also be used to fabricate scaffolds for genitourinary regenerative medicine with controlled properties (Peppas et al, 1994).

Nanotechnology, the ability to use small molecules that have distinct properties in a small scale, has been used to create "smart" biomaterials for regenerative medicine (Boccaccini et al, 2005; Harrison et al, 2007). Nanoscaffolds have been manufactured specifically for bladder applications (Harrington et al, 2006). The manufacturing of biomaterials can also lead to enhanced cell alignment and tissue formation (Choi et al, 2008).

Vascularization

The goals in regenerative medicine include the replacement of damaged, injured or missing body tissues with biological compatible substitutes. **A limiting factor for the engineering of tissues is that cells cannot be implanted in volumes exceeding 3 mm^3** (Folkman et al, 1973)**. Nutrition and gas exchange is limited by this maximal diffusion distance. If cells were implanted in volumes exceeding 3 mm^3, only the cells on the surface would survive, and the central cell core would undergo necrosis resulting from a lack of vascularity.** Therefore a critical obstacle in regenerative medicine is the ability to maintain large masses of cells alive upon transfer from the in vitro culture conditions into the host (in vivo) (Mooney et al, 1999). To achieve the goals of engineering large complex tissues, and possibly internal organs, vascularization of the regenerating cells is essential.

Formation of new blood vessels and capillaries comprises two different processes: vasculogenesis, the in-situ assembly of capillaries from undifferentiated endothelial cells (EC), and angiogenesis, the sprouting of capillaries from preexisting blood vessels. The formation of the first capillaries takes place mostly during the early stages of embryogenesis (Folkman et al, 1996; Yancopoulos et al, 1998).

Vasculogenesis can be divided into five consecutive steps: (1) EC are generated from precursor cells, called angioblasts, in the bone marrow; (2) EC form the vessel primordia and aggregates that establish cell-to-cell contact but have no lumen; (3) a nascent endothelial tube is formed, composed of polarized EC; (4) a primary vascular network is formed from an array of nascent endothelial tubes; and (5) pericytes and vascular smooth muscle cells are recruited (Drake et al, 1998).

Angiogenesis is a morphogenic process, which describes the formation of new blood capillaries from EC of preexisting vessels. There are six basic steps in angiogenesis: (1) vasodilatation of the parental vessel, reducing the contact between adjacent EC, (2) degradation of the basement membrane of a parental vessel by secretion and activation of a wide range of proteolytic enzymes, (3) EC migration and proliferation to form a leading edge of the new capillary, (4) generation of the capillary lumen and formation of a tube-like structure, (5) basement membrane synthesis, and (6) recruitment of pericytes and vascular smooth muscle cells (Folkman et al, 1992).

When converting to the angiogenic stage, EC will capture new properties that enable them to neovascularize the tissue (Hanahan et al, 1996). When the new vessels are in place and the vascular network matures, the neovascular EC resume their quiescent phenotype (Darland et al, 1999). Several growth factors serve as stimuli for EC conversion to the angiogenic phenotype (Battegay, 1995). Vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF) are two well-characterized and important angiogenic molecules that have a direct effect on EC.

The understanding of the angiogenic process and the isolation of potent and specific angiogenic growth factors has encouraged the use of these factors therapeutically (Loges et al, 2009; Phelps et al, 2009). Efforts have been aimed at incorporating the knowledge acquired in angiogenesis of ischemic tissues into practical approaches to vascularize bioengineered tissues (Stosich et al, 2009). Bioengineered tissues are usually supported by scaffolds of biocompatible matrices made from natural or artificial sources (Hubbell et al, 1991). Successful vascularization is dependent on the porosity of the supporting matrix. A positive correlation between the pore size of poly-L-lactic acid (PLLA) implants and the rate of vascularization has been observed (Mikos et al, 1993).

Three approaches have been used for vascularization of bioengineered tissue: (1) incorporation of angiogenic factors in the bioengineered tissue, (2) seeding EC with other cell types in the bioengineered tissue, and (3)

prevascularization of the matrix prior to cell seeding. Angiogenic growth factors may be incorporated into the bioengineered tissue before implantation, to attract host capillaries and to enhance neovascularization of the implanted tissue. Angiogenic growth factors can be embedded in specific biomaterials, and can be controlled for slow release (Eiselt et al, 1998). Cells can also be genetically engineered to secrete high levels of angiogenic proteins (Springer et al, 1998).

Another approach for enhancing angiogenesis employed cultured EC, which are incorporated into the bioengineered tissue prior to implantation. Human penile corpus cavernosum–derived smooth muscle cells and EC were seeded on biodegradable polymer scaffolds, in order to reconstruct penile corporeal tissue in vitro and in vivo (Park et al, 1999). The use of EC improved the formation of the engineered tissue. In another study, the addition of both EC and angiogenic growth factors (VEGF) accelerated the formation of engineered muscle tissue (De Coppi et al, 2005). An alternative direction in vascularization of bioengineered tissue is the prevascularization of the supporting polymer prior to cell seeding. In this manner, the bioengineered tissue will be organized around the vascular network, providing sufficient tissue perfusion (Fontaine et al, 1995).

Despite the successes in bioengineering tissues consisting of thin layers of cells such as skin, a major challenge for regenerative medicine in the future is the production of larger organs with more complex structures like the kidney. Tissues with a large mass of cells will require a vascular network of arteries, veins, and capillaries to deliver nutrients to each cell. The development of efficient methods to vascularize bioengineered tissues is critical for a successful outcome. There are many obstacles to overcome before large entire tissue-engineered solid organs are produced. Recent developments in angiogenesis research may provide important knowledge and essential.

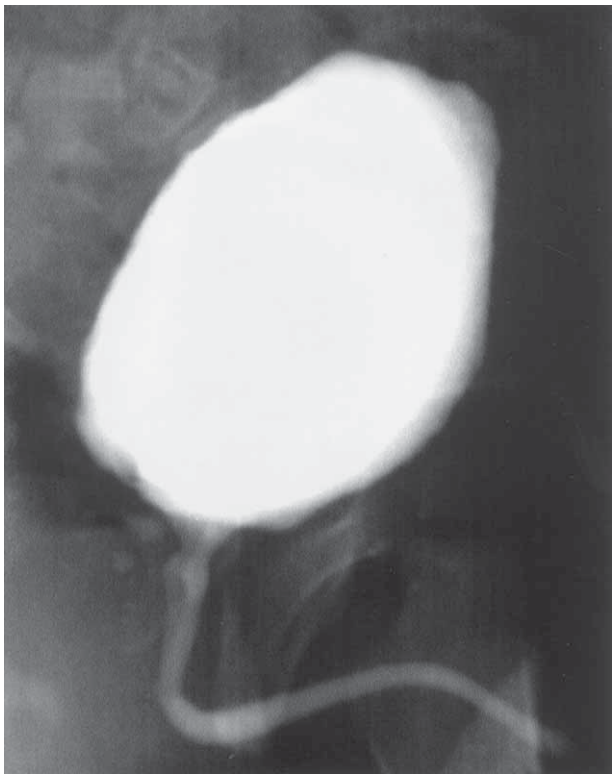

Figure 19–5. Urethrogram 6 months after surgery in a patient who had a portion of his urethra replaced with the use of regenerative medicine techniques.

REGENERATIVE MEDICINE OF UROLOGIC STRUCTURES

Urethra

Various strategies have been proposed over the years for the regeneration of urethral tissue. Woven meshes of PGA without cells (Bazeed et al, 1983; Olsen et al, 1992) or with cells (Atala et al, 1992b) were used to regenerate urethras in various animal models. Naturally derived collagen-based materials, such as bladder-derived acellular submucosa (Chen et al, 1999), and an acellular urethral submucosa (Sievert et al, 2000), have also been tried experimentally in various animal models for urethral reconstruction.

The bladder submucosa matrix (Chen et al, 1999), proved to be a suitable graft for repair of urethral defects in rabbits. The neourethras demonstrated a normal urothelial luminal lining and organized muscle bundles. These results were confirmed clinically in a series of patients with a history of failed hypospadias reconstruction wherein the urethral defects were repaired with human bladder acellular collagen matrices (Atala et al, 1999). The neourethras were created by anastomosing the matrix in an onlay fashion to the urethral plate. The size of the created neourethra ranged from 5 to 15 cm. After a 3-year follow-up, three of the four patients had a successful outcome in regard to cosmetic appearance and function (Fig. 19–5). One patient who had a 15-cm neourethra created developed a subglanular fistula. The acellular collagen-based matrix eliminated the necessity of performing additional surgical procedures for graft harvesting, and both operative time and the potential morbidity from the harvest procedure were decreased. Similar results were obtained in pediatric and adult patients with primary urethral stricture disease using the same collagen matrices (El-Kassaby et al, 2003). Another study in 30 patients with recurrent stricture disease showed that a healthy urethral bed (two or fewer prior urethral surgeries) was needed for successful urethral reconstruction using the acellular collage-based grafts (El Kassaby et al, 2008). **More than 200 pediatric and adult patients with urethral disease have been successfully treated in an onlay manner with a bladder-derived collagen-based matrix. One of its advantages over nongenital tissue grafts used for urethroplasty is that the material is "off the shelf."** This eliminates the necessity of additional surgical procedures for graft harvesting, which may decrease operative time as well as the potential morbidity due to the harvest procedure.

The above techniques, using nonseeded acellular matrices, were applied experimentally and clinically in a successful manner for onlay urethral repairs. However, when tubularized urethral repairs were attempted experimentally, adequate urethral tissue regeneration was not achieved, and complications ensued, such as graft contracture and stricture formation (De Filippo et al, 2002). Autologous rabbit bladder epithelial and smooth muscle cells were grown and seeded onto preconfigured tubular matrices. Entire urethra segments were resected and urethroplasties were performed with tubularized collagen matrices, either seeded with cells or without cells. The tubularized collagen matrices seeded with autologous cells formed new tissue that was histologically similar to native urethra. The tubularized collagen matrices without cells led to poor tissue development, fibrosis, and stricture formation. These findings were confirmed clinically. A clinical trial using tubularized nonseeded small intestinal submucosa (SIS) for

urethral stricture repair was performed with eight evaluable patients. Two patients with short inflammatory strictures maintained urethral patency. Stricture recurrence developed in the other six patients within 3 months of surgery (le Roux, 2005). Other cell types have also been tried experimentally in acellular bladder collagen matrices, including foreskin epidermal cells and oral keratinocytes (Fu et al, 2007; Li et al, 2008). Vascular endothelial growth factor gene–modified urothelial cells have also been used experimentally for urethral reconstruction (Guan et al, 2008).

The normal wound-healing response to injury has been studied extensively, and this knowledge has been helpful in maximizing success for the engineering of tissues. At the time of tissue injury, cell ingrowth is initiated from the wound edges to cover the tissue defect. **The cells from the edges of the native tissue are able to traverse short distances without any detrimental effects. If the wound is large, more than a few millimeters in distance or depth, increased collagen deposition, fibrosis, and scar formation ensue. Matrices implanted in wound beds are able to lengthen the distances that cells can traverse without initiating an adverse fibrotic response. However, these distances are also limited. The maximum distance that adjacent cells from the wound edge have to travel to create normal tissue over a biologic matrix is approximately 1 cm** (Dorin et al, 2008). **Tissue defects greater than 1 cm, which are treated with a matrix alone (without cells), usually have increased collagen deposition, increased fibrosis, and scar formation. Cell-seeded matrices implanted in wound beds are able to further lengthen the distance for normal tissue formation without initiating an adverse fibrotic response. Studies in the field of regenerative medicine have shown that very large defects (>30 cm), can be successfully treated using cell-seeded scaffolds. This explains the described experimental and clinical results noted with urethral repair. Nonseeded matrices are able to replace urethral segments when used in an onlay fashion, because of the short distances required for tissue ingrowth. However, if a tubularized urethral repair is needed, the matrices need to be seeded with autologous cells in order to avoid the risk of stricture formation and poor tissue development.**

Bladder

Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair. However, gastrointestinal tissues are designed to absorb specific solutes, whereas bladder tissue is designed for the excretion of solutes. **When gastrointestinal tissue is in contact with the urinary tract, multiple complications may ensue, such as infection, metabolic disturbances, urolithiasis, perforation, increased mucus production, and malignancy** (McDougal, 1992; Atala et al, 1993a; Kaefer et al, 1997, 1998). Because of the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative reconstructive procedures for bladder replacement or repair. These include autoaugmentation (Cartwright et al, 1989a, 1989b) (Fig. 19–6) and ureterocystoplasty (Bellinger, 1993; Churchill et al, 1993; Adams et al, 1998). In addition, alternative methods for bladder reconstruction have been explored, such as the use of tissue expansion and regenerative medicine with cell transplantation.

Tissue Expansion for Bladder Augmentation

A system of progressive dilation for ureters and bladders has been proposed but has not been attempted clinically (Lailas et al, 1996; Satar et al, 1999). In an animal experiment, rabbits underwent

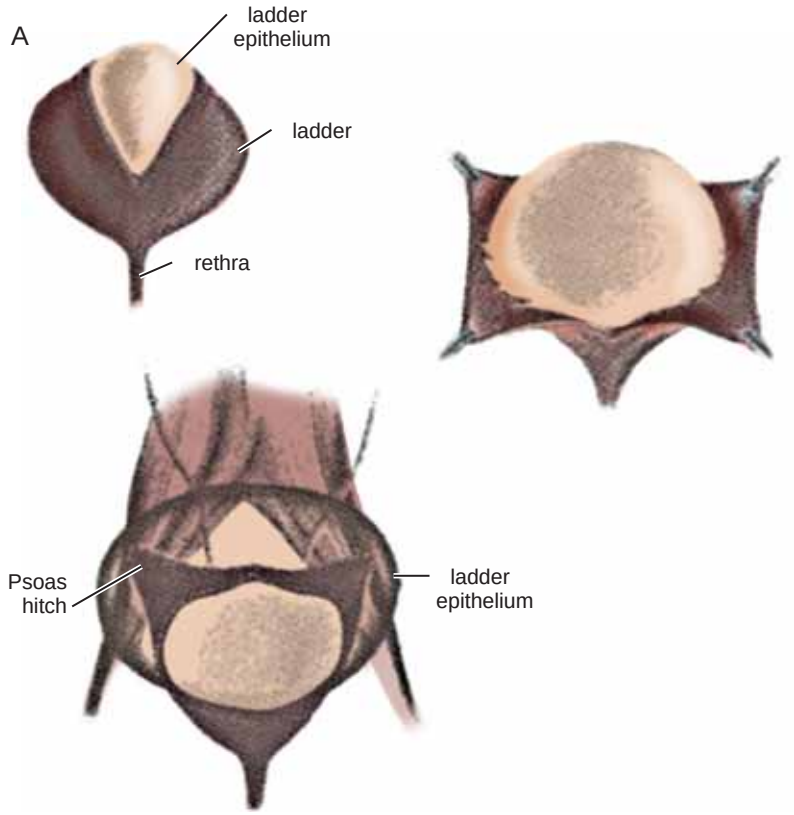

Figure 19–6. Autoaugmentation is performed by incising the detrusor **(A)** and stripping it from intact bladder epithelium **(B),** which allows the urothelial layer to bulge with bladder filling **(C).** (From Cartwright PC, Snow BW. Bladder autoaugmentation: early clinical experience. J Urol 1989;142:505.)

unilateral ureteral ligation at the ureterovesical junction. A catheter was threaded into the proximal ipsilateral ureter and connected to an injection port that was secured subcutaneously. A saline-antibiotic solution was injected daily subcutaneously into the injection port. After 1 month of daily saline-antibiotic–solution injections, the ureteral units were dilated at least 10-fold, and the diameter exceeded that of adjacent colon in each instance (Fig. 19–7). Augmentation cystoplasty was performed with the reconfigured dilated ureteral segment, resulting in an increased bladder capacity ranging from 190% to 380% (Lailas et al, 1996). In a similar system, a dilating indwelling catheter was used to dilate ureteral tissue in pigs (Ikeguchi et al, 1998).

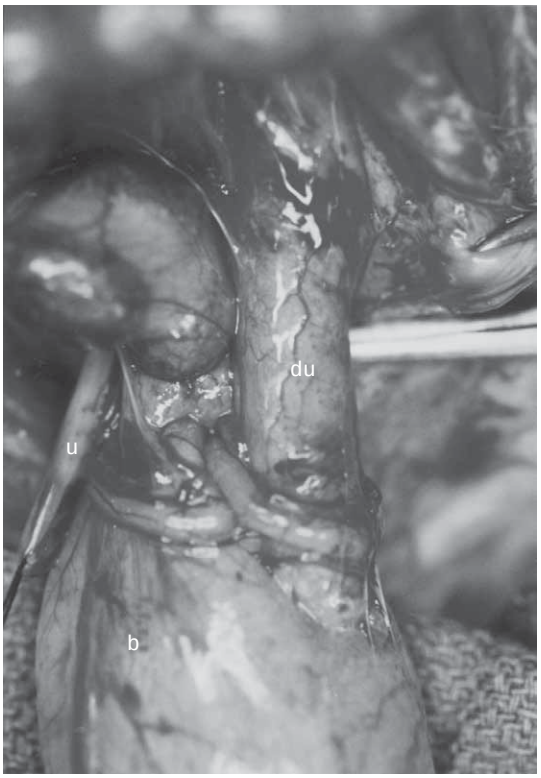

Figure 19–7. Progressive dilation can be performed in a normal-caliber ureter, which can be subsequently used for ureterocystoplasty. After placement of a ureteral dilation device, comparison is made of progressively dilated ureter (du) and native undilated ureter (u) coming off the bladder (b).

A system for the progressive expansion of native bladder tissue has also been used for augmenting bladder volumes (Satar et al, 1999). Beagle dog bladders were divided horizontally into two segments: a superior bladder neoreservoir, and an intact smaller bladder inferiorly with both ureters left intact and draining. A Silastic catheter was threaded into the newly formed, superiorly located neoreservoir and connected to an injection port, which was secured subcutaneously. Four weeks after surgery, a saline-antibiotic solution was injected daily into the palpable injection port, dilating the neoreservoir through the Silastic catheter. Within 30 days after progressive dilation, the neoreservoir volume was expanded at least 10-fold (Fig. 19–8). Urodynamic studies showed normal compliance in all animals, and microscopic examination of the expanded neoreservoir tissue showed a normal histology. A series of immunocytochemical studies demonstrated that the dilated bladder tissue maintained normal phenotypic characteristics (Satar et al, 1999).

Ideally, bladder tissue expansion could be performed with an indwelling dilation catheter, similar to a Foley catheter with a large balloon. In the future, one could foresee placing a dilating catheter intravesically in a patient who requires augmentation, either in an intermittent fashion (e.g., four times daily) or left indwelling. An expanding balloon within the catheter could then be filled progressively, with either continuous or intermittent filling until the desired bladder volume is achieved.

Matrices for Bladder Regeneration

Over the last few decades, several bladder wall substitutes have been attempted with both synthetic and organic materials. Synthetic materials that have been tried in experimental and clinical settings include polyvinyl sponge, Teflon, collagen matrices, Vicryl (PGA) matrices, and silicone. Most of these attempts have failed because of mechanical, structural, functional, or biocompatibility problems. **Usually, permanent synthetic materials used for bladder reconstruction succumb to mechanical failure and urinary stone formation, and use of degradable materials leads to fibroblast deposition, scarring, graft contracture, and a reduced reservoir volume over time** (Atala, 1995a, 1998).

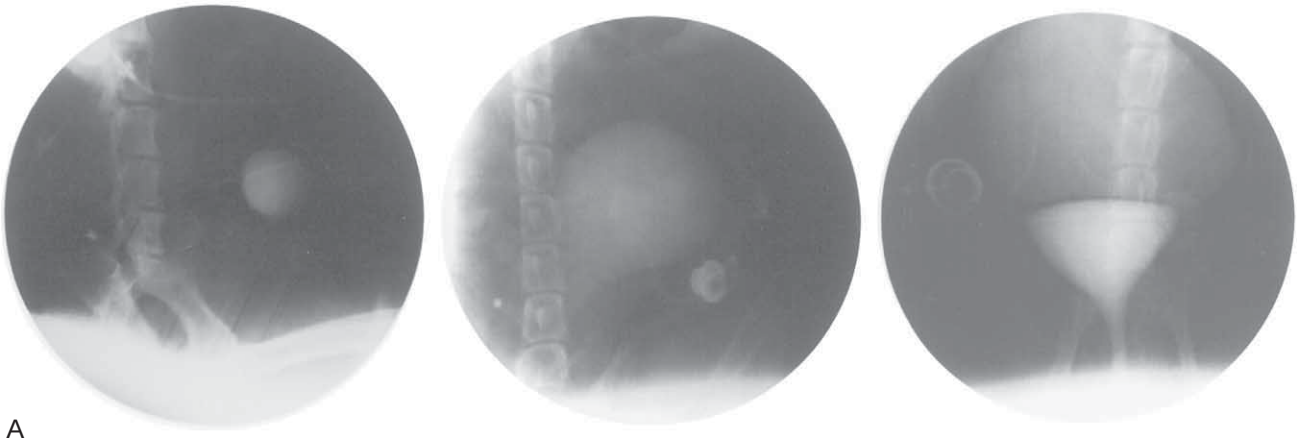

Figure 19–8. Progressive bladder dilation can be performed with adequate increases in capacity. Cystography of bladder neoreservoir before progressive dilation **(A)** is compared with cystography results after progressive dilation **(B)** and with cystogram showing dilated neoreservoir and intact bladder segment **(C).**

There has been a resurgence in the use of various collagen-based matrices for tissue regeneration. Nonseeded allogeneic acellular bladder matrices have served as scaffolds for the ingrowth of host bladder wall components. The matrices are prepared by mechanically and chemically removing all cellular components from bladder tissue (Sutherland et al, 1996; Probst et al, 1997; Piechota et al, 1998; Yoo et al, 1998b; Wefer et al, 2001). The matrices serve as vehicles for partial bladder regeneration, and relevant antigenicity is not evident.

Cell-seeded allogeneic acellular bladder matrices were used for bladder augmentation in dogs (Yoo et al, 1998b). The regenerated bladder tissues contained a normal cellular organization consisting of urothelium and smooth muscle and exhibited a normal compliance. **Biomaterials preloaded with cells before their implantation showed better tissue regeneration compared with biomaterials implanted with no cells, in which tissue regeneration depended on ingrowth of the surrounding tissue.** The bladders showed a significant increase (100%) in capacity when augmented with scaffolds seeded with cells, compared to scaffolds without cells (30%) (Fig. 19–9). The acellular collagen matrices can be enhanced with growth factors to improve bladder regeneration (Kikuno et al, 2008).

SIS, a biodegradable, acellular, xenogeneic collagen-based tissue-matrix graft, was first described by Badylak and colleagues in the 1980s as an acellular matrix for tissue replacement in the vascular field (Badylak et al, 1989). It has been shown to promote regeneration of a variety of host tissues, including blood vessels and ligaments (Badylak, 2002). The matrix is derived from pig small intestine in which the mucosa is mechanically removed from the inner surface, and the serosa and muscular layer are removed from the outer surface. Animal studies have shown that the nonseeded SIS matrix used for bladder augmentation is able to regenerate in vivo (Kropp et al, 1996a, 1996b). Histologically, the transitional layer was the same as that of the native bladder tissue, but, as with other nonseeded collagen matrices used experimentally, the muscle layer was not fully developed. A large amount of collagen was interspersed among a smaller number of muscle bundles. A computer-assisted image analysis demonstrated a decreased muscle-to-collagen ratio with loss of the normal architecture in the SIS-regenerated bladders. In-vitro contractility studies performed on the SIS-regenerated dog bladders showed a decrease in maximal contractile response by 50% from those of normal bladder tissues. Expression of muscarinic, purinergic, and α-adrenergic receptors and functional cholinergic and purinergic innervation were demonstrated (Kropp et al, 1996b). Cholinergic and purinergic innervation also occurred in rats (Vaught et al, 1996).

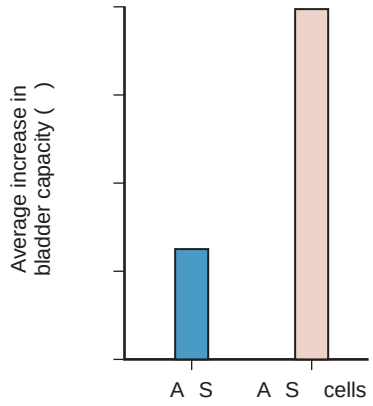

Figure 19–9. Bladders augmented with a collagen matrix derived from bladder submucosa seeded with urothelial and smooth muscle cells (allogenic bladder submucosa [ABS] + cells) showed a 100% increase in capacity compared with bladders augmented with the cell-free ABS, which showed only a 30% increase in capacity within 3 months after implantation.

Bladder augmentation using laparoscopic techniques was performed on mini-pigs with porcine bowel acellular tissue matrix, human placental membranes, or porcine SIS. At 12 weeks postoperatively, the grafts had contracted to 70%, 65%, and 60% of their original sizes, respectively, and histologically the grafts showed predominantly only mucosal regeneration (Portis et al, 2000). The same group evaluated the long-term results of laparoscopic hemicystectomy and bladder replacement with SIS with ureteral reimplantation into the SIS material in mini-pigs. Histopathology studies after 1 year showed muscle at the graft periphery and center, but it consisted of small fused bundles with significant fibrosis. Nerves were present at the graft periphery and center, but they were decreased in number. Compared with primary bladder closure after hemicystectomy, no advantage in bladder capacity or compliance was documented (Landman et al, 2004). More recently, bladder regeneration has been shown to be more reliable when the SIS was derived from the distal ileum (Kropp et al, 2004).

In multiple studies using various materials as nonseeded grafts for cystoplasty, the urothelial layer was able to regenerate normally, but the muscle layer, although present, was not fully developed (Kropp et al, 1996b; Probst et al, 1997; Sutherland et al, 1996; Jayo et al, 2008b; Yoo et al, 1998b; Zhang, 2008). Studies involving acellular matrices that may provide the necessary environment to promote cell migration, growth, and differentiation are being conducted (Chun et al, 2007). With continued bladder research in this area, these matrices may have a clinical role in bladder replacement in the future.

Regenerative Medicine for Bladder Using Cell Transplantation

Regenerative medicine with selective cell transplantation may provide a means to create functional new bladder segments (Atala, 1997). The success of cell transplantation strategies for bladder reconstruction depends on the ability to use donor tissue efficiently and to provide the right conditions for long-term survival, differentiation, and growth. Various cell sources have been explored for bladder regeneration. Native cells are currently preferable due to their autologous source, wherein they can be used without rejection (Cilento et al, 1994). It has been shown experimentally that the bladder neck and trigone area has a higher propensity of urothelial progenitor cells (Nguyen et al, 2007), and these cells are localized in the basal region (Kurzrock et al, 2008). Amniotic fluid and bone marrow–derived stem cells can also be used in an autologous manner and have the potential to differentiate into bladder muscle (De Coppi et al, 2007a; Shukla et al, 2008) and urothelium (Anumanthan et al, 2008). Embryonic stem cells also have the potential to differentiate into bladder tissue (Oottamasathien et al, 2007).

Formation of Bladder Tissue. Human urothelial and muscle cells can be expanded in vitro, seeded onto polymer scaffolds, and allowed to attach and form sheets of cells. The cell-polymer scaffold can then be implanted in vivo. Histologic analysis indicated that viable cells were able to self assemble back into their respective tissue types, and would retain their native phenotype (Atala et al, 1993c). These experiments demonstrated,

for the first time, that composite layered tissue-engineered structures could be created de novo. Before this study, only nonlayered structures had been created in the field of regenerative medicine.

In order to determine the effects of implanting engineered tissues in continuity with the urinary tract, animal models of bladder augmentation were used (Yoo et al, 1998b). Partial cystectomies were performed in dogs. The animals were divided into two experimental groups. One group had their bladder augmented with a nonseeded bladder-derived collagen matrix, and the second group had their bladder augmented with a cell-seeded construct. The bladders augmented with matrices seeded with cells showed a 100% increase in capacity compared with bladders augmented with cell-free matrices, which showed only a 30% increase in capacity (see Fig. 19–9).

Most of the free grafts (without cells) used for bladder replacement in the past were able to show adequate histology in terms of a well-developed urothelial layer, but they were associated with an abnormal muscular layer that varied in terms of its full development (Atala, 1995a, 1998).

It has been well established for decades that the bladder is able to regenerate generously over free grafts. Urothelium is associated with a high reparative capacity (de Boer et al, 1994). Bladder muscle tissue is less likely to regenerate in a normal fashion. Both urothelial and muscle ingrowth are believed to be initiated from the edges of the normal bladder toward the region of the free graft (Baker et al, 1958; Gorham et al, 1989). Usually, however, contracture or resorption of the graft has been evident. The inflammatory response toward the matrix may contribute to the resorption of the free graft. It was hypothesized that building the three-dimensional structure constructs in vitro, before implantation, would facilitate the eventual terminal differentiation of the cells after implantation in vivo and would minimize the inflammatory response toward the matrix, thus avoiding graft contracture and shrinkage. The dog study demonstrated a major difference between matrices used with autologous cells (tissue-engineered matrices) and those used without cells (Yoo et al, 1998b). **Matrices implanted with cells for bladder augmentation retained most of their implanted diameter, as opposed to matrices implanted without cells for bladder augmentation, in which graft contraction and shrinkage occurred. The histomorphology demonstrated a marked paucity of muscle cells and a more aggressive inflammatory reaction in the matrices implanted without cells.** Epithelial-mesenchymal signaling is important for the differentiation of bladder smooth muscle (Master et al, 2003).

The results of initial studies showed that the creation of artificial bladders may be achieved in vivo; however, it could not be determined whether the functional parameters noted were caused by the augmented segment or by the intact native bladder tissue. To better address the functional parameters of tissue-engineered bladders, an animal model was designed that required a subtotal cystectomy with subsequent replacement with a tissue-engineered organ (Oberpenning et al, 1999).

Cystectomy-only and nonseeded controls maintained average capacities of 22% and 46% of preoperative values, respectively. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue engineered bladder replacements. These findings were confirmed radiographically (Fig. 19–10). The subtotal cystectomy reservoirs that were not reconstructed and the polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42% total compliance). The compliance of the cell-seeded tissue-engineered bladders showed almost no difference from preoperative values that were measured when the native bladder was present (106%). Histologically, the nonseeded scaffold bladders presented a pattern of normal urothelial cells with a thickened fibrotic submucosa and a thin layer of muscle fibers. The retrieved tissue-engineered bladders showed a normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle (Fig. 19–11). Immunocytochemical analyses confirmed the muscle and urothelial phenotype. S-100 staining indicated the presence of neural structures (Oberpenning et al, 1999). These studies, performed with polyglycolic acid–based scaffolds, have been repeated by other investigators, showing similar results in large numbers of animals long-term (Jayo et al, 2008a, 2008b). The strategy of using biodegradable scaffolds with cells can be pursued without concerns for local or systemic toxicity (Kwon et al, 2008). However,

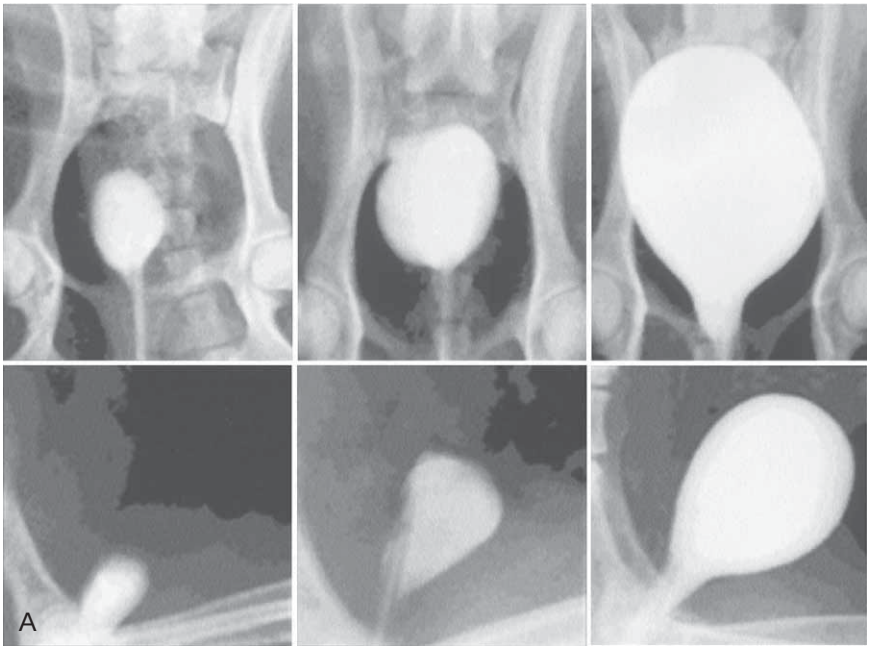

Figure 19–10. Radiographic cystograms in beagles 11 months after subtotal cystectomy without reconstruction **(A);** with reconstruction using a polymer without cells **(B);** and with reconstruction with a polymer and cell-seeded tissue-engineered organ **(C).** Organs after trigone-sparing cystectomy retained a small-sized reservoir. Tissue-engineered neobladders showed a normal configuration and a larger capacity than the trigones grafted with polymer only.

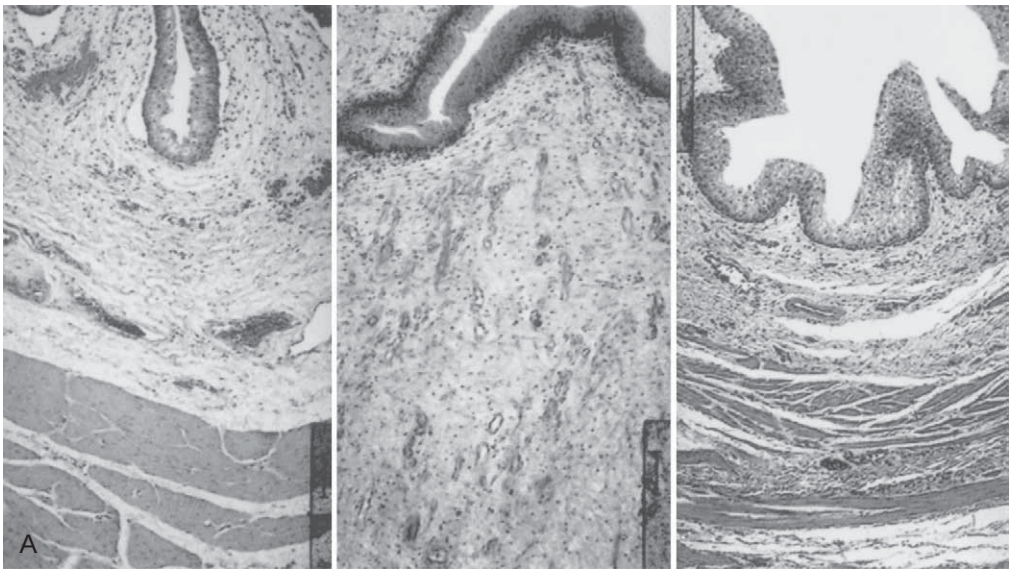

Figure 19–11. Hematoxylin and eosin staining shows histologic results 6 months after surgery (original magnification, ×250). **A,** Normal canine bladder. **B,** The bladder dome of the bladder reconstructed with cell-free polymer consists of normal urothelium over a thickened layer of collagen and fibrotic tissue; only scarce muscle fibers are apparent. **C,** The tissue-engineered neo-organ has a histomorphologically normal appearance. A trilayered architecture consisting of urothelium, submucosa, and smooth muscle is evident.

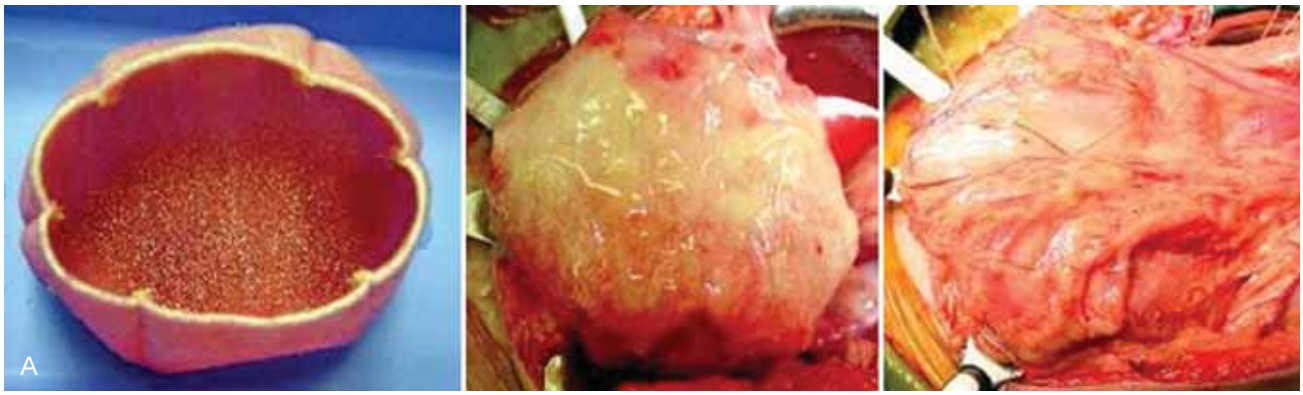

Figure 19–12. Construction of engineered bladder. **A,** Scaffold material seeded with cells for use in bladder repair. **B,** The seeded scaffold is anastomosed to native bladder with running 4-0 polyglycolic sutures. **C,** Implant covered with fibrin glue and omentum.

not all scaffolds perform well if a large portion of the bladder needs replacement. In a study using SIS for subtotal bladder replacement in dogs, both the unseeded and cell-seeded experimental groups showed graft shrinkage and poor results (Zhang et al, 2006b). The type of scaffold used is critical for the success of these technologies. The use of bioreactors, wherein mechanical stimulation is started at the time of organ production, has also been proposed as an important parameter for success (Farhat et al, 2008).

A clinical experience involving engineered bladder tissue for cystoplasty reconstruction was conducted starting in 1998. A small pilot study of seven patients was reported, using a collagen scaffold seeded with cells either with or without omentum coverage, or a combined PGA-collagen scaffold seeded with cells and omental coverage (Fig. 19–12). The patients reconstructed with the engineered bladder tissue created with the PGA-collagen cell-seeded scaffolds with omental coverage showed increased compliance, decreased end-filling pressures, increased capacities, and longer dry periods over time (Atala et al, 2006). It is clear from this experience that the engineered bladders continued their improvement with time, mirroring their continued development. Although the experience is promising in terms of showing that engineered tissues can be implanted safely, it is just a start in terms of accomplishing the goal of engineering fully functional bladders. This was a limited clinical experience, and the technology is not yet ready for wide dissemination, because further experimental and clinical studies are required. FDA Phase II studies have now been completed.

An area of concern in the field of tissue engineering in the past was the source of cells for regeneration. The concept of creating engineered constructs involves initially obtaining cells for expansion from the diseased organ. How can one be assured that the cell population that is obtained and being expanded for later autologous implantation is normal and will lead to normal tissue formation? For example, if one is dealing with a patient, will the cells obtained from a neuropathic bladder lead to the engineering of another neuropathic bladder? Cultured neuropathic bladder smooth muscle cells possess and maintain different characteristics than normal smooth muscle cells in vitro, as demonstrated by growth assays, contractility, adherence tests, and microarray analysis (Lin et al, 2004; Dozmorov et al, 2007; Hipp et al, 2008). However, when neuropathic smooth muscle cells were cultured in

vitro, and seeded onto matrices and implanted in vivo, the tissue engineered constructs showed the same properties as the tissues engineered with normal cells (Lai et al, 2002). **The progenitor cells, which reside within stem cell niches within each organ, are responsible for new cell differentiation and tissue formation during the normal process of tissue regeneration due to natural turnover, ageing, and tissue injury. It is known that genetically normal nonmalignant progenitor cells, which are the reservoirs for new cell formation, are programmed to give rise to normal tissue, regardless of whether the niche resides in either normal or diseased tissues** (Faris et al, 2001; Lai et al, 2002; Haller et al, 2005). Therefore although the mechanisms for tissue self-assembly and regenerative medicine are not fully understood, it is known that the progenitor cells are able to "reset" their program for normal cell differentiation. The stem cell niche and its role in normal tissue regeneration remains a fertile area of ongoing investigation.

From the above studies, it is evident, as with the urethral studies, that the use of cell-seeded matrices is superior to the use of nonseeded matrices for the creation of engineered bladder tissues. Although advances have been made with the engineering of bladder tissues, many challenges remain. Current research in many centers is aimed at the development of biologically active and "smart" biomaterials that may improve tissue regeneration.

Ureters

Collagen tubular sponges have been used to transplant bladder cells for replacement of ureteral segments in dogs. The study showed severe stricture formation and papillary mucosal thickening at the anastomotic sites. In addition, muscle regeneration into the collagen grafts was not evident (Tachibana et al, 1985).

Ureteral decellularized matrices have been used as a scaffold for both the ingrowth of ureteral tissue (Dahms et al, 1997) and as a cell delivery vehicle using urothelial and bone marrow–derived cells (Matsunuma et al, 2006). Laparoscopic segmental ureteral replacement with an acellular matrix prepared from ureters and small-intestinal submucosa was performed in mini-pigs (Shalhav et al, 1999). At 12 weeks, all animals had complete obstruction at the level of the replacement. Ureteral replacement with polytetrafluoroethylene (Teflon) grafts was attempted in dogs, also with poor functional results (Baltaci et al, 1998). Nonseeded ureteral collagen acellular matrices were tubularized and used to replace 3 cm segments of canine ureters. At the time of sacrifice, there was moderate to marked hydroureteronephrosis above the level of the new tube in all dogs with significant narrowing of the ureteral lumen, up to complete occlusion (Osman et al, 2004).

Cell-seeded biodegradable polymer scaffolds have been used as cell transplantation vehicles to reconstruct ureteral tissues. In one study, urothelial and smooth muscle cells isolated from bladders and expanded in vitro were seeded onto PGA scaffolds with tubular configurations and implanted subcutaneously into athymic mice. After implantation, the urothelial cells proliferated to form a multilayered luminal lining of tubular structures, while the smooth muscle cells organized into multilayered structures surrounding the urothelial cells. Abundant angiogenesis was evident. The degradation of the polymer scaffolds resulted in the eventual formation of natural urothelial tissues (Atala et al, 1993c). This study suggested that it was possible to engineer urologic tissues containing multiple cell types. This approach was expanded to replacement of ureters in dogs by transplantation of smooth muscle cells and urothelial cells on tubular polymer scaffolds (Yoo et al, 1995). The limitations of transferring this technology to humans are the small number of patients requiring this type of tissue, and the large investment that would be required for regulatory approval.

Genital and Reproductive Tissues

Reconstructive surgery is required for a wide variety of pathologic penile conditions, including penile carcinoma, trauma, severe erectile dysfunction, and congenital conditions such as ambiguous genitalia, hypospadias, and epispadias. One of the major limitations of phallic reconstructive surgery is the availability of sufficient autologous tissue. Nongenital autologous tissue sources have been used for decades. Phallic reconstruction was initially attempted in the late 1930s, with rib cartilage used as a stiffener for patients with traumatic penile loss (Frumpkin, 1944; Goodwin et al, 1952). This method, involving multiple staged surgeries, was soon discouraged due to the unsatisfactory functional and cosmetic results. Silicone rigid prostheses were popularized in the 1970s and have been used widely (Small et al, 1975; Bretan, 1989). However, biocompatibility issues have been a problem in selected patients (Thomalla et al, 1987; Nukui et al, 1997). Tissue transfer techniques with flaps from various nongenital sources, such as the groin, dorsalis pedis, and forearm, have been used for genital reconstruction (Jordan, 1999). However, operative complications such as infection, graft failure, and donor site morbidity are not negligible. Phallic reconstruction with autologous tissue, derived from the patient's own cells, may be preferable in selected cases.

Reconstruction of Corporeal Tissues

Reconstruction of Corporeal Smooth Muscle. One of the major components of the phallus is corporeal smooth muscle. The creation of autologous functional and structural corporeal tissue de novo would be beneficial. Initial experiments showed that cultured human corporeal smooth muscle cells may be used in conjunction with biodegradable polymers to create corpus cavernosum tissue de novo (Kershen et al, 2002). **When grown on collagen, corporeal cavernosal endothelial cells formed capillary structures that created complex three-dimensional capillary networks** (Fig. 19–13). In a subsequent study, human corporeal smooth muscle cells and endothelial cells seeded on biodegradable polymer scaffolds were able to form vascularized

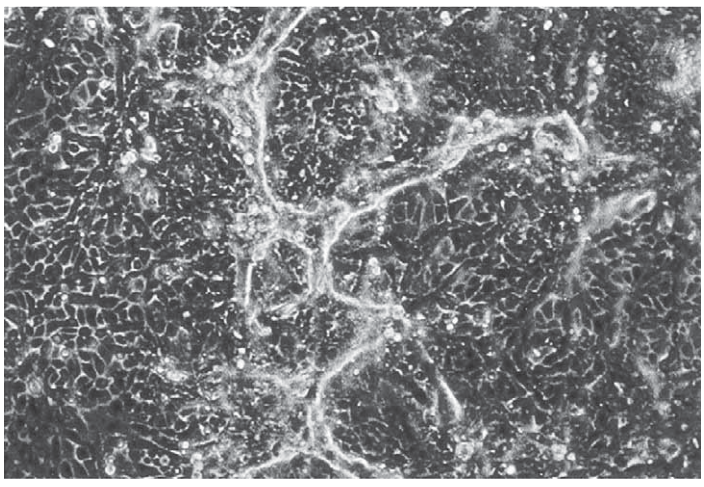

Figure 19–13. Human corporal cavernosal endothelial cells form capillary-like structures in vitro (original magnification, ×100).

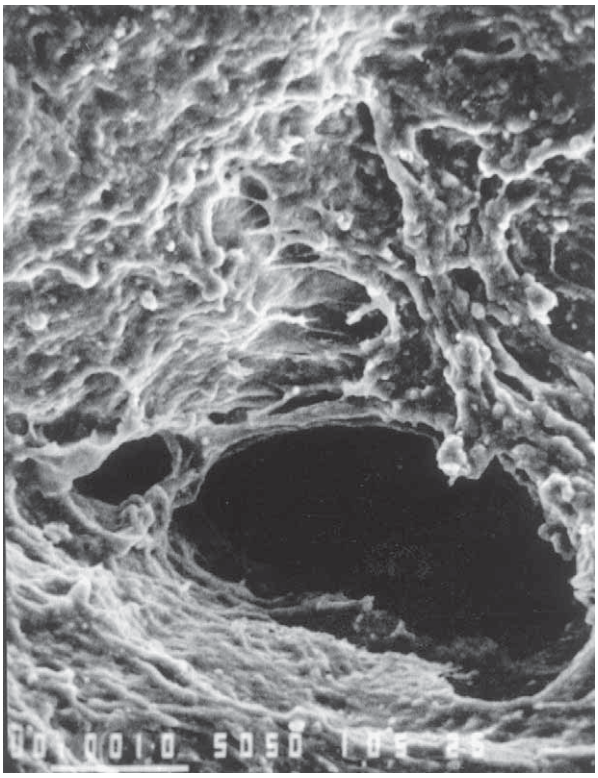

Figure 19–14. Scanning electron microscopy of human cavernosal smooth muscle and endothelial cells seeded on acellular matrices.

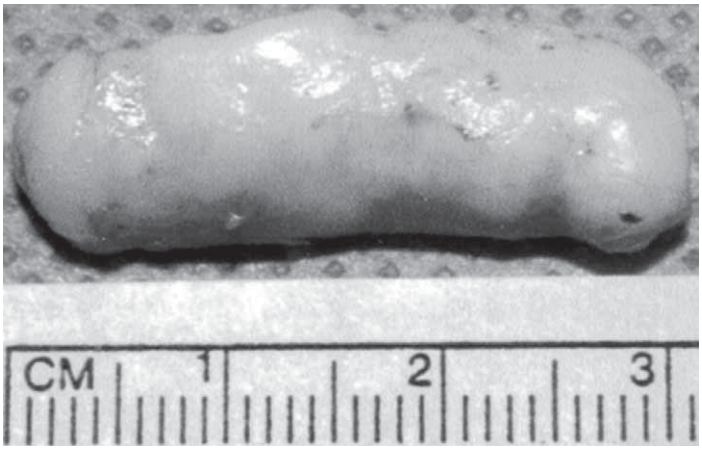

Figure 19–15. Cylindrical polymer scaffolds seeded with chondrocytes and implanted in vivo formed milky-white, rod-shaped, solid cartilaginous structures.

cavernosal muscle when implanted in vivo (Park et al, 1999). A naturally derived acellular corporal tissue matrix that possesses the same architecture as native corpora was developed (Fig. 19–14). Acellular collagen matrices were derived from processed donor rabbit corpora using cell lysis techniques. Human corpus cavernosal muscle and endothelial cells were derived from donor penile tissue, and the cells were expanded in vitro and seeded on the acellular matrices (Fig. 19–15). The matrices were covered with the appropriate cell architecture 4 weeks after implantation (Falke et al, 2003). The use of these tissue-derived matrices as cell-delivery scaffolds allowed the development of adequate structural and vascular corpora cavernosa constructs.

To look at the functional parameters of the engineered corpora, acellular corporeal collagen matrices were obtained from a donor rabbit penis, and autologous corpus cavernosal smooth muscle and endothelial cells were harvested, expanded, and seeded on the matrices. An entire cross-sectional segment of protruding rabbit phallus was excised, leaving the urethra intact and the cell-seeded matrices were interposed into the excised corporal space. Functional and structural parameters (cavernosography, cavernosometry, mating behavior, and sperm ejaculation) were followed, and histochemical, immunocytochemical and Western blot analyses were performed up to 6 months after implantation. The engineered corpora cavernosa achieved adequate structural and functional parameters (Kwon et al, 2002). This technology was further confirmed when the entire rabbit corpora was removed and replaced with the engineered scaffolds. The experimental corporeal bodies demonstrated intact structural integrity by cavernosography and showed similar pressure by cavernosometry when compared with the normal controls. The control rabbits without cells failed to show normal erectile function throughout the study period. Mating activity in the animals with the engineered corpora appeared normal by 1 month after implantation. The presence of sperm was confirmed during mating, and was present in all the rabbits with the engineered corpora. The female rabbits mated with the animals implanted with engineered corpora and also conceived and delivered healthy pups. Animals implanted with the matrix alone were unable to demonstrate normal mating activity and failed to ejaculate into the vagina. Grossly, the corporeal implants with cells showed continuous integration of the graft into native tissue. Histologically, sinusoidal spaces and walls, lined with endothelium and smooth muscle, were observed in the engineered grafts. Grafts without cells contained fibrotic tissue and calcifications with sparse corporal elements. Each cell type was identified immunocytochemically and by Western-blot analyses. The engineered corporeal tissues were able to contract and relax in response to electric field and pharmacologic stimulation, and the contractile response reached levels similar to normal corpora by 6 months after implantation (Chen et al, 2005). Dynamic cell seeding using bioreactor systems have been shown to enhance cell penetration in the acellular tissue-derived matrices (Eberli et al, 2008b).

The above series of studies demonstrate that penile corpora cavernosa tissue can be engineered. The engineered tissue is able to achieve adequate structural and functional parameters sufficient for erection, copulation, ejaculation, conception, and delivery in rabbits. Further studies will be needed to confirm the long-term functionality of these organs. In addition, further studies are needed to show that human structures can also be engineered.

Engineered Penile Prostheses. **Although silicone is an accepted biomaterial for penile prostheses, biocompatibility is a concern** (Thomalla et al, 1987; Nukui et al, 1997). The use of a natural prosthesis composed of autologous cells may be advantageous. A feasibility study for the creation of natural penile prostheses made of cartilage was performed initially (Yoo et al, 1998a).

Cartilage, harvested from the articular surface of calf shoulders, was isolated, grown, and expanded in culture. The cells were seeded onto preformed cylindrical polyglycolic acid polymer rods and implanted in mice. At retrieval, all polymer scaffolds seeded with cells formed milky-white, rod-shaped, solid cartilage structures, maintaining their preimplantation size and shape (see Fig. 19–15). In a subsequent study using an autologous system, the feasibility of applying the engineered cartilage rods in situ was

investigated (Yoo et al, 1999). Autologous chondrocytes harvested from rabbit ear were grown and expanded in culture. The cells were seeded onto biodegradable poly-L-lactic acid coated polyglycolic acid polymer rods and implanted into the corporal spaces of rabbits. Examination at retrieval showed the presence of well-formed, milky-white cartilage structures within the corpora at 1 month. The animals were able to copulate and impregnate their female partners. In another study, human cartilage rods were engineered in vitro for potential use as penile prostheses. Chondrocytes isolated from human ear were seeded on rod-shaped biodegradable polymer scaffolds (1.2 cm in diameter, 6.0 cm long). The engineered human cartilaginous rods were flexible, elastic, and able to withstand high degrees of compressive forces. The mechanical properties were comparable to those of commercially available silicone prostheses (Kim et al, 2002).

Testis

Leydig cells are the major source of testosterone production in males. Patients with testicular dysfunction require androgen replacement for somatic development. Conventional treatment for testicular dysfunction consists of periodic intramuscular injections of chemically modified testosterone or, more recently, skin patch applications. However, long-term nonpulsatile testosterone therapy is not optimal and can cause multiple problems, including erythropoiesis and bone density changes.

A system was designed wherein Leydig cells were microencapsulated for controlled testosterone replacement. **Microencapsulated Leydig cells offer several advantages, such as serving as a semipermeable barrier between the transplanted cells and the host's immune system, as well as allowing for the long-term physiologic release of testosterone.** Purified Leydig cells were isolated and encapsulated in an alginate-poly-L-lysine solution (Fig. 19–16). The encapsulated Leydig cells were injected into castrated animals, and serum testosterone was measured serially; the animals were able to maintain testosterone levels in the long term (Machluf et al, 1998). These studies suggest that microencapsulated Leydig cells may be able to replace or supplement testosterone in situations where anorchia or testicular failure is present. A novel technique to isolate Leydig stem cells and to study Leydig cell development has also been described (Lo et al, 2004). The successful transplantation of functional Leydig stem cells into a hypogonadal recipient showed that the de novo synthesis of testosterone is possible.

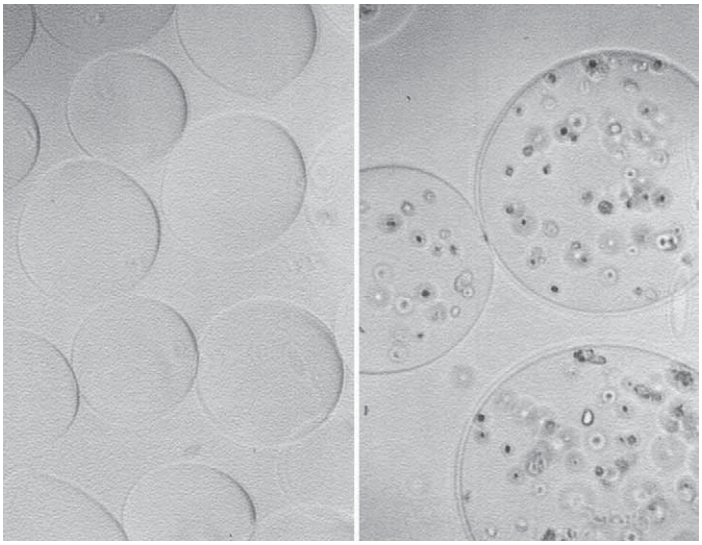

Figure 19–16. *Left,* Hydrogel microcapsules without cells. *Right,* Leydig cells encapsulated in hydrogel microcapsules secrete testosterone in vitro and in vivo.

Further studies showed that testicular prostheses created with chondrocytes in bioreactors, could be loaded with testosterone. The prostheses were implanted in athymic mice with bilateral anorchia, and testosterone was released long term, maintaining the androgen level at a physiologic range (Raya-Rivera et al, 2008). One could envision combining the Leydig cell technology described above with engineered prostheses for the long-term functional replacement of androgen levels. The ability to have spermatogenesis for infertility purposes has been a major area of interest in the last decade. Spermatogonial transplantation and reconstitution of donor cell spermatogenesis was shown in recipient mice (Nagano et al, 1998). The same group was able to show the restoration of fertility in mice with the transplantation of male germ-line stem cells (Ogawa et al, 2000). Spermatogonial stem cells can be isolated and enriched with specific markers (Lo et al, 2005). Sertoli cells, the main component of the testicular germ-cell niche, were recovered and dissociated from testes of donor male mice and microinjected into recipient testes, forming mature seminiferous tubule structures, and supporting spermatogenesis (Shinohara et al, 2003). The germ-line niche transplantation was also able to restore fertility in mice (Kanatsu-Shinohara et al, 2005).

Female Genital and Reproductive Tissues

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy and intersex disorders may not have sufficient uterine tissue present for future reproduction. We investigated the possibility of engineering functional uterine tissue using autologous cells (Wang et al, 2003). Autologous rabbit uterine smooth muscle and epithelial cells were harvested, then grown and expanded in culture. These cells were seeded onto pre-configured uterine-shaped biodegradable polymer scaffolds, which were then used for subtotal uterine tissue replacement in the corresponding autologous animals. Upon retrieval 6 months after implantation, histological, immunocytochemical, and Western-blot analyses confirmed the presence of uterine tissue components. Biomechanical analyses and organ bath studies showed that the functional characteristics of these tissues were similar to those of normal uterine tissue. Breeding studies using these engineered uteri are currently being performed.

Similarly, several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. Vaginal reconstruction has traditionally been challenging due to the paucity of available native tissue. Acellular materials have been used experimentally for vaginal reconstruction in rats (Wefer et al, 2002). The feasibility of engineering vaginal tissue with cells in vivo was also investigated (De Filippo et al, 2003). Vaginal epithelial and smooth muscle cells of female rabbits were harvested, grown, and expanded in culture. These cells were seeded onto biodegradable polymer scaffolds, and the cell-seeded constructs were then implanted into mice. Functional studies in the tissue-engineered constructs showed similar properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement in a rabbit model, patent functional vaginal structures were noted in the tissue-engineered specimens, while the non–cell-seeded structures were noted to be stenotic (De Filippo et al, 2008) (Fig. 19–17) These studies indicated that a regenerative medicine approach to clinical vaginal reconstruction would be a realistic possibility. Clinical trials are currently being conducted.

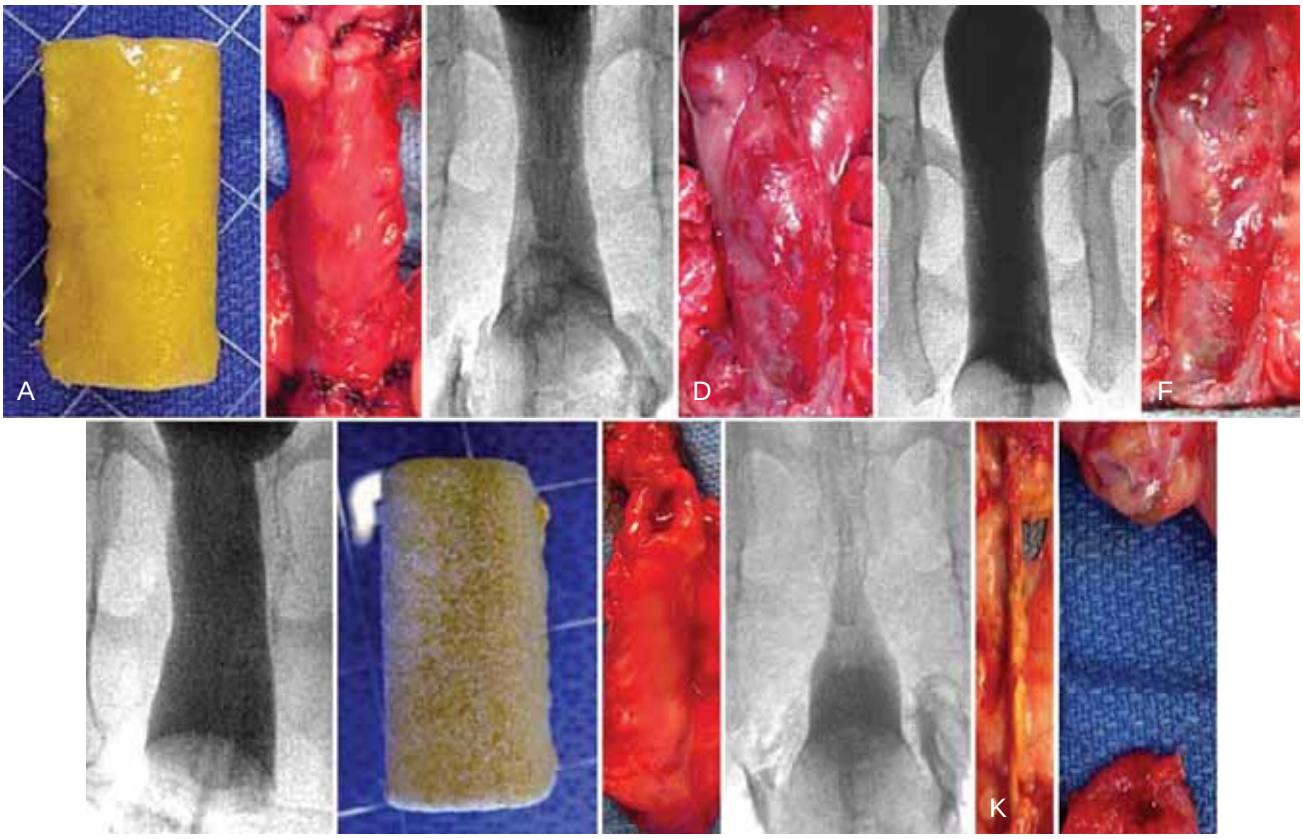

Figure 19–17. Appearance of tissue engineered neovaginas. **A,** Tubular polymer scaffold after cell seeding and 1-week in vitro culture, prior to implantation in vivo. **B, D,** and **F** indicate gross appearance and **C, E,** and **G** show vaginography of cell-seeded constructs 1, 3, and 6 months, postimplantation, respectively. **H,** Unseeded control scaffold prior to implantation. **I, K,** and **L,** Gross appearance of unseeded construct at 1, 3, and 6 months postimplantation. **J,** Vaginography of unseeded graft at 1 month.

Renal Structures

Although the kidney was the first organ to be substituted by an artificial device and the first successfully transplanted organ (Guild et al, 1955), current modalities of treatment are far from satisfactory. Renal tissue is arguably one of the most difficult tissues to replicate in the laboratory. The kidney is a complex organ and the unique structural and cellular heterogeneity present within this organ creates many challenges. The system of nephrons and collecting ducts within the kidney is composed of multiple functionally and morphologically distinct segments. For this reason, appropriate conditions must be provided to ensure the long-term survival, differentiation and growth of many types of cells. Efforts in the area of kidney tissue regeneration have focused on the development of a reliable cell source (Prockop, 1997; Kale et al, 2003; Lin et al, 2003; Ikarashi et al, 2005; Lin et al, 2005; Yokoo et al, 2005). Moreover, optimal growth conditions have been extensively investigated to provide adequate enrichment to achieve stable renal cell expansion systems (Milici et al, 1985; Carley et al, 1988; Humes et al, 1992; Schena, 1998).

Isolation of particular cell types that produce specific factors may be a good approach for selective cell therapies. For example, cells that produce erythropoietin have been isolated in culture, and these cells could eventually be used to treat anemia that results from end stage renal failure (Aboushwareb et al, 2008). Other more ambitious approaches involve working towards the goal of total renal function replacement. To create kidney tissue that would deliver full renal function, a culture containing all of the cell types comprising the functional nephron units should be used. Optimal culture conditions to nurture renal cells have been extensively studied and cells grown under these conditions have been reported to maintain their cellular characteristics (Lanza et al, 2002a). Cells obtained through the initial process of nuclear transfer were retrieved and expanded from cloned tissue. Moreover, renal cells placed in a three-dimensional culture environment are able to reconstitute into renal structures.

Recent investigative efforts in the search for a reliable cell source have been expanded to stem and progenitor cells. Use of these cells for tissue regeneration is attractive due to their ability to differentiate and mature into specific cell types needed. This is particularly useful in instances where primary renal cells are unavailable due to extensive tissue damage. Bone marrow–derived human mesenchymal stem cells have been shown to be a potential source due to their ability to differentiate into several cell lineages (Prockop, 1997; Kale et al, 2003; Ikarashi et al, 2005). These cells have been shown to participate in kidney development when they are placed in a rat embryonic niche that allows for continued exposure to a repertoire of nephrogenic signals (Yokoo et al, 2005). These cells, however, were found to contribute mainly to regeneration of damaged glomerular endothelial cells after injury. The major cell source of kidney regeneration was found to originate from intrarenal cells in an ischemic renal injury model (Lin et al, 2005). Systemic administration of bone marrow–derived mesenchymal stem cells in mice has led to prevention of nephropathy in a diabetic model, the acceleration of acute renal injury, and to angiogenesis and vasculogenesis in a renal injury model (Humphreys et al, 2008; Lin, 2008).

Another potential cell source for kidney regeneration is circulating stem cells, which have been shown to transform into tubular and glomerular epithelial cells, podocytes, mesangial cells, and interstitial cells after renal injury (Ito et al, 2001; Poulsom et al, 2001; Gupta et al, 2002; Iwano et al, 2002; Kale et al, 2003; Lin et al, 2003; Rookmaaker et al, 2003). Other stem cell types, such as human embryonic stem cells (Lin, 2006), and the more recently discovered human amniotic fluid and placental stem cells can also lead to renal differentiation (Perin et al, 2007). These observations suggest that controlling stem and progenitor cell differentiation may lead to successful regeneration of kidney tissues.

Although isolated renal cells are able to retain their phenotypic and functional characteristics in culture, transplantation of these cells in vivo may not result in structural remodeling. In addition, cell or tissue components cannot be implanted in large volumes due to limited diffusion of oxygen and nutrients (Folkman et al, 1973). Thus a cell-support matrix, preferably one that encourages angiogenesis, is necessary to allow diffusion across the entire implant. A variety of synthetic and naturally derived materials has been examined in order to determine the ideal support structures for regeneration (Tachibana et al, 1985; Atala, 1995b; Oberpenning et al, 1999; El-Kassaby et al, 2003; Atala et al, 2006). Biodegradable synthetic materials, such as poly-lactic and polyglycolic acid polymers, have been used to provide structural support for cells. Synthetic materials can be easily fabricated and configured in a controlled manner, which make them attractive options for regenerative medicine. However, naturally derived materials, such as collagen, laminin, and fibronectin, are much more biocompatible and provide a similar extracellular matrix environment to normal tissue. For this reason, collagen-based scaffolds have been used increasingly in many applications (De Filippo et al, 2002; El-Kassaby et al, 2003; Falke et al, 2003; Atala et al, 2006; Murray et al, 2006).

Developmental Approaches to Kidney Regeneration

Transplantation of a kidney precursor, such as the metanephros, into a diseased kidney has been proposed as a possible method for functional restoration. In an animal study, human embryonic metanephroi, transplanted into the kidneys of an immune-deficient mouse model, has developed into mature kidneys (Dekel et al, 2003). The transplanted metanephroi produced urine-like fluid, however, failed to develop ureters. This study suggests that development of an in-vitro system in which metanephroi could be grown may lead to transplant techniques that could produce a small replacement kidney within the host. In another study, the metanephros was divided into mesenchymal tissue and ureteral buds, and each of the tissue segments was cultured in vitro (Steer et al, 2002). After 8 days in culture, each portion of the mesenchymal tissues had grown to the original size. A similar method was used for ureteral buds, which also propagated. These studies were expanded further by staging renal structure reconstitution in vitro and later implanting these structures in vivo in a mouse model (Rosines et al, 2007). These studies indicate that if the mesenchyme and ureteral buds were placed together and cultured in vitro, a metanephros-like structure would develop and suggest that the metanephros could be propagated under an optimal condition.

In another study, transplantation of metanephroi into a nonimmunosuppressed rat omentum showed that the implanted metanephroi are able to undergo differentiation and growth that is not confined by a tight organ capsule (Rogers et al, 1998). When the metanephroi with an intact ureteric bud were implanted, the metanephroi are able to enlarge and become kidney shaped tissue within 3 weeks. The metanephroi transplanted into the omentum were able to develop into kidney tissue structure with a well-defined cortex and medulla. Mature nephrons and collecting system structures are shown to be indistinguishable from those of normal kidneys by light or electron microscopy (Hammerman, 2002a, 2002b). Moreover, these structures become vascularized by arteries that originate at the superior mesenteric artery of the host (Hammerman, 2002a, 2002b). It has been demonstrated that the metanephroi transplanted into the omentum survive for up to 32 weeks postimplantation (Rogers et al, 1999). These studies show that developmental approach may be a viable option for regenerating renal tissue for functional restoration.

Regenerative Medicine Approaches to Kidney Regeneration

The ability to grow and expand renal cells is one of the essential requirements in engineering tissues. The feasibility of achieving renal cell growth, expansion, and in-vivo reconstitution using regenerative medicine techniques was investigated (Atala, 1995b). Donor rabbit kidney cells, including distal tubules, glomeruli, and proximal tubules were plated separately in vitro and, after expansion, were seeded onto biodegradable polyglycolic acid scaffolds and implanted subcutaneously into host athymic mice. This included implants of proximal tubular cells, glomeruli, distal tubular cells, and a mixture of all three cell types. Histologic examination demonstrated progressive formation and organization of the nephron segments within the polymer fibers with time. BrdU incorporation into renal cell DNA was confirmed. These results demonstrated that renal specific cells can be successfully harvested and cultured, and can subsequently attach to artificial biodegradable polymers. However, it was unclear whether the tubular structures reconstituted de novo from dispersed renal elements, or if they merely represented fragments of donor tubules that survived the original dissociation and culture processes intact. Further investigation was conducted in order to examine the process (Fung, 1996). Mouse renal cells were harvested and expanded in culture. Subsequently, single isolated cells were seeded on biodegradable polymers and implanted into immune competent syngeneic hosts. Renal epithelial cells were observed to reconstitute into tubular structures in vivo. Sequential analyses of the retrieved implants over time demonstrated that renal epithelial cells first organized into a cordlike structure with a solid center. Subsequent canalization into a hollow tube could be seen by two weeks. Histologic examination with nephron segment-specific lactins showed successful reconstitution of proximal tubules, distal tubules, loop of Henle, collecting tubules, and collecting ducts. These results showed that single suspended cells are capable of reconstituting into tubular structures, with homogeneous cell types within each tubule.

In a subsequent study mouse renal cells were harvested, expanded in culture, and seeded onto a tubular device constructed from polycarbonate (Yoo et al, 1996). The tubular device was connected at one end to a Silastic catheter that terminated into a reservoir. The device was implanted subcutaneously in athymic mice. Histological examination of the implanted device demonstrated extensive vascularization, as well as formation of glomeruli (Fig. 19–18) and highly organized tubule-like structures. Immunocytochemical staining with antiosteopontin antibody, which is secreted by proximal and distal tubular cells and the cells of the thin ascending loop of Henle, stained the tubular sections. Immunohistochemical staining for alkaline phosphatase stained

proximal tubule-like structures. Uniform staining for fibronectin in the extracellular matrix of newly formed tubes was observed. The fluid collected from the reservoir was yellow and contained 66 mg/dL uric acid (compared with 2 mg/dL in plasma), suggesting that these tubules are capable of unidirectional secretion and concentration of uric acid. The creatinine assay performed on the collected fluid showed an 8.2-fold increase in concentration when compared with serum. These results demonstrated that single cells form multicellular structures can become organized into functional renal units that are able to excrete high levels of solutes through a urine-like fluid (Yoo et al, 1996).

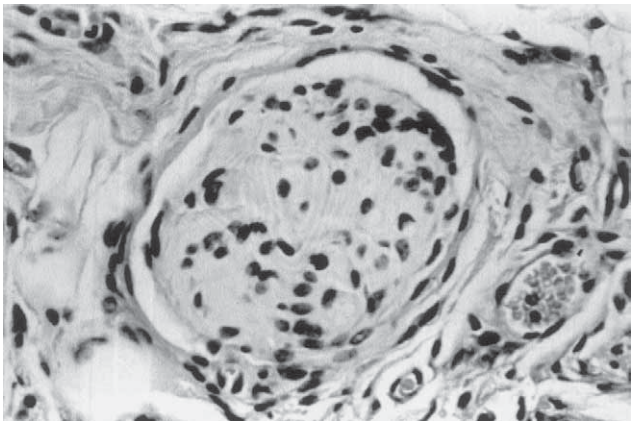

Figure 19–18. Retrieved tissue-engineered renal units demonstrate formation of glomeruli (hematoxylin and eosin stain; original magnification, ×400).

To determine whether renal tissue could be formed using an alternative cell source, nuclear transplantation (therapeutic cloning) was performed to generate histocompatible tissues, and the feasibility of engineering syngeneic renal tissues in vivo using these cloned cells was investigated (Lanza et al, 2002a) (Fig. 19–19). Nuclear material from bovine dermal fibroblasts was transferred into unfertilized enucleated donor bovine eggs. Renal cells from the cloned embryos were harvested, expanded in vitro, and seeded onto three-dimensional renal devices. The devices were implanted into the back of the same steer from which the cells were cloned, and were retrieved 12 weeks later. This process produced functioning renal units. Urine production and viability were demonstrated after transplantation back into the nuclear donor animal. Chemical analysis suggested unidirectional secretion and concentration of urea nitrogen and creatinine. Microscopic analysis revealed formation of organized glomeruli and tubular structures. Immunohistochemical and real-time polymerase chain reaction (RT-PCR) analysis confirmed the expression of renal mRNA and proteins. These studies demonstrated that cells derived from nuclear transfer can be successfully harvested, expanded in culture, and transplanted in vivo with the use of biodegradable scaffolds on which the single suspended cells can organize into tissue structures that are genetically identical to that of the host. These studies were the first demonstration of the use of therapeutic cloning for regeneration of tissues in vivo.

A naturally derived tissue matrix with existing three-dimensional kidney architecture would be preferable to the artificial matrix used in the above experiments, because it would allow transplantation of a larger number of cells, resulting in greater renal tissue volumes. Thus an acellular collagen-based kidney matrix, which

Production of kidney tissue by therapeutic cloning and regenerative medicine. **A,** Illustration of the tissue-engineered renal unit. **B,** Renal unit seeded with cloned cells, three months after implantation, showing the accumulation of urine-like fluid. **C,** There was a clear unidirectional continuity between the mature glomeruli, their tubules, and the polycarbonate membrane. **D,** ELISPOT analyses of the frequencies of T cells that secrete interferon-γ after primary and secondary stimulation with allogeneic renal cells, cloned renal cells, or nuclear donor fibroblasts.

is similar to the native renal architecture, was developed. In a subsequent study, it was investigated whether these collagen-based matrices could accommodate large volumes of renal cells and form kidney structures in vivo (Amiel et al, 2000).

Acellular collagen matrices, derived from porcine kidneys, were obtained through a multistep decellularization process. During this process, serial evaluation of the matrix for cellular remnants was performed using histochemistry, scanning electron microscopy (SEM), and RT-PCR. Mouse renal cells were harvested, grown, and seeded on decellularized collagen matrices. Cell matrix constructs grown in vitro and implanted in the subcutaneous space of 20 athymic mice were analyzed over time. Renal cells seeded on the matrix adhered to the inner surface and proliferated to confluency by 7 days after seeding. Renal tubular and glomerulus-like structures were observed 8 weeks after implantation.

OTHER APPLICATIONS OF GENITOURINARY REGENERATIVE MEDICINE

Please see the Expert Consult website for this section, including Figure 19–20.

Key Points

- New advances in the ability to expand cells in vitro, to use smart biomaterials, and new techniques for vascularization are allowing more complex organs to be engineered.
- Tissue injury can be repaired with minimal fibrosis by the natural wound-healing response for small defects, by the use of nonseeded matrices for defects up to 1 cm from any edge and by the use of cell-seeded matrices for defects greater than 1 cm.
- Stem cells may provide large repositories of different cell types for tissue and organ repair. Embryonic and induced pluripotent stem cells differentiate easily but may form tumors and may require immunosuppression. Fetal stem cells replicate readily and do not form tumors but may be more limited than embryonic stem cells in their differentiation potential. Adult stem cells do not form tumors or require immunosuppression, but they may not replicate readily.
- Nuclear transfer can be used for either reproductive cloning or for therapeutic cloning.

SUMMARY

Regenerative medicine efforts are currently being undertaken for every type of tissue and organ within the urinary system. Most of the efforts expended in the genitourinary field have occurred within the last two decades. Regenerative medicine strategies involve the use of biomaterials alone, as has been accomplished clinically in patients with urethral disease; biomaterials with cells, as is currently being tested clinically with bladder and vaginal tissues; and cell therapies alone, as those applied clinically for urinary incontinence, initially with chondrocytes and now with muscle cells. Regenerative medicine is a multidisciplinary field that requires expertise in a wide variety of scientific disciplines, including cell and molecular biology, physiology, pharmacology, chemical engineering, biomaterials, nanotechnology, and clinical sciences. Although, to date, modest clinical success has been achieved in specific areas, the field is still in its infancy. Long-term studies are still essential to assure safety and efficacy before these technologies have widespread clinical application.

Male Reproductive Physiology

Paul J. Turek, MD, FACS, FRSM

Hypothalamic-Pituitary-Gonadal Axis
The Testis
The Epididymis
Ductus (Vas) Deferens
Seminal Vesicle and Ejaculatory Ducts
Spermatozoa

The male reproductive axis of hormones and organs is a remarkably efficient, well-orchestrated, and precisely managed biological system that has evolved over millions of years. It is responsible for reproductive tract formation and development, maturation of fertility potential at puberty, and the maintenance of maleness in the adult. This chapter explores our current understanding of this complex system by defining the anatomy and physiology of its component parts, including the hypothalamic-pituitary-gonadal hormonal axis, spermatogenesis and androgen production within the testicle, and maturation and transport of sperm in the excurrent ductal system. In addition, new concepts in genetic infertility, stem cell science, and the physiology of ejaculation are introduced and explained. Through such rigorous intellectual dissection, the true beauty and sophistication of the reproductive process is realized and appreciated.

HYPOTHALAMIC-PITUITARY-GONADAL AXIS

The hypothalamic-pituitary-gonadal (HPG) axis plays a critical role during development and adulthood in four physiological processes: 1) **phenotypic gender** development during embryogenesis, 2) **sexual maturation** at puberty, 3) testis endocrine function—**testosterone production,** and 4) testis exocrine function—**sperm production.**

Basic Endocrine Concepts

Two classes of hormones mediate communication in the reproductive axis: peptide and steroid. **Peptide hormones are small, secretory proteins that act through cell surface receptors.** Hormone signals are transduced by one of several second-messenger pathways (Fig. 20–1). Ultimately, most peptide hormones induce phosphorylation of proteins that alter cell function. Examples of peptide hormones are luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In contrast, **steroid hormones are derived from cholesterol. They are not stored in secretory granules; consequently, steroid secretion rates directly reflect rates of production.** In plasma, these hormones are usually bound to carrier proteins, and because they are lipophilic, steroid hormones are cell membrane–permeable. After binding to intracellular receptors, steroids are translocated to nuclear DNA recognition sites and regulate the transcription of target genes. Examples of reproductive axis steroid hormones are testosterone and estradiol.

Hormonal signaling within the HPG axis is hierarchically governed by a **free-running pulse generator** within the hypothalamus. The specific amplitude and frequency with which hormone secretions occur within the reproductive axis determine downstream organ responsiveness. Feedback control is the principal mechanism through which hormonal regulation occurs in the HPG axis (Fig. 20–2). With feedback control, a hormone can regulate the synthesis and action of itself or of another hormone. **In the HPG axis, negative feedback activity is primarily responsible for minimizing hormonal perturbations and maintaining homeostasis.**

Components of the Reproductive Axis

Hypothalamus

As the integrative center of the HPG axis, the hypothalamus receives neuronal input from the amygdala, thalamus, pons, retina, olfactory cortex, and many other areas (see Fig. 20–2). The pulse generator for the cyclical secretion of pituitary hormones, **the hypothalalmus, is anatomically linked to the pituitary gland by both a portal vascular system and neuronal pathways.** By avoiding the systemic circulation, the portal vascular system allows direct delivery of hypothalamic hormones to the anterior pituitary.

The most important hypothalamic hormone for reproduction is gonadotropin-releasing or LH-releasing hormone (GnRH or LHRH), a 10–amino acid peptide secreted from the neuronal cell bodies in the preoptic and arcuate nuclei. **Currently, the only known function of GnRH is to stimulate the secretion of luteinizing hormone (LH) and follicle-stimulating hormones (FSH) from the anterior pituitary.** GnRH has a plasma half-life of approximately 5 to 7 minutes, and is almost entirely removed on the first pass through the pituitary either by receptor internalization or enzymatic degradation. GnRH secretion results from integrated input from the effects of stress, exercise, and diet from higher brain centers, gonadotropins secreted from the pituitary, and circulating gonadal hormones. Substances known to regulate GnRH secretion are listed in Table 20–1. In Kallman syndrome, characterized by congenital hypogonadotropic hypogonadism, the GnRH precursor neurons fail to migrate normally with a subsequent absence of

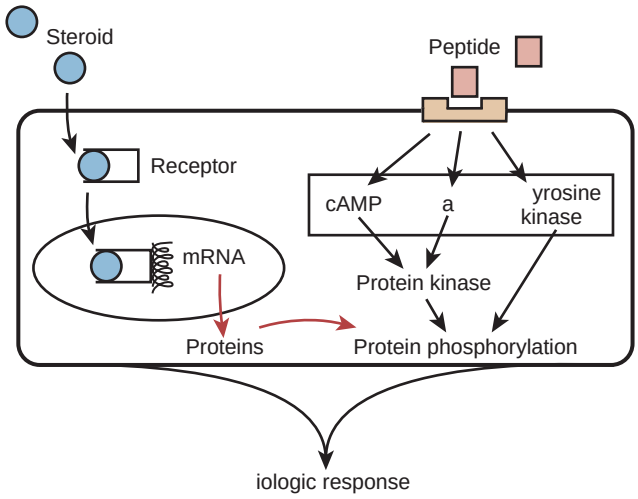

Figure 20–1. Two kinds of hormones classes mediate intercellular communication in the reproductive hormone axis: peptide and steroid. (Adapted from Turek PJ. Male infertility. In: Tanagho EA, McAninch JC, editors. Smith's urology. 16th ed. Stamford, CT: Appleton & Lange; 2008 [chapter 44–1].)

Substances That Modulate GnRH Secretion

GnRH MODULATOR	TYPE OF FEEDBACK	EXAMPLES
Opioids	Negative	β-Endorphin
Catecholamines	Variable	Dopamine
Peptide hormones	Negative	FSH, LH
Sex steroids	Negative	Testosterone
Prostaglandins	Positive	PGE_2
Insulin	Positive	Insulin
Kisspeptins	Positive	Kisspeptin (puberty)
Leptins	Positive	Leptin

FSH, follicle-stimulating hormone; LH, luteinizing hormone; PGE_2, prostaglandin E_2.

hypothalamic secretion of GnRH (Bick et al, 1992; Dode et al, 2003). Affected individuals present with delayed puberty or infertility due to lack of testosterone production.

GnRH output exhibits several types of rhythmicity: seasonal, on a time scale of months and peaking in the spring; circadian, resulting in higher testosterone levels during the early morning hours; and pulsatile, with GnRH peaks occurring every 90 to 120 minutes on average. The importance of a pulsatile GnRH secretory pattern in normal HPG axis function is aptly demonstrated by the ability of exogenously given GnRH agonists (leuprolide acetate) to stop testicular testosterone production by changing pituitary exposure to GnRH from a cyclic to a constant pattern.

Anterior Pituitary

Located within the bony sella turcica of the cranium, the pituitary has two lobes: posterior and anterior. The posterior lobe, or neurohypophysis, secrets two hormones, oxytocin and vasopressin, and is driven by neural stimuli. In contrast, **the anterior pituitary or adenohypophysis is regulated by blood-borne factors and is the site of action of GnRH** (see Fig. 20–2). GnRH stimulates the production and release of FSH and LH by a calcium flux–dependent mechanism. The sensitivity of the pituitary gonadotrophs for GnRH varies with patient age and hormonal status. **LH and FSH are the primary pituitary hormones that regulate testis function.** They are glycoproteins composed of two polypeptide chain subunits, termed α and β, each coded by a separate gene. The α subunit of each hormone is identical and is similar to that of all other pituitary hormones; biologic and immunologic activities are conferred by the unique β subunit. Both subunits are required for endocrine activity. Sugars linked to these peptide subunits, consisting of oligosaccharides with sialic acid residues, differ in content between FSH and LH and likely account for differences in plasma clearance of these hormones. Secretory pulses of LH vary in frequency from 8 to 16 pulses in 24 hours and vary in amplitude by one- to threefold. These pulse patterns closely reflect GnRH release. **Both androgens and estrogens regulate LH secretion through negative feedback.** On average, FSH pulses occur approximately every 1.5 hours and vary in amplitude by 25%. The FSH response to GnRH is more difficult to measure than that of LH for two reasons: (1) FSH has a smaller amplitude response and a longer serum half-life, (2) **the gonadal proteins inhibin and activin may affect FSH secretion and are thought to account for the relative secretory independence of FSH from GnRH secretion.**

FSH and LH are only known to act in the gonads. They activate adenylate cyclase, which leads to increases in intracellular cAMP. In the testis, LH stimulates steroidogenesis within Leydig cells by inducing the mitochondrial conversion of cholesterol to pregnenolone and testosterone. **FSH binds to Sertoli cells and spermatogonial membranes within the testis and is the major stimulator of seminiferous tubule growth during development. FSH is essential for the initiation of spermatogenesis at puberty.** In the adult, the major physiologic role of FSH is to stimulate quantitatively normal levels of spermatogenesis.

A third anterior pituitary hormone, prolactin, can also affect the HPG axis and fertility. Prolactin is a large, globular protein of 199 amino acids (23 kD) that is responsible for milk synthesis during pregnancy and lactation in women. No human mutations have been found in either the human prolactin gene or its receptor (Goffin et al, 2002). **The normal role of prolactin in men is less clear, but it may increase the concentration of LH**

receptors on Leydig cells and sustain normal, high intratesticular testosterone levels. It may also potentiate the effects of androgens on the growth and secretions of the male accessory sex glands (Wennbo et al, 1997; Steger et al, 1998). Normal prolactin levels may be important to maintain libido. Although low prolactin levels are not necessarily pathologic, hyperprolactinemia abolishes gonadotropin pulsatility by interfering with episodic GnRH release. In addition, the anterior pituitary contains cells that secrete other glycoprotein hormones: adrenocorticotropic hormone (ACTH), growth hormone (GH), and thyroid-stimulating hormone (TSH). These glycoprotein hormones can also have significant effects on male reproductive function.

Testis

Normal male virility and fertility requires the collaboration of the exocrine and endocrine testis (see Fig. 20–2). The interstitial compartment, composed mainly of Leydig cells, is responsible for steroidogenesis. The seminiferous tubules produce spermatozoa.

Normal testosterone production in men is approximately 5 g/day, and secretion occurs in a damped, irregular, pulsatile manner (nyctehemeral). Testosterone is metabolized into two major active metabolites in target tissue: (1) the major androgen **dihydrotestosterone (DHT)** from the action of 5α-reductase and (2) the estrogen **estradiol** through the action of aromatases. DHT is a much more potent androgen than is testosterone. In most peripheral tissues, testosterone reduction to DHT is required for androgen action, but in the testis and skeletal muscle, conversion to DHT is not essential for hormonal activity.

The primary site of FSH action is on Sertoli cells within seminiferous tubules. In response to FSH, Sertoli cells produce androgen-binding protein, transferrin, lactate, ceruloplasmin, clusterin, plasminogen activator, prostaglandins, and growth factors. Through these FSH-mediated factors, seminiferous tubule growth is stimulated during development, and sperm production is initiated during puberty. Interestingly, mice FSH knockout studies suggest that FSH is not essential for spermatogenesis, because affected mice can be fertile (Levallet et al, 1999). In humans, it is thought that FSH is required for normal spermatogenesis (Tapanainen et al, 1997).

The testis also produces the protein hormones inhibin and activin (Itman et al, 2006). Inhibin is a 32-kD protein made by Sertoli cells that inhibits FSH release from the pituitary. Within the testis, **inhibin production is stimulated by FSH and acts by negative feedback at the pituitary or hypothalamus. Activin, a testis protein with close structural homology to transforming growth factor–β, exerts a stimulatory effect on FSH secretion.** Activin receptors are found in a host of extragonadal tissues, suggesting that this hormone may have growth factor or regulatory roles in the body.

Negative feedback suppression of GnRH release by testosterone occurs through androgen receptors (AR) present in hypothalamic neurons and in the pituitary. **In studies of genetic mutations, it is clear that both testosterone and estrogen participate in negative feedback** (Shupnik and Schreihofer, 1997). Steroid negative feedback results mainly from AR binding to testosterone, with a smaller contribution from estradiol binding. **Testosterone feedback occurs mainly at the hypothalamus, whereas estrogens feedback to the pituitary** (Santen, 1975). It also appears that although testosterone is the primary regulator of LH secretion, estradiol (along with inhibin from Sertoli cells) is the predominant regulator of FSH secretion (Hayes et al, 2001).

Development of the HPG Axis

Sex determination is genetically determined in humans. **A critical gene for sex determination is *SRY* (sex-determining region Y gene) on the short arm of the Y chromosome.** The *SRY* gene product is a protein with a high mobility group box (HMG) sequence, a highly conserved DNA-binding motif that kinks DNA. This DNA bending effect alters gene expression, leading to testis formation and subsequently to the male phenotype. However, the *SRY* gene does not act in isolation to determine human sex. *DAX1*, a nuclear hormone receptor gene, can alter *SRY* activity during development by suppressing genes downstream to *SRY* that would normally induce testis differentiation. A second gene, *WNT4*, largely confined to the adult ovary, may also serve as an "antitestis" gene. The discovery of these genes has significantly altered theories of sex determination. In the past, the female genotype was considered the "default," *SRY*-negative, developmental pathway. **It is now clear that genes such as *WNT4* and *DAX1* can proactively induce female gonadal development, even in the presence of *SRY*** (DiNapoli and Capel, 2008).

Once gonadal sex is determined, Leydig cells make **testosterone** that induces development of the **internal genitalia** (Fig. 20–3). Leydig cells also synthesize **insulin-like-3** to promote **transabdominal testis migration** into the scrotum. **DHT** masculinizes the genital anlage to form the **external genitalia** (see Fig. 20–3). In addition, Sertoli cells within the developing testis synthesize **müllerian-inhibiting substance (MIS, AMH)** that **prevents the müllerian duct from developing into uterus and fallopian tubes and keeps the early germ cells quiescent** in the testis (Fig. 20–4). Deficiencies in these developmental pathways generally result in either birth defects or intersex disorders.

The hormonal feedback relationships within the HPG axis also become established during gestation. **The expression of kisspeptin protein is in part responsible for activating GnRH neurons and triggering GnRH release.** In addition, SF-1, an orphan nuclear receptor, is secreted by developing Sertoli cells and contributes to HPG axis development (Val et al, 2003). After the withdrawal of placental steroids at birth, there is a period of high

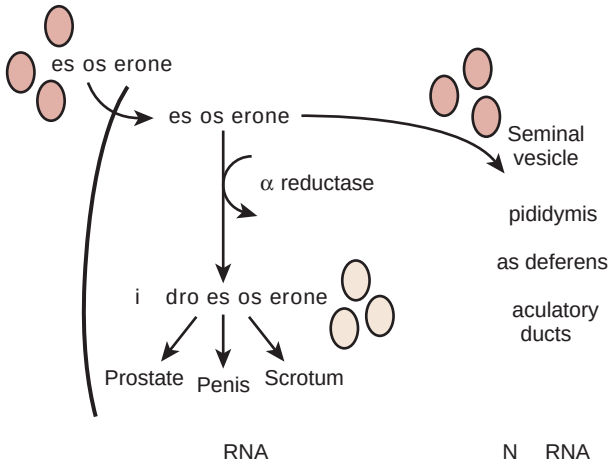

Figure 20–3. Diagram of internal and external genitalia development. Testosterone is the main androgenic steroid responsible for the developing male external genitalia, whereas dihydrotestosterone is the main androgen responsible for development of male internal genitalia.

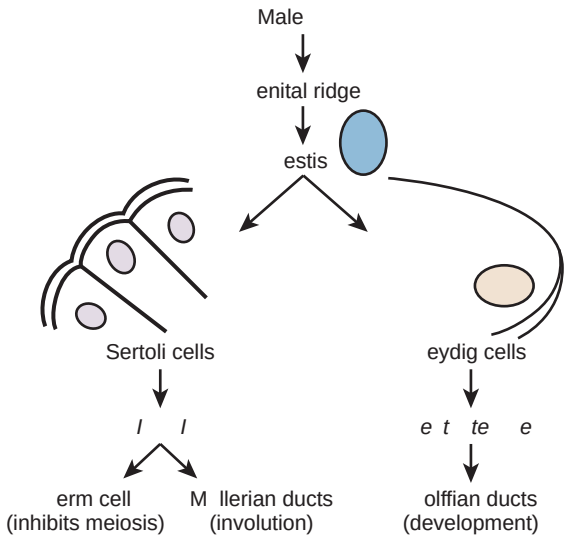

Figure 20–4. Early differentiation pathway of the male. *MIF/MIS,* müllerian inhibiting factor/substance. (Adapted from Turek PJ: Male infertility. In: Tanagho EA, McAninch JC, editors. Smith's urology. 16th ed. Stamford, CT: Appleton & Lange; 2008 [chapter 44–13].)

gonadotropin secretion in the neonate. Subsequently, as axis sensitivity to gonadotropins increases, FSH and LH secretions fall to the low levels characteristic of childhood. Puberty begins with GnRH pulsing, leading gonadotropins to increase to adult levels and, subsequently, to increase sex hormones. **The hypothalamic capacity to generate GnRH pulses arises at puberty, usually starting around the 12th year. Puberty begins at critical growth, weight, and nutritional rates for boys and girls, and is likely initiated by kisspeptin, melatonin, and leptin** (Clement et al, 1998). The adipocyte hormone leptin is the body's regulatory signal governing the size of the fat stores, and there is increasing evidence that leptin modulates hypothalamic and pituitary activity (Caprio et al, 1999; Kiess et al, 1999; Quinton et al, 1999).

Aging and the HPG Axis

A progressive decline in testosterone and sperm production occurs with age, such that men in the 7th decade have mean plasma testosterone levels 35% lower than young men (Vermeulen et al, 1995). The consequence of this is a phenomenon has been variously termed **male menopause, male climacteric, andropause, or, more appropriately, partial androgen deficiency in the aging male (PADAM).** The changes to the seminiferous epithelium with age include decreases in seminiferous tubule volume and length. **An age-related decrease in sperm production in older testes appears to stem from a decrease in germ cell proliferation rather than cellular degeneration. Correspondingly, FSH levels also increase with age, with mean values threefold higher in older than younger men.** The etiology of the age-related decline in HPG axis function is multifactorial. Testosterone production is reduced because of decreased numbers of Leydig cells and an increase in testosterone binding proteins. Diurnal variation of testosterone secretion is also lost in elderly men. There is also evidence for a blunted HPG feedback response to low testosterone (despite generally high levels of gonadotropins) and to GnRH stimulation. Finally, normal pulsatile GnRH release is replaced by irregular pulses that are less effective in stimulating gonadotropin release (Mulligan et al, 1997). A combination of these effects is likely responsible for diminished HPG axis function with age in men.

Key Points: HPG Axis

- Normal testosterone and sperm production by the testis depends on the pulsatile secretion of hypothalamic GnRH and LH and FSH from the anterior pituitary gland.
- Regulation of HPG axis hormones occurs primarily through negative feedback.
- The determination of maleness is derived from the *SRY* gene on the Y chromosome. Other developmental genes such as *WNT4* and *DAX1* are considered "antitestis" genes and can proactively induce female gonadal development.
- Changes that occur to the HPG axis with paternal age include lower testosterone levels, blunted HPG axis feedback, and irregular hormone pulsatility.

THE TESTIS

Gross Architecture

The testis is a white, ovoid organ that is normally 15 to 25 mL in volume (Prader, 1966) and has a length of 4.5 to 5.1 cm (Tishler, 1971; Winter and Faiman, 1972). The tunica albuginea has smooth muscle cells that course through predominantly collagenous tissue (Langford and Heller, 1973). These smooth muscle cells may impart contractile capability to the capsule (Rikmaru and Shirai, 1972), may affect blood flow into the testis (Schweitzer, 1929), and promote the flow of seminiferous tubule fluid out of the testis (Davis and Horowitz, 1978).

The testis parenchyma is divided into compartments separated by septa. Each septum divides seminiferous tubules into lobes that each contain a centrifugal artery. **Individual seminiferous tubules harbor developing germ cells and interstitial tissue. Interstitial tissue is composed of Leydig cells, mast cells, macrophages, nerves, and blood and lymph vessels. In humans, interstitial tissue comprises 20% to 30% of total testicular volume** (Setchell and Brooks, 1988). The relationship between seminiferous tubules and interstitial tissue anatomy is demonstrated in Fig. 20–5. Seminiferous tubules are long, highly coiled, and looped. Both ends usually terminate in the rete testis. **It is estimated that the combined length of the 600 to 1200 tubules in the human testis is approximately 250 meters** (Lennox and Ahmad, 1970) (Fig. 20–6). The "hub" of the testis, also termed the rete testis, coalesces to form 6 to 12 ductuli efferentes that carry testicular fluid and spermatozoa into the caput epididymis (see Fig. 20–6).

The arterial supply to the testis and epididymis is derived from three sources: the internal spermatic artery, the deferential (vasal) artery, and the external spermatic (or cremasteric) artery (Harrison and Barclay, 1948). The internal spermatic artery arises from the abdominal aorta and is intimately associated with the pampiniform plexus of veins. The vascular arrangement within the pampiniform plexus, with the counterflowing artery and veins, facilitates the exchange of heat and small molecules. For example, testosterone passively diffuses

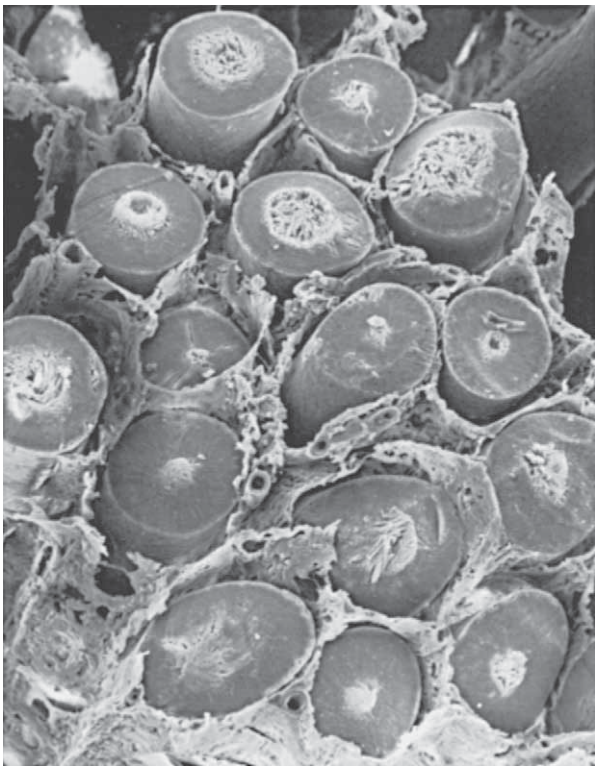

Figure 20–5. Scanning electron micrograph of the cut surface of the human testis. Note the relationship of interstitial tissue to seminiferous tubules. (From Christensen AK. Leydig cells. In: Greep RO, Astwood EB, editors. Handbook of physiology. Washington, DC: American Physiology Society; 1975. p. 57–94.)

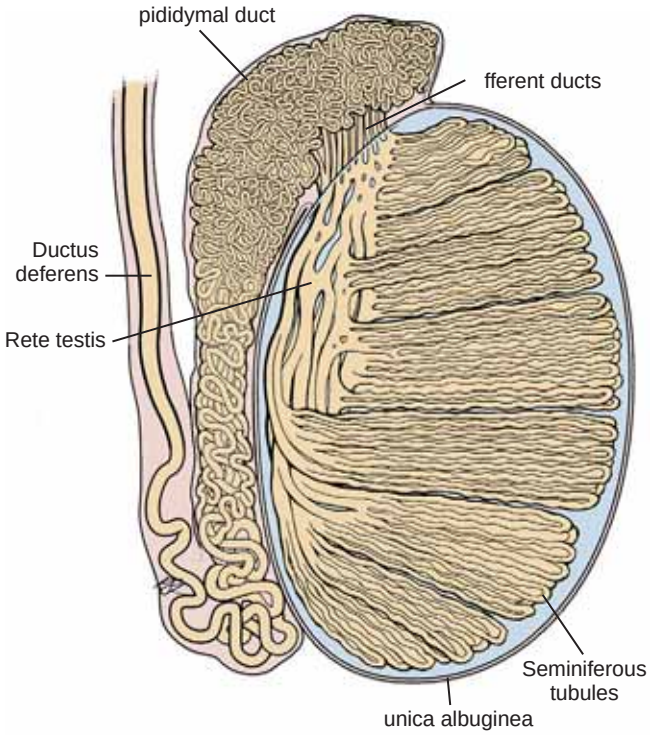

Figure 20–6. Drawing of the human testis showing the seminiferous tubules (250 meters length), epididymis (3 to 4 meters length), and vas deferens. (Based on Hirsh AV. The anatomical preparations of the human testis and epididymis in the Glasgow Hunterian Collection. Hum Reprod Update 1995;1:515–21.)

from veins to the artery in a concentration-limited manner (Bayard et al, 1975). **The countercurrent heat exchange supplies arterial blood to the testis that is 2° C to 4° C lower than the rectal temperature in normal men** (Agger, 1971). A loss of the temperature differential is associated with testicular dysfunction in men with varicocele (Goldstein and Eid, 1989) and cryptorchidism (Marshall and Edler, 1982). As the spermatic cord is commonly dissected during varicocele repair, it is surgically relevant to know that a single artery is observed in 50% of spermatic cords, with two arteries in 30% and three arteries in 20% of cases (Beck et al, 1992).

Inferior to the scrotal pampiniform plexus and near the mediastinal testis, the spermatic artery is highly coiled and branches before entering the testis. Extensive interconnections, especially between the internal spermatic and deferential arteries, allow maintenance of testis viability even after division of the internal spermatic artery (Fig. 20–7). From angiographic studies, a single artery enters the testis in 56% of cases; two branches enter in 31% of cases and three or more branches in 13% of testes (Kormano and Suoranta, 1971). In men with a single testicular artery, its interruption can result in testicular atrophy (Silber, 1979). The testicular arteries penetrate the tunica albuginea and then travel

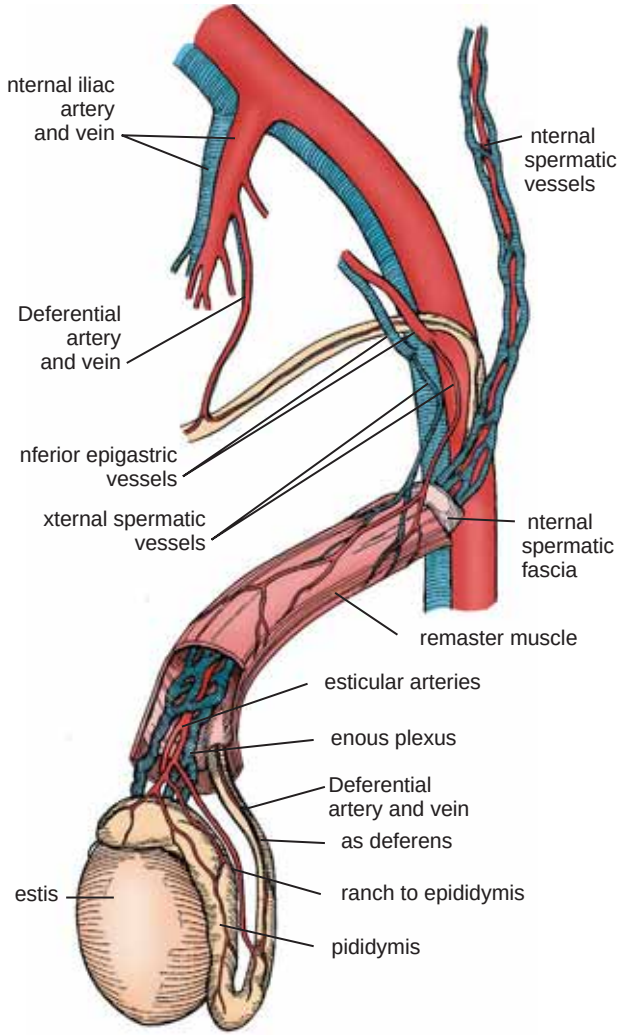

Figure 20–7. Schematic illustration of the interconnections between internal spermatic, external spermatic (cremasteric), and deferential vessels in the peritesticular region and spematic cord.

inferiorly along the posterior surface of the testis within the parenchyma. Branching arteries pass anteriorly over the testicular parenchyma. Major testicular artery branches also travel over the inferior pole of the testis, pass anteriorly and branch out over the surface of the testis. The location of these vessels is clinically important, because they may be injured during orchiopexy or testis biopsy procedures (Jarow, 1991; Schlegel and Su, 1997). **The midsection of the testis has relatively fewer vessels compared with superior or inferior areas of the testis.** Individual arteries to the seminiferous tubules, termed centrifugal arteries, travel within the septa that contain tubules. Centrifugal artery branches give rise to arterioles that supply individual intertubular and peritubular capillaries (Muller, 1957). The intertubular capillaries are located within the columns of interstitial tissue, whereas the ladder-like capillaries running near the seminiferous tubule are called peritubular capillaries. Through this vascular complex, the human testis is provided with 9 mL of blood per 100 g of tissue per minute (Pettersson et al, 1973).

Veins within the testis are unusual in that they do not run with the corresponding intratesticular arteries. Small parenchymal veins empty into either the veins on the testis surface, or into a group of veins near the mediastinum testis that travels along the rete testis (Setchell and Brooks, 1988). These two sets of veins join together with deferential veins to form the pampiniform plexus as they ascend into the scrotum. Pampiniform plexus veins are thin walled, which likely contributes to the passive diffusion of testosterone and temperature exchange with the closely associated spermatic artery.

The testis has no known somatic innervation. It receives autonomic innervation primarily from the intermesenteric nerves and renal plexus (Mitchell, 1935). These nerves run along the testicular artery into the testis. It appears that testicular adrenergic innervation is restricted primarily to small blood vessels that supply Leydig cell clusters that may regulate Leydig cell steroidogenesis (Baumgarten et al, 1968; Turnbull and Rivier, 1997). It is thought that vascular tone in the testis may involve regulation at several levels (Linzell and Setchell, 1969), including autoregulation of capsular arteries (Davis et al, 1990), regional variation based on local metabolic need and governed by peptides such as atrial natriuretic peptide (Collin et al, 1997), and assisted transport of molecules such as LH across the vascular endothelium (Milgrom et al, 1997). Indeed, these observations suggest a highly specialized function for the microvasculature of the testis (see review by Desjardins [1989]).

Prominent lymphatics can be observed within the spermatic cord (Hundeiker, 1971). Obstruction of these ducts results in dilatation of the testis interstitium but not the seminiferous tubules, suggesting that the interstitial space is drained by lymphatics, but the seminiferous tubules are not. **Lymphatic obstruction can also result in hydrocele formation, a known complication of certain varicocelectomy and herniorrhaphy procedures.** The sperm containing intratubular fluid that baths Sertoli cells flows from the seminiferous tubules into the rete testis and, subsequently, into the caput epididymis. This fluid, isosmotic with plasma, is thought to be mainly of seminiferous tubule origin (Setchell and Brooks, 1988). **Reabsorption of this fluid within the rete testis and efferent ductules is regulated by estrogens** (Lee et al, 2000). Tubular fluid composition is markedly different from blood plasma or lymphatics, suggesting that substances are not freely diffusible into and out of the tubules (Setchell and Waites, 1975). This has led to the concept of a "blood-testis barrier" to be discussed later.

Testis Cytoarchitecture

Interstitium

Leydig Cells. The testis interstitium contains blood vessels, lymphatics, fibroblasts, macrophages, mast cells, and Leydig cells (Fig. 20–8). **Leydig cells are responsible for the bulk of testicular steroid production. Leydig cells differentiate from mesenchymal precursor cells by the 7th week of gestation.** The activation of Leydig cell steroidogenesis correlates with the onset of androgen-dependent differentiation of the male reproductive system. Although it is apparent that Leydig cells express steroidogenic enzymes before becoming responsive to LH (El-Gehani et al, 1998; Majdic et al, 1998), they also differentiate from precursor cells under the influence of LH, placental-derived human chorionic gonadotropin (HCG), and from the effect of local paracrine factors such as IGF-1 (Huhtaniemi and Pelliniemi, 1992; Teerds and Dorrington, 1993; Le Roy et al, 1999). **At 2 to 3 months after birth, a second wave of Leydig cell differentiation occurs in response to gonadotropin production from the pituitary, briefly elevating testosterone levels in infants.** Androgen produced during the the early male neonate's life is thought to hormonally imprint the hypothalamus, liver, and prostate such that they respond appropriately to androgen stimulation later in life. **After reactivation of the HPG axis at puberty, stereologic analysis has revealed that a single testis from a young adult contains approximately 700 million Leydig cells** (Kaler and Neaves, 1978).

Testosterone. **Testosterone, synthesized from cholesterol, is the principal steroid produced by the testis** (Lipsett, 1974). In addition, numerous C_{18}, C_{19}, and C_{21} steroids are also produced (Lipsett, 1974; Ewing and Brown, 1977). Cholesterol must be transported into Leydig cell mitochondria, where the cholesterol side-chain cleavage enzyme converts it to pregnenolone. The three main sources of cholesterol in the Leydig cell are (1) externally, from blood-borne lipoprotein and internalization of cholesterol-lipoprotein receptor complexes, (2) from de novo synthesis from acetate, and (3) from stored cholesterol esters in lipid droplets. Maintenance of cholesterol stores is part of the normal resting function of the Leydig cell; LH stimulation evokes cholesterol mobilization through cholesterol esterase activity. Pregnenolone is transported out of the mitochondrial membrane into the smooth endoplasmic reticulum, where it is converted into testosterone. Testosterone diffuses across the cell membrane and is trapped within the extracellular fluid and blood plasma by steroid-binding proteins.

Cholesterol transport to the inner membrane of the mitochondrion is regulated by two transport proteins: steroid acute regulatory protein (StAR) and peripheral benzodiazepine receptor (PBR). LH binding elicits protein synthesis in the Leydig cell, and the newly-synthesized StAR contains a signal sequence that enables it to be threaded through the outer mitochondrial membrane to faciliate cholesterol transport (Stocco, 2000). PBR forms a channel for cholesterol in the mitochondrial membrane (Culty et al, 1999), but it is not clear whether PBR functionally interacts with StAR (West et al, 2001).

The four major enzymes participating in testosterone biosynthesis from pregnenolone are cholesterol side-chain cleavage enzyme, 3β-hydroxysteroid dehydrogenase, cytochrome P450 17α-hydroxylase/$C_{17\text{-}20}$-lyase, and 17β-hydroxysteroid dehydrogenase. The enzymology, chromosomal locations, and molecular genetics of these enzymes are well described (Payne and Hales,

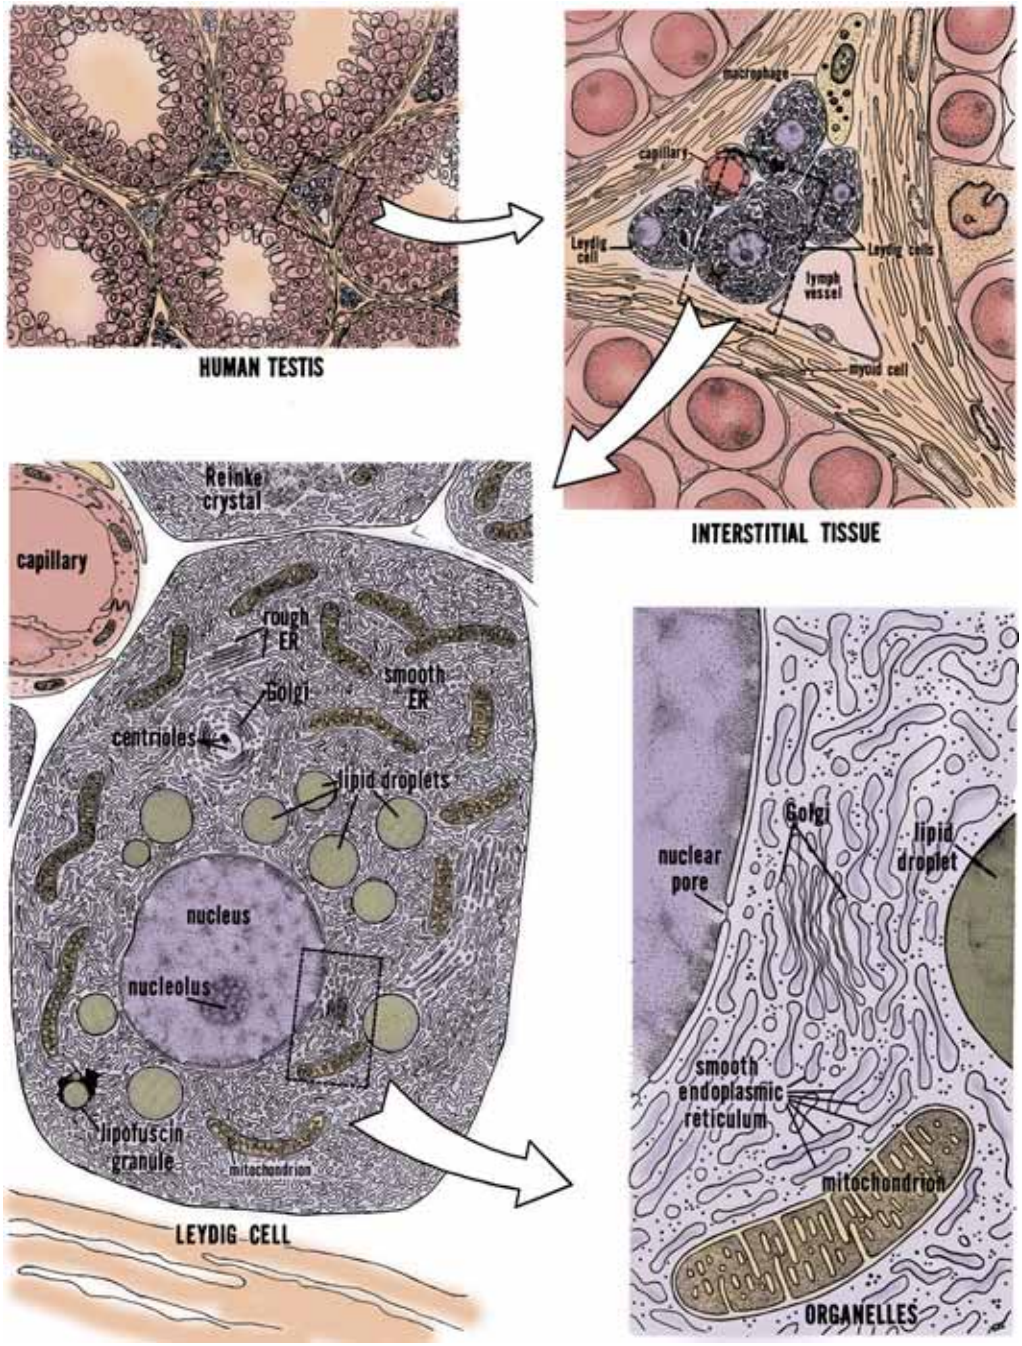

Figure 20–8. Fine structure of human Leydig cells. Leydig cells occur in clusters in the interstitium between seminiferous tubules *(upper left)*. Interstitial tissue *(upper right)* contains macrophages and fibroblasts and capillaries and lymph vessels. The most abundant organelle within the Leydig cell cytoplasm is the smooth endoplasmic reticulum *(lower left)*. Organelles seen in greater detail *(lower right)*. (From Christensen AK. Leydig cells. In: Greep RO, Astwood WB, editor. Handbook of physiology, section 7, Endocrinology. Baltimore: Williams & Wilkins; 1975. Copyright 1975, The American Physiological Society, Bethesda, MD.)

2004). Gene mutations in the genes encoding these enzymes have been described and the resulting disorders of androgen biosynthesis are a relatively rare cause of sexual ambiguity in chromosomally normal males (Miller, 2002).

Control of Testosterone Synthesis. The control of Leydig cell steroidogenesis is complex and involves both pituitary and nonpituitary factors (Payne and Youngblood, 1995). **The most important regulator of testosterone production is LH. LH binding, through the second messenger cyclic adenosine monophosphate (cAMP), initiates transport of cholesterol into mitochondria.** Pituitary peptides other than LH (e.g., FSH and prolactin) modify the response to LH (Ewing, 1983). Other, nonpituitary factors capable of modifying steroid production by Leydig cells include **GnRH** (Sharpe, 1984), **inhibin and activin** (Bardin et al, 1989), **epidermal growth factor (EGF), IGF-1, and transforming growth factor-β (TGF-β)** (Ascoli and Segaloff, 1989; Saez et al, 1991), prostaglandins (Eik-Nes, 1975), and adrenergic stimulation (Eik-Nes, 1975). Moreover,

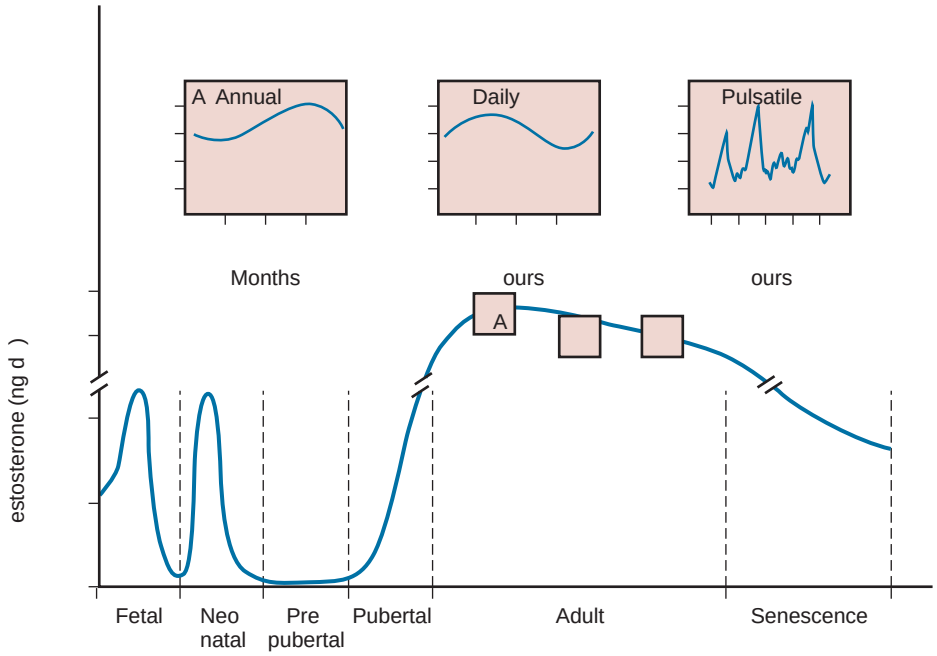

Figure 20–9. Peripheral blood testosterone levels in the human male during the life cycle. The fetal testosterone peak occurs between 12 and 18 weeks of gestation *(lower left corner; gestational age not shown)*. The neonatal peak occurs at approximately 2 months of age. Testosterone declines to low levels during the prepubertal period. The pubertal increase in testosterone occurs between 12 and 17 years of age. Testosterone concentration in the adult reaches its maximum during the second or third decade of life and then declines slowly through the 5th decade. Testosterone declines dramatically during senescence. *Inset A* shows the annual rhythm in testosterone concentration in the human male. The peak and nadir occur in the fall and spring, respectively. *Inset B* shows the daily rhythm in testosterone concentration. The peak and nadir occur in the morning and evening, respectively. *Inset C* shows the frequent and irregular fluctuations in testosterone concentration. (From Ewing LL, Davis JC, Zirkin BR. Regulation of testicular function: a spatial and temporal view. In: Greep RO, editor. International review of physiology. Baltimore: University Park Press; 1980. p. 41.)

direct inhibition of Leydig cell steroidogenesis may also occur through **estrogens and androgens** (Ewing, 1983; Darney et al, 1996).

