Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

# ■ CONTENTS

<i>Editors</i>	<i>xi</i>
<i>Contributors</i>	<i>xiii</i>
<i>Remembrances</i>	<i>xxvii</i>
<i>Preface</i>	<i>xxix</i>
<b>SECTION I ■ ADRENAL, RENAL, URETER, PELVIS</b>	<b>1</b>
<i>Jerome P. Richie</i>	
<b>Chapter 1 Anatomy of the Adrenal Glands, Kidney, Ureter, and Pelvis</b>	<b>1</b>
<i>Ricardo Beduschi, Unyime O. Nseyo, and Sam D. Graham, Jr.</i>	
<b>Chapter 2 Partial Nephrectomy</b>	<b>6</b>
<i>Samir S. Taneja</i>	
<b>Chapter 3 Radical Nephrectomy</b>	<b>14</b>
<i>Michael S. Cookson and Sam S. Chang</i>	
<b>Chapter 4 Intracaval Tumors</b>	<b>23</b>
<i>Viraj A. Master and Fray F. Marshall</i>	
<b>Chapter 5 Transplant Nephrectomy</b>	<b>32</b>
<i>Sanjaya Kumar</i>	
<b>Chapter 6 Renovascular Disease</b>	<b>36</b>
<i>John A. Libertino and Chad Wotkowicz</i>	
<b>Chapter 7 Anatomic Nephrolithotomy</b>	<b>45</b>
<i>Elizabeth J. Anoaia, Michael L. Paik, and Martin I. Resnick</i>	
<b>Chapter 8 Renal and Retroperitoneal Abscesses</b>	<b>51</b>
<i>Davis P. Viprakasit and Anthony J. Schaeffer</i>	
<b>Chapter 9 Renal Trauma</b>	<b>58</b>
<i>Jill C. Buckley and Jack W. McAninch</i>	
<b>Chapter 10 Renal Allotransplantation</b>	<b>65</b>
<i>John W. McGillicuddy, Justin D. Ellett, and Kenneth D. Chavin</i>	
<b>Chapter 11 Ureteral Complications Following Renal Transplantation</b>	<b>71</b>
<i>Rodney J. Taylor</i>	
<b>Chapter 12 Renal Autotransplantation</b>	<b>76</b>
<i>Venkatesh Krishnamurthi and David A. Goldfarb</i>	
<b>SECTION II ■ BLADDER</b>	<b>85</b>
<i>Charles B. Brendler</i>	
<b>Chapter 13 Anatomy of the Bladder</b>	<b>85</b>
<i>Clinton W. Collins and Adam P. Klausner</i>	
<b>Chapter 14 Simple and Partial Cystectomy</b>	<b>92</b>
<i>Jonathan C. Picard and J. Nathaniel Hamilton</i>	

<b>Chapter 15</b>	<b>Radical Cystectomy in Men</b>	<b>97</b>
	<i>Mohamed A. Ghonheim</i>	
<b>Chapter 16</b>	<b>Radical Cystectomy in Women</b>	<b>104</b>
	<i>Alon Z. Weizer and Cheryl T. Lee</i>	
<b>Chapter 17</b>	<b>Bladder Diverticulectomy</b>	<b>113</b>
	<i>Michael S. Cookson and Sam S. Chang</i>	
<b>Chapter 18</b>	<b>Bladder Augmentation</b>	<b>118</b>
	<i>Anne Pelletier Cameron, R. Duane Cespedes, and Edward J. McGuire</i>	
<b>Chapter 19</b>	<b>Management of the Distal Ureter for Nephroureterectomy</b>	<b>125</b>
	<i>J. Stuart Wolf, Jr.</i>	
<b>Chapter 20</b>	<b>Vesicovaginal Fistula</b>	<b>130</b>
	<i>Helen G. Zafirakis and O. Lenaine Westney</i>	
<b>Chapter 21</b>	<b>Enterovesical and Rectourethral Fistulas</b>	<b>137</b>
	<i>Kenneth W. Angermeier, Aaron J. Milbank, and Eric A. Klein</i>	
<b>Chapter 22</b>	<b>Vesical Trauma and Hemorrhage</b>	<b>143</b>
	<i>Kamal S. Pohar and Robert R. Bahnson</i>	
<b>Chapter 23</b>	<b>Interstitial Cystitis/Painful Bladder Syndrome</b>	<b>150</b>
	<i>Michael S. Ingber and Kenneth M. Peters</i>	
<b>SECTION III ■ PROSTATE</b>		<b>163</b>
	<i>Randall G. Rowland</i>	
<b>Chapter 24</b>	<b>Anatomy of the Prostate</b>	<b>163</b>
	<i>Sam D. Graham, Jr.</i>	
<b>Chapter 25</b>	<b>Surgery for Benign Prostatic Hypertrophy</b>	<b>166</b>
	<i>Brian R. Matlaga and James E. Lingeman</i>	
<b>Chapter 26</b>	<b>Prostatic Imaging and Biopsy</b>	<b>175</b>
	<i>Frances M. Martin, William T. Conner, and Randall G. Rowland</i>	
<b>Chapter 27</b>	<b>Pelvic Lymphadenectomy</b>	<b>179</b>
	<i>Michelle L. Ramirez, Raj S. Pruthi, Joon-Ha Ok, and Ralph W. deVere-White</i>	
<b>Chapter 28</b>	<b>Open Radical Retropubic Prostatectomy</b>	<b>186</b>
	<i>Misop Han and William J. Catalona</i>	
<b>Chapter 29</b>	<b>Radical Perineal Prostatectomy</b>	<b>194</b>
	<i>Sam D. Graham, Jr., Jeffrey C. Lou, and Thomas E. Keane</i>	
<b>Chapter 30</b>	<b>Brachytherapy for Localized Prostate Cancer</b>	<b>202</b>
	<i>John A. Fortney, A. Jason Zauls, and David T. Marshall</i>	
<b>SECTION IV ■ URETHRA</b>		<b>211</b>
	<i>E. Ann Gormley</i>	
<b>Chapter 31</b>	<b>Anatomy of the Urethra</b>	<b>211</b>
	<i>E. Ann Gormley</i>	
<b>Chapter 32</b>	<b>Female Urethral Diverticulum</b>	<b>214</b>
	<i>Ahmed M. El-Zawahry and Eric S. Rovner</i>	
<b>Chapter 33</b>	<b>Reconstruction of the Female Urethra</b>	<b>220</b>
	<i>Jerry G. Blaivas and Rajveer S. Purohit</i>	
<b>Chapter 34</b>	<b>Surgical Management of the Incompetent Bladder Outlet in the Patient with a Neurogenic Bladder</b>	<b>228</b>
	<i>Alienor S. Gilchrist, Gary E. Lemack, and Philippe E. Zimmern</i>	

<b>Chapter 35</b>	<b>Surgery for Urethral Stricture Disease</b> <i>Jack R. Walter and George D. Webster</i>	<b>236</b>
<b>Chapter 36</b>	<b>Surgery for Urethral Trauma Including Urethral Disruption</b> <i>Jack W. McAninch and Bryan B. Voelzke</i>	<b>245</b>
<b>Chapter 37</b>	<b>Carcinoma of the Female Urethra</b> <i>Peter L. Steinberg and William Bihrlle III</i>	<b>252</b>
<b>Chapter 38</b>	<b>Carcinoma of the Male Urethra</b> <i>Peter L. Steinberg and William Bihrlle III</i>	<b>257</b>
<b>Chapter 39</b>	<b>Injectable Therapies for Incontinence in Women</b> <i>Rodney Appell</i>	<b>263</b>
<b>Chapter 40</b>	<b>Pubovaginal Fascial Slings</b> <i>Anne Pelletier Cameron, Christina Lewicky-Gaup, and Edward J. McGuire</i>	<b>271</b>
<b>Chapter 41</b>	<b>Synthetic Midurethral Retropubic Slings</b> <i>Bhavin N. Patel and Gopal H. Badlani</i>	<b>278</b>
<b>Chapter 42</b>	<b>The Transobturator Approach to the Midurethral Sling</b> <i>Paul Hanissian and James Whiteside</i>	<b>282</b>
<b>Chapter 43</b>	<b>Abdominal Retropubic Approaches for Female Incontinence</b> <i>Leslie M. Rickey</i>	<b>288</b>
<b>Chapter 44</b>	<b>The Artificial Urinary Sphincter</b> <i>Helen Zafirakis and O. Lenaine Westney</i>	<b>292</b>
<b>Chapter 45</b>	<b>The Male Sling for Postprostatectomy Incontinence: Current Concepts and Controversies</b> <i>Craig V. Comiter</i>	<b>299</b>
<b>Chapter 46</b>	<b>Sacral Neuromodulation</b> <i>Sarah E. McAchran, Raymond R. Rackley, and Sandip Vasavada</i>	<b>305</b>
<b>Chapter 47</b>	<b>Surgical Treatment of Pelvic Organ Prolapse: Anatomy of the Pelvic Floor</b> <i>Ariana L. Smith, Ja-Hong Kim, and Shlomo Raz</i>	<b>311</b>
<b>Chapter 48</b>	<b>Vaginal Hysterectomy for Uterine Prolapse</b> <i>Ja-Hong Kim, Ariana L. Smith, and Shlomo Raz</i>	<b>318</b>
<b>Chapter 49</b>	<b>Cystocele and Anterior Vaginal Prolapse</b> <i>Melissa R. Kaufman, Harriette M. Scarpero, and Roger R. Dmochowski</i>	<b>326</b>
<b>Chapter 50</b>	<b>Transvaginal Repair of Apical Prolapse</b> <i>Katie N. Ballert and Victor W. Nitti</i>	<b>335</b>
<b>Chapter 51</b>	<b>Posterior Vaginal Prolapse Repair</b> <i>Lior Lowenstein and Elizabeth R. Mueller</i>	<b>343</b>
<b>Chapter 52</b>	<b>Abdominal Sacral Colpopexy</b> <i>J. Christian Winters and Scott Delacroix, Jr.</i>	<b>349</b>
<b>SECTION V ■</b>	<b>VAS DEFERENS, SEMINAL VESICLE, TESTIS</b> <i>Marc Goldstein</i>	<b>355</b>
<b>Chapter 53</b>	<b>Anatomy of the Epididymis, Vas Deferens, and Seminal Vesicle</b> <i>Howard H. Kim and Marc Goldstein</i>	<b>355</b>
<b>Chapter 54</b>	<b>Seminal Vesicle and Ejaculatory Duct Surgery</b> <i>Jay I. Sandlow</i>	<b>361</b>
<b>Chapter 55</b>	<b>Vasectomy</b> <i>Douglas G. Stein</i>	<b>372</b>

<b>Chapter 56</b>	<b>Vasoepididymostomy</b> <i>Peter T. K. Chan</i>	<b>379</b>
<b>Chapter 57</b>	<b>Vasovasostomy</b> <i>Marc Goldstein and Howard H. Kim</i>	<b>387</b>
<b>Chapter 58</b>	<b>Microsurgical Varicocelectomy</b> <i>Armand Zini and Ziv Maianski</i>	<b>397</b>
<b>Chapter 59</b>	<b>Testis Biopsy and Testicular Sperm Extraction (TESE)</b> <i>Peter N. Schlegel</i>	<b>401</b>
<b>Chapter 60A</b>	<b>Epididymal Sperm Aspiration</b> <i>Cigdem Tanrikut and Marc Goldstein</i>	<b>407</b>
<b>Chapter 60B</b>	<b>Epididymectomy</b> <i>David M. Nudell and Larry I. Lipshultz</i>	<b>410</b>
<b>Chapter 61</b>	<b>Ejaculation Induction Procedures: Penile Vibratory Stimulation and Electroejaculation</b> <i>Dana A. Ohl, Susanne A. Quallich, Jens Sønksen, Nancy L. Brackett, and Charles M. Lynne</i>	<b>412</b>
<b>Chapter 62</b>	<b>Anatomy of the Testis</b> <i>Howard H. Kim and Marc Goldstein</i>	<b>419</b>
<b>Chapter 63</b>	<b>Simple Orchiectomy</b> <i>Brett S. Carver and Sherri M. Donat</i>	<b>428</b>
<b>Chapter 64</b>	<b>Inguinal Orchiectomy</b> <i>David A. Swanson</i>	<b>433</b>
<b>Chapter 65</b>	<b>Organ-Preserving Surgery in Testicular Tumors</b> <i>Axel Heidenreich</i>	<b>438</b>
<b>Chapter 66</b>	<b>Retroperitoneal Lymphadenectomy</b> <i>Michael Leveridge and Michael A. S. Jewett</i>	<b>442</b>
<b>Chapter 67</b>	<b>Torsion of the Testicle</b> <i>Blake W. Moore and Harry P. Koo</i>	<b>448</b>
<b>Chapter 68</b>	<b>Scrotal Trauma and Reconstruction</b> <i>Timothy O. Davies and Gerald H. Jordan</i>	<b>453</b>
<b>SECTION VI ■ PENIS AND SCROTUM</b> <i>Gerald H. Jordan</i>		<b>465</b>
<b>Chapter 69</b>	<b>Anatomy of the Penis and Scrotum</b> <i>Sam D. Graham, Jr.</i>	<b>465</b>
<b>Chapter 70</b>	<b>Partial and Total Penectomy in the Management of Invasive Squamous Cell Carcinoma of the Penis</b> <i>Antonio Puras Baez and Alex M. Acosta Miranda</i>	<b>467</b>
<b>Chapter 71</b>	<b>Inguinal Lymphadenectomy for Penile Carcinoma</b> <i>Shahin Tabatabaei and W. Scott McDougal</i>	<b>473</b>
<b>Chapter 72</b>	<b>Surgical Treatment of Peyronie Disease</b> <i>Uri Gur and Gerald H. Jordan</i>	<b>481</b>
<b>Chapter 73</b>	<b>Priapism</b> <i>Trinity J. Bivalacqua and Arthur L. Burnett</i>	<b>487</b>
<b>Chapter 74</b>	<b>Penile Prosthesis Implantation</b> <i>Culley C. Carson</i>	<b>492</b>

<b>Chapter 75</b>	<b>Penile Venous Surgery</b> <i>Audrey C. Rhee, Mark R. Licht, and Ronald W. Lewis</i>	<b>499</b>
<b>Chapter 76</b>	<b>Microvascular Arterial Bypass Surgery for Erectile Dysfunction</b> <i>Irwin Goldstein and Martin Bastuba</i>	<b>505</b>
<b>Chapter 77</b>	<b>Penile Trauma</b> <i>Daniel I. Rosenstein, Allen F. Morey, and Jack W. McAninch</i>	<b>514</b>
<b>Chapter 78</b>	<b>Penile Replantation</b> <i>Uri Gur and Gerald H. Jordan</i>	<b>519</b>
<b>Chapter 79</b>	<b>Varicocele: General Considerations</b> <i>Carin V. Hopps and Marc Goldstein</i>	<b>523</b>
<b>Chapter 80</b>	<b>Hydrocele and Spermatocele</b> <i>John A. Nesbitt</i>	<b>528</b>
<b>Chapter 81</b>	<b>Congenital Curvature</b> <i>Timothy O. Davies and Kurt A. McCammon</i>	<b>532</b>
<b>Chapter 82</b>	<b>Reconstruction of the Penis for Complications of Penile Enhancement Surgery</b> <i>Gary J. Alter</i>	<b>537</b>
<b>SECTION VII ■ URINARY DIVERSION</b> <i>Urs E. Studer</i>		<b>545</b>
<b>Chapter 83</b>	<b>Ileal Conduit Urinary Diversion</b> <i>Michael C. Lee and Eric A. Klein</i>	<b>545</b>
<b>Chapter 84</b>	<b>Transverse Colonic Conduit</b> <i>Margit Fisch, Rudolf Hohenfellner, Raimund Stein, and Joachim W. Thüroff</i>	<b>549</b>
<b>Chapter 85</b>	<b>Managing the Patient with Orthotopic Bladder Substitution</b> <i>Urs E. Studer and N. Bhatta-Dhar</i>	<b>555</b>
<b>Chapter 86</b>	<b>Orthotopic Urinary Diversion Using an Ileal Low-Pressure Reservoir with an Afferent Tubular Segment</b> <i>Stephan Jeschke and Urs E. Studer</i>	<b>561</b>
<b>Chapter 87</b>	<b>Ileal Neobladder</b> <i>Richard E. Hautmann</i>	<b>566</b>
<b>Chapter 88</b>	<b>The Padua Ileal Bladder</b> <i>Francesco Pagano and Pierfrancesco Bassi</i>	<b>574</b>
<b>Chapter 89</b>	<b>The T-Pouch Ileal Neobladder</b> <i>John P. Stein and Donald G. Skinner</i>	<b>578</b>
<b>Chapter 90</b>	<b>Colonic Orthotopic Bladder Substitution</b> <i>Joachim W. Thüroff and Ludger Franzaring</i>	<b>586</b>
<b>Chapter 91</b>	<b>Continent Catheterizable Reservoir Made from Ileum</b> <i>Hassan Abol-Enein and Mohamed A. Ghoneim</i>	<b>594</b>
<b>Chapter 92</b>	<b>Continent Catheterizable Reservoir Made from Colon</b> <i>Hubertus Riedmiller and Elmar W. Gerharz</i>	<b>599</b>
<b>Chapter 93</b>	<b>Ureterosigmoidostomy: Mainz Pouch II</b> <i>Margit Fisch, Rudolf Hohenfellner, Jörg Schede, and Joachim W. Thüroff</i>	<b>610</b>
<b>Chapter 94</b>	<b>Palliative Urinary Diversion</b> <i>Burkhard Ubrig and Stephan Roth</i>	<b>618</b>

<b>SECTION VIII ■ PEDIATRIC</b>	<b>623</b>
<i>H. Gil Rushton</i>	
<b>Chapter 95 Neuroblastoma</b>	<b>623</b>
<i>W. Robert DeFoor, Jr., Pramod P. Reddy, and Curtis A. Sheldon</i>	
<b>Chapter 96 Wilms Tumor</b>	<b>628</b>
<i>Sarah Conley and Michael L. Ritchey</i>	
<b>Chapter 97 Renal Fusion and Ectopia</b>	<b>634</b>
<i>Ross M. Decter</i>	
<b>Chapter 98 Transureteroureterostomy</b>	<b>643</b>
<i>H. Gil Rushton</i>	
<b>Chapter 99 Pyeloplasty</b>	<b>647</b>
<i>Evan J. Kass and Kevin M. Feber</i>	
<b>Chapter 100 Megaureter</b>	<b>649</b>
<i>J. Christopher Austin and Douglas A. Canning</i>	
<b>Chapter 101 Prune Belly (Triad) Syndrome</b>	<b>654</b>
<i>David B. Joseph</i>	
<b>Chapter 102 Childhood Rhabdomyosarcoma</b>	<b>662</b>
<i>Hsi-Yang Wu and Howard M. Snyder III</i>	
<b>Chapter 103 Vesicoureteral Reflux</b>	<b>665</b>
<i>Mark R. Zaontz</i>	
<b>Chapter 104 Endoscopic Treatment of Vesicoureteral Reflux</b>	<b>676</b>
<i>Wolfgang H. Cerwinka and Andrew J. Kirsch</i>	
<b>Chapter 105 Ureterocele</b>	<b>681</b>
<i>Richard N. Yu, Chester J. Koh, and David A. Diamond</i>	
<b>Chapter 106 Urachal Anomalies and Related Umbilical Disorders</b>	<b>684</b>
<i>Leslie T. McQuiston and Anthony A. Caldamone</i>	
<b>Chapter 107 Vesical Neck Reconstruction</b>	<b>689</b>
<i>John C. Pope IV and John H. Makari</i>	
<b>Chapter 108 Surgery for Posterior Urethral Valves</b>	<b>697</b>
<i>Rosalia Misseri and Kenneth I. Glassberg</i>	
<b>Chapter 109 Hypospadias</b>	<b>703</b>
<i>Laurence S. Baskin</i>	
<b>Chapter 110 Complete Primary Repair for Exstrophy</b>	<b>711</b>
<i>Richard W. Grady</i>	
<b>Chapter 111 Bladder Exstrophy and Epispadias</b>	<b>722</b>
<i>Thomas E. Novak and John P. Gearhart</i>	
<b>Chapter 112 Congenital Anomalies of the Scrotum</b>	<b>731</b>
<i>Sean T. Corbett and David R. Roth</i>	
<b>Chapter 113 Pediatric Cryptorchidism, Hydroceles, and Hernias</b>	<b>735</b>
<i>Kenneth G. Nepple and Christopher S. Cooper</i>	
<b>Chapter 114 Laparoscopic Management of the Undescended Testicle</b>	<b>742</b>
<i>Danielle D. Sweeney, Michael C. Ost, and Steven G. Docimo</i>	
<b>Chapter 115 Pediatric Laparoscopic Pyeloplasty</b>	<b>752</b>
<i>Pasquale Casale and Walid A. Farhat</i>	
<b>Chapter 116 Pediatric Laparoscopic Nephrectomy and Partial Nephrectomy</b>	<b>757</b>
<i>Glenn M. Cannon, Jr., and Richard S. Lee</i>	

<b>Chapter 117</b>	<b>Urogenital Sinus and Cloacal Anomalies</b> <i>Jeffrey A. Leslie and Richard C. Rink</i>	<b>761</b>
<b>Chapter 118</b>	<b>Surgery to Correct Ambiguous Genitalia (46XX Disorder of Sexual Development)</b> <i>Anthony J. Casale</i>	<b>769</b>
<b>Chapter 119</b>	<b>Circumcision</b> <i>Irene M. McAleer and George W. Kaplan</i>	<b>778</b>
<b>Chapter 120</b>	<b>Augmentation Cystoplasty in Children</b> <i>Hans G. Pohl</i>	<b>783</b>
<b>Chapter 121</b>	<b>The Mitrofanoff Procedure in Pediatric Urinary Tract Reconstruction</b> <i>Mark P. Cain</i>	<b>793</b>
<b>SECTION IX ■ LAPAROSCOPIC</b> <i>Leonard G. Gomella</i>		<b>801</b>
<b>Chapter 122</b>	<b>Basic Principles of Laparoscopy: Transperitoneal, Extraperitoneal, and Hand-Assisted Techniques</b> <i>Gaurav Bandi and Leonard G. Gomella</i>	<b>801</b>
<b>Chapter 123</b>	<b>Laparoscopic Pelvic and Retroperitoneal Lymph Node Dissection</b> <i>Howard N. Winfield and William J. Badger</i>	<b>811</b>
<b>Chapter 124</b>	<b>Laparoscopic Nephrectomy and Partial Nephrectomy</b> <i>James A. Brown</i>	<b>819</b>
<b>Chapter 125</b>	<b>Laparoscopic Nephroureterectomy</b> <i>Scott G. Hubosky and Michael D. Fabrizio</i>	<b>830</b>
<b>Chapter 126</b>	<b>Laparoscopic Renal Procedures: Renal Cystectomy, Biopsy, and Nephropexy</b> <i>Chad A. LaGrange and Stephen E. Strup</i>	<b>837</b>
<b>Chapter 127</b>	<b>Laparoscopic Ablation of Small Renal Masses</b> <i>Ilia S. Zeltser and David E. McGinnis</i>	<b>842</b>
<b>Chapter 128</b>	<b>Donor Nephrectomy: Laparoscopic Techniques</b> <i>Erik P. Castle, Rafael Nunez, Costas D. Lallas, and Paul E. Andrews</i>	<b>846</b>
<b>Chapter 129</b>	<b>Laparoscopic and Robotically Assisted Pyeloplasty in Adults</b> <i>Kristofer R. Wagner and Thomas W. Jarrett</i>	<b>853</b>
<b>Chapter 130</b>	<b>Laparoscopic Adrenalectomy</b> <i>Arvin K. George and Louis R. Kavoussi</i>	<b>859</b>
<b>Chapter 131</b>	<b>Laparoscopic and Robotic Radical Prostatectomy</b> <i>Costas D. Lallas and Edouard J. Trabulsi</i>	<b>867</b>
<b>Chapter 132</b>	<b>Laparoscopic Management of Lymphoceles</b> <i>Sean P. Hedican and Stephen Y. Nakada</i>	<b>879</b>
<b>Chapter 133</b>	<b>Laparoscopic Bladder Procedures: Radical Cystectomy, Partial Cystectomy, Urachal Excision, Diverticulectomy</b> <i>Sebastien Crouzet, Georges-Pascal Haber, and Inderbir S. Gill</i>	<b>885</b>
<b>Chapter 134</b>	<b>Laparoscopic Bladder Neck Suspension</b> <i>Richard W. Graham</i>	<b>892</b>
<b>Chapter 135</b>	<b>Miscellaneous Laparoscopic Urologic Procedures: Calculus, Varicocele, Ureterolysis</b> <i>Gordon L. Fifer and Raju Thomas</i>	<b>897</b>

<b>SECTION X ■ NEW FRONTIERS</b>	<b>905</b>
<i>Thomas W. Jarrett</i>	
<b>Chapter 136 Tissue-Engineering Strategies for Urogenital Repair</b>	<b>905</b>
<i>Anthony Atala</i>	
<b>Chapter 137 Image-Guided Therapy: Current Practice and Future Directions</b>	<b>913</b>
<i>Peter Pinto and Hal B. Hooper</i>	
<b>Chapter 138 Robotic Surgery</b>	<b>919</b>
<i>David Canes and Mihir M. Desai</i>	
<b>Chapter 139 Energy Sources in Urology</b>	<b>926</b>
<i>Moses M. Kim and Richard E. Link</i>	
Index	<b>937</b>

University of Kentucky College of Medicine  
Lexington, Kentucky  
Section: Prostate

<sup>†</sup>Deceased

**H. Gil Rushton, MD**

Department of Urology  
George Washington University  
Chairman, Urology  
Children's National Medical Center  
Washington, DC  
Section: Pediatric

**Urs E. Studer, MD**

Professor and Chairman  
Department of Urology  
University Hospital Bern  
Bern, Switzerland  
Section: Urinary Diversion

## ■ CONTRIBUTORS

### **Hassan Abol-Enein MD, PhD**

Professor  
Department of Urology  
Faculty of Medicine, Mansoura University  
Director  
Department of Urology  
Urology and Nephrology Center  
Mansoura, Egypt  
Chapter 91

### **Alex M. Acosta Miranda, MD**

Assistant Professor  
Department of Urology  
University of Puerto Rico School of Medicine  
Staff Urologist  
San Juan Veterans Affairs Hospital  
San Juan, Puerto Rico  
Chapter 70

### **Gary J. Alter, MD**

Assistant Clinical Professor  
Division of Plastic Surgery  
University of California  
Los Angeles, California  
Chapter 82

### **Paul E. Andrews, MD**

Professor of Urology  
Mayo Clinic  
Phoenix, Arizona  
Chapter 128

### **Kenneth W. Angermeier, MD**

Center for Genitourinary Reconstruction  
Glickman Urological and Kidney Institute  
Cleveland Clinic  
Cleveland, Ohio  
Chapter 21

### **Elizabeth J. Anoaia, MD**

Urology Health Specialists, LLC  
Abington, Pennsylvania  
Chapter 7

### **Rodney Appell, MD<sup>†</sup>**

Vanguard Urology  
Houston, Texas  
Chapter 39

### **Anthony Atala, MD**

William H. Boyce Professor and Chair  
Department of Urology  
Director  
Wake Forest Institute for Regenerative Medicine  
Winston-Salem, North Carolina  
Chapter 136

### **J. Christopher Austin, MD, FAAP, FACS**

Associate Professor, Pediatric Urology  
University of Iowa Hospitals and Clinics  
Iowa City, Iowa  
Chapter 100

### **William J. Badger, MD**

Endourology Fellow  
The University of Iowa  
Department of Urology  
Iowa City, Iowa  
Chapter 123

### **Gopal H. Badlani, MD, FACS**

Professor, Vice Chair of Clinical Affairs  
Department of Urology  
Wake Forest University School of Medicine  
Wake Forest University/Baptist Medical Center  
Winston Salem, North Carolina  
Chapter 41

### **Robert R. Bahnson, MD, FACS**

The Dave Longaberger Chair in Urology  
Professor and Chairman  
Department of Urology  
Ohio State University  
Columbus, Ohio  
Chapter 22

### **Katie N. Ballert, MD**

Assistant Professor of Urology  
Department of Surgery  
Attending Surgeon  
Department of Surgery, Division of Urology  
University of Kentucky  
Lexington, Kentucky  
Chapter 50

### **Gaurav Bandi, MD**

Assistant Professor  
Department of Urology  
Thomas Jefferson University  
Philadelphia, Pennsylvania  
Chapter 122

<sup>†</sup>Deceased

**Laurence S. Baskin, MD**

Professor of Urology  
 University of California San Francisco  
 Chief, Pediatric Urology  
 Department of Urology  
 UCSF Children's Medical Center  
 San Francisco, California  
 Chapter 109

**Pierfrancesco Bassi, MD**

Chief and Chairman  
 Department of Urology  
 Catholic University School of Medicine  
 Rome, Italy  
 Chapter 88

**Martin Bastuba, MD**

Male Fertility Specialists  
 San Diego, California  
 Chapter 76

**Ricardo Beduschi, MD**

Chapter 1

**William Bihrlle, III, MD**

Associate Professor, Surgery  
 Dartmouth Medical School  
 Section Chief, Urology  
 Dartmouth-Hitchcock Medical Center  
 Lebanon, New Hampshire  
 Chapters 37 and 38

**Trinity J. Bivalacqua, MD, PhD**

Assistant Professor of Urology  
 The James Buchanan Brady Urological Institute  
 Johns Hopkins Hospital  
 Baltimore, Maryland  
 Chapter 73

**Jerry G. Blaivas, MD**

Clinical Professor  
 Department of Urology  
 Weill Cornell Medical College  
 Attending  
 Department of Urology  
 New York Presbyterian Hospital  
 New York, New York  
 Chapter 33

**Nancy L. Brackett, PhD, HCLD**

Associate Professor  
 Neurological Surgery and Urology  
 University of Miami Miller School of Medicine  
 Miami, Florida  
 Chapter 61

**James A. Brown, MD**

Associate Professor  
 Head, Section of Urologic Oncology  
 Division of Urology  
 Medical College of Georgia  
 Augusta, Georgia  
 Chapter 124

**Jill C. Buckley, MD**

Assistant Professor  
 Department of Urology  
 Tufts University School of Medicine  
 Lahey Clinic Medical Center  
 Burlington, Massachusetts  
 Chapter 9

**Arthur L. Burnett, MD, MBA, FACS**

Patrick C. Walsh Professor  
 Department of Urology  
 Johns Hopkins University  
 Johns Hopkins Hospital  
 Baltimore, Maryland  
 Chapter 73

**Mark P. Cain, MD, FAAP**

Professor of Urology  
 Department of Urology  
 Indiana University  
 Division of Urology  
 Riley Hospital for Children  
 Indianapolis, Indiana  
 Chapter 121

**Anthony A. Caldamone, MD**

University Urology Associates  
 Providence, Rhode Island  
 Chapter 106

**Anne Pelletier Cameron, MD**

Assistant Professor  
 Clinical Lecturer  
 Department of Urology  
 University of Michigan  
 Ann Arbor, Michigan  
 Chapters 18 and 40

**David Canes, MD**

Lahey Institute of Urology  
 Parkland Medical Center  
 Derry, New Hampshire  
 Chapter 138

**Douglas A. Canning, MD**

Division of Urology,  
 Children's Hospital of Philadelphia  
 Philadelphia, Pennsylvania  
 Chapter 100

**Glenn M. Cannon Jr., MD**

Fellow, Pediatric Urology  
 Harvard Medical School  
 Department of Urology  
 Boston, Massachusetts  
 Chapter 116

**Brett S. Carver, MD**

Assistant Member  
 Department of Surgery  
 Assistant Attending  
 Department of Surgery  
 Memorial Sloan-Kettering Cancer Center  
 New York, New York  
 Chapter 63

**Culley C. Carson, MD**

Rhodes Distinguished Professor  
Chief of Urology  
University of North Carolina  
Chapel Hill, North Carolina  
Chapter 74

**Anthony J. Casale, MD**

Department of Urology  
University of Louisville School of Medicine  
Louisville, Kentucky  
Chapter 118

**Pasquale Casale, MD**

Assistant Professor of Urology in Surgery,  
University of Pennsylvania  
Children's Hospital of Philadelphia  
Philadelphia, Pennsylvania  
Chapter 115

**Erik P. Castle, MD**

Associate Professor of Urology  
Urologic Oncology  
Laparoscopic and Robotic Urology  
Mayo Clinic  
Phoenix, Arizona  
Chapter 128

**William J. Catalona, MD**

Northwestern University  
Feinberg School of Medicine  
Chicago, Illinois  
Chapter 28

**Wolfgang H. Cerwinka, MD**

Clinical Instructor  
Department of Urology  
Emory University School of Medicine  
Attending Physician  
Department of Pediatric Urology  
Children's Healthcare of Atlanta  
Atlanta, Georgia  
Chapter 104

**R. Duane Cespedes, MD**

Director, Female Urology  
Wilford Hall Medical Center  
Lackland AFB, Texas  
Chapter 18

**Peter T. K. Chan, MD, CM, MSc, FRCS(C), FACS**

Associate Professor  
Department of Surgery  
McGill University  
Director of Male Reproductive Medicine  
Department of Urology  
McGill University Health Center  
Montreal, Quebec, Canada  
Chapter 56

**Sam S. Chang, MD, FACS**

Associate Professor  
Department of Urologic Surgery  
Vanderbilt University  
Department of Urologic Surgery  
Vanderbilt University Medical Center  
Nashville, Tennessee  
Chapters 3 and 17

**Kenneth D. Chavin, MD**

Professor of Surgery, Microbiology, and Immunology  
Department of Surgery  
Medical University of South Carolina  
Charleston, South Carolina  
Chapter 10

**Clinton W. Collins, MD**

Chief Resident, Division of Urology  
Virginia Commonwealth University School of Medicine  
Richmond, Virginia  
Chapter 13

**Craig V. Comiter, MD**

Associate Professor  
Department of Urology  
Stanford University Medical School  
Stanford, California  
Associate Professor  
Department of Urology  
Stanford Hospital and Clinics  
Palo Alto, California  
Chapter 45

**Sarah Conley, MD**

Resident  
Department of Urology  
Mayo Clinic  
Phoenix, Arizona  
Chapter 96

**William T. Conner, MD**

Division of Urology  
University of Kentucky Medical Center  
Lexington, Kentucky  
Chapter 26

**Michael S. Cookson, MD, FACS**

Professor  
Department of Urologic Surgery  
Vanderbilt University Medical Center  
Nashville, Tennessee  
Chapters 3 and 17

**Christopher S. Cooper, MD**

Professor  
Department of Urology  
University of Iowa  
Associate Dean for Student Affairs and Curriculum  
University of Iowa Carver College of Medicine  
Director, Pediatric Urology  
Children's Hospital of Iowa  
Iowa City, Iowa  
Chapter 113

**Sean T. Corbett, MD**

Assistant Professor of Urology  
University of Virginia Health System  
Charlottesville, Virginia  
Chapter 112

**Sebastien Crouzet, MD**

Glickman Urological and Kidney Institute  
Cleveland Clinic  
Cleveland, Ohio  
Chapter 133

**Mihir M. Desai, MD**

Director, Stevan B. Strem Center for Endourology  
Glickman Urological and Kidney Institute  
Cleveland Clinic  
Cleveland, Ohio  
Chapter 138

**Timothy O. Davies, MD**

Instructor, Adult and Pediatric Reconstructive Fellow  
Department of Urology  
Eastern Virginia Medical School  
Norfolk, Virginia  
Chapters 68 and 81

**Ross M. Decter, MD**

Associate Professor of Surgery  
Department of Surgery  
Milton S. Hershey Medical Center  
Penn State College of Medicine  
Hershey, Pennsylvania  
Chapter 97

**W. Robert DeFoor, Jr., MD, MPH**

Associate Professor  
Division of Pediatric Urology  
Cincinnati Children's Hospital  
Cincinnati, Ohio  
Chapter 95

**Scott Delacroix, Jr., MD**

Department of Urologic Surgery  
Ochsner Clinic Foundation  
New Orleans, Louisiana  
Chapter 52

**Ralph W. deVere-White, MD**

Department of Urology and Cancer Center  
University of California at Davis  
Sacramento, California  
Chapter 27

**Nivedita Bhatta-Dhar, MD**

Assistant Professor of Urology  
Wayne State University School of Medicine  
Detroit, Michigan  
Chapter 85

**David A. Diamond, MD**

Professor  
Department of Urological Surgery  
Harvard Medical School  
Associate  
Department of Urology  
Children's Hospital  
Boston, Massachusetts  
Chapter 105

**Roger R. Dmochowski, MD**

Professor  
Department of Urologic Surgery  
Vanderbilt University  
Director, Vanderbilt Continence Center  
Department of Urologic Surgery  
Vanderbilt Medical Center  
Nashville, Tennessee  
Chapter 49

**Steven G. Docimo, MD**

Professor of Urology, Director Pediatric Urology  
Department of Urology  
University of Pittsburgh School of Medicine  
Vice President, Medical Affairs and Chief Medical Officer  
Department of Medical Affairs  
Children's Hospital of Pittsburgh of UPMC  
Pittsburgh, Pennsylvania  
Chapter 114

**Sherri M. Donat, MD, FACS**

Associate Professor  
Department of Urology  
Weill Medical College of Cornell University  
Associate Attending Surgeon  
Dept of Surgery/Division of Urology  
Memorial Sloan-Kettering Cancer Center  
New York, New York  
Chapter 63

**Ahmed M. El-Zawahry, MD**

Resident in Urology  
Department of Urology  
Medical University of South Carolina  
Charleston, South Carolina  
Chapter 32

**Justin D. Ellett, PhD**

Student  
Department of Microbiology/Immunology  
Surgery, Division of Transplant  
Medical University of South Carolina  
Charleston, South Carolina  
Chapter 10

**Michael D. Fabrizio, MD, FACS**

Associate Professor  
Department of Urology  
Eastern Virginia Medical School  
Sentara Medical Group  
Department of Urology  
Sentara Norfolk General Hospital  
Norfolk, Virginia  
Chapter 125

**Walid A. Farhat, MD**

Associate Professor  
Department of Surgery  
University of Toronto  
Pediatric Urologist  
Department of Urology  
Hospital for Sick Children  
Toronto, Ontario  
Chapter 115

**Kevin M. Feber, MD**

Pediatric Urologist  
William Beaumont Children's Hospital  
Royal Oak, Michigan  
Chapter 99

**Gordon L. Fifer, MD**

Department of Urology  
Tulane University Health Sciences Center  
New Orleans, Louisiana  
Chapter 135

**Margit Fisch, MD, FEBV, FEAEV**

Professor of Urology  
 Department of Urology and Pediatric Urology  
 Center of Operative Medicine  
 University of Hamburg  
 Director, Department of Urology and Pediatric Urology  
 UKE University Clinic Eppendorf  
 Hamburg, Germany  
 Chapters 84 and 93

**John A. Fortney, MD**

Medical University of South Carolina  
 Charleston, South Carolina  
 Chapter 30

**Ludgar Franzaring, MD**

Chapter 90

**John P. Gearhart, MD**

Professor and Director of Pediatric Urology  
 Department of Urology  
 Johns Hopkins University School of Medicine  
 Baltimore, Maryland  
 Chapter 111

**Arvin K. George, MD**

Resident Physician  
 The Smith Institute of Urology  
 North Shore-Long Island Jewish Health System  
 New Hyde Park, New York  
 Chapter 130

**Elmar W. Gerharz, MD**

Department of Urology and Pediatric Urology  
 Julius Maximilians-University Medical School  
 Würzburg, Germany  
 Chapter 92

**Mohamed A. Ghoneim, MD**

Professor of Urology  
 Department of Urology  
 Nephrology Center  
 Mansoura, Egypt  
 Chapter 91

**Alienor S. Gilchrist, MD**

Resident in Urology, Department of Urology  
 University of Texas Southwestern Medical Center  
 Dallas, Texas  
 Chapter 34

**Inderbir S. Gill, MD, MCh**

Chair, Department of Urology  
 USC Institute of Urology  
 Keck School of Medicine  
 Los Angeles, California  
 Chapter 133

**Kenneth I. Glassberg, MD, FAAP, FACS**

Director, Division of Pediatric Urology  
 Morgan Stanley Children's Hospital of New York-Presbyterian  
 Professor of Neurology, Columbia University  
 College of Physicians and Surgeons  
 New York, New York  
 Chapter 108

**David A. Goldfarb, MD**

Professor of Surgery  
 Glickman Urological and Kidney Institute  
 Cleveland Clinic Lerner College of Medicine  
 Director, Center for Renal Transplantations  
 Department of Urology  
 Cleveland Clinic  
 Cleveland, Ohio  
 Chapter 12

**Irwin Goldstein, MD**

Clinical Professor  
 Department of Urology  
 University of California, San Diego  
 Director  
 Department of Sexual Medicine  
 Alvarado Hospital  
 San Diego, California  
 Chapter 76

**Marc Goldstein, MD, DSc (hon)**

Matthew P. Hardy Distinguished Professor  
 Cornell Institute for Reproductive Medicine and Urology  
 Surgeon-in-Chief, Male Reproductive  
 Medicine and Surgery  
 New York-Presbyterian/Weill Cornell Medical Center  
 New York, New York  
 Chapters 53, 57, 60A, 62, and 79

**Leonard G. Gomella, MD, FACS**

The Bernard W. Godwin Professor of Prostate Cancer  
 Chairman, Department of Urology  
 Thomas Jefferson University  
 Associate Director of Clinical Affairs  
 Jefferson Kimmel Cancer Center  
 Philadelphia, Pennsylvania  
 Chapter 122

**E. Ann Gormley, MD**

Professor of Surgery (Urology)  
 Section of Urology  
 Department of Surgery  
 Dartmouth Medical School  
 Hanover, New Hampshire  
 Urologist  
 Section of Urology, Department of Surgery  
 Dartmouth-Hitchcock Medical Center  
 Lebanon, New Hampshire  
 Chapter 31

**Richard W. Grady, MD**

Associate Professor of Urology  
 The University of Washington School of Medicine  
 Children's Hospital and Regional Medical Center  
 Seattle, Washington  
 Chapter 110

**Richard W. Graham, MD, FACS**

Urologic Specialists of Virginia  
 Richmond, Virginia  
 Chapter 134

**Sam D. Graham, Jr., MD**

Urologic Specialists of Virginia  
 Medical Director, Thomas Johns Hospital  
 Richmond, Virginia  
 Chapters 1, 24, 29, and 69

**Uri Gur, MD**

Fellow, Adult and Pediatric Reconstructive Urology  
 Eastern Virginia Medical School  
 Norfolk, Virginia  
 Chapters 72 and 78

**Georges-Pascal Haber, MD**

Section of Laparoscopic and Robotic Surgery  
 Glickman Urological and Kidney Institute  
 The Cleveland Clinic Foundation  
 Cleveland, Ohio  
 Chapter 133

**J. Nathaniel Hamilton, MD**

Resident Physician  
 Department of Urology  
 Medical University of South Carolina  
 Charleston, South Carolina  
 Chapter 14

**Misop Han, MD**

John Hopkins University  
 School of Medicine  
 Baltimore, Maryland  
 Chapter 28

**Paul Hanissian, MD**

Assistant Professor  
 Department of Obstetrics and Gynecology  
 Dartmouth Medical School  
 Hanover, New Hampshire  
 Department of Obstetrics and Gynecology  
 Dartmouth-Hitchcock Medical Center  
 Lebanon, New Hampshire  
 Chapter 42

**Richard E. Hautmann, MD, MD (hon)**

Professor of Urology  
 Department of Urology  
 University of Ulm Medical Faculty  
 Chief of Department of Urology  
 Urologische Universitasklinik  
 Ulm, Germany  
 Chapter 87

**Sean P. Hedican, MD**

Associate Professor  
 Department of Urology  
 University of Wisconsin School of Medicine  
 and Public Health  
 Madison, Wisconsin  
 Chapter 132

**Axel Heidenreich, MD**

Professor and Chairman of Urology  
 Department of Urology  
 RWTH University Aachen  
 Aachen, Germany  
 Chapter 65

**Rudolf Hohenfellner, MD**

Professor of Urology  
 Department of Urology  
 Emer. Director  
 Mainz Medical School  
 Mainz, Germany  
 Chapters 84 and 93

**Hal B. Hooper, MD**

Resident  
 Department of Urology  
 Georgetown University Hospital  
 Washington, DC  
 Chapter 137

**Carin V. Hopps, MD**

Clinical Assistant Professor of Urology  
 Medical University of Ohio  
 Toledo, Ohio  
 Chapter 79

**Scott G. Hubosky, MD**

Assistant Professor of Urology  
 Thomas Jefferson University Hospital  
 Philadelphia, Pennsylvania  
 Chapter 125

**Michael S. Ingber, MD**

Clinical Fellow  
 Glickman Urological and Kidney Institute  
 Cleveland Clinic  
 Cleveland, Ohio  
 Chapter 23

**Thomas W. Jarrett, MD**

Professor and Chairman  
 Department of Urology  
 George Washington University Medical Center  
 Washington, DC  
 Chapter 129

**Stephan Jeschke, MD**

University of Bern  
 Department of Urology  
 Inselspital  
 Bern, Switzerland  
 Chapter 86

**Michael A. S. Jewett, MD, FRCSC, FACS**

Professor of Surgery (Urology)  
 Department of Oncology  
 University of Toronto  
 Farquharson Clinical Research Chair in Oncology  
 Division of Urology, Department of Surgical Oncology  
 Princess Margaret Hospital, University Health  
 Toronto, Ontario, Canada  
 Chapter 66

**Gerald H. Jordan, MD, FACS, FAAP**

Professor of Urology  
 Eastern Virginia Medical School  
 Director of Adult Reconstructive Surgery  
 The Devine Center for Genitourinary Reconstruction  
 Sentara Norfolk General Hospital  
 Devine-Fiveash Urology, Ltd.  
 Norfolk, Virginia  
 Chapters 68, 72 and 78

**David B. Joseph, MD, FACS, FAAP**

Professor of Surgery  
 Department of Surgery  
 University of Alabama at Birmingham  
 School of Medicine  
 Chief of Pediatric Urology  
 Department of Surgery  
 Children's Hospital  
 Birmingham, Alabama  
 Chapter 101

**George W. Kaplan, MD**

Clinical Professor  
 Department of Surgery (Urology) and Pediatrics  
 University of California at San Diego School of Medicine  
 Chief Department of Urology  
 Rady Children's Hospital San Diego  
 San Diego, California  
 Chapter 119

**Evan J. Kass, MD, FAAP, FACS**

Chief of Pediatric Urology  
 Department of Urology  
 William Beaumont Children's Hospital  
 Rouaz Oak, Michigan  
 Chapter 99

**Melissa R. Kaufman, MD, PhD**

Assistant Professor  
 Vanderbilt University, Department of Urologic Surgery  
 Nashville, Tennessee  
 Chapter 49

**Louis R. Kavoussi, MD**

Chairman and Waldbaum Professor of Urology  
 Smith Institute for Urology  
 Hofstra University School of Medicine  
 North Shore-LIJ Health System  
 Long Island, New York  
 Chapter 130

**Thomas E. Keane, MD**

Professor and Chair  
 Department of Urology  
 Medical University of South Carolina  
 Charleston, South Carolina  
 Chapter 29

**Howard H. Kim, MD**

Fellow and Instructor  
 Department of Reproductive  
 Medicine and Urology  
 Weill Cornell Medical College  
 Assistant  
 Department of Urology  
 New York-Presbyterian/Weill Cornell  
 Medical Center  
 New York, New York  
 Chapters 53, 57 and 62

**Ja-Hong Kim, MD**

Department of Urology  
 University of California  
 Los Angeles, California  
 Chapters 47 and 48

**Moses M. Kim, MD**

Scout Department of Urology  
 Baylor College of Medicine  
 Houston, Texas  
 Chapter 139

**Andrew J. Kirsch, MD, FAAP, FACS**

Clinical Professor of Urology  
 Department of Pediatric Urology  
 Children's Healthcare of Atlanta  
 Emory University School of Medicine  
 Atlanta, Georgia  
 Chapter 104

**Adam P. Klausner, MD**

Associate Professor, Division of Urology  
 Virginia Commonwealth University School of Medicine  
 Richmond, Virginia  
 Chapter 13

**Eric A. Klein, MD**

Chairman  
 Glickman Urological and Kidney Institute  
 Professor of Surgery  
 Cleveland Clinic Lerner College of Medicine  
 Cleveland, Ohio  
 Chapters 21 and 83

**Chester J. Koh, MD, FAAP**

Division of Pediatric Urology  
 Childrens Hospital Los Angeles  
 Los Angeles, California  
 Chapter 105

**Harry P. Koo, MD, FAAP, FACS**

Barbara and William Thalheimer Professor  
 Division of Urology  
 Virginia Commonwealth University School of Medicine  
 Chairman of Urology  
 Division of Urology/Department of Surgery  
 VCU Medical Center-Medical College of Virginia  
 Richmond, Virginia  
 Chapter 67

**Venkatesh Krishnamurthi, MD**

Glickman Urological and Kidney Institute  
 Cleveland Clinic  
 Cleveland, Ohio  
 Chapter 12

**Sanjaya Kumar, MD, MPH**

President and Chief Medical Officer  
 Quantros, Inc.  
 Milpitas, California  
 Chapter 5

**Chad A. LaGrange, MD**

Assistant Professor  
 Department of Surgery  
 University of Nebraska  
 Omaha, Nebraska  
 Chapter 126

**Costas D. Lallas, MD, FACS**

Assistant Professor  
 Department of Urology  
 Thomas Jefferson University  
 Assistant Professor  
 Department of Urology  
 Jefferson Kimmel Cancer Center  
 Philadelphia, Pennsylvania  
 Chapters 128 and 131

**Cheryl T. Lee, MD**

Associate Professor  
 Department of Urology  
 University of Michigan  
 Ann Arbor, Michigan  
 Chapter 16

**Michael C. Lee, MD**

Resident Physician  
 Glickman Urological and Kidney Institute  
 Cleveland Clinic  
 Cleveland, Ohio  
 Chapter 83

**Richard S. Lee, MD**

Urology Resident  
 University of Washington  
 Seattle, Washington  
 Chapter 116

**Gary E. Lemack, MD**

Professor and Residency Program Director  
 Department of Urology  
 University of Texas Southwestern Medical Center  
 Dallas, Texas  
 Chapter 34

**Jeffrey A. Leslie, MD**

Assistant Professor  
 Department of Urology and Pediatrics  
 University of Texas Health Science Center at San Antonio  
 Pediatric Urologist  
 Department of Urology  
 Christus Santa Rosa Children's Hospital  
 San Antonio, Texas  
 Chapter 117

**Michael Leveridge, MD, FRCSC**

Clinical Fellow-Urologic Oncology  
 Division of Urology  
 University of Toronto  
 Clinical Fellow-Urologic Oncology  
 Department of Surgical Oncology  
 Division of Urology  
 University Health Network  
 Princess Margaret Hospital  
 Toronto, Ontario  
 Chapter 66

**Christina Lewicky-Gaupp, MD**

Urogynecology Fellow  
 Department of Obstetrics and Gynecology  
 University of Michigan  
 Ann Arbor, Michigan  
 Chapter 40

**Ronald W. Lewis, MD**

Medical College of Georgia  
 Augusta, Georgia  
 Chapter 75

**John A. Libertino, MD**

Professor  
 Department of Urology  
 Tufts University School of Medicine  
 Boston, Massachusetts  
 Chair  
 Institute of Urology  
 Lahey Clinic Medical Center  
 Burlington, Massachusetts  
 Chapter 6

**Mark R. Licht, MD**

Urology Associates of South Florida  
 Boca Raton, Florida  
 Chapter 75

# ■ REMEMBRANCES

## DR. JAMES FRANCIS GLENN

### MAY 10, 1928 – JUNE 10, 2009

On June 10, 2009, on the eve of the publication of this Seventh Edition, the originator of this textbook, James F. Glenn, died at the age of 81 in Lexington, Kentucky. I have asked two of his closest friends and urologic colleagues, Everett Anderson and Randy Rowland, to each write their thoughts on Dr. Glenn's career. The purpose is not to delineate his curriculum vitae, which would fill another volume of this text, but to allow the reader to

appreciate who Jim Glenn actually was.

For those of us who trained under him, Dr. Glenn was a mentor, a role model, and a great friend. Three personal attributes defined him: integrity, loyalty, and a principled life. He was always straightforward in his relationships with his residents, colleagues, and others with whom he worked. There was never any question as to where he stood and whether he would follow through on all that he promised. It was easy to follow someone so open, and though there may have been times when honesty was painful, Jim Glenn was always a gentleman and true to his word.

Nearly every resident, fellow, and faculty member who worked with Dr. Glenn can relate major events in his or her life on which Dr. Glenn had a significant influence, both professionally and personally. He treated all he worked with as family and was intensely loyal to all of us. Once he was your friend, you could count on him as a friend for life. Many of us who became departmental chairs and national and international leaders in urology owe him not only for the opportunities that he provided for us but also for being available and standing in when we needed help. He truly loved all of his protégées, no matter how much that love was returned by each of us.

Dr. Glenn had high expectations of his staff and residents, and though all of us on occasion did not meet his expectations, after his expression of displeasure, the incident was forgiven, and he never carried a grudge. His ultimate goal was to instill a compulsion for excellence, which he taught by example.

Finally, he lived a life that was based on principles and was unwilling to compromise those principles for political expediency. His principles were truth and excellence. He was a perpetual student; when confronted with a challenge, he gathered all the data, made a decision based on his principles, and stuck

to his decision. There were no gray areas, and he never compromised his core principles. If he was assured of the rightness of his position, he delivered the message regardless of the political consequences. Although he usually tried to convince people with his great sense of humor and intelligence, in the end he remained steadfast in his beliefs. Many others would have taken the easier road, but Jim Glenn was not an ordinary man, and for that reason he will forever be a guide in our lives.

Jim Glenn was born in Lexington, Kentucky, on May 10, 1928. He attended the local university school for the first 12 years of his education and then entered the University of Rochester, where he received a BA degree in 3 years. The fast track continued with a medical degree from Duke University in 3 years. There followed a 2-year residency in General Surgery at Peter Bent Brigham Hospital and a 3-year residency in Urologic Surgery at Duke University. With a chosen career in academic medicine, he spent the next 2 years on the faculty at Yale, followed by 2 years at Bowman Gray. Four years after completing his urologic residency he returned to Duke as Chief of Urology. In 4 years he had progressed from Instructor, to Assistant Professor, to Associate Professor, to Full Professor—an unbelievable accomplishment. During his 17 years at Duke, he trained 67 residents, 12 of whom became heads of urology at other institutions.

Apart from his academic and professional achievements, Dr. Glenn was known for his warmth, good humor, and concern for his patients, house staff, and colleagues. He derived great pleasure in promoting his residents and senior staff. Dr. Glenn knew every resident's wife's name and made every resident accepted into the program quickly feel that he was now a member of the Duke urology family. Dr. Glenn entertained his "family" on many occasions at his home, and when the residency period was over, he would use his many contacts to obtain jobs for his residents in academia or private practice.

After leaving Duke, Dr. Glenn served as Dean of Emory University School of Medicine from 1980 to 1983 and then as President of Mt. Sinai School of Medicine, Medical Center, and Hospital from 1983 to 1987. Subsequently he returned to Lexington and was appointed as Professor of Surgery and then Professor Emeritus of Surgery at the University of Kentucky (UK). Dr. Glenn served as Executive Director of the Markey Cancer Center at UK from 1989 to 1993; as Associate Dean for Clinical Affairs, UK College of Medicine, and Chief of Staff, UK Hospital, from 1993 to 1995; and as Interim Chair, Department of Surgery, from 1996 to 1997.

In addition to his administrative duties at UK, Dr. Glenn maintained a close relationship with the Division of Urology.

He was especially helpful in advising the division in the “art of fundraising.” With his assistance and generosity, three endowed chairs, one professorship, and two research endowments were established and funded, totaling over \$9 million.

Dr. Glenn was a major contributor to advancements in both adult and pediatric urology. He was quick to recognize changing trends and to adopt the best of these in his constant quest for excellence. Dr. Glenn was a member of 37 professional societies and President of the most prestigious, including the American Association of Genitourinary Surgeons, the Clinical Society of Genitourinary Surgeons, the International Society of Urology, the Society for Pediatric Urology, the Society of Pelvic Surgeons, and the Society of University Urologists. He was elected to Alpha Omega Alpha in medical school and later became its President. He was also a past-President of the Southeastern Section and an honorary member of five sections and of the American Urological Association. His curriculum vitae includes 4 textbooks, 6 exhibits, 18 scientific movies, 37 book chapters, and 279 manuscripts. He has received the Hugh Hampton Young Award from the American Urological Association and the St. Paul’s Medal for

professional contributions from the British Association of Urological Surgeons. In 2007 Dr. Glenn was also awarded the Félix Guyon Medal by the Société Internationale d’Urologie in Paris for his contributions to the society.

Dr. Glenn actively supported community as well as university causes and programs, helping raise money for and contributing generously to many organizations: the St. John’s Episcopal Church Building Fund, the UK Division of Urology, the Duke University Division of Urology, Transylvania University, the Bluegrass Trust for Historical Preservation, the Lexington History Museum, and Cardinal Hill Rehabilitation Hospital.

Dr. Glenn shared his wit, cheer, knowledge, and enthusiasm with all people with whom he interacted, playing a constructive role in community as well as academic organizations.

We will miss him.

## ■ P R E F A C E

In 1969 when the First Edition of *Urologic Surgery* was published, the avowed purpose of the work was to present authoritative expositions of various surgical procedures, authored by acknowledged experts in the field. It was the conviction of the editors that there were atlases and textbooks that presented urology well, but there were no volumes on surgical technique, and that urology is—first and foremost—a surgical specialty.

In developing that initial effort, I was joined (and guided) by my good friend and wise mentor William H. Boyce, superb clinician, outstanding scientist, and master surgeon. Between us, we were able to recruit some of the most respected urologic surgeons to contribute to the volume. Over the years, that tradition has continued, and I am forever grateful to all of my colleagues who have given of their time, talent, and expertise to the several iterations of this book.

Having observed my 81st birthday and retired from active clinical practice, I recognize that the time has come to pass the responsibility to others, and I happily do so. Two friends—Sam D. Graham Jr., MD, Director of the Johns Cancer Center in Richmond, Virginia, and Thomas E. Keane, MD, Chairman of Urology at the Medical University of South Carolina, Charleston—have already demonstrated their proficiency in co-editing previous editions. Both Dr. Graham and Dr. Keane are products of the Duke system, as I am.

As our French friends say, “Vive urologie!”

*James F. Glenn, BA, MD, DSc, FACS, FRCS*

## CHAPTER 1 ■ ANATOMY OF THE ADRENAL GLANDS, KIDNEY, URETER, AND PELVIS

## ADRENAL

RICARDO BEDUSCHI AND UNYIME O. NSEYO

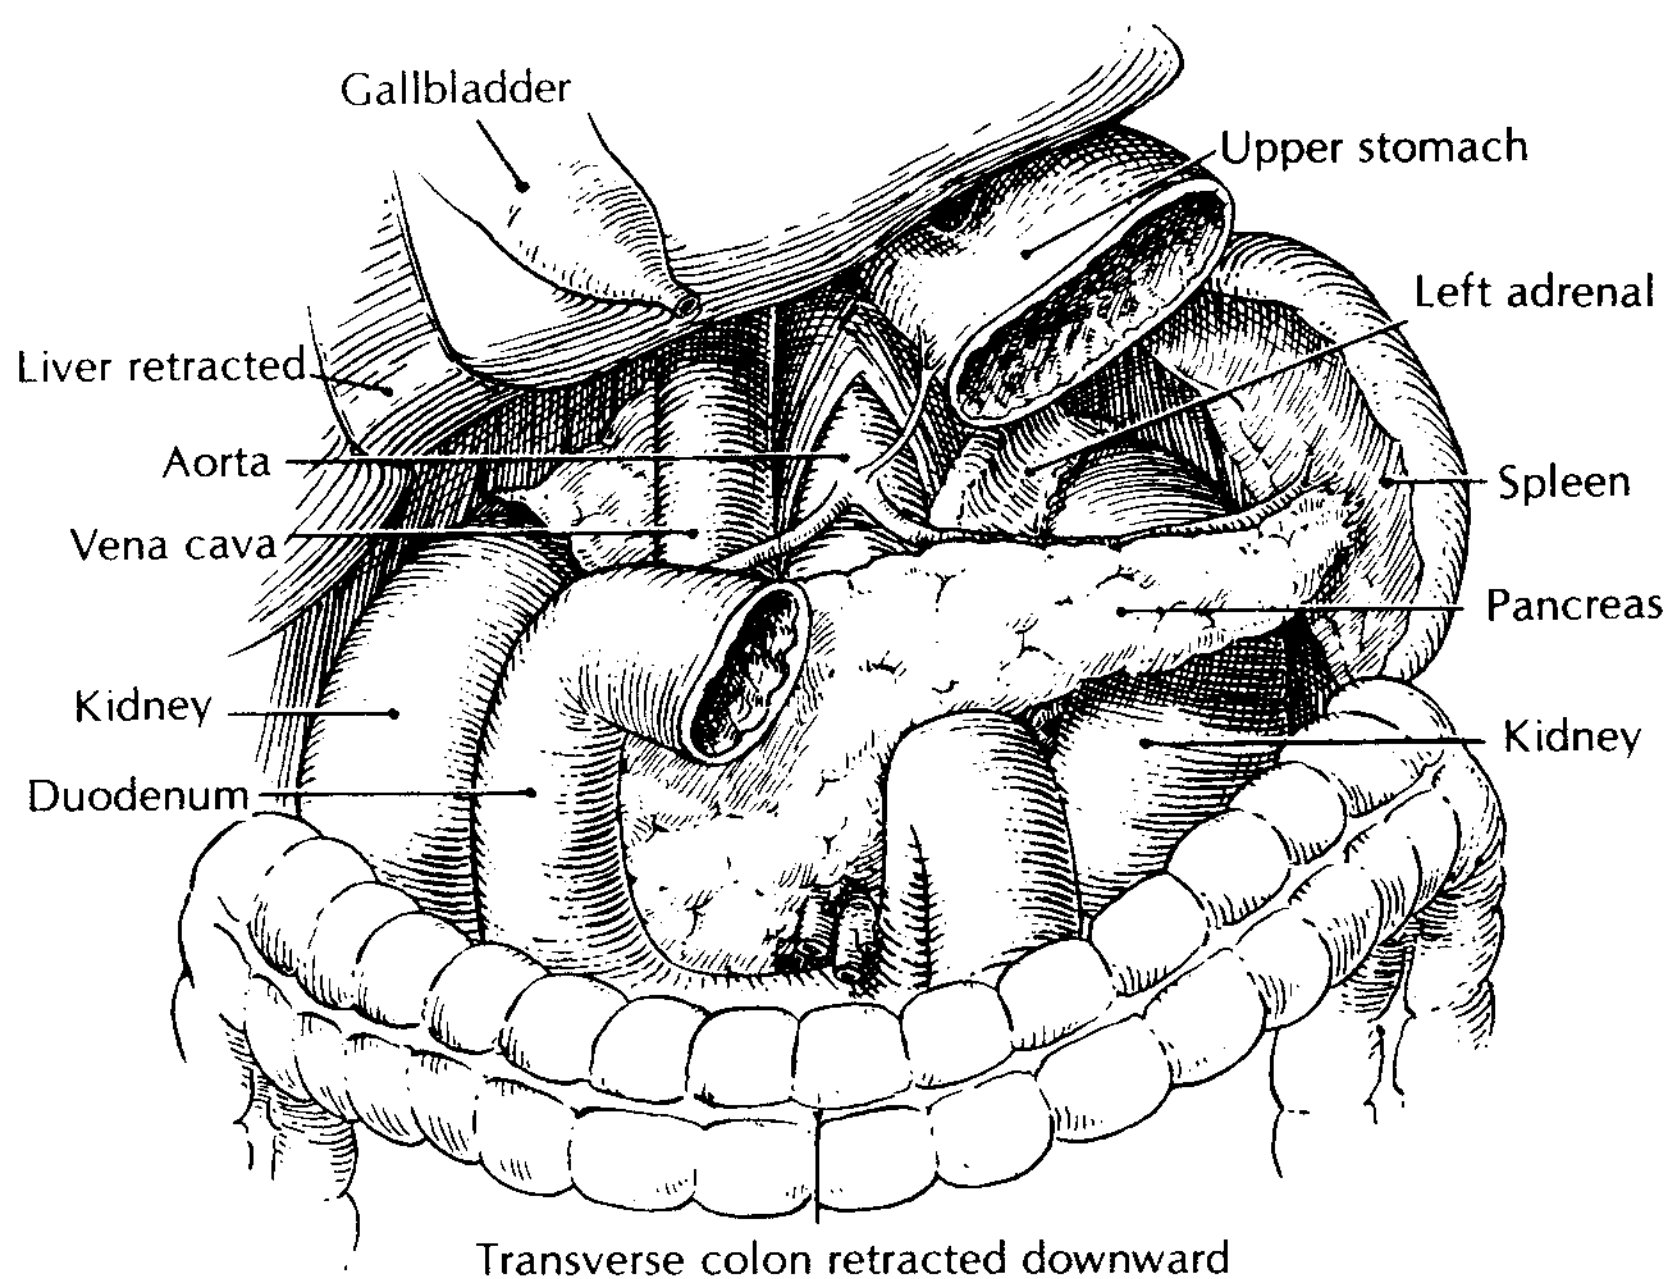

The adrenal glands are paired and located high in the retroperitoneum, on the anterior craniomedial aspect of the kidney (Figs. 1.1, 1.2, and 1.3). Their characteristic yellow color distinguishes them from the surrounding fat or pancreas. They weigh approximately 5 g, but weight and size may change significantly after prolonged illness or as the result of prolonged adrenocorticotrophic hormone (ACTH) stimulation. The atrophic gland is thin and pale, and its easily recognizable hyperplasia makes it readily visible. The left adrenal gland has a semicircular or crescent shape. The right gland has an inverted pyramidal or V-shape. The adrenal gland consists of the cortex and medulla and arose from the mesoderm (cortex) and ectodermal (medulla) elements in the medial aspect of the coelomic cavity.

## Embryology

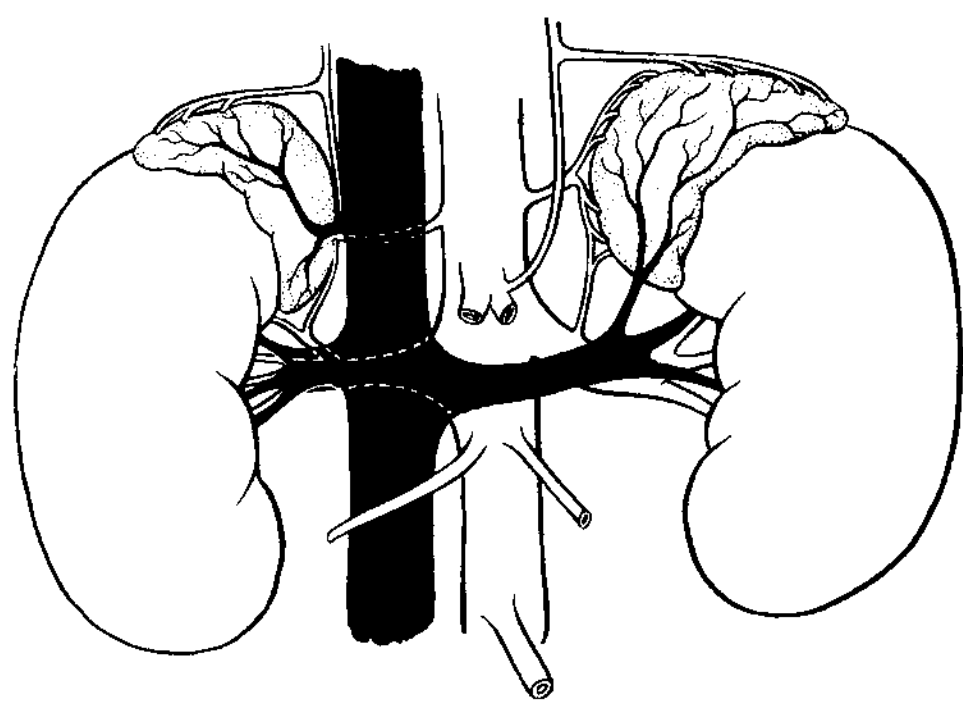

Embryologically, the ectodermal medullary elements migrate from the same primordial neural crest that gives rise to the sympathetic chain. The mesodermal cortical tissues arise from the dorsal cells of the blastema cord at the medial aspect of the mesonephric bodies. However, the ventral cells of these bodies are the origin of the interstitial cells of the testis or the theca cells of the ovary. The 8-week embryo has massive adrenals, approximately the size of the kidney, and they remain enlarged and very vascular until birth. Rapid regression occurs in the adrenal size during the first month. The large adrenal size with hypervascularity may predispose to adrenal hemorrhage in the newborn as well as misdiagnosis for Wilms tumor or neuroblastoma. The medullary tissue within the gland imparts a unique tripartite structure of the head (most medial), body, and tail (most lateral). Each adrenal gland resides within the Gerota fascia with the kidney. However, in

**FIGURE 1.1** The anatomic relationship of the adrenal glands to the aorta and inferior vena cava. Multiple arterial vessels entering the glands indicate the rich arterial supply, while a single central adrenal vein illustrates the limited and relatively constant venous drainage.

**FIGURE 1.2** An anterior view of the abdomen illustrating the anatomic relationship of the adrenal glands to the surrounding gastrointestinal tract and organs.

**FIGURE 1.3**

the case of renal ectopy, the adrenal remains in its natural position.

Ectopic adrenal tissues may develop in certain locations of the body. Although rare, they may undergo neoplastic changes or hyperplasia. Ectopic adrenal tissues in most cases consist of cortex only; rarely do they contain cortex and medulla. The embryological relationship in the urogenital ridge predisposes to adrenal ectopy in the retroperitoneum, the testis, the spermatic cord, and the region of the celiac ganglion.

### Vascular Anatomy

The arterial supply remains variable; the main sources include primarily the branches from the aorta, inferior phrenic artery, and renal artery. The multiple small-caliber arterial branches must be appreciated for hemostasis during surgery. The venous drainage, although less variable, usually represents a bigger challenge, especially during operations on large adrenal masses. The right adrenal vein is short and empties directly into the inferior vena cava (IVC) in its most posterolateral aspect. Large adrenal tumors may obscure its visualization,

making identification of this vein very challenging. Bleeding from this site can be profuse and even life-threatening if not identified and controlled immediately. The left adrenal vein is much smaller than the right adrenal vein. It usually exits anteroinferiorly, draining into the ipsilateral renal vein.

### Contiguous Structures

Thorough knowledge of the anatomic relationships holds the key to preventing injury to the contiguous structures during surgical dissection (Fig. 1.2). The right adrenal gland lies superior to the upper pole of the right kidney, posterolaterally to the IVC. Dissection of the right adrenal gland is limited medially by the duodenum and superiorly by the right hepatic lobe. Access to the right adrenal gland is more easily obtained by entering the retroperitoneum behind the liver. The right hepatic lobe can be mobilized from the colon and diaphragm by transecting the triangular, coronary, and hepatocolic ligaments, allowing visualization of the right adrenal gland just superior to the upper pole of the right kidney. Mobilization of the duodenum is also required for easier identification of the right adrenal vein. This step is of special interest for large pheochromocytomas, in which early access to the adrenal vein is essential. Using the Kocher maneuver, the duodenum can be retracted medially, allowing easier access to the IVC and a complete dissection of the right adrenal vein. Once the right adrenal vein is controlled, an avascular plane can be developed toward the lateral aspect of the gland, allowing quick and bloodless removal of the gland. Attention should be paid to the main arterial trunks as well as the multiple small-caliber arteries, which can be easily controlled with electrocautery and/or surgical clips.

The left adrenal gland is usually more medial than the right gland, and it lies on the upper pole of the left kidney, just lateral to the aorta. The left adrenal gland lies in close contact with the spleen and stomach, and it is crossed on its antero-inferior surface by the body of the pancreas and the splenic

artery and vein. A special technical effort must be made to prevent inadvertent injury to the tail of the pancreas and/or capsule of the spleen. Releasing the splenocolic ligament allows free mobilization of the spleen, and gentle blunt dissection allows medial mobilization of the left abdominal viscera and adequate exposure of the left adrenal gland. The left adrenal vein is usually isolated in the anteroinferior aspect of the gland, and control of this vein is usually less of a problem, with minimal blood loss (Fig. 1.3). The lowest extent of this gland is close to the renal vessel, which remains at risk of injury during adrenalectomy.

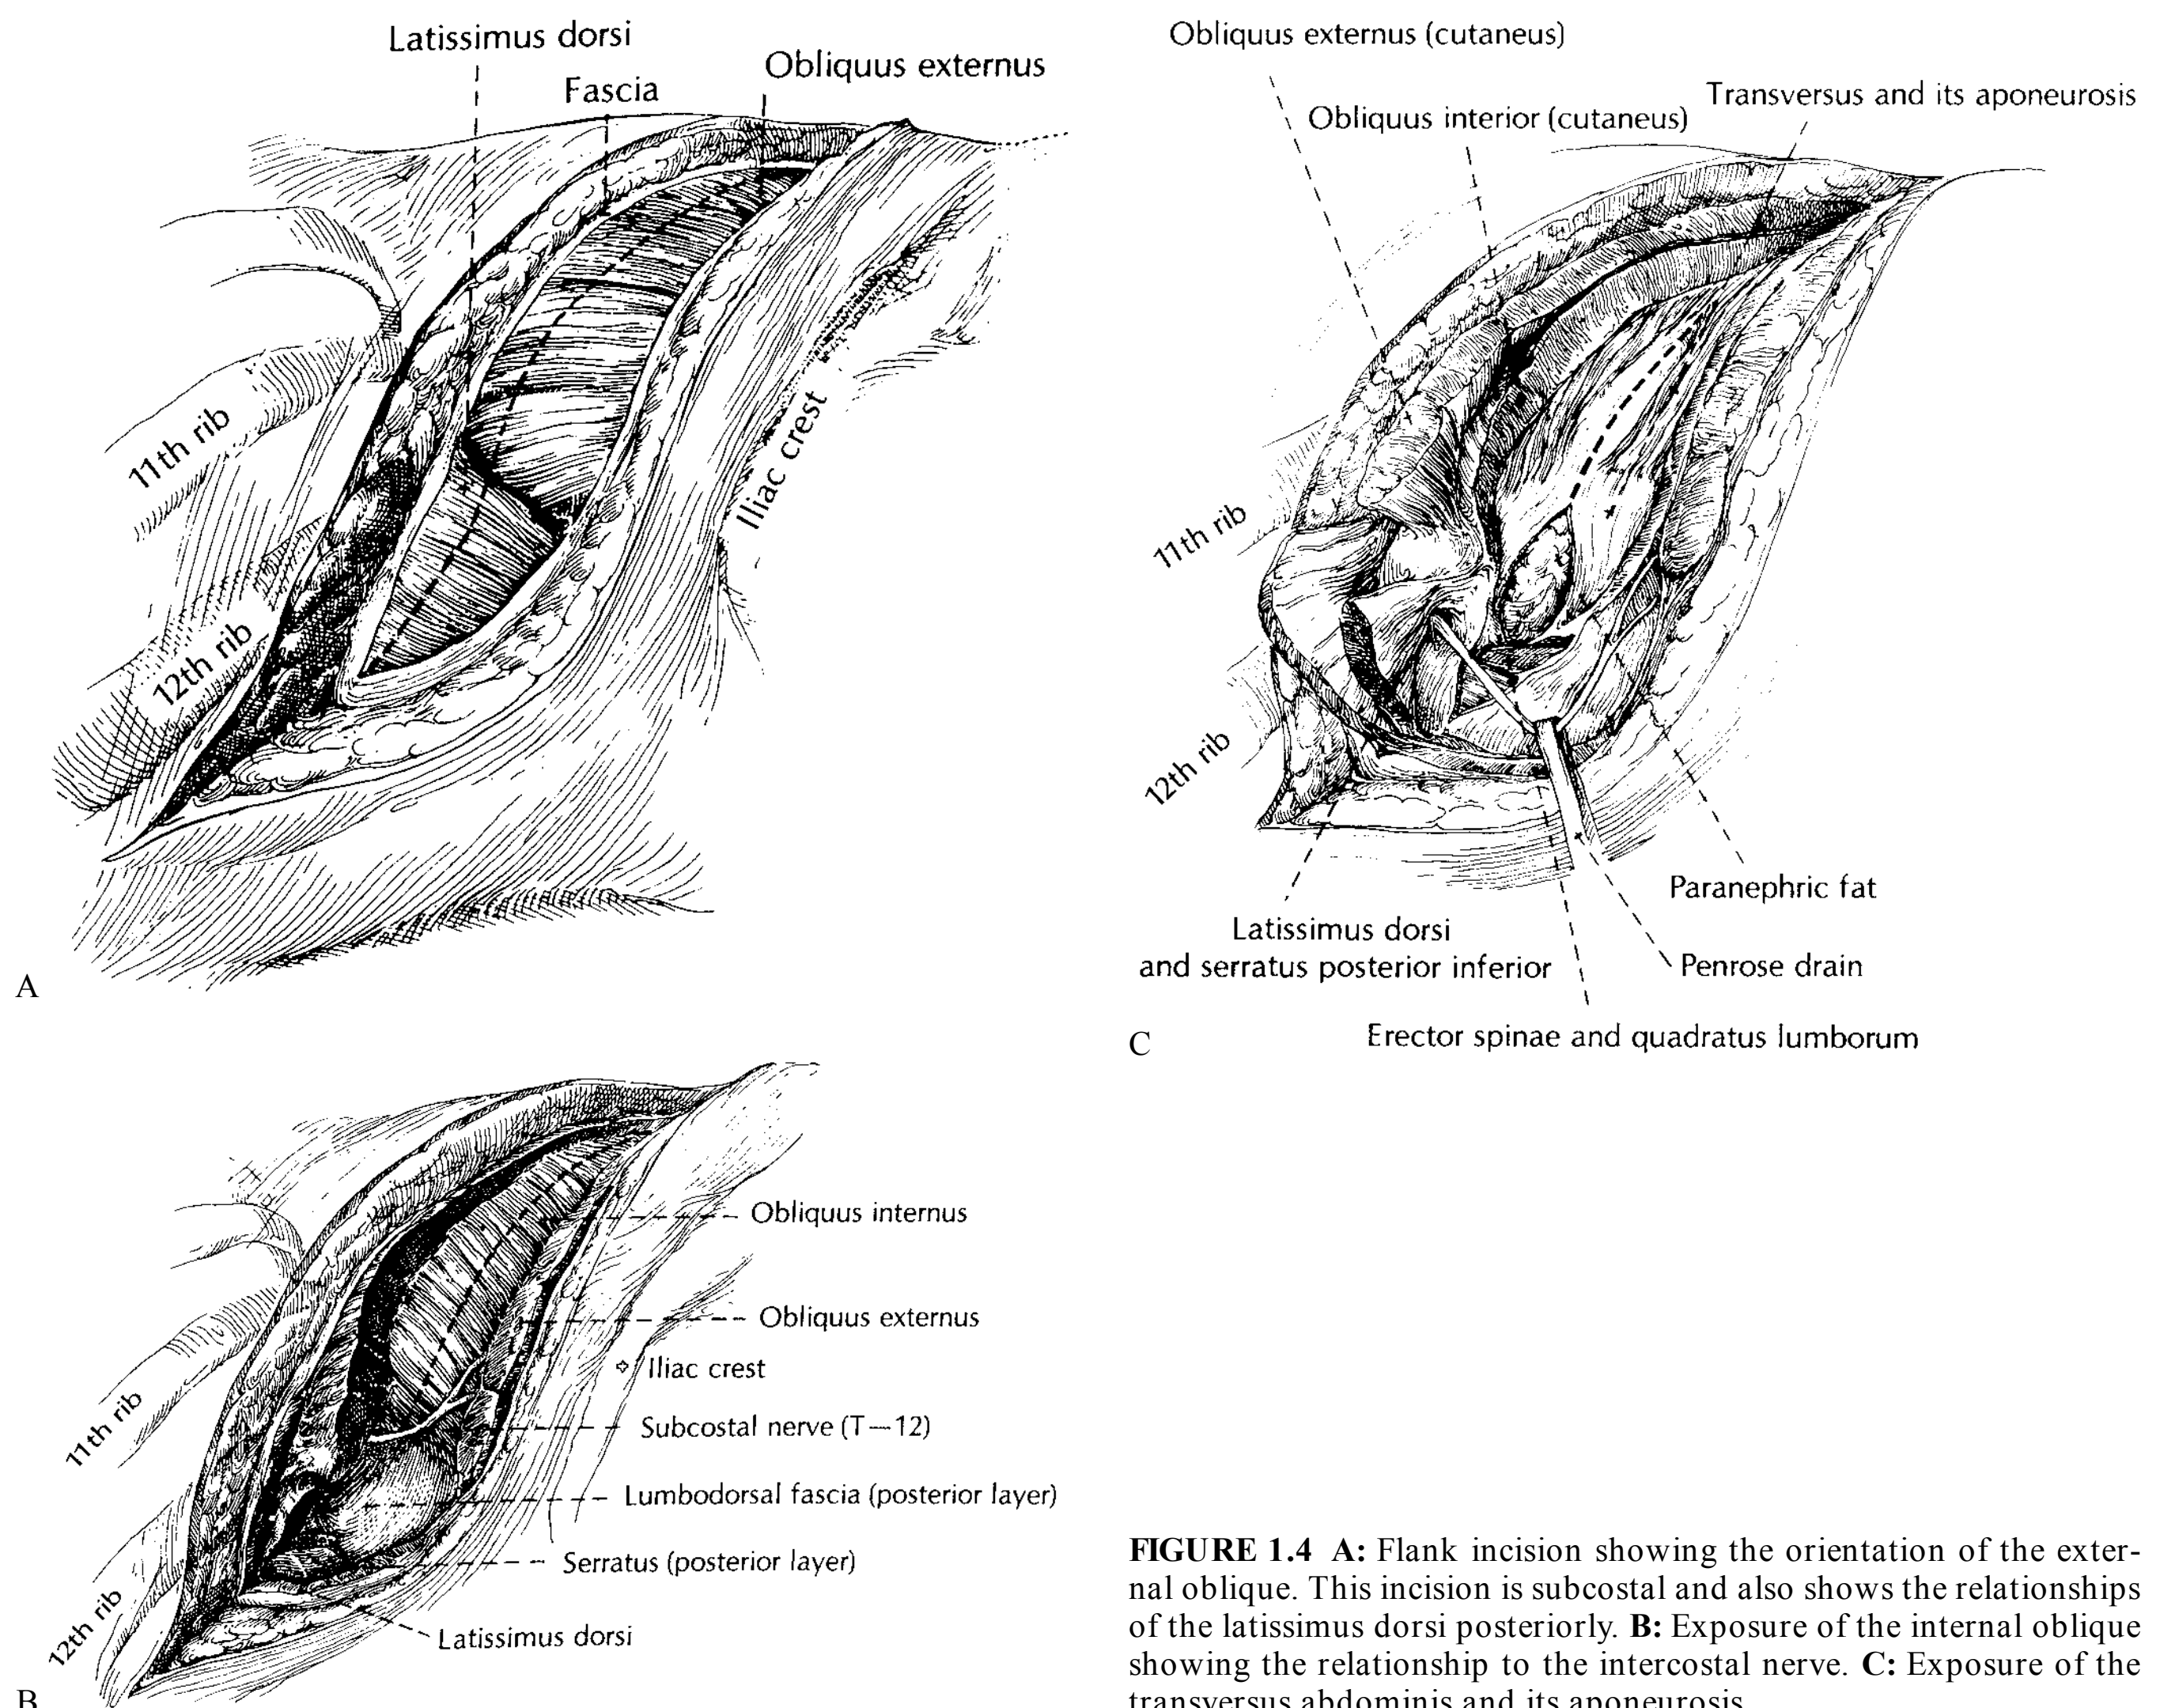

## KIDNEY

SAM D. GRAHAM, JR.

The abdominal wall is composed of three layers of muscle and fascia that are derived from the same embryonic muscle sheets as the intercostal muscles. Each muscle is covered by its own layer of deep fascia and is innervated by the intercostal nerves.

The external oblique fibers are oriented anteriorly and inferiorly, attaching posteriorly to the iliac crest, and the anterior fibers attach to the linea alba in the midline (Fig. 1.4A). The internal oblique fibers are oriented anteriorly and superiorly (Fig. 1.4B). Posteriorly, the fibers of the internal oblique attach to the lower four ribs, and anteriorly they attach to the linea alba. In the upper abdomen, the internal oblique fascia splits to enclose the rectus muscle, while inferiorly the fascia only covers the rectus muscle anteriorly. The ilioinguinal and iliohypogastric nerves are found in the internal oblique fascia anterior to the internal oblique muscle. The transversus abdominis are horizontally oriented fibers that attach to the linea alba (Fig. 1.4C). The ribs are supported by the intercostal muscles and fascia as well as the costovertebral (costotransverse) ligament, which must be divided if the rib is to be retracted inferiorly (Fig. 1.5).

The kidneys are located on either side of the vertebral column in the lumbar fossa of the retroperitoneum and vary in length in adults from 11 cm to 14 cm, or from approximately 3.0 to 4.5 times the height of the second lumbar vertebrae (Fig. 1.1). The parenchyma of the kidney is covered by a thin

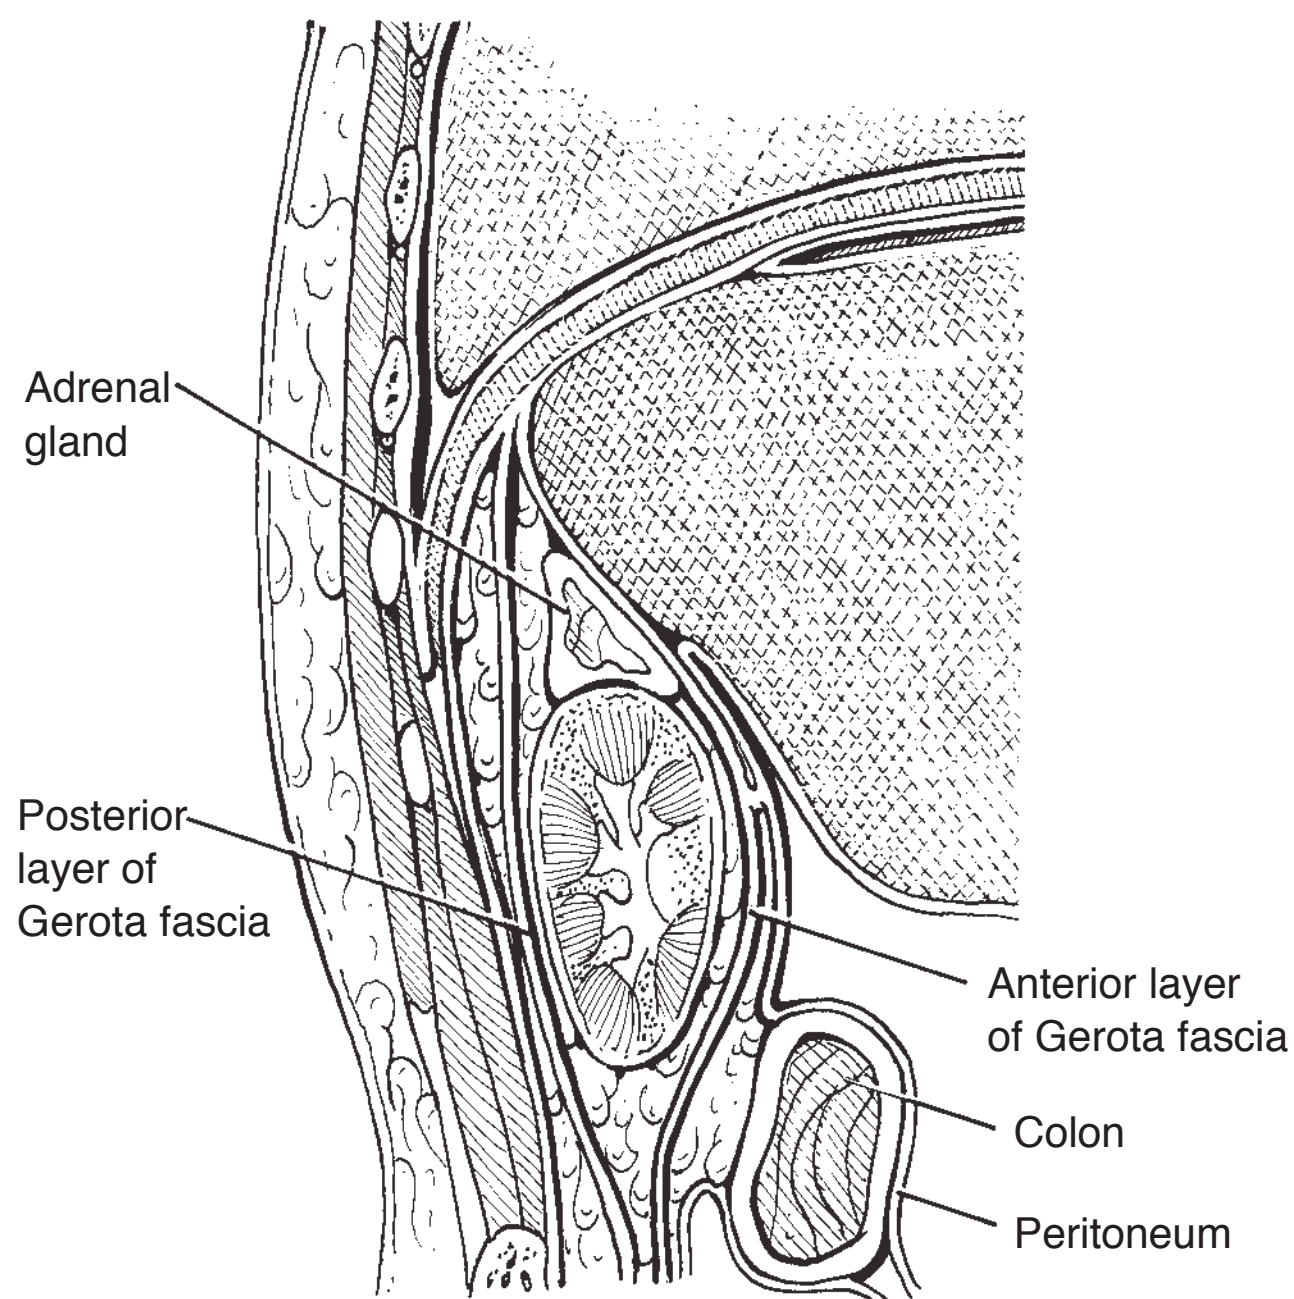

**FIGURE 1.4** **A:** Flank incision showing the orientation of the external oblique. This incision is subcostal and also shows the relationships of the latissimus dorsi posteriorly. **B:** Exposure of the internal oblique showing the relationship to the intercostal nerve. **C:** Exposure of the transversus abdominis and its aponeurosis.

**FIGURE 1.5** Costovertebral (costotransverse) ligaments extend from the transverse process of the vertebra immediately above the rib to the neck of the rib. In order to gain exposure during a thoracolumbar or supracostal approach, this must be divided to allow the rib to rotate inferiorly.

transparent capsule, which in turn is covered by a layer of perinephric fat enclosed in a distinct layer of fascia (Gerota fascia) (Fig. 1.6). The capsule is attached to Gerota fascia by fibrous trabeculae (1). Gerota fascia is completely fused superiorly and laterally, but it is open inferiorly and to some extent medially, where it is adherent to the adventitia of the renal vessels, aorta, and inferior vena cava. Gerota fascia extends above the kidney to form a special compartment for the adrenal gland (2). Posteriorly, Gerota fascia is connected to the sheaths of the psoas and quadratus lumborum muscles

**FIGURE 1.6** Retroperitoneal anatomy showing Gerota fascia in sagittal section.

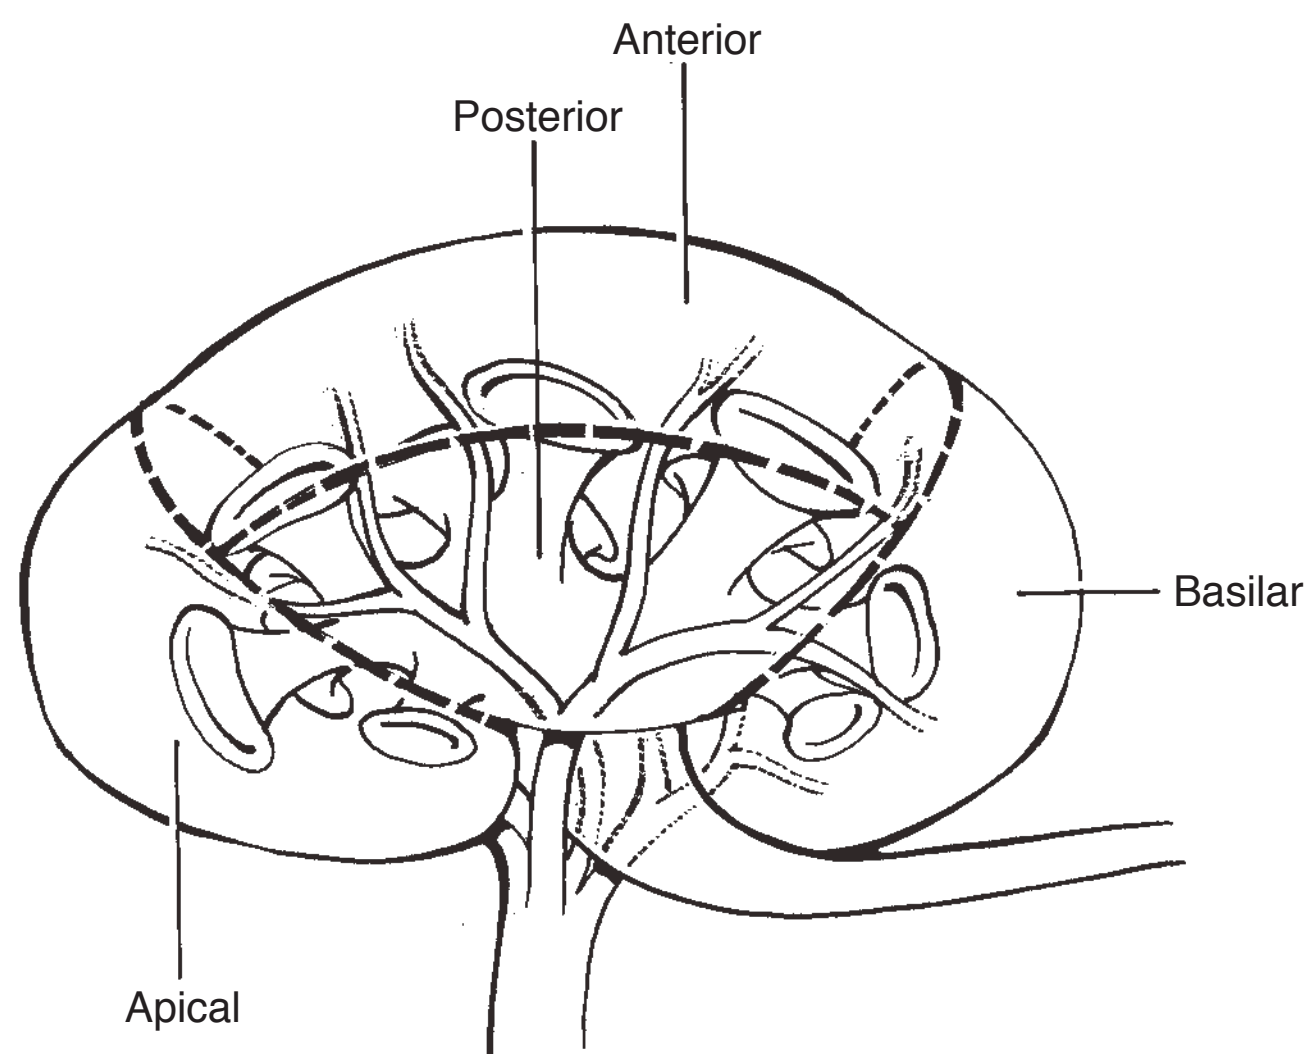

by connective tissue septae. Anteriorly, Gerota fascia is closely applied to the peritoneum. On the left, the hilum of the spleen is attached to the ventral aspect of the kidney by a double layer of peritoneum known as the splenorenal ligament (2).

## Vascular Anatomy

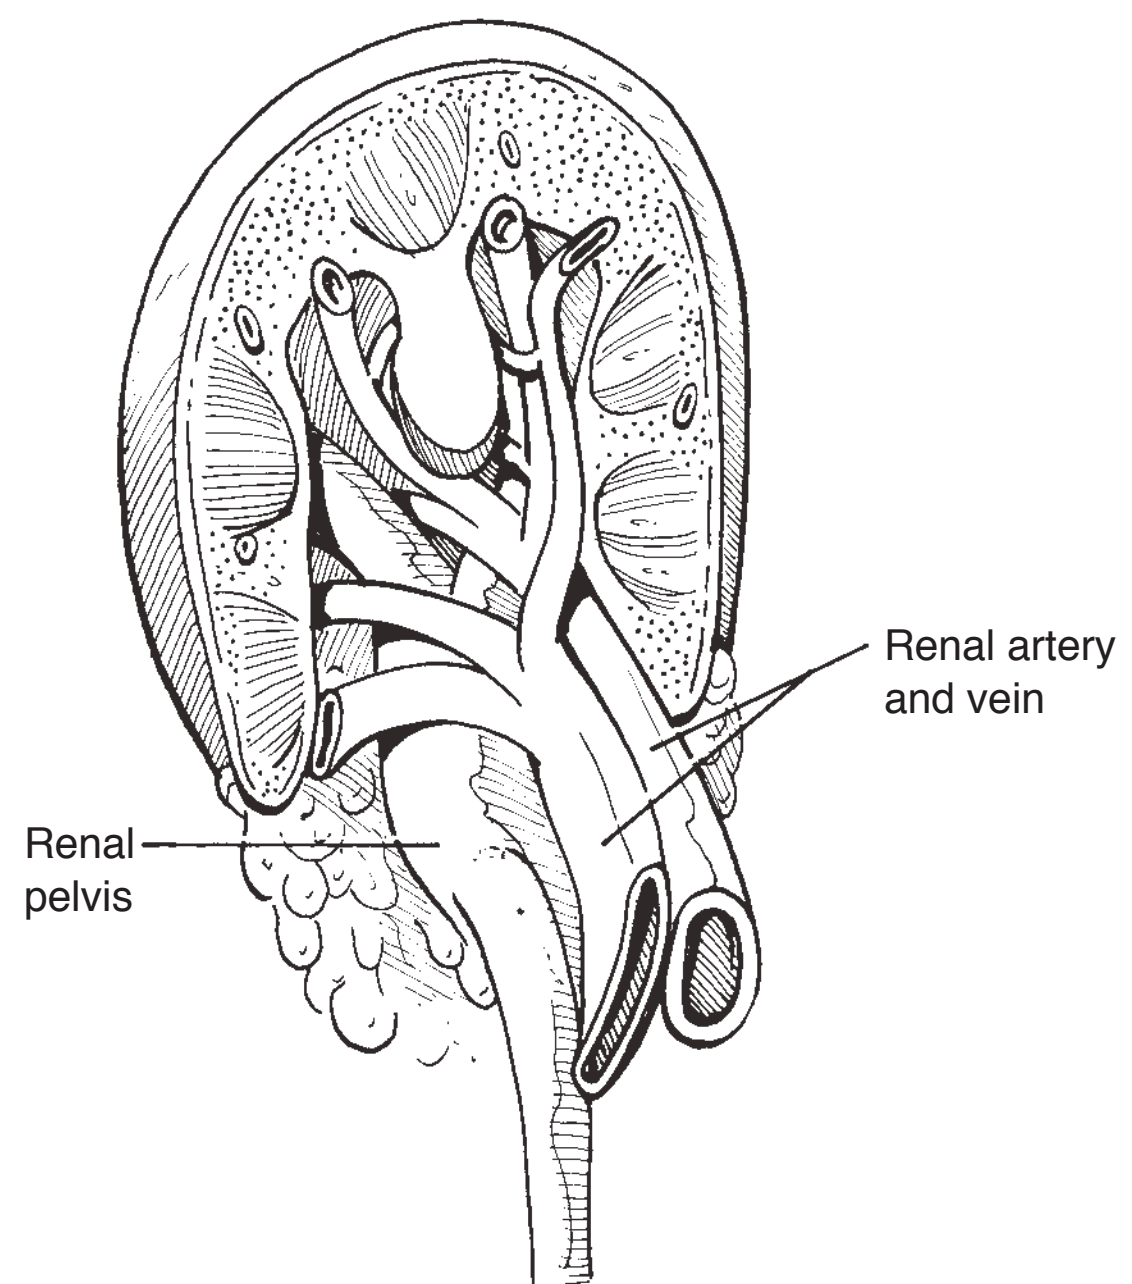

The main renal arteries are branches of the aorta emanating from the lateral portion of the aorta at approximately L-2. In general, the renal arteries divide into segmental branches at the junction of the middle and final third of their course. A single left artery most commonly lies dorsal to the renal vein, and a long right renal artery lies dorsal to the vena cava and the renal vein. Up to 35% of kidneys have an accessory renal artery, with 1.5% having more than one accessory artery (2). As the renal artery approaches the hilum, it has two branches, the inferior suprarenal (adrenal) and the ureteric arteries (Fig. 1.6). At the hilum, the main renal artery divides into an anterior and posterior branch, which further divide into segmental arteries. The kidney can be divided into four segments based upon the arterial supply (Fig. 1.7). Both the apical and basilar segmental arteries supply each respective pole of the kidney anteriorly and posteriorly. The largest segment is the anterior segment, which is supplied by two segmental arteries and extends posteriorly to the avascular plane where it meets the posterior segment (3).

The renal veins directly join the vena cava. The right renal vein is usually less than one-half the length of the left renal vein and has no significant branches. The left renal vein, however, is usually joined by the adrenal and inferior phrenic vein superiorly, the gonadal vein inferiorly, and frequently by lumbar vein(s) posteriorly (Fig. 1.8). These collaterals are of great importance in patients in whom the vena caval ligation or resection is contemplated.

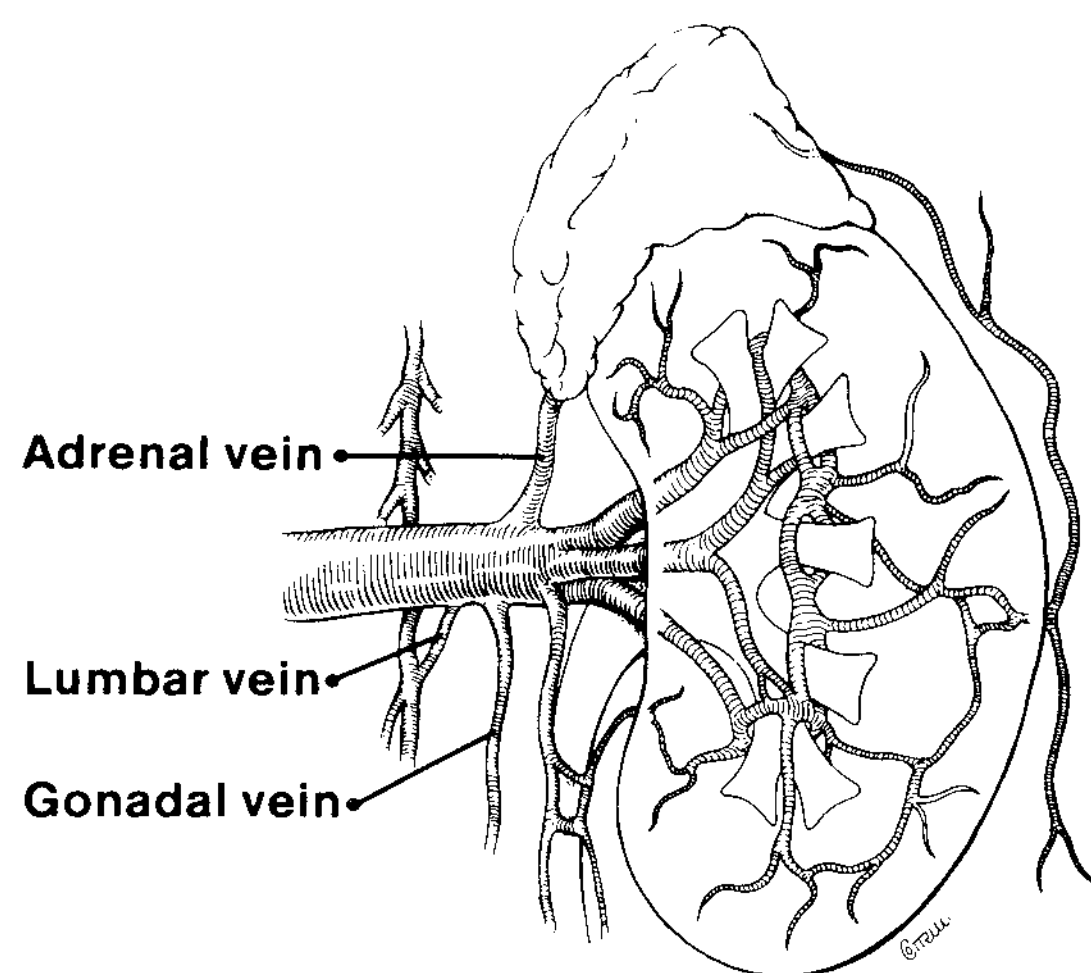

The renal vein is usually the most anterior structure in the renal hilum. Posterior to the vein is the renal artery, and

**FIGURE 1.7** Segmental anatomy of the kidney. The relatively avascular plane between the anterior and posterior segments is the line of Brödel. In general, calyces tend to extend from the renal pelvis to the central mass of the segment they supply.

**FIGURE 1.9** Transverse section of kidney showing relative anatomy of vascular structures in the renal hilum.

**FIGURE 1.8** The complex and varied anatomy of the left renal vein. Note that there may be one or even two lumbar veins from the renal vein posteriorly, allowing alternative venous flow if the vena cava is occluded.

the most posterior structure in the hilum is the renal pelvis. The hilum is filled with fibrofatty tissue that can usually be easily dissected from these structures to allow access into the renal sinus (Fig. 1.9).

### Lymphatic Anatomy

Parenchymal and capsular lymphatics coalesce and drain into the right lumbar or paraaortic chains, respectively. These lymphatics become part of the cisterna chyli superior to the renal artery.

### Contiguous Structures (Fig. 1.10)

Posterior to the kidney lies the psoas major and quadratus lumborum muscles. Posteriorly and superiorly, the upper pole of each kidney is in contact with the diaphragm. The pleura is also adjacent to the upper poles of both kidneys, usually extending down below the level of the twelfth rib posteriorly and to the eleventh rib anteriorly (1).

Embryologically, when the gut rotates, this leaves the posterior parietal peritoneum covering the upper three-fourths of the right kidney and is directly related to the hepatorenal pouch of Morrison. The duodenum is fixed to the original peritoneal covering of the lower pole of the right kidney by fusion of the embryonic dorsal mesentery to the posterior parietal peritoneum (2). On the left, the rotation of the foregut causes a fusion of the embryonic mesogastrium with the original peritoneal covering of the upper anterior kidney, thereby causing the relationship of the left kidney to the omental bursa (2). The midportion of the left kidney loses its contact with the peritoneum due to growth of the tail of the pancreas.

Superiorly, the anteromedial surface of the right kidney is in contact with the right adrenal gland. The liver overlies the anterior two-thirds of the right kidney, and the hepatic flexure of the colon overlies the lower one-third of the right kidney. The second portion of the duodenum overlies the renal hilum. In >90% of patients, the right kidney is lower than the left (2).

The medial surface of the left kidney is also in contact with the left adrenal gland. Other structures anterior and in close approximation to the left kidney are the spleen, the tail of the pancreas, the stomach, and the splenic flexure of the colon.

**FIGURE 1.10** The kidney in relation to contiguous structures.

## CHAPTER 2 ■ PARTIAL NEPHRECTOMY

SAMIR S. TANEJA

While partial nephrectomy was described over 125 years ago, its widespread use is truly confined to the last 20 years (1,2). Partial nephrectomy is utilized for a number of urologic processes, including stone disease, nonfunction within a duplicated moiety, trauma, infection, and renal tumors. Within the last 10 to 20 years, the major application of partial nephrectomy has been in the treatment of small renal tumors as an alternative to radical nephrectomy (1,2). Downward stage migration, more frequent incidental detection of tumors, better imaging techniques, and increasing surgeon comfort have led to increased utilization and expanded indications for partial

nephrectomy. Despite these developments, recent surveys suggest that partial nephrectomy remains underutilized nationally in the treatment of small renal tumors.

### INDICATIONS

The primary indication for partial nephrectomy is in the resection of renal tumor. The procedure may also be performed for a nonfunctioning duplicated moiety, trauma, or stone disease, in addition to a number of less common indications. While it

is acceptable to remove a solitary kidney or both kidneys if required for oncologic efficacy, in general, the presence of tumor in a solitary kidney or bilaterally is considered an absolute indication for partial nephrectomy. Likewise, cases in which radical nephrectomy would result in a need for permanent dialysis due to severe baseline azotemia should be considered absolute indication. In these cases, “absolute” implies that partial nephrectomy should be contemplated regardless of the tumor size or stage.

Relative indications include medical illnesses predisposing to renal disease, pre-existing medical renal disease, renal stones, recurrent renal infection, mild azotemia, and multifocal tumors associated with a genetic syndrome. An elective partial nephrectomy is defined as that in which the patient has none of the above risk factors, normal renal function, and a radiologically normal contralateral renal moiety. Historically, elective partial nephrectomy has been recommended only for exophytic or peripherally located tumors <4 cm in size. Much of the literature on which this recommendation was made was based upon series in which worsened oncologic outcomes were noted for central tumors and those >4 cm in size. Within these series, it is notable that many of these larger or central tumors were removed for absolute indications, potentially biasing the oncologic outcomes. As surgeons have become comfortable with the technique, indications for elective partial nephrectomy have been expanded to include central tumors and those in the T1b (4- to 7-cm) category. Thus far, there is no apparent decline in cancer control among those series reported (2).

Recent studies have suggested that partial nephrectomy may result in better long-term renal function than radical nephrectomy (3). A large cohort comparison demonstrated a higher likelihood of a glomerular filtration rate (GFR) >45 mL per minute or >60 mL per minute among those undergoing partial nephrectomy as compared to radical nephrectomy (4). Because GFR strongly correlates with the likelihood of cardiovascular mortality and other medical illnesses, in this regard partial nephrectomy may be beneficial.

---

## ALTERNATIVE THERAPIES

---

Alternative therapies to open partial nephrectomy include radical nephrectomy, laparoscopic partial nephrectomy, laparoscopic radical nephrectomy, or laparoscopic/percutaneous ablative procedures. A discussion of candidate selection for open or laparoscopic partial nephrectomy is beyond the scope of this chapter. Selection in this regard is highly dependent upon operator experience.

---

## SURGICAL TECHNIQUE

---

The technique of partial nephrectomy can be divided into renal preparation, renal incision, vascular repair and hemostasis, and collecting system reconstruction. These fundamental aspects of the operation should be considered individually in order for the surgeon to master the technique. It is most important to remember that despite the desire to preserve the kidney, partial nephrectomy for tumor is first a cancer operation, and margin control remains the primary consideration.

---

## Renal Preparation

---

In preparing a kidney for partial nephrectomy, full renal mobilization is most often necessary. The selected incisional approach can include a transperitoneal subcostal or midline incision, a thoracoabdominal incision, or an extraperitoneal flank incision, but when performing the operation through the flank, full mobilization is possible, allowing the kidney to easily stretch to the level of the skin. We have found that other advantages of the flank approach include containment of postoperative bleeding and/or urine leak, earlier resolution of ileus, and direct access to the kidney.

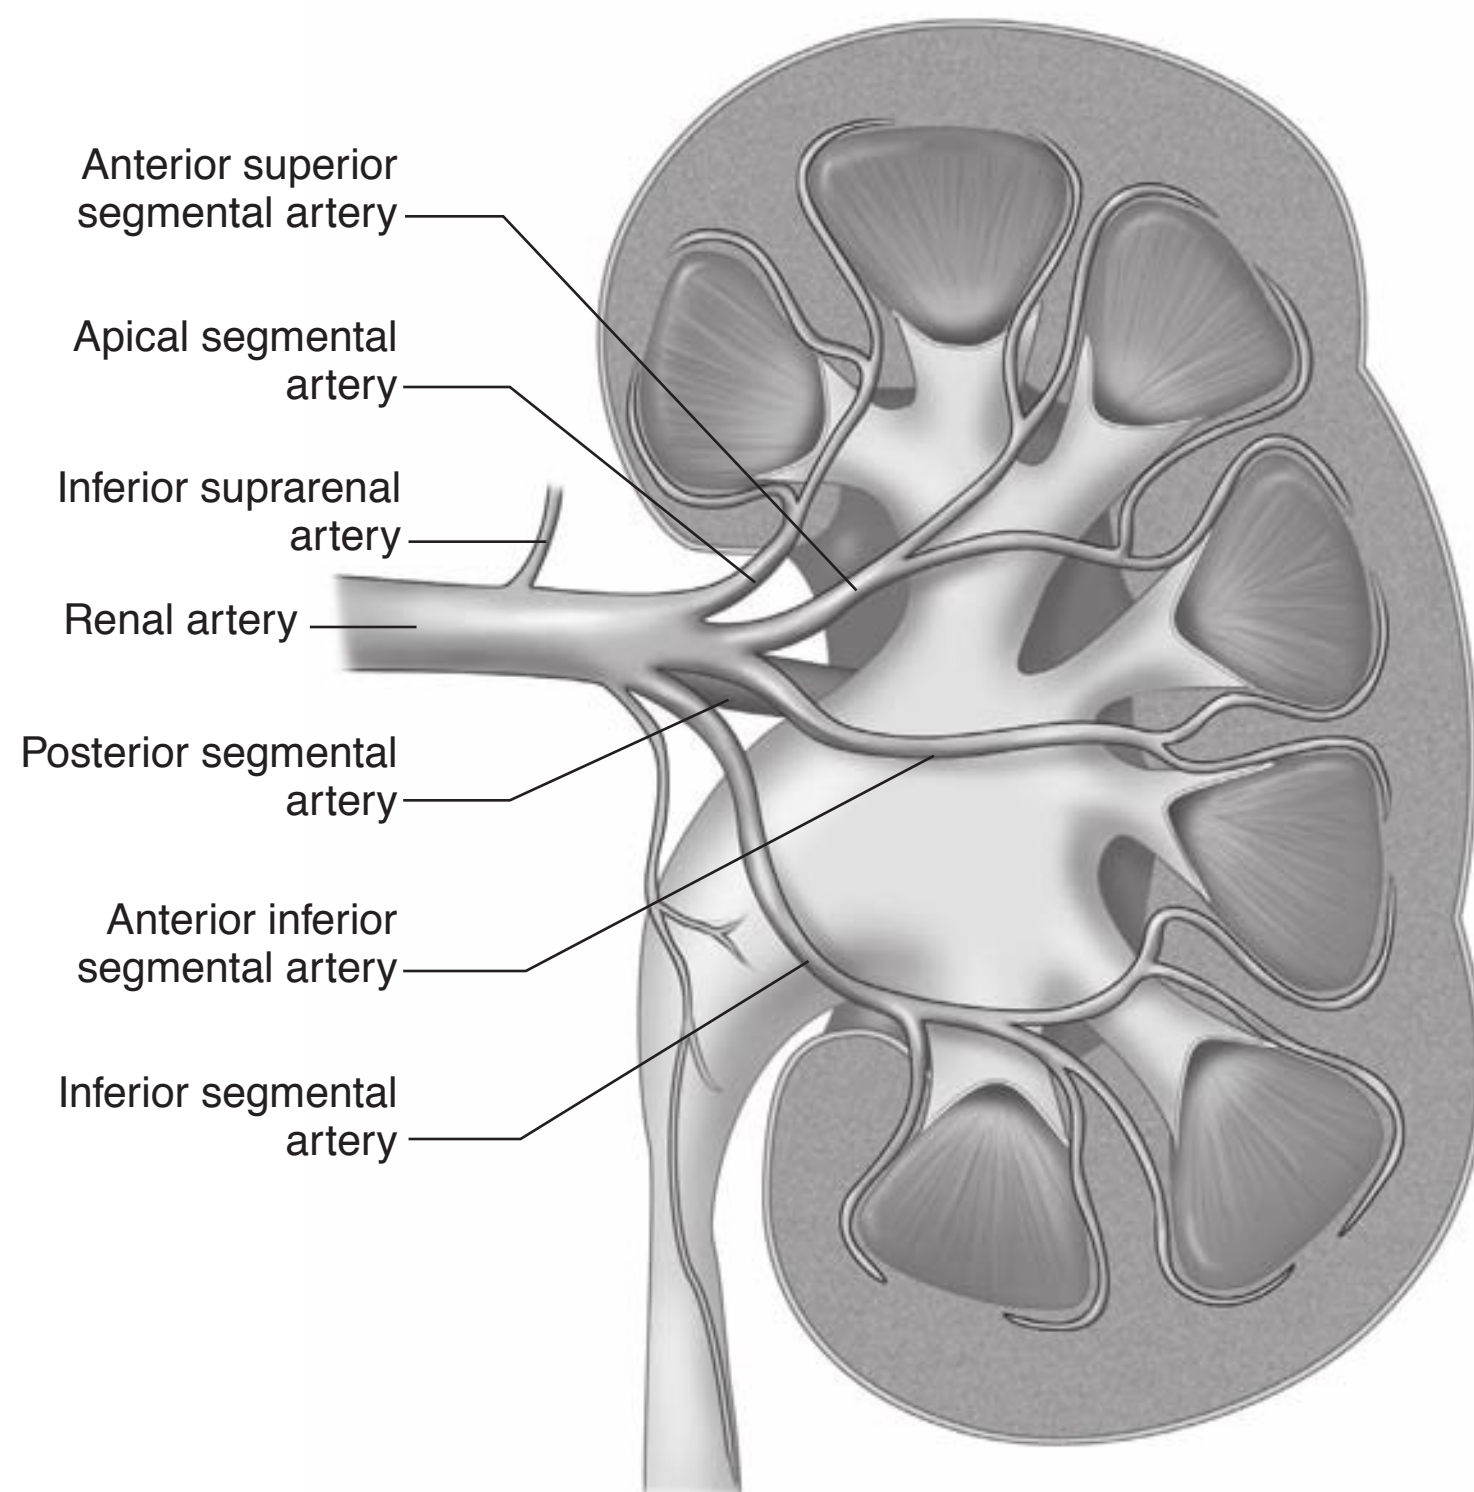

During renal mobilization, minimal handling of the kidney, avoidance of torque on the pedicle, and care to the position of the ureter to avoid crush injury are advisable. Rough handling can lead to subcapsular hematoma, capsule avulsion, vasospasm, and the potential for acute tubular necrosis (ATN). Destruction of the renal capsule during mobilization adds to the difficulty of reconstruction later in the operation.

When mobilizing the kidney, knowledge of variations in the renal arteriovenous anatomy is essential (Fig. 2.1). Anomalous or supernumerary renal vessels are common, and early recognition will avoid inadvertent vascular injury. We have found magnetic resonance imaging (MRI) to be useful in assessing the number and position of renal hilar vessels (5), but certainly a good computerized tomographic (CT) image should allow this as well. In resecting hilar or deep intraparenchymal tumors, a good MR or CT angiogram is advisable to understand the relationship of vessels to the tumor.

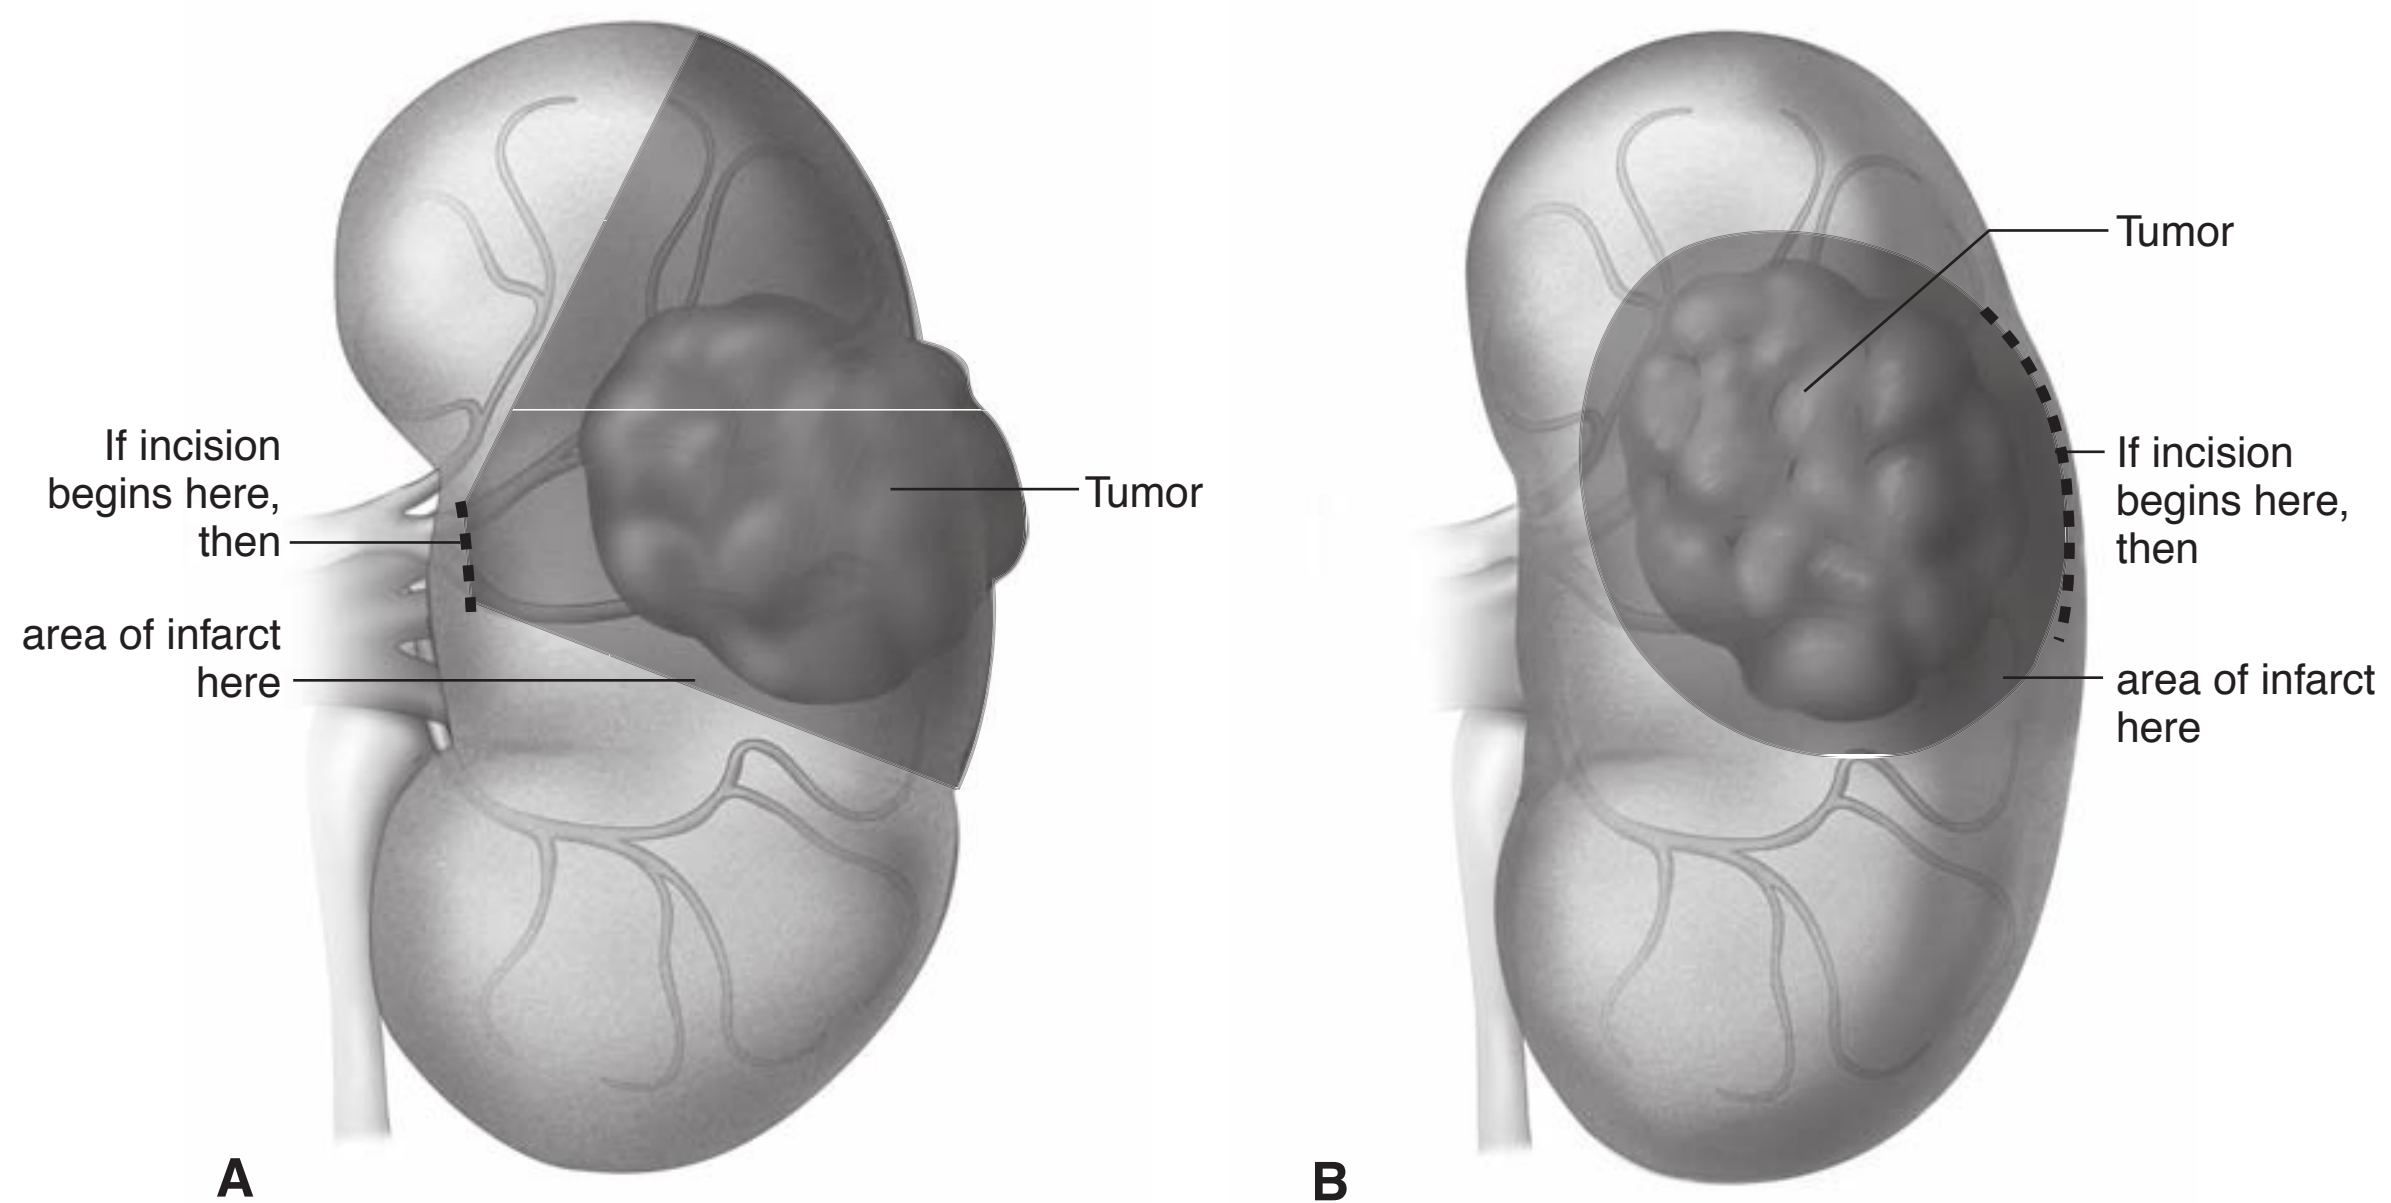

Polar renal arteries are usually divided to facilitate renal mobility as they usually feed only a small portion of the renal pole (apical branch) but may greatly limit mobility. In patients with a left-sided renal tumor and a retroaortic renal vein, hilar mobilization can be difficult, and stretching of the kidney to the skin may not be possible. As these are often secondary renal veins, division of the vein could be considered if another exists and mobility is limited. Because the renal venous anatomy has collateral parallel branches, venous branches can generally be divided to increase mobility without major sequelae.

Upon full mobilization of all hilar attachments, the renal vessels can be followed into the hilum to identify first and second segmental branchings. This may allow selective renal ischemia or arterial ligation if the tumor is located conveniently within one segment. We have found this to be rare, and more often early ligation of segmental branches results in inadequate ischemia and infarct within nonoperated areas of the kidney (Fig. 2.2). Therefore, it is generally preferable to clamp the main renal artery.

It is our preference to provide renal ischemia to facilitate renal incision and margin control, but this is certainly not uniformly necessary. Depending upon tumor location and depth, simple manual compression may be adequate to allow resection. Pitfalls of manual compression during incision include the potential for subcapsular hematoma, bleeding despite compression, poor view of the margin, destruction of the specimen, and the potential for ATN despite renal perfusion. Avoidance of renal ischemia is particularly appealing in patients at high risk of ATN due to baseline renal disease and decreased GFR, or in those with a solitary kidney in whom transient renal dysfunction could have deleterious short-term effects.

**FIGURE 2.1** The renal arterial anatomy is generally predictable, with five major known segments: basilar or inferior, apical, anterior superior, anterior inferior, and posterior. Based upon the position of the tumor, a prediction can be made regarding the number of segments involved. This allows the direction and angle of the line of incision to be planned.

**FIGURE 2.2** When incising the kidney from the hilar aspect of a tumor, particularly a tumor in the anterior or posterior segment, the incision will often result in infarct radial to the position of the tumor. Therefore, incising the kidney along the border of the tumor opposite the hilum will allow the tumor to be “lifted” from the kidney, exposing only those vessel branches that extend directly into the tumor.

We have utilized renal ischemia primarily to allow good visualization of the margin. Prior to clamping the renal artery, 12.5 g of mannitol is administered intravenously and allowed to circulate for 5 to 10 minutes. The kidney is placed in an intestinal/bowel bag and the drawstring cinched around the

hilum. The closed end of the bag is cut open and filled with ice for purposes of in situ cooling. The kidney is packed in ice for 10 minutes prior to clamping the renal artery to allow surface cooling. During this time, intraoperative ultrasound may be performed to assess tumor location and plan the resection.

The renal artery is then clamped with a small spring-loaded “bulldog” clamp. We have found it unnecessary to clamp the renal vein in open partial nephrectomy, even for deep resection, as the vein is often compressed by stretch of the hilum and/or manual compression of the parenchyma. In cases of multiple arteries, it may be easier to mass-clamp the hilum with a straight or angled vascular clamp, but this may give inadequate ischemia and venous hypertension if not properly applied.

Conventional wisdom states that the kidney should be packed completely in ice for 10 to 20 minutes prior to resection in order to cool the core temperature to  $<20^{\circ}\text{C}$ . As cold ischemia extends the period of safe ischemia from 30 to 40 minutes up to a theoretical 3 hours, this cooling is probably necessary for anticipated prolonged resection beyond 30 to 40 minutes. In general, it has been our preference to proceed with resection immediately upon placing the arterial clamp, while assigning a member of the operating room team to monitor and maintain the submersion of the kidney in ice throughout the resection. In using this approach, we have been able to keep the overall cold ischemia time low while maintaining adequate cooling of the parenchyma.

### Renal Incision and Margin Control

Renal incision planning is based upon position of the tumor and the arterial segment of kidney involved. For tumors lying within the anterior and posterior segment, a wedge resection technique is generally employed, whereas tumors located in the apical or basilar segments are generally managed by straight or tangential polar resection. In those cases in which the tumor lies across multiple segments, incision should be

planned so as to maintain perfusion to the remaining renal segments following resection. In so doing, the surgeon minimizes the risk of renal infarct.

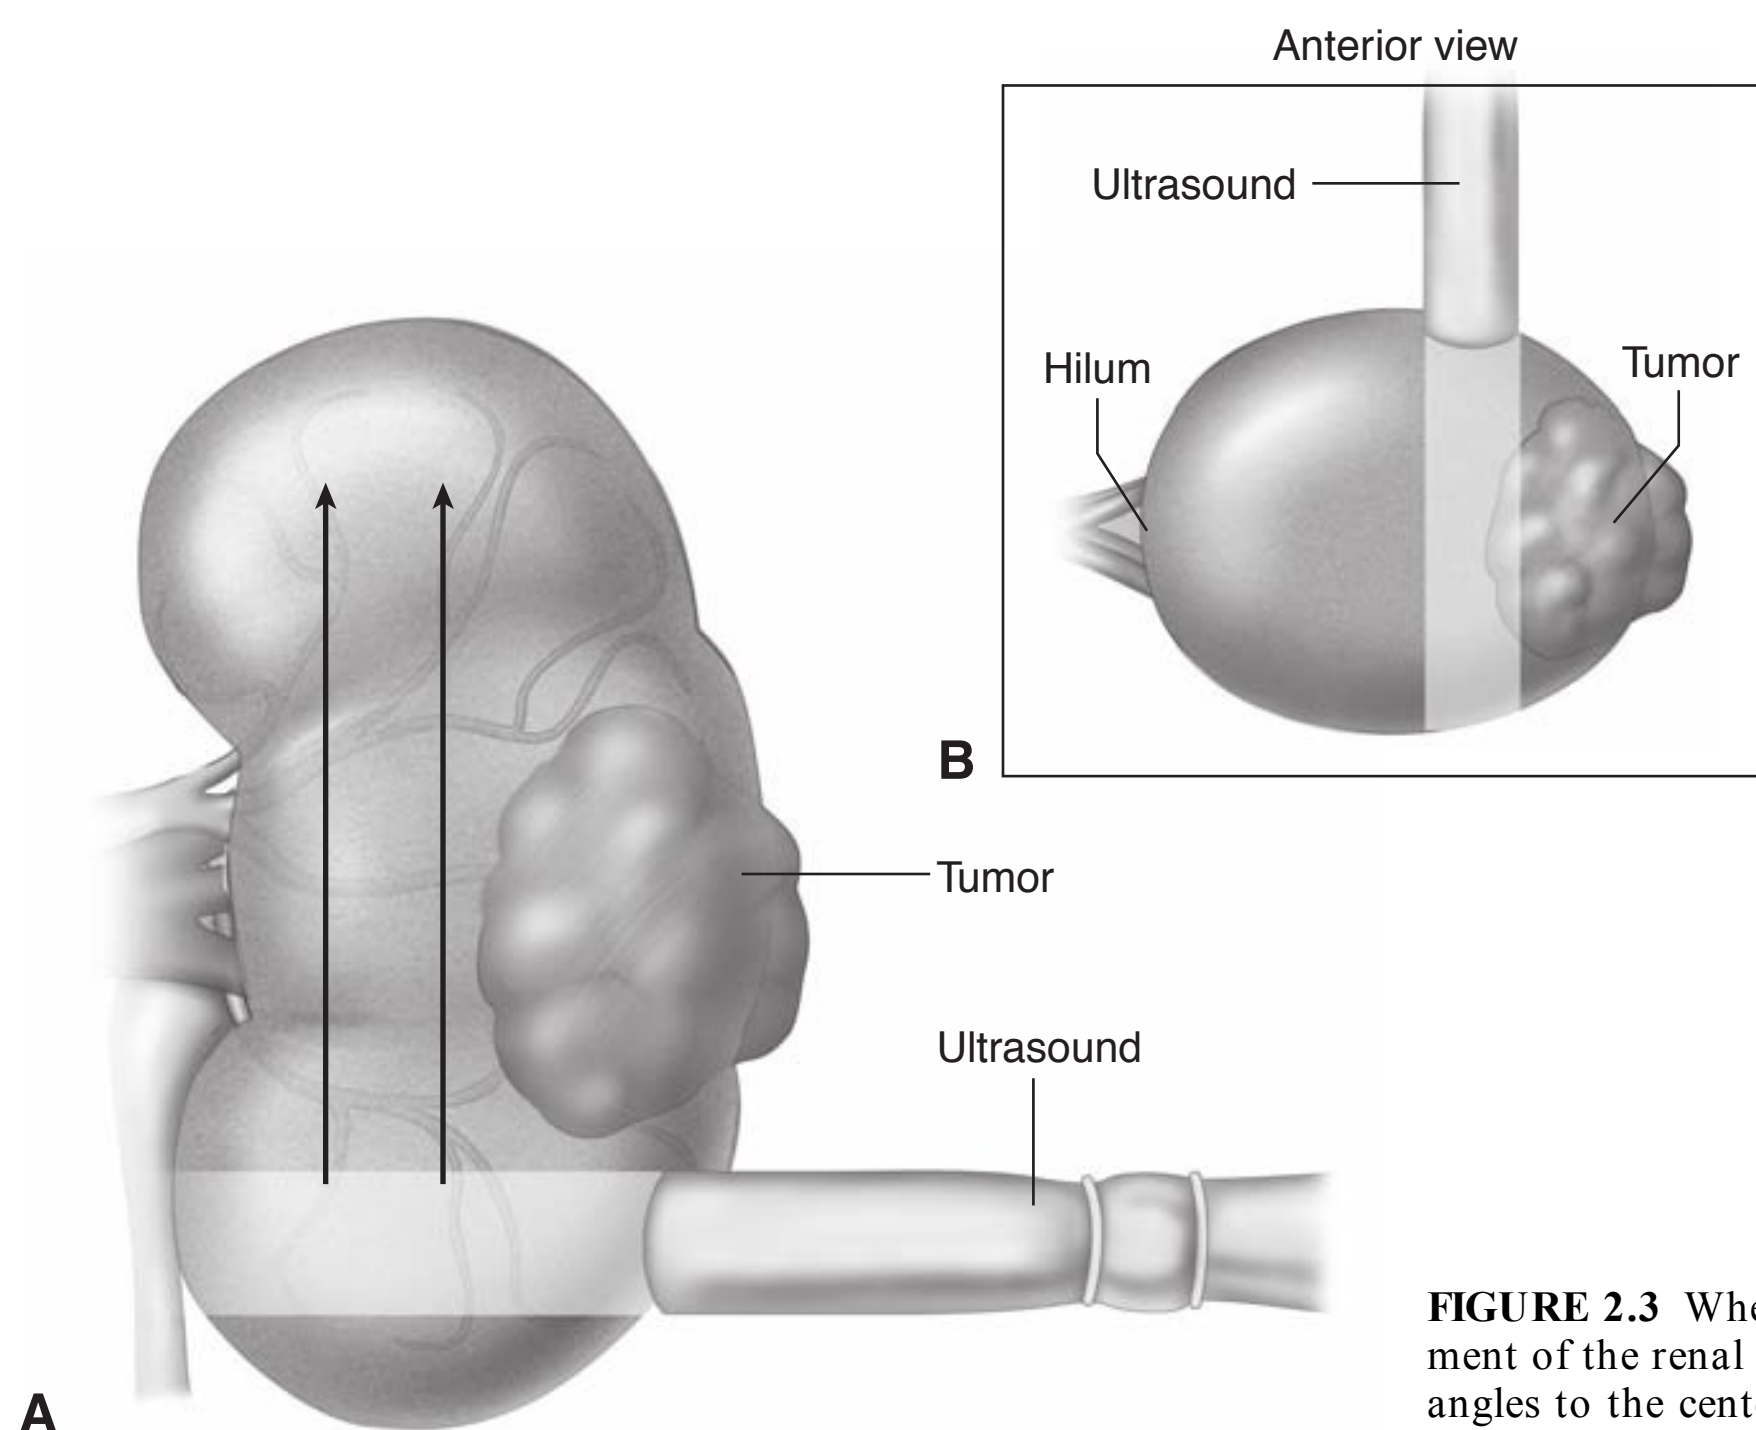

For tumors located in a single segment, we have generally utilized an approach of total renal ischemia. An exception to this rule might be in cases of anomalous vasculature in which multiple renal arteries are encountered. In these cases, it may not be necessary or advisable to clamp all arteries if the tumor is confined to a polar region of the kidney.

Tumor position can be best assessed by a combination of preoperative imaging and intraoperative ultrasound. Our approach with intraoperative ultrasound has been to pass the probe over the kidney in radial angles to the center of the tumor. This allows assessment of the subcortical extent of the tumor by assessing the transition from normal kidney to tumor interface in multiple planes (Fig. 2.3).

Renal incision should be carried out at a level adequate to provide a 1- to 2-cm margin of normal parenchyma. It should be noted that recent literature suggests that locoregional oncologic control is dependent upon a negative margin, and not the thickness of margin.

Nonetheless, in planning a minimum 1-cm margin, the final specimen often shows a thinner margin due to splaying and retraction of the normal parenchyma around the more dense tumor upon incision of the capsule.

For tumors that lie within 10 mm of the renal sinus, incision should be carried into visible sinus fat to ensure adequacy of margin. The same can be said for tumor within 10 mm of the collecting system. In cases of tumor abutting the collecting system, calyceal excision will usually provide an adequate margin. For those tumors invading or lying within the renal sinus fat, it is often difficult to obtain a thick margin due to

**FIGURE 2.3** When performing intraoperative ultrasound for assessment of the renal tumor, the probe is passed over the kidney in radial angles to the center of the tumor. This allows assessment of the subcortical extent of the tumor in each angle, by assessing the transition from normal kidney to tumor interface in multiple planes. On the basis of this assessment, the position and line of incision are selected.

juxtaposed blood vessels. In these cases, sharp division of the surrounding sinus fat allows the surgeon to maintain a layer of normal tissue around the tumor capsule.

The technique of polar resection usually involves division of the renal parenchyma straight across the pole, or, if the tumor has an anterior or posterior lie, the incision can be carried out at a tangential angle. In polar amputation, central vascular retraction is less likely to occur upon dividing the kidney. As such, the surgeon can sharply amputate the tumor/pole with a knife or scissors. The central defect is then repaired with direct suture-ligature placement or running closure (Fig. 2.4). Alternatively, a traditional blunt separation of the parenchyma with sequential ligation and sharp incision of renal sinus structures can be carried out. This is particularly useful when attempting tangential amputation.

The technique of wedge resection within the anterior or posterior segment requires more thought on the part of the surgeon as assessing the depth and width of resection, maintaining blood supply to the opposite segment, and avoiding central vessel retraction can all pose a challenge. We have preferred a wide resection bed to bring the deepest portion of the

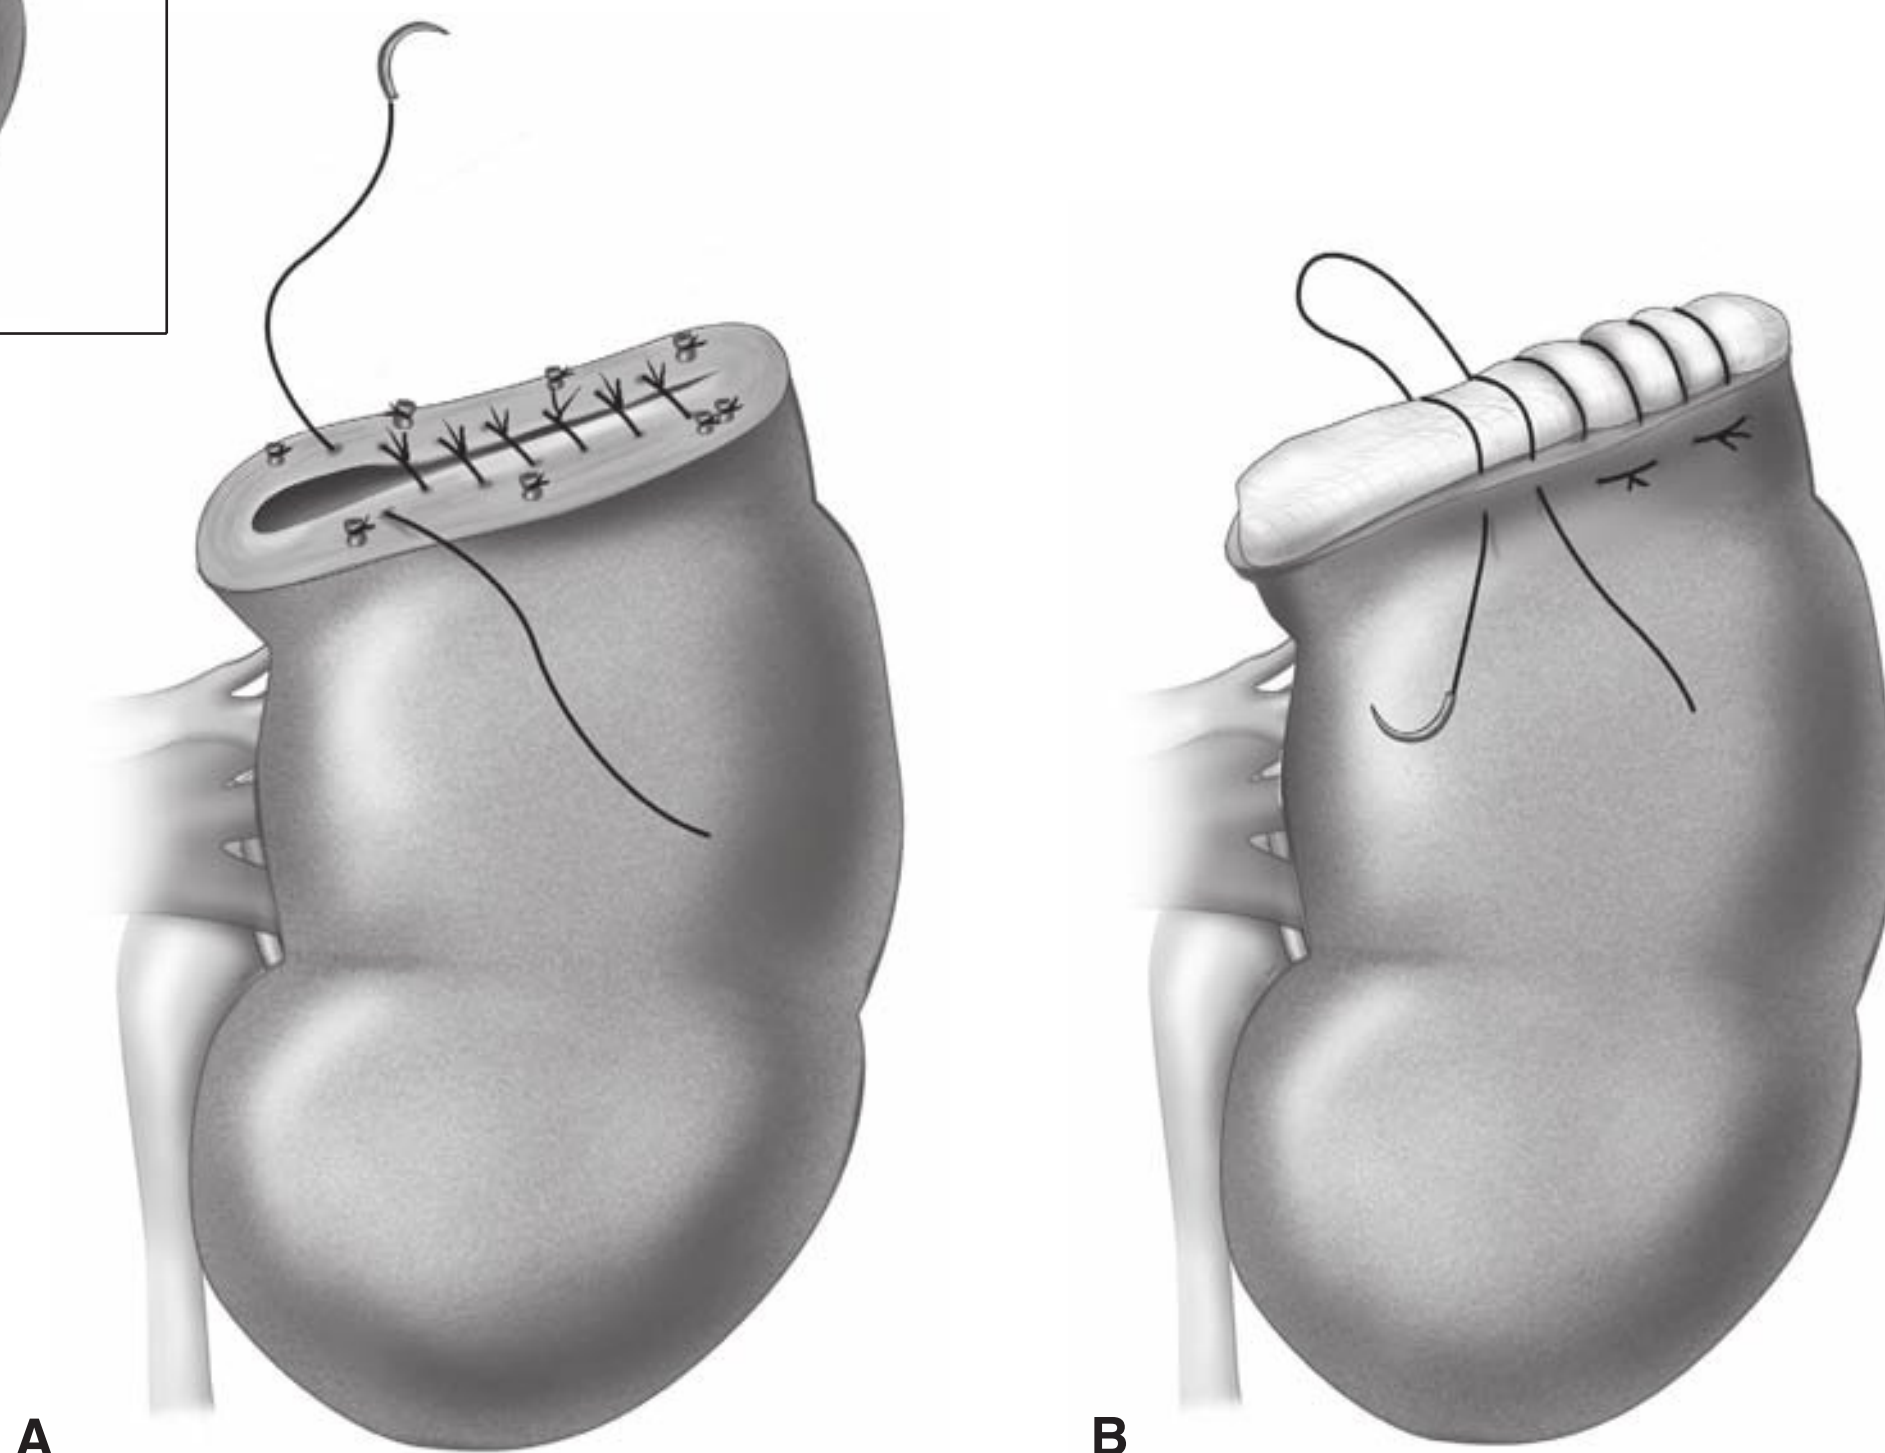

resection up to the surface of the kidney. A narrow resection bed results in a centrally retracted, “ice cream cone” defect in which central suturing can be difficult.

The technique of wedge resection should start with a capsular incision at the leading edge of the resection. The parenchyma is gently separated with a flat instrument. We have utilized two orthopedic “freer” instruments working opposite one another to allow a well-visualized separation of the parenchyma (Fig. 2.5). Individual vessels entering the tumor specimen are identified and directly suture-ligated with 4-0 chromic catgut prior to division with tenotomy scissors.

Directed suture-ligature of vessels as they branch into the specimen avoids vessel retraction, deeper suture placement, and secondary injury to deeper vessels proximal to the branch point. Tenotomy scissors are used to divide the vessel and redirect the line of incision as needed. We have found that simple blunt division or fracturing of the parenchyma with a knife handle inevitably leads to tearing into the renal sinus structures, regardless of the tumor position. When it is necessary to traverse renal sinus structures, including the collecting system, they should be sharply divided.

**FIGURE 2.4** Polar amputation of the kidney is usually done with a flush blunt or sharp cut across the pole, allowing for a 1-to 2-cm margin of normal kidney around the tumor. Such cuts can be straight across the kidney or tangential in placement. Once the tumor has been amputated, the collecting system and central vessels are closed with interrupted absorbable sutures. A hemostatic bolster is then placed on the defect and sewn into place with horizontal mattress sutures pledgeted to the surrounding renal capsule.

**FIGURE 2.5** The technique of wedge resection should start with a capsular incision at the leading edge of the resection. The parenchyma is gently separated with a flat instrument. We have utilized two orthopedic “freer” instruments working opposite one another to allow a well-visualized separation of the parenchyma. Individual vessels entering the tumor specimen are identified and directly suture-ligated with 4-0 chromic catgut prior to division with tenotomy scissors. Directed suture-ligature of vessels as they branch into the specimen avoids vessel retraction, deeper suture placement, and secondary injury to deeper vessels proximal to the branch point.

We do not routinely employ intraoperative frozen sections to assess tumor margin. It has been suggested recently that such margins are rarely informative. Exceptions may be in the renal sinus when invasion into fat is suspected or when gross tumor violation is noted. In these cases, the presence of residual tumor in the sinus or resection bed may warrant consideration for nephrectomy.

## Renal Reconstruction

Renal reconstruction following tumor excision can be divided into vascular and collecting system repair. As these structures are juxtaposed, it is often necessary to provide simultaneous closure. Renal reconstruction usually involves three basic tenets: (a) closure of the collecting system; (b) direct suture repair of large vessels; (c) prevention of vascular retraction within the sinus; and (d) radial compression of the defect.

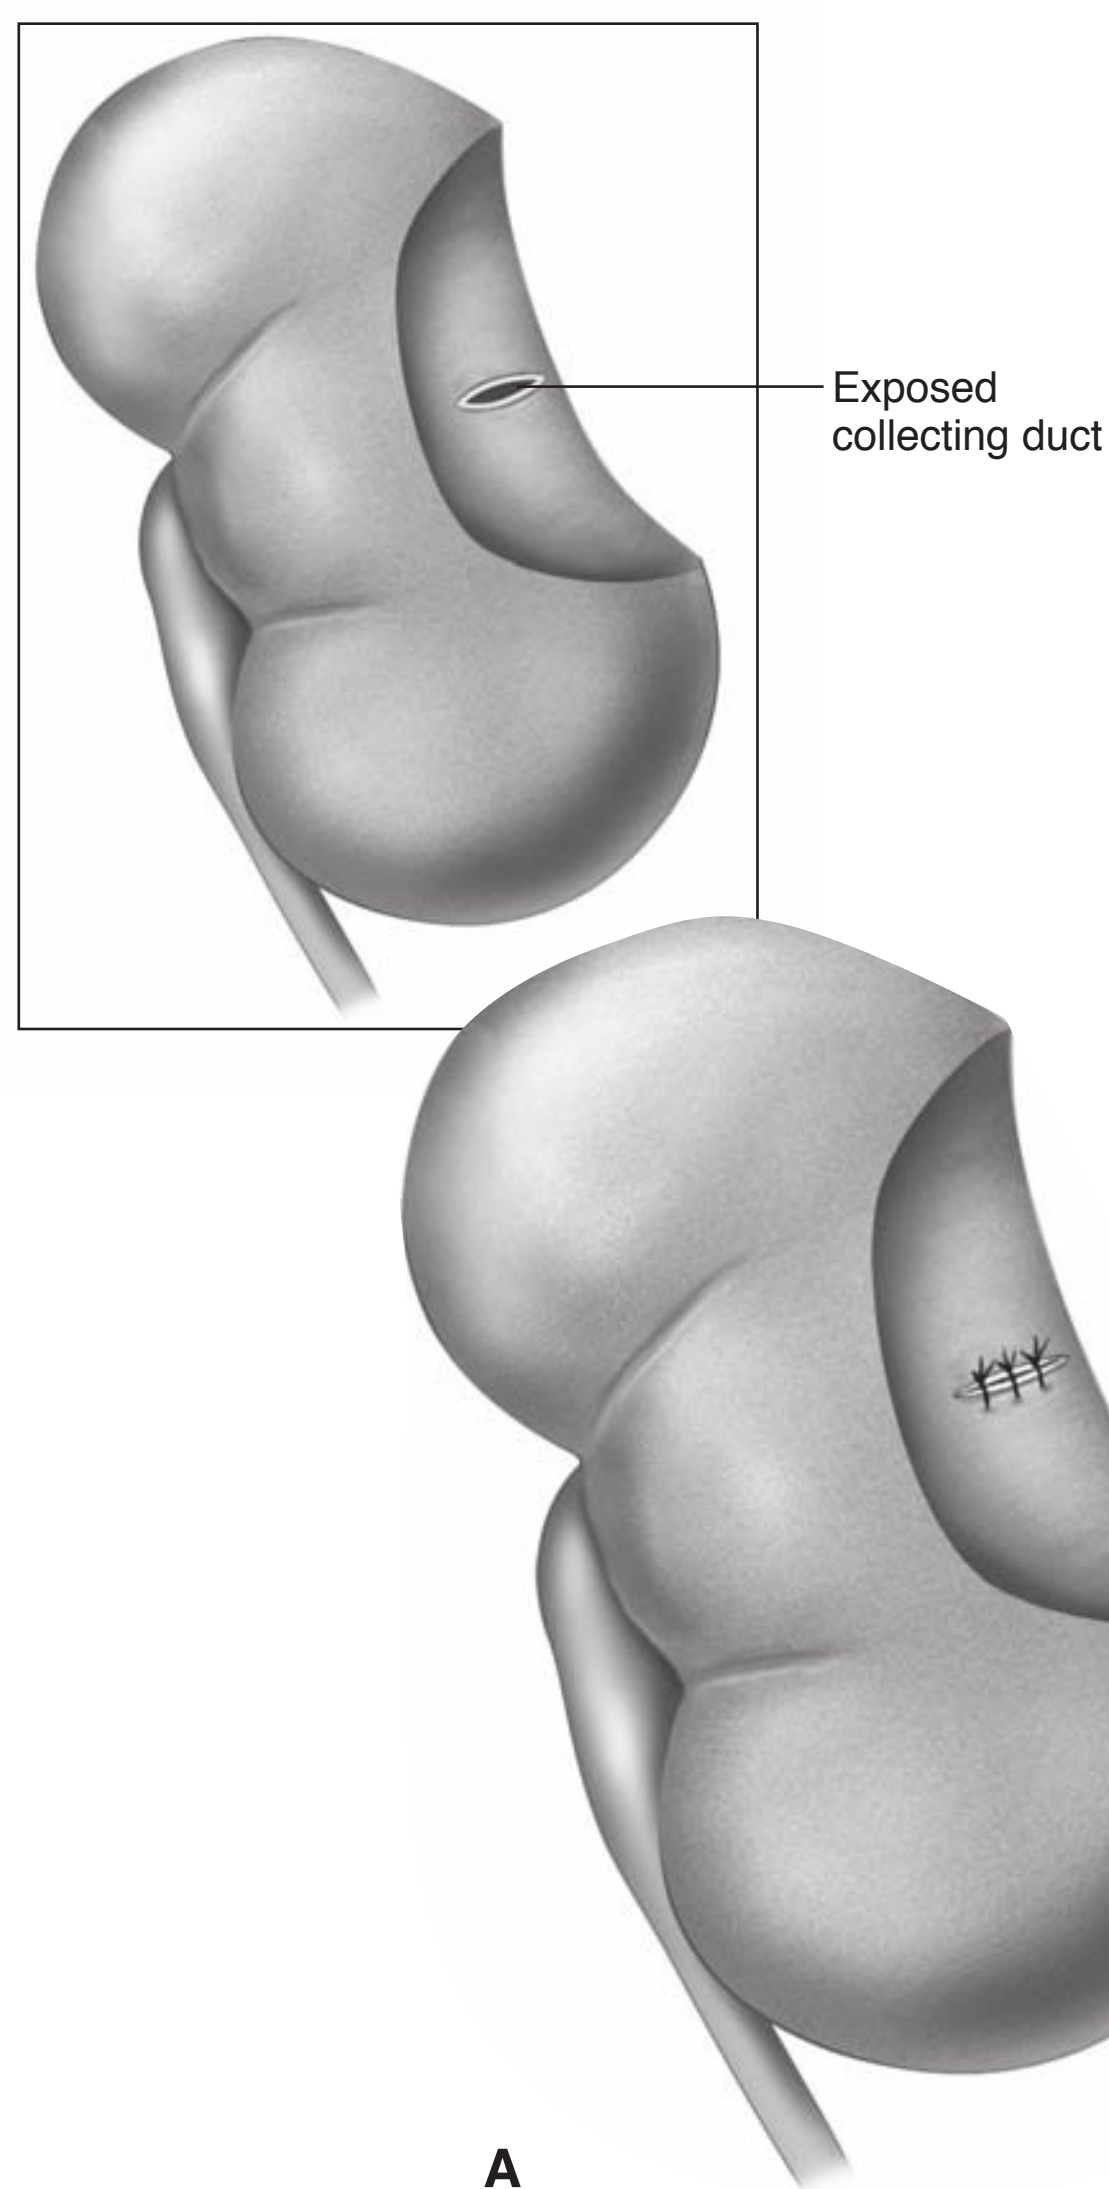

In the technique of wedge resection, the majority of vessels are suture-ligated during the incision. Thus, upon removal of the arterial clamp and reperfusion, there is relatively little bleeding in most cases. Missed vessels or those partially ligated are generally directly sutured with 4-0 or 3-0 chromic catgut. It is important to note that the perfused kidney parenchyma has more turgor than the ischemic kidney and thus there is a tendency for sutures to “saw” through the parenchyma. Sutures should be placed widely across cut vessels to allow compression of the parenchyma around them. Open venous channels are usually controlled by “figure-of-eight” suture placement or, in the case of large openings, a running suture incorporating surrounding tissues for compression.

The collecting system is closed with interrupted sutures of 4-0 polyglycolic acid suture after renal perfusion has been re-established. While running closure can be tried, tension on the collecting system opening often tears the fragile calyceal walls or creates holes along the suture line. For this reason, we have preferred a single-layer interrupted closure followed by a second layer of imbricating parenchymal sutures to reinforce the closure (Fig. 2.6). In polar resection, the collecting system and central vessels can often be closed in the same layer of interrupted sutures (Fig. 2.4), either before or after.

Following closure of the collecting system, retrograde instillation of methylene blue in the renal pelvis by a fine-gauge needle can confirm the integrity of closure and rule out additional sites of collecting system injury. After repair, the addition of a tissue adhesive layer can minimize the likelihood of leak. We have utilized a layer of Gelfoam TM (Pharmacia and Upjohn, New York) infiltrated with fibrin sealant (Tisseal, Baxter International).

A folded bolster of Surgicel TM (Johnson and Johnson, Piscataway, NJ) wrapped around fibrillar collagen (Surgicel) is placed in the defect. The kidney is then gently compressed around the bolster using horizontal mattress sutures of 4-0 chromic catgut anchored to the renal capsule as a pledget.

Following reconstruction, the kidney is returned to a normal anatomic lie with no kinking of the artery. The perinephric fat is layed over the defect and interposed between the lower-pole parenchyma and the ureter to avoid peri-ureteral scarring. Nephropexy is only required if the kidney is notably mobile within the fossa.

**FIGURE 2.6** Collecting system repair following wedge resection should aim for a 2-layer closure. The defect is first closed with interrupted 4-0 absorbable sutures anchored to the surrounding parenchyma. The renal parenchyma is then imbricated around the closure in a row of interrupted sutures to relieve tension on the first line. Hemostatic materials may then be used over this.

---

## OUTCOMES

---

### Complications

---

While partial nephrectomy is still considered by most surgeons to represent a technically challenging procedure, outcomes in recent series have suggested morbidity comparable to radical nephrectomy. Among 1,800 renal tumor resections performed between 1991 and 1998 in 123 Veterans Affairs Medical Centers, no difference in the mortality and morbidity rates between the radical and the nephron-sparing approach was observed (6). Certainly the likelihood of morbidity relates to operator experience and training.

Complications from partial nephrectomy include bleeding, urinary fistula, ureteral injury or obstruction, renal dysfunction, loss of kidney, and arteriovenous malformations. In a recent series comparing two groups of patients operated before and

after 1995 (7), hemorrhage was uniformly infrequent, occurring in 1.5% and 1.2% of patients, respectively. The incidence of acute renal failure was also much less frequent (3.8% and 1%, respectively), requiring dialysis in only 2% of those operated before 1995 and in 0.6% of those treated thereafter. Urinary fistula or leak has also been a historically frequent complication in some early series, but in the same series urine leak was noted in 2.6% and 0.6% of cases before and after 1995.

In a phase III multicenter comparison of partial and radical nephrectomy, the rates of severe hemorrhage (defined as blood loss  $>1$  L) and urinary fistula were 3.1% and 4.4%, respectively. Reoperation for complications was necessary in 4.4% of the nephron-sparing group and in 2.4% of the radical nephrectomy group (8). Complications such as arteriovenous fistula, pseudoaneurysm due to vascular injury, ureteral stricture, and renal loss are extremely rare.

Renal infarct of small portions of the kidney is common following renal reconstruction. If little perfused parenchyma is

noted upon removal of the arterial clamp, vasospasm may be the culprit, and in these cases intra-arterial verapamil may improve perfusion. If the kidney is not viable, it should be removed. The general management of infarct is observation. In cases of severe hypertension due to infarcted kidney, nephrectomy should be performed.

The fundamental tenet of leak management is maximal drainage of the extrarenal collection until output diminishes. In general, a ureteral stent is not necessary unless there is evidence of ureteral obstruction, blood clots or debris within the collecting system, or a very large collecting system opening. Resolution of urine leak generally requires scarring in the potential space around the kidney during a variable time course of weeks to months. At that point the drain is slowly advanced out.

---

## Results

---

A number of studies, both open and laparoscopic, have demonstrated excellent long-term oncologic outcomes for patients undergoing partial nephrectomy. Early reports of partial nephrectomy for tumor included a large subset of patients with absolute or relative indication for surgery. Thus, recurrence-free survival often reflected survival of a nonselected population, including those with a higher tumor stage than in a contemporary elective partial nephrectomy series.

Hafez et al. (9) reviewed the Cleveland Clinic series of 485 partial nephrectomies, of which only 9% were electively performed. They reported a significant decrease in both 5-year and 10-year cancer-specific survival (CSS) for lesions  $>4$  cm compared to those lesions  $<4$  cm. Also observed was a statistically significant correlation between recurrence and size  $>4$  cm. Based on these data, these authors suggested that stage T1 tumors ( $<7$  cm) should be subdivided into T1a and

T1b tumors, for those lesions  $<4$  cm and  $>4$  cm. In an updated study, Fergany et al. (11) reported on 10-year outcomes in 107 patients undergoing open partial nephrectomy from the same institution. Five- and 10-year CSS of 88.2% and 73%, respectively, was observed. In that series, only 10% of patients had elective indication, 50% of tumors were bilateral, and 45% were  $>4$  cm in size. If including only the patients with tumors  $<4$  cm, 5- and 10-year CSS improved to 98% and 95%, respectively.

A recent update of the University of California Los Angeles partial nephrectomy series (12) allows evaluation of 15-year outcomes for the procedure. Overall CSS was 98%, 96%, and 96% at 5, 10, and 15 years of follow-up, respectively. Recurrence was noted in 7%, 13%, and 13% at 5, 10, and 15 years of follow-up, but it is notable that 7% of patients had metastatic disease at time of surgery.

In a multicenter comparison of the outcomes of partial and radical nephrectomy among 1,454 patients (13), CSS was equivalent among patients undergoing partial or radical nephrectomy for either pT1a or pT1b tumor. Overall CSS at a median follow-up of 62 months was 97.8% for T1a and 93.8% for T1b tumors undergoing partial nephrectomy.

Partial nephrectomy for tumor resection is an increasingly important technique for practicing urologists to master. Oncologically, it is shown to be equivalent to radical nephrectomy for tumors  $<7$  cm in size, and it results in quite good oncologic control for even larger tumors. The long-term benefits may be greater than initially perceived with regard to preservation of renal function and overall health. Careful preoperative imaging, knowledge of renal anatomy, attention to patient and tumor risk factors, and meticulous surgical technique are essential for achieving good surgical outcomes. Complication rates should be acceptably low if fundamental tenets of surgical technique are followed.

# CHAPTER 3 ■ RADICAL NEPHRECTOMY

MICHAEL S. COOKSON AND SAM S. CHANG

Renal cell carcinoma (RCC) is the most common malignancy of the kidney and accounts for about 3% of all adult neoplasms. The estimated number of new cases of RCC in the United States in 2007 was 51,190 with a projected 12,890 deaths, and this incidence is expected to continue to increase as a result of the expanded use of radiographic imaging coupled with the aging population (1).

While emerging technologies such as ablative techniques may offer effective treatment for selective patients with smaller primary tumors, surgery remains the mainstay for curative treatment in the majority of patients with RCC. Furthermore, despite the expanded role of partial nephrectomy for tumors <4 cm, radical nephrectomy remains an important treatment option for most large and almost all locally advanced tumors.

The role of open radical nephrectomy in the management of RCC has changed somewhat over the last decade. Pure laparoscopic and laparoscopic hand-assisted radical nephrectomy have emerged as less morbid alternatives to open surgery in the management of low- to moderate-volume (8 to 10 cm or smaller), localized RCCs without local invasion, renal vein involvement, or lymphadenopathy (2).

However, this has placed an increased emphasis on the performance of open radical nephrectomy in a higher percentage of patients who have either comorbid illnesses or advanced tumors that preclude a minimally invasive approach. Furthermore, the beneficial impact of cytoreductive nephrectomy has increased the clinical situations in which open radical nephrectomy may be performed in the setting of metastatic disease (3).

This chapter focuses on the open surgical approach for radical nephrectomy.

---

## DIAGNOSIS

---

Typically, RCCs are characterized on computerized tomography (CT) scan by a solid parenchymal mass with a heterogeneous density and enhancement with IV contrast injection (between 15 and 40 Hounsfield units). However, despite modern imaging, some benign tumors and complex cysts may be indistinguishable from cancer and confirmed only after surgical excision. The role of percutaneous biopsy or needle aspiration in differentiating an indeterminate renal mass remains controversial and is currently used in select cases, such as in patients with known second primary tumors, suspected metastases, or lymphoma.

Clinical staging in patients suspected of RCC usually includes a contrast-enhanced CT scan of the abdomen, which may include CT angiography as well as three-dimensional reconstructions, and magnetic resonance imaging (MRI) is used on occasion, depending on the clinical scenario.

---

## INDICATIONS FOR SURGERY

---

The indication for radical nephrectomy is a clinically localized solid renal mass in a patient with a normal contralateral kidney. Patients with solitary kidneys, renal insufficiency, or bilateral renal masses should be considered candidates for nephron-sparing surgery. Increasingly, partial nephrectomy is becoming accepted for smaller T1a lesions in the “elective” setting. However, for larger lesions, radical nephrectomy remains the treatment of choice. A thorough preoperative history and physical examination should be performed before the procedure. If significant comorbidities are suspected, preoperative consultation with the appropriate physician is recommended. In an elective radical nephrectomy, the patient should be expected to physically withstand the operation, have a reasonable overall performance status, and have a 5-year life expectancy.

Radical nephrectomy in combination with immunotherapy has been demonstrated to improve survival among patients with metastatic RCC over immunotherapy alone (4). Accordingly, radical nephrectomy is being offered to an increasing number of patients with a resectable primary tumor in the setting of metastatic disease as an initial treatment strategy prior to immunotherapy. Radical nephrectomy may also be performed for palliation, such as for patients with intractable pain or life-threatening hemorrhage who fail conservative treatment despite the presence of metastases. The role of radical nephrectomy among patients with a solitary metastatic site is controversial; however, 5-year survival rates of 30% have been reported in selected patients, with best results reported in patients with solitary pulmonary metastases (2).

Although local extension of primary RCC into the perinephric fat, vena cava, or ipsilateral adrenal gland may portend a worse prognosis, in the absence of metastatic disease these factors alone should not dissuade the surgeon from attempting a radical nephrectomy. In addition, radical nephrectomy has been successfully performed in the setting of direct extension of the tumor into adjacent organs such as the liver, colon, spleen, pancreas, or psoas muscle. However, surgical removal in this setting is technically difficult and is associated with a higher morbidity and a potentially poor prognosis. Therefore, it should be attempted only after careful preparation and in cooperation with appropriate surgical consultants.

---

## ALTERNATIVE THERAPY

---

Surgery remains the only effective and potentially curative form of therapy for primary RCC. Along this line, the main challenge to radical nephrectomy in the near future appears to be from

more conservative surgical approaches, including nephron-sparing surgery and minimally invasive approaches. Elective partial nephrectomy, enucleation, and wedge resection have been proven to be nearly equivalent in terms of cancer control and may afford potential advantages in terms of preserved renal function and quality of life in properly selected patients (5–7).

Radical nephrectomy is also being performed through laparoscopic approaches, including hand-assisted techniques, which again have shown equivalent cancer control and significant advantages in terms of reduced pain, shorter convalescence, and improvements in quality of life (7,8).

Open radical nephrectomy continues to play an important role in the management of RCC, and it is essential that any surgeon who employs minimally invasive techniques be well versed in its performance.

---

## SURGICAL TECHNIQUE

---

There are a variety of factors that influence the choice of incision during radical nephrectomy. These include location of the affected kidney, tumor size and characteristics, body habitus, and physician preference. There are advantages and disadvantages to each incision, and it is important to be familiar with several approaches to the kidney as no one incision is appropriate in all settings. The most commonly used incisions for radical nephrectomy are the flank, thoracoabdominal, and transabdominal (subcostal or chevron) (Fig. 3.1).

---

### Flank Incision

---

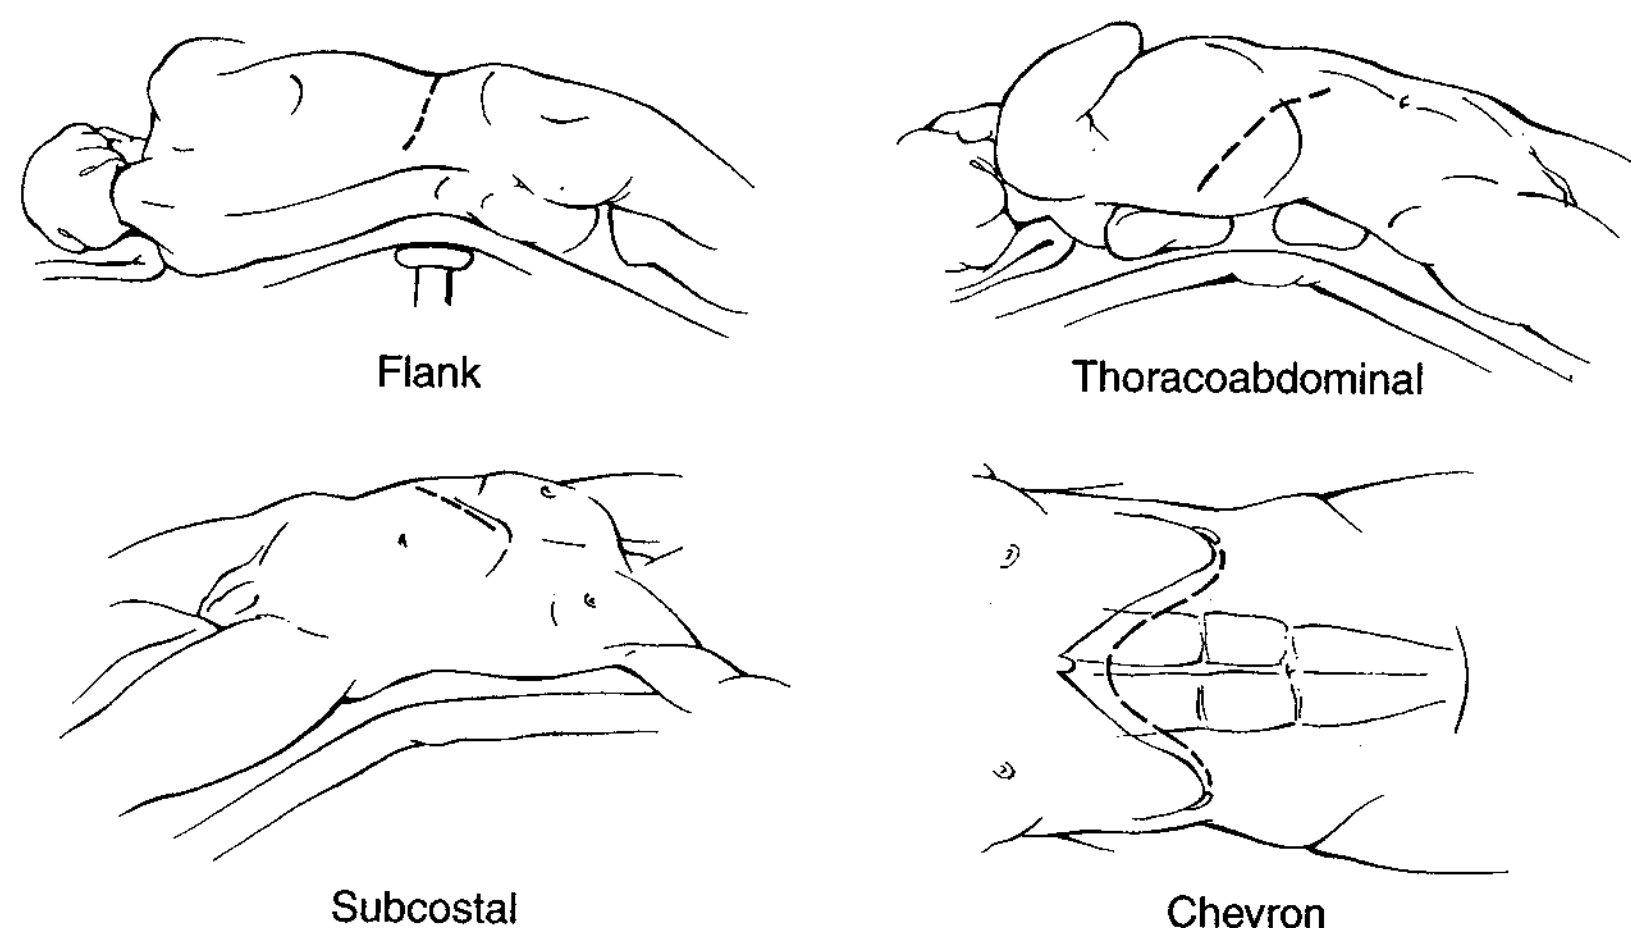

The flank approach can be advantageous for several reasons. First, it allows direct access to the retroperitoneum and kidney, and the entire procedure can often be performed in an extrapleural and extraperitoneal fashion. In addition, the incision is anatomic in that it follows the track of the intercostal nerves with minimal risk of denervation. However, in large tumors, tumors involving the upper pole, or situations where vena cava access is critical, a flank approach is often suboptimal. Although a flank approach may be performed through a subcostal incision, an eleventh- or twelfth-rib incision is

superior for exposure of the upper pole and ipsilateral adrenal gland during radical nephrectomy.

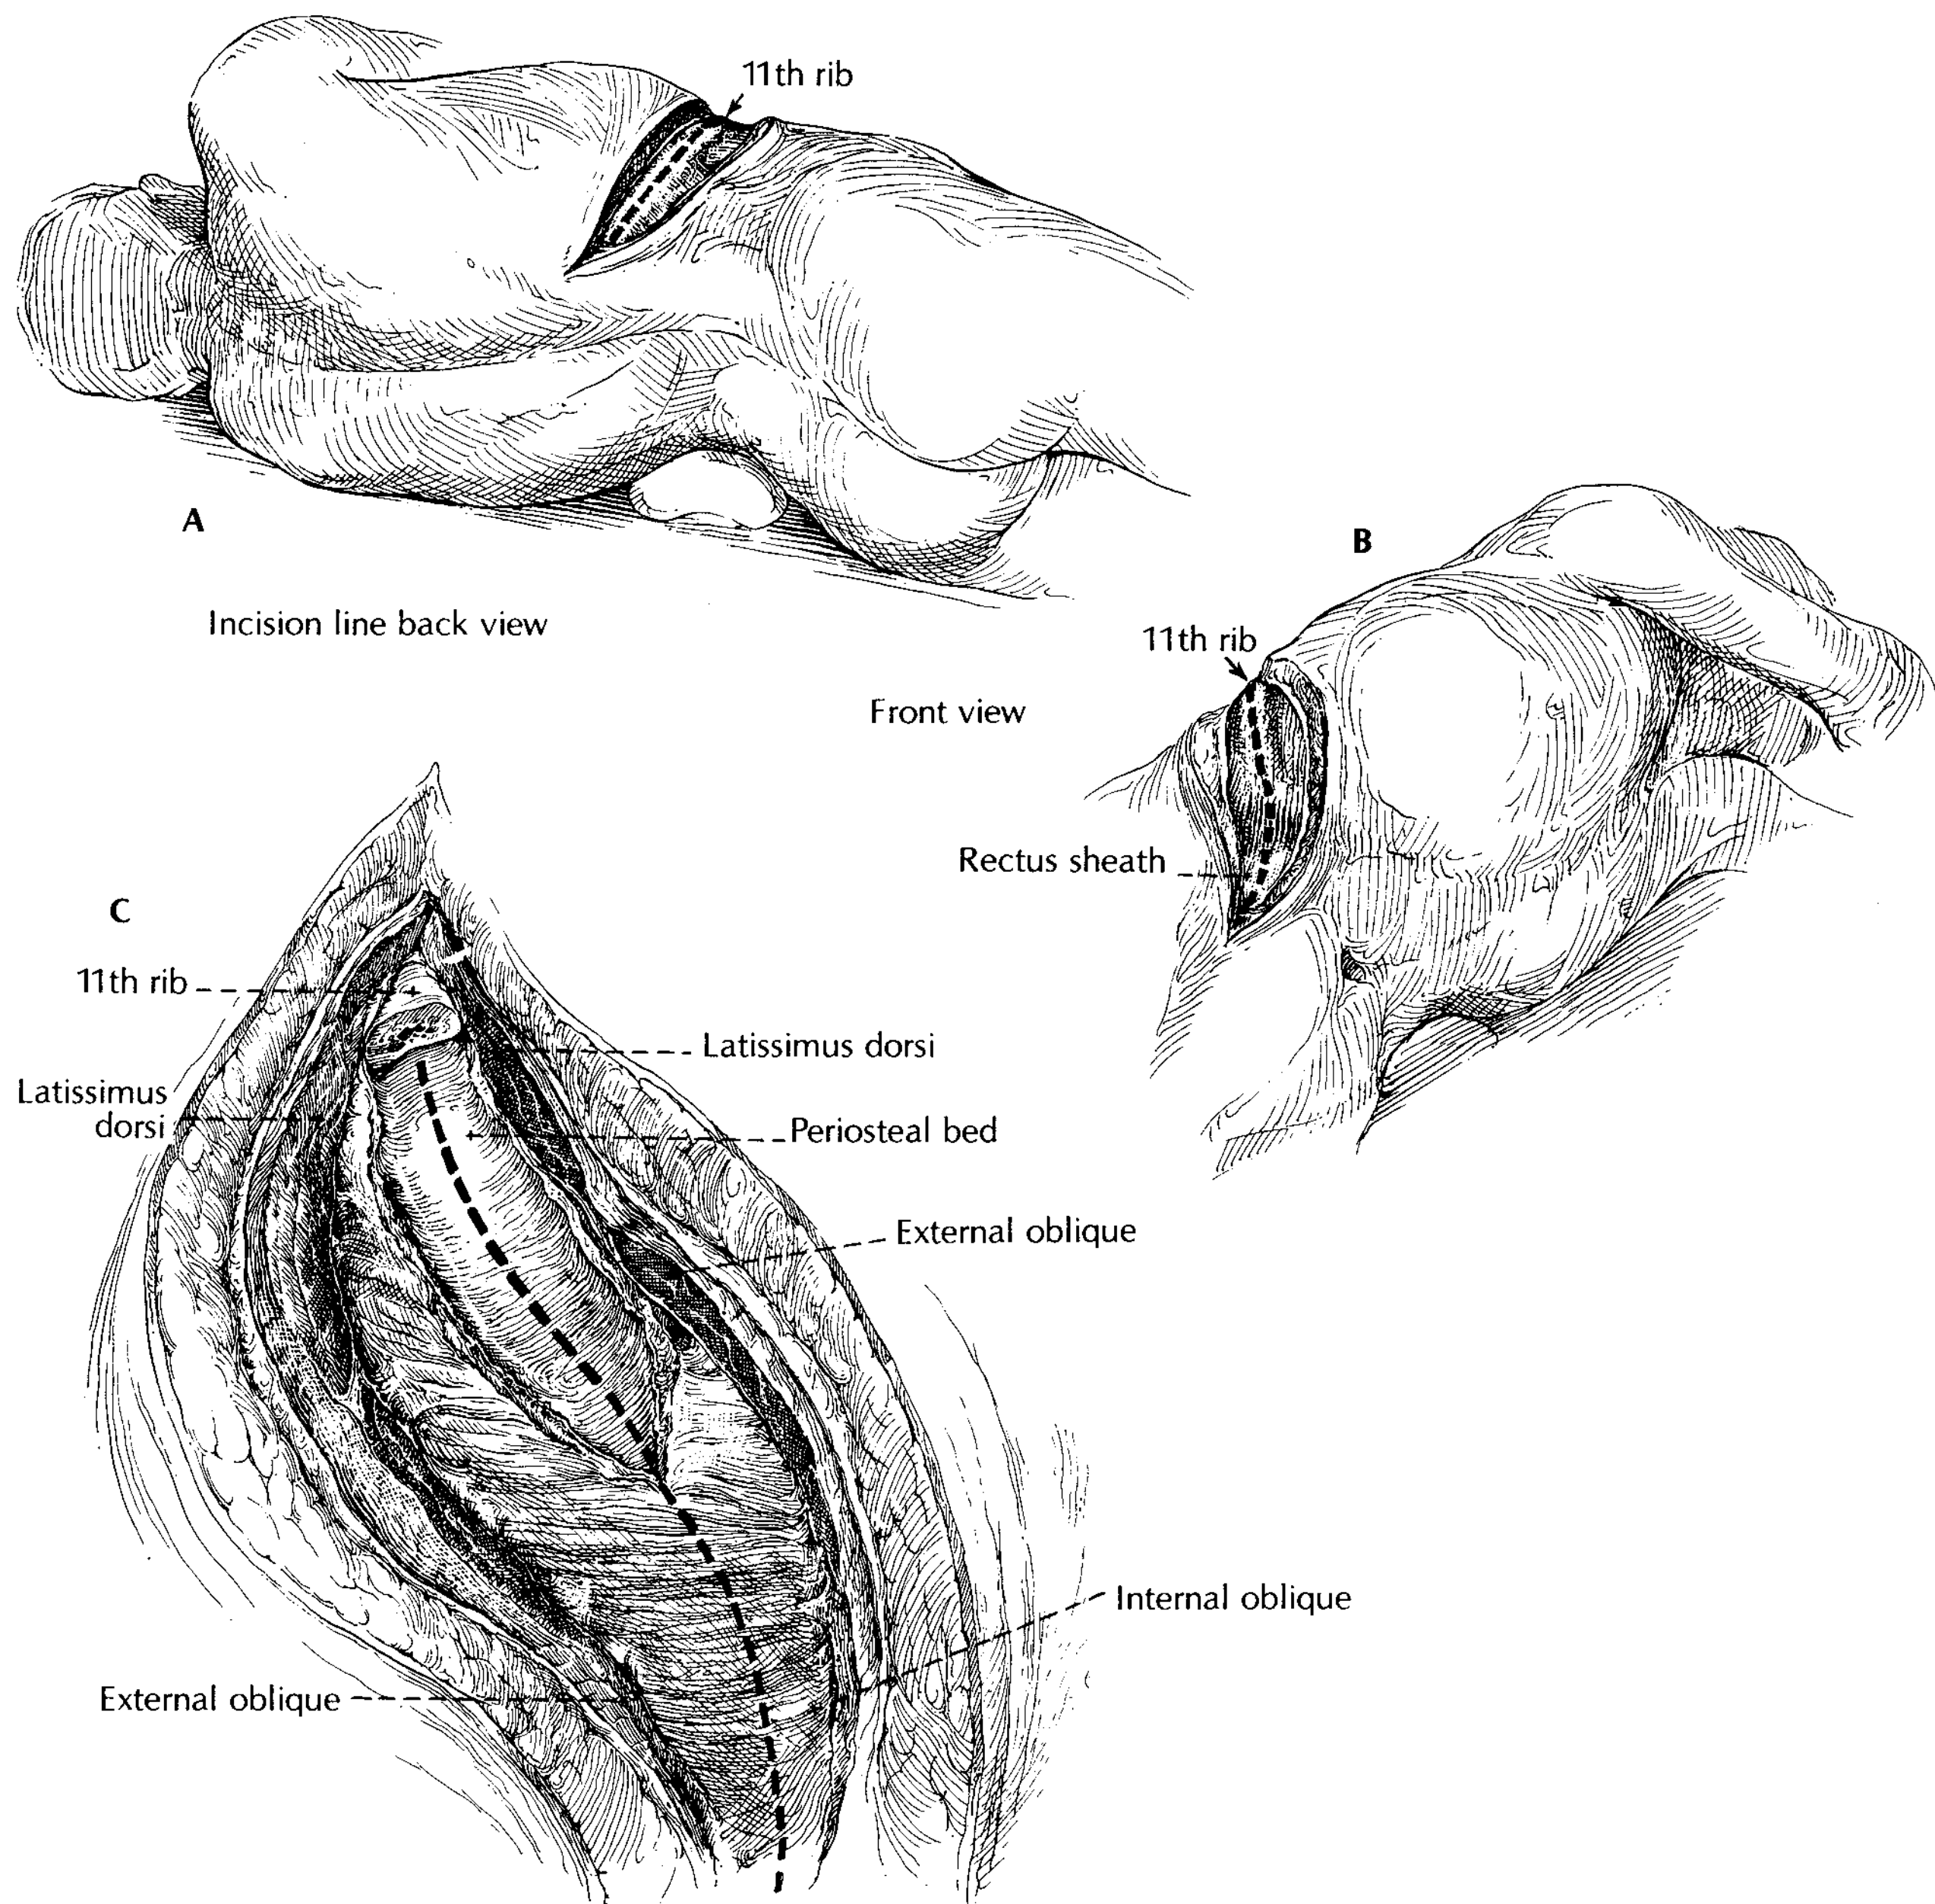

The patient is positioned in the lateral decubitus position with the upper chest at about a 45-degree angle. An axillary roll is placed under the patient to cushion against pressure on the brachial plexus, and the elbows are padded to prevent ulnar nerve injury. The upper arm is draped across the body and placed on a Mayo stand or padded support. The lower leg is flexed at 90 degrees, and the upper leg is extended over one or two pillows. The kidney rest is raised and the table is flexed to elevate the flank and adjusted to make the flank horizontal to the floor. The beanbag or inflatable mattress may be helpful, and if utilized can be activated to further support the patient. The patient is then padded and secured with wide adhesive tape and safety straps.

An eleventh- or twelfth-rib incision is made based on several factors, including the kidney position, the cephalad extent of the tumor, and the patient's body habitus. A general rule is to incise over the rib so that, when extended medially, the incision will be over the renal hilum. The incision is then made off of the tip or over the rib from the posterior axillary line to the tip and extended medially as far as necessary, usually stopping short of the lateral border of the rectus abdominis (Fig. 3.2). The latissimus dorsi is divided, and the upper portion of the incision is carried down to the rib or near its tip. The incision is usually created between the ribs in the intercostal space, and additional exposure may be obtained by incising the costovertebral ligament. With larger tumors and depending on patient body habitus, a partial rib resection may be accomplished as shown in Fig. 3.3. An Alexander periosteal elevator is used to deflect the periosteum from the bone to avoid injury to the intercostal bundle located under the inferior portion of the rib. A Doyen elevator is then used to strip the periosteum from the entire undersurface of the rib to be resected. Next, a rib cutter is used to divide the proximal segment of the rib. The posterior layer of the periosteum is then incised carefully, and the pleura is protected superiorly.

Anteriorly, the external and internal oblique muscles are divided and the transversus abdominis muscle is split in the direction of its fibers, taking care not to enter the peritoneum. The peritoneum is swept medially, and the intermediate stratum of the retroperitoneal connective tissue is incised sharply to expose the perinephric space. Approaching this in a posterior

**FIGURE 3.1** Types of incisions during radical nephrectomy.

**FIGURE 3.2** Technique of eleventh-rib resection. **A and B:** The incision is made over the eleventh rib. **C:** After division of the latissimus dorsi and external oblique muscles, subperiosteal resection of the rib is performed.

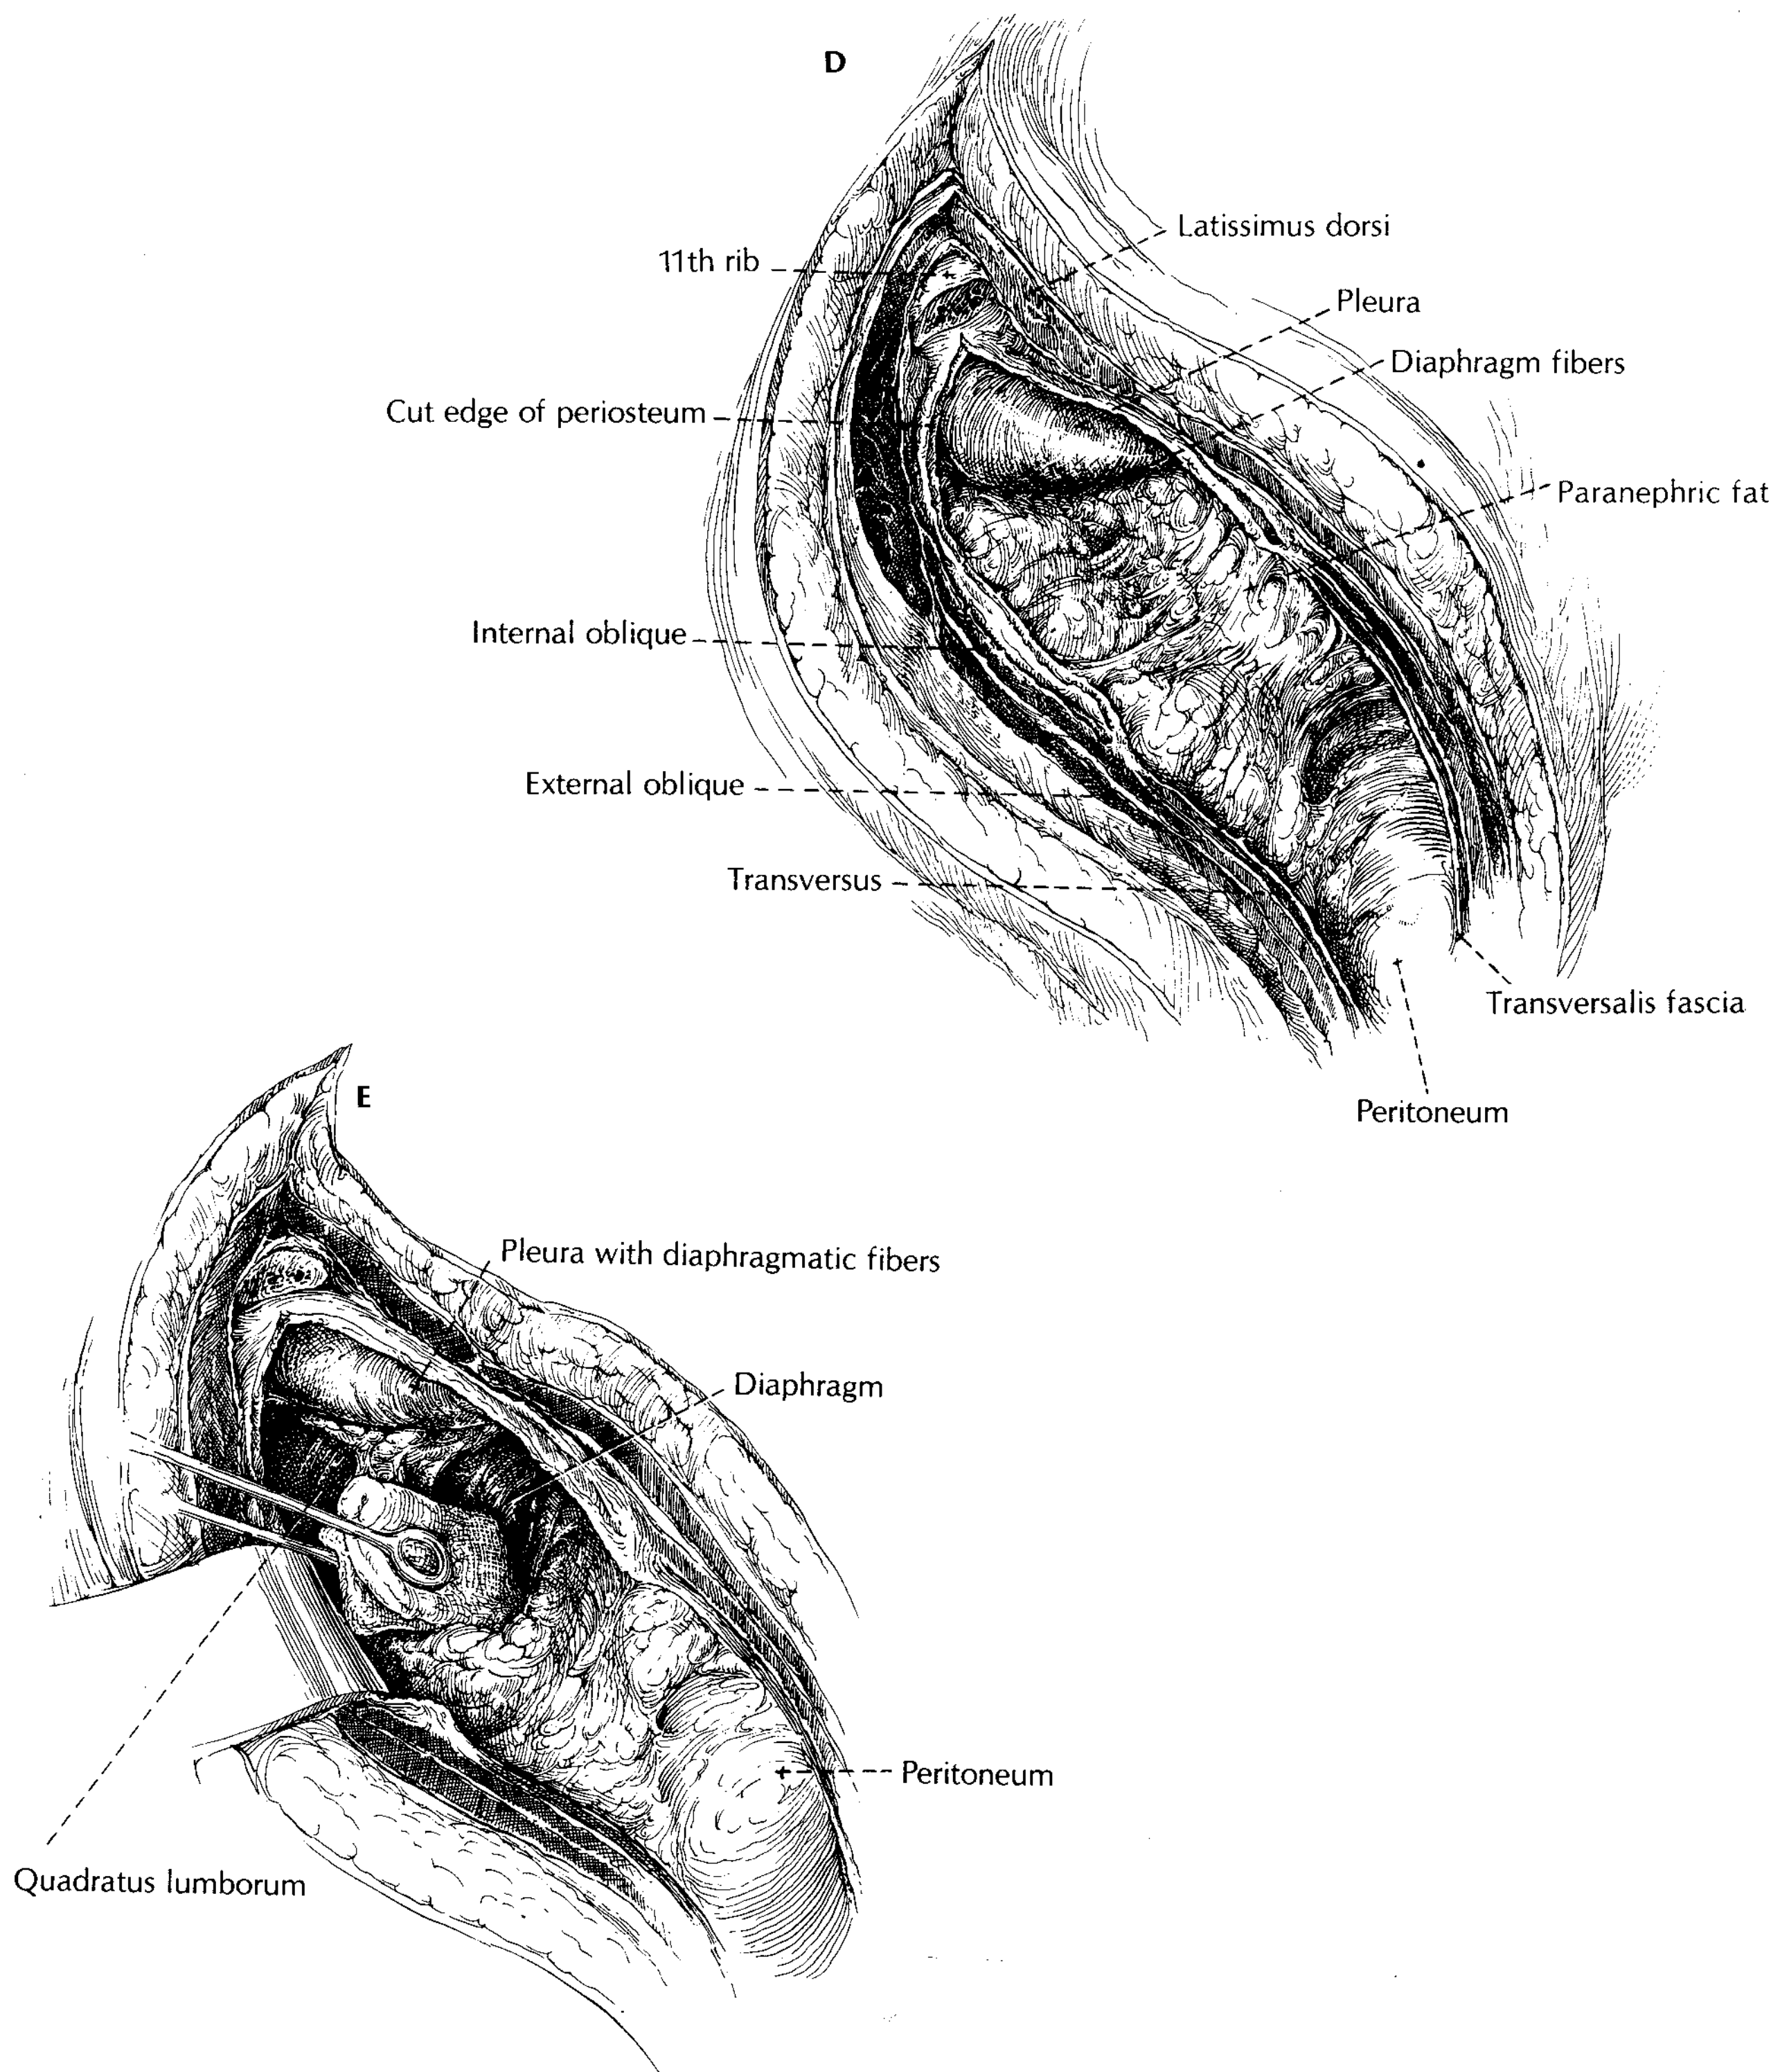

fashion with early identification of the psoas muscle helps keep proper orientation. A self-retaining retractor such as a Balfour, Bookwalter, or Finochietto rib spreaders helps maintain exposure. A radical nephrectomy is then performed.

The wound is closed after checking to ensure that no injury to the pleura has occurred (see complications). The table flex is released and the kidney rest is lowered. The posterior layer consisting of the fascia of the transversus abdominis and the internal oblique is closed in a running fashion with no. 1 PDS (polydioxanone suture) or Prolene. The anterior layer of external oblique fascia is closed with a running no. 1 PDS or Prolene. Alternatively, interrupted figure-of-eight sutures of no. 1 Vicryl can be used for both layers. The skin is closed in accordance with the surgeon's preference.

### Thoracoabdominal Incision

The thoracoabdominal approach allows for excellent exposure of large tumors as well as upper-pole tumors, in particular on the left. In addition, it affords easy access to the adrenal gland and thoracic cavity. The patient is positioned with the hips flat and with the break of the table located just above the iliac crest. The pelvis can be torqued up to about 30 degrees if necessary. The patient's ipsilateral shoulder is rotated 45 degrees, and the ipsilateral arm is extended over the table and properly supported on a Mayo stand or padded armrest (Fig. 3.4). It is important to properly pad all pressure points, including between the legs and the contralateral shoulder. The

**FIGURE 3.2** Technique of eleventh-rib resection. **D:** The incision is carried through the periosteum posteriorly and the internal oblique and transversus muscles medially, exposing the paranephric space. A tongue of pleura lies in the upper portion of the wound. Diaphragmatic slips that come into view are divided, and the pleura can be retracted upward. **E:** The paranephric fat is dissected bluntly. (*continued*)

kidney rest may be elevated to accentuate the proper extension, and the break in the table is made to optimize the incision. After positioning, the patient is secured with wide adhesive tape and safety straps.

The thoracoabdominal incision is made over the bed of the eighth, ninth, or tenth rib, depending on the surgeon's prefer-

ence based on patient and tumor characteristics. The incision may be made between the ribs, or a portion of the rib may be removed. The incision is made over the rib beginning at the posterior axillary line. The incision is carried medially across the costal cartilage margin to the midline and then carried down the midline to the umbilicus. Alternatively, the medial

**FIGURE 3.3** Rib resection technique. **A:** After exposure of the rib, the intercostal muscles are stripped from the upper and lower rib surfaces with an Alexander–Farabeuf costal periosteotome. **B:** The rib is freed from the periosteum by subperiosteal resection or from the pleura with a periosteum elevator. **C:** A Doyen costal elevator is slipped beneath the rib to free it. The proximal and distal portions of the rib are immobilized with Kocher clamps, and the rib is divided proximal to its angle with a right-angled rib cutter. **D:** The costal cartilage is cut free with scissors. The cut surface of the rib is inspected for spicules, which are removed with a rongeur and covered with bone wax.

portion of the incision may be carried across the midline or combined with a low midline to form a T-shape. The latissimus dorsi is divided, and the upper portion of the incision is carried down to the rib. At this point, a rib resection can be performed as previously described (Fig. 3.3).

The peritoneum may be entered by incising the external and internal obliques, the transversus abdominis, and the ipsilateral rectus abdominis. Next, the costochondral cartilage at

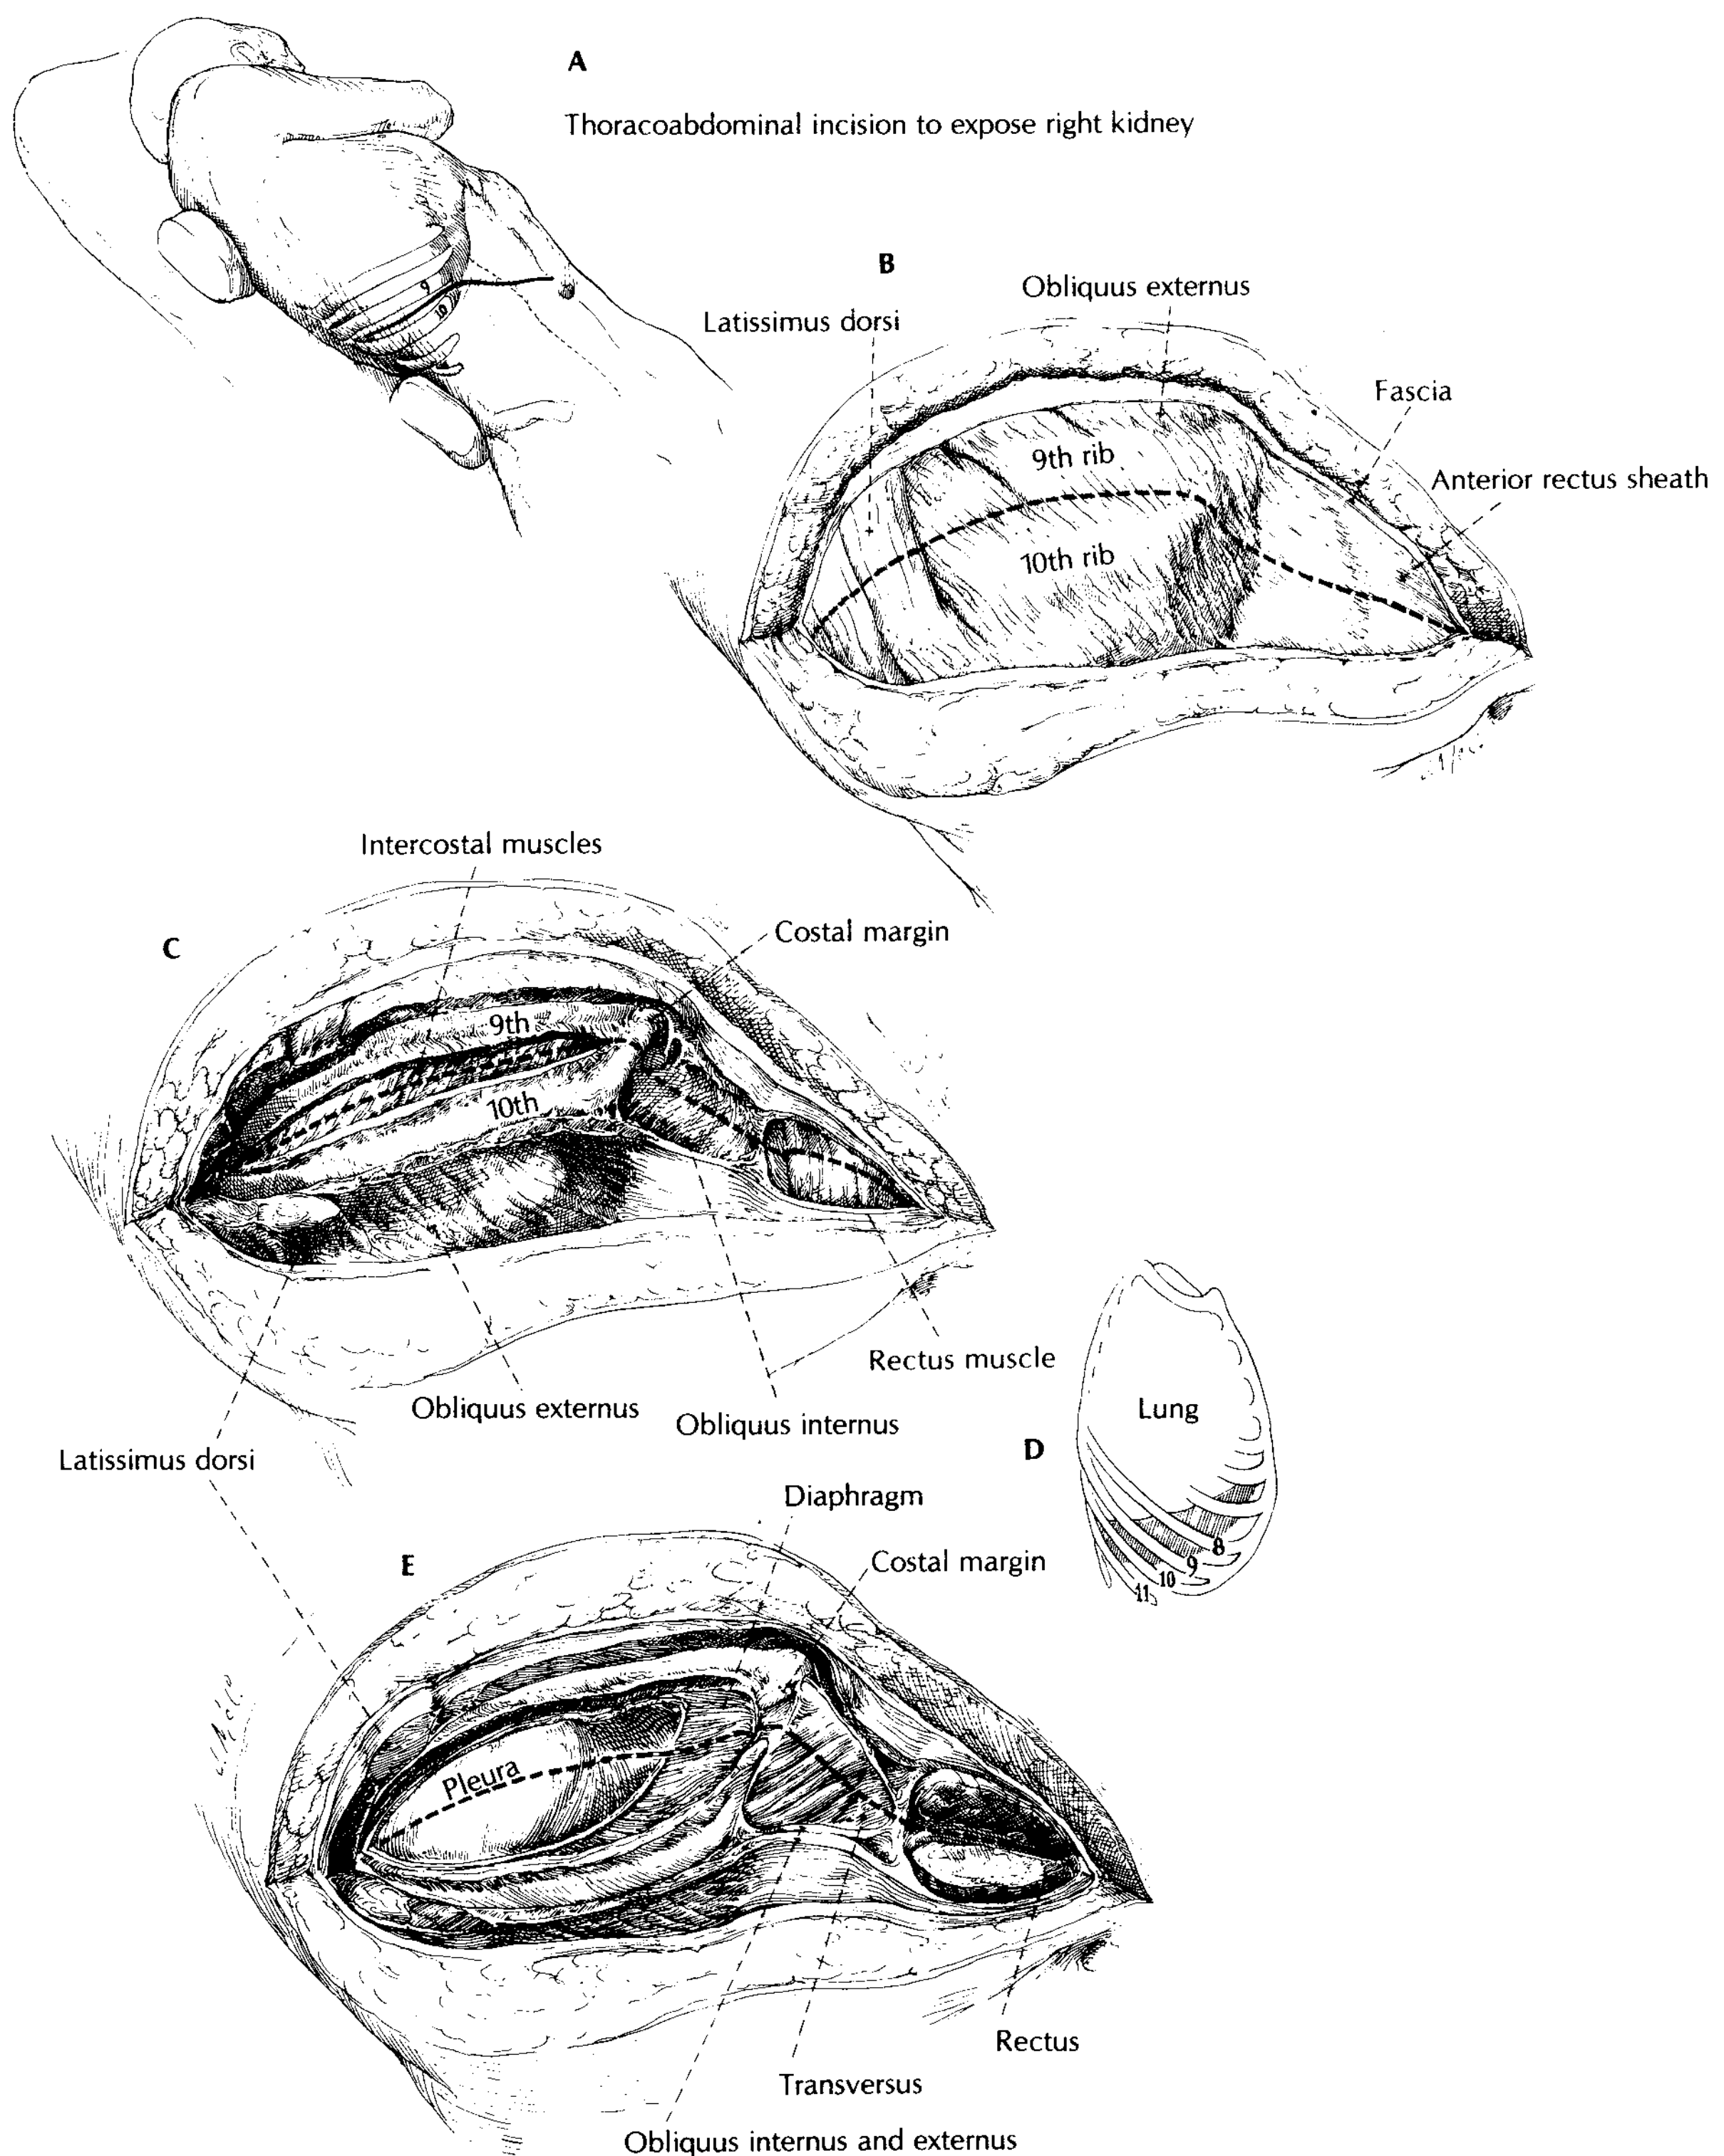

the inferior portion of the upper thoracic incision is divided, and the chest is entered along the entire length of the periosteal bed. The pleural space is entered, and care should be taken not to injure the lung. The lung is protected, and the diaphragm is divided in the direction of the muscle fibers, which helps avoid injury to the phrenic nerve. A self-retaining retractor such as a Balfour, Bookwalter, or Finochietto rib spreaders is properly padded and placed to maintain exposure. A radical nephrectomy is then performed.

After completion of the radical nephrectomy, the table flex is removed and the diaphragm is closed with interrupted 2-0 permanent sutures with knots placed on the inferior (peritoneal) side. After a 20Fr to 18Fr chest tube has been inserted through a separate incision and properly positioned, the ribs are reapproximated with 2-0 absorbable sutures. The thoracic portion of the incision is closed with interrupted figure-of-eight 1-0 Vicryl sutures through all layers of the chest wall. The medial portion of the intercostal muscle closure should include at least a small portion of the diaphragm. An intercostal nerve block is administered before closure and may be accomplished by injecting approximately 10 mL of 1.0% lidocaine or 0.5% bupivacaine hydrochloride into the intercostal space of the incision and two interspaces above and below. The costal cartilage can be reapproximated with 0 chromic sutures. This is essential to prevent “clicking” of the ribs, which is oftentimes bothersome to the patient. The posterior rectus fascia, the fascia of the transversus abdominis, and the internal oblique muscles are closed with a running no. 1 PDS suture. The anterior rectus and the external oblique fascia are closed with either a running or interrupted no. 1 PDS suture. Skin closure is determined by surgeon preference. The chest tube is secured in place with a 0 silk and taped securely in place.

### Transabdominal (Chevron or Anterior Subcostal)

Anterior incisions offer several advantages, including excellent exposure of the renal pedicle and access to the entire intraperitoneal contents and contralateral retroperitoneum. With the patient in the supine position, the operative side is elevated slightly with a flank roll and the patient hyperextended to accentuate the line of incision. An incision is made from near the tip of the eleventh or twelfth rib on the ipsilateral side two finger breadths below the costal margin and extended medially to the xiphoid process. The incision is then gently curved across the midline and as far laterally as necessary for exposure up to near the tip of the contralateral eleventh rib.

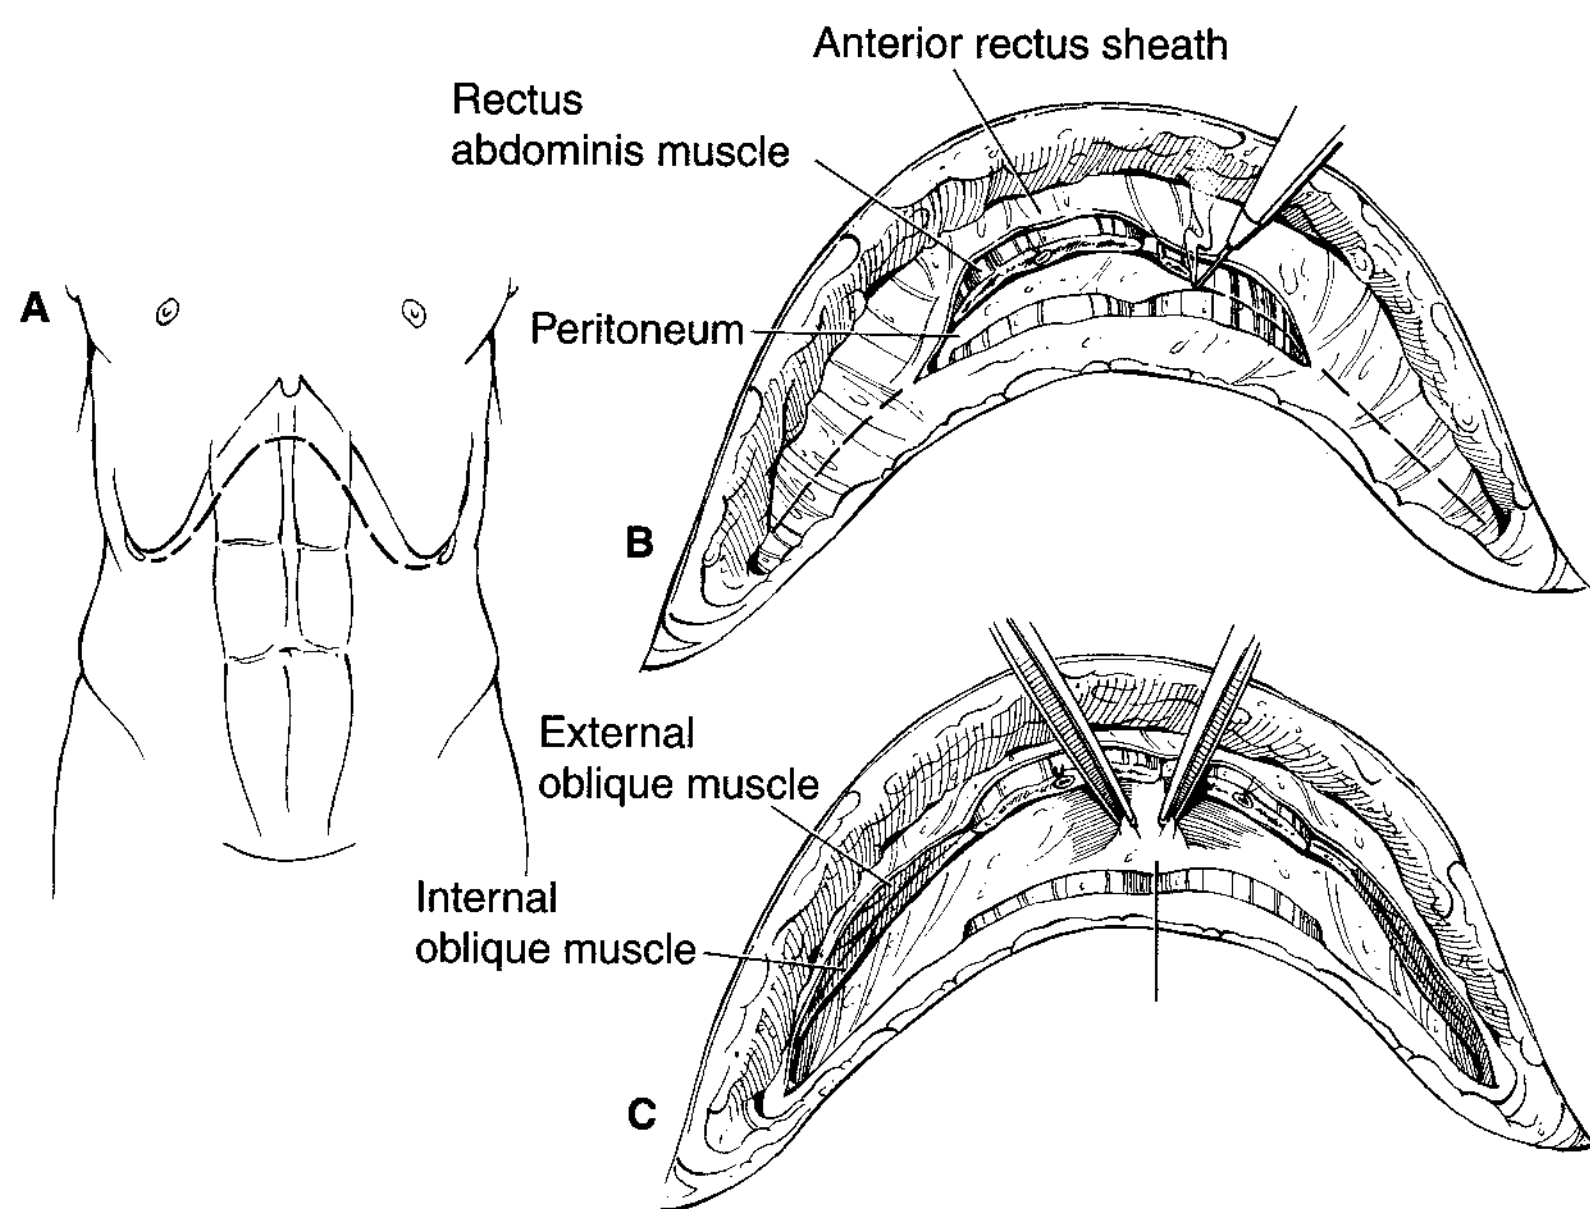

On occasion, only a portion of the contralateral side will be incised just across the rectus abdominis. The incision is carried down to the anterior rectus fascia, which is then divided (Fig. 3.5). Next, the external and internal oblique fascia and muscles are divided and the fibers of the transversus abdominis split. The rectus muscle and posterior rectus sheath are divided with electrocautery by placing a straight clamp underneath and gently elevating it. The peritoneal cavity is then entered, and the falciform ligament is ligated between two Kelly clamps, divided, and ligated. To facilitate exposure, use of a self-retaining retractor such as a Bookwalter (oval or segmented) or an Omni-Flex is helpful. A radical nephrectomy is then performed.

**FIGURE 3.4** Thoracoabdominal incision. **A:** The patient is placed in a semirecumbent position using sandbags. If the chest is entered through the ninth intercostal space, the incision extends from the midaxillary line across the costal margin at the intercostal space to the midline or across it just above the umbilicus. **B:** The anterior rectus sheath and the external oblique and latissimus dorsi muscles are divided. **C:** The intercostal muscles parallel the direction of the three abdominal layers and are divided. The costal cartilage and the internal oblique and rectus muscles are incised. If more exposure is desired, the linea alba and opposite rectus can be divided. **D:** The pleural reflection (*shaded areas*) lies progressively closer to the costal margin in the more cephalic intercostal spaces. **E:** The pleura, reflecting as the costophrenic sinus near the costal margin, is exposed beneath the intercostal muscles. The diaphragm can be seen inferior and dorsal to the pleura. The pleura is opened with care to avoid injuring the lung, which comes into view with inspiration. After the lung is packed away gently, the diaphragmatic surface of the pleura is seen. The diaphragm is incised on its thoracic surface, avoiding the phrenic nerve.

**FIGURE 3.4** Thoracoabdominal incision. **F:** The transversus abdominis muscle is divided, exposing the peritoneum with the liver lying beneath it. **G:** The peritoneum is incised, and a rib-spreading retractor (Finochetto) is inserted, enabling upward displacement of the liver (or the spleen on the left) into the thoracic cavity and giving wider access to the posterior peritoneum than in an anterior abdominal incision. (*continued*)

**FIGURE 3.5** Transabdominal chevron incision. **A:** With the patient in the supine position and slightly hyperextended, an incision is made two finger breadths below the costal margin to just below the xiphoid process and then curved gently down across to the tip of the opposite eleventh rib. **B:** The subcutaneous tissue and the anterior rectus sheath are divided bilaterally. A Kelly or an Army-Navy retractor is insinuated under the rectus muscle, and the muscle is divided with electrocautery. **C:** The external oblique and internal oblique muscles are divided, and the transversus abdominis is split. The peritoneal cavity is entered in the midline by tenting up on the peritoneum and incising sharply with Metzenbaum scissors.

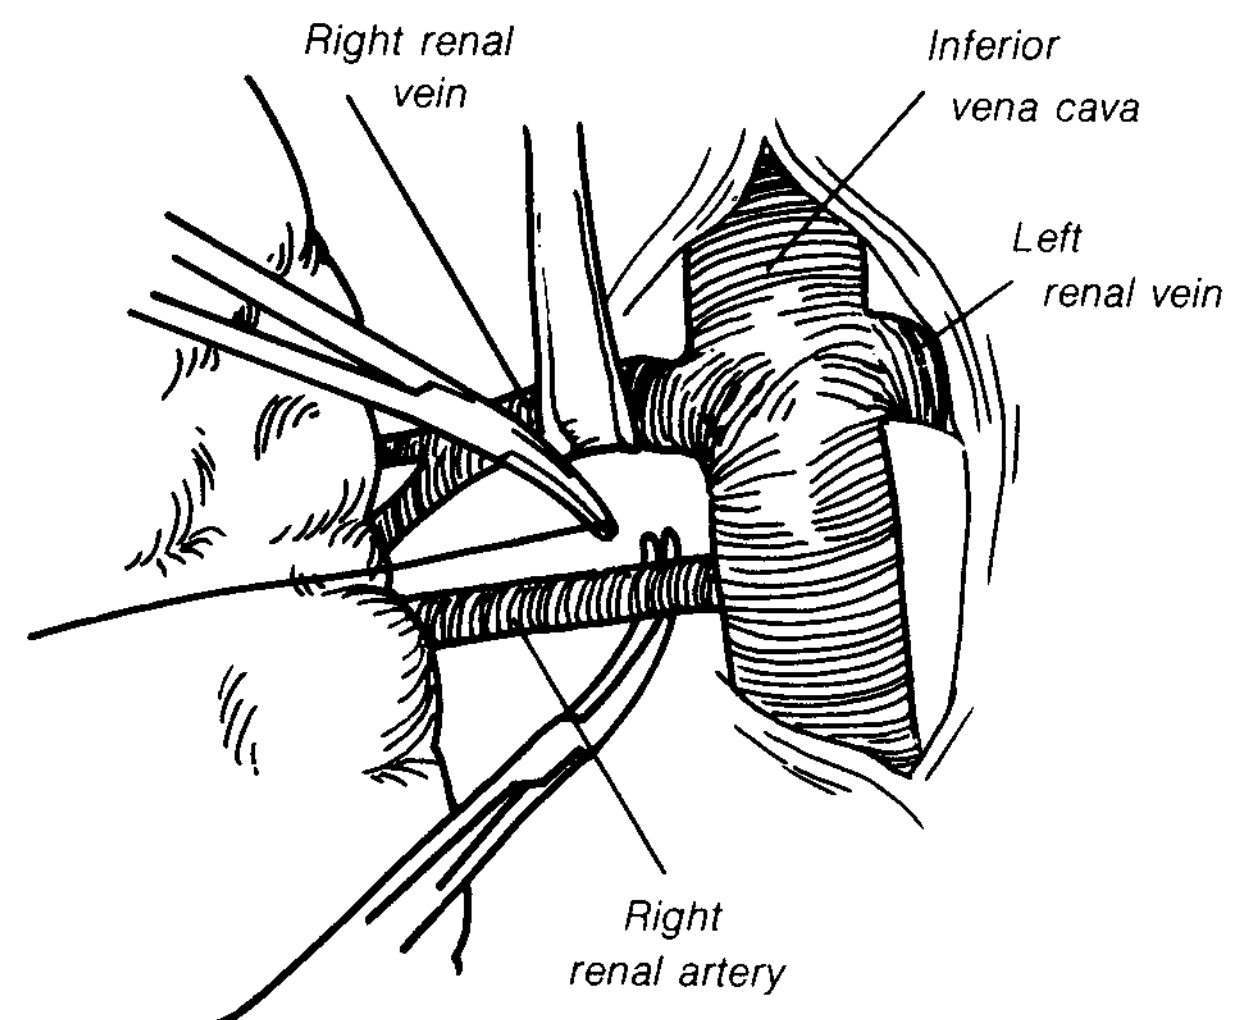

Closure of the wound is performed after the table is returned to the horizontal position. The wound is then closed in two layers. The posterior layer consisting of the fascia of the transversus abdominis and the internal oblique laterally along with the posterior rectus fascia medially is closed with two running no. 1 PDS sutures, each starting at the lateral aspect and running medially to the midline. The anterior layer of external oblique and anterior rectus fascia is closed in a similar fashion with no. 1 PDS. On occasion, it is helpful to place a U stitch of no. 1 Prolene at the apex of the chevron incision (at the location of the linea alba) before closure, including the rectus fascia on either side of the midline, securing this suture after the anterior fascia has been approximated. The skin is then closed according to the surgeon's preference.

## Radical Nephrectomy

Irrespective of the choice of incision, certain caveats are universal for the safe and successful completion of a radical nephrectomy. They include a systematic approach with careful mobilization of Gerota fascia and careful vascular control. For a flank approach, the posterior peritoneum lateral to the colon is incised along the length of the descending colon (left side) or ascending colon (right side) and reflected medially. For left-sided exposure, the lienorenal ligament is incised to mobilize the spleen cephalad. On the right side, the hepatic flexure of the colon is mobilized. The ureter is identified and encircled with a vessel loop. The gonadal vein is ligated and divided routinely on the left and when necessary on the right. The plane between the mesentery of the colon and Gerota fascia (often referred to as the gonadal space) is then developed using a combination of sharp and blunt dissection. On the right side, Kocherizing the duodenum is essential and exposes the vena cava. Using blunt and/or sharp dissection with electrocautery, the retroperitoneal fat overlying the renal vessels is separated, exposing the renal hilum. It is often helpful to ligate and divide the ureter before attempting to expose the renal hilum to allow for mobilization and upward displacement of the lower pole of the kidney.

The dissection is then carried cephalad along the vena cava (right side) or aorta (left side). On the right side, the right renal vein is identified exiting from the vena cava, isolated, and encircled with a right-angle clamp and a 0 silk suture and tagged. After identification of the renal artery (exposure from the anterior approach may be enhanced by the use of a vein retractor on the renal vein), the artery is dissected free and cleaned for a distance of approximately 2 to 3 cm. With a right-angle clamp, the renal artery is encircled, and 2-0 silk ties are passed (Fig. 3.6). The sutures are then separated and tied, allowing a safe distance for division of the artery, and it is preferable to leave two ties on the aortic side. A right-angle clamp is placed under the artery to be divided and gently elevated, and the artery is cut with either a knife (no. 15 blade) or Metzenbaum scissors. The right renal vein is then ligated with two 0 silk sutures and one additional 2-0 suture ligature on the side of the vena cava.

On the left, the renal vein is isolated as it courses over the aorta. The left adrenal and gonadal veins are identified emanating from the left renal vein, and, if present, a posteriorly directed lumbar venous tributary is noted. A right-angle clamp

**FIGURE 3.6** The right renal artery is identified by palpation beneath the vein. After identification with a right-angle clamp, the artery is cleaned in the same manner as the vein. With a right-angle clamp beneath the artery, a suture is passed on a tonsil clamp to the mouth of the right-angle clamp, and the suture is passed around the artery. (From Donohue RE. Radical nephroureterectomy for carcinoma of the renal pelvis and ureter. In: Crawford ED, Borden TA, eds. *Genitourinary cancer surgery*. Philadelphia: Lea & Febiger, 1982:101, with permission.)

is passed around the renal vein, followed by a 0 silk suture proximal to the tributaries, and tagged. The venous tributaries are then individually ligated and divided with 2-0 or 3-0 silk where necessary, leaving the 0 silk suture on the main renal vein tagged (Fig. 3.7). The left renal artery and vein are then ligated similarly to the technique described previously for the right side.