Testosterone Cycles. Testosterone blood levels change dramatically during human fetal, neonatal, and adult life. Fig. 20–9 shows that a testosterone peak occurs in the human fetus between 12 and 18 weeks of gestation. Another testosterone peak occurs at approximately 2 months of age. A third testosterone peak occurs during the 2nd or 3rd decade of life. After this, there is a plateau, and then a slow decline with age. Superimposed on this, there are annual and daily rhythms of testosterone production (see Fig. 20–9, insets A and B) and irregular daily fluctuations in testosterone (see Fig. 20–9, inset C). These temporal changes in testosterone production during human life reflect a complex interaction between the pituitary gland and the testis. **The testosterone peaks correspond temporally to the following developmental events: (1) the differentiation and development of the fetal reproductive tract, (2) the neonatal organization or "imprinting" of androgen-dependent target tissues, (3) the masculinization of the male at puberty, and (4) the maintenance of growth and function of androgen-dependent organs in the adult.** This topic has been reviewed thoroughly by Swerdloff and Heber (1981).

Seminiferous Tubules

The seminiferous tubules consist of germ cells and supporting cells and are a unique environment for gamete production. Support cells include the Sertoli cells and fibrocyte and myoid cells of the basement membrane. The germ cells include a slowly dividing stem cell population, more rapidly proliferating spermatogonia and spermatocytes, and metamorphosing spermatids.

Sertoli Cells. The seminiferous tubules are lined with Sertoli cells that rest on the tubular basement membrane and extend cytoplasmic ramifications into its lumen (Fig. 20–10). The ultrastructural features of Sertoli cells are well described (Bardin et al, 1994). They have irregularly shaped nuclei, prominent nucleoli, low mitotic index, and exhibit unique **tight junctional complexes** between adjacent Sertoli cells. **These tight junctions are the strongest intercellular barriers in the body. They divide the seminiferous tubule space into basal (basement membrane) and adluminal (lumen) compartments** (see Fig. 20–10). This anatomic arrangement forms the basis for the **"blood-testis barrier"** and allows spermatogenesis to occur in an immunologically privileged site. **Sertoli cells serve as "nurse" cells for spermatogenesis, nourishing developing germ cells that are arranged between Sertoli cell cytoplasmic projections. The undifferentiated spermatogonia are near the basement membrane of the tubule, whereas the more advanced spermatocytes and spermatids are located near the luminal surface.** Thus the Sertoli cell is a polarized epithelium in which the base approximates the plasma environment, and its apex harbors an environment unique to the seminiferous tubule (Ewing et al, 1980).

Sertoli cells nurture germ cell development by: (1) providing a specialized adluminal microenvironment, (2) supporting germ cells through gap junctions between Sertoli and germ cells, and (3) allowing migration of developing germ cells within the tubule (see Fig. 20–10). The tight junctions between Sertoli cells are constantly remodeled to allow "opening" and "closing" necessary for germ cell interaction and migration (Mruk and Cheng, 2004). Ligand-receptor complexes, such as c-kit and kit ligand, are likely involved in

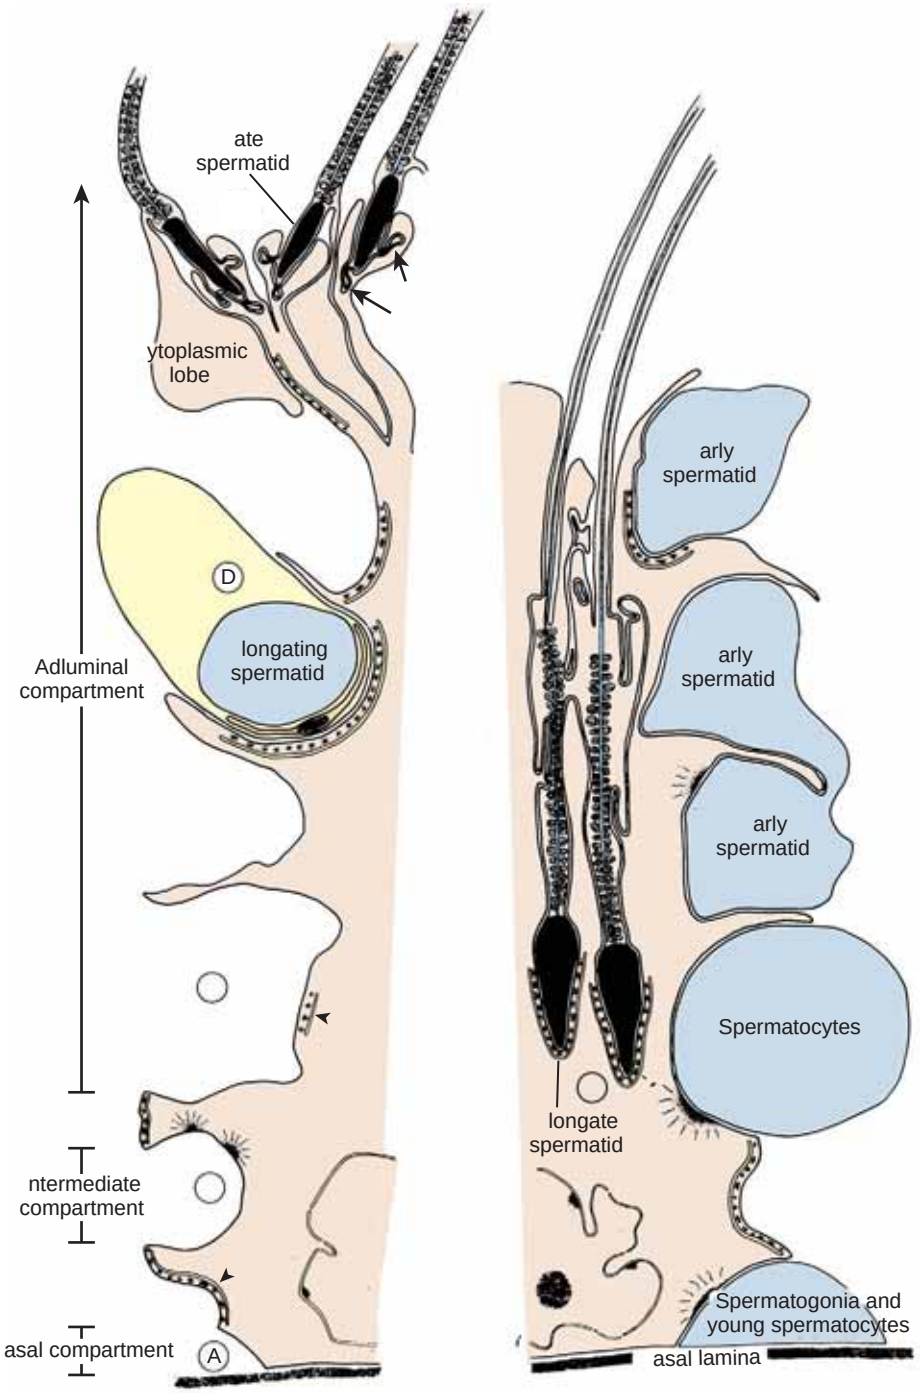

Figure 20–10. Representation of the tree-shaped Sertoli cell with a thickened central portion, or "trunk," and more delicate processes, or "limbs." The major configurational changes that occur during spermatogenesis are noted. Note the basal, intermediate, and adluminal compartments of the seminiferous epithelium. **A**, Spermatogonia and early spermatocytes share positions on the basal lamina and are enveloped by adjacent Sertoli cells that join to form tight junctional complexes (site of blood-testis barrier). **B**, Sertoli cells form junctional complexes both above and below leptotene-zygotene spermatocytes as they translocate from the basal to adluminal compartments. **C**, The spermatocytes enter the adluminal compartment when Sertoli tight junctions dissociate. **D**, The elongating spermatid is situated within a narrow recess of the Sertoli cell trunk. **E**, As the spermatid elongates further, the cell becomes lodged within the body of the Sertoli cell. The advanced spermatid moves toward the lumen of the epithelium in preparation for spermiation. Only the sperm head remains in intimate contact with the Sertoli cell. Specialized cell-to-cell contacts: *asterisks,* desmosome-gap junction complex; *arrowheads,* ectoplasmic specializations; *isolated arrows,* tubulobulbar complexes. (From Russell L. Sertoli-germ cell interactions: a review. Gamete Res 1980;3:179.)

mediating communication between germ and Sertoli cells. Sertoli cells also participate in germ cell phagocytosis and produce and secrete fluid and important effector molecules. Androgen-binding protein (ABP) is one of earliest described Sertoli cell secretory products (Hansson and Djoseland, 1972). ABP is an intracellular carrier of androgen within the Sertoli cell. **By binding testosterone, ABP maintains high levels of androgen (50-fold, as observed in serum) within the seminiferous tubules.** Testosterone also plays an important role in the regulation of Sertoli cell function, including ABP production (Griswold, 1988). Inhibin is Sertoli cell–derived and plays an important regulatory role in the negative feedback loop of FSH secretion. Inhibin B is emerging as an important endocrine marker of Sertoli cell function in the male infertility evaluation.

As keepers of the immunological sanctuary in the testis, Sertoli cells maintain a germ cell microenvironment entirely distinct from that of plasma. As such, Sertoli cells secrete numerous other products including extracellular matrix components (lamin, collagen type IV, and collagen type I) and proteins such as ceruloplasmin, transferrin, glycoprotein 2, plasminogen activator, somatomedin-like substances, T proteins, H-Y antigen, clusterin, cyclic proteins, growth factors, and somatomedin (Mruk and Cheng, 2004). Steroids, such as DHT, testosterone, androstenediols, 17β-estradiol, and numerous other C_{21} steroids are also produced by Sertoli cells

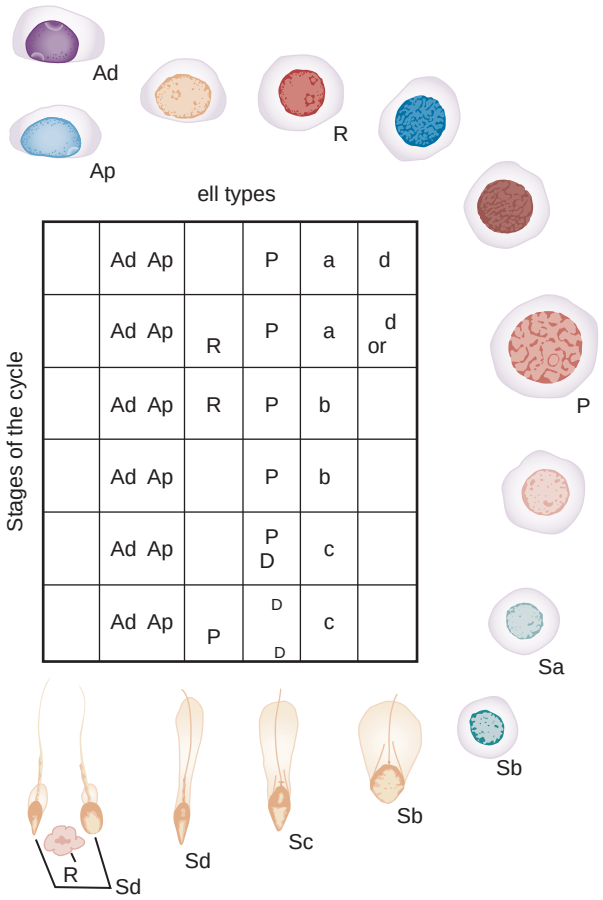

Figure 20–11. The steps of spermatogenesis in man. Ad, dark type A spermatogonium; Ap, pale type A spermatogonium; B, type B spermatogonium; II, secondary spermatocyte; L, leptotene spermatocyte; P, pachytene spermatocyte; R, resting or preleptotene primary spermatocyte; Rb, residual body; Sa(a), $Sb_1(b_1)$, $sb_2(b_2)$, Sc(c), $sd_1(d_1)$, $Sd_2(d_2)$, spermatids; Z, zygotene spermatocyte. The table shows cells that make up the six stages of the "cycle" of the seminiferous epithelium (I to VI): D_1, diakenesis; ID and IID, first and second maturation divisions of spermatocytes. (Modified from Clermont Y. Renewal of spermatogonia in man. Am J Anat 1966;118:509.)

(Ewing et al, 1980; Mather et al, 1983). Although the function of many Sertoli cell– and peritubular-derived substances is unclear, further research will enlighten our understanding of how Sertoli cells orchestrate and support spermatogenesis.

Germ Cells. Within the human seminiferous tubule, germ cells give rise to approximately 123×10^6 (range: 21 to 374×10^6) spermatozoa daily (Amann and Howards, 1980). This equates to the production of about 1200 sperm per heartbeat. Within the seminiferous tubule, germ cells are arranged in a highly ordered sequence from the basement membrane to the lumen. **Morphologic analysis of the various germ cells reveals at least 13 recognizable germ cell types in the human testis** (Clermont, 1963; Heller and Clermont, 1964) (Fig. 20–11). Each cell type is thought to represent a different step in the spermatogenic process. Proceeding from the least to the most differentiated, based on morphologic appearance, they have been named **dark type A spermatogonia (Ad); pale type A spermatogonia (Ap); type B spermatogonia (B); preleptotene (R), leptotene (L), zygotene (z), and pachytene primary spermatocytes (p); secondary spermatocytes (II); and Sa, Sb, Sc, Sd_1, and Sd_2 spermatids.** The tight junctions maintain

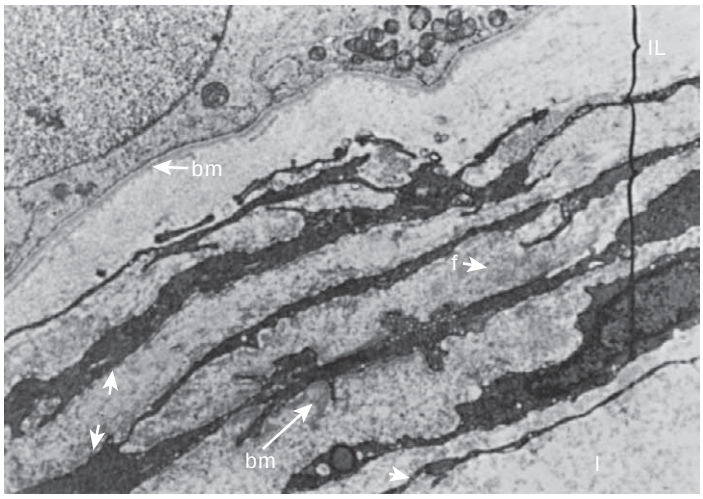

Figure 20–12. Low-power electron micrograph of human peritubular testis tissue. Peritubular tissue lies between the basement membrane (bm) of the seminiferous epithelium (SE) and the interstitial tissue (IS). Peritubular tissue has three zones: the inner lamella (IL); the myoid layer (M), containing myoid cells (MY) with abundant microfibrils (Mf); and an adventitial layer containing fibroblasts (F). (From Hermo L, Lalli M, Clermont Y. Arrangement of connective tissue elements in the walls of seminiferous tubules of man and monkey. Am J Anat 1977;148:433–46.)

spermatogonia and early spermatocytes within the basal compartment and all subsequent germ cells in the adluminal compartment.

Peritubular Structure

The human seminiferous tubule is surrounded by several layers of peritubular tissue (Hermo et al, 1977) (Fig. 20–12). The outer adventitial layer consists of fibrocytes. In the middle layer are myoid cells interspersed with connective tissue lamellae. The inner layer consists of a collagen matrix. In humans the peritubular myoid cells are thought to have contractile function (Toyama, 1977). Myoid cells actively secrete extracellular matrix components fibronectin and collagen type I, and produce the inner collagenous layer (Tung et al, 1984). Myoid cells may also affect Sertoli cell function and are known to associate with Sertoli cells in a precise mesenchymal-epithelial interaction. Skinner and coworkers (1988) isolated a paracrine factor produced by myoid cells, P-Mod-S (peritubular modifies Sertoli), that profoundly affects Sertoli cell synthetic and differentiation functions in vitro. Human peritubular cells have also been shown to secrete testosterone, and exert regulatory Sertoli cell secretory activity (Cigorraga et al, 1994).

Blood Testis Barrier

Dyes and other substances, when injected into the bloodstream of animals, will rapidly appear throughout all body tissues but fail to penetrate regions of the brain and testis. From this observation, the concept of a "blood-testis barrier" was derived. **More appropriately termed the "blood–seminiferous tubule barrier," the barrier has two components: an anatomic or mechanical element and functional elements.** The mechanical barrier is created, in part, by muscle-like myoid cells that surround seminiferous tubules (Dym and Fawcett, 1970; Fawcett et al, 1970). Regulation of molecular traffic also occurs at the level of capillary endothelial cells. However, the most important component of this barrier is the synaptic tight junctions between Sertoli

cells that preclude the passage of large molecules and lymphocytes. These anatomical elements of the blood-testis barrier are necessary but not sufficient for maintaining the immunologic "sanctuary" status within the tubule, because they are not observed in other "protected" areas of the reproductive tract (Tung et al, 1971; Brown et al, 1972).

Thus, although the mechanical barrier contributes to the isolation of the testis, other "functional" components must also exist that suppress the normal immune response. Several mechanisms likely work in concert to protect sperm from destruction. First, lymphocytes are diverted by the vascular endothelium and are excluded from anatomically vulnerable regions in the germinal epithelium (Mahi-Brown et al, 1988). Second, these vulnerable regions harbor mainly T-suppressor cells (el-Demiry et al, 1985; Anderson and Hill, 1988). Due to deficiencies in antigen–HLA association, there may be a lack of sperm antigen presentation to lymphocytes, impairing the immune response (Jenkins et al, 1987; Anderson and Hill, 1988). There is also evidence to suggest that immunologic tolerance plays a role in the functional blood-testis barrier. Tung and colleagues have proposed that within the anatomically weaker areas (rete testis, efferent tubule, epididymis), there is a small, continuous leak of sperm antigens (Tung, 1980). This leak generates T-suppressor cells and immune tolerance, similar to desensitization protocols for common environmental allergens. However, with larger antigenic challenges, a true immune response results (Turek, 1997). Cytokines may contribute to immune tolerance, including interferon gamma, soluble Fc receptor, and transforming growth factor–β (Perussia et al, 1987; Ben Rafael, 1992; Turek, 1997). In addition, androgens have mild immunosuppressive activity and also appear to help regulate immunity (Diemer et al, 2003).

Why does the blood-testis barrier exist? Since it develops at spermarche, when spermatogenesis begins at puberty (Kormano, 1967), it is likely important for meiosis. In addition, it may immunologically isolate developing male gametes that are not recognized as "self" by the adult male immune system. In this sense, **the value of a blood-testis barrier is fully realized after puberty, because foreign "antigens" on postmeiotic germ cells only exist after spermarche. A testicular insult such as biopsy, torsion, or trauma will not induce antisperm antibodies if it occurs before puberty.** After puberty, however, immunologic infertility is a known risk (Turek, 1997). Clinically, the blood-testis barrier may also limit chemotherapy access to cancer cells sequestered behind it and result in isolated cancer recurrence within the testis.

Spermatogenesis

Spermatogenesis is a remarkably complex and specialized process of DNA reduction and germ cell metamorphosis. Older studies have estimated that the entire process in humans requires approximately 64 days (Clermont, 1972). **However, a recent in-vivo kinetic study in healthy men revealed that the total time to produce an ejaculated sperm ranges from 42 to 76 days, suggesting that the duration of spermatogenesis can vary widely among individuals** (Misell et al, 2006) (Fig. 20–13). **Spermatogenesis involves (1) a proliferative phase** as spermatogonia divide to replace their number (self-renewal) or differentiate into daughter cells that become mature gametes; (2) **a meiotic phase** when germ cells undergo a reduction division, resulting in haploid (half the normal DNA complement) spermatids; and (3) **a spermiogenesis phase** in which spermatids undergo a profound metamorphosis to become mature spermatozoa. (For excellent reviews, see Steinberger, 1976, and de Kretser and Kerr, 1988.)

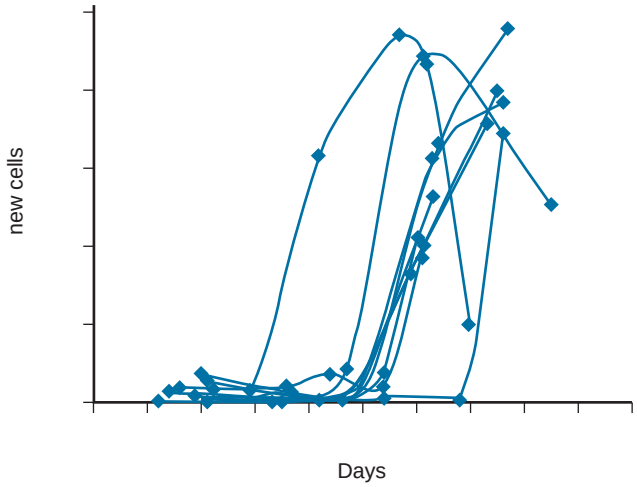

Figure 20–13. Time to make and ejaculate human sperm. Combined spermatocyte labeling curves for 11 individuals with normal semen quality who ingested 50 mL of ^2H_2O twice daily for 3 weeks. Note that new ejaculated sperm was found as soon as 42 days after ingesting the label, and that there is considerable interindividual variation in the time to make and ejaculate sperm among normal men. (From Misell LM, Holochwost D, Boban D, et al. A stable isotope/mass spectrometric method for measuring the kinetics of human spermatogenesis in vivo. J Urol 2006;175: 242–46.)

A cycle of spermatogenesis involves the division of primitive spermatogonial stem cells into subsequent germ cells. **Several cycles of spermatogenesis coexist within the germinal epithelium at any one time, and they are described morphologically as stages.** If spermatogenesis is viewed from a single fixed point within a seminiferous tubule, six recognizable cellular associations or stages exist in a predictable and constant fashion in humans (Heller and Clermont, 1964) (see Fig. 20–11). **In addition, there is also a specific organization of spermatogenic cycles within the tubular space, termed spermatogenic waves.** The best evidence suggests that human spermatogenesis exists in a spiral or helical cellular arrangement that ensures sperm production is a continuous and not a pulsatile process (Schulze, 1989) (Fig. 20–14).

Testis Stem Cell Migration, Renewal, and Proliferation

Testis Stem Cell Migration. During early prenatal development, **primordial germ cells** migrate to the gonadal ridge and associate with Sertoli cells to form primitive testicular cords (Witschi, 1948). These primitive germline stem cells are termed **gonocytes** after the gonad differentiates into a testis by forming seminiferous cords. They are called **spermatogonia** after migration to the periphery of the tubule (Gondos and Hobel, 1971). **Interestingly, these early migrating germ cells have properties very similar to embryonic stem cells and are likely the source of adult seminoma germ cell tumors** (Ezeh et al, 2005).

Testis Stem Cell Renewal. Spermatogonia within the testis stem cell niche are replenished in a process termed stem cell renewal. The growth factor-receptor kit ligand/c-kit receptor system and the niche factor glial cell line-derived neurotrophic factor (GDNF) appear to be involved in this process (Oatley and Brinster, 2008). In fact, the c-kit receptor is a marker of spermatogonial stem cells

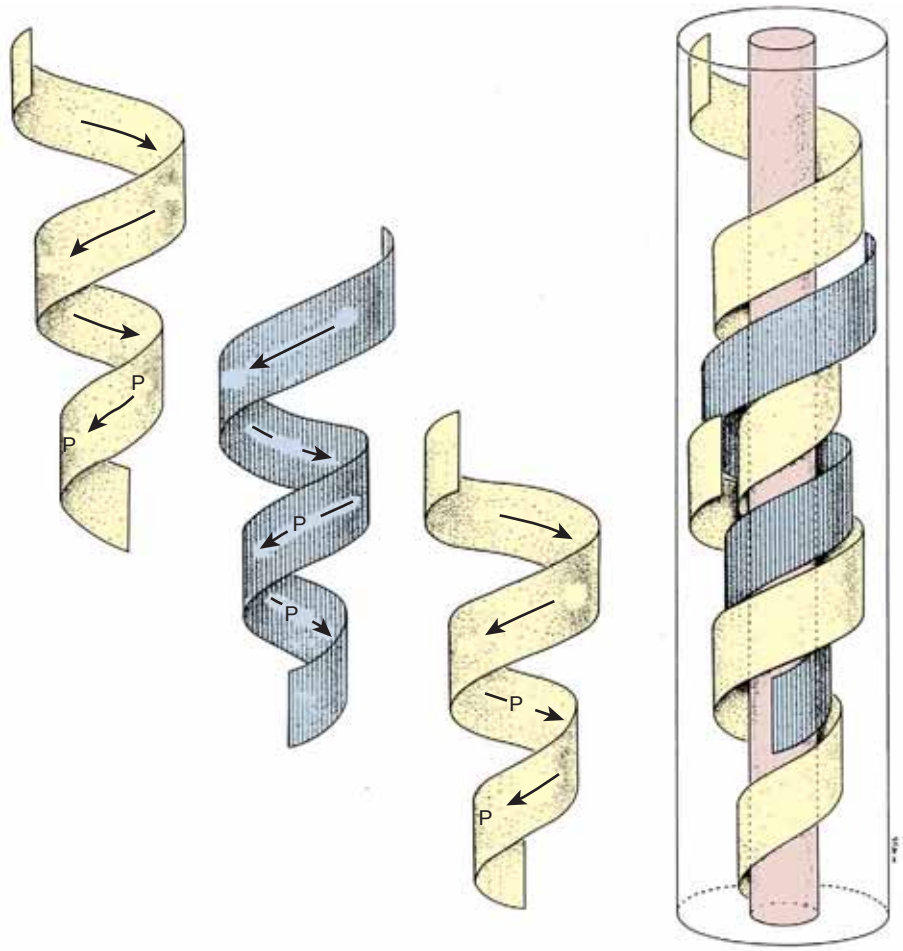

Figure 20–14. Helical configuration of seminiferous tubule epithelial cycles in man, forming overlapping "waves" of spermatogenesis that keep sperm production constant. (From Schulze W, Rehder U. Organization and morphogenesis of the human seminiferous epithelium. Cell Tissue Res 1984;237:395–407.)

in rats (Dym, 1994) and spermatogenesis in the rat is a c-kit–dependent process, whereas spermatogonial stem cell renewal may be c-kit–independent (Yoshinaga et al, 1991). **Recent studies have also shown that human spermatogonial stem cells can be reprogrammed in vitro to become embryonic-like stem cells** (Conrad et al, 2008; Kossack et al, 2009) (Fig. 20–15). Obtained from adult testis biopsies, the embryonic-like cells express distinct markers of pluripotency (*OCT-4, SOX-2, STELLAR, GDF-3*), can form all three germ layers, maintain a normal karyotype, form teratomas, and express appropriate levels of epigenetic markers and telomerase (Kossack et al, 2009). This finding suggests that, in the future, the testis may be a source of patient-specific, embryonic stem cells for cell-based therapy.

Testis Stem Cell Proliferation. In the human, pale type A (Ap) spermatogonia in the basal, stem cell niche of the seminiferous tubule divide at 16-day intervals (Clermont, 1972) to form B spermatogonia. B spermatogonia are committed to become spermatocytes, but the cytoplasm between spermatogonial daughter cells remains conjoined after mitosis, forming cytoplasmic bridges between adjacent cells. These **cytoplasmic bridges are observed between all classes of germ cells throughout spermatogenesis** (Ewing et al, 1980). These bridges could be important for synchronized cellular proliferation and differentiation, and possibly for regulation of gene expression.

Meiosis

Somatic cells replicate by mitosis, in which genetically identical daughter cells are formed. **Germ cells replicate by meiosis, in which the genetic material is halved to allow reproduction.** Meiosis generates genetic diversity, providing a richer source of material on which natural selection can act. Cell replication by mitosis is a precise, well-orchestrated sequence of events involving duplication of the genetic material (chromosomes), breakdown of the nuclear envelope, and equal division of the chromosomes and cytoplasm into two daughter cells. **The essential difference between mitotic and meiotic replication is that a single DNA duplication step is followed by only one cell division in mitosis, but two cell divisions in meiosis (four daughter cells).** Consequently, daughter cells contain only half of the chromosome content of parent cells. Thus a diploid ($2n$) parent cell becomes a haploid (n) gamete. Other major differences between mitosis and meiosis are outlined in Table 20–2. Recent research has shown that small RNA molecules (small RNAs), including small interfering RNAs (siRNAs), microRNAs (miRNAs), and piwi-interacting RNAs (piRNAs), are important regulators of gene germ cell expression at the post-transcriptional or translation level (Tolia and Joshua-Tor, 2007; He et al, 2009).

Spermatogenesis begins with type B spermatogonia dividing mitotically to form primary spermatocytes within the adluminal compartment. **Mature spermatocytes are the first germ cells to undergo meiosis** (Kerr and de Kretser, 1981). In this process, a meiotic division is followed by a typical mitotic reduction division, resulting in daughter cells with a haploid chromosome complement. In addition, as a consequence of chromosomal recombination, each daughter cell contains different genetic information. The resultant cell is the Sa spermatid (see Fig. 20–11).

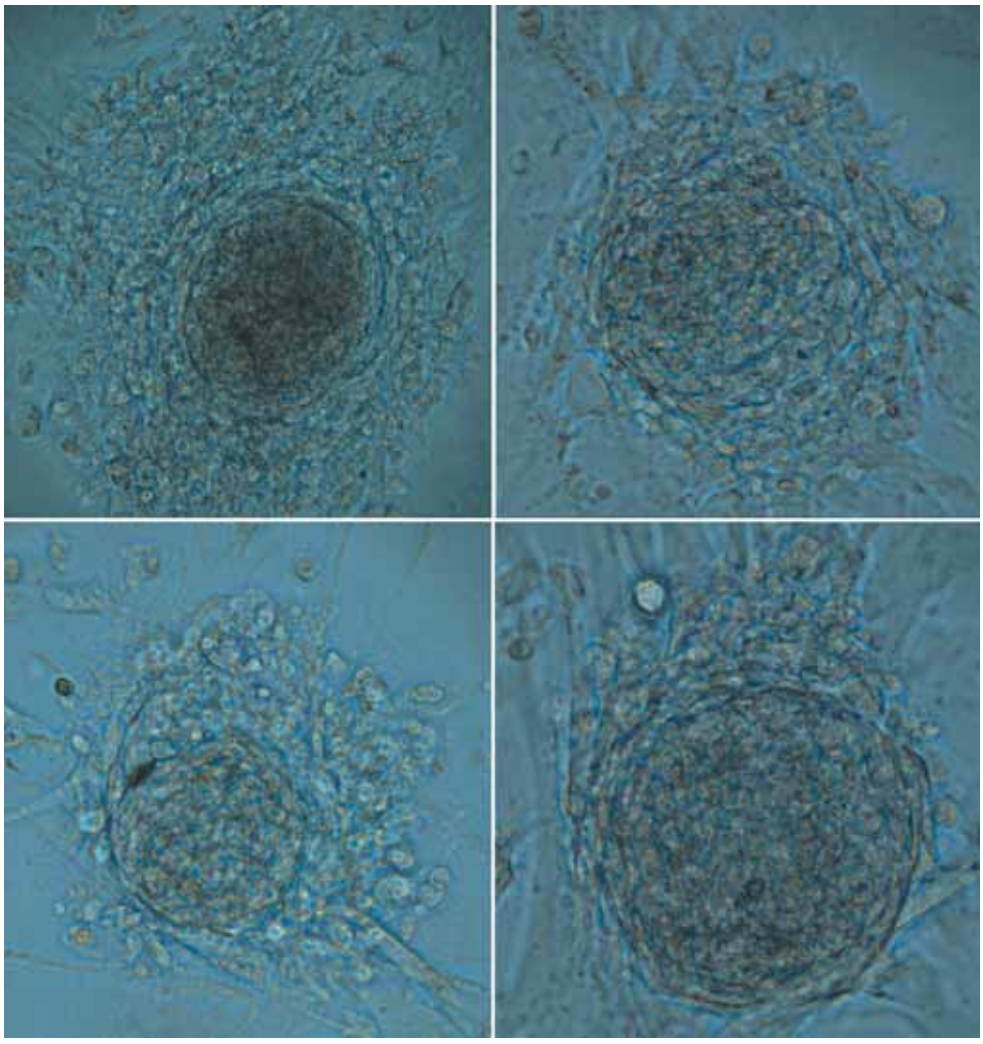

Figure 20–15. Microphotograph of four different colonies of adult testis spermatogonial–derived stem cells. These cell clusters are the result of reprogramming of adult spermatogonia in culture conditions used for human embryonic stem cells (HESCs). They exhibit the typical "cobblestone" appearance of HESCs and have also been shown to be functionally multipotent and even pluripotent.

Table 20–2.

Essential Differences: Mitosis and Meiosis

MITOSIS	MEIOSIS
Occurs in somatic cells	Occurs in sexual cells
1 cell division, 2 daughter cells	2 cell divisions, 4 daughter cells
Chromosome number maintained	Chromosome number halved
No pairing, chromosome homologs	Synapse of homologs, prophase I
No crossovers	>1 crossover per homolog pair
Centromeres divide, anaphase	Centromeres divide, anaphase II
Identical daughter genotype	Genetic variation in daughter cells

Chromosomal recombination, the defining feature of mammalian meiosis, ensures that haploid gametes differ genetically from their adult precursors and is the real engine of genetic diversity and evolution. During meiotic prophase, there is formation of a synaptonemal complex with pairing of homologous (maternal and paternal) chromosomes, and physical interaction and exchange of DNA through reciprocal sites of crossing over **(chiasmata)** between homologs. Recent research has shown that defects in the fidelity of recombination within human male germ cells can cause azoospermia and male infertility (Walsh et al, 2009). **In one study, 10% of nonobstructive azoospermic men had significant defects in recombination compared to men with normal spermatogenesis** (Gonsalves et al, 2004). In addition, among men with maturation arrest pattern on testis biopsy, faulty recombination was observed in about half of cases, providing evidence that faulty recombination is linked to poor sperm production (Gonsalves et al, 2004). Variations in recombination also have implications for sperm aneuploidy, because alterations in crossover position are risk factors for chromosomal nondisjunction. **Indeed, molecular evidence suggests that the correlation of faulty recombination and sperm aneuploidy in azoospermic men is strong enough to explain the higher de novo rate of chromosomal abnormalities in offspring conceived with in-vitro fertilization–intracytoplasmic sperm injection (IVF-ICSI)** (Sun et al, 2008).

Spermiogenesis

During spermiogenesis, round Sa spermatids mature into spermatozoa (see Fig. 20–11). During this maturation sequence, cell division does not occur, but there are extensive changes to the

spermatid nucleus and cytoplasm**. These include the loss of cytoplasm, migration of cytoplasmic organelles, formation of the acrosome from the Golgi apparatus, formation of the flagellum from the centriole, nuclear compaction to about 10% of former size, and reorganization of mitochondria around the sperm midpiece** (Kerr and de Kretser, 1981). The nucleus of the round spermatid changes from spherical to asymmetrical as chromatin condenses. Many cellular elements contribute to the reshaping process, including chromosome structure, associated chromosomal proteins, the perinuclear cytoskeletal theca layer, the manchette of nuclear microtubules, subacrosomal actin, and Sertoli cell interactions. With completion of spermatid elongation, the Sertoli cell cytoplasm retracts around the developing sperm, stripping it of all unnecessary cytoplasm and extruding it into the tubule lumen. The mature sperm has remarkably little cytoplasm, and it is an elaborate, specialized cell produced in massive quantity—up to 300 per gram of testis per second.

Sertoli Cell–Germ Cell Interaction

A complex network of cell–cell interactions exists within the testis between Leydig cells and Sertoli cells, between Leydig cells and peritubular cells, between Sertoli and peritubular cells, and between Sertoli cells and germ cells. There are several kinds of Sertoli cell–germ cell associations in mammalian testes as illustrated in Figure 20–10 (Russell and Clermont, 1976; Romrell and Ross, 1979; Skinner, 1995). Physical contact between these cells plays a role in propelling the germ cell toward the tubule lumen and casting off of the residual cytoplasm from the spermatid. Lastly, there are factors that can reversibly disrupt the blood-testis barrier, including transforming growth factor–β3 (TGF-β3) and tumor necrosis factor–α (TNF-α). These substances act by reducing the levels of occludin and zonula occludens-1 (ZO-1) in the barrier through a p38 mitogen-activated protein (MAP) kinase signaling pathway (Xia et al, 2009). This represents only a piece of the remarkably complex and highly interactive process that characterizes spermatogenesis.

Genetics

Genetic causes of abnormal spermatogenesis have been identified as point mutations in single genes inherited in mendelian fashion (e.g., cystic fibrosis), and as chromosomal disorders, in which segments of (or entire) chromosomes have structural or numerical abnormalities. The reader is referred to Turek and Reijo Pera (2002) for a comprehensive review of such disorders. The postulation that deletions in the long arm of the Y chromosome cause azoospermia was made over thirty years ago (Tiepolo et al, 1976). Based on cytogenetic analysis, this theoretical region was termed the azoospermia factor (AZF). **Currently, the positional patterns of deletions (termed "microdeletions") in the AZF region are used to subdivide this region into AZFa, b, and c subregions** (Vogt et al, 1996). **Regional deletions of the Y chromosome, termed Yq microdeletions, occur in 6% to 8% of severely oligospermic men and in up to 15% of azoospermic men** (Reijo et al, 1996). Taken together, such deletions are the most commonly defined molecular cause of male infertility (Kostiner et al, 1998).

There is emerging literature addressing the prognostic value of specific AZF deletions. In contrast to partial and complete AZFc-deletion patients, in which sperm is often found on semen analysis or testis biopsy, the chance of finding ejaculated or testis sperm in men with complete AZFa or AZFb deletions is highly unlikely (Hopps et al, 2003). Complete AZFa deletions are associated with germ cell aplasia or Sertoli cell–only histology. Complete AZFb deletions are generally associated with maturation arrest at the primary spermatocyte (early) or spermatid (late) stages. AZFc deletions are associated with hypospermatogenesis or a Sertoli cell–only pattern with foci of spermatogenesis. Sperm have been detected in ejaculates of men with presumed and confirmed partial AZFa and AZFb deletions (Foresta et al, 2001). Similarly, ejaculated sperm in men with AZFa + b, and AZFb + c deletions (presumably partial deletions) has also been reported, but the finding of AZFa–c deletions has been associated with azoospermia and no sperm on testis biopsy.

More recently, it has become clear that the X chromosome may also be important for spermatogenesis. Insight into the role of the X chromosome in male infertility has been garnered mainly from rodent studies. In 2001, Wang and colleagues reported on a systematic search for genes expressed exclusively in mouse spermatogonia (Wang et al, 2001). Twenty-five genes were identified by complementary DNA (cDNA) subtraction, of which 10 (9 novel) localized to the X chromosome, suggesting that the X chromosome may have a key role in premeiotic stages of spermatogenesis. Further, human homologues of six of these genes were mapped to chromosomal regions of conserved synteny between mouse and human genomes. Thus, similar to genes on the Y chromosome, it is possible that these X chromosome genes may also prove to be sites of mutation in cases of human spermatogenic failure. Studies have also examined mutations in X-linked genes in male infertility patients, including the *SOX3* gene (sex determining region Y box 3) and the *FATE* gene (Olesen et al, 2003; Raverot et al, 2004). Although not commonly identified at this point, mutations on X chromosome genes will likely prove to contribute significantly to human male infertility in the future.

Genetics and Paternal Age

Age-Related Sperm Chromosomal Anomalies. The aneuploidy and polyploidy status of sperm were first investigated due to concern that advanced paternal age was associated with increased cases of trisomy, especially trisomy 21 or Down syndrome in offspring. With fluoresence in-situ hybridization technology (FISH), subtle paternal-age effects on sperm aneuploidy have been detected. **The paternal age effect appears to increase the fraction of sperm with sex chromosomal aneuploidies** (Wyrobek et al, 1996). **However, there is little evidence to support a paternal age–related increase in aneuploid births, except for possibly trisomy 21 and disomy 1 (very rare).** Examining sperm chromosome structural abnormalities, Martin and Rademaker (1987) found that a highly significant linear relationship exists between paternal age and the frequency of structural anomalies in sperm ($r = 0.63$). **One explanation for this association may be that continued cell division during spermatogenesis places germ cells at risk for chromosomal injury, especially with advanced paternal age.** Except for reciprocal translocations, however, there is little evidence to indicate that this association leads to an increased frequency of offspring with de novo structural chromosomal anomalies.

Age-Related Sperm Genetic Mutations. Single gene defects in sperm result from errors in DNA replication. To date, it has been difficult to assess the presence or absence of such defects in sperm. However, the effect of advanced paternal age on cases of conditions associated with single-gene deletions has been studied extensively. These disorders are listed in Table 20–3 and consist of autosomal dominant diseases that have known associations with advanced paternal age. They are termed "sentinel phenotypes" because they are disorders of significant frequency and low fitness,

Table 20–3.

Selected Genetic Disorders Associated with Advanced Paternal Age

Achondroplasias
Aniridia
Apert syndrome
Bilateral retinoblastoma
Crouzon syndrome
Fibrodysplasia ossificans
Hemophilia A
Lesch-Nyhan syndrome
Marfan syndrome
Neurofibromatosis
Oculodentodigital syndrome
Polycystic kidney disease
Polyposis coli
Progeria
Treacher Collins syndrome
Tuberous sclerosis
Waardenburg syndrome
Schizophrenia (postulated)
Autism (postulated)

and occur sporadically due to highly penetrant mutations. **One mechanism for the development of new single-gene mutations with age implicates the characteristic and continuous process of spermatogonial cell division in spermatogenesis.** By puberty, 30 cell divisions of spermatogonia have occurred, resulting in a large pool of undifferentiated cells. After puberty, 23 divisions per year occur in these cells. **The simple fact that the spermatogonia of older men have undergone numerous cell divisions may make them more likely to harbor errors in DNA transcription, the source of single-gene defects.** Formal risk estimates exist for the contribution of advanced paternal age to autosomal dominant mutations: In men <29 years old, the risk of a mutation occurring in offspring is 0.22 per 1000. This risk doubles (0.45 per 1000) at paternal ages 40 to 44, and then climbs to 3.7 per 1000 at ages >45 (Friedman, 1981).

Key Points: Testis

- The testis contains 250 meters of seminiferous tubules and 700 million Leydig cells in the young adult male.
- Spermatogenesis occurs in stages, cycles, and waves to ensure constant sperm production.
- Genes on the X, as well as the Y, chromosome control spermatogenesis and can contribute to male infertility.
- With paternal age, there are increases in structural chromosomal abnormalities in sperm and autosomal dominant mutations leading to "sentinel phenotypes" in offspring.

THE EPIDIDYMIS

Gross Architecture

The epididymis is a comma-shaped organ located along the posterolateral surface of the testis. **Passage through the epididymis induces many changes to newly formed sperm,**

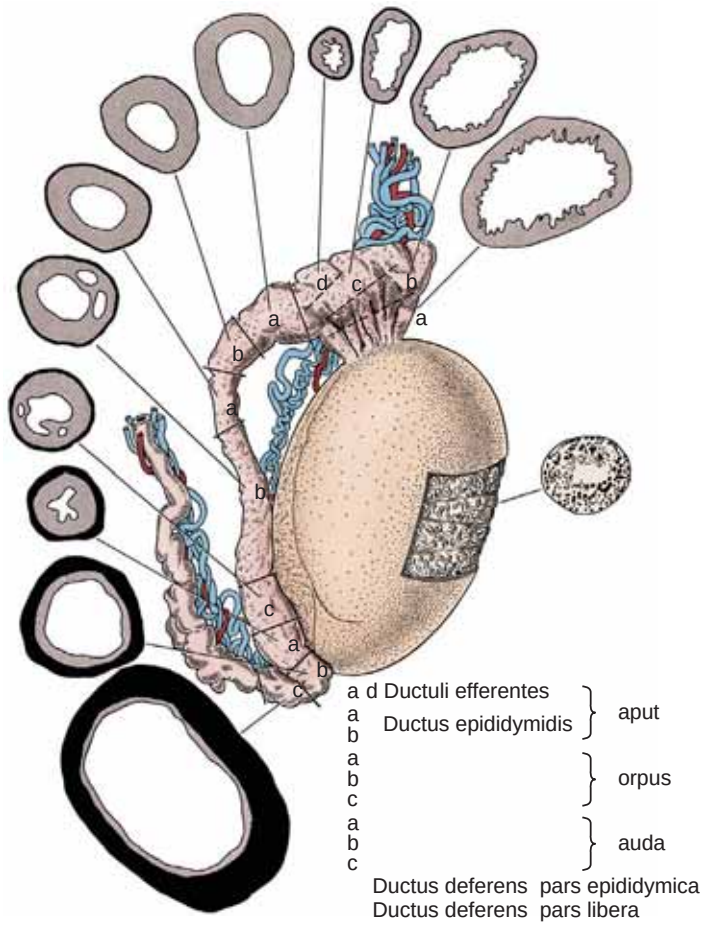

Figure 20–16. Drawing of the human epididymis showing regionalization of the ductal epithelium and muscle layer. Epididymal segment locations are shown in cross section and are identified by number. (From Baumgarten HG, Holstein AF, Rosengren E. Arrangement, ultrastructure, and adrenergic innervation of smooth musculature of the ductal efferentes, ductus epididymidis, and ductus deferens in man. Z Zellforsch Mikrosk Anat 1971;120:37.)

including a gain in functional motility, and alterations in surface charge, membrane proteins, immunoreactivity, phospholipids, fatty acid content, and adenylate cyclase activity. These changes improve cell membrane structural integrity, increase fertilization ability, and improve motility. Spermatozoa within the testis have very poor or no motility. They become progressively motile and functional only after traversing the epididymis. The transit time of sperm through the epididymis is thought to take up to 12 days in humans (Johnson and Varner, 1988).

The epididymis is a tubule or duct that is 3 to 4 meters in length and is tightly coiled and encapsulated within the sheath of connective tissue of the tunica vaginalis (Lanz and Neuhauser, 1964; Turner et al, 1978). Extensions from the sheath enter interductal spaces and form septa that divide the duct into histologically characteristic regions (Kormano and Reijonen, 1976). **Anatomically, these are classically divided into three regions: caput or head, corpus or body, and cauda (or tail)** (Fig. 20–16). The caput epididymis consists of 8 to 12 ductuli efferentes from the testis. The lumen of the ductuli efferentes is large and somewhat irregular in shape near the testis, becoming narrow and oval near the junction with the ductus epididymis. Distal to this junction, the duct diameter increases

slightly and, thereafter, remains constant in the corpus epididymis. In the bulky cauda epididymis, the tubule diameter enlarges substantially and acquires an irregular shape. Progressing distally, the tubule gradually assumes the characteristic appearance of the vas deferens.

Vascular and Lymph Supply

In humans, the caput and the corpus epididymis receive arterial blood from a branch of the testicular artery (see Fig. 20–7). It subsequently divides into superior and inferior epididymal branches (MacMillan, 1954). The epididymis also receives blood from branches of the deferential arteries (artery of the vas deferens), and collateral vessels connect the deferential artery to the testicular blood supply. The cauda epididymis is supplied by branches of the deferential artery. **The deferential and cremasteric arteries serve as collateral sources to the epididymis, when the main testicular artery is obstructed or ligated.** The arterial branches within the epididymis enter along septa formed from the connective tissue sheath. These vessels coil extensively before transforming into the straight vessels of the microvascular bed (Kormano and Reijonen, 1976). Microvascularization density varies significantly along the length of the epididymis, with the proximal caput containing the densest subepithelial capillary network, and the more distal segments harboring less dense vascularization. From animal studies, the epididymal capillary network is under hormonal control. For example, in rabbits, bilateral hormonal castration results in progressive deterioration and eventual disappearance of the epididymal capillary network (Clavert et al, 1981). It is not clear whether vascularization in the human epididymis is similarly controlled.

According to MacMillan (1954), venous drainage from the corpus and cauda epididymis joins to form the vena marginalis epididymis of Haberer. These veins drain into the pampiniform plexus through the vena marginalis testis, or through the cremasteric or deferential veins. Lymphatic drainage of the epididymis occurs through two routes (Wenzel and Kellermann, 1966). Lymph from the caput and corpus epididymis is removed through the same route as that described for the testis. These vessels course beside the internal spermatic vein and ultimately terminate in the preaortic nodes. Lymph vessels from the cauda epididymis join those draining the vas deferens and terminate in the external iliac nodes.

Innervation

The innervation of the human epididymis is derived primarily from the intermediate and inferior spermatic nerves that arise from the superior portion of the hypogastric plexus and pelvic plexus, respectively (Mitchell, 1935). The ductuli efferentes and the proximal segments of the epididymis are sparsely innervated by sympathetic fibers (Baumgarten and Holstein, 1967; Baumgarten et al, 1968). In these regions, the fibers are observed in a peritubular plexus and are principally associated with blood vessels. Many more fibers are observed in the midcorpus epididymis, and their density increases progressively with distal progression along the epididymis, coincident with the appearance and proliferation of smooth muscle cells in these areas (Baumgarten et al, 1971). The distribution of contractile cells and sympathetic nerves within the epididymis may explain the rhythmic peristaltic movements of the ductuli efferentes and initial epididymal segments, as well as the intermittent contractile activity of the cauda epididymis and the vas deferens during emission (Risely, 1963). These physiologic contractions are critical to the movement of sperm through the epididymis.

Cytoarchitecture

Epididymal Epithelium

The histology of the human epididymis has been reviewed by Holstein (1969) and Vendrely (1981). It consists of two main cells types: **principal cells and basal cells** (seen at low ultrastructural magnification in Fig. 20–17). Principal cells vary in height along the length of the epididymis due to the length of stereocilia (microvilli, not cilia). Tall stereocilia (120 μm) are generally found in the proximal epididymis, and smaller or shorter stereocilia (50 μm) are observed in more distal regions. The nuclei in principal cells are elongated and often possess large clefts and one or two nucleoli. Consistent with the idea that principal cells carry out both absorptive and secretive processes, their cellular apices have numerous coated pits, micropinocytotic vesicles, multivesicular bodies, irregularly shaped membranous vesicles, and an extensive Golgi apparatus. Because these cytologic features vary along the length of the epididymis, it suggests that there is varying absorptive and secretory capacity along the length of the duct (Vendrely and Dadoune, 1988).

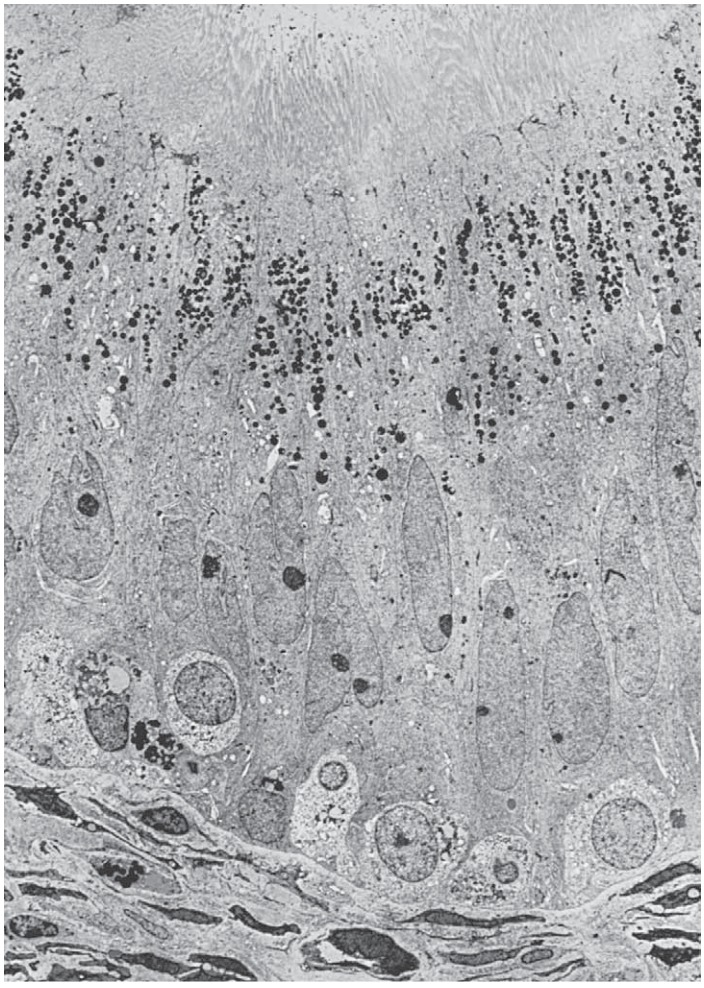

Figure 20–17. Electron micrograph of a human epididymis in cross section. Major components of the luminal epithelium are principal cells (1), basal cells (2), stereocilia (3), and myofilaments (4). Magnification approximately ×1800. (From Holstein AF. In: Hafez ESE, editor. Human semen and fertility regulation in men. St Louis: Mosby; 1976.)

There are far fewer basal cells than principal cells lining the epididymal epithelium, and they are dispersed among the more numerous principal cells. Tear-shaped basal cells rest on the basal lamina and extend approximately 25 µm toward the lumen, their apices forming threads between adjacent principal cells. They are thought to be derived from macrophages. Unlike the principal cells, the morphology of basal cells remains relatively constant throughout the epididymal duct. They are thought to be the precursors of the principal cells.

Overall, the epithelium of the epididymis exhibits regional differences along the length of the duct. Within the epididymis proper, the epithelium is pseudostratified in nature and consists of principal and basal cells as described above. More proximally, at the junction of the rete testis and ductuli efferentes, there is a distinct transition from a low to a high cuboidal epithelium. The epithelium in the ductuli efferentes appears uneven and consists of ciliated and nonciliated cells (Holstein, 1969). The ciliated cells are dispersed throughout the epithelium and conduct sperm from the efferent ducts into the epididymis. The nonciliated cells with protruding apices are likely secretory in nature and predominate in the proximal ductuli efferentes (Vendrely, 1981). Other nonciliated cells have microvilli suggestive of resorptive activity and predominate in the distal ductuli efferentes. Nonciliated cells likely are involved in testis fluid reabsorption. Both nonciliated and ciliated cells are joined apically through junctional complexes. This suggests the existence of a blood-epididymis barrier analogous to the blood-testis barrier (Suzuki and Nagano, 1978; Hoffer and Hinton, 1984). **Although not as dense as the blood-testis barrier, the blood-epididymis barrier extends from the caput to the cauda epididymis and may play an important role in influencing the composition of fluid within different segments of the epididymal lumen** (Turner, 1979).

Epididymal Contractile Tissue. Peripheral to the basal lamina of the ductuli efferentes and the epididymal tubule, there are various contractile cells (Baumgarten et al, 1971) (see Fig. 20–17). In the ductuli efferentes (distal regions of the caput and the proximal corpus epididymis), the contractile cells form a loose layer, two to four cells deep, around the tubule. These cells contain myofilaments and are connected by numerous nexus-like junctions. In the distal corpus epididymis, there are larger contractile cells with fewer nexus-like intracellular junctions that resemble thin smooth muscle cells. In the cauda epididymis, the thin contractile cells are replaced by thick smooth muscle cells that form three layers—the outer two layers oriented longitudinally and the central layer circularly. This distal contractile layer increases in thickness as it forms the vas deferens. The contractile tissue throughout the epididymis is likely involved in sperm transport.

Epididymal Function

Described variations in the anatomy and histology of the epididymal tubule from the caput to cauda regions suggest that the epididymis is actually several different functional tissues (Vendrely, 1981). It is clear that sperm transport and storage, sperm-fertilizing ability, and motility maturation are several consequences of passage through this organ. This is addressed more fully in reviews by Robaire and Hermo (1988), and Moore and Smith (1988).

Sperm Transport

Sperm transport through the human epididymis has been calculated to take from 2 to 12 days (Johnson and Varner, 1988). **Sperm transit time through the caput-corpus epididymis is roughly similar to the transit time through the cauda epididymis and is more likely related to daily testicular sperm production rather than a man's age or the frequency of ejaculation** (Amann, 1981; Johnson and Varner, 1988). In one study, sperm epididymal transit time averaged 2 days in men with a high daily rate of sperm production (137 million per testis), compared with 6 days in men with low daily sperm production (34 million per testis) (Johnson and Varner, 1988). Although the frequency of sexual activity does not affect sperm transit time through the caput and corpus epididymis, "recent emissions" can reduce transit time through the cauda epididymis by 68% (Amann, 1981).

Because normal human testicular sperm are immotile as they enter the epididymis, and remain relatively immotile within the caput, **mechanisms other than sperm motility must exist to transport sperm through the epididymis.** Animal studies have been very revealing in this regard (Bedford, 1975; Hamilton, 1977; Courot, 1981; Jaakkola and Talo, 1982; Jaakkola, 1983). Initially, sperm are carried into the ductuli efferentes by rete testis fluid, and **fluid flow is facilitated by fluid resorption by ductal epithelial cells mediated by the estrogen receptor. Motile cilia and myoid cell contractions within the ductuli efferentes also assist with sperm movement. Within the epididymis proper, the principal mechanism responsible for sperm transport is likely the spontaneous, rhythmic contraction of the contractile cells surrounding the epididymal duct.**

Sperm Storage

After migrating through the caput and corpus epididymis, sperm are retained in the cauda epididymis for varying lengths of time, depending on the frequency of sexual activity. In men 21 to 55 years of age, **an average of 155 to 209 million sperm are present in each epididymis** (Amann, 1981; Johnson and Varner, 1988), **and approximately half are stored in the caudal region.**

Spermatozoa stored in the cauda epididymis, unlike testicular sperm, are capable of progressive motility and are able to fertilize eggs. The exact amount of time that sperm can remain fertile within the epididymis is unclear, but animal studies have shown that sperm can remain viable for several weeks within the cauda epididymis after vas deferens ligation (Hammond and Asdell, 1926; Young, 1929). However, it is also clear that sperm fertility measured in vivo diminishes when sperm are maintained in the epididymis for prolonged periods of time (Cooper and Orgebin-Crist, 1977; Cuasnicu and Bedford, 1989). In humans, sperm aging as a result of extended epididymal transit time and prolonged storage may contribute to reduced fertility (Johnson and Varner, 1988).

The exact fate of unejaculated epididymal sperm is unknown. In animals, sperm are lost through spontaneous seminal discharge, oral self-cleaning (Martan, 1969), through urine (Lino et al, 1967), or by epididymal reabsorption (Amann and Almquist, 1961). Phagocytosis of spermatozoa by macrophages (spermiophages) within the epididymal lumen has been observed in humans after ligation of the vas deferens (Alexander, 1972). However, whether this mechanism can remove large numbers of spermatozoa from the epididymis of unvasectomized men is unclear.

Sperm Maturation

Sperm Motility. Sperm gain an increased capacity for motility with migration through the epididymis. This is observed as both a change in the pattern of motility, and

as an increase in the proportion of sperm exhibiting "mature" motility patterns. Bedford and coworkers (1973) first observed that the majority of sperm from the ductuli efferentes, when placed in culture medium, are immotile or show only weak, twitching movement. Occasionally, they also observed sperm showing "immature" tail movements characterized by "thrashing" beats in wide arcs that result in little forward progression. The proportion of sperm with this immature motility pattern increased within the initial epididymal segment. However, in the corpus region, the proportion of sperm exhibiting this motility pattern decreased. Within the corpus region, there was an increase in the fraction of sperm with a "mature" motility pattern characterized by high-frequency, low-amplitude beats that result in progressive motility (Fig. 20–18). Within the cauda epididymis, >50% of sperm had a mature motility pattern, with the remainder either immotile or showing the immature motility patterns described earlier. Moore and colleagues (1983) also formally demonstrated the increased capacity of human sperm to show progressive forward motility with epididymal transit. When placed in buffer in vitro, 0%, 3%, 12%, 30%, and 60% of sperm were motile from the efferent ducts, caput, proximal corpus, distal corpus, and cauda epididymis, respectively (Fig. 20–19).

The relative importance of overall epididymal contact time versus region-specific maturation to the gain in mature sperm motility patterns is unknown. Animal studies indicate that motility maturation may, in part, be an intrinsic sperm process that occurs independent of specific epididymal interactions. For example, although hamster and rabbit sperm are generally immotile within the caput epididymis, motile sperm are found in this region (albeit developing motility far more slowly and persisting for shorter periods than in the normal system) after epididymal duct ligation within the corpus region (Orgebin-Crist, 1969; Horan and Bedford, 1972). Human studies in obstructed patients with congenital absence of the vas deferens or epididymal obstruction also frequently report poor motility in spermatozoa aspirated from the distal epididymis, and better sperm motility in the proximal epididymis (Silber, 1989; Matthews et al, 1995). When combined, **these observations suggest that spermatozoa are able to develop motility based on contact time with the proximal epididymal epithelium.** However, this maturation process may not be the same as that which occurs through sperm interaction with the epididymis during migration through all ductal regions.

Sperm Fertility. Testicular sperm are incapable of fertilizing eggs unless injected into them with micromanipulation (Orgebin-Crist, 1969; Bedford, 1974; Yanagimachi, 2005). In most animals, the ability of sperm to fertilize eggs is acquired gradually as the sperm pass through the distal epididymis (see Fig. 20–19). Indeed, it has been shown in rabbits that sperm from the caput, corpus, and cauda epididymis can fertilize 1%, 63%, and 92% of rabbit eggs, respectively (Orgebin-Crist, 1969). Human in-vitro experiments using zona pellucida–free hamster eggs have corroborated these findings (Moore et al, 1983). In a study that assessed the fertilizing capacity of human epididymal sperm, Hinrichsen and Blaquier (1980) demonstrated that although sperm from the proximal epididymis are able to bind to zona-free eggs, only sperm from the cauda epididymis can both bind and penetrate eggs. **Thus sperm fertility maturation is, for the most part, achieved at the level of the late corpus or early cauda epididymis.**

Recent clinical observations, however, challenge the idea that fertility maturation requires sperm migration through the entire epididymis. Indeed, patients with epididymal obstruction or congenital absence of the vas deferens can achieve natural pregnancies after vasoepididymostomy at the level of the ductuli efferentes (Schoysman and Bedford, 1986; Silber, 1989). This suggests that obstruction induces proximal "skewing" of the maturation sequence along the epididymal duct, or that there may be a

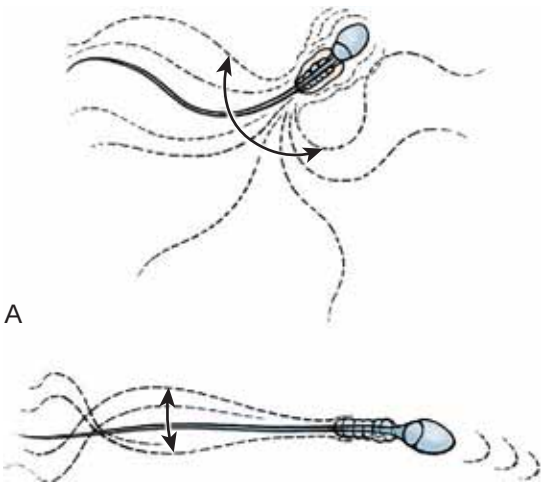

Figure 20–18. Patterns of tail movement of human epididymal sperm. **A,** The pattern shown by sperm taken from proximal epididymis is characterized by high-amplitude, low-frequency beats producing little forward movement. **B,** In contrast, tail movement in a large proportion of sperm from the cauda epididymis is characterized by low-amplitude, rapid beats with forward progression. (From Bedford JM, Calvin HI, Cooper GW. The maturation of spermatozoa in the human epididymis. J Reprod Fertil 1973;18:199–213.)

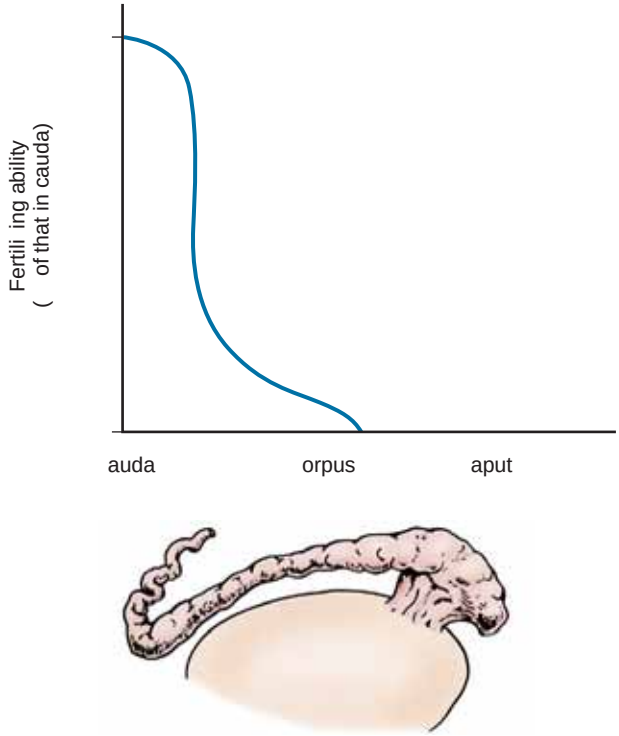

Figure 20–19. Sperm fertility maturation in the human epididymis. Sperm fertilizing ability was assessed using zona pellucida–free hamster eggs and by changes in motility. (From Bedford JM. The bearing of epididymal function in strategies for in vitro fertilization and gamete intrafallopian transfer. Ann N Y Acad Sci 1988;541:284–91.)

reduced flow of sperm through the epididymis after such bypass procedures, allowing more contact time and sperm maturation (Orgebin-Crist, 1969; Turner and Roddy, 1990). Despite this observation, **is it generally believed that the likelihood of fertility is greater as the surgical anastomosis is performed more distally in the epididymis** (Thomas, 1987).

Sperm Biochemical Changes. Sperm undergo many biochemical changes with passage through the epididymis (Brooks, 1983). Although human information is limited, **epididymal sperm transit induces a net negative surface membrane charge** (Bedford et al, 1973) **and sperm membrane sulfhydryl groups oxidize to disulfide bonds, improving sperm structural rigidity necessary for progressive motility and egg penetration** (Bedford et al, 1973; Reyes et al, 1976). Other post-testicular modifications of sperm membranes include changes in sperm lectin-binding properties (Courtens and Fournier-Delpech, 1979; Olson and Danzo, 1981), phospholipid and lipid content (Nikolopoulou et al, 1985), glycoprotein composition (Brown et al, 1983), immunoreactivity (Tezón et al, 1985), and iodination characteristics (Olson and Danzo, 1981). **Overall, these membrane modifications during epididymal passage may enhance sperm adherence to the egg zona pellucida** (Orgebin-Crist and Fournier-Delpech, 1982; Blobel et al, 1990). Sperm also undergo numerous metabolic changes during epididymal transit (Dacheux and Paquignon, 1980). These include gaining an increased capacity for glycolysis (Hoskins et al, 1975), changes in intracellular pH and calcium content, modification of adenylate cyclase activity (Casillas et al, 1980), and alterations in cellular phospholipid and phospholipid-like fatty acid content (Voglmayr, 1975).

Regulation of Epididymal Function

Sperm changes within the epididymis are likely influenced by fluids and secretions within the epididymal lumen (Robaire and Hermo, 1988; Blaquier et al, 1989). The biochemical composition of epididymal fluid not only differs from that of serum, but there are also regional differences in the osmolarity, electrolyte content, and protein composition of epididymal fluid (Robaire and Hermo 1988). These differences are likely the consequence of variations in vascularization, blood-epididymis barrier activity, and selective absorption and secretion of fluid constituents such as glycerylphosphorylcholine (GPC), carnitine, and sialic acids along the epididymal duct. Proteins within the epididymal fluid that are known to have physiologic effects on sperm in vitro include forward motility protein (Brandt et al, 1978), sperm survival factor (Morton et al, 1978), progressive motility sustaining factor (Sheth et al, 1981), sperm motility-inhibiting factor (Turner and Giles, 1982), acidic epididymal glycoprotein (Pholpramool et al, 1983) and the EP2-EP3 proteins that induce sperm binding to zona pellucida (Cuasnicu et al, 1984; Blaquier et al, 1988). Thus variations in epididymal tubule fluid characteristics play an important role in sperm maturation during epididymal transit. It is not surprising, then, that epididymis is a potentially important source of sperm dysfunction and male infertility.

Epididymal function is hormonally regulated. Testosterone and DHT are found in very high concentrations within the epididymis, and there are no regional gradients in androgen levels (Leinonen et al, 1980). This suggests the importance of androgens for epididymal function, a finding confirmed in animal studies (Brooks and Tiver, 1983). Bilateral castration results not only in the loss of androgen-dependent epididymal proteins but also losses in epididymal weight, changes in luminal histology, and alterations in the synthesis and secretion of epididymal fluid GPC, carnitine, and sialic acid. Ultimately, the castrated epididymis loses the ability to sustain sperm motility, fertility maturation, and sperm storage capacities, but most of these degenerative processes are reversed with androgen replacement.

Compared with other accessory sex glands, the epididymis requires relatively higher levels of androgen for maintenance of its structure and function (Prasad and Rajalakshmi, 1976). **Androgen effects on the epididymis appear to be mediated mainly through dihydrotestosterone (DHT), the primary androgen in epididymal tissue extracts** (Pujol et al, 1976) and/or 5α-androstane-3α, 17β-diol (3α-diol) (Orgebin-Crist et al, 1975). Indeed, this is corroborated by the fact that the enzymes Δ4-5α-reductase (catalyzes the DHT formation from testosterone), and 3α-hydroxysteroid dehydrogenase (converts DHT to 3α-diol) that produce these testosterone metabolites are also found in the human epididymis (Kinoshita et al, 1980; Larminat et al, 1980).

Epididymal function is also influenced by temperature (Foldesy and Bedford, 1982; Wong et al, 1982). Chronic exposure of the epididymis to elevated temperatures, by placing them within the abdomen, results in the loss of sperm storage and electrolyte transport functions. The influence of temperature on epididymal function in humans may be an important consideration for how varicocele and cryptorchidism induce male infertility. Abnormalities in epididymal myoid cell contractility may also influence epididymal function. In the rat, partial surgical denervation of the epididymis results in an abnormal accumulation of sperm within the cauda epididymis and a decrease in the swimming speed of retained sperm (Billups et al, 1990). These findings certainly have implications for infertility due to neuropathic causes such as spinal cord injury and diabetes mellitus.

Key Points: Epididymis

- The epididymis consists of principal cells, with absorptive and secretory function, basal cells derived from macrophages, and contractile cells that facilitate sperm transport.
- During passage through the epididymis, sperm mature by gaining progressive motility and the ability to bind to and penetrate the egg zona pellucida.
- Epididymal function is temperature- and androgen- (mainly DHT) dependent, important considerations for cryptorchidism and varicocele.

DUCTUS (VAS) DEFERENS

Gross Architecture

The vas deferens is a tubular organ derived from the mesonephric (wolffian) duct. In humans, the vas deferens is 30 to 35 cm long, beginning at the cauda epididymis and terminating in the ejaculatory duct, medial to the seminal vesicle and posterior to the prostate. It is classically divided into 5 regions: (1) the sheathless epididymal segment contained within the tunica vaginalis, (2) the scrotal segment, (3) the inguinal segment, (4) the retroperitoneal or pelvic portion, and (5) the ampulla (Lich et al, 1978). In cross section, the vas deferens consists of an outer adventitial connective tissue sheet containing blood vessels and small nerves, a muscular coat that consists of a middle circular layer surrounded by inner and outer longitudinal muscle layers, and an inner mucosal layer with an epithelial lining (Neaves, 1975). The outer

diameter of the vas deferens varies from 1.5 to 3 μm, and the lumen of the unobstructed vas deferens varies from 200 to 700 mm in diameter (Middleton et al, 2009).

The vas deferens receives its blood supply from the deferential artery, a branch of the superior vesicle artery. Venous drainage corresponds to arterial supply. The vas deferens receives innervation from both the sympathetic and the parasympathetic nervous systems (Sjostrand, 1965). The cholinergic supply does not appear important for motor activity of the vas deferens (Baumgarten et al, 1975). There is a rich supply of sympathetic adrenergic nerves derived from hypogastric nerve coursing via the presacral nerve (Batra and Lardner, 1976; McConnell et al, 1982). Adrenergic nerve fibers have been observed in all three layers of the vas tunica muscularis, with the greatest concentration in the outer longitudinal layer (McConnell et al, 1982). The vas deferens also receives a short adrenergic nerve (Sjostrand, 1965) and has an abundance of ligand-gated, purinergic receptors in its smooth muscle membranes, suggesting sympathetic and purinergic cotransmission in sperm transport and ejaculation (Gur et al, 2007). Neurons containing other neurotransmitters, including neuropeptide Y, enkephalin, galanin, somatostatin, vasoactive intestinal polypeptide, and nitric oxide, have also been identified; however, their role in vas deferens function is unknown (Dixon et al, 1998). Interestingly, observations from human vas deferens specimens obtained at vasovasostomy from 1 to 15 years after vasectomy show a marked reduction in the density of muscular noradrenergic and subepithelial secretomotor nerves in testicular compared to abdominal segments. These changes after vasectomy may influence subsequent sperm maturation and transport, and hence procedural success after vasectomy reversal (Dixon et al, 1998).

Cytoarchitecture

The human vas deferens is lined by pseudostratified epithelium (Paniagua et al, 1981). The height of the epithelium decreases along the length of the vas deferens from the testis to the seminal vesicle. In addition, the longitudinal epithelial folds are simpler proximally near the testis and become more complex distally. The pseudostratified epithelium lining of the vas deferens is composed of basal cells and three types of tall, thin columnar cells (Hoffer 1976; Paniagua et al, 1981). The columnar cells, extending from the epithelial base to the lumen, include principal cells, but also pencil cells and mitochondria-rich cells. All columnar cells exhibit stereocilia and irregular convoluted nuclei. Principal cells are the most frequent columnar cell type in the proximal vas deferens, whereas both pencil cells and mitochondria-rich cells increase in density distally. The thickness of the total muscle layer gradually decreases along the length of the vas deferens. This complex cytoarchitecture strongly suggests that the vas deferens is more than simply a passive conduit for sperm transport.

Vas Deferens Function

Sperm Transport

Sperm transport through the vas deferens is influenced by several physiologic processes. First, **the human vas deferens exhibits spontaneous motility** (Ventura et al, 1973). **It also has the capacity to respond when stretched** (Bruschini et al, 1977). **Finally, fluid within the vas deferens can be propelled into the urethra by strong peristaltic contractions elicited either by electrical stimulation of the hypogastric nerve** (Bruschini et al, 1977) or by adrenergic neurotransmitters (Bruschini et al, 1977; Lipshultz et al, 1981). This suggests that immediately before emission, with sympathetic stimulation, rapid transport of sperm from the distal epididymis through the vas deferens to the ejaculatory duct occurs. **This rapid transport ability is consistent with the vas deferens having the greatest muscle to lumen ratio (≈10:1) of any hollow viscus in the body.**

Sperm reserves in the vas deferens have been estimated at approximately 130 million, suggesting that a significant proportion of human ejaculated sperm is stored in the vas deferens (Amann and Howards, 1980). In addition, vasal sperm quality, as assessed from fertile men at the time of vasectomy, is very similar to that of the ejaculate, with 71% motility and 91% viability (Bachtell et al, 1999). In the rabbit, it has been shown that during sexual rest, epididymal sperm are transported through the vas deferens and leak into the urethra in small amounts and at irregular intervals (Prins and Zaneveld, 1979, 1980a, 1980b). This suggests that the vas deferens is involved in ridding the epididymis of excess, stored sperm. Upon sexual stimulation, rabbit sperm are transported through the vas deferens similar to humans. **After sexual stimulation, however, the vas deferens contents are propelled proximally toward the epididymis as the distal vas deferens contracts with greater amplitude, frequency, and duration than the proximal segment** (Prins and Zaneveld, 1980a). Notably, with prolonged sexual rest, excess epididymal sperm are once again transported distally, supporting the idea that the vas deferens is important not only for sperm transport, but also for the maintenance of epididymal sperm reserves.

Absorption and Secretion

Based on its cytoarchitecture, it has been suggested that the human vas deferens has both absorptive and secretory functions (Hoffer 1976 and Paniagua et al, 1981). The principal cells are typical of cells that synthesize and secrete glycoproteins, as has been demonstrated in the rat model (Gupta et al, 1974; Bennett et al, 1974). The stereocilia, apical blebbing, and primary and secondary lysosomes within principal cells are also characteristic of cells involved in absorptive function (Murakami et al, 1988), which has also been confirmed in the rat (Friend and Farquhar, 1967). Lastly, spermiophagy by epithelial cells in the ampullary vas deferens has been observed with scanning electron microscopy in both men and monkeys (Murakami et al, 1988). **Importantly, normal vas deferens function is likely to be androgen dependent because the vas deferens actively converts testosterone to DHT** (Dupuy et al, 1979). Castration causes atrophy of—and testosterone treatment, restoration of—monkey vas cytoarchitecture (Dinakar et al, 1977), and spontaneous and α- and β-adrenergic–stimulated contractions of the rat vas deferens are altered by castration (Borda et al, 1981). Thus, although once thought to be a simple muscular conduit for sperm, the vas deferens is now viewed as a complex reproductive organ.

SEMINAL VESICLE AND EJACULATORY DUCTS

Gross and Cytoarchitecture

Seminal Vesicle

In the adult, the seminal vesicles are paired, elongated, hollow viscous organs located posterior to the prostate and bladder. Each

seminal vesicle is 5 to 7 cm long and up to 1.5 cm wide. Each seminal vesicle actually consists of a tubule that is 15 cm long and highly coiled and convoluted. **The tubule itself is composed of three layers: The inner lining is a moist and folded mucous membrane; the middle layer is largely collagenous; and the outer layer consists of circular and longitudinal muscles layers that constitute 80% of the wall thickness** (Nguyen et al, 1996). The mucosa of the seminal vesicle, mainly nonciliated, pseudostratified columnar or cuboidal cells, is notable for many thin, complicated folds that produce numerous crypts. The excretory duct of the seminal vesicle opens into the ampullary vas deferens as it enters the prostate gland.

The blood supply to the seminal vesicle arises from the internal iliac artery and inferior vesicular artery through the prostatovesicular branch (Clegg, 1955). The prostatovesicular artery can also arise from the superior vesicular artery or from the pudendal artery. Most commonly, the prostatovesicular artery has anterior and posterior branches that supply the respective surfaces of the seminal vesicle. The lymphatic drainage of the seminal vesicle is through the internal iliac lymph nodes. The seminal vesicles are innervated through sympathetic nerves from the superior lumbar and hypogastric nerves. Parasympathetic innervation occurs through the pelvic plexus.

Ejaculatory Ducts

The ejaculatory ducts are paired, collagenous, tubular structures that commence at the junction of the vas deferens and seminal vesicle, course through the prostate, and empty into the prostatic urethra at the verumontanum. Histologically, the ejaculatory ducts are a continuation of the seminal vesicle, except that the outer circular muscle layer does not extend into the ducts (Nguyen et al, 1996). There are three distinct anatomic regions to the ejaculatory duct: the proximal, extraprostatic portion; the middle intraprostatic segment; and a short distal segment incorporating the lateral aspect of the verumontanum in the urethra (Nguyen et al, 1996) (Fig. 20–20). Although the ejaculatory duct contains an outer muscular layer in its extra- and intraprostatic segments, as the duct courses distally, the outer muscular layer dissipates, and **there is no valvelike, muscular "sphincter" at the ejaculatory duct orifice,** as was once thought (Nguyen et al, 1996) (Fig. 20–21). Instead, urinary reflux is prevented and ejaculatory continence is maintained by the acute angle of duct insertion into the urethra. The inner epithelial layer of the ejaculatory ducts is also complex and folded, and consists of simple and pseudostratified columnar cells. The ejaculatory ducts receive their blood supply from branches of the inferior vesicle artery and are innervated through the pelvic plexus.

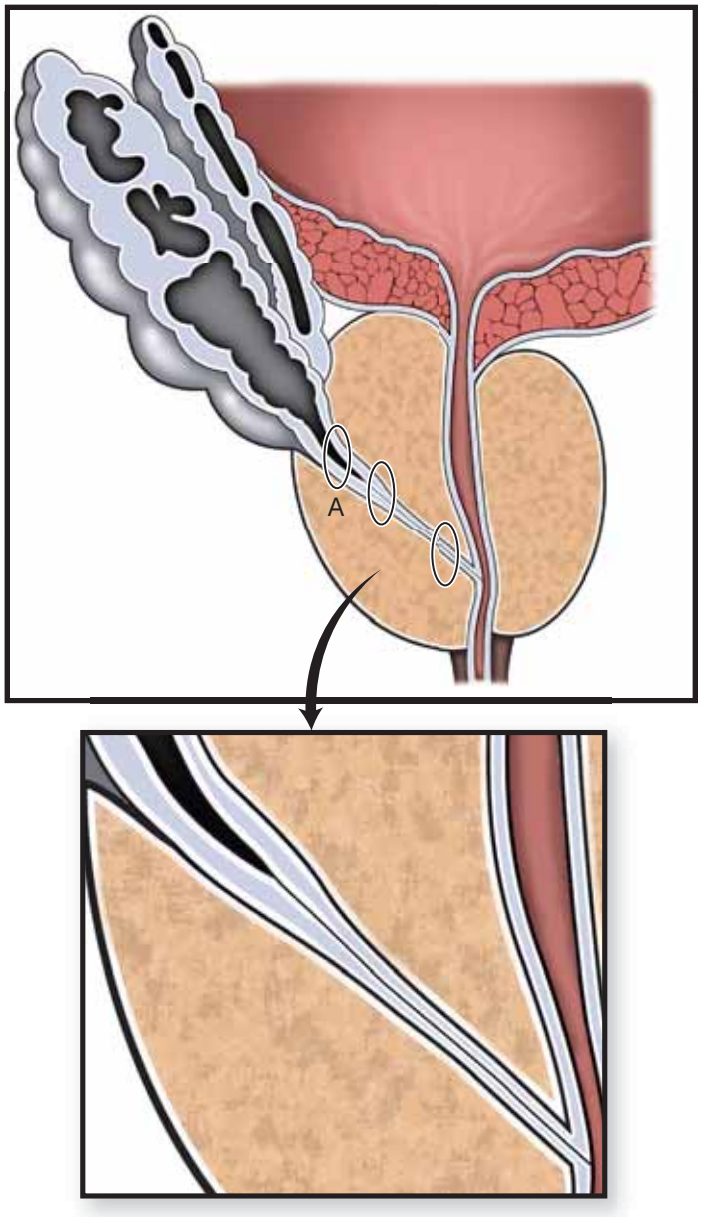

Figure 20–20. Schematic anatomy of the human ejaculatory duct complex. *A,* Proximal, *B,* intraprostatic or middle, and *C,* distal ejaculatory duct regions. The *inset* shows how the muscle layer thins out in the middle segment. (From Nguyen HT, Etzell J, Turek PJ, et al. Normal human ejaculatory duct anatomy: a study of cadaveric and surgical specimens. J Urol 1996;155:1639–42.)

Seminal Vesicle and Ejaculatory Duct–Unit Function

Animal studies suggest that the seminal vesicle and ejaculatory ducts are functionally similar to the bladder and urethra (Turek et al, 1998). **The seminal vesicle is a contractile, compliant, smooth muscular organ with dynamic properties analogous to those of the bladder, and the ejaculatory ducts serve as a urethra-like conduit. This theory allows the classification of ejaculatory duct obstruction into two types of disorders, analogous to bladder outlet obstruction: (1) obstruction resulting from physical blockage of the ducts, similar to bladder outlet obstruction, and (2) "functional" obstruction of the seminal vesicle, similar to voiding dysfunction due to bladder myopathy.** In addition, this has implications for the diagnosis of ejaculatory duct disorders because "static" anatomical imaging, such as transrectal ultrasonography, may not be sufficient to differentiate between these disorders, and medications and conditions (such as diabetes) might predispose the system to seminal vesicle dysfunction (Smith et al, 2008).

Seminal Vesicle Function

The seminal vesicles secrete a significant proportion (80%) of the seminal fluid, and these secretions are found in later fractions of the ejaculate, after the sperm-rich

Figure 20–21. (From Nguyen HT, Etzell J, Turek PJ, et al. Normal human ejaculatory duct anatomy: a study of cadaveric and surgical specimens. J Urol 1996;155:1639–42.)

epididymal, and prostatic secretions. After ejaculation, sperm pass into and through the female cervical mucus and, subsequently, the uterus to enter the oviduct, where fertilization occurs. During residence in the female reproductive tract, sperm must undergo capacitation prior to oocyte fertilization. Capacitation occurs at different rates for individual sperm. During capacitation, the acrosome reaction and development of hyperactivated motility occurs (Yanagimachi, 1994). It is not clear if prostatic or seminal vesicle secretions contribute to capacitation.

In fact, the exact physiologic role of seminal vesicle fluid is not clear, although in rodents it functions as a plug or barrier that reduces the chances for sperm from a subsequent male to fertilize the oocyte. Before ejaculation, semen is a liquid, and after all components mix with the seminal vesicle secretions, it coagulates. The major component of the coagulum is **semenogelin I, a 52-kD protein expressed exclusively in the seminal vesicles** (Robert et al, 1999). **Through coagulating semen, seminal vesicle secretions may promote sperm motility, increase stability of sperm chromatin, and suppress immune activity in the female reproductive tract.** The best-elucidated function of human semen appears to be its ability to provide antioxidative protection to sperm. Semen is rich in antioxidant enzymes, including glutathione peroxidase, superoxide dismutase, and catalase (Yeung et al, 1998). In addition, the antioxidant molecules taurine, hypotaurine, and tyrosine are present in high concentrations (van Overveld et al, 2000). Lipofuscin granules from dead epithelial cells give seminal vesicle secretions a yellow-white color. In addition, seminal vesicle secretions are alkaline and contain fructose, mucus, vitamin C, flavins, phosphorylcholine, and prostaglandins. High fructose levels provide nutrient energy for the sperm when studied in vitro. The mixing of seminal vesicle with prostatic secretions results in human semen having a mildly alkaline pH. Acidic ejaculate (pH <7.2) is associated with blockage or absence of seminal vesicles (Turek, 2005).

Key Points: Vas Deferens, Seminal Vesicle, and Ejaculatory Ducts

- The vas deferens is of wolffian (mesonephric) duct origin and serves to transport sperm from the cauda epididymis to the ejaculatory duct during seminal emission.
- The seminal vesicle and ejaculatory duct–unit is analogous to the bladder and urethra, and is subject to both physical blockage and functional disorders that result in infertility.

SPERMATOZOA

Anatomy and Physiology

The human spermatozoon is approximately 60 μm in length and is divided into 3 morphological sections: head, neck, and tail (Fig. 20–22). The oval **sperm head,** about 4.5 μm long and 3 μm wide, contains a nucleus with highly compacted **chromatin,** and an **acrosome,** a membrane-bound organelle that harbors enzymes required for penetration of the outer vestments of the egg before fertilization (Yanagimachi, 1978). The **sperm neck** maintains the connection between the sperm head and tail. It consists of the **connecting piece** and **proximal centriole.** The **axonemal complex** extends from the proximal centriole through the sperm tail. The **tail** harbors the **midpiece, principle piece, and end piece** (Zamboni, 1992). The midpiece is 7 to 8 μm long and is the most proximal segment of the tail, terminating in the annulus. It contains the axoneme, which is the **9 + 2 microtubule arrangement,** and surrounding **outer dense fibers** (Fig. 20–23). It also contains the **mitochondrial sheath,** which is helically arranged around the outer dense fibers. The outer dense fibers, rich in disulfide bonds, are not contractile proteins but are thought to provide the sperm tail with the elastic rigidity necessary for progressive motility (Oko and Clermont, 1990). Similar in structure to the midpiece, the principal piece has several columns of outer dense fibers that are replaced by the fibrous sheath. The fibrous sheath consists of **longitudinal columns** and **transverse ribs.** The sperm terminates in the endpiece, the most distal segment of the sperm tail, and contains axonemal structures and the fibrous sheath. Except for the end-piece region, the sperm is enveloped by a highly specialized plasma membrane that regulates the transmembrane movement of ions and other molecules (Friend, 1989).

The spermatozoon is a remarkably complex metabolic and genetic machine. **The 75 sperm mitochondria that surround the axoneme contain enzymes required for oxidative metabolism and produce adenosine triphosphate (ATP), the primary energy molecule for the cell.**

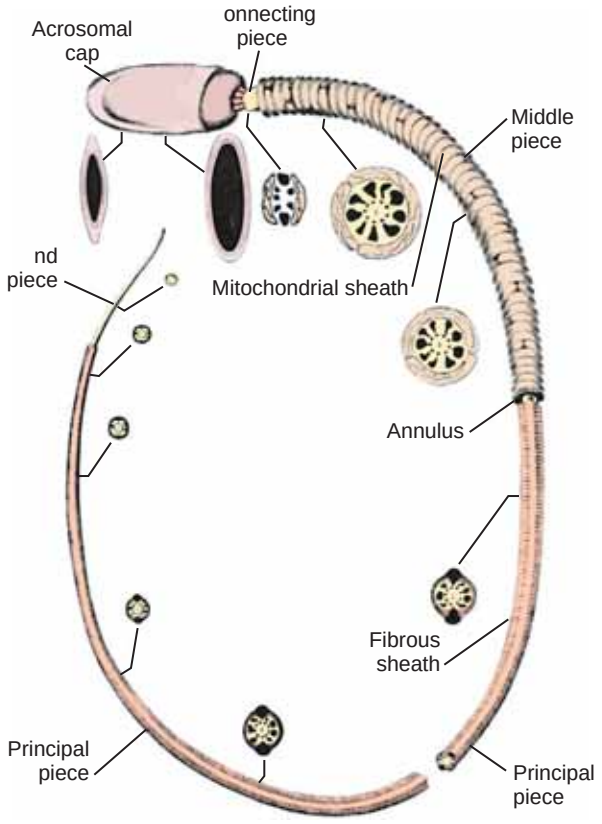

Figure 20–22. Diagram of a typical mammalian spermatozoon. The plasma membrane is omitted to illustrate the major cellular components. Cross-sectional insets show the orientation of the internal cell structures. (From Fawcett DW. The mammalian spermatozoon. Dev Biol 1975;44:394–436.)

Mitochondria are semiautonomous organelles that produce cellular energy and can also cause apoptotic cell death through the release of cytochrome *c*. Mitochondria are composed of outer and inner membranes. As an organelle, the mitochrondrion has two compartments: the space between the outer and inner membranes, the intermembrane space, and the space surrounded by the inner membrane, termed the matrix. The inner membrane forms deep folds into the matrix, called the cristae, which make the surface area of the inner membrane larger than that of the outer membrane. Five distinct respiratory chain complexes span the width of the inner membrane and are necessary for oxidative phosphorylation: the nicotinamide adenosine diphosphate (NADPH) dehydrogenase, succinate dehydrogenase, cytochrome *bc1*, cytochrome *c* oxidase, and ATP synthase complexes. Contained within the matrix are citric acid cycle, fatty acid and amino acid oxidative enzymes, newly made ATP, mitochondrial DNA (mtDNA), and ribosomes. From animal studies, it is clear that the plasma membrane covering the sperm-head region harbors specialized proteins that participate in sperm–egg interaction (Saling, 1989). Indeed, carbohydrate-binding proteins on the sperm membrane interact with the species-specific ZP3 protein in the egg zona pellucida, resulting first in sperm binding to the zona and, subsequently, to induction of the acrosome reaction (Shabanowitz, 1990). Another sperm membrane protein, PH30, is present on testicular sperm and is modified during sperm migration through the epididymis and function as a fusion protein between the sperm and egg membranes at fertilization (Primakoff, 1987; Blobel et al, 1990).

Physiologically, the axoneme is the true motor assembly and requires 200 to 300 proteins for proper function. Among these, the microtubules are the best-understood components. **Sperm microtubules are arranged in the classic "9 + 2" pattern of 9 outer doublets encircling an inner central doublet** (Fig. 20–23). The complex protein dynein extends from one microtubule doublet to the adjacent doublet, and forms both the inner and outer "arms" of the axoneme. **The sperm axoneme contains the enzymes and structural proteins necessary for the chemical transduction of ATP into mechanical movement and motility.** Dynein is large (2000 kD), Mg^{+}-stimulated, ATPase responsible for ATP-generated microtubule sliding that causes axonemal bending and, ultimately,

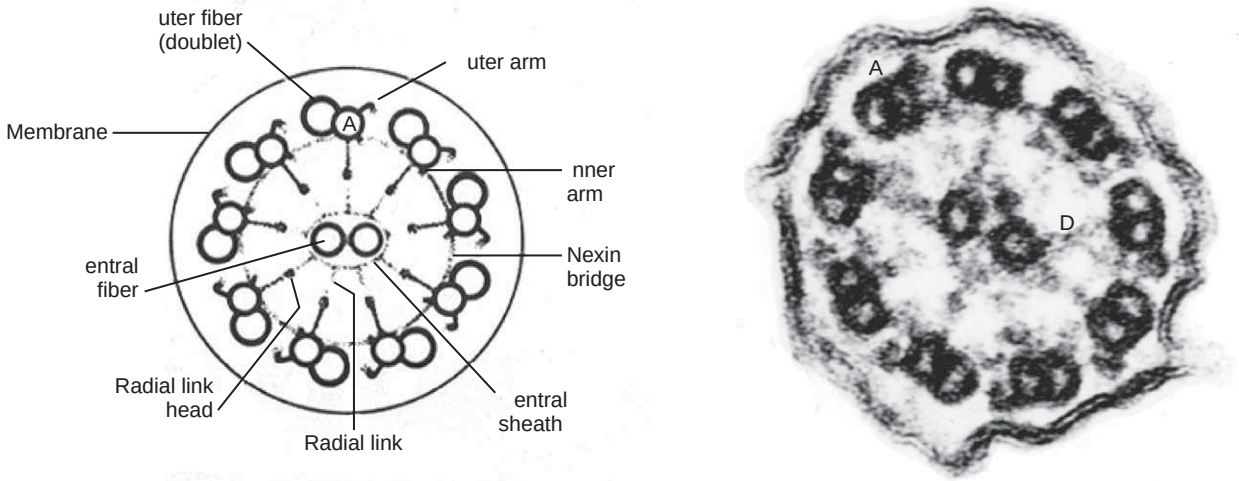

Figure 20–23. The "9 + 2" sperm axonemal structure. *Left:* schematic cross section of axoneme, demonstrating microtubule arrangement. *Right:* electron micrograph of axoneme. *(A)* outer doublet; *(B)* inner central doublet; *(C)* outer dynein arm; *(D)* radial link.

sperm flagellar movement. The dynein structure has 2 to 3 globular, outer (heavy) chain heads (500 kD) joined to a common stem. The heads control movement along the microtubules. The inner (light) chain arms (14 to 120 kD) are the primary effectors of movement and are associated with the radial spokes of the dynein assembly. Sperm with outer arm mutants have reduced motility, and those with inner arm mutants have no motility. Radial links or spokes connect a microtubule of each doublet to the central inner doublet and consist of a complex of proteins. The central inner doublet is surrounded by a ringlike helical sheath to which the radial links from the outer doublets are attached. Tektins are proteins associated with the outer microtubular doublets, and nexin links are proteins that connect the outer doublets to each other and maintain the cylindrical axonemal shape.

The human mitochondrial DNA (mtDNA) is distinct from the sperm nuclear DNA. It consists of a circular, histone-free chromosome of 16,569 bp of DNA arranged in a single heavy and single light strand. **MtDNA encodes 13 respiratory-chain-complex subunit proteins, 2 mitochondrial rRNAs, and 22 tRNAs used for protein synthesis.** These genes have no introns. Expression of mtDNA genes are regulated by strand-specific, but not gene-specific, promoters in response to activation of a transcription factor (mtTFA). MtDNA is also far more susceptible to mutations than is nuclear DNA (estimated 40 to 100 times higher). Reasons for this may include the fact that mitochondria are near respiratory-chain complexes and may be easily attacked by reactive oxygen species. **In addition, mtDNA is not coated with protective histones, and mitochondria have very limited DNA repair mechanisms** (Hirata et al, 2002). **The fact that mitochondria rapidly accumulate mutations suggests the necessity of degrading all paternal mtDNA in the fertilized egg.** This degradation is likely mediated by the small proteolytic polypeptide ubiquitin that regulates proteolysis in many tissues (Sutovsky et al, 1999).

The phenotype of defective sperm structure has been recognized as ciliary dyskinesia. Although infertility is the rule with ciliary dyskinesias, ejaculated sperm can be motile and sperm concentrations can be normal. With ICSI, clinical pregnancies and live births have been reported using affected sperm (Cayan et al, 2001). Because the inheritance is usually recessive, normal offspring are likely. Patients suspected of harboring sperm structural defects generally exhibit severely compromised sperm motility (<10%). Sperm electron microscopy can reveal ultrastructural or functional abnormalities of the sperm. Sperm structural abnormalities are currently categorized by Chemes (2000) as follows:

1. **Nonspecific flagellar anomalies.** The most frequent flagellar anomaly underlying severely low motility with a structural phenotype of random, heterogeneous, microtubular alterations. They are sometimes due to correctable disorders such as varicocele, reactive oxygen species, and gonadotoxin exposure. There is no evidence of familial occurrence.
2. **Dysplasia of the fibrous sheath.** This condition is a systematic sperm abnormality, usually associated with near-total or total immotility. It has a more homogenous and distinctive phenotype characterized by sperm fibrous sheath, axonemal, and periaxonemal distortions. A subset of these patients exhibits the classical ciliary dykinesias (formerly immotile cilia syndrome), in which sperm immotility is associated with respiratory disease and dextrocardia. There is a strong familial incidence of these conditions, suggesting that they are genetic in origin.

Key Points: Sperm

- Sperm are ciliated cells that possess a "9 + 2" axonemal structure that allows motility.
- It is estimated that 200 to 300 genes regulate sperm motility.
- Sperm motility defects, termed ciliary dyskinesias, are common and can be either correctable (nonspecific flagellar anomalies) or genetic (dysplasia of the fibrous sheath).
- Human sperm mitochondrial DNA (mtDNA) is a circular, histone- and intron-free DNA ring that encodes for respiratory-chain-complex proteins and is very susceptible to mutations.

SUMMARY

Spermatogenesis is a remarkably intricate and complex process that is driven by precisely regulated and pulsatile secretions of GnRH, LH, and FSH from the hypothalamic-pituitary-gonadal axis. Pertubations in this hormonal milieu are common causes of male infertility. Sperm production occurs in the testis, a specialized structure that functions optimally at 2° C to 4° C below body temperature and generates a mature human sperm in 64 days. Well-integrated cycles and waves of spermatogenesis ensure that human sperm production is constant at about 1200 sperm per second. Spermatogenesis is an androgen-dependent process that occurs with very high intratesticular levels of testosterone. The product of spermatogenesis, the spermatozoa, leave the testis as immotile cells with limited capacity to fertilize an oocyte. After epididymal transit, sperm are typically motile and capable of fertilization. During ejaculation, sperm are rapidly transported through the ejaculatory ducts into the urethra from the distal epididymis. The ejaculate itself supports sperm metabolism, motility, serves as an antioxidant, and serves as a barrier to exclude subsequent gamete deposits from gaining access to the egg.

History and Review of Systems
Physical Examination
Laboratory Evaluation of Male Infertility
Other Testing
Diagnostic and Treatment Categories of Male Infertility
Assisted Reproduction

INTRODUCTION: DEFINITION AND DEMOGRAPHICS OF INFERTILITY

Over the past 50 years, we have witnessed dramatic advances in the understanding and treatment of male fertility. The introduction of intracytoplasmic sperm injection (ICSI) in 1992 (Palermo et al, 1992), a technique of in-vitro fertilization using direct insertion of a single sperm into an egg, offered the ability to bypass even some of the most severe etiologies of male subfertility but raised a variety of cost and safety issues. Growing understanding of the genetics of fertility, environmental influences on gonadocytes, and the endocrine basis for germ cell development holds promise to allow more targeted diagnostic and therapeutic interventions. Unlike many other disease states, fertility represents a complex interaction between two individuals involving multiple organ systems. Attempts to isolate pathology to one gender are confounded by the fact that male fertility is not a clearly quantifiable parameter but is dependent on requirements of the individual female reproductive system. Older studies have related 20% of cases of infertility to purely male factor etiology, while an additional 30% to 40% involve both male and female factor pathology (Simmons, 1956). Newer studies have shown little change in this distribution with more than 50% attributable to male factor, despite advances in the diagnosis and management of infertility (Mosher and Pratt, 1991; Thonneau et al, 1991).

Knowledge of the inherent inefficiency of normal human reproduction is critical before we can define infertility. Studies of conception in normal couples reveal that 60% to 75% will conceive within 6 months of unprotected intercourse and 90% by 1 year (Tietze et al, 1950; Spira, 1986). On the basis of this, the classic definition of infertility became the absence of conception after 12 months of regular, unprotected intercourse, a definition supported by the Practice Committee of the American Society for Reproductive Medicine (ASRM). Because a small number of normal couples will conceive between 1 and 2 years, the World Health Organization (WHO) recommends 24 months of unprotected intercourse as the preferred definition of infertility (Rowe, 1993). Geographically diverse population-based studies have reported a remarkably consistent 15% to 20% incidence of infertility (WHO, 1991; Gunnell and Ewings, 1994; Philippov et al, 1998). Although the classic definition of infertility would suggest deferring medical assessment until 12 months of unprotected intercourse, we support performance of a basic, cost-effective evaluation of both partners at the time of presentation for evaluation. Current recommendations by the Practice Committees of the American Urological Association and the American Society for Reproductive Medicine (Male Infertility Best Practice Committee Report, 2006a, 2006b) recommend infertility evaluation before 1 year if (1) male infertility risk factors such as a history of bilateral cryptorchidism are known to be present, (2) female infertility risk factors including advanced female age (older than 35 years) are suspected, or (3) the couple questions the male partner's fertility potential. A timely but limited evaluation provides early identification and correction of factors that may reduce fertility, as well as reassurance in an emotionally difficult situation for couples. Alleviation of anxiety related to infertility may in itself provide therapeutic value.

Perhaps more than in many other medical assessments, evaluation of infertility requires a methodic approach involving a comprehensive medical history, review of systems, targeted physical examination, and basic laboratory tests. An effective initial approach should be rapid, cost-effective, and noninvasive. Concurrent basic evaluation of the female partner is prudent given the multifactorial etiology of infertility, as well as the potential need for assisted reproductive technologies (ARTs) to treat the male factor. Initial male factor evaluation may suggest the need for more advanced semen, genetic, endocrine, or radiologic tests to arrive at the correct diagnostic and treatment plan.

Whenever possible, treatment should involve correction of a specific problem rather than blanket application of costly assisted reproductive technologies. ART use for male factor infertility in the United States has been estimated to cost almost $18 billion dollars in 1 year alone (Meacham et al, 2007), underscoring the need for addressing the specific cause of male factor infertility. More importantly, ART application without attention to the male factor may mask potentially significant and even life-threatening conditions present in the infertile male, conditions that may occur in up to 1.3% of men and that would only have been diagnosed with a complete medical evaluation (Kolettis and Sabenegh, 2001). However, ART retains an important role in the management of male factor infertility, especially where no etiology for infertility can be identified or in the setting of noncorrectable causes. In

addition to assisted reproduction, donor sperm insemination and adoption remain excellent options for the management of noncorrectible infertility.

HISTORY AND REVIEW OF SYSTEMS

Successful diagnosis and treatment of infertility requires careful attention to obtaining a thorough history. A diverse variety of specific factors can affect subsequent fertility or sexual function (Table 21–1). Although focus may be on long-term factors that can affect fertility, human spermatogenesis is estimated to involve a 64-day cycle with an additional 5 to 10 days of epididymal transit time on the basis of radioisotope labeling studies (Clermont and Heller, 1963; Franca et al, 2005; Misell et al, 2006). Factors such as fever, illness, or drug use in the several months before semen testing should prompt repeat testing after an additional 3 months to rule out transient detrimental effects.

Table 21–1.

Pertinent History in Evaluation of the Infertile Male

- Infertility history
  - Duration
  - Prior conceptions
    - Current or previous partner
    - Outcome
  - Previous fertility evaluation and treatment
- Sexual history
  - Erectile function
  - Lubricants
  - Frequency/timing of intercourse
- Past history
  - Childhood
    - Cryptorchidism
    - Onset of puberty
    - Testicular pathology
      - Torsion
      - Trauma
    - Midline defects (cleft palate)
  - Medical
    - Diabetes mellitus
    - Neurologic disease
      - Spinal cord injury
      - Multiple sclerosis
    - Infection
      - Urinary infections
      - Sexually transmitted disease
      - Epididymitis/prostatitis
      - Tuberculosis
      - Mumps orchitis
      - Recent viral/febrile illness
    - Renal disease
    - Cancer
      - Chemotherapy/radiotherapy
  - Surgical
    - Orchidopexy
    - Retroperitoneal/pelvic surgery
    - Herniorrhaphy
    - Vasectomy
    - Bladder neck/prostatic surgery
  - Medications
  - Gonadotoxins
    - Environmental exposures (pesticides, heavy metals)
    - Radiation
    - Habits (tobacco, recreational drugs, anabolic steroids)
- Family history
  - Infertility
  - Cystic fibrosis
  - Androgen receptor deficiency

Reproductive history is of particular importance in the initial evaluation. Details regarding any prior conceptions the patient may have caused with his present or prior partner, duration of infertility, method of reproductive timing, and prior contraceptive history should be obtained. Primary infertility is defined as the failure to conceive at any time in the past with any prior partner, whereas secondary infertility indicates a prior conception with the current or previous partner. This simple classification can be helpful in narrowing the differential diagnoses because those with secondary infertility are presumed to have normal embryologic development of their reproductive tract and genetic complement.

The timing and frequency of intercourse are an important component of the reproductive history. In recent years, the ease and availability of ovulation predictor kits, which measure midcycle urinary luteinizing hormone (LH) surge as a predictor of impending ovulation, have allowed couples to approach reproductive timing in a more informed and effective fashion. However, many couples are not aware of the viability of spermatozoa within the female reproductive tract with sperm surviving between 2 and 5 days in favorable cervical mucus (Wilcox, 1995). This finding is the basis for the widely offered recommendation of intercourse frequency every 2 days near the time of ovulation, maximizing the chance that viable sperm are available to the oocyte (Tur-Kaspa et al, 1994). Intercourse that is too frequent does not allow replenishment of adequate numbers of spermatozoa within the epididymis, whereas infrequent intercourse may miss the potential window for fertilization. An assessment of erectile and ejaculatory function is also germane to the initial evaluation.

Use of vaginal lubricants is commonplace in reproductive-aged couples with almost one half of couples reporting intermittent use (Oberg et al, 2004). A number of commercially available lubricants that are not marketed as spermicidal agents have been shown to adversely affect sperm motility (Miller, 1994; Kutteh et al, 1996; Anderson et al, 1998) and sperm deoxyribonucleic acid (DNA) integrity (Agarwal et al, 2008). Although some lubricants such as vegetable oil, raw egg white, and Pre-Seed have minimal spermicidal effect (Goldenberg and White, 1975; Edvinsson et al, 1983; Agarwal et al, 2008), it remains optimal to avoid lubricant use if possible and to use minimal concentrations of the least toxic lubricant available, if required.

A variety of pediatric conditions including cryptorchidism, postpubertal mumps orchitis, and testicular torsion or trauma can have significant implications on eventual fertility. Although prepubertal mumps is unlikely to have detrimental effects on fertility, mumps occurring in the postpubertal timeframe is associated with unilateral or bilateral orchitis in up to 40% of children (Werner, 1950) with potentially devastating testicular damage. Testicular torsion or trauma can result in testicular atrophy, as well as the development of antisperm antibodies, which are detrimental to sperm function and motility (Bronson et al, 1984; Puri et al, 1985).

The timing of the onset of puberty may suggest underlying endocrinologic abnormalities. A history of delayed puberty, especially in conjunction with anosmia, is associated with the diagnosis of Kallmann syndrome, or primary hypogonadotropic hypogonadism. On the other hand, precocious puberty may be secondary to congenital adrenal hyperplasia, which may affect future fertility.

Prior scrotal, inguinal, or retroperitoneal surgeries can obstruct the ductal system or interfere with emission or ejaculation of

sperm. Classic retroperitoneal lymphadenectomy for testicular cancer frequently results in sympathetic nerve injury leading to anejaculation or retrograde ejaculation (Kedia et al, 1977). Fortunately, with modifications in the surgical template and intentional nerve sparing, ejaculation can be preserved in almost all patients with low-stage disease and in selected patients with more advanced disease (Donohue et al, 1990). Bladder neck surgery and transurethral resection of the prostate can lead to retrograde ejaculation due to bladder neck incompetence. In selected patients, transurethral incision of the prostate can allow preservation of antegrade ejaculation. Vasal injuries from inguinal surgery have seen resurgence with the popularity of polypropylene mesh hernia repairs, which can induce dense fibroblastic reactions leading to vasal obstruction (Shin, 2005).

Systemic diseases in adulthood can affect fertility through a number of different mechanisms. Diabetes mellitus, spinal cord injuries, and multiple sclerosis exert effects through impairment of both ejaculatory and erectile function (Sønksen and Biering-Sørenson, 1992; Sexton and Jarow, 1997). Diseases of the thyroid, both hyper and hypo function, affect both steroid hormone metabolism and sperm quality and have been associated with subfertility (Velazquez and Bellabarba, 1997; Abalovich et al, 1999; Krassas et al, 2002). Subclinical hypothyroidism does not produce significant seminal abnormalities (Trummer et al, 2001).

Neoplasms in general can induce marked impairment of spermatogenesis due to endocrine disturbances, malnutrition, hypermetabolism with associated fever, and immunologic factors (Costabile and Spevak, 1998; Wong et al, 2000). In addition to the global effects of malignancy on reproductive health, specific malignancies such as Hodgkin disease (HD) and testicular germ cell tumors produce significant direct gonadotoxic effects (Petersen et al, 1999; Rueffer et al, 2001). Pretreatment testicular dysfunction associated with HD has been postulated to be due to a variety of mechanisms including genetic abnormalities at the germ cell level, endocrinopathies, systemic release of cytokines injurious to both the seminiferous tubules and the Leydig cells, and negative local effects from intratesticular lymphatic tissue. Testicular tumors impair spermatogenesis by the destruction of surrounding tissue, local secretion of HCG and other paracrine factors, intrascrotal temperature elevation, and alterations in the local blood flow. Cancer treatments including chemotherapy and radiation produce direct toxicity on surviving germ cells, potentially depressing spermatogenic function for many years if recovery occurs at all (Nalesnik et al, 2004; Ståhl et al, 2006).

A detailed history should include a comprehensive assessment of medications, recreational, environmental, and occupational exposures that can impact fertility. Medications can impair fertility by direct toxic effects on gonadocytes, disturbance of the hypothalamic-pituitary-gonadal axis, disruption of ejaculatory or erectile function, and inhibition of libido. Antibiotics including nitrofurantoin, erythromycin, tetracycline, and gentamycin exhibit direct gonadotoxicity or impair sperm function. Androgen production is inhibited by spironolactone, ketoconazole, and cimetidine (Griffin and Wilson, 1991). Treatments for ulcerative colitis such as sulfazalazine are associated with reversible reductions in sperm concentration and motility (Toth, 1979). α Blockers, which are commonly used for treatment of benign prostatic hypertrophy and hypertension, are associated with retrograde ejaculation, an effect that may be more prominent with tamsulosin than with other selective α blockers (Giuliano, 2006). 5-α reductase inhibitors such as finasteride and dutasteride inhibit conversion of testosterone to the metabolically active dihydrotestosterone and are commonly used for treatment of benign prostatic hypertrophy. Use of these agents has been associated with reductions in semen volume, as well as erectile and ejaculatory dysfunction (Giuliano, 2006). Psychotherapeutic medications including the selective serotonin reuptake inhibitors (SSRI), monoamine oxidase inhibitors, phenothiazines, and lithium can suppress the hypothalamic-pituitary-gonadal axis, impair ejaculation and erectile function, and reduce libido (Nudell et al, 2002). Exogenous testosterone and steroid supplementation, whether medically prescribed or used for recreational purposes, can have the most profound detrimental effects on spermatogenesis of the medical agents. Androgenic agents induce hypogonadotropic hypogonadism leading to azoospermia, which can last 6 months or more after cessation of the supplements and, on occasion, may be irreversible (Sigman et al, 2006). Testosterone replacement therapy in hypogonadal men desiring fertility should be avoided, and alternate regimens such as antiestrogens (clomiphene citrate, tamoxiphene) should be considered instead. Recreational drugs have also been implicated as gonadotoxic agents. Marijuana use is associated with gynecomastia, reductions in serum testosterone, decreased sperm counts, and elevated seminal leukocytes (Harmon and Aliapoulios, 1972; Hembree et al, 1979; Close et al, 1990). Abnormal sperm morphology, decreased motility, and low sperm concentrations have been associated with cocaine use (Bracken et al, 1990; Hurd et al, 1992). Although long-term abuse of alcohol is associated with global suppression of the hypothalamic-pituitary gonadal axis and spermatogenesis, moderate intake is not associated with significant deterioration in fertility (Muthusami and Chinnaswammy, 2005).

Although the role of smoking in lung and heart diseases is widely established, the adverse effect of tobacco on male reproductive health is less well known by the general public. Smoking is associated with declines in basic semen parameters such as sperm concentration, viability, forward motility, and morphology (Vine et al, 1996; Künzle et al, 2003), as well as declines in sperm penetration ability and hence fertilization rates (Sofikitis et al, 1995). Defects in these parameters not only affect normal fecundity but also lower assisted reproduction success rates (Joesbury et al, 1998; Zitzmann et al, 2003).

The impacts of environmental and occupational exposures on spermatogenesis are more difficult to prove and quantify. Certain agents such as heavy metals, pesticides such as dibromochloropropane, organic solvents, and heat have been widely associated with gonadotoxicity (Lipshultz and Corriere, 1980; Moreira and Lipshultz, 2008). Industrial lead exposure exerts direct negative effects on both seminiferous tubules and the hypothalamic pituitary axis, resulting in asthenospermia, oligospermia, teratospermia, and ultimately reduced fertility (McGregor and Mason, 1990; Gennart et al, 1992; Shiau et al, 2004).

Inflammatory diseases can have profound effects on the patency of the genital tract and function of the spermatozoa. Infectious diseases such as prostatitis or sexually transmitted infections such as *Chlamydia* or *Neisseria gonorrhea* are associated with elevated seminal oxidative stress and leukocytospermia, resulting in abnormal bulk semen parameters, elevated sperm DNA fragmentation, and reduced fertility (Trum, 1998; Pasqualotto, 2000; Aitken et al, 2007). A history of bilateral epididymitis with subsequent azoospermia suggests the possibility of epididymal obstruction. Epididymal granuloma may result from noninfectious diseases such as sarcoidosis (Rao, 2009) or from the sequelae of an active tuberculosis infection. Epididymal sarcoidosis has been associated with azoospermia, which may be reversible with corticosteroid treatments (Svetec, 1998).

Questions regarding a family history of infertility are an underemphasized component of the initial assessment because of a misperception that genetic conditions that cause infertility are inherently nontransmissible. A family history of cystic fibrosis may suggest the diagnosis of congenital bilateral absence of the vas deferens (CBAVD) with its associated vasal, epididymal, and seminal vesicle anomalies. Abnormalities of the androgen receptors should be considered in the setting of a family history of intersex disorders. Today's widespread use of assisted reproductive technologies such as ICSI allow us to overcome subtle genetic abnormalities that may account for many cases of idiopathic male subfertility. With up to 2% to 4% of European and more than 1% of U.S. children born today (Wright et al, 2007) as a result of these technologies, we would expect the genetic causes of infertility to represent a growing etiology of infertility as these men attempt to conceive in the future, further reinforcing the importance of obtaining a comprehensive family history.

Finally, a complete history should also include an assessment of female factor fertility issues because almost two thirds of infertility can be attributed to the female side, either wholly or in combination with male factors. Failure to incorporate these considerations into the evaluation and management can result in ineffective and unnecessarily expensive treatment courses. Risk factors for female subfertility include but are not limited to advanced age, irregular menstrual cycles, and a history of pelvic pathology including endometriosis and pelvic infections. Fecundity begins to decline sharply after age 35 and is less than 5% by age 40 (Robins and Carson, 2008). Ovulatory dysfunction occurs in 40% of infertile women, accounting for the largest single cause of female infertility (Mosher and Pratt, 1991). A variety of tools are used to assess ovulation; these include basal body temperature charts, midluteal serum progresterone levels, endometrial biopsy, urinary LH prediction kits and transvaginal sonographic detection of ovarian follicles. Tests of ovarian reserve involve an assessment of remaining ovulatory capability and a de facto assessment of ovarian aging. Standard testing includes basal hormone measurements of follicle-stimulating hormone (FSH) and estradiol, as well as dynamic ovarian testing, which involves stimulation of ovulation using clomiphene citrate or gonadotropin (Hofmann et al, 1996). Abnormalities of uterine cavity or tubal anatomy occur in up to 25% of infertile women (Thonneau et al, 1991). Uterine and tubal patency can be assessed with hysterosalpingography (HSG) or laparoscopy with chromotubation. HSG testing involves transcervical injection of contrast material allowing assessment of intrauterine and tubal anatomy. In addition, a number of reports have suggested that the use of oil-based contrast materials may be therapeutic, in addition to the diagnostic value (Al-Fadhli et al, 2006; Luttjeboer et al, 2007). Laparoscopy allows confirmation of HSG findings by direct observation of free spill of contrast (methylene blue or indigo carmine introduced via cervix) and detection of other pathologies such as endometriosis, fibrial phimosis, or peritubular adhesions. At the time of laparoscopy, tubal reconstruction and surgical ablation of endometriosis may be undertaken.