**FIGURE 3.7** The same technique for ligation is employed on the left side. A suture is passed around the lumbar vein proximally and distally after the vein has been cleaned, and the vein is ligated. Sutures are passed around the main renal vein but are not tied until after the branches have been ligated. The artery is identified above the vein and cleaned, isolated, and ligated, and the proximal end is sutured with a 5-0 cardiovascular silk suture. (From Donohue RE. Radical nephroureterectomy for carcinoma of the renal pelvis and ureter. In: Crawford ED, Borden TA, eds. *Genitourinary cancer surgery*. Philadelphia: Lea & Febiger, 1982:101, with permission.)

Alternatively, a stapling device can be used to control both the renal artery and vein for either right or left-sided approaches.

Depending on the location of the tumor, prior to control of the renal hilum, Gerota fascia may be initially mobilized posteriorly and superiorly using a combination of sharp and blunt dissection, or this can follow ligation and division of the renal vessels. Small clips placed along the superior and medial border are useful to control any potential bleeding during this portion of the procedure. These should be avoided anywhere near the renal hilum as they may prove problematic if bleeding is encountered. The adrenal hilum is then dissected from caudal to cranial with the aid of either clips or straight clamps and ties. On the right side, the short posteriorly located right adrenal vein should be anticipated as it exits directly from the vena cava. When encountered, the right adrenal vein is isolated, ligated, and divided. The specimen is then delivered and meticulous hemostasis is achieved.

---

## OUTCOMES

---

### Complications

---

The potential for bleeding during radical nephrectomy necessitates careful patient preparation and preoperative planning to significantly reduce the chance of bleeding. Any medications that interfere with platelet function or clotting should be discontinued. A preoperative hematocrit should be obtained, and a type and screen are in general recommended. In patients with significant anemia or in those in whom significant blood loss is anticipated, a type and cross-match for possible transfusion should be performed. The patient should have either two large-bore peripheral IV lines or a central venous line to allow for rapid infusion of fluids or blood products if necessary.

Bleeding during radical nephrectomy may be from a variety of locations, including the renal hilum, collateral tumor vessels, or adjacent structures. Venous bleeding is usually the most problematic. The first maneuver is to apply direct pressure to the area of bleeding and allow for appropriate resuscitation before additional maneuvers are considered. The point of bleeding is then carefully exposed and controlled by a suture ligation. In the case of venal caval injury, pressure can be applied carefully with sponge sticks, and then an Allis or Satinsky clamp may be carefully placed; a vascular 5-0 or 6-0 Prolene suture is used to oversew the defect. Lumbar veins should be exposed by gentle retraction of the vena cava, appropriately clamped, ligated with vascular silk suture, and divided. Renal artery bleeding may be controlled by direct pressure on the aorta proximally and distally until adequate exposure can be obtained, and the artery is then ligated. Only in certain circumstances will a pedicle clamp or en bloc ligation be necessary.

Adrenal tears may result in significant hemorrhage during radical nephrectomy, in particular on the right side, where the short adrenal vein enters into the vena cava directly posterior. Control of the right adrenal vein should be attempted only after control of the vena cava, adequate exposure, and proper suction. The vein is then ligated with a 2-0 or 3-0 silk tie or vascular Prolene. Venous bleeding from a torn adrenal gland

can be oversewn with a running suture or stopped by placement of surgical clips. However, removal of the ipsilateral adrenal may be the most expeditious method of controlling bleeding.

Failure to recognize a rent in the pleura during flank incision will result in a pneumothorax. Filling the flank wound with sterile water or saline and administering a deep inspiratory breath may help recognize small openings in the pleura. Small tears recognized intraoperatively can be managed by closing the pleura with a 3-0 chromic pursestring suture over a 12Fr or 14Fr Robinson catheter. Before it is removed, all air is aspirated from the pleural cavity either by suction or by placing the Robinson catheter under water and administering a deep inspiratory breath. The air is evacuated from the pleural space and the tube is removed while the pursestring suture is simultaneously tied in place. Alternatively, the Robinson catheter can be temporarily left in place with the chromic suture secured and the fascial layers closed around the catheter, which exits from the corner of the wound. Just before skin closure, after all air has been evacuated under water seal as described above, the catheter is removed. The latter technique is helpful when the pleura is attenuated or contains multiple small holes that are not easily closed. Alternatively, a 22Fr or 24Fr chest tube may be placed and left to suction and removed postoperatively.

An upright end-expiratory chest X-ray is obtained after all flank incisions to ensure that no significant pneumothorax exists. A small (usually <15%), asymptomatic pneumothorax can be followed conservatively with serial chest X-rays and oxygen therapy. In a symptomatic or large pneumothorax, aspiration of the pleural space using a needle or a central venous catheter (Seldinger technique) introduced just over the rib in the anterior fourth or fifth interspace can be therapeutic. However, if these attempts are not successful, a chest tube should be inserted and placed on suction.

Injuries to the colon during radical nephrectomy are uncommon. In locally advanced tumors suspected of extension into either the colon or mesentery, patients should undergo a mechanical and antibiotic bowel preparation. Segmental colon resection and primary anastomosis should be possible in most cases. Inadvertent injury to the colon during radical nephrectomy can usually be repaired primarily; however, in situations where there is gross spillage of fecal contents or a devascularized segment, a diverting colostomy should be considered, and a general surgery consultation is advisable. Defects in the mesentery of the colon should be closed to prevent internal herniation of peritoneal contents.

Right radical nephrectomy is also associated with the potential for injury to the duodenum and liver. The duodenum must be carefully mobilized, and care must be taken to properly pad retractors to prevent injury to the bowel and adjacent structures, including the head of the pancreas. The second portion of the duodenum may be injured during a right radical nephrectomy. Duodenal hematomas should only be observed, but rapidly enlarging hematomas will require control of the bleeding, and an intraoperative general surgery consultation should be obtained. Duodenal lacerations should be repaired in multiple layers with interrupted nonabsorbable sutures for the mucosal and serosal layers (1). When possible, an omental wrap may provide additional support, and all patients should be managed with a nasogastric tube during the postoperative period.

Bleeding from superficial liver lacerations may be controlled with Bovie electrocautery or an argon beam electrocoagulator. More significant bleeding may be repaired with absorbable horizontal mattress sutures utilizing a Surgicel or Gelfoam bolster. Deep liver lacerations, which may involve the hepatic ducts, could result in bile leakage and should be drained following repair; an intraoperative general surgical consultation is strongly recommended. Direct invasion of the liver by renal cell carcinoma is rare; however, resection including en bloc removal is possible in selected cases. If a major lobectomy or a partial hepatectomy is to be performed because of either direct extension or major hemorrhage, a general surgeon should be present to assist in its performance.

Splenic injury is one of the most common intraoperative complications during a left nephrectomy, with an incidence as high as 10% in some series. Most superficial lacerations or tears can be managed conservatively without the need for splenectomy. Although minor tears may require only some gentle pressure and the application of a Gelfoam or Surgicel bolster with spray thrombin, closure of a moderate splenic capsular tear is facilitated through the use of nonabsorbable sutures over bolsters of Surgicel. Major hemorrhage secondary to severe splenic lacerations may require splenectomy (9).

The splenic artery and vein are controlled by compressing these structures, which are located in the splenic hilum near the tail of the pancreas. Initially, this can be accomplished manually by compressing the tail of the pancreas between the thumb and forefinger. Once bleeding has been temporarily

controlled, the spleen is mobilized by dividing the splenocolic and splenorenal ligaments as well as taking down the peritoneal attachments to the diaphragm. The short gastric vessels are then ligated, and the hilum of the spleen is dissected free from the tail of the pancreas. The splenic artery and vein are ligated and divided. The pancreas should be inspected closely to rule out inadvertent injury. Following splenectomy, patients will have a reduced resistance to pneumococcal organisms and should receive Pneumovax and HibTITER on a yearly basis.

---

## Results

---

Surgical excision remains the only effective and potentially curative therapy for clinically localized RCC. Pathologic staging remains the best prognostic variable in terms of patient survival, and the most commonly used staging system is the American Joint Committee on Cancer recommendations (TNM) classification (10).

The 5-year survival rate for patients with organ-confined tumors treated with radical nephrectomy for  $T_1N_0M_0$  tumors is between 80% and 91%, whereas that for  $T_2N_0M_0$  tumors is 68% to 92% (2). For those patients with  $T_{3a}N_0M_0$  (tumor invading into the adrenal gland) and  $T_{3b}N_0M_0$  (tumor invading into the renal vein) carcinomas, the 5-year survival rate is 77% and 59%, respectively. Finally, patients with node-positive disease ( $N_{1-3}M_0$ ) have a 5-year survival rate between 5% and 30%.

# CHAPTER 4 ■ INTRACAVAL TUMORS

VIRAJ A. MASTER AND FRAY F. MARSHALL

A unique feature of renal cell carcinoma (RCC) is its frequent pattern of growth intraluminally into the renal venous circulation, which is also known as venous tumor thrombus. This is the most common intracaval tumor that the urologist manages, with approximately 4% to 10% of patients having tumor extension

into the muscular branches of the renal veins, with further extension into the main renal vein and then into the vena cava. The extension of thrombus is variable. Many research reports use a staging system proposed by Montie, or small variations of this system, namely: Level 0, limited to the renal vein; Level I,

extending into the inferior vena cava (IVC) but  $<2$  cm above the renal vein; Level II,  $>2$  cm above the renal vein but under the hepatic veins; Level III, involving the intrahepatic portion of the IVC (hepatic veins) but below the diaphragm; and Level IV, extending above the diaphragm.

IVC involvement was historically considered a poor prognostic finding for RCC, but many reports have demonstrated that patients with tumor thrombi can achieve reasonable increased longevity with an aggressive surgical approach.

A

B

Studies have documented approximately 45% to 70% 5-year survival rates for patients with venous tumor thrombi. There continues to be a reasonable correlation between cephalad extent of the thrombus and survival, although striking survival is observed even with suprahepatic tumor thrombus. The critical feature is that there should be an absence of nodal or metastatic disease; otherwise survival is low.

## DIAGNOSIS

The vast majority of the time, the diagnosis of an intracaval tumor is made on the basis of a cross-sectional imaging study. However, physical examination findings may sometimes be the first sign of this kind of tumor. Asymmetric leg swelling may be present. Also in men, a unilateral, acute-onset varicocele may be observed, although possibly the most sensitive sign is unintentional weight loss. CT scans of the chest, abdomen, and pelvis without and with intravenous contrast are the most commonly performed examinations. Generally, these studies demonstrate the size of the primary renal tumor and the presence, size, and rough cranial extent of the tumor thrombus. Additionally, the presence of metastatic disease can be detected. Most often MRI of the abdomen is the next examination performed. Historically, this examination has been performed to precisely locate the cranialmost extent of the tumor (Fig. 4.1). However, with advancement in MRI, this study can be powerful at detecting the number, size, and location of lumbar veins, which is critical for achieving a bloodless field (Fig. 4.1). Additionally, MRI can be highly effective at discriminating between bland thrombus (benign clot) and tumor thrombus. A bone scan should also be performed. Given the rather poor clinical course of patients with brain metastases, it is prudent to obtain brain imaging. In the modern era of advanced cross-sectional imaging, it is usually unnecessary to obtain an inferior vena cavogram. An echocardiogram, performed transthoracically or, if needed, transesophageally, is exceedingly helpful in understanding subtle issues of tumors that

C

**FIGURE 4.1** MRI is helpful in determining (A) bland thrombus versus tumor thrombus, (B) cranial extent, and (C) number and location of lumbar veins.

invade the supradiaphragmatic cava and heart. Tumors that are bulky and space-filling in the atrium will certainly require cardiac bypass for safe extraction, while those with tumor thrombus in the intrapericardial IVC or very-small-volume intracardiac tumor thrombus may be treated with an abdominal approach, sparing the patient significant morbidity. If a significant period of time has elapsed since the last imaging study and presentation to our institution ( $\geq 4$  weeks), we favor repeat imaging to detect further cephalad growth of thrombus and the development of metastatic disease, as surgical management (need for bypass) may change with increasing growth.

---

## INDICATIONS FOR SURGERY

---

Historically, these challenging cases were reserved, in the main, for those fit to undergo surgery, without evidence of metastatic disease. Two general lines of evidence have emerged to expand the indications for surgery. First, the advent of the tyrosine kinase inhibitors in 2005 (sunitinib and sorafenib) and of mTOR inhibitors in 2007 (temsorilimus) provided tools to manage metastatic kidney cancer where previously therapeutic nihilism was prevalent. Second, data from the EORTC/SWOG randomized, prospective studies on the value of cytoreductive nephrectomy emerged to show that patients with good performance status, those with pulmonary-only metastatic disease burden, and those whose tumor burden was reduced by 75% after nephrectomy would benefit from cytoreductive nephrectomy (2).

Perhaps the most important issue is whom not to operate on. Patients with compromised cardiac status should be excluded. Additionally, we have observed that overall performance status is an important, sometimes subtle, clue about whom to operate on. Those patients with ECOG performance status of 0 or 1 are good candidates, while those with worse performance status have a dismal, moribund clinical course, regardless of a perfectly performed operation.

---

## ALTERNATIVE THERAPY

---

Renal cell carcinoma is classically described as a surgical disease. Neither radiation nor chemotherapy is effective as primary treatment. Since the introduction of multitargeted tyrosine kinase inhibitor medications and mTOR inhibitors, especially in patients with intracaval tumors and metastatic disease, neoadjuvant therapy may be used to potentially shrink tumors and make the operation technically easier. It may also allow for the delineation of those patients who have rapidly progressive metastatic disease and allow these patients to avoid the morbidity of an operation. This approach has not been specifically used for intracaval tumors particularly, but with locally advanced tumors with no increased risk of bleeding (3). The use of angioembolization as a means of palliation for patients with metastatic RCC has been reported in a few small case series, but it certainly will not provide a cure, and it has significant side-effects for the patient (4). Moreover, we have observed some cases of parasitization of adjacent organs after embolization, thus requiring nephrectomy down the line. Some authors have advocated for the use of preoperative embolization of the primary tumor with a view to making the

operation easier. We have not noted an advantage of this approach. Metal coils can obstruct the ability to ligate the renal artery. Ethanol and/or microsphere embolization is prone to reflux from the intended site given the significant intratumor arteriovenous fistulas that occur, and indeed may cause massive systemic embolization, resulting in death.

---

## SURGICAL TECHNIQUE

---

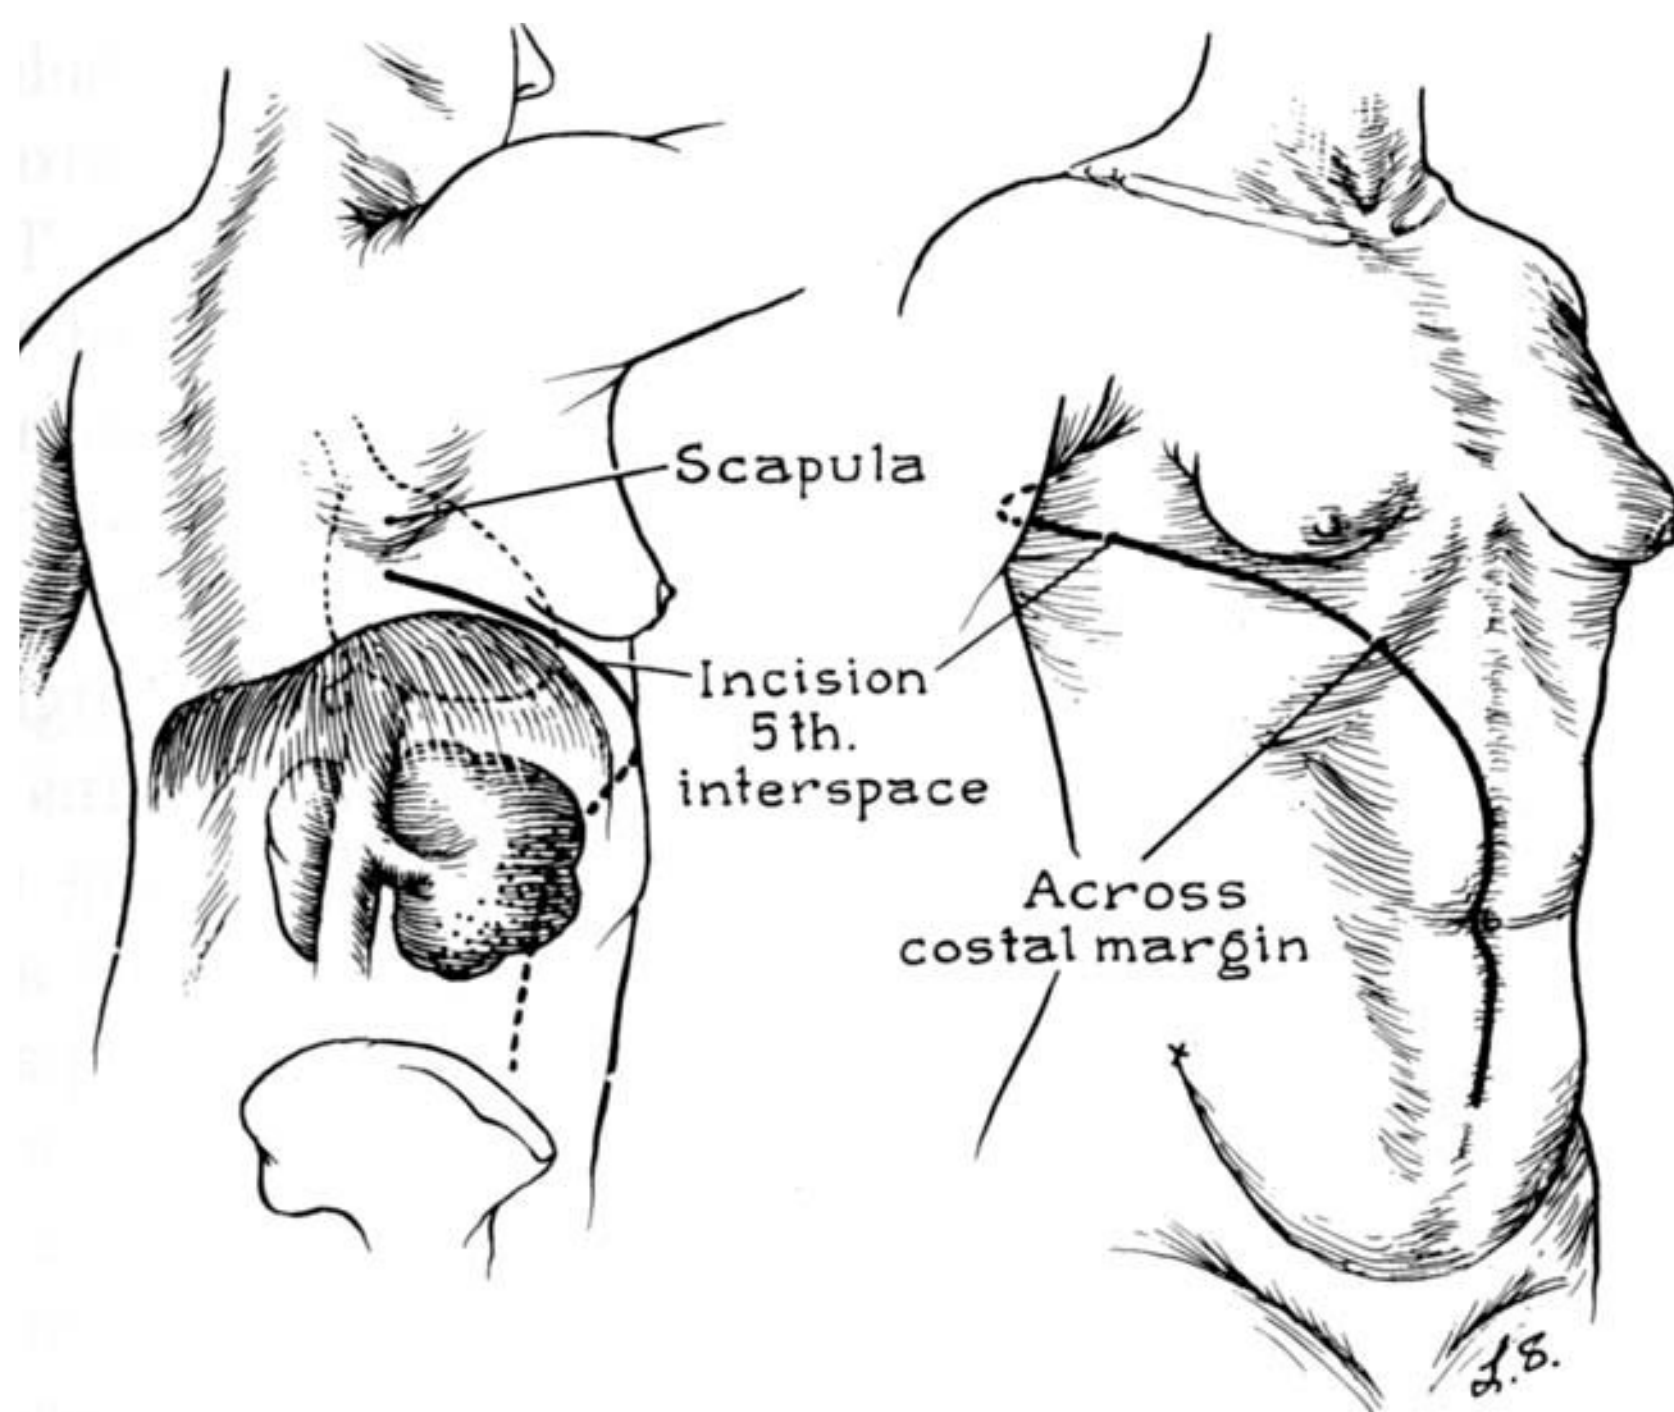

Multidisciplinary staff communication before the case starts is critical to success. The cell-saver machine needs to be on standby if needed. In addition to a general anesthetic, a thoracic epidural can be utilized and may be effective with post-operative pain management. Alternatively, an On-Q pain pump device (I-Flow Corp, Lake Forest, CA) can replace the need for an epidural. For a thrombus at the level of the hepatic veins, transesophageal sonography is a vital tool for examining the position of the thrombus, ascertaining possible migration, and also looking at cardiac function during the case.

The patient's body habitus and extent of both the primary and intracaval tumor direct the surgical approach. For renal tumors with neoplasm extending minimally into the IVC, a supra-eleventh-rib or standard thoracoabdominal approach with rib excision is ideal (Fig. 4.2), especially in obese patients, and actually can be performed occasionally, in a completely extraperitoneal fashion. For left-sided tumors and more extensive caval tumors, an anterior incision will provide good exposure. We have used a thoracoabdominal incision extending from the tip of the scapula across the costal margin to the midline halfway between the umbilicus and the xyphoid process for right-sided tumors with intrahepatic and supradiaphragmatic intracaval tumor extension. Using this approach, the patient should be positioned with the right shoulder rotated toward the contralateral side while the hips remain in the supine position and the table is slightly extended. Although this incision provides both intra-abdominal and intrathoracic exposure and the dissection is easier for the urologist, cannulating the aortic arch for cardiopulmonary bypass is more difficult.

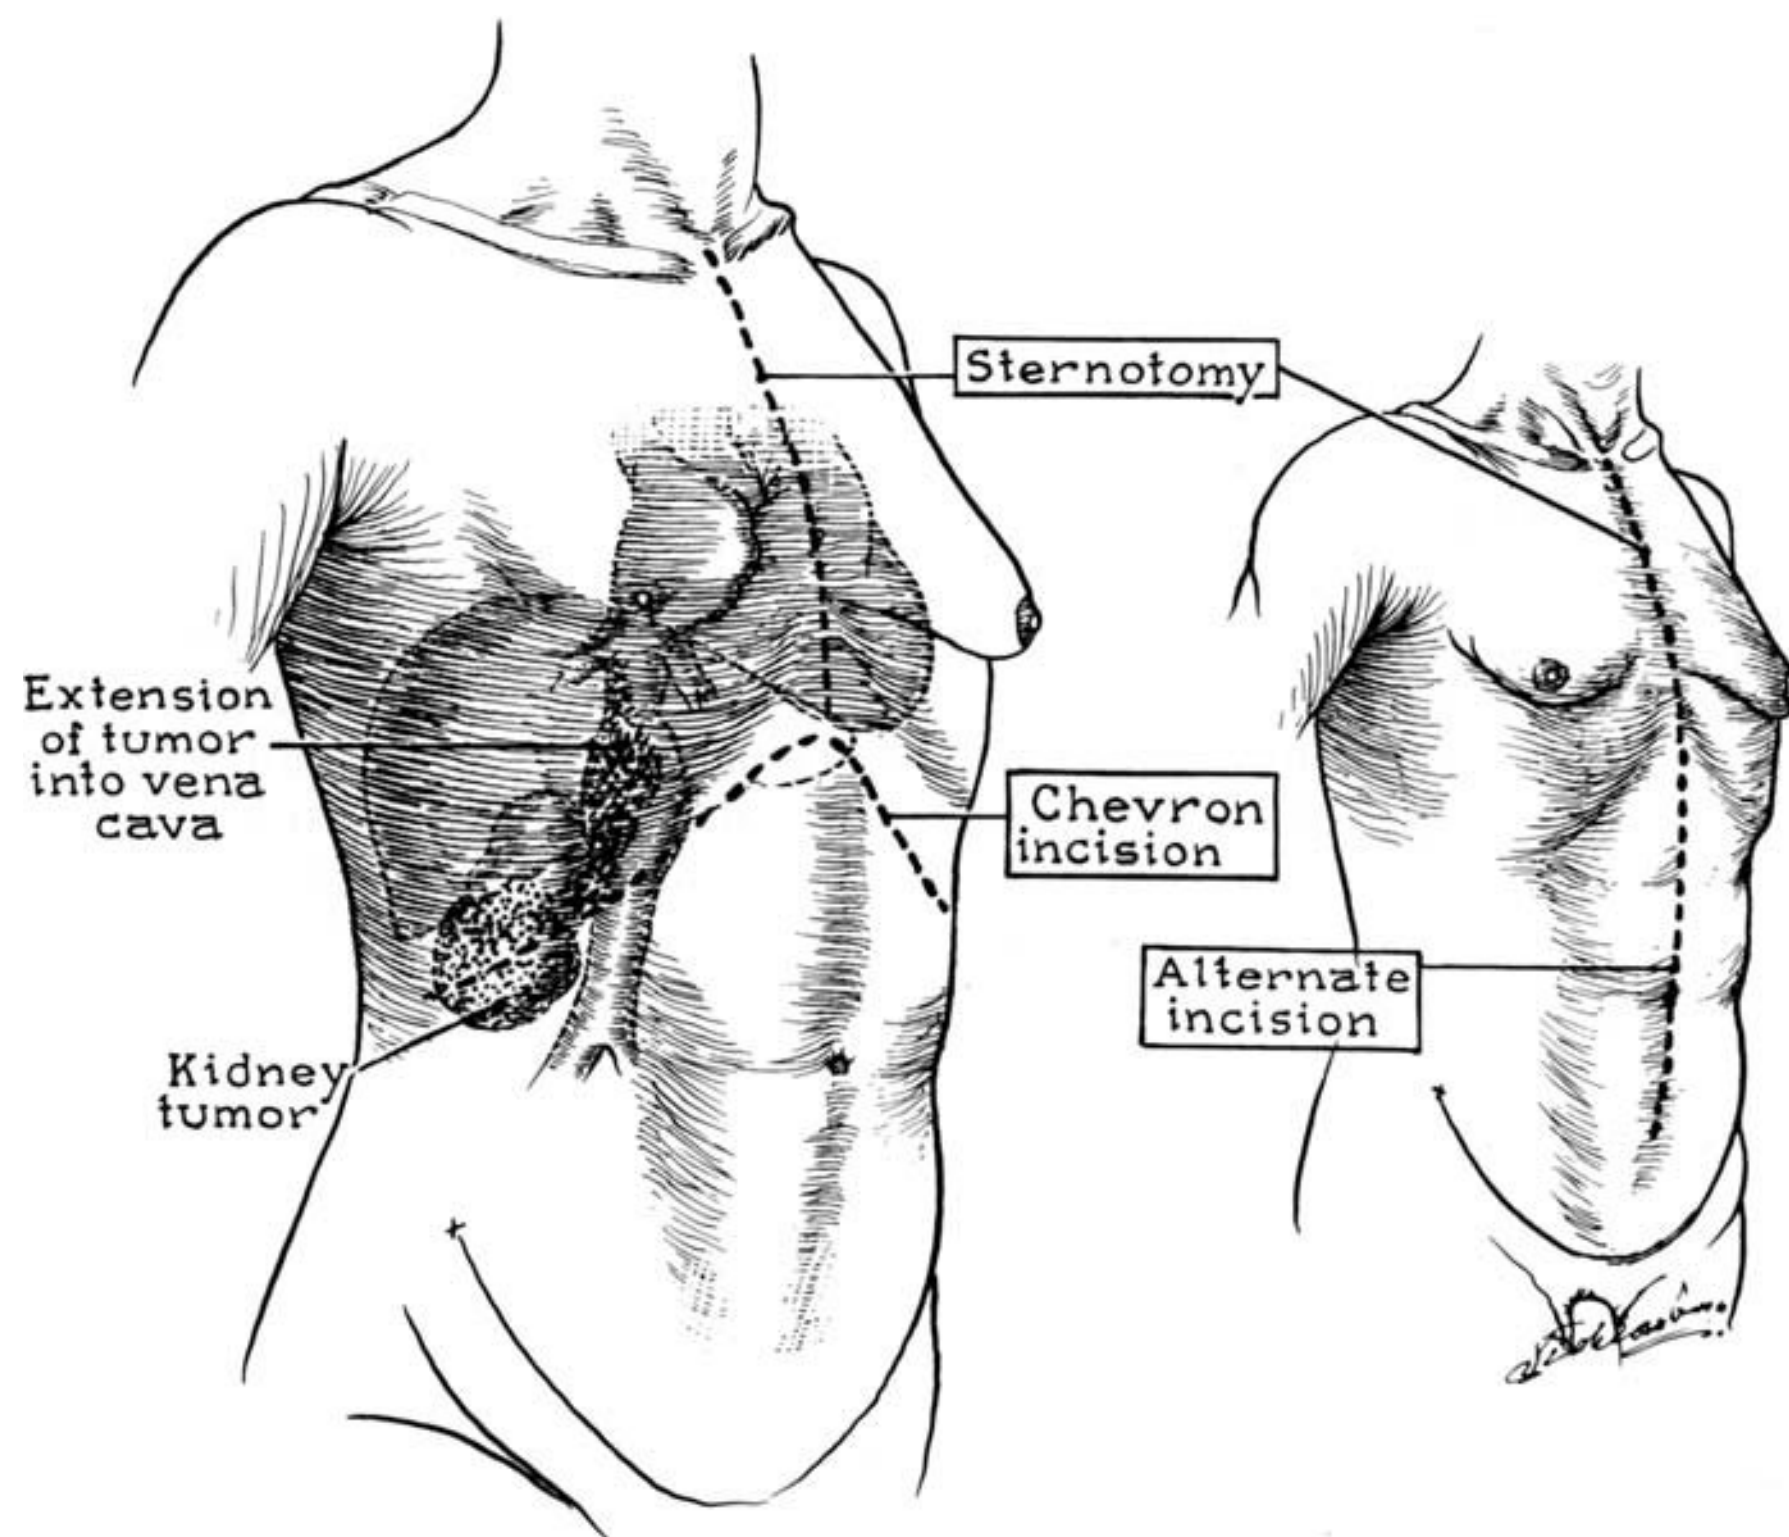

We typically use a median sternotomy extending into either a midline abdominal or a chevron incision when the intracaval neoplasm extends into or beyond the liver and cardiopulmonary bypass is considered (Fig. 4.3) (5). The chevron incision is useful in patients with a wide abdominal girth, in those with bulky primary tumors, and when using liver mobilization and rotation techniques to gain access to the upper retroperitoneum and chest. Although these extensive incisions provide excellent exposure, allowing for additional operations to be performed, we recommend limiting the procedure to nephrectomy and caval thrombectomy.

The patient should be widely prepared with antiseptic solution and draped to approach an extensive infra- or supradiaphragmatic tumor, and consideration should be given to preparing the neck and groin if venovenous bypass is considered. In the absence of overt metastasis, the incision is extended to include a median sternotomy, as this approach gives the best exposure.

The primary renal malignancy is approached first. For a right renal tumor, the right colon is mobilized along the line of Toldt and reflected medially to gain access to the retroperitoneum (Fig. 4.4). For significant tumors via a midline approach, incision of the root of the mesentery up to the

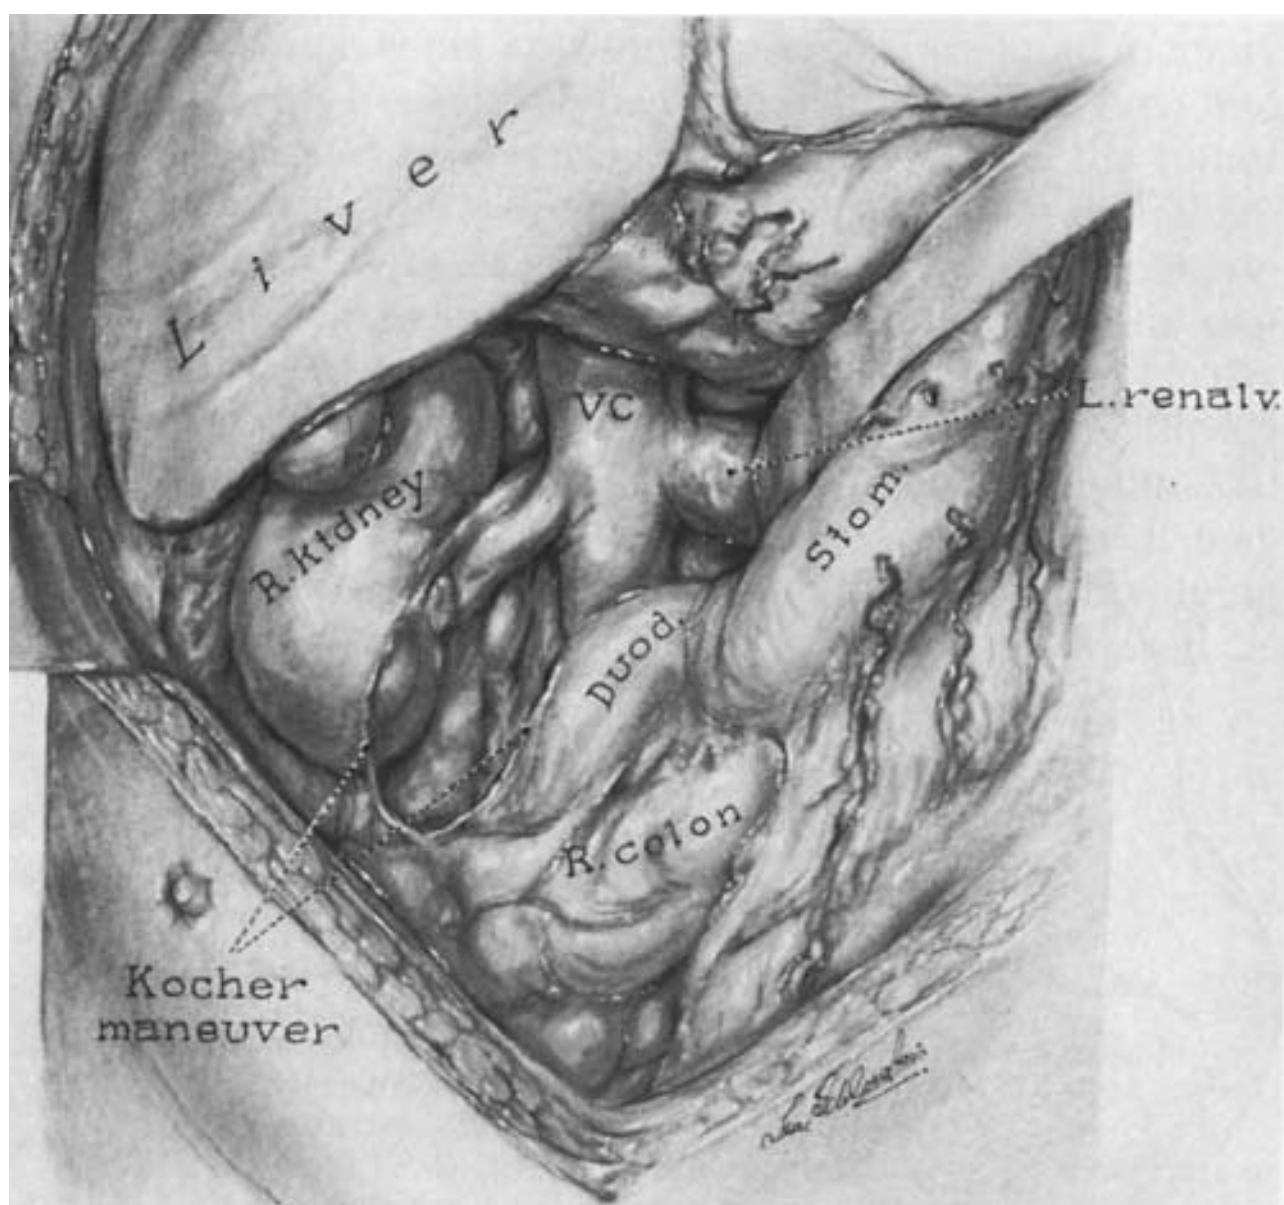

**FIGURE 4.2** Thoracoabdominal incision extending from the tip of the scapula across the costal margin to the midline halfway between the umbilicus and the xyphoid process of the sternum. The shoulder is rotated by placement onto a bolster or a 3-L saline bag, but the pelvis is flat. (From Marshall FF, Reitz BA. Radical nephrectomy with excision of vena cava tumor thrombus. In: Marshall FF, ed. *Marshall's textbook of operative urology*. Philadelphia: WB Saunders, 1996:265, with permission.)

**FIGURE 4.3** A midline sternotomy can be performed with a straight vertical incision or with a chevron incision extending laterally. The choice may be best made based on the body habitus of the patient. The large, obese patient is better suited to the chevron with cephalad midline extension. The acute angle of the chevron can be lessened depending on the choice of retractor. The Bookwalter retractor favors an acute angle, while the hepatic Thompson retractor favors an almost inverted-T incision. (From Marshall FF, Reitz BA. Radical nephrectomy with excision of vena cava tumor thrombus. In: Marshall FF, ed. *Marshall's textbook of operative urology*. Philadelphia: WB Saunders, 1996:265, with permission.)

Treitz ligament with placement of the bowel into an intestinal bag retracted onto the chest provides additional exposure. We tend to use the Omni-Tract retractor (Minnesota Scientific Inc.) as it provides excellent superficial and deep exposure of the surgical field. The entire kidney within the Gerota fascia is mobilized, first by a posterolateral approach developing the plane between the quadratus/psoas muscles and the Gerota fascia. After mobilizing the kidney posteriorly, the renal artery is ligated early to keep blood loss to a minimum. An even

more rapid approach to the renal artery is possible using an approach popularized for renal trauma. The transverse colon is lifted superiorly and the small bowel pulled to the right. The posterior peritoneum is incised medial to the inferior mesenteric vein right on the aorta up to where the left renal vein is seen. At this point, palpation with a finger or ultrasound probe in the interaortocaval space for the right renal artery or the para-aortic space for the left renal artery will identify the artery. A small pediatric Yankauer sucker can clear enough

**FIGURE 4.4** Completed incision for radical nephrectomy with removal of a right-sided caval thrombus. The right colon has been widely mobilized and the cava is isolated. (From Marshall FF, Reitz BA. Radical nephrectomy with excision of vena cava tumor thrombus. In: Marshall FF, ed. *Marshall's textbook of operative urology*. Philadelphia: WB Saunders, 1996:269, with permission.)

space to allow the artery to be controlled with a clip, tie, or stapler. This move rapidly decompresses the venous back pressure and seems to allow for shrinkage of the thrombus (Fig. 4.5). Anteriorly, the mesocolon is then reflected medially from the anterior surface of the Gerota fascia until the vena cava is visualized. A Kocher maneuver provides additional

medial exposure near the vena cava. Superiorly, dissection above the adrenal is undertaken using clips and the adrenal vein is ligated. Inferiorly, the kidney is mobilized along with ligation of the gonadal vein and ureter. Mobilization of the primary tumor is complete when the kidney remains attached to the vena cava by the renal vein.

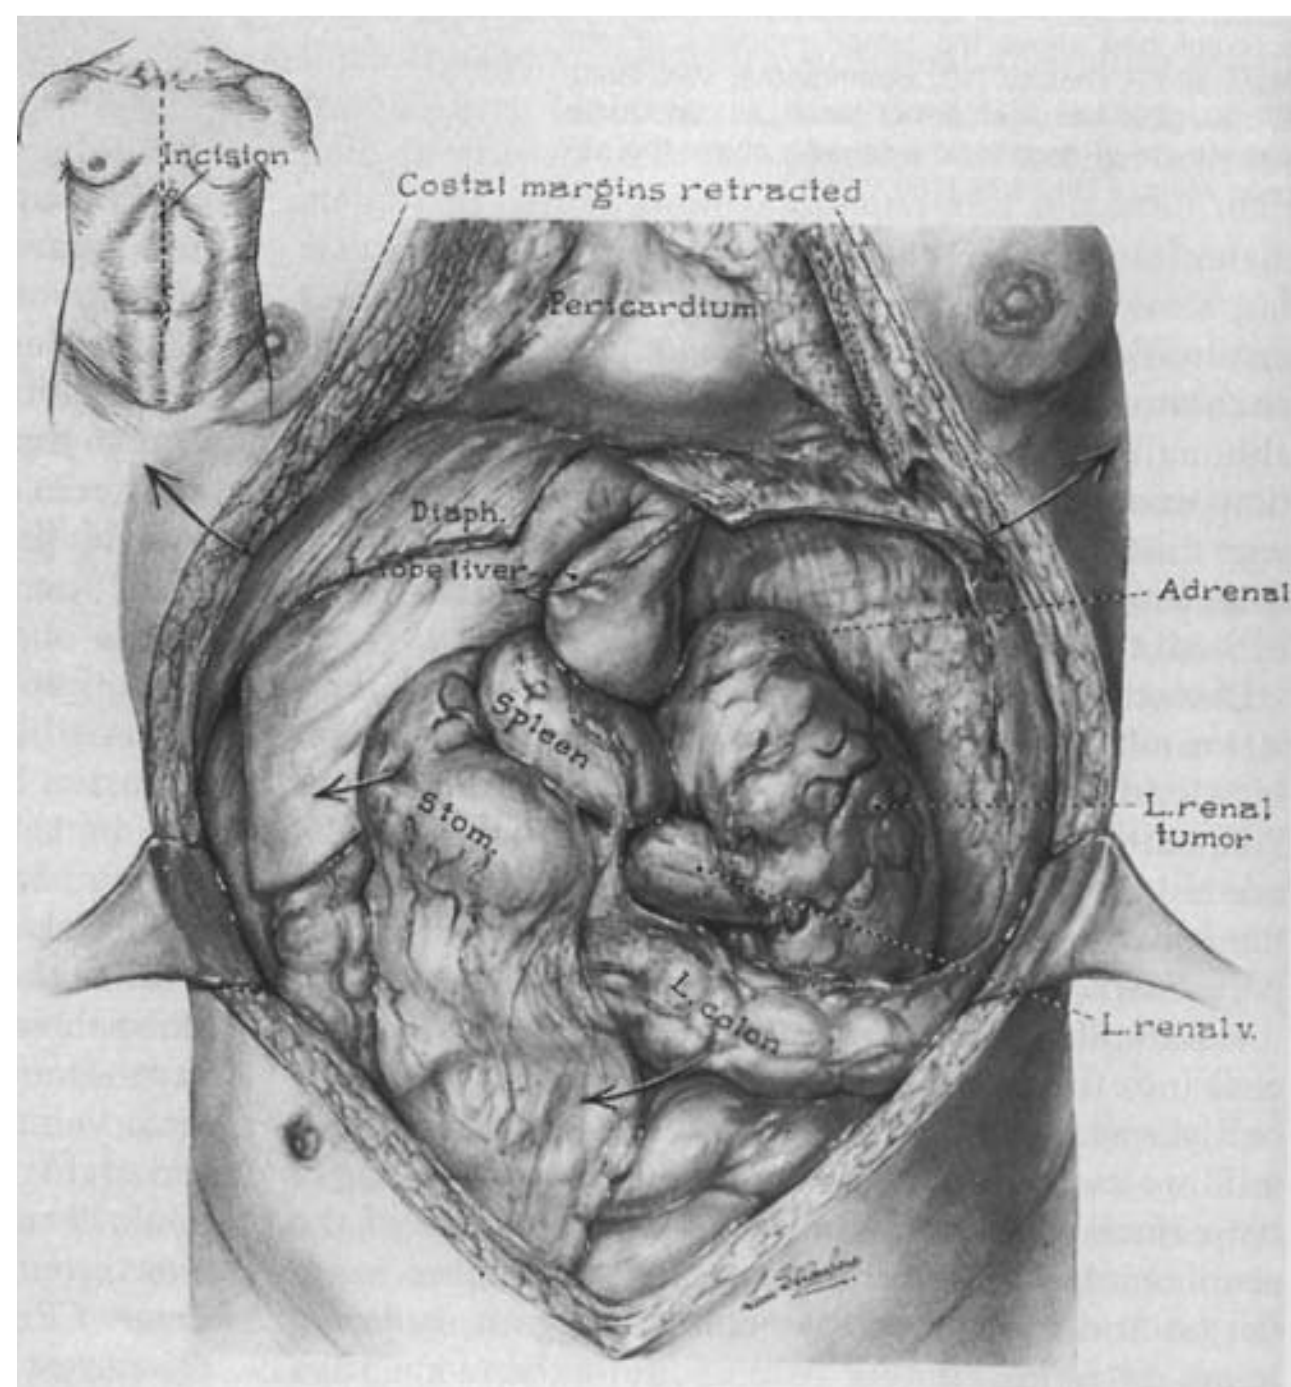

A left-sided renal tumor with caval thrombus requires dissection on both sides of the abdomen to access both the vena cava and the left kidney (Fig. 4.6). A midline or chevron incision usually provides excellent exposure. The descending colon is reflected medially by incising the line of Toldt. In a dissection similar to that for a right-sided tumor, the entire kidney within the Gerota fascia is mobilized until only the left renal vein remains. For large, left-sided renal tumors, the pancreas and spleen can be mobilized to provide greater exposure of the left upper retroperitoneum (6). The ascending colon is then mobilized medially by incising the line of Toldt, and the duodenum is reflected by the Kocher maneuver. Once adequate exposure to the vena cava is obtained, the remainder of the procedure is similar to that for a right-sided renal primary tumor.

The extent of the intracaval tumor dictates the length the vena cava that needs to be isolated. Dissection should proceed directly upon the vena cava, using care to prevent potential dislodgement of caval tumor. If the intracaval tumor extends slightly beyond the ostium of the renal vein into the vena cava, a Satinsky vascular clamp can be placed on the caval sidewall beyond the tumor. This segment of caval wall can be excised with the nephrectomy specimen en bloc, and the cava can be oversewn with 4-0 polypropylene suture on a cardiovascular needle.

With a more extensive infra- or suprahepatic intracaval tumor, control of the vena cava must be obtained above and below the extent of the caval tumor thrombus, as well as the contralateral renal vein. Often, it may be advantageous to mobilize and rotate the liver to achieve additional surgical

**FIGURE 4.5** Rapid exposure of the renal arteries for early proximal vascular control. This technique is widely used in renal trauma cases. **A:** After an appropriate incision is made, the first maneuver is to place the transverse colon onto the chest. **B:** The small bowel is reflected out of the body toward the right nipple. **C:** Small bowel contents are placed into a bowel bag or covered in moist laparotomy pads. The root of the small bowel mesentery should be visible, allowing for excellent visualization of the posterior peritoneal incision overlying the aorta from the ligament of Treitz to the aortic bifurcation. The posterior peritoneum is incised over the aorta medial to the inferior mesenteric vein. The left renal vein is easily visualized, and using that as a landmark, the right renal artery can be identified and controlled in the interaortocaval space, while the left renal artery may be controlled in the para-aortic space in a rapid fashion. (From Brandes SB, McAninch JW. Surgical exposure and repair of the traumatized kidney. *Atlas Urol Clin North Am* 1998;6(2):32-33, with permission.)

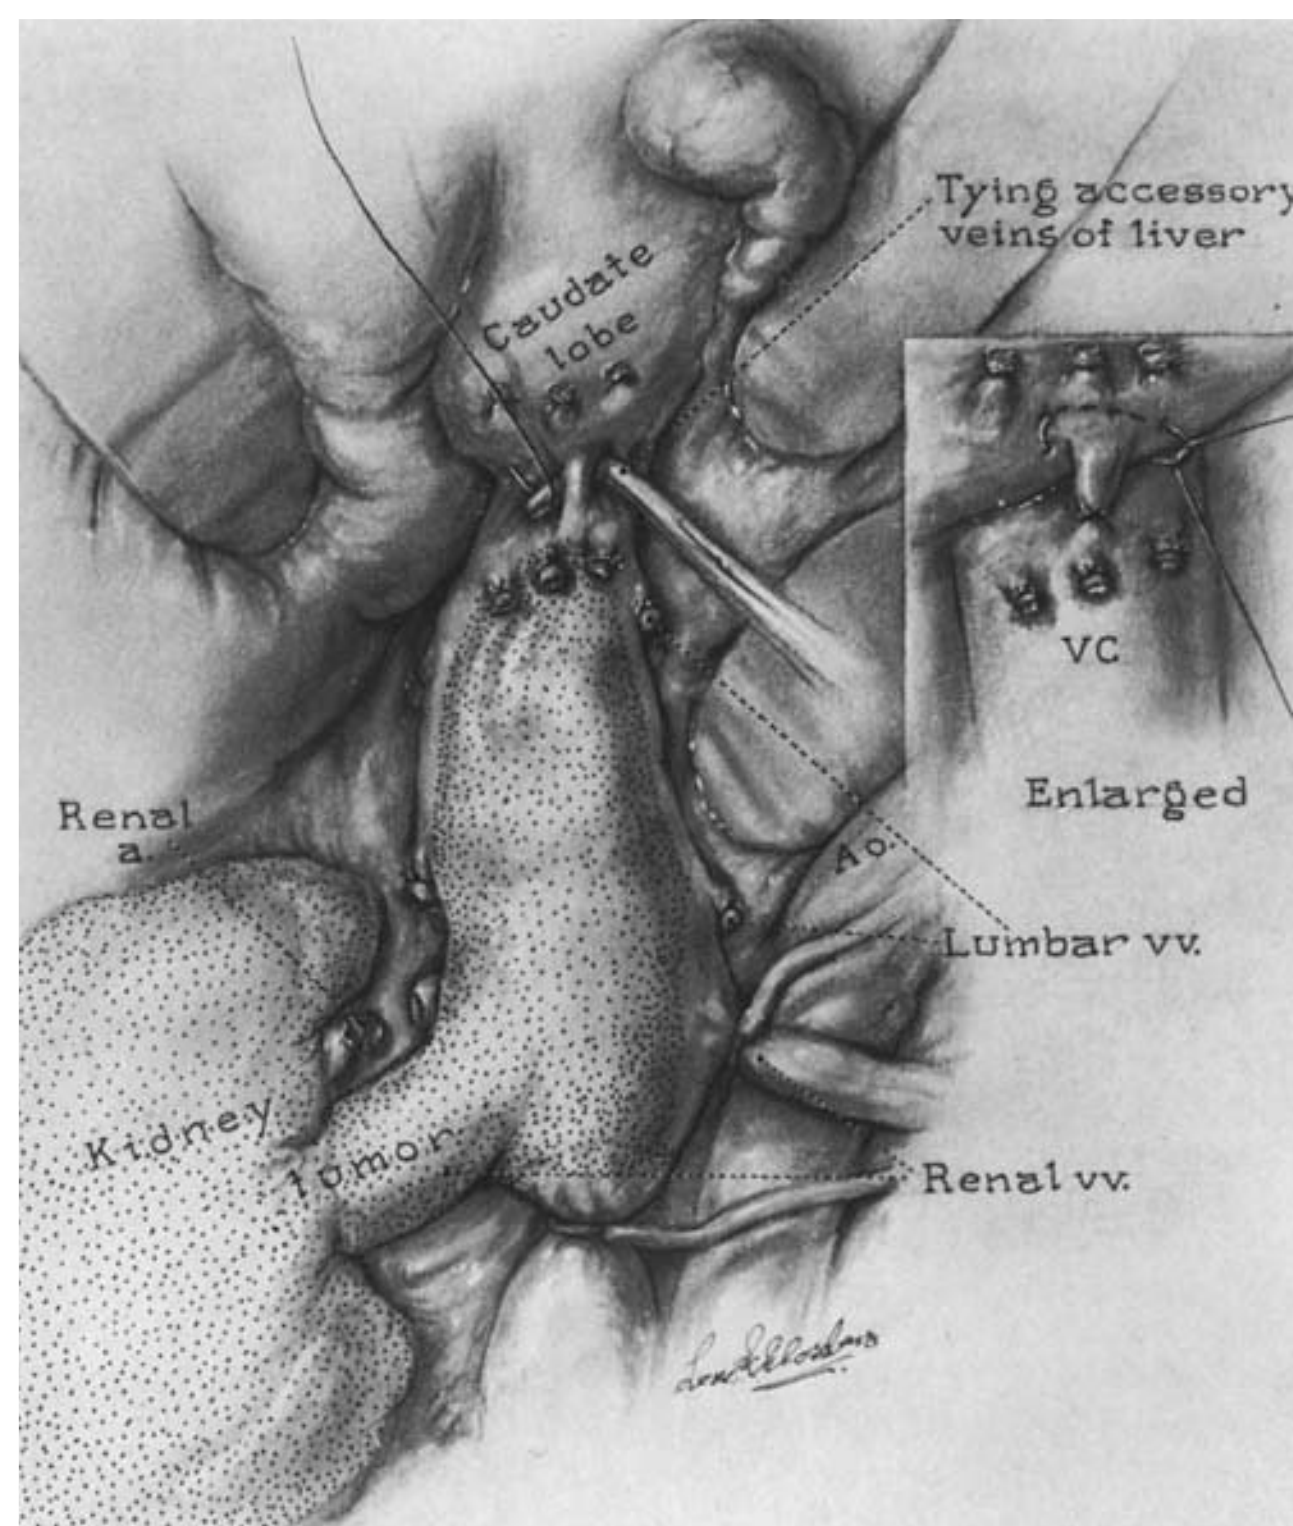

**FIGURE 4.6** Completed incision for radical nephrectomy with removal of Level IV vena cava tumor thrombus with a left renal primary tumor. Note the extensive medial visceral rotation performed to safely remove the tumor for these left-sided lesions. Colon, spleen, pancreas, and stomach have all been widely mobilized. (From Marshall FF, Reitz BA. Radical nephrectomy with excision of vena cava tumor thrombus. In: Marshall FF, ed. *Marshall's textbook of operative urology*. Philadelphia: WB Saunders, 1996:268, with permission.)

exposure to the vena cava in the upper abdomen and lower chest. Several of these innovative descriptions of hepatic mobilization derive from liver transplantation techniques (6,7). To maximize surgical exposure, a bilateral subcostal incision is recommended that can be extended superiorly into a partial or conventional median sternotomy if additional exposure or cardiac bypass is necessary. The round ligament and the falciform ligament are ligated and divided to facilitate exposure of the coronary ligaments. The right and left coronary ligaments of the liver are incised, detaching the liver from the diaphragm. The posterior fold between the liver and the right kidney is incised to further mobilize the right lobe of the liver. This maneuver allows the liver to rotate medially, typically providing sufficient exposure of the suprahepatic infradiaphragmatic IVC. In addition, the hepatoduodenal and hepatogastric ligaments can be incised to expose the lesser sac. One can usually appreciate a variable number of short venous branches draining the caudate lobe into the IVC. One or more of these veins may require ligation to prevent unexpected bleeding. If these veins are short, they can be controlled using suture ligatures placed into the liver parenchyma, although a series of medium clips creating a "wall of steel" can be more rapid (Fig. 4.7). Often, mobilization and rotation of the liver will allow the surgeon direct access to the main hepatic vein and the porta hepatis, which may be controlled with a Rummel tourniquet (umbilical tape passed through a 16Fr red rubber catheter) if needed. Inferiorly, a Rummel tourniquet is placed loosely below the tumor thrombus and both renal veins. For a right-sided

tumor, a Rummel tourniquet is placed loosely around a segment of the left renal vein to secure control of this vessel. Cardiopulmonary bypass can be obviated when vascular control using a vascular clamp or Rummel tourniquet can be gained above the superior extent of the tumor. Division of the diaphragm may aid in gaining vascular control above the superior extent of the tumor thrombus. It must be emphasized that minimal handling of the primary tumor and intracaval neoplasm is paramount to prevent inadvertent embolism. A Rummel tourniquet slightly tightened can be placed above the level of the caval tumor to prevent inadvertent thromboembolism.

After adequate mobilization of the vena cava superior and inferior to the tumor thrombus with ligation of any lumbar veins, all vascular clamps or Rummel tourniquets are secured. A narrow elliptical incision circumscribing the ostium of the involved renal vein is made. If the tumor is inseparable from the caval endothelium superior to the renal veins, the involved cava is excised. The renal primary and caval tumor is removed en toto under direct vision. On occasion, we have used a dental mirror to inspect the hepatic veins or a flexible cystoscope to inspect the cava to ensure complete removal of tumor. If additional verification is necessary, transesophageal echography can be used to evaluate the superior extent of the cava, or direct intraoperative sonography can be used to evaluate the extent of the cava (8).

**FIGURE 4.7** Ligation and division of the venous tributaries of the caudate lobe of the liver. Note that there are significant variations in the number, diameter, and location of these short caudate veins. Multiple ties or clips are required for control of these short veins. This maneuver allows for proximal control of the cava above the thrombus, or of full liver mobilization off the vena cava. (From Marshall FF, Reitz BA. Radical nephrectomy with excision of vena cava tumor thrombus. In: Marshall FF, ed. *Marshall's textbook of operative urology*. Philadelphia: WB Saunders, 1996:267, with permission.)

To close the vena cava, a 4-0 or 5-0 cardiovascular polypropylene suture on either RB-1 or SH needles is used. Before completing the cavotomy closure, the inferior tourniquet is released to allow trapped air to escape through the cavotomy site. If excision of the cava decreases the vascular diameter by  $>50\%$ , reconstruction of the vena cava is recommended to prevent caval thrombosis. Initial cases of vena cava reconstruction were done using pericardium because it is less thrombogenic, although more recently prosthetic grafts have been employed. Venous drainage of the right kidney must always be preserved to prevent venous infarction. In some instances, the cava has been oversewn to prevent subsequent embolism if the thrombus below the renal veins is adherent to the caval endothelium, as is often the case with bland thrombus. Alternatively, an Adams-DeWeese clip can be placed on the IVC for this purpose. For the sake of expediency, the endovascular stapler can be used to quickly divide the vena cava.

---

### Abdominal Approaches to Suprahepatic and Supradiaphragmatic Thrombi (Levels III and IV)

---

With increasing utilization of liver transplantation worldwide, there has been a spillover of techniques with applicability to advanced retroperitoneal surgery (9). For those tumors with persistent tumor thrombus extension above the diaphragm, absolutely complete liver mobilization, followed by careful division of the central tendon of the diaphragm, entry into the pericardium, and circumferential dissection of the intrapericardial vena cava, will allow for transdiaphragmatic intrapericardial IVC control. It should be emphasized that this maneuver should be performed by those with extensive experience with the anatomy of the vena cava in the pericardium. Our experience has been that working with cardiothoracic transplant surgeons allows for the performance of this maneuver by those surgical specialists with an intimate knowledge of mediastinal anatomy, and we have not experienced problems in four such cases. That said, cardiopulmonary bypass approaches have a significantly longer track record, and many more cardiac surgeons are familiar with this approach, as outlined below.

---

### Cardiopulmonary Bypass, Hypothermia, and Temporary Cardiac Arrest for Level IV Thrombus

---

The need for cardiac bypass exists, in general, for tumor thrombi that are above the diaphragm and not obviously amenable to the techniques for abdominal access of supradiaphragmatic thrombus cases. Cardiopulmonary bypass, hypothermia, and temporary cardiac arrest greatly facilitate the resection of a suprahepatic caval thrombus (8). It is best to dissect as much of the kidney and the vena cava as possible prior to cardiac bypass. Following isolation of the renal tumor, the pericardium is opened and retracted with stay sutures. Typically, the right atrial appendage is cannulated with a 32Fr venous cannula and the aorta is cannulated with a 22Fr Bardic cannula. Heparin is then administered to maintain an activated clotting time  $>450$  seconds. The patient is placed on bypass with flow rates maintained between 2.5 and 3.5 L per

minute. A core temperature of 18°C to 20°C is attained within 30 minutes while maintaining an 8°C to 10°C gradient between the perfusion and the patient's core temperature. When a rectal temperature of 20°C is reached, the aorta is cross-clamped and 500 cc of cardioplegic solution is administered. Once cardiac arrest is achieved, bypass is terminated and the patient is temporarily exsanguinated into an oxygen reservoir. The patient's brain is protected by placing ice bags around the head. At this point, there is no anesthesia, ventilation, or circulation. To reduce the incidence of complications, circulatory arrest time is best limited to 45 minutes.

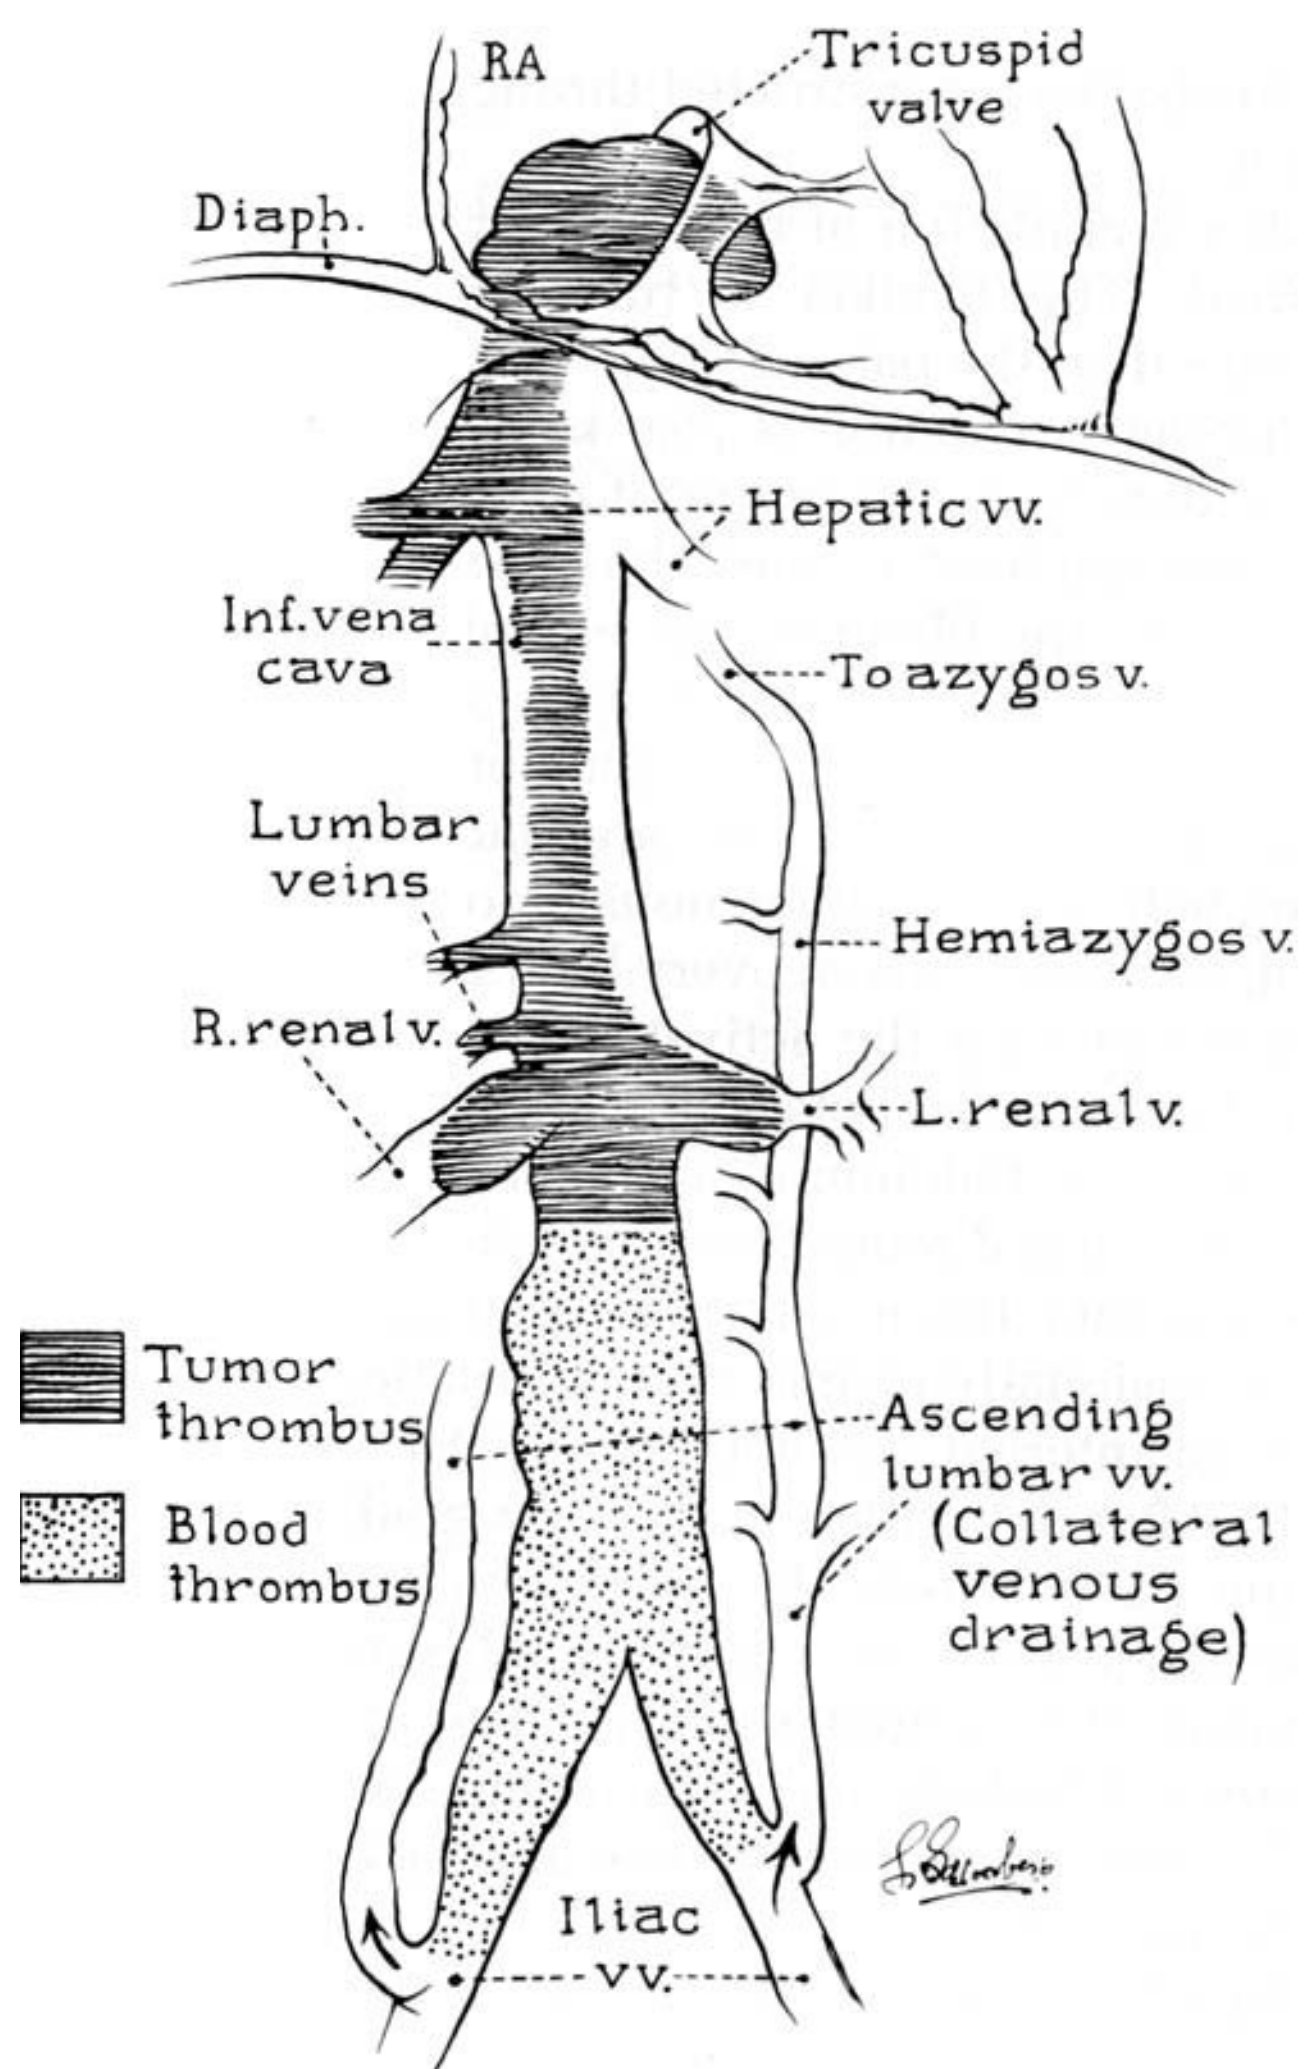

An elliptical incision is made around the ostium of the renal vein and carried superiorly along the length of the vena cava. The incision can extend into the right atrium or ventricle, depending upon the superior extent of the thrombus. Using cardiopulmonary bypass and deep hypothermic circulatory arrest, the thrombus can be removed in a bloodless field and the interior of the vena cava and heart can be inspected under direct vision (Fig. 4.8). It is not uncommon to find some degree of adherence of the tumor to the endothelium. In this case, the tumor thrombus can be "endarterectomized" from the interior of the vena cava or atrium. Reconstruction of the vena cava is as previously mentioned.

Following closure of the venacavotomy, cardiopulmonary bypass is begun. The patient is slowly warmed using a 10°C gradient between the bypass machine and a warming blanket. Mannitol (12.5 g) is given along with 1 g of calcium chloride when core temperature reaches 25°C. Electrical defibrillation is necessary if the heart does not resume spontaneous beating. Following resumption of cardiac activity, blood is returned to the patient from the oxygen reservoir. Following the rewarming process, which can take up to 1 hour, heparin is neutralized with protamine. The patient is returned to the cardiac intensive care unit intubated.

Advances in surgery have prompted investigators to describe alternatives to cardiopulmonary bypass with deep hypothermic cardiac arrest to minimize the risks associated with bypass and circulatory arrest and/or diminish the morbidity of the surgical incision. Venovenous bypass may be used as an alternative to cardiopulmonary bypass for patients with an infra-diaphragmatic tumor and near occlusion of the vena cava who do not tolerate clamping of the vena cava. Test clamping of the vena cava should always be performed prior to the clamping and opening of the cava. Generally, those patients with bulky thrombus that is completely occlusive have naturally developed venous collaterals and can tolerate clamping of the cava (Fig. 4.9). Venovenous bypass avoids the risks of cardiopulmonary bypass while ensuring adequate circulation during the venacavotomy. Traditionally, to establish venovenous bypass, an incision overlying the saphenofemoral junction is made and the saphenous vein is isolated. A similar incision is made in the axilla and the axillary vein is identified. The saphenous and axillary veins are incised and cannulated with a 7-mm heparinized Gott aneurysm shunt and secured with a Rummel tourniquet. Bypass is commenced with clamping of the IVC. Following completion of the procedure, the shunts are removed, the axillary vein is reconstructed with 6-0 polypropylene, and the saphenous vein is ligated. Alternatively, with an experienced liver transplantation anesthesiologist, a large-bore venous cannula such as a Cordis (Cordis Corp, Warren, NJ), can be placed into the femoral vein and jugular vein and an adequate veno-veno bypass created.

**FIGURE 4.8** A: The ostium of the renal vein is circumferentially incised and the right atrium is opened. B: Following removal of the tumor thrombus, the atriotomy and vena cavotomy incisions are closed. (From Novick AC, Montie JE. Surgery for renal cell carcinoma. In Novick AC, Strem SB, Pontes JE, eds. *Stewart's operative urology*, Vol. 1, 2nd ed. Baltimore: Williams & Wilkins, 1989, with permission.)

**FIGURE 4.9** The vena cava can have thrombus throughout its entire extent. Below the renal vein ostia, this is generally a blood thrombus, also known as a "bland" thrombus. Attempted extraction of this thrombus is fraught with complications and is best avoided. In the setting of complete caval obstruction, the cava can actually be ligated at this point to prevent thrombus migration. Venous collaterals as shown in the figure are very well developed in this setting and will drain the lower body. From the level of the renal veins above, the thrombus is a tumor thrombus. Such thrombus has been extracted from the contralateral renal vein, lumbar veins, hepatic veins, right atrium, and right ventricle. (From Marshall FF, Reitz BA. Radical nephrectomy with excision of vena cava tumor thrombus. In: Marshall FF, ed. *Marshall's textbook of operative urology*. Philadelphia: WB Saunders, 1996:269, with permission.)

For tumors extending into the right atrium, a minimally invasive cardiac surgical approach using a right parasternal incision has been described, and extensive experience has been documented (10). This approach would enable access to the right atrium and right subclavian artery for cannulation of arterial inflow. Following isolation of the vena cava and primary renal tumor, an incision below the right clavicle is made to expose the subclavian artery. A separate incision is made from the lower segment of the third rib to the fifth rib along the right sternal border. A 3-cm segment of cartilage from the fourth and fifth ribs is resected, and the right internal thoracic artery is ligated and divided. After opening the pericardium, an 8-mm collagen-coated graft is sewn to the right subclavian artery and a venous cannula is placed into the right atrium. Following cardiopulmonary bypass, circulatory arrest, tumor excision, and decannulation, a flap of periosteum, muscle, and pleura is used to close the defect associated with this minimally invasive incision.

---

## OUTCOMES

---

The 5-year survival rates in most reported large series vary from 14% to 68% following complete surgical removal of the renal tumor and caval extension. The largest series, comprising 614 patients from the Mayo Clinic with tumor thrombus and clear cell RCC, had a 50% 5-year cancer specific survival. However, this rate significantly worsened to 15% to 20% in the presence of intercurrent lymph node involvement or distant metastatic disease, and it was further reduced to 4% if both adverse features were present. Differences in reported survival may reflect several factors, including local extension of the primary tumor, presence of lymphatic or visceral metastases, or invasion into the vascular wall. The level of caval extension correlating with survival is a matter of active and current debate in the literature. It is in general agreed that patients with metastatic disease and significant perinephric fat involvement tend to have a poorer prognosis. The majority of patients eventually dying of their disease succumb to metastases, which suggests that occult metastatic disease is frequently present at the time of surgery (11). Patients with good performance status who have tumors confined to the renal capsule and are without evidence of metastatic disease

are ideal candidates for this surgery and have improved long-term survival.

---

## Complications

---

Surgery for intracaval tumors is subject to a number of complications that occur approximately 10% to 30% of the time. Certainly, over time, there is a declining incidence of complications, likely due to better patient selection and better postoperative care. For example, one large 30-year series noted a 40% decline in complications in cases done in the 1980s versus those done in the 1990s (12).

Intraoperative complications include excessive bleeding and coagulopathy. Coagulopathy is more common with prolonged cardiopulmonary bypass and cardiac arrest times. Intraoperatively, red blood cells, platelets, fresh frozen plasma, and calcium chloride are routinely administered. Furosemide and/or mannitol is given if urine output remains low. Transient hypotension can occur when clamping the vena cava. This can be managed with volume expansion. It tends to be less of a problem with bulky vena cava thrombus or completely occluded cava because this situation usually creates multiple venous collaterals. However, this difference comes at a price, as the dilated lumbar veins that drain the obstructed cava are often simultaneously large and thin-walled. Finally, embolization of a segment of tumor thrombus can be a potentially lethal intraoperative complication, and extreme care should be taken when handling the vena cava to prevent such an occurrence. Overall mortality has decreased over time but still remains present (1.5% to 7.5%).

Postoperatively, several complications can occur due to the magnitude of the surgical procedure or in those patients who also underwent the use of cardiopulmonary bypass. Potential complications include caval thrombosis, deep venous thrombosis, pulmonary embolus, postoperative bleeding, and coagulopathy. Patients may also develop hepatic dysfunction, renal failure, sepsis, or myocardial infarction. Although the modern mortality rate associated with this procedure is approximately lower over time in modern series, most patients who die of complications within the first postoperative month succumb to multisystem organ failure.

# CHAPTER 5 ■ TRANSPLANT NEPHRECTOMY

SANJAYA KUMAR

In the United States, renal allograft survival for all transplants is 91% at 1 year and 82% at 3 years since the introduction of cyclosporine (9,13). Notwithstanding optimal immune suppression, some allografts will fail. Failed allografts frequently result in a transplant nephrectomy in similar frequency in both cadaveric and living-related transplants. The etiology and timing of graft failure play an important role in the need for transplant nephrectomy.

---

## DIAGNOSIS

---

Transplant nephrectomy is performed when the graft has failed. This may occur in the acute or chronic setting. Renal allograft rupture within days of the transplant is usually due to acute allograft rejection, renal vein thrombosis, or even acute tubular necrosis (8). Symptoms include severe allograft pain, a drop in hematocrit, and hypotension. Renal scan, Doppler ultrasound, and computerized tomography (CT) scan can help establish the diagnosis. Urgent transplant nephrectomy may be warranted under these circumstances.

In the chronic setting, graft function deteriorates slowly and the patient becomes azotemic and requires dialysis. Radiologic evaluation with Doppler ultrasound and renal scan are helpful. Renal biopsy is almost always performed to confirm rejection. Once it is confirmed that renal function is irreversible, immune suppression is tapered and sometimes completely withdrawn. The patient is placed on chronic dialysis and the need for graft nephrectomy is ascertained.

---

## INDICATIONS FOR SURGERY

---

A renal allograft may fail for several reasons. These primarily include rejection, irreversible renal vascular compromise, or significant graft sepsis. Policy regarding graft nephrectomy varies according to the transplant institution. While most failed grafts were removed in the past, the recent trend is to remove the allograft only when necessary. Further, there is some suggestion that retaining the primary graft in situ may have a protective effect on the subsequent transplant (1). Over the years, the incidence of graft nephrectomy continues to trend down. The incidence varies from 4% to 8% in some recent series (5,7,14).

Graft failure within the first few weeks following transplant is usually due to accelerated rejection or technical failure secondary to vascular compromise, and those failing within the first few months are due to irreversible acute rejection. Renal allografts rejected within the first 12 months of transplant are usually removed prophylactically regardless of the cause, even if these patients are asymptomatic (10,12,14).

Significant symptoms usually develop due to the retained graft, necessitating its removal in the future. However, the policy of some centers is to remove failed transplants only when they interfere with health (7).

Graft failure that occurs 1 year after transplant is usually due to chronic rejection. Progressive withdrawal of immunosuppression may allow the patient to retain the graft in the majority (50% to 90%) of instances (4,7,10,14). Many patients, however, develop symptoms such as fever, malaise, gross hematuria, graft tenderness, and thrombocytopenia related to platelet consumption by the graft. It can be difficult to distinguish these symptoms from superimposed acute rejection or infection, and graft nephrectomy may be the only solution. Thus, the primary indication today to remove a failed graft is graft intolerance by the host after withdrawal of immunosuppression.

Rare indications for allograft nephrectomy include the development of a renal mass (11). This may involve lesions unintentionally transmitted from the donor or lesions arising in the transplant kidney. CT scan and needle biopsy help confirm the diagnosis. Intractable urinary problems such as leaks and fistulas rarely require transplant nephrectomy today. Advances in urologic endoscopy and percutaneous techniques have virtually eliminated the need for graft nephrectomy in these patients.

---

## ALTERNATIVE THERAPY

---

An alternative to graft nephrectomy is embolization of the failed allograft. The graft is embolized through femoral arterial access using coils or ethanol. The presence of multiple renal arteries is not considered a problem, although it can be technically challenging to catheterize these small arteries with their thickened intimal layer and narrow ostium. Although successful embolization has been reported in 85% of patients (3), postembolization syndrome can occur in many patients, including graft abscess and sepsis (6). These patients eventually require a nephrectomy. Graft embolization may thus be considered in patients with a failed renal graft and intolerable symptoms that do not improve with medical management and in whom transplant nephrectomy has a significant morbidity and risk of mortality.

---

## SURGICAL TECHNIQUE

---

If available, it is important to review the previous operative notes of the transplant. This will help the surgeon understand the anatomy of the vascular anastomosis and pre-empt any potential catastrophe. Patients with renal failure usually have

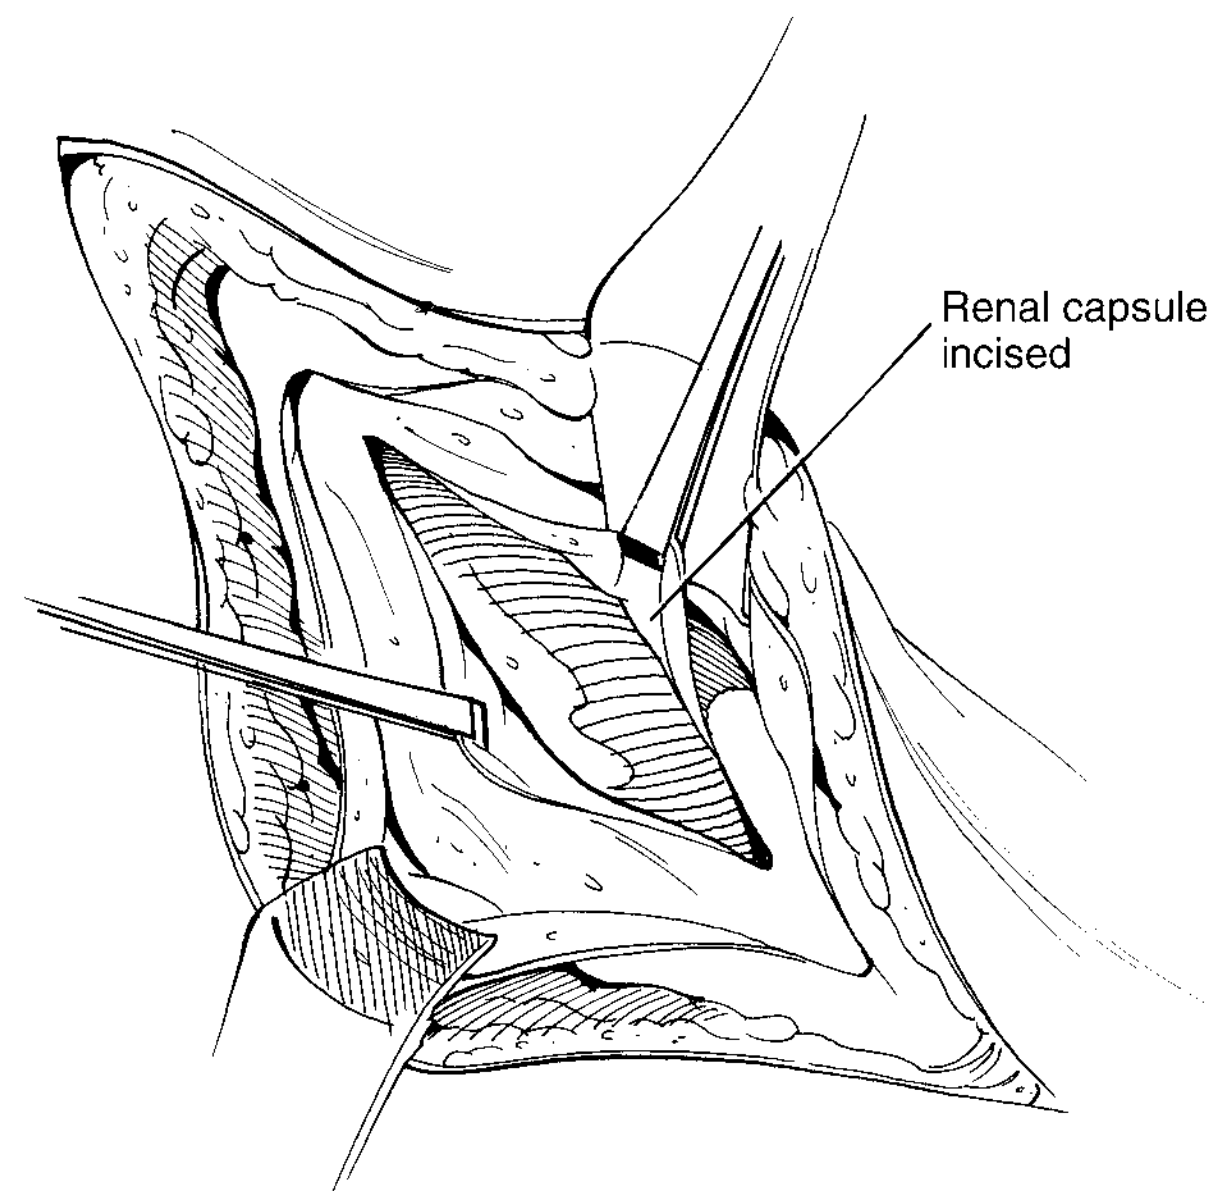

**FIGURE 5.1** The patient is positioned in the supine position and the incision is made over the previous lower-quadrant transplant incision.

platelet dysfunction. Even though their coagulation parameters are normal, desmopressin (DDAVP) is usually given to improve platelet function. The adult dose of DDAVP is 0.3  $\mu\text{g}$  per kg body weight.

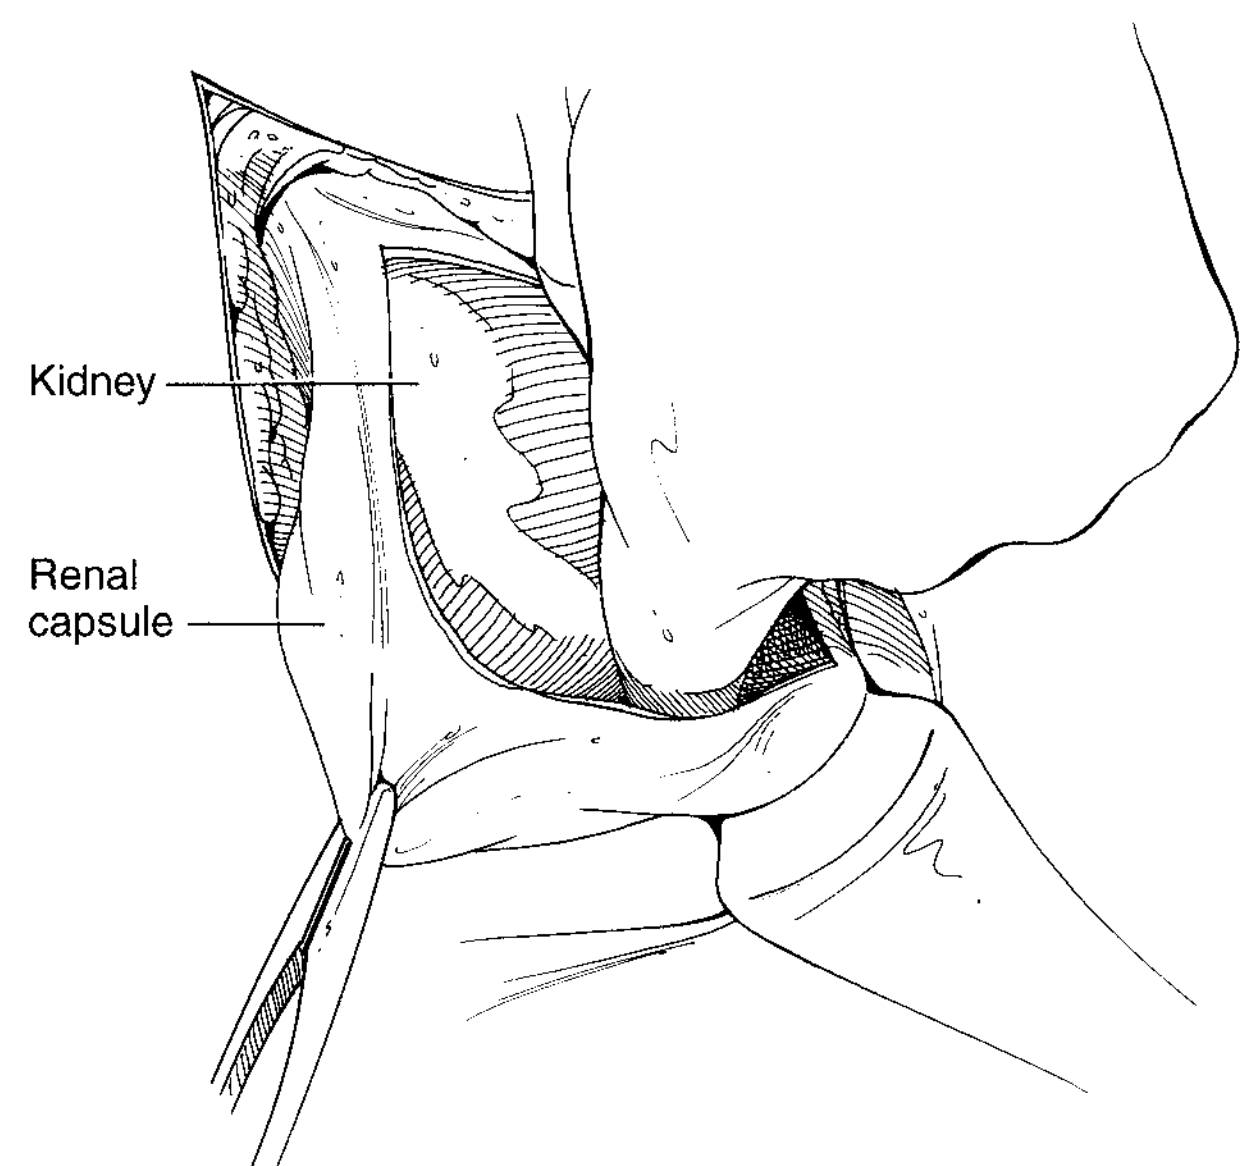

The patient is placed in the supine position. An incision is made over the previous incision, which is usually in the lower quadrant (Fig. 5.1). The previous skin scar is excised. If the kidney is large and swollen, it may be necessary to extend the incision laterally. The external and internal oblique muscles and, in the lateral part of the incision, the transversalis are incised. As a result of previous surgery, rejection, or multiple renal biopsies, the kidney is stuck to the undersurface of the muscle, the pelvic sidewall laterally, and the peritoneum medially. The colon may drape over the entire anterior surface of the kidney. Under these circumstances, it may be easier to extend the incision laterally and enter the retroperitoneum above the superior pole of the kidney. Once the kidney has been identified, space is created in the retroperitoneum for a self-retaining retractor (e.g., Bookwalter). The relationship of the iliac vessels, bowel, and peritoneum vis-à-vis the kidney is established so as not to injure them. The kidney is identified by palpation. In cases of rejection the kidney may be large, swollen, and friable.

A decision is now made on whether to perform a subcapsular nephrectomy or to use an extracapsular approach. Depending on the degree of reaction, one may be able to perform the entire nephrectomy by staying extracapsular and removing all renal tissue. Certainly, the initial attempt can be made to perform an extracapsular nephrectomy, and as the dissection approaches the hilum or if dissection is impossible due to the inflammatory reaction, one can resort to a subcapsular approach. Extracapsular graft nephrectomy is possible when the allograft has to be removed within a few weeks of transplant. Often, the planes of dissection may be so effaced that the only recourse may be to directly enter the renal capsule and perform a subcapsular nephrectomy from the outset. Because of the increased morbidity and mortality of the extracapsular approach, many centers routinely perform a subcapsular nephrectomy when indicated in patients with chronic rejection.

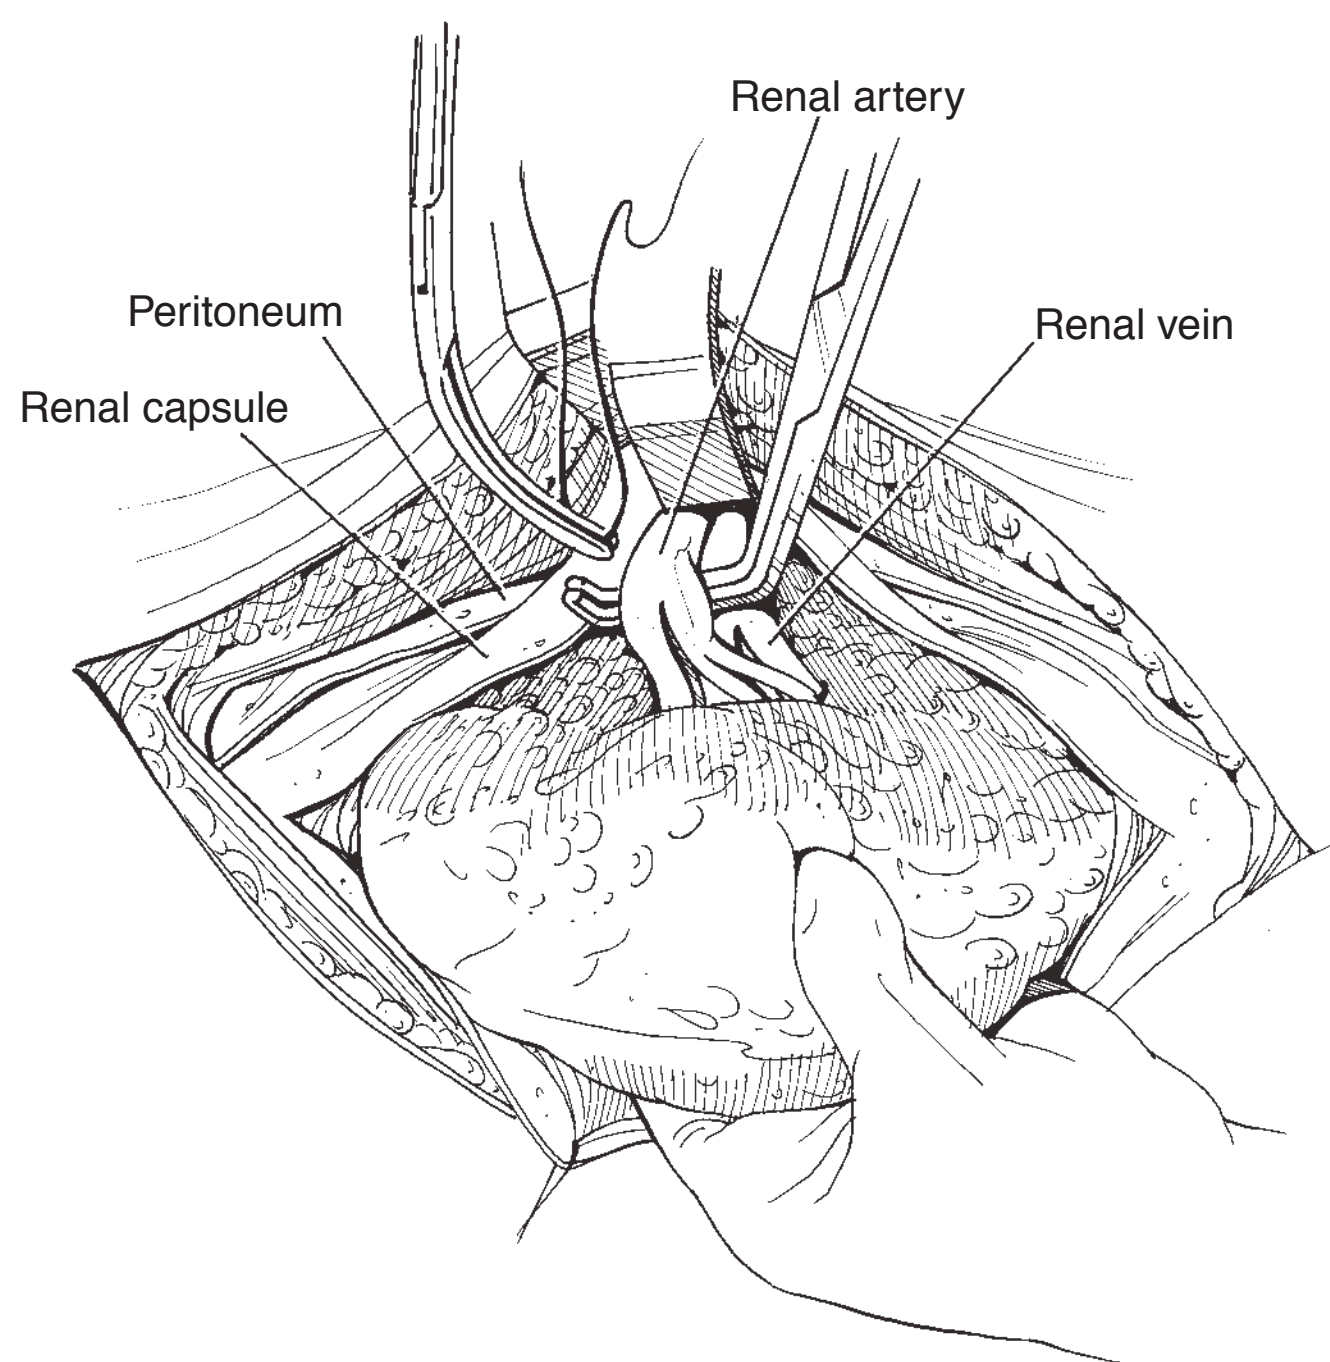

**FIGURE 5.2** The incision is carried through the external and internal oblique muscles to the capsule of the kidney, where a small capsular incision is made.

Upon identifying the kidney, the renal capsule is opened with a knife (Fig. 5.2). A plane of dissection between the renal capsule and parenchyma is developed using blunt and sharp dissection. This can usually be done bluntly with a finger (Fig. 5.3). The upper and lower poles of the kidney are mobilized, inside the capsule, and delivered into the wound. Careful dissection proceeds toward the hilum, medially and laterally. The kidney is tethered at the hilum to the iliac vessels. Great caution is exercised here so as not to avulse the kidney. Bleeding from the cortical surface of the kidney is inevitable but can be controlled with pressure.

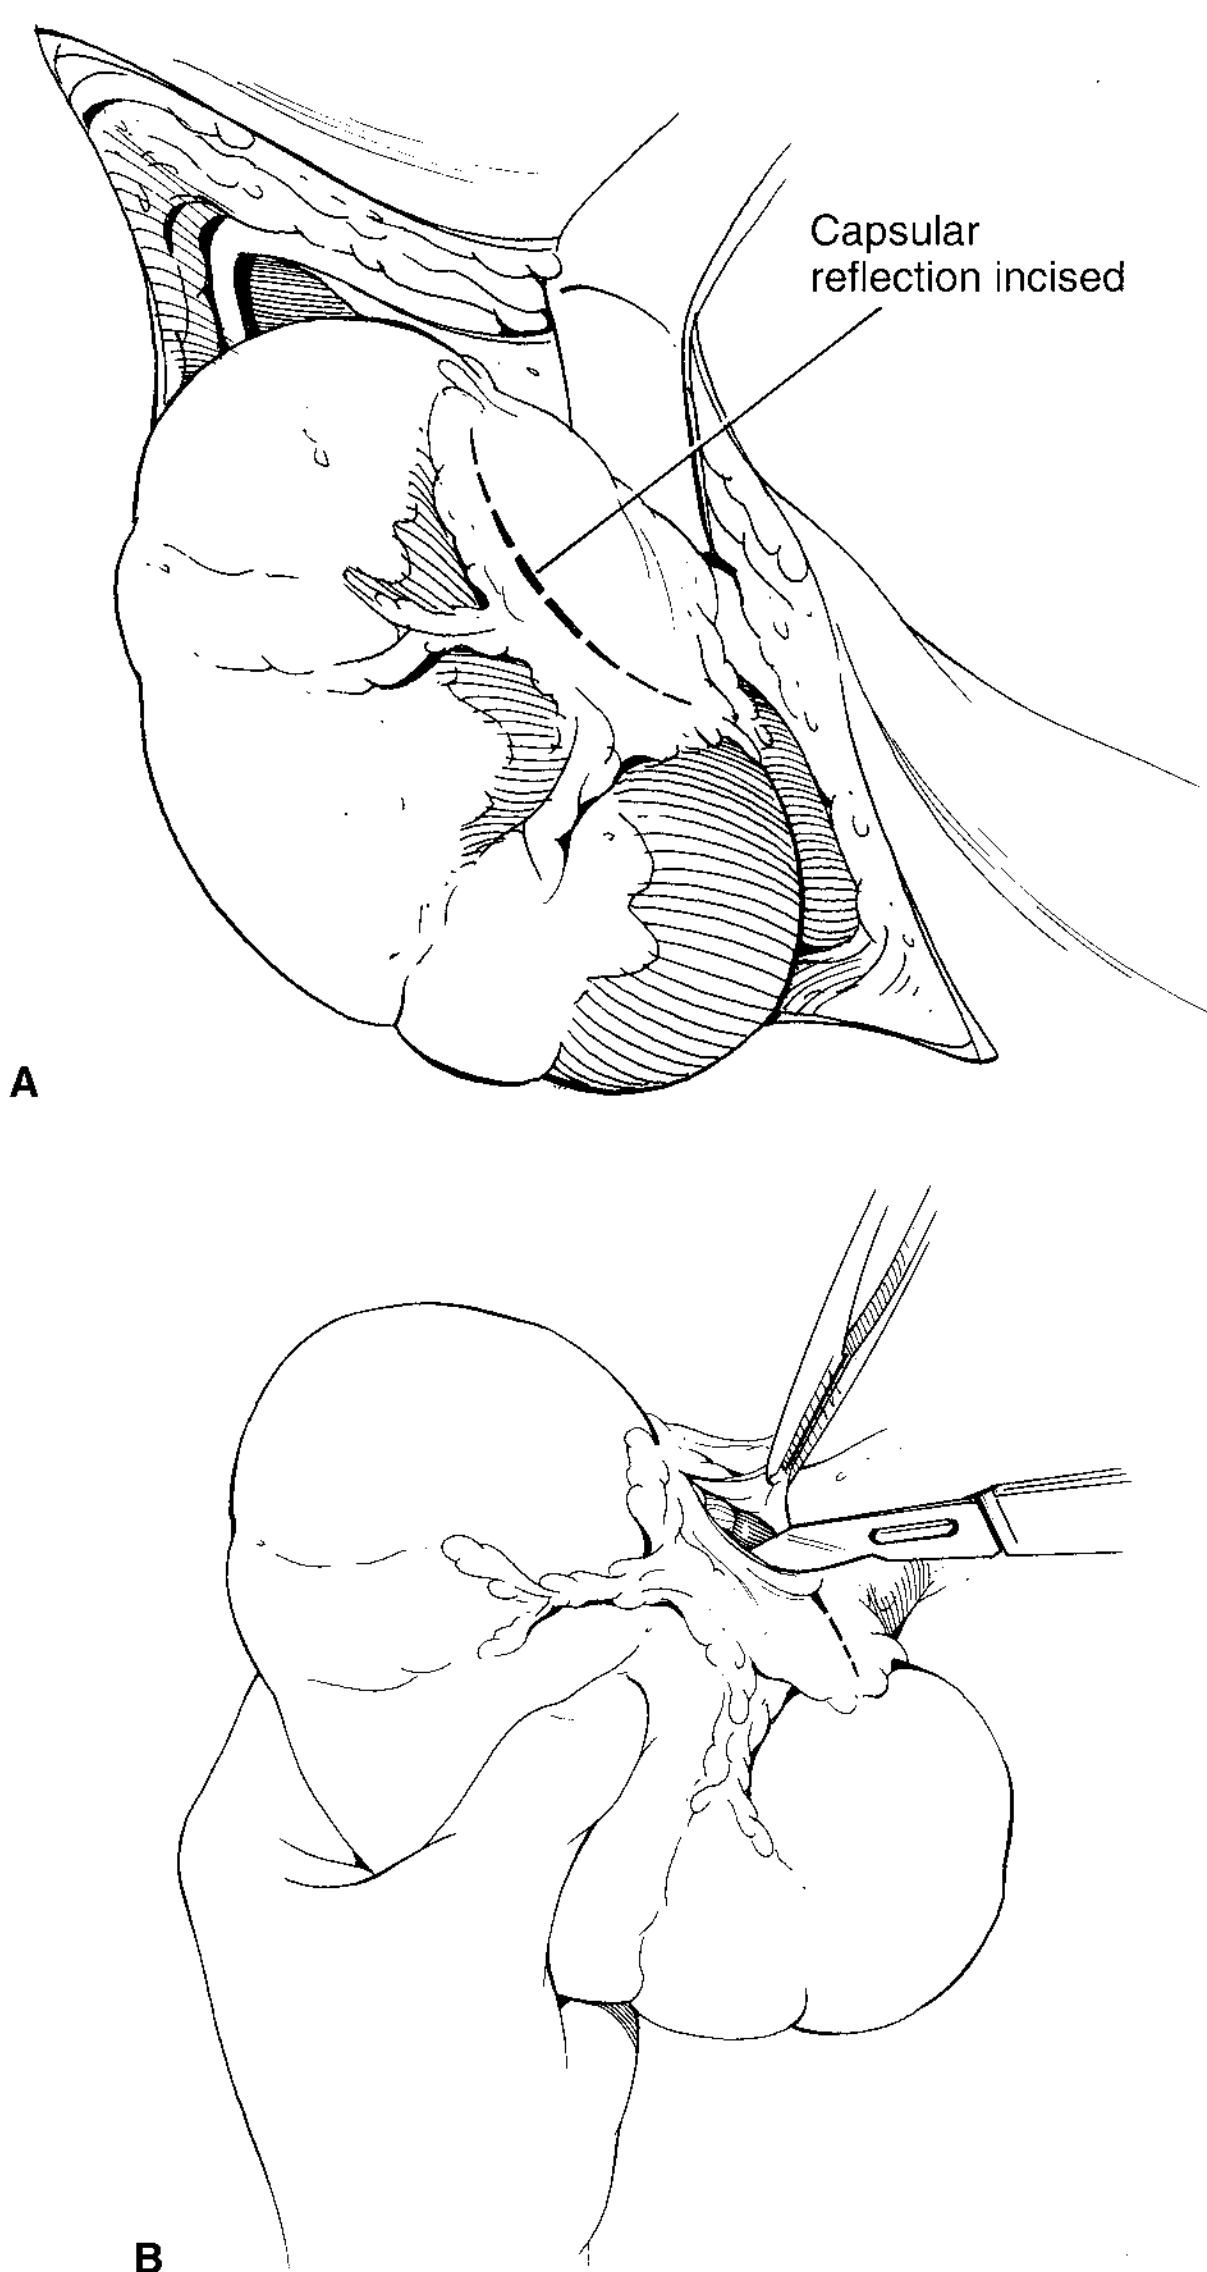

**FIGURE 5.3** The renal parenchyma is enucleated subcapsularly.

**FIGURE 5.4** Intracapsular ligation of renal vessels.

Once the base of the hilum is reached, the vessels are identified and ligated. This can be done entirely intracapsularly (Fig. 5.4) or extracapsularly (Fig. 5.5). The advantage of the former is that damage to the iliac vessels is minimized. One disadvantage is that donor material may be left in situ (14). To ligate the vessels outside the capsule, the reflected capsular surface is incised either posteriorly or anteriorly. The peritoneum may be adherent to the renal hilum and iliac vessels. The vessels are carefully dissected. The renal artery and vein are suture-ligated individually (Fig. 5.6). It is easier to do this if the artery is an end-to-end hypogastric-to-renal-artery anastomosis. A permanent suture such as Prolene or silk can be used for ligation. The knot is tied down to vessels. Friable vessels can tear easily. Injuries to the iliac vein can be repaired with 5-0 Prolene. While small arterial bleeding can be controlled with a fine Prolene stitch, arterial constriction must be avoided, and larger defects therefore require repair with a synthetic graft (Fig. 5.7). Satinsky clamps are helpful in obtaining temporary vascular control. In the event that the hilum is plastered to the iliac vessel and the renal artery and vein are not identifiable, en masse ligation of the hilum may be necessary. Satinsky clamps are placed at the base of the hilum and the kidney transected distal to the clamps. The stump is oversewn with Prolene (Fig. 5.8). When performing an extremely difficult nephrectomy, it may be necessary to deliberately enter the peritoneum to gain proximal control of the iliac artery. The ureter is identified, dissected, and removed along with the graft. The surgeon may not be able to remove the entire ureter.

The wound is gently irrigated with antibiotic solution. Strict hemostasis is obtained, and the wound is closed without a drain. Bleeding from the capsule can be controlled with electrocautery or an argon beam coagulator. For additional security, Surgicel or Gelfoam soaked in thrombin can be placed on the surgical bed prior to closure. A drain is not used routinely

**FIGURE 5.5** The hilar vessels are exposed by (A) making an incision close to the renal parenchyma and (B) incising the overlying capsule.

because it can predispose to infection. The wound is closed in layers, if possible, with 0 Prolene. The skin is usually closed in a subcutaneous fashion.

---

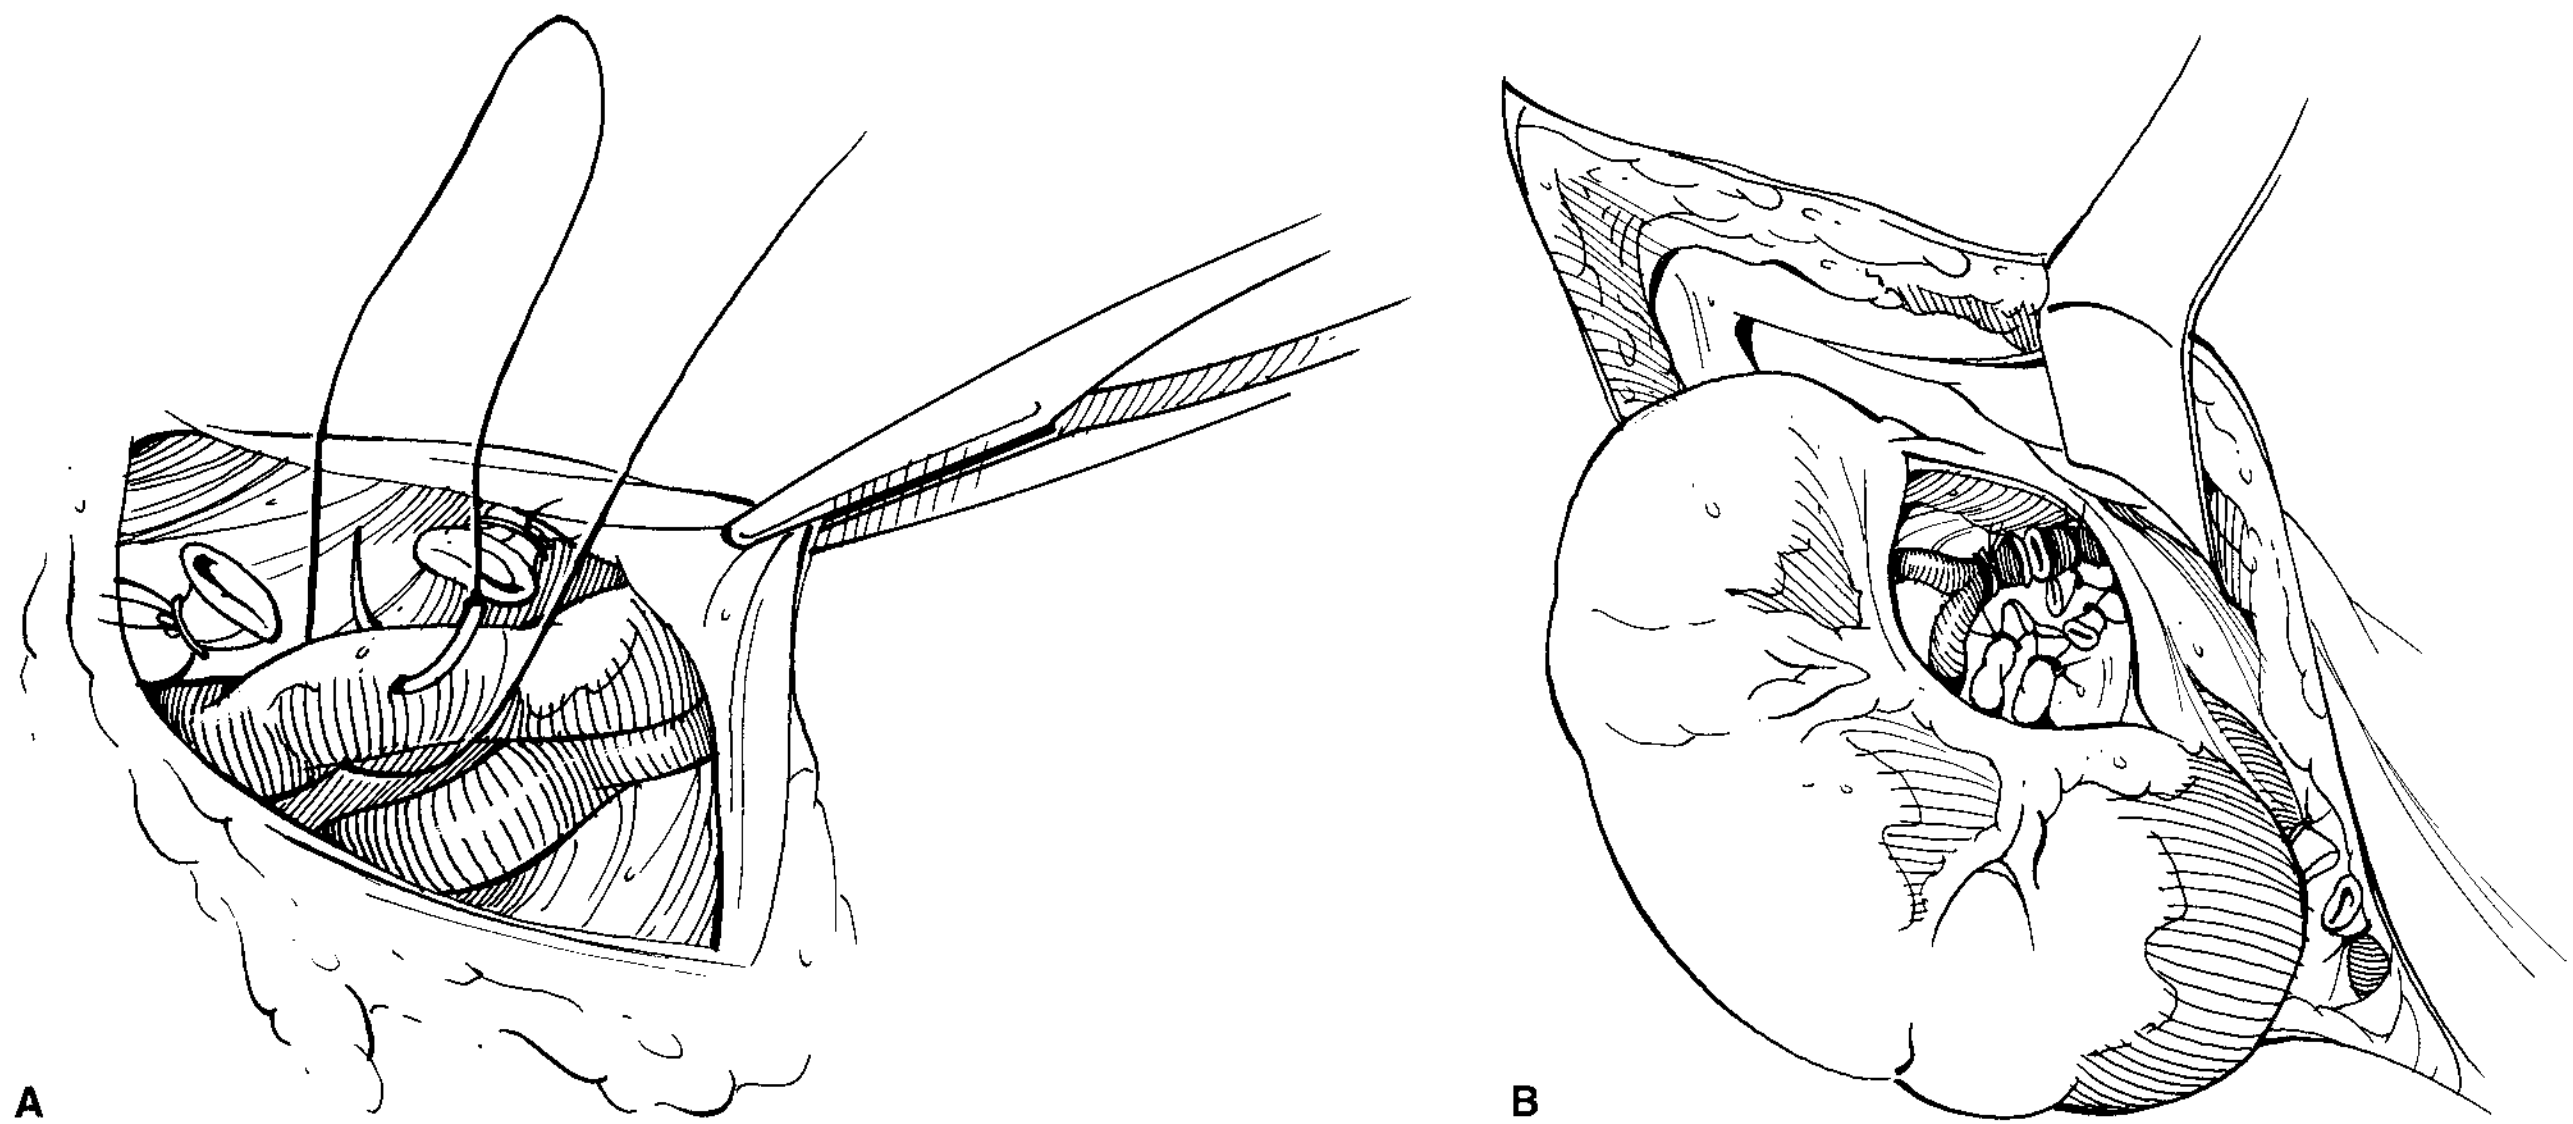

## OUTCOMES

---

### Complications

---

The complication rate of transplant nephrectomy in recent series is acceptable considering the dire comorbidities in this patient population. In the past, the complication rate of transplant nephrectomy was high (24% to 60%) due to underlying uremia and immunosuppression; the mortality rate is approximately 5% (5,7). With modern immunosuppressive drugs, better control of systemic factors, and anesthetic and surgical advancements, the complication rate has been reduced

**FIGURE 5.6** The renal artery and vein are (A) suture-ligated and (B) divided.

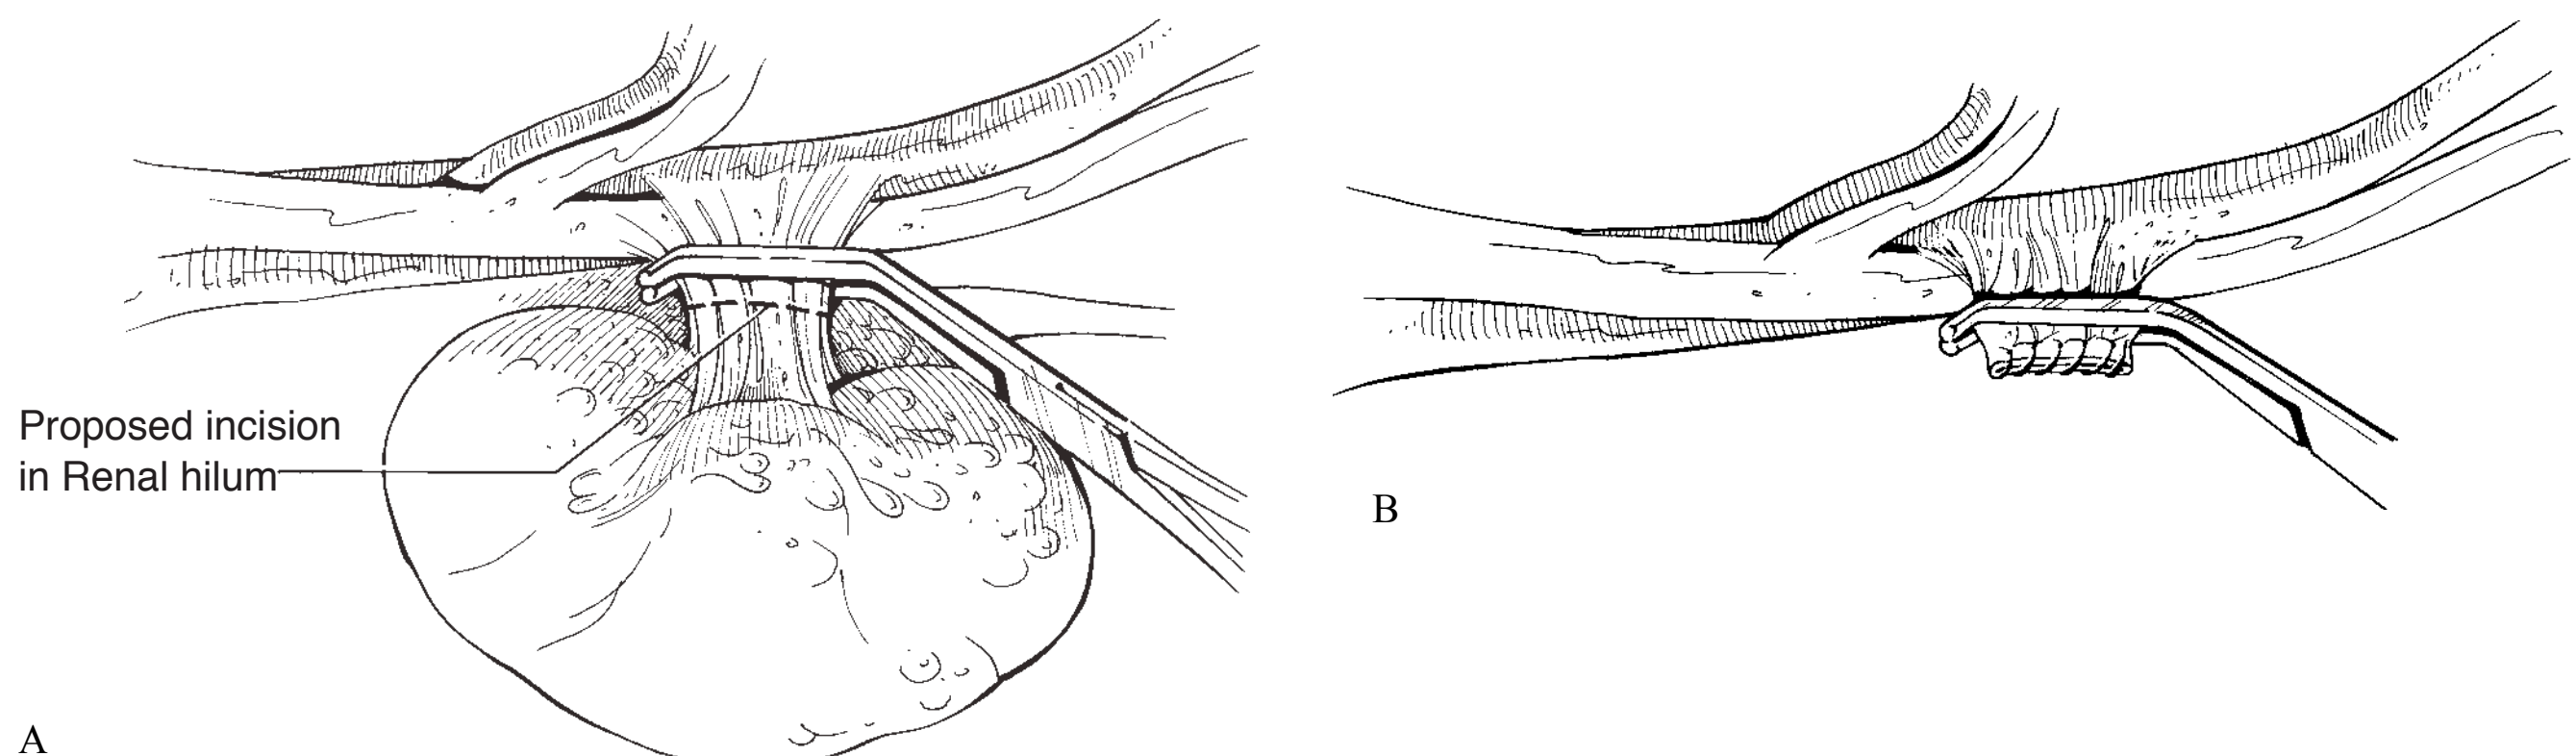

**FIGURE 5.7** If the renal allograft artery is completely removed, it may be necessary to cover the defect in the iliac artery with a patch graft.

considerably. The morbidity and mortality are much higher when the nephrectomy is performed under emergent circumstances. Complications usually ensue from bleeding, infection, injury to adjacent structures, and systemic causes. Today, the overall complication rate of transplant nephrectomy for chronic rejection is about 5% and mortality is <1% (2,10,14).

## Results

Transplant nephrectomy is not necessary in all cases of transplant failure. When indicated, it can be performed successfully via an extra- or subcapsular approach. The subcapsular approach is preferred in cases of chronic rejection. Adequate preoperative patient preparation and meticulous surgical technique can minimize morbidity and mortality.

## CHAPTER 6 ■ RENOVASCULAR DISEASE

JOHN A. LIBERTINO AND CHAD WOTKOWICZ

The true incidence of renovascular hypertension has yet to be determined, with estimates ranging from 5% to 10% within the hypertensive population (1). Stenosis or occlusion within the renal vasculature promotes hypertension via the renin-angiotensin-aldosterone pathway, resulting in renal insufficiency and dialysis dependence over long periods of time. Improved diagnostic studies and imaging modalities have provided internists an easier means of attributing hypertension to renal lesions versus an “essential” etiology. Technological advances in minimally invasive angioplasty techniques and stenting have provided alternatives to surgical bypass in select patient populations. Despite advances in pharmacology and degrees of invasiveness, surgical revascularization remains a constant in the management of renovascular disease, especially within the atherosclerotic population. The outcomes of vascular reconstruction are tightly linked to proper preoperative evaluation, surgical planning, and sound technique.

---

### DIAGNOSIS

---

In the past, the clinician’s task of identifying potentially curable patients in a safe, cost-effective, and reliable manner was difficult. A single-dose captopril test is reported by some investigators to be a reliable screening test well suited to outpatient settings. In patients with functional renal artery stenosis, angiotensin-converting enzyme (ACE) inhibitors lead to a disproportionate increase in peripheral plasma renin activity; however, baseline renal insufficiency impairs the sensitivity of this test for detecting renal artery stenosis. Renal scintigram with isotopic nephrography following the administration of captopril has also been used to diagnose renal artery stenosis. Technetium DTPA (pentetic acid) scintigraphy has a sensitivity range of 71% to 92% and a specificity range of 72% to 97% (2).

Digital venous subtraction angiography (DSA) remains a definitive and reliable screening test with sensitivity and specificity near 90% and with lower contrast exposure than conventional angiography. 3D-Gd-magnetic resonance angiography (MRA) in detecting hemodynamically significant renal artery stenosis (RAS) has been shown to be effective in the absence of accessory renal arteries. This last-mentioned technique, in addition to CO<sub>2</sub> DSA, is useful in azotemic patient populations.

---

### SURGICAL INDICATIONS

---

The last 50 years have seen a dramatic change in the management of renal artery stenosis. The first renal thromboendarterectomy was performed by Freeman in 1954 with an excellent outcome (3). The ability to restore renal function in kidneys with compromised inflow serves as a primary indication for intervention. With such a significant aging population, the indications for restoration of flow to preserve renal function will continue to grow. Percutaneous transluminal renal angioplasty was first reported by Dotter and Judkins in 1964 with equally impressive outcomes (4). Minimally invasive techniques have limited the morbidity and mortality associated with open surgery in select hypertensive populations often plagued with significant cardiac and pulmonary comorbidity. In fact, the rates of aortic and renal revascularizations decreased by 73% from 1998 to 2001, while percutaneous procedures increased by 173% (5).

Despite this trend, the basic principles and knowledge of extra-anatomic bypass techniques are essential to the urologist in training. The use of the hepatic artery, gastroduodenal artery, and other alternative procedures instead of the aortorenal saphenous vein bypass has not only reduced the morbidity

and mortality of surgery but has also dramatically changed the operative potential in an expanded patient population. Equally important are the complications associated with these procedures that urologists may encounter.

The indications for angioplasty and stenting versus vascular bypass are widely variable and continue to adjust with advances in technology. Fibrous dysplasia and mid–main renal artery atherosclerosis are optimal for balloon angioplasty, while renal ostial and branch disease may be more amenable to revascularization. Renal artery aneurysms associated with hypertension can also be managed with revascularization procedures. Another strong indication for surgical repair is pregnant women with noncalcified aneurysms over 2 cm due to risk of rupture. Patients experiencing disease following balloon angioplasty are better managed surgically, as repeat angioplasty has a high complication rate. Nephrectomy may be a prudent choice in high-risk surgical patients: those with extensive branch vessel disease, nonsalvageable parenchyma, and failed arterial reconstructions.

---

## MEDICAL THERAPIES

---

Chronic azotemic renovascular disease is common in patients with atherosclerosis, whose prevalence appears to be increasing in the aging population. The pharmaceutical industry has been instrumental in the treatment of hypertension in our patient population. The advent of ACE inhibitors and angiotensinogen receptor blockers (ARB) therapy in conjunction with calcium channel blockers have improved the management of renovascular hypertension. In addition to normalizing blood

pressure parameters, these medications help to retrieve renal function, as evidenced by improved glomerular filtration rates (GFRs). Despite maximal medical therapies, certain individuals will have progressive renal artery disease with associated ischemia and azotemia. Avoiding dialysis in this patient population is critical due to the inherent morbidity associated with renal replacement therapy. Identifying the group of suitable patients refractory to medical management will continue to grow in importance as the population at large grows.

---

## SURGICAL MANAGEMENT

---

### Aortorenal Bypass Graft

---

Bypass grafts are particularly suitable for fibrous lesions that affect the long and multiple segments of the renal artery and associated branches (Fig. 6.1). Autogenous artery (hypogastric and spleen) and autogenous saphenous veins are all options in properly selected patients. When exhausted of autogenous resources, a Dacron interposition graft may be used; however, there are concerns of thrombosis and some technical difficulty in crafting the appropriate diameter to accommodate the native renal artery. Hypogastric arteries are an excellent graft choice in the pediatric population, unlike in adults, who are often afflicted with atherosclerosis. The autologous saphenous vein remains the conduit of choice at our institution due to the ease of access and size equivalence to the renal artery. The pliability of the venous versus the arterial vasculature provides for more contoured anastomoses, and the limited intima is less thrombogenic.

**FIGURE 6.1** **A:** An aortogram shows a double right renal artery with stenoses at the ostias of both trunks. **B:** A postoperative aortogram with the vein graft making a side-to-side anastomosis to the stenotic lower renal artery and an end-to-end anastomosis to the distal stump of the upper renal artery.

## Procurement of the Saphenous Vein

The saphenous vein is initially exposed from the contralateral side, providing operative room for two surgeons and limiting operative time. Prior to the date of surgery, the saphenous vein is outlined with permanent marker and ultrasound assistance. Mobilization begins with a single incision parallel to and below the groin crease over the palpable femoral pulses and extended to the knee after the junction of the saphenous and femoral vein have been exposed. Incisions should be made over the femoral vascular complex with limited subcutaneous dissection to avoid flap devascularization (Fig. 6.2). We recommend using blunt finger dissection with a moist sponge dissector for mobilization.

In general, we harvest a 20-cm-long vein graft with an ideal outer circumference between 4 to 6 mm. Excess vein harvesting is advisable in case of technical complications and the need for revision. Venous tributaries are tied with 5-0 silk, and excess areolar tissue is dissected free, leaving the intima undisturbed.

To decrease transmural ischemia, the vein graft is left in situ until the renal vessels are mobilized. If the graft is removed inadvertently, we place in cool Ringer solution or autologous blood. The distal end of the graft is then intubated with a Marks needle and secured with a silk tie (Fig. 6.3). Dilute heparinized autologous blood is infused to dilate the vein prior to proximal transection to evaluate for untied tributaries. Once the vein is removed, the thigh incision is packed with moist gauze until the renal revision is complete to ensure that any delayed bleeding caused by systemic heparinization is identified and controlled.

**FIGURE 6.2** A: Position of patient for harvesting of saphenous vein graft. B: Line of incision of saphenous vein graft harvest. C: Exposure of saphenous vein.

## Insertion of the Saphenous Vein Graft

Once the renal vessels and aorta are completely mobilized, systemic heparin is given and a 30-minute window is observed prior to arterial clamping. The vein graft is next orientated to ensure proper implantation, with an end-to-end anastomosis being the preferred technique to limit nonlaminar flow associated with end-to-side reconstructions. The aorta is next palpated to locate an area free of atherosclerotic plaque for the proper location of the aortotomy.

Preoperative imaging should rule out extensive aortic atherosclerotic disease and avoid the need for plaque endarterectomy and associated emboli risk. A medium-sized DeBakey clamp is next placed on the anterolateral portion of the infrarenal aorta in a tangential manner. A vertical 13- to 16-mm aortotomy is made without excising any aortic wall or attempting to perform localized endarterectomy (Fig. 6.4).

Excision of the aortic wall is not necessary because intraluminal aortic pressure spreads the dimensions of the linear aortotomy to appropriate dimensions after the clamp is released. The vein graft is anastomosed to the aorta with 5-0 Prolene after being adequately spatulated (Fig. 6.5). A microvascular Schwartz clamp is placed on the end of the saphenous vein graft and the aorta unclamped. The graft will lie anterior to the inferior vena cava on the right side and anterior to the renal vein on the left side. The graft should be relatively mobile to limit undue stress on the anastomosis; however, excess length is not recommended due to possibility of graft kinking. A second Schwartz microvascular clamp is placed on the distal main renal artery or branches. An end-to-end anastomosis is performed using 6-0 Prolene suture in a continuous or interrupted fashion, depending on the diameter of the anastomosis (Fig. 6.6). Interrupted sutures are preferable for diameters of 3 mm or less. Pediatric patients are treated with interrupted sutures to prevent a “pursestring” effect with vessel growth at a later age. Interrupted sutures should be placed at four quadrants initially to limit additional “pursestring” effects. Precision is a

**FIGURE 6.3** Harvest of saphenous vein graft.

**FIGURE 6.4** The bypass graft is placed along the lateral aortic wall to determine the best position for its placement. (From Novick AC, Strem SB, Pontes JE, eds. *Stewart's operative urology*. Baltimore: Williams & Wilkins, 1989, with permission.)

**FIGURE 6.5** Following partial aortic occlusion, an oval aortotomy is made for end-to-side anastomosis with a spatulated bypass graft. (From Novick AC, Strem SB, Pontes JE, eds. *Stewart's operative urology*. Baltimore: Williams & Wilkins, 1989, with permission.)

must in placing sutures to limit unnecessary vascular trauma at the anastomosis that may impair strength or lead to intimal inflammatory reaction and narrowing of the lumen.

Once the anastomosis is complete, the bulldog clamps are removed and the anastomosis evaluated for bleeding (Fig. 6.7). Rarely may there be a need to place an additional interrupted stitch. We cannot stress enough the importance of visualization during these procedures, and we insist on the use of surgical loupes and fiberoptic lighting. In addition, the operating staff should have a wide array of equipment available due to the delicacy of these procedures. Fogarty balloons of all sizes need to be readily available in the event of a

thrombus. Novice urologists should not hesitate to corroborate with a vascular surgeon in the early part of their career.

## Splenorenal Artery Bypass

The indications for splenorenal bypass include patients with diffuse atherosclerotic disease of the aorta or prior aortic surgery needing left renal artery revascularization.

Lateral and oblique angiography is essential in surgical decision making to confirm that the celiac axis is free of atherosclerotic disease. Recent advances in three-dimensional computerized tomography and magnetic resonance imaging can be implemented; however, the gold standard remains angiography because of the dynamic real-time imaging effect. Surgical exploration and intraoperative evaluation with splenic blood flow measurements can be helpful as well. Alternative bypass routes should be considered if splenic blood flow is  $<125$  mL per minute.

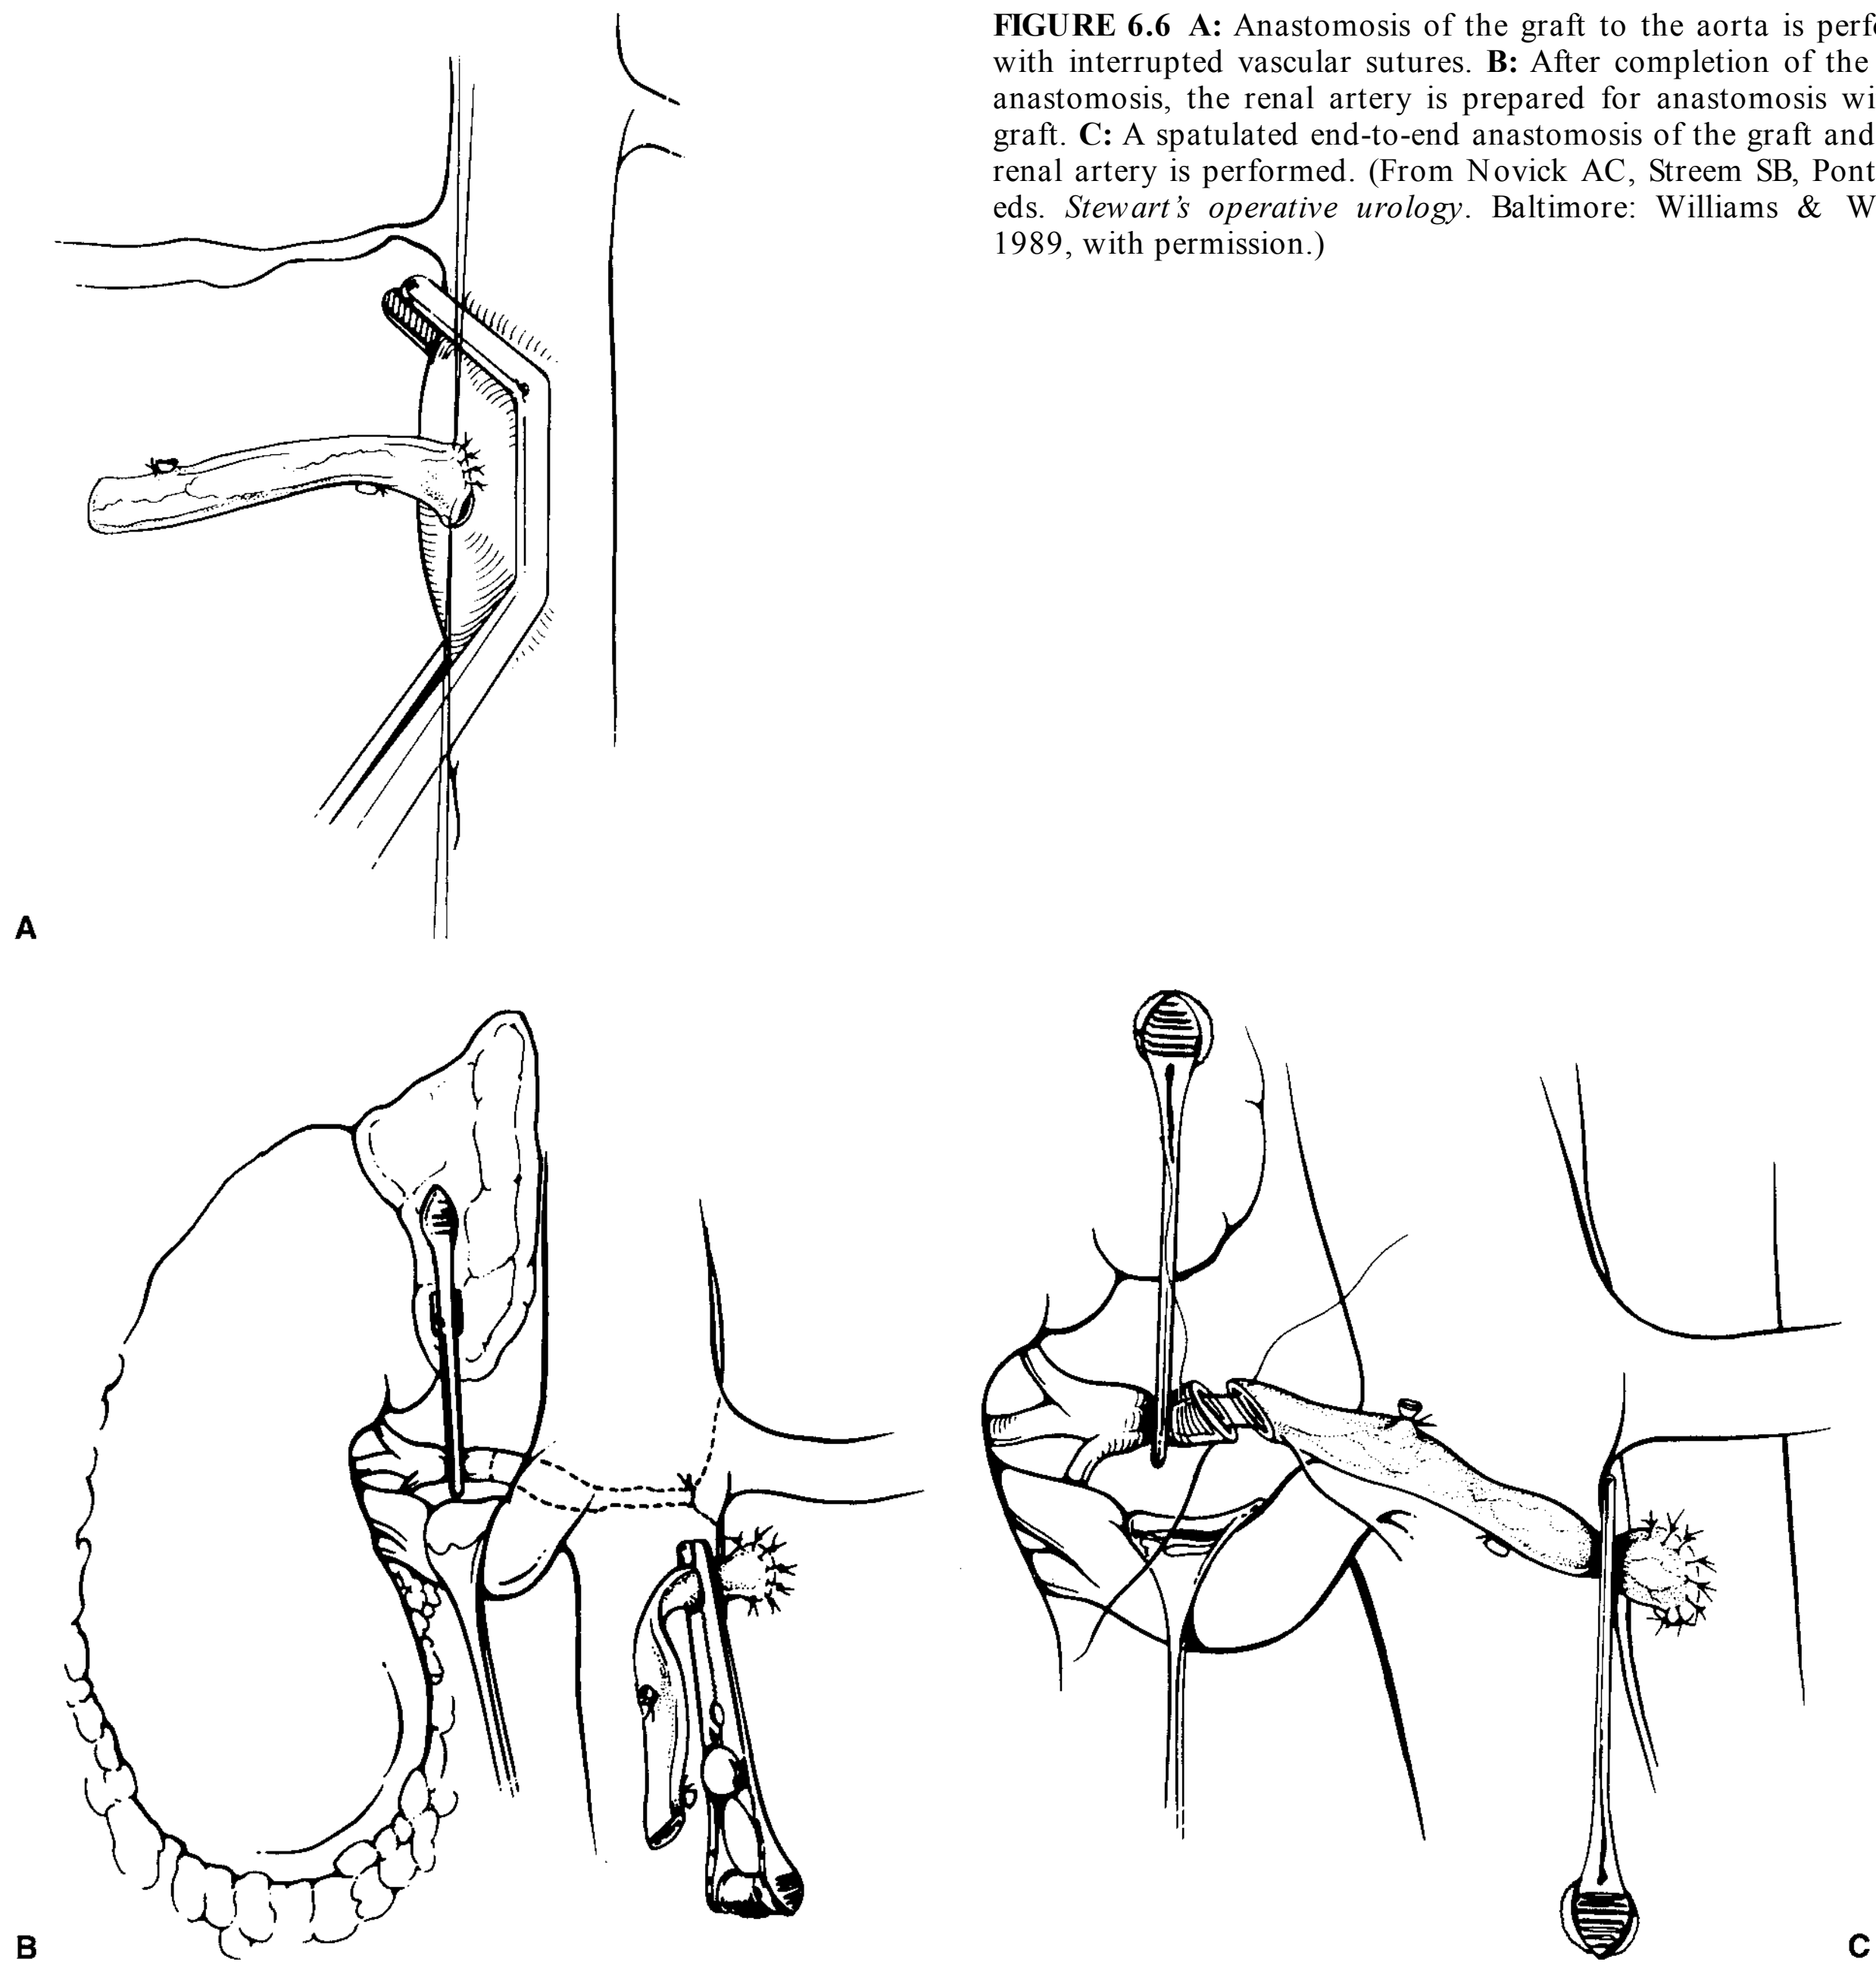

A supracostal eleventh-rib incision is made, and dissection is carried along the upper border of the rib, avoiding the neurovascular complex on the underside (Fig. 6.8). The overlying latissimus dorsi, the serratus posterior inferior, and intercostal muscles are next divided with electrocautery. The next group of muscles to be divided includes the external and internal obliques and the transversus abdominis muscle. Intercostal muscle attachments are divided approximately on the distal inch of the rib until the corresponding intercostal nerve is identified and spared. This approach allows an extrapleural approach and provides excellent exposure as the rib can pivot downward in a "bucket-handle" fashion.

The plane between Gerota fascia and the adrenal gland posteriorly and the pancreas anteriorly is then entered and the splenic artery identified at the upper border of the pancreas. The investing fascia is entered and the splenic artery mobilized by a purely retroperitoneal approach. Associated pancreatic feeding vessels are isolated, ligated, and divided. A properly performed dissection should provide mobilization of the splenic artery from the hilum to the celiac axis, providing a tension-free anastomosis.

After the splenic artery is mobilized, a sponge soaked with papaverine is placed on it to permit dilation. A vascular clamp is placed at the origin, and the artery is divided proximal to the bifurcation at the hilum. Splenectomy is not required because the spleen will receive blood supply from the short gastric arteries. Arterial circumference may be increased with a Fogarty catheter or Gruentzig balloon. The left kidney is approached with a posterior approach and the renal artery identified. The renal artery is ligated distal to the point of obstruction and an end-to-end anastomosis carried out with 6-0 Prolene in an interrupted or continuous fashion (Fig. 6.9). We have employed the posterior approach in over 10 patients at our institution and now prefer it to the transabdominal technique. In the rare circumstance that length is insufficient, a saphenous vein interposition graft may be required to prevent undue tension (Fig. 6.10).

## Hepatorenal Bypass Graft

The hepatic artery arises from the celiac axis and continues along the upper border of the pancreas until the portal vein

**FIGURE 6.6** **A:** Anastomosis of the graft to the aorta is performed with interrupted vascular sutures. **B:** After completion of the aortic anastomosis, the renal artery is prepared for anastomosis with the graft. **C:** A spatulated end-to-end anastomosis of the graft and distal renal artery is performed. (From Novick AC, Strem SB, Ponted JE, eds. *Stewart's operative urology*. Baltimore: Williams & Wilkins, 1989, with permission.)

complex, where it branches into ascending and descending limbs. The ascending branch is a continuation of the main hepatic artery upward within the lesser omentum; it lies in front of the portal vein and to the left of the biliary tree. The descending limb forms the gastroduodenal artery. In the porta hepatis, the hepatic artery divides into the right and left hepatic branches, which supply the corresponding lobes of the liver (Fig. 6.11). The right-upper-quadrant vasculature—the hepatic artery—has marked variability in up to 48% of patients as documented in living liver donors (6). Accessory hepatic arteries provide ischemic insurance for hepatorenal bypass procedures. It is essential to identify the following arteries prior to attempting anastomosis: common hepatic, gastroduodenal, right and left hepatic arteries. In addition, the portal vein and common bile duct are isolated.

Once mobilized, the right renal artery is mobilized and the vascular clamps applied to the proximal portion of the hepatic artery and its distal branches. The gastroduodenal artery is divided and the inferior surface of the hepatic artery is mobilized from the underlying portal vein and common bile duct (Fig. 6.12). A 10- to 12-mm arteriotomy is made in the anterior inferior wall of the common hepatic artery, beginning at the ostium of the gastroduodenal artery. A reversed autogenous saphenous vein is inserted with an end-to-side anastomosis between the vein graft and hepatic artery using 6-0 Prolene suture (Fig. 6.13). A microvascular clamp is placed on the vein graft after it has been filled with heparin and after the proper alignment and length for the renal artery anastomosis has been determined. The clamps are removed from the hepatic circulation, and a small Schwartz microvascular clamp is paced on the distal renal artery.

### Ileorenal Bypass

The presence of severe atherosclerotic disease of the aorta may preclude aortorenal bypass and requires alternative vascular bypass conduits. One option includes the ileorenal bypass, with a caveat being adequate aortic flow to that level of the common bifurcation. Our surgical approach starts with a mid-line abdominal incision with concomitant saphenous vein graft acquisition. The corresponding colon is mobilized to expose the ipsilateral renal vessels and the iliac bifurcation. Vessel loops are applied to the common iliac in standard fashion, and an end-to-side anastomosis is performed with an end-to-end anastomosis at the level of the renal artery using a saphenous vein graft (Fig. 6.14).

### Additional Bypass Options

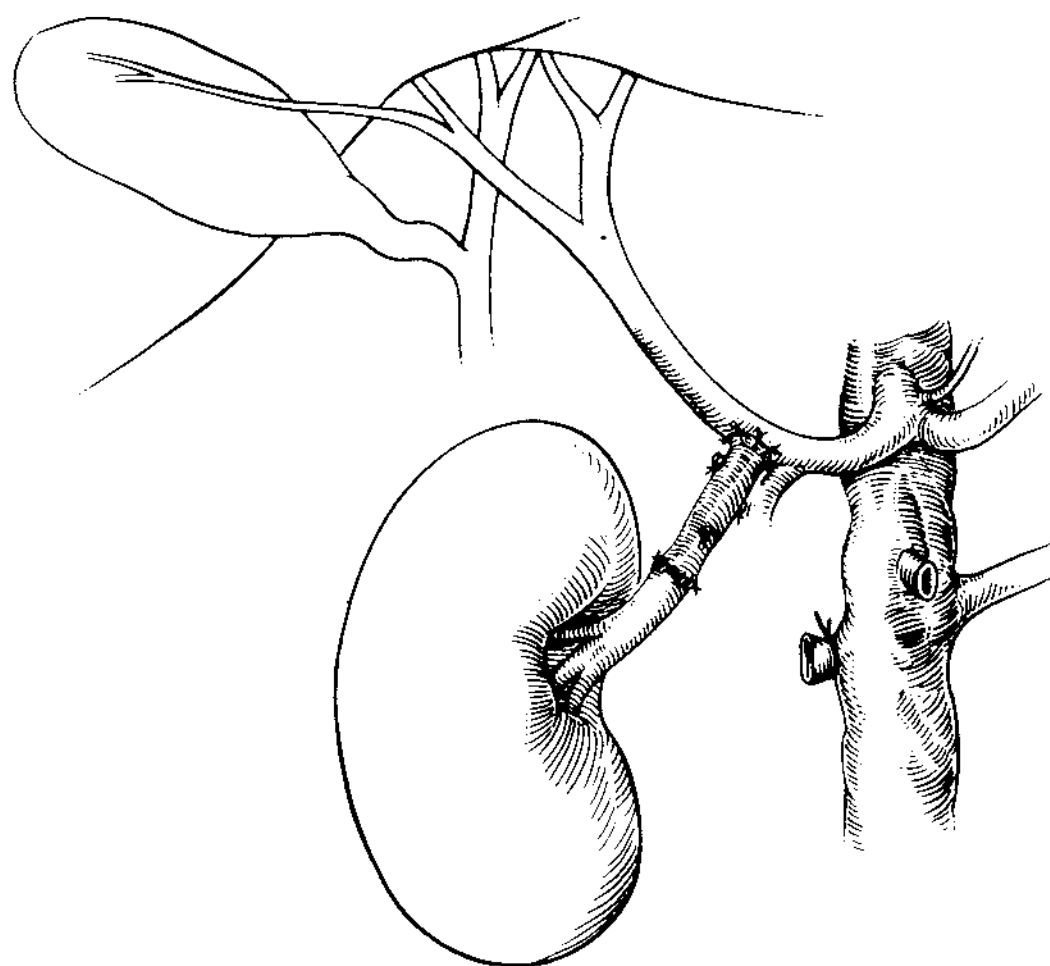

Case reports from various sources vary depending on the anatomy. Superior mesenteric artery, supraceliac aorta and lower thoracic aorta bypass have been performed using autogenous saphenous vein interposition grafts. These procedures are high risk and often reserved as last resort procedures.

Simultaneous aortic replacement with renal revascularization is indicated in the presence of significant aneurysmal disease; however, morbidity and mortality are higher.

Transplant renal artery stenosis is best managed with percutaneous angioplasty. Lohr et al. reviewed 90 transplant patients with transplant stenosis. Percutaneous transluminal renal angioplasty (PTRA) intervention led to the loss of one graft

**FIGURE 6.12** Hepatorenal bypass performed with an interposition saphenous graft anastomosed end-to-side to the common hepatic artery and end-to-end to the right renal artery. (From Novick AC. Diminished operative risk and improved results following revascularization for atherosclerotic renal artery disease. *Urol Clin North Am* 1984;11:435, with permission.)

**FIGURE 6.13** Use of the gastroduodenal artery to perform hepatorenal revascularization through direct end-to-end anastomosis with the right renal artery. (From Novick AC, Strem SB, Pontes JE, eds. *Stewart's operative urology*. Baltimore: Williams & Wilkins, 1989, with permission.)

and restenosis in another; however, the rates of graft loss and restenosis were 11% and 6% with open surgical repair (7).

### Renal Artery Reconstruction Using Prosthetic Grafts

Autogenous reconstruction using reversed saphenous vein grafts, arterial autografts, and transaortic endarterectomy has proven efficacious in the restoration of blood flow and renal function in numerous clinical studies. Implementation of prosthetic grafts was initially viewed with some skepticism secondary to concerns about durability and the sequelae of possible infections. A review by Paty et al. of over 400 prosthetic grafts provided excellent clinical outcomes with patency rates over 95% at the 7-year period using polytetrafluoroethylene (PTFE)

**FIGURE 6.14** Ileorenal bypass with a saphenous vein graft anastomosed end-to-side to the common iliac artery and end-to-end to the renal artery. (From Novick AC, Strem SB, Pontes JE, eds. *Stewart's operative urology*. Baltimore: Williams & Wilkins, 1989, with permission.)

grafts for primary renal arterial reconstruction and concomitant aortorenal reconstructions (8). PTFE graft size can be customized to the renal artery, and the high flow rates can retard thromogenicity.

### Renovascular Salvage Surgery

PTRA is the preferred treatment of choice for fibroplastic and nonstrial unilateral lesions sparing the anterior and posterior divisions of the renal artery. Complications can occur in the immediate postoperative period in up to 13%, with restenosis rates ranging from 15% to 25%. Lacombe et al. reviewed their experience with over 50 failed PTRAs managed via 38 in situ repairs, 10 extracorporeal repairs, and 3 nephrectomies (9). Although technically difficult, failed PTRAs are surgically correctable; however, planes of dissection are often compromised, and the increasing use of endoluminal stents precluded thromboembolectomy and reimplantation. Revisions for fibromuscular dysplasia demonstrated improved outcomes versus atherosclerosis, which tend to harbor significant inflammatory changes. These authors recommend surgical revascularization as the primary treatment in all types of arterial fibrodysplasia, citing only 17 (2.5%) postoperative occlusions in their series of 689 primary revascularizations.

### Renal Autotransplantation and Ex Vivo Bench Surgery

On rare occasions, kidneys with lesions of the renal artery or its branches are not amenable to in situ reconstruction. In

**FIGURE 6.15** **A:** An arteriogram shows complex involvement of the right renal artery by disease extending into the primary branches. **B:** A postoperative arteriogram shows patent anastomoses.

these circumstances, temporary removal of the kidney, *ex vivo* preservation, microvascular repair (bench surgery), and autotransplantation may permit salvage. This technique should be considered in patients with traumatic arterial injuries and when disease of the major vessels extends beyond the bifurcation of the main renal artery into segmental branches, and also when multiple vessels supplying the affected kidney are repaired. Bench surgery may also be required in patients with larger aneurysms, arteriovenous fistulas, dissecting aneurysms, or malformations (Fig. 6.15). At our institution we have performed over 25 autotransplants with renovascular disease (renal artery aneurysm and renal artery stenosis) as the primary indication with over 90% success. Novick described his experience with 66 renal autotransplants with resolution of hypertension (no medical therapy) in 55 patients and improved or stable renal function in all patients (10). Taken together, these clinical outcomes support the role of renal autotransplantation and microvascular reconstruction for renovascular disease.

---

## SURGICAL COMPLICATIONS

---

Early complications include hemorrhage, graft thrombosis, distal branch vessel embolization, subintimal dissection, false aneurysm, and nephrectomy. Bleeding in the immediate postoperative period is due to surgical error often accentuated by marginal arterial wall integrity. In addition, the presence of systemic heparinization will stress the coagulation cascade and promote bleeding at suture holes from Prolene suture. We recommend the use of thrombogenic mesh to control bleeding at these anastomoses. Enlarged perihilar vessels are seen in high-

grade stenosis, and cognizance of adrenal vasculature during dissection is important. Delayed bleeding may also occur with false aneurysm formation or erosion of graft anastomosis into duodenum or bowel. Infected graft suture lines may lead to delayed bleeding.

Intimal dissection can occur, and the use of a double-armed suture with needle passage from intima to adventitia can aid in decreasing the chance of dissection and associated embolization or aneurysm formation. Systemic heparinization has some prophylactic benefit for atheroemboli; however, the lower extremities need to be fully prepped in case a thromboembolectomy is warranted.

With respect to overall complications, the leading cause of morbidity and mortality in nonfibrodysplastic patients is cardiovascular in nature. This same population is afflicted with cerebrovascular comorbidities in an estimated 30%. We recommend surgical correction of these comorbidities when feasible prior to revascularization procedures.

---

## OUTCOMES

---

Balloon angioplasty is primarily used to treat mural dysplasia in a younger patient population with limited atherosclerotic disease. Using this modality, we have seen success rates of 80% to 85% at our institution. We have performed over 100 surgical revascularizations at our institute for preservation and restoration of renal function with a success rate of 85%, which is equivalent to that of our contemporary colleagues (11). In one of the largest series to date, Lawrie et al. documented improved hypertension in 82% of 919 patients observed over 6 years (12).

# CHAPTER 7 ■ ANATROPHIC NEPHROLITHOTOMY

ELIZABETH J. ANOIA, MICHAEL L. PAIK, AND MARTIN I. RESNICK

The treatment of nephrolithiasis has undergone a rapid evolution over the past 25 years. The introduction and refinement of extracorporeal, endourologic, and percutaneous techniques have caused a shift in the first-line management of even complex renal stones. Anatomic nephrolithotomy is a procedure that has been used by urologists for >30 years in the removal of staghorn renal calculi. The original description of anatomic nephrolithotomy was by Smith and Boyce in 1968 (14). The operation they described was based on the principle of placing the nephrotomy incision through a plane of the kidney that was relatively avascular. This approach would avoid damage to the renal vasculature and subsequent atrophy of the renal parenchyma, hence the term *anatomic*. Staghorn stones are often associated with urinary tract infections, and the coexistence of these two conditions makes it difficult to eradicate either. Definitive treatment of these stones is generally advocated because of the significant morbidity and mortality associated with untreated staghorn calculi. Blandy and Singh (3) found that patient survival is reduced with untreated staghorn calculi, with a mortality rate of 28% at 10 years.

Anatomic nephrolithotomy also involves reconstruction of the intrarenal collecting system to eliminate anatomic obstruction. Thus, this procedure would improve urinary drainage, thereby reducing the likelihood of urinary tract infection, which would prevent recurrent stone formation. Over the past 25 years, with the development of less invasive approaches such as extracorporeal shock wave lithotripsy (ESWL), percutaneous nephrolithotomy (PCNL), and ureteroscopic surgery, the role of anatomic nephrolithotomy and other open stone operations has certainly diminished (2). The American Urologic Association Nephrolithiasis Clinical Guidelines Panel in 1994 recommended a percutaneous procedure with or without ESWL as an initial treatment for complex

staghorn calculi. However, in specific situations anatomic nephrolithotomy remains the best treatment option for renal calculi and thus has maintained an important, albeit smaller, role in the treatment of these large, complex stones.

---

## DIAGNOSIS

---

Diagnosing nephrolithiasis is based on the patient's history, physical exam, urinalysis (UA) findings, and radiographic studies. Patients may have the typical symptoms of flank pain, fever, hematuria, and dysuria or they may be asymptomatic. Physical examination may reveal costovertebral angle tenderness. The UA may show erythrocytes, leucocytes, and nitrites or bacteria if the stone is associated with an infection. The diagnosis of chronic urinary tract infection is common in patients with staghorn stones. Urine culture is often positive, and typical organisms include urea-splitting organisms such as *Proteus*, *Klebsiella*, *Providencia*, and *Pseudomonas*.

Common radiographic studies by traditionally obtained include plain abdominal radiographs, nephrotomograms, and excretory urograms to identify the stones and the collecting system and, if present, define the degree of obstruction. Retrograde pyelography is usually performed in cases of equivocal findings on excretory urography. Recently, helical nonenhanced computed tomography scanning with thin cuts of the kidneys, ureters, and bladder has become the gold standard for identifying urinary tract stones and radiolucent or poorly calcified stones. Nuclear renal scans can help determine differential renal function when such information might affect the surgical approach. Renal arteriography is usually not indicated unless there is suspicion of anomalous arterial anatomy, such as in renal fusion anomalies.

Before elective surgery, a metabolic evaluation is recommended to attempt to determine an etiology for stone formation and aid in preventing a recurrence. For instance, it is important to determine the presence of hypercalciuria, hyperuricosuria, hyperoxaluria, cystinuria, hyperparathyroidism, and renal tubular acidosis in multiple urine specimens. The measurement of serum and urine calcium, phosphorus, creatinine, uric acid, and electrolytes should be routine. A 24-hour urine collection for creatinine clearance as well as urinary calcium, phosphorus, oxalate, citrate, cystine, and uric acid is also an integral part of the workup (9).

---

## INDICATIONS FOR SURGERY

---

The indications for anatomic nephrolithotomy have changed somewhat with advances in minimally invasive methods of treating stones. However, the inability to successfully eradicate a stone with less invasive methods remains an important indication for open stone surgery. Other relative indications include select cases of complex stone disease, especially those with a dilated collecting system, stones associated with urologic anatomic abnormalities, previous renal surgery, certain features of patient anatomy, comorbid disease, and patient preference (7,8). Specific urinary tract abnormalities account for up to 24% of open stone surgeries. These include a ureteropelvic junction (UPJ) obstruction, infundibular stenosis, calyceal diverticula, ureteral stricture, or the presence of a crossing vessel. By openly the defect can be corrected simultaneously. Patient features such as morbid obesity, limb contractures, or certain cases of transplanted kidneys may preclude proper positioning for endourologic procedures, ESWL, or percutaneous access (4). The presence of significant comorbid disease and patient preference must each be considered in choosing the best individualized treatment option.

Overall, the goals of open stone surgery should be to remove all calculi and fragments, improve urinary drainage of any obstructed intrarenal collecting system, eradicate infection, preserve and improve renal function, and prevent stone recurrence (15).

---

## ALTERNATIVE THERAPY

---

As open stone surgery accounts for <5% of treatment modalities for staghorn and other complex stones, there are now other less invasive techniques either alone or in combination that have replaced this procedure. Most staghorn calculi can now be preferentially treated with percutaneous nephrolithotomy, with or without ESWL. The stone-free rates reported vary between 50% and 87%, whereas for anatomic nephrolithotomy stone-free rates range from 90% to 100% (7). The advantage of the former is shorter convalescent periods; the disadvantage is the possibility of requiring multiple different procedures to accomplish a stone-free state. Endoscopic therapy with holmium:YAG laser lithotripsy is reported to have an overall stone-free rate of 95% (10). ESWL monotherapy was found to have a 61% stone-free rate <10 years after its development (8). Despite impressive advances with the less invasive techniques, anatomic nephrolithotomy remains a viable treatment option for large staghorn calculi

not expected to be eliminated with a reasonable number of less invasive procedures or staghorn stones associated with anatomic abnormalities requiring open surgical correction (13).

---

## SURGICAL TECHNIQUE

---

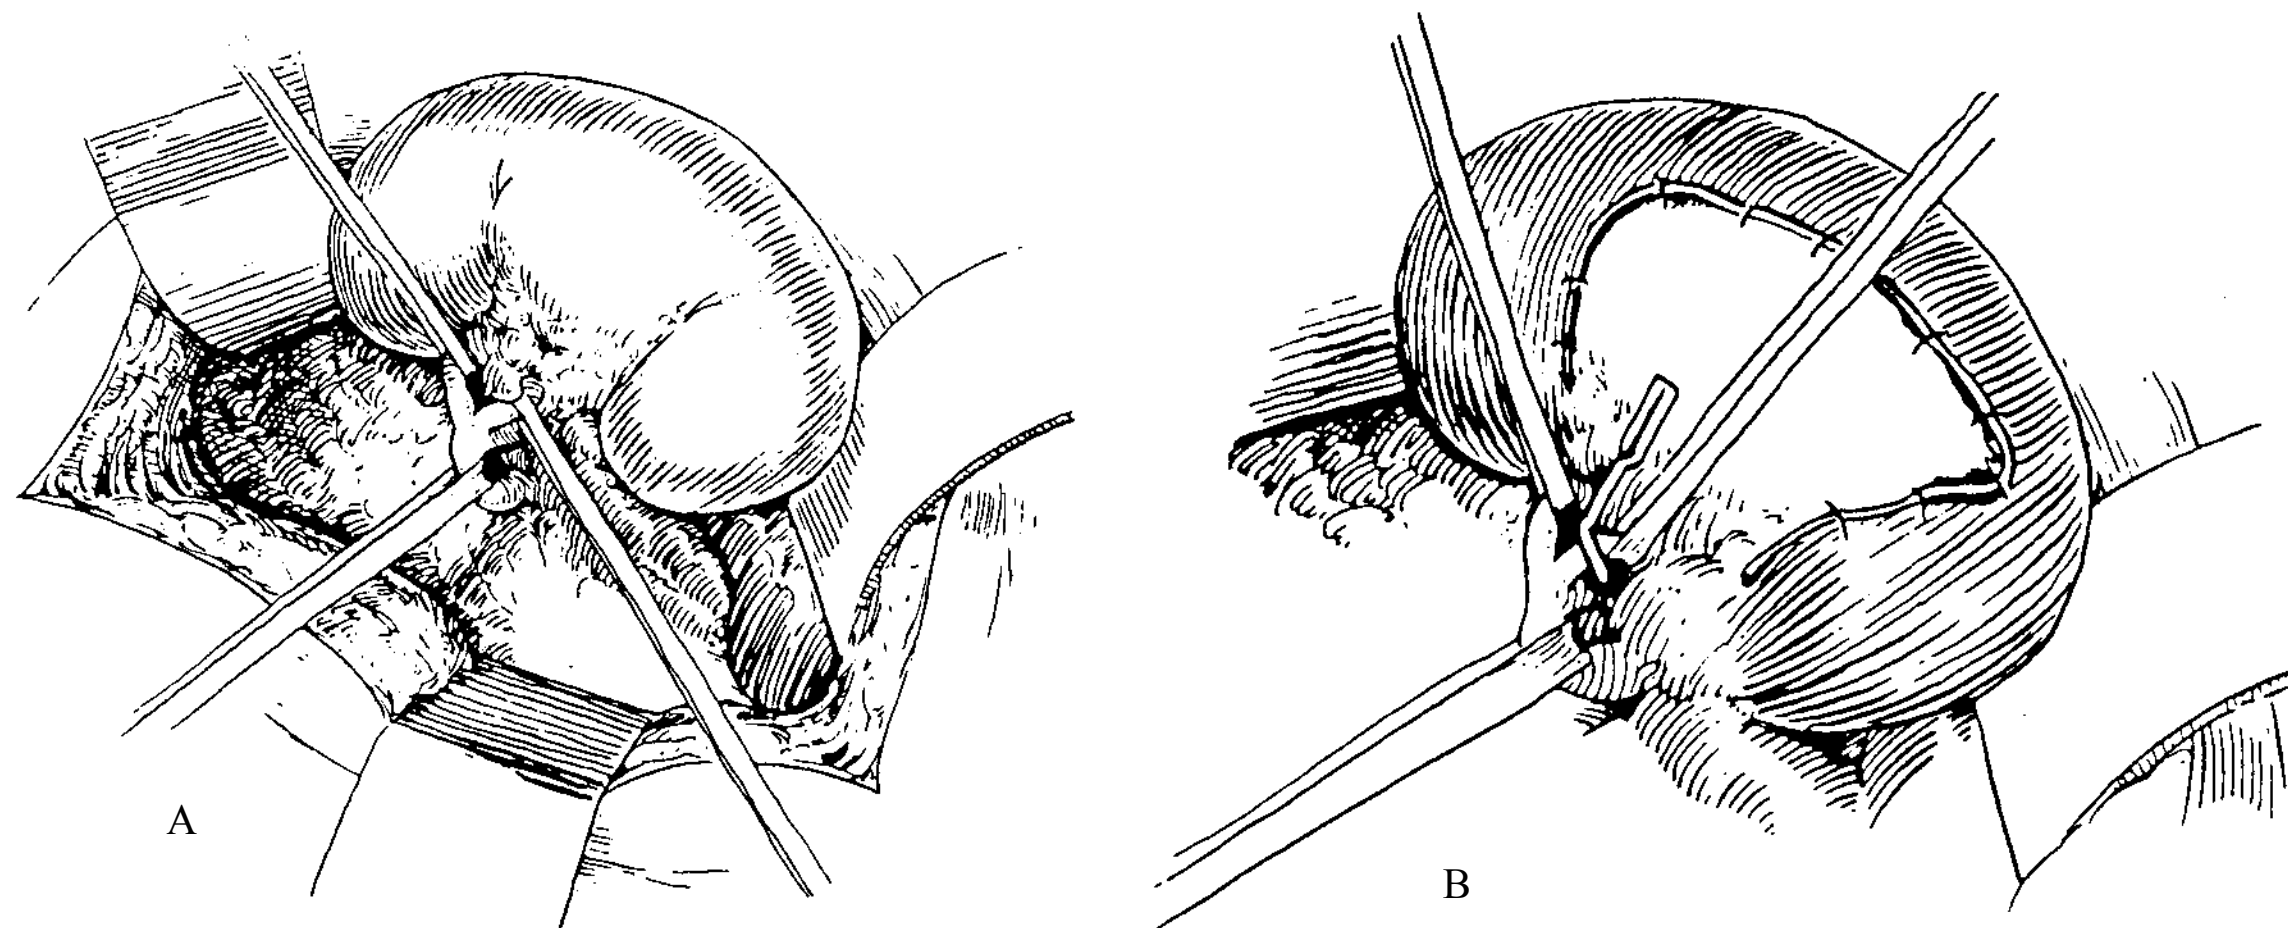

After administration of appropriate preoperative intravenous (IV) antibiotics and induction of general anesthesia, a Foley catheter is placed. The patient is then placed in the standard flank position with elevation of the kidney rest and flexion of the operating table to achieve adequate spacing between the lower costal margin and the iliac crest. Three-inch-wide adhesive tape applied at the shoulders and hips can be used to secure the patient to the table. Adequate padding should be used to protect pressure points.

A standard flank approach is used. The incision can be placed through the bed of either the eleventh or twelfth rib, depending on the estimated position of the kidney. If a previous flank incision has been made for renal surgery, it is preferable to place the incision above the old scar, ensuring that access to the kidney can be achieved through unscarred tissue. After rib resection, when access has been gained into the retroperitoneal space, the Gerota fascia is identified overlying the kidney. The Gerota fascia is incised in a cephalad-caudal direction, which facilitates returning the kidney to its fatty pouch at the end of the operation. The kidney is then fully mobilized, and the perinephric fat is carefully dissected off the renal capsule with care taken not to disrupt the capsule. Should the capsule become inadvertently incised, it can be closed at that time with chromic catgut sutures. The kidney is now free to be suspended in the operative field by utilizing a broad tape at each pole. At this point a preliminary portable plain radiograph can be obtained.

Next is the renal hilar dissection. The main renal artery and the posterior segmental branch are approached posteriorly, carefully identified, and dissected (Fig. 7.1A). The renal pelvis and ureter should be identified but not dissected. The avascular plane, or Brödel line, can be identified by temporarily clamping the posterior segmental artery and injecting 20 mL of methylene blue intravenously. This results in the blanching of the posterior renal segment while the anterior portion turns blue, allowing identification and marking of the avascular plane (Fig. 7.1B) (6). Placing the nephrotomy incision through this plane will achieve maximal renal parenchymal preservation and minimize blood loss. The avascular plane can also be identified with the use of a Doppler stethoscope to localize the area of the kidney with minimal blood flow.

More extensive renal hilar dissection can be avoided by utilizing a modification of the original procedure described by Smith and Boyce (14). Redman et al. (11) relied on the relatively constant segmental renal vascular supply in the identification of the Brödel line. They advocated placing the incision at the expected location of the avascular plane after clamping the renal pedicle with a Satinsky clamp in an effort to prevent vasospasm of the renal artery and warm ischemia. This modification can save time and spare extensive dissection of the renal hilum. However, we continue to advocate precise identification of the avascular plane to minimize parenchymal loss.

At this point, 25 g of IV mannitol is administered. This will promote a postischemic diuresis and prevent the formation of

**FIGURE 7.1** Anatomic nephrolithotomy. **A:** The main renal artery and branches are isolated. **B:** The posterior segmental artery is occluded and methylene blue is administered intravenously. The resulting demarcation between pale ischemic and bluish perfused parenchyma defines a relatively avascular nephrotomy plane.

intratubular ice crystals by increasing the osmolarity of the glomerular filtrate. The main renal artery can now be occluded with an atraumatic bulldog vascular clamp (Fig. 7.2). A bowel bag or barrier drape is quickly placed around the kidney, and it is insulated from the body wall and peritoneal contents with dry gauze packs. Hypothermia is then initiated with iced saline slush covering the kidney. The kidney should be cooled for 10 to 15 minutes before the nephrotomy incision is made. This should allow achievement of a core renal temperature of 15°C to 20°C, which will allow safe ischemic times from 60 to 75 minutes and minimize renal parenchymal damage (5). The ice slush should be continuously reapplied as needed throughout the case.

The renal capsule is then incised sharply over the previously identified line, being careful to avoid extension into the upper and lower poles (Fig. 7.3). The renal parenchyma can be bluntly dissected with the back of the scalpel handle. Blunt dissection minimizes injury to the intrarenal arteries that are

traversed (Fig. 7.4). Small bleeding vessels can be controlled with 4-0 or 5-0 chromic catgut figure-of-eight suture ligatures. If renal back-bleeding continues to be a problem despite these measures, the main renal vein can be occluded.

As the nephrotomy incision proceeds toward the renal hilum, the ideal location to enter the collecting system is at the base of the posterior infundibula. The intraoperative radiograph can be used as a guide to the pelvis and the base of the calyx. On occasion, with large posterior calyceal calculi, a dilated posterior calyx will be entered initially. The remainder of the collecting system can then be identified with a probe and opened. If a posterior infundibulum is entered first, the incision is then carried toward the renal pelvis (Fig. 7.5). The stone is visualized, and all ramifications of the stone are

**FIGURE 7.2** The main renal artery is clamped and a bowel bag or rubber dam is placed around the kidney. Dry gauze packs are placed anterior to the kidney to protect the intra-abdominal organs from hypothermia.

**FIGURE 7.3** A superficial incision is made in the renal capsule through the avascular plane.

**FIGURE 7.4** The parenchyma is bluntly dissected with the back of a scalpel handle. The incision closely approximates the avascular plane.

**FIGURE 7.6** After the collecting system is opened, calculi are extracted and total removal is confirmed radiographically.

**FIGURE 7.5** The collecting system is carefully incised.

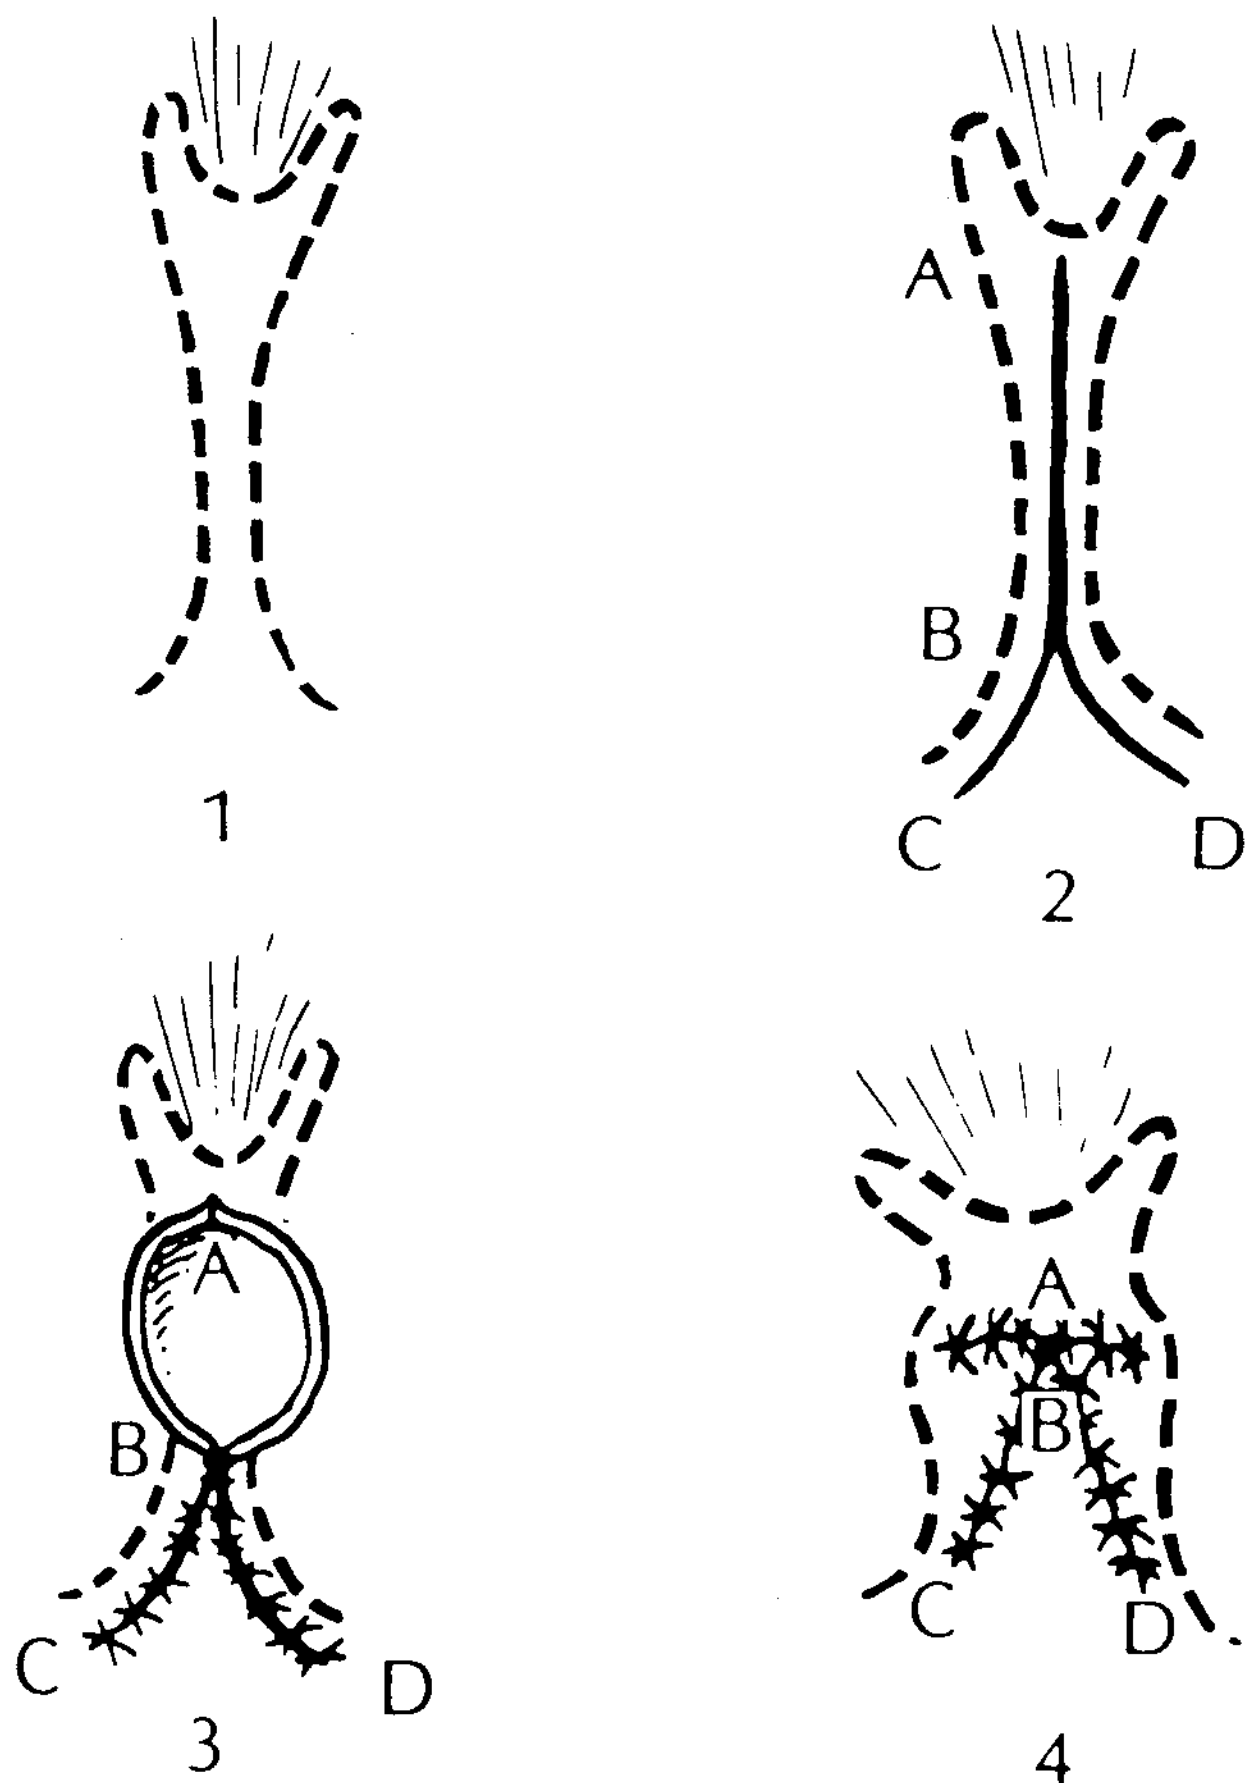

exposed by opening adjacent infundibula into the calices. To minimize stone fragmentation and retained calculi, the stone should not be manipulated or removed until all of the calyceal and infundibular extensions are appropriately identified and incised. This allows for complete visualization and mobilization of the collecting system and calculi. Ideally, the stone or stones should be removed without fragmentation; however, often it is inevitable that there will be some piecemeal extraction (Fig. 7.6). If this is necessary, a ureteral stent can be inserted to prevent stone migration during manipulation. Each calyx should be inspected for stone fragments. After removal of all stone fragments, the renal pelvis and calices are copiously irrigated with cold saline and the irrigant is aspirated. A nephroscope can be used to look for residual fragments. A plain radiograph or ultrasonography are also options. At this time, a “double-J” ureteral stent is passed from the renal pelvis into the bladder if this was not done at the time of stone

**FIGURE 7.7** A ureteral stent is passed in an antegrade fashion from the pelvis to the bladder. Traction sutures are placed to mark the walls of adjacent calices before suturing them together with a running 6-0 chromic suture.

manipulation (Fig. 7.7). The routine use of internal ureteral catheters is encouraged. They provide good urinary drainage, protect the freshly reconstructed collecting system, and minimize postoperative urinary extravasation. The next step in the procedure is the reconstruction of the intrarenal collecting system with correction of a coexistent anatomic abnormality if present. Infundibular stenosis or stricture that results in obstruction promoting urinary stasis and recurrent stone formation should be corrected with caliorrhaphy or calicoplasty. The former is the repair of a single narrowed calyx, achieved by incising the calyx along its appropriate margin (anterior margin for posterior calices and posterior margin for anterior

**FIGURE 7.8** Technique of repairing strictured infundibula. 1: Narrowed elongated infundibulum. 2: Incision into calyx forms an inverted Y. 3: Pelvic flap is advanced into infundibulotomy. 4: Incision in calyx is closed transversely.

calices) and suturing those margins to the renal pelvis, resulting in a shorter, wider calyx (Fig. 7.8). The infundibulum can also be incised longitudinally and then closed transversely in a Heineke-Mikulicz fashion. Calicoplasty is the repair of adjacent stenotic calices by suturing the adjacent walls of the neighboring calices, thus forming a single structure (Figs. 7.9 and 7.10). All intrarenal reconstructive suturing should be accomplished with 5-0 or 6-0 chromic catgut sutures. When suturing the mucosal edges, it is important to avoid incorporation of underlying interlobular arteries, thus preventing ischemia.

The renal pelvis is then closed, first with reinforcing corner sutures and then with a running 6-0 chromic catgut suture (Fig. 7.11). The arterial clamp is briefly released to identify parenchymal bleeding points, and hemostasis is obtained with 4-0 or 5-0 chromic catgut figure-of-eight suture ligatures before closing the renal capsule. The renal capsule is closed with a running lock stitch of 4-0 chromic catgut suture (Fig. 7.12), or mattress sutures over bolsters can be used. After the capsule is closed and adequate hemostasis has been achieved, the slush surrounding the kidney is removed and the renal artery unclamped. The kidney is observed for good hemostasis and return of pink color and good turgor after unclamping. It is then returned into the Gerota fascia, and the kidney and proximal ureter are covered with some perirenal fat to minimize the postoperative scar formation. If the Gerota fascia is unavailable because of prior surgery, omentum can be mobilized

**FIGURE 7.9** Adjacent infundibula are sutured together starting in the renal pelvis. Peripelvic fat is depressed during this closure.

**FIGURE 7.10** The collecting system is completely reconstructed.

**FIGURE 7.11** The renal pelvis is closed with a running 6-0 chromic suture.

**FIGURE 7.12** The renal capsule is closed with a running locking 4-0 chromic suture.

through a peritoneal opening and wrapped around these structures. The peritoneal opening should be sutured to the omentum to prevent herniation of the abdominal viscera.

A Penrose or suction-type drain is placed within the Gerota fascia and brought out through a separate stab incision. This drain is left in place until minimal drainage occurs, usually by the third or fourth postoperative day. Nephrostomy tubes are in general avoided because of their potential for causing infection or further renal damage. The flank musculature and skin are closed in the standard fashion.

Postoperative management after anatomic nephrolithotomy should follow the same principles that guide management after other major operations. Intravenous fluids are maintained to achieve brisk urine output and until the patient is able to tolerate a clear liquid diet. Broad-spectrum IV antibiotics are administered perioperatively and continued postoperatively for 5 to 7 days. Antibiotic coverage is guided by preoperative urine culture and sensitivity results. The ureteral stent is removed cystoscopically at approximately 7 days postoperatively in uncomplicated cases. A urine culture is checked for persistence of infection.

---

## OUTCOMES

---

### Complications

---

Pulmonary complications are perhaps the most common following anatomic nephrolithotomy, especially atelectasis. Patients with a history of pulmonary disease should likely undergo preoperative evaluation with pulmonary function testing and initiation of vigorous pulmonary toilet prior to surgery. Postoperatively, patients should be encouraged to breathe deeply, and use of an incentive spirometer should be routine. Early ambulation will also be beneficial.

Pneumothorax should occur in fewer than 5% of patients (15). A patient with a history of pyelonephritis or previous renal surgery is at increased risk. Inadvertent opening of the pleura, usually during incision and resection of a rib, should

be readily identified intraoperatively. The defect should be closed immediately with a running chromic catgut suture. The lung is hyperinflated just before the final suture is placed to ensure re-expansion of the lung. Chest tubes are not routinely used but may be necessary if any question remains regarding the reliability of the pleural closure. A chest radiograph should be obtained in the recovery room for any patient who undergoes repair of a pleural defect. Pulmonary embolism remains a potential complication of any major surgery. Routine use of elastic support hose and sequential compression stockings can lower the risk of deep venous thrombosis. Encouragement of early ambulation is also an important preventative measure. Significant postoperative renal hemorrhage should occur in fewer than 10% of patients. Assimos et al. (1) reported an incidence of 6.4%. Bleeding usually occurs immediately or about 1 week postoperatively. Extensive intrarenal reconstruction, older age, worse renal function, and presence of blood dyscrasias were found to be significant risk factors. Slow bleeding will usually resolve on its own; management includes correction of any bleeding abnormalities and replacement with blood products as necessary. Oral  $\epsilon$ -aminocaproic acid can be successful in certain cases. Bleeding that is brisk or cannot be adequately treated conservatively will require a more aggressive approach. A renal arteriogram can help identify the lesion, and an attempt at arteriographic embolization can be considered. Re-exploration may be required in the remainder of the cases, with reinstatement of hypothermia and suture ligation of the bleeding vessel(s). Persistent hematuria 1 to 4 weeks postoperatively should alert the clinician to the possibility of renal arteriovenous fistula formation or a false aneurysm (1). Urinary extravasation should occur infrequently with the routine use of perinephric drains and ureteral catheter drainage. Should drainage recur or persist following removal of the drain and/or ureteral stent, replacement of the ureteral stent should be considered to decompress the system and relieve any obstruction. Other possible complications resulting from arterial clamping include renal injury and hypertension.

---

## Results

---

When performed for appropriate indications and with meticulous technique, anatomic nephrolithotomy can achieve successful removal of all calculi, preservation of renal function, improved urinary drainage, and eradication of infection. Stone-free rates  $>90\%$  should be achieved. Stone recurrence rates following anatomic nephrolithotomy have been reported from 5% to 30% (15). Recurrent calculi usually form in those with persistent urinary tract infections, persistent urinary drainage impairment, and previously unidentified or refractory metabolic disturbances (12).

For large, complex staghorn calculi, especially those associated with some anatomic abnormality leading to impaired urinary drainage, anatomic nephrolithotomy remains a first-line treatment. This modality achieves comparable or better stone-free rates and the achievement of a stone-free state with a single operative procedure. In the long term, treatment of these staghorn calculi with anatomic nephrolithotomy should preserve renal function in the involved kidney and, in a majority of patients, eradicate stone disease and chronic urinary infection.

# CHAPTER 8 ■ RENAL AND RETROPERITONEAL ABSCESSSES

DAVIS P. VIPRAKASIT AND ANTHONY J. SCHAEFFER

---

## INTRODUCTION

---

Renal and retroperitoneal abscesses are uncommon clinical entities that often pose a significant diagnostic challenge. Nonspecific signs and symptoms frequently lead to a delay in diagnosis and treatment. Early experiences reported mortality rates approaching 50%. In contemporary series with improved diagnostic imaging allowing early recognition and treatment, mortality rates of <15% are noted. However, continued significant morbidity is associated with these insidious disease processes. An understanding of the anatomy of the retroperitoneal space is essential for classification, timely diagnosis, and management of renal and retroperitoneal abscesses.

The retroperitoneal space is bounded by the posterior parietal peritoneum and transversalis fascia (Figs. 8.1 and 8.2). It is divided into the perirenal space and the pararenal space. The perirenal space surrounds the renal capsule and capsular artery and is bounded by the renal (Gerota) fascia. The anterior and posterior leaves of Gerota fascia fuse above the adrenal gland, becoming continuous with the diaphragmatic fascia. A thinner, more variable layer meets between the adrenal gland and the kidney. Laterally, the fascial layers join to form the lateroconal fascia, which becomes continuous with the posterior parietal peritoneum. Medially, the posterior layer fuses with the psoas muscle fascia and the anterior layer fuses with the connective tissue surrounding the great vessels and organs of the anterior retroperitoneum (i.e., the pancreas, duodenum, and colon). Because the perirenal space rarely crosses the midline, perirenal abscesses usually remain unilateral. Inferiorly, the Gerota fascial layers do not fuse, but become continuous with the psoas and ureteral coverings (11).

This opening inferiorly allows the spread of perirenal infections to the pararenal space, pelvis, psoas muscle, and in some cases, contralateral retroperitoneum.

The pararenal space is divided into two compartments: the anterior compartment, which is bounded by the posterior parietal peritoneum and the anterior Gerota fascia, and the posterior compartment, which is bounded by the posterior Gerota fascia and transversalis fascia. Because the anterior pararenal space extends across the midline, infections arising in one space may become bilateral. The posterior pararenal space does not cross the midline, and infection within it remains unilateral. The retrofascial compartment lies posterior to the transversalis fascia. It is important only in the development of the rare retrofascial abscess from abscesses of the psoas, iliacus, and quadratus muscles.

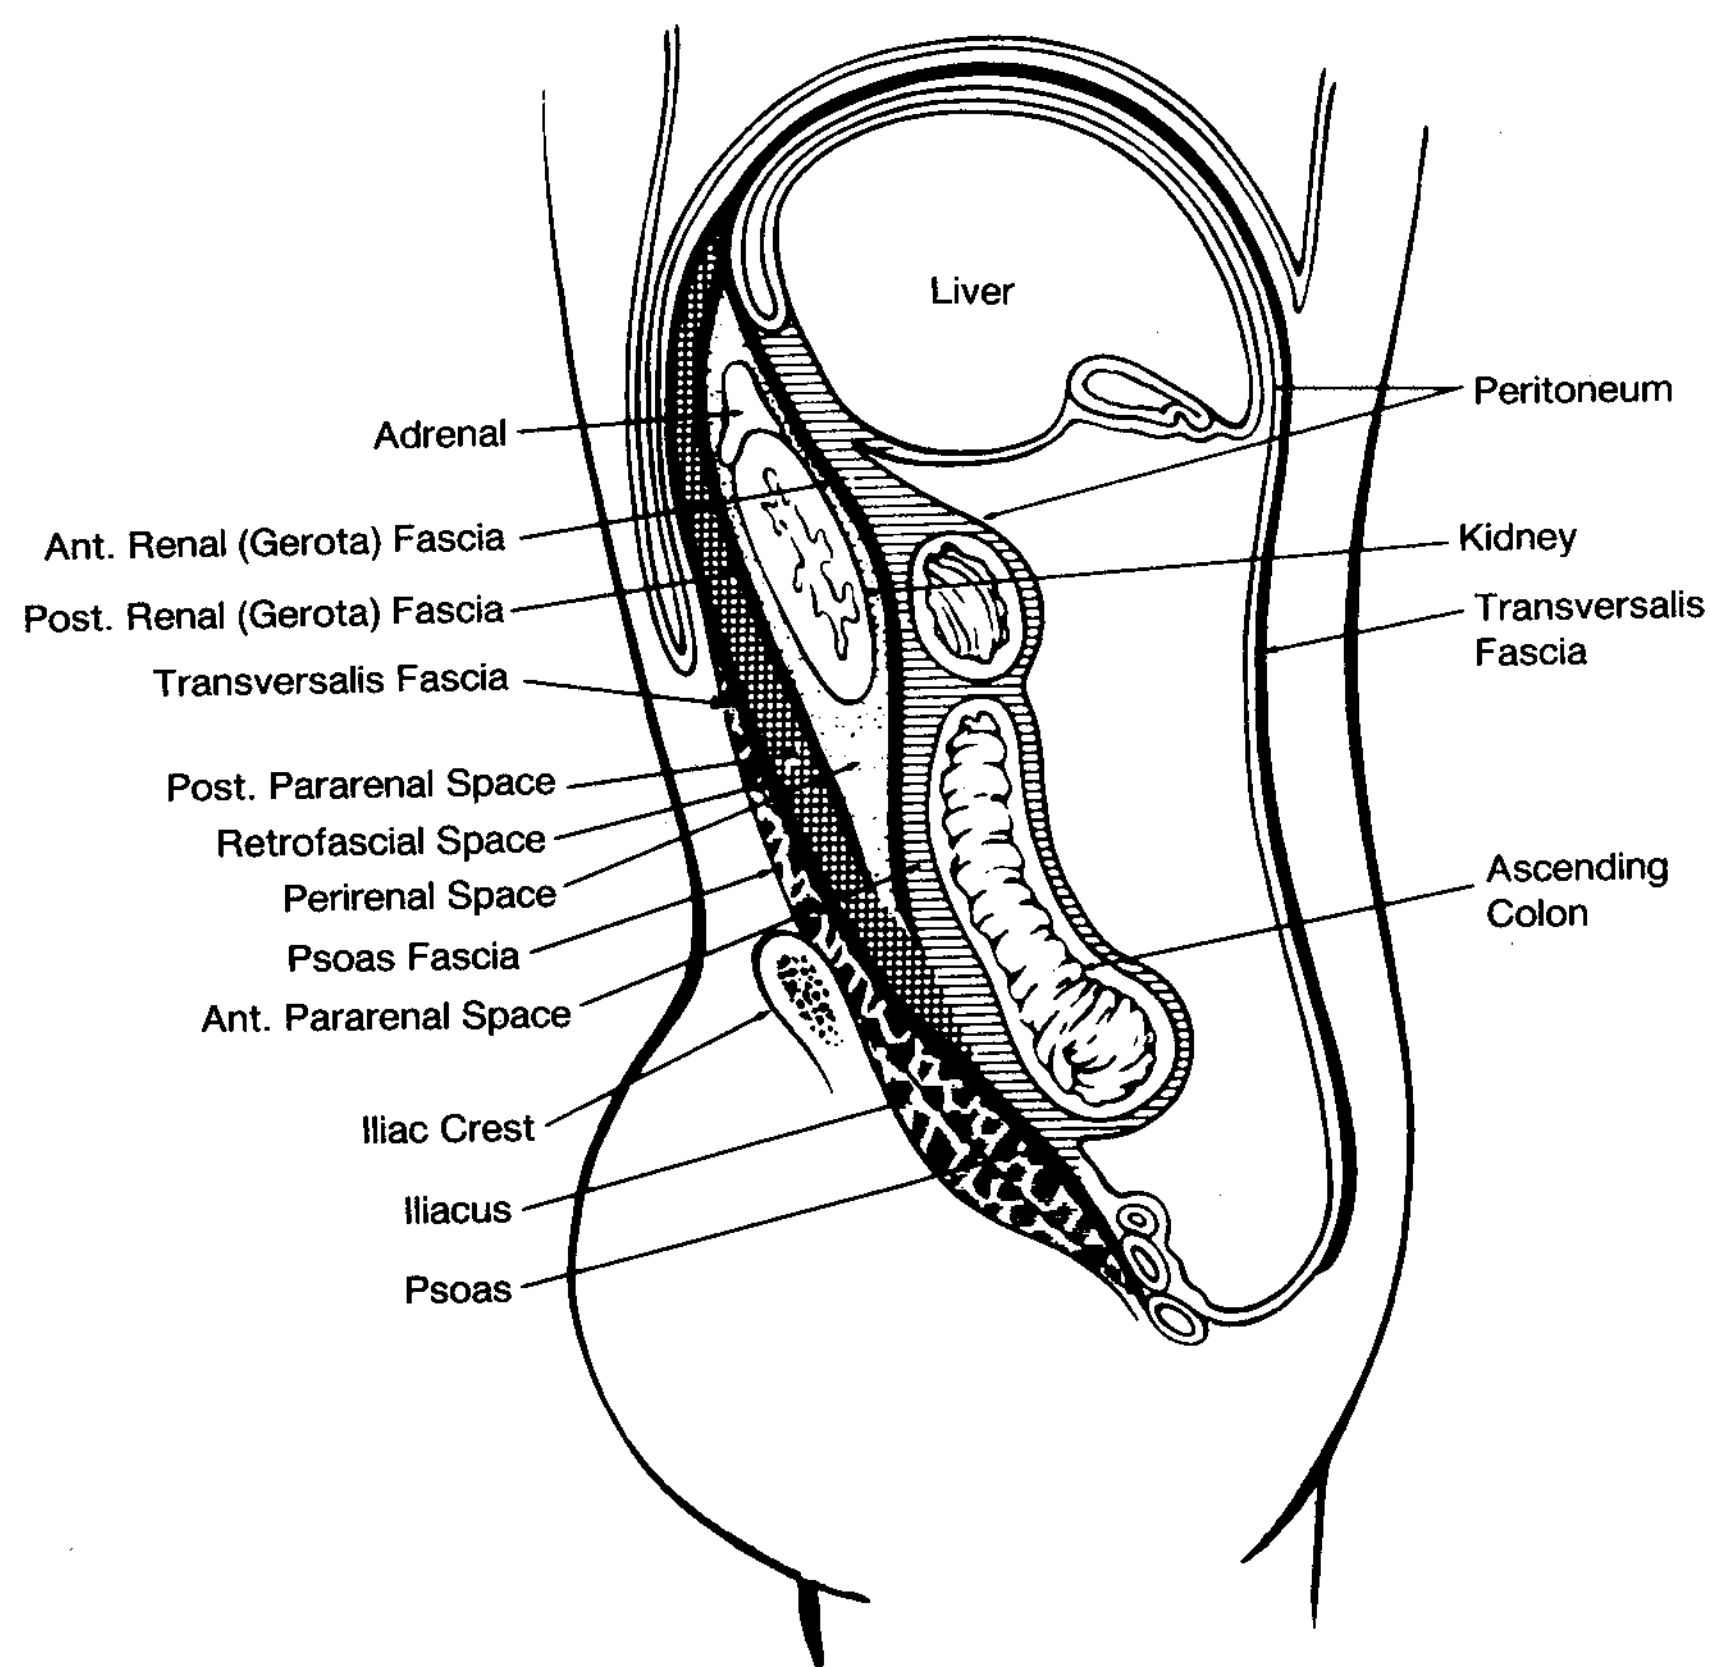

The term “renal abscess” includes a wide range of abscesses arising from within or around the kidney. An intrarenal abscess is an abscess located within the renal parenchyma or on the renal capsule between the renal parenchyma and capsular artery. A perirenal abscess arises within Gerota fascia external to the capsular artery. A pararenal abscess is located outside of Gerota fascia within the pararenal space (Table 8.1).

---

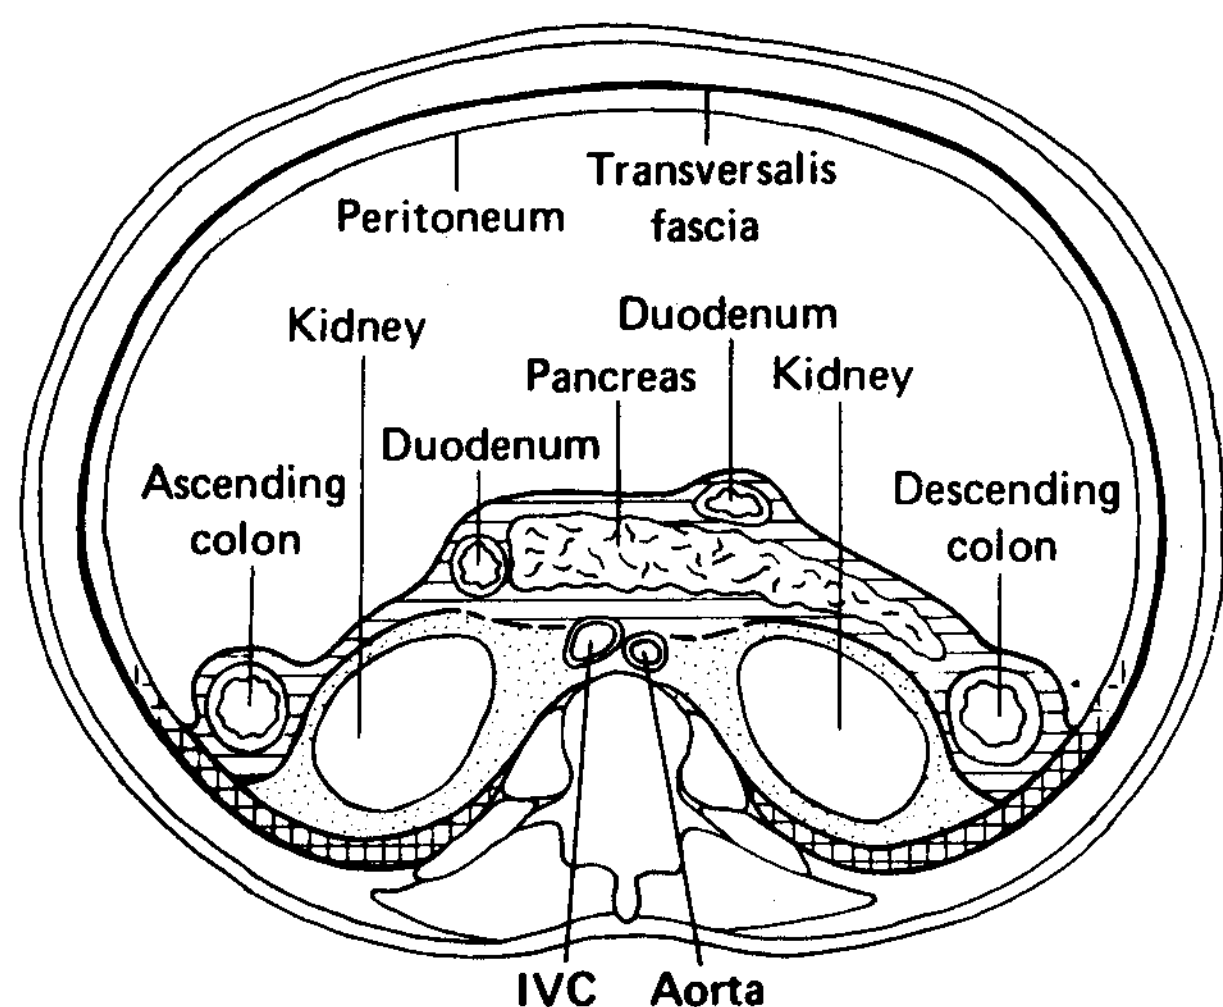

## Renal Tuberculosis

---

Renal tuberculosis is caused by hematogenous dissemination from an infected source elsewhere in the body. Though both kidneys are seeded with tuberculosis bacilli in 90% of cases, clinical renal tuberculosis is usually unilateral. The initial lesion involves the renal cortex, and if they fail to heal spontaneously,

**FIGURE 8.1** Right sagittal view showing the anterior pararenal, perirenal, posterior pararenal, and retrofascial spaces. (From Simons GW, Sty JR, Starshak RJ. Retroperitoneal and retrofascial abscess. *J Bone Joint Surg* 1983;65A:1041, reprinted with permission from The Journal of Bone and Joint Surgery, Inc.)

**FIGURE 8.2** The three retroperitoneal compartments. The striped and crosshatched areas correspond to the perirenal and posterior pararenal space, respectively. (From Meyers MA. Dynamic radiology of the abdomen. In: *Normal and pathologic anatomy*, 2nd ed. New York: Springer-Verlag, 1982:107–110, with kind permission of Springer Science and Business Media.)

the lesions may progress slowly and remain asymptomatic for 10 to 40 years. As the lesions progress, caseous necrosis and parenchymal cavitation occur with fibrous walls that resemble solid mass lesions. Once cavities form, spontaneous healing is rare and destructive lesions ensue, with spread of the infection to the renal pelvis, resulting in a pyonephroticlike

“putty” kidney and development of a parenchymal or perinephric abscess.

## Echinococcus

Echinococcosis is a benign parasitic infection caused by the larval growth of the canine tapeworm *Echinococcus granulosus*. Echinococcal or hydatid cysts occur in the kidney in 3% of patients with this disease. The hydatid cyst gradually develops at a rate of about 1 cm per year and is usually solitary and located in the cortex. The hydatid cyst is composed of a parasitic membrane that is surrounded by a nonparasitic pericyst membrane due to the resultant reactive renal tissue.

## DIAGNOSIS

The diagnosis of renal and retroperitoneal abscesses requires a high index of suspicion, as they typically present with insidious, nonspecific signs and symptoms. The physical findings often do not correlate with the severity of disease (4,10). Many contemporary studies show that only one-third of patients are correctly diagnosed at the time of hospital admission, with an average delay in diagnosis of 3 to 4 days (10). Presenting symptoms may include any combination of fever, chills, abdominal or flank pain, irritative voiding symptoms, nausea, vomiting, lethargy, or weight loss. Patients with renal and retroperitoneal abscesses more often have a longer duration of symptoms as compared with patients with pyelonephritis. The

TABLE 8.1

## CHARACTERISTICS OF RENAL AND RETROPERITONEAL ABSCESES

Site	Source	Organism	Cofactors	Treatment
Cortical intrarenal	Hematogenous	<i>Staphylococcus aureus</i> and other gram positives	IV drug use and immunocompromised patients	Antibiotics
Intrarenal	Urinary tract	Gram negative Anaerobe (2) ( <i>Escherichia coli</i> , <i>Proteus</i> , <i>Klebsiella</i> ), immunocompromised (opportunistic organisms, including <i>Candida albicans</i> , <i>Aspergillus</i> , <i>Torulopsis glabrata</i> ) (12,13)	Pyelonephritis with reflux, obstruction, (calculous disease) (16) or immunocompromised patient	Antibiotics + drainage, +/- nephrectomy if non-functional kidney or progressive infection
Perirenal	Intrarenal abscess or pyonephrosis eroding into perirenal space	Gram negative ( <i>Escherichia coli</i> , <i>Proteus</i> , <i>Klebsiella</i> )	Often localizes to the lower pole kidney	Antibiotics + drainage, +/- nephrectomy if non-functional kidney or progressive infection
Posterior pararenal	Spinal infections, perirenal abscesses, or anterior pararenal abscesses			Antibiotics + drainage, +/- nephrectomy if non-functional kidney or progressive infection
Anterior pararenal	Gastrointestinal (colon, appendix, pancreas, duodenum)	Mixture including <i>Escherichia coli</i> and anaerobes		Antibiotics + drainage, +/- nephrectomy if non-functional kidney or progressive infection

majority of patients diagnosed with renal and retroperitoneal abscesses have underlying, predisposing medical conditions. These include diabetes mellitus, urinary tract calculi, previous urologic surgery, urinary tract obstruction, polycystic kidney disease, malignancy, and immunosuppression.

A palpable flank or abdominal mass is present in about one-third of cases. The mass may be better appreciated by examination of the patient in the knee-chest position. There may also be signs of psoas muscle irritation with flexion of the thigh.

Laboratory tests are helpful but nondiagnostic. Leukocytosis, elevated serum creatinine, and pyuria are common. In up to 30% of gram-negative abscesses, the abscess does not involve the collecting system and urine cultures are frequently negative. Positive urine cultures will generally correlate with blood cultures in the setting of retrograde gram-negative abscesses. In abscesses secondary to gram-positive organisms, however, the urine culture and blood culture may reflect different isolates. Overall, positive urine cultures coincide with culture results from the abscess in only 40% of cases, and the microorganisms isolated in positive blood cultures are similar to those in the abscess culture in 60% of cases.

Computerized tomography (CT) of the abdomen and pelvis with intravenous contrast remains the radiographic study of choice and can precisely localize and detect an abscess <2 cm in size, thereby determining the type of intervention and its anatomic approach. The presence of gas within a lesion is pathognomonic for an abscess. Additional CT findings characteristic of an abscess include a mass with low attenuation, rim enhancement of the abscess wall after contrast, obliteration of tissue planes, and displacement of surrounding structures. Other studies that may be used include ultrasonography or magnetic resonance imaging (MRI).

## INDICATIONS FOR SURGERY

Renal and retroperitoneal abscesses are generally lethal if untreated. Therapeutic options include antimicrobial therapy alone or in combination with percutaneous catheter drainage or open surgical drainage. Nephrectomy is typically reserved for those with nonfunctioning kidneys. If a perinephric abscess is due to long-standing obstruction and there is no functioning renal tissue, a nephrectomy at the time of drainage is theoretically attractive. Initially, however, drainage of the abscess should be performed as the primary procedure, with nephrectomy performed at a later date if necessary. Patients are frequently too ill for prolonged general anesthesia and surgical manipulation. After drainage of the abscess, removal of obstruction, and appropriate antimicrobial therapy, many kidneys may regain sufficient function to obviate future nephrectomy. Nephrectomy, if indicated, can be performed using a standard simple open nephrectomy approach or as a subcapsular nephrectomy. A small renal abscess confined to one pole of the kidney may be managed by partial nephrectomy. If the infection extends beyond the apparent line of cleavage, however, it is essential to remove all infection, and the line of excision should extend through healthy tissue. If multiple abscesses are present, internal drainage is difficult and nephrectomy may be required.

Antimicrobial therapy should be instituted after the urine has been Gram stained and urine and blood cultures have been obtained. Broad-spectrum coverage should be guided by the presumptive diagnosis and the presumed pathogen. A third-generation cephalosporin or an aminoglycoside for gram-negative rods and ampicillin for gram-positive cocci are preferred. Intravenous piperacillin/tazobactam may be used in patients

with renal insufficiency. Anaerobic coverage with a drug such as clindamycin is warranted when Gram stain reveals a polymicrobial flora or when a GI source is suspected. If the abscess is suspected of staphylococcal origin, a penicillinase-resistant penicillin, such as nafcillin, should be added. Antimicrobial therapy should be re-evaluated when culture and sensitivity test results are available. Unfortunately, urine and blood cultures are frequently sterile, and empirical therapy must be modified on the basis of clinical response and changes in imaging studies.

---

### Renal Tuberculosis

---

Surgery for renal tuberculosis is reserved primarily for management of local complications, such as drainage of abscesses or tuberculous cavities or for treatment of nonfunctioning kidneys. If segmental renal damage is obvious and salvage of the kidney is possible, a drainage procedure or cavernostomy can be performed (6). Removal of a nonfunctioning kidney is usually indicated for advanced unilateral disease complicated by sepsis, hemorrhage, intractable pain, newly developed severe hypertension, suspicion of malignancy, inability to sterilize the urine with drugs alone, abscess formation with development of fistula, or inability to have appropriate follow-up (3,9,14). If surgery is warranted, it is wise to precede the operation with at least 3 weeks and preferably 3 months of a four-drug chemotherapy regimen. In adults, use of isoniazid, 300 mg per day; pyrazinamide, 20 to 25 mg per kg daily; rifampin, 600 mg per day; and ethambutol, 15 to 20 mg per kg daily is recommended unless individual drug resistance exists.

---

### Echinococcus

---

The symptoms are those of a slowly growing tumor; most patients are asymptomatic or have a dull flank pain or hematuria. Hydatiduria is pathognomonic for the disease but occurs in only 5% to 25% of cases. As a result of cyst rupture directly into the collecting system, patients exhibit passage of grapelike materials in the urine. Excretory urography typically shows a thick-walled cystic mass that is occasionally calcified. Ultrasonography and CT usually show either a unilocular or multivesicular cyst. Confirmation of the diagnosis is most reliably made by diagnostic tests using partially purified hydatid antigens in a double-diffusion test (14). Complement fixation and hemagglutination are less reliable. Diagnostic needle puncture is associated with significant risk of anaphylaxis as a result of leakage of toxic cyst contents. Cyst removal is indicated when an enlarging cyst threatens renal function or produces obstruction.

---

## ALTERNATIVE TREATMENT

---

Antimicrobial therapy as the sole treatment is an option with resolution of symptoms in a small percentage of renal abscesses depending on size, location, and other factors (1). Small intrarenal abscesses (<4 to 5 cm) may resolve if they are treated early at the carbuncle stage or have minimally liquefied through aggressive antimicrobial therapy. Similarly,

antimicrobial therapy with close observation alone has been advocated in select patients with small perirenal abscesses (<3 cm) and stable patient conditions (4,10). Prolonged antimicrobial therapy without drainage is indicated only if favorable clinical response and radiological confirmation of abscess resolution indicate that therapy is effective. This form of therapy has proven more successful in children when compared to adults and least successful in immunocompromised patients. If antimicrobial therapy is not effective, prompt percutaneous or open surgical drainage of the pus is mandatory.

---

## SURGICAL TECHNIQUE

---

---

### Percutaneous Drainage

---

Most renal and retroperitoneal abscesses are treated with empirical antimicrobial therapy and immediate percutaneous drainage. With resolution of the abscess occurring at least two-thirds of the time, minimally invasive therapy eliminates operative morbidity and allows for preservation of renal tissue. In those patients with a remaining surgical indication, percutaneous drainage can help delay surgery and allow the patient's condition to be optimized. The abscess must be confirmed by CT- or ultrasonography-guided needle aspiration and must be drainable without injury to other organs. Contraindications to percutaneous puncture include coagulation disorders and calcified masses, which may indicate other processes. Immediate surgical drainage must be instituted if the procedure fails. After a multiport drainage catheter (8Fr to 12Fr) is positioned, the abscess should be drained and adequate evacuation should be confirmed by CT or ultrasonography. In the setting of abscess septation or multiloculation, multiple catheters or septal perforation during catheter placement may be utilized. The catheter should then be connected to low intermittent suction, and drainage outputs should be monitored daily. If drainage stops abruptly, occlusion of the catheter should be suspected and gentle irrigation with small amounts of normal saline performed. CT or ultrasonography should be performed periodically to monitor catheter position and size of the abscess. Direct instillation of contrast through the drainage tube may be helpful to confirm the catheter position or rule out a fistula. To avoid bacteremia, prophylactic antimicrobial coverage should be given, and the contrast should be instilled under gravity or by gentle injection. Instillation of 2,500 U of urokinase in 50 mL of normal saline on a daily basis may be successful in evacuating an organizing infected hematoma. Routine abscess irrigation with antimicrobials is of questionable benefit and may promote overgrowth of resistant bacteria. The catheter should be withdrawn gradually as the abscess cavity shrinks and the drainage decreases. The usual duration of drainage is 1 to 3 weeks. The catheter is removed when drainage stops, CT or ultrasonography confirms complete resolution, and fevers and leukocyte count normalize.

---

### Open Surgical Drainage

---

In the case of failed percutaneous therapy, open surgical drainage is usually the next step. Open surgery allows for direct anatomic evaluation and a determination of the extent of the inflammatory process. In addition, more complex

pathology may be delineated, including chronic fistulas suggesting residual stone, foreign body, or persistent renal obstruction or, rarely, carcinomas that predispose a kidney to abscess formation and thus prevent a cure with only simple drainage.

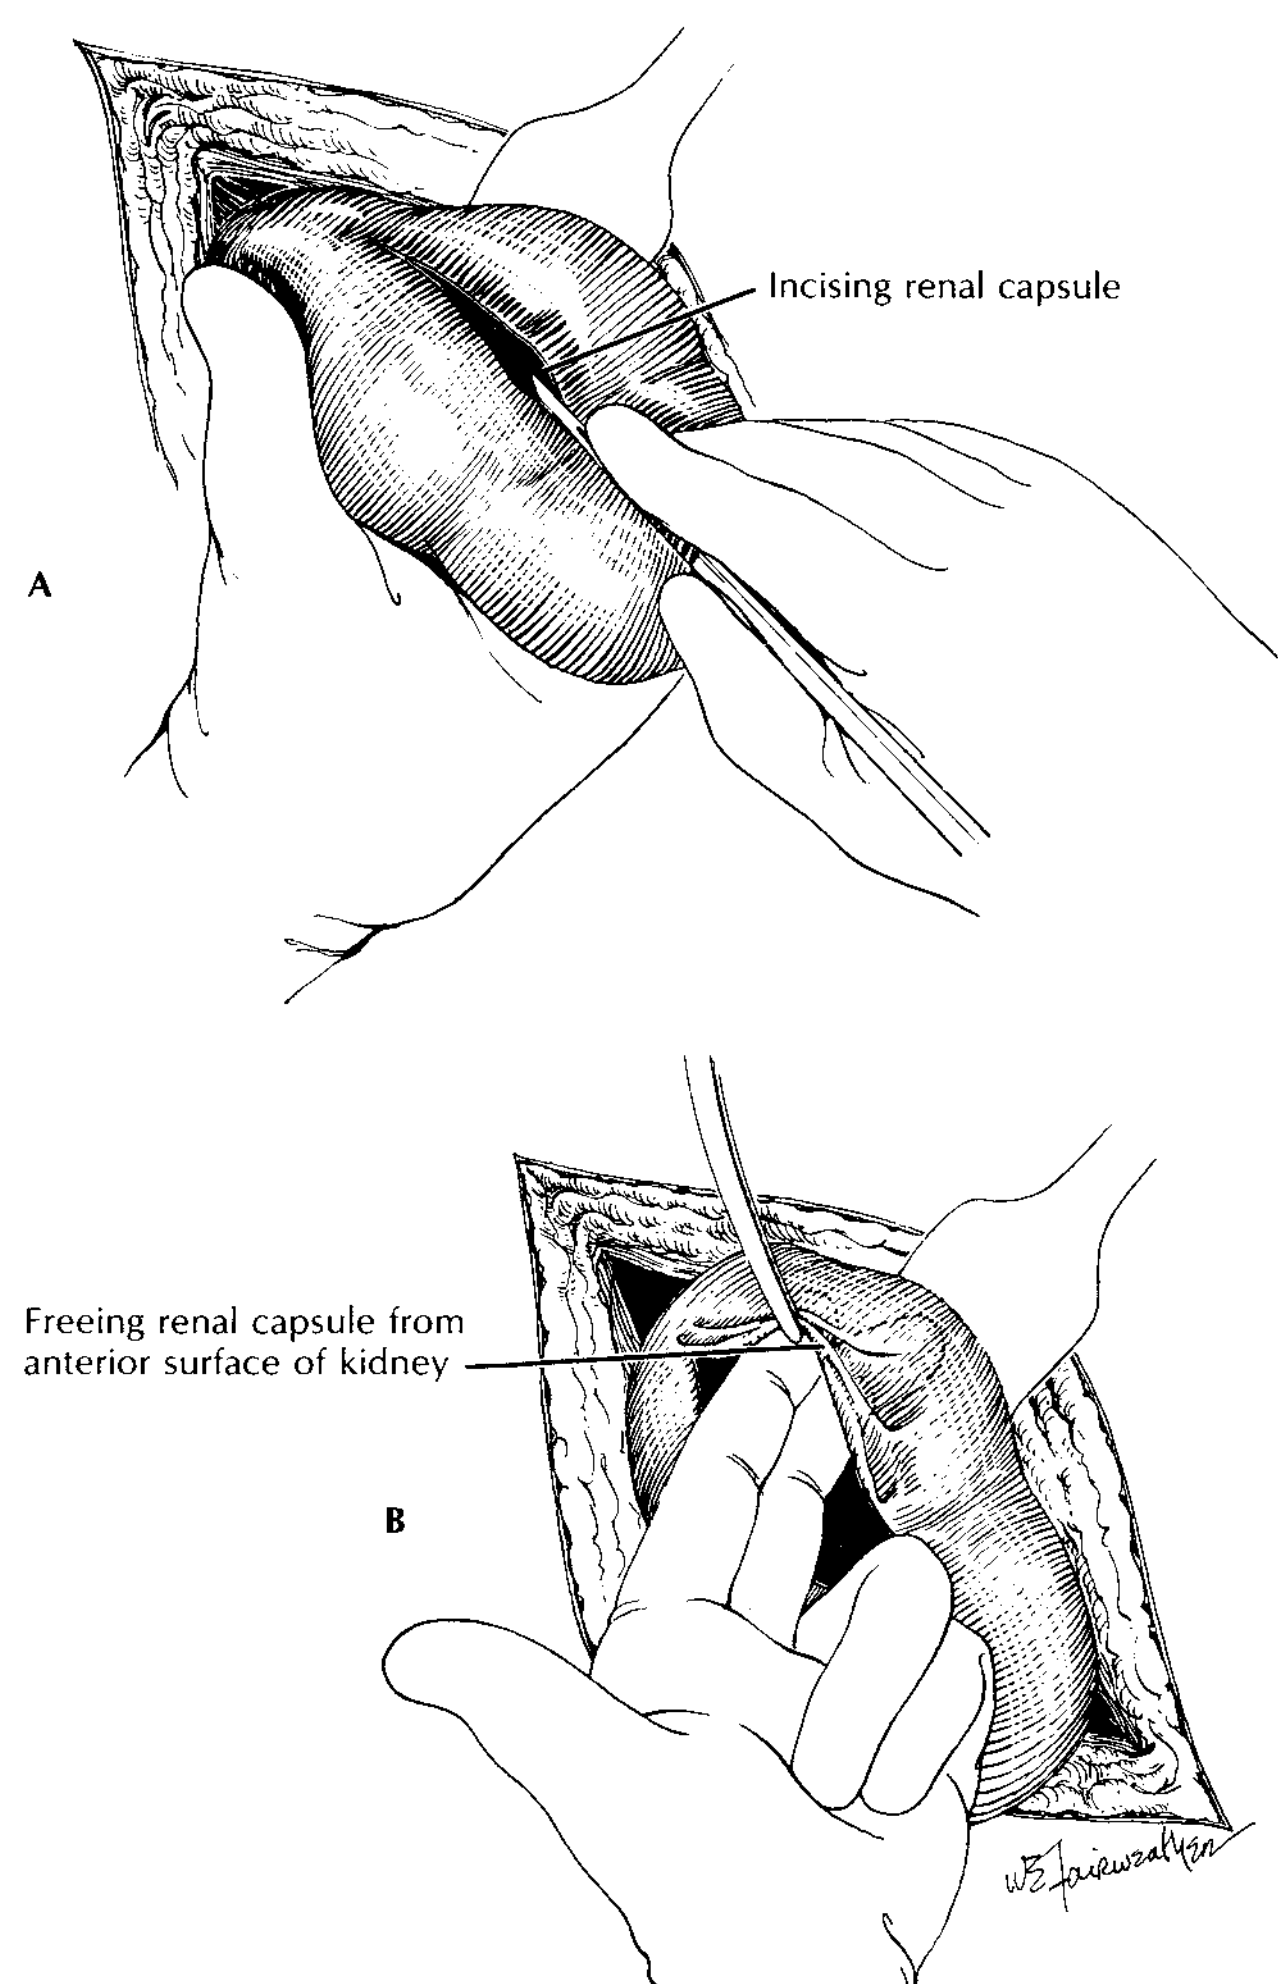

For open surgical drainage, the incision should be smaller than that used for routine nephrectomy, and usually a posterior flank muscle-splitting incision below the twelfth rib is sufficient. When the retroperitoneal abscess is entered, the pus should be cultured and the space gently but thoroughly explored to ensure that all loculated cavities are drained. Thorough irrigation of the cavity is essential. Multiple Penrose drains should be inserted into the space through separate stab wounds, and the ends of the drains should be sutured to the skin and tagged with safety pins. Fascial and muscular closure may be performed with chromic catgut suture, but skin and subcutaneous tissue should be left open to prevent the formation of a secondary body wall abscess. The wound can be left to heal from within, or skin sutures may be placed and left untied for dermal approximation 5 to 7 days postoperatively after drainage has ceased. The wound should be packed with gauze and the packs changed daily. The drains should be left in place until purulent drainage has decreased, and then removed slowly over several days.

### Subcapsular Nephrectomy

When a kidney is so adherent to surrounding tissues that dissection is difficult and hazardous, a subcapsular nephrectomy is indicated. These conditions may result after multiple or chronic infections or previous operations resulting in significant fibrotic adhesions between Gerota fascia and the perirenal fat. Blunt dissection can result in tearing of structures such as the bowel wall. Sharp dissection when there is no definable tissue plane often results in lacerations of the vena cava, aorta, duodenum, spleen, and other structures. In subcapsular nephrectomy, dissection beneath the renal capsule enables one to avoid these vital structures. Subcapsular nephrectomy should not be performed for malignant disease.

The main difficulty with subcapsular nephrectomy is that the capsule is adherent to the vessels in the hilum, and one usually must go outside the capsule to ligate the renal pedicle. In this setting, the renal hilum is usually involved in the inflammatory reaction, and separate identification of the vessels is difficult.

Kidney exposure is accomplished through the flank using a twelfth-rib incision. For low-lying kidneys, a subcostal incision may be satisfactory. When the kidney is reached, the capsule is incised and freed from the underlying cortex (Fig. 8.3). To avoid damage to the duodenum or major vessels, pieces of capsule may be left behind. However, prolonged drainage can ensue, and as much of the infected tissue should be removed as possible. The capsule is stripped from the surface of the kidney and an incision is made carefully in the capsule where it is attached to the hilum (Fig. 8.4). The vessels may be protected by placing a finger in front of the pedicle when cutting the capsule. The dense apron of the capsule can usually be incised best on the anterior aspect. Controlling bleeding can be difficult in this procedure, and a harmonic scalpel or bipolar electric coagulation device may be utilized to minimize hemorrhage.

**FIGURE 8.3** Subcapsular secondary nephrectomy showing freeing of the capsule from anterior surfaces of the kidney.

Frequently, all landmarks are obscured and the renal artery and vein cannot be identified. Sharp dissection is usually required, and major vessels may be entered before they are recognized. Fortunately, the dense fibrous tissue tends to prevent their retraction. Frequently, a combination of suture ligatures, clips, or a vascular load stapler can be used to divide the renal vessels. After ligation and cutting of the pedicle, the ureter is identified and cut and the distal end is ligated. If distal ureteral obstruction has caused pyonephrosis, a small, 8Fr to 10Fr red Robinson catheter may be placed in the distal ureter to allow postoperative antimicrobial irrigation. Multiple drains should be placed and brought through separate stab wounds.

### Laparoscopic Treatment of Renal Abscesses

Historically, the dense perinephric adhesions associated with renal abscess disease and the resultant high open conversion rate were relative contraindications to laparoscopic simple and subcapsular nephrectomy. However, more recent series involving laparoscopic techniques have shown feasibility in select patients with possible advantages in postoperative

**FIGURE 8.4** Subcapsular secondary nephrectomy showing incision in and removal of a portion of the renal capsule to expose and ligate the renal pedicle.

recovery and blood loss as compared to open studies. Similar to the open technique, dissociation and ligation of the renal pedicle remain the most challenging surgical step and may be facilitated with careful dissection using a harmonic or bipolar scalpel and an endoscopic linear stapler for the hilum. Given the potential to limit seeding of the peritoneum with infectious tissue, a retroperitoneal approach has been advocated. However, laparoscopic therapies remain technically challenging, and current reported experiences in the literature are small (7,17).

---

### Cavernostomy for Segmental Renal Tuberculosis

---

Renal tuberculosis sometimes results in caliceal infundibular scarring, causing a closed pyocalix abscess. In cases of sepsis, cavernostomy or unroofing of the pyocalix may be necessary. If the calyx still communicates with the renal pelvis, or if it is connected to significant functioning parenchyma, a cavernostomy should not be done as a urinary fistula or urinoma may result. To minimize wound contamination and tuberculous spread, thorough needle aspiration of purulent material and

saline irrigation of the abscess cavity should be performed using a large-bore needle and syringe (Fig. 8.5). The abscess cavity is then unroofed and the edge is sutured with a running suture for hemostasis. Any unsuspected connection with the renal pelvis by an open infundibulum must be closed using 5-0 chromic catgut sutures to prevent fistula or urinoma formation. After thorough wound irrigation, multiple drains are placed and closure is undertaken. Drains are managed as previously described for perinephric abscess.

---

### Nephrectomy for Renal Tuberculosis

---

When unilateral tuberculosis causes more extensive parenchymal destruction or nonfunction, a partial or total nephrectomy, respectively, should be performed. Particular care should be taken to avoid entering the peritoneum or pleura. For partial nephrectomy, a guillotine incision is made 1 cm beyond the abscess. If the renal pedicle can be freed and the polar vessel located and occluded, the incision can be made at the line of demarcation of the ischemia. In partial nephrectomy, it is important to try to save the

**FIGURE 8.5** Cavernostomy drainage of tuberculous renal abscess. (From Hanley HG. Cavernostomy and partial nephrectomy in renal tuberculosis. *Br J Urol* 1970;42:661, with permission.)

capsule (if it is not involved with the infection) to cover the raw surface for hemostasis. Alternatively, fat can be used for hemostasis. The amputated calyx is carefully ligated with a 4-0 chromic catgut suture to prevent urinary fistula or urinoma formation.

After nephrectomy, the distal ureter can be ligated and in most cases does not need to be brought to the skin because tuberculosis of the ureteral stump generally heals with chemotherapy after nephrectomy. If renal tuberculosis is associated with severe tuberculosis cystitis, ureteral catheterization for 7 days postoperatively to minimize subsequent ureteral stump abscess formation should be considered (3).

### Resection of Echinococcal Cyst

The cyst should be removed without rupture to reduce the chance of seeding or anaphylactic-type reaction, which can prove fatal in the operating room. In cases where cyst removal is impossible because of its size or involvement of adjacent organs, marsupialization is required. Initially the cyst should be isolated with sponges, the contents aspirated, and the cyst filled with a scolicial agent such as 30% sodium chloride, 2% formalin, or 1% iodide for about 5 minutes to kill the germinal portions. Complete evacuation of all hydatid tissue and

thorough postmarsupialization irrigation are critical to preventing systemic effects. Total or partial pericystectomy can subsequently be carried out to remove the surrounding pericyst, and any open calyces can be closed. Penrose drains are left in the cystic cavity until drainage ceases. If large amounts of renal tissue have been damaged, partial or simple nephrectomy may be required.

## OUTCOMES

### Complications

Complications associated with percutaneous drainage include the formation of additional abscesses that communicate with the renal collecting system and may require temporary urinary diversion via percutaneous nephrostomy drainage to affect a cure. Sepsis, the most frequent complication of percutaneous drainage, occurs in fewer than 10% of patients. Other complications, such as transpleural puncture, vascular or enteric injury, and cutaneous fistula, are rare.

Additional complications to open or percutaneous drainage include prolonged purulent drainage, which may indicate a retained foreign body, calculus, or fistula.

---

## Results

---

Cure rates for percutaneous drainage of renal and retroperitoneal abscesses range from 60% to 90% (9,16). Multiloculated, viscous abscesses and abscesses in immunocompromised hosts are associated with lower cure rates. Large abscesses may require more than one percutaneous access procedure to completely drain them.

In the past, mortality rates were reported to be as high as 50% in patients with retroperitoneal or perinephric abscesses. More recent reports indicate a significant improvement in mortality (<15%); this is largely due to more accurate diagnosis and drainage using improved imaging techniques, more effective antimicrobial therapy, and better supportive care (4,5,10).