PHYSICAL EXAMINATION

General Examination

Because fertility issues can be a reflection of the general health, the physical examination should be comprehensive with special attention to the genital examination. Body habitus provides clues to the adequacy of virilization with androgen deficiency suggested by decreased body hair, absence of temporal pattern balding, gynecomastia, and eunuchoid proportions. Abnormalities in these areas suggest possible endocrinopathies to include low serum testosterone, hyperprolactinemia, abnormalities in the estrogen to testosterone ratio, adrenal dysfunction, and genetic syndromes associated with subvirilization to include Klinefelter syndrome (KS). Low androgen levels at the time of puberty may cause disproportionately long extremities due to delayed closure of the epiphyseal plates. Palpation of the thyroid gland will occasionally disclose nodules suggesting hyperfunction or hypofunction, which can affect fertility. Hepatomegaly on abdominal examination raises suspicion for hepatic dysfunction, which may induce altered sex steroid metabolism.

Genital Examination

Genital examination starts with a careful examination of the phallus. Penile curvature, chordee, or hypospadias may interfere with semen deposition in the vaginal vault. A careful examination of the scrotal contents is the most critical part of the examination. The testes should be examined with the patient in both supine and standing positions in a warm room to assist relaxation of the cremasteric muscle. The entire testicular surface should be carefully palpated to assess consistency and rule out masses because infertility has been consistently established as a risk factor for testicular carcinoma (Kolettis and Sabanegh, 2001). Testicular size should be assessed with either an orchidometer, calipers, or sonographic measurement. Normal adult testicular measurements have been established to be at least 4 × 3 cm or 20 mL in volume (Charny, 1960). Because 85% of the testicular volume involves sperm production, decreased testicular size portends impaired spermatogenic potential (Lipshultz and Corriere, 1977). The epididymides should be carefully palpated for enlargement or induration, which can indicate downstream obstruction or inflammatory conditions such as epididymitis. Granulomatous changes of the epididymis have been associated with tuberculosis, bacile Calmette-Guerin (BCG) treatments, and sarcoidosis. Small cystic lesions of the epididymis are common and are usually spermatoceles, which are often nonobstructing. Papillary cystadenomas are less commonly seen and may present in conjunction with von Hippel-Lindau (VHL) disease.

Examination of the spermatic cord in the supine and standing position allows the detection of varicoceles, defined as abnormally dilated scrotal veins. Varicoceles are detected by palpation for assymetry of the spermatic cord, or an impulse, during the Valsalva maneuver. Gentle traction on the testis during this examination can be helpful in more difficult examinations such as patients with high riding testes or exaggerated cremasteric muscle response to Valsalva. Varicoceles are present in 15% of normal males, 19% to 41% in men presenting with primary infertility, and up to 81% of men with secondary infertility (Agarwal et al, 2007). Varicoceles are graded by size with small grade I varicoceles, which are detectable only during the Valsalva maneuver; moderate size grade II varicoceles, which can be palpated without Valsalva; and the large grade III varicoceles, which are visible through the scrotal skin and classically described as feeling like a "bag of worms." Due to the right-angle insertion of the left gonadal vein into the renal vein with the resulting turbulent flow, varicoceles are more prevalent on the left side with almost 90% presenting on the left side alone. Large unilateral right-side varicoceles and varicoceles that fail to decompress with the supine position suggest the possibility of retroperitoneal or caval pathology such as renal neoplasms and warrant dedicated imaging. A variety of ancillary procedures including ultrasonography with and without Doppler

examination, radionucleotide scans such as technetium 99m pyrophosphate, thermography, and venography have been used to corroborate clinical examination findings. In the absence of physical examination findings, varicoceles detected by these procedures alone are considered subclinical and not of clinical significance.

Careful palpation of the vas deferens is also a critical component of the spermatic cord assessment. Inability to palpate the vas deferens is consistent with unilateral or bilateral vasal agenesis and may have genetic or renal implications, which are discussed later in this chapter. Nodularity of the vas is also observed from prior infections such as tuberculosis. Vasal thickening is associated with prior scrotal surgery or downstream obstructions such as inguinal vasal obstruction, potentially from prior surgery or ejaculatory duct obstruction.

Finally, a rectal examination should be performed to evaluate prostatic anatomy for midline cysts such as müllerian duct cysts, which can obstruct the ejaculatory ducts. Prostatic induration or tenderness may be seen in acute or chronic prostatitis. Under normal conditions, the seminal vesicles may not be palpable but may be prominent in the setting of ejaculatory duct obstruction. After obtaining a thorough history and a comprehensive physical examination, the clinician has a number of available tools to further evaluate the infertile male, ranging from the basic semen analysis to testicular biopsy, as well as imaging studies.

LABORATORY EVALUATION OF MALE INFERTILITY

Semen Analysis

Semen analysis is one of the most important predictors in determining the fertility potential of a man. Appropriate laboratory testing of semen plays a key role in evaluation of men presenting with infertility. However, semen analysis does not allow for the definitive separation of patients into fertile and sterile, in case of azoospermia. It is important to understand that although the statistical chance of conception decreases as the semen quality declines, it does not reach zero. The basic semen testing is inexpensive and determines the quality and the quantity of the spermatozoa. More advanced testing is available to patients who suffer from idiopathic infertility in order to determine specific causes. The analysis of semen evaluates a variety of parameters including characteristics of spermatozoa, seminal plasma, and non–sperm cells.

Collection and Timing

Physicians should provide patients with standard guidelines for the collection of semen because suboptimal sperm collection remains a frequent cause of error in semen analysis. There should be 2 to 7 days of sexual abstinence before collection. Two separate samples at least 7 days apart should be analyzed (Rowe, 2000; Jeyendran, 2003). The duration of abstinence should be constant, if possible, because each additional day can add as much as 25% in sperm concentration (Carlsen et al, 2004). Lubricants should be avoided because they may interfere with motility results. Coitus interruptus should be discouraged because it often leads to inaccurate results (i.e., the first part of the ejaculate, which contains most of the sperm, may be lost).

Masturbation in a clinical setting is the recommended procedure. Collection is done in a private room in the same facility where the semen will be analyzed. The glans and the penis should be cleaned with a wet paper towel (soap should be avoided). Lubricant use is discouraged but, if necessary, should not be applied to the glans. A clean, sterile container should be used for specimen collection. The container should be provided by the laboratory to avoid contamination or spermicidal effects. The main advantages of this collection method are its simplicity, noninvasiveness, and inexpensiveness (Jeyendran, 2003).

Some men may not be able to achieve adequate erection and ejaculation. Assistance can be provided to them by oral medications such as phosphodiesterase type 5 inhibitors given 30 to 60 minutes before collection. Cavernosal and subcutaneous injections of prostaglandins are less popular but remain possible options for patients who have erectile dysfunction. Seminal pouches that do not contain any spermicides allow the patient to engage in sexual activity if he is incapable of or uncomfortable producing specimens by masturbation. Vacuum erection devices can also be used to obtain erection by creating a vacuum around the penis, generating a pressure differential that fills the corpora with blood. Vibratory stimulation may be used for patients who have suffered spinal cord injury, if the spinal cord lesion is T8 and above (Brown et al, 2006). Rectal probe electro-stimulation induces ejaculation by stimulation of the efferent fibers of the hypogastric plexus. Precautions for autonomic dysreflexia should be taken while doing these procedures because some patients with high spinal cord lesions (T6 and above) can have life-threatening hypertension (Jeyendran, 2003).

In order to allow liquefaction and mixing, semen is placed in a 37° C gently shaking incubator for 30 minutes. The semen sample should be examined within 1 hour of production and receipt in the laboratory. Some of the semen parameters can be affected by a delay in assessment. Motility decreases significantly after 2 hours and progressively diminishes afterwards as free radical activity increases.

The semen analysis characteristics can be classified into two groups: macroscopic and microscopic.

Macroscopic Assessment

The five macroscopic measurements in a standard sperm analysis have remained fairly constant, with the normal values remaining relatively unchanged since the inception of the semen analysis in the 1950s (Table 21–2). Normal human semen is an off-white to grayish-yellow opalescent fluid. In event of urine contamination, the semen sample has a yellow discoloration. The semen may appear pink in patients with urethral bleeding and yellowish in jaundice patients. During the time of ejaculation, the spermatozoa are suspended in the secretions of prostate, seminal vesicles, bulbo-urethral glands, and other accessory glands that form a coagulum. The specimen usually liquefies within 30 minutes. However, semen obtained from patients with congenital bilateral absence of the vas usually does not form a coagulum and is acidic. Liquefaction is aided by the proteolytic enzyme fibrinolysin, secreted by the prostate. Improper or prolonged liquefaction indicates an ejaculatory duct obstruction or poor prostatic secretion. Viscosity and nonliquefaction are two different phenomena often confused. Viscosity relates to the fluid nature of the sample. It is measured by dropping the semen sample into a container using a pipette and observing the length of the thread formed. Increased viscosity is often associated with infertility because it is known to impair sperm movement. Semen samples that are highly viscous can be treated with enzymes such as trypsin before they are processed for therapeutic purposes. Measurement of pH is a standard component of semen analysis and is largely determined by the

Table 21–2.

Macroscopic Features of Semen Analysis

PARAMETERS	NORMAL VALUES	ABNORMALITIES	CLINICAL SIGNIFICANCE
Ph	7.8	Acidic: <6.5-7	With low volume and noncoagulation: congenital bilateral absence of vas deferens Ejaculatory duct obstruction Partial retrograde ejaculation
Coagulation/ liquefaction	Coagulates and liquefies within 20 minutes at room temperature of 37° C	No coagulation Prolonged liquefaction	Congenital absence of the seminal vesicles Poor prostatic secretions
Color	Whitish-gray; pearl-white	Yellowish color Reddish brown	Jaundice, carotenemia, drugs Haemato-spermia secondary to urethral bleeding or inflammation of the seminal vesicles, exclude genitourinary tumors
Viscosity	4-mm threading	>6 mm No threading	Important when associated with low motility
Volume	2-4 mL	0 (aspermia) <2 mL (hypospermia) >4 mL	Retrograde ejaculation Incomplete collection Partial retrograde ejaculation Short duration of sexual abstinence Prolonged sexual abstinence

secretions from the seminal vesicles and the prostate. The normal range of pH has been defined as 7.2 to 8.0. Because the secretions of seminal vesicles are alkaline, acidic pH indicates congenital absence of the vas with the associated seminal vesicle hypoplasia seen in azoospermic patients (WHO, 1999).

Microscopic Assessment

Sperm Agglutination. The microscopic examination starts with the creation of a wet smear by placing a drop of semen on a slide covered with a cover slip and observing it under 1000× magnification. Sperm agglutination, sperm presence, and subjective motility can be assessed by this method. Sperm adhesion to nonsperm elements (nonspecific agglutination) may indicate accessory gland infection. Sperm-to-sperm agglutination (site-specific agglutination) can be secondary to antisperm antibodies; however, it should be kept in mind that a small degree of agglutination is normal (WHO, 1999). When agglutination is observed, semen cultures and antibody assessment should be performed.

Count and Concentration. Assessment of sperm concentration (number of sperm per milliliter) and sperm count (number of sperm per ejaculate) is conducted after liquefaction. Multiple counting chambers are used for sperm count determination where sperm are counted within a grid pattern. The normal sperm concentration is reported as greater than or equal to 20 million sperm/mL. Attention should be given to collection problems in order to rule out incomplete collection or a short abstinence period before starting evaluation of oligospermia (<20 million sperm/mL). Azoospermia (absence of sperm) may be the result of abnormal spermatogenesis, ejaculatory dysfunction, or obstruction. These specimens should be centrifuged and the pellet examined for the presence of any sperm. Polyspermia (abnormally elevated sperm concentration), although rare, may be caused by a long period of abstinence and is often associated with sperm of poor quality.

When oligospermia is reported, the levels of motility and morphology become especially important. Total motile sperm counts guide decisions on appropriate therapies including the use of ARTs. In cases of azoospermia and severe oligospermia, hormonal evaluation (FSH and testosterone) should be requested. Karyotyping and Y microdeletion may provide valuable information regarding the etiology of the patient's abnormal semen parameters and important information if in-vitro fertilization (IVF) is being entertained as a treatment option. Foci of microdeletions in the Y chromosome are associated with impaired spermatogenesis and, depending on their location, may predict poor sperm retrieval even with testicular biopsy. Karyotyping may also detect autosomal or X-linked genetic aberrations causing infertility. Knowledge of the chromosome status is important because male offspring conceived with intracytoplasmic sperm insemination (ICSI) or even natural conception most likely will inherit the same microdeletion (Krausz et al, 2000).

Motility. Motility is recognized as the most important predictor of the functional aspect of spermatozoa. Sperm motility is a reflection of the normal development of the axoneme and the maturation that it undergoes within the epididymis. This parameter is subject to significant potential for technical mistakes in the laboratory. The method most commonly employed by laboratories is the simple estimation of the motility of sperm on several fields. This subjective assessment is prone to inaccuracy. Moreover, in-vitro motility of sperm may not reflect the true motility within the female reproductive tract. The sperm motility is graded according to the WHO as follows: A—Rapid forward progress motility; B—Slow or sluggish progressive motility; C—Nonprogressive motility; and D—Immotility. The cutoff value for normal is 50% grade A+B or 25% grade A motility (Rowe, 2000). In addition to organic causes, asthenospermia (sperm motility less than the WHO cutoff levels) can also be artifactual when spermicides, lubricants, or rubber condoms are used. Occasional clumps of agglutinated sperm are of no consequence. However, more than 10% to 15% of clumping of spermatozoa is indicative of antisperm antibodies (ASAs). ASA is known to reduce sperm motility and cause a peculiar shaking pattern that prevents spermatozoa from penetrating through the cervical mucus. ASA testing must be performed to rule out the presence of antibodies. Other potential causes of asthenospermia include prolonged abstinence periods, genital tract infection, partial ductal obstruction, and varicocele. Loss of motility in all spermatozoa or less than 5% to 10% motility can be caused by ultrastructural defects such as absence of axonemal dynein arms or dead sperm (necrospermia) (McLachlan, 2003).

Morphology. Sperm morphology is the most subjective and most difficult-to-standardize semen parameter. Accurate

assessment of morphology is critical in the evaluation of an infertile male because it can be a significant predictor of pregnancy. Normal sperm possess an oval head with a well-defined acrosomal region composing 40% to 70% of the head area. The dimensions of the head are 4 to 5.5 µm in length and 2.5 to 3.5 µm in width. The normal sperm are free from head, midpiece, or tail defects. Head defects include microcephalic head (approximately half the size of a normal sperm head), megalocephalic head (one-and-a-half times the size of a normal sperm head), tapered head, round sperm (missing acrosome), and bicephalic or multicephalic head. Neck defects include no tail or improper tail insertions. Midpiece defects comprise elongated, distended, thin, or bent midpieces. Some of the tail defects commonly noted are short, multiple, bent, or broken tails. One common defect includes coiled tail, which is indicative of osmotic stress (McLachlan, 2003).

Sperm morphology is expressed as percentage of abnormal forms present in the semen. The two most common classifications used for the assessment of sperm morphology are the WHO criteria and Kruger's strict criteria (Table 21–3). When correctable causes of male infertility are not identified, couples with teratozoospermia (<15% normal morphology by WHO method) may be directed to proceed with IVF and ICSI as compared with intrauterine insemination (IUI). Teratozoospermia may occur due to several factors such as fever, varicocele, and stress. Some drugs that affect spermatogenesis are also known to cause morphologic abnormalities. With the advent of ICSI, which requires only one morphologically and functionally normal spermatozoa to fertilize an oocyte, morphologic assessment is losing its significance (Zinaman, 2000).

Viability. When the motility is reported as less than 5% to 10%, viability testing is recommended because profoundly low motility may indicate dead sperm or necrospermia (McLachlan, 2003). The most common viability assessment involves staining with Eosin Y followed by counter staining with Nigrosin. The viable sperm with its intact cell membrane will not take up the dye and will remain unstained. This test will differentiate necrospermia from immotile sperm secondary to ultrastructural defects such as in Kartagener syndrome and primary cilia dyskinesia.

Hypo-osmotic swelling test (HOST) is an alternative method to assess sperm viability. It is based on the principle that viable sperm have intact cell membranes. Exposure of the sperm to hypo-osmotic fluid will cause water to flow into the viable cells seen as swelling of the cytoplasmic space and curling of the sperm tail. Nonviable sperm with nonfunctional cell membranes will not exhibit this effect because they cannot maintain an osmotic gradient. This reproducible and relatively inexpensive test aids in selection of viable sperm for use in IVF or ICSI, especially when no motile sperm are seen in the cryopreserved specimens (Check, 2002).

Nonsperm Cells. Several nonsperm elements noted on seminal microscopic examination are immature germ cells, epithelial cell, and leukocytes (Branigan et al, 1995; Fedder, 1996). Epithelial cells when present in high numbers are indicative of poor collection. Leukocytes are the most significant nonsperm cellular elements in the semen and are a frequent finding in patients who have unexplained infertility (Branigan et al, 1995). However, in the initial microscopic analysis, the immature spermatozoa may be confused with leukocytes. To confirm the presence of leukocytes, additional testing is therefore required when there are greater than five round cells per high-power field (HPF). Immunocytochemistry is the procedure of choice, but given its expense, it is not widely used in most laboratories. The Endtz test is a reliable alternative because it allows accurate identification of leukocytes that contain enzymes that will react with peroxide and can be visualized with the orthotoluidine dye (Shekarriz et al, 1995). Initially considered solely as a marker of genital tract infection, contemporary research has shown that leukocytes can be present in the absence of other signs of infection or immune response (Lackner et al, 2006) and that they have intimate links with reactive oxygen species (ROS) (Aitken et al, 1994; Sharma et al, 2001; Saleh et al, 2002; Lackner et al, 2006). The WHO has defined leukocytospermia as levels above 1×10^6 WBC/mL. Studies have shown, however, that ROS levels are elevated even at WBC counts of less than 0.2×10^6/mL, suggesting that much lower levels of leukocytes are pathologic (Sharma et al, 2001; Athayde et al, 2007). In a 12-month follow-up, men who had a negative Endtz test (zero) had a 23.7% chance of initiating pregnancy, whereas leukocytes levels of less than 1×10^6/mL lowered the chances to 15.5% (Athayde et al, 2007). In many andrology laboratories, leukocytospermia

Table 21–3.
Sperm Morphology Classification

	WORLD HEALTH ORGANIZATION 3RD	STRICT WORLD HEALTH ORGANIZATION 4TH (KRUGER)
Normal reference range	>30%	>14%
Head		
Shape	Oval	Oval, smooth borders
Acrosome	40%-70% of head surface	40%-70% head surface
Size	4-5.5 mm length 2.5-3.5 mm width Length/width 1.5-1.75	3-5 mm length 2-3 mm width
Vacuoles	<20% head area	Up to 4
Midpiece		
Shape	Straight regular outlined Axially arched	Slender, straight, regular outline Axially arched

Tail		
Appearance	Slender, uncoiled	Uniform, uncoiled
Width		Thinner than midpiece
Length	>45 mm	10 × head

determination still has to be requested separately. However, its significance and the ease of determination should place this test among the standard testing that accompanies a basic semen analysis. When leukocytospermia is identified, semen cultures should be performed. Furthermore, red blood cells (RBCs) are also often present in semen. Although small amounts are usually a normal finding, they can be indicative of infection, inflammation, ductal obstruction, or rarely vascular abnormalities.

Computer-Assisted Sperm Analysis

Computer-assisted sperm analysis (CASA) is a semiautomated technique that provides data on sperm density, motility, straight-line and curvilinear velocity, linearity, average path velocity, amplitude of lateral head displacement, flagellar beat frequency, and hyperactivation. It has two distinct advantages over traditional manual analyses: high precision and quantitative assessment of sperm kinematics. Sperm concentration, samplepreparation, and frame rate can, however, affect accuracy of the CASA (Mortimer, 1994). The use of some stains has also affected the accuracy of determining the sperm morphology. Although this technology has theoretic advantages, it has not translated into benefits in clinical practice. This test requires expensive equipment and still requires the active participation of a technician. Therefore at present, these machines are found commonly in andrology laboratories, not in general pathology laboratories, where most of the initial semen analyses are analyzed (Amann and Katz, 2004). Presently, the most important role of CASA is to provide standardized aids in quality control and quality assurance in andrology laboratories, as the emerging use of ICSI has diminished the role of motility assessment in sperm selection (Amann and Katz, 2004).

Limitations of Semen Analysis

The true litmus test for male fertility remains the ability to cause pregnancy in vivo. Although the semen analysis is used as a surrogate measure of a man's fertility potential, it is not a direct measure by any means. Clinical research has shown that normal semen analysis may not reflect defects in sperm function (idiopathic infertility), and men with poor sperm parameters still may cause spontaneous pregnancies. Only 50% of infertile men have recognizable causes detectable by the basic semen analysis (MacLachlan, 2003). The presence of several criteria further reinforces the emerging opinion that the current standards do not reflect the true fertility potential of subjects. The current normal values fail to satisfy clinical and statistical standards (McLachlan, 2003; Nallella et al, 2006) and pose the risk of misclassifying a subject's true fertility status. In fact, 20% of 18-year-olds would be classified as subfertile using the WHO cutoff of 20×10^6 sperm/mL (Andersen et al, 2000). Studies on semen donors with known fertility status have revealed a significant overlap in the sperm characteristics between fertile and subfertile men (Li et al, 2006; Nallella et al, 2006). Guzick and colleagues (2001) in a study of 1461 men found different cutoff levels in sperm concentration ($<13.5 \times 10^6$ in subfertile and 48×10^6 in fertile men), percent motility (<32% in subfertile and >63% in fertile men), and normal morphology (<9% in subfertile and >12% in fertile men). Nallella and colleagues in 2006 did a similar study ($n = 572$) and used the WHO and Tygerberg criteria on subjects with known fertility. They noted that there is low sensitivity (0.48) in detecting subfertile subjects using WHO reference values for sperm concentration and low sensitivity (0.83) using Tygerberg criteria for percentage of normal morphology. Among the variables, motility had the least overlap range and gave the best prediction of the subject's fertility potential. This is in contrast with the earlier study by Guzick and colleagues, where morphology was reported to provide the highest discriminating power in detecting subfertility among all the semen variables. Clearly, each variable alone is neither a powerful sole discriminator nor a predictor of fertility status, and they must be considered in the context of other parameters and the clinical setting. There remains a need for further studies in larger populations and different demographics before a consensus can be reached on the necessity of resetting current values to increase the predictiveness and utility of the semen analysis (Table 21–4).

Sperm Function Assessment

Sperm-Mucus Interaction/Postcoital Test

Cervical mucus is a heterogenous fluid that is composed of 90% water. In order to reach the site of fertilization, the spermatozoon must be able to successfully traverse the cervix and the cervical mucus. In-vitro penetration of spermatozoa through cervical mucus is comparable to in-vivo conditions. The cervical mucus is shown to demonstrate cyclical changes in consistency and to be highly receptive around the time of ovulation. Increase in penetrability is often observed one day before the LH surge. Cervical mucus has been shown to protect the spermatozoa from the hostile environment of the vagina. The penetrability of the spermatozoa through the cervical mucus can be detected by the cervical mucus migration assay. Some methods by which migration can be detected include the postcoital test (PCT). This test can assess cervical environment as a cause of infertility. Accurate timing is crucial because it must be conducted when the cervical mucus is thin and clear just before ovulation. In this test, cervical mucus is examined 2 to 8 hours after normal intercourse. Progressively motile sperm greater than 10 to 20 per HPF is designated as normal. Practical guidelines of the American Society of Reproductive Medicine recommend PCT in the setting of hyperviscous semen, unexplained infertility, or low-volume semen with normal sperm count (Van der Steeg et al, 2004). Medical history and semen analysis can predict PCT results in half of the infertile couples. Poor-quality semen most likely will have poor PCT. Therefore it is not recommended routinely for men who have abnormal semen analyses. Couples who show defective sperm mucus interaction may be advised to proceed with IUI because additional tests are unlikely to affect the management (Guzick et al, 2001). However, abnormal PCT may result from inappropriate timing of the test. Other causes of abnormal PCT include anatomic abnormalities, semen or cervical mucus antisperm antibodies, inappropriately performed intercourse, and abnormal semen. Persistently abnormal PCT in the presence of reasonably good semen parameters should indicate poor cervical mucus quality. The finding of good-quality mucus with nonmotile spermatozoa or immobilized

Table 21–4.

Characteristics of Normal Semen (World Health Organization, 1999)

Color	White, opalescent
Specific gravity	1.028
pH	7.35-7.50
Volume	2-6 mL
Count	2×10^6 spermatozoa/mL or more
Motility	≥50% motile (grades A + B) or 25% with progressive motility (grade A)
Morphology	>30% sperm with normal morphology
Viability	≥50% viable sperm
Pus cells	$<1 \times 10^6$/mL of semen

sperm demonstrating shaking motion should lead to the evaluation of both partners for the presence of antisperm antibodies. Although it has fallen out of favor, this test may be useful in patients who are unable or unwilling to produce an ejaculate.

Acrosome Reaction

The Acrosome is a membrane-bound organelle that covers the anterior two thirds of the sperm head. Acrosome reaction is an important prerequisite for successful fertilization. It is an exocytotic event that involves fusion of outer acrosomal membrane and sperm plasma membrane, which enables the exposure of acrosomal contents through the formation of vesicles. The two important acrosomal enzymes that are required to digest the oocyte cumulus cells and zona pellucida include acrosin and hyaluronidase. Acrosome reaction testing is not widely practiced in laboratories and only remains a research interest. However, this test may be recommended in cases of profound abnormalities of head morphology or in the setting of unexplained fertility in patients with poor IVF pregnancy rates. Normal semen samples demonstrate spontaneous acrosome reaction rates of less than 5% and induced acrosome reaction rates of 15% to 40%. Infertile populations have shown high spontaneous rates of acrosome-reacted sperm and low rates of induced acrosome reactions. Although not widely practiced due to its cost and labor, the structure of the acrosome can be studied under transmission electron microscopy. Other techniques such as fluorescence microscopy and beads coated with antiacrosomal antibodies have been developed, but these tests are also not readily available in standard laboratories.

Sperm Penetration Assays/Sperm Zona Binding Tests

The sperm penetration assay (SPA) or the hamster egg penetration assay (HEPT) determines the functional capacity of the spermatozoa necessary to fertilize an oocyte. It is based on the principle that normal spermatozoa can bind and penetrate the oocyte membrane, which is a prerequisite for the fusion of sperm and the oocyte. Zona pellucida is the outermost layer protecting the cytoplasm of the oocyte. It plays an important role in the fertilization process and is shown to be the only physiologic inducer of acrosome reaction. Sperm binds to the species-specific receptor, ZP3, which is found on the zona pellucida of the oocyte. The zona-free hamster oocytes, in which the zona pellucida is stripped, are used to allow cross-species fertilization. Human sperm penetration assay with zona-free hamster eggs determines the ability of sperm to successfully undergo capacitation, acrosome reaction, membrane fusion with oocytes, and chromatin decondensation. The assay is performed by incubating zona-free hamster oocytes in sperm droplets for 1 to 2 hours. The oocytes are examined microscopically for sperm penetration. Penetrations are indicated by swollen sperm heads within the oocyte cytoplasm. Normally, 10% to 30% of ova are penetrated (WHO, 1999). Oligozoospermic and severely teratospermic men have a higher number of defective sperm-zona pellucida interactions, which may account for their low fertility potential in both spontaneous and IVF pregnancies (Liu and Baker, 2004). Despite its low predictive power, SPA is correlated positively with spontaneous pregnancy outcomes (Corson et al, 1988). Sperm capacitation index (SCI) is a variant of the SPA test, assessing the mean number of penetrations per ovum. ICSI has been recommended for couples with an SCI less than 5 instead of standard IVF procedures (Ombelet et al, 1997). Compared with SPA, the zona binding test uses oocytes that failed to fertilize in IVF clinics. The need for human oocyte supply, however, remains a limitation to the use of this test.

Advanced Semen Testing

Antisperm Antibody Testing

The tight Sertoli-cell junctions provide the testis with a barrier that prevents the immune system from coming in contact with the post-meiotic germ cells. However, in certain conditions such as testicular torsion, vasectomy, and testicular trauma, this unique barrier can be violated, resulting in an immune response to sperm, displayed as antisperm antibodies (ASABs). These antisperm antibodies can be several types—sperm agglutinating, sperm immobilizing, or spermotoxic. The sperm agglutinating type causes agglutination of spermatozoa, which reduces the availability of motile spermatozoa penetrating the cervical mucus. Sperm-immobilizing antibodies induce loss in motility of the sperm, which can be identified by the characteristic "shaking" pattern in motility on postcoital test. The spermotoxic type of ASAB causes a complement-dependent loss in viability of spermatozoa.

Approximately 10% of infertile men will present with ASA as compared with 2% of fertile men (Guzick et al, 2001). Sperm parameters are often normal in men with ASA (Munuce et al, 2000). Hence it has been suggested to be tested routinely in all men undergoing infertility work-ups (McLachlan, 2003). Excessive sperm agglutination or an abnormal PCT can suggest the presence of ASA.

The direct ASA test detects sperm-bound immunoglobulins. Indirect testing detects the biologic activity of circulating ASA. False positives can result from nonimmunologic factors (Francavilla et al, 2007). Because only antibodies present on the sperm surface are clinically significant, most investigators prefer direct assays that determine sperm-bound antibodies instead of indirect detection of serum antisperm antibodies. IgG-MAR (mixed antiglobulin reaction) and Sperm MAR are recommended screening tests that are economical and readily available. Immunobead Test (IBT), which measures IgG, IgA, and IgM, may be additionally recommended when either of the previous tests gives a positive result in order to determine if IgA are bound to sperm surface. Acceptable normal values by WHO (1992) standards include less than 10% (IgG MAR) or 20% (IBT) of spermatozoa with adherent particles.

Clinical implications of ASA on male infertility are varied. A weakly positive IgG MAR/IBT in men who have low motile sperm rules out immunologic factors, and no further testing is necessary (Francavilla et al, 2007). ASA are present in 34% to 74% of vasectomized men and persist in 38% to 60% after vasectomy reversal (Broderick et al, 1989; Francavilla et al, 2007). Routine ASA testing is not recommended in this setting because it is of uncertain significance and usually does not affect the decision to do a vasectomy reversal. There are conflicting reports regarding ASA levels after orchidopexy for cryptorchidism (Mirilas et al, 2003). In genitourinary infections, ASA is thought to be a consequence of the inflammatory process rather than cross reactivity to the microorganism (Francavilla et al, 2007).

The decision to proceed with IUI versus ICSI in immunologic infertility can be aided by a zona pellucida (ZP) test. If the sperm exhibit inability for ZP binding, ICSI is the procedure of choice. Presently, flow cytometry techniques are being developed to quantify ASA in individual spermatozoa (Shai et al, 2005). These techniques are also being explored to identify sperm surface antigens for possible immunocontraceptive development.

Electron Microscopy

Spermatozoa may test positive for viability even in the presence of ultrastructural defects. Ultrastructural details of the sperm can

only be seen under the electron microscope (EM). Patients who have low sperm motility (<5% to 10%) with high viability (as determined by HOST or Eosin-Nigrosin staining) and density may be appropriate candidates for EM assessment. Subfertile men may demonstrate more serrated and blurred circular sulcus, less intact acrosome membrane, a bigger proportion of the spermatic head, and more droplets attached to the acrosome membrane. Mitochondrial and microtubular defects that are not visible under the usual Papanicolaou smear can be detected.

Biochemical Tests

Acrosin is a serine protease-like enzyme that exhibits a lectin-like carbohydrate binding activity to the zona pellucida glycoproteins. Low acrosin activity has been associated with low sperm density, motility, and poor normal morphology (Xu and Zhan, 2006).

Zinc is necessary for chromatin stability and decondensation, as well as for head–tail detachment during fertilization. It is measured by colorimetric methods with a reference value of 13 mmoL per ejaculate (WHO, 1999). Reports on the effects of zinc in sperm function and semen parameters are quite conflicting. Mankad and colleagues (2006) reported positive correlations between seminal zinc levels, alpha glucosidase, and sperm count; however, there are other reports that showed no significant changes in sperm count and motility with variations in zinc concentration (Abou-Shakra et al, 1989; Lewis-Jones et al, 1996; Sorensen et al, 1999). Zinc levels in seminal plasma are decreased, but spermatozoal zinc levels are increased in asthenozoospermic and oligoasthenozoospermic men (Zhao and Xiong, 2005). A low zinc-to-calcium ratio has been shown to be associated with better motility than high ratio (Sorensen et al, 1999). However, dietary supplementation of zinc did not improve semen variables (Agarwal and Said, 2004).

The seminal vesicles contribute to the bulk of seminal fluid that serves as the transport medium for sperm and contribute to the nutrition in the form of fructose. There is a positive correlation between sperm motility and seminal fructose levels (Lewis-Jones, 1996). Low or absent fructose is seen in ductal obstruction and congenital conditions like CBAVD. Semen fructose testing may be requested when hypo-functioning seminal vesicles are suspected, although morphometric analysis of seminal vesicles using transrectal ultrasound (TRUS) is the recommended test nowadays.

L-carnitine is secreted by the epididymis and is concentrated in the seminal plasma at up to 10 times the serum levels. It has a role in sperm maturation. Low L-carnitine levels are found in oligoasthenozoospermic men (Agarwal and Said, 2004; Sigman et al, 2006). The levels of carnitine can possibly serve as indicators of the level of obstruction in the ductal system. Extremely low concentrations of L-carnitine are found in azoospermic men who have postepididymal obstructions, whereas normal levels are found in azoospermic men who have intratesticular obstructions (Agarwal and Said, 2004). Administration of L-carnitine supplements did not improve sperm density, but contrasting results have been reported for sperm motility changes (Sigman et al, 2006). L-carnitine determinations remain far from becoming mainstream tests in male infertility until significant well-designed studies are conducted.

Alpha glucosidase, tested by fluorimetric methods, has been used to distinguish nonobstructive from obstructive azoospermia. It is used as a specific marker for epididymal function and is believed to play a role in sperm maturation in the epididymis. A cutoff value of 12 mIU/mL distinguishes ductal obstruction from primary testicular failure (Comhaire et al, 2002). The usefulness of this test was questioned by Krause and Bohring (1999), but Comhaire and colleagues (2002), in their review, showed a strong association between α-glucosidase and semen parameters. The cutoff level had 95% specificity in identifying obstructive azoospermia. This suggests that the test can predict IUI response (higher pregnancy rate >78 U per ejaculate) because high levels indicate better zona-binding capacity (Comhaire et al, 2002). The presence of commercial test kits using colorimetric methods promises to make testing accessible and affordable.

Reactive Oxygen Species

Research conducted during the past decade has provided growing support for the concept that excessive production of reactive oxygen species (ROS) is related to abnormal semen parameters and sperm damage. Routine semen analysis remains the backbone of clinical evaluation in male infertility, and determining the levels and sources of excessive ROS generation in semen is currently not included in the routine evaluation of subfertile men. However, the diagnostic and prognostic capabilities of seminal oxidative stress measurement exceed the capabilities of conventional sperm quality tests. An oxidative stress test may accurately discriminate between fertile and infertile men and identify those with a clinical diagnosis of male factor infertility who are likely to initiate a pregnancy if they are followed over a period of time. In addition, such a test can help select subgroups of patients with infertility in which oxidative stress is an important factor and who may benefit from antioxidant supplementation. Although consensus is still required about the type and dosage of antioxidants to be used, rationale and evidence exist supporting their use in infertile men with elevated oxidative stress (Deepinder et al, 2008).

Currently, clinical practice as to the inclusion of ROS measurement is variable, primarily because of the lack of standardization of ROS analytic methods, equipment, and range of normal levels of ROS in semen. The evidence defining high ROS levels as a cause or an effect of abnormal semen parameters and sperm damage is still insufficient on both sides of the question. However, it has been reported that a high level of ROS is an independent marker of male factor infertility in leukocytospermic samples after adjustment for semen characteristics. This finding suggests that ROS may play an important role in the etiology of male factor infertility and encourages the use of ROS measurement as a diagnostic tool in clinical practice, particularly in cases of idiopathic infertility. Although numerous assays for ROS measurement have been introduced, the chemiluminescence assay, determining ROS levels in neat semen, has proven to be an accurate and reliable test for evaluating oxidative stress status. This technique accurately represents an individual's true in vivo oxidative stress status and overcomes the drawbacks of earlier methods that involve processing semen, a step that may generate ROS by itself. The ROS level for healthy donors with normal standard semen parameters is 1.5×10^4 cpm/20 million sperm/mL. Using this value as a cutoff, infertile men can be classified as either oxidative stress positive ($>1.5 \times 10^4$ cpm/20 million sperm/mL) or oxidative stress negative ($\leq 1.5 \times 10^4$ cpm/20 million sperm/mL), regardless of their clinical diagnosis or standard semen analysis results (Deepinder, et al, 2008).

Sperm DNA Damage

DNA fragmentation was initially described in 1993 and has since been researched as a test to aid fertility prediction in subfertile males. The spermatozoal chromatin is a tightly packed structure because of the disulfide cross linkages between protamines that allow compaction of the nuclear head and protect the DNA fragments from stress and breakage. DNA damage is multifactorial and theories on its etiology include protamine deficiency and mutations that may affect DNA packaging or compaction during spermiogenesis (Agarwal and Said, 2003). Various factors found to be

associated with increased sperm DNA damage include tobacco use, chemotherapy, testicular carcinoma, and other systemic cancers (Agarwal and Said, 2003). DNA damage is correlated positively with poor semen parameters, especially low sperm concentration and low sperm motility, leukocytospermia, and oxidative stress (Erenpreiss et al, 2002; Agarwal and Said, 2003; Zini and Libman, 2006). Approximately 8% of subfertile men who have normal semen parameters will have high abnormal DNA (Aitken et al, 1991).

Many tests of sperm DNA damage are now available (Table 21–5). The use of these tests has been driven largely by the growing use of assistive reproductive technologies and awareness that the integrity of the male genome plays an important role in IVF. Sperm DNA damage can be measured directly (fragmentation, oxidation) or indirectly (sperm chromatin compaction). Direct assessment of DNA damage can be obtained by means of single-cell gel electrophoresis assay or "comet" assay (electrophoresis causes DNA fragments to migrate away from the central DNA core, revealing a "comet"), terminal deoxynucleotidyl transferase-mediated dUTP-nick end-labeling or "TUNEL" assay (the ends of fragmented DNA are tagged), and liquid chromatography to measure DNA oxidation levels. DNA damage can also be assessed indirectly by means of sperm chromatin integrity assays and by evaluation of nuclear protein levels. Sperm chromatin integrity assays include slide-based sperm nuclear protein stains (e.g., aniline or toludine blue [detects histones], CMA3 [detects underprotamination]) and DNA stains (e.g., acridine orange [detects denatured or single-stranded DNA]). The sperm chromatin structure assay (SCSA) uses flow cytometry to estimate the percentage of spermatozoa with DNA denaturation (spermatozoa are stained with acridine orange). A cutoff rate of greater than 30% has been shown to be associated with a significant decrease in in-vivo fertilization rates (Evenson and Wixon, 2002). A DNA fragmentation index (DFI) of greater than 30% has a sensitivity of 15% and a specificity of 96%. Meta-analyses by Evenson and Wixon (2002) and Li and colleagues (2006) showed that couples are twice as likely to become pregnant with regular IVF methods if the DFI is less than 30%. Contrasting reports, however, have failed to show significant correlation between DNA damage and idiopathic infertility (Verit et al, 2006). In addition, significant intraindividual variation exists making conclusions using SCSA problematic (Erenpreiss et al, 2006). There is a higher rate of DNA damage in ejaculated or epididymal sperm than in intratesticular spermatozoa. Hence the use of intratesticular spermatozoa from high DFI men is recommended for ICSI (Steele et al, 1999; Greco et al, 2005). ICSI is advised when DFI is above cutoff levels. DNA fragmentation testing can help couples decide on what fertility modality and possible lifestyle modifications they can employ to increase their chances of conception.

Table 21–5.

Commonly Used Tests of Sperm DNA Damage

TEST	MEASURES	CHARACTERISTICS
Sperm chromatin structure assay	Susceptibility of sperm DNA to denaturation	Objective, flow cytometry–based, indirect assay, complex analysis, used clinically
Nuclear protein composition (by protein separation)	Sperm histone and protamine levels	Objective, gel electrophoresis assay, indirect assay, labor intensive
Sperm nuclear maturity test (by nuclear staining)	Chromatin compaction, protamine content	Simple, semiquantitative, slide-based, indirect assay
Comet assay (by single-cell gel electrophoresis)	Double-stranded DNA breaks (neutral assay)	Objective, quantitative, direct assay, complex image analysis
TUNEL assay	Double-stranded DNA breaks	Semiquantitative, direct assay, quantitative if flow cytometry based
DNA oxidation	8-hydroxy-2-deoxyguanosine	Quantitative, direct assay, labor intensive

Endocrine

Although an uncommon cause of male subfertility, up to 3% of infertile men will have an underlying endocrinopathy (Sigman et al, 1997). Although some authors recommend routine screening of the male hypothalamic-pituitary-gonadal axis in all patients, the consensus opinion favors endocrine evaluation in men with (1) an abnormally low sperm concentration, especially if less than 10 million/mL; (2) impaired sexual function; or (3) other clinical findings suggestive of endocrinopathy such as marked reduction in testicular size or gynecomastia (AUA/ASRM Practice Committee Recommendations, 2006).

Initial endocrine evaluation in those with indications for testing should include serum follicle-stimulating hormone (FSH) and morning serum testosterone measurements. Gonadotropins and testosterone are secreted in a pulsatile manner, and some advocate pooled specimens drawn at 15 minute intervals to increase accuracy, although most recommend screening with a single morning specimen. Morning specimens are preferred due to a normal physiologic decline in testosterone levels throughout the day. Table 21–6 demonstrates commonly observed endocrine patterns associated with various clinical diagnoses. Under normal conditions, FSH secretion is under negative feedback control via inhibin B, which is produced by the Sertoli cells (Fig. 21–1). Elevations in serum FSH are indicative of disturbances in spermatogenesis such as primary testicular failure (hypergonadotropic hypogonadism), although normal FSH levels do not rule out spermatogenic failure. Obstructive azoospermia is usually associated with normal gonadotropin and testosterone levels. Low serum testosterone levels may indicate hypogonadism of pituitary or hypothalamic origin, as well as primary testicular failure. If initial testing is abnormal, further endocrine testing should be obtained to include a repeated testosterone assay including free and total testosterone levels, serum luteinizing hormone (LH), and serum prolactin levels. Low FSH and LH levels indicate hypogonadotropic hypogonadism such as Kallman syndrome and warrant a complete pituitary hormonal assessment including thyroid stimulating hormone (TSH), adrenal corticotropic hormone (ACTH), and growth hormone assays. Direct measurement of serum inhibin levels may provide a more accurate assessment of spermatocytic health than FSH levels, although most find that the cost of this assay and lack of widespread availability limit its clinical utility (Sussman et al, 2008).

Hyperprolactinemia is usually associated with low serum testosterone often without associated increases in LH levels, suggesting that the hypothalamic-pituitary axis is unresponsive in the setting of elevated serum prolactin levels (Carter et al, 1978). Prolactin tests should be repeated due to marked physiologic variability in serum prolactin levels. Mild serum prolactin elevations (<50 ng/mL) may be seen with medications, stress, and renal insufficiency or may be idiopathic. However, if the prolactin level is persistently elevated, a pituitary tumor such as a prolactinoma should be ruled

Table 21–6.

Patterns of Endocrine Testing by Diagnosis

DIAGNOSIS	FSH (mIU/mL)	LH (mIU/mL)	TESTOSTERONE (ng/dL)
Normal	Normal	Normal	Normal
Obstruction	Normal	Normal	Normal
Primary Testicular Failure Histology			
Hypospermatogenesis	High	Normal or high	Normal or low
Germinal cell aplasia	Very high	High	Low
Maturation arrest	Normal	Normal	Normal
Klinefelter syndrome	Very high	High	Low
Hypogonadotropic Hypogonadism	Low	Low	Low

FSH, follicle-stimulating hormone; LH, luteinizing hormone.

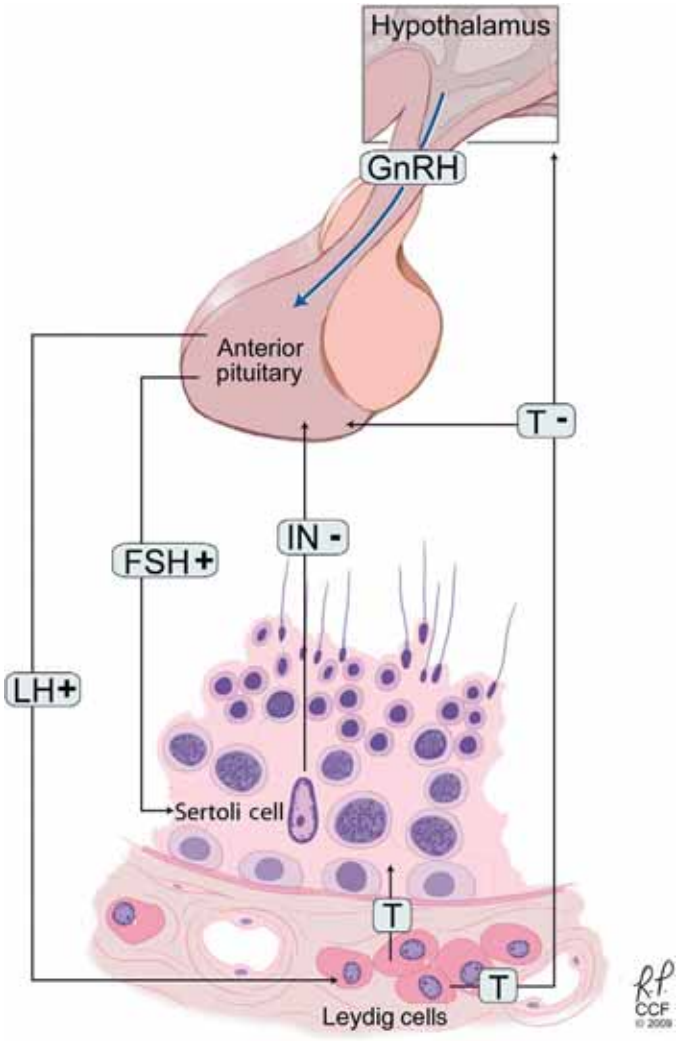

Figure 21–1. The hypothalamic-pituitary-testicular axis. Gonadotropin-releasing hormone (GnRH) is released from the hypothalamus, stimulating luteinizing hormone (LH) and follicle-stimulating hormone (FSH) release. The gonad is stimulated with FSH inducing stimulation of germinal cell epithelium and LH inducing testosterone production by the Leydig cells. Both testosterone (T) and inhibin (IN) downregulate gonadotropin release.

out with a focused neurologic examination including visual field testing and magnetic resonance imaging of the pituitary fossa.

Estrogen excess may be manifested by gynecomastia, decreased libido, erectile dysfunction, and low serum testosterone levels. Although elevated serum estradiol levels may be from exogenous

Table 21–7.

Factors That Impact Sex Hormone Binding Globulin Levels

INCREASE	DECREASE
Estrogen	Obesity
Medications	Medications
Anticonvulsants	Progestins
Thyroid replacement	Insulin
	Glucocorticoids
Hyperthyroidism	Hypothyroidism
Cirrhosis	Acromegaly
Aging	Nephrotic syndrome

intake, they are more commonly associated with morbid obesity due to the peripheral aromatization of testosterone to estradiol in adipose cells. Estradiol stimulates sex steroid hormone binding globulin (SHBG) production in the liver, which reduces levels of bioavailable testosterone. SHBG levels are also influenced by a number of other conditions (Table 21–7).

On rare occasions, endocrinopathies involving adrenal or thyroid functions may present with male subfertility. Patients with congenital adrenal hyperplasia (CAH) present with a history of precocious puberty and short stature due to premature closure of the epiphyseal plates. The common variant involving 21-hydroxy deficiency will have elevated serum levels of 17-hydroxyprogesterone and urinary pregnanetriol. Although CAH patients may retain fertility, many will have reduced testicular function due to suppression of gonadotropin levels from direct feedback inhibition of the pituitary from the excessive adrenal androgens.

Thyroid disease, both hyperfunction and hypofunction, may occasionally be associated with male factor infertility, although subclinical hypothyroidism does not impact semen parameters (Trummer et al, 2001). Thyroid function testing of the infertile male is not justified for routine screening but should be reserved for patients with clinical symptoms of thyroid dysfunction.

Genetic Testing

Genetic testing is important for establishment of the etiology of infertility, identification of potential future medical issues for the patient, prediction of therapeutic efficacy from various fertility interventions such as varicocele repair and sperm retrieval, and counseling information to couples regarding transmission risk to offspring. Clinically relevant genetic testing for the infertile male include karyotype and y-linked microdeletion assessment, which are used for evaluation of both nonobstructive azoospermia (NOA)

and severe oligospermia, as well as the cystic fibrosis transmembrane conductance regulator (CFTR) gene, which is assessed in men with obstructive azoospermia due to CBAVD. Almost 7% of infertile men will have structural or numeric chromosomal abnormalities. The incidence of karyotype anomalies is inversely proportional to the sperm concentration with a prevalence of 10% to 15% in azoospermia, 5% in oligospermia, and less than 1% in patients with normal sperm counts (De Braekeleer and Dao, 1991; Samli et al, 2006). Microdeletions of the Y chromosome have been described in 10% to 15% of patients with severe oligospermia or azoospermia (Pryor et al, 1997). CFTR mutations have been identified in 88% of patients with CBAVD (Ratbi, 2007). Specific genetic syndromes are reviewed later in this chapter.

OTHER TESTING

Imaging Studies

Radiographic evaluation of the infertile male focuses on identification of patients with genital tract obstruction in the vas deferens or ejaculatory duct, as well as ruling out associated pathologies in certain individuals such as testicular masses or renal anomalies. The tests described here are not required in most individuals but should be used judiciously in those with appropriate indications.

Transrectal Ultrasonography

TRUS provides excellent definition of the prostate, seminal vesicles, ampulla of the vas deferens, and the ejaculatory ducts. TRUS is primarily employed to examine patients suspected to have ejaculatory duct obstruction (EDO). These patients usually have low-volume azoospermia (volume <1 mL) with acidic pH and negative semen fructose. TRUS typically employs the 5- to 7-MHz endocavitary probe with scanning in both the longitudinal and transverse planes. Careful examination of verumontanum may identify midline prostatic cysts such as müllerian or wolffian duct cysts or stones obstructing the ejaculatory duct (Fig. 21–2). Often the ejaculatory duct may not be well visualized, but dilation of the seminal vesicles serves as a de facto sign of ejaculatory duct obstruction. Although not always present with ejaculatory duct obstruction, seminal vesicle width in excess of at least 12 to 15 mm or ejaculatory duct diameter greater than 2.3 mm is considered suggestive of obstruction (Carter et al, 1989; Vazquez-Levin et al, 1994; Smith et al, 2008).

Seminal vesicle aspiration using a 20-gauge needle at the time of TRUS has been used to further increase the specificity of the diagnostic techniques. Significant quantities of sperm are not normally present in the seminal vesicles. Findings of three or more sperm per HPF in the seminal vesicle aspirate support the diagnosis of EDO (Jarow, 1994). Test accuracy is improved by performing aspiration within 24 hours of ejaculation (Jarow, 1996).

Seminovesiculography using transrectal injection of radiopaque contrast (50% renografin) into the seminal vesicles under TRUS guidance with postinjection radiographs can provide excellent anatomic detail of the seminal vesicles and ejaculatory ducts. Seminal vesicle chromotubation is a variation of seminovesiculography using the injection of dilute indigo carmine or methylene blue (1:5 dilution with saline) into the seminal vesicles via TRUS guidance followed by cystoscopic inspection of the ejaculatory ducts in the prostatic urethra to confirm patency. The dynamic tests of chromotubation and seminal vesiculography offer higher specificity for detection of EDO than static TRUS imaging alone (Purohit et al, 2004). The newest adjunctive technique, ejaculatory duct manometry, involves hydraulic assessment of the ejaculatory ducts at the time of seminal vesicle chromotubation, noting that men with EDO have higher mean ejaculatory duct opening pressures, 116 cm H_2O versus 33 cm H_2O in fertile controls (Eisenberg, 2008). Despite these advances in diagnostic techniques, criteria for diagnosis of complete EDO remain unclear and those for partial EDO remain controversial.

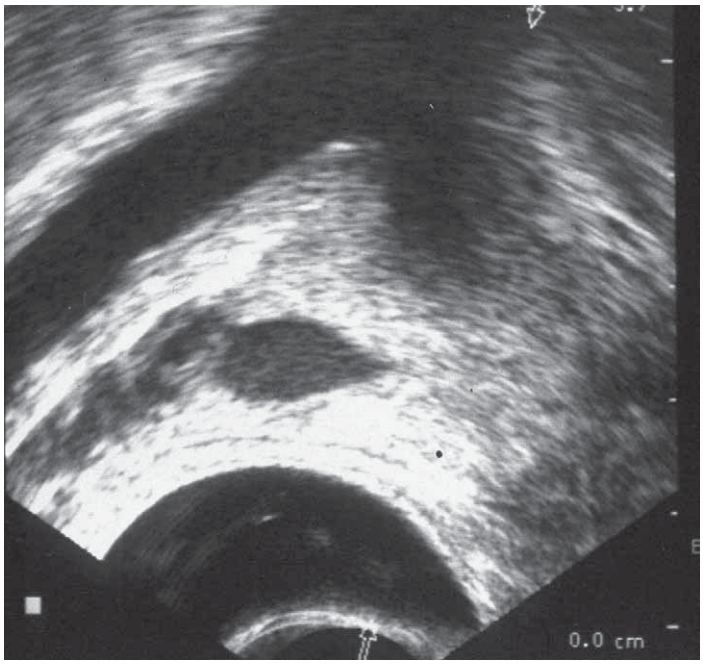

Figure 21–2. Transrectal ultrasound (sagittal image) demonstrating a dilated ejaculatory duct culminating in an ejaculatory duct cyst.

Scrotal Ultrasonography

Scrotal ultrasound for the infertile male is primarily used to confirm the presence of clinical varicoceles, although it also provides high-quality imaging of scrotal contents that offers the advantage of widespread availability without exposure to ionizing radiation. Although clinical varicoceles do not require confirmation with ultrasound examination, color Doppler ultrasound may be required when the clinical examination is difficult due to body habitus or when the examination is equivocal. Demonstration of reversal of venous blood flow with the Valsalva maneuver or spermatic vein diameters of 3 mm or greater (Fig. 21–3A and B) support the diagnosis of varicocele (Meacham et al, 1994). Scrotal ultrasound is not recommended for screening for subclinical varicoceles because repair of these has not been demonstrated to be of clinical benefit.

In addition, ultrasound examination provides excellent anatomic details of the epididymis and testis, potentially disclosing a number of conditions that may affect fertility. Epididymitis is associated with epididymal enlargement with diffuse hypoechogenicity and is often associated with a reactive hydrocele. Doppler ultrasound will often reveal increased vascularity in the involved epididymis or adjacent testicular region. Epididymal cysts or spermatoceles appear as simple or minimally complex cysts and may cause epididymal outflow obstruction. Testicular germ cell tumors are noted with increased frequency in the subfertile population, and even small, nonpalpable lesions (<0.5 cm) are well visualized with ultrasonography (Fig. 21–4). Testicular microlithiasis are diffuse 1- to 2-mm hyperechogenic nonshadowing foci and have been reported in 3% of subfertile men (Thomas et al, 2000).

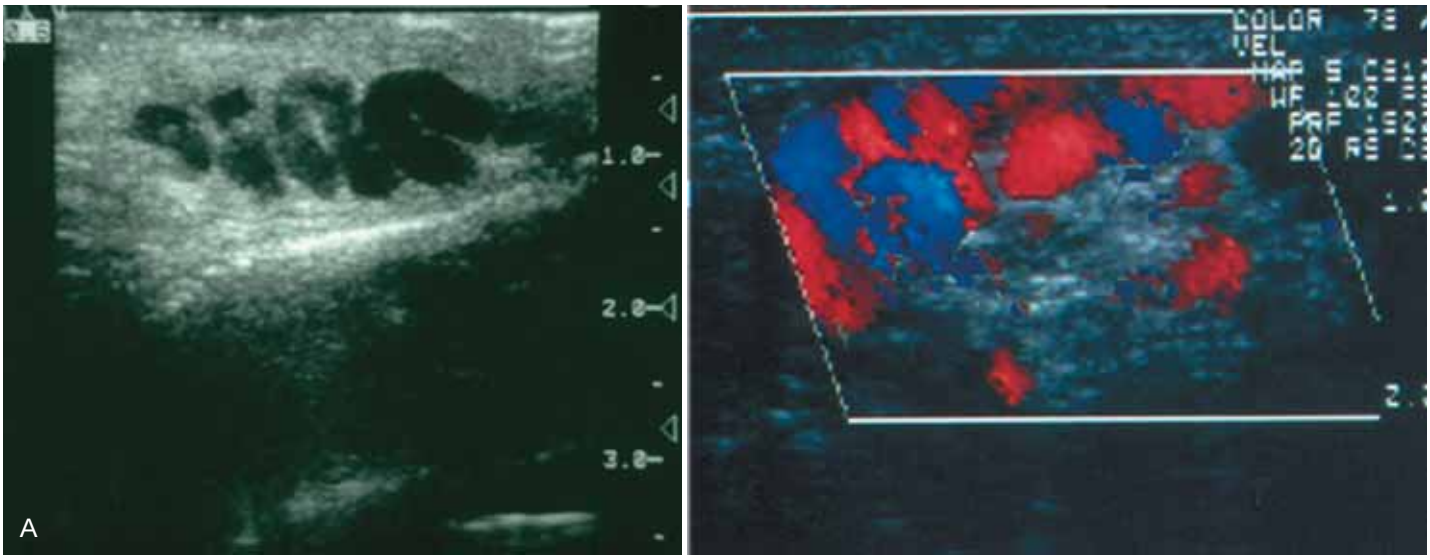

Figure 21–3. Scrotal ultrasound of varicocele. **A,** Dilated veins in spermatic cord. **B,** Color Doppler image revealing typical venous reflux with Valsalva maneuver.

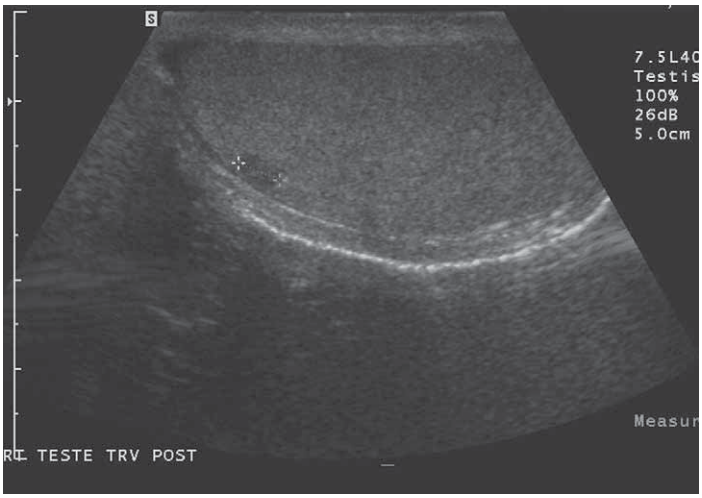

Figure 21–4. Testicular ultrasound—small nonpalpable testicular mass (seminoma) noted on fertility evaluation.

Although originally thought to represent a radiologic precursor to the development of germ cell tumors, it is now known that testicular microlithiasis is common and does not represent a risk factor for germ cell tumor development or necessitate continued medical surveillance (Costabile and Spevak, 1998).

Abdominal Ultrasonography

Abdominal ultrasound imaging in the infertile male is primarily indicated to rule out associated renal anomalies in patients with vasal agenesis. Vasal agenesis is theorized to result from one of two mechanisms—either mutations in the CFTR gene that do not incur associated renal anomalies or improper morphogenesis of the mesonephric duct before week 7 of gestation, which causes vasal agenesis and unilateral renal agenesis.

The CFTR gene is responsible for regulation of chloride ion transport across epithelial cell membranes. Dysfunction in this transport results in abnormal luminal fluid quality during vasal morphogenesis with resulting vasal agenesis (Oates and Amos, 1993). In patients with proven CFTR gene mutation in association with CBAVD, renal anomalies are unlikely and routine abdominal imaging is not indicated. However, up to 20% of men with CFTR mutation-negative vasal agenesis will have ipsilateral renal anomalies, most commonly renal agenesis, and should have routine abdominal ultrasonography as part of their evaluation.

Vasography

Vasography remains the gold standard test for assessing the patency of the male ductal system. Although procedures such as TRUS, seminal vesicle aspiration, and seminal vesiculography offer minimally invasive imaging to diagnose obstruction, properly performed vasography provides unequalled anatomic detail of the vas deferens, seminal vesicles, and ejaculatory ducts. Vasography is indicated for determination of the site of obstruction in the azoospermic patient with confirmed normal spermatogenesis on testis biopsy. On occasion, it may be used for the severely oligospermic patient in whom there is a high clinical suspicion of unilateral vasal obstruction from iatrogenic injury such as prior inguinal hernia repair (Matsuda, 2000). Vasography may also be used to rule out ejaculatory duct obstruction in the setting of ejaculatory pain. However, it should be emphasized that vasography is not necessary in oligospermic patients who do not have clinical evidence or history (i.e., inguinal surgery) that suggests unilateral obstruction.

Vasography is ideally performed at the time of anticipated reconstruction due to the potential to cause vasal scarring at the vasogram site, although this complication has not been observed in large series (Payne et al, 1985). For antegrade vasography, the straight portion of the vas deferens is isolated in the scrotal region, immediately adjacent to the convoluted vas to allow maximum length of vas deferens if a reconstruction such as a vasoepididymostomy is eventually required. Either a puncture or vasotomy technique may be used to inject contrast into the vas deferens. The puncture technique is preferred if possible because it avoids a full-thickness vasotomy, which necessitates subsequent microsurgical closure, although it is technically more difficult to enter the vasal lumen than with the vasotomy method. With the puncture procedure, a 30-gauge lymphangiogram needle is inserted directly into the proximal vas lumen and contrast is injected in an antegrade fashion (Fig. 21–5A). Alternatively, a microsurgical

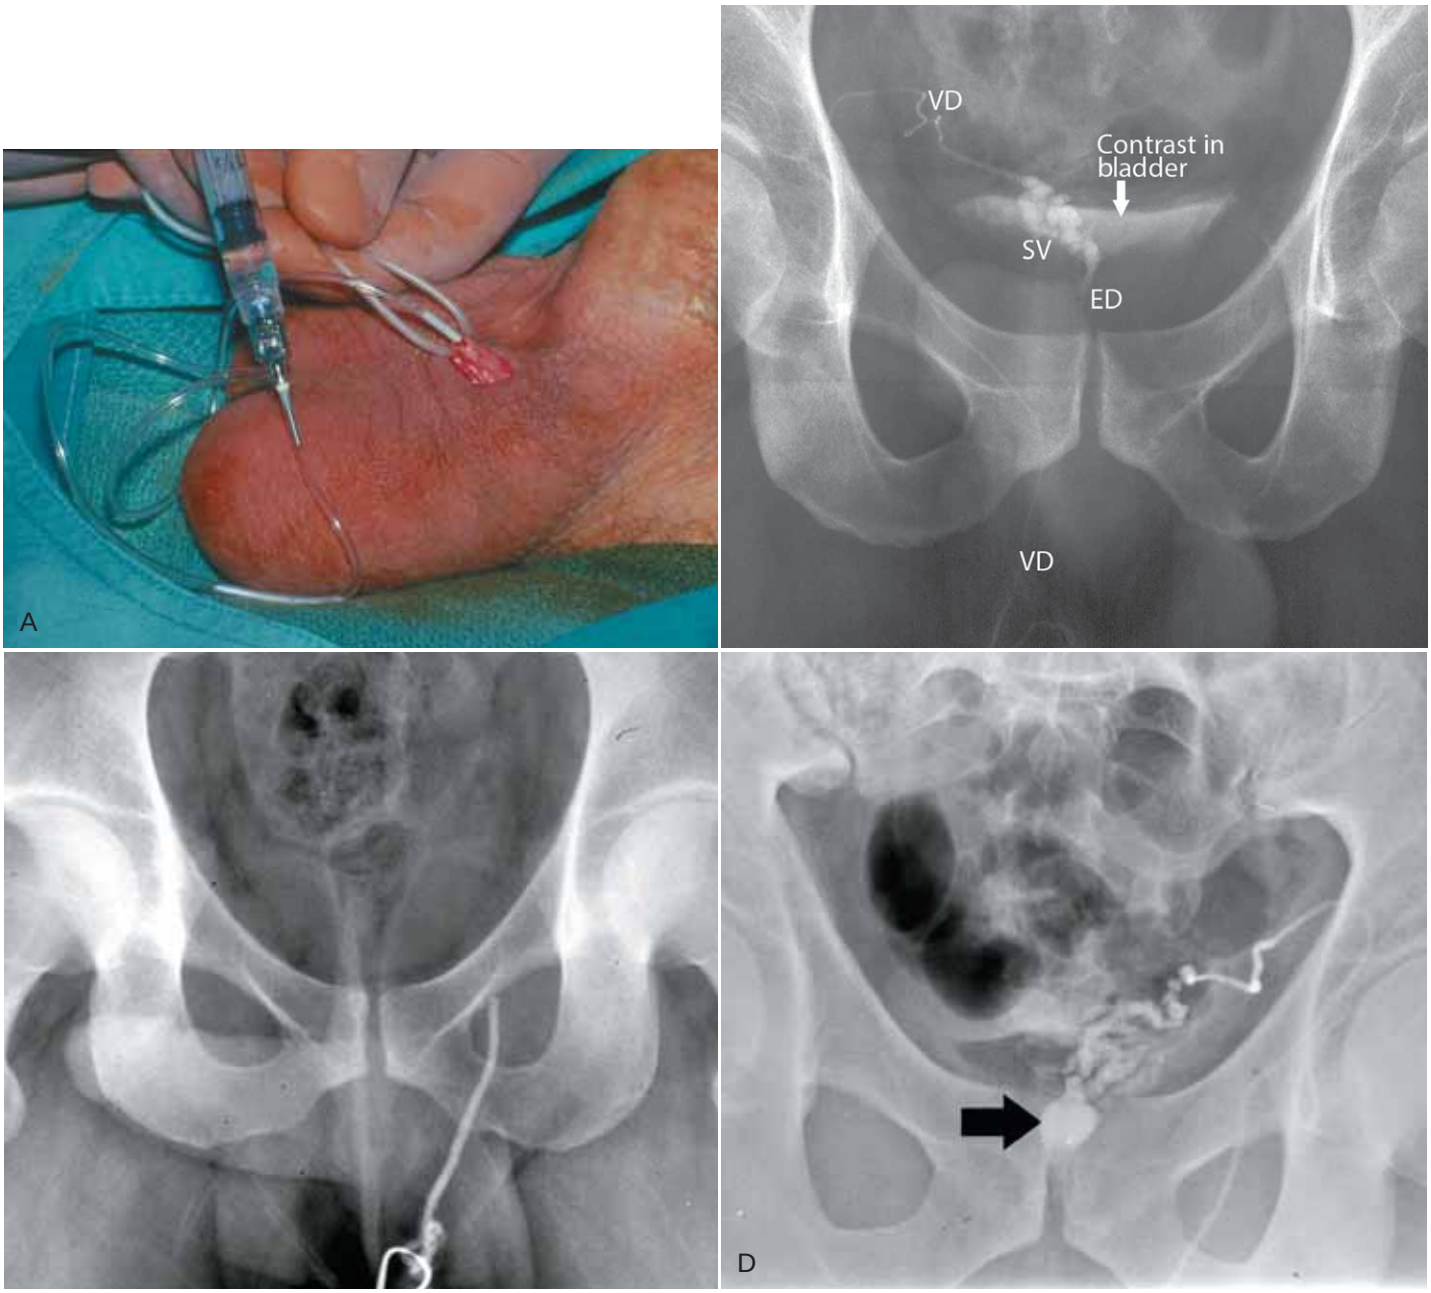

Figure 21–5. Vasography—examples of technique and findings. **A,** Technique for antegrade injection of contrast into proximal vas deferens. **B,** Normal vasogram with clearly defined vas deferens (VD), seminal vesicles (SV), ejaculatory duct (ED), and contrast spilling into bladder. **C,** Obstruction of left inguinal vas deferens due to prior herniorrhaphy. **D,** Ejaculatory duct obstruction with large cyst *(arrow)*.

scalpel may be used to make a hemivasotomy incision through the anterior wall of the vas deferens to expose the vasal lumen and allow placement of a 25-gauge angiocatheter for contrast injection (Fig. 21–5B). This techique allows examination of the intravasal fluid for presence of sperm to confirm epididymal patency. If a hemivasotomy technique is used for the vasogram, the vas will require reconstruction at the end of the procedure with 9-0/10-0 nylon interrupted sutures using standard microsurgical technique. Once the vasal lumen has been intubated, 5 to 10 mL of full- or half-strength contrast (Renografin) is injected in an antegrade fashion. Retrograde injection is not recommended due to the potential for subsequent epididymal scarring or obstruction. Vasography images are obtained using either standard radiographs or fluoroscopy. Methylene blue or indigo carmine may be mixed with contrast (1:10 dilution) to guide the depth of transurethral resection if the vasogram is performed at the time of ejaculatory duct resection. On occasion, contrast will not flow and a 2-0 monofilament suture may be passed in an antegrade fashion to identify the level of obstruction.

A properly performed vasogram will opacify the scrotal and inguinal portions of the vas deferens with subsequent filling of the ipsilateral seminal vesicle and the bladder (Fig. 21–5C). Failure to opacify the bladder represents either insufficient injection of contrast or evidence of obstruction (Fig. 21–5D).

Venography

Venography of the internal spermatic veins has been used to diagnose and treat varicoceles. As a diagnostic test, venography is

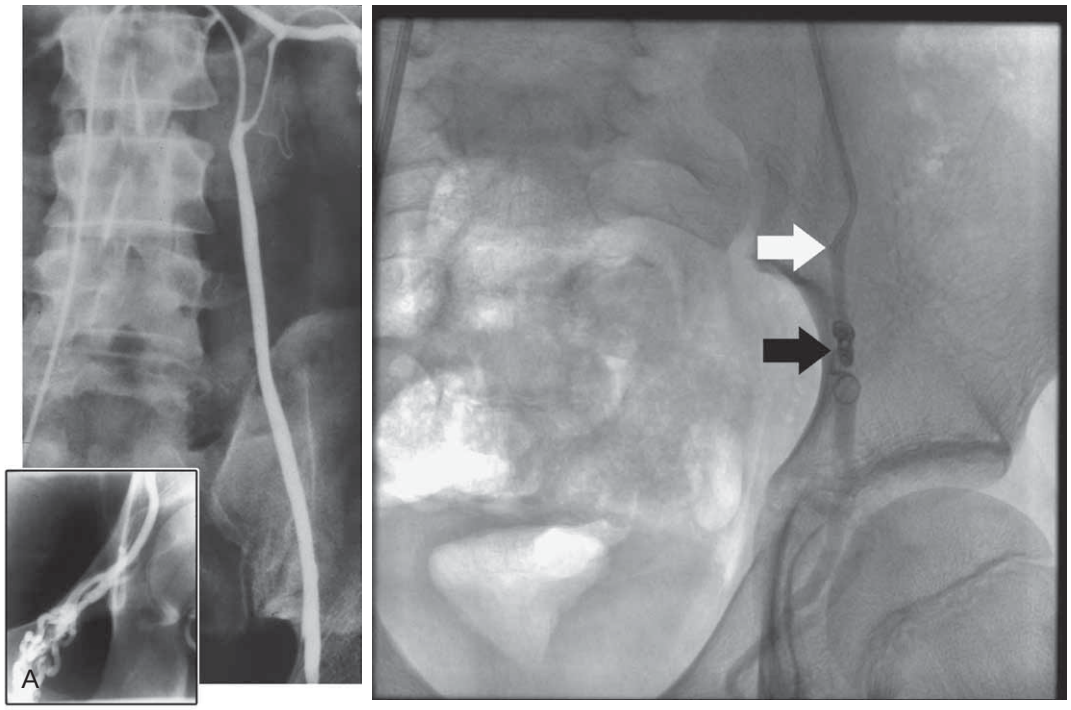

Figure 21–6. Venography for evaluation and treatment of varicoceles. **A,** Venogram demonstrates reflux through incompetent venous valves of the left internal spermatic vein consistent with left varicocele. *Inset* reveals inguinal plexis of gonadal veins. **B,** Venous embolization procedure with catheter tip *(white arrow)* and deployed coils *(black arrow)*.

arguably the most sensitive imaging modality but specificity remains its limitation. Although nearly 100% of clinical varicocele patients will demonstrate reflux on venographic examination, left internal spermatic vein reflux has been reported in up to 70% of patients without a palpable varicocele (Ahlberg et al, 1966; Narayan et al, 1980). False-positive studies may be due to examination technique factors such as high-pressure contrast instillation or placement of the catheter tip through a valve in the proximal portion of the internal spermatic vein. Because of the high false-positive rate and the invasive nature of the test, venography is not indicated for routine screening in the subfertile male. It does have utility in patients with presumed postvaricocelectomy recurrence both for confirmation of the diagnosis and embolization of persistent vessels (Fig. 21–6A and B).

Percutaneous embolization of varicoceles has been described using deployed coils, balloons, and sclerotherapy. Although it may be used for initial treatment, higher recurrence rates than surgical repair and unsuccessful procedure rates support embolization as a second-line therapy (Khera and Lipshultz, 2008). In addition, rare safety issues such as balloon migration, femoral vein injury, and anaphylactic reactions to contrast material further reinforce the recommendation that embolization is not the initial procedure of choice (Matthews et al, 1992; Zini et al, 1997). However, embolization does have a role in the management of patients with a persistent or recurrent varicocele after varicocele ligation. Antegrade scrotal sclerotherapy has also been described as first-line varicocele therapy with success rates as high as 95%, although this technique awaits validation with larger series and with long-term follow-up (Tauber and Johnson, 1994; Ficarra et al, 2002).

Testicular Biopsy

Testicular biopsy has two roles in the management of male infertility: diagnostic for the differentiation of obstruction from nonobstructive testicular pathology and therapeutic for sperm harvest with the intention of use for ICSI. Sperm retrieval techniques are discussed later in the chapter and reviewed in detail in Chapter 22.

Diagnostic testicular biopsy is primarily indicated for evaluation of the azoospermic patient presenting with a clinical picture suggestive of obstruction to include normal testicular size and consistency and normal serum FSH levels. Although some have suggested testicular biopsy for moderate oligospermia (<5 to 10 million/mL), most clinicians do not find that this provides useful prognostic or therapeutic information. On occasion, a diagnostic biopsy may be performed in a patient with clinical evidence of testicular failure (small-volume testes, high serum FSH level) to assess ability to perform sperm harvest for ICSI in the future. However, in this setting, a diagnostic biopsy should be coupled with sperm retrieval and cryopreservation to mitigate the need for a repeat biopsy in the future. Men with known obstructive etiologies such as prior vasectomy or vasal agenesis do not require routine testicular biopsy. Unilateral testicular biopsy is usually sufficient to assess the azoospermic patient for obstruction. Bilateral biopsy may be performed if there is suggestion of asymmetric pathology such as unilateral testicular failure from a situation such as cryptorchidism and contralateral obstruction such as from prior inguinal surgery with vasal injury. Although testicular biopsy may be performed concurrently with planned reconstruction, reconstruction is often performed at a later surgery to allow permanent section analysis of the tissue by pathologists. Frozen sections of the testis or touch preparations of testicular tissue have less accuracy for identification of normal spermatogenesis than permanent sections. Testicular biopsy specimens should be placed in specific solutions such as Bouin's, Zenker's, or buffered glutaraldehyde because the normal formalin tissue preservative will introduce distortion artifacts into the specimen, making histologic analysis less accurate.

Interpretation of testicular biopsies requires an experienced pathologist because analysis is descriptive rather than quantitative in nature. Electron microscopy of the germinal epithelium has not been shown to provide clinical benefit over standard light microscopy. A variety of objective histologic scoring methods have been described in an effort to quantify spermatogenesis and predict outcomes from surgical reconstruction for obstruction, but these have not gained widespread acceptance due to the time-consuming nature of the analysis and the lack of validated studies (Johnsen, 1970; Silber and Rodriguez-Rigau, 1981). DNA flow cytometry has also been employed to quantify spermatogenesis, but this has not gained popularity for similar reasons (Kaufman and Nagler, 1987; Hellstrom et al, 1990). At the present time, the most commonly used system for analysis of testicular biopsy remains the histologic classification across a spectrum of standard patterns ranging from normal to germ cell aplasia with hypospermatogenesis and maturation arrest in between. Although single patterns may be seen throughout the biopsy, multiple patterns may often be identified.

Normal

More than 85% of testicular volume consists of seminiferous tubules made up of progressively maturing germ cells and their supporting Sertoli cells. Blood vessels and Leydig cells in the interstitial areas provide the rest of the cellular complement. Spermatogenesis proceeds in an orderly fashion from spermatogonia along the basement membrane to spermatocytes and finally mature spermatozoa adjacent to the tubular lumen (Fig. 21–7A). Type A spermatogonia provide the stem cell complement and have a diploid complement of chromosomes (2N). These cells undergo a mitotic division to replenish the stem cell complement and

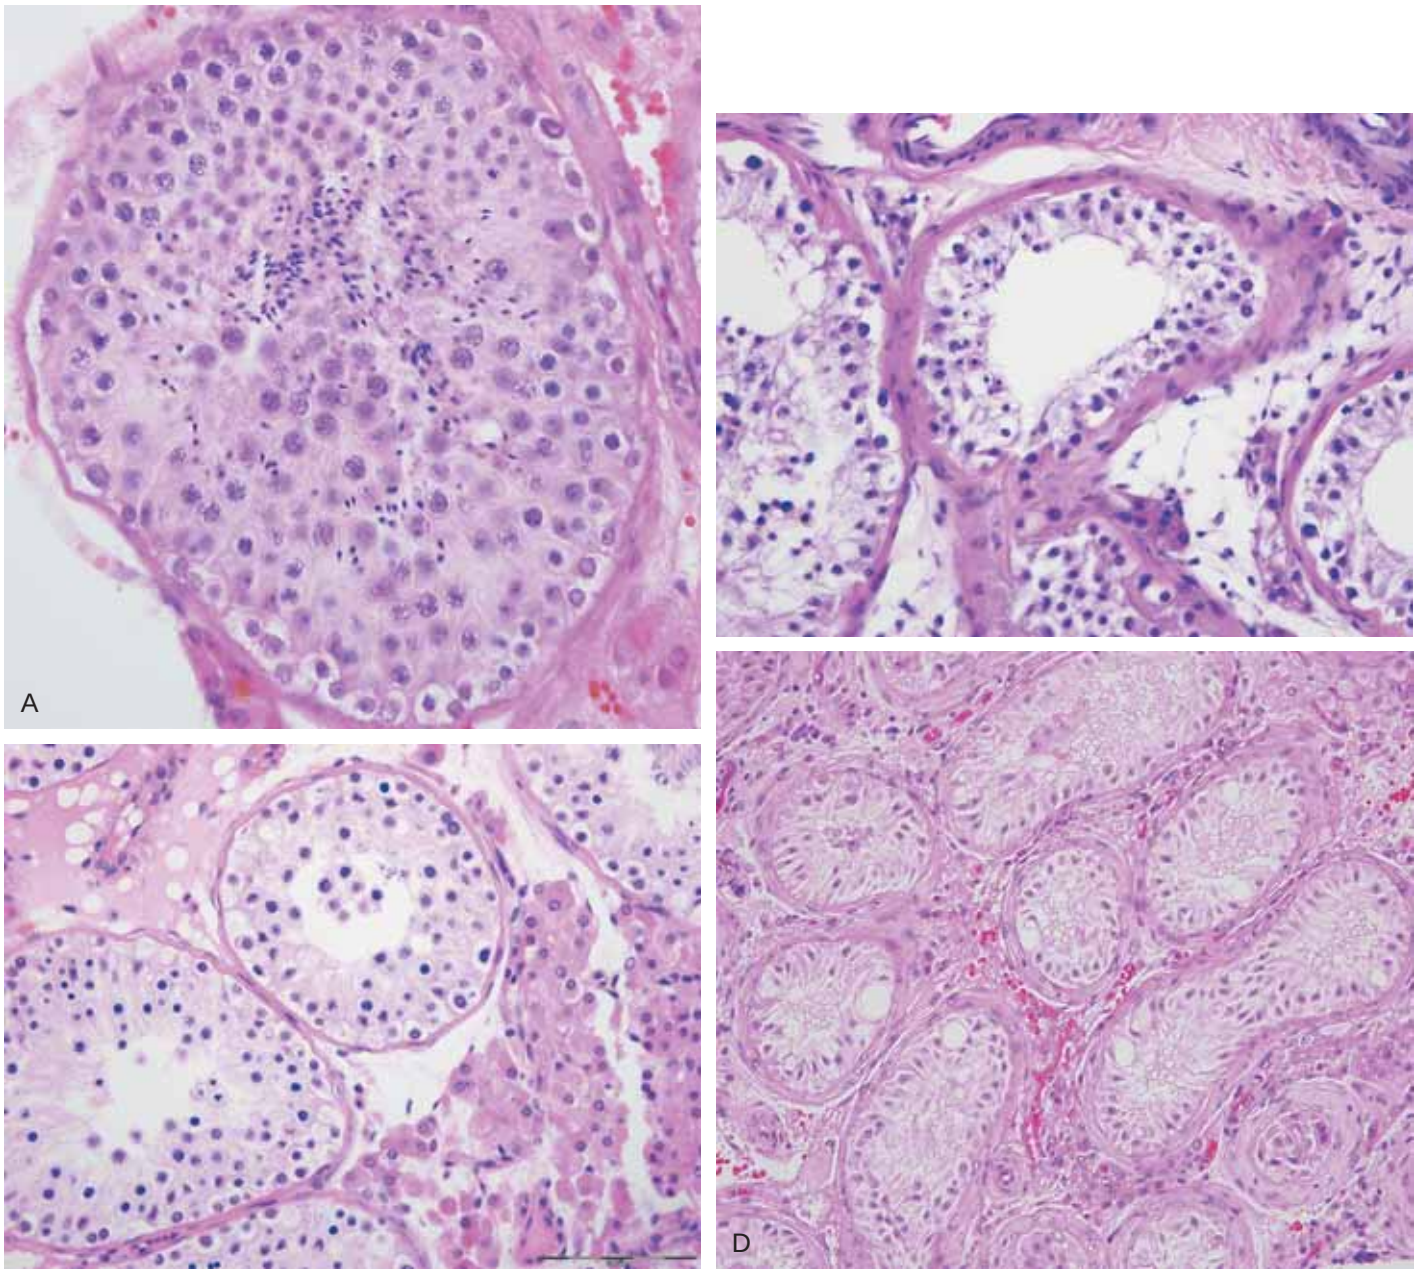

Figure 21–7. Diagnostic findings on testicular biopsy. **A,** Normal. **B,** Hypospermatogenesis. **C,** Maturation arrest. **D,** Germinal cell aplasia (Sertoli cell–only pattern).

provide type B spermatogonia (2N). Type B spermatogonia undergo DNA synthesis, resulting in spermatocytes that have a tetraploid complement of chromosomes (4N). Two subsequent meiotic divisions result in spermatids with the final haploid number of chromosomes (1N). Further maturation results in a progression from round to elongated spermatids and then to the final product, mature spermatozoa. Human testes exhibit multiple stages of spermatogenesis in a single tubular section (patchwork pattern), unlike other mammalian testes, which produce waves of spermatogenesis progressing along a tubule.

In the setting of azoospermia, a normal testicular biopsy is considered pathognomonic of ductal obstruction. Although focal areas of hypospermatogenesis and maturation arrest have been observed in the presence of obstruction, particularly in the setting of prior vasectomy, these are not classic findings for obstruction (Joshi et al, 1972; Perera, 1978). Dilated tubules with intraluminal debris are also commonly noted in patients exhibiting obstruction.

Hypospermatogenesis

Hypospermatogenesis is associated with reduced numbers of all germ cells, but all stages of spermatogenesis remain present in the histologic section (Fig. 21–7B). The degree of reduction determines whether the patient is oligospermic or azoospermic. A critical level of sperm production is required before sperm can be detected in the ejaculate, accounting for the common observation of hypospermatogenesis in the azoospermic patient.

Maturation Arrest

As the name suggests, maturation arrest involves a block of sperm maturation at a specific stage anywhere along the path of spermatogenesis (Fig. 21–7C). Maturation arrest most commonly occurs at the primary spermatocyte or late spermatid stages. Late maturation arrest may be difficult to distinguish from a normal biopsy, but the presence of mature sperm on testicular touch prep supports the diagnosis of normal spermatogenesis. Complete maturation arrest will produce azoospermia, whereas patients with partial maturation arrest may present with severe oligospermia. The remaining testicular architecture including the Sertoli and Leydig cells, as well as the basement membranes, are usually normal. Interestingly, maturation arrest is often associated with normal endocrine profiles such as FSH and inhibin levels due to an intact hypothalamic-pituitary-gonadal negative feedback system. Thus the clinical presentation of maturation arrest and ductal obstruction may be similar because both are associated with normal testicular volume and similar endocrine profiles.

Germinal Aplasia

Germinal aplasia, also called Sertoli cell-only syndrome, has small seminiferous tubules that are completely devoid of germ cells (Fig. 21–7D). The interstitial component, as well as the Sertoli cells and basement membranes, are normal. The diagnosis of germinal aplasia is suggested in an azoospermic patient with small-volume testes and elevated levels of FSH consistent with primary testicular failure. Although there are no current treatments to repopulate the testis with germ cells, low levels of spermatogenesis may be seen in other areas of the testis, which forms the basis for the use of microsurgical dissection testis biopsy (micro-TESE) to retrieve sperm in some of these patients for eventual ICSI use.

End-Stage Testes

Thickened basement membranes, tubular and peritubular sclerosis, and absence of both germ cells and Sertoli cells are characteristic histologic findings for end-stage testes. These patients will have azoospermia with profoundly small, soft testes (2- to 3-mL volume). Although this is characteristic of KS, some patients may still have small foci of retained spermatogenesis, which may be identified by micro-TESE. This histology may also be seen with cryptorchid testes.

DIAGNOSTIC AND TREATMENT CATEGORIES OF MALE INFERTILITY

Upon completion of a focused physical and laboratory examination, patients may be grouped into common patterns on the basis of seminal parameters (Table 21–8) and etiologic categories (Table 21–9). In the following sections, we review diagnostic criteria and appropriate therapy for specific diseases.

The goal of the infertility evaluation is to cause a successful pregnancy in the safest, most natural, expeditious, and cost-effective manner possible. Although advanced ART technologies such as ICSI are helpful tools in the armentarium for the management of infertility, all attempts should be made to correct underlying male factor etiologies before proceeding with these treatments. The high cost of these technologies, the shifting of treatment burden of male factor to the female partner, and intrinsic safety issues with ICSI mandate a complete exploration of correctable male factor issues before proceeding with ICSI.

Table 21–8.

Distribution of Seminal Parameters in Patients Presenting for Infertility Evaluation

TYPE	INCIDENCE (%)
Abnormal semen parameter	37
Motility	26
Asthenospermia	24
Oligospermia	8
Agglutination	2
Volume	2
Morphology	1
Azoospermia	8
All parameters normal	55

Semen Parameter Categories

Azoospermia

Azoospermia is defined as the absence of sperm in the ejaculate and is identified in 10% to 15% of infertile males (Jarow et al, 1989). Before proceeding with further diagnostic procedures, the diagnosis of azoospermia should be confirmed with at least two centrifuged semen specimens to rule out severe oligospermia. The finding of even small quantities of sperm in the centrifuged specimen rules out complete ductal obstruction such as CBAVD and also offers the potential for immediate sperm cryopreservation for ICSI cycles.

Although there is a myriad of causes of azoospermia, etiologies fall into three general categories: pretesticular, testicular, and posttesticular. Causes can usually be differentiated on the basis of semen volume (low vs. normal), physical exam findings of testicular volume and presence of vas deferens as well as serum FSH level (Fig. 21–8).

Pretesticular causes, also called *secondary testicular failure,* are usually endocrine in nature and relate to either congenital (Kallman syndrome) or acquired hypogonadotropic hypogonadism, which are addressed in detail later in this chapter.

Testicular etiologies, broadly termed as *primary testicular failure,* are intrinsic disorders of spermatogenesis. Direct testicular pathology may derive from genetic abnormalities such as Y-chromosome

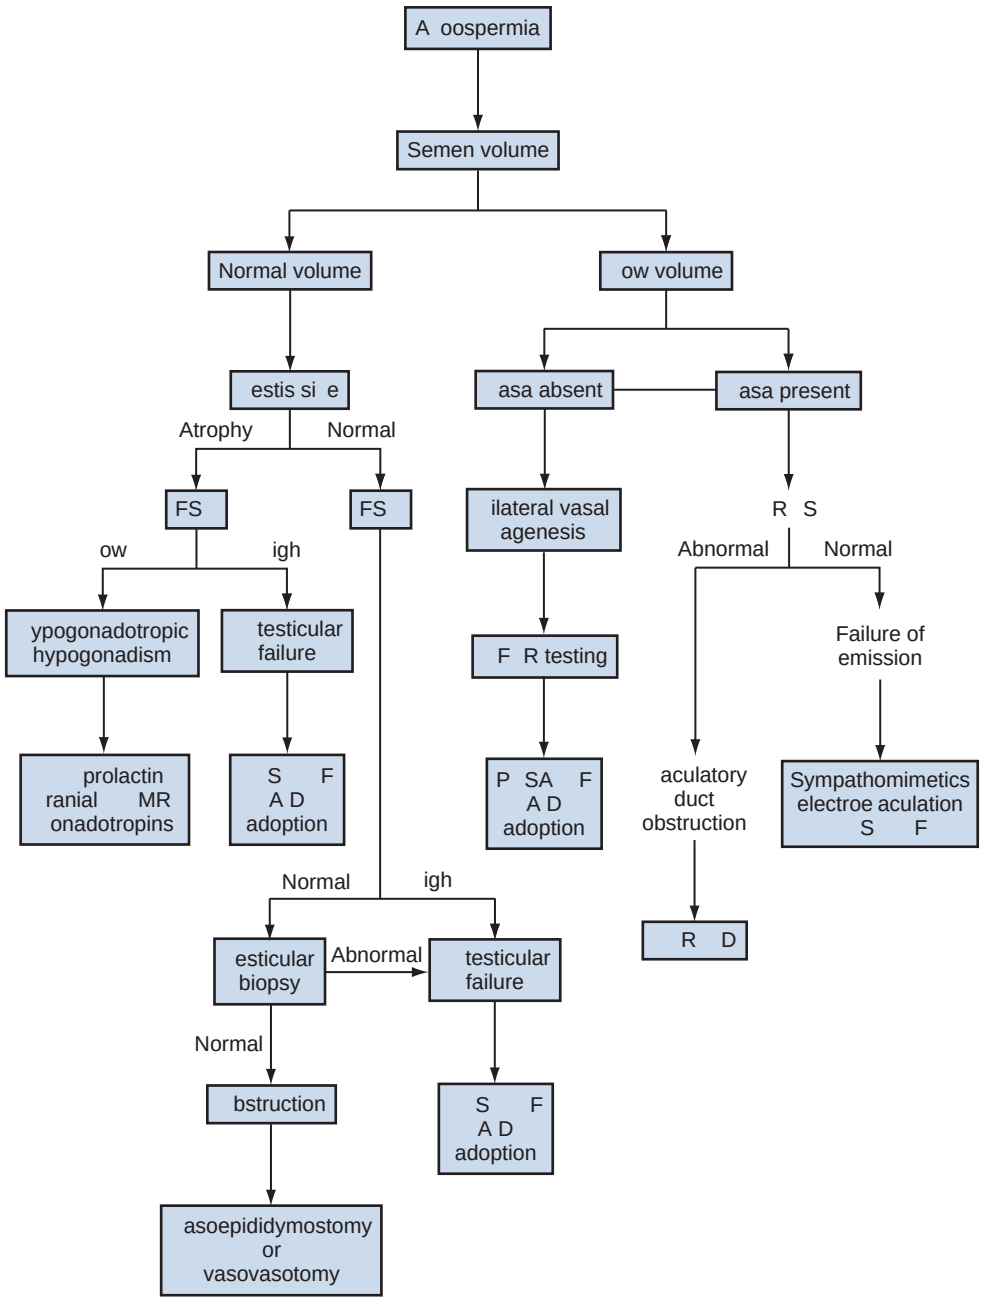

Figure 21–8. Algorithm for evaluation and treatment of azoospermia. AID, artificial insemination by donor semen; CFTR, cystic fibrosis transmembrane conductance regulator; CT/MRI, computed tomography/magnetic resonance imaging; FSH, follicle-stimulating hormone; IVF, in-vitro fertilization; LH, leuteinizing hormone; PESA, percutaneous epididymal sperm aspiration; TESE, testicular sperm extraction; TRUS, transrectal ultrasound; TUREJD, transurethral resection of the ejaculatory ducts.

microdeletions or chromosomal abnormalities, varicocele-induced testicular damage, gonadotoxic effects from medications or environmental exposures, and idiopathic infertility, which constitute the majority.

Ejaculatory dysfunction or obstruction of the genital tract account for the post-testicular pathologies, which constitute 40% of cases of azoospermia (Best Practice Committees of American Urological Association and American Society for Reproductive Medicine, 2006). Pretesticular and post-testicular causes are often amenable to treatment, which may restore fertility, whereas the success rates for intervention in testicular pathology are much more modest.

Although both primary and secondary testicular failure will be associated with marked reduction in testicular volume, these entities can be distinguished by serum endocrine testing to include FSH, LH, testosterone, and prolactin levels. High serum FSH levels, typically greater than two times normal, are indicative of primary testicular failure, and diagnostic testicular biopsy is not required to rule out obstructive etiologies. Primary testicular failure in conjunction with azoospermia, commonly termed *nonobstructive azoospermia* (NOA), is best managed with testicular sperm harvest for eventual ICSI. The absolute degree of serum FSH elevation has not proven predictive of success rates for sperm retrieval (Vernaeve et al, 2004; Hibi et al, 2005; Harris and Sandlow, 2008). Azoospermic patients with normal testicular size, palpable vas deferens, and normal serum FSH levels require a diagnostic testicular biopsy to differentiate genital tract obstruction from disorders of spermatogenesis such as maturation arrest.

Obstructive azoospermia accounts for 40% of cases of azoospermia (Practice Committee, American Society of Reproductive Medicine, 2008). A normal testicular biopsy is pathognomonic for genital tract obstruction. If these patients desire restoration of patency, they will require scrotal exploration and vasography at the time of planned reconstruction to identify the site of obstruction. Genital tract obstruction may occur anywhere along the sperm transport system to include the rete testis, efferent ductules, epididymis, vas deferens, or ejaculatory ducts. Obstruction at the level of the epididymis or vas deferens may be successfully treated with microsurgical reconstruction, either vasoepididymostomy for epididymal obstruction or vasovasostomy for vasal obstruction. Elective vasectomy remains the leading cause of obstructive azoospermia and subsequent infertility. In the absence of prior injury to the vas either intentionally from vasectomy or iatrogenic injury of inguinal vas from hernia repair, most men with idiopathic ductal obstruction will be obstructed at the level of the epididymis. Epididymal obstruction may be due to prior trauma, infection, or the result of downstream vasal obstruction from an elective vasectomy. Although vasectomy usually results in a single obstructive site, the development of high intraluminal pressures after a vasectomy can result in rupture of the delicate epididymal tubule with secondary obstruction in the epididymis. Epididymal obstruction rarely occurs within 4 years of a vasectomy but is present in more than 60% of patients on one or both sides after 15 years of vasal obstruction (Fuchs and Burt, 2002). The absence of proximal vasal fluid or thick, viscous, pastelike fluid is indicative of a concurrent epididymal obstruction and such patients will require a vasoepididymostomy for their reconstruction. The outcome of reconstruction in vasectomized men depends on a number of factors including the obstructive interval, the quality of the fluid from the proximal vas at the time of surgery, and the surgeon's microsurgical experience (Sabanegh, 2009).

Azoospermia in conjunction with low semen volumes and palpable vas deferens is most likely caused by ejaculatory duct obstruction (EDO), although rarely, ejaculatory dysfunction can cause a similar presentation. Disorders of ejaculation such as retrograde ejaculation will more frequently cause oligospermia in conjunction with low semen volume and are readily diagnosed by the presence of sperm in a postejaculation urine specimen. The diagnosis of EDO is suggested by low semen volume with acidic pH and absent semen fructose. TRUS will often reveal midline prostatic cysts, dilated ejaculatory ducts, or dilated seminal vesicles (>1.5 cm in width), and seminal vesicle aspiration may produce large numbers of sperm. Ultimately, EDO may be confirmed by vasography at the time of planned transurethral resection of the ejaculatory ducts (TUREJD) to relieve the obstruction.

Oligospermia

Oligospermia is defined as a sperm density of less than 20 million/mL. Unlike the situation with azoospermia, the number of potential diagnoses causing oligospermia can be quite vast and the etiology is often idiopathic. Oligospermia is rarely seen as an isolated seminal abnormality but is usually associated with disturbances in motility and morphology. Endocrinopathies are rarely observed in patients with concentrations higher than 10 million/mL, so routine endocrine screening with serum testosterone and FSH levels are reserved for counts lower than 10 million (Sigman and Jarow, 1997). Testis biopsy is not indicated in the setting of mild to moderate oligospermia, although it can be considered in patients with sperm concentrations under 1 million/mL in whom ductal obstruction is considered on the basis of history or physical examination findings.

Seminal Quality Abnormalities

Isolated defects may occur in motility or morphology, known as *asthenospermia* or *teratospermia,* respectively, while global sperm quality abnormalities are described with the term *oligoasthenoteratospermia* (OAT). Asthenospermia may be iatrogenic from delayed processing in the laboratory or may be due to a prolonged abstinence period. Persistent asthenospermia in a properly processed specimen, while often idiopathic, may be seen in association with varicoceles, genital tract infections, ultrastructural cilia abnormalities such as immotile cilia syndrome, and immunologic infertility in association with antisperm antibodies.

Teratospermia is a common finding, especially with use of the strict morphologic criteria (Tygerberg or Kruger) applied by many andrology laboratories. Bizarre morphologies of the sperm head such as pinhead sperm, multiheaded sperm, or round-headed sperm, which suggest acrosome deficiency, undoubtedly have clinical significance, although there is growing controversy regarding the predictive utility of abnormal morphology in general, largely due to the subjective nature of the test making it difficult to standardize (Agarwal et al, 2008). Abnormal sperm morphology has not been correlated with recurrent spontaneous miscarriages or abnormalities in offspring (Rosenbusch et al, 1992; Hill et al, 1994).

Low ejaculate volume may also be a contributing factor to subfertility. Reduction in ejaculate volume is most commonly due to improper specimen collection but may be associated with CBAVD with associated hypoplasia of the seminal vesicles, hypoandrogenism, retrograde ejaculation, or obstruction of the ejaculatory duct. Relative acidity of the seminal pH and low semen fructose suggest absence of seminal vesicle contribution to the semen, pointing to either CBAVD or EDO as lead possible causes of subfertility.

Normal Bulk Semen Parameters

Up to 50% of men presenting for an infertility evaluation will have normal bulk semen parameters, representing a particularly

difficult population to be assigned an etiology for subfertility and reinforcing the inherent inability of standard semen analyses to assess sperm function. In these couples, particular attention should be given to identifying occult female factor fertility issues, as well as assessing coital frequency to optimize reproductive timing for conception. On occasion, antisperm antibodies in the cervical mucus may inhibit sperm motility in vivo and prevent fertilization. This situation can be quantified with indirect antisperm antibody testing of the cervical mucus, although an in-vivo assessment of compatibility of sperm with the cervical mucus can be provided with the postcoital test (PCT). Couples with an abnormal PCT may benefit from intrauterine insemination, which bypasses the hostile cervical factors.

Varicocele

Varicoceles represent the most common attributable cause of primary and secondary infertility in the male (see Table 21–9). Although there is a large body of research on varicoceles dating back to Tulloch's first report of varicocele ligation for male infertility in 1955, much of the subsequent research has suffered from methodologic flaws, lack of standardized definitions for varicoceles, and failure to control confounding issues such as concurrent female factor infertility. Despite these limitations, varicocele treatment remains the most commonly performed surgery for the correction of male factor subfertility.

Varicoceles have been attributed to turbulent venous flow related to the right angle insertion of the left testicular vein into the left renal vein, an explanation supported by the left-sided predominance of these lesions. The insertion of the right testicular vein directly into the inferior vena cava is believed to provide less flow turbulence and back pressure, which translates into a lower incidence of venous dilation in the right spermatic cord. In addition, incompetent or absent venous valves in the gonadal veins allow retrograde reflux of blood into the scrotum with the standing position (Braedel et al, 1994). On rare occasions, a "nutcracker phenomenon" has been described where the left renal vein may be compressed between the superior mesenteric artery and the aorta producing elevated pressure in the left gonadal vein and resulting in a varicocele.

The mechanism of varicocele-induced impairment of spermatogenesis remains the subject of much debate. The lead theory postulates that testicular cellular processes are exquisitely temperature dependent. Venous pooling from a varicocele produces elevated intrascrotal temperature resulting in reductions in testosterone synthesis by Leydig cells, injury to germinal cell membranes, altered protein metabolism, and reduced Sertoli cell function (Khera and Lipshultz, 2008). Varicocele ligation has been demonstrated to be associated with reductions in intrascrotal temperature (Wright et al, 1997). It has also been suggested that free reflux of renal and adrenal metabolites from the left renal vein are directly gonadotoxic. Spermatic cord blood catecholamine and prostaglandin levels appear elevated in varicocele patients, although the direct gonadotoxic effects of these compounds remain to be established in humans (Comhaire et al, 1974; Ito et al, 1982). Other proposed mechanisms for varicocele-induced subfertility include impaired venous drainage with resulting hypoxia, poor clearance of gonadotoxins, and elevated levels of oxidative stress. The level of seminal oxidative stress correlates with varicocele grade and improves with treatment of the varicocele (Allamaneni et al, 2004; Khera et al, 2007). Although conflicting evidence exists for each theory, it appears that the mechanism of varicocele damage is multifactorial.

Treatment of varicoceles in the subfertile patient has produced variable results on the basis of the definition of the varicocele (subclinical vs. clinical) and the method of intervention used. The various methods of varicocele treatment all involve ligation or occlusion of dilated gonadal veins. Surgical ligation has been approached through retroperitoneal, inguinal, and subinguinal dissection, whereas embolization is a radiologic procedure. These techniques are discussed in depth in a later chapter. The most current guidelines in 2008 by the Best Practice Committee of the American Society for Reproductive Medicine recommend treatment of a varicocele in the infertile patient when all of the following conditions are met: (1) varicocele is palpable on physical examination; (2) the couple has known infertility; (3) the female partner has normal fertility or a potentially treatable cause of infertility; and (4) the male partner has abnormal semen parameters or abnormal results from sperm function tests. Patients with subclinical varicoceles are not candidates for varicocele treatment due to a lack of demonstrated efficacy in this population (Yamamoto et al, 1996). On occasion, large varicoceles will produce clinical symptoms such as dull hemiscrotal discomfort or sense of heaviness and these patients will benefit from varicocele treatment.

Adolescent males with unilateral or bilateral clinical varicoceles and ipsilateral testicular hypotrophy are also candidates for varicocele repair. Although there remains controversy with the threshold for testis size reduction to support varicocele intervention in the adolescent, authors have suggested 2-mL volume or 20% volume decrement from the contralateral testis as evidence of significant varicocele-induced damage (Gargollo and Diamond, 2009). Further support can be provided by pretreatment semen analysis, although this can be challenging to obtain in the adolescent patient. Recovery of testicular volume, so called "catch-up growth," has been reported to occur in up to 80% of boys with grade II or III varicoceles (Kass and Belman, 1987; Gershbein et al, 1999), although this has been challenged by a more recent study that suggests testicular growth will occur spontaneously in conservatively managed patients with varicoceles (Kolon et al, 2008). In the absence of testicular growth retardation, adolescents with varicoceles should be followed with annual testicular size assessments, as well as semen analysis if possible to assist early identification and intervention of varicocele-induced testicular damage.

Outcomes of varicocele treatment remain the subject of some controversy, although substantial evidence exists to support intervention in patients with clinical varicoceles and abnormal semen quality. The bulk of studies (Table 21–10) has shown improvements in seminal parameters with varicocele repair (Schlesinger et al, 1994) and specific functional testing to include sperm penetration assay (Ohl et al, 2007), sperm DNA fragmentation levels (Zini et al, 2005), and oxidative stress levels (Mostafa et al, 2001). A recent meta-analysis incorporating studies using current clinical guidelines for varicocele repair reported mean increases in sperm density of 9.7 million/mL, motility increases of 9.9%, and WHO sperm morphology improvement by 3% (Agarwal et al, 2007). Semen quality has been reported to improve in 51% to 78% of infertile men after varicocele treatment (Turek, 2005). The impact of varicocele grade on post-treatment semen quality remains unclear, although the bulk of studies suggests that larger varicoceles produce more significant impairment in semen parameters and the repair of bilateral varicoceles produced increased benefit over the repair of unilateral varicoceles (Richardson et al, 2008). In the setting of underlying genetic abnormalities associated with the subfertility, varicocele treatment does not appear to produce significant improvement in outcomes (Cayan et al, 2001). Azoospermic patients with varicoceles have shown some potential for

return of sperm to their ejaculate after varicocele treatment (Table 21–11), although studies have been relatively small with modest conception results. The vast majority of azoospermic patients with return of sperm postvaricocele treatment will still require advanced ART such as in-vitro fertilization to obtain conception.

Spontaneous pregnancy rates after varicocele treatment have been reported to average between 30% and 50% in the larger series (Abdulmaaboud et al, 1998; Segenreich et al, 1998; Perimenis et al, 2001) with pregnancies occurring at an average of 8 months after treatment (Pryor, 1987). A recent meta-analysis after surgical varicocelectomy noted that the odds of spontaneous pregnancy were 2.87 times higher over the nontreatment group (Marmar et al, 2007). Cost-benefit analyses have generally been supportive of varicocele treatment over ART techniques (Schlegel, 1997). In addition, 30% to 50% of couples who are felt to require ART due to low semen quality may be able to avoid this after varicocele treatment (Cayan et al, 2002) or have improved efficacy with post-treatment intrauterine insemination (Daitch et al, 2001).

Cryptorchidism

Cryptorchidism is a relatively common condition noted in 2.7% of newborns and up to 0.8% of 1 year olds (Score, 1964). It is a well-known etiology for subfertility and has been associated with reduced testicular size and sperm concentration, as well as reductions in serum inhibin and elevations in serum FSH levels (de Gouveia Brazao et al, 2003; Caroppo et al, 2005). It is important to distinguish cryptorchid testes from retractile testes, a condition involving hyperactive cremasteric muscles causing the testis to periodically reside in the inguinal canal or high scrotum. Although retractile testes have been associated with depressed spermatogenesis, more severe reductions in semen quality have been identified in cryptorchid patients (Caroppo et al, 2005). Suggested mechanisms for cryptorchidism-induced subfertility include testicular dysgenesis, impaired endocrine axis, immunologic damage, and obstruction. Controversies remain as to the exact effect on fertility from unilateral versus bilateral cryptorchidism and the protective effect and timing of orchidopexy. Early studies reported significant detrimental effects on semen parameters with even unilateral cryptorchidism (Kogan, 1985; Cendron, 1989), but newer work suggests that unilateral cryptorchidism may be associated with modest or no significant impact on fertility (Lee, 2005; Murphy, 2007). The level of the cryptorchid testis is predictive of spermatogenic impairment with germinal cell aplasia found in 20% to 40% of inguinal testes versus 90% of intra-abdominal testes (Hadziselimovic, 1984). One epidemiologic study comparing fertility in men with either unilateral or bilateral cryptorchidism versus age-matched controls reported paternity rates of 89% in unilateral cryptorchidism, 93% in age-matched controls, and 65% in patients with a history of bilateral cryptorchidism (Lee, 2005). Some studies have suggested that orchiopexy at younger ages, typically younger than 4 years of age, is associated with improved fertility outcomes (Coughlin et al, 1999; Lee, 2002), although the question still awaits large longitudinal studies.

Endocrinopathies

Endocrine-derived causes of infertility may occur at the hypothalamic, pituitary, or gonadal levels. Originally believed to be a rare cause of infertility, growing evidence suggests that hypogonadism, as defined by the U.S. Food and Drug Association (FDA), established normal testosterone level of 300 ng/dL may be highly prevalent in infertile males, occurring in 45%, 43%, and 35% of men with nonobstructive azoospermia, oligospermia, and normal semen parameters, respectively (Sussman et al, 2008).

Primary hypogonadism, also called *primary testicular failure* or *hypergonadotrophic hypogonadism,* is defined as low serum testosterone and elevated gonadotropin level consistent with organ function failure at the level of the testes.

Secondary hypogonadism, also called *hypogonadotropic hypogonadism,* has low testosterone levels in conjunction with low gonadotropin levels.

The time of onset of hypogonadism induces variable clinical presentations. Failure of testosterone surge at the expected time of puberty produces delayed or absent puberty, growth retardation, and small, soft testis. Patients with onset of hypogonadism after puberty will have normal secondary sexual characteristics and body habitus but small firm testis consistent with possible fibrosis after normal testicular development.

Hypogonadotropic Hypogonadism

Isolated gonadotropin deficiency or hypogonadotropic hypogonadism (HH) is a relatively rare cause of subfertility accounting for less than 1% of cases of male infertility and may be congenital or acquired (Sigman and Jarow, 1997).

Acquired causes of hypogonadotropic hypogonadism include pituitary disease, which may result from prior surgery, infarction, tumors, or infection; metabolic disorders; and a variety of other medical conditions (Table 21–12).

Although variants of congenital hypogonadotropic hypogonadism have been described (Table 21–13), the anosmic form or Kallman syndrome is the most commonly reported, occurring in between 1:10,000 and 1:60,000 births (Oates, 1997). In addition to the anosmia and azoospermia noted with Kallman syndrome, other clinical features may include midline facial defects such as cleft palate; gynecomastia; neurologic abnormalities (mental retardation, oculomotor defects, deafness, and synkinesia); unilateral renal agenesis; cryptorchidism; micropenis; and pes cavus (Sussman et al, 2008). Kallman syndrome results from failure to secrete gonadotropin-releasing hormone (GnRH) by the hypothalamus, leading to low gonadotropin levels and ultimately, failure to transition the prepubertal testis to postpubertal level of function. The GnRH deficiency noted with Kallman syndrome is the result of failed embryonic migration of neuroendocrine GnRH cells from the olfactory epithelium to the forebrain. Absence or hypoplasia of the olfactory bulbs accounts for the concurrent anosmia. Kallman syndrome represents a genetically diverse group of diseases with both X-chromosome linked inheritance via mutations in the *KAL1* gene, as well as autosomal dominant inheritance via mutations in the fibroblast growth factor receptors 1 and 8 (*FGFR1, FGFR8*), the prokineticin receptor-2 (*PROKR2*), and the prokineticin-2 *(PROK2)* genes. Mutations in these five genes are found in less than 30% of Kallman syndrome patients reinforcing the need for further genetic study on these complex patients (Dode, 2009).

Prader-Willi syndrome (PWS), another form of congenital hypogonadotropic hypogonadism, has features that include infantile hypotonia, obesity, cryptorchidism, short stature, and mental retardation. It is caused by microdeletions or mutations on the paternal chromosome 15 at the q11 or q13 location (Smeets et al, 1992). Because of concurrent medical problems in these patients, most do not seek treatment for infertility.

Hypogonadotropic hypogonadism usually presents in the late teenage years when the patient fails to undergo the usual pubertal changes with secondary virilization. It is of critical importance to distinguish HH from constitutional delay of growth and puberty (CGDP) because they share many clinical and hormonal features and yet require markedly different treatments. Usually, CGDP patients will attain spontaneous puberty by age 18 or may require transient androgen replacement for puberty induction but then will progress through normal development and fertility. HH patients will require lifelong androgen replacement for maintenance of virilization and episodes of exogenous gonadotropin treatment off androgen therapy for fertility induction as described later. Because differentiation is not always possible on the basis of serum testosterone and gonadotropin levels, a number of physiologic and stimulatory tests have been described to discriminate these conditions to include serial serum LH measurements, prolactin response to TRH, and GnRH and human chorionic gonadotropins (HCG) stimulation tests (Segal, 2009). Patients with CGDP often demonstrate LH pulses with serial overnight blood draws and gonadotropin surge in response to GnRH stimulation. HH patients have minimal variability in LH levels and do not demonstrate significant increases in gonadotropins levels with administration of GnRH.

In general, treatment of HH syndromes is directed to two ultimate goals: (1) induction of normal serum androgen levels to allow appropriate virilization and bone growth and (2) the induction of spermatogenesis and, ultimately, fertility. During adolescence, puberty and virilization are usually initiated with exogenous androgen treatment. Various effective methods of testosterone replacement therapy exist including intramuscular testosterone enanthate or cypionate (200 mg every 2 weeks), transdermal patches (5 to 10 mg/day), testosterone gel, or buccal tablets. Adequacy of replacement can be assessed by serum testosterone levels, which should be within the midrange of normal, and observation of the desired phenotypic response to therapy. Exogenous

testosterone is effective in induction of virilization but will inhibit spermatogenesis, so alternate therapies will be required when the patient desires fertility.

Induction of spermatogenesis in the HH patient requires the maintenance of intratesticular testosterone levels that are exponentially higher than that obtainable with conventional androgen replacement therapy. To obtain such levels, the usual first-line therapy for HH involves treatment with human chorionic gonadotropin (hCG), which is biologically similar to LH, inducing Leydig cell production of testosterone. hCG is administered subcutaneously at a dose of 1500 to 2000 IU two to three times per week for 4 to 6 months. When testicular volume and serum testosterone levels are stable without significant further improvement, FSH stimulation is added to the treatment regimen to induce spermatogenesis. FSH may be administered in the form of human menopausal gonadotropin (hMG), a compound that contains both FSH and LH in equal doses or with recombinant human FSH formulations. Human menopausal gonadotropin is administered at a dose of 75 IU two to three times per week, and recombinant FSH usually uses doses of 37.5 to 75 IU three times per week. FSH therapy is continued until attainment of sperm concentrations of at least 5 million per mL in the ejaculate or pregnancy is obtained. The vast majority of patients will be able to conceive after gonadotropin therapy, although 71% of the patients with subsequent fertility have sperm concentrations considerably lower than normal, suggesting that these patients are often able to conceive with low counts (Burris et al, 1988). Interestingly, 10% of patients may maintain normal serum testosterone levels after cessation of all endocrine therapy, implying that HH may be reversible in some patients (Raivio et al, 2007). Prior treatment of HH patients with testosterone does not affect success with future gonadotropin therapy (Ley and Leonard, 1985; Hamman and Berg, 1990).

Hypogonadotropic hypogonadism patients with intact pituitary function can also be effectively treated with pulsatile GnRH therapy supplied via subcutaneous infusion from portable pump or intranasal administration (Klingmuller, 1985; Aulitzky, 1988). Although direct GnRH therapy is effective, inconvenience of administration and expense do not justify this choice over traditional gonadotropins therapy at the present time (Liu, 1988). In addition, selected patients with HH presenting after puberty with intact pituitary function may respond to clomiphene citrate, an antiestrogen therapy (Whitten et al, 2006).

Androgen Excess

Excess systemic levels of androgen paradoxically inhibit spermatogenesis due to direct feedback inhibition of gonadotropin secretion at the level of the hypothalamus and pituitary. This ultimately results in low intratesticular levels of testosterone, which are inadequate for the maintenance of spermatogenesis, an observation that provides the impetus for growing research examining the potential contraceptive role of exogenous testosterone.

Excess states may result from either endogenous production or exogenous administration of androgens. Elevations in endogenous production of androgens may be caused by congenital abnormalities of steroid metabolism such as congenital adrenal hyperplasia or androgen-producing tumors of the testis or adrenal gland. Congenital adrenal hyperplasia (CAH), the most common endogenous etiology of androgen excess, encompasses a variety of specific enzyme defects in cortisol and aldosterone synthesis. Inadequate systemic cortisol levels result in excessive pituitary release of ACTH leading to hyperstimulation of the adrenal gland with subsequent release of adrenal androgens and suppression of pituitary gonadotropin release. Deficiency in the 21-hydroxylase enzyme accounts for 90% of cases of CAH. Although severe deficiency in 21-hydroxylase activity can present in the neonatal period with salt wasting, milder deficiencies present more commonly in childhood with phallic enlargement, precocious puberty, and advanced skeletal maturation. Elevated levels of serum 17-hydroxyprogesterone (often >1000 ng/dL) and urinary pregnanetriol support the diagnosis of 21-hydroxylase deficiency. The impact on subsequent fertility is variable, depending on the degree of androgen excess. Treatment for CAH consists of glucocorticoid replacement, which reduces ACTH levels and adrenal androgen production. In one small series of adult patients with CAH, 60% of men were able to cause pregnancies either with treatment or even in the absence of CAH treatment (Urban, 1978).

Anabolic steroids represent a growing etiology of male subfertility with a similar mechanism of spermatogenic disruption to that observed with CAH. It remains problematic to accurately predict the impact of these agents because of the variety of performance-enhancing substances used, as well as the variation in doses employed. Older studies of semen quality in athletes using high doses of anabolic steroids revealed severe impairment of sperm concentration, motility, and morphology (Knuth et al, 1989). Although cessation of use allowed normalization of seminal parameters in an average of 4 months, cases of persistent azoospermia have been reported occurring more than 1 year later (Jarow, 1990). To avoid the fertility-related side effects, anabolic steroid users have employed modified regimens that add hCG with steroid to protect spermatogenesis. These combinations, although causing transient impairment in semen quality, seem to allow preservation of spermatogenesis in some patients (Karila et al, 2004). In patients with persistent azoospermia or severe oligospermia after steroid abuse, hCG alone or in combination with hMG has been successfully used to restore spermatogenesis (Pundir, 2008).

Hyperprolactinemia

Because of its low yield, screening serum prolactin measurements in the infertile male is not indicated unless associated with erectile dysfunction, low serum testosterone levels, or decreased libido. Although often idiopathic, hyperprolactinemia can be associated with medications, physiologic stress, and pituitary tumors. Because of the marked physiologic variability noted with serum prolactin levels, elevated levels should be confirmed by at least one additional measurement. If elevated prolactin levels are confirmed (>18 ng/dL), anatomic imaging of the sella turcica is required, usually with magnetic resonance imaging with gadolinium contrast. Although macroadenomas may require surgical excision, microadenomas are usually responsive to dopamine agonist therapy with either bromocriptine or cabergoline. Cabergoline offers advantages over bromocriptine to include longer half-life, allowing less frequent dosing and an improved side effect profile without compromising therapeutic efficacy. Despite limited data on the therapeutic efficacy of dopamine agonist therapy for the infertile male with hyperprolactinemia, several small studies have reported improvements in sperm concentration and motility, as well as normalization of serum prolactin levels with treatment (Laufer et al, 1981; Mancini et al, 1984).