# CHAPTER 9 ■ RENAL TRAUMA

JILL C. BUCKLEY AND JACK W. MCANINCH

Renal injuries occur infrequently in trauma patients, with a reported incidence between 2% and 3% (1). The vast majority of renal injuries occur as a result of blunt trauma, are grades I to III, and can be managed nonoperatively (1,2). Penetrating renal trauma usually occurs in conjunction with other intra-abdominal injuries where urgent laparotomy is performed. Grade V renal injuries by definition represent life-threatening renal injuries that require operative exploration and often nephrectomy. Grade IV renal injuries represent the most controversial management issue in renal trauma care. Many blunt and penetrating grade IV renal injuries can be successfully managed nonoperatively if the patient has been appropriately staged with computerized tomography (CT) and can be closely monitored in an intensive care unit (ICU) (3). If radiographic renal staging is not available or the patient requires immediate abdominal laparotomy for an associated neurologic injury, renal exploration is indicated after obtaining an intraoperative single-shot intravenous pyelogram (IVP). In hemodynamically stable patients, renal reconstruction at the

time of laparotomy provides excellent functional results in the majority of cases (4). The goal of all renal trauma care is preservation of enough functioning nephron mass to avoid end-stage renal failure. Nephrectomy is reserved for a life-threatening injury where damage control is necessary.

---

## DIAGNOSIS

---

As with all trauma situations, the patient should undergo an acute assessment and resuscitation as defined by the American Association for the Surgery of Trauma (AAST). The hemodynamic stability of the patient will determine if an immediate operative exploration is required versus radiographic CT staging. The type of trauma (blunt versus penetrating), mechanism of injury (e.g. deceleration injury), physical examination (presence of a rib fracture or spinous process fracture, abdominal or flank tenderness, flank ecchymosis, etc.), associated neurologic injuries, hemodynamics, and degree of

hematuria are important to obtain in the initial assessment. If gross hematuria is not present, a urine dipstick analysis or formal urine analysis should be performed to detect microscopic hematuria. The degree of hematuria does not correlate with the degree of renal injury but is useful in guiding the initial emergency department assessment.

---

## IMAGING

---

All penetrating trauma should undergo CT radiographic imaging. Any patient sustaining a blunt trauma injury with a positive physical examination, a deceleration injury, gross hematuria, microscopic hematuria in the setting of hypotension (systolic blood pressure  $<90$  mmHg in the field or in the emergency department), or serial decreasing hematocrits should undergo radiographic CT imaging to stage the renal injury (1,5). Triple-phase CT radiographic imaging allows detailed staging of the renal injury by evaluating the renal hilum, parenchyma, collecting system, and surrounding tissue, as well as detecting other intra-abdominal injuries. It is important to obtain delayed images to document that the collecting system is intact, with contrast passing down into the distal ureter without extravasation (6).

In pediatric trauma patients, special attention should be given to the degree of microscopic hematuria present, as this alone may warrant CT radiographic imaging. Children are often able to maintain their hemodynamics despite underlying hypovolemia; thus blood pressure readings can be falsely reassuring. Unlike with the adult patient, isolated significant microscopic hematuria defined as  $>50$  red blood cells per high-powered field should prompt radiographic CT imaging (7,8). As stated above, the type of trauma (blunt versus penetrating), mechanism of injury (e.g. deceleration injury), physical examination (presence of a rib fracture or spinous process fracture, abdominal or flank tenderness, flank ecchymosis, etc.), and associated nonurologic injuries in hemodynamically stable children should all undergo radiographic CT staging of the renal injury.

If immediate laparotomy is required, a single-shot IVP should be performed in the operating room. A bolus IV injection of 2 cc per kg of radiographic contrast is given followed by a 10-minute plain film of the abdomen and pelvis. It is critical to document a functioning contralateral kidney should a nephrectomy be required of the injured renal unit. With a normal single-shot intraoperative IVP demonstrating two intact renal units and a nonexpanding retroperitoneal hematoma, exploration can be avoided (9).

---

## MANAGEMENT

---

Management of the injured kidney is based on consideration of the patient's mechanism of injury, hemodynamic stability, associated injuries, and accurate radiographic staging of the injury (1). The vast majority of blunt traumatic renal injuries are clinically insignificant. Fewer than 2% of patients with blunt renal trauma require renal exploration (1,2) (Fig. 9.1).

Historically, all penetrating abdominal injuries underwent laparotomy. Now, with improved diagnostic radiographic imaging, many intra-abdominal and renal injuries can be staged and managed with nonoperative active surveillance in ICUs

**FIGURE 9.1** Abdominal computerized tomography (CT) reveals left renal laceration after blunt trauma (grade III). Even major renal lacerations occurring after blunt trauma are usually amenable to nonoperative management. Renal CT provides detailed information regarding the depth of laceration, size of perirenal hematoma, tissue viability, urinary extravasation, and status of the contralateral kidney.

combined with repeat imaging (3,10). If conservative management is chosen, it is the responsibility of the treating physician to document a stable or improving situation through clinical parameters and repeat imaging. All patients who sustain a major renal trauma should be admitted to the ICU for serial hematocrits, placed on bedrest, and have repeat CT imaging performed 48 hours after the initial staging CT scan or earlier if there is a significant change in their clinical course (3). Active surveillance ensures appropriate management either by demonstrating resolution of the renal injury or by prompting intervention, such as ureteral stent placement for nonresolving urinary extravasation or angioembolization of a segmental artery for persistent arterial extravasation (11,12). In all cases of severe renal injury, nonoperative management should only occur after radiographic CT renal staging in hemodynamically stable patients with close peritraumatic monitoring.

---

## ANGIOEMBOLIZATION

---

The minimally invasive technique of angioembolization along with radiographic CT imaging has led to a dramatic shift in trauma care in large urban centers where interventional radiology expertise is available. A clear role has emerged for selective segmental arterial embolization in a subset of severe renal injuries to control significant bleeding (13,14). Renal hilar injuries are life-threatening and require immediate operative exploration (15). As with all severe renal injuries, selection is critical for successful management, along with having available and capable interventional radiologists or trained vascular or trauma surgeons. Indications include non-life-threatening bleeding isolated to a segmental renal artery or vein in the setting of an expanding perirenal hematoma or refractory hypovolemia ( $>3$  units of blood transfusion). The embolized vessel is typically a segmental artery, as venous bleeding will often tamponade provided Gerota fascia is still intact (Fig. 9.2). Embolization will lead to nephron loss and should be restricted to active arterial extravasation. Selective embolization has

**FIGURE 9.2** Angioembolization of active segmental arterial extravasation.

demonstrated excellent preservation of the remaining kidney for not only renal trauma injuries but also for symptomatic angiomyolipomas, spontaneous perirenal bleeds, pseudoaneurysms, and iatrogenic renal vascular injuries and has resulted in shorter hospital stays, decreased pain, and fewer complications by avoiding open exploration (14,16,17). Endovascular procedures will continue to expand their role in the acute trauma setting as comfort and experience with these minimally invasive techniques grow.

## INDICATIONS FOR RENAL EXPLORATION

An absolute indication for renal exploration is life-threatening hemorrhage from a severely injured renal unit. Relative indications for operative exploration include ureteropelvic junction disruption, extensive nonviable renal parenchyma with urinary extravasation, incomplete radiographic staging, and limited observational facilities (Table 9.1). In the setting of a concomitant exploratory laparotomy by the trauma surgeons, our preference is to formally explore and reconstruct any

**TABLE 9.1**

### INDICATIONS FOR RENAL EXPLORATION

<p><b>ABSOLUTE</b></p> <ul style="list-style-type: none"> <li>Expanding renal hematoma</li> <li>Pulsatile hematoma</li> <li>Complete ureteropelvic junction disruption</li> </ul> <p><b>RELATIVE</b></p> <ul style="list-style-type: none"> <li>Urinary extravasation associated with nonviable tissue</li> <li>Large area of nonviable renal parenchyma</li> <li>Significant arterial extravasation<sup>a</sup></li> <li>Incomplete staging</li> </ul>
<p><sup>a</sup>Interventional radiology is not available or is unable to control the bleeding.</p>

significant renal injury (grade III or greater) in a hemodynamically stable patient. Minimal time is added to the operation, and outcomes are excellent (4). Successful reconstruction can be undertaken despite spillage from bowel injury, pancreatic injury, or other associated injuries (18).

In both blunt and penetrating isolated severe renal trauma (no other significant intra-abdominal injuries), selective management is employed to determine if exploration is indicated based on the hemodynamics of the patient, radiographic CT staging of the renal injury, and clinical assessment (3,19). In our large series of grade IV renal injuries, 28% were isolated kidney injuries, 42% underwent exploration, and the remaining 58% were managed nonoperatively. Persistent bleeding requiring multiple blood transfusions was the primary indication for renal exploration (average transfusion requirement of 8.5 U packed red blood cells (prbc)). Our guidelines for intervention are hemodynamic instability causing severe hypotension and shock, a rapidly expanding renal hematoma, persistent hemodynamic instability despite 3 U prbc, and clinical decompensation (3). Renal salvage rates were high (>85%) for both operative and nonoperative management, demonstrating the utility and importance of selective management.

## NEPHRECTOMY

Nephrectomy should be reserved for critically ill patients during a damage control situation and/or renal pedicle avulsions that require complex vascular reconstruction. Critical to document in those acute settings is a functioning contralateral kidney with a single-shot IVP. These patients are often in shock, have high injury severity scores, receive large volumes of blood transfusions, and overall experience a high mortality rate. As stated by Nash et al., “It is not the exploration that results in the nephrectomy but the injury itself” (20).

## SURGICAL TECHNIQUE

Renal exploration in the trauma setting should be carried out through a standard midline abdominal incision (Fig. 9.3). This approach provides complete access to the intra-abdominal viscera and vasculature and also gives the greatest flexibility to assess and repair a variety of genitourinary injuries. Major bleeding noted on opening the abdominal cavity should be controlled immediately with laparotomy packs followed by surgical control and repair. Associated injuries to other abdominal organs are usually addressed before examination of the kidneys if the patient is stable. The bowel, liver, spleen, pancreas, and other organs should be inspected systematically and carefully. During this period, Gerota fascia maintains its natural tamponade effect on the perinephric hematoma.

The renal vasculature is routinely isolated before entering the retroperitoneal hematoma surrounding the injured kidney. This reduces the risk of uncontrolled renal bleeding and unplanned nephrectomy (21,22). To facilitate access to the retroperitoneum, the transverse colon is lifted out of the abdomen superiorly and placed on moist laparotomy packs. The small bowel is rotated to the patient's right and extracted from the body to allow access to the great vessels. An incision is

**FIGURE 9.3** A midline incision provides the optimal exposure for abdominal exploration, vascular control, and repair of a variety of genitourinary injuries.

made in the retroperitoneum over the aorta from the level of the inferior mesenteric artery to the ligament of Treitz, which can be divided for additional exposure. If a large retroperitoneal hematoma obscures the aorta, the inferior mesenteric vein is identified and the incision into the retroperitoneum is placed just medial to this important landmark. Once the aorta is identified in the lower part of the incision, it is followed superiorly to the left renal vein, which reliably crosses anteriorly. The renal arteries can be found just posterior to the left renal vein on either side of the aorta. The right renal artery can be isolated in the interaortocaval location. If it is difficult to identify the right renal artery through this approach, the second portion of the duodenum can be reflected to expose the right renal hilum. The artery is located posterior to the right renal vein.

The renal artery and vein associated with the injured renal unit are individually isolated with vessel loops. These vessels are not occluded initially unless uncontrollable bleeding is encountered. Most bleeding is successfully controlled with manual compression alone. Because the vessels are not routinely clamped, renal perfusion is continuous and warm ischemia is avoided.

Following proximal vascular control, the kidney is exposed by incising the retroperitoneum just lateral to the colon. The colon is reflected medially. Gerota's fascia is sharply opened, and the kidney is expeditiously mobilized to allow complete exposure of the renal surface (Fig. 9.4). Only after complete exposure can the extent and number of injuries be determined (Fig. 9.5/6). Maintaining the renal capsule during mobilization

**FIGURE 9.4** The colon is reflected medially to allow access to the retroperitoneum. Gerota's fascia is sharply opened.

is important as it provides hemostasis and tensile strength for the closure. If necessary for uncontrollable hemorrhage, clamping of the previously isolated vessels can be done with vascular clamps or bulldogs.

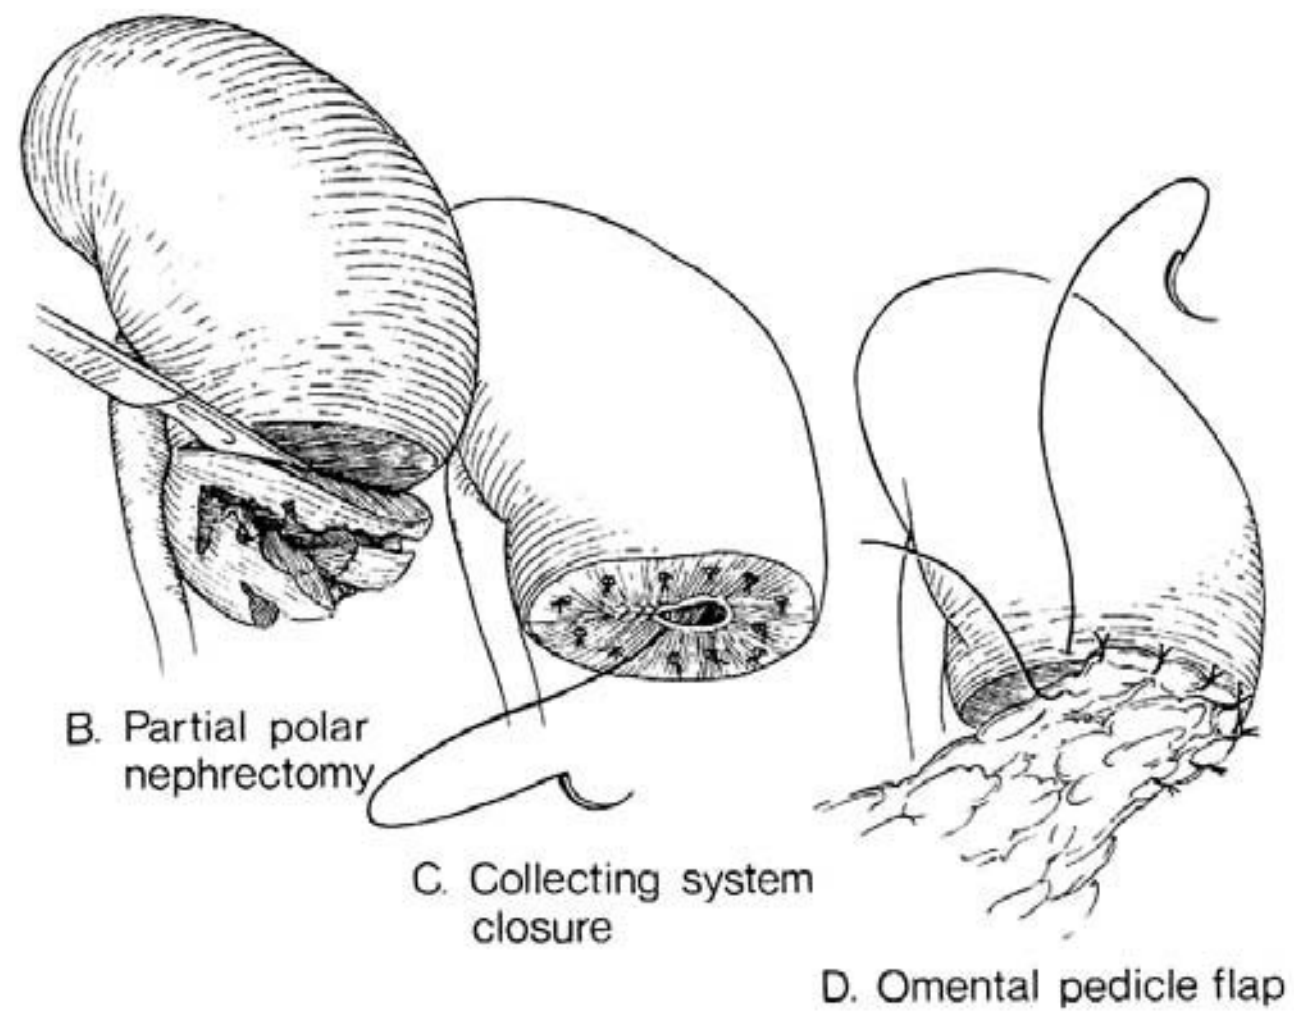

The following principles are applied to all renal reconstructions: early vascular control, complete renal exposure, sharp debridement of nonviable tissue, oversewing of bleeding vessels for hemostasis, and watertight collecting system closure. If available, the renal capsule is loosely reapproximated over thrombin-soaked Gelfoam or another thrombogenic substance. Ideally an omental flap is placed over the reconstructed kidney for additional protection and its absorptive properties.

Major polar injuries are best approached by a polar partial nephrectomy. The kidney should be sharply debrided back to viable bleeding tissue. End vessels are individually suture-ligated with 4-0 absorbable sutures to gain hemostasis. The collecting system is then closed with a continuous watertight 4-0 absorbable suture. Methylene blue may be injected into the renal pelvis with simultaneous compression of the ureter to elucidate any leaks in the collecting system, which may then be oversewn however, oversewing is not routinely performed. The renal parenchymal defect is covered with thrombin-soaked Gelfoam or another thrombogenic bulking agent to enhance hemostasis and is covered with loosely approximated, interrupted 3-0 absorbable renal capsular sutures. If no capsule is available or the defect is too large to close primarily, an omental pedicle flap can be used to cover the defect (Fig. 9.7). Its absorbent properties and rich vascular supply make it an excellent alternative to the renal capsule. Another substance we commonly use to cover the renal defect is Vicryl mesh as it is readily available, absorbable, and can easily be tailored to the size and shape of the renal defect. A passive drain is placed, and it is removed in 48 to 72 hours after confirming closure of the collecting system.

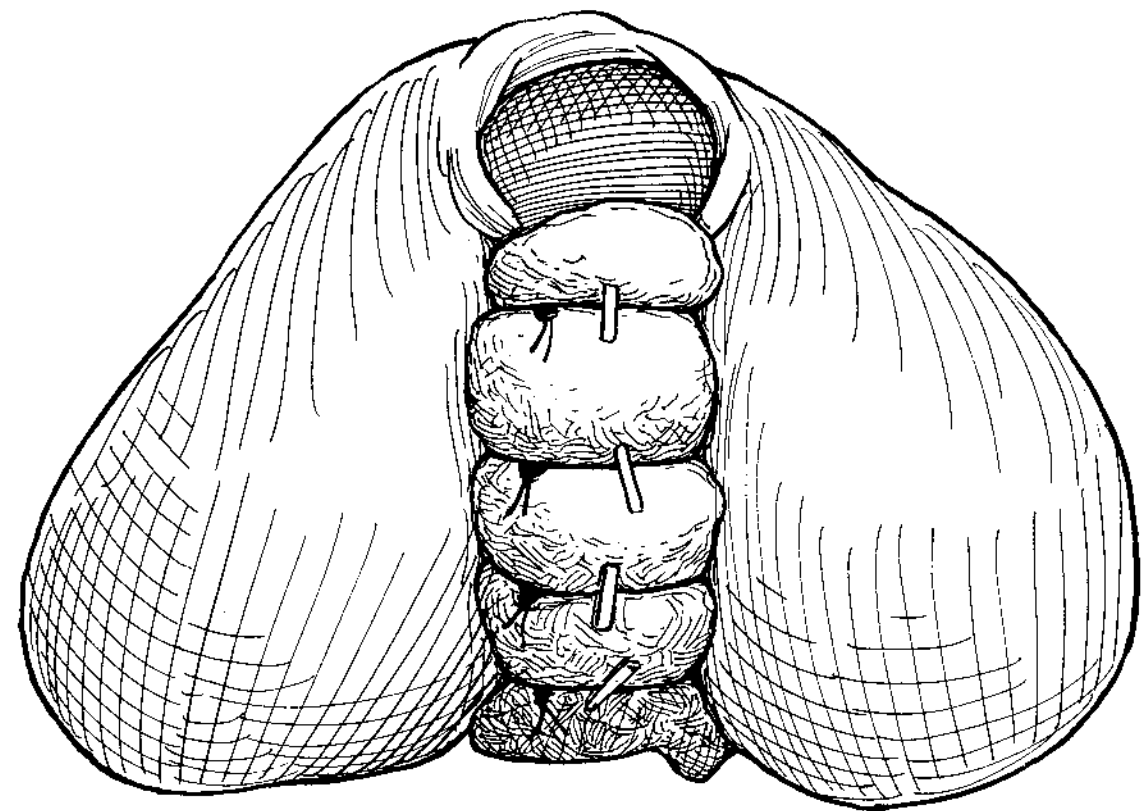

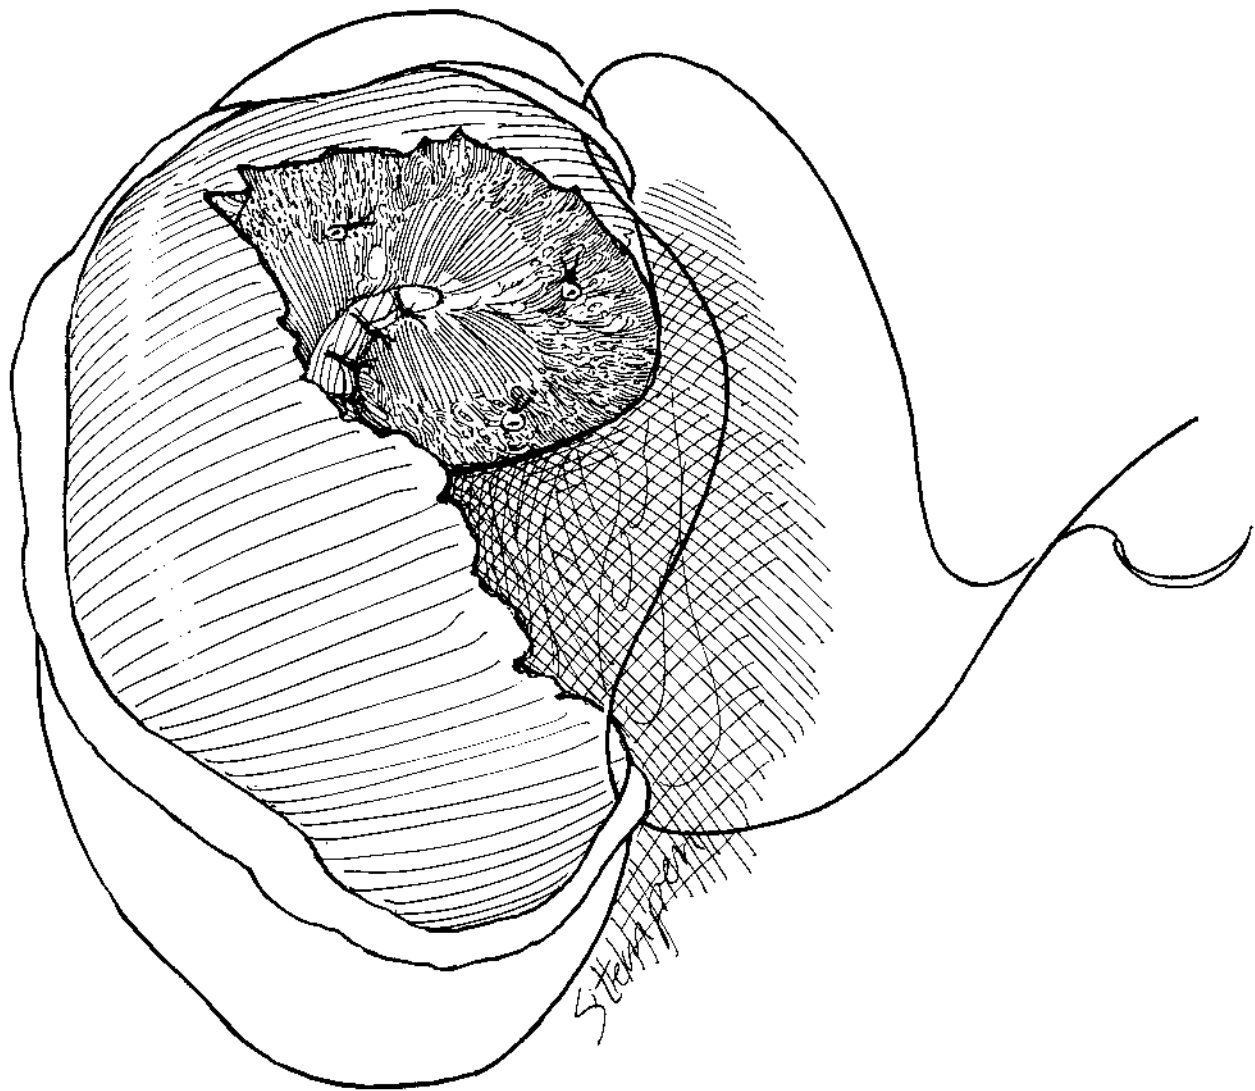

**FIGURE 9.5/6** The kidney is explored. A small gunshot entrance wound on the anterior aspect of the left kidney is identified. On the posterior surface, a complex gaping exit wound is identified. Nonviable tissue is sharply debrided, segmental vessels are individually suture-ligated, and the collecting system is closed with a continuous absorbable suture. Capsular 3-0 Vicryl sutures are used to reapproximate wound edges.

Major injuries to the midportion of the kidney are best repaired by sharp wedge resection of the nonviable tissue and renorrhaphy. Devitalized tissue is sharply removed. Sites of bleeding are individually ligated with fine absorbable sutures, and the collecting system is closed with a continuous suture. Thrombin-soaked Gelfoam bolsters are placed into the defect to enhance hemostasis and reduce tension on the capsular sutures (Fig. 9.8). Interrupted absorbable 3-0 sutures are placed through the renal capsule, excluding the underlying parenchyma, as it provides no additional strength. Omentum or Vicryl mesh can be used if primary renal capsular closure cannot be achieved.

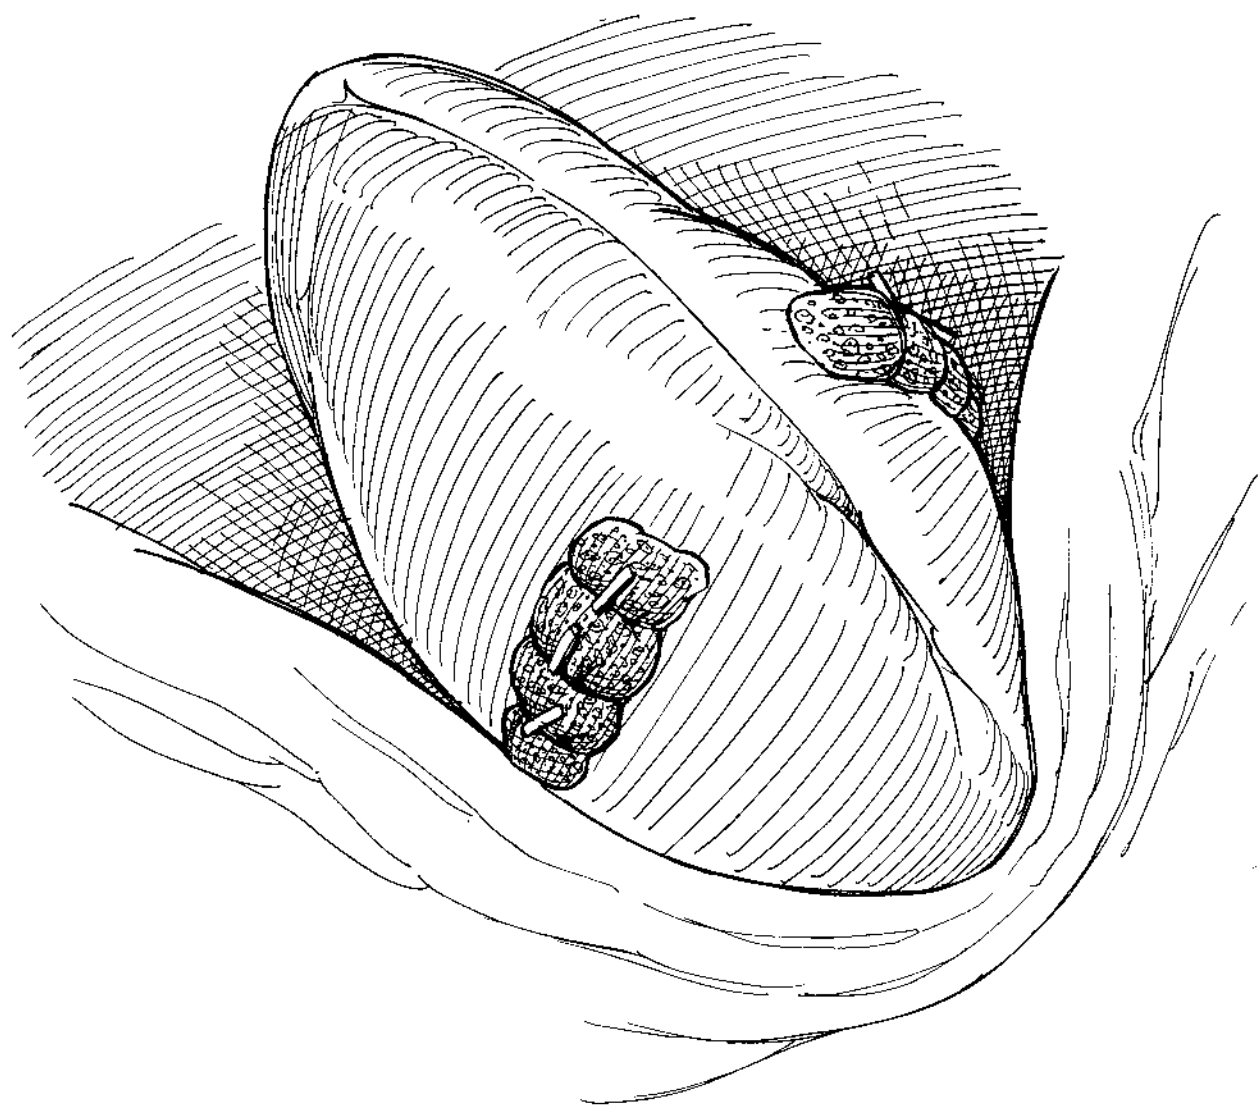

**FIGURE 9.7** During a polar partial nephrectomy with reconstruction, if the renal capsule is not available for defect closure, a Vicryl mesh patch or the omentum can be used to cover the defect.

**FIGURE 9.8** Closure of parenchymal defect after central renal injury. Capsular sutures of 3-0 Vicryl may be used to sew gelatin foam bolsters into the repair site. Titanium clips may be placed along the repair line to identify the area of reconstruction on subsequent imaging studies. Alternatively, if primary renal closure cannot be achieved, an omental flap may be tacked over the defect using small interrupted chromic sutures.

**FIGURE 9.9** Technique of renorrhaphy after stab wound. Gelfoam bolsters are laid into the capsular defect, and overlying 3-0 Vicryl sutures are placed superficially to approximate the adjoining renal capsule, thus sealing the reconstructed area.

**FIGURE 9.10** Completed renal reconstruction after stab wound. The entire kidney has been mobilized and evaluated for associated wounds. Titanium clips along the capsular sutures denote the area of repair.

Renal stab wounds often do not result in displaced or missing renal tissue. Frequently, entrance and exit wounds can be oversewn, and liquid thrombogenic agents such as FloSeal can be applied, resulting in excellent hemostasis (Figs. 9.9 and 9.10). Collecting system injuries that may have occurred will usually resolve with closure of the overlying parenchyma and should not be aggressively pursued. If delayed urinary

extravasation is detected by a perirenal drain or radiographic imaging, a ureteral stent can be placed with anticipated collecting system closure (3,11).

---

## RENOVASCULAR INJURIES

---

Renovascular injuries are closely associated to the grade of renal injury and are a major cause of partial or total renal loss. Main renal artery or vein avulsion, in the acute trauma situation, is deemed irreparable and results in nephrectomy. Proximal control of the renal pedicle is critical in these injuries to avoid life-threatening hemorrhage. Attempts at complex hilar arterial or venous reconstruction have shown poor results and should be reserved for the solitary kidney or bilateral renal hilar injuries in a non–damage-control situation (1,19,23). If necessary, the left main renal vein can be suture-ligated with sufficient drainage through the left adrenal and gonadal vessels. Reconstruction of a partial venous or arterial hilar injury can be performed with a continuous fine nonabsorbable suture after obtaining vascular control (Fig. 9.11).

---

## POSTOPERATIVE CARE

---

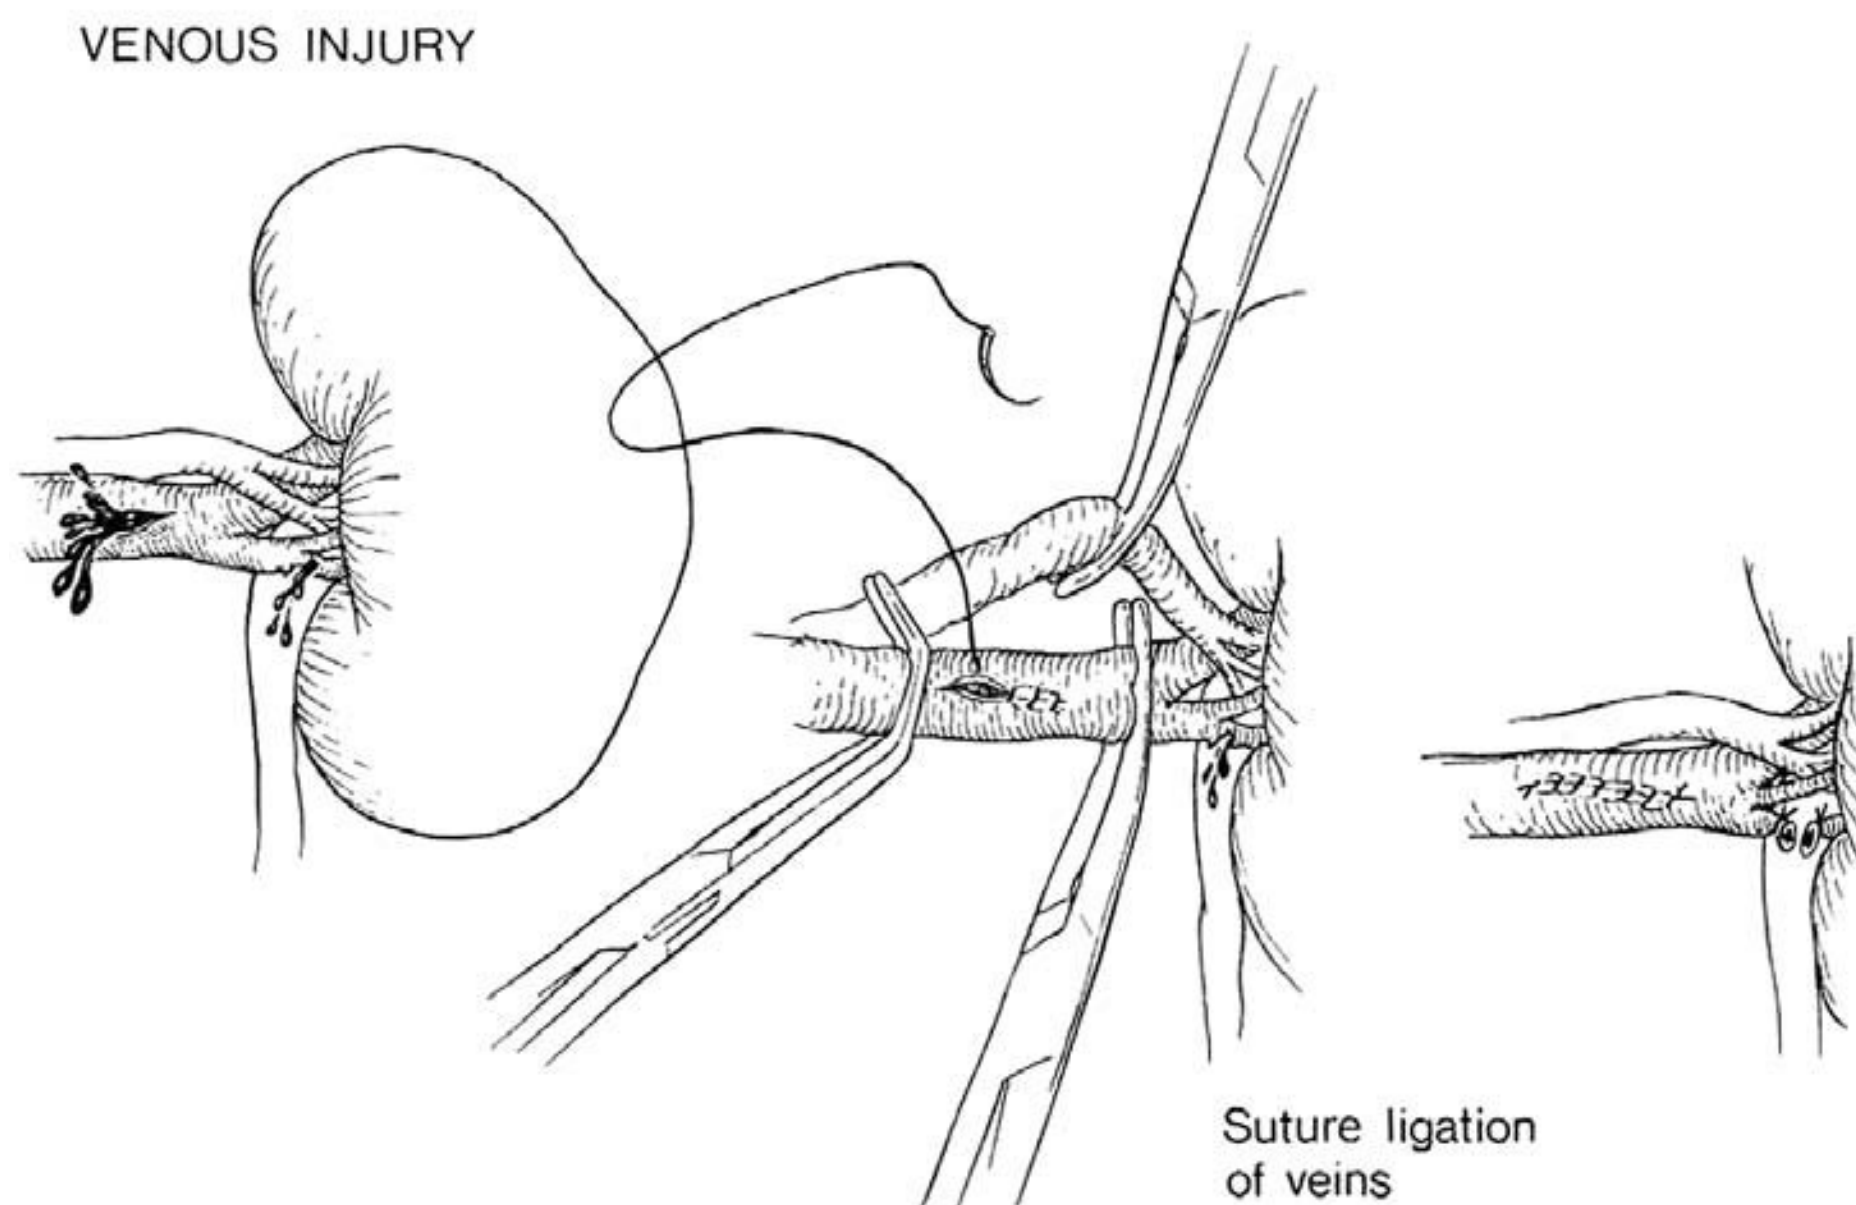

Gross blood in the urine usually clears within 24 hours, and patients should be observed on bedrest until this occurs. Ambulation is resumed once the urine is clear. Routine laboratory studies are obtained. In the event of a delayed bleed, renal angiography and selective angioembolization can be utilized to control the hemorrhage. Retroperitoneal drains are normally removed within 48 to 72 hours. If drainage is excessive, an aliquot may be checked for creatinine; a level similar to that of serum suggests peritoneal fluid rather than urine. All strenuous activity is suspended for a minimum of 3 months, at which time a radiographic CT imaging study is obtained to document complete renal healing. A radionuclide study can be obtained to assess renal function.

---

## COMPLICATIONS

---

Delayed renal hemorrhage or development of an arteriovenous malformation (AVM) or pseudoaneurysm usually occurs in the acute peritrauma period and presents with flank pain and/or gross hematuria (cardiovascular issues may also develop with AVM). These situations are best managed by selective angioembolization, which is a safe and effective treatment modality. Mild to moderate urinary extravasation is rarely clinically significant and can be followed by repeat CT imaging to ensure resolution. Large urinomas can be treated with percutaneous drainage and may require a ureteral stent if repeat CT imaging demonstrates persistent or worsening urinary extravasation. Hypertension after renal trauma is classically associated with a Page kidney injury and is otherwise infrequent. Delayed nephrectomy or preferably, capsulectomy and drainage can successfully manage hypertension secondary to a Page kidney injury, as this is an anatomical compression of the renal parenchyma. Medical therapy is otherwise utilized as indicated for essential hypertension.

**FIGURE 9.11** Repair of partial main renal vein or artery injury using a nonabsorbable continuous suture after gaining vascular control.

## SUMMARY

Radiographic CT staging, improved endovascular minimally invasive techniques, and growing experience have allowed more successful nonoperative renal trauma care to occur. Although limited, the role for renal exploration still exists in

critically ill patients with potentially life-threatening hemorrhage and in those who cannot be preoperatively staged by radiographic CT imaging and observed in ICUs. If renal exploration is necessary, early vascular control and adherence to reconstructive principles will ensure high renal salvage rates.

# CHAPTER 10 ■ RENAL ALLOTRANSPLANTATION

JOHN W. MCGILICUDDY, JUSTIN D. ELLETT, AND KENNETH D. CHAVIN

Successful transplantation of a kidney allograft and subsequent long-term immunosuppression management demand medical and surgical precision. The consequences of vascular, urologic, and infectious complications in renal transplantation, with their associated morbidity, mortality, and graft loss, can be devastating. Strict adherence to proper techniques and sound surgical principles, as outlined in this chapter, can reduce the incidence of these complications.

---

## DIAGNOSIS

---

Renal allotransplantation is performed as a treatment for end-stage renal disease (ESRD). Although there is no specific study required to make the diagnosis of ESRD, a thorough preoperative evaluation of the patient will include multiple studies to confirm the patient's candidacy as a transplant recipient.

---

## INDICATIONS FOR SURGERY

---

The primary indication for renal allotransplantation is ESRD requiring chronic dialysis. Some patients with poor and deteriorating renal function, but who are not yet requiring dialysis, may also be candidates. Patients need to have a creatinine clearance of  $<30$  cc to be considered for transplantation.

Active infections and malignancies are generally considered contraindications for transplantation due to the immunosuppressive therapy that is required postoperatively. Comorbidity in other organ systems, especially cardiovascular and pulmonary, may impose operative risks or compromise long-term prognosis significantly enough to preclude transplantation. Inadequate patient motivation, commitment, compliance, psychological stability, or social support may also be contraindications.

---

## ALTERNATIVE THERAPY

---

ESRD patients may choose from the two modalities of chronic dialysis for long-term life-sustaining treatment. Hemodialysis may be done at home or at a treatment center. Peritoneal dialysis is in general performed by the patient on a continuous ambulatory or overnight schedule. Renal allotransplantation offers significant quality of life improvements and a long-term survival advantage as compared to dialysis. Studies show that patients on the kidney transplant waiting list have a death rate of 6.3 deaths per 100 patient years, which is improved to a death rate of 3.8 deaths per 100 patient years in those who were transplanted. Correspondingly, the long-term mortality risk in transplant recipients is 20% lower than those on the

waiting list and 69% lower than those who remain on chronic hemodialysis (1).

---

## SURGICAL TECHNIQUE

---

The prospective transplantation recipient should be in metabolic, fluid, and electrolyte balance to avoid perioperative hyperkalemia, unstable blood pressure, pulmonary edema, dehydration, or difficult operative hemostasis associated with inadequate dialysis. When dialysis can be scheduled in advance, as with living donor transplantation, it should be performed on the day before surgery. The patient's cardiopulmonary status needs to be optimized, and central venous pressure monitoring can be useful in select patients. Swan-Ganz monitoring is rarely necessary.

The abdomen, from 2 to 3 cm above the umbilicus to below the symphysis pubica, is shaved and prepared after the induction of anesthesia and insertion of an indwelling Foley catheter. The bladder is gently distended with approximately 150 mL of a neomycin/bacitracin antibiotic solution. An alternative involves a three-way Foley catheter, allowing intraoperative bladder distention at the time of ureteroneocystostomy. Care must be taken to avoid inadvertent bladder rupture in these patients, who often have small, nondistensible bladders. Distention greatly facilitates the anterior cystostomy later in the procedure and, in addition, protects against possible wound contamination when the bladder is opened. After instillation of the antibiotic solution, the catheter is clamped. The clamp is removed after the cystostomy is created.

---

## Incision and Iliac Fossa Dissection

---

A right or left lower-quadrant curvilinear incision is created from the symphysis pubica to a point 2 cm medial to and just above the anterior superior iliac spine (Fig. 10.1A). While this is ultimately determined by surgeon preference, the implantation of a right kidney on the left side or a left kidney on the right side brings the renal pelvis anterior, simplifying re-exploration and revision should complications arise. The upper half of the incision is extended through the external oblique, internal oblique, and transversus abdominis muscles; in the lower half of the incision, the anterior rectus fascia is incised. The rectus muscle can then be dissected inferiorly to its tendinous insertion on the symphysis pubica and retracted medially. The inferior epigastric vessels are identified as they pass across the incision and are preserved if possible. An anterolateral retroperitoneal fascial plane is developed bluntly, permitting extraperitoneal entry into the iliac fossa.

**FIGURE 10.1** **A:** The incision is depicted for the right abdomen. The renal transplantation, however, can be performed on either the right or left side. **B:** The iliac vessels are best exposed with a self-retaining retractor. Sequential separation, ligation, and division of perivascular tissue containing lymphatics are essential and must precede skeletonization of the iliac vessels.

With medial retraction of the peritoneum, the spermatic cord in the male patient or the round ligament in the female patient is easily identified. Usually, cord ligation should be avoided to prevent hydrocele formation, testicular atrophy, or infertility. In women, the round ligament is divided and ligated. Further development of the extraperitoneal space in the iliac fossa is accomplished with exposure of the distal common and external iliac arteries. The insertion of a self-retaining retractor at this point ensures adequate exposure for the subsequent iliac vessel dissection and vascular anastomoses.

The dissection and skeletonization of the iliac vessels must be performed in a manner that allows secure ligation of the divided lymphatics passing along and across these vessels. Usually, this process is best approached on the superior aspect of the external iliac artery, working cephalad with a right-angle clamp toward the internal iliac artery, which crosses the internal iliac vein. In rare cases, when the donor kidney is very large or has an unusually short vein, the internal iliac artery must be sacrificed to allow sufficient mobilization of the underlying vein. The external iliac vein is similarly skeletonized as far cephalad as the vena cava if necessary. Posterior venous tributaries can be divided as necessary to permit maximum anterior mobility of the iliac vein. It is best to ligate all tributaries doubly with 2-0 or 3-0 silk in continuity before division because a double-clamping maneuver may sometimes result in injury or avulsion of a poorly accessible stump during ligation. If avulsion occurs, establishment of hemostasis risks injury to the obturator nerve. Unless the internal iliac artery already has been selected for an end-to-end allograft anastomosis, right-angle clamp dissection is used to partially skeletonize the common and external iliac arteries (Fig. 10.1B).

The tissue overlying the arteries and containing the lymphatics is sequentially separated, doubly ligated with 3-0 silk, and divided, a strategy that greatly reduces the incidence of lymphocele. As with the vein, the anterior separation of tissue over the iliac artery is more easily performed in a cephalad direction.

At this point, palpation of the iliac arteries allows the surgeon to determine the most appropriate site for anastomosis. If there is moderate or severe atherosclerosis extending along the entire length of the external iliac artery, the internal iliac artery can be used for an end-to-end anastomosis. Most commonly, however, an end-to-side anastomosis of the renal artery to the external or common iliac artery is preferred as it preserves the internal iliac artery and diminishes the risks of impotency in men and gluteal or pelvic ischemia in the elderly. If the internal iliac artery is to be used, skeletonization of this vessel prepares it for end-to-end anastomosis. Before skeletonization is begun, the lymphatics on the medial aspect of the iliac bifurcation should be doubly ligated and divided. The internal iliac artery may then be clamped proximally with a Fogarty clamp and divided distal to its bifurcation with appropriate ligation of the distal stumps deep in the pelvis. The mobilized internal iliac artery is irrigated with heparinized saline solution.

---

### Allograft Positioning and Vascular Anastomoses

---

Before recipient vessel anastomotic sites are selected, placement of the allograft lateral or anterior to the iliac vessels should be considered, all anatomic factors being taken into

account. The iliac vein is prepared for the end-to-side renal vein anastomosis by placement of clamps proximal and distal to the proposed venotomy. Fogarty clamps or a single broken-back Satinsky clamp usually serves this purpose well. A longitudinal incision is made on the anterior or anteromedial portion of the iliac vein segment with a no. 11 blade and extended as necessary with Potts right-angle scissors. The isolated segment of the iliac vein is irrigated with heparinized saline. After this, four 5-0 cardiovascular sutures are placed at the superior and inferior apices and at the midpoints of the medial and lateral margins of the venotomy. These sutures later are passed through corresponding points on the donor renal vein or vena cava patch for a four-quadrant, end-to-side anastomosis.

If a cadaveric kidney is used, the allograft is removed from cold storage or perfusion preservation at this point. With living-related transplantation, the flushed and cooled graft is obtained from the live donor in an adjacent operating room.

The kidney is secured in a sling containing ice slush and held in position for the vascular anastomosis by the assistant. A clamp is used to secure the sling to relieve the assistant from holding the kidney in position with the hands, which might accelerate warming or compress the kidney during the performance of the vascular anastomoses.

The previously placed sutures through the iliac vein are passed through the corresponding points of the donor renal vein or vena cava conduit and secured, bringing the renal vein into juxtaposition with the iliac vein (Fig. 10.2A). The medial and lateral sutures are retracted to separate the venotomy opening and facilitate rapid anastomosis without inadvertent suturing of the back wall. With the table rotated laterally, the superior suture is used as a running suture down the medial side of the renal vein to meet the inferior suture running up. The lateral suture line is then run in a similar fashion after the table has been rotated medially.

The external iliac artery is prepared for the end-to-side renal artery anastomosis by placement of Fogarty clamps

proximal and distal to the proposed arteriotomy. This anastomosis usually is placed just cephalad to the level of the venous anastomosis. The location of clamp placement must be carefully selected so as not to disrupt existing arteriosclerotic plaques and precipitate embolization or thrombosis. A longitudinal incision is made on the anterior or anterolateral portion of the iliac artery segment with a no. 11 blade and extended as necessary with Potts right-angle scissors. If the surgeon prefers, a 4.8- or 5.6-mm aortic punch can be used to prepare an ideal oval arteriotomy. The isolated segment of the iliac artery is irrigated with heparinized saline. This anastomosis is performed with 6-0 Prolene continuous or interrupted sutures after initial fixation of the end of the renal artery to the apices of the arteriotomy, leaving one suture untied to allow for better visualization of the intima.

Less commonly, when the internal iliac artery is to be used for the arterial anastomosis, an end-to-end anastomosis is then performed with the renal artery (see Fig. 10.2B). The two vessels are positioned to allow a gentle upward curve from the iliac bifurcation to the kidney by fixing the superior and inferior arterial apices with interrupted 6-0 Prolene sutures. The anastomosis is completed with continuous or interrupted sutures. A preference for interrupted sutures instead of a running suture in this end-to-end anastomosis prevails when one needs to avoid absolutely any pursestring effect that might occur from a running suture or to achieve optimal accommodation of the two vessels to each other when a size or thickness discrepancy exists.

Upon completion of the anastomoses, the vascular clamps are released, venous clamps before arterial. Any bleeding along the line of the anastomoses is controlled with a combination of topical hemostatic agents, direct pressure, and suture repair. The sling around the kidney is removed, and any bleeding identified in the hilum or on the surface of the kidney is controlled, taking care to avoid injuring the hilar vessels. Maintenance of adequate perfusion pressure is essential and

**FIGURE 10.2** **A:** The renal vein is brought into exact juxtaposition with the iliac vein phlebotomy by previously placed four-quadrant sutures. A running suture anastomosis will follow. **B:** The renal artery is positioned to the end of the internal iliac artery by superior and inferior apical sutures. Subsequent placement of interrupted sutures completes the anastomosis. Note the occluding bulldog clamp on the renal vein. **C:** The completed venous and arterial anastomoses are demonstrated.

**FIGURE 10.3** A donor aorta Carrel patch encompassing two renal arteries is positioned by apical sutures to an iliac arteriotomy fashioned to accommodate the length and width of the patch.

can be achieved with judicious intravenous hydration and the use of mannitol and a dopamine drip as needed.

### Multiple Renal Vessels

Although the Carrel patch may frequently be used with single arteries and veins, a cadaveric kidney with multiple renal arteries perfused through the aorta is especially well suited to an end-to-side anastomosis of a Carrel patch encompassing the multiple arteries (Fig. 10.3) (2). If the vessels are close to each other, a single Carrel patch is sufficient. The Carrel patch of donor aorta is fashioned to accommodate the multiple vessels, and its anastomosis to the common or external iliac artery is performed as previously described.

If the donor renal vessels are  $>2$  cm apart or the allograft comes from a living donor where taking a Carrel patch is not possible, there are several strategies for arterial anastomosis: (a) double end-to-side renal arteries to iliac artery, (b) end-to-end superior renal artery to internal iliac artery with end-to-side inferior renal artery to external iliac artery, and (c) implantation of an accessory artery end-to-side into the larger main renal artery, with the larger renal artery anastomosed to the internal, external, or common iliac artery. If two renal arteries are of similar diameter, the spatulation edges of the renal arteries can be joined by the “trousers technique” with running 6-0 or 7-0 Prolene sutures to create a single bifurcating artery (2). An accessory-artery-to-main-renal-artery anastomosis should be performed with an ex vivo bench technique in cold

ice slush prior to beginning implantation. Finally, some recipients have a deep inferior epigastric artery that is suitable for an end-to-end 7-0 suture interrupted anastomosis of a small lower-pole artery, which may be essential for ureteral viability (3).

### Ureteral Considerations

When the recipient urinary bladder is functional, ureteroneocystostomy is the preferred technique for establishing urinary tract continuity unless the donor ureter is absent, very short, abnormal, or damaged. Ureterectasis is not a contraindication. When the donor ureter is not suitable for reasons listed above, the recipient ureter may be used for ureteroureterostomy or ureteropyelostomy (4). If a recipient ureter is not available but the bladder is large, psoas hitch or Boari flap techniques may be used for ureteroneocystostomy or pyelocystostomy.

Some patients are prepared for kidney transplantation by creation of an ileal loop or isolated ileal stoma to divert urine from a dysfunctional or absent bladder. Other patients may come to transplantation with pre-existing bladder augmentations or continent urinary diversions utilizing ileum and colon. The nuances of techniques in these settings are beyond the scope of this discussion.

Typically,  $>95\%$  of all renal transplantations are performed with various modifications of the Lich-Gregoir (5), Politano-Leadbetter (6), or Shanfield (7) techniques for allograft ureteral implantation into the bladder. In our experience, the Lich technique is appropriate in almost all cases (8). Previous filling of the bladder facilitates identification and opening of the bladder. The detrusor muscle is separated from the bladder mucosa for a length of 2 to 4 cm. A small mucosal opening is created, and the ureter is pulled down and brought into position near the site of cystostomy by gentle traction (Fig. 10.4). This avoids any excess handling of the ureter, which is important because the ureter of the transplanted kidney receives its blood supply exclusively from the renal vessel branches that course in its adventitia. In male patients, it is important to pass the ureter beneath the spermatic cord. The ureter is trimmed to an appropriate length and spatulated about 1 cm.

Two 5-0 polydioxanone sutures (PDS) are used to bring the ureteral orifice down to the cystostomy and to construct the anastomosis incorporating bladder mucosa and ureter. The ureter is routinely stented with a 6Fr, 12-cm double-J stent to reduce major ureteral complications (9). The detrusor muscle is then reapproximated over the stented ureter to provide an antireflux mechanism. Kidneys with a double ureter can also be transplanted successfully. These ureters should be dissected en bloc within their common adventitial sheath and periureteral fat so that the ureteral blood supply is protected. The technique of ureteroneocystostomy is essentially the same as with a single ureter except that the ureters are brought through together side by side in a nonconstricting tunnel. The distal end of each ureter is spatulated, and the adjacent margins are approximated with 5-0 PDS.

Rarely, situations occur in which ureteroneocystostomy unexpectedly cannot be performed and native ureters are not available. In this setting, cutaneous ureterostomy is preferred. Alternatively, an ileal loop may be created at the time of transplantation. Ureterosigmoidostomy should be avoided.

**FIGURE 10.4** Ureteroneocystostomy. **A:** A small Robinson catheter or heavy silk suture with donor ureter attached is brought into the bladder through an oblique hiatus. **B:** The completed transplant ureteroneocystostomy is demonstrated. Four interrupted sutures secure the spatulated ureteral orifice.

---

### Pediatric Kidneys

---

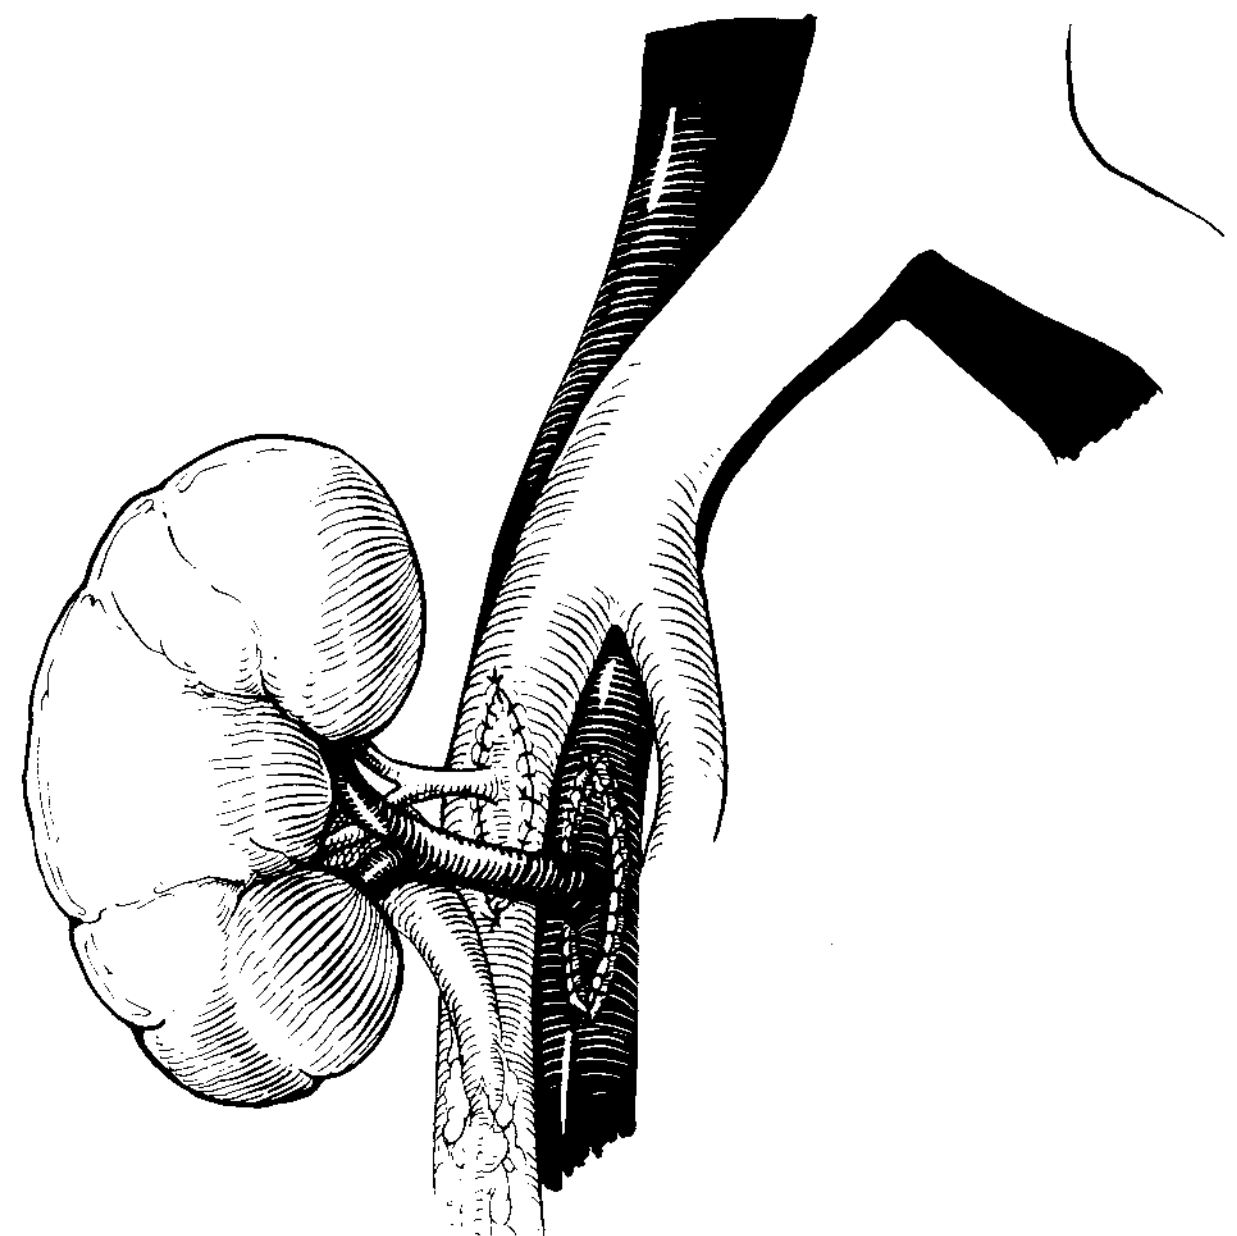

Although en bloc transplantation of kidneys from very young children is often desirable (10), it is not necessary to transplant both kidneys from young children en bloc; each kidney can be used for a different recipient, as is the case with adult cadaveric donors, using Carrel patches of donor aorta and vena cava (Fig. 10.5) (11). A Carrel patch is mandatory in these cases because direct implantation of a small vessel into a much larger or diseased vessel may result in thrombosis or produce functional stenosis as the kidney grows. When the en bloc technique is used, the two ureters are implanted separately and stented. Pediatric kidneys have proven to be excellent donor grafts for carefully selected adults and children. Avoidance of older recipients or diabetics with advanced arteriosclerosis will minimize the potential for thrombosis. Rapid growth and hypertrophy occur in the immediate posttransplantation period. If early rejection can be avoided, these allografts achieve adult size and function in adult recipients within several weeks.

---

### Pediatric Transplantation

---

In small children, the iliac fossa is not large enough to accommodate a kidney from an adult donor, and the pelvic vessels in

**FIGURE 10.5** Small pediatric cadaver renal vessels are anastomosed to larger recipient iliac vessels using Carrel patches of donor aorta and vena cava. Note donor right kidney in right iliac fossa with renal pelvis posterior to renal vessels.

**FIGURE 10.6** Anatomic relationships of an adult donor kidney in a small child are shown with renal vessel anastomoses to the inferior vena cava and aorta.

a small child are so small that the disparity between the donor renal vessels and the recipient vessels precludes the technique described for adults. In these small children, graft implantation must use the recipient aorta and vena cava, which is best accomplished through a right-sided retroperitoneal or, in children <10 kg, a transperitoneal midline abdominal incision that provides ready access to the great vessels as well as the urinary bladder. After the right colon is reflected medially, the vena cava is freed from the level of the right renal vein inferiorly to its bifurcation or beyond. Posterior lumbar veins are doubly ligated with 5-0 silk and divided as needed. Mobilization of the vena cava is important to facilitate the end-to-side anastomosis of the renal vein, which is performed with running 6-0 Prolene sutures, as described for the adult (Fig. 10.6). Performing the venous anastomosis superiorly allows room for an end-to-side anastomosis of the renal artery to the inferior abdominal aorta. Aortic mobilization should be limited to its distal portion, from the level of the inferior mesenteric artery, and including both common iliac arteries. The segment of the aorta to be used for the end-to-side renal artery anastomosis can be isolated in any number of ways, but most simply by applying a small vascular Satinsky clamp. The end-to-side anastomosis is performed with interrupted 6-0 Prolene sutures.

Important to the revascularization of an adult kidney in small children is the need to anticipate the impending consumption of several hundred milliliters of effective blood volume by the renal allograft. Initiation of volume loading before beginning the vascular anastomoses will avoid hypotension after release of the vascular clamps. Immediately after establishing circulation in the graft, the anesthesiologist must be continually attentive to the blood pressure. A dopamine drip

is often necessary. The ureteral implantation is carried out as previously described.

---

## Wound Closure

---

Except in unusual cases, the space of Retzius and iliac fossa are not drained. Jackson-Pratt suction may be employed, but Penrose drains are never used. If good hemostasis has been obtained, and if the principles of implantation as outlined in this chapter have been followed, there is no need for postoperative drainage other than a urethral catheter. The optimal period of Foley catheter drainage is debatable. We prefer to remove the catheter at 72 hours unless the patient has worrisome hematuria, large diuresis, or poor bladder function, or had a technically difficult neoureterocystostomy.

In preparation for closure, the wound is thoroughly irrigated with antibiotic-containing saline. Depending on surgeon preference, a heavy absorbable or nonabsorbable suture is used to approximate transversus abdominis and internal oblique muscles in a single-layer closure; the adjacent fascia is included inferiorly at the tendinous insertion of the rectus muscle. Next, the rectus fascia anteriorly and the fascia of the external oblique are approximated in the same manner.

The subcutaneous tissue is thoroughly irrigated with saline and then may be approximated with interrupted 2-0 or 3-0 Vicryl sutures. These sutures are placed about 3 cm apart and include both edges of the Scarpa fascia and the underlying fascia. In this manner, one can obliterate dead space in the subcutaneous area in which a seroma in an immunosuppressed patient might cause dehiscence and become secondarily infected. The skin is approximated with a running 4-0 Monocryl suture in a subcuticular fashion or with surgical staples.

---

## OUTCOME

---

### Complications

---

Early vascular complications of kidney transplantation include arterial thrombosis, venous thrombosis, and anastomotic bleeding. These each occur in <1% of cases unless the recipient or donor vessels are diseased or small caliber. Renal or iliac artery stenosis may lead to allograft ischemia or thrombosis days or even years posttransplant in 2% to 12% of cases (12).

Urologic complications are slightly more common than vascular complications but less likely to lead to graft loss. When donor ureter and recipient bladder are normal, early ureteral necrosis, ureteral anastomotic leak, or obstruction each occur in <1% of cases. Compromised ureteral blood supply during donor nephrectomy and abnormal bladder are the most likely factors increasing these risks. Ureteral stenosis months or years posttransplant is most often a result of chronic rejection. Lymphocele occurring in 6% to 10% of transplants may be considered a urologic complication if it causes extrinsic ureteral obstruction or bladder compression. Lymphocele requires intervention posttransplant only if it becomes infected or causes pain, iliac vein compression, or allograft ureteropyelocaliectasis. Infectious, cardiovascular,

metabolic, pharmacologic, and psychosocial complications of transplantation are beyond the scope of this presentation. Acute rejection superimposed on preservation injury produced irreversible failure in more than half of all cadaver donor renal allografts in the early days of transplantation. In recent years the rate of irreversible acute rejection is <10% in nearly all programs. Chronic allograft nephropathy, however, continues to contribute significantly to long-term graft loss and morbidity.

## Results

The 2007 Annual Report of the U.S. Organ Procurement and Transplantation Network documents 1-year patient survival at 98.0% and 95.8%, depending on whether the graft was from a living or cadaveric donor, respectively. It also documents 5-year allograft survival for living donor and cadaveric donor renal transplantation of 80.2% and 69.8%, respectively, as seen in Table 10.1.

TABLE 10.1

### 2007 ANNUAL REPORT OF THE U.S. ORGAN AND TRANSPLANTATION NETWORK AND THE SCIENTIFIC REGISTRY OF TRANSPLANT RECIPIENTS: TRANSPLANT DATA 1997 TO 2006

	Living donor	Cadaveric donor
3-mo patient survival	99.3%	98.3%
1-yr patient survival	98.0%	95.8%
3-yr patient survival	94.7%	90.1%
5-yr patient survival	90.3%	82.8%
3-mo graft survival	97.3%	95.3%
1-yr graft survival	95.1%	91.3%
3-yr graft survival	88.5%	80.9%
5-yr graft survival	80.2%	69.8%

# CHAPTER 11 ■ URETERAL COMPLICATIONS FOLLOWING RENAL TRANSPLANTATION

RODNEY J. TAYLOR

Historically, the incidence of urologic complications following kidney transplantation, manifested primarily as ureteral leaks or obstruction, was as high as 10% (1,5). These complications often resulted in significant morbidity, graft loss, and occasional patient death. Improvements in surgical techniques, immunosuppression, and methods for easily diagnosing and treating the complications have not only led to a significant decline in the rate of urologic complications to the current reported incidence of 2% to 2.5% (4,7,9) but have also resulted

in lower morbidity and rare loss of a kidney or patient due to these complications. However, despite these changes, the need for diligence in diagnosing and quickly addressing complications remains as true today as in the past.

The most common cause for ureteral complications following kidney transplantation is technical error (1,5,7). Damage to the ureteral blood supply during graft recovery or transplantation may result in ureteral ischemia and subsequent leak or obstruction. Additional technical errors, such as excessive

tension at the ureteroneocystostomy site or hematoma development within the tunnel, may also cause problems (4,7). With careful attention to detail, most of these problems can be minimized, especially in the early postoperative setting. Long-term or delayed ureteral obstruction may be the result of ischemic changes secondary to chronic rejection or a continuation of the spectrum of damage associated with the organ harvest and transplantation, and although not all these problems are preventable, the incidence can be markedly reduced with good surgical technique (1,4). The types of ureteral complications can be divided into ureteral leaks and ureteral obstruction.

---

## DIAGNOSIS

---

### Urinary Leaks

---

In current practice, most surgeons utilize an extravesical ureteroneocystostomy that uses a shorter ureter, decreasing the likelihood of ureteral ischemia, and utilizes a limited cystostomy that rarely leads to leakage from the bladder (4,10). Therefore, virtually all urinary leaks currently seen after transplantation are ureteric. The majority of these leaks that occur early after transplantation are usually present with excessive drainage from the wound, unexplained graft dysfunction, or a pelvic fluid collection. Signs and symptoms can also include fever, graft tenderness, and lower-extremity edema (8). It is critical to differentiate a suspected urinary leak from a lymphocele, as the management is entirely different.

Urinary leaks in the early postoperative period can be divided into two types according to the timing of presentation. The first usually occurs within the first 1 to 4 days and is almost always related to technical problems with the implantation. In this case, the heel of the ureter has usually retracted out of the tunnel. This is usually caused by excessive tension at the site of the anastomosis. This complication appears to be more common with extravesical ureteroneocystostomies and may be the result of too much shortening of the ureter and subsequent tension on the anastomosis when the kidney is positioned in the pelvis (8). Some investigators have recommended the use of a ureteral stent to lessen the likelihood of this complication (4,5). We recommend placing the kidney in its eventual position before deciding how much to shorten the ureter. The old adage "measure twice and cut once" applies in this circumstance.

The second type of early ureteral leak is associated with distal ureteral ischemia, which may be a consequence of injury during the donor organ recovery, technical causes such as tunnel hematoma, or distal stripping of the blood supply. This type usually presents between 5 and 10 days posttransplant (7).

Urinary leaks are often suspected because of increased drainage from the wound while at the same time associated with decreased urinary output. This is especially true in patients with limited pretransplant urine production. In patients with normal pretransplant urinary output, wound drainage and graft dysfunction are the key signs. The drainage fluid should be tested for blood urea nitrogen (BUN)/creatinine to see if it is compatible with urine. The preferred radiographic tests include an abdominal ultrasound and nuclear renal scan. A renal scan demonstrating extravasation is the most sensitive

method to differentiate a urine leak from other fluid collections such as lymphoceles or hematomas (2). A cystogram should be performed if a bladder leak is suspected.

---

## Ureteral Obstruction

---

Ureteral obstruction can also be the result of ureteral ischemia but usually occurs later than ureteral leaks and usually presents as acute graft dysfunction. It may occur years after the transplant and in this situation may represent vascular injury associated not only with the technical complications but also with chronic rejection (1,7,8). The spectrum of ureteral ischemic injury extends from early necrosis and urinary leakage to delayed ureteral obstruction, presenting months to years after the actual transplantation.

Ureteral obstruction, usually manifested by graft dysfunction, requires evaluation, and again an ultrasound and nuclear renal scan are the most common screening studies. Additional radiographic studies such as a computerized tomography (CT) scan may be of assistance in some cases. With both ureteral leak and obstruction, endourologic techniques can be both diagnostic and therapeutic.

---

## INDICATIONS FOR SURGERY

---

Anything that causes graft dysfunction or results in disruption of the urinary tract in a renal transplant patient is of utmost concern and requires rapid diagnosis, control, and treatment. In the case of ureteral leakage or obstruction, the goals of treatment include careful and accurate diagnosis of the exact cause and site. To correct the leak caused by excessive tension, it is often possible to do a repeat ureteroneocystostomy as soon as the diagnosis is made. In most other cases, especially with the current techniques of extravesical reimplantation, a different operative procedure is often more suitable (5,7).

If the graft dysfunction problem has a physical cause such as a leak or an obstruction and is not associated with an acute rejection episode, then treatment is directed at stabilization of the renal function, minimization of morbidity, and restoration of the continuity and function of the urinary tract. If there is concomitant rejection, then definitive operative therapy is withheld pending the treatment of rejection (7,8).

---

## ALTERNATIVE THERAPY

---

Immediate open operative surgical intervention has been replaced, to a large extent, by early endourologic intervention (1,6-8). The placement of a percutaneous nephrostomy can divert a leak or relieve obstruction and allow more definitive diagnosis. As described by Stroom, endourologic management algorithms can select patients for whom the likelihood of successful nonoperative management is good. Depending on the selection criteria, the results of management of distal ureteral leaks with stenting and a nephrostomy tube show that approximately one-third of patients do well long term and require no additional treatment. For ureteral strictures or stenoses, approximately 45% of patients, carefully selected, will avoid an open operative repair (8). For the other patients, percutaneous access can allow stabilization of renal function

and a more critical assessment before open surgical repair is carried out. In a few cases, percutaneous access can offer long-term treatment with chronic stent management. This choice, in my opinion, is of limited application in most patients with a well-functioning graft because of the long-term risks (i.e., stone formation, infection, etc.) and inherent costs. However, in patients who are not operative candidates and for some patients with marginal graft function, chronic endourologic treatment can be an alternative to definitive repair (5).

## SURGICAL TECHNIQUE

There are many procedures available to restore the continuity of the urinary tract (1–3,5–7). In our experience in dealing with a difficult ureteral stenosis or a leak from significant ureteral ischemic necrosis, we favor the use of the native ureter to replace the transplant ureter. Advantages of this repair include the following: The native ureter is usually non-refluxing, the results are reliable, there is a low likelihood of recurrence of the primary problem, and a tension-free anastomosis with good blood supply is easily attained. The focus of this operative description is on that surgical choice. Other operative alternatives include reimplantation of the ureter, Boari flap ureteral replacement, pyelovesicostomy and psoas hitch with reimplantation. As with many operative procedures, having a variety of alternatives available enhances the likelihood of a successful result.

Surgical access to the transplanted kidney and ureters (transplant and native) is usually achieved by reopening the old incision. On occasion, if extensive mobilization of transplanted kidney is anticipated or access to the contralateral native ureter is planned, a midline incision is another option (7). Surgical access to repair an early ureteral leak is usually simplified because dense fibrosis has not yet occurred, the fascial layers are easily opened, the peritoneum and its contents are freely mobilized medially and cephalad, and the kidney and ureter are identified without much difficulty. A primary repair can often be performed, and in most cases a repeat ureteroneocystostomy at a new site in the bladder is the best choice. Use of a mechanical retractor greatly simplifies exposure and allows excellent access to the pelvis. We also recommend the use of loupe magnification (2× to 3×) to enhance the repair.

If the repair has been delayed because of attempted endourologic management or because of delay in presentation or diagnosis, then access to the ureter and kidney can be much more challenging and hazardous. In these cases, mandatory preoperative preparation includes a review of the operative note, especially if the operation was performed by someone else. It is important to know whether the kidney to be operated on was the donor's right or left kidney. It is critical to know the position of the ureter and renal pelvis in relation to the renal vessels (below or above), and this depends on which kidney was used and into which side of the recipient's pelvis it was transplanted. Additional information to be sought includes the type of vascular anastomosis performed (end-to-end versus end-to-side, etc.) and whether or not the iliac vessels (especially the iliac vein) were mobilized. All of this information can help determine the likely position of the kidney in relation to the transplanted and native ureter and the anticipated ease in gaining access to these structures. Figure 11.1

**FIGURE 11.1** Relationship of the transplanted kidney and its vasculature to the recipient's iliac vessels and ureter.

demonstrates the relationship of the transplanted kidney, vessels, and ureter to the recipient's iliac vessels and ureter. Note that this figure depicts a donor left kidney on the right side, as the renal pelvis is posterior to the renal vessels.

In terms of the recipient, it is critical to know the status of the recipient's urinary tract. This is especially true if the recipient has a history of ureteral reflux or has undergone nephroureterectomy and might not have a suitable native ureter available to use for repair. Finally, the status of the recipient's urinary bladder in terms of capacity, compliance, and function can be important in determining which other repair options are available.

Additional preoperative preparation involves stabilization of the patient and function of the graft. It is important to delay any open operative repair until concurrent rejection episodes have been adequately treated and renal function stabilized. All patients should be treated with preoperative antibiotics based on anticipated contaminants or cultures obtained from the urine. If there is a likelihood that bowel might be needed (an unusual circumstance) to repair the urinary tract, then a full bowel preparation is indicated.

The goals of surgery are to repair the ureteral defect, re-establish continuity of the urinary system, get rid of all foreign bodies as quickly as possible, and avoid graft or patient loss. With a well-planned and executed procedure, these goals should be easily obtained in essentially all cases.

Delayed surgical repair because of attempted endourologic management, delayed diagnosis, or late presentation of obstruction can make surgical exposure of the kidney and ureter challenging. As noted earlier, access is almost always achieved

through the old transplant incision, and cephalad extension of the incision is often needed in these cases because of perinephric fibrosis, the increased size of the kidney posttransplant, and the need to achieve access to the iliac vessels and native ureter. It is usually possible to extend the incision several centimeters cephalad. Additional exposure, if needed, can also be obtained by extending the inferior aspect of the incision across the midline, although this is rarely needed and should be delayed until the need presents itself.

With delayed repair, the normal tissue planes are obliterated and a dense fibrosis has occurred around the graft. This makes it easy to violate the “renal capsule” and get into significant bleeding. As a routine, it is preferable to operate from a position of “known to unknown” with good exposure. The surgeon should also plan to gain vascular control proximally and distally if it appears that the kidney may need to be mobilized to permit access to the renal pelvis. A three-way Foley catheter should always be placed into the bladder before the start of surgery to allow for irrigation and filling with an antibiotic solution.

To ensure a safe and adequate exposure, I usually open the peritoneum early in cases where there is dense fibrosis. This allows better cephalad exposure, protects the bowel, and gives good access to the bladder.

Because the transplant ureter usually crosses the external iliac vessels below the renal vessels, one should take care to avoid these structures while gaining access to the ureter. This is a critical feature of this operative procedure because exact visualization of the renal vascular structures is often difficult, and many times one is operating based on the expected, not visualized, location of these structures. In some cases a percutaneous nephrostomy tube will be placed as well as a ureteral stent. If present, the nephrostomy tube should be accessible during a procedure as injection of saline or methylene blue may aid in identifying the ureter and renal pelvis. In some cases, because of the dense fibrosis, the ureter is identified only when it is actually cut. The routine placement of a ureteral stent is of limited value in most cases because the fibrosis is so dense that it is hard to discern the presence of the catheter. If the ureter is not in dense fibrosis, then access is usually easy.

Once access to the bony pelvis is obtained, careful dissection along the lateral wall of the bladder usually leads to the ureter. Once it is identified, care must be used in mobilizing the ureter to avoid any further vascular injury. When the site of leakage and/or obstruction has been identified, the most commonly used repairs include (a) a repeat ureteroneocystostomy, (b) use of the bladder (Boari flap or bladder hitch) to help bridge the gap, or (c) use of a native ureter to perform a ureteroureterostomy or ureteropyelostomy. Repeat ureteroneocystostomies are indicated only to repair early leaks when the problem was from tension at the anastomosis or distal ureteral ischemia and a well-vascularized, minimally fibrosed ureter is present. In most circumstances, especially late, with a lot of periureteral reaction or ischemia, our preferred option is the use of the ipsilateral native ureter if it is present and of adequate caliber. If not, then a Boari flap is an excellent choice.

Access to the native ureter is obtained by identifying it as it crosses the common iliac vessels. Care must be used in mobilizing the ureter down into the pelvis to the level of the superior vesical artery to avoid injury to the ureter blood supply. The ureter is divided well above the iliac vessels, and the

**FIGURE 11.2** Mobilization of the native ureter distally with the proximal segment ligated.

proximal end of the ureter is doubly ligated. In our experience of >50 cases, this has not resulted in problems of hydronephrosis with the native kidney or ureter requiring any further intervention. Figure 11.2 shows the native ureter mobilized distally and doubly ligated proximally in preparation for a ureteropyelostomy.

The operative positioning of the native ureter depends on access to the transplant ureter and/or pelvis. In addition, whether a side-to-side ureteral anastomosis or a ureteropyelostomy is to be performed may make a difference in the exact positioning of the native ureter. All of these factors relate to the extent of fibrosis and the appearance of the transplant ureter. To prevent any additional future problems, a tension-free, widely spatulated anastomosis of well-vascularized ureter to either the transplant ureter or renal pelvis is critical (Fig. 11.3). The anastomosis is performed using 5-0 Maxon (Davis and Geck, Danbury, CT) or polydioxanone (PDS, Ethicon, Somerville, NJ) in a watertight single layer. The critical aspect is to obtain a mucosa-to-mucosa approximation to avoid tension, devascularization, and urinary leak. A 12-cm 4.7 double-J stent is routinely used on all anastomoses. The anastomosis may in addition be wrapped in omentum or peritoneal flap, if available, to decrease further the risk of leak. The wound is well irrigated with antibiotic solution, and if no preoperative infection was present, we close the wound without a drain. If there is concern about urinary leak, lymphatic leak, or possible infection, one or two Jackson–Pratt drains are indicated. The

FIGURE 11.3 Anastomosis of spatulated native ureter to (A) transplant ureter and (B) transplant renal pelvis.

fascia is closed in layers with a 0 or no. 1 permanent monofilament suture. The subcutaneous tissue is not closed. The skin is usually closed with staples. A nephrostomy tube, if present, is removed at day 5 to 7 after an antegrade nephrostogram has been obtained to be sure that there is no leak. The ureteral catheter is left in for 4 to 6 weeks.

---

## OUTCOMES

---

### Complications

---

Complications that can occur postprocedure include infection, urinary leak, bleeding, recurrence of the stricture, and possible loss of graft. In all series, these are uncommon complications (1,7).

---

## Results

---

We have performed over 50 native-to-transplant uretero-ureterostomies or ureteropyelostomies to treat ureteral obstruction or ureteral leaks or to deal with damaged ureters at the time of the transplant. In our experience, all kidneys involved have been “salvaged” and none lost to urologic complications. There have been no significant postoperative complications and no patient deaths. We have not had to repeat any procedures in any of the patients we have treated and have not had any recurrence of either leak or stricture. As noted earlier, we routinely tie off the proximal native ureter, do not do a nephrectomy, and have not had any problems related to the native kidney. We feel that routine native nephrectomy is not indicated, and if one is ever subsequently indicated, a laparoscopic nephrectomy would be our choice.

# CHAPTER 12 ■ RENAL AUTO TRANSPLANTATION

VENKATESH KRISHNAMURTHI AND DAVID A. GOLDFARB

Renal autotransplantation is usually considered a last resort in the spectrum of surgical treatment for extensive ureteral tissue loss. It is valuable for any disease where intervention on the kidney would expose it to prolonged warm ischemia resulting in permanent renal damage. This is the case for complex distal renal arterial disease and large kidney tumors where renal preservation is imperative. The basic techniques have evolved as a consequence of developments in the field of renal allotransplantation, particularly an improved understanding of renal preservation. The advantages of back-table reconstruction include optimal exposure, use of optical magnification (loupes), a bloodless surgical field, and incorporation of renal preservation techniques (intracellular flush solutions and hypothermia) (7).

---

## DIAGNOSIS

---

Since there are a variety of indications for autotransplantation, diagnostic studies will vary accordingly. Extensive ureteral loss is usually documented by computerized tomography (CT) scan, intravenous urography, retrograde urography, antegrade urography, or a combination of these imaging modalities. Complex renal vascular diseases are typically screened with CT or magnetic resonance (MR) angiography. Due to the distal nature of renal vascular disease (branch disease) amenable to autotransplant, almost all candidates may also have catheter-based arteriographic studies. Renal tumors are assessed by CT or magnetic resonance imaging (MRI). Extensive investigation is typical for the loin-pain hematuria syndrome. Patients have usually had the full spectrum of radiographic testing to assess the renal vasculature, parenchyma, and collecting system. They have also had diagnostic ureteroscopy. Most have had visceral pain blocks that have failed to provide durable pain relief.

---

## INDICATIONS FOR SURGERY

---

Autotransplantation of the kidney is an acceptable treatment option for patients with impassable proximal ureteral obstruction and extensive ureteral loss (1). Complex renal vascular lesions requiring *ex vivo* repair can also be successfully managed with renal autotransplantation (7).

Urinary tract disorders that require consideration for autotransplantation include proximal ureteral obstruction that cannot be managed with bladder-based methods of repair (Boari flap, with or without psoas hitch). Such repairs can rarely extend beyond the pelvic ureter. Moreover, even if

bladder-based flaps can reach beyond the area of obstruction, successful re-establishment of urinary tract continuity may be compromised by excessive tension at the site of reconstruction.

The causes of proximal ureteral obstruction include multiple failed repairs of ureteropelvic junction (UPJ) obstruction (failed pyeloplasty or endoscopic repair), desmoid tumor (with or without the Gardner syndrome) obstructing the proximal ureter, and extensive ureteral stricture. Prior to pursuing autotransplantation, these patients have generally been managed with indwelling ureteral stents and/or percutaneous nephrostomy tubes. They are completely stent-dependent and often have developed recurrent episodes of pyelonephritis.

An uncommon condition that is amenable to autotransplant would be the loin-pain hematuria syndrome (2). This is characterized by flank pain with gross or microscopic hematuria for which exhaustive diagnostic testing has failed to disclose a specific etiology. Aggressive treatment is driven by the chronic pain that accompanies the syndrome.

Finally, some centers have used *ex vivo* back-table excision, reconstruction, and autotransplantation for large renal cancers that are not felt to be amenable to *in situ* repair (8,9).

---

## ALTERNATIVE THERAPY

---

An alternative to renal autotransplantation in patients with proximal ureteral obstruction is ileal ureteral substitution; however, ileal substitution may not be possible in patients with a history of extensive intestinal surgery, such as those patients with the Gardner syndrome who have undergone total proctocolectomy with ileostomy or ileal pouch creation. Additionally, the long-term consequences of intestinal interposition within the urinary tract are not completely known and must be considered when utilized in younger patients. Therefore, for patients in whom an ileal substitution does not seem favorable, autotransplantation may be the only option.

Complex renal vascular disorders are also an indication for renal autotransplantation. These are most often arterial disorders such as stenoses or aneurysms involving the segmental renal arteries and are difficult to treat with *in situ* methods. As an extension of the techniques routinely applied in renal allotransplantation, the renal hilum can be readily accessed while the kidney is on the “back table.” Revascularization to branch vessels or excision of aneurysms deep in the hilum is much easier on the back table and thus can be accomplished satisfactorily prior to autotransplantation.

---

## TECHNIQUE OF RENAL AUTO TRANSPLANTATION

---

### Surgical Instrumentation

---

Renal autotransplantation is a combination of living donor nephrectomy and standard renal transplant within the same patient. A satisfactory performance of these procedures requires instrumentation to facilitate fine vascular repairs. Although the specific instrument is a matter of individual preference, instrumentation for vascular surgical procedures should include (a) noncrushing vascular clamps designed for blood vessel occlusion, (b) forceps with fine tips designed to atraumatically grasp vessel walls as well as suture needles, (c) needle holders with fine tips to grasp small needles yet prevent unwanted needle movement, and (d) an assortment of silastic vessel loops and umbilical tapes for atraumatic vessel manipulation.

Vascular clamps are manufactured in a variety of shapes and sizes. Their selection depends upon the size of the vessel to be occluded and the desired direction of vessel wall occlusion (longitudinal, transverse, or oblique). The jaws of vascular clamps should have rows of interdigitating teeth that allow vessel wall apposition without endothelial damage. Vascular clamps should be applied by compressing the jaws only to the point necessary for blood flow cessation. Overaggressive application can result in endothelial damage and subsequent dissection.

For small, delicate vessels or relatively inaccessible areas, spring-loaded (bulldog) clamps are useful devices. These also come in a variety of sizes, strengths, and shapes. Additionally, plastic varieties with soft padded jaws may be useful for extremely delicate vessels.

Vascular forceps must have tines that are in direct apposition, and the tips should be fine enough to grasp the vascular adventitia as well as a suture needle. Forceps with rows of interdigitating teeth serve to accomplish both of these purposes. In contrast, forceps designed for stable needle grasp, such as diamond jaw forceps, do not allow for reliable manipulation of tissue.

Vascular needle holders should have fine tips to grasp fine suture needles. The two common choices in vascular needle holders are a ring-handled needle holder and the spring-loaded type. Needle holder selection, again, is a matter of individual preference; however, spring-loaded needle holders generally allow for precise needle placement without large degrees of wrist rotation. Ring-handled needle holders enable a more stable needle grasp and facilitate accurate placement in deep structures or through densely calcified vessels.

To some degree, the selection of vascular suture is also a matter of individual preference. The caliber of the suture should be as fine as possible, without risking suture line disruption, to minimize bleeding through suture holes. In most cases, suture sizes between 2-0 and 7-0 will be applicable for vascular procedures in the abdomen and pelvis. At the level of the aorta, a 2-0 or 3-0 suture should suffice, and 4-0 is almost always suitable for the inferior vena cava. As one progresses to smaller vessels, including the common and external iliac arteries and veins, a 5-0 and 6-0 suture is most often satisfactory. Repair of small vessels, such as segmental renal arteries, may require a 7-0 or 8-0 suture.

Nonabsorbable sutures are most often selected for vascular procedures. Although silk suture has favorable handling and tying characteristics, its popularity has waned with the development of synthetic, nonabsorbable sutures such as polypropylene. In comparison to silk, synthetic monofilament sutures are relatively inert in tissue, have a low coefficient of friction and thereby result in less tissue drag, and tend to retain a greater amount of tensile strength over time. Vascular sutures are swaged onto fine, one-half-circle or three-eighths-circle needles. The vascular needle should be large enough to penetrate tissue yet small enough so as not to cause hemorrhage from the needle holes. A common practice in vascular repair is to use a continuous suture with needles swaged onto both ends. This construction allows for greater flexibility in accomplishing the repair (e.g., closure from both directions). In select instances, specifically that of pediatric vascular surgery, absorbable monofilament suture with a long half-life (e.g., polydioxanone suture) can be used to allow anastomotic growth.

Another essential component for autotransplantation of the kidney is retraction. We prefer to use a self-retaining, ring-based retractor system that is fixed to the table. For flank exposure, the Bookwalter retractor (Codman & Shurtleff, Inc., Raynham, Mass.) provides for excellent exposure of the kidney and renal hilum. We have modified the medium oval ring on the Bookwalter by creating a modest angle (20 to 30 degrees) along the two ends of the ring. This enables the ring to better “fit” the patient’s flank during the operative procedure. A standard oval ring works very well in the iliac fossa. Lastly, for midline intraperitoneal abdominal incisions, we have utilized both the Bookwalter retractor system and the Thompson retractor (Thompson Surgical Instruments, Inc., Traverse City, Mich.). We feel that the Thompson retractor provides better exposure in more obese patients as the side bars of the retractor can be placed further from the incision. One disadvantage of this feature, however, is that the side bars tend to be closer to the operating surgeon and can be difficult to work around.

---

### Renal Autotransplantation: Operative Approaches

---

The selection of the incision for renal autotransplantation depends on (a) the patient’s prior surgical history and (b) the indication for autotransplantation. When the autotransplant is being performed for urinary tract conditions (as opposed to vascular disorders), we prefer to place the kidney into the contralateral iliac fossa. This approach allows the renal pelvis and ureter to be the most superficial structures so that the urinary tract can be reaccessed without needing to dissect or retract the main renal vessels. Although the kidney can be placed in either iliac fossa through a midline intraperitoneal incision, a retroperitoneal flank donor nephrectomy works quite favorably (4). Following completion of the flank approach for the “donor” nephrectomy, the patient is placed back in the supine position, the contralateral iliac fossa is reprepared and draped, and exposure of the iliac vessels is commenced. In theory, this combination of two separate procedures may result in longer total operative time; however, this must be counterbalanced by the benefit of extraperitoneal procedures and improved exposure along both the flank and iliac operative fields.

A midline intraperitoneal approach is also quite satisfactory for renal autotransplantation. We prefer to use this technique when the autotransplant is being performed for vascular conditions, since the midline approach enables dissection of any abdominal structure. During repair of vascular disorders, arterial conduits (e.g., hypogastric artery) are often necessary for reconstruction, and these vessels can be easily exposed through a midline intraperitoneal approach. In contrast to two retroperitoneal procedures, the midline approach does require mobilization and retraction of the small bowel and colon, which may add to postoperative ileus. A transverse intraperitoneal approach is not recommended because it is very difficult to expose structures caudal to the aortic bifurcation, such as the iliac vessels.

Lastly, a laparoscopic approach has been quite effectively utilized for the donor nephrectomy portion (3,6). In order to efficiently utilize the laparoscopic approach, however, the kidney extraction incision is made over the ipsilateral iliac vessels so that the autograft can be implanted at this location. As mentioned previously, when autotransplantation is performed for urinary tract disorders, placement of the kidney in the ipsilateral iliac fossa puts the urinary tract structures in the most posterior location, which is suboptimal should further procedures become necessary.

---

### Technique of Flank Donor Nephrectomy

---

Following satisfactory induction of general endotracheal anesthesia and placement of the necessary arterial and central venous monitoring lines, a Foley catheter is placed in the bladder. The patient is then placed on his or her side with the kidney that will be operated on facing “up.” The “down” leg is then bent and the “up” leg is maintained in a straight position. Pillows are placed between both legs, and the greater trochanter along the table surface is padded with egg crate mattresses. The kidney rest is maximally elevated and the table is fully flexed. This enables a maximum distance between the lower ribs and the iliac crest. An axillary roll is placed, and the arms are padded and secured to a double arm board. The patient is then adequately secured to the table prior to preparation and drape of the operative field.

We prefer to utilize an incision over the course of the eleventh rib. Although selection of the twelfth rib may be suitable in many instances, the exposure of the kidney through the bed of the eleventh rib always provides for adequate exposure of the kidney and renal hilum. Although an approach through the eleventh rib has a slightly greater chance of pleural entry, this is easily managed by evacuation of the entrained air or by placement of a thoracostomy tube. The most important aspect of flank donor nephrectomy is exposure of the renal hilum, and the disadvantage of approaching this through the twelfth rib is that the hilum may be at the most superior portion of the operative field. Additionally, exposure through the twelfth rib bed may require significant caudal retraction on the kidney during mobilization, which may add to trauma to the kidney.

After the skin is incised sharply, the subcutaneous tissue and flank musculature are divided with the electrocautery. The anterior surface of the eleventh rib is exposed, and the rib is then dissected in a subperiosteal plane. The rib can be dissected in a subperiosteal manner. Once the rib is mobilized to a suitable posterior location, it is transected. It is some-

times necessary to cauterize the cut end of the rib or obtain hemostasis with bone wax. The retroperitoneal space is then entered along the tip of the removed rib, and, once retroperitoneal entry is verified, the abdominal contents are swept off the undersurface of the flank musculature. These muscles are then further opened in the direction of the incision.

The next step in the flank exposure is mobilization of the diaphragm and pleura. The neurovascular bundle associated with the removed rib is identified and is swept inferiorly and laterally. The attachments of the periosteum and diaphragm against the adjacent lower rib are then divided sharply with the electrocautery. We prefer to continue this division all the way back to the insertion of the diaphragm on the psoas muscle, or lumbocostal arch. This allows for excellent exposure, and, by completely mobilizing the pleura and diaphragm, avoids retraction-related tears on the pleura. Finally, the kidney can be mobilized within Gerota fascia since the procedure is being done for benign conditions. Once the kidney is suitably mobilized, the self-retaining retractor can be positioned to retract everything but the kidney and associated structures.

At the time of kidney mobilization, intravenous mannitol 12.5 g is given. A second 12.5-g dose is usually given just prior to renal artery clamping. The perinephric fat is then completely removed. The renal artery and vein are skeletonized to as proximal a level as possible. The renal artery should be dissected so that an adequate length is maintained for the implantation and the diseased portion can be reconstructed; however, it is extremely important not to dissect the artery too close to the aorta, since a minimal amount of artery must be maintained for suitable control. Too short of a stump on the aorta can lead to catastrophic complications; however, too short of a stump on the kidney side can be reconstructed through a variety of techniques. One must differentiate the dissection of the renal artery during an autotransplant from that of in situ revascularization procedures. In revascularization procedures, the aorta is more accessible and may be more readily controlled, in contrast to flank exposures.

On the right side, the renal vein should be dissected all the way to the inferior vena cava (IVC), and the juxtarenal IVC must also be exposed. It is essential to mobilize the IVC posterior to the insertion of the renal vein, as the posterior wall of the IVC must be easily clamped during extraction of the kidney. On the left side, the adrenal, gonadal, and lumbar venous branches should be divided.

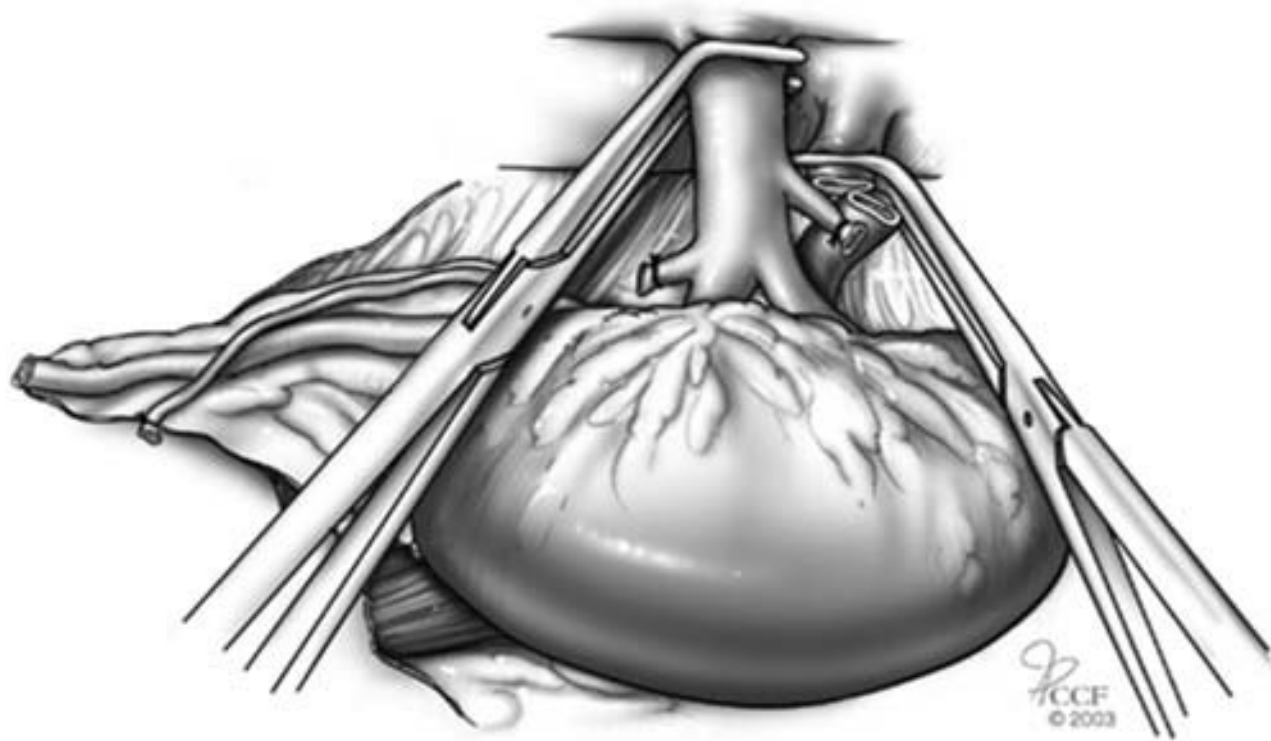

The ureter is dissected usually to the level of its crossing over the iliac vessel. In cases of proximal ureteral obstruction, the ureter should be dissected approximately to the level of obstruction, but more importantly, it must be dissected to only a length suitable for reimplantation. A generous amount of periureteral tissue should be maintained with the ureteral dissection. We prefer to include the gonadal vein and intervening tissue along with the ureter. In cases where the ureter is dilated due to chronic obstruction, the need to maintain an adequate amount of periureteral tissue is less important due to the development of neovascularity. The ureter is then divided above the level of the obstruction (if present), and a satisfactory diuresis is verified by observing urine flow from the cut end of the ureter.

The kidney should be palpated to ensure a turgid feel. A soft kidney with no urine production should raise concern for arterial spasm. In these situations, the kidney should not be handled, and warm saline can be placed as an initial maneuver. If the kidney turgor has not improved and the spasm has

not abated after a period of several minutes, papaverine can be applied topically along the renal artery adventitia.

When the kidney is firm and there is an adequate diuresis of urine, it is acceptable to proceed with removal. Mannitol (12.5 g) is given intravenously. The renal artery is then clamped and transected and the kidney mobilized so that the renal vein is placed on stretch. The renal vein, or inferior vena cava, is then clamped, and the vein is divided sharply at a suitable location. The kidney is then passed off to a separate team, who will commence with both surface hypothermia and in situ cold perfusion.

Attention is directed toward securing the renal vessels. The renal vessels can be secured with any combination of ties, clips, or suture ligatures. Our typical practice is to place two ties with 0 silk. When two ties are not possible, we may use a single clip and oversew the renal artery stump with a 5-0 polypropylene suture. The left renal vein can be similarly controlled (Figs. 12.1 and 12.2). On the right side, however, it is

**FIGURE 12.1** Control of left renal hilum. Note that the renal vein is clamped as close to the IVC as possible.

**FIGURE 12.2** A small stump of left renal artery is preserved to ensure safe ligation.

**FIGURE 12.3** Control of the renal vein includes a small cuff of IVC.

**FIGURE 12.4** Securing the IVC with a running suture.

essential to remove the kidney with a small (few millimeters) margin of IVC (Figs. 12.3 and 12.4). In this situation, the vena cava is closed with a 4-0 polypropylene suture. We generally place one suture at each apex and run toward the midpoint. It is not essential to run this closure in an over-and-back manner as the low-pressure venous system is unlikely to leak between the suture lines. It is also important to leave a suitable margin of vein above the clamp so the cavotomy can be safely closed. If the renal vein is inadvertently transected directly on the clamp, two options exist. One option would be to place a larger clamp below the existing clamp and to remove the first clamp. If this option is pursued, it is imperative to make sure that the second clamp is properly placed and that the walls of the vena cava are firmly apposed. Another option, which may be potentially safer, would be to reapproximate the IVC walls in a horizontal mattress fashion by

sewing “under” the clamp. In all cases, we recommend that the vena caval clamp be released slowly so that it can be reapplied immediately should there be unexpected significant bleeding from the vena caval closure.

Once the renal vessels are secured, the operative field is irrigated and inspected for hemostasis. The retractor is then removed, and the flank musculature and fascia are closed in two layers. Following completion of the flank procedure, general anesthesia is maintained and the patient is repositioned for the renal transplant procedure.

---

### Donor Nephrectomy via a Midline Intraoperative Approach

---

The patient is placed in the supine position. General endotracheal anesthesia is induced. The appropriate arterial and central venous monitor lines are placed. A Foley catheter is placed in the bladder in a sterile manner. Surgical preparation should include the field from the nipples to the lower thighs. The genitalia should be shaved and prepped and covered with a sterile surgical towel. Both groins should be available for access should there be a need for saphenous vein procurement.

For renal autotransplantation, a midline incision from xiphisternum to pubic symphysis should be employed. The subcutaneous tissues and linea alba are divided with the electrocautery, and the abdominal wall can be retracted with a self-retaining retractor. It is important to ensure complete neuromuscular blockade so that the abdominal wall can be retracted maximally. For right-sided autotransplantation, we prefer to mobilize the right colon and duodenum medially to expose the entire infrarenal vena cava, left renal vein, and abdominal aorta. For left renal autotransplantation, the left colon should be mobilized medially so that the left renal vein can be accessed as it crosses over the aorta. Following mobilization, the viscera are retracted with the self-retaining retractor. The kidney can be mobilized within Gerota fascia, as mentioned previously. The ureter should be mobilized with a generous amount of periureteral tissue until the point of obstruction or to a level where it crosses the iliac vessels. When autotransplantation is being performed for vascular conditions, the ureter does not always need to be divided as the renal vascular reconstruction can be performed in a basin containing iced slush placed on the patient’s abdomen. We prefer to divide the ureter so that the kidney can be taken off the operative field and exposed maximally on the back table, during which time the iliac fossa can be prepared by a separate surgical team.

With the kidney fully mobilized and the ureter divided, the renal vessels are dissected. Because cases of renal autotransplantation for vascular diseases usually involve arterial disorders, it is necessary to completely skeletonize the renal vein so that it can be mobilized away from the posterior renal artery. Accurate preoperative judgment is essential to determine the feasibility of in situ repair. However, even in cases in which in situ repair is thought to be unfeasible, intraoperative findings may dictate otherwise, and the surgeon should be prepared to reconstruct the kidney in situ. However, in cases of proximal ureteral obstruction and in cases of vascular disease requiring ex vivo repair, the kidney has to be removed and reconstructed on the back table. As previously described, the vessels are dissected as proximally as is necessary to correct the lesion. Intravenous mannitol (12.5 g) is administered. After an

adequate diuresis and a firm kidney are verified, the renal artery is clamped and divided, the renal vein or IVC is clamped, and the vein is divided. The kidney is passed off to a separate team, who will commence surface hypothermia and in situ cooling. The main renal vessels are secured, and the field is inspected. As the kidney is being perfused, the iliac fossa can be prepared by a separate surgical team.

---

### Back-Table Preparation of the Renal Autograft

---

Once removed, the kidney is placed in a basin containing ice slush. The renal artery is cannulated and in situ perfusion with cold preservation solution started. Cannulation may be achieved with a large-gauge angiocatheter (14 gauge) or a metal-tipped cannulation device.

Since there is minimal ischemic time during renal autotransplantation, almost any electrolyte solution can be used to provide in situ cooling for the kidney. In our center, we routinely use a Euro-Collins solution. We prefer to perfuse the kidney with an entire volume of perfusate (approximately 1,000 mL); however, it is necessary to perfuse a kidney only until the venous effluent is clear. In cases of multiple arteries, all arterial branches need to be separately perfused as these represent end vessels to the kidney. Very small vessels may require manual perfusion with a syringe and a small-caliber (22-gauge) angiocath tip. Once the kidney has been perfused, the renal vasculature can be prepared. The renal vein should be dissected back to its segmental branches. Small venous tributaries can be ligated with silk ties and divided. Large segmental branches should be preserved, and it is imperative to maintain at least 50% of the total venous drainage of the kidney. Once the vein is skeletonized back to its segmental branches, it can be retracted away from the artery, which can then be similarly dissected. The lymphatic tissue surrounding the artery is sharply excised and secured along the segmental arterial branches. Large lymphatic trunks in this location should be secured with silk ties in order to prevent a lymph leak, particularly if the implantation of the kidney is going to be placed in a retroperitoneal location. Once the artery has been mobilized to its segmental branches, it should be ready for implantation. Any remaining perinephric fat should be removed, and we also prefer to perform a needle biopsy of the kidney at this time to provide any additional histologic information.

In cases of renal vascular disease, the renal artery should be dissected distally, beyond the level of the disease. The diseased segment of the artery or arteries should be excised, and the remaining normal artery or branch artery can be reconstructed in a variety of techniques (Fig. 12.5).

---

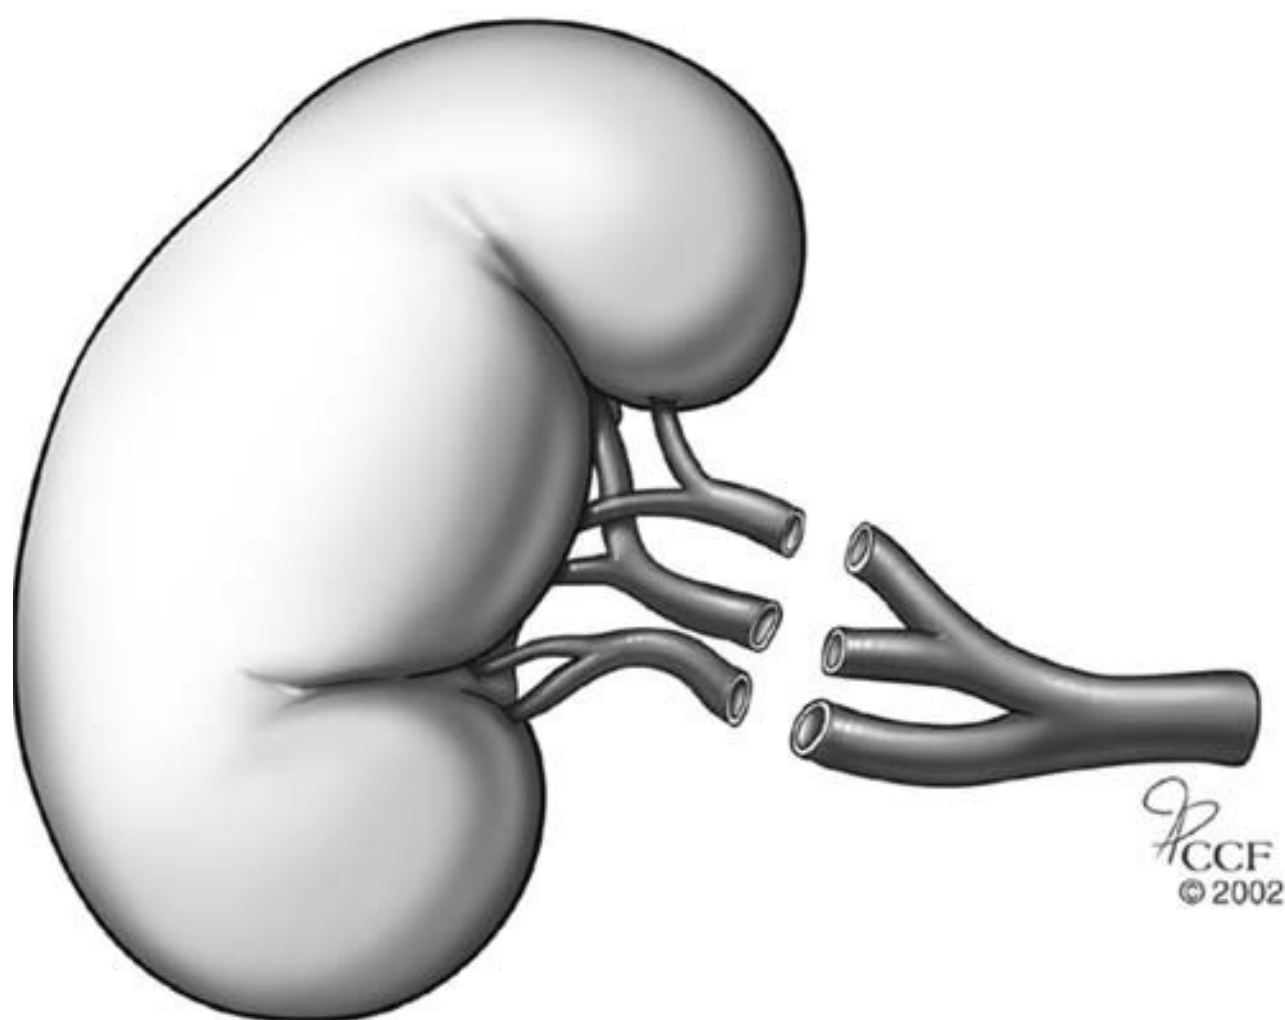

### Implantation of the Renal Autograft

---

#### Exposure of the Iliac Vessels

As mentioned previously, the site for renal autograft implantation can be exposed by a second surgical team while the kidney is being prepared on the back table (5). A standard lower-quadrant oblique (Gibson) incision can be used to enter the retroperitoneum when two separate incisions are utilized for autotransplantation. Of particular importance with the

**FIGURE 12.5** The native hypogastric artery can often be used as an interposition graft in complex branch renal artery repair. The hypogastric artery must be free of significant vascular disease to be useful.

retroperitoneal approach, large lymphatic trunks should be ligated prior to division to prevent postoperative lymphocele. We typically expose the full length of the external iliac artery followed by the external iliac vein. The external iliac artery is almost always free of branches until the most distal aspect, where the epigastric vessels arise. The external iliac vein can often have posterior tributaries (e.g., obturator vein), and division of these vessels lends significant mobility to the external iliac vein. The internal iliac or hypogastric vein is a large trunk, often comprised of three veins, entering along the posterior aspect. Division of this vessel must be approached with extreme care as the hypogastric vein is very short and very wide and loss of control of this vein can lead to massive hemorrhage. We prefer to divide this vein only when the iliac vein needs to be mobilized lateral to the external iliac artery due to a short renal vein. Our approach to dividing the hypogastric vein(s) is to (a) medially mobilize the external, internal, and common iliac arteries, (b) obtain control of the external iliac vein and common iliac vein (we prefer to encircle these vessels with silastic loops), and (c) divide the hypogastric vein only after flow is interrupted both proximally and distally. It can be very difficult to obtain enough distance between two ties; consequently, we have found that titanium clips provide satisfactory occlusion along the proximal aspect. If another tie cannot be placed on the distal aspect (insertion into the external iliac vein), this orifice can be suture-ligated after occluding flow in the external and common iliac veins.

In contrast to an extraperitoneal approach, the iliac vessels can be exposed directly when using an intraperitoneal approach. Lymphatic trunks are simply cauterized, and similar exposure of the iliac vessels is obtained. Another distinction of an intraperitoneal approach is that it is often easier to expose larger vessels for implantation, specifically the common iliac artery and infrarenal vena cava. These vessels are more accessible and larger caliber, features that may facilitate renal vascular anastomoses.

Important points in selecting the target for renal autograft implantation are that (a) the vessels should be adequately mobile to allow for tension-free anastomoses to the renal artery and

**FIGURE 12.6** This figure demonstrates regional control of the external iliac artery and vein. It also shows the final appearance of the transplanted kidney.

vein, and (b) the inflow artery should be adequately free of atherosclerotic disease. The second point deserves further elaboration in that, not only should the anastomotic site be acceptable, but the location for clamp placement should also be “soft.” If there is concern over the suitability of the artery, a “softer” location should be explored both proximally and distally.

#### Renal Autograft Revascularization

Revascularization of the kidney is commenced by anastomosis of the renal vein to the iliac vein (or vena cava) (Fig. 12.6). We typically occlude the iliac vein with a tangentially occluding or Satinsky-type clamp. An appropriate-length venotomy is made on the anterior wall, and the lumen is irrigated with heparinized saline. The kidney is brought into the operative field, and a continuous anastomosis is completed by first placing sutures at both apices of the venotomy and then running around each “side.” For anastomosis to the iliac vein, both 5-0 and 6-0 polypropylene sutures are acceptable, and when the vena cava is used for outflow, 5-0 polypropylene is suitable.

We perform the arterial anastomosis following completion of the venous anastomosis. The iliac artery (common or external) is occluded with vascular clamps both proximally and distally. Alternatively, a single clamp (Satinsky type) can be used for arterial occlusion as well, but the disadvantage to this approach is that the artery cannot be unclamped without restoring the high-pressure antegrade flow. Following clamp control, the periadventitial tissue at the proposed site of anastomosis is sharply excised, an arteriotomy is made with a no. 11 blade, which is then further fashioned to match the caliber of the renal artery, and the lumen is irrigated with heparinized saline. We commonly use a continuous 6-0 or 7-0 polypropylene suture to complete the end-to-side anastomosis to the iliac artery.

Following completion of the vascular anastomoses, we release the venous clamp first, then the distal arterial clamp, and last the proximal arterial clamp. This allows the anastomoses to be “tested” in a low- to high-pressure direction. Once hemostasis is ensured, the operative field and kidney are bathed in warm saline solution, after which the kidney is inspected for

**FIGURE 12.7** The location and creation of the extravascular ureteroneocystostomy is demonstrated.

uniform perfusion. The renal cortex may take several minutes to become homogeneously perfused (pink-appearing), and soon after this occurs, urine production should be seen from the distal ureteral end.

#### Ureteroneocystostomy

In general, we prefer to reimplant the autograft ureter in an extravascular manner (Figs. 12.7 and 12.8). We do not feel that creation of an antireflux tunnel is essential.

Unlike dialysis-dependent patients who are undergoing renal allotransplantation, nearly all patients who are undergoing autotransplantation have “normal” urine volumes and

**FIGURE 12.8** Final appearance of a tunneled anastomosis.

“normal” bladder capacities. The bladder, which is readily distensible, is filled by instillation of saline solution. The perivesical fat over the intended site of ureteral reimplantation is removed with electrocautery dissection. Occasionally, large veins in the perivesical fat must be ligated, for which we prefer to use absorbable suture to avoid potential migration into the anastomosis.

We then trim the ureter at an appropriate length. For renal autotransplantation, the ureter is not excessively long and, in general, does not need to be trimmed to any significant degree (1 to 2 cm at most). Additionally, unlike the ureter received with a deceased donor renal allograft, the viability of the autograft ureter can be ensured during the nephrectomy. Periureteral vessels are ligated with absorbable ties, and the ureter is spatulated for a distance of 8 to 12 mm. The detrusor musculature is then divided with the electrocautery, with care taken to avoid entering the bladder mucosa. The bladder mucosa is entered sharply, and the ureter is anchored at this site with one or two absorbable sutures placed at the “heel” and “toe” of the anastomosis, respectively. We prefer to complete the typical extravascular ureteroneocystostomy with a continuous 5-0 polydioxanone suture. Routine use of an indwelling double J stent is dependent on surgeon preference; however, if there are concerns over the integrity of the anastomosis or the viability of the ureteral end, use of a stent is recommended.

#### Closure of Incision

Prior to closing the incision, we ensure an appropriate position for the kidney. In most cases, the kidney can be placed on the psoas muscle, with the lateral aspect of the kidney directed laterally and the hilum directed medially. This position places the urinary tract in a medial position, should later access be necessary. Once the kidney is positioned, cortical perfusion should be verified and the hilum should be palpated to ensure a strong arterial pulse. Additionally, satisfactory drainage from the renal vein can be ensured by the palpation of a soft, easily compressible renal vein.

We reapproximate the musculature most often in a single layer. When a midline incision is used, we always close this with a single layer of no. 1 polydioxanone or polypropylene. For most retroperitoneal incisions, one layer is satisfactory. In cases where the abdominal wall is thin and the musculature is attenuated, closure in two layers can provide adequate reapproximation.

#### OUTCOMES

The end points for outcomes vary according to the indication for the procedure (ureteral obstruction, renal vascular disease, loin-pain hematuria syndrome). Preservation of the affected kidney is very high. Several reports have demonstrated >90% technical success rates for renal autotransplantation that seem durable. Understand that autotransplantation for a diseased kidney is a more complicated endeavor than renal allotransplantation. Simultaneous donor and transplantation procedures are performed on the same individual, which is an enormous physiological burden. The kidney being autotransplanted is often anatomically compromised. This is in contrast to the donor kidneys in standard allotransplantation, which are normal, and for which the reported technical loss rates are <5%.

---

## COMPLICATIONS

---

Complications of using autotransplantation may derive from the procurement of the kidney or may be related to the implantation of the kidney. The main complications arising from procurement would be bleeding and injury to adjacent viscera (colon, pancreas, spleen, liver). From the implantation portion of the procedure there may be vascular problems. The biggest concern is the potential for arterial or venous thrombosis. Attending to proper vascular technique and ensuring appropriate geometric alignment of the kidney in its final location will help prevent vessel kinking. Recipient vessel dissection or embolization is rare;

nonetheless, early recognition and repair are required to avoid catastrophic limb-threatening problems. With respect to the ureter, there is potential for urine leak or obstruction. Attention to creating a tension-free anastomosis by using a ureter with a well-preserved blood supply is important. Given the diseased status of the vessels or ureter, a ureteral stent is recommended. Finally, when kidneys are autotransplanted into a retroperitoneal position, lymphocele is possible. Meticulous ligation of perivascular lymphatics will help to prevent this complication. A retroperitoneal drain for a brief period may also help avoid this complication. If a lymphocele is causing graft dysfunction, it can be drained percutaneously or surgically.

## CHAPTER 13 ■ ANATOMY OF THE BLADDER

CLINTON W. COLLINS AND ADAM P. KLAUSNER

## GENERAL DESCRIPTION

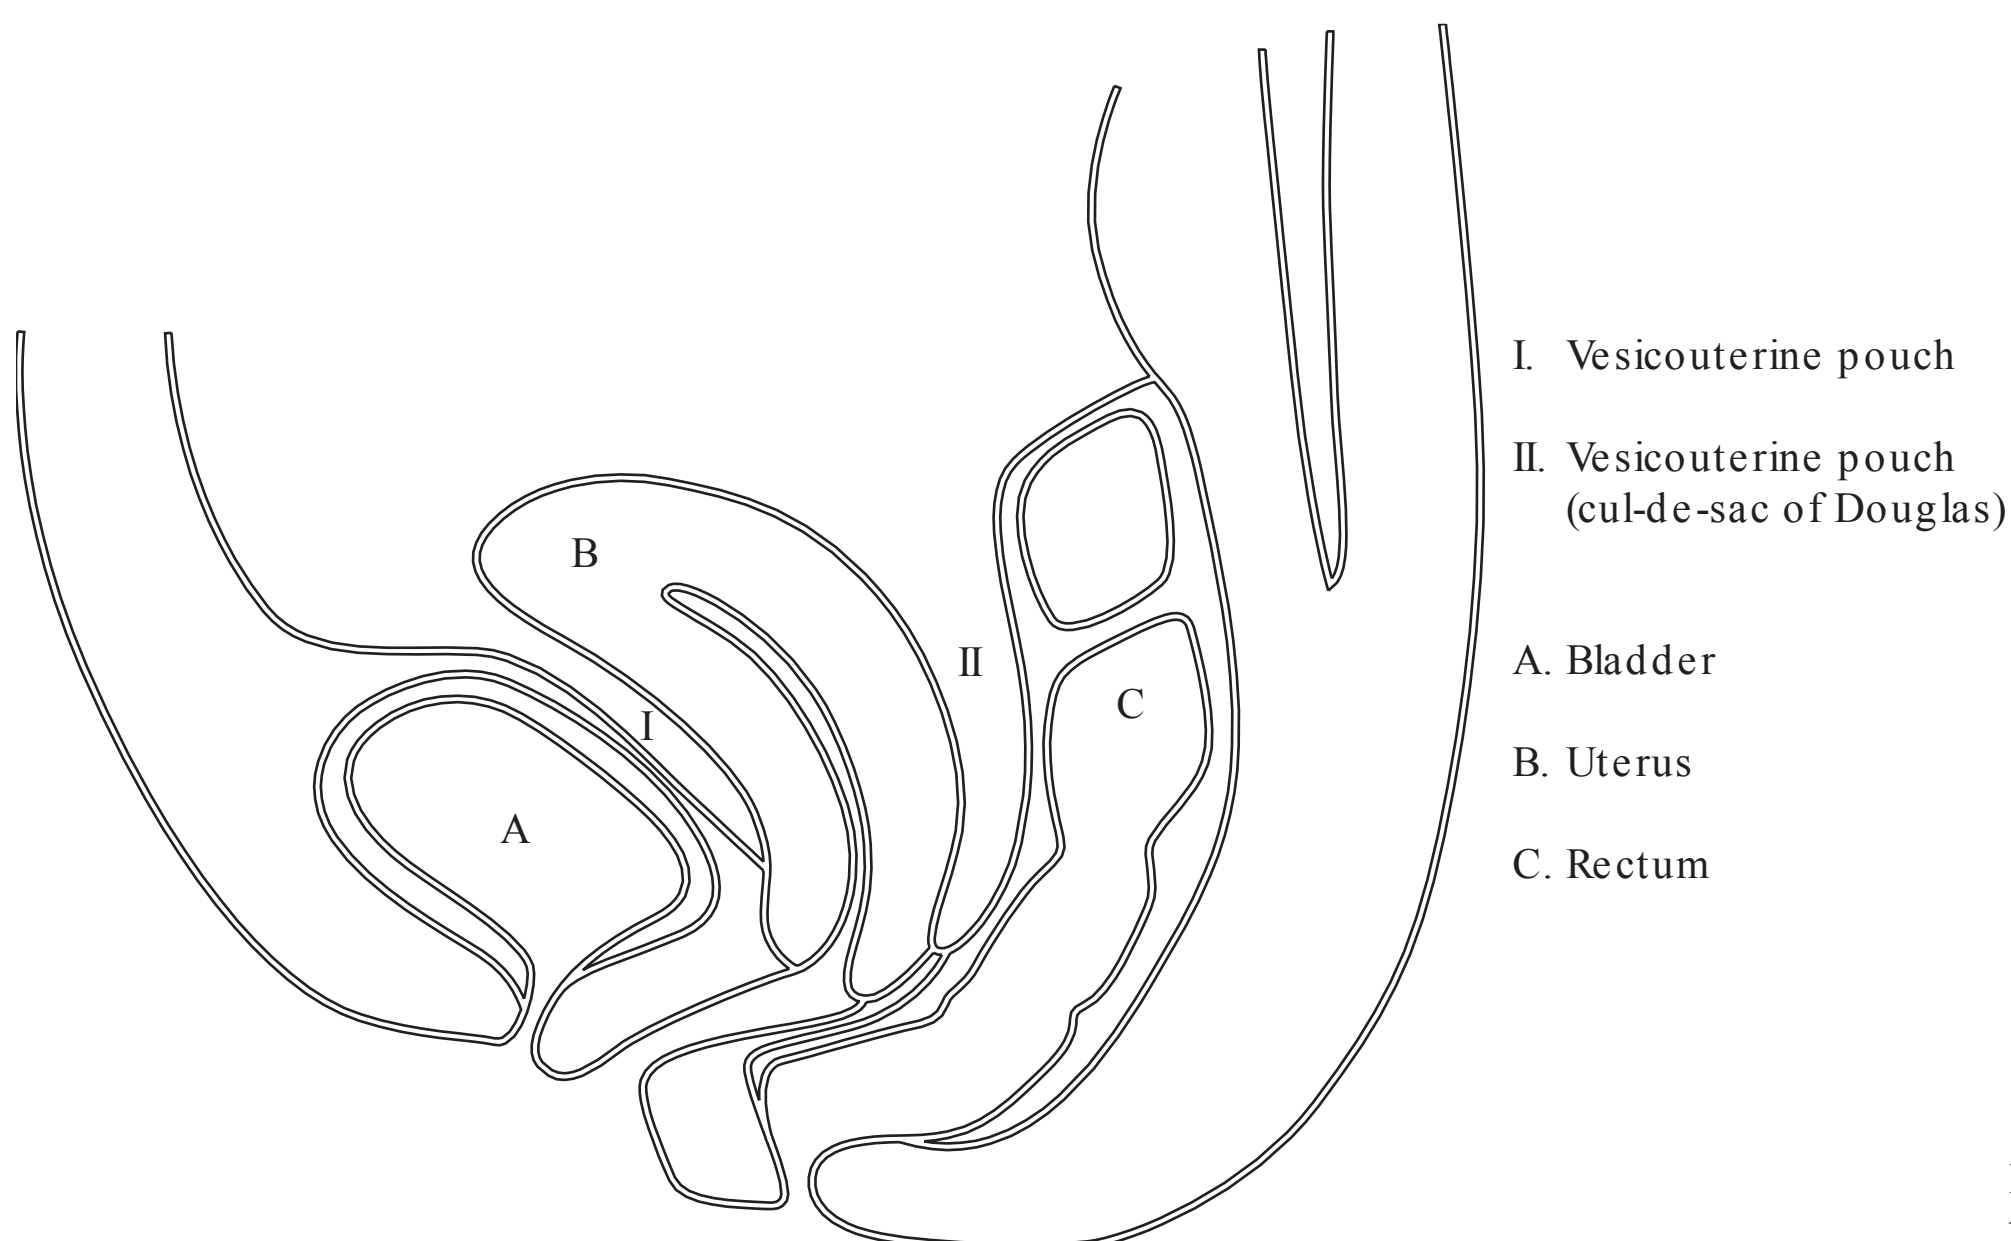

The bladder is a hollow, muscular retroperitoneal organ with a capacity of 400 to 500 mL in the normal adult. When empty, it is a pelvic organ, lying behind the pubic symphysis. However, when distended, it can be palpated above the pubic symphysis and can protude well into the abdomen during an episode of severe urinary retention.

## PERITONEAL RELATIONSHIPS

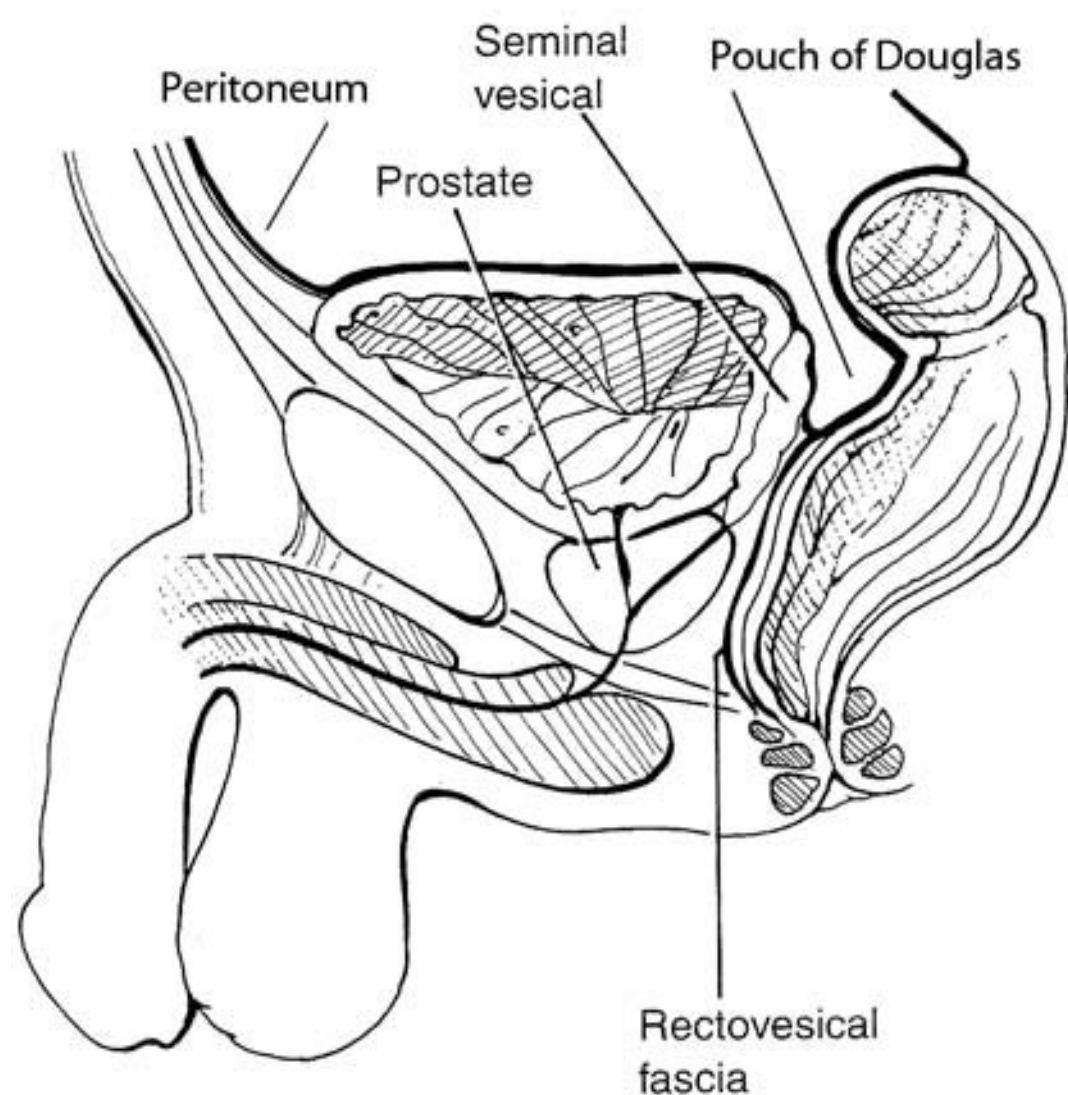

The peritoneum covers the superior bladder and a portion of the posterior bladder. In women, the peritoneum continues posteriorly onto the surface of the uterus and rectum, establishing the vesicouterine and rectouterine pouches, respectively (Fig. 13.1) (1). In men, the peritoneum continues along the surface of the rectum, establishing the rectovesical pouch of Douglas. The two leaves of the peritoneum embryologically coalesce to form the anterior and posterior layers of the Denonvilliers fascia (rectovesical fascia), a critical landmark in the performance of a radical retropubic prostatectomy (Fig. 13.2) (13).

## Peritoneal Folds

As seen from a typical laparoscopic approach to the abdominal cavity, the anterior surface of the peritoneum has three characteristic deflections, also called folds. The midline fold is called the “median umbilical ligament,” and the paired paramedian folds are called the “medial umbilical ligaments.” Fortunately, the anatomy itself is less confusing than the terminology. In relation to the bladder, the median umbilical fold is the most important of these structures as it contains the urachal ligament. Attaching to the bladder anteriorly at its dome, this ligamentous structure, containing fatty and vascular tissue, tethers the bladder to the umbilicus. This structure, which represents the obliterated urachus, contains paraumbilical veins and must be ligated when divided during surgical exposure of the bladder. The bladder muscle, also called the “detrusor,” is attenuated where the urachal ligament attaches, predisposing this area to the formation of diverticuli. Retropubic and perivesical fat is present anteroinferior and lateral to the bladder.

**FIGURE 13.1** Sagittal view of female pouches.

**FIGURE 13.2** Lateral view of the male pelvis showing the peritoneal reflection and the pouch of Douglas.

## LIGAMENTOUS ATTACHMENTS

In the pelvis, the bladder is supported anatomically by two types of ligaments: fibroareolar (true) ligaments and peritoneal folds. True ligaments provide support for the bladder laterally via the lateral ligament of the bladder and posteriorly via the vesicovenous plexus. The lateral ligament derives from the transversalis (endopelvic) fascia as it courses over the levators and attaches the bladder to the tendinous arch of the endopelvic fascia. This ligament contains the inferior vesical and vesicodiferential arteries in the lateral extensions, as well as the pudendal plexuses of nerves and vessels. In addition, in men, this ligament contains the vasa deferentia. The posterior ligaments provide posterolateral support to the bladder. These ligaments are connective tissue condensations in which the vesicovenous plexus drains into the internal iliac veins.

- D. cardinal ligament
- E. uterosacral ligament
- I. bladder
- II. uterus
- III. rectum

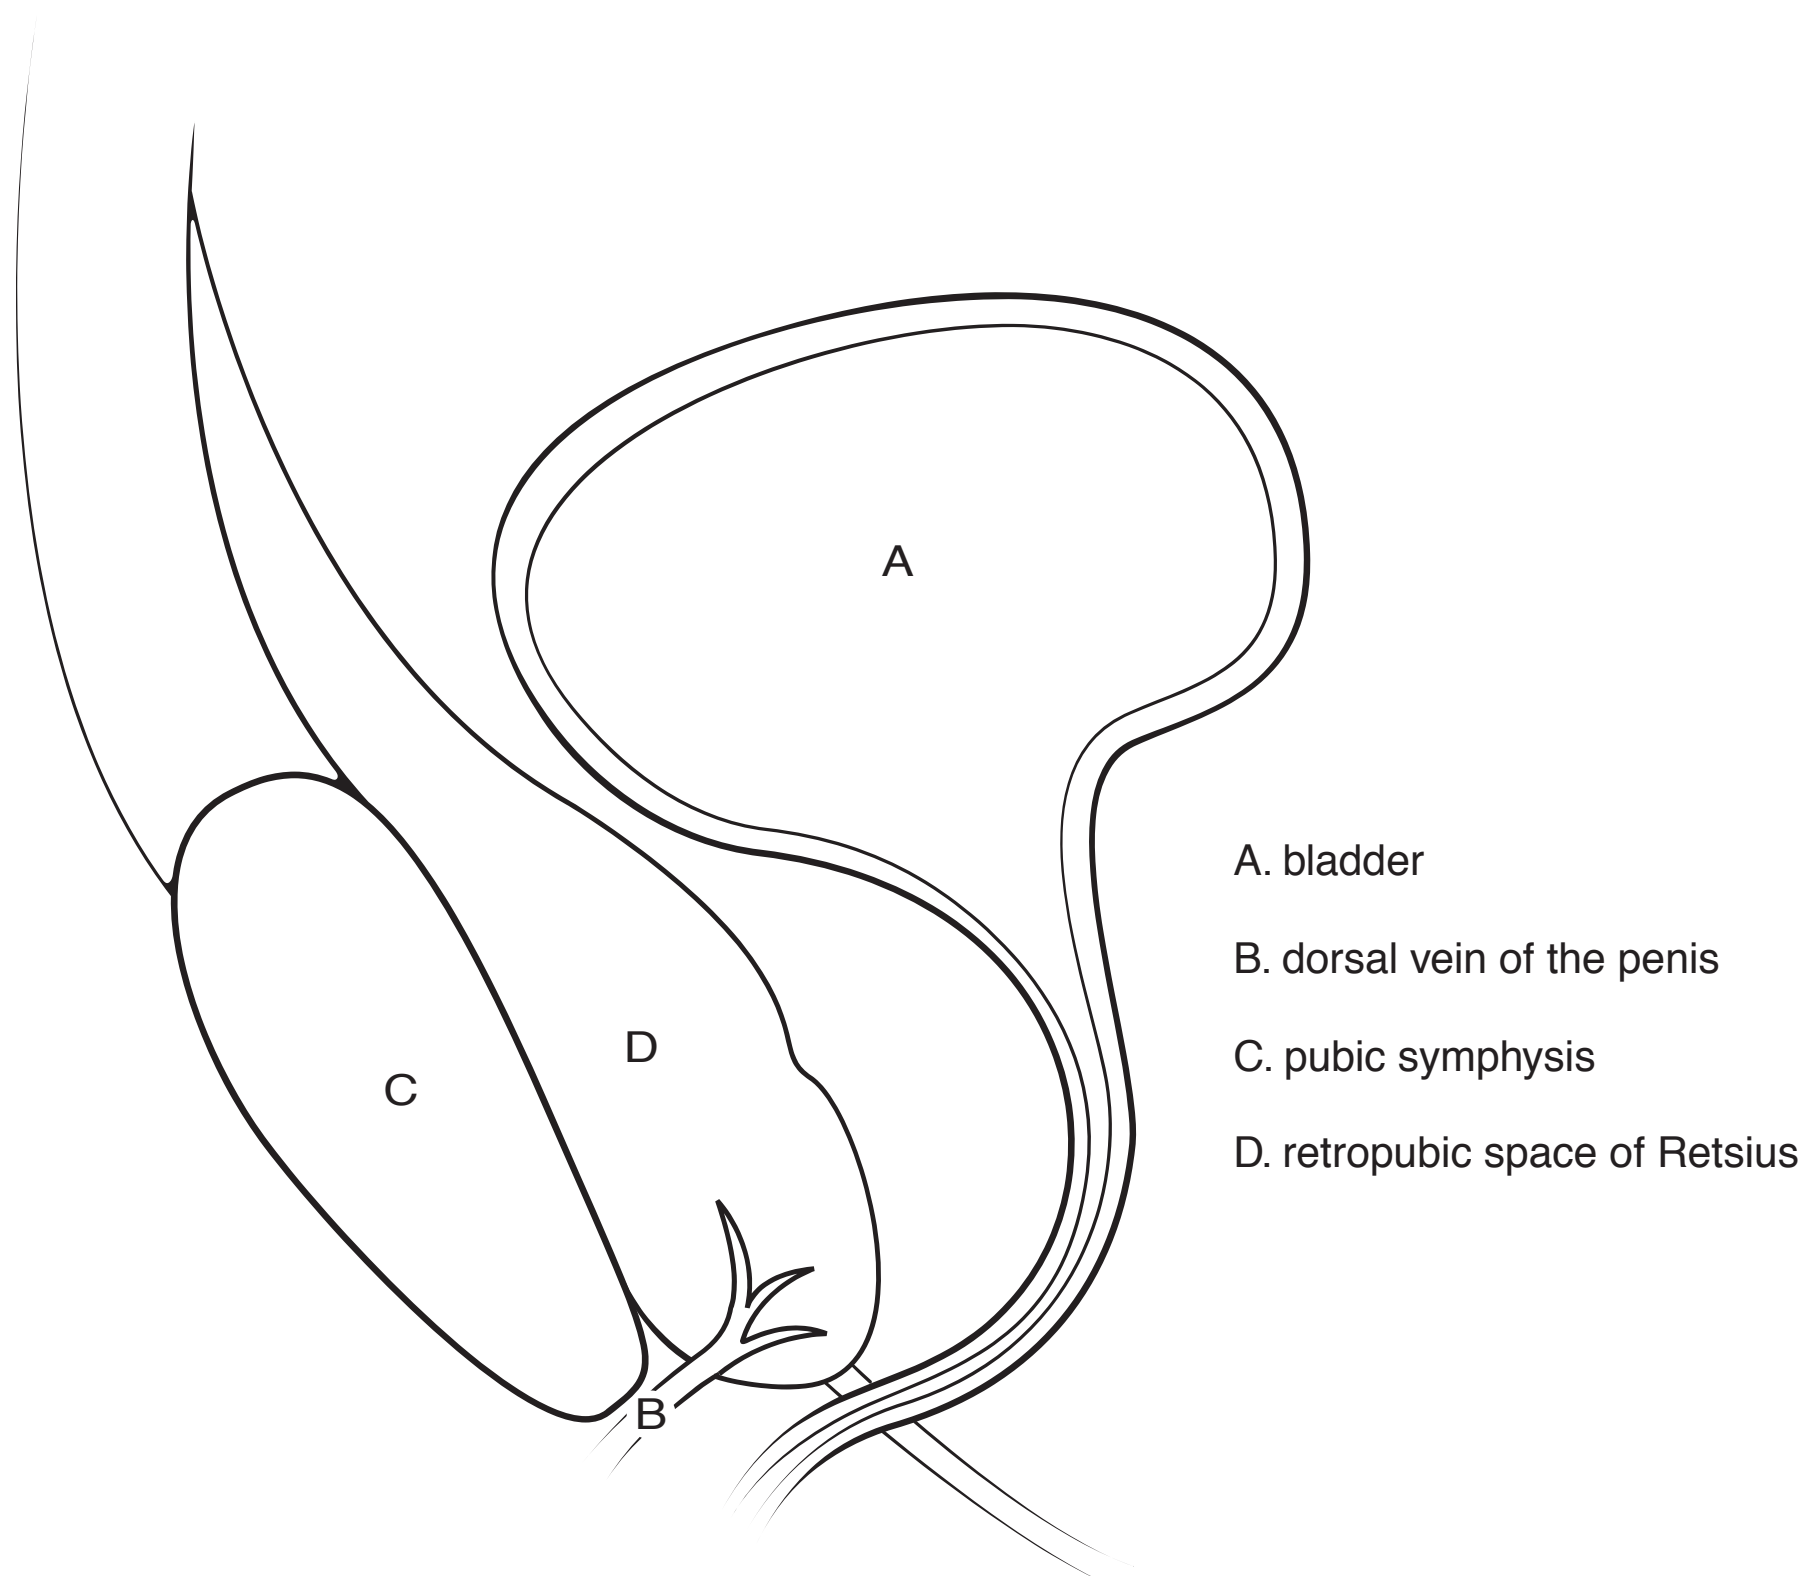

**FIGURE 13.3** Axial view of the female pelvis illustrating the ligamentous supports of the bladder.

Peritoneal folds also connect the bladder to the pelvic sidewalls and consist of the median, medial, and lateral umbilical folds as well as the sacrogenital folds. The median umbilical fold and medial umbilical folds originate at the bladder and terminate at the umbilicus. They contain the urachus and the obliterated umbilical arteries, respectively. The lateral umbilical folds attach the bladder to the pelvic sidewalls and contain the inferior epigastric arteries. The sacrogenital folds connect the bladder to the sacrum (Fig. 13.3) (7).

The bladder is also fixed to the symphysis pubica by the pubovesical ligaments in women and the puboprostatic ligaments in men. The dorsal vein of the clitoris or penis passes between these paired ligaments. These ligaments represent an important surgical landmark as they form the anteromedial portion of the retropubic space, also called the space of Retzius. The space of Retzius is bound anteriorly by the transversalis fascia, inferiorly by the puboprostatic (pubovesical) ligaments, and infralaterally by the lateral ligaments of the bladder (Fig. 13.4).

## HISTOLOGIC STRUCTURE

The lumen of the bladder is lined by transitional epithelium, also called “urothelium.” This unique epithelium is characterized by its outer layer of “umbrella cells,” which are sealed closely together and communicate via tight junctions. The term *transitional* denotes the ability of these outer cells to undergo significant transitions in shape depending on the state of bladder filling. Thus, the cells are puffy and cuboidal when the bladder is empty and become flat and elongated when the bladder is distended (6). Beneath these umbrella cells, the transitional epithelium contains additional layers of cells (usually about seven) and a distinct layer of basal cells. Deep to the transitional epithelium lies the lamina propria, composed of fibroelastic connective tissue through which vessels course. Wisps of smooth muscle also course within the lamina propria, and this portion of the lamina propria is sometimes referred to as the muscularis mucosa (Fig. 13.5).

**FIGURE 13.4** Lateral view of a portion of the male pelvis showing the space of Retzius. The space of Retzius is bound anteriorly by the transversalis fascia, inferiorly by the puboprostatic (pubovesical) ligaments, and infra-laterally by the lateral ligaments of the bladder.

The distinction between the muscularis mucosa and the muscularis propria, or true muscular layer of the bladder that lies deep to the lamina propria, is critical in the staging and prognosis of urothelial cancer. Cancer that is confined to the urothelium or lamina propria, even when surrounded by wisps of muscularis mucosa, is considered superficial disease and is mainly treated via local resection or with intravesical immuno- or chemotherapeutic agents. However, cancer that penetrates into the muscularis propria, characterized histologically by large, distinct detrusor smooth muscle bundles

**FIGURE 13.5** Microscopic cross-sectional image of normal human bladder. Note wisps of smooth muscle (*arrow*) within the lamina propria (*star*). (Courtesy of Dr. Marigny Roberts.)

(Fig. 13.6), is considered invasive cancer and is treated more aggressively; it usually requires surgical removal of the entire bladder. Within the muscularis propria, detrusor smooth muscle bundles course in inner longitudinal, middle circular, and

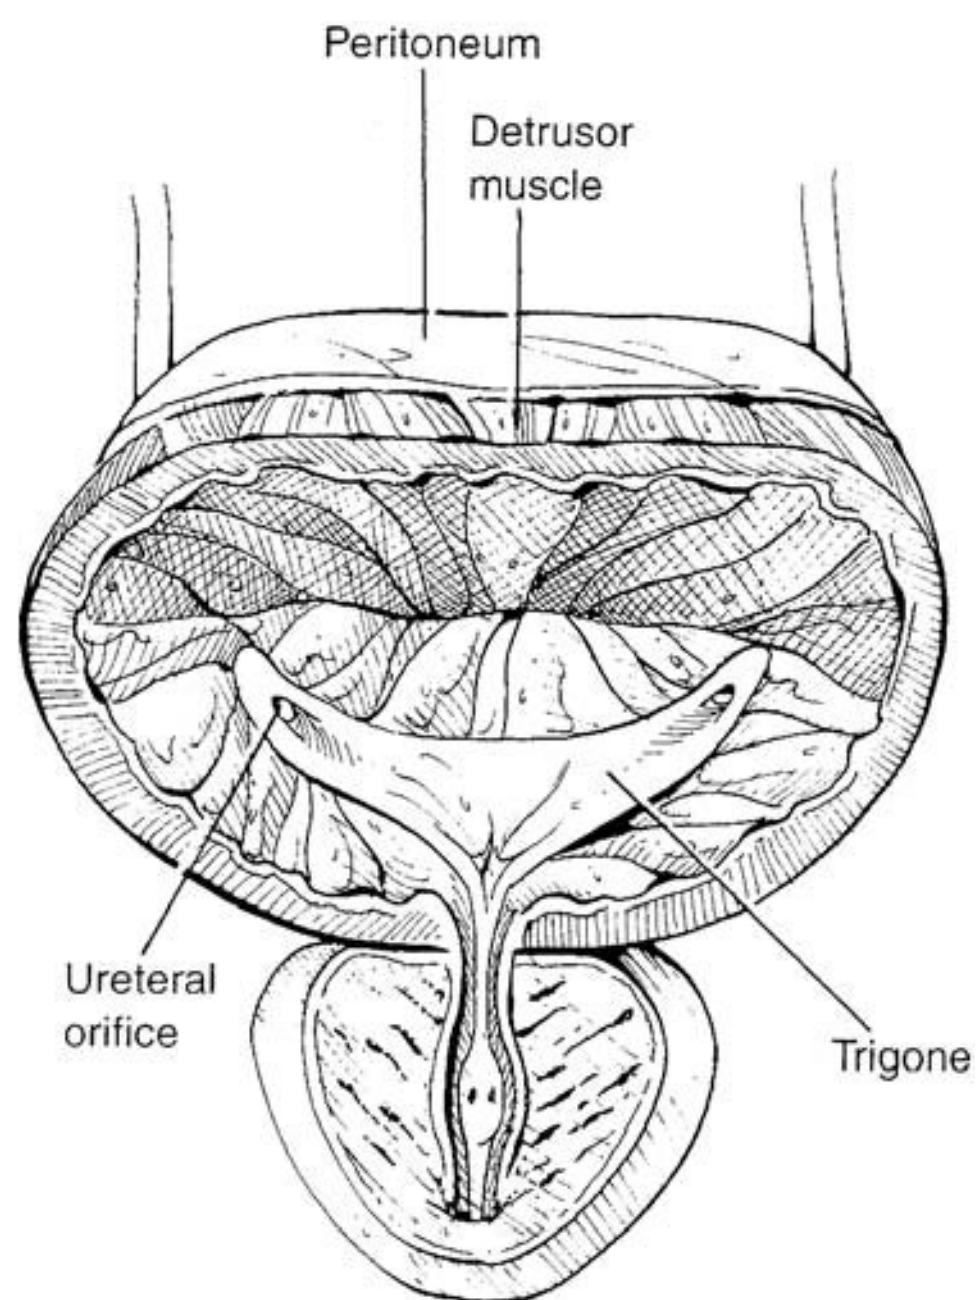

**FIGURE 13.6** Confocal immunohistochemical imaging showing rabbit detrusor bundle. **A:** Densely packed hexagonal shaped detrusor smooth muscle cells. **B:** Interstitial area between smooth muscle bundles containing interstitial cells and fibroblasts.

outer longitudinal orientations. In addition, interstitial cells surround and percolate within the muscle bundles and may be important in the maintenance or modulation of bladder muscle tone (8). These muscle layers are less distinct in the upper aspect of the bladder. However, they become quite prominent at the bladder neck, although composed of finer fibers. In men, the middle layer of circular detrusor smooth muscle forms a preprostatic layer that has robust expression of alpha receptors (mainly alpha 1a) and contributes to continence at the bladder neck. Furthermore, the success in treatment of benign prostatic hypertrophy (BPH) with alpha blockers stems, in part, from a pharmacologic reduction in tone in the smooth muscle surrounding the prostate and bladder neck (2). In women, the bladder neck differs dramatically, having a less distinct middle layer of smooth muscle (1,5).

## URETEROVESICAL JUNCTION AND TRIGONE

The spiral fibers of the ureter become more longitudinally oriented near the bladder and are encased in the fibromuscular Waldeyer sheath from a distance just proximal to its entrance into the bladder wall through its course to the trigone (1,11). Obliquely, the ureters enter the bladder posteroinferiorly and course approximately 2 cm toward the ureteral orifice, narrowing as the intramural ureter is compressed by the detrusor of the bladder surrounding it. The ureter lies just beneath the bladder mucosa with a muscular layer backing (1).

A distinct landmark is formed at a triangle located between the ureteral orifices and the bladder neck, referred to as the bladder trigone. Layers of ureteral and bladder smooth muscle coalesce here as a raised ridge of tissue between the two orifices

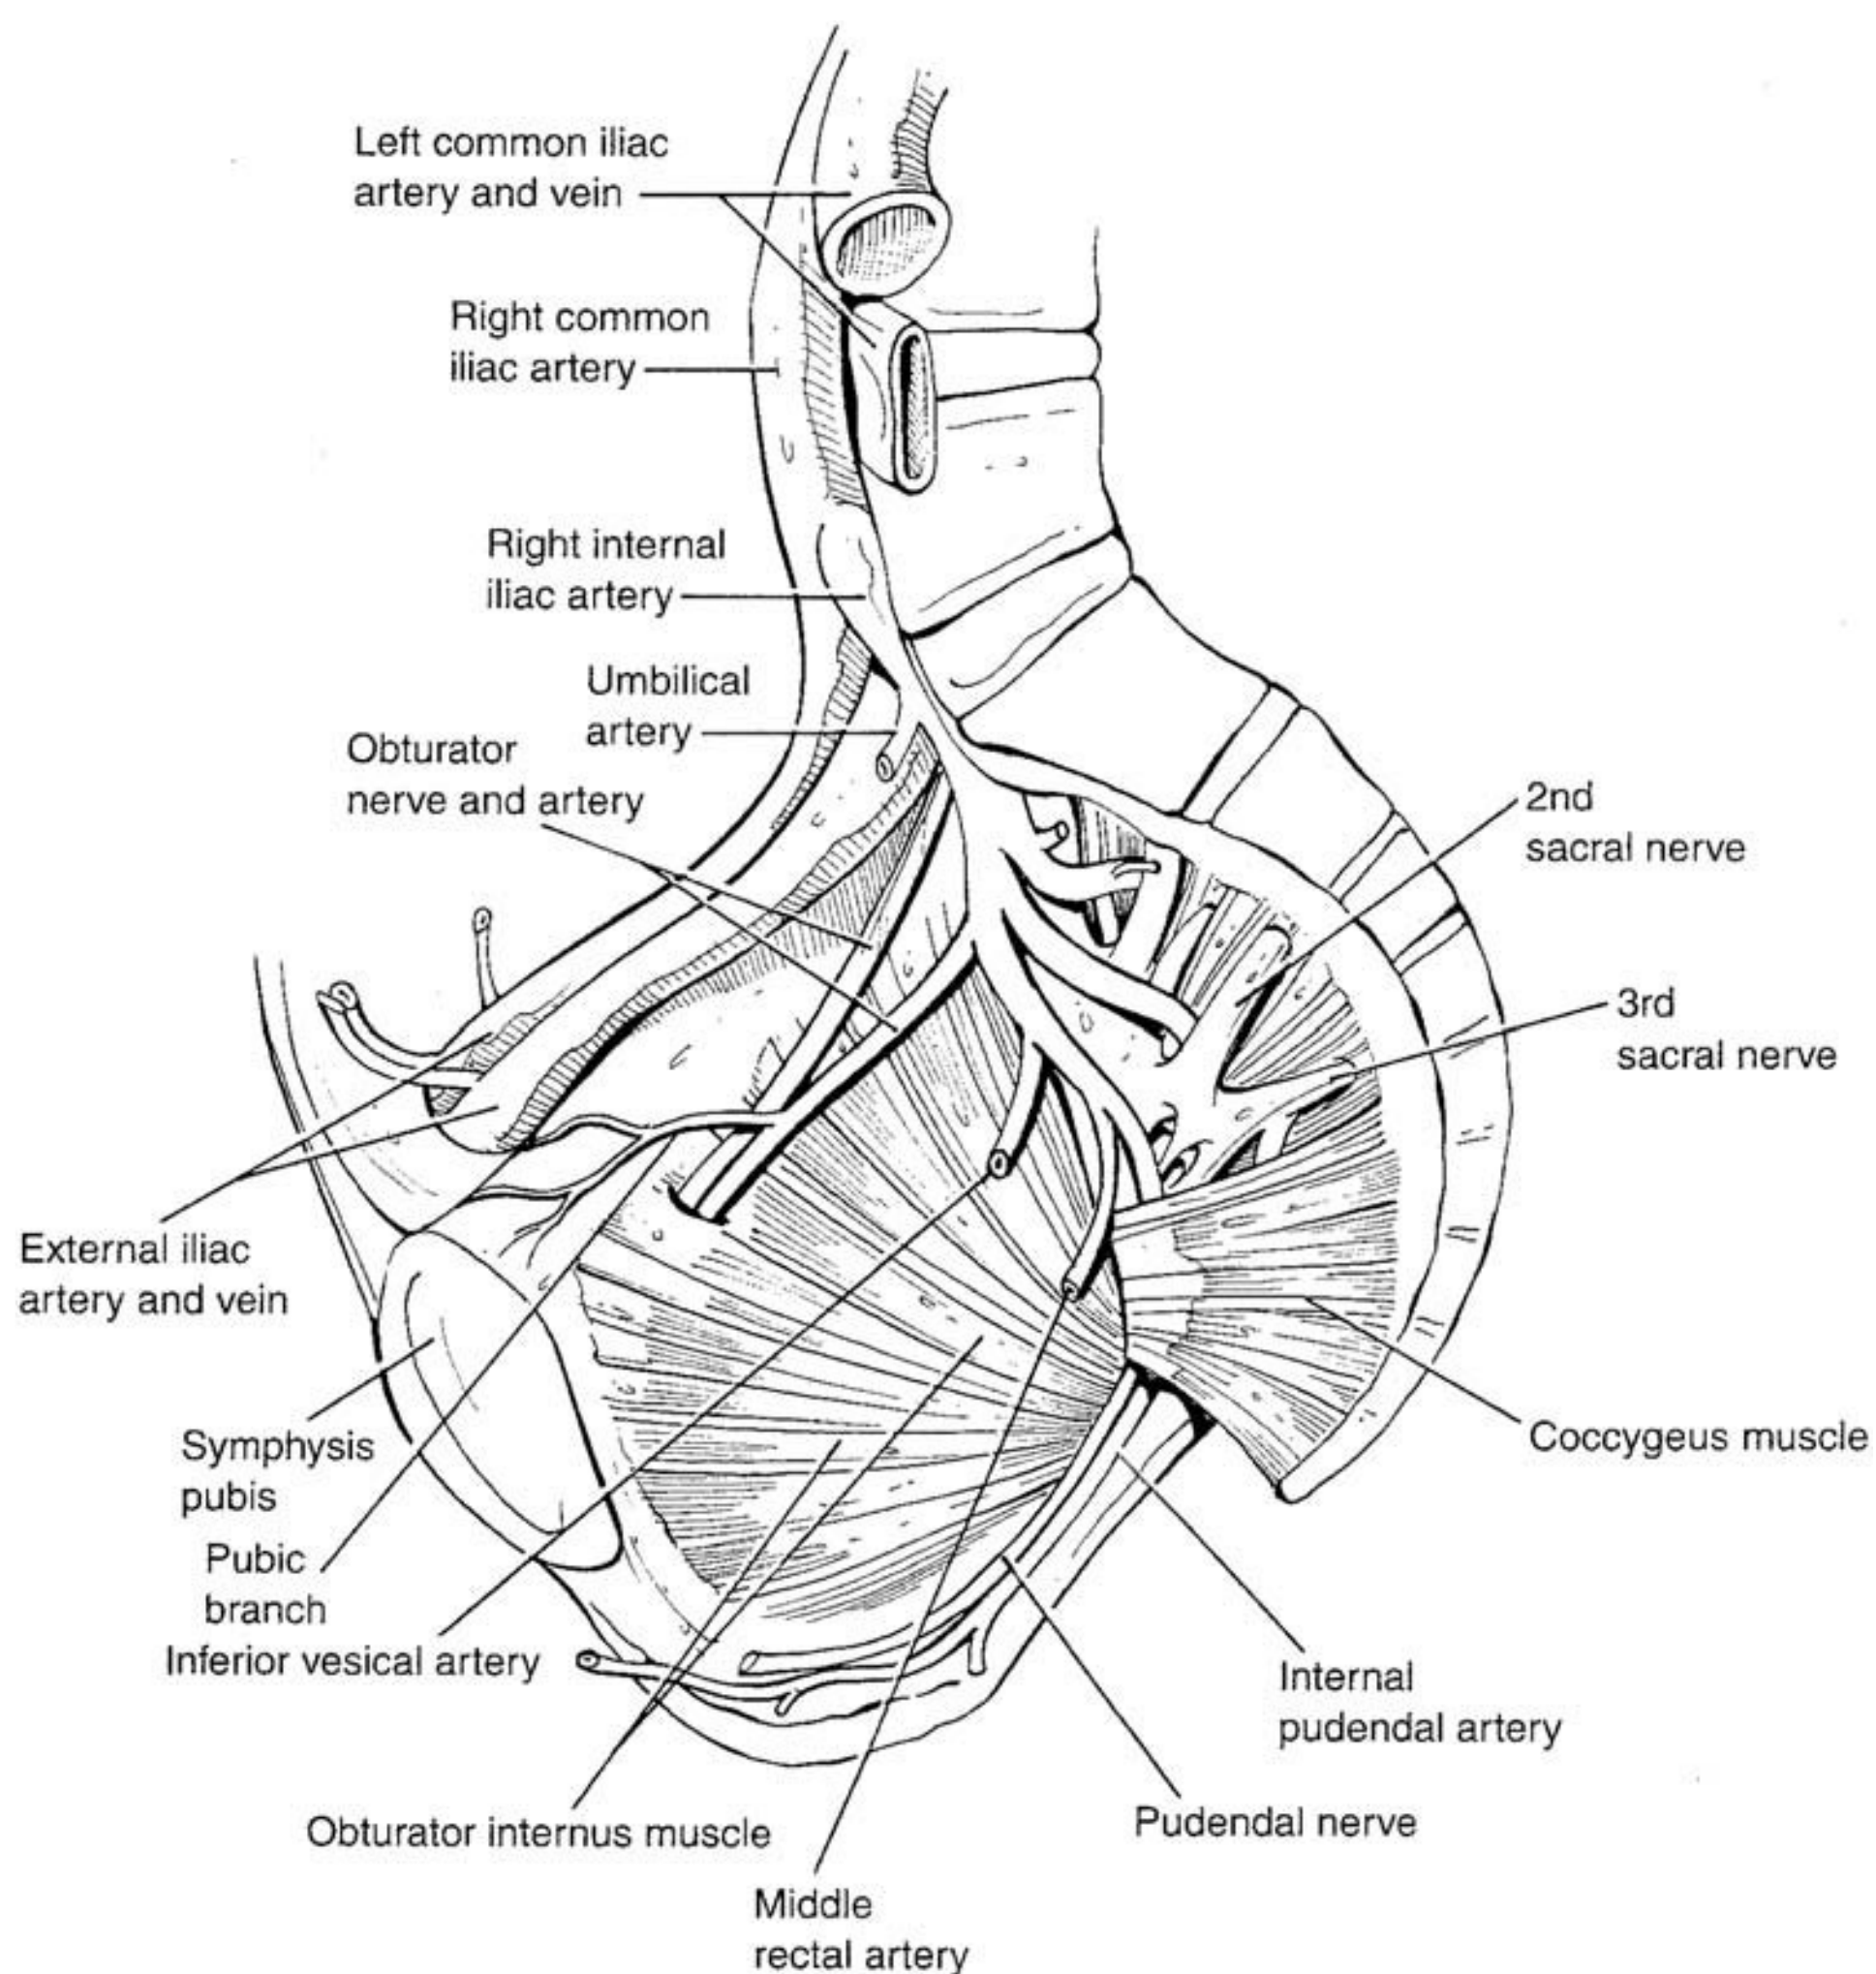

**FIGURE 13.7** Anterior view of the bladder of a man opened and demonstrating intravesical anatomy. Note that the trigone continues into the prostatic urethra.

referred to as the interureteric ridge. This ridge is helpful in identifying orifices endoscopically (Fig. 13.7). The trigone is composed of three distinct layers: (a) a superficial layer derived from the longitudinal layer of ureteral smooth muscle; (b) a deep layer that is continuous from the Waldeyer sheath, inserting at the bladder neck (Fig. 13.8); and (c) the detrusor

**FIGURE 13.8** Lateral view of ureter as it enters the bladder via the intramural tunnel. Note that the Waldeyer sheath extends from the bladder to encase the distal ureter just proximal to the bladder and fuses to the ureteral musculature. The Waldeyer sheath is a continuation of the deep trigone and connects by a few fibers to the detrusor muscle at the ureteral hiatus.

**FIGURE 13.9** Lateral pelvic sidewall demonstrating the vasculature and innervation of the deep pelvis. The arterial supply of the bladder is from the superior lateral vesical artery and the inferior vesical artery enclosed in the posterior pedicle.

layer, derived from the outer longitudinal and middle circular layers of smooth muscle (1). The unique anatomic structure of the intramural ureter and trigone contributes to the intrinsic continence mechanism that prevents vesicoureteral reflux during bladder filling and voiding.

---

## BLOOD SUPPLY

---

Multiple blood vessels supply the urinary bladder; however, the exact vascular anatomy can vary somewhat between individuals. Less variable is the presence of two more distinct collections of vessels, referred to as the lateral and posterior pedicles (Fig. 13.9). In men, the lateral and posterior pedicles are also called the lateral and posterior ligaments. In women, these vascular pedicles are part of the cardinal and uterosacral ligaments. The blood vessels within these pedicles branch from the superior and inferior vesical arteries. The superior vesical artery arises from the internal iliac close to its origin from the common iliac. It can also arise as a branch from the umbilical artery, which branches off of the proximal internal iliac. The inferior vesical artery branches off of the internal iliac artery at a more distal location. However, it is important to

recognize that the arterial supply to the bladder may arise from *any* portion of the internal iliac. In terms of venous drainage, veins from the bladder drain predominantly into lateral plexuses and then empty into veins within the lateral prostatic ligaments and ultimately into the internal iliac veins (1).

---

## INNERVATION

---

### Sensory Innervation

---

In the bladder, there are two types of sensory (afferent) nerve fibers: alpha-delta and C fibers. Alpha-delta fibers are partially myelinated and carry information to the central nervous system regarding bladder fullness and wall tension. These sensory fibers are responsible for initiating the normal voiding reflex. On the other hand, C fibers are unmyelinated nociceptive fibers that mainly carry information to the central nervous system regarding noxious or painful stimuli. Although these C fibers comprise about 70% of the total afferent nerves supplying the bladder, they are generally silent and only become sensitive during inflammation, irritation, or suprasacral spinal cord injury. Prolonged activation of C fiber afferents may be

responsible for the development of pathologic voiding reflexes associated with some forms of overactive bladder.

### Motor Innervation

Motor innervation to the bladder arises from three sets of nerves: (a) the *parasympathetic* sacral (pelvic) nerve, arising from the sacral spinal cord between S2 and S4; (b) the *sympathetic* thoracolumbar (hypogastric) nerve, arising from the spinal cord between T10 and L2; and (c) the *somatic* pudendal nerve, which also arises between S2 and S4.

Preganglionic parasympathetic motor efferent fibers exit between S2 and S4 via pelvic nerves, with nerve bodies located in the sacral parasympathetic nucleus (SPN). The SPN is located in the intermediolateral region of the sacral spinal cord. Importantly, an increase in parasympathetic tone, supplied by these nerves, is the main trigger for a coordinated contraction of the detrusor muscle that leads to voiding. In the bladder body, sympathetic fibers supply beta receptors contributing to smooth muscle relaxation during filling and also synapse prejunctionally along axons of parasympathetic nerves. This anatomic relationship may allow for additional reduction of detrusor smooth muscle tone during the filling phase, a process that is likely necessary to prevent involuntary contractions and urge incontinence. The only somatic (voluntary) motor fibers in the lower urinary tract supply the external urethral sphincter, sometimes called the rhabdosphincter (9). Preganglionic somatic motor efferent fibers exit between S2 and S4 with nerve bodies located in the Onuf nucleus in the anterolateral horn of the sacral spinal cord. These somatic fibers run in the pudendal nerve, modulating striated (voluntary) urethral sphincter contraction.

### The Micturition Reflex

Sensory or “afferent” fibers from the bladder are contained in the pelvic, hypogastric, and pudendal nerves. The pelvic and pudendal nerves enter the sacral spinal cord via dorsal root ganglia, with the most prominent projection passing anterolateral toward the SPN. Afferent fibers in the hypogastric nerves also enter the spinal cord via dorsal root ganglia in the lumbar spinal cord. Afferent fibers from the external urethral sphincter pass through the Onuf nucleus in the sacral spinal cord. All of these inputs relay sensory information to the lateral pons, referred to as the pontine storage center. After processing in higher brain centers, motor signals are then relayed back through the pontine micturition center (PMC) located in the Barrington nucleus in the dorsal medial pons. These pontine centers receive input indirectly through relay neurons in the periaqueductal gray (PAG) or directly from lateral spinal tract neurons. There is also input from the cerebellum, basal ganglia, thalamus, hypothalamus, and cerebral cortex (4,12). Therefore, these PMCs are responsible for the coordination of urine storage and voiding. Thus, damage to the spinal cord between the sacral motor outflow and the PMCs leads to a characteristic pattern of neurogenic detrusor overactivity (involuntary contractions) and detrusor sphincter dyssynergia (lack of coordination between the bladder and urethral sphincter). In this situation, the coordinated spinal–bulbo–spinal reflex is converted to an uncoordinated spinal–spinal reflex.

**FIGURE 13.10** Autonomic and somatic innervation of the lower urinary tract. There is extensive motor outflow to the bladder and urethral sphincter from the spinal cord. Parasympathetic outflow (as shown in gray) is conveyed by the pelvic nerve and leads to bladder contraction during voiding and contraction of urethral smooth muscle during filling. Sympathetic outflow originates from the thoracolumbar cord, travels in the hypogastric nerve (as shown in black), and leads to bladder relaxation and bladder neck contraction during filling. Somatic outflow also originates from the sacral cord and travels via the pudendal nerve (dashed line). Outflow leads to contraction of the urethral sphincter during filling and relaxation during voiding (possibly nitric oxide-mediated).

### Storage Reflex

Storage is facilitated by bladder afferent stimulation of the Onuf nucleus, which increases the tone of the external urethral sphincter via the somatic pudendal nerve. The pontine storage center, in the lateral pons, also stimulates the Onuf nucleus and the pudendal nerve output to the external urethral sphincter. Simultaneously, the hypogastric (sympathetic) nerve, receiving input from pelvic afferents, inhibits the detrusor muscle and bladder ganglia while stimulating the internal urethral sphincter (bladder neck), which has robust expression of alpha-1 receptors. As mentioned earlier, pharmacologic reduction in this bladder neck tone with alpha blockers is a mainstay for the treatment of BPH as well as detrusor-sphincter dyssynergia and other forms of voiding dysfunction (Fig. 13.10).

---

## Emptying Reflex

---

Emptying is mediated through the PMC, which stimulates parasympathetic motor or “efferent” fibers whose cell bodies are in the SPN. Parasympathetic outflow via the pelvic nerve causes detrusor contraction and inhibition of the internal sphincter (bladder neck), processes that facilitate emptying. In addition, signals from the PMC also inhibit sympathetic outflow from the hypogastric nerve, leading to relaxation of the bladder neck, a process that also facilitates emptying. Furthermore, signals from the PMC also inhibit the motor outflow to the pudendal nerve, leading to relaxation of the striated urethral sphincter, again facilitating emptying (Fig. 13.11) (10).

---

## LYMPHATICS

---

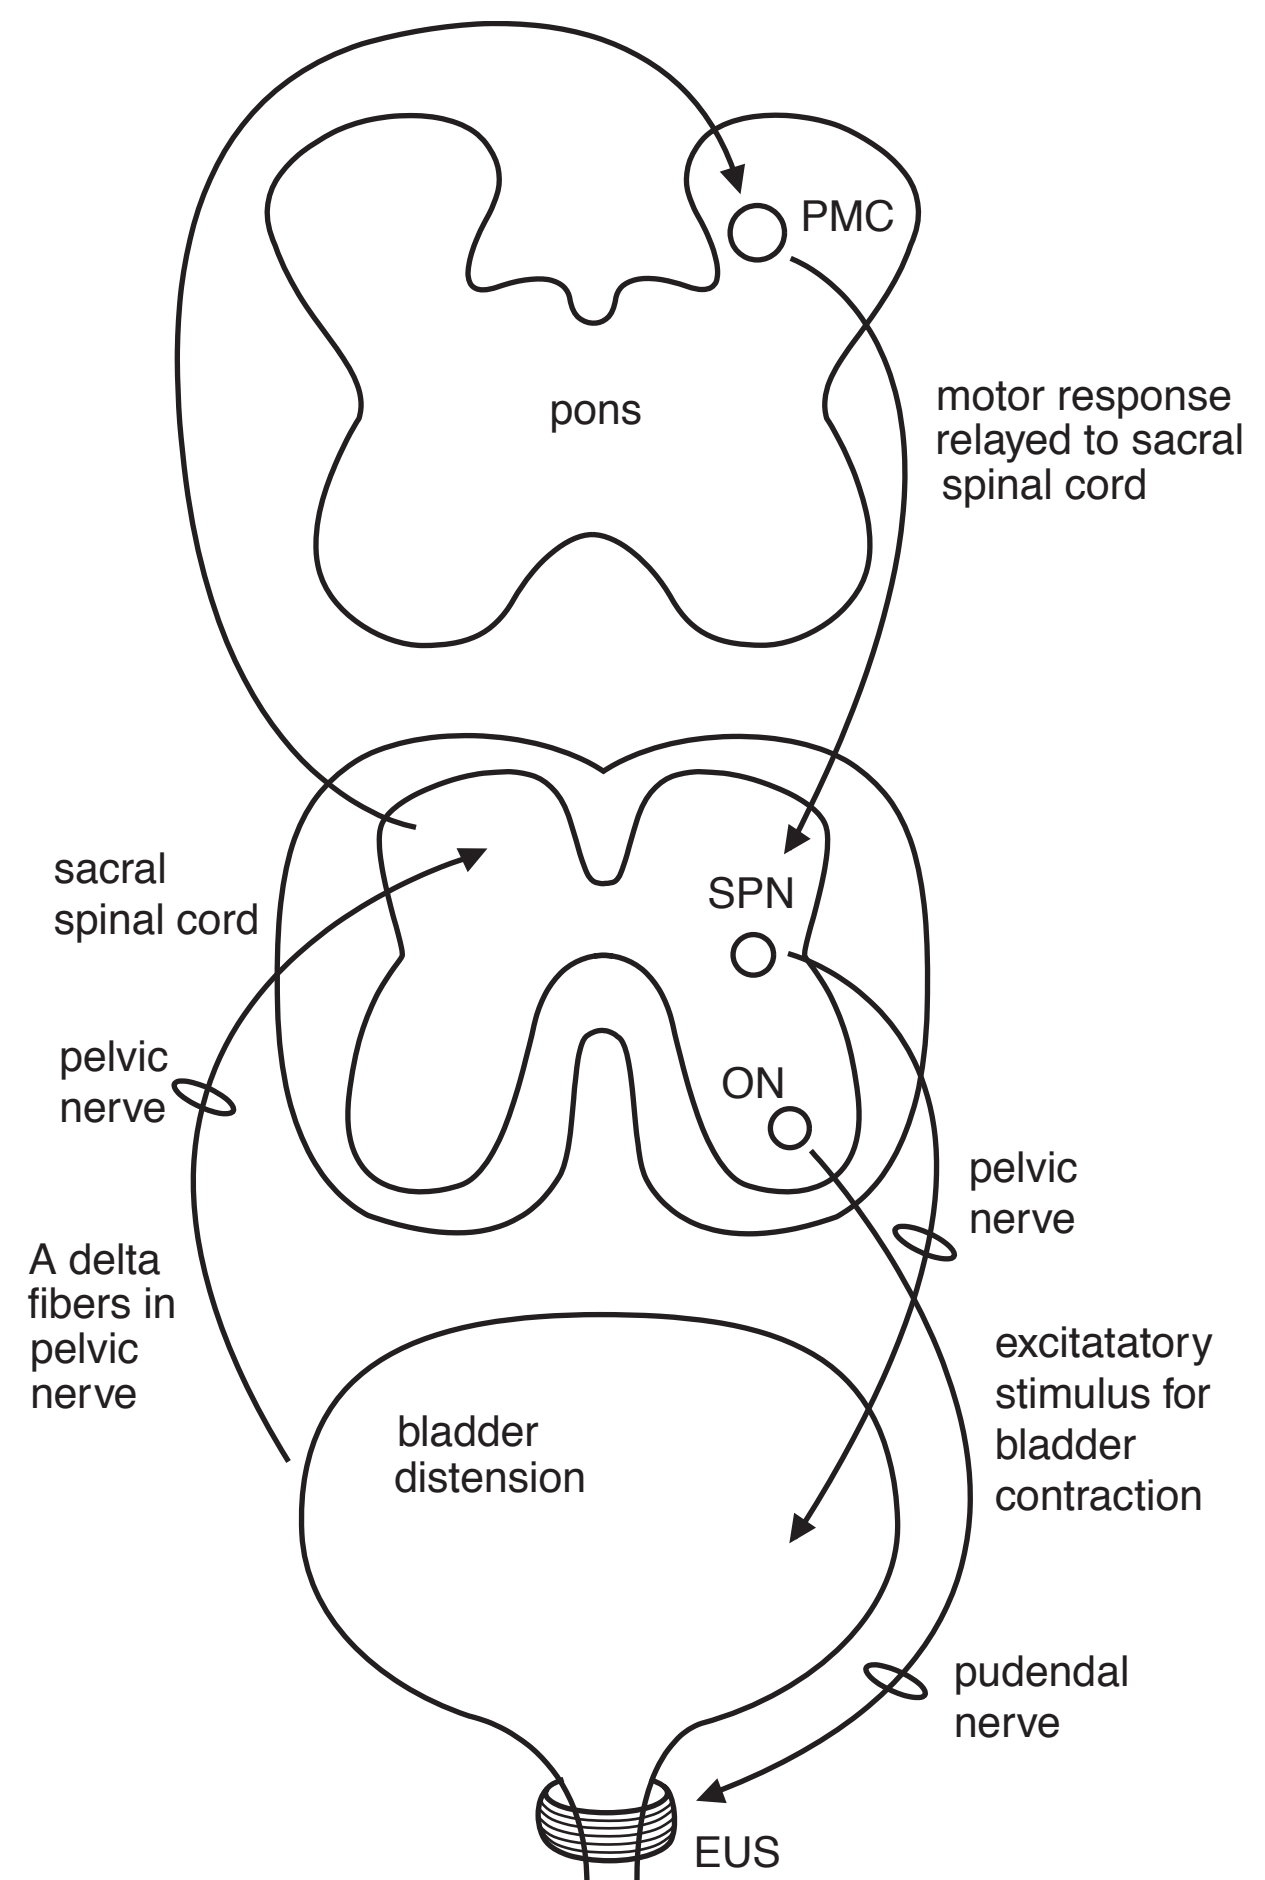

The lymphatic drainage of the bladder is to the external iliac vein, the hypogastric nodes, or the presacral promonotory.

---

## CONTIGUOUS STRUCTURES

---

In men, the bladder joins the prostate and is anterior to the seminal vesicles and ampulla of the vas deferens. In women, the bladder is in more direct contact with the pubococcygeus portion of the levator ani. Superiorly, the bladder is covered by peritoneum in both men and women. Posteriorly in women, the bladder is adjacent to the uterus and vagina. In men, the posterior bladder is adjacent to the seminal vesicles and rectum.

**FIGURE 13.11** Micturition phase of bladder function. As shown in this diagram, micturition is stimulated by bladder distention. Sensory fibers carry information about bladder distention to the sacral spinal cord. Signals then ascend via pathways in the dorsal columns to the pontine micturition center (PMC). The PMC is the main center for coordination of lower-urinary-tract function. Information may pass through projections from the periaqueductal gray (PAG) to the PMC (3). Motor responses then relay information back to the sacral spinal cord, ultimately triggering an excitatory stimulus for bladder contraction.

# CHAPTER 14 ■ SIMPLE AND PARTIAL CYSTECTOMY

JONATHAN C. PICARD AND J. NATHANIEL HAMILTON

---

## SIMPLE CYSTECTOMY

---

Simple cystectomy is performed in the setting of benign disease requiring urinary diversion or locally invasive nonurologic malignancy. Simple cystectomy involves removal of the bladder without resection of adjacent structures or performance of a formal lymph node dissection. The other pelvic organs are also left intact; to preserve sexual function, the prostate, seminal vesicles, and urethra are spared in the male patient and the uterus, anterior vagina, adnexa, and urethra are spared in the female patient. Removal of a defunctionalized bladder is often very beneficial and can prevent many complications.

---

### Diagnosis

---

Preoperative evaluation should include a complete history and physical examination. Specifically, a thorough investigation into the etiology of the voiding dysfunction, radiation treatments, prior pelvic surgeries, and all other interventions leading up to this evaluation should be performed. Biopsy should be undertaken if primary bladder malignancy is a consideration. Preoperative imaging of the abdomen and bladder are usually helpful, and we prefer a contrasted CT scan of both the abdomen and pelvis with delayed images to allow for visualization of the ureters and any abdominal or pelvic pathology that would preclude the procedure.

---

### Indications for Surgery

---

Urinary diversion is indicated for patients who have refractory conditions such as severe radiation or chemical cystitis, intractable bladder pain from interstitial cystitis, severe urinary incontinence, neurogenic bladder, extensive trauma, large vesical fistula, or recurrent pyocystis. Simple cystectomy can also be undertaken for invasive nongenitourinary cancers that are not amenable to resection with partial cystectomy.

Previous attempts at urinary diversion without concomitant simple cystectomy have led to complications in 54% to 80% of patients (1, 2, 7). Complications include pyocystis, intractable hemorrhage, severe pain or spasms, and the sensation of incomplete emptying. In these patients, the salvage cystectomy rate ranges from 20% to 30% (1, 2, 7). We therefore recommend concomitant simple cystectomy when permanent urinary diversion is undertaken.

Additionally, the risk of developing urothelial cancer of the bladder is significantly increased in patients who have received previous pelvic irradiation (relative risk = 4.6) (7). Some authors have even cited a risk for malignant degeneration in the setting of chronic irritation such as interstitial cystitis (6).

---

### Alternative Therapy

---

Radical cystoprostatectomy in men and radical cystectomy in women should be considered as alternatives to simple cystectomy in the setting of possible prostate cancer or urothelial carcinoma (UCC) and can be considered as alternatives in nonurologic malignancies that are locally invasive into the bladder or in many benign diseases of the bladder. In the majority of patients, continued observation, hyperbaric oxygen, analgesic prescription, and other symptomatic treatments are the initial options, with simple cystectomy only being offered as a final intervention in patients with refractory disease.

In patients with nonurologic malignancies that are locally invasive into the bladder, simple cystectomy can be considered if the resection can be accomplished with negative margins. Laparoscopic and robotic-assisted laparoscopic techniques are also being refined and are certainly an option for appropriately trained surgeons, despite the fact that these procedures are often difficult due to the challenges of previously irradiated fields, previous surgery, and chronic infection or inflammation.

---

### Surgical Technique

---

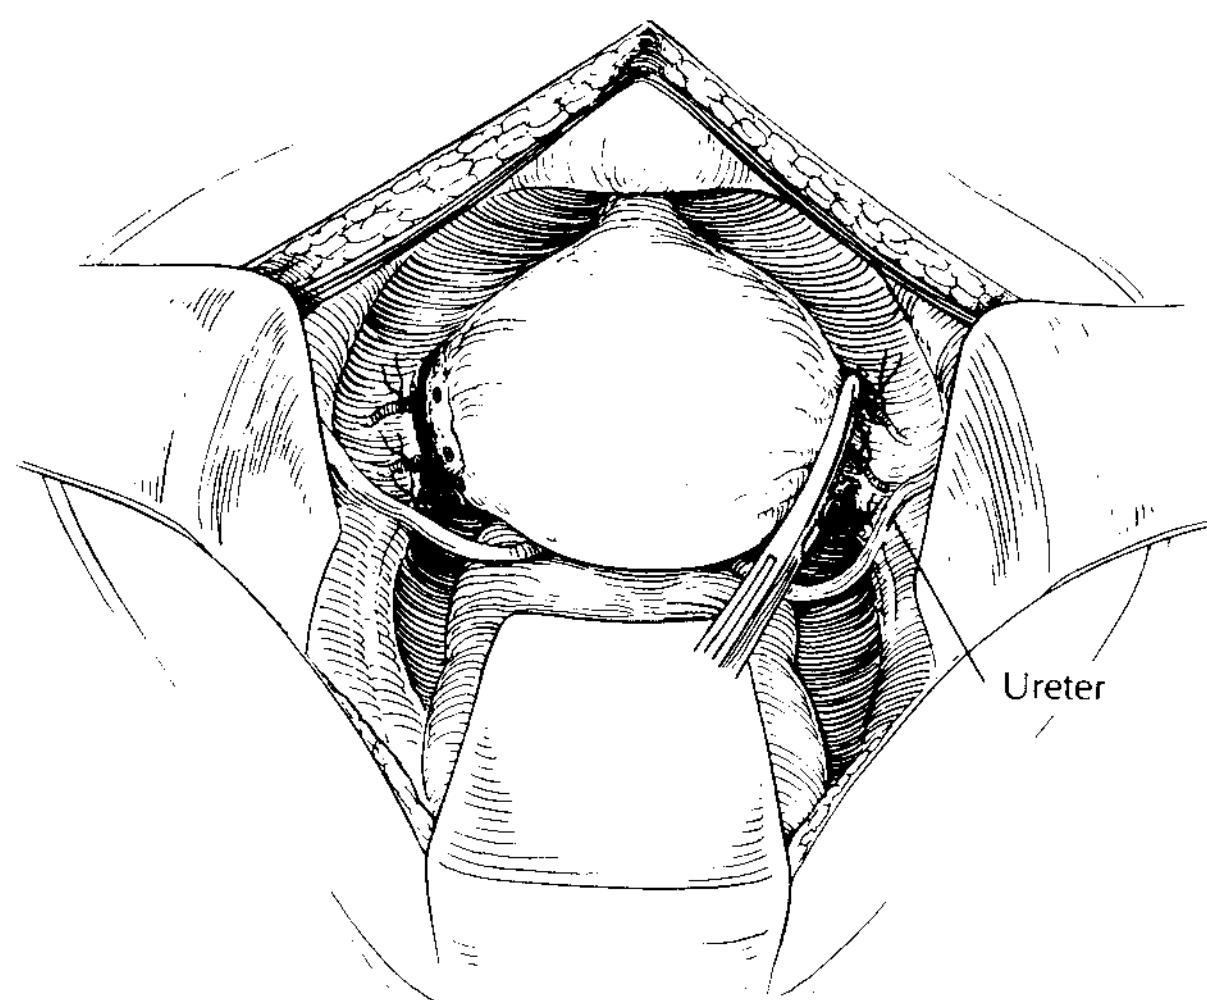

Simple cystectomy can be undertaken extraperitoneally to avoid abdominal adhesions due to multiple previous surgeries or radiation; however, we prefer an intraperitoneal approach as these patients also frequently require concomitant urinary diversion. Antithrombotic medication, pneumatic compression cuffs, or compression stockings should be strongly considered prior to induction of anesthesia. The patient is positioned supine on the operating room table with the anterior superior iliac spines positioned over the inferior portion of the table break or kidney rest. The table is flexed to facilitate exposure, and the bed is slightly tilted in the Trendelenburg position until the abdomen is parallel to the floor. When urethrectomy is planned, a modified lithotomy position provides improved exposure to the perineum. The abdomen and pelvis are then prepped with an antibiotic solution extending from the costal margin superiorly to the perineum,

including the penis in men and the vagina in women. The patient is draped, and a Foley catheter is inserted following sterile procedures. The bladder is allowed to drain completely. Filling the bladder with 150 to 200 mL of sterile water may facilitate the dissection.

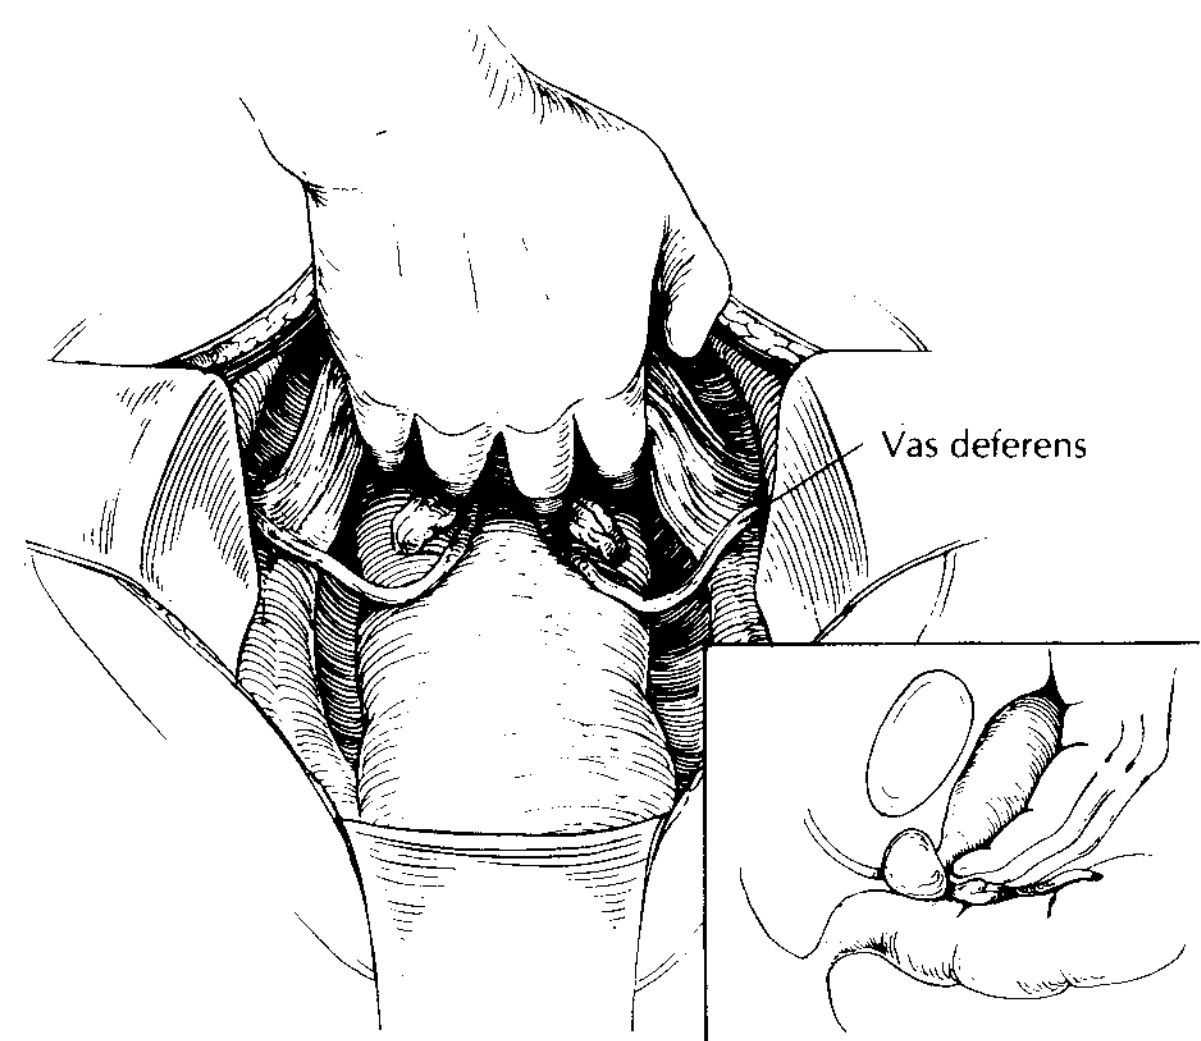

An intravenous antibiotic agent should be administered prior to skin incision. A lower midline incision extending from the umbilicus to the pubic symphysis is made using a no. 10 blade scalpel and deepened with Bovie cautery to the anterior rectus fascia. The anterior rectus fascia should be opened sharply, and the rectus abdominis muscles in the midline should then be separated to facilitate entry into the space of Retzius.

The extraperitoneal space lateral to the bladder should be bluntly developed by extending the dissection from the bladder neck cranially to the dome of the bladder. In benign conditions, incising the anterior bladder wall may facilitate the dissection. The peritoneum should be incised lateral to the bladder in a posterior direction. The ureters can often be identified as the peritoneum is divided and reflected. They should then be dissected from their surrounding attachments, with care being taken to maintain a sufficient amount of periureteral tissue. The ureteral dissection should be continued proximally and distally. In women, care must be taken to avoid the uterine artery during the distal ureteral dissection. When the superior vesical arteries are encountered crossing anterior to the distal ureters, they should be ligated with 2-0 silk ties and divided (Fig. 14.1) to allow for improved exposure of the distal ureter and maximization of the ureteral length. The ureters are then clipped close to their insertion into the bladder and divided sharply. They can be packed away to prevent injury during the remainder of the bladder dissection.

In male patients, we begin our posterior dissection several centimeters anterior to the peritoneal reflection and enter the plane between the bladder (anterior) and the vasa deferentia and seminal vesicles (posterior) (Fig. 14.2). This dissection is continued to the prostatovesical junction using a combination of blunt and sharp dissection. Attention is then returned to the anterior dissection of the prostatovesical junction. The veins overlying the prostate and bladder can be ligated with 3-0 silk

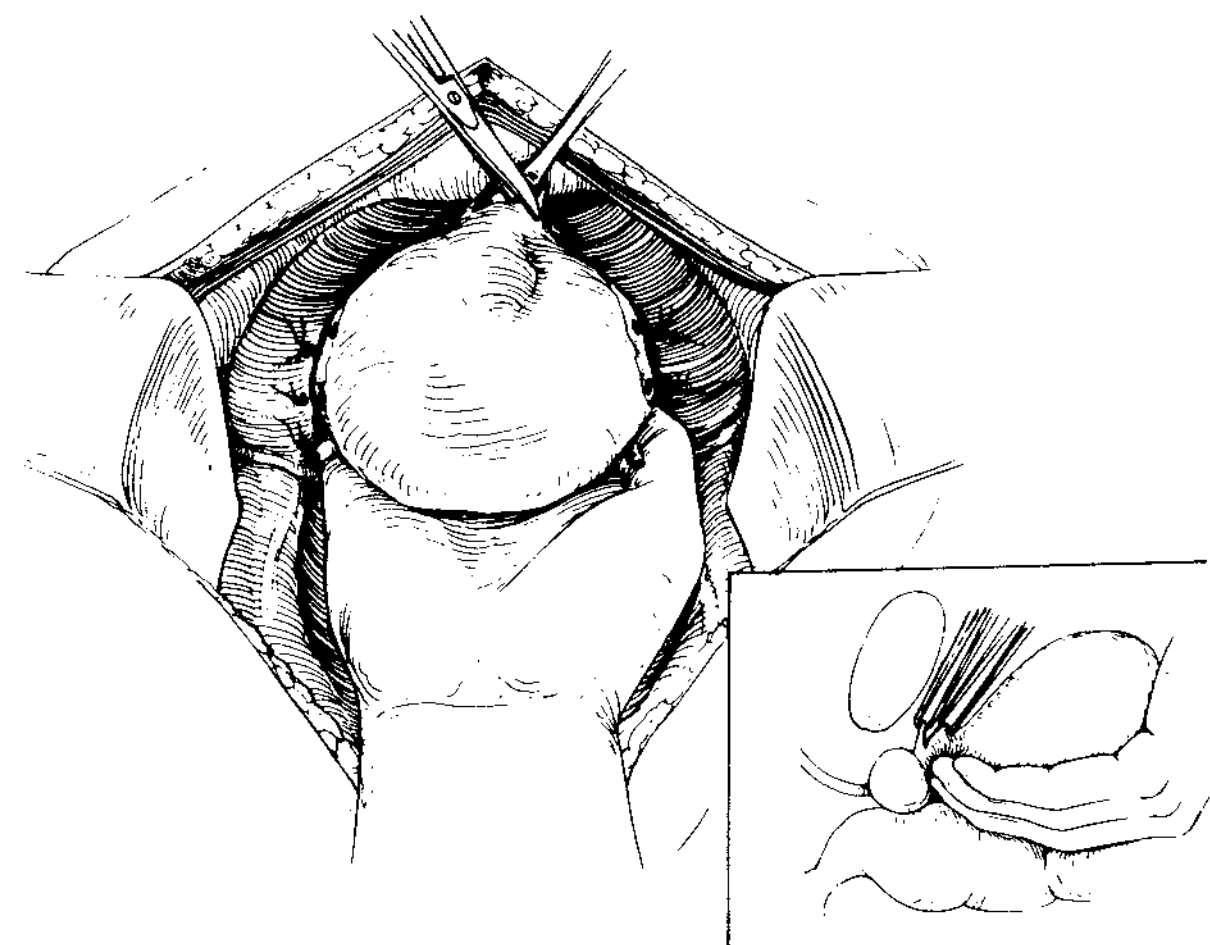

**FIGURE 14.1** The vesical pedicles are clipped and divided.

**FIGURE 14.2** The plane between the bladder (anterior) and the vasa deferentia and seminal vesicles (posterior) is dissected.

suture and divided. The bladder is then drained and the Foley catheter removed. Bovie cautery is used to transect the bladder in an anterolateral direction, and the posterior bladder wall is then divided to expose the previously exposed vasa deferentia and seminal vesicles (Fig. 14.3). The lateral vascular pedicles should be readily visible and can be ligated with 2-0 silk ties and divided. At this point, the bladder should be free and can be removed. The urethra is oversewn with 3-0 Vicryl suture, and the prostatic surgical capsule is oversewn with 0 Vicryl suture (Fig. 14.4). If significant prostatic hyperplasia prevents adequate closure of the capsule, a simple prostatectomy should be considered followed by closure of the prostatic surgical capsule as previously described.

In female patients, the posterior dissection begins anterior to the peritoneal reflection. The plane between the bladder and the anterior vaginal wall is entered and is developed with sharp and blunt dissection. An intravaginal sponge stick is beneficial for traction and identification of the proper planes. During this dissection the lateral pedicles are ligated with 2-0

**FIGURE 14.3** The bladder neck is incised anteriorly.

**FIGURE 14.4** The bladder is removed. The urethra is oversewn. The prostatic surgical capsule is oversewn.

silk ties and divided as they are encountered. Upon reaching the bladder neck, the Foley catheter is removed and Bovie cautery is used to transect the urethra. The urethral stump is then oversewn with 3-0 Vicryl sutures. Some authors advocate complete urethrectomy including the meatus in patients who have cystectomy performed for interstitial cystitis.

After the cystectomy is complete, the wound is copiously irrigated with sterile water. A closed drainage system, such as a Jackson-Pratt or Blake drain, is almost universally placed in the pelvis because this procedure is frequently performed in the setting of chronic inflammation or infection. Attention is next turned to creation of the urinary diversion of the surgeon's choice.

The abdominal wall is closed beginning with the rectus fascia. The edges of the rectus fascia are reapproximated using a 0 looped polydioxanone (PDS) suture in a running fashion. The wound is copiously irrigated with sterile water. If there is a large amount of subcutaneous tissue, the Scarpa fascia can be reapproximated using a 3-0 or 4-0 Vicryl suture to minimize the dead space. The skin is closed with a subcuticular 4-0 Monocryl suture or skin staples.

---

### Outcomes

---

Surgical outcomes are generally very good, although the available literature is limited. One series suggested a mortality rate of 0% with no morbidities directly attributable to the cystectomy itself (2). Likely, the most important aspect of simple cystectomy is the morbidity that is prevented by removing the bladder at the time of urinary diversion. In patients not undergoing concomitant cystectomy with urinary diversion, major complications and hospitalization occur in >50% with >20% requiring a salvage operation (1, 2, 7).

---

### Complications

---

For both partial cystectomy and simple cystectomy, the usual risks associated with urologic surgeries exist, including pulmonary embolus, myocardial infarction, bleeding that requires transfusion, ileus, and wound complications such as infections or seromas. The majority of complications are related to the urinary diversion rather than the simple cystectomy itself.

Although there are no data directly related to simple cystectomy, the overall complication rate of partial cystectomy is classically reported as 11% to 29%, and the complication rate for simple cystectomy is likely similar.

---

## PARTIAL CYSTECTOMY

---

Partial cystectomy is a full-thickness excision of abnormal bladder and a margin of adjacent normal bladder with the goal of preserving adequate bladder function and capacity. Traditionally, this surgery has been utilized in the management of localized urachal adenocarcinoma, an isolated UCC associated with a diverticulum, localized unifocal urothelial carcinoma in favorable locations, or in patients who are unable or unwilling to undergo radical cystectomy. This procedure offers the advantages of full-thickness resection of the diseased bladder in conjunction with a pelvic lymph node dissection for pathologic review while allowing for conservation of the native bladder and preservation of potency and continence.

---

### Diagnosis

---

Preoperative evaluation before undertaking a partial cystectomy should include a thorough history and physical examination with a focus on prior pelvic surgeries or procedures and previous bladder pathology. Cystoscopy should be performed with biopsy of the lesion for histological diagnosis. Additional mapping biopsies should be performed to confirm unifocality of the disease and to exclude carcinoma in situ. Both noncontrasted and contrasted CT scans of the abdomen and pelvis should be performed to assist with staging. Delayed images of the urinary collecting system should be performed if upper-tract UCC is a consideration. Findings such as upper-urinary-tract involvement with disease, metastatic lesions, enlarged lymph nodes >1 cm, or other pelvic pathology may preclude utilizing this procedure.

---

### Indications for Surgery

---

Partial cystectomy has emerged as the treatment of choice for localized urachal adenocarcinoma. The urachus is an embryological remnant that persists in approximately 30% of the population and is capable of malignant transformation. In this setting, open partial cystectomy or laparoscopic partial cystectomy should be undertaken with *en bloc* resection of the involved bladder with a 2-cm margin of normal tissue, umbilicus, peritoneum, and posterior rectus fascia with concomitant pelvic lymphadenectomy. The 5-year survival rate in this setting is approximately 88% (3).

In the setting of UCC, partial cystectomy is indicated only in highly selected patients with limited disease, patients who are not candidates for radical cystectomy due to comorbid conditions, and patients who refuse radical cystectomy. Selection criteria should include no history of previous urothelial cancer, localized disease that is unifocal in nature without coexisting carcinoma in situ (CIS), and disease that is present in an area of the bladder that is amenable to complete resection with a negative margin. Patients must have a bladder

volume that allows for resection of the diseased site with an adjacent 2-cm margin while still maintaining adequate functional capacity with normal compliance. We do not recommend partial cystectomy if resection of the bladder neck is required.

A special circumstance exists in the patient who presents with a bladder diverticulum containing a UCC. Because of the thin, amuscular walls of the diverticulum, these lesions are often associated with higher-stage disease. Additionally, attempted transurethral resection of a UCC within a diverticulum has a higher risk of perforation. For these reasons, this pathology is particularly amenable to partial cystectomy.

Other indications for partial cystectomy include resection of nonurologic cancers in the bladder, including pheochromocytoma, paraganglioma, rhabdomyosarcoma, osteosarcoma, lymphoma, and adjacent tumors that are locally invasive into the bladder, such as invasive colorectal cancer. Partial cystectomy may also be indicated in benign diseases such as a symptomatic diverticulum.

---

### Alternative Therapy

---

Any malignant bladder tumor that is removable by partial cystectomy can also be removed by radical cystectomy, although morbidity may be increased. There have also been many advances in endoscopic tools and techniques. Some tumors may now be approached endoscopically via an aggressive transurethral approach or laparoscopically with a simple cystectomy. In regards to urothelial cancer, intravesical agents—including chemotherapy and bacille Calmette-Guérin (BCG) immunotherapeutic agents—have also been utilized to manage some of these patients. Radiotherapy and chemotherapy, alone or in combination, are also alternatives to cystectomy in the setting of muscle-invasive UCC. For many benign indications, simple cystectomy is an alternative.

---

### Surgical Technique

---

Antithrombotic medication, pneumatic compression cuffs, or compression stockings should be strongly considered prior to induction of anesthesia. The patient is positioned supine on the operating room table with the anterior superior iliac spines positioned over the inferior portion of the table break or kidney rest. The table is flexed to facilitate exposure, and the bed is tilted slightly in the Trendelenburg position until the abdomen is parallel to the floor. The abdomen and pelvis are then prepped with an antibiotic solution extending from the costal margin superiorly to the perineum, including the penis in men and the vagina in women. After the patient is draped, a Foley catheter is inserted following sterile procedures. The bladder is then allowed to drain completely. At this point, filling the bladder with 150 to 200 mL of sterile water may facilitate the dissection.

An intravenous antibiotic agent should be administered prior to skin incision. A lower midline incision from just below the umbilicus (around and including the umbilicus if for urachal adenocarcinoma) to the pubic symphysis is made using a no. 10 blade scalpel and deepened with Bovie cautery to the anterior rectus fascia. The anterior rectus fascia should be opened

sharply, followed by separation of the rectus abdominis muscles in the midline to facilitate entry into the space of Retzius.

Using blunt dissection, the tissues are dissected down to the level of the bladder dome at the reflection of the peritoneum. For dome or anterior tumors, it is possible to remain extraperitoneal; however, for posterior tumors, an intraperitoneal approach is recommended.

---

### Extraperitoneal Partial Cystectomy

---

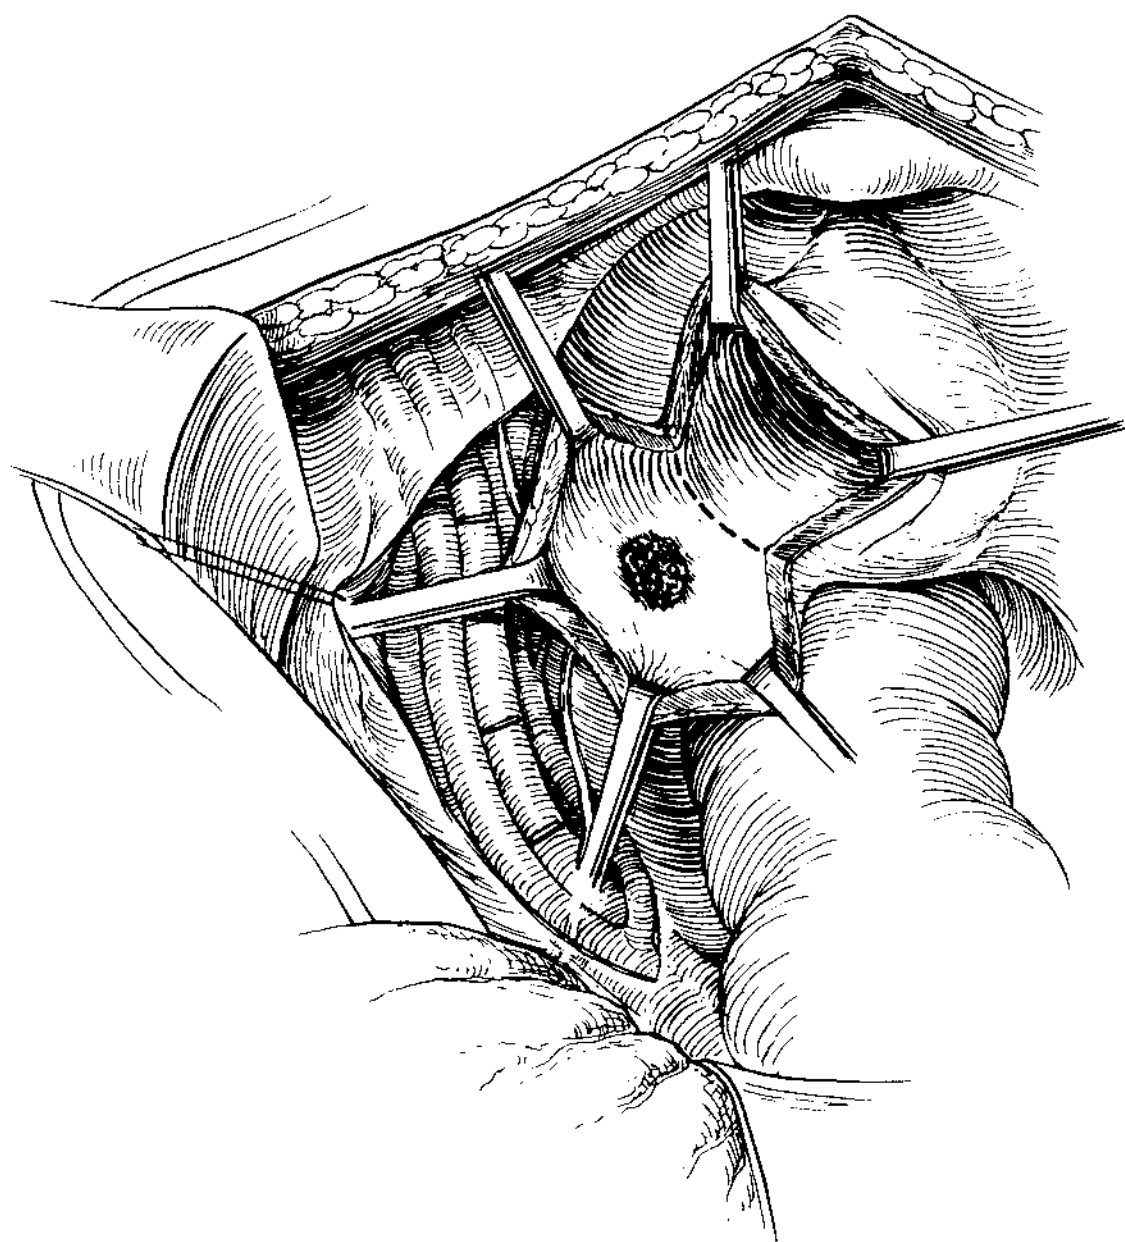

The extraperitoneal space lateral to the bladder is developed bluntly, extending from the bladder neck cranially to the dome of the bladder. The anterior aspect of the bladder is exposed to the peritoneal reflection, which is mobilized where it is readily separable. A bilateral pelvic lymph node dissection is undertaken using the bifurcation of the common iliac artery as the cranial limit, the pubic symphysis as the caudal limit, the genitofemoral nerve as the lateral limit, and the bladder as the medial limit of the dissection. All nodal tissue is dissected and sent for pathologic review. Prudent use of silk ties or titanium clips, especially at the cranial and caudal limits of the dissection, may limit the risk of lymphocele formation.

The bladder is freed from its surrounding attachments, with care being taken to preserve the perivesical fat overlying the region of interest. Blunt dissection is the primary approach, along with judicious use of cautery to minimize the risk to adjacent peritoneal contents. The superior vesical pedicle may be divided to provide adequate exposure of the resection site. This division may be performed with a LigaSure (Valleylab) device or in the traditional manner with hemostats and 2-0 silk ties. Once the bladder is freed, the area of the tumor should be localized with preoperative or intraoperative cystoscopy.

Several sutures are placed some distance from the known pathology. At this point, the bladder should be drained completely to prevent urinary spillage. The free wound edges can be covered with laparotomy pads moistened with sterile water. The bladder is incised using Bovie cautery in an area at least 2 cm away from the expected lesion. The incision is extended to allow for visualization of the pathology. The tumor is excised using Bovie cautery with a 2-cm margin on all sides, and the specimen is removed *en bloc* with the overlying perivesical fat and any adherent peritoneum (Fig. 14.5).

In general, we do not recommend this operation when ureteral reimplantation is necessary. However, in the event that a ureteral reimplantation is needed to complete the partial cystectomy, the ureter should be divided and the proximal ureter reimplanted into the bladder via the Politano-Leadbetter technique or the simple nipple reimplantation technique. A 4-0 Vicryl suture should be used for performing an interrupted ureterovesical anastomosis over a ureteral stent.

Once excision of the tumor is completed and adequate hemostasis is ensured, the bladder can be closed in two layers utilizing a running 4-0 Vicryl suture on the urothelium and a running, locking 2-0 Vicryl suture to close the muscularis layer (Fig. 14.6). Special consideration should be given to the apices of the closure because these are the most frequent sites of urinary leakage after closure. A suprapubic cystostomy is contraindicated in the setting of UCC; however, it can be considered for other pathologies. The wound is copiously irrigated with warm sterile water. A closed drainage system, such as a Jackson-Pratt drain or Blake drain, can be placed in a

**FIGURE 14.5** A 2-cm margin of normal bladder is taken around the tumor.

dependent position within the area of dissection. To minimize fistula formation, this drain should not be placed directly adjacent to the cystostomy closure. The anterior rectus fascia is reapproximated using a 0 looped PDS in a running fashion, and the wound is copiously irrigated with sterile water. If there is a large amount of subcutaneous tissue, the Scarpa fascia can be reapproximated using a 3-0 or 4-0 Vicryl suture to minimize the dead space. The skin is closed with a subcuticular 4-0 monocryl suture.

The drain is removed on postoperative day 2 or 3 or when the output is  $<30$  mL per shift. The catheter is removed on postoperative day 7. If complete bladder healing is a concern, a low-pressure cystogram can be performed.

**FIGURE 14.6** The bladder is closed in two layers.

## Intraperitoneal Partial Cystectomy

Partial cystectomy through an intraperitoneal approach is often necessary with tumors on the posterior bladder wall. The extraperitoneal space lateral to the bladder is bluntly developed by extending the dissection from the bladder neck cranially to the dome of the bladder. The posterior rectus sheath and peritoneum just inferior and lateral to the umbilicus are divided sharply to enter the peritoneal cavity. The bowel is retracted into the upper abdomen using a retraction system such as the Buchwalter or Omni-Tract system. Trendelenburg can be steepened to assist in packing the bowel away. The peritoneum is incised over the iliac vessels, and the node dissection is undertaken using the same landmarks as described in the extraperitoneal approach. The procedure follows the steps previously described; the posterior aspect of the bladder is freed to allow adequate exposure, and the superior vesical artery is divided as needed. The lesion is located, and stay sutures are placed some distance away from the site of disease. After the bladder dissection is complete, the bladder is drained. The bladder is then incised, and the tumor is excised with a 2-cm margin followed by bladder closure and management of the Foley catheter and drains as previously described in the extraperitoneal approach.

## Outcomes

In modern partial cystectomy series for the management of UCC, outcomes are good, with a 5-year overall survival rate of 64% to 70% and a 5-year disease-specific survival rate of 74% to 84% (4, 5, 8). However, UCC is well known for its high recurrence rates. In partial cystectomy series, recurrence rates range from 28% to 49%, with an approximate recurrence rate of 20% to 25% in locally advanced or metastatic disease. Because of this high recurrence rate, most authors agree that lifelong cystoscopy and repeat abdominal and pelvic imaging should be performed in these patients. Disease recurrence requires aggressive treatment similar to treatment for recurrence with other treatment modalities, including repeat transurethral resection, use of intravesical agents, chemotherapy and/or radiation protocols, and radical cystectomy with urinary diversion when indicated.

The success of partial cystectomy for urachal adenocarcinoma with *en bloc* resection of the urachus, umbilicus, and surrounding soft tissues with negative margins has resulted in an 88% 5-year disease-free survival rate (3). Local recurrence rates are approximately 18% with aggressive resection. Furthermore, a review of multiple small surgical series would suggest no survival benefit to radical cystectomy over extended partial cystectomy with *en bloc* resection, but a randomized trial has not been done.

## Complications

For both partial cystectomy and simple cystectomy, the usual risks associated with urologic surgeries exist, including pulmonary embolus, myocardial infarction, bleeding that requires transfusion, ileus, and wound complications such as infections or seromas. Other more specific complications include reduction of bladder capacity, urinary leakage, fistula

formation, and lymphocele formation. Recurrence is a concern and is discussed previously. The overall complication rate of partial cystectomy is classically reported as 11% to 29%.

Of special consideration is the reduction in functional capacity during partial cystectomy. There are no good data to

determine how much bladder capacity can be removed while still allowing good function. Preoperative urodynamic testing may be of some benefit in accurately assessing preoperative bladder capacity.

# CHAPTER 15 ■ RADICAL CYSTECTOMY IN MEN

MOHAMED A. GHONHEIM

One of the first detailed operative descriptions of radical cystoprostatectomy and pelvic lymphadenectomy was probably provided by Marshall and Whitmore in 1949 (2). In the 1950s and early 1960s, the operation was attended with significant mortality and morbidity. Although more complex urinary diversions are increasingly employed, contemporary cystectomy is associated with very low mortality. Furthermore, the advent of nerve-sparing cystectomy and orthotopic bladder substitution has significantly reduced functional losses and provided many patients with good locoregional control as well as a good quality of life. The technique, herein described, is based on cumulative experience of >20 years during which >1,000 cystectomies were carried out at the Department of Urology, Mansoura University, Egypt.

---

## DIAGNOSIS

---

The diagnosis of transitional-cell carcinoma is generally made by transurethral resection of the tumor in the bladder (see Chapter 111). Once the diagnosis has been established, it is important to know the histologic stage, particularly if the tumor invades the muscularis propria. Invasion of the muscularis mucosa is not considered as constituting a muscle-invasive tumor. The clinical staging of transitional-cell carcinoma can generally be performed by abdominal and pelvic computerized tomographic (CT) scans. Occasionally radionuclide bone scans are indicated if there is either symptomatic bone pain or abnormalities on the CT scan, or if the

patient has either an elevated serum calcium or alkaline phosphatase.

---

## INDICATIONS FOR RADICAL CYSTECTOMY IN MEN

---

The major indication for cystectomy in men is carcinoma of the bladder. In general, the operation is carried out for the following:

1. Patients with superficial tumors in whom endoscopic control has failed in spite of adjuvant intravesical chemo- and/or immunotherapy. Although these measures have proved effective in the management of such cases (<T1), an important minority fail. High tumor grade, multifocal lesions, diffuse carcinoma in situ, and involvement of the prostatic urethra were all reported as high-risk factors.
2. Infiltrating tumor without evidence of distant metastasis. These include tumors infiltrating the muscle layers (P<sub>2</sub>, P<sub>3a</sub>) or the perivesical fat short of the pelvic wall (P<sub>3b</sub>). Infiltration of adjacent organs (P<sub>4</sub>) or involvement of the regional lymph nodes is not considered a contraindication for the procedure.

The radical operation in men includes the removal of the bladder, its peritoneal covering, the perivesical fat, the lower ureters, the prostate, the seminal vesicles, and the vasa deferentia. In the standard procedure, as much as possible of the membranous urethra is also removed, and total urethrectomy is carried out only if there is involvement of the prostatic urethra (4).

## ALTERNATIVE THERAPY

Alternatives to radical cystectomy include local therapy, partial cystectomy, intravenous chemotherapy, radiation therapy, or a combination of chemotherapy and radiation therapy. Local therapy in invasive disease generally results in progression of the disease and death of the patient within 5 years. Systemic chemotherapy or radiation therapy is associated with a 25% 5-year survival, though the combination of the two modalities results in significant synergy, with up to 50% 5-year survival.

## SURGICAL TECHNIQUE

### Preparation of the Patient

In view of the extent of surgery and the length of the operative time, a thorough medical evaluation and anesthetic consultation are required.

Bowel preparation is necessary before surgery. If it is planned to use the small bowel, oral neomycin and a low-residue diet are all that are needed. More rigorous preparation with full bowel prep is required if the colon is utilized.

Patients with histories of thromboembolic disease or varicose veins should receive a prophylactic dose of heparin (5,000 U subcutaneously) the night before the operation and every 12 hours thereafter until ambulation. A parenteral broad-spectrum antibiotic is given just before induction of anesthesia and continued postoperatively for 3 days. The region extending from the midchest to the midthigh should be cleaned and prepared on the night before surgery.

### Anesthesia and Instrumentation

Full relaxation of the abdominal muscles by an appropriate anesthetic is necessary throughout the entire procedure. Hypotensive anesthesia would provide an additional advantage and would reduce blood loss.

The choice of instruments depends mainly on the surgeon's preference. Standard retractors of various sizes and curves as well as long curved and angled scissors are needed. Long curved clamps should also be available.

### Position and Initial Exposure

The patient is put in the supine position with a Trendelenberg tilt. Slight bending of the knees would further help in the relaxation of the abdominal muscles, facilitate retraction, and provide a wider exposure. If a total urethrectomy is planned, the patient is put in a slight lithotomy position for access to the perineum.

The surgical area to be sterilized and draped extends from the lower chest down to the root of the penis. A self-retaining catheter is introduced into the bladder and kept indwelling for its evacuation throughout the procedure.

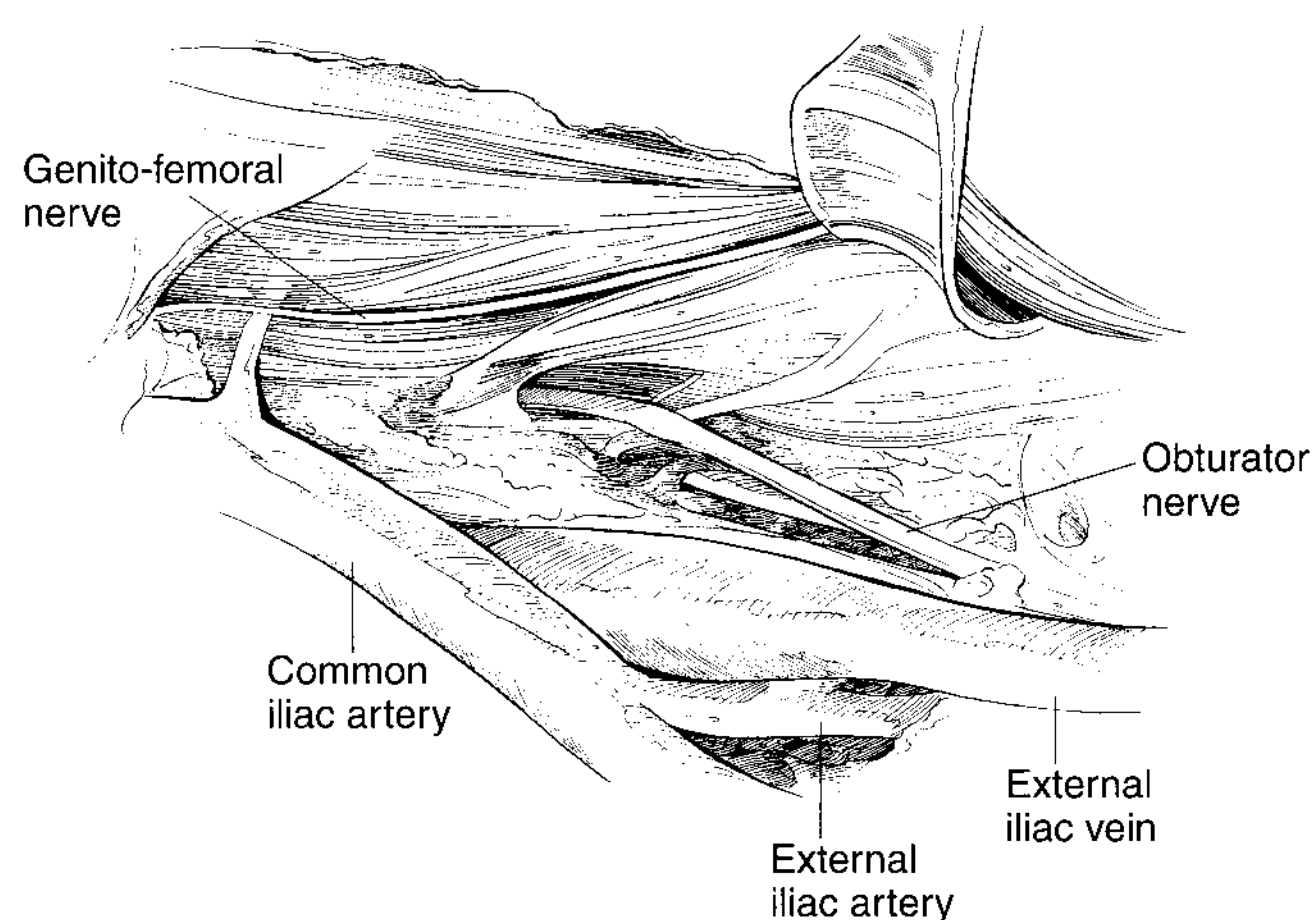

A long, vertical, right paramedian incision extending from the symphysis pubis inferiorly to a point halfway between the umbilicus and xyphoid process of the sternum superiorly is

generally employed. Alternatively, a midline incision encircling the umbilicus can also be utilized. For obese patients a lower abdominal muscle-cutting transverse incision is preferred. Under such circumstances it provides a wide and direct exposure of the pelvis.

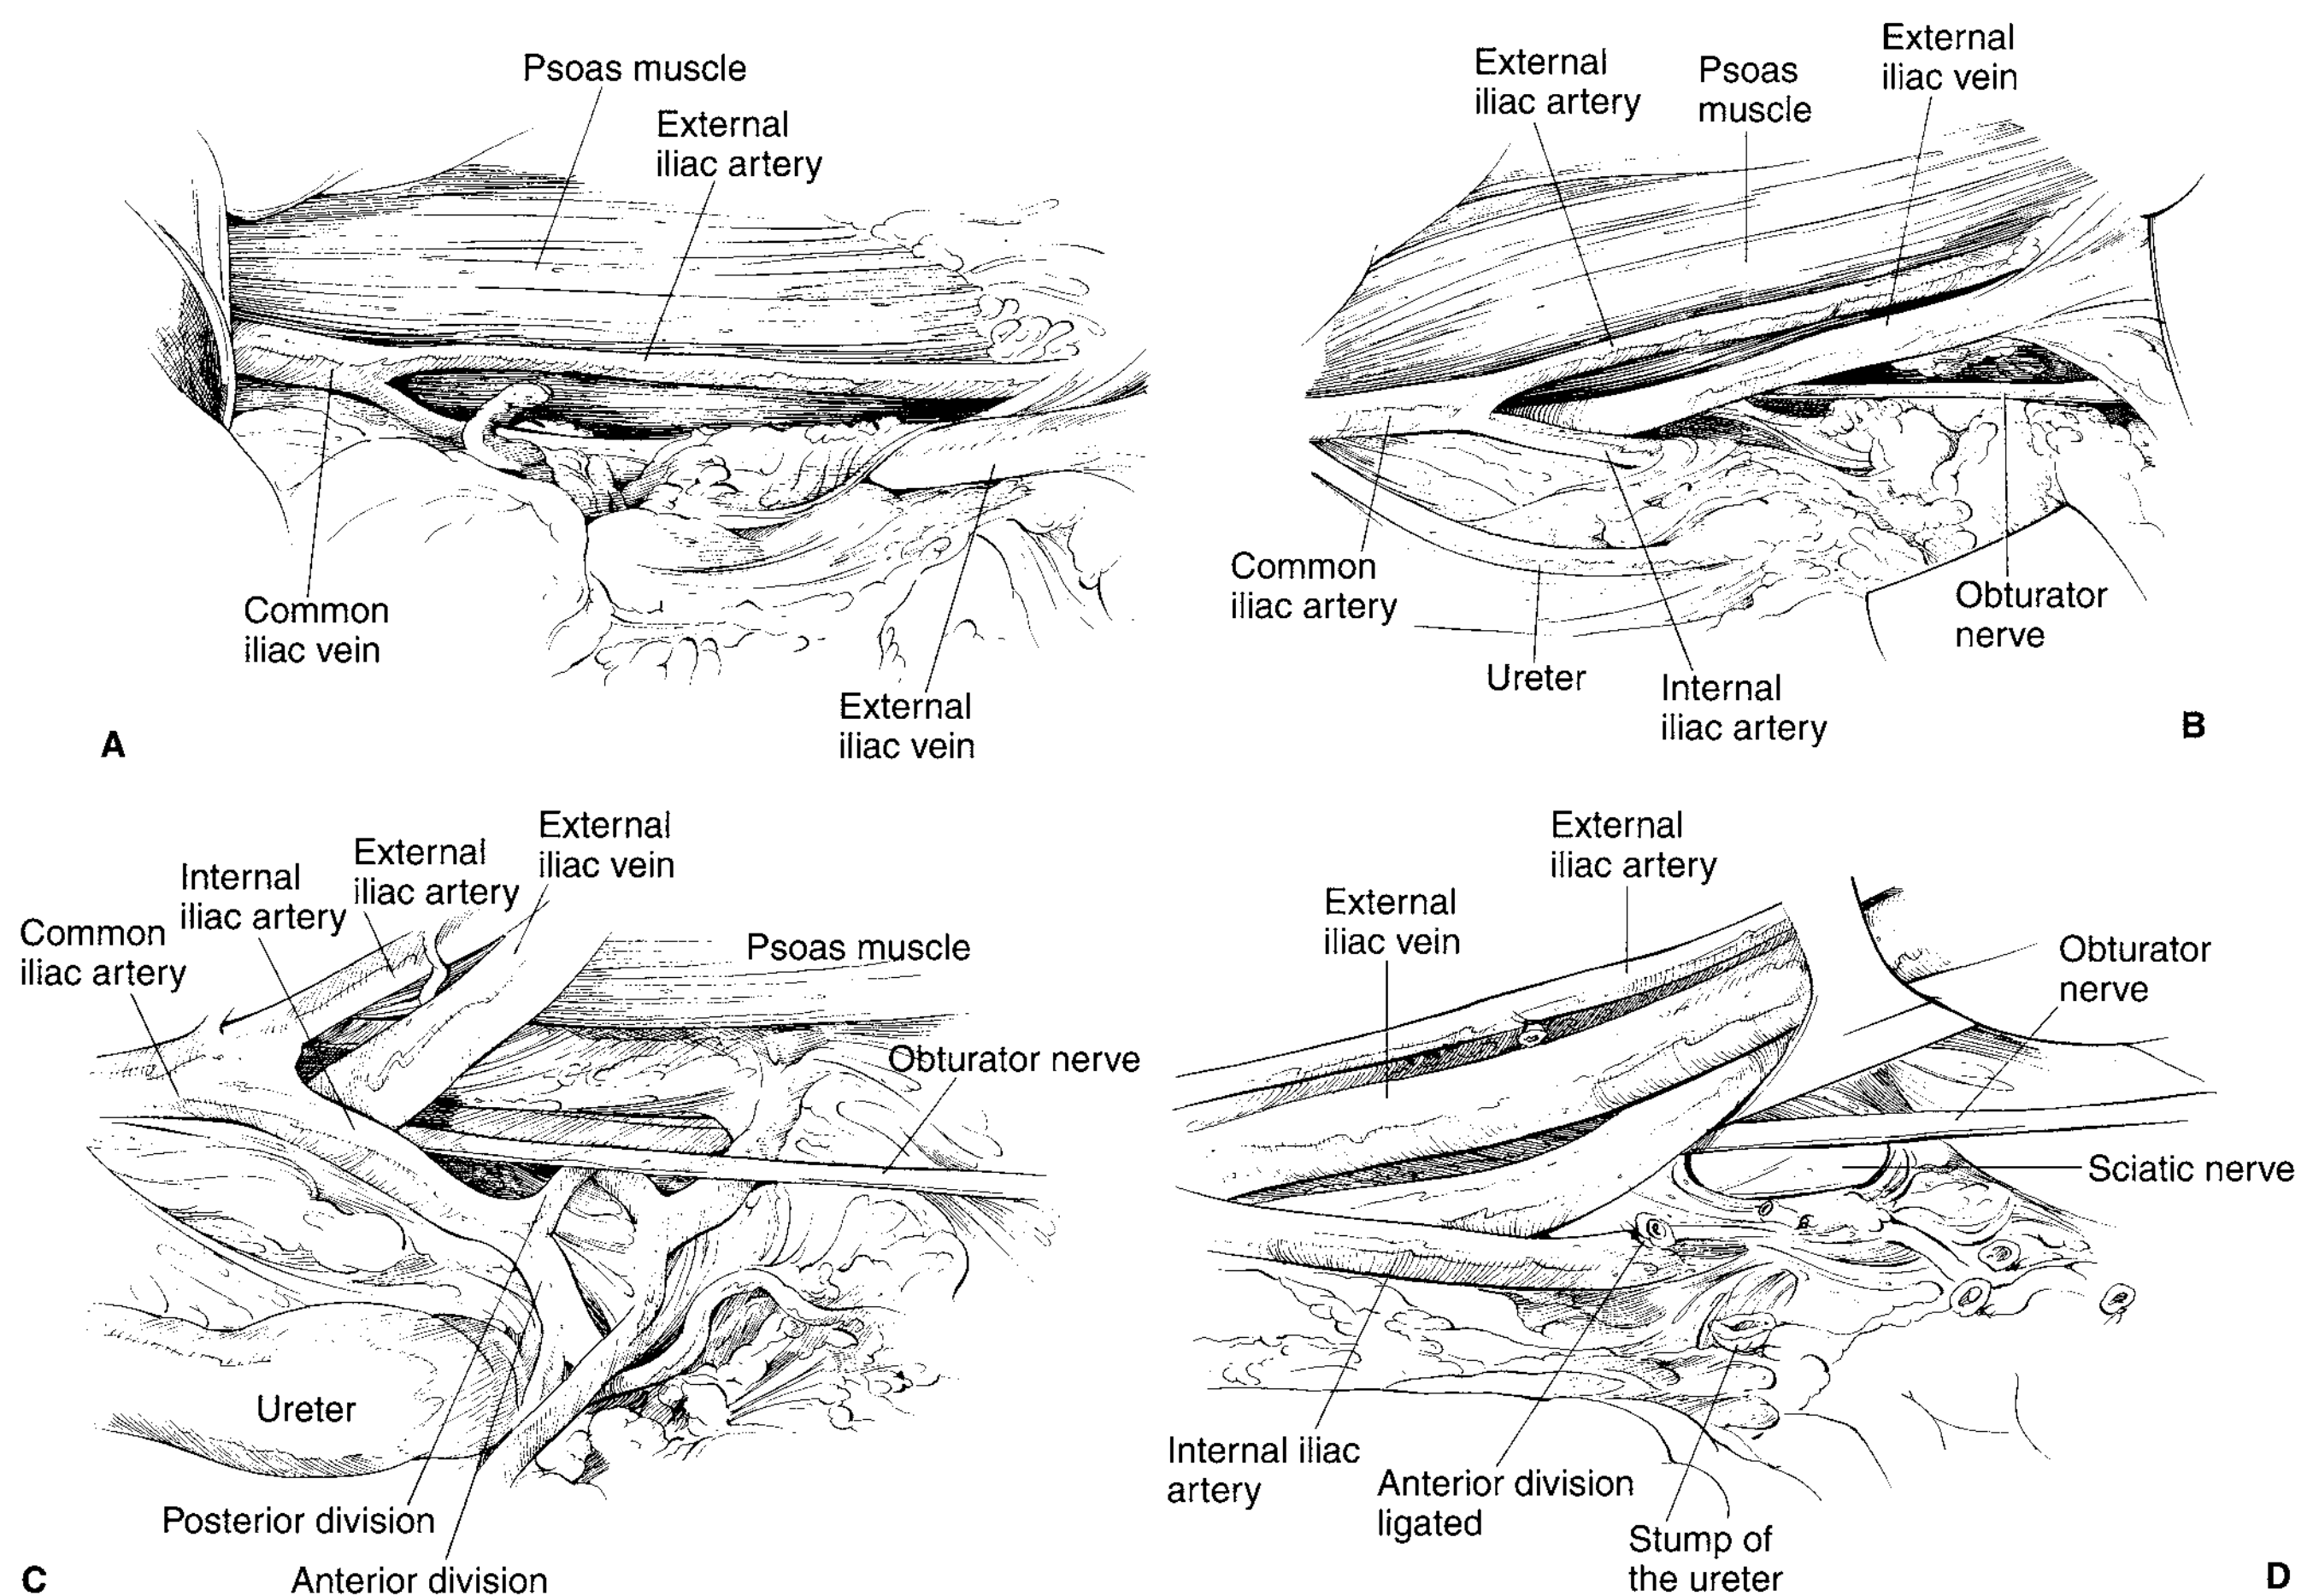

Initially, the abdominal and pelvic cavities are explored. The growth is palpated, its degree of mobility determined, and its relation to the adjacent structures assessed. The endopelvic and aortic lymph nodes are palpated, and frozen sections are taken if necessary. The general peritoneal cavity, omentum, intestinal tract, kidney, spleen, and liver are thoroughly examined. If the decision is to proceed with the radical operation, the intestines are packed out of the pelvis, and the retropubic space is opened by blunt dissection. Any small bleeders are coagulated. This dissection is extended inferiorly and laterally until the ventral surface of the bladder and prostate are exposed. The peritoneal incision is extended inferiorly on either side of the urachal remnant. The urachal remnant is dissected off its attachment with the umbilicus and clamped. In this manner a triangular peritoneal flap with its apex pointing superiorly is raised and will be removed later en bloc with the bladder.