Estrogen Excess

Regardless of the source of the estrogen excess, estrogens inhibit GnRH secretion by the hypothalamus and gonadotropin release by the pituitary. In addition to the effects on the hypothalamic-pituitary-gonadal axis, elevations in serum estrogen levels produce direct deleterious effects on spermatogenesis (Hammoud et al, 2008). Hormonal evaluation in the infertile patient will reveal low

levels of serum FSH, LH, and testosterone with elevations in serum estrone and estradiol (E_2).

In the male, hyperestrogenemia may result from hepatic disease, estrogen-producing tumors, or, most commonly, obesity. Sertoli or Leydig cell testicular tumors and adrenal cortical tumors may rarely produce elevated estrogen levels. In the obese patient, elevations in serum estrogen derive from elevated peripheral aromatization of androgen to estrogen occurring in adipose tissue via an aromatase enzyme. The level of serum androgen inversely correlates with the degree of obesity (Giagulli et al, 1994; Tchernof et al, 1995). This provides the scientific basis for the use of selective medical therapy with aromatase inhibitors in men with reduced testosterone-to-estrogen ratios, which are discussed later in this chapter. In the obese patient, weight loss and bariatric surgery have been associated with improvements in endocrine profiles (Kaukua et al, 2003; Globerman et al, 2005), although the ultimate effect on fertility remains subject to further study.

Genetic Syndromes

Disorders of Sex Chromosome Number and Structure

Klinefelter Syndrome (47,XXY). KS, or 47,XXY male syndrome, is the most common genetic cause of nonobstructive azoospermia (NOA), accounting for up to 10% of these cases (Oates, 2003; Visootsak and Graham, 2006). It has been reported to occur in between 1:500 and 1:1000 live male births (Nielsen and Wohlert, 1991; Simpson et al, 2003). The majority of KS patients have a pure 47,XXY karyotype due to nondisjunction during the meiotic phase of the parental gametes, although 10% of patients are mosaic if the nondisjunction occurs during the mitotic cell division of embryogenesis (Therman et al, 1993). The extra X chromosome may be of maternal or paternal origin, but advancing paternal age is a risk factor for sperm with an XY complement and subsequent KS offspring. The frequency of XY sperm was reported to be 10%, 31%, and 160% higher in men in their 30s, 40s, and 50s, respectively, as compared with men in their 20s (Lowe et al, 2001; Eskenazi et al, 2002).

Although the exact mechanism of the subfertility induced by the supernumerary X chromosome remains to be defined, this karyotype results in severe spermatogenic and androgenic failure. In 1942 Klinefelter originally described a triad of gynecomastia, hypergonadotropic hypogonadism, and infertility (Klinefelter et al, 1942). Since the original report, KS has been identified with a wide spectrum of clinical presentations. The most severe form presents with delayed or absent puberty, incomplete virilization, and eunuchoid appearance. These patients tend to have tall, slender statures with long legs, narrow shoulders, and proportionately shorter torsos. Often they present for medical attention during adolescence and may be placed on testosterone replacement to induce puberty. On the other end of the developmental spectrum are patients who have adequate androgen levels to induce puberty but are noted to have KS during a fertility evaluation in their adulthood. Both extremes of presentation share common features of small testicular size (<8 to 10 mL testis volume), elevated serum gonadotropin levels, and azoospermia, although mosaic patients may occasionally have rare sperm identified in semen.

In addition to the detrimental effects on testicular function, KS is associated with significant developmental, neoplastic, and metabolic implications. Early studies suggested severe cognitive and behavioral abnormalities in KS patients, yet more recent reports have identified only mild cognitive impairment with speech and language deficiencies, as well as fine motor developmental delays (Youings et al, 2000; Fales et al, 2003). KS patients have been described to have as much as a 50-fold increased risk of breast cancer development reinforcing the need for monthly breast self-examination and screening in this population (Swerdlow et al, 2005). They have also been noted to have an increased risk of non-Hodgkin lymphoma and extragonadal mediastinal germ cell tumors (Aguirre et al, 2006; Oates, 2008). The underlying hypogonadism in KS patients predisposes them to the development of metabolic syndrome with the associated findings of abdominal obesity, hyperlipidemia, diabetes mellitus, and cardiovascular disease with an associated increase in risk of mortality from diabetic or cardiovascular complications (Lanfranco et al, 2004; Ishikawa, 2008).

Although most KS patients will present with azoospermia, rare cases of unassisted paternity in these patients exist, reinforcing the need for careful semen analysis of centrifuged specimens to assess for severe oligospermia, or cryptospermia. The predominant testicular histology in these patients is germinal cell aplasia with seminiferous tubular sclerosis, but there can be small areas of residual complete spermatogenesis. Advances in testicular biopsy techniques including microsurgical dissection have allowed successful sperm retrieval in up to 69% of KS patients (Denschlag et al, 2004; Gonsalves et al, 2005; Schiff et al, 2005). These techniques are covered in detail in Chapter 22. Sperm retrieved from KS patients is associated with high fertilization rates with ICSI, although there have been isolated reports of KS genotypes in offspring (Ron-El et al, 2000; Komori et al, 2004; Okada et al, 2005). This reinforces the need for all KS patients to be offered genetic counseling before proceeding with surgical sperm retrieval, both for their own health issues and the potential implications for offspring.

46,XX Male Syndrome. Also called the *sex reversal syndrome,* 46,XX male syndrome has an incidence of 1:20,000 male babies (de la Chapelle, 1972). Although sharing some similarities in presentation with KS including small testicular size, gynecomastia, and azoospermia, these patients have shorter stature than average men, an increased incidence of hypospadias, and normal levels of cognitive function (Vorona et al, 2007). In 90% of these patients, the testis-determining *(SRY)* gene including a small distal portion of the short arm of the Y chromosome (Yp) has been translocated to either one of the X chromosomes or to an autosome allowing differentiation of the bipotential gonads into testes (Schiebel et al, 1997). In the remaining 46,XX men, the *SRY* gene is not identified and it is presumed that other Y-chromosome genes have translocated to an autosome (Rajender et al, 2006). Unlike KS patients, these men are missing the *AZFa, AZFb,* and *AZFc* genetic regions, resulting in a complete absence of spermatogenesis. At the current time, there are no reports of successful sperm harvest and testicular biopsy is not recommended for prognostic or therapeutic purposes.

47,XYY Syndrome. Found in 0.1% of male births, the 47,XYY karyotype is characterized by a normal male phenotype and endocrine profile (Oates, 2002). This syndrome has been associated with reduced intelligence and antisocial behavior, although its mechanism has been controversial (Oates, 1997). These patients typically retain some degree of spermatogenesis, although they may have severe oligospermia or complete azoospermia. Fortunately, only a small percentage of spermatogonia have an abnormal genetic complement (0.35% 24,XY; 0.43% 24,YY) suggesting a low risk of genetic abnormalities in spontaneous or ICSI-derived offspring of these patients (Egozcue et al, 2000). It is still recommended that these patients receive genetic counseling before any testicular sperm harvest or ART procedure.

Noonan Syndrome. Noonan syndrome (NS) is commonly referred to as *male Turner syndrome* because both syndromes share numerous clinical features. Unlike the female Turner syndrome (45X0), the inheritance pattern for NS is autosomal dominant with a normal 46,XY karyotype. Although the exact chromosomal locus remains to be determined, studies have implicated chromosome 12 in some cases (Jamieson et al, 1994; Robin et al, 1995). The syndrome is characterized by short stature, webbing of the neck, cubitus valgus, pulmonary stenosis, hypertrophic cardiomyopathy, low-set ears, and ptosis. Fertility may be normal, but 77% of these patients will have cryptorchidism with resulting spermatogenic failure and elevated gonadotropin levels (Sharland et al, 1992).

Y-Linked Microdeletions. Testing for Y chromosome microdeletion is indicated in men with presumed nonobstructive etiology of azoospermia and severe oligospermia (concentration < 5 million/mL) to assess the prognosis for surgical sperm retrieval and to assist genetic counseling for affected couples. Normal molecular anatomy of the Y chromosome is critical both for gonadal development and function. The Y chromosome is an acrocentric chromosome with an off-center centromere creating asymmetric short (Yp) and long (Yq) arms incorporating 60 million base pairs (Morton, 1991). The Y chromosome has two important regions—the euchromatic zone, which includes Yp, the centromere, and the proximal portion of Yq, and the heterochromatic zone, which comprises the distal Yq. The heterochromatic region does not appear to have transcriptional function, while the euchromatic zone has a number of important genetic loci that are critical to the development of normal spermatogenesis (Fig. 21–9). Of particular importance is the sex-determining region Y (SRY) gene located on Yp, which is critical in initiating the cascade that converts the embryonic bipotential gonad to the eventual testis.

Deletions or mutations of critical areas of the Y chromosome may cause profound disruption of spermatogenesis. Early cytogenetic analysis of infertile men suggested the presence of a specific region on Yp termed the *azoospermia factor* (AZF), which is of paramount importance for normal spermatogenesis (Tiepolo and Zuffardi, 1976). Subsequent advances in chromosomal molecular mapping allowed the identification of three regions of Y-chromosome microdeletion: AZFa, AZFb, and AZFc (Vogt, 1998). Deletions in the AZFa region have been reported in 1% of men with nonobstructive azoospermia. This region contains two genes, DDX3Y (also known as DBY) and USP9Y, which are felt to be important for normal spermatogenesis (Kamp et al, 2000). AZFa microdeletion is associated with germinal cell aplasia histology of the testis, and current literature suggests that an attempt at testicular sperm retrieval (TESE) is not indicated because the success rate is poor (Blagosklonova et al, 2000; Hopps et al, 2003; Oates, 2008).

Like AZFa, microdeletions in the AZFb region are uncommon and are associated with poor surgical sperm retrieval success rates, especially if associated with concurrent microdeletion in other loci. The critical spermatogenic gene in the AZFb region is the RNA-binding motif (RBM) gene, which produces an RNA-binding protein localized to germ cell nuclei (Ma et al, 1993). Microdeletion in the AZFc region is the most most commonly noted, in up to 13% and 6% of azoospermic and severely oligospermic men, respectively (Reijo et al, 1996). The AZFc region is the location for the Deleted in Azoospermia (DAZ) gene, which encodes an RNA-binding protein noted primarily in spermatogonia (Saxena et al, 2000; Collier et al, 2005). Isolated AZFc microdeletion portends a better prognosis because more than 50% of azoospermic men will have successful sperm retrieval (Silber et al, 1998; Oates 2002).

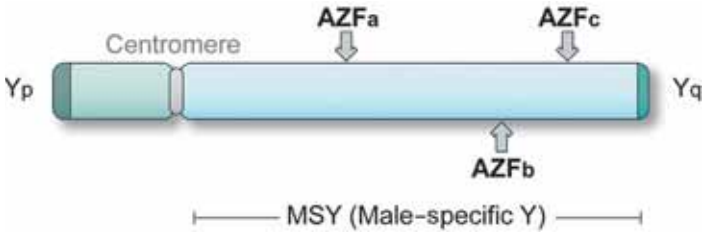

Figure 21–9. Y chromosome with azoospermia factor (AZF) region.

Considering the fact that Y chromosome microdeletions do not have direct health implications to patients other than in the fertility arena, couples should receive genetic counseling before obtaining and using surgically retrieved sperm for ICSI. The male offspring of these patients will be phenotypically normal but will harbor the father's microdeletion and thus are expected to have similar fertility challenges in their adulthood (Silber and Repping, 2002).

Disorders of Internal Ductal Development

Congenital Bilateral Absence of the Vas Deferens. CBAVD represents the mildest phenotypic presentation of cystic fibrosis transmembrane conductance regulator (CFTR) dysfunction with cystic fibrosis at the severe end of the spectrum (Oates, 2008). The cystic fibrosis (CF) gene is located on chromosome 7 and encodes for CFTR, a membrane-spanning protein that assists transmembrane chloride ion transport, which is critical for the maintenance of epithelial-lined lumen. If only one CF allele is mutated, the patient may present with CBAVD without the pulmonary and pancreatic manifestations described in classic cystic fibrosis. However, if both alleles manifest mutations and critically reduce the CFTR reserve, patients may exhibit full-blown CF, although the degree of dysfunction depends on the nature of the CF gene mutations involved.

CBAVD accounts for 6% of cases of obstructive azoospermia. The descriptive name incorporates only a portion of the associated anomalies because these patients will also have a prominent caput with absence of the distal two thirds of the epididymis, atrophy, or hypoplasia of the seminal vesicles in addition to the characteristic vasal agenesis. In the absence of seminal vesicle contributions, the ejaculate will be azoospermic with low volume (typically <0.5 mL) and acidic pH (6.5) due to unbuffered scant prostatic secretions. Although TRUS can be used to confirm the seminal vesicle anomalies, the diagnosis of CBAVD can usually be made on the basis of clinical and semen findings. Spermatogenesis is normal and biopsy is not required unless undertaken for sperm retrieval for eventual ICSI. Renal anatomy is usually normal except in cases of non-CF mutation CBAVD, as discussed later.

Development of vasal agenesis is secondary to one of two genetic transmission patterns, either CF gene mutation or aberrant development of the early mesonephric duct. Almost 80% of men with CBAVD will have at least one detectable CF mutation with more than 500 types identified to date (Claustres, 2005). The most common mutation observed in CBAVD patients is a three-base pair deletion called delta-508, which accounts for almost 70% of CFTR mutations (Kerem et al, 1989). In CBAVD men without identifiable CF mutation, the syndrome is probably secondary to yet unidentified CF mutations or to improper morphogenesis of the mesonephric duct. These patients should be screened with a renal imaging study because up to 40% will have renal agenesis or fusion anomalies (Oates, 2002). Renal screening is not necessary for CBAVD patients testing positive for CF mutations. Clearly, all

patients with CBAVD should have thorough genetic counseling before proceeding with fertility treatment.

Because spermatogenesis is usually normal in these patients, sperm retrieval techniques via a percutaneous or open surgical route from either the caput epididymis or testis are usually successful in extracting excellent quality spermatozoa for ICSI (Phillipson, 2000). Cryopreserved sperm from these patients produce equally high pregnancy rates with ICSI similar to those observed with fresh specimens (Oates, 1996).

Ultrastructural Sperm Anomalies

Primary Ciliary Dyskinesia. Primary ciliary dyskinesia (PCD), also known as the *immotile cilia syndrome,* encompasses a spectrum of disorders involving ultrastructural abnormalities of the flagellum affecting all ciliated cells including the lining of the respiratory and sinus tracts, as well as sperm motility. Normal ciliary axonemal structure involves a 9 + 2 microtubular arrangement with 9 pairs surrounding a central doublet with axonemal bridges that connect the outer doublet to the central pair. Movement generation requires intact ATPase function that localizes to the dynein complex located in the peripheral doublets. Electron microscopy studies have demonstrated a variety of abnormalities in PCD including absence of outer and inner dynein arms, radial spokes, and central doublet. Of these, the lack of both dynein arms is the most commonly observed deficiency (Rott, 1979).

Typically, affected patients may rarely present with infertility as their initial complaint. They will rather initially present in childhood with chronic bronchiectasis and sinusitis due to dysfunctional movement of mucus through the upper airways and sinuses.

Kartagener syndrome is a variant of PCD with three components including chronic sinusitis and bronchiectasis, situs inversus, and infertility as manifested by low or absent sperm motility. The prevalence of PCD and Kartagener syndrome are 1 in 20,000 and 1 in 40,000, respectively (McClure, 1997). Ciliary dyskinesia has also been described in association with retinitis pigmentosa, presumably due to the axonemal support requirements of retinal cells (van Dorp et al, 1992). The genetic basis for PCD has been elusive due to the heterogeneous nature of the syndrome and the multitude of substructures required for ciliary function. Most cases appear to be inherited in an autosomal recessive pattern, although there have been isolated reports of autosomal dominant or X-linked transmission (Yokota et al, 1993; Narayan et al, 1994; Blouin et al, 2000). Diagnosis can be confirmed by electron microscopy examination of ciliary axonemal structure. Although there is no cure for the ultrastructural defects, sperm have been used successfully for ICSI with resulting normal births (Kay and Irvine, 2000). Genetic counseling is highly recommended before pursuing ICSI in these patients.

Globozoospermia. Globozoospermia, also called the *round-headed sperm syndrome,* is an unusual condition noted in less than 0.1% of infertile males (Dam et al, 2007a). Although sperm concentration and motility are normal, spermatozoa have a characteristic circular head due to the absence of the acrosomal cap and enzyme package including acrosin. This deficiency prevents the sperm from penetrating the zona pellucida and outer investment of the oocyte and from obtaining fertilization. Morphologic abnormalities have also been described in the nuclear chromatin, midpiece, and mitochondrial sheath. Familial studies strongly argue for genetic transmission with some evidence suggesting a mutation in the *SPATA16* gene, which is a spermatogenesis-specific locus, although the exact mode remains to be described (Carrell et al, 1999; Dam et al, 2007b). Standard ICSI has been successfully used for these patients, although some authors have suggested that it be combined with calcium ionophore oocyte activation to improve fertilization rates (Rybouchin et al, 1997; Kilani et al, 1998; Dirican et al, 2007).

Fibrous Sheath Dysplasia. Fibrous sheath dysplasia (FSD), also known as the *Stump-tail syndrome,* describes a malformation of the fibrous sheath investing the sperm tail, resulting in structural and functional impairment (Rawe et al, 2001). Spermatozoa have a distinctive morphologic appearance with coiled or markedly shortened tails and are immotile. Although the genetic basis of FSD has not yet been established, there are troubling reports that the sperm have higher rates of diploidy and sex chromosomal disomy, suggesting the need for genetic counseling before proceeding with fertility treatment (Baccetti et al, 2005; Moretti and Collodel, 2006). Despite these concerns, ICSI has been used successfully for patients with FSD (Olmedo et al, 2000).

Ejaculatory Dysfunction

Although an uncommon cause of male infertility, ejaculatory dysfunction is responsive to a variety of therapies allowing restoration of fertility in most patients. Ejaculation is a complex process requiring coordinated inputs from both the central and peripheral neural systems to produce expulsion of semen from the urethra. There are three distinct phases of semen production: emission, closure of the bladder neck, and ejaculation. In response to visual or sensory erotic stimulation to the cerebral cortex, signals are conducted down the thoracolumbar sympathetic nerves, resulting in contraction of prostatic smooth muscle, seminal vesicles, and the vas deferens and allowing deposition of pre-ejaculatory fluid into the posterior urethra, a process called *emission.* Bladder neck closure occurs concurrently with emission in response to sympathetic innervations. Finally, semen is propelled in an antegrade fashion from the posterior urethra in response to rhythmic contractions of the periurethral and pelvic floor muscles.

Various classifications of ejaculatory dysfunction have been described, but three broad categories account for most of the disturbances observed in the infertile male: functional, neurogenic, and retrograde.

Functional Ejaculatory Dysfunction

Functional disorders include premature and delayed ejaculation. Premature ejaculation (PE) is a common form of male sexual dysfunction, occurring in more than 30% of men between the ages of 18 and 60 (Laumann et al, 1999). PE may cause significant emotional distress in couples, yet the vast majority of patients will still have intravaginal ejaculation minimizing the infertility implications of this condition. If ejaculation is consistently occurring before intromission, semen may be collected by the couple and used for intravaginal insemination at home.

Delayed ejaculation is defined as persistent difficulty or inability to ejaculate despite the presence of sexual desire and erection. No clear neurologic basis for this condition has yet been established and it is widely believed to represent a psychogenic issue (Ohl et al, 2008). Some authors have described an association with strict religious upbringing and frequent use of masturbation (Stewart and Ohl, 1989; Perelman, 2006). Some men may benefit from sex therapy or vibratory stimulation to induce ejaculation, but many will require electroejaculation or surgical sperm retrieval for eventual fertility.

Neurogenic Anejaculation

Neurogenic anejaculation is usually the result of a spinal cord injury (SCI). In addition to the ejaculatory dysfunction in these

patients, many will also have erectile dysfunction and deficiencies in spermatogenesis related to thermal dysregulation of the testes, stasis of spermatozoa, and chronic genital tract infections. Oral therapies are rarely of value in these patients and most require penile vibratory stimulation (PVS), electroejaculation (EEJ), or surgical sperm retrieval to circumvent the lack of ejaculation.

Penile vibratory stimulation involves direct vibratory stimulation of the penile frenular region using specially designed equipment. Specific vibratory parameters including a vibration amplitude of 2.5 at 100 Hz appear optimal for ejaculation induction in SCI men (Sønksen, 1994). The best candidates for PVS are patients with complete SCI who have an intact ejaculatory reflex system: Specifically, patients with complete upper motor neuron lesions above T10 with preservation of sacral efferents, thoracolumbar sympathetic outflow, and intact communication between sacral and thoracolumbar segments will exhibit the best response to PVS because approximately 70% of these patients will have ejaculation in response to treatment (Ohl et al, 1996; Bird et al, 2001). Men with incomplete spinal cord lesions may have poor response to PVS because of cortical inhibition of the reflex arc preventing ejaculation. In addition, patients with lower spinal cord lesions or peripheral neural root injuries are unlikely to respond to PVS. The most serious adverse event associated with both PVS and EEJ is autonomic dysreflexia, a massive sympathetic discharge generally associated with SCI above the T6 level. Blood pressure monitoring is essential during any procedure on SCI patients. Men who are prone to autonomic dysreflexia may be given sublingual nifedipine, 10 to 20 mg 10 minutes before the procedure to minimize the blood pressure elevation (Steinberger et al, 1990). In general, PVS is well tolerated and can even be performed by the patient at home in the absence of autonomic dysreflexia. Sønksen reviewed the efficacy of PVS in SCI men reporting 102 pregnancies in 619 couples using home vaginal insemination or clinic intrauterine insemination (Sønksen and Biering-Sørenson, 1992). PVS remains the first-line therapy for SCI patients, producing better ejaculate quality than noted with EEJ procedures (Brackett et al, 1997; Ohl et al, 1997).

Electroejaculation may be used for SCI men who have failed a trial of PVS and is usually effective for any level of spinal cord injury, as well as in men with anejaculation from a variety of other mechanisms including retroperitoneal nerve injury from prior surgery such as retroperitoneal lymphadenectomy, diabetic neuropathy, multiple sclerosis, spina bifida, and psychogenic anejaculation. In the EEJ procedure, a rectal probe is inserted and pulsed direct electrical stimulation is applied to induce ejaculation. Although SCI patients often do not require an anesthetic during the procedure, men who retain normal pelvic and perirectal sensation will need general or spinal anesthesia. Because retrograde ejaculation often results, patients should have bladder catheterization before the procedure to minimize urine contact with the ejaculate. In addition, instillation of a sperm-friendly buffered medium into the bladder, systemic alkalinization with sodium bicarbonate, and hydration before the procedure will improve sperm survival in the bladder. Antegrade ejaculate is collected and the patient is again catheterized at the end of the procedure to recover any retrograde ejaculate. Sigmoidoscopy is also performed before and after the procedure to evaluate for preexisting rectal pathology that could interfere with the EEJ procedure, as well as identify any injuries resulting from the electrical stimulation of the rectal wall. Rectal injuries are rare, occurring in less than 0.1% of EEJ procedures, but they require prompt identification and treatment to minimize morbidity (Ohl and Sønksen, 1997). Electroejaculation procedures have been reported to produce ejaculates adequate for intrauterine insemination in 71% of men with SCI and 87% of patients with anejaculation postretroperitoneal lymph node resection (Ohl, 1989, 1995).

Regardless of the etiology of anejaculation, surgical sperm retrieval via either percutaneous or open biopsy of the epididymis or testis remains an effective option for management. One study conducted a cost-benefit analysis of EEJ coupled with intrauterine insemination versus ICSI using surgical sperm retrieval in SCI patients, noting that EEJ was the cost-effective approach if the procedure could be performed without anesthesia. However, in those patients requiring anesthesia for the EEJ, the cost-benefit analysis favored surgical sperm retrieval via local anesthetic followed by ICSI (Ohl, 2001).

Retrograde Ejaculation

Retrograde ejaculation occurs when seminal fluid preferentially flows into the bladder, instead of the normal antegrade direction due to failure of the bladder neck to close. The diagnosis is confirmed by identification of 10 to 15 sperm per HPF in a centrifuged specimen of postejaculation urine. The causes of retrograde ejaculation include incompetence of the bladder neck usually from prior surgery such as transurethral resection of the prostate gland, medications including α blockers and antidepressants, and diseases causing neurologic pathology such as diabetes and multiple sclerosis. Before initiating therapy, potential reversible etiologies such as medications should be removed if possible. In the absence of correctible etiologies, a trial of sympathomimetic medication therapy may be useful in increasing sympathetic tone of the bladder neck and vas deferens, especially in patients with slowly progressive disease such as diabetic neuropathy or in those with failure of emission due to disruption of retroperitoneal sympathetic innervation from prior surgery. Table 21–14 lists some of the standard medication regimens described. Medical therapy can produce a spectrum of results including conversion of retrograde to antegrade ejaculation, increase in ejaculatory volume, and development of retrograde ejaculation in a previously anejaculatory patient (Brooks et al, 1980; Kamischke and Nieschlag, 2002). These regimens must be used judiciously because side effects include tachycardia and hypertension, which may be particularly concerning in the diabetic patient at risk for occult cardiovascular disease.

Patients with retrograde ejaculation who do not respond to medical therapy may have sperm recovered from the bladder for use in intrauterine insemination as detailed earlier. With proper preparation of the bladder to retain sperm viability and laboratory sperm processing, this technique is an effective and economical method of treatment (Van der Linden, 1992).

Immunologic Infertility

Immunologic mechanisms of infertility remain poorly understood and controversial, both in cause and treatment. The development

Table 21–14.

Medication Regimens for Treatment of Retrograde Ejaculation

MEDICATION	DOSE
Phenylpropanolamine	75 mg po bid
Ephedrine	25-50 mg po qid
Pseudoephedrine	60 mg po qid or 120 mg po bid
Imipramine	25 mg po bid

of antisperm antibodies (ASA) results from a variety of conditions that cause disruption of the blood-testis immune barrier, resulting in exposure of sperm antigens to the systemic immune system. Elevated levels of ASA have been associated with gonadal trauma, testicular torsion, cryptorchidism, varicocele, genital infections, and prior testicular biopsy, although it has long been recognized that many patients will have no clear inciting event (Ansbacher and Gangai, 1975; Koskimies and Hovatta, 1982; Witkin and Toth, 1983; Golomb et al, 1986). Prior vasectomy is a leading cause of clinically significant immunologic infertility with ASA development reported in 34% to 74% of vasectomized men and persisting in 38% to 60% after vasectomy reversal (Broderick et al, 1989; Francavilla et al, 2007). The potential detrimental effects of ASA depend on the location of binding to the sperm and include impaired sperm motility, reduced binding and penetration of the zona pellucida, inhibition of the acrosome reaction, and reduced sperm survival in the female reproductive tract. The degree of fertility impairment is related to the amount of antibody binding, with one series noting IVF fertilization rates of 27% in men with 80% or more of sperm bound with IgG or IgA versus 78% in patients with less than 80% binding (Clarke et al, 1985).

A critical assessment of effective treatment options for immunologic infertility is hampered by a lack of controlled, prospective studies and the absence of a standard definition of the disease. Current treatment strategies use two main approaches: immunosuppressive therapy or assisted reproduction using laboratory techniques to lower antibody levels. Immunosuppression using corticosteroid therapy remains the most commonly used therapeutic approach with reported pregnancy rates ranging from 6% to 50% despite consistent reductions in antibody titers (Turek and Lipshultz, 1994). Many different regimens have been employed in uncontrolled studies, making it difficult to critically compare results. Hendry conducted a 6-month randomized trial using high-dose prednisolone given on days 1 through 10 of the female partner's cycle followed by a rapid taper over 2 days (Hendry et al, 1990). Pregnancy rates were 31% in the treatment group compared with 9% in the untreated men. A more recent double-blind, placebo-controlled study using methylprednisolone treatment for three cycles reported a significant reduction in sperm-associated IgG titers but no significant improvement in pregnancy rates in the treated group (Haas and Manganiello, 1997). Although therapy may be helpful in some patients, this therapeutic benefit must be weighed against the potential risks of steroid treatment including fluid retention, bone loss, gastrointestinal bleeding, and aseptic necrosis of the femoral head (Naz, 2004).

Assisted reproduction strategies for immunologic infertility have centered on using semen processing techniques to attempt removal of ASA for IUI and IVF. Simple sperm wash and percoll gradient methods of sperm preparation do not reliably remove ASA attached to the sperm surface (Haas and D'Cruz, 1988; Windt et al, 1989; Almagor et al, 1992). Despite the persistent presence of ASA after sperm processing, studies have suggested that IUI may be an effective and economical treatment for ASA-mediated infertility in some couples. One series reported a pregnancy rate of 64% after three cycles of IUI in men with ASA who produced ejaculate into a sterile medium (Ombelet et al, 1997). These results were considerably better than the conception rates per cycle of 3% to 10% reported in ASA-positive men using untreated sperm (Haas,1991; Francavilla et al, 1992). Intracytoplasmic sperm injection appears to be an effective treatment for ASA-mediated infertility when IUI fails, although there have been some concerning reports regarding postfertilization development. Fertilization and cleavage rates with ICSI treatment appear to be similar in ASA-positive and ASA-negative men (Lahteenmaki et al, 1995). However, ASA may have direct negative effects on developing embryos as manifested by higher embryonic degeneration and miscarriage rates than those observed in ASA-negative men (Naz, 2004).

Idiopathic Infertility

Despite the diagnostic advances in the field of male infertility, more than 30% of patients will still have no discernible cause for abnormal semen analyses (Nieschlag, 1997). Although it is anticipated that future developments will allow identification of the etiology for subfertility in these patients, at present they are considered idiopathic disorders that defy specific treatment recommendations. In the absence of obvious causality, therapy involves the employment of empiric medical therapy or assisted reproductive techniques to be discussed later. Empiric pharmacologic treatments have usually involved endocrine agents, with a variety of different tested therapies (Table 21–15). Although small series provide support for some empiric therapies, large placebo-controlled trials are lacking in this area, further confounding decision making in this difficult population, especially in the context of a 26% background pregnancy rate for untreated couples with abnormal semen parameters (Collins et al, 1983; Siddiq and Sigman, 2002).

Empiric Medical Therapy

Gonadotropin-Releasing Hormone Agonists. The justification for use of gonadotropin-releasing hormone agonists (GnRHs) involves the observation that these agents are effective for treatment of hypogonadotropic hypogonadism, implying that stimulation of FSH elevation may be beneficial even in the absence of known deficiency. Although multiple studies of empiric GnRH therapy have yielded conflicting results, two small controlled studies failed to show significant improvements in semen parameters (Badenoch et al, 1988; Crottaz et al, 1992). In addition, most studies have not shown significant increases in pregnancy rates, further reinforcing the conclusion that the expense of the therapy is not justified by improvements in fertility outcomes.

Table 21–15.

Empiric Pharmacologic Therapy

Gonadotropin-releasing hormone
Gonadotropins
Luteinizing hormone (human chorionic gonadotropin)
Follicle-stimulating hormone (human menopausal gonadotropin)
Antiestrogens
Clomiphene citrate
Tamoxifen citrate
Aromatase inhibitors
Testolactone
Anastrozole
Other
Antioxidant vitamins
L-carnitine
Kallikrein
Thyroid hormone
Dopamine agonist for hyperprolactin-associated infertility
Bromocriptine
Cabergoline

Gonadotropins. Multiple studies employing various formulations to include hCG, hMG and recombinant forms of gonadotropins have yielded conflicting results. A Cochrane meta-analysis suggested a modest 9% increase in pregnancy rates in the 3-month GnRH treatment group over controls, although even this analysis was underpowered to allow definitive assessment of impact due to lack of studies meeting selection criteria (Attia et al, 2006). Studies of GnRH treatment in men before ICSI have not shown significant improvements in pregnancy rates (Ashkenazi et al, 1999; Baccetti et al, 2004).

Antiestrogens. Antiestrogens remain the most commonly employed medical therapy for idiopathic male infertility. The two main formulations, clomiphene citrate and tamoxifen citrate, are nonsteroidal selective estrogen receptor modulators. By blocking the estrogen receptors at the hypothalamus and pituitary levels, this class of agents minimizes the estrogenic-mediated inhibition of gonadotropin release, resulting in elevation of gonadotropin levels. Numerous clinical trials with both agents have been conducted with conflicting results. Although some controlled studies with clomiphene citrate have shown improvement in semen parameters (Ronnberg, 1980; Wang et al, 1983; Micic and Dotlic, 1985), others have failed to show significant changes (Abel et al, 1982; Sokol et al, 1988; WHO, 1992). A meta-analysis of available studies did not reveal a significant improvement in pregnancy rates with clomiphene therapy (Liu, 2003). Similar randomized controlled trials using tamoxifen therapy have not conclusively supported efficacy in either improved semen parameters or pregnancy rates (Torok, 1985; Krause et al, 1992). A Cochrane meta-analysis combining 10 clomiphene and tamoxifen randomized controlled studies failed to show improvements in pregnancy rates with therapy (Vandekerckhove et al, 2000). A more recent study examined combination therapy with tamoxifen (20 mg/day) and testosterone replacement (120 mg/day testosterone undecanoate) for patients with idiopathic oligoteratospermia, noting improvements in semen parameters and pregnancy rates (Adamopoulos et al, 2003). These results remain to be confirmed in other large controlled studies. Other investigators used clomiphene therapy for men with nonobstructive azoospermia, titrating the dose to elevate serum testosterone levels to between 600 and 800 ng/dL (Hussein et al, 2005). In this noncontrolled trial, 64% had spontaneous return of sperm to the ejaculate with mean density of 3.8 million/mL. In those with persistent azoospermia, testicular biopsy was successful in retrieving sperm for ICSI in all cases.

Aromatase Inhibitors. Aromatase inhibitors suppress the activity of aromatase, a cytochrome P-450 enzyme concentrated in the testes, liver, brain, and adipose tissue. Aromatase is responsible for the conversion of testosterone to estradiol, so blockade produces functional effects similar to the antiestrogen class of medications. Aromatase inhibitors have been postulated to have incremental benefit over antiestrogens in patients with lower serum testosterone to estradiol ratios (<10) and in obese patients. Testolactone and anastrozole are the two main agents that have been used for the treatment of idiopathic infertility. Although one study using testolactone noted improvement in semen parameters in men with severe idiopathic oligospermia (Pavlovich et al, 2001), a controlled crossover trial failed to identify treatment benefit over placebo (Clark and Sherins, 1989). A newer study by Raman examined subgroups of infertile men with abnormal testosterone to estradiol (T/E2) ratios treated with either testolactone or anastrozole (Raman and Schlegel, 2002). Men in both treatment groups had significant improvements in their T/E2 ratios, sperm concentration, morphology, and motility, although pregnancy rates were not reported. Although these reports are intriguing, the expense of these agents and the absence of large controlled studies will limit use until further study.

Antioxidant Therapy. With growing awareness of the role of oxidative stress in idiopathic male infertility, antioxidant supplementation has become a common form of empiric therapy. The antioxidant vitamins α-tocopherol (vitamin E), ascorbic acid (vitamin C), and the retinoids (vitamin A), as well as L-carnitine, an amino acid important for mitochondrial metabolism, have all been postulated to have therapeutic benefit for male subfertility. Various studies of antioxidant vitamin supplementation have yielded conflicting conclusions on both semen parameter and pregnancy rate results (Suleiman et al, 1996; Rolf et al, 1999; Keskes-Ammar et al, 2003). More recent studies in infertile men with elevated levels of sperm DNA fragmentation revealed improvements in fragmentation rates and increased rates of ICSI-derived pregnancy following vitamin C and E supplementation (Greco et al, 2005a-c). Randomized double-blind studies examining the effect of L-carnitine administration in men with idiopathic asthenospermia have yielded contrasting results on post-treatment semen parameters, preventing definitive conclusions on the efficacy of supplementation (Balercia et al, 2005; Sigman et al, 2006).

ASSISTED REPRODUCTION

Assisted reproductive techniques have become increasingly popular for the management of idiopathic male infertility, unexplained infertility, or in cases in which no therapy is available or has effectively resulted in conception. These techniques involve the manipulation of sperm, ova, or both in an attempt to improve the chances of conception. Controlled ovarian hyperstimulation is used to induce simultaneous development of multiple ova in females by giving oral clomiphene citrate or parenteral gonadotrophins.

Artificial Insemination

Artificial insemination is an assisted conception method that can be used to alleviate infertility in selected couples. The rationale behind the use of artificial insemination is to increase the gamete density near the site of fertilization. Several different techniques have been used for artificial insemination. The original technique used for more than a century was intravaginal insemination, where an unprocessed semen sample is placed high in the vagina. In the latter half of the 20th century, the cervical cap was developed to maintain the highest concentration of semen at the external os of the cervix. It was soon discovered that placing the semen sample into the endocervix (intracervical insemination) resulted in pregnancy rates similar to that obtainable using a cervical cap and superior to those seen with high vaginal insemination.

The effectiveness of artificial insemination has been clearly established in specific subsets of infertile patients such as those with idiopathic infertility, infertility related to a cervical factor, or a mild male factor infertility (Keck et al, 1997; Cohlen, 2004). An accepted advantage of artificial insemination is that it is generally less expensive and less invasive than other assisted reproductive technology (ART) procedures (Goverde et al, 2000). The source of semen for artificial insemination can be either from the woman's male partner or a donor, who usually remains anonymous. In the past, the only available options for couples with severe male factor infertility including severe oligospermia or failure to conceive using partner insemination were either donor insemination or

adoption. Since the widespread availability of IVF using ICSI, many couples with severe male factor infertility have chosen to procreate their own genetic children using these techniques. However, donor insemination remains an option when IVF/ICSI has been unsuccessful. Alternatively, many candidates for IVF/ICSI initially choose donor insemination because it is less invasive and ultimately more likely to achieve pregnancy for couples with limited resources. Some women choose donor insemination because they are not candidates for IVF/ICSI. Perhaps the most obvious situation is women without male partners who seek pregnancy. The use of donor insemination is also indicated when the male partner has no viable sperm or when IVF/ICSI fails to achieve fertilization. Finally, men with a known genetic disorder often choose donor insemination to avoid transmission to their children.

Thorough evaluation of all potential sperm donors other than sexually intimate partners is necessary to avoid inadvertent transmission of sexually transmitted diseases or known genetic syndromes (ASRM, 1990). All donors should undergo a review of relevant medical records, personal and family history, and a physical examination. Determination of normal semen characteristics is extremely important. In addition, blood grouping and karyotyping are performed. Each donor must be screened for risk factors and clinical evidence of communicable diseases including human immunodeficiency virus types 1 and 2; human T-lymphotropic virus types I and II; hepatitis B and C; cytomegalovirus; human transmissible spongiform encephalopathy (including Creutzfeldt-Jakob disease); *Treponema pallidum; Chlamydia trachomatis;* and *Neisseria gonorrheae*. If the donor is deemed acceptable and is aware of the ethical and legal implications, semen can be collected. All donor semen samples are cryopreserved and quarantined for 6 months. Before a donor sample is used for insemination, the donor is retested and his eligibility is determined.

Presently, there is no general consensus as to the best sperm preparation technique for IUI. In general, swim-up, simple sperm washing, density gradient centrifugation, and glass wool filtration methods all effectively produce adequate sperm samples. However, some preparation techniques appear better suited for particular types of samples; thus the technique chosen should be tailored to individual samples. The preparation techniques most commonly used today are the double-density gradient centrifugation and the glass wool filtration sperm washing techniques. These techniques have been shown to improve the number of morphologically normal spermatozoa with grade A motility and normal chromatin condensation in the prepared sample (Erel et al, 2000; Sakkas and Tomlinson, 2000; Hammadeh et al, 2001). In addition, these techniques best reduce the amount of reactive oxygen species and leukocytes in the prepared sample and provide spermatozoa with minimal chromatin and nuclear DNA anomalies and high nuclear maturity rates. For semen samples with normal or near-normal sperm parameters, it has been shown that swim-up and density gradient techniques result in higher pregnancy rates compared with the washing, swim-down, and refrigeration/heparin techniques (Carrell et al, 1998). For poor samples, the density gradient centrifugation and glass wool filtration techniques appear to be superior. In cases of very low sperm counts, simple sperm washing will recover the highest number of sperm, both motile and nonmotile.

In-Vitro Fertilization/ICSI

IVF involves using controlled ovarian hyperstimulation to recruit multiple oocytes during each cycle from the female partner. Follicular development is monitored ultrasonically, and ova are harvested before ovulation with the use of ultrasound-guided needle aspiration. The recovered oocytes are mixed with processed semen to perform in-vitro fertilization. The developing embryos are incubated for 2 to 3 days in culture and then placed transcervically into the uterus. Generally, only 20% to 30% of transferred embryos result in clinical pregnancies.

Notwithstanding the broad success of in-vitro fertilization (IVF), failure to achieve fertilization still plagues a substantial group of patients, with sperm abnormalities being the main culprit. In the 1980s, several micromanipulation procedures were adopted from animal husbandry to assist gamete interaction, and this resulted in the development of intracytoplasmic sperm injection (ICSI), a procedure through which an oocyte can be fertilized independently of the morphology and/or motility of the single spermatozoon injected. The procedure was first used in cases of fertilization failure after standard IVF or when an inadequate number of sperm cells were available. The consistency of fertilization independent of the functional quality of the spermatozoon has extended the application of ICSI to immature spermatozoa retrieved surgically from the epididymis and testis. Moreover, the need to denude the oocyte has allowed assessment of the nuclear maturity of the oocyte. ICSI is also preferred in conjunction with preimplantation genetic diagnosis and has recently been used to treat HIV-discordant couples, where there is a pressing need to minimize the exposure of the oocyte to a large number of spermatozoa. For all ages and with all the different sperm types used, fertilization after ICSI is at approximately 70% to 80% and it ensures a clinical pregnancy rate of up to 45%. These results have made ICSI a procedure comparable in popularity with IVF and have minimized the need for couples suffering from all forms of male infertility to resort to adoption or the use of donor sperm (Palermo et al, 2009).

Key Points

- Male factor infertility accounts for almost 50% of infertility.
- There are three different approaches to treat male infertility depending on the cause:
  - Treat the man to maximize his fertility
  - Extract sperm for use in assisted reproduction if optimization is not possible
  - Use donor sperm or adoption
- Comprehensive male factor evaluation is critical to identify factors that may affect the man's health, as well as that of his offspring.

Vasovasostomy
Surgery of the Epididymis
Transurethral Resection of the Ejaculatory Ducts
Electroejaculation
Sperm Retrieval Techniques
Varicocelectomy
Orchiopexy in Adults

Since the previous edition, the indications for and techniques of surgery for male infertility have been significantly refined, resulting in substantially increased success in the management of male factor infertility. These advances include (1) increasing use of genetic and molecular biologic markers (see Chapters 20 and 21) to better select patients for surgical treatment; (2) improved techniques for microsurgical reconstruction for obstruction; (3) the use of varicocelectomy for enhancement of spermatogenesis in azoospermic or severely oligospermic men (Matthews et al, 1998; Kim et al, 1999); and (4) refined microsurgical techniques for sperm retrieval combined with in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) for men with nonobstructive azoospermia. Even **men with nonobstructive azoospermia due to Klinefelter syndrome, once regarded as hopeless cases, can now father biologic offspring with assisted reproductive techniques** (Tournaye et al, 1996; Palermo et al, 1998; Ramasamy et al, 2009).

Use of transrectal high-resolution ultrasound, as well as scrotal ultrasound with color flow Doppler, has substantially improved our diagnostic and therapeutic abilities. Transrectal ultrasound of the seminal vesicles provides not only diagnostic information but ultrasound-guided aspiration of the seminal vesicles that allows retrieval of sperm to be used for IVF with ICSI (Jarow, 1996). Power Doppler may allow identification of pockets of sperm production in the testis, which may help guide sperm retrieval in men with nonobstructive azoospermia (Har-Toov et al, 2004; Herwig et al, 2004; Tunc et al, 2005).

IVF with ICSI has expanded our ability to treat even the most severe forms of male-factor infertility such as unreconstructable reproductive tract obstruction and nonobstructive azoospermia. It is, however, a costly procedure and an intense process for the female partner, with associated risks of complications including ovarian hyperstimulation, multiple gestations, and complications of the procedures for oocyte retrieval. Furthermore, as ICSI bypasses all natural biologic barriers, it raises realistic concerns of passing genetic abnormalities to the offspring (Kim et al, 1998; Foresta et al, 2005). Thus proper selection of couples for advanced assisted reproductive technology, along with adequate genetic counseling, is mandatory.

On the other hand, recent analyses clearly indicate that **specific treatments for male-factor infertility such as microsurgical reconstruction for obstructive azoospermia and varicocelectomy for impaired testis function, in properly selected patients, remain the safest and most cost-effective ways of managing infertile men** (Kolettis and Thomas, 1997; Pavlovich and Schlegel, 1997; Lee et al, 2008). Specific treatment aimed at correcting or enhancing male infertility can upgrade a couple from intensive levels of assisted reproduction to simpler methods or even to naturally conceived pregnancies.

For men with unreconstructable obstruction, as well as men with nonobstructive azoospermia, surgical retrieval of sperm to achieve fertilization, pregnancy, and live birth with IVF and ICSI is a feasible management option. The development and recent refinement of the various techniques of surgical sperm retrieval, from testes, epididymides, or seminal vesicles with percutaneous or open surgical approaches, have expanded the armamentarium of urologists treating infertile men. In particular, the employment of the operating microscope to evaluate and identify individual seminiferous tubules more likely to contain sperm has significantly improved the success of testicular sperm extraction (Schlegel, 1999) while minimizing morbidity significantly (Tsujimura et al, 2002; Ramasamy et al, 2005).

The use of microsurgical techniques has also been extended to varicocelectomy. Varicoceles have long been known to be associated with male infertility and have now clearly been shown to result in progressive, duration-dependent testicular injury (Russell, 1957; Lipshultz and Corriere, 1977; Nagler et al, 1985; Gorelick and Goldstein, 1993; Sigman and Jarow, 1997). **Furthermore, microsurgical varicocelectomy, previously reserved only for men with oligospermia, has now been applied to men with nonobstructive azoospermia, resulting in**

induction of spermatogenesis and successful return of sperm to the ejaculate in many cases (Matthews et al, 1998; Kim et al, 1999; Pasqualotto et al, 2003; Pasqualotto et al, 2006; Ishikawa et al, 2008). Although varicocelectomy has historically been reserved for the treatment of infertile men and varicocele-induced pain, there is an emerging concept of **early repair of varicoceles to prevent both future infertility and Leydig cell dysfunction.** Substantial evidence has accumulated suggesting that varicocele adversely affects Leydig cell function, resulting in lower serum testosterone levels when compared with age-matched controls without varicocele. Varicocelectomy can halt and even partially reverse this decline (Castro-Magana et al, 1989; Su et al, 1995; Cayan et al, 1999). **In selected men, varicocelectomy may be an effective treatment for symptomatic, age-related androgen deficiency** (Tanrikut et al, 2011) **a condition increasingly referred to as andropause or testosterone deficiency syndrome (TDS). Thus with safer and more effective microsurgical techniques, early varicocelectomy has expanded the urologist's role from that of salvaging remaining testicular function to that of preventing future infertility and TDS.**

When surgery for male infertility is undertaken, only rarely is the life (or death) of the patient at stake. What is at stake when the surgery described in this chapter is undertaken is new life, with the potential for altering not only the quality of a couple's life but the future of our species. The responsibilities assumed by the surgeon in these circumstances demand the utmost in judgment and skill. **Many of the procedures described in this chapter are among the most technically demanding in all of urology.** Acquisition of the skills required to perform them demands intensive laboratory training in microsurgery and a thorough knowledge of the anatomy and physiology of the male reproductive system. **Attempting such surgery only occasionally and without proper training is a terrible disservice to the patient, the couple, and future humanity.**

SURGICAL ANATOMY

The scrotal contents are unique in their accessibility for physical examination, imaging modalities, and surgical intervention. The success of surgery for male infertility and scrotal disorders is predicated on selection of the correct operation and the most appropriate surgical approach. The details of the history and careful physical examination followed by confirmatory, judiciously selected laboratory and imaging procedures are presented in Chapter 21. When surgical intervention for diagnostic or therapeutic purposes is indicated, a thorough understanding of the anatomy (see Chapter 2) and physiology (see Chapter 20) of the male reproductive system is requisite for planning and carrying out a surgical procedure with the highest probability of success and lowest morbidity.

The key points of surgical anatomy follow.

Testicular Blood Supply

The main blood supply to the testis is from the testicular (internal spermatic) artery arising directly from the aorta (Table 22–1). A second blood supply comes from the artery of the vas deferens (deferential artery), which derives from the hypogastric (internal iliac) artery or the superior vesicle artery (also a branch of the hypogastric). The third blood supply, primarily to the tunica vaginalis but with branches going to the testes, comes from the cremasteric (external spermatic) artery, which derives from the inferior epigastric artery. **The testicular artery is the main blood supply to the testes.** Its diameter exceeds the diameter of the deferential (vasal) artery plus the cremasteric artery combined (Raman and Goldstein, 2004). Although vasal and cremasteric arteries can provide adequate blood supply to the testes in the event that the testicular artery is ligated, especially in children, **atrophy and/or azoospermia has resulted from testicular artery ligation both in adults and children.** Experience with the one-stage Fowler-Steven operation for orchiopexy, in which the testicular artery is intentionally ligated, indicates that 20% to 40% of such testes atrophy, although the rate of atrophy is lower in the staged procedure.

Special attention should be paid to men who have undergone vasectomy because the vasal artery has likely been compromised. In these men, maintaining the integrity of the testicular artery in any future operations such as varicocelectomy is critical (Lee JS et al, 2007).

Table 22–1.

Blood Supply to Testis, Epididymis, and Vas Deferens

Testis

1. Testicular (internal spermatic) artery from aorta (main blood supply)
2. Deferential artery from internal iliac (hypogastric) artery/superior vesicle artery
3. Cremasteric (external spermatic) artery from inferior epigastric artery

Epididymis

1. Superior epididymal artery derived from testicular artery
2. Inferior epididymal artery derived from vasal (deferential) artery

Vas Deferens

1. Seminal vesicle end: deferential artery
2. Testicular end: deferential artery and inferior epididymal artery

Epididymal Blood Supply

The epididymis has a rich blood supply (see Table 22–1). The superior and medial epididymal arteries derive from the testicular artery. The blood supply to the cauda (inferior pole) of the epididymis derives from the vasal (deferential) artery. The two main blood supplies to the epididymis, running superiorly and inferiorly, form an extensive interconnection such that if the vasal artery is ligated from previous vasectomy, the blood supply to the epididymis from the testicular artery is more than adequate. In addition, in preparation for vasoepididymostomy or vasovasostomy, the epididymis can be intentionally dissected off of the testis and mobilized to the caput (see Technique When Vasal Length Is Severely Compromised) with the inferior and medial epididymal arteries intentionally ligated without adverse consequence. **As long as the superior epididymal artery remains intact, the blood supply to the epididymis will be adequate.**

Blood Supply of the Vas Deferens

The vas deferens obtains its blood supply from two sources (see Table 22–1). The seminal vesical (abdominal) end of the vas derives

its blood supply from the deferential (vasal) artery, a branch of the internal iliac (hypogastric) artery or of its branch, the superior vesicle artery. The testicular end of the vas receives additional blood supply from the inferior epididymal arterial interconnections, which extends onto the vas deferens. The two blood supplies to the vas deferens freely anastomose with each other. **After vasectomy, if the vasal vessels are ligated, the testicular end of the vas receives all of its blood supply from branches of the testicular artery and epididymal artery, whereas the seminal vesical (abdominal) end of the vas receives all of its blood supply from the deferential artery. The vas deferens receives no blood supply from the surrounding cremaster muscle or from any blood vessels from the spermatic cord. Therefore if the vas deferens is sectioned or obstructed in two different locations, the intervening segment will fibrose due to lack of blood supply. Therefore two simultaneous vasovasostomies cannot be safely performed on the same vas if the vasal vessels have been interrupted in both locations.**

Anatomy of the Excurrent Ducts

Sperm and testicular fluid exit the testes through 7 to 11 tiny efferent ducts. These ducts become convoluted when they exit the testes and form the caput of the epididymis (see Chapter 20). At that level, they freely anastomose with each other. They all coalesce at the distal caput to form a single epididymal tubule from the caput-corpus junction all the way to the vas deferens. Therefore **if the epididymis is accidentally injured or ligated distal to the caput, the entire system on that side will be completely obstructed.** This is an important consideration when performing epididymal surgery or surgery near the epididymis. **Hydrocelectomy** is a common surgical procedure that can result in **iatrogenic injury to the epididymis.** In long-standing large hydroceles, the epididymis is often splayed out and difficult to identify. **Generous margins from the epididymis should be allowed when performing hydrocelectomy** (see Chapter 37). Orchiopexy for torsion can also result in inadvertent injury to the epididymis. **A single stitch through an epididymal tubule in the corpus or cauda will result in complete obstruction** of that side. Because there are multiple lobules at the levels of the caput, **puncture of a single tubule for sperm aspiration can be safely performed at the most proximal region of the caput** without significantly compromising the flow of sperm into the corpus. Multiple punctures of many tubules at the caput, or any puncture distal to the caput, however, can cause obstruction.

Ejaculatory Ducts

The left and right ejaculatory ducts enter the prostatic urethra at the level of the utricle. Obstruction of ejaculatory ducts can lead to azoospermia. Transurethral resection of the ejaculatory ducts (TURED) can relieve the obstruction. TURED should not be considered a benign procedure because it is occasionally associated with significant morbidity (see Transurethral Resection of the Ejaculatory Ducts later). Normally, the ejaculatory ducts contain a valvelike mechanism that prevents reflux of urine into the ejaculatory duct. **After transurethral resection of the ejaculatory ducts, a significant percentage of men will develop reflux of urine up the excurrent ductal system** (Vazquez-Levin et al, 1994), **causing chemical and/or bacterial epididymitis.**

TESTIS BIOPSY

Indications

The indications for testis biopsy are detailed in Chapter 21. Briefly, **testis biopsy is indicated in azoospermic men with testis of normal size and consistency, palpable vasa deferentia, and normal serum follicle-stimulating hormone (FSH) levels.** Under these circumstances, **biopsy will distinguish obstructive from nonobstructive azoospermia.** In men with **congenital absence of vasa and normal serum FSH levels,** biopsy always reveals spermatogenesis (Goldstein and Schlossberg, 1988) and **biopsy is not necessary** before definitive sperm aspiration and IVF with ICSI. **Diagnostic biopsy should usually be performed bilaterally irrespective of the size discrepancy of the two testes.** Good spermatogenesis is sometimes found in small, firm testes, whereas biopsies of large, healthy testes may reveal maturation arrest.

The ability to achieve pregnancy with only a single testicular sperm has turned biopsy into a potentially therapeutic, as well as diagnostic, procedure. Even men with markedly elevated serum FSH levels and small, soft testes (meaning certain testicular failure) often harbor rare mature sperm in their testes. These sperm can be extracted using techniques described later (see Testicular Sperm Extraction) and employed for IVF with intracytoplasmic injection of testicular sperm.

The recently discovered heterogeneity of the testes of men with nonobstructive azoospermia, coupled with the ability of testicular sperm to acquire motility (Jow et al, 1993), has resulted in changes in the techniques of testis biopsy. **Examination of fresh, unfixed tissue for the presence of sperm with tails** and possible motility, **as well as examination of multiple samples if sperm are not found initially, are now recommended. Furthermore, optimal care requires the availability, at the time of biopsy, of an andrology laboratory capable of processing and cryopreserving any sperm found at the time of biopsy.**

Open Testis Biopsy—Microsurgical Technique

Open biopsy remains the gold standard because it provides an optimal amount of tissue both for accurate diagnosis and retrieval of sperm for IVF (Rosenlund et al, 1998; Schlegel, 1999; Dardashti et al, 2000). Open testis biopsy may be performed using either general, spinal, or local anesthetic. Although local anesthesia of just the skin and tunicas without a cord block is uncomfortable, local anesthesia with spermatic cord block can be effective and comfortable. However, there are limitations of the cord block. In animal studies, the incidence of accidental damage to the testicular artery during blind cord block is 5% (Goldstein et al, 1983). In addition, if there has been previous scrotal surgery with scar or adhesions and more extensive dissection and manipulation may be required, the author prefers to use general or spinal anesthetic.

The surgeon's goals when performing a testis biopsy are to provide an optimal tissue sample, avoid trauma to the specimen, and avoid injury to the epididymis or testicular blood supply. Open biopsy under magnification (preferably with an operating microscope) satisfies these requirements.

An assistant stretches the scrotal skin tightly over the anterior surface of the testis and confirms that the epididymis is posterior.

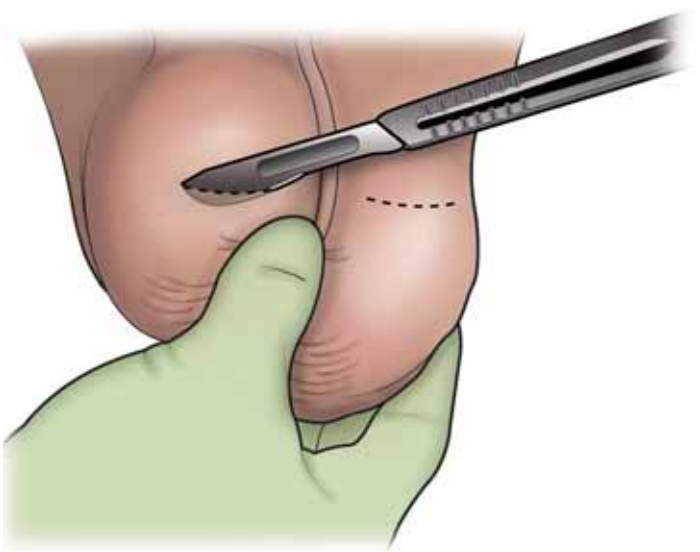

Figure 22–1. Bilateral 1-cm incisions made on each hemiscrotum.

Bilateral 1-cm transverse scrotal incisions provide good exposure with a minimum of scrotal bleeding (Fig. 22–1). Alternatively, a single vertical incision in the median raphe may be employed. The incision is carried through the skin and dartos muscle, and the tunica vaginalis is opened. **If the anatomy is distorted from previous surgery, the epididymis cannot be clearly palpated posteriorly. If the tunica albuginea cannot be clearly identified, the incision should be enlarged and the testis delivered.** The edges of the tunica vaginalis are held open with hemostats and any bleeding vessels are cauterized. **Use of loupes or, better yet, the operating microscope allows ready identification of a spot on the tunica albuginea relatively free of visible surface vessels.** The wound should be dry before incising the tunica albuginea to prevent saturation of the biopsy with blood. A 3- to 4-mm incision is made in the tunica albuginea with a 15-degree microknife (Fig. 22–2A). Small crossing vessels are cauterized with bipolar cautery and divided before excising a pea-sized sample of seminiferous tubules with razor-sharp iris scissors (Fig. 22–2B). **When handling testis biopsy material for permanent fixation, avoid tissue handling in any way (including with forceps) because this may traumatize and distort the testicular architecture.** The specimen is then deposited directly into Bouin, Zenker, or collidine-buffered glutaraldehyde solution. **Formalin fixation** results in distortion of testicular histology and **should not be used for testis biopsy. A touch-prep is made by blotting the cut surface of the testis several times with a glass slide** (Fig. 22–2C) **and adding a drop of saline, lactated Ringer, or human tubal fluid with IVF medium and a cover slip. Examination under high power using a light microscope with or without phase contrast will reveal the presence of sperm with tails and allow assessment of motility** (Fig. 22-2D). If no sperm are found in the touch prep, a second specimen may be cut for a wet squash prep. In this case the specimen is placed on a slide, a drop of saline is added, and the specimen is crushed under a coverslip (Jow et al, 1993). If no sperm are found, the tunica is closed with two to three interrupted sutures of 5-0 Vicryl (Fig. 22-2E) and another area is biopsied through the same skin incision. As described later in this chapter, **use of an operating microscope providing 10× to 25× magnification may allow selective biopsy of larger seminiferous tubules more likely to contain sperm** (Schlegel, 1999). **If sperm are identified,** the slide and additional **tissue removed are sent for cryopreservation** in the andrology laboratory. The location of the biopsy site where sperm were found is noted, and the tunica albuginea is closed with two to three interrupted sutures of 6-0 nylon. This assists identification of sites of spermatogenesis for future testicular sperm extraction for IVF/ICSI.

The tunica vaginalis is closed with 5-0 Vicryl suture for hemostasis. **Careful closure will assist structural identification in any future scrotal explorations such as epididymal reconstruction, aspiration, or testicular sperm retrieval** at the time of IVF with ICSI. The skin is closed with a subcuticular 5-0 Monocryl suture. The wounds are covered with Bacitracin ointment and a fluff-type dressing secured with a snug scrotal support. Antibiotics are unnecessary.

Percutaneous Testis Biopsy

Percutaneous testis biopsy using the same 14-gauge biopsy gun employed for prostatic biopsy is a blind procedure and could result in unintentional injury to either the epididymis or testicular artery. This technique should not be used when previous surgery has resulted in scarring and obliteration of normal anatomy. Diagnostic specimens obtained in this way often contain few tubules with poorly preserved architecture. When performed under local anesthesia, a cord block is necessary to minimize pain. The technique of percutaneous biopsy is described later in Testicular Sperm Extraction. As a therapeutic tool for sperm retrieval, percutaneous biopsy is most useful for fresh sperm retrieval for IVF/ICSI in men with obstructive azoospermia and normal spermatogenesis.

Percutaneous Testicular Aspiration

Testicular aspiration performed with a 23-gauge needle or angiocath sheath (Marmar) is probably less invasive and less painful than percutaneous biopsy. Although flow cytometric evaluation of this material can distinguish haploid from diploid cells and therefore confirm the presence or absence of late stages of spermatogenesis (Chan et al, 1984), direct wet examination of the aspirate for sperm and assessment of motility provide the most practical clinical information. Three or four aspirations can be performed until sperm are identified. In cases of obstructive azoospermia, these sperm can be used for IVF with ICSI (Craft et al, 1995) when sperm cannot be retrieved from the epididymis (see Testicular Sperm Extraction).

Complications of Testis Biopsy

Carefully performed, testis biopsy is associated with few complications (Schlegel and Su, 1997; Dardashti et al, 2000). **The most serious complication associated with testis biopsy is inadvertent biopsy of the epididymis.** If histologic evaluation of the biopsy material reveals epididymis with sperm within the epididymal tubule, obstruction of the epididymis at the site of the biopsy is certain. If, however, there are no sperm within the epididymal tubules, the patient is either obstructed above the level of the epididymal biopsy or has primary seminiferous tubular failure and no harm has been done.

Figure 22–2. **A,** A 3- to 4-mm incision is made in the tunica albuginea with a 15-degree ultrasharp microknife. **B,** Small crossing vessels are cauterized with bipolar cautery, and a pea-sized sample of seminiferous tubules are taken with a no-touch technique. **C,** A touch-prep is made by blotting the cut surface of the testis several times with a glass slide. **D,** Examination under high power using a light microscope will reveal the presence of sperm and allow assessment of motility. **E,** The biopsy site is closed with two to three interrupted sutures of 6-0 nylon.

The most common complication of testis biopsy is hematoma. Hematomas can be quite large and may require drainage. Use of magnification to avoid vessels and a bipolar cautery for hemostasis will help prevent this complication. Proper closure of the well-vascularized tunica vaginalis with a continuous suture of 5-0 Vicryl will minimize bleeding and adhesions.

With the rich blood supply of the scrotum and its contents, wound infection is rare in the absence of hematoma and antibiotics are unnecessary.

VASOGRAPHY

Indications

The absolute indications for vasography are as follows:

1. Azoospermia, plus
2. Complete spermatogenesis with many mature spermatids on testis biopsy, plus
3. At least one palpable vas

Relative indications for vasography are as follows:

1. Severe oligospermia with normal testis biopsy.
2. High level of sperm-bound antibodies that may be due to obstruction (Lee et al, 2009).
3. Low semen volume and poor sperm motility (partial ejaculatory duct obstruction).

Vasography should answer the questions:

1. Are there sperm in the vasal fluid?
2. Is the vas obstructed?

If the testis biopsy reveals many sperm, consider the following:

1. **Absence of sperm in vasal fluid indicates** obstruction proximal to the vasal site examined, most likely an **epididymal obstruction.** Vasography is done in this case with saline or indigo carmine to confirm patency of the seminal vesicle (distal) end of the vas before vasoepididymostomy.
2. **Copious vasal fluid containing many sperm indicates vasal or ejaculatory duct obstruction,** and formal contrast vasography is performed as described later to document the exact location of the obstruction.
3. **Copious thick white fluid without sperm in a dilated vas indicates secondary epididymal obstruction** in addition to a potential vasal or ejaculatory duct obstruction.

Vasography with radiographic contrast media and intraoperative radiograph are rarely indicated. There is no need to perform vasography at the time of testis biopsy for azoospermia unless immediate reconstruction is planned and the touch/wet prep biopsy reveals mature sperm with tails. If not meticulously performed, vasography can cause stricture or even obstruction at the vasography site, which can complicate subsequent reconstruction (Howards et al, 1975a; Poore et al, 1997). In addition, vasography is of no value in making the diagnosis of epididymal obstruction and the majority of nonvasectomy-related obstructions are epididymal.

If testis biopsy reveals normal spermatogenesis and the vasa are palpable, vasography, if necessary, should be performed only at the time of definitive repair of obstruction. General anesthesia provides the most flexibility for scrotal exploration, vasography, and repair of obstruction. Although local anesthesia can provide adequate analgesia, patients are often unable to lie still through several hours of microsurgery. Long-acting hypobaric spinal or continuous epidural anesthesia can be satisfactory alternatives.

Technique of Vasography and Interpretation of Findings

Inguinal hernia repair, particularly when performed in childhood, is known to be associated with vasal injury leading to obstruction. If there is no previous inguinal incision and the side of obstruction is unknown, the testis is delivered through a high vertical scrotal incision (see Scrotal later). The vas deferens is identified and isolated at the junction of the straight and convoluted portions of the vas deferens. Using an operating microscope and 10-power magnification, the vasal sheath is longitudinally incised and the vasal vessels carefully preserved (Fig. 22–3A).

A clean segment of bare vas is delivered and surrounded with a vessel loop. A straight clamp is placed beneath the vas to act as a platform. Under 25-power magnification, a 15-degree microknife is used to hemitransect the vas until the lumen is revealed (Fig. 22–3B). **Any fluid exuding from the lumen is placed on a slide, mixed with a drop of saline, and sealed with a coverslip for microscopic examination. If the vasal fluid is devoid of sperm with repeated sampling** after milking the epididymis and convoluted vas, **epididymal obstruction is present.** The end of the vas toward the seminal vesicles is then cannulated with a 24-gauge angiocatheter sheath and injected with 1 mL of lactated Ringer solution with a 1-mL tuberculin syringe to confirm its patency (Fig. 22–4). If the Ringer passes easily, formal vasography is not necessary. If further proof of patency of the vas deferens is desired, 1 mL of 50% dilute indigo carmine may be injected and the bladder catheterized. The presence of blue/green dye in the urine confirms patency of the vas. Indigo carmine diluted 50/50 with lactated Ringer solution is preferred instead of methylene blue because, even at low concentrations, methylene blue kills sperm and renders them useless for cryopreservation or for immediate IVF/ICSI (Chang et al, 1998; Sheynkin et al, 1999b; Wood et al, 2003). **If motile sperm are found in the vas, the testicular end should be gently barbotaged with 0.2 mL of human tubal fluid media and the fluid processed by the andrology laboratory for**

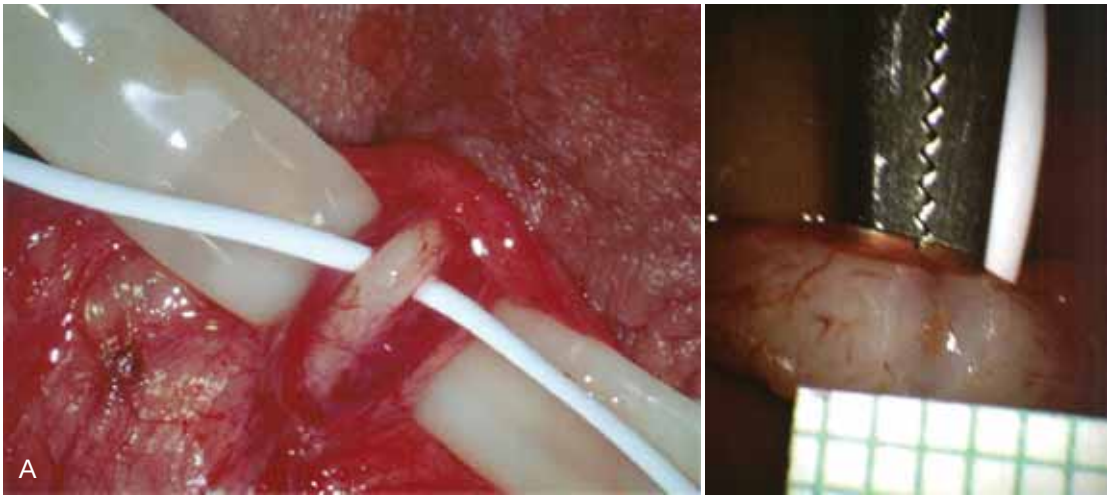

Figure 22–3. **A,** Using an operating microscope and 10× magnification, the vasal sheath is longitudinally incised and vasal vessels carefully preserved. **B,** Under 25× magnification, a 15-degree microknife is used to hemitransect the vas until the lumen is revealed.

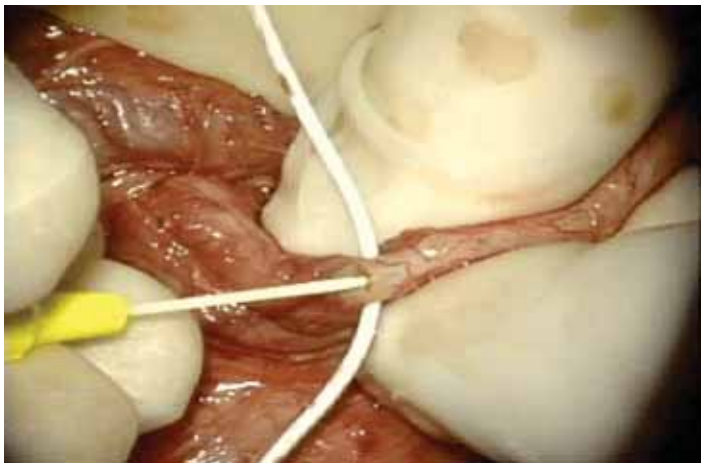

Figure 22–4. The end of the vas toward the seminal vesicles is cannulated with a 24-gauge angiocatheter and then injected with 1 mL of lactated Ringer solution with a 1-mL tuberculin syringe to confirm its patency.

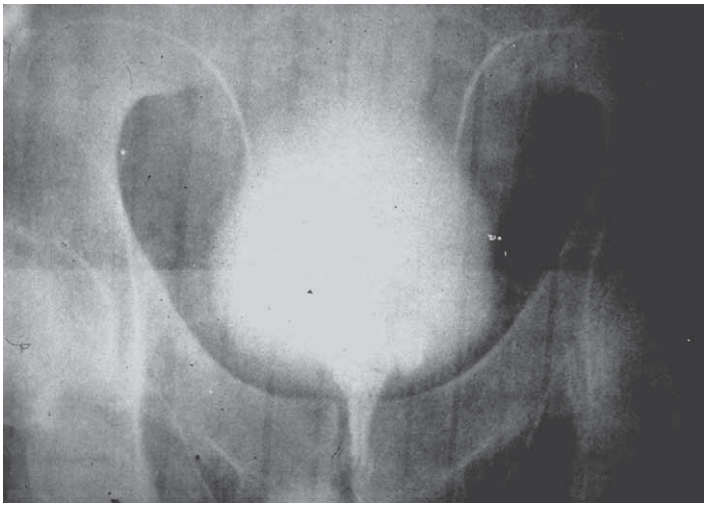

Figure 22–5. Placing the balloon on gentle traction before vasography prevents reflux of contrast into the bladder, which can obscure detail.

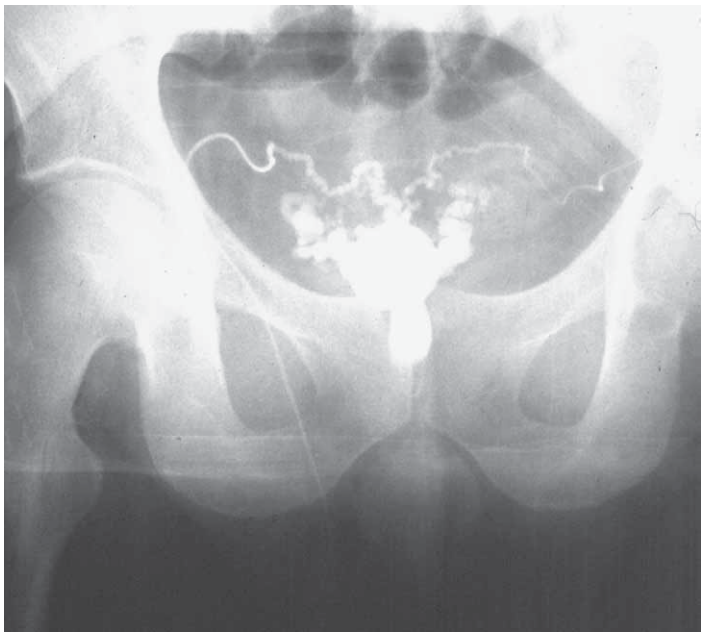

Figure 22–6. Vasograms are performed with 0.5 mL of water-soluble contrast media.

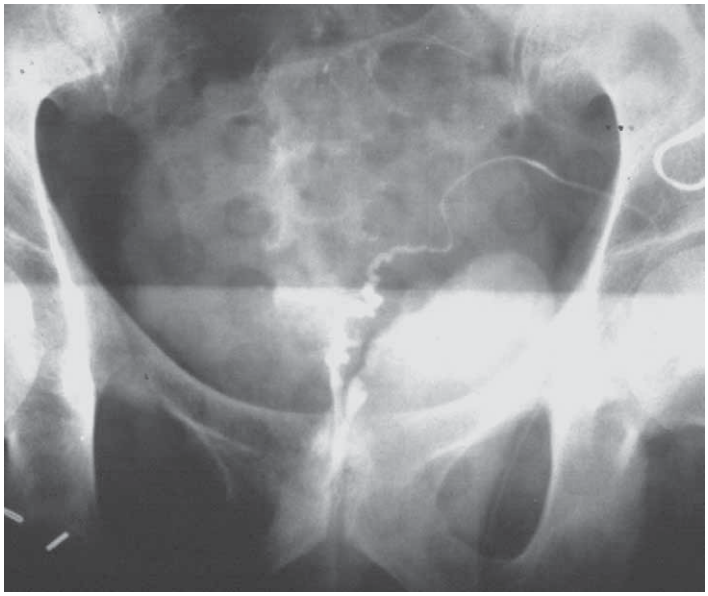

Figure 22–7. Vasography reveals obstruction at the site of the ejaculatory ducts.

sperm cryopreservation for potential future use for IVF/ICSI. This should be done before injection with indigo carmine or x-ray contrast material (Sheynkin et al, 1999a).

If a large amount of fluid is found in the vasal lumen and microscopic examination reveals the presence of sperm, the obstruction is toward the seminal vesicle end of the vas. In these cases the vas is usually markedly dilated. A 2-0 Proline suture can be passed toward the seminal vesicle end of the vas and a clamp placed on the Proline when the suture passes no farther. This is particularly useful for delineating the site of inguinal obstruction from prior groin surgery. If the obstruction is proximal to the inguinal scar, formal vasography is performed by passing a No. 3 whistle-tip ureteral catheter toward the seminal vesicle end of the vas. A 16-Fr Foley catheter is placed in the bladder, and the balloon is filled with 5 mL of air. Placing the balloon on gentle traction before vasography prevents reflux of contrast into the bladder, which can obscure detail (Fig. 22–5). The air-filled balloon also identifies the location of the bladder neck relative to any obstruction. After the vasa have been cannulated, vasograms are performed with the injection of 0.5 mL of water-soluble contrast media (Fig. 22–6). **If vasography reveals obstruction at the site of the ejaculatory ducts** (Fig. 22–7), **indigo carmine is injected in both vasa to assist a transurethral resection (TUR) of the ejaculatory ducts** (see Diagnosis later). If both vasa are visualized after injection of contrast into only one vas (Fig. 22–8), it means both vasa empty into a single cavity, usually a midline ejaculatory duct cyst.

Vasography may reveal the vas deferens ending blindly, far from the ejaculatory ducts (Fig. 22–9). This finding indicates congenital partial absence of the vas deferens, and these patients should be tested for cystic fibrosis mutations (see Chapter 21). If this is found bilaterally (Fig. 22–10), reconstruction is impossible but vasal or epididymal sperm can be aspirated into standard laboratory

Figure 22–8. Both vasa are visualized after injection of contrast into one vas only, revealing distal obstruction.

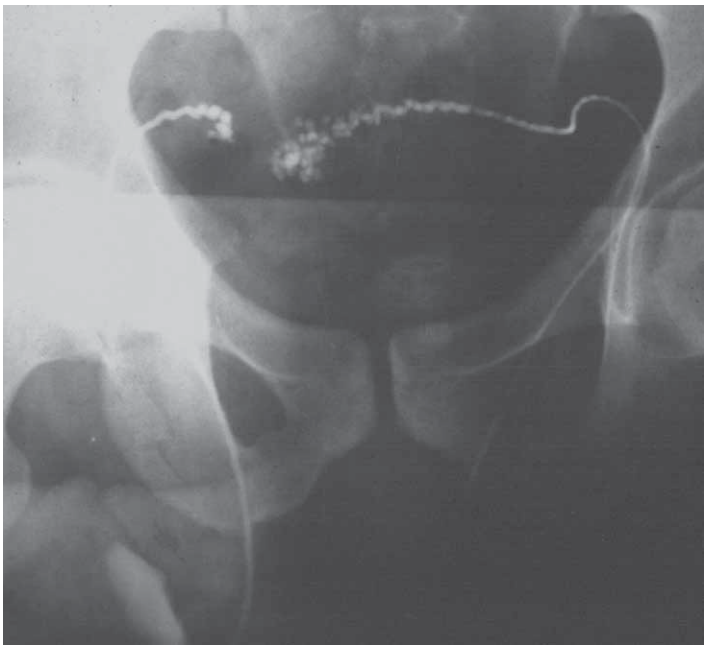

Figure 22–10. Vasogram demonstrating partial absence of the vas deferens.

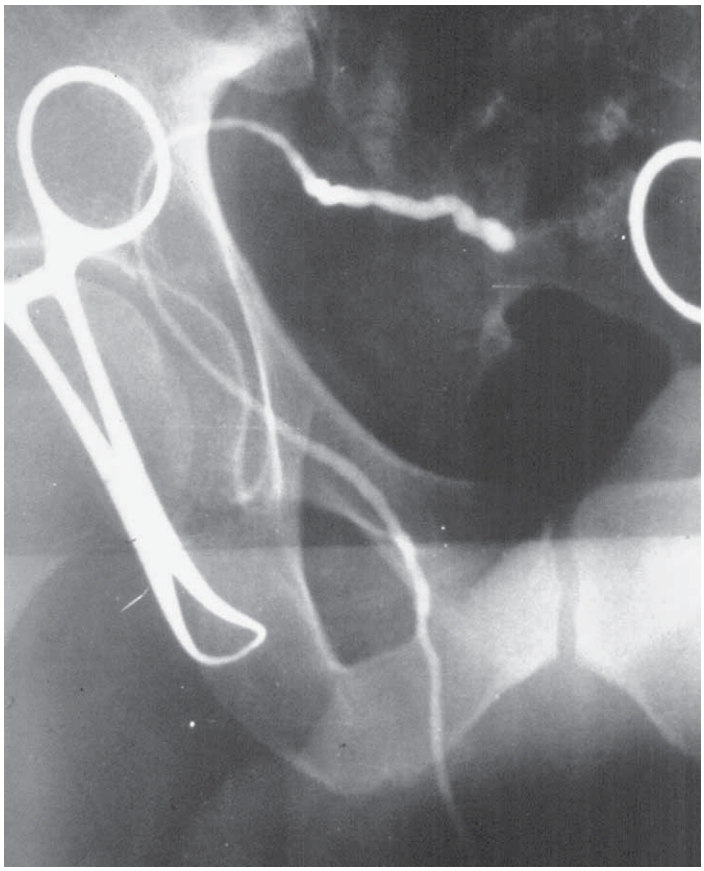

Figure 22–9. Vasography reveals a blind-ending vas deferens far from the ejaculatory duct.

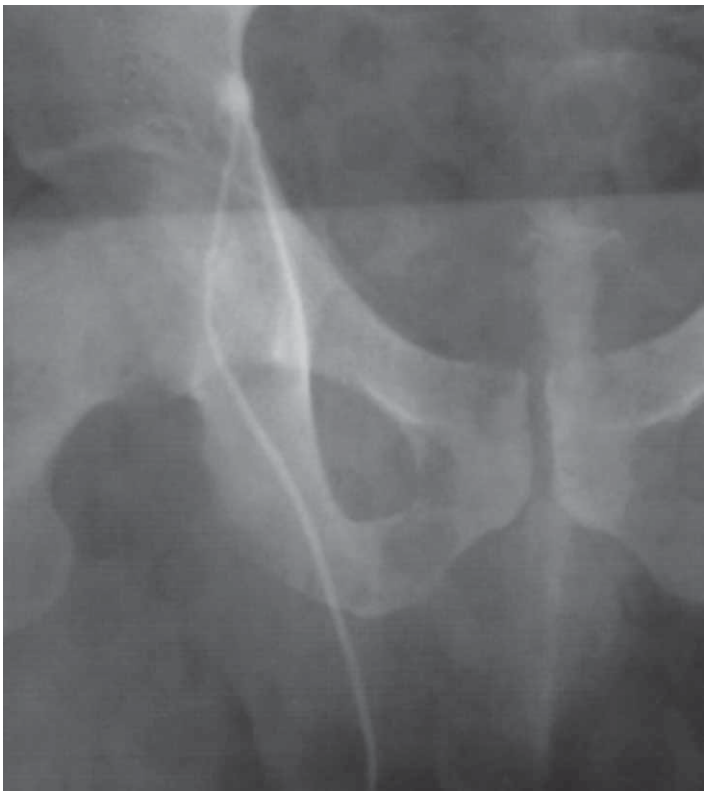

Figure 22–11. Vasography reveals an obstruction in the inguinal region.

pipettes (see Microsurgical Epididymal Sperm Aspiration Techniques later) and cryopreserved for future IVF with ICSI. If vasography reveals obstruction in the inguinal region (Fig. 22–11), either inguinal vasovasostomy or crossed transeptal vasovasostomy, using the contralateral unobstructed vas (see Crossed Vasovasostomy later), may be performed. **The hemitransected vasography sites are carefully closed microsurgically** using two or three interrupted 10-0 monofilament nylon for the mucosa and 9-0 for the muscularis and adventitia (see Microsurgical Multilayer Microdot Method later).

If the vasal fluid reveals no sperm and vasography confirms patency of the seminal vesicle end of the vas, the vas is completely transected and the seminal vesicle end is prepared for

vasoepididymostomy (see Vasoepididymostomy later). If the vasal fluid reveals many sperm and vasography is normal, either retrograde ejaculation, lack of emission, or aperistalsis of the vas (Tiffany and Goldstein, 1985; Tillem and Mellinger, 1999) is the cause of the azoospermia.

Fine-Needle Vasography

Exposure of the vas in its straight portion may allow vasography to be performed with a fine needle, obviating the need for hemitransection of the vas. Dewire and Thomas (1995) employed a 30-gauge lymphangiogram needle attached to Silastic tubing. When the sensation of puncture of the lumen is detected, 50% water-soluble contrast is injected to confirm patency radiographically. This has proven to be a difficult technique for even experienced microsurgeons to master. Accurate evaluation of vasal fluid for sperm is difficult because it is so scant. If barbotage with saline or lactated Ringer solution reveals the presence of sperm, then epididymal obstruction has been excluded and contrast can be injected. Collection of vasal sperm for cryopreservation is difficult with this technique. Percutaneous vasography through the scrotal skin has been successfully performed in China (Li) using the same ringed percutaneous fixation clamp employed for the no-scalpel vasectomy. After fixation of the vas beneath the scrotal skin, the vas lumen is punctured with a 22-gauge sharp needle and cannulated with a 24-gauge blunt needle through which vasography is performed. This technique is even more difficult than the direct-vision technique with a fine needle.

Complications of Vasography

Stricture

Multiple attempts at percutaneous vasography using sharp needles can result in stricture or obstruction at the vasography site. Imprecise closure of a vasotomy can also result in stricture and obstruction (Howards et al, 1975b; Poore et al, 1997). Non-water-soluble contrast agents may also result in stricture and should not be employed for vasography.

Injury to the Vasal Blood Supply

If the vasal blood supply is injured at the site of vasography, vasovasostomy proximal to the vasography site may result in ischemia, necrosis, and obstruction of the intervening segment of vas.

Hematoma

A bipolar cautery should be used for meticulous hemostasis at the time of vasostomy to prevent hematoma in the perivasal sheath.

Sperm Granuloma

Leaky closure of a vasography site may lead to the development of a sperm granuloma, which can result in stricture or obstruction of the vas. The microsurgical technique for closure of vasography sites is identical to that employed for vasovasostomy described later in this chapter.

Transrectal Vasography and Seminal Vesiculography

If transrectal ultrasound reveals markedly dilated seminal vesicles and/or a midline müllerian duct cyst in a man with obstructive azoospermia, transrectal aspiration followed by instillation of indigo carmine mixed with radiographic contrast is a useful diagnostic maneuver (Jarow, 1994; Katz et al, 1994; Riedenklau et al, 1995).

The same bowel prep and antibiotic coverage used for transrectal prostate biopsy is employed. The fine-needle aspirate is examined for sperm. If sperm are present it means at least one vas and epididymis are patent. One-half mL of indigo carmine is diluted with 1.5 mL of 50% water-soluble contrast and instilled. If a flat plate reveals a potentially resectable lesion, a TUR of the ejaculatory ducts is performed (see Transurethral Resection of the Ejaculatory Ducts later). Visualization of blue dye effluxing from the ejaculatory ducts or an unroofed cyst aids in determining the adequacy of the resection (Cornel et al, 1999).

This technique obviates the need for formal open scrotal vasography in men with transrectally accessible lesions. If sperm are found in the aspirate, a TUR may immediately be undertaken without violating the scrotum. Sperm-laden aspirates may be frozen for future IVF with ICSI if surgery fails.

If no sperm are found in the aspirated fluid, it suggests that secondary epididymal obstruction exists. Simultaneous TUR of the ejaculatory ducts and vasoepididymostomy is rarely successful. In the face of both ejaculatory duct obstruction and bilateral epididymal obstruction, the best option would be epididymal sperm aspiration for cryopreservation for future IVF/ICSI.

Summary

1. **Perform vasography only if testicular biopsy confirms spermatogenesis consistent with obstructive azoospermia.**
2. **Perform vasography only at the time of planned reconstruction.**
3. **Always sample vasal fluid first to allow cryopreservation of motile sperm if found.**
4. **Use indigo carmine instead of methylene blue to confirm patency.**
5. **Formal vasography with x-ray contrast is only needed to locate obstructions proximal to the internal inguinal ring.**
6. **If transrectal ultrasound reveals dilated seminal vesicles and/or a midline (Mullerian duct) cyst, transrectal fine needle aspiration followed by instillation of contrast and indigo carmine should be performed. If motile sperm are found they should be cryopreserved.**

VASOVASOSTOMY

Introduction

The number of American men who undergo vasectomy has remained stable at about 500,000 per year, as has the divorce rate of 50%. Surveys suggest that 2% to 6% of vasectomized men will ultimately seek reversal. Furthermore, obstructive azoospermia can be the result of iatrogenic injuries to the vas deferens, usually from hernia repair, in 6% of azoospermic men (Sheynkin et al, 1998a; Shin et al, 2005).

Preoperative Evaluation

Before attempted surgical reconstruction of the reproductive tract, adequate spermatogenesis should be documented. A prior history

of natural fertility prevasectomy is usually adequate. In other cases a testicular biopsy may be indicated to confirm the presence of spermatogenesis.

Physical Examination

a. Testis: Small or soft testes suggest impaired spermatogenesis and predict a poor outcome.
b. Epididymis: An indurated, irregular epididymis often predicts secondary epididymal obstruction, necessitating vasoepididymostomy.
c. Sperm granuloma: **A sperm granuloma at the testicular end of the vas suggests that sperm have been leaking at the vasectomy site. This vents the high pressures away from the epididymis and is associated with a better prognosis for restored fertility** regardless of the time interval since vasectomy.
d. Vasal gap: When a destructive vasectomy has been performed, most of the scrotal straight vas may be absent or fibrotic and the patient should be advised that inguinal extension of the scrotal incision will be necessary to mobilize adequate length of vas to enable a tension-free anastomosis.
e. Scars from previous surgery: Operative scars in the inguinal or scrotal region should alert the surgeon to the possibility of iatrogenic inguinal (hernia repair), vasal, or epididymal obstruction (hydrocelectomy, orchiopexy) (Sheynkin et al, 1998a; Hopps and Goldstein, 2006).

Laboratory Tests

a. **Semen analysis with centrifugation and examination of the pellet for sperm should be performed preoperatively. Complete sperm with tails are found in 10% of preoperative pellets a mean of 10 years after vasectomy** (Lemack and Goldstein, 1996). **Under these circumstances sperm are certain to be found in the vas on at least one side, indicating a favorable prognosis for restored fertility.** Men with a low semen volume should have a transrectal ultrasound to alert one to the possibility of an additional ejaculatory duct obstruction.
b. Serum and antisperm antibody studies: **The presence of serum antisperm antibodies corroborates the diagnosis of obstruction and the presence of active spermatogenesis** (Lee et al, 2009). At present this test is of unknown prognostic value and is optional.
c. Serum FSH: Men with small soft testes should have serum FSH measured. An elevated FSH predicts impaired spermatogenesis and a poorer prognosis.
d. Prostate-specific antigen (PSA): All vasectomy reversal candidates older than age 40 should have serum PSA measured.

Anesthesia

General anesthesia is preferred. Slight movements are greatly magnified by the operating microscope and disturb performance of the anastomosis. In cooperative patients regional or even local anesthesia with sedation can be employed if the vasal ends are easily palpable, a sperm granuloma is present, and/or the time interval since vasectomy is short, decreasing the likelihood of secondary epididymal obstruction. When large vasal gaps are present, extensions of the incisions high into the inguinal canal may be necessary. Furthermore, if vasoepididymostomy is necessary, the operating time could exceed 4 or 5 hours. **Local anesthesia limits the options available to the surgeon.**

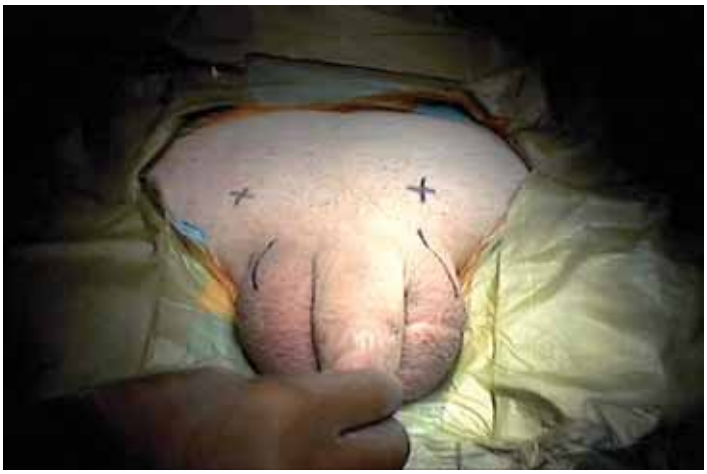

Figure 22–12. The X's mark the locations of the external ring. Incisions are marked on the hemiscrotums.

Hypobaric spinal anesthesia with long-acting agents such as Marcaine can provide 4 to 5 hours of anesthesia time and has the advantage of eliminating lower body motion. Epidural anesthesia with an indwelling catheter can be equally effective.

Surgical Approaches

Scrotal

Bilateral high vertical scrotal incisions provide the most direct access to the obstructed site in cases of vasectomy reversal. Length is usually a problem on the abdominal end but not on the testicular end. Mark the location of the external inguinal ring (Fig. 22–12). **If the vasal gap is large or the vasectomy site is high, this incision can easily be extended toward the external ring.** If the vasectomy site is low, it is easy to pull up the testicular end. This incision should be made at least 1 cm lateral to the base of the penis. **The testis should be delivered with the tunica vaginalis left intact.** This provides excellent exposure of the entire scrotal vas deferens and, if necessary, the epididymis.

Infrapubic Incision

An infrapubic incision provides excellent exposure when the abdominal end of the vas is short but awkward when vasoepididymostomy is necessary. In addition, surgeons should be cautious that, when vasal gaps are large, tension on the anastomosis may not be apparent during the surgery until an attempt is made to place the testis back into the scrotum. Overall this incision has no advantage over inguinal extension of a high scrotal incision.

Inguinal Incision

An inguinal incision is the preferred approach in men when obstruction of the inguinal vas deferens from prior herniorrhaphy or orchiopexy is strongly suspected. Incision through the previous scar usually leads directly to the site of obstruction. If the obstruction turns out to be scrotal or epididymal, it is a simple matter to deliver the testis through the inguinal incision or through a separate scrotal incision to perform the anastomosis.

Preparation of the Vasa

The vas is grasped above and below the site of obstruction with two Babcock clamps. Penrose drains replace the Babcock clamps and assist the dissection. The vasal vessels and periadventitial sheath are included. **Transillumination of the periadventitial sheath,** by properly adjusting the operating light, **allows clear visualization of the blood vessels, which facilitates dissection of the periadventitial sheath and prevents damage to the vasal vessels.** The vas is mobilized enough to allow a tension-free anastomosis. In order to preserve good blood supply **the vas should not be stripped of its sheath.** The obstructed segment and, if present, sperm granuloma at the vasectomy site should be dissected out and excised. By staying right on the vas and/or sperm granuloma during this dissection, the risk of injuring the testicular artery is reduced. **Injury to adjacent cord structures, especially the testicular artery, is likely to result in testicular atrophy because the vasal artery has usually been interrupted at the vasectomy site.**

When large vasal gaps are present, a gauze-wrapped index finger is used to bluntly separate the cord structures from the vas. Blunt finger dissection through the external ring will free the vas to the internal inguinal ring if additional abdominal side length is necessary. These maneuvers will leave all the vasal vessels intact. **When the vasal gap is extremely large, additional length can be achieved by dissecting the entire convoluted vas free of its attachments to the epididymal tunica** (Fig. 22–13), allowing the testis to drop upside down. These maneuvers can provide an additional 4 to 6 cm of length. In order to maintain the integrity of the vasal vessels, this dissection is best performed using magnifying loupes or the operating microscope under low power. If the amount of vas removed is so large that even these measures fail to allow a tension-free anastomosis, the incision can be extended to the internal inguinal ring, the floor of the inguinal canal cut, and the vas rerouted under the floor, as in a difficult orchiopexy. An additional 4 to 6 cm of length can be obtained by dissecting the epididymis off of the testis from the vasoepididymal junction to the caput epididymis (Fig. 22–14A and B). The superior epididymal vessels are left intact and provide adequate blood supply to the testicular end of the vas. With this combination of maneuvers, up to 10 cm gaps can be bridged.

After the vasa have been freed, the testicular end of the vas is cut transversely. An ultrasharp knife drawn through a slotted 2-, 2- to 5-, or 3-mm diameter nerve holding clamp (Accurate Surgical

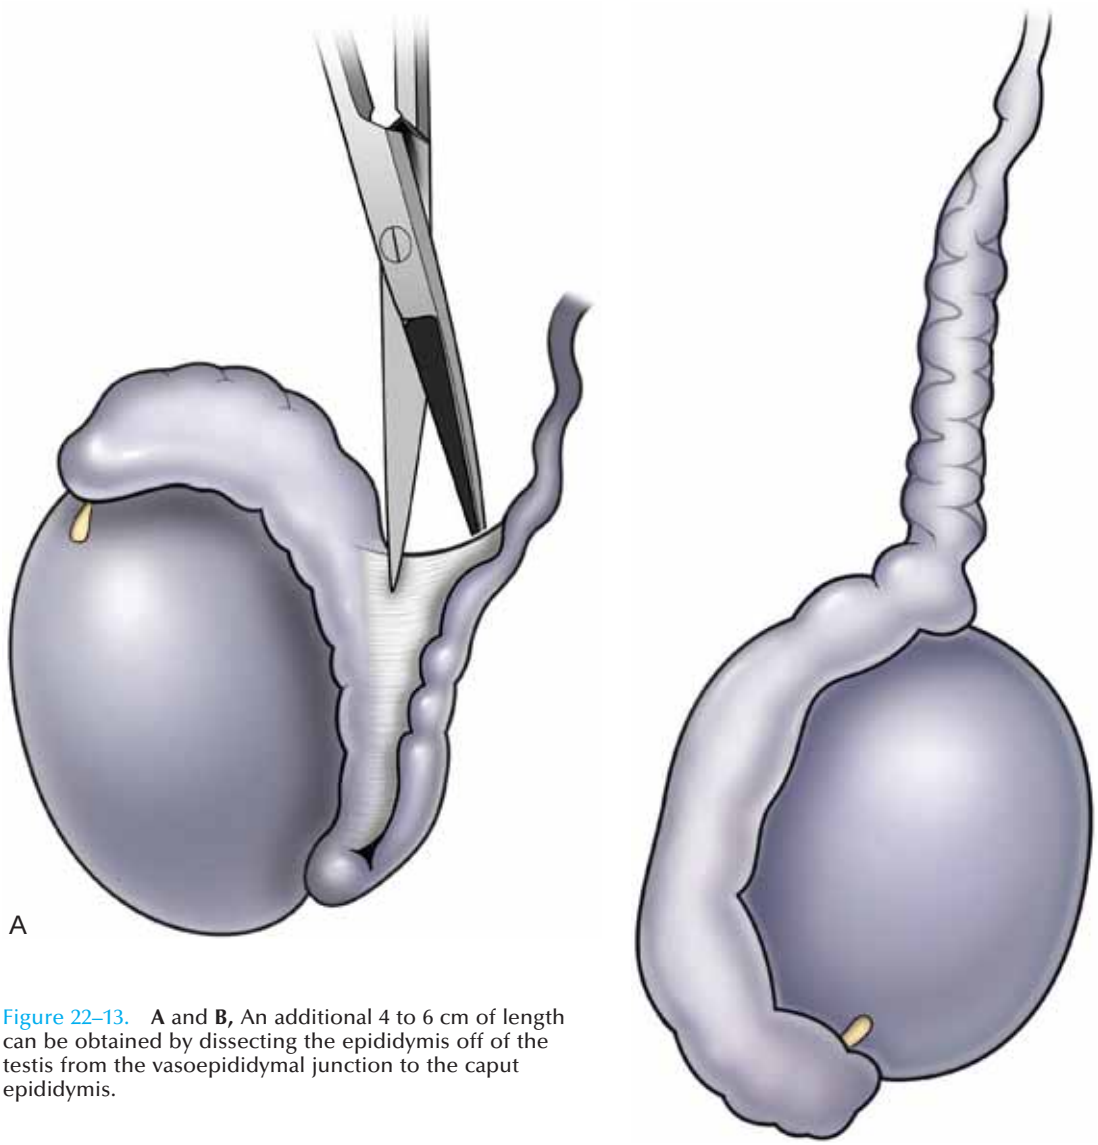

Figure 22–13. **A** and **B,** An additional 4 to 6 cm of length can be obtained by dissecting the epididymis off of the testis from the vasoepididymal junction to the caput epididymis.

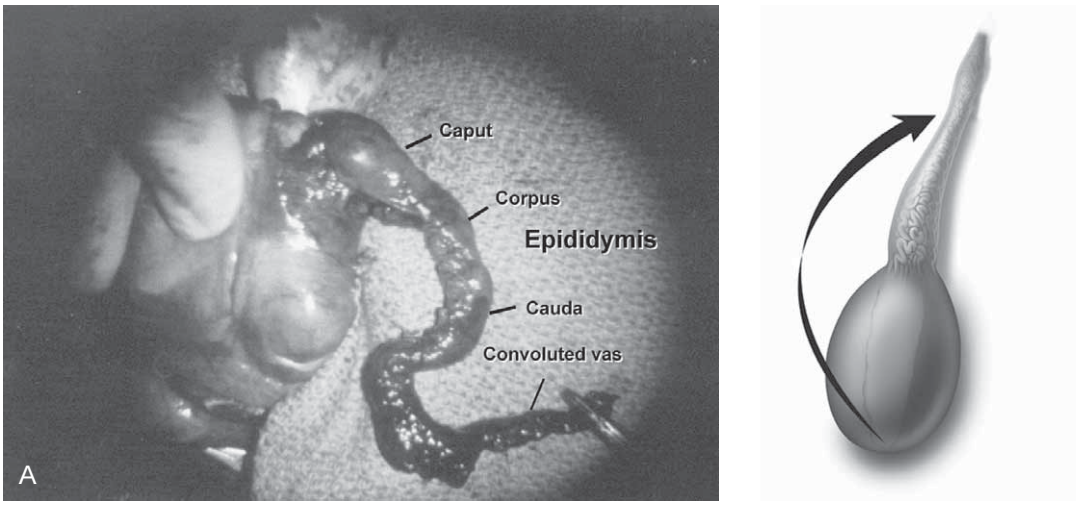

Figure 22–14. **A** and **B,** An additional 4 to 6 cm of length can be obtained by dissecting the epididymis off of the testis from the vasoepididymal junction to the caput epididymis.

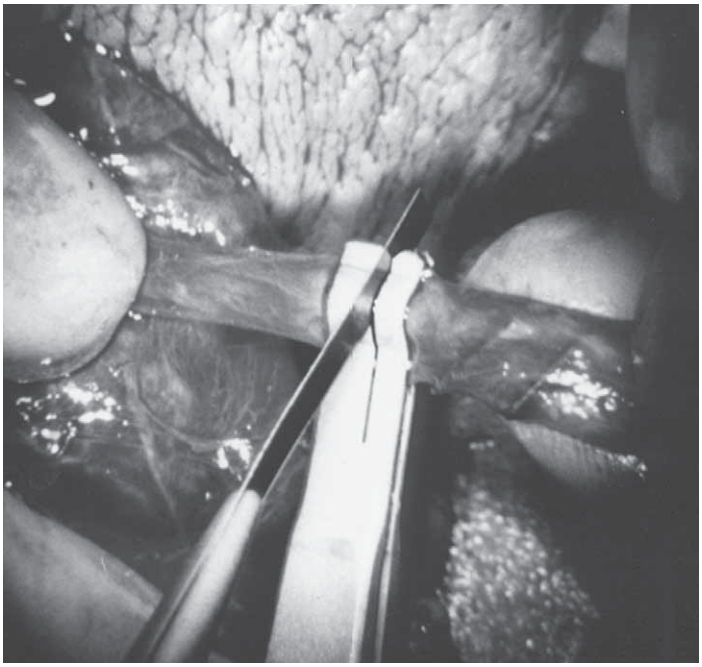

Figure 22–15. An ultrasharp knife drawn through a slotted 2.5- or 3-mm diameter nerve-holding clamp (Accurate Surgical and Scientific Instrument Corp., Westbury, NY) yields a perfect 90-degree cut.

and Scientific Instrument Corp., Westbury, NY) yields a perfect 90-degree cut (Fig. 22–15). The cut surface of the testicular end of the vas deferens is inspected using 15- to 25-power magnification. **A healthy white mucosal ring that springs back immediately after gentle dilation should be seen. The muscularis should appear smooth and soft. A gritty-looking muscularis layer indicates the presence of scar/fibrotic tissues.** The cut surface should look like a bull's-eye with the three vasal layers distinctly visible. Healthy bleeding should be noted from both the cut edge of the mucosa and the surface of the muscularis. If the blood supply is poor or the muscularis is gritty, the vas is recut until healthy tissue is found. The vasal artery and vein are then clamped and ligated with 6-0 nylon. Small bleeders are controlled with a microbipolar forcep set at low power. Once a patent lumen has been established on the testicular end, the vas is milked and a clean glass slide is touched to its surface. The vasal fluid is immediately mixed with a drop or two of saline or lactated Ringer solution and preserved under a cover slip for microscope examination. The abdominal end of the vas deferens is prepared in a similar manner, and the lumen gently dilated with a microvessel dilator and cannulated with a 24-gauge angiocatheter sheath. Injection of saline or lactated Ringer solution confirms its patency. After the Ringer injection and a test dilation, the vas is recut to obtain a fresh surface. **A minimum of instrumentation of the mucosa should be performed.**

After preparation, the ends of the vasa are stabilized with a Microspike approximating clamp (Goldstein, 1985) to remove all tension before performing the anastomosis. Isolating the field through a slit in a rubber dam prevents microsutures from sticking to the surrounding tissue. A sterile tongue blade covered with a large Penrose drain is placed beneath the ends of the vasa to provide a platform on which to perform the anastomosis.

When to Perform Vasoepididymostomy

The gross appearance of fluid expressed from the testicular end of the vas is usually predictive of findings on microscopic examination (Table 22–2). If microscopic examination of the vasal fluid reveals the presence of sperm with tails, vasovasostomy is performed. If no fluid is found, a 24-gauge angiocatheter sheath is inserted into the lumen of the testicular end of the vas and barbotaged with 0.1 mL of saline while the convoluted vas is vigorously milked. The barbotage fluid is expressed onto a slide and examined. **Men with large sperm granulomas often have virtually no dilation of the testicular end of the vas and little or no fluid initially; however, with barbotage and vigorous milking, sperm can invariably be found in this scant fluid.** If there is no sperm granuloma and the vas is absolutely dry and spermless after multiple samples are examined, vasoepididymostomy is indicated. If the fluid expressed from the vas is found to be thick, white, water insoluble, and like toothpaste in quality, microscopic examination rarely reveals sperm. Under these circumstances, the tunica vaginalis is opened and the epididymis inspected. If clear evidence of obstruction is found (i.e., an epididymal sperm granuloma with dilated tubules above and collapsed tubules below), vasoepididymostomy is performed.

Table 22–2.
Relationship between Gross Appearance of Vasal Fluid and Microscopic Findings

VASAL FLUID APPEARANCE	MOST COMMON FINDINGS ON MICROSCOPIC EXAMINATION	SURGICAL PROCEDURE INDICATED
Copious, crystal clear, watery	No sperm in fluid	Vasovasostomy
Copious, cloudy thin, water soluble	Usually sperm with tails	Vasovasostomy
Copious, creamy yellow, water soluble	Usually many sperm heads; occasionally sperm have short tails	Vasovasostomy
Copious, thick, white toothpaste-like, water insoluble	No sperm	Vasoepididymostomy
Scant white thin fluid	No sperm	Vasoepididymostomy
Dry spermless vas—no granuloma at vasectomy site	No sperm	Vasoepididymostomy
Scant fluid, granuloma present at vasectomy site	Barbotage fluid reveals sperm	Vasovasostomy

When in doubt or if not experienced with vasoepididymostomy, vasovasostomy should be performed. However, only 15% of men with bilateral absence of sperm in the vasal fluid after barbotage and an intensive search will have sperm return to the ejaculate after vasovasostomy (Sheynkin et al, 2000).

When copious, crystal-clear, water-like fluid squirts out from the vas and no sperm are found in this fluid, a vasovasostomy is performed because the likelihood is that sperm will return to the ejaculate after vasovasostomy is performed.

Multiple Vasal Obstructions

If saline injection reveals that the abdominal end of the vas deferens is not patent, a 2-0 nylon or polypropylene suture is gently threaded into the vas lumen to determine the site of obstruction. If the obstruction is within 5 cm of the original vasectomy site, the abdominal end of the vas deferens may be dissected to this site and excised. The incision should then be extended inguinally to free the vas up extensively toward the internal inguinal ring. The testicular end then should also be freed up to the vasoepididymal junction. If the site of the second obstruction is so far from the vasectomy site that two vasovasostomies are necessary, a single crossed vasovasostomy should be performed to yield one good system (see Crossed Vasovasostomy earlier). If this is not possible, vasal or epididymal sperm is aspirated into micropipets and cryopreserved for future IVF with ICSI (see Sperm Retrieval Techniques later). **Simultaneous vasovasostomies at two separate sites may lead to devascularization of the intervening segment with fibrosis and necrosis.**

Varicocelectomy and Vasovasostomy

When men presenting for vasovasostomy or vasoepididymostomy are found to have significant varicoceles on physical examination, it is tempting to repair the varicoceles at the same time. **When varicocelectomy is properly performed, all spermatic veins are ligated and the only remaining avenues for testicular venous return are the vasal veins. In men who have had vasectomy and are presenting for reversal, the vasal veins are likely to be compromised from either the original vasectomy or the reversal itself. Furthermore, the integrity of the vasal artery in those men is also likely to be compromised. Varicocelectomy in such men requires preservation of the testicular artery as the primary remaining testicular blood supply, as well as preservation of some avenue for venous return.**

Microscopic varicocelectomy can assure preservation of the testicular artery in most cases. Deliberate preservation of the cremasteric veins provides venous return. In one series of 570 men presenting for vasectomy reversal, 19 had large varicoceles (20 left, 7 bilateral). Microsurgical varicocelectomy was performed at the same time as vasovasostomy. The cremasteric veins and the fine network of veins adherent to the testicular artery were left intact for venous return and to minimize the chances of injury to the testicular artery. Postoperatively 5 of 26 varicoceles recurred (22%) (Goldstein, 1995). This compares with a recurrence rate of less than 1% in 2700 varicocelectomies performed by the author in nonvasectomized men in whom the vasal vessels were intact and the cremasteric veins and periarterial venous network were ligated. However, Mullhall and colleagues performed a series of simultaneous microsurgical vasovasostomies and varicocelectomies without intentionally preserving the cremasteric and periarterial network. They reported a low recurrence rate and no cases of atrophy (Mulhall et al, 1997). Interestingly, the increase in recurrences when the cremasteric veins and periarterial venous network were left intact suggests that these veins contribute to a significant proportion of varicocele recurrences.

If varicocelectomy is performed at the same time as vasovasostomy or vasoepididymostomy, it is important that a microscope be used and the testicular artery preserved. A safer approach is to do the vasovasostomy or vasoepididymostomy first. The semen quality is then assessed postoperatively. **If necessary, varicocelectomy can be safely performed 6 months or more later when venous and arterial channels have formed across the anastomotic line.** This two-stage delayed approach has been completed a dozen times with no atrophy or recurrence.

Anastomotic Techniques: Keys to Success

All successful vasovasostomy techniques depend on adherence to surgical principles that are universally applicable to anastomoses of all tubular structures.

These include the following:

1. **Accurate mucosa to mucosa approximation.**
   In human vasovasostomy, the lumen on the testicular side is usually dilated, often to diameters two to five times that of the abdominal side. Techniques that work well with lumina of equal diameters may be less successful when applied to lumina of markedly discrepant diameters.
2. **Leakproof anastomosis.**
   Sperm are highly antigenic and provoke an inflammatory reaction when they escape from the normally intact lining of the excurrent ducts of the male reproductive tract. Extravasated sperm adversely influence the success of

vasovasostomy (Hagan and Coffey, 1977). **Unlike blood vessel anastomoses, in which platelets and clotting factors seal the gaps between sutures, vasal and epididymal fluid contain no platelets or clotting factors, so the water-tightness of the anastomosis is entirely dependent on the mucosal sutures.**

3. **Tension-free anastomosis.**
   When an anastomosis is performed under tension, sperm may appear in the ejaculate for several months after surgery. Ultimately, sperm counts and motility will decrease and azoospermia may ensue. At re-exploration only a thin fibrotic band is found at the anastomotic site. This can be prevented by adequately freeing up the vasa and placement of re-enforcing sutures in the sheath of the vas.
4. **Good blood supply.**
   If the cut vas exhibits poor blood supply, it should be recut until healthy bleeding is encountered. If extensive resection is necessary, additional length should be obtained using the techniques previously described.
5. **Healthy mucosa and muscularis.**
   If the mucosa or cut surface of the vas exhibits poor distensibility after dilation, peels away from the underlying muscularis, or shreds easily, then the vas should be cut back until healthy mucosa is found. Surgeons should be aware that if a needle electrocautery was used in vasectomy, the area of damage to the mucosa and muscularis by the electric current may extend far beyond the tip of the needle cautery. If the muscularis is found to be fibrotic or gritty, the vas must be recut until healthy tissue is found.
6. **Good atraumatic anastomotic technique.**
   If multiple surgical errors occur during the procedure such as inadvertent cutting of the mucosa with the needles when placing sutures, tearing through of sutures, or backwalling of the mucosa, the anastomosis should be resected and redone immediately.

Setup

An operating microscope providing variable magnification from 6 to 32 power is employed. A diploscope providing identical fields for both surgeon and assistant is preferred. Foot pedal controls for a motorized zoom and focus leave the surgeon's hands free.

Both surgeon and assistant should be comfortably seated on microsurgical chairs that stabilize the chest and arms. This dramatically improves stability and accuracy. An inexpensive alternative is a simple rolling stool with a round bean bag (meditation pillow) taped on top for padding. Two arm boards, placed on either side of the surgeon and built up to the appropriate height with folded blankets taped to the board, provide excellent arm support. **A right-handed surgeon should sit on the patient's right side** so that his or her forehand stitch is always on the smaller, more difficult abdominal-side lumen.

Microsurgical Multilayer Microdot Method

This method of vasovasostomy can handle lumina of markedly discrepant diameters in the straight or convoluted vas. **The microdot technique ensures precise suture placement by exact mapping of each planned suture. The microdot method separates the planning from the placement** (Goldstein et al, 1998). This allows focus on only one task at a time and results in substantially improved accuracy.

A microtip marking pen (Devon Skin Marker Extra Fine No. 151) is used to map out planned needle exit points. **Exactly six mucosal sutures are used for every anastomosis** because it is easy to map out and always results in a leakproof closure even when the lumen diameters are markedly discrepant.

Immediately after drying the cut surface of the testicular end of vas with a Weck cell, a dot is made at 3 o'clock halfway between the mucosal ring and the outer edge of the muscle layer. A line is extended out from this dot to serve as a reference point. The second dot is made at 9 o'clock, and a line is extended from this dot as well. Additional dots are placed at 11, 1, 5, and 7 o'clock for a total of six. The abdominal end of the vas is marked in the same way to exactly match the testicular end (Fig. 22–16). Monofilament 10-0 nylon sutures, double-armed with 70-µm diameter taper-point needles bent into a fish hook configuration (available from Sharpoint and Ethicon), are used. **Double-armed sutures allow inside-out placement** (Fig. 22–17), **eliminating the need for manipulation of the mucosa and the possibility of back-walling.** If the mucosal rings are not sharply defined, stain the cut surfaces of the vasal ends with indigo carmine to highlight the mucosa (Sheynkin et al, 1999a). The anastomosis is

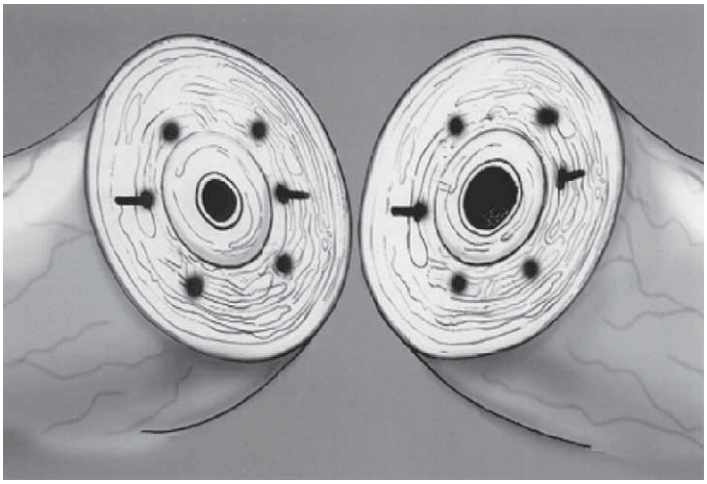

Figure 22–16. The abdominal end of the vas is marked in the same way to exactly match the testicular end.

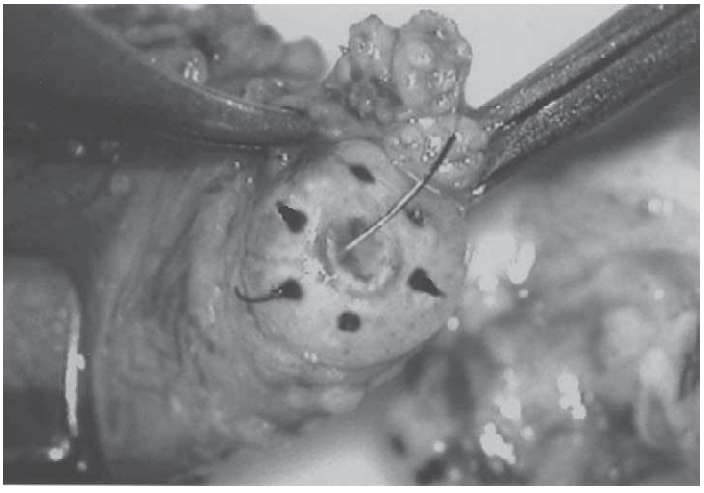

Figure 22–17. Double-armed sutures allow inside-out placement.