### Lymphadenectomy

The peritoneal incision, on either side, is extended posterolaterally along the lateral border of the external iliac and common iliac vessels up to the aortic bifurcation. The vas deferens is identified and ligated near the internal ring. The fascia on the iliopsoas is incised and reflected medially. The triangle of Marceille is exposed by retracting the common and external iliac arteries medially and dissecting the space between these vessels and the medial border of the psoas muscle (3). Dissection of the fibrolymphatic tissues in this space will expose the obturator nerve as it emerges from the medial border of the psoas muscle (Fig. 15.1). The fibrofascial sheath covering the distal half of the common iliac and the external iliac vessels is then opened and stripped medially to remove the

**FIGURE 15.1** Dissection of the triangle of Marceille. The psoas muscle is retracted laterally and the iliac vessels medially. The obturator nerve is exposed in the floor of the triangle as it emerges from the medial border of the psoas muscle.

**FIGURE 15.2** The lymphadenectomy. **A:** The fibroareolar tissue has been dissected from the anterior and medial aspects of the psoas major muscle. The external and common iliac arteries are exposed and skeletonized. **B:** Further dissection exposes the external vein. The obturator fossa is cleared with separation of the obturator nerve. **C:** Further dissection of the internal iliac artery and its branches prior to their control. **D:** The lateral dissection is completed. The anterior division of the internal iliac artery is divided with control of its parietal branches. The ureter is divided and the ligature on its stump is used for traction.

perivascular lymphatics and lymph nodes. The vessels are gently retracted, laterally and immediately below and medial to the cleaned external iliac vein, and the obturator space is entered. By working right on the psoas and obturator muscles, one can strip all the pelvic fascia medially without difficulty. The obturator neurovascular bundle is included in the stripped mass. The obturator nerve is identified and separated from the vessels, which are divided and ligated as they leave the pelvis through the obturator foramen. Dissection is facilitated and the operating time reduced by the use of electrocoagulation to control lymphatic and small blood vessels throughout the lymphadenectomy.

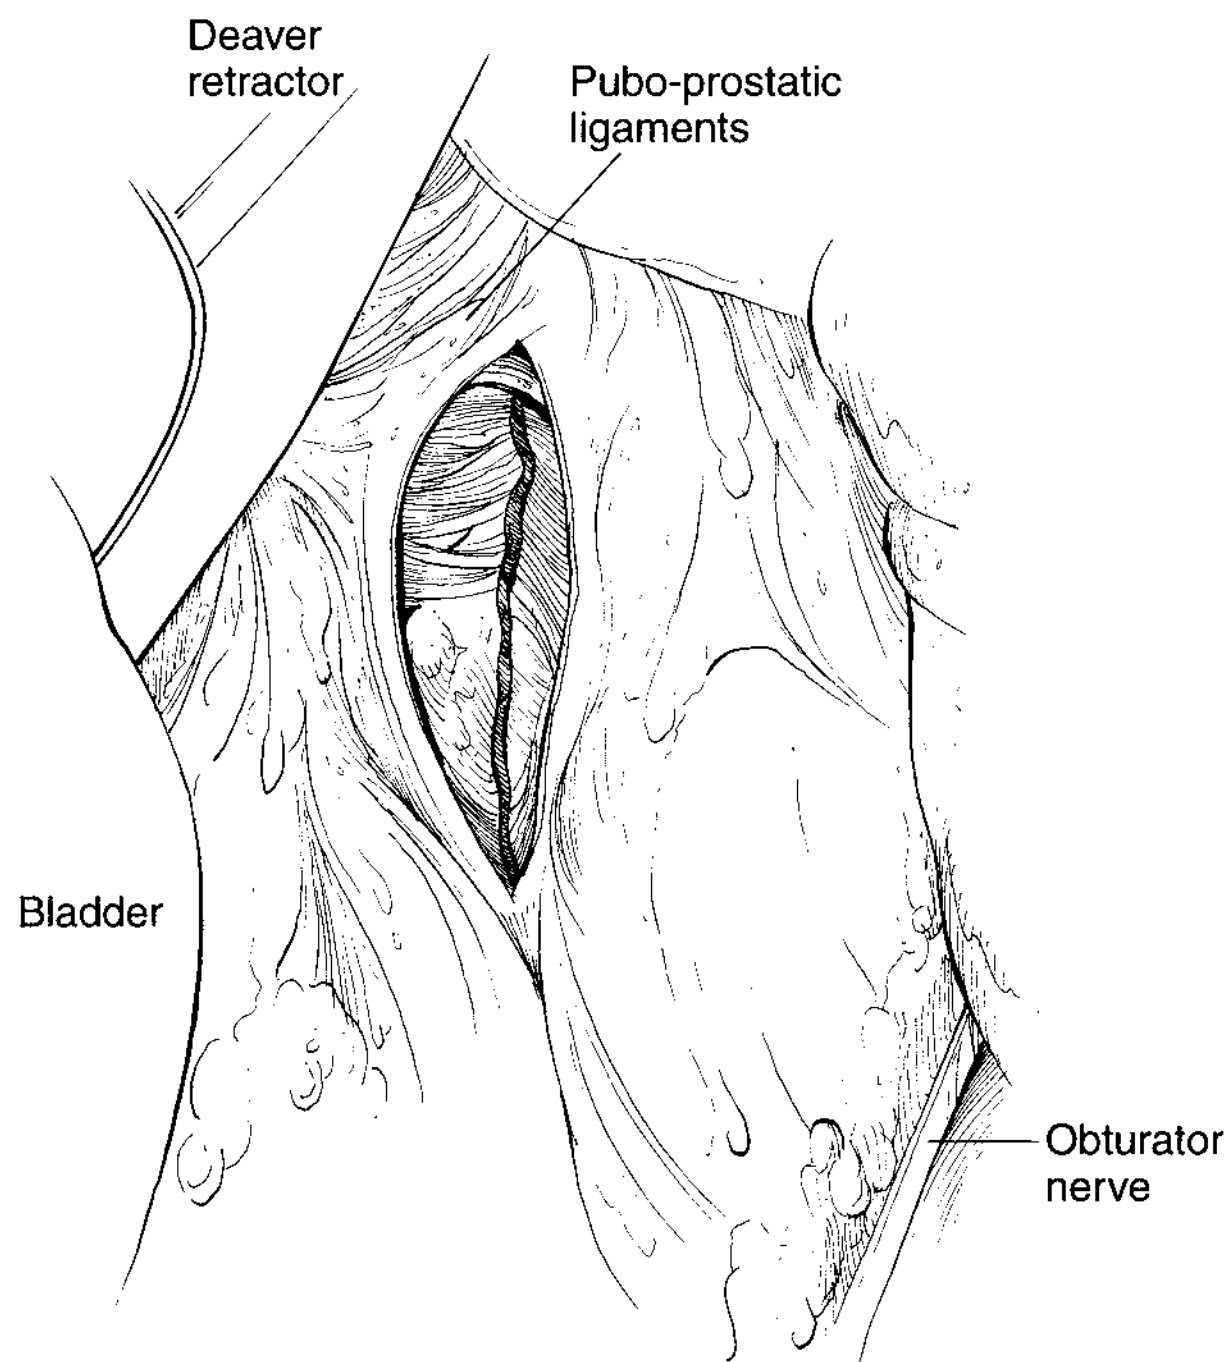

### Cystoprostatectomy

The fibrolymphatic mass is now reflected medially. The internal iliac artery is dissected free, and its anterior division is divided and ligated. The ureter is identified where it crosses the common iliac bifurcation, dissected free for 3 to 4 cm, divided, and its distal end ligated. While traction is applied on

the ligated ureteric stump of the ureter, finger dissection along its posteromedial border opens the space of Denonvilliers laterally. The step greatly helps in the definition of the plane between the bladder and rectum, which will be required at a later stage in the operation. The phases of the lateral dissection are illustrated in Figure 15.2.

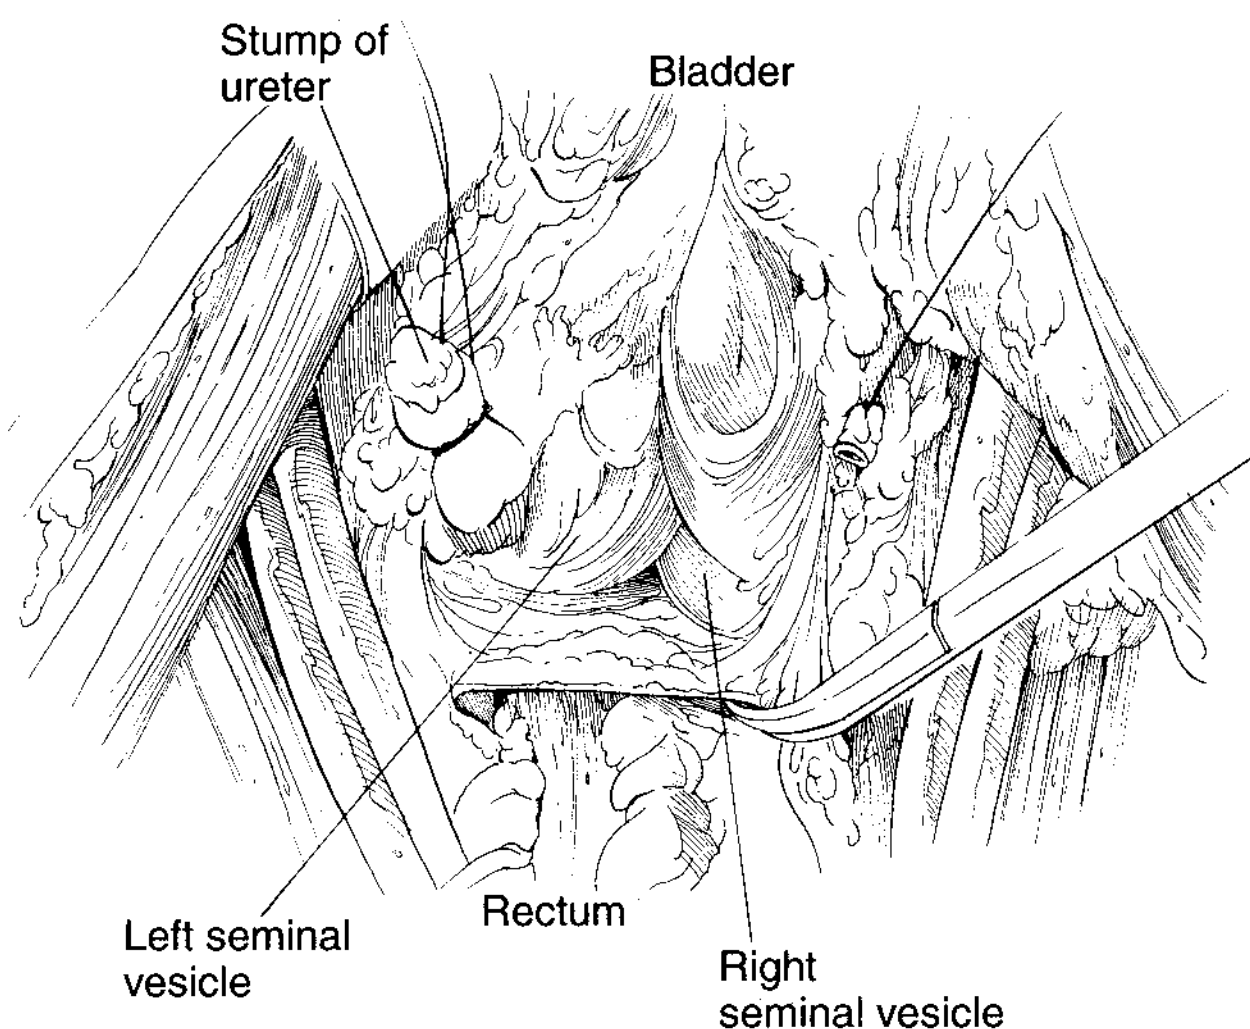

The endopelvic fascia on either side on the prostate is then opened by the tip of a blunt pair of scissors (Fig. 15.3). The optimal site for the creation of this opening is a white line marking the fusion of the parietal fascia lining the pelvic surface of the levator ani with the visceral fascia covering the lateral surface of the prostate. A right-angled clamp is used to lift the fascia from the underlying venous plexus, and it is further incised medially until the prostatic ligaments are reached. By blunt dissection, this plane is further developed posteriorly on either side of the prostate. Further anterior dissection is deferred to the final stages of the procedure to minimize the possibility of sudden blood losses from inadvertent injury of the prostatic venous plexus.

The specimen is now lifted ventrally by applying traction on the median umbilical ligament (urachus). The two planes

**FIGURE 15.3** The bladder and prostate are retracted medially by a Deaver retractor. The reflection of the endopelvic fascia from the ventral surface of the levator ani to the prostate is opened. Blunt dissection would further develop this space and expose the lateral surface of the prostate.

developed along the posteromedial borders of the ureter on either side are easily joined together by blunt dissection. As a result, the peritoneal reflection from the anterior surface of the rectum to the back of the bladder could be stretched and safely incised by diathermy. The potential space between the rectum posteriorly and the bladder, seminal vesicles, and prostate anteriorly is opened by blunt dissection (Fig. 15.4). As the prostatic apex is reached, this space becomes obliterated as a result of fusion of the two layers of the fascia of

**FIGURE 15.4** The peritoneum of the floor of the Douglas pouch is incised by diathermy. The space between the rectum posteriorly and the bladder and seminal vesicles anteriorly is dissected and opened.

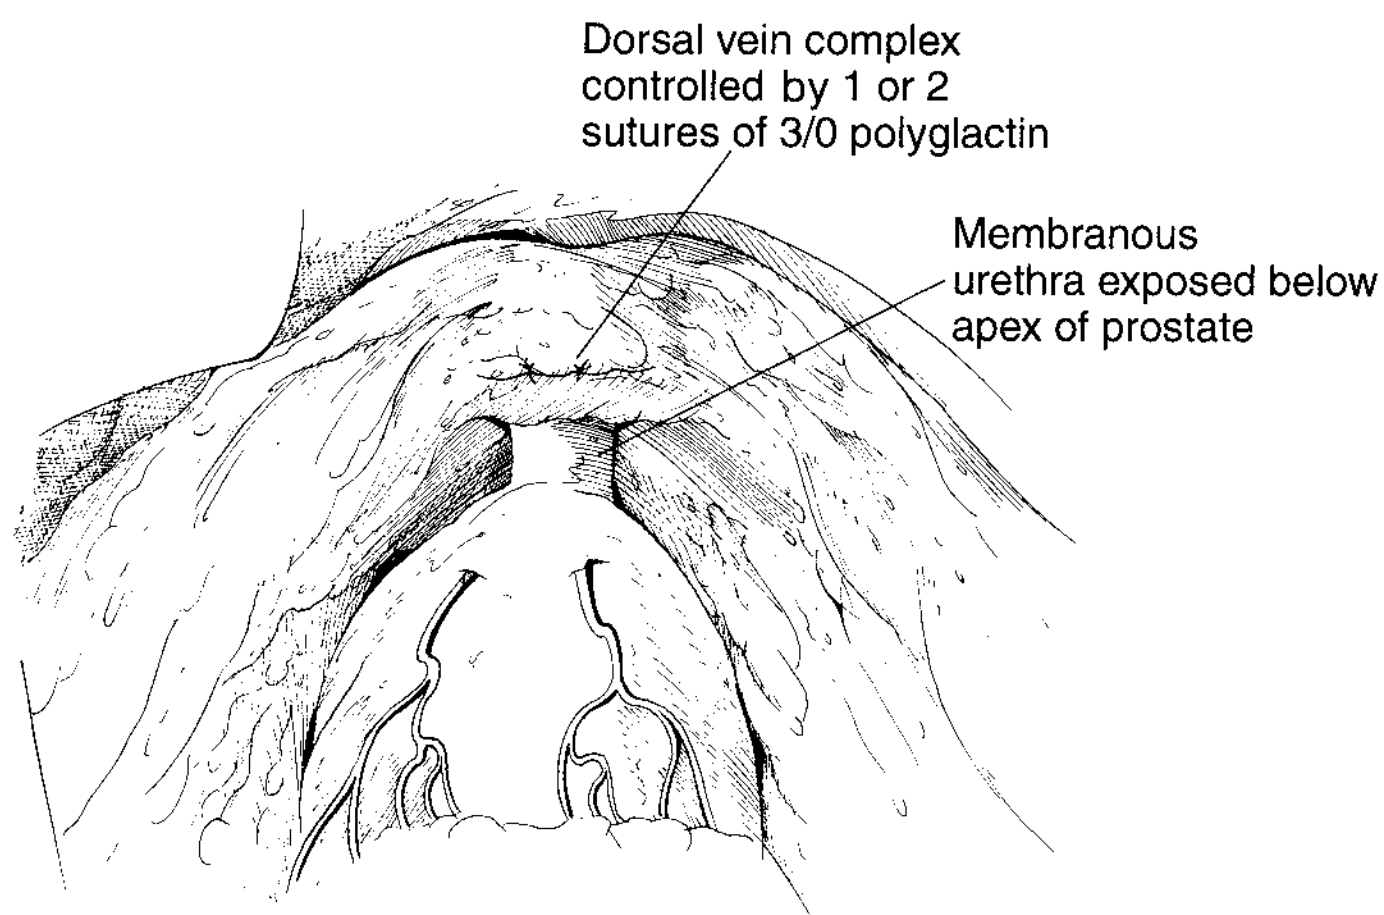

**FIGURE 15.5** The cul-de-sac formed by the fusion of the two layers of the fascia of Denonvilliers is opened by the tip of a blunt pair of long scissors. Thereafter, the tip of the surgeon's forefinger would feel the apex of the prostate and the catheter in the urethra. If the forefinger is directed laterally, it will appear through the previously created openings on either side of the prostate. Thus a thick, wide, fascial band is defined (the vesicoprostatic pelvic fascia). It is divided piecemeal between clamps (*arrow and interrupted line*).

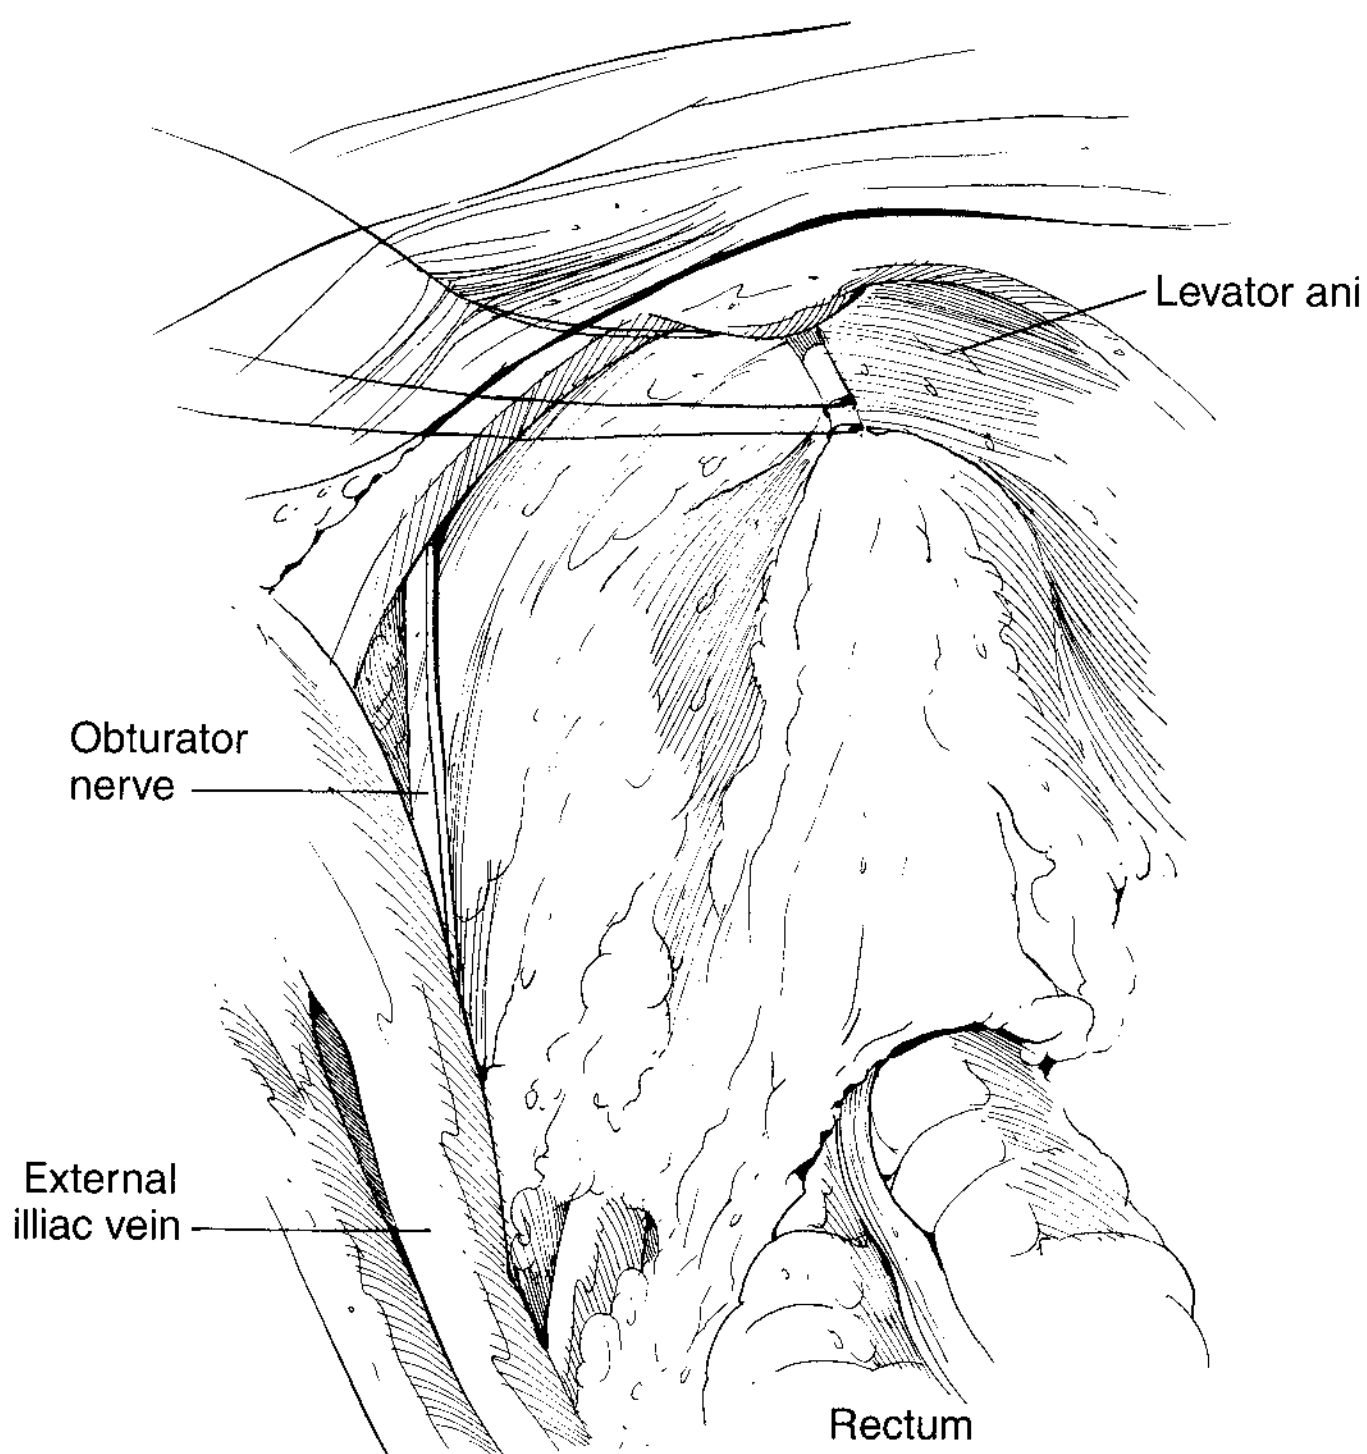

Denonvilliers. This cul-de-sac is opened by the blunt tip of long angled scissors. Once this is completed, the tip of the surgeon's forefinger can readily feel the apex of the prostate as well as the catheter in the urethra in the midline. Alternatively, if it is directed laterally, it will appear through the previously created openings on either side of the prostate (Fig. 15.5).

In this manner, a thick and wide fascial band is created on either side, connecting the bladder, vesicles, and prostate anteriorly with the pararectal fascia posteriorly (the vesicoprostatopelvic fascia). This is divided piecemeal between clamps, which are under-run by 2-0 polyglactin sutures.

The bladder is now free laterally and posteriorly, and the mass is left to drop in the pelvis. Attention is now focused on the anterior and final phase of the procedure. The puboprostatic ligaments are identified by applying traction on the prostate in a cephalad and posterior direction. These ligaments are carefully severed at the point of their insertion in the pubic bone. The prostatic venous plexus is controlled by one or two sutures of 3-0 polyglactin acid placed near the prostatic apex. A transverse incision is made proximal to these sutures with a long scalpel and extended with sharp dissection by scissors, exposing the urethra, within which the catheter can be palpated (Fig. 15.6). The catheter is then withdrawn; the urethra is clamped and transected; the distal end is ligated; and the specimen is removed. Final hemostasis is achieved by inserting deep 2-0 polyglactin sutures between the edges of the levator ani muscles on either side (Fig. 15.7). No attempt is made to reperitonealize the pelvis. Two tube drains are placed in the pelvic cavity and brought out through separate incisions in the abdominal wall. The wound is closed in layers with particular attention for careful closure of the anterior rectus sheath. This is closed with interrupted sutures of nylon with the knots tied to the inside.

**FIGURE 15.6** The puboprostatic ligament is incised and the prostatic venous complex controlled. The membranous urethra is thus exposed.

**FIGURE 15.7** The specimen is removed. Final hemostasis is achieved by two to three interrupted sutures of 3-0 polyglactin between the two medial borders of the levator ani muscles.

## Variations on a Theme

### One-Stage Cystoprostatourethrectomy

Urethrectomy is indicated in a subpopulation of patients with multifocal tumors, diffuse carcinoma in situ, or tumor involving the bladder neck and/or the prostate. Following incision of the puboprostatic ligaments and control of the prostatic venous plexus described, traction is applied on the cystectomy specimen in a cephalad direction. The urethra is dissected from the urogenital diaphragm with a long pair of dissecting scissors. In this manner, 2 to 3 cm of the membranous urethra can be mobilized. The pelvis is temporarily packed with gauze,

and further steps are carried out perineally without urethral transection.

A midline incision in the perineum is usually employed. The skin, subcutaneous tissue, and bulbocavernosus muscle are incised in the midline. The Foley catheter can now be palpated in the urethra. The urethra is dissected sharply from the overlying corpora cavernosus. Further dissection is carried out in the direction of the glans penis. Traction on the urethra results in inversion on the penis, allowing dissection of the urethra as far as the coronal sulcus. The penis is then allowed to restore its normal position. The urethral meatus is circumscribed sharply, and the glans penis is incised in the midline to allow dissection of the fossa navicularis. The entire penile urethra is now free. The glans penis is reconstructed by a few sutures of interrupted 3-0 chromic catgut.

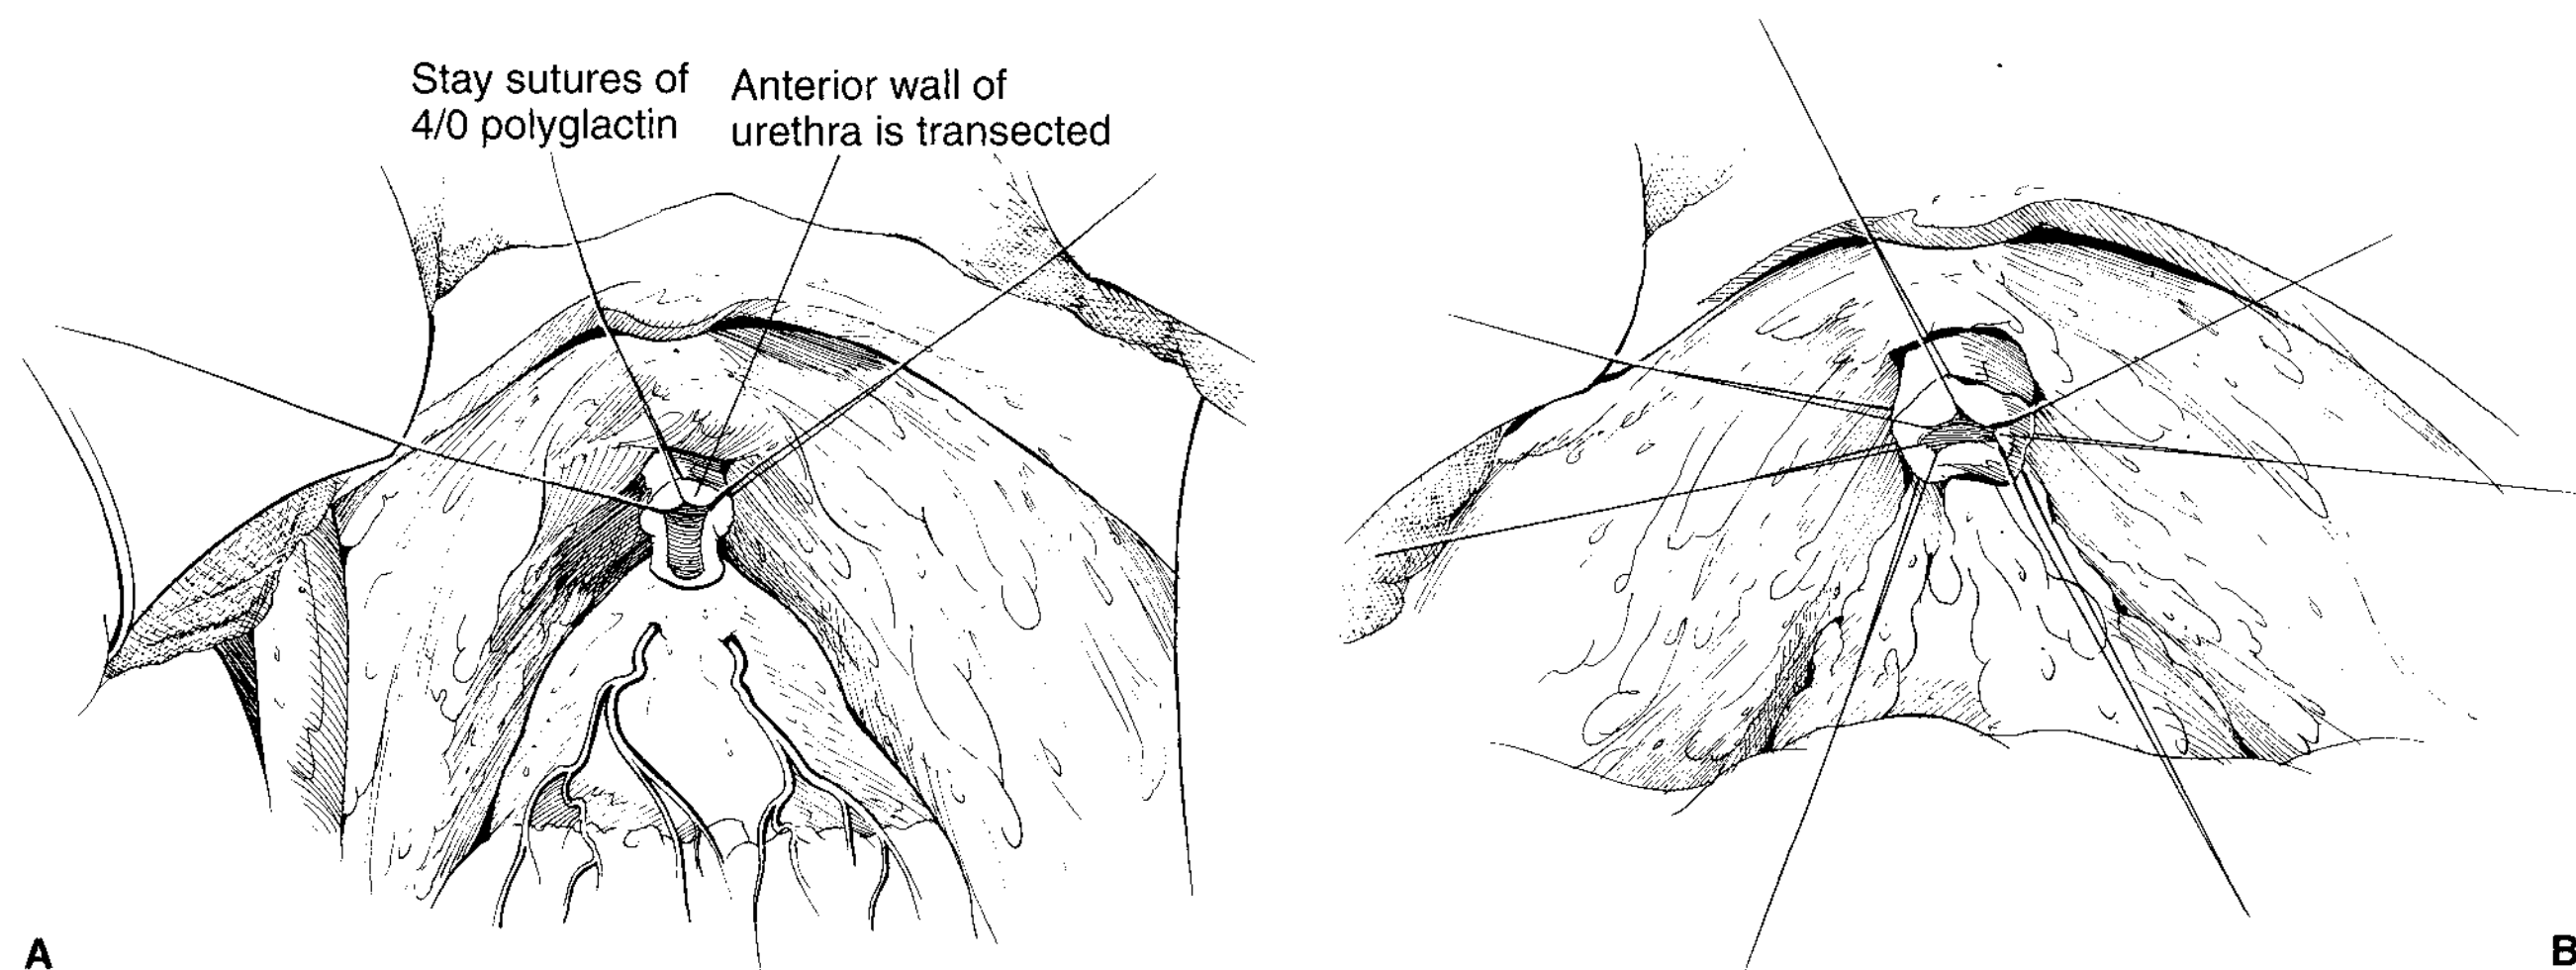

Attention is now focused on dissection of the bulbar urethra. The relatively avascular tissues ventral to the bulbar urethra and beneath the symphysis pubis are dissected first. Thus, the corresponding part that had been previously dissected in the pelvis can be reached, and the pelvic and perineal exposures joined. Dissection is further developed laterally and posteriorly with control of the bulbar urethral arteries. In this manner the urethra is freed totally, and the whole specimen is removed in one block.

### Radical Cystoprostatectomy with Orthotopic Bladder Substitution

A standard radical cystoprostatectomy is performed except that the final stages of the operation must be done with attention to detail to avoid damage to the urethra and periurethral musculature. The integrity of these structures has a central role in the functional success of orthotopic substitution. Following lymphadenectomy and control of the pedicles, the endopelvic fascia on either side of the prostate is opened by the tip of a blunt pair of scissors. A right-angled clamp is used to lift the fascia from the underlying venous plexus, and then it is further incised medially until the puboprostatic ligaments are reached. These ligaments are carefully severed at the point of their insertion in the pubic bone. The prostatic venous plexus is controlled by one or two suture ligatures of 3-0 polyglactin just distal to the vesicoprostatic junction. A transverse incision is made proximal to these sutures and extended by sharp dissection with scissors toward the apex of the prostate. The catheter is palpated in the urethra, the anterior wall of which is then incised just distal to the prostatic apex. The exposed Foley catheter is transected, clamped, and held for traction. At this point, three stay sutures of 4-0 polyglactin are placed through the urethra at the 3, 9, and 12 o'clock positions, incorporating the mucosa as well as the periurethral musculature (Fig. 15.8). These sutures prevent retraction of the urethra following its complete transection and are used later for the urethroileal anastomosis. The posterior urethral wall is then incised to expose the dorsal fibrous raphe formed by the fascia of Denonvilliers, which is lifted from the anterior surface of the rectum by a right-angled clamp and divided. The divided fascia is then included in two posterior stay sutures at the 5 and 7 o'clock positions for its later incorporation in the urethrointestinal anastomosis.

### Radical Cystoprostatectomy with Nerve Sparing

This procedure was initially described by Schlegel and Walsh (5). It can be carried out in an antegrade or a retrograde manner,

**FIGURE 15.8** Preparation of the urethral stump for orthotopic substitution. **A:** The anterior wall of the urethra is transected. Three stay sutures of 4-0 polyglactin are placed through the urethra at the 3, 9, and 12 o'clock positions. **B:** Transection of the urethra is completed and further stay sutures applied. These will prevent retraction of the urethral stump and will be later used for the urethroileal anastomosis.

though in our practice we prefer the antegrade approach. During radical cystectomy there are two points where the neurovascular bundle could be injured: (a) posterolateral to the prostate and (b) behind the seminal vesicles. If the extent of the pathology allows the surgeon to avoid these areas, potency can be preserved.

Bilateral lymphadenectomy with creation of the space between the rectum posteriorly and the bladder, seminal vesicles, and prostate anteriorly is carried out as previously described. By a combination of blunt and sharp dissection, the lateral surface of the seminal vesicles is freed from the medial aspect of the vesicoprostatopelvic fascia. This allows the control of these ligaments at a more ventral plane. As a result, the neurovascular pathway behind the seminal vesicles is avoided. These pedicles are controlled by a series of simple interrupted sutures of 3-0 Vicryl. The use of heavy clamps, clips, and diathermy should be avoided. The dorsal vein complex is now controlled, and the urethra isolated carefully from the adjacent fascia. The urethra is then transected, and the Foley catheter is clamped and held for traction. The prostate can thus be elevated superiorly. A right-angle clamp is used to identify branches of the neurovascular bundle to the prostate. These are ligated and divided, freeing the prostate from all its lateral attachments.

### Prostate-Sparing Radical Cystectomy

Several authors have advocated retaining the prostate in some selected patients for whom orthotopic diversion is contemplated (6,7). It was suggested that preserving the prostate in whole or in part can circumvent problems related to continence and results in the preservation of erectile function. However, serious concerns were raised by other authorities of the possible increased oncological risks following such a procedure. In a review by Hautmann and Stein it was reported that the incidence of prostatic carcinoma in cytoprostatectomy specimens ranged between 29% and 46% and that of prostate TCC between 33% and 58% (8). In a prospective pathologic

evaluation of 425 cystoprostatectomy specimens at our institution, there was histological evidence of adenocarcinoma of the prostate in 21.2% of cases and concomitant noncontiguous TCC in 6.4% (9). In view of all of these observations, we feel that the potential oncologic risks of prostate-sparing cystectomy outweigh any small and possible functional benefits. Properly conducted radical cystoprostatectomy with orthotopic substitution should remain the standard for treating invasive bladder tumors.

### Postoperative Management

Intravenous alimentation and nasogastric suction are maintained until normal bowel activity is resumed. Systemic antibiotics are continued for 3 days postoperatively. Chest exercises and physiotherapy to the lower limbs should be carried out. Subcutaneous heparin should be administered if indicated. The tube drains are removed when drainage becomes <100 mL per day. It is advisable to estimate the creatinine content of the fluid to ensure that it is not the result of a urinary leak. Patients with an ileal conduit can be discharged on the 10th to the 12th postoperative day. Following orthotopic substitution, patients are usually kept in the hospital for 3 weeks. Before discharge, a pouchography is carried out to make sure that there are no leaks from the neobladder or from the urethroileal anastomosis.

## OUTCOMES

### Complications

The two most serious complications that may occur during the procedure are excessive blood loss and rectal perforation. Sudden massive bleeding is usually venous in origin, arising from tributaries of the external iliac vein during the lymphadenectomy: the deep circumflex iliac vein laterally and an abnormal obturator vein medially. Since both are located near

the inguinal ligament, good retraction, illumination, and suction are needed. A laceration of the external iliac vein is then sutured with 5-0 Prolene.

Another source of bleeding is in relation to the dorsal vein complex. Dissection of this area has to be deferred to the final phase of the procedure. This venous complex is usually injured when the puboprostatic ligaments are incised. Compression of the bleeding area by a piece of gauze (4 × 8) and the tip of a long thin blade of a Deaver retractor is necessary until the dissection of the urethra is completed. Thereafter, bleeding is controlled by one or two interrupted 3-0 sutures of polyglactin acid placed between the two medial borders of the levator ani muscles.

However, the most serious source of bleeding is from the internal iliac vein or one of its tributaries. Sudden excessive bleeding occurs from the depth of a narrow deep recess. Blind attempts to control the bleeding with clamps usually fail and result in more damage. In our experience, one has to achieve an initial temporary control by packing. One or two 4 × 8 pieces of moist gauze are sufficient. The pack is tightly and constantly compressed for a few minutes and then is left in place. The operator should proceed with further operative steps until the specimen is removed. Now, the working space is wide enough to allow manipulations under vision. The ipsilateral external iliac and common iliac veins as well as the main stem of the internal iliac artery are controlled by bulldog clamps. The gauze pack is then removed. There will still be some back bleeding, but with the help of a little suction, the bleeding vessels are readily located and easily secured by suture ligation using 4-0 silk.

The other serious intraoperative complication is rectal perforation. This usually takes place during the final phase of the operation if the space between the prostate and rectum was not adequately and completely opened. Under such circumstances, traction on the specimen will lead to tenting of the anterior wall of the rectum. Sharp dissection with scissors or application of clamps would result in an injury of the anterior wall of the rectum well below the peritoneal reflection. If this injury is recognized, the tear is meticulously repaired. The edges are trimmed and closed in two layers using 3-0 polyglactin acid: the first through and through, and the second inverting as a fascia muscular layer (Lembert technique). An omental flap is raised, brought down to the pelvis, and

sutured over the repair for additional security. The pelvic cavity is then thoroughly irrigated with 1% solution of kanamycin in saline. At the end of surgery, while the patient is still under anesthesia, anal dilation is carried out up to three to four fingers to establish adequate decompression. Generally, by following these principles, one can avoid the need for a temporary proximal colostomy.

The postoperative mortality following contemporary cystectomy is 2% or less (10). The most common postoperative complication is prolonged ileus. This is treated by nasogastric suction, intravenous alimentation, and hyperalimentation if necessary. Septic complications, including abdominal and/or pelvic abscesses, wound sepsis, and septicemia, are not uncommon. These are treated by the appropriate antibiotics and drainage of the infected collection. This is best achieved by ultrasound-guided aspiration and/or insertion of a percutaneous tube drain. Wound dehiscence should be immediately repaired by proper closure using tension sutures. Urinary collections (urinoma) are drained under ultrasound guidance. If the source of leak is the ureterointestinal anastomosis, a percutaneous nephrostomy tube is inserted until healing is achieved and checked with an antegrade study.

---

## Results

---

Radical cystectomy has evolved as the standard therapeutic modality for muscle-invasive bladder cancer. It can be accomplished with very low mortality, and technical innovations with nerve sparing and orthotopic substitution can provide many patients with a good quality of life with minimal functional losses.

All contemporary series demonstrate that radical cystectomy can result in a substantial rate of cure with overall survival ranges between 48% and 53% (1,11). For low-stage tumors (<P2), the survival could be as high as 75%. With further stage progression, the survival expectancy is decreased. Radical cystectomy with pelvic lymphadenectomy also provides a survival advantage for cases with nodal disease (5-year survival in the range of 20%) (7). Evidence has also been provided that adjuvant cisplatin-based polychemotherapy improves the chances of survival among patients with advanced locoregional disease (12).

# CHAPTER 16 ■ RADICAL CYSTECTOMY IN WOMEN

ALON Z. WEIZER AND CHERYL T. LEE

In 2007, 67,000 new cases of bladder cancer were diagnosed in the United States; over 17,000 occurred in women, with 4,000 dying from their disease (1). Although most urothelial carcinomas are noninvasive, up to one-third of patients present with muscle-invasive disease. In addition, 30% to 40% of patients presenting with non-muscle-invasive tumors will progress to muscle invasion. Once patients progress to muscle-invasive disease, their 5-year survival declines substantially. Radical cystectomy remains the most effective single-modality treatment for these patients and also for those with refractory non-muscle-invasive disease, with a reported 10-year survival of 70% to 80% in patients with organ-confined tumors (2). Improvements in processes of care, particularly at high-volume centers, have led to a reduction in perioperative mortality, further strengthening the role of cystectomy (3).

Historically, radical cystectomy in women has posed several technical challenges and concerns, including (a) bleeding from the paravaginal tissues and venous plexus around the urethra, which can be brisk and tedious to control; (b) an intraoperative position change for the surgeon during urethrectomy; and (c) vaginal reconstruction, which can be complex, requiring tissue flaps to maximize organ function.

More recently, additional challenges have related to female organ preservation. Radical cystectomy in women has traditionally been equated with anterior exenteration, including resection of the bladder, urethra, uterus, ovaries, and the anterior one-third of the vagina. This approach is certainly indicated for extensive posterior invasive bladder tumors at risk for reproductive organ involvement. However, tumor involvement of adjacent reproductive organs is rare, suggesting that the routine removal of female reproductive and sex organs is not necessary to achieve local cancer control (4). Moreover, the increasing attention to preserving quality of life after cancer surgery provides another incentive to spare part or all of the reproductive organs and urethra when feasible and when dictated by the diversion choice.

---

## INDICATIONS FOR SURGERY

---

Radical cystectomy is indicated for patients with muscle-invasive urothelial malignancy or non-muscle-invasive disease refractory to transurethral resection and intravesical therapy. While radical cystectomy is well accepted as a standard for

patients with muscle-invasive disease, other indications for cystectomy are well supported by the literature.

---

### Non-Muscle-Invasive Disease

---

Radical cystectomy may be considered an alternative to intravesical therapy in patients with high-grade lamina-propria-invasive disease, especially in the setting of associated carcinoma in situ with the potential for improved survival benefit. The presence of additional adverse histologic features, such as mixed histology, lymphovascular invasion, inverted growth pattern, or nested variant, should also drive consideration of early cystectomy. Patients with non-muscle-invasive disease refractory to intravesical therapy (bacille Calmette-Guérin) are at significant risk of progression, and repeated courses of intravesical therapy can compromise overall survival (5); this may be due to the 30% incidence of understaging in patients with noninvasive disease.

---

### Intractable Local Symptoms

---

Radical cystectomy can be considered in patients with persistent local symptoms related to tumor or intravesical therapy side effects failing conservative management without the presence of invasive disease. This decision requires an active discussion between the physician and patient to balance the risks of surgical intervention with the impact of the symptoms on the patient's quality of life.

---

### Failure of Other Primary Forms of Intervention

---

Patients undergoing organ preservation strategies are at life-long risk of local recurrence. These patients require surveillance and management of recurrence with transurethral resection. While some recurrences can be managed with intravesical therapies, patients with high-grade noninvasive and invasive tumors should be considered for cystectomy. In most series of patients undergoing primary chemoradiation for bladder cancer, 30% to 40% require radical cystectomy for recurrence of disease or intractable local symptoms (6).

## OTHER OPERATIVE CONSIDERATIONS

### Elderly/Multiple Medical Comorbidities

While cystectomy is readily applied to younger populations, the elderly often have limited access to radical surgery and are counseled toward nonsurgical interventions. However, cystectomy is often the best treatment option for invasive bladder cancer in the elderly who are in reasonably good health (7). Invasive bladder cancer is not an indolent disease, and death from uncontrolled urothelial carcinoma is high in the first 3 to 4 years. Thus, for a healthy 75-year-old woman, the invasive bladder cancer is her biggest health risk. Furthermore, the risk of radiation therapy and chemotherapy is substantial, with the continued need for bladder surveillance and the potential need for subsequent cystectomy in patients who have continued to age with progression of their medical comorbidities and of their bladder cancer (6). Improved perioperative care allows cystectomy to be done with a low operative mortality, supporting an expedient cystectomy as the overall safest and most effective approach (8).

## Extent of Surgery

When proceeding to definitive surgical treatment in the female bladder cancer patient, the physician should consider the woman's age, sexual function, and childbearing status in conjunction with her clinical stage. For premenopausal patients with carcinoma in situ, early invasive disease (T1), or anterior low-volume T2 disease, radical cystectomy should be performed with intent to preserve the vagina, uterus, and ovaries, potentially preserving sexual and reproductive quality of life. In addition, we must consider the need to maintain body image for women by offering continent and orthotopic diversions. Table 16.1 outlines our paradigm for the extent of surgical intervention. Indications for urinary diversion are outlined in Section 7 of this text.

## ALTERNATIVE THERAPY

Alternatives to cystectomy include observation, systemic chemotherapy, radiation therapy, or a combination of chemotherapy and radiation along with aggressive transurethral resection of the tumor. These modalities have historically been

reserved for surgically ineligible patients, those refusing surgery, or the elderly. More recently newer chemoradiation regimens have been proposed, even for non-muscle-invasive tumors, in an effort to provide greater sexual and urinary quality of life in bladder cancer patients (9).

---

## PREOPERATIVE CARE

---

Optimization of preoperative nutritional status will reduce the risk of perioperative complications. Patients are encouraged to augment their diet with protein and caloric supplements if they have anorexia or significant unintended weight loss. Although some have abandoned bowel preparation in patients with diversions utilizing small intestine (10), the current authors still prefer formal bowel preparation prior to cystectomy. In the majority of patients, preparation consists of a clear liquid diet and either GoLytely (Braintree Laboratory, Braintree, MA) or Phospho-Soda (Fleet Corporation, Lynchburg, VA) solutions on the day prior to surgery. Wound prophylaxis is achieved in the perioperative period with a second-generation cephalosporin antibiotic administered over a 24-hour period.

---

## SURGICAL TECHNIQUE

---

### Anatomic Considerations

---

#### Female Continence

An understanding of the female continence mechanism in women is critical prior to creation of an orthotopic neobladder. There are two continence mechanisms in women (11). One is in the proximal urethra, which is innervated via the pelvic plexus that courses adjacent to the bladder neck and vagina. These nerves often are transected during a radical cystectomy. In the middle to lower third of the urethra there is an intermingling of smooth and striated muscle fibers called the rhabdosphincter muscle that is innervated via the pudendal nerves and appears to be the critical sphincter mechanism for continence in women. Because the rhabdosphincter is present in the middle to lower urethra, the entire bladder and bladder neck can be resected in a woman without compromising eventual continence. Complete resection of the bladder is necessary to minimize the transitional epithelium left in situ and thus reduce the risk of local tumor recurrence and also hypercontinence after orthotopic urinary diversion.

#### Female Sexual Function

A similar pelvic plexus supporting erectile function exists in both men and women. Anterior exenteration with removal of the urethra has been shown to result in clitoral devascularization with decreased sexual arousal. In addition, resection of the vagina is often associated with disruption of the autonomic neurovascular plexus, further compounding the impact on sexuality. Preservation of all or the lateral portions of the vaginal wall as well as the urethra can avoid injury to the pelvic plexus and may reduce the impact on sexual function (12).

---

## Anterior Exenteration

---

Access to the urethra and vagina is necessary during the anterior pelvic exenteration in women. A modified lithotomy position is used with Allen, Lloyd-Davies, or Yellofin stirrups. The vagina and perineum must be well prepared with an iodine or Betadine scrub. An infraumbilical vertical midline incision gives ideal exposure; however, patient habitus or a planned extended lymph node dissection may necessitate an extension of this incision another 2 to 3 cm superiorly. The urachal remnant provides a convenient handle for traction on the bladder (Fig. 16.1). The peritoneum is divided along the lateral umbilical ligaments (Fig. 16.2), and the round ligament is clipped and divided. A self-retaining retractor, such as the Bookwalter device, will maintain exposure. The fallopian tubes and ovaries are present and nonfunctional in this predominantly postmenopausal population and thus are ultimately removed with the uterus, cervix, and anterior vagina. The gonadal vessels and suspensory ligament are divided above the ovaries (Fig. 16.3). The ureters are mobilized with substantial peri-ureteral adventitia to preserve optimal blood supply and later divided at the bladder hiatus (Fig. 16.4). Ligation and division of the uterine and vaginal arteries branching from the hypogastric artery is usually required to accomplish this.

The lateral blood supply to the bladder and uterus is isolated as it courses from the internal iliac artery and vein. The endopelvic fascia and the perirectal "fat pad" are exposed with medial traction on the bladder and ureter. The index finger is used to bluntly develop a plane just medial to the well-defined superior vesical artery, aiming obliquely toward the perirectal tissue. This will isolate the superior vesical artery, which requires ligation. Several small associated arteries and veins are controlled with ligaclips or the Gyrus device (Gyrus ACMI, MA), thus dividing the lateral pedicle under direct vision (Fig. 16.5). Medial traction on the bladder with fingers above and below the pedicles enhances exposure.

**FIGURE 16.1** The urachal remnant provides a convenient handle for traction on the bladder through the case and is divided between Kelly clamps and ligated.

**FIGURE 16.2** The division of the peritoneum follows the course of the lateral umbilical ligament until the round ligament is identified, clipped, and divided.

**FIGURE 16.3** The fallopian tubes and ovaries, if present, are commonly removed with the uterus and bladder. The gonadal vessels, surrounded by the suspensory ligament, are divided and ligated cephalad to the ovary.

After division of the lateral pedicles on each side, the technique is modified depending on the type of extirpative procedure to be performed. In a classic anterior pelvic exenteration, the bladder, uterus, bilateral fallopian tubes and ovaries, anterior vaginal wall, and urethra are removed en bloc (Fig. 16.6).

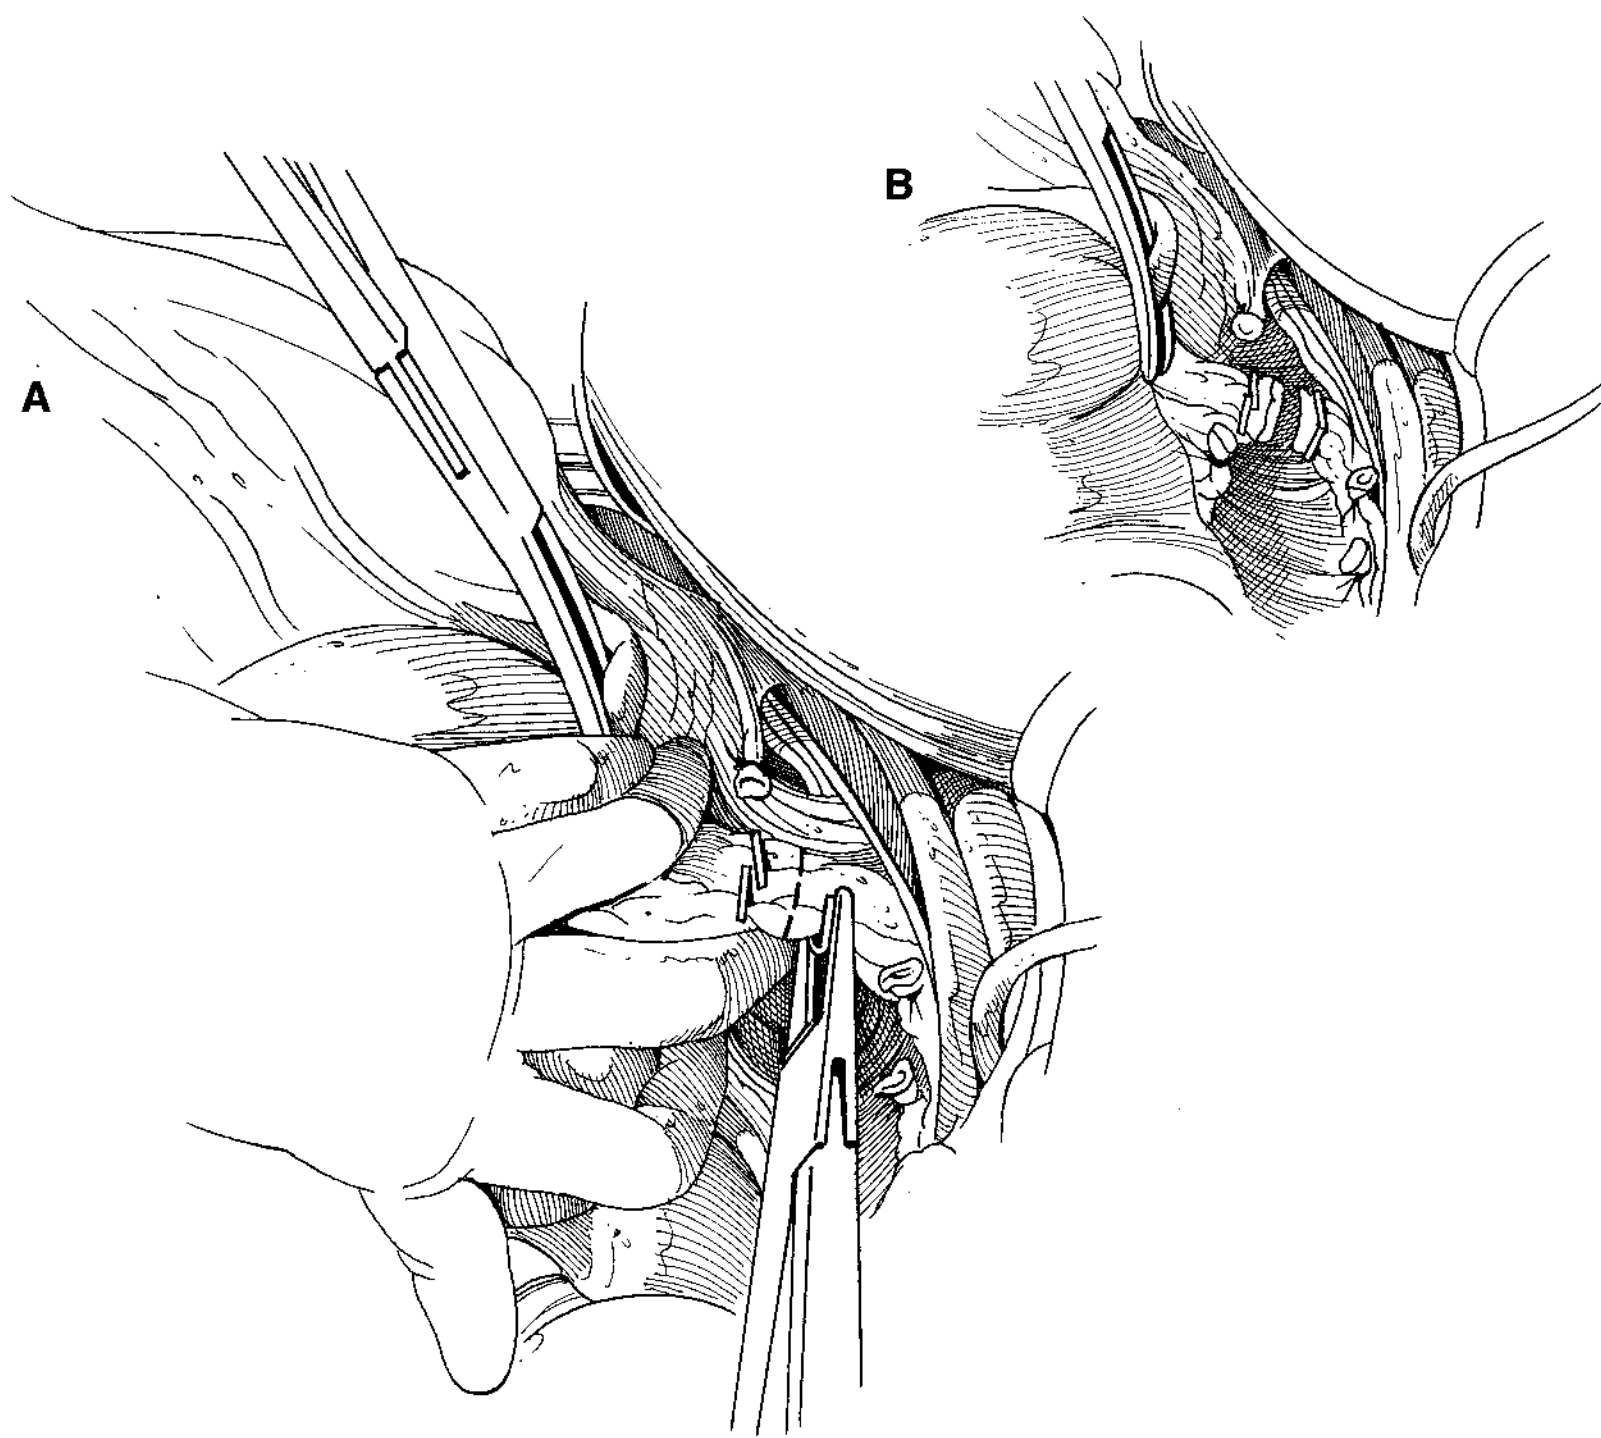

**FIGURE 16.4** Each ureter is mobilized with a large amount of peri-ureteral adventitial tissue to preserve optimal blood supply. The ureter is divided a short distance above the bladder.

This is warranted for a deeply invasive posterior bladder wall cancer. Alternatively, partial or complete preservation of the reproductive organs can be considered, especially if orthotopic urinary diversion is planned, as described below. To mobilize the anterior pelvic organs, an incision is made in the posterior peritoneum down to the rectovaginal cul-de-sac. Blunt and sharp dissection in the midline mobilizes the posterior vaginal wall; this mobility will allow the posterior vaginal wall to be rolled anteriorly away from the rectum for vaginal reconstruction.

A Betadine-soaked sponge stick is placed in the vagina, elevating the apex of the vagina just posterior to the cervix. Cautery is used to open the apex of the vagina in the midline; this incision is carried laterally down the anterior vaginal wall on each side (Fig. 16.6A–C). The Gyrus device is useful in this maneuver, greatly minimizing venous bleeding from the vaginal wall. Additional bleeders from the adjacent tissue may be controlled with 2-0 Vicryl suture ligatures. This dissection is continued to the bladder neck. If cutaneous diversion is planned, the endopelvic fascia and pubovesical attachments are sharply divided and the proximal urethra is mobilized. Depending on the tumor location, a portion of the proximal urethra can be sharply dissected off of the anterior vaginal wall, which is transected at the bladder neck, leaving a portion of the anterior vaginal wall intact within the pelvis. This preserves a greater portion of the vagina and allows for an easier vaginal reconstruction later. The dissection then moves to the perineum after reasonable hemostasis has been ensured in the pelvis.

## Urethrectomy

To perform the urethrectomy, the labia are retracted laterally with suture ligatures. Army-Navy or self-retaining retractors provide exposure to the urethral meatus. An inverted

**FIGURE 16.5** Division of the lateral pedicle is one of the more important technical aspects of the procedure. The endopelvic fascia should be well exposed with blunt dissection. A perirectal fat pad lying adjacent to the rectum defines the lower limit of the lateral pedicle coursing from the internal iliac vesical. Medial traction on the urachal remnant and retraction of the ureter medially allow an index finger to create a plane just medial to the origin of the superior vesical artery outlining the lateral pedicle. The caudad extent of blunt dissection is the perirectal fat tissue. **A:** The medial traction on the bladder with the surgeon's nondominant hand easily exposes the entire pedicle. **B:** The superior vesical artery is ligated, but the remainder of the small vessels can be controlled with clips on both sides.

U-shaped incision is made around the urethra (Fig. 16.7A), and the urethra is mobilized anteriorly and laterally. Returning to the pelvic approach, suture ligatures are placed in the venous plexus anterior to the urethra, analogous to control of the dorsal venous plexus in men. Further simultaneous antegrade dissection can help to direct the retrograde dissection from the perineum until there is a continuum from the pelvis to perineum. Ultimately, from the perineal approach, the anterior vaginal wall posterolateral to the urethra is divided to connect with the pelvic dissection, permitting removal of the entire specimen. Alternatively, a circumferential periurethral incision can be made, preserving a portion of the anterior vagina located posterior to the urethra (Fig. 16.7B and C). Subsequent simultaneous antegrade and retrograde dissection will allow complete urethral mobilization and excision, as noted above.

### Vaginal Reconstruction

The vagina is reconstructed by rotating the apex of the posterior vaginal wall anteriorly to create a foreshortened vagina that maintains the previous width (Fig. 16.8). A stay suture in the apex of the posterior vaginal wall brings the vaginal wall to the perineum, if a total anterior vaginectomy was required; this flap of vagina is sutured to the periurethral vaginal tissue anteriorly in the midline and then sequentially on each side. After two to three interrupted sutures are placed on each side from the perineum, additional sutures higher up on the vaginal wall are more easily placed from the pelvic exposure. A watertight closure provides optimal hemostasis of the paravaginal tissue.

If the tumor characteristics permitted partial anterior vaginectomy, and a portion of the anterior vaginal wall was preserved within the pelvis below the bladder neck, the posterior vaginal flap is apposed to this anterior stump within the pelvis (Fig. 16.8). The lateral walls are then closed sequentially from within the pelvis with running Vicryl suture. Using this approach, a circumferential urethral incision would have been used (Fig 16.7B), and the prevaginal tissues identified in the perineum would then be sutured to the retropubic tissues with running or interrupted Vicryl suture. A vaginal pack soaked in Betadine is left in the vagina for 24 hours.

### Reproductive Organ Preservation

In appropriately selected patients, all or part of the female reproductive tract can be preserved. Certainly, the age, child-bearing status, and sexual function of the patient must be considered when planning radical extirpative procedures (Table 16.1). If the disease is felt to be organ-confined and located favorably, it is reasonable in young women with child-bearing potential to spare the reproductive organs, since it is increasingly clear that most female organs are uninvolved by primary bladder cancer and that local recurrence is uncommon (4). When orthotopic diversion is planned in the sexually active postmenopausal woman with a tumor site away from the trigone or bladder neck, the anterior vagina should be preserved.

The surgical approach begins with a similar midline incision as described for anterior pelvic exenteration followed by the development of the extravesical space. The urachus is divided, and peritoneal flaps are developed on either side of the

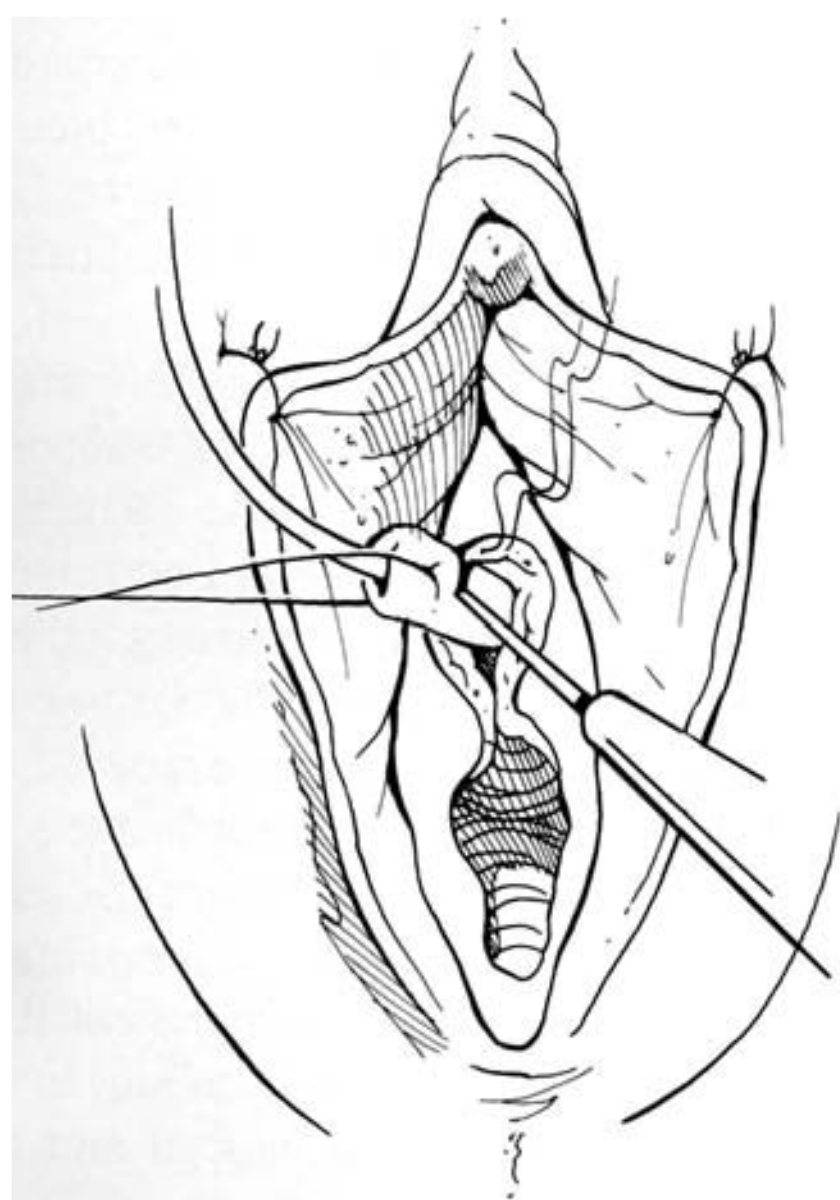

**FIGURE 16.6** The classic anterior pelvic exenteration includes removal of the bladder, uterus, bilateral fallopian tubes and ovaries, anterior vaginal wall, and urethra. **A and B:** An incision is made with cautery at the apex of the vagina. This is often facilitated with a Betadine-soaked sponge stick placed in the vagina on upward traction. The incision should be as close as possible to the posterior aspect of the cervix. **C:** The incision is then carried around laterally along the anterolateral aspect of the vagina. There is commonly a rich blood supply to the lateral aspect of the vagina, and this is most easily controlled with multiple suture ligatures in a stepwise fashion. The incision stops just before the endopelvic fascia. **D:** With this dissection, the entire anterior vaginal wall, posterior bladder wall, and urethra are removed en bloc.

A

B

C

**FIGURE 16.7** **A:** Attention is now turned to the perineum, where an inverted U-shaped incision is made around the urethral meatus and the anterior and lateral aspects of the urethra are mobilized. Dissection returns to the pelvic exposure, where suture ligatures are placed in the venous plexus anterior to the urethra, analogous to control of the dorsal venous complex in men. Incisions in the anterolateral vaginal wall are connected between the perineum and the pelvic dissection. The entire specimen can then be removed. **B and C:** Alternatively, a circumferential periurethral incision can be made preserving a portion of the anterior vagina located posterior to the urethra.

bladder. The round ligament is still-ligation, and the ureters are mobilized as described previously. A sponge stick is placed in the vagina to readily identify the vaginal apex and cervix and also to provide countertraction. The plane between the posterior bladder and anterior vaginal wall is developed (Fig. 16.9). This dissection must hug the anterior vaginal wall so as not to compromise the cancer surgery but also to avoid the troublesome bleeding that can be encountered when the dissection is in the wrong plane. An advantage of this approach is avoidance of the rich vascularity of the vagina, which is appreciated when the entire anterior vaginal wall is resected. During this dissection, care should be taken to avoid entry into the vagina, which could increase the risk of fistula

formation when orthotopic diversion is planned. In this circumstance, an omental flap can be used to cover any significant vaginal reconstruction.

If appropriate, the uterus, fallopian tubes, and ovaries should be left in situ. This is an optimal choice for the sexually active female with low-volume or early-stage disease who has concerns about future fertility. If hysterectomy is required after vaginal-sparing surgery, a sharp incision is created at the vaginal apex and carried circumferentially around the cervix, preserving as much vaginal tissue as is feasible. The vaginal cuff is closed using 3-0 Vicryl in a continuous fashion, followed by an additional layer of 2-0 Vicryl interrupted Lembert sutures.

**FIGURE 16.8** Several methods of closure of the vagina are feasible. One that appears to supply strong support of the pelvis uses the posterior vaginal wall as a flap to create a neovagina. This foreshortens the vagina but does not narrow it as a side-to-side closure does and thus provides for a better return of sexual function, if appropriate. A suture is placed in the apex of the posterior vaginal wall from above; this is used to bring the posterior flap of the vagina down to the perineum. Several sutures are placed from below, incorporating a full thickness of the periurethral vaginal tissue to the posterior vaginal wall flap. Sutures closer to the apex of the vagina are more easily placed from the pelvic exposure.

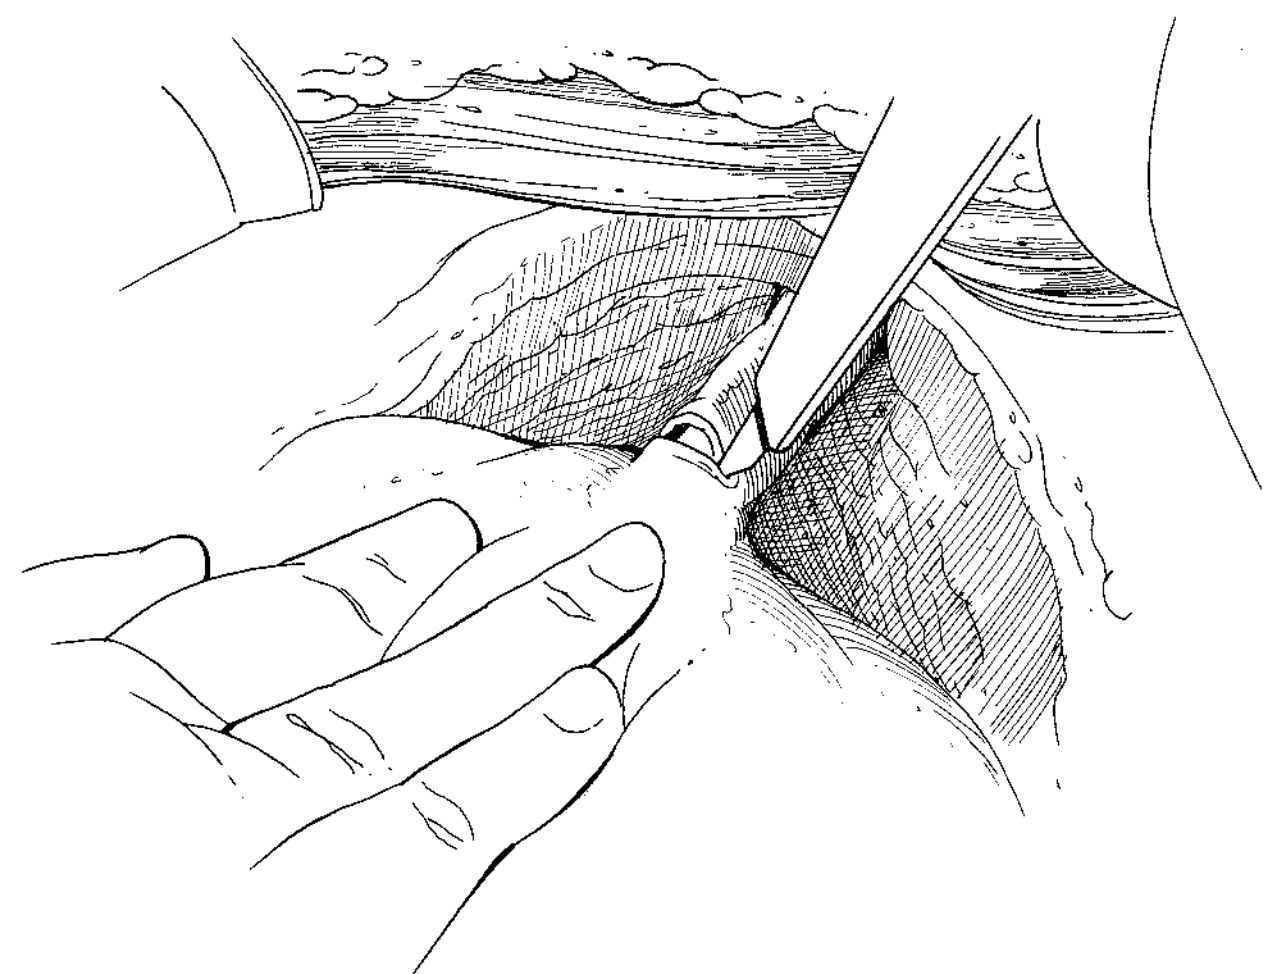

### Retrograde Dissection and Urethral-Sparing Technique

In planning for orthotopic diversion, modifications in the technique of pelvic exenteration are necessary when approaching the bladder neck and urethra. It is important to maintain the integrity of the endopelvic fascia and thus preserve the support of the external sphincter. Dissection of the lateral wall of the vagina should also be avoided to prevent injury to the neurogenic innervation of the rhabdoid sphincter. Lastly, the bladder neck must be removed entirely to minimize postoperative urinary retention.

Once the bladder has been mobilized off the vagina down to the bladder neck, fine sutures are used anteriorly in the periurethral tissue as necessary for hemostasis of the venous plexus. The urethra is amputated sharply at the junction with the bladder neck, avoiding distal mobilization or dissection of the urethra (Fig. 16.10). After the bladder has been removed, a sample of the urethra is circumferentially excised from the specimen or the urethral stump (if necessary) and sent for frozen section to ensure a negative urethral margin. Exposure is often ideal for the enterourethral anastomosis. The authors

**FIGURE 16.9** When partial or complete female pelvic organ preservation is planned with or without orthotopic urinary diversion, a plane is created sharply between the posterior bladder wall and anterior vagina. Care should be taken to avoid entry into the vagina as this increases the risk of fistula formation. Vaginotomies should be closed. (from Lee CT, Montie. Orthotopic bladder replacement in women. In: JE Kreder KJ, Stone AR eds. Urinary Diversion, 2nd edition. Oxfordshire, UK: Taylor and Francis, 2005: 190, with permission).

**FIGURE 16.10** In the situation in which an orthotopic diversion is planned, neither the endopelvic fascia nor the anterior venous plexus is disturbed. An incision is made in the anterior urethra just distal to the junction with the bladder neck. The urethra is divided completely, and the dissection of the bladder off the anterior vaginal wall can be done in either an antegrade or retrograde fashion.

prefer six to eight fine absorbable sutures using 2-0 to 3-0 Monocryl, taking small bites on the urethra. Mobility of the intestinal reservoir to the urethra is generally not a problem in women, although it can be in men.

In the initial experience with orthotopic diversion, the concern for stress incontinence was such that anterior urethral fixation sutures were placed to prevent hypermobility of the

urethra. This maneuver is not only unnecessary (unless documented stress incontinence from hypermobility is evident preoperatively) but is also counterproductive by contributing to increased urinary retention or “hypercontinence.” A possible additional mechanism for postoperative urinary retention may be exacerbation of a pre-existing but previously insignificant cystocele. After the cystectomy, the urethra is fixed anteriorly and the patient voids by Valsalva maneuver after relaxing the external sphincter. If a cystocele is present, the increased abdominal pressure needed for voiding across the fixed urethra and bladder neck could be blunted by the cystocele.

---

## Postoperative Care

---

Establishment of a critical care pathway is useful for cystectomy patients (8). Compliance with the ideal postoperative course is difficult after cystectomy because of a high frequency of comorbid disease and complications, which may delay discharge even if they are not life-threatening. Epidural analgesia, patient-controlled analgesia, and nonsteroidal anti-inflammatory agents are useful adjuncts to provide better postoperative pain control, which translates into better pulmonary hygiene, ambulation, and return of bowel function. The authors no longer routinely utilize nasogastric decompression postoperatively, though it can be helpful intraoperatively. Overall, excellent pain control, judicious use of diuretics to combat fluid retention, and aggressive pulmonary toilet are important strategies to prevent complications. Early ambulation, intermittent compression stockings, and 5000 U of subcutaneous heparin sulfate are currently used for deep venous thrombosis prophylaxis. Routine perioperative parenteral nutrition is not necessary in the well-nourished patient; however, the clinician should consider this therapy in the early postoperative period for nutritionally debilitated patients or those likely to have prolonged ileus. In our experience, approximately 10% to 20% of patients need postoperative nutritional support.

---

## OUTCOMES

---

From July 1995 through January 2008, we have performed 1,058 cystectomies; 240 (23%) patients were women. The median age in women was 70 years old. For us, age has not been a deterrent to providing definitive treatment in a patient with a reasonable life expectancy. This is reflected by the fact that 40% of patients undergoing cystectomy at our institution are

over 70 years of age, including 8% of patients over 80 years. In addition, 35% of our patients are obese (body mass index  $>30$  kg per  $m^2$ ), and 38% of patients have an American Society of Anesthesiologists class of 3 or higher, suggesting greater operative risk. Adding to the patient complexity are the 30% of patients receiving neoadjuvant systemic chemotherapy (most frequently consisting of gemcitabine, carboplatin, and paclitaxel), which impacts nutritional status prior to surgical intervention.

Our median operative time was 6 hours for women, which is comparable to the operative time for men; this time included anesthetic induction and reversal. Our median length of stay for women undergoing cystectomy is 8 days, reflecting our willingness to offer cystectomy to an often medically complex group of patients. Urinary diversion consisted of 57% ileal conduit, 40% orthotopic neobladder, and 3% cutaneous continent diversion, reflecting our growing use of orthotopic diversion in women.

---

## COMPLICATIONS

---

Cystectomy remains a difficult operation in men or women, with a mortality rate of 2% to 3%. Twenty percent to 30% of patients will have a complication delaying discharge. Many of the specific complications after cystectomy are a consequence of the urinary diversion. Complications from the cystectomy portion include bleeding with subsequent coagulation abnormalities and rectal injury. Pelvic bleeding can be more difficult to control in women. Since 1995, the median blood loss in women has been 1,011 cc. A rectal injury should be extremely rare in women and seen only in association with prior surgery or radiation therapy. The most frequent complications experienced in our female cystectomy series were prolonged ileus in 15% of patients, anemia in 9%, incisional complications in 5%, and dehydration or failure to thrive in 5%. Thirty-day mortality was under 1%.

The postoperative care after cystectomy requires a diligence over and above that seen with other urologic procedures. Some complications are preventable. A regimented, reproducible plan for the technique of cystectomy and diversion is enormously helpful to prevent errors during a 4- to 6-hour operation. Some complications are unavoidable, but recognition early in their evolution may drastically minimize the negative consequences, and a high index of suspicion is essential. Early recognition of a complication may prevent a cascade of other successive complications that may ultimately lead to increased morbidity or mortality.

## CHAPTER 17 ■ BLADDER DIVERTICULECTOMY

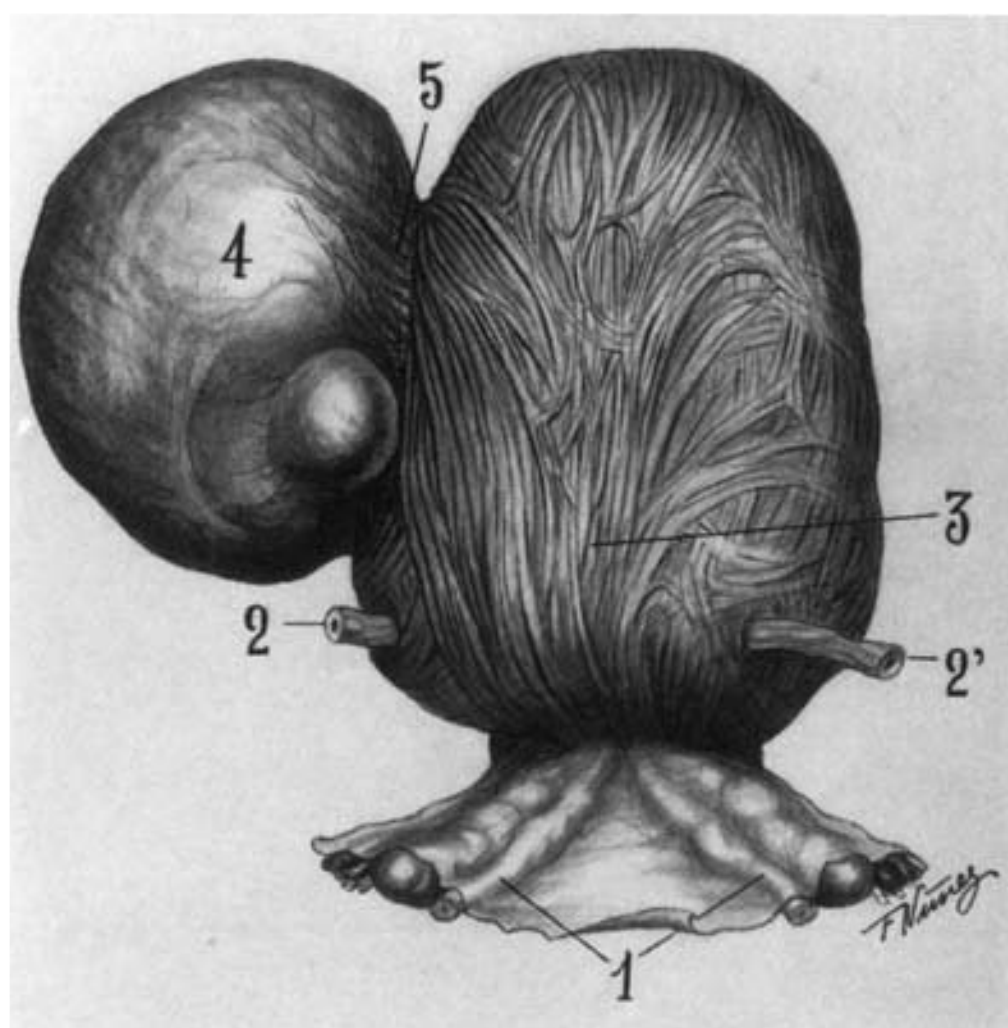

MICHAEL S. COOKSON AND SAM S. CHANG

A bladder diverticulum is the protrusion or herniation of the bladder mucosa through the detrusor muscle fibers as a result of a structural defect in the bladder or as a secondary change due to chronic dysfunctional voiding (8). The wall of the diverticulum is composed of the following layers from inside out: mucosa, subepithelial connective tissue or lamina propria, isolated and thin muscle fibers, and adventitial tissue (Figs. 17.1 and 17.2) (7). Diverticula may be congenital or acquired, the latter developing secondary to increased intravesical pressure (5,8). The most frequent causes of increased bladder voiding pressure and the eventual formation of an acquired diverticulum are benign prostatic hyperplasia, urethral strictures, contracture of the bladder neck or urethral valves, and neurogenic voiding dysfunction, such as detrusor–sphincteric dyssynergy. The diverticula are located in the weakest points of the bladder, such as the ureteral

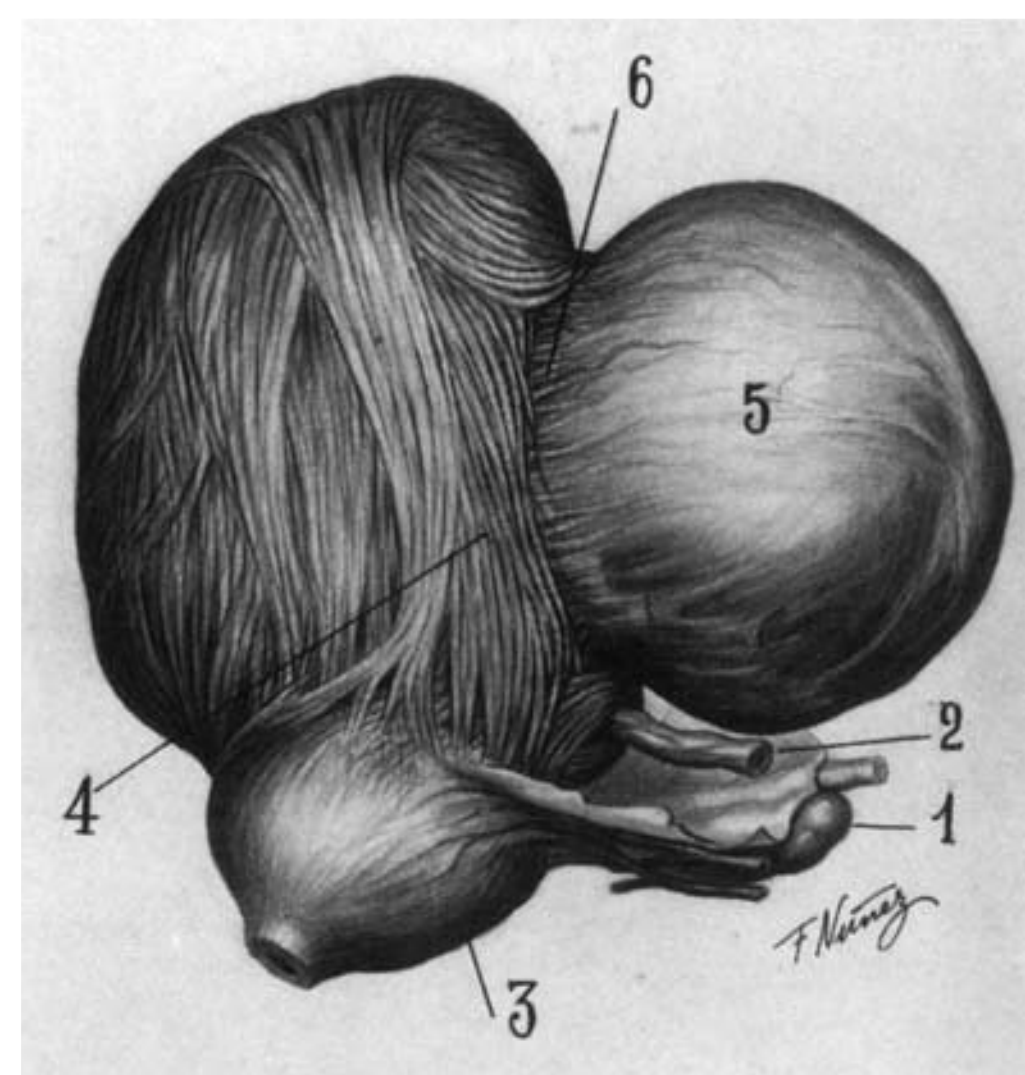

hiatus (paraureteral or Hutch diverticulum) and both posterolateral walls (2,3,5,8).

### DIAGNOSIS

Congenital diverticula are more common in men than in women, and while they may be discovered incidentally in adulthood, the peak incidence is <10 years of age (2,8). In contrast, acquired diverticula have a peak incidence of >60 years of age and are almost exclusively found in men (5). Acquired bladder diverticula are commonly asymptomatic, although irritative and/or obstructive voiding symptoms, pelvic pain, and hematuria may arise from complications thereof, including infection, stones, obstruction, and tumor.

**FIGURE 17.1** Posterior view of bladder and diverticulum: ampulla of vas deferens (1); ureters (2 and 2'); posterior longitudinal bundle of the outer layer of the detrusor (3); diverticulum (4); circular fibers of the middle layer of the detrusor around the diverticular neck (5).

**FIGURE 17.2** Lateral view of bladder and diverticulum: seminal vesical (1); ureter (2); prostate (3); anterolateral longitudinal fibers of the outer layer of the detrusor (4); diverticulum (5); fine, circularly oriented fibers around the diverticular neck (6).

A

B

**FIGURE 17.3** Contrast-enhanced computerized tomography scan demonstrating a large posteriorly based bladder diverticulum seen on (A) transverse and (B) sagittal images.

Given the nonspecific nature of the presenting symptoms, diverticula are most commonly diagnosed by radiographic imaging, including ultrasound, intravenous pyelogram (IVP), voiding cystourethrogram (VCUG), and contrast-enhanced computerized tomography (CT scan) (Fig. 17.3). Diverticula are also found on ultrasound of an empty and full bladder performed for the study of bladder outlet obstructive symptoms in men or repeated urinary infections in women. Cystograms obtained by IVP or through retrograde instillation of contrast medium may provide information with regard to the number, location, size, and urinary retention volume of the diverticulum. However, a VCUG with lateral, oblique, and postvoid images is important in defining the extent of the diverticulum and of particular use in congenital cases to rule out possible vesicoureteral reflux

(2,8). A video urodynamics study can provide not only important anatomic information but also information regarding bladder function and voiding pressure, which may be of special interest in cases where neurogenic voiding dysfunction is suspected (8).

Cystourethroscopy should be performed to exclude urethral stricture disease and/or bladder neck contractures but is most important to rule out occult pathology such as a stone or carcinoma within the diverticulum (1). The entire surface of the diverticulum should be visualized, and the relative location of the ureteral orifices should be noted to assist in planning for any potential surgical procedure. The differential diagnosis includes “pseudodiverticular” images observed in cystograms such as bladder ears, hourglass bladder, and vesical hernias. Other diagnoses include urachal cysts, prostatic utricle cysts, or müllerian duct cysts and blind-ending bifid ureters. Other less frequent congenital anomalies should also be considered, such as vesicourachal diverticulum, incomplete bladder duplication, and septation of the bladder (2).

## INDICATIONS FOR SURGERY

Patients who have poor bladder emptying after relief of obstruction or who are unable or unwilling to undergo surgical treatment of the bladder diverticulum may be effectively treated with clean intermittent catheterization (CIC) or an indwelling catheter (8). In such patients, and in the absence of future complicating factors, surveillance of the bladder diverticulum and monitoring of the upper tracts, including renal function, may be all that is required. Importantly, long-term CIC and periodic renal ultrasound may be a viable option in these patients.

In general, the indications for surgical intervention include chronic infections, stones, and premalignant changes such as dysplasia or carcinoma in situ and frank carcinoma (8). A large diverticulum may be the cause of deficient voiding and chronic urinary infection or obstruction of the ureter and even of the posterior urethra in children, whereas a paraureteral or hiatal diverticulum is usually associated with different degrees of reflux (4,5). In addition, spontaneous diverticular rupture or complications related to the size or location of the diverticulum are indications for surgery. With the aim of improving functional voiding, we recommend the simultaneous resection of all poorly emptying bladder diverticula if the patient must undergo open prostatectomy, cystolithotomy, ureteroneocystostomy, or YV-plasty of the bladder neck. Similarly, a vesical diverticulum should never be operated on without previously or simultaneously correcting the cause, whether anatomic or functional (neurogenic bladder), of the outlet obstruction that provoked it.

Although occurring in a small subset of these patients (0.8% to 10%), urothelial carcinoma can develop within bladder diverticula at a mean age of 65 years (range, 45 to 80) (1). Approximately 75% to 80% of these tumors are urothelial carcinoma, while 20% to 25% are squamous cell carcinomas likely induced from chronic stasis of urine and infection. Because of this potential malignant risk and the fact that these tumors can be difficult to diagnose, some have advocated prophylactic diverticulectomy. Alternatively, a more conservative strategy may be offered that should include surveillance cystoscopy and urinary cytology obtained at 6- to 12-month intervals.

---

## ALTERNATIVE THERAPY

---

Many children with congenital diverticula who are asymptomatic do not require therapy, and a conservative approach has been advocated (2). Saccules and small diverticula may be treated successfully by electrocoagulation of their mucosa when the primary obstructive disease is endoscopically resolved. In addition, laparoscopic approaches to bladder diverticulum may be effective as an alternative to open surgery with the distinct advantage of shortened convalescence time (6).

---

## PREOPERATIVE ASSESSMENT

---

Aside from the laparoscopic approach, there are essentially two methods of surgical therapy: (a) transurethral resection of the diverticular neck and (b) open diverticulectomy. In either case, infection must be adequately treated prior to surgery. If the lesion is acquired due to obstruction, the obstruction must be relieved prior to repair of the diverticula to prevent recurrence and subsequent treatment failure (9). If the diverticulum is due to high detrusor pressure of neurological origin, this must also be addressed prior to surgical correction.

---

## SURGICAL TECHNIQUE

---

### Transurethral Resection

---

Endoscopic management may be important in the management of elderly patients, those that are not good open surgical candidates, or those with a smaller diverticulum that can be addressed at the time of a transurethral resection of the prostate (8). Transurethral resection of the neck of small to midsized diverticula in situations where the opening is not immediately impinging on the ureter is a well-recognized treatment (10). If the opening is small, a Collins knife or right-angle hooked electrode can be used to open the ostium of the diverticulum to allow for subsequent inspection of the entire diverticular wall and facilitate drainage. Transurethral resection or fulguration of the mucosa with a rollerball electrode can then be used to ablate the mucosa of the inner wall.

In the case of tumor within a bladder diverticulum, caution must be exercised. Because there is no muscular backing, transurethral resection of bladder tumors within diverticula carries a high risk of perforation. Cold-cup biopsy and fulguration may be appropriate for low-grade, low-stage tumors. The holmium laser may also be of use in this unique situation because it has a small fiber and a shallow depth of penetration (only 0.3 to 0.5 mm) and would certainly lower the risk of perforation or injury to adjacent structures. In those patients with high-grade or large diverticular carcinomas, in particular those with narrow openings in which the risk of endoscopic perforation or inadequate resection is high, open diverticulectomy/partial cystectomy or total cystectomy has been advocated.

---

### Open Surgical Technique

---

A Foley catheter is placed in the bladder on the surgically prepared field to allow for passive drainage and active filling of

the bladder as needed throughout the procedure. The bladder is approached via an infraumbilical midline extraperitoneal incision, although alternatively a Gibson incision may be used. The linea of the rectus fascia is divided in the midline, along with the transversalis fascia, and the pelvis is exposed. In the case of benign bladder pathology, the dissection is carried into the space of Retzius and the anterior bladder wall and vesical neck are identified. After reflecting the peritoneum cephalad off the bladder dome, a transverse cystotomy is performed at this level. This provides better exposure of bladder contents and facilitates placement of a small self-retaining retractor and additional stay sutures. The trigone, ureteral orifices, bladder neck, and all possible diverticular orifices are clearly visualized from the bladder dome opening.

In cases of intradiverticular tumor, some have advocated the instillation of 40 mg of mitomycin C by urethral catheter before the surgery. Intraoperatively, we carefully protect the surgical field with moist, sterile towels draped around the wound to avoid possible tumor contamination during diverticulectomy. The bladder mucosa should also be thoroughly inspected to rule out papillary tumors that may have gone unnoticed on the previous endoscopic examination. The mouth of the diverticulum can also be packed with a small gauze pad to avoid or minimize potential tumor spillage.

Diverticulum excision has been described in three different approaches: extravesical; intravesical, also known as transvesical; and the intravesical and extravesical combination. The most commonly used procedures and the points of technique that we use are the following.

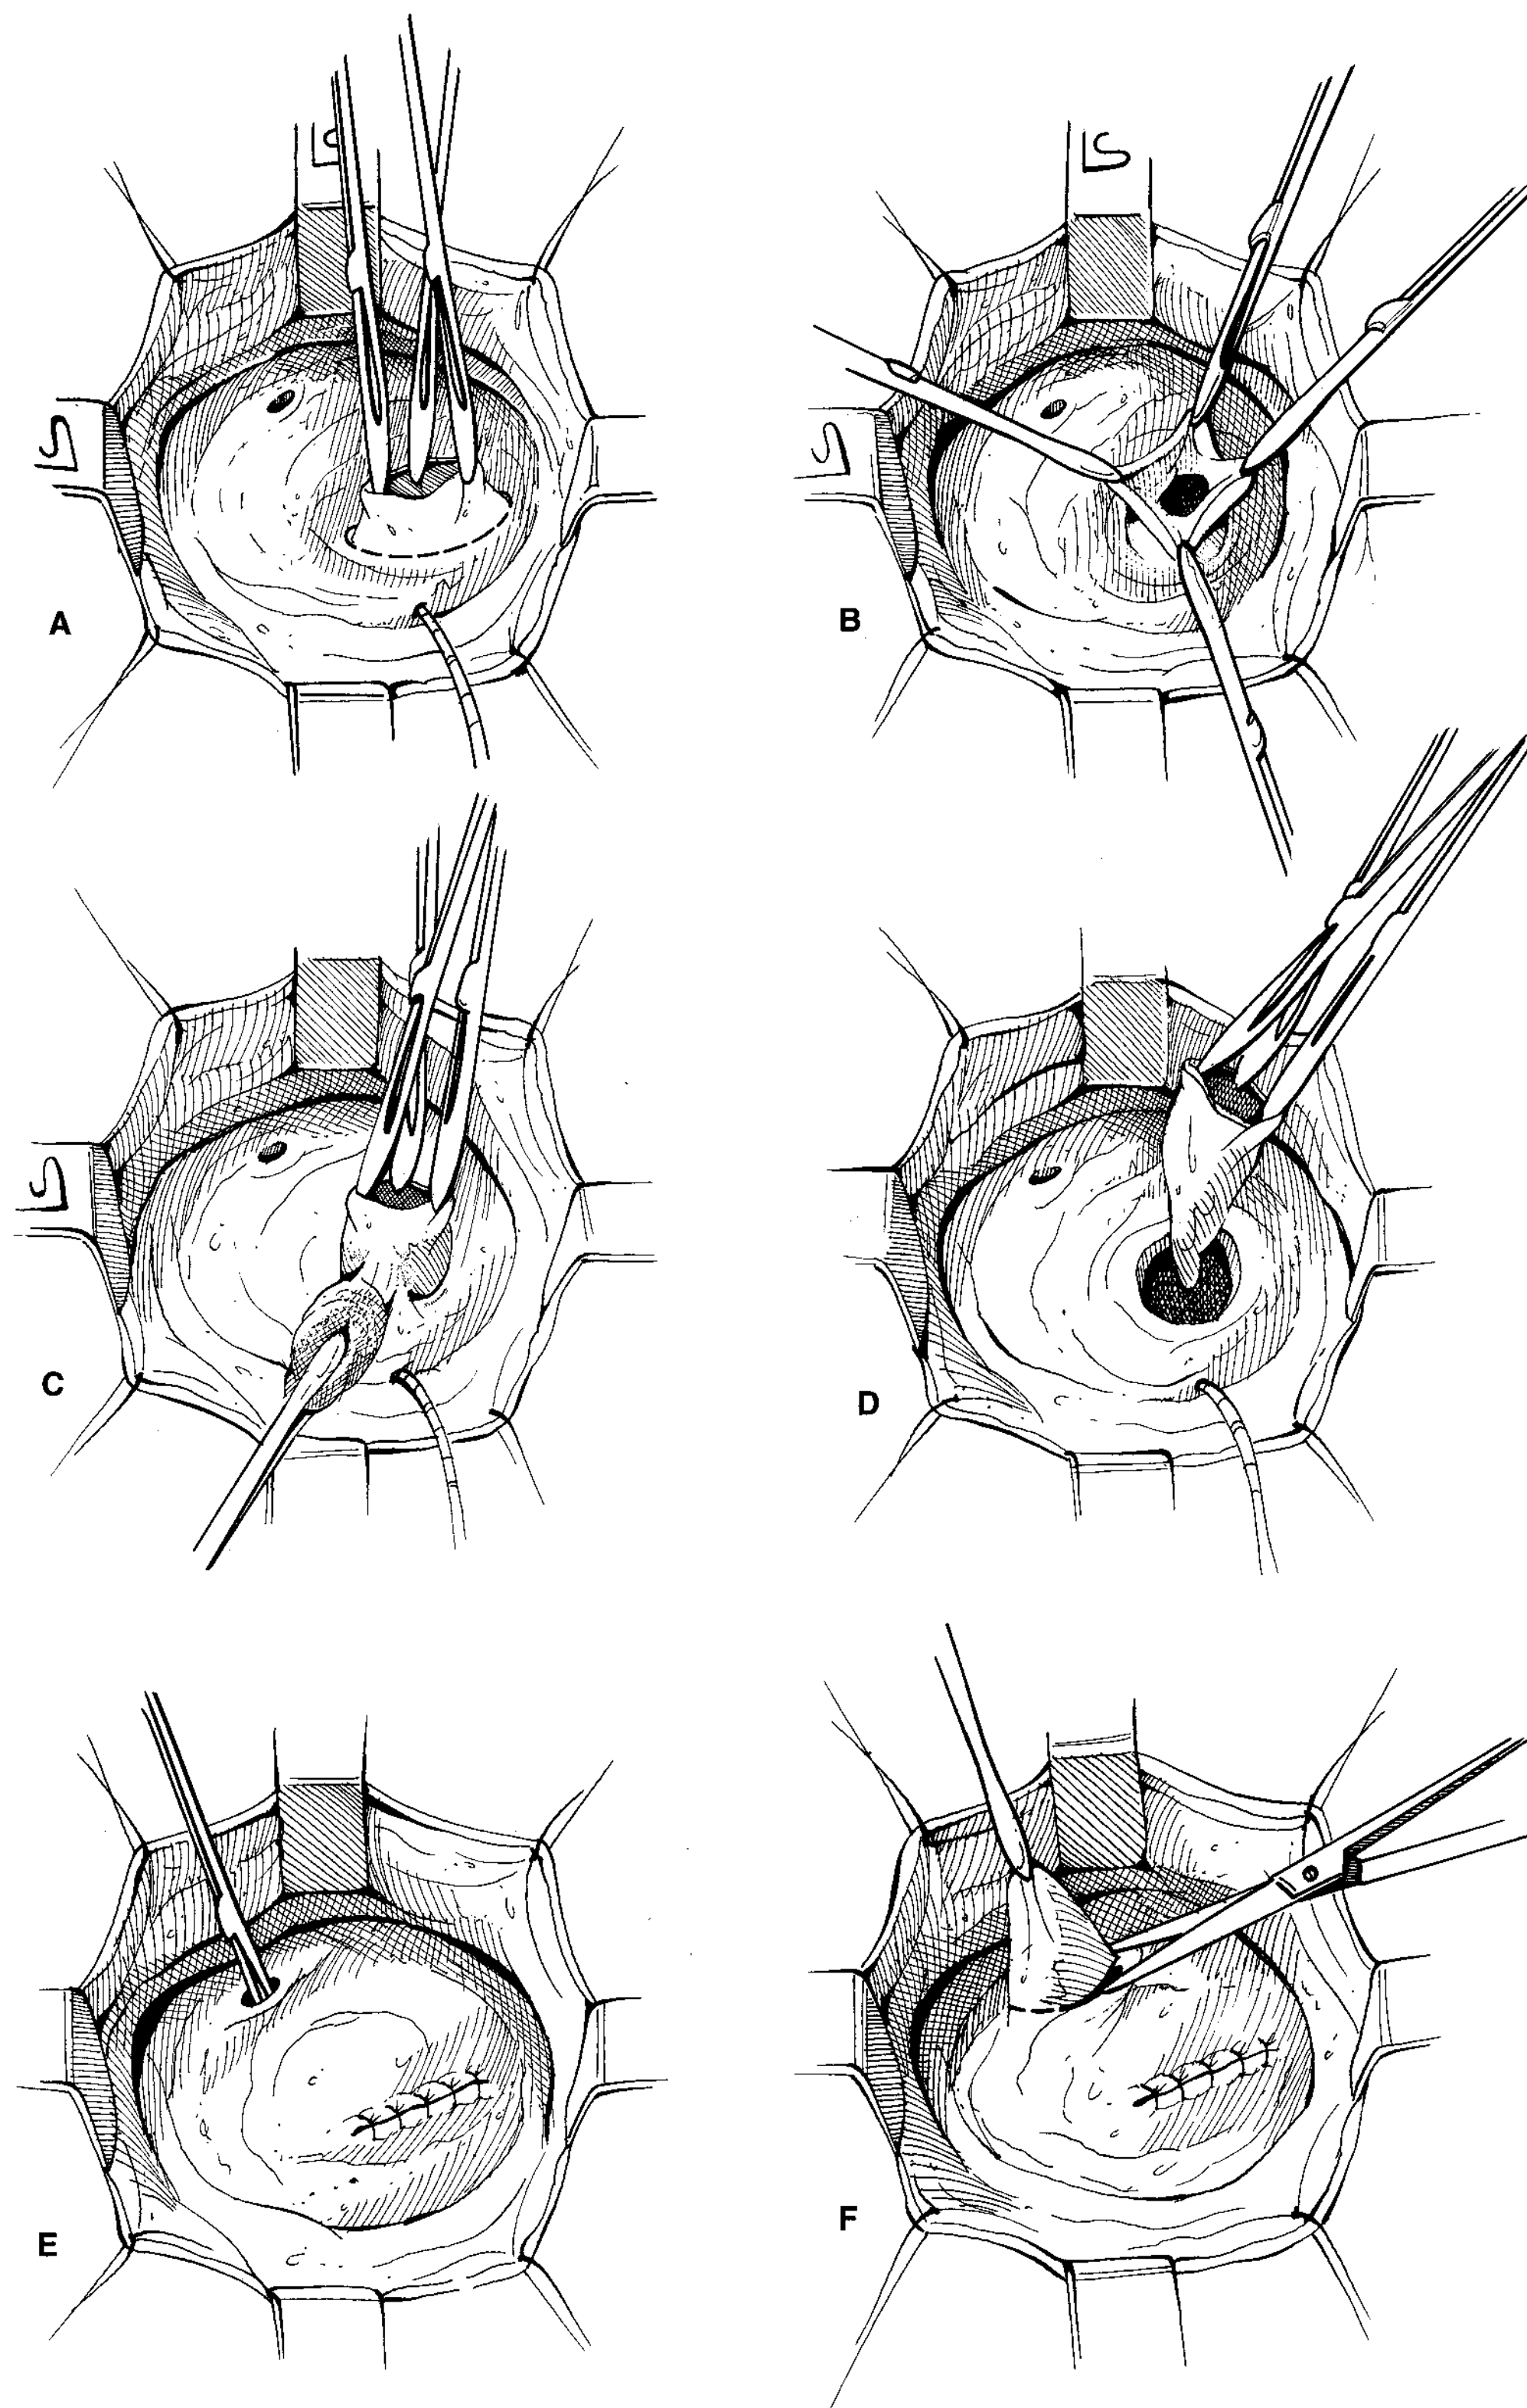

### Intravesical or Transvesical Diverticulectomy

If the diverticulum is small (<2.5 cm diameter), we perform intravesicalization and eversion of its wall, grasping and tractioning its bottom gently with an Allis- or Péan-type clamp inserted through its neck. If this maneuver is performed carefully and fibrosis secondary to infection is absent, the majority of these diverticula are rapidly and easily removed. The mucosa of the everted diverticular neck is divided using electrocautery, and the defect of the bladder wall is sutured with 3-0 chromic catgut or Vicryl using separate submucosal and muscular sutures in two separate layers. In case of a sacculum, a fine ligature of the neck and resection of its everted mucosa will suffice.

If this maneuver is not feasible because of peridiverticular adhesions, we proceed to sharply split the mucosa around the diverticular orifice and dissect with scissors as far as the periadventitial space. In this way, the diverticular neck remains separated from the bladder wall and is pulled toward the vesical cavity with Allis-type clamps. At the same time, the adventitial adhesions that fix the diverticular sac are freed gently with a small moist gauze and the sac is drawn into the bladder. The bladder wall is then closed as mentioned previously (Fig. 17.4).

### Combined Intravesical and Extravesical Diverticulectomy

In a large diverticulum complicated with peridiverticulitis or in a paraureteral location, it is obligatory to place a 7Fr or 8Fr catheter into the ipsilateral ureter before dissection. This will allow for easy identification of the ureter and hopefully avoid inadvertent ureteral injury. If the dissection is extensive, a double-J ureteral catheter remains indwelling for a short

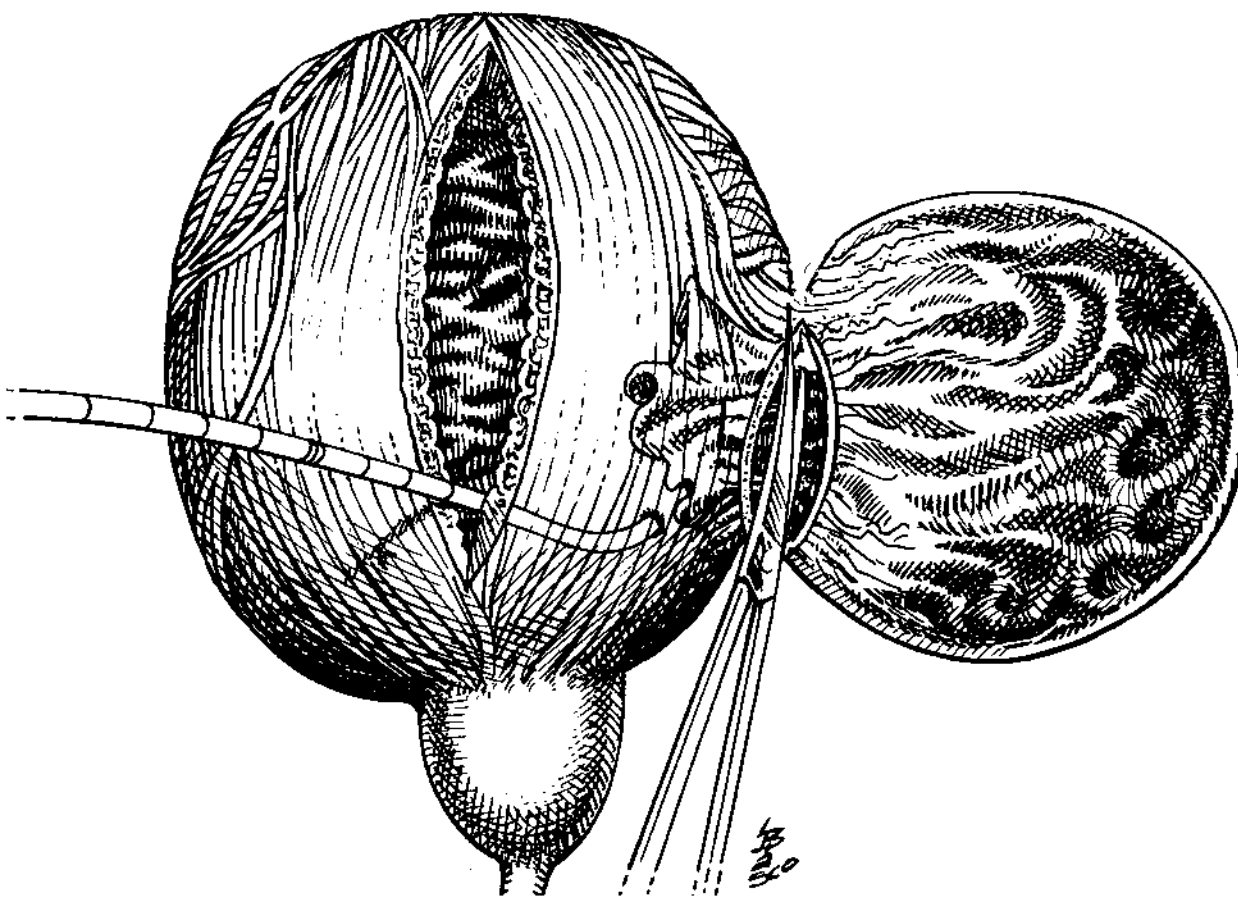

**FIGURE 17.4** Technique of intravesical diverticulectomy.

period of time (usually 2 to 3 weeks). These diverticula must be excised by a combined intra- and extravesical approach, first identifying and dissecting the diverticular neck. For this, the maneuver of inserting the surgeon's index finger into the diverticulum and gently tractioning the upper face of its neck

toward the surface is useful. We also recommend completely filling the diverticular sac with a moist gauze to unfold its wall and delimit its margins as accurately as possible. Dissection must begin at the diverticular neck, which is incised extravesically with electrocautery and separated from the bladder wall,

**FIGURE 17.5** Procedure of combined intravesical–extravesical diverticulectomy. A finger is inserted into the bladder diverticulum from within the bladder.

**FIGURE 17.6** Procedure of combined intravesical–extravesical diverticulectomy. Once the diverticulum has been dissected, the mouth of the diverticulum is excised sharply.

whose orifice is sutured with 3-0 chromic catgut using extramucosal separate stitches (Figs. 17.5 and 17.6).

Tractioning the edges of the diverticular mouth toward the surface with Allis-type clamps allows the sac wall to be dissected from neighboring tissue with scissors and a small moist swab. It should always be borne in mind that the ureteral course may have been modified by the great diverticular volume, and the ureter may be closely adhered to its wall if repeated infectious processes have occurred. This dissection will be difficult if extensive peridiverticulitis is present, and it is more advisable simply to denude it of its mucosal lining with fine scissors or with the cutting current and the ball electrode from inside the diverticular cavity and then place a

suction drain within it (first described by Pousson in 1901 and Geraghty in 1922). The bladder wall is closed with absorbable 3-0 interrupted or continuous absorbable sutures, and a two-layer closure is preferable when possible. We leave a 10Fr closed suction drain in the space of Retzius and a urethral 18Fr or 20Fr Foley catheter, which may both be removed after 5 or 6 days. For more extensive cases, those requiring large cystotomies, or in situations where there is prolonged drain output, a Foley catheter may be left in place for 10 to 14 days and a cystogram may be indicated prior to catheter removal.

---

## OUTCOMES

---

### Complications

---

The most serious specific complication of excision of a bladder diverticulum is an injury to the intramural or pelvic ureter during dissection of a large diverticulum. With prior placement of an ipsilateral ureteral catheter, this injury should be avoidable or at least recognizable and promptly repaired. A small ureterotomy can be easily sutured with absorbable 5-0 or 6-0 chromic or Vicryl. If the ureter has been severely damaged or its section is complete and near the vesical hiatus, the distal ureter must be abandoned, and it is preferable to carry out ureteral reimplantation following the technique of Leadbetter–Politano with or without vesical mobilization to the psoas muscle (“psoas hitch”). More extensive injuries to the ureter may require a bladder tube (Boari flap) or a transureteroureterostomy. End-to-end suture of ureteral edges must never be performed in precarious conditions because it is highly likely that it will be complicated by urinary fistula or ureteral stenosis, which will further aggravate the situation.

Other complications include urinary fistula, rectal injury, and pelvic abscess. Less serious complications include vesical urine leakage, which may cease spontaneously if the Foley catheter is maintained for additional days, providing the obstructive pathology has been resolved.

---

## Results

---

With transurethral resection, approximately one-third of these lesions are cured or significantly improved. For benign disease, an open excision of the diverticulum is in general curative for that particular lesion, although correction of the underlying cause (e.g., outlet obstruction) is required to prevent formation of additional diverticula or recurrence. In cases of diverticula involving carcinoma, the prognosis has in general been poor and attributed to the difficult and often delayed diagnosis with early escape from the confines of the bladder through the thin mucosal backing. However, more contemporary reports suggest relatively high rates of survival (about 70% 5-year survival), attributed in part to earlier detection through improved radiographic imaging and a lower threshold for cystoscopy in the presence of hematuria, coupled with early aggressive surgical treatment (1). Nevertheless, due to the relative paucity of cases, treatment recommendations for these unique situations will continue to be based largely on patient characteristics and surgeon preferences.

# CHAPTER 18 ■ BLADDER AUGMENTATION

ANNE PELLETIER CAMERON, R. DUANE CESPEDES, AND EDWARD J. MCGUIRE

Bladder augmentation, also referred to as augmentation cystoplasty or enterocystoplasty, is the addition of tissue to the bladder to increase its capacity. The goal of this procedure is to create a large capacity and compliant bladder to achieve continence, decrease detrusor overactivity, and protect the renal units from vesicoureteric reflux and high storage pressures. The most common indication for bladder augmentation is the neurogenic bladder that has failed conservative therapy. The majority of neurogenic bladder disorders can be managed with medical therapy, but a significant minority will require augmentation cystoplasty. In the past, these patients would have been treated with an incontinent urinary diversion such as an ileal conduit. With the advent of clean intermittent catheterization (CIC) and decreased morbidity of the procedure, augmentation has almost replaced incontinent diversion as bladder management for this typically young population, resulting in great improvements in patient quality of life. Patients with incontinent diversions like ileal conduits more frequently develop urinary infections and upper-tract deterioration compared to those with a large, low-pressure reservoir employing the urethra as a continence method (1).

Most urologists are familiar with the use of ileum and prefer to use this segment for bladder reconstructions. It must be noted that each bowel segment has its own advantages and disadvantages, but none is universally superior (2).

The ileum, 25 cm from the ileocecal valve, when detubularized for augmentation, ensures low pressures, produces only a moderate amount of mucus, and results in the least metabolic disturbances of all the bowel segments. The sigmoid is low pressure if detubularized, is thicker than ileum allowing reimplantation of ureters, has a large lumen and a long mesentery, but has more mucus production and a greater risk of subsequent urinary infections.

The cecum is typically only used in conjunction with the terminal ileum. The ileocecal valve can be used as an antireflux mechanism for ureter reimplantation; however, the resulting diarrhea and malabsorption become problematic in the

neurogenic population, who often only maintain fecal continence with purposeful constipation. We avoid this segment if at all possible. The stomach is used only in the event that both the small and large bowel are not suitable for augmentation. It has a thick wall and produces little mucus, but most urologists are not familiar with its mobilization, and, although the hydrochloric acid production is bactericidal, the associated hematuria-dysuria syndrome can be troublesome. The segment chosen should be based on the patient's past medical and surgical history, findings during the procedure, and the surgeon's experience (2,3).

---

## INDICATIONS FOR SURGERY

---

Bladder augmentation is indicated for the following:

1. Severe medically refractory neurogenic detrusor overactivity. This is most commonly due to spinal cord injury or spina bifida.
2. Poorly compliant bladder from neuropathic conditions secondary to pelvic radiation or intravesical chemotherapy, or bladder scarring from surgical or traumatic injury.
3. Idiopathic detrusor overactivity refractory to all therapy.
4. Prolonged bladder defunctionalization after long-term catheter drainage, cutaneous vesicostomy drainage, or bilateral cutaneous ureterostomy.
5. Inflammatory conditions such as interstitial cystitis or bilharzial or tuberculosis bladder dysfunction.
6. Patients previously diverted who are candidates for undiversion.
7. Intractable autonomic dysreflexia that is associated with detrusor hyperactivity or irritation from indwelling catheters.

Incontinence from detrusor overactivity in patients who do not suffer from identifiable neurogenic disease (i.e., idiopathic detrusor overactivity) can be an indication for augmentation cystoplasty if other treatments, including medication, sacral

nerve stimulation therapy, botulinum toxin detrusor injection, and myomectomy, have failed.

Interstitial cystitis is a difficult disease to manage by any means. Treating it with augmentation cystoplasty has been disappointing unless supratrigonal cystectomy is also performed, but success with this approach has not been universal (4).

Patient selection is critical in the success of augmentation cystoplasty. Patients unwilling or unable to catheterize are not candidates for this procedure. Postoperatively, even those patients who do not have neurologic bladder dysfunction require CIC 39% to 89% of the time (3,4). We counsel all augmentation patients at our institution that they will have to self-catheterize at least temporarily after surgery. Persons with progressive neurologic or cognitive diseases, such as multiple sclerosis and dementia, may be poor augmentation candidates since their ability to perform CIC may deteriorate with time. This makes them dependent on others for catheterization, which puts them at risk for recurrent urinary tract infections (UTIs) and bladder perforation. Patients unable to self-catheterize because of their anatomy should be considered for a continent catheterizable stoma along with the augmentation.

In some instances, certain bowel segments may be unavailable because of pre-existing disease. The small bowel should not be used if extensive pelvic radiation has been performed. The large bowel is contraindicated if the patient has a history of colon cancer, diverticulitis, or ulcerative colitis. Any disease, such as Crohn disease, or prior surgery that results in a critically short or abnormal bowel is another contraindication to augmentation cystoplasty using bowel, especially if the removal of the segment will have adverse effects on bowel absorptive function.

Chronic renal failure is a relative contraindication to augmentation cystoplasty since both the ileum and colon absorb urinary solutes that may result in worsening renal function and metabolic disturbances. However, in many cases the bladder dysfunction itself is the cause of the renal deterioration, and the procedure will slow the decline in their renal function (2). In such instances gastrocystoplasty has been suggested because of the stomach's limited adverse effects on metabolic balance.

---

## DIAGNOSIS

---

The decision to perform an augmentation cystoplasty is complex and is not guided by a single test or office visit. It is a last resort once all conservative measures such as medications, clean intermittent catheterization, and minimally invasive procedures have failed. "Failure" in this context is defined as persistent incontinence, recurrent symptomatic UTIs, urosepsis, vesicoureteric reflux, or hydronephrosis. These clinical problems are common in patients with neurogenic bladder dysfunction and are all secondary to uncontrolled detrusor pressure and poor compliance. These variables are controllable with an augmentation cystoplasty.

The basic evaluation includes a urodynamic study, preferably using fluoroscopy to evaluate bladder compliance, the status of the bladder neck, and the presence of vesicoureteric reflux.

Incontinence in this population is often a complex problem. It can be a result of elevated detrusor pressures, a lack

of urethral closing function, or both. Accurate assessment of urethral function in cases where the bladder is very poorly compliant or grossly hyperreflexic is difficult.

Incontinence due to an open urethra as demonstrated on upright cystogram will persist after augmentation. This condition is associated with low thoracic or lumbar spinal cord injury, myelodysplasia, long-term urethral catheter drainage, and certain pelvic surgeries, such as abdominal perineal resection or radical hysterectomy. These conditions are best treated by urethral closure at the time of the augmentation. This can be achieved with a tight pubovaginal sling, an artificial urinary sphincter, or deliberate surgical closure of the bladder neck.

Vesicoureteric reflux is also a common complication of neurogenic bladder and is almost always driven by increased bladder pressures. "Low-pressure reflux" is a condition in which reflux occurs at relatively low detrusor pressures and can be very difficult to diagnose. Our practice is to ignore reflux and augment the bladder, and the reflux in most cases resolves provided the augmentation is a low-pressure and compliant reservoir. Other authors support this stance and have found that simply augmenting the bladder resolves vesicoureteric reflux in 86% of patients, and success does not depend on the grade of reflux or the bowel segment used for augmentation (5).

---

## ALTERNATIVE THERAPY

---

Recently, several options have become available for intractable detrusor overactivity or poor compliance. Botulinum toxin injections of the detrusor have been shown to be effective in both the neurogenic and nonneurogenic populations (6). Given the procedure's low morbidity, it should be tried before augmentation cystoplasty; however, it is still not approved by many regulatory agencies. Its high cost and need for repeat injections are a barrier to its widespread use. Sacral nerve stimulation has been available since 1997 for the treatment of refractory urgency and urge incontinence of nonneurogenic etiology (7). Autoaugmentation of the bladder, also known as partial detrusor myomectomy, is the excision of the detrusor muscle over the dome and anterior wall of the bladder. This allows the bladder epithelium to distend outward, improving storage capacity and bladder compliance (8). This significantly less morbid procedure has the advantage of not incorporating any mucus-producing bowel into the bladder, the almost uniform ability to void spontaneously after the procedure, and no increased risk of malignancy. In general, patients achieve less improvement in compliance than after formal enterocystoplasty. The gains in bladder capacity and compliance in patients with neurogenic bladder are small, so the routine use of myomectomy is not recommended in these patients. We continue to use this technique, especially in younger patients with intractable idiopathic urge incontinence, with favorable results.

For patients in whom a low-pressure diversion is required but the patient is unable to self-catheterize, an ileovesicostomy, or "bladder chimney," can be a good option (9). In the neurogenic patient whose only other option is an ileal conduit, an ileovesicostomy provides the same benefits of decreasing storage pressures and eliminating urethral incontinence, but it

does not involve dissection of the ureters or bladder removal, thus significantly reducing both early and late morbidity.

Laparoscopic bladder augmentation using ileum has been reported, but this technique is still under investigation (10). Other nonautologous tissues (Teflon, Silastic, human dura, Gore-Tex, bovine dura) have been utilized to augment the bladder; however, complications with the anastomosis, contracture, fistulas, infections, and stone formation have precluded their use (2). An innovative alternative is the tissue-engineered autologous bladder. A small clinical trial in children with spina bifida augmented with their own urothelial and muscle cells grown on a biodegradable bladder-shaped scaffold has promising results with little morbidity (11). Clinical trials are under way to better study this novel alternative.

## SURGICAL TECHNIQUE

Preoperatively all patients require a urine culture one week prior to the surgery date and urine sterilization with antibiotics based on sensitivities. Serum electrolytes including creatinine should be drawn at baseline for future comparison and to help dictate the segment of bowel best suited for the patient.

Patients with idiopathic detrusor overactivity should start a clear liquid diet for 2 to 3 days prior to the operative procedure. No antibiotic or mechanical bowel preparation is needed if ileum is the bowel segment to be utilized for the augmentation.

Patients with neurogenic conditions can be treated with a 3-day clear liquid diet and enemas without mechanical bowel preparation or oral antibiotics if ileum is the segment to be utilized. This bowel regime has been well supported in the general surgery literature and has been shown to be safe, even in children undergoing augmentation cystoplasty (12).

When large bowel is the segment to be used, a mechanical preparation is required along with oral antibiotics. Mechanical bowel preparation in neurogenic patients may take slightly longer than in patients with normal bowel function and should be done gently over a 2- to 3-day period.

A nasogastric tube is inserted after induction of anesthesia but is removed prior to extubation. We have eliminated the use of routine nasogastric tube drainage after bowel surgery. This is based on results of a trial showing that bowel function returns more swiftly and there are no increases in complications in neurogenic bladder patients undergoing augmentation treated without postoperative nasogastric tube drainage (13).

After preparation of the skin from xiphoid to genitalia, a urethral catheter is placed and positioned so that the bladder can be filled and emptied during the case. In general, if an anti-incontinence procedure is necessary, it is performed first.

A midline incision is the best approach for augmentation cystoplasty. A Pfannenstiel incision can be used, but it is suitable only when ileum will be used since a colonic augmentation through a Pfannenstiel incision is a rather difficult operative procedure. It should be kept in mind that occasionally it is only discovered intraoperatively that the ileum is unusable and one is forced to use colon.

After entry into the peritoneum, a self-retaining retractor is placed (the Bookwalter is our preference in the adult), and the bladder is filled with saline and identified. The peritoneum is dissected off the bladder down to the level of the trigone posteriorly (Fig. 18.1). A wide U-shaped incision is made

**FIGURE 18.1** The peritoneum is dissected off the posterior bladder to the level of the trigone and 2 to 3 cm above the level of the ureters.

**FIGURE 18.2** A U-shaped incision is made on the bladder with the transverse portion just superior to the trigone and the limbs of the incision extending to the dome of the bladder.

posteriorly on the bladder starting just above the ureters, creating an anteriorly based bladder flap with a posteriorly facing opening (Fig. 18.2). This approach will allow a tension-free augmentation.

A 25- to 30-cm segment of ileum at least 20 cm proximal to the ileocecal valve is selected and marked with sutures. Before harvesting the bowel, the surgeon should fold this section of ileum in two and ensure that it can easily reach the bladder without tension; if not, a new section should be selected. The mesentery is incised on either end of the 25-cm segment, and both ends of the ileum section are divided using standard stapling devices (Fig. 18.3).

The exact length of ileum required varies between individuals, but enough length should be used to allow an estimated 4 hours between catheterizations after the bowel is fully “stretched” over the ensuing months. Ileal continuity is then achieved using one of the hand-sewn or stapled techniques and the mesenteric defect closed. To prevent stone formation, the ileal ends are oversewn with running 2-0 chromic catgut to exclude the staples (Fig. 18.3), and then the antimesenteric

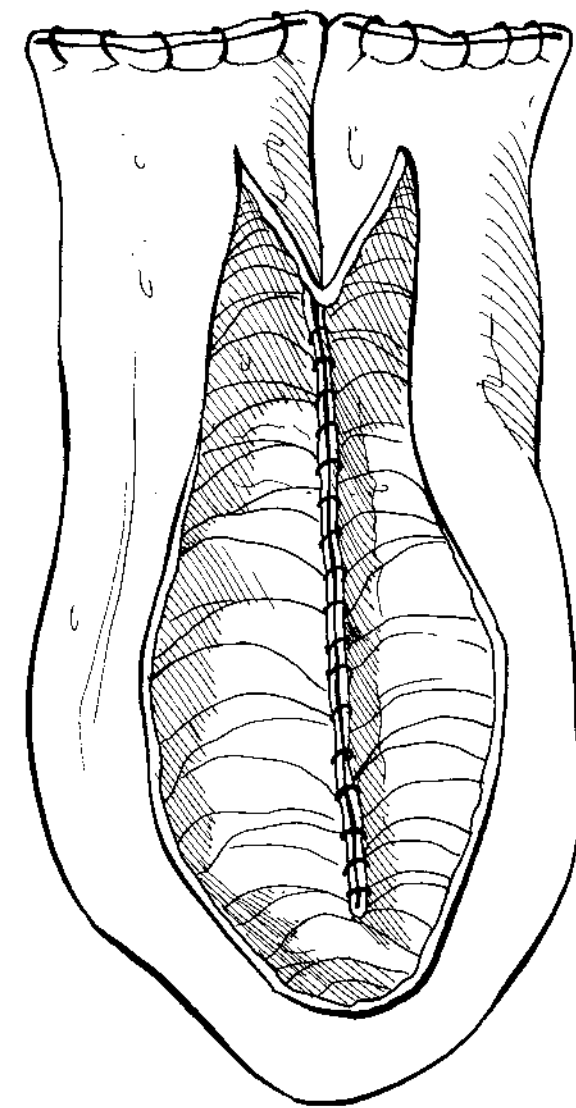

**FIGURE 18.3** Approximately 15 cm proximal to the ileocecal valve, a 25-cm segment of bowel is selected, the mesentery cleared, and the segment removed using standard stapling techniques. The segment of ileum is oversewn at the ends to exclude the staples and then opened along the antimesenteric border.

surface of the bowel is opened using electrocautery. The posterior wall of the ileum is folded back on itself and sutured together using a running 2-0 delayed absorbable synthetic stitch such as Vicryl (Figs. 18.4 and 18.5). The required size of the augmentation opening on the bladder is roughly measured, and the superior, anterior wall of the ileum is partially closed with running 2-0 Vicryl to match this opening (Fig. 18.6).

**FIGURE 18.4** The ileal segment is folded, and closure of the posterior wall is initiated using a running absorbable suture.

**FIGURE 18.5** The posterior wall of the augment is completely closed.

**FIGURE 18.6** The superior, anterior wall of the augment is partially closed. The size of the augment opening should roughly correspond to the size of the opened bladder.

A large-bore suprapubic (SP) tube is placed through the lateral bladder wall, not the bowel segment, prior to suturing the augment onto the bladder. The SP tube allows reliable postoperative drainage and irrigation of mucus until the suture lines are healed. Alternatively, a large-bore urethral catheter can be left in place. The choice of an SP tube or a urethral catheter, or both, is surgeon dependent, although we prefer a urethral catheter since it is simpler to remove. The ileal segment is then sewn onto the opened bladder using running 2-0 Vicryl, with the initial suture placed at the most inferior

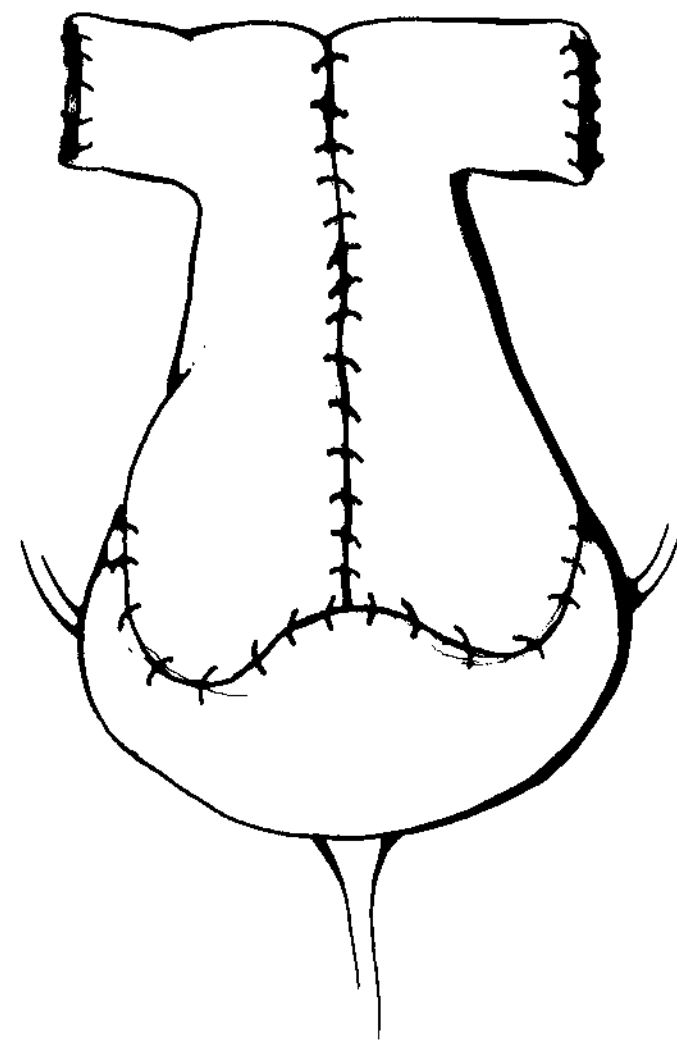

**FIGURE 18.7** Initial suture placement for enterocystoplasty. Note that the bladder flap opens anteriorly.

portion of the bladder opening posteriorly (Fig. 18.7). Suture lines must be watertight and full thickness, and the bladder mucosa must oppose the bowel mucosa. Once the posterior closure is finished, the anterior closure is completed in a similar fashion (Fig. 18.8). The completed enterocystoplasty is shown in Fig. 18.9. A closed-suction drain is placed near the suture line and brought through the skin on the side opposite the SP tube. The abdomen is closed in standard fashion. If a continence procedure has been performed, it is imperative that a urethral catheter can be easily passed.

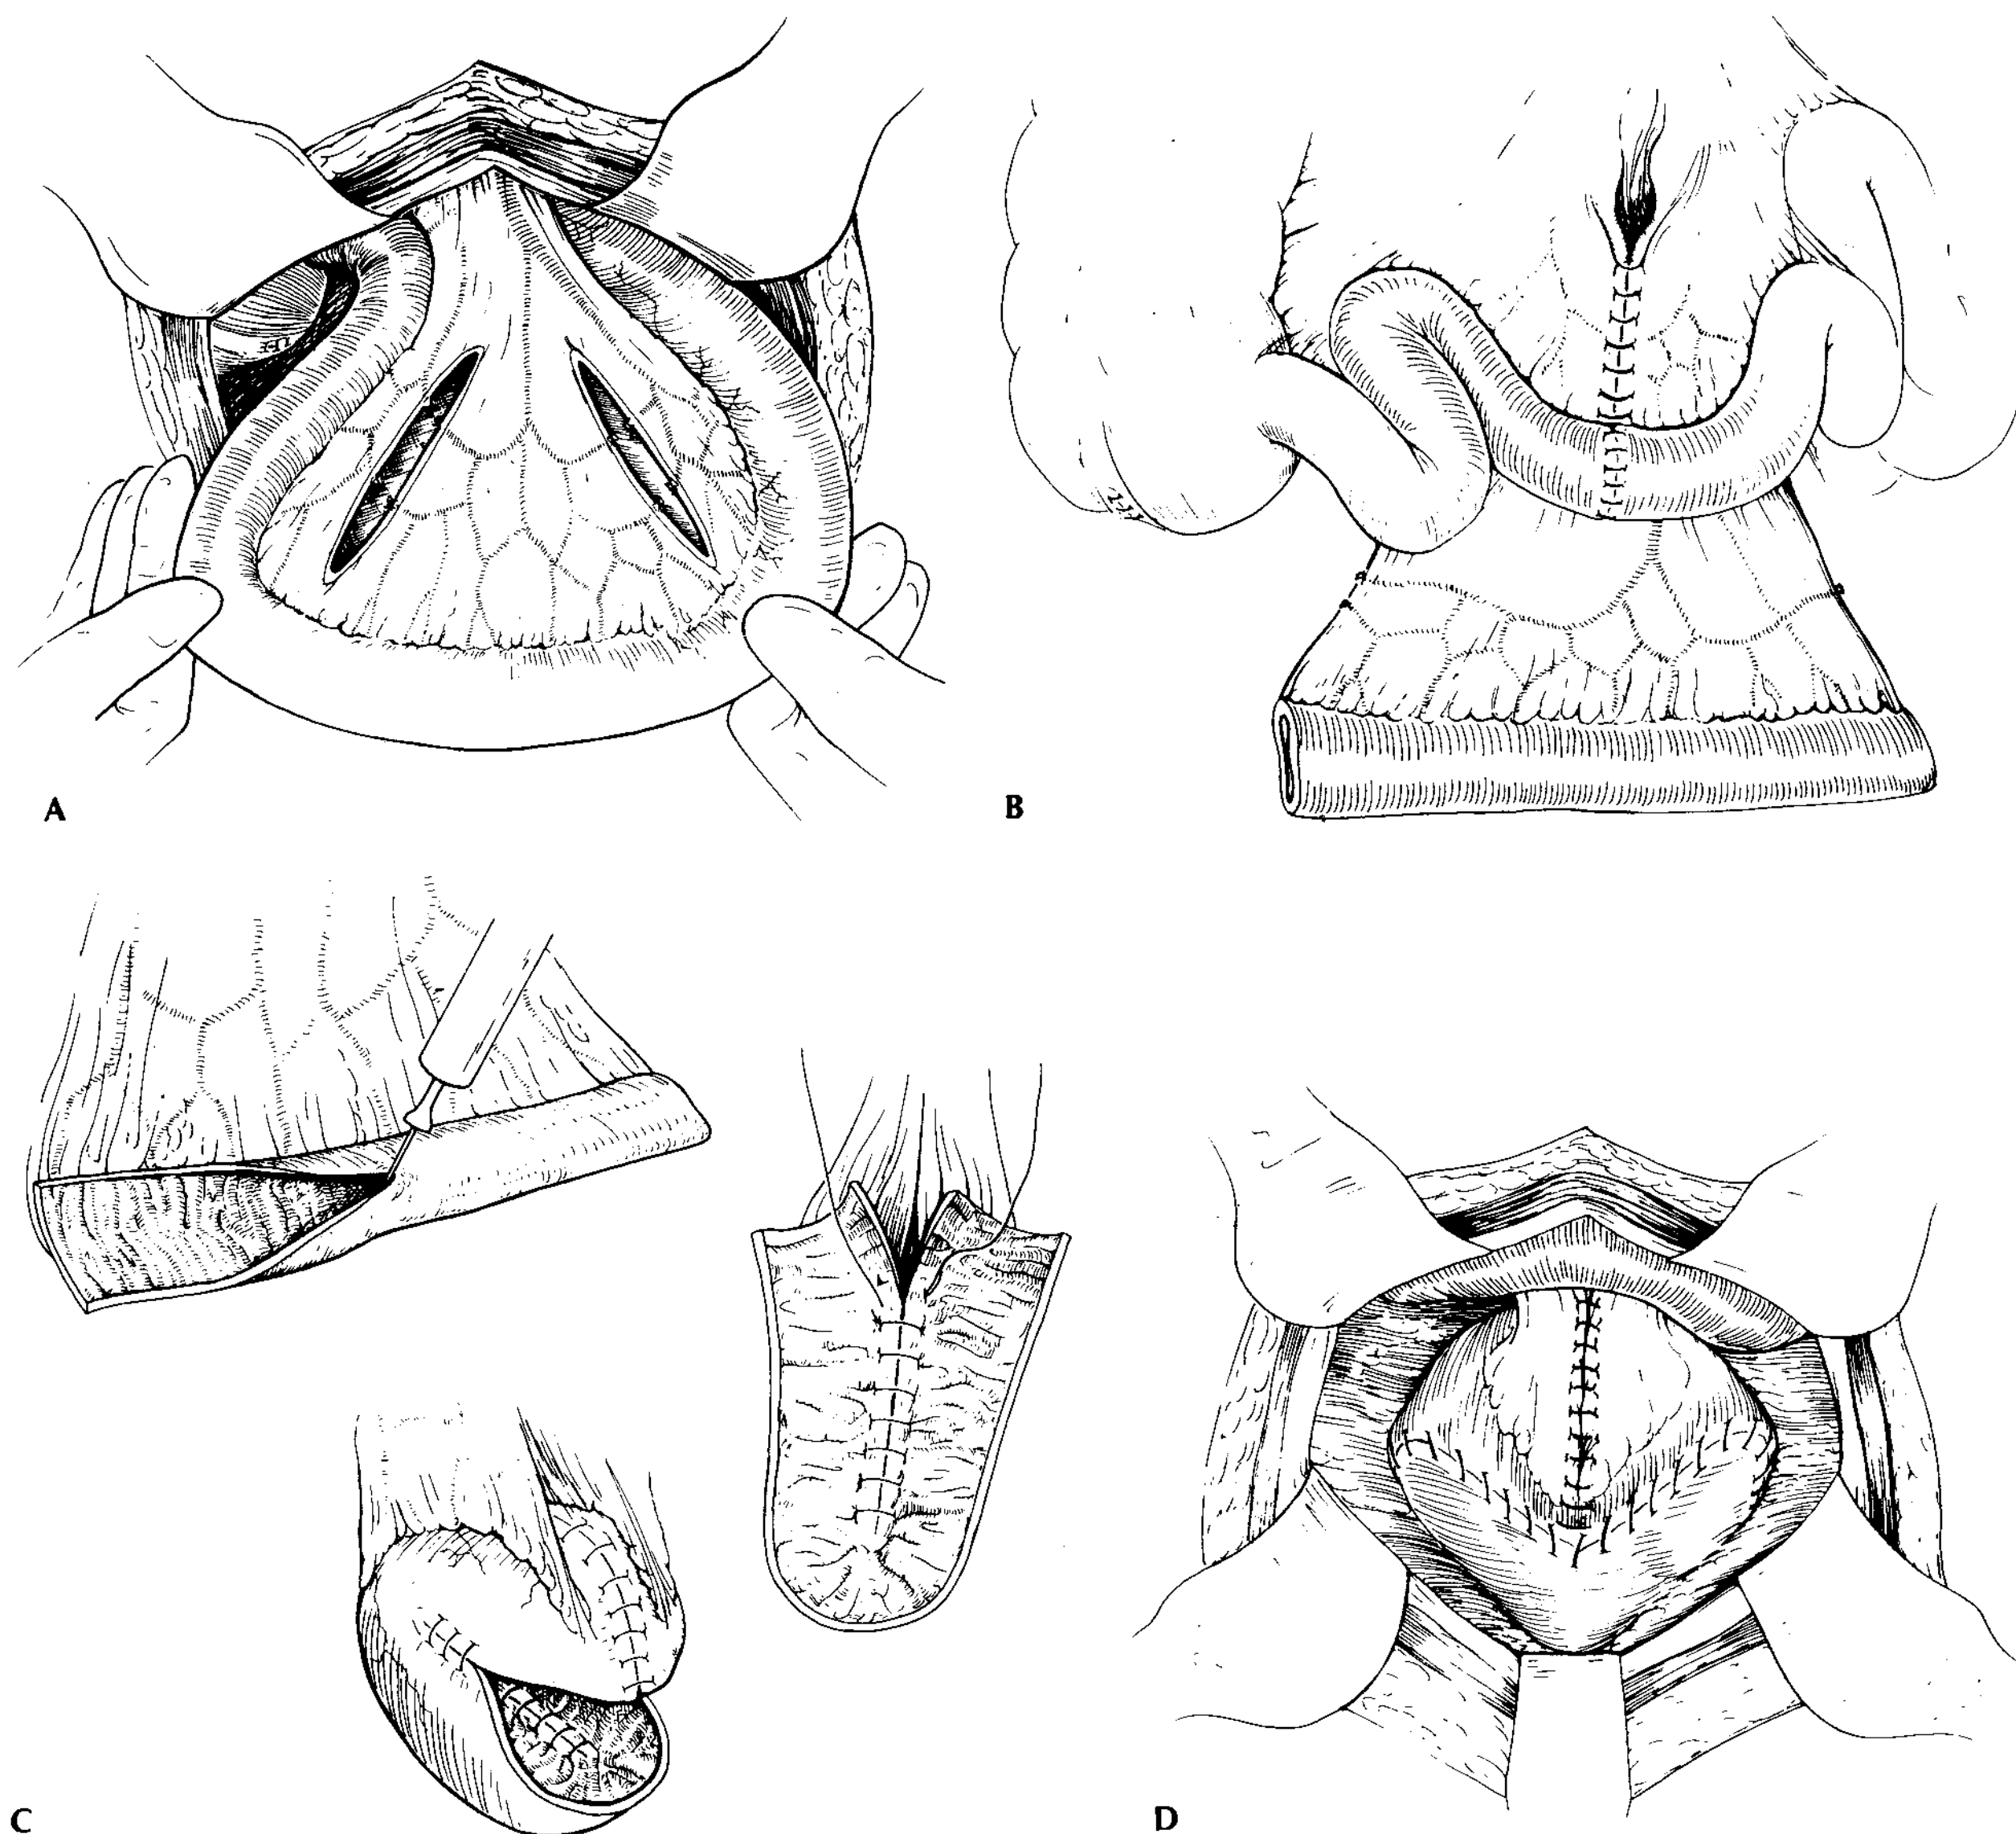

**FIGURE 18.8** Closure of the anterior aspect of the enterocystoplasty.

**FIGURE 18.9** View of the completed enterocystoplasty.

Although this is our preferred technique, other methods of performing an augmentation exist. One such method involves splitting the bladder sagittally from just above the bladder neck and ending near the level of the ureters posteriorly to form a “clam shell” (3). A 23- to 30-cm segment of ileum is isolated and divided completely along the antimesenteric border (Fig. 18.10). The posterior wall of the augment is closed with running 2-0 Vicryl and then either anastomosed to the bladder as a “patch” or folded again and partially closed to form a “cup.” A cup is especially useful if the patient’s own bladder is very small, but it sometimes requires the use of up to 40 cm of bowel. In both cases, the anastomosis is started on the posterior wall until approximately one third is closed, and then the anterior wall is closed. The lateral walls are closed last, and any redundant bowel is closed to itself.

Postoperatively, fluid and electrolyte management is important due to large third-space losses and suction drainage. Although the nasogastric tube is not left in place, it is important to remember that bowel function is often deranged in the neurogenic bladder patient, and recovery of bowel motility may be significantly delayed. The abdominal drain is removed once drainage is consistently minimal. The bladder is irrigated via the catheter while in hospital and after discharge at least three times per day with 30 to 60 mL of saline to clear mucus. Typically a cystogram is performed at 2 to 3 weeks, and if no urinary extravasation is noted, the patient begins CIC. If an SP tube was originally placed, the patients can perform CIC with the SP tube clamped until proficient at CIC. At 3 to 4 weeks, the SP tube is removed and the patient continues CIC every 2 to 3 hours during the day and twice at night. It typically requires up to 6 to 12 months for the augment to stretch to full capacity, during which time more frequent CIC is necessary. This may be distressing to the patient at first. Continuing the regimen of anticholinergic therapy will help maintain native bladder compliance and maximize capacity. As capacity increases, the CIC intervals can lengthen, and, ultimately, most patients are able to wait 4 to 5 hours between catheterizations during the day and catheterize only once at night. Patients who are able to void per urethra must document consistently small postvoid residuals before CIC is stopped. In some cases, apparent early normal

**FIGURE 18.10** Augmentation cystoplasty with formation of a cup patch. **A:** Isolation of a distal ileal segment. **B and C:** Isolated ileal segment opened on antimesenteric border and double-folded to create a reservoir. **D:** Cup patch reservoir sutured to the bladder-incised sagittal plane.

voiding deteriorates over time, and in some cases the bowel segment can become overstretched and either rupture or become overly capacious and defunctionalized. Patients who are able to void postoperatively should be followed with intermittent postvoid residuals. Daily irrigation to clear mucus is essential, especially for the first few months.

Routine electrolytes, creatinine, blood urea nitrogen, and upper-tract studies should be performed at regular intervals. It is unlikely that vitamin B<sub>12</sub> deficiency should develop because a short ileal segment is usually used.

## COMPLICATIONS

A comprehensive long-term study of 122 patients by Flood and colleagues reported an overall 28% early and 44% late complication rate in a complex group of patients (4). Most of

the complications were manageable and consisted primarily of prolonged ileus, transient urinary extravasation, or stomal problems. Surgical interventions were necessary in only 15% of patients, with stomal revisions being most common.

Small-bowel obstructions occur in approximately 3% of patients, similar to the rate reported in urinary diversions. The rate of bladder stones varies from 13% to 21% (2,4), but it has been reported to be much higher (3). Stone formation is lowest in those patients who void spontaneously but is five times higher in those who catheterize urethrally and ten times higher in those with continent cutaneous stomas (2). Stones usually form secondary to retained mucus or exposed staples as a nidus. Routine bladder irrigation, treatment of infections, and excluding staples at the time of surgery minimize stone formation.

Although patients with bacteriuria and recurring urinary infection remain as bacteriuric after augmentation as they were before the surgery, the infections and their resulting

complications are ameliorated by the procedure. This results from improved control of detrusor pressure, which is the ultimate goal of treatment of any bladder dysfunction. Since bacteriuria is extremely common, especially if the patient is performing self-catheterization, routine urine culture is not helpful. Bacteriuria is only considered an infection if the patient becomes symptomatic (fever, pain, foul-smelling urine, incontinence, or increased mucus production) (3). The treatment of asymptomatic bacteriuria, unless it is a urease-splitting organism, is of no benefit and will only promote antibiotic resistance.

Reservoir perforation is perhaps the most feared complication, with reported rates of up to 6% (4). Perforation is a catastrophic event, and the patient may quickly become septic, but the presentation is variable, and patients with spinal cord injury may not present with the classic signs of an acute abdomen (3). Fortunately, fatalities are uncommon if diagnosed early. Different theories have been proposed to explain the etiology of bladder perforation. Obviously, acute trauma can rupture the augmented bladder, but the majority of perforations are nontraumatic. Infrequent catheterization, recurrent urinary infections, and bowel ischemia secondary to recurrent overdistention have all been implicated (3). Clinical suspicion of a perforation must always be high in this population, and the method of diagnosis is a cystogram both filled and post drainage. Standard treatment is open repair of the rupture, which is typically at the bowel-to-bladder junction.

Metabolic acidosis that requires bicarbonate treatment is uncommon if patients are properly selected and a reasonable length of bowel is used. Patients should be screened for this disturbance at least annually.

The development of tumors has been reported with the use of all bowel segments. Although the risk to any individual patient is small, after 5 years annual cystoscopic surveillance should be considered, especially if a colonic segment is used.

If the bladder is extremely small or the bladder incision is not generous, the “augmentation” may ultimately become no more than a large, nondraining bladder diverticulum. This complication may be manifested by recurrent urinary tract

infections and can easily be identified by the classic hourglass appearance on a cystogram. Reaugmentation is the only solution to this rare problem, but prevention by creating a very large bladder opening initially (Fig. 18.2) is the key.

Augmentation cystoplasty has gained widespread use in both the pediatric and adult populations such that there are many women of reproductive age who are currently living with a bladder augmentation. There are small case series indicating an increase in pyelonephritis, ureteric dilatation or obstruction, renal deterioration, and premature labor in these women. These potential complications should be actively screened for during the pregnancy, and bacteriuria should be aggressively treated. Women with an augmentation cystoplasty alone, without any contraindications to vaginal delivery, should be allowed to deliver vaginally, thereby avoiding any possible injury to the pedicle of the augmented bowel during Caesarean section. Women who have a bladder outlet procedure along with their augmentation should be counseled about the risks and benefits of vaginal delivery versus cesarean, and if the latter is chosen, their urologists should be present for the procedure (2,3).

---

## RESULTS

---

Achieving a successful augmentation cystoplasty depends on three factors: performing the procedure for the correct indications only after exhausting all other conservative measures, proper patient selection, and good operative technique. In selected patients with neuropathic bladders requiring improved compliance and capacity, augmentation cystoplasty has a high likelihood of improving compliance and capacity and can be equally efficacious in the nonneurogenic patient with intractable bladder symptoms. An augmentation is less successful in treating the symptoms of interstitial cystitis and by itself does not guarantee continence, especially in patients with high rates of intrinsic sphincter deficiency (ISD), such as in the case of myelomeningocele and radiation cystitis, who will often require an anti-incontinence procedure.

# CHAPTER 19 ■ MANAGEMENT OF THE DISTAL URETER FOR NEPHRO URETERECTOMY

J. STUART WOLF, JR.

The traditional therapy for urothelial cell carcinoma of the renal pelvis or ureter is nephroureterectomy, including a 1-cm cuff of bladder around the ureteral orifice. When performed using open surgery, this entails a long midline or thoraco-abdominal incision or two incisions (a flank incision for the nephrectomy and a lower midline or Gibson incision for the distal ureterectomy). Because of the morbidity associated with the extension of the incision for the distal ureterectomy, alternative approaches such as the “pluck” and “intussusception” techniques were devised. The advent of laparoscopic nephroureterectomy, which further reduces morbidity by eliminating the flank incision for the renal portion of the procedure, has stimulated the development of additional minimally invasive approaches to the distal ureter. Although there is some advantage in terms of reducing the intensity and duration of convalescence with these less invasive approaches, since intact extraction of the specimen is recommended after laparoscopic nephroureterectomy (owing to the importance of pathologic staging and the propensity for urothelial carcinoma to implant into wounds), an open surgical approach to the distal ureterectomy does not necessarily mean a much larger incision than would be required for the nephrectomy portion of the case.

---

## DIAGNOSIS

---

The most common presenting symptom or sign of upper-tract urothelial tumors is hematuria, which occurs in approximately 75% of patients, and the second most common symptom or sign is flank pain, present in approximately 30% of patients (3). The subsequent evaluation entails an upper-tract imaging study with intravenous urography, computerized tomography, magnetic resonance imaging, or retrograde pyelography. Most patients will have a filling defect that suggests upper-tract urothelial tumor. Both sides of the urinary system need to be evaluated due to the potential for bilateral tumors.

The combination of urinary cytology positive for upper-tract urothelial tumor with radiographic abnormality consistent with an upper-tract urothelial tumor is adequate for diagnosis if nephroureterectomy is intended. If either cytology or imaging is not definitive, or if a nephron-sparing approach is being considered, then ureteroscopy and biopsy are recommended. In either case, cystoscopy is essential due to the high association with urothelial tumors of the bladder.

Once urothelial malignancy is diagnosed, metastatic evaluation consists of an abdominal and pelvic computerized tomogram and a chest radiograph. A bone scan is performed if there is bone pain, the alkaline phosphatase is elevated, or

bony abnormalities are seen on other imaging studies. A complete blood count, serum electrolytes with creatinine, and liver function tests should also be obtained. If the creatinine is elevated, a renal scan to determine differential function may aid in decision making.

---

## INDICATIONS FOR SURGERY

---

Radical nephroureterectomy with complete distal ureterectomy is the standard therapy for upper-tract urothelial tumors, using either laparoscopic (standard or hand-assisted) or open surgical techniques. Nephrectomy without complete ureterectomy should be avoided due to a 30% incidence of recurrence in the ureteral stump (2). Patients with a positive cytology but without an identifiable lesion on imaging or ureteroscopy should be followed closely rather than undergo nephroureterectomy without a definitive diagnosis.

---

## ALTERNATIVE THERAPY

---

Endoscopic resection and fulguration are acceptable for patients with low-grade, low-stage, and small-tumor burdens. An alternative for a distal ureteral tumor is a distal ureterectomy with a ureteroneocystostomy or other reconstruction. Topical therapy with bacille Calmette-Guérin or mitomycin C may be attempted for patients with carcinoma in situ who have limited renal function or bilateral disease.

---

## SURGICAL TECHNIQUE

---

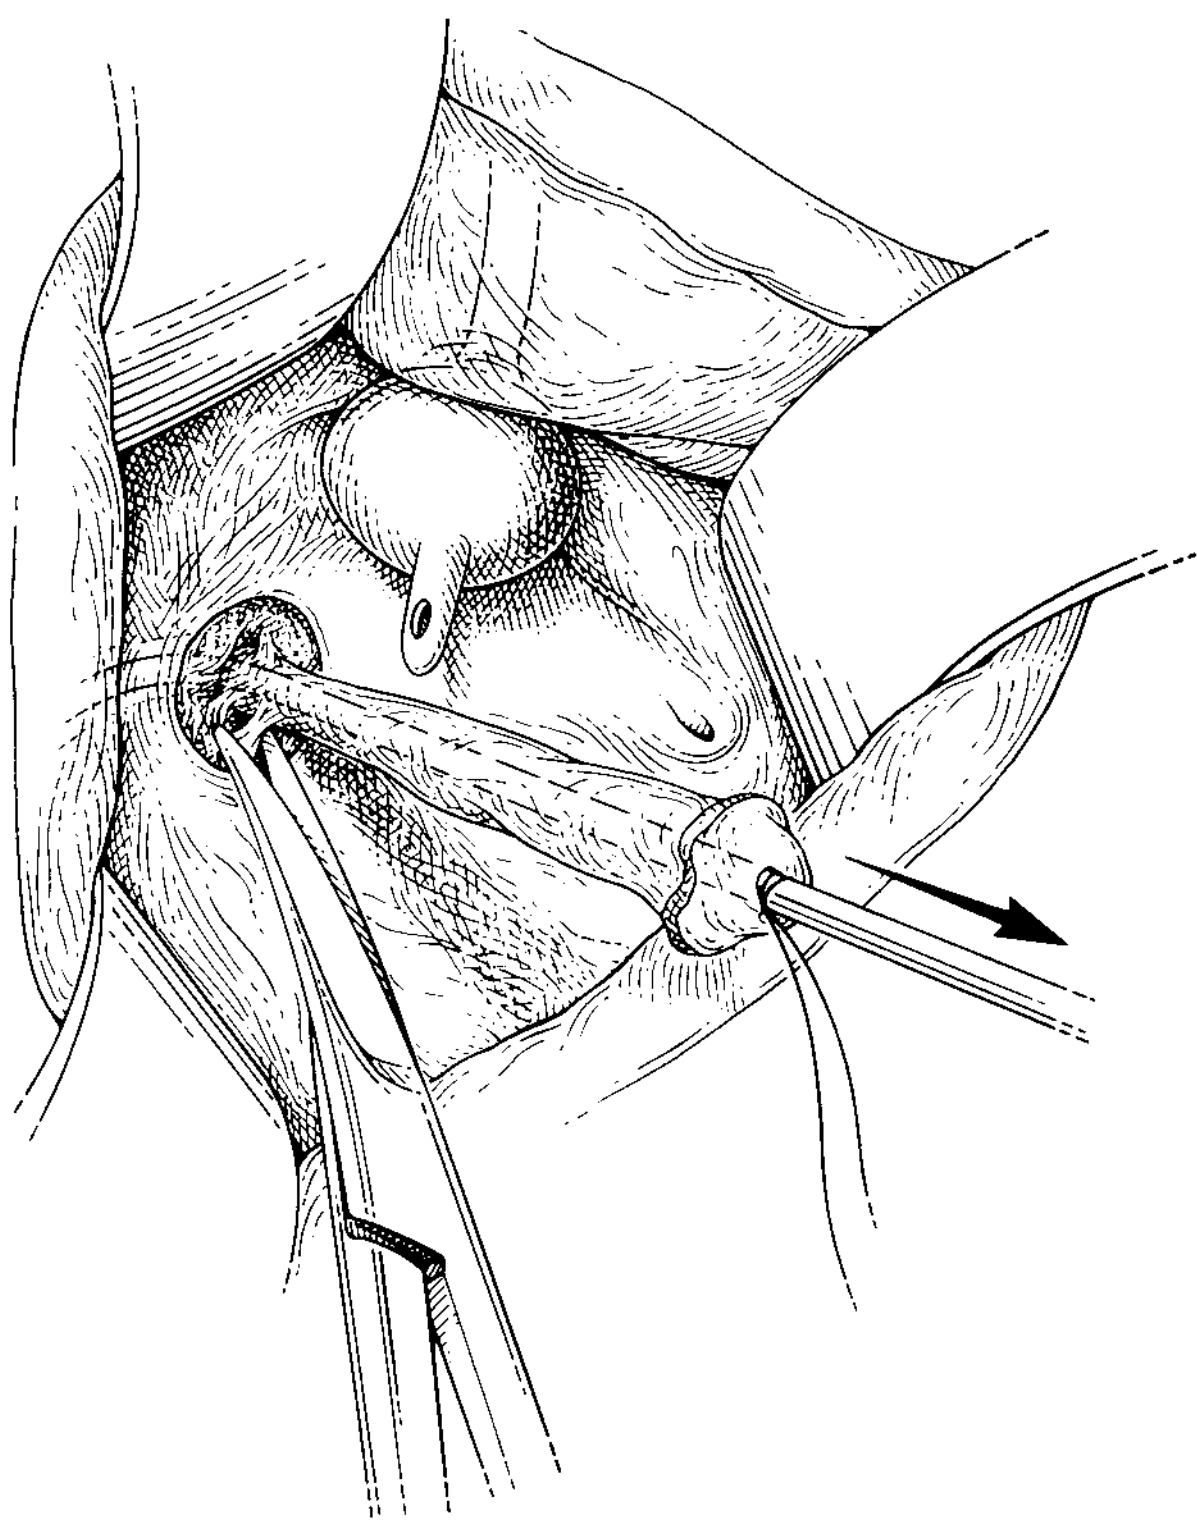

---

### Open Surgical Techniques

---

#### Intravesical Approach

Open surgical distal ureterectomy can be used in conjunction with any technique of nephrectomy. After completing the nephrectomy and proximal ureteral dissection, place the patient in the supine position, with or without flexion of the table. Insert a three-way 20Fr urethral catheter into the bladder. Make a lower midline incision, divide the rectus fascia, develop the space of Retzius, and place a self-retaining retractor. Fill the bladder with saline and then open it longitudinally between two stay sutures. Place additional stay sutures at the apices of the bladder incision. Pack the dome of the bladder with a gauze sponge, and use a bladder blade to retract the bladder dome cephalad. Insert a ureteral catheter or feeding tube in the targeted ureteral orifice and sew it in place

**FIGURE 19.1** A ureteral catheter is secured to the ureteral orifice. Tenotomy scissors and electrocautery are used to dissect free the intramural ureter. (From Lange PH. Carcinoma of the renal pelvis and ureter. In: Glenn JF, ed. *Urologic surgery*, 4th ed. Philadelphia: JB Lippincott Co, 1991:273, with permission.)

with a 4-0 suture. Use electrocautery cutting current to incise the mucosa 1 cm around the ureteral orifice. Dissect the intramural ureter using tenotomy scissors and pinpoint electrocautery (Fig. 19.1).

Dissect the entire distal ureter free to join the point of previous dissection completed during the nephrectomy portion of the procedure. Close the posterior bladder wall in two layers (2-0 absorbable sutures for the serosa and muscle and 4-0 absorbable sutures for the mucosa), and close the anterior bladder incision similarly. Insert a pelvic drain through a separate stab incision. Leave the urethral catheter in place for 3 to 5 days. Some perform a cystogram to ensure the bladder has healed prior to removing the catheter, while others remove the catheter and perform a voiding trial.

At times, the dissection of the distal ureter may be difficult and the ureter may need to be dissected extravesically as well. This may require division of the superior vesical artery to provide access to the distal ureter.

### Extravesical Approach

A completely extravesical approach is best performed through a Gibson incision. After entering the retroperitoneal space and identifying the distal ureter, retract the bladder to the contralateral side. Divide the superior vesical artery to facilitate dissection of the distal ureter. Identify the ureteral hiatus and dissect the intramural ureter using electrocautery. Cephalad traction on the ureter will help identify the bladder mucosa. Use a right-angle clamp to secure the ureteral orifice, and then

excise the ureter. Tie a 2-0 absorbable suture around the right-angle clamp to close the bladder mucosa, or use running 4-0 absorbable suture. Close a second layer over the resection site using 2-0 absorbable sutures. Manage drains and catheters as above.

## Laparoscopic Extravesical Bladder Cuff Technique (6)

This technique is similar to the open surgical extravesical approach. Place the patient in a modified flank position for transperitoneal laparoscopic nephrectomy. Using flexible cystoscopy, insert a ureteral catheter. At the conclusion of the laparoscopic nephrectomy, dissect the ureter distally and place clips on the ureter to prevent extravasation of tumor cells. Retract the ureter cephalad and continue dissecting it distally to the bladder. After inserting a 10-mm port in the lower abdomen to facilitate resection of the distal ureter, incise the bladder just anterior to the ureter using electrocautery. Upon entering the bladder, the ureteral catheter identifies the ureteral orifice. Excise the posterior portion of the bladder cuff and detach the ureter after dividing the ureteral catheter. Suture the bladder closed using laparoscopic techniques (recently, robotic assistance has been described to facilitate this step). Manage drains and catheters as above.

## Endoscopic Techniques

Except for the “pluck” procedures, all of the endoscopic techniques described in this section have been developed specifically for use in conjunction with laparoscopic nephroureterectomy. The techniques are described below in the settings in which they were initially described or are in common use at this time. The hand-assisted approach to laparoscopic nephroureterectomy may be preferable with particular techniques, as indicated below, but any approach to nephroureterectomy—laparoscopic or open surgical—can be used in conjunction with any of the following techniques, with modifications.

### Transvesical Bladder Cuff Technique: Single Port (5)

After completing a hand-assisted laparoscopic nephrectomy with the patient in the modified flank position, dissect the ureter to the bladder. Place clips on the ureter to prevent tumor spillage.

Without repositioning the patient, fill the bladder with fluid through a three-way urethral catheter. Make an incision for a 10-mm laparoscopic port in the midline, three finger breadths above the pubis. Using the surgeon’s hand via the hand-assist port, push the bladder upward toward the abdominal wall. Insert a spinal needle through the incision into the bladder to ascertain proper angle and depth of entry, and then insert a 10-mm laparoscopic port directly into the bladder through the extraperitoneal space. Using a 24Fr resectoscope with a Collins knife through this port, and with the surgeon’s hand alternately elevating the ipsilateral hemitrigone and retracting the ureter, incise around the ureteral orifice and intramural ureter with the Collins knife (Fig. 19.2). During the

**FIGURE 19.2** The surgeon's hand elevates the ipsilateral hemitrigone while the Collins knife is used to incise around the ureteral orifice. (Adapted from Gonzalez CM, Batler RA, Schoor RA, et al. A novel endoscopic approach towards resection of the distal ureter with surrounding bladder cuff during hand assisted laparoscopic nephroureterectomy. *J Urol* 2001;165:484.)

resection, controlling the height of the urethral catheter drainage bag controls the filling of the bladder. As soon as the ureter is detached, placing the drainage bag on the floor minimizes extravasation of urine and irrigant. Note that once the bladder has been opened into the retroperitoneum, it collapses quickly, so take care to keep the dissection at equal depth all around the orifice so that once the bladder collapses the ureter can be pulled free easily.

After specimen removal, remove the bladder port. Neither the port site nor the resection site needs to be closed, but placement of a pelvic drain through a laparoscopic port site is optional. The initial description of this technique includes a cystogram performed on postoperative day 7 to verify lack of extravasation prior to catheter removal, but in the author's experience with this technique the cystotomy is adequately healed by this time and a voiding trial is sufficient.

#### Transurethral Bladder Cuff Technique

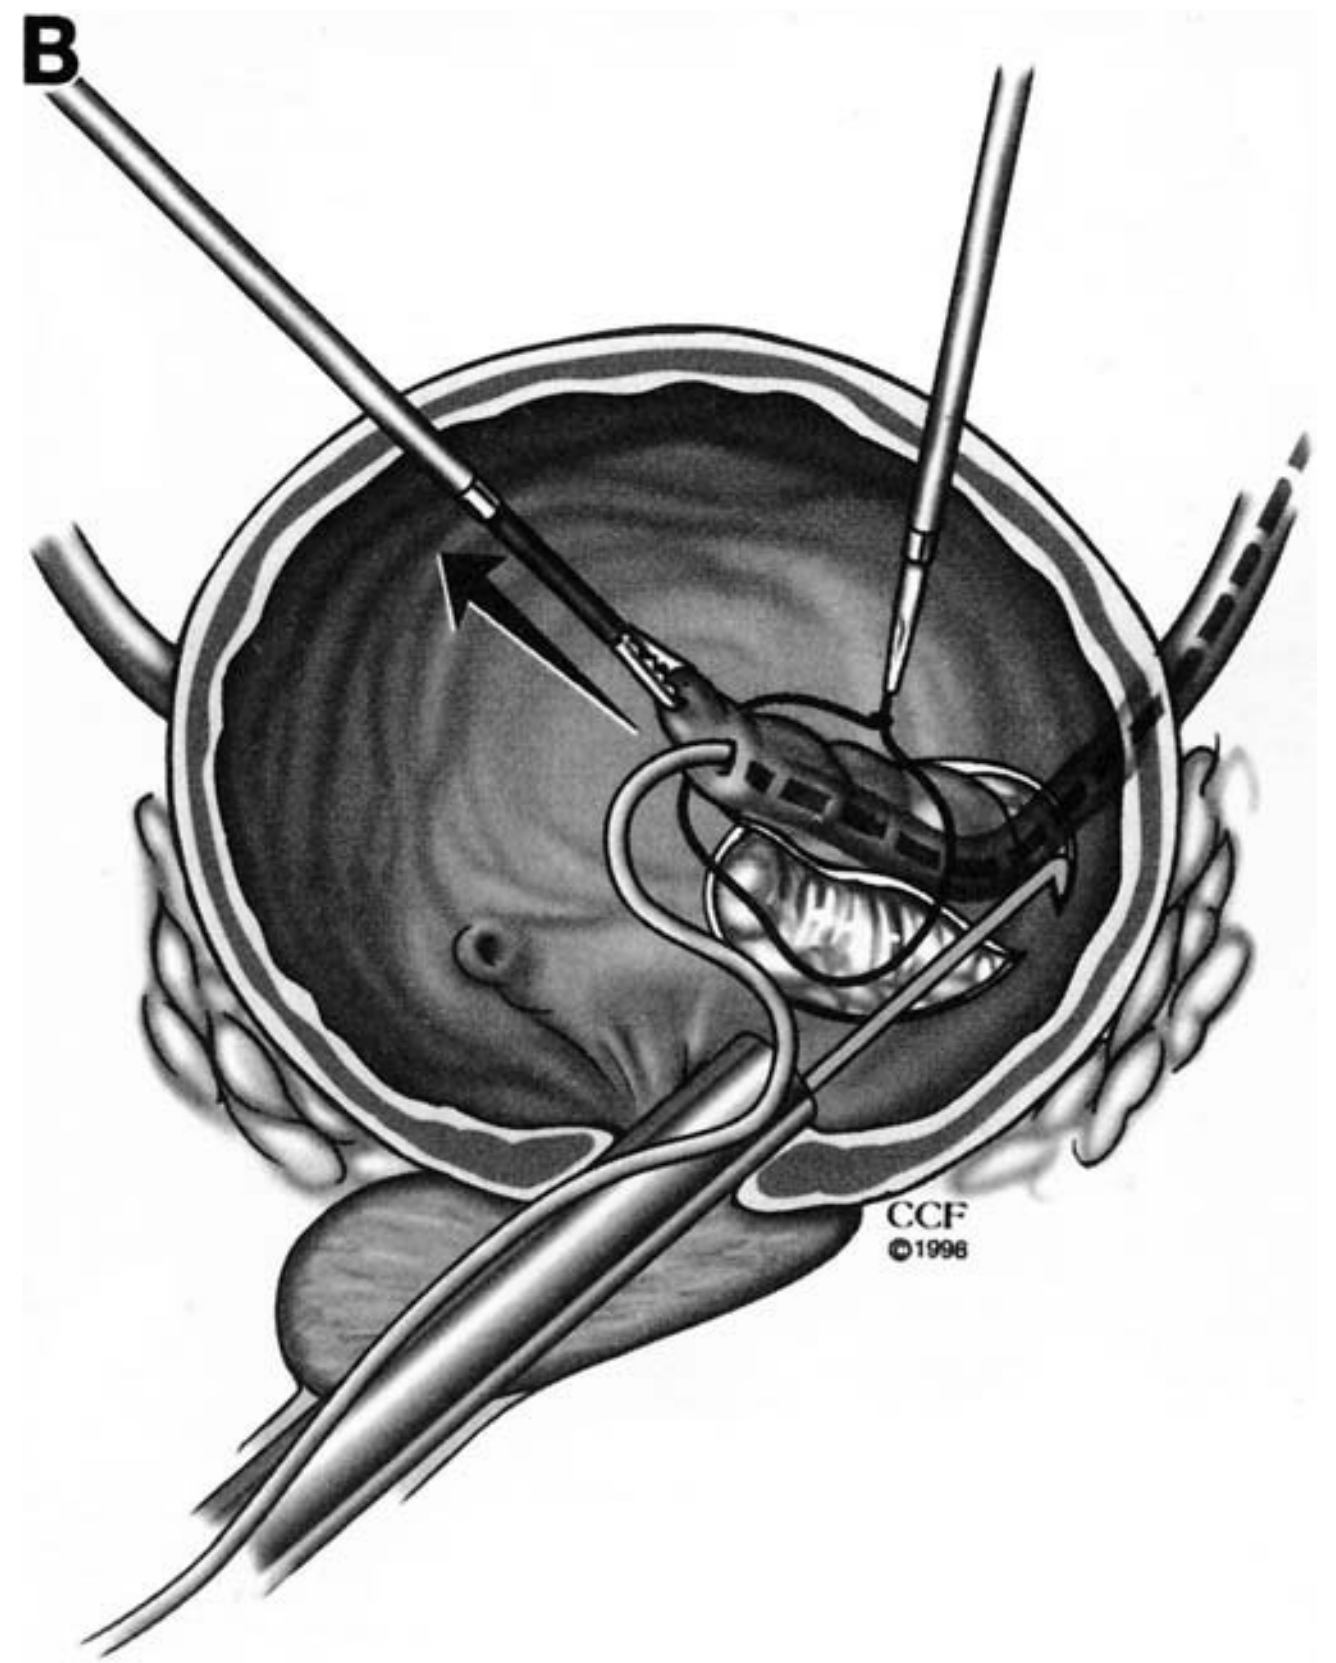

This technique is similar to the transvesical bladder cuff technique except that the resection is performed transurethrally, which obviates the need for placement of a transvesical port. One option is to use a flexible cystoscope with an electrocautery probe to perform the periureteral dissection (11). Another alternative is to position the patient in a combined lithotomy-semiflank position that allows simultaneous laparoscopic

nephrectomy and transurethral access with a 24Fr resectoscope with a Collins knife (12).

#### Transvesical Bladder Cuff Technique: Two Ports (4)

Prior to performing the nephrectomy portion of the procedure, place the patient in the lithotomy position. Perform cystoscopy to evaluate the bladder mucosa and distend the bladder. Under cystoscopic guidance, place two 5-mm balloon-tipped laparoscopic ports into the bladder just above the pubic bone on both sides of the midline, placing both ports to wall suction to prevent extravasation and overdistention of the bladder. Insert a 5-mm endoloop through the ipsilateral port, and then insert a 6Fr ureteral catheter cystoscopically into the targeted ureter. Exchange the cystoscope for a resectoscope with a Collins knife, which is used to incise around the ureteral orifice. Using a grasper inserted through the other laparoscopic port that is passed through the endoloop, retract the ureteral orifice anteriorly. After freeing up 3 to 4 cm of ureter, suspend the ureter from the anterior bladder wall with the grasper (Fig. 19.3); then remove the ureteral catheter and tighten the endoloop around the ureter to occlude the lumen.

After removing the laparoscopic ports, place a urethral catheter to gravity drainage. Perform the nephrectomy portion of the procedure after repositioning, and with cephalad traction dissect the ureter distally such that the distal ureter can be pulled into the operative space for intact removal. Again, a urethral catheter is left in place for 1 week, with the option of

**FIGURE 19.3** The Collins knife is used transurethrally while a grasper elevates the ureter and the endoloop is around the resected orifice. (Adapted from Gill IS, Soble JJ, Miller SD, et al. A novel technique for the management of the en bloc bladder cuff and distal ureter during laparoscopic nephroureterectomy. *J Urol* 1999;161:432.)

a cystogram to confirm adequate bladder healing prior to catheter removal.

### Ureteral Unroofing Technique (10)

Prior to performing the nephrectomy portion of the procedure, place the patient in the lithotomy position. Perform cystoscopy and insert a ureteral dilating balloon (5 mm diameter, 10 cm length) into the targeted intramural ureter. Inflate the balloon to 1-atm pressure with dilute contrast material using fluoroscopic guidance. Exchange the cystoscope for a resectoscope with a Collins knife, and incise the ureteral tunnel at the 12 o'clock position along the entire length of the intramural ureter. Remove the dilating balloon and use a rollerball electrode to cauterize the edges and floor of the intramural ureter. Insert a 7Fr 11.5-mm balloon occlusion catheter into the renal pelvis and inflate it at the ureteropelvic junction, to prevent urine extravasation. Connect this catheter, and a urethral catheter, to gravity drainage.

Take the patient out of the lithotomy position and perform the nephrectomy. Once completed, mobilize the distal ureter to the ureteral hiatus, dividing the superior vesical artery if necessary. Ligate and incise the remaining distal ureter and bladder cuff using an endoscopic stapler (Fig. 19.4), removing the ureteral balloon occlusion catheter just prior to engaging the stapler. Leave the urethral catheter in place for 3 to 5 days, removing it after cystography or a voiding trial demonstrates no urinary extravasation. A modification of the technique, which allows for nephrectomy to be performed before ureterectomy, is to address the distal ureter with a stapler as described above and then reposition the patient into the lithotomy position.

Use a resectoscope and a rollerball to ablate the intramural ureter until the staple line is visible.

### Pluck Technique

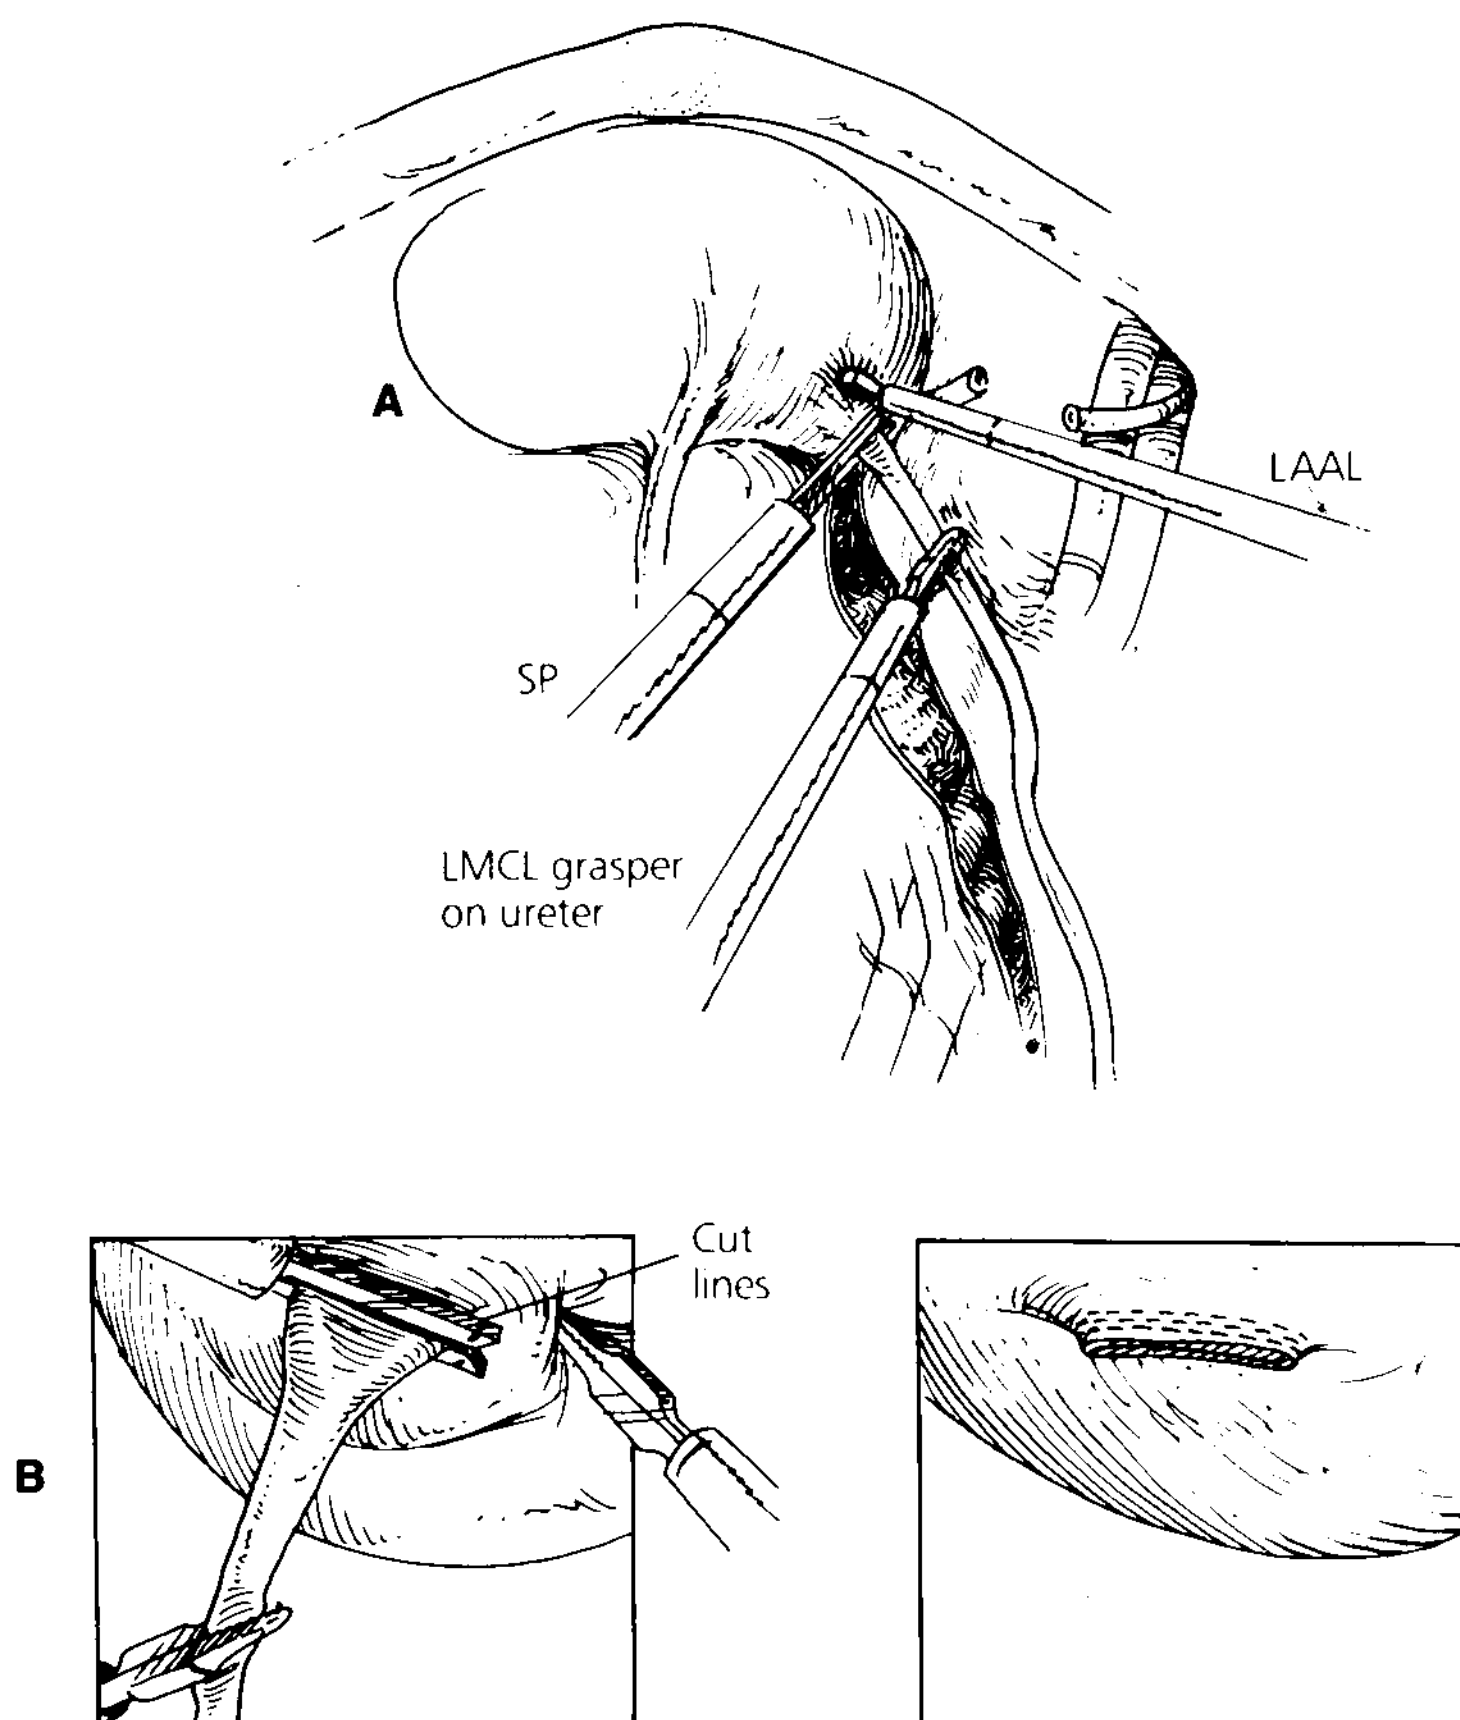

Place the patient in the lithotomy position prior to performing nephrectomy. Insert a ureteral catheter into the targeted ureteral orifice cystoscopically. Incise the ureteral orifice and surrounding bladder cuff with a Collins knife to the level of retroperitoneal fat. Alternatively, use a loop resectoscope to resect the orifice and intramural ureter. Place a 24Fr urethral catheter to gravity drainage. Take the patient out of lithotomy position and perform the nephrectomy. Dissect the ureter distally, and with cephalad traction on the ureter detach it from the bladder. Leave the urethral catheter in place for 7 days, removing it after cystography or a voiding trial.

A modification of this technique is to pass a 7Fr, 11.5-mm balloon occlusion catheter into the renal pelvis, snugging it down at the ureteropelvic junction, to minimize urine extravasation. Mitomycin can be instilled into the renal pelvis through this catheter (9).

## Combined Open and Endoscopic Technique

### Ureteral Intussusception (Stripping) Technique (1)

Initially, in the lithotomy position, insert either a stone basket or ureteral catheter into the targeted proximal ureter. Reposition the patient and perform nephrectomy, dissecting

**FIGURE 19.4** **A:** The endoscopic stapler is placed across the ureterovesical junction. **B:** Close-up view of the stapler across the ureterovesical junction. **C:** Staples are seen securing the bladder cuff. (Adapted from Clayman RV. Laparoscopic ureteral surgery. In: Clayman RV, McDougall EM, eds. *Laparoscopic urology*. St. Louis, MO: Quality Medical Publishers, 1993:360.)

**FIGURE 19.5** The proximal ureter is divided and secured to the ureteral catheter. The ureter is then intussuscepted as the catheter is removed. (Adapted from Angulo JC, Hontoria J, Sanchez-Chapado M. One incision nephroureterectomy endoscopically assisted by transurethral stripping. *Urology* 1998;52:204.)

the ureter to the pelvic brim. Clip the proximal ureter, and then divide the ureter cephalad to the basket/ureteral catheter. Advance the stone basket into the retroperitoneum and open and close it to entrap the ureteral wall, or, if a ureteral catheter has been used, tie it to the ureter with a 0-silk suture (Fig. 19.5). Apply gentle traction to the stone basket/ureteral catheter to intussuscept the ureter into the bladder (Fig. 19.6). Then use a Collins knife mounted on a resectoscope inserted transurethrally (after repositioning into the lithotomy position) to incise the bladder cuff around the intussuscepted ureter while exerting traction on the stone basket/ureteral catheter out of the urethra.

**FIGURE 19.6** The catheter is retracted through the bladder wall and urethra. (Adapted from Angulo JC, Hontoria J, Sanchez-Chapado M. One incision nephroureterectomy endoscopically assisted by transurethral stripping. *Urology* 1998;52:204.)

Place a urethral catheter for 7 days, following a normal cystogram or voiding trial. This technique should not be used for distal or midureteral tumors.

---

## OUTCOMES

---

Survival after nephroureterectomy is strongly dependent on the grade and stage of the tumor (7). Five-year survival rates following a radical nephroureterectomy for low-grade tumors are 40% to 87%, compared to 0% to 33% for high-grade disease. Five-year survival estimates according to stage are as follows: stage Tis/Ta/T1, 60% to 90%; stage T2, 43% to 75%; stage T3, 26% to 33%; stage T4/N+/M+, 0% to 5% (7).

---

## COMPLICATIONS

---

Early complications include hematuria, retroperitoneal hematoma, and retroperitoneal abscess. Ureteral intussusception may be technically unsuccessful in 10% of patients. Prolonged urinary extravasation can in general be managed conservatively with urethral catheter drainage. Although not yet reported clinically, there is the potential for calculi to form on the staple line when the ureteral unroofing technique is used, or for urothelial cells to survive in between the staples. Other factors to be considered in the choice of technique include the risk of tumor spillage, the addition of a bladder incision, the timing of the ureterectomy relative to nephrectomy, the need for repositioning, the approach to nephrectomy that is desired, and surgeon preference. Of these, the potential for tumor cell spillage is probably the most important with regard to outcome. The technique to excise the distal ureter is probably not a factor for recurrence as long as there is no spillage of tumor cells in the retroperitoneum. Of note, isolated retrovesical recurrences following “pluck” ureterectomy have been reported. There is not yet enough reported experience with the newer endoscopic techniques to allow reliable comparison of the risk of local, regional, and port site recurrences among the new techniques and the standard open surgical techniques, although one group has reported a greater intravesical recurrence rate after the intussusception technique compared to open surgical bladder cuff (8).

## CHAPTER 20 ■ VESICO VAGINAL FISTULA

HELEN G. ZAFIRAKIS AND O. LENAINE WESTNEY

A vesicovaginal fistula (VVF) is an epithelialized or fibrous communication between the bladder and vagina. Physically, psychologically, and socially, it is a source of major distress for the patient contending with urine leakage from the vagina. Documentation of VVFs exists from as early as 1550 B.C. in the Eber papyrus of ancient Egypt (10). In 1845 James Marion Sims, considered the father of American gynecology, began his exploration into the challenges of treating the condition in Montgomery, Alabama (10). He is credited with developing the foundation of VVF repair and establishing sound surgical principles for repair of fistulas.

The causative factors leading to VVF formation can be broadly categorized into congenital and acquired (Table 20.1). The majority of cases fall into the iatrogenic and obstetric trauma subcategories. In underdeveloped countries, the leading cause of VVFs is obstetric trauma, in which prolonged labor causes ischemic pressure necrosis of the bladder and anterior vaginal wall. In contrast, obstetric trauma accounts for only 5% of VVFs in nations where modern healthcare is present. The leading cause of VVFs in industrialized countries is iatrogenic surgical trauma, accounting for 82% to 91% of VVFs. Ninety-one percent are due to gynecologic procedures, with 80% due to abdominal hysterectomy (9). The incidence of VVF after transabdominal hysterectomy is 1.0 in 1,000, as opposed to 0.2 in 1,000 after transvaginal hysterectomy. The incidence is highest (2.2 in 1,000) with laparoscopic hysterectomy (7). The most common location for a posthysterectomy VVF is the apex of the vaginal vault or “cuff” corresponding to an intravesical location just superior to the trigone (9). Theoretically, the fistula develops secondary to the unintentional inclusion of full-thickness bladder wall during closure

of the vaginal cuff, an unrecognized bladder injury adjacent to the cuff suture line, or cuff abscess.

## DIAGNOSIS

---

Classically, the postoperative VVF presents with “continuous” urine leakage from the vagina. The time of presentation peaks at 7 to 10 days after surgery but may be variable, with some patients presenting immediately after catheter removal, ranging from 4 to 6 weeks after surgery (7). In the early postoperative period, there may also be associated ileus and abdominal pain due to intraperitoneal urine extravasation. VVFs due to pelvic irradiation usually have a delayed presentation, developing many months or years posttreatment due to progressive obliterative endarteritis causing tissue ischemia and necrosis.

The key to diagnosis of a VVF is a high suspicion. Often, a complete history and physical examination expose the pathology. In the case of less obvious fistula, a dye test is utilized to more clearly visualize the passage of fluid through the fistula. In its simplest form, a saline and dye (indigo carmine or methylene blue) mixture is instilled into the bladder via a Foley catheter while inspecting the vagina for leakage or staining of a previously placed tampon. The failure to identify any discoloration of the tampon may indicate a small fistula or ureterovaginal fistula. The second level of testing requires reinsertion of a vaginal gauze or tampon followed by administration of 5 mg indigo carmine intravenously to determine whether the source is ureteral. Dye from a ureterovaginal fistula may be present on the first gauze inspection prior to intravenous (IV) indigo carmine if there is vesicoureteral reflux, which can be determined with a voiding cystourethrogram (VCUG). An alternative to IV dye injection is oral phenazopyridine hydrochloride, but it requires several hours of lead time before examination.

All patients should have an IV pyelogram (IVP) for uppertract evaluation. Abnormalities to look for include extravasation into the vagina or peritoneal cavity or a displaced or partially obstructed ureter. In patients with VVF, up to 25% will have hydroureteronephrosis, with 10% having a concomitant ureterovaginal fistula (6). In patients with ureteral pathology, a retrograde pyelogram is warranted to evaluate for ureterovaginal fistula if the IVP is not definitive.

Cystoscopy is performed to localize and evaluate the VVF, which often has surrounding edematous mucosa. The size and number of VVFs, their location in relation to the ureteral orifices, any lesions such as foreign bodies (i.e., sutures), tumors, and tissue quality must be noted. If there is a history of malignancy, biopsy of the VVF is indicated to rule out recurrent tumor. Vaginoscopy is performed simultaneous with cystoscopy to assess the vaginal aspect of the fistula. If IVP and retrograde pyelograms are inconclusive, then a fistulogram may be performed transvaginally.

A urodynamic study is recommended to look for other factors that may contribute to the urinary incontinence and may require surgical correction (augmentation cystoplasty, incontinence surgery) with the VVF repair simultaneously. Bladder compliance, capacity, and leak point pressure should be assessed if possible.

---

## INDICATIONS FOR SURGERY

---

The issue of how long to wait before attempting surgical repair of a VVF has long been debated. By tradition, VVF repair is delayed 3 to 6 months to allow inflammation to resolve. In

cases where a VVF is due to a complicated operation or after obstetric trauma, this rationale holds true. However, independent studies by Blaivas et al. and Blandy et al. demonstrated comparable results with early (6 to 12 weeks) repair in cases related to an uncomplicated hysterectomy (1,2). Once surgical repair is decided upon, another issue that has to be considered is the approach: transvaginal, transvesical, or transabdominal. Often, the approach is the one that the surgeon is most experienced in performing. Advantages of the transvaginal approach are less blood loss, shorter hospital stay, avoidance of a laparotomy, and thus decreased morbidity. Many reserve the transabdominal approach for those patients requiring concomitant intra-abdominal surgery (ureteral reimplantation, augmentation cystoplasty) or those patients with a narrow and deep vagina causing poor exposure to the VVF. However, Dupont and Raz reported that nearly all VVFs can be accessed and repaired transvaginally (3).

---

## ALTERNATIVE THERAPY

---

Upon diagnosis, a trial of conservative therapy is started depending on fistula size. Conservative therapy consists of prolonged bladder drainage with a Foley catheter, anticholinergic agents to prevent bladder spasms, antibiotics, and estrogen if the patient is postmenopausal. Successful closure of a VVF via conservative therapy can be expected only in those 3 mm in diameter or less.

Other adjunctive minimally invasive treatments include attempts to destroy the epithelial lining of the VVF with fulguration (using electrocautery or laser) and use of occlusive substances. Since the late 1980s, glue materials have been used to treat a variety of fistulas. There are two main types of glues used to treat VVF: fibrin, which is a biologic product, and synthetic cyanoacrylic glue. Fibrin glue has the longest reported follow-up.

There have been a few small series reported on the use of fibrin glue to treat VVF that demonstrate a good success rate. Schneider et al. reported on six cases using endoscopic techniques and found a 66% closure rate using glue compared with 88% success with a traditional repair (11). Although it may involve more than one injection to treat the fistula, fibrin glue promotes healing, is biodegradable, and has been used successfully in a large variety of urologic fistulas, including those caused by irradiation.

Synthetic cyanoacrylic glue is a relatively newer product in occlusion therapy of fistulas. It polymerizes in 90 seconds once injected and can be used without difficulty in a wet environment such as the bladder; this, together with its antimicrobial properties, makes it an attractive option for the treatment of VVF. The best results are achieved in long fistulas <1 cm in diameter. Application can be performed both endovaginally and endoscopically, with the Foley catheter removal between 48 hours to 3 weeks depending on the size of the fistula. Generally, follow-up cystography is performed in 1 to 3 months.

The benefits of using occlusion therapy to treat VVFs include the ability to treat the fistula earlier rather than expecting the patient to live with the distressing symptoms of the fistula for up to 3 months while awaiting definitive surgery. Additionally, there is very low morbidity associated with using occlusion therapy; there have been no reported complications

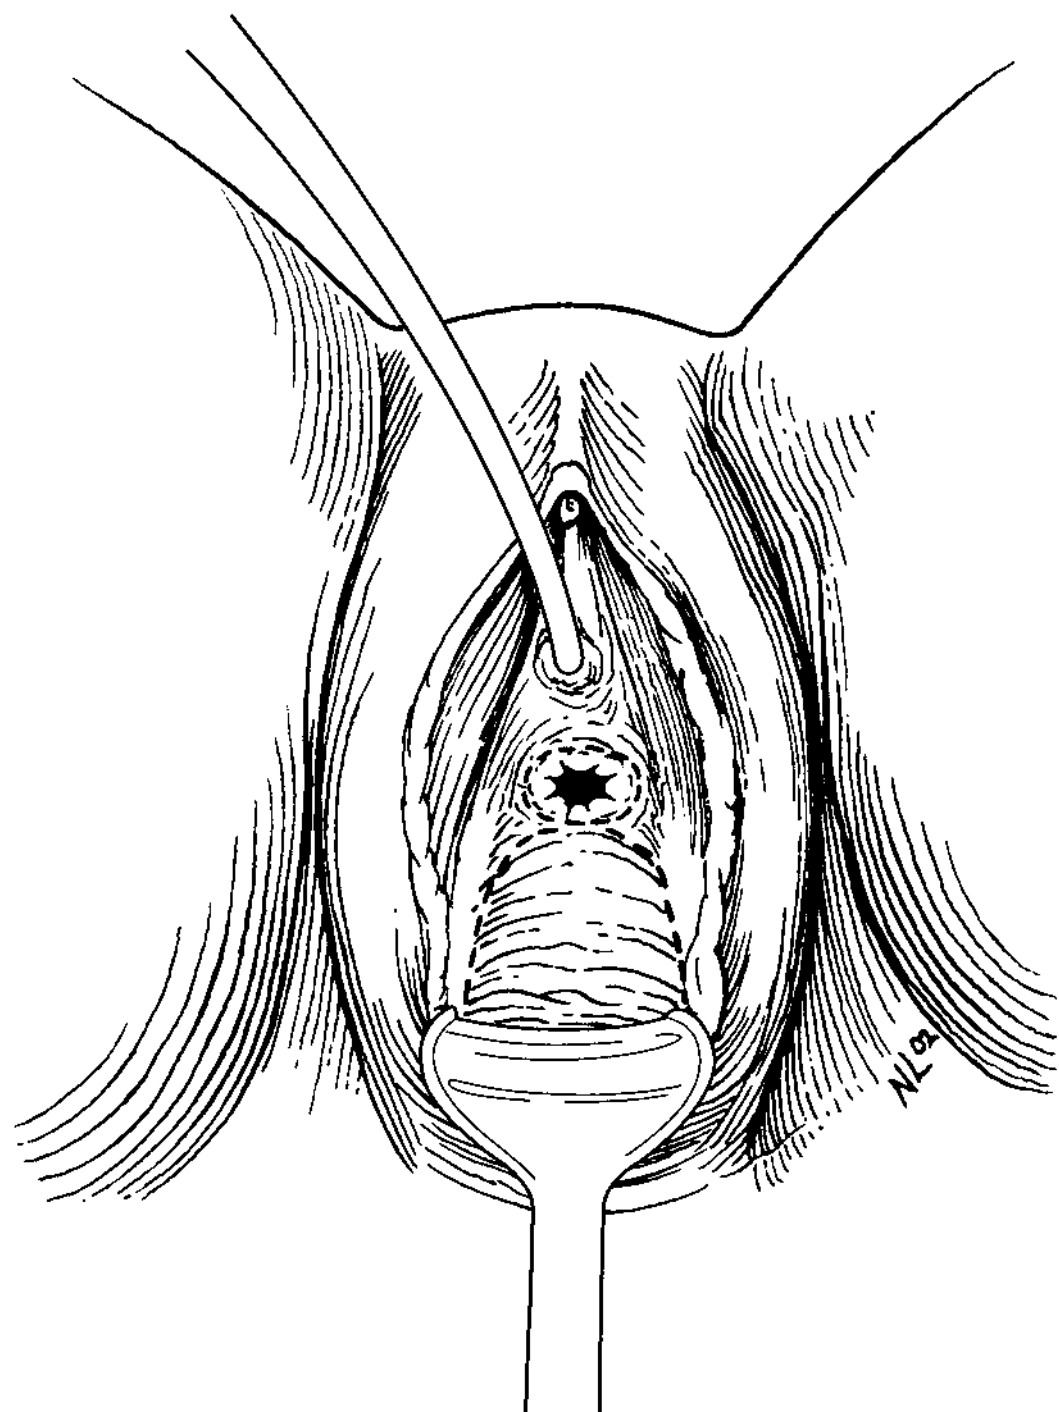

from occlusion therapy treatment of VVF, other than the occasional necessity of removing excess glue endoscopically. Importantly, it does not preclude other forms of treatment if it is unsuccessful. Although occlusion therapy appears to be safe and efficacious in selected, small VVFs, more longer-term and randomized studies are needed to evaluate its durability.

## SURGICAL TECHNIQUE

### Transvaginal Approach

The patient is placed in the dorsolithotomy position. If a narrow vagina is present or the VVF site is high lying, a Schuchardt posterolateral relaxing incision at the 4 o'clock position of the vaginal introitus and distal vaginal wall may be performed to improve exposure. A suprapubic catheter may be placed with a Lowsley retractor, and a urethral Foley catheter is placed. The labia minora are sutured to the inner thigh and a weighted vaginal speculum placed. The VVF is dilated to place an 8Fr Foley catheter. Applying gentle traction to the catheter aids in exposure and dissection of the VVF.

After submucosal injection of a vasopressin mixture (10 U per 100 mL normal saline), lidocaine with 1% epinephrine, or saline to elevate the anterior vaginal mucosa, the VVF is circumferentially incised. A posteriorly based inverted U-shaped incision is made with the apex continuous with the VVF incision (Fig. 20.1). If the VVF is situated deep in the vaginal vault, an anteriorly based U-shaped incision is utilized. The vaginal mucosa is dissected away from the perivesical fascia to form vaginal flaps anterior and posterior to the VVF (Fig. 20.2). Unless nonviable, the fistulous tract is not excised as excision

**FIGURE 20.1** The apex of the vaginal inverted-U incision is continuous with the circumferential fistula incision. (Modified from Raz S, Bregg KJ, Nitti VW, et al. Transvaginal repair of vesicovaginal fistula using a peritoneal flap. *J Urol* 1993;150:56–59.)

**FIGURE 20.2** The vaginal mucosa is dissected away from the perivesical fascia. (Modified from Raz S, Bregg KJ, Nitti VW, et al. Transvaginal repair of vesicovaginal fistula using a peritoneal flap. *J Urol* 1993;150:56–59.)

enlarges the defect and risks injury to the intramural ureter. Left intact, the fistula tract also provides strength to the VVF closure, helping decrease the risk of VVF repair disruption due to bladder spasms.

The fistula is closed in two nonoverlapping, perpendicular layers to prevent fistula recurrence. The first layer closes the fistula with interrupted 4-0 polyglycolic acid sutures, incorporating the vaginal wall overlying the VVF, the fistula tract, and the partial thickness of the bladder wall (Fig. 20.3). The second layer, using 2-0 polyglycolic acid sutures, imbricates the perivesical fascia and the deeper musculature of the bladder over the first layer in a tension-free fashion. The repair is checked for leaks by instilling indigo carmine into the bladder. The vaginal wall is advanced over the VVF repair and closed with an interlocking, running 2-0 polyglycolic acid suture. A Betadine-soaked vaginal pack is placed.

If there is any concern about the repair, an interposing layer may be placed between the vaginal wall and bladder. The most common options are the Martius labial fat pad and the peritoneal flap. Alternative tissues include labial, vaginal wall, gluteal, and gracilis muscle flaps.

The Martius labial fat pad provides neovascularity and lymphatic drainage, fills dead space, and enhances granulation tissue formation. The flap is harvested by making a vertical incision on the labium majus; the underlying fibrofatty tissue is mobilized. The anterior portion of the graft is tied off (sacrificing the blood supply from the external pudendal artery), leaving the fibrofatty pad supplied by its posterior blood source: the posterior labial artery from the internal pudendal artery. A tunnel is developed from the vaginal incision to the labium majus; the labial fat pad is transferred through the tunnel to cover the VVF repair and secured in place with

**FIGURE 20.3** Closure of the first layer, including the fistulous tract and partial-thickness bladder wall. (Modified from Raz S, Bregg KJ, Nitti VW, et al. Transvaginal repair of vesicovaginal fistula using a peritoneal flap. *J Urol* 1993;150:56–59.)

interrupted 3-0 polyglycolic acid sutures (Fig. 20.4). The tunnel must be sufficiently sized to prevent constriction of the fat pad's blood supply. The labial incision is closed with a 1/4-in. Penrose drain in place unless the graft bed is dry (Fig. 20.5).

**FIGURE 20.4** Using a right-angle clamp, the Martius flap is passed from the labial incision to the vaginal incision.

**FIGURE 20.5** Closure of the labial and vaginal wall incisions.

Another effective method is peritoneal interposition as described by Dupont and Raz for routine use in fistula repair (3). With further posterior dissection of the anterior vaginal wall from the bladder, the glistening surface of the peritoneum in the anterior cul-de-sac is exposed. Without entering the intraperitoneal space, the peritoneum is mobilized from the posterior bladder wall to bring it down into the vagina and suture it over the VVF repair site (Fig. 20.6). The peritoneal flap has a 96% success rate when used in transvaginal VVF repair (4).

The vaginal pack is removed on postoperative day 1. The patient is given perioperative antibiotics and anticholinergics to prevent bladder spasms. Two weeks postoperatively the urethral catheter and suprapubic tube are removed if the

**FIGURE 20.6** Interposition of the peritoneum between the bladder and vagina. (Modified from Raz S, Bregg KJ, Nitti VW, et al. Transvaginal repair of vesicovaginal fistula using a peritoneal flap. *J Urol* 1993;150:56–59.)

cystogram reveals no persistent fistula or extravasation. If a fistula is still present, bladder drainage continues for another 2 to 3 weeks and the cystogram repeated at that time.

### Transabdominal (Intraperitoneal) Approach

The patient is placed in a low lithotomy position. Cystoscopy is performed to visualize and cannulate the VVF with a 5FR to 6Fr ureteral catheter or guide wire. If unable to pass the guide wire through the VVF transvesically, it is passed from the vaginal side into the bladder, grasped cystoscopically, and brought out through the urethra.

A midline infraumbilical incision is made; the rectus muscle is split midline to enter the pelvis. The bladder is opened with a midline vertical cystotomy between two stay sutures (Fig. 20.7). The VVF is identified with the guide wire exiting its opening into the bladder. The urethral end of the guide wire is pulled into the cystotomy incision. The VVF's position in relation to the ureteral orifices is noted and the ureters are cannulated with stents, if necessary. If there is any difficulty identifying the orifices due to local inflammation, IV indigo carmine may be administered.

Entering the peritoneal cavity, the dissection along the posterior bladder wall is carried out until the guide wire traversing the VVF is palpated, indicating the junction between the vagina and bladder. With a sponge stick or endoanal sizer in the vagina to help delineate the vagina, the bladder is carefully dissected away from the vagina. Wide mobilization of the bladder and vagina to allow tension-free closure of each side of the VVF is critical. The dissection bisects the fistula tract without excising the tract extending 1.5 to 2.0 cm beyond the

**FIGURE 20.7** The bladder is opened in the midline without extending the cystotomy to the fistula.

**FIGURE 20.8** After dissecting between the bladder and vaginal, both defects are closed in two layers.

VVF, allowing for tension-free closure (Fig. 20.8). Using interrupted 3-0 polyglycolic acid sutures, the vaginal defect is closed in two nonoverlapping layers. The bladder defect is also closed in two nonoverlapping layers with running 4-0 polyglycolic acid and 3-0 interrupted sutures.

After the bladder and vaginal fistulous defects are closed, attention is turned to developing an omental pedicle flap to interpose between the bladder and vagina. Evans et al. recommended routine use of an interposition flap during intra-abdominal VVF repair, noting a success rate of 100% with a flap versus 63% to 67% without a flap (5). Not only does the interposition flap add an extra layer to the VVF repair to prevent recurrence, but it also increases lymphatic drainage and decreases the risk of infected fluid collection. Alternatives to omentum include lateral pelvic peritoneum, pericolic or mesenteric fat, and free bladder mucosal graft.

The omentum is identified, and an omental flap based on the more reliable right gastroepiploic artery is developed (Fig. 20.9). The flap is brought down to the pelvis and placed between the bladder and vagina, covering the fistula repair (Fig. 20.10). The graft is secured in place with interrupted 3-0 polyglycolic acid sutures.

With the VVF repair completed, a suprapubic catheter and urethral Foley catheter are placed with 5-mL balloon inflation each. In patients with prolonged large fistula, the bladder capacity is reduced due to the constant drainage. Therefore, the placement of two fully inflated balloons in combination with irritation from the incisions may lead to intensification of bladder spasms. The vertical bladder incision is closed in two layers with 2-0 polyglycolic acid sutures. A closed pelvic drain is also placed. Postoperative care is similar to that after transvaginal VVF repair.

**FIGURE 20.9** Development of an omental pedicle flap based on the right gastroepiploic artery.

**FIGURE 20.10** Placement of the distal end of the omental graft posterior to the detrusor covering the repairs.

An alternative to the above intra-abdominal technique is the standard O'Connor technique. The bladder is bivalved posteriorly from the dome to the level of the VVF. Then, the VVF is excised entirely (Figs. 20.11 through 20.13). After further dissection of the bladder from the vagina, the vaginal defect is closed in two nonopposing layers with interrupted absorbable

**FIGURE 20.11** Cystostomy extended down to the fistula site.

**FIGURE 20.12** Circumscribing incision around the fistula.

**FIGURE 20.13** Sharp excision of the fistula tract.

**FIGURE 20.14** Relation of the cystostomy to the vaginal closure.

sutures (Fig. 20.14). An interposition flap is tacked over the vaginal closure and the bladder is closed. The first technique is slightly more difficult in that the fistula is approached posteriorly and transected between the bladder and vagina. However, the advantages are that the smaller cystostomy is separated from the repair.

### Transvesical (Extraperitoneal) Approach

The advantage of this approach is that one can avoid entering the peritoneal cavity. Through a midline infraumbilical incision, the bladder is identified and opened with a midline vertical incision. The VVF is located and the ureteral orifices are cannulated with stents. The fistulous opening is circumscribed carefully with a scalpel, incising only the thickness of the bladder mucosa and staying out of the vagina. This is performed to leave the fistula tract intact, along with a 2- to 3-mm ring of bladder mucosa. With sharp dissection directed radially away from the VVF for 1 to 2 cm, the bladder is mobilized away from the vagina (Fig. 20.15). To help with exposure, a Foley catheter may be placed transvesically in the VVF for upward traction.

With interrupted 3-0 polyglycolic acid sutures, the fistula and vagina are closed together. Next, the bladder muscle is closed perpendicular to the fistula and vaginal closure, also with 3-0 polyglycolic acid sutures. Finally, the bladder mucosa is closed with running 4-0 polyglycolic acid sutures. A suprapubic cystostomy catheter and a urethral Foley catheter are placed, and the bladder is closed in two layers with 2-0 polyglycolic acid sutures. Postoperative care is similar to that previously described.

### Laparoscopic and Robot-Assisted Repair of Vesicovaginal Fistulas

The decision to repair a VVF using a transabdominal approach is controversial. High VVFs and those that lie close to the ureteric orifices, or those with failed vaginal repair, may be better served by using a transabdominal approach because of its higher success rate. This approach is, however, associated

**FIGURE 20.15** Transvesical development of the plane between the bladder and vaginal walls.

with a higher morbidity risk and longer recovery time for the patient. Also, the area of the fistula may be difficult to dissect out without performing a long cystostomy. With the development of minimally invasive surgical techniques, the laparoscope has been applied to the repair of the VVF. Its limitations have centered mostly around dissection of adhesions and fibrosis around the fistula and application of sutures in a tension-free manner. The development of robot-assisted laparoscopy has offset many of the challenges faced in the surgical repair of the VVF.

The potential benefits offered by laparoscopic and robotic repair of these fistulas include shorter recovery time, reduced morbidity, less blood loss, better cosmesis, and better visualization of the fistula area, reducing the need for extensive dissection around the fistula. The surgeon is also able to perform other concomitant procedures. As the operation is traditionally performed using a transperitoneal approach, it is easily amenable to laparoscopic techniques. The first complete transabdominal laparoscopic repair of a VVF and robotic repair of a VVF were performed in 1994 and 2005, respectively. Evidence for the efficacy and safety of this approach is based a small series of nonrandomized reports and case reports. In Sotello's series, 14 out of 15 patients were cured using the laparoscopic approach at a mean follow-up of 26 months (12).

The technical advances afforded by the laparoscopic technique include the need for a minimal cystostomy, often in a reverse tennis racquet fashion with minimal bladder mobilization and magnified anatomy such that it is easier to see the margins of the fistula. Robotic assistance has improved the fatigue factor of the surgeon and has allowed improvement in applying the tension-free sutures to the bladder and vagina. It also improves the surgeon's depth perception.

Either a four- or five-port system is used via a transabdominal approach. The fistula may be catheterized to reduce loss of pneumoperitoneum, and the bladder is catheterized after careful

localization of the fistula using vaginoscopy and cystoscopy. If the fistula is close to the ureteric orifices, the ureters are cannulated also, to allow easier localization. Minimal cystotomy is performed around the fistula, and the fistula is repaired in the usual fashion. Tissue interpositioning can also be applied, usually using omentum. Average operation times run around 140 to 233 minutes, with an average length of stay of approximately 4 days. The Foley catheter is removed on days 10 to 14, preceded by cystography.

Laparoscopic and robotic techniques can be applied safely and effectively in the treatment of supratrigonal and large VVFs. This technique offers many potential benefits to the patient; however, there remains a paucity of randomized studies to quantitate its true effectiveness. It is also an evolving area, with the potential for further advances in surgical technique.

---

## OUTCOMES

---

### Complications

---

Clearly, the most problematic complication is recurrent or persistent fistula. The catheter is replaced for several weeks and the cystogram repeated. If the fistula fails to resolve or improve, then endoscopic evaluation—vesical and vaginal—is performed

in preparation for a second procedure. For recurrent fistulas complicated by prior pelvic irradiation, a conservative approach is wise, waiting 6 to 12 months before attempting repair. Frequency, urgency, and urge incontinence in the early preoperative period are treated symptomatically with anticholinergic therapy. These, however, are expected due to bladder decompression and trigonal/suture line irritation. Residual incontinence must be evaluated with physical examination and fluoroscopic urodynamics. Occult or de novo stress urinary incontinence occurring in 10% to 12% of patients requires separate treatment after recovery from the VVF repair. Ureteral obstruction, prolonged ileus, and bowel obstruction are uncommon.

---

## Results

---

A review of the VVF series from the last two decades demonstrates the success rate of transvaginal and transabdominal repairs to be 92.5% to 96% and 85% to 100%, respectively (1,2,4,8). Therefore, when the appropriate approach is selected based on the etiology, location, concomitant pathologies, and surgeon experience, excellent results can be expected in the great majority of patients. However, in those who have failed multiple repairs due to severe tissue compromise secondary to radiation or who have developed the end-stage detrusor, diversion may be the only alternative.

# CHAPTER 21 ■ ENTEROVESICAL AND RECTOURETHRAL FISTULAS

KENNETH W. ANGERMEIER, AARON J. MILBANK, AND ERIC A. KLEIN

An enterovesical fistula is an extra-anatomic, epithelialized connection between the intestines and the bladder. This chapter will describe the etiology, evaluation, and management of enterovesical fistulas and the less common rectourethral/rectovesical fistulas. The last half-century has seen a dramatic change in the management of enterovesical fistulas with a reduction in morbidity and mortality.

---

## ENTEROVESICAL FISTULAS

---

In unselected series, the most common etiology of enterovesical fistulas is diverticulitis. In seven series of patients with enterovesical fistulas, the etiology was diverticulitis in 53% (range, 39% to 77%). Moreover, it has been reported that

TABLE 21.1

**SPECIFIC CAUSES OF VESICOENTERIC FISTULAS**

<b>INFLAMMATORY</b>
Diverticulitis
Crohn disease
Ulcerative colitis
Appendiceal/pelvic abscess
Meckel diverticulum
Tuberculosis
Actinomycosis
Bladder malakoplakia
Colonic duplication
<b>NEOPLASTIC</b>
Carcinoma of sigmoid colon and rectum
Lymphomas
AIDS-related lymphomas
Carcinoma of cervix
Leiomyosarcoma of bladder
<b>TRAUMATIC</b>
Gunshot wounds
Penetrating injuries
Pelvic fractures
Transurethral or open prostatectomy
Vesical formalinization
Pelvic external beam radiation
Prostatic brachytherapy
Cryoablation of the prostate
Transurethral microwave thermotherapy
<b>PELVIC</b>
Gynecologic cancer
Foreign body
AIDS, acquired immunodeficiency syndrome.

10% of surgically treated cases of diverticulitis are associated with a colovesical fistula. There is a significant male predominance, a finding that has been attributed to a “protective barrier” provided by the uterus and broad ligament (16).

Other common causes of enterovesical fistula are pelvic malignancy (21%) and Crohn disease (15%). Crohn disease patients tend to present at a younger age than those patients with diverticular or malignant etiologies. Radiation injury is an infrequent cause of enterovesical fistulas. Most enterovesical fistulas following pelvic radiotherapy are secondary to recurrent disease. The etiologies of enterovesical fistulas are listed in Table 21.1.

---

## Diagnosis

---

Although enterovesical fistulas are almost always secondary to extravescical pathology, the presenting symptoms are in general urinary in nature. The most common presenting symptom

is pneumaturia, reported in 50% to 85% of patients, although some series report irritative voiding symptoms in as many as 71% to 93%. Fecaluria is reported in 21% to 68% of patients with enterovesical fistulas and tends to be more common with diverticular and malignant fistulas. Other symptoms include hematuria, abdominal pain, diarrhea, urinary retention, perineal pain, hematochezia, and fever. Urine in the stool is rarely reported with enterovesical fistulas; these fistulas tend to be unidirectional, with flow from the high-pressure intestinal tract to the low-pressure urinary tract.

Physical signs of enterovesical fistulas are subtle or absent. Abdominal tenderness and a palpable mass may be reported in as many as 35% and 27% of patients, respectively, and are not specific. In patients with rectal disease, a rectal mass or rectal tenderness may be present. Rarely, an enterovesical fistula may present as epididymitis. In general, physical findings are most commonly seen in patients with Crohn disease.

Urinalysis discloses pyuria, and cultures are positive in 80% to 100% of cases of enterovesical fistula. *Escherichia coli* is the most commonly identified organism, and approximately one-third to two-thirds of cultures show polymicrobial growth.

The diagnosis of an enterovesical fistula is clinical, and in some instances, despite numerous radiographic studies, the first objective demonstration of the fistula is at laparotomy. Nonetheless, numerous studies have been described to aid in the diagnosis and/or localization of fistulas. Functional studies include the charcoal test, administration of visible dyes (methylene blue, indigo carmine), and the Bourne test, in which urine voided after a barium enema is radiographed for the presence of barium. The charcoal test involves the ingestion of nonabsorbable charcoal followed by the observation of charcoaluria. Although these tests have been reported to have sensitivities of 80% to 100%, they are rarely performed because they provide no localizing anatomic information, and the information they do provide is usually evident from the patient's history.

Cystoscopy is the most common abnormal investigation in patients with enterovesical fistulas, although direct observation of a fistula is relatively unlikely. Approximately 90% of cystoscopies show at least indirect evidence of the fistula, most commonly bullous edema, and in 33% to 46% of cystoscopies the fistulous opening is identified.

Barium enema has been a commonly utilized study in the evaluation of enterovesical fistulas, with some series reporting 100% abnormal studies and fistula identification in as many as 16% to 63% of patients. Colonoscopy rarely demonstrates a fistulous tract, but the study is important in the evaluation of potentially malignant fistulas.

Computerized tomography (CT) has supplanted most of the older imaging studies in the evaluation of suspected enterovesical fistulas. Although the fistula tract may be identified in some cases, indirect evidence of the fistula, including air in the bladder, focal bladder and bowel wall thickening, and closely apposed bowel and bladder, may be present in 85% to 100% of cases. CT also provides important information in the evaluation of patients with Crohn disease and colorectal carcinoma. CT cystography in our institution has replaced many other studies, including standard cystography, intravenous pyelography (IVP), and magnetic resonance imaging (MRI).

---

## Indications for Surgery

---

Given the symptomatic nature of enterovesical fistulas and their association with recurrent urinary tract infections and sepsis, most fistulas should be addressed surgically. Over the course of the past 30 years, a one-stage operation has become the favored procedure because of reports of fewer complications and lower mortality. It has been demonstrated that a one-stage procedure may be safely performed in the setting of an abscess or purulent peritonitis provided that the inflammatory focus can be removed and the bowel anastomosis can be “quarantined from any inflammatory nest” (16). In general, diverticular disease is particularly well suited to one-stage procedures because the fistulous process is either chronic or, if acute, controllable with antibiotics.

A two-stage procedure should be considered in patients who have an obstructed bowel, have residual significant intra-abdominal inflammation, are significantly ill, and in whom a healthy anastomosis is unlikely (due to poor blood supply or tension at the anastomosis). The two stages (for colovesical fistulas) may consist of resection with the Hartmann pouch and end colostomy followed by reanastomosis or resection, anastomosis, and transverse colostomy followed by reversal of the colostomy. Fistulas secondary to radiation injury in general require multiple staged repairs and, frequently, permanent bladder and bowel diversion (10).

---

## Alternative Therapy

---

Nonoperative management may be considered in patients who are extremely debilitated. There are a few reports of spontaneous closure of fistulas with medical management. This spontaneous resolution has been reported with traumatic fistulas and in a subset of fistulas secondary to Crohn disease. Placement of bowel stents and endoscopic clipping of the colonic terminus of the fistula have also been reported for patients who are too ill to undergo open surgical procedures. Experimental evidence suggests that enterovesical fistulas, when chronic, are physiologically well tolerated (5). Amin et al. followed a cohort of four patients with diverticular colovesical fistulas who refused surgery; with 3 to 14 years of follow-up, there were no significant complications (1).

---

## Surgical Technique

---

### One-Stage Surgery

On the day prior to the operation, a mechanical bowel preparation is administered and the patient is maintained on a clear liquid diet. Gram-negative and anaerobic coverage is provided by administering a third-generation cephalosporin (ceftizoxime) and metronidazole 1 hour prior to the surgical procedure.

Most fistulas are best approached via a midline incision extending from the pubic ramus to the umbilicus (Fig. 21.1). This incision may be extended cranially as needed. Some authors prefer an infraumbilical transverse incision. The peritoneal cavity is entered and adhesiolysis is performed. The point of the fistula is identified. The remainder of the procedure is determined by the disease causing the fistula and intraoperative findings. In the setting of diverticular fistulas, the diseased colon is resected and

an anastomosis is performed suturing normal bowel to normal bowel without tension and with adequate blood supply. Patients with Crohn disease often have multiple fistulas not involving the urinary tract and require multiple resections or stricturoplasties. With diverticular disease, the fistula may often be “pinched off” from the bladder with curettage of the fistula tract. For malignant fistulas, the requisite oncological procedure is performed and the malignant fistula tract is excised. Partial cystectomy may be required for large or malignant fistulas; radical cystectomy is in general not required.

Closure of small bladder fistulas is not essential. Large defects should be closed in two layers using absorbable sutures. In the setting of ureteral involvement, ureteroneocystostomy may be required. Ideally, an omental flap should be interposed between the anastomosed bowel and the bladder. When an omental flap is not constructable, a peritoneal flap may be used. Suprapubic catheters and drainage of the extraperitoneal space are optional. In general, a urethral catheter is maintained until 1 week after surgery. Complete healing of the bladder defect may be confirmed with a cystogram prior to removal of the catheter. The aforementioned procedure has also been performed laparoscopically with good results.

---

## Outcomes

---

### Complications

Major complications of operative repair of enterovesical fistulas include death (0% to 5%), myocardial infarction (2% to 6%), anastomotic leak (0% to 5%), enterocutaneous fistula (0% to 1%), wound infection (0% to 21%), wound dehiscence (0% to 2%), pulmonary embolus (0% to 1%), deep vein thrombosis (0% to 1%), prolonged ileus (0% to 5%), and urine leak (0% to 3%) (4,11,15,16). One of the largest surgical series (104 patients) reported a 6.4% overall complication rate with no operative mortality (9). Significantly greater morbidity is observed in series focusing on radiation-induced and malignant fistulas (6,10).

### Results

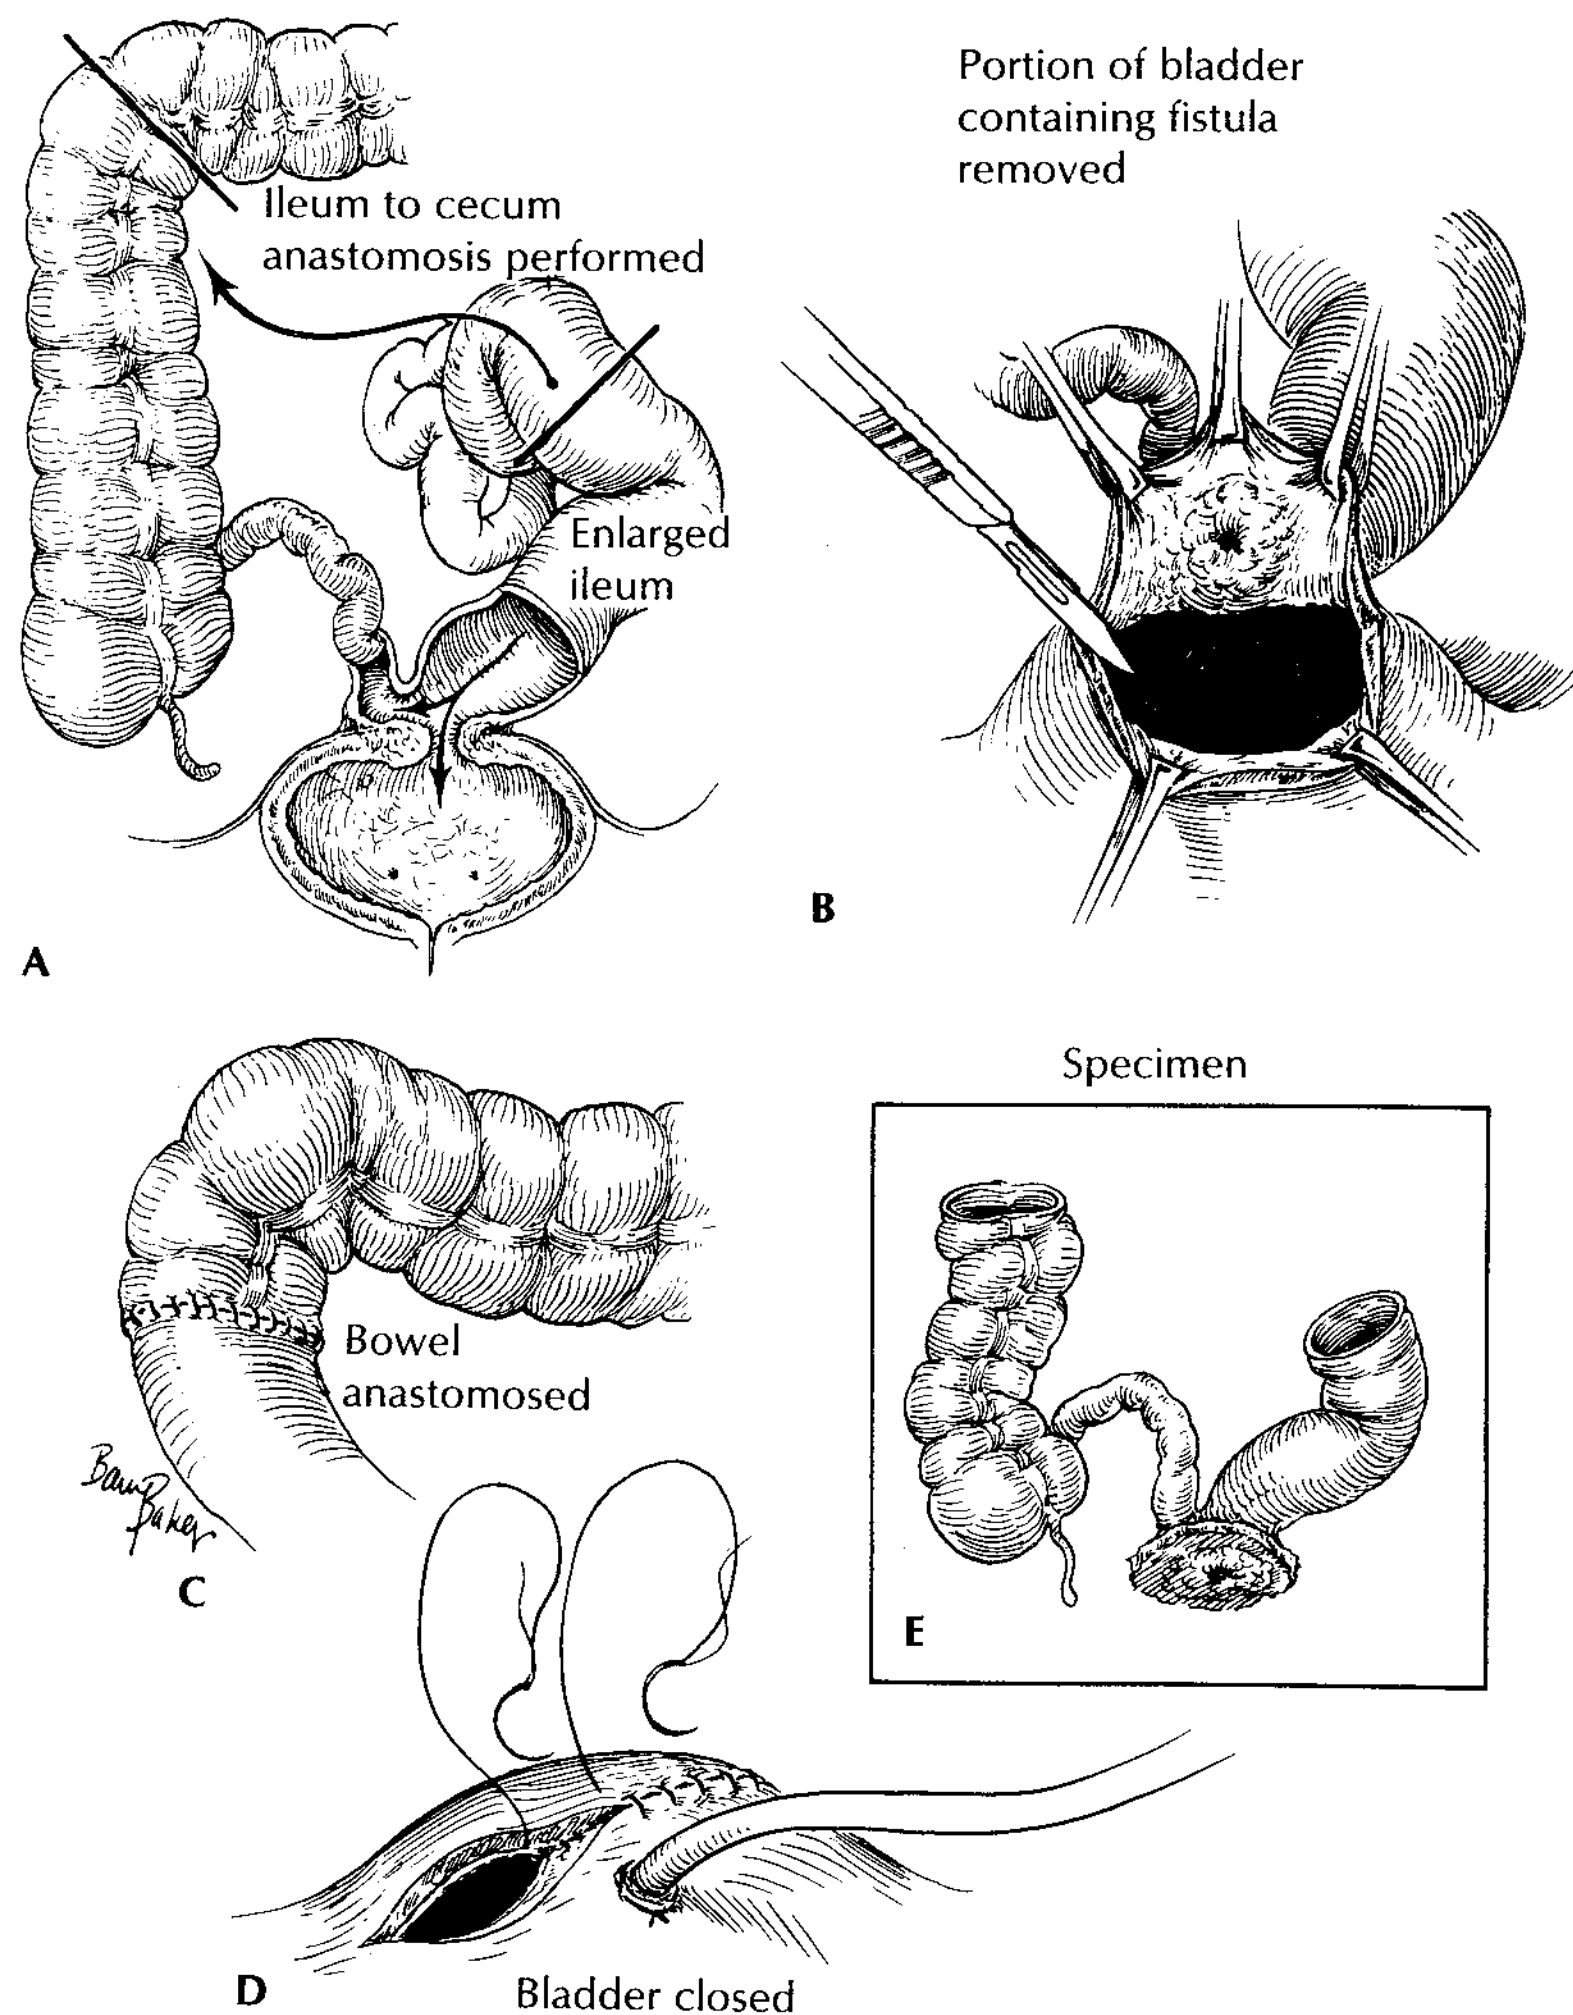

The results of the one-stage procedure for enterovesical fistulas are very much dependent upon the etiology of the fistula. Fistula recurrence following colonic resection in patients with diverticular fistulas is virtually nonexistent (16). Following surgical intervention for Crohn disease with enterovesical fistulas, recurrent enterovesical fistulas are observed in 0% to 13% of patients (4,11). In a surgical series of 13 patients with malignant fistulas, 2 (15%) patients developed recurrent fistulas (6). In a surgical series of 13 patients with radiation-induced fistulas, 5 (39%) failed to resolve or recurred (10). It should be noted that seven of these operations were diversions or isolations; of the six patients who underwent resections, only one developed a recurrent fistula.

---

## RECTOURETHRAL FISTULAS

---

Rectourethral fistulas are rare clinical entities. The most common cause is iatrogenesis, usually incurred during prostatic or rectal surgery or following radiation. Other etiologies include congenital, infectious, and neoplastic fistulas.

**FIGURE 21.1** Management of an enterovesical fistula using bowel resection and restitution with primary bladder closure.

## Diagnosis

Diagnosis of a rectourethral fistula is usually straightforward and suggested by the medical history. Preoperatively, antegrade and retrograde studies of the urinary tract, cystoscopy, proctoscopy, and, if indicated, anal manometry are performed to delineate the site and extent of the fistula as well as rule out distal obstruction or sphincteric incompetence. If there is clinical suspicion of disease recurrence, a biopsy should be performed.

## Indications for Surgery

Many different approaches have been proposed for the management of rectourethral fistulas. It is imperative to individualize management. There are five key factors that must be considered prior to determining the ideal approach:

1. *Sphincteric function.* In the setting of anal sphincteric incompetence, complex anal sphincter-sparing procedures should be deferred and consideration given to permanent fecal diversion. Similarly, in the setting of failure of the

urinary sphincter, supravescical diversion is a valid consideration if placement of an artificial urinary sphincter is not feasible.

2. *Presence of urethral stricture or vesical neck contracture.* Coexisting urethral disease may be present in patients with rectourethral fistulas, in particular iatrogenic fistulas (surgical or radiation-induced). Distal obstruction will compromise a technically adequate repair and should be treated prior to or at the time of fistula repair.
3. *Status of adjacent tissue.* Pelvic radiation induces both delayed endothelial cell damage and damage to the connective tissue stroma of blood vessels (12). This arteritis may result in atrophy, fibrosis, and necrosis. As a result, radiation-induced fistulas in general require more extensive repairs involving interposition of omentum or muscle flaps, have higher failure rates, and on occasion require permanent diversion.
4. *Size and location of the fistula.* Whereas small distal fistulas may be effectively repaired via a transanal approach, large fistulas often require the greater exposure provided by transsphincteric, transperineal, or abdominoperineal approaches. Moreover, large defects may require the interposition of vascularized tissue (omentum or muscle flaps).
5. *Overall condition and life expectancy of the patient.*

## Surgical Therapy

Initial treatment of iatrogenic fistulas in general consists of colostomy, prolonged urinary drainage with a suprapubic catheter, and broad-spectrum antibiotics, although some authors have advocated the selective use of elemental or parenteral nutrition in lieu of bowel diversion (3). Approximately 25% of nonradiated iatrogenic fistulas will resolve with conservative management (2). For those fistulas that do not close, numerous surgical repairs have been proposed (2). In appropriate candidates, our preferred surgical approach is either transanal or posterior transanosphincteric (York–Mason) (14). Transperineal repairs allow for formal tissue interposition and are useful for large or complex fistulas. Abdominoperineal repair allows for a colonic pull-through if necessary and also for the interposition of omentum or a gracilis or rectus abdominis muscle flap. It is limited, however, by an increased risk of fecal incontinence and the morbidity of an abdominal operation. The anterior transanorectal approach (sphincter divided) and the Kraske laterosacral (sphincter not divided) approach both provide excellent exposure of the fistula; however, the former may be associated with erectile dysfunction if the plane of dissection strays from the midline, and the latter procedure risks fecal incontinence associated with denervation.

## Surgical Technique

### Transanal Approach

The procedure is performed in the prone jackknife position. A speculum is introduced into the anus and the fistula is exposed. Two alternative procedures may be performed: the fistula may be circumscribed with mobilization of the rectal mucosa in a circumferential fashion; the fistula is excised and the underlying rectal wall muscle and mucosa are closed separately. Alternatively, the mucosal dissection may be limited to the rectal wall lateral and distal to the fistula. The proximal rectal wall is then mobilized for 4 cm, thereby creating a full-thickness U-shaped flap that is pulled down over the fistula and sutured to the edge of the rectal mucosa (Fig. 21.2). A catheter is maintained for 2 to 3 weeks. The main limitation of this approach is the limited exposure, and it is best suited for small distal fistulas.

### York–Mason Approach

The York–Mason procedure is performed in a prone jackknife position with the buttocks taped laterally (14) (Fig. 21.3). A midline incision is made from the sacrococcygeal articulation to the anal verge. Prior to dividing the muscular layers of the posterior anus, matching sutures are placed on either side of the intended incision so as to allow for subsequent precise reapproximation. Each layer is marked separately and then divided. Once the sphincter is divided, the mucosa of the posterior anus and the entire posterior rectal wall are divided in midline, thereby providing excellent exposure of the fistula. The fistula is then entirely excised and any inflammatory tissue is removed. The plane between the anterior rectal wall and the urethra/bladder may then be dissected to allow sufficient mobility for closure of the rectal defect. The urethra (or bladder) is closed with absorbable sutures in either one or two layers.

**FIGURE 21.2** Through the anal canal, an ellipse of rectal mucosa is removed. A full-thickness U-shaped flap of rectal wall is elevated above the fistula. The full-thickness flap of rectal wall is brought down over the fistula and sutured in two layers to the rectal wall. (From Tiptaft RC, Motson RW, et al. *Fistulae involving rectum and urethra: the place of Parks' operations. Br J Urol* 1983; 55:711–715, with permission.)

The rectum is closed in two layers. The posterior rectal wall and anal mucosa are then reapproximated. Finally, using the previously placed marking sutures, the anal sphincter is reapproximated in layers. Drainage of the presacral space is optional. A Foley catheter is placed and maintained for 2 to 3 weeks, at which point the absence of a leak is confirmed radiographically.

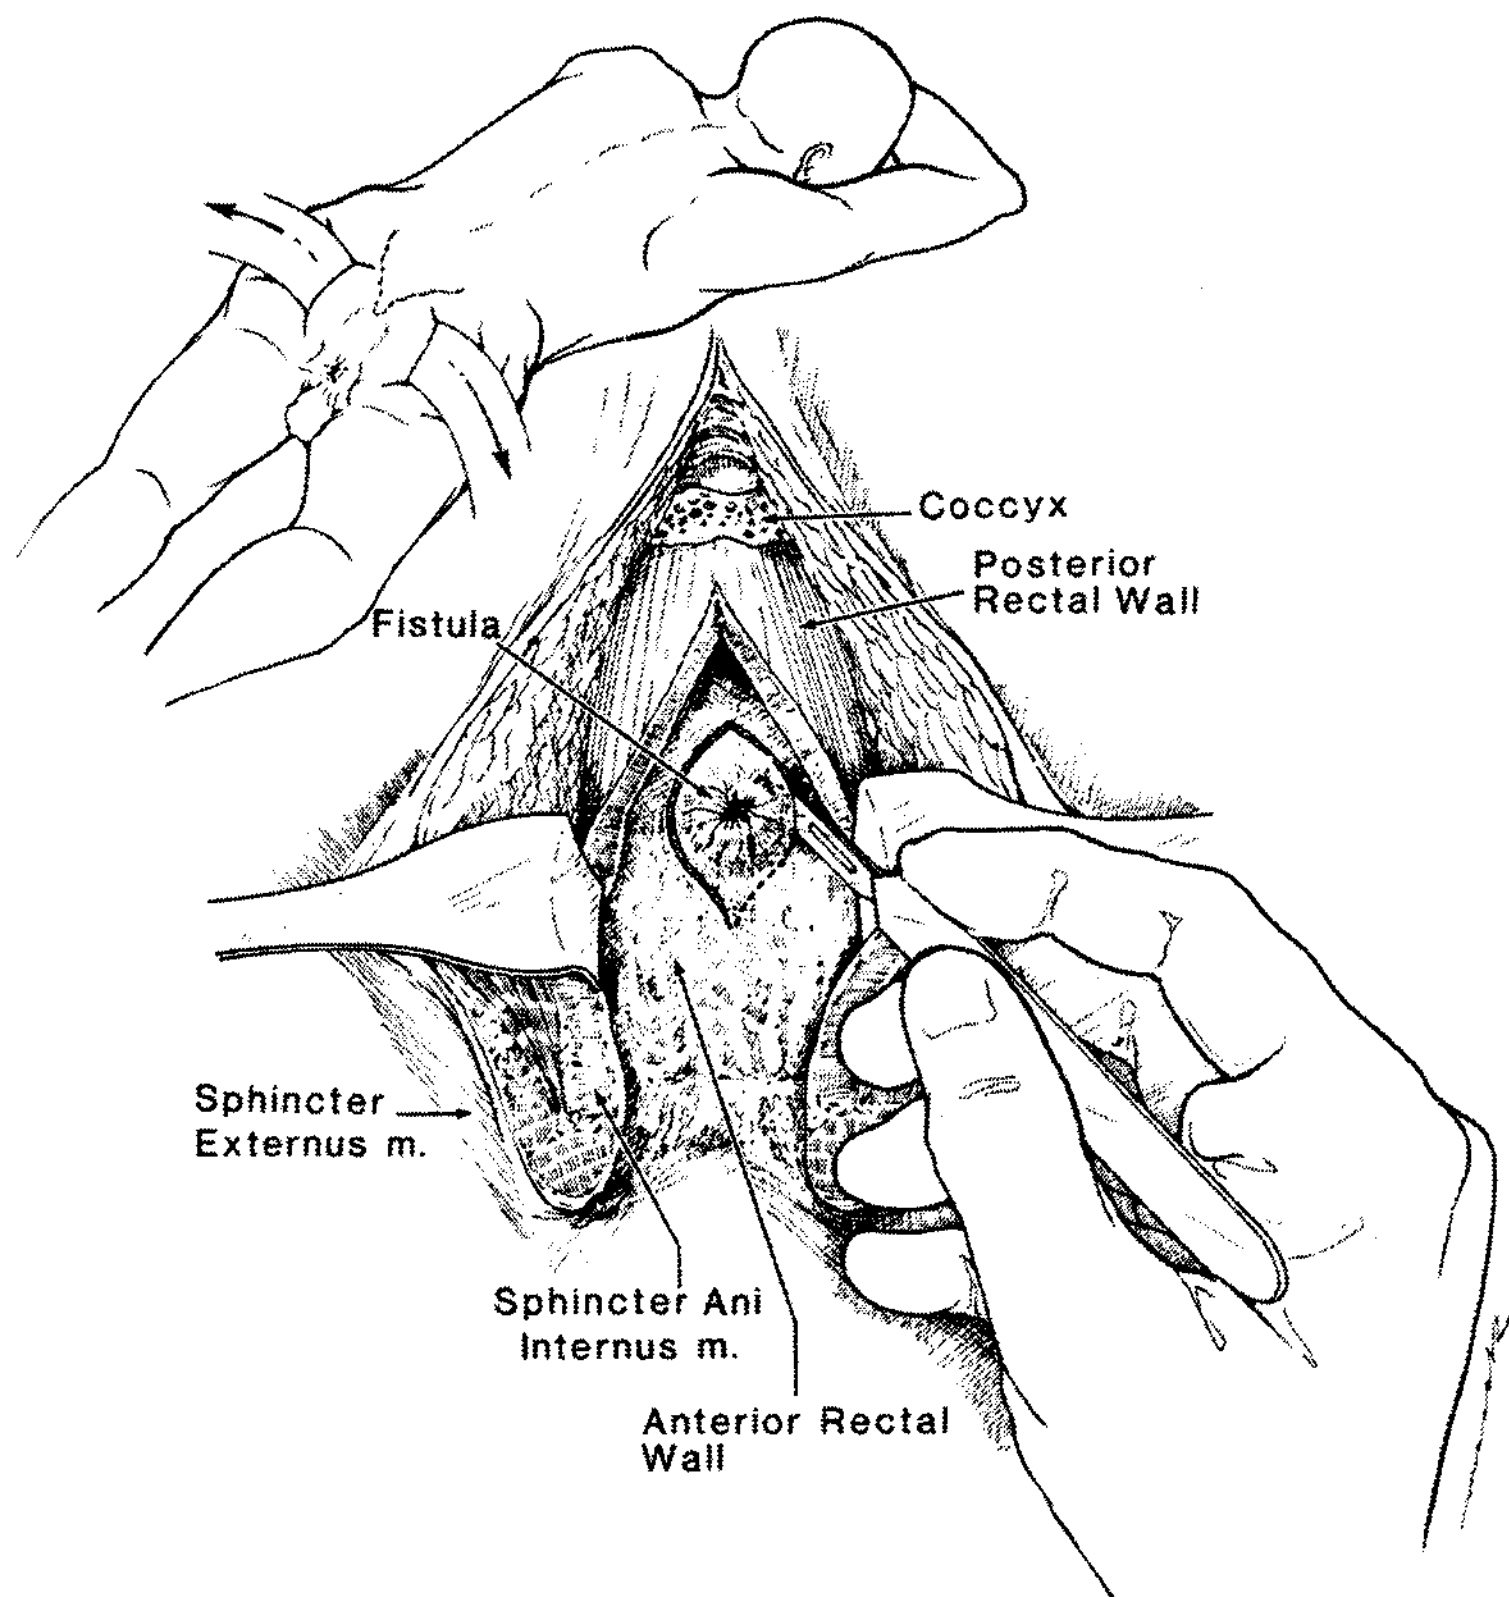

## Outcomes

### Complications

Specific complications include recurrent fistula formation, urinary and/or fecal incontinence, and erectile dysfunction.

### Results

Based upon literature reports, the York–Mason approach has become the favored repair for rectourethral fistulas not amenable to a transanal approach. There have been two relatively large series reported recently. Fengler and Abcarian performed eight York–Mason repairs for rectourethral fistulas with no recurrences and no fecal incontinence (3). Fecal diversion was performed in three of the eight patients. Stephenson and Middleton reported on 16 York–Mason repairs for rectourethral fistulas (rectovesical in 8, rectourethral in 7), with 1 recurrence and no fecal incontinence (14). The one recurrence was treated successfully with a second York–Mason procedure.

**FIGURE 21.3** Posterior sagittal, transanorectal (York-Mason) approach for repair of rectourinary fistulas. The patient is placed in the prone jackknife position with tape used to displace the buttocks laterally. After division of the posterior anus and rectum, the fistula is easily identified with ample room for excision and repair. (From Stephenson RA, Middleton RG. Repair of rectourinary fistulas using a posterior sagittal transanal transrectal (modified York-Mason) approach: an update. *J Urol* 1996;155:1989-1991, with permission.)

In this series, four patients with urinary incontinence prior to the repair subsequently underwent artificial urinary sphincter placement; no patients developed urinary incontinence as a result of the repair. A diverting colostomy was used in nine of the patients.

## Surgical Reconstruction for Large or Complex Fistulas

### Preservation of Urinary or Bowel Function

Based upon the presurgical evaluation, some patients with a rectourethral fistula are candidates for surgical restoration of only one system. The most common setting would be a patient with anorectal dysfunction or sphincteric incompetence who is a candidate for permanent colostomy and urinary tract reconstruction. Urinary reconstruction is optimized by concomitant proctectomy. A small urethral fistula may be closed primarily, followed by omental mobilization to the pelvis for coverage of the area. Some fistulas too large for primary closure have been managed with omental or gracilis transposition alone (7); however, we have preferred to close the urethral defect with a buccal mucosa graft in this setting as this seems to lead to decreased urinary extravasation and more rapid healing overall. The buccal graft is buttressed with omentum or a gracilis muscle flap for optimal take.

### Preservation of Urinary and Bowel Function

In patients who are candidates for attempted preservation of both urinary and bowel function, a transperineal procedure is our preferred technique and begins with placing the patient

into high lithotomy position. A very careful and meticulous dissection is then conducted in the plane between the rectum and the prostate and bladder to the level of the peritoneal reflection. The plane of dissection typically starts superior to the anal sphincter and then is carried down onto the rectum. Development of the space between the urinary tract and rectum can be quite difficult, as it is often performed in the setting of radiotherapy or previous attempts at fistula repair. Once completed, the urinary tract defect is closed primarily when feasible or patched with a buccal mucosa graft. In the setting of an associated membranous urethral stricture, a urethrotomy incision is created from the level of the fistula through the stricture into the proximal bulbous urethra. Buccal mucosa is then grafted into the resulting urethrotomy defect, with distal graft coverage using the corpus spongiosum and proximal buttressing with a gracilis muscle flap (17). The rectum is then closed and a gracilis muscle is rotated into the space between the rectum and urinary tract and anchored to the peritoneal reflection. Lateral sutures are also placed between the gracilis and the levators to ensure that its position is maintained with complete coverage of the reconstruction. Primary closure of the urethral and rectal defects with gracilis interposition was successful in 13 of 15 (87%) patients in two studies (13,18). In 2004 Zinman and colleagues reported excellent results using a transperineal approach for repair of complex rectourethral fistulas with buccal mucosa graft closure of the urethra, primary closure of the rectum, and gracilis interposition (17). We have used a similar technique in over 20 patients to date with only 1 failure of fistula closure thus far. It would seem to be most useful when the rectum and perirectal tissues are preserved well enough to allow adequate healing with primary rectal closure, as opposed to situations requiring resection of a severely

diseased rectum. In these cases, we have successfully used an abdominoperineal approach in patients in whom the rectum was deemed to be too extensively damaged by radiotherapy to allow a reliable primary closure, due to either severe proctitis or extensive tissue loss (8). In these cases, proctectomy and buccal graft closure of the urethral defect were done initially in the prone jackknife position, and the patient was then placed supine for the remainder of the procedure. Turnbull–Cutait staged coloanal pull-through is then carried out via an abdominoperineal approach. We have found that simple rotation of the sigmoid mesentery anteriorly during the pull-through

provides an excellent host bed for the buccal mucosa graft when omentum is not available, or if there is insufficient room in the pelvis to accommodate the omentum. This approach allows repair of large fistulas, restores fecal and urinary continuity, and eliminates a severely diseased rectum. Potentially difficult aspects of this procedure include the morbidity of an abdominal operation and the need to reposition the patient from the prone to the supine position during the case. A minor potential complication that we have encountered in two patients is the occurrence of minor rectal ectropion or prolapse that may require simple outpatient excision at a later date.

# CHAPTER 22 ■ VESICAL TRAUMA AND HEMORRHAGE

KAMAL S. POHAR AND ROBERT R. BAHNSON

---

## VESICAL TRAUMA

---

Vesical injury can occur as a result of blunt or penetrating trauma to the lower abdomen and pelvis. It is more commonly associated with blunt trauma such as that sustained from motor vehicle accidents, falls, blows, and during contact sports. Penetrating trauma resulting in vesical injury occurs from gunshot wounds and knife wounds. Bladder injuries can also be iatrogenic from transurethral surgery, gynecologic procedures, laparoscopy, and other intra-abdominal surgery. Bladder injury, in particular bladder rupture, is associated with pelvic fractures in 75% to 83% of patients (1). However, only 5% to 10% of patients with pelvic fractures will have associated bladder rupture (2,3). There is also a high incidence of injuries to other organs in patients with

bladder rupture (3). Concomitant bladder rupture is found in 10% to 29% of patients who present with rupture of the posterior urethra, and this is the most common injury to the genitourinary tract associated with bladder rupture (1,3). The mortality rate in patients with bladder rupture ranges from 11% to 44% and is mainly attributable to other associated organ injuries.

Bladder injury occurs as three predominant types: contusion with only intramural injury and extraperitoneal or intraperitoneal bladder rupture. The exact incidence of bladder contusion is not known as it is often a diagnosis of exclusion. It is a partial-thickness tear of the bladder mucosa with ecchymosis of the bladder wall. It is often associated with a “teardrop”-shaped bladder, which occurs as a result of a compressive pelvic hematoma from a pelvic fracture (4). It is usually self-limiting and rarely requires treatment.

Traumatic extraperitoneal ruptures usually are associated with pelvic fractures (89% to 100%). Previously, the mechanism of injury was believed to be a direct perforation by a bony fragment or a disruption of the pelvic girdle. It is now generally agreed that the pelvic fracture is likely coincidental and that the bladder rupture is most often due to a direct burst injury or the shearing force of the deforming pelvic ring (5). These ruptures usually are associated with fractures of the anterior pubic arch, and they may occur from a direct laceration of the bladder by the bony fragments of the osseous pelvis. The anterolateral aspect of the bladder typically is perforated by bony spicules. Forceful disruption of the bony pelvis and/or the puboprostatic ligaments also tears the wall of the bladder. The degree of bladder injury is directly related to the severity of the fracture.

Some cases may occur by a mechanism similar to intraperitoneal bladder rupture, which is a combination of trauma and bladder overdistention. The classic cystographic finding is contrast extravasation around the base of the bladder confined to the perivesical space; flame-shaped areas of contrast extravasation are noted adjacent to the bladder. The bladder may assume a teardrop shape from compression by a pelvic hematoma. Starburst, flame-shape, and featherlike patterns also are described. Classic intraperitoneal bladder ruptures are described as large horizontal tears in the dome of the bladder. The dome is the least supported area and the only portion of the adult bladder covered by peritoneum. The mechanism of injury is a sudden large increase in intravesical pressure in a full bladder. When full, the bladder's muscle fibers are widely separated and the entire bladder wall is relatively thin, offering relatively little resistance to perforation from sudden large changes in intravesical pressure.

---

## Diagnosis

---

Patients with bladder injury usually complain of lower abdominal pain and tenderness. Such an injury should be suspected in any patient with a pelvic fracture. Most patients with bladder trauma, including those with bladder contusions, will have gross or microscopic hematuria. Patients with contusion alone are usually able to void, whereas those with a ruptured bladder are often unable to void spontaneously. Acidosis with prerenal azotemia and elevated blood urea nitrogen is sometimes noticeable when there is a delay in diagnosis (6).

Presence of blood at the urethral meatus mandates performing a retrograde urethrogram. This is performed to rule out urethral injury before catheterization or instrumentation. If the retrograde urethrogram is normal, a urethral catheter is placed and a cystogram is obtained by plain film radiography (static), fluoroscopy (dynamic), or CT scan. The cystogram is usually normal in the presence of a bladder contusion. Intraperitoneal rupture results in ill-defined spillage of contrast into the peritoneum (Fig. 22.1). The extravasated contrast may outline loops of bowel or accumulate in the paracolic gutters, beneath the diaphragm, or over the bladder, in an hourglass pattern. Extraperitoneal rupture is seen as streak-like extravasation of contrast confined to the pelvis on retrograde cystogram (Fig. 22.2). Corriere and Sandler (7) further distinguished extraperitoneal ruptures as simple (confined to

**FIGURE 22.1** In intraperitoneal rupture of the bladder, free contrast within the peritoneal cavity outlines bowel loops.

**FIGURE 22.2** In extraperitoneal rupture of the bladder, contrast fills the pelvic cavity around the bladder.

the perivesical space) or complex (extravasation into the scrotum, retroperitoneum, abdominal wall, etc.). Displacement of the bladder by a pelvic hematoma can result in a teardrop-shaped bladder on cystogram (7).

**FIGURE 22.3** A CT cystogram showing evidence of intraperitoneal rupture of the bladder with extravasation around the (A) bladder (*arrow*), (B) paracolic space (*solid arrows*), and (C) abdominal viscera (*solid arrows*).

The most sensitive means of evaluating for the presence of bladder injury has traditionally been a cystogram performed by fluoroscopy. This is performed by obtaining a scout radiograph followed by instilling at least 250 to 400 cc of water-soluble contrast (Cystografin) in the bladder under gravity to ensure adequate distention and visualization of possible areas of rupture (1,6). One of the principal reasons for false-negative cystograms is instillation of an inadequate amount of contrast in the bladder. Static anteroposterior, oblique, or lateral films are obtained with the bladder full, and a washout film is obtained after drainage of the contrast material from the bladder. These additional films are useful in evaluating patients with posterior wall ruptures, which may be obscured in the anteroposterior view by a contrast-filled bladder. The drainage film also helps detect residual extravasation. In children the bladder is filled with contrast according to the formula,  $\text{Bladder capacity} = 60 \text{ cc} + (30 \text{ cc} \times \text{age in years})$ .

Although it is preferable to perform the study under fluoroscopy, if clinical circumstances do not permit, a static cystogram is satisfactory with portable equipment at the bedside.

Recently, examination of a contrast-filled bladder during computerized tomography (CT) scan has been used as a method of assessing injury. This is particularly applicable in patients who first undergo abdominal CT scans to rule out suspected visceral injuries. In these situations, the ability to

simultaneously evaluate the bladder would obviate the need for an additional plain-film cystogram. However, during routine abdominopelvic CT scan, the bladder may not be adequately distended to allow evaluation for rupture. The results of CT cystography improved as studies demonstrated improved sensitivity when the bladder was filled in a retrograde fashion with large volumes of contrast (250 to 500 cc) (8). Intraperitoneal bladder rupture can be distinguished from extraperitoneal rupture on CT scan. Presence of contrast around the bladder (Fig. 22.3A), in the paracolic gutters on either side (Fig. 22.3B), and around abdominal viscera such as the liver (Fig. 22.3C) indicates intraperitoneal rupture. In the case of extraperitoneal rupture, contrast extravasation is usually seen around the bladder, in the presacral space (Fig. 22.4A), and in the retroperitoneum anterior to the great vessels (Fig. 22.4B). Bladder contusions may be seen on CT scan as intramural hematomas. The recently reported improved accuracy of CT scan has resulted in CT being considered equivalent to plain-film cystography in diagnosing bladder ruptures. The accuracy of CT cystography may be significantly improved if retrograde bladder filling are performed with an adequate amount of contrast.

Intraoperatively, bladder rupture can be diagnosed by extravasation of saline, sterile milk, methylene blue, or indigo carmine, which is instilled in the bladder through a Foley catheter.

**FIGURE 22.4** Extraperitoneal rupture showing contrast in the (A) presacral space (*curved arrow*), prevesical space (*open arrow*), and (B) retroperitoneum (*solid arrow*). B, bladder.

### Indications for Surgery

1. Intraperitoneal bladder rupture
2. Bladder rupture or perforation sustained during another surgical procedure
3. Extraperitoneal bladder rupture in the presence of other intra-abdominal injuries requiring surgical intervention
4. Extraperitoneal bladder rupture with the bladder being inadequately drained by urethral catheter drainage

### Alternative Therapy

Alternative treatments of bladder trauma are predominantly Foley catheter drainage, which is indicated in patients with bladder contusions and extraperitoneal extravasation. Most extraperitoneal ruptures can be managed safely with simple catheter drainage (i.e., urethral or suprapubic). The catheter is placed to drain for 7 to 10 days and a cystogram is

performed. Approximately 85% of the time, the laceration is sealed and the catheter is removed for a voiding trial. Most extraperitoneal ruptures will heal within 3 weeks of catheter drainage. Most, if not all, intraperitoneal bladder ruptures require surgical exploration. These injuries do not heal with prolonged catheterization alone.

Injuries occurring during other procedures such as laparoscopic surgery may be repaired laparoscopically.

### Surgical Technique

#### Intraperitoneal Bladder Rupture

Intraperitoneal bladder rupture requires immediate surgical repair. The abdomen is opened through a vertical lower midline incision, which affords better exposure and is extendable in the event a laparotomy is required. The rupture, which is usually located horizontally on the dome of the bladder, is identified. In some situations, this may require instillation of

saline or colored dye in the bladder through a previously placed urethral catheter. Combined intra- and extraperitoneal rupture may coexist, and it is recommended that the opening in the bladder wall be extended to allow better visualization of the interior and bladder neck. Extraperitoneal tears can be closed from inside the bladder in two layers using running absorbable suture (3-0 chromic or polyglycolic/polyglactin acid). The intraperitoneal rupture(s) are closed in at least two layers using running 3-0 chromic or polyglycolic/polyglactin acid suture. The mucosa, muscle, and peritoneum are all closed in separate layers. The bladder is filled with saline after completion of the closure to evaluate for leaks. If any leaks are detected, they can be closed using interrupted figure-of-eight sutures.

In some situations, bony spicules that have penetrated the bladder wall may need to be removed before closure of the bladder. In cases of penetrating trauma or erosion of the bladder wall by pelvic abscess, nonviable tissue must be debrided and the edges of the perforation freshened prior to closure. In these cases, the tissue may be extremely friable, and a single-layer closure may need to be performed. The ureteral orifices should be identified and observed to ensure normal efflux of urine. This may be done after administration of IV indigo carmine to facilitate visualization. If efflux of urine is not seen, proximal ureteral obstruction, especially by fractured bony fragments, should be ruled out. This can be done by performing a retrograde or intravenous pyelogram on the operating table.

In addition to a urethral catheter, a suprapubic catheter is placed through a separate cystotomy to drain the bladder. Care must be taken not to disturb the pelvic hematoma that is invariably present. Disruption of the pelvic hematoma may give rise to significant bleeding. This can be controlled by packing the area with Gelfoam, Surgicel, or laparotomy tapes. The abdomen can be temporarily closed with the packing in place for about 24 hours; the packing is removed at the time of re-exploration. In extreme cases, angiographic embolization of the pelvic vessels may be necessary.

A 0.5-in. Penrose drain is placed adjacent to the bladder and left in place for 48 hours. In some cases, if the pelvic hematoma has not been disturbed and the bladder closure is truly watertight, drains can be omitted altogether. The abdominal fascia and skin are closed in the usual fashion.

Iatrogenic bladder injury, if suspected to have occurred during other operative procedures, should be documented by instilling methylene blue or indigo carmine in the bladder and noting any extravasation. The rupture or tear can be closed primarily in two or three layers using absorbable suture, as in other cases of rupture. Bladder perforations sustained during laparoscopic procedures can be diagnosed by noting distention of the urethral catheter drainage bag with gas (9). These injuries can be repaired as described previously by laparotomy or even laparoscopically (10).

Intravenous antibiotics are continued until hospital discharge, and the pelvic drain is removed within 48 to 72 hours of the procedure. When the follow-up cystogram confirms bladder healing, the urethral catheter is removed and a voiding trial is initiated by clamping the suprapubic catheter. The suprapubic catheter is removed when spontaneous voiding has returned.

### Extraperitoneal Bladder Rupture

Until the 1970s, extraperitoneal bladder rupture was managed as an intraperitoneal rupture. Since then several studies have

demonstrated that these injuries can be managed nonoperatively (1,7). Corriere and Sandler successfully managed 41 patients with extraperitoneal bladder rupture by prolonged urethral catheterization alone. All patients healed the bladder injury spontaneously without complications (7). Since then, other studies have duplicated these results.

Isolated extraperitoneal rupture can be treated by simple urethral catheter drainage. Once urethral injury has been ruled out by means of a retrograde urethrogram, a urethral catheter is placed. The catheter is left in place for 7 to 14 days. Repeat cystograms are performed at the end of this period. If no extravasation is observed, the catheter can be removed. If any contrast extravasation is evident on the cystogram, catheter drainage is continued. Cystograms are repeated at weekly intervals until no extravasation is demonstrable. A majority of extraperitoneal ruptures treated in this manner will heal by 2 weeks, and almost all will show healing within 3 weeks.

Severe bleeding with clots or sepsis should prompt surgical exploration even in cases of extraperitoneal rupture. If patients are undergoing laparotomy for other intra-abdominal injuries, it is reasonable to repair extraperitoneal ruptures surgically.

---

## Outcomes

---

### Complications

Some patients may notice persistent urgency and increased frequency of micturition after repair of bladder ruptures. These symptoms are usually temporary and tend to subside with time. Vesical neck injuries increase the risk of subsequent incontinence, and attention should be paid to careful repair of these injuries. Infection of pelvic hematomas can result in abscess formation requiring prolonged drainage and antibiotic treatment. This can be prevented to some extent by taking care to avoid disrupting the hematoma intraoperatively. Unrecognized injury to adjacent structures can lead to subsequent vesicovaginal or vesicoenteric fistula formation. Otherwise, this complication is uncommon.

Complications such as clot retention and pseudodiverticulum formation are seen in fewer than 10% of patients treated with catheter drainage alone for extraperitoneal rupture (1,11). Significant sepsis, delayed healing, formation of bladder calculi, and vesicocutaneous fistula formation have been noted to occur in patients treated with urethral or suprapubic catheter drainage for extraperitoneal rupture (12). These patients most often had poorly functioning catheters or did not receive prophylactic antibiotics. Hence, it is important to ensure that urethral catheters are functioning adequately when used in these situations. Using a larger catheter and considering surgical intervention in 24 to 48 hours if the catheter is not functioning will reduce complications. Prophylactic antibiotics with gram-negative coverage, when administered for the duration of catheterization, will help prevent urinary tract infections.

### Results

Open repair with adequate closure of the rupture is almost uniformly successful in all patients treated in this manner, and 74% to 87% of patients managed with urethral catheter drainage for extraperitoneal rupture will show evidence of healing by 10 to 14 days (1,12). The remainder will heal with an additional 7 to 10 days of catheter drainage.

TABLE 22.1

## ETIOLOGIC AGENTS FOR HEMORRHAGIC CYSTITIS

Infectious causes	Noninfectious causes
Viral: BK virus, adenovirus, JC virus, influenza virus Bacterial: <i>Escherichia coli</i> , <i>Staphylococcus saprophyticus</i> , <i>Proteus mirabilis</i> , <i>Klebsiella</i> Fungal: <i>Candida albicans</i> , <i>Aspergillus fumigatus</i> , <i>Cryptococcus neoformans</i> , <i>Torulopsis glabrata</i> Parasitic: <i>Schistosoma haematobium</i> , <i>Echinococcus granulosus</i>	Amyloidosis Radiation  Chemicals: anilines and toluidines, pesticides (chlordimeform), ether, gentian violet, spermicidal suppositories, turpentine Drugs: penicillins (carbenicillin, penicillin G, K, ticarcillin, methicillin, piperacillin), methenamine mandelate, danazol Chemotherapeutic agents: busulfan, thiotepa, cyclophosphamide, isophosphamide

## VESICAL HEMORRHAGE

Significant bleeding from the bladder in the absence of trauma is usually associated with hemorrhagic cystitis. This can result from a variety of infectious and noninfectious etiologies. Possible etiologic factors for hemorrhagic cystitis are listed in Table 22.1. Infection-related hemorrhagic cystitis is usually treatable by addressing the underlying cause.

Radiation therapy to the prostate, bladder, or other pelvic organs can result in hemorrhagic cystitis. Initially, there is mucosal edema with submucosal hemorrhage. Chronically, radiation causes obliterative endarteritis with subsequent urothelial ischemia. Various measures, such as steroids, vitamin E, and trypsin, have proved futile in treating radiation-induced cystitis, which can manifest many years after exposure. Coating the bladder mucosa with synthetic agents such as pentosan polysulfate sodium has some beneficial effect (13). Hyperbaric oxygen therapy has also proved effective (14).

Urothelial malignancies can also cause significant bleeding, which can be controlled by transurethral resection of tumor and fulguration with electrocautery in most cases. In patients with metastatic or unresectable bladder tumors and severe hematuria, local radiation can be used to palliate the symptoms. In some cases, cystectomy or urinary diversion by means of percutaneous nephrostomy or conduit urinary diversion may be the only viable option.

A wide range of drugs and industrial toxins can also give rise to hemorrhagic cystitis. Conservative treatment with adequate hydration, bladder irrigation, and discontinuation of the causative agent will suffice as treatment for most cases.

Chemotherapeutic agents are a major cause of hemorrhagic cystitis. Busulfan, alkylating agents such as cyclophosphamide and isophosphamide, and thiotepa are commonly associated with hemorrhagic cystitis. The incidence ranges from 2% to 40%, and significant mortality rates have also been reported (15). Hemorrhagic cystitis is dose-dependent and related to the route of administration of the chemotherapeutic agent (higher with IV administration). It is more severe in dehydrated patients. Acrolein, which is a liver metabolite of cyclophosphamide, is the principal inciting agent and acts by direct contact with the bladder mucosa. Histological changes that occur in the bladder are similar to those seen with radiation and include edema, ulceration, neovascularization, hemorrhage, and necrosis. Prophylactic hydration and the use of

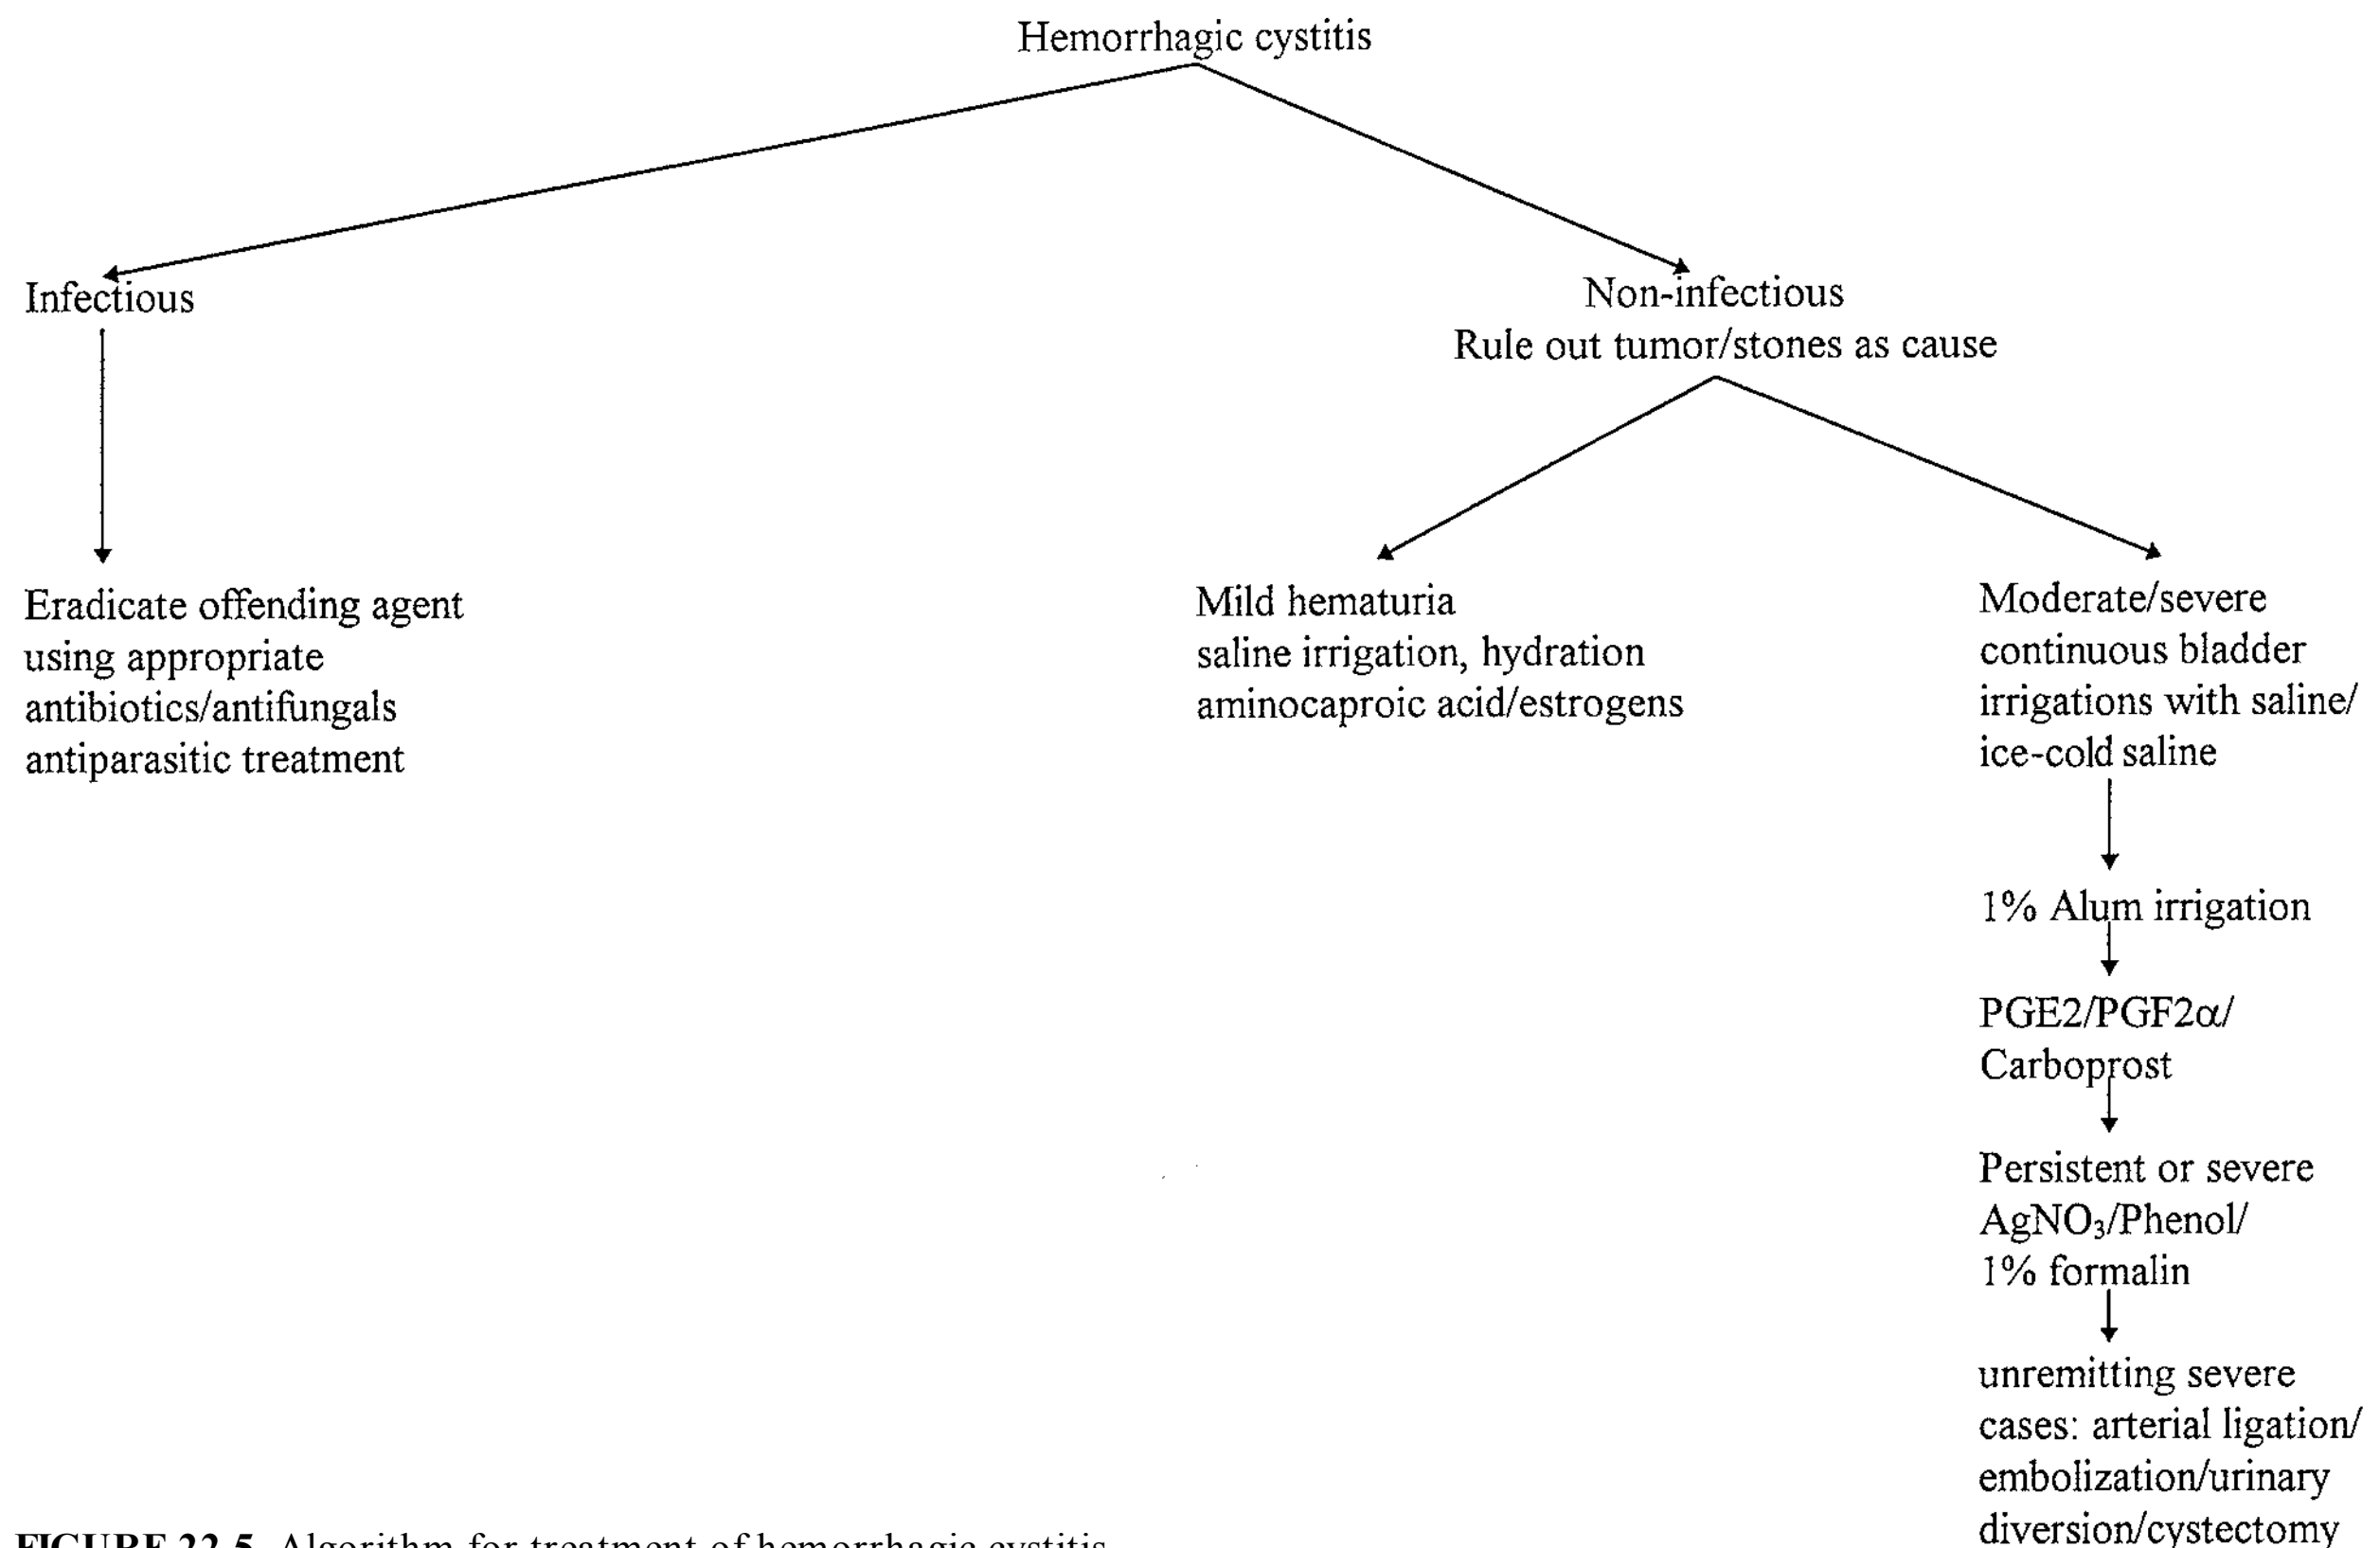

protective agents such as N-acetyl-cysteine (Mucomyst) or 2-mercaptoethane sulfonate (mesna) can reduce the incidence of this complication. Systemic administration of Mucomyst can decrease the antineoplastic effect of cyclophosphamide and may exacerbate the hemorrhage seen with busulfan.

## Treatment of Hemorrhagic Cystitis

A practical algorithm for the management of hemorrhagic cystitis is outlined in Fig. 22.5. Mild hematuria can be managed by vigorous hydration.

Moderate hematuria can be treated with continuous saline irrigation through a Foley catheter after all clots have been evacuated. In some situations, such as with radiation cystitis, irrigation with cold saline for 24 to 48 hours may prove more effective. If hematuria persists, continuous bladder irrigation with 1% alum (potassium or ammonium aluminum sulfate) is helpful. The alum acts as an astringent and precipitates the surface proteins. Aluminum levels must be monitored, particularly in patients with renal insufficiency. Severe acidosis and encephalopathy can occur in such patients as a result of high aluminum levels. Periodic intravesical instillation of prostaglandins (PGE<sub>2</sub>, PGF<sub>2α</sub>) and PGF<sub>2α</sub> analogs (carboprost) have also proved effective. They decrease the inflammatory response and reduce the hemorrhage. They can be used prophylactically or therapeutically. Prostaglandin E<sub>2</sub> has been used in a dose of 0.75 mg in 200 cc of normal saline instilled for 4 hours. The effective dose of PGF<sub>2α</sub> has been 1.4 mg in 200 cc of normal saline. Carboprost has been used in a dose of 0.8 mg per dL diluted in normal saline and instilled for 1 hour at 6-hour intervals; good results occurred in 62% of patients, according to one study (16). Instillation of silver nitrate (0.5% to 1.0% solution) for short periods of time followed by saline irrigation of the bladder to remove residual silver nitrate is also an effective technique.

Persistent severe hemorrhage that has not subsided despite the above-mentioned measures can be treated with intravesical instillation of carbolic acid (phenol) or 1% formalin. This requires general anesthesia. Phenol is instilled in a dose of 30 cc of a 100% solution mixed with an equal volume of glycine for 1 minute. This is washed out with 95% ethanol (60 cc) and saline to prevent methemoglobinemia. It is necessary to rule out vesicoureteral reflux by performing a voiding

**FIGURE 22.5** Algorithm for treatment of hemorrhagic cystitis.

cystourethrogram before using formalin as it can cause fibrosis and scarring of the ureters and renal pelvis. If need be, the ureters can be occluded with Fogarty balloon catheters to prevent reflux while formalin is instilled. Fifty milliliters of 1% formalin (0.37% formaldehyde) diluted with saline should be instilled for 4 to 10 minutes. This should then be washed out with saline and the saline irrigation continued for 24 hours. The external genitalia are covered with towels or Vaseline to prevent irritation.

In recalcitrant cases, use of medical antishock trousers and cryotherapy has been reported (17). Embolization of the hypogastric arteries with autologous clot, Gelfoam, coils, or ethanol can also be resorted to in such cases. This may result in temporary gluteal claudication. Open ligation of the hypogastric artery can also be performed. Supravesical urinary diversion by means of percutaneous nephrostomy tubes or ileal or sigmoid conduit urinary diversion with or without cystectomy remains a final but viable option.

## CHAPTER 23 ■ INTERSTITIAL CYSTITIS/ PAINFUL BLADDER SYNDROME

MICHAEL S. INGBER AND KENNETH M. PETERS

Interstitial cystitis/painful bladder syndrome (IC/PBS) is a chronic, unrelenting condition with considerable morbidity. The symptoms were first described in the early 20th century, and IC/PBS continues to be one of the most commonly missed diagnoses in urology (1). While the etiology of IC/PBS has not been clearly identified, much is now known about its characteristics and natural history. The presentation may be variable; however, the more common symptoms are urinary frequency, urgency, and pelvic pain. Until recently, IC/PBS has been considered a disease predominantly affecting women; however, more men are now being diagnosed with this disease. Men presenting with symptoms of genital or perineal pain, frequency, or dysuria are often labeled as having chronic, abacterial prostatitis; in fact, many of them suffer from IC/PBS.

---

### DIAGNOSIS

---

Before one can diagnose IC/PBS, causes that can mimic the disease must be ruled out. These include bacterial cystitis, overactive bladder, endometriosis, bladder cancer, and urethral diverticulum. Defining IC/PBS has been extremely controversial, and to date there remains considerable disagreement among experts. In 1987 and 1988 the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) developed a research definition for IC/PBS in order to provide homogenous groups of patients that may be compared to one another in clinical studies (2). However, experts in female urology and urogynecology have found this definition to be far too restrictive, as the majority of patients with IC/PBS were being excluded. According to the International Continence Society, IC/PBS should be suspected in anyone with symptoms of suprapubic pain related to bladder filling, accompanied by urinary frequency and urgency, in the absence of urinary infection or other pathology (3). The European Society for the Study of IC/PBS (ESSIC) has developed specific diagnostic criteria that are based on a combination of urinary symptoms and bladder findings during cystoscopic evaluation.

Symptoms of IC/PBS are extremely variable and may present as mild irritative symptoms to severe symptoms refractory to all standard therapies. Treating the disease early often leads to rapid improvement in symptoms; thus, recognizing IC/PBS early so that therapy can be initiated is extremely important.

The diagnosis of IC/PBS begins with a complete history. Onset of symptoms may be days, weeks, or even months. Often

patients have been clinically diagnosed with urinary tract infections despite negative cultures. Other misdiagnoses include endometriosis, fibroids, or other pelvic disorders, and some have even undergone surgery for them (4). A full dietary and fluid history is useful, as certain foods and drinks may exacerbate IC/PBS symptoms (5). A voiding diary provides objective evidence of daytime and nighttime frequency, and pain symptoms can be recorded with this as well. Sequential voiding diaries and symptom questionnaires allow one to determine the impact of various treatments for IC/PBS.

A physical examination that includes a thorough pelvic and neurological examination should be performed. The female pelvic examination should include evaluation for tenderness of the anterior vaginal wall and levator muscles, the ability to contract and relax the pelvic floor muscles, and the degree of pelvic relaxation. Urethral fullness, tenderness, or expression of pus may suggest a urethral diverticulum requiring further workup. A rectal examination can rule out any rectal abnormalities or masses, and in men the prostate should be palpated for nodules or tenderness.

A urinalysis, urine culture, and cytology should be performed to exclude active infection or evidence of carcinoma in situ. Sterile pyuria should prompt staining for acid-fast bacilli to rule out genitourinary tuberculosis. If microscopic or gross hematuria is present, a workup including CT urography, cystoscopy, and urine cytology is required in order to evaluate for bladder cancer or stone disease.

In patients with urinary urgency, frequency, or incontinence, a trial of anticholinergics may cause symptoms to subside. However, if symptoms persist, or if pelvic pain or severe dysuria is present, a cystoscopic evaluation is warranted. Interstitial cystitis was first described as a distinct ulcer seen on cystoscopic examination. This lesion is typically red, raised, and friable and can be seen during cystoscopy without hydrodistention. The lesion is difficult to distinguish from carcinoma in situ, and a biopsy with cauterization of the lesion is warranted. Only 15% to 20% of patients diagnosed with IC/PBS have an ulcer in their bladder. They are typically older and have more severe bladder-associated pain and a smaller anesthetic bladder capacity.

In patients in whom a diagnosis of IC/PBS is highly suspected, cystoscopy with hydrodistention under anesthesia may reveal petechial hemorrhages and glomerulations, which are found in over 90% of women with the syndrome. However, the presence of petechial hemorrhages alone is not diagnostic, as they can also be seen in normal men and women (6). A computerized cystometrogram may also be performed to look

for uninhibited contractions and to determine the functional bladder capacity. Some investigators have suggested the use of the potassium sensitivity test (PST) to diagnose IC/PBS (7). The PST is based on the hypothesis that there is increased epithelial permeability in the bladder of IC patients. However, a significant false-positive rate exists, and many patients will eventually be diagnosed with a normal bladder (8). Additionally, 17% of women with IC/PBS may have a negative test (9). For these reasons, PST should be used only as an adjunct during evaluation and diagnosis.

## INDICATIONS FOR SURGERY

Any patient with unexplained urinary urgency, frequency, and pelvic pain is a candidate for an operative hydrodistention, which may be not only diagnostic but also therapeutic. Patients with ulcerative disease may benefit from ablation of the ulcers with cautery or laser (10).

Radical surgery for IC/PBS is rarely indicated and should be used as a last resort. Magnetic resonance imaging (MRI) of the pelvis may demonstrate a thickened, end-stage bladder that may be amenable to radical surgery (Fig. 23.1). Patients who undergo bladder augmentation or continent diversion need to be willing and able to perform clean intermittent catheterization. Additionally, patients must accept that frequency symptoms may improve but that pain may persist. Diverting the urine without removing the diseased bladder is not always sufficient to relieve the symptoms of IC/PBS. Therefore, any diversion procedure for pain should be accompanied by cystectomy (11). Finally, neuromodulation has been effective in treating refractory urinary urgency and frequency (12). Because IC/PBS is a syndrome of urgency, frequency, and

pain, patients who are refractory to standard therapies would be candidates for nerve stimulation.

## ALTERNATIVE THERAPY

Establishing a diagnosis of IC/PBS in itself is usually therapeutic and alleviates patient frustrations. A multimodality approach along with patient education is the most effective means of treating IC/PBS. Behavioral therapies must be stressed, such as fluid management, pelvic floor physical therapy, dietary restrictions, and relaxation therapy (13). Many patients suffer from pelvic floor spasm, which causes pelvic pain, dyspareunia, and urinary hesitancy. Treatment by a therapist knowledgeable in myofascial release techniques may be of benefit (14). Once behavioral therapy is optimized, oral medication is a reasonable first-line treatment for IC/PBS.

At the present time, the only oral therapy approved by the U.S. Food and Drug Administration (FDA) for IC/PBS is pentosan polysulfate sodium (Elmiron, Ortho-McNeil Pharmaceuticals), a glycosaminoglycan that binds tightly to the bladder mucosa. Pentosan polysulfate should be considered a first-line therapy for IC/PBS; however, because it may require several months before any clinical improvement is seen, it should not be used as a single agent for the treatment of IC/PBS. Hydroxyzine has antihistaminic and anti-anxiety properties and affects mast-cell degranulation, which may play a role in symptoms of IC/PBS (15). However, neither pentosan polysulfate nor hydroxyzine showed high response rates in recent clinical trials (15). Muscle relaxants such as diazepam or low-dose baclofen may be useful in women with accompanying pelvic floor spasm, although to date no major studies have been performed on these medicines. Tricyclic antidepressants such as amitriptyline or imipramine may improve symptoms due to their anticholinergic and antipain effects (16). Finally, chronic pain is recognized as a legitimate complaint and should be treated aggressively. Various narcotics and anti-inflammatories can be tried, along with nerve blocks or implantable pain pumps, to treat the severe pain that can be associated with IC/PBS. Cyclosporine has been used in some clinical trials, but results are inconclusive.

Intravesical therapies have been a mainstay in treatment for many years. Dimethyl sulfoxide (DMSO) is the only FDA-approved intravesical therapy for this disease. DMSO is a product derived from paper pulp and is mainly used as an industrial solvent. It is given in the office setting as a 50% solution in 50 mL of sterile saline. Patients rarely have side-effects, although they may complain of transient urethral pain or irritation after the first instillation, or a garliclike odor from their mouth. If effective, symptoms may resolve for months to even years (17).

Bacille Calmette-Guérin (BCG) is prepared from an attenuated strain of bovine tuberculosis bacillus, *Mycobacterium bovis*, and is given intravesically as a 50-mg dose in 50 mL saline solution. While traditionally used for treating carcinoma in situ of the bladder or low-stage urothelial carcinoma, it appeared to show promise as an intravesical agent in treating IC/PBS. In a randomized placebo-controlled clinical trial, 21% of patients

**FIGURE 23.1** MRI scan of pelvis of 28-year-old woman with end-stage interstitial cystitis demonstrating a small, thickened, contracted bladder. (Courtesy of Raymond Rackley, Cleveland Clinic Foundation.)

responded to BCG, compared to 12% of placebo. However, the difference was not statistically significant ( $p = 0.062$ ), and therefore this should not be offered as first-line therapy.

Other second-line agents that have been used include capsaicin, heparin, sodium oxychlorosene, and silver nitrate.

---

## SURGICAL TECHNIQUE

---

### Bladder Hydrodistention

---

A complete cystoscopy is performed to assess the urethra and bladder for any masses, stones, or diverticulae (Fig. 23.2). After careful inspection, the bladder is filled by gravity drainage under anesthesia at 100 cm H<sub>2</sub>O pressure to its capacity. Upward pressure with a finger along each side of the urethra is often needed to maximally distend the bladder to prevent leakage around the cystoscope. The bladder is distended until no further water will run into the bladder, and this is allowed to dwell for 2 minutes. The bladder is drained and the volume measured. The procedure is then repeated a second time.

A normal bladder will accommodate up to (or over) 1 L under a general anesthetic. On the other hand, the bladder of a patient with the ulcerative form of IC/PBS will be less compliant, often stretching to <350 mL. Typically with IC/PBS there is terminal hematuria noted when the bladder is drained. Upon reinspecting the bladder, the vast majority of patients will have glomerulations seen in all sectors of the bladder,

**FIGURE 23.2** Hydrodistention is carried out with the irrigation bag hung 100 cm above the level of the bladder. Bladder capacity is reached when irrigant flow stops. During filling, the bladder mucosa is typically normal-appearing. After 2 minutes of distention, the bladder is drained and the capacity is measured. At the termination of bladder emptying, the irrigant fluid is often blood-tinged or grossly hemorrhagic in patients with interstitial cystitis (IC). Repeat cystoscopy will demonstrate diffuse glomerulations in all sectors of the bladder consistent with IC. Repeat hydrodistention is performed to maximally distend the bladder.

suggestive of interstitial cystitis. Patients having the ulcerative form will have distinct inflammatory lesions on cystoscopy called Hunner ulcers, and with hydrodistention deep cracks in their bladder at the site of ulcers may occur (1) (Fig. 23.3).

---

### Endoscopic Resection or Fulguration of Ulcers

---

Approximately 15% of IC/PBS patients comprise the ulcerative subset, and they generally have worse pain and frequency symptoms. A resectoscope with loop electrocautery can be used to resect these lesions and cauterize the base (18). Alternatively, the involved areas can be cauterized with a Bugbee electrode, ball electrode, or neodymium:YAG laser. The laser is set at 15 W with a firing duration of 1 to 3 seconds. The laser fiber is maintained in constant motion over the target, and the procedure is completed when the ulcer is completely blanched (10).

---

### Augmentation Cystoplasty

---

Simple augmentation of the bladder should only be performed if one has an operative bladder capacity with hydrodistention of <300 cc. The bladder is isolated and a posterior-based U-shaped incision is created on the anterior bladder (Fig. 23.4). A 30-cm segment of distal ileum is isolated in the standard fashion and opened along its antimesenteric border. The ileal segment is folded to create a nonperistaltic ileal patch. This is secured to the anterior bladder with running absorbable suture, effectively increasing the functional capacity of the bladder. Patients undergoing an augmentation must understand that their pelvic pain symptoms may not resolve from augmentation alone. Additionally, because the detrusor is incised, the emptying mechanism of the bladder is altered, and patients may need to perform intermittent straight catheterization to effectively empty their bladder.

---

### Partial Cystectomy and Substitution Cystoplasty

---

Supratrigonal cystectomy with enterocystoplasty is preferred over simple augmentation cystoplasty because most of the diseased bladder is removed (19) (Fig. 23.5). This technique should be reserved for patients with small bladder capacity found on hydrodistention under an anesthetic (<300 mL). Patients with a primary pain complaint are not good candidates for supratrigonal cystectomy, particularly if the pain is urethral in nature. In addition, patients should be able to perform intermittent straight catheterization and bladder irrigation in case of poor emptying or mucus formation.

The patient is placed in a supine position and a Foley catheter is placed sterilely in the bladder. The peritoneal cavity is entered through a vertical midline incision, and an appropriate segment of either large or small bowel with a mesentery long enough to reach down to the bladder is selected. The preferred bowel segments are the cecum, sigmoid colon, or ileum. The bladder is filled via the Foley catheter and divided using a clamshell technique, exposing the trigone. Ureteral catheters are

**FIGURE 23.3** **A:** Normal appearance of the bladder urothelium before hydrodistention in a patient with symptoms consistent with interstitial cystitis. **B:** Same patient following hydrodistention. The urothelium is abnormal, revealing minimal to moderate glomerulation. **C:** Cystoscopic appearance of a patient with moderate glomerulations and submucosal hemorrhage. **D:** Hunner ulcer with marked hemorrhage surrounding the ulcer. This patient was successfully treated with neodymium:YAG laser ablation therapy.

placed before resection of the bladder to avoid injury to the ureters. Using electrocautery, a supratrigonal cystectomy is performed, resecting all but a 1- to 2-cm cuff of bladder that includes the trigone and bladder neck. Placing Allis clamps on the edges of the remaining bladder controls hemostasis. The vesicoenteric anastomosis is completed using a single-layer running closure of 3-0 Vicryl suture. A 22Fr Foley catheter is placed through the bowel segment and used as a suprapubic tube. Both tubes are kept to dependent drainage for 21 days, when a cystogram is performed to ensure the integrity of the anastomosis. The patient is then started on intermittent catheterization.

---

### Total Cystectomy with Orthotopic Neobladder or Urinary Diversion

---

A total cystectomy has the benefit of removing the entire diseased bladder and may be the treatment of choice for the patient with an “end-stage” bladder. The choice of performing a continent versus incontinent diversion is based mainly on patient preference. If a patient has significant urethral symptoms, an orthotopic neobladder may not be the preferred conduit. The benefits of continent diversions are obvious;

**FIGURE 23.4** Ileal augmentation cystoplasty. **A:** A posterior-based U-shaped incision is created on the anterior bladder. **B:** Completion of the posterior-based bladder flap. **C:** A 30-cm segment of the distal ileum is isolated and divided along the antimesenteric border. **D:** The ileal segment is then folded and the posterior surface is closed completely with a running absorbable suture. The anterior segment is partially closed. **E:** Completed ileal bladder anastomosis.

however, there have been reports of IC/PBS developing in the continent bowel segments. An informed and motivated patient would be the best candidate for a continent diversion. The techniques of cystectomy and urinary diversion, including complications, are described elsewhere.

### Sacral Nerve Stimulation

Chronic inflammation in a pelvic organ may lead to nerve upregulation to the spinal cord, affecting all pelvic structures. Sacral nerve modulation (InterStim, Medtronic, Inc,

Minneapolis, MN) is approved by the FDA for urinary urgency, frequency, urge incontinence, and idiopathic urinary retention. Preoperatively, the efficacy of sacral nerve stimulation is determined by a test performed prior to placing a permanent generator. If patients experience at least a 50% improvement in their symptoms and desire a permanent implant, an implantable generator can be placed permanently in a subcutaneous pocket in the upper buttocks. Patients have an external programmer to control the degree and frequency of stimulation.

InterStim therapy has evolved since its approval in the United States in 1997. Initially, a percutaneous lead was

**FIGURE 23.5** Technique of subtotal cystectomy and substitution cystoplasty. **A:** The bladder is being bivalved with electrocautery. **B:** View of the bladder with both ureteral orifices cannulated with ureteral catheters to avoid injury to ureters during bladder resection. **C:** Completion of subtotal cystectomy with only a small cuff of bladder remaining, which consists of the urethra, bladder neck, and trigone. **D:** Completed anastomosis of the bowel onto the bladder cuff. A Foley catheter (not shown) and a suprapubic tube are placed to ensure adequate drainage during the immediate postoperative period.

placed in the sacral foramen under local anesthetic in the office, and the lead was taped to the skin. The patient was discharged to home with an external stimulating box, and the lead was stimulated for 3 to 5 days while voiding diaries were kept. The lead was then removed, and patients responding to the test were candidates for a permanent implant that was performed in the operating room under a general anesthetic. The permanent implant was relatively complicated because it required exposing the periosteum of the sacrum, dissecting the foramen, and securing the permanent lead to the bone after testing for muscle response. This lead was then connected to an implantable pulse generator placed in a subcutaneous pocket under the upper buttocks.

Several problems were identified with the percutaneous testing/implant technique. These included migration of the percutaneous lead resulting in an inadequate test period, uncomfortable sensory response when the permanent lead was placed under a general anesthetic, the morbid nature of placing the permanent lead, and the inability to duplicate placement of the permanent lead in the identical location of the temporary percutaneous lead, resulting in a poor clinical

response. The most significant advance with InterStim therapy is the introduction of a timed permanent quadripolar lead, allowing for percutaneous placement of the permanent lead for the test period. The most common procedure for InterStim therapy is a “staged implant.”

### Staged Implant

The patient is given broad-spectrum antibiotic coverage, lightly sedated, and placed in the prone position on the operating room table. The lower back and buttocks are prepped and draped. Fluoroscopy is used to mark the midline of the sacrum and the inferior border of the sacral iliac junction. This intersection corresponds to the area of the S3 foramen. A mark is made 2 cm lateral and superior to this intersection, the area is infiltrated with lidocaine, and the foramen needle is advanced at a 60-degree angle into the S3 foramen with fluoroscopic guidance (Fig. 23.6). Current is applied to the needle, and the motor and sensory response is assessed. An ideal motor response is good levator ani contraction in the form of

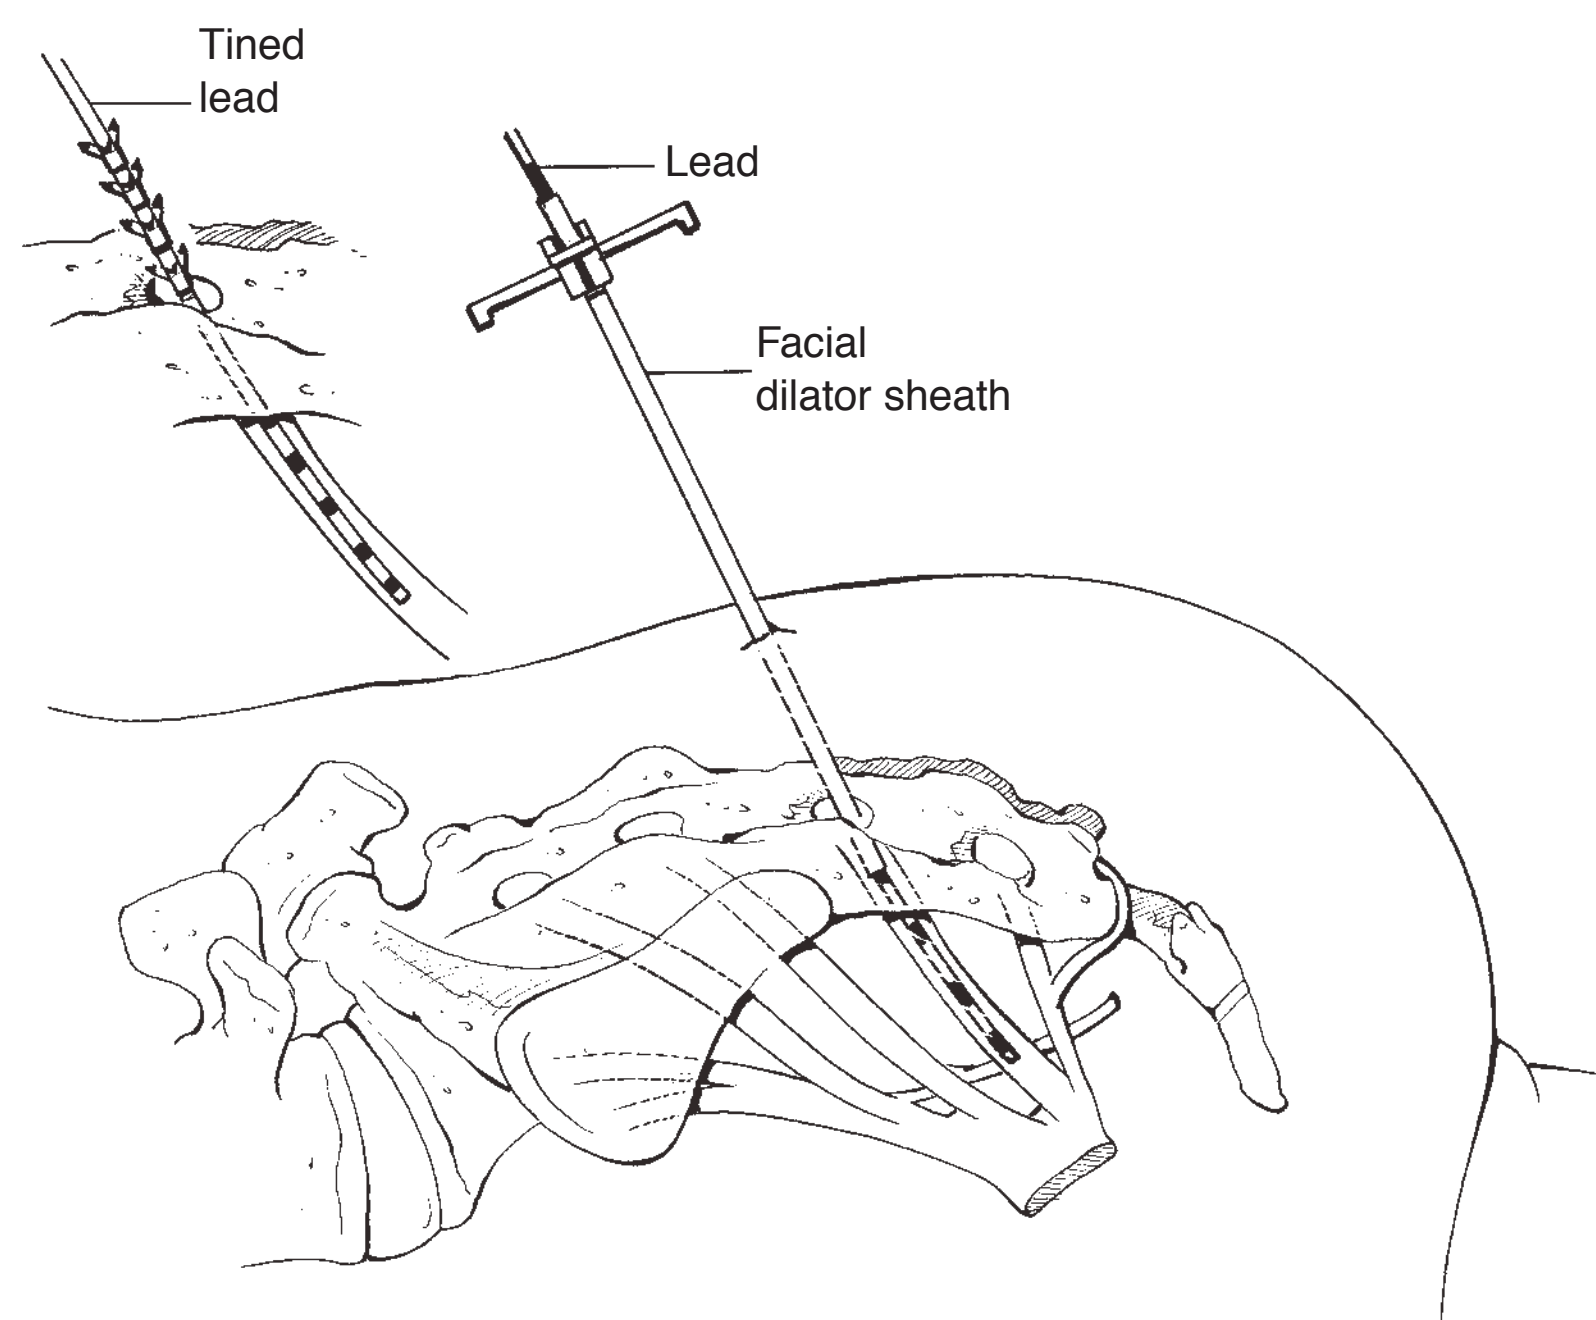

**FIGURE 23.6** Insertion of a foramen needle through the S3 foramen in preparation for testing the motor and sensory responses.

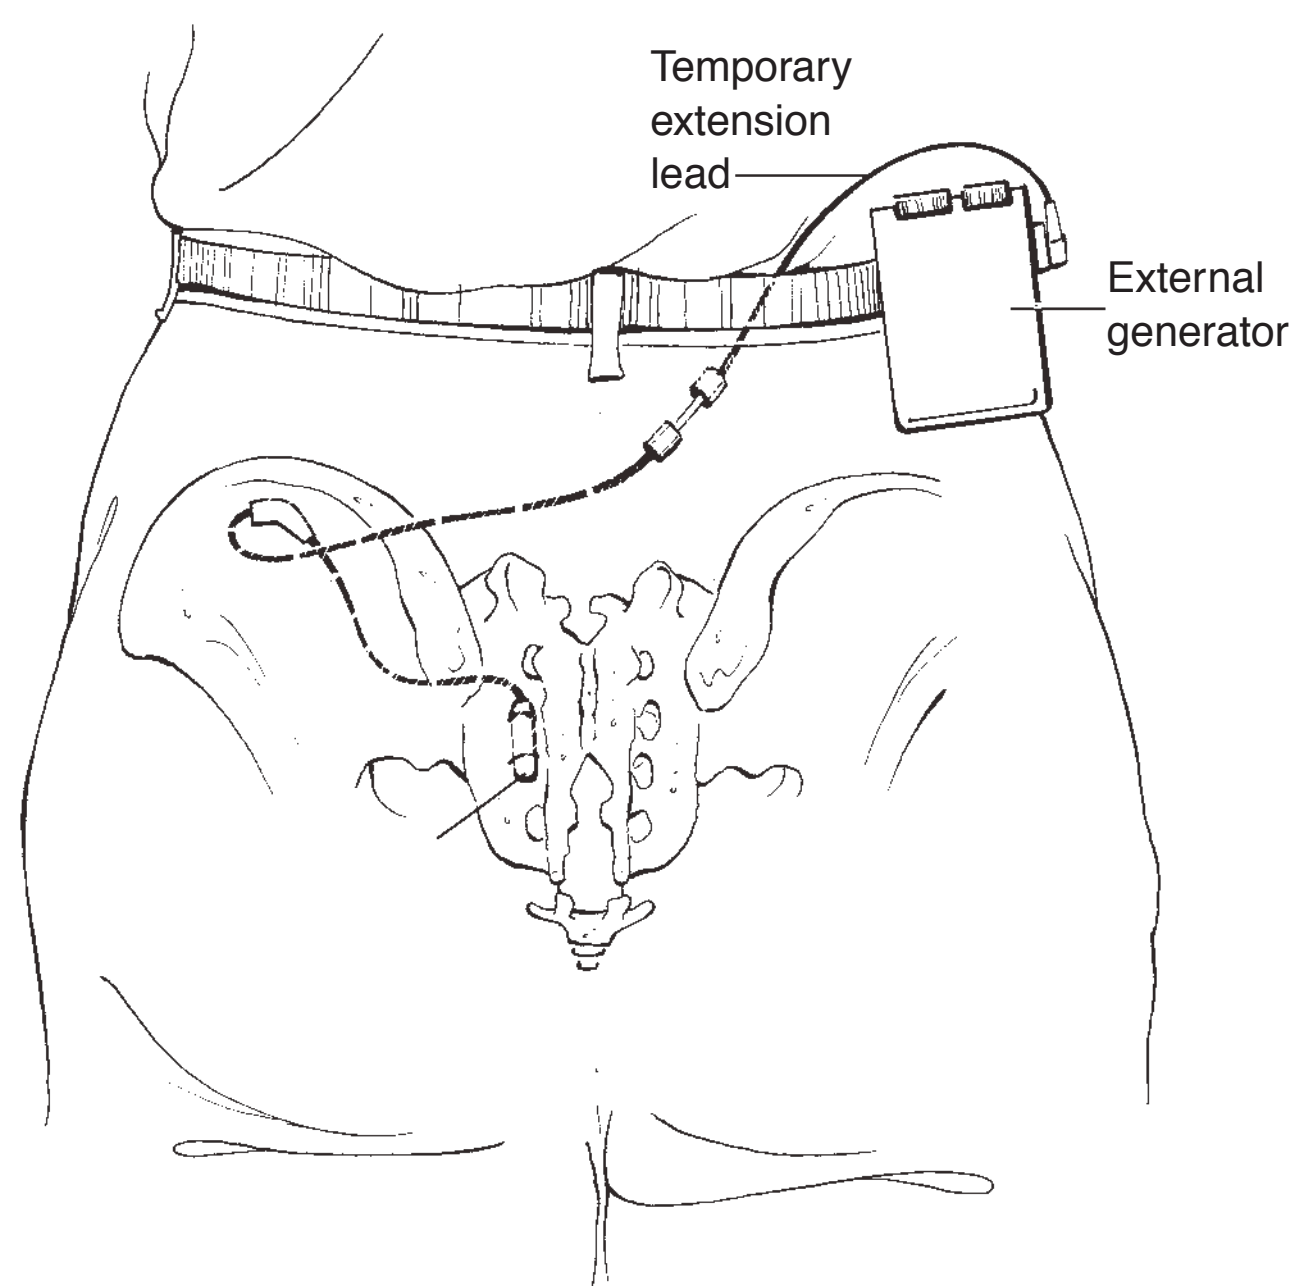

anal bellows, sacral flattening, and minimal dorsiflexion of the greater toe from stimulation of the S3 portion of the medial plantar nerve. The patient should be alert enough intraoperatively to report a gentle tapping or pulsating sensation in the rectal, vaginal, or perineal region. If the stimulation is painful, the lead should be readjusted in the operating room.

To confirm S3 placement, a needle is always passed into the foramen superior to the first. Stimulation of this lead results in leg rotation consistent with S2 placement, and this ensures S3 placement of the first electrode. Next, a small skin nick is made alongside the needle, through the dermis of the skin. A directional guide wire is passed through the foramen needle,

and the needle is removed. The lead introducer is advanced over the guide wire, through the dorsolumbar fascia and the foramen, and below the bone plate. The trocar is removed, and the permanent quadripolar lead is advanced through the lead introducer (Fig. 23.7). Fluoroscopy is used to confirm that all four stimulation points lie beneath the sacral bone plate. The patient remains awake and sensory, and motor responses are assessed with stimulation of each electrode. After confirming good lead placement, the lead introducer is removed under fluoroscopy, deploying the tines to secure the lead. A site on the ipsilateral upper buttocks is chosen where a future permanent generator will be placed if the patient

**FIGURE 23.7** Stage I implant. Advancement of permanent tined lead through the lead introducer parallel to the nerve (see inset). Motor and sensory response tested and lead introducer removed, deploying the tines and securing the lead.

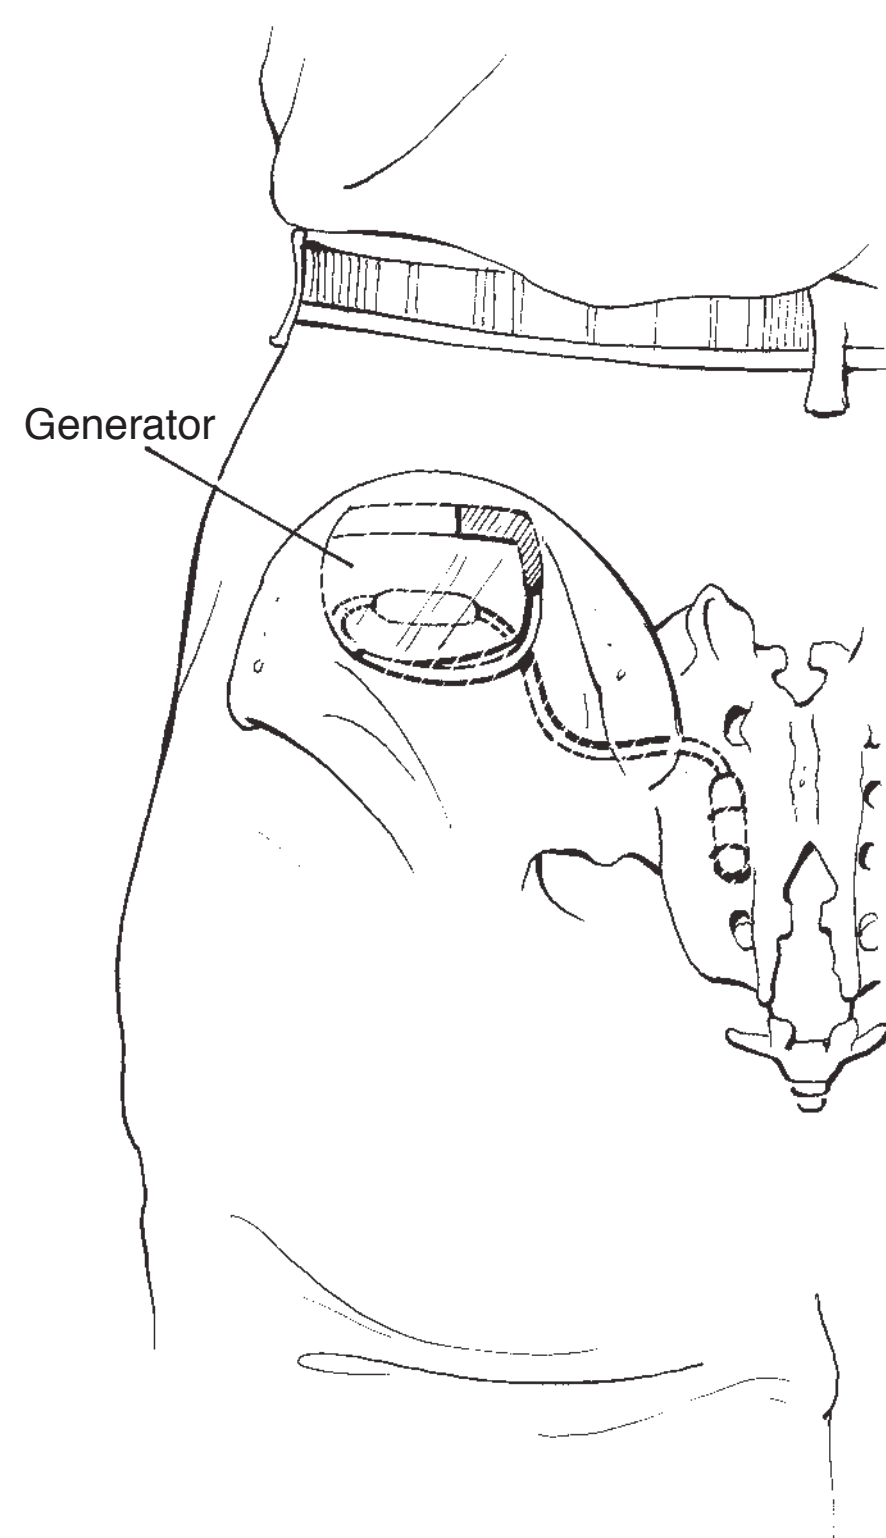

**FIGURE 23.8** Stage I implant. The lead is tunneled to a small, subcutaneous pocket on the ipsilateral side. The lead is then connected to a temporary extension lead, which is tunneled to the contralateral side and externalized. The external generator is then connected to the extension lead. The patient is discharged to home, and sacral nerve stimulation is tested over a 14- to 21-day period. Voiding logs and pain scores are maintained, and the program is changed as needed to maximize the clinical response.

responds to therapy. A small (2-cm) transverse incision is made and a subcutaneous pocket created. The proximal end of the lead is then tunneled to this pocket using the lead introducer. The permanent lead is then connected to a temporary extension wire, and the distal end of the wire is tunneled to the contralateral upper buttocks and externalized (Fig. 23.8).

One of four electrodes is chosen for initial outpatient stimulation, and the patient is discharged wearing the standard external generator for 2 weeks. The permanent lead allows for four different points of stimulation along the nerve. Variables such as rate, pulse width, and voltage can be adjusted by the patient with guidance from the clinician over the phone. The patient monitors voids per day, voided volume, urge scores, incontinence episodes, and pelvic pain during the 2-week test period. Responders are considered those with at least a 50% improvement in symptoms and the desire for a permanent implant based on improvement in quality of life. Nonresponders have the leads removed, and responders have a permanent generator placed. Permanent generator placement in the staged technique involves extending the incision and subcutaneous pocket in the ipsilateral buttocks, removing the temporary extension lead, and connecting the permanent generator (Fig. 23.9). At the end of the procedure, the generator is programmed to the settings to which the patient responded during the test stimulation so that there is no interruption in therapy.

Currently, a smaller generator is available that may be easier to implant and more comfortable for patients. Battery life on this smaller device is 4 years, compared to 8 years for the larger generator. Regardless, patients must be aware that they will require replacement of their generator later in life.

**FIGURE 23.9** Stage II implant. Patients not responding to the therapy have the lead removed. Responders have the extension lead removed, the ipsilateral subcutaneous pocket extended, and the generator placed. The generator is then programmed to the settings that gave a good clinical response during the test phase.

## Pudendal Neuromodulation

Stimulation of the pudendal nerve, as with sacral nerve stimulation, affects the sacral nerve roots of S2, S3, and S4. Multiple studies have shown inhibition of the micturition reflex with afferent pudendal stimulation, which also results in an increase in bladder capacity, and a decrease in uninhibited bladder contractions (20,21). Devices used to stimulate the pudendal nerve include InterStim and the BION device (Advanced Bionics, Valencia, CA). At the present time, however, neither of these nerve stimulation devices is FDA-approved for use at the pudendal nerve. Nevertheless, some studies have shown promise in using the pudendal nerve as a site of stimulation in patients with urinary urgency, frequency, and pelvic pain (22). The electrode is implanted along the course of the pudendal nerve toward Alcock's canal, at the level of the ischial spine. Intraoperative monitoring of EMG is used to confirm pudendal nerve stimulation. The exact technique is described elsewhere.

In a recent single-blind crossover trial, patients had both sacral and pudendal tined leads placed. Each was stimulated in random order. In responders (>50% improvement in their symptoms), the "better" lead was chosen by the patient (Fig. 23.10). Pudendal lead placement took a mean of 19.6 minutes compared to 27.4 minutes for sacral leads ( $p = 0.039$ ). Of 22 patients involved in the study, 17 (77%) had a permanent generator placed. The mean Interstitial Cystitis Symptom Index score decreased from 14.3 preoperatively to 10.7 at 6 months

**FIGURE 23.10** Postoperative photograph showing both sacral and pudendal leads in place. The pudendal lead was chosen by the majority of patients in a randomized, single-blind crossover study.

postoperatively in the sacral nerve stimulation group ( $p = 0.03$ ) and decreased from 15.7 to 8.6 in the pudendal group ( $p = 0.009$ ). The decrease in the Interstitial Cystitis Problem Index was statistically significant only for the pudendal group, with a decrease from 12.9 to 7.5 at 6 months ( $p = 0.002$ ). Average preoperative frequency was 24.07 per 24 hours for both groups. At 6 months, the mean total 24-hour voids decreased to 13.94 in the sacral group ( $p = 0.001$ ) and to 12.84 in the pudendal group ( $p = 0.001$ ). Mean voided volume increased from the preoperative value of 81.8 mL to 152.8 mL in the sacral group ( $p = 0.001$ ) and to 158.0 in the pudendal group ( $p = 0.001$ ). Of patients having a permanent generator placed, the majority (77%) chose to have the pudendal lead permanently implanted (22). Nevertheless, further studies with larger numbers are needed to determine if pudendal nerve stimulation is as effective or better at reducing urgency, frequency and pain symptoms than sacral stimulation.

### Posterior Tibial Nerve Stimulation

The tibial nerve arises from L4 through S3 and is a branch of the sciatic nerve. As with sacral and pudendal stimulation, it is possible to stimulate the posterior tibial nerve and modulate the innervation to the bladder, urinary sphincter, and pelvic

**FIGURE 23.11** Neuromodulation of the posterior tibial nerve. A 34-gauge acupuncturelike needle is inserted approximately 3 to 4 cm deep to the tibial nerve for stimulation.

floor (23,24) (Fig. 23.11). The technique stimulates the posterior tibial nerve with a 34-gauge needle placed bilaterally at SP-6. The needles are placed approximately 4 cm deep at a 30-degree angle cephalad. An adhesive grounding electrode is applied on each side near the medial calcaneus. Stimulation of the posterior tibial nerve is done by an amplitude of 0.5 to 10.0 mA, with a fixed pulse width (200  $\mu$ s) and frequency (20 Hz). Stimulation is applied for 30 minutes. The stimulation needs to be done on a weekly basis for 12 weeks, after which an attempt to wean treatments to once a month is tried. Unfortunately, there are no sham studies done on posterior tibial nerve stimulation for voiding dysfunction, so its use remains in question.

## Cytolysis

Bladder denervation procedures have been reported in the treatment of patients with intractable bladder pain and urinary frequency and urgency (25). Division of the posterior sacral roots, posterior rhizotomy, or division of the inferior vesical neurovascular pedicle may result in temporary improvement in urinary frequency, urgency, and pain. Ingelmann-Sundberg described a more selective denervation in which a transvaginal approach is used to resect the inferior hypogastric plexus, dividing both the sympathetic and parasympathetic fibers (25). Candidates for the transvaginal denervation are selected by first performing a subtrigonal injection of bupivacaine, which, if successful, results in significant relief of their irritative symptoms. However, with the advent of more oral therapies, along with neuromodulation, denervation is mainly mentioned in this section for its historical significance.

## OUTCOMES

### Complications

Complications of hydrodistention with or without fulguration are listed in Table 23.1. The most serious complication is bladder rupture, which should be considered if there is resumption of fluid inflow after maximally distending the bladder, return of significantly less fluid than what was instilled upon bladder drainage, or severe suprapubic or abdominal pain or distention. If a bladder rupture is suspected, an immediate cystogram should be performed. If the rupture is extraperitoneal, prolonged Foley catheter drainage is usually all that is needed to allow the rupture to heal spontaneously. If intraperitoneal leakage of contrast is seen, however, immediate exploration

### COMPLICATIONS OF MAJOR BLADDER RECONSTRUCTIVE SURGERY

EARLY
Ileus
Intraperitoneal abscess
Upper-tract obstruction
Thromboembolic events
Pneumonia
Wound infection
Cardiac events
Difficulty with catheterization
LATE
Persistence of interstitial cystitis symptoms
Upper-tract deterioration
Urolithiasis
Metabolic abnormalities
Spontaneous rupture of bowel conduit
Difficulty with catheterization
Ureteral stenosis
Ureteral reflux
Neoplasia
Bladder neck contracture
Urinary incontinence
Pyelonephritis/urinary tract infection

and repair are warranted to prevent peritonitis from urine leakage in the peritoneal cavity.

Early and late complications secondary to major bladder reconstruction are listed in Table 23.2. Persistence of IC/PBS symptoms is probably the most common and disheartening outcome for both the patient and surgeon.

The major risk of selective denervation cytolysis is ureteral injury during the vaginal dissection and is avoidable by placing ureteral catheters.

No serious, irreversible, adverse events have been reported with sacral nerve stimulation. Complications associated with InterStim are listed in Table 23.3. Reoperation occurs in approximately 25% of patients undergoing sacral nerve implantation. Causes for reoperation include sensory discomfort,

TABLE 23.3

### COMPLICATIONS OF INTERSTIM NEUROMODULATION THERAPY

Pain at generator site
Infection
Lead migration
Transient electric shock
Pain at lead site
Change in bowel function
Device malfunction
Change in menstrual cycle

lead migration, device failure, pocket revision, and infection. Infection of the device requiring explantation occurs infrequently, in 5% of patients in a recent review of a large series (26). Perioperative, broad-spectrum antibiotic coverage during implantation of the lead and generator should be administered to decrease the rate of infection.

## Results

Symptoms of IC/PBS may worsen for 2 to 3 weeks after a hydrodistention. Approximately 40% to 50% of IC/PBS patients undergoing a hydrodistention will have prolonged symptom improvement. If symptoms improve significantly for at least 4 to 6 months, repeat bladder hydrodistention may be indicated. Fulguration of Hunner ulcers improves symptoms in over 80% of patients undergoing this therapy. The improvement in pain is usually seen in the first 2 to 3 days and may be long-lasting. For those who relapse, repeat fulguration of ulcers usually yields a similar response.

The more aggressive, open surgical approaches have shown good results in carefully selected patients. Relief of symptoms in patients undergoing reconstructive surgery ranges between 60% and 90%. Patients with ulcerative disease have been reported to have better results. Although a significant percentage of this highly select group of patients who undergo cystectomy will experience significant relief, there are reports of patients having persistent pelvic pain despite having no pelvic organs.

Recently, we reviewed our experience with sacral nerve modulation for refractory IC/PBS (27). When a traditional test was performed with a temporary lead, we had a test-to-implant rate of 52% versus a 94% test-to-implant rate in the staged approach. The benefit of the staged test is that the permanent lead is more programmable and can be tested for an extended period of time. If a response is found, the lead does

not need to be removed prior to placing the generator, and the settings that worked on the temporary generator can be programmed into the permanent implanted neurostimulator so that there is no interruption in therapy. Twenty-six patients with refractory IC/PBS who had failed six previous treatments for their disease were implanted with a permanent generator. With a mean follow-up of 5.6 months, 96% of patients said they would undergo the implant again and would recommend the therapy to a friend. Significant improvements were seen in the number of day voids (47%) and nocturia (60%). The majority of patients reported at least a 50% improvement in frequency (72%), urgency (68%), pelvic pain (71%), pelvic pressure (67%), quality of life (76%), incontinence (69%), and vaginal pain (60%). No patients showed a >50% worsening in any symptom. The overall reoperation rate was 11.5% (3 of 26). An objective measurement of pain improvement was reported. Twenty IC/PBS patients with pelvic pain had a permanent implant placed with a median follow-up of 272 days. Seventeen of 20 (85%) used chronic narcotics prior to implant. Nineteen of 20 (95%) reported moderate or marked improvement in pain after implantation of a permanent generator. Morphine dose equivalents (MDEs) decreased from 86 mg per day to 56 mg per day (34%) ( $p = 0.015$ ) after implant, and 24% stopped all narcotics.

In a recent prospective study, patients with symptoms of IC/PBS refractory to more conservative treatments were followed after having InterStim implanted. At 14 months follow-up, mean voided volume increased from 111 mL to 264 mL, mean daytime frequency decreased from 17.1 to 8.7, and mean nighttime voids decreased from 4.5 to 1.1. Additionally, pain and symptom scores, measured using the Interstitial Cystitis Symptom and Problem Indices, all improved. Overall, 16 of 17 patients who underwent permanent implantation (94%) had improvement in all parameters at their most recent postoperative visit (28).

## SECTION III ■ PROSTATE

RANDALL ROWLAND

### CHAPTER 24 ■ ANATOMY OF THE PROSTATE

SAM D. GRAHAM, JR.

The normal prostate is a firm, elastic organ located immediately below the bladder and resting on the superior layer of the urogenital diaphragm to which it is firmly attached. The normal adult prostate is approximately 4 cm in length and 4 to 5 cm in width. It is traversed throughout its length by the urethra and ejaculatory ducts entering at the base and terminating in the posterior prostatic urethra.

In the past the prostate has been divided into three to seven lobes. Most commonly, these segments are the two lateral lobes, a median lobe, a posterior lobe, and an anterior lobe. With the advent of ultrasound, the anatomy is now defined as a transition zone comprised of periurethral glands and a peripheral zone or true prostate. Anatomically, no true lobar anatomy exists, and the prostate has been shown to have the two concentric areas seen on ultrasound. The peripheral zone is mostly posteriorly located and is comprised of long, branched glands from which most carcinomas are thought to arrive. The central zone is comprised of submucosal glanduloductal units and short glands from which prostatic hypertrophy is thought to arise. Scattered throughout the prostate are smooth muscle fibers that are thought to be involved in ejaculation.

The prostate has a tough capsule of fibrous tissue and muscular elements that completely envelops the prostate and is densely adherent to it. This capsule is actually aglandular prostatic tissue that is connected to the acini and inseparable from the parenchyma. This is surrounded by a periprostatic fascia.

There are significant fascial investments around the prostate. The endopelvic fascia is a continuation of the endoabdominal fascia. In the pelvis, there are three parts of this fascial plane (1). The parietal layer covers the muscles lining the pelvic wall (piriformis and obturatorius internus) and continues superiorly to connect with the transversalis and iliopsoas fascias. All somatic nerves except for the obturator nerve are beneath this fascial layer. A thickening of this fascia extending from the pubis to the ischial spine is known as the arcus tendineus. The second portion of the endopelvic fascia (diaphragmatic portion) covers the two muscles on each side of the pelvis that make up the pelvis diaphragm (coccygeus and levator ani). A third (visceral) portion of the endopelvic fascia is continuous with the diaphragmatic fascia and extends upon the pelvic organs for a variable distance, blending into their fibrous coats. Anteriorly, the endopelvic fascia coalesces into the medial puboprostatic ligaments connecting the pubis to the prostatic capsule. The lateral puboprostatic ligaments extend from the superior diaphragmatic layer of the endopelvic fascia to the prostate.

Posteriorly, the prostate is invested by the two layers of Denonvilliers fascia, which embryologically is derived from the peritoneum. The posterior layer exists as the rectal fascia, while the anterior layer fuses laterally to the endopelvic and periprostatic fascia.

The urethra runs completely through the prostate, although the path is angled approximately 45 degrees at the verumontanum. The verumontanum represents the terminal end of the ejaculatory ducts as they course through the prostate from the seminal vesicles/vas deferens (Fig. 24.1). The opening in the apex of the verumontanum is known as the prostatic utricle. In addition, there are a series of ductal openings directly into the prostatic urethra from the prostatic glands. The urethra exits the prostate at the apex, and although the anatomical drawings traditionally show the apex directly on the pelvic floor, dissections during radical prostatectomies show that there is approximately a 1-cm gap from the apex to the pelvic floor.

---

#### VASCULAR ANATOMY

---

The prostatic blood supply comes predominantly from the internal iliac artery and is a series of lateral pedicles, the most prominent and constant of which is the pedicle at the base of the prostate (superior prostatic artery). Additional branches may also exist, usually at the apex of the prostate (Fig. 24.2). The superior prostatic artery enters just below the bladder neck and forms two branches, one to the capsule and the other to the urethra. As patients age, the latter becomes more prominent with prostatic enlargement (2). Other sites of origin for the prostatic artery are the internal pudendal, the superior vesical, or the obturator artery.

The past 20 years have emphasized the “nerve-sparing” technique for both prostatectomy and cystectomy. This operation is actually a neurovascular-sparing technique that involves separating the neurovascular bundle from the prostate. The neurovascular bundle can be located along the posterior lateral prostate at the base of the prostate beneath the anterior layer of Denonvilliers fascia. More distally, the neurovascular bundle crosses the apex of the prostate and enters the pelvic diaphragm posterolaterally to the membranous urethra.

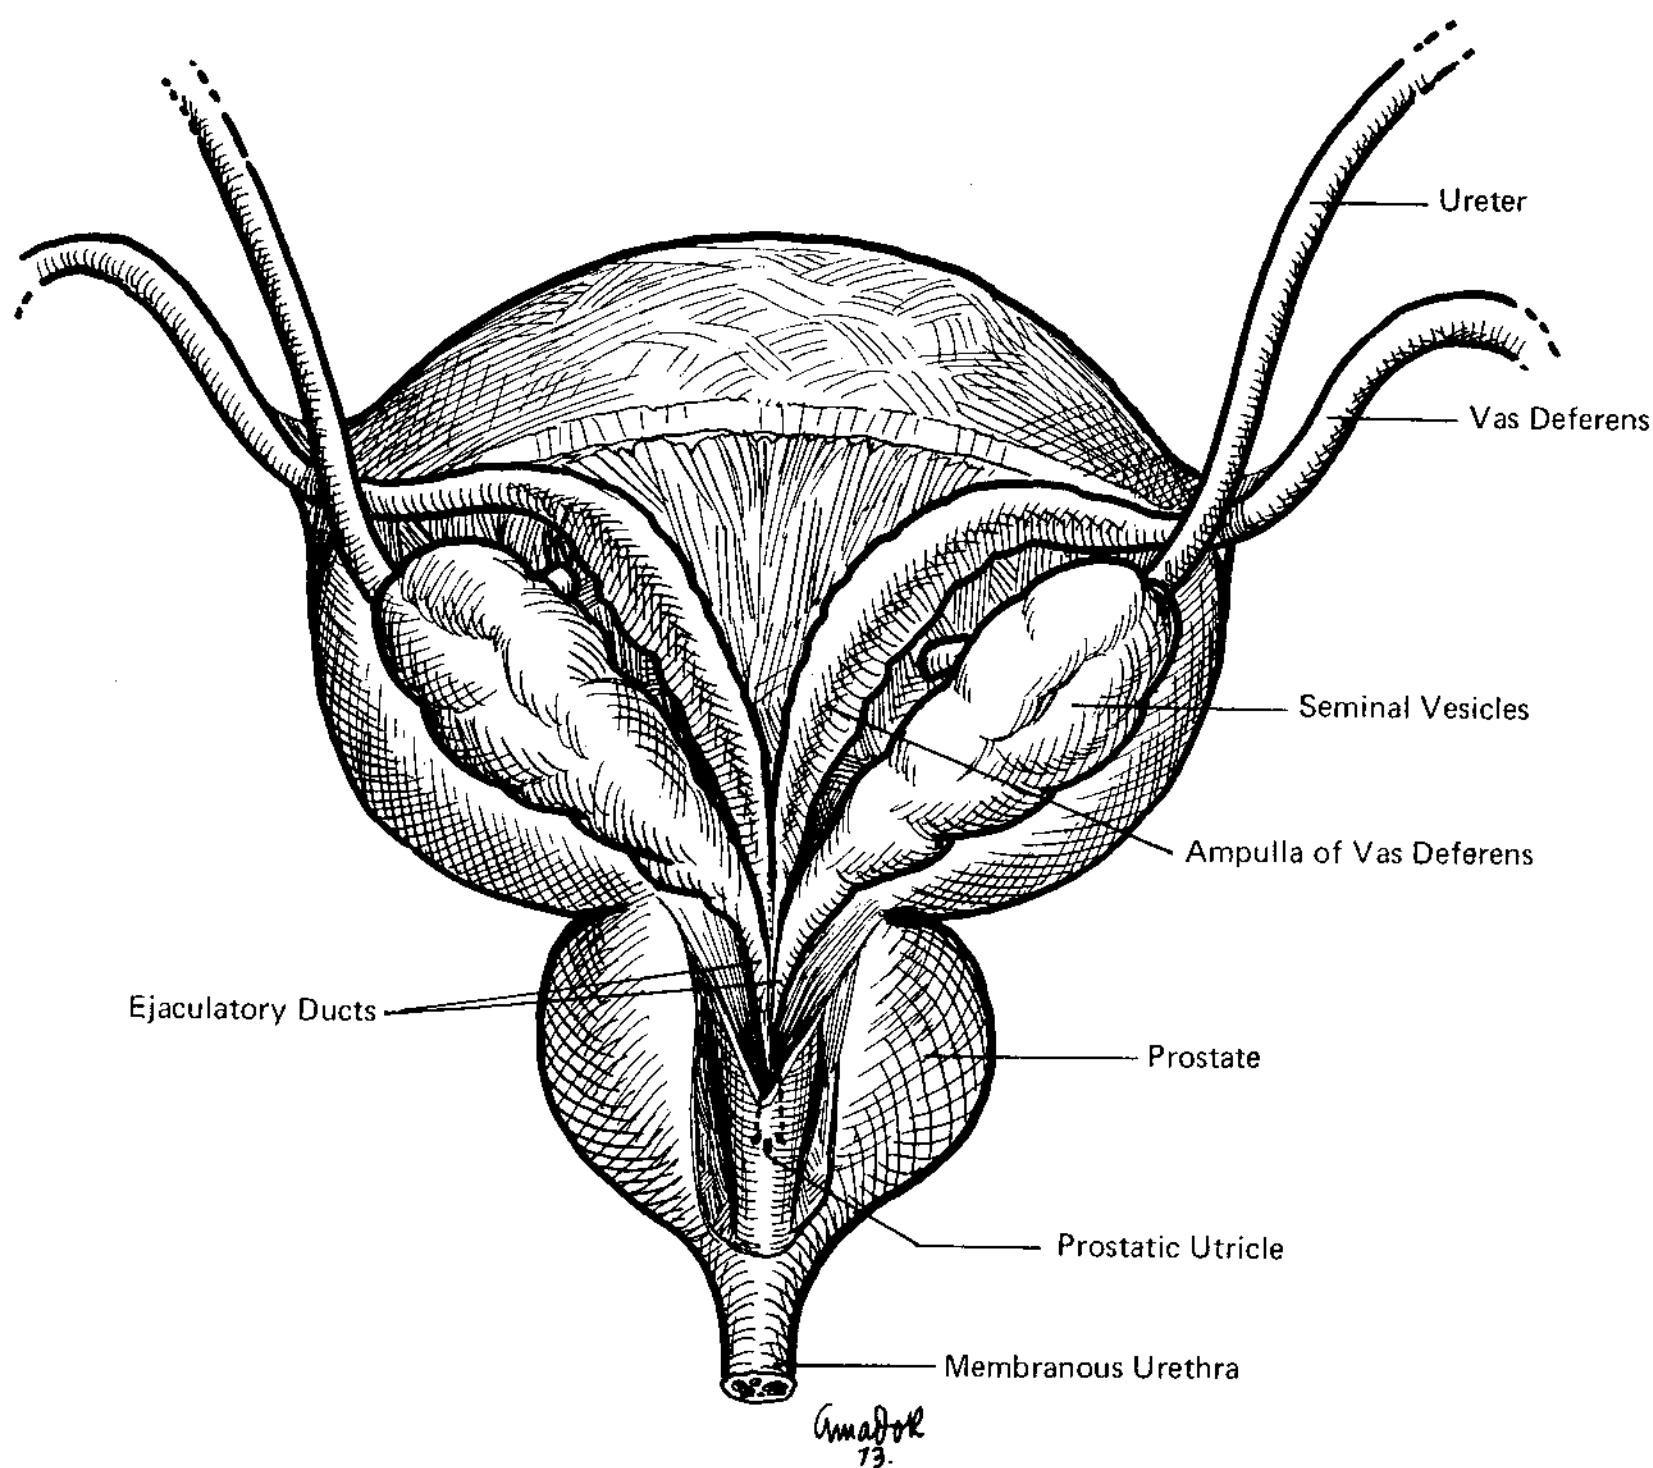

The venous drainage of the prostate is via the anterior venous plexus (Santorini), which is found on the anterior and lateral prostate. This plexus receives blood from the dorsal vein of the penis and empties into the hypogastric vein.

---

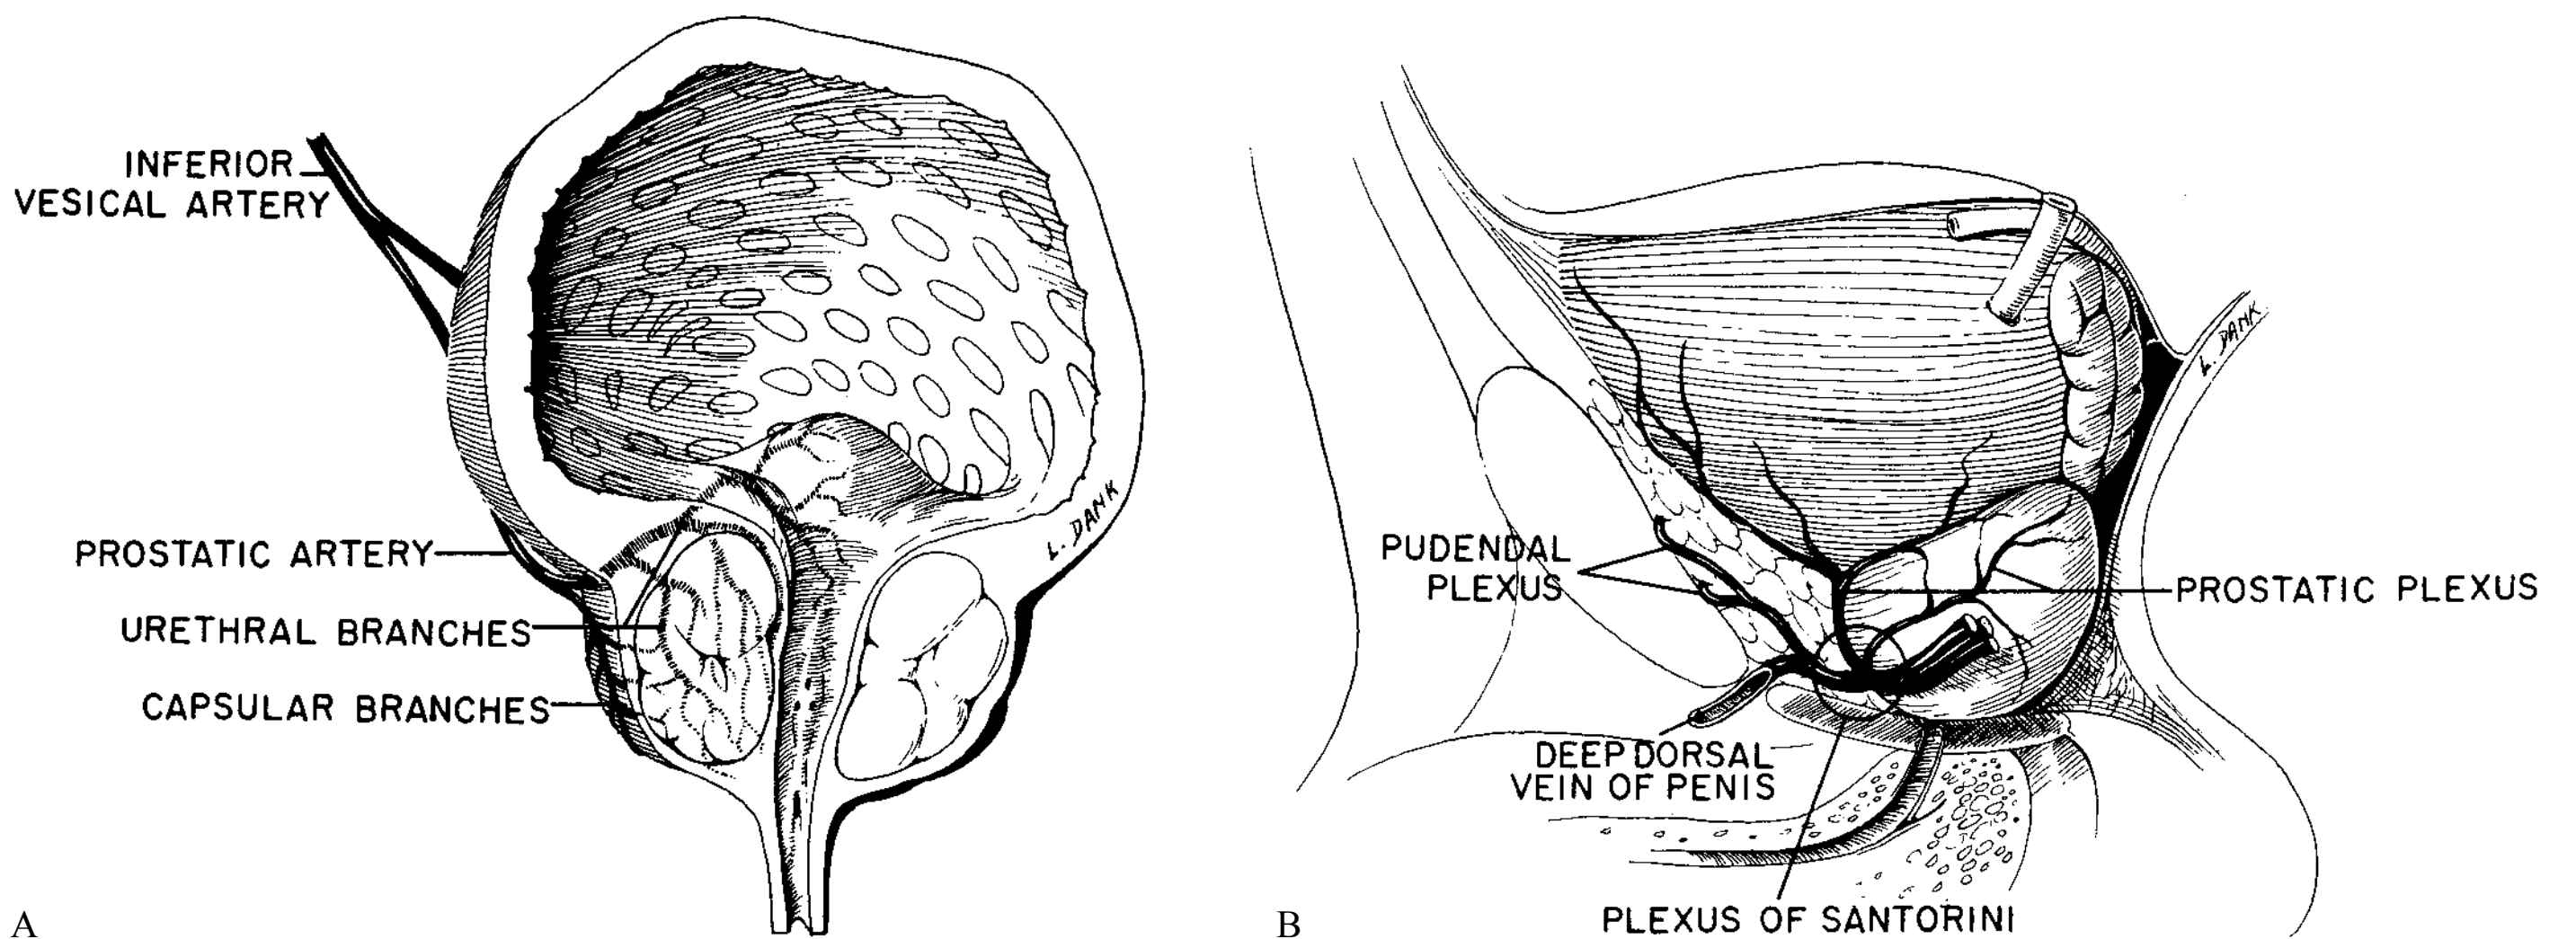

#### LYMPHATIC ANATOMY

---

The lymphatic drainage of the prostate is predominantly along the path of the prostatic artery, with the primary nodal drop site being the obturator nodes. Other potential sites of nodal metastases include the external iliac and presacral nodes.

**FIGURE 24.1** Relationship of the prostate and the seminal vesicles.

**FIGURE 24.2** Vascular anatomy of the prostate. **A:** Arterial anatomy. **B:** Venous anatomy.

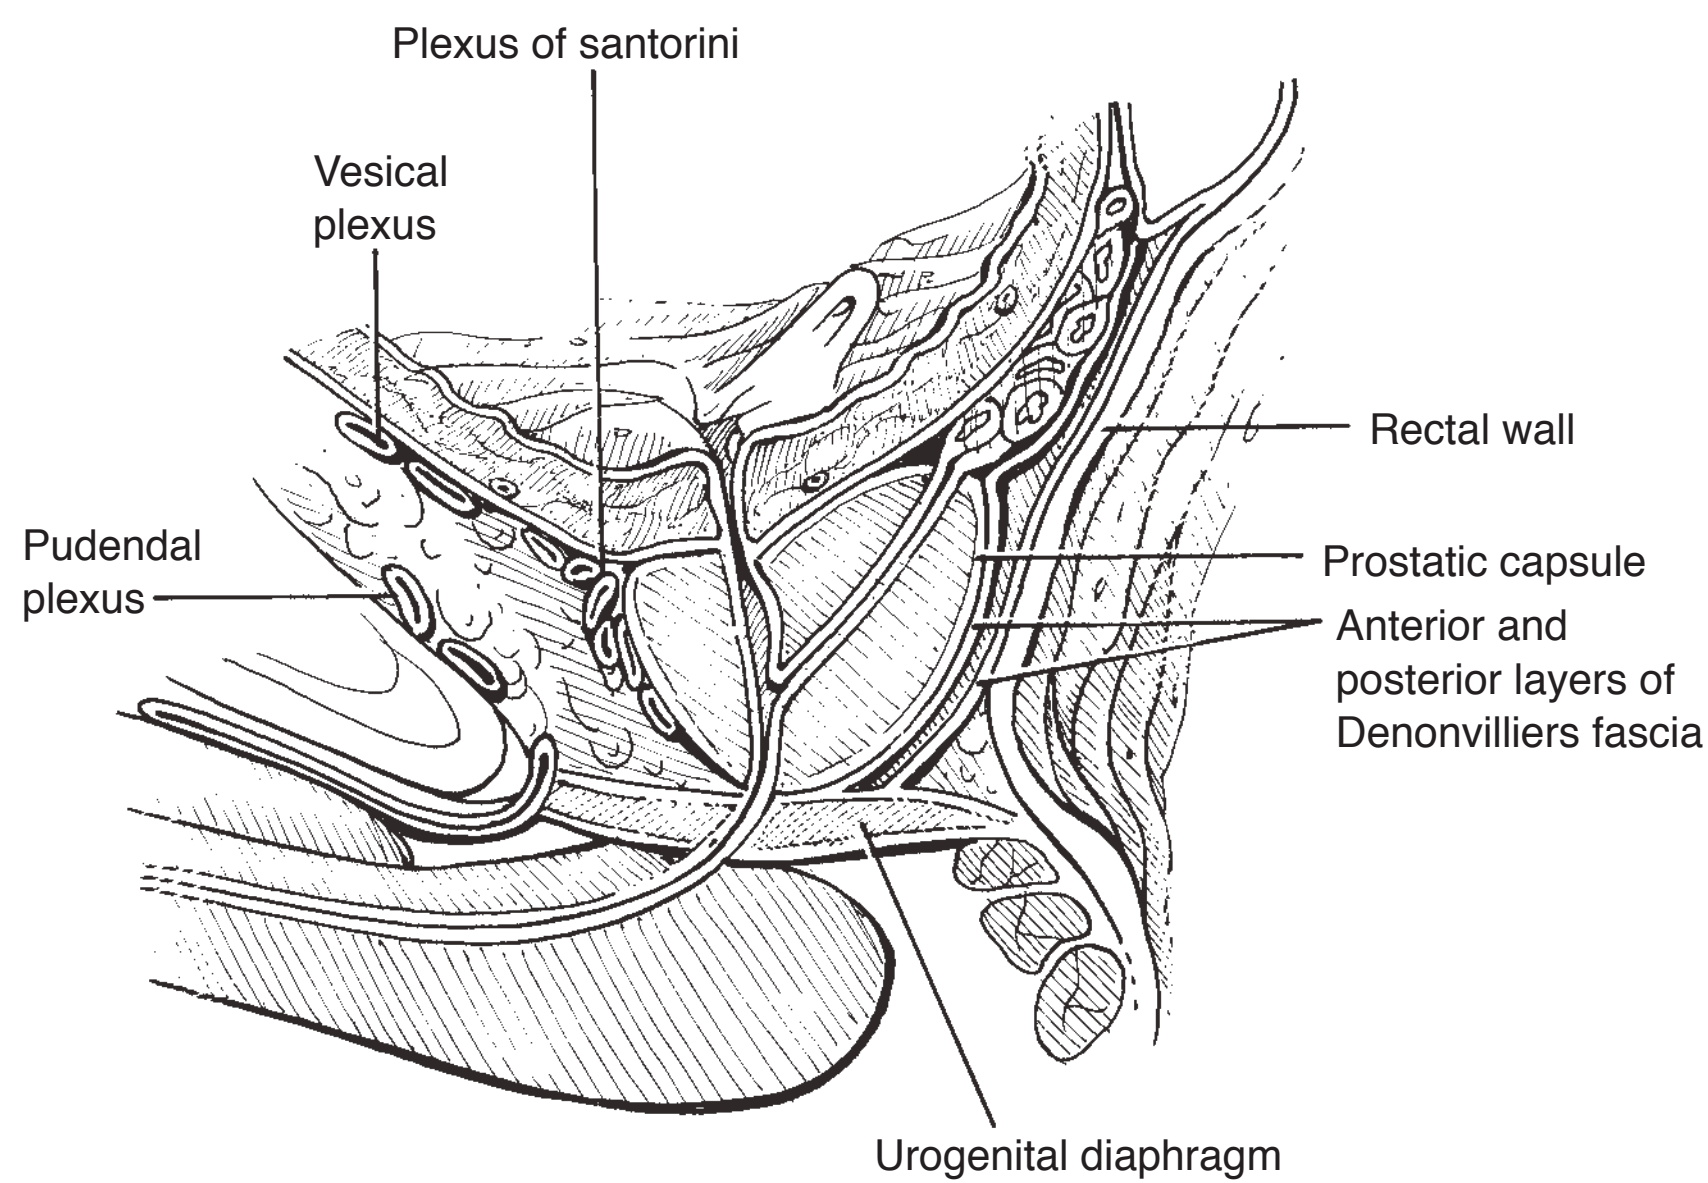

## NEUROANATOMY

The prostate has sympathetic, parasympathetic, and somatic innervation. The sympathetic innervation is from L1 and L2 via the superior hypogastric plexus. The parasympathetic and somatic innervation is from S2,3,4 via the inferior hypogastric plexus and pudendal nerves, respectively.

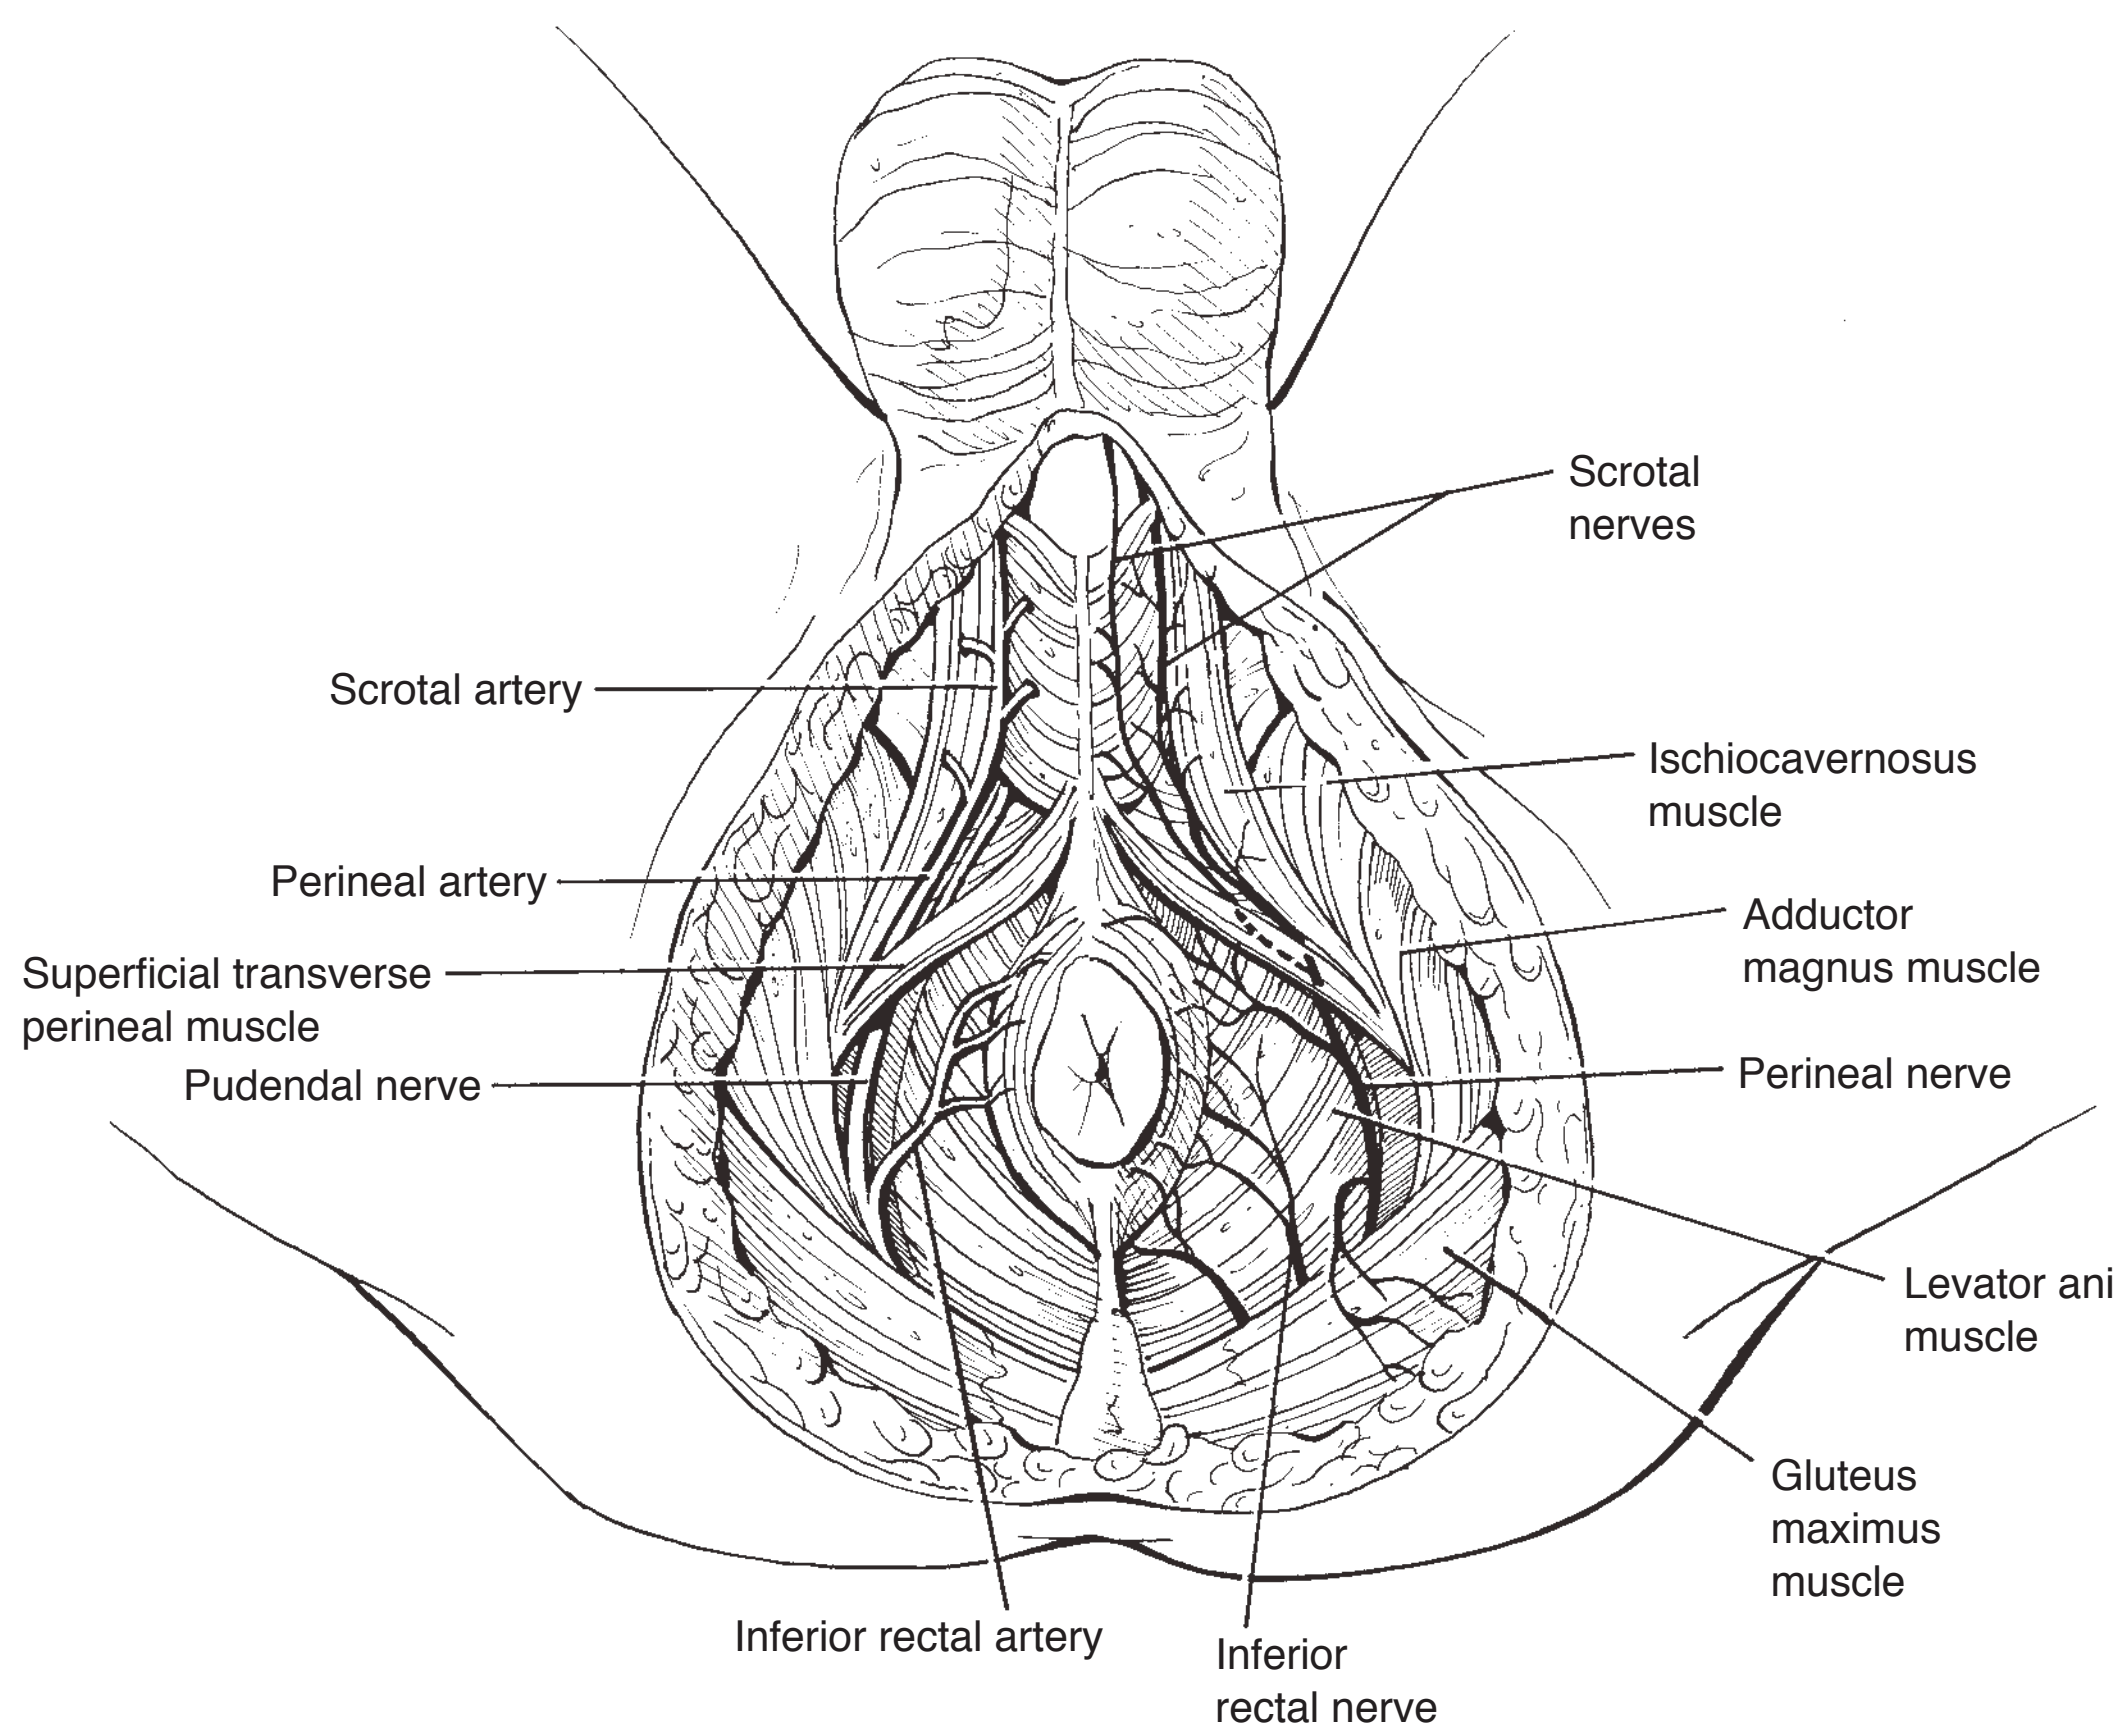

## CONTIGUOUS STRUCTURES

The prostate is inferior to the bladder and anterior to the rectum (Fig. 24.3). The perineal anatomy is a complex of muscles and tendons that comprise the pelvic floor, beginning from the

skin of the perineum, the superficial (Camper) fascia and the deep (Colle) fascia. The latter is attached to the ischiopubic rami and the border of the urogenital diaphragm and is continuous with the Scarpa fascia. The most superficial pelvic musculature includes the ischiocavernosus, the bulbocavernosus, the superficial transverse perineal muscles, and the external anal sphincter (Fig. 24.4). These muscles are united in the midline as a central tendon (perineal body) and function as a single muscle. This central tendon is attached to the bulb of the rectum by fibrous bands of muscle known as the rectus urethralis (3). Beneath this layer of muscles is the deep perineal compartment that is predominantly the urogenital diaphragm, which is attached to the inferior rami of the ischia and pubis.

# CHAPTER 25 ■ SURGERY FOR BENIGN PROSTATIC HYPERTROPHY

BRIAN R. MATLAGA AND JAMES E. LINGEMAN

The prevalence of benign prostatic hypertrophy (BPH) is an age-dependent phenomenon; by 60 years of age its prevalence is >50%, and by age 85 it has been reported to be as high as 90% (1). The natural history of BPH is generally considered to be one of progression, with mild symptoms becoming increasingly more bothersome over time. It has been reported that among 50-year-old men the lifetime incidence of surgical or medical intervention for BPH may be as high as 35% (1). Wasson et al. found that in a 3-year, multicenter, randomized controlled trial comparing men with moderate symptoms of BPH treated by either watchful waiting or transurethral resection of the prostate (TURP), 24% of men in the watchful waiting arm underwent surgical intervention (2).

A century ago, open suprapubic prostatectomy was considered the standard treatment of men with severe symptoms of BPH requiring removal of the adenoma. Subsequently TURP was developed and became the first significant “minimally invasive surgical procedure.” More recently, a number of alternative surgical therapies have been introduced to treat men with BPH, most prominently the laser-based therapies. The American Urologic Association (AUA) convened a clinical guidelines panel that, following a meta-analysis of the published literature, determined that for patients with significant lower-urinary-tract symptoms (LUTS) due to BPH, surgical intervention is an appropriate treatment and that selection of the surgical modality should be based upon the surgeon’s experience, the patient’s individual prostatic anatomy, and medical comorbidities (Fig. 25.1).

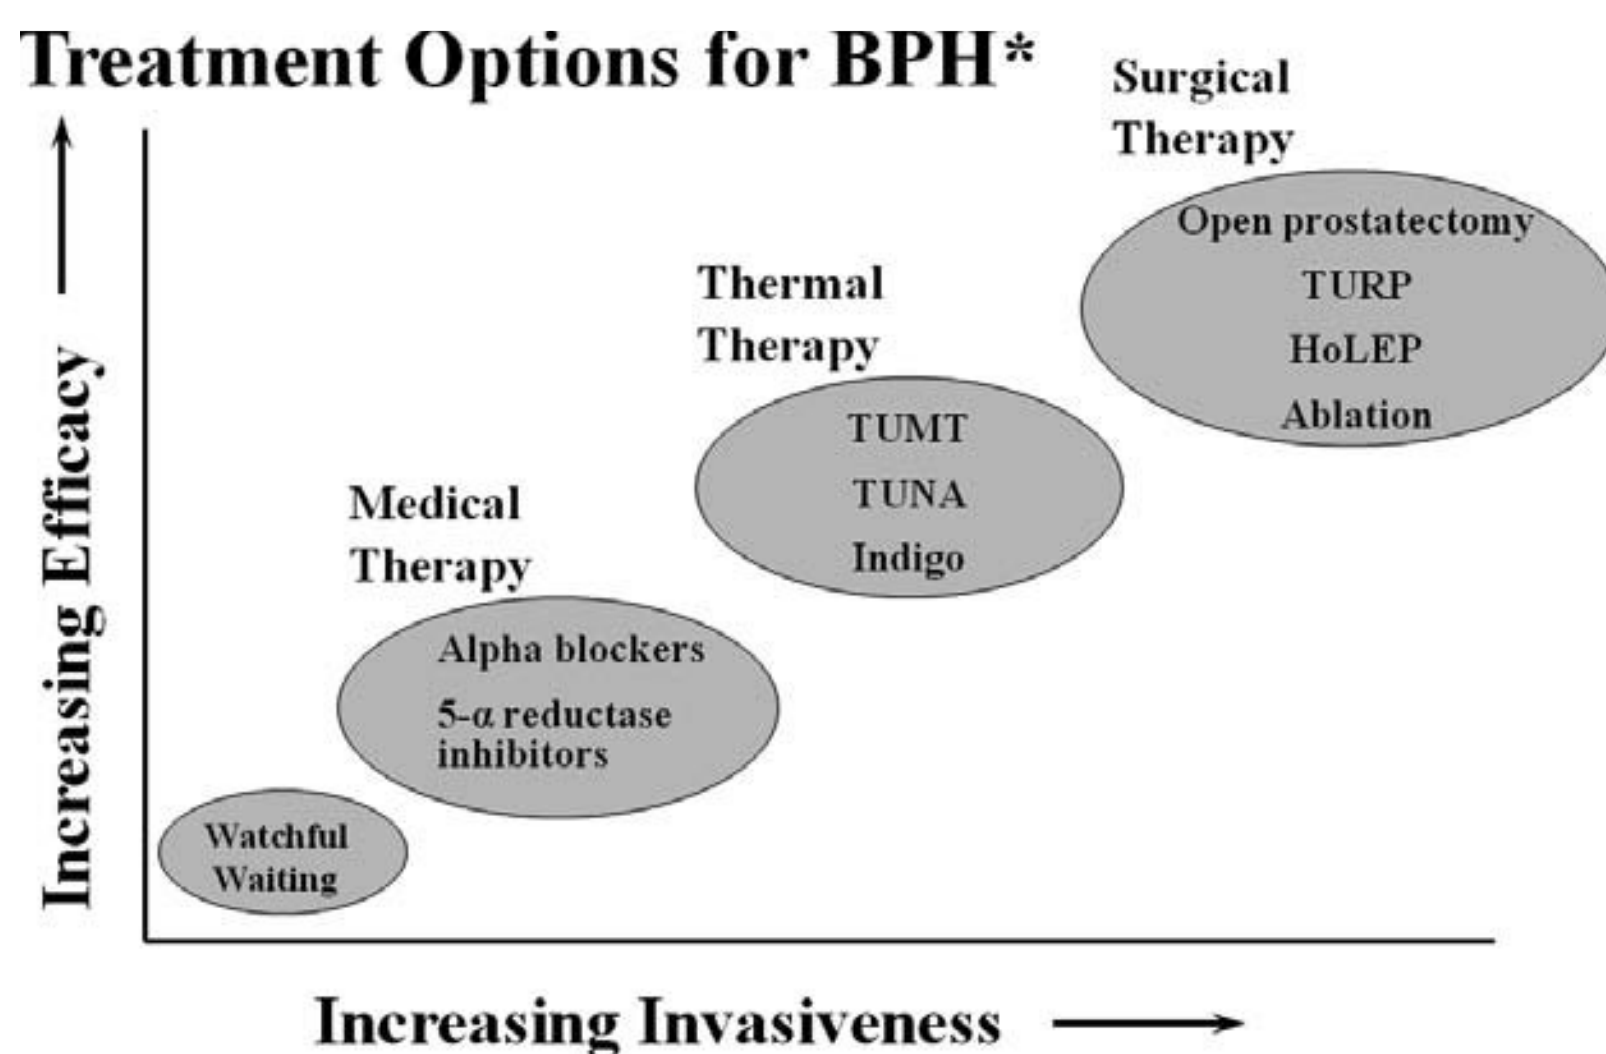

## DIAGNOSIS

The AUA guidelines on the management of BPH explicitly define the appropriate evaluation of patients with LUTS, and the following recommendations are based on the meta-analytic data presented in these guidelines (Table 25.1) (3). A validated questionnaire, such as the AUA Symptom Index or the International Prostate Symptom Score (IPSS), will better quantify the effect of patients’ LUTS on their quality of life.

All patients should undergo a screening urinalysis, and serum prostate specific antigen (PSA) should be measured as a screening for prostate cancer. Urinary flow-rate measures and quantification of postvoid residual urine may provide additional data, particularly for those patients with a complex medical history or those undergoing surgical therapy. A cystoscopy or transrectal ultrasound is not mandatory before a surgical treatment, but both can provide valuable information for preoperative planning.

## INDICATIONS FOR SURGERY

There are certain absolute indications for surgical treatment of BPH (Table 25.2). Typically, however, the management of patients depends on the degree of inconvenience they experience from their LUTS. The AUA clinical guidelines on BPH recommend that men who experience nonbothersome symptoms

- Renal insufficiency
- Moderate or severe LUTS

of BPH should not be managed surgically. Patients with bothersome symptoms should undergo treatment, and the physician should review the benefits and risks of all approaches and interventions with the patient.

---

## ALTERNATIVE THERAPY

---

There are a number of alternative therapies besides surgery for BPH (Table 25.3).

---

### Watchful Waiting

---

Some patients experience certain mild symptoms related to BPH. For such patients, the risks may outweigh the benefits they may achieve from the therapy. With watchful waiting, patients are monitored by their urologist but do not receive any active treatment. Such patients are examined on a regular basis to monitor for progression of symptoms, when a more active intervention can be discussed.

---

### Medical Therapy

---

There are two main medical therapies for patients with symptoms of BPH: alpha-adrenergic blockers and 5 alpha reductase inhibitors. These therapies can be administered alone or in combination. Alpha blocker therapy is based on the

TABLE 25.3

**TREATMENT OPTIONS FOR PATIENTS WITH SYMPTOMS OF BPH**

- Watchful waiting
- Medical therapy
  - Alpha-adrenergic blockers
  - 5 alpha reductase inhibitors
  - Combination therapy
- Minimally invasive therapies
  - Transurethral microwave treatment
  - Transurethral needle ablation
- Surgical therapies
  - Transurethral resection of the prostate (TURP)
  - Transurethral incision of the prostate (TUIP)
  - Holmium laser enucleation of the prostate (HoLEP)
  - Laser ablation: holmium:YAG or potassium titanyl phosphate (KTP)
  - Open prostatectomy: suprapubic or retropubic

hypothesis that the symptoms of BPH are potentiated by the alpha-adrenergic-mediated contraction of prostatic smooth muscle. Five alpha reductase inhibitors block the conversion of testosterone to dihydrotestosterone, which can reduce prostate size and BPH symptoms. Both therapies have been studied extensively, and they may be most appropriately used for patients who experience mild inconvenience related to the symptoms of BPH.

---

### Minimally Invasive Therapy

---

These therapies typically are available for the treatment of patients with symptomatically bothersome BPH. Many of these minimally invasive treatments rely on the administration of high temperatures to produce coagulation necrosis of the prostate tissue. Ultimately, the goal of such hyperthermic treatment is to enlarge the prostatic fossa, similar to a surgical debulking but without the morbidity of surgery. Transurethral microwave thermotherapy (TUMT) is likely more effective than medical therapy in reducing patients' LUTS, but it is likely less effective than surgical therapy.

Transurethral needle ablation (TUNA) also affects prostate tissue by a thermal mechanism, but with this intervention heat is delivered via radiofrequency energy. A TUNA procedure involves cystoscopically placing two needles directly into the prostate by piercing the urethra and then administering radiofrequency energy that heats the prostate tissue to 100°C. As with microwave therapy devices, TUNA induces a coagulative necrosis effect. The efficacy of TUNA is comparable to that of microwave thermotherapy.

---

### Surgical Techniques

---

#### Transurethral Incision of the Prostate (TUIP) and Transurethral Resection of the Prostate (TURP)

The patient is placed in a dorsal lithotomy position, with the thighs abducted to allow manipulation of the resectoscope. After sterile preparation and draping is completed, the patient's

urethra is calibrated using van Buren sounds up to 30Fr. It is only necessary to calibrate the anterior urethra; excessive manipulation of the prostatic urethra may result in bleeding, which can make visualization difficult. Proper calibration is essential to reduce the risk of subsequent urethral stricture caused by the resectoscope manipulation. A 26Fr or 28Fr resectoscope is then inserted into the urethra. A 3% glycine or sorbitol solution is used for irrigation, at gravity pressure. Cutting and coagulation currents should be adjusted to the appropriate levels for the electrical generator used for the case.

If the prostate volume is small (20 g or less), the lateral lobes of the prostate are not coapting, and there is a high bladder neck or median bar present, it may be appropriate to proceed with a transurethral incision of the prostate (TUIP). The bladder should be filled via the continuous-flow resectoscope, and with a TUIP-type electrocautery knife, incisions should be created at the 5:00 and 7:00 positions. The incisions should be deepened until the capsule of the prostate is reached, and they should also be extended to just proximal to the verumontanum.

If the prostate is  $>20$  g, or if there is a median lobe or the lateral lobes are coapting, a TURP is the more appropriate procedure to perform (Table 25.4). TURP is performed with an electrocautery loop and glycine or sorbitol irrigation. However, bipolar TURP devices have been developed that permit the resection of prostate tissue in a saline irrigant. A procedural difference between the two approaches is that when the bipolar device is used, the speed with which the loop is withdrawn through the tissue should be much slower than with the standard TURP electrocautery loop. If there is a median lobe present, resection should initially begin with this structure. In a stepwise fashion, the lobe is resected with the electrocautery loop. Resection of the median lobe is complete when bladder neck fibers are visualized. Particularly during the resection of the median lobe, care should be taken to not involve the ureteral orifices in the resection.

Following complete resection of the median lobe of the prostate, attention can be turned to resection of the lateral lobes. First, the right lobe is resected, starting at the 7:00

position, and proceeding from the bladder neck to a point just proximal to the verumontanum. Resection should be carried down to the fibers of the bladder neck and prostatic capsule. The left lobe of the prostate can be resected in a similar fashion. The surgeon should take care not to resect too deeply and perforate the capsule, as well as not to resect beyond (distal to) the verumontanum.

Following complete resection of the lateral lobes, the anterior tissue of the prostate should be inspected. If obstructing tissue is present at this location, it may be resected. The Ellik evacuator can then be used to remove the resected tissue fragments, which may be sent for pathologic analysis. The prostatic fossa should be reinspected, as oftentimes open blood vessels may become more apparent following Ellik evacuation. Hemostasis should be ensured, and a three-way Foley catheter should be placed. Continuous bladder irrigation with saline is generally necessary overnight; if bleeding persists, the Foley catheter may be placed on traction.

### Holmium Laser Enucleation of the Prostate (HoLEP)

The patient is positioned as for a TURP. A 26Fr or 28Fr resectoscope is then inserted into the urethra. The inner sheath of the resectoscope should be specially configured with a purpose-built laser bridge or laser-stabilizing catheter to minimize vibration of the laser fiber during the procedure. The 550- $\mu$ m end-fire laser fiber is placed through the laser bridge or laser-stabilizing catheter. Normal saline irrigant is used during the procedure, and the resectoscope should be configured to continuous gravity flow.

Once the resectoscope has been passed via the urethra into the bladder, the ureteral orifices should be identified. The verumontanum and the external urinary sphincter should be identified and their location confirmed. If there is a significantly enlarged median lobe, it is often most expeditious to enucleate this structure first, as this maneuver will provide more room to accomplish the lateral lobe dissection (Table 25.5). To enucleate the median lobe, the holmium laser should be set at an energy of 2 J and a frequency of 50 Hz. Two sulci will be

TABLE 25.4

#### TRANSURETHRAL INCISION OR RESECTION OF THE PROSTATE

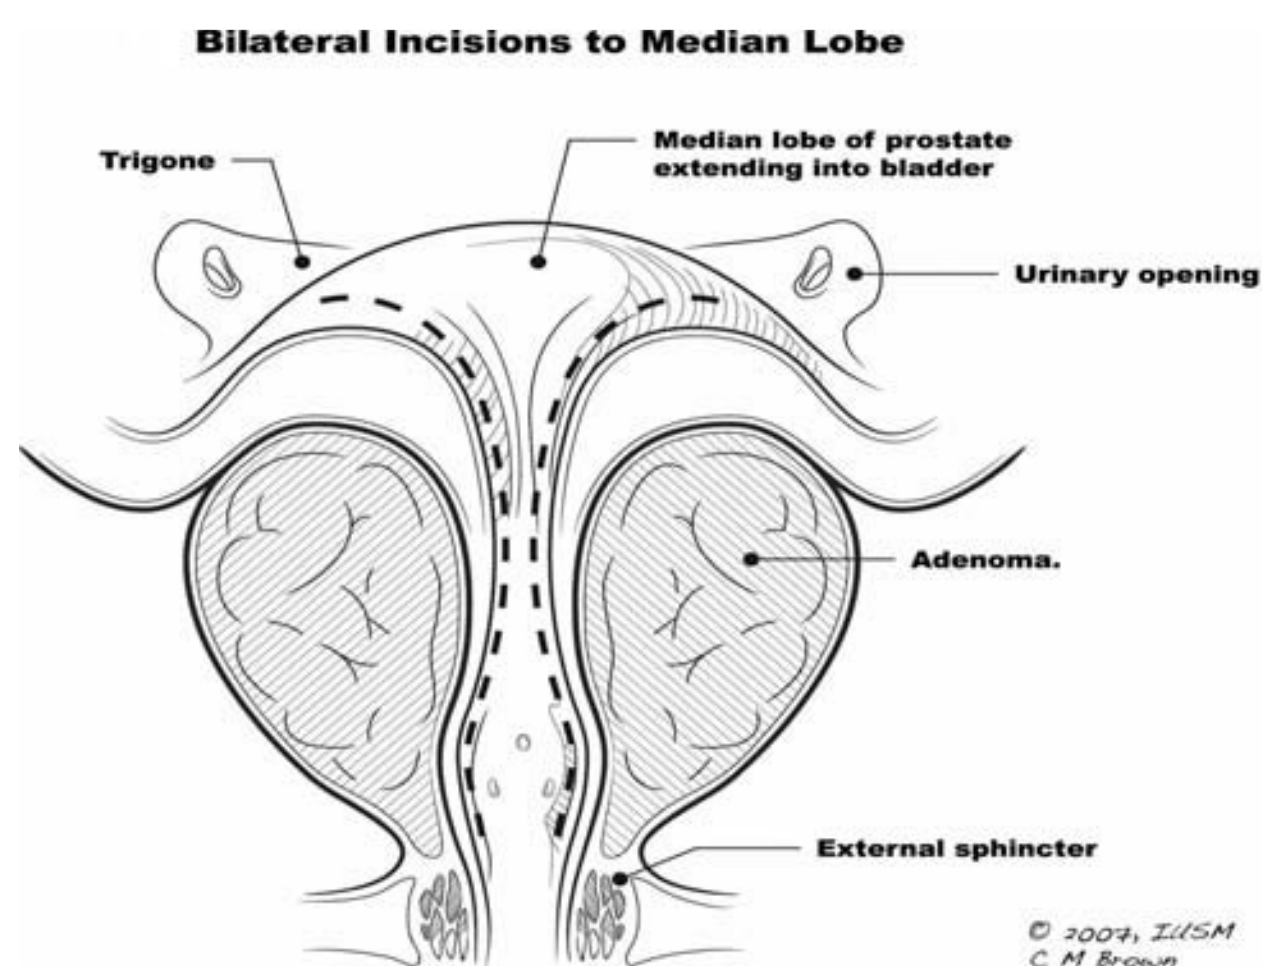

- Assessment of prostate
- TUIP if:
  - Prostate volume  $<20$  cc, high bladder neck, no lateral lobe hypertrophy
  - Incisions at 5:00 position, from bladder neck to verumontanum
  - Deepen to level of prostate capsule
- TURP if:
  - Prostate volume  $>20$  cc, coapting lateral lobes, median lobe
  - Resect median lobe, if present, first
  - If no median lobe, create groove in 6:00 position
  - Resect to bladder neck and capsular fibers
  - Resect lateral lobes in stepwise fashion, from bladder neck to verumontanum
  - Resect anterior tissue if present

TABLE 25.5

#### HOLMIUM LASER ENUCLEATION OF PROSTATE

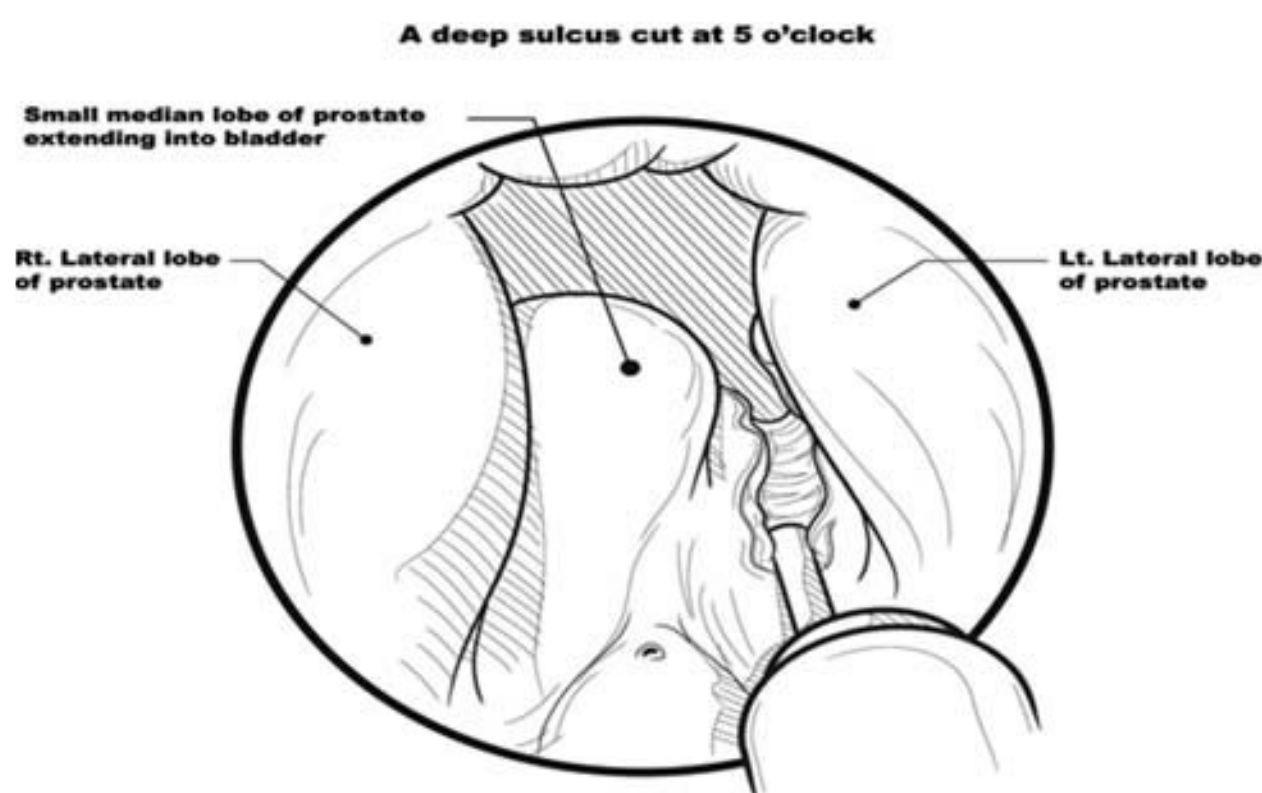

- If median lobe present:
  - Create grooves in 5:00 and 7:00 positions
  - Carry down to surgical capsule
  - Join grooves just proximal to verumontanum
  - Enucleate median lobe in retrograde fashion
- Lateral lobe dissection begins just lateral to verumontanum
- Develop plane under lateral lobe, on floor of capsule
- Dissection moves anteriorly, proceeding from apex to bladder neck
- Make incision at 12:00 position
- Join anterior and lateral dissections
- Divide remaining mucosal attachments
- Once both lobes are completely enucleated, morcellation can proceed
  - Take care to always keep morcellator tip in view

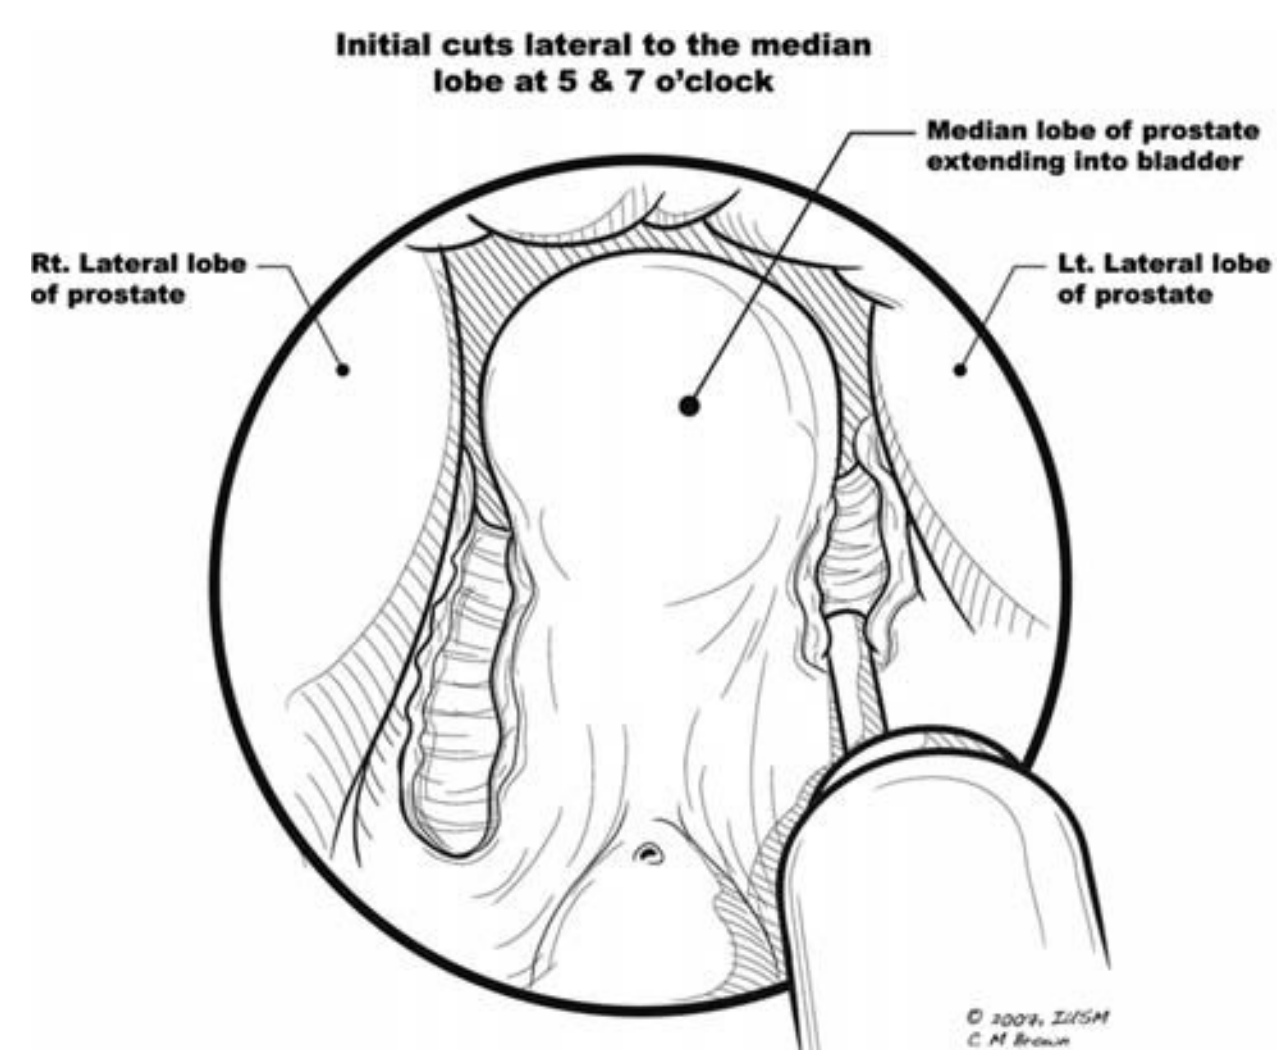

**FIGURE 25.2** Cartoon representation of the architecture of the prostate and bladder neck. Dashed lines represent the 5:00 and 7:00 grooves.

visualized, one at the 5:00 position and the other at the 7:00 position (Fig. 25.2). Beginning at the level of the bladder neck in the 5:00 position, a groove is cut with the laser along the sulcus, from the bladder neck to a point proximal to the verumontanum (Fig. 25.3). This groove is deepened to the level of the surgical capsule. As the groove is developed, it should be undermined and widened to permit the separation of the right lateral lobe and median lobe. Once accomplished, the process should be repeated at the 7:00 position (Fig. 25.4). The final step in the enucleation of the median lobe can then be initiated at a point just prior to the verumontanum. The laser fiber is moved in a transverse fashion between the apical extent of the 5:00 and 7:00 grooves. As the distal portion of the median lobe begins to separate away from the capsule, the beak of the resectoscope should be used as a leverage point to assist in lifting the median lobe upward. The capsule will begin to slope anteriorly toward the bladder neck; careful attention to this anatomy is important, as it will prevent inadvertent undermining of the trigone. Once the dissection has reached the level of the bladder neck, the most proximal attachments of the median lobe can be divided and the entire median lobe pushed into the bladder.

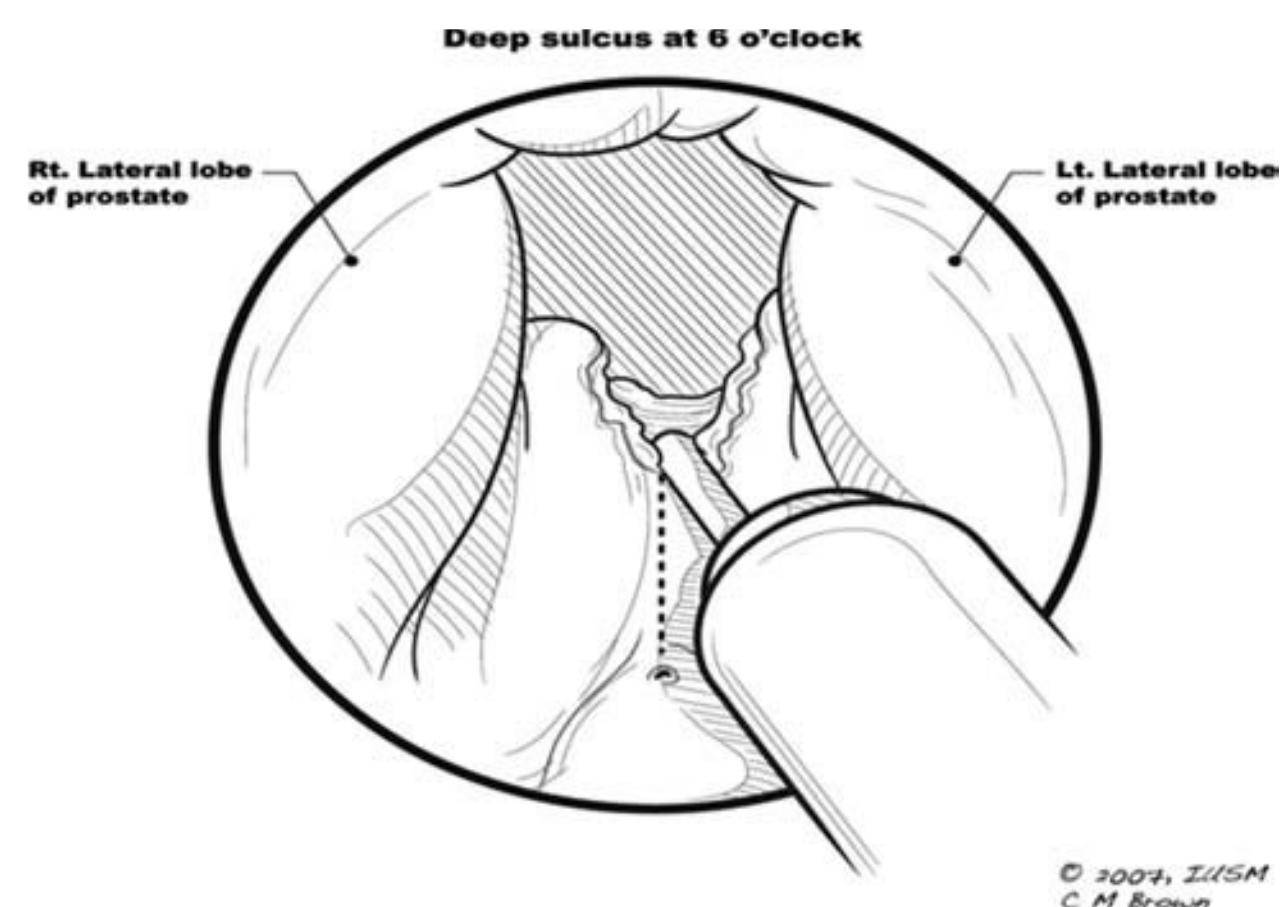

**FIGURE 25.3** The 5:00 incision is created with the end-fire holmium laser fiber.

**FIGURE 25.4** The 7:00 incision is subsequently developed, which isolates the median lobe.

Following enucleation of the median lobe, attention can be turned to the lateral lobes. If a median lobe was not present, an incision should be created at the 6:00 position, and this midline groove should extend from the bladder neck to a point just proximal to the verumontanum (Fig. 25.5). Dissection of the right lobe is initiated by incising the mucosa lateral to the verumontanum in a transverse fashion, thereby exposing the adenoma near the apex. Once the initial plane is developed under the right lobe, dissection should proceed proximally toward the bladder neck, freeing the lateral lobe from the capsular floor by moving the laser fiber in a transverse, side-to-side motion; simultaneously, the beak of the resectoscope can advance this effort by applying upward traction on the adenoma. Care should be taken not to maneuver the resectoscope into the adenoma, which will disorient the surgeon and lose the plane of enucleation.

At some point, it will become apparent that the lateral attachments of the lobe impede dissection. At this point, the surgeon should detach the lateralmost aspect of the right lobe, near the apex. During the apical dissection, the laser frequency should be changed to 40 Hz to prevent thermal injury of the

**FIGURE 25.5** When no median lobe is present, a groove is created in the 6:00 position.

urinary sphincter. The surgeon should continue to dissect in this plane, staying between the apical tissue of the right lobe and the capsule by rotating the resectoscope in a clockwise direction. The lateral dissection should proceed anteriorly, and the lateral wall of the right lobe will be freed from the surgical capsule by proceeding proximally along the already defined plane. At this point, the surgeon should be rotating the resectoscope in alternating clockwise and counterclockwise directions, which causes the tip of the laser fiber to proceed in a smooth arc back and forth within the established plane. The dissection should be continued until difficulty is encountered with exposure of the plane proximally.

Attention should then be turned to the 12:00 region of the prostatic fossa, where the midline groove between the lateral lobes is located. The resectoscope is turned 180 degrees to allow the laser fiber to be positioned at the 12:00 position. The laser frequency should be readjusted to 50 Hz. Beginning at the bladder neck and proceeding distally, a groove is cut along this anterior position and should span from the bladder neck to the level of the verumontanum. The surgeon should occasionally reconfirm the location of the verumontanum by looking toward the floor to ensure that the groove is not extended too far distally. Once the groove is created, it is again widened and deepened to the level of the surgical capsule along its entire extent. The right lobe should then be enucleated from the anterior aspect of the capsule by angling the tip of the laser fiber between the adenoma and the capsule. Capsular definition is often much easier at the bladder neck, so dissection should begin at that point. The attachments between the anterior portion of the lobe and the capsule are taken down sequentially until the lateral extent of the lobe is reached. It is crucial at this stage to identify the extent of the remaining lateral attachments near the apex of the lobe. Once the junction between the planes is defined, usually by a mucosal strip or bridge, it is cut by the laser to join the planes. Laser settings are 2 J and 20 Hz during division of the mucosal strip. The surgeon can then continue the dissection proximally, at 2 J and 50 Hz, to free the lateral extent of the lobe.

At this point, the right lobe will be held only by attachments at the bladder neck level. By following this plane further laterally, any remaining attachments in this area can be freed. Finally, one should proceed under the lobe and finish dividing attachments at the floor of the capsule and the posterior bladder neck. The lobe can then be pushed into the bladder by leveraging upward with the beak of the resectoscope. With complete enucleation of the right lobe, attention should be turned to the left lobe, which is enucleated as previously described.

Once all lobes have been dissected free and pushed into the bladder, the capsular surface is then inspected carefully, and any bleeding sites should be addressed by defocusing the laser (positioning the tip of the fiber 2 to 3 mm away from the surface). A dry fossa is essential before beginning morcellation to optimize visualization and minimize the risk of bladder injury. If any residual portions of adenoma remain along the surface of the capsule, these can be easily vaporized or enucleated with the laser.

The final aspect of HoLEP is to remove the enucleated adenoma by morcellation. The inner sheath of the resectoscope, along with the laser fiber and stabilizing catheter, is removed, and the rigid offset nephroscope is then inserted into the outer resectoscope sheath. A commercially available morcellator,

which is a set of hollow reciprocating blades attached to a handle apparatus, can be used for this portion of the procedure. Under direct visualization, the tip of the morcellator is inserted into the bladder and guided beneath a portion of adenoma. Once a portion of adenoma is engaged by the morcellator, it is important to keep the tip of the morcellator anteriorly within the bladder and within the visual field at all times. The morcellator shaft should be moved in and out of the working channel in small increments and rotated at times to optimize engagement of tissue. When the remaining tissue pieces are small, the surgeon should engage them with suction alone and pull them into the prostatic fossa, where morcellation can be done safely by pinning the tissue against the capsule. If difficulty is encountered in engaging these smaller pieces, an alligator forceps can be used to facilitate their removal. Lastly, an Ellik evacuator is utilized to remove any remaining pieces of adenoma or clot. A 20Fr, three-way Foley catheter is placed at the conclusion of the case with the aid of a catheter guide, and continuous bladder irrigation can be used if necessary.

#### Laser Ablation of the Prostate: Holmium (Ho:YAG) and Potassium Titanyl Phosphate (KTP)

Laser ablation of the prostate employs laser energy to vaporize prostate tissue through the generation of temperatures  $>100^{\circ}\text{C}$ . There are two lasers that are commonly used to ablate the prostate: the KTP laser and the Ho:YAG laser. The KTP laser is an 80-W system that generates laser energy at a wavelength of 532 nm. The laser energy of the KTP laser is preferentially absorbed by the hemoglobin pigment. The Ho:YAG laser is a 100-W system that generates laser energy at a wavelength of 2,140 nm. The holmium laser energy is preferentially absorbed by water. Despite the different inherent attributes of the laser energy sources, the fundamental techniques of laser ablation are the same for both laser types. One of the inherent limitations of all laser approaches is that laser energy will desiccate the prostate tissue, ultimately impairing the tissue ablation as the procedure proceeds. With smaller glands, this may not be a meaningful issue; however, with larger glands, tissue desiccation will impede the ablation procedure.

A side-firing laser fiber is used, with a 26Fr or 28Fr continuous-flow resectoscope configured with a laser bridge. Saline is the irrigation of choice. The resectoscope is passed into the bladder, and the locations of the ureteral orifices and verumontanum are confirmed. Laser ablation is a near contact procedure, meaning that the laser fiber should be maintained 1 to 2 mm away from the prostate tissue. The aiming beam and the side-markings of the fiber should be identified. If a median lobe is present, this structure should be addressed first. The laser fiber is placed in close approximation to the median lobe tissue, and a rotating lateral motion of the laser fiber is performed while activating the laser energy. The tissue should be vaporized in layers, with a sagittal motion of the fiber, taking care to not vaporize the trigone or ureteral orifice. If a median lobe is not present, the laser should be positioned at the bladder neck in the 7:00 position, and the tissue should be ablated with a lateral sweeping motion until the fibers of the bladder neck are visualized (Table 25.6). A groove should then be extended from the bladder neck to a point just proximal to the verumontanum. The groove should be deepened until capsular fibers are seen. A similar groove

TABLE 25.6

**LASER ABLATION OF THE PROSTATE**

- Troughs created at the 5:00 and 7:00 positions
- Direct ablation of lateral lobes
- Carried to depth of capsular fibers
- Tissue ablation moves anteriorly, proceeding from bladder neck to apex
  - To coagulate bleeding vessels, laser is defocused 2 to 3 mm away from tissue surface

should be created in the 5:00 position, and then the tissue between the grooves should be ablated.

Returning to the 5:00 position, the tissue from this location up to the 1:00 position should then be ablated with a slow, continuous sweeping motion. Again, the laser should be maintained near the tissue but not buried into the tissue. Once the lobe is ablated, the contralateral lobe from the 7:00 position to the 11:00 position should be ablated in the same fashion. Bleeding vessels, most commonly encountered at the 5:00 and 7:00 positions, can be coagulated by defocusing the laser 2 to 3 mm away from the tissue. Following ablation of the prostate tissue and assurance of hemostasis, a Foley catheter should be placed. In general, bleeding is not significant, and continuous bladder irrigation should not be required.

**Suprapubic Prostatectomy**

The patient is placed in a supine position, and the lower abdomen and genitalia are prepared and draped as a surgical field. A Foley catheter is placed on the surgical field and secured into position. The initial approach is through a low midline incision, and the fascia should be opened from the umbilicus to the symphysis pubica (Table 25.7). The space

TABLE 25.7

**OPEN SURGICAL PROSTATECTOMY**

- Low midline incision
- Suprapubic
  - Cystotomy created
  - Ureteral orifices identified
  - Incision at posterior aspect of intravesical component of prostate
  - Adenoma freed from capsule with blunt digital dissection
  - Following complete removal of adenoma, bleeding vessels controlled
    - Sutures at 5:00 and 7:00 positions
  - Foley catheter and suprapubic tube, in addition to perivesical drain
- Retropubic
  - Ligation of superficial prostate capsular vessels
  - Transverse incision in midcapsule
  - Adenoma bluntly dissected away from capsule and extracted through capsulotomy
  - Hemostasis ensured, sutures placed at 5:00 and 7:00 positions
  - Foley catheter and periprostatic drain placed

**FIGURE 25.6** Incision of mucosa over the adenoma.

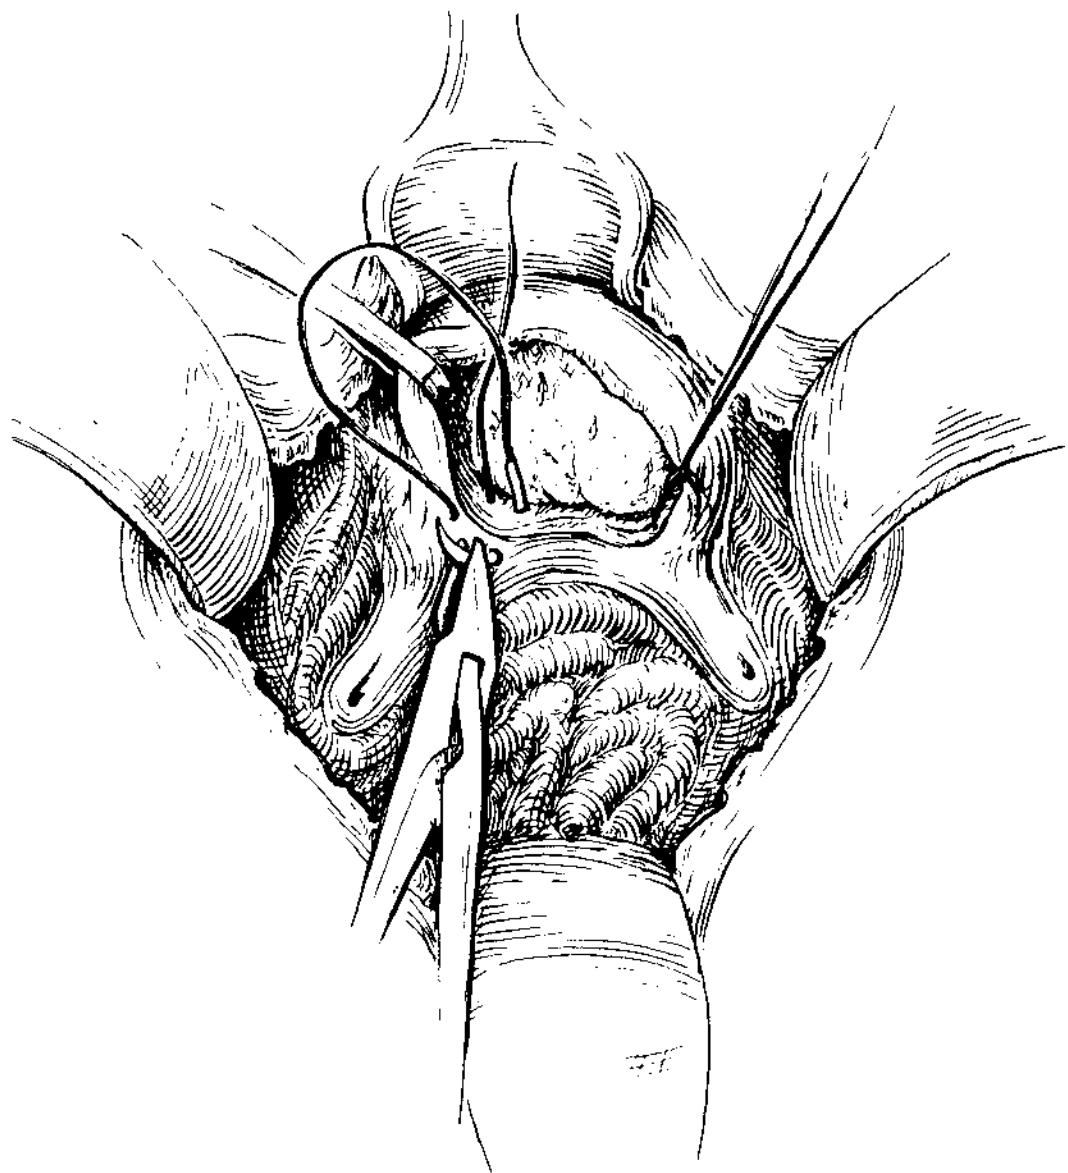

of Retzius is entered, perivesical fat identified, and a self-retaining retractor positioned. The bladder should be identified and cleaned of the perivesical fatty tissue. The bladder should be filled to capacity by gravity. Stay sutures should be positioned in the detrusor just to the left and right of midline, and a vertical incision in the bladder should then be created with electrocautery.

After opening the bladder, the intravesical component of the prostate should be identified. The ureteral orifices should be located, and to facilitate identification as the procedure progresses they may be cannulated with 5Fr feeding tubes. To begin the enucleation process, an incision in the posterior aspect of the intravesical component of the prostate is made with electrocautery (Fig. 25.6). Care should be taken to ensure that the incision is safely away from the ureteral orifices and trigonal region. The capsule should be sharply freed from the adenoma, and the surgeon's finger can then be used to develop the space between the adenoma and the capsule (Fig. 25.7). By moving the finger in a lateral arc, this plane is extended down to the apical aspect of the prostate. Once the adenoma is completely freed from its attachments by this blunt dissection technique, it may be removed from the surgical field (Fig. 25.8). The prostatic fascia should be packed with sponges and pressure held for 5 minutes to aid in hemostasis. Absorbable sutures, of a 2-0 size, should be placed in a figure-of-eight

**FIGURE 25.7** Digital enucleation of the adenoma.

**FIGURE 25.8** View of the empty prostatic fossa.

**FIGURE 25.9** Hemostatic suture ligatures at the 5:00 and 7:00 positions.

fashion at the 5:00 and 7:00 positions to control any blood vessels, which are commonly encountered at these locations (Fig. 25.9). A 22Fr Foley catheter, with a 30-cc balloon, should be placed transurethraly (Fig. 25.10).

The bladder should be closed in two layers with running 3-0 and 2-0 monofilament absorbable suture. A suprapubic tube should be placed through the dome of the bladder, and the bladder closed around this tube in a pursestring fashion. A Penrose or Blake closed suction drain is then placed in the space of Retzius. The fascia is then reapproximated with no. 1 braided absorbable suture, and the skin is reapproximated with staples. The drains are sutured into place with 0 silk suture. A continuous bladder setup using the suprapubic tube

**FIGURE 25.10** Foley catheter snug at the bladder neck: prevesical drain and suprapubic tube.

and the Foley catheter may be of help in maintaining patent drainage and minimizing blood clot formation.

### Retropubic Prostatectomy

The patient is placed in a supine position, and the lower abdomen and genitalia are prepared and draped as a surgical field. A Foley catheter is placed on the surgical field and secured into position. The initial approach is through a low midline incision, and the fascia should be opened from the umbilicus to the symphysis pubica. The space of Retzius is entered, perivesical fat identified, and a self-retaining retractor positioned. The fatty tissue overlying the bladder and prostatic capsule should be cleared.

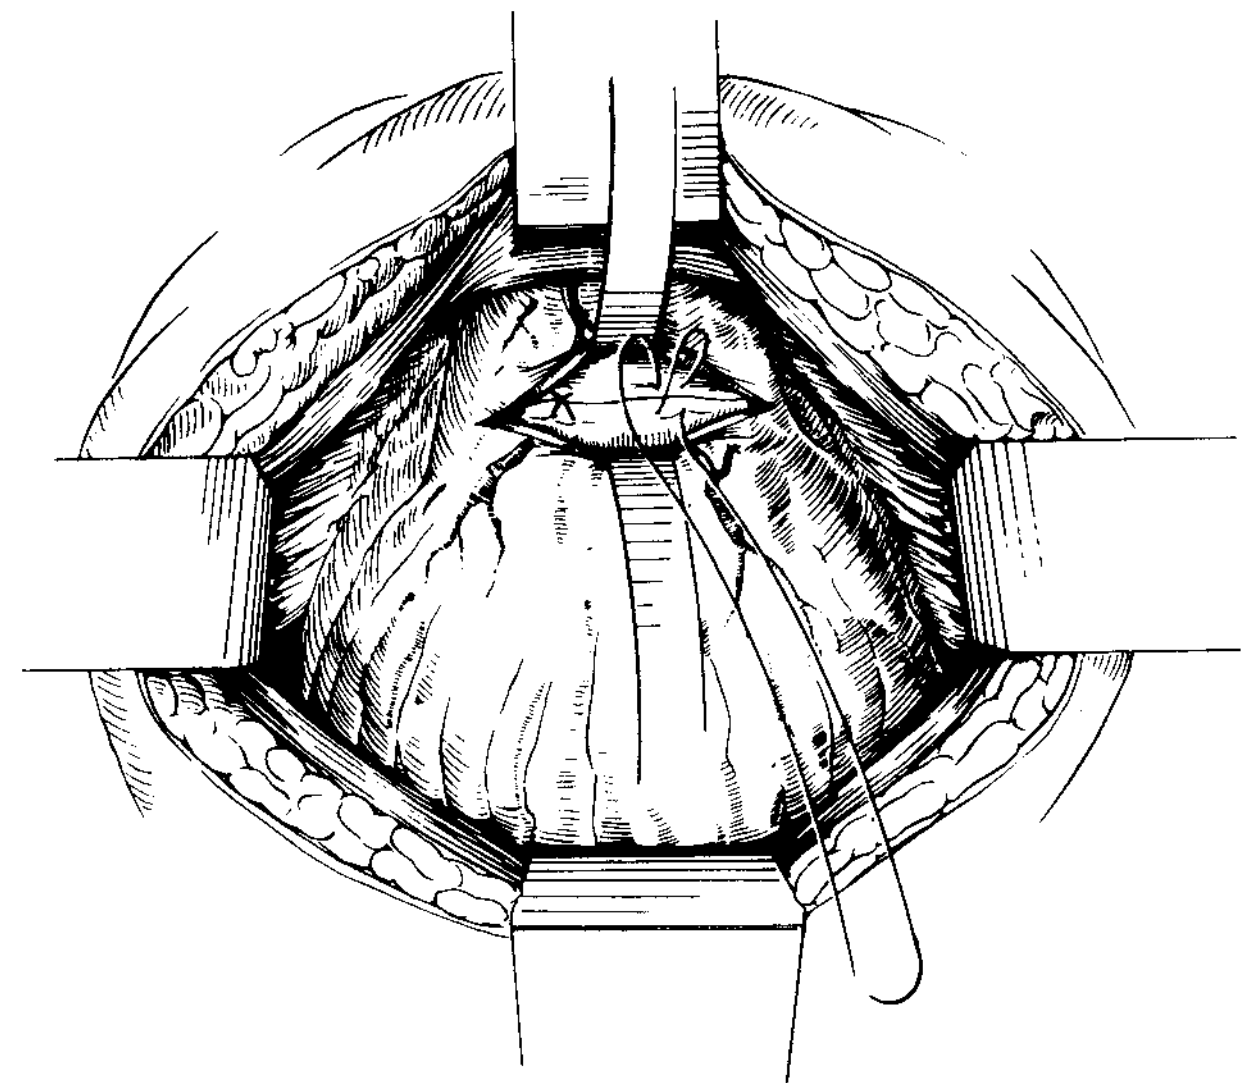

At the midportion of the prostatic capsule, two 0 chromic sutures should be placed proximally and distally, to ligate the superficial blood vessels (Fig. 25.11). With electrocautery, an incision is created transversely between these two sutures

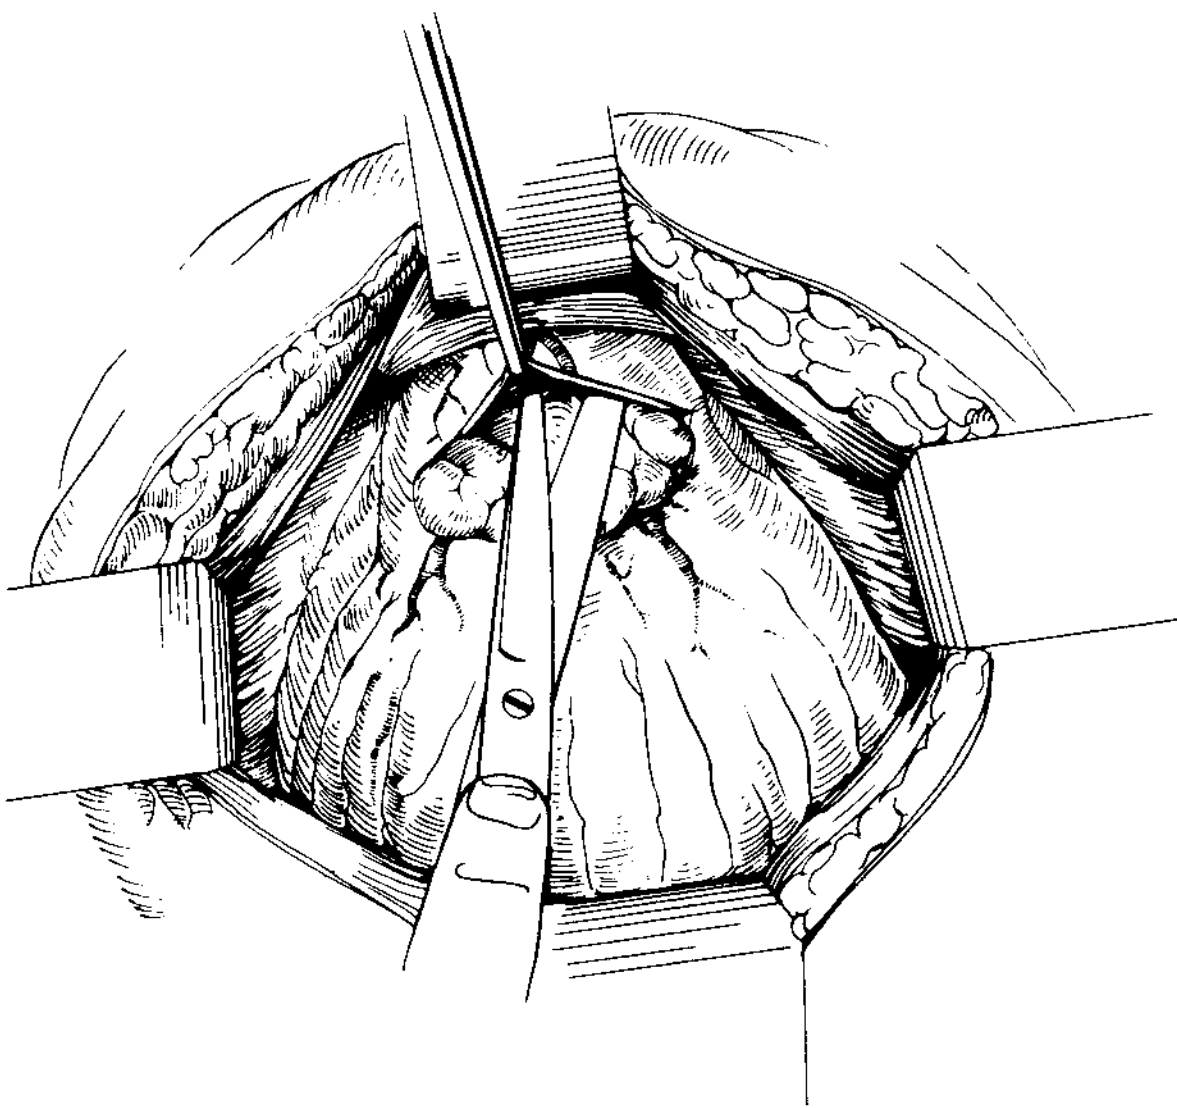

**FIGURE 25.11** Ligation and division of periprostatic veins over the prostatic capsule anteriorly.

**FIGURE 25.12** Transfixion sutures placed on the capsule anteriorly with an incision made transversely in the prostatic capsule.

**FIGURE 25.14** Figure-of-eight sutures are applied at the vesicle neck at the 5:00 and 7:00 positions to secure hemostasis.

**FIGURE 25.13** Continuing the dissection of the prostate of the adenoma from the prostatic capsule using Metzenbaum scissors.

**FIGURE 25.15** Closure of the incision of the prostate capsule anteriorly with interrupted chromic sutures.

(Fig. 25.12). A plane of dissection between the adenoma and the capsule should be bluntly created on either side of this incision (Fig. 25.13). The adenoma is progressively freed of its anterior, lateral, and posterior attachments with digital dissection. Following complete mobilization of the adenoma, its attachment to the membranous urethra can be sharply divided and the adenoma retrieved through the capsular incision; 2-0 chromic sutures should be placed in the 5:00 and 7:00 positions for hemostasis (Fig. 25.14). A 22Fr Foley catheter with a 30-cc balloon is placed, and the prostatic capsule is closed with 2-0 chromic sutures (Fig. 25.15). A closed suction drain is placed in the space of Retzius; the fascia should be reapproximated with no. 1 braided absorbable suture, and the skin should be reapproximated with staples.

---

## TREATMENT OUTCOMES

---

The ultimate assessment of the efficacy of a surgical treatment for BPH is a measure of its treatment outcome. The AUA Clinical Guidelines Panel on BPH assessed the literature on surgical therapies in order to define the treatment outcomes for particular interventions (3). TURP is considered by many to be the gold standard surgical therapy for men requiring surgical treatment of BPH. However, all surgical therapies have been reported to significantly improve patients' AUA Symptom Index; in fact, the greatest magnitude of improvement among patients undergoing surgical treatments was observed in those undergoing HoLEP (3). Similarly, all surgical therapies produced significant improvements in peak urinary flow rates; it was not possible to distinguish among the different therapies based on this outcome measure. Quality-of-life data, a measure

that is perhaps most important to the patient being treated, demonstrate equivalent improvements among all surgical technologies. All prostate interventions will have an effect on serum PSA. The more complete a debulking of the prostate, the greater the fall in PSA the patient should experience (Table 25.8) (4–10).

## COMPLICATIONS

### Endoscopic Surgery

One of the more common intraoperative complications for patients undergoing endoscopic surgical treatment of BPH is bleeding. Due to the continuous irrigation flow, it can often be difficult to estimate the magnitude of bleeding. When bleeding is appreciated, though, a systematic inspection of the prostatic fossa will permit identification of the source, which can then be fulgurated with cautery or coagulated with laser. If bleeding is refractory to these maneuvers, a Foley catheter placed on traction may be helpful.

Overaggressive resection may result in perforation of the prostatic capsule. Sequelae of this event may include extravasation of fluid into the retroperitoneum as well as electrolyte derangements. When a capsular perforation is encountered, it should be assessed. In the case of a small perforation, the procedure should be completed expeditiously. If a large perforation is identified, however, the procedure should be terminated. In the case of a retroperitoneal fluid collection, conservative management (catheter drainage and furosemide) is a reasonable approach, as the collections generally reabsorb spontaneously. If the perforation is extensive, however, transurethral resection (TUR) syndrome may occur, a condition brought about by intravascular absorption of hypotonic irrigating solutions, which ultimately induces a dilutional hyponatremia. Hypertension, mental confusion, and nausea and vomiting are all associated with this syndrome. TUR syndrome can be managed by diuresis and repletion with normal saline intravenous fluid or, in extreme circumstances, hypertonic (3%) saline in 100-cc boluses.

Structures in the vicinity of the prostate may be injured in the course of endoscopic surgical treatment. In some patients,

the ureteral orifice may be close to the bladder neck and can be inadvertently ablated or resected. Should the ureteral orifice be injured, an attempt should be made to stent the ureter at the conclusion of the procedure. Stricture formation is the most concerning sequelae of this complication. The bladder neck may also be undermined, which can complicate the placement of a catheter at the conclusion of the procedure. In severe cases, the bladder and prostatic urethra can become completely dissociated. If the bladder neck is identified as being undermined, a Foley catheter should be placed with a catheter guide, or alternatively over a wire, to ensure proper placement.

Transient urinary incontinence or urinary retention may occur following an endoscopic prostate resection or ablation. These symptoms generally resolve in the weeks following the procedure. Permanent incontinence or retention following these procedures is exceedingly rare. All patients who undergo any of these previously described procedures will experience retrograde ejaculation and should be forewarned of this eventuality. Patients who are suffering from urinary retention prior to an intervention for BPH are at increased risk for postoperative complications (11).

### Open Surgery

Severe bleeding following open prostatectomy has been recorded to occur in up to 35% of patients; blood transfusion rates are similarly high. Urinary clot retention has been reported to occur following open prostatectomy procedures. Urinary leakage from the cystotomy is not uncommon following catheter removal, and it generally resolves within 1 to 2 days. Transient urge urinary incontinence occurs following open surgical prostatectomy, usually due to bladder instability, but this generally resolves within several weeks of surgery. Total incontinence is rare. Retrograde ejaculation occurs in all patients undergoing adenectomy, but other effects on sexual function are rare. Postoperative bladder neck contracture may occur in up to 8% of patients undergoing open prostatectomy; its etiology is unclear. Treatment of the bladder neck contracture may require dilation or even incision of the bladder neck.

# CHAPTER 26 ■ PROSTATIC IMAGING AND BIOPSY

FRANCES M. MARTIN, WILLIAM T. CONNER, AND RANDALL G. ROWLAND

Adenocarcinoma of the prostate (PC) is the most common cancer of men in the United States and Europe. Concomitant development of prostatic-specific antigen (PSA) assays and transrectal ultrasound (TRUS) provided the tools for diagnosis of PC at an earlier, and presumably more curable, stage. The transvaginal ultrasound probe was adapted to transrectal use, and the spring-loaded Biopsy gun with a disposable 18-gauge needle was invented to permit ultrasound-guided biopsies (USBs) with TRUS guidance. PSA, TRUS, and USB are now the standard methods for diagnosis of PC. TRUS is an adjunct for staging PC, while PSA is the most sensitive method of evaluating response to therapy. TRUS is currently the most common method to image the prostate for initial staging, biopsy, and anatomical assessment. Ultrasound is also useful in evaluating brachytherapy and cryotherapy. Studies using three-dimensional (3-D) TRUS may show improved detection of tumor and extraglandular extension (1). Additional imaging modalities may change future management and detection.

---

## SCREENING AND DIAGNOSIS

---

Screening PSA tests are in general performed between ages 50 and 75, starting 5 years earlier in African American and high-risk men. Values up to 4 ng per mL are considered acceptable in men younger than age 60, although some laboratories consider values >2.6 ng per mL moderately elevated. PSA

levels may fluctuate, and the decision for biopsy should not be based solely on one value alone. In-office screening should also include a digital rectal examination and a complete history and physical examination.

Increased PSA velocity >0.75 ng per mL per year is an indication for careful surveillance and possible biopsy. A value of >0.75 ng per mL per year requires three PSA values over a 2-year period to be statistically valid (2). PSA levels increase with age. The formula for calculating the “age-adjusted normal” is age minus 20 divided by 10. Thus, a 50-year-old man would have an age-adjusted normal of 3.0 ng per mL, while the value for a 70-year-old man would be 5.0 ng per mL. There is controversy concerning the use of the age-adjusted values, although it seems clear that this technique improves the sensitivity for cancer detection in men below age 60 (3). It is unclear if PSA velocity, PSA density, or free-to-total PSA values provide a significantly better screening test for prostate cancer. Additional markers and proteomics profiling, including prostate-specific membrane antigen (PSMA), prostate stem cell antigen (PSCA), and hepsin, are being evaluated and may provide improved screening for prostate cancer (4). Currently, PSA is the most widely used marker for screening and biopsy indication.

Both benign and malignant prostatic cells produce PSA. Infection, trauma, and ejaculation are some of the benign conditions that may cause a PSA elevation. After excluding other causes for an increased PSA, TRUS and USB are scheduled.

---

## INDICATIONS FOR SURGERY

---

The most common reasons for TRUS and USB are an elevated screening PSA or an abnormal digital rectal exam (DRE). Prior to the mid-1980s, PC was usually suspected because of an abnormal DRE. Biopsies were typically performed under spinal or general anesthesia using a digitally guided transperineal approach. With the development of PSA and TRUS with USB, the procedure became simpler, safer, more precise, and more economical.

Other indications for TRUS and USB are a suspicious prostatic nodule, asymmetry of the prostate, active surveillance, and, rarely, unexplained metastatic malignancy. TRUS without USB is used for evaluation of ejaculatory duct cysts, prostatic stones, unexplained urinary tract infection (UTI), and suspected prostatic abscess. Prostatic biopsy without TRUS is on occasion performed for very ill patients with highly suspicious prostate glands, for whom the procedure is performed at the bedside. Confirmation of the diagnosis allows prompt hormonal ablation, often with improvement in hematuria or pain. An Iowa Trumpet (©V. Mueller, McGraw Park, Illinois) allows access for the digitally guided transrectal biopsy while protecting the finger of the operator.

---

## ALTERNATIVE THERAPY

---

Not everyone who has an elevated PSA or abnormal DRE should have a prostatic biopsy. Patients should be counseled concerning the risks and benefits of both the biopsy and possible treatment. Thus, an 85-year-old man with Alzheimer's disease and no significant urinary symptoms who has an ill-advised PSA test with a result of 8 ng per mL should not have a biopsy unless there is an unusual reason. He should have another PSA in 6 months. If there is no significant change, PSA testing should be stopped.

General medical evaluation should detect anticoagulation, medications, significant cardiovascular disease, diabetes mellitus, and excessive apprehension. Any of these factors may require a change of plans for USB. Of importance, an interactive discussion with the patient should take place regarding the recommendations for or against a biopsy in light of all findings and overall health status.

---

## SURGICAL TECHNIQUE

---

Anticoagulation must be stopped before USB. Consultation with the patient's physician or cardiologist will determine if it is safe to stop oral anticoagulation 5 to 10 days in advance, depending upon the medication. If not, he is changed to a form of heparin, which is stopped for 6 to 12 hours before the biopsy. Gross hematuria and clot retention that requires a Foley catheter are more common in this group.

Antibiotics are commonly given before and after the biopsy. Regimens vary, but the usual protocol in the United States includes a full dose of a fluoroquinolone before the biopsy. Previously, routine use of antibiotics for several days after biopsy was standard. Prolonged prophylaxis can lead to resis-

tant organisms. Single-dose regimens were evaluated to reduce this risk and support single-dose prophylaxis against infective complications (5). Patients with artificial heart valves, total joint prostheses, or implanted devices are routinely treated using standard American Heart Association guidelines. Some American urologists use cleansing rectal enemas, although there is some controversy concerning their need (6).

Some patients require monitored anesthesia care. These include those with anal stenosis, excessive apprehension, or serious cardiac arrhythmias and patients without a rectum. Oral sedatives and analgesics may be given, provided the patient has a driver to take him home.

Initial vital signs are monitored, including blood pressure and heart rate. The patient is placed in the left lateral recumbent (decubitus) position on the table in the US suite. The operator sits at a comfortable level beside the table and again explains the procedure as it is being performed. A gentle, thorough rectal examination is performed, noting significant external hemorrhoids, anal sphincter diameter and tone, and lesions in the rectum. Examination of the prostate includes specific notes concerning size, texture, tenderness, borders, fixation or mobility of the apex, symmetry, location of the midline sulcus, and the seminal vesicles. Any prostatic nodules or abnormal areas are noted.

We use a B&K Medical (Wilmington, MA) US system with either a 7.0- or 7.5-MHz endorectal probe. For the rare instances of TRUS for patients without a rectum, a 3.5- or 4.0-MHz probe is used. The TRUS probe has been prepared in advance by decontamination with glutaraldehyde solution or heated 35% peroxyacetic acid solution (STERIS) sterilization. A finger cot is placed snugly over the inflation port and inflated to exclude air bubbles, which interfere with the US image. Finally, a condom containing about 15 cc of US gel is placed over the rectal end of the probe. The US gel reduces artifacts during TRUS. The probe is lubricated and gently inserted into the rectum. Lidocaine gel (1%) may be used, if the patient is not allergic, to provide topical analgesia to the rectal wall. Inflation of the finger cot with 25 to 40 mL of water produces an acoustic window, which allows better definition of the rectal wall and prostate.

Local anesthesia has become a frequent adjunct to TRUS and USB (7). Periprostatic nerves can be blocked by injecting 5 to 10 cc of 1% lidocaine without epinephrine just lateral to the junction of the seminal vesicle and prostate on each side (Fig. 26.1). After guiding a 22-gauge, 7-in. spinal needle (Becton/Dickinson, Franklin Lakes, NJ) to the correct spot with US, and aspirating to be sure a vein has not been entered, the anesthetic is slowly injected. The area of injection expands and produces a hypoechoic image that confirms the proper location of the drug. Local anesthesia allows multiple biopsies to be taken with little discomfort for most patients. As with all procedures with conscious patients, each event must be announced in advance. Lidocaine causes the same stinging sensation in the periprostatic area that occurs with dental or other local injections. Neutralizing the lidocaine solution with alkali can prevent this, but the shelf life of the drug is significantly reduced.

The prostate is then imaged in transverse and longitudinal planes, noting areas of abnormal echogenicity, cysts, calcifications, indistinct borders, lesions of the seminal vesicles or ejaculatory ducts, and other abnormalities. Tiny corpora amylicata are easily visible and usually define the border of the transitional and peripheral zones. Bladder US can be performed if

**FIGURE 26.1** Prostate ultrasound. Dotted line indicates path of biopsy needle on sagittal view.

desired but is best accomplished as a suprapubic exam with a 3.5- to 4-MHz probe.

Prostatic volume is calculated using the greatest transverse, anterior–posterior, and longitudinal dimensions. Most modern TRUS machines have computer programs for computing the volume. One formula for calculating the volume of a prostate ellipse by US is as follows: height multiplied by width multiplied by length multiplied by 0.52. Images are recorded to show anatomy of the prostate and seminal vesicles, abnormalities, and prostatic volume. Digital recording of the procedure is possible. The volume of suspicious hypoechoic lesions is measured and recorded. The classical appearance of a prostate tumor is hypoechoic, but some cancers can appear isoechoic or hyperechoic. The TRUS procedure takes several minutes, enough time for the lidocaine to anesthetize the periprostatic nerves.

Biopsies are obtained with a sharp, disposable, spring-loaded 18-gauge needle, which produces a 17-mm specimen with little crush artifact. Several such needles are available. Some are completely disposable devices, whereas others use a permanent biopsy gun and disposable needles. Most brands of needles have a slightly abraded tip that makes them echogenic and easier to see. We currently use either a Bard Magnum Biopsy Needle Gun with a disposable needle or a Microvasive Topnotch disposable gun and needle. The device is fired before the biopsy to familiarize the patient with the sound.

We routinely obtain 12 biopsies: lateral and medial at each base, lateral and medial at the midgland on each side, and 2 biopsies at each apex, as described by Gore et al. (8) and others. Patients who need a second biopsy because of a high suspicion of cancer will have 12 to 20 biopsies, including specimens from the transition zones (TZs) and far lateral peripheral zone. “Saturation” biopsy under anesthesia obtains up to 45 cores of tissue, although this technique is reserved for the patient who has had multiple negative biopsies and still has a suspicious PSA or rectal exam (9). The great value of TRUS is to be able to precisely sample specific areas of the prostate. Anesthetizing the urethra with lidocaine reduces the additional urethral pain with TZ biopsies but does not

decrease the additional urethral bleeding. Bleeding usually stops without treatment within 24 hours.

After all biopsies are obtained and carefully labeled, the US probe is removed. A useful technique to control rectal bleeding is to roll a hand towel into a tight roll about 6 in. long and 3 in. in diameter and then have the patient sit with the towel between his ischial tuberosities for 10 minutes. This places pressure on the perineum, compressing the prostate against the symphysis pubis. Blood pressure and heart rate are again recorded. The patient sits on the table for about 10 minutes, then voids. The urine usually contains blood, especially if TZ biopsies have been obtained.

When the patient is stable and voiding well, he is given his postbiopsy instructions and allowed to leave, with a return appointment for 1 to 2 weeks depending upon the response time of the pathology department.

Instructions include the following:

1. Expect blood with urination and bowel movements for 1 to 7 days.
2. Expect blood with ejaculate for up to 6 weeks.
3. Take medications as prescribed.
4. Report temperature over 101°, passage of clots after 24 hours, persistent rectal bleeding, difficulty with urination, pain, or any other symptom that concerns him.
5. Return for discussion of the biopsy as scheduled.
6. Resume all other medications, with special instructions for anticoagulants.
7. Resume preoperative activities after 24 hours, avoiding heavy lifting or strenuous activity for 72 hours.

---

## OUTCOMES

---

### Complications

---

Hematuria, hematochezia, and hematospermia are expected, as mentioned above. Excessive bleeding requires evaluation and appropriate treatment. Rarely, patients require admission

for bladder irrigation for urinary bleeding. Patients who are on anticoagulants on occasion require cystoscopy with fulguration of bleeding vessels. Rectal bleeding is usually minor and self-limited. If rectal bleeding is persistent or causes the hematocrit to fall, proctoscopic examination is indicated. The urologist, a general surgeon, or a gastroenterologist, depending upon the time of occurrence and the training of the physician, may perform this. Arterial or venous bleeding may be controlled with direct suture ligation or injection of epinephrine around the vessel. Hematospermia requires reassurance only. Urinary retention usually resolves unless the patient has bladder outlet obstruction, but it may require temporary catheterization.

Bacteriuria and bacteremia are fairly common but usually asymptomatic and resolve without further complications (10). Persistent rectal pain or fever  $>101.5^{\circ}\text{F}$  may signal prostatic abscess or early sepsis. Isolated reports of perirectal abscess, septic shock, disseminated intravascular coagulation, and osteomyelitis are in the literature. Seeding of the biopsy tract with implantation of cancer is a theoretical complication that has been rarely reported. The biopsy technique does not interfere with radical prostatectomy, external radiation, or brachytherapy.

---

## ADDITIONAL IMAGING MODALITIES FOR EVALUATION OF THE PROSTATE

---

### Computerized Tomography (CT)

---

The contrast resolution of CT is ineffective in distinguishing the prostate from cancers or surrounding organs. Its use in prostate cancer detection is limited. CT can be useful in evalu-

ating for lymphatic involvement and nodal staging, but it is based upon size criteria. It is less sensitive for bony involvement than magnetic resonance (MR) or bone scan.

---

### Magnetic Resonance Imaging (MRI)

---

Use of MRI to detect prostate cancer and locally advanced disease has provided mixed results. It provides improved anatomic visualization with better soft tissue resolution. The use of the endorectal coil may improve the specificity of MRI for detection of cancer and extraprostatic extension. Prostatitis, hemorrhage, and benign hyperplasia can mimic cancer on MRI. Studies suggest that it may be more valuable to detect local recurrence after prostatectomy (11). Newer advances, including magnetic resonance spectroscopic imaging (MRSI), may improve evaluation of tumor size, location, and extent (12). MRSI displays relative concentrations of citrate, choline, and creatinine, which are typically higher in cancer cells. Criteria for diagnosing prostate cancer are based upon choline-citrate ratios. Some authors state that combined MRI/MRSI can help stratify patients' risk by assessing the aggressiveness of the tumor biology (12).

---

### Positron Emission Tomography (PET)

---

Although PET scans have been useful in evaluating metastatic disease, the use of  $^{18}\text{F}$ -FDG tracer is not helpful in diagnosing or imaging localized prostate cancer. This tracer has confounding uptake in prostate cancer cells and benign prostatic hyperplasia (13). Numerous additional tracers are under investigation and may prove more useful in diagnosing prostate cancer.

# CHAPTER 27 ■ PELVIC LYMPHADENECTOMY

MICHELLE L. RAMÍREZ, RAJ S. PRUTHI, JOON-HA OK, AND RALPH W. DEVERE WHITE

Pelvic lymph nodes are the initial site of the spread of prostatic, bladder, and proximal urethral cancers. Tumors of the penis, scrotum, and distal urethra spread primarily to the inguinal lymph nodes but can involve the pelvic lymph nodes at a later stage. Testicular tumors rarely involve the pelvic lymph nodes unless there is massive retroperitoneal disease (retrograde spread) or a history of orchiopexy or prior pelvic procedures.

Standard practice had been that all patients undergoing radical prostatectomy undergo pelvic lymphadenectomy for staging. Currently, pelvic lymph node dissection is performed only if a patient is at significant risk for metastasis. Preoperative prostate-specific antigen (PSA), PSA kinetics, biopsy Gleason score, and clinical stage define those patients at risk for nodal metastasis. Identifying lymph node involvement is important for accurate tumor staging, prognosis, and selection of adjuvant therapy; however, the therapeutic value of lymph node removal for prostate cancer remains controversial. When cystectomy is indicated for bladder cancer, bilateral pelvic lymphadenectomy remains the standard of practice.

## PROSTATE CANCER

### Indications for Surgery

Pelvic lymphadenectomy adds modest operating room time, cost, and complication risk to a radical prostatectomy, but when performed independently, results in additional anesthetic risk and exposure to cardiopulmonary, thromboembolic, and wound complications. Several investigators have therefore attempted to identify prostate cancer patient groups in which pelvic lymphadenectomy can be omitted with an acceptable risk of understaging. By combining these criteria, patients can be grouped as low (2% to 5%), moderate (20%), and high (40%) risk categories for lymph node metastases (8). Patients at highest risk for lymph node metastases include those with a Gleason score equal to or  $>7$  and a PSA equal to or  $>20$  ng per mL, a Gleason score equal to or  $>8$  and a PSA equal to or  $>10$  ng per mL, or a PSA equal to or  $>50$  ng per mL (Table 27.1). Using a decision analysis, Meng and

TABLE 27.1

associates have suggested that lymph node dissection is unwarranted in those with <18% risk for lymph node involvement (7). Application of the selection criteria (Table 27.1) may help to decrease the number of what at least some believe are unnecessary lymph node dissections.

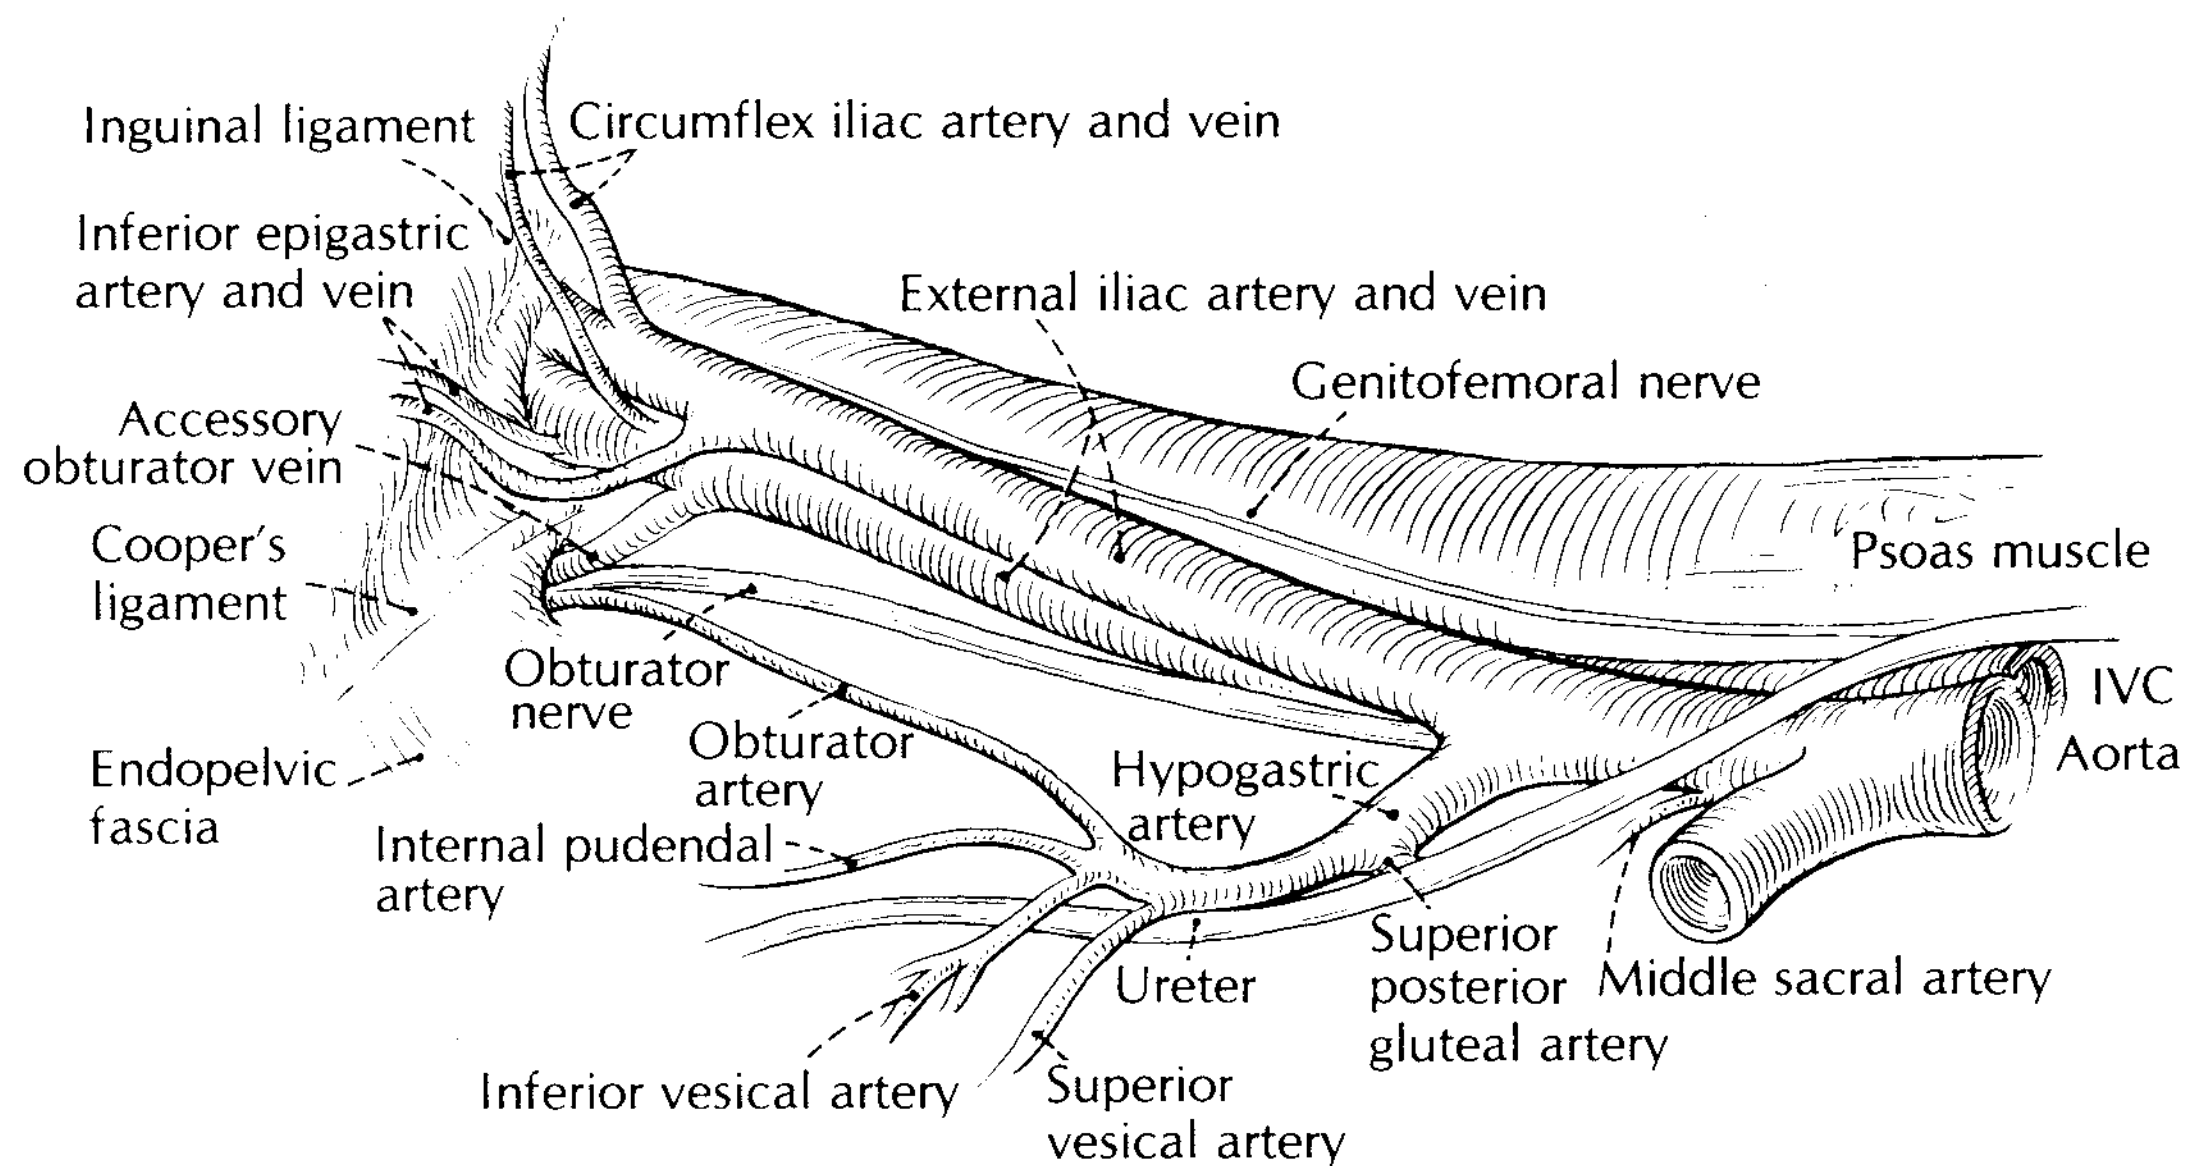

We currently perform pelvic lymph node dissection concomitantly with retropubic prostatectomy in those patients with clinical T2a disease, a PSA equal to or >10 ng per mL, and/or those with high-grade tumors (biopsy Gleason score equal to or >7). Due to the stage migration, we feel that performance of lymphadenectomy as a separate procedure, that is, laparoscopically, is not cost-effective. The yield of cancerous nodes for a clinical stage T1c tumor of a Gleason sum <7 and a preoperative PSA <10 ng per mL is well within the 5% to 10% margin of error of a false-negative diagnosis at frozen section. Routine pelvic node dissection in such patients is not cost-effective regardless of technique and subjects the patient to an unnecessary procedure with possible morbidity. We no longer perform lymph node dissection prior to radiation therapy.

## Surgical Technique

The boundaries of the traditional pelvic lymph node dissection for prostate cancer include the pelvic sidewall laterally, the paravesical fascia and peritoneum medially, the genitofemoral nerve superiorly, the obturator nerve inferiorly, and the femoral canal distally (Fig. 27.1). Proximally, the dissection is carried varying distances up the common iliac artery (Figs. 27.2 and 27.3). Many urologists feel that only the obturator nodal packet need be removed, for three reasons:

1. The obturator nodes are involved in 87% of cases when lymphatic metastases are found.
2. The procedure is for staging and not therapy.
3. If radiation therapy is used for local control following surgery, patients who had an extensive lymphadenectomy have a higher incidence of scrotal or lower-limb edema.

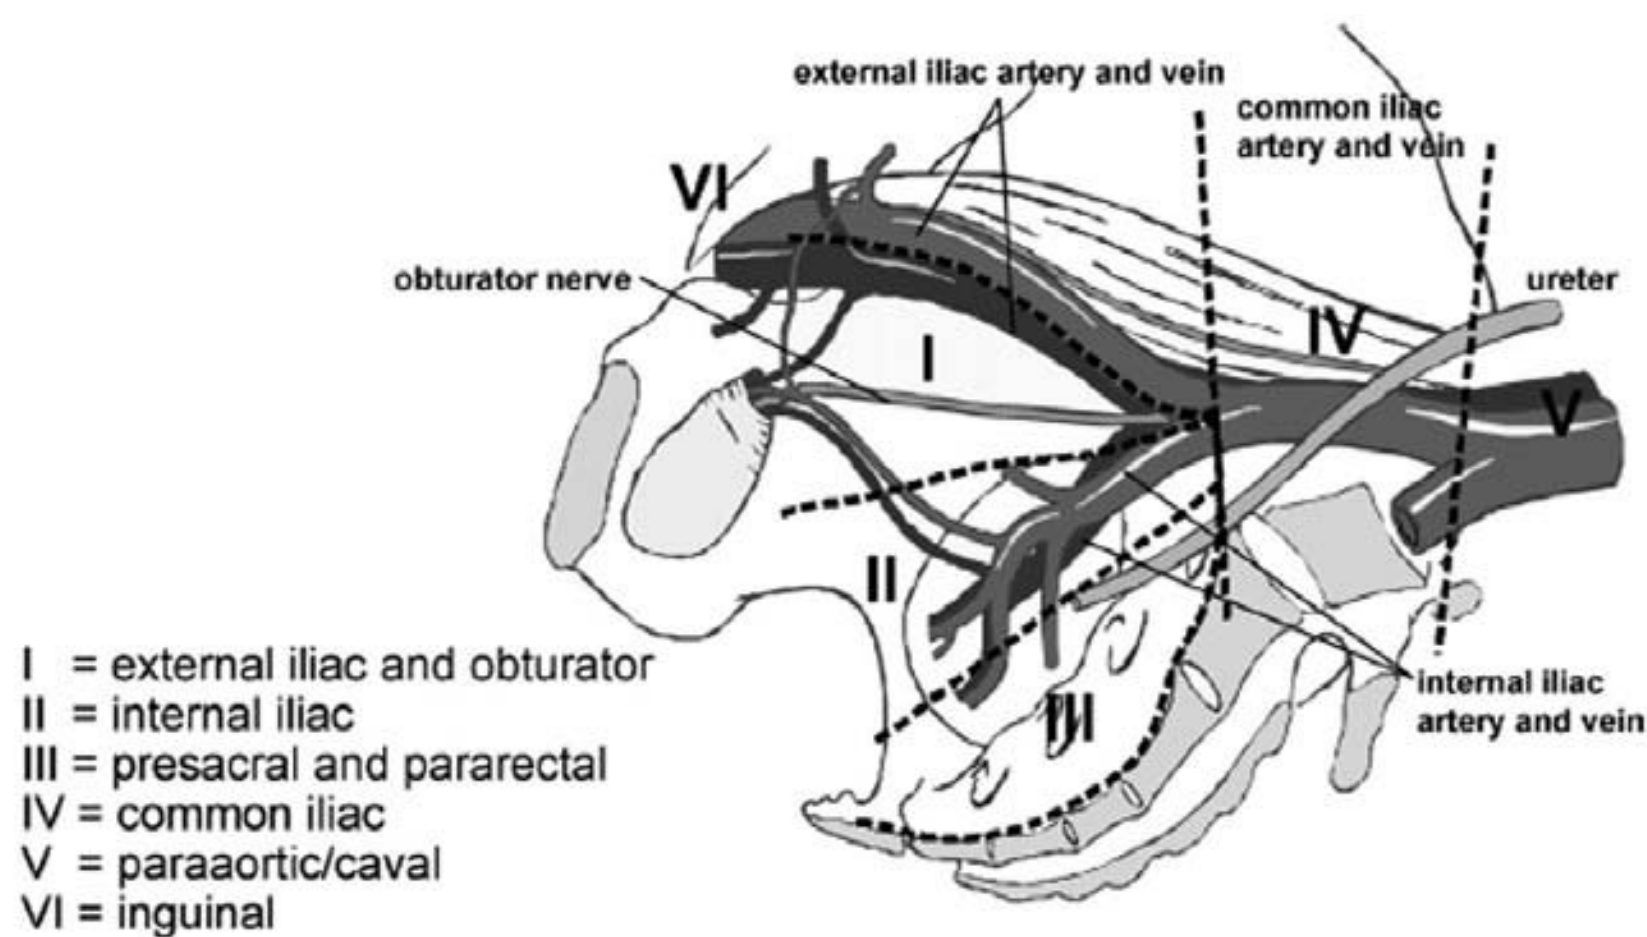

As prophylaxis against deep venous thrombosis, patients are administered 7,500 U of subcutaneous heparin in the arm,

**FIGURE 27.1** Right lateral pelvic wall. Anatomy of pelvic blood vessels and nerves encountered in a pelvic lymph node dissection is depicted.

**FIGURE 27.2** Incision of fibroareolar tissue loosely adherent to adventitia of the iliac artery and vein. This allows a portion of the areolar tissue to pass lateral to the iliac vessels into the obturator fossa.

**FIGURE 27.3** Boundaries of pelvic lymph node dissection subdivided into different regions. “Limited” dissection removes tissue from the obturator fossa (*region I*). “Extended” template dissection removes tissue along the major pelvic vessels (external iliac vein, obturator fossa, and internal iliac artery and vein) (*regions I and II*). The dissection is carried varying distances up the common iliac artery and vein (*region IV*). (From Mattei A, Fuechsel FG, Bhatta Dhar N, et al. The template of the primary lymphatic landing sites of the prostate should be revisited: results of a multimodality mapping study. *Eur Urol* 2008;53(1):118–125, printed with permission from Elsevier.)

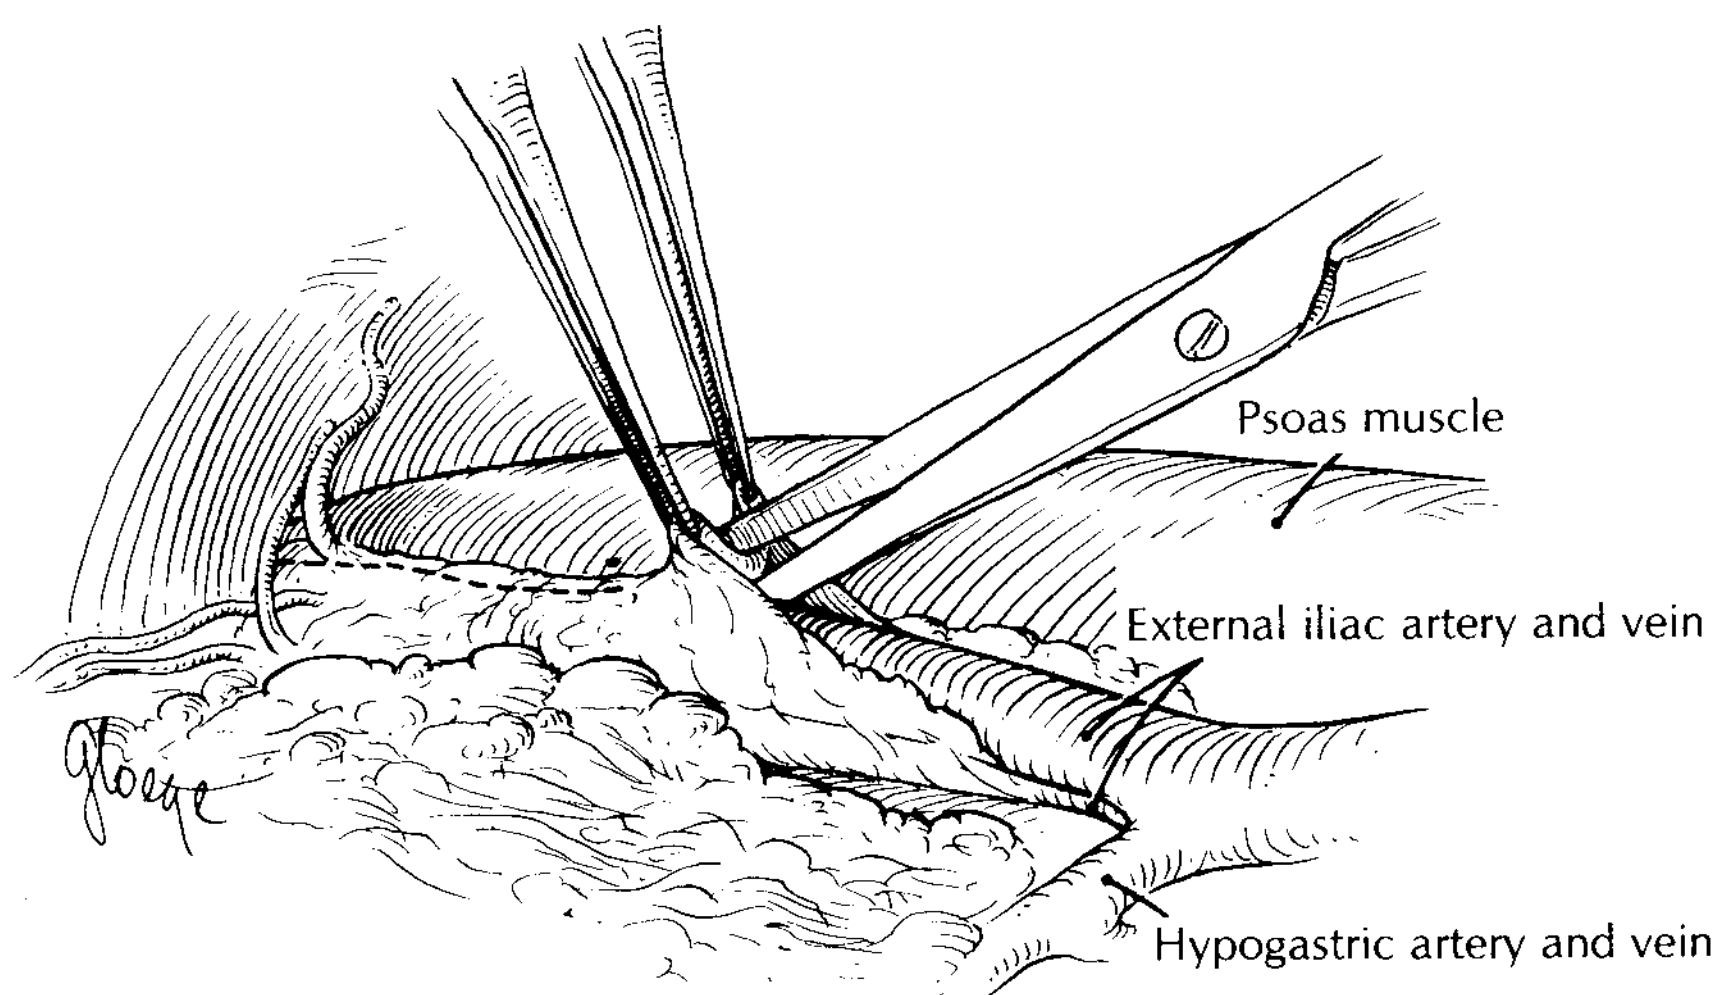

which may reduce lower limb edema (1). The supine or lithotomy position may be used, although we recommend the low lithotomy position. The sacrum is positioned over the table break or a roll to allow for hyperextension of and better vision into the pelvis. The bladder is emptied using a Foley catheter. A midline incision is made from below the umbilicus to the symphysis pubica down through the anterior rectus sheath. The posterior rectus sheath is incised for 2 to 3 cm above the linea semilunaris to aid in lateral retraction of the wound. An extraperitoneal lymph node dissection is performed. If the peritoneum is entered during this incision, the defect is closed with absorbable sutures.