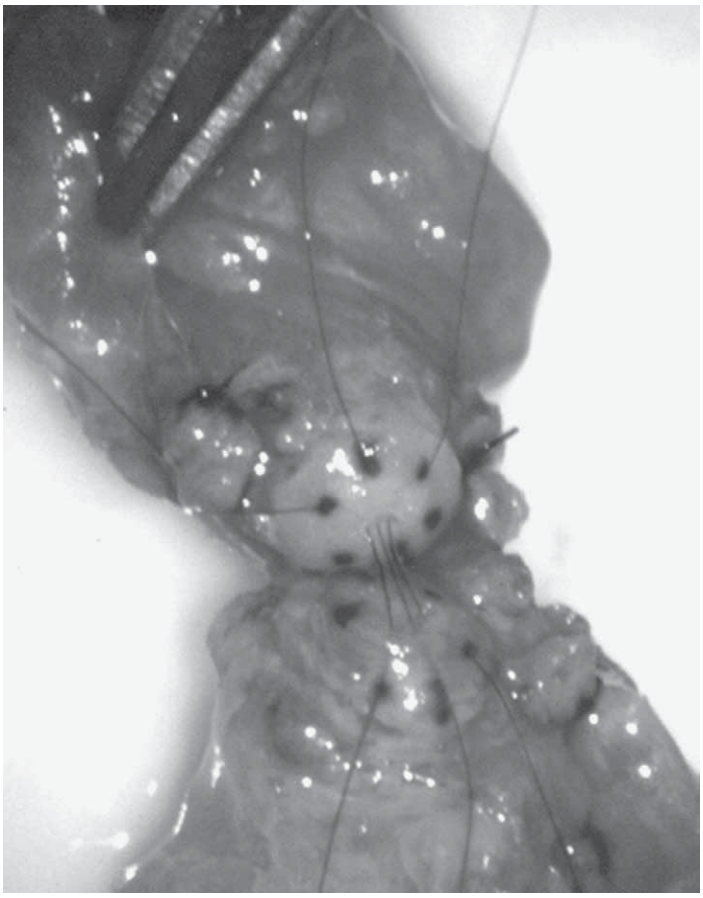

Figure 22–18. The anastomosis is begun with the placement of three 10-0 mucosal sutures anteriorly.

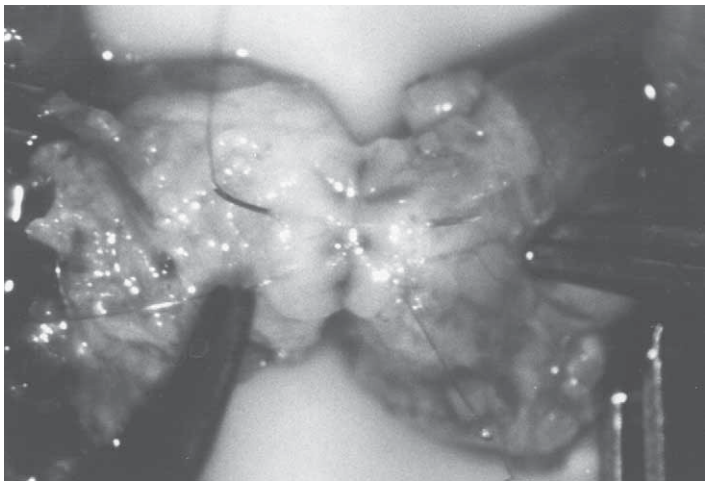

Figure 22–19. Place two 9-0 monofilament nylon deep muscularis sutures exactly in between the previously placed mucosal sutures, just above, but not through, the mucosa.

begun with the placement of three 10-0 mucosal sutures anteriorly (Fig. 22–18). **On the small abdominal side lumen, gently and momentarily dilate the lumen with a microvessel dilator just before placement of the sutures.** For accurate mucosal approximation, include only a small amount of mucosa but one-third to one-half the muscle wall thickness. **Include exactly the same amount of tissue in the bites on each side. The needle should exit through the center of each dot.** After placement, tie the three mucosal sutures. Place two 9-0 monofilament nylon deep muscularis sutures exactly in between the previously placed mucosal sutures, just above, but not through the mucosa (Fig. 22–19) and then tie them. These sutures seal the gaps between the mucosal sutures without trauma to the mucosa from the larger 100-μm diameter cutting needle required to penetrate the tough vas muscularis and adventitia. Rotate the vas 180 degrees (Fig. 22–20) and place three additional 10-0 sutures through each microdot and then tie them to complete the mucosal portion of the anastomosis (Fig. 22–21). Just before tying the last mucosal suture, irrigate the lumen with heparinized Ringer solution to prevent the formation of clot in the lumen. After completion of the mucosal layer (Fig. 22–22), place four more 9-0 deep muscularis sutures exactly in between each mucosal suture, just above but not penetrating the mucosa. Place four to six 9-0 nylon interrupted sutures, between each muscular suture. This is a purely adventitial layer that covers the underlying mucosal suture. Finish the anastomosis by approximating the vasal sheath with six interrupted sutures of 8-0 nylon completely covering the anastomosis and relieving it of all tension (Fig. 22–23).

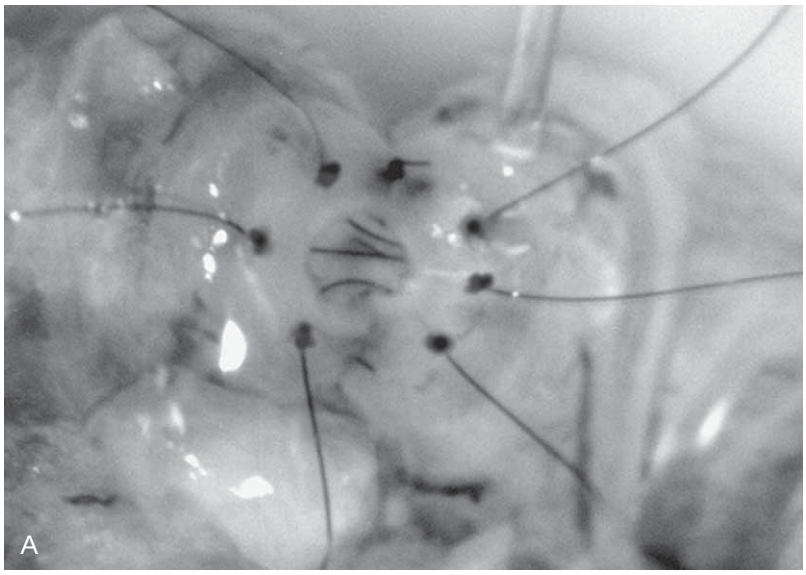
Anastomosis in the Convoluted Vas

Vasovasostomy performed in the convoluted portion of the vas deferens is technically more demanding than anastomoses in the straight portion. **Fear of cutting back into the convoluted vas in order to obtain healthy tissue may lead surgeons to complete an anastomosis in the straight portion when the testicular end of the vas has poor blood supply, unhealthy or friable mucosa, or gritty fibrotic muscularis.** Adherence to the following principles will enable anastomosis in the convoluted vas to succeed as often as those in the straight portion.

1. **A perfect transverse cut yielding a round ring of mucosa and a lumen directed straight down is essential.** An oblique lumen with a thin flap of muscle and mucosa on one side is not acceptable (Fig. 22–24). The vas should be recut at 0.5-mm intervals until a perfect cut with good blood supply and healthy tissue is obtained. A slotted nerve clamp 2.5 or 3 mm in diameter and ultrasharp knife assists this part of the procedure (see Fig. 22–15). Often the vas must be recut two or three times until a satisfactory cut is obtained.
2. **The convoluted vas should not be unraveled.** This disturbs the blood supply at the anastomotic line.
3. The sheath of the convoluted vas may be carefully dissected free of its attachments to the epididymal tunica (see Fig. 22–13). This will minimize disturbance of its blood supply and provide the necessary length to perform a tension-free anastomosis.
4. Care must be taken to avoid taking large bites of the muscularis and adventitial layers on the convoluted side to prevent inadvertent perforation of adjacent convolutions.
5. Reinforce the anastomosis by approximating the vasal sheath of the straight portion to the sheath of the convoluted portion with six interrupted sutures of 7-0 nylon. This will remove all tension from the anastomosis.

Crossed Vasovasostomy

This is a useful procedure that often provides an easy solution for otherwise difficult problems (Lizza et al, 1985; Hamidinia, 1988;



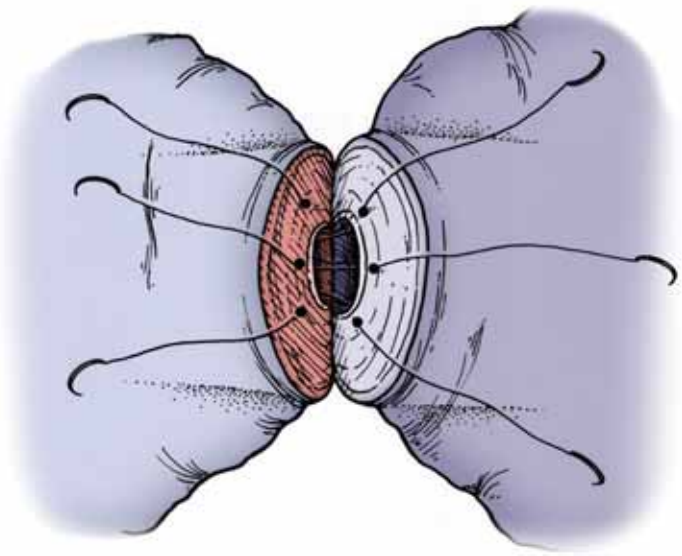


Figure 22–20. **A** and **B,** Rotate the vas 180 degrees and then place three more 10-0 sutures through the remaining microdots.

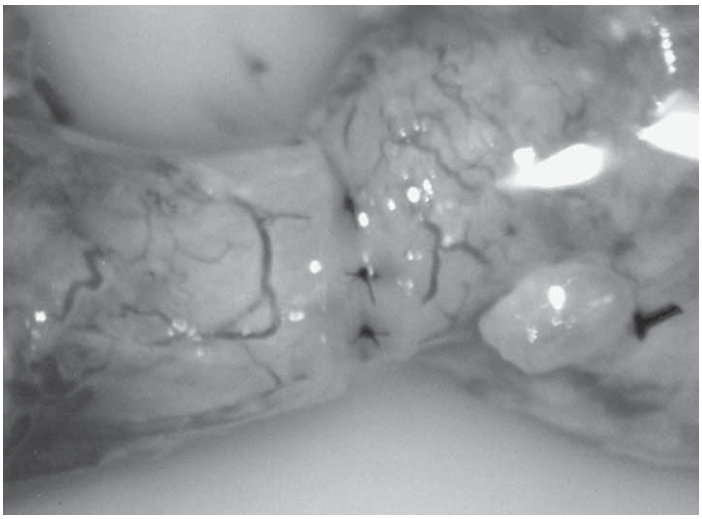

Figure 22–21. The mucosal layer is complete.

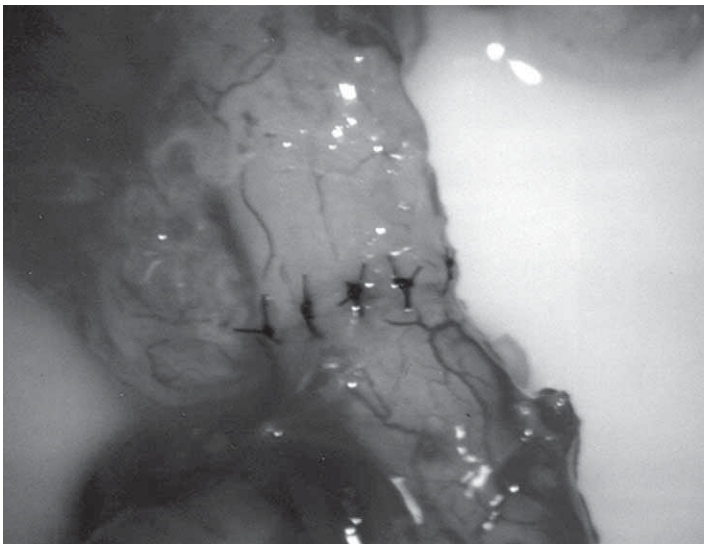

Figure 22–22. Additional sutures are placed in between the mucosal sutures, completing the anastomosis.

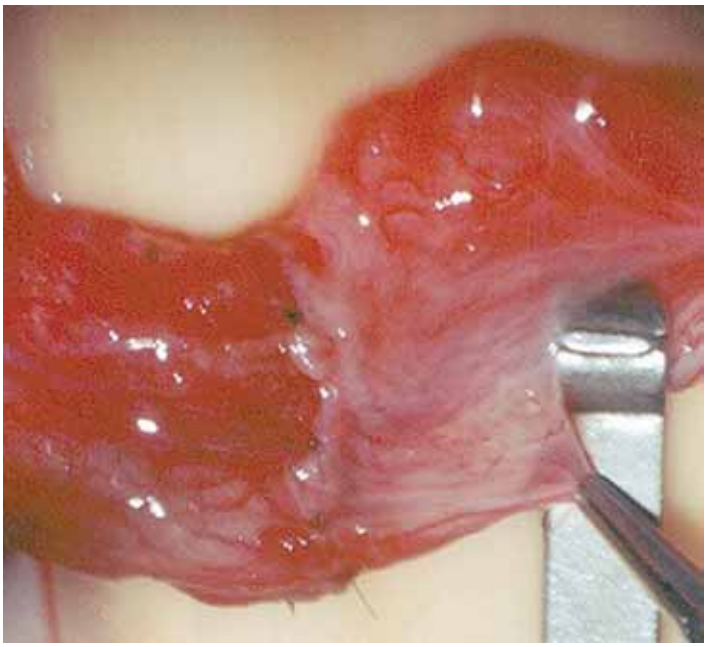

Figure 22–23. Finish the anastomosis by approximating the vasal sheath with six interrupted sutures of 7-0 polydioxanone, completely covering the anastomosis and relieving it of all tension.

Sheynkin et al, 1998a). **Crossover is indicated in the following circumstances:**

1. **Unilateral inguinal obstruction of the vas deferens associated with an atrophic testis on the contralateral side. A crossover vasovasostomy should be performed to connect a healthy testicle to the contralateral unobstructed vas.**
2. **Obstruction or aplasia of the inguinal vas or ejaculatory duct on one side and epididymal obstruction on the contralateral side.**

It is preferable to perform one anastomosis with a high probability of success (vasovasostomy) rather than two operations with a much lower chance of success (i.e., unilateral vasovasoepididymostomy and contralateral transurethral resection of the ejaculatory ducts).

Technique

Transect the vas attached to the atrophic testis at the junction of its straight and convoluted portion and confirm its patency with a Ringer or indigo carmine vasogram (Fig. 22–25). Dissect the contralateral vas with the normal testis toward the inguinal obstruction. Clamp and transect it as high up as possible with a right-angle clamp. Cross the testicular end of the vas through a capacious opening made in the scrotal septum and proceed with vasovasostomy as described earlier. This procedure is much easier than inguinal vasovasostomy, which requires finding both ends of the vas within the dense scar of a previous inguinal operation.

Transposition of the Testis

Occasionally when vasal length is critically short, a tension-free crossed anastomosis can best be accomplished by testicular transposition (Fig. 22–26). The spermatic cord is always longer than the vas. The testes will comfortably cross through a generous opening in the septum and sit nicely in the contralateral scrotal compartment.

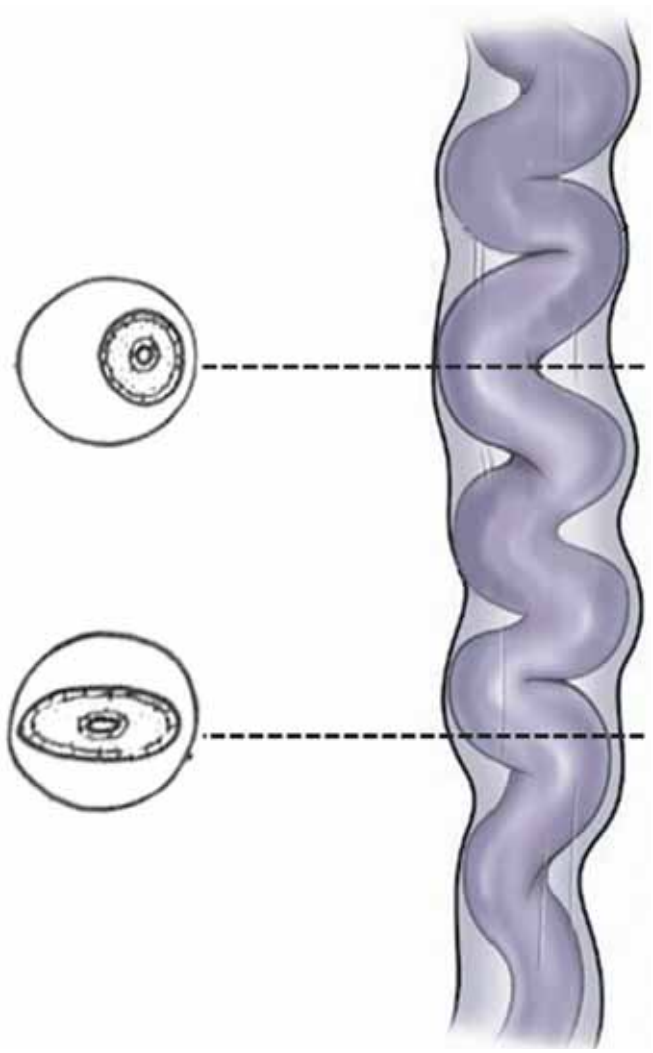

Figure 22–24. An oblique lumen with a thin flap of muscle and mucosa on one side is not acceptable.

Wound Closure

If the vasal dissection was extensive, Penrose drains are brought out the dependent portion of the right and left hemiscrota and fixed in place with sutures and safety pins preferably before beginning the anastomosis. Placement of drains at the end of the procedure may potentially disturb the anastomosis. The dartos layer is approximated with interrupted 4-0 absorbable sutures and the skin with subcuticular sutures of 5-0 Monocryl. The wound heals with a fine scar. The use of through-and-through skin closures, which give an unacceptable railroad-track-looking scar, should be avoided. **Virtually all of our procedures are performed on an ambulatory basis.** If drains were placed, the patients are given detailed instructions (with explicit drawings) on how to remove the drains the next morning.

Postoperative Management

Sterile fluff gauze dressings are held in place with a snug-fitting scrotal supporter. Only perioperative antibiotics are used. Patients are discharged with a prescription for acetaminophen with codeine. They shower 48 hours after surgery. **They wear a scrotal supporter at all times (except in the shower),**

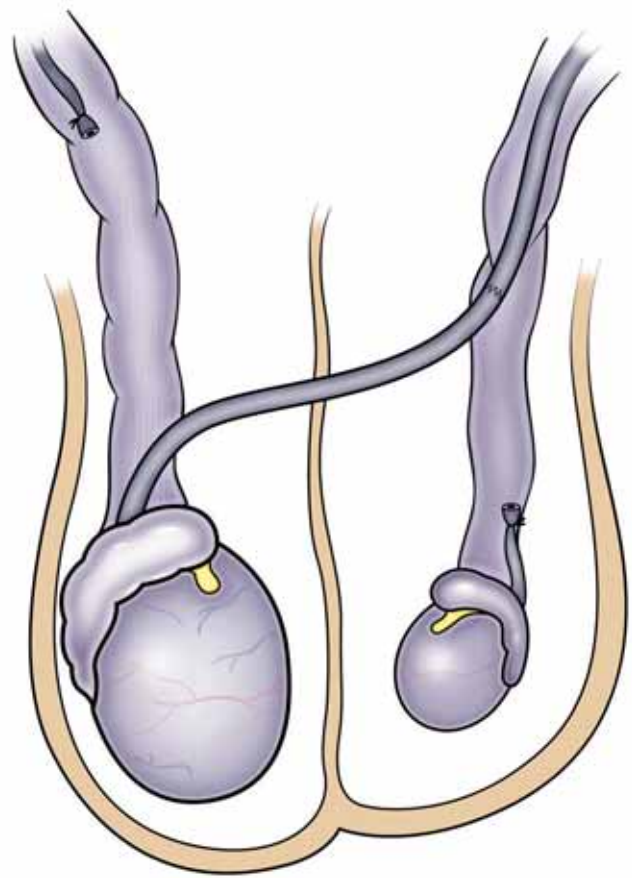

Figure 22–25. A crossed vasovasostomy can be done in cases with a unilateral atrophic testis.

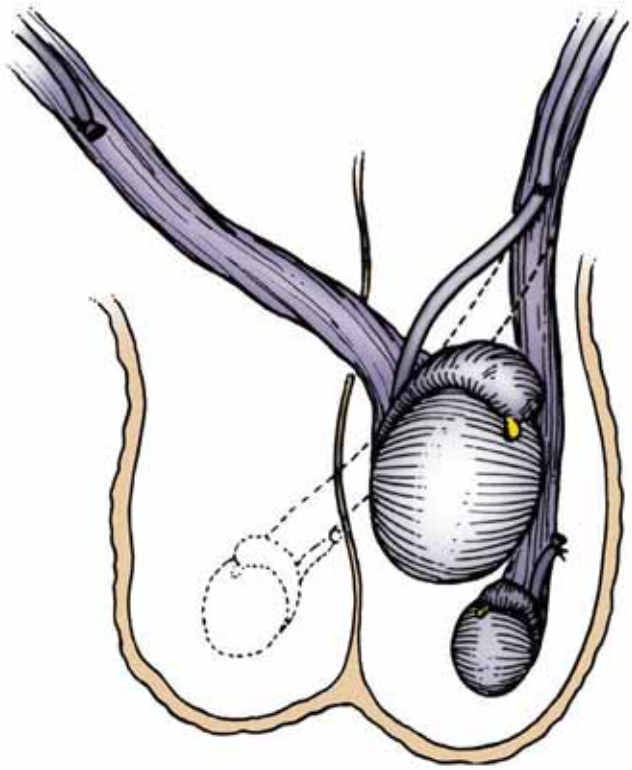

Figure 22–26. Occasionally, when vasal length is critically short, a tension-free crossed anastomosis can best be accomplished by testicular transposition.

even when sleeping, for 6 weeks postoperatively. Thereafter a scrotal supporter is worn during athletic activity until pregnancy is achieved. Desk work is resumed in 3 days. No heavy work or sports are allowed for 3 weeks. **No intercourse or ejaculation is allowed for 4 weeks postoperatively.** Semen analyses are obtained at 1, 3, and 6 months postoperatively and every 6 months thereafter. If azoospermia persists at 6 months, a redo vasovasostomy or vasoepididymostomy will be necessary.

Postoperative Complications

The most common complication is hematoma. In 2500 operations seven small hematomas occurred. None required surgical drainage. Most were walnut sized and perivasal. They take 6 to 12 weeks to resolve. Wound infection has not occurred. Late complications include sperm granuloma at the anastomotic site (≈5%). This is usually a harbinger of eventual obstruction. Late stricture and obstruction are disappointingly common (see later). **Progressive loss of motility followed by decreasing counts indicates stricture.** Our recent change from Proline to **nylon sutures** (Sheynkin et al, 1999a), **use of the microdot system to prevent leaks, extensive dissection of the vas until healthy mucosa and muscularis are identified, constant attention to the preservation of good blood supply, as well as generous use of scrotal support until pregnancy is established, has reduced the incidence of late obstruction from 12%** (Matthews et al, 1995) **to 5%** (Kolettis and Thomas, 1997) **at 18 months after surgery. Because of the risk of late stricture and obstruction, we strongly encourage cryopreservation of semen specimens as soon as motile sperm appear in the ejaculate.**

Long-Term Follow-Up Evaluation after Vasovasostomy

When sperm are found in the vasal fluid on at least one side at the time of surgery, the anastomotic technique described results in appearance of sperm in the ejaculate in 99.5% of men (Goldstein et al, 1998). Pregnancy has occurred in 52% of couples followed for at least 2 years and 63% when female factors are excluded with outcomes dependent on the time since vasectomy and female partner age (Kolettis et al, 2003; Boorjian et al, 2004; Kolettis et al, 2005; Gerrard et al, 2007).

SURGERY OF THE EPIDIDYMIS

Introduction

Detailed knowledge of epididymal anatomy and physiology (presented in Chapters 2 and 20) is essential before undertaking surgery of this delicate but important structure. Sperm motility and fertilizing capacity progressively increase during passage through the 200-µm diameter, 12- to 15-foot-long, tightly coiled single tubule. When the epididymis is obstructed and functionally shortened after vasoepididymostomy, even short lengths of epididymis are able to adapt and allow some sperm to acquire motility and fertilizing capacity (Silber, 1989a, 1989b; Jow et al, 1993). Adaptation may gradually continue up to 2 years after surgical reconstruction, with progressive improvement in the fertility and motility of sperm. Nevertheless, preservation of the greatest possible length of functional epididymis is most likely to result in the best sperm quality after vasoepididymostomy (Schoysman and

Bedford, 1986; Schlegel and Goldstein, 1993). Furthermore, because the wall of the epididymis is thinnest in the caput region and gradually thickens, due to the increasing numbers of smooth muscle cells in its more distal (inferior) end, anastomoses are technically easier to perform and more likely to succeed in distal regions. **Because the corpus and cauda epididymis is a single tubule with a small diameter, injury or occlusion of a tubule anywhere along its length will lead to total obstruction of outflow at that level.** For these reasons, **magnification, with loupes for macrodissection and with the operating microscope for anastomosis, is essential for performing all epididymal surgery.**

Fortunately, the epididymis is blessed with a rich blood supply derived from the testicular vessels superiorly and the deferential vessels inferiorly (see Testicular Blood Supply earlier and Chapter 2). Because of the extensive interconnections between these branches, either the testicular or deferential branches (but not both) to the epididymis may be divided without compromising epididymal viability.

Conversely, because the epididymal branches of the testicular artery are medial to and separate from the main testicular artery and veins, surgical procedures may be performed on the epididymis without compromise to testicular blood supply.

Table 22–3.

Comparison of Three Common Techniques for Vasoepididymostomy

TECHNIQUES	ADVANTAGES	DISADVANTAGES
Intussusception	2-3 sutures placed in the epididymal tubule provide 4 and 6 points of fixation. Virtually bloodless anastomosis.	Cannot assess tubular fluid for sperm before anastomosis setup.
End-Side	Virtually bloodless anastomosis. Epididymal fluid can be examined before anastomosis.	Difficult suture placement to a collapsed tubule.
End-End	Epididymal fluid can be examined before anastomosis. Easy and rapid identification of the level of obstruction in the epididymis. Allows upward mobilization of epididymis to bridge a large vasal gap.	Difficult hemostasis on transected epididymis. Difficult to identify the proper tubule for anastomosis. Difficult outer-layer closure. Vasal blood supply from inferior epididymal artery is sacrificed.

Vasoepididymostomy

Introduction

Before the development of microsurgical techniques, accurate approximation of the vasal lumen to that of a specific epididymal tubule was not possible. Vasoepididymostomy was performed by aligning the vas deferens adjacent to a slash made in multiple epididymal tubules and hoping a fistula would form. Results with this primitive technique were poor. Microsurgical approaches allow accurate approximation of the vasal mucosa to that of a single epididymal tubule (Silber, 1978), resulting in marked improvement in the patency and pregnancy rates (Schlegel and Goldstein, 1993; Chan et al, 2005). **Microsurgical vasoepididymostomy,** however, **is the most technically demanding procedure in all of microsurgery.** In virtually no other operation are results so dependent on technical perfection. **Microsurgical vasoepididymostomy should only be attempted by experienced microsurgeons who perform the procedure frequently.**

Indications

The indications for vasoepididymostomy at the time of vasectomy reversal are reviewed in Vasovasostomy earlier. For obstructive azoospermia not due to vasectomy, **vasoepididymostomy is indicated when the testis biopsy reveals complete spermatogenesis and scrotal exploration reveals the absence of sperm in the vasal lumen with no vasal or ejaculatory duct obstruction.** The preoperative evaluation is identical to that described in the previous section on vasovasostomy.

Microsurgical End-to-Side Vasoepididymostomy

End-to-side techniques of vasoepididymostomy have the advantage of being minimally traumatic to the epididymis and relatively bloodless (Table 22–3) (Wagenknecht et al, 1980; Krylov and Borovikov, 1984; Fogdestam et al, 1986; Thomas, 1987). The end-to-side technique does not disturb the epididymal blood supply. When the level of epididymal obstruction is clearly demarcated by the presence of markedly dilated tubules proximally and collapsed tubules distally, the site at which the anastomosis should be performed is readily apparent. The end-to-side approach has the advantage of allowing accurate approximation of the muscularis and adventitia of the vas deferens to a precisely tailored opening in the tunica of the epididymis. This is the preferred technique when vasoepididymostomy is performed simultaneously with inguinal vasovasostomy because it is possible to preserve the vasal blood supply deriving from epididymal branches of the testicular artery (Fig. 22–27). This provides blood supply to the segment of vas intervening between the two anastomoses. Maintenance of the deferential artery's contribution to the testicular blood supply is also important in situations where the integrity of the testicular artery is in doubt due to prior surgery such as orchiopexy, nonmicroscopic varicocelectomy, or hernia repair.

The testis is delivered through a 3- to 4-cm-high vertical scrotal incision. The vas deferens is identified, isolated with a Babcock clamp, and then surrounded with a Penrose drain at the junction of the straight and convoluted portions of the vas deferens. Using 8- to 15-power magnification provided by the operating microscope, the vasal sheath is longitudinally incised with a microknife and a bare segment of vas stripped of its carefully preserved vessels is delivered. The vas is hemitransected with the ultrasharp knife until the lumen is entered (Fig. 22–28). **The vasal fluid is sampled. If microscopic examination of this fluid reveals the absence of sperm, the diagnosis of epididymal obstruction is confirmed.** Patency of the vas and ejaculatory ducts is confirmed by cannulating the abdominal end of the vas with a 24-gauge angiocatheter sheath and gently injecting lactated Ringer solution with a 1-mL tuberculin syringe (see Fig. 22–4). Further confirmation of patency may be obtained by injecting indigo carmine, catheterizing the bladder, and observing blue-tinged urine. The vas is then completely transected using a 2.5-mm slotted nerve clamp (see Fig. 22–28), and the vas is prepared as for vasovasostomy as described earlier (see Preparation of the Vasa).

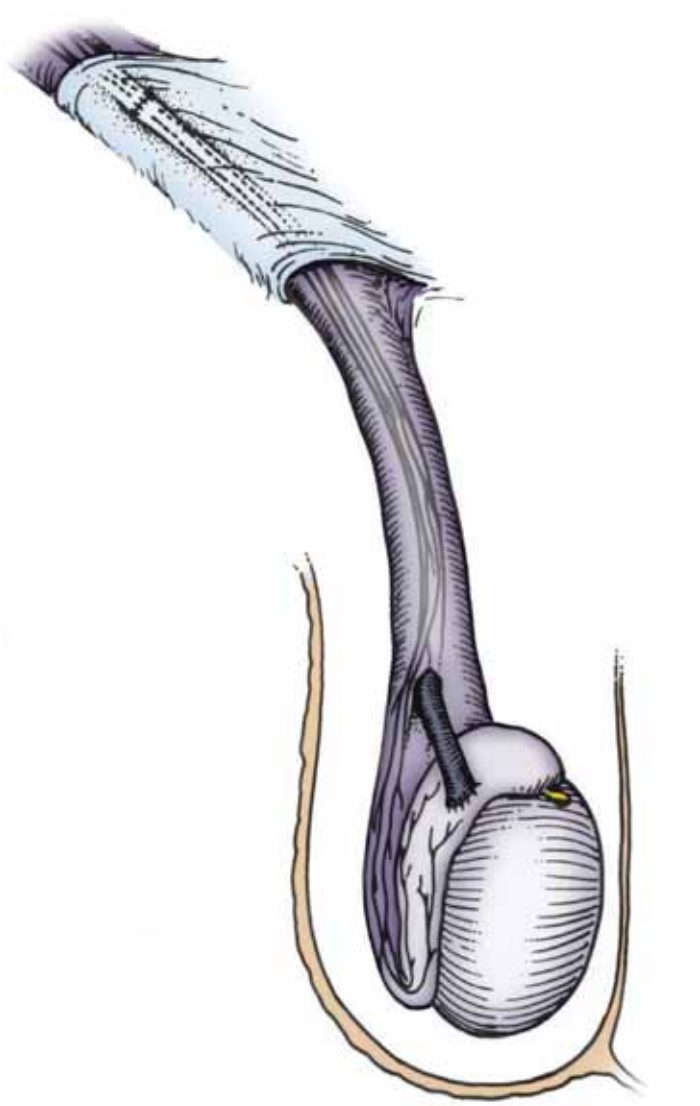

Figure 22–27. A diagram of a finished vasoepididymostomy.

After opening the tunica vaginalis, the epididymis is inspected under the operating microscope. An anastomotic site is selected above the area of suspected obstruction, proximal to any visible sperm granulomas, where dilated epididymal tubules are clearly seen beneath the epididymal tunica (Fig. 22–29). A relatively avascular area is grasped with sharp jeweler's forceps and the epididymal tunica tented upward. **A 3- to 4-mm buttonhole is made in the tunica with microscissors to create a round opening that matches the outer diameter of the previously prepared vas deferens.** The epididymal tubules are then gently dissected with a combination of sharp and blunt dissection until dilated loops of tubule are clearly exposed (Fig. 22–30). **If the level of obstruction is not clearly delineated after the buttonhole opening is made in the tunic, a 70-μm diameter tapered needle from the 10-0 nylon microsuture is used to puncture the epididymal tubule beginning as distal as possible and fluid is sampled from the puncture site. When sperm are found, the puncture sites are sealed with microbipolar forceps, a new buttonhole is made in the epididymal tunic just proximally, and the tubule is prepared as described previously.**

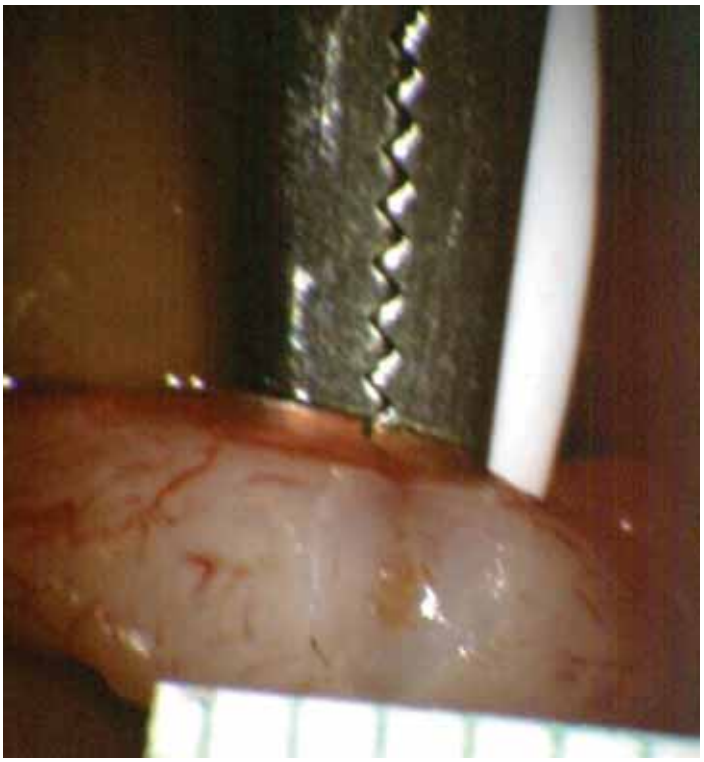

Figure 22–28. The vas is hemitransected with the ultrasharp knife until the lumen is entered.

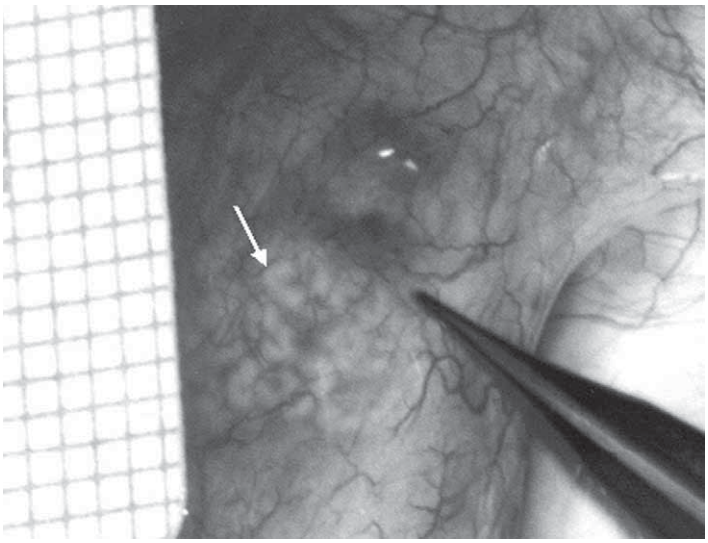

Figure 22–29. An anastomotic site is selected above the area of suspected obstruction, proximal to any visible sperm granulomas, where dilated epididymal tubules are clearly seen beneath the epididymal tunica, as marked by an *arrow*.

The vas deferens is drawn through an opening in the tunica vaginalis and secured in proximity to the anastomotic site with two to four interrupted sutures of 6-0 polypropylene placed through the vasal adventitia and the tunica vaginalis. **The vasal lumen should reach the opening in the epididymal tunica easily, with length to spare.** The posterior edge of the epididymal tunica is then approximated to the posterior edge of the vas muscularis and adventitia with two to three interrupted sutures of double-armed 9-0 nylon (Fig. 22–31). This is done in

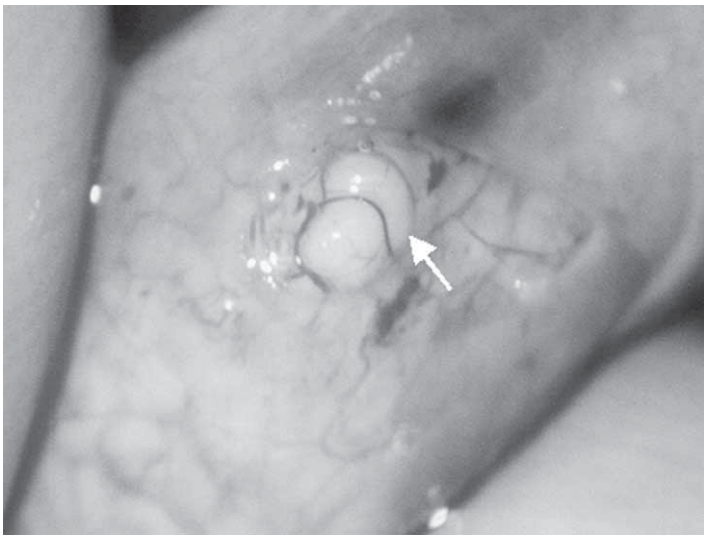

Figure 22–30. The epididymal tubules are then gently dissected with a combination of sharp and blunt dissection until dilated loops of tubule are clearly exposed.

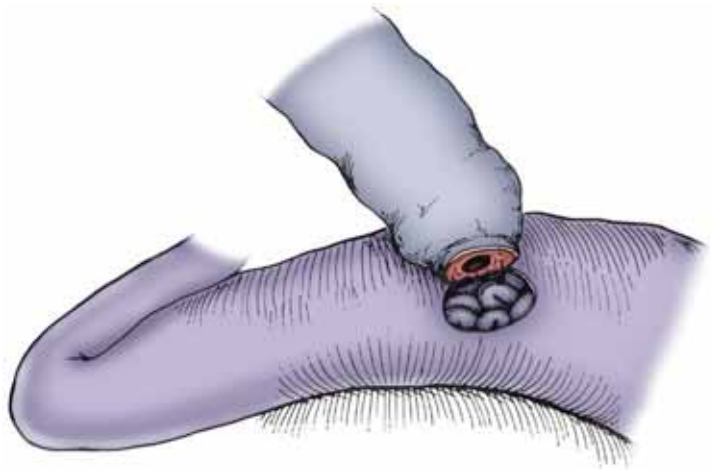

Figure 22–31. The posterior edge of the epididymal tunica is then approximated to the posterior edge of the vas muscularis and adventitia with two to three interrupted sutures of double-armed 9-0 nylon.

such a way as to bring the vasal lumen in close approximation to the epididymal tubule selected for anastomosis.

Classic End-to-Side Technique

Under 25× to 32× magnification, using small curved microscissors or a 15-degree microknife, an opening about 0.3 to 0.5 mm in diameter is made in the selected tubule. Epididymal fluid is touched to a slide, diluted with saline or lactated Ringer solution, and inspected under the microsope for sperm. If no sperm are found, the opening in the tubule is closed with 10-0 sutures, the vas is detached, and the tunica incision is closed with 9-0 nylon. The procedure is then repeated more proximally in the epididymis.

Once sperm are identified, they are aspirated into glass capillary tubes and flushed into media for cryopreservation (Fig. 22–32) (see Open Tubule Technique later) (Matthews et al, 1995). **Indigo carmine solution is dripped on the cut tubule to outline the mucosa.** Methylene blue kills sperm instantly even when diluted, rendering the sperm useless for

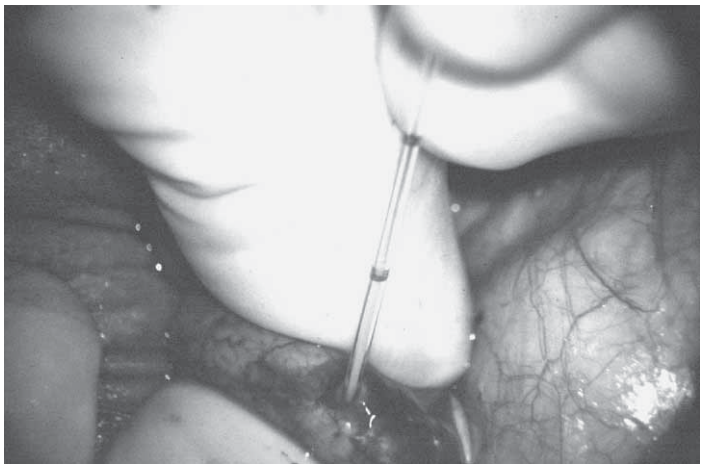

Figure 22–32. Once sperm are identified, they are aspirated into glass capillary tubes and flushed into media for cryopreservation.

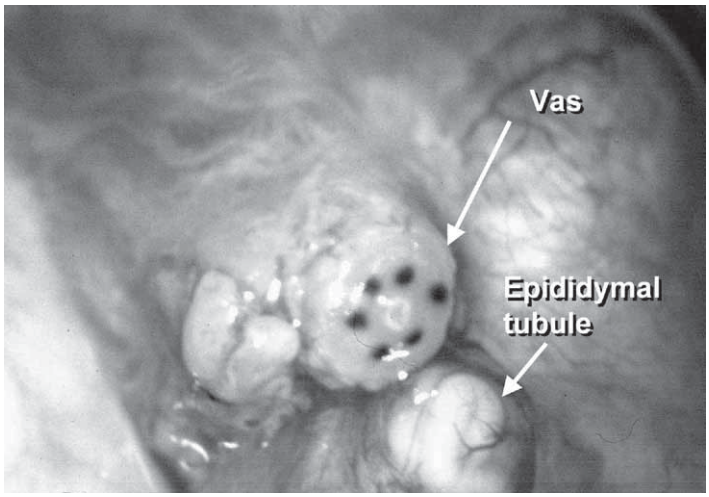

Figure 22–33. The posterior mucosal edge of the epididymal tubule is approximated to the posterior edge of the vasal mucosa with two interrupted sutures of 10-0 monofilament nylon sutures double-armed with a fish-hook 70-µm diameter tapered needles.

cryopreservation (Sheynkin et al, 1999b). Indigo carmine, diluted 50%, is safe for sperm. The posterior mucosal edge of the epididymal tubule is approximated to the posterior edge of the vasal mucosa with two interrupted sutures of 10-0 monofilament nylon sutures double armed with fish-hook 70-µm diameter tapered needles (Fig. 22–33). The lumen is irrigated with lactated Ringer solution just before placement of each suture to keep the epididymal lumen open. The lumen is irrigated with heparinized saline just before tying the last mucosal suture to prevent clots from obstructing the lumen. Unlike blood vessels, there are no platelets and fibrinogen to seal a leaky anastomosis and no clot lysis factor to dissolve clots. After these mucosal sutures are tied, the anterior mucosal anastomosis is completed with two to four additional 10-0 sutures. The outer muscularis and adventitia of the vas are then approximated to the cut edge of the epididymal tunica with 6 to 10 additional interrupted sutures of 9-0 nylon double armed with 100-µm diameter needles (Fig. 22–34A and B). The vasal sheath is secured to the epididymal tunica with three to five sutures of 9-0 nylon. The testis and epididymis are gently returned to the tunica vaginalis, which is closed with 5-0 Vicryl. Penrose drains are usually not necessary. The scrotum is closed as previously described for vasovasostomy.

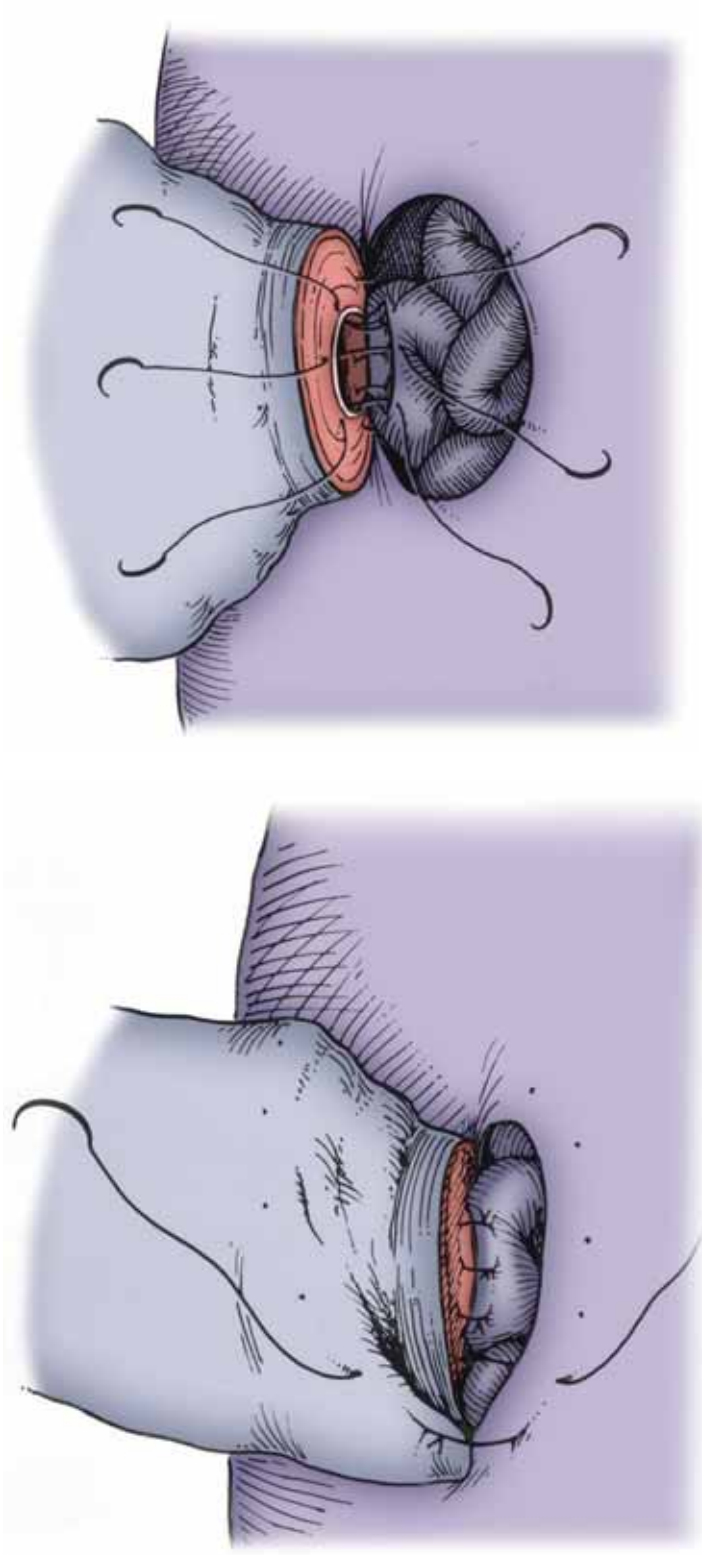

Figure 22–34. The outer muscularis and adventitia of the vas are then approximated to the cut edge of the epididymal tunica with 6 to 10 additional interrupted sutures of 9-0 nylon double-armed with 100-µm diameter needles.

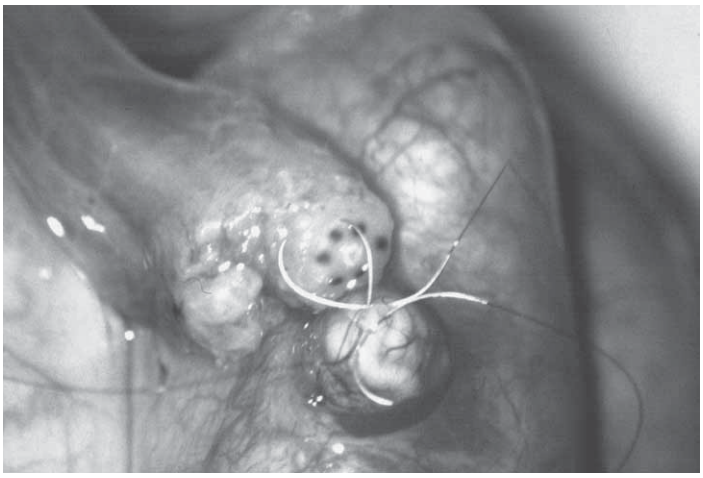

Figure 22–35. The needles are not pulled through but left in situ, creating a triangle of needles.

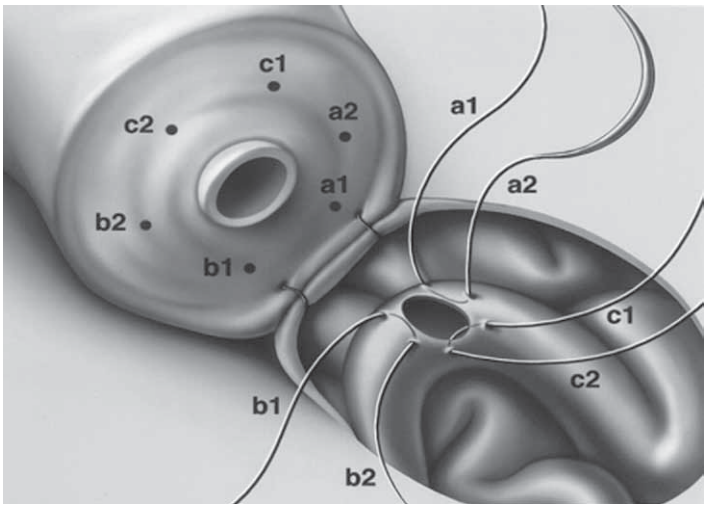

Figure 22–36. Using a 15-degree microknife with the blade pointing upward, a generous opening is made in the epididymal tubule in the center of the triangle created by the three needles.

End-to-Side Intussusception Techniques

This method, originally described as the triangulation technique, was introduced by Berger (1998). There are several advantages of the methods over previous techniques (see Table 22–3) (Goldstein, 1999). The setup is identical to that for the classical end-to-side vasoepididymostomy. After the vas is fixed to the opening in the epididymal tunica, six microdots are placed on the cut surface of the vas in an identical fashion to that described for vasovasostomy. The epididymal tubule selected is dissected with blunt microscissors and the micro needle holder until it is free of surrounding tissue and prominent. The tubule is then stained with indigo carmine. Using 10-0 monofilament nylon sutures approximately 2 inches in length, double armed with 70-µm diameter fish hook–shaped tapered needles, three sutures are placed in the epididymal tubule in a triangulation fashion. The apex of the triangle faces the inferior edge of the vasal mucosa. **The needles are not pulled through but left in situ,** creating a triangle of needles (Fig. 22–35). Using a 15-degree microknife with the blade pointing upward, a generous opening is made in the epididymal tubule in the center of the triangle created by the three needles (Fig. 22–36).

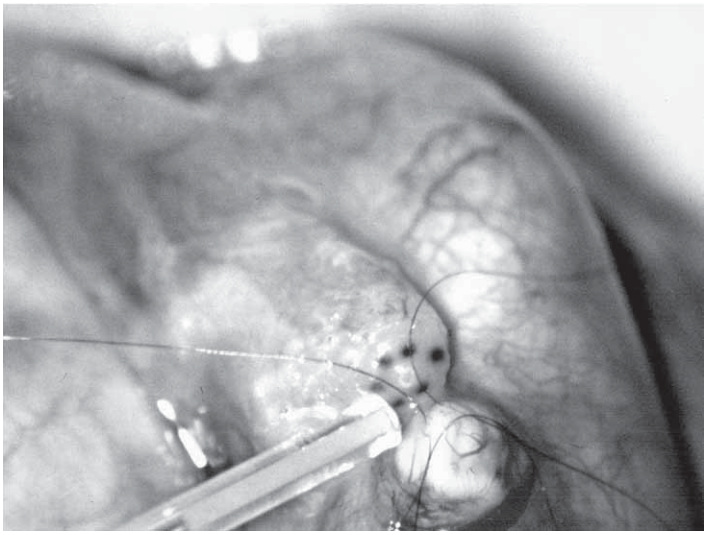

Figure 22–37. Sperm are aspirated into micropipets first.

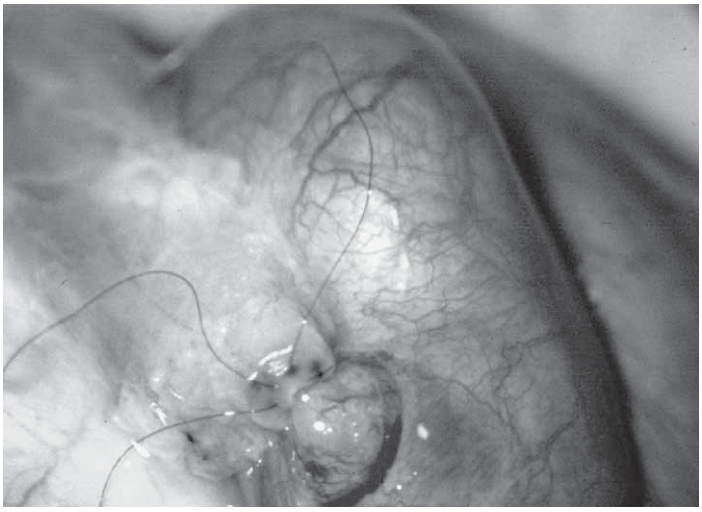

Figure 22–38. After abundant sperm have been aspirated into micropipets and cryopreserved, the six needles are passed inside out the vas deferens, exiting through the six previously placed microdots in the order indicated in Fig 22-36.

The three needles are then pulled through. The six needles are now laid out so as to avoid a spaghetti-like tangle. A glass slide is touched to the fluid exuding from the opening in the epididymal tubule and mixed with human tubal fluid media, covered with a coverslip, and examined by the surgeon using the separate bench microscope under 400-power magnification. If sperm are present (whether motile or not), the decision is made to proceed with the anastomosis. Sperm are aspirated into micropipets first (Fig. 22–37) and expressed into human tubal fluid media and sent for cryopreservation if motility is observed. Sperm that initially appear immotile, when mixed with human tubule fluid, often regain motility adequate for successful cryopreservation. Even immotile sperm should be placed in the media and evaluated for potential cryopreservation. **If the needles are pulled through before placing the microsurgical sutures or before making an opening in the epididymal tubule, epididymal fluid and sperm would immediately leak through the suture hole, causing the tubule to collapse.** This makes placement of subsequent sutures and creation of the opening in the tubule

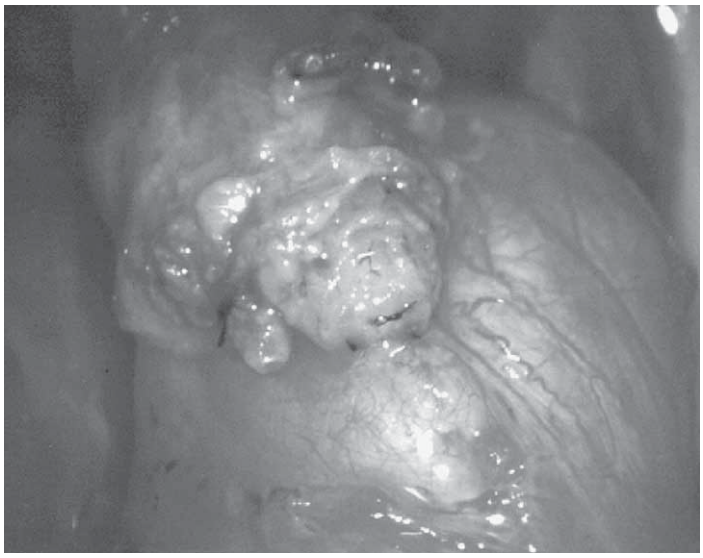

Figure 22–39. Tying of these sutures intussuscepts the epididymal tubule into the vas lumen.

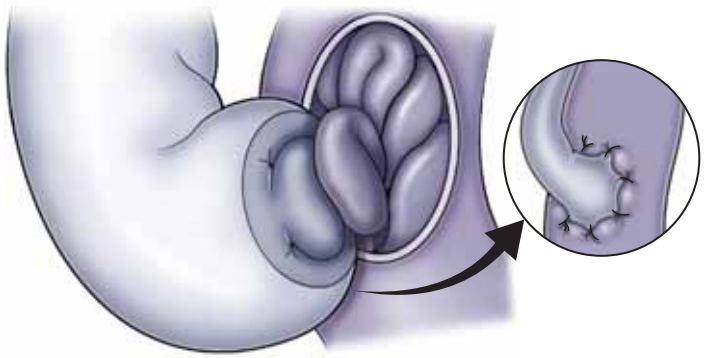

Figure 22–40. This creates a water-tight closure.

considerably more difficult. **Leaving the needles in the epididymal tubule before making the opening also prevents accidental cutting of the sutures when making the opening in the center of the triangle.** After abundant sperm have been aspirated into micropipets and cryopreserved, the six needles are passed inside out the vas deferens exiting through the six previously placed microdots in the order indicated (Fig. 22–38). Each pair of sutures is then sequentially tied beginning with suture a1 and a2, then b1 and b2, and finally c1 and c2. Tying of these sutures intussuscepts the epididymal tubule into the vas lumen (Fig. 22–39). This creates a water-tight closure (Fig. 22–40). In addition, the flow of epididymal fluid from the epididymal tubule into the vas deferens tends to plaster the edges of the epididymal tubule against the mucosal walls of the vas deferens, further helping create a leakproof closure. The second layer of the anastomosis is completed in an identical fashion to that described for the classical end-to-side operation described earlier (Fig. 22–41A and B).

Two-Stitch Variation of the Intussusception Technique (Preferred Technique)

For anastomoses to small epididymal tubules such as those found in the caput or to the efferent ductules (Chan et al, 2005), the three-stitch triangulation technique may be impossible. **We now**

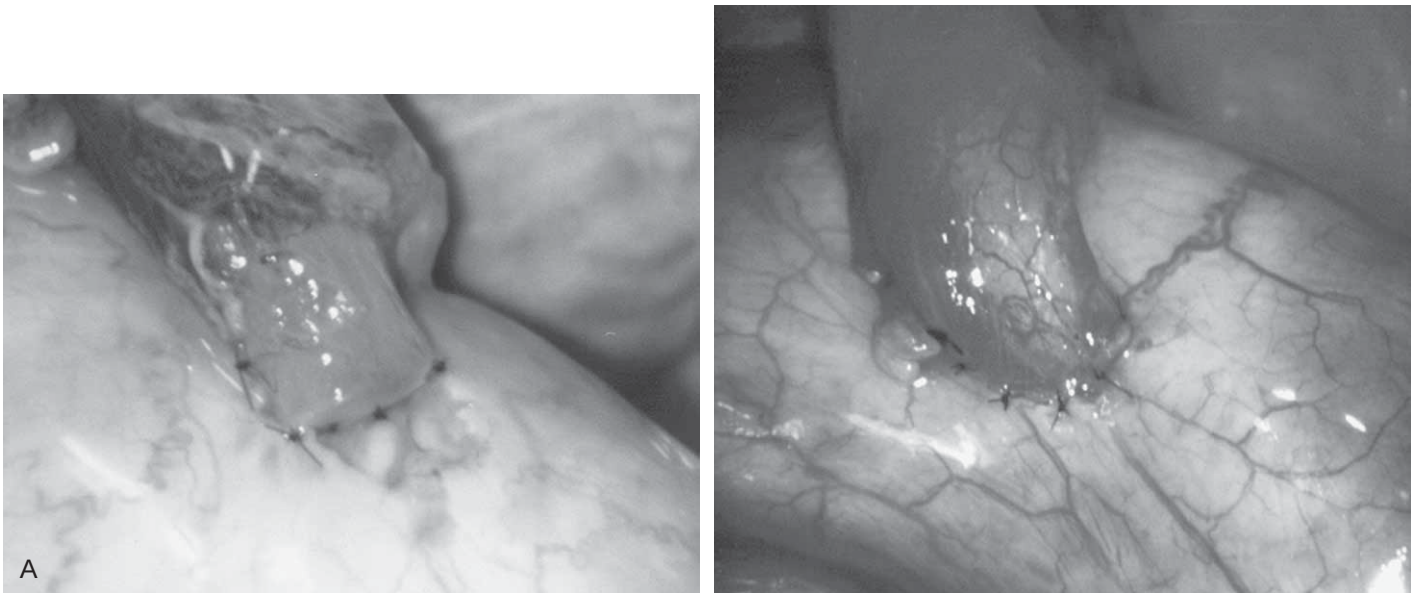

Figure 22–41. **A** and **B,** The second layer of the anastomosis is completed in an identical fashion to that described for the classical end-to-side operation described earlier.

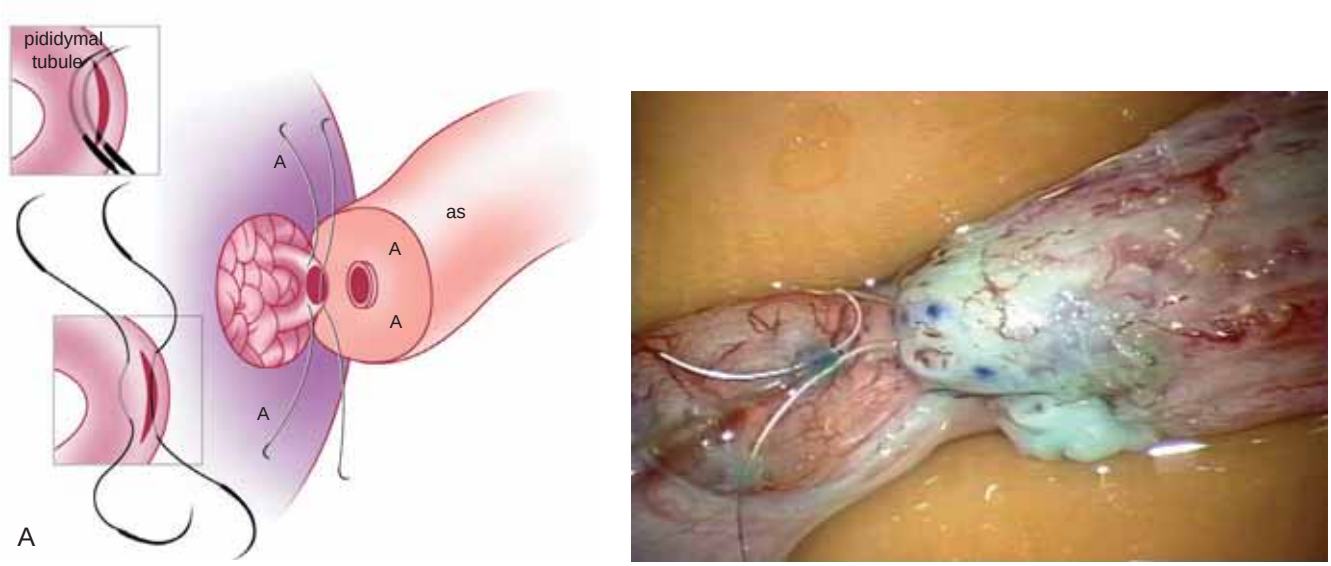

Figure 22–42. **A** and **B,** With this method, four microdots are marked on the cut surface of the vas deferens and two parallel sutures are placed in the distended epididymal tubule longitudinally, but not pulled through.

employ a two-stitch longitudinal intussusception technique for all vasoepididymostomies. It is much easier to perform and is even more successful. With this method, four microdots are marked on the cut surface of the vas deferens and two parallel sutures are placed in the distended epididymal tubule longitudinally, but not pulled through (Fig. 22–42A and B). Marmar suggests mounting two needles in the needle holder and placing them simultaneously transversely in the tubule. However, if the needles are not pulled through to avoid leakage of fluid and tubular collapse, they can be placed one at a time with greater control and accuracy (Chan et al, 2005; Schiff et al, 2005). Using a 15-degree microknife, an opening is made exactly between and parallel to the two previously placed sutures. Of note, we have also developed a single-arm technique of vasoepididymostomy, which is almost as effective as the double-arm technique (Fig. 22–43) (Monoski et al, 2007). This technique is valuable when double-armed sutures are not available.

Technique When Vasal Length Is Severely Compromised

When there is inadequate length of the vas deferens to reach the dilated epididymal tubule without tension, the epididymis can be dissected down to the vasoepididymal junction and then dissected off the testes as in the older end-to-end operation.

After the vas has been prepared, the tunica vaginalis is opened and the testis is delivered. Inspection of the epididymis under the operating microscope may reveal a clearly delineated site of obstruction. Often, a discrete yellow sperm granuloma is noted, above which the epididymis is indurated and the tubules are dilated and below which the epididymis is soft and the tubules

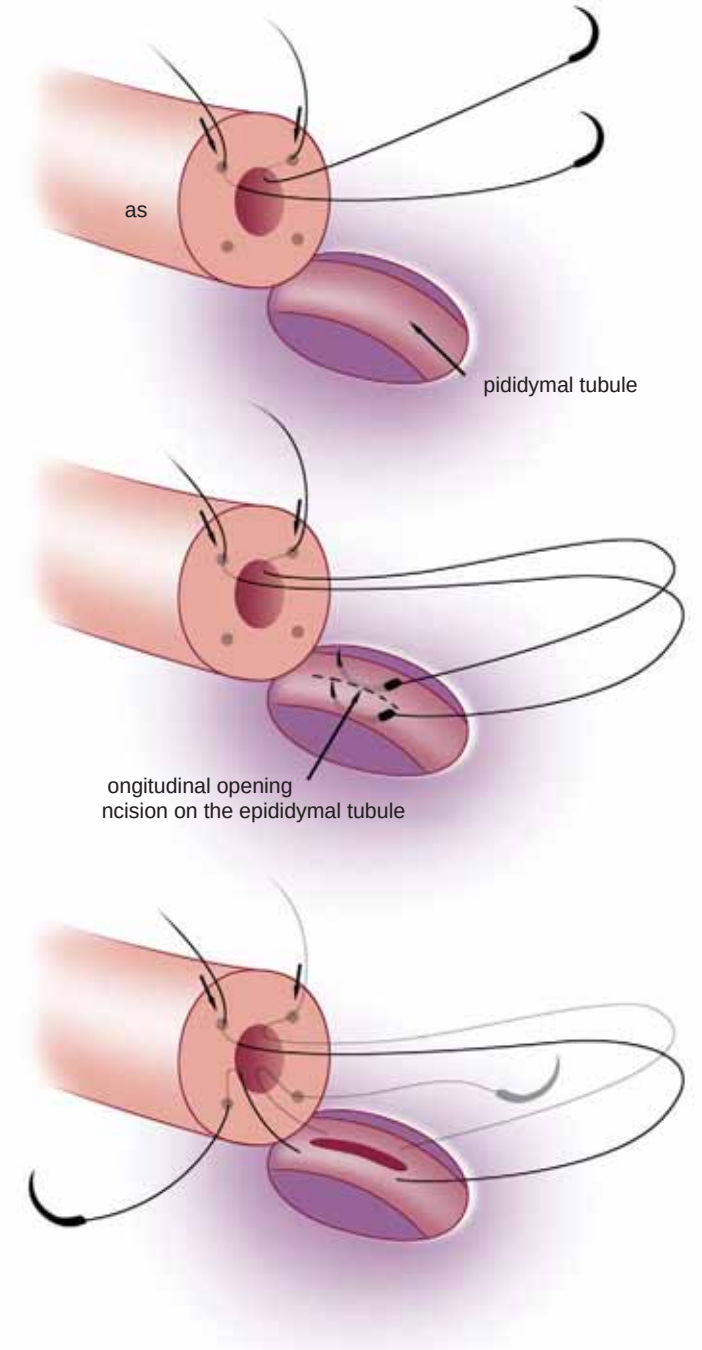

Figure 22–43. Of note, we have also developed a single-arm technique of vasoepididymostomy, which is almost as effective as the double-arm technique.

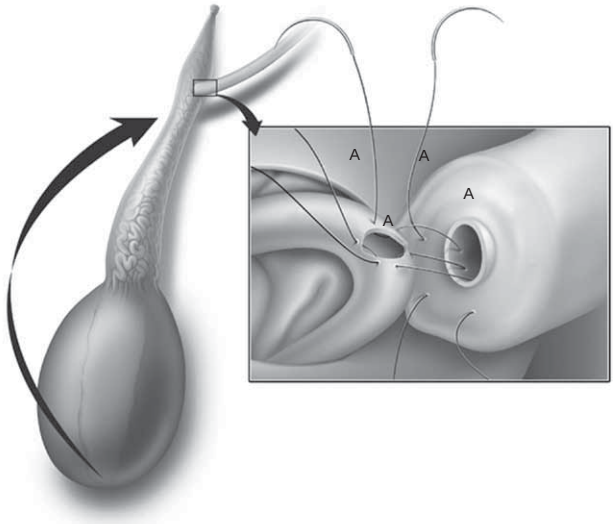

Figure 22–44. In addition, if vasal length is compromised, the epididymis can be dissected to the caput by ligating the inferior and medial epididymal vessels and flipping the epididymis up, providing additional length.

are collapsed. **If the level of obstruction is not clearly delineated, a 70-μm tapered needle from the 10-0 nylon microsuture is used to puncture the epididymal tubule beginning as distal as possible and fluid is sampled from the puncture site until sperm are found. At that level the puncture is sealed with microbipolar forceps, and the epididymis is ligated just proximal to the puncture site with a 6-0 nylon. The epididymis is then dissected off the testis and flipped up to obtain additional length** (Fig. 22–44). To do this, the epididymis is encircled with a small Penrose drain at the level of obstruction and, using 2.5-power loupe magnification, dissected off of the testis for 3 to 5 cm, yielding sufficient length to perform the anastomosis. Usually a nice plane can be found between the epididymis and testis, and injury to the epididymal blood supply can be avoided by staying right on the tunica albuginea of the testis. The inferior and, if necessary, middle epididymal branches of the testicular artery are ligated and divided to free up an adequate length of epididymis. The superior-epididymal branches entering the epididymis at the caput are always preserved and can provide adequate blood supply to the entire epididymis. The tunica vaginalis in then closed over the testis with 5-0 Vicryl. This prevents drying of the testis and thrombosis of the surface testicular vessels during the anastomosis. The dissected epididymis remains outside the tunica vaginalis.

If the epididymis is indurated and dilated throughout its length, it is dissected to the vasoepididymal (VE) junction. This dissection is often assisted by first dissecting the convoluted vas to the VE junction from below, and then, after encircling the epididymis with a Penrose drain, dissecting the epididymis to the VE junction from above. In this way the entire VE junction can be freed up. This will allow preservation of maximal epididymal length in cases of distal obstruction near the VE junction. After the epididymis is dissected off of the testis and flipped up, a three-stitch end-to-side intussusception anastomosis is performed as described earlier.

Long-Term Follow-Up—Evaluation and Results

Microsurgical vasoepididymostomy in the hands of experienced and skilled microsurgeons will result in the appearance of sperm in the ejaculate in 50% to 85% of men. Patency rates with the intussusception technique can exceed 80% (Berger, 1998; Brandell, 1999; Marmar, 2000). With the classic end-to-side or older end-to-end method, the patency rate is about 70% and 43% of men with sperm will impregnate their wives after a minimum follow-up of 2 years (Schlegel and Goldstein, 1993; Pasqualotto et al, 1999). With the intussusception techniques, patency rates

are 70% to 90% (Kolettis and Thomas, 1997; Chan et al, 2005; Schiff et al, 2005). Regardless of technique, pregnancy rates are higher the more distal the anastomosis is performed (Silber, 1989a). **With the older end-to-end or end-to-side methods, at 14 months after surgery 25% of initially patent anastomoses have shut down** (Matthews et al, 1995). **With intussusception technique, the late shut-down rates appear to be less than 10%** but long-term follow-up with these techniques has not been reported. **Nevertheless, we recommend banking sperm both intraoperatively** (Matthews and Goldstein, 1996) **and as soon as they appear in the ejaculate postoperatively after vasoepididymostomy, regardless of technique employed.** In men with low counts or poor sperm quality postoperatively and men who remain azoospermic, the sperm intraoperatively cryopreserved can be used for IVF with intracytoplasmic sperm injection. Persistently azoospermic men without cryopreserved sperm can opt for either a redo vasoepididymostomy and/or microscopic epididymal sperm aspiration combined with IVF and intracytoplasmic sperm injection (see Microsurgical Epididymal Sperm Aspiration Techniques).

TRANSURETHRAL RESECTION OF THE EJACULATORY DUCTS

Ejaculatory duct obstruction is usually a congenital anomaly that represents the opposite end of the spectrum of excurrent ductal system anomalies that begin with congenital complete absence of the vas deferens and most of the epididymis. When the aplastic segment occurs at the terminal end of the vas, where the ejaculatory duct enters the urethra, it is potentially correctable by transurethral resection (Paick et al, 2000; Schroeder-Printzen et al, 2000; Kadioglu et al, 2001; Ozgok et al, 2001; Yurdakul et al, 2008). Occasionally ejaculatory duct obstruction results from chronic prostatitis or extrinsic compression of the ejaculatory ducts by prostate or seminal vesical duct cysts (Cornel et al, 1999; Paick et al, 2000; Kadioglu et al, 2001). Higher ejaculatory duct pressures have been directly measured in men with ejaculatory duct obstruction (Eisenberg et al, 2008).

Diagnosis

The workup leading to the diagnosis of probable ejaculatory duct obstruction is covered in Chapter 21. Briefly, **ejaculatory duct obstruction is suspected in azoospermic or severely oligospermic and/or asthenospermic men with at least one palpable vas deferens, a low semen volume, acid semen pH and negative, equivocal, or low semen fructose levels.** If these men have normal serum levels of FSH and testis biopsy reveals normal spermatogenesis, the diagnosis of ejaculatory duct obstruction is entertained.

Digital rectal examination may reveal a midline cystic structure. **Transrectal sonography is key for the diagnosis and treatment of ejaculatory duct obstruction.** A midline cystic lesion or dilated ejaculatory ducts and seminal vesicles can be visualized sonographically. As described in Transrectal Vasography and Seminal Vesiculography earlier in this chapter, **transrectal ultrasound-guided aspiration of the cystic or dilated ejaculatory ducts or seminal vesicles is performed** (Jarow, 1994). **The aspirate is examined microscopically and if motile sperm are found, they are cryopreserved and 2 to 3 mL indigo carmine diluted with water-soluble radiographic contrast are instilled. If a radiograph confirms a potentially resectable lesion, TUR of the ejaculatory ducts is performed without the need for prior vasography** because the presence of sperm in the seminal vesicles indicates that at least one epididymis is patent and that the cyst or dilated ejaculatory duct communicates with a nonobstructed vas. The instillation of indigo carmine assists in localizing the opening of the ejaculatory duct and confirms when resection has successfully opened the obstructed system. **Transrectal sonography with aspiration should be performed immediately before anticipated surgery and employs the same bowel prep and antibiotic prophylaxis used for transrectal prostate biopsy.**

If no sperm are found in the aspirate, vasography, as described earlier in Technique of Vasography and Interpretation of Findings, is necessary. **If no sperm are found in either vas when the vasotomy is made and vasography reveals ejaculatory duct obstruction, it is best to abandon attempts at reconstruction and simply perform microsurgical epididymal sperm aspiration and cryopreservation for future IVF/ICSI. Simultaneous vasoepididymostomy and TUR of the ejaculatory ducts rarely works.** If ejaculatory duct obstruction is confirmed by vasography employing a 50% water-soluble contrast medium and sperm are present in the vasa, the 3-Fr whistle-tip ureteral vasography stents are left in place so that a dilute indigo carmine solution can be injected by the assistant to aid resection.

Technique

Cold knife incision alone almost always leads to reobstruction. The resectoscope, with the 24-Fr cutting loop, is engaged with a finger placed in the rectum providing anterior displacement of the posterior lobe of the prostate. The ejaculatory ducts course between the bladder neck and the verumontanum and exit at the level of and along the lateral aspect of the verumontanum (Fig. 22–45). **Resection of the veru will often reveal the dilated ejaculatory duct orifice or cyst cavity. Resection should be**

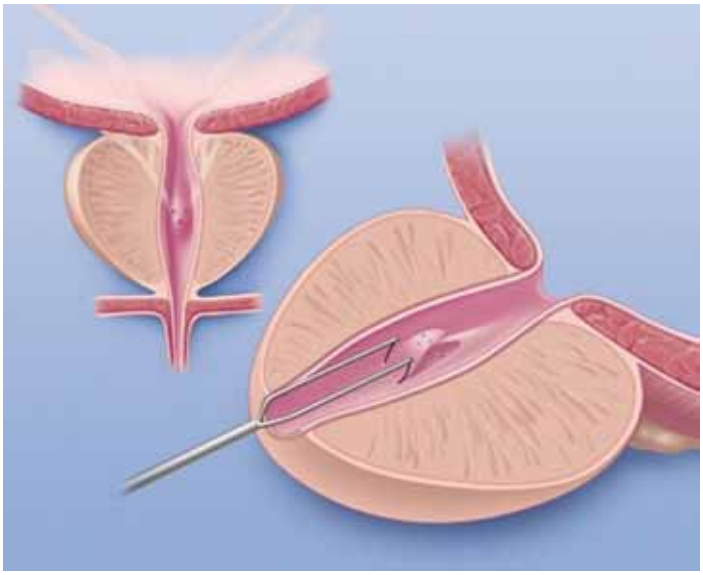

Figure 22–45. The ejaculatory ducts course between the bladder neck and the verumontanum and exit at the level of and along the lateral aspect of the verumontanum.

carried out in this region with great care in order to preserve the bladder neck proximally, the striated sphincter distally and the rectal mucosa posteriorly. Efflux of indigo carmine from dilated orifices confirms adequate resection. **Avoid excessive coagulation.** If formal vasography was performed, the hemivasotomies are carefully closed employing microsurgical technique. A Foley catheter is left overnight and the patient receives an additional 7 days of oral antibiotics.

Complications

Reflux

Reflux of urine into the ejaculatory ducts, vas, and seminal vesicles occurs after a majority of resections. This can be documented by voiding cystourethrography or measuring semen creatinine levels (Malkevich et al, 1994). Contamination of semen by urine impairs sperm quality.

Epididymitis

Reflux can lead to acute and chronic epididymitis. Recurrent epididymitis often results in epididymal obstruction. The incidence of epididymitis after TUR is probably underestimated. Symptomatic chemical epididymitis may occur from refluxing urine. **Chronic low-dose antibacterial suppression such as that employed for vesicoureteral reflux may be necessary until pregnancy is achieved.** If epididymitis is chronic and recurrent, vasectomy or even epididymectomy may be necessary.

Retrograde Ejaculation

Even when care has been taken to spare the bladder neck, retrograde ejaculation is common after TUR. Pseudoephedrine 120 mg orally, 90 minutes before ejaculation, or Ornade Spansules (chlorpheniramine and phenylpropanolamine) twice a day for a week may prevent this. If this is not successful, sperm can be retrieved from alkalinized urine and used for either intrauterine insemination or IVF with ICSI.

Results

TUR of the ejaculatory ducts results in increased semen volume about two thirds of the time and appearance of sperm in the ejaculate in about 50% of previously azoospermic men. Pregnancy rates are based on case reports and small series (Goldwasser et al, 1985; Paick et al, 2000; Ozgok et al, 2001; Fuse et al, 2003; Yurdakul et al, 2008). If viable sperm appear in the ejaculate but the quality is poor, IVF with ICSI is recommended. This approach currently yields delivery rates of up to 38.5% per attempt. Because of the potential for serious complications, **TUR should only be performed in azoospermic men or in severely oligoasthenospermic men and only after the couple has stated they are unwilling to do IVF and have been fully apprised of the risks of TUR.**

ELECTROEJACULATION

Men with neurologic impairments in sympathetic outflow such as seen in traumatic spinal cord injury, demyelinating neuropathies (multiple sclerosis), and diabetes following retroperitoneal lymph node dissection frequently have abnormalities in or absence of seminal emission. **Ejaculation can be induced in most of these men, especially those with high spinal cord injury, with vibratory stimulation** (Schellan, 1968; Brindley, 1981; Bennett et al, 1987; Brackett et al, 1997; Ohl et al, 1997). **For those men that do not respond to vibratory stimulation, electroejaculation has proven to be a safe and effective means of obtaining motile sperm suitable for assisted reproduction techniques (IUI, IVF/ICSI).**

The procedure is performed under general anesthesia except for men with a complete spinal cord injury, who do not require anesthesia. **In men with a high thoracic spinal cord lesion (above T6) or in those men with prior history of autonomic dysreflexia, pretreatment, 15 minutes before the procedure, with 20 mg of sublingual nifedipine is employed.** These men should have intravenous access and their blood pressure and pulse should be monitored every 2 minutes before, during, and for 20 minutes following electroejaculation. In the event of a sympathetic outflow (autonomic dysreflexia), termination of the procedure should be sufficient to break the response. However, intravenous access allows for delivery of sympatheticolytic agents should they become necessary.

Before placing the patient in the lateral decubitus position, the bladder is catheterized and emptied. A 12-Fr or 14-Fr Silastic catheter lubricated with a small amount of mineral oil is used because commonly employed lubricants are spermicidal. Ten mL of buffer (HEPES-BSA) is instilled into the bladder. Before the electroejaculation sequence, a digital rectal examination and anoscopy are performed. A rectal probe with three large horizontal stripes is well lubricated, inserted with the electrodes facing anteriorly and applied against the posterior aspect of the prostate and seminal vesicles. The probe is connected to a variable-output power source that simultaneously records probe temperature through a thermistor in the rectal probe. Electrostimulation is started at 3 to 5 volts and increased in 1-volt increments with each stimulation (Ohl et al, 2001). An assistant records probe temperatures and number of stimulations to full erection and ejaculation and collects the ejaculate in a sterile wide mouth plastic container. The number of stimulations and maximum voltage required are variable and the ejaculate may be retrograde. If probe temperature rises rapidly or above 40° C, stimulation is suspended until the temperature falls below 38° C or probes are changed. At the completion of stimulation, anoscopy is again performed to check for rectal injury. The bladder is recatheterized to obtain any retrograde-ejaculated sperm. The specimens are then delivered to the laboratory for processing. **A second electroejaculation sequence can be immediately performed under the same anesthetic to obtain additional sperm.**

Employing this technique, sperm can be recovered in more than 90% of men. Overall pregnancy rates of up to 40% can be achieved after multiple cycles with intrauterine insemination. Use of IVF with ICSI will yield 50% live delivery rates for a single (albeit costly) procedure if motile sperm are obtained.

SPERM RETRIEVAL TECHNIQUES

Men with congenital absence or bilateral partial aplasia of vas deferens, or those with failed or surgically unreconstructable obstructions, can now be treated by using sperm retrieval techniques in conjunction with in vitro fertilization (Table 22–4) (Temple-Smith et al, 1985; Silber et al, 1990; Schlegel et al, 1994; Craft et al, 1995; Sheynkin et al, 1998b; Janzen et al, 2000; Levine et al, 2003; Qiu et al, 2003; Anger et al, 2004). These techniques are also useful for intraoperative retrieval of sperm during reconstructive procedures such as vasoepididymostomy, which have significant failure rates. The intraoperatively retrieved sperm may

Table 22–4.

Surgical Techniques for Sperm Retrieval

	ADVANTAGES	DISADVANTAGES
MESA (microsurgical epididymal sperm aspiration)	Microsurgical procedure allows lower complication rate. Epididymal sperm has better motility than testicular sperm. Large number of sperm can be harvested for cryopreservation of multiple vials in a single procedure.	Requires anesthesia and microsurgical skills. Not indicated for nonobstructive azoospermia.
PESA (percutaneous epididymal sperm aspiration)	No microsurgical skill required. Local anesthesia. Epididymal sperm has better motility than testicular sperm.	Complications include hematoma, pain, and vascular injury to testes and epididymis. Variable success in obtaining sperm. Small quantity of sperm obtained than with MESA. Not indicated in nonobstructive azoospermia.
TESA (testicular sperm aspiration)	No microsurgical skill required. Local anesthesia. Can be used for obstructive azoospermia.	Immature or immotile testicular sperm. Small quantity of sperm obtained. Poor results in nonobstructive azoospermia. Complications include hematoma, pain, and vascular injury to testes and epididymis.
TESE (testicular sperm extraction)	Low complication rate if performed microsurgically. Preferred technique for nonobstructive azoospermia.	Requires anesthesia and microsurgical skills.

be used immediately if the wife has been prepared for IVF or may be cryopreserved for a future IVF with ICSI cycle in the event the reconstructive surgery is unsuccessful. Sperm obtained from chronically obstructed systems usually have poor motility and decreased fertilizing capacity. **The use of intracytoplasmic sperm injection (ICSI) combined with IVF is essential to achieve optimal results.**

Microsurgical Epididymal Sperm Aspiration Techniques

Open Tubule Technique

The technique described here can be employed for either intraoperative sperm retrieval at the time of vasoepididymostomy or as an isolated procedure in men with congenital absence of the vas or unreconstructable obstructions (Matthews and Goldstein, 1996; Nudell et al, 1998). A median raphe approach through two small transverse scrotal incisions within the scrotal skin folds is used. After delivery of the testis, the tunica vaginalis is opened and the epididymis inspected under 16× to 25× magnification using the operating microscope. The epididymal tunica is incised over a dilated tubule as described previously for vasoepididymostomy. Meticulous hemostasis is obtained using the bipolar cautery. A dilated tubule is isolated and incised with a 15-degree microknife. The fluid is touched to a slide, a drop of human tubal fluid media is added, a coverslip is placed, and the fluid examined. If no sperm are obtained, the epididymal tubule and tunica are closed with 10-0 and 9-0 monofilament nylon sutures, respectively, and an incision is made more proximally in the epididymis or even at the level of the efferent ductules until motile sperm are obtained.

As soon as motile sperm are found, a dry micropipet (5 µL; Drummond Scientific Co., Broomall, PA) is placed adjacent to the effluxing epididymal tubule (Fig. 22–46). A standard hematocrit pipette is less satisfactory but can be used if micropipets are not available. **Sperm are drawn into the micropipet by simple capillary action.** Negative pressure, as is generated by action of an in-line syringe, should not be applied during sperm recovery because this may disrupt the delicate epididymal mucosa. Two micropipets may be employed simultaneously to increase the speed of sperm recovery.

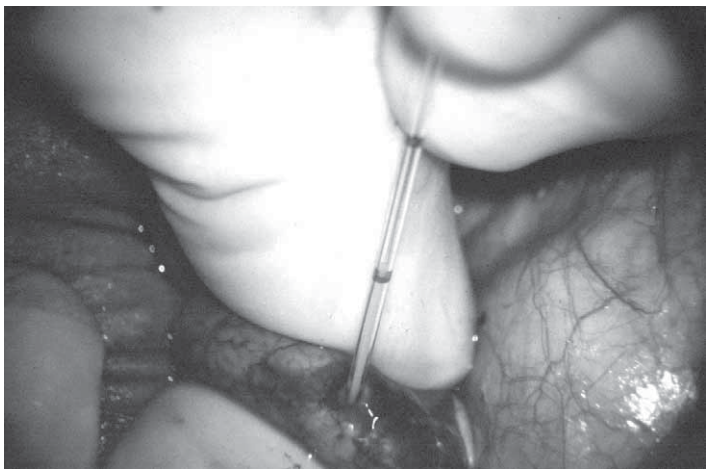

Figure 22–46. As soon as motile sperm are found, a dry micropipet (5 µL; Drummond Scientific Co., Broomall, PA) is placed adjacent to the effluxing epididymal tubule.

The highest rate of flow is observed immediately following incision of the tubule. Progressively better-quality sperm are often found following the initial washout. **Gentle compression of the testis and epididymis enhances flow from the incised tubule.** With patience, 10 to 20 µL of epididymal fluid can be recovered.

The micropipet is connected to a short (3 to 5 cm) segment of medical-grade silicone tubing (American Scientific Products; McGaw Park, IL). Alternatively, the tubing attached to a 22-gauge butterfly needle may be employed. A 20-gauge needle fitted to a Luer-tip syringe is then placed in line. The fluid is flushed with IVF media (0.5 to 1.0 mL) into a sterile container. Once a micropipet has been used, it is discarded. Residual fluid in the pipette

will disrupt capillary action. A typical procedure requires 4 to 12 micropipets. The sperm bank should be instructed to cryopreserve the aspirate in multiple vials (aliquots) so that several IVF cycles may be attempted if required (Janzen et al, 2000; Anger et al, 2004).

Experience with the technique has revealed that, **paradoxically, in obstructed systems, sperm motility is better more proximally in the epididymis with the most motile sperm often found in the efferent ductules** (Fig. 22–47). Motility immediately after aspiration and, consequently, fertilization rates are highest in men who have the longest length of epididymal tubule available. Even when packed with debris distally, the epididymal tubule may be capable of secreting substances that can diffuse proximally and benefit sperm motility and fertilizing capacity.

Employing ICSI, ongoing pregnancy or delivery rates exceeding 60% have been achieved with this technique using either fresh or cryopreserved epididymal sperm (Schlegel et al, 1995; Nudell et al, 1998). **Epididymal sperm aspiration can be done electively, with the cryopreserved sperm used for multiple future IVF cycles** (Janzen et al, 2000; Anger et al, 2004).

Percutaneous Epididymal Sperm Aspiration

Percutaneous puncture of the epididymis with a fine needle (Fig. 22–48) has been successfully employed to obtain sperm and achieve pregnancies (Shrivastav et al, 1994; Craft and Tsirigotis, 1995; Levine et al, 2003; Qiu et al, 2003; Lin et al, 2004). The technique is less reliable than the open retrieval, and the small quantities of sperm obtained are sometimes inadequate for cryopreservation. Reported pregnancy rates are half those achieved with open techniques (Sheynkin et al, 1998b). In view of the enormous costs and effort involved in IVF, epididymal sperm retrieval under direct vision is the preferred technique.

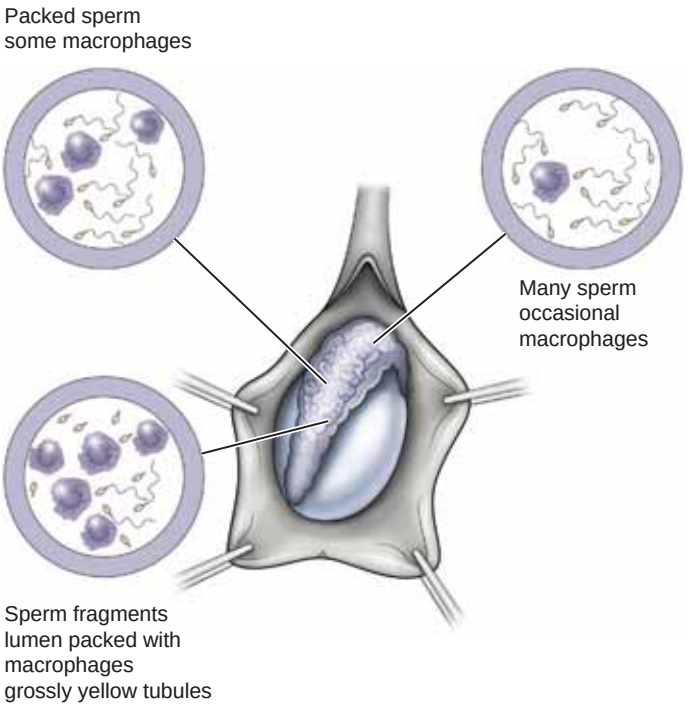

Figure 22–47. Experience with the technique has revealed that, paradoxically, in obstructed systems, sperm motility is better more proximally in the epididymis with the most motile sperm often found in the efferent ductules.

Testicular Sperm Extraction

The indications for testicular sperm extraction (TESE) are:

1. **Failure to find sperm in the epididymis** in the presence of the spermatogenesis or complete absence of the epididymis.
2. **Nonobstructive azoospermia** (Schlegel et al, 1997; Ostad et al, 1998; Su et al, 1999; Tsujimura et al, 2002).

Testicular sperm has been retrieved employing one of three techniques:

1. **Open testicular sperm extraction**—allows retrieval of the largest member of sperm with potential for cryopreservation; this **is the best technique in men with nonobstructive azoospermia.**
2. Percutaneous core biopsy; uses the same 14-gauge biopsy gun used for prostate biopsy (Fig. 22–49).
3. Percutaneous aspiration (testicular sperm aspiration—TESA) with a high-suction glass syringe and a 23-gauge needle. This is the least invasive but requires 10 to 20 passes to obtain an adequate yield (Fig. 22–50) (Rajfer and Binder, 1989; Harrington et al, 1996; Friedler et al, 1997; Sheynkin et al, 1998b; Mercan et al, 2000; Carpi et al, 2005).

The percutaneous methods are most appropriate in men with normal spermatogenesis and obstructive azoospermia in whom adequate numbers of sperm can be retrieved in a small amount of tissue (Craft et al, 1995). The pros and cons of these three methods are discussed earlier in Testis Biopsy.

Microsurgical Testicular Sperm Extraction

The use of an operating microscope for standard open diagnostic testes biopsy allows identification of an area in the tunica albuginea free of blood vessels (Fig. 22–51), minimizing the risk of injury to testicular blood supply and allowing a relatively blood-free biopsy specimen (Dardashti et al, 2000). Employing the microscope for testis biopsy, Schlegel (1999) discovered that in men with nonobstructive azoospermia, some of the tubules were larger than others. **The larger tubules are more likely to**

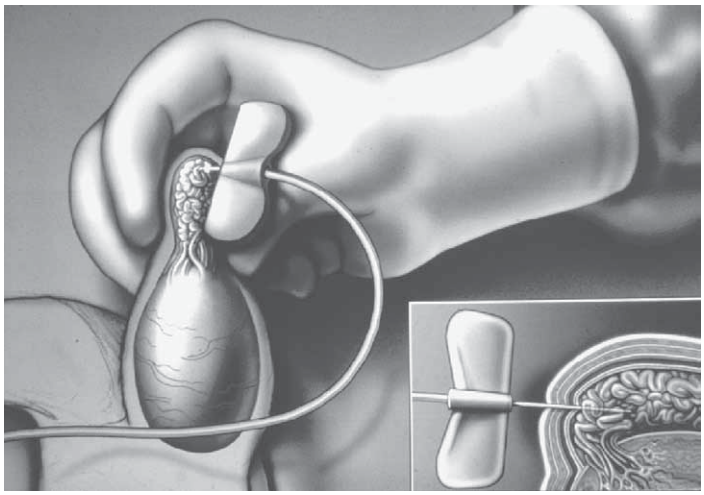

Figure 22–48. Percutaneous puncture of the epididymis with a fine needle.

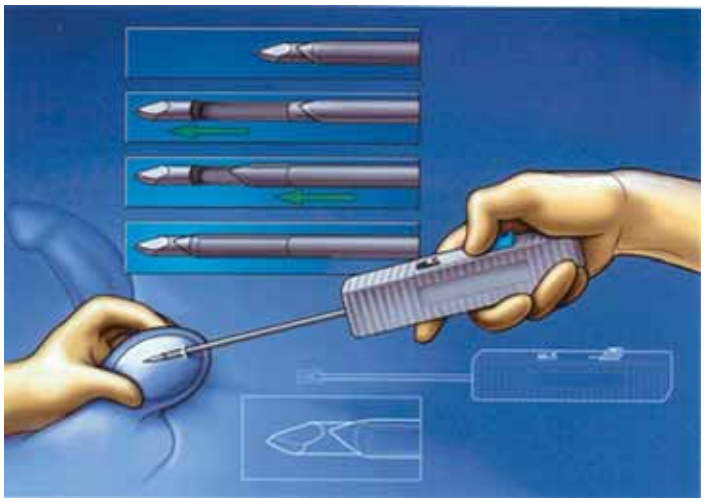

Figure 22–49. Percutaneous core biopsy; uses the same 14-gauge biopsy gun used for prostate biopsy.

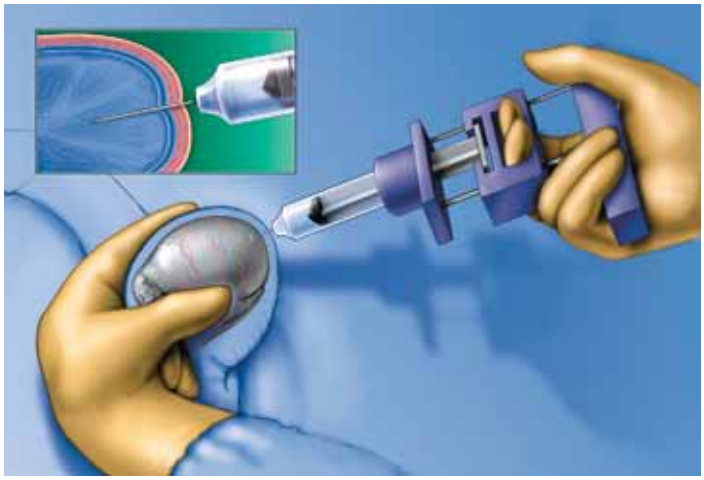

Figure 22–50. Percutaneous aspiration (testicular sperm aspiration) with a high-suction glass syringe and a 23-gauge needle. This is the least invasive but requires 10 to 20 passes to obtain an adequate yield.

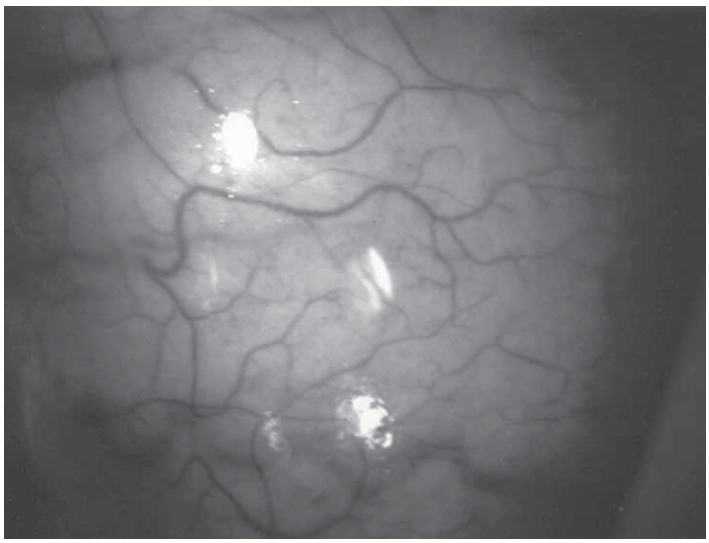

Figure 22–51. The use of an operating microscope for standard open diagnostic testes biopsy allows identification of an area in the tunica albuginea free of blood vessels.

yield sperm. Previous studies revealed that testicular biopsy in men with nonobstructive azoospermia display considerable heterogeneity. Examination of permanently fixed biopsy specimens that display heterogeneity reveal that **tubules with spermatogenesis are of considerably larger diameter than tubules composed of Sertoli cells only. This difference can be readably observed under the operating microscope** (Fig. 22–52).

Technique. With the patient under general or regional anesthetic, the testes are exposed through either a single midline median raphe incision or two transverse incisions within the skin lines and between the scrotal blood vessels. The testes are delivered into the wound. The tunica vaginalis is opened, and the operating microscope is brought into the field. Using 10-power magnification, an avascular plane is identified on the anterior surface of the tunica albuginea. Using a 15-degree microknife, a generous transverse incision is made between the blood vessels through the tunica albuginea. Small blood vessels that are seen coursing across the incision are coagulated with the microbipolar cautery prior to incising them. This yields a blood-free field. The seminiferous tubules are observed. **Sertoli-cell-only tubules tend to be thin, white, and stringy. Tubules with active spermatogenesis are larger, plumper, and somewhat yellow.** Using a micro needle holder, the seminiferous tubules are dissected in an attempt to identify larger tubules. If such a tubule is found, a sharp curved iris scissor is used to selectively excise these tubules. The sample is placed in human tubal fluid media, microdissected, and immediately examined by an andrology laboratory technician present in the operating room. After sperm have been found, hemostasis is obtained with the microbipolar cautery. The incision in the tunica albuginea is closed with a 6-0 nylon suture. The testis is returned to the tunica vaginalis, which is closed with a continuous suture of 5-0 Vicryl. If necessary, the opposite testis is explored.

Results. Using the microdissection technique, sperm have been identified in 50% of men explored. In those men in whom sperm are found, a pregnancy rate of 50% has been achieved at Cornell using IVF/ICSI. The spontaneous abortion rate is 19%. The high rate of spontaneous abortion is probably owing to the increased incidence of chromosomal abnormalities and DNA damage in the sperm of men with nonobstructive azoospermia (Rucker et al, 1998). Even in severe cases of congenital or acquired testicular failure, as in Sertoli-cell-only syndrome (Su et al, 1999), postchemotherapy azoospermia (Chan et al, 2001) and nonmosaic (47XXY) Klinefelter syndrome (Palermo et al, 1998; Ramasamy et al, 2009) sperm have been found and pregnancy and live births achieved (Table 22–5).

Table 22–5.

Testicular Sperm Extraction Outcomes by Diagnosis from Schlegel

CONDITION	RETRIEVAL
Klinefelter syndrome	68%
AZFc deletions	70%
Sertoli cell only	37%
Postchemotherapy	53%
Cryptorchidism (postorchiopexy)	74%
Maturation arrest	40%
AZFa, AZFb deletions	0%

Postmortem Sperm Retrieval

Postmortem sperm retrieval and cryopreservation (but no pregnancies) were initially reported by Rothman in 1980 and employed removal and mincing of the epididymis. The retrieved sperm can be frozen and subsequently used to achieve pregnancy. Pregnancy has now been achieved with sperm retrieved postmortem using IVF with ICSI (Tash et al, 2003; Dostal et al, 2005; reviewed in Benshushan and Schenker, 1998).

Retrieval of sperm from the vas can be performed using the technique described previously for vasography. Once the vas has been delivered, a hemivasotomy is made with a 15-degree microknife (as described earlier in Technique of Vasography and Interpretation of Findings). The testicular end of the vas is cannulated with a 22-gauge angiocatheter and the vas irrigated with a 0.2-mL volume of human tubal fluid medium while the convoluted vas and epididymis are massaged.

Twenty-four million sperm with 70% grade 1 motile sperm were retrieved 13 hours after death with this technique (Schlegel, personal communication). The ethical appropriateness of such retrieval is the most important issue surrounding its use.

VARICOCELECTOMY

Introduction

Varicocele is by far the most commonly performed operation for the treatment of male infertility. **Varicocele is found in approximately 15% of the general population, 35% of men with primary infertility, and 75% to 81% of men with secondary infertility.** Animal and human studies have demonstrated that **varicocele is associated with a progressive and duration-dependent decline in testicular function** (Russell, 1957; Lipshultz and Corriere, 1977; Nagler et al, 1985; Harrison et al, 1986; Kass and Belman, 1987; Hadziselimovic et al, 1989; Chehval and Purcell, 1992; Gorelick and Goldstein, 1993; Witt and Lipshultz, 1993).

Repair of varicocele will halt any further damage to testicular function (Kass and Belman, 1987; Gorelick and Goldstein, 1993) and, in a large percentage of men, result in improved spermatogenesis (Dubin and Amelar, 1977; Schlegel and Goldstein, 1992), as well as enhanced Leydig cell function (Su et al, 1995). The potentially important role of urologists in preventing future infertility underscores the importance of using a varicocelectomy technique that minimizes the risk of complications and recurrence. Table 22–6 summarizes the pros and cons of various methods of varicocele repair.

Scrotal Operations

Various surgical approaches have been advocated for varicocelectomy. The earliest recorded attempts at repair of varicocele date to antiquity and involved external clamping of the scrotal skin including the enlarged veins. In the early 1900s an open scrotal approach was employed, involving the mass ligation and excision of the varicosed plexus of veins. At the level of the scrotum, however, the pampiniform plexus of veins are intimately entwined with the coiled testicular artery. Therefore **scrotal operations are to be avoided because damage to the arterial supply of the testis frequently results in testicular atrophy and further impairment of spermatogenesis and fertility.**

Retroperitoneal Operations

Retroperitoneal repair of varicocele involves incision at the level of the internal inguinal ring (Fig. 22–53), splitting of the external and internal oblique muscles, and exposure of the internal spermatic artery and vein retroperitoneally near the ureter. This approach has the advantage of isolating the internal spermatic veins proximally, near the point of drainage into the left renal

Table 22–6.
Techniques of Varicocelectomy

TECHNIQUE	ARTERY PRESERVED	HYDROCELE (%)	FAILURE (%)	POTENTIAL FOR SERIOUS MORBIDITY
Retroperitoneal	No	7	15-25	No
Conventional inguinal	No	3-30	5-15	No
Laparoscopic	Yes	12	3-15	Yes
Radiographic	Yes	0	15-25	Yes
Microscopic inguinal or subinguinal	Yes	0	1.0	No

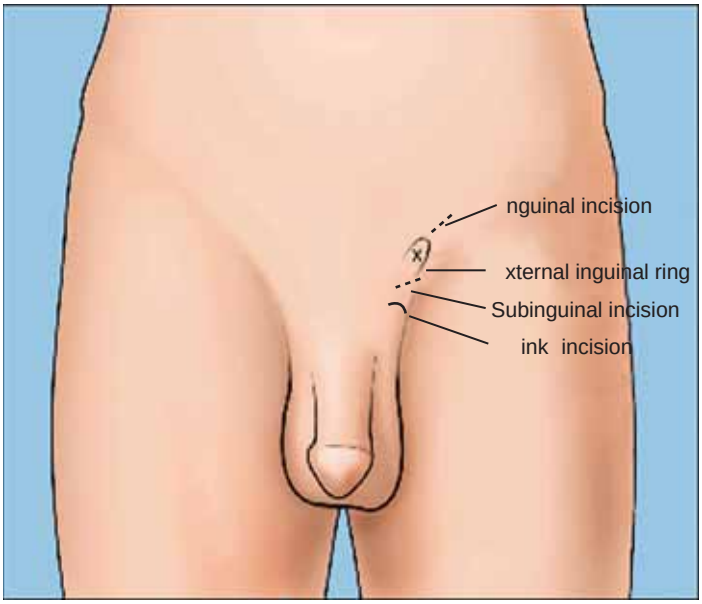

Figure 22–53. Retroperitoneal repair of varicocele involves incision at the level of the internal inguinal ring.

vein. At this level, only one or two large veins are present and, in addition, the testicular artery has not yet branched and is often distinctly separate from the internal spermatic veins. Retroperitoneal approaches involve ligation of the fewest number of veins. This approach is still a commonly employed method for the repair of varicocele, especially in children.

A disadvantage of a retroperitoneal approach is the high incidence of varicocele recurrence, especially in children and adolescents, when the testicular artery is intentionally preserved. Recurrence rates after retroperitoneal varicocelectomy are in the range of 15% (Homonnai et al, 1980; Rothman et al, 1981; Watanabe et al, 2005). Failure is usually due to preservation of the periarterial plexus of fine veins (venae comitantes) along with the artery. These veins have been shown to communicate with larger internal spermatic veins. If left intact, they may dilate and cause recurrence. Less commonly, failure is due to the presence of parallel inguinal or retroperitoneal collaterals, which may exit the testis and bypass the ligated retroperitoneal veins, rejoining the internal spermatic vein proximal to the site of ligation (Sayfan, 1981; Murray et al, 1986). Dilated cremasteric veins, another cause of varicocele recurrence (Sayfan et al, 1980), cannot be identified with a retroperitoneal approach. Positive identification and preservation of the 1.0- to 1.5-mm testicular artery via the retroperitoneal approach is difficult, especially in children where the artery is small. The operation involves working in a deep hole. Because at this level the internal spermatic vessels cannot be delivered into the wound, they must be dissected and ligated in situ in the retroperitoneum. In addition, the difficulty in positively identifying and preserving lymphatics using this approach results in postoperative hydrocele formation after 7% to 33% of retroperitoneal operations (Szabo and Kessler, 1984). The incidence of recurrence appears to be higher in children, with rates reported between 15% and 45% in adolescents (Gorenstein et al, 1986; Levitt et al, 1987; Reitelman et al, 1987). Kass (1992) reports that **recurrence can be markedly reduced in children and adolescents by intentional ligation of the testicular artery** (Kass and Marcol, 1992). This assures ligation of the periarterial network of fine veins. Although reversal of testicular growth failure has been documented with intentional testicular artery ligation at the time of retroperitoneal repair in children, **the effect of artery ligation on subsequent spermatogenesis is uncertain.** In adults bilateral artery ligation has been documented to occasionally cause azoospermia and testicular atrophy. At least **it is inarguable that testicular artery ligation will not enhance testicular function.**

Laparoscopic Varicocelectomy

Laparoscopic repair is in essence a retroperitoneal approach and many of the advantages and disadvantages are similar to those of the open retroperitoneal approach (Donovan and Winfield, 1992; Hagood et al, 1992; Enquist et al, 1994; Hirsch et al, 1998; Riccabona et al, 2003; Watanabe et al, 2005).

Using the laparoscope, the internal spermatic vessels and vas deferens can be clearly visualized through the laparoscope as they course through the internal inguinal ring. **The magnification provided by the laparoscope allows visualization of the testicular artery. With experience, the lymphatics may be visualized and preserved as well** (Glassberg et al, 2008). With laparoscopic varicocelectomy the internal spermatic veins are ligated at the same level as the retroperitoneal (Palomo) approach described earlier in Retroperitoneal Operations. Laparoscopic varicocelectomy should allow preservation of the testicular artery in a majority of cases, as well as preservation of lymphatics. The incidence of varicocele recurrence would be expected to be similar to that associated with the open retroperitoneal operations. These recurrences would be due to collaterals joining the internal spermatic vein near its entrance to the renal vein, or entering the renal vein separately.

Currently reported series of laparoscopic varicocelectomy report a recurrence rate of 2.9% to 4.5% in most recent series (May et al, 2006; Glassberg et al, 2008; Barroso et al, 2009), but up to 17% in some (Al-Said et al, 2008). An artery ligation but lymphatic-sparing

laparoscopic technique has markedly reduced the incidence of postoperative hydrocele formation in children (Glassberg et al, 2008). The potential complications of laparoscopic varicocelectomy (injury to bowel, vessels or viscera, air embolism, peritonitis) are significantly more serious than those associated with the open techniques. Furthermore, laparoscopic varicocelectomy requires a general anesthetic. The microsurgical techniques described next can be performed using local or regional anesthesia and employ an incision of 2.5 to 3 cm for unilateral repair. This is equal to or less than the sum of incisions employed for a laparoscopic approach. Postoperative pain and recovery from the laparoscopic technique are the same as those associated with subinguinal varicocelectomy (Hirsch et al, 1998). Finally, laparoscopic varicocelectomy is less cost-effective than open varicocelectomy. In the hands of an experienced laparoscopist, the approach is a reasonable alternative for the repair of bilateral varicoceles (Donovan and Winfield, 1992; Diamond et al, 2009; Mendez-Gallart et al, 2009; Tong et al, 2009).

Microsurgical Inguinal and Subinguinal Operations: Preferred Approaches

Introduction

Inguinal and subinguinal varicocelectomy are currently the most popular approaches. They have the advantage of allowing the spermatic cord structures to be pulled up and out of the wound so that the testicular artery, lymphatics, and small periarterial veins may be more easily identified. In addition, **an inguinal or subinguinal approach allows access to external spermatic and even gubernacular veins,** which may bypass the spermatic cord and result in recurrence if not ligated. Lastly, an inguinal or subinguinal approach allows access to the testis for biopsy or examination of the epididymis for obstruction.

Traditional approaches to inguinal varicocelectomy involve a 5- to 7-cm incision made over the inguinal canal, opening of the external oblique aponeurosis, and encirclement and delivery of the spermatic cord. The cord is then dissected, and all the internal spermatic veins are ligated (Dubin and Amelar, 1977). The vas deferens and its vessels are preserved. An attempt is made to identify and preserve the testicular artery and, if possible, the lymphatics. In addition, the cord is elevated and any external spermatic veins that are running parallel to the spermatic cord or perforating the floor of the inguinal canal are identified and ligated. Compared with retroperitoneal operations, conventional nonmagnified inguinal approaches lower the incidence of varicocele recurrence but do not alter the incidence of either hydrocele formation or testicular artery injury. **Conventional inguinal operations are associated with an incidence of postoperative hydrocele formation varying from 3% to 15% with an average incidence of 7%** (Szabo and Kessler, 1984). Analysis of the hydrocele fluid has clearly indicated that hydrocele formation following varicocelectomy is due to ligation of the lymphatics (Szabo and Kessler, 1984). The incidence of testicular artery injury during nonmagnified inguinal varicocelectomy is unknown. Case reports, however, suggest that this complication may be more common than realized. It can result in testicular atrophy and, if the operation is performed bilaterally, azoospermia may ensue in a previously oligospermic man. Furthermore, Starzl and his transplant group reported a 14% incidence of testicular atrophy and 70% incidence of hydrocele formation when the spermatic cord was divided and only the vas and vasal vessels were preserved (Penn et al, 1972).

The introduction of **microsurgical technique** to varicocelectomy **has resulted in a substantial reduction in the incidence of hydrocele formation** (Goldstein et al, 1992; Marmar and Kim, 1994; Matthews et al, 1998; Cayan et al, 2000). This is **because the lymphatics can be more easily identified and preserved.** Furthermore, the use of **magnification enhances the ability to identify and preserve the 0.5- to 1.5-mm testicular artery, thus avoiding the complications of atrophy or azoospermia.**

Advocates of nonmicrosurgical techniques contend that the deferential (vasal) artery and, if preserved, the cremasteric artery, will provide adequate blood supply to the testes to prevent atrophy. However, anatomic studies have known that the diameter of the testicular artery is greater than the diameter of the deferential artery and cremasteric artery combined (Raman and Goldstein, 2004). **The testicular artery is the main blood supply to the testis.** Experience with the one-stage Fowler and Steven orchiopexy, in which the testicular artery is intentionally ligated, reveals that a substantial percentage of such procedures results in an atrophic testis. Also, animal models indicate that artery preservation varicocelectomy results in improved testicular ultrastructure, whereas artery ligation resulted in further deterioration of ultrastructure (Zheng et al, 2008). At the very least, it is inarguable that **ligation of the testicular artery is unlikely to enhance testicular function.**

Anesthesia

If the testis is delivered, as described later, regional or light general anesthesia is preferred. If only the cord is delivered, local anesthesia with a 50/50 combination of 0.25% bupivacaine and 1% lidocaine is satisfactory with adjunctive intravenous heavy sedation. After infiltration of the skin and subcutaneous tissues, the cord is infiltrated before delivery. Blind cord block carries with it a small risk of inadvertant testicular artery injury (Goldstein, 1983). A 30-gauge needle should therefore be employed for cord block to minimize the risk of injury and hematoma.

Inguinal and Subinguinal Approaches

The introduction of the subinguinal approach, just below the external inguinal ring (Marmar et al, 1985) obviates the need for opening any fascial layer and is associated with less pain and a rapid recovery comparable with laparoscopic procedures. At the subinguinal level, however, significantly more veins are encountered, the artery is more often surrounded by a network of tiny veins that must be ligated, and the testicular artery has often divided into two or three branches, making arterial identification and preservation more difficult (Hopps et al, 2003a).

Subinguinally, the arterial pulsations are often dampened by compression on the edge of the external ring, making its identification somewhat more difficult than when the external oblique is opened. Table 22–7 summarizes the criteria for performing the operation inguinally (external oblique opened) versus subinguinally (fascia intact). **In general, it is best to use a subinguinal approach in men with a history of any prior inguinal surgery.** Under these circumstances the cord is usually stuck to the undersurface of the external oblique and opening the fascia risks injury to the cord. A subinguinal approach is easier in obese men in whom opening and closing the fascia is difficult through a small incision. A subinguinal approach is easier in men with high, lax, capacious external rings and in men with long cords and low-lying testes. In these men the level of the external ring is fairly proximal to the testis and opening the fascia will not result

Table 22–7.

Indications for Inguinal (External Oblique Opened) versus Subinguinal (Fascia Intact) Varicocelectomy

INGUINAL	SUBINGUINAL
Children or prepubertal adolescents	Prior inguinal surgery
Solitary testis	Obesity
Tight, low external ring	Lax, capacious external ring High external ring
Short cord, high-lying testis	Long cord with low-lying testis
Less experienced with microsurgical repair	Very experienced with microsurgical repair

in a significant diminution in the number of veins to be ligated or in the branching of the testicular artery.

Always open the external oblique in children or prepubertal adolescents without prior inguinal surgery. In children the testicular artery is very small and systemic blood pressure is low, making identification of the artery difficult in a subinguinal approach. The fascia should also be opened in men with a solitary testis in whom preservation of the artery is critical. Exposure of the cord more proximally (at the inguinal level) allows identification of the artery before it has branched, where clear pulsations are more readily observed.

Open the fascia in thin men with tight low external rings, high-riding testes, and short cords. The microdissection will be quicker and easier and it is easy to open and close the fascia in thin men. **A subinguinal operation is significantly more difficult than a high inguinal operation and should only be used by surgeons who perform the operation frequently. An inguinal operation is employed when simultaneous ipsilateral hernia repair is performed.**

Before making the incision, the location of the external inguinal ring is determined by invagination of the scrotal skin and marked. The size of the incision is determined by the size of the testis when delivery of the testis (see later) is planned. Atrophic testes can be delivered through a 2- to 2.5-cm incision. Large testes require a 3-cm incision. The incision is made within Langer lines to minimize scarring.

If the decision is made to perform an inguinal operation and thus to open the fascia, the incision is begun at the external ring and extended laterally 2 to 3.5 cm along Langer lines (Fig. 22–54). If the operation is to be performed subinguinally, the incision is placed in the skin lines just below the external ring (Fig. 22–55).

Camper fascia and Scarpa fascia are divided with the electrocautery between the blades of a Crile clamp. The superficial epigastric artery and vein, if encountered, are retracted or, alternately, clamped, divided, and ligated.

If an inguinal approach is selected, the external oblique aponeurosis is cleaned and opened the length of the incision to the external inguinal ring in the direction of its fibers. A 3-0 absorbable suture placed at the apex of the external oblique incision assists later closure.