The transversalis fascia is sharply divided in the midline to allow lateral dissection superficial to the peritoneum, which helps avoid injury to the inferior epigastric vessels. The iliac vessels are exposed by bluntly sweeping the peritoneum superomedially. The vasa deferentia are encountered during this maneuver and may be divided. The table is tilted toward the first side for evaluation. If the prostate cancer is confined to one lobe, the dissection is begun on that side. A self-retaining retractor is applied, with care taken not to injure the inferior epigastric vessels. We use the Bookwalter retractor without the post, as it can be more quickly applied and the post can interfere with the surgeon. Other self-retaining retractors may be used.

We place the Bookwalter retractor on top of sterile towels, one on each thigh and one on the abdomen. A bladder blade and moist lap sponge are used for lateral retraction on the side of the dissection. A malleable retractor and moist lap sponge are placed on the bladder and used to retract the bladder toward the contralateral side. A third blade is placed at the apex of the incision. With these three blades, excellent visibility can be obtained.

The nodal packet is palpated to detect grossly enlarged lymph nodes. If such nodes are found, they are sent for frozen section evaluation following removal. If no enlarged nodes are palpated, we continue with the lymphadenectomy and prostatectomy and do not send the lymph nodes for frozen section.

The external iliac artery is identified, and dissection of the lymph node packet is begun over its anteromedial aspect. The correct plane of dissection is easily found here, and there are no other structures in this area to be damaged (Fig. 27.4). Blunt dissection is performed with a sponge stick, and the suction tip and smooth forceps are used to clean away adipose tissue. The dissection is brought proximally to the bifurcation of the common iliac vessels and distally to the femoral canal. The lymph node of Cloquet is the most distal aspect of the dissection. Lymphatic channels into this node and surrounding the external iliac vein are meticulously clipped and divided. We place a right-angle clamp around the lymph node packet

**FIGURE 27.4** Correct plane of dissection is shown.

and ligate it with a 2-0 Vicryl tie. A large right-angle clip is placed below the tie. As the nodal packet is divided and swept superiorly, an accessory obturator vein may be found medial to the internal iliac artery and should be ligated (rather than clipped) and divided to avoid avulsion. Identification of this vein is necessary as damage can cause extensive bleeding.

With gentle lateral retraction of the external iliac vein, the lymph node packet is dissected off the pelvic sidewall laterally. Although a vein retractor is usually used for this maneuver, we use a peanut/Kitner dissector. Identification of the obturator nerve is essential to avoid injury as the dissection is carried into the pelvic fossa. The packet is freed from the obturator nerve and vessels. The obturator vessels are spared if they are in their usual location below the nerve. If the vessels are above the nerve or involved with the lymph node packet, it is best to ligate and divide them to prevent avulsion and bleeding. This is especially true near the femoral canal. The superior attachment of the packet is now near the internal iliac artery. Previously we used to identify and dissect out the ureter, but, in most cases, we no longer do this. To ensure the ureter is not damaged by a clip, the specimen is split over the obturator nerve, and a right-angle clip is placed over either limb of the split packet on each side of the nerve in a cranial-to-caudal fashion so that the ureter cannot accidentally be included in the clip. Additional loose attachments to the proximal hypogastric vessels are clipped and divided. The entire packet is sent to pathology as the two portions divided over the obturator nerve. The obturator fossa is irrigated with sterile saline. It had been our routine to leave a gauze sponge in the fossa for hemostasis; however, we now do this only for minimal oozing. The same dissection is then performed on the contralateral side to complete the lymph node dissection. We place one or two Jackson–Pratt drains in the pelvis postoperatively.

---

### Laparoscopic and Robotic Approach

---

In recent years laparoscopic and robotic approaches have become increasingly utilized in the surgical treatment of prostate and bladder cancers. Accordingly, the ability to perform an adequate laparoscopic pelvic lymphadenectomy is necessary, particularly at the time of the primary laparoscopic procedure.

Changes in port placement are not necessary, and the same instrumentation and setup can be used as is required for the primary surgical procedure. Instrumentation used includes broad graspers in the nondominant hand and cautery scissors in the dominant hand. Typically, we utilize nontraumatic graspers such as Hunter graspers in laparoscopic cases or fenestrated bipolar forceps in robotic cases. The surgical assistant also should be available with nontraumatic graspers and a suction irrigator.

When the lymphadenectomy is performed following a laparoscopic or robotic prostatectomy or cystectomy, the posterior peritoneum has already been incised and the retroperitoneal space exposed. If the lymph node dissection is to be performed initially, the posterior peritoneum should be incised in a cephalad-caudad direction just lateral to the medial umbilical ligament on each side. This will expose the retroperitoneal space and relevant landmarks.

The primary surgical step is to identify and expose the external iliac artery and vein by blunt dissection (e.g., with the closed scissor tips by the surgeon or with the suction irrigator by the assistant). The vein can be located lying immediately posterior

and medial to the artery. It is important to dissect down to the correct fibroalveolar plane just overlying the artery and the vein. This will allow for easier and more precise dissection of the lymph node packets for the remainder of the procedure.

Our initial approach is to perform the obturator and hypogastric dissection by locating and developing the medial border of the iliac vein, thereby exposing the obturator fossa posteriorly. Typically the patient is placed in the steep Trendelenburg position and maintained relatively hypovolemic. Consequently, the iliac vein is decompressed and less prone to grasping or sharp injury. With the medial edge of the external iliac vein identified, the plane between the vein and the obturator packet can be extended down to the pubic bone distally. Blunt and sharp dissection, often with the aid of monopolar scissors, bipolar graspers, and the appropriate countertraction placed by the assistant or the surgeon's non-dominant hand, can be used to facilitate retraction of the vein laterally and the obturator packet medially. With the dissection completed off the iliac vein, the nodal packet can then be dissected off the obturator nerve and vessels posteriorly. Monopolar and bipolar cautery can aid in the division of smaller lymphatic channels, and laparoscopic clips (e.g., Hemolock clips) can be used to ligate larger lymphatic channels, pedicles, and vein branches as necessary. The pubic bone and anterior surface of the obturator nerve and vessels help to mark the distal margin of the nodal packet. With the obturator packet freed and divided distally, it is peeled back in the cephalad direction to the level of the hypogastric artery while keeping the obturator nerve, medial border of the external iliac vein, and the medial umbilical ligament in clear view. The medial umbilical ligament should be retracted medially to achieve proper exposure for the hypogastric dissection.

If an extended dissection is to be performed, we begin above and along the external iliac artery. Again, it is vital to dissect down to the correct fibroalveolar plane over the artery, beginning the dissection distally. While avoiding the circumflex vein distally, all tissue between the external iliac vein and artery, as well as lymphatic tissue out to the psoas muscle and genitofemoral nerve laterally, is included. With this packet divided distally, this lymph tissue is teased and dissected in the cephalad direction with blunt and sharp dissection, occasionally with the use of monopolar and bipolar cautery. Unlike the external iliac vein, it is quite rare to encounter aberrant branches off of the artery, and this dissection is readily performed proximally up to and along the common iliac vessels. One needs to remain aware during the common iliac dissection that the ureter will be crossing over the common iliac vessels. If desired, a para-aortic dissection is achievable laparoscopically or robotically. If this dissection is anticipated, it may be necessary to place the laparoscopic or robotic ports approximately 2 cm superior or cephalad than typically positioned.

With the lymph node dissection complete, the lymph node specimen can be extracted through the 10- to 12-mm port or preferably placed in an impermeable sack and extracted.

---

### Limited Versus Extended Lymph Node Dissection

---

Though there is individual variability in lymphatic drainage, the principal location for prostate cancer lies in the pelvis, along the external and internal iliacs and in the obturator

fossa. Limited dissection involves only the obturator region bounded by the external iliac artery and the obturator nerve, whereas extended dissection involves all three regions (Fig. 27.3). Extended dissection results in the resection of approximately two-thirds of all primary prostatic landing sites, compared to only one-third with a limited dissection (6). In low-risk patients, up to 7% of positive lymph nodes may be missed with limited lymph node dissection, while as high as 20% may be missed in intermediate- and high-risk patients (1). Mapping studies have also demonstrated a considerable amount of drainage to nodes along the common iliacs, in the presacral/pararectal regions, and along the aorta and vena cava as high as the origin of the inferior mesenteric artery. Using an extended template that includes the nodes along the common iliac arteries up to the ureteric crossing may remove approximately 75% of prostate primary lymphatic landing sites (6). The risk-benefit ratio may not justify a complete dissection up to the inferior mesenteric artery.

While controversy exists on the extent of lymph node dissection, evidence suggests that extended dissection improves the accuracy of surgical staging and prognosis, given that the percentage of positive lymph nodes predicts for disease progression. Data from a few retrospective analyses with long-term follow-up reveal that extended lymph node dissection may reduce the risk of disease progression and disease-specific mortality (4). Joslyn and Konety examined the Surveillance, Epidemiology and End Results (SEER) database on 1,923 patients and detected an association between the extent of lymphadenectomy and prostate cancer-specific mortality at 10 years after controlling for other variables (4). Patients undergoing excision of at least four lymph nodes (node-positive and node-negative patients) or more than ten nodes (only node-negative patients) had a lower risk of death than did those who did not undergo lymphadenectomy. The extended dissection may result in the removal of unidentified metastatic disease, explaining the potential therapeutic benefits in patients with not only positive but also negative nodes.

In contrast, several high-powered studies do not show any survival advantage, and complication rates have been reportedly higher in those undergoing extended dissection versus limited dissection. In fact, the probability of complications may increase in direct proportion to the number of lymph nodes removed and needs to be taken into account when the benefits associated with more extensive dissection are considered. A multi-institutional, randomized clinical trial is needed to determine the value of extending the boundaries of pelvic lymphadenectomy.

At this time, we do not routinely perform an extended dissection for prostate cancer; however, if indicated, it is carried out as described previously while extending the boundaries to the internal iliac vessels, bladder wall, and pelvic sidewall. Lymphatic tissue is cleared from the pubis to the bifurcation of the common iliac vessels. The lateral dissection proceeds along the external iliac vessels lateral to the circumflex vein and medial to the genitofemoral nerve as described previously. As the dissection is carried cephalad along the anterior border of the common iliac artery, any psoas branches are clipped and divided. As with the dissection for bladder cancer, the vas deferens is located over the medial umbilical ligament as it enters the internal inguinal ring and is divided. This allows exposure of the medial umbilical ligament, which is then traced back to the internal iliac artery. The medial border of dissection begins with the ureter as it crosses the common iliac artery and

continues along the lateral border of the medial umbilical ligament and bladder. Large lymphatic channels are clipped and divided, and gentle traction is applied to pull lymphatic tissue from the sidewall. Posteriorly, the dissection continues deep to the obturator nodal packet to the internal iliac vessels. This packet is dissected along the obturator nerve as formerly described until the nerve passes posterior to the iliac vein, that is, the border of the lateral dissection.

---

## BLADDER CANCER

---

### Indications for Surgery

---

There are compelling data that regional lymphadenectomy during radical cystectomy can prolong survival in patients with locally advanced bladder cancer and should be considered the standard of care. Most urologists perform a standard bilateral pelvic lymphadenectomy (to include lymphatics as far lateral as the genitofemoral nerve) based on Skinner's early 1980s data that such a dissection can improve 5-year survival by up to 36% (11), which suggests that lymphadenectomy may have some curative potential in bladder cancer patients with limited nodal disease. Survival rates have been shown to be similar (55%) in those with minimal pelvic lymph node involvement (N1) and those without pelvic lymph node involvement if the primary cancer is organ-confined (pT0 to pT3a). Recently, a prospective, multi-institutional trial randomized 270 patients to receive neoadjuvant chemotherapy followed by radical cystectomy or radical cystectomy alone (2). Twenty-four patients forewent lymphadenectomy, 98 underwent a limited lymph node dissection (obturator nodes only), and 146 underwent a standard lymph node dissection. The 5-year survival rates for the three groups were 33%, 46%, and 60%, respectively.

The presence of positive lymph nodes in bladder cancer has therapeutic implications. If detected, some urologists forego surgery and treat with systemic therapy, whereas others favor debulking the tumor with cystectomy followed by postoperative chemotherapy. If we find grossly enlarged lymph nodes with histological evidence of metastasis, our decision to proceed with cystectomy is influenced by whether the patient received neoadjuvant chemotherapy, the bulk of local disease, and preoperative discussion with the patient. However, if the lymph nodes are grossly normal, we proceed with the radical cystectomy without sending the nodes for frozen section evaluation.

---

### Surgical Technique

---

The dissection is similar to the one described previously for prostate cancer with some differences. The incision is carried to just above the umbilicus and down to the pubic bone. We palpate the pelvic lymph nodes while remaining extraperitoneal. If no grossly enlarged nodes are palpable, the dissection becomes intraperitoneal and is performed after the cystectomy is completed, rendering the operation easier and quicker. The peritoneum is entered in midline, and inspection is performed of the intra-abdominal organs for signs of metastases. If none are found, dissection is continued by mobilizing the cecum and ascending colon. The peritoneum is incised along the white line of Toldt and the right colon is rolled medially. The right ureter is identified and freed superiorly

and inferiorly. Inferiorly, this leads to the bifurcation of the iliac vessels. In freeing the peritoneum, we routinely divide the vas deferens. On the left, the peritoneum is incised lateral to the sigmoid colon, and it is reflected medially. The left ureter is identified and freed as on the right. Mobilization is aided by dividing the vas deferens.

A self-retaining retractor may be placed as described above. The bowel can easily be retracted into the upper abdomen, as it has been mobilized. The node dissection begins over either common iliac artery just proximal to the bifurcation. It is carried down the hypogastric artery to the superior vesical artery, which is identified and divided. The remainder of the lymph node dissection is similar to that for prostate cancer. Based on data demonstrating that excising and submitting lymph nodes from each site separately increases the lymph node yield and improves nodal status assessment (13), we routinely send lymph nodes from different sites separately as opposed to *en bloc* with the bladder specimen.

### Limited Versus Extended Lymph Node Dissection

There is no accepted standard for either the optimal number of lymph nodes to be removed or the surgical limits of lymph node dissection. The most common dissection includes the bifurcation of the common iliac, external and internal iliacs, and the obturator lymph nodes, and generally yields 10 to 14 nodes. Further extending the dissection to the bifurcation of the aorta, presacral, and presciatic nodes can yield >40 nodes from 13 separate nodal packets (Fig. 27.5). The surgical time

**FIGURE 27.5** Total of 13 separate nodal packets: left paraaortic (1), right paracaval (2), right common iliac (3), left common iliac (4), right external iliac (5), left external iliac (6), right lymph node of Cloquet (7), left lymph node of Cloquet (8), right obturator/hypogastric (9), left obturator/hypogastric (10), right presciatic (11), left presciatic (12), presacral (13). (From Stein JP, Penson DF, Cai J, et al. Radical cystectomy with extended lymphadenectomy: evaluating separate package versus *en bloc* submission for node positive bladder cancer. *J Urol* 2007;177(3):876–882, with permission.)

is lengthened approximately 1 hour without a significant increase in complications (5).

Mapping studies have attempted to identify a pattern of anatomic distribution of metastatic lymph nodes and to demonstrate an increase in the number of positive nodes outside the boundaries of the standard dissection as the pathologic stage increases. Up to a third of patients with positive common iliac nodes will have metastases to the presacral region, which lies outside the standard template. Results from a prospective, multinational study of 290 patients with pT1G3-T4 disease revealed positive lymph nodes in 81 patients (27.9%). For analysis, three anatomic regions were identified: (I) below the bifurcation of the common iliacs, (II) between the aortic and common iliac bifurcation, and (III) between the inferior mesenteric artery and aortic bifurcation. Approximately 14% had positive nodes confined to either level I or level II. There were no skip lesions identified in level III. If level I disease was present, 57% had level II positive nodes and 31% at level III. The authors concluded that if only the obturator nodes were removed in the 81 patients, then 74.1% of the positive nodes would be left behind, potentially compromising survival.

Variation in reported 5-year survival rates (5% to 30%) in lymph-node-positive bladder cancer treated with radical cystectomy and pelvic lymph node dissection may be partly explained by the extent of the lymph node dissection. Retrospective studies suggest that recurrence-free and cancer-specific survival depend on the extent of local and regional disease and maximizing its removal. In the late 1990s, Poulsen and associates demonstrated that extending the limits of pelvic lymph node dissection from the common iliac bifurcation to the bifurcation of the aorta, along with removal of the perivesical fat containing paravesical lymph nodes, improves the recurrence-free survival rate following radical cystectomy for bladder cancer confined to the bladder wall (pT3a) (85% for <pT3a versus 64% for those with pT3b) (10). Moreover, Herr et al. reported a 92% survival rate in patients with pT2N0 disease with the removal of at least nine lymph nodes, compared to 53% survival in those who underwent less extensive dissections. Significant differences in mortality were also found among patients with pT3N0 and pT4N0 disease using the same threshold of nine lymph nodes. In those with nodal disease, a survival benefit was noted with the removal of >11 nodes (3). Similarly, Stein et al. determined that >15 lymph nodes was the cutoff point associated with a significant benefit in 5- and 10-year recurrence-free survival. They also calculated the lymph node density (ratio of positive lymph nodes to total lymph nodes) and found a density of <20% to be associated with decreasing recurrence-free survival (12).

While the extent of lymphadenectomy necessarily remains debatable and a randomized, prospective trial is needed to determine which dissection should be employed, what is not in question is that a pelvic lymph node dissection is the standard of care.

## OUTCOMES

Although pelvic lymph node dissection is usually a relatively short procedure with little morbidity, it has potential for significant complications. These can be divided into intra- and postoperative (early and late) complications (Table 27.2). Paul

TABLE 27.2

**COMPLICATIONS OF PELVIC LYMPHADENECTOMY**

<b>INTRAOPERATIVE COMPLICATIONS</b>
Vascular injury
Ureteral injury
Obturator nerve injury
<b>POSTOPERATIVE COMPLICATIONS</b>
<i>Wound-Related</i>
Hematoma
Seroma
Wound infection
Wound dehiscence
<i>Non-Wound-Related</i>
Pulmonary atelectasis
Pneumonia
Myocardial infarction
Congestive cardiac failure
Prolonged lymph drainage
Lymphocele formation
Deep venous thrombosis/pulmonary embolism
Epididymo-orchitis
Urinary tract infection
Prolonged ileus
Urinary retention
Chronic lymphedema

and associates (9) reported an 8.6% incidence of intraoperative complications, an 8.7% immediate postoperative wound complication incidence, and an additional 31.4% immediate non-wound-related complication rate (3). They also reviewed the complication rates reported in multiple studies. These ranged from 4% to 53% with a mean rate of 26.6% (3). Intraoperative complications can be minimized by familiarity with the pelvic anatomy and careful dissection to identify vulnerable structures. The most common vascular injury is to the accessory obturator vein. Care should be taken not to avulse the obturator vessels as they enter the pelvic foramina because they will retract caudally and ligation will be difficult. If this occurs, bone wax can be used. Significant injuries to the external iliac vessels require repair, sometimes with the aid of a vascular surgeon. Transection or avulsion of the obturator nerve leads to difficulties with adduction of the ipsilateral leg and is usually irreparable. Splitting the nodal packet as described reduces the chance of inadvertent nerve injury.

Ureteral injuries are uncommon and require repair when encountered. A problem with ureteral injuries is that they are not always identified at the time of surgery. These are often the result of a clip inadvertently being placed across the ureter. Therefore, as we now dissect out the lymph node packet, we no longer specifically look for the ureter. However, we always place a clip on the upper end of the nodal packet after splitting it over the obturator nerve in a cranial-to-caudal direction to

avoid ureteral injury, identified or not. If there is any concern for ureteral injury, the ureter must be dissected out and fully visualized.

Postoperative complications include those related and unrelated to the wound. Wound infections and dehiscence are uncommon. Seroma and hematoma formation are more common and may require drainage and local wound care.

Prolonged lymph drainage and lymphocele formation may occur in 3% to 12% of patients. Prolonged drainage is treated by instilling autologous blood or Betadine solution through the preexisting drains as sclerosing agents. If Jackson-Pratt or similar drains are used, tissue will eventually grow into the drains. This has occurred twice in our experience, and in both cases a general anesthetic was required for drain removal. Although it has been reported that the use of subcutaneous heparin increases the incidence of prolonged lymph drainage, this has not been our experience. Our rate of prolonged lymph drainage and/or symptomatic lymphocele formation is <3%. Treatment of symptomatic lymphoceles varies from percutaneous drainage under radiological guidance and sclerotherapy to laparoscopic or open marsupialization into the peritoneal cavity. Although some lymphatic drainage is expected, careful dissection and meticulous ligation of lymphatic channels help minimize the risk of prolonged drainage.

Any patient with prolonged or excessive lymph drainage must be evaluated for a urinary leak. This may be done by sending a sample of the fluid for creatinine testing.

Thrombophlebitis and deep venous thrombosis are recognized complications of pelvic lymph node dissection. Although the studies are conflicting, most have shown that some method of anticoagulation, low-dose heparin, or pneumatic compression stockings are beneficial in reducing the risk of these complications. We routinely administer subcutaneous heparin preoperatively and every 8 to 12 hours postoperatively as well as use pneumatic compression stockings until the patient is discharged.

Chronic lymphedema of the lower extremities and external genitalia may occur, and this may be worsened by radiotherapy. Although extended dissections have been reported to result in improved survival rates in retrospective studies, they may be associated with increased incidence of lymphedema. The modified pelvic lymph node dissection has been a reliable way of preventing chronic lymphedema.

---

## ALTERNATIVE THERAPY

---

Pelvic lymph node dissection is currently the only definitive means of evaluating lymph node status. Enlarged lymph nodes suspicious for metastases may be identified by ultrasound, cross-sectional imaging with thin-cut computerized tomography (CT) scans, magnetic resonance imaging (MRI), and pedal lymphangiography, all of which have low sensitivity. Unless bulky disease is seen on a CT scan (1 cm), a tissue sample (e.g., by CT-guided needle aspiration core biopsy) is required for validation of a suspicious scan finding. Drawbacks with biopsy include size limitation, random sampling error, disruption of nodal architecture, low cellular yield, and need for an expert cytopathologist. While CT scans are routinely done prior to a cystectomy, we very rarely employ them prior to a radical prostatectomy.

The use of PSA alone is not a good predictor of pathological stage, as there can be significant overlap between the two variables. Costly alternatives such as radioisotopic metabolic imaging using positron emission tomography scans and tumor-directed imaging by labeled antibody scans ( $^{111}\text{In}$ -capromab pendetide, the ProstaScint scan, Cytogen Corp., Princeton, NJ)

may offer improvement in detection of nodal metastases over conventional imaging and are only indicated in high-risk patients. Methods to improve specificity, such as fusion of acquired images with three-dimensionally reconstructed MRI, are currently being investigated.

# CHAPTER 28 ■ OPEN RADICAL RETRO PUBIC PROSTATECTOMY

MISOP HAN AND WILLIAM J. CATALONA

Over the past two decades, the management of patients with clinically localized prostate cancer has changed dramatically. Widespread screening with serum prostate-specific antigen (PSA) and digital rectal examination has allowed much earlier detection of prostate cancer (1, 2). Modification of the surgical technique of radical retropubic prostatectomy has allowed better hemostasis, improved visualization during dissection, and facilitated preservation of neurovascular bundles supplying the corpora cavernosa (3). As a result, radical prostatectomy can be performed with a high cure rate while preserving urinary and erectile function in the majority of patients. Thus, radical prostatectomy has become the most commonly performed treatment for clinically localized prostate cancer, with abundant long-term data confirming its efficacy. In this chapter, we discuss the technique, outcomes, and complications of anatomic radical retropubic prostatectomy using the senior author's surgical series, now including >5,000 anatomic radical retropubic prostatectomies as an example.

## INDICATIONS FOR SURGERY

---

Radical prostatectomy is indicated for men with a life expectancy of at least ten years, a completely resectable and biologically significant tumor, and no comorbidity that might make the operation unacceptably risky. Actuarial life tables can project the life expectancy of US men, and with appropriate adjustment for comorbidities, life expectancy can be estimated for the individual patient.

After confirming the likelihood of a sufficiently long life expectancy, the next step in patient selection is to identify those with potentially curable disease. Radical prostatectomy provides the best chance for cure for men whose tumor is confined to the prostate gland. Nomograms predicting the pathologic stage based on preoperative clinical and pathologic parameters have been widely used to identify patients who are likely to benefit from the surgical resection and those who are

not (4). Alternatively, nomograms predicting recurrence-free survival probabilities following treatment also are sometimes useful for patients (5,6).

---

## ALTERNATIVE THERAPY

---

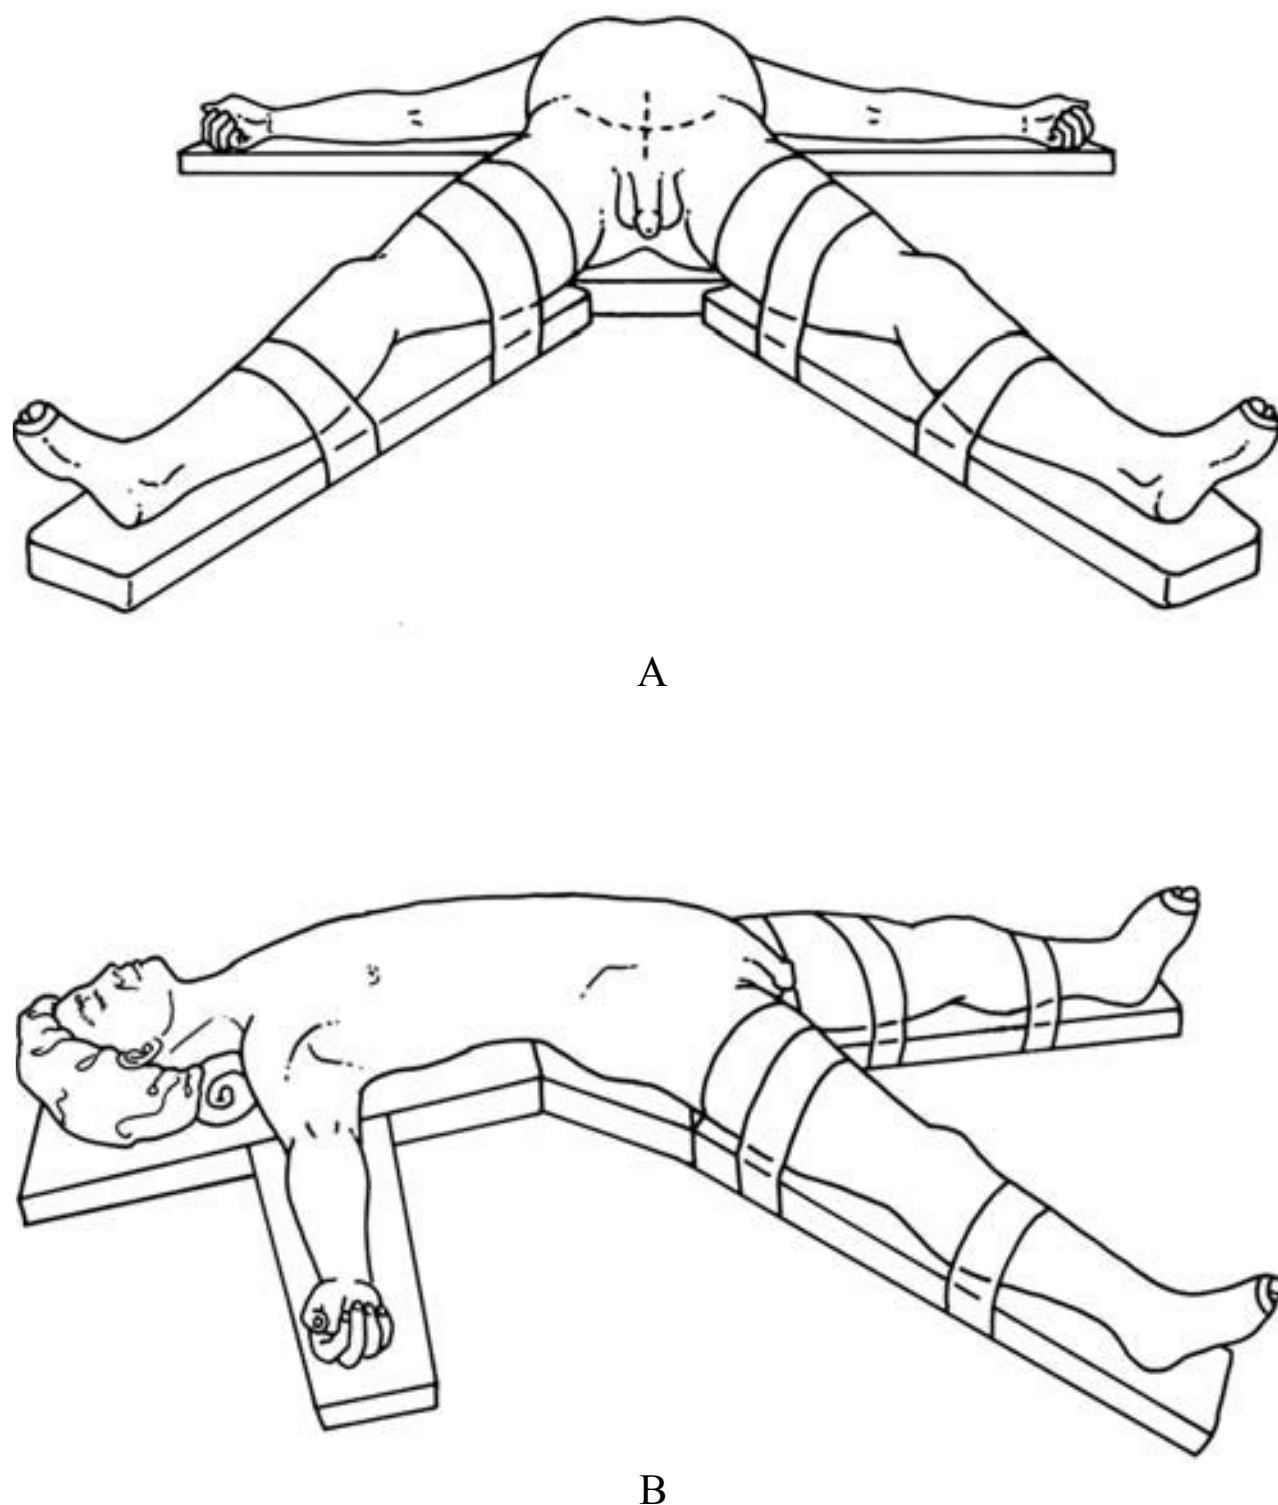

Alternatives to radical retropubic prostatectomy include watchful waiting/expectant management, hormonal manipulation, brachytherapy, external beam radiation therapy, and other alternative surgical approaches such as radical perineal prostatectomy and laparoscopic radical prostatectomy with or without robotic assistance.

---

## SURGICAL TECHNIQUE

---

Before the operation, a first-generation cephalosporin (or appropriate substitute, if the patient is allergic to cephalosporins) antibiotic is given intravenously. After a general endotracheal or regional anesthesia is administered, thigh-high elastic hose are placed on the patient. Sequential compression devices and prophylactic low-dose heparin are used only in patients with increased risk for thromboembolic complications. The patient is positioned with his legs on spreader bars, and the operating table is dorsiflexed with the break just above the patient's anterosuperior iliac spine (Fig. 28.1). The abdomen and genitalia are appropriately prepared and draped.

**FIGURE 28.1 A and B:** Positioning of the patient. Legs are separated on spreader bars. The operating table is flexed with the break just above the patient's anterosuperior iliac spine. (From M Han, WJ Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. Chapter 29, 2005; 514–527, with permission.)

There are nine key steps in performing anatomic nerve-sparing radical prostatectomy:

1. A limited pelvic lymphadenectomy
2. Incision of the endopelvic fascia and the puboprostatic ligaments
3. Proximal and distal suture ligation, and transection of the dorsal venous complex
4. Placement of hemostatic sutures in the neurovascular bundles and the prostatic pedicles
5. Dissection of the prostate from the neurovascular bundles
6. Vascular control and transection of the prostatic pedicles
7. Transection and reconstruction of the bladder neck
8. Dissection of the seminal vesicles and ampullary portions of the vasa deferentia
9. Performance of the vesicourethral anastomosis

These steps are described in detail below with corresponding illustrations.

---

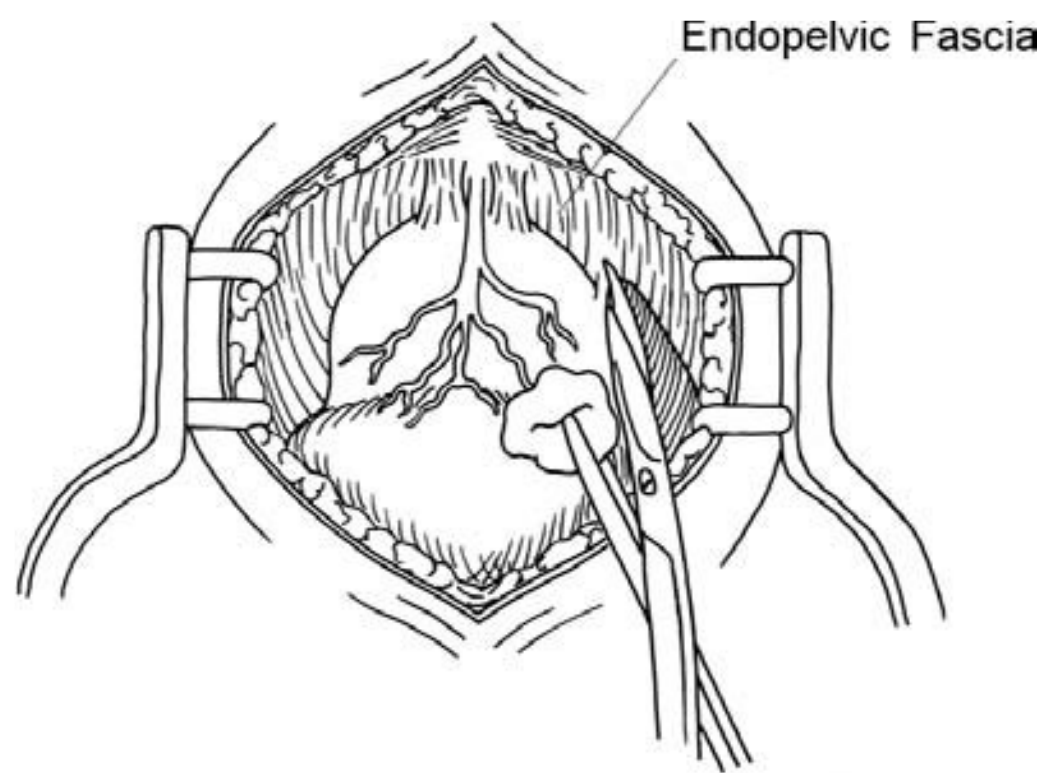

### 1. A Limited Pelvic Lymphadenectomy

---

A superficial midline (or transverse) lower abdominal incision (usually between 4 and 5 in. in length, depending upon the patient's body habitus) is made with a scalpel. The linea alba is incised and the space of Retzius is entered. Anatomic radical retropubic prostatectomy performed in the extraperitoneal space is arguably less invasive than laparoscopic and robotic prostatectomy, in which a transperitoneal approach is frequently used. By avoiding any entry into the peritoneal cavity, anatomic radical retropubic prostatectomy can be performed while minimizing the risk of injury to bowel, major vascular structures, and other adjacent organs. In addition, the cosmetic results are not significantly different between a single, limited infraumbilical incision for anatomic radical retropubic prostatectomy and multiple laparoscopic port site incisions and an incision for prostate removal during laparoscopic or robotic prostatectomy.

Taking care to avoid disrupting the lymphatic tissue lateral to the external iliac vein and to avoid compression of the vein itself, a Balfour retractor is placed. A modified pelvic lymphadenectomy is performed, removing only the lymph nodes medial to the external iliac vein. Care is taken during the lymphadenectomy to preserve any accessory arterial branches to the corpora cavernosa that arise from the distal external iliac or obturator arteries. The obturator nerve is identified and preserved. In most incidences, the patient elects to have the prostate gland removed, even if there are pelvic lymph node metastases; otherwise, the excised lymph node packet is sent for frozen section examination. If the patient elects not to have the prostate removed and there are lymph node metastases, frozen section examination of the lymph nodes is performed. If frozen sections reveal metastatic cancer, the operation is terminated. Lymphadenectomy is optional in patients who are at low risk for pelvic lymph node metastases by virtue of a low Gleason grade, low PSA, and low biopsy tumor volume.

After completing the lymphadenectomy, the adipose and areolar tissues are swept gently from the anterior surface of the prostate and the endopelvic fascia to expose the puboprostatic ligaments. Care is taken to avoid injury to the perforating branches of the Santorini plexus that pierce the

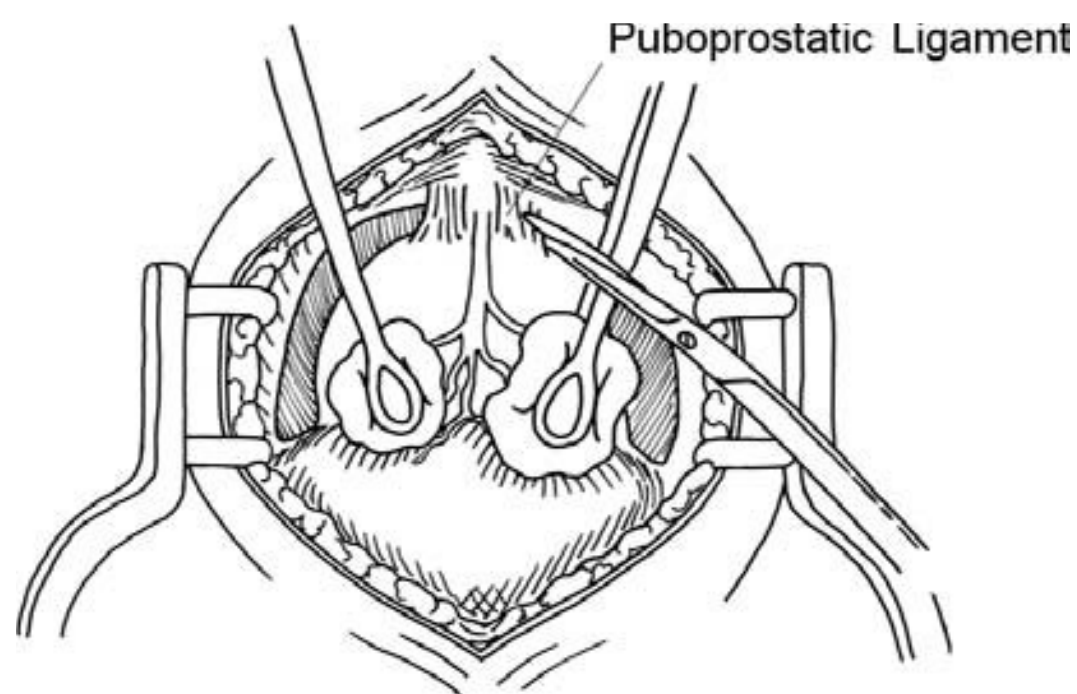

**FIGURE 28.2** The endopelvic fascia is incised in the groove between the levator ani muscles and the lateral border of the prostate. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005; 516–525, with permission.)

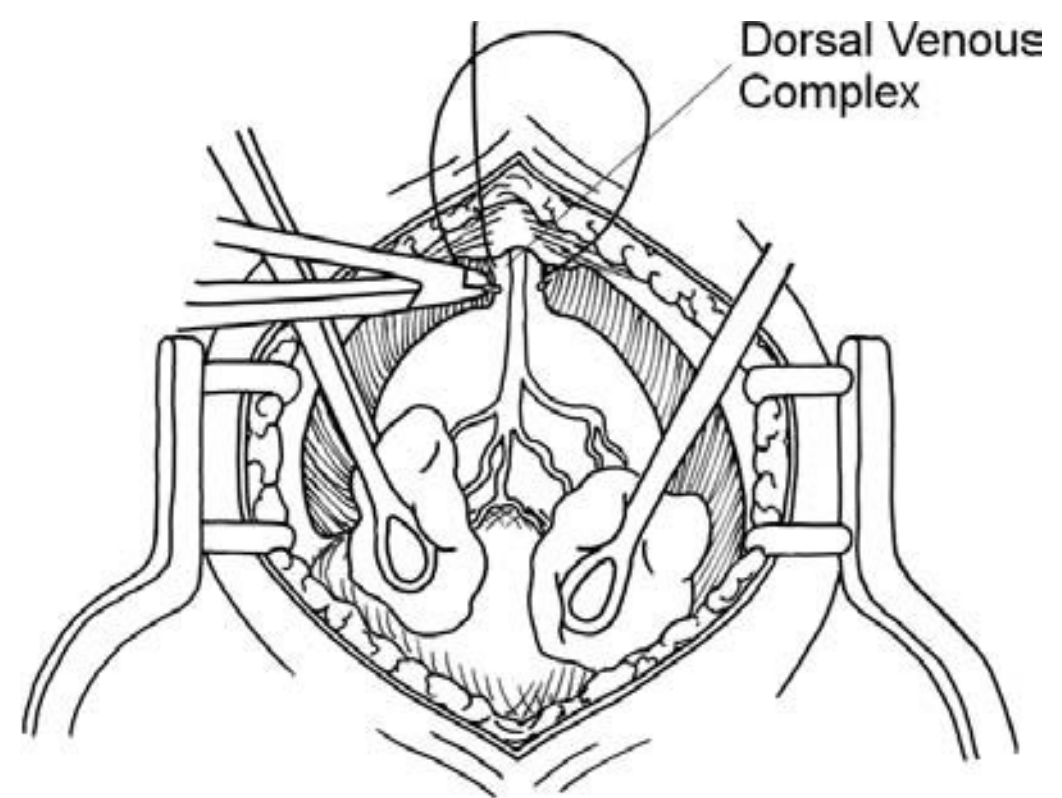

endopelvic fascia between the puboprostatic ligaments and pass cephalad on the anterior surface of the prostate gland and bladder.

## 2. Incision of the Endopelvic Fascia and the Puboprostatic Ligaments

The endopelvic fascia is incised in the groove between the levator ani muscles and the lateral border of the prostate (Fig. 28.2). Inside the endopelvic fascia, the lateral surface of the prostate is covered by a smooth, glistening membrane overlying the lateral portion of the Santorini plexus. Strands of the levator ani muscles are gently dissected off the prostate to the level of the urogenital diaphragm. Often, venous tributaries pass from the levator ani muscles to the prostate just lateral to the puboprostatic ligaments. These vessels are cauterized, secured with hemostatic clips, or ligated laterally; then they are clamped medially with a delicate snub-nose right-angle clamp. After the vein is transected sharply, its medial portion is ligated. When the endopelvic fascia has been opened from the base to the apex of the prostate, the superficial branch of the Santorini plexus is gently retracted medially, and the puboprostatic ligaments are placed on stretch and partially divided close to the pubic symphysis (Fig. 28.3). To avoid

**FIGURE 28.3** The puboprostatic ligaments are placed on stretch and incised. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

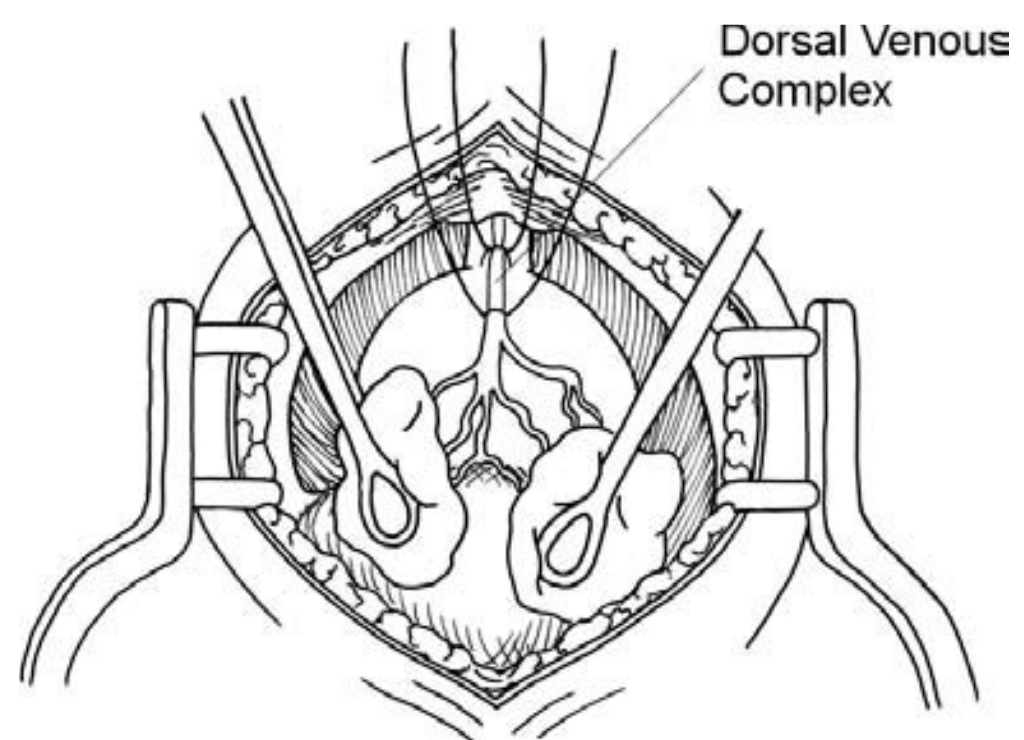

**FIGURE 28.4** The dorsal venous complex is suture-ligated with a 2-0 chromic catgut suture on a CT-1 needle. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005; 516–525, with permission.)

injuring the dorsal venous complex, care is taken not to divide the puboprostatic ligaments too medially or too far under the pubic symphysis.

## 3. Suture Ligation and Transection of the Dorsal Venous Complex

After the puboprostatic ligaments have been divided, the lateral surfaces of the urethra are palpated. The groove between the anterior surface of the urethra and the dorsal venous complex is developed with a pinching motion of the left index finger and thumb. The plane between the urethra and the dorsal venous complex is then developed gently, first with a large right-angle clamp. This facilitates tight ligation of the dorsal venous complex. After the dorsal venous complex has been ligated, it is also suture-ligated in a slightly more caudal site with a 2-0 chromic catgut suture on a CT-1 needle (Fig. 28.4). A suture ligation is also placed in the anterior surface of the prostate to reduce the back-bleeding from the Santorini plexus (Fig. 28.5).

The right-angle clamp is then passed behind the dorsal venous complex, and the jaws of the clamp are spread. The dorsal venous complex is transected with electrocautery or a

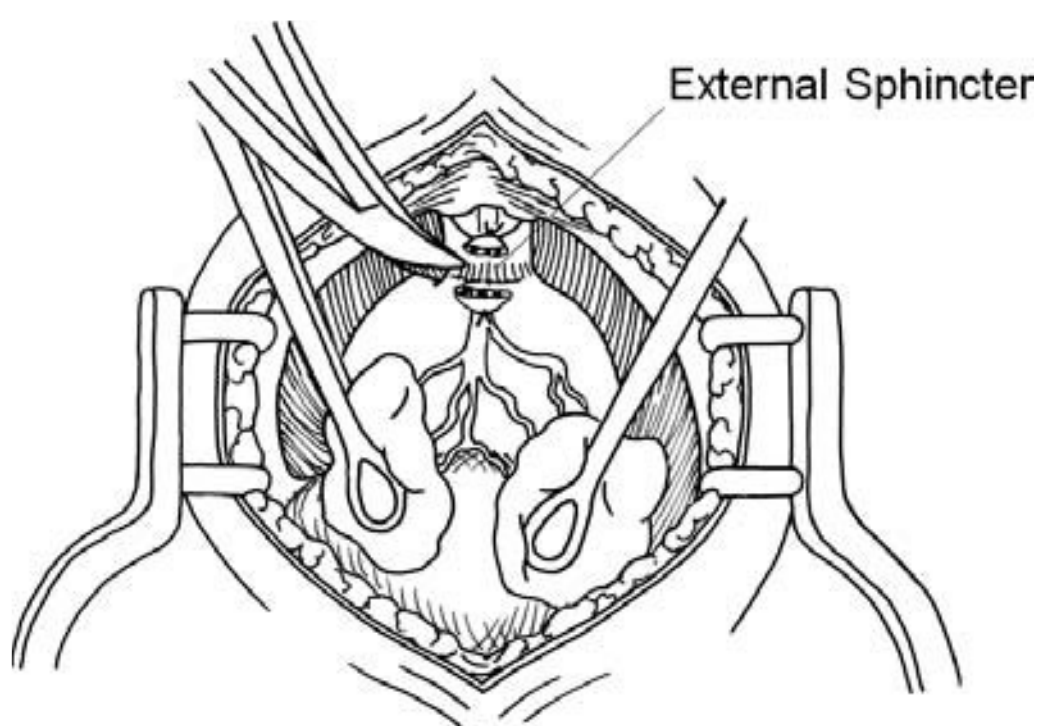

**FIGURE 28.5** To reduce back-bleeding from the Santorini plexus, the cephalad aspect of the dorsal venous complex is suture-ligated. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

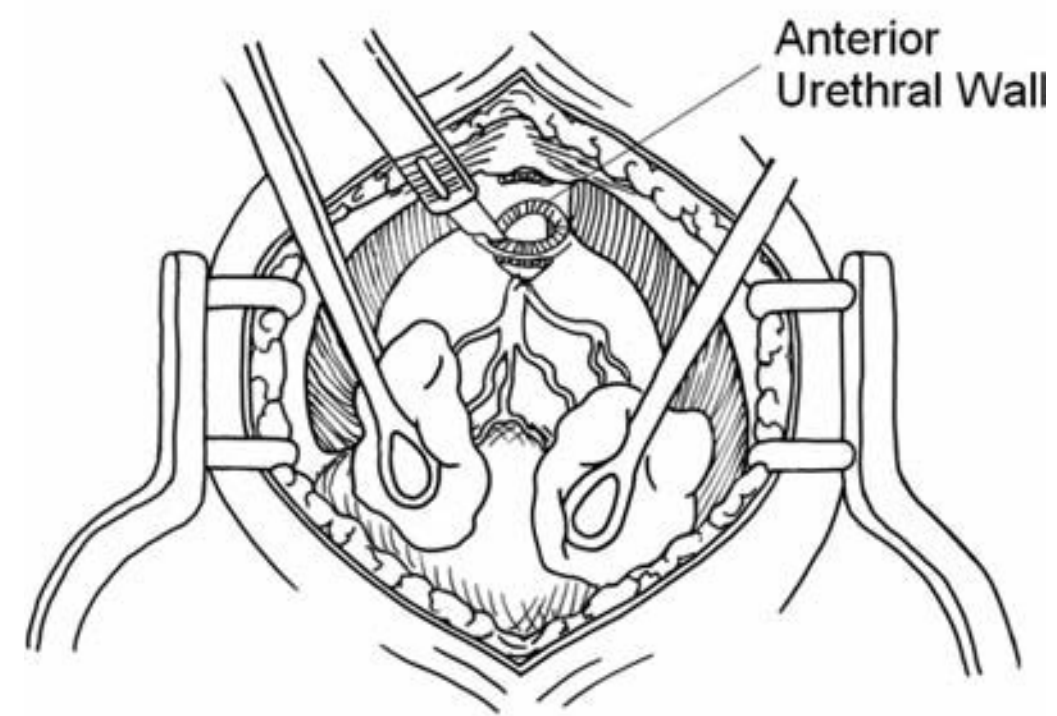

**FIGURE 28.6** The dorsal venous complex is transected with a right-angle clamp jaws spread behind the complex. (From Han, Catalana. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

scalpel (Fig. 28.6). Back-bleeding from the dorsal venous complex is controlled with figure-of-eight 3-0 sutures. It is important to obtain good hemostasis at this time to allow the apical dissection of the prostate to be performed in a relatively bloodless field. If the dorsal venous complex ligature slips off, the complex is oversewn using a 3-0 chromic catgut suture on a 5/8-circle needle. The goal in oversewing the complex is to pass the suture just through the lateral borders of the complex itself in its anterior, middle, and posterior aspects. Wide, imprecisely placed sutures may damage the neurovascular bundles.

The anterior surface of the urethra is palpated between the neurovascular bundles. The circumurethral sphincter muscle and the anterior wall of the urethra are incised with a scalpel just distal to the apex of the prostate without dissecting around the lateral or posterior surfaces of the urethra (Figs. 28.7 and 28.8). The incision should not be carried too far laterally, or it may injure the neurovascular bundles. The urethral catheter is exposed and carefully hooked with a delicate right-angle clamp. Gentle traction on the clamp in a cephalad direction exposes the posterior urethral wall. The catheter is divided and placed on gentle cephalad traction, and the posterior urethral wall is sharply transected.

**FIGURE 28.7** The circumurethral external sphincter muscle fibers are incised to expose the urethra. (From Han, Catalana. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

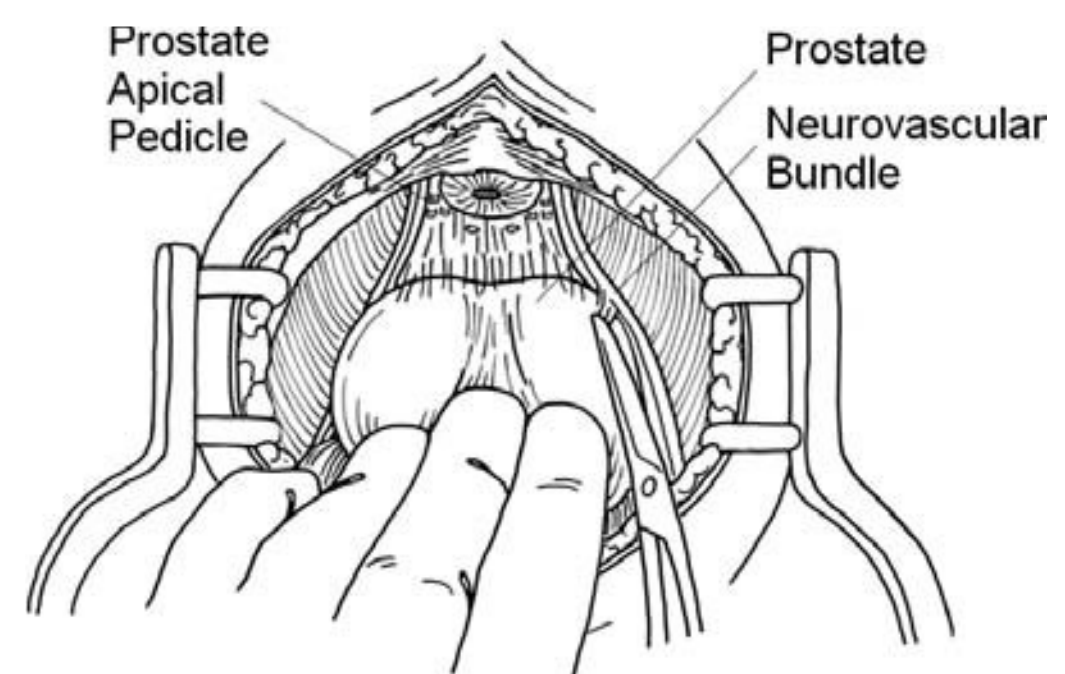

**FIGURE 28.8** The anterior wall of the urethra is incised with a scalpel without dissecting around the lateral or posterior surfaces of the urethra. (From Han, Catalana. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

Fibromuscular bands tethering the apex of the prostate to the pelvic floor are incised using sharp dissection (Fig. 28.9). The rectourethralis muscle is incised, exposing the prerectal fat.

#### 4. Placement of “Prophylactic” Hemostatic Sutures in the Neurovascular Bundles and Prostatic Pedicles

To reduce bleeding during the dissection of the neurovascular bundles and prostatic pedicles in a manner similar to that achieved with the pneumoperitoneum during laparoscopic surgery, “prophylactic” hemostatic figure-of-eight suture ligatures of 4-0 plain catgut are placed in the neurovascular bundles lateral to the prostate. Similarly, 3-0 suture ligatures are placed in the prostatic pedicles. After these sutures have been placed on both sides of the prostate, sharp, energy-free dissection can be used to dissect the neurovascular bundles from the prostate. The prophylactic hemostatic sutures are tied “softly” to avoid crushing the nerve fibers in the neurovascular bundles, and the plain catgut sutures are quickly absorbed. This technique minimizes or avoids the use of hemostatic clips and sutures that may permanently entrap the neurovascular bundles.

**FIGURE 28.9** The apical pedicles of the prostate may require suture ligation. Fibromuscular bands tethering the apex of the prostate to the pelvic floor are incised using sharp dissection. The prostate gland is dissected from neurovascular bundles. (From Han, Catalana. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

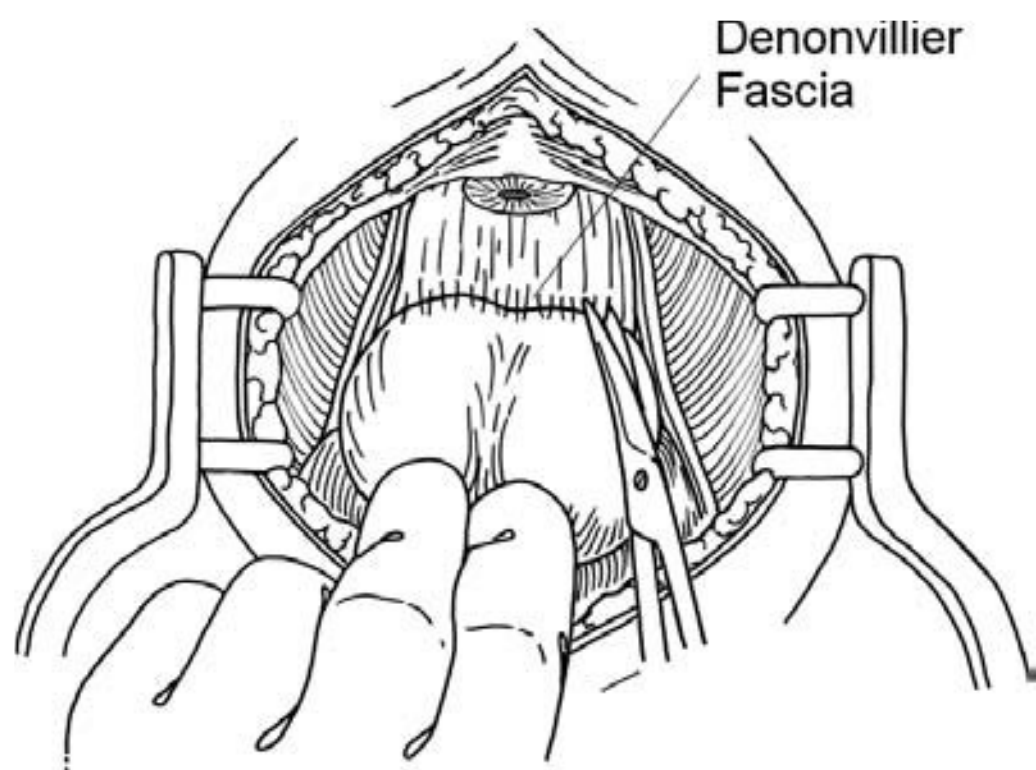

## 5. Separation of the Prostate from the Neurovascular Bundles

The lateral pelvic fascia is incised from the apex of the prostate to the base. A delicate right-angle clamp may be used to elevate the lateral pelvic fascia from the underlying veins on the surface of the prostate. Recent studies suggest that high, anterior release of the neurovascular bundles is associated with improved potency rates. This maneuver must be performed carefully in patients with high-grade and high-volume disease and is sometimes difficult to perform in patients with periprostatic fibrosis or inflammatory changes. Small perforating bleeders not controlled by the prophylactic hemostatic sutures may be secured with hemoclips, ties, or ligatures to ensure adequate hemostasis. The plane between the prostate and the neurovascular bundles is developed using sharp and blunt dissection, allowing the prostate to assume a more anterior position in the pelvis.

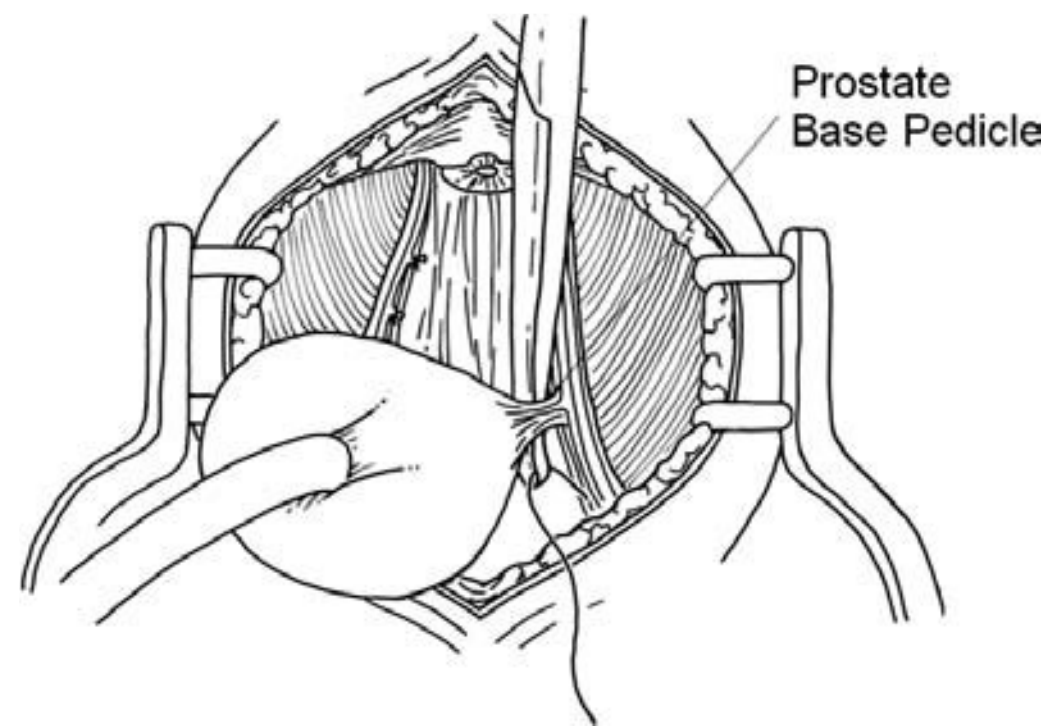

The lateral aspect of the prostate is then dissected from the neurovascular bundles, allowing the bundles to retract laterally. In a case of extensive fibrosis, the dissection is performed only sharply to avoid tearing into the rectum with blunt dissection. The dissection is carried cephalad until the portion of the Denonvilliers fascia covering the ampullary portions of the vasa deferentia and the seminal vesicles is exposed (Fig. 28.10). The Denonvilliers fascia is incised with the cautery. The Metzenbaum scissors are then used to develop the proper plane of dissection for the prostatic vascular pedicles. If there is continued bleeding from the periurethral tissues and apical pedicles of the prostate, hemostatic sutures should be placed at this juncture to avoid continued blood loss during the remainder of the procedure.

## 6. Vascular Control and Transection of Prostatic Pedicles

The prostatic pedicles are divided by inserting the right-angle clamp medial to them, with the tip of the clamp directed almost parallel to the lateral surface of the prostate. The prostatic pedicle is ligated or hemoclipped laterally, taking care to place the tie or clip medial to the neurovascular bundle

**FIGURE 28.10** The dissection is carried cephalad until the portion of the Denonvilliers fascia covering the ampullary portions of the vasa deferentia and the seminal vesicles is exposed. The Denonvilliers fascia is incised with cautery to expose vascular pedicles at prostate base. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

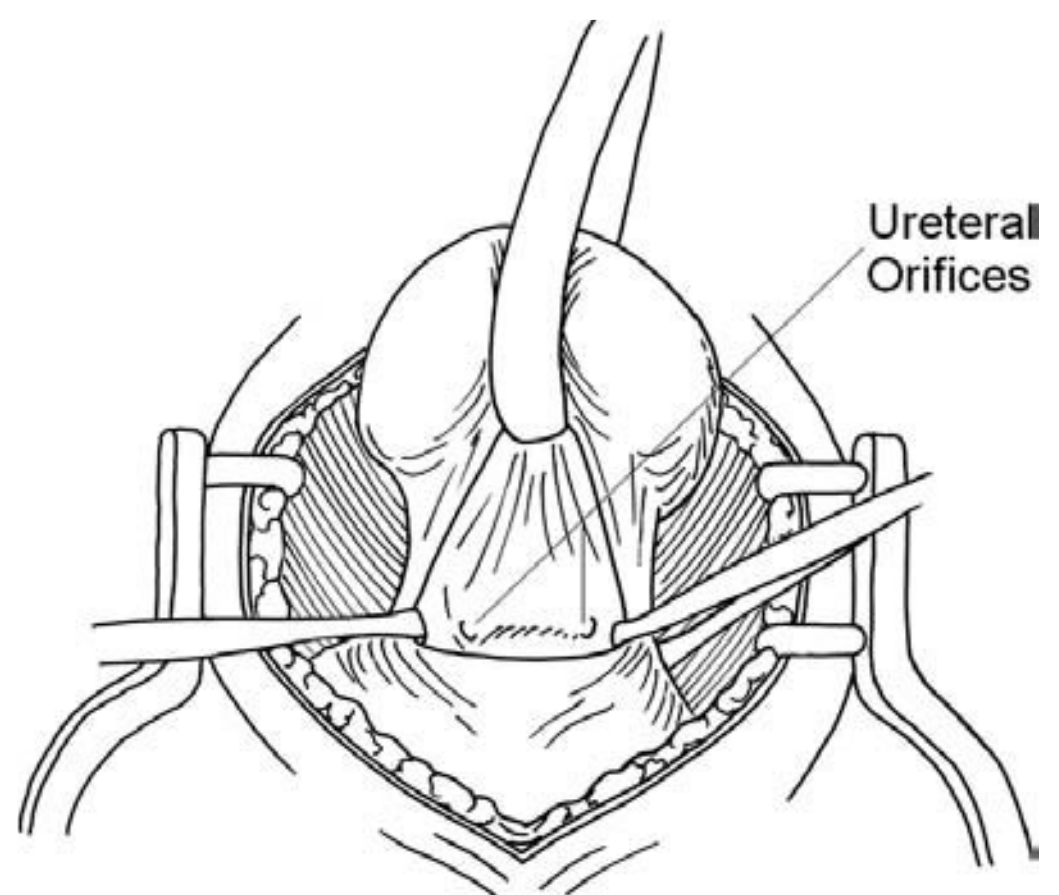

**FIGURE 28.11** The prostate base pedicle is ligated or hemoclipped laterally, taking care to place the tie medial to the neurovascular bundle. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

(Fig. 28.11). The pedicle is divided close to the prostate. This dissection is performed on both sides to a point cephalad to the seminal vesicles. Care is taken when dissecting near the seminal vesicles to avoid injuring the neurovascular bundles that are situated just lateral to the seminal vesicles. The seminal vesicles are freed from the bladder base using sharp and blunt dissection, and a large right-angle clamp may be used to further develop this plane. Two hemostatic sutures of 3-0 chromic catgut are placed in the lateral bladder pedicles cephalad to the seminal vesicles, one just lateral to the prostate and another just medial to the neurovascular bundles. The lateral bladder neck fibers are then partially incised with the cautery but not through their entire thickness.

## 7. Transection and Reconstruction of the Bladder Neck

The anterior bladder neck is transected with electrocautery in the natural groove between the bladder and the prostate. The bladder neck opening is enlarged with scissors, and the catheter is pulled through and used as a tractor on the prostate (Fig. 28.12). The posterior bladder neck is incised with the

**FIGURE 28.12** The anterior bladder neck is transected in the natural groove between the bladder and the prostate. The bladder neck opening is enlarged with scissors. The ureteral orifices are identified. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

cautery. The muscular attachments between the bladder and prostate are divided using electrocautery and/or hemostatic clips for hemostasis.

## 8. Dissection of Seminal Vesicles and Ampullary Portions of the Vasa Deferentia

The seminal vesicles are dissected first along their lateral edges, carrying the plane of dissection medially. Many small perforating arteries enter the lateral and terminal portions of the seminal vesicles. These are secured with small hemoclips. The ampullae are freed, using sharp and blunt dissection, and then are clipped and transected. After the seminal vesicles have been dissected to their tips and the hemoclips placed, the surgical specimen is removed. At this point, the pelvis is carefully inspected for hemostasis. Small bleeders on the neurovascular bundles may require 4-0 absorbable suture ligatures. It is important not to use the cautery for hemostasis on the neurovascular bundles, to avoid cautery injury to the cavernosal nerves. Suture ligatures of 3-0 or 4-0 absorbable material are placed in the “pockets” of the seminal vesicle pedicles on the medial aspects of the neurovascular bundles to ensure good hemostasis in this difficult-to-visualize region.

## 9. Vesicourethral Anastomosis

Reconstruction of the bladder neck begins by placing a continuous running everting suture of 3-0 chromic catgut that encompasses bladder mucosa and underlying muscle for a distance of nearly the entire anastomotic circumference (Fig. 28.13). The bladder neck is then reconstructed in a tennis racket fashion, with the handle of the racket directed posteriorly. The bladder neck closure is accomplished with a continuous 2-0 chromic catgut suture. Care should be taken to avoid compromising the ureteral orifices. The bladder neck is closed to a size of approximately 22Fr to 24Fr. Closing the bladder neck to a smaller caliber may lead to postoperative vesicourethral anastomotic stricture.

An 18Fr catheter is passed through the urethra. While an assistant exerts pressure on the perineum with a sponge forceps

**FIGURE 28.13** A continuous running mucosa-everting suture of 3-0 chromic catgut is placed for a distance of nearly the entire anastomotic circumference. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

**FIGURE 28.14** Perineal pressure is applied with a sponge forceps to better expose the cut end of the urethra. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005;516–525, with permission.)

**FIGURE 28.15** Double-armed 2-0 chromic catgut sutures are used for the vesicourethral anastomosis. (From Han, Catalona. Anatomic nerve-sparing radical retropubic prostatectomy. *Urol Oncol* 2005; 516–525, with permission.)

to better expose the cut end of the urethra (Fig. 28.14), double-armed 2-0 chromic catgut sutures are used for the vesicourethral anastomosis (Fig. 28.15). A 5/8-circle needle is used to place the sutures in the urethra from inside to outside, avoiding placing the suture into the neurovascular bundles. The tip of the catheter is grasped and brought out of the wound to expose the posterior lip of the cut end of the urethra. The posterior sutures are similarly placed. The anterior sutures are placed at the 10 o'clock and 2 o'clock positions, and the posterior sutures are placed at the 5 o'clock and 7 o'clock positions. In addition, a stronger 2-0 monocril suture is placed at the 6 o'clock position to secure the most posterior aspect of the reconstructed bladder neck to the urethral stump. The other ends of the sutures containing an 1/2 circle taper point needle are placed in the corresponding positions of the bladder neck from inside to outside. These sutures encompass mucosa and muscle and exit at the edge of the mucosa. The catheter tip is placed in the bladder, and the bladder neck is guided gently toward the cut end of the urethra. The anastomotic sutures are tied carefully under direct vision. The bladder is then irrigated free of clots, and a single suction drain is placed in the pelvis and brought out the lower end of the wound. The incision is closed with no. 1 loop Maxon running sutures on the fascia, 2-0 chromic catgut suture on the subcutaneous tissue, and a 4-0 monofilament absorbable

subcuticular suture on the skin. The skin incision is covered with Steri-Strips.

---

## Postoperative Care

---

Patients are ambulated with assistance once or twice on the day of surgery, 5 times on the first postoperative day, and 7 times on the second postoperative day. A clear liquid diet is given on the night of surgery, advancing to a regular diet as tolerated on the following days. A suction drain and dressing are removed, and the patient is usually discharged from the hospital on the second postoperative day. Intravenous antibiotics are discontinued after the suction drain is removed. For analgesia, ketorolac (30 to 60 mg) is given intravenously every 6 hours for the first 48 hours. It may be supplemented with acetaminophen or sparingly with morphine, as needed.

Although some claim a quicker recovery following laparoscopic surgery compared to anatomic radical retropubic prostatectomy, a recent study has shown similar low narcotic usage and patient-reported pain scores regardless of which approach was used (7). Therefore, the same clinical care pathway, without a significant difference in length of hospital stay, can be applied to patients treated by either open radical prostatectomy or laparoscopic/robot-assisted radical prostatectomy. Most patients are discharged from the hospital on the second or third postoperative day following anatomic radical retropubic prostatectomy.

Antibiotic ointment is applied to the urethral meatus around the catheter 4 to 6 times a day until catheter removal. The catheter may be removed on the seventh, tenth, or fourteenth postoperative day, depending upon the perceived amount of tension on the vesicourethral anastomosis. A cystogram is not performed before removing the catheter unless an anastomotic leak is suspected. The catheter should not be removed before 7 days, as 10% to 15% of men may experience urinary retention from edema and require recatheterization. An oral fluoroquinolone antibiotic is given 1 day before and 1 week following the catheter removal. Daily Kegel exercises are performed in four sets of ten, before the surgery and following the catheter removal until continence returns. A protective pad or diaper is used until complete urinary control is achieved. The first postoperative serum PSA level is measured 1 month after the operation.

---

## OUTCOMES

---

---

### Cancer Control Outcome

---

The most important objective of radical prostatectomy is cancer control. A rising serum PSA level is usually the earliest evidence of recurrence or progression following prostatectomy. Because follow-up data are not sufficiently mature to effectively evaluate cancer-specific survival trends, biochemical-recurrence-(detectable serum PSA)-free survival has been used frequently as a surrogate in evaluating treatment efficacy in radical retropubic prostatectomy series.

Analyses of the senior author's series recently have been reported (8). They include almost 3,500 men who underwent

anatomic radical retropubic prostatectomy between 1983 and 2003, including those with adverse prognostic features. Cancer progression was defined as detectable serum PSA ( $>0.2$  ng per mL), local recurrence, or distant metastases. With a mean follow-up of 65 months (range, 0–233), actuarial ten-year cancer progression-free survival probability was 68%. Actuarial ten-year cancer-specific and overall survival rates were 97% and 83%, respectively. Other large radical prostatectomy series have reported similar excellent results (9,10). Similar long-term oncological outcome results are not yet available in laparoscopic or robotic prostatectomy series.

---

### Urinary Continence Outcome

---

The overall urinary continence outcome following nerve-sparing radical retropubic prostatectomy was excellent in the current series. More than 93% of men achieved complete urinary continence, defined as requiring no protection for daily activities (11). The return of urinary continence was strongly associated with the age of the patient. For example,  $>95\%$  of men younger than age 50 were continent following surgery. In contrast, 86% of men above age 70 were continent postoperatively. Only four men (0.2%) eventually required an artificial urinary sphincter placement for stress urinary incontinence. The relative long-term functional outcomes of laparoscopic and robotic prostatectomy methods are yet unknown.

---

### Erectile Function Outcome

---

There are several possible goals of the nerve-sparing aspect of radical retropubic prostatectomy. Patients with intact libido and erectile potency want to maintain their current quality of erections or erections sufficient for penetration with the help of oral medication, such as phosphodiesterase type 5 inhibitors. Others with poor-quality erections preoperatively might accept erections that at least offer some rigidity to provide sensory satisfaction for both sexual partners. The erectile potency in the current series was defined as an ability to maintain erections strong enough for penetration with or without the help of oral phosphodiesterase inhibitors.

The return of erectile potency following radical retropubic prostatectomy was strongly associated with the age of the patient, preoperative potency status, nerve-sparing status (bilateral versus partial sparing), and the era of surgery (1980s versus 1990s) (11). More than 75% of men younger than age 60 regained potency following bilateral nerve-sparing radical retropubic prostatectomy. In the modern era,  $>95\%$  of men below age 50 recovered potency following surgery. Between 62% and 72% of men in their 60s became potent following bilateral nerve-sparing surgery. Finally, there was a significant improvement in recovery of potency in men treated in the 1990s compared to those treated in the 1980s, even after correcting for the age and nerve-sparing status. In the most favorable candidates in whom preoperative potency is normal and bilateral nerve-sparing surgery can be performed, approximately 95% in their 40s, 85% in their 50s, 75% in their 60s,

and 50% in their 70s will recover erections sufficient for penetration and intercourse with or without the aid of phosphodiesterase type 5 inhibitors.

The senior author now strongly encourages patients to begin an erectile dysfunction rehabilitation program beginning 1 month postoperatively, using intracavernosal injections of Tri-Mix two to three times per week. This regimen provides excellent rigid erections with well-oxygenated arterial blood and also provides the patient with a method to return to a relatively normal sex life soon after surgery. Patients may transition to oral phosphodiesterase inhibitor therapy when spontaneous erections begin to return.

---

## COMPLICATIONS

---

With careful selection of patients and performance of necessary cardiovascular evaluation, perioperative mortality can be largely avoided. There was no intraoperative or immediate postoperative mortality in the current series.

The overall complication rate of radical prostatectomy was 9% in the current series (12). Initially, the complications occurred more commonly in older men, but the overall complication rate gradually decreased with the surgeon's experience. The most common complications of anatomic nerve-sparing radical retropubic prostatectomy included anastomotic stricture (bladder neck contracture), thromboembolic complications (deep vein thrombosis and pulmonary embolism), and postoperative inguinal hernia. In the current series, the rate of anastomotic stricture decreased from 8% in the 1980s to < 1% after 1990. Similarly, a marked decrease in thromboembolic events was observed, with the rate decreasing from 3% to 1% during the past 20 years. Other rare complications (<1%)

associated with radical prostatectomy included infection, lymphocele formation, neurologic deficit, and cardiovascular events.

Anastomotic stricture can be initially managed with a gentle, serial dilation. Alternatively, a careful internal urethrotomy can be performed. For a long and persistent stricture, a transurethral resection of the scar tissue cephalad to the external sphincter may be necessary. Care should be taken to avoid cutting too deeply in the posterior direction to avoid creating a fistula with the rectum. After resection, triamcinolone can be injected via a cystoscopic approach to prevent inflammatory response and subsequent, recurrent scar formation. Usually, an interval of self-catheter dilation of the anastomosis is required.

Inadvertent injury to the obturator nerve can occur during the pelvic lymphadenectomy. When a tension-free primary nerve repair is not feasible, nerve grafting can be performed utilizing either the sural nerve or the lateral antebrachial cutaneous nerve. However, even without a nerve repair, conservative management with physical therapy can compensate for the deficit, and many patients do not exhibit significant thigh adductor deficit following the injury.

An injury to the ureter can occur inadvertently during the transection of the bladder neck or the dissection of the lateral prostate pedicles. When recognized, a simple mobilization of the distal ureter and ureteroneocystostomy should be performed. The reimplanted ureter should be cannulated using a 5Fr or 8Fr pediatric feeding tube to prevent the urinary obstruction due to the edema at the reimplantation site.

Usually, a rectal injury can be repaired primarily using a multiple-layer closure. However, a diverting colostomy should be strongly considered in men with a large rectal defect, a history of pelvic radiotherapy, or long-term preoperative steroid therapy.

# CHAPTER 29 ■ RADICAL PERINEAL PROSTATECTOMY

SAM D. GRAHAM, JR., JEFFREY C. LOU, AND THOMAS E. KEANE

Radical perineal prostatectomy, first performed in 1869 by Buchler and popularized in the United States by Young in 1903, remained the primary surgical approach to carcinoma of the prostate into the mid-1970s. With the recognition of the importance of assessing pelvic lymph nodes preoperatively and the advantage that retropubic prostatectomy offered with the concomitant pelvic node dissection, perineal prostatectomy declined in popularity for the treatment of prostate cancer. The perineal approach, however, saw a resurgence in the 1990s for several reasons: (a) the trend toward minimally invasive surgery with a focus on reducing the morbidity and therefore hospital stay of patients, (b) the advent of laparoscopic surgery for lymph node assessment, (c) the introduction of prostate-specific antigen (PSA) for screening for prostate cancer with reduction in the numbers of patients with node-positive disease, (d) algorithms that may predict patients at high risk for positive lymph nodes, and (e) increased recognition of similar results compared to all other methods of radical prostatectomy. The procedure is also associated with reduced blood loss and low morbidity, and it can be modified to incorporate the neurovascular sparing techniques for preservation of potency.

---

## DIAGNOSIS

---

All patients who are potential candidates for radical perineal prostatectomy should undergo appropriate preoperative staging to ensure that they are operable candidates; preoperative imaging is rarely required in low- to intermediate-risk patients. Methods of differentiating local versus advanced disease include digital rectal examination, transrectal ultrasonography, radionuclide bone scan, assessment of pelvic lymph nodes, and pathologic indicators of progression such as Gleason sum and other markers.

PSA screening has made a significant impact on the preoperative stage of patients with prostate cancer. Patients presenting for surgery are generally younger, healthier, and more likely to have organ-confined prostate cancer than the population treated only a decade earlier, and in many ways this attributes to the large increase in the number of radical prostatectomies done in the United States in the past decade.

Digital rectal examination has a limited role in the clinical staging of prostate cancer. It is primarily used to crudely estimate the volume of the cancer. Transrectal ultrasonography is another modality that also has limitations in assessing local disease, but combined with digital rectal examination it at least gives some gross assessment of the likelihood of extracapsular disease. Other modalities, such as transrectal magnetic resonance

imaging (MRI), computerized tomography (CT) scan, and pelvic MRI, have been shown to have limited usefulness. The new generation of MRI scanners and ProstaScint scanning using fusion technology with CT or MRI have the potential to improve prostate cancer staging. Radionuclide bone scans are useful in assessing advanced bone disease but generally are not positive in patients with PSAs below 20 and no other sign of advanced disease.

For the past 20 years we have prospectively provided data that has been applied to an algorithm for the preoperative assessment of patients with prostate cancer developed through data on over 400 patients who had undergone pelvic node dissection. The current algorithm includes patients with a Gleason sum of 7, providing that the predominant pattern is 3, a low-volume cancer (T1b-c, T2a), and PSA of <10 ng per mL. Patients meeting all of these criteria have a <5% chance of positive lymph nodes, and therefore we do not routinely perform pelvic lymph node dissections (1). Patients exceeding any one of the above criteria are considered to be in the high-risk group and have undergone pelvic lymph node dissections. Using this method of assessment, our overall PSA recurrence rate from 1986 to 1993 was 24%. This compares favorably to other series of retropubic prostatectomies from that time in which all patients had a node dissection; in those series PSA recurrence rates were between 24% and 28% (2–5).

---

## INDICATIONS FOR SURGERY

---

Patients who are candidates for radical prostatectomy must have clinically organ-confined prostate cancer (T1-2). Other factors that need to be taken into consideration are the patient's life expectancy, other comorbidities, or any other factors that may affect the patient's choice. We generally do not offer a radical prostatectomy to patients who have a <10-year expectancy. Over the age of 70, we offer a radical prostatectomy only in selected cases where we feel that the benefits that can be obtained from radical prostatectomy outweigh the potential risks, particularly when compared to alternative therapies.

---

## ALTERNATIVE THERAPY

---

Alternatives to perineal prostatectomy include retropubic and laparoscopic or robot-assisted laparoscopic prostatectomies. The retropubic approach allows simultaneous node dissection and removal of larger prostate glands, though the length of hospitalization and immediate postoperative morbidity are

higher in our institution. The robotically assisted laparoscopic approach allows some improvement in visualization compared to the retropubic or laparoscopic surgeries due to the magnification and three-dimensional visualization, but it has yet to show any significant advantages in terms of operative morbidity, length of stay, or reduction in long-term morbidity. There are few if any large comparisons with radical perineal prostatectomy, although results to date indicate that no significant differences exist.

Alternatives to radical prostatectomy include observation, hormonal deprivation, and radiation therapy. We do not consider either observation or hormonal deprivation to be curative; these are good options only for patients with less than a 5-year life expectancy, patients who are  $>70$  years old with a well-differentiated cancer, and patients who are at high risk for surgery and refuse radiation. Radiation therapy, however, may be definitive and has a 5- to 10-year survival rate equivalent to that of surgery. The recurrence rates with radiation therapy are bimodal, with initial recurrences within 1 to 2 years of treatment and a delayed peak at 5 to 7 years after treatment. If the patient is young with a 15-year or longer outlook, we feel that our results would favor radical prostatectomy.

## SURGICAL TECHNIQUE

The patient is placed in an exaggerated lithotomy position (Fig. 29.1). It is important that the patient's perineum be parallel to the floor because this directly affects exposure. We use a standard operating room table with seven folded sheets under the patient's sacrum supporting the patient's entire weight. Shoulder braces are not recommended, and if a patient tends to slide off the sheets, we will place the table in a slight reverse Trendelenburg position. The patient's legs are stabilized using candy cane or Allen stirrups, again taking precautions to prevent stretching the hamstring or causing pressure on the legs.

**FIGURE 29.1** Positioning of the patient requires the perineum to be parallel to the floor. The sacrum supports the patient's weight, and the legs are positioned with no traction on the hamstrings. No shoulder braces are indicated.

Prior to putting the patient in position, the legs are wrapped with ACE bandages.

Five instruments are significant in assisting the surgeon for this operation. These include the Lowsley curved tractor, the Young straight prostatic tractor, a Halogen head lamp, a harmonic scalpel, and an Omni-Tract miniwishbone retractor system. The curved Lowsley tractor is used to bring the prostate up into the perineum to allow dissection against the prostate while mobilizing the rectum from the prostate. The straight Young tractor is used to manipulate the prostate laterally as well as cephalad and caudad after the membranous urethra has been divided. The Halogen head lamp is important because it allows the surgeon to aim a strong light into the operative field, which may be too deep and narrow for standard operating lights to adequately illuminate the structures. The harmonic scalpel allows coagulation and closure of vessels without transmission of electrical current, thereby reducing the risks to the neurovascular bundles. The Omni-Tract miniwishbone allows virtually unlimited retraction in any direction. We have developed a posterior weighted speculum that is compatible with the Omni-Tract (Fig. 29.2).

It should be noted that in manipulating the prostate within the pelvis, the pelvis should be viewed as a cone with the apex of the cone being the incision (Fig. 29.3). To achieve better visualization, it is sometimes necessary to actually push the

**FIGURE 29.2** Posterior weighted speculum can be articulated to adapt to each patient's anatomy.

**FIGURE 29.3** The bony pelvis is a cone with the apex at the incision. Better visualization can be obtained in many cases by actually pushing the prostate deeper into the pelvis.

prostate further into the pelvis. Also note that traction is not placed directly on the bulb or membranous urethra, as this will decrease the likelihood of restoration of potency and potentially affect the patient's continence postoperatively.

The incision is made from the ischial tuberosity crossing the midline at the juncture between the squamous epithelium and the mucocutaneous border of the rectum (Fig. 29.4). The incision extends posteriorly to a line equal to the posterior portion of the anus. Using sharp dissection and electrocautery, the ischiorectal fossae are entered, and using blunt dissection the central perineal tendon is identified and transected with electrocautery. At this point, we employ the Belt approach, dissecting down to the white fascia of the rectum and proceeding subsphincterically (Fig. 29.5). A transsphincteric or supra-sphincteric approach is also an option. Using predominantly blunt dissection with an index finger in the rectum, the rectal sphincter and levator ani can be dissected free of the rectum with minimal bleeding (Fig. 29.6). The blades from the mini-wishbone retractor are then used to retract these muscles anteriorly and laterally. With tension on these muscles and tension on the rectum, the rectourethralis is identified and divided, allowing the surgeon to dissect the rectum free of the apex of the prostate (Fig. 29.7).

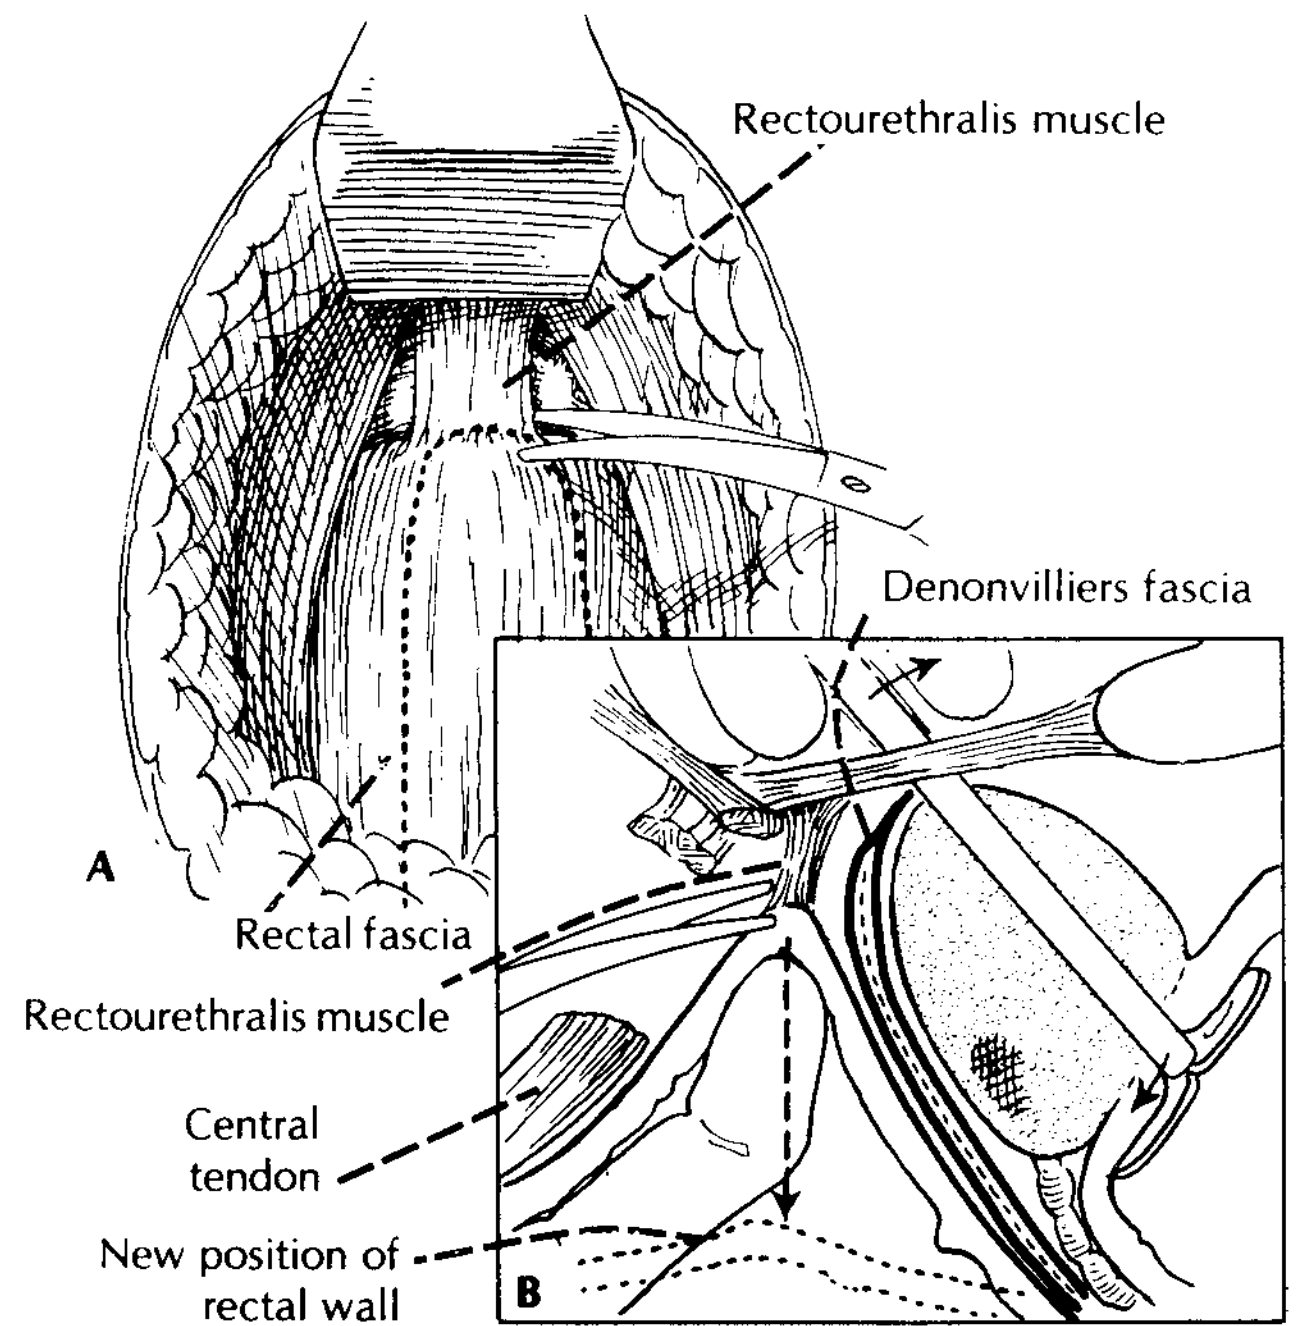

In patients who are undergoing nerve-sparing surgery, the dissection is carried down to approximately 1.5 to 2.0 cm from the apex, at which point the external layer of the Denonvilliers fascia is divided and dissection is carried between the two layers of the Denonvilliers fascia (Fig. 29.8). Care is taken not to

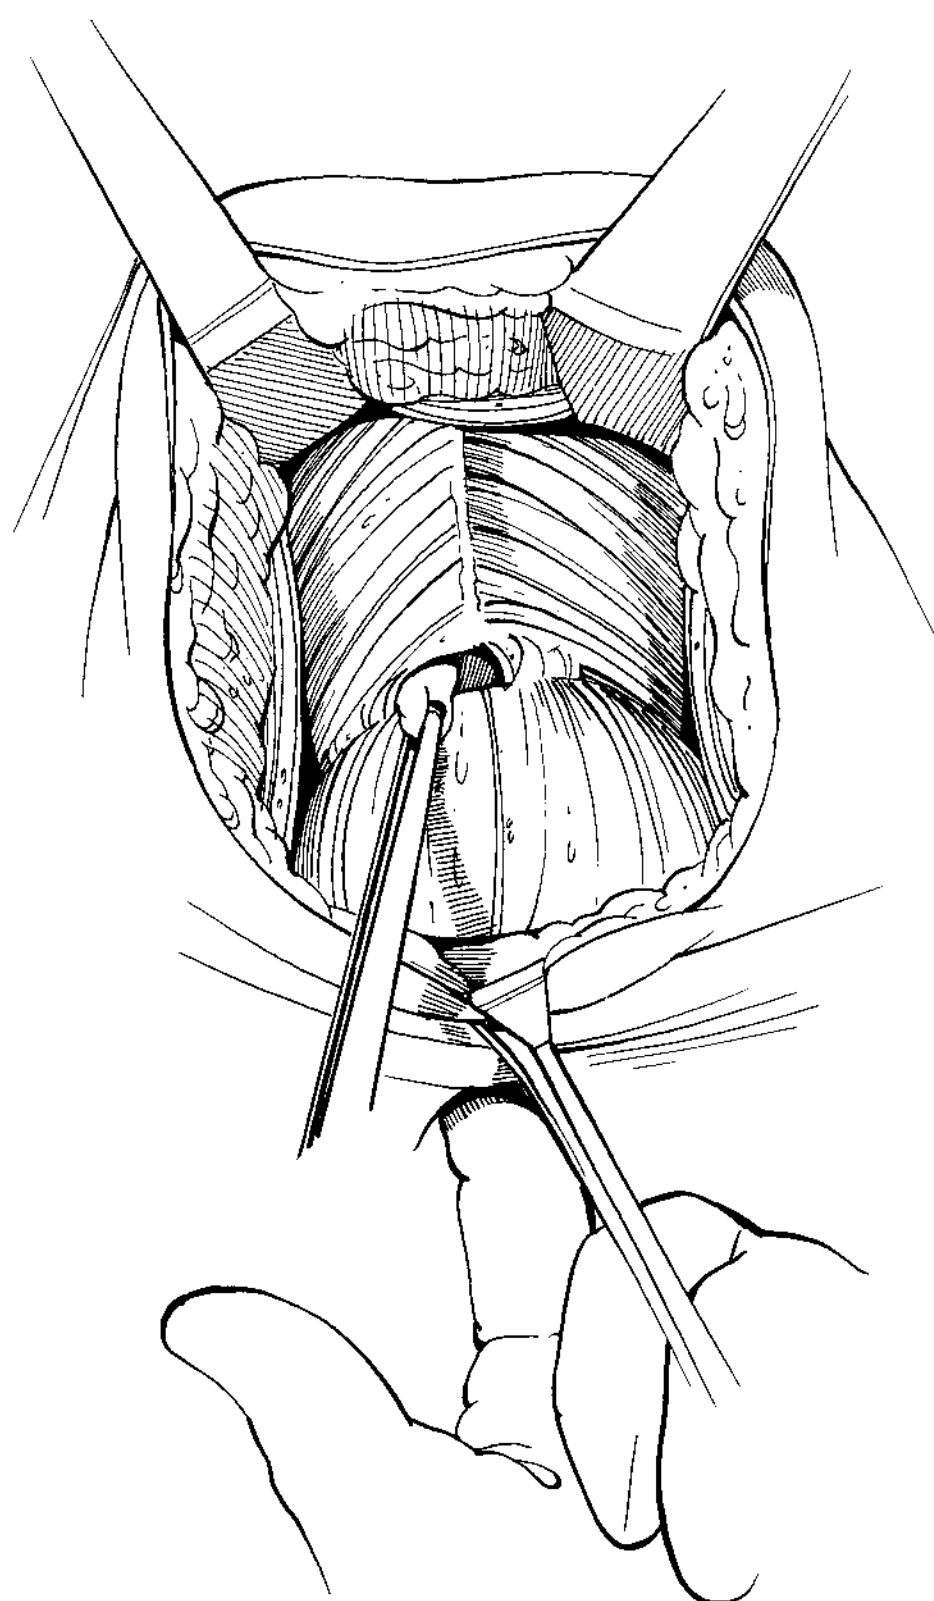

**FIGURE 29.4** An inverted U-shaped incision is made in the perineum extending from ischial tuberosity to ischial tuberosity.

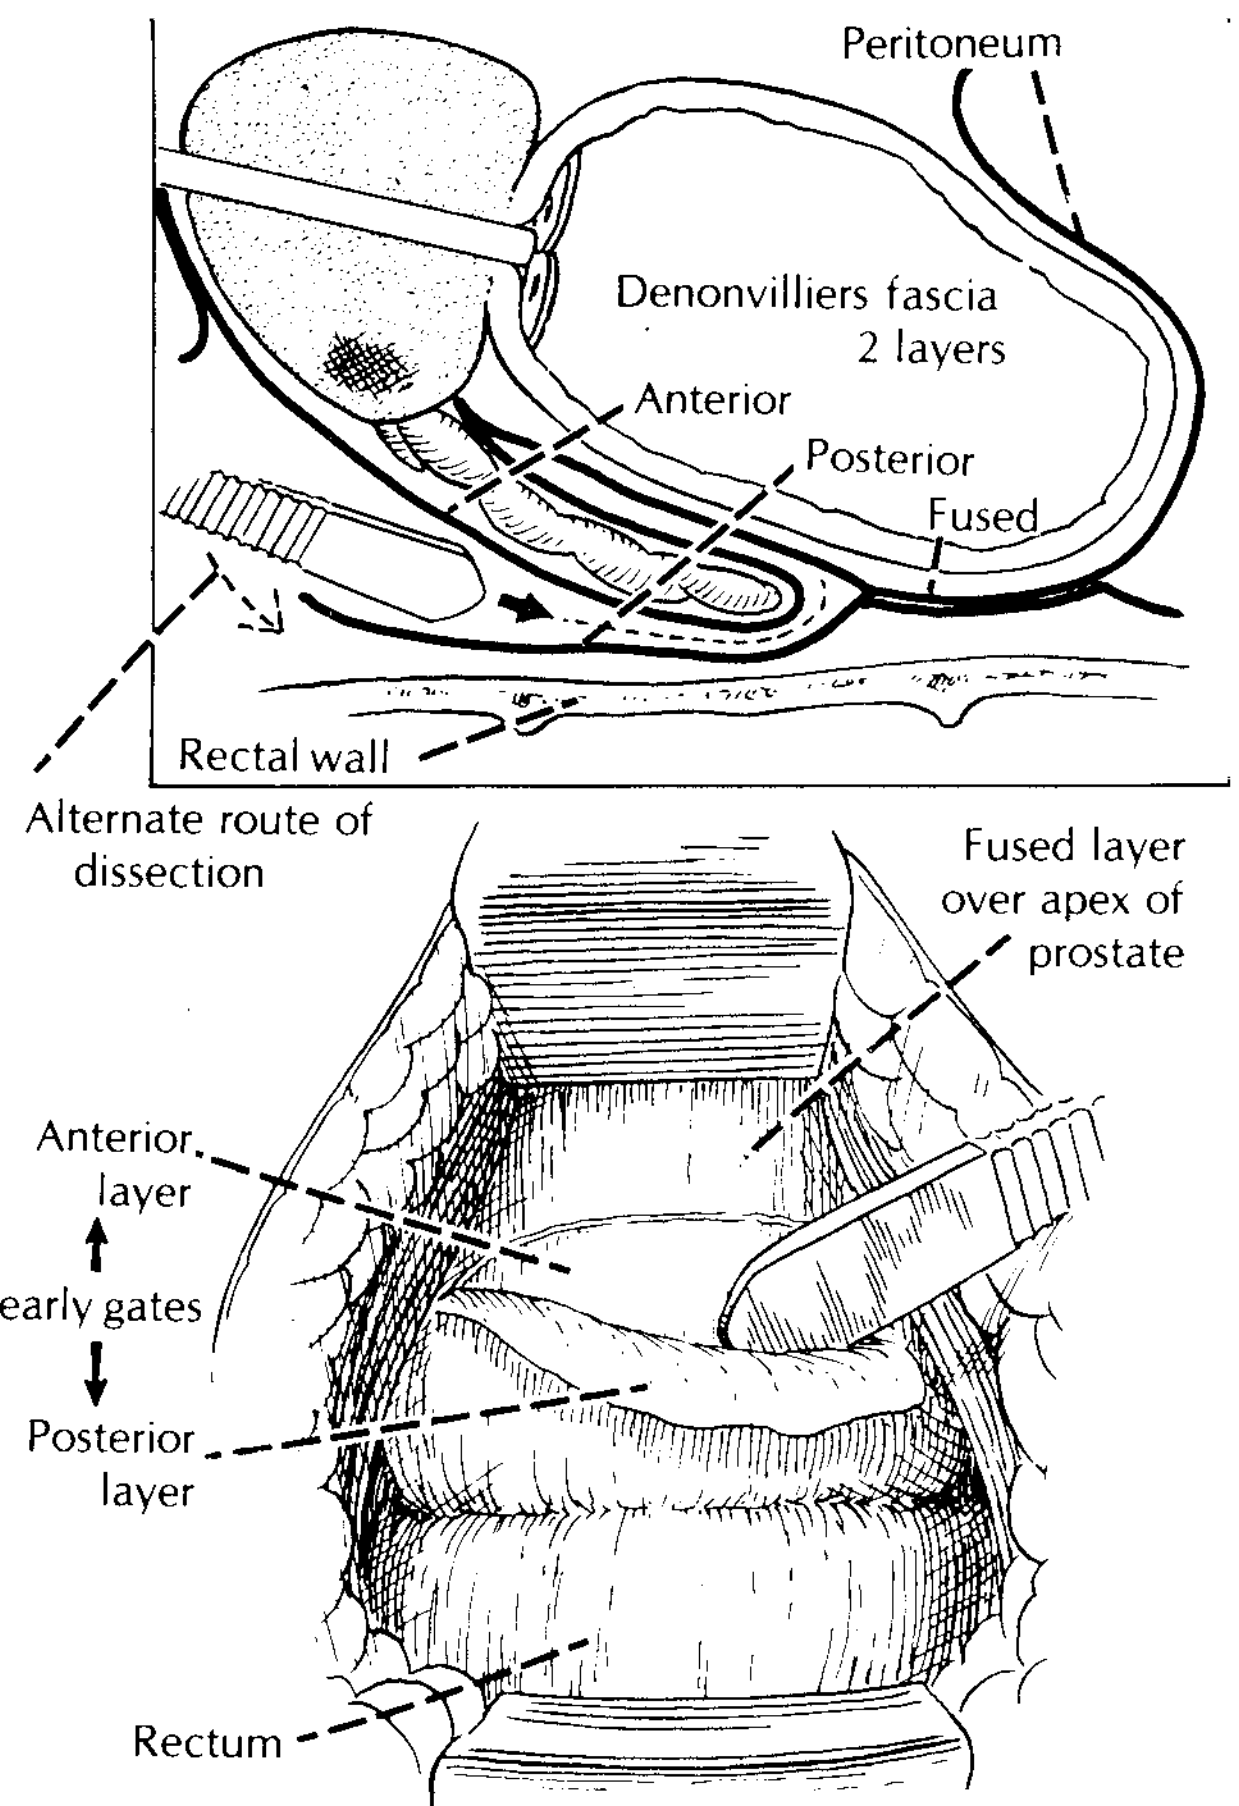

**FIGURE 29.5** The dissection is carried along the rectal fascia, sparing the anal sphincter.

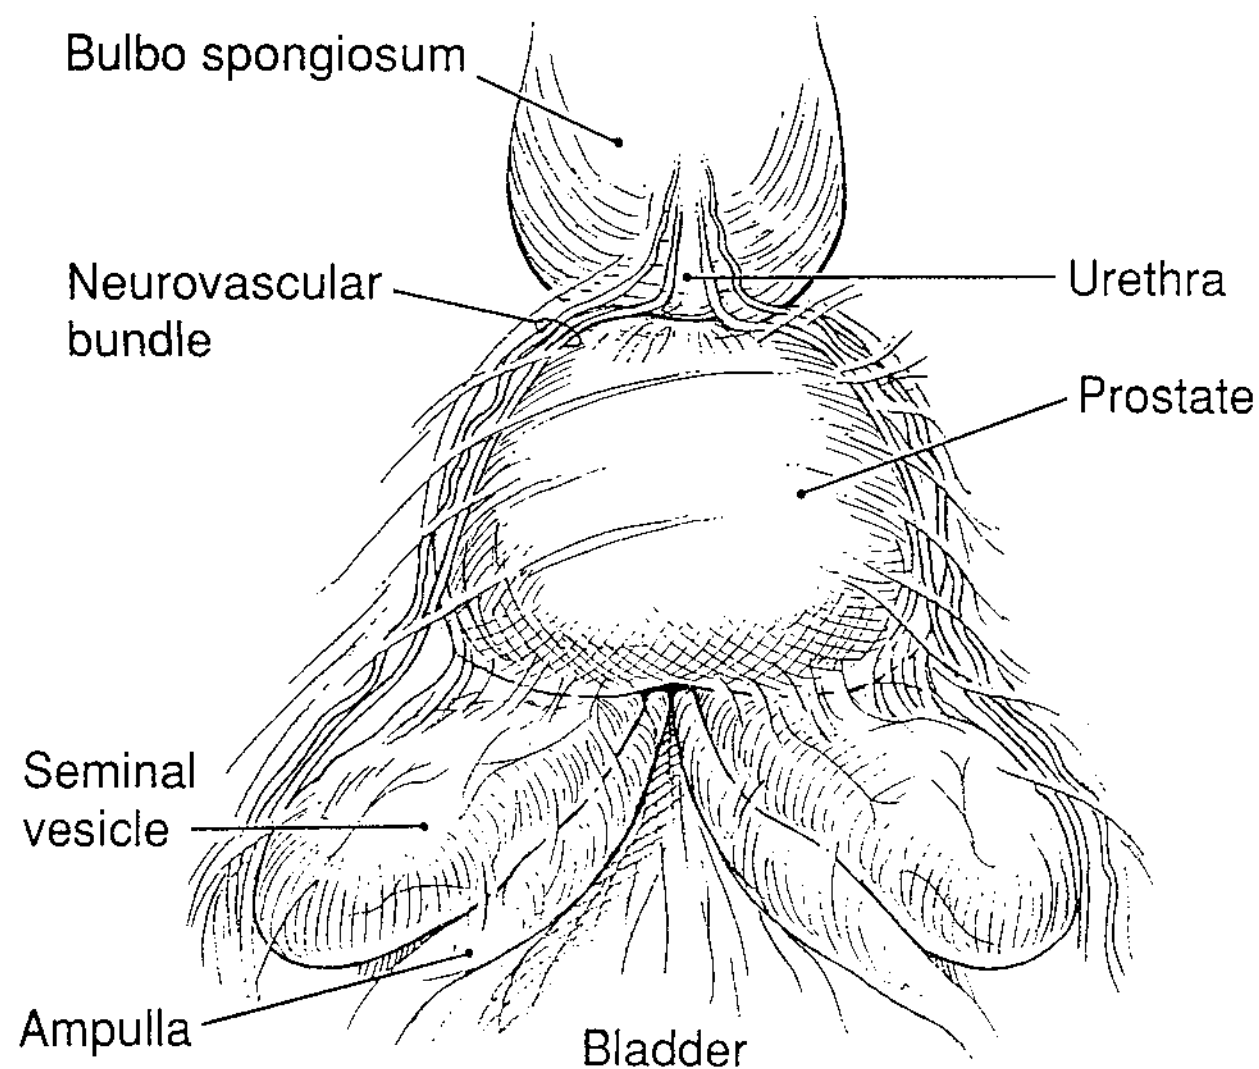

**FIGURE 29.7** Dissection of the rectum from the prostate after division of the rectourethralis is facilitated with the surgeon's finger in the rectum.

**FIGURE 29.6** The Levator ani and the anal sphincter are retracted to expose the rectourethralis.

**FIGURE 29.8** An incision into the posterior layer of the Denonvilliers fascia allows the dissection to continue between the two layers. For a nerve-sparing technique, this incision is made transversely 1 to 2 cm proximal to the apex of the prostate, avoiding carrying the incision into the neurovascular bundles.

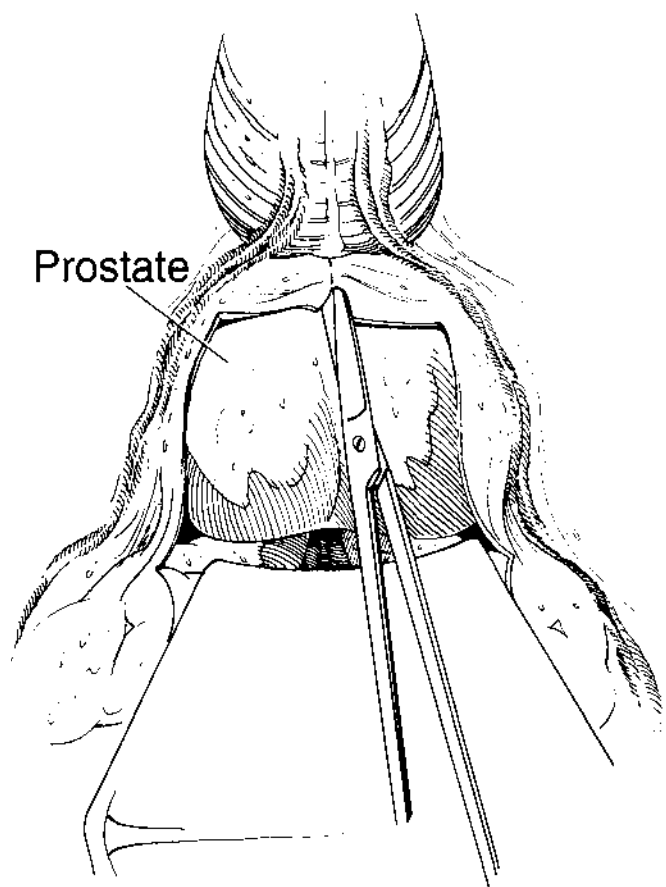

**FIGURE 29.9** Anatomic view of the neurovascular bundles from the posterior view of the prostate. The vessels course along the lateral and posterior prostate and cross the apex to enter the urogenital diaphragm posterior to the membranous urethra.

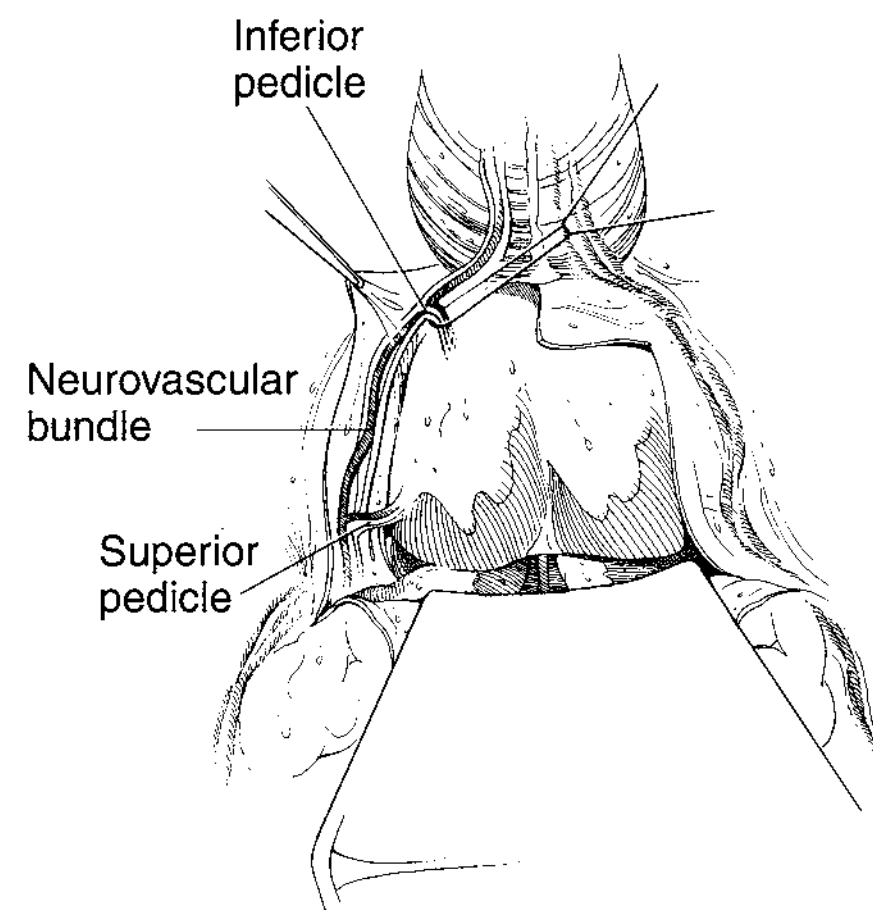

damage the neurovascular bundles that course along the lateral posterior prostate on either side (Fig. 29.9).

The distal portion of the Denonvilliers fascia is then incised in the midline with scissors, and the tag is used to facilitate dissection of the neurovascular bundle from the prostate (Fig. 29.10); the inferior pedicle, if present, is then ligated and divided (Fig. 29.11). If the dissection is in any way impaired by fibrosis such that there is a potential for prostatic tissue to be left behind, the neurovascular bundle is sacrificed on that side.

It should be noted during this dissection that the neurovascular bundle actually courses across the posterior surface of the prostate at the apex and enters the urogenital diaphragm just posterior to the membranous urethra. This proximity is important in that the vesicourethral anastomosis may incorporate the neurovascular bundle if the surgeon is not precise with the placement of sutures in the posterior urethra. The retraction of the neurovascular bundle on either side thereby exposes the proximal membranous urethra.

**FIGURE 29.10** Incision of the distal posterior layer of the Denonvilliers fascia in the midline. This is best done *without* electrocautery if a nerve-sparing technique is planned.

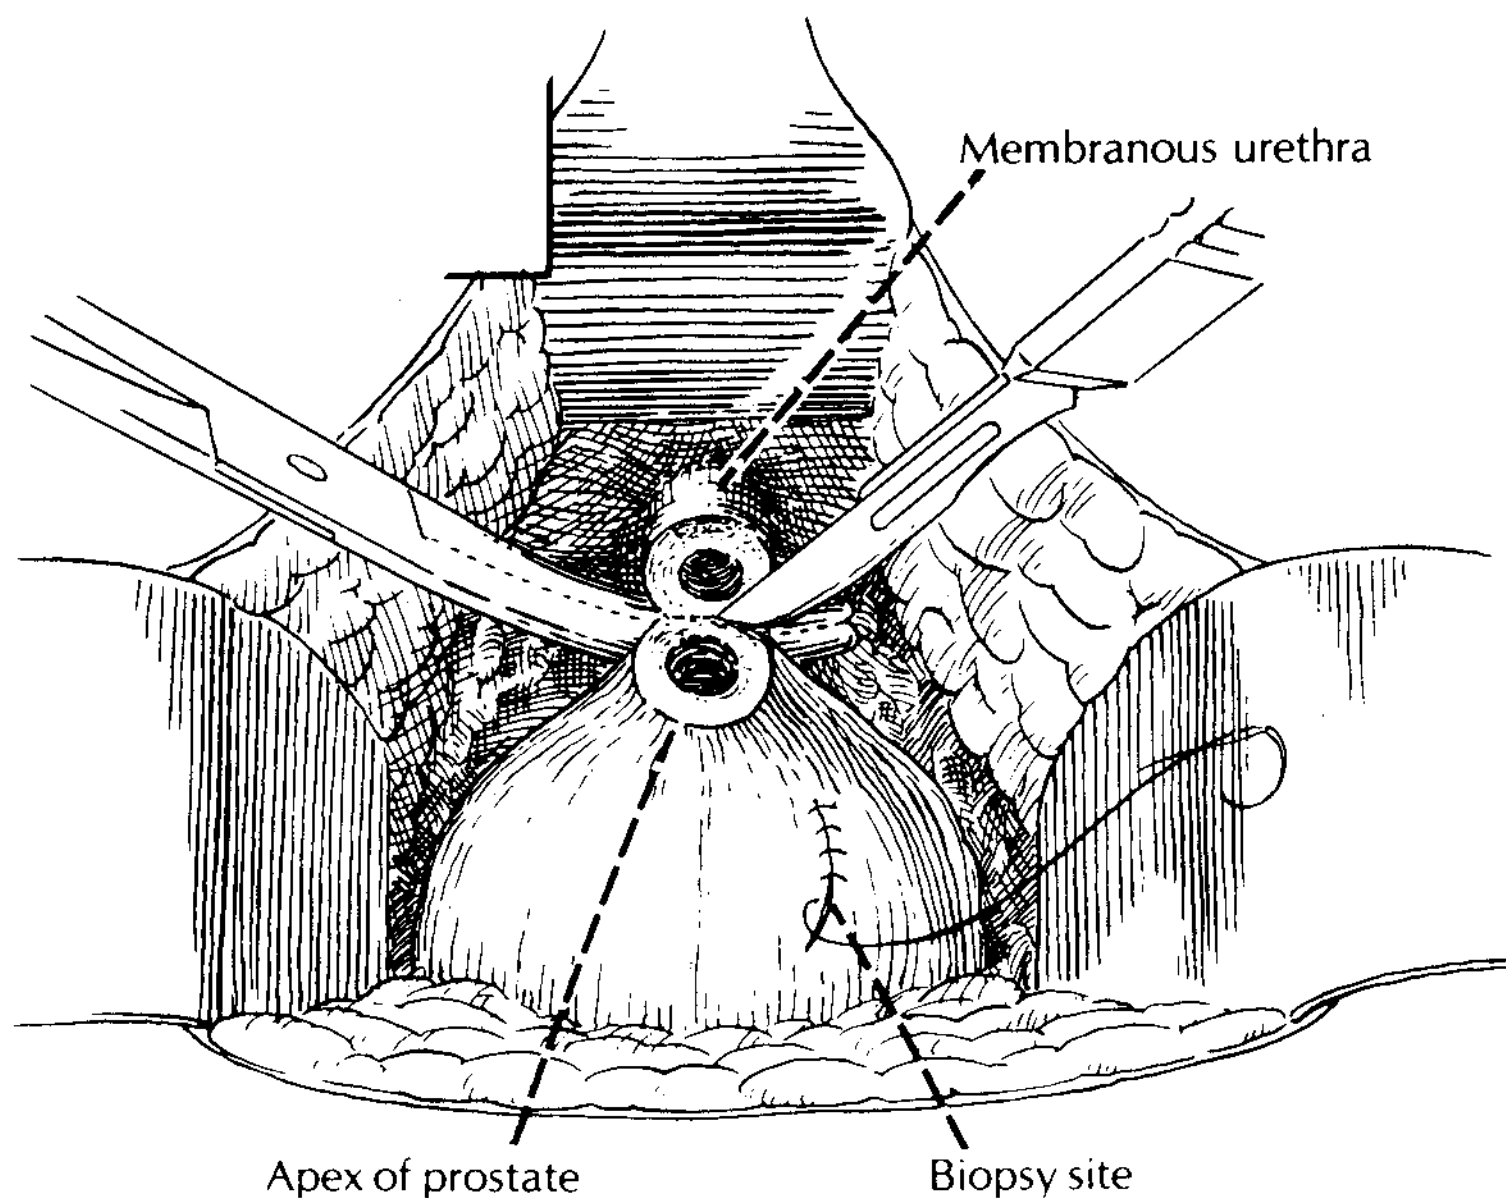

**FIGURE 29.11** Using the wings of the distal posterior layer of the Denonvilliers fascia to aid in dissection, the inferior branch from the neurovascular is isolated and divided.

A right-angled clamp is placed around the membranous urethra and generally meets little resistance if one stays posterior to the endopelvic fascia (Fig. 29.12). The Lowsley tractor is removed and the membranous urethra divided. The Young tractor is then placed into the bladder through the prostatic urethra, and the endopelvic fascia is divided with the harmonic scalpel.

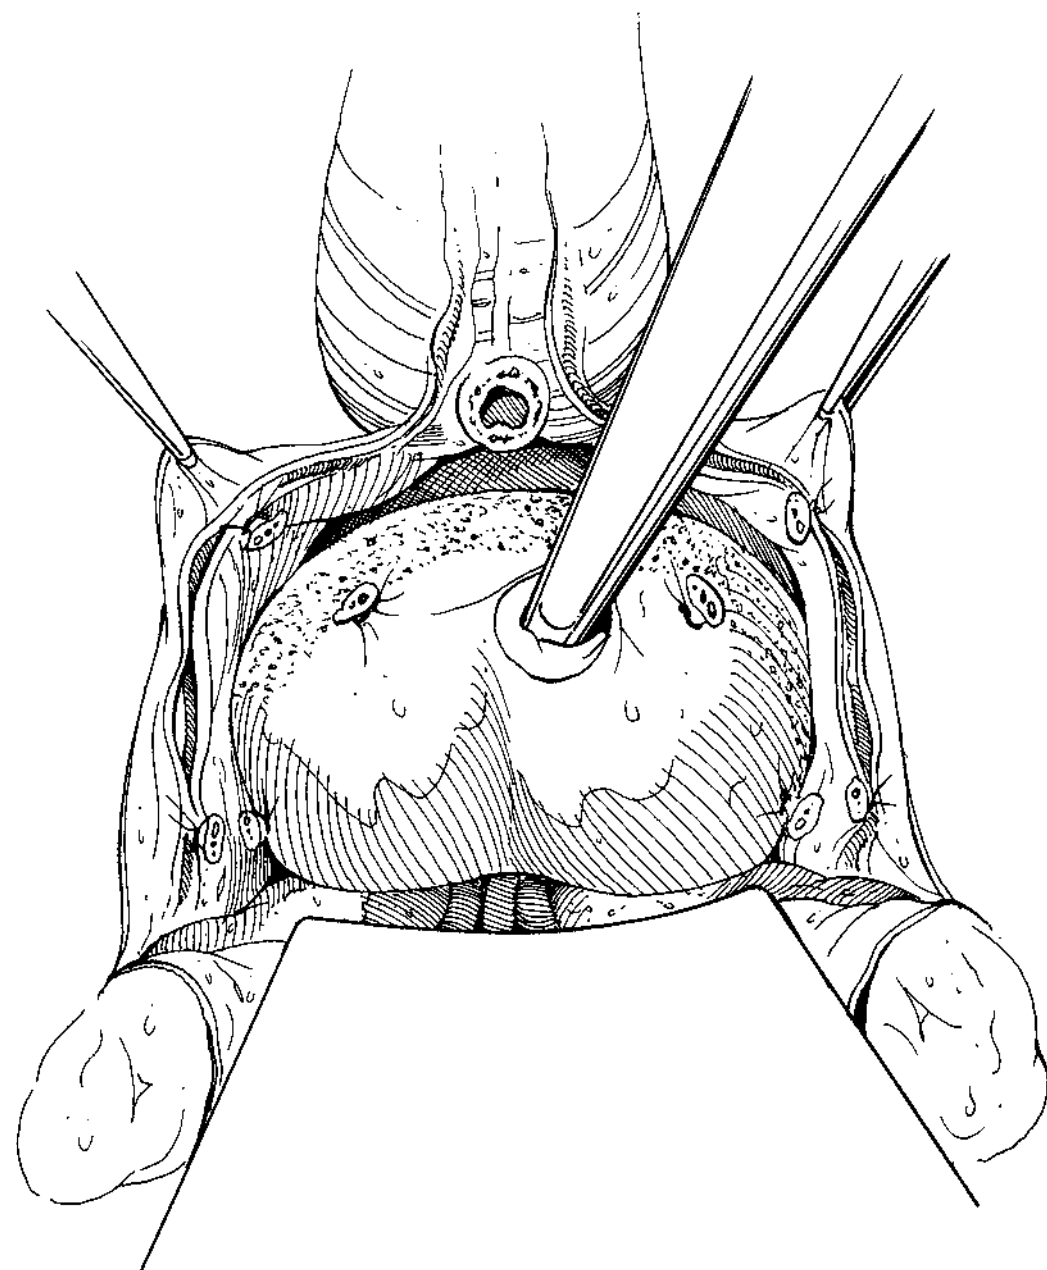

The anterior prostate is dissected free of the bladder. It should be noted that there are generally two small arteries that enter the prostate along the anterior bladder at 10 and 2 o'clock positions that should be cauterized and divided. The groove between the prostate and bladder is identified, and the prostate and bladder can be separated with either sharp or blunt dissection. If the plane between the prostate and bladder is not easily developed, the dissection should be performed sharply and biopsies taken of the bladder neck to ensure that there is no invasion of the bladder neck by the cancer. In patients who have had prior transurethral resections of the prostate, palpation of the blades of the Young tractor can be used to identify the bladder neck.

In most cases, there is insignificant bleeding from the dorsal venous complex in the endopelvic fascia. However, if there should be communicating veins, they may be suture-ligated using 3-0 Vicryl. The prostate is dissected from the bladder anteriorly to posteriorly to the 5 and 7 o'clock positions, respectively, on the patient's left and right, and the bladder neck is divided over the Young tractor and the Young tractor removed; a stay suture may be inserted in the bladder neck at this point (Fig. 29.13). The bladder is evacuated of any urine, and the posterior bladder neck is divided with the harmonic scalpel. The prostate is then dissected free from the posterior bladder. A plane is entered after dividing the posterior bladder neck, which is anterior to the seminal vesicles and the ampulla of the vas but posterior to the bladder. The superior pedicles lie in the lateral aspect of this plane and can be divided at this point.

Attention is then directed to the posterior surface of the prostate. The rectum is swept free of the neurovascular bundles, which also allows identification of the superior pedicles of the prostate as well as the seminal structures. The superior pedicles can be divided with the harmonic scalpel at this point,

**FIGURE 29.12** Division of the membranous urethra at the apex of the prostate.

**FIGURE 29.13** A Young prostatic tractor is used to manipulate the prostate and to identify the vesical neck.

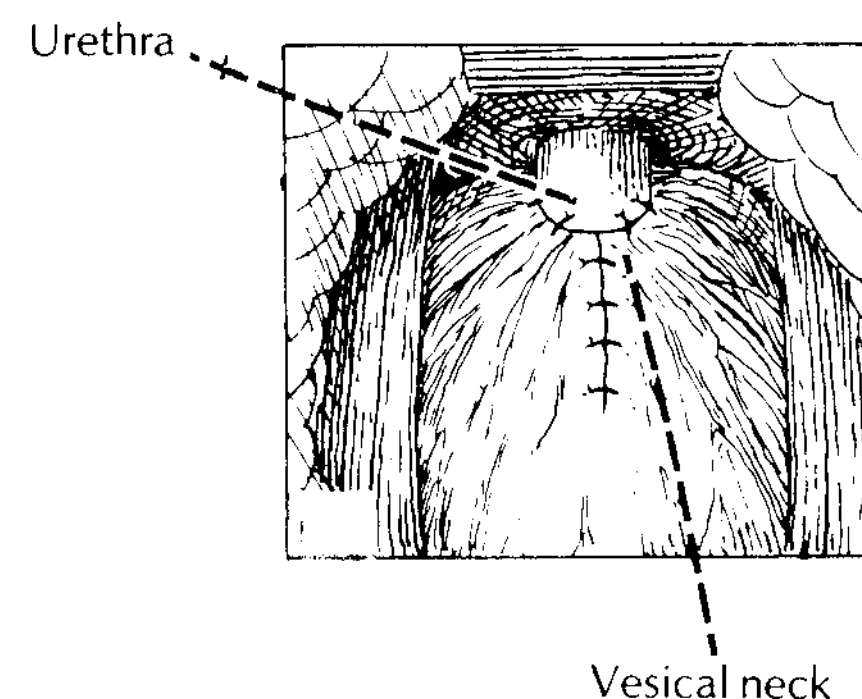

if not done earlier. The seminal vesicles are dissected to their tips with blunt dissection, and the artery from the seminal vesical is divided by the harmonic scalpel. The vasa deferens are likewise divided with the harmonic scalpel. Any remaining fibrolymphatic tissue is then divided, allowing removal of the prostate.

After ensuring complete hemostasis, the bladder neck is reconstructed using 3-0 Vicryl on an SH needle beginning posteriorly to anteriorly (Fig. 29.14). This direction of the closure, beginning in the posterior bladder, is done to facilitate the closure without injury to the ureters and also to take advantage of the anatomic relationship between the bladder neck and the membranous urethra with a shorter distance being anteriorly.

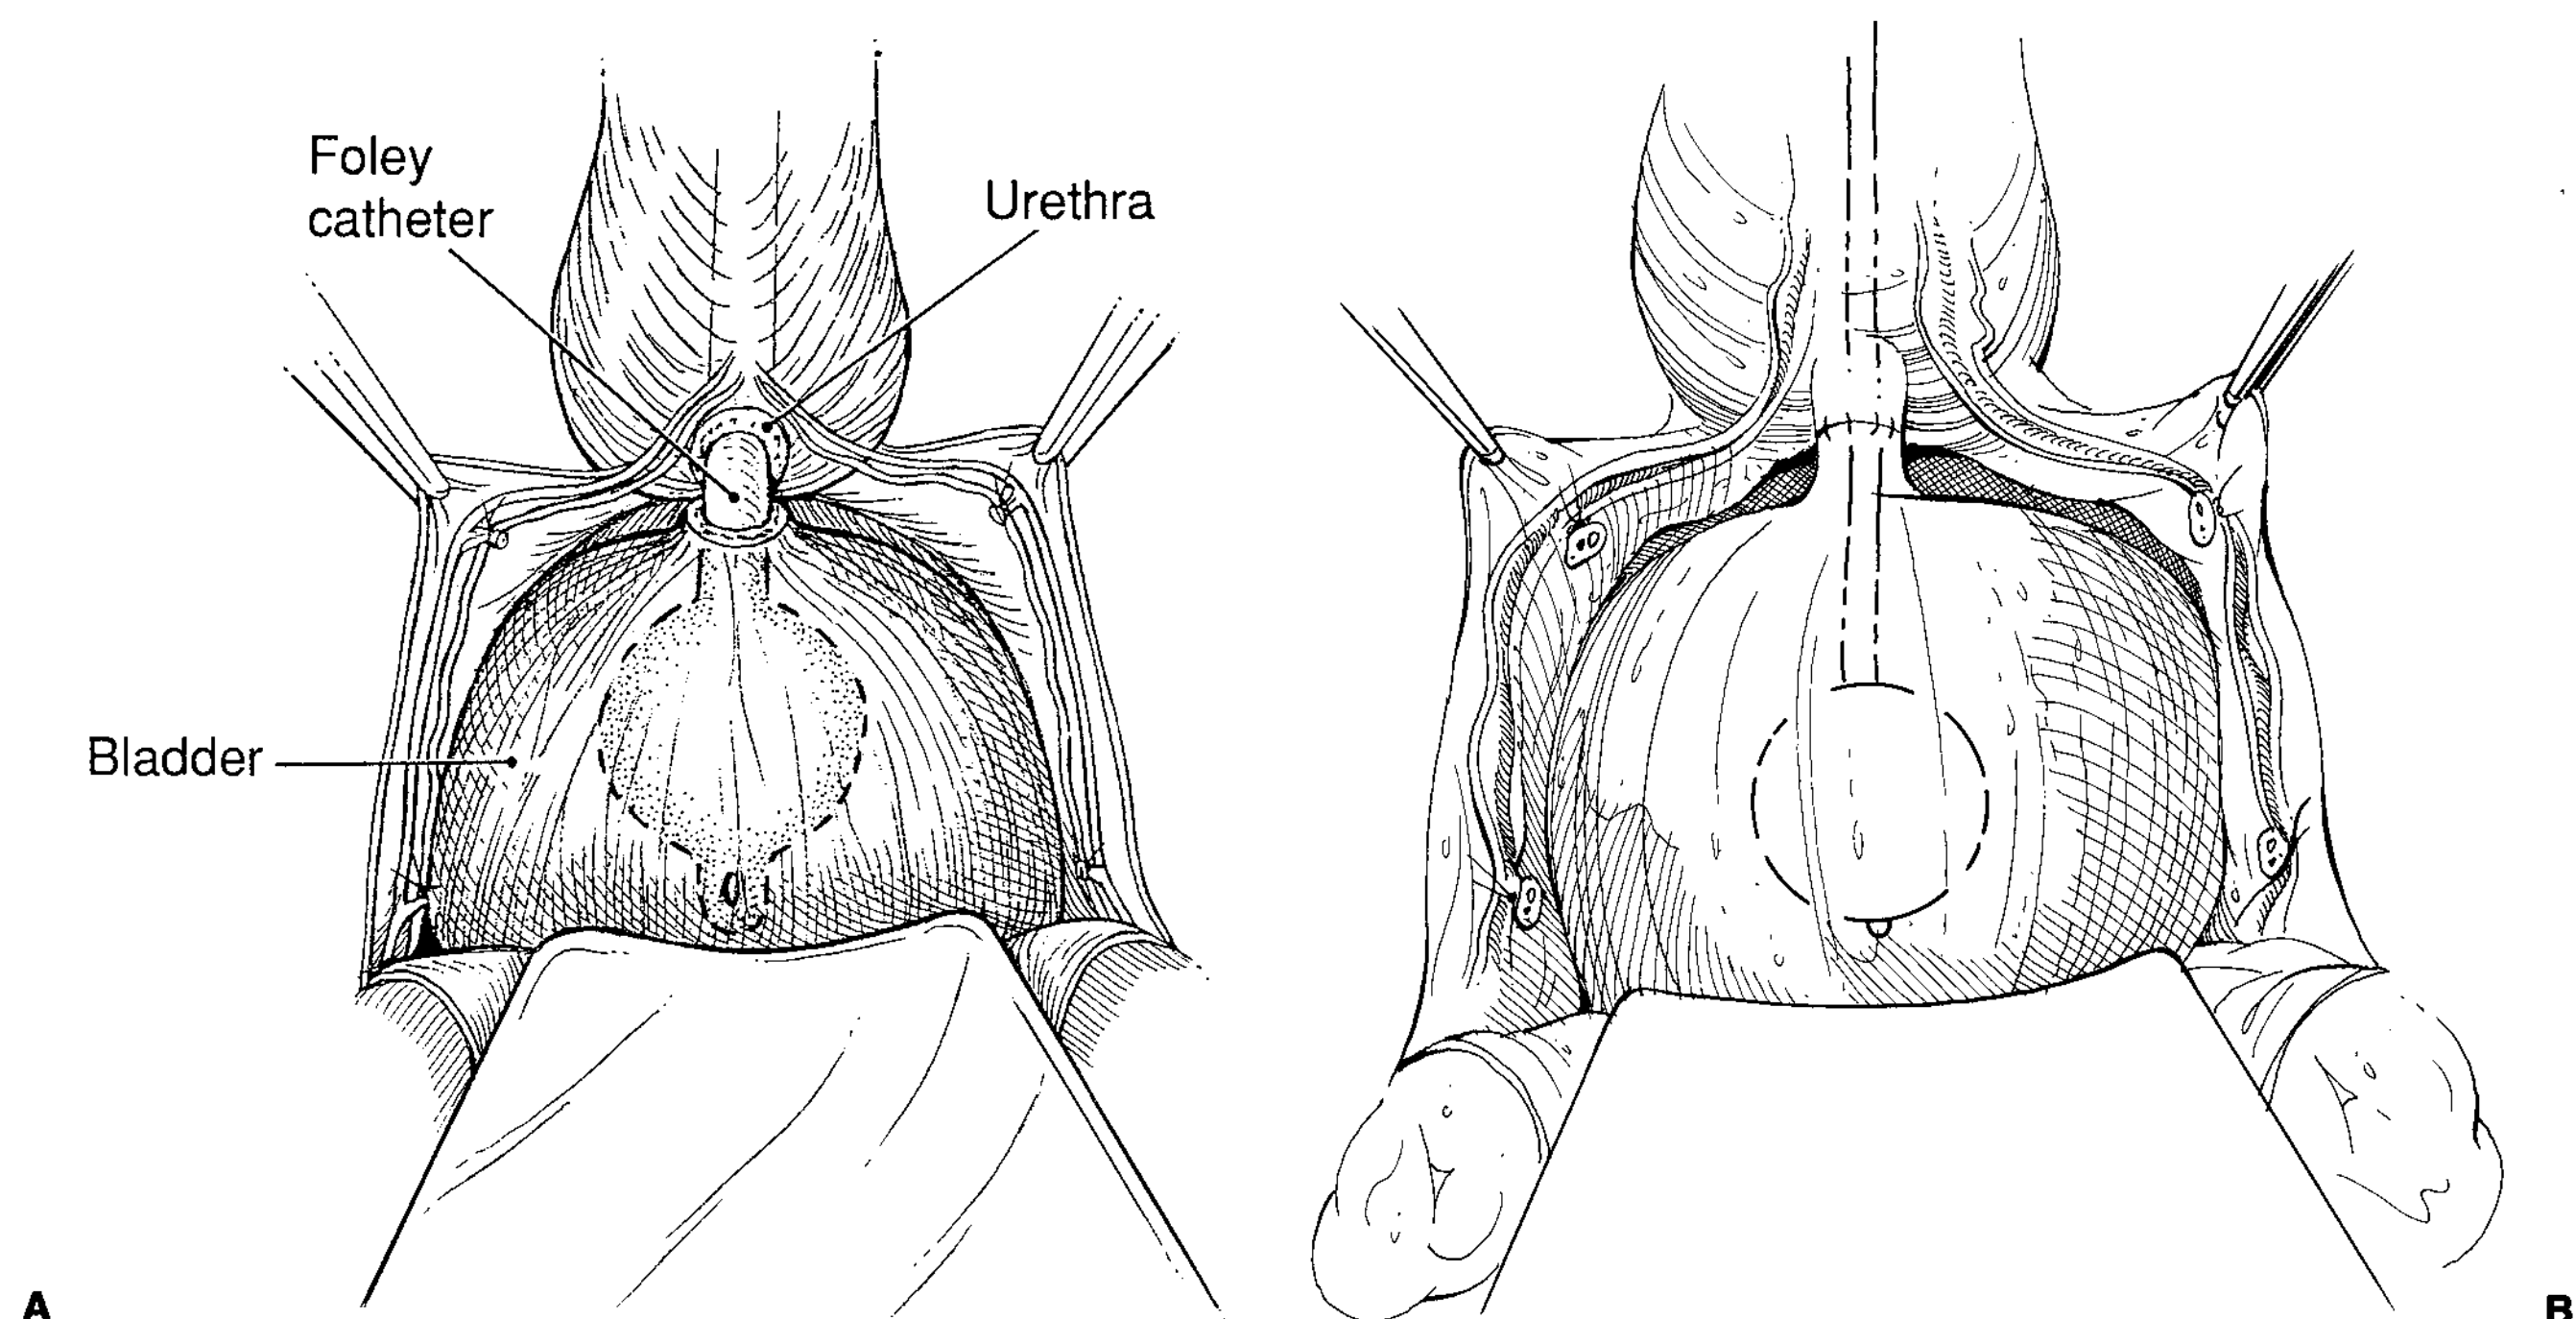

The anastomosis is performed using 3-0 Vicryl simple sutures and an RB-1 controlled-release needle (Fig. 29.15). The anastomosis is performed around a 22Fr, 5-cc Foley catheter, and generally seven to eight sutures are used. Care should be taken that small portions of the membranous urethra are incorporated in the anastomosis such that the continence mechanism is left undisturbed as well as the neurovascular bundles, which contribute to potency.

The rectum is then inspected, a Foley balloon inflated, and a Penrose drain placed through the left ischiorectal fossa and a separate stab incision. The incision is closed with a 3-0 chromic gut closure. One suture is placed to reapproximate the central tendon, and the remainder of the sutures are used to close the skin in a horizontal mattress (Fig. 29.16).

Postoperatively, patients have a very low requirement for pain medication. Most patients either do not require parental pain medication or are off the parental medications within 12 to 24 hours. Average time to discharge is approximately 24 hours from the time of surgery (Table 29.1). The patient's catheter is removed on day 12. The Penrose drain is removed prior to discharge. One of the authors, Tom Keane, discharges patients and removes the catheter on day 7 (6).

**FIGURE 29.14** Reconstruction of the posterior bladder neck is carried from posterior to anterior, leaving an opening of approximately 22Fr.

**FIGURE 29.15** Anastomosis of the urethra to the bladder is performed over a 22Fr Foley catheter.

**FIGURE 29.16** Closure of the incision.

---

## OUTCOMES

---

### Complications

---

Perioperative complications include hemorrhage, wound infection, cardiovascular complications, and rectal injury. The instance of rectal injury is  $<1\%$  with current techniques and antibiotics, preoperative bowel preparation (two Fleet enemas, the night before and morning of surgery), or GoLytely and antibiotics. The rectal injury is closed primarily in two layers without the need to perform a diverting colostomy. Wound infection rates are  $<1\%$ , and cardiovascular complications are approximately 1% to 2%. The average blood loss in these patients is approximately 300 to 400 cc, and our transfusion rate is  $<1\%$ .

Long-term complications include incontinence and impotence. Incontinence requiring intervention such as pads, clamps, or inflatable devices occurs in 2.8% of patients. We have found that incontinence generally occurs in patients

who are older, obese, and have had prior radiation therapy. Potency following nerve-sparing perineal prostatectomy is dependent upon the patient's age and preoperative status. Patients under the age of 60 who are fully potent and have both neurovascular bundles spared have approximately a 50% to 60% potency rate. Patients who are over the age of 60 have a reduced rate of potency, and we have not yet had a patient over the age of 70 who has spontaneously regained his potency. Patients who are having difficulties with potency prior to surgery and patients in whom the neurovascular bundles could not be spared will likely be impotent. We generally advocate early use of pharmacotherapy or other means of assistance in these patients.

---

## Results

---

Following radical prostatectomy, recurrence can be measured using PSA, which is exquisitely sensitive. Any patient who undergoes a radical prostatectomy can expect his PSA to fall

below detectable levels. Failure to do so generally means that the patient has significant residual disease, either locally or distantly. Another group of patients will have an initial drop of their PSA to undetectable levels and then a return to measurable levels. These patients may have local and/or distant recurrence of their disease, or possibly residual malignancy. Patients who develop recurrence based upon PSA will generally manifest a clinical progression within 18 months. Additionally, if the PSA is going to rise, it will do so within 2 years in 90% of patients and within 4 years in virtually

every patient. Based upon PSA, we can now predict disease recurrence earlier, allowing assessment of the outcome of radical prostatectomy within 5 years as opposed to the older data, which required a 7- to 10-year follow-up (3).

Using a clinical care pathway, we have seen better pain control, earlier ambulation, quicker short-term recovery, and earlier discharge than in patients undergoing radical retropubic prostatectomy in the same institution. This has been confirmed in other studies and will lead to a lower cost of care (2,7).

# CHAPTER 30 ■ BRACHYTHERAPY FOR LOCALIZED PROSTATE CANCER

JOHN A. FORTNEY, A. JASON ZAULS, AND DAVID T. MARSHALL

The term *brachytherapy* describes the process of placing a radioactive source directly inside or in close proximity to the intended target. The use of brachytherapy in prostate cancer was first reported by Pasteau in 1913 (1), and various techniques have been explored since. Retropubic implantation of radioactive sources was used initially until the introduction of the transrectal ultrasound probe (TRUS) in the early 1980s (2). With significant advancements in ultrasound technology, ultrasound-guided transperineal prostate brachytherapy is now the accepted technique used for prostate brachytherapy and has experienced substantial growth over the last 15 years.

Brachytherapy offers several advantages over radical prostatectomy, including patient convenience, no surgical incision, decreased anesthesia requirement, minimal blood loss, rapid recovery, and less risk of incontinence. Brachytherapy also offers advantages over external beam radiation therapy (EBRT). Proper brachytherapy technique can lead to decreased radiation dose to surrounding structures, thereby limiting normal tissue morbidity. Evidence continues to accumulate stressing the importance of dose escalation in prostate cancer. In order to deliver an acceptable dose via EBRT, patients must undergo several weeks of treatment, whereas brachytherapy can be completed in one outpatient procedure. Finally, the position of the prostate and surrounding critical organs may be difficult to reproduce daily during a protracted course of treatment, which may lead to an increased dose to normal tissues or a decreased dose to the prostate.

Three isotopes ( $^{125}\text{I}$ ,  $^{103}\text{Pd}$ , and  $^{131}\text{Cs}$ ) are now available for low-dose-rate (LDR) brachytherapy. The majority of the radiation dose is delivered over 2 to 10 months, depending on which isotope is used. The timing and severity of acute side effects have been described regarding the different sources; however, no convincing evidence is available to recommend one source over another. High-dose-rate (HDR) brachytherapy has been increasingly utilized as well. Catheters are placed within the prostate as described below for LDR needles, and a dosimetric plan is developed with CT imaging and computer planning. An iridium-192 source can then be moved in and out of each catheter remotely via a robotic device. The time the radioactive source spends in each catheter and at each dwell position within each catheter can be manipulated via computer control to achieve a conformal radiotherapy plan. HDR brachytherapy typically requires a short hospital stay and two to ten treatments over a 2- to 5-day period.

## DIAGNOSIS

The diagnosis and risk-stratification of prostate cancer is via 12 to 16 core prostate biopsies following an elevated PSA or abnormal digital rectal exam. Patients with high risk of seminal vesicle involvement, such as those with clinical stage  $>T2a$  or perineural invasion seen on prostate biopsy, should undergo TRUS-guided biopsy of the seminal vesicles. Pelvic lymphadenectomy is not commonly performed for patients with low-risk disease. Patients with high risk of lymph node involvement (patients with seminal vesicle involvement, Gleason score  $>7$ , PSA  $>20$ ) may benefit from laparoscopic pelvic lymph node dissection as nodal involvement changes treatment recommendations.

## INDICATIONS FOR SURGERY

When considering brachytherapy as monotherapy for prostate cancer, it is critical to carefully select patients with low-risk disease. A number of tools have been developed to aid the physician when making this selection, including the Partin tables (3) and the Roach formulas (4,5). These tools can help estimate the risk of extraprostatic extension, seminal vesicle invasion, and pelvic lymph node involvement. Recommendations have been made regarding classification of patients into low-, intermediate-, and high-risk categories as illustrated in Table 30.1. Low-risk prostate cancer can be summarized as PSA  $<10$ , Gleason score  $<7$ , and clinical stage  $<T2b$ . Other risk factors, such as PSA velocity, PSA doubling time, presence of perineural invasion or lymphovascular space invasion, and

TABLE 30.1

### PATIENT SELECTION FACTORS

	Monotherapy (Low Risk)	Combination Therapy (Intermediate to High Risk)
Nodule	None or small	Large or multiple
Gleason score	2–6	7–10
PSA <sup>a</sup>	$<10$ ng/mL	$\geq 10$ ng/mL
Clinical stage	$<T2b$	$\geq T2b$

<sup>a</sup>PSA, prostate-specific antigen.

number of cores positive on biopsy, should be considered when stratifying patients and choosing appropriate treatment modalities.

Clinical outcomes for prostate brachytherapy alone in the setting of intermediate- or high-risk disease have been conflicting. Furthermore, there is a growing body of evidence supporting the use of dose-escalated EBRT or combined androgen deprivation therapy and EBRT in this setting. Brachytherapy is often used in this situation in combination with EBRT to augment dose escalation, but it is not generally recommended as monotherapy for intermediate- or high-risk patients.

## ALTERNATIVE THERAPY

Prostate brachytherapy is an ideal treatment for men with localized, low-risk prostate cancer, but alternatives exist and may be more appropriate in certain situations. Men with high International Prostate Symptom Scores (IPSS), large prostate volume, or history of previous transurethral resection of the prostate (TURP) may tolerate EBRT or prostatectomy better than brachytherapy while achieving a similar therapeutic outcome. High IPSS before treatment predicts significant risk of severe lower urinary tract symptoms (LUTS) and acute urinary obstruction following brachytherapy (6). Similarly, large prostates have been shown to be at increased risk for urinary retention (7), although the absolute risk may still be low depending on the technique used (8). Patients with a history of prior TURP may be at increased risk for significant toxicity, including incontinence, if brachytherapy is used (9,10).

## SURGICAL TECHNIQUE

### Selection of Isotope

As noted above, three isotopes ( $^{125}\text{I}$ ,  $^{103}\text{Pd}$ , and  $^{131}\text{Cs}$ ) are currently being used for LDR prostate brachytherapy. Each delivers radiation to a volume of tissue within millimeters of each source; however, they differ in initial activity, dose rate, and half-life, as illustrated in Table 30.2. Some investigators believe  $^{103}\text{Pd}$  may be more effective than  $^{125}\text{I}$  at eradicating more rapidly proliferating tumors due to higher initial activity (20 to 25 cGy per hour and 7 to 10 cGy per hour, respectively). This belief has been propagated by convincing mathematical models and has led to the emergence of  $^{131}\text{Cs}$  (32 cGy per

<sup>b</sup>Rivard MJ, Butler WM, Devlin PM, et al. American Brachytherapy Society recommends no change for prostate permanent implant dose prescriptions using iodine-125 or palladium-103. *Brachytherapy* 2007;6(1):34–37.

<sup>c</sup>Bice WS, Prestidge BR, Kurtzman SM, et al. Recommendations for permanent prostate brachytherapy with (131)Cs: a consensus report from the Cesium Advisory Group. *Brachytherapy* 2008;7(4):290–296.

<sup>d</sup>In addition to 40- to 50-Gy external beam radiation therapy.

hour) as another option. However, no conclusive clinical evidence proving this theory has yet been made available, and one clinical trial has shown equivalence between  $^{125}\text{I}$  and  $^{103}\text{Pd}$  regarding PSA control at 3 years (11). The current recommended doses for the three isotopes in monotherapy and in combination with external beam therapy are shown in Table 30.3. The selection of  $^{103}\text{Pd}$  or  $^{131}\text{Cs}$  may be most appropriate in the setting of combination therapy as EBRT may be initiated sooner in the treatment paradigm after prostate brachytherapy due to earlier resolution of urinary symptoms following brachytherapy.

## Treatment Planning

Prostate brachytherapy has evolved significantly over the years, and two methods now predominate: preplanned implant as popularized by the Seattle Prostate Institute and intraoperative planning as described by Stock and Stone at Mount Sinai School of Medicine (MSSM) in New York.

### Preplanning Approach

With this approach pioneered in Seattle (12), the patient is placed in the dorsal lithotomy position (Figs. 30.1 and 30.2) and an imaging study is performed using transrectal ultrasound 1 to 2 weeks before the implant. This image data set is imported into the brachytherapy planning software and utilized to develop an optimized plan. The number of seeds ordered for the procedure is then determined from this preplan. The patient returns to the operating room (OR) on the day of the operation and is placed in position as he was on the day of planning. It is critically important that the patient is repositioned as accurately as possible. Seeds are then placed within the prostate using needles preloaded with seeds or strands of connected seeds according to the previously developed plan. Seeds may also be placed with a gun-type applicator, such as the Mick applicator (Mick Radio-Nuclear Instruments, Mount Vernon, NY),

**FIGURE 30.1** Schematic of the closed, ultrasound-guided implantation technique.

**FIGURE 30.2** Patient prepared for surgery in the dorsal lithotomy position.

based on the planning study completed earlier. With the pre-planned approach, the Mick applicator allows the practitioner to make minor adjustments to more accurately reproduce the preplanning study.

#### Real-Time Intraoperative Planning Approach

With this approach developed by Stock and Stone at MSSM (13), no preplanning study is acquired; however, the prostate volume is measured via a computerized tomography (CT), magnetic resonance imaging (MRI), or TRUS study (Fig. 30.3) at some point prior to the day of the implant in order to determine how many seeds to order for the procedure. This can be the volume determined at TRUS for biopsy. The patient is then brought to the OR and placed in the dorsal lithotomy position. TRUS (Fig. 30.4) is utilized to localize the bladder, prostate, and anterior rectal wall in three-dimensional space, and these data are recorded in the intraoperative treatment planning software. An initial intraoperative plan (Figs. 30.5

**FIGURE 30.3** CT images obtained to estimate prostate volume to determine activity and number of seeds to order.

and 30.6) is then developed based on a prostate volume-to-activity nomogram developed at MSSM. Needles are placed in the periphery of the prostate at approximately 1-cm intervals (Figs. 30.7 and 30.8). Once the needles are placed, images are reacquired to account for changes in size, shape, and position of the prostate that occurs with the trauma of needle placement. Longitudinal views on the TRUS are used to observe placement of the seeds into the prostate according to the intraoperative plan. Seeds are most often placed using the Mick applicator. Typically 75% of the required activity is placed in the periphery of the gland, while 25% is placed in the interior of the gland. Then needles are placed in the central portion of the gland and the Mick applicator is then used to

**FIGURE 30.4** Transrectal ultrasound probe in ratcheting cradle/stepper.

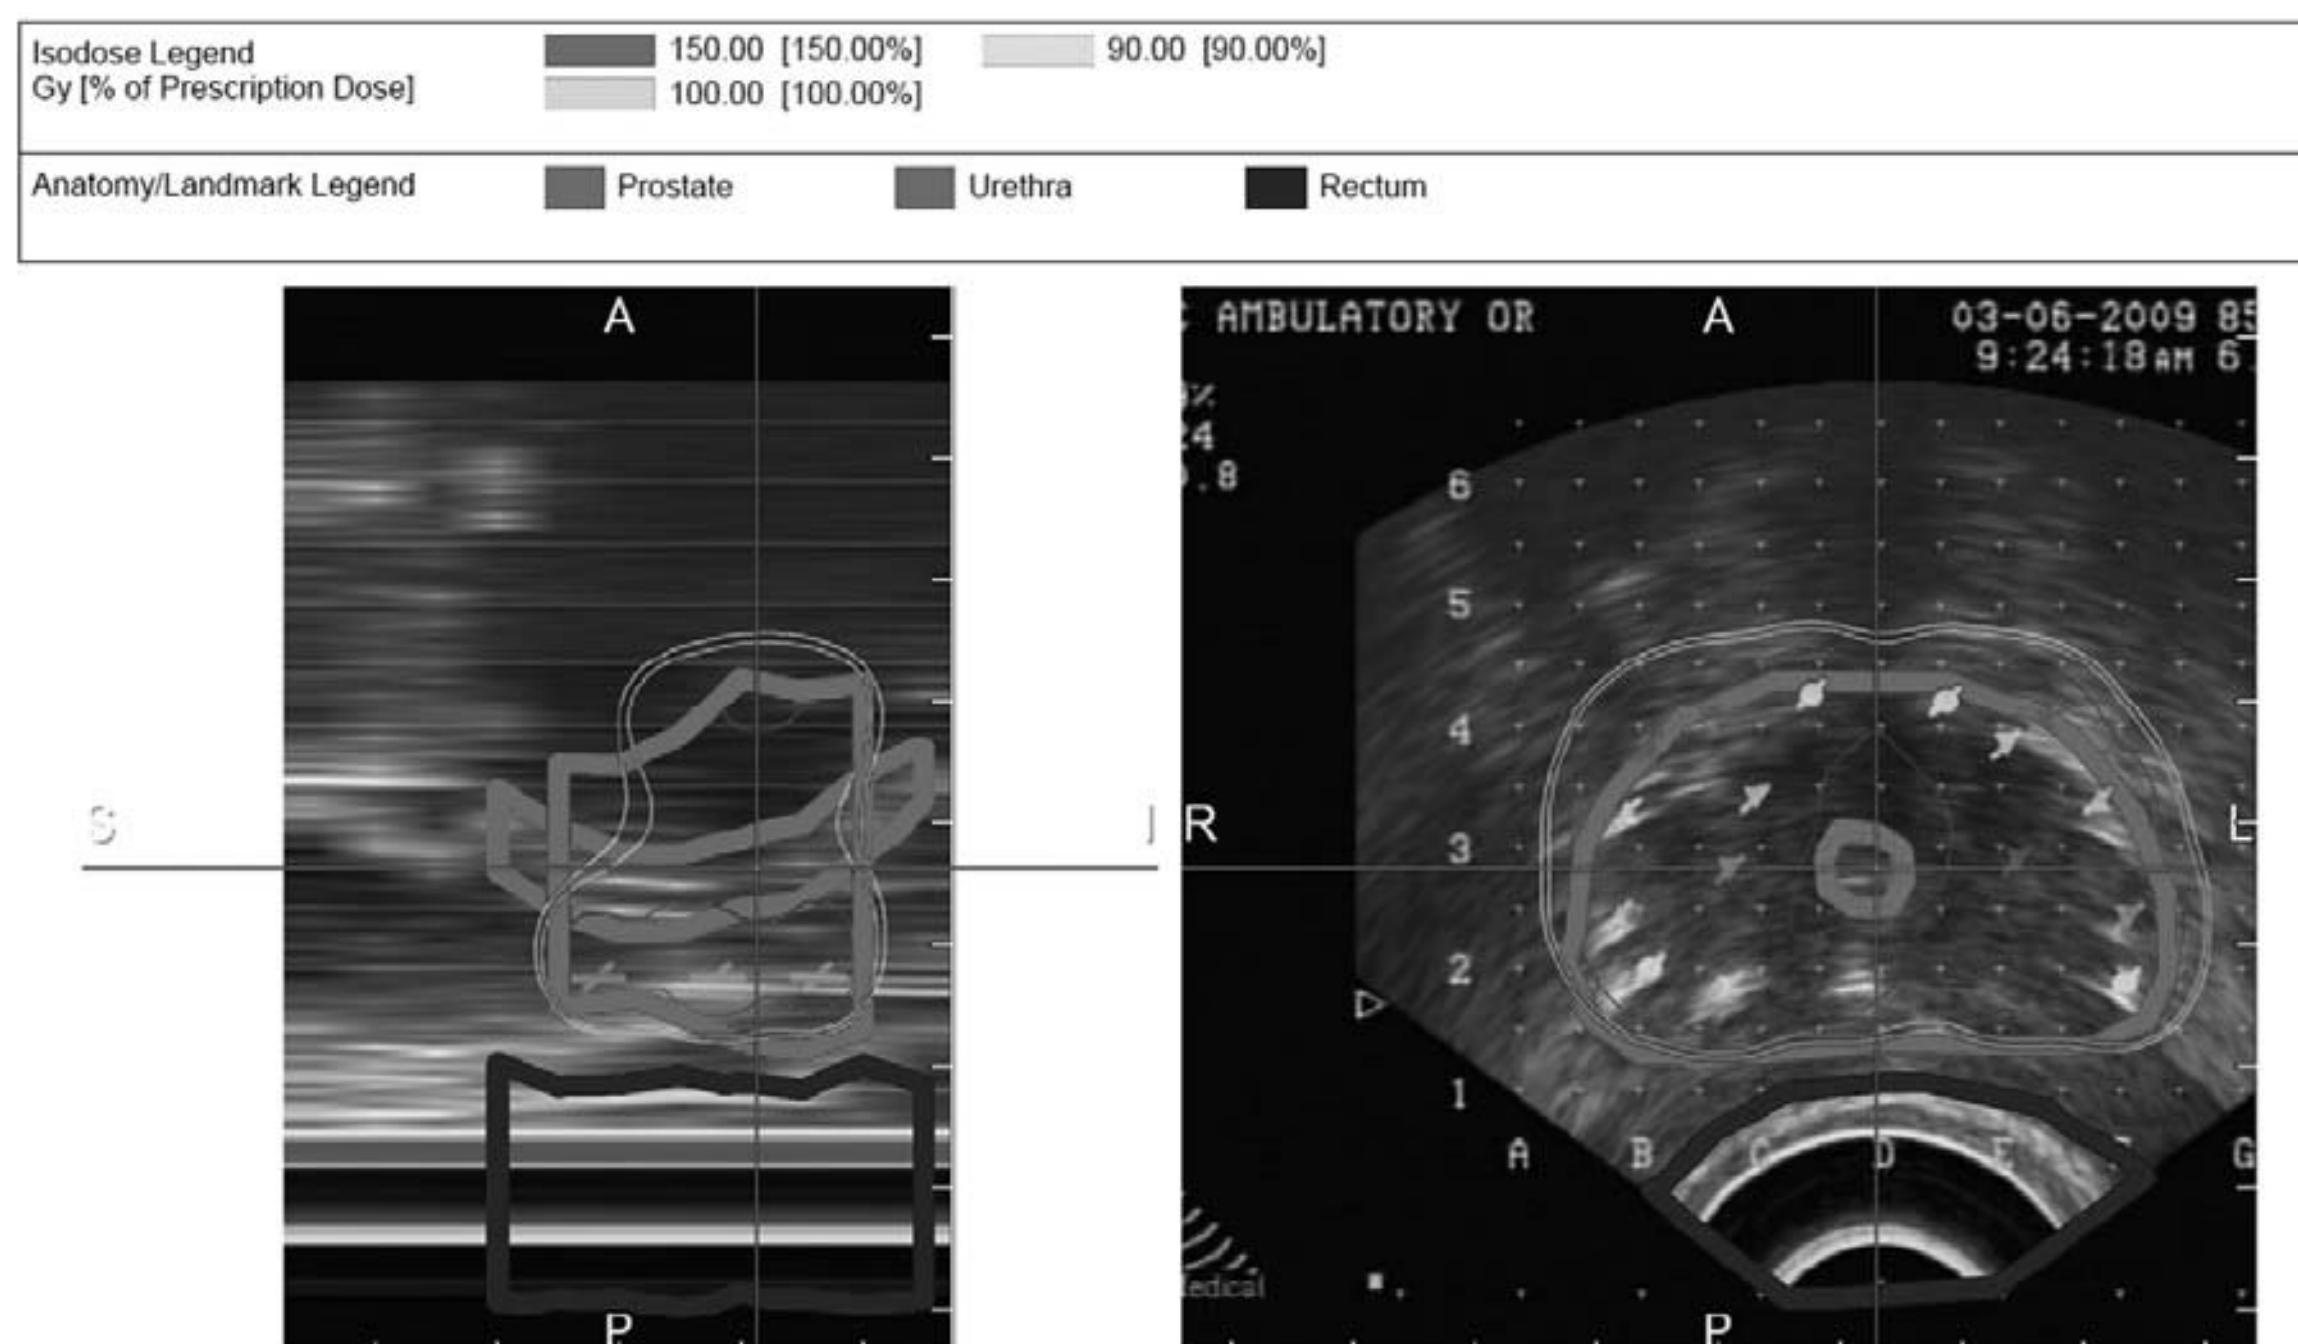

place the remaining 25% of the required activity in the gland according to the intraoperative plan. The majority of the inner seeds are placed at the apex and base of the gland in order to “cap” the prostate. Using modern treatment planning software and TRUS, the actual seed location can be documented as the seeds are placed and the intraoperative plan can better reflect reality, allowing for dosimetric inadequacies to be detected and corrected during the procedure.

This approach offers many advantages over the previously described technique as well as some disadvantages. The most significant advantage offered by this technique is that intraoperative planning allows for real-time optimization of the plan as each seed placed in the prostate is accounted for in the planning software and the resultant isodose lines are generated. Three variables unaccounted for with the previous technique (changes in prostate size and shape with needle placement, needle deviation from planned position, and seed movement

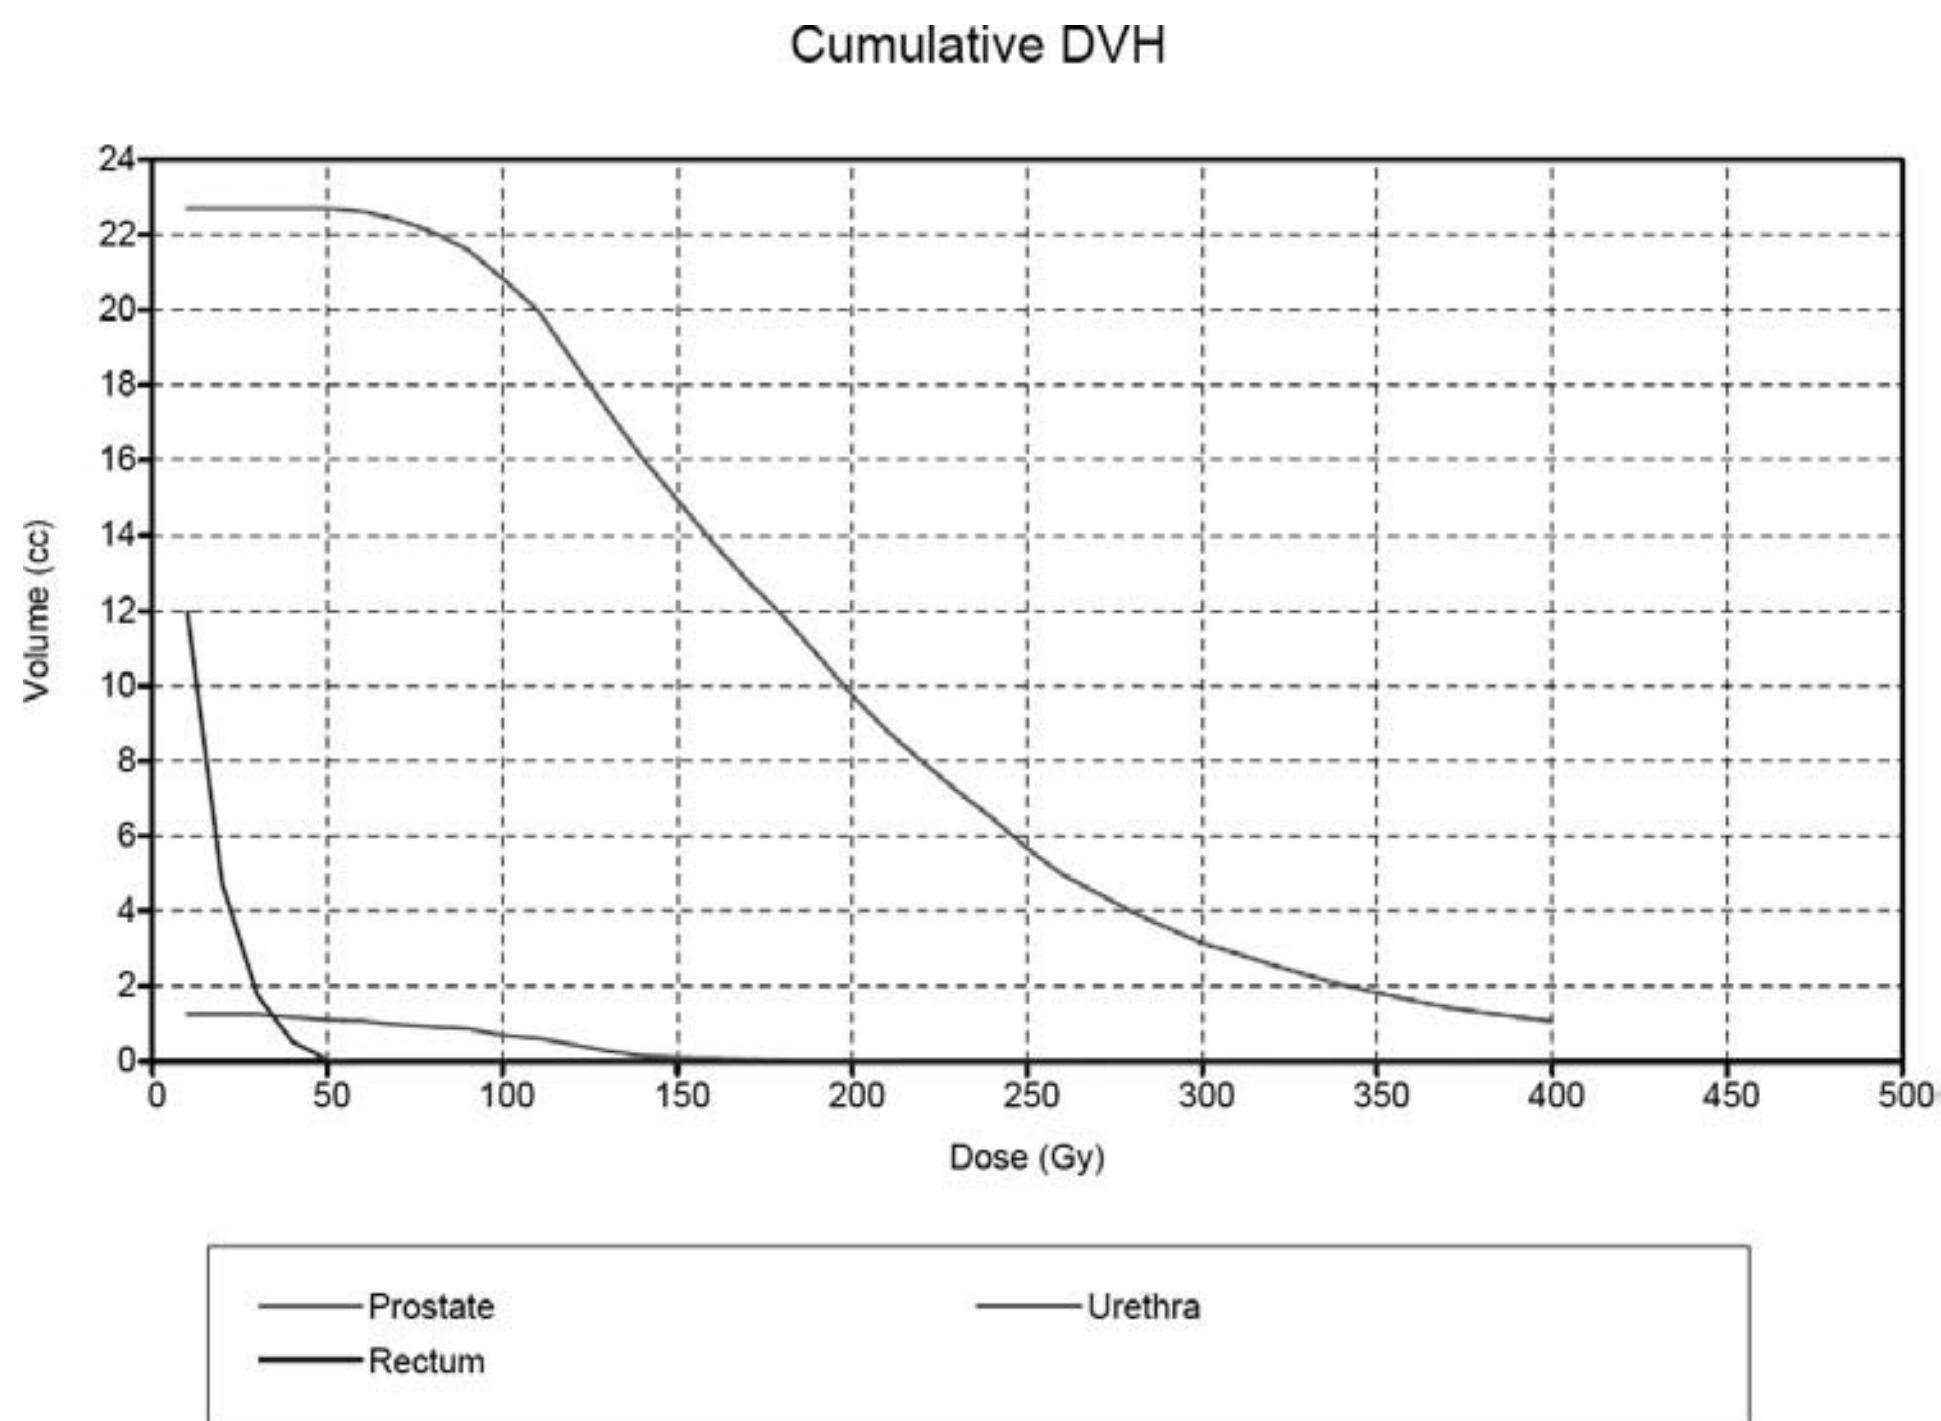

from initial placement) can be actively detected in the intraoperative treatment planning software and therefore corrected with subsequent seed deposition. Disadvantages include longer procedure duration and Mick applicator utilization, which some practitioners may find unwieldy. Although the Mick applicator requires significant operator skill, in practiced hands this applicator allows precise placement of individual seeds and significant flexibility. Some investigators have noted seed migration when seeds are placed individually in the prostate and surrounding tissues and have therefore argued for the use of stranded seeds. In fact, seeds have been observed to move significant distances and even to the lungs or other remote locations. When compared to stranded or linked seeds, single seed placement has been documented to result in increased overall seed migration (14,15). However, this has not been definitively shown to affect overall dosimetric outcome or toxicity (16–18).

### Hybrid Approach with Real-Time Planning and Linked Seeds

A novel technique has been developed and is currently being pursued at a few institutions in an attempt to combine the advantages of real-time intraoperative planning and linked seeds (19). This technique is very similar to the intraoperative technique described above; however, stranded seeds are formed in the OR at the time of implant and in response to real-time treatment planning. As before, an imaging study is obtained approximately 2 weeks before the date of implant to determine the prostate volume, and an appropriate number and activity of seeds are ordered according to nomograms developed at MSSM. On the day of implant the patient is placed in the dorsal lithotomy position and TRUS is utilized to build a three-dimensional model of the prostate, bladder, and anterior rectal wall within the treatment planning system. An initial intraoperative plan (Figs. 30.5 and 30.6) is then developed by the radiation oncologist while the urologist places needles in the periphery of the prostate at approximately 1-cm intervals (Figs. 30.7 and 30.8). Once the needles are placed, images are

**FIGURE 30.5** Treatment planning transverse and axial images of the prostate showing preliminary isodose lines for a  $^{103}\text{Pd}$  implant (prescription dose = 100 Gy).

**FIGURE 30.6** Dose-volume histogram for  $^{103}\text{Pd}$  implant depicting percentage of prescribed dose to the prostate, rectum, and urethra (prescription dose = 100 Gy).

**FIGURE 30.7** Operator implanting linked seeds at surgery.

**FIGURE 30.8** Sagittal ultrasound image of implant needle in the prostate preparing to place seed.

**FIGURE 30.9** Custom-constructed linked seeds. Note asymmetrical seed pattern that can be constructed in the operating room according to the real-time plan.

reacquired and the plan reoptimized. Longitudinal views of each individual needle are used to calculate the distance each needle traverses through the prostate. A push-button delivery system (QuickLink, C. R. Bard, Inc., Covington, GA) is then used to construct links (Fig. 30.9) of the appropriate number of seeds for the length measured along the longitudinal path of each needle in the prostate. Each strand can be customized according to the number of seeds needed and the overall length of the needle path in the prostate via custom-sized linkers. The linked seeds are then transferred to the prostate via the appropriate needle in a manner similar to that used with a preloaded needle in a preplanned approach (Figs. 30.7 and 30.10). The process is then repeated until all peripheral seeds have been placed. The inner needles are then placed (usually five to seven). The plan is then reoptimized to determine placement

of the remaining required activity. Once the plan has been approved, the remaining interior links of seeds are constructed and placed within the prostate as described previously. Preliminary data regarding this hybrid planning approach

**FIGURE 30.10** Ultrasound image of linked seeds in prostate after implantation.

reveal similar quality of dosimetry and OR times as compared to the traditional gun method (20).

---

### Postimplant Cystoscopy

---

Following prostate seed implantation, flexible cystoscopy is performed to verify an intact urethra and bladder wall and to account for any misplaced seeds. At the end of the procedure, C-arm radiography may also be performed to verify seed position and to document the presence or absence of loose seeds in the bladder.

---

### Postimplant Dosimetry

---

Postimplant dosimetry should be obtained at a consistent interval following prostate seed implant; however, the most appropriate interval is yet to be determined. Many institutions have patients return at 1 month following the implant for CT imaging. This image data set can then be imported into the treatment planning system, allowing for determination of dosimetric end points. Using this study, seed count should be verified, and isodose curves at 50%, 80%, 90%, 100%, 150%, and 200% of the prescribed dose should be displayed on axial images of the prostate, urethra, bladder, and rectal wall. The D90 or minimum dose delivered to 90% of the prostate as well as rectal and urethral doses should be recorded (21).

---

## OUTCOMES

---

### Complications

---

Immediate symptoms following brachytherapy are related to needle placement and include edema, bleeding, pain, and infection. The risk of infection can be minimized with the use of

intraoperative antibiotics and a short course of postoperative antibiotics. Intraprostatic edema and bleeding may lead to urinary retention in approximately 5% to 25% of patients. Large prostate volume and an elevated pretreatment IPSS predict an increased risk of urinary retention, and some studies have shown that a short course of androgen deprivation may reduce this risk (8).

Urinary irritation may develop within 1 to 2 months after  $^{125}\text{I}$  implantation and within 1 to 2 weeks with  $^{103}\text{Pd}$  or  $^{131}\text{Cs}$ . These symptoms can be monitored and prospectively recorded through utilization of IPSS evaluation at each subsequent follow-up. The majority of men undergoing prostate brachytherapy will experience urinary symptoms such as increased frequency, dysuria, nocturia, and weakened stream, which can be treated symptomatically with alpha blockers and antimuscarinics. Most men will return to their baseline function at 1 to 2 years. Proctitis may also occur in approximately 15% of men and manifest as mild hematochezia typically 1 to 2 years after treatment. These symptoms can often be managed conservatively by avoiding constipation and in severe cases with argon-plasma coagulation.

Late complications associated with prostate brachytherapy include incontinence, erectile dysfunction, and the remote possibilities of severe rectal injury or secondary malignancies involving the bladder or rectum. The risk of developing incontinence is limited except for men who have undergone a previous TURP or require TURP for obstruction after brachytherapy (10).

Patients with a history of prior TURP have an approximate 20% risk of developing stress incontinence, and a post-brachytherapy TURP portends an even higher risk unless the TURP is of very limited volume. Erectile function will likely decrease in 20% to 30% of men 2 to 3 years after brachytherapy. The risk of severe rectal injury is remote but does occur in <1% of patients and can require permanent colostomy. Finally, EBRT has been associated with an absolute 1% increase in secondary malignancies of the rectum or bladder as compared to patients undergoing prostatectomy alone (22). Theoretically, prostate brachytherapy would carry a similar risk; however, this remains unproven.

---

## Results

---

Defining and subsequently reporting low-risk prostate cancer outcomes has been the subject of much debate. Unlike with prostatectomy, PSA levels rarely become undetectable following radiation therapy. Therefore, the American Society for Therapeutic Radiology and Oncology Consensus Panel issued a consensus statement in 1997 defining biochemical failure following radiation therapy for prostate cancer as three consecutive increases in PSA value. Furthermore, the date of failure has been defined as the midpoint between the postirradiation nadir PSA and the first of the three consecutive rises (23). These recommendations were subsequently revised in 2006 and defined as a PSA rise of 2 ng per mL or more above the nadir PSA with no backdating (24).

Prostate cancer outcomes have been actively studied following brachytherapy, and long-term outcomes have now been published confirming the utility of this procedure in the setting of low-risk prostate cancer. Table 30.4 summarizes four series reporting  $\geq 10$ -year outcomes following brachytherapy as the sole intervention for localized prostate cancer. Freedom

from PSA failure at 10 years is approximately 90% and compares favorably with outcomes obtained from other therapeutic options such as EBRT and prostatectomy. Table 30.5 summarizes three series that combined brachytherapy and EBRT for intermediate- to high-risk prostate cancer. Long-term outcomes reveal that freedom from PSA failure at a minimum of 5 years is >75% for intermediate-risk patients and >60% for high-risk patients. Relatively early data (median follow-up of 50 months) from MSSM show promising results using brachytherapy combined with EBRT and 9 months of hormonal therapy, with 86% PSA control at 5 years for high-risk patients.

CHAPTER 31 ■ ANATOMY OF THE URETHRA

FEMALE URETHRA

Gross/Microscopic

The female urethra extends from the bladder neck to the external urethral meatus and varies in length from 3 to 5 cm. The urethra is a fibromuscular tube composed of a mucosal lining, a submucosal layer, and a muscle layer. Proximally the transitional cell mucosa is continuous with the bladder epithelium. Distally the mucosa is nonkeratinized stratified squamous epithelium (Fig. 31.1). The submucosa consists of

abundant longitudinal and circular elastic fibers and contains a prominent venous system. The mucosa and submucosa act as a washer producing a seal that contributes to urethral closure pressure (1). These tissues are estrogen-dependent, and in hypoestrogenic states thinning of the tissue may result in incontinence (2). The smooth muscle layer consists of a thick sheet of longitudinally oriented fibers and a thin outer layer of circular fibers. These muscles are continuous with the bladder neck proximally and terminate distally in the subcutaneous tissue surrounding the external urethral meatus. Colleselli and others have shown in the cranial and most of the middle third of the urethra that there are three smooth muscle layers, including outer and inner longitudinal layers and a middle transverse layer (3). The density of urethral circular smooth muscle is lower in older women, which may account for the change in urethral closure pressure that is seen with increasing age (4).

In the distal two thirds of the urethra a layer of striated muscle, the rhabdosphincter, surrounds the smooth muscle layer, on the ventral and lateral aspects making an omegalike-shaped sphincter. The rhabdosphincter is composed of delicate Type I (slow-twitch) fibers and consists of three distinct muscles. Proximally the muscle forms a ring (sphincter urethrae) that encircles the urethra. Distally the muscle (compressor urethrae) fans out laterally along the curve of the inferior border of the pubic rami to compress the urethra against the anterior vaginal wall. At the vestibule the muscle completely surrounds the urethra and vagina to form a urethrovaginal sphincter (Fig. 31.2) (5). The three muscles work together to provide

FIGURE 31.1 The female urethra.

FIGURE 31.2 Striated urogenital sphincter muscle seen from below after removal of the perineal membrane and pubic bones. (From Oelrich TM. The striated urogenital sphincter muscle in the female. *Anat Rec* 1983; 205:223, with permission.)

**FIGURE 31.3** Location of various structures along the urethra. Note the three parts of the rhabdosphincter. (Copyright University of Michigan, 1989, with permission.)

constant urethral tone (Fig. 31.3) (6). Normally the striated sphincter plays a minimal role in resisting abdominal pressure. However, preservation of the rhabdosphincter is necessary for continence after creation of a female neobladder (3).

Paired periurethral (Skene) glands drain on either side of the midline just posterior to the urethral meatus. There are also numerous small periurethral mucous glands that open into small recesses in the mucosa.

### Vascular Anatomy

The arterial supply to the female urethra is from the urethral artery, a branch of the internal pudendal artery, which in turn is a branch of the internal iliac artery (7). The venous drainage is via the pelvic venous plexus.

**FIGURE 31.4** Cross section of the urethra (*U*), vagina (*V*), arcus tendineus fasciae pelvis (*ATRP*), and superior fascia of levator ani (*SFLA*) just below the vesical neck (drawn from cadaver dissection). Pubovesical muscles (*PVM*) lie anterior to urethra and anterior and superior to paraurethral vascular plexus (*PVP*). The urethral supports (*U<sub>su</sub>*) (the pubourethral ligaments) attach the vagina and vaginal surface of the urethra to the levator ani muscles (*MA<sub>t</sub>*, muscular attachment) and to the superior fascia of the levator ani (*Fat*, fascial attachment). *R*, rectum; *RP*, rectal pillar; *VM*, vaginal wall muscularis. (From DeLancey JOL. The pubovesical ligament, a separate structure from the urethral supports. *Neurol Urodynam* 1989;8:53, with permission.)

### Innervation

The smooth muscle of the urethra is innervated by parasympathetic nerves. The predominant sympathetic receptors are alpha-adrenergic (8). These receptors are responsible for urethral smooth muscle contraction and possibly engorgement of the submucosal vasculature to create a watertight seal of the urethral mucosa (9). The striated muscle fibers of the external intrinsic sphincter receive innervation from the pudendal and pelvic somatic nerves (10). Both somatic and autonomic nerves to the urethra travel on the lateral walls of the vagina near the urethra. Various authors have advised against dissection in this area during transvaginal surgery to prevent development of stress urinary incontinence due to intrinsic sphincter dysfunction (11).

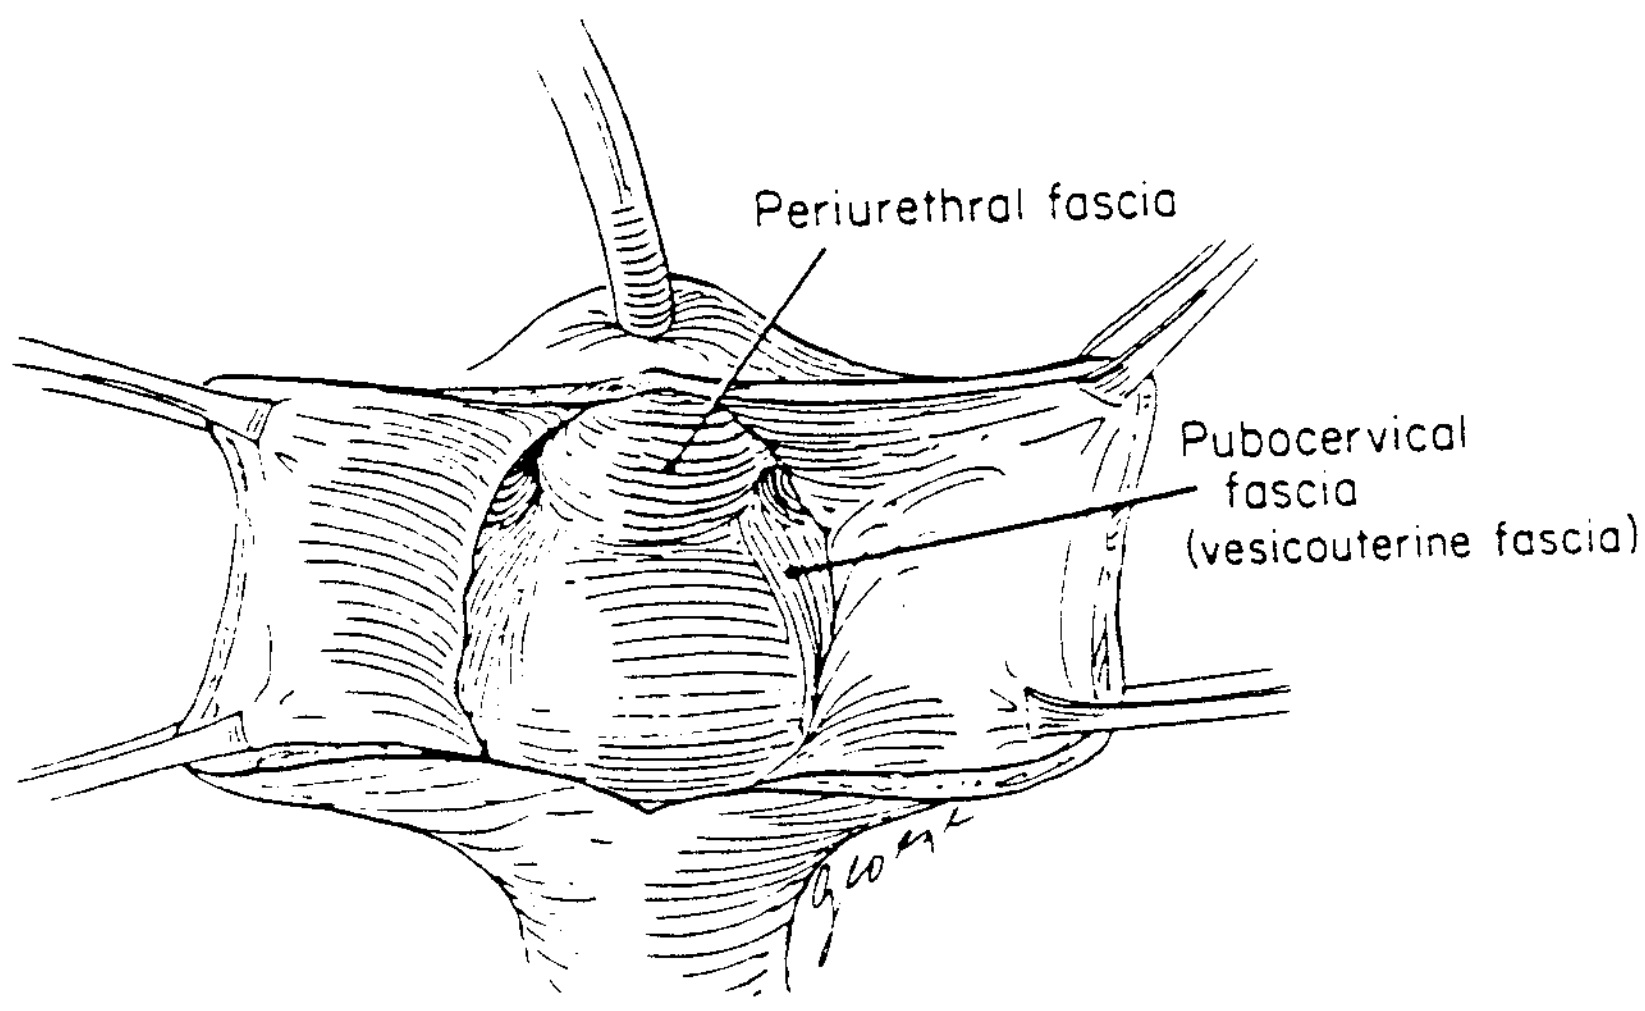

### Lymphatics

The lymphatic drainage of the proximal urethra is to the deep pelvic nodes. The drainage of the distal portion of the urethra is to the inguinal nodes.

### Contiguous Structures

A “hammock” of vaginal tissue supports the urethra (12). The urethral supports, also termed pubourethral ligaments, include fascial and muscular attachments to the arcus tendineus fasciae pelvis and levator ani muscles. These supports are only present in the distal third of the urethra and fix the urethra to the pubic bone. The pubovesical muscle is a separate structure that is an extension of the smooth muscle of the bladder, which extends from the detrusor muscle to the arcus tendineus fasciae pelvis and pubic bone (Fig. 31.4) (13).

Posteriorly the urethra is intimately related to the anterior surface of the vagina. The periurethral fascia is located immediately beneath the vaginal epithelium and is seen as the glistening white layer that surrounds the urethra when an incision is made in the anterior wall of the vagina. The fascia extends

**FIGURE 31.5** View of the anterior vaginal fascial support, which is found beneath the vaginal wall (shown retracted). The periurethral fascia, which forms the vaginal layer of the urethropelvic ligaments, is continuous with the pubocervical fascia proximally.

from the meatus to the bladder neck and laterally to where it fuses with the endopelvic fascia at the pubic bone (Fig 31.5).

## MALE URETHRA

### Gross/Microscopic

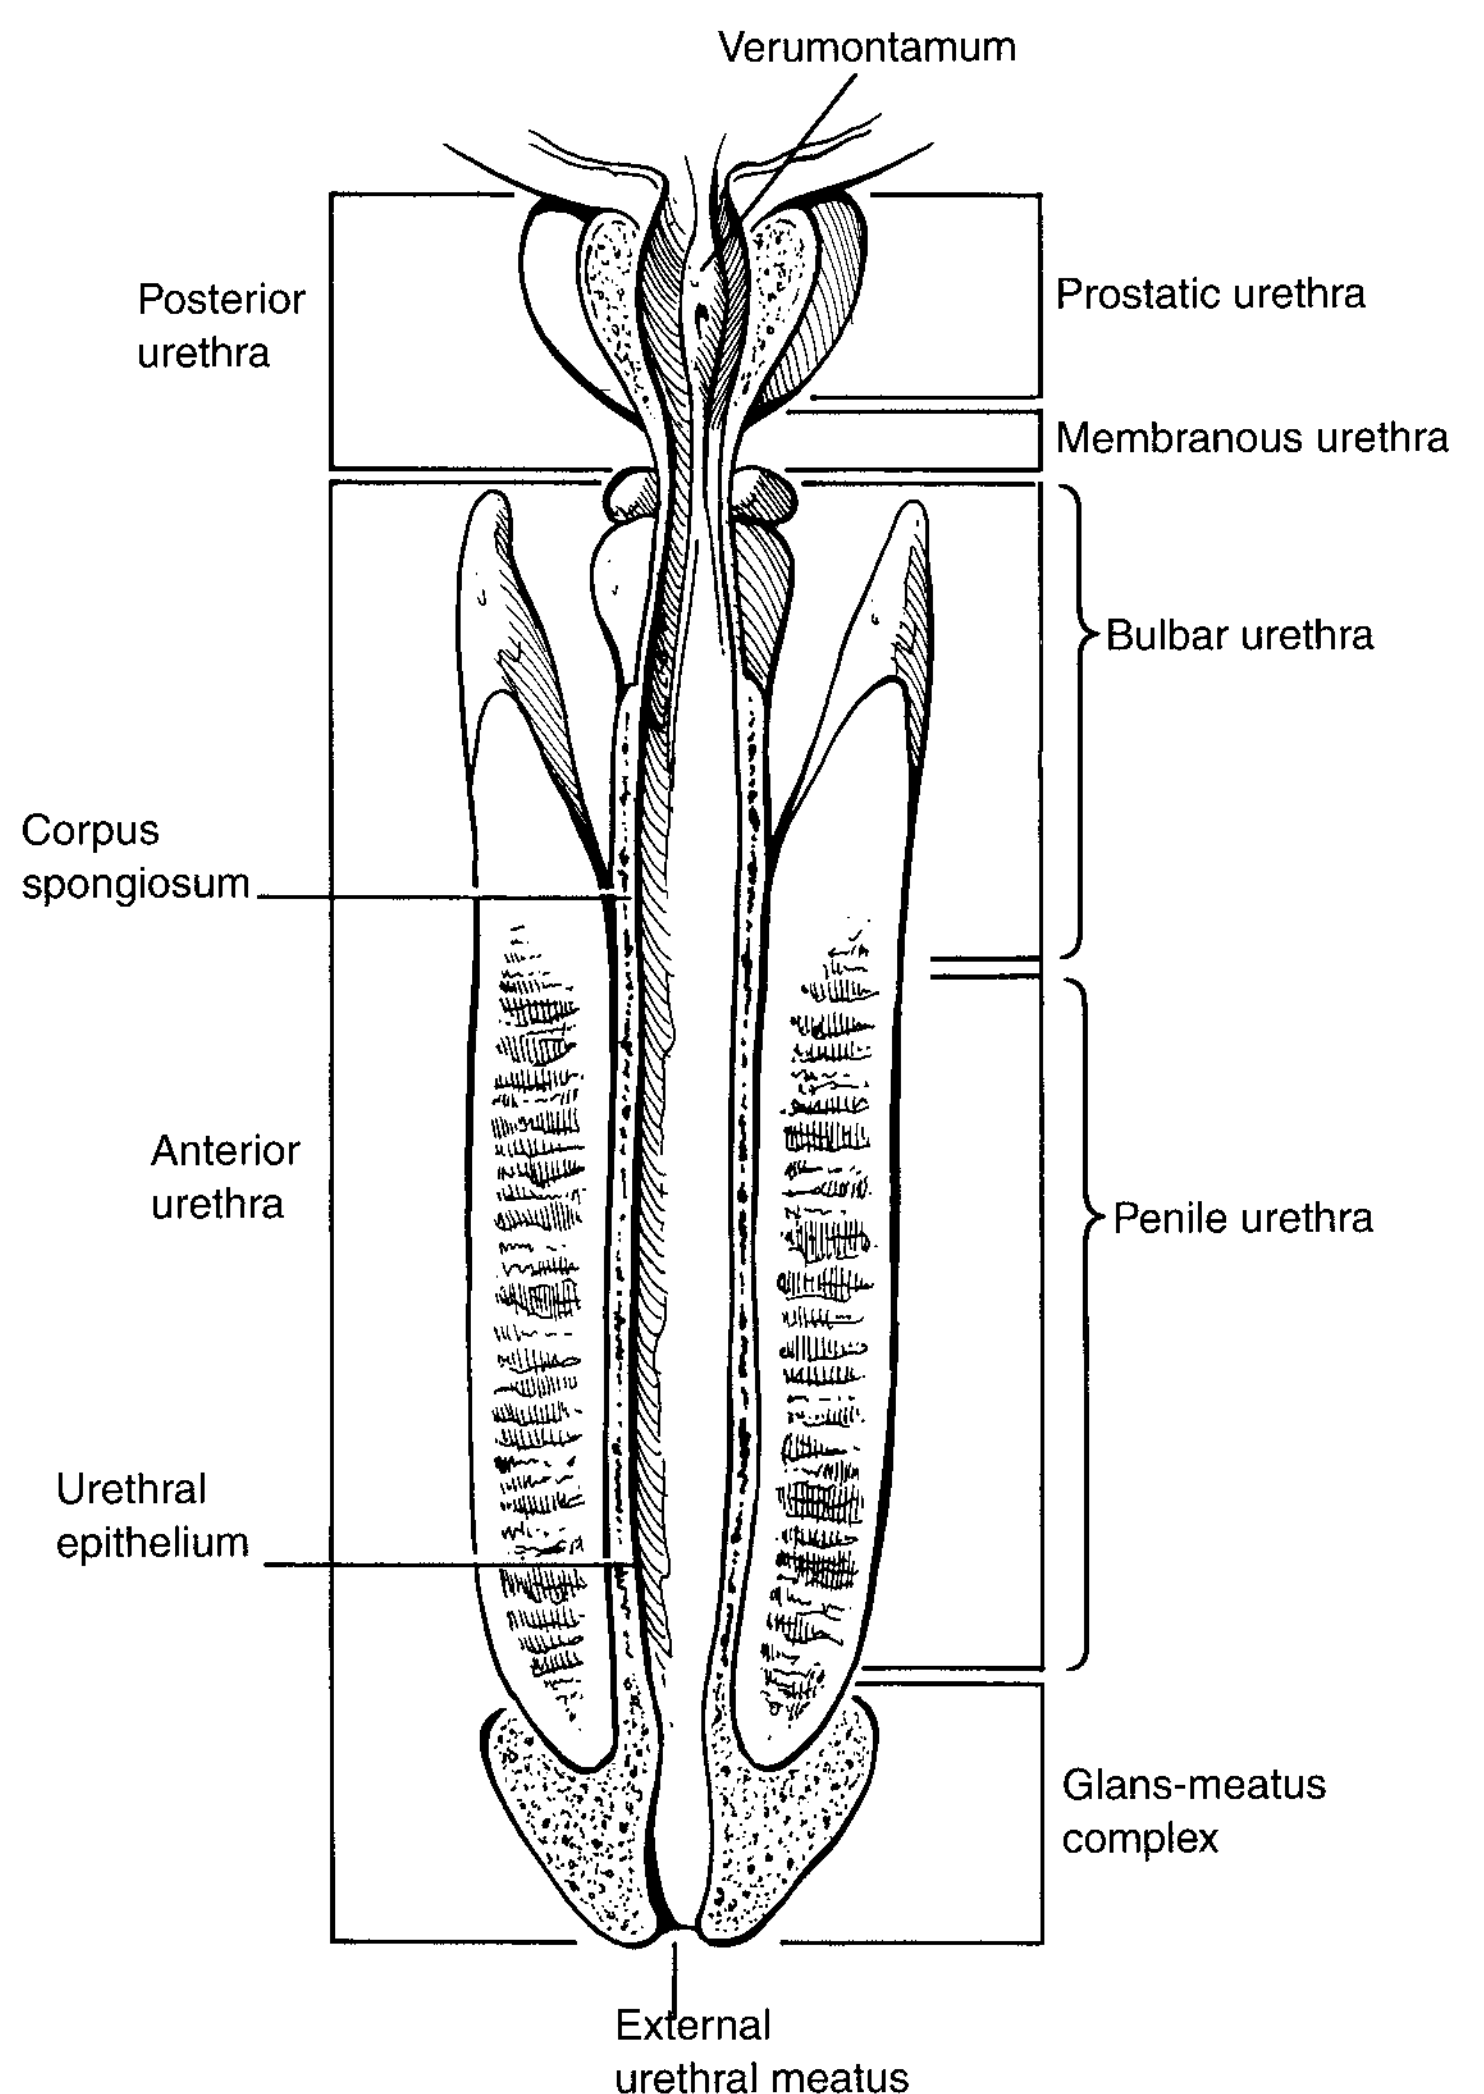

The posterior urethra is the portion of the urethra extending from the bladder neck through the prostate and through the urogenital diaphragm. It is divided into the prostatic urethra and the membranous urethra, which traverses the urogenital diaphragm just prior to entering the corpora spongiosa. The anterior urethra runs from the urogenital diaphragm to the tip of the glans penis and may be further divided into the bulbous urethra extending from the root of the penis to the convergence of the corpora cavernosa and the pendulous or penile urethra that traverses the pendulous portion of the penis. There is a dilation of the urethra in the area of the glans penis called the fossa navicularis (Fig. 31.6).

A number of ducts empty into the lumen of the urethra. Two to 3 cm distal to the membranous urethra the paired orifices of the Cowper glands (bulbourethral glands) are noted on the floor. On the roof of the pendulous urethra there are openings for the glands of Littre, or the submucosal urethral glands, and small recesses termed urethral lacunae. The lacuna magna is a larger lacuna in the midportion of the anterior aspect of the fossa navicularis.

The urethral epithelium varies along the length of the urethra. In the prostatic urethra the cells are transitional, whereas in the membranous urethra they are stratified columnar. The epithelium of the penile urethra is composed of pseudostratified and columnar cells. In the fossa navicularis, the epithelium is composed of stratified squamous cells.

### Vascular Anatomy

Paired bulbourethral arteries, which arise as the first of three penile branches of the internal pudendal artery, supply the urethra. The venous drainage is via the emissary veins, which drain to the circumflex branches of the deep dorsal vein of the penis.

**FIGURE 31.6** The male urethra and its divisions with associated histology.

---

### Innervation

---

The urethra mucosa is innervated via the urethrobulbar nerve. It is a branch of the nerve to the bulbocavernosus, which is a branch of the perineal nerve, which is derived from the pudendal nerve. A branch of the bulbocavernosus nerve at the 3 and 9 o'clock positions penetrates the striated urethral sphincter (14). The pudendal nerve, consisting of fibers from the second, third, and fourth sacral spinal nerves, is thus both motor to the urethral sphincter and sensory to the urethra and glans penis.

---

### Lymphatics

---

The lymphatic drainage of the anterior urethra is into the superficial and deep inguinal node and ultimately to the external iliac nodes. The lymphatics of the posterior (the bulbous, membranous, and prostatic) urethra can take three routes: to the external iliac nodes, to the obturator and internal iliac nodes, or to the presacral nodes.

---

### Contiguous Structures

---

The membranous urethra is covered by the fibers of the striated urethral sphincter (rhabdosphincter). Brooks et al. used computer-generated, three-dimensional reconstruction of the male pelvis from the visible human data set to show that the striated urethral sphincter is circular with abundant posterior tissue, making it more signet-ring shaped (16). Ventrally and laterally, the rhabdosphincter is separated from the membranous urethra by a thin sheath of connective tissue (15). Anteriorly the sphincter is approximately twice as long as it is posteriorly. An intrinsic smooth muscle lies between the urethral mucosa and the striated urethral sphincter. This muscle begins above the striated sphincter and then gradually thins distal to the striated sphincter (16).

The remainder of the anterior urethra lies within the corpus spongiosum lying in the ventral groove of the corpora cavernosa of the penis. The Cowper glands (bulbourethral glands) lie within the urogenital diaphragm posterior and lateral to the membranous urethra.

## CHAPTER 32 ■ FEMALE URETHRAL DIVERTICULUM

AHMED M. EL-ZAWAHRY AND ERIC S. ROVNER

Urethral diverticulum (UD) in women represents a challenge in both diagnosis and reconstruction for the urologist. The actual prevalence of UD is not known, but it is reported to occur in 1% to 6% of adult women (1). UD is an epithelialized cavity dissecting within the fascia of the urethropelvic ligament (Fig. 32.1) (2). This cavity forms an isolated cystlike appendage, usually with a single connection to the urethral

lumen, termed the neck or ostium. Complicated UD may extend partially around the urethra to form a “saddlebag” UD, or more uncommonly anterior to the urethra (3), or circumferentially around the urethra (4).

It is generally believed that an adult UD is formed as a result of infection and obstruction of the periurethral glands. These tubuloalveolar glands are anatomically located in the

**FIGURE 32.1** Diverticulum forms within the urethropic ligament.

distal one-third of the urethra ventral and lateral to the urethral lumen. Infection of these glands leads to abscess formation and eventual rupture of the abscess back into the urethral lumen, resulting in an epithelialized cavity in communication with the urethra.

Often, although not invariably highly symptomatic due to the location, the most common coexisting condition is probably urinary incontinence, especially stress urinary incontinence (SUI), which may coexist in up to 50% of individuals (1). Malignant and benign tumors in UD are quite rare. The most common malignant pathology in UD is adenocarcinoma, followed by transitional cell and squamous cell carcinomas. Calculi within UD may be diagnosed in 4% to 10% of cases and is most likely due to urinary stasis and/or infection.

## DIAGNOSIS

The diagnosis of UD can be made with a combination of a thorough history, physical examination, and selected imaging. The symptoms of UD are classically described as the “three Ds”: dysuria, dyspareunia, and dribbling (postvoid). However, common presenting symptoms include irritative lower urinary tract symptoms, pain, and urinary tract infection (UTI), which is reported in almost one-third of patients (5). Other symptoms include a vaginal mass, hematuria, vaginal discharge, obstructive voiding symptoms, and urinary retention. Up to 20% of patients may be completely asymptomatic and are thus diagnosed incidentally on imaging or physical examination. Patients may often be misdiagnosed and treated for years for a number of unrelated conditions, such as interstitial cystitis, recurrent cystitis, vulvodynia, endometriosis, and vulvovestibulitis, before the diagnosis of UD is made.

Physical examination should include a careful inspection of the anterior vaginal wall. Masses or areas of tenderness should be noted and further examined. Suspected UD should be carefully differentiated from vaginal prolapse, including cystourethrocele. Most UD are located ventrally over the middle and proximal portions of the urethra corresponding to the area of the anterior vaginal wall 1 to 3 cm inside the introitus. During physical examination, the anterior vaginal wall may be gently “stripped” or “milked” distally in an attempt to express purulent material or urine from within the urethral lumen out through the urethral meatus, which strongly suggests the diagnosis of UD.

Endoscopic examination of the bladder and urethra is performed in an attempt to visualize the UD ostium (communication to the urethra) as well as to evaluate for other causes of the patient’s presenting symptoms. A flexible cystoscope or a specially designed rigid female cystoscope with a short beak to maintain the discharge of the irrigation solution immediately adjacent to the lens is most useful in visualizing the lumen of the relatively short female urethra. During cystoscopy, simultaneous gentle compression of the bladder neck and the diverticular sac with an assistant’s finger can express luminal discharge of purulent material during urethroscopy localizing the ostium.

High-quality preoperative imaging is important in the diagnosis of UD as well as in planning operative therapy. This will help to provide an accurate reflection of the relevant anatomy of the UD and its anatomical relationships. No single study can be considered the gold standard for the evaluation of UD. Furthermore, the availability and quality of individual radiological techniques is quite variable across centers. Currently available techniques for the evaluation of UD include double-balloon positive-pressure urethrography (PPU), voiding cystourethrography (VCUG), ultrasound (US), and magnetic

**FIGURE 32.2** Axial T-2 weighted MRI of an unusual anterior urethral diverticulum.

resonance imaging (MRI) with or without an endoluminal coil (eMRI). eMRI has several distinct advantages over VCUG; however, these studies are often complementary (6). We currently utilize MRI in the evaluation of all patients with known or suspected UD as the complexity of these lesions is more readily appreciated using this technique (Fig. 32.2). Urodynamic studies, especially videourodynamics, are utilized in patients with urinary incontinence or significant voiding dysfunction in order to characterize these symptoms, especially if surgery is planned. These studies are useful in evaluating the anatomy of the UD, assessing the competence of the bladder neck, assessing bladder function, and confirming the diagnosis of SUI.

## INDICATIONS FOR SURGERY

Symptomatic patients should be offered surgical excision and reconstruction. Those with concomitant SUI can be considered for a simultaneous anti-incontinence procedure at the time of UD excision.

Asymptomatic patients may not desire surgical excision. Other patients may be unwilling or medically unable to undergo surgical excision. However, the natural history of untreated UD is unknown. In such cases, patients should be counseled that certain carcinomas or other complications such as stones or urinary incontinence may arise and that close follow-up is warranted.

## ALTERNATIVE THERAPY

Patients electing nonoperative management can be treated with daily low-dose antibacterial preparations and digital stripping of the anterior vaginal wall following micturition to prevent postvoid dribbling and reduce the risk of UTI due to stasis in the UD.

Most commonly, UD are treated with a complete excision and urethral reconstruction. However, a variety of other surgical interventions for UD have been reported. Approaches

have included transurethral and open marsupialization, endoscopic unroofing, fulguration, incision and obliteration, and coagulation (1). One noteworthy alternative to excision and reconstruction is transvaginal marsupialization as described by Spence and Duckett (7). This approach may reduce operative time, blood loss, and recurrence rate but is probably only applicable to UD in very select cases involving the distal one-third of the urethra due to the risk of sphincteric injury and resulting *de novo* SUI.

In rare cases, when the UD is highly symptomatic, acutely infected, and unresponsive to antibiotic therapy, or in cases when a complete elective excision should be postponed, such as during pregnancy, a transvaginal incision (diverticulotomy) can be performed directly into the UD cavity. This will create a temporary urethrovaginal fistula from the UD ostium through the UD cavity into the vagina, thus decompressing the UD. The UD and fistula are subsequently repaired at the time of planned elective excision and reconstruction.

## SURGICAL TECHNIQUE

Excision and reconstruction is probably the most common surgical approach to UD in the modern era. The principles of the urethral diverticulectomy operation have been well described (Table 32.1). There are only a few minor differences between surgical approaches, including the type of vaginal incision (inverted “U” versus inverted “T”), whether it is necessary to remove the entire mucosalized portion of the UD, and finally, the optimal type of postoperative catheter drainage (urethra only versus urethra and suprapubic).

Preoperative preparation includes (a) antibiotic administration in patients with recurrent or persistent UTIs; (b) stripping of the anterior vaginal wall to prevent urinary stasis and recurrent UTIs; and (c) application of topical estrogen creams for several weeks prior to surgery in postmenopausal patients with atrophic vaginitis.

The patient is placed in the high lithotomy position with all pressure points well padded. We have found that the use of padded adjustable stirrups for the lower extremities greatly enhances operative access to the female perineum. A standard vaginal antiseptic preparation is applied. The use of a headlight as well as operative magnification (1.5 × to 2.0 ×) assists with the dissection and precise reconstruction. A Foley catheter (16Fr) is placed in the urethra. A suprapubic tube may

**TABLE 32.1**

### PRINCIPLES OF TRANSVAGINAL URETHRAL DIVERTICULECTOMY

Mobilization of a well-vascularized anterior vaginal wall
Preservation of periurethral fascia
Identification and excision of the neck of the UD or ostium
Removal of the entire UD wall or sac (mucosa)
Watertight closure of the urethra
Multilayered, nonoverlapping closure with absorbable suture
Closure of dead space
Preservation or creation of continence

**FIGURE 32.3** Incision along the anterior vaginal wall, with the base of the “U” at the level of the distal urethra, provides an excellent lateral exposure at the midvagina for transvaginal urethral diverticulectomy. (From Rovner ES. Urethral diverticula. In: Raz S, Rodriguez L, eds. *Female urology*, 3rd ed. Philadelphia: Elsevier, 2008: 825–844, with permission.)

**FIGURE 32.4** A transverse incision is made into the periurethral fascia. Proximal and distal layers will be carefully developed without entering the UD. (From Rovner ES. Urethral diverticula. In: Raz S, Rodriguez L, eds. *Female urology*, 3rd ed. Philadelphia: Elsevier, 2008: 825–844, with permission.)

be utilized for an additional postoperative urinary drainage if desired.

A weighted vaginal speculum and Scott retractor with hooks are placed to assist with exposure. An inverted “U” is marked out along the anterior vaginal wall proximal from the urethral meatus with the limbs extending to the bladder neck or beyond (Fig. 32.3). The inverted “U” incision provides excellent exposure laterally at the level of the midvagina and can be extended proximally as needed for lesions that extend beyond the bladder neck. Normal saline can be injected along the lines of the incision beneath the vaginal wall to facilitate dissection. A posterolateral episiotomy may be of help in some patients with a narrow introitus, especially in nulliparous women.

An anterior vaginal wall flap is created by careful dissection in the potential space between the vaginal wall and the periurethral fascia. The use of sufficient countertraction during this portion of the procedure is important in maintaining the proper plane of dissection. During the dissection it is important to preserve the periurethral fascia, maintain an adequate blood supply to the anterior vaginal wall flap, and avoid inadvertent entry into the UD. The periurethral fascia forms a distinct layer that is usually interposed between the vaginal wall and the UD; however, in some lesions it may be deficient (8). Preservation and later reconstruction of the periurethral fascia is of paramount importance in order to prevent UD

recurrence, close dead space, and avoid urethrovaginal fistula formation postoperatively. Pseudodiverticula have been described where this layer of tissue is considerably attenuated or even absent (8). In these patients, an interpositional flap, or graft such as a pubovaginal sling, may be utilized for reconstruction.

Following the completed takedown of the anterior vaginal wall flap, the periurethral fascia is incised transversely (Fig. 32.4). Proximal and distal layers of periurethral fascia are carefully developed, avoiding entrance into the UD. The UD is then grasped and sharply dissected back to its origin on the urethra within the leaves of the periurethral fascia (Fig. 32.5). In many cases it is necessary to open and enter the UD to facilitate dissection from the surrounding tissues, especially if the patient had a previous recent infection. The ostium or connection to the urethra is identified and the walls of the UD are completely excised. Every effort should be made to remove the entire mucosalized surface of the UD in order to prevent recurrence. All abnormal tissue in the area of the ostium should be removed if possible to ensure that no mucosal elements of the UD wall remain that could result in postoperative urine leakage and recurrence. Following complete excision of the UD, the urethral catheter is often seen (Fig. 32.6). The urethra can be reconstructed over a Foley catheter as small as 12Fr without long-term risk of urethral stricture and should be closed in a watertight fashion with 4-0

**FIGURE 32.5** Following mobilization of the anterior and posterior leaves of the periurethral fascia, the urethral diverticulum is dissected back to its origin on the urethra within the leaves of the periurethral fascia. (From Rovner ES. Urethral diverticula. In: Raz S, Rodriguez L, eds. *Female urology*, 3rd ed. Philadelphia: Elsevier [in press], with permission.)

**FIGURE 32.7** Closure of the urethra with absorbable suture should be watertight and tension-free. (From Rovner ES. Urethral diverticula. In: Raz S, Rodriguez L, eds. *Female urology*, 3rd ed. Philadelphia: Elsevier [in press], with permission.)

**FIGURE 32.6** Following removal of the entire urethral diverticulum, the Foley catheter is often seen. (From Rovner ES. Urethral diverticula. In: Raz S, Rodriguez L, eds. *Female urology*, 3rd ed. Philadelphia: Elsevier [in press], with permission.)

synthetic absorbable suture (Fig. 32.7). The closure should be tension-free and should include the full thickness of the urethral wall. The periurethral fascial flaps are reapproximated with 3-0 synthetic absorbable sutures in a perpendicular orientation to the urethral closure line in order to minimize overlap and hence the risk of postoperative urethrovaginal fistula formation (Fig. 32.8). Care is taken to secure the periurethral fascial flaps in such a way as to close all dead space.

If desired, a fibrofatty labial (Martius) flap can be harvested at this point and placed over the periurethral fascia as an additional layer of closure. Indications for such a flap are not universally agreed upon. However, in patients with poor-quality tissues or attenuated periurethral fascia, or in whom significant inflammation is encountered intraoperatively, a well-vascularized adjuvant flap such as a Martius flap may reduce the risk of wound breakdown and subsequent complications such as urethrovaginal fistula. The anterior vaginal wall flap is then repositioned and reapproximated with absorbable suture (Fig. 32.9). This completes a three-layer closure (four layers if a Martius flap is utilized). An antibiotic impregnated vaginal pack is placed postoperatively.

The vaginal packing is removed within 6 to 24 hours, and the patient is discharged home with closed urinary drainage. Antispasmodics are used liberally to reduce bladder spasms. A pericatheter VCUG is obtained at 14 to 21 days postoperatively. If there is no extravasation, the catheters are removed. If extravasation is seen, then repeat pericatheter VCUGs are performed weekly until resolution is noted. In the vast majority of cases, extravasation will resolve in several weeks with this type of conservative management.

**FIGURE 32.8** Closure of the periurethral fascia should be perpendicular to the urethral closure line to minimize overlap and the risk of urethrovaginal fistula. (From Rovner ES. Urethral diverticula. In: Raz S, Rodriguez L, eds. *Female urology*, 3rd ed. Philadelphia: Elsevier [in press], with permission.)

**FIGURE 32.9** Closure of the vaginal wall with reapproximation of the anterior vaginal wall flap. This completes a three-layer closure including closure of the urethra, periurethral fascia, and vaginal wall. (From Rovner ES. Urethral diverticula. In: Raz S, Rodriguez L, eds. *Female urology*, 3rd ed. Philadelphia: Elsevier [in press], with permission.)

## COMPLICATIONS

Postoperative complications can be avoided by careful adherence to the principles of transvaginal urethral diverticulectomy. Nevertheless, complications may arise. Large diverticula (>4 cm) or those associated with a lateral or horseshoe configuration may be associated with a greater likelihood of postoperative complications (9). Complications include recurrent diverticulum (1% to 29%), stress incontinence (1.7% to 16.0%), urethral stricture (0% to 5%), and recurrent UTIs (0% to 31%) (1).

Intraoperative bleeding can be avoided by maintaining the proper plane of dissection during takedown of the anterior vaginal wall flap. If bleeding is encountered, cautery or suture ligation can be used. Excessive use of cautery should be avoided as this can lead to flap necrosis and fistula formation.

Urethrovaginal fistula is a devastating but fortunately rare complication that may result from diverticulectomy. A fistula can be located either distal or proximal to the sphincteric mechanism. A distally located fistula is usually not associated with symptoms other than perhaps a split urinary stream and/or vaginal voiding. As such a distal urethrovaginal fistula may not require repair, although some patients may request repair. Conversely, a proximal fistula located at the bladder neck or within the proximal half of the urethra in patients with an incompetent bladder neck will likely result in considerable symptomatic urinary leakage. These patients should undergo repair with or without the use of an adjuvant tissue flap such as a Martius flap to provide a well-vascularized additional tissue layer. Meticulous attention to surgical technique, good hemostasis, avoidance of infection, preservation of the periurethral fascia, a well-vascularized anterior vaginal wall flap, and a multilayered closure with nonoverlapping suture lines should minimize the potential for postoperative urethrovaginal fistula formation.

Coexisting SUI can be treated at the time of urethral diverticulectomy as noted previously. However, *de novo* SUI may occur following urethral diverticulectomy. The proximity of most urethral diverticula to the sphincter mechanism puts the patient at risk for this complication even with meticulous attention to surgical technique.

Persistence or recurrence of symptoms following diverticulectomy may occur in some patients. This may be caused by a new medical problem (e.g., UTI, etc.), a new UD, or alternatively, recurrence of the original lesion. Recurrence of a UD may be due to incomplete excision of the UD, inadequate closure of the urethra or residual dead space, or other technical factors. Ljungqvist et al. found recurrence in 11 out of 68 of their patients over 26-year follow-up with a 92% overall satisfaction (10). Repeat urethral diverticulectomy surgery can be challenging due to altered anatomy, scarring, and the difficulty of identifying the proper anatomic planes.

## OUTCOMES

The significance of appropriate preoperative patient counseling regarding surgery and postoperative expectations of cure cannot be overemphasized. Individuals with UD have a myriad of symptoms, including pain, UTIs, and urinary dysfunction. Although these are often related to the presence of the

UD, sometimes they do not resolve even with a technically successful surgery. Nevertheless, surgical outcome for the UD has generally been good. Outcome can be evaluated by resolu-

tion of the patient's symptoms or recurrence of the diverticulum. Successful excision of UD has been reported in 86% to 100% of patients.

## CHAPTER 33 ■ RECONSTRUCTION OF THE FEMALE URETHRA

JERRY G. BLAIVAS AND RAJVEER S. PUROHIT

Reconstruction of the female urethra is technically challenging, but when done correctly can restore anatomy and function in women with a urethrovaginal fistula or urethral stricture using a single procedure. Conversely, surgical failure necessitates multiple operations with decreasing chances of success and may leave patients functionally crippled or in need of a urinary diversion. For this reason, technical proficiency and a comprehensive preoperative diagnostic examination to understand the patient's pathophysiology are mandatory. The goal of surgery should be repair of the damaged urethra in such a way as to allow the patient voluntary, unobstructed, and painless micturition.

In the developing world, the most common cause of urethral damage requiring reconstruction is urethrovaginal fistula resulting from obstetric trauma. Prolonged obstructed labor with compression of the fetal head against the symphysis pubica may cause pressure necrosis of the urethra and, consequently, the development of complicated fistulas. Cesarean section performed to relieve this condition also carries a risk of subsequent fistula formation (1). Where modern obstetric care is available, urethral damage is commonly the result of reconstructive surgery for urethral diverticulum but can also occur from bladder neck suspensions, anterior colporrhaphy, and, rarely, vaginal hysterectomy (Table 33.1). Urethrovaginal fistulas are also caused by erosion of synthetic materials placed during pelvic reconstructive surgery or anti-incontinence procedures (2), locally invasive malignancies, and long-term effects of radiation (3). Less commonly reported

causes include damage from Shirodkar cerclage sutures for cervical incompetence in gravid women, complications from operative vaginal delivery, and pressure necrosis from tightly placed Kelly plication sutures over an indwelling catheter. The presence of an indwelling urethral catheter itself can cause erosive necrosis, typically in the population of paralyzed or

comatose patients. Finally, pelvic trauma can cause laceration of the urethra, usually when accompanied by separation or fracture of the symphysis pubica (4).

---

## DIAGNOSIS

---

A thorough history and physical examination are critical for evaluating a patient suspected of urethral injury. In our experience, pelvic examination will reveal the vast majority of injuries. If concurrent sphincteric urinary incontinence complicates the diagnosis, the urethral meatus can be occluded by the examiner's finger while the patient strains or coughs. If the anterior vaginal wall is visualized with the assistance of a speculum blade placed into the posterior fornix, urinary leakage from the fistula can usually be detected.

Cystoscopic examination is essential in the diagnostic investigation. Cystoscopy enables visualization of the extent of the pathology as well as the evaluation of both concurrent injuries or defects and the quality of the surrounding local tissue that is available for use in a reconstructive procedure. The addition of methylene blue to the cystoscopic irrigant may be useful if a fistula is suspected but has not been observed. After the surgeon occludes the urethra with a partially inflated Foley catheter, the vagina is examined for signs of urinary leakage.

It is important to recognize that urethral damage alone causes neither urinary incontinence nor detrusor instability. In patients who have coexisting urologic symptoms, the physician should be suspicious of injury to the proximal urethra and/or vesical neck. Videourodynamic examination provides vital information about the presence of involuntary bladder contractions, bladder outlet obstruction, ureteral reflex, and bladder compliance and can also identify concurrent fistulas or diverticula. A low urinary flow rate can suggest posttraumatic stricture.

Radiographic imaging is of great value in patients with urethral and urovaginal pathology. Abdominal and pelvic CT with intravenous contrast can reveal complicated fistulas that are associated with concomitant ureteral pathology. Retrograde pyelography should be performed when ureteral injury is suspected and may show ureteral injury despite a normal CT scan.

---

## INDICATIONS FOR SURGERY

---

Surgical repair is usually undertaken due to the presence of urethral obstruction, sphincteric urinary incontinence, or associated vesicovaginal fistula. We advocate the simultaneous correction of all of the coexisting anatomic and functional pathologies that led to the surgery. In patients with sphincteric incontinence, we recommend an autologous fascial pubovaginal sling with a supporting labial fat flap interposed between the vesical neck and the sling and with the vaginal mucosa closed directly over the fascial sling; however, others have alternatively proposed transvaginal bladder neck suspension in patients with favorable anatomy and incontinence due to urethral hypermobility (5).

In our experience, the majority of patients with urethral damage who also have impaired detrusor contractility, low bladder compliance, or detrusor instability improve after urethral

reconstruction; however, patients with radiation damage are unique. The poor tissue quality in this subset of patients makes successful anatomic repair difficult and often results in functional problems. In this situation, supravescical diversion is often the more prudent and successful choice. In such patients, when repair of the fistula is undertaken, it may be wise to use a vascularized muscular flap as part of the initial procedure and to perform synchronous augmentation cystoplasty in patients who have low bladder compliance.

Past teaching suggested that 3 to 6 months of delay was necessary to allow the quality of the local tissue to improve as inflammation and edema subsided; however, we believe that although pliable tissue must be available and free of infection and inflammation, lengthy delay is not necessary, and under the right conditions successful repair can be accomplished within days or weeks of the injury.

---

## ALTERNATIVE THERAPY

---

Alternatives to urethral reconstruction include observation, catheterization, or urinary diversion. Occasionally, women may decide against any form of surgical repair or drainage, particularly if the fistula does not result in any bothersome symptoms or if other significant medical problems preclude operative intervention. Chronic catheterization is an option if patients are too sick to undergo surgery, but this is associated with infections, stones, detrusor spasms, further urethral erosions, and the development of squamous cell cancer. In patients with radiation-induced urethral damage, a urinary diversion may be the best long-term option, although labial fat interposition and rectus or gracilis flaps combined with a buccal graft may be an alternative.

---

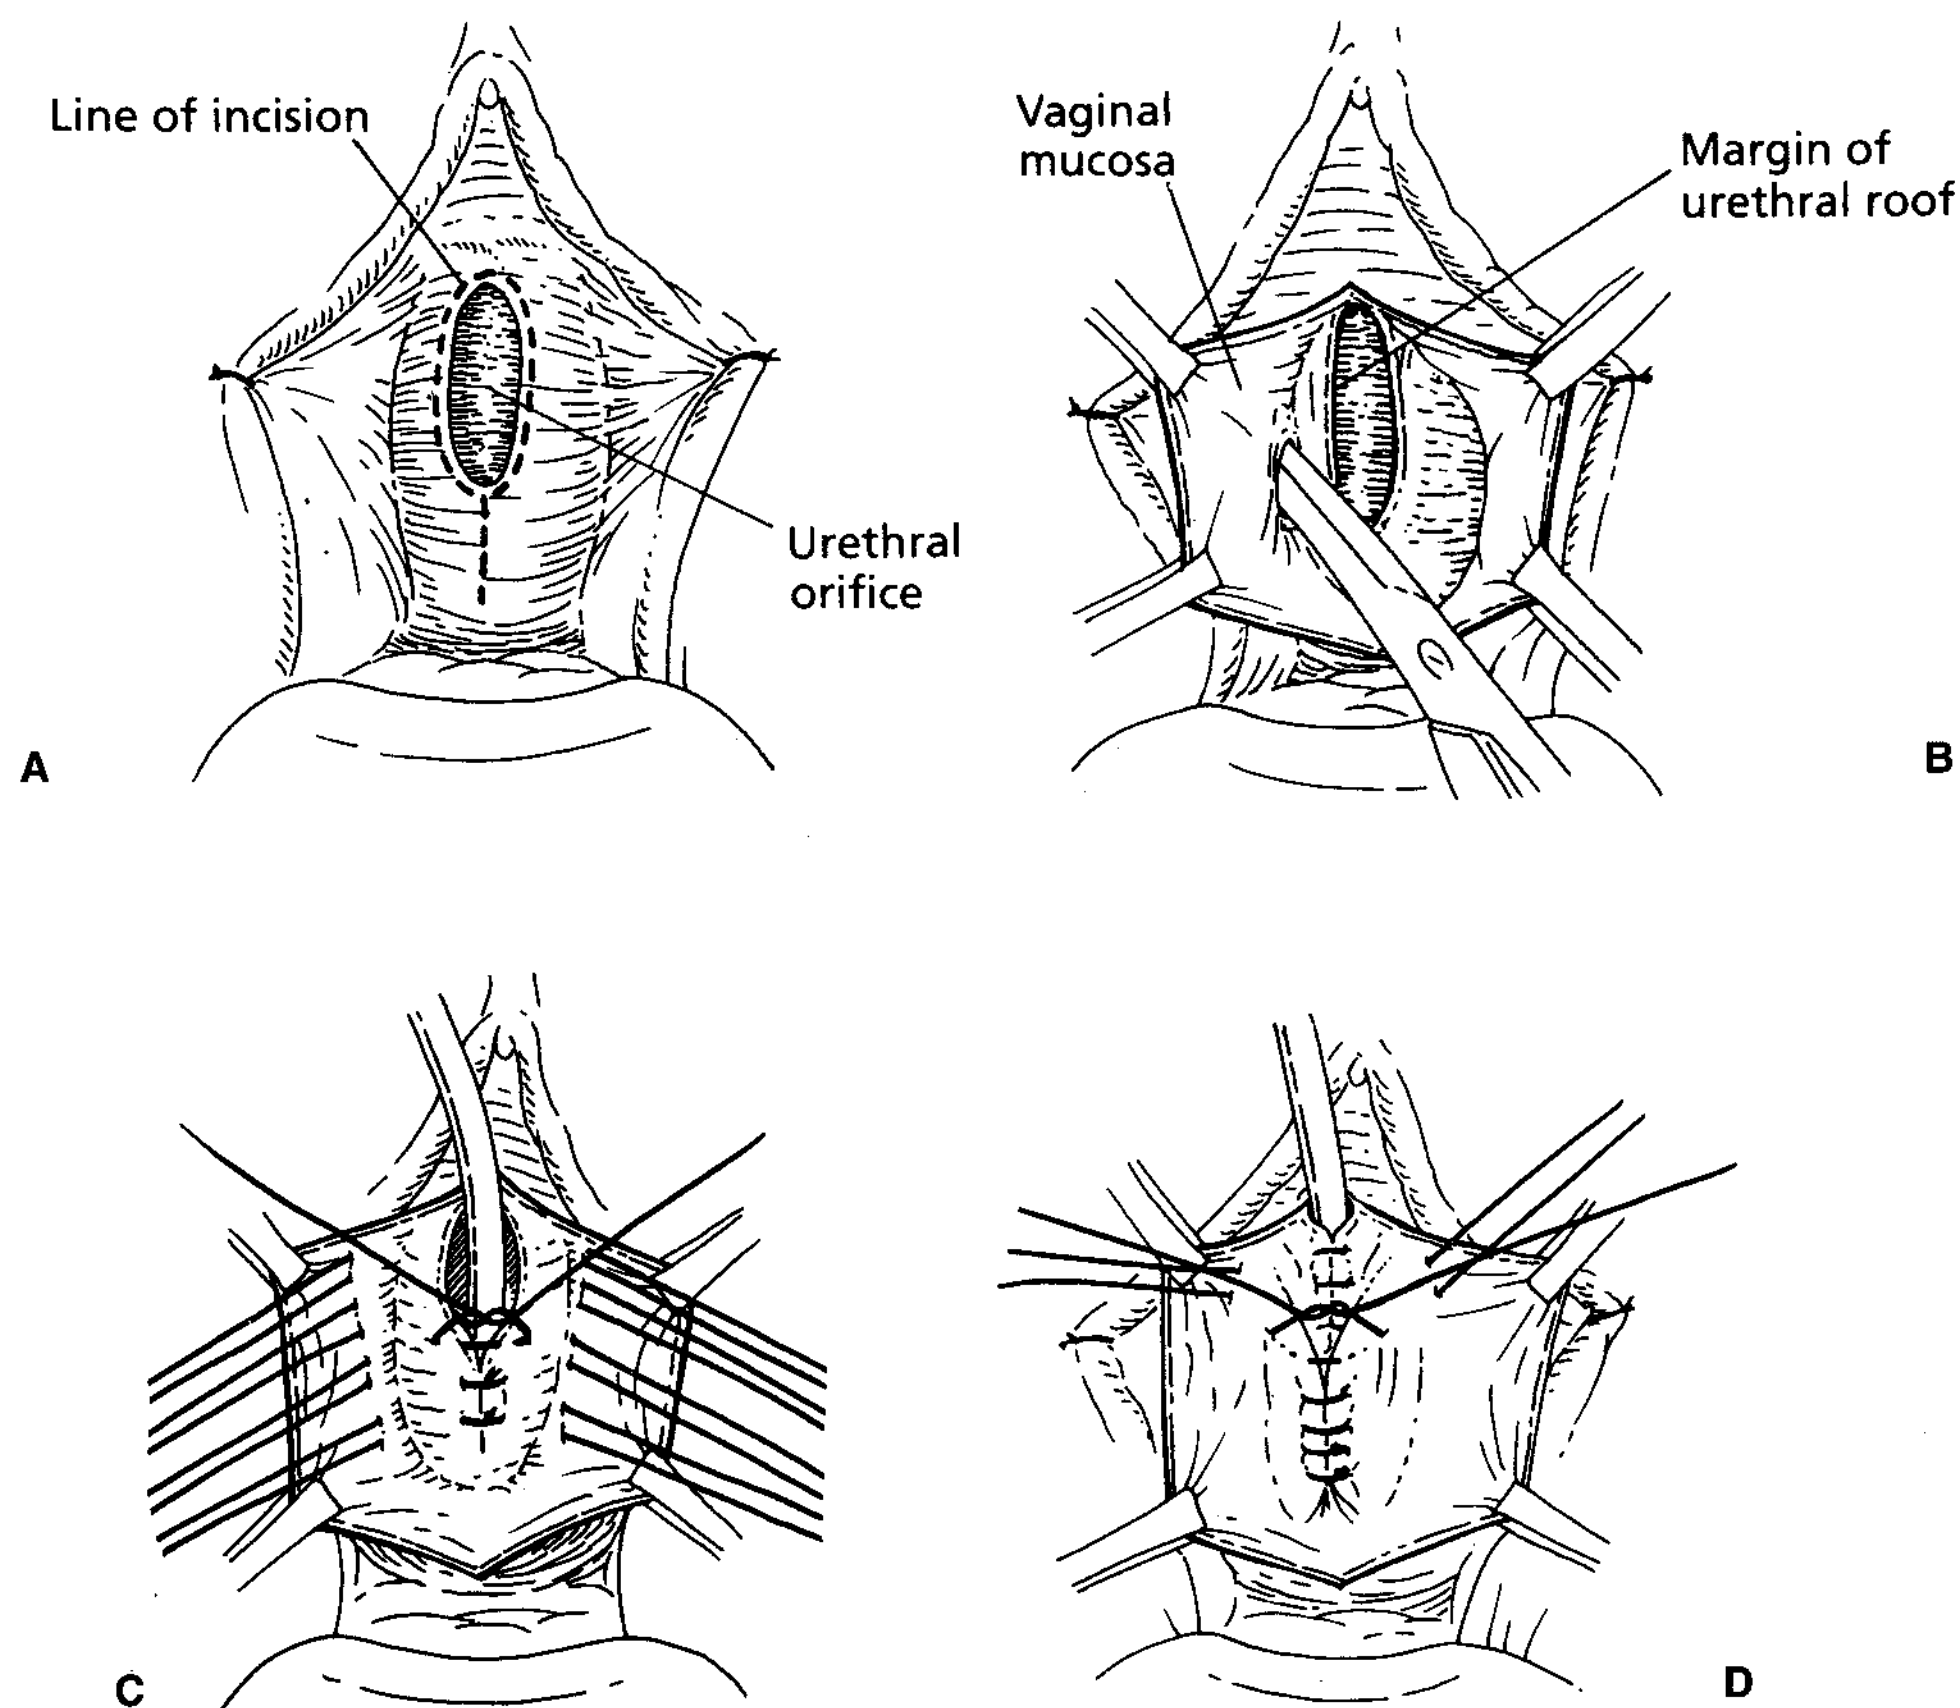

## SURGICAL TECHNIQUE

---

Regardless of the specific nature of the pathology and the precise procedure chosen to correct it, certain general principles should be followed: the operative site should be clearly exposed and the closure tension-free, in multiple layers, with local flaps or relaxing incisions used to mobilize the anterior vaginal wall. Appropriate postoperative bladder drainage is also essential and is accomplished through the placement of a large suprapubic catheter as well as a urethral catheter employed as a stent.

It is usually helpful to employ a well-vascularized pedicle flap to promote healing and prevent fistula formation; potential sources of this flap include the labia majora (6) and the rectus abdominis muscle (7); gracilis myocutaneous (8) or perineal artery axial fasciocutaneous (Singapore) flaps (9) may also be used. Regardless of the specific anatomic findings and the choice of vascular supply, the basic procedure is described as follows.