The spermatic cord is grasped with a Babcock clamp and delivered through the wound. The ilioinguinal and genital branches of the genitofemoral nerve are excluded from the cord, which is then surrounded with a large Penrose drain. If a subinguinal incision was made, Camper and Scarpa fascia are incised as described earlier. An index finger is introduced into the wound and along the cord into the scrotum. The index finger is then hooked under the external inguinal ring, retracting it cephalad. A small

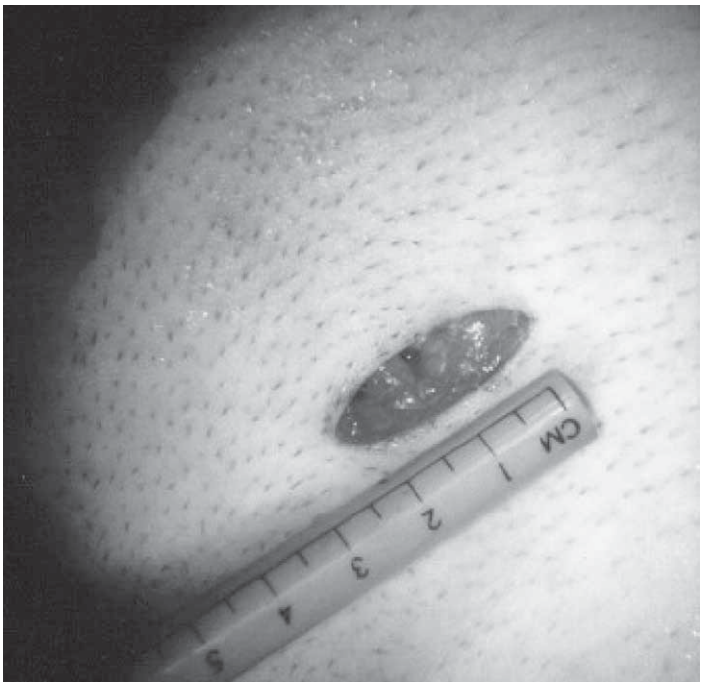

Figure 22–54. If the decision is made to perform an inguinal operation, and thus to open the fascia, the incision is begun at the external ring and extended laterally 2 to 3/5-cm along Langer lines.

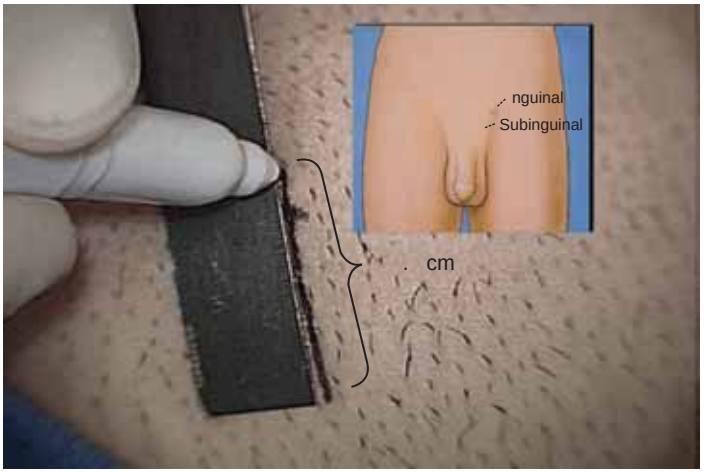

Figure 22–55. If the operation is to be performed subinguinally, the incision is placed in the skin lines just below the external ring.

Richardson retractor is slid along the back of the index finger and retracted caudad over the cord toward the scrotum (Fig. 22–56). The spermatic cord will be revealed between the index finger and retractor. The assistant grasps the cord with a Babcock clamp and delivers it through the wound. The cord is surrounded with a large Penrose drain.

Dissection of the Cord

The operating microscope is then brought into the field. Under 10-power magnification, the external and internal spermatic fascias are opened (Fig. 22–57A and B). The magnification is increased to 10 to 25 power and, after irrigation with 1% papaverine solution, the cord is inspected for the presence of pulsations

revealing the location of the testicular artery**. A micro-Doppler is extremely useful in identifying arteries** (Fig. 22–58). **Once the testicular artery is identified, it is dissected free of all surrounding tissue, tiny veins, and lymphatics using a fine-tipped nonlocking micro needle holder and microforceps.** The artery is encircled with a vessel loop for positive identification and gentle retraction (Fig. 22–59). The suspected artery is tested by elevating the artery with the tips of the micro needle holder until it is completely occluded and then slowly lowering it until a pulsating blush of blood appears just over the needle holder. If the artery is not immediately identified, the cord is carefully dissected beginning with the largest veins. The veins are stripped clean of adherent lymphatics (Fig. 22–60) and the underside of the largest veins inspected for an adherent artery. **In approximately 50% of cases the testicular artery is adherent to the undersurface of a large vein** (Beck et al, 1992). All veins within the cord, with the exception of the vasal veins, are doubly ligated with either hemoclips (Fig. 22–61A) or by passing two 4-0 silk ligatures, one black and one white, beneath the vein (Fig. 22–61B). These are then tied, and the vein is divided.

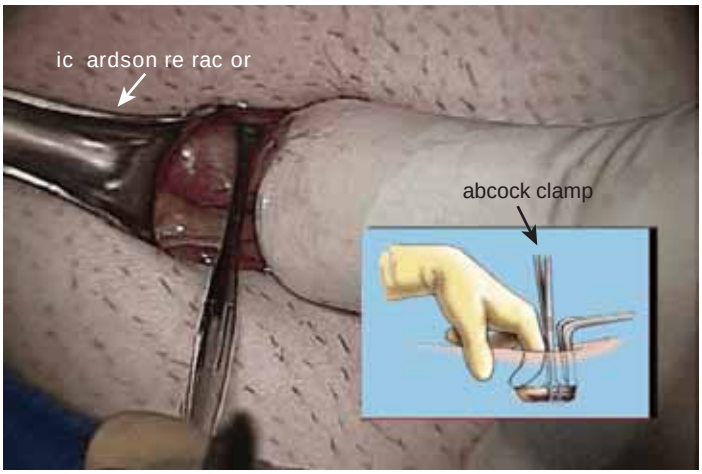

Figure 22–56. A small Richardson retractor is slid along the back of the index finger and retracted caudad over the cord toward the scrotum.

Medium hemoclips are used for veins 5 mm or larger, small automatic hemoclips for veins 1 to 5 mm, and 4-0 silk for veins smaller than 2 mm. **The use of an automatic clip applier** (Ligaclip small size, Ethicon, Somerville, NJ) **significantly reduces operating time.** The bipolar cautery can be used for veins smaller than 0.5 mm. The vasal veins are preserved providing venous return. If the vas deferens is accompanied by dilated veins greater than 3 mm in diameter, they are dissected free of the vasal artery and ligated. The vas deferens is always accompanied by two sets of vessels. **As long as at least one set of vasal veins remains intact, venous return will be adequate.** At the completion of the dissection, the cord is run over the index finger and inspected to verify that all veins have been identified and ligated. Small veins adherent to the testicular artery are dissected free and ligated or, if smaller than 1 mm, cauterized using a bipolar unit with a jeweler's forcep tip and divided. Cremasteric arteries are found (usually between and adherent of two cremasteric veins) and preserved in at least 90% of cases. Recent studies employing power-Doppler in men with nonobstructive azoospermia undergoing testicular sperm extraction have found that tubules containing sperm are most likely to be found in areas of the testis with the greatest blood supply. Therefore logic would dictate that preservation of maximum testicular blood supply including both testicular and cremasteric arteries would be beneficial to testicular function. **At the completion of the dissection, only the testicular arteries, cremasteric arteries, cremaster muscle fibers, nerves, lymphatics, and vas deferens with its vessels remain** (Fig 22–62). After adequate hemostasis is achieved, the cord is returned to its bed.

Delivery of the Testis

Delivery of the testis through a small inguinal or subinguinal incision guarantees direct visual access to all possible avenues of testicular venous drainage. Delivery of only the cord allows access to most external spermatic collaterals but may miss those close to the testis and will not allow access to scrotal or gubernacular collaterals, which have been demonstrated radiographically to be the cause of 10% of recurrent varicoceles (Kaufman et al, 1983). With gentle upward traction on the cord and upward pressure on the testis through the invaginated scrotum, the testis is easily delivered through the wound. All

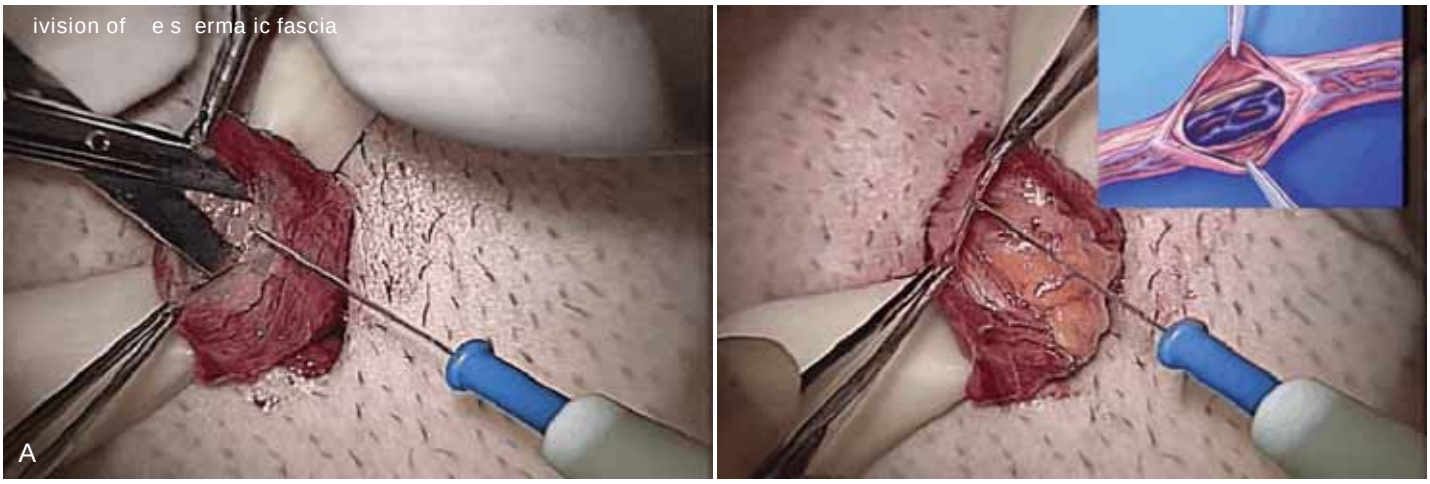

Figure 22–57. **A** and **B,** The operating microscope is then brought into the field. Under 4- to 6-power magnification, the external and internal spermatic fascias are opened.

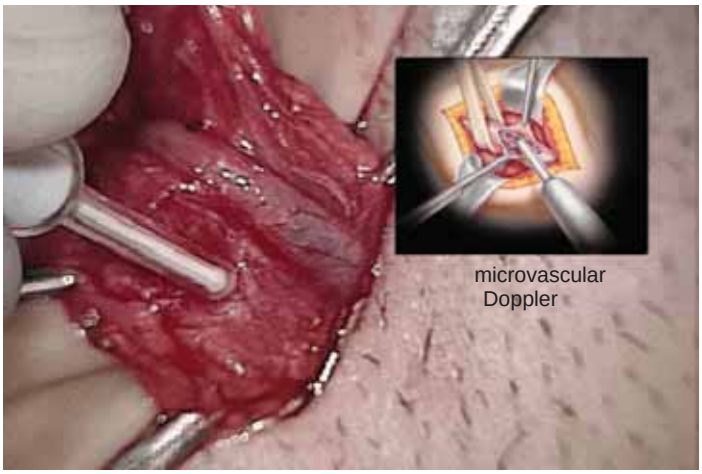

Figure 22–58. A micro-Doppler is extremely useful in identifying arteries.

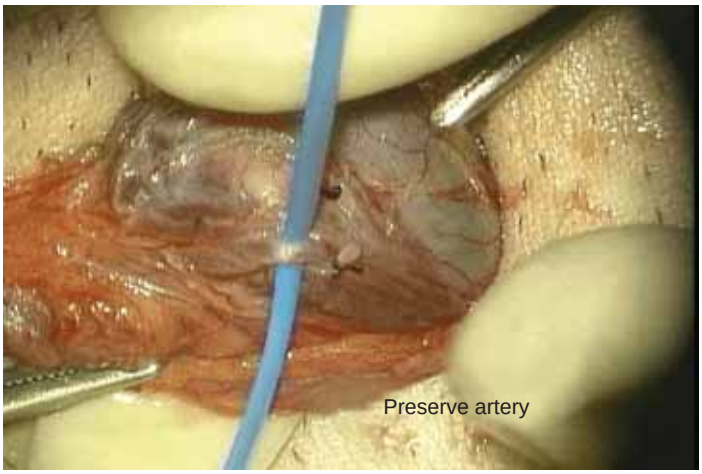

Figure 22–59. The artery is encircled with a vessel loop for positive identification and gentle retraction.

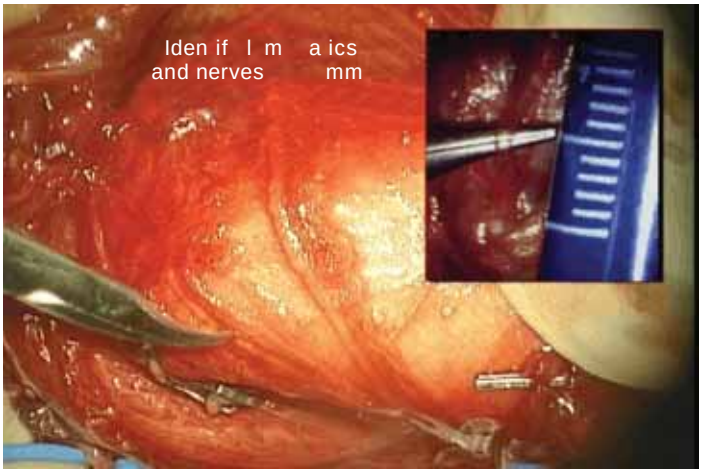

Figure 22–60. If the artery is not immediately identified, the cord is carefully dissected, beginning with the largest veins. The veins are stripped clean of adherent lymphatics.

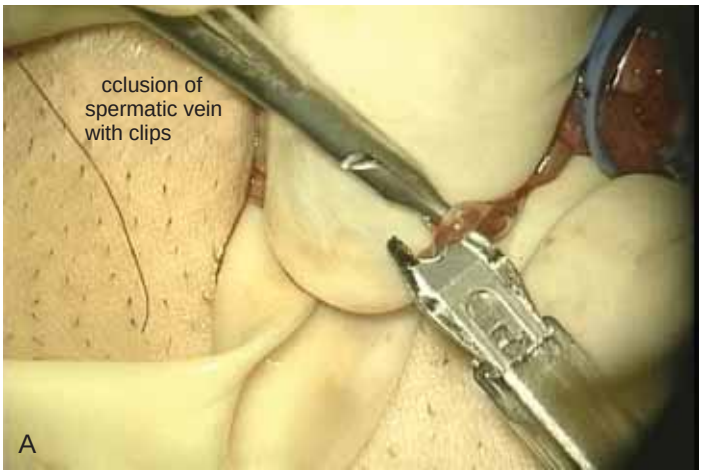

Figure 22–61. All veins within the cord, with the exception of the vasal veins, are doubly ligated, either with hemoclips **(A)** or by passing two 4-0 silk ligatures, one black and one white, beneath the vein **(B).**

external spermatic veins are identified and doubly ligated with hemoclips and divided (Fig. 22–63). The gubernaculum is inspected for the presence for veins exiting from the tunica vaginalis. These are either cauterized or doubly clipped and divided. **When this step is completed, all testicular venous return must be within the Penrose-surrounded cord.**

Hydroceles are found in 15% of testes associated with varicoceles. **As little as 3 mL of hydrocele fluid can significantly alter testicular temperature regulation** (Wysock et al, 2009). If a hydrocele is noted when the testis is delivered, it is repaired. Small ones may be treated with excision of a segment of the hydrocele sac and cauterization of the edges. Larger hydroceles are treated with either a bottleneck or excision technique. **The temporary high-venous pressure immediately after varicocelectomy can make good hemostasis difficult to achieve after excisional hydrocelectomy. Therefore there should be no hesitation to employ a scrotal Penrose drain placed in the dependant portion of the scrotal for 24 hours after combined varicocelectomy and excisional hydrocelectomy.** The testis is then returned to the scrotum, and the Penrose drain is left beneath the cord structures.

The external oblique aponeurosis, if opened, is reapproximated with continuous suturing using the previously placed 3-0 suture.

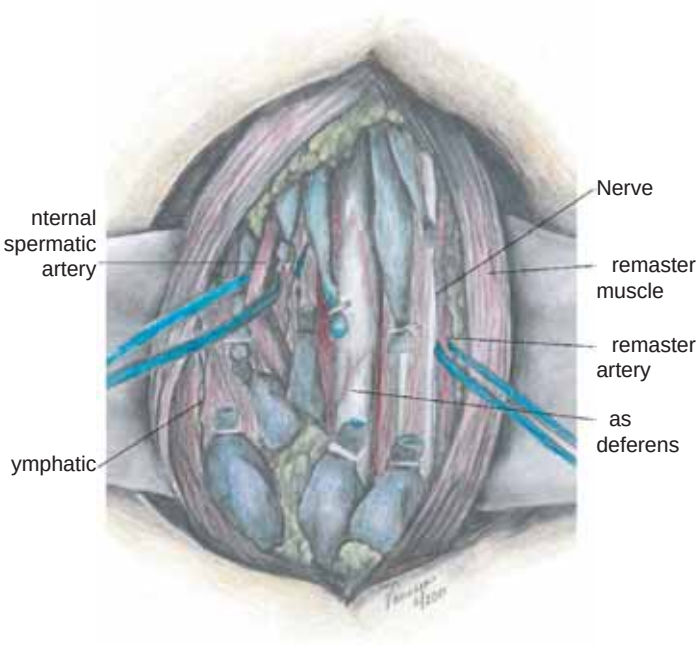

Figure 22–62. At the completion of the dissection, only the testicular arteries, cremasteric arteries, cremaster muscle fibers, nerves, lymphatics, and vas deferens with its vessels remain.

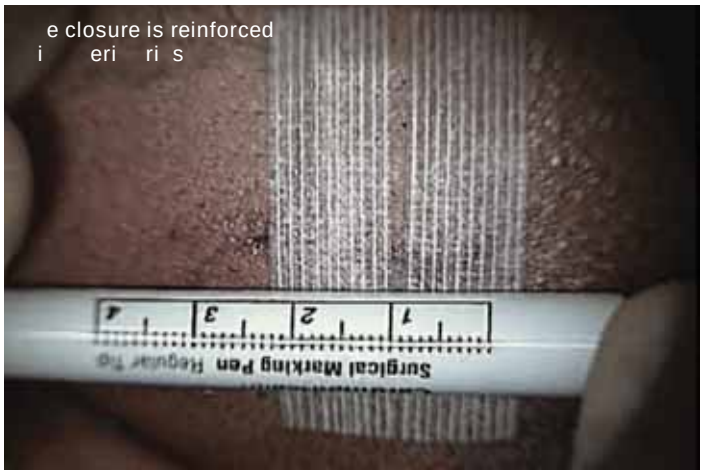

Figure 22–64. Scarpa fascia and Camper fascia are reapproximated with a single or continuous 3-0 monocryl suture, and the skin is approximated with a 5-0 monofilament absorbable subcuticular suture, reinforced by two to three sterile adhesive strips (Steri-Strips).

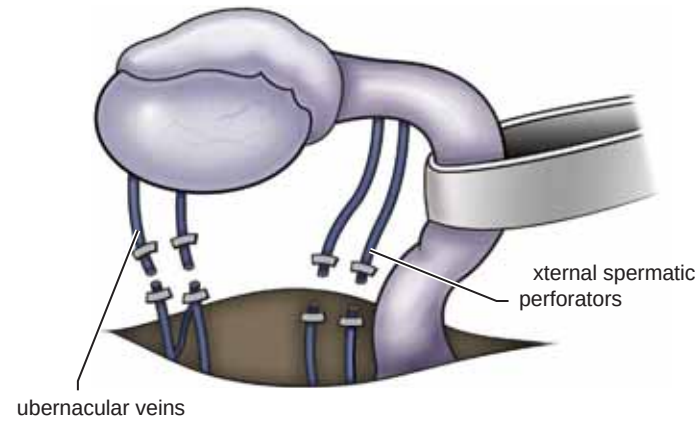

Figure 22–63. All external spermatic veins are identified and doubly ligated with hemoclips and divided.

Scarpa fascia and Camper fascia are reapproximated with a single or continuous 3-0 plain catgut suture, and the skin is approximated with a 5-0 monofilament absorbable subcuticular suture reinforced by two to three sterile adhesive strips (Steri-Strips) (Fig. 22–64). A scrotal supporter is applied and stuffed with fluff-type dressings. The patient is discharged on the day of surgery with a prescription for Tylenol with codeine. Light work may be resumed in 2 or 3 days.

Radiographic Occlusion Techniques

Intraoperative venography has been employed to visualize the venous collaterals, which if left unligated, may result in varicocele recurrence (Sayfan, 1981; Belgrano et al, 1984; Levitt et al, 1987; Zaontz and Firlit, 1987). Intraoperative venography does reduce the incidence of varicocele recurrence, but the two-dimensional view afforded often does not enable the surgeon to identify the location of all collaterals.

Radiographic balloon or coil occlusion of the internal spermatic veins has been successfully employed for varicoceles (Lima et al, 1978; Walsh and White, 1981; Weissbach et al, 1981). These techniques are performed under a local anesthetic through a small cut-down incision over the femoral vein. The recurrence rate after balloon occlusion was originally 11% and more recently is reportedly as low as 4% (Kaufman et al, 1983; Mitchell et al, 1985; Murray et al, 1986; Matthews et al, 1992). Failure to successfully cannulate small collaterals and external spermatic veins results in recurrence. **Venographic placement of a balloon or coil in the internal spermatic vein is successfully accomplished in 75% to 90% of attempts** (White et al, 1981; Morag et al, 1984; Winkelbauer et al, 1994; Sivanathan and Abernethy, 2003). **Therefore a significant number of men undergoing attempted radiographic occlusion will ultimately require a surgical approach.** In addition, the radiographic techniques take between 1 and 3 hours to perform compared with 25 to 45 minutes required for surgical repair. Although rare, serious complications of radiographic balloon or coil occlusion have included migration of the balloon or coil into the renal vein, resulting in loss of a kidney, pulmonary embolization of the coil or balloon (Matthews et al, 1992), femoral vein perforation or thrombosis, and anaphylactic reaction to radiographic contrast medium. Antegrade scrotal sclerotherapy via cannulation of a scrotal vein has been employed in Europe (Tauber and Johnsen, 1994; Ficarra et al, 2002; Minucci et al, 2004). The recurrence rate is similar to balloon or coil techniques. Long-term follow-up is not available, and the consequence of escape of the sclerosing agent into the renal vein and vena cava is unknown. In addition, the larger the varicocele, the higher the failure and recurrence rate with this technique. **We have seen many men referred with late (2 to 5 years) recurrence after radiographic occlusion. They typically present as slow-filling veins that become prominent at the end of the day. Initial cursory physical examination can miss these recurrences. We believe these recurrences are likely due to recanalization**

through the coils because, unlike surgical repair, the veins are not ligated and divided.

Complications of Varicocelectomy

Hydrocele

Hydrocele formation is the most common complication reported after nonmicroscopic varicocelectomy. The incidence of this complication varies from 3% to 33%, with an average incidence of about 7%. Analysis of the protein concentration of hydrocele fluid indicates that **hydrocele formation after varicocelectomy is due to lymphatic obstruction** (Szabo and Kessler, 1984). At least half of postvaricocelectomy hydroceles grow to a size large enough to warrant surgical excision due to the discomfort and growth of the hydrocele to a large size. The effect of hydrocele formation on sperm function and fertility is uncertain. It is known that men with varicocele have significantly elevated intratesticular temperatures (Zorgniotti et al, 1979; Goldstein and Eid, 1989), and this appears to be an important pathophysiologic phenomenon mediating the adverse effects of varicocele on fertility (Saypol et al, 1981). The development of a large hydrocele creates an abnormal insulating layer that surrounds the testis. This may impair the efficiency of the counter-current heat exchange mechanism and therefore obviate some of the benefits of varicocelectomy (Wysock et al, 2009).

Use of magnification to identify and preserve lymphatics can virtually eliminate the risk of hydrocele formation after varicocelectomy (Goldstein et al, 1992; Marmar and Kim, 1994; Glassberg et al, 2008). The management of postvaricocelectomy hydrocele is identical to that for other forms of hydrocele (see Chapter 37).

Testicular Artery Injury

The diameter of the testicular artery in humans is 1.0 to 1.5 mm. The testicular artery supplies two thirds of the testicular blood supply, and the vasal and cremasteric arteries supply the remaining one third (Raman and Goldstein, 2004). Microdissections of the human spermatic cord have revealed that the testicular artery is closely adherent to a large internal spermatic vein in 40% of men. In another 20% of men the testicular artery is surrounded by a network of tiny veins (Beck et al, 1992). During the course of cord dissection for varicocelectomy, the artery may go into spasm and even in its unconstricted state is often difficult to positively identify and preserve. **Injury or ligation of the testicular artery carries with it the risk of testicular atrophy and/or impaired spermatogenesis.** Starzl's transplant group (Penn et al, 1972) reported a 14% incidence of frank testicular atrophy when the testicular artery was purposely ligated. The actual incidence of testicular artery ligation during varicocelectomy is unknown, but some studies suggest it is common (Wosnitzer and Roth, 1983). Animal studies indicate that the risk of testicular atrophy after testicular artery ligation varies from 20% to 100% (MacMahon et al, 1976; Goldstein, 1983). In humans, atrophy after artery ligation is probably less likely due to the contribution of the cremasteric and vasal arterial supply (Raman and Goldstein, 2004). **In children the potential for neovascularization and compensatory hypertrophy of the vasal and cremasteric vessels is probably greater than in adults, making atrophy after testicular artery ligation less likely.** Use of magnifying loupes, or preferably an operating microscope and/or a fine-tipped Doppler probe, assists identification and preservation of the testicular artery and therefore minimizes the risk of testicular injury. Radiographic balloon or coil occlusion techniques also eliminate this risk.

Varicocele Recurrence

The incidence of varicocele recurrence following surgical repair varies from 0.6% to 45% (Barbalias et al, 1998; Lemack et al, 1998; Cayan et al, 2000; Al-Kandari et al, 2007). Recurrence is more common after repair of pediatric varicoceles. Radiographic studies of recurrent varicoceles visualize periarterial, parallel inguinal or midretroperitoneal collaterals, or, more rarely, transcrotal collaterals (Kaufman et al, 1983). **Retroperitoneal operations miss parallel inguinal collaterals.** Nonmagnified inguinal operations have a lower incidence of varicocele recurrence but fail to address the issue of scrotal collaterals or small veins surrounding the testicular artery. The microsurgical approach with delivery of the testis lowers the incidence of varicocele recurrence to less than 1% compared with 9% using conventional inguinal techniques (Goldstein et al, 1992; Marmar and Kim, 1994).

Results

Varicocelectomy results in significant improvement in semen analysis in 60% to 80% of men. Reported pregnancy rates after varicocelectomy vary from 20% to 60% (Marmar et al, 2007). A randomized controlled trial of surgery versus no surgery in infertile men with varicoceles revealed a pregnancy rate of 44% at 1 year in the surgery group versus 10% in the control group (Abdel-Meguid, 2010). In our series of 1500 microsurgical operations 43% of couples were pregnant at 1 year (Goldstein and Tanrikut, 2006) and 69% at 2 years when couples with female factors were excluded. **Microsurgical varicocelectomy results in return of sperm to the ejaculate in up to 60% of azoospermic men with palpable varicoceles** (Matthews et al, 1998; Kim et al, 1999; Pasqualotto et al, 2006; Lee et al, 2007; Ishikawa et al, 2008).

The results of varicocelectomy are also related to the size of the varicocele. **Repair of large varicoceles results in a significantly greater improvement in semen quality than repair of small varicoceles** (Steckel et al, 1993; Jarow et al, 1996). In addition, large varicoceles are associated with greater preoperative impairment in semen quality than small varicoceles, and consequently overall pregnancy rates are similar regardless of varicocele size. Some evidence suggests that the younger the patient is at the time of varicocele repair, the greater the improvement after repair and the more likely the testis is to recover from varicocele-induced injury (Kass et al, 1987). Varicocele recurrence, testicular artery ligation, or postvaricocelectomy hydrocele formation are often associated with poor postoperative results. **In infertile men with low serum testosterone levels, microsurgical varicocelectomy alone results in substantial improvement in serum testosterone levels** (Su et al, 1995; Cayan et al, 1999; Younes, 2003; Rosoff et al, 2009).

Summary

Varicocele is an extremely common entity, present in 15% of the male population. Varicoceles are found in approximately 35% of men with primary infertility but 75% to 81% of men with secondary infertility. Mounting evidence clearly demonstrates that varicocele causes progressive duration-dependent injury to the testis. Larger varicoceles appear to cause more damage than small varicoceles and, conversely, repair of large varicoceles results in greater improvement of semen quality. **Varicocelectomy can halt the**

progressive duration-dependent decline in semen quality found in men with varicoceles. The earlier the age at which varicocele is repaired, the more likely is recovery of spermatogenic function. **Variococelectomy can also improve Leydig cell function, resulting in increased testosterone levels** (Su et al, 1995; Cayan et al, 1999; Younes, 2003).

The most common complications after varicocelectomy are hydrocele formation, testicular artery injury, and varicocele persistence or recurrence. **The incidence of** these **complications can be reduced by employing microsurgical techniques, inguinal or subinguinal operations, and exposure of the external spermatic and scrotal veins.** Employment of these advanced techniques of varicocelectomy provide a safe, effective approach to elimination of varicocele, preservation of testicular function, and, in a substantial number of men, an increase in semen quality and likelihood of pregnancy (Abdel-Meguid, 2010).

ORCHIOPEXY IN ADULTS

It is well known that cryptorchidism is associated with a high incidence of infertility even when unilateral. Long hot baths and saunas in humans, on a regular basis, have been shown to impair spermatogenesis. Elevated testicular temperature is also thought to be the primary pathophysiology feature of varicocele (Zorgniotti, 1980; Saypol et al, 1981; Goldstein and Eid, 1989; Wright et al, 1997). Spermatogenesis is exquisitely temperature sensitive. Both animal and human studies have shown that artificial elevation of testicular temperature results in impaired spermatogenesis (Shin et al, 1997; Perez-Crespo et al, 2008; Shiraishi et al, 2009). It will also preserve testicular hormonal function. The technique of orchiopexy in adults is identical to that employed for children. Even with a normal contralateral testis, orchiopexy is worthwhile to bring down a unilateral undescended testis to, if possible, a scrotal location where it can be examined. Leydig cell function in undescended testis can be retained. Orchiopexy in adults with bilateral undescended testes can induce spermatogenesis and allow pregnancy (Shin et al, 1997). Even **a solitary cryptorchid testis, when properly placed in scrotum, can provide enough testosterone to obviate the need for hormone replacement. When orchiopexy is performed in adults, regular self-examination and yearly sonography are mandatory.**

Retractile Testes in Adults

Retractile testes in boys are usually not surgically repaired if the testes can be manually manipulated to stay down into the scrotum either in the office or under anesthesia. The fate of persistently retractile testis in adults is unknown. A subset of infertile men have retractile testis (Caucci et al, 1997). The semen analyses of these men often demonstrate a typical stressed pattern similar to those of men with varicoceles. These men, however, do not have palpable varicoceles. They all have at least one and frequently both testes that retract out of the scrotum and into the abdomen and remain there for an hour or more a day. In some men these testes remain in the abdomen virtually all the time, except when in a warm shower or under anesthesia. It is likely that these testes will suffer from impaired temperature regulation and impaired spermatogenesis. Scrotal orchiopexy can improve the semen quality and fertility of some of these men.

When scrotal orchiopexy is performed for retractile testis, a dartos pouch operation should be performed. Simple suture orchiopexy of the tunica albuginea of the testis to the dartos, such as is performed sometimes to prevent torsion, will not prevent retraction of these testes into the groin. Creation of a dartos pouch will keep the testis well down into the scrotum and permanently prevent retraction. **This is also the most reliable and safest technique for the prevention of testicular torsion** (Redman and Barthold, 1995).

A 3- to 4-cm transverse incision is made in the low scrotal skin folds overlying the testis. **The incision is kept superficial, just through the dermis and not into the dartos. A large pouch must be created to accommodate the adult testis.** The place of dissection is above the dartos and just below the skin, which is kept thin.

After a capacious pouch is created, the dartos and underlying tunica vaginalis are vertically incised and the testis delivered. The cremasteric fibers overlying the spermatic cord are divided and ligated to minimize the tendency of the testis to retract. The opening in the dartos is closed around the cord (but not too tightly) to prevent the testis from falling out of the pouch. The cut edge of the everted tunica is approximated to the opening in the dartos with interrupted synthetic monofilament absorbable sutures. This allows placement of the testis in the pouch without the need for fixation sutures in the tunica albuginea (Redman and Barthold, 1995). The skin is closed over the testis with interrupted sutures of 4-0 chromic catgut. This technique obviates the risk of inadvertent injury to and bleeding from the testicular artery, which courses just under the tunica albuginea (Jarow, 1990).

Physiology of Penile Erection and Pathophysiology of Erectile Dysfunction

Tom F. Lue, MD, ScD (Hon), FACS

Physiology of Penile Erection
Pathophysiology of Erectile Dysfunction
Perspectives

"The penis does not obey the order of its master, who tries to erect or shrink it at will. Instead, the penis erects freely while its master is asleep. The penis must be said to have its own mind, by any stretch of the imagination."

—*Leonardo da Vinci*

PHYSIOLOGY OF PENILE ERECTION

Historical Aspects

The first description of erectile dysfunction (ED) dates from about 2000 BC and was set down on Egyptian papyrus. Two types were described: natural ("the man is incapable of accomplishing the sex act") and supernatural (evil charms and spells). Later, Hippocrates reported many cases of male impotence among the rich inhabitants of Scythia and ascribed it to excessive horseback riding. Aristotle stated that three branches of nerves carry spirit and energy to the penis and that erection is produced by the influx of air (Brenot, 1994). His theory was well accepted until Leonardo da Vinci (1504) noted a large amount of blood in the erect penis of hanged men and cast doubt on the concept of the air-filled penis. His writings, however, were kept secret until the beginning of the 20th century (Brenot, 1994). Nevertheless, in 1585, in *Ten Books on Surgery* and the *Book of Reproduction,* Ambroise Paré gave an accurate account of penile anatomy and the concept of erection. He described the penis as being composed of concentric coats of nerves, veins, and arteries and of two ligaments (corpora cavernosa), a urinary tract, and four muscles. "When the man becomes inflamed with lust and desire, blood rushes into the male member and causes it to become erect," Paré wrote. The importance of retaining blood in the penis was stressed by Dionis (1718; quoted by Brenot, 1994), who attributed this to the muscles cramping the veins at the proximal end, and by Hunter (1787), who thought that venous spasm prevented the exit of blood.

Modern investigations of penile hemodynamics began in the 1970s with xenon washout and cavernosography studies in human volunteers exposed to audiovisual sexual stimuli. These studies yielded conflicting results: Shirai and associates (1978) concluded that penile venous flow is increased during erection, but markedly increased arterial flow compensates for this; in contrast, Wagner (1981) also demonstrated increased arterial flow but concluded that venous drainage is decreased during erection.

Much of the current understanding of erectile physiology was gained in the 1980s and 1990s. In addition to the role of smooth muscle in regulating arterial and venous flow, the three-dimensional structure of the tunica albuginea and its role in venous occlusion were elucidated. An important breakthrough in the understanding of neural influences was the identification of nitric oxide (NO) as the major neurotransmitter for erection and of phosphodiesterases (PDEs) for detumescence. The role of endothelium in regulating smooth muscle tone and of the intercellular links affected by gap junctions has been uncovered. Furthermore, the importance of ion channels (potassium and calcium) and Rho/Rho kinase pathways in contraction and relaxation of smooth muscle has been shown. In pathophysiology, changes in smooth muscle, nerve endings, endothelium, and the fibroelastic framework associated with disease have been identified. These developments are discussed in detail in this chapter.

Functional Anatomy of the Penis

The penis is composed of three cylindrical structures: the paired corpora cavernosa and the corpus spongiosum (which houses the urethra), covered by a loose subcutaneous layer and skin. Its flaccid length is controlled by the contractile state of the erectile smooth muscle and varies considerably, depending on emotion and outside temperature. In one study, penile length, measured from the pubopenile junction to the meatus, was 8.8 cm flaccid, 12.4 cm stretched, and 12.9 cm erect, with neither age nor the size of the flaccid penis accurately predicting erectile length (Wessells et al, 1996). In another study, the author concluded that about 15% of men have a downward curve during erection; erect angle is below horizontal in one quarter; and shorter erect lengths (from 4.5 to 5.75 inches) occur in 40% of men (Sparling, 1997).

Modified from Awwad Z, Abu-Hijleh M, Basri S, et al. Penile measurements in normal adult Jordanians and in patients with erectile dysfunction. Int J Impot Res 2005;17:191–5.

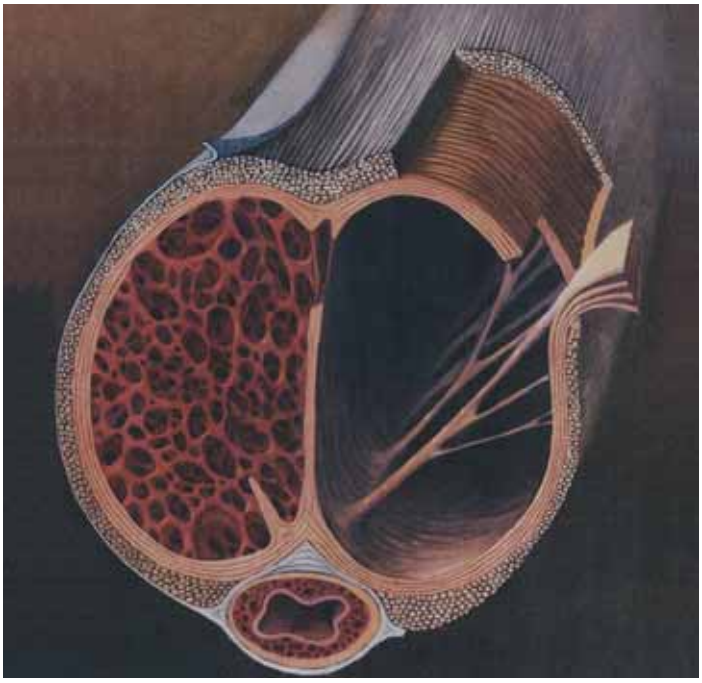

Figure 23–1. Artist's cross-sectional drawing of the penis, depicting the inner circular and outer longitudinal layers of the tunica albuginea, as well as the intracavernous pillars. The longitudinal layer is absent in the ventral groove housing the corpus spongiosum. (From Lue TF, Akkus E, Kour NW. Physiology of erectile function and dysfunction. Campbell's Urology Update 1994;12:1–10.)

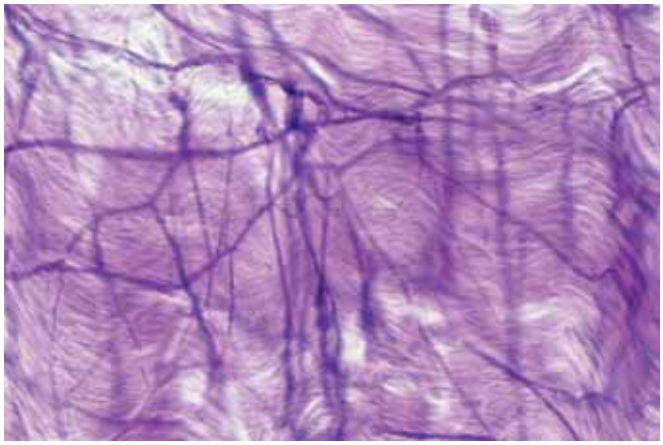

Figure 23–2. Micrograph of the human tunica albuginea, showing the interwoven elastic fibers and the finer collagen fibers (Hart stain ×100).

Since then, more studies have been reported from several countries (Awwad et al, 2005) (Table 23–1). Regarding penile morphology and erection, one study showed that, during erection, the penile buckling forces are dependent not only on intracavernous pressures but also on penile geometry and erectile tissue properties. The authors concluded that, in patients with normal penile hemodynamics but without adequate rigidity, structural causes should be investigated (Udelson et al, 1998).

Tunica Albuginea

The tunica affords great flexibility, rigidity, and tissue strength to the penis (Hsu et al, 1992) (Fig. 23–1). **The tunical covering of the corpora cavernosa is a bilayered structure with multiple sublayers. Inner-layer bundles support and contain the cavernous tissue and are oriented circularly. Radiating from this inner layer are intracavernous pillars that act as struts to augment the septum and provide essential support to the erectile tissue. Outer-layer bundles are oriented longitudinally, extending from the glans penis to the proximal crura; they insert into the inferior pubic rami but are absent between the 5 and the 7 o'clock positions. In contrast, the corpus spongiosum lacks an outer layer or intracorporeal struts, ensuring a low-pressure structure during erection.**

The tunica is composed of elastic fibers that form an irregular, latticed network on which the collagen fibers rest (Fig. 23–2). The detailed histologic composition of the tunica varies with anatomic location and function. Emissary veins run between the inner and outer layers for a short distance, often piercing the outer bundles obliquely. However, the cavernous artery and the branches of the dorsal artery that give additional blood supply to the corpus cavernosum take a more direct route and are surrounded by a periarterial soft-tissue sheath, which protects the arteries from occlusion by the tunica albuginea during erection.

The outer tunical layer appears to play an additional role in compression of the emissary veins during erection. It also

determines, to a large extent, the variability in tunical thickness and strength (Hsu et al, 1992). Between the 6 and 7 o'clock positions, the tunical thickness is 0.8 ± 0.1 mm; at the 9 o'clock position, 1.2 ± 0.2 mm; and at the 11 o'clock position, 2.2 ± 0.4 mm. At the 3, 5 to 6, and 1 o'clock positions, the measurements are nearly identical in mirror-image fashion. (Differences at specific locations have been found to be statistically significant.)

The stress on the tunica before penetration has been measured as $1.6 \pm 0.2 \times 10^7$ N/m^2 between the 6 and 7 o'clock positions, $3.0 \pm 0.3 \times 10^7$ N/m^2 at the 9 o'clock position, and $4.5 \pm 0.5 \times 10^7$ N/m^2 at the 11 o'clock position. **The strength and thickness of the tunica correlate in a statistically significant fashion with location. The most vulnerable area is located on the ventral groove (between the 5 and 7 o'clock positions), where the longitudinal outer layer is absent; most prostheses tend to extrude here** (Hsu et al, 1994).

The tunica albuginea is composed of fibrillar collagen (mostly type I, but also type III) in organized arrays interlaced with elastin fibers. Although collagen has a greater tensile strength than steel, it is unyielding. In contrast, elastin can be stretched up to 150% of its length. It is the elastin content that allows tunical expansion and helps to determine stretched penile length.

External penile support consists of two ligamentous structures: the fundiform and suspensory ligaments. The fundiform ligament arises from Colles' fascia and is lateral, superficial, and not adherent to the tunica albuginea of the corpora cavernosa. The suspensory ligament arises from Buck fascia and consists of two lateral bundles and one median bundle, which circumscribe the dorsal vein of the penis. Its main function is to attach the tunica albuginea of the corpora cavernosa to the pubis, and thus it provides support for the mobile portion of the penis (Hoznek et al, 1998). In patients with congenital deficiency or in whom this ligament has been severed in "penile elongation" surgery, the erect penis may be unstable or droop.

Corpora Cavernosa, Corpus Spongiosum, and Glans Penis

The corpora cavernosa comprise two spongy, paired cylinders contained in the thick envelope of the tunica albuginea. Their proximal ends, the crura, originate at the undersurface of the puboischial rami as two separate structures but merge under the pubic arch and remain attached up to the glans. **The septum between the two corpora cavernosa is incomplete in men but is complete in some species such as the dog.**

The corpora cavernosa are supported by a fibrous skeleton that includes the tunica albuginea, the septum, the intracavernous pillars, the intracavernous fibrous framework, and the periarterial and perineural fibrous sheath (Goldstein and Padma-Nathan, 1990; Hsu et al, 1992). Within the tunica are the interconnected sinusoids separated by smooth muscle trabeculae surrounded by elastic fibers, collagen, and loose areolar tissue. The terminal cavernous nerves and helicine arteries are intimately associated with the smooth muscle. Each corpus cavernosum is a conglomeration of sinusoids, larger in the center and smaller in the periphery. In the flaccid state, the blood slowly diffuses from the central to the peripheral sinusoids and the blood gas levels are similar to those of venous blood. During erection, the rapid entry of arterial blood to both the central and the peripheral sinusoids changes the intracavernous blood gas levels to those of arterial blood (Sattar et al, 1995).

The structure of the corpus spongiosum and glans is similar to that of the corpora cavernosa, except that the sinusoids are larger; the tunica is thinner in the spongiosum (with only a circular layer [see earlier]) and is absent in the glans (Table 23–2).

Table 23–2.
Penile Components and Their Function during Penile Erection

Corpora cavernosa	Support corpus spongiosum and glans
Tunica albuginea (of corpora cavernosa)	Contains and protects erectile tissue Provides rigidity of the corpora cavernosa Participates in veno-occlusive mechanism
Smooth muscle	Regulates blood flow into and out of the sinusoids
Ischiocavernosus muscle	Pumps blood distally to hasten erection Provides additional penile rigidity during rigid erection phase
Bulbocavernosus muscle	Compresses the bulb to help expel semen
Corpus spongiosum	Pressurizes and constricts the urethral lumen to allow forceful expulsion of semen
Glans	Acts as a cushion to lessen the impact of penis on female organs Provides sensory input to facilitate erection and enhance pleasure Facilitates intromission because of its cone shape

Arteries

The source of penile blood is usually the internal pudendal artery, a branch of the internal iliac artery (Fig. 23–3A). **In many instances, however, accessory arteries exist, arising from the external iliac, obturator, and vesical and femoral arteries, and they may in some men constitute the dominant or only arterial supply to the corpus cavernosum** (Breza et al., 1989). **In a study of 20 fresh human cadavers,** Droupy and colleagues (1997) reported three patterns of penile arterial supply: type I arising exclusively from internal pudendal arteries (3/20); type II arising from both accessory and internal pudendal arteries (14/20); and type III arising exclusively from accessory pudendal arteries (3/20). Nehra and colleagues (2008) **studied 79 consecutive patients with a history of erectile dysfunction (ED) and noted that 35% had an accessory pudendal artery, typically arising from the obturator artery. In these men, the accessory pudendal was the dominant blood supply in 54% and the only corporal blood supply in 11%. The importance of accessory pudendal artery preservation during radical prostatectomy was demonstrated by Mulhall and colleagues, who reported more rapid recovery of sexual function in men who underwent artery-sparing radical prostatectomy** (Mulhall et al, 2008).

The internal pudendal artery becomes the common penile artery after giving off a branch to the perineum. The three branches of the penile artery are the dorsal, bulbourethral, and cavernous. Distally, they join to form a vascular ring near the glans. The dorsal artery is responsible for engorgement of the glans during erection. The bulbourethral artery supplies the bulb and corpus spongiosum. The cavernous artery effects tumescence of the corpus cavernosum and enters it at the hilum of the penis, where the two crura merge. Along its course, it gives off many helicine

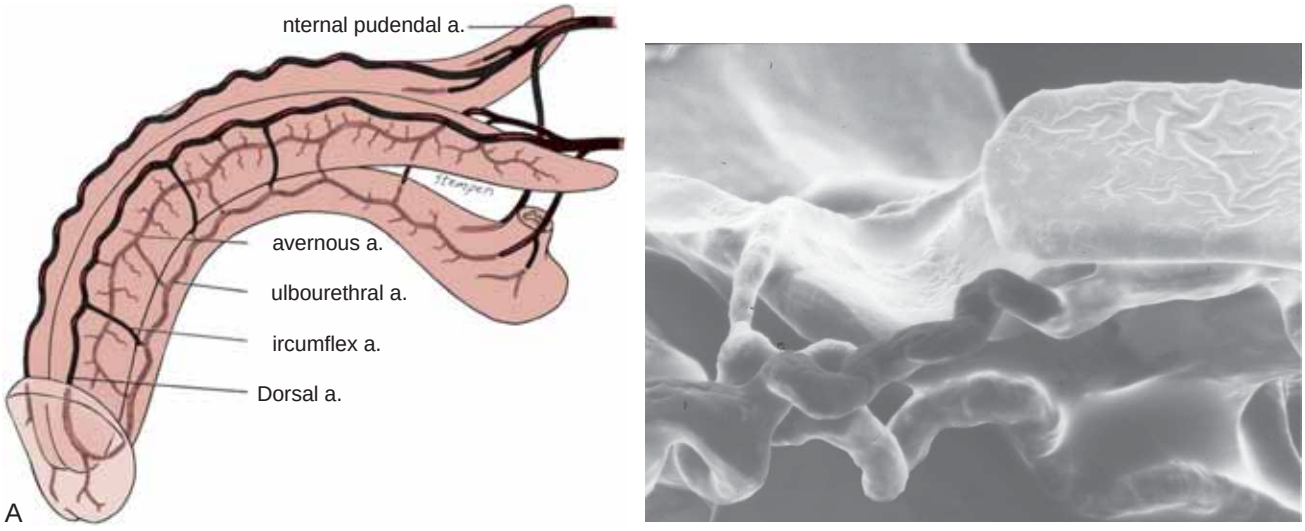

Figure 23–3. **A,** Penile arterial supply. **B,** Scanning electron micrograph of a human penile cast showing helicine arteries opening directly into the sinusoids without intervening capillaries.

arteries, which supply the trabecular erectile tissue and the sinusoids (Fig. 23–3B). These helicine arteries are contracted and tortuous in the flaccid state and become dilated and straight during erection.

Veins

The venous drainage from the three corpora originates in tiny venules leading from the peripheral sinusoids immediately beneath the tunica albuginea. These venules travel in the trabeculae between the tunica and the peripheral sinusoids to form the subtunical venous plexus before exiting as the emissary veins (Fig. 23–4A). Outside the tunica albuginea, venous drainage is as follows:

Skin and Subcutaneous Tissue. Multiple superficial veins run subcutaneously and unite near the root of the penis to form a single (or paired) superficial dorsal vein, which in turn drains into the saphenous veins. Occasionally, the superficial dorsal vein may also drain a portion of the corpora cavernosa.

Pendulous Penis. The emissary veins from the corpus cavernosum and spongiosum drain dorsally to the deep dorsal, laterally to the circumflex, and ventrally to the periurethral veins. Beginning at the coronal sulcus, multiple venous channels coalesce to form the deep dorsal vein, which is the main venous drainage of the glans penis and distal two thirds of the corpora cavernosa. Usually a single vein, but sometimes more than one deep dorsal vein, runs upwards behind the symphysis pubis to join the periprostatic venous plexus. There are also small venous channels accompanying the paired dorsal artery. In addition, many veins also travel longitudinally within the layers of the tunica albuginea to join the dorsal vein or Santorini plexus proximally (Hsu et al, 2003). These become enlarged after the deep dorsal vein is ligated and may be the cause of recurrent leakage in venogenic ED (Chen et al, 2005).

Infrapubic Penis. Emissary veins draining the proximal corpora cavernosa join to form cavernous and crural veins. These join the periurethral veins from the urethral bulb to form the internal pudendal veins.

The veins of the three systems communicate variably with each other. Indeed, variations in the number, distribution, and termination of these venous systems are common (Fig. 23–4B and C).

Hemodynamics and Mechanism of Erection And Detumescence

Corpora Cavernosa

The penile erectile tissue, specifically the cavernous smooth musculature and the smooth muscles of the arteriolar and arterial walls, plays a key role in the erectile process. **In the flaccid state, these smooth muscles are tonically contracted, allowing only a small amount of arterial flow for nutritional purposes.** The blood partial pressure of oxygen (pO_2) is about 35 mm Hg (Sattar et al, 1995). The flaccid penis is in a moderate state of contraction, as evidenced by further shrinkage in cold weather and after phenylephrine injection.

Sexual stimulation triggers release of neurotransmitters from the cavernous nerve terminals. This results in relaxation of these smooth muscles and the following events (Fig. 23–5): **(1) dilation of the arterioles and arteries by increased blood flow in both the diastolic and systolic phases; (2) trapping of the incoming blood by the expanding sinusoids; (3) compression of the subtunical venous plexuses between the tunica albuginea and the peripheral sinusoids, reducing venous outflow; (4) stretching of the tunica to its capacity, which occludes the emissary veins between the inner circular and outer longitudinal layers and further decreases venous outflow to a minimum; (5) an increase in Po_2 (to about 90 mm Hg) and intracavernous pressure (around 100 mm Hg), which raises the penis from the dependent position to the erect state (the full-erection phase); and (6) a further pressure increase (to several hundred millimeters of mercury) with contraction of the ischiocavernosus muscles (rigid-erection phase).**

The angle of the erect penis is determined by its size and attachment to the puboischial rami (the crura) and the anterior surface of the pubic bone (the suspensory and funiform ligaments). In men with a long heavy penis or a loose suspensory ligament, the angle usually will not be greater than 90 degrees, even with full rigidity.

Three phases of detumescence have been reported in an animal study (Bosch et al, 1991). The first entails a transient

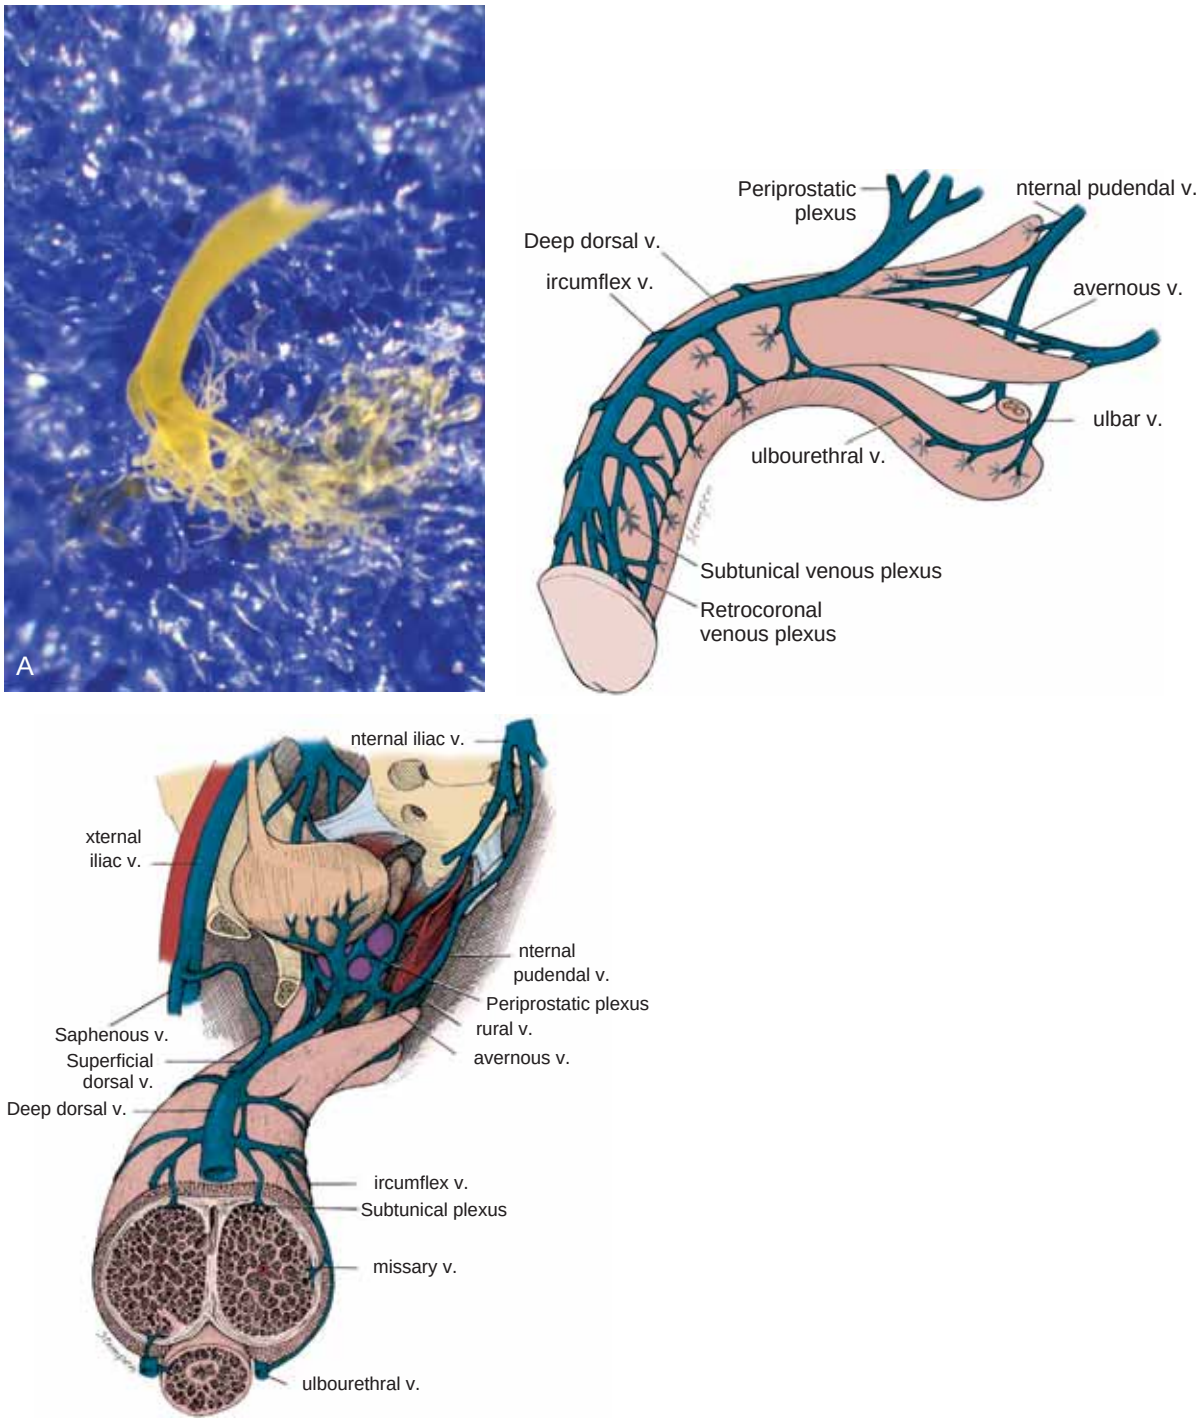

Figure 23–4. **A,** Photograph of an emissary vein with subtunical venous plexus of a human penile cast. The cast was made by injecting blue material into the corpus cavernosum and yellow material into the deep dorsal vein. The skin and tunica albuginea were then digested away with KOH solution. **B** and **C,** Penile venous drainage.

intracorporeal pressure increase, indicating the beginning of smooth muscle contraction against a closed venous system. The second phase shows a slow pressure decrease, suggesting a slow reopening of the venous channels with resumption of the basal level of arterial flow. The third phase shows a fast pressure decrease with fully restored venous outflow capacity.

Erection thus involves sinusoidal relaxation, arterial dilation, and venous compression (Lue et al, 1983). The importance of smooth muscle relaxation has been demonstrated in animal and human studies (Saenz de Tejada et al, 1989a; Ignarro et al, 1990). To summarize the hemodynamic events of erection and detumescence, seven phases have been observed in animal experiments that reflect the changes in and the relationship between penile arterial flow and intracavernous pressure (Fig. 23–6).

Corpus Spongiosum and Glans Penis

The hemodynamics of the corpus spongiosum and glans penis are somewhat different from those of the corpora cavernosa. **During erection, the arterial flow increases in a similar manner;**

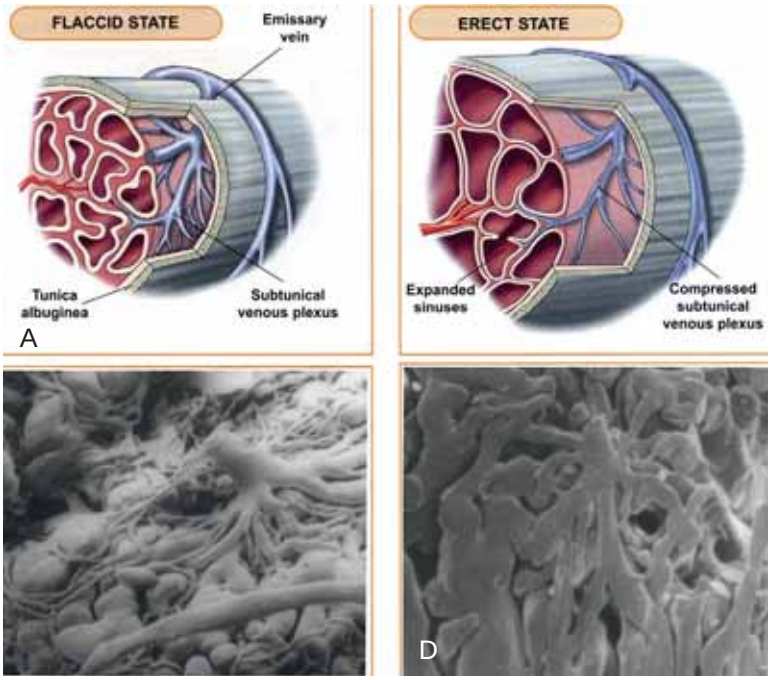

Figure 23–5. The mechanism of penile erection: **A,** In the flaccid state, the arteries, arterioles, and sinusoids are contracted. The intersinusoidal and subtunical venous plexuses are wide open, with free flow to the emissary veins. **B,** In the erect state, the muscles of the sinusoidal wall and the arterioles relax, allowing maximal flow to the compliant sinusoidal spaces. Most of the venules are compressed between the expanding sinusoids. The larger venules are sandwiched and flattened between the distended sinusoids and the tunica albuginea. This effectively reduces the venous capacity to a minimum. **C** and **D,** Scanning electron micrographs of casts of a canine subtunical venous plexus in the flaccid and erect states, respectively. (**A** and **B,** From Lue TF, Giuliano F, Khoury S, Rosen R. Clinical manual of sexual medicine: sexual dysfunction in men. Paris: Health Publications; 2004.)

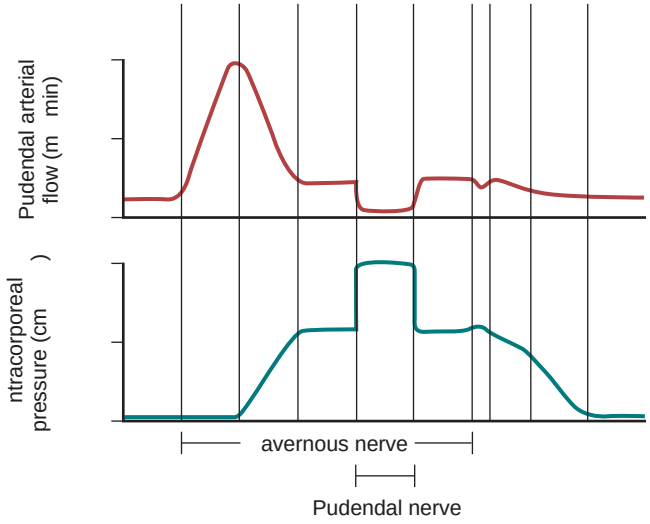

Figure 23–6. Blood flow and intracavernous pressure changes during the seven phases of penile erection and detumescence: 0, flaccid; 1, latent; 2, tumescence; 3, full erection; 4, rigid erection; 5, initial detumescence; 6, slow detumescence; 7, fast detumescence.

however, the pressure in the corpus spongiosum and glans is only one-third to one-half that in the corpora cavernosa because the tunical covering, which is thin over the corpus spongiosum and virtually absent over the glans, ensures minimal venous occlusion. During the full-erection phase, partial compression of the deep dorsal and circumflex veins between Buck fascia and the engorged corpora cavernosa contributes to glanular tumescence, although the spongiosum and glans essentially function as a large arteriovenous shunt during this phase. In the rigid-erection phase, the ischiocavernosus and bulbocavernosus muscles forcefully compress the spongiosum and penile veins, resulting in further engorgement and increased pressure in the glans and spongiosum (Table 23–3).

Table 23–3.

Comparison of Corpus Spongiosum and the Glans

	CORPUS SPONGIOSUM	GLANS PENIS
Tunica albuginea	Thin (circular layer only)	Absent
Main blood supply	Bulbal and spongiosal arteries	Dorsal artery
Venous occlusion during erection	No	No
Compression by skeletal muscle	Yes (ischiocavernosus, bulbocavernosus)	No

Neuroanatomy and Neurophysiology of Penile Erection

Spinal Centers and Peripheral Pathways

The innervation of the penis is both autonomic (sympathetic and parasympathetic) and somatic (sensory and motor) (Fig. 23–7). From the neurons in the spinal cord and peripheral ganglia, the sympathetic and parasympathetic nerves merge to form the cavernous nerves, which enter the corpora cavernosa and corpus spongiosum to modulate the neurovascular events during erection and detumescence. The somatic nerves are primarily responsible for sensation and the contraction of the bulbocavernosus and ischiocavernosus muscles.

Autonomic Pathways. The sympathetic pathway originates from the 11th thoracic to the 2nd lumbar spinal segments and passes through the white rami to the sympathetic chain ganglia. Some fibers then travel through the lumbar splanchnic nerves to the inferior mesenteric and superior hypogastric plexuses, from which fibers travel in the hypogastric nerves to the pelvic plexus. In humans the T10 to T12 segments are most often the origin of the sympathetic fibers, and the chain ganglia cells projecting to the penis are located in the sacral and caudal ganglia (de Groat and Booth, 1993).

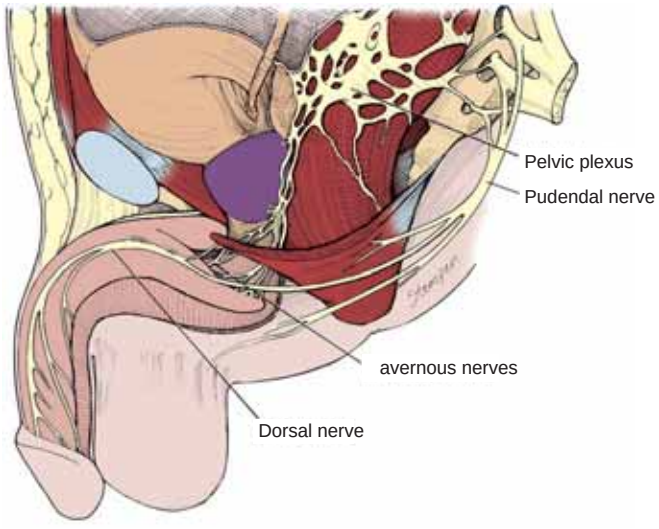

Figure 23–7. Penile neuroanatomy.

Figure 23–8. Drawing from a human cadaveric dissection shows the medial *(red arrow)* and lateral *(green arrow)* bundles of the cavernous nerve distal to the prostate. (Reprinted with permission from Paick JS, Donatucci EF, Lue TF. Anatomy of cavernous nerves distal to prostate: microdissection study in adult male cadavers. Urology 1993;42:145–9, with permission from Exerpta Medica, Inc.)

The parasympathetic pathway arises from neurons in the intermediolateral cell columns of the second, third, and fourth sacral spinal cord segments. The preganglionic fibers pass in the pelvic nerves to the pelvic plexus, where they are joined by the sympathetic nerves from the superior hypogastric plexus. The cavernous nerves are branches of the pelvic plexus that innervate the penis. Other branches innervate the rectum, bladder, prostate, and sphincters. The cavernous nerves are easily damaged during radical excision of the rectum, bladder, and prostate. A clear understanding of the course of these nerves is essential to the prevention of iatrogenic ED (Walsh et al, 1990). Human cadaveric dissection has revealed medial and lateral branches of the cavernous nerves (the former accompanying the urethra and the latter piercing the urogenital diaphragm 4 to 7 mm lateral to the sphincter) and multiple communications between the cavernous and dorsal nerves (Fig. 23–8) (Paick et al, 1993). In addition to the cavernous nerve proper, pelvic ganglion cells also exist in and along the nerve components and pelvic viscera. These are seen at the bladder/prostate junction, the dorsal aspect of the seminal vesicles, and along the prostate. Takenaka and colleagues (2005) reported individual variations in distribution of these extramural ganglion cells in the male pelvis, which may complicate nerve-sparing efforts.

Stimulation of the pelvic plexus and the cavernous nerves induces erection, whereas stimulation of the sympathetic trunk causes detumescence. This clearly implies that the sacral parasympathetic input is responsible for tumescence and the thoracolumbar sympathetic pathway is responsible for detumescence. In experiments with cats and rats, removal of the spinal cord below L4 or L5 reportedly eliminated the reflex erectile response, but placement with a female in heat or electrical stimulation of the medial preoptic area (MPOA) produced marked erection (Giuliano et al, 1996; Sato and Christ, 2000). Paick and Lee (1994) also reported that apomorphine-induced erection is similar to psychogenic erection in the rat and can be induced by means of the thoracolumbar sympathetic pathway in case of injury to the sacral parasympathetic centers. In man, many patients with sacral spinal cord injury retain psychogenic erectile ability even though reflexogenic erection is abolished. These cerebrally elicited erections are found more frequently in patients with lower motoneuron lesions below T12 (Courtois et al, 1999); no psychogenic erection occurs in patients with lesions above T9. The efferent sympathetic outflow is thus suggested to be at the levels T11 and T12 (Chapelle et al, 1980). These authors have also reported that, in patients with psychogenic erections, lengthening and swelling of the penis are observed but rigidity is insufficient.

It is therefore possible that, for rigid-erection production in normal men, cerebral impulses travel as follows: inhibiting the sympathetic pathway and thus decreasing norepinephrine release; through the parasympathetic, releasing NO and acetylcholine; and the somatic, releasing acetylcholine. In patients with a sacral cord lesion, the cerebral impulses can still travel by means of the sympathetic pathway to inhibit norepinephrine release, and NO and acetylcholine can still be released through synapse with postganglionic parasympathetic and somatic neurons. Because the number of these synapses is less than in men with an intact sacral spinal cord, the resulting erection will not be as strong.

Somatic Pathways. The somatosensory pathway originates at the sensory receptors in the penile skin, glans, and urethra and within the corpus cavernosum. In the human glans penis are numerous afferent terminations: free nerve endings and corpuscular receptors in a ratio of 10:1. The free nerve endings are derived from thin myelinated A_d and unmyelinated C fibers and are unlike any other cutaneous area in the body (Halata and Munger, 1986). The nerve fibers from the receptors converge to form bundles of the dorsal nerve of the penis, which joins other nerves to become the pudendal nerve. The latter enters the spinal cord via the S2-S4 roots to terminate on spinal neurons and interneurons in the central gray region of the lumbosacral segment (McKenna, 1998).

Table 23–4.

Spinal Reflexes Involved in Stimulation of Penile Dorsal Nerve

STIMULATION	SPINAL CENTER	EFFERENT	EFFECT
Noxious, abrupt stimulation	Sacral motor neurons	Pudendal nerve (motor)	Bulbocavernous reflex
Low-intensity continuous (e.g., vibratory, manual)	Sacral parasympathetic neurons and interneurons	1. Pelvic nerves 2. Cavernous nerve	1. Bladder inhibition and closure of bladder neck 2. Penile erection
High-intensity continuous	Sacral motor and parasympathetic Thoracolumbar sympathetic neurons	Pudendal, pelvic, and cavernous nerves	Ejaculation

Activation of these sensory neurons sends messages of pain, temperature, and touch by means of spinothalamic and spinoreticular pathways to the thalamus and sensory cortex for sensory perception.

The dorsal nerve of the penis used to be regarded as purely somatic; however, nerve bundles testing positive for NO synthase (NOS), which is autonomic in origin, have been demonstrated in the human by Burnett and colleagues (1993) and in the rat by Carrier and colleagues (1995). Giuliano and colleagues (1993) have also shown that stimulation of the sympathetic chain at the L4-L5 level elicits an evoked discharge on the dorsal nerve and that stimulation of the dorsal nerve evokes a reflex discharge in the lumbosacral sympathetic chain of rats. These findings clearly demonstrate that the dorsal nerve has both somatic and autonomic components that enable it to regulate both erectile and ejaculatory functions.

The Onuf nucleus in the second to fourth sacral spinal segments is the center of somatomotor penile innervation. These nerves travel in the sacral nerves to the pudendal nerve to innervate the ischiocavernosus and bulbocavernosus muscles. **Contraction of the ischiocavernosus muscles produces the rigid-erection phase. Rhythmic contraction of the bulbocavernosus muscle is necessary for ejaculation.** In animal studies, direct innervation of the sacral spinal motoneurons by brainstem sympathetic centers (A5-catecholaminergic cell group and locus ceruleus) has been identified (Marson and McKenna, 1996). This adrenergic innervation of pudendal motoneurons may be involved in rhythmic contractions of perineal muscles during ejaculation. In addition, oxytocinergic and serotonergic innervation of lumbosacral nuclei controlling penile erection and perineal muscles in the male rat has also been demonstrated (Tang et al, 1998).

Depending on the intensity and nature of genital stimulation, several spinal reflexes can be elicited (Table 23–4). The best known is the bulbocavernosus reflex, which is the basis of genital neurologic examination and electrophysiologic latency testing. Although impairment of bulbocavernosus and ischiocavernosus muscles may impair erection, the significance of obtaining a bulbocavernosus reflex in overall sexual dysfunction assessment is controversial.

Supraspinal Pathways and Centers

Integration and processing of afferent inputs (e.g., visual, olfactory, imaginative, genital stimulation) in the supraspinal centers are essential in the initiation and maintenance of penile erection. Many brain areas have been found to be associated with sexual function including the medial amygdala, the medial preoptic area (MPOA), the paraventricular nucleus (PVN), the periaqueductal gray, and ventral tegmentum (Table 23–5). Marson and colleagues (1993) injected pseudo-rabies virus into the rat corpus cavernosum and traced labeled neurons from major pelvic ganglia to neurons in the spinal cord, brainstem, and hypothalamus. Mallick and colleagues (1994) also showed that stimulation of the dorsal nerve in the rat influenced the firing rate of about 80% of the neurons in the MPOA but not in other areas of the hypothalamus. Efferent pathways from the MPOA enter the medial forebrain bundle and the midbrain tegmental region (near the substantia nigra). Pathologic processes in these regions such as Parkinson disease or cerebrovascular accidents are often associated with erectile dysfunction. Axonal tracing in monkeys, cats, and rats has shown direct projection from hypothalamic nuclei to the lumbosacral autonomic erection centers. The neurons in these hypothalamic nuclei contain peptidergic neurotransmitters including oxytocin and vasopressin, which may be involved in penile erection (Sachs and Meisel, 1988). Several brainstem and medullary centers are

Table 23–5.

Brain Centers Involved in Sexual Function

LEVEL	REGION	FUNCTION
Forebrain	Medial amygdala Stria terminalis	Control sexual motivation
	Pyriform cortex	Inhibits sexual drive (hypersexuality when destroyed)
	Hippocampus	Involved in penile erection
	Right insula and inferior frontal cortex Left anterior cingulate cortex	Increased activity during visually evoked sexual stimulation (sexual arousal)
Hypothalamus	Medial preoptic area (MPOA) Lateral preoptic area (LPOA)	Ability to recognize a sexual partner, integration of hormonal and sensory cues Control nocturnal penile tumescence in rats
	Paraventricular nucleus (PVN)	Facilitates penile erection (via oxytocin neurons to lumbosacral spinal autonomic and somatic efferents)
Brainstem	Nucleus paragigantocellularis	Inhibits penile erection (via serotonin neurons to lumbosacral spinal neurons and interneurons)
	A5-catecholaminergic cell group Locus ceruleus	Major noradrenergic center
Midbrain	Periaqueductal gray	Relay center for sexually relevant stimuli

also involved in sexual function. The A5-catecholamine cell group and locus ceruleus have been shown to provide adrenergic innervation to the hypothalamus, thalamus, neocortex, and spinal cord. Projections from the nucleus paragigantocellularis, which provides inhibitory serotonergic innervation, have also been demonstrated in the hypothalamus, limbic system, neocortex, and spinal cord.

Central Neural Activation during Arousal. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have allowed a greater understanding of brain activation during human sexual arousal by demonstrating increases in regional cerebral blood flow or changes in regional cerebral activity during a particular moment in time. Generally, in young heterosexual men sexual arousal is triggered with sexually explicit pictures or videos. Scanned brain images taken during arousal are compared with images taken in response to sexually neutral media (e.g., documentaries or humorous video clips). Centers of activation and deactivation can be demonstrated. Although the simplicity of these study designs is elegant, multiple factors are involved in sexual arousal—especially when triggered by visual clues. The authors of these studies have placed many necessary conditions in an attempt to standardize the methods and participants; however, the complexity of human emotion and sexual response is extremely difficult to regulate.

In 1999 Stoléru and colleagues studied eight healthy right-handed heterosexual men with PET during visually evoked sexual arousal (Stoléru et al, 1999). Regions of brain activation were correlated with testosterone plasma levels and penile tumescence. Significant activation was seen in the bilateral inferior temporal cortices, right insula, right inferior frontal cortex, and left anterior cingulate cortex. From this landmark study a tentative model was introduced, suggesting that **visually evoked sexual arousal has three components associated with neuroanatomic regions: (1) a perceptual-cognitive component that recognizes the visual stimuli as sexual and is performed in the bilateral inferior temporal cortices; (2) an emotional/motivational component that processes sensory information with motivational states and is performed in the right insula, right inferior frontal cortex, and left cingulate cortex (paralimbic areas); and (3) a physiologic component that coordinates the endocrine and autonomic functions and is performed in the left anterior cingulate cortex.**

Bocher and colleagues (2001) demonstrated increased activation in the inferior lateral occipital cortex, bilateral posterior temporal cortices (right greater than left), right inferior lateral prefrontal cortex, left postcentral gyrus, bilateral inferior parietal lobules, left superior parietal lobules, frontal pole (Brodmann area 10), left prefrontal cortex, and midbrain regions. They also noted deactivation in the medial frontal and anterior cingulate, contrary to Stoleru's report. Again, visual association centers were noted to be activated, in particular the posterior temporal cortices and postcentral gyrus. Interestingly, the midbrain activation seen in this study correlates with the location of the dopaminergic neurons. It was not demonstrated in other studies, but that may owe to these authors' use of prolonged provocation: the visual sexual stimulus was a 30-minute continuous video clip, whereas other studies used brief visual stimuli (2 to 10 minutes).

Park and colleagues studied 12 healthy men with fMRI (Park et al, 2001) in response to erotic and nonerotic film clips. With the former, regional brain activation was generally seen in the inferior frontal lobe, cingulate gyrus, insular gyrus, corpus collosum, thalamus, caudate nucleus, globus pallidus, and inferior temporal lobes. Some activation regions were similar to those in other studies, in particular the inferior frontal lobes, inferior temporal lobes, and insular gyrus.

In a well-designed study with fMRI and visual stimuli, correlated with penile turgidity, Arnow and colleagues demonstrated a significant region of activation in the right subinsular/insular region, including the claustrum (Arnow et al, 2002), a response also seen in previous studies with PET (Stoléru et al, 1999; Redouté et al, 2000). This region has been associated with sensory processing, and this activation may represent somatosensory processing and recognition of erection. Other brain regions activated during visual sexual stimuli were the right middle gyrus, right temporal gyrus, left caudate and putamen, bilateral cingulate gyri, right sensimotor and premotor regions. Also, a lesser activation was seen in the right hypothalamus. (Dopamine is projected to the hypothalamus, and the evidence that dopamine assists male sexual behavior is substantial.) The activation of the right middle temporal gyrus is probably associated with visual processing.

In 2003 Mouras and colleagues studied eight men with fMRI. Video clips were not used; rather, still photographs (neutral and sexually arousing) were shown quickly. The authors believed that, by using shorter visual sexual stimuli, early neural responses would be generated instead of responses to the perception of penile tumescence. Again, activation of the middle and inferior occipital gyri was demonstrated, most likely linked to the visual stimuli, but not necessarily to the sexual component. In addition to multiple brain centers that showed activation with visual sexual stimuli (bilateral parietal lobules, left inferior parietal lobule, right postcentral gyrus, right parieto-occipital sulcus, left superior occipital gyrus, bilateral precentral gyrus), the cerebellum demonstrated activation in three subjects and deactivation in four. As many other reports have demonstrated activation of the cerebellum in response to erotic films and pictures of love partners (Garavan et al, 2000; Beauregard et al, 2001), visual sexual stimuli likely promote activation in regions within the cerebellum.

With the advances with fMRI, detailed comparisons of brain activation in response to visual sexual stimuli have been performed on varied groups. Stoléru and colleagues (2003) compared healthy men with men with hypoactive sexual desire disorder (HSDD) and reported that the left gyrus rectus, a portion of the medial orbitofrontal cortex, remained activated in the latter group in contrast to its deactivation in healthy men. This region is believed to mediate inhibition of motivated behavior, and its continued activation may help explain the pathophysiology of HSDD. Montorsi and colleagues (2003) compared men with psychogenic ED and potent controls after the administration of apomorphine. During visual sexual stimulation, the former group evidenced extended activation of the cingulated gyrus, frontal mesial, and frontal basal cortex, suggesting an underlying organic cause for psychogenic ED. However, their fMRI images after apomorphine were similar to those of the potent controls. Apomorphine caused additional activation of foci in the psychogenic ED patients (seen in the nucleus accumbens, hypothalamus, mesencephalon), and it was significantly greater in the right hemisphere than in the left. This greater right-sided activation is a common finding in sexually evoked brain activation studies.

Brain scanning with PET and fMRI has become a powerful tool in the study of central activation of sexual arousal, with many brain regions of activation demonstrated in these reports (Table 23–6). Psychogenic ED, premature ejaculation, sexual deviations, and orgasmic dysfunction are just a few conditions that may

Table 23–6.

Common Brain Activation Regions with Visual Sexual Stimuli*

BRAIN ACTIVATION REGIONS	FUNCTIONAL ASSOCIATION
Bilateral inferior temporal cortex (right > left)	Visual association area
Right insula	Processes somatosensory information with motivational states
Right inferior frontal cortex	Processes sensory information
Left anterior cingulate cortex	Controls autonomic and neuroendocrine function
Right occipital gyrus	Visual processing
Right hypothalamus	Male copulatory behavior
Left caudate (the striatum)	Processes attention and guides responsiveness to new environmental stimuli

*These regions demonstrate activation with visual sexual stimuli in multiple studies.

Table 23–7.

Brain Centers of Orgasm

	BRAIN AREAS	RELEVANCE
Increased activity Primary area	Mesodiencephalic transition zone (including the ventral tegmental area)	"Reward" center also activated by opioid
Increased activity Secondary areas	Midbrain lateral central tegmental field, the zona incerta, subparafascicular nucleus, ventroposterior, midline, and intralaminar thalamic nuclei	
	Lateral putamen and adjoining parts of the claustrum	
	Brodmann areas 7/40, 18, 21, 23, and 47, exclusively on the right side	
Increased activity Other area	Cerebellum	Emotional processing
Deceased activity	Amygdala and adjacent entorhinal cortex	

accompany alterations in higher brain function and perhaps now can be studied. As we begin to understand brain function with normal sexual response and arousal, the causes of dysfunction may be elucidated.

The structures discussed earlier are responsible for the three types of erection: psychogenic, reflexogenic, and nocturnal. **Psychogenic erection is a result of audiovisual stimuli or fantasy. Impulses from the brain modulate the spinal erection centers (T11-L2 and S2-S4) to activate the erectile process. Reflexogenic erection is produced by tactile stimulation of the genital organs. The impulses reach the spinal erection centers; some then follow the ascending tract, resulting in sensory perception, while others activate the autonomic nuclei to send messages via the cavernous nerves to the penis to induce erection. This type of erection is preserved in patients with upper spinal cord injury. Nocturnal erection occurs mostly during rapid-eye-movement (REM) sleep. PET scanning of humans in REM sleep shows increased activity in the pontine area, the amygdalae, and the anterior cingulate gyrus but decreased activity in the prefrontal and parietal cortex. The mechanism that triggers REM sleep is located in the pontine reticular formation; the cholinergic neurons in the lateral pontine tegmentum are activated, while the adrenergic neurons in the locus ceruleus and the serotonergic neurons in the midbrain raphe are silent.** This differential activation may be responsible for these nocturnal erections. In rats, the area of the brain that appears to control nocturnal penile tumescence is the lateral preoptic area (LPOA) (Schmidt et al, 2000).

The brain centers activated during orgasm and ejaculation have also been studied. Holstege and colleagues (2003) used positron emission tomography (PET) to measure increases in regional cerebral blood flow during ejaculation versus sexual stimulation without orgasm in heterosexual male volunteers. Manual penile stimulation was performed by the volunteer's female partner. Primary brain activation was found in the mesodiencephalic transition zone (including the ventral tegmental area), an area frequently activated with "reward" behaviors and with injection of opioids such as heroin. Other activated mesodiencephalic structures included the midbrain lateral central tegmental field, the zona incerta, the subparafascicular nucleus, and the ventroposterior, midline, and intralaminar thalamic nuclei. Increased activation was also observed in the lateral putamen and adjoining parts of the claustrum. Neocortical activity was found in Brodmann areas 7/40, 18, 21, 23, and 47, exclusively on the right side. Conversely, in the amygdala and adjacent entorhinal cortex, a decrease in activation was observed. Remarkably strong blood flow increases were observed in the cerebellum. These findings corroborate the notion that the cerebellum plays an important role in emotional processing. Although activation of these particular areas is of great interest, it is apparent that further studies are necssary to truly understanding the neurobiologic basis of orgasm, ejaculation, and sexual satisfaction in men (Table 23–7).

Neurotransmitters

Peripheral Neurotransmitters and Endothelium-Derived Factors

Flaccidity and Detumescence. **α-Adrenergic nerve fibers and receptors have been demonstrated in the cavernous trabeculae and surrounding the cavernous arteries, and norepinephrine has generally been accepted as the principal neurotransmitter to control penile flaccidity and detumescence** (Hedlund and Andersson, 1985; Diederichs et al, 1990). Receptor-binding studies have shown the number of α adrenoceptors to be 10 times higher than the number of β adrenoceptors (Levin and Wein, 1980). Currently, it is suggested that sympathetic contraction is mediated by activation of postsynaptic α_{1a}- and α_{1d}-adrenergic receptors (Christ et al, 1990; Traish et al, 1995) and modulated by presynaptic α_2-adrenergic receptors (Saenz de Tejada et al, 1989b). Contraction mediated by α_2 receptors depends on the entry of calcium from the extracellular compartment, while the activation of α_1 receptors provokes the release of intracellular calcium, initially, with subsequent extracellular calcium entry for the maintenance of the contractile tone.

Endothelin, a potent vasoconstrictor produced by the endothelial cells, has also been suggested to be a mediator for detumescence (Holmquist et al, 1990; Saenz de Tejada et al, 1991a). Endothelin-1 is a member of a family of three peptides and is a

potent constrictor synthesized by the sinusoidal endothelium (Holmquist et al, 1990; Saenz de Tejada et al, 1991a). Its presence in human cavernous tissue suggests the participation of this peptide in the regulation of trabecular smooth muscle. Endothelin also potentiates the constrictor effects of catecholamines on trabecular smooth muscle (Christ et al, 1995b). Two receptors for endothelin, ETA and ETB, mediate the biologic effects of endothelin in vascular tissue: ETA receptors mediate contraction, whereas ETB receptors induce relaxation.

Several constrictor prostanoids including prostaglandin I2 (PGI2), $PGF2_{\alpha}$, and thromboxane A2 (TXA2) are synthesized by the human cavernous tissue. In-vitro studies have demonstrated that prostanoids are responsible for the tone and spontaneous activity of isolated trabecular muscle (Christ et al, 1990). Functional characterization of prostanoid receptors in human trabecular and arterial penile smooth muscle has revealed that only TP receptors mediate contractile effects of prostanoids in these tissues (Angulo et al, 2002). Also, it has been observed in vitro that constrictor prostanoids, simultaneously released with NO, attenuate the dilator effect of the latter (Azadzoi et al, 1992; Minhas et al, 2001).

The renin-angiotensin system may also play a significant role in the maintenance of penile smooth muscle tone. Angiotensin II has been detected in endothelial and smooth muscle cells of human corpus cavernosum (Kifor et al, 1997) and evokes contraction of human (Becker et al, 2001a) and rabbit (Park et al, 1997) corpus cavernosum in vitro. This contractile effect is mediated by interaction with AT-I subtype receptors (Park et al, 1997). Intracavernous injection of angiotensin II reverses spontaneous erections in dogs, while the AT-I receptor antagonist, losartan, increases the intracavernous pressure (Kifor et al, 1997). Finally, intracavernous blood levels of angiotensin II, which are higher than in systemic peripheral blood, increase in the detumescence phase (Becker et al, 2001b). Thus local production of angiotensin II may increase penile smooth muscle contractility by way of AT-I receptors, assisting penile detumescence. In addition, the endothelium has been shown to release potent vasoconstrictors including endoperoxides, thromboxane A2, and superoxide anions.

The current consensus holds that the maintenance of the intracorporeal smooth muscle in a semicontracted (flaccid) state likely results from three factors: intrinsic myogenic activity (Andersson and Wagner, 1995); **adrenergic neurotransmission; and endothelium-derived contracting factors such as angiotensin II, $PGF2_{\alpha}$, and endothelins. On the other hand, detumescence after erection may be a result of cessation of NO release, the breakdown of cyclic guanosine monophosphate (cGMP) by phosphodiesterases, and/or sympathetic discharge during ejaculation.**

Erection. Acetylcholine has been shown to be released with electrical field stimulation of human erectile tissue (Blanco et al, 1988). Traish and colleagues (1990) reported the density of muscarinic receptors in cavernous tissue to range from 35 to 65 fmol/mg protein and in endothelial cell membrane from 5 to 10 fmol/mg protein. However, intravenous or intracavernous injection of atropine has failed to abolish erection induced in animals by electrical neurostimulation (Stief et al, 1989a) and in men by erotic stimuli (Wagner and Uhrenholdt, 1980). **Although acetylcholine is not the predominant neurotransmitter, it does contribute indirectly to penile erection by presynaptic inhibition of adrenergic neurons and stimulation of NO release from endothelial cells** (Saenz de Tejada et al, 1989a).

Most researchers now agree that NO released from nonadrenergic/noncholinergic (NANC) neurotransmission and from the endothelium is the principal neurotransmitter mediating penile erection. NO increases the production of cGMP, which in turn relaxes the cavernous smooth muscle (Ignarro et al, 1990; Holmquist et al, 1991; Kim N et al, 1991; Pickard et al, 1991; Burnett et al, 1992; Knispel et al, 1992; Rajfer et al, 1992; Burnett et al, 1993; Trigo-Rocha et al, 1993a). The consensus is that NO derived from nNOS in the nitrergic nerves is responsible for the initiation and majority of the smooth muscle relaxation whereby NO from eNOS contributes to the maintenance of the erection (Hurt et al, 2002). (For a fuller discussion of NO, see specific "Nitric Oxide" sections later.)

Aside from its role in releasing vasoconstrictors, the endothelium can also release factors that induce smooth muscle relaxation including carbon monoxide, endothelium-derived hyperpolarizing factor (EDHF), prostacyclin (PGI2), and endothelin (which may induce relaxation via activation of ETB receptors).

Interactions among Nerves and Neurotransmitters. Acetylcholine, by acting on the presynaptic receptors on adrenergic neurons, has been shown to modulate the release of norepinephrine (Saenz de Tejada et al, 1989b), which also can be inhibited by PGE_1 (Molderings et al, 1992). In the human corpus cavernosum, noradrenergic responses are under nitrergic control. Conversely, adrenergic neurons, through prejunctional α2 receptors, can also regulate the release of NO.

Several studies have demonstrated that the interaction between the two systems also occurs in the smooth muscle (Brave et al, 1993; Angulo et al, 2001). The NO-cGMP-PKGI pathway can lead to inhibition at several sites on the noradrenergic contractile pathway in the vascular smooth muscle, impairing IP3 production by phospholipase C (Hirata et al, 1990), IP3 receptor activity (Schlossmann et al, 2000), and the RhoA/Rho-kinase pathway (Sauzeau et al, 2000). However, interaction sites have not yet been identified in penile smooth muscle. A nitrergic-noradrenergic imbalance owing to defective nitrergic neurotransmission has been implicated in penile tissue from patients and in animal models with erectile dysfunction (Christ et al, 1995a; Cellek et al, 1999). Similar to the interaction between nitrergic and noradrenergic pathways, vasoconstrictive actions of endothelin have been shown to be inhibited by NO during erection (Mills et al, 2001).

A number of factors have been reported to increase both NOS activity and NO release. These include molecular oxygen, androgen, chronic administration of L-arginine, and repeated intracavernous injection of PGE1 (Kim N et al, 1993; Escrig et al, 1999; Marin et al, 1999). Decreased NOS activity has been associated with castration, denervation, hypercholesterolemia, and diabetes mellitus. Interaction of different types of NOS may also occur. For example, nNOS activity has been to shown to decrease and iNOS levels to increase after injection of transforming growth factor (TGF)-β1 into the penis (Bivalacqua et al, 2000), and eNOS levels are reportedly significantly higher in nNOS-knockout mice (Burnett et al, 1996).

In a study of neurotransmitters in human corpus cavernosum and spongiosum, Hedlund and colleagues (2000) reported that vesicular acetylcholine transporter (VAChT), vasoactive intestinal polypeptide (VIP), and neuronal nitric oxide synthase (nNOS) are found in the same nerve terminals. Tyrosine hydroxylase (TH) positive nerves do not contain VAChT, VIP, or NOS. Heme oxygenases (HO-1 and HO-2) and eNOS are localized to the endothelium. Interaction of these neurotrasmitters may modify the effect of parasympathetic and sympathetic activation on penile function.

Role of Caveolae. Caveolae are invaginated microdomains of plasma membrane that are rich in eNOS and caveolins, as well as cholesterol, sphingolipids, and glycosylphosphatidylinositol-linked proteins. In addition, caveolae contain numerous other signaling proteins such as receptors with seven-transmembrane domains, G-proteins, adenylyl cyclase, phospholipase C, protein kinase C, calcium pumps, and calcium channels. Decreased caveolin-1 expression has been reported in the cavernous smooth muscle of aged rat (Bakircioglu et al, 2001). Linder and colleagues (2006) demonstrated that penile erection requires association of soluble guanylyl cyclase with endothelial caveolin-1 in rat corpus cavernosum. Shakirova and colleagues (2009) reported that nerve-mediated relaxation of penile tissue from caveolin-1 deficient mice was impaired. Caveolon-1 in the cavernous smooth muscle and endothelium are both decreased after bilateral cavernous nerve injury (Becher et al, 2009). These reports strongly suggest that the caveolae and caveolin are involved in the regulation of penile function.

Central Neurotransmitters and Neural Hormones. **A variety of neurotransmitters (dopamine, norepinephrine,5-hydroxytestosterone [5-HT], and oxytocin) and neural hormones (oxytocin, prolactin) have been implicated in regulation of sexual function. It is suggested that dopaminergic and adrenergic receptors may promote sexual function and 5-HT receptors inhibit it** (Foreman and Wernicke, 1990).

Dopamine. There are many dopaminergic systems in the brain with ultrashort, intermediate, and long axons. The cell bodies are located in the ventral tegmentum, substantia nigra, and hypothalamus. One of these dopaminergic systems, the tuberoinfundibular system, secretes dopamine (DA) into the portal hypophysial vessels to inhibit prolactin secretion (Ganong, 1999a). Five different DA receptors have been cloned (D1 to D5), and several of these exist in multiple forms (Ganong, 1999b). **In men, apomorphine, which stimulates both D1 and D2 receptors, induces erection that is unaccompanied by sexual arousal** (Danjou et al, 1988). In male rats, Hull and colleagues (1992) have found that low levels of dopaminergic stimulation through the D1 receptor increase erection; higher levels or prolonged stimulation produces seminal emission through D2 receptors. The erectile response induced by injection of apomorphine into the paraventricular area can be suppressed by blockers of both DA and oxytocin receptors (Melis et al, 1989). Injection of oxytocin into the paraventricular area also induces erection, but this cannot be blocked by DA receptor blockers. These findings suggest that dopaminergic neurons activate oxytocinergic neurons in the paraventricular area and that the release of oxytocin produces erection (Melis et al, 1992).

In general terms, DA is supportive of copulation and 5-HT is inhibitory. DA is released in the MPOA at the time of ejaculation (5-HT is not), and changes in DA and 5-HT in different areas of the brain may promote copulation and sexual satiety, respectively (Hull et al, 1999). Testosterone enhances DA release in the MPOA at rest and with sexual challenge, possibly by upregulating NOS, which increases NO and thereby increases DA release. The same pattern of copulatory activity promoting DA release in the MPOA and the enhanced effect of the presence of sex hormones is seen in female rats. Longer-lasting changes may be seen through the postcopulatory effects of gene expression, and this expression increases with increased sexual experience, effectively changing the phenotype of certain cells in sexually experienced animals. Cells of the MPOA have high densities of α_2-noradrenergic receptors, as well as DA receptors, and the effects of DA in the MPOA are most likely assisted by the activation of α_2 (inhibition) and α_1 (excitation) adrenoceptors owing to cross-talk within central nervous system (CNS) catecholamine systems (Cornil et al, 2002).

DA agonists (apomorphine and pergolide) and DA uptake inhibitors (nomifensine and bupropion) have been reported to enhance sexual drive (Stimmel and Gutierrez, 2006). Sublingual apomorphine is available for the treatment of ED in many countries but its utility is limited due to emetic side effects. A selective DA D4 receptor agonist, ABT-724, has been shown to assist penile erection in a dose-dependent fashion in conscious rats; interestingly, this drug lacked emetic effects in a ferret model (Brioni et al, 2004; Osinski et al, 2005). A similar compound, ABT-670, with superior oral bioavailability has also been identified for potential clinical use (Patel et al, 2006).

Serotonin. Neurons containing 5-HT have their cell bodies in the midline raphe nuclei of the brainstem and project to a portion of the hypothalamus, limbic system, neocortex, and spinal cord (Ganong, 1999a). Currently, 5-HT receptors 1 to 7 have been cloned and characterized. Within the 5-HT1 group are the 5-HT1 A, B, D, E, and F subtypes. Within the 5-HT2 group are the 5-HT2 A, B, and C subtypes. There are two 5-HT5 subtypes, 5-HT5 A and B (Ganong, 1999b). **General pharmacologic data indicate that 5-HT pathways inhibit copulation, but 5-HT may have both facilitory and inhibitory effects on sexual function, depending on the receptor subtype, the receptor location, and the species investigated** (de Groat and Booth, 1993). Andersson and Wagner (1995) have summarized the results of administration of selective agonists and antagonists as follows: 5-HT1A receptor agonists inhibit erectile activity but assist ejaculation; stimulation of 5-HT2C receptors causes erection; and 5-HT2 agonists inhibit erection but assist seminal emission and ejaculation. Steers and de Groat (1989) have also shown increased firing of the cavernous nerve and erection when *m*-chlorophenylpiperazine, a 5-HT2C receptor agonist, is given to rats. Applying a novel 5-HT2c receptor agonist (YM348) and antagonist SB242084, Kimura and colleagues (2006) confirmed the pro-erectile effect of the 5-HT2c receptor stimulation in rats. Stimulation of both 5-HT2 and 5-HT2C receptors has also been reported to increase oxytocin secretion (Bagdy et al, 1992). In addition, 5-HT may also affect the spinal reflex because Marson and McKenna (1992) have reported that endogenous 5-HT may act in the lumbar cord to inhibit sexual reflexes.

5-HT is believed to be an inhibitory transmitter in the control of sexual drive (Foreman et al, 1989). Suppressed libido has been reported in patients taking fenfluramine, a 5-HT-releasing agent, but elevated libido occurred in patients taking buspirone, a 5-HT neuron suppressor (Buffum, 1982).

Norepinephrine. The cell bodies of the norepinephrine-containing neurons are located in the locus ceruleus and the A5-catecholaminergic cell group in the pons and medulla. The axons of these noradrenergic neurons ascend to innervate the paraventricular, supraoptic, and periventricular nuclei of the hypothalamus, the thalamus, and neocortex. They also descend into the spinal cord and the cerebellum. **Central norepinephrine transmission seems to have a positive effect on sexual function.** In both humans and rats, inhibition of norepinephrine release by clonidine, an α_2-adrenergic agonist, is associated with a decrease in sexual behavior, and yohimbine, an α_2-receptor antagonist, has been shown to increase sexual activity (Clark et al, 1985). β Blockers have also been implicated in sexual dysfunction, probably because of their central side effects such as sedation, sleep disturbances, and depression.

γ-Aminobutyric Acid. γ-Aminobutyric acid (GABA) activity in the PVN provides a mechanism to balance (inhibit) proerectile signaling. Agonism for the type A receptor for GABA in the PVN can reduce both pharmacologically (apomorphine) and physiologically induced erections (Melis et al, 2001).

Opioids. Endogenous opioids are known to affect sexual function, but the mechanism of action is far from clear. Injection of small amounts of morphine into the MPOA assists sexual behavior in rats. Larger doses, however, inhibit both penile erection and yawning induced by oxytocin or apomorphine. It is suggested that endogenous opioids may exert an inhibitory control on central oxytocinergic transmission (Argiolas, 1992). Injection of morphine into the paraventricular nucleus of the hypothalamus prevents noncontact penile erections and impairs copulation in rats. It is speculated that intracellular nitric oxide may be involved in this process (Melis et al, 1999).

Cannabinoids. Cannabinoid CB_1 receptor activation inhibits sexual function by modulating the paraventricular oxytocinergic neurons, which mediate erection. Antagonism of CB_1 receptors in the paraventricular nucleus of male rats induces penile erection, which seems to involve glutamic acid and nitric oxide (Melis et al, 2004, 2006).

Oxytocin. Oxytocin is a neural hormone secreted by the neurons into the circulation. These are found in the posterior pituitary gland, but, because they are also found in the neurons projecting from the PVN to the brainstem and spinal cord, oxytocin can also function as a neurotransmitter. The blood level is increased during sexual activity in humans and animals and, when injected into the paraventricular area in rats, oxytocin produces yawning and penile erection. Calcium has been suggested as the second messenger mediating oxytocin-induced penile erection. Oxytocin release following stimulation of dompamine receptors in the paraventricular nucleus influences the appetitive and reinforcing effects of sexual activity (Succu et al, 2007). Because neurons in the paraventricular area have been shown to contain NOS, and NOS inhibitors prevent apomorphine- and oxytocin-induced erection, it is suggested that oxytocin acts on neurons whose activity is dependent on certain levels of NO (Vincent and Kimura, 1992; Melis and Argiolas, 1993).

Nitric Oxide. Nitric oxide (NO) is a gaseous molecule produced from various tissues, in particular the endothelium and nerve. It mediates penile erection at the level of the PVN (Melis et al, 1998) and at other levels of the neural pathway supporting sexual response. The presence of NO and the soluble guanylyl cyclase needed to generate cGMP is seen throughout the human brain. The NO/cGMP pathway (see later) is affected by aging in the brain and offers a potentially significant but unexplored site for mediating the deleterious effects of age on sexual function (Ibarra et al, 2001). Reduced nNOS protein within the PVN leading to blunting of the erectile response has been reported in streptoxotosin-induced diabetic rats (Zheng et al, 2007). Testosterone or its metabolite dihydrotestosterone (DHT) downregulates NOS activity and mRNA expression and the number of nNOS-containing neurons (Singh et al, 2000). Direct evidence of the importance of NO in central signaling related to erectile function resulted from a series of experiments designed to alter CNS NO activity (Sato et al, 2001): Manipulation of NO or cGMP levels altered MPOA-triggered intracavernous pressure response through CNS, not peripheral, mechanisms.

Melanocortins. Melanocortin-4 receptor (MC4R), implicated in the control of food intake and energy expenditure, also modulates erectile function and sexual behavior. Evidence supporting this notion is based on several findings: (1) a highly selective nonpeptide MC4R agonist augments erectile activity initiated by electrical stimulation of the cavernous nerve in wild-type, but not MC4R-null, mice; (2) copulatory behavior is enhanced by administration of a selective MC4R agonist and is diminished in mice lacking MC4R; (3) RT-PCR and non-PCR-based methods demonstrate MC4R expression in the rat and human penis and rat spinal cord, hypothalamus, brainstem, and pelvic ganglion (major autonomic relay center to the penis) but not in rat primary corpus cavernosum smooth muscle cells; and (4) in situ hybridization of glans tissue from the human and rat penis reveals MC4R expression in nerve fibers and mechanoreceptors in the glans. Collectively, these data implicate MC4R in the modulation of penile erectile function and provide evidence that MC4R-mediated proerectile responses may be activated through neuronal circuitry in spinal cord erectile centers and somatosensory afferent nerve terminals of the penis (Van der Ploeg et al, 2002).

Prolactin. **Increased levels of prolactin suppress sexual function in men and experimental animals. In rats, high levels of prolactin decrease the genital reflex and disturb copulatory behavior** (Rehman et al, 2000). **It is suggested that the mechanism of prolactin's action is through inhibition of dopaminergic activity in the MPOA and decreased testosterone. In addition, prolactin may have a direct effect on the penis through its contractile effect on the cavernous smooth muscle** (Ra et al, 1996). In a study of sexual activity of married men with ED, men with sexual inactivity were noted to have a significanly higher mean prolactin level (Paick et al, 2006) (Table 23–8).

Smooth Muscle Physiology

Spontaneous contractile activity of cavernous smooth muscle has been recorded in vitro and in vivo. In isolated strips of rabbit corpus cavernosum, Mandrek (1994) demonstrated spontaneous mechanical activity with a frequency of 6 to 30 contractions per minute accompanied by fluctuations in membrane potential. In a human study, Yarnitsky and colleagues (1995) found two types of electrical activity recorded from the corpus cavernosum:

Table 23–8.
Central Neurotransmitters and Their Function

NEUROTRANSMITTER	RECEPTOR AND FUNCTION
Dopamine	D1 and D4 receptor—enhances erection D2 receptor—enhances seminal emission
Serotonin (5HT)	5HT—inhibits sex drive and spinal sexual reflex 5HT1A—inhibits erection, facilitates ejaculation 5HT2C—enhances erection
Norepinephrine	Enhances sexual function
Gamma-aminobutyric acid	Inhibits erectile signals
Opioids	Inhibit penile erection
Cannabinoids	Inhibit sexual function
Oxytocin	Enhances appetitive and reinforcing effects of sexual activity
Nitric oxide	Mediates erection at paraventricular nucleus
Melanocortins	McR4—enhances erection
Prolactin	Suppresses sexual function

spontaneous and activity induced. Levin and colleagues (1994) reported that in-vitro spontaneous contractile activity is correlated with a phasic increase in intracellular calcium and a biphasic change in the NADH/NAD ratio, suggesting an initial increase and then a decrease of intracellular energy. Italiano and colleagues (1998) suggested that phasic contraction of the penis is through the enzyme Na-K-ATPase and the resting tone is mediated by the endothelium through the release of $PGF2_a$. Field stimulation results in a decrease in tension and intracellular calcium at low frequencies and an increase in tension and intracellular calcium at high frequencies. In general, the response to pharmacologic agents correlates with the change in intracellular calcium: for example, phenylephrine produces muscle contraction and an increase in intracellular calcium, whereas nitroprusside causes the opposite.

In a study of myosin isoforms in smooth muscle cells in the corpus cavernosum, DiSanto and colleagues (1998) reported their overall composition to be between that in aorta and bladder smooth muscles, which generally express tonic- and phasic-like characteristics, respectively. Further studies of isoform changes may elucidate the increased contractility or impaired relaxation of the cavernous smooth muscle in pathologic conditions.

Molecular Mechanism of Smooth Muscle Contraction

Smooth muscle contraction and relaxation are regulated by intracellular free calcium (Ca^{2+}) acting through calmodulin. Calcium-bound calmodulin undergoes a conformational change, increasing its affinity for myosin light chain kinase (MLCK). MLCK is activated by binding of the calcium-calmodulin complex, leading to phosphorylation of the serine-19 residue of regulatory myosin light chain MLC_{20}. In the presence of ATP, this phosphorylation enables actin to activate the myosin ATPase and initiates cross-bridge cycling. Hydrolysis of ATP by ATPase supplies the energy for the contractile process (Fig. 23–9).

Regulatory Molecules Affecting Smooth Muscle Contraction. The muscle contractile process ends when MLC_{20} is dephosphorylated (inactivated) by myosin light chain phosphatase (MLCP). MLCP is a holoenzyme consisting of a type 1 phosphatase (PP1c), a myosin-targeting subunit (MYPT1), and a 20 kD subunit of unknown function (Hersch et al, 2004; Ito et al, 2004). Theoretically, MLCP inhibition may lead to enhanced smooth muscle contraction. This is also termed "calcium sensitization" pathway. The activity of MLCP can be modulated by Rho/Rho-kinase pathway (Fig. 23–10). Rho-kinase can phosphorylate multiple substrates including MYPT1, the 17 kD protein kinase C-potentiated inhibitor protein (CPI-17), and MLC_{20}. Phosphorylation of MYPT1 and CPI-17 results in the inhibition of PP1c phosphatase activity. RhoA and Rho-kinase have been shown to be expressed in penile smooth muscle (Rees et al, 2002; Wang et al, 2002). Interestingly, the amount of RhoA expressed in the cavernous smooth muscle is 17-fold that in vascular smooth muscle (Wang et al, 2002). A selective inhibitor of Rho-kinase has been shown to elicit relaxation of human corpus cavernosum in vitro and to induce erection in animal models (Chitaley et al, 2001; Rees et al, 2001). The emerging consensus is that phasic contraction of penile smooth muscle is regulated by an increase in cytosolic Ca2+ and that tonic contraction is governed by the calcium-sensitizing pathways (Cellek et al, 2002). The presence of CPI-17 protein has been detected in human and rabbit penile corpus cavernosum (Wang et al, 2002), but its functional significance remains to be determined.

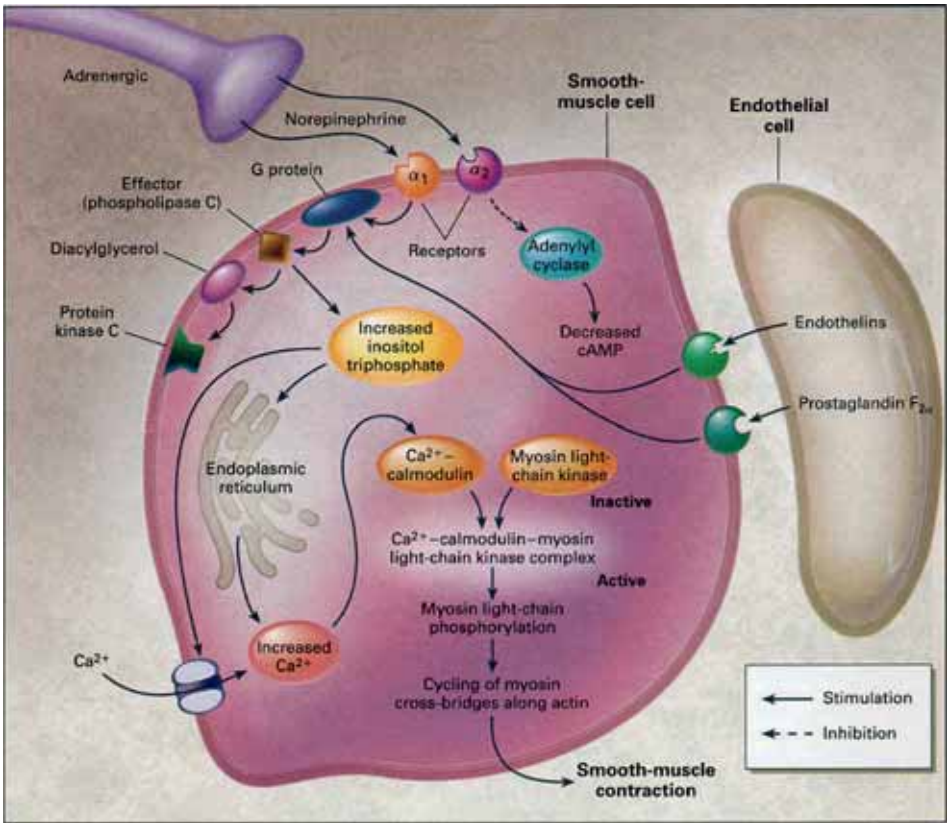

Figure 23–9. Molecular mechanism of penile smooth muscle contraction. Norepinephrine from sympathetic nerve endings and endothelins and prostaglandin $F_{2\alpha}$ from the endothelium activate receptors on smooth muscle cells to initiate the cascade of reactions that eventually result in elevation of intracellular calcium concentrations and smooth muscle contraction. Protein kinase C is a regulatory component of the Ca^{2+}-independent, sustained phase of agonist-induced contractile responses. (From Lue TF. Erectile dysfunction. N Engl J Med 2000;342:1802–13.Copyright © 2000 Massachusetts Medical Society. All rights reserved.)

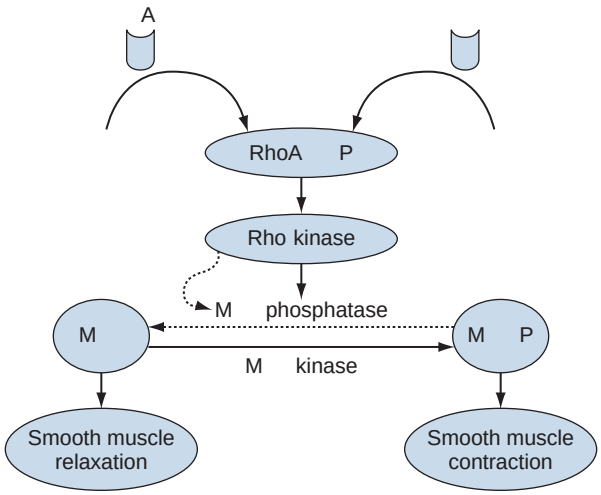

Figure 23–10. RhoA/Rho kinase pathway: the calcium sensitization pathway. ET-1, endothelin receptor 1; GTP, guanosine triphosphate; MLC, myosin light chain; MLC-P, phosphorylated myosin light chain; NA, noradrenalin.

Latch State—a Unique Characteristic of Smooth Muscle Contraction. Smooth muscle has the ability to maintain tension for prolonged periods with minimal energy expenditure. This efficiency has been termed the ***latch*** state and is critical for sustaining the "basal" tone of the smooth muscle. It has been proposed that dephosphorylated myosin remains bound to actin in the high-affinity state to help stabilize the latch state. Others have proposed that calponin participates in the latch state by simultaneously binding actin and myosin to stabilize cross-bridge interactions and slow the rate of detachment (Szymanski, 2004).

Pathways Involving IP_3, DAG, and PKC. Vasoconstrictor agonists such as norepinephrine (α_1-adrenergic receptors), endothelin-1 (ET_A receptors), angiotensin II (AT1 receptors), prostaglandin $F_{2\alpha}$ (FP receptors), and thromboxane A_2 (TP receptors) bind their respective receptors to activate Gq, which in turn stimulates phospholipase C beta (PLC-β). This membrane-bound enzyme hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) to liberate inositol 1,4,5-trisphosphate (IP_3) and 1,2-diacylglycerol (DAG). IP_3 binds to specific receptors (IP_3R) on the smooth endoplasmic reticulum (SER) to stimulate the release of Ca^{2+} from intracellular stores. Binding of IP_3 to these receptors not only activates the channel but also increases the sensitivity of the IP_3R to Ca^{2+} and assists ***calcium-induced calcium release*** (CICR).

Another mechanism of increased intracellular Ca^{2+} is by permitting entry of extracellular Ca^{2+} through ***receptor-operated channels*** without a change in membrane potential (Large, 2002). Norepinephrine, endothelin, vasopressin, and angiotensin II cause the opening of Ca^{2+}-permeable, nonselective cation channels.

Molecular Mechanism of Smooth Muscle Relaxation

After contraction, relaxation of the muscle follows a decrease of free Ca^{2+} in the sarcoplasm. Calmodulin then dissociates from myosin light-chain kinase and inactivates it. Myosin is dephosphorylated by myosin light-chain phosphatase and detaches from the actin filament, and the muscle relaxes (Walsh, 1991) (Fig. 23–11).

Another mechanism of smooth muscle relaxation is through cyclic adenosine monophosphate (cAMP) and cGMP, which are the two major second messengers involved in smooth muscle relaxation. They activate cAMP- and cGMP-dependent protein kinases, which in turn phosphorylate certain proteins and ion channels, resulting in (1) opening of the potassium channels and hyperpolarization; (2) sequestration of intracellular calcium by the endoplasmic reticulum; and (3) inhibition of voltage-dependent calcium channels, blocking calcium influx. The consequence is a drop in cytosolic free calcium and smooth muscle relaxation.

Cyclic AMP-Signaling Pathway. Cyclic-AMP-signaling molecules include adenosine, calcitonin gene–related peptides (CGRPs), prostaglandins, and vasoactive intestinal peptide (VIP).

Adenosine. Adenosine is released from a variety of cells as a result of increased metabolic rates, and its actions on the vasculature are most prominent when oxygen demand is high (Tabrizchi and Bedi, 2001). However, the vascular response to the action of adenosine can be either relaxation or constriction, depending on which type of adenosine receptor is activated. Currently four AR subtypes (A1, $A2_A$, $A2_B$, and A3) belonging to the gene protein–coupled receptor (GPCR) superfamily have been recognized (Tabrizchi and Bedi, 2001). In general, the A1 receptor is believed to be coupled to G_i and G_o proteins, and its activation results in inhibition of adenylyl cyclase (AC) and activation of phospholipase C, both of which lead to vasoconstriction. The A2 receptors are coupled to the G_s proteins, and their activation stimulates AC and thus vasorelaxation. The A3 receptor is coupled to G_i and G_q proteins, and its activation results in the activation of phospholipase C/D and the inhibition of AC, leading to vasoconstriction. The differential distribution of these adenosine receptor subtypes largely determines whether a particular vessel relaxes or contracts as a result of adenosine stimulation (Tabrizchi and Bedi, 2001). Whether adenosine plays a role in physiologic erection is unclear. **Nevertheless, excessive adenosine accumulation in the penis, coupled with increased A(2B)R signaling, contributes to priapism in two independent lines of mutant mice. One is adenosine deaminase (ADA)-deficient mice (the only animal displaying spontaneously prolonged penile erection), and the other is sickle cell disease (SCD) transgenic mice, a well-accepted animal model for priapism** (Bivalacqua et al, 2009; Dai et al, 2009).

Calcitonin Gene–Related Peptide Family. Calcitonin gene–related peptide, amylin, and adrenomedullin are members of the CGRP family. These short-chain peptides are potent vasodilators released from perivascular nerve fibers. They act through the calcitonin receptor–like receptor (CRLR), which belongs to the GPCR superfamily (Conner et al, 2002).

In rats the CGRP levels in the penis, bladder, kidney, testis, and adrenal gland were found to increase gradually up to maturity and then rapidly decline (Wimalawansa, 1992). In ED patients given CGRP intracavernously, a dose-related increase in penile arterial inflow (and erection) occurred (Stief et al, 1991). Adenovirus-mediated gene transfer of CGRP also enhanced erectile responses in aged rats, apparently through an increase of cAMP levels in the corpora cavernosa (Bivalacqua et al, 2001). Intracavernous administration of adrenomedullin also results in cavernous relaxation; however, the effect is through an NO-cGMP, rather than cAMP, pathway (Nishimatsu et al, 2001).

Prostaglandins. Prostaglandins (PGs) are a family of eicosanoids capable of initiating numerous biologic functions. The prime mode of PG action is through specific PG receptors that all belong to the GPCR family. There are at least nine known PG receptor subtypes in mouse and humans, as well as several additional splice

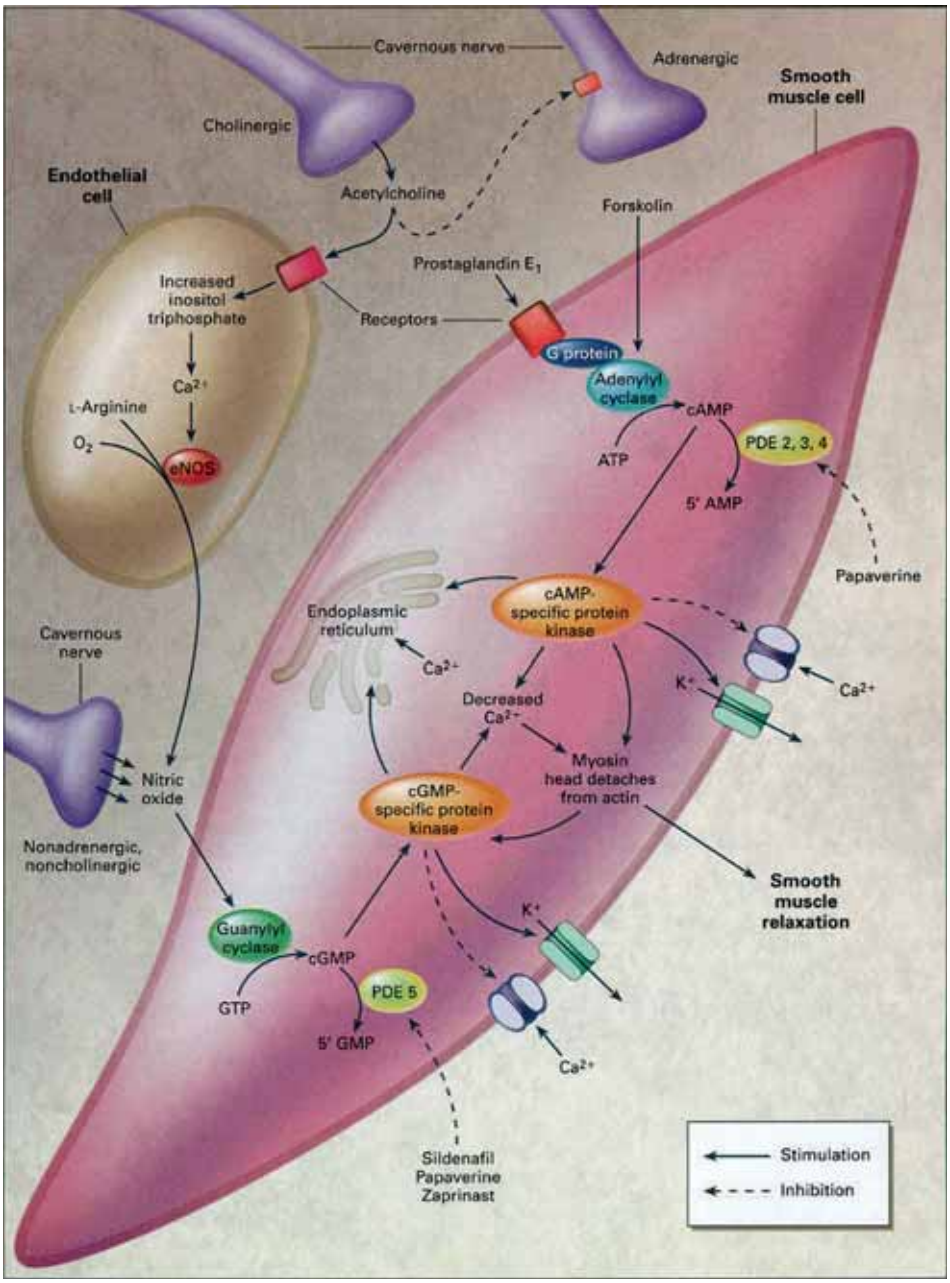

Figure 23–11. Molecular mechanism of penile smooth muscle relaxation. The intracellular second messengers mediating smooth muscle relaxation, cAMP and cGMP, activate their specific protein kinases, which phosphorylate certain proteins to cause opening of potassium channels, closing of calcium channels, and sequestration of intracellular calcium by the endoplasmic reticulum. The resultant fall in intracellular calcium leads to smooth muscle relaxation. Sildenafil inhibits the action of PDE5 and thus increases the intracellular concentration of cGMP. Papaverine is a nonspecific phosphodiesterase inhibitor. eNOS, endothelial nitric oxide synthase; GTP, guanosine triphosphate. (From Lue TF. Erectile dysfunction. N Engl J Med 2000;342:1802–13. variants with divergent carboxyl termini (Narumiya and FitzGerald, 2001). Four of the subtypes (EP1-EP4) bind PGE2, two (DP1 and DP2) bind PGD2, and the other three subtypes (FP, IP, and TP) bind $PGF2_{\alpha}$, PGI2, and TXA2, respectively. On the basis of signaling attributes, the PG receptors are classified into three types. The "relaxant" receptors IP, DP1, EP2, and EP4 are coupled to an α_s-containing G-protein and therefore are capable of stimulating AC to increase intracellular cAMP. The "contractile" receptors EP1, FP, and TP are coupled to an α_q-containing G-protein, which activates phospholipase C instead of AC. These contractile receptors therefore do not signal through the cAMP pathway, and their signaling outcome is an increase of intracellular calcium. The EP3 receptor is also a contractile receptor, but it is coupled to an α_i-containing G-protein that inhibits AC to result in a decrease of cAMP formation.

Animal and human corpora cavernosa produce several PGs including $PGF2_{\alpha}$, PGE2, PGD2, PGI2, and TXA2 (Moreland et al, 2001). In studies in isolated human penile tissue, different PGs have been shown to elicit different effects in human corpus cavernosum, corpus spongiosum, and cavernous artery (Hedlund and Andersson, 1985). Although $PGF2_{\alpha}$, PGI2, and TXA2 contract the corpus cavernosum and corpus spongiosum, PGE1 and PGE2 (but not PGI2) relax the corpus cavernosum and spongiosum that have been precontracted with noradrenaline or $PGF2_{\alpha}$. Therefore although PGI2 is the predominant vasorelaxant in blood vessels, its action in the erectile tissue is either contractile or neutral. This disparity in the action of PGI2 between blood vessels and the erectile tissue and the difference between the effects of PGI2 and PGE1/2 in the erectile tissue are most likely due to differences in the distribution of PG receptors. Indeed, recent

studies have shown that, in the corpus cavernosum, the relaxant effects of prostanoids are mediated by EP2 and/or EP4 receptors (for PGE1 and PGE2) but not IP receptor (for PGI2) (Angulo et al, 2002).

Although the production of PGs and the expression of PG receptors in the erectile tissue have been clearly demonstrated, their roles in physiologic erection are yet to be defined. On the other hand, **the erectogenic effects of PGE1 as a pharmaceutic agent have been extensively documented. First described in 1998, intracavernous injection of PGE1 is one of the safest and most effective treatments for ED** (Stackl et al, 1988). Transurethral application is an effective alternative.

Vasoactive Intestinal Peptide. The human or animal penis is richly supplied with nerves containing VIP (Andersson, 2001). Two subtypes of VIP receptors, VPAC1 and VPAC2, belonging to the GPCR family have been cloned from human and rat tissues. VPAC2, but not VPAC1 mRNA, has been identified in cultured rat cavernous smooth muscle cells (CSMCs) (Guidone et al, 2002). In the dog, intracavernous VIP injection has been found to induce penile erection (Juenemann et al, 1987); in men, it has not produced rigid erection but can improve success rates when combined with papaverine and phentolamine (Kiely et al, 1989). However, it has been shown that VIP release is not essential for neurogenic relaxation of human cavernous smooth muscle (Pickard et al, 1993), and VIP failed to stimulate cAMP production in cultured human CSMCs (Palmer et al, 1994).

Adenylyl Cyclase. Signaling molecules in the cAMP pathway bind to and activate specific cytoplasmic membrane receptors that, through their coupled G-proteins, activate ACs. To date, nine membrane-bound isoforms and one soluble form of mammalian AC have been cloned and characterized (Patel et al, 2001). Although different membrane-bound ACs are regulated differently, they are all stimulated by the GTP-bound form of the G_α subunit and are all (except AC9) stimulated by forskolin.

In rabbits with alloxan-induced diabetes, cAMP formation in the corpus cavernosum in response to forskolin has been shown to be reduced, suggesting impaired AC function in diabetes mellitus (Sullivan et al, 1998).

Protein Kinase A. PKA, also called cAMP-dependent kinase (cAK), is the principal receptor for cAMP, and it mediates the vast majority of the cellular effects of cAMP by phosphorylating a wide variety of downstream targets in both the cytoplasmic and nuclear compartments (Johnson et al, 2001). PKA is composed of two regulatory (R) and two catalytic (C) subunits that form a tetrameric holoenzyme R_2C_2. Binding of cAMP to the R subunits causes the holoenzyme to dissociate into an $R_2(cAMP)_4$ dimer and two free catalytically active C subunits. The presence of multiple C subunit genes further adds to the diversity and complexity of the various holoenzyme complexes, which differ in biochemical and functional properties, as well as patterns of expression and localization. These differences among the isozymes contribute to the broad specificity of PKA in a wide variety of physiologic processes in response to cAMP signaling.

More than 100 different cellular proteins have been identified as physiologic substrates of PKA, with more than 90% (135 of 145) being phosphorylated at serine and the remainder at threonine (Shabb, 2001). The predominant target sequence (>50%) is Arg-Arg-X-Ser, in which Ser is the phosphate acceptor. Three PKA substrate proteins have been identified in penile tissue: PDEs, cAMP-responsive element-binding protein (CREB), and ATP-sensitive potassium (K_{ATP}) channel.

Cyclic GMP-Signaling Pathway. Signaling molecules in the cGMP pathway include nitric oxide, carbon monoxide, and natriuretic peptides.

Nitric Oxide (NO). Because of its small size, NO can diffuse inside its target cell, where it interacts with molecules that contain iron in either a heme or iron-sulfur complex. The most physiologically relevant receptor for NO is soluble guanylyl cyclase (sGC), and the NO-sGC-cGMP pathway is responsible for the vasorelaxing effect of many endothelium-dependent vasodilators including histamine, estrogens, insulin, corticotrophin-releasing hormone, nitrovasodilators, and acetylcholine. This pathway is also principally responsible for erection.

Synthesis of NO is catalyzed by NOS, which converts L-arginine and oxygen to L-citruline and NO. NOS exists as three isoforms in mammals: nNOS and eNOS are preferentially expressed in neurons and endothelial cells, respectively, and iNOS in virtually all cell types. All three NOS isoforms have been identified in the corpus cavernosum, with nNOS and eNOS being considered responsible for initiating and sustaining erection, respectively (Hurt et al, 2002). Downregulation of nNOS expression has been found in the corpus cavernosum of aging rats (Carrier et al, 1997), a model in which corpus cavernous smooth muscle relaxation is impaired (Cartledge et al, 2001). Despite its secondary role in erectile function, the endothelium-dependent cavernous smooth muscle relaxation is attenuated in the aging rabbit, and this age-related defect is paradoxically accompanied with upregulated eNOS expression in both the endothelium and cavernous smooth muscle (Haas et al, 1998; Bakircioglu et al, 2001). A contradictory observation, however, was made in another study, which showed downregulation of eNOS in the corpus cavernosum of aging rats (Rajasekaran et al, 2002).

Gene transfer of nNOS or eNOS to the penis has been shown to augment erectile responses in aging rats (Champion et al, 1999; Magee et al, 2002), and gene transfer of iNOS has enhanced intracavernous pressure (Chancellor et al, 2003). However, despite these encouraging results, it should be noted that mice with disrupted nNOS or eNOS gene have normal erectile function (Burnett et al, 1996; Burnett et al, 2002). Compensatory mechanisms, alternative splicing of the disrupted gene (Ferrini et al, 2003), and/or other unknown mechanisms are possibly involved in the preservation of erectile function in the NOS-knockout mice.

Carbon Monoxide (CO). CO is a gaseous second messenger that occurs in biologic systems during the oxidative catabolism of heme by the heme oxygenase (HO) enzyme. HO exists as constitutive (HO-2, HO-3) and inducible isoforms (HO-1). The latter is upregulated in response to multiple stress stimuli. HO-1 confers protection in vitro and in vivo against oxidative cellular stress. CO regulates vascular processes such as vessel tone, smooth muscle proliferation, and platelet aggregation and may function as a neurotransmitter. The neurotransmitter effect of CO is dependent on the activation of guanylate cyclase by direct binding to the heme moiety of the enzyme, stimulating the production of cyclic AMP. Recent research indicates that CO exerts novel anti-inflammatory and anti-apoptotic effects dependent on the modulation of the p38 mitogen–activated protein kinase (MAPK)–signaling pathway. By virtue of these effects, CO confers protection in oxidative lung injury models and likely plays a role in HO-1–mediated tissue protection (Ryter et al, 2002).

Natriuretic Peptides. The natriuretic peptide family is involved in the regulation of cardiovascular homeostasis and consists of atrial (ANP), brain (BNP), and C-type (CNP) natriuretic peptides (Matsuo, 2001). Whereas ANP and BNP are ligands for the NPR-A

receptor, CNP is a ligand for the NPR-B receptor. Both receptors are members of the guanylyl cyclase (GC) family and are therefore also called GC-A and GC-B.

The effects of ANP, BNP, and CNP on cGMP production and smooth muscle relaxation in isolated human and animal corpus cavernosum and in cultured CSMCs have been investigated (Kim et al, 1998; Guidone et al, 2002; Kuthe et al, 2003). The results indicate that CNP is the most potent natriuretic peptide and that it relaxes the isolated cavernous smooth muscle by binding to NPR-B. However, whether CNP and NPR-B play a role in physiologic erection remains to be seen.

Guanylyl Cyclase. In mammals, seven membrane-bound (particulate) GC isoforms (GC-A to GC-G) and one soluble isoform (sGC) have been identified (Andreopoulos and Papapetropoulos, 2000). On the basis of their ligand specificity, the particulate GCs (pGCs) have been classified as (1) natriuretic peptide receptors (GC-A and GC-B), which are activated by natriuretic peptides including ANP, BNP, and CNP; (2) intestinal peptide receptor (GC-C), which is activated by intestinal peptides including guanylin, uroguanylin, and lymphoguanylin; and (3) orphan receptors (GC-D, -E, -F, and -G). Although the membrane-bound GC system is not known to play a role in physiologic erection, expression of GC-B in human and rat corpus cavernosum and induction of cavernous smooth muscle relaxation by CNP (ligand for GC-B) have been demonstrated recently (Guidone et al, 2002; Kuthe et al, 2003).

The soluble isoform sGC plays a pivotal role in erectile function because it provides the link between NO and cGMP, which represent the extracellular and intracellular signaling molecules, respectively, in physiologic erection (Andersson, 2001). A heterodimeric protein, sGC consists of α and β subunits, each of which exists in two isoforms (α1, α2, and β1, β2) that are encoded by two separate genes (Andreopoulos and Papapetropoulos, 2000). Messenger RNAs of these four subunits have been detected in human corpus cavernosum (Behrends et al, 2000). In animal studies, sGC activator YC-1 has been shown to cause erectile responses (Mizusawa et al, 2002). However, mmunohistochemical examination has found sGC expression to be similar in the corpus cavernosum of potent and impotent patients (Klotz et al, 2000).

Protein Kinase G. Protein kinase G (PKG), also called cGMP-dependent kinase (cGK), is the principal receptor and mediator for cGMP signals. In mammals, PKG exists in two major forms, PKG-I and PKG-II, which are encoded by two separate genes. In smooth muscle, only PKGI is expressed and exists as two splice variants (PKG-Iα and PKG-Iβ). Immunoprecipitation studies in smooth muscle indicate that PKG-Iβ is associated with IP_3R and a 125 kD protein known as ***IP_3R-associated PKG substrate*** (IRAG), both of which act as substrates for the kinase (Schlossmann et al, 2000). Phosphorylation of IP_3R and IRAG decreases agonist-induced Ca^{2+} release from the smooth endoplasmic reticulum (SER). Deletion mutation studies demonstrate that IRAG is a critical protein in mediating cGMP-dependent relaxation of smooth muscle (Geiselhöringer et al, 2004). In addition, PKG-I is known to phosphorylate phospholamban, a small membrane-associated protein (6 kD homopentamer) that constitutively inhibits SER. Phosphorylation of phospholamban inactivates its inhibitory control of SER Ca^{2+}-ATPase pump (SERCA) and increases Ca^{2+} reuptake into the SER, where Ca^{2+} is bound by proteins such as calsequestrin and calreticulin. Interestingly, cAMP-mediated relaxation is unaffected by mutated, nonfunctional IRAG (Geiselhöringer et al, 2004), whereas PKA can phosphorylate phospholamban to increase Ca^{2+} reuptake (Raeymaekers et al, 1988) Thus the combined actions of PKG-I and PKA inhibit Ca^{2+} release from intracellular stores and stimulate Ca^{2+} reuptake.

Additionally, and perhaps of equal importance, cGMP and/or PKGI may induce relaxation via activation of the plasma membrane Ca^{2+}-ATPase pump, inhibition of IP_3 generation, inhibition of Rho-kinase, stimulation of MLCP, and phosphorylation of heat shock proteins (Carvajal et al, 2000; Lincoln et al, 2001). These mechanisms have been demonstrated in various cells, but their relevance to smooth muscle cells in genital tissues has not been explicitly shown. The PKG-I polypeptide contains three functional domains: the N-terminal, the regulatory, and the catalytic. The N-terminal domain has three functions: dimerization, autoinhibition, and localization. The regulatory domain contains two tandem cGMP-binding sites, and the catalytic domain catalyzes the transfer of the γ phosphate from ATP to a serine/threonine residue of the substrate protein.

Cavernous smooth muscle strips from PKG-I knockout mice cannot be relaxed by agents that raise cGMP levels, and these mice have a low ability to reproduce, presumably owing to ED (Hedlund et al, 2000). This observation further affirms the essential role of the cGMP/PKG-I pathway in physiologic erectile function.

Cross-Activation. Increased levels of intracellular cAMP and cGMP cause the activation of ***cAMP-dependent*** and ***cGMP-dependent protein kinases*** (PKA and PKG). Each cyclic nucleotide-dependent kinase can be activated by either cAMP or cGMP, although cross-activation requires an approximately 10-fold higher concentration of cyclic nucleotide (Walsh, 1994). Although PKA and PKG may phosphorylate a number of common substrates, several lines of evidence indicate that the activation of PKG by cGMP and cAMP is the predominant mechanism by which cyclic nucleotides decrease intracellular Ca^{2+} to cause vascular smooth muscle relaxation (Lincoln et al, 1990; Jiang et al, 1992; Komalavilas and Lincoln, 1996). On the other hand, PKA (but not PKG) can inhibit Ca^{2+}-calmodulin activation of MLCK by phosphorylation and may play an important role in Ca^{2+} desensitization of the contractile apparatus (Hathaway et al, 1985).

Phosphodiesterase. In each episode of cyclic nucleotide signaling, the increase of intracellular cAMP or cGMP concentration is typically twofold to threefold baseline (Francis et al, 2001). Decline occurs rapidly and often during the continued presence of the signaling hormone (Francis et al, 2001). Termination of cyclic nucleotide signals is principally carried out by PDEs, which catalyze the hydrolysis of cAMP and cGMP to AMP and GMP, respectively. Feedback mechanisms that increase PDE activities and/or expression by the increased cyclic nucleotide level assist cyclic nucleotide degradation (Corbin et al, 2000; Lin et al, 2001a, 2001b).

The superfamily of mammalian PDEs consists of 11 families (PDE1 to PDE11) that are encoded from 21 distinct genes (Lin et al, 2003; Montorsi et al, 2004). Each PDE gene usually encodes more than one isoform through alternative splicing or from alternate gene promoters. Phosphodiesterase-1, PDE3, PDE4, PDE7, and PDE8 are multigene families, whereas PDE2, PDE5, PDE9, PDE10, and PDE11 are unigene families. PDE1, PDE2, PDE3, PDE10, and PDE11 hydrolyze both cAMP and cGMP; PDE4, PDE7, and PDE8 hydrolyze cAMP; and PDE5, PDE6, and PDE9 are specific for cGMP.

With the exception of PDE6, which is specifically expressed in photoreceptor cells, all PDEs have been identified in the corpus cavernosum (Küthe et al, 2001). However, there is ample evidence that **PDE5 is by far the principal PDE for the termination of cavernous cGMP signaling** (Fig. 23–12) (e.g., inhibition of

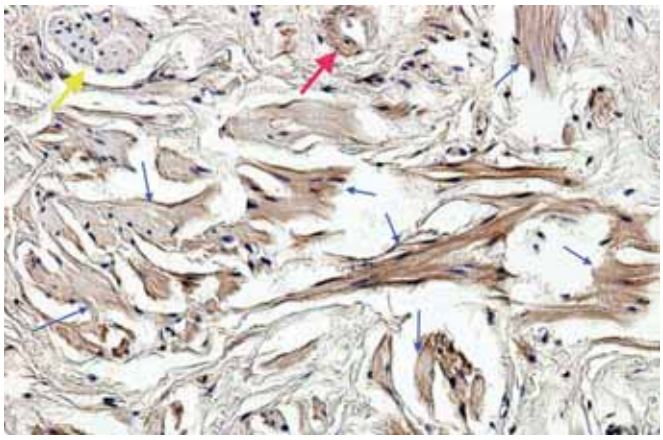

Figure 23–12. Immunohistochemistry of human penile tissue, showing positive PDE5 staining of cavernous smooth muscle fibers *(small blue arrows),* nerve *(yellow arrow),* and blood vessel wall *(red arrow)* (×100).

the cGMP-catalytic activity of PDE5 by specific inhibitors has been shown to be highly effective in treating ED) (Eardley et al, 2002).

Phosphodiesterase-3 also appears to play a role in erection, as demonstrated by the erectogenic effect of a PDE3-specific inhibitor, milrinone (Kuthe et al, 2002). Furthermore, although direct inhibition of PDE5 is the main mechanism through which sildenafil exerts its erectogenic effect, it has been shown that sildenafil also significantly increases cAMP concentration in isolated human cavernous tissue strips (Stief et al, 2000). This effect is thought to involve PDE3 because cGMP, which is accumulated as a result of PDE5 inhibition by sildenafil, is capable of preventing cAMP degradation by competing for the same catalytic sites on the PDE3 molecules (Francis et al, 2001). This attenuating effect of cGMP on the cAMP-catalytic activity of PDE3 is also believed to explain why inhibition of PKG could suppress the relaxing effect of forskolin in isolated human cavernous smooth muscle (Uckert et al, 2004).

Ion Channels. In general, there are four major types of ion channels: (1) external ligand-gated, which open to a specific extracellular molecule (e.g., acetylcholine); (2) internal ligand-gated, which open or close in response to an intracellular molecule (e.g., ATP); (3) voltage-gated, which open in response to a change in membrane potential (e.g., sodium, potassium, and calcium channels); and (4) mechanically gated, which open in response to mechanical pressure.

Smooth muscle has neither a T-tubule system nor a well-developed sarcoplasmic reticulum. Therefore extracellular calcium plays an important role, and calcium must enter the cytoplasm through the plasma membrane during an action potential. Three transmembrane proteins are known to regulate calcium inflow and outflow: Calcium channels are the major inflow regulators, whereas the calcium-sodium exchanger and calcium-ATPase regulate calcium exit from muscle cells. The presence of voltage-dependent L-type calcium channels (long-duration current, slow calcium channel) in isolated cavernous smooth muscle and cultured muscle cells has been documented. Christ and colleagues (1993) have reported that both calcium influx through calcium channels and mobilization of intracellular calcium stores are involved during phenylephrine- and endothelin-induced contraction, but only calcium channel influx is apparent for potassium chloride-induced contraction.

Studies have shown at least four types of potassium channel subtypes in the cavernous smooth muscle: (1) the calcium-sensitive potassium channel (e.g., maxi-K); (2) the metabolically regulated potassium channels (K_{ATP}); (3) the delayed rectifier; and (4) the fast transient A current (IA) (Christ et al, 1993a; Fan et al, 1995). The calcium-sensitive potassium channels may be involved in cAMP-mediated smooth muscle relaxation. Decreased intracytosolic potassium and altered potassium conductance have been shown to occur in acetylcholine- and sodium nitroprusside-treated corpus cavernosum smooth muscle (Seftel et al, 1996). A stretch-sensitive chloride channel has also been demonstrated in CSMCs (Fan et al, 1999).

Hyperpolarization of the Smooth Muscle Cells. Hyperpolarization causes closure of voltage-dependent calcium channels, a decrease in the intracellular free calcium concentration, and relaxation of the smooth muscle. One of the hyperpolarization mechanisms is through the opening of potassium channels. The opening of ATP-sensitive K+ channels (KATP) and Ca^{2+}-activated K+ channels (KCa) causes hyperpolarization and relaxation of vascular smooth muscle. These two types of channels are present in human corpus cavernosum smooth muscle (Christ et al, 1993b), and pharmacologic stimulation of KATP channels induces penile smooth muscle relaxation (Venkateswarlu et al, 2002). Furthermore, PNU-83757, an opener of KATP channels, has been shown to induce erection when given intracavernously to patients with ED (Vick et al, 2002). The opening of large-conductance KCa channels, also known as *maxi-K,* has been found to hyperpolarize and relax human corpus cavernosum (Spektor et al, 2002). The opening of K+ channels can be stimulated by PKA, PKG, or cGMP.

Hyperpolarization of penile smooth muscle is also important in endothelium-dependent relaxation of human penile arteries, in which significant relaxation remains despite blockade of NO and prostaglandin synthesis (Angulo et al, 2003). This activity has been attributed to the endothelium-derived hyperpolarizing factor (EDHF), which opens KCa channels and produces hyperpolarization and vasodilation. The nature of EDHF remains undetermined.

Molecular Oxygen as a Modulator of Penile Erection. The pO_2 level of cavernous blood in the flaccid state is similar to that of venous blood (≈35 mm Hg). During erection, the large inflow of arterial blood raises pO_2 to approximately 90 mm Hg (Sattar et al, 1995). Molecular oxygen is a substrate, together with L-arginine, for the synthesis of NO by NOS. In the flaccid state the low oxygen concentration inhibits NO synthesis; during erection, the higher level of substrate induces NO synthesis. It has been estimated that the minimal concentration of oxygen in the cavernous bodies necessary to reach full NOS activity is 50 to 60 mm Hg (Kim et al, 1993).

Similarly, prostaglandin H synthase is also an oxygenase (cyclooxygenase) and uses oxygen as substrate for the synthesis of prostanoids. Production of PGE1 has been shown to be inhibited in flaccidity and stimulated during erection. Endothelin synthesis is also modulated by oxygen: a low oxygen concentration promotes production, whereas a high concentration inhibits it.

Intercellular Communication. During erection and detumescence, communication should exist among cavernous smooth muscles to mediate synchronized relaxation and contraction (Christ et al, 1991). **Several studies have demonstrated the presence of gap junctions in the membrane of adjacent muscle cells. These intercellular channels allow exchange of ions such as calcium and second-messenger molecules** (Christ et al, 1993a). The major component of gap junctions is connexin-43, a membrane-sparing protein of less than 0.25 μm

that has been identified between smooth muscle cells of human corpus cavernosum (Campos de Calvalho et al, 1993). Cell-to-cell communication through these gap junctions most likely explains the synchronized erectile response, although their pathophysiologic impact is still unclear.

Intracavernous Tissue Architecture

The trabeculae of the corpora cavernosa provide the structural support and regulatory mechanism for the endothelial-lined sinusoidal spaces, as well as the conduit for blood vessels and nerves. Relaxation of the trabeculae allows the expansion and filling of the sinuoids by the incoming blood, while "recoil" of the trabeculae expels blood to the emissary veins and returns the penis to a flaccid state. In 24 men undergoing penile prosthesis implantation for severe ED, Nehra and colleagues (1996) categorized the smooth muscle content of the corpus cavernosum into four groups: high (39% to 42%), intermediate (30% to 37%), low (13% to 29%), and normal (42% to 50%) and reported that increasing degree of venous leakage correlates with decreasing muscle content. Costa and colleagues (2006) showed that the major constituents of the trabeculae are collagen fibers (40.8%), smooth muscle (40.4%), and elastic fibers (13.2%) in specimens from six men who died of nongenital causes. Interestingly, in seven men undergoing penile prosthesis implantation, the content of the three components were collagen fibers (41.6%), smooth muscle (42%), and elastic fibers (9.1%); the only significant change in ED compared with normals was a reduction of elastic fibers. From these two reports, it seems likely that the histologic changes associated with ED consist primarily of decline in either smooth muscle or elastic fibers.

The complex architecture of the penis is maintained by the dynamic expression and interaction of numerous trophic factors. One of them is sonic hedgehog (SHH), which plays a key role in regulating vertebrate organogenesis such as the growth of digits on limbs and organization of the brain. SHH remains important in the adult. It controls cell division of adult stem cells and has been implicated in development of some cancers. SHH has been identified in the penis; inhibition of SHH in the adult rat leads to rapid atrophy and disorganization of the corpus cavernosum (Podlasek et al, 2003, 2005). **In addition, SHH has been shown to stimulate the expression of vascular endothelial growth factor (VEGF) and nitric oxide synthase (NOS) in the penis** (Podlasek et al, 2005) (Table 23–9).

Key Points: Smooth Muscle Physiology

- Relaxation of the cavernous smooth muscle is the key to penile erection.
- Nitric oxide released by nNOS contained in the terminals of the cavernous nerve initiates the erection process, whereas nitric oxide released from eNOS in the endothelium helps maintain erection.
- Upon entering the smooth muscle cells, NO stimulates the production of cGMP.
- Cyclic GMP activates protein kinase G, which in turn opens the potassium channels and closes the calcium channels.
- Low cytosolic calcium favors smooth muscle relaxation.
- The smooth muscle regains its tone when cGMP is degraded by phosphodiesterase.

Table 23–9.

Key Molecules Involved in the Physiologic Regulation of Cavernous Smooth Muscle

Contraction	
NAME	FUNCTION
High cytosolic calcium	Binds calmodulin to activate MLC kinase
MLC kinase	Converts MLC to active form, MLCp
Phosphorylated MLC (MCLp)	Cycling of myosin cross-bridges along actin results in muscle contraction
MLC phosphatase	Dephosphrylate MLCp to inactive form, MLC
Rho kinase	Inhibits MLC phosphatase to enhance contraction (calcium sensitization pathway)
Relaxation	
NAME	FUNCTION
Nitric oxide	Bind soluble guanylyl cyclase to produce cGMP
cGMP	Activate protein kinase G
Protein kinase G	Opens potassium channels and closes calcium channels
Low cytosolic calcium	Calcium dissociates from calmodulin, muscle relaxes

PATHOPHYSIOLOGY OF ERECTILE DYSFUNCTION

Incidence and Epidemiology

The increasing incidence of impotence with age was noted by Kinsey and colleagues in 1948: only 1 of 50 men at age 40 years, but 1 in 4 by age 65. In 1990 Diokno and colleagues reported that 35% of married men aged 60 years and older suffer from erectile impotence.

Modern probability sampling techniques were used by two surveys obtaining prevalence data of ED in the United States: the Massachusetts Male Aging Study (MMAS) and the National Health and Social Life Survey (NHSLS). The MMAS consisted of 1709 noninstitutionalized men between the ages of 40 and 70 years living in the greater Boston area first surveyed between 1987 and 1989 and resurveyed between 1995 and 1997 (Feldman et al, 1994; Johannes et al, 2000). Extensive physiologic measures, demographic information, and self-reported ED status (nine items related to potency on a questionnaire) were components of this report. The MMAS was the first cross-sectional, community-based, random-sample, multidisciplinary epidemiologic survey on ED and its physiologic and psychosocial correlates in men in the United States. **From the prevalence rates reported in the MMAS study, between the ages of 40 and 70 years, the probability of complete ED increased from 5.1% to 15%, moderate dysfunction increased from 17% to 34%, and mild dysfunction remained constant at about 17%.**

The NHSLS was a national probability survey of men ($N = 1410$) and women between the ages of 18 and 59 years living in households in the United States in 1992 (Laumann et al, 1999) and was principally a broad-ranging inquiry into sexual practices and beliefs within that age group. Therefore the survey collected only limited information on sexual function broadly defined. The following prevalence rates for ED were reported (responses to questions regarding obtaining and maintaining erection): 7% for ages 18 to 29 years, 9% for ages 30 to 39, 11% for ages 40 to 49, and 18% for ages 50 to 59.

Regarding worldwide prevalence of ED, 24 international studies were reported between 1993 and 2003 (Lewis et al, 2004). All that were stratified by age showed a rising prevalence of ED. Below age 40 the rate was 1% to 9%, from 40 to 59 it ranged from 2% to 9% to as high as 20% to 30%, with some studies showing marked differences between the 40 to 49 and the 50 to 59 groups. The 50- to 59-year groups showed the greatest range of reported prevalence rates. For the group from 60 to 69 years, most of the world showed a rather high rate (20% to 40%), with some increasing after age 65, except for the Scandinavian reports, in which the 70s and older were the time of major rate change. Almost all of the reports showed high prevalence rates for men in their 70s and 80s, ranging from 50% to 75%.

Incidence Studies

The MMAS (Johannes et al, 2000) is the only longitudinal study conducted in the United States (1987-1989 and 1995-1997). Analyses were performed on 847 of the 1297 men without ED at baseline (1987-1989) and with follow-up information from 1995 to 1997. The average age of these men at baseline was 52.2 years (range, 40 to 69 years). **From this group of patients, the crude incidence rate of impotence in white men in the United States was 25.9 cases/1000 man-years (95% confidence interval [CI], 22.5 to 29.9). The annual incidence rates increased with each decade (per 1000 man-years): 12.4 cases for 40 to 49 years; 29.8 cases for 50 to 59 years; and 46.4 cases for 60 to 69 years. Age-adjusted risk (per 1000 man-years) of ED was higher for men with diabetes mellitus (50.7 cases), treated heart disease (58.3 cases), and treated hypertension (42.5 cases). By using these data and the known population of the United States, it was estimated that, for white men, the new cases in the 40- to 69-year age group would be 617,715 per year** (Lewis et al, 2000). **Rates reported from Europe and Brazil also suggest an incidence of 25 to 30/1000 man-years** (Moreira et al, 2003; Schouten et al, 2005). A study using a validated questionnaire in a random sample of 2213 men conducted in Olmsted County, MN, from 1996 to 2004 revealed that the five sexual function domains change together over time in this community-based cohort. Erectile function, ejaculatory function, and sexual drive decrease over time with greater rates of decline for older men. However, older men are less likely to perceive these declines as a problem and are less likely to express dissatisfaction referable to them (Gades et al, 2009).

Risk Factors

Common risk factor categories associated with sexual dysfunction include the following: general health status, diabetes mellitus, cardiovascular disease, concurrence of other genitourinary disease, psychiatric/psychologic disorders, other chronic diseases, and socio-demographic conditions. In a study of race/ethnicity and socioeconomic status in 2301 men aged 30 to 79 years from the city of Boston, it is reported that men in the low socioeconomic status (SES) category had a greater than twofold increase in risk of ED (adjusted odds ratio of 2.26, 95% confidence interval 1.39, 3.66). The increased risk of ED in Black and Hispanic men in this study was thought to be associated with differences in SES rather than biologic factors (Kupelian et al, 2008).

For ED, smoking, medications, and hormonal factors also serve as well-defined risk-factor-associated conditions. In men, diabetes has been associated with a greater prevalence of decreased desire and orgasmic dysfunction, as well as ED. A higher odds ratio is seen with insulin-dependent diabetes mellitus; diabetes present for more than 10 years; fair or poor control based on glycosylated hemoglobin; management by means other than diet; a history of diabetes-related arterial, renal, or retinal disease and neuropathy; and concurrent cigarette smoking. Endothelial dysfunction is a condition present in many cases of ED, and thus there are common etiologic pathways for other vascular disease states (Lewis et al, 2004).

Classification

Many classifications have been proposed (Fig. 23–13). Some are based on the cause (diabetic, iatrogenic, traumatic) and some on the neurovascular mechanism (failure to initiate [neurogenic], failure to fill [arterial], and failure to store [venous] [I. Goldstein, personal communication, 1990]). A classification recommended by the International Society of Impotence Research is shown in Table 23–10 (Lizza and Rosen, 1999).

Psychogenic

Previously, psychogenic impotence was believed to be the most common, thought to affect 90% of impotent men (Masters and Johnson, 1965). This belief has given way to the realization that **ED is usually a mixed condition that may be predominantly functional or physical.**

Sexual behavior and penile erection are controlled by the hypothalamus, limbic system, and cerebral cortex. Therefore stimulatory or inhibitory messages can be relayed to the spinal erection centers to assist or inhibit erection. **Two possible mechanisms have been proposed to explain the inhibition of erection in psychogenic dysfunction: direct inhibition of the spinal erection center by the brain as an exaggeration of the normal suprasacral inhibition** (Steers, 2000); **and excessive sympathetic outflow or elevated peripheral catecholamine levels, which may increase penile smooth muscle tone to prevent its necessary relaxation.** Animal studies demonstrate that the stimulation of sympathetic nerves or systemic infusion of epinephrine causes detumescence of the erect penis (Diederichs et al, 1991a, 1991b). Clinically, higher levels of serum norepinephrine have been reported in patients with

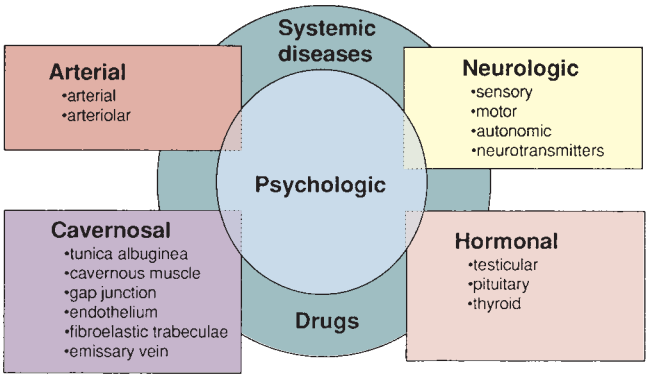

Figure 23–13. A functional classification of impotence. Note that it is unlikely for an individual patient's impotence to derive solely from one source. Most cases have a psychogenic component of varying degree, and systemic diseases and pharmacologic effects can be concomitant and causative. (Modified from Carrier S, Brock G, Kour NW, Lue TF. Pathophysiology of erectile dysfunction. Urology 1993;42:468–81, with permission of Exerpta Medica, Inc.)

Table 23–10.

Classification of Male Erectile Dysfunction

Organic

I. Vasculogenic
  A. Arteriogenic
  B. Cavernosal
  C. Mixed
II. Neurogenic
III. Anatomic
IV. Endocrinologic

Psychogenic

I. Generalized
  A. Generalized unresponsiveness
    1. Primary lack of sexual arousability
    2. Aging-related decline in sexual arousability
  B. Generalized inhibition
    1. Chronic disorder of sexual intimacy
II. Situational
  A. Partner-related
    1. Lack of arousability in specific relationship
    2. Lack of arousability owing to sexual object preference
    3. High central inhibition owing to partner conflict or threat
  B. Performance-related
    1. Associated with other sexual dysfunction/s (e.g., rapid ejaculation)
    2. Situational performance anxiety (e.g., fear of failure)
  C. Psychologic distress or adjustment related
    1. Associated with negative mood state (e.g., depression) or major life stress (e.g., death of partner)

psychogenic ED than in normal controls or patients with vasculogenic ED (Kim and Oh, 1992).

Bancroft and Janssen theorized that male sexual response depends on the balance between excitatory and inhibitory impulses within the CNS (Bancroft and Junssen, 2000). One example is the high prevalence of sexual/erectile dysfunction in men with psychiatric disorders. Mosaku and Ukpong (2009) surveyed patients (mean age 39.6, standard deviation [SD] = 11.6 years) carrying the diagnosis of schizophrenia, bipolar affective disorder, recurrent depressive disorder, and/or substance use disorder with mean duration of illness of 10.24 years (SD 8.2 years) who were attending a psychiatry clinic. In this population the prevalence of ED was 83%; older age, unmarried status, use of medications, and the presence of comorbid medical conditions were significantly predictive of ED.

Neurogenic

It has been estimated that 10% to 19% of ED is neurogenic. If one includes iatrogenic causes and mixed ED, the prevalence is likely much higher. The presence of a neurologic disorder or neuropathy does not exclude other causes, and confirming that ED is neurogenic can be challenging. Because erection is a neurovascular event, **any disease or dysfunction affecting the brain, spinal cord, and cavernous or pudendal nerves can induce dysfunction.**

As discussed earlier, the MPOA, the PVN, and the hippocampus have been regarded as important integration centers for sexual drive and erection (Sachs and Meisel, 1988), and pathologic processes in these regions such as **Parkinson disease, stroke, encephalitis, or temporal lobe epilepsy are often associated with ED.** Parkinsonism's effect may result from the imbalance of the dopaminergic pathways (Chaudhuri and Schapira, 2009). **Other brain lesions associated with ED are tumors, dementias, Alzheimer disease, Shy-Drager syndrome, and trauma.** In studies of sexual function in men after stroke, lack of sexual desire was found to be common (Jung et al, 2008). ED is more prevalent in patients who have cerebrovascular accident lesions in the thalamic area (Jeon et al, 2009).

In men with a **spinal cord injury,** its nature, location, and extent will largely determine erectile function. In addition to ED, they may also have impaired ejaculation and orgasm. **Reflexogenic erection is preserved in 95% of patients with complete upper-cord lesions but in only about 25% of those with complete lower-cord lesions** (Biering-Sørensen and Sønksen, 2001). Sacral parasympathetic neurons are important in the preservation of reflexogenic erection, although the thoracolumbar pathway may compensate for sacral loss through synaptic connections. In these patients, minimal tactile stimulation can trigger erection, albeit of short duration and requiring continuous stimulation. **Other disorders at the spinal level** (e.g., spina bifida, disc herniation, syringomyelia, tumor, transverse myelitis, and multiple sclerosis) **may affect the afferent or efferent neural pathway in a similar manner.**

Because of the close relationship between the cavernous nerves and the pelvic organs, the incidence of iatrogenic impotence from pelvic surgical procedures is reportedly high: radical prostatectomy, 43% to 100% (Walsh and Donker, 1982; Borchers et al, 2006), and abdominal perineal resection, 15% to 100% (Weinstein and Roberts, 1977).

An improved understanding of the neuroanatomy of the pelvic and cavernous nerves (Walsh and Donker, 1982) has resulted in modified surgery for cancer of the rectum, bladder, and prostate, producing a lower incidence of iatrogenic impotence. For example, the introduction of nerve sparing has reduced the incidence of impotence after radical prostatectomy to 30% to 50% (Catalona and Bigg, 1990; Quinlan et al, 1991) and less than 10% after radical rectal surgery (Liang et al, 2008).

In cases of **pelvic fracture,** ED can be a result of cavernous nerve injury or vascular insufficiency or both. In men with posterior urethral injury, early realignment has been associated with better potency preservation rate relative to delayed anastomosis (ED rate 34% vs. 42%) (Mouraviev et al, 2005). In **diabetics,** impairment of neurogenic and endothelium-dependent relaxation results in inadequate NO release (Saenz de Tejada, 1989a). Because autonomic penile innervation cannot be tested directly, clinicians should be cautious in diagnosing neurogenic ED. A corpus cavernosum electromyograph has been developed and refined for diagnosis of various conditions affecting the penis (including autonomic neuropathy), but the clinical utility of this device is still under investigation (Meuleman et al, 2007).

A decrease in penile tactile sensitivity with increasing age was also reported by Rowland and colleagues (1993). Sensory input from the genitalia is essential to achieve and maintain reflexogenic erection, and the input becomes even more important when older people gradually lose psychogenic erection. Therefore sensory evaluation should be an integral part of the evaluation for ED in all patients with or without an apparent neurologic disorder.

Endocrinologic

Hypogonadism is a frequent finding in the impotent population. Androgens influence the growth and development of the male reproductive tract and secondary sex characteristics; their effects on libido and sexual behavior are well established. In a review of published articles from 1975 to 1992, Mulligan and

Schmitt (1993) **concluded that testosterone (1) enhances sexual interest; (2) increases the frequency of sexual acts; and (3) increases the frequency of nocturnal erection, but has little or no effect on fantasy-induced or visually stimulated erections.** Granata and colleagues (1997) have reported that the threshold level of testosterone for normal nocturnal erections is about 200 ng/dL. In a population-based, observational survey conducted in the Boston area, Araujo and colleagues (2007) reported a 5.6% prevalence of symptomatic androgen deficiency in men between the ages of 30 and 79 years, with older men at greater risk. Prevalence of symptoms were low libido (12%), erectile dysfunction (16%), osteoporosis/fracture (1%), and two or more nonspecific symptoms (20%); however, it is noteworthy that many men with low testosterone levels are asymptomatic. In a study of patients presented with ED, Köhler and colleagues (2008) reported androgen deficiency symptoms in 47%, 33%, 23%, and 7% in men with testosterone levels of less than 200, less than 300, less than 346, and less than 400 ng/dL, respectively. Age, the presence of uncontrolled diabetes, high total cholesterol, and anemia all correlated with significantly decreased testosterone levels in men with ED. In another report from the same group, waist circumference was noted to be the most important predictor of low testosterone and symptomatic androgen deficiency (Hall et al, 2008). In men with BMI of more than 30 kg/m^2, total testosterone was subnormal in 57.5% and free testosterone subnormal in 35.6% of the subjects. Most of these men had isolated hypogonadotropic hypogonadism (Hofstra et al, 2008). In a comprehensive literature review, Traish and colleagues (2009) noted that low testosterone precedes elevated fasting insulin, glucose, and hemoglobin A1c (HbA1C) values in men who develop diabetes, suggesting that hypogonadism may be a sentinel event in the development of diabetes. **The authors further suggest that androgen deficiency is associated with insulin resistance, type 2 diabetes, metabolic syndrome, and increased deposition of visceral fat. Visceral fat may serve as an endocrine organ, producing inflammatory cytokines and thus promoting endothelial dysfunction and vascular disease.**

The mechanism of androgen's effect has been examined by several investigators. Beyer and González-Mariscal (1994) have reported that testosterone and dihydrotestosterone (DHT) are responsible for male pelvic thrusting and estradiol or testosterone is responsible for female pelvic thrusting during copulation. Androgens have beneficial effects on endothelial cells and smooth-muscle cells: androgens promote endothelial cell survival, reduce endothelial expression of proinflammatory markers, and inhibit proliferation and intimal migration of vascular smooth-muscle cells. Low androgen levels are associated with apoptosis of endothelial cells and smooth-muscle cells. Moreover, low androgen levels impair proliferation, migration, and homing of endothelial progenitor cells, as well as myogenic differentiation of mesenchymal progenitor cells (Mirone et al, 2009). Testosterone and dihydrotestosterone may also relax penile artery and cavernous smooth muscle through their nongenomic effects (Waldkirch et al, 2008). In rats, castration has been reported to decrease arterial flow, induce venous leakage, and reduce the erectile response to stimulation of the cavernous nerve by about 50% (Mills et al, 1994; Penson et al, 1996). Castration also increases α-adrenergic responsiveness of penile smooth muscle (Traish et al, 1999). Clinically, many men on long-term androgen ablation therapy for prostate cancer have reported poor libido and ED.

Any dysfunction of the hypothalamic-pituitary axis can result in hypogonadism. Hypogonadotropic hypogonadism can be congenital or caused by a tumor or injury; hypergonadotropic hypogonadism may result from a tumor, injury, surgery, or mumps orchitis.

Hyperprolactinemia, whether from a pituitary adenoma or drugs, results in both reproductive and sexual dysfunction. Symptoms may include loss of libido, ED, galactorrhea, gynecomastia, and infertility. Hyperprolactinemia is associated with low circulating levels of testosterone, which appear to be secondary to inhibition of gonadotropin-releasing hormone secretion by the elevated prolactin levels (Leonard et al, 1989). Interestingly, in a study of subjects consulting for sexual dysfunction, prolactin in the lowest quartile levels was noted to be associated with metabolic syndrome and arteriogenic ED, as well as with premature ejaculation and anxiety symptoms (Corona et al, 2009).

ED may also be associated with both hyperthyroidism and hypothyroidism. The former is commonly associated with diminished libido (which may be caused by the increased circulating estrogen levels) and less often with ED. In hypothyroidism, low testosterone secretion and elevated prolactin levels contribute to ED.

Arteriogenic

Atherosclerotic or traumatic arterial occlusive disease of the hypogastric-cavernous-helicine arterial tree can decrease the perfusion pressure and arterial flow to the sinusoidal spaces, thus increasing the time to maximal erection and decreasing the rigidity of the erect penis. In the majority of patients with arteriogenic ED, the impaired penile perfusion is a component of the generalized atherosclerotic process. Common risk factors associated with arterial insufficiency include hypertension, hyperlipidemia, cigarette smoking, diabetes mellitus, blunt perineal or pelvic trauma, and pelvic irradiation (Feldman et al, 1994; Martin-Morales et al, 2001). Shabsigh and colleagues (1991) reported that abnormal penile vascular findings increased significantly as the number of risk factors for ED increased. On arteriography, bilateral diffuse disease of the internal pudendal, common penile, and cavernous arteries has been found in impotent patients with atherosclerosis. Focal stenosis of the common penile or cavernous artery is most often seen in young patients who have sustained blunt pelvic or perineal trauma (Levine et al, 1990). **Long-distance cycling is also a risk factor for vasculogenic and neurogenic ED.** The impact of cycling on penile circulation seems to depend on the rider position and the seat design (Cohen and Gross, 2005; Dettori and Norvell, 2006; Gemery et al, 2007; Schrader et al, 2008).

Erectile dysfunction and cardiovascular disease share the same risk factors such as hypertension, diabetes mellitus, hypercholesterolemia, and smoking (Feldman et al, 1994; Martin-Morales et al, 2001). Lesions in the pudendal arteries are much more common in impotent men than in the general population of similar age. Interestingly, natural remission and progression do occur in a substantial number of men with erectile dysfunction. The association of body mass index with remission and progression, as well as the association of smoking and health status with progression, offer potential avenues for facilitating remission and delaying progression using lifestyle intervention (Travison et al, 2007).

Atherosclerosis/Cardiovascular Diseases. High prevalence of ED has been reported in men with coronary, cerebral, and peripheral vascular diseases (Kloner et al, 2003; Montorsi et al, 2003; Bener et al, 2008; Chai et al, 2009). Among men

with coronary arterial disease, the prevalence of ED increases as the severity of coronary arterial lesions increases (Montorsi et al, 2006). Similarly, cardiovascular diseases are also prevalent in men with ED, and ED tends to manifest before other signs of cardiovascular disease. In patients with chronic coronary disease who also had ED, onset of sexual dysfunction occurred before CAD onset in 93%, with a mean time interval of 24 (12 to 36) months (Montorsi et al, 2006). This has led some to advocate screening for ED as a means to identify men at risk for cardiovascular disease (Jackson, 2008).

Hyperlipidemia. Erectile dysfunction has been associated with a high prevalence of hyperlipidemia and coronary heart disease (Roumeguere et al, 2003). Hypercholesterolemia at baseline was also shown to be a predictor of subsequent ED over the course of 25 years in 570 male patients included in the Rancho Bernardo Study (Fung et al, 2004). On the other hand, a survey of 1899 men aged 30 to 79 in the Boston area did not show an association between untreated hyperlipidemia and ED (Hall et al, 2009). Although several reports suggest an association of ED and dyslipidemia, there is no consistency in the involvement of the different lipid fractions. Therefore a subcommittee of the Sexual Medicine Society of North America has suggested a more precise analysis of hyperlipidemia as an independent risk factor for ED (Mulhall et al, 2006).

The effect of hypercholesterolemia on erectile function has been studied in different experimental models. In hypercholesterolemic rabbits, examination of the corpus cavernosum ultrastructure revealed an early atherosclerotic process in the sinusoids (Kim et al, 1994). Although the endothelial NO/cGMP pathway is impaired in this model, neuronal vasodilation does not appear affected (Azadzoi et al, 1998). The NO/cGMP pathway effect likely owes to increased superoxide production (Kim et al, 1997) or endogenous NOS inhibitors such as NG-monomethyl-L-arginine monoacetate (L-NMMA) and asymmetric dime thylarginine (ADMA). L-arginine supplementation reverses endothelium-dependent relaxation impairment (Azadzoi et al, 1998). Vascular endothelial growth factor (VEGF) is an important angiogenic factor for maintenance of endothelial health. Ryu and colleagues (2006) reported that VEGF and VEGF receptor 2 (VEGFR-2) are downregulated in the corporal tissue of rats eating a 4% cholesterol diet for 3 months. In rabbits fed with 1% cholesterol diet, Xie and colleagues (2005) also noted that levels of VEGF mRNA are reduced with subsequent observation of impaired endothelium-dependent relaxation.

Studies have also been conducted in apolipoprotein E knockout mice. After being fed a moderate- to high-cholesterol diet, these mice developed atherosclerosis and ED with reduced endothelium-dependent and endothelium-independent relaxation, as well as alteration of structure of the cavernosal tissue (Behr-Roussel et al, 2006; Xie et al, 2007).

In a more severe ischemic experimental model, rabbits underwent balloon de-endothelization of the iliac arteries followed by a high-cholesterol diet (Azadzoi et al, 1992). They developed both penile arterial insufficiency and veno-occlusive dysfunction owing to decreased expandability of the cavernous smooth muscle (Azadzoi et al, 1997; Nehra et al, 1998). Changes in iliac and penile vasculature were noted, associated with decreased NOS activity and reduced endothelium-dependent and neurogenic NO-mediated relaxation of the cavernous tissue (Azadzoi et al, 1999). As a result of the impaired NO activity, production of contractile thromboxane and prostaglandin increased, leading to potentiation of neurogenic contractions of the cavernous smooth muscle (Azadzoi et al, 1998, 1999).

In large arteries in rabbits, oxidized low-density lipoproteins (ox-LDLs) inhibited endothelium-dependent NO-mediated relaxation (Murohara et al, 1994). Enhanced corpus cavernosum muscle contractility by ox-LDL has also been reported by Ahn and colleagues (1999).

Hypertension. **Hypertension is an independent risk factor for ED** (Feldman et, 1994; Johannes et al, 2000), **and its consequent cardiovascular complications such as ischemic heart disease and renal failure are associated with even higher ED prevalence** (Feldman et, 1994; Kaufman et al, 1994; Johannes et al, 2000). **However, in hypertension, the increased blood pressure itself does not impair erectile function; rather, the associated arterial biochemical and structural changes are thought to be the causes** (Hsieh et al, 1989; Behr-Roussel et al, 2005).

In two analyses including more than 270,000 men with ED from a U.S. care claim database, the prevalence of hypertension in men with and without ED were 41.2% versus 19.2%, respectively (Seftel et al, 2004; Sun and Swindle, 2005).

The potential determinants for ED in hypertensive men include older age, longer duration of disease, greater severity of hypertension, and the use of antihypertensive medications (Doumas et al, 2006). Other researchers have studied arterial function and intima/media thickness in hypertensive men with ED and have suggested that high levels of the endogenous inhibitor of eNOS, asymmetric dimethylarginie (ADMA), are a potential marker of endothelial dysfunction (Vlachopoulos et al, 2008).

In animal models of spontaneously hypertensive rats (SHR) and DOCA-salt hypertensive rats, intracavernous pressure was decreased in two studies when expressed as a percentage of mean arterial pressure (Dorrance et al, 2002; Behr-Roussel et al, 2005). However, the absolute increases in intracavernous pressure did not appear different. Interestingly, in the longitudinal study of the SHR rats, the impairment of cavernosal endothelium-dependent and independent relaxation occurred before systemic vascular alteration, suggesting that corporal vascular tissue is affected early in the disease process (Behr-Roussel et al, 2005). In SHR rats, the impairment appears to involve both NO-mediated and carbon monoxide (CO)-mediated relaxation (Ushiyama et al, 2004). Treating these rats with an antioxidant, alpha-tocopherol, enhanced both NO- and CO-mediated relaxation, as well as endothelial function, suggesting that oxidative stress may play a significant role in this condition (Ushiyama et al, 2008). Increased activity of angiotensin II–mediated NADPH-oxidase in hypertensive rats is suggested to be the cause of increased superoxide anions (Jin et al, 2008).

Mechanism of Vascular Erectile Dysfunction

Structural Changes. In arteriogenic ED, oxygen tension in corpus cavernosum blood is less than that in psychogenic ED (Tarhan et al, 1997). Formation of PGE_1 and PGE_2 is oxygen dependent, and, in rabbit and human corpus cavernosum, increased oxygen tension was associated with elevation of PGE_2 and suppression of TGF-β1-induced collagen synthesis (Moreland et al, 1995; Nehra et al, 1999). A decrease in oxygen tension may diminish cavernous trabecular smooth muscle content and lead to diffuse venous leakage (Saenz de Tejada et al, 1991; Nehra et al, 1998).

A narrowed lumen or increased wall-to-lumen ratio in the arteries contributes to increased peripheral vascular resistance in hypertension. Increased resistance has also been found in the penile vasculature of SHR—an alteration ascribed to structural changes of the arterial and erectile tissue (Gradin et al, 2006; Arribas et al, 2008). Mitochondrial damage (in both smooth muscle and endothelial cells) and nerve degeneration have been described in SHR

rats (Jiang et al, 2005). Partial success in the prevention/reversal of the structural changes has been described when rats are treated with type 1 angiotensin II receptor (AT1) blocker, AT1 blocker with phosphodiesterase type 5 inhibitor, and a selective β_1 blocker, nebivolol (Mazza et al, 2006; Toblli et al, 2006).

Enhanced Smooth Muscle Contraction and Vasoconstriction. Enhanced basal and myogenic tone has been observed in arteries from hypertensive rats (Schubert and Mulvany, 1999). The RhoA/Rho kinase calcium sensitization pathway is responsible for maintenance of muscle tone. Both hypercholesterolemia and hypertension enhance smooth muscle tone via RhoA/Rho kinase activity (Morikage et al, 2006; Fibbi et al, 2008). Interestingly, both statins and Rho kinase inhibitors enhance the erectile effect of PDE 5 inhibitors in hypertensive rats (Wilkes et al, 2004; Fibbi et al, 2008).

Endothelin-1 (ET-1) levels are elevated in plasma of men with atherosclerosis, hypertension, and hypercholesterolemia. Men with organic ED have higher venous and cavernous blood levels of ET-1 as well (Nohria et al, 2003; El Melegy et al, 2005). Despite this, a pilot study using an ETa receptor antagonist as a treatment for men with ED did not produce positive results (Kim et al, 2002). On the other hand, angiotensin type 1 receptor antagonist and angiotensin conversion enzyme inhibitor have shown promise in the treatment of men with ED hypertension and atherosclerosis, respectively (Speel et al, 2005; Baumhakel et al, 2008).

Impaired Endothelium-Dependent Smooth Muscle Relaxation. Endothelial dysfunction has been proposed as the common link between cardiovascular disease and ED (Brunner et al, 2005). Impairment of endothelium-dependent flow-mediated dilation (FMD) of the brachial artery has been reported in men with ED, and the degree of impairment correlates with the severity of ED (Kovacs et al, 2008). On the other hand, a plethysmography device designed to assess endothelium-dependent vasodilation of the penis did not find a correlation between brachial and penile arteries in ED men (Vardi et al, 2009).

Endothelial progenitor cells (EPCs) are regenerative cells produced in bone marrow that migrate to peripheral vessels to repair endothelial defects. The number of EPCs is reduced in men with ED and coronary heart disease, as well as in overweight men (Foresta et al, 2005; Baumhakel et al, 2006; Esposito et al, 2009). Importantly, both acute and chronic administration of PDE 5 inhibitors increases the number of circulating EPCs and improves both endothelial and erectile function (Foresta et al, 2005, 2009).

In SHR, the relaxing effect of acetylcholine is blunted in corporeal strips (Behr-Roussel et al, 2003). Impairment of endothelium-dependent relaxation in arteries from SHR could be ascribed to angiotensin II (Rajagopalan et al, 1996), thromboxane, and superoxide (Cosentino et al, 1998) or to high blood pressure per se (Paniagua et al, 2000) (Table 23–11).

Table 23–11.

Vascular and Structural Changes Leading to Erectile Dysfunction (ED)

PENILE STRUCTURE	CHANGES IN ED
Cavernous artery	Increased vascular resistance, narrow lumen
Smooth muscle	Increased tone (hypertonicity)
	Decreases muscle content
	Alteration of K channels and GAP junctions
Erectile tissue	Fibrosis
	Impaired veno-occlusive mechanism
Endothelium	Impaired endothelium dependent relaxation
Tunica albuginea	Alteration of elastic and collagen fibers
Neurotransmitters	Decreased nNOS, eNOS

Cavernous (Venogenic)

Failure of adequate venous occlusion has been proposed as one of the most common causes of vasculogenic impotence (Rajfer et al, 1988). **Veno-occlusive dysfunction may result from a variety of pathophysiologic processes: degenerative tunical changes; fibroelastic structural alterations; insufficient trabecular smooth muscle relaxation; and venous shunts.**

Degenerative changes (Peyronie disease, old age, and diabetes) or traumatic injury to the tunica albuginea (penile fracture) can impair the compression of the subtunical and emissary veins (Gonzalez-Cadavid, 2009). **In Peyronie disease, the inelastic tunica albuginea may prevent the emissary veins from closing** (Metz et al, 1983). Chiang and colleagues (1992) have postulated that a decrease in the elastic fibers of the tunica albuginea and an alteration in its microarchitecture may contribute to impotence in some men. Changes in the subtunical areolar layer may impair the veno-occlusive mechanism, as is occasionally seen in patients after surgery for Peyronie disease (Dalkin and Carter, 1991).

Structural alterations in the fibroelastic components of the trabeculae, cavernous smooth muscle, and endothelium may result in venous leakage. Insufficient trabecular smooth muscle relaxation, causing inadequate sinusoidal expansion and insufficient compression of the subtunical venules, may occur in anxious individuals with excessive adrenergic tone or in patients with inadequate neurotransmitter release. It has been shown that alteration of an α adrenoceptor or a decrease in NO release may heighten smooth muscle tone and impair relaxation in response to endogenous muscle relaxant (Christ et al, 1990).

Acquired venous shunts—the result of operative correction of priapism—may cause persistent glans/cavernosum or cavernosum/spongiosum shunting.

Fibroelastic Component. Loss of compliance of the penile sinusoids associated with increased deposition of collagen and decreased elastic fiber may be seen in diabetes, hypercholesterolemia, vascular disease, penile injury, or old age. Sattar and colleagues (1994) have reported significant differences in the mean percentage of penile elastic fibers: 9% in normal men; 5.1% in patients with venous leakage; and 4.3% in patients with arterial disease. In an animal model of vasculogenic ED, Nehra and colleagues (1998) demonstrated that cavernous expandability correlates with smooth muscle content and may be used to predict trabecular histology. Moreland and colleagues (1995) have shown that PGE1 suppresses collagen synthesis by TGF-β1 in human cavernous smooth muscle, which implies that intracavernous injection of PGE1 may be beneficial in preventing intracavernous fibrosis.

Smooth Muscle. Because corporeal smooth muscle controls the vascular events leading to erection, a change in smooth muscle content and ultrastructure can be expected to affect erectile response. In a study of human penile tissue, Sattar and colleagues (1996) demonstrated a significant difference between the mean percentage of cavernous smooth muscle in normal potent men, stained with antidesmin (38.5%) or antiactin (45.2%), and that in a venogenic group (antidesmin, 27.4%; antiactin, 34.2%) or arteriogenic group (antidesmin, 23.7%, antiactin, 28.9%). An in-vitro biochemical study has shown impaired neurogenic and

endothelium-related relaxation of penile smooth muscle in impotent diabetic men (Saenz de Tejada et al, 1989a). In vasculogenic and neurogenic ED, the damaged smooth muscle can be a key factor, aggravating the primary cause (Mersdorf et al, 1991). Pickard and colleagues (1994) have also shown impairment of nerve-evoked relaxation and α-adrenergic-stimulated contraction of cavernous muscle, as well as reduced muscle content in men with venous or mixed venous/arterial impotence.

Ion channels are intimately involved in the biochemical events of muscle function. Fan and colleagues (1995) reported an alteration of the maxi-K^+ channel in cells from impotent patients and suggested that this might contribute to decreased hyperpolarizing ability, altered calcium homeostasis, and impaired smooth muscle relaxation. In animal studies, Junemann and colleagues (1991) showed significant smooth muscle degeneration with loss of cell-to-cell contact in rabbits fed a high-cholesterol diet for 3 months. In a rabbit model of vasculogenic impotence, Azadzoi and colleagues (1997) demonstrated that veno-occlusive dysfunction could be induced by cavernous ischemia. Cavernous nerve injury may also affect cavernous smooth muscle relaxation, as demonstrated in neurotomized dogs (Paick et al, 1991).

Gap Junctions. These intercellular communication channels are responsible for synchronization and coordination of the erectile response (Christ et al, 1991). In severe arterial disease, the presence of collagen fibers between cell membranes reduces or abolishes their contact (Persson et al, 1989). In aged and streptozotocin-induced diabetic rats, Suadicani and colleagues (2009) reported a significant decrease of gap junction protein connexin 43 in the corpus cavernosum.

Endothelium. By release of vasoactive agents, the endothelium of the corpus cavernosum can modify the tone of adjacent smooth muscle and affect the development or inhibition of erection. NO, prostaglandins, and the polypeptide endothelins have been identified in endothelial cells (Ignarro et al, 1990; Saenz de Tejada et al, 1991a, 1991b). Activation of cholinergic receptors on endothelial cells by acetylcholine or the cells' expansion as a result of increased blood flow may elicit underlying smooth muscle relaxation through the release of NO (Saenz de Tejada et al, 1988). Diabetes and hypercholesterolemia have been shown to alter the function of endothelium-mediated relaxation of the cavernous muscle (Azadzoi et al, 1991) and impair erection. In a study of cell junction proteins in hypercholesterolemic mice, Ryu and colleagues (2009) reported downregulation of endothelium-specific cell-to-cell junction proteins including claudin-5, VE-cadherin, and PECAM-1, as well as decreased endothelial content, which may contribute to ED in these mice.

Maintenance of Structural Integrity. Sonic hedgehog homolog (SHH) is one of three proteins in the mammalian hedgehog family, the others being desert hedgehog (DHH) and Indian hedgehog (IHH). SHH is the best studied ligand of the hedgehog signaling pathway. It plays a key role in regulating vertebrate organogenesis, such as in the growth of digits on limbs and organization of the brain. SHH remains important in the adult. It controls cell division of adult stem cells and has been implicated in development of some cancers. SHH has been shown to regulate cavernous smooth muscle apoptosis in response to signals from cavernous nerve. In an animal model of neurogenic ED, SHH protein treatment of the penis prevents cavernous nerve (CN) injury–induced apoptosis and structural changes (Podlasek, 2009).

Markers of Erectile Function. Variable coding sequence protein A1 (Vcsa1) has been proposed as a marker of erectile function in rats. Vcsa1 is downregulated in animal models of neurogenic, diabetic, and aging-associated ED. In rat models of ED treated with human Ca2+-activated K+ channels (hslo) and tadalafil, the erectile function improved and the gene expression of Vcsa1 was also upregulated (Calenda et al, 2009). The Vcsa protein product sialorphin is an endogenous neutral endopeptidase inhibitor. Tong and colleagues (2008) proposed that downregulation of sialorphin could result in prolonged activation of G-protein activated signaling pathways by their peptide agonists and thus heighten the cavernous smooth muscle tone. In humans, there are at least three homologues to the Vcsa1 gene (hSMR3A, hSMR3B, and PROL1). Downregulation of hSMR3A has been reported in men with ED (Davies and Melman, 2008).

Drug-Induced

ED is common among older men and therefore will inevitably coexist with other conditions that are themselves risk factors for ED such as depression, diabetes, and cardiovascular disease (Feldman et al, 1994). In addition, sexual symptoms related to medication can involve a combination of complaints concerning desire, arousal, and orgasm rather than being limited to impaired function. Self-reported and questionnaire data concerning ED as a side effect of medication should be interpreted with caution.

Antihypertensive Agents. Almost all antihypertensive drugs have ED listed as a potential side effect, nevertheless, recent well-designed controlled clinical trials have clarified some myths.

Diuretics. Thiazide diuretics are carbonic anhydrase inhibitors that alkalinize cells and causes vasodilation. Nevertheless, the predominant activity of thiazide diuretics is to inhibit a directly coupled Na-Cl cotransporter (NCC) along the distal convoluted tubule of the kidney. Acutely, when ECF volume depletion occurs because of salt wasting, cardiac output tends to decline, resulting in reactive vasoconstriction. Chronically, however, cardiac output is regulated according to metabolic needs and vasodilation supervenes, returning cardiac output toward baseline; this transforms hypotension from hypovolemic to vasodilatory (Ellison et al, 2009).

This class of drug has been extensively studied. Data from a large U.K. trial showed that twice as many men taking thiazides for mild hypertension reported ED than did those treated with propranolol or placebo—the most common reason for withdrawal from the bendrofluazide arm of the study (Medical Research Council, 1981).

Similar findings were documented from the Treatment of Mild Hypertension Study (TOMHS), where the prevalence of ED at 2 years in men taking low-dose thiazide was twice that of those on placebo or alternative agents (Grimm et al, 1997). Interestingly, after 4 years of treatment, the prevalence of ED in the placebo group approached that of the thiazide group, a finding not fully explained by dropouts. It may be that thiazide therapy, rather than causing ED directly, unmasks it at an earlier stage. A study comparing sexual side effects of thiazide, placebo, or atenolol in hypertensive patients also found a higher rate of ED in the thiazide group, although this was ameliorated by weight loss (Wassertheil-Smoller et al, 1991). The mechanism of diuretic-induced ED remains to be elucidated.

β-Adrenergic Blockers. Receptor studies show that only 10% of adrenoceptors in the penile tissue are of the β type, and their stimulation is thought to mediate relaxation (Andersson and Wagner, 1995). This response is attenuated in vitro by nonselective drugs such as propranolol, possibly via a prejunctional β_2-receptor effect (Srilatha et al, 1999), but not by cardiac-selective agents such as practolol. Beta antagonists also exert an inhibitory effect within the CNS, perhaps leading to lowered sex hormone levels (Suzuki et al, 1988).

The differential effects of β-adrenoceptor antagonists on erectile function may be explained by whether they are general antagonists, selective antagonists, or possess vasodilatatory properties. **Nonselective drugs such as propanolol are associated with higher prevalence of ED** compared with what is observed in patients treated with placebo or angiotensin-converting enzyme (ACE) inhibitors (Croog et al, 1986). Later trials using **agents with higher selectivity for the β_1 adrenoceptor such as acebutolol have shown a substantial reduction in ED** with no difference between placebo and ACE inhibitor groups (Grimm et al, 1997). Carvedilol, a general β-adrenoceptor antagonist that also causes vasodilation by blocking α_1 adrenoceptors, has been associated with worsening sexual function (Fogari et al, 2001). Some recently introduced β_1-adrenoceptor antagonists, such as nebivolol, have vasodilatatory effects mediated by release of nitric oxide (Reidenbach et al, 2007). In cross-over studies using nebivolol versus the selective β_1-adrenoceptor antagonists metoprolol and atenolol, nebivolol did not decrease sexual intercourse activity in hypertensive men and in some cases had positive effects on erectile function (Boydak et al, 2005; Brixius et al, 2007).

α-Adrenoceptor Blockers. Animal studies have demonstrated a positive effect on erection for α antagonists, particularly those acting on the α_1 receptor, by increasing or prolonging the relaxant response of cavernous smooth muscle (Andersson and Wagner, 1995). In addition, prejunctional α_2-receptor activation modulates the release of noradrenaline, suggesting a putative relaxant role for α_2 blockers. In clinical observations, **drugs such as doxazosin,** used to treat hypertension (Grimm et al, 1997) or lower urinary tract symptoms (Flack, 2002), **were not associated with complaints of ED** and indeed had lower rates than in placebo groups. Not surprisingly, **drugs stimulatory to the α_2 receptor such as clonidine do result in diminished erectile function,** both clinically and experimentally, by peripheral and central mechanisms (Srilatha et al, 1999). The centrally acting drug, **methyldopa, has also been associated with ED** in controlled trials comparing it with placebo and other antihypertensive agents (Croog et al, 1988,) and it may act by antagonizing hypothalamic α_2 adrenoceptors.

Angiotensin-Converting Enzyme Inhibitors. **These drugs lack any easily appreciated peripheral or central effect that would interfere with sexual function.** An in-vivo experiment showed that the ACE inhibitor captopril did not cause any significant adverse effect on sexual function in awake normotensive rats (Srilatha et al, 1999). In three clinical studies of hypertension treatment comparing an ACE inhibitor with other agents and placebo, all found either no difference from placebo or improved sexual function over baseline when compared with other agents (Croog et al, 1988; Suzuki et al, 1988; Grimm et al, 1997).

Angiotension II Type 1 (AT_1) Receptor Antagonist. In studies of hypertensive or aging normotensive animals, the AT_1 receptor antagonists (e.g., losartan, valsartan, candesartan) reverse structural changes in the penile vasculature and appear to conserve erectile function (Hale et al, 2001, 2002; Park et al, 2005; Hannan et al, 2006). Moreover, in clinical cross-sectional studies, AT_1 receptor antagonists, in contrast to other antihypertensive drugs, seem to improve erectile function (Doumas et al, 2006). In a cross-over study comparing valsartan with the β-adrenoceptor antagonist carvedilol, valsartan had a beneficial effect on preexisting sexual dysfunction and had no adverse sexual effects during 12 months of treatment (Fogari et al, 2001). Three-month treatment with losartan has also been reported to improve sexual function (Llisterri et al, 2001).

Calcium-Channel Blockers. Clinical studies have demonstrated **no adverse effect on erection;** ejaculatory complaints, which may owe to decreased force of bulbocavernous muscles, seem short-lived (Suzuki et al, 1988). In the TOMHS study there was no ED increase over placebo in the amlodipine group (Grimm et al, 1997). Another study also showed no increase in the prevalence of ED when hypertension was treated with diltiazem alone or in combination with an ACE inhibitor (Cushman et al, 1998).

Aldosterone Receptor Antagonist. Spironolacotone and eplerenone are mineralocorticoid-blocking agents used for their ability to block both the epithelial and nonepithelial actions of aldosterone. Spironolactone is a nonselective mineralocorticoid receptor antagonist with moderate affinity for both progesterone and androgen receptors. The latter property increases the likelihood of endocrine side effects including loss of libido, gynecomastia, and impotence. Eplerenone is a next-generation aldosterone receptor antagonist selective for aldosterone receptors alone. It has less affinity for progesterone and androgen receptors (Sica, 2005).

Summary. Treatment of mild to moderate hypertension requires agents with an acceptable side effect profile to minimize noncompliance. Thiazide diuretic is associated with higher rates of ED, although this may be reduced by combination therapy and weight loss. α_1 Blockers and angiotensin II receptor blockers both tend to improve sexual functioning during treatment and may therefore be useful when commencing antihypertensive therapy in men with preexisting ED (Khan et al, 2002) (Table 23–12).

Psychotrophic Medication. As with hypertension, the underlying disorder may be more relevant for ED than the medication. On the other hand, **receptor complexity and interrelation of pathways within the CNS make it extremely likely that neurons and ganglia involved in sexual functioning will be affected by psychotropic drugs, leading to functional changes that may be positive or negative.** One example is the loss of sexual desire among nonmedicated patients with schizophrenia, while those on antipsychotic drugs have shown greater desire but increased erectile and ejaculatory disturbance (Aizenberg et al, 1995).

Table 23–12.

Effect of Antihypertensive Agents on Sexual Function

AGENT	EFFECT	MECHANISM
Diuretics	ED (twice as placebo)	Unknown
β blocker (nonselective)	ED	Prejunctional α_2-receptor inhibition
β_1 blocker (selective)	None	
α_1 blocker	Decreases ED rate but may cause retrograde ejaculation	Failure of sympathetically induced closure of internal sphincter and proximal urethra during ejeculation
α_2 blocker	ED	Inhibition of central α_2 receptor
Angiotensin-converting enzyme inhibitor	None	
Angiotensin II receptor blocker	Decreases ED rate	
Calcium channel blocker	None	

Antipsychotics. Members of this class of drug have many effects on CNS receptors and may also act peripherally. Their therapeutic effect is thought to relate to doperminergic receptor blockade within the limbic and prefrontal areas of the brain. Their unwanted effects owe to β-adrenergic blockade and anticholinergic properties, as well as to antidopaminergic actions within the basal ganglia, causing extrapyramidal side effects that commonly produce sexual symptoms (Sullivan and Lukoff, 1990).

The occurrence of extrapyramidal effects differentiates the older "typical" antipsychotics, with which they are frequent, from the newer "atypical" antispychotics, with which they are less common. This difference probably relates to differential affinities for particular classes of receptor (Strange, 2001) or avidity for particular areas of the cerebral cortex (Westerink, 2002). An additional effect of DA blockade, hyperprolactinaemia, which also alters sexual function by reducing DA release in permissive cerebral centers, is more common with older "typical" agents (Smith and Talbert, 1986).

Animal experiments, chiefly in the rat, show that D1-receptor activation in the MPOA of the hypothalamus facilitates erection through intermediary oxytocinergic and spinal cholinergic pathways. It is also possible that activation of D2 receptors in this area has the opposite effect (Zarrindast et al, 1992). Older agents such as haloperidol and flupenthixol have been shown to reduce apomorphine-induced erections in experimental animals by means of D1-receptor antagonism (Andersson and Wagner, 1995). In addition, systemic administration of antipsychotic agents in the rabbit produced erection by a local nondoperminergic action, possibly involving anatagonism of α_1 adrenoceptors (Naganuma et al, 1993). Therefore **the clinical effect of antipsychotics on sexual function will vary according to their affinity for particular receptors.**

In a nonrandomized comparative study of antipsychotic medications, the prevalence of sexual dysfunction ranged from 40% to 70% (Wirshing et al, 2002). Newer agents such as clozapine showed a lower reduction in sexual desire, and the group taking risperidone had the greatest decrease in erectile frequency.

Antidepressants. Sexual side effects in both men and women are varied but are important factors governing compliance because these drugs are commonly prescribed to younger and middle-aged adults. **In a Cochrane review of 15 randomized trials, besides changing medications, addition of bupropion or a phosphodiesterase 5 inhibitor (PDE5I) to antidepressant seems to be an effective method to correct antidepressant-associated erectile dysfunction** (Rudkin et al, 2004).

Tricyclics act by inhibiting the reuptake of catecholamines in the CNS. **Their sexual side effect profile is thought to relate to peripheral anticholinergic and β-adrenergic effects.** It is also possible that they antagonize 5-HT receptors. Controlled clinical studies suggest that **orgasmic disorders in both sexes are frequent,** explaining the use of these drugs as inhibitors of ejaculation (Harrison et al, 1986; Monteiro et al, 1987).

Monoamine oxidase inhibitors are associated with **higher rates of orgasmic dysfunction** in controlled trials (Harrison et al, 1986), but the nature of the central or peripheral mechanisms involved is uncertain.

Selective serotonin reuptake inhibitors (SSRIs) are the class of drug commonly used to treat depression at the present time. They inhibit the reuptake of 5-HT into CNS neurons and can therefore produce stimulatory effects on various 5-HT receptors. It is estimated that **up to 50% of patients taking these drugs experience a change in sexual function** (Rosen et al, 1999; Keltner et al, 2002). Possible mechanisms include stimulation of 5-HT2 and 5-HT3 receptors, which may inhibit erectogenic pathways within the spinal cord (Tang et al, 1998), decreased DA release in the MPOA (Maeda et al, 1994), inhibition of NOS, and lower serum levels of LH, FSH, and testosterone (Safarinejad, 2008). A controlled clinical study suggested that the improvement in sexual function resulting from SSRIs' alleviation of clinical depression outweighed any negative effect (Michelson et al, 2001). However, other placebo-controlled randomized studies revealed increased sexual dysfunction, mainly anorgasmia, in the SSRI-treated group (Labbate et al, 1998; Croft et al, 1999). Further studies have suggested that **these adverse effects can be modified by cotreatment with other drugs such as sildenafil** (Fava et al, 2006) **or mianserin** (Aizenberg et al, 1997).

SSRIs differ in their ability to cause ED. A high incidence has been observed in patients treated with paroxetine (Kennedy et al, 2000), while a lesser impact has been reported with citalopram (Mendels et al, 1999). This suggests that mechanisms other than inhibition of serotonin reuptake may be involved, which is supported by a report that acute or chronic paroxetine, but not citalopram, caused ED in rats by inhibiting NO production (Angulo et al, 2001). Indeed, the inhibitory effects induced by acute paroxetine on erectile function in the rat can be prevented by inhibition of PDE5 with vardenafil (Angulo et al, 2003).

Other Antidepressants. Animal experiments suggest that stimulation of 5-HT-1 receptors within the CNS modulates sexual function, with the 5-HT-1A subtype increasing ejaculation and the 5-HT-1C subtype improving erection. Recently developed antidepressants such as mirtazapine and nefazodone tend to have beneficial effects on sexual function, possibly by activating the 5-HT-1C receptor, which augments sexual response (Stancampiano et al, 1994), although they may also antagonize the 5-HT-2C receptor (Millan et al, 2000). The isolated reports of priapism seen with a prototype agent, trazodone, may be related to the 5-HT-1C erectogenic effect seen with its primary metabolite, *m*-chlorophenylpiperazine, in experimental animals (Andersson and Wagner, 1995). In a clinical study, trazodone was shown to increase nocturnal erectile activity, despite reducing REM sleep (Ware et al, 1994).

Anxiolytics. Although not previously associated with ED, anxiolytics have been implicated in sexual problems by the MMAS study (Derby et al, 2001). Benzodiazepines are thought to potentiate the action of GABA in the reticular and limbic system, but they may also affect the serotonin and dopaminergic pathways. Experimental studies suggest that GABA-ergic drugs inhibit erection induced by apomorphine, a DA agonist (Zarrindast and Farahvash, 1994). A controlled clinical study demonstrated that a combination of lithium and benzodiazepine was associated with a significantly higher rate of sexual dysfunction than treatment with lithium alone (Ghadirian et al, 1992). More recent anxiolytic agents such as bupropion, acting mainly by inhibiting DA reuptake, and buspirone, acting on 5-HT-1A receptors, were not associated with sexual side effects in placebo-controlled trials (Coleman et al, 2001) and can be used to alleviate sexual symptoms caused by other antidepressant medication (Gitlin et al, 2002).

Anticonvulsants. Epileptic discharges may affect the function of the hypothalamic-pituitary axis and thus the level of hormones important for sexual function (Morris et al, 2005). Sexual function, bioavailable testosterone levels, and gonadal efficiency in men with epilepsy who take lamotrigine are comparable with control

and untreated values and significantly greater than in men treated with carbamazepine or phenytoin (Herzog et al, 2004). Orgasmic dysfunction is common in patients who receive carbamazepine therapy, and loss of sexual desire is common in men treated with valproate (Kuba et al, 2006). There are reports of improved sexual function and hypersexuality in patients treated with lamotrigine (Gil-Nagel et al, 2006; Grabowska-Grzyb et al, 2006).

Antiandrogens

Androgens are believed to modify sexual behavior by modulating AR within the CNS. **Antiandrogens cause partial or near-complete blockade of androgen's action by inhibiting production of or antagonizing the androgen receptor (AR).** The effects of androgen deficiency on sexual activity are variable, ranging from complete loss to normal function. Experimental studies in humans suggest that nocturnal erections during REM sleep are androgen dependent, while erections in response to visual sexual stimulation are independent (Andersson and Wagner, 1995). An additional peripheral effect has been suggested from animal experiments in which castration decreased nitric oxide synthase (NOS) activity within the rat corpus cavernosum, leading to reduced erectile activity. Testosterone restored NOS activity, but treatment with finasteride prevented this recovery, suggesting that dihydrotestosterone (DHT) may be the important androgen in penile tissue (Lugg et al, 1995).

Indeed, the 5-α-reductase inhibitor, finasteride, is the antiandrogen with the least effect on circulating testosterone. In randomized placebo-controlled studies of patients given finasteride (5 mg daily) for prostatic symptoms, approximately **5% complained of decreased desire and ED compared with 1% in the placebo group** (Gormley et al, 1992). At the lower dose used to treat male-pattern alopecia (1 mg daily), no sexual dysfunction was seen (Tosti et al, 2001).

More complete androgen ablation is achieved by competitive antagonism at the AR, thus preventing signal transduction of testosterone and DHT. Nonsteroidal drugs such as flutamide and bicalutamide have relatively pure effects on the AR. The steroidal antiandrogen cyproterone acetate also has inhibitory effects on the hypothalamus. These drugs are used in the palliative treatment of locally advanced and metastatic prostate cancer, either alone or in combination with a luteinizing hormone-releasing hormone (LHRH) agonist. When used alone, nonsteroidal antiandrogens are associated with a rise in serum testosterone levels; when combined with an LHRH agonist, they reduce testosterone to the castrate range. The main effect is a reduction of sexual desire, which occurs in up to 70% (Iversen et al, 2001).

In a clinical trial with larger sample size and longer duration, treatment with bicalutamide alone resulted in a lesser decrease in sexual desire than did castration (Iversen et al, 2000). However, in another large controlled trial, treatment with either flutamide or cyproterone resulted in a gradual loss of sexual desire over 2 to 6 years in approximately 80% (Schroder et al, 2000). In a placebo-controlled study, half the patients on bicalutamide therapy suffered loss of erectile function, even at a low dose of 50 mg (Eri and Tveter, 1994).

The near-complete androgen deprivation achieved by medical castration with LHRH agonists results in a profound loss of sexual desire, which is usually accompanied by ED (Basaria et al, 2002). This was objectively confirmed by nocturnal penile tumescence (NPT) monitoring before and after initiation of therapy in a small study (Marumo et al, 1999).

Miscellaneous Drugs. Many other drugs are suggested as having sexual side effects, in particular that of ED in men, but these contentions are usually based on anecdotal case reports or postmarketing drug alerts rather than controlled trials.

Digoxin. In an experimental in-vitro study with isolated human corpus cavernosum tissue, digoxin attenuated the relaxant response to acetylcholine and intrinsic nerve stimulation; this was linked to findings of reduced penile rigidity not seen in men given a placebo after visual sexual stimulation (Gupta et al, 1998). A randomized clinical study confirmed a negative effect on general sexual functioning linked to a decrease in plasma testosterone (Neri et al, 1987). However, others did not find change in sex and adrenal hormone levels in men taking digitalis (Kley et al, 1984).

Statins. **Statins** are used to lower lipid levels and thus are commonly used in men likely to have established risk factors for sexual dysfunction, particularly ED. In a single placebo-controlled trial, the rate of ED was twice as high (12% vs. 6%) in men taking a statin, despite improvement in other parameters of hyperlipidemic endothelial dysfunction (Bruckert et al, 1996). In another study of 93 men attending cardiovascular risk clinics, after 6 months of statin therapy, the mean IIEF scores were reduced from 21 to 6.5 (range 0 to 25) ($p < 0.001$), and 22% experienced new-onset ED. The authors suggest that ED following statin therapy is more likely in patients with severe endothelial dysfunction due to established cardiovascular risk factors including age, smoking, and diabetes (Solomon et al, 2006). In contrast, in the large Scandinavian simvastatin survival study, 4444 patients with coronary arterial disease were randomized to treatment with simvastatin or placebo for up to 6 years. ED was found in 28 placebo-treated patients (8 resolved) and in 37 simvastatin-treated patients (14 resolved) (Pedersen and Faergeman, 1999). Therefore the **underlying disease process appears to be the cause of ED in men treated with statins rather than the drug itself.**

Regarding sexual side effects, the most studied statin is atorvastatin. In clinical studies, atorvastatin has been reported to have the following positive effects: (1) improvement in nocturnal penile activity and mean scores on the Sexual Health Inventory in Men (SHIM) questionnaire from 14.2 to 20.7 in hyperlipidemic patients treated for 4 months (Saltzman et al, 2004); (2) when combined with the ACE inhibitor quinapril, positive effects on ED in men with established penile disease and suboptimal response to phosphodiesterase inhibitors (Bank et al, 2006); (3) improvement in the response to sildenafil in men with ED not initially responsive to sildenafil (Herrmann et al, 2006); (4) when combined with sildenafil, improvement in erectile function recovery in men who had undergone bilateral nerve-sparing radical prostatectomy (Hong et al, 2007); and (5) positive effect on International Index of Erectile Function (IIEF) questionnaire scores in patients with hyperlipidemia followed for 12 months (Dogru et al, 2008).

Statins are classified as natural (lovastatin), semisynthetic (simvastatin), and synthetic (atorvastatin, cerivastatin) and are structurally heterogenous. Therefore the statins may have different effects on sexual function, which remain to be elucidated.

Histamine H_2 Receptor Antagonists. Cimetidine and ranitidine were widely prescribed for prophylaxis and treatment of peptic ulcer disease. Case reports suggested that cimetidine was associated with ED. A single in-vitro animal study suggested that H_2 receptor stimulation causes cavernous relaxation, possibly via endothelial release of NO (Andersson and Wagner, 1995).

Opiates. Long-term intrathecal administration of opiates results in hypogonadatropic hypogonadism and associated sexual dysfunction that can be restored with appropriate supplementation (Abs et al, 2000). However, administration of opioid antagonists to older men with ED was not found to improve erectile function

measured objectively by NPT monitoring (Billington et al, 1990). Opioids do have a generalized depressant effect on sexual function when directly administered to the MPOA in rat brain, but treatment with the opioid receptor antagonist naloxone had no sexual effect on healthy male volunteers (Andersson and Wagner, 1995).

Antiretroviral Agents. Hypogonadism and erectile dysfunction (ED) appear to be more common among men infected with HIV compared with age-matched men within the general U.S. population (Crum et al, 2005). **Sexual dysfunction seems to be a common event after the introduction of highly active antiretroviral therapy** (HAART). The average prevalence is erectile dysfunction (46%), decreased libido (44%), ejaculatory disturbances (39%), and orgasmic disorders (27%) (Collazos, 2007). These disturbances seemed to be more common in patients treated with protease inhibitors. Because these patients may have diseases involving several organ systems and taking multiple drugs, the precise mechanism is difficult to determine.

Tobacco. **Cigarette smoking may induce vasoconstriction and penile venous leakage because of its contractile effect on the cavernous smooth muscle** (Juenemann et al, 1987). In an NPT study in cigarette smokers, Hirshkowitz and colleagues (1992) reported an inverse correlation between nocturnal erection (both rigidity and duration) and the number of cigarettes smoked per day: Men who smoked more than 40 cigarettes had the weakest and shortest nocturnal erections. **The Boston Area Community Heath (BACH) survey** used a multistage stratified random sample to recruit 2301 men, aged 30 to 79 years, from the city of Boston. The authors' report **indicates a dose-response association between smoking and ED with a statistically significant effect observed with 20 or more pack-years of exposure.** Passive smoking is associated with a small, statistically insignificant increase in risk of ED comparable with approximately 10 to 19 pack-years of active smoking (Kupelian et al, 2007). In an experiment to elucidate the mechanisms of tobacco use–associated ED, nicotine- and tar-free cigarette smoke extract (CSE) was injected subcutaneously into adult male rabbits once a day for 5 weeks. The authors reported impaired NO production from blunted NOS activity, downregulation of nNOS protein, accumulation of endogenous NOS inhibitors, enhanced arginase activity, and upregulation of arginase I protein in cavernous tissue. CSE also caused accumulation of endogenous NOS inhibitors due to impaired dimethylarginine dimethylaminohydrolase (DDAH) activity and decreased expression of DDAH I protein. These alterations may be relevant to erectile dysfunction following CSE (Imamura et al, 2007).

Alcohol. Alcohol in **small amounts improves erection and sexual drive because of its vasodilatory effect and suppression of anxiety;** however, **large amounts can cause central sedation, decreased libido, and transient ED.** In the Western Australia Men's Health Study, Chew and colleagues (2009) reported that, compared with never-drinkers, the age-adjusted odds of ED were lower among current, weekend, and binge drinkers and higher among exdrinkers.

Chronic alcoholism may result in liver dysfunction, decreased testosterone and increased estrogen levels, and alcoholic polyneuropathy, which may also affect penile nerves (Miller and Gold, 1988). In an in-vitro study of rabbits given 5% alcohol for 6 weeks, Saito and colleagues (1994) reported augmented smooth muscle contraction and relaxation to both electrical field stimulation and vasoconstrictors such as phenylephrine and potassium chloride, but not to sodium nitroprusside, suggesting changes in neurovascular function. In a study of subacute alcohol effect, mice were exposed to alcohol vapor for 7 or 14 days. The authors reported impaired endothelium-dependent relaxation of cavernous smooth muscle, as well as damage of endothelium in 14-day exposure group of mice but not the 7-day group (Aydinoglu et al, 2008) (Table 23–13).

Table 23–13.

Drug-Induced Erectile Dysfunction (ED) and Suggested Alternatives

CLASS	KNOWN TO CAUSE ED	SUGGESTED ALTERNATIVES
Antihypertensives	Thiazide diuretics General β blockers	α blockers Calcium channel blockers Specific β blockers Angiotensin-converting enzyme inhibitors Angiotenin II receptor antagonists
Psychotropics	Antipsychotics Antidepressants Anxiolytics	Newer anxiolytics (bupropion, buspirone)
Antiandrogen	Androgen receptor antagonists LHRH agonists 5-α reductase inhibitors	
Opiates		
Antiretroviral agents		
Tobacco		Quit smoking
Alcohol	Large amount	Small amount

Aging, Systemic Disease, and Other Causes

A number of studies have indicated a progressive decline in sexual function in "healthy" aging men. Masters and Johnson (1977) **noted a number of changes in older men including greater latency to erection, less turgidity, loss of forceful ejaculation and decreased volume, and a longer refractory period. Decreased frequency and duration of nocturnal erection with increasing age were reported in a group of men who had regular intercourse** (Schiavi and Schreiner-Engel, 1988). Other research has also indicated a decrease in penile tactile sensitivity with age (Rowland et al, 1989). A heightened cavernous muscle tone may also contribute to the decreased erectile response in older men (Christ et al, 1990). In one study, a decrease in testosterone in aging impotent men in association with relatively normal gonadotropins was reported, suggestive of hypothalamic-pituitary dysfunction (Kaiser et al, 1988). Penile structural and functional changes have been documented in various animal studies. Costa and Vendeira (2008) reported progressive decline of smooth muscle content and increase in the caliber of vascular spaces in the corpus cavernosum with increasing age in Wister rats. This may be due to increases in smooth muscle cell apoptosis due to oxidative stress and/or increase in caspase 2-mediated intrinsic pathway signaling (Braga et al, 2008). Suadicani and colleagues (2009) showed a significant decrease in gap junction protein connexin 43 and purinoceptor subtypes P2X1R and an increase in P2X7R in the corpus cavernosum of aging Fischer-344 rats. Change of nitric oxide expression or activity has also been reported. Numao and colleagues (2007) have demonstrated attenuated neuronal nitric oxide synthase protein expression and accelerated arginase

activity. Ferrini and colleagues (2001a and b) reported an increase of inducible nitric oxide, peroxynitrite formation, and elevation of apoptotic index in the corpus cavernosum and hypothalamic regions. The increased contractile property of the erectile tissue associated with aging may be due to elevated RhoA/Rho-kinase activity (Jin et al, 2006), enhanced rennin-agniotension system (Park et al, 2005) or impaired angiotensin-(1-7)-mediated relaxation (Yousif et al, 2007).

Diabetes Mellitus. Diabetes mellitus is a common chronic disease, affecting 0.5% to 2% of worldwide population. The **prevalence of ED is three times higher in diabetic men (28% vs. 9.6%)** (Feldman et al, 1994), **occurs at an earlier age, and increases with disease duration,** being approximately 15% at age 30 and rising to 55% at 60 years (McCullough et al, 1980, 1984). Erectile dysfunction among men with diabetes is **more frequent in those with coexisting neuropathy.** In a study of men presenting with ED, the authors found a twofold increase of hypogonadism in men with diabetes (24% vs. 12%) (Corona et al, 2006). **The presence of ED is associated with more than 14 times higher risk for silent coronary artery disease, higher major cardiovascular morbidity, and mortality in diabetic men** (Gazzaruso et al, 2004). This evidence indicates the presence of ED in diabetic patients could predict the future major cardiovascular events. Diabetes mellitus may cause ED by affecting one or a combination of the following: psychologic well-being, CNS function, androgen secretion, peripheral nerve activity, endothelial cell function, and smooth muscle contractility (Dunsmuir and Holmes, 1996).

In 12% of diabetic men, deterioration of sexual function can be the first symptom. Duplex ultrasound after intracavernous injection has revealed a high prevalence (>75%) of penile arterial insufficiency among diabetic men with ED (Wang et al, 1993). Pathologic changes in the cavernous arteries (Michal, 1980), ultrastructural changes in the cavernous smooth muscle (Mersdorf et al, 1991), and impaired endothelium-dependent relaxation of the corporeal smooth muscle (Saenz de Tejada et al, 1989a) have also been noted in penile specimens from diabetic men with ED. Hirshkowitz and colleagues (1990) have reported that impotent men with diabetes have fewer sleep-related erections, shorter tumescence time, diminished penile rigidity, decreased heart rate response to deep breathing, and lower penile blood pressure than do age-matched nondiabetic men.

A number of type 1 and type 2 diabetic animal models have been used to study the basic mechanisms of diabetes-induced ED. In these animals, diabetes causes endothelial cell dysfunction, resulting in an increased prevalence of vascular disease. Other effects include decreased nNOS, reduced activity of eNOS, oxidative stress, increased advanced glycation endproducts (AGEs), decreased elastin, reduced vascular endothelial growth factor (VEGF), hypercontractility of cavernous erectile tissue, and decreased smooth muscle/collagen ratio leading to impairment of the veno-occlusive mechanism. Summaries of mechanistic studies in humans and animal models, derived from the committee report of the Second International Consultation of Sexual Medicine (Saenz de Tejada et al, 2005), are shown in Tables 23–14 and 23–15.

Metabolic Syndrome. The metabolic syndrome (MetS) includes glucose intolerance, insulin resistance, obesity, dyslipidemia, and hypertension. Higher prevalence of ED (26.7%) in men with MetS relative to controls (13%) has been reported. Furthermore, the prevalence of ED increases as the number of MetS components increases (Esposito et al, 2005). **In an analysis of the Baltimore Longitudinal Study of Aging, in which men were followed for a mean of 5.8 years, Rodriguez and colleagues** (2007) **confirmed that the prevalence of MetS increases with age and is associated with lower androgen levels. They also found that lower total T levels, along with lower sex hormone binding globulin (SHBG) levels, predicts a higher incidence of MetS. Men with MetS have an increased prevalence of ED, reduced endothelial function score, and higher circulating concentrations of**

Table 23–14.

Summary Findings of Studies in Diabetic Patients

FOCUS	FINDING
Anatomic	More atheromatic lesions in large vessels and stenosis in pudendal and iliac arteries
Functional	Decreased number and rigidity of nocturnal erections
	Lower penile rigidity after intracavernous injection of vasodilators
	High prevalence of penile arterial insufficiency studied with duplex ultrasound
Cavernous Tissue Studies	
A. Ultrastructural	Decreased smooth muscle content, increased collagen, thickening of basal lamina, and loss of endothelial cells (more severe in men with diabetes)
B. Functional	• Reduced endothelial and neurogenic NO-mediated penile smooth muscle relaxation, but not nitroprusside-induced relaxation (suggesting impaired NO release or synthesis)
	• Increased advanced glycation end products (AGEs) in cavernous tissue
	• Contractile response to α-adrenergic agonist is higher in type 1 but not type 2 diabetics
	• In human penile arteries, EDHF-mediated endothelium-dependent relaxation is significantly reduced in penile resistance arteries from diabetic patients
	• Exposure to hyperglycemia induces increased expression of collagen, decreased proliferation, and increased programmed cell death (apoptosis). Expression of TNF_{α} is also increased
	• Insulin is thought to enhance NOS activity by increasing transport of L-arginine into the cell and furnishing greater quantities of the essential co-factor NADPH. These effects are reversed in insulin deficiency or insulin resistance in diabetes.
	• The inducible form (arginase II) of arginase, an enzyme that competes with NOS for the substrate L-arginine, is overexpressed in corpus cavernosum from diabetic patients, where inhibition of arginase restores NOS activity

EDHF, endothelium-derived hyperpolarizing factor; NOS, nitric oxide synthase.

Table 23–15.

Summary Findings of Studies in Diabetic Animal Models

MODEL	FINDING
Streptozocin-induced diabetic rats or mice	• Increased activity of AC and GC, resulting in production of more cAMP and cGMP in response to prostaglandin E1 and nitroprusside, respectively • Decreased endothelial and neurogenic NO-mediated cavernous muscle relaxation • Increased prostacyclin synthesis • Increased cavernous muscle tone owing to upregulation of endothelin ETA receptors • Increased contractile prostaglandins and free oxygen radicals in hyperglycemic state, resulting in reduced response to acetylcholine (reversed by indomethacin and antioxidants) • Increased levels of oxygen free radicals and oxidative stress injury. Preventive treatment with an antioxidant prevented the appearance of endothelial dysfunction in cavernosal tissue, whereas restorative treatment with same antioxidant only partially reversed the impairment of endothelium-dependent relaxation • Increased glycated hemoglobin, which impairs endothelium-dependent relaxation in aorta and corpus cavernosum from diabetic rats. This effect is reversed by superoxide dismutase (SOD), the scavenger of superoxide anions • Inhibition of AGE formation improves endothelium-dependent relaxation and restores erectile function in diabetic rats • Impaired responses attributable to endothelium-derived hyperpolarizing factor (EDHF) in the vasculature of diabetic animals • Plasma concentration and vascular content of L-arginine are reduced in diabetic rats • NO-dependent selective nitrergic nerve degeneration in diabetes
Diabetic rabbit	• Production of cAMP in response to PGE_1 or forskolin is reduced after 6 months, but not 3 months • Increased glucose-induced production of PKC mediated by oxidative stress in rabbit corpus cavernosum smooth muscle cells • Oxidative stress interferes with endothelial function in diabetic erectile tissue. This is supported by the potentiating effect of SOD or the natural antioxidant, vitamin E, on endothelium-dependent relaxation of corpus cavernosum from rabbits

C-reactive protein compared with men without metabolic disorders (Esposito et al, 2005). **Low levels of androgens in men with erectile dysfunction and obesity were also reported by Corona and colleagues (2008).**

Chronic Renal Failure. Sexual dysfunction is common in men with chronic renal failure. In a survey of 69 men on hemodialysis, only 55% were sexually active and the predominant sexual dysfunctions were loss of or diminished sexual needs (84.7%), erectile dysfunction (44.5%), and inhibited or lack of ejaculation (51.5%) (Lew-Starowicz and Gellert, 2009). Similarly, ED was reported in 52% of men undergoing peritoneal dialysis (Lai et al, 2007). The presence of depressive symptoms, highly prevalent in hemodialysis patients, is an independent factor of sexual dysfunction in male hemodialysis patients (Peng et al, 2007). Significant improvement of sexual function has been reported after kidney transplantation (Tavallaii et al, 2009). Nevertheless, in a report of 182 men who had undergone kidney transplantation, Espinoza and colleagues (2006) noted that 49% of men continued to have erectile dysfunction, whereas 33% of men had normal sexual function and 18% had no sexual activity. Many of the effects of uremia can potentially contribute to the development of ED including disturbance of the hypothalamic-pituitary-testis sex hormone axis, hyperprolactinemia, accelerated atheromatous disease, and psychologic factors (Ayub and Fletcher, 2000).

Bagcivan and colleagues (2003) suggest that ED may be due to either decreased production or reduced bioavailability of endogenous NO (Bagcivan et al, 2003). Evidence from animal models of chronic uremia therefore suggests that a decrease in functional NO may be responsible for vascular side effects including ED. Several putative mechanisms may lead to such a deficiency such as reduced bioavailability of the NO substrate L-arginine, reduced expression of NOS isoforms in the relevant organs, rapid quenching of NO by reactive oxygen species known to be increased in chronic renal failure, and the accumulation of uremic inhibitors of NOS (Vaziri, 2001).

Evidence of autonomic neuropathy as a factor contributing to ED in men with chronic renal failure comes from studies that found a high rate of abnormality in vascular and bulbocavernous reflexes, suggesting nerve dysfunction (Campese et al, 1982; Vita et al, 1999). Neuropathy is a common complication of end-stage kidney disease (ESKD), typically presenting as a distal symmetric process with insidious onset progressing over months. Neuropathy has been estimated to occur in 60% to 100% of patients on dialysis. Nerves of uremic patients have been shown to exist in a chronically depolarized state before initiation of dialysis, with subsequent improvement and normalization of resting membrane potential after initiation of dialysis. The degree of depolarization correlates with serum K(+), suggesting that chronic hyperkalemic depolarization plays an important role in the development of nerve dysfunction in ESKD (Krishnan and Kiernan, 2007). Investigation of cavernous vascular function in 20 men undergoing renal replacement therapy showed that 80% had both arterial insufficiency and veno-occlusive dysfunction (Kaufman et al, 1994). A link between impairment of the NO-cGMP pathway relating to failure of cavernous relaxation is provided by the finding of increased serum levels of asymmetric dimethylarginine (ADMA) in uremic patients (Kielstein and Zoccali, 2005).

Patients with severe pulmonary disease often fear aggravating dyspnea during sexual intercourse. Patients with angina, heart failure, or myocardial infarction can become impotent from anxiety, depression, or arterial insufficiency. Other systemic diseases such as cirrhosis of the liver, scleroderma, chronic debilitation, and cachexia are also known to cause ED.

Primary Erectile Dysfunction

Primary ED refers to a **life-long inability to initiate and/or maintain erections beginning with the first sexual encounter.** Although most cases owe to psychologic factors, a small number of afflicted men do have a physical cause resulting from maldevelopment of the penis or the blood and nerve supply. Primary psychologic dysfunction is usually related to anxiety about sexual performance stemming from adverse childhood events, traumatic early sexual experience, or misinformation. Endocrine abnormalities, particularly low testosterone levels, may also be implicated in primary ED, although lowered sex drive is likely to be the main symptom. Evidence to support these concepts is confined to observation studies with varying numbers of cases. The largest study described 67 patients, of whom 10 (15%) had a predominantly psychologic cause (Stief et al, 1989b). Those with physical abnormalities had a variety of neurologic, arterial, and veno-occlusive dysfunction.

Micropenis. Symmetric hypoplasia of the phallus, micropenis, is often related to urethral developmental abnormalities such as hypospadias and epispadias (Reilly and Woodhouse, 1989) or endocrine deficiency. The erectile tissue in such cases often functions normally; sexual dysfunction usually relates to lack of penile length or the degree of chordee, rather than to ED (Woodhouse, 1998).

Vascular Abnormalities. Primary ED in the presence of an externally normal phallus is unusual. Authors have described structural abnormalities of the cavernous tissue such as absence (Teloken et al, 1993) or replacement by fibrous tissue (Aboseif et al, 1992). Others have found vascular abnormalities including hypoplasia of the cavernous arteries (Montague et al, 1995) or veno-occlusive dysfunction owing to aberrant cavernous venous drainage (Lue, 1999). The underlying cause of these congenital abnormalities is unknown. Treatment in most cases has been vascular surgery or implantation of a penile prosthesis.

Key Points: Other Causes of Erectile Dysfunction

- Aging is the single most important contributing factor to ED. The aging process can affect the central regulatory mechanism, hormonal and neural function, and penile structure.
- Diabetes mellitus and metabolic syndrome may affect multiple organ systems and cause premature aging of both central and peripheral structures and molecules that regulate erectile process.
- The diseases that cause chronic renal failure may also cause ED, and the condition may persist in spite of successful renal transplantation.
- Primary ED may be due to psychogenic cause, inexperience, congenital arterial insufficiency or abnormal venous channels.

PERSPECTIVES

The past two decades have seen a continuing explosion of new information on the physiology of penile erection and the pathophysiology of ED. These new discoveries not only enhance our understanding of the disease process but also provide a solid basis for improving our diagnosis and treatment. We can expect that the application of new research tools and information in molecular biology, signal transduction, growth factors, microarrays, and stem cells will bring the investigation of erectile function and dysfunction to an even higher level in the near future.

Key Points: Pathophysiology

- The prevalence of ED increases with age and concomitant medical diseases. The incidence is about 25 to 30 cases per thousand person-years.
- ED is a symptom of many underlying conditions and diseases.
- Any condition that affects penile nerve, artery, endothelium, smooth muscle, or tunica albuginea can cause ED.
- Endothelial dysfunction seems to be a common final pathway to ED in patients with hyperlipidemia, diabetes mellitus, hypertension, and chronic renal failure.
- Drugs most commonly associated with ED include antiandrogens, antidepressants, and antihypertensives.

Evaluation and Management of Erectile Dysfunction

Arthur L. Burnett, MD, MBA, FACS

Historical Perspective
Public Health Significance
Management Principles
Diagnostic Evaluation
Specialized Evaluation and Testing
Treatment Considerations
Future Directions

HISTORICAL PERSPECTIVE

Over just the past quarter century, the clinical management of erectile dysfunction (ED) has changed remarkably (Table 24–1). This comment relates to the success of greatly improved therapeutic options in the field, well demonstrated by oral phosphodiesterase type 5 (PDE5) inhibitor pharmacotherapy. Previously, ED management was mostly empirical and frequently used options were psychoanalysis, sex therapy, and endocrine treatments. Other notional prescriptions ranged from aphrodisiacs and erection enhancement pills to penile rigidity-inducing devices and surgically implanted penile prosthetics.

The modern management of ED marks a surge in the science of penile erection and a trend toward applying an evidence-based methodology (guided by outcomes from controlled and systematic scientific research) in the evaluation and institution of clinical therapies. Movement in this direction was witnessed in the early 1970s with the development of penile revascularization as a plausibly curative intervention for ED, which hinged on new insights regarding the vascular etiopathology of the problem. Although the place of the surgery is today relegated to select ED clinical presentations, it nonetheless ushered in a new era for therapies having an evidentiary basis. This era espoused therapeutic applications based on real scientific advances, from deciphering the pathophysiologic grounds for ED to elucidating the essential biochemical and molecular factors governing the erectile response. Additionally, efficacies of treatments were demonstrated by way of proper clinical investigation. Innovative pharmacologic delivery routes including intracavernosal, intraurethral, and oral treatments were similarly devised and introduced successively in the 1980s, mid-1990s, and late 1990s.

Besides advances in its therapeutic dimension, the field emerged overall as a recognized clinical discipline. Additional highlights in this regard included reaffirmations of its nosological foundations and its principles of practice for the patient with ED. Physiologic penile erection and its impairment were described within the context of the male sexual response cycle, and the historically pejorative and ambiguous term "impotence" was replaced with the more euphemistic and well-defined term "erectile dysfunction." Along the way, the importance of the patient's subjective claim of the existence of the problem was fully recognized, with emphasis given to the roles of both the patient and partner in its evaluation and management. Lue originally proposed the concept of the "goal-directed approach" for the management of ED, recognizing that lesser-invasive, reversible therapeutic methods had become available by the 1980s that did not require extensive and costly diagnostic testing before their implementation (Lue, 1990). The approach pronounced the imperative role of the clinician in performing a standard evaluation on the basis of a thorough and adequate sexual, medical, and psychosocial history in combination with a focused physical examination and select laboratory testing. However, it also acknowledged that diagnostic and therapeutic decisions should rely on the goals and preferences of the patient (and partner). This manner emphasizes the "patient-centered" intent brought to ED management (Rosen et al, 2004c).

The clinician's responsibility in recognizing and managing ED, as for all sexual dysfunctions, has gained the support of many thought leaders in the field of sexual medicine. Guidelines for the management of sexual dysfunctions with worldwide acceptance have resulted from numerous consensus meetings. Prominent among these were the series of International Consultations on Sexual Medicine (ICSM), cosponsored variously by the World Health Organization, International Consultation on Urological Diseases, American Urological Association, Société Internationale d'Urologie, and the International Society for Sexual Medicine, the first held in July 1999 with subsequent conferences convened in July 2004 and in July 2009 (Jardin et al, 2000; Lue et al, 2004; Montorsi et al, 2010). **Published proceedings from these congresses established diagnostic and therapeutic algorithms, which were founded on the principles of the goal-directed clinical management approach and obliged the trained clinician/physician to assess the patient and couple completely and prescribe therapy appropriately. They have also proclaimed that sexual medicine should be practiced in accordance with the highest standards of ethics, quality, safety and cost-effectiveness.**

PUBLIC HEALTH SIGNIFICANCE

ED is a medical condition of major health significance, with implications that extend beyond treating the occasionally presenting patient who possesses a problem of seemingly non-life-threatening magnitude. **The value of properly assessing and managing ED relates not only to affected individuals and their partners but also to society as a whole, and its scope encompasses physical and mental wellness aspects related to addressing (or failing to address) the sexual dysfunction, concurrent disease management issues, and socioeconomic burden.**

Epidemiology

Epidemiologic investigation, which specifies that study results are readily generalized to the overall male population, has provided powerful information regarding the nature, etiology, and prognostic ramifications of ED. **The most thoroughly studied sexual dysfunction in the context of epidemiologic research, ED is estimated to carry an overall adult male (older than 20 years of age) prevalence rate of 10% to 20% worldwide, with the majority of studies reporting a rate closer to 20%** (Derogatis and Burnett, 2008). It was estimated that there were more than 152 million men worldwide who experienced ED in 1995, with a projection of the prevalence reaching approximately 322 million men having ED by 2025 (Aytac et al, 1999). This trend is maintained irrespective of racial/ethnic background or geographic region. **Current data have also confirmed that the prevalence of ED mounts with increasing age and the presence of comorbid medical conditions, which include type 2 diabetes mellitus, obesity, cardiovascular disease, hypertension, dyslipidemia, depression, and prostate disease/benign prostatic hypertrophy (BPH)** (Braun et al, 2000; Martin-Morales et al, 2001; Nicolosi et al, 2004; Rosen et al, 2004b; Saigal et al, 2006; Laumann et al, 2007; Selvin et al, 2007). This correlation has supported the premise that ED and comorbid medical conditions share pathophysiologic mechanisms such as endothelial dysfunction, arterial occlusion, and systemic inflammation (Solomon et al, 2003; Montorsi et al, 2004; Billups, 2005; Ganz, 2005; Kloner, 2005; Guay, 2007).

Although they are few in number, prospectively conducted longitudinal studies have documented the true incidence and disease risk relationships for ED. In one study, a crude ED incidence rate was 25.9 cases/1000 man-years among men aged 40 to 69 years (Johannes et al, 2000). According to another study, incident ED statistics were 57% at 5 years and 65% at 7 years in men 55 years or older (Thompson et al, 2005). **Such studies have uniquely affirmed predictors for the development of ED, which include age, lower education, diabetes, cardiovascular disease, hypertension, cigarette smoking, cigar smoking, passive exposure to cigarette smoke, and overweight condition** (Feldman et al, 2000; Johannes et al, 2000; Inman et al, 2009).

However, the strength of the risk association is also gauged from the opposite analytic direction, and incident ED may indeed inform the risk of subsequent disease morbidity and mortality. This relationship has been best demonstrated so far with respect to cardiovascular disease. The placebo arm of the Prostate Cancer Prevention Trial found that ED is a sentinel for future risk of cardiovascular events, comparable with that of current cigarette smoking or a family history of myocardial infarction (Thompson et al, 2005). This study established that men with ED were 45% more likely than men without ED to experience a cardiac event after 5 years of follow-up (Thompson et al, 2005). In another population-based study of community-dwelling men followed longitudinally, ED was associated with an approximately 80% higher risk of subsequent coronary artery disease at 10 years (Inman et al, 2009). In a long-term follow-up (15 years) of the Massachusetts Male Aging Study (Feldman et al, 1994), ED was found to be positively associated with subsequent all-cause and cardiovascular disease mortality and constituted a risk in this regard similar to that of conventional risk factors such as increased body mass index, diabetes, and hypertension (Araujo et al, 2009). **These compelling data, considered alongside results generated from multiple smaller clinical cohort studies in the field, have contributed profoundly toward the understanding that the diagnosis of ED represents a clinical barometer of overall male health status and further serves to catalyze efforts to prevent disease, promote health and, moreover, improve survival.**

Health Policy

Sexual dysfunctions and ED specifically have taken on increasing importance with respect to their socioeconomic impact. **Besides its medical comorbidity associations, ED is recognized to**

adversely affect quality of life, decrease occupational productivity, and increase health care resource utilization (Krane et al, 1989; Litwin et al, 1998). Because of the heightened ease of use and availability of effective first-line treatments combined with a growing societal awareness of ED and acceptance of its treatment, it is understandable that a trend toward increased health care services utilization surrounding ED has been observed (Wessells et al, 2007).

ED can be included among a host of urologic diseases having a substantial burden on the public financially. Total expenditures for outpatient clinical management of ED (exclusive of pharmaceutical costs) in the United States in 2000 approximated $330 million, ranking ninth most costly among most frequent urologic diagnoses (Litwin et al, 2005). By contrast, this cost was approximately $185 million in 1994 (Wessells et al, 2007). Individual-level expenditures on an annual basis associated with an ED diagnosis (inclusive of pharmaceutical costs) among affected 18- to 64-year-old males in the United States in 2002 were calculated to be $1107 (Wessells et al, 2007). These data have enormous implications for governmental, as well as nongovernmental agencies in the United States and worldwide, whose work must consider the practical distribution and fiscal allocation of health care services for ED.

Key Points: Epidemiology and Health Policy

- Approximately 20% of adult men worldwide experience ED.
- Risk factors for ED include increasing age and presence of comorbid medical conditions such as type 2 diabetes mellitus, obesity, cardiovascular disease, hypertension, dyslipidemia, depression, and prostate disease/BPH.
- Between 1994 and 2000, expenditures solely for outpatient clinical management of ED in the United States nearly doubled from $185 million to $330 million.
- ED ranks among the top 10 most costly urologic diagnoses in the United States and must be included in considerations for fiscal allocation of health care services.