With the patient in the dorsal lithotomy position, cystourethroscopy is performed and the urethral orifices are visualized. Inadvertent injury to the ureter when the fistula extends close to the trigone can be avoided by placing ureteral stents and removing them at the conclusion of the case. A 14Fr percutaneous suprapubic cystostomy tube is placed under direct visualization unless concurrent abdominal incisions are planned (such as those used in autologous fascial pubovaginal

**FIGURE 33.1** Bladder flap reconstruction. Tanagho anterior bladder flap reconstruction can be used in lieu of vaginal flap reconstruction. (From Tanagho EA. Bladder neck reconstruction for total urinary incontinence: 10 years of experience. *J Urol* 1981;125:321, with permission.)

sling), in which case the placement of the tube is deferred until the end of the procedure. A 16Fr urethral Foley catheter is placed and the balloon inflated to secure the catheter in place at the bladder neck.

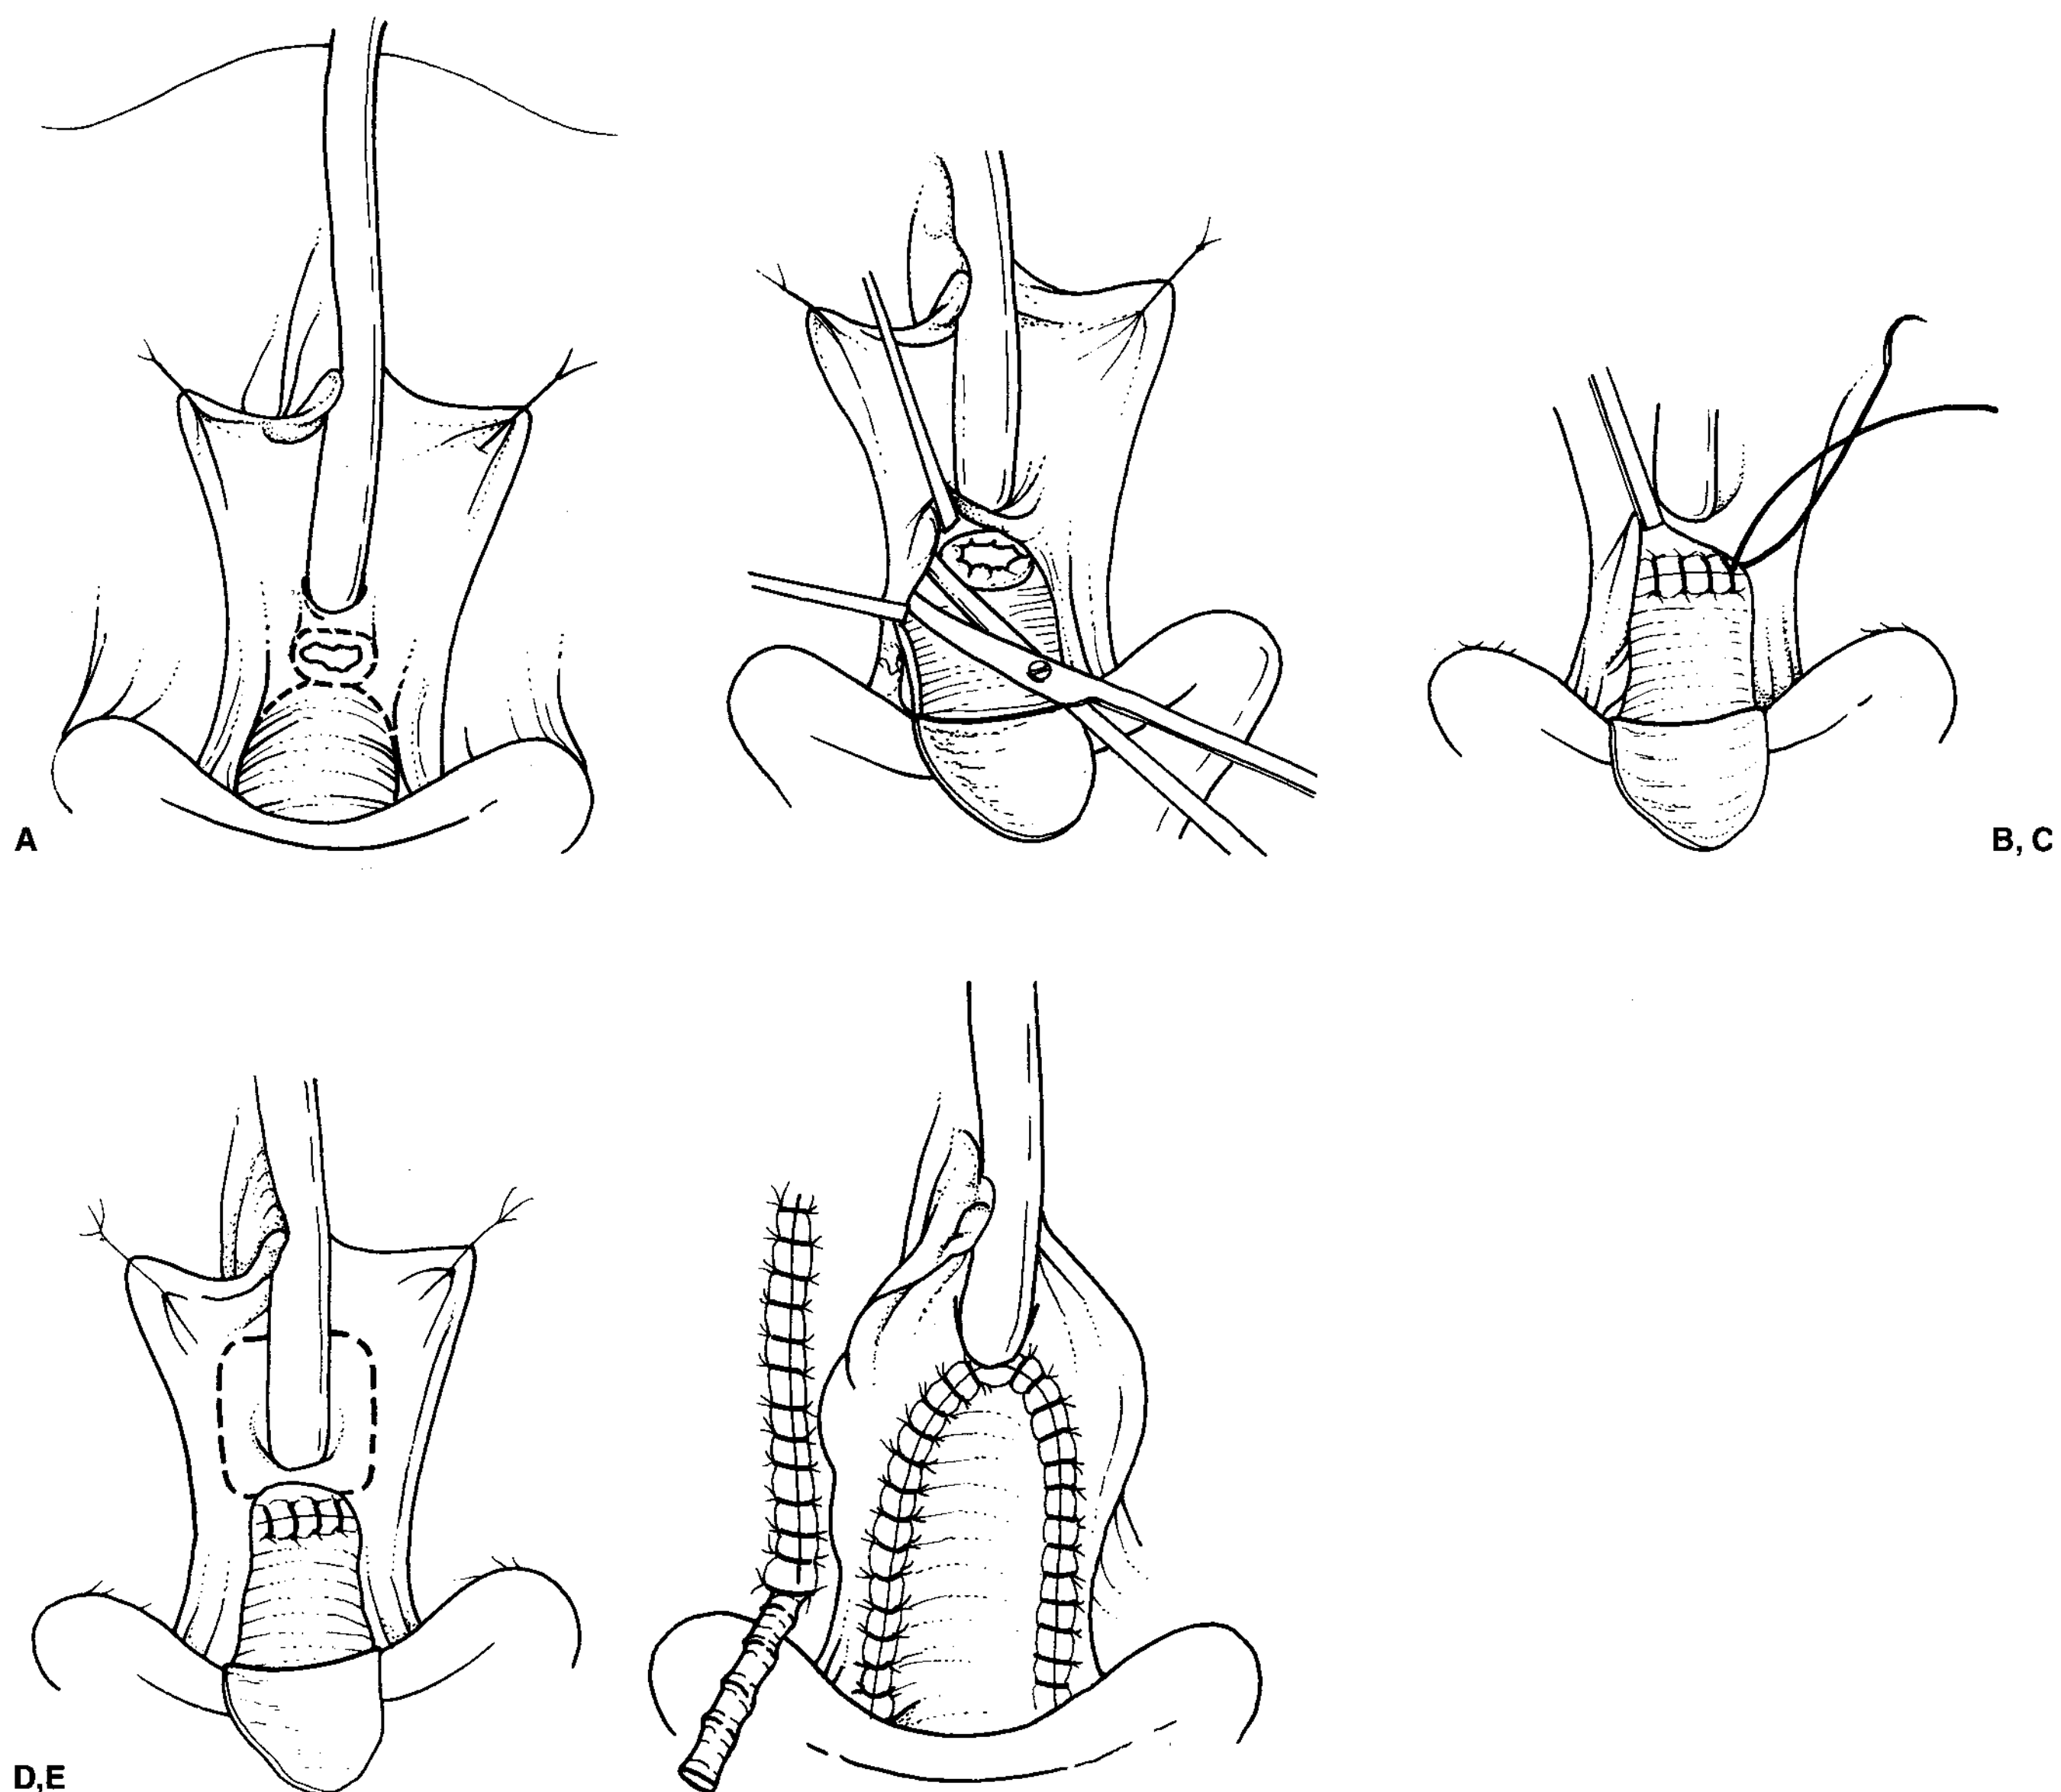

Three basic methods are available for urethral repair, depending on the anatomic defect and the availability of local tissue for flaps: primary closure, local tissue flaps originating from the vaginal wall close to the urethra or from the bladder, or a buccal graft. Small urethral defects can be fixed with a tension-free *primary closure* (Fig. 33.1). The urethra is closed over a 16Fr catheter with interrupted 3-0 or 4-0 chromic

catgut sutures, which in our experience result in less dysuria and long-term urethral pain than do longer-acting synthetic absorbable sutures. If possible, a second layer of periurethral tissue is closed over the first. The vaginal mucosa is closed using lateral flaps elevated alongside the urethral repair or, alternatively, using an inverted U incision of vaginal mucosa; chromic suture is also employed.

If insufficient urethral tissue exists for primary closure, the use of a flap is an alternative. Rotation of a U-shaped *advancement flap* of the anterior vaginal wall is one option (Fig. 33.2). The cephalad aspect of the anterior vaginal wall is mobilized

**FIGURE 33.2** Primary closure. **A:** The fistula is circumscribed. **B:** The lateral vaginal wall flaps are elevated, and the lateral urethral walls are mobilized if possible. **C:** The urethra is closed primarily with interrupted sutures of 3-0 chromic catgut. The vaginal wall is closed either primarily or with a U-shaped flap, depending on the availability of local tissue. (Modified from Mattingly RF, Thompson JD. In: *Telinde's operative gynecology*, 6th ed. Philadelphia: JB Lippincott Co, 1985:662.)

**FIGURE 33.3** Advancement flap. **A:** A U-shaped incision is made with the arms of the U extending caudally as far as the planned urethral meatus. **B:** The flap is elevated and rotated 180 degrees. The flap is sutured to the edges of the parallel distal incisions over the catheter to form the new urethra. The vaginal wall is closed either primarily or with a U-shaped flap, depending on the availability of local tissue. (Modified from Mattingly RF, Thompson JD. In: *Telinde's operative gynecology*, 6th ed. Philadelphia: JB Lippincott Co, 1985:660–661.)

with Metzenbaum scissors, advanced, and rotated to form the posterior and lateral walls of the neourethra, using the urethral catheter as a guide around which the tissue is sutured. The harvested site in the vaginal wall can usually be repaired by closing the lateral and cephalad edges of the wound; however, pedicle flaps are sometimes necessary if the graft is large.

A larger vaginal wall flap can be employed as a *tube flap* (Fig. 33.3) in the case of extensive loss of urethral tissue. A rectangular incision is made with wide margins and the vaginal wall flap is rolled into a tube over the urethral catheter. It is best to provide a vascular pedicle flap for successful wound healing, and a pubovaginal sling is usually required if continence is to be achieved. As with vaginal advancement flaps, the vaginal wound may be too large for primary closure, and a secondary rotational flap of vaginal wall or labia minora can be used to close the principal defect created by the initial

tube graft incisions. In our experience, gracilis myocutaneous and rectus pedicle flaps have been necessary in only 2 of over 110 patients.

In cases of extensive vaginal scarring and urethral damage, there may be insufficient vaginal wall for use in the repair. A *labia minora pedicle flap* (Fig. 33.4) is a potential solution to this problem. The labia is cut as close as possible to the site of the urethral repair and in such a manner as to allow a rotational patch graft or tube graft of labial mucosa to be employed as a neourethra that is loosely approximated over the urethral catheter. The graft with underlying vascular supply is passed beneath the vaginal wall such that the mucosal surface forms the inner wall of the reconstructed urethra.

At the conclusion of the procedure, a Penrose drain is placed in the labial harvest sites if applicable and is removed usually on postoperative day 1 or 2. The Foley catheter should

**FIGURE 33.4** Tube graft. **A:** An inverted U-shaped incision is made in the anterior vaginal wall with the apex of the U at the vesical neck just proximal to the urethral fistula. The fistula is circumscribed. **B:** A plane is created in the avascular plane just underneath the vaginal epithelium, and the vaginal wall flap is reflected posteriorly. If a pubovaginal sling is to be performed, the dissection into the retropubic space is completed at this time. **C:** The urethrovaginal fistula is closed with interrupted sutures of 3-0 or 4-0 chromic catgut. **D:** Two parallel incisions are made alongside the Foley catheter, and medially based flaps are elevated. **E:** The vaginal and labial wounds are closed. (From Blavais JG. Vaginal flap urethral reconstruction. An alternative to the bladder flap neurourethra. *JUrol* 1989;41:542–545, with permission.)

be fixed in a tension-free manner to the anterior abdominal wall to prevent trauma and pressure necrosis of the repair; this catheter is usually removed within postoperative days 2 to 5, before the patient is discharged from the hospital. A voiding cystourethrogram should be performed through the suprapubic catheter about 2 weeks after the procedure. If the patient successfully voids and there is no extravasation, the suprapubic catheter can be removed; if not, the voiding trial is repeated in another 2 weeks. None of our patients has required a catheter for longer than 4 weeks.

Alternatives to vaginal wall flaps include anterior and posterior bladder flaps. Creating a neourethra using these methods is possible with a comparable degree of success to the procedures

outlined previously; however, continence is not as easily achieved, with success rates of about 50% (6). Accordingly, we prefer vaginal reconstruction with anti-incontinence surgery as the preferred management of urethral injury associated with incontinence rather than employing these alternatives and their associated complications. Nonetheless, when extensive vaginal scarring in conjunction with large fistulas precludes vaginal flap reconstruction, a bladder flap procedure is an option (Fig. 33.5).

After the edges of the fistula are dissected free from the pubic rami and the anterior and inferior aspect of the bladder is separated from its attachments, a rectangular flap of anterior bladder wall is raised and rolled into a tube over a 16Fr catheter. The distal end of this tube is sutured either to the vaginal portion of the remaining urethra or at the site of the new urethral meatus. “Fixation sutures” are used to attach the neourethra/tubular bladder flap to the pubic periosteum, and a Martius fat pad is placed beneath the suture lines (6).

While skin grafts have not been widely utilized, buccal mucosal grafts have been employed for repair of female urethral strictures (10,11). We generally use a two-team approach to harvesting the graft, with the oral cavity prepared and draped separately and instrument trays also kept separate. A Steinhauser mucosal retractor is used to improve visualization, and the graft harvest site is marked and lidocaine with epinephrine injected just below the mucosa. The graft is incised and removed sharply, taking care to remain in the fatty layer superficial to the buccinator muscle. Once removed, the graft is defatted and the wound closed primarily. The graft tissue has been used on the dorsal urethra, where it is quilted to the adventitia of the clitoris and the urethra anastomosed to this (10). Buccal grafts have also been sutured to the ventral (vaginal) edge of the urethra after the stricture is incised (11).

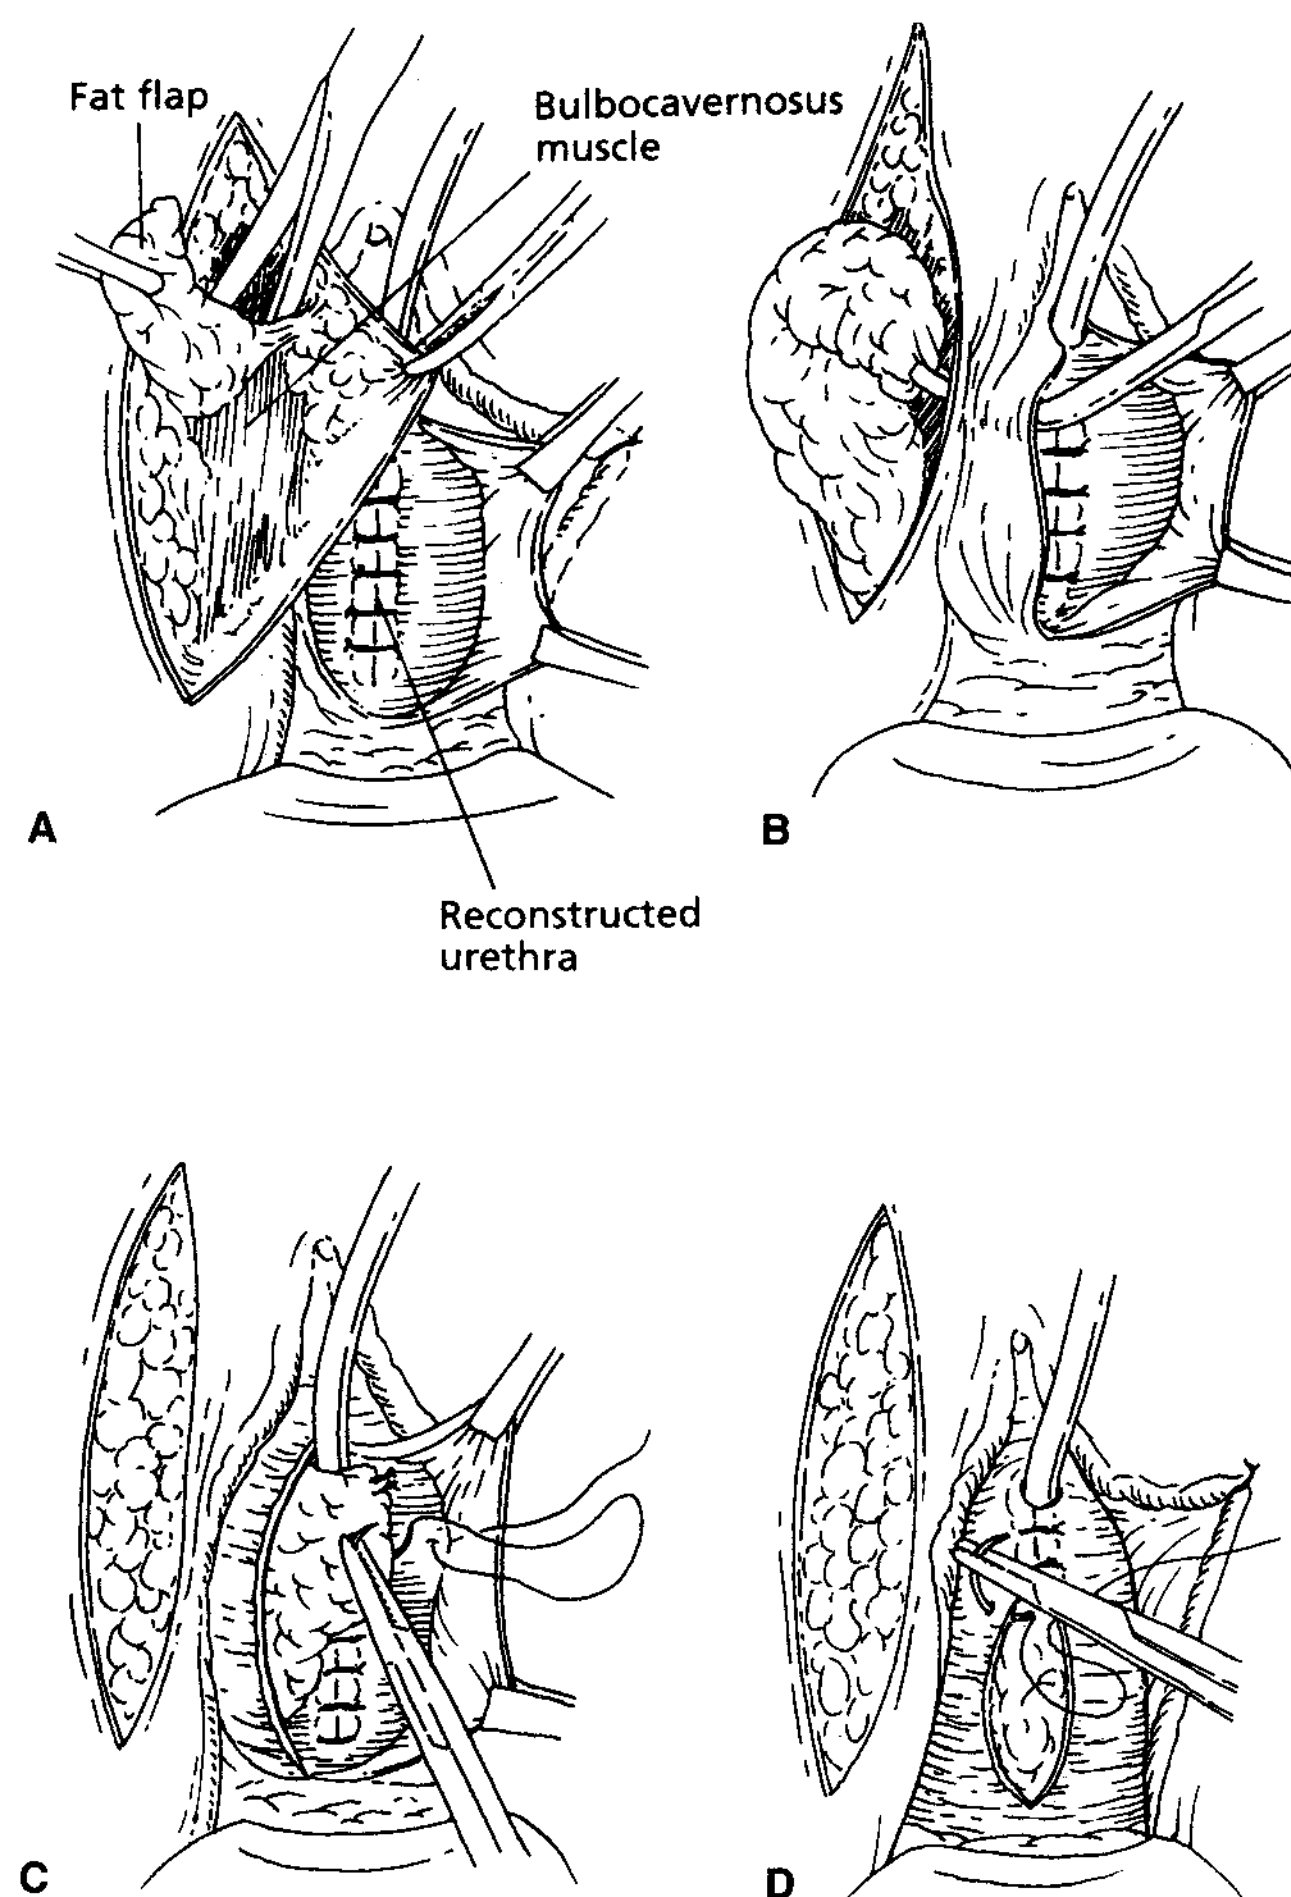

An autologous fascial pubovaginal sling can be prepared as part of the reconstructive procedure (Fig. 33.6) in cases associated with sphincteric incontinence or fistula where extensive dissection under the bladder neck puts the patient at risk for postoperative incontinence. Further, we recommend against the use of synthetic materials for concurrent incontinence surgery due to the risk of complications from erosion of the synthetic graft. It is crucial to note that if a pubovaginal sling is to be employed, it is harvested, but no vaginal dissection is performed to place the sling until after the urethra is repaired; vaginal tissue should not be compromised by additional incisions until successful repair of the urethra is complete, leaving the widest variety of possible solutions to the patient’s primary problem.

A Pfannenstiel incision is made approximately two finger breadths above the symphysis pubica. The surface of the rectus fascia is freed from adherent subcutaneous tissue and two parallel horizontal incisions are made in the midline, defining the 2- to 3-cm width of the rectus fascial strip that will become the sling. These incisions are extended laterally and superiorly until approximately 10 cm of fascia is marked by the parallel incisions. The fascial strip is then freed from the underlying muscle and scar using careful sharp dissection. Each end of the sling is then secured with long 2-0 nonabsorbable monofilament sutures and a running mattress suture directed across the width of the sling. The sling is then cut free, and the security of the suspension sutures is checked by pulling each suture separately with moderate tension created by grasping each end of the fascia; it is then placed in a saline bath.

**FIGURE 33.5** Labia minora pedicle graft. **A:** An oval incision in the labia minora mobilizes the labial tissue and underlying fat. **B:** The flap is passed through the wall of the labia minora and sutured into position as a neourethra with the mucosal surface of the labia becoming the interior of the neourethra.

**FIGURE 33.6** Pubovaginal sling. **A:** A 2- to 3-cm-wide graft is outlined with the incision kept parallel to the direction of the fascial fibers. The incision is extended laterally to the point where the fascia divides and passes to the internal and external oblique muscles. **B:** A 2-0 nonabsorbable running horizontal mattress suture is placed across the most lateral portion of the graft, and the ends are left long. **C:** Each end of the fascial graft is transected approximately 1 cm lateral to the mattress suture. **D:** Dissection is begun with Metzenbaum scissors in the avascular plane just beneath the vaginal epithelium. The tips of the scissors are directed toward the patient's ipsilateral shoulder. **E:** The endopelvic fascia is perforated with the index finger and the retropubic space is entered. **F:** A long DeBakey clamp is passed from the abdominal to the vaginal wound lateral to the urethra. **G:** The fascial graft is passed around the urethra and brought to the abdominal wound on either side. **H:** The long ends of the sling are tied together in the midline with no tension. The labial fat pad is positioned between the sling and the vesical neck. (A–G from Blavais JG. Pubovaginal sling procedure. In: Whitehead ED, ed. *Current operative urology*. Philadelphia: JB Lippincott Co, 1990: 93–101, with permission.)

The lateral edges of the vaginal incisions are retracted laterally using Allis clamps, and a closed Metzenbaum scissor is used to dissect bluntly into the retropubic space, keeping the scissor directed laterally by exerting pressure against the lateral aspect of the underside of the vaginal mucosa. There is usually a distinct and abrupt decrease in tissue resistance as the retropubic space is entered. The surgeon then places a fingertip into the dissected tract and further mobilizes the bladder neck and urethra through blunt dissection. With the

surgeon's finger displacing the vesical neck medially, a long, curved (DeBakey) clamp is fed abdominally under the inferior aspect of the free rectus fascia, against the pubic periosteum, and is then guided by the surgeon's abdominal hand onto the lateral aspect of the vaginal fingertip, thus protecting the bladder from injury.

The clamp is then fed through into the vagina, where it is used to grasp and pull through one of the nonabsorbable sling sutures into the abdominal wound. The procedure is repeated on the contralateral side, and the absorbable sutures are threaded through separate small stab incisions of the inferior leaf of the rectus fascia. Following this, the rectus fascia is closed using 0 delayed absorbable monofilament suture, and the vascular pedicle graft is positioned between the pubovaginal sling and reconstructed urethra (Fig. 33.7). The vaginal mucosa is then closed, and at the conclusion of the operation the long ends of the sling are tied together in the midline over the rectus fascia without any tension at all.

## OUTCOMES

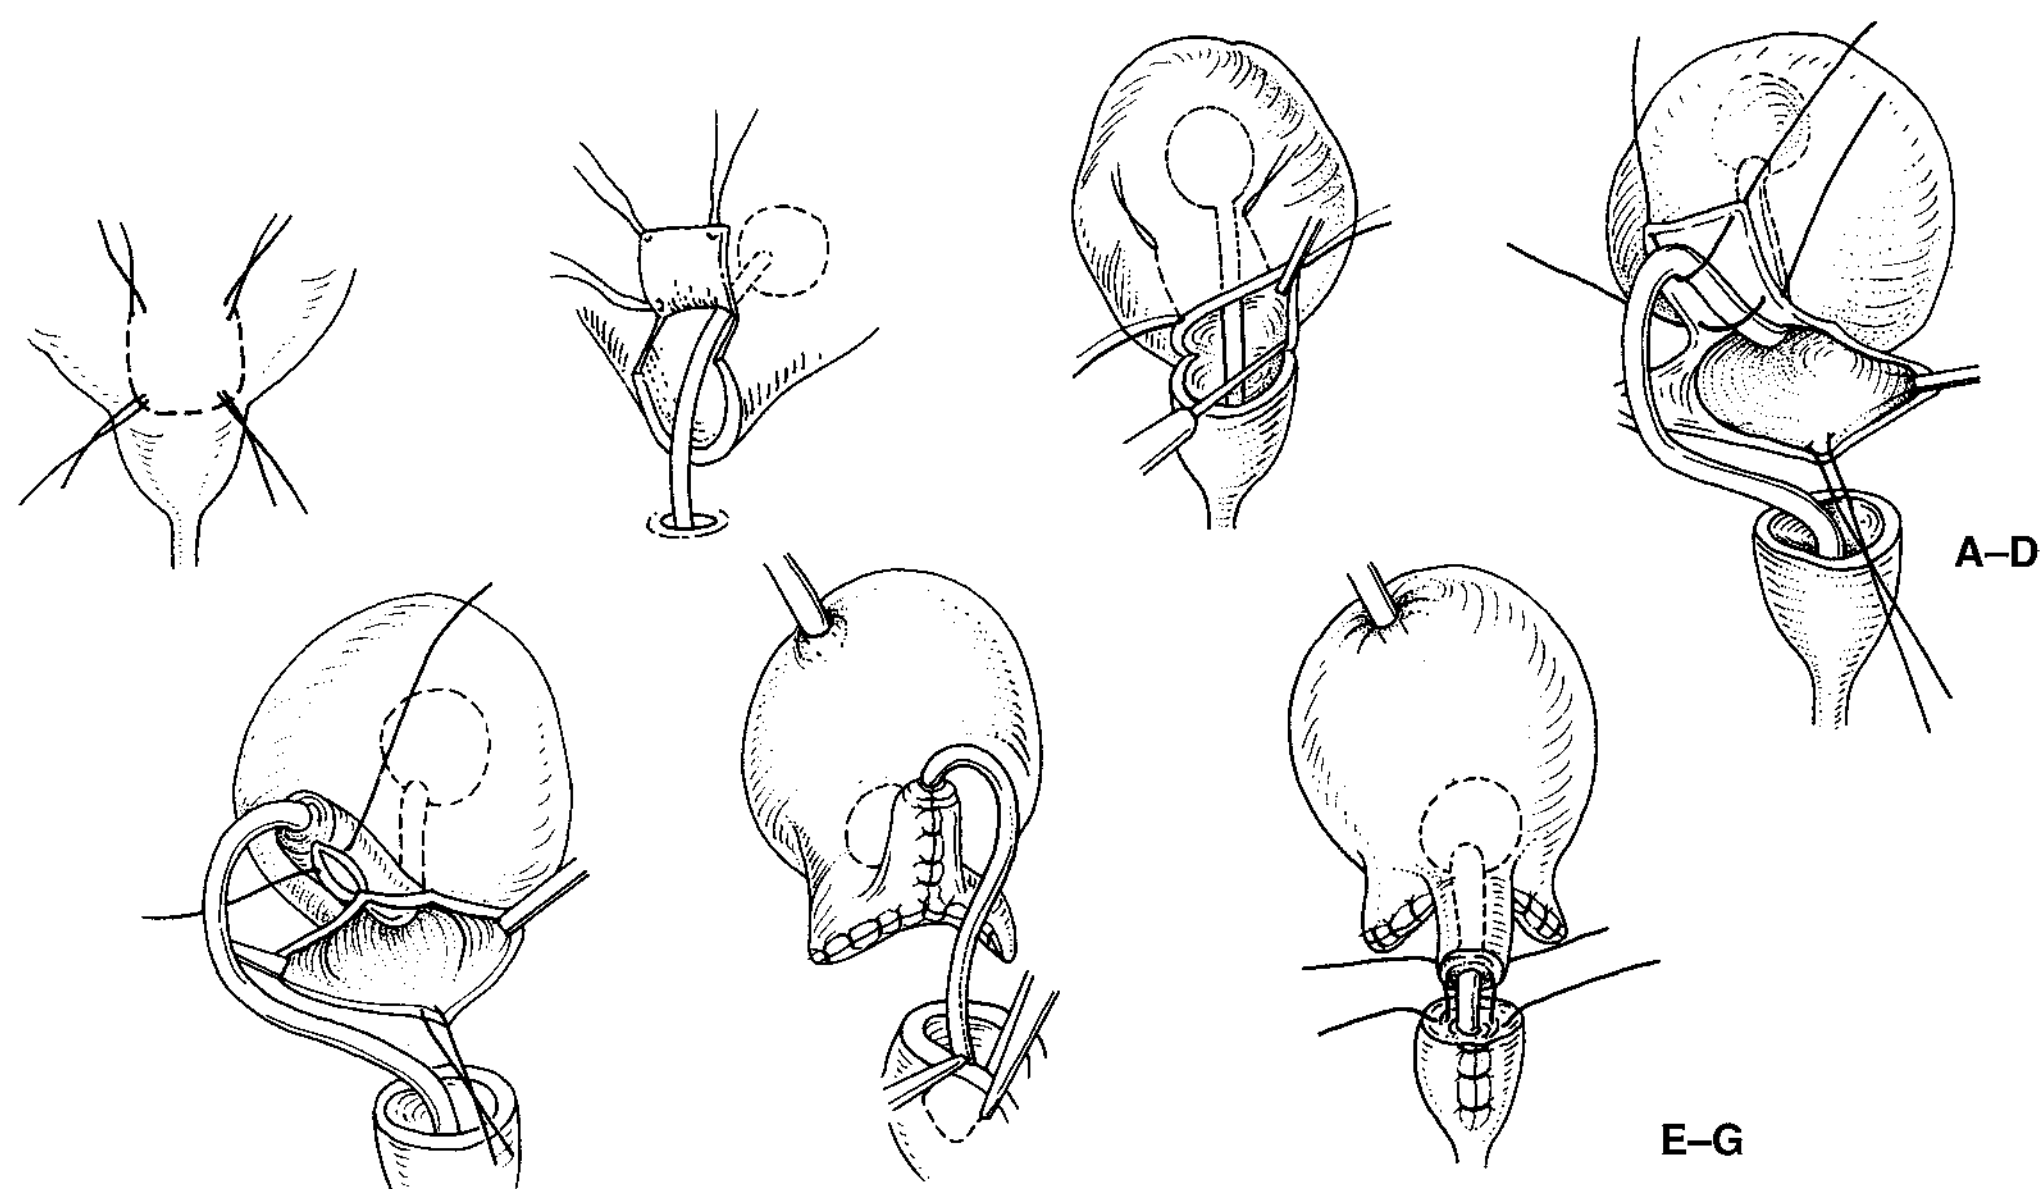

### Results

A review of published results reveals that successful anatomic reconstruction has been reported in 67% to 100% of cases, with emphasis on the need for vascular pedicle flaps to ensure viability of the repair (5,12). Continence varied from 55% to 93% in patients after a single operation, and resulting urethral obstruction varied from 2% to 41%; however, most studies did not specify the method of evaluating continence. It was clear that anti-incontinence procedures were in general successful and dramatically improved the continence rates, with postoperative incontinence in 50% to 84% of patients who underwent anatomic reconstruction only. Table 33.2 summarizes these studies.

We have performed 110 urethral reconstructive procedures in women. All but 1 underwent primary or vaginal wall repairs, and the 1 Tanagho anterior bladder flap was unsuccessful because of refractory overactive bladder. A Martius flap was used in all but 4 patients. We did not perform pubovaginal sling routinely until later in the series, and 50% of the early patients who underwent modified Pereyra procedures were incontinent; of these, all were subsequently cured or improved by a pubovaginal sling. For this reason we are strongly in favor of a pubovaginal sling for concurrent anti-incontinence surgery.

### Complications

Three patients experienced necrosis of the flap, which in one case was associated with the development of sphincteric incontinence and in one with overactive bladder. One patient had urinary obstruction from the pubovaginal sling, and one patient had an unrecognized vesicovaginal fistula that was successfully repaired transvaginally. All patients who suffered from sphincteric incontinence were cured or improved by successful reoperation at 1 year follow-up, except for one patient who declined surgery. No patients required intermittent catheterization.

**FIGURE 33.7** Vascular pedicle graft. **A:** Incisions in the labia majora expose the underlying fat pad, which is suture-ligated at its superior margin and mobilized posteriorly. **B:** The graft is drawn through a perforation in the vaginal wall. **C:** A 2-0 chromic catgut suture is used to fix the graft over the reconstruction. **D:** The vaginal wall is closed over the reconstruction. If a pubovaginal sling is performed, it is placed beneath the vaginal wall prior to the closure. (Modified from Mattingly RF, Thompson JD. In: *Telinde's operative gynecology*, 6th ed. Philadelphia: JB Lippincott Co, 1985:663.)

Urethral reconstruction in women can be highly complicated and requires considerable surgical expertise as well as a thorough diagnostic workup. In most women successful anatomic and functional repair can be achieved with a single

surgical procedure employing vaginal flap reconstruction with a grafted vascular supply and a pubovaginal sling as an anti-incontinence measure. Bladder flap techniques can also be used, especially in cases of extensive vaginal scarring.

# CHAPTER 34 ■ SURGICAL MANAGEMENT OF THE INCOMPETENT BLADDER OUTLET IN THE PATIENT WITH A NEUROGENIC BLADDER

ALIENOR S. GILCHRIST, GARY E. LEMACK, AND PHILIPPE E. ZIMMERN

Patients with a neurogenic bladder can exhibit one of two main abnormalities of the urethra and bladder neck: bladder outlet overactivity, leading to obstruction, and bladder outlet underactivity, leading to incontinence.

Detrusor contraction with involuntary contraction of the urethra and/or sphincter, known as detrusor striated sphincter dyssynergia (DSD), is a common pattern of voiding dysfunction in patients with suprasacral spinal cord lesions. Sphincterotomy is the gold standard for treatment of DSD and renders the patient completely and continuously incontinent via endoscopic incision of the external urethral sphincter at the 12 o'clock position. Sphincterotomy may also ameliorate symptoms of autonomic dysreflexia in patients suffering from this condition (7). Risks associated with the procedure include erectile dysfunction, hemorrhage, and urinary extravasation. Patients are subsequently managed with a condom catheter, which can lead to skin breakdown and ulceration. Some patients may require a concurrent bladder neck incision to treat obstruction, and in many cases a repeat incision may ultimately be required as the efficacy may diminish over time.

Incontinence in the neurogenic population can originate from sphincteric and bladder neck deficiency in addition to detrusor overactivity. Outlet insufficiency is frequently neurologic in origin but may also arise from iatrogenic destruction of tissue from long-term urethral catheter use. For patients with sphincteric incompetence, a variety of treatments exists, including injectables, slings, artificial urinary sphincters (Fig. 34.1), adjustable continence therapy, and bladder neck closure with tissue interposition.

Bladder neck closure (BNC) is an uncommon procedure that has traditionally been reserved as a final alternative for the management of the female patient with neurogenically induced intractable incontinence arising from long-term urethral catheter drainage (9,14). It has also been used in the treatment of nonneuropathic conditions such as traumatic urethral destruction or fistulas that have failed surgical repair. BNC in men is usually reserved for patients with incontinence secondary to neurogenic bladder, recalcitrant urethrocutaneous fistula, or trauma who have failed surgical correction or artificial sphincter placement. In recent years, salvage prostatectomy and BNC in the management of recurrent prostate cancer after radiation therapy and in the management of severe complications after salvage cryotherapy have been reported (5).

---

## DIAGNOSIS

---

Preoperative evaluation and patient selection are extremely important to the success of BNC. A detailed history should elicit any prior abdominal or pelvic surgeries, including previous reconstructive flaps or grafts. A thorough physical examination is important to assess for the following: (a) the presence of lower-extremity contractures that may limit vaginal access; (b) perineal skin integrity and the presence of decubitus; and (c) a body habitus that may impede successful intermittent catheterization. In patients with adequate manual dexterity or a reliable caregiver, a catheterizable efferent limb from the

TABLE 34.1

## COMPARISON OF APPROACHES TO BLADDER NECK CLOSURE IN THE FEMALE PATIENT

FACTOR	VAGINAL CLOSURE	ABDOMINAL CLOSURE
Multiple prior abdominal procedures	Preferred approach	Alternate approach
Prior radiation	No prior pelvic radiation	History of pelvic radiation
Postoperative drainage	Suprapubic tube drainage	Desires incontinent vesicostomy or catheterizable bladder drainage
Vascularized interposition	Martius flap	Omentum; rectus flap; peritoneal flap
Lower-extremity flexibility	Adequate	Impaired
Perineal skin condition	Adequate	Decubitus or infected

bladder may be chosen for postoperative drainage. When intermittent catheterization is not feasible, postoperative bladder drainage is achieved via suprapubic tube or incontinent ileovesicostomy (8).

Evaluation of the upper urinary tract is important, and when upper-tract deterioration is noted, strong consideration must be given to supravescical diversion or bladder preservation with augmentation cystoplasty to lower intravesical pressures. A voiding cystogram may assist in detecting bladder diverticula or vesicoureteral reflux. In most cases, reflux should resolve after regularizing intravesical pressures (in the case of augment), and therefore ureteral reimplantation is typically not recommended unless severe obstruction at the level of the ureterovesical junction is noted on preoperative imaging. In the case of urethral fistula or stricture, a retrograde urethrogram or fistulogram can document the nature and extent of the patient's underlying disease.

Cystoscopy with biopsy to exclude bladder malignancy is essential for patients managed long term with indwelling catheters. The extent of urodynamic evaluation is tailored to the type of postoperative bladder management. In patients desiring continent, catheterizable access to the bladder, preoperative urodynamic or preferably video-urodynamic evaluation of bladder storage parameters such as capacity, compliance, and detrusor overactivity helps determine the need for concomitant augmentation cystoplasty.

---

## INDICATIONS FOR SURGERY

---

### Women

Patients suffering from neurogenic incontinence often have intractable leakage from urethral destruction due to the long-term effects of an indwelling urethral catheter. A common indication is the patient with advanced multiple sclerosis and detrusor overactivity resulting in leakage around the catheter or repeated catheter extrusions. Though control of incontinence has been achieved by some using a pubovaginal sling, many patients with urethral destruction and reduced urethral length are not suitable candidates for this procedure (2,10). The indications for bladder neck closure in the nonneurogenic patient are urethral destruction, severe intrinsic sphincteric deficiency that is not amenable to or has failed conventional treatment, and failed urethrovaginal fistula repair. For the woman who has failed attempts at urethrovaginal fistula

closure, BNC with a continent catheterizable efferent channel, incontinent vesicostomy, or suprapubic tube may represent a viable option for management.

The vaginal approach is favored in the patient without history of prior radiation who desires suprapubic tube drainage. An abdominal approach is preferred for the patient with a history of radiation in whom vaginal tissues may be poorly vascularized and in whom omental interposition between the bladder neck and vagina is desirable. It is also the approach of choice in the patient who elects a continent efferent limb (bowel or appendix) or an incontinent ileovesicostomy, or has failed a prior attempt at vaginal closure of the bladder neck (Table 34.1) (8).

---

### Men

---

The role of BNC in men with benign disease resides in the management of refractory urethrocutaneous or urethrorectal fistula and in cases of severe neurogenic or postoperative incontinence (with low outlet resistance) when an artificial sphincter is not an option. It may also be used in the treatment of recalcitrant urethral strictures when reconstruction is impossible or undesired. BNC may be considered in conjunction with salvage prostatectomy for locally recurrent prostate adenocarcinoma after radiation therapy. Complications encountered after salvage cryotherapy, such as osteitis pubis, recurrent gross hematuria, bladder outlet obstruction, urinary incontinence, puboprostatic fistula, urethral stricture disease, and intractable perineal pain, can be managed by prostatectomy with BNC as well.

---

## ALTERNATIVE THERAPY

---

Options for local reconstruction in women with severe incontinence or fistula are limited. Though urethral reconstruction with vaginal wall or bowel is an available option, maintaining a urethral outlet that is both patent and continent can prove extremely challenging. Continence following these reconstructive procedures may be provided by autologous or synthetic sling materials, injectable bulking agents, an artificial urinary sphincter, or bladder neck reconstruction (Young-Dees) (2). In men with refractory incontinence or fistula, when previously irradiated tissue is not present, the artificial urinary sphincter and formal fistula closure are other viable alternatives.

A

B

**FIGURE 34.1** **A:** Lateral view cystogram in a severely incontinent woman demonstrating a wide open and incompetent bladder neck and proximal urethra. **B:** Intraoperative view of AUS placement at the bladder neck with a 10 cm cuff and a 61–70 cm H<sub>2</sub>O pressure reservoir in the same patient.

Historically, supravescical diversion and ureterosigmoidostomy (nonneurogenic patients) have been advocated for treatment of patients with this severity of incontinence. However, it is our opinion that BNC should be considered before embarking on these more extensive surgical options. BNC not only preserves the bladder, but it also preserves the integrity of the ureterovesical junction, thereby protecting the upper tracts. In addition, BNC is performed through either a vaginal or retropubic approach, avoiding complications associated with open abdominal surgery.

---

## SURGICAL TECHNIQUE

---

The goals of the procedure are the same for both male and female patients, regardless of the approach utilized. These goals include wide mobilization of the bladder neck to allow for tension-free closure; multilayer closure of the outlet without overlapping suture lines, thereby reducing secondary fistula formation; interposition of vascularized tissue between the vesical outlet and urethral stump or vagina; and adequate postoperative bladder drainage with a large-bore catheter.

---

### Vaginal Approach (Women)

---

The vaginal approach is preferred in the woman who will be managed with suprapubic tube drainage, has no history of prior radiation, and is not undergoing a concomitant abdominal procedure. Preoperative preparation includes antibiotics to sterilize the urine, vaginal douching, and deep venous thrombosis prophylaxis. The patient is placed in high lithotomy position with careful attention to padding of all pressure points and extremities. A Lone Star ring retractor (Houston, TX) is recommended along with a weighted vaginal speculum and headlight to provide maximal vaginal exposure. In the

case of a small contracted bladder, a curved Lowsley retractor is employed to place a suprapubic tube. The patient is placed in deep Trendelenburg position to displace bowel contents, and the curved retractor is introduced through the urethra and directed to the anterior abdominal wall 1 to 2 cm above the symphysis pubica. A small suprapubic incision is made over the tip of the Lowsley, which can be palpated beneath the fascia. The tip of the retractor is then pushed out through the skin incision, and a 20Fr Foley catheter is grasped between the open jaws and delivered back into the bladder. Its intravesical position can be confirmed with cystoscopy or irrigation with normal saline.

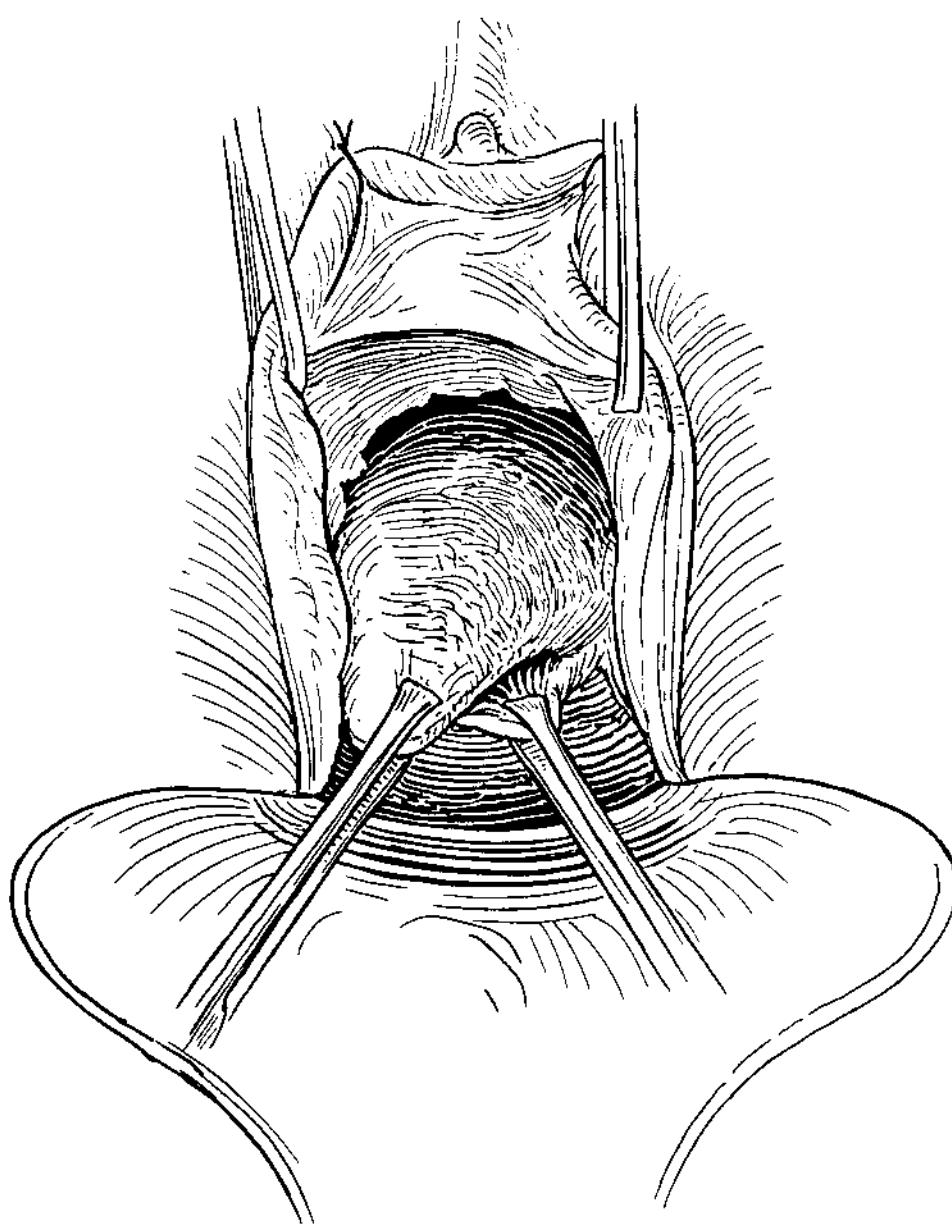

A waterproof surgical ink pen marks the proposed inverted U-shaped vaginal wall incision. Normal saline or a dilute solution of vasopressin 60 U per 100 cm<sup>3</sup> is injected into the periurethral tissues and anterior vaginal wall to facilitate dissection of both the urethra and anterior vaginal flap. Vasopressin can reduce local bleeding (Fig. 34.1).

After a circumscribing incision has been made around the destroyed urethra, a broad-based vaginal flap is elevated (Fig. 34.2). This flap not only aids in the exposure of the remainder of the bladder neck dissection, but will also serve as an advancement flap over the closed vesical outlet and interposed labial fat pad graft. The bladder neck is freed from its lateral and anterior fascial attachments to achieve a tension-free closure (Fig. 34.3). The anterior mobilization includes detaching the bladder neck from the pubic symphysis attachments with sharp and blunt dissection and entering the retropubic space. Main concerns during this portion of the case include bleeding and injury to the bladder. Indigo carmine is given intravenously to aid in visualizing the ureteral orifices. Remnant urethral edges, when present, may be trimmed before formal closure.

The bladder neck is closed in a vertical fashion with absorbable suture (Fig. 34.4). The bladder is then filled through the suprapubic tube to ensure that the closure is

**FIGURE 34.2** Elevation of the vaginal flap.

**FIGURE 34.3** Detachment of the bladder neck.

watertight. To reduce the likelihood of secondary vesicovaginal fistula, a second horizontal layer of interrupted sutures imbricates the first layer in such a way that the closed bladder outlet is elevated to a position high behind the symphysis pubica (Fig. 34.5). This technique not only avoids a dependent closure but also directs the force of bladder spasms away from the vagina.

The use of a Martius flap is recommended to reinforce the bladder neck closure and reduce the risk of fistula. The technique relies on a well-vascularized fibrofatty labial pad (from the labia majora) that is based posteriorly on a labial branch

**FIGURE 34.4** Primary closure with tension-free anastomosis.

of the internal pudendal artery. The Martius flap is tunneled beneath the vaginal wall and fixed in place over the bladder neck closure (Fig. 34.6). The vaginal flap is advanced to close the vagina (Fig. 34.7). The vagina is packed for 24 hours with an antibiotic-soaked pack.

### Abdominal Approach (Women)

The patient is placed in low lithotomy position with adjustable stirrups to provide continuous access to the vagina. Alternatively, if lower-extremity contractures prohibit the lithotomy position, the supine position may be used. A urethral Foley catheter is placed, and an infraumbilical midline incision is made. This incision not only provides excellent exposure but also can be extended for omental harvest or use of bowel for an efferent catheterizable limb. A Pfannenstiel incision may be considered if a chronic suprapubic tube has been chosen for long-term bladder management. The rectus muscles are retracted laterally, and the prevesical space (Retzius) is developed bluntly. The peritoneum is retracted superiorly, and a self-retaining retractor (Balfour or Bookwalter) provides exposure of the retropubic space.

By palpating the Foley catheter balloon, the bladder neck and urethra are identified. An absorbable figure-of-eight suture is placed through the distalmost aspect of the deep dorsal vein over the proximal urethra. Using electrocautery or sharp dissection, the anterior bladder neck is incised over the most distal aspect of the Foley catheter. The lip of the bladder neck is grasped with traction sutures or Allis clamps, and the Foley catheter is identified and delivered into the surgical field. After intravenous administration of indigo carmine, ureteral catheters may be placed for safe dissection of the posterior bladder neck (Fig. 34.8). Placing a hand in the vagina can help identify and maintain the appropriate plane between the posterior bladder neck and the vaginal wall. Using electrocautery or sharp dissection, the posterior bladder neck is freed from the anterior vaginal wall. This dissection

**FIGURE 34.5** A: Photograph of closure of the bladder neck. B: Lateral view of bladder neck closure.

**FIGURE 34.6** A: Martius flap tunneled beneath the labia minora. B: Intraoperative photograph of Martius flap to close over the bladder neck.

continues until the bladder neck is rolled up and out of its dependent position. The edges of the bladder neck are trimmed to allow approximation of healthy tissues, and the ureteral catheters are removed. If an incontinent vesicostomy or catheterizable efferent limb is selected for postoperative bladder drainage, they may be fashioned at this time. Otherwise, a large-bore (24Fr) Malecot or Foley suprapubic tube is placed at the bladder dome. The bladder neck is closed in two layers as described for vaginal closure. The bladder is then filled through the suprapubic tube to verify that the

closure is watertight. A well-vascularized interposition tissue is placed over the two-layer closure to minimize the risk of fistula.

### Approach in the Man

The technique of bladder neck closure in men differs from that in women in several distinct ways: (a) lack of direct perineal access to the bladder neck; (b) limited selection of vascularized

**FIGURE 34.7** Closure of the vaginal flap.

interposition tissue; and (c) challenging intraoperative closure and postoperative care due to prostatic anatomy.

### Perineal Access (Men)

The perineal approach to BNC, though conceptually and technically feasible, is not considered to be the procedure of choice in the man. Perineal access to the bladder neck necessitates either a concomitant prostatectomy with its own inherent morbidity or closure of the infraprostatic urethra, a procedure associated with a high rate of spontaneous fistulization. Closure

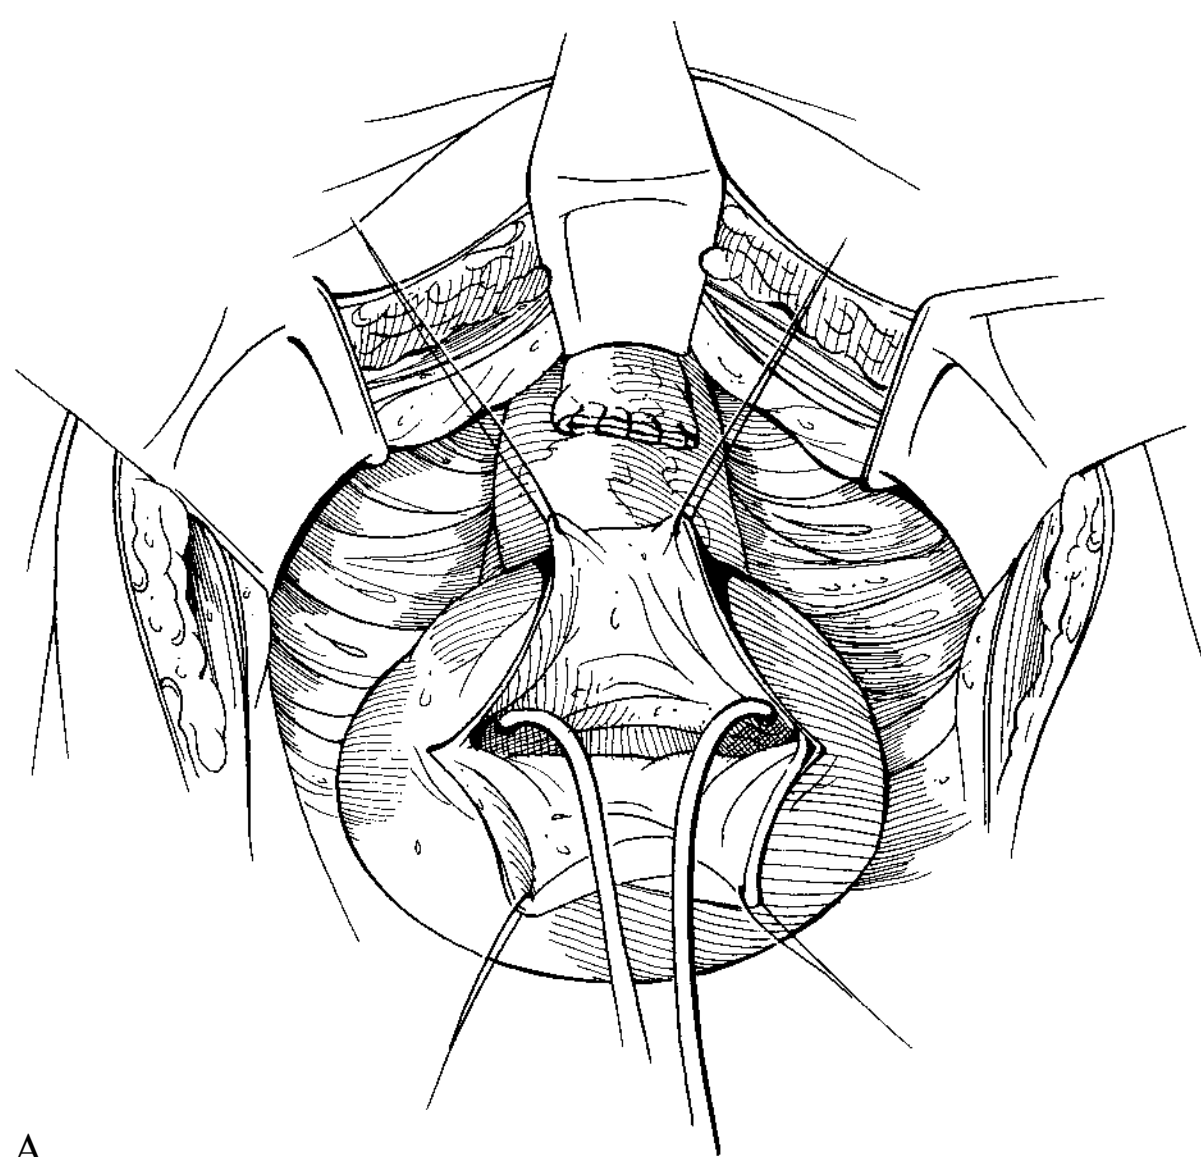

of the infraprostatic urethra, though easily performed, is not desirable for the following reasons:

1. The surgical closure continues to remain in a dependent position.
2. With the exception of a gracilis or gluteal flap, there is little opportunity for interposition of a large healthy segment of vascularized tissue.
3. Prostatic secretions can only drain in a retrograde fashion into the bladder or, in dyssynergic patients, remain trapped in the prostatic fossa, leading to high rates of fistulization.
4. Perineal closure does not preserve antegrade ejaculation and compromises future fertility.

### Abdominal Closure (Men)

The abdominal approach to bladder neck closure has two distinct advantages over perineal closure: (a) the bladder neck can be rotated anteriorly and out of a dependent position and (b) the choices for vascularized interposition are abundant (omentum, rectus flap, and peritoneal flap). Two techniques have historically been employed for abdominal closure of the bladder neck in men with benign disease: supraprostatic and infraprostatic closure. Supraprostatic bladder neck closure has been our choice as it offers several distinct advantages over infraprostatic closure. It is technically easier and does not involve deep pelvic dissection or transection of the dorsal venous complex. It also allows better mobilization of the bladder neck, resulting in a tension-free closure. Lastly, it provides opportunity for future fertility as an antegrade flow of ejaculate is preserved.

When BNC is to be performed in conjunction with salvage prostatectomy, the extirpative portion of the procedure is performed first. Description of this portion of the procedure is beyond the scope of this chapter, but those who have published reports in the care of these patients describe it as technically challenging (5). A distinct advantage of this operation, when compared to salvage prostatectomy with vesicourethral anastomosis, is that it allows for wider excision, particularly at the apex of the prostate.

**FIGURE 34.8** **A:** Opened bladder with mobilization of the bladder neck. **B:** Intraoperative photograph of divided urethral stump and mobilized open bladder neck.

After supine or low lithotomy positioning, the patient is prepared and a catheter is placed in sterile fashion. An infraumbilical vertical midline incision is performed, and the retropubic space is accessed as described earlier. The bladder neck is identified, and absorbable sutures are used to ligate the superficial dorsal venous complex at the prostatovesical junction. The prostate and vesical neck are grasped, and electrocautery or sharp dissection is then used to amputate the anterior vesical neck from the prostate. Once the bladder neck mucosa is entered, the Foley balloon may be deflated and removed to permit visualization of the posterior vesical neck. Indigo carmine and ureteral catheters are used as previously described. The posterior bladder wall is transected and the plane between the bladder and the rectum identified. Mobilization of the posterior bladder neck from the Denonvilliers fascia and rectum should continue until the vesical outlet has reached an anterior, nondependent position. Excessive mobilization should be avoided to prevent injury to the ureters or vascular pedicles of the bladder. A large-bore Malecot or Foley suprapubic tube is then placed through a separate stab incision. If an alternative bladder drainage method is desired (incontinent vesicostomy, catheterizable efferent limb), it may be constructed at this time.

Depending on its size, bladder neck closure can be performed by one of two methods. In the patient with a small bladder neck, a series of two absorbable pursestring sutures may be used to invert the outlet similar to the inversion of an appendiceal stump. For a larger bladder neck, or where closure is more difficult, the outlet may be closed in two layers as described above. Placement of a well-vascularized flap of omentum, rectus muscle, or peritoneum in the fossa between the bladder neck closure and prostate is performed to not only facilitate healing but also to help prevent fistulization (Fig. 34.9).

Concomitant prostatectomy may be planned in the case of salvage prostatectomy, or it may be indicated in the case of a strictured urethra or prostatorectal fistula that poses a problem to postoperative prostatic drainage.

### Vascularized Interposition (Men)

Following the BNC, it is highly advisable to interpose vascularized tissue between the bladder neck and the pelvic outlet to reduce the risk of secondary fistula. Choices for interposition include omentum, a flap of adjacent peritoneum, or a rectus flap. We prefer omentum because of its size, reliable blood supply, and abundant lymphatic drainage. In patients with a generous omentum, a tongue may be easily mobilized with only limited dissection. If, however, the patient is extremely thin or has had radiation or prior intra-abdominal surgery, the incision may be extended to mobilize the omentum on a pedicle supplied by the right gastroepiploic artery. The right side is preferred due to its more dependent position in the abdomen and its more generous blood supply. The omentum is positioned between the BNC and the pelvic outlet, and it is sutured in place with absorbable sutures. When a rectus flap is selected, it may be mobilized and based on an inferior epigastric vascular pedicle with careful attention to tie all lateral vascular collaterals. The mobilized rectus flap is then rotated downward and positioned as described above for omentum. Alternatively, a paravesical peritoneal flap may be interposed; however, its vascular supply may not be as reliable as that of omentum or a rectus flap. A suction drain is left in the pelvis and brought out through a separate stab wound along with the suprapubic catheter.

### Postoperative Care

Postoperative intravenous antibiotics are used for 3 to 5 days, after which patients are placed on daily oral antibiotic suppression. The suction drain is usually left for 1 to 2 days. In our experience a nasogastric tube is not usually necessary. The suprapubic tube is carefully secured to avoid kinking or dislodgement. Patients are kept on either oral or rectal anticholinergic medication (belladonna and opium suppositories) to prevent bladder spasms. A cystogram is obtained at 2 to 3 weeks to document the integrity of bladder neck closure. If

**FIGURE 34.9** **A:** Omental interposition in the man. **B:** Intraoperative photograph showing omental wrap over bladder neck closure to prevent secondary vesicourethral fistula.

there is no evidence of leak or fistula, the suprapubic tube may be changed or removed if a catheterizable stoma was chosen for bladder drainage.

---

## OUTCOMES

---

### Complications

---

The primary complication of bladder neck closure is postoperative fistula. Such a fistula may occur as early as 1 week postoperatively or as late as 1 year. When a fistula is suspected, the patient should undergo a cystogram with a mixture of contrast and methylene blue dye. The site of leakage (vagina or perineum) should then be assessed both visually and radiographically. If a small fistula is encountered early in the postoperative period, bilateral percutaneous nephrostomies may be used to divert the urine away from the fistulous site. Reoperation is a more complex but reliable method of dealing with postoperative fistula. When the initial procedure was performed from a vaginal or perineal approach, reoperation should be performed suprapubically to allow extensive bladder mobilization and interposition of a large, well-vascularized omental flap. Supravesical diversion is reserved for patients in whom all attempts at repair have failed.

Loss of access to the bladder may also represent a source of postoperative morbidity. Loss of a suprapubic tube and closure of its tract is an underreported but not uncommon complication. Access may be re-established by using a flexible cystoscope or ureteroscope and may require fluoroscopy to

negotiate the tract and pass a flexible wire down to the bladder. If this procedure fails, the patient may be given a fluid bolus and the bladder may be percutaneously accessed under sonographic guidance. Once access has been established, the tract may be dilated and a council catheter passed over the wire. Inability to catheterize a continent efferent limb may be treated similarly, and endoscopic negotiation of the conduit usually suffices to reestablish access.

---

### Results

---

Though a number of authors have reported their results with BNC, most series have been small, retrospective, and with a great deal of variability in technique (3,4,8,11). Consequently, long-term outcomes and overall success rates are difficult to judge. In series where the bladder neck is anteriorly mobilized and appropriate vascularized interposition tissue is utilized, long-term continence rates range from 83% to 100% with a 7% to 8% reoperation rate (4,6,11). In series where these principles have not been employed, fistula formation and reoperation rate range from 30% to 46% and 25% to 46%, respectively (1,3,9). In one series where female multiple sclerosis patients were treated with vaginal urethral closure and suprapubic cystostomy, approximately 80% of the patients who were continent (and available for reliable follow-up) remained continent at an average follow-up of 6.5 years (range, 2 to 17 years) (3). Upper-tract deterioration has been noted in a single series (11%) and has been causally related to the use of continent, catheterizable efferent channels in patients with persistent bladder dysfunction (1).

# CHAPTER 35 ■ SURGERY FOR URETHRAL STRICTURE DISEASE

JACK R. WALTER AND GEORGE D. WEBSTER

Urethral stricture have been described and managed since antiquity. Egyptians used reeds to dilate strictures in 1700 B.C., documenting the first nonsurgical intervention reported for the management of strictures. Urethral strictures remain a relevant disease process in present times. Their etiology remains trauma, inflammation, or ischemia, with trauma being the most common cause. Traumatic injuries may result from external violence, including blunt trauma to the perineum, pelvic fracture, or penetrating injury with knife or projectile injury. More frequently, iatrogenic injury secondary to urethral catheterization and endoscopic surgery create strictures. Inflammatory processes, including gonococcal urethritis or lichen sclerosis, can result in stricture formation. Rarely, urethral strictures can result from malignancy, typically of urethral, penile, or lymphoid origin. The central process of urethral stricture pathophysiology is progressive fibrosis of the epithelium with subsequent involvement of the underlying spongiosum. The urethral lumen narrows, leading to a weak urinary stream and difficulty voiding, culminating in complete obliteration with urinary retention. Rarely, stricture disease will lead to fistula or abscess formation.

---

## DIAGNOSIS

---

The presentation of urethral strictures ranges from insidious to obvious. Men may have stricture disease for many years and never seek evaluation or suspect they have a problem. These men are commonly diagnosed when urethral catheters are placed for surgery or when their long-standing strictures lead to bladder decompensation. Frequently, strictures present with symptoms of bladder outlet obstruction and irritative symptoms, including urgency, frequency, and dysuria. Occasionally, patients will present with microscopic or gross hematuria. Recurrent urinary tract infection can accompany these symptoms. In cases of traumatic stricture, the history will include prior urethral instrumentation or an episode of external injury.

Men with newly diagnosed strictures require a thorough history and physical examination with special attention to the genitalia. Penile length should be noted. The character, color, and laxity of penile shaft skin and preputial skin, when present, should be assessed to determine flap and graft availability. The urethra is palpated to help determine the severity of spongiositis. Laboratory evaluation should include urine analysis, urine culture, and assessment of renal function. Conventional radiological studies adequately delineate urethral strictures in most men. Retrograde urethrography (RUG) provides the length, location, caliber, and multiplicity of the

stricture (8). If one is unable to adequately distend the proximal urethra due to near obliteration of the lumen, voiding cystourethrography (VCUG) provides additional information. Simultaneous RUG–VCUG is indispensable in the evaluation of the obliterative urethral defect that follows pelvic fracture. Urethral ultrasonography and magnetic resonance imaging have also been used in the evaluation of urethral disease but are not as widely available. Uroflowmetry provides insight on the functional significance of the stricture. Cystourethroscopy provides little additional information in the clinic setting as visualization of the proximal urethra is limited by the stricture. Urethroscopy if performed is primarily used to rule out malignancy and complement the radiological findings.

---

## INDICATIONS FOR SURGERY

---

The presence of stricture alone does not necessitate surgical intervention as many wide-caliber strictures are of little consequence. Prior to surgery, strictures should demonstrate outlet obstruction. Stricture location and characteristics dictate initial management. In most settings dilation or optical urethrotomy is acceptable. Such intervention is rarely curative but usually temporizes the acute event for a variable duration (11). Indications for open urethroplasty include frequent urethral dilation or complications associated with dilation, including false passage, diverticulum, fistula, bacteremia, hemorrhage, and excessive pain. In addition, strictures that occur in children or long, obliterative strictures justify earlier consideration for open repair.

Numerous urethroplasty techniques have been described, and no single technique is appropriate for all strictures. Consider two broad technical groups of urethroplasty: anastomotic and substitution repairs. Anastomotic, as the name implies, involves removal of the diseased urethra and reanastomosis of the healthy ends. Substitution repairs augment or replace the urethral lumen with a pedicled flap or graft performed in single or multiple stages. Traditionally, grafts and flaps originated from genital skin. However, buccal mucosal grafts have emerged as the preferred urethral substitute in adults due to their favorable inherent qualities and consistent availability.

The goals of any reconstructive urologic surgery are functional and anatomic success. Location, length, and etiology of the stricture as well as personal experience determine the appropriate surgical technique. Additional factors, including concomitant fistulas, inflammation, and prior repairs, need to be considered. With these thoughts in mind, excellent function—urethral patency and stable sexual function—and cosmetic results are attainable.

---

## ALTERNATIVE THERAPY

---

Nonsurgical and minimally invasive alternatives exist for management of urethral stricture. Nonsurgical options include expectant management and dilation performed by the patient or physician. Minimally invasive techniques include optical urethrotomy using cold knife, electrocautery, or laser. In general, urethrotomy is contraindicated in the pendulous urethra due to the paucity of surrounding spongy tissue, which is necessary for urethral re-epithelialization. More recently transurethral placement of metallic urethral stents has been utilized. Currently, urethral stenting is discouraged in the pendulous urethra due to patient discomfort and potential compromise of erectile function. In the bulbar urethra all of the mentioned options are available. In terms of cure rates, optical urethrotomy has no advantage over urethral dilation (11). Further, if one urethrotomy or dilation fails to cure a patient, then subsequent procedures are rarely if ever successful (6). With poor success of repeat internal urethrotomy, the cost-effective strategy is to move to open surgical repair following one failed endoscopic treatment (12). Strictures that may be cured by dilation or urethrotomy are usually short (<1 cm) bulbar strictures, whereas longer strictures or those of the pendulous urethra are rarely cured by dilation or urethrotomy.

---

## SURGICAL TECHNIQUE

---

### General Surgical Principles

---

Prior to incision, controlled variables should be optimized. The preoperative urine culture must be negative. If the patient has an indwelling suprapubic tube, broad-spectrum oral antibiotics should be provided during the 24 hours prior to surgery. On-call parenteral antibiotics should be given. Appropriate radiological studies must be available in the operative room. The surgeon should communicate openly with anesthesia about anticipated length of surgery, expected blood loss, and type of anesthetic required. Most anterior urethral strictures can be managed with a spinal anesthetic. If one determines that a buccal mucosal graft will be needed, one should advise anesthesia that general endotracheal anesthesia is necessary. We prefer to position patients in modified lithotomy using padded Allen stirrups. Exaggerated lithotomy is rarely necessary and carries a significant risk of neuronal injury and compartment syndrome, especially with prolonged operative time (1). Staining the urethra with methylene blue assists in identifying the urethral lumen as well as differentiating urethral scar from healthy urothelium. “Table-fixed” ring retraction (Bookwalter or Omni) provides ideal exposure for bulbar or posterior urethroplasty, while nonfixed ring retraction (Lone Star) is optimal for pendulous urethroplasty. Polyglycolic acid (PGA) suture material has ideal tensile strength, absorption rate, and tissue reactivity; and 5-0 is generally used. Wound drainage when necessary is accomplished with a 7Fr closed-suction drain. Dressings should be supportive and noncompressive.

Postoperative urinary drainage should be effective and cause minimal urothelial irritation. For this purpose 12Fr silicone urethral catheters function adequately. When surgical repair in bulbar stricture disease requires a graft or flap, the

catheter is fenestrated to promote drainage of the operative site (Fig. 35.1). One rarely needs suprapubic catheter drainage with anterior urethral surgery. If present, it may facilitate postoperative urethral stent management, allowing removal of the urethral catheter without requiring the patient to void. The type and location of repair determine the length of time that catheterization is required. Meatal or glanular repairs require 5 to 7 days, anastomotic repairs require 10 to 14 days, and one-stage graft repairs require 21 days of urinary drainage. Prior to catheter removal, the anastomotic lines are assessed for healing with a pericatheter RUG for all urethroplasties proximal to the fossa navicularis. If there is no extravasation at the repair site, the catheter is removed and the patient resumes normal voiding. History and examination, uroflowmetry, and RUG are performed at 3 and 12 months following repair. Subsequently, symptomatic follow-up is indicated, and some use periodic uroflow studies.

---

### Strictures of the Glanular Urethra

---

Strictures in the glanular urethra arise commonly from inflammatory conditions, instrumentation, or improper circumcision. Simple meatotomy, a glans-based Y–V advancement flap for very distal stenosis, or a ventral shaft skin onlay flap in the case of stricture involving the entire fossa navicularis may accomplish surgical repair. For Y–V advancement, a V-shaped incision is made on the dorsal aspect of the glans with the apex terminating at the urethral meatus (Fig. 35.2). A dorsal midline extension of this incision is made into the urethra to widen the lumen to accept a 22Fr sound. The glans flap can be elevated using skin hooks and sharp dissection to allow its mobilization into the most proximal limit of the dorsal urethral incision, where it is anchored with a 4-0 PGA suture. Care must be taken to leave this glans flap with a wide base to avoid vascular compromise.

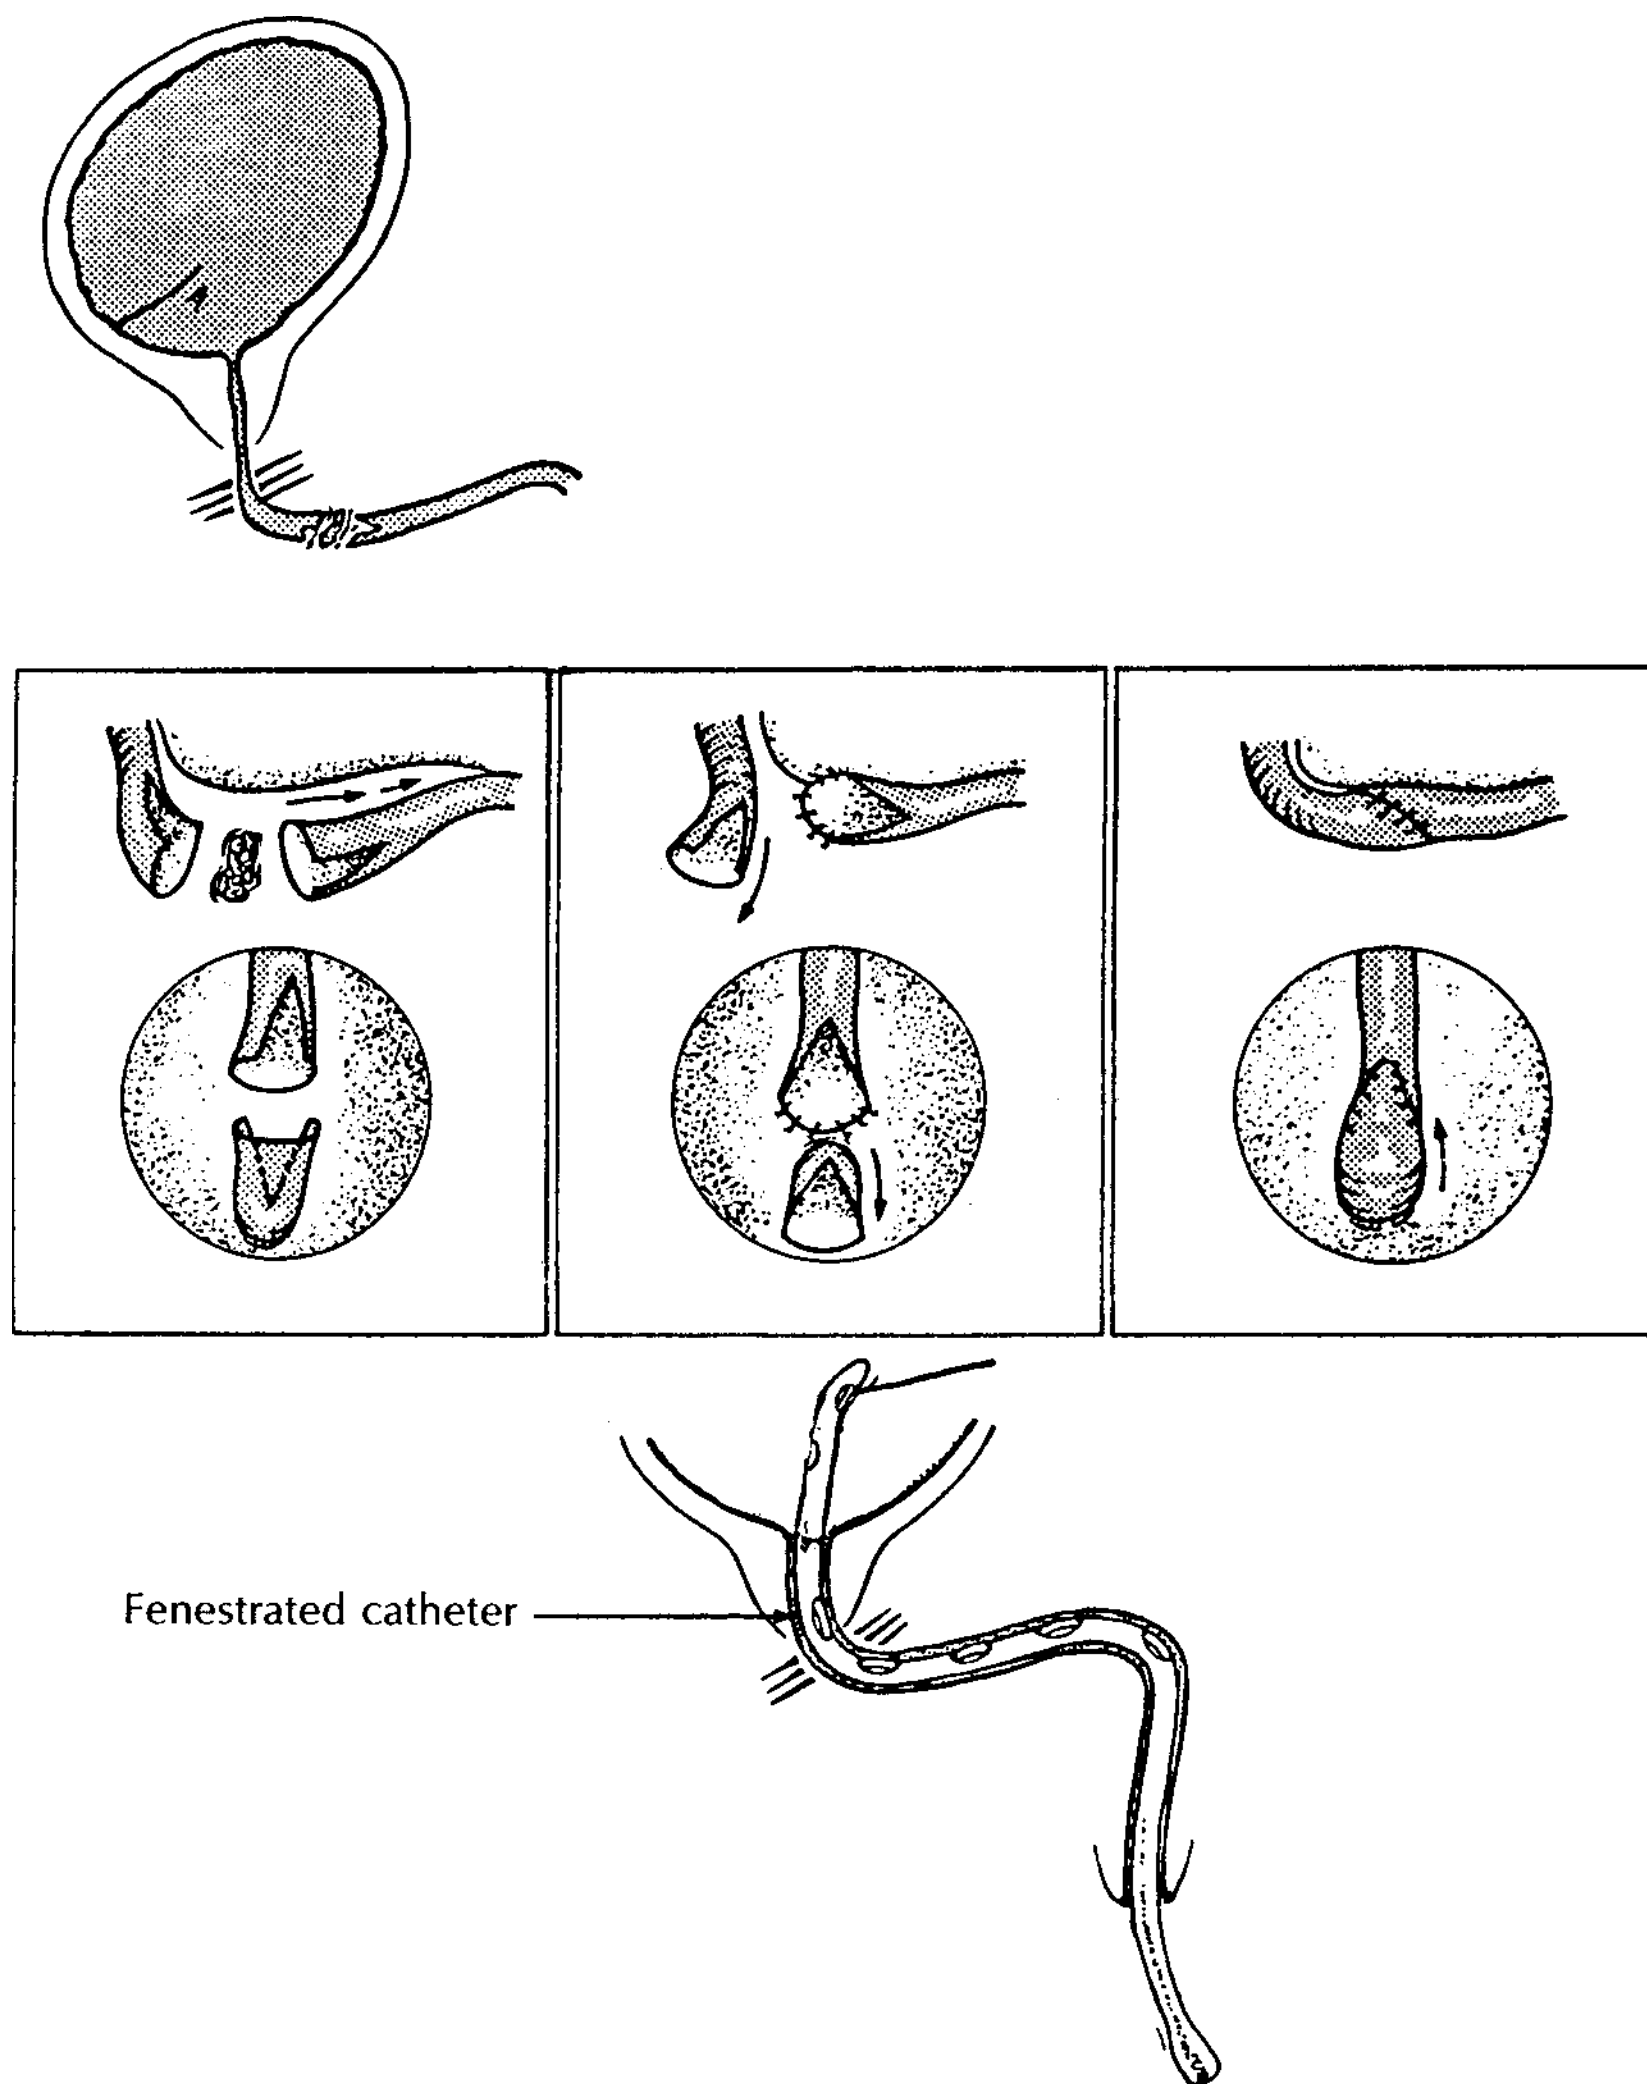

More extensive strictures of the glanular and distal penile urethra should be managed according to their etiology. If one suspects lichen sclerosis (LS), biopsies may be obtained to confirm diagnosis and exclude possible malignancy. Strictures associated with LS are best repaired with nongenital skin as the penile skin is considered blighted and may eventually develop LS. In these cases, the diseased urethra is excised, the buccal mucosa is inlayed, and the urethra is left open. A second stage, during which the urethra is then tubularized, occurs 6 to 12 months later after the graft matures, and the adjacent urethra is observed for further development of LS. If extensive stricture disease is unrelated to LS, then a flap of skin obtained from the penile shaft allows repair in a single stage. The flap may be fashioned as an onlay or as a tube, depending on the extent of the disease (Fig. 35.3).

---

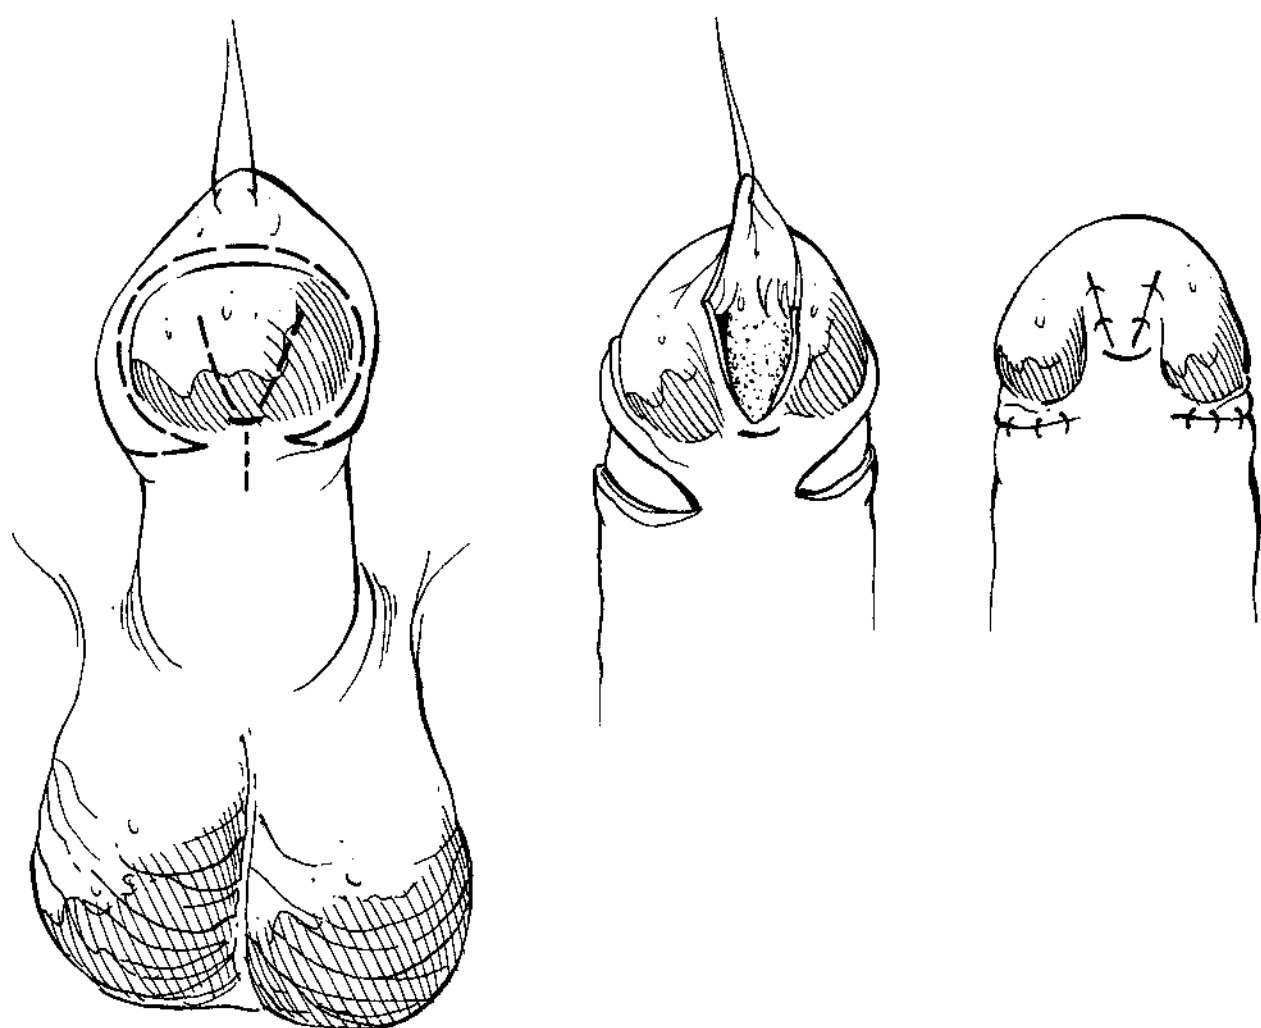

### Strictures of the Pendulous Urethra

---

Pendulous urethral strictures are most often repaired using an onlay flap of penile skin. Although many variations of this technique have been described, the laterally based pedicled island flap originally described by Orandi gives excellent results and is technically forgiving. It is in general suitable for repairs measuring up to 8 cm (depending on penile length), although longer repairs can be performed by harvesting a penile “J”

**FIGURE 35.1** The fenestrated urethral catheter is optimal following urethroplasty. Either a balloon or straight catheter may be used, and fenestrations are made in the catheter shaft in the region of repair. The fenestrations allow debris and exudate to be washed away from the site of repair. Bladder irrigation cannot be performed unless the catheter is inserted all the way into the bladder so that the most distal fenestration is intravesical.

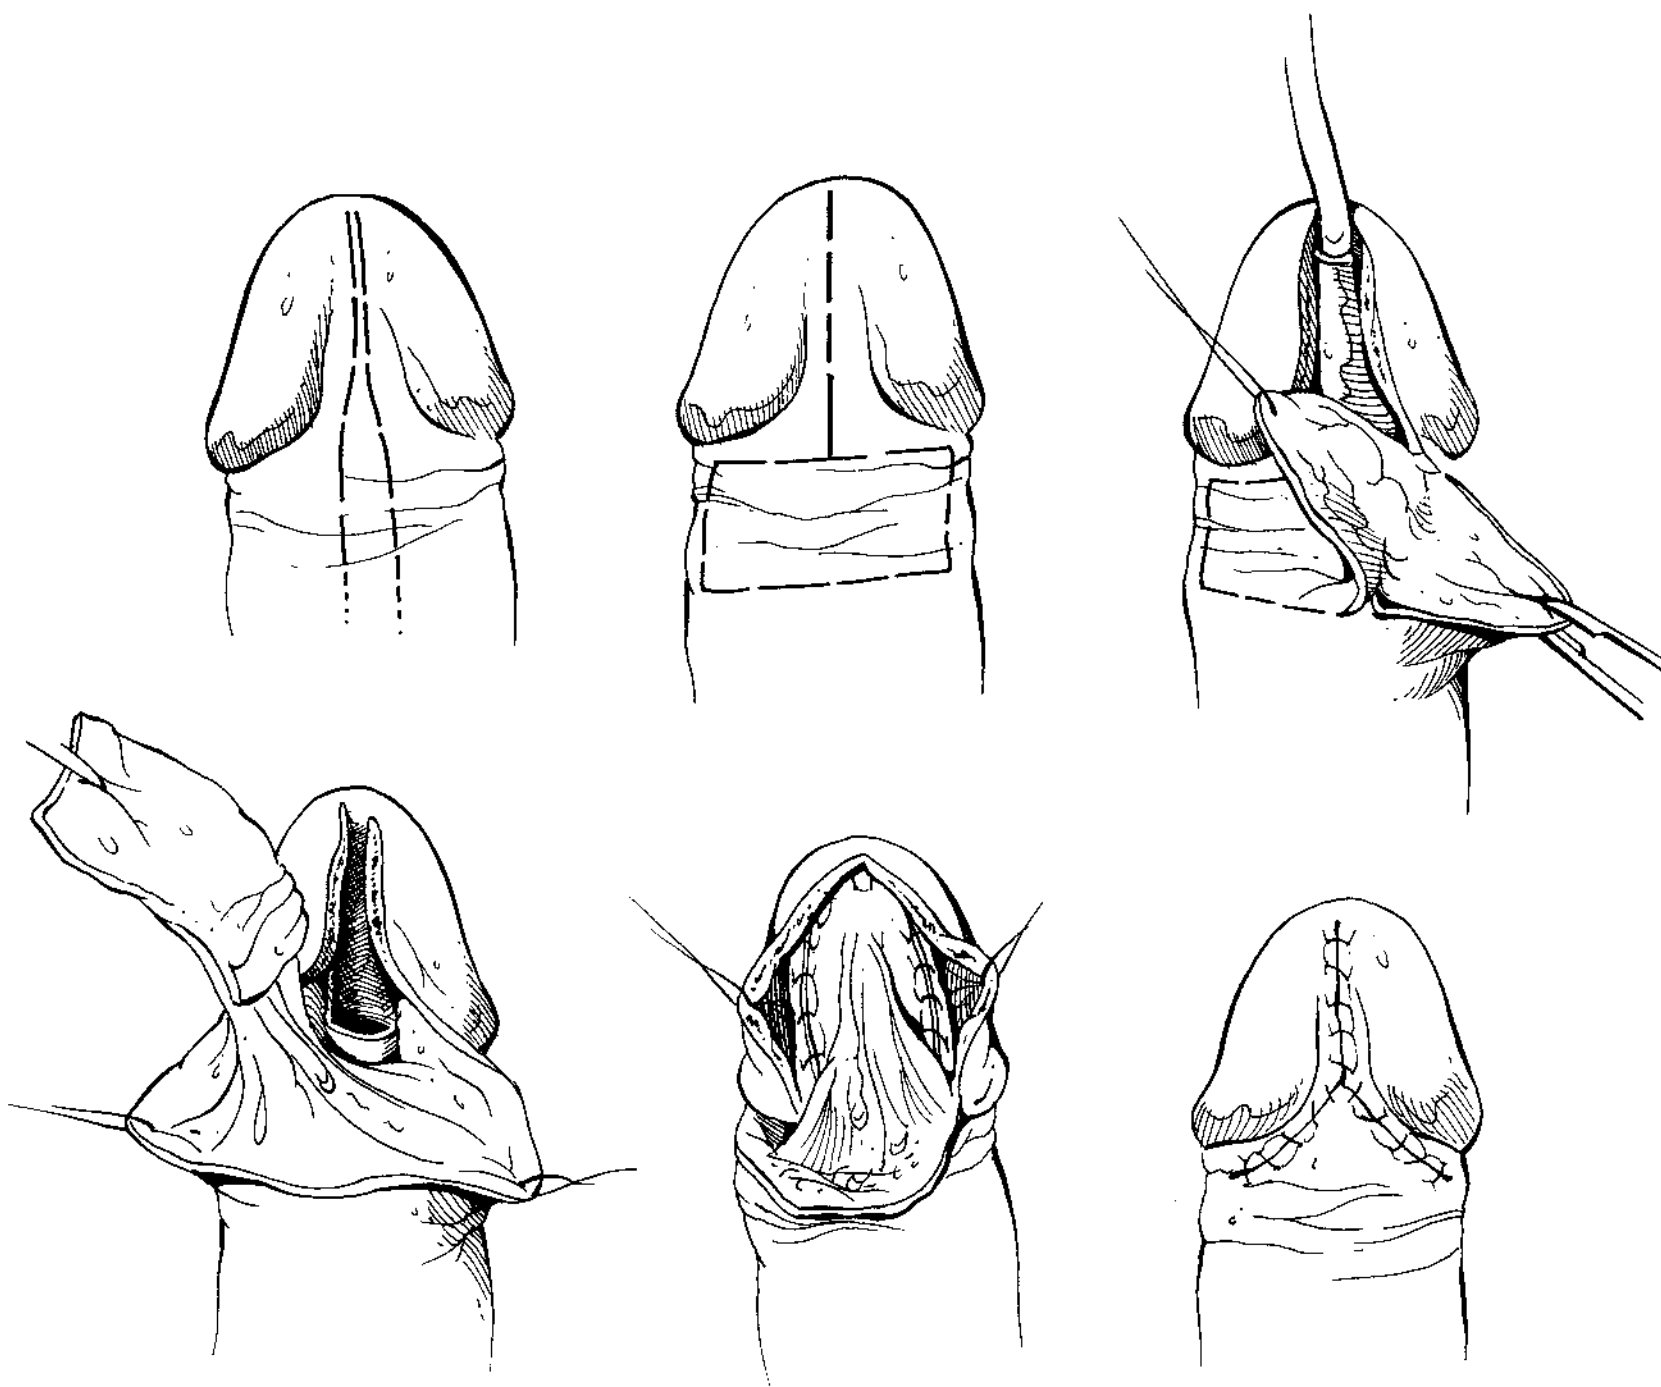

**FIGURE 35.2** Glans flap meatoplasty.

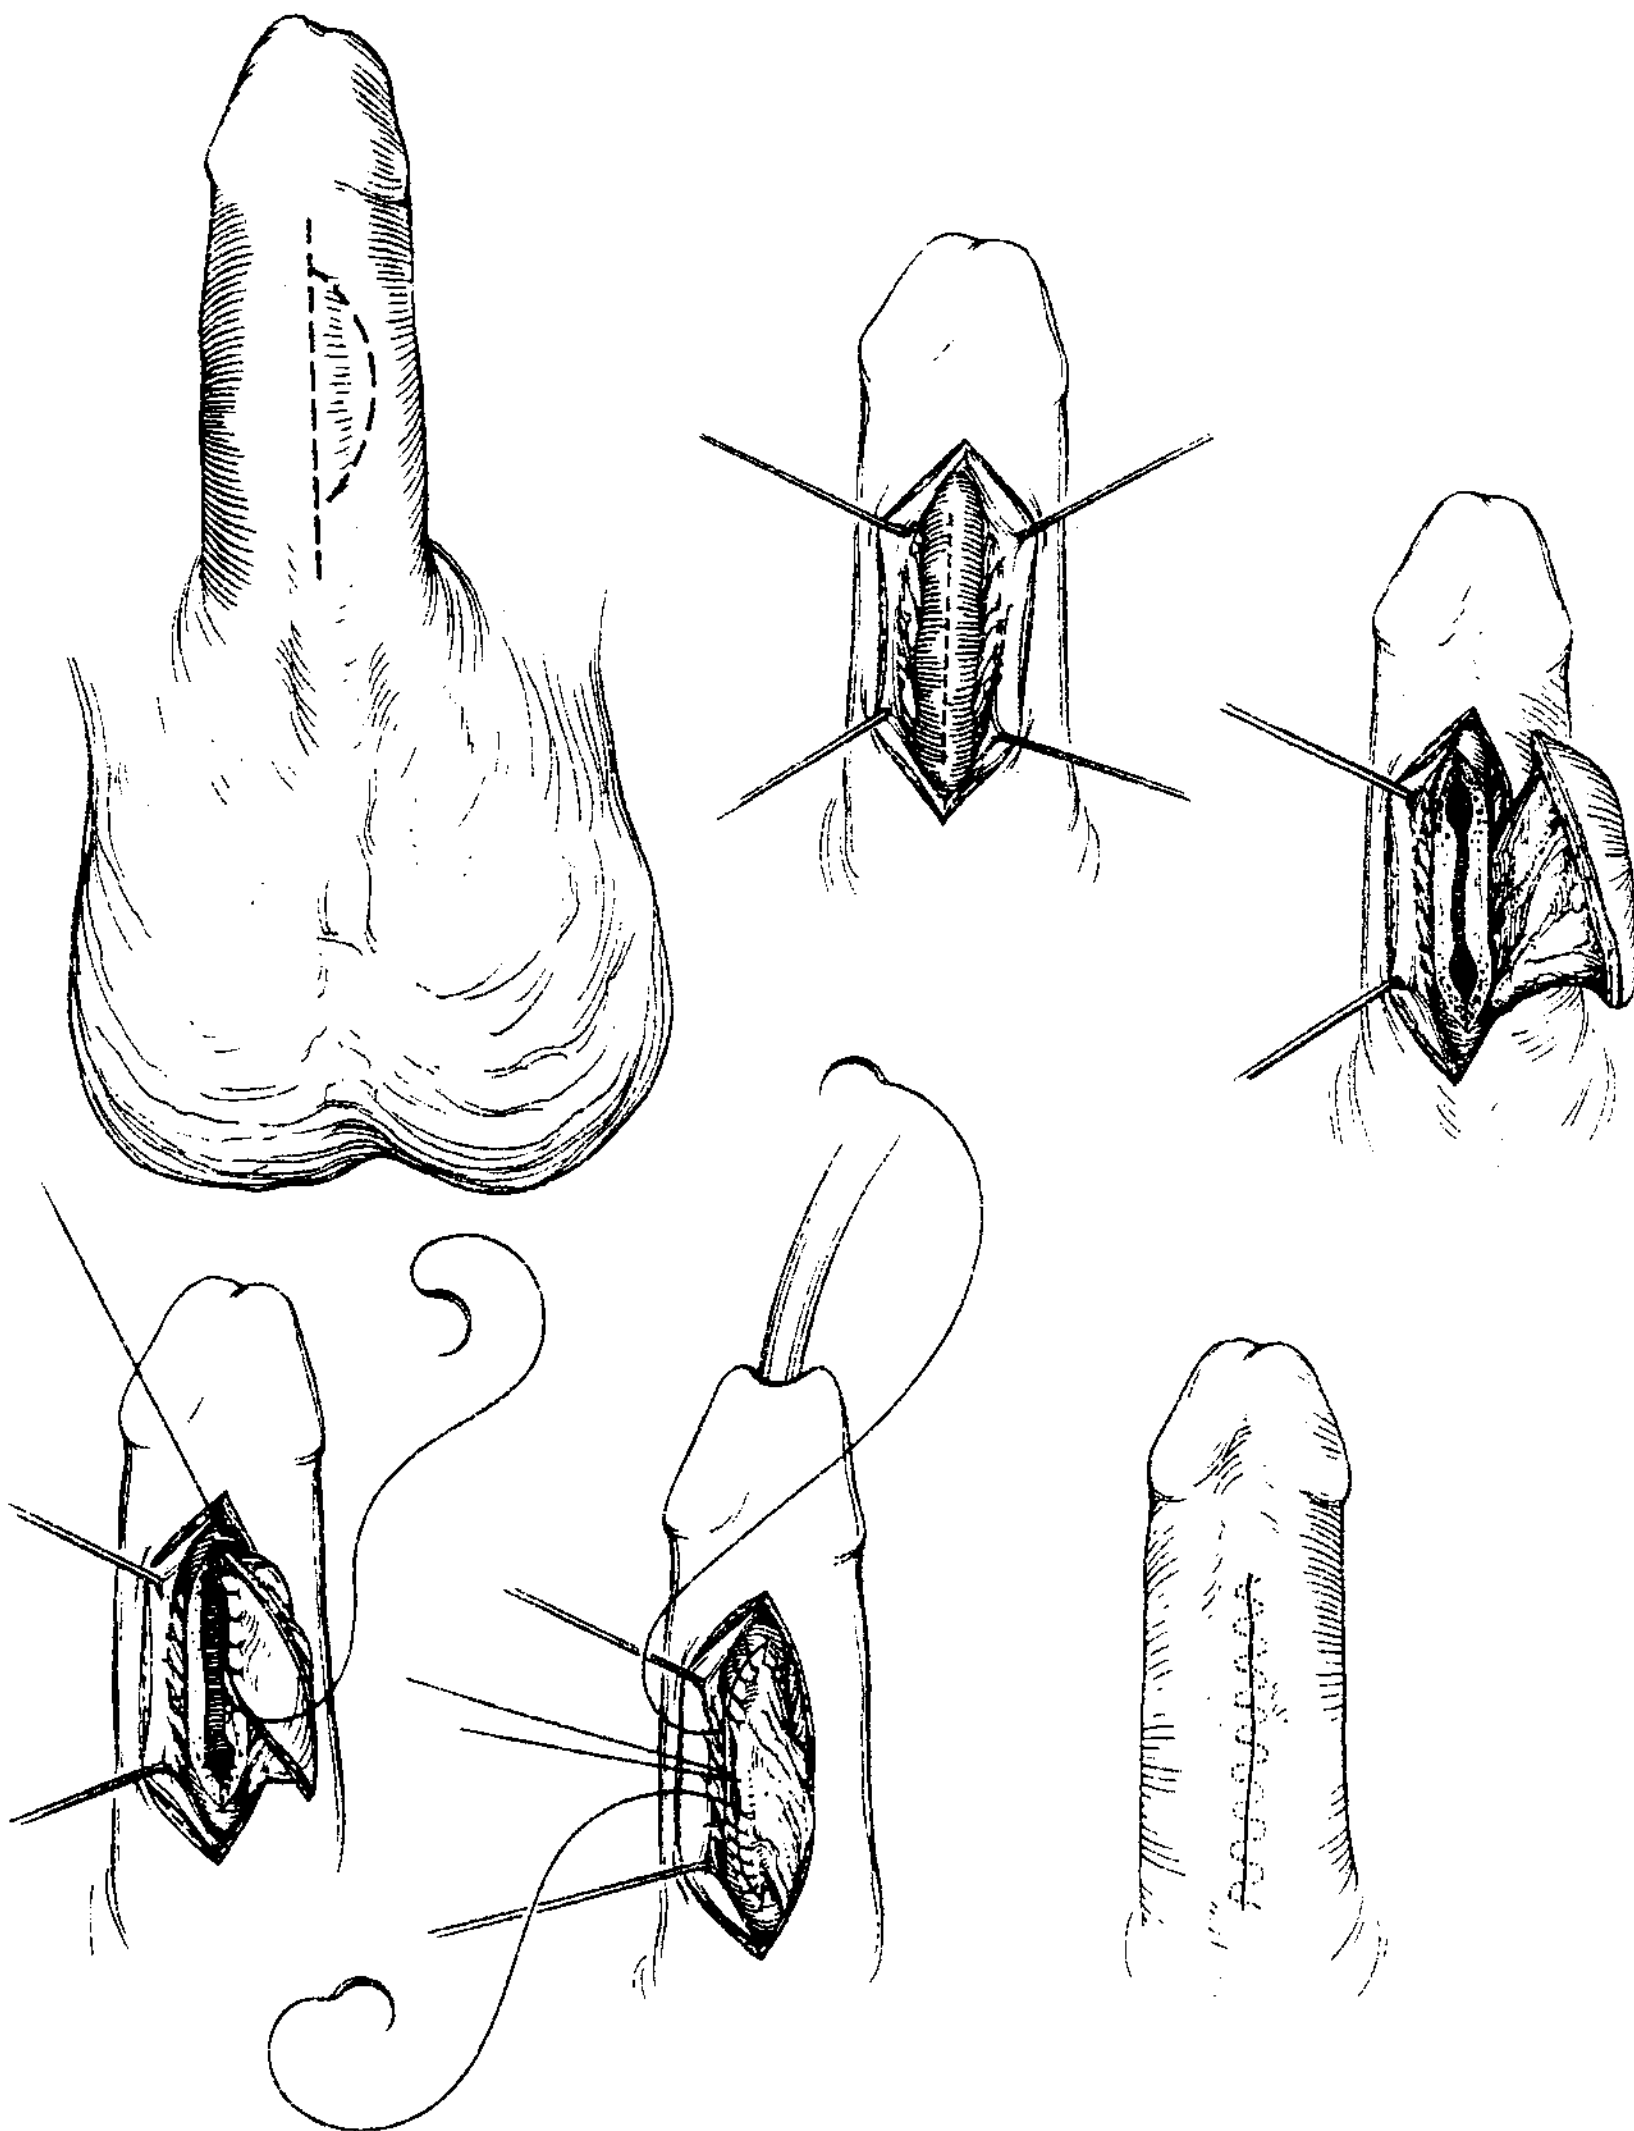

flap that has a vertical and a distal circumferential component. A flap width up to 25 mm can be used without compromising penile skin closure. The patient is placed in either the lithotomy or supine frog-legged position. An incision is made

along the ventral penile raphe through the Buck fascia down to the strictured segment of urethra. Using skin hooks to elevate the flap and fine scissors for dissection, one skin margin is mobilized from the corpus cavernosum for 10 to 15 mm, staying deep to the Buck fascia (Fig. 35.4). With the urethra adequately exposed, a suitable catheter or filiform is placed in the urethral lumen as a guide and the urethra incised ventrally along the stricture. This incision is then extended to expose at least 1 cm of healthy urethra proximal and distal to the stricture. An onlay flap of suitable width to achieve a 24Fr lumen (in general, 18 to 25 mm) is then outlined on the mobilized lateral penile shaft skin. The flap length corresponds to the length of the urethrotomy and is tapered at the proximal and distal ends. Care must be taken not to incorporate a significant segment of hair-bearing shaft skin in the repair.

Once the flap has been outlined, the projected new skin edges are approximated in the midline to ensure that wound closure with minimal tension is possible. The lateral aspect of the flap is then incised through the subcutaneous connective tissue, leaving the underlying dartos and deeper Buck fascia intact. With exposure of the correct tissue plane, the lateral penile shaft skin will retract with minimal additional dissection. The medial border of the island flap is then anchored to the lateral edge of the incised urethra with 5-0 PGA stay sutures. The flap is sutured to the urethra beginning at the distal margin, using a

**FIGURE 35.3** Repair of meatal and distal penile urethral stricture using a pedicled island of distal penile skin. This procedure allows for reapproximation of glans tissue around the neourethra, giving an excellent cosmetic and functional result.

**FIGURE 35.4** Onlay urethroplasty of a pendulous urethral stricture (Orandi repair). The stricture is approached through a ventral penile incision. The outline of the skin island to be used for onlay is marked once the stricture has been opened and its length and caliber determined. The skin island is raised on a subcutaneous vascular pedicle, rotated inward, and sutured as an onlay to augment urethral caliber. Skin closure is in at least two layers to avoid fistula formation.

running 5-0 PGA suture, incorporating the urothelium in the closure. When the lateral suture line is complete, the free edge of the island flap can be rolled over and secured with 5-0 PGA stay sutures to the contralateral margin, recreating the urethral lumen. A similar running suture line is performed with 5-0 PGA to complete the onlay repair. Local wound drainage may be accomplished with a suction drain placed underneath the vascular pedicle along the length of the flap to obviate hematoma or urinoma formation, which could compromise the flap.

Wound closure is performed in two layers using 5-0 interrupted PGA sutures. Care must be taken when approximating the subdermal connective tissue of the skin margins to avoid injury to the flap pedicle. This first layer of closure covers the exposed urethral suture line and minimize the risk of fistula formation. Skin closure is performed with a running subcuticular 5-0 PGA suture. The wound is supported with adhesive strips and covered with a gauze and loosely applied Coband dressing to reduce edema formation. The urethral catheter is secured to the abdominal wall and remains in place for up to 3 weeks. If a suction drain is used, it is removed within 24 hours. The supportive dressing is taken down on postoperative day 2. The patient is allowed to ambulate on postoperative day 1, and the procedure is usually performed as an outpatient.

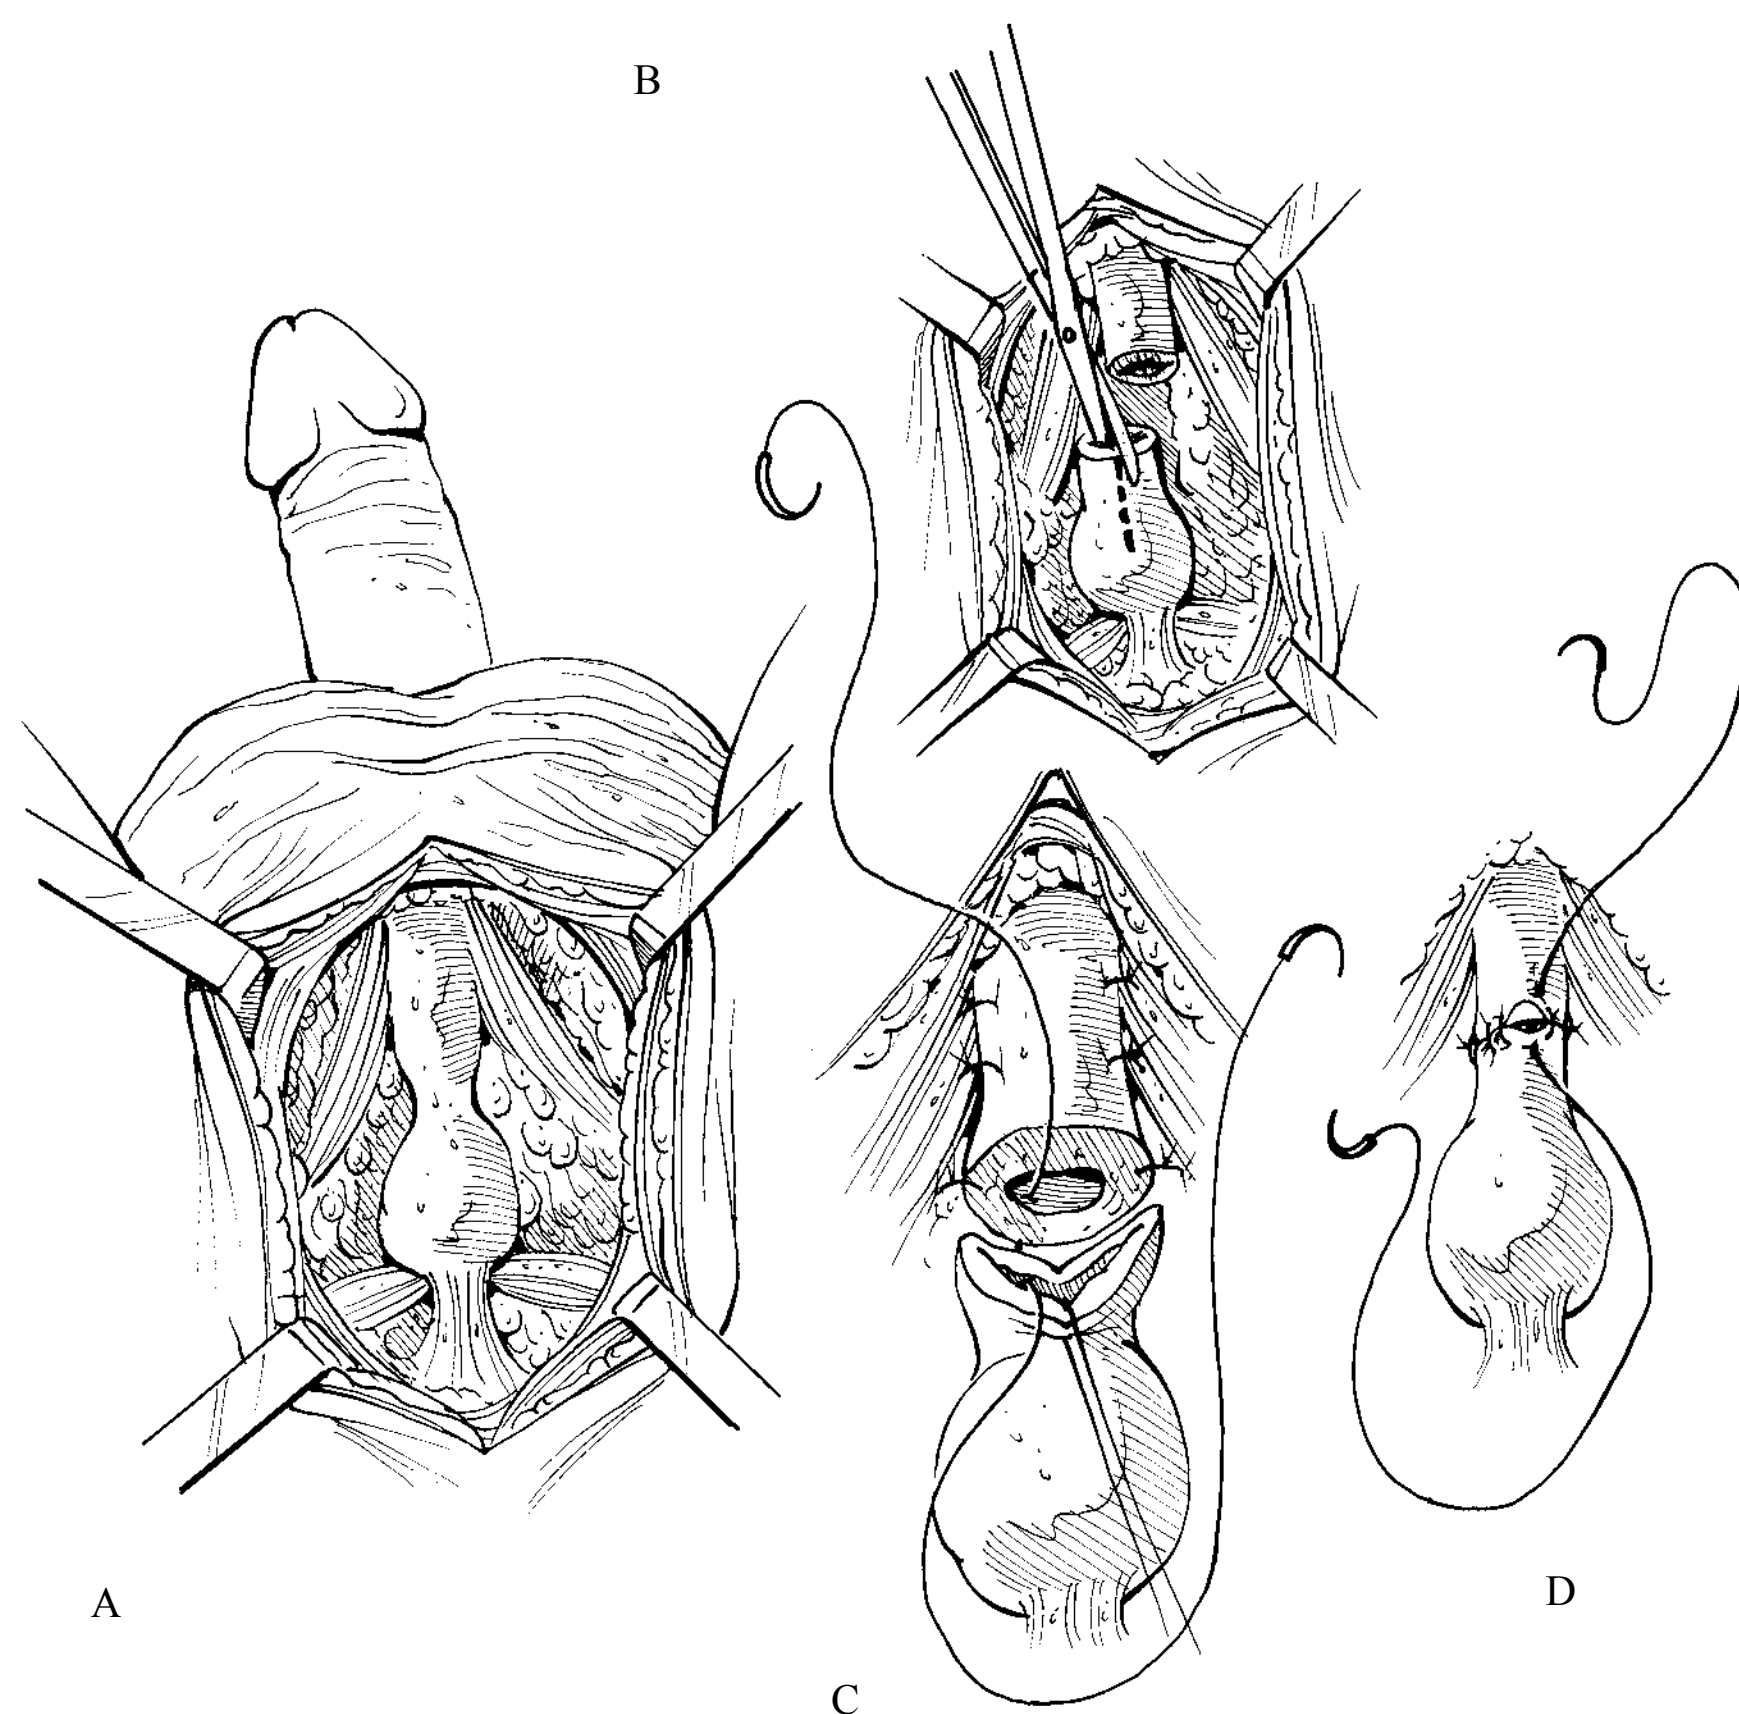

## Bulbar Urethral Stricture Repair

### Anastomotic Urethroplasty

Strictures of the bulbar urethra originate most commonly from straddle injuries or iatrogenic trauma during endoscopy or catheterization. Optimal management is dictated

by stricture length. Strictures under 1 cm in length are best managed with excision and anastomotic urethroplasty. The patient is placed in modified lithotomy position. A midline perineal incision is made and bifurcated posteriorly 2 cm above the anus. The bulbospongiosus muscle is divided in the midline, exposing the bulbar urethra. The bulbospongiosus muscle can frequently be separated from the underlying bulbar urethra with blunt dissection if the correct plane is identified. By sharply dividing the reflection of the Buck fascia lateral to the urethra as it drapes over the corporal bodies proximal to the crus, one can safely dissect the urethral circumferentially. A space deep to the Buck fascia and between the separating corporal bodies is entered on each side. This dorsal dissection, separating the urethra from the corporal bodies, is continued sharply until the entire strictured urethra has been circumferentially mobilized. One should avoid mobilization distal to the suspensory ligament of the penis if possible, as this will increase the risk of chordee and penile length shortening. Further mobility of the proximal bulbar urethra is obtained by dividing the ventral attachments to the perineal body.

Once the strictured segment is fully mobilized, the urethra is divided at the distal extent of the stricture as defined by a catheter or bougie à boule placed from the meatus. The urethra should be spatulated through the diseased segment defining the extent of disease. Complete removal of fibrotic tissue with exposure of healthy proximal and distal urethra is essential for successful repair, but no  $>1$  cm of urethra should be excised. If the urethral ends appose in a tension-free fashion, they are spatulated sharply for 1 cm (Fig. 35.5). Using 5-0 interrupted PGA sutures, the dorsal wall of the anastomosis is

**FIGURE 35.5** Anastomotic repair of bulbar urethral stricture that may follow straddle injury. **A:** The urethra is exposed through a midline perineal incision and the stricture site identified and excised. **B:** Following stricture excision, apposing spatulations of 1 cm are accomplished. **C:** The proximal urethral opening is spread-fixed to the underlying corporal body, and spatulated anastomosis is performed with interrupted sutures. **D:** The anastomosis is completed, and additional tension-relieving sutures between urethral adventitia and adjacent corporal bodies are placed to avoid anastomotic tension during erection.

completed while spread-fixing the urethra to the corporal bodies. Circumferential partial-thickness anastomotic sutures incorporating the urothelium and some of the corpora spongiosum complete the first layer of the repair on the ventral surface. A second layer of closure is accomplished using the redundant spongiosum. The bulbospongiosus muscle and the Colle fascia are approximated in the midline with interrupted 5-0 PGA sutures. Final skin closure is made with interrupted 5-0 PGA sutures. The perineum is dressed and bolstered with fluff gauze and mesh underwear. The urethral catheter is secured to the abdominal wall to minimize traction and pressure on the urethra.

### Augmented Anastomotic Urethroplasty

Excision of 1 cm of urethra and associated 1-cm spatulated repair results in a total of 2 cm of urethral shortening, an amount that can be easily accommodated by the elasticity of the mobilized bulbar urethra. As bulbar urethral strictures extend beyond 1 cm in length, the risk of chordee and shortening increases if primary anastomotic repairs are performed. A variety of alternative procedures that avoid penile shortening and chordee may be used for strictures that are  $>1$  cm in length.

For strictures of up to 2 cm in length, stricture excision and augmented anastomotic repair is a good option (5). The 2-cm segment of stricture is excised. The urethra is then spatulated proximally and distally for 1 cm into healthy urethra on the same side. The anastomosis is then augmented with a graft (or a flap), increasing the lumen and avoiding the need for spatulation. This in effect spares an additional 1-cm loss of urethral length. In the ventral onlay, spatulation is at the 6 o'clock position (floor), and the unspatulated dorsal (roof) strips are then reapproximated end-to-end after spread-fixation, thereby securing the anastomosed urethral roof strip to the overlying corporal body. The anastomosis is not completed circumferentially, resulting in a diamond-shaped ventral urethral defect into which is laid either a graft of penile skin or buccal mucosa or, alternatively, a diamond-shaped flap of penile skin mobilized on a pedicle through the scrotum. This repair is called an augmented roof strip anastomotic procedure. It provides the advantages of an anastomosis while augmenting the repair to limit penile shortening to 2 cm, which is usually acceptable (Fig. 35.6). Alternatively, and our preference, is to perform a floor strip anastomosis, placing the augmenting graft, typically buccal mucosa, on the dorsal aspect, where it is spread-fixed to the overlying corporal body. This approach permits superior spread-fixation of the graft and therefore reduces graft shrinkage and enhances graft take because of the reliable apposition to the corporal body; it also avoids graft or flap sacculation. Consequently, since 1996, we prefer the dorsal onlay in the bulbar urethra (3).

### Onlay Bulbar Urethroplasty

As bulbar stricture length increases to  $>2$  cm in length, it is rarely possible to complete any type of anastomotic repair without causing some penile chordee and tension on the anastomosis. In this setting we have found success using a buccal mucosal or skin graft onlay applied to the dorsal aspect of the strictured portion of the bulbar urethra (Fig. 35.7). The urethral bulb is exposed circumferentially. The distal extent of the stricture is defined with a 20Fr catheter. The urethra is rotated 180 degrees to expose its dorsal aspect. Stay sutures of 4-0 silk

are placed along the exposed dorsal aspect, and the urethra is then incised along the strictured segment in the 12 o'clock (dorsal) position. The incision is extended for 1 cm into healthy urethra proximal and distal to the stricture.

Confirmation of proximal and distal patency is confirmed endoscopically and by calibration with a 24Fr bougie à boule. A suitable skin donor site, selected on the ventral penile shaft or prepuce, or a buccal mucosa graft is harvested. The graft is spread-fixed on a paraffin block and defatted. It is then fenestrated with a scalpel and sized and shaped to fit the defect created by urethral incision. The graft is then anchored in a spread-fixed fashion to the corporal bodies opposing the dorsally incised strictured urethra. The urethra is then rotated back to its normal anatomic position, and the margins of the urethral incision are sutured to the fixed graft edge and corporal body using interrupted 5-0 PGA sutures. In this fashion, the dorsal graft becomes the new urethral roof, augmenting the urethral caliber at the stricture site. This dorsal approach mitigates blood loss from a ventral bulbar incision and provides excellent graft stabilization. Of note, the residual floor of the strictured urethra functions as the foundation for the repair. If the stricture is severe, outcomes may be compromised.

---

## Panurethral Stricture or Failed Urethroplasty

---

The management of extensive stricture of the anterior urethra involving both the pendulous and bulbar portions can be extremely challenging. These are usually of inflammatory origin (often due to lichen sclerosis) and can be up to 20 cm in length. Urethral repair in these circumstances is undertaken either by combination repairs using grafts and flaps or, more conservatively, by multistaged repairs that may also use perineal inlays of full- or split-thickness skin grafts. One must consider the use of perineal urethrostomy or repeat dilations, as reconstructive results in other locations and situations are not as successful.

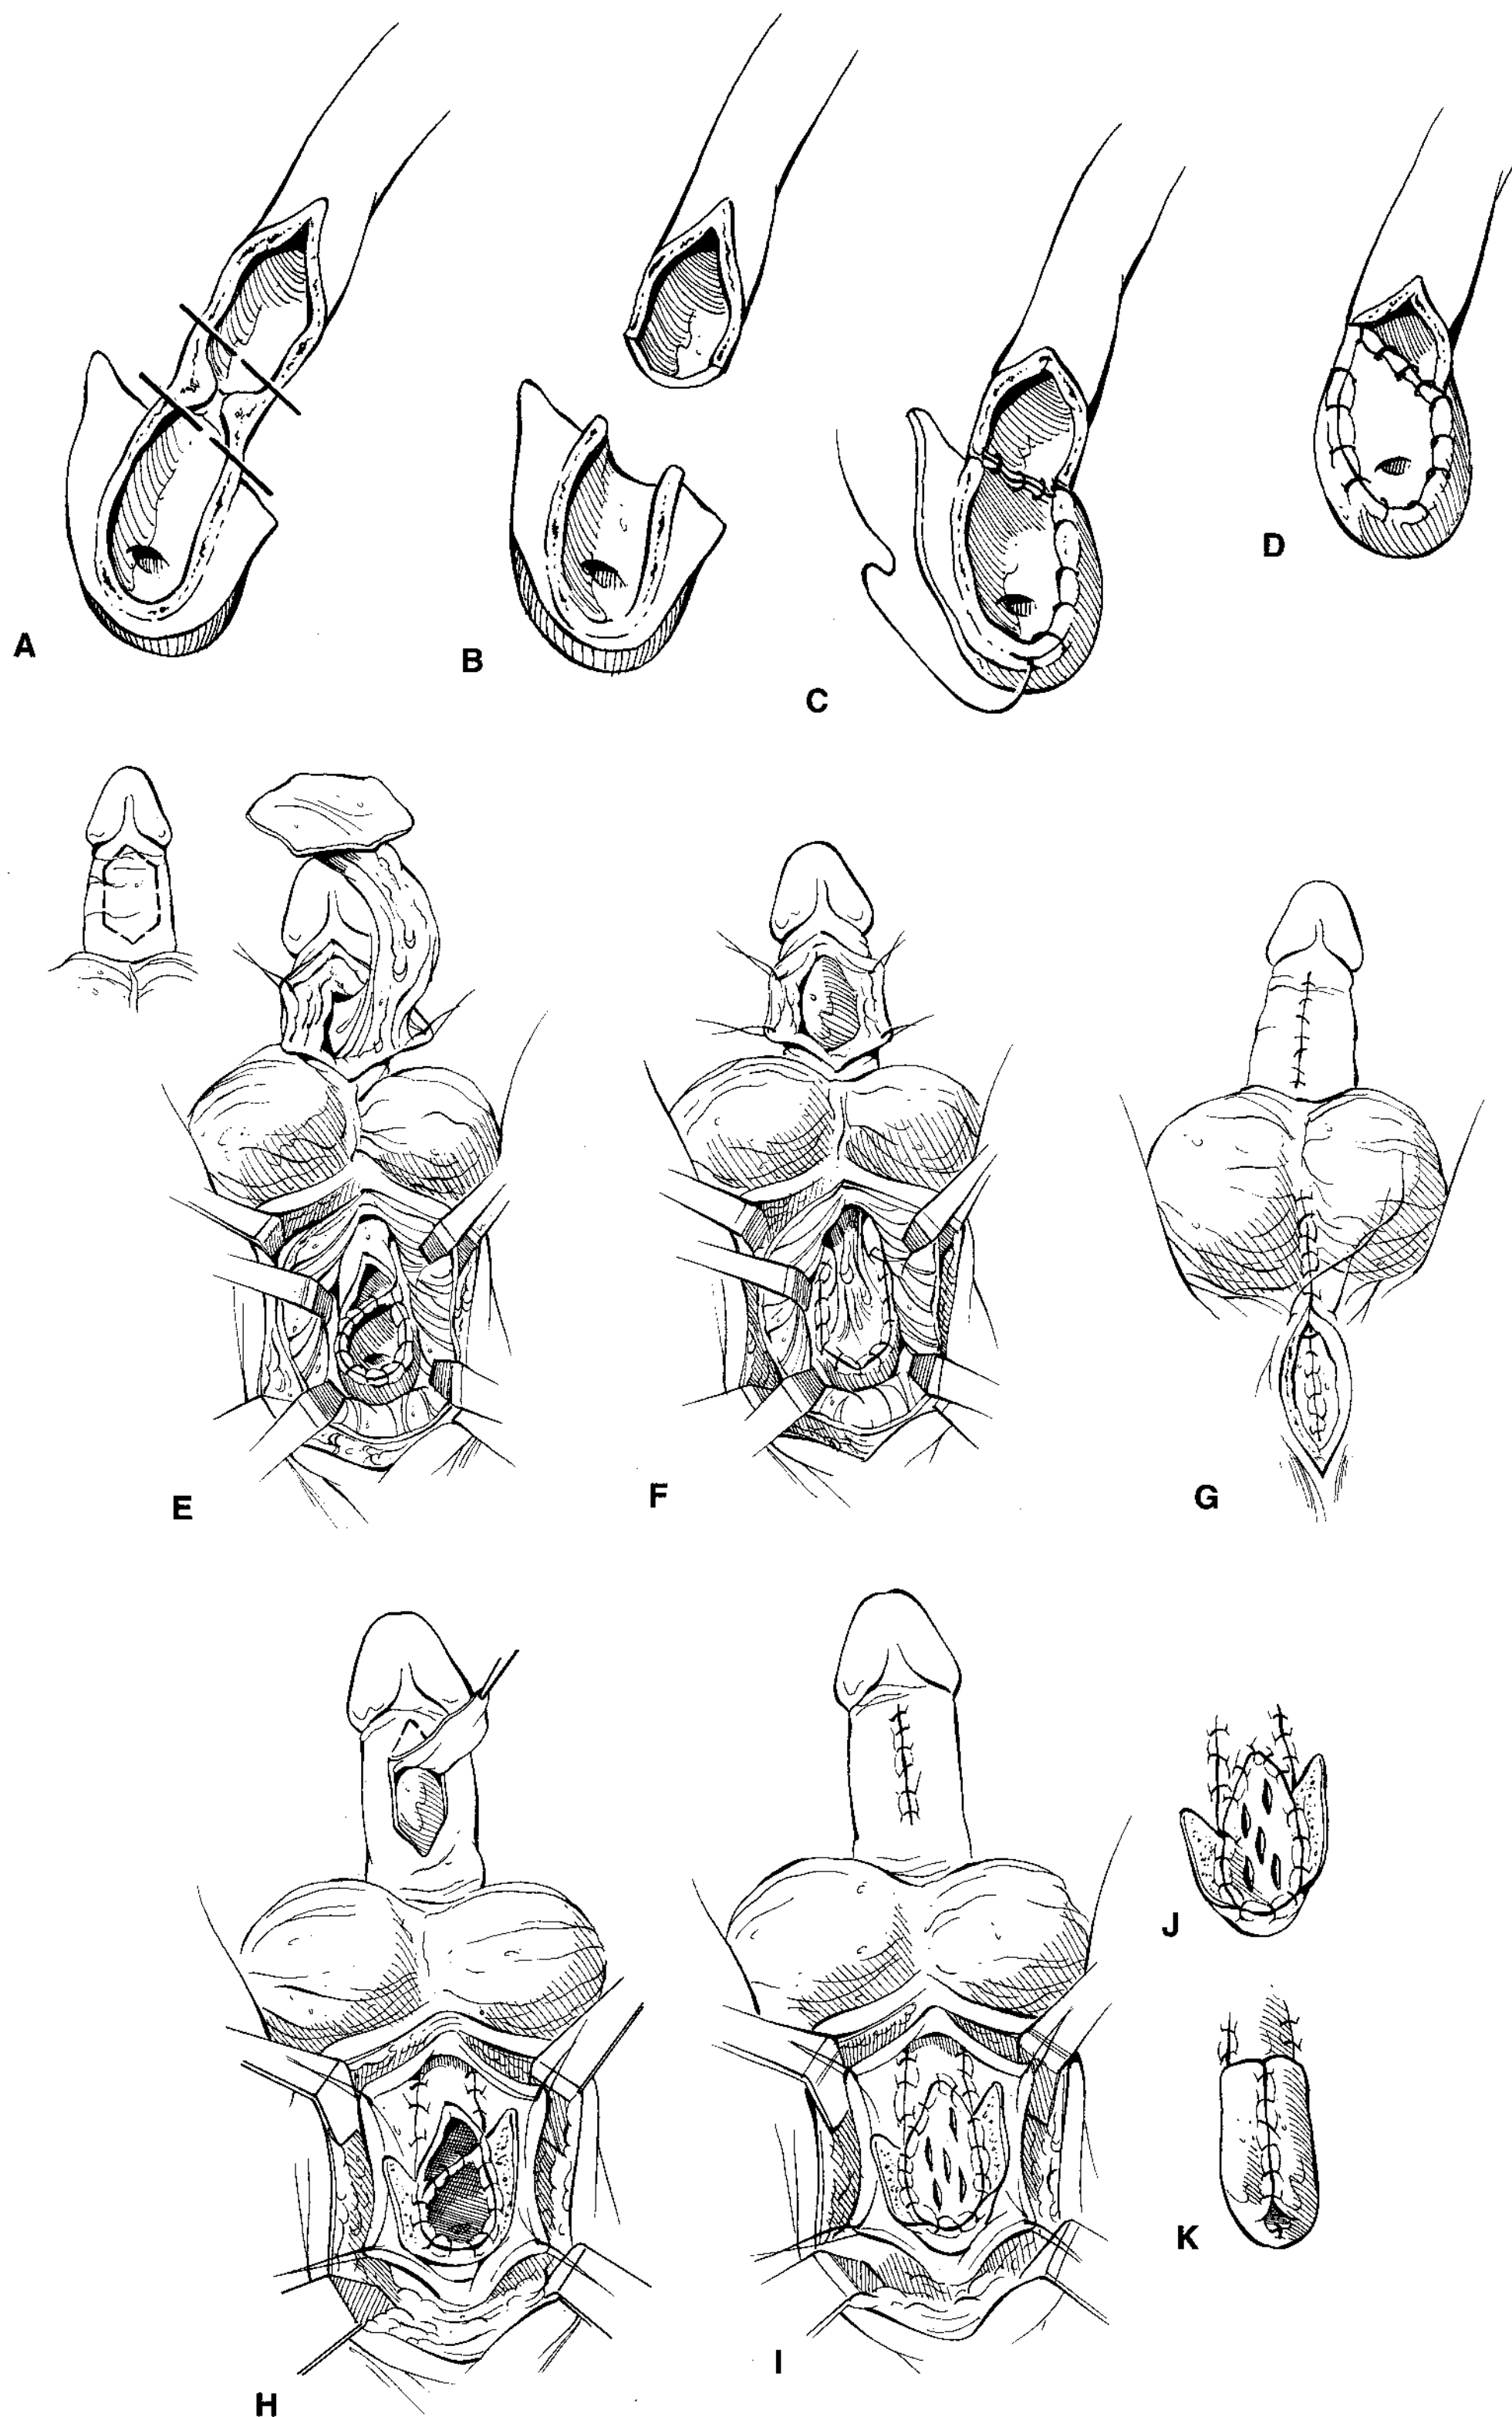

---

## One-Stage Combination Urethroplasty

---

One-stage combination procedures make use of both a flap repair for the pendulous portion of the urethra and a graft repair for the bulbar area, with the two procedures being performed in continuity (7). The patient is placed in the lithotomy position for access to the perineum as well as the penile shaft. In uncircumcised men the prepuce can be used as a skin graft donor site, leaving the remaining shaft skin for island pedicle flap construction. In the event there is insufficient penile skin, buccal mucosa may be used for the graft repair of the contiguous scrotal/bulbar urethra, or buccal mucosa may be preferred even in cases where penile skin is sufficient. One should avoid the use of penile skin when lichen sclerosis is present.

A ventral incision is made over the pendulous urethra, and this portion of the stricture is repaired using a ventral onlay repair in the fashion of Orandi, as described earlier. The more proximal scrotal portion of the stricture is then repaired in continuity by a dorsal or ventral onlay. This portion of the repair is approached through a separate incision in the perineum for exposure of the bulbar urethra. If a dorsal onlay is used, which is our preference, the bulbar urethra is circumferentially mobilized as far distally as the proximal limit of the penile flap

**FIGURE 35.6** Augmented roof strip anastomotic repair. **A–D:** A healthy roof strip of urethra is created by stricture excision and roof strip reanastomosis. **E–G:** An appropriately sized and shaped island of ventral penile skin is mobilized on its vascular pedicle, tucked through the scrotum, and sutured over the anastomosis, augmenting its caliber (closure is in layers). **H–K:** This series illustrates the augmented roof strip anastomotic repair using a fenestrated full-thickness skin graft from the ventral penile shaft rather than a pedicled island of penile skin.

**FIGURE 35.7** The dorsal onlay graft bulbar urethroplasty. **A:** Exposure of the urethra. **B, B1:** Fenestrated graft sutured to the undersurface of the corporal body. Strictured portion of the urethra either excised or rotated. **C:** Suture of the opened urethra to dorsal onlay graft. **D:** Completed repair.

repair, and the urethra is then incised dorsally through the stricture, with the distal limit being the visible ventral onlay; the dorsal onlay graft is then completed as described earlier. Hence, the long stricture is repaired by a ventral onlay flap for the pendulous portion and a dorsal onlay graft for the more proximal urethra, with the composite repair being completed nose to tail.

### Staged Repair

Extensive anterior urethral stricture disease, in particular full-length strictures, strictures complicated by fistula or inflamma-

tion, and long recurrent strictures following prior repair, is best managed by a staged repair. Historically, such repairs were performed as scrotal inlay procedures with the resultant neourethra being constructed from hair-bearing scrotal skin, which experience has proven to be a suboptimal substitute. Variations on this theme now inlay fenestrated full-thickness preputial skin, split-thickness thigh skin, or buccal mucosa alongside the marsupialized urethra in the first stage. In the second stage, the neourethra is formed by tubularization of the graft. Full-thickness skin is superior for this purpose but is not often available in communities where circumcision is common. If split-thickness skin is to be used, it is in general harvested from the thigh,

which is easily accessed with a patient in the lithotomy position. The strictured anterior urethra is exposed through a ventral midline perineal incision that may bifurcate the scrotum, and the urethra is then incised along the length of the stricture to healthy urethra proximally and distally. This again is confirmed by calibrating the urethra with a 24Fr to 28Fr bougie à boule, which should pass easily through each ostium. Using a dermatome set to 20 thousandths of an inch, a split-thickness graft is harvested from the thigh and meshed to a ratio of 1.5:1.0. A strip of meshed graft measuring 3 to 5 cm is then inlayed around the marsupialized strictured urethra (Fig. 35.8). Medially it is sutured to the incised urethral margin and laterally to the incised scrotal and perineal skin edges using 5-0 PGA. This width of graft accounts for the up to 50% shrinkage that may occur with split-thickness skin, resulting in suitable graft width for a future neourethra. If buccal mucosa is inlayed (preferable but not always adequately available), a fenestrated graft of 2.5 to 3.0 cm in width is usually adequate because it undergoes less contraction. A suprapubic tube is placed for urinary diversion in the postoperative period, and the graft is dressed with an Adaptic gauze and a tie-down dressing of sterile cotton fluffs soaked in Bunnell solution. The graft is kept

**FIGURE 35.8** Staged urethroplasty for full-length stricture disease using meshed split-thickness skin graft. The meshed graft is laid alongside the marsupialized urethra so that the neourethra will be tubularized from the graft rather than from hair-bearing scrotal skin. Tubularization of the neourethra is delayed for 3 to 6 months.

moist by periodic application of Bunnell solution until the dressing is removed after 5 days. Graft take is in the order of 95% or greater.

The second stage is performed a minimum of 3 months later and in practice usually 6 to 12 months later to allow thorough vascularization of the graft and to allow adjacent stricture disease to declare itself. The proximal and distal urethral openings should again freely calibrate to 28Fr and 24Fr, respectively, prior to second-stage closure. If the ostia have narrowed, revision rather than dilation should be undertaken, usually using a Y-V advancement technique. Second-stage repair is begun by incising the graft circumferentially to a width that will allow neourethral tubularization to approximately 28Fr. The tubularization is performed by midline anastomosis with a running 5-0 PGA suture, interlocking every third pass, followed by a multilayer wound closure. The urethra is stented for 20 days.

## OUTCOMES

---

### Complications

---

Hematoma or hemorrhage is in general rare if meticulous attention is paid to hemostasis during the repair. Wound infection is an uncommon complication that in general presents with erythema and induration at the incision site.

Flap necrosis is uncommon in experienced hands and is most often due to technical errors in preparation of skin flaps or poor flap selection. Flap viability may also be adversely affected by prior surgery, infection, tissue ischemia, tobacco usage, and malnutrition. Contraction of 15% to 25% is anticipated for full-thickness skin grafts and must be accounted for during preparation. Removal of subcutaneous fat and fascia must be achieved for adequate exposure of the subdermal vascular plexus but should not be so excessive as to convert the graft to a split-thickness variety. Fenestration of free grafts will promote drainage of the graft bed, and a well-vascularized graft bed must be assumed, sometimes requiring redeployment of spongy tissue. Split-thickness grafts are not advocated for one-stage urethroplasty because their shrinkage is unpredictable and may be excessive (up to 50%).

Fistula is in general uncommon in adult urethral surgery but is on occasion encountered in the setting of underlying infection or vascular compromise. It most commonly occurs following repair of pendulous urethral strictures. Suprapubic urinary diversion may allow for spontaneous healing of fistulas encountered within the first few weeks following urethroplasty. Fistulas that fail to close with proximal diversion generally need reoperation after a minimum of 6 months.

With use of an oversized or poorly supported ventral onlay flap or graft, in particular in the bulbar urethra, there is on occasion formation of a redundant urethral segment in which urine may pool, leading to poor urethral emptying and recurrent infection. Urethral stones can form as a result of urinary stasis in the diverticulum or as a result of retained hair on flaps and grafts. Proper measurement of flaps and grafts to provide a 26Fr to 28Fr lumen, as well as adequate spread-fixation of the onlay, may obviate sacculation. Preoperative epilation and proper selection of donor sites can prevent the hairy urethra.

Penile curvature may result because of inappropriate procedure selection in attempting anastomotic repair or long-graft

onlay repair to the pendulous urethra distal to the suspensory ligament. It may also follow excessive urethral excision (>2 cm) when performing anastomotic repair in the bulbar urethra. A downward deflection of the erect penis may also occur. Grafts of nonpenile origin frequently will not have the same elasticity as the penis, contributing to curvature.

In experienced hands erectile dysfunction as a result of anterior or posterior urethroplasty is rare. Temporary (3 months or less) impotence occurs in 53% of those who undergo anastomotic urethroplasty and in 33% of those who undergo patch repair. However, permanent impotence is unusual: 5% and 0.9%, respectively. Further, Coursey et al. reported that erectile dysfunction after anterior urethroplasty is no more common than in men who undergo circumcision (4). In a prospective evaluation of the effect of bulbar urethroplasty on erectile function using International Index of Erectile Function scores, surgery proved to have an insignificant effect (2). These results can be attributed to judicious scar excision, minimal use of electrocautery, and dissection away from the dorsally based neurovascular structures.

## Results

As understanding of urethral anatomy and tissue transfer techniques has grown, so too has the effectiveness of urethral reconstruction for stricture disease. Patency rates in excess of 90% are reported for anastomotic repairs in bulbar strictures (10). With regard to substitution repairs, tube grafts fare less well than onlay procedures, both of which are best applied to the more proximal portion of the anterior urethra. A discouraging constant annual attrition rate of 5% per year has been reported for substitution urethroplasty at follow-up of 10 years, although this is not these authors' experience (9). For repair of pendulous urethral strictures, flaps perform best in terms of patency and avoidance of penile curvature. Buccal mucosal grafts show promise and conceptually seem to be superior, but long-term data are necessary to define their emerging role in urethral reconstruction. Certainly the most common cause for stricture recurrence appears to be ongoing fibrosis in the adjacent unmanaged urethra, in particular that proximal to the repair.

# CHAPTER 36 ■ SURGERY FOR URETHRAL TRAUMA INCLUDING URETHRAL DISRUPTION

JACK MCANINCH AND BRYAN B. VOELZKE

A solid understanding of the etiology, evaluation, and management of traumatic urethral injuries is dependent upon the location of urethral trauma. The urethra is divided into anterior (pendulous and bulbar urethra) and posterior (membranous and prostatic urethra) divisions, which have specific mechanisms of injury that will influence eventual therapy and outcome. Immediate management of anterior and posterior urethral trauma predominantly involves temporizing solutions to divert urine away from the urethral injury. A small

cohort of patients will be cured by these temporizing measures; however, the majority will require an invasive surgical repair 3 to 6 months after the initial injury. Early recognition and diagnosis of urethral injuries are crucial to the successful management and prevention of long-term complications. This chapter will divide the diagnosis and management of urethral trauma into anterior and posterior injuries to better enable the reader to learn how to manage their unique presentations.

## ANTERIOR URETHRAL INJURIES

The anterior urethra extends distally from the membranous urethra to the urethral meatus (Fig. 36.1). Contrary to the posterior urethra, the anterior urethra is encompassed by the corpus spongiosum, the deep (Buck) fascia, and the superficial (dartos) fascia along its entire length. The penoscrotal junction divides the shorter, proximal bulbar urethra from the longer, distal pendulous urethra. The bulbospongiosus muscle ventrally covers the bulbar urethra and terminates at the penoscrotal junction, prior to the origination of the distal pendulous urethra. The pendulous urethra closely approximates the corpora cavernosa during most of its length, with the lumen of the distal pendulous urethra dilating distally to form the fossa navicularis.

Blunt or penetrating injury can result in anterior urethral trauma; however, blunt forces predominate along the entire urethra. Etiologies include blunt compression or straddle injuries, penile fracture with concomitant urethral disruption, constriction rings, iatrogenic trauma (e.g., after Foley catheterization or endoscopic urethral surgery), and penetrating trauma (e.g., stab or gunshot wounds). Compression of the bulbar urethra against the pubic bone (straddle injury) is the most common anterior urethral injury and occurs after a direct force to the perineum compresses the relatively immobile bulbar urethra against the pubic bone. Additionally, penile constriction rings can damage the anterior urethra secondary to tissue ischemia. Foley catheterization or endoscopic urethral surgery can damage the bulbar urethra, resulting in contusion or partial urethral disruption. The true extent of iatrogenic injuries, along with trauma from constriction rings, may not become evident until many years after the original event (1). Anterior urethra injuries are rarely associated with pelvic fractures but are seen in approximately 20% of penile fractures (2). The close relation of the corpora cavernosa to the pendulous urethra contributes to this association.

## Diagnosis

Anterior urethral injuries can present in an immediate or delayed fashion. A careful history and physical examination should raise suspicion for anterior urethral injury. Straddle injuries often present in a delayed fashion with obstructive voiding symptoms and an idiopathic etiology. In a series of 78 patients with straddle injuries, 40% presented to the emergency department in an acute setting, versus 60% of patients who presented 6 months to 10 years after the original injury (3). Hematuria, difficulty voiding, penile sleeve hematoma (injury confined to the Buck fascia), and perineal “butterfly” hematoma (injury penetration to the Buck fascia) are common presenting symptoms in the acute or delayed setting. In addition to a perineal “butterfly” hematoma, penetration of the Buck fascia can allow the spread of urine and/or blood to the scrotum (dartos fascia), anterior abdominal wall (Colles fascia), and/or thighs (fascia lata).

All patients with a suspected anterior urethral injury should undergo a retrograde urethrogram prior to an attempt at urethral catheter placement. Ideally the patient should be placed obliquely at a 30- to 45-degree angle with the bottom leg flexed at 90 degrees and the top leg kept straight (Fig. 36.2). In the acute setting, associated pelvic fracture may preclude this position; therefore, a supine retrograde urethrogram should be employed to answer the simple question of whether or not the urethral lumen has been disrupted. Flexible cystoscopy has been advocated to aid the diagnosis of urethral trauma; however, we prefer radiographic imaging when possible.

The retrograde urethrogram should be performed with undiluted water-soluble contrast medium [full-strength (60%) ionic contrast medium]. A scout film provides initial information on patient position and the potential presence of a foreign body. A 12Fr Foley catheter is then placed into the fossa navicularis, and the balloon is inflated with 2 to 3 mL of sterile water to prevent

**FIGURE 36.1** Anatomy of the anterior and posterior urethra.

**FIGURE 36.2** Proper positioning for retrograde urethrography. The patient is placed obliquely at a 45-degree angle with the bottom leg flexed and the top leg straight. Slight traction on the penis during injection of contrast helps avoid telescoping of the urethra and allows more accurate characterization of the injury.

catheter dislodgment during the urethrogram. The penis is positioned laterally on a slight stretch to provide a more descriptive study, and 20 to 30 mL of contrast is then injected in a retrograde fashion. Dynamic fluoroscopy is ideal; however, in the setting of acute trauma in the emergency department, static radiographs will suffice. The entire anterior urethra can be visualized during a retrograde urethrogram; however, the posterior urethra is typically excluded by reflex contraction of the external sphincter. If a catheter is present at the time of evaluation, then a cystogram is recommended to confirm the catheter's presence in the bladder. After documenting the correct location of the urethral catheter, a pericatheter retrograde urethrogram can delineate possible urethral injury.

Anterior urethral injuries are classified into three groups based upon radiographic, clinical, or endoscopic findings. *Contusions* appear normal on retrograde urethrogram or as urethral elongation from compression by periurethral hematoma. Contusions are best appreciated by cystoscopy in the setting of a "normal" retrograde urethrogram; however, we are not recommending cystoscopy for all "normal" urethrogram studies with a suspicious clinical history. *Partial disruptions* appear as extravasated urine on retrograde urethrogram with visualization of contrast in the urethra or bladder proximal to the injury. *Complete disruptions* appear as total extravasation without visualization of contrast in the more proximal urethra or bladder.

### Indications for Surgery

Primary surgical repair of acute anterior urethral injuries should be avoided, with the exception of a stable patient with a complete urethral disruption and an open or penetrating injury. We also recommend an attempt at anterior urethral repair in the setting of emergent surgery for penile fracture. Successful

repair of all acute anterior urethra injuries is dependent upon minimal associated inflammation; therefore, surgeons should consider waiting for delayed, definitive repair when possible.

### Alternative Therapy

Alternative options to surgical repair are placement of a urethral or suprapubic catheter to divert urine from the injured area. Contusions to the anterior urethra should be managed with a urethral catheter for approximately 2 to 3 weeks followed by a retrograde urethrogram. The patient should be counseled on the possibility of delayed development of a urethral stricture at the site of contusion; however, stricture development is uncommon.

Percutaneous suprapubic catheter placement should be considered in patients with penetrating urethral trauma and hemodynamic instability, multiple associated injuries, or a long anterior urethra defect. Ultrasound guidance should be considered in the setting of a nonpalpable bladder or a history of prior abdominal surgery. If there is an associated pelvic fracture, urologists are urged to speak with orthopedic staff to ensure that future internal or external fixation hardware will not interfere with the planned suprapubic tube location. If radiographic staging was precluded by the patient's concomitant injuries, then a suprapubic cystogram and retrograde urethrogram should be done at the earliest opportunity. Broad-spectrum antibiotics are essential to maintain the sterility of extravasated urine or blood. A voiding cystogram is recommended after 3 weeks of urinary diversion. We do not advocate blind urethral catheter placement in the presence of blood at the urethral meatus, pelvic fracture, or perineal hematoma if hemodynamic instability precludes a retrograde urethrogram; however, some would argue that one attempt at urethral catheter placement by an experienced physician or urologist is acceptable.

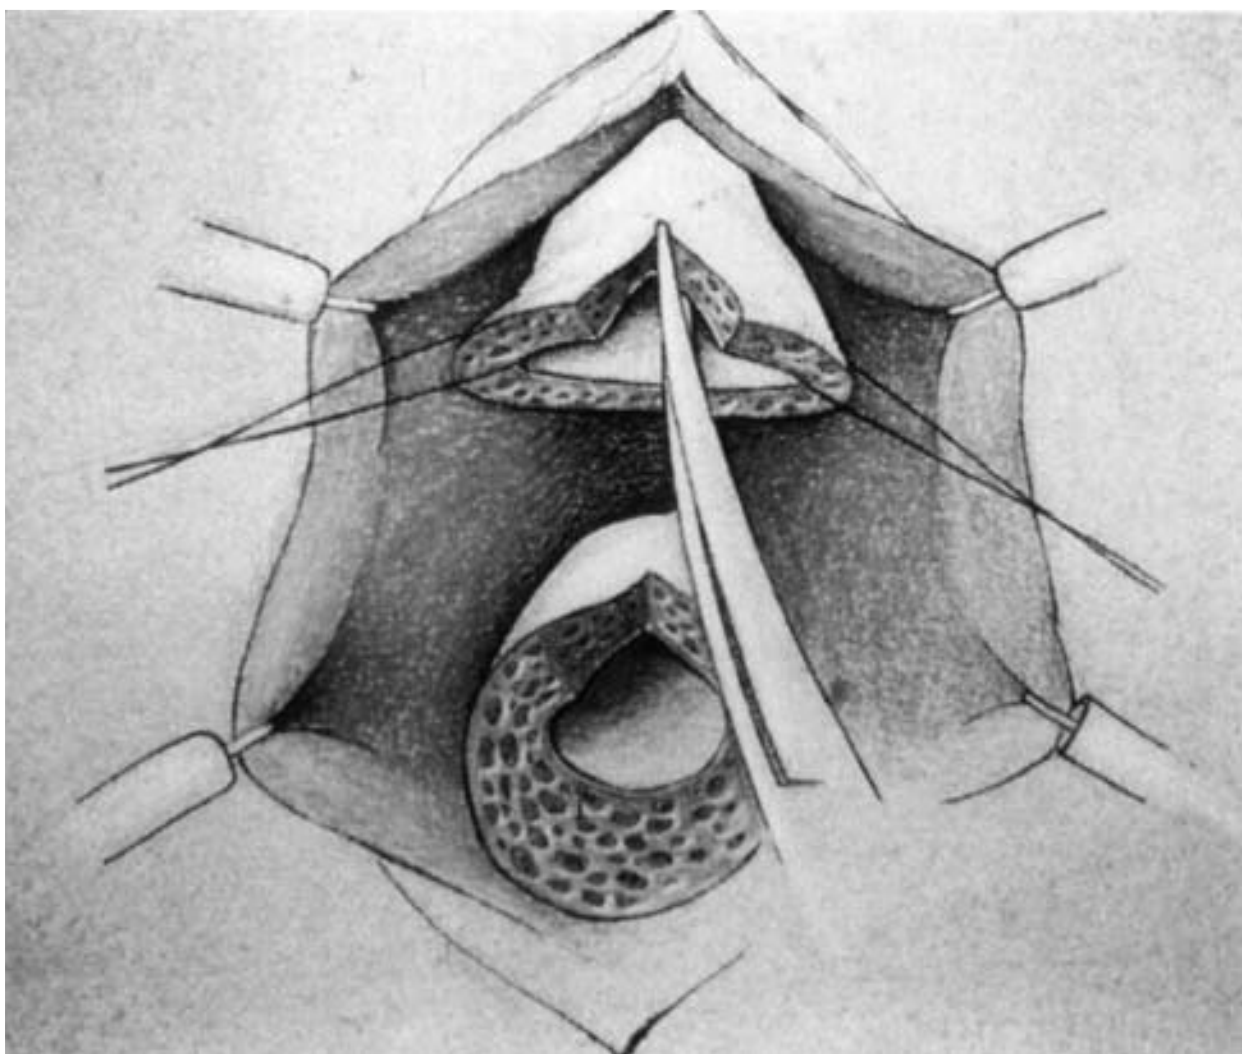

Partial urethral disruptions diagnosed by retrograde urethrogram may be managed via various algorithms. Urinary diversion with formal repair after a minimum of 3 months to allow resolution of inflammation and maturation of scar tissue is our preference. As mentioned above, one attempt at urethral catheter placement by experienced medical personnel is acceptable; however, the possibility of creating a complete urethral disruption during this attempt should be considered. If urethral placement is unsuccessful, percutaneous suprapubic tube placement should be performed. The preservation of urethral mucosa with partial disruptions may be adequate for re-epithelialization and eventual luminal recanalization; however, if successful, we would recommend periodic evaluation with pressure-flow urine studies and counseling patients regarding the possibility of future stricture development.

Endoscopic alignment of the anterior urethra has been described in a limited series of 16 men with partial and complete bulbar straddle injuries (4). With this management, 14 out of 16 patients were successfully managed with endoscopic urethral alignment alone. The 2 failures had a history of a failed attempt at blind urethral catheter placement. The authors stressed the importance of not advancing the cystoscope past the stricture during endoscopic alignment, but rather to only pass guide wires through the urethral disruption in an attempt to prevent worsening the degree of urethral injury.

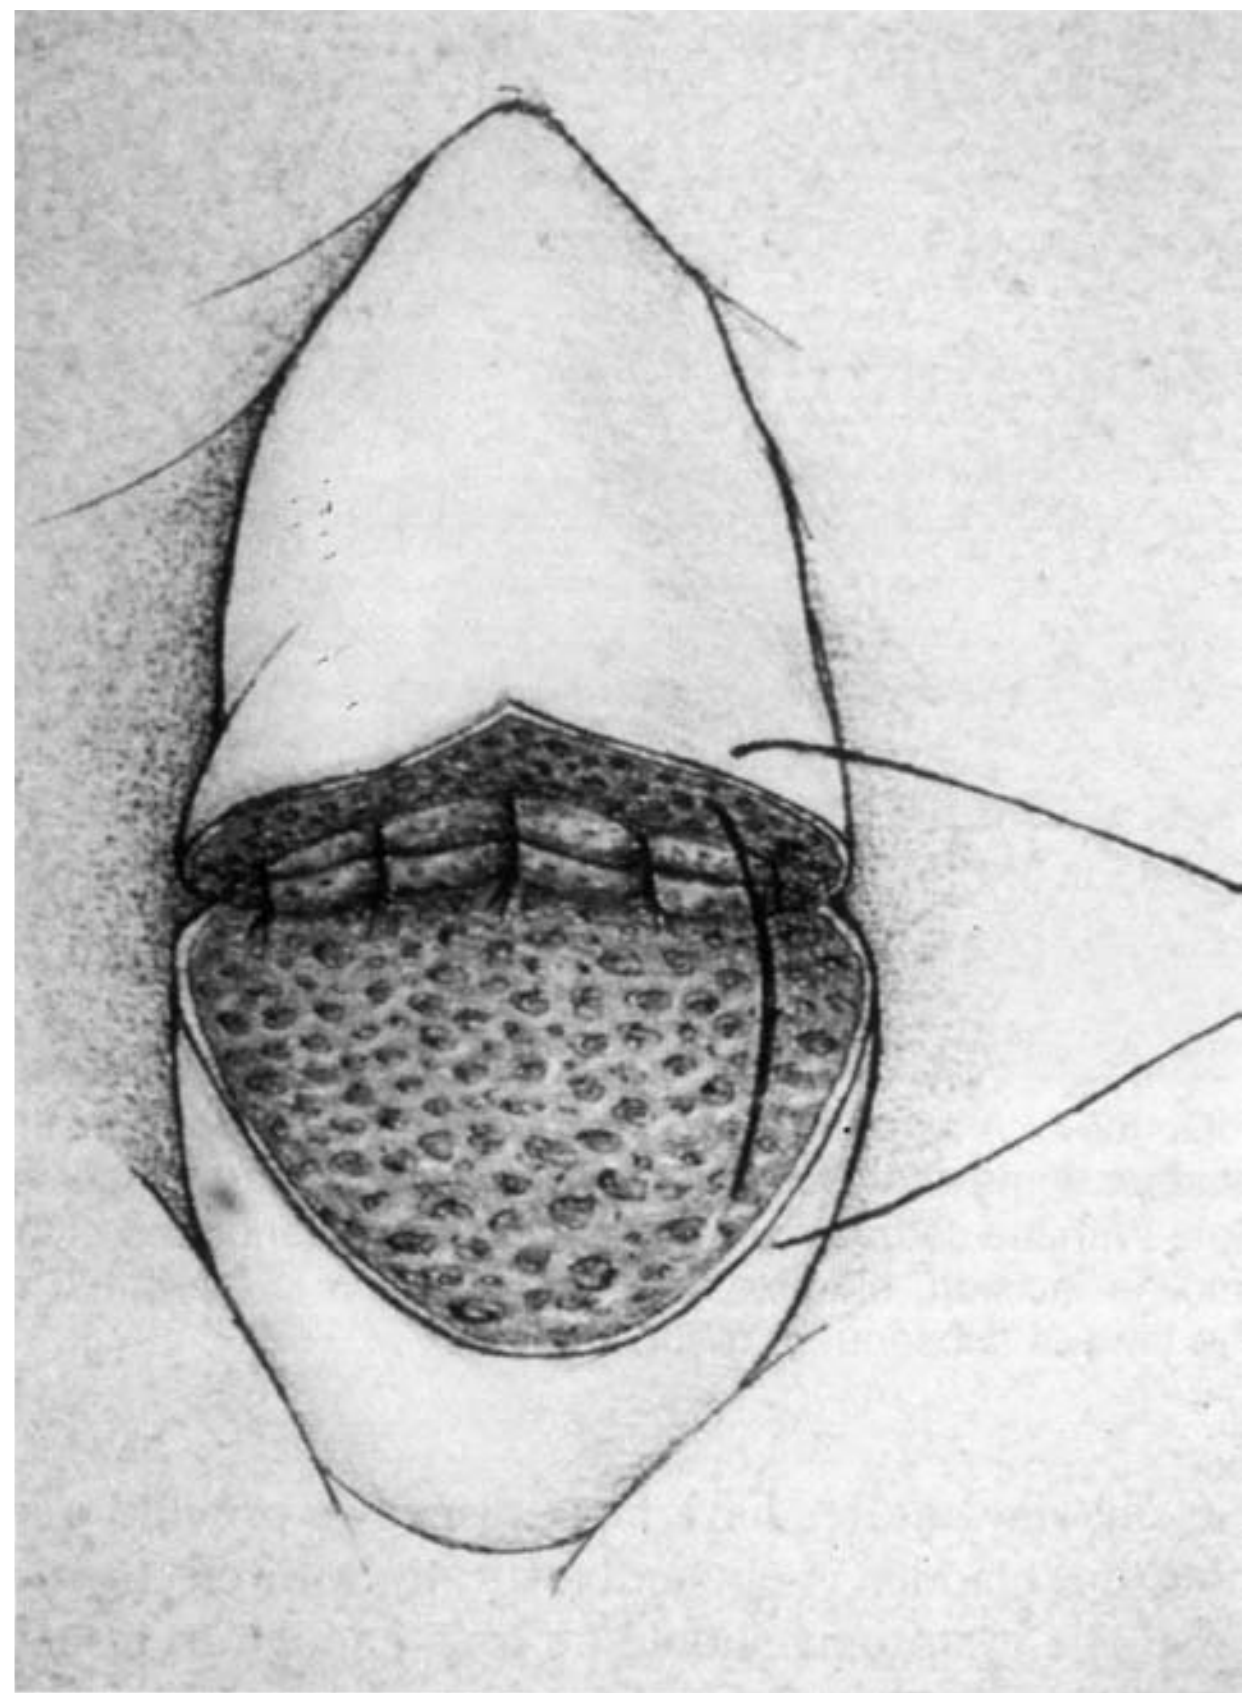

## Surgical Technique

Open surgical repair is primarily reserved for stable patients after open or penetrating injury to the anterior urethra. The patient is placed in either the supine position or lithotomy position and draped widely to allow exploration of potential concomitant injuries to the penis, testes, perineum, and rectum. Clean wounds need only minimal debridement followed by urethral closure with interrupted or running 6-0 polyglyconate monofilament (polydioxanone, Maxon) sutures over a 16Fr catheter. Contaminated wounds require thorough irrigation and debridement of devitalized tissues to ensure reapproximation of healthy tissue.

With open or penetrating bulbar urethra injuries, the patient is placed in the high lithotomy position and a vertical perineal incision is performed along the raphe. As expected, only stable patients without injury precluding the high lithotomy position should be offered acute surgical intervention. The urethra is exposed after division of Colles fascia and the bulbospongiosus muscle. As with elective bulbar urethra stricture surgery, anastomotic urethroplasty should only be considered for defects <20 mm. Surgeons should avoid acute repair of bulbar urethra defects longer than 20 mm as more complex intervention with grafts of flaps will be required. The most important tenet allowing successful outcome is a tension-free anastomosis; therefore, mobilization of the distal urethra is an important step to ensure adequate urethral length. Once adequate length is achieved, the urethral ends are spatulated (Fig. 36.3). The anastomosis is performed with interrupted 5-0 and 6-0 polyglyconate monofilament suture to create a tension-free, watertight closure. The dorsal surface is closed in one layer with 5-0 interrupted polyglyconate monofilament incorporating the urethral mucosa and spongiosal adventitia. Since the ventral bulbar urethra is vascularized by the spongy urethra, we advocate ventral closure in two layers with interrupted 6-0 polyglyconate monofilament suture (Fig. 36.4). We make no attempt to control bleeding from the spongy urethra during closure, as we theorize that

**FIGURE 36.3** Repair of bulbar urethral injuries. The urethra is mobilized and spatulated in preparation for a tension-free end-to-end anastomosis.

**FIGURE 36.4** Repair of bulbar urethral injuries. Anastomosis is carried out with a single-layer dorsal closure and a two-layer ventral closure using interrupted 5-0 or 6-0 Maxon sutures.

the added vascularity from the spongy urethra will provide enhanced healing of the anastomosis after two-layer closure. We strongly recommend that a first-stage marsupialization of healthy proximal urethra be considered if tension-free closure cannot be achieved or if there is significant wound inflammation or contamination.

Penile urethral injuries are best exposed via a subcoronal circumferential incision. Contrary to bulbar urethral injury, anastomotic repair should not be considered for defects >15 mm, as the risk of penile chordee is higher with penile anastomotic repairs. In prior editions of this textbook, we have advocated utilization of a 16Fr silicone Foley catheter; however, we now use regular latex catheters, if possible. Suppressive antibiotics are given while the catheter is in place to maintain urine sterility, with a voiding cystogram performed after 2 to 3 weeks. If extravasation is noted, we gently replace the catheter for an additional period of time with repeat imaging at the time of urethral catheter removal.

## Outcomes

### Complications

The major complications relating to anterior urethral trauma include urethral stricture formation and infection. If untreated, persistent extravasation of infected urine or blood may lead to urethral abscess, urethrocutaneous fistula, or urethral diverticula. Prolonged urine extravasation into the corpus spongiosum

can also lead to added spongiositis, resulting in a longer urethral stricture. Consequently, a longer anterior urethral stricture translates to more complex management with a buccal mucosa graft or fasciocutaneous flap.

With early urine diversion, a percentage of anterior urethral strictures will never progress to functional significance; however, of those that do, early diversion can limit stricture length to allow a wider array of future options. Incontinence and impotence, although common in posterior urethral injuries, are uncommon in anterior urethral injuries. Stricture recurrence after formal anastomotic urethroplasty is most common in the first 12 months. Stricture recurrence after urethroplasty is generally short and can be successfully treated in one session with internal urethrotomy.

### Results

Anastomotic urethroplasty can be successfully performed in a high percentage of patients who sustain a bulbar urethra (straddle) injury requiring surgery. The procedure has an overall success rate of approximately 95% when performed in a delayed setting (3). As mentioned previously, patients sustaining open or penetrating injuries associated with minimal inflammation are the best candidates for acute repair; otherwise, urine diversion is recommended with formal repair at a later date.

---

## POSTERIOR URETHRAL INJURIES

---

The posterior urethra is shorter than the anterior urethra and consists of the membranous and prostatic urethra (Fig. 36.1). The more proximal prostatic urethra extends from the bladder neck to the apex of the prostate and is secured to the pubic bone by the paired puboprostatic ligaments. During cystoscopy, the verumontanum marks the most distal aspect of the prostatic urethra. The proximal urethral sphincter is present within the prostatic urethra and is an extension of smooth muscle fibers of the trigone and prostatic urethra cephalad to the verumontanum. Conversely, the distal urethral sphincter encompasses smooth muscle fibers caudad to the verumontanum, including the rhabdosphincter (slow-twitch skeletal muscle fibers) (5). In the absence of a functional distal urethral sphincter, the proximal urethral sphincter can maintain urinary continence in select patients; however, the bladder must be compliant and free from periodic elevations of detrusor pressure (e.g., overactive bladder). The membranous urethra is the least supported portion of the urethra, and injury to the membranous urethra is not uncommon given its location between two relatively fixed points (prostate and bulbar urethra). Since the distal urethral sphincter is located in the membranous urethra, shear injuries leading to partial or complete membranous urethral disruption can result in distal urethral sphincter damage.

Posterior urethral trauma is almost always associated with pelvic fracture; conversely, only 10% to 15% of pelvic fractures are associated with urethral injury. Furthermore, bladder injury has also been diagnosed in 10% to 20% of patients with pelvic fracture and urethral injury (6). Since the blunt forces required to generate a pelvic fracture are significant, the associated urethral injuries are highly correlated with serious injuries (e.g., intra-abdominal and vascular injuries to the pelvic vasculature). Other sources of injury to the posterior

urethra include penetrating injuries and iatrogenic injuries secondary to endoscopic or open prostate surgery.

The clinical and surgical appearance of each form of posterior urethral injury will differ. Endoscopic or open prostate surgery is associated with continuity strictures and preservation of the distal external urinary sphincter. As such, these injuries have been termed “sphincter stenoses” (bladder neck sphincters). In contradistinction, pelvic fractures are associated with urethral disruptions to the membranous urethra. These injuries have been termed “pelvic fracture urethral disruption defects” (PFUDDs). Interestingly, a recent report has found that 7 of 10 patients examined at autopsy had urethral disruption after pelvic fracture *distal* to the external urinary sphincter, disputing the historical view that these injuries occur at the interface of the fixed prostatic apex and the less supported membranous urethra (7). Additionally, urodynamic studies have demonstrated a functional rhabdosphincter at the prostatomembranous region in many patients after anastomotic posterior urethroplasty for PFUDD (5).

---

### Diagnosis

---

This section will primarily focus on PFUDD injuries, as these injuries are the most common presentations in the acute trauma setting. Given the close association of more serious concomitant injuries with PFUDD, the first goal is resuscitation of the patient. Suspicious findings after PFUDD mirror those of anterior urethral injuries, namely, hematuria, blood at the meatus, perineal hematoma, and difficulty voiding. Additionally, a high-riding prostate on digital rectal exam and specific pelvic fractures are linked with PFUDD. The prostate can appear elevated in position on digital rectal exam due to displacement from a pelvic hematoma and/or digital confirmation of the prostate may be indistinguishable from the pelvic hematoma. Regarding pelvic fractures, displacement of the inferomedial pubic bone and symphysis pubica diastasis are independently associated with urethral injury (8).

Retrograde urethrogram should be performed on all patients suspected of having PFUDD before any attempt at urethral catheter placement (Fig. 36.5). If normal, the catheter should be gently advanced into the bladder and a formal cystogram should be obtained to assess for bladder perforation. The technique for retrograde urethrogram was discussed in the section on anterior urethra injuries. A formal cystogram can be performed in the emergency department or radiology suite. Three radiographic views should be obtained, including an anterior-posterior scout film, a full-bladder anterior posterior film, and a drainage film. False-negative results are strongly correlated with inadequate filling; therefore, passive filling to discomfort or 350 mL of contrast is recommended. Other studies to further delineate posterior urethral injuries include flexible cystoscopy; however, we caution against advancing the cystoscope past the site of injury for fear of worsening the injury. Lastly, in a nonacute setting MRI can be useful to provide more descriptive analysis of complex PFUDD.

Posterior urethral injuries secondary to blunt trauma have historically been classified based upon the Colapinto and McCallum system (9). A recent modification maintains the original three classes of injury; however, this revised system also includes posterior urethral injuries that extend to the bladder neck and blunt anterior urethral injuries (Table 36.1) (10).

A

C

**FIGURE 36.5** Posterior urethral injuries. **A:** Type I: stretched urethra without rupture. Note the displaced and compressed bladder and fractures of the right symphysis and superior and inferior rami. **B:** Type II: complete rupture of the membranous urethra with intact urogenital diaphragm. Note the limited extravasation and venous filling. **C:** Type III: Note the pattern of extravasation when the urogenital diaphragm is disrupted, as compared with type II. (From Dixon CM. Diagnosis and acute management of posterior urethral disruptions. In: McAninch JW, ed. *Traumatic and reconstructive urology*. Philadelphia: WB Saunders, 1996:347–355, with permission.)

TABLE 36.1

## CLASSIFICATION OF BLUNT URETHRAL INJURIES (9)

Class	Description
I	Posterior urethra stretched but intact
II	Tear of the prostatomembranous urethra above the urogenital diaphragm
III	Partial or complete tear of both the anterior and posterior urethra with disruption of the urogenital diaphragm
IV	Bladder injury extending into the urethra
IVa	Injury of the bladder base with periurethral extravasation simulating posterior urethral injury
V	Partial or complete pure anterior urethral injury

### Indications for Surgery

Controversy and confusion exist regarding whether primary alignment or suprapubic diversion is better for acute management of PFUDD. There is no correct answer for this question, despite what has been written in the literature regarding the impact of each on eventual incontinence, impotence, and urethral stricture rates. Since each procedure is governed by different definitions for successful outcome, neither should be considered the best therapy option. The obvious benefit of

primary alignment is a lower stricture rate of 56% versus the 97% stricture rate seen with suprapubic catheter placement (11). In addition, urethral strictures after endoscopic alignment can result in shorter stricture length and the possibility of a less invasive option, such as internal urethrotomy instead of formal perineal urethroplasty. Despite claims that periodic office urethral dilations are trivial to the patient, we would disagree with this assertion and counsel the patient for posterior urethroplasty to definitively treat the persistent stricture.

Impotence and incontinence outcomes in the literature can be difficult to compare, with multiple reports claiming different results after endoscopic alignment and suprapubic tube with delayed urethroplasty. In experienced centers, incontinence and impotence rates after endoscopic alignment are 4% and 36%, respectively (11). A suprapubic tube with delayed urethroplasty in the same study found minimal improvement in incontinence (2.7%) but a more significant reduction in impotence among those with erections preinjury (18% versus 36% endoscopic alignment).

Given the above findings, we would agree that endoscopic alignment and suprapubic tube placement are acceptable options for management of PFUDD; however, in the setting of a severely injured patient, we favor percutaneous suprapubic catheter placement. A review of our experience with posterior urethral disruption after pelvic trauma shows that the average stricture length was 2.08 cm during posterior urethroplasty and the delayed posterior urethroplasty was predominantly amenable to one-stage repair (12). We believe this average length of stricture is acceptable, especially given that approximately 33% of the patients in our series had a prior failed attempt at treatment (cut-to-the-light approach, urethral dilation, internal urethrotomy, and failed urethroplasty).

---

### Alternative Therapy

---

Given the association of PFUDD with bladder injury, we recommend open suprapubic cystostomy to allow repair of associated bladder injuries when present. If the patient is too unstable to allow operative exploration, then percutaneous suprapubic placement with or without ultrasound guidance is appropriate; however, percutaneous placement may be difficult if there is associated bladder injury. Therefore, we would advocate open suprapubic catheter placement after the patient is stabilized. Most bladder injuries associated with PFUDD are extraperitoneal and heal spontaneously with catheter drainage; however, if surgical management of pelvic fractures is planned, we recommend operative repair of the associated bladder injury to reduce complication rates.

Primary suture repair of PFUDD in the acute setting is associated with elevated impotence and incontinence rates. Primary suture repair of PFUDD is not recommended for this reason, and also because of the more important risk of hemorrhage and contamination associated with evacuation of the retroperitoneal hematoma to gain access to the injury site. The only clinical scenario in which we favor acute repair of PFUDD is in the setting of a class IV injury (Table 36.1). This is because of the risk of bladder neck stenosis from urine extravasation at the bladder neck. We would also recommend repair of rectal and vaginal lacerations in this clinical scenario. Lastly, endoscopic alignment should be considered in the setting of a stable patient with a stable pelvis. Furthermore, we advocate utilization of fluoroscopy during cystoscopy to aid alignment in the safest possible manner.

---

### Surgical Technique

---

For open suprapubic catheter placement, the patient is placed in the low lithotomy position to allow simultaneous access to the rectum if needed. If orthopedic injuries preclude this positioning,

**FIGURE 36.6** A large-caliber Foley catheter is placed in the bladder dome after inspection for concomitant bladder laceration. With the catheter placed through the superior end of the midline incision, bladder neck identification is facilitated at the time of subsequent reconstruction.

a supine approach will suffice. An infraumbilical incision is made to allow access to the prevesical space anterior to the bladder dome. After placing stay sutures around the anticipated cystostomy site, the bladder is opened vertically at the bladder dome, which will provide ample exposure to examine the bladder and urethra for injury. *Strict avoidance* of dissection into the space of Retzius and lateral perivesical space is essential to prevent pelvic hemorrhage and contamination. Therefore, in the presence of an associated bladder neck or bladder base injury, intravesical repair is recommended. An additional benefit of bladder neck repair is that it prevents the laceration from extending into the external urethra sphincter complex.

Bladder lacerations, if present, should be repaired in two layers with a deeper 2-0 polyglactin (Vicryl, Dexon) suture incorporating the detrusor muscle and a superficial 4-0 chromic suture incorporating the bladder mucosa. Open suprapubic catheter placement is performed in the bladder dome, and the bladder cystostomy site is fixed in place with a pursestring suture (Fig. 36.6). We do not favor Malecot catheters, as they have a higher propensity to be accidentally dislodged. Instead, we utilize a 20Fr to 24Fr Foley catheter with an inflation balloon. The vesicostomy is closed in two layers with 2-0 polyglactin suture. Regarding associated pelvic fractures, we recommend communicating with the orthopedic service to ensure that the suprapubic tube skin site does not interfere with future operative endeavors. We do not use abdominal drains unless an associated bowel injury is present.

---

### Outcomes

---

#### Complications

Complications after treatment of posterior urethral trauma are directly related to the severity of injury. Acute complications include pelvic hemorrhage and infection or abscess of the pelvic hematoma, which can occur after ill-advised retroperitoneal exploration or attempts at pelvic hematoma evacuation.

Delayed complications include incontinence, impotence, and urethral stricture formation. Regarding impotence, recent studies have demonstrated that sexual dysfunction is commonly associated with pelvic fracture, even in the absence of urethral injury (13). Delayed return of potency has been reported after definitive urethroplasty; however, this would depend upon the severity of the initial injury (14). Nearly all patients remain continent if their bladder neck continence mechanism is undamaged; however, they should be counseled on the potential negative impact of future transurethral prostate surgery.

## Results

At our institution, delayed urethroplasty after suprapubic tube is the preferred management algorithm for PFUDD. Posterior urethroplasty has been successful for resolution of stricture in 86% of patients; however, definition of success is improved to 93% if an additional internal urethrotomy is utilized for stricture recurrence (12). Endoscopic alignment is also an appropriate management strategy in the acute setting; however, urologists should seriously consider formal urethroplasty (or referral to a tertiary care center) if internal urethrotomy or urethral dilation is unsuccessful.

## CHAPTER 37 ■ CARCINOMA OF THE FEMALE URETHRA

PETER L. STEINBERG AND WILLIAM BIHRLE III

Carcinoma of the female urethra is a histologically heterogeneous disease; while most cases are squamous cell (55%) in origin, transitional cell carcinoma (TCC) and adenocarcinoma equally account for between 15% and 20% of new cases. Melanoma and clear cell carcinoma represent rare subsets of disease. Disease developing in urethral diverticuli is, most commonly, adenocarcinoma and often presents at a higher stage than the squamous carcinomas.

Disease progression occurs by way of local invasion into the muscularis of the urethra followed by extension to local structures, including the anterior vaginal wall, vulva, and bladder neck. Lymphatic spread is not uncommon; distal urethral disease migrates into the superficial and deep inguinal nodes, while more proximally based cancers spread preferentially into the pelvic lymph chain (iliac, obturator, and presacral). Metastatic disease, while uncommon at presentation, occurs via hematogenous spread to the liver, lung, bone, and brain.

Primary urethral carcinoma is extremely uncommon, accounting for <1% of adult malignancies. Urologic orthodoxy holds that urethral carcinoma is the only genitourinary malignancy with a higher incidence in women than in men. However, findings from the most recent SEER population database suggest that, with an incidence of <1 case per 100,000 women annually, urethral cancer appears to be less common in women (1,2). With the exception of adenocarcinoma in the African American population, for which the incidence in women remains elevated, there is a higher rate of all three subtypes of urethral cancer in men relative to women. Excepting adenocarcinomas, urethral carcinoma is rare in women under the age of 60; the incidence of adenocarcinoma begins to rise about ten years earlier. Urethral cancer is distinctly uncommon in the premenopausal population. Its incidence peaks between ages 75 and 84 for TCC and squamous cancer, whereas the incidence of adenocarcinoma appears to

remain stable throughout. For reasons that remain conjectural, the incidence of female urethral carcinoma has dropped by 50% over the past 30 years.

Staging is based upon the tumor-nodes-metastasis (TNM) system, although many practitioners continue to use the system developed by Grabstald noted in Table 37.1.

## DIAGNOSIS

Nearly all women are symptomatic at presentation (3–5). Urinary symptoms, specifically hematuria, splayed stream, and urinary retention, indicate the presence of an obstructing lesion. Many patients have long-standing symptoms and often have been diagnosed with and treated for a myriad of benign conditions, including urethral diverticuli, caruncles, and urethral stenosis. Any process that does not respond to conservative measures should be investigated to rule out a urethral malignancy. Physical examination may reveal a palpable mass at the meatus, induration of the urethra, a mass along the anterior vaginal wall, or a mass that ball valves and protrudes from the urethral meatus. Ulceration of the meatus or the vaginal wall can also occur. The diagnosis of urethral cancer within a urethral diverticulum is a rare occurrence (5).

Endoscopy of the urethra and bladder neck and a well-performed bimanual pelvic examination are essential to tumor assessment. Examination under anesthesia, performed at the time of tumor biopsy, is essential in confirming the diagnosis and aiding in the assessment of tumor resectability. Evaluation of the proximal urethra and bladder neck for disease extension guides the recommendation for bladder-preserving techniques. Either a CT scan of the abdomen and pelvis with and without intravenous contrast or an enhanced MRI of the pelvis can help assess local extension of the tumor to the vagina or bladder, as well as the status of the pelvic lymph nodes. A chest X-ray is used to complete staging studies, and a CT of the chest may be needed in the event an equivocal lesion is noted. Liver function tests should also be assessed. Suspiciously enlarged pelvic lymph nodes may be biopsied via CT guidance or removed via laparoscopic node dissection.

## INDICATIONS FOR SURGERY

Given the rarity of this disease, there are no large-volume, randomized data to guide management. Treated disease has a 5-year survival of roughly 50% (3,4); left untreated, almost all urethral carcinomas will progress, with a mean survival of <1 year. The presence of metastatic disease or deep pelvic lymphadenopathy represents a strong contraindication to major extirpative surgery. Disease localized to the urethra may be treated in a variety of ways depending on the anatomical location and local stage. Generally, low-stage, distal cancers carry a more favorable prognosis than higher-stage and more proximally located lesions and may be amenable to less radical extirpation. There appears to be a limited role for topical ablative therapy in women presenting with superficial disease. Surgical therapy is suggested in women who are free from metastasis and will tolerate an operative intervention.

## ALTERNATIVE THERAPY

External beam radiation, brachytherapy, and local ablative therapy either alone or in combination have been reported in the treatment of both distal and proximally located tumors. Success is better with distal tumors; several small series report 5-year survival rates of 50% to 70% (5). Unfortunately, the treatment of more proximal tumors is associated with a 5-year survival rate of 30% to 50% (5). As in the case with surgery, no randomized data exist to guide treatment.

The role of chemotherapy in a neoadjuvant or adjuvant setting is also lacking in randomized data. Centers that see a larger volume of this disease often utilize chemotherapy in a

neoadjuvant or adjuvant fashion, though specific management strategies cannot be suggested based on the existing literature.

There is case report evidence only that combined chemotherapy and radiation therapy can offer long-term control of female urethral cancer. Using a combination of 5-fluorouracil, mitomycin C, and/or cisplatin, as well as 30 to 60 Gy or radiation, there are reports of survival exceeding 5 years in the literature. It is emphasized, however, that these data have been accrued over a period of 20 years and consist of nine case reports (6). The failure of single-arm therapies to improve long-term outcomes has led clinicians to consider more flexible, multimodal approaches to the treatment of urethral carcinoma.

---

## SURGICAL TECHNIQUE

---

This chapter considers the operative techniques for both distal and proximal lesions of squamous and glandular origin—diseases that originate in the urethra—and bladder-sparing approaches for large distal lesions. Management using minimally invasive approaches such as neodymium or holmium: YAG lasers will not be described, as there is a paucity of data in the literature to support their use. The specific management of the female urethra in the case of TCC will not be discussed because this represents pathology of the lower urinary tract and should be considered separately.

---

### Distal Urethral Tumors

---

Tumors involving the distal third of the urethra, and especially those of the urethral meatus, are amenable to a distal urethrectomy. Preoperative preparation should include full staging studies, a detailed history and physical examination with particular attention given to a history of bleeding or anesthetic complications, and a urine culture, with any infection managed before surgery.

TED hose and sequential compression devices are mandatory for deep venous thrombosis (DVT) prophylaxis, and the use of 5,000 U of subcutaneous heparin or 40 mg of subcutaneous enoxaparin is prudent in a patient with any pelvic malignancy prior to surgery. Prophylactic antibiotics should be administered within the hour prior to the first incision, and a first-generation cephalosporin along with gram-negative coverage from an aminoglycoside should be adequate; patients allergic to penicillin can receive either vancomycin or clindamycin as an alternative gram-positive prophylactic.

The patient should be placed in the lithotomy position, with attention paid to the padding of pressure points on the legs; the patient's perineum should sit at the edge of the operating room table. After preparation and draping, a weighted vaginal speculum is placed and the labia are retracted with a 1-0 silk suture that is then secured to the drape. The use of a versatile perineal retraction system, that is, the Lone Star or Jordan-Bookwalter devices, facilitates exposure of the vaginal introitus. Placement of a Foley catheter aids in the palpation and localization of the urethra and tumor during dissection (Fig. 37.1).

Once a circumcising incision is made around the urethral meatus, it may be secured with an Allis clamp or silk tie, allowing for retraction and manipulation of the urethra during its dissection. An incision is made in the epithelium of the

vagina to aid in the posterior urethral dissection. A combination of electrocautery and sharp dissection is utilized to free the urethra circumferentially, taking care not to enter the urethra and using the Foley catheter to guide the dissection. The anterior vaginal wall is also resected with a 1-cm margin of healthy tissue. A margin of 1 cm of normal tissue from the proximal margin of the tumor is desirable from an oncological standpoint. When healthy tissue has been encountered proximally, stay sutures of 3-0 Vicryl are placed into the urethra at 3 and 9 o'clock to prevent proximal migration, the specimen is amputated, and the margin is assessed with a frozen section.

Hemostasis is achieved with cautery, and the wound is copiously irrigated with normal saline. The remaining urethral stump is approximated to the edges of the vaginal incision with interrupted 3-0 Vicryl or other absorbable suture. The vaginal wall is closed with interrupted 3-0 Vicryl sutures in two layers. A vaginal pack with estrogen crème is placed, as is a new small-caliber Foley catheter. The vaginal pack is removed on postoperative day 1, and the Foley catheter is removed 7 days after surgery. The patient is placed on a general diet the night of surgery and should ambulate as soon as she has recovered from anesthesia. DVT prophylaxis is also maintained postoperatively, and antibiotics are stopped within 24 hours of surgery.

---

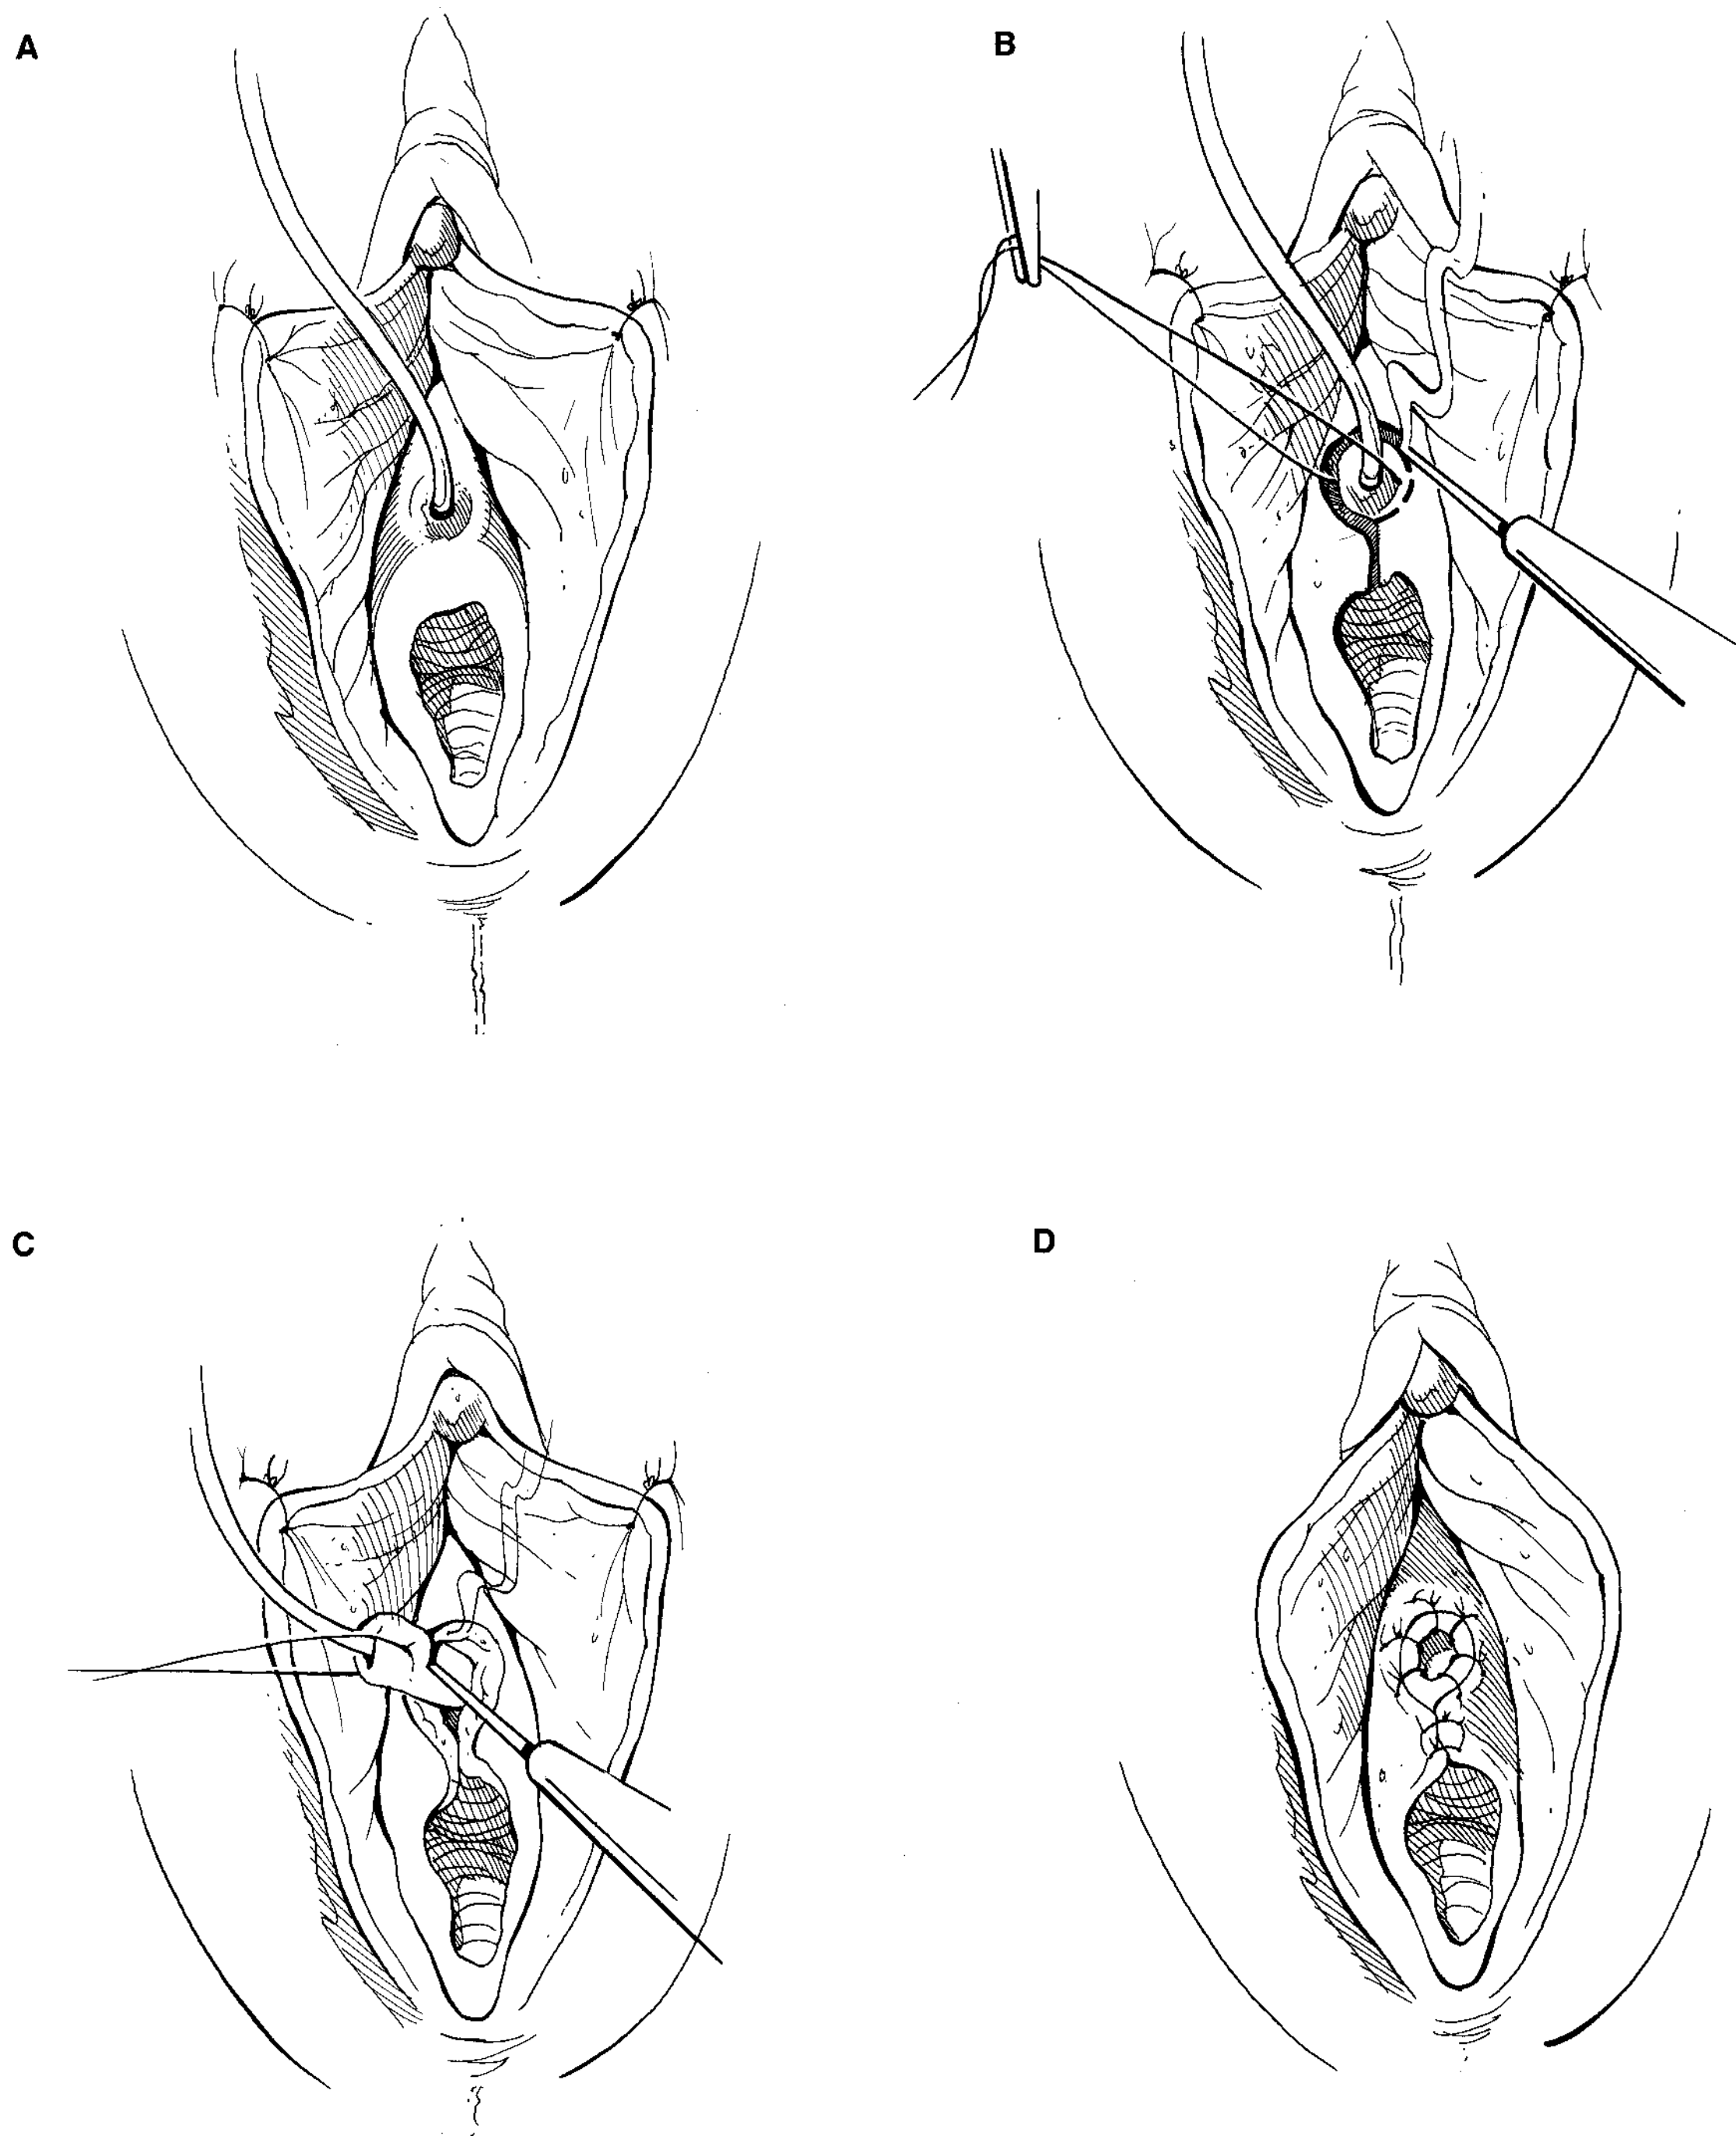

### Distal Tumors, Bladder-sparing Approach

---

Bladder sparing is feasible for large distal urethral tumors, including T3 disease, not involving the bladder neck. Although reports exist of bladder sparing for more aggressive tumors involving the genitalia, the high risk of local recurrence makes exenterative surgery the standard of care (4). Following resection of the diseased urethra, the bladder neck is closed and one of a variety of continent urinary diversions is performed. Currently there are no data to suggest that pelvic or inguinal lymph node sampling improves survival, though pelvic node dissection is useful for staging purposes (4).

The presurgical regimen is identical to that described for surgery of small distal disease, with the addition of a bowel preparation and clear liquids the day before surgery. Once in the operating room, the patient is placed in the low lithotomy position in Allen stirrups. Both the abdomen and the genitals are prepared into the field, and a weighted vaginal speculum is placed. Cystoscopy can be performed to place bilateral ureteral catheters if desired. To assess for tumor resectability and lymph node status, the procedure is begun through a midline or Pfannenstiel trans- or extraperitoneal incision. Surgeons with advanced laparoscopic skill may choose to perform the lymph node dissection and mobilization of the bladder neck and proximal urethra in a laparoscopic fashion. The lymph nodes are sent for frozen section analysis if it is the intent of the surgeon to alter the surgical plan in the face of lymphatic spread. There are insufficient data in the literature to either support or refute abandoning resection in the face of positive pelvic lymph nodes.

The endopelvic fascia is incised, allowing mobilization of the lateral aspects of the bladder with electrocautery. Urethral attachments to the pelvic floor are taken down with cautery and between 2-0 or 3-0 silk ties as needed. The uterus and ovaries are preserved with this approach. Once the bladder neck is mobilized, the vaginal portion of the procedure is performed. If sufficient assistance is available, this can be performed as a two-team simultaneous procedure.

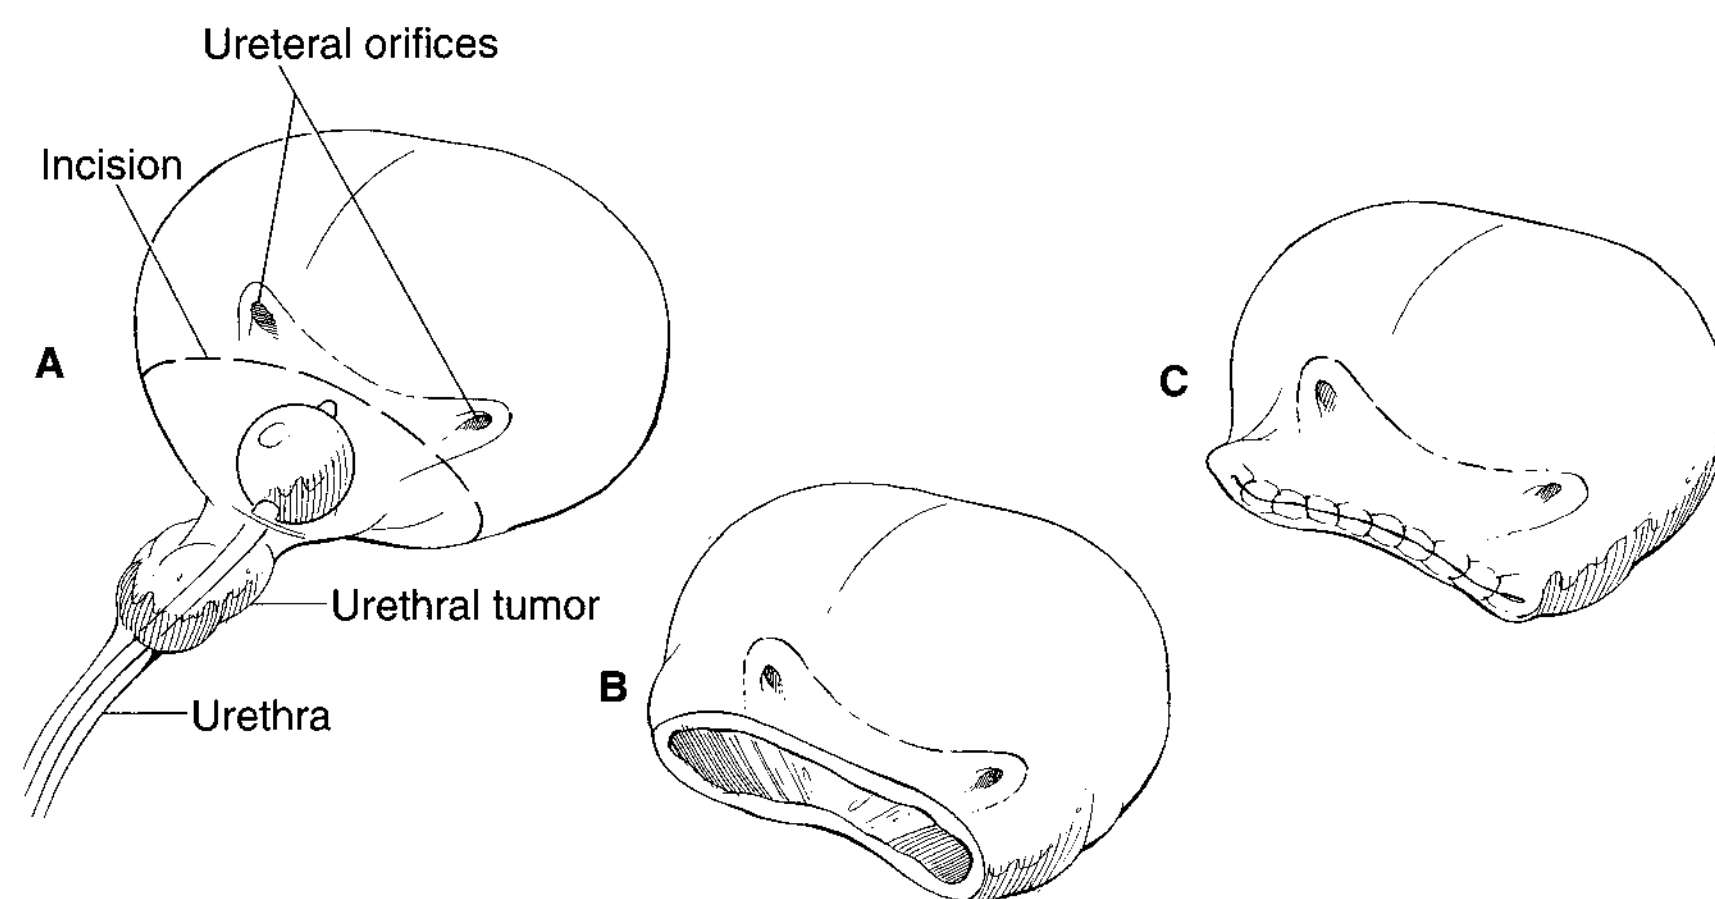

**FIGURE 37.1** Technique of distal urethrectomy.

To excise the urethra, distal bladder neck, and a margin of anterior vaginal wall, again the meatus is circumscribed with a scalpel, and then cautery and sharp dissection are used to take down the periurethral tissues proximal to the palpable tumor. The pubourethral ligaments are identified with blunt and sharp dissection and divided with cautery.

Through the abdominal incision, the bladder neck is opened anteriorly with electrocautery; the ureteral orifices are identified and cannulated with stents if these were not placed at the time of cystoscopy. With care taken to preserve the ureteral orifices, the bladder neck is divided distal to the orifices and the incision is carried through the anterior vaginal wall. The ure-

thra, bladder neck, and vaginal wall are then removed en bloc. A frozen section is taken of the bladder neck margin, and if positive anterior exenteration is performed (Fig. 37.2).

With a negative bladder neck margin, the vaginal defect is closed in layers using a combination of 2-0 or 3-0 Vicryl or other absorbable suture on the vaginal mucosa. Large partial vaginal wall defects resulting from this resection may require coverage with a regional flap. A pudendal-based medial thigh flap or rectus flap may be necessary to close such a defect, and given the propensity toward multimodality therapy in this disease, consultation with a plastic surgeon is likely to yield the best outcome (7).

**FIGURE 37.2** Technique of urethrectomy and bladder preservation by excision of the tumor at the level of the bladder neck, with subsequent bladder neck closure.

Urinary diversion is then performed, as is bladder neck closure. Postoperatively, the patient is managed with a 14Fr catheter running through the stoma, a 20Fr to 22Fr suprapubic tube, a vaginal pack, and a pelvic drain. The vaginal pack is removed 24 hours after surgery. The diversion is irrigated with normal saline every 8 hours beginning on postoperative day 1. Nasogastric suction is not needed postoperatively, and the diet can be slowly advanced, beginning with sips of clear liquids on postoperative day 1 or 2, followed by clear liquids ad lib, and finally a general diet prior to discharge (8). Return of flatus is not needed to advance the diet, though intake should be restricted if nausea or vomiting occur. The patient should ambulate as soon as she has recovered from anesthesia. DVT prophylaxis is also maintained postoperatively, and antibiotics are stopped within 24 hours of surgery.

### Proximal Urethral Tumors

For patients who have large tumors or tumors involving the bladder base, bladder-preserving approaches are not feasible and anterior pelvic exenteration is indicated. A stoma site on the abdomen is selected preoperatively for urinary diversion. Preoperative preparation is identical to that for distal tumors, and again a bowel preparation and clear liquids are utilized the day before surgery.

Radical cystourethrectomy, pelvic lymph node dissection, and urinary diversion are then performed in the standard fashion (see Chapters 19, 81, 83). For larger lesions, wide excision of the vulva, pelvic floor, and pubic rami may also be indicated. The assistance of an orthopedic and plastic surgeon is invaluable in these circumstances. Pelvic floor reconstruction with either rectus or gracilis flap will be necessary, and thus planning with a plastic surgeon is mandatory preoperatively.

### OUTCOMES

Data from multiple sources confirm that distal lesions have a better prognosis than proximal disease or panurethral disease. In a representative series, Dalbagni et al. (3) demonstrated a 71% survival in distal lesions, 48% in proximal lesions, and 24% in lesions involving the entire urethra. Local recurrence after partial urethrectomy occurs roughly 20% of the time, though this number is based on a series of 19 patients (4). Pelvic lymph node disease is associated with a poor prognosis, with only 23% disease-specific survival at 5 years (4). Disease-specific survival at 5 and 10 years is roughly 50%, with the best prognosis in low-grade, low-stage distal lesions without lymph node metastases (4). Roughly one-third of patients with stage T3 or T4 disease remain recurrence-free. The overall recurrence rate is roughly 50%, and after recurrence 71% of women are dead within 5 years (4).

### COMPLICATIONS

Distal urethrectomy is associated with urinary incontinence in nearly 40% of patients (4), a finding drawn from a number of small series. Both worsening stress and urge incontinence are reported in this series, as is a small rate of urinary retention. More proximal resections and pelvic exenteration are associated with risks of wound infection, wound dehiscence, DVT, metabolic complications from urinary diversion, and bowel-related complications. We would direct the reader to the specific chapters dealing with cystectomy and urinary diversion for a better treatment of this topic.

# CHAPTER 38 ■ CARCINOMA OF THE MALE URETHRA

PETER L. STEINBERG AND WILLIAM BIHRLE III

Carcinoma of the male urethra is a heterogeneous disease, encompassing transitional cell carcinoma (TCC), squamous carcinoma, adenocarcinoma, and very rare malignancies such as melanoma. This chapter focuses on management of primary malignancies of the urethra and does not discuss management of TCC of the urethra or management of urethral recurrence of TCC after cystectomy, though the operative principles are readily transferable.

Urethral cancer in men is an exceedingly rare condition, with an incidence of <1 case per 100,000 men annually (1,2). Fifty percent of male urethral cancers are of transitional cell origin, with the remainder divided principally between adenocarcinoma and squamous cell carcinoma, as well as a small number of other tumors. Recent information from the SEER database suggests that men may have a higher incidence of all three types of urethral tumor than women, indicating a major shift in the incidence ratio of this disease between the sexes (1,3). These tumors are rare in men under the age of 50; the incidence is highest between ages 75 and 84. Over the past 20 years the incidence of all urethral cancers has declined in men. Causal factors of urethral cancer may include chronic irritative processes, urethral stricture disease, and certain forms of sexually transmitted disease. Evidence of an association between human papilloma virus (HPV-16) and squamous cell carcinoma continues to mount.

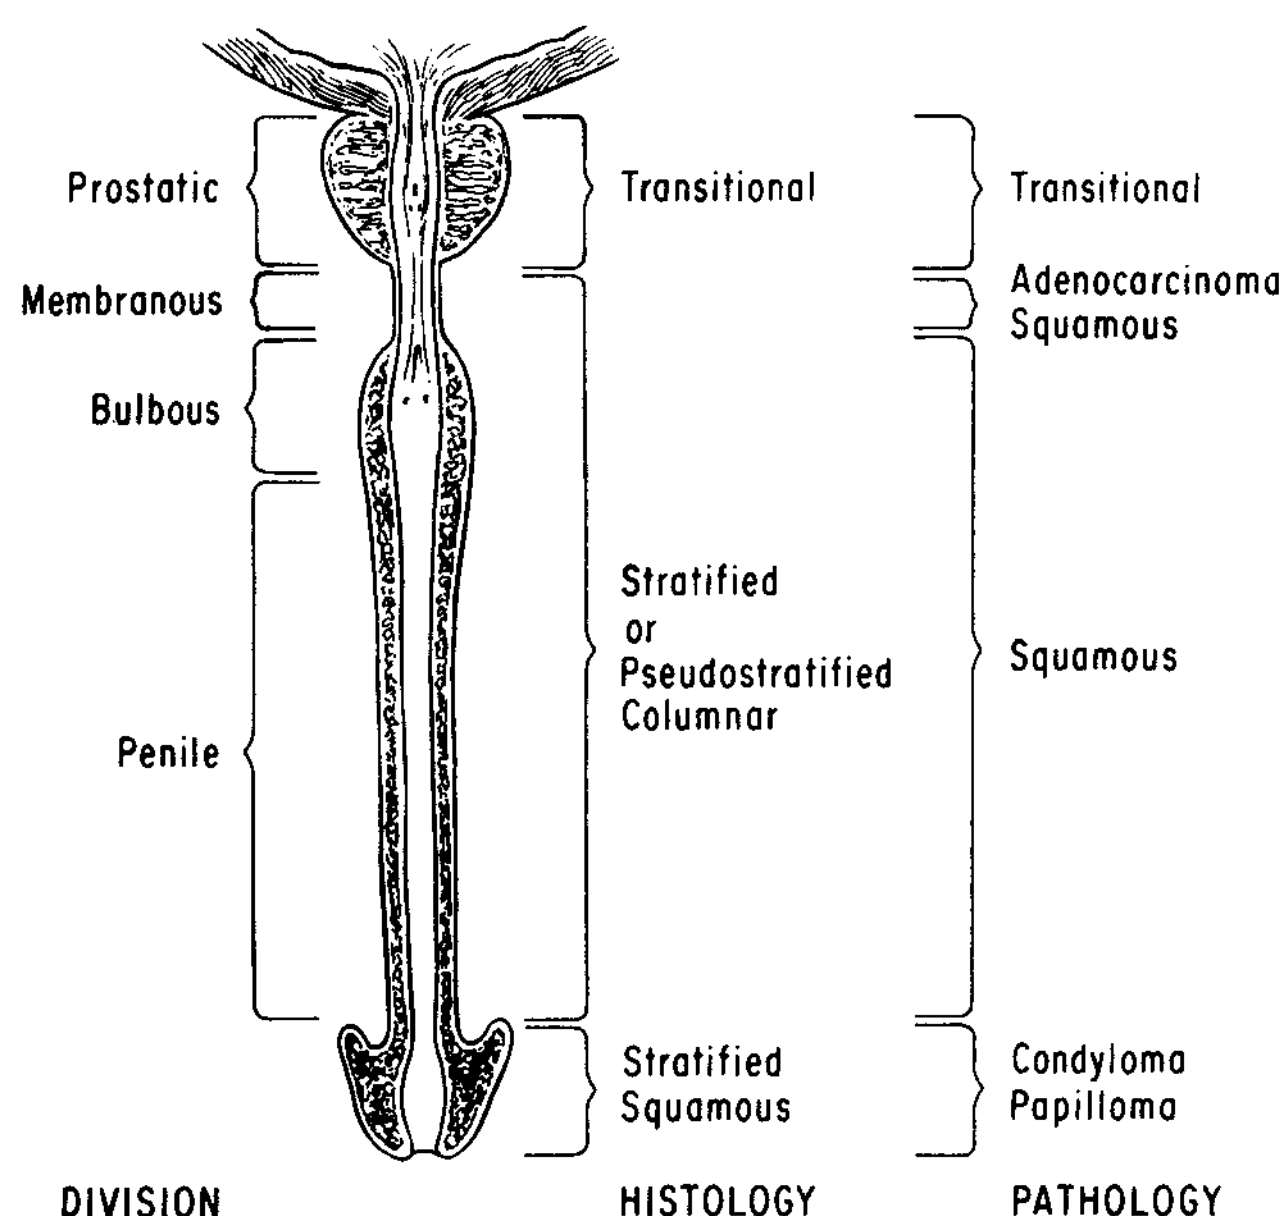

Tumors of the urethra are defined by location and histology. The male urethra is divided into a number of discrete

anatomical segments (Fig. 38.1). The bulbomembranous urethra is the most common site of disease (60%); the penile urethra represents another 30% of cancers, and the prostatic urethra comprises 10% of all tumors (4). The anterior portion of the urethra, penile and bulbomembranous, almost always develops squamous cell carcinomas, whereas the prostatic urethra, lined by transitional epithelium, is the site of TCC >90% of the time. Adenocarcinoma or undifferentiated tumors, which represent approximately 5% of all malignancies, usually develop in the bulbomembranous urethra.

Urethral cancers may spread through direct extension to adjacent structures or via the lymphatic system to regional lymph nodes. The anterior urethra of the male lymphatically drains into the superficial and deep inguinal nodes, and the posterior urethra drains to the pelvic lymph nodes. Palpable inguinal adenopathy is worrisome for metastatic disease, as inflammatory nodal involvement occurs infrequently. Disseminated disease is rare until late in the disease process.

## DIAGNOSIS

Nearly all men are symptomatic at presentation, though the low incidence of this disease, combined with failure on the part of the clinician to consider it, often results in a significant delay in diagnosis. In Dalbagni's series of 46 patients, 96% of men presented with some form of lower-urinary-tract symptom

**FIGURE 38.1** Changes in the histology of the epithelial lining within the divisions of the male urethra tend to dictate the pathology of the tumor most likely to occur. (From Webster GD. The urethra. In: Paulsen DF, ed. Genitourinary surgery. New York: Churchill Livingstone, 1983:567, with permission.)

or palpable mass (5). Hematuria, obstructed voiding, urethral discharge, and a palpable mass are the most common presenting symptoms and signs. Approximately 25% of men diagnosed with urethral cancer have a history of sexually transmitted infection. Fully half of these patients have been treated for urethral stricture disease; the diagnosis of cancer needs to be suspected in men with recalcitrant or nonhealing strictures (4). Urethral stricture in association with bloody discharge, penile or urethral mass, or urethrocutaneous fistula should heighten the suspicion of urethral cancer.

The diagnosis of urethral cancer is histologically confirmed by transurethral or percutaneous biopsy of the suspicious lesion. Examination under anesthesia, complete with bimanual assessment of the external genitalia, rectum, and perineum, aids in local staging of the disease. The inguinal lymph nodes are palpated, as adenopathy is usually attributable to metastatic disease rather than inflammation. Either a CT scan of the abdomen and pelvis with and without contrast or MRI of the pelvis can help assess local extension of the tumor to the rectum or bladder, as well as the status of the pelvic lymph nodes. The MRI may aid in the detection of corporal cavernosal invasion. Lung imaging with a chest radiograph, augmented by CT scanning for equivocal lesions, completes the radiological staging. Liver function tests should also be assessed.

Staging is based upon the tumor-nodes-metastasis (TNM) system.

## INDICATIONS FOR SURGERY

Given the paucity of data regarding this disorder, there are no randomized trials to support a particular treatment approach. That said, urethral cancer is a lethal disease that, if left untreated, has a median survival of <6 months. Although survival has not changed for this disease in the past 50 years, treatment still consists of extirpative surgery if the patient's condition will allow it (5). Evidence of distant metastatic disease limits treatment options to palliative measures. Local treatment is a function of the location of the disease within the urethra as well as the local stage of the malignancy. Superficial disease, especially of the penile urethra, may be managed with transurethral resection, local excision, or distal urethrectomy. Partial penectomy with a 2-cm urethral margin is the preferred treatment for disease of the distal half of the penile urethra with local invasion of the corpus spongiosum.

For more proximal lesions, total penectomy is indicated. As in women, distal disease portends a better prognosis in men.

Carcinoma of the bulbomembranous urethra, often presenting at a higher stage with local extension into adjacent organs, is only occasionally amenable to local therapy, resection, or segmental excision with primary anastomosis. Radical cystoprostatectomy, complete penectomy, and pelvic lymphadenectomy represent the best option for local disease control and cure. The margins of excision may be extended into the urogenital diaphragm and pubis in an effort to extirpate locally advanced disease.

Prophylactic ilioinguinal lymphadenectomy is not routinely performed.

## ALTERNATIVE THERAPY

Given the rarity of this entity, there are no randomized data to delineate the role of radiation therapy, chemotherapy, or combination therapy in this disorder. Radiation therapy and chemotherapy have been used as part of multimodality therapy or as monotherapy, but few conclusions can be inferred from most series, which are small in patient numbers and retrospective in nature. A recent series from the Lahey Clinic suggests that a combination of 5-fluorouracil, mitomycin C, and perineal, genital, and pelvic radiotherapy—an adaptation of the regimen successfully employed in the treatment of squamous carcinoma of the anus—has an 80% 5-year disease-specific survival rate, a 30% improvement over that reported in most published series (6). In this study salvage surgery was offered to patients who failed conservative therapy. General recommendations for treatment based on these data are limited due to the small cohort of patients studied. It is difficult to support or refute the role of neoadjuvant or adjuvant chemo- or radiotherapy in this disease, though the accruing data are provocative.

## SURGICAL TECHNIQUE

Given the rarity of this disease and the limited experience with management even at large referral centers, there are no randomized data to guide management. Treated disease has a 5-year survival of roughly 50%, and untreated disease has a worse prognosis (5). On the basis of these facts, surgical therapy is suggested in men who are free from metastasis and will

TABLE 38.1

### STAGING OF MALE URETHRAL CARCINOMA

Ray	TNM	
Stage 0	Tis	Confined to Mucosa Only (In Situ)
Stage A	Ta	Into But Not Beyond Lamina Propria
Stage B	T2	Into But Not Beyond Substance of Corpus Spongiosum or Into But Not Beyond Prostate
Stage C	T3, T4	Direct Extension Into Tissues Beyond Corpus Spongiosum (Corpora Cavernosa, Muscle, Fat, Fascia, Skin, Direct Skeletal Involvement), or Beyond Prostatic Capsule
Stage D1	N1, N2	Regional Metastasis Including Inguinal and/or Pelvic Lymph Nodes (With any Primary Tumor)
Stage D4	M1	Distant Metastasis (With Any Primary Tumor)

tolerate an operative intervention. Distal lesions have a better response to surgery than more proximal lesions, and they often are amenable to less radical curative surgery.

Tumors of the anterior urethra have a better prognosis than more proximal lesions. The surgical management of anterior lesions continues to evolve. Endoscopic ablation or local excision of the diseased urethra allows preservation of the penis in men with limited, superficial disease. Candidates for penile-sparing surgery must have well-defined disease with a negative surgical margin confirmed by frozen section analysis. Any question of the adequacy of resection or the malignant status of the proximal urethral margin should prompt the surgeon to perform a more complete extirpative procedure, including partial or total penectomy (7,8). Surgical description of partial and total penectomy is found in the chapter on surgery of the penis. Smith et al. (8) have achieved impressive results in the treatment of very distal urethral lesions by performing local excision of the involved urethra followed by penile reconstruction using skin grafts (8). The Indiana University group has recently reported a series of men with in situ carcinoma of the pendulous urethra who were treated with urethrectomy and one-stage urethroplasty with a tubularized penile fasciocutaneous pedicle flap (*personal communication*). In men who are not candidates for immediate urethral reconstruction, creation of a penile urethrostomy maintains standing micturition.

---

### Urethrectomy with Penile Preservation

---

It must be emphasized that a penile-preserving approach is indicated for disease limited to the corpus spongiosum and urethra; any disease that extends into the corpora is best managed with partial or total penectomy. Preoperative preparation should include full staging studies, a detailed history and physical examination with particular attention to a history of bleeding or anesthetic complications, and a urine culture, with any infection managed before surgery.

TED hose and sequential compression devices provide deep venous thrombosis (DVT) prophylaxis; the use of 5,000 U of subcutaneous heparin or 40 mg of subcutaneous enoxaparin is prudent in a patient with a pelvic malignancy undergoing extirpative surgery. Prophylactic antibiotics with a first-generation cephalosporin should be administered within the hour prior to the first incision; patients allergic to penicillin can receive either vancomycin or clindamycin as an alternative. An aminoglycoside or quinolone to augment gram-negative coverage is reasonable. The patient should be placed in lithotomy, with care taken to adequately pad all pressure points on the legs and dorsum of the feet. The patient's sacrum may be elevated with a rolled towel or Gelfoam pad to facilitate exposure of the proximal bulbar urethra. The perineum, proximal thigh, genitalia, and lower abdomen are prepared into the field; the anus is excluded from the operative field by a sterile towel secured by staples to the perineum and posterior thighs. A 16Fr Foley urethral catheter is placed.

A 4- to 5-cm vertical perineal incision extending inferiorly from just below the scrotum provides exposure to the proximal portion of the anterior urethra. A Scott, Lone Star, or Jordan-Bookwalter ring retractor system facilitates exposure of the bulbar urethra. Using electrocautery, the superficial fascial and fatty tissue is dissected to the level of the bulbospon-

giosus muscle. The bulbospongiosus is divided sharply over the ventral aspect of the urethral bulb and dissected from the lateral aspects of the urethra. Careful, sharp dissection of the dense attachment between the dorsum of the bulb and the corpus cavernosum circumferentially liberates the urethra; a vessel loop or small Penrose drain placed around the urethra serves as a "handle" for the surgeon in mobilizing the urethra distally. Frequent palpation of the urethral catheter ensures that the plane between the spongiosum and corpora is accurately assessed (Fig. 38.2).

As the dissection is carried distally, the penis will begin to invert into the wound. There is a tendency to overestimate the extent of distal urethral mobilization as the inverted glans is approached. Indeed, the urethral plane becomes less distinct within the spongy tissue of the glans penis. The authors find it helpful at this point to evert the penis and complete the distal urethral dissection from the meatus.

Using a no. 15 scalpel blade, the urethral meatus, including a small cuff of glanular skin, is circumscribed. A holding suture may be placed through the meatal urethra to aid in the dissection of the intraglanular portion of the urethra. Sharp and cautery dissection are used to free the urethra from its spongy glanular attachments. With the urethra liberated distally, it is maneuvered into the perineal aspect of the wound and amputated at least 2 cm proximal to the tumor. Frozen section analysis of the proximal resection margin confirms that a disease-free margin has been achieved. The wound is copiously irrigated with sterile saline, and all bleeding is arrested with cautery.