MANAGEMENT PRINCIPLES

The approach to the evaluation and treatment of ED is most assuredly different from that of many other urologic diseases in several basic respects. The diagnosis of ED customarily involves an acknowledgment of the subjective complaint of erectile inability by the patient (or patient and partner), and extensive diagnostic procedures are generally not required to proffer the diagnosis. Additionally, current first-line intervention in the form of effective oral pharmacotherapy is easily prescribed and administered and is frequently successful for the majority of patients. **However, notwithstanding the semblance that the management of ED is fairly uncomplicated, it is a structured process that critically incorporates several clinical practice concepts for bringing the best therapeutic outcomes to patients.**

Early Detection

Epidemiologic and clinical investigation has suggested that many patients with ED retain adverse clinical conditions and also lifestyle factors (e.g., diabetes, cardiovascular disease, prostate disease, overweight condition, current cigarette smoking, physical inactivity) that potentially compromise erectile function (Saigal et al, 2006; Laumann et al, 2007; Selvin et al, 2007). It is estimated that as much as 75% of men with diabetes have ED to some degree (Hakim and Goldstein, 1996). Similar rates of ED diagnoses are described for men presenting clinically with other chronic diseases, which constitute risk factors for ED (Jackson, 1999; Burchardt et al, 2000; Montorsi et al, 2003b; Solomon et al, 2003).

In addition to adverse health conditions having risk associations with ED, medication use has also been associated with ED in up to 25% of presentations (Keene and Davies, 1999; Francis et al, 2007). The most commonly implicated classes of drug include antihypertensive drugs such as thiazide diuretics and β-adrenoceptor antagonists and psychotherapeutic drugs, particularly selective serotonin reuptake inhibitor (SSRI) antidepressants. Table 24–2 lists several drug classes commonly associated with ED. It is importantly recognized that medications may affect other components of the male sexual response cycle including sexual desire, arousal, and orgasm, which secondarily hampers erectile function. Of additional importance, the assignment of causation of ED for any particular medication is conditional, requiring that an increased prevalence exists in the target population compared with the placebo group after stratification for known risk factors or compared with another drug with an equivalent therapeutic effect, and further, a credible physiologic mechanism should be established experimentally (Sáenz de Tejada et al, 2005).

Calculated odds ratios underscore the extent to which various ED risk factors correlate with ED (Table 24–3). **These data**

Table 24–2.
Drugs Associated with Erectile Dysfunction

CLASS	SPECIFIC AGENTS
Antihypertensives	Thiazide diuretics, nonselective β-blockers
Antidepressants	Tricyclics; selective serotonin reuptake inhibitors
Antipsychotics	Phenothiazines
Antiandrogens	Nonsteroidal (flutamide); steroidal (cyproterone acetate); luteinizing hormone-releasing hormone analogues
Antiulcer drugs	Histamine H_2 receptor antagonists (cimetidine)
Cytotoxic agents	Cyclophosphamide, methotrexate
Opiates	Morphine

Antihypertensive use	4.0

From Selvin E, Burnett AL, Platz EA. Prevalence and risk factors for erectile dysfunction in the US. Am J Med 2007;120:151–57; and Francis ME, Kusek JW, Nyberg LM, Eggers PW. The contribution of common medical conditions and drug exposures to erectile dysfunction in adult males. J Urol 2007;178:591–6.

support the contention that patients with identifiable ED risk factors likely experience the sexual dysfunction currently or will eventually develop it at some time. Clinical screening of such patients based on these indications may allow advantageous opportunities to diagnose and treat ED.

Goal-Directed Management

A goal-directed approach to the management of patients with ED has largely been practiced in the field over the past two decades since Lue's original description (Lue, 1990). The approach dictates that the diagnostic evaluation and therapeutic plan relates to the individual patient's presentation and manner of deriving satisfaction, in accordance with a patient-centered framework (Hatzichristou et al, 2010). **The basic aim of goal-directed management is to allow the patient or couple to make an informed selection of the preferred therapy for sexual fulfillment on the basis of a sound understanding of all treatment options after completing a thorough discussion with the treating clinician. The approach recognizes that patients vary in their acceptance of their sexual disorders and in their interest to pursue management. Their decisions accordingly follow individual preferences, needs, and expectations regarding management options.** Evaluations of this approach have affirmed its utility and demonstrated that patient therapeutic preferences accord with the least invasive forms of therapy (Jarow et al, 1996; Hanash, 1997).

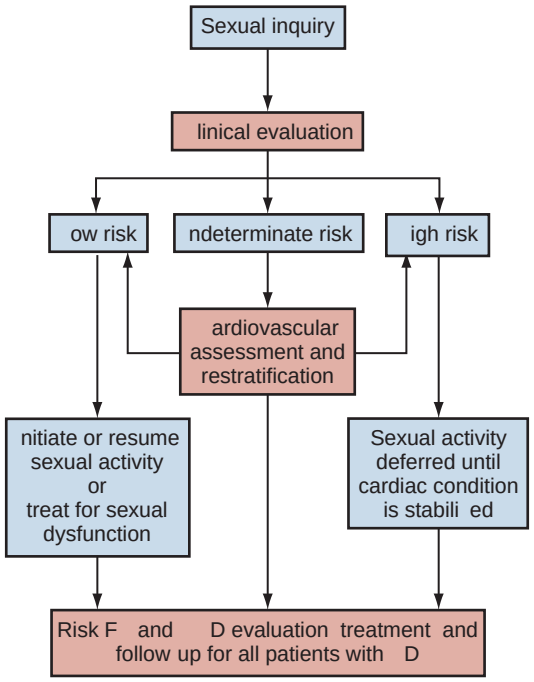

Figure 24–1. Algorithm for evaluation of the patient with cardiovascular disease recommended by the Second Princeton Panel. CHD, coronary heart disease; ED, erectile dysfunction; FX, factors.

Role of Partner Interview

The partner interview is a critical component in initiating management of ED. Partner interviews have been shown to impact diagnosis and treatment in up to 58% of cases (Tiefer and Schuetz-Mueller, 1995; Chun and Carson, 2001). **The partner may be the source of important information that guides optimal intervention and response to therapy. The partner may share a new and different perspective on sexual issues affecting the couple, provide insight into the quality of the couple's relationship, and relate his/her role in the sexual dysfunction** (Speckens et al, 1995; Fisher et al, 2009). **The partner's involvement and attitude may also affect the patient's initiation of and adherence to therapy** (Jackson and Lue, 1998; Fisher et al, 2005).

An important additional consideration is that partners' well-beings may be affected by the patients' ED conditions. Studies have shown that women partners of men with ED are themselves more likely to have sexual dysfunction or to cease sexual activity entirely (Ichikawa et al, 2004; Montorsi and Althof, 2004; Fisher et al, 2005; Sand and Fisher, 2007). This observation further prompts the facilitatory role of the partner in ED management, which maximizes the success of therapy and inherently satisfaction of the couple.

In practice, additional office visits as needed, in which the partner accompanies the patient, and the communication of educational information to the partner via the patient are recommended techniques for involving partners in ED management (Dean et al, 2008).

Cardiac Risk Assessment

The frequent coexistence of ED and cardiovascular disease, as established by clinical epidemiologic study and by basic science research, has steered ED management to include procedures that account for the ED patient's cardiovascular health risks. The second Princeton Consensus Guidelines Panel reinforced the linkage between sexual activity and cardiac risk, which was acknowledged with the first conference (DeBusk et al, 2000), and pronounced that all men with ED, even in the absence of manifesting cardiac symptoms, should be regarded as having potential risks for cardiovascular disease (Kostis et al, 2005; Jackson et al, 2006).

ED patients are recommended to undergo a full medical assessment with stratification of cardiovascular risk as high, medium, or low (Fig. 24–1). **Patients classified as having high risk would be those with unstable or refractory angina, a recent history of myocardial infarction, certain arrhythmias, or uncontrolled hypertension. For these patients, sexual activity with any particular ED therapy should be deferred until the cardiac condition is stabilized. Such patients should ideally undergo cardiologic referral for cardiovascular stress testing and subsequent risk reduction therapy. Importantly, even patients at low risk for cardiovascular events should receive the minimum recommendations of cardiovascular disease management.** Basic intervention includes counseling for lifestyle modifications such as increased physical activity and improved weight control combined with regular health monitoring by the patient's general practitioner (Kostis et al, 2005).

Step-Care Approach

Practitioners of ED management have always sought a rational approach for implementing diagnostic and therapeutic options. The "Process of Care Model for Erectile Dysfunction" was proposed as a stepwise methodology, combining processes, actions,

and outcomes in the management of the ED patient (Process of Care Consensus Panel, 1999). **It specified an algorithm for therapeutic decision making that takes into account patient needs and preferences (goal-directed management), although it was also based on specific criteria such as ease of administration, reversibility, relative invasiveness, and cost of therapies. This algorithm presented a strategy of staged therapy (i.e., first-, second-, and third-line interventions), which ranged from lifestyle modification to surgery.** In concept, the scheme has been borrowed and endorsed by other consensus panels, which acknowledged the purpose of patient education and counseling along with medical therapies as initial forms of ED management in common practice (Montague et al, 2005; Hatzichristou et al, 2010).

Shared Decision Making and Treatment Planning

The therapeutic plan may vary for each patient and couple and ultimately depends on a host of factors including patient considerations and clinical indications and contraindications. **An informed decision-making process should dictate the best therapeutic option. It follows a balanced and thorough discussion led by the clinician of all treatment options, both medical and nonmedical, and their expected advantages and disadvantages. Perceived risks and benefits, which may be influenced by the individual clinical situation, should be weighed.** It is understood that the patient may appropriately select a preferred treatment option without necessarily adhering to a strictly prescribed succession of attempted therapies. Indeed, the patient may elect to defer treatment altogether. Whatever the patient (or couple) chooses, this option can then be pursued within the boundaries of safety, under the supportive partnership of his clinician.

Specialist Referral

The advent of effective oral pharmacotherapy for ED has recently enabled many primary practitioners to feel comfortable with managing the majority of clinical presentations of ED. At the same time, it is understood that situations arise in which the patient or primary practitioner may request the assistance of a consultant/specialist (e.g., cardiologist, endocrinologist, psychologist, urologist) for further diagnostic evaluation and treatment beyond the boundaries of initial management (Process of Care Consensus Panel, 1999). **Such referrals may be required for individuals with complicated or atypical presentations of ED, representing diagnostic challenges that exceed common clinical practices of nonspecialists. Specialized evaluation and management potentially offer improved therapeutic outcomes for these presentations.**

Generally recommended indications for specialized evaluations and associated consultants are failure of initial treatment, referred to a urologist; younger patients with a history of pelvic or perineal trauma, referred to a urologist; patients with significant penile deformity (e.g., Peyronie disease, congenital chordee), referred to a urologist; complicated endocrinopathies (e.g., secondary hypogonadism, pituitary adenoma), referred to an endocrinologist; complicated psychiatric or psychosexual disorders (e.g., refractory depression, hypoactive sexual desire), referred to a psychiatrist; presentations requiring vascular or neurosurgical intervention (e.g., aortic aneurysm, lumbosacral disc disease), referred to a vascular surgeon or neurosurgeon, respectively; medicolegal reasons (e.g., workman's compensation claims), referred to a urologist.

A caveat is that effort should be taken at the time of referral to be sure that patients are fully informed about the rationale, costs, potential risks, and potential outcomes of the referral and possible additional procedures. This recommendation is made in accordance with the principles of patient-centered medicine, by which patients (and partners where possible) should be included in the decision-making process.

Follow-up Care

Follow-up care is an essential part of ED management and should not be overlooked. The objectives of this action are manifold. **A primary basis is to ensure continual success with the therapeutic outcome. It has been shown that treatment discontinuation occurs at high rates among patients who are not reassessed regularly** (Albaugh et al, 2002). Additional purposes are to reassess medical and psychosocial conditions adversely impacting ED and success of therapy, evaluate the need for dosage titration or treatment substitution, and monitor adverse drug interactions or drug interaction effects. As always, follow-up attention offers educational opportunities for patient and partner with regard to addressing sexual health concerns, as well as lending guidance for related health care matters.

DIAGNOSTIC EVALUATION

The cornerstone in the evaluation of ED involves a detailed case history, preferably taken from patient and partner, physical examination, and proper laboratory tests (Fig. 24–2). **The diagnosis can be submitted on the basis of an individual's report of consistent inability to attain and maintain an erection of the penis sufficient to permit satisfactory sexual intercourse** (NIH Consensus Statement, 1992; Lewis et al, 2004). It is noteworthy that the original National Institutes of Health definition did not specify a parameter for the duration of symptoms to accept the diagnosis. Subsequent organizational statements did apply a 3-month interval as a minimal requirement diagnostically, except for cases of trauma or surgically induced ED (Lewis et al, 2004).

Sexual, Medical, and Psychosocial History

The comprehensive assessment of any sexual problem begins with the performance of a detailed case history including sexual, medical, and psychosocial components. The clinician may employ brief checklists or questionnaires for the purpose of recognizing the problem and initiating its evaluation, although he or she should standardly perform a detailed interview to understand the nature of the sexual complaint. The sexual history component in particular should be elicited with utmost sensitivity, given the intrapersonal and interpersonal aspects of sexual dysfunction (Rosen et al, 2004c). Additional emphasis has recently been given to providing cultural competence when interacting with patients (Hatzichristou et al, 2010). **All discussion of sexual matters is done privately and**

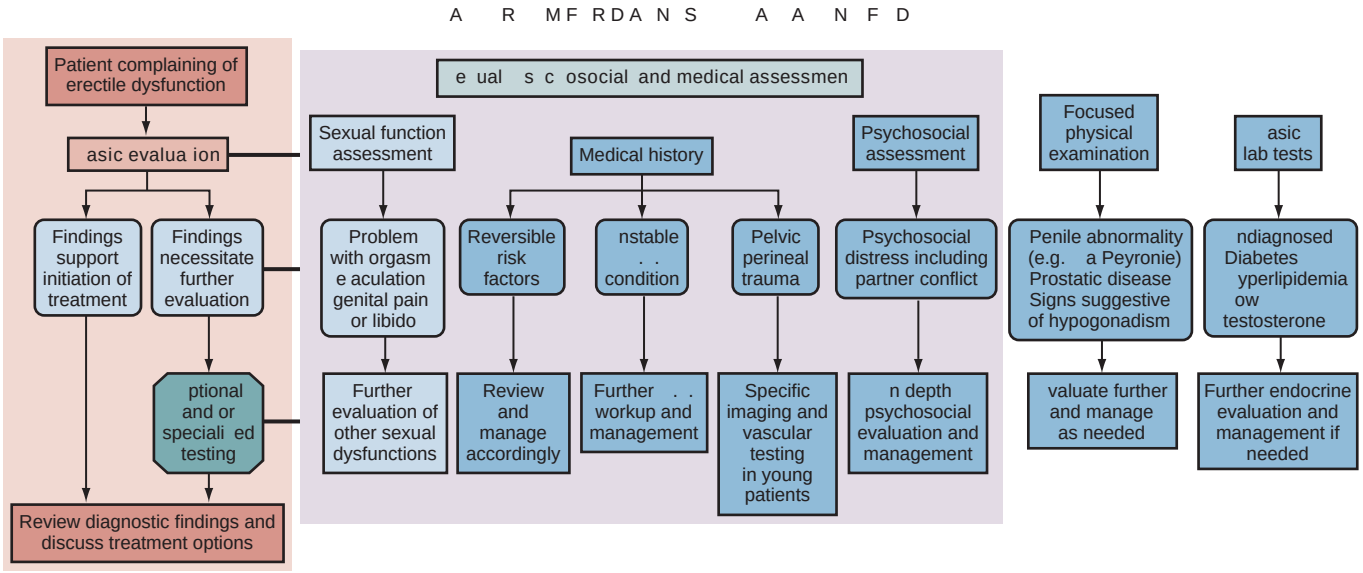

Figure 24–2. Diagnostic algorithm for erectile dysfunction (ED) recommended by the International Consultations on Sexual Medicine.

confidentially, and the clinician is required to express trust and concern, as well as a nonjudgmental manner that epitomizes the doctor-patient relationship. The clinician should not assume that every patient is involved in a monogamous, heterosexual relationship. However, the situation may be presented whereby the partner can be interviewed, and this opportunity may be used, with the approval of the patient, to corroborate aspects of the clinical history and confirm mutual therapeutic goals.

Sexual History

The sexual history is the central component of the clinical history and serves to confirm the patient's sexual dysfunction complaint of ED. **Objectives of the interview are also to delineate the problem according to such features as its onset, duration, conditions, severity, and etiology. The conditions of the problem are often determined by reviewing circumstances that facilitate or hinder erectile function.** Circumstances for achievable erections include stimuli used during sexual encounters, erections on awakening, and the role of self-stimulation. Circumstances associated with erectile difficulty include performance anxiety, inability to perform with a designated partner, and motivational factors affecting lovemaking. Other pertinent issues include availability, interest and health of the partner, changes in medical status or other events relating to the onset of ED, and prior attempts to manage the problem by the patient or another caregiver.

The severity of ED can be defined as mild, moderate, or severe/complete, according to increasing degrees of loss of penile rigidity and the associated interference with sexual activity. For instance, mild ED may refer to minimally decreased ability to attain and/or maintain an erection with intermittent satisfactory sexual performance, moderate ED may refer to minimally decreased ability to attain and/or maintain an erection with infrequent satisfactory sexual performance, and severe ED may refer to substantially decreased ability to attain and/or maintain an erection with rare or absent satisfactory performance.

The potential etiology of ED is commonly probed and may be categorized as psychogenic, organic, or mixed according to whether there is a presumed psychologic or interpersonal determinant (psychogenic); a specific endocrinologic, neurologic, or cardiovascular cause (organic); or coexistence of psychologic or relationship factors and organic causes (mixed) (Table 24–4) (Ralph and McNicholas, 2000). It is accepted that ED many times cannot be fully dichotomized into psychogenic and organic categories. However, its characterization by a predominant etiologic basis may nonetheless assist therapeutic objectives. The interview should also assess whether ED is the primary source of the presenting complaint or secondary to some other aspect of the sexual response cycle (e.g., desire, ejaculation, orgasm) that may also relate to the clinical presentation (Rosen et al, 2004c). The association of decreased arousal, if present, may be explored as well and evaluated as to whether it preceded or was incidental to the development of ED.

Table 24–4.
Classification of Erectile Dysfunction

PSYCHOGENIC	ORGANIC
Sudden onset	Gradual onset
Complete immediate loss	Incremental progression
Situational dysfunction	Global dysfunction
Waking erections present	Waking erections poor/absent

Adapted from Ralph D, McNicholas T. UK management guidelines for erectile dysfunction. BMJ 2000;321:499–503.

Medical History

The medical history primarily serves to identify and evaluate predictors and risk factors associated with ED. **The main objective is to explore the role of possibly related or underlying medical conditions and to ascertain the existence of comorbidities. Recognition of the association between medical conditions and ED not only may lend insight into the possible basis for the ED, which may guide choice of therapy, but it may also specify reversible or treatable factors associated with ED that may be**

corrected with an expectation of improving the level of erectile function.

Medical conditions associated with ED include disease states (e.g., type 2 diabetes mellitus, cardiovascular disease, hypertension, dyslipidemia, neurologic disease, hypogonadism, thyroid disorders); consequences of trauma involving aspects of the body, pelvis, or genitalia (e.g., spinal cord injury, pelvic surgery or radiation, sexual injury); and side effects of medications or recreational substances that disturb biochemical processes of penile erection. Age is recorded, in accordance with the well-known association between aging and ED. Comorbidities (e.g., depression, anxiety, anger) are importantly registered because of their bidirectional relationship with ED.

Psychosocial History

The intake of psychosocial history is a necessary part of the clinical history. **The very best sexual performance most assuredly implies wellness of mind and body acting together, and unstable psychosocial circumstances of both intrapersonal and interpersonal contexts may adversely affect sexual function.** Accordingly, the presence and interaction of mental health problems, emotional stressors, and interpersonal relationship difficulties, both past and present, should be ascertained. Additional questions may be asked relating to occupational status, financial security, family life, and social support, which may also influence sexual function.

Physical Examination

The physical examination is a necessary component of the comprehensive assessment of sexual dysfunctions and complements the clinical case history. It may reveal possible etiologies for ED.

This evaluation consists of basic anthropometrics (i.e., height, weight, waist circumference); assessment of body habitus (appearance of secondary sexual characteristics); and examination of relevant body parts pertaining to cardiovascular, neurologic, and genital systems, with a particular focus on the external genitalia. The observation of a classically distinctive body habitus consistent with Kallman or Klinefelter syndrome or obvious physical signs of hypogonadism such as gynecomastia and general poor masculine development may suggest an endocrinologic basis for ED.

Findings of obesity, elevated blood pressure, or abnormal femoral or pedal pulses—all signs representative of cardiovascular disease—convey a potential vascular causation. Findings of abnormal genital and perineal sensation or bulbocavernosus reflex, indicative of a peripheral neuropathy, suggest the involvement and effects of a neurologic disorder or diabetes.

Detection of a penile deformity such as micropenis, congenital chordee, or Peyronie disease–related fibrous plaques in the corpora cavernosa supports the possibility that a physical impediment accounts for ED. Genital examination findings of abnormal position, size, and consistency of testes may also suggest hypogonadism and suggests that ED exists on endocrinologic grounds.

Questionnaires and Sexual Function Symptom Scores

Self-administered ED questionnaires are extremely useful adjuncts to the case history, and they concur with the patient's self-report in establishing the diagnosis. Early supplied questionnaires in the field such as the Derogatis Sexual Function Inventory (245 items) (Derogatis and Melisaratos, 1979) and the Golombok Rust Inventory of Sexual Satisfaction (GRISS) (28 items) (Rust and Golombok, 1986) were detailed, and they commonly aimed to differentiate psychogenic and nonpsychogenic ED or evaluate sexual functioning in the context of the couple. More recently developed instruments were implemented primarily in clinical trials associated with new drug development, and they captured particular efficacy end points including sexual interest, performance, and satisfaction. However, as part of practice pattern shifts that have occurred in ED management in recent years, there has been a growing emphasis on and application of patient self-reported instruments for clinical practice. **These self-report measures have been meant to be brief and practical and to serve in documenting the presence, severity, and responsiveness to treatment of ED.**

The most widely referenced instruments include the International Index of Erectile Function (IIEF) by Rosen and colleagues (1997), the Brief Male Sexual Function Inventory (BMSFI) by O'Leary and colleagues (1995), the Center for Marital and Sexual Health Sexual Functioning Questionnaire by Glick and colleagues (1997), the Changes in Sexual Functioning Questionnaire by Clayton and colleagues (1997), and the Erectile Dysfunction Inventory of Treatment Satisfaction (EDITS) by Althof and colleagues (1999). The IIEF, which contains 15 items that address and quantify five domains—erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction—is the most widely used questionnaire (Fig. 24–3). An abridged five-item version of this instrument, the IIEF-5, has been useful to clinicians in routine clinical practice specifically for the evaluation of ED (Rosen et al, 1999). The instrument classifies ED severity into five categories: severe (5 to 7), moderate (8 to 11), mild to moderate (12 to 16), mild (17 to 21), and no ED (22 to 25). The Male Sexual Health Questionnaire offers another instrument that assesses core components of male sexual function (i.e., desire, erection, ejaculation, satisfaction) and has utility in both clinical and research settings (Rosen et al, 2004a). The Sexual Experience Questionnaire has also recently been developed as a tool for evaluating health-related quality of life concepts and comprises erection, individual satisfaction, and couple satisfaction domains (Mulhall et al, 2008).

A known limitation of self-administered questionnaires is that they do not distinguish an etiologic basis for ED, that is, they do not differentiate among the various causes of ED (Blander et al, 1999; Kassouf and Carrier, 2003). **Further, they may not sufficiently indicate the severity of ED that is evidenced on objective grounds** (Tokatli et al, 2006). Although the exact nature of the ED diagnosis arguably is not absolutely necessary to initiate ED treatment today with current management options, it is understood that further clinical evaluation with diagnostic tests may be required to discern the basis and extent of the ED by system (e.g., vascular, neurologic, endocrinologic) and take action that may be most effective and possibly corrective.

Laboratory Tests

Appropriate laboratory testing can be considered part of a systematic clinical evaluation for individuals presenting with ED. **Such evaluation may confirm or define etiologic medical conditions associated with the sexual dysfunction. At times, it may identify treatable conditions or previously undetected disease states that may contribute to ED.** A

Patient Name: _____ **MR#:** _____ **Date:** _____

OVER THE PAST 4 WEEKS

1. How often were you able to get an erection during sexual activity?
   0 No sexual activity
   1 Almost never/never
   2 A few times (much less than half the time)
   3 Sometimes (about half the time)
   4 Most times (much more than half the time)
   5 Almost always/always

2. When you had erections with sexual stimulation, how often were your erections hard enough for penetration?
   0 No sexual activity
   1 Almost never/never
   2 A few times (much less than half the time)
   3 Sometimes (about half the time)
   4 Most times (much more than half the time)
   5 Almost always/always

3. When you attempted sexual intercourse, how often were you able to penetrate (enter)?
   0 Did not attempt intercourse
   1 Almost never/never
   2 A few times (much less than half the time)
   3 Sometimes (about half the time)
   4 Most times (much more than half the time)
   5 Almost always/always

4. During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered) you partner?
   0 Did not attempt intercourse
   1 Almost never/never
   2 A few times (much less than half the time)
   3 Sometimes (about half the time)
   4 Most times (much more than half the time)
   5 Almost always/always

5. During sexual intercourse, how difficult was it to maintain your erection to complete intercourse?
   0 Did not attempt intercourse
   1 Extremely difficult
   2 Very difficult
   3 Difficult
   4 Slightly difficult
   5 Not difficult

6. How many times have you attempted sexual intercourse?
   0 No attempts
   1 One to two attempts
   2 Three to four attempts
   3 Five to six attempts
   4 Seven to ten attempts
   5 Eleven or more attempts

7. When you attempted sexual intercourse, how often was it satisfactory to you?
   0 Did not attempt intercourse
   1 Almost never/never
   2 A few times (much less than half the time)
   3 Sometimes (about half the time)
   4 Most times (much more than half the time)
   5 Almost always/always

8. How much have you enjoyed sexual intercourse?
   0 No intercourse
   1 No enjoyment
   2 Not very enjoyable
   3 Fairly enjoyable
   4 Highly enjoyable
   5 Very highly enjoyable

9. When you had sexual stimulation or intercourse, how often did you ejaculate?
   0 No sexual stimulation/intercourse
   1 Almost never/never
   2 A few times (much less than half the time)
   3 Sometimes (about half the time)
   4 Most times (much more than half the time)
   5 Almost always/always

10. When you had sexual stimulation or intercourse, how often did you have the feeling of orgasm or climax?
    0 No sexual stimulation/intercourse
    1 Almost never/never
    2 A few times (much less than half the time)
    3 Sometimes (about half the time)
    4 Most times (much more than half the time)
    5 Almost always/always

11. How often have you felt sexual desire?
    1 Almost never/never
    2 A few times (much less than half the time)
    3 Sometimes (about half the time)
    4 Most times (much more than half the time)
    5 Almost always/always

12. How would you rate your level of sexual desire?
    1 Very low/none at all
    2 Low
    3 Moderate
    4 High
    5 Very high

13. How satisfied have you been with your overall sex life?
    1 Very dissatisfied
    2 Moderately dissatisfied
    3 About equally satisfied and dissatisfied
    4 Moderately satisfied
    5 Very satisfied

14. How satisfied have you been with your sexual relationship with your partner?
    1 Very dissatisfied
    2 Moderately dissatisfied
    3 About equally satisfied and dissatisfied
    4 Moderately satisfied
    5 Very satisfied

15. How do you rate your confidence that you could get and keep an erection?
    1 Very low
    2 Low
    3 Moderate
    4 High
    5 Very high

Figure 24–3. International Index of Erectile Function Questionnaire.

standardized panel of tests can be offered for the man presenting routinely with sexual dysfunction including ED. Further laboratory testing can be tailored to the clinical situation. Similarly, specialized endocrinologic assessment can be performed when indicated for select clinical presentations.

Recommended laboratory tests for men with sexual problems typically include serum chemistries, fasting glucose, complete blood count, lipid profile, and serum total testosterone. Total testosterone, measured from a morningtime blood draw, serves to screen androgenic status and, if

abnormally low, serum-free (or bioavailable) testosterone and leutinizing hormone should be measured. Prolactin measurement may also be done for hormonal assessment. Thyroid function tests may be performed at the clinician's discretion. Serum PSA testing is performed as needed if prostate pathology is suspected that might be promoted by exogenously administered testosterone. Dipstick analysis of urine may reveal glucosuria, which suggests the diagnosis of diabetes.

SPECIALIZED EVALUATION AND TESTING

The implicit goal of specialized evaluations in medicine in general is to improve diagnostic accuracy and direct successful therapy on the basis of the specific diagnosis. A similar principle applies to sexual medicine. However, at the present time, despite the availability of various technologies that may specify and define the causation for ED (i.e., vasculogenic, neurogenic, endocrinogenic, psychogenic), the treatment plan for this sexual dysfunction can often be formulated without carrying out extensive diagnostic testing. **Nonetheless, such testing is frequently applied for diagnostic precision, typically by specialists, particularly in settings of complex clinical presentations.** Table 24–5 summarizes the most frequently used evidence-based test procedures for diagnostic evaluations of ED (Rosen et al, 2004c).

Vascular Evaluation

The vascular evaluation for ED conceptually connotes surveying the vascular requirements of the sexual organ for the erectile response: arterial blood inflow, blood engorgement, and blood retention within the corporal structures. **From a diagnostic standpoint, the studies aim to assist in deriving the classical diagnoses of arterial impairment and veno-occlusive dysfunction.** As for all diagnostic testing, hemodynamic tests of the penis require that the patient is counseled regarding the purpose, alternatives, risks, and benefits of any procedure before its implementation.

Combined Intracavernous Injection and Stimulation

The CIS test serves as a first-line evaluation of penile blood flow because of its basic manner of administration and assessment. **The test involves the intracavernous injection of a vasodilatory drug or drugs as a direct pharmacologic stimulus, combined with genital or audiovisual sexual stimulation, and the erectile response is observed and rated by an independent assessor** (Donatucci and Lue, 1992; Katlowitz et al, 1993). **The test is designed to bypass neurologic and hormonal influences involved in the erectile response and allows the clinician to evaluate the vascular status of the penis directly and objectively.**

The clinician may decide the protocol for using vasodilator drugs. Alternative regimens include alprostadil alone (Caverject or Edex, 10 to 20 µg), a combination of papaverine and phentolamine (Bimix, 0.3 mL), or a mixture of all three of these agents (Trimix, 0.3 mL). The procedure requires a syringe with a ⅝-inch needle (27 to 29 gauge), which is inserted at the lateral base of the penis directly into the corpus cavernosum for medication delivery. After needle withdrawal, manual compression is applied to the injection site for 5 minutes to prevent local hematoma formation. The assessment is done periodically afterwards to rate both rigidity and duration of response. Repeated dosing may be performed if the initial erectile response is poor. Return to penile flaccidity is required before allowing the patient to leave the office, and if detumescence does not occur spontaneously in approximately an hour after dosing, intracavernous injection of a diluted phenylephrine solution (500 µg/mL) can be done every 3 to 5 minutes until flaccidity returns.

A normal CIS test, based on the assessment of a sustainably rigid erection, is understood to signify normal erectile hemodynamics. Alternative diagnoses of psychogenic, neurogenic, or endocrinogenic ED may then be considered. However, it is known that false-positive results may occur in up to 20% of patients with borderline arterial inflow (as defined by the measurement of 25 to 35 cm/sec peak cavernous artery systolic

Table 24–5.
Evidence-Based Tests for Organic Erectile Dysfunction and Recommendations

TEST	RECOMMENDATION*
Vascular	
Dynamic infusion cavernosometry and cavernosography (DICC)	B
Intracavernous injection pharmacotesting (ICI)	B
ICI and color duplex ultrasound	B
Arteriography	C
Computed tomography angiography	D
Magnetic resonance imaging (MRI)	D
Infrared spectrophotometry	D
Radioisotope penography	D
Audiovisual Sexual Stimulation (AVSS)	
Independent or jointly with vascular testing	C
With or without: pharmacologic stimulation (oral, ICI)	C
Neurophysiologic	
Nocturnal penile tumescence and rigidity (NPTR)	B
Erectiometer/rigidometer	D
Biothesiometry (vibratory thresholds)	C
Dorsal nerve conduction velocity	C
Bulbocavernosus reflex latency	B
Plethysmography/electrobioimpedance	D
Corpus cavernosum electromyography (CC-EMG)	C
MRI or positron emission tomography scanning of brain (during AVSS)	D

*Grades of recommendation:
A: At least one meta-analysis, systematic review, or randomized controlled trial with a low level of bias and directly applicable to the target population.
B: A body of evidence including high-quality systematic reviews of case-control or cohort studies directly applicable to the target population and demonstrating overall consistency of results.
C: A body of evidence including well-conducted case-control or cohort studies with a low risk of confounding, bias, or chance and a moderate probability that the relationship is causal, directly applicable to the target population, with overall consistency of results.
D: Nonanalytic studies (e.g., case reports, case series, expert opinion).

Sexual medicine: sexual dysfunctions in men and women. Paris: Health Publications; 2004. p. 173–220; and Harbour R, Miller J. A new system for grading recommendations in evidence-based guidelines. BMJ 2001;323:334–6.

flow on duplex ultrasound) (Pescatori et al, 1994). False-negative results are also possible and occur most commonly because of patient anxiety, needle phobia, or inadequate dosage.

Duplex Ultrasonography (Gray Scale or Color Coded)

Duplex ultrasound of the penis following pharmacostimulation or CIS represents second-line evaluation of penile blood flow. **However, it is the most reliable and least invasive diagnostic modality for assessing ED. The test adds an imaging dimension and a quantification component to the evaluation of blood flow in the penis distinct from first-line evaluation, which relies on the assessor's judgment alone.**

The technique consists of high-resolution (7 to 10 MHz) real-time ultrasonography and color pulsed Doppler, which serves to visualize the dorsal and cavernous arteries selectively and to perform hemodynamic blood flow analysis (Lue et al, 1989). Scanning is applied to the surface of the penis and may include the entire penis from the crura in the perineum to the tip. Color-coded duplex ultrasound indicates the direction of blood flow within vessels, with red designating direction toward the probe and blue designating direction away from the probe (Broderick and Arger, 1993; Herbener et al, 1994). Flow velocities are measured at baseline before injection and commonly every 5 minutes afterwards up to 20 minutes. Cavernous arterial diameters may also be measured. Vascular anatomic communications between the paired cavernous arteries or between the dorsal and cavernous arteries should be noted (Fig. 24–4). Erection quality should also be simultaneously assessed and rated. An observed poor erection, possibly associated with patient anxiety, should prompt vasodilator redosing as recommended for the CIS test.

A standard pattern of Doppler waveforms occurs with hemodynamic changes in corporeal pressure during progression to normal full erection (Fig. 24–5) (Schwartz et al, 1991). In the filling phase when sinusoidal resistance is low (within 5 minutes after vasodilator injection), the waveform increases in size consistent with high forward flow during both systole and diastole. As intracavernous pressure increases, diastolic velocities decrease. With full erection, the systolic waveforms sharply peak and may be slightly less than during full tumescence. At maximal rigidity, when intracavernous pressure exceeds systemic diastolic blood pressure, diastolic flow may be zero. The sonographic color pattern of the cavernous artery may demonstrate an impressive shift from red to blue in association with the reversal of diastolic flow.

Normative values have been described for peak systolic velocity (PSV) and diameter of the cavernous arteries during increases in arterial inflow to the penis. Early studies documented that the PSV of the cavernous arteries consistently exceeded 25 cm/sec within 5 minutes of vasodilator injection in patients with nonarteriogenic causes of ED (i.e., psychogenic, neurogenic) (Lue et al, 1985; Mueller and Lue, 1988). Investigators subsequently confirmed mean PSV of cavernous arteries after pharmacostimulation to range from 35 cm/sec to 47 cm/sec in normal subjects (Benson and Vickers, 1989; Shabsigh et al, 1990). A cut point at 25 cm/sec

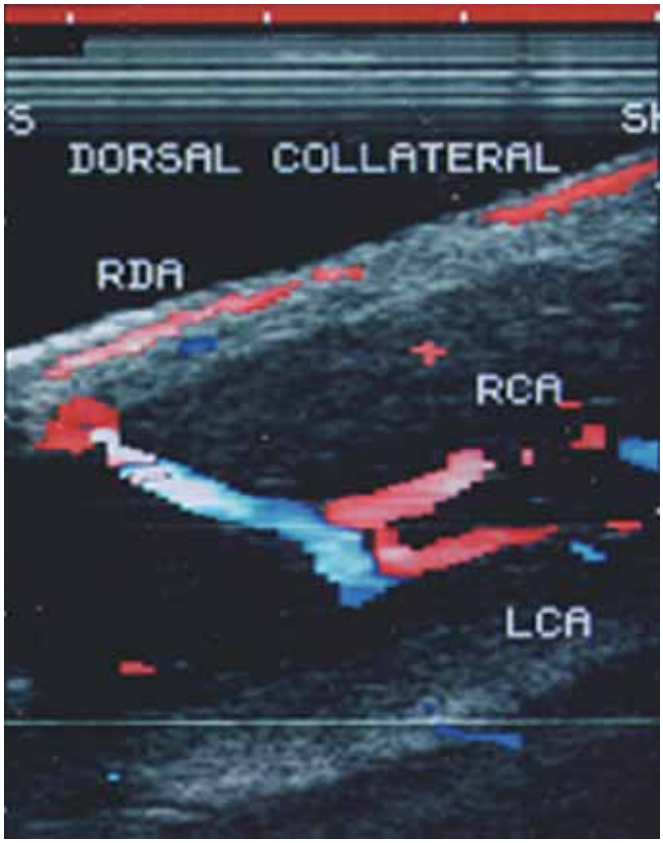

Figure 24–4. Collateral circulation connecting the right dorsal artery (RDA) to the right cavernous artery (RCA) and the left cavernous artery (LCA) is shown by color duplex ultrasound in a longitudinal view.

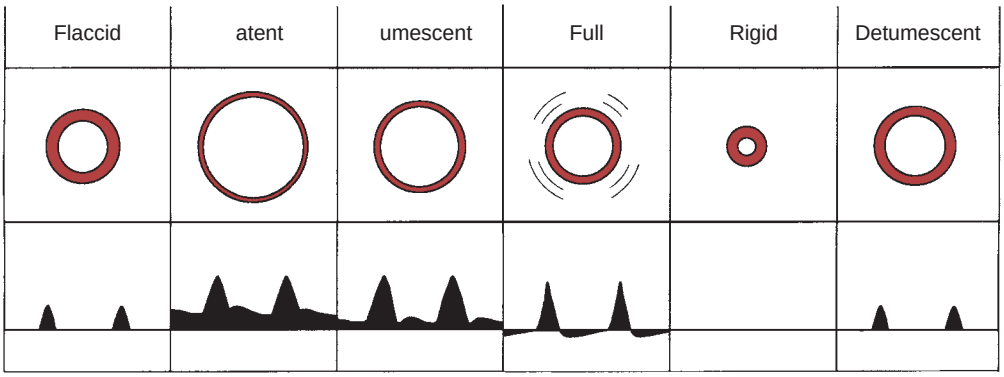

Figure 24–5. Artist's conception of the changes in diameter and flow waveform in the cavernous arteries induced by intracavernous injection of prostaglandin E_1 in a potent young man as demonstrated by duplex ultrasound. Forceful concentric pulsations are particularly noticeable during full erection.

had a sensitivity of 100% and a specificity of 95% in patients with abnormal pudendal arteriography (Quam et al, 1989). Diameter changes of the cavernous artery after vasodilator injection were found to increase less than 75% and rarely exceed 0.7 mm in patients with severe vascular ED (Lue and Tanagho, 1987; Mueller and Lue, 1988). Importantly, unlike PSV changes, percentage of cavernous arterial vasodilation was not found to correlate well with findings on pudendal arteriography (Jarow et al, 1993).

Vascular arterial anatomic variants may confound the interpretation of duplex ultrasonography (Breza et al, 1989; Jarow et al, 1993). Early cavernous arterial branching or the presence of multiple such branches may affect blood flow velocity determinations of the main cavernous artery. The presence of distal arterial perforators extending from the dorsal or spongiosal arteries also may alter the measurement of cavernous arterial blood flow velocity. Accordingly, the clinician must recognize these variants to avoid making the incorrect diagnosis of arteriogenic ED. On the other hand, asymmetric blood flow of the cavernous arteries may have diagnostic significance. The findings of dissimilar cavernous artery velocity measurements, which are greater than 10 cm/sec between sides, or reversal of flow across a collateral may suggest a significant atherosclerotic lesion (Benson et al, 1993).

Duplex ultrasound measurements are informative for diagnosing vasculogenic ED (Rosen et al, 2004c). **Cavernous arterial insufficiency is suggested when PSV is less than 25 cm/sec; a PSV consistently greater than 35 cm/sec defines normal cavernous arterial inflow.** Cavernous artery acceleration time (i.e., PSV divided by systolic rise time) greater than 122 msec may also indicate this diagnosis. Cavernous veno-occlusive dysfunction, which refers to failure of erection maintenance despite adequate cavernous arterial inflow, is suggested by assorted sonographic parameters. Generally meaningful at 15 to 20 minutes after stimulatory onset, these parameters include persistent high systolic flow velocities (i.e., PSV > 25 cm/sec) and high end-diastolic flow velocities (EDV > 5 cm/sec), accompanied by rapid detumescence, following stimulatory onset. In addition, vascular resistive index (RI), based on the formula: RI equals PSV minus EDV that is then divided by PSV, has had tremendous diagnostic utility in this regard. The parameter is based on the concept that, as penile intracavernous pressure during erection achievement equals or exceeds diastolic pressure, diastolic flow in the corporal bodies will approach zero and the value for RI will approach one. **An RI greater than 0.9 has been associated with normal penile vascular function, and that less than 0.75 is consistent with veno-occlusive dysfunction** (Naroda et al, 1996).

Several technical modifications of sonographic evaluation of the penis have been described. A portable Midus pulsed Doppler unit connected to a laptop computer for in-office testing reliably records the Doppler waveform of the cavernous arteries despite not providing a real-time ultrasound image (Metro and Broderick, 1999). Power Doppler offers an even more specialized technique to visualize distal ramifications of the main cavernous artery down to the level of arterioles (Sarteschi et al, 1998; Golubinski and Sikorski, 2002). A somewhat more invasive approach that evaluates the integrity of cavernosal arterial flow involves the measurement of the cavernous artery systolic occlusion pressure (CASOP) by a Doppler transducer during saline intracavernous infusion (Rhee et al, 1995). As a variation on the stimulatory component of penile sonographic testing, a combination of an oral PDE5 inhibitor in association with visual erotic stimulation has been shown to be an effective, noninvasive method (Bacar et al, 2001; Speel et al, 2001). Sonographically measured postocclusive vasodilation of the cavernous arteries, which is believed to relate to the level of intact endothelial function in the penis, has been found to be diagnostic for organic ED (Virag et al, 2004). Cavernous artery intima media thickness as demonstrated by high-resolution echo color Doppler ultrasound has been suggested to be more accurate than PSV in predicting vasculogenic ED (Caretta et al, 2009).

Dynamic Infusion Cavernosometry and Cavernosography

Cavernosometry and cavernosography, precisely referring to functional hemodynamic and radiographic assessments of the corpora cavernosa, represents third-line evaluation of the vascular integrity of the penis. **The testing is indicated for select patients who are suspected to have a site-specific vasculogenic leak resulting from perineal or pelvic trauma or who have had life-long ED (primary ED). When used, it generally precedes consideration for corrective penile vascular surgery.**

The technique involves two needles inserted into the penis for simultaneous saline infusion and intracavernous pressure monitoring following intracavernous pharmacologic injection. The testing requires complete trabecular smooth muscle relaxation to avoid erroneous results, and repeated and maximal pharmacologic dosing protocols are recommended (Hatzichristou et al, 1995). Measurements of maintenance flow rate, pressure drop, and CASOP are done to verify complete smooth muscle relaxation (Fig. 24–6).

Dynamic infusion cavernosometry and cavernosography evaluate the penile venous outflow system. **The existence of veno-occlusive dysfunction is indicated by the failure to increase intracavernous pressure to the level of the mean systolic blood pressure with saline infusion or the demonstration of a rapid drop of intracavernous pressure after cessation of saline infusion** (Puyau and Lewis, 1983; Rudnick et al, 1991; Shabsigh et al, 1991; Motiwala, 1993). The flow rate required to maintain erection at an intracavernous pressure of more than 100 mm Hg is normally less than 3 to 5 mL/min, and the pressure decrease in 30 seconds from 150 mm Hg is normally less than 45 mm Hg. **Cavernosography follows cavernosometric evaluation and is intended to reveal the site of venous leakage** (Fig. 24–7). With normal veno-occlusive function, there should be opacification of the corpora cavernosa with minimal or no visualization of venous structures or corpus spongiosum. With impaired veno-occlusive function, leakage may be identified into such sites as the glans, corpus spongiosum, superficial dorsal veins, and cavernous and crural veins. More than one site is visualized in the majority of patients (Lue et al, 1986; Rajfer et al, 1988; Shabsigh et al, 1991).

Penile Angiography

Penile angiography essentially refers to an anatomic study of the arterial vasculature of the penis and also represents third-line evaluation of the penile vascular system. **It is commonly reserved for the young patient with ED secondary to a traumatic arterial disruption or the patient with a history of penile compression injury, who is being considered for penile revascularization surgery.**

The procedure involves selective cannulation of the internal pudendal artery and injection of radiographic contrast. The intracavernous injection of a vasodilating agent is optimally used to induce maximal vasodilation of the penile arterial supply. The anatomy and radiographic appearance of the iliac, internal

pudendal, and penile arteries are then evaluated and documented (Fig. 24–8). The inferior epigastric arteries are frequently studied as well to determine their suitability for use in surgical revascularization. It should be recognized that significant variation of the intrapenile arterial anatomy exists, challenging the angiographer to differentiate congenital variations from acquired abnormalities and establish their clinicopathologic relevance (Bähren et al, 1988; Benson et al, 1993).

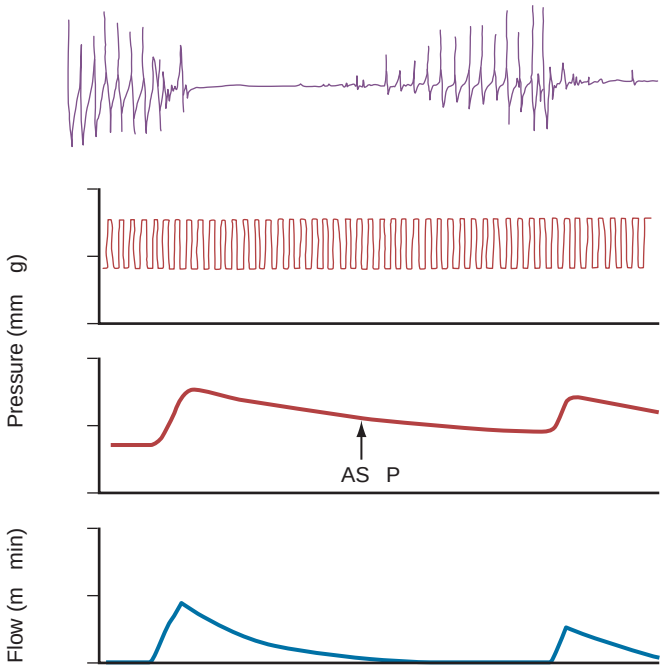

Figure 24–6. This tracing depicts four simultaneous variables obtained during the third phase of dynamic infusion cavernosometry and cavernosography. Top to bottom, Cavernosal artery flow recorded by using a continuous-wave Doppler ultrasound probe; systemic brachial systolic and diastolic arterial blood pressure (150/87 mm Hg); intracavernosal pressure, which varied from 70 to 160 mm Hg in this tracing; and intracavernosal heparinized saline inflow. The intracavernosal pressure at which the cavernosal artery pulsations returned, the effective cavernosal artery systolic occlusion pressure (CASOP), was 108 mm Hg. The gradient between the brachial and the cavernosal artery systolic occlusion pressures was 150 to 108, or 42 mm Hg, which is abnormal.

Historical and Investigational Studies of Penile Blood Flow

Penile Brachial Pressure Index

This test refers to the penile systolic blood pressure divided by the brachial systolic blood pressure. The technique involves applying a small pediatric blood pressure cuff to the base of the flaccid penis and measuring the systolic blood pressure with a continuous-wave Doppler probe. A PBI of 0.7 or less has been used to indicate arteriogenic ED (Metz and Bengtsson, 1981). **The technique has not been found to be valid, basically because it does not assess the hemodynamic properties of a functionally relevant, induced erection, and thus it is not recommended for use** (Aitchison et al, 1990; Mueller et al, 1990).

Penile Plethysmography (Penile Pulse Volume Recording)

This test evaluates arterial pressure waveforms in the penis with an aggregate of the contributions of all penile vessels (Kedia, 1983). It requires the application of a 2.5- or 3-cm cuff connected to an air plethysmograph applied to the base of the penis, inflating the cuff to a pressure above brachial systolic pressure, and then decreasing the pressure by 10–mm Hg increments while recording pressure waveform tracings. Abnormal pressure waveforms by diagnostic criteria have been used to indicate vasculogenic ED (Doyle and Yu, 1986). **Because this study is done in the flaccid penis like the PBI, its clinical relevance has been questioned.** Despite this concern, a technical modification that measures postischemic flow-mediated dilation was introduced as being informative regarding penile vascular endothelial function (Dayan et al, 2005; Vardi et al, 2009).

Radioisotopic Penography

This test quantifies changes in penile blood volume after intracavernous injection of a vasoactive agent using ^{99m}Tc-labeled red blood cells (Shirai et al, 1976). Extremely low flow is understood to mean arteriogenic ED (Smith et al, 1998). An evaluation comparing color Duplex ultrasound and radionuclide penography showed poor correlation (Glass et al, 1996).

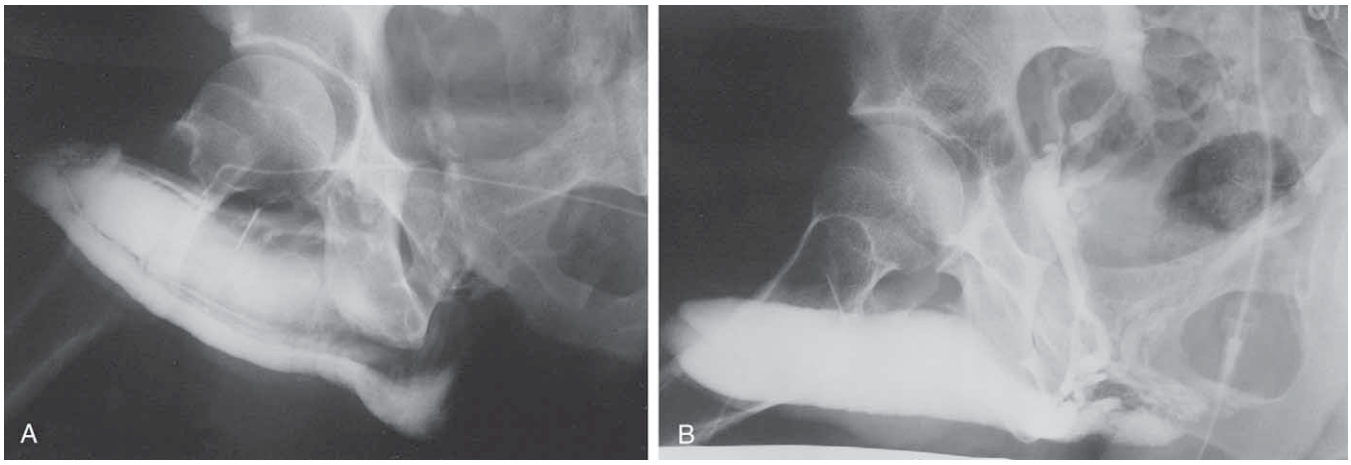

Figure 24–7. Pharmacologic cavernosography. **A,** In a patient 1 year after a penile fracture, a communication between the corpus cavernosum and the spongiosum is seen. **B,** In a 27-year-old man with primary impotence, venous leakage from the crura is seen.

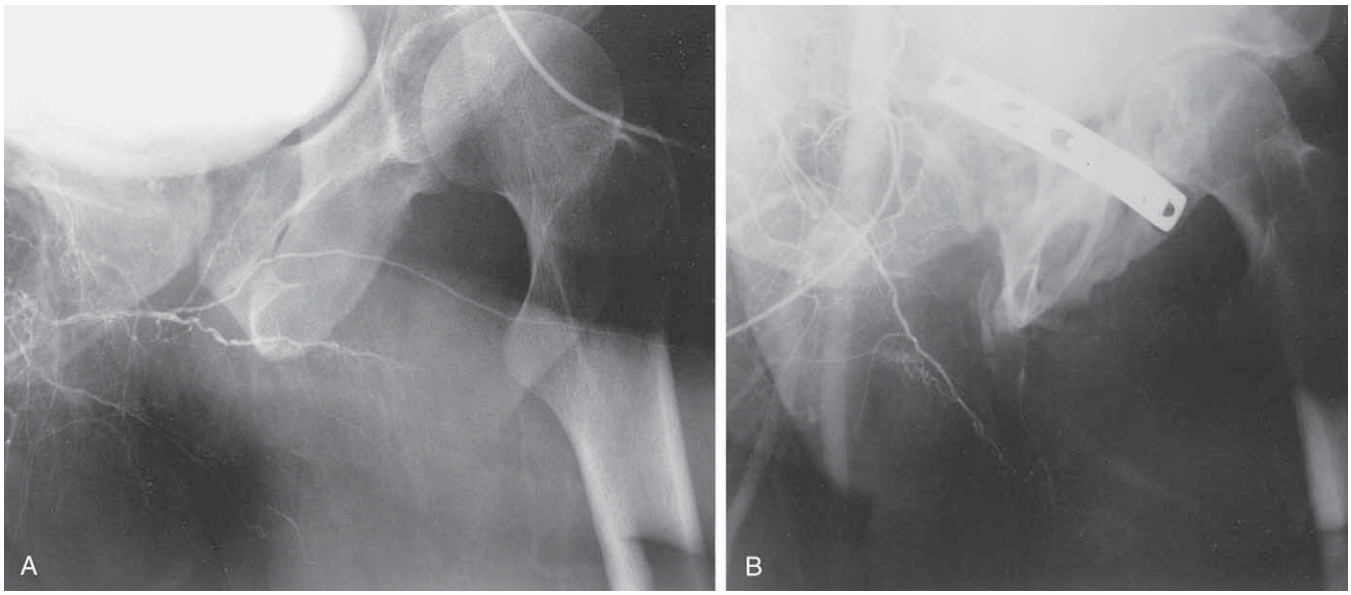

Figure 24–8. In this patient with a pelvic injury, pharmacologic penile arteriography (after intracavernous injection of 60 mg of papaverine) shows patent common penile, dorsal, and cavernous arteries **(A)** and nonvisualization of the common penile artery and its branches **(B)**.

Penile Magnetic Resonance Imaging

This test has significant potential applications for the assessment of anatomic details of the penis and penile microcirculation. Angiographic techniques may be combined with it to evaluate the anatomic condition of the internal iliac and penile vasculature. Magnetic resonance angiography has been shown to have good correlation with color duplex ultrasound testing (Stehling et al, 1997; John et al, 1999).

Penile Near-Infrared Spectrophotometry

This test provides continuous, quantitative measurements of penile blood flow using a specialized near-infrared spectrophotometry instrument (Burnett et al, 2000). It may be applied with an erectile stimulus and documents the hemodynamic phenomena of erection. Penile spectrophotometry has been further investigated in combination with intraurethral pharmacotherapy documenting blood flow increase to the penis with this erectogenic modality (Padmanabhan and McCullough, 2007). Further investigation of this technique is necessary to establish its clinical utility.

Cavernous Smooth Muscle Content

This test evaluates the smooth muscle composition of the corporeal tissue by light microscopic and computed morphometric assessment of biopsies of the penis and may serve adjunctively in the diagnosis of vasculogenic ED (Wespes et al, 1992). A reduced proportion of corporeal smooth muscle (and correspondingly increased collagen) has been observed in older men with veno-occlusive dysfunction (19% to 36% smooth muscle) and arteriogenic ED (10% to 25%), compared with that of young, healthy men with normal erections and penile curvature (40% to 52%) (Wespes et al, 1991). In part because of its invasiveness, the test is controversial and thus it remains investigational at present.

Psychophysiologic Evaluation

The psychophysiologic evaluation of ED seeks to evaluate the erectile response applying techniques that directly measure penile tumescence and rigidity. From the historical perspective of ED diagnostics, testing was applied primarily to differentiate psychogenic from organic ED. In general, the documentation of a full erection indicates functional integrity of the neurovascular axis regulating penile erection and thereby raises suspicion of a psychogenic etiology. There are several approaches to perform this evaluation. Importantly, the psychophysiologic evaluation does not currently represent first-line evaluation for ED, largely because of technical and cost limitations associated with current techniques. When considered to undergo any of these tests as part of a diagnostic plan, patients are counseled with regard to their expected utility and risks and benefits.

Penile Tumescence and Rigidity Monitoring

Nocturnal penile tumescence (NPT) monitoring, which describes the study of erections that occur with nighttime sleep, was classically described as a technique offering assessment of physiologic erectile ability (Wasserman et al, 1980). **Standardly, sleep laboratory nocturnal penile tumescence and rigidity (NPTR) testing applies nocturnal monitoring devices that measure the number of episodes, tumescence (circumference change by strain gauges), maximal penile rigidity, and duration of nocturnal erections** (Kessler, 1988). The conventional approach is to perform monitoring in conjunction with electroencephalography, electro-oculography, and electromyography (EMG), with nasal airflow and with oxygen saturation to document rapid eye movement (REM) sleep and the presence or absence of hypoxia (sleep apnea). Importantly, documentation of REM sleep is done because of the observation that true erectile phenomena occurring during sleep are associated with the REM sleep phase (Fisher et al, 1965). Sleep movement patterns are also monitored because periodic limb movement disorders are associated with abnormal NPT. Axial rigidity is measured along with photography of the erect penis on awakening the patient at maximal tumescence; a buckling device is applied to the tip of the penis to measure resistance (500 g minimum for vaginal penetration, 1.5 kg suggestive of complete rigidity) (Karacan et al, 1977). NPT has traditionally been performed over two to three nights to

overcome the so-called first-night effect when REM sleep is inconsistent. Formal testing, which involves a specially equipped sleep laboratory staffed with trained observers, is costly. The monitoring of diurnal penile tumescence, in reference to monitoring performed during daytime napping, has served alternatively as an in-office evaluation (Morales et al, 1994).

Rigiscan (Timm Medical Technologies, Inc. Minneapolis, MN) is an automated, portable device used for NPTR, which combines the monitoring of radial rigidity, tumescence, number, and duration of erectile events (Bradley et al, 1985). The device employs two loops, one placed at the base of the penis and the other placed at the coronal sulcus (respectively, base and tip recording sites), which record penile tumescence (circumference) and radial rigidity with timed, standardized constrictions of the loops. A baseline initialization is done with the patient in the office, and then it is calibrated for home use. At home, registrations of penile rigidity are done every 3 minutes and increased to every 30 seconds when the base loop detects a circumference increase of greater than 10 mm (Fig. 24–9). **Recommended criteria for normal NPTR include four to five erectile episodes per night, mean duration longer than 30 minutes, an increase in circumference of more than 3 cm at the base and more than 2 cm at the tip, and maximal rigidity above 70% at both base and tip** (Cilurzo et al, 1992). A computerized program has yielded standardized data measurements according to cumulative distribution of time-intensity measures, defined as tumescence activity units (TAU) and radial rigidity activity units (RAU) (Burris et al, 1989; Levine and Carroll, 1994). Potential limitations of Rigiscan include that radial rigidity does not accurately predict axial rigidity (Allen et al, 1993; Licht et al, 1995) and considerable variability apparently exists even in normal subjects (Levine and Carroll, 1994). Further, the manner of testing does not allow verification of the presence of REM sleep.

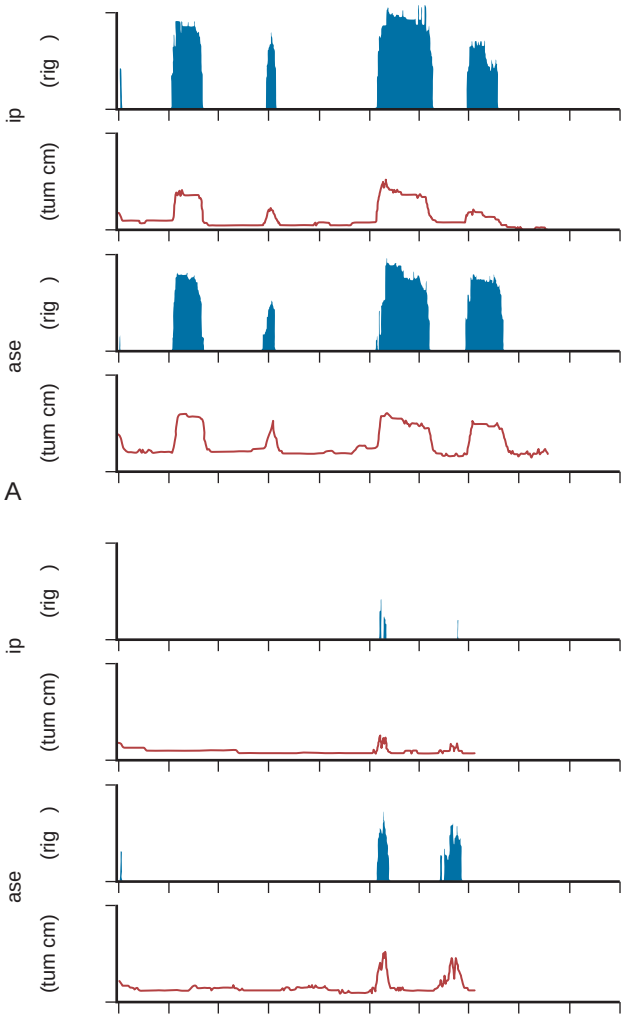

Figure 24–9. The RigiScan device has been designed to measure penile rigidity during home nocturnal monitoring. **A,** A study in a patient with at least two episodes of well-sustained, completely rigid nocturnal erections. **B,** A study with two episodes of poorly sustained, poorly rigid nocturnal erections. Such home studies fail to document sleep quality.

NPT electrobioimpedance (NEVA, American Medical Systems, Inc., Minnetonka, MN) is a more recently introduced device that assesses volumetric changes in the penis during nocturnal erections (Knoll and Abrams, 1999). The device consists of three small electrode pads applied to the hip and the penile base and glans and a small recording device attached to the patient's thigh. In operation, an undetectable alternating current is transmitted from the glans electrode to the hip ground, and the penile base electrode measures impedance and changes in penile length. Impedance measures decrease in concert with increases in cross-sectional area of the penis during nocturnal tumescence. Further investigation is necessary to establish the relationship of volumetric changes and rigidity of the penis. Similar to Rigiscan, the technique does not include REM sleep monitoring and correlations.

In summary, NPTR monitoring is an attractive approach for objectively evaluating the somatic basis of erectile ability, theoretically devoid of psychologic interference. However, it has several apparent shortcomings, which limit its routine use for diagnostic purposes (Jannini et al, 2009). Central issues are that the testing does not indicate the cause and severity of ED and that it may be poorly reproducible. A fundamental issue, too, is whether the testing appropriately evaluates wakeful, sexually relevant erections. Indeed, erections observed during NPTR monitoring do not unequivocally equate with erections sufficient for sexual performance, and false-positive results are possible for various clinical situations (e.g., multiple sclerosis). False-negative results may occur in aging patients and in patients with depression or anxiety, which may conditionally affect the physiology of sleep-related erectile phenomena. Nonetheless, NPTR monitoring may be considered in special circumstances such as when the cause of ED is obscure and noninvasive testing is desirable.

Audiovisual and Vibratory Stimulation

Alternative erectogenic methods can be used in conjunction with diagnostic testing of erectile function. **Erotic stimulation by explicit videotape material with monitoring has been used as a reliable and time- and cost-effective alternative to NPTR for differentiating between organic and psychogenic ED presentations** (Sakheim et al, 1987; Bancroft et al, 1991). **It is also considered more physiologic, consistent with erectile behavior when awake.** The testing has potential limitations, with possible false-negative responses occurring in the presence of endocrine abnormalities (Carani et al, 1992; Greenstein et al, 1995) and false-positive responses occurring in psychologic situations such as erotic excitement inhibition (Chung and Choi, 1990). As one may infer, these methods can be applied in conjunction with other stimulatory conditions (e.g.,

pharmacologic erection testing), as well as erectile function assessment approaches (e.g., Rigiscan monitoring) (Katlowitz et al, 1993; Martins and Reis, 1997).

Neuroimaging

Diagnostic techniques to evaluate central mechanisms of male sexual arousal have contributed to the psychophysiologic investigation of ED. Positron emission tomography (Miyagawa et al, 2007) and functional magnetic resonance imaging (Park et al, 2001; Montorsi et al, 2003; Mouras et al, 2003; Ferretti et al, 2005) have been used in association with video sexual stimulation or an erectogenic pharmacologic stimulus (e.g., oral apomorphine). Studies have documented key brain regions associated with sexual arousal that induce penile erection (i.e., anterior cingulate, insula, amygdala, hypothalamus, and secondary somatosensory cortices). Interestingly, functional abnormalities in the brain have been shown in patients with psychogenic ED, suggesting that this diagnosis may be attributable to an actual biologic basis. More investigation in this area is necessary before determining its clinical role.

Psychologic Evaluation

The psychologic evaluation of ED addresses psychogenic contributions to clinical presentations, essentially psychologic and interpersonal factors interfering with erectile function. These aspects should not be underestimated, and it is well documented in population studies that ED is associated with anxiety, depression, low degrees of self-esteem, negative outlook on life, self-reported emotional stress, and a history of sexual coercion (Feldman et al, 1994; Laumann et al, 1999). The urologist's role in initiating a psychologic evaluation is not necessarily complicated, and a basic attempt employing queries about a patient's psychologic health is useful in assessing sexual health (Rowland et al, 2005).

The diagnostic interview is central to the psychologic evaluation, and this process should be done straightforwardly. **Immediately discernible causes of sexual dysfunction may be elicited such as fear of failure; performance anxiety (for widowers, this may include complex interactions of dating, new partners, and unresolved mourning/guilt); insufficient sexual stimulation; loss of attraction for the partner; adjustment to a chronic illness or surgery; and relationship conflicts.** Less immediately discernible causes may be identified as well to include unresolved parental attachments, sexual identity issues, history of sexual trauma, occurrence of extramarital affairs, and cultural-religious taboos (Leach and Bethune, 1996; Laumann et al, 1999).

The interviewer should be mindful of the possibility of a primary psychogenic ED presentation (Turnbull and Weinberg, 1983). **In the absence of organic risk factors, a primary psychogenic ED causation may be suspected. Further support for the diagnosis may follow the confirmation of noncoital erections (i.e., masturbatory, nocturnal or on awakening).** Clinical subtypes of psychogenic ED may be further identified: (1) generalized versus situational and (2) lifelong (primary) versus acquired (secondary including substance abuse or major psychiatric illness).

The interviewer should also inquire about relationship factors (Rosen, 2001). Relationship conflicts may be the source of psychogenic ED or otherwise may exacerbate organic ED. Couple's issues include intimacy and trust, status and dominance, loss of sexual attraction, ability to achieve sexual satisfaction without erection, and communication problems. Important information may derive not just from interviewing the patient alone, and interviews both with the couple together and of partners separately may prove insightful.

Complex intrapsychic causes of sexual dysfunction are often relevant for the ED presentation and may become evident during the diagnostic interview. The clinical history may reveal a significant traumatic life experience, cultural or religious strife, compulsive sexual behavior, or neurotic process. It may suggest the presence of serious psychiatric comorbidities such as substance abuse, depressive symptoms, anxiety disorder, or personality disorder. It is recognized that the urologist may not have the professional background, comfort, or time to address these issues definitively, and a referral to a psychologic expert for further attention would certainly be appropriate.

Neurologic Evaluation

The neurologic evaluation of ED is concerned with neurogenic associations with ED presentations. **The importance of testing for deficits in the neurologic system relates to the principal regulatory role of this system for governing erectile function. Target sites for evaluation include peripheral, spinal, and supraspinal centers, as well as both somatic and autonomic pathways involved in this biologic response.** In line with this purpose, several diagnostic tests have been introduced. However, thus far they have had limited impact on routine clinical management decisions, and much of the available testing in this realm is reserved for research protocols and medicolegal investigations. Additionally, fundamental problems surround the lack of sensitivity, reproducibility, reliability, and validity for many of these tests. This concern is particularly so for autonomic function tests, distinct from somatic function testing, which has been shown to be reproducible and valid. Otherwise, tests that could be most useful for evaluating penile erection (e.g., neurotransmitter release) await development altogether.

Somatic Nervous System

Biothesiometry. This test represents a technique to assess afferent sensory function of the penis (Padma-Nathan, 1988). Testing involves a hand-held electromagnetic device placed on the pulp of the index fingers, both sides of the penile shaft, and the glans penis. Measurements of sensory perception threshold are obtained in response to various amplitudes of vibratory stimulation. Investigators have questioned the utility of penile glans biothesiometry, which does not accurately portray neurophysiologic function of the dorsal penile nerve because of limitations in recording responses to vibratory stimuli of glanular skin (Bemelmans et al, 1995).

Sacral Evoked Response—Bulbocavernosus Reflex Latency. This test is used to assess the somatosensory reflexogenic mechanism of penile erection. Testing consists of a direct-current stimulator, which delivers square-wave impulses via two stimulating ring electrodes placed around the penis, one secured near the corona and the other secured 3 cm more proximally, and a recorder, which gauges responses via concentric needle electrodes placed in the right and left bulbocavernous muscles. Latency period is measured as the interval from the beginning of each stimulus to the beginning of each response. An abnormal latency time, defined as a value more than three standard deviations above the mean (30 to 40 msec), indicates a high probability of neuropathology (Padma-Nathan, 1988). However, the utility of this test has been

questioned, and it has been shown that a full battery of electrophysiologic tests evaluating limb nerve function is more sensitive in diagnosing neuropathy than such tests specific to pudendal nerve function alone (Vodusek et al, 1993; Ho et al, 1996).

Dorsal Nerve Conduction Velocity. This test in concept extends from pudendal nerve function reflex testing and involves electrophysiologic stimulation with two stimulating electrodes placed at the glans and the base of the penis for obtaining two bulbocavernosus reflex latency measurements. Conduction velocity of the dorsal nerve is represented by dividing the distance between the two stimulating electrodes by the difference in latency times recorded from both sites. An average conduction velocity of 23.5 m/sec with a range of 21.4 to 29.1 m/sec is found in normal subjects (Gerstenberg and Bradley, 1983). Abnormal nerve conduction velocities were found to be diagnostic for neurogenic ED in patients with diabetes (Kaneko and Bradley, 1987).

Genitocerebral Evoked Potential. This test is designed to assess afferent sensory mechanisms and stimulus processing at spinal and supraspinal nervous system levels. The testing requires complex electronic equipment for recording the evoked potential waveforms overlying the sacral spinal cord and cerebral cortex in response to dorsal penile nerve electrical stimulation (Spudis et al, 1989). Central conduction time is recorded as the difference between the latency times after stimulation of the first replicated spinal response and the first replicated cerebral response (Padma-Nathan, 1988). The test has been questioned as having poor discriminatory value of response latencies (Pickard et al, 1994). However, it may still serve as an objective tool to define characteristics of afferent penile sensory dysfunction in patients with subtle abnormalities on neurologic examination.

Autonomic Nervous System

Heart Rate Variability and Sympathetic Skin Response. The test of heart rate control (mainly parasympathetic) consists of measuring heart rate variations during quiet breathing, deep breathing, and in response to raising the feet. Normative parameters have been documented. The test of sympathetic skin response involves producing an electrical shock stimulus at a certain location (e.g., median or tibial nerve) and recording the evoked potential elsewhere (e.g., contralateral hand or foot or penis). Recording from the penis is considered to be a potentially useful method of testing penile autonomic innervation (Daffertshofer et al, 1994).

Penile Thermal Sensory Testing. This test serves to assess the conductance of small sensory nerve fibers, which are affected by autonomic disturbances consistent with neuropathy. The testing measures thermal threshold. In studies of the penis, it seems to correlate very well with the clinical determination of neurogenic ED (Lefaucheur et al, 2001; Bleustein et al, 2003).

Corpus Cavernosum Electromyography (CC-EMG) and Single Potential Analysis of Cavernous Electrical Activity. This test offers a direct recording of cavernous electrical activity, which varies between penile flaccidity and tumescence (Wagner et al, 1989). In the normally flaccid penis, electrical activity is described to have a rhythmic slow wave with intermittent bursts of activity. As penile tumescence occurs (such as in response to visual sexual stimulation or after intracavernous injection of a smooth muscle relaxant), this activity ceases. During detumescence, the baseline electrical activity returns. Patients with suspected autonomic neuropathy were demonstrated to display a discordant pattern, having continued electrical activity during erectogenic stimuli (Wagner et al, 1989). Recording techniques have been standardized, and normative values have been defined to include maximum peak-to-peak amplitudes between 120 and 500 mV and mean potential durations of 12 seconds (Stief et al, 1994). However, its clinical utility remains in question (Kellner et al, 2000; Jiang et al, 2003).

Hormonal Evaluation

The hormonal evaluation for ED explores an endocrinologic basis for the sexual dysfunction and recognizes accumulating evidence that endocrinopathies potentially affect the physiology of penile erection (Traish and Guay, 2006; Mirone et al, 2009). **Several endocrine conditions are particularly relevant in this regard: hypogonadism (decrease or absence of hormonal secretion from the gonads), hyperthyroidism (excessive thyroid hormone release), and diabetes (altered modulation of androgen function). The diagnostic evaluation may be undertaken in view of their possible influences on erectile function.** The clinical history may raise suspicion of the diagnosis, although the clinical presentation of an endocrinopathy may be quite variable. Several questionnaires have been proposed for use in screening, particularly with respect to hypogonadism (Morley et al, 2000; Daig et al, 2003; Heinemann, 2005). However, their general lack of specificity for most presentations and lack of sensitivity for some others has limited their widespread applications (Morales et al, 2007). The central feature of this evaluation involves biochemical testing for serum hormonal levels.

Serum Testosterone Measurements

Much focus in assessing the impact of endocrinopathies on male sexual function has centered on the role of androgens. Androgen deficiency or low testosterone levels are observed in as low as 2% and as high as one-third of men presenting clinically with ED (Korenman et al, 1990; Citron et al, 1996; Soran and Wu, 2005). Differences in patient populations under study likely account for the variation in statistics. In acknowledgment that aging may represent the primary cause of declining androgens, thought leaders have variously applied such terms as androgen deficiency of the aging male (ADAM), partial androgen deficiency of the aging male (PADAM), hypoandrogenism, symptomatic late-onset hypogonadism (SLOH), and andropause to designate this association.

It is important to understand the biology of testosterone production and function in order to proceed with its laboratory evaluation. **Testosterone circulates in three fractions: free (0.5% to 3%), tightly bound to sex hormone binding globulin (SHBG) (≈30%), and loosely bound to albumin and other serum proteins (≈67%)** (Basaria and Dobs, 2001; Freeman et al, 2001). **Free testosterone and albumin-bound portions comprise the bioavailable testosterone fraction. The relative concentrations of the carrier proteins (SHBG and albumin) serve to modulate androgen function.** Numerous conditions can alter the SHBG fraction and accordingly affect bioavailable testosterone to some extent even if the total testosterone measurement is unchanged (Bhasin et al, 2006). Decreased SHBG is associated with moderate obesity, nephrotic syndrome, and hypothyroidism, as well as use of glucocorticoids, progestins, and androgenic steroids, and it produces an elevation in bioavailable testosterone. Increased SHBG is associated with aging, hepatic cirrhosis, hyperthyroidism, human immunodeficiency virus infection, and use of anticonvulsants and estrogens, and it produces a lowering in bioavailable testosterone. Despite the observation that lower levels of SHBG are associated with insulin resistance (Stellato et al, 2000), variable SHBG levels have been documented in diabetic men, possibly because of confounding obesity and aging factors, and the diagnosis of hypogonadism

in this population should rely on the measurement of a low bioavailable testosterone level (see later) (Kapoor et al, 2007).

Theoretically, the unbound or free fraction measurement of testosterone offers the most relevant determination of testosterone bioavailability. However, commercial assays for free testosterone are known to be inconsistent and have been considered to be invalid by some investigators (Vermeulen et al, 1999). **The best indicator of androgen status is the calculated bioavailable testosterone (free testosterone and albumin-bound testosterone).** A formula for this calculation is found on the website of the International Society for the Study for the Aging Male at http://www.issam.ch/freetesto.htm and requires entries for the values of total testosterone and SHBG. In men with serious liver disease or hypoalbuminemia, entry of the serum albumin value may be useful for obtaining the best calculation.

For screening purposes, measurement of total serum testosterone level is generally sufficient. It is recommended that the blood draw be done between 7 and 11 AM, when there is a peak serum testosterone level, accounting for the fact that diurnal variation occurs in younger and middle-aged men (Wang et al, 2009). **The typical reference range for the total testosterone measurement is 280 to 1000 ng/dL. It is recognized that because of individual variability the normal range for testosterone beyond which replacement therapy should be initiated remains unresolved.** If the testosterone level is below or at the low limit of normal, it should be repeated for confirmation. On the other hand, a mildly abnormal testosterone may be found to be normal in 30% of patients on repeat testing (Bhasin et al, 2006). The clinical scenario, such as the presence of conditions that alter testosterone carrier proteins, may prompt further testing and assessment decisions.

Serum Gonadotropin Measurements

When proceeding with a second total testosterone determination, assessment of leutinizing hormone (LH) and prolactin should also be included. Measurement of serum gonadotropins will help to localize the source of the hypogonadism. It is understood that testosterone release involves the integrative activity of the hypothalamic-pituitary-gonadal axis and its regulatory feedback mechanisms, and disruption at any level of this axis may account for hypogonadism (Bhasin et al, 2006). Low testosterone results in decreased negative feedback to the hypothalamus and pituitary, causing increased secretion of LH and follicle-stimulating hormone (FSH). Elevated serum LH and FSH releases are appropriate pituitary responses to low serum testosterone levels, which is consistent with testicular failure (primary hypogonadism). In contrast, normal or low serum LH and FSH releases in the setting of low serum testosterone levels indicate an inappropriate response and suggest a central disorder (secondary hypogonadism).

Serum Prolactin Measurement

Hyperprolactinemia causes hypogonadism by suppression of gonadotropin-releasing hormone from the hypothalamus, which impairs pulsatile LH secretion required for serum testosterone production by the gonads (Morales et al, 2004). An additional possible mechanism for sexual dysfunction, specifically loss of sexual libido, in patients with hyperprolactinemia independent of the circulating level of testosterone relates to an interference of the peripheral conversion of testosterone to dihydrotestosterone (Lobo and Kletzky, 1983). **Suspicion of hyperprolactinemia is raised in the patient with low serum testosterone and low or inappropriately normal LH.** However, controversy surrounds the consideration of routine determinations of prolactin in men with ED, with some indicating the low yield in doing so (Johnson and Jarow, 1992; Govier et al, 1996) and others finding that low serum testosterone or low sexual desire does not always coincide with the diagnosis (Buvat and Lemaire, 1997; Johri et al, 2001). Causes of the condition include various medications such as antipsychotic agents, tricyclic depressants and opiates, prolactin-secreting tumors, hypothyroidism, hypothalamic lesions, renal insufficiency, cirrhosis, and chest wall lesions (Zeitlin and Rajfer, 2000; Molitch, 2005).

Magnetic Resonance Imaging Scans

Cases of central (hypogonadotropic) hypogonadism and unexplained hyperprolactinemia prompt central imaging of the pituitary. This evaluation commonly involves magnetic resonance imaging, which can identify structural abnormalities (Citron et al, 1996; Petak et al, 2002; Rhoden et al, 2003). **Generally accepted guidelines provide indications for pituitary imaging: cases of severe central hypogonadism (testosterone <150ng/dL) and suspicion of pituitary disease (i.e., panhypopituitarism, persistent hyperprolactinemia, or symptoms of tumor mass effect).**

Serum Thyroid Function Tests

Hyperthyroidism is associated with ED, possibly by increasing aromatization of testosterone into estrogen (which raises levels of SHBG) (Morales et al, 2004) **or by increasing adrenergic tone (which causes smooth muscle contractile effects or exerts psycho-behavioral effects)** (Carani et al, 2005). Symptoms of hyperthyroidism such as hyperactivity, irritability, heat intolerance, palpitations, fatigue, and weight loss are often reported, and physical signs such as tachycardia, tremor, goiter, and eyelid retraction are often identified. **The diagnosis is made biochemically by measurement of high levels of thyroid hormone (total or free T4 or T3) with a low serum thyroid-stimulating hormone level.**

Key Points: Diagnostic Evaluation

- The basic evaluation of ED consists of a detailed case history, physical examination, and proper laboratory tests.
- The sexual history should define the characteristics of the ED presentation according to such features as its onset, duration, conditions, severity, and etiology.
- Cardiac risk assessment and risk reduction interventions are appropriate when necessary for all patients presenting for ED evaluations.
- The hormonal evaluation for ED explores an endocrinologic basis for the disorder, with special consideration given to hypogonadism, hyperthyroidism, and diabetes as possible influences.
- Questionnaires and other patient self-report measures offer practical utility in documenting the presence, severity, and responsiveness to treatment of ED.
- Specialized evaluation and testing may be required for individuals with complicated or atypical presentations of ED and potentially offer improved therapeutic outcomes for these presentations.

TREATMENT CONSIDERATIONS

The treatment of ED axiomatically follows an appropriate diagnostic workup. Although current interventions are both etiologically specific and nonspecific, an intervention that is specific for the cause of ED ideally offers the opportunity to treat ED with a corrective purpose in mind. **Current recommendations adhere to a patient goal-directed focus to therapy and specify that therapeutic options are presented according to a step-care clinical management approach** (Fig. 24–10) (Montague et al, 2005; Hatzichristou et al, 2010).

Lifestyle Modification

The risk of developing ED is highly associated with the presence of comorbid health conditions such as diabetes, cardiovascular disease, and metabolic syndrome that are either preventable or to a minimal extent treatable in the endeavor to optimize health status (Kostis et al, 2005). It stands to reason that optimization of these diseases offers opportunities to prevent the development of ED or ameliorate its extent.

Epidemiologic studies have examined potentially modifiable risk factors and in some instances provided support that risk modification may indeed improve erectile function. For instance, several reports have suggested that discontinuation of cigarette smoking results in a recovery of functional erection status (Mannino et al, 1994; Feldman et al, 2000; Bacon et al, 2006). A beneficial role of increasing exercise for those with sedentary lifestyle in men with ED was also shown (Feldman et al, 1994; Derby et al, 2000). In a recent prospective study, obese men with moderate ED and no overt symptoms of cardiovascular disease showed significant improvements in IIEF scores after exercise and weight control compared with a control group, which followed an educational program alone (Esposito et al, 2004). Significant changes in body mass index, C-reactive protein and physical activity scores were observed in the intervention group compared with the control group. Mediterranean-style diets and a reduction in caloric intake have been found to improve erectile function in men with metabolic syndrome (Esposito et al, 2006). A change to a no-nose saddle from a conventional saddle was shown to recover erectile function, presumably by alleviating perineal trauma, in a short-term interventional study of men with ED associated with occupational bicycle riding (Schrader et al, 2008).

Reports indicating that ED is potentially ameliorated by lifestyle modifications of risk factors that predispose this sexual dysfunction are most illuminative. **More definitive clinical and basic science evidence is certainly necessary to evaluate biologic mechanisms associated with these risk factors and affirm the benefits of risk modification.** However, current knowledge about these risks still prompts recommendations for a healthy and fit lifestyle for maximal erectile function preservation.

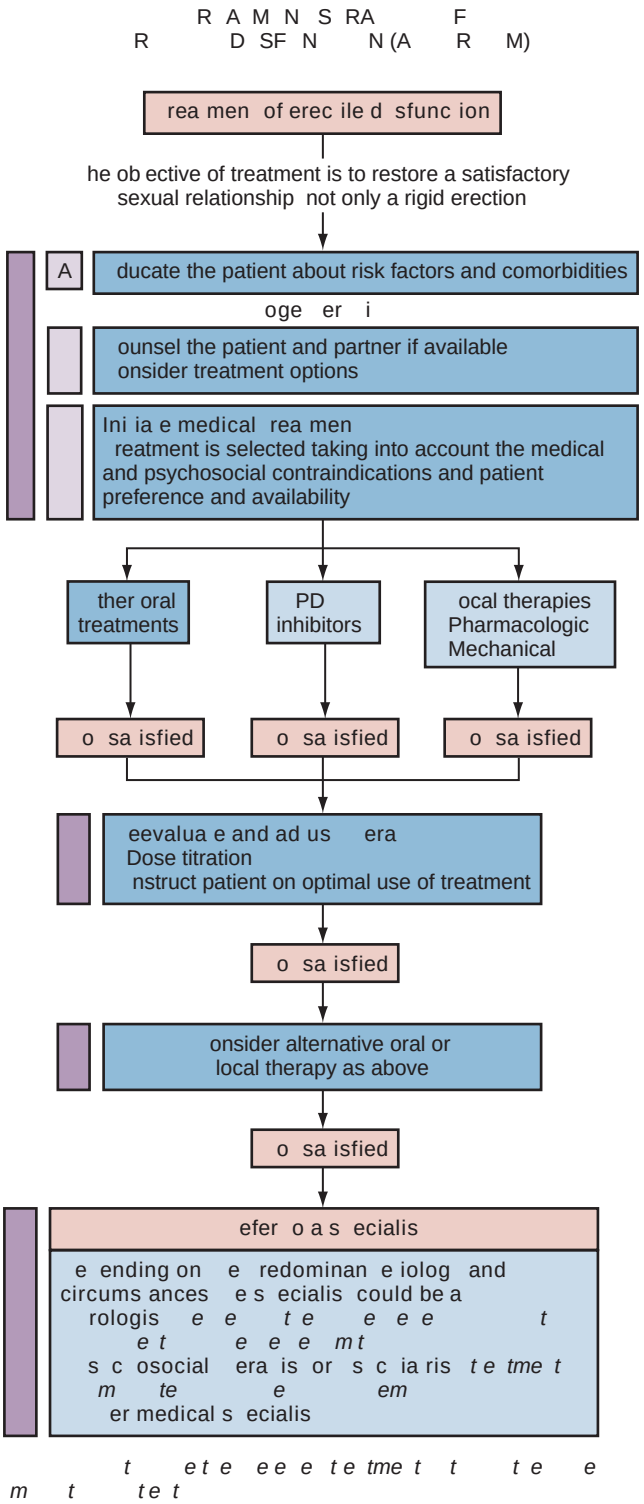

Figure 24–10. Treatment algorithm for erectile dysfunction recommended by the International Consultations on Sexual Medicine.

Medication Change

It is quite possible that a certain medication is an offending factor resulting in the clinical presentation of ED. After this inference is made, an appropriate next step would be to change to a different dose or type of medication entirely considering that this action may reverse ED in some patients (Ralph and McNicholas, 2000). For instance, switching antihypertensive therapies from thiazide diuretics and β-blockers to calcium channel blockers and renin-angiotensin system inhibitors (i.e., angiotensin-converting enzyme inhibitors and angiotensin receptor blockers) may recover erectile function in men developing ED in this clinical setting. Similarly, in patients suffering adverse sexual dysfunction effects from use of selective serotonin reuptake inhibitors (SSRI) (e.g., ED, retarded ejaculation), such treatment strategies as drug substitution (e.g., bupropion, nefazodone, buspirone, mirtazapine), drug holidays, SSRI dosage reduction, watchful waiting, and administration of PDE5

inhibitors have enabled sexual function recovery (Rosen et al, 1999; Nurnberg et al, 2001).

Psychosexual Therapy

Because of the frequent interplay of psychologic and interpersonal factors in clinical presentations of ED, it is hardly surprising to consider that psychosexual therapy should be included in the therapeutic armamentarium for this sexual dysfunction. A strong limitation of this area is that evidence-based investigation and well-controlled, large-scale outcome research documenting the efficacy of interventions are generally lacking. In practice, psychosexual therapy does represent an ill-defined combination of interventions and interpretations on the basis of behavioral, relational, psychoanalytic, and cognitive psychology concepts. **A variety of interventions are used: systematic anxiety reduction/desensitization, sensate focus, interpersonal therapy, cognitive-behavior therapy, sex education, couples' communication and sexual skills training, and masturbation exercises** (Althof et al, 2005). **Integrated treatments, which combine psychosexual interventions with medical therapies such as oral therapy, intracavernosal injection, or vacuum device therapy have been successful, too, in managing ED presentations, particularly those associated with motivational obstacles** (Hawton, 1998; Althof et al, 2005). For urologists, collaborative efforts with other specialists who have expertise in psychosexual therapy may be advantageous to provide effective, comprehensive treatment.

Hormonal Therapy

A prescription of hormonal therapy is considered for the patient in whom a hormonal disturbance is identified to affect the clinical presentation of ED. The urologist's role is fitting for the treatment of primary hypogonadism and hyperprolactinemia, whereas endocrinologists would be considered foremost consultants for other endocrinopathies.

Testosterone Replacement

Androgen replacement straightforwardly addresses the clinical complaint that is associated with hypogonadism. As a general principle of sex steroid replacement therapy, serum hormone levels to be achieved over the 24 hours of the day should ideally achieve normal reference values and resemble the normal diurnal pattern. **Evaluating serum testosterone levels both before and during treatment is imperative, although the efficacy of testosterone supplementation is best judged by clinical response rather than a precise testosterone determination. Current recommendations suggest that a short (e.g., 3-month) therapeutic trial is justified, and in the absence of a response testosterone administration should be discontinued** (Wang et al, 2009). Potential adverse effects of androgen therapy (i.e., erythrocytosis, sleep apnea, urinary symptoms, prostate cancer progression risk, gynecomastia, acne) should be recognized (Morales et al, 2004; Wald et al, 2006). **Monitoring of patients on therapy consists of a baseline assessment that includes digital rectal examination and serum PSA testing along with laboratory evaluation (i.e., hemoglobin/hematocrit levels, liver function tests, cholesterol level, and lipid profile) followed by assessment of treatment efficacy after 1 to 3 months and annually thereafter to assess symptom response and any adverse events** (Morales et al, 2004; Bhasin et al, 2006). Short-acting preparations may be preferred over long-acting depot preparations in the initial treatment of patients so that therapy can be discontinued on the occasion of an adverse event (Wang et al, 2009).

For the treatment of hypogonadism, several testosterone preparations are offered and can be delivered by various routes: injectable, subcutaneous, transdermal (patch and gel), buccal, and oral (Edelstein et al, 2006; Morgentaler et al, 2008; Wang et al, 2009). A brief description of available therapies follows (see also Table 24–6).

Injectable. Testosterone enanthate, an injectable depot preparation of testosterone, is delivered by deep intramuscular injection 150 to 300 mg every 2 to 4 weeks). The schedule of therapy results in supraphysiologic levels of testosterone for 72 hours with a steady exponential decline to subphysiologic levels by 10 to 12 days. Alternative dosing of 100 mg every 7 to 10 days can be considered in situations when patients experience symptomatic mood or sexual fluctuations associated with documented early hypogonadal troughs. Another parenteral preparation, testosterone cypionate, is also delivered intramuscularly at a dosage 200 mg every 2 to 3 days because of its shorter half-life, and it may also display serum testosterone fluctuations. Testosterone undecanoate (TU), as a depot formulation consisting of 750 mg or 1000 mg dosages administered at 10-week dosing intervals, has been used in Europe since 2003 but is not yet available in the United States.

Subcutaneous. Pellets offer a subcutaneous, long-acting depot formulation of testosterone. Testopel is a pellet containing 75 mg of testosterone. Dosing usually requires two to six pellets (150 to 450 mg testosterone) implanted subcutaneously every 3 to 6 months.

Transdermal. Transdermal delivery options comprise patches and gels, with a delivery approach that intendedly simulates normal circadian levels of testosterone. When patients apply medication in the morning, higher initial absorption will mimic normal diurnal variation.

Testoderm was approved initially as a daily administered scrotal patch without adhesive (4 to 6 mg), but it came under disuse because of difficulties with its application and the requirement for scrotal shaving, as well as finding that it significantly produced high levels of dihydrotestosterone (DHT) by conversion by 5α-reductase activity that is plentiful on scrotal skin. Testoderm TTS represented an alternative formulation avoiding the inconveniences of the scrotal application. Its application is to the arm, back, or buttock as a 5-mg patch. Androderm, an alternative product, delivers 2.5 or 5 mg testosterone daily. Both patches have been associated with itching, chronic skin irritation, and allergic contact dermatitis. The skin irritation is alleviated by local application of cortisone cream. Patients are advised to alternate application sites and avoid sun-exposed areas.

AndroGel (testosterone gel) 1% gel pack is a topical gel, which contains 50, 75, or 100 mg of testosterone, with only 10% of the drug being absorbed during a 24-hour period. Testim, also providing 1% testosterone, is an alternative product packaged as a 5-g tube containing 50 mg of testosterone. Both are similarly applied once daily in the morning to clean, dry skin over the shoulders, upper arms, or abdomen and allowed to dry before dressing.

Buccal. Striant refers to a tablet-like, mucoadhesive treatment system (30 mg of testosterone) that continuously delivers medication. It is applied twice daily to the gum tissue above the incisors, allowing testosterone to be absorbed through the buccal mucosa.

Oral. Oral testosterone preparations are limited. Concern is associated with the liver toxicity of testosterone (i.e., hepatitis, cholestatic jaundice, hepatomas, hemorrhagic liver cysts, and hepatocellular carcinoma) related to large doses necessary to

Table 24–6.

Testosterone Preparations

PREPARATION	DOSE	ROUTE	SCHEDULE
Oral			
Methyltestosterone (Metandren)	10-30 mg	Sublingual	Daily
Testosterone undecanoate (Andriol)	120-160 mg	Oral	Daily
Fluoxymesterone (Halotestin)	5-20 mg	Oral	Daily
Methandrostenolone	5-10 mg	Oral	Daily
Buccal			
Striant	30 mg	Buccal	q 12 hr
Transdermal Patches			
Testoderm TTS	5 mg	Skin	Daily
Testoderm	4-6 mg	Scrotum	Daily
Androderm	2.5-5 mg	Skin	Daily
Transdermal Gel			
Androgel 1%	5 g	Skin	Daily
Testim 1%	5 g	Skin	Daily
Intramuscular			
Cypionate (Depo-testosterone)	150-300 mg	IM	q 2-4 wk
Enanthate (Delatestryl)	150-300 mg	IM	q 2-4 wk
Pellet			
Testopel	150-450 mg	SC	q 3-6 mo

Modified from Maas D, Jochen A, Lalande B. Age-related changes in male gonadal function. Drugs Aging 1997;11:45–50.

achieve normal serum levels (Bagatell and Bremner, 1996). Large doses (>200 mg/day) are required orally because much of the administration is rendered metabolically inactive during the "first pass" circulation through the liver. Chemical modifications of oral testosterone have been explored to overcome adverse reactions. Both 17α-methyltestosterone and fluoxymesterone have been formulated, but because of their patient variability of effect with potential liver toxicity risk, they should not be prescribed (Wang et al, 2009). TU, as an oral formulation in oleic acid, is safe by partly escaping hepatic inactivation (Köhn and Schill, 2003). However, it has shown a large individual variability for the time of maximal responses, as well as when maximal serum testosterone is attained. Oral TU remains unapproved in the United States.

Alternative Hormone Treatments

Alternative hormonal replacement therapies have been suggested, and they have posed certain desirable features and caveats. DHT as a direct mode of therapy is attractive because of its action as a pure androgen that is not aromatizable to estradiol, and accordingly it has been demonstrated that the hormone does not exert adverse estrogenic effects on prostate growth or lipid profile measurements (Kunelius et al, 2002; Sakhri and Gooren, 2007). A therapeutic DHT gel is available at a dose of 125 to 250 mg/day, yielding plasma DHT levels comparable with physiologic testosterone levels (Kunelius et al, 2002). Dehydroepiandrosterone (DHEA), a hormone supplement with androgen-like and estrogen-like effects, has been used although limited evidence exists showing it improves sexual function (Baulieu et al, 2000; Morales et al, 2004). Importantly, the treatment cannot be considered harmless, and the potential exists for DHEA and other non-testosterone androgen precursor preparations (e.g., DHEA-S, androstenediol, androstenedione) to stimulate hormone-sensitive diseases such as breast or prostate cancer. Human chorionic gonadotropin (HCG) has been found to increase total and free testosterone and estradiol 50% above baseline and conceivably would benefit hypogonadal men similar to effects of androgen administration. Clinical investigation of HCG has shown some anthropometric effects (i.e., decrease in fat mass, increase in lean body mass) and improvements in serum testosterone concentrations in androgen deficient men without documented benefits for sexual function (Liu et al, 2002; Tsujimura et al, 2005). Anti-estrogens and aromatase inhibitors have been shown to increase endogenous testosterone levels, and selective androgen receptor modulators are under development. Because of insufficient evidence about the therapeutic benefits and adverse effects of alternative replacement therapies in older men with hypogonadism, they are not currently recommended for use (Wang et al, 2009).

Hyperprolactinemia Treatments

The treatment of hyperprolactinemia is undertaken acknowledging that testosterone replacement therapy is neither corrective nor sufficient to improve sexual function. The therapeutic objective, rather, is to identify and address the underlying cause, which may then ameliorate ED. Offending drugs such as estrogens, morphine, sedatives, and neuroleptics should be discontinued (Molitch, 2008). A prolactin-secreting adenoma should be treated medically and, if necessary, surgically. Bromocriptine, a dopamine agonist that lowers prolactin level and restores testosterone production to normal, serves to reduce the size of the tumor. Neurosurgical ablation becomes necessary if the therapeutic response to medication does not occur or visual effects are noted in association with optic nerve compression (Gillam et al, 2006). Erection recovery is most evident after treatment of men with significant serum elevations of prolactin (>40 ng/mL) (Netto Júnior and Claro, 1993).

Pharmacologic Therapies

The premise of pharmacologic therapies is that they simulate the biochemical and molecular mechanisms of action naturally

governing the erectile response. **Conceptually, erectogenic therapies serve strategically either to promote proerectile mechanisms or oppose antierectile mechanisms, at both peripheral and central levels of the neurovascular axis responsible for penile erection** (Rowland and Burnett, 2000). At a peripheral level, these mechanisms influence corporal smooth muscle tone. Promotion of proerectile mechanisms is achieved by either inducing corporal smooth muscle activation through cell-receptor agonists or effectors of tissue relaxant pathways (e.g., stimulating second messenger cyclic nucleotide [cyclic guanosine monophosphate, cGMP or cyclic adenosine monophosphate, cAMP] synthesis) or inhibiting the deactivation of smooth muscle relaxation pathways (e.g., inhibiting phosphodiesterases), whereas opposition of antierectile mechanisms are achieved by decreasing smooth muscle contraction through receptor antagonists of tissue contractile pathways (e.g., α_1-adrenergic inhibitors). At a central nervous system level (i.e., brain or spinal cord), neuronal pathways are affected and potential opportunities exist to promote proerectile pathways (e.g., agonists of dopaminergic D_2 receptors in the medial hypothalamus) or oppose antierectile pathways (e.g., antagonists of 5-$HT_{1A/2}$ [serotonergic] receptors in the spinal cord).

Diverse therapies have been touted over time, although their efficacy and safety characteristics have not always been clearly defined. Current standards of regulatory agency approval have helped to clarify the qualifications of commercially developed and marketed therapies (Hirsch et al, 2004).

Oral Therapy

Orally administered medication for ED meets many of the attributes of "ideal therapy," which include convenience, simplicity, and noninvasiveness (Morales et al, 1995). Oral therapies are increasingly demanded to meet the therapeutic objective of clinical efficacy as well.

Phosphodiesterase Type 5 Inhibitors. This class of medication was famously inaugurated as an effective ED treatment in the United States following U.S. Food and Drug Administration (FDA) approval of sildenafil citrate (Viagra, Pfizer, Inc, New York) in 1998 and vardenafil hydrochloride (Levitra, Bayer Schering Pharma AG, Berlin) and tadalafil (Cialis, Lilly LLC, Indianapolis, IN) in 2003 (Burnett, 2005). **PDE5 inhibitors similarly work to block the catalytic action of the enzyme that degrades cGMP, the downstream effector of the erection mediator nitric oxide, which then facilitates the signal transductional mechanisms of corpus cavernosal smooth muscle relaxation required for penile erection. It is important to recognize that the medications augment but do not induce the erectile response and the induction of penile erection requires the release of nitric oxide from penile nerve endings and vascular endothelium under the influence of sexual stimulation.** The high concentration of PDE5 in the smooth muscle of the penile corpora cavernosa accounts for the selectivity of their effect.

Despite their similar modes of actions, PDE5 inhibitors differ somewhat in their biochemical properties, pharmacokinetic profiles, and clinical performances (Table 24–7). The chemical structures of sildenafil and vardenafil are similar, unlike that for tadalafil, and this difference does explain some phenomenological differences observed between the agents (Corbin and Francis, 1999). **Distinct from the action of tadalafil, sildenafil and vardenafil cross-react slightly with phosphodiesterase (PDE) type 6, which is expressed in the retina, and this difference may explain the complaint of visual disturbances observed with sildenafil and vardenafil use.** Tadalafil minimally cross-reacts with PDE type 11, unlike the other two PDE5 inhibitors, although the significance of this effect is unclear. The remaining side effects commonly observed with PDE5 inhibitor treatment are associated with inhibition of PDE5 localized in other target tissues such as vascular and gastrointestinal smooth muscle. Tadalafil possesses a longer half-life of elimination than the other two PDE5 inhibitors. This feature suggests a longer therapeutic window uniquely afforded for tadalafil, which may translate into increased convenience for couples to have sexual intercourse with this agent.

All three PDE5 inhibitors have demonstrated equivalent efficacy and tolerability in clinical trials for the treatment of ED of varying severity and cause (Carson and Lue, 2005; Hellstrom, 2007; Giuliano et al, 2009). Trial designs for the three PDE5 inhibitors have differed, limiting useful comparisons between them, and in the absence of directly comparative studies superiority cannot be claimed for any particular agent (Carson and Lue, 2005). **In general, the agents effectively achieve successful sexual intercourse rates of approximately 70%** (Carson and Lue, 2005). A somewhat reduced intercourse success rate of 40% to 50%

Table 24–7.

Comparison of Three PDE5 Inhibitors Currently Available in the United States

	SILDENAFIL	VARDENAFIL	TADALAFIL
Cmax (ng/mL)	450	20.9	378
Tmax (hr)	0.8	0.7-0.9	2
Onset of action (min)	15-60	15-60	15-120
Half-life (hr)	3-5	4-5	17.5
Bioavailability	40%	15%	Not tested
Fatty food	Reduced absorption	Reduced absorption	No effect
Recommended dosage	25, 50, 100 mg	5, 10, 20 mg	5, 10, 20 mg
Side effects:			
Headache, dyspepsia, facial flushing	Yes	Yes	Yes
Backache, myalgia	Rare	Rare	Yes
Blurred/blue vision	Yes	Rare	Rare
Precaution with antiarrhythmics	No	Yes	No
Contraindication with nitrates	Yes	Yes	Yes

Cmax, maximal plasma concentration; Tmax, time required to attain Cmax; Half-life, time required for elimination of one half of the medication from plasma.

has been reported in diabetic patients with ED (Fonseca et al, 2004; Safarinejad, 2004) and in patients with ED associated with radical prostatectomy in general (Hatzimouratidis et al, 2009). However, the intercourse success rate for patients specifically after bilateral nerve-sparing radical prostatectomy is somewhat better than for the entire group, and reports have commonly documented rates of functional erections with therapy that approach 60% to 70%.

According to standard dosing recommendations, patients are instructed to take the medications on demand approximately an hour before intended sexual activity. This lead-time interval is specified to take advantage of the duration by which the medications achieve peak serum concentrations (i.e., approximately 1 hour for sildenafil and vardenafil and 2 hours for tadalafil). Although the onset of activity has been documented to occur possibly within 20 minutes for each agent, this characteristic is less important to patients than erection hardness and maintenance of erections with therapy (Claes et al, 2008). A daily dosing regimen has been approved for tadalafil as an alternative treatment schedule to afford patients greater convenience in having sexual intercourse while using this agent (Porst et al, 2006; Shabsigh et al, 2010). **Optimization of effect for all PDE5 inhibitors is also achieved by properly applying sexual stimulation as a prerequisite for nitric oxide release; reducing food intake, which may delay drug absorption; escalating drug dosing as needed; and repeating attempts with the medications several times (up to 9 or 10 attempts affords maximal probability of success)** (McCullough et al, 2002; Barada, 2003; Shindel, 2009). **Correcting or improving adverse health conditions (e.g., glycemic control, hyperlipidemic control, androgen replacement), which affect drug efficacy, has also been demonstrated to be potentially beneficial** (Guay, 2003; Sadovsky et al, 2009). As evidence of therapeutic efficacy, patient and partner satisfaction with therapy (as shown for sildenafil) has been well demonstrated (Montorsi and Althof, 2004). Suboptimal acceptance or lack of long-term adherence to therapy (up to 47% of patients) has been reported, which may indicate the influence of psychosocial factors or challenges of a treatment that requires repeated dosing (Seftel, 2002; Al-Shaiji and Brock, 2009).

Patients using PDE5 inhibitors should be thoroughly counseled regarding precautions (Table 24–8). Cardiovascular safety using the medication has been well demonstrated, although it should be emphasized that given the cardiovascular risks of sexual activity and potential for adverse drug interactions with this therapy, cardiovascular risk assessment and stabilization should be considered for all men before institution of PDE5 inhibitor therapy. **Controlled and postmarketing studies involving these agents have shown that they do not cause an increase in myocardial infarction or death rates when compared with expected rates in study control populations** (Jackson et al, 2006; Hellstrom, 2007; Nehra, 2009). In addition, patients with known coronary artery disease or heart failure receiving PDE5 inhibitors did not exhibit worsening ischemia, coronary vasoconstriction, or worsening hemodynamics on exercise testing or cardiac catheterization. Caution is advised for the use of PDE5 inhibitors in patients with certain conditions: aortic stenosis, left ventricular outflow obstruction, hypotension, and hypovolemia. The agents have a minimal effect on QTc interval (Morganroth et al, 2004). Vardenafil among PDE5 inhibitors is not recommended in patients who take type-1A antiarrhythmics (e.g., quinidine or procainamide) or type-3 antiarrhytmics (e.g., sotalol, amiodarone) or in patients with congenital prolonged QT syndrome.

Table 24–8.

Warnings and Drug Interactions

The package inserts of all three PDE5 inhibitors warn against the use in patients with severe cardiovascular diseases and left ventricular outflow obstruction (e.g., aortic stenosis, idiopathic subaortic stenosis), those with severely impaired autonomic control of blood pressure, and patients not studied in clinical trials (U.S. prescribing information of Viagra, Cialis, and Levitra, August 2009). These include patients with:

- Myocardial infarction, stroke, or life-threatening arrhythmia within the previous 6 mo
- New York Heart Association class II or greater heart failure or coronary artery disease causing unstable angina
- Resting hypotension (<90/50 mm Hg) or hypertension (>170/100 mm Hg)
- Known hereditary degenerative retinal disorders including retinitis pigmentosa
- Severe hepatic impairment (Child-Pugh C) or end-stage renal disease requiring dialysis

Certain drugs such as ketoconazole and itraconazole and protease inhibitors such as ritonavir can impair the metabolic breakdown of PDE5 inhibitors by blocking the CYP3A4 pathway. Such agents may increase blood levels of inhibitors, requiring a PDE5 dose reduction. On the other hand, agents such as rifampin may induce CYP3A4, enhancing the breakdown of inhibitors and requiring higher PDE5 doses. Kidney or hepatic dysfunction may require dose adjustments or warnings.

Nitrate use in any form (e.g., sublingual nitroglycerin, isosorbide dinitrate, other nitrate preparations used to treat angina, amyl nitrite, and amyl nitrate "poppers") represents an absolute contraindication. Past use of nitrates (more than 2 weeks before the use of PDE5 inhibitors) is not considered a contraindication. **If angina occurs during sexual activity having used a PDE5 inhibitor, patients should cease this activity and seek emergency care immediately.** They should inform medical personnel that a PDE5 inhibitor was taken and avoid nitroglycerin use for a period of 24 hours for sildenafil and vardenafil and 48 hours for tadalafil (Cheitlin et al, 1999). If acute myocardial infarction occurs with the use of PDE5 inhibitors, usual therapies with the exception of organic nitrates may be administered. If hypotension results from PDE5 inhibitor use, patients should be placed in the Tredelenburg position and given intravenous fluids along with administration of α-adrenergic agonists (e.g., phenylephrine) as needed. Refractory hypotension warrants intra-aortic balloon counterpulsation, as specified by the American College of Cardiology/American Heart Association guidelines. **No pharmacologic antidote to the PDE5 inhibitor/nitrate interaction exists. Caution is advised when PDE5 inhibitors are coadministered with α-adrenergic blockers because both agents are vasodilators with blood pressure–lowering effects.**

Side effects observed with PDE5 inhibitor therapy include headache (15% to 16%), dyspepsia (4% to 10%), flushing (4% to 10%), myalgia/back pain (0% to 3%), nasal congestion (3% to 4%), and visual disturbances (e.g., photophobia, blue vision) (0% to 3%). Randomized, controlled trials have documented that flushing and visual side effects are more common in patients receiving sildenafil or vardenafil, whereas back pain/myalgia is more common in patients receiving tadalafil. These events have been found to be mild, abate with time, and prompt discontinuation in few patients (Hellstrom, 2007). **The concern of the development of nonarteritic anterior optic neuropathy (NAION), which can cause blindness, with PDE5 inhibitor therapy has been posed,**

although a careful review of pooled data from clinical trials for all three agents did not demonstrate an increased risk of NAION or other adverse ocular events associated with their use (Laties, 2009). Affected patients in postmarketing reports possibly carried risk factors for blindness to include hypertension, diabetes, and hyperlipidemia. At this time, despite the absence of a proven link between PDE5 inhibitor use and serious ocular disorders, physicians should continue to advise patients to stop use of PDE5 inhibitors and seek immediate medical attention as a safety measure in the event of a sudden loss of vision (Laties, 2009).

The interest to extend the utility of PDE5 inhibitors beyond an on-demand erectogenic role and rather apply them to recover or maintain the natural vitality of the penis in the face of an ED-associated disease state or condition has been investigated. This proposal has been considered particularly in the clinical context of radical prostatectomy and introduced as a therapeutic strategy à la "penile rehabilitation," by which the medications are taken in some regularly scheduled fashion to promote the recovery of spontaneous erectile function. Presently, this role remains unclear. Opposing outcomes were found in two controversial albeit well-designed and conducted (i.e., randomized, controlled) clinical trials of PDE5 inhibitor use after bilateral nerve-sparing radical prostatectomy. In one trial involving sildenafil treatment of 36 weeks starting 4 weeks after the surgery, 27% of patients using the agent recovered erections defined as "good enough for sexual activity" compared with 4% of patients on placebo at about 1 year after surgery (Padma-Nathan et al, 2008). In another trial involving vardenafil treatment of 9 months either on demand or daily starting 14 days after surgery, erection recovery was no different in patients administered vardenafil by either form of administration or placebo at about 1 year after surgery (Montorsi et al, 2008). Randomized, controlled trials in other ED contexts have also failed to show sustained natural erectile function improvement after discontinuing continuous regimens of PDE5 inhibitor therapy (Zumbé et al, 2008; Burnett et al, 2009).

The notion to combine PDE5 inhibitors with other ED therapies such as vasoactive penile pharmacotherapies has been proposed (Lau et al, 2006; McMahon et al, 2006). This strategy is to be considered "off label," and clinical precautions are advised.

α-Adrenoceptor Antagonists. Phentolamine mesylate is a nonspecific α-adrenergic receptor antagonist with equal affinity for blocking both α_1- and α_2-adrenoreceptors. Its mode of action presumably is to produce corporal smooth muscle relaxation by blocking the (antierectile) postsynaptic α_1-adrenergic receptor (Juenemann et al, 1986). Clinical trials suggested an efficacy rate in men with minimal ED of approximately 40% (Goldstein, 2000). The drug was considered to be relatively safe, with less than 10% of patients using the 40-mg dosage experiencing headaches, facial flushing, or nasal congestion. However, further investigation is required before determining whether it will produce erectile responses of sufficient quality for reliable sexual intercourse, particularly in men with more severe ED.

Yohimbine hydrochloride (Yocon), an indolalkylamine alkaloid derived from the bark of the yohimbe tree, reportedly exerts central effects on the mediation of penile erection operating as an α_2-adrenoreceptor antagonist (Clark, 1991; Giuliano and Rampin, 2000). Originally proposed to be an erectogenic and aphrodisiac agent, the drug has been investigated recently as an authentic ED treatment. It is conventionally prescribed orally at a dosage of 5.4 mg three times daily with observation for improvement over at least a month. A meta-analysis of all randomized, placebo-controlled trials involving yohimbine suggested a superior effect for the medication compared with placebo (Ernst and Pittler, 1998). **However, the drug does not appear to enable successful sexual intercourse any better than placebo in men with confirmed organic ED** (Montague et al, 1996; Teloken et al, 1998). Adverse effects appear to be relatively infrequent but include hypertension, anxiety, tachycardia, and headache. Although yohimbine may be well tolerated, its modest results suggest that it may be best limited to men with psychogenic ED.

Dopaminergic Agonists. Apomorphine (Uprima, TAP Pharmaceutical Products Inc, Lake Forest, IL) is a dopaminergic agent activating D_1 and D_2 receptors at a central level within the paraventricular nucleus of the brain, indicating its particular relevance in the treatment of men with psychogenic ED (Lal et al, 1987). The medication is taken in sublingual form, having a dosage range of 2, 4, and 6 mg, and it has no erectile efficacy if it is swallowed (Heaton, 2000). It has a rapid onset of action, with a mean time to erection of 12 minutes. Apomorphine achieves a maximal plasma concentration in 50 minutes, although its window of opportunity extends for approximately 2 hours from administration. In clinical trials involving men with ED of varying severities and etiologies, the drug achieved a successful sexual intercourse rate of 50.6% at the 4-mg dosage compared with the 33.8% placebo rate (Heaton, 2000). Side effects include nausea (16.9%), dizziness (8.3%), yawning (7.9%), somnolence (5.8%), sweating (5%), and emesis (3.7%). Syncope occurred in 0.6% of patients using the medication at the highest recommended dosage and was accompanied by a prodrome consisting of nausea, vomiting, sweating, dizziness, and light-headedness but no cardiac sequelae. Side effects were minimized when patients were titrated from higher to lower dosages. The drug achieved regulatory approval for commercialization by European authorities in early 2001, but it has not been so approved in the United States.

Melanocortin-Receptor Agonists. Melanocortin analogues (e.g., melanotan II, PT-141) have been studied showing efficacy in inducing erectile responses in early clinical trials (Wessells et al, 2000; Diamond et al, 2004). These drugs operate centrally at melanocortin-4 receptors, which have been implicated in controlling food intake and energy expenditure, as well as modulating erectile function and sexual behavior. Flushing and nausea have been reported as side effects. The drugs have not achieved regulatory approval for the treatment of ED.

Serotonin-Receptor Effectors. Trazodone (Desyrel) is an antidepressant that has been associated with priapism, prompting its "off-label" investigation as a possible treatment for ED (Lal et al, 1990). It is purported to work through mechanisms at the spinal cord level with multiple serotonergic effects (Allard and Giuliano, 2001). The active metabolite of trazodone acts as an agonist of the proerectile 5-HT_{2C} receptor through reuptake inhibition, with some affinity for the 5-HT_{2A} receptor, although it may also operate as an antagonist of antierectile 5-HT_{1A} receptors (Andersson and Wagner, 1995). Rigorous recent evaluations have not shown clinical efficacy that exceeds placebo responses in eliciting penile erection (Costabile and Spevak, 1999). Given its potential side effects (i.e., drowsiness, nausea, emesis, blood pressure changes, urinary retention, and priapism) and general lack of effect, this medication would appear to have a limited role for ED treatment.

Other Oral Therapies. Additional possibilities for the oral treatment of ED including L-arginine (the amino acid precursor of nitric oxide), L-dopa (dopamine precursor), limaprost (prostaglandin E_1), and naltrexone (opioid antagonist) have been proposed

(Burnett, 1999). Each of these agents has a plausible mechanism of action to induce erections. However, they remain insufficiently studied and their clinical roles remain unclear.

Intracavernous Injection

The discovery in 1982 that vasoactive agents, delivered by injection into the penis, induced erections is credited with launching the movement toward medical therapies for the treatment of ED (Virag, 1982; Zorgniotti, 1985). **Since that time, there has been an explosion of basic scientific and clinical research leading to the development and use of various locally administered vasoactive medications having mechanisms of action that result in corporal smooth muscle relaxation.** Although a host of medications have been explored for this purpose, three medications are used regularly in clinical practice: alprostadil, papaverine, and phentolamine (Table 24–9). **These have been administered clinically as a single agent (i.e., monotherapy) or in various combinations (e.g., bi-mix, tri-mix). Combination therapy offers a synergistic mechanism of the vasoactive agents to elicit maximal erectile responses, particularly among patients who have failed monotherapy** (Zorgniotti and Lefleur, 1985; Bennett et al, 1991; Floth and Schramek, 1991). This alternative may also be used to circumvent side effects of a certain agent (e.g., penile pain associated with alprostadil).

A general rule of thumb is to start with a small dose of medication, especially in patients with nonvasculogenic forms of ED. In-office self-injection training and education are recommended before home injection, and this opportunity may also be used to titrate medication toward a dosage that safely yields an erection of sufficient rigidity for sexual intercourse yet lasts no more than an hour (Benard and Lue, 1990; Fallon, 1995). **The therapy is contraindicated for men with psychologic instability, a history or risk for priapism, histories of severe coagulopathy or unstable cardiovascular disease, reduced manual dexterity (although the partner can be trained in the injection technique), and use of monoamine oxidase inhibitors (because of the risk of precipitating a life-threatening hypertensive crisis in the event that an intracavernosal α-adrenergic agonist is used to reverse a priapic episode)** (Sharlip, 1998).

Table 24–9.

Intracavernous Pharmacotherapies

TRADE NAME	DRUG	DOSAGES	EFFICACY (INTERCOURSE)
Caverject	Alprostadil (Prostin VR)	5-40 µg/mL	≈70%
Edex	Alprostadil (Prostin VR)	5-40 µg/mL	≈70%
Bi-mix	Alprostadil + phentolamine	20 µg/mL + 0.5 mg/mL	≈90%
Bi-mix Androskat (EU)	Papaverine + phentolamine	30 mg/mL + 0.5 mg/mL	≈90%
Tri-mix	Alprostadil + papaverine + phentolamine	10 µg/mL + 30/mg/mL + 1.0 mg/mL	≈90%
Invicorp	VIP + phentolamine	NA	≈80%
Thymoxamine	Moxisylyte	NA	≈70%

EU, European Union; VIP, vasoactive intestinal polypeptide.