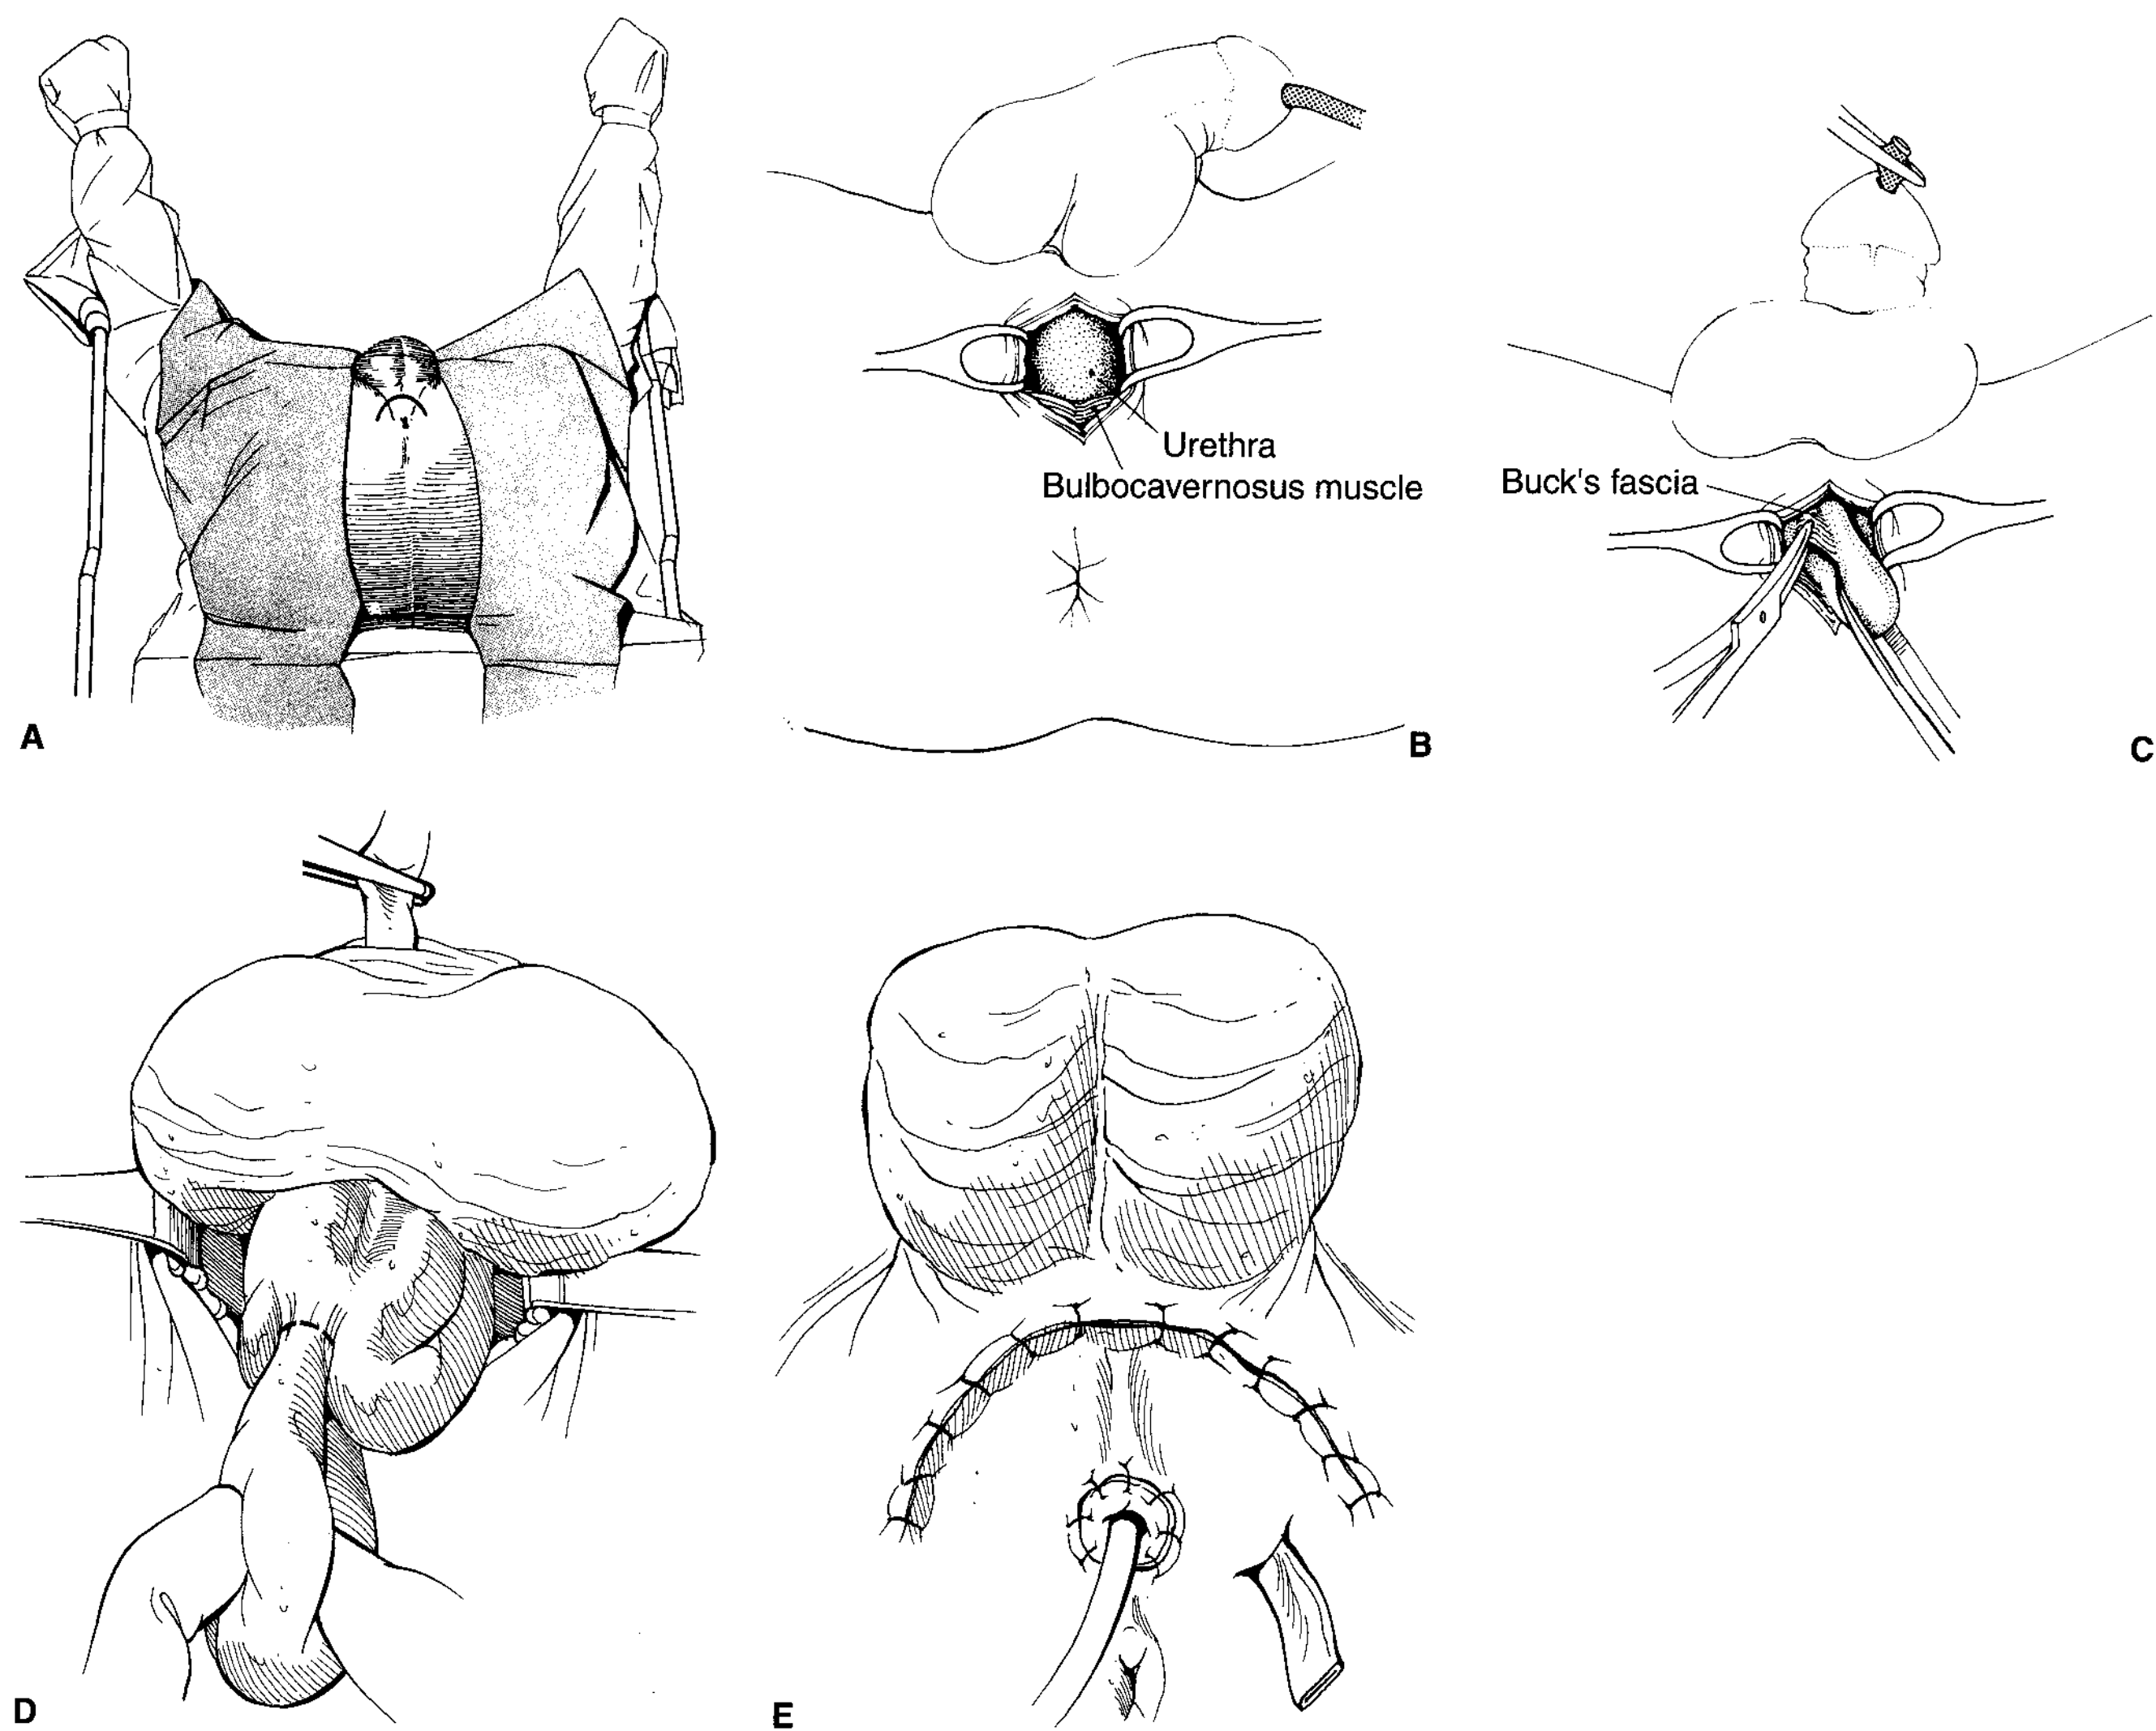

Following resection of the surgical specimen, attention is directed to the creation of a perineal urethrostomy. A site for the urethrostomy is selected ventral to the anus and, preferably, lateral to the initial skin incision. The urethra is spatulated on its ventral aspect for a distance of at least 1 cm. The urethrocutaneous anastomosis is matured with a 3-0 or 4-0 absorbable suture, such as Vicryl or Monocryl. Four 3-0 interrupted sutures are placed between the urethra and perineal skin at the apical spatulation, the distal end of the urethra, and laterally along each side of the urethra equidistant from the first two. The anastomosis is completed with 4-0 interrupted or running sutures placed between the quadrant sutures. Care is taken not to kink or twist the urethra. With the urethrostomy complete, a 16Fr Foley catheter is inserted into the bladder. The perineal incision is closed in a layered fashion; both the superficial fascia and deep dermis are approximated using a running 3-0 Vicryl or PDS suture, and the skin is closed with a running 4-0 Monocryl subcuticular stitch. The incision is covered with a layer of tissue glue, such as Dermabond or Indermil, obviating the need for a wound dressing. A generous portion of petroleum-based ointment is placed over the urethrostomy at the conclusion of the procedure. The catheter is left in place for 10 to 14 days and the urethrostomy inspected for stenotic changes on a regular basis.

---

### Proximal Urethral Tumors

---

Tumors of the posterior urethra generally present at a more advanced stage, limiting the possibility of endoscopic resection or segmental resection with end-to-end anastomosis. Bulbomembranous cancers, though responding poorly to all forms of treatment, require radical extirpative techniques to

**FIGURE 38.2** A and B: Incisions used for penile-sparing urethrectomy. C: The urethra is dissected off the corpora cavernosa using electrocautery. D: Distal dissection of the urethra results in inversion of the penis. E: The spatulated urethra is sewn to the skin edges with interrupted 3-0 chromic sutures, and the drain is brought out through a separate stab incision.

achieve disease control. Radical cystoprostatectomy with an en bloc total penectomy, although mutilative and disfiguring, provides the patient with his best opportunity for cure. Resection of part of the pubic arch and urogenital diaphragm may be needed to achieve an adequate surgical margin. Complete removal of the tumor may result in the creation of a large pelvic floor defect; in situations where this degree of extirpation is anticipated, consultation with a plastic surgeon will prove beneficial in planning for reconstruction and “dead space” closure. Bladder-sparing procedures may be considered when it has been confirmed, through biopsy, that the bladder neck is free of disease. The extirpative portion of the procedure is similar to what will be described herein except that the prostate and seminal vesicles are dissected, in an antegrade fashion, from the base of the bladder. Once the bladder neck has been closed, a continent or noncontinent small bowel limb (e.g., A Monti procedure) is matured to the lower abdominal wall.

A mechanical bowel preparation consisting of a clear liquid diet and oral Fleet Phospho-Soda is initiated on the day prior to surgery. Broad-spectrum antibiotics to provide coverage for

gram-positive, gram-negative, and anaerobic bacteria are delivered 1 hour before the procedure. In all other respects the preparation is similar to that described for surgery of the distal urethra.

The patient is positioned in the low lithotomy position, and all pressure points are well padded. The abdominal component of the procedure is begun first; the abdominal and perineal components may be performed simultaneously by two experienced surgical teams, reducing operative time. Although an experienced laparoscopic or robotic surgeon may be capable of performing both the pelvic node dissection and the cystoprostatectomy, many urologists will feel more comfortable approaching the pelvic dissection through an open approach.

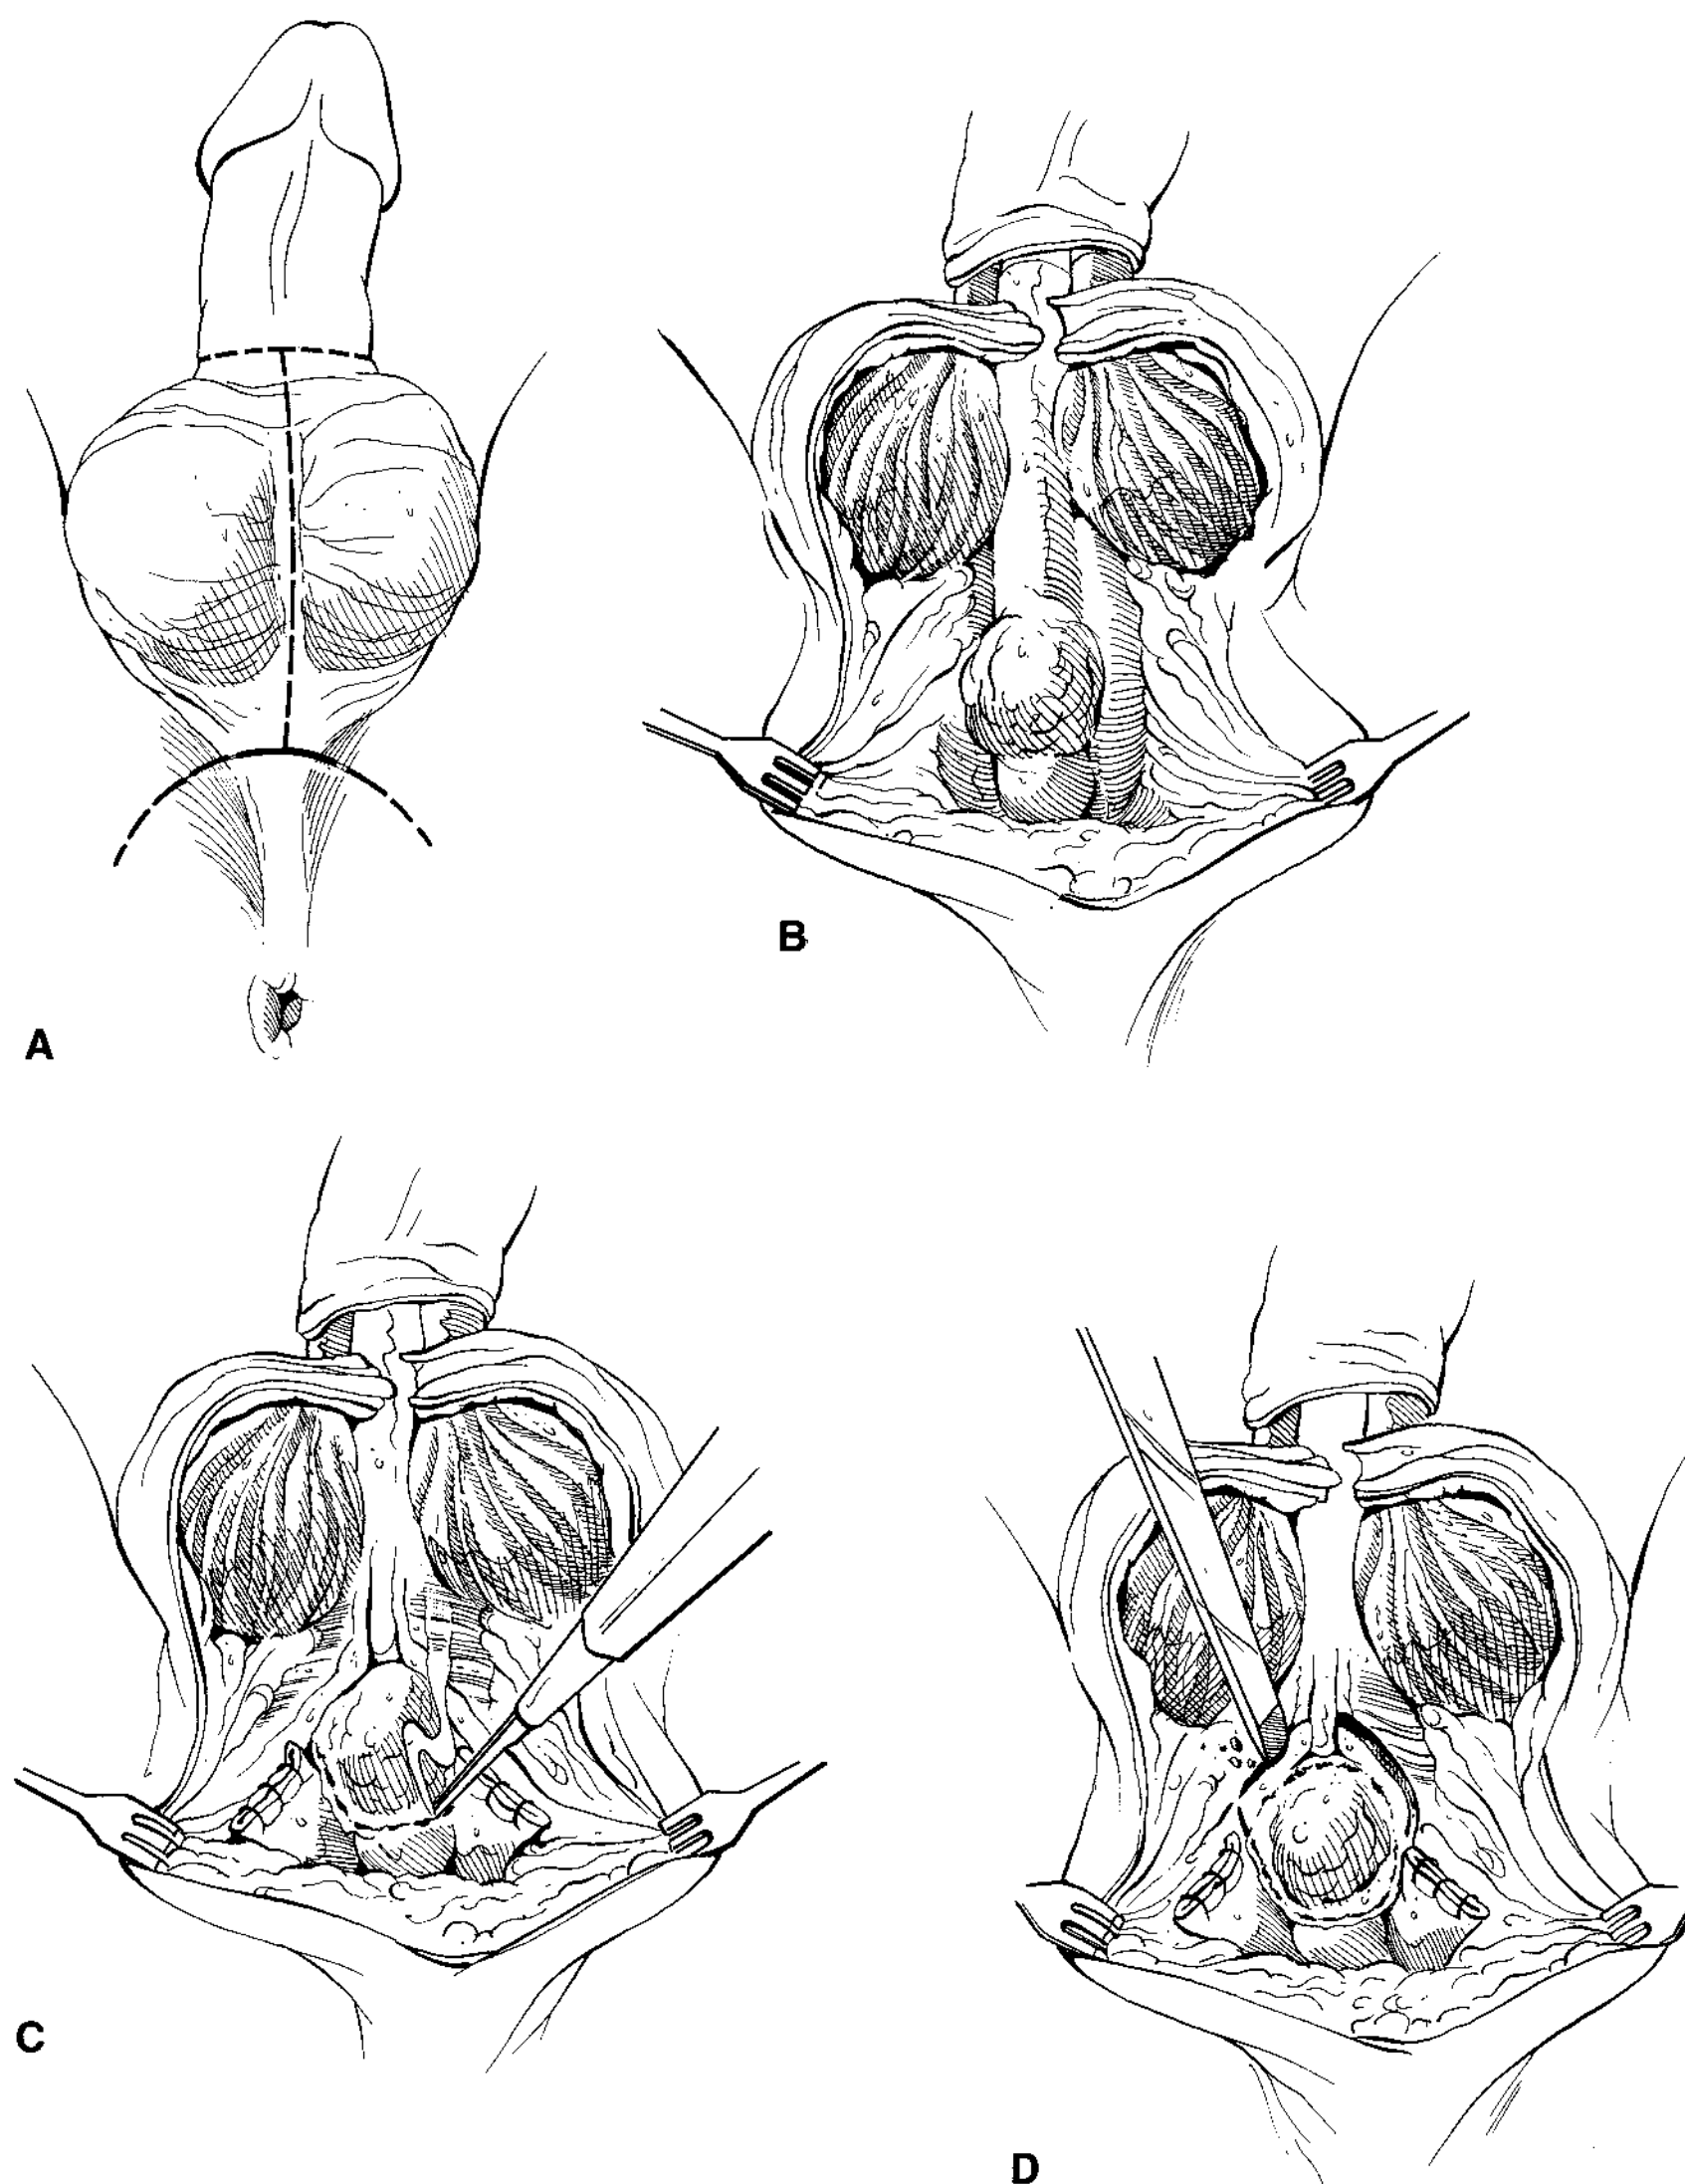

A vertical midline incision is made between the umbilicus and the pubis. The preperitoneal space is developed bluntly, and the pelvic sidewalls are cleared for the pelvic lymph node dissection. Following placement of a Bookwalter or Omni retraction device, the external iliac, obturator, and internal iliac nodes are dissected to the bifurcation of the iliac vessels and sent for frozen and permanent pathologic examination.

Next, the peritoneum is entered, the abdomen explored, and the bowel packed clear of the pelvis. The bladder is mobilized and the ureters divided as in a radical cystectomy for bladder cancer. Prostatectomy is performed in an antegrade fashion, though the puboprostatic ligaments are not divided, in the event the pubis is resected en bloc. Please see chapter on cystoprostatectomy for a complete description of this surgical technique.

With the bladder and prostate widely mobilized, a modified lambda or inverted U incision is made in the prepared perineum, extending laterally to points just medial to the ischial tuberosities. The apex of the incision is based in the midperineum. The superficial fascia is opened with cautery, and the ischioanal fossae are bluntly developed bilaterally. After division of the perineal body, a tunnel is developed anterior to the rectum in a manner similar to the technique described for the perineal prostatectomy. The perineal contents are cleared off between the ischial tuberosities and up to the pubic arch. The suspensory ligament of the penis and the neurovascular bundles of the penis are divided between 0 silk ties (Fig. 38.3).

With mobilization of the prostate and proximal urethra complete, the penoscrotal junction is then incised circumferentially

with a scalpel. The incision may be extended along the median raphe of the scrotum, joining with the previously created perineal dissection to allow for enhanced exposure of the distal bulb and pendulous urethra. Using electrocautery, the dartos fascia is divided to expose the neurovascular bundle of the penis, which is divided between silk or Vicryl ties. If the suspensory ligament has not been divided during the perineal portion of the surgery, it is done so now. With the corporal bodies and urethral spongiosum exposed, the penis may be transposed into the perineal aspect of the incision. The corpora cavernosa are then divided at the ischial tuberosities and oversewn with a running 2-0 Vicryl or PDS suture. Dissection of the spongiosum from its investing tissues is performed sharply, with care taken to avoid a positive surgical margin. Tumor invasion of the superficial periosteum of the pubic arch requires vigorous resection of the periosteum with electrocautery. Deeper involvement of the pubic bone will require removal of the inferior portion of the pubic arch with orthopedic rongeurs and surgical drills. In the face of extensive disease, consultation with an orthopedic surgeon may be necessary to achieve an adequate margin. The puboprostatic ligaments are generally divided at this time.

**FIGURE 38.3 A and B:** Incision used to gain access to the perineum for total penectomy, total urethrectomy, radical prostatectomy, and continent cutaneous bladder augmentation. **C:** Electrocautery and suture ligatures are used to resect the urethral mass. **D:** If pubic bone invasion is present, the pubic arch is first scored with electrocautery; then, an orthopedic hammer and chisel are used to resect the inferior pubic arch to ensure a negative margin.

With the penis free, a negative surgical margin on the pubic arch, and the cystoprostatectomy completed, the entire specimen is removed en bloc. If additional room is needed at the penile incision to remove the specimen, the scrotum can be incised along its median raphe as previously described. In patients in whom a bladder-sparing procedure is being contemplated, the bladder neck margin is assessed with frozen section. Disease found at the bladder neck should prompt the surgeon to consider complete cystectomy and urinary diversion.

The type of urinary diversion performed—conduit or continent reservoir—is a function of surgeon and patient preference and should be discussed and planned prior to surgery. We prefer a variation of the right colon detubularized continent reservoir in motivated patients capable of performing intermittent catheterization. The ileal conduit is our preferred choice of intestinal segments for patients electing an incontinent diversion; in patients with irradiated small bowel or inflammatory bowel disease, the transverse colon conduit, based on the middle or right colic arteries, provides a safe, easy-to-handle alternative to the terminal ileum.

Small pelvic defects may be filled with a pedicled flap of omentum, unhinged from the greater curvature of the stomach and based on either the right or left gastroepiploic vessels. Large perineal defects, especially those resulting from wide resection of the pubic arch, require placement of a pedicled muscle flap. Many reconstructive urologists are conversant with the gracilis muscle flap, which is relatively easy to harvest and has a reliable blood supply. Rectus abdominus or gluteal muscle flaps may be necessary to fill even larger spaces. A Jackson-Pratt drain is placed deeply in the perineal wound and brought out through a stab incision. The superficial perineal fascia is closed with a running 3-0 Vicryl suture, as is deep dermis. The skin is approximated with a running 4-0 Monocryl suture. A tissue glue such as Indermil or Dermabond is utilized to seal the skin; in such cases, no dressing is needed. A Jackson-Pratt or Penrose drain, placed abdominally in close proximity to the ureteral reconstruction, is exteriorized lateral to the midline incision.

Postoperatively patients are managed in a standard fashion (9). A nasogastric tube, placed at the time of surgery, is routinely removed on the first postoperative day. DVT prophylaxis is maintained with heparin or enoxaparin postoperatively, and antibiotics are stopped within 24 hours, unless an active infection is being treated. Patients are aggressively ambulated beginning the first night or the morning of postoperative day 1;

pulmonary toilet with incentive spirometry is initiated on the day following surgery. The diet is advanced on a schedule, with sips begun on postoperative day 2 and advancing on a daily basis to a regular diet on postoperative day 5. Ketorolac is utilized to minimize opiates and help bowel function, and metoclopramide is also given to enhance motility.

---

## OUTCOMES

---

Tumors of the distal urethra enjoy the best prognosis, with a nearly 70% 5-year survival rate. In patients with superficial squamous cell carcinoma resection, laser ablation or local excision provides progression-free rates approaching 100%. More locally advanced disease requiring partial penectomy can be cured when a 2-cm urethral margin is achieved. Proximal urethral tumors, on the other hand, due to the more advanced nature of disease at presentation, respond poorly to extirpative surgery; they are associated with a 25% to 40% 5-year survival rate (5). The reported disease-specific survival rate in most series is around 50%, a figure that has changed little over the last few decades, owing, in part, to little improvement in adjuvant therapies.

---

## COMPLICATIONS

---

With penile-preserving surgery, the possibility of local recurrence dictates the need for compulsive monitoring. Endoscopic therapies and local excision may result in the development of urethral strictures. Stenotic lesions failing to respond to dilation should be evaluated for the presence of recurrent cancer. Recalcitrant benign stricture disease needs to be addressed with open urethroplasty. Stenoses of the meatus or perineal urethrostomy are common complications seen in patients undergoing partial and total penectomies, respectively, and may be managed conservatively with patient self-dilation.

Pelvic exenteration for bulbar urethral tumors carries a similar profile of complications as that seen with other exenterative procedures. Pelvic abscesses need immediate attention with open or radiological drainage. Perineal wound breakdown, especially when associated with the placement of pedicled flaps, is treated with surgical debridement and local wound care.

# CHAPTER 39 ■ INJECTABLE THERAPIES FOR INCONTINENCE IN WOMEN

RODNEY APPELL

The idea of increasing urethral resistance by an injectable agent is nothing new. It was first reported in 1938 (1). Twenty women had either sodium morrhuate or cod liver oil injected into the anterior vaginal wall to provoke an inflammatory response resulting in scar formation and contracture of tissue around the urethra. Seventeen patients reported being cured or improved, but pulmonary infarction and cardiopulmonary arrest were reported. In 1955 the first injections into the urethra were reported by Quackels (2). Two patients were treated successfully without complications. In 1963 Sachse (3) used Dondren, a sclerosing agent, to treat 7 women and 24 men. Four women and 12 men were reported as cured, but several patients experienced pulmonary embolism. These first bulking agents were far from ideal. Such an ideal agent would be non-immunogenic, hypoallergenic, biocompatible, heal with minimal fibrosis, be nonmigratory, and retain its bulking effect over a long period of time (be durable) (4).

---

## MECHANISM

---

Injectable agents work by forming a “seal” through restoring mucosal coaptation. They have several advantages over surgical procedures in treating stress urinary incontinence (SUI). Compared to surgical procedures that create a functional obstruction, injectable agents restore continence by increasing urethral resistance at rest. With bulking agents, the urethra maintains its ability to funnel and open, keeping urethral resistance low during micturition. This spares a resultant increase in detrusor pressure (Pdet), which could lead to overactive bladder symptoms and/or upper-tract damage. In comparison, surgical procedures may result in increased resistance at rest and during micturition by not allowing the urethra the same physiologic movement. Most bulking agents are placed at the level of the bladder neck within the smooth muscle in the area of the continence mechanism. Since the placement is within the urethra, *intraurethral* is a more accurate term than the commonly used terms *periurethral* or *submucosal*.

---

## CRITERIA FOR SELECTION

---

Ideal patients for intraurethral bulking have SUI due to intrinsic sphincter deficiency (ISD) and a normal contractile bladder. Clues such as leaking a large amount of urine with cough or sneeze, significant leakage upon exertion, leakage while supine, bed wetting, or leakage with the sensation of urinary urgency may suggest ISD. On physical examination, the patient should have a well-supported, fixed urethra. This can

be determined by placing a cotton swab through the urethra with the tip just past the urethrovesical junction. If the angle is  $>30$  degrees from the horizontal or the change in angle is  $>30$  degrees when the patient bears down or coughs, the patient is said to have a hypermobile rather than fixed urethra (5,6).

The use of intraurethral bulking agents in women with urethral hypermobility, type II incontinence, is an area of controversy. A comparison between pubovaginal slings and intraurethral collagen injections was performed by Kreder and Austin (7). In their study, they compared success rates in patients with ISD alone or mixed with urethral hypermobility. In the mixed group, those receiving a pubovaginal sling fared better, with a cure rate of 81% versus 25% in the collagen group. However, the collagen group only received a single injection, whereas it has been demonstrated that many patients require two to three injection sessions to affect their continence (8). In another study, despite more injections and the amount of material injected in the group with urethral hypermobility, both those with and without hypermobility had equal success (9). In a later study by Herschorn and Radomski (10), no statistically significant difference was found between those with and without urethral hypermobility. Over time, 72% remained dry at 1 year, 57% at 2 years, and 45% at 3 years, with no significant difference between the type of incontinence and time to failure. Others have documented similar findings in patients with urethral hypermobility or type II incontinence (11–14).

Urodynamics should be performed to rule out other causes of urinary incontinence, such as detrusor overactivity. Urethral function can be assessed by measuring the abdominal leak point pressure (ALPP), which is the amount of abdominal pressure (Pabd) necessary to overcome the bladder's continence mechanism. The definition of ISD by ALPP has varied from a low ALPP (60 cm H<sub>2</sub>O) to an ALPP  $<100$  cm H<sub>2</sub>O. An absolute value for ALPP suggesting ISD has become unimportant due to limitations in urodynamic testing as well as different values used by different clinicians. With videourodynamics, radiographic evidence of an open bladder neck and proximal urethra without detrusor contraction during the storage phase of the bladder is felt to imply ISD.

As more is understood about the continence mechanism, it appears that most women with SUI have some component of ISD, since there are numerous women with urethral hypermobility who do not leak with significant intra-abdominal pressures. Women who do have a fixed, nonmobile urethra are, however, more likely to have a greater degree of ISD (15). Exclusion criteria for intraurethral bulking would include urinary incontinence due to abnormal detrusor contractions, active urinary tract infection, or allergy to the material used as a bulking agent.

---

### Key Concepts

---

- *Ideal patients for intraurethral bulking have SUI due to intrinsic sphincter deficiency (ISD) and a normally contractile bladder.*
- *Most women with SUI have some component of ISD.*

---

## INJECTION TECHNIQUES

---

When performing intraurethral bulking, precise placement of the bulking material into the wall of the proximal urethra near the bladder neck in the area of the continence mechanism is of the utmost importance. The plane of delivery, the tissue quality at the injection site, and the cause of incontinence are all important factors in successful therapy. If material is delivered too distally, the treatment is likely to fail and may cause irritative voiding symptoms. Prior to injection, patients are placed in lithotomy position and prepared in standard sterile fashion. A local anesthetic in the form of 20% benzocaine ointment or cream may be applied to the vestibule covering the urethra, and a topical 2% lidocaine jelly may be applied to the urethra. Approximately 4 mL of 1% lidocaine is then injected periurethraly at the 3 and 9 o'clock positions.

---

### Key Concept

---

- *Precise placement of the bulking material into the wall of the proximal urethra near the bladder neck in the area of the continence mechanism is of the utmost importance.*

---

## TRANSURETHRAL INJECTION

---

Several approaches may be taken when performing injections of bulking agents. They may be performed by placing a needle through a cystourethroscope and injecting suburothelially, also known as a "transurethral injection" (16). A 0-, 12-, or 30-degree lens is best for providing a good view of the urethra as well as the injection needle. Once the cystourethroscope is placed into the urethra and passed into the bladder, the bladder is usually drained because the patient's bladder may become distended toward the end of the procedure. The endoscope is then backed to the midurethra, at which time the needle is deployed at the 4 o'clock position. The needle is then inserted submucosally into the urethral muscle beyond the midurethra and advanced to the proximal urethra near the bladder neck. Once the desired positioning is achieved, the bulking agent is slowly delivered to allow it to spread underneath the urethral mucosa. Once the mucosa on that side has expanded to the midline, the needle is slowly withdrawn while injecting. Attention is then turned to the 8 o'clock position, where the technique is repeated again. After completion of both sides, a fair amount of coaptation should be noted.

---

### Key Concepts

---

- *Once the mucosa at the 4 o'clock position has expanded to the midline, the technique is repeated again at the 8 o'clock position.*

- *A 0-, 12-, or 30-degree lens is best for providing a good view of the urethra as well as the injection needle.*

---

## PERIURETHRAL INJECTION

---

Injections may also be performed periurethraly via a needle placed percutaneously lateral to the urethral meatus and parallel to the urethra. While the needle is placed, the urethra is visualized through a cystourethroscope (17,18). Localization of the needle tip may be facilitated by preinjecting the urethra with methylene blue during the periurethral approach (19). With the periurethral approach, there is often less bleeding, which can improve visualization. There is also less extrusion of the material injected, although this also depends upon the type of material injected. The desired amount of coaptation is the same as when performed via a transurethral technique. After the periurethral block, a 20-gauge spinal needle is placed at the 4 o'clock position into the periurethral tissue within the lamina propria. Urethroscopy is then performed as the needle is further inserted with minimal resistance up to the level of the bladder neck. The needle is then rocked in a horizontal plane to assess the location of the needle tip and ensure placement at the proper depth. The material is then injected slowly while observing for coaptation, similarly to the transurethral technique, and the process is repeated at the 8 o'clock position. If material is noted in the lumen of the urethra, the needle is removed and relocated to a more anterior position, where the injection is repeated again. Once sufficient coaptation is noted, the procedure is ended. A needle with a "bent tip" has been manufactured (Boston Scientific Inc, Natick, MA) to facilitate placement into the proper plane. With advancement of the needle, the tip is brought more medially. These needles were originally designed to ease the injection of Durasphere, since a larger bore size (18 gauge) also aids in the passage of the particles, but they certainly can be used for the periurethral injection of other bulking agents.

The differences between the transurethral and periurethral techniques were reviewed by Faerber et al. (20). They found similar outcomes with no significant differences in adverse events using collagen. Of significance, the amount of material injected was less using a transurethral approach. A prospective, randomized comparison was later performed in women with again no noted differences in efficacy, but a higher rate of urinary retention and also an increased volume of injected material were seen in the periurethral group (21). It appears that a periurethral approach tends to use larger volumes of material and has been noted to have a longer learning curve than the transurethral approach.

---

## ULTRASOUND GUIDANCE

---

Although transurethral and periurethral injections are the most commonly performed injections, injections may also be performed in women with an ultrasound probe (22). Theoretically, this technique circumvents the passage of instruments through the urethra, which may alter the placement of the bulking agent affecting coaptation. First, a transrectal ultrasound probe with a biopsy port is placed into the vagina. Once the bladder neck has been identified, a needle of the same type for transurethral injection is placed through the

port. Longitudinal views by ultrasound are used to determine coaptation of the bladder neck. Studies have demonstrated that three-dimensional ultrasound views may predict long-term outcomes and may provide an objective measure for the amount of material to be placed (23). In later studies with three-dimensional ultrasound, collagen injections were shown to maintain their volume and ultrasound appearance with an associated improved continence and quality of life. It was also found that the most desirable appearance on ultrasound was either a circumferential or horseshoe configuration (24). Regardless of the technique, coaptation of the urethra is the goal.

---

## POSTOPERATIVE CARE

---

Immediate postoperative complications are rare. After completion of the procedure, the patient should demonstrate the ability to void. If the patient is in acute urinary retention, most often the patient will be able to urinate shortly after the periurethral block loses effect. Meanwhile, the patient is usually catheterized with a small 10Fr to 14Fr catheter to relieve the patient's full bladder after cystourethroscopy. An indwelling Foley catheter should be avoided since there is a theoretical risk of the bulking agent molding around the catheter and losing its effect, although there is no evidence to support that short-term catheterization decreases the efficacy of intraurethral bulking. If long-term catheterization is necessary, a suprapubic catheter until return of voiding would be best to avoid disrupting the placement of the bulking agent. Prophylactic treatment with antibiotics is recommended to avoid urinary tract infections. Many patients will require more than one treatment session to achieve maximal continence. Different waiting periods are required for each individual bulking agent. Bulking agents such as GAX-collagen can be repeated after 1 week (in the original multicenter study, a 4-week waiting period was used). With polytetrafluoroethylene, a 4-month wait is required since improved coaptation occurs with time. On repeat injection, if erosion is noted, injection into that side should be avoided until re-epithelialization occurs.

Irritative voiding symptoms may also develop after placement of bulking agents. Surprisingly, in a study by Steele et al. (13), 50% of patients were reported to have developed de novo detrusor overactivity. In a study by Cross et al. (25), 28% of patients were found to have de novo urge incontinence without ISD when undergoing urodynamics for post-treatment incontinence. Stothers et al. (26) reported a 12.6% rate of de novo urgency with urge incontinence in 337 women enrolled in a prospective trial of which 21% failed anticholinergic treatment. Commonly, minor urethral bleeding may occur. If the urethral mucosa becomes disrupted, perforation and extravasation of the bulking agent may occur. An advantage of the periurethral approach involves placement of the bulking agent without disruption of the mucosa.

---

### Key Concept

---

- *If the patient is in acute urinary retention, catheterize with a small 10Fr to 14Fr catheter to relieve the patient's full bladder.*

---

## INJECTABLE AGENTS

---

Other methods of treatment for SUI include urethropexies, slings, and artificial urinary sphincters. Often bulking agents are compared to these other methods of treatment. What has been demonstrated in some studies is that midurethral slings and Burch urethropexies tend to have higher failure rates in patients with a "fixed urethra" (27,28). These patients are better off treated with intraurethral bulking agents, bladder neck slings, or artificial urinary sphincters. Compared to injectable agents, the artificial urinary sphincter and bladder neck slings both involve undergoing a surgical procedure, which involves surgical risk as well as the risk of anesthesia, whereas the intraurethral bulking agent involves only local anesthesia and minimal complications.

Comparing the different injectable agents is a difficult task. There are few controlled, long-term studies involving commonly used bulking agents. Even within those rare studies, there are many variables that make it difficult to compare one to another. This is due to the different patients with different severities and etiologies of stress incontinence. Not all studies differentiate the results in patients with and without urethral hypermobility and/or ISD. The procedures themselves have also varied due to different technical factors such as injection technique and instrumentation. Additionally, reported results have been largely subjective rather than objective, creating a difficult situation to compare data. Variability also exists within the reported outcomes, as different criteria have been used to define *cured* or *improved*.

---

## AUTOLOGOUS MATERIALS

---

---

### Autologous Blood

---

Autologous blood is readily available and accessible. In a study of 14 women, 30 mL of blood was obtained in a heparinized syringe from the antecubital vein. Continence was achieved after two treatments. Unfortunately, all patients became incontinent again after 10 to 17 days (18).

---

### Autologous Fat

---

Although not as accessible as blood, autologous fat can be easily obtained through liposuction. In 1989 this technique was reported in 10 women (29). In a different study with 1 year follow-up, 0 of 5 men and 5 of 15 women reported improvement (30). In a study by Santarosa and Blaivas (31), 83% of 12 women with ISD were subjectively improved, although at 1 year the results were much poorer. In a randomized double-blind controlled trial of women with urethral hypermobility, fat was found to be as effective as the saline control group at 6 months (33).

These poor results are thought to be secondary to fat degradation. After injection, neovascularization never becomes adequate at the fat graft's center, leaving only a miniscule amount of viable fat, which may hinder its bulking effect. After 3 weeks, 60% of the fat injected is degraded. Once the fat is reabsorbed, inflammation occurs with resulting fibrosis, which leads to the bulking effect (31). Although this material

is accessible and complications are rare, it has been reported to be associated with systemic embolization and death (33,35). Therefore, the use of autologous fat as a bulking agent is discouraged.

---

## BIOMATERIALS

---

### Glutaraldehyde Cross-Linked Bovine Collagen (GAX-Collagen)

---

Of all the injectables, glutaraldehyde cross-linked bovine collagen (GAX-collagen) is probably the most commonly used, with most publications describing its safety and efficacy. Before its use as a bulking agent, bovine dermal collagen was primarily used to make absorbable sutures and hemostatic agents. When used as a bulking agent, bovine collagen is cross-linked with glutaraldehyde to create a stabilized, fibrillar collagen that confers resistance to denaturation by collagenases. It consists of 35% purified bovine collagen in a phosphate buffer. The collagen itself is composed of 95% type I collagen, which is the type found predominately in ligaments and confers structural strength; however, between 1% and 5% is composed of type III collagen, which is the type abundant in vaginal tissue, giving added flexibility (36). GAX-collagen is prepared by selective hydrolysis of the collagen molecule at the nonhelical amino-terminal and carboxy-terminal segments, also known as telopeptides. This serves two functions. One is to decrease the antigenicity, and the other is to increase resistance to collagenases and thus to increase the durability of the implant (37,38).

When injecting this material, the surgeon inserts the exact amount needed to achieve the desired effect, since there is no expansion or shrinking after injection. Acting as a matrix, the material promotes ingrowth of new collagen within the implant (39). Since GAX-collagen is both biocompatible and biodegradable, only minimal inflammatory changes occur (40). After 12 weeks, the collagen starts to degrade, but it persists until 19 months (41). Despite the fact that GAX-collagen is degraded, it maintains effectiveness in 80% of those who become continent, a result that is thought to be secondary to the ingrowth of new collagen (42).

One series reported that 55% of women could achieve continence after one injection session (43). In a multicenter clinical study involving 127 women with ISD, 88 patients completed 2-year follow-up. At 2 years, 46% of patients were dry and 34% were significantly improved, requiring only a single pad or tissues. Urodynamic studies also revealed a rise of 40 cm H<sub>2</sub>O in ALPP. A mean volume of 18.4 mL of GAX-collagen with a mean of 2.1 (+/- 1.5) treatment sessions was given to those who achieved continence (44). Other independent studies have supported these results (9,45,46). These reported rates have compared favorably with other treatment modalities for ISD (47). As time progresses, a noted decline in efficacy has been witnessed. Forty-five percent of elderly women were improved at 24.4 months in a report by Winters et al. (12). Of note in this group, at an average of 7.9 months, 40% required more injections; after additional material was injected, only 42% became continent again. Forty-two patients with ISD were followed at an average of 46 months by Richardson et al. (48), who reported a 40% dry rate, 43%

improved rate, and 17% rate of failure. At 50 months, Corcos and Fournier (49) reported a cured rate of 30% and an improved rate of 40% in 40 women, although four women in the cured group and five women in the improved group required "maintenance" injections. In a study up to 5 years, Gorton et al. (50) reported that only 26% of 53 women reported continued improvement.

Few complications have been found with the use of GAX-collagen. In the U.S. clinical trials (51), 15% developed transient urinary retention, 5% had a UTI, and 1% experienced irritative voiding. Rates of de novo urgency and frequency have been reported to be as high as 10% (49). There has been no evidence of foreign-body response or migration (39), partly because of the small amount of glutaraldehyde in GAX-collagen, which creates minimal immunoreactivity and cytotoxicity (52). GAX-collagen is biocompatible and allows fibroblasts to deposit native collagen as well as neovascularization to occur as the implant is degraded over 12 weeks (53). After 10 to 19 months all of the implant has completely degraded (40). There have been several case reports of sterile abscesses at the injection sites, some of which required drainage (35,55).

One potential hazard of GAX-collagen involves an allergic reaction to the bovine protein, although this is reduced by cross-linking and skin testing. Approximately 4% of female patients will have a positive skin test, which precludes them from treatment (44). Despite being extraordinarily rare, delayed hypersensitivity has been reported at the skin test site. Overall, due to its complete degradation with minimal inflammatory response and lack of migration, GAX-collagen has been the most popular intraurethral bulking agent used to treat incontinence.

---

### Key Concepts

---

- *As time progresses, a noted decline in efficacy has been witnessed.*
- *Approximately 4% of female patients will have a positive skin test, which precludes them from treatment.*

---

## SYNTHETIC MATERIALS

---

### Polytetrafluoroethylene (Polytef)

---

Many authors have been able to demonstrate the efficacy of polytetrafluoroethylene (PTFE) as a bulking agent (58-63). Success rates have ranged from 70% to 90% with PTFE (64). This material was also studied by the Department of Technology Assessment of the American Medical Association and was found to be an easily performed, effective treatment with good short-term results (65). However, longer follow-up has proven otherwise. In one study, a 38% success rate between 21 to 72 months (mean, 49 months) was noted in women (66).

In addition to the shortcomings in long-term efficacy, rates of urinary retention have ranged from 20% to 25% (67). Transient irritative voiding symptoms may develop in approximately 20% of patients (62). Urinary tract infection has been reported to occur at a rate of 2% (61).

Of greater concern, the long-term safety profile of this agent has been brought into question. Foreign-body reaction

with granuloma formation is a known risk (68). After injection, histiocytic and giant cells are responsible for this reaction. Particles have been found in blood vessels as well as lymphatics. These particles have been thought to elicit an allergic response in some patients, which is believed to be responsible for culture negative fevers in 25% of patients. Five percent of patients also complain of transient perineal discomfort with spontaneous resolution, which is also thought to be an immune-related phenomenon (67,69).

Once inside blood vessels or lymphatics, particles can migrate to distant locations. In animal models, PTFE particles have been found in pelvic lymph nodes, lungs, brain, kidneys, and spleen at 1 year (70,71). Particle migration to distant sites has been reported in humans as well. First reported by Mittleman and Marraccini in 1983 (72), a PTFE granuloma was found in the lung of a patient 2 years after injection. Claes et al. (73) reported on a patient experiencing fevers with biopsy-proven PTFE granulomas in the lung 3 years after PTFE injection. In another field, PTFE was used to inject the larynx for vocal cord paralysis. Twenty months after injection, a granuloma was found in the anterior lobe of the thyroid (74).

Despite granuloma formation, patients rarely have had any clinical consequences. It is the formation of granulomas and their association with cancer that is of more concern, although PTFE has not been linked to carcinogenesis with 30 years of use as a bulking agent for the urethra and larynx (76). In fact, there have been reported cases of cancer near PTFE injection sites, but none have demonstrated PTFE as the precipitating factor (77–79). This risk was reviewed by Dewan et al. (80). It was concluded that the available evidence did not support PTFE as a carcinogenic agent but suggested that if a risk existed, it was low. In 1995 Dewan et al. (80) reviewed the risk of both PTFE and Bioplastique in a rat model. A similar incidence of tumors was found in the PTFE, Bioplastique, and control groups. Additional late adverse events include fibrosis of the urethra and granuloma balls in the bladder at a rate of 15% (66). Currently, the U.S. Food and Drug Administration (FDA) is investigating the product.

---

### Key Concept

---

- *Particle migration with granuloma formation to distant sites has been reported, though patients rarely have had any clinical consequences.*

---

### Silicone Polymers (Macroplastique, Bioplastique)

---

Silicone polymers such as Macroplastique and Bioplastique are made of polydimethylsiloxane macroparticles suspended in a carrier hydrogel consisting of polyvinylpyrrolidone (povidone). The solid particles make up 33% of the total volume and are  $>100 \mu\text{m}$  in size. Silicone polymer was first used in 1992 with encouraging short-term follow-up. Like other agents as time progressed, the cure rate fell from an initial 82% to 70% at 14 months (82). In other studies with Macroplastique, 19.6% were considered cured and 41.1% significantly improved at 19 months (83). To date there has been one prospective, randomized study comparing Macroplastique to GAX-collagen in 62 women (85). The authors

concluded that there was no significant objective difference between the two agents at 12 months. The only difference was that the Macroplastique group had less volume injected, although the pretreatment pad test loss was significantly less in that group.

Complications with the use of this material included urinary retention at a rate of 5.9% to 17.5%, urinary frequency at a rate of 0% to 72.4%, dysuria from 0% to 100%, and UTI from 0% to 6.25% (86). A study to determine the migratory properties of this material was performed on dogs. Small particles were found in the lungs, kidney, brain, and lymph nodes within 4 months of injection. In comparison, only one large particle was found in the lung without any associated reaction (87). In a rat model, four sarcomas with the Bioplastique group were associated with silicone particles. Given the recent controversy over silicone used in breast implants as well as the possibility of migration, it is unlikely that silicone will become a popular agent for intraurethral injections.

---

### Carbon-Coated Zirconium Beads (Durasphere and Durasphere EXP)

---

Durasphere, a new synthetic material, was approved by the FDA in 1999. It is composed of pyrolytic carbon-coated zirconium oxide beads in a 2.8% beta-glucan water-based gel. The bulking effect lasts for at least 2 years as the beads are encapsulated into the periurethral tissue. Compared to collagen, it is an inert and nonimmunogenic material, eliminating the need for skin testing. However, Durasphere can be more technically difficult to inject given its higher viscosity.

Durasphere was compared to GAX-collagen in a multicenter, randomized, controlled, double-blind study with follow-up at 1 year. The Durasphere group achieved improvement in one Stamey grade or more in 80% of patients compared to 69% of patients in the GAX-collagen group, although the difference did not reach statistical significance. Pad weights at 12 months were equivalent between the two groups. The Durasphere group had significantly less volume injected and were more successfully treated with a single injection (88). Although permanent, questions concerning longevity, similar to GAX-collagen, were brought forth. Panneck et al. (89) noted a decrease in success from 77% at 6 months to 33% at 12 months in a group of 13 women. In their study, one female patient was also noted to have asymptomatic distant particle migration into the regional and distal lymph nodes. Due to intraneedle resistance secondary to bead size, injection of Durasphere can be technically difficult. In response to this issue, Madjar et al. (90) used a periurethral approach at a single injection site. With 92% of 46 patients achieving excellent or good coaptation, 65% considered themselves cured or improved at a mean of 9.4 months. Additionally, 50% of 36 patients had a 24-hour pad test with 8 g or less of urine. Long-term data have been reported in a multicenter, comparative trial of Durasphere and GAX-collagen. Durasphere remained effective in 33% of patients at 24 months and in 21% at 36 months. Those who received GAX-collagen reported effectiveness in 19% of patients at 24 months and in 9% at 36 months. However, when controlled for differences in follow-up time, the time to failure between the two groups did not reach statistical significance. Interestingly, one third of each group felt that treatment was successful (91).

In the trials for FDA approval, the most common adverse events were acute retention ( $\leq 7$  days) at 13%, dysuria at 12%, UTI at 9%, hematuria at 6%, and retention  $> 7$  days at 6%. Other adverse events occurred at  $\leq 4\%$  (92). There have also been case reports of sterile abscess formation.

Durasphere's beads are much larger than either PTFE or silicone polymers. In spite of their size, there have been reports of migration, although clear evidence is lacking. As determined by studies involving polytetrafluoroethylene, macrophages are able to phagocytize particles smaller than 80  $\mu\text{m}$ . Once phagocytized, the particles can then be carried to different parts of the body. Since Durasphere ranges from 212 to 500  $\mu\text{m}$ , phagocytosis and therefore migration should not occur. Case reports involving beads found in lymphatics and other places are likely due to a high-pressure embolization effect, which may displace beads into vascular or lymphatic spaces. Delivery with large particles under low pressure should eliminate the risk of embolization. Durasphere-EXP is a modification of the original Durasphere that should allow lower-pressure injection due to the smaller bead size (95 to 550  $\mu\text{m}$ ) yet above 80  $\mu\text{m}$  to avoid migration.

---

### Key Concept

---

- *Durasphere achieved improvement in one Stamey grade or more in 80% of patients compared to 69% of patients in the GAX-collagen group, although the difference did not reach statistical significance.*

---

### Ethylene Vinyl Alcohol Copolymer (Tegress, Uryx)

---

Approved by the FDA in 2004, Tegress is composed of an 8% ethylene vinyl alcohol (EVOH) copolymer dissolved in dimethyl sulfoxide (DMSO), which is a permanent, hypoallergenic, nonimmunogenic implant. It comes prepared in 3-mL glass vials with a 3-mL DMSO-compatible syringe. The material is injected via a 25-gauge needle. Once Tegress is exposed to fluid within the tissue, the DMSO diffuses out, causing the precipitation of EVOH into a soft, spongy, hydrophilic material. The time required for the chemical reaction to occur is within 60 seconds. Care must be taken to avoid contamination of this agent with fluid prior to injection. At 1 month, an acute inflammatory response has been noted to be at its greatest. This effect lasts until 3 months, when the reaction has become more mild and localized with some resultant mineralization. There has been no evidence of EVOH affecting tissue at remote sites from the injection site. There also has been no evidence of migration.

When EVOH is used as a bulking agent, a different technique must be applied. If an excessive amount of material is injected, erosion through the urethral mucosa is likely to occur. To decrease the risk of erosion, the manufacturer suggests injecting at a more distal location in the urethra approximately 1.5 cm distal to the bladder neck. Each injection is to take place over 1 minute, with an additional minute of waiting to allow the chemical reaction to occur before removing the needle (95). When the needle is removed, a twisting motion often helps to separate the precipitated material off the needle tip and minimize

the length of tail left at the injection site. Injections should not be performed until coaptation is noted, unlike with many of the other bulking agents. Urethral coaptation may suggest that too much material may have been injected.

Currently for EVOH, the only large study is from the trial for FDA approval. A multicenter, prospective, randomized trial was conducted with 177 of 253 women completing follow-up at 12 months comparing EVOH to GAX-collagen. The first 16 patients were excluded from the data since they were the first patients undergoing a new technique. At 12 months, efficacy was assessed by Stamey grade, pad weight, and quality-of-life questionnaire. Of those who received EVOH, 18.4% of patients were dry by Stamey grade compared to 16.5% of those who received collagen. The difference between the two groups regarding who had improvement by at least one Stamey grade did not reach clinical significance. In respect to pad weights, 37.8% were dry in the EVOH group compared to 32.1% undergoing collagen injection. This study resulted in FDA approval of EVOH (95,97).

In the trials for FDA approval, EVOH has been shown to have similar rates and severity of adverse events when compared to collagen. The one exception is the 16% rate of material exposure. During this study, it was noted that the exposure rate was higher with periurethral injection, and therefore this method is not recommended. Exposed material did not result in any adverse consequences and usually resolved. However, in the authors' experience, erosion rates of 37% in women and 41% in men necessitated multiple office visits for several patients with severe dysuria. Other common adverse events included UTI (29%), delayed voiding (18%), dysuria (18%), urinary urgency (14%), and frequency (13%). Interestingly, 9% of patients developed urge incontinence and 8% had worsening of incontinence. This injectable agent has been removed from utilization in the United States.

---

### Key Concepts

---

- *With EVOH, injections should not be performed until coaptation is noted, unlike with many of the other bulking agents.*

---

### Calcium hydroxyapatite (Coaptite)

---

Approved in December 2005, calcium hydroxyapatite is a synthetic agent that consists of carboxymethylcellulose in the form of an aqueous gel. Calcium hydroxyapatite is biocompatible, does not encapsulate, facilitates ingrowth of native tissues, and can be identified on radiographic studies as well as ultrasound. Another advantage includes ease of injection of material.

In a study with 1 year follow-up, 7 of 10 women reported substantial improvement in continence, a 90% decrease in mean pad weight, and an increase in mean Valsalva leak point pressure from 39 to 46 cm H<sub>2</sub>O (100). In the data for FDA approval, 158 patients received Coaptite with a mean follow-up of 11.2 months. No statistical difference was found in change in Stamey grade, pad weight, or quality of life when compared to GAX-collagen as the control. (101).

Common adverse events included urinary retention (41%), hematuria (19.6%), dysuria (15.2%), and UTI (8.3%). Changes in voiding occurred with urinary urgency at 7.6%, frequency at 7.0%, and urge incontinence at 5.7%. Two serious adverse events occurred: one erosion through the vaginal wall requiring surgery and dissection into the bladder causing tissue bridging, for which no surgical correction was needed. The overall erosion rate was 1.3% (101).

### Key Concept

- *No statistical difference was found in change in Stamey grade, pad weight, or quality of life when compared to GAX-collagen as the control.*

### FUTURE AGENTS

In patients with minimal urethrovesical junction mobility, ISD, and a stable bladder with an adequate capacity, intra-urethral injections can offer treatment responses similar to that of surgical correction with minimal complications. However, most of these data are short-term; there is a scarcity of data over 5 years, with the majority of studies followed for much less time. For GAX-collagen, reinjection rates can be as high as 22% at 32 months after having achieved continence. The other injectable agents on the market have much fewer data and lack long-term follow-up. For younger patients, the cost of reinjection can become significant.

Myoblasts
Microballoons

Although numerous injectable agents have entered the market over the last several years, the search for the ideal bulking agent continues. Listed in Table 39-1 are some of the current agents undergoing investigation.

### CONCLUSION

Currently, injectable agents are best used for those who are good candidates for successful treatment, those who wish to avoid a surgical procedure, or those who have problematic medical comorbidities that preclude them from undergoing surgical correction. Research continues the search for an effective, inert, nonmigratory, nonimmunogenic material that allows incorporation into native tissue, maintains its shape, and injects with ease. Currently, intraurethral bulking remains an art, as there is no exact measurement or amount of material used for each patient to achieve continence.

## CHAPTER 40 ■ PUBOVAGINAL FASCIAL SLINGS

ANNE PELLETIER CAMERON, CHRISTINA LEWICKY-GAUPP, AND EDWARD J. MCGUIRE

The first urethral sling procedure was described by Giordano in 1907. This procedure was modified numerous times and employed several different sling materials, yet it never gained popularity because of the high incidence of permanent urinary retention, de novo detrusor overactivity, and urethral erosion. The pubovaginal autologous fascial sling (PVS) was repopularized by McGuire and Lytton in 1978 when they reported their modification of the technique with little morbidity and 80% success in a complicated population with urodynamic proven intrinsic sphincter deficiency (ISD)(1). In a more contemporary series with 247 patients who had either Type II or III stress urinary incontinence (SUI) and 44% patients who had concomitant urge incontinence, the authors reported a cure rate of 91% for Type II incontinence and 84% for Type III. Also in this series, of those patients with preoperative urge incontinence, 74% had resolution after surgery (2). Other authors have duplicated these results, with cure or improvement in up to 92% of women with >10 years of follow-up (3).

Female SUI is classified as being due to urethral hypermobility (Type I and Type II SUI), intrinsic sphincter deficiency (Type III SUI), or a combination of the two. In Type I and II SUI the urethral sphincter functions essentially normally, but abdominal pressure drives the sphincter into a position where its function is compromised. Therefore, procedures that correct this urethral hypermobility, such as the Burch colposuspension or synthetic midurethral slings, are effective. In contrast, ISD is characterized by a relatively immobile urethra

with urethral sphincter weakness or scarring resulting in leakage with increases in abdominal pressure. This is not effectively treated by correcting only hypermobility. Splitting SUI into these two distinct categories is not quite that simple because urethral hypermobility and ISD are not mutually exclusive. It is important to note that the severities of urethral hypermobility and sphincteric incompetence are on a continuum and that both exist to some degree in all incontinent patients. Also, significant urethral hypermobility can be present in a woman, yet she can be completely continent since her sphincteric mechanism is intact (4).

Traditionally, many urologists routinely used a PVS for all types of incontinence since it effectively corrected both ISD and urethral hypermobility. In 1996 Ulmsten et al. (5) introduced an effective synthetic midurethral sling procedure that was minimally invasive and very effective for SUI secondary to urethral hypermobility [Tension-Free Vaginal Tape (TVT, Gynecare)]. In later studies, the TVT has been shown to be somewhat effective in treating ISD; however, success rates vary significantly, from 17.0% to 91.4% (6,7). The polypropylene midurethral sling and its modifications (including the transobturator route of sling placement: the TOT) have changed the landscape of stress incontinence surgery. The need to determine if a patient has a small amount of ISD versus pure hypermobility is less critical, and for many surgeons synthetic slings are their operation of choice for primary treatment of SUI. Currently, more invasive surgery like the pubovaginal sling is reserved for specific indications.

---

## DIAGNOSIS

---

Preoperative evaluation is directed toward identifying ISD, which can often be done on history, as these patients have severe leakage with minimal activity. ISD only occurs in 9% of women with SUI who have never had any incontinence surgery, but that percentage increases to 25% if they have had one prior failed incontinence surgery and to 75% after two failures (8). Concurrent urgency symptoms are not uncommon, and most patients have a history of multiple urethral or vaginal surgeries, have had radiation therapy, or are elderly. Neurologic ISD is characterized by severe incontinence with total nonfunction of the proximal sphincter and an open bladder neck on fluoroscopic urodynamics (FUDS). It is common in myelodysplasia, sacral agenesis, and T12–L1 spinal cord injuries. These injuries result in loss of the sympathetic innervation of the urethra at a central level, and the incontinence is almost always due to ISD.

---

## PHYSICAL EXAMINATION

---

The physical examination is directed toward the pelvis. A thorough vaginal examination in the supine position with a half-speculum both at rest and with straining is essential. If present, prolapse should be identified, since it can be concomitantly repaired to achieve optimal surgical success. If the patient has had previous vaginal or pelvic surgery, the mucosa should be assessed thoroughly for the possibility of a fistula or erosion of foreign material. The urethra should be palpated for lesions and then visualized at rest and with straining to assess for hypermobility. We do not routinely perform a Q-tip test, but if there is any uncertainty about the amount of hypermobility, one can be performed. A supine stress test should then be done to identify urethral incontinence. One can safely presume that a patient with an immobile urethra plus severe SUI has ISD.

---

## INVESTIGATIONS

---

One should always confirm the absence of urinary tract infection with a urinalysis. If infection is present, it must be treated preoperatively. A cystoscopy is performed if hematuria is present to rule out malignancy or if the patient has had previous incontinence surgery to rule out suture or tape erosion. Routine cystoscopy is not necessary.

Urodynamic evaluation is performed on patients with severe incontinence or mixed symptoms. A postvoid residual is measured before insertion of the urodynamic catheter. A cystometrogram is then carried out to rule out poor detrusor compliance and detrusor overactivity (DO). Poor compliance needs to be medically or surgically treated before PVS placement or the upper tracts can be at risk of deterioration after the outlet no longer leaks. Also, one needs to counsel patients that although DO may actually resolve 74% to 77% of the time (2,3), it may persist or worsen. The urodynamic abdominal leak point pressure (ALPP) is the key to diagnosing ISD. With the bladder filled to 200 mL (with children to one-half their functional bladder capacity) and the patient in an upright position, a Valsalva maneuver is performed until leakage is

noted. If no leakage can be elicited with several well-performed Valsalva maneuvers, vigorous coughing can be used with the knowledge that the ALPP will be falsely elevated. If the patient has significant prolapse, it should be reduced with a vaginal pack or pessary to ensure that the prolapse is not masking the incontinence. Even if the patient has SUI without reduction of the prolapse, placement of a vaginal pack will often demonstrate a greatly reduced ALPP, which can change the contemplated procedure. The exact urodynamic definition of ISD is controversial, with some authors utilizing maximum urethral closure pressure (MUCP)  $\leq 20$  cm H<sub>2</sub>O (6), others valsalva leak point pressure (VLPP)  $< 60$  cm H<sub>2</sub>O (2), and some the combination (7). We consider an ALPP  $< 60$  cm H<sub>2</sub>O to be consistent with ISD. A pubovaginal sling is ideal to correct this kind of severe incontinence. Pure urethral hypermobility is an ALPP  $> 90$  cm H<sub>2</sub>O, and a gray area exists where both hypermobility and ISD coexist between 60 and 90 cm H<sub>2</sub>O. Both of these latter conditions with less severe incontinence, barring contraindications, are well suited for a midurethral sling.

---

## INDICATIONS FOR SURGERY

---

Before the era of the TVT and TOT, a pubovaginal sling could be used to treat any kind of incontinence. However, since these minimally invasive procedures carry less morbidity, they have become the primary treatment for uncomplicated stress incontinence. Pubovaginal slings are now reserved for the following specific indications:

1. **Severe ISD:** Severe ISD with an ALPP  $< 60$  cm H<sub>2</sub>O, especially when combined with little urethral hypermobility, is poorly treated with the minimally invasive midurethral slings. Cure rates are reported to be as low as 17% if both conditions coexist (6). An autologous PVS is ideal in this instance, and success is expected to be from 84% to 92% even in the presence of DO (2,3).
2. **Neurogenic incontinence:** Children or adults with neurogenic voiding dysfunction from myelodysplasia, sacral agenesis, or T12-S1 spinal cord injury are ideal candidates for autologous PVS (Fig. 40.1). Their incontinence is invariably due to ISD, and they have both proximal sphincter dysfunction and an open bladder neck that requires a compressive sling to resolve their leakage (9). The anatomy is similar with incontinence from a pelvic nerve injury secondary to rectal surgery, a traumatic pelvic crush injury, or posthemipelvectomy incontinence. Midurethral slings are designed to be tension-free and do not compress the urethra. In addition, many of these patients have an areflexic bladder or have had augmentation cystoplasty and require lifelong clean intermittent catheterization that could cause urethral erosion in the presence of synthetic mesh. Also, the use of an autologous material for a PVS is especially important in the pediatric population since it will grow with the child and can safely allow vaginal delivery if the child has a pregnancy later in life (9).
3. **Failed midurethral sling:** If patients have persistent stress incontinence after a midurethral sling, it is possible that they had severe ISD initially. Their persistent incontinence is unlikely to be corrected by placing another midurethral sling. A prior midurethral sling does not make placement of a PVS more difficult or less successful.

A

B

C

**FIGURE 40.1** **A:** Fluoroscopic urodynamics (FUDS) image of a girl with myelomeningocele and a previous bladder augmentation with small bowel. She has an artificial sphincter in place, but it has eroded and requires removal. **B:** After removal she has severe stress incontinence from a wide-open bladder neck. **C:** A pubovaginal sling (PVS) was placed and this girl is now continent.

4. **Previous tape erosion:** Any patients with erosion of tape or mesh into the urethra are at high risk of ISD after removal and may have some urethral tissue loss. They should not have any more synthetic material placed in their vagina due to a high risk of re-erosion or urethrovaginal fistula formation. Also, any patients with persistent incontinence and a vaginal extrusion of mesh or a tape are better served with removal of the foreign body and a PVS rather than placement of more mesh.
5. **Contraindications to midurethral slings:** There are several conditions in which urethral reconstruction is necessary, such as an eroded urethra from a neglected indwelling catheter, severe urethral stricture requiring female urethroplasty, urethrovaginal fistula, or a urethral diverticulum. In these procedures, mesh cannot be left near the healing urethra because there is a significant risk of erosion and/or fistula formation. A pubovaginal sling provides another tissue layer of closure for the urethral repair that actually promotes healing. Similarly, if a patient has SUI and has had bladder or cervical radiation, the placement of synthetic material in the vagina is at high risk for complications like erosion, so only autologous tissue PVS should be used. Other specific circumstances in which the use of synthetics is contraindicated include neobladder-related SUI or any other previous bowel substitution of the urethra.
6. **Permanent clean intermittent catheterization:** In any instance where lifelong clean intermittent catheterization (CIC) will be required, an autologous material should be used, as patients are at risk for urethral erosion of their mesh.

---

## ALTERNATIVE THERAPY

---

Midurethral slings do have moderate success in cases of milder ISD, and they could be attempted with the knowledge that the success will not be equivalent to a PVS. For patients with significant comorbidities and high surgical risk, urethral calcium hydroxyapatite or collagen injections are a good option for ISD. Published results show a 74% to 71% improvement in incontinence and a 39% to 37% cure with an average of two injections (10). Urinary diversion is a last resort when a pubovaginal sling would be impossible, such as in instances of complete urethral loss or concomitant intractable vesicovaginal fistula.

---

## SURGICAL TECHNIQUE

---

A single dose of a prophylactic antimicrobial agent is administered, and the patient is given a general or spinal anesthetic. The procedure is performed in a low modified dorsal lithotomy position using Allen stirrups. A 16Fr urethral catheter is placed, and the balloon is inflated with 10 mL of water to allow palpation of the bladder neck. Preparation and draping of the patient is done in a manner to allow for the simultaneous exposure of the vagina and lower abdomen. We prefer to perform the abdominal dissection first to minimize vaginal bleeding.

In order to harvest the autologous fascial sling, an 8- to 10-cm Pfannenstiel skin incision is made 2 cm above the symphysis. This incision is carried down to the underlying fascia, and the subcutaneous fatty tissue is cleaned off the fascia. A

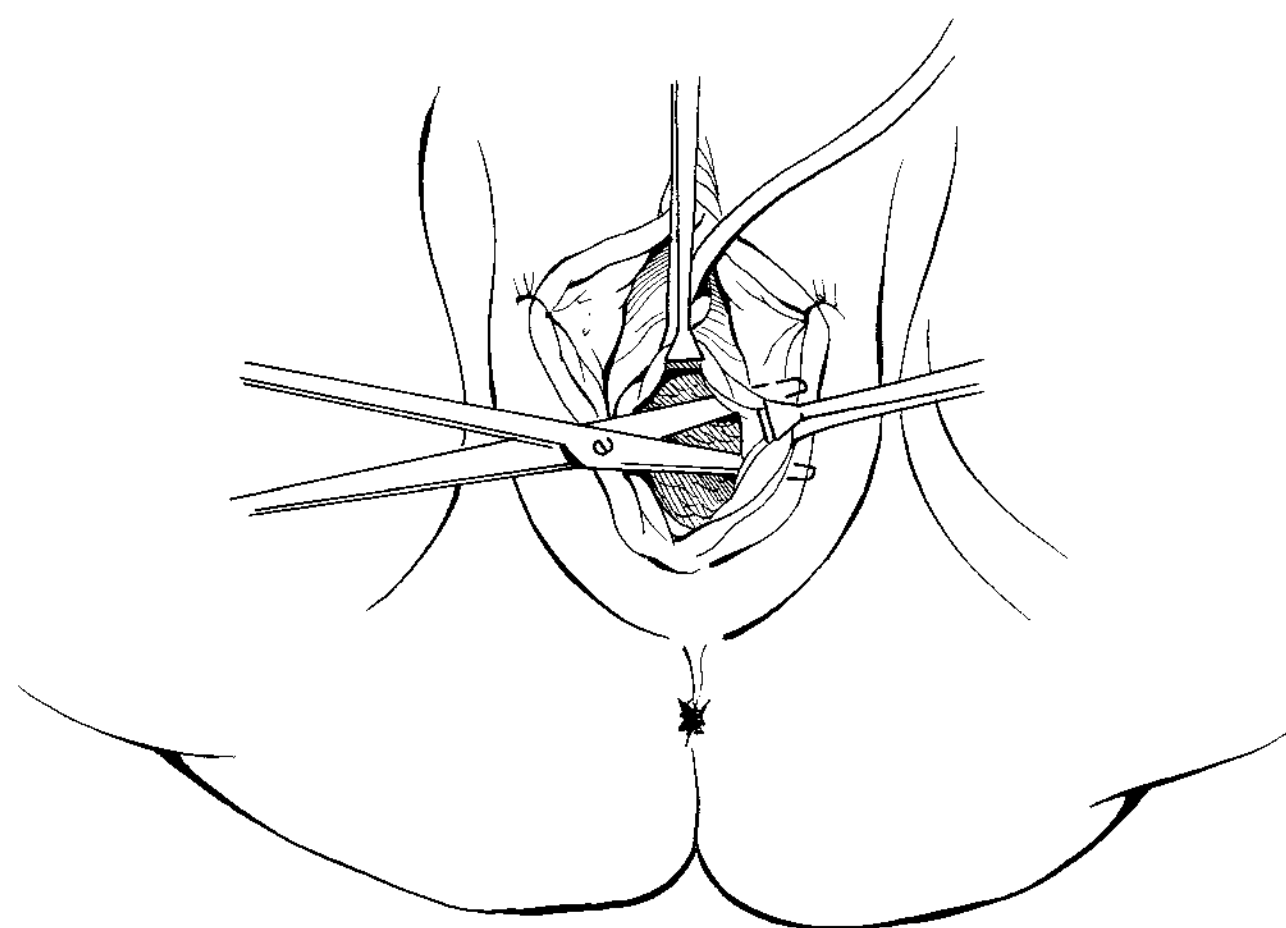

**FIGURE 40.2** Harvesting of the rectus abdominis fascial sling. The sling should be at least 8 to 10 cm long and 1.5 to 2.0 cm wide in the center. The sling ends are folded and then sutured with 1-0 absorbable sutures incorporating all of the fibers.

relatively scar-free area of fascia is selected for the sling, but even thickened and scarred fascia can be used with success. Using a scalpel, the fascia is incised 2 cm above the symphysis in the midline. With the Metzenbaum scissors, the incision is carried out laterally, parallel to the fibers. The superior leaf of the fascia is grasped with two Allis clamps and the underlying rectus muscles dissected off for a distance of 2 to 3 cm. The inferior leaf is then freed in a similar fashion. This aggressive mobilization will later allow a tension-free fascial closure. Next, the sling should be harvested from the inferior leaf. The upper leaf can alternatively be used if the tissue appears healthier or stronger. The sling should ideally be 8 to 10 cm long, 1.5 cm wide in the midline, and tapered to about 1 cm on either end (Fig. 40.2). The ends of the sling are tapered to facilitate its passage through the endopelvic fascia. Using 0-Vicryl or Prolene, both ends of the sling are then sutured 0.5 cm from the end of the sling. A figure-of-eight stitch is placed and then tied and cut, leaving 15 cm of free suture. Once the sling is harvested, it is placed in normal saline.

Attention should now be turned to the vaginal dissection. If necessary, the position of the patient's legs can be adjusted for better visualization. A weighted vaginal speculum is placed. Using the catheter as a reference, the urethrovesical junction is identified via palpation. To assist with hemostasis, the vaginal mucosa can then be injected with a dilute vasopressin solution (we prefer 10 U or 0.5 mL of vasopressin in 50 mL of normal saline). The mucosa inferolateral to the urethral meatus is grasped with two Allis clamps and traction placed superiorly for the entire vaginal part of the procedure. An inverted U incision is made in the vaginal epithelium at the level of the midurethra (1 to 2 cm proximal to the urethral meatus) using a scalpel. This flap is carefully dissected down to the level of the periurethral fascia using Church scissors and carried out laterally to the endopelvic fascia with the Metzenbaum scissors. Then, using blunt-tipped scissors, the retropubic space is entered by perforating the endopelvic fascia bilaterally using a careful "push and spread" technique (Fig. 40.3).

In the abdominal incision, the transverse fascia can be seen with medial retraction on the lateral border of the rectus muscle. It appears as a yellowish cleft where the rectus muscle

**FIGURE 40.3** The vaginal dissection is performed superficially to the white periurethral fascia. With the scissors parallel to the plane of the perineum and tips pointing superiorly and laterally, the retropubic space is entered and subsequently enlarged by further advancing the scissors 1 to 2 cm and then opening them.

inserts on the symphysis. The fascia is bluntly perforated, and a tunnel is created by hugging the posterior aspect of the pubic symphysis to avoid perforating the bladder. The blunt dissection continues distally to the level of the bladder neck (Fig. 40.4). If the patient has not had prior surgeries, this tissue plane is easily dissected. However, if the patient has had prior procedures (e.g., retropubic suspension, bone-anchored sling, or transobturator tape placement), Metzenbaum scissors may need to be used to develop the retropubic tunnels. In this instance, it is especially important to place the tips of the scissors only directly on the posterior pubis periosteum to avoid bladder or vascular injury. Also, scarring may necessitate starting the tunnel dissection between the two rectus

**FIGURE 40.4** Blunt finger dissection creates a tunnel to the rectus muscles above. Wide dissection is unnecessary and may cause significant bleeding or bladder injury.

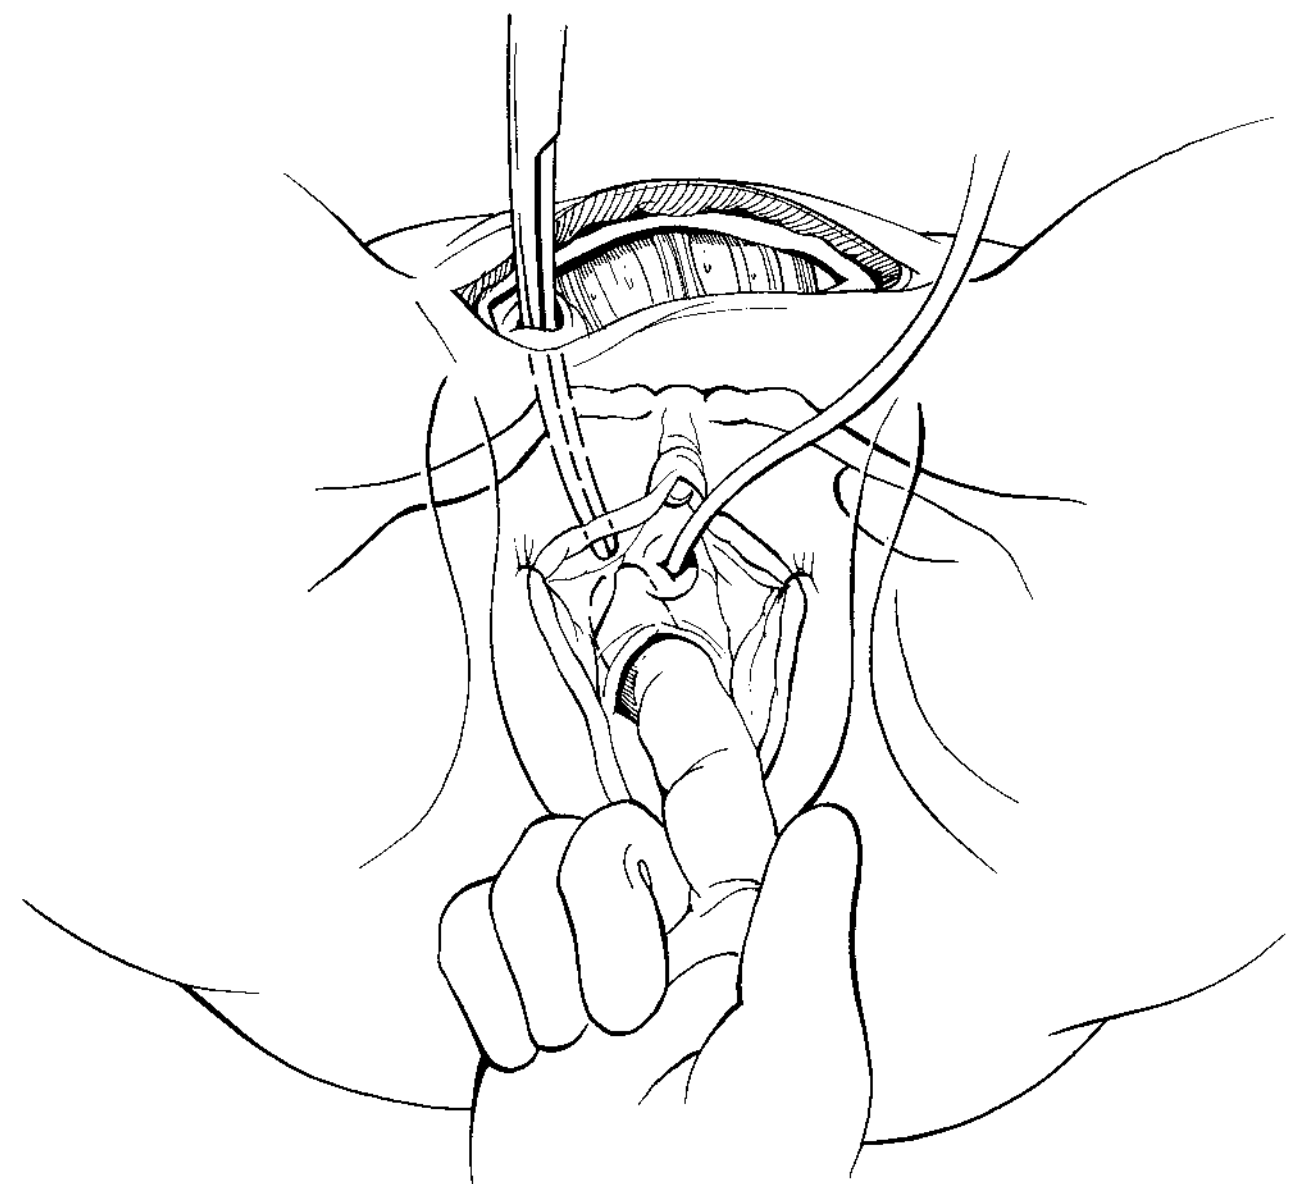

**FIGURE 40.5** The approach to the retropubic space from above is located below the rectus fascia and lateral to where the rectus muscles attach to the pubic symphysis. Minimal dissection in the area allows safe and easy access to the retropubic space previously dissected by the vaginal operator.

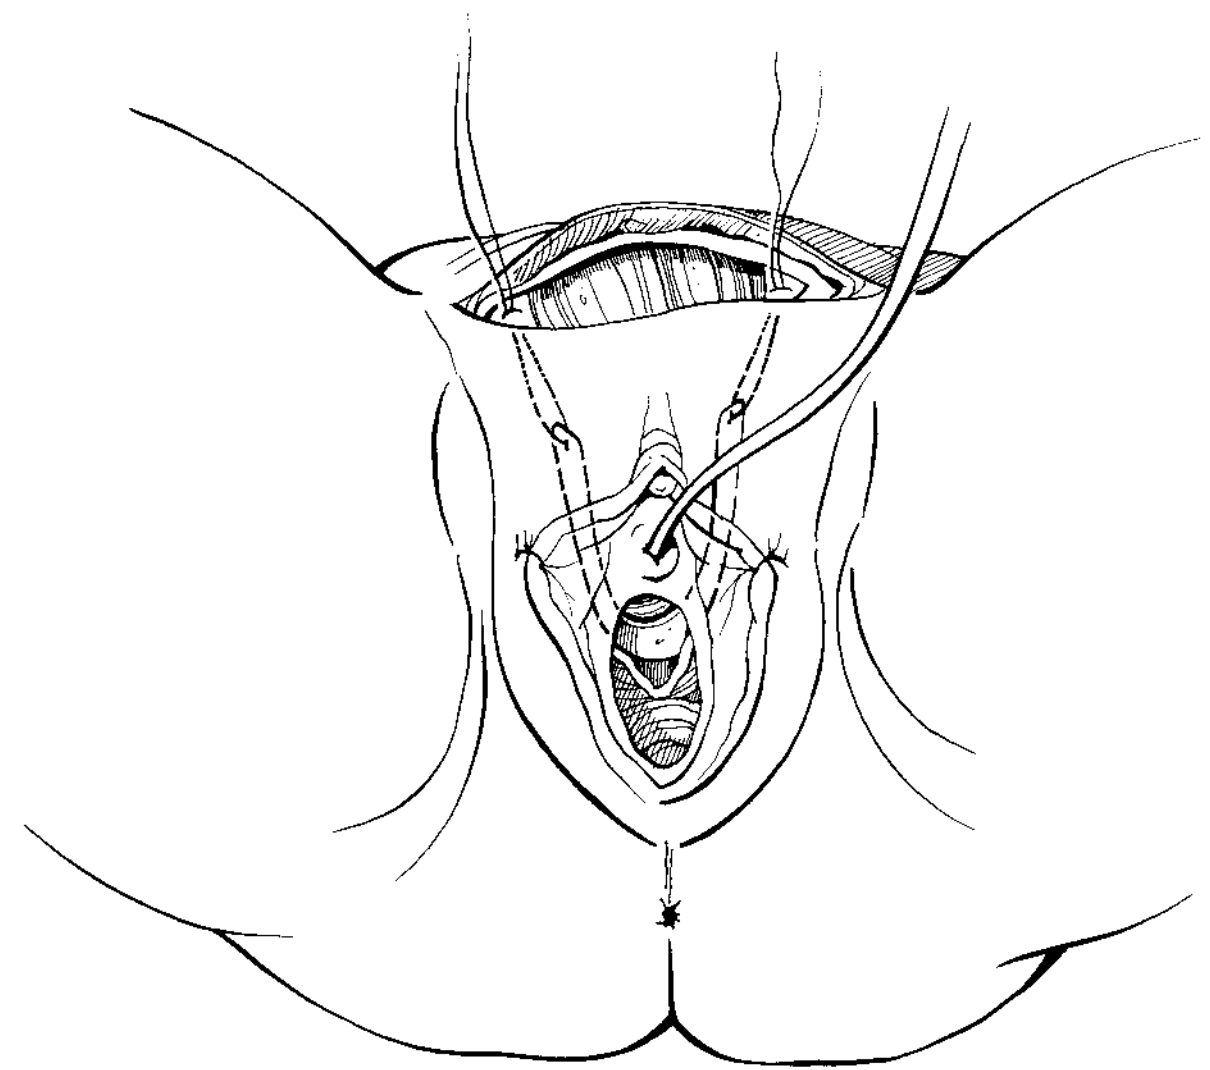

muscles (rather than lateral to them) before developing the retropubic space.

Ultimately, the bladder should be cleared from the created tunnels, and the tunnel should easily accommodate one finger. This step ensures that the sling will be easily advanced through the endopelvic fascia once it is placed and that the bladder will not be perforated with passage of the sling.

A long curved clamp such as the Crawford clamp or, in cases of scarring, the McGuire ligature passer, can be used to pass the sling through the created tunnels. The ligature can be passed either from “bottom to top” or “top to bottom.” Generally, we prefer to pass from “top to bottom” unless there is severe vaginal scarring. In order to accomplish this, the carrier is gently advanced into the created cleft lateral to the rectus from above until its leading flat portion is in contact with the symphysis (Fig. 40.5). Now with one hand above and one below in the vagina, it is advanced along the symphysis until its tip is palpable from the vaginal incision (Fig. 40.6). Then the carrier is advanced past the bladder into the vaginal incision over one’s finger. There are typically only a few millimeters of tissue that need to be perforated during this step. If more tissue is present, one has to be highly suspicious that the bladder has not been mobilized sufficiently and is at risk of perforation. The sling sutures on one end are loaded on the passer, which is then pulled back up into the abdominal incision and marked with a clamp. The same procedure is repeated on the opposite side. The sling is now in a position behind the proximal urethra with both suture ends in the suprapubic incision. After each pass of the ligature carrier, cystoscopy should be performed to ensure bladder integrity. The longevity of the sling does not depend on the sutures to hold tension (because they are absorbable); rather, it depends on the sling being well advanced into the retropubic space bilaterally. Thus, it is critical that a good portion of the sling extends into the retropubic space to allow proper fixation with healing (Fig. 40.7).

**FIGURE 40.6** Using manual guidance, a Crawford clamp is passed from above toward the vaginal incision with the tip of the clamp in contact with the pubic periosteum and the vaginal operator’s finger. After the passage of clamps bilaterally, cystoscopy is performed to ensure no injury to the bladder has occurred.

**FIGURE 40.7** The sling ends are pulled well into the retropubic space to allow good fixation. The sling is seated at the proximal urethra and sutured to the periurethral fascia using 3-0 absorbable sutures.

Next, the center of the sling is anchored to the midline periurethral tissues with a fine, absorbable suture. This is to prevent malpositioning of the sling with tensioning later. The vaginal epithelium is then closed with an absorbable suture in a running fashion to maintain hemostasis.

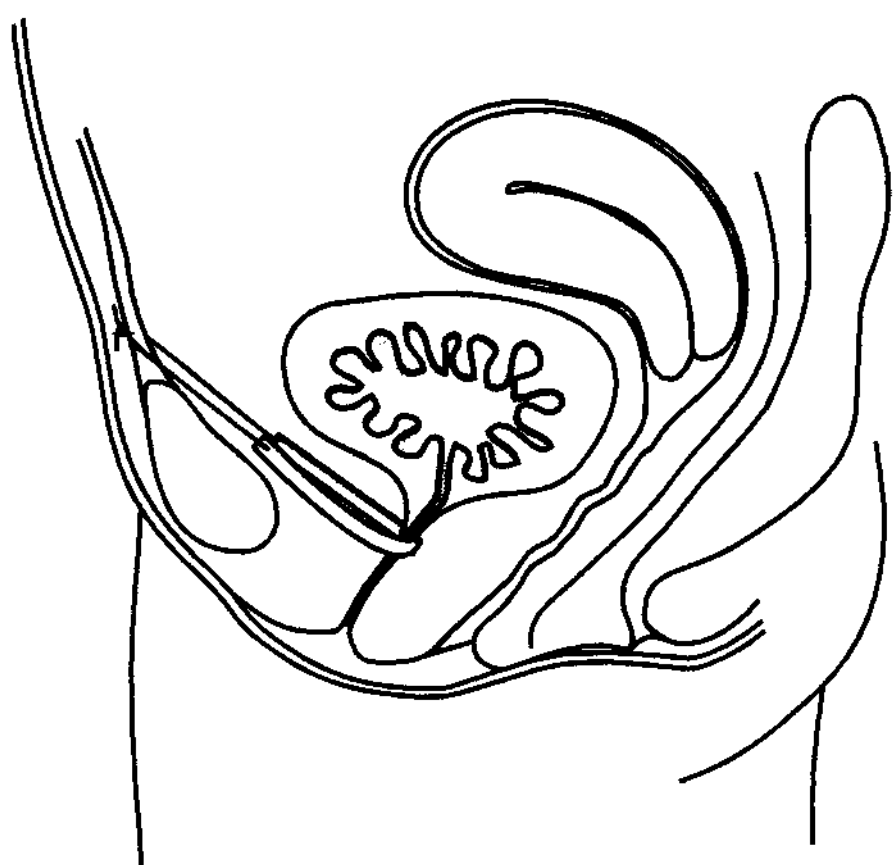

Tensioning the sling is the final abdominal portion of the procedure. Using a pointed-tip clamp like a Tonsil, two lateral perforations are made through the inferior leaf of the rectus fascia. The sling sutures are passed through these perforations and marked with clamps. The rectus fascia is then

**FIGURE 40.8** The sling sutures are passed through the rectus fascia before the fascia is closed. The vaginal mucosa is closed, the weighted speculum removed, and the sling sutures tied down over the rectus fascia under minimal tension.

closed using a running delayed absorbable suture (Fig. 40.8). The sling can then be tensioned. The appropriate tension is the minimum amount required to stop urethral motion. This can be judged by pulling on the transurethral catheter and ensuring that the bladder neck descends no  $>0.5$  to 1.0 cm. A shodded clamp can be used to hold tension on the crossed sutures until this appropriate tension is obtained (Fig. 40.9). The sutures are then tied down. Two fingers should be able to be passed under the sutures in the suprapubic incision. Finally, the skin is closed with an absorbable fine suture such as 4-0 Monocryl, and a vaginal pack is placed if needed.

The urethral catheter and any vaginal packing are removed the following morning, and patients are started on CIC. Once they are adept at self-catheterization, they are discharged home. Most patients are discharged on the first post-operative day since they were given instructions on CIC preoperatively.

**FIGURE 40.9** A lateral view of the completed pubovaginal sling procedure.

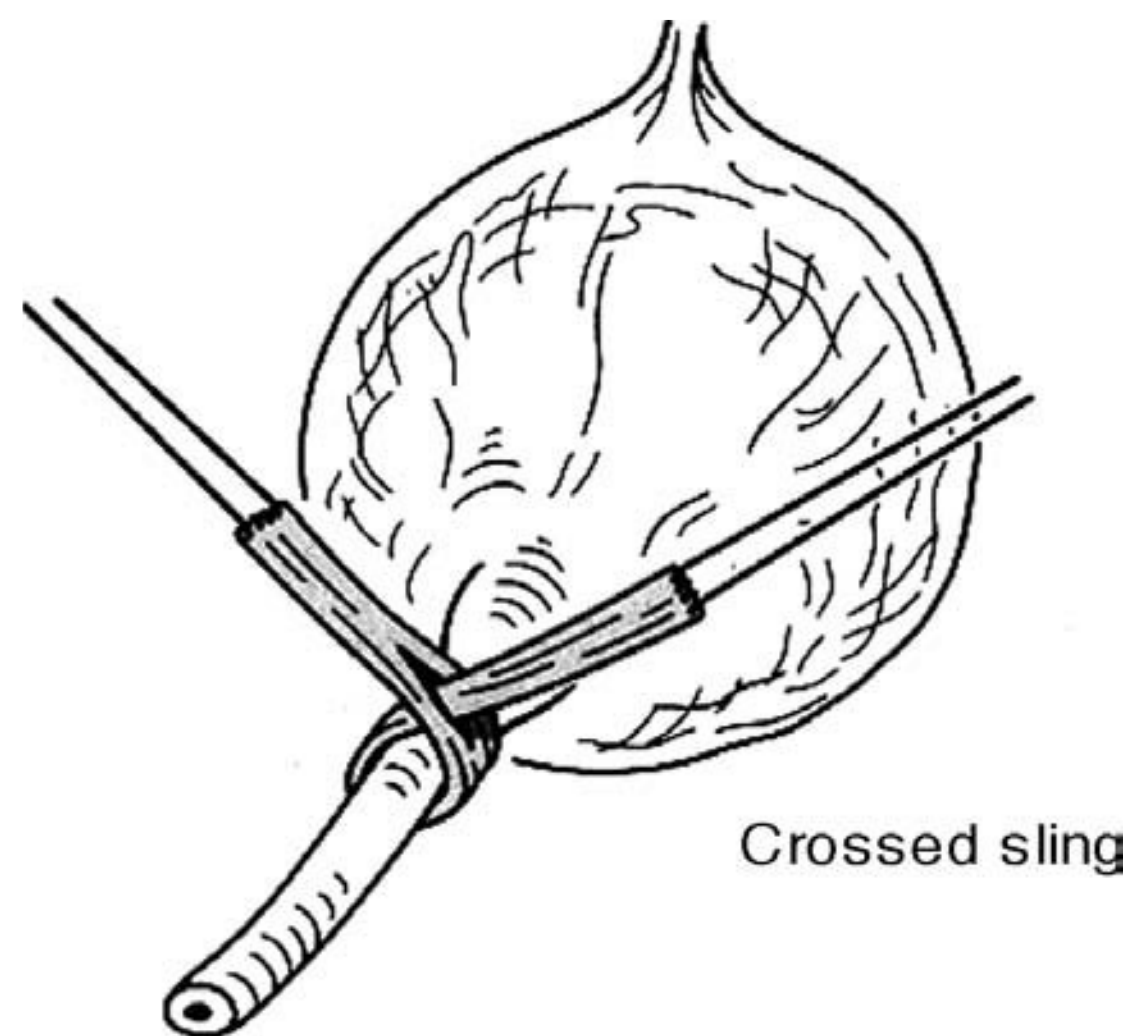

## Crossover Sling

In patients with a widely open bladder neck and proximal urethra, such as with myelomeningocele or with extremely low ALPP ( $<10$  cm H<sub>2</sub>O), more circumferential compression is required from the sling. To accomplish this, the sling can be “crossed over.” The sling is harvested longer than usual (10 to 14 cm). During retropubic dissection, not only are tunnels created, but the entire retropubic space is dissected to expose the anterior bladder and proximal urethra. The sling is passed in the usual fashion and fixed on the urethra through the vaginal incision, but before passing the sling sutures through the fascial perforations, they are crossed over, allowing the sling to surround the bladder neck rather than just suspending it. The sutures are tied as usual, but tensioning is more difficult to judge since the force is compressive (Fig. 40.10).

## Alternative Graft Material

When considering choices for sling graft materials, there is much debate in the literature. Some have advocated decreasing the potential morbidity of harvesting the sling by using allografts such as cadaveric fascia (11) or other synthetic materials. However, autologous fascia has been shown to have better surgical outcomes than any of these other materials. Several synthetic materials have been used as sling material for the PVS: woven polyester injected with collagen (ProteGen, recalled from market), polytetrafluoroethylene (Gore-Tex), silicone, and polypropylene. They have all been associated with significant complications like fistulas and urethral and vaginal erosions (12), and none are in common usage for PVS.

Recently, Howden et al. (13) compared cadaveric with autologous fascial slings in 303 women. They found that the group of women who underwent placement of cadaveric fascia had a higher rate of urinary incontinence (16 versus 5 per 100 woman-years,  $p = 0.0001$ ) and had greater reoperation rates (4 versus 1 per 100 woman-years,  $p < 0.0003$ ) than the group with autologous fascia. Several studies have also shown

**FIGURE 40.10** This crossed sling surrounds the urethra. It provides a more compressive force than a traditional sling. For ease of placement, a slit can be made in the center of the sling and the other end threaded through.

superior continence in the use of autologous fascia over the porcine xenograft Pevichol as a PVS (14). While autologous fascia remains the sling material of choice, Pevichol is a viable alternative when native fascia cannot be harvested due to poor quality. Autologous fascia lata is a good-quality alternative to rectus fascia (11), but its use is limited because it requires another incision.

---

## OUTCOMES

---

### Complications

---

#### Bladder Perforation and Hematoma

Bladder perforation is very rare during PVS, since the bladder is exposed during dissection. It has been reported to occur in only 0.6% of cases in two large series (3,15). This is much lower in comparison to other surgeries for SUI like the TVT (8.6%) (7) and the Burch (3%) (15). Bladder perforation occurs during passage of the ligature from above and is detected either by cystoscopy or by observing that the urine is bloody. The clamp should be repassed and its position verified by cystoscopy. A urethral catheter should be left in place for 7 to 10 days while on antibiotic prophylaxis and a voiding trial done upon removal. Pelvic hematoma can also occur in 0.8% (2) of cases, and these patients should be followed closely for superinfection.

#### Prolonged Urinary Retention

With autologous pubovaginal slings, all women will need to initially perform CIC for a period of approximately 2 weeks, with an average of 8.4 days (2). Thus, all patients should be given preoperative instructions about CIC technique and reassured that this is a common occurrence. However, the prolonged need for CIC for >6 weeks occurs in 2.0% to 13.5% of women (2,3,14) and requires surgical intervention in 2.5% to 6.3% (2,3,15). It is our practice to surgically intervene with vaginal midline sling incision at a maximum of 4 to 6 weeks, should spontaneous voiding not return. The goal of this procedure is not to remove the sling, but to simply divide it in the middle. It is a straightforward procedure with little morbidity, and surprisingly few patients have recurrence of their SUI. Thiel et al. (16) reported a case series with 11 patients who had their PVS cut at an average of 65 days after surgery. Even after 5 years of follow-up, 7 out of 11 patients had no incontinence episodes per day, and only 1 out of 11 had more than three episodes of incontinence daily, with all 11 patients voiding spontaneously.

### De Novo Urge Incontinence

Many patients have preexisting urge incontinence, and this should not preclude PVS placement, since as many as 74% to 77% (2,3) will actually have resolution of their urge incontinence along with their stress incontinence. De novo, or new-onset, urge incontinence will occur in 3% to 7% (2,3,15) of patients. One needs to ensure that bladder outlet obstruction is not present, since the symptoms of these two conditions often overlap. They can be differentiated with a careful history, physical examination, postvoid residual, and often urodynamic examination. For de novo urge incontinence or overactive bladder symptoms that persist in the postoperative period, anticholinergic medications are helpful and often can be discontinued after 3 months (1). If patients do have actual obstruction, they require midline sling incision.

#### Erosion

Erosion of sling material into the urethra or vagina is a difficult complication to treat, especially with synthetic materials. Although not impossible, the occurrence of autologous PVS has been reported in a few series, but the rate is estimated to be as low as 0.007% (12).

---

## Results

---

In 1998, Chaikin et al. (3) found that 92% of 251 women with Type II or Type III SUI who underwent placement of a pubovaginal sling had cure or improvement of their incontinence at a follow-up of 3 years with durable results at ten years. Similarly, Morgan et al. (2) reported continence rates of 88% at 4 years in 247 patients after sling placement. Of this cohort, 92% reported that they were “highly satisfied” with their outcomes on a quality-of-life assessment. A randomized controlled trial involving 520 women by the Urinary Incontinence Treatment Network (15) compared the PVS to the Burch colposuspension and at 2 years found the PVS to be superior in the treatment of SUI.

---

## CONCLUSION

---

The autologous pubovaginal sling is a durable and highly successful treatment for SUI. It is more invasive than the TVT or TOT, but it is the most appropriate treatment for SUI in certain specific instances like severe ISD or if the risk of erosion is high. The PVS should be included in the armamentarium of any surgeon treating SUI.

## CHAPTER 41 ■ SYNTHETIC MIDURETHRAL RETROPUBIC SLINGS

BHAVIN N. PATEL AND GOPAL H. BADLANI

The past decade has seen a shift from suspension procedures to sling procedures as the treatment of choice for stress urinary incontinence (SUI). The bladder neck and proximal urethra were considered zones for continence procedures in patients with SUI. Traditionally, a sling at the bladder neck, using fascia, was reserved for failed suspension or severe cases of intrinsic sphincteric deficiency (ISD).

The integral theory, proposed by Petros and Ulmsten, advanced the concept of midurethral support for a hypermobile urethra and anterior vaginal wall (1). The tension-free synthetic tape replaces and recreates the midurethral ligaments, which results in kinking or coaptation of the urethra with increase in the intra-abdominal pressure but has little or no effect on detrusor-initiated voiding or incontinence.

### DIAGNOSIS

Patients with SUI present with the complaint of involuntary urinary loss with increased intra-abdominal pressures, as in coughing, laughing, or during Valsalva. The diagnosis can be made based on history and physical examination and quantified with a pad test. Attention should be paid to any associated prolapse, symptoms of overactive bladder (OAB), urge incontinence (UI), or significant postvoid residual urine. The utility of urodynamic testing is debatable in the diagnosis of primary SUI; however, it is helpful in cases that are not as straightforward and in cases complicated by the aforementioned pathologies, and it is required in recurrent SUI after failed surgery.

In patients with associated vaginal prolapse, the SUI may be occult and become evident only with the reduction of the prolapse. Patients with OAB and/or UI with SUI should be counseled regarding the fact that their OAB or UI may not improve with a midurethral sling. Finally, patients with postvoid residual urine, depending upon its etiology, should be coun-

seled regarding an increased risk of urinary retention after a midurethral sling.

### INDICATIONS FOR SURGERY

Those patients with SUI and a moderate to severe bother on the quality-of-life (QOL) score who fail or cannot tolerate nonsurgical modes of management should be considered for surgical correction. Patients with urethral hypermobility (indicated by  $>30$ -degree deflection on office Q-tip test), no significant prolapse, and mild to moderate intrinsic sphincteric deficiency (leak point pressures  $>60$  cm H<sub>2</sub>O) are ideal candidates for midurethral synthetic slings. Patients with ISD, lack of hypermobility, and leak point pressure (LPP)  $<60$  cm H<sub>2</sub>O are candidates for bladder neck sling.

Prior anterior vaginal wall surgery, age over 70, obesity, and prior failed sling are not contraindications to midurethral slings but require a higher degree of skill and prior experience with vaginal surgery. Studies have demonstrated no overall difference in outcome when procedures such as vaginal hysterectomy or vault suspension are performed in conjunction with a midurethral sling (2). Severe ISD at rest with or without hypermobility, previous urethral surgery or injury, urethral diverticulum, pelvic radiation, poor vaginal epithelium, pipe-stem urethra, and hypersensitivity to the synthetic materials are contraindications to midurethral synthetic slings.

### ALTERNATIVE THERAPIES

Nonsurgical alternative therapies to the midurethral sling include limited fluid intake, bladder training, timed voiding, Kegel exercises, pessaries, and medical therapy, including alpha-adrenergic drugs and off-label use of imipramine and

duloxetine. The use of hormone replacement therapy is controversial. The use of pads and in rare cases an indwelling catheter to deal with SUI is to be discouraged. Nonsurgical management is only efficacious in mild SUI and often does not provide adequate relief in moderate or severe SUI. Surgical alternatives include injectable bulking agents, open or laparoscopic Burch procedure, bladder neck sling, transobturator sling (TOT), and the recently introduced minisling and prepubic sling.

Injectable bulking agents work by increasing urethral resistance and are indicated in patients with ISD and a fixed (not hypermobile) urethra. There are a variety of techniques and injectable materials, each of which has a material-specific success rate that decreases as time from injection increases. They require reinjection, and complications may include sterile abscess formation, irritative voiding symptoms, pelvic pain, ectopic calcifications, and transient urinary retention.

Open Burch and midurethral sling in a randomized trial showed an equal efficacy in a short-term follow-up with decreased morbidity with the midurethral sling (3).

Bladder neck sling is indicated in patients with ISD with or without urethral hypermobility and SUI manifested by lower urethral closure pressures. The material used in the suspension varies per the surgeon's preference. To minimize the morbidity of the traditional fascial sling, synthetic and other biomaterials can be used; success with these materials has been reported (4).

Transobturator suburethral support was developed in an effort to decrease the risk of injury to adjacent structures such as large vessels, bowel, and the bladder. Its indications are the same as those for the midurethral sling described above. Compared with the midurethral sling, TOT required less operative time (5) and had similar rates of success, but it was associated with a higher rate of groin or thigh pain, vaginal injuries, and tape erosion (6).

There is limited peer-reviewed information on the use of minislings or prepubic slings.

---

## CHOICE OF MATERIAL

---

The choice of sling material is a key component of midurethral sling surgery. The materials used for the slings are divided into the following categories: autologous fascia, cadaveric allograft, xenograft, and synthetics. Rectus fascia and fascia lata have been harvested for SUI surgery. The advantages of using autologous fascia are its durability, its availability, and its nonimmunogenic quality. However, difficulty in procurement, longer operative times, increased patient morbidity, and late sling contraction limit its use today. Cadaveric allograft and xenograft tissues have also been used because they are readily available and do not require procurement from the patient. On the other hand, their costs, theoretical risk of infectious transfer, mechanical variability, and unpredictable outcome have limited their use. In our practice we reserve cadaveric allograft and xenograft to cases where synthetic mesh is contraindicated.

Synthetic meshes are readily available and highly durable, maintain their strength over time, are free of potential pathogens, and are less expensive. A variety of synthetic materials are available; the current standard is a monofilament, large-pore, soft mesh made out of polypropylene. This mesh has lower rates of erosion when compared to multifilament (Mersilene). Pore size is pivotal in allowing incorporation of host fibroblasts, macrophages, and leukocytes. Stiffness is an important factor

too, as stiffer slings are more prone to erosion. Additionally, our research shows a biochemical defect in patients with SUI and prolapse resulting in a faster rate of breakdown of collagen and elastin, supporting the use of synthetic mesh (7).

---

## SURGICAL TECHNIQUE

---

An informed consent is obtained, informing the patient of expected outcomes and possible complications such as retention, de novo or persistent OAB, adjacent organ injury, recurrence of incontinence, risk of developing prolapse, erosion, and exposure of mesh, in addition to the standard surgical and anesthetic risks.

Aspirin and other anticoagulants are discontinued 5 to 7 days preoperatively. A fluoroquinolone is started 48 hours prior to surgery, and the patient receives routine preanesthetic instructions for the night preceding the surgery. No food or liquid is allowed 8 to 10 hours prior to the procedure, laxatives are prescribed for patients who suffer from constipation, and preoperative labs including complete blood count, serum electrolytes, coagulation studies, urinalysis, and urine culture are obtained. The procedure should be postponed in the presence of active urinary tract infection or coagulopathy.

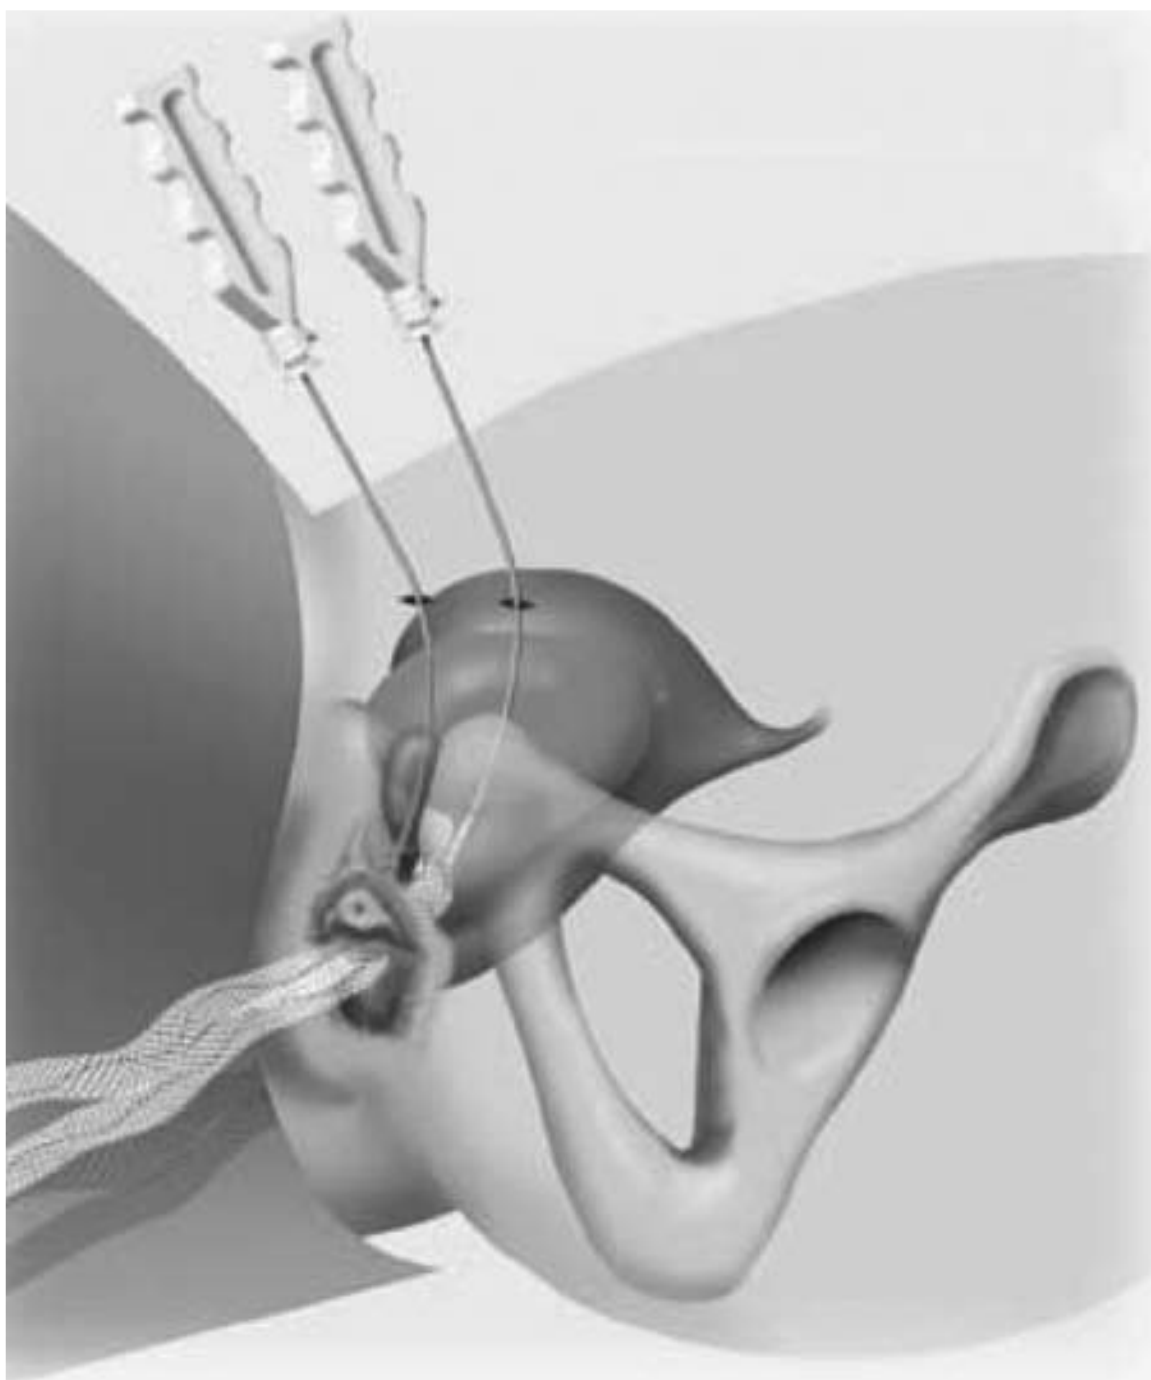

On the day of surgery, a parenteral antibiotic, such as a first-generation cephalosporin or a fluoroquinolone, is administered and continued for 24 hours. The choice of local anesthesia with sedation, spinal block, or general anesthesia depends on the surgeon, anesthesiologist, and patient preferences. Sequential compression devices are used on the lower extremities prior to the induction of anesthesia. The procedure is performed in the dorsal lithotomy position using Allen stirrups. The lower abdominal and pubic areas are shaved, prepared, and draped using a Lingeman Gyn surgery drape (Microtek Medical, Isolyser Healthcare, Columbus, MS).

To retract the labia, a Lone Star surgical retractor (Medical Products Inc, Houston, TX) is used. Alternatively, the labia can be sutured laterally. Weighted vaginal speculums can be used to better expose the anterior vaginal wall during dissection, but they should be removed before tensioning the sling. A 20Fr urethral catheter is placed, the bladder is drained, and the balloon is palpated at the bladder neck.

An Allis clamp is placed at the bladder neck and 1 cm proximal to the urethral meatus. Injectable Marcaine, 5 mL, is infiltrated into the anterior vaginal wall, along the midline between the two Allis clamps, to facilitate the dissection. A 2-cm midline incision is made between the urethral meatus and the bladder neck to avoid injury to the somatic and autonomic neurons that travel laterally through the anterior vaginal wall to the urethra and supply the urethral sphincter.

With Metzenbaum scissors, flaps of the anterior vaginal wall are developed bilaterally, aiming toward the ipsilateral shoulder. Traction is applied on the vaginal wall with Allis clamps to facilitate flap dissection, avoiding too much traction, which may tear the flap. Minimal bleeding is noted if the correct depth of dissection is reached.

For the suprapubic arch (SPARC) sling kit (American Medical Systems), 1% lidocaine is injected at the skin on the superior portion of the symphysis, 2.5 cm lateral to the midline. Small stab incisions are made at the areas of infiltration with a no. 15 blade knife. At this point, the bladder is once again emptied to avoid injury, and the needle is passed with

**FIGURE 41.1** Placement of the suprapubic arch (SPARC) needles.

the dominant hand through the suprapubic incision behind the pubic bone. The needle is advanced toward the ipsilateral vaginal dissection, guided by contact with the posterior aspect of the bone. The needle handle is displaced posteromedially as the tip advances further through the space of Retzius.

At this point the nondominant hand should be placed along the ipsilateral vaginal dissection plane, and the needle tip should be palpated. The needle is then advanced out of the vaginal wound. This method of needle placement minimizes the risk of injuring adjacent large vessels and nerves but not the bladder or the urethra. The needle placement is then repeated on the contralateral side (Fig. 41.1). The urethral catheter is removed and cystoscopy is performed to assess for bladder injury. Injury to the bladder most commonly occurs along the superolateral aspects of the bladder. Blood seen on entering the bladder, visualization of the needle, or bladder submucosal movement with motion of the needle are all indicators of bladder injury. If bladder injury has occurred, the ipsilateral needle should be removed and repositioned once the bladder has been drained. Also, catheter drainage postoperatively for additional days is indicated. A key step here is to drain the bladder before removing the cystoscope, as the connector width is larger than the needle, resulting in possible shearing injury of the bladder wall if it is full. The sling, covered in a protective plastic sheath, is locked onto the needles with the sling indicator positioned in the midline at the midurethra. Once secured, the needles with attached sling are brought back out through the suprapubic stab incisions (Fig. 41.2).

### Tension-Free Vaginal Tape (Gynecare)

The procedure for tension-free vaginal tape (TVT) follows the same vaginal dissection as described above, for the placement of the SPARC sling. At this point, a solution of normal saline and

**FIGURE 41.2** Anatomic lie of the midurethral sling.

local anesthetic is injected suprapubically at the lateral aspects of the pubic symphysis toward the ipsilateral vaginal dissection to aid in sling placement. The tip of the Foley catheter with a catheter guide is placed on contralateral traction to avoid injury to the bladder. The TVT needle is placed in the vaginal incision and aimed toward the ipsilateral scapula. The needle is advanced along the posterior aspect of the pubic bone and then brought to the skin at the lateral aspect of the symphysis, and a stab incision is made to deliver the needle through the skin. The needle placement is repeated on the contralateral side. A key step is to avoid lateral rotation of the needle and avoid proximal passage away from the bone. Cystoscopy is performed to identify bladder injury. Extra care is needed if the patient has had an open or laparoscopic procedure in the pelvis, as bowel may be adherent to the retropubic space.

The sling should be examined to ensure that no twisting has occurred. The sling is then adjusted until the appropriate tension has been achieved, avoiding too much or too little tension. This is often done by ensuring that a 22Fr cystoscopic sheath passes freely through the urethra or by placing a pair of clamps between the tape and the midurethra as the sling is adjusted. Once positioning is satisfactory, the plastic covering is cut and removed, redundant sling at the suprapubic incision is excised, and the suprapubic wounds are closed with Dermabond and the vaginal wound closed with 2-0 Vicryl suture.

At the end of the case, a Foley catheter is placed as well as a Betadine-soaked vaginal pack. Patients are then discharged with or without the Foley or kept in observation overnight, depending on surgeon preference. At discharge patients are given a 5-day course of antibiotics, pain medications, and stool softeners. They are also told to abstain from sexual activity for 4 to 6 weeks. Trial of voiding can be initiated in the recovery room if the patient has had a local anesthesia. We prefer overnight use of a Foley catheter if general or spinal anesthesia was used.

## OUTCOMES

There is good initial and durable success in treating SUI with midurethral sling compared to the standard Burch colposuspension (3). A recent prospective randomized study showed no difference in outcome between TVT (95%) and SPARC (83%) (8). These findings have been confirmed by

other studies. Further comparison has shown no difference in the cure rate of SUI with TVT (95%), SPARC (90%), or TOT (94%) (8).

---

## COMPLICATIONS

---

### Perioperative Complications

Intraoperative complications are mostly related to the dissection and placement of the trocar. There have been four FDA-reported deaths due to TVTs, two associated with bowel injury, and two associated with vascular injury. During the procedure there is a risk of bleeding, infection, and injury to the bladder, urethra, ureter, bowel, vessels, and nerves. One thousand cases of TVT in Finland were reviewed (10), and the incidence of bladder injury, the most common complication during needle placement, was reported as 3.8%. The risk of postoperative bleeding was 1.9%, and that of wound infection was <1%. Mortality associated with injury to vessels has been reported but is exceedingly rare and has been mentioned previously. A key point is awareness, immediate recognition, and management of the complication.

### Postoperative Complications

Postoperative complications include outflow obstruction, de novo or persistent OAB, extrusion, and erosion. Urinary obstruction after a midurethral sling can be brief and transient or persistent. Transient postoperative obstruction is often due to edema of the urethra and the supporting structures along with pelvic pain. As the edema and pain subside, so does the obstruction. However, patients can have persistent urinary obstruction due to a combination of previously undiagnosed prolapse and/or a “tight” sling. They often present with urgency, frequency, decreased force of stream, positional voiding, and/or retention. Treatment includes anticholinergic medication with monitoring of PVR, use of CIC or consideration of sling loosening, incision, or uretholysis with or without sling revision. A recent multicenter trial of an adjustable sling is being evaluated. The cost of such a sling is considerably higher and not supported by the low rate of retention with tension-free slings.

Persistent incontinence can occur after midurethral sling. The cause, whether it is persistence of SUI, urgency- or OAB-related, urge-related, or rarely iatrogenic fistula, must be determined.

**FIGURE 41.3** Vaginal extrusion of midurethral tape.

Vaginal extrusion (Fig. 41.3) of the tape usually occurs within 6 months of the initial surgery. Patients often present with vaginal discharge, dyspareunia, and feeling the tape material within the vagina. The treatment of the extrusion varies according to the degree of erosion and the patient's symptomatology, but it can include partial or complete removal of the tape and closure of the vaginal mucosa over the extrusion.

Urethral or bladder erosion can occur at any time in the postoperative course but often occurs in the first 6 months after surgery. Most patients present with recurrent SUI, hematuria, perineal pain, urinary tract infections, and/or irritative voiding symptoms. The treatment of erosion involves removal of the intraviscous sling. This can be achieved endoscopically in the urethra or laparoscopically in the bladder. A vaginal approach can result in a fistula formation and recurrence of incontinence. Thus, for a bladder erosion we prefer removing the intravesical portion with either a laparoscopic or open approach without disturbing the suburethral portion.

---

## CONCLUSIONS

---

The midurethral sling has revolutionized the approach to SUI. It allows many patients to improve their quality of life with minimal morbidity. The success depends on proper case selection and patient education.

# CHAPTER 42 ■ THE TRANSOBTURATOR APPROACH TO THE MIDURETHRAL SLING

PAUL HANISSIAN AND JAMES WHITESIDE

There has been significant innovation in the treatment of urinary incontinence over the last 15 years. In the early 1990s there was growing understanding that needle urethropexies did not have long-term efficacy compared to retropubic urethropexies and pubovaginal slings. The morbidity of these latter procedures, however, set the stage for the development of a minimally invasive approach. The tension-free vaginal tape (TVT) procedure was the first minimally invasive midurethral sling that came into use in the late 1990s. Developed by the late Ulf Ulmstem, the TVT placed a polypropylene mesh suburethrally with the use of curved needles passed transvaginally through the retropubic space and out through cutaneous abdominal incisions (1). Unlike its pubovaginal sling predecessors, the TVT mesh was not fixed to bone or fascia. The TVT mesh maintains its position through friction with the surrounding tissue and ultimately through fibroblast ingrowth into the mesh. Though clinical trials ultimately showed this procedure to have similar efficacy to more traditional approaches (e.g., Burch urethropexy [2]), rare complications such as life-threatening bowel and major vascular injury along with the requirement of cystoscopy inspired improvements in this technique.

In 2001 Delorme (3) published “Transobturator Urethral Suspension: Mini-invasive Procedure in the Treatment of Stress Urinary Incontinence in Women,” introducing the transobturator approach for the placement of a midurethral sling. Using a two-dimensional Emmet needle, a polypropylene mesh was passed through thigh muscles, around the ischiopubic ramus, and into a vaginal epithelial tunnel for placement at the midurethra. This approach dramatically reduced the possibility of an intra-abdominal injury. While two approaches have evolved in the placement of the mesh (inside-out [e.g., TVT-O, Gynecare] versus outside-in [e.g., Monarc, American Medical Systems]), the transobturator procedure is relatively simple to learn and can be accomplished with minimal anesthesia in an awake patient. Controlled randomized studies have documented the safety and efficacy of the transobturator approach compared to retropubic midurethral slings (4).

---

## DIAGNOSIS

---

A thorough understanding of urinary incontinence is important before implementing therapy. Urinary incontinence as defined by the International Continence Society can be a symptom, sign, or condition. It is the condition of stress incontinence that is appropriate for surgical treatment, and a distinction needs to be drawn between stress incontinence and

other types of urinary incontinence, including urge incontinence. The symptom of stress urinary leakage can alone be misleading; hence it is imperative to document the sign of stress urinary leakage before performing surgery. It is also worthwhile to understand the patient’s fluid intake volume and output (i.e., bladder diary) before surgery to support the patient’s perceptions of leakage and exclude other incontinence etiologies.

There is disagreement regarding the optimal preoperative testing for urinary incontinence among women. At initial evaluation, the patient should provide a urine specimen for dipstick analysis, and then urine microscopy and culture can be done as necessary. Postvoid residual volumes should be determined to assess the possibility of disordered bladder sensation or detrusor pathology leading to retention. Documentation of stress urine leakage should be done; this could include multichannel urodynamic studies or could be done with a standardized cough stress test. A cough stress test involves filling the bladder to 300 mL or to subjective fullness and then having the patient forcefully cough while in an upright position. Witness of gross urine loss from the urethral meatus during coughing is considered a positive test. The necessity of multichannel urodynamic testing is unclear, particularly in the low-risk patient, if the sign of stress urinary leakage is documented by some alternative means and the postvoid residual volumes are normal. Multichannel urodynamic testing could render insight into voiding and urethral competency issues. The reliability and value of this insight are a matter of debate. Ideally, the patient should not have urge incontinence or voiding dysfunction. Patients with mixed urinary incontinence may be appropriate candidates for a transobturator midurethral sling if their stress symptoms outweigh their urge symptoms and they recognize what the surgery could do to their incontinence problems. Urge incontinence can be exacerbated or occur de novo following surgical treatment of stress incontinence, although it is also possible that urge leakage improves following sling surgery. Information gleaned from the bladder diary can clarify ambiguous mixed urinary incontinence symptoms.

Vaginal examination and assessment for pelvic organ prolapse are essential. It has been long recognized that patients with pelvic organ prolapse (particularly anterior vaginal wall prolapse) can become newly incontinent of urine with reduction of the prolapse (occult urinary incontinence). A corollary to this recognition is that if an incontinence procedure alone is done in a woman with Stage III or IV prolapse that is not concurrently treated, postoperative urinary retention or voiding dysfunction can ensue. In addition, placement of a transobturator midurethral sling carries a higher risk of bladder injury without reduction of the prolapse at the time of insertion. The

question of whether and how the prolapse should be corrected and the nuances of simultaneous continence surgery are beyond the scope of this chapter.

---

## INDICATIONS

---

Transobturator midurethral slings are indicated for urinary incontinence that by both symptom and sign is consistent with urethral incompetence and where placement of the sling could not be expected to compromise voiding (e.g., pelvic organ prolapse, diabetes, neuropathy). Stress-associated urine leakage occurs when urethral pressure is exceeded by transmitted bladder pressure. The reasons this may occur are not well understood, despite years of definitions and debate. Historically, when selecting the appropriate surgical procedure for treatment of stress incontinence, it has been considered important to distinguish between incontinence related to hypermobility of the bladder neck and incontinence related to a urethral sphincter that cannot maintain a watertight seal even at rest (e.g., intrinsic sphincter deficiency, ISD). This dichotomy, from a pathophysiologic view, could be distilled into support versus sphincter problems. In the case of a hypermobile urethra, inadequate pelvic floor support allows the urethra to escape transmitted abdominal pressure to the urethra. In the case of ISD, the urethra is fixed and theoretically does benefit from transmitted abdominal pressures, but this cannot compensate for whatever issues led to a nonfunctioning sphincteric mechanism. The dichotomy, while appealing on theoretical grounds, finds little experimental support. Although it is true that lower abdominal pressures are required to induce leakage in women whose incontinence is more subjectively severe, this relationship is fuzzy at best, and it must be accepted that the treatment outcomes among subjectively severe incontinent women will likely be less ideal than among women with subjectively less severe incontinence. This relationship is not necessarily offset by information gleaned from measurements of urethral competence (e.g., urethral pressure profilometry or leak point pressures). Indeed, the outcomes of transobturator midurethral slings appear to be independent of leak point pressures, allowing us to leave this quandary for the laboratory.

---

## ALTERNATIVE THERAPY

---

Though the most common treatments for stress incontinence are surgical, a number of nonsurgical alternatives are available for women who either do not desire surgery or who are not good surgical candidates. These approaches include behavioral techniques, medications, urethral inserts and occlusive devices, and vaginal pessaries. It would not be uncommon for more difficult cases of urinary incontinence to require more than one treatment to achieve a satisfactory outcome. Nonsurgical and nonsling surgical options (e.g., Burch urethropexy) for female urinary incontinence are beyond the scope of this chapter.

The transobturator approach to placement of a midurethral sling represents a second-generation concept based on the TVT that was popularized in the mid 1990s. Retropubic midurethral procedures continue to be popular and enjoy considerable supportive evidence. Most recently, single-incision midurethral

slings (TVT-SECUR, Gynecare; MiniArc, American Medical Systems) have been introduced with claims of better safety and the possibility of office placement. These third-generation midurethral slings differ in that they are inserted through a midline suburethral vaginal incision, traverse the periurethral tissue, and are anchored in some fashion retropubically or behind the ischiopubic ramus. To date, there are no long-term efficacy and safety data for these products. Prior to 1995, traditional pubovaginal slings and retropubic procedures (e.g., Burch, Marshall-Marchetti-Krantz) were the mainstay of surgical treatment of female stress urinary incontinence. These procedures continue to be viable options; however, they are mostly reserved for patients who will otherwise need laparotomy. It is worth noting that in the SISTEr trial traditional pubovaginal slings were found to be more successful in correcting female urinary incontinence but at the price of greater morbidity relative to the Burch colposuspension (5).

---

## SURGICAL TECHNIQUE

---

In placement of a midurethral sling, the technical goal is to position the sling material through the obturator foramen and beneath the midurethra with as little trauma as possible (Fig. 42.1). Using one of the commercially available kits, a transobturator suburethral mesh is placed through three incisions: a 1- to 2-cm midline suburethral vaginal incision, and two smaller groin incisions. Device needles are passed either toward or away from the urethra, depending on the manufacturer. Table 42.1 lists various products on the market. Irrespective of the direction of passage, the needles will traverse skin; subcutaneous fat; the gracilis, adductor brevis, and obturator externus muscles; the obturator membrane; the obturator internus muscle; and the periurethral endopelvic fascia (6). Although there are differences in the type of mesh offered by the various manufacturers, there are few controlled studies comparing them. Most available mesh used in this application today are macroporous polypropylene.

Anesthesia for the procedure can be delivered by local block with sedation, by spinal block, or by general anesthesia. The patient should be administered preoperative antibiotics based on their utility in vaginal surgery; however, there is no evidence to support soaking the mesh in antibiotic solution or giving antibiotics postoperatively. Following adequate anesthesia, the

patient is positioned in a neurologically neutral lithotomy position using padded stirrups. A Foley catheter is inserted and the position of the midurethra determined as the midpoint between the palpable Foley bulb at the bladder neck and the urethral meatus. A weighted speculum is inserted for exposure of the anterior vaginal wall. Next, 10 to 20 cc of a vasoactive solution (1% lidocaine with 1:200,000 epinephrine or vasopressin, 20 U diluted in 100 cc of sterile saline) is injected in the subepithelial vagina before making a 1.5- to 2.0-cm vertical vaginal incision at the midurethra. The injection is also carried laterally toward the vaginal sulcus medial to the ischiopubic ramus bilaterally. Ideally, the operator will see blunting of this vaginal crease as the injected epithelium expands outward (Fig. 42.2). Applying this technique may help the surgeon avoid “buttonholing” the vagina while passing the helical needles. Allis clamps are useful for grasping the vaginal epithelium for exposure.

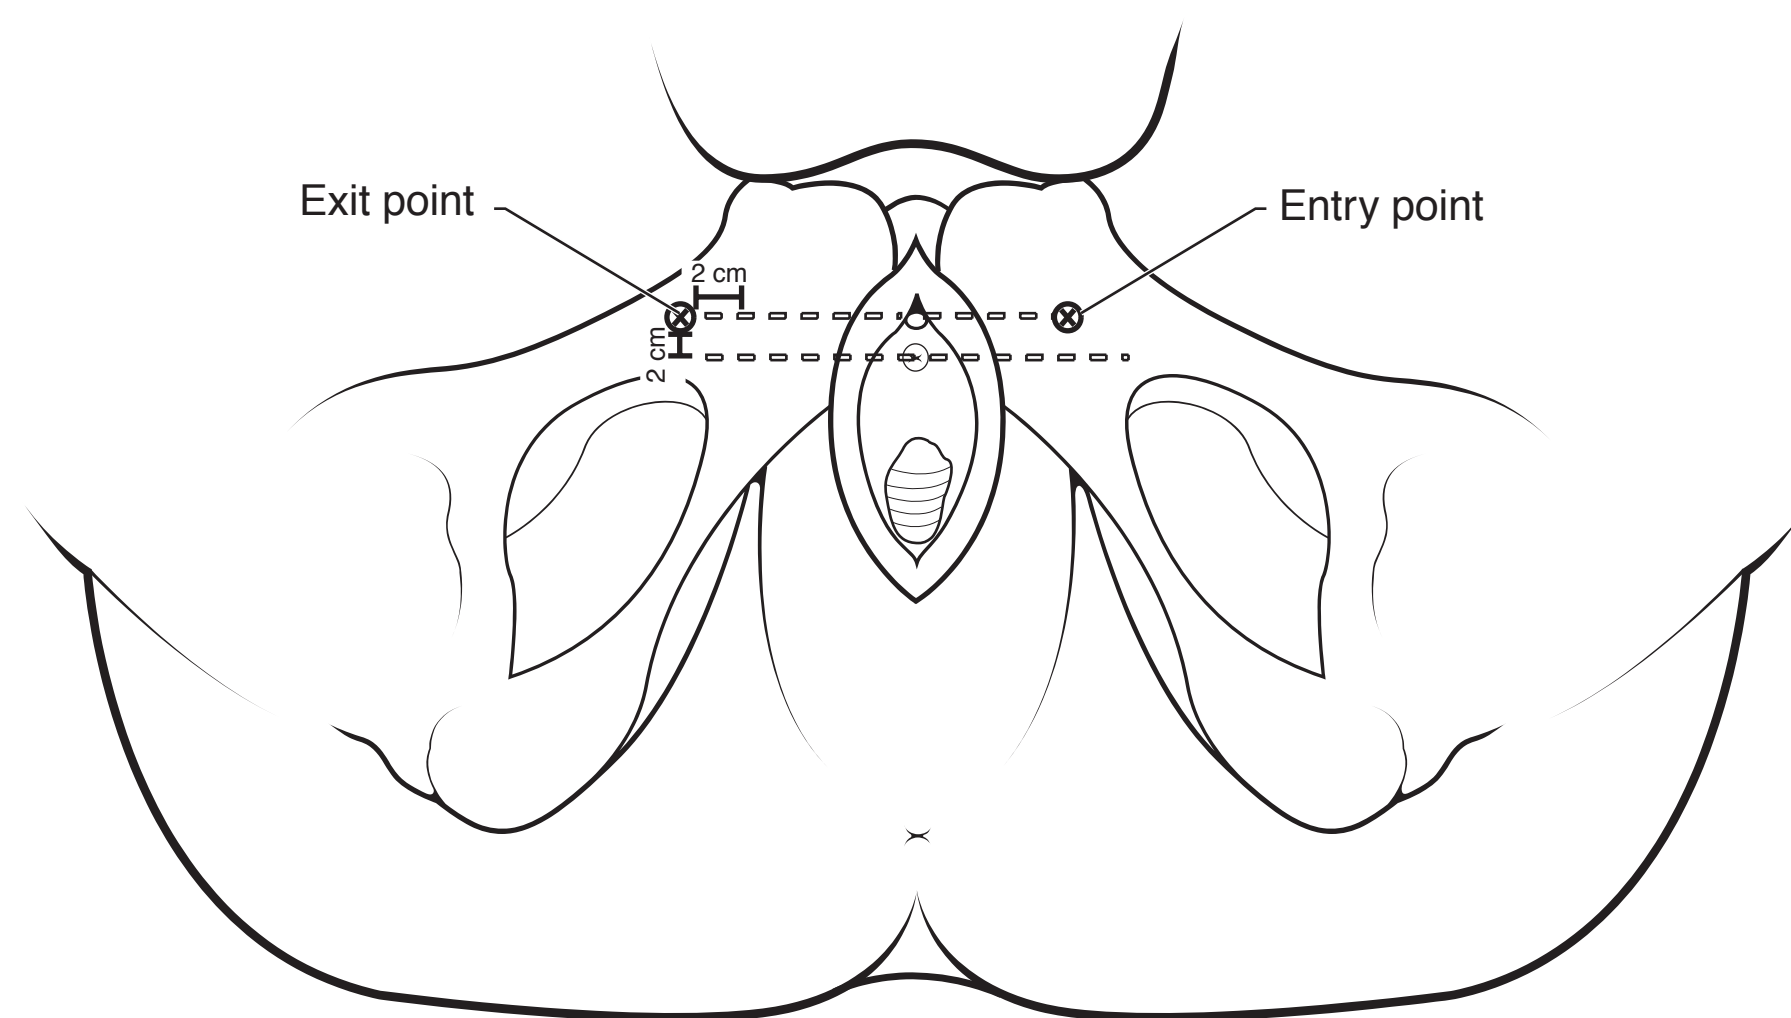

The midurethral vaginal incision should include both the vaginal epithelium and portions of the muscularis. Too shallow of an incision may promote postoperative vaginal mesh extrusion. The operator then dissects using a fine scissors (Church, Metzenbaum, or sternotomy) in the periurethral tis-

**FIGURE 42.2** Blunting of the vaginal crease while injecting lidocaine helps to decrease the risk of buttonholing the vaginal mucosa as the needles are passed through the periurethral tissues.

sues toward the ischiopubic ramus, until a tunnel is created and the tip of the surgeon’s finger can touch the ischiopubic ramus. The dissection is carried out bilaterally. It is also advantageous to continue developing the plane between the vagina and urethra at the inferior aspect of the incision for approximately 0.5 cm to create a pocket for the mesh and to limit tearing the vaginal tissue with digital manipulation of the subepithelial tunnel.

The adductor longus tendon is palpated, and a marking pen is used to identify the genital crural fold below the tendon. This typically is at the level of the clitoris at the lateral edge of the labia majora (Fig. 42.3). Local anesthetic is injected along the proposed needle path followed by a small stab incision. In reference to the outside-in technique, the cut edge of the vaginal incision is grasped with an Allis clamp, and the operator’s same-hand index finger is placed behind the Allis clamp into the vaginal epithelial tunnel. The needle passer is then grasped in the operator’s opposite hand and positioned so that the axis of the passer is parallel to the ischiopubic ramus. The needle tip is placed perpendicular to the skin and advanced through the soft tissues around the ramus, meeting the operator’s index finger that guides the needle tip out of the vaginal epithelial

**FIGURE 42.3** Demonstration of placement for the groin incisions. The patient’s right side shows the exit points of the needles for the outside in technique, and the patients left side shows the entry points for the inside out technique.

**FIGURE 42.4** The needle tip is placed perpendicular to the skin and advanced through the soft tissues around the ramus meeting the operator's index finger that guides the needle tip out of the vaginal epithelial tunnel lateral to the urethra.

tunnel lateral to the urethra (Fig. 42.4). At this point, it is important to determine that the lateral sulci of the vagina are free of inadvertent mesh passage. This done, the mesh is attached to the needle and removed, reversing the path of insertion. The process is then repeated on the contralateral side. The products are marketed such that the mesh is ensheathed in plastic that overlaps in the middle. The plastic allows the mesh to slip through the tissue during placement. It is useful to place a hemostat to stabilize the overlapping plastic, ensuring that the mesh is not prematurely exposed. At this point, cystoscopy is recommended.

Although the concept for the inside-out technique is similar, the surgical steps do vary from the outside-in technique described above. Gynecare manufactures the TVT Obturator System, which includes helical passers, a plastic ensheathed polypropylene mesh, and a winged guide that facilitates introduction and passage of the helical needle passers. The groin incisions are made along a line 2 cm above the level of the urethral meatus. The exit points for the helical needle lie on this line, 2 cm lateral to the folds of the thigh (Fig. 42.3). A mid-line vaginal incision is then made superficial to the urethra as described above. Sharp and blunt dissection is employed to traverse the periurethral tissues to the obturator membrane, which is perforated with scissor tips. The winged guide is inserted into the dissected track and through the obturator membrane. The helical needle passer is then inserted through the vaginal incision following the channel of the winged guide so that the tip is beyond the obturator membrane (Fig. 42.5). At the starting point, the handle is 45 degrees from midline. The guide is then removed and the helical needle passer is rotated (clockwise for the patient's left side and counterclockwise for the right) while the handle is moved simultaneously toward the midline. The tip of the needle passer with an overlying plastic tube that is attached to the mesh then exits the marked groin incisions. The tubing is grasped with a clamp, and the needle passer is backed out of the plastic tubing by

**FIGURE 42.5** The winged guide is inserted into the dissected track and through the obturator membrane. The helical needle passer is then inserted through the vaginal incision following the channel of the winged guide so the tip is beyond the obturator membrane.

reverse rotation of the handle. The tubing is then pulled through the skin until the plastic-covered mesh appears. At this point, the previous steps are repeated on the contralateral side.

Once bladder and urethral integrity is confirmed by cystoscopy, the mesh is tensioned. There is considerable variability in how “proper” tension is determined. Given that a transobturator sling can be done with the patient awake, perhaps the best technique involves having the patient perform a cough stress test at a specific bladder volume (usually 300 cc). There is evidence that deeper anesthesia techniques are associated with lower treatment outcomes; however, it cannot be said that the “tailoring” of the mesh tension in the awake patient is responsible for this finding. Another technique for tensioning mesh is to place a no. 9 Hegar dilator between the mesh and the urethra before pulling back on the plastic sheaths exiting the groin incisions. Alternatively, a Babcock clamp can be used to grasp a 4-mm knuckle of mesh under the urethra before tensioning that, when released, will render “proper” tension. Care should be taken to use a similar technique on all patients. Once the appropriate tension has been determined, the mesh is stabilized, the hemostat in the middle is released, the plastic sheaths alone are grasped, and, applying equal pressure, the sheaths are removed out of the groin incisions. The vaginal epithelial incision is next closed with a running suture of delayed absorbable suture on a taper needle. The groin incisions are closed with suture or skin adhesive.

---

## OUTCOMES

---

Of equal importance to the technical issues of pelvic floor surgery is the measurement of treatment outcomes by the performing surgeon. In general, treatment outcomes can be assessed with objective or subjective measures, and these should

TABLE 42.2

**INCONTINENCE SEVERITY INDEX**

How often do you experience urinary leakage?	How much urine do you lose each time?
1. Less than once a month	1. Drops
2. A few times a month	2. Small splashes
3. A few times a week	3. More
4. Every day and/or night	

The four-level severity index is based on the following index values (1–12), which is a product of the score of each question.

1–2 = slight  
3–6 = moderate  
8–9 = severe  
12 = very severe

*Source:* Sandvik H, Seim A, Vanvik A, et al. A severity index for epidemiological surveys of female urinary incontinence: comparison with 48-hour pad-weighing tests. *Neurourol Urodynam* 2000;19(2):137–145.

match those used before treatment. There are several subjective survey tools to assess urinary incontinence. These tools vary in length and psychometric properties (e.g., validity, reliability, and responsiveness) and also in the degree to which they indicate the kind of incontinence. For example, the Urinary Distress Inventory (UDI) can render insight into whether the leakage is stress or urge; however, the overall

score blends these issues and is less concise in assessing the overall severity of leakage. In contrast, the Incontinence Severity Index (ISI) (Table 42.2) renders a quick assessment of leakage severity but does not distinguish the kind of leakage.

Pelvic floor disorders are multidimensional issues and should be assessed with composite outcomes to capture, reasonably, as many aspects as possible. In clinical practice the burden to

patient and provider of using validated surveys to assess pelvic organ prolapse, bowel dysfunction, sexual function, and bladder function can be daunting. Subjective outcomes, as noted previously, can identify (UDI) and quantify (ISI) symptoms or assess general (SF-36) or condition-specific quality of life (Incontinence Impact Questionnaire, IIQ).

Objective outcomes include the pelvic organ prolapse quantification system (7), bladder diaries, cough stress tests, pad tests, office cystometrics with cough stress testing, and multichannel urodynamics. Although there are settings in which objective assessment would be useful in routine clinical practice (e.g., treatment failure), regular posttreatment use can be burdensome to both patient and clinician, rendering little additional information than that gathered from the subjective assessments. However, long-term outcomes data are not currently available.

---

## COMPLICATIONS

---

As with any surgical procedure, complications can arise intraoperatively or postoperatively that can have either short- or long-term sequelae. The transobturator technique was developed as a safer approach compared to the retropubic technique. The needles are unlikely to enter the peritoneal cavity, virtually eliminating the potential for bowel injury, and they do not pass near large blood vessels, making major vascular injury less likely. Regardless, brisk bleeding can ensue intraoperatively from the vaginal incision, periurethral tissues, or while passing the needles close to the obturator artery and its branches. Typically this responds to pressure applied for a short duration or vaginal packing. Vaginal mucosal damage is more likely with transobturator than retropubic midurethral slings (8). In patients with deep lateral vaginal sulci, the helical needle can “buttonhole”: doubly pierce the vaginal epithelium and result in a “bridge” of mesh superficial to the epithelium. Bladder injury is less common than with retropubic techniques (9), but cystoscopy is still recommended to ensure the integrity of the bladder and urethra. Recurrent postoperative urinary tract infections should alert the physician to the possibility of mesh in the bladder. It is notable, however, that postoperative urinary tract infections can be common following any incontinence surgery.

Short-term complications of bleeding include hematomas, ecchymosis, and anemia. Vaginal erosion can present days to months postoperatively. Numerous factors may contribute to

erosion, including operative technique, mesh properties (pore size, stiffness, elasticity), and tissue properties (local ischemia, infection, and tissue integrity). Depending on the extent of the erosion, it can be managed by freshening up the vaginal edges and oversewing the epithelium, or by excision of the exposed mesh followed by closure of the epithelium. Infectious complications can present in a number of ways. Cellulitis can occur in both the groin and vaginal incisions, and it can lead to mesh erosion even after the infection has cleared. Abscess formation has been reported in both the adductor muscles of the thigh and the ischioanal fossa. Treatment of these can be challenging, as they are rare and there is minimal experience in any single institution. Based on individual cases, drainage of the abscess, debridement of the infected tissue, and removal of the mesh are options. The latter can be challenging, depending on the time course of the infection and the amount of tissue ingrowth that has occurred.

Other complications that can have either short- or long-term sequelae include new-onset detrusor instability, continued incontinence, urinary retention, nerve injuries, and pain or dyspareunia.

Rates of major complications, including abscess formation, nerve injury, and life-threatening hemorrhage, are unknown, as they are rare events and even large studies are underpowered to report them. In 2006 Boyles (10) published on complications of three commercially available transobturator slings reported to the MAUDE data base (maintained by the FDA to collect and report complications of medical devices) between January 2004 and July 2005. During this time, 173 complications were listed in 140 reports. Sixty percent of these complications were mesh erosions, and one third of those were associated with infection. One urethral erosion was reported. Two abscesses of the ischioanal fossa presented 2 months after the surgical procedure and required drainage. Two infections involved abscesses of the adductor muscles. Four cases of neuropathy were reported, and in two of these cases the patients had difficulty with ambulation. Five cases of bleeding in excess of 300 cc were reported. There was one documented case of injury to an iliac vessel with the medial to lateral technique that required embolization in radiology. Although these data are useful for understanding the types of complications that can occur, the number of cases they are pooled from are unknown. The FDA estimates that the actual number of complications is 10 to 100 times higher than reported to the MAUDE database.

# CHAPTER 43 ■ ABDOMINAL RETRO PUBIC APPROACHES FOR FEMALE INCONTINENCE

LESLIE M. RICKEY

Urinary incontinence (UI) is common, with approximately 30% of women reporting any incontinence; about 25% to 50% of these cases are estimated to be stress urinary incontinence (SUI) (1–3). In addition, the number of women seeking care for UI is increasing. Office visits for UI more than doubled, from 815,832 visits in 1992 to 1,932,768 visits in 2000 (4). A recent analysis of population growth and future demand for care concluded that consults for pelvic floor disorders will increase by 45% from 2000 to 2030 (5). In terms of surgical management, one out of nine women will have surgery for a pelvic floor disorder in their lifetime, and this number represents only a subset of women who have the condition (6). About one third of the surgeries were for SUI alone, and another 20% of surgeries were performed for combined SUI and pelvic organ prolapse (POP).

Although the exact mechanism that leads to SUI is not known, proposed theories include loss of proximal urethral support, or the “hammock” theory, and intrinsic deficiency of the external urethral sphincter. Surgical procedures are directed towards correction of the deficiency, either re-establishing support of the proximal urethral or improving urethral closure. The suburethral sling procedure can be performed using autologous fascia (rectus fascia or fascia lata) or synthetic material. The sling procedures are covered in other chapters.

Urethral position depends on anterior vaginal wall support. Retropubic colposuspension, or urethropexy, aims to improve the support of the vesicourethral junction by lifting the periurethral tissue towards the pubic bone, thus restoring the proper anatomy. The procedure is believed to treat incontinence by providing improved resistance to increases in intra-abdominal pressure, resulting in more effective urethral compression. The Marshall–Marchetti–Krantz (MMK) procedure involves suturing the periurethral tissue at the level of the bladder neck directly to the periosteum of the pubic symphysis. Burch, a gynecologist, modified this technique by altering the suspension laterally to the iliopectineal line, or Cooper’s ligament. The Burch technique was further modified by Tanagho, a urologist, to include a suture bridge instead of direct apposition of the anterior vaginal wall to Cooper’s ligament. The Burch urethropexy has traditionally been performed via a small Pfannenstiel incision, but the laparoscopic approach has been utilized as well.

The MMK is largely a historical procedure as the Burch appears to be slightly more efficacious. In addition, the complication of osteitis pubis is specific to the MMK approach due to the placement of suture directly into the periosteum. Although the Burch urethropexy may be regarded

as an outdated procedure as well, it is still a reasonable option for a woman desiring an incontinence procedure, particularly if she is undergoing a concomitant abdominal surgery. In addition, as will be discussed later in the chapter, it is indicated for an asymptomatic, stress-continent woman undergoing an abdominal sacrocolpopexy for prolapse.

---

## DIAGNOSIS

---

A thorough and detailed patient history should elicit whether the patient has stress incontinence, urge incontinence, or mixed incontinence. It is important to ascertain a history of previous incontinence or pelvic surgeries, as this may affect surgical decision making. Prolapse symptoms should also be queried, as almost two thirds of women with SUI have coexisting POP (7), and additional procedures may be necessary at the time of the incontinence surgery. Finally, it is prudent for physicians performing pelvic surgery to inquire about whether the patients Pap screening is up to date.

The physical examination should include a bimanual and speculum examination to assess the vaginal tissue and vaginal support and to rule out any pelvic masses. A positive empty supine cough stress test is highly predictive of urodynamic stress incontinence (8). Urethral hypermobility should be confirmed before considering a Burch urethropexy. Traditional teaching has utilized the cotton-tipped swab test to measure urethral hypermobility. A cotton-tipped swab is inserted transurethraly to the proximal urethra, and the patient is asked to maximally Valsalva. A deflection of  $>30$  degrees from the resting angle during Valsalva is considered to reflect urethral hypermobility. The surgeon should inspect the lower abdominal wall for scars indicative of previous pelvic surgery and correlate with the patient’s surgical history.

If the patient relates SUI symptoms and desires surgical treatment, many surgeons choose to perform urodynamics (UDS) to confirm the diagnosis. It is believed that the Burch is not as effective in women with “intrinsic sphincter deficiency,” typically defined by indirect measures of urethral function, including leak point pressure  $<60$  mm Hg or urethral closure pressure of 20 mm Hg or less. However, a randomized trial comparing Burch to sling in women with low urethral closure pressures (20 cm H<sub>2</sub>O or less) did not show a difference in subjective success between the two procedures at a mean 5 years of follow-up (84% versus 93%, respectively,  $p = 0.47$ ) (9). Although the study was not powered to detect

small differences between the treatment groups, the findings still demonstrate that the Burch procedure can be effective in women with low urethral closure pressures. Valsalva leak point pressure (VLPP) has not been shown to be a significant predictor of success after the Burch procedure (10). In addition, a retrospective review of women who underwent a Burch urethropexy with preoperative VLPPs of  $<60$  cm H<sub>2</sub>O showed an objective success rate of 91.7%, indicating that a low VLPP is not necessarily predictive of Burch failure (11). Direct measurement of striated urethral sphincter function using electromyography suggested that women with better innervation of their urethral sphincters were more likely to be cured by the Burch urethropexy (12). In summary, there are no UDS parameters clearly predictive of Burch success or failure. Therefore, traditional urodynamic testing does not seem to aid in the surgeon's decision of which incontinence procedure to perform. However, the study can provide helpful information about the coexistence of detrusor overactivity, clarify confusing symptomatology, and confirm diagnoses in patients who have undergone previous incontinence surgeries.

## INDICATIONS FOR SURGERY

The main indication for an incontinence procedure is the presence of symptomatic SUI that adversely affects the woman's quality of life. The patient should also have the sign of transurethral loss of urine with a cough stress test or during formal urodynamic testing. Additionally, the patient must be sufficiently healthy to undergo regional or general anesthesia, be able to be placed in dorsal lithotomy position and have a habitus that allows a suprapubic incision. There appears to be a risk of worsening POP after a Burch procedure (13–15); therefore, a Burch urethropexy probably should not be performed as a solitary procedure if there is significant apical descent. Lack of urethral hypermobility and a previously failed retropubic approach would be considered indications for a suburethral sling by most pelvic surgeons.

A Burch urethropexy is also appropriate for an asymptomatic woman (without SUI) undergoing a sacrocolpopexy for POP. A randomized controlled trial showed that performing a concomitant Burch urethropexy at the time of abdominal sacrocolpopexy resulted in a decrease of new-onset postoperative SUI from 40% to 20% in stress-continent women (16).

## ALTERNATIVE THERAPY

Conservative therapies for SUI may involve use of pessaries or physical therapy for pelvic floor muscle (PFM) rehabilitation. In women successfully fitted with a pessary for UI, rates of continued use and satisfaction range from 16% to 59% at 1 year (17,18). PFM physical therapy includes both strengthening and instruction on timing of activation of PFMs to avoid leakage. A Cochrane review in 2007 supported that PFM training should be included in first-line conservative management for women with UI (19). In women with SUI who participated in a course of PFM exercise, 44% to 56% of patients

were satisfied with symptom improvement and desired no further treatment (20,21).

## SURGICAL TECHNIQUE

### Open Burch Urethropexy

The patient is placed in the low dorsal lithotomy position and the vagina and abdomen are prepped and draped for combined access. A Foley catheter is placed and a Pfannenstiel incision is made. Dissection of the space of Retzius is performed (Fig. 43.1). The first and second fingers of the surgeon's non-dominant hand are placed in the vagina, with one finger on each side of the urethral catheter. The bladder is retracted medially so that the perivaginal tissue lateral to the vesicourethral junction is exposed. Using the vaginal finger as a guide, a peanut sponge can be used to carefully sweep away the overlying fat until the glistening white perivaginal "fascia" is visualized. Care must be used as vaginal and pelvic veins are often encountered in this area. Palpation of the Foley balloon will help delineate the vesicourethral junction. Two figure-of-eight sutures are placed in the periurethral vaginal tissue, one at the vesicourethral junction and another more distally at the level of the midurethra. Avoid placing the sutures through any fatty tissue. Placement of the sutures into the vagina is aided by elevation of the anterior vaginal wall using the hand in the vagina (Fig. 43.2A). The vaginal finger should be used as a guide to ensure that the sutures are sufficiently lateral to the urethra. The suture bite should encompass vaginal tissue without perforating the vaginal epithelium (Fig. 43.2B). The procedure is repeated on the other side. A total of four permanent, nonabsorbable sutures such as no. 0 or no. 1 polyester (Ethibond) or polytetrafluoroethylene (Gore-Tex) sutures are placed (two on each side; Fig. 43.3A). Cooper's ligament is identified and any overlying tissue is gently swept off using a peanut sponge.

The sutures are then placed through Cooper's ligament on the respective sides (Fig. 43.3B). Note that the sutures are tied off the midline. The proximal sutures will be placed slightly

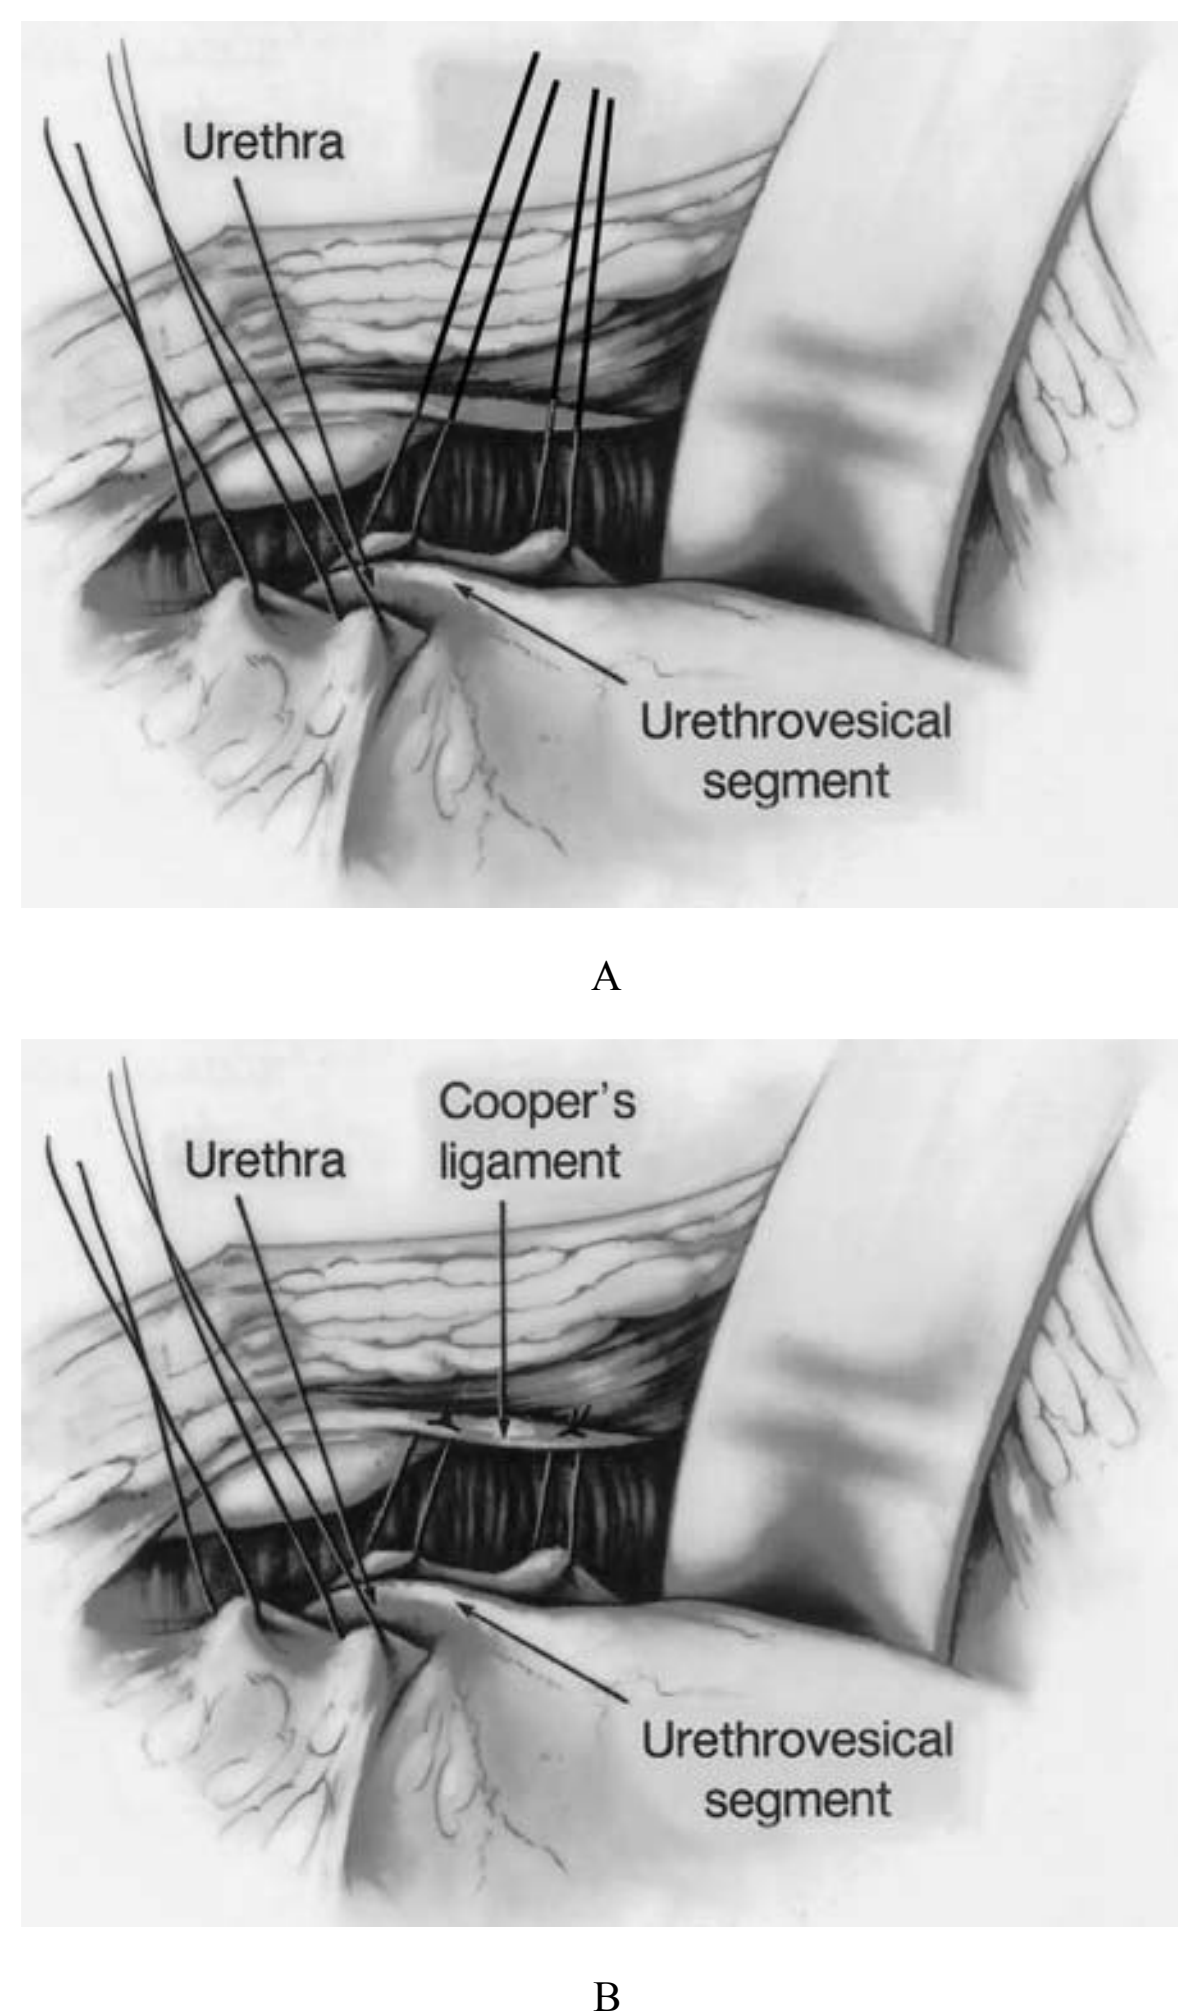

**FIGURE 43.1** Retropubic space showing the bladder neck, Foley balloon, and Cooper's ligament.

**FIGURE 43.2** **A:** The first suture at the level of the vesicourethral junction. The surgeon's finger in the vagina helps guide the suture lateral to the urinary tract. **B:** The finger in the vagina also helps exclude the suture from the vaginal epithelium.

lateral to the more distal midurethral sutures. The obturator vessels and nerve pass through the obturator fascia; this obturator “notch” is the lateral limit for suture placement into Cooper's ligament and should be avoided. The assistant ties the sutures down while the operator's fingers remain in the vagina to ensure the proper degree of suspension. The operator should feel that the anterior wall is slightly lifted without overcorrection of the urethrovesical junction. It is imperative that the sutures are tied such that there is distance between Cooper's ligament and the vaginal tissue (Fig. 43.3B), seen as a suture bridge of approximately 2 cm. This prevents over-compression of the urethra, which can cause obstruction. The placement of these sutures and how tightly they are tied differ from the initial description of Burch, in which the sutures were tied down with complete approximation of the perivaginal tissue onto Cooper's ligament. After tying the sutures, cystoscopy is performed to ensure that the sutures did not perforate the bladder and that the ureters are patent. Methylene blue can be used to help identify efflux of urine from the ureteral orifices.

**FIGURE 43.3** **A:** A total of four sutures are placed in the periurethral tissue. **B:** The two right-sided sutures are passed through Cooper's ligament and tied; note that there is a gap between the vaginal tissue and Cooper's ligament, creating a suture bridge.

### Laparoscopic Burch Urethropexy

Apart from the incisions, the laparoscopic Burch is performed in an identical manner to the open Burch procedure. There are a variety of port placement strategies described. A common approach is to place a 10-mm laparoscopic port at the umbilicus and two 5-mm ports in the lower lateral abdominal wall, approximately two fingerbreadths superior and medial to the anterior superior iliac spine. An additional suprapubic port is sometimes utilized. As in the open approach, cystoscopy should be performed at the end of the procedure to exclude intravesical suture and ensure ureteral patency. The laparoscopic procedure is covered in more detail in the chapter dedicated to laparoscopic surgery for urinary incontinence.

## OUTCOMES

### Results

A recent Cochrane review showed overall cure rates between 69% and 88% for open retropubic colposuspension (22). A randomized controlled trial comparing Burch to suburethral

sling showed stress-specific success of 49% (compared to 66% for the sling group) at 2 years, using a very strict definition of success (23). However, there was also a lower rate of adverse events in the Burch group. The overall patient satisfaction was slightly lower in the Burch group (78% versus 86%,  $p = 0.02$ ). Another randomized trial comparing Burch to tension-free vaginal tape (TVT) revealed 63% of women reporting cure after the Burch (versus 70% in TVT group,  $p = 0.54$ ) at 5 years, but overall 90% of women who had undergone colposuspension were satisfied or very satisfied with the results of surgery (14). Using a negative 1-hour pad test ( $<1$  g change in weight) for definition of cure, and using pad test data from the last available follow-up visit for missing data, the cure rates were computed as 69% for colposuspension versus 75% for TVT ( $p = 0.28$ ).

In a randomized controlled trial comparing laparoscopic to open Burch, there were no significant differences seen at 24 months in patient-reported cure of stress incontinence (66%), although the study was not powered to detect a difference of  $<20\%$  (24). There was not a significant difference in perioperative complications. Out of six cases of suture penetration into the bladder, five occurred in the laparoscopic group, but this difference did not reach statistical significance ( $p = 0.11$ ). Mean operating time was less in the open group (87 versus 42 minutes,  $p < 0.0001$ ), and blood loss was less in the laparoscopic group (126 versus 170 mL,  $p = 0.03$ ). There was no difference in length of hospital stay, but the average return to normal activities was 5 days less in the laparoscopic group (24.6 versus 19.7 days,  $p = 0.01$ ). A meta-analysis of studies comparing laparoscopic versus open Burch had similar findings of longer operating times, marginally less blood loss, decreased hospital stay, and faster return to normal activity in the laparoscopic group (25). There was not a significant difference in subjective or objective cure rates up to 2 years postoperatively.

Finally, a randomized trial comparing laparoscopic Burch to TVT with a median follow-up of 65 months concluded that the two procedures have similar long-term efficacy (26). Although only 52% of subjects in the TVT group and 43% in the Burch group reported no urine leakage under any circumstances, bothersome urine leakage was present in only 8% and 11%, respectively ( $p = 0.26$ ), and overall patient satisfaction rates were similar as well (79% versus 88%). Operating time was less in the TVT group, but there was no difference in blood loss or hospital stay. In terms of bladder injury, there were two cysto-

tomies in the TVT group and two patients with bladder sutures detected intraoperatively in the laparoscopic Burch group.

---

## Complications

---

Delayed bladder emptying was seen in 2% of patients after undergoing a Burch urethropexy in a large multicenter study, but no additional procedures were required for urinary retention (23). These patients may require temporary intermittent self-catheterization. Occasionally, the periurethral sutures must be released transvaginally to relieve the urethral obstruction if there is not adequate bladder emptying at 4 to 6 weeks postoperatively. New-onset urge urinary incontinence occurs in 3% to 4% of patients, and 5% report de novo urgency (14,23). In a patient with significant postoperative urgency and frequency, urinary retention and urinary tract infection should be ruled out: as many as 30% of patients may develop a urinary tract infection in the postoperative period (23).

Ureteral injuries occur in  $<1\%$  of patients. Bladder injury is more common, with incidental cystotomy rates of 2% to 4%, usually due to suture passage into the bladder. A recent study showed that 2 of 329 (0.6%) patients sustained a ureteral injury and 10 of 329 (3.3%) had an incidental cystotomy when undergoing a Burch urethropexy (23). A cystoscopy at the time of surgery can aid in identifying intravesical sutures, and ureteral patency can be confirmed as well.

Approximately 8% to 13% of women are found to have vaginal vault or uterine prolapse during the follow-up period after Burch (14,15,27). The clinical significance of the prolapse has been unclear; however, a randomized controlled trial comparing Burch to TVT showed that surgery for prolapse was more common after the Burch colposuspension (7.5% versus 1.8%,  $p = 0.025$ ) (14). Therefore, a sling may be a more appropriate choice for a woman desiring an incontinence procedure who has asymptomatic prolapse with apical descent of several centimeters or more.

---

## CONCLUSION

---

A Burch urethropexy should be considered for a woman desiring an incontinence procedure, particularly if she is undergoing a concomitant abdominal surgery, or for a stress-continent woman undergoing an abdominal sacrocolpopexy.

## CHAPTER 44 ■ THE ARTIFICIAL URINARY SPHINCTER

HELEN ZAFIRAKIS AND O. LENAINE WESTNEY

The artificial urinary sphincter (AUS) is the most effective treatment for intrinsic urethral sphincter dysfunction. The three components, consisting of a cuff that is placed around the urethra, a reservoir, and a pump (Fig. 44.1), have not changed since the initial device was introduced in 1983. However, in the late 1980s several modifications were made to the device, such as a narrow-backed cuff and kink-resistant tubing, that resulted in a significant reduction in the number

**FIGURE 44.1** The AMS 800 Artificial Urinary Sphincter. The three components are the pump, the reservoir, and the cuff, connected with tubing and connectors.

of mechanical failures. The pump, which is placed either in the scrotum in men or the labium majorum in women, has both a mechanical pump section and a deactivation button. When activated, the cuff maintains continence by circumferential compression of the urethra. If voiding is desired, the patient uses the pump to force fluid from the cuff toward the reservoir. Fluid automatically returns into the cuff over about 2 minutes as the pressure reequilibrates in the system, allowing adequate time for bladder emptying. The deactivation button prevents the reentry of fluid in the cuff. To reactivate the device, the patient presses the pump forcefully and thus releases the poppet valve, allowing the fluid to enter the cuff and thus restore continence.

---

### DIAGNOSIS

---

Physical examination should include examination of the genitalia, neurological assessment, and assessment of the integrity of the perineal skin. Investigations should include a voiding diary and cystoscopy to look at the quality of the urethral tissue, especially at the bladder neck and bulbar urethra, in order to exclude conditions that would need to be dealt with prior to placing the AUS, such as stricture disease. Fluoroscopic urodynamics are necessary to verify the cause of incontinence, assess bladder capacity and compliance, and exclude detrusor overactivity, which, in conjunction with an AUS being placed and especially in the setting of neurogenic patients, can be dangerous to kidney

function over time. Urethral pressure profiles are not obligatory but may add weight to the diagnosis of intrinsic sphincter deficiency, depending on the leak point pressures.

## INDICATIONS FOR SURGERY

The most common indication for AUS insertion is postprostatectomy sphincter incompetence. Other indications include congenital or acquired neurogenic conditions of the bladder. Patients with congenital genitourinary abnormalities (such as exstrophy-epispadias complex), those with posterior trauma where the sphincter has been compromised, and female incontinence where other anti-incontinence therapies have failed may also benefit from an AUS.

The AUS is contraindicated in patients who have an intellectual or physical disability that would render them unable to utilize the device properly. Other relative contraindications include patients with progressive neuromuscular disorders who would develop such a disability in a relatively short time or patients with an untreated small-capacity or noncompliant bladder or with detrusor overactivity that is not controlled. Women with a previous history of pelvic irradiation [1] also fall into the group of relative contraindications because they may have a poor outcome with AUS due to urethral and/or vaginal device erosion.

## ALTERNATIVE THERAPIES

Alternative therapies to the artificial sphincter include closure of the bladder neck, injection of bulking agents, and urinary diversion.

## SURGICAL TECHNIQUE

### Preoperative Preparation

Urinary tract infection must be either excluded or treated if identified prior to surgery. The perineal skin must be in good condition and intact. If there is irritation of the skin due to urine contact, a catheter should be placed and then removed a week or so before implantation of the AUS. Antibiotics are given 1 hour preoperatively or at induction, and they need to cover both aerobic and anaerobic organisms. Common combinations of antibiotics include vancomycin and gentamicin or cefuroxime, and metronidazole and gentamicin (2). The patient is shaved on the operating table, not beforehand, to reduce the risk of infection. An additional measure is the use of a chlorhexidine wash to reduce the microbial load 24 hours prior to surgery. If the patient was on an intermittent catheterization program, prophylactic antibiotics should be given for 3 days leading up to surgery (3).

Spinal or general anesthesia is usually given, and the lower abdomen and genitalia are shaved carefully. A povidone-iodine or chlorhexidine wash of the skin is performed for 10 minutes, with a separate povidone-iodine or equivalent skin preparation followed by an alcohol scrub. The patient is draped to allow access to the lower abdomen, suprapubic area, and genitalia and is placed supine in a lithotomy or spreader bar position. A 16Fr Foley catheter is then placed into the bladder.

## AUS Placement in Men

### Perineal Incision

The traditional method of AUS placement involves a perineal incision. For bulbous urethra cuff placement, a midline perineal incision is made over the bulbar urethra with dissection extended to just distal to the bulbocavernosus muscle so that a 2-cm length of urethra has been dissected (Fig. 44.2). The most proximal placement of the cuff possible should be attempted. Care should be handle the corpus spongiosum gently and to avoid opening the urethral lumen. Injury to the spongiosal tissue should be repaired with a 4-0 absorbable suture rather than with cautery. Circumferential dissection of the urethra requires careful sharp removal of the midline dorsal urethra attachment to the corpora. The sound of the scissor blade when dissect in the correct plane should be a distinct snip. Once the urethral dissection is complete, the cuff size is determined using a sizer in the AUS kit. The most common

**FIGURE 44.2** **A:** Diagram demonstrating the perineal incision for placement of the AUS. **B:** Dissection of the urethra. The urethra is dissected free circumferentially (demonstrated by the Penrose drain behind the urethra).

size for an adult male bulbar urethra in this position is 4.5 cm. The cuff should be snug, but not too loose or tight.

A small lateral transverse groin incision is made approximately 2 to 3 cm above the symphysis pubica to the side of the desired pump placement. A transverse 2-cm incision is made in the fascia. Closure sutures are placed in the fascia at this point prior to reservoir placement. After opening the rectus fascia, a space is developed beneath the transversalis fascia in the retropubic space for the reservoir. The reservoir is positioned and inflated to 23 to 25 mL of solution, depending on the size and number of cuffs. The most commonly selected reservoir pressure is 61 to 70 cm of water in postprostatectomy patients. The pathway for the pump tubing is developed from the suprapubic incision, beneath the Scarpa fascia, utilizing a ring clamp. The subdartos space is developed by spreading the clamp in the most dependent scrotal position. The pump should be on the lateral aspect of the scrotum with the deactivation button directed laterally. The length of tubing required to ensure continued dependent placement is facilitated by securing the tubing to the scrotal skin with a Babcock clamp until the connections are performed.

The pressure of the reservoir balloon is a balance between adequate continence and avoidance of extreme cuff pressures. Generally, in most postprostatectomy patients, a balloon with 61–70 cm of water pressure is adequate; however, where the urethra has been compromised or in cases of previous irradiation, a reduced pressure, such as 51 to 60 cm of water, is used to reduce the risk of urethral erosion and atrophy.

The cuff tubing is directed to the suprapubic incision utilizing a tubing passer. At this time, the tubing connections are completed using either the Quick Connect (American Medical Systems, Minnetonka, MN) system or tied connections. Injectable normal saline is preferred to the use of isotonic contrast solutions as these can alter the pressure dynamics in the system over time.

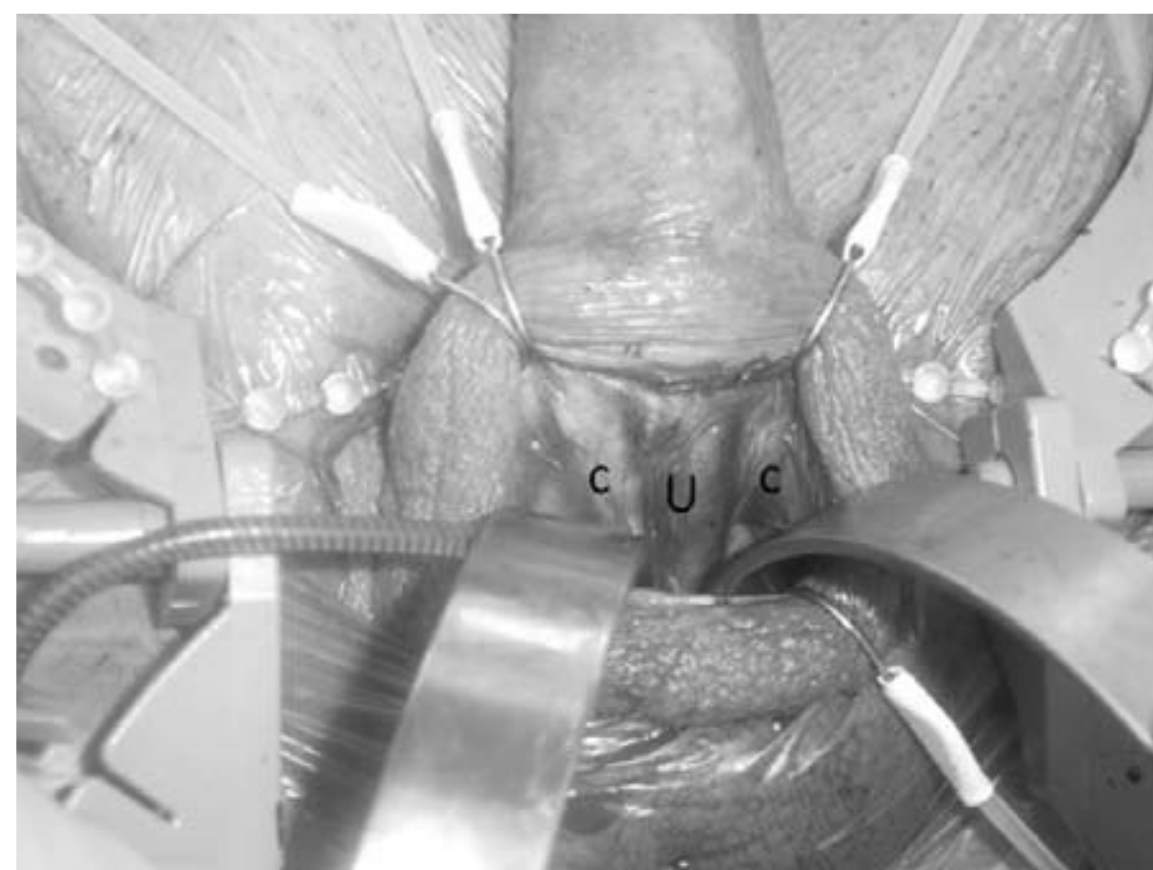

After inserting the AUS, the system should be cycled to ensure that it functions, then deactivated to allow healing for 4 to 6 weeks. It is important to allow the pump to partially fill prior to deactivation to decrease the difficulty of activation. This is done by waiting until there is enough fluid in the pump to create a small dimple when it is palpated as the AUS is activated, then deactivating it. Once all the components are in place and tested, the wounds are closed in layers with absorbable sutures. No urethral catheter needs to be left in situ, unless there are concerns about bladder emptying, such as in some neurogenic patients. Antibiotics are continued for 24 hours parenterally and then orally for a further 5 to 7 days. This implies that the patient can usually be discharged the following day. No drains are left. The AUS is left in the deactivated position for 6 weeks to allow healing. Patients are encouraged to gently milk the pump inferiorly to encourage maintenance of the appropriate scrotal dependency.

---

### Transcorporeal Cuff Placement

---

Patients with urethral erosion or infection of the AUS device can be difficult to manage. The cuff can be placed at a different site once the urethral tissues are ready for reimplantation; however, the urethral re-erosion rate is 11.8% (4). In some cases there is not adequate room to place a cuff in a

**FIGURE 44.3** Initial dissection of the urethra, showing the urethra (U) and the corpora cavernosa (C) on either side.

position more proximal to the original urethral position, and using the urethra distal to the bulbar urethra can generate problems with a thin urethral wall, increasing the risk of recurrent erosion. The ability to augment in the urethra while protecting from the pressure from the cuff would theoretically decrease the risk of erosion. There are also reports of some encouraging results using a gracilis muscle transposition flap to the proximal urethra in conjunction with electrical stimulation (5).

Guralnick et al. (6) developed the technique of transcorporeal cuff placement, which utilizes a buttress of tunica albuginea from the corpora cavernosa to protect the dorsal urethral wall from erosion in cases of revision due to either erosion or atrophy. The essential principles of this technique involve utilizing a segment of urethra 2 to 3 cm distal to the bulbar urethra (where the original cuff was placed), avoiding dissection of intervening urethra. A urethral site is selected using urethroscopy, and an incision is made over the urethra at this site, exposing both the urethra and corporal bodies (Fig. 44.3). Longitudinal incisions 2.5 cm long are made in the corporal bodies bilaterally, with a tunnel being formed between the two corporotomies (Fig. 44.4A). This results in a layer of tunica albuginea attached onto the roof of the urethra, around which the new cuff is placed, giving extra protection to the urethra at this point (6) (Fig. 44.4B). The tunica left on the corpora cavernosa is reconstituted behind the cuff prior to cuff placement (Fig. 44.4C). With the supplemental tissue, the circumferential measurement is increased, allowing for larger cuff placement (6).

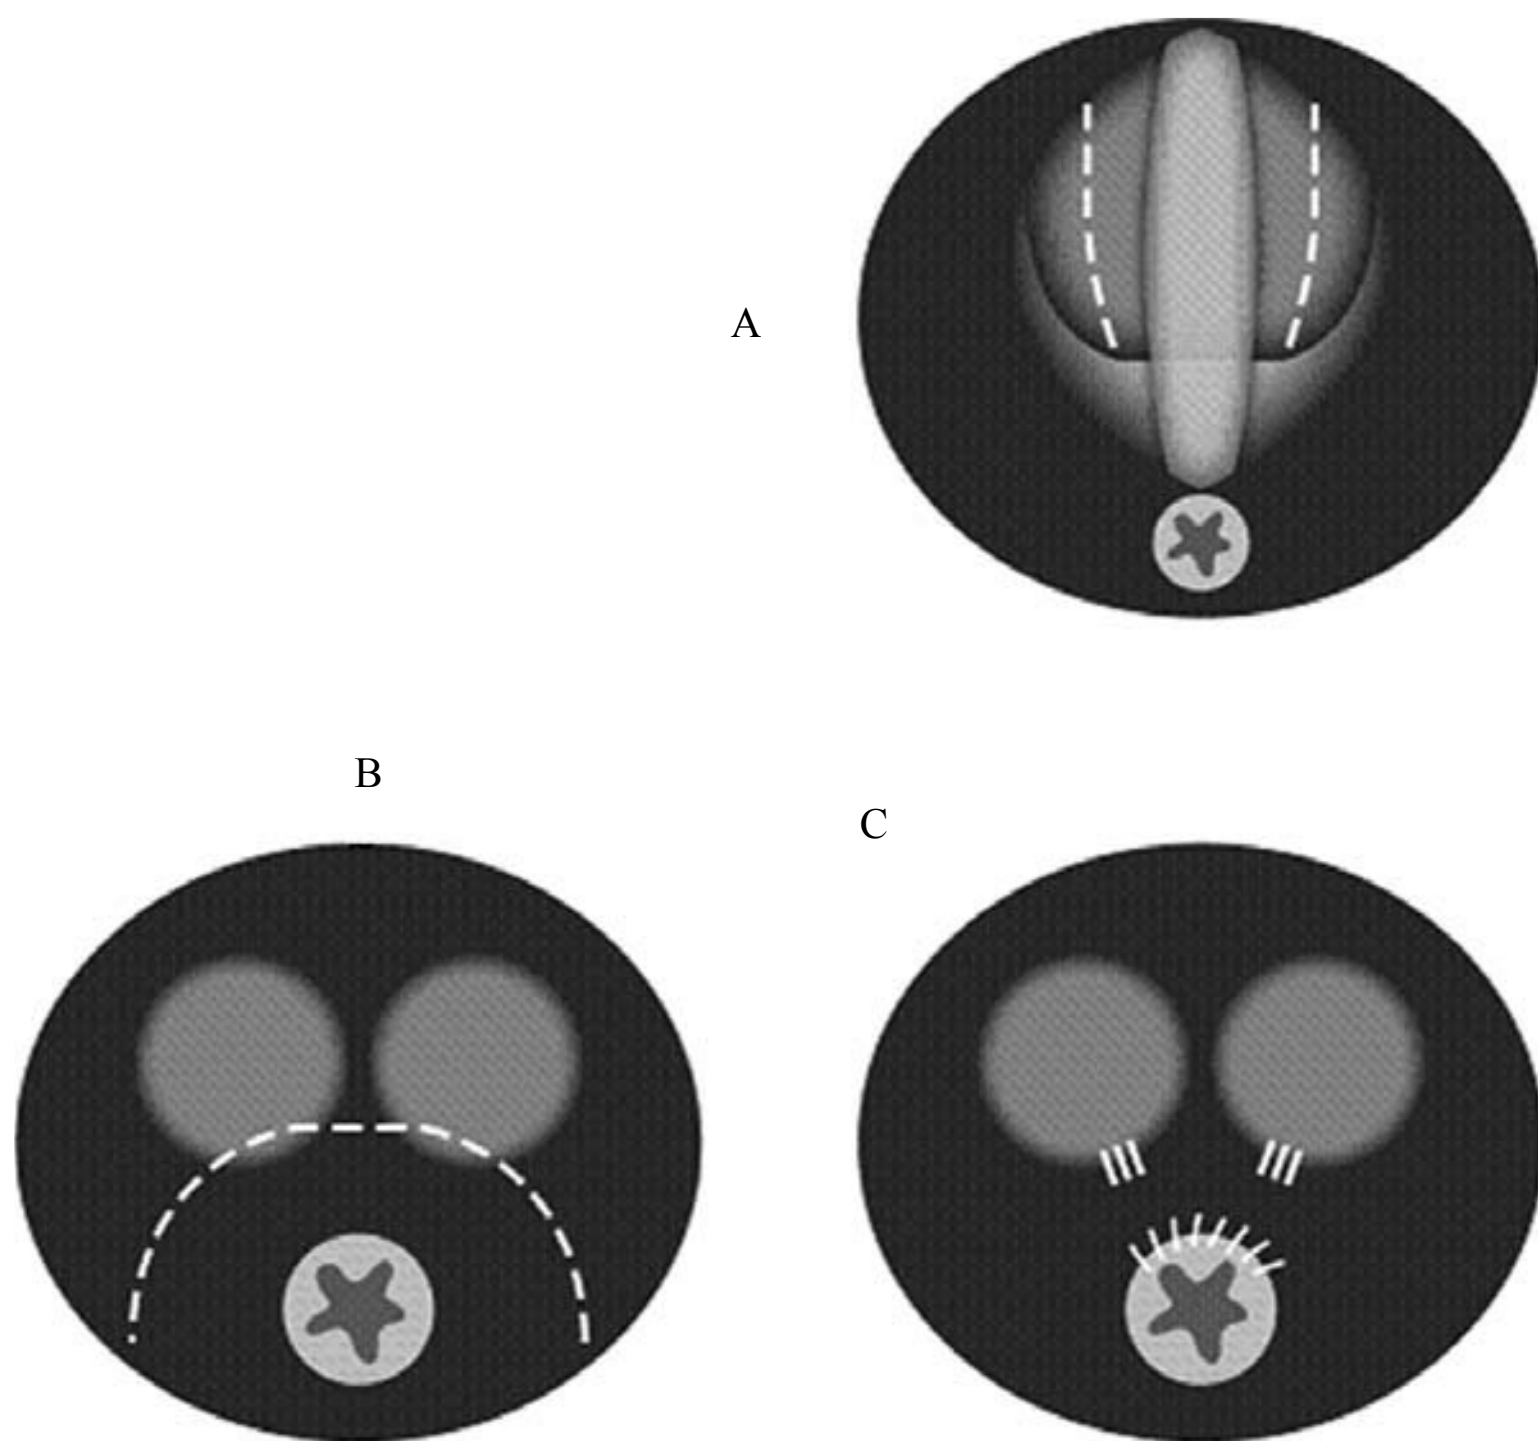

---

### Transverse Scrotal Incision for Placement of AUS

---

Conventional placement of the AUS is via a perineal incision and a separate suprapubic incision for the pressure-regulating balloon. In 2003, Wilson et al. (7) reported on the transverse scrotal incision, which uses a single incision to place all components of the AUS (Fig. 44.5). The patient is placed in the supine position with gentle abduction of the hips with the legs on spreader bars, rather than in the lithotomy position.

The perineum and lower abdomen are prepared and draped in the standard fashion. A 2.5- to 3.0-cm upper transverse

**FIGURE 44.4** **A:** Transcorporeal cuff placement: Vertical corporotomies are made bilaterally. **B:** The tunica over the corpora is left attached to the urethra for extra support of urethral tissues. **C:** The remaining tunica albuginea is reconstituted behind the position of the cuff. (Adapted from Guralnick ML, et al. *J Urol* 2002;167(5):2075–2079, with permission.)

**FIGURE 44.5** Transverse scrotal incision for placement of AUS with Lone Star ring retractor in place.

scrotal incision is made. The dissection is optimized by utilization of a self-retaining retractor combined with a dorsal meatal glans hook to stretch the penis superiorly and a penile band at the dorsal aspect of the base of the penile shaft.

The corpora are exposed proximally, and the midline attachment between the Corpora spongiosa and the scrotal septum is divided sharply (7). Pediatric Deaver retractors positioned adjacent to the corpora cavernosa are utilized to retract the scrotal wall and the bulbocavernosus muscle. The dissection is carried to the level of the perineal body. The bulbar urethra is then dissected circumferentially at the desired cuff location (Fig. 44.6). Blunt dissection is used to identify the external ring, which is placed on tension by upward retraction with a Rich or Deaver retractor. Metzenbaum scissors are used to perforate the transversalis fascia just above

### Bladder Neck Cuff Placement

For bladder neck cuff placement, a suprapubic incision (either transverse or vertical) is made to allow access to the prevesical space. Blunt dissection continues to expose the endopelvic fascia, prostate, and bladder neck area. Some surgeons leave the endopelvic fascia intact while others opt to open it, but ultimately, a plane is developed between the bladder neck and the rectum posteriorly to allow room for the cuff. If additional space is required, the endopelvic fascia may be incised and the dissection can involve some of the prostate laterally and posteriorly. The bladder can also be opened to facilitate this dissection. The dorsal vein complex can usually be left undisturbed. The sizing tape is then passed around the dissected bladder neck to determine the cuff size of the AUS, and the cuff is placed. At this level, larger cuff sizes are often used 6–8 cm. The balloon is then placed in the prevesical space. The cuff tubing is passed anteriorly and the balloon tubing inferiorly and above the rectus fascia. The reservoir balloon is filled with 22 mL of fluid. The pump is placed in the ipsilateral scrotum in a subdartos space similar to the two-incision approach. The tubing is then positioned, trimmed, and connected Quick Connect connectors. At all stages of insertion of the AUS, extreme care should be taken to avoid air bubbles getting into the system by the use of rubber shods.

## AUS Placement in Women

The main indication for insertion of AUS in the female patient is in the neurogenic population, especially those with congenital neurogenic conditions, such as spina bifida. Increasingly, however, the sphincter is being placed for patients with primary, secondary, or recurrent incontinence, especially when alternative or less invasive procedures have failed. The evaluation prior to AUS insertion is the same as that previously discussed. However, the use of topical estrogens to the vaginal tissues in postmenopausal women can improve the quality and resilience of these tissues preoperatively.

There are two approaches to the female AUS: abdominal (8) and transvaginal (9). The bladder neck is the only position available for insertion of the cuff in women. There is limited urethral length, and the dissection is more difficult due to a lack of a surgical plane between the posterior urethra and vagina. This increases the risk of early erosion in this gender. The abdominal approach involves a transverse lower midline, or Pfannenstiel, incision. A 2-cm area of bladder neck is developed, carefully avoiding perforation of the urethra, bladder, and vagina (Fig. 44.10). The dissected area is measured and the cuff is placed, with the tubing away from the vaginal wall toward the desired placement for the reservoir. Next, the balloon is placed in the paravesical space, with care taken to avoid direct contact with the tubing and connections. The pump is placed in a dependent subcutaneous portion of the ipsilateral labia majora.

The transvaginal technique involves an inverted U incision in the anterior vaginal wall, centered at the level of the bladder neck. The posterior urethral and bladder neck dissection is done under direct vision; however, the anterior part of the urethra needs to be dissected bluntly and with careful sharp dissection to avoid entering the urethral lumen and bladder. If this dissection is difficult because of previous scarring, a separate supraurethral vaginal incision can be made. The cuff is then positioned once the circumferential dissection is completed. A separate small transverse suprapubic incision is used to place the reservoir balloon and the pump, which is tunneled into the labia majora. The tubing from the cuff is passed on the suprapubic incision utilizing the tubing passer. A vaginal

**FIGURE 44.10** The abdominal approach to implantation of the AUS in women. The bladder neck region has been dissected ready for placement of the cuff.

pack is used for 24 hours, and a Foley catheter is left in place for 1 or 2 days. There have been concerns raised over an increased risk of infections and erosions using the transvaginal approach; however, in Appell's series (9), out of the 34 women studied, 56% were dry at 3 years and there were no infections or erosions reported. Others have reported conflicting opinions (10).

## Synchronous AUS and Penile Implant Insertion

The transscrotal approach for insertion of the AUS has naturally led to the development of an extended procedure to place penile implants via the same incision. The upper transverse scrotal incision used to insert an AUS is also ideal for exposing the corpora for access to penile prosthesis procedures. Despite this, there have been concerns about the risk of infection and erosion with this technique. The preparation of the patient is the same as for AUS, except that the patient is supine with legs slightly abducted. After the incision is made, the septum is incised to free the corpora. The urethra is dissected enough to place a bulbar cuff, followed by corporotomy for insertion of the penile prosthesis. The reservoirs are placed in either retropubic space and the pumps in the scrotum as usual. Bhalchandra et al. (21) recommend implanting the AUS first and deactivating the device, prior to placing the penile prosthesis. They also suggest that, to reduce the rate of erosion, primary deactivation and nocturnal deactivation are used. Furthermore, they suggest the use of a low-pressure reservoir and an inflatable penile prosthesis.

## AUS in the Pediatric Population Simultaneous with Bladder Augmentation

The usual subgroup requiring AUS in the pediatric population is either those with congenital neurogenic bladder dysfunction or those with exstrophy-epispadias complex. They often have abnormal detrusor function, which can often manifest after insertion of the AUS. Studies that have looked at the medium- and long-term outcome in the pediatric group have noted excellent continence rates of 92% at 4 years (11) and 71% to 86% at 10 years (12,13). In patients with neurogenic bladder dysfunction who are inadequately controlled by antimuscarinic medication, an augmentation cystoplasty is required. Ideally, AUS placement and augmentation may be performed at the same setting. Also, post-AUS bladder dysfunction is being recognized as a potential problem. Following augmentation with AUS, the rate of needing to self-catheterize is 60% to 70% (11–14); therefore, it is important that the patient is capable of catheterizing in some way prior to operation.

Finally, the potential problem of renal failure needs to be discussed. Levesque et al. (12) reported an 11% risk of renal failure due to high bladder pressures in their population. These patients failed to attend follow-up because they were continent and otherwise well. This problem has also been seen in other studies and highlights the need to educate patients and their family about the importance of regular follow-up after insertion of an AUS, irrespective of whether they have had an augmentation.

---

## COMPLICATIONS

---

Early complications of AUS insertion are commonly urinary retention and hematoma. Urinary retention can be managed easily with either a temporary Foley catheter or intermittent catheterization. Hematomas can occur adjacent to any part of the AUS but are more commonly found around the pump.

Infection and urethral erosion are often discussed simultaneously in studies on the AUS. Although the generally quoted incidence for this serious complication is around 3%, its incidence has varied considerably and in some studies is surprisingly high. A recent review of 270 AUS patients with 36 months follow-up reports an infection rate of 5.5% and an erosion rate of 6% (15). In a long-term study with a mean follow-up of 11 years, the infection and erosion rate was 25% (13), and in Hajivassiliou's review of the literature the incidence of erosion is 12% with infection in 4% to 5% (16). Once suspected, all components of the AUS have to be removed and a period of antimicrobial treatment and recovery needs to take place before reimplantation. The standard waiting period prior to attempting replacement is usually 3 to 6 months. Erosion can occur early and is often due to an unrecognized perforation in the urethra, or it may occur late due to chronic pressure of the cuff on the urethral tissues. Previous irradiation, trauma, or urethral scarring for any reason may increase the risk of erosion. Women are also at increased risk, as discussed previously.

Mechanical failure can occur from the outset of AUS insertion or later due to wear and tear on the AUS components. The long-term incidence of revisions secondary to mechanical failure is 32% over 11 years (13); however, in one review the figure is 12% (16). This percentage has decreased to 7.6% due to developments in AUS design such as the narrow-backed cuff (17).

If incontinence recurs, one needs to consider the patient, the device, and the bladder. It may be due to the patient not using the device properly, mechanical failure of the device, urethral spongiosal atrophy, the development of detrusor overactivity, or overflow incontinence. If the device seems to be cycling correctly, one should perform urodynamics with leak point pressures and cystoscopy to investigate the cause. If urethral atrophy is the cause, the cuff can be downsized, or, if a small cuff is already in situ, another cuff can be placed in tandem or transcorporeal cuff placement can be attempted. Overactivity of the detrusor can usually be treated with antimuscarinics; however, in the neuropathic population it often requires augmentation of the bladder.

---

## OUTCOMES

---

Of the long-term follow-up studies for the AUS, Hajivassiliou (16) found that the overall continence rates are 73% with 88% improved continence. Venn et al. (13) found an overall continence rate at 10 years of 84%. The best results were in the postprostatectomy group, who had cuffs placed at the bulb (92% dry at 10 years). This group also had the least chance of infection of the AUS. The overall risk of revision was 54% (13). The continence rate in patients with postprostatectomy incontinence is excellent, with long-term continence exceeding 90% (13,17,18). The revision rate in this group is about one-third, but patient satisfaction is consistently high.

Revision rates of the AUS vary, but of the studies looking at long-term survival of grafts, the overall revision rates are between 26% and 32% (16,17). Hajivassiliou (16) found a revision rate of 32%, with 90% of revisions needing to be done within the first 3 years following insertion of the AUS. Revisions are generally due to mechanical or nonmechanical failure. Mechanical failure is usually due to leakage of the device, malfunction of the pump, or kinks in the AUS tubing. Nonmechanical failure is due to infection or erosion and urethral atrophy. The incidence of mechanical failure is between 13% and 27%, and that of nonmechanical failure is 13% to 37% (13,17,18). Problems with the pump account for the majority of mechanical failures (43.8%) (17).

In women, results of AUS are variable and population numbers often small. One recent series (19) studied the long-term follow-up of 68 female patients. They found that at 7 years, 81% were dry, with a revision rate for erosion or infection of 46%. Those with neuropathic etiologies had a continence rate of 90%, although 50% of these required revision surgery. In the Type III incontinence group, 83% were dry.

---

### Influence of Previous Radiotherapy on Results of AUS

---

Previous irradiation is known to be a risk factor for urethral erosion and the need for revision of the AUS (4). Irradiation of tissues is thought to produce a change in vascularity and fibrosis over time. It can cause hypovasculation of the urethral tissue and may affect the function of the bladder by similar mechanisms. Continence rates following insertion of the AUS in irradiated patients vary from 64% to 70% (20,22), and overall continence rates do not differ significantly between the nonirradiated and irradiated groups. Revision rates can be higher in the irradiated group, usually due to atrophy. In one study, 42% of patients had previous radiotherapy, and in this group, 51% (compared with 15% of the nonirradiated group) needed revision, mostly for urethral atrophy (22). Urethral atrophy seems to be related to intrinsic urethral hypovascularity, which has been reported in many studies looking at this group. In other studies, however, the revision rates for those with and without previous radiation treatment are similar, with rates of 25% versus 22.5% (20) and 15.4% versus 20.6% (17). The risk of infection and erosion may also be higher in irradiated patients, although evidence is inconsistent.

Cuffs are usually placed at the bulb in this group, and the cuff size is determined in the usual way by sizing the urethra. Generally, however, most authors prefer to place lower-pressure reservoir balloons to reduce the risk of pressure necrosis of the urethra and thereby reduce urethral atrophy and erosion (22,23). There is a higher reported incidence of detrusor overactivity in patients who have been previously irradiated (20,22); however, this does not seem to influence the failure rate of AUS insertion, presumably because this is treated prior to placement.

AUS insertion is currently the best long-term treatment in patients with sphincter dysfunction and previous irradiation. Despite higher revision rates, the results are good in the male population. Importantly, patient satisfaction rates are consistently high (20). In women, the results of AUS insertion in conjunction with radiotherapy are particularly poor. In one series (19), all women with a history of irradiation failed and had their AUS removed.

## CHAPTER 45 ■ THE MALE SLING FOR POSTPROSTATECTOMY INCONTINENCE: CURRENT CONCEPTS AND CONTROVERSIES

CRAIG V. COMITER

### PREVALENCE OF POSTPROSTATECTOMY INCONTINENCE

The most common cause of stress urinary incontinence (SUI) in men is iatrogenic injury during prostate surgery. The rate of incontinence following surgery for benign prostatic hyperplasia is approximately 2% (1). On the other hand, the risk of urinary incontinence is significantly higher following surgery for prostate cancer. While reports of postprostatectomy incontinence (PPI) vary, contemporary cohort studies generally agree that between 5% and 11% of patients will have enough leakage after radical prostatectomy to seek further treatment (2,3). In a recent study by Stanford et al, patients were evaluated using a self-administered questionnaire. Only 32% claimed total urinary control, 40% had occasional leakage, 7% had frequent leakage, and 2% suffered from no control at 2 years

postoperatively. Regarding pad usage, 18% utilized one to two pads per day, while only 3% required 3 or more pads per day (3). Regardless of the definition of PPI, a significant minority of patients will have enough urinary leakage to require pad usage and seek further therapy.

The male sling (MS) has recently emerged as an alternative to the artificial urinary sphincter (AUS) for the surgical treatment for PPI. The modern MS is based on the early concepts described by Berry in the 1960s and Kaufman and Kishev in the early 1970s. The Kaufman and Kishev prostheses ultimately fell out of favor due to long-term failure, infectious complications, and pelvic pain, concomitant with the emergence of the modern artificial urinary sphincter (AUS). Schaeffer from Northwestern (Clemens et al., [4]) described a novel bulbourethral sling procedure in 1999. Bolsters were placed beneath the bulbar urethra to form a sling; the bolsters were suspended from the rectus fascia by sutures. However, despite excellent continence rates, 21% of patients required

revision of the sling, and in 6% bolster removal was necessary secondary to infection or erosion (4). Recent alterations of the MS have been described with modification of the sling material but preservation of the concept of suburethral compression. By far, the most significant innovation affecting male sling surgery has been the use of bone screws. *This purely perineal approach transformed the surgery into a reproducible, standardized, and minimally invasive outpatient procedure.*

---

## DIAGNOSIS

---

Evaluation of a patient should begin with a detailed history of the lower-urinary-tract symptoms. However, the pathophysiology of PPI is variable, and history alone is not sufficient to distinguish between bladder causes (poor compliance, detrusor overactivity, detrusor underactivity) and outlet causes (sphincteric insufficiency or bladder outlet obstruction) of incontinence. A micturition diary is useful for quantifying frequency, incontinence episodes, and functional bladder capacity. Physical examination should focus on neurourological assessment, and urinalysis is helpful to rule out infection. Urodynamic evaluation is strongly recommended prior to consideration of invasive therapy. Filling cystometry can assess bladder storage, and outlet function may be evaluated by measurement of antegrade or retrograde leak point pressure. While the majority of men with PPI suffer from intrinsic sphincter deficiency (ISD), only 25% to 50% will have ISD alone on urodynamics. Approximately 40% of patients with ISD will demonstrate concomitant bladder dysfunction, and 15% of patients with PPI demonstrate only bladder dysfunction (5).

While patient preference and pad usage clearly dictate the implementation of surgical treatment, it is important to accurately quantify the *degree* of sphincteric incompetence, as this factor may affect the type of treatment recommended for the management of the stress incontinence. For example, patients with higher abdominal leak point pressure (ALPP) (and therefore a lower degree of ISD) tend to respond better to periurethral bulking agents than do patients with a lower ALPP. Patients with more profound sphincteric incompetence are more appropriately treated with artificial sphincter or sling surgery.

---

## INDICATIONS FOR SURGERY

---

Surgical intervention is indicated for treating bothersome SUI due to ISD that fails to adequately improve following 12 months of active conservative management. Severity, effect on quality of life, and the ability of the patient to conservatively manage incontinence must be balanced against the risks of surgery. The male sling and artificial urinary sphincter both address the underactive outlet by increasing resistance to urinary flow during storage. Resistance to leakage is created by applying pressure over a length of urethra utilizing the MS mesh or the AUS cuff. These forces are concomitantly applied to the blood supply of the compressed urethral segment, and may thereby result in urethral ischemia. Device construction, component selection, and implantation technique must therefore aim to optimize urethral compression while minimizing the risk to urethral viability.

The frequency, severity, social impact, and effect on hygiene and quality of life of the incontinence must be balanced against the ability of the patient to conservatively manage the condition. In addition, reasonable physician and patient expectations based on reproducible results of clinical efficacy, acceptable morbidity (severity, duration, and need for additional therapy), and the avoidance of serious complications are essential. The AUS and the MS should be implanted cautiously in patients with uncontrolled detrusor overactivity or decreased compliance. In addition, those conditions that may require future transurethral management are relative contraindications to outlet surgery, especially if the AUS or MS would impair transurethral access or if repeated instrumentation would put the devices at risk for infection or erosion.

---

## ALTERNATIVE THERAPY

---

---

### Nonoperative Management

---

Many patients will regain satisfactory continence within the first 12 months following prostate cancer surgery. Thus treatment within the first year is usually conservative. Unfortunately, there is currently no effective FDA-approved pharmacotherapy for intrinsic sphincter deficiency. Furthermore, blood pressure effects and a generalized lack of supportive evidence for the use of alpha-agonists have limited their utility in the management of PPI. Active conservative management therefore usually relies on fluid restriction, prompted voiding, and pelvic floor exercises. While pelvic floor exercise therapy instituted prior to radical prostatectomy aids in the earlier achievement of urinary continence, the value of the various approaches to prolonged conservative management for PPI generally remains uncertain.

Noncurative management options to control urinary leakage also include the use of an indwelling catheter, an external collection device (condom catheter or pads), or a penile clamp. However, these conservative options are not without risk. An indwelling catheter may cause recurrent urinary tract infections, stone formation, urethral injury, and even metaplastic and neoplastic changes in the bladder mucosa. A condom catheter requires a drainage bag, and with the penile shortening that commonly occurs after radical prostatectomy, it may be difficult to secure. The penile clamp may cause discomfort and skin irritation but may be particularly useful during the period of active conservative management.

Periurethral bulking agents represent another “nonoperative” treatment for PPI. Carbon-coated zirconium beads in beta-glucan gel, bovine glutaraldehyde cross-linked collagen, and polydimethylsiloxane are the most popular injectable agents for SUI in men due to ISD. “Cure” rates for transurethral (retrograde) collagen injection have generally been low for PPI, and antegrade injection does not offer any significant advantage over the retrograde technique.

---

### Artificial Urinary Sphincter

---

The AUS circumferentially occludes the urethra by exerting continuous compressive pressure. The AUS was introduced in 1973, and numerous design changes have culminated in the AMS 800 urinary prosthesis (American Medical Systems,

Minnetonka, MN; hereafter AMS). Cuff closure pressure is controlled by a balloon reservoir, generally at 61- to 70-cm H<sub>2</sub>O pressure. Normal voiding can only occur during temporary relief of urethral occlusion by activation of a scrotal pump that diverts compressive fluid from the cuff to the balloon reservoir. *Experience with the AUS for greater than three decades has demonstrated consistent and excellent results. The circumferential compression of the urethra, with an appropriately sized cuff and appropriately pressurized balloon reservoir, appears to be efficacious in treating all degrees of SUI.*

When reported by itself, the infection rate with initial AUS surgery is generally 1% to 3%, but it can be as high as 10% in patients' status after pelvic radiation and in reoperations (2). In most recent reports, with the routine practice of delayed cuff activation, erosion rates are in the range of 1% to 5% following initial surgery (2). The introduction of the narrow-backed cuff has led to substantial decreases in device failure, with nonmechanical failure decreasing from 17% to 9% and mechanical failure decreasing from 21% to 8% (2). With recurrent ISD due to urethral atrophy, revision of the AUS may be indicated. The AUS revision rate is generally 17% to 25% at 5 years since the introduction of the narrow-backed cuff (2).

## RATIONALE FOR THE MALE SLING

The impetus for the design of the modern male sling (MS) was to decrease the risk of device infection and urethral erosion, minimize the incidence of urethral atrophy that is associated with the AUS, and allow for spontaneous voiding without the need for device manipulation. The MS is a noncircumferential device that is placed with the aim of applying sufficient urethral occlusive pressure to prevent leakage yet permit normal spontaneous voiding without the need for device manipulation. Recent experience with the MS has taught several lessons regarding the management of PPI with sling surgery: (a) adequate but not excessive tension is necessary for urethral compression and continence; (b) well-designed synthetic materials have an acceptably low rate of infection and erosion; (c) adequate detrusor contractility is necessary to overcome the fixed resistance of the sling; (d) various methods of sling fixation can achieve successful urethral compression; and (e) patients with more severe or total urinary incontinence appear to have a lower success rate with the MS than do patients with more mild to moderate degrees of incontinence (6).

## SURGICAL TECHNIQUE

As the bone-anchored MS is the most commonly performed sling procedure for the treatment of PPI, the technique for this particular approach is described. The surgery is performed under general anesthesia with the patient in lithotomy position. A negative urine culture is required prior to surgery. Intravenous cephazolin (or vancomycin plus gentamycin, if allergic) is given within 1 hour of surgery. After the patient is prepared and draped in a sterile fashion, a 14Fr Foley catheter is passed per urethra to help identify the perineal portion of the urethra. A 3- to 4-cm midline incision centered over the bulbous urethra is made. The bulbospongiosa are exposed in the midline, and the medial aspects of the descending pubic

**FIGURE 45.1** Three bone anchors with no. 1 polypropylene sutures are placed into each descending ramus.

rami are then exposed bilaterally. Using the InVance bone drill (AMS), three titanium bone screws, each loaded with a pair of no. 1 polypropylene or braided polyester sutures, are inserted in the medial aspect of each descending ramus: just beneath the pubic symphysis, at the level of the bulbar urethra, and midway between the proximal and distal screws (Fig. 45.1).

Retrograde leak point pressure (RLPP) is measured via perfusion sphincterometry. With the catheter repositioned to the penile urethra and the balloon inflated with 0.5 cc saline, a 1-L saline bag is connected to the catheter via cystoscopy tubing. The RLPP is recorded in centimeters of water as the height of the fluid column above the symphysis at which fluid flow commences (6). The RLPP represents that pressure required to overcome sphincteric resistance.

A 4- by 7-cm silicone-coated polyester mesh (InteMesh, AMS) is recommended for the sling. The left-sided bone-anchored sutures are passed through the sling 0.5 cm from the left edge, equally spaced along the width of the sling, and tied down to the bone. The right-sided sutures are then passed through the sling (Fig. 45.2) and temporarily tensioned with a single throw. RLPP is again measured, and sling tension may be adjusted by moving the right sutures medially or laterally along the sling edge until an RLPP of 60 cm of water can be demonstrated. The sutures are then tied down to the pubic bone to maintain proper sling compression. The

**FIGURE 45.2** The left sutures have been tied and cut. The right sutures are passed through the sling. Tension is determined by how laterally or medially the right sutures are placed through the sling.

catheter is then replaced into the bladder, and the wound is irrigated with antibiotic solution and closed in multiple layers with running suture, using 2-0 polyglycolic acid suture for the deep layer, 3-0 polyglycolic acid suture for the dartos layer, and 4-0 polyglycolic acid suture for the skin. A trial of voiding is performed when the patient is able to stand comfortably to void, usually within 6 to 36 hours postoperatively. Alternatively, a 14Fr suprapubic tube may be placed intraoperatively and used to monitor residual urine volume. The suprapubic tube may be removed when residual urine volume is appropriately low (i.e., equal to the preoperative postvoid residual urine volume).

## OUTCOMES

Unlike the AUS literature, reports of the success for the MS are more difficult to interpret, as most reports come from single-institution cohorts that are hampered by small numbers and usually short follow-up.

Similar to reports of AUS surgical results, “success” depends on the definition of continence, the method of evaluation, the length of follow-up, and the experience of the surgeon. In addition, the sling material and method of tensioning may also contribute to the success or failure of the procedure. However, despite these limitations that may hinder the objective evaluation of this relatively new technique, there is relatively good consistency within the literature, with success rates for the MS generally ranging from 65% to 90% (2,6).

At the author’s institution, a cohort of 48 patients with a minimum follow-up of 24 months (range, 24 to 60 months) and a median follow-up of 48 months have been followed since they underwent MS surgery between 1999 and 2003. Twenty patients had follow-up of at least 48 months, and 35 patients had follow-up of at least 36 months. The average age was  $67.6 \pm 9.7$  years. Six patients had a previous artificial urinary sphincter, 8 had adjuvant radiation treatment (XRT), 2 had primary XRT, and 9 had a previous collagen injection. All patients rated their incontinence as a “big problem” on the UCLA Prostate Cancer Index (PCI) incontinence score, and all used three or more pads daily. Preoperative mean RLPP was  $27.3 \pm 8.0$  cm of water, and patients used an average of  $4.6 \pm 2.1$  pads per day. The median preoperative UCLA PCI incontinence score was 63 (scale of 0 to 500) (6).

At a mean follow-up of 48 months (range, 24 to 60 months), the median UCLA PCI incontinence score improved to 343, and postoperative pad usage decreased to a mean of  $1.0 \pm 1.7$  pads per day. Overall, 31 out of 48 patients (65%) were cured of their leakage (no problem, no pads), 7 out of 48 (15%) were much improved (small problem, 1 pad), 3 out of 48 (6%) were mildly improved (moderate problem, 2 pads daily), and 7 out of 48 (15%) failed (big problem, 3 or more pads). Thirty-eight out of 48 patients (79%) were cured or much improved and were “socially continent,” using 0 to 1 pad per day (6).

Previous collagen injection and previous *adjuvant* XRT did not affect outcome, but both patients with primary XRT failed, and 5 out of 6 patients (83%) who had previously had AUS implantation failed. In the group of 7 patients who failed to improve, 2 had primary XRT, 5 had previous AUS, and 1 had pelvic trauma.

TABLE 45.1

### URODYNAMIC EFFECT OF MALE SLING ON VOIDING

	$Q_{\max}$ (mL/s)	$P_{\det}Q_{\max}$ (cm water)
Preoperative	$19.2 \pm 9.7$	$40.3 \pm 9.2$
Postoperative	$17.7 \pm 6.5$	$45.8 \pm 14.7$

Urodynamic evaluation of a subgroup of 22 volunteer patients at an average of 25 months follow-up revealed an increase in RLPP from a mean of  $30.4 \pm 15.7$  to  $59.9 \pm 9.7$  cm water following sling surgery ( $p < 0.001$ ). There was no significant change between intraoperative RLPP and RLPP on postoperative urodynamics ( $59.9 \pm 9.7$  versus  $56.7 \pm 10.4$  cm water). No patient demonstrated BOO on urodynamics preoperatively, and none developed iatrogenic bladder outlet obstruction (BOO) following sling surgery. The average maximum flow rate ( $Q_{\max}$ ) following surgery ( $17.7 \pm 6.5$  mL per second) did not significantly differ from preoperative  $Q_{\max}$  ( $19.2 \pm 9.7$  mL per second). Nor was there a significant change in detrusor pressure at  $Q_{\max}$  ( $P_{\det}Q_{\max}$ ), averaging  $40.3 \pm 9.2$  cm water preoperatively and  $45.8 \pm 14.7$  cm water postoperatively (Table 45.1). Average postvoid residual urine was  $17 \pm 26$  mL (range, 0 to 94 mL). While 4 patients demonstrated detrusor overactivity (DO) postoperatively, none developed symptomatic de novo urgency or urge urinary incontinence postoperatively.

## COMPLICATIONS

The infection or erosion rate for the MS is quite low (2.1%), and the rate for the need for revision (secondary to bone-anchor dislodgement) is 4.2% (6). In addition, there have been no reported instances of urethral atrophy resulting in recurrent incontinence. Bothersome scrotal pain or numbness affects 5% to 16% of patients, which typically resolves within 3 months (6).

## CONTROVERSIES IN MALE SLING SURGERY

### Tensioning Sling

Unlike the woman with urethral hypermobility and preserved intrinsic sphincter function, the male with SUI suffers mostly from ISD. And just as one measures the circumference of the urethra to determine appropriate AUS cuff size, one should measure sling tension to provide sufficient urethral compression when placing the MS as a surgical treatment for ISD. Various successful tensioning techniques have been described, including measurement of leak point pressure, tensioning based on “cough leakage,” and tensioning based on visual estimation. The author recommends perfusion sphincterometry, with a goal of 60 to 70 cm water compression pressure based on the well-known success of the 61- to 70-cm water balloon pressure of the AUS. Ullrich and Comiter (7) demonstrated that patients who achieve a RLPP of 60 cm have a better outcome than those who demonstrated a lower compression

pressure. Furthermore, in patients who have undergone surgery with targeted tensioning based on measurement of RLPP, there have been no instances of prolonged urinary retention (6).

---

### Sling Material

---

It is vital that synthetic material be utilized so that the tension can be maintained adequately over time. The rate of infection with synthetic material is acceptably low.

---

### Contraindications

---

Similar to AUS surgery, MS surgery is contraindicated in patients who may require future transurethral surgery (e.g., recurrent urolithiasis, transitional cell carcinoma, or unstable anastomotic or urethral stricture disease). Not only might the MS impair transurethral access, but also repeated instrumentation may put the devices at risk for infection or erosion. In addition, sling surgery should be carefully considered in patients with uncontrolled detrusor overactivity or decreased compliance, as increasing outlet resistance will not help either of these conditions and could theoretically put the upper urinary tract at risk.

---

### Detrusor Hypocontractility

---

Bladder contractility can be measured preoperatively via pressure flow study. In patients with normal detrusor contractility, there have been no reported instances of prolonged postoperative urinary retention when using 60 cm water RLPP as an intraoperative guide to sling tensioning (6). Whereas the AUS can be deflated to allow voiding with abdominal straining, the fixed resistance of the sling will interfere with Valsalva voiding. *Therefore, in patients with detrusor hypocontractility, AUS implantation is recommended rather than MS surgery.*

---

### Radiation

---

Full-course external beam radiotherapy appears to be a contraindication to sling surgery. In fact, radiation was the only factor that predisposed to failure of the Northwestern sling (success rate was only 29% for irradiated patients, versus 68% for nonirradiated patients) (4). Interestingly, the success rate for bone-anchored MS surgery is not adversely affected by *adjuvant* radiation following prostatectomy (6).

---

### Severe Incontinence

---

Two recent reports demonstrated that patients with more severe incontinence preoperatively are at higher risk for postoperative incontinence following sling surgery (8). Experience with the AUS for greater than three decades has demonstrated consistent and excellent continence results for all levels of urinary incontinence (7). The circumferential compression of the urethra, with an appropriately sized cuff and appropriately pressurized balloon reservoir, appears to be efficacious in treating most cases of male SUI. *Thus, in men with severe incontinence (>450 g per 24 hours urinary leakage), AUS may be more appropriate than MS surgery.*

---

### Sling Failure

---

In the case of suboptimal continence following sling surgery, it is preferential to leave the previously placed sling in situ and to place the AUS cuff distal to the sling, via a transscrotal approach. This approach has two advantages: (a) it avoids the previous operative field, minimizing dissection through potentially scarred tissue; and (b) it leaves the proximally placed sling as a partially effective compressive device, similar to a tandem-cuff AUS. In cases where the surgeon elects to place the AUS cuff transperineally, the previous sling neither renders the operation more difficult nor decreases AUS efficacy (2,6). The silicone-coated polyester sling is only partially incorporated into the subcutaneous or periurethral tissue, and it is relatively straightforward to remove. The bulbospongiosus may then be split and dissected off the underlying spongy urethra without difficulty, and the AUS may be placed in routine fashion.

---

### Previous AUS Surgery or Previous MS Surgery

---

In patients who have failed previous AUS surgery or previous MS surgery, AUS is preferred over the MS, as previous AUS implantation and explantation may contribute to urethral fibrosis, thereby preventing adequate urethral coaptation with the ventrally placed sling (2,6). In cases of severe urethral atrophy, double-cuff AUS placement or transcorporal AUS cuff placement may be indicated.

---

### Transobturator Male Sling

---

The advent of bone screws has simplified the sling procedure and obviated the need for an abdominal incision, and subsequently the bone-anchored perineal sling has become the most common sling surgery for PPI. However, despite the small size of the perineal incision, bothersome, albeit temporary, scrotal pain or numbness affects 5% to 16% of patients and can last for up to 3 months (2,6). Such pain is likely due to irritation of pudendal nerve branches along the medial pubic rami in the area of the bone screws and/or to the sling “pulling” the pubic rami toward each other. Other limitations include the theoretical risk of osteitis and osteomyelitis, and the high cost of the disposable drill and bone screws. Hence there is a quest for a suburethral sling independent of bone-anchor fixation, which at the same time does not rely on retropubic suture placement and the associated risk of bladder injury.

This has led to a recent interest in an MS placed via a transobturator approach. However, a recent report comparing transobturator sling and retropubic sling demonstrated that the tension-free transobturator sling has been shown to be six times more likely to fail than a retropubic sling in women with significant ISD, due to the fact that the transobturator placement of the sling results in lower upward tension on the urethra than with retropubic slings (9). *Since PPI is due to ISD rather than urethral hypermobility, it is unlikely that a transobturator sling alone can provide enough urethral resistance for adequate continence in men with PPI.*

A recent series of 20 patients who underwent transobturator sling placement (AdVance, AMS) for PPI had disappointing

results, with a continence rate of only 40% at 6 weeks post-operatively (10). Klingler and Marberger (11) observed in their series of removal of unsuccessful transobturator slings that there was significant narrowing and kinking of the urethra, which led to voiding symptoms and elevated residual urine without providing significant continence. They hypothesized that the narrow transobturator sling could not adequately stabilize the posterior urethra and bladder neck, but rather produced a narrow and suboptimal urethral compression.

It appears, based on these early reports, that the transobturator approach, by ventral elevation and compression of the bulbous urethra, may not be an adequate substitute for the more distal urethral compression against the perineal membrane and pubis provided by a perineal sling. On the other hand, the transobturator ventral urethral elevation and compression may be more successful as an *adjunct* to the perineal sling, rather than a *substitute* for it, by adding a component of ventral urethral elevation to the urethral compression provided by the perineal sling. Comiter and Rhee (12) have recently described a combination transobturator-plus-suprapubic sling utilizing a 5.5- by 7-cm woven polypropylene sling with two 1.5- by 22.5-cm inferior extensions and two 1.5- by 25-cm superior extensions (Fig. 45.3A). The inferior extensions are passed via a transobturator approach, providing ventral urethral elevation and compression, and the superior extensions are passed via a suprapubic approach, providing broad perineal urethral compression, similar to the bone-anchored sling (Fig. 45.3B). This combination sling, using the VIRTUE sling system (Coloplast, Minneapolis, MN), was initially evaluated in a cadaveric study, with each of the two sling components mediating increased urethral resistance (as demonstrated by urethral pressure profilometry). Two patients with severe ISD who had failed previous artificial sphincter placement, each requiring six pads per day, have realized total resolution of their SUI at >1 year follow-up (12).

## SUMMARY

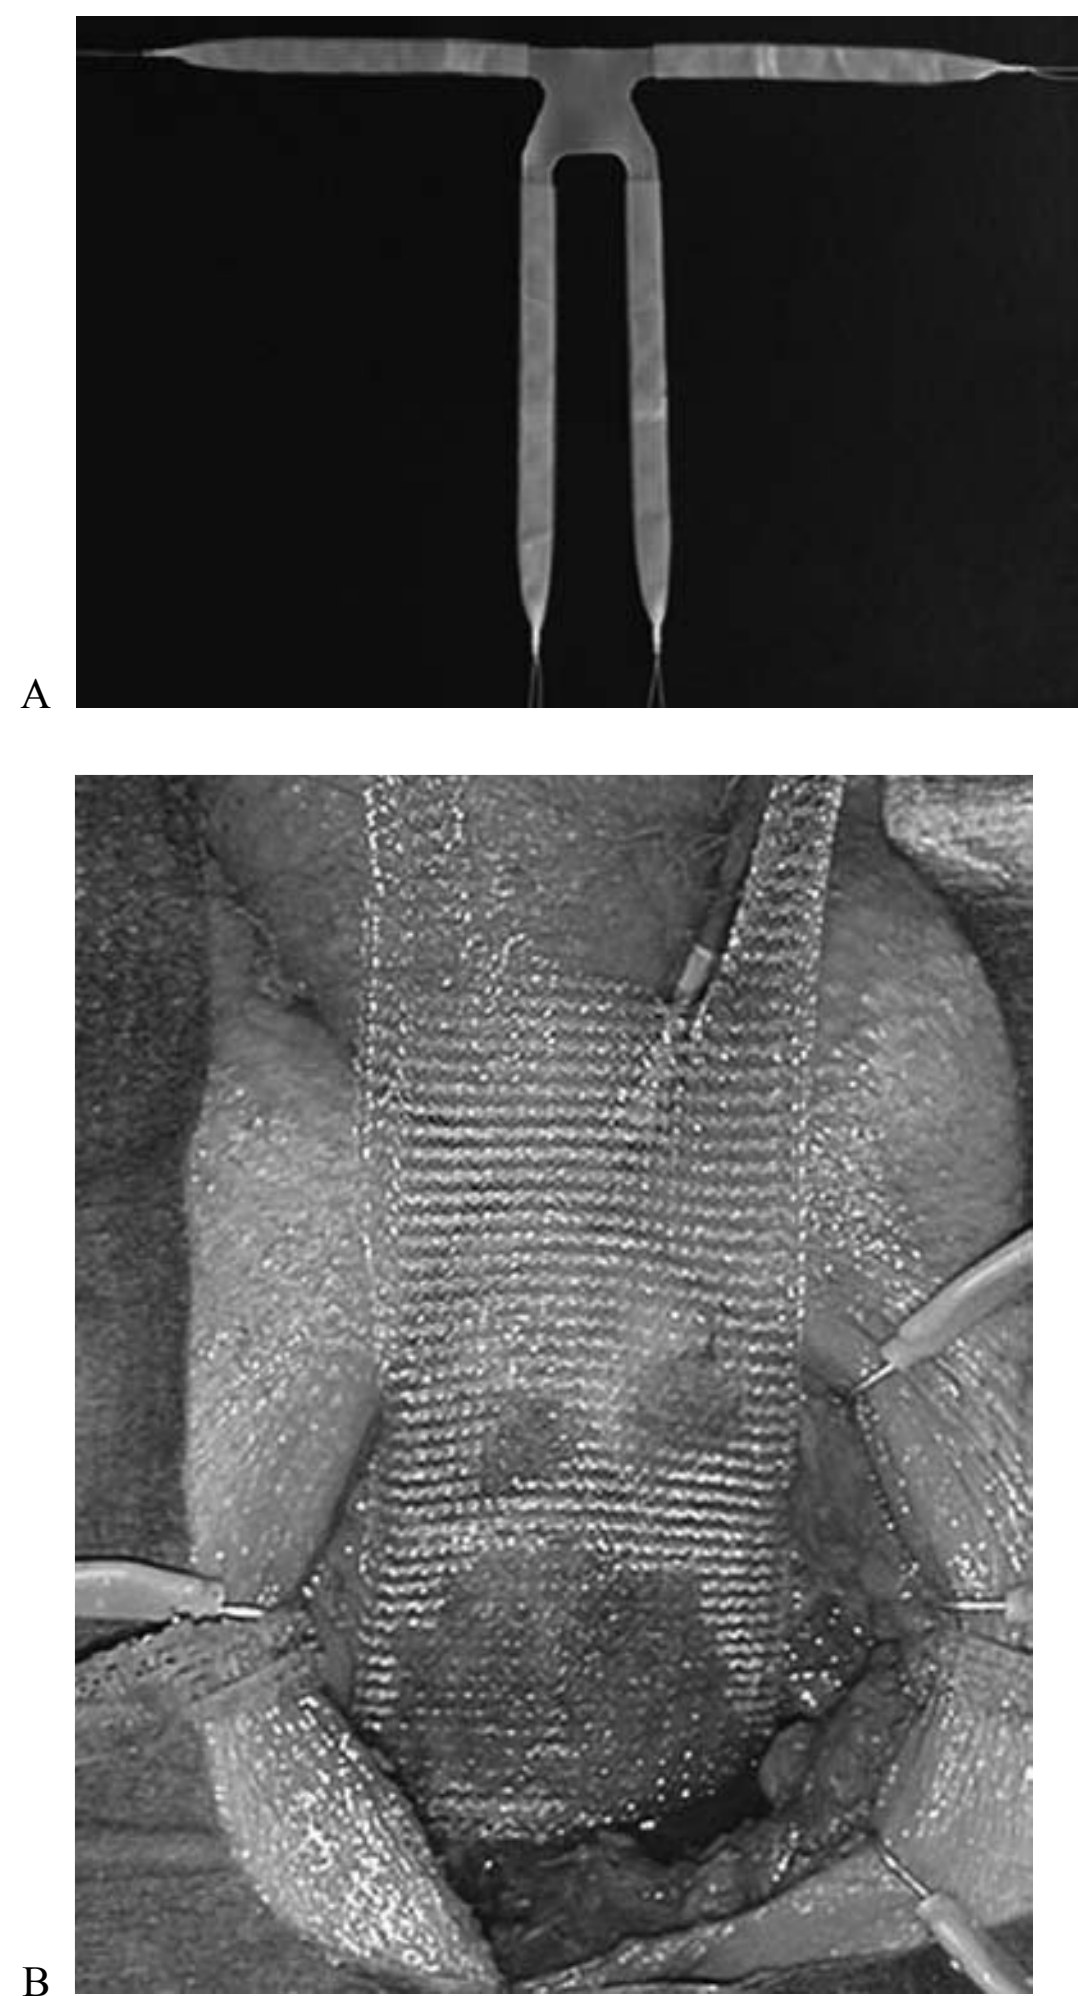

Male SUI is usually iatrogenic and can be a bothersome complication of prostate cancer surgery, causing approximately 10% of patients to seek further treatment. After 12 months of active conservative management, surgical intervention is often indicated. Transurethral injection of bulking agents, while minimally invasive, has not proven successful in either the short or long term. The AUS and suburethral sling are both safe and efficacious treatments for PPI secondary to ISD.

For severe incontinence, including total urinary incontinence due to profound sphincteric insufficiency, the AUS appears to have higher efficacy than does the MS. For more

mild to moderate SUI, where the patient has sufficient intrinsic sphincteric function to store urine but leaks during strenuous activity, the success rates for the two procedures appear more or less equivalent. While the AUS has a longer track record of success than the more recently described MS, the complication rate and revision rate for the latter appear lower, at least in the short term. And while spontaneous voiding without the need for device manipulation is a relative advantage of the MS, the patient must have adequate detrusor contractility to realize this benefit. Both techniques represent efficacious and acceptably safe methods for the treatment of PPI, yet each has its specific role in managing patients with various degrees of leakage.

## CHAPTER 46 ■ SACRAL NEUROMODULATION

SARAH E. MCACHRAN, RAYMOND R. RACKLEY, AND SANDIP VASAVADA

The refractory overactive bladder represents one of the most challenging problems in urology as well as a clinical problem that significantly erodes patient quality of life. Symptoms include urinary frequency, urgency, urge incontinence, and nocturia. Initial treatment for patients with overactive bladder without any remediable anatomic cause is anticholinergic therapy. For patients who are not candidates for, refractory to, or cannot tolerate anticholinergic pharmacotherapy, options are limited. Augmentation cystoplasty, in which a piece of small or large intestine is used to enlarge the bladder, has traditionally been offered as a last resort. However, this is a major operation with significant potential short-term and long-term complications. Even without complications, most patients are troubled by the need for lifelong intermittent bladder catheterization after such reconstructive procedures. Sacral neuromodulation (SNM) offers an alternative to patients who have failed more conservative treatments and may be considering irreversible surgical options.

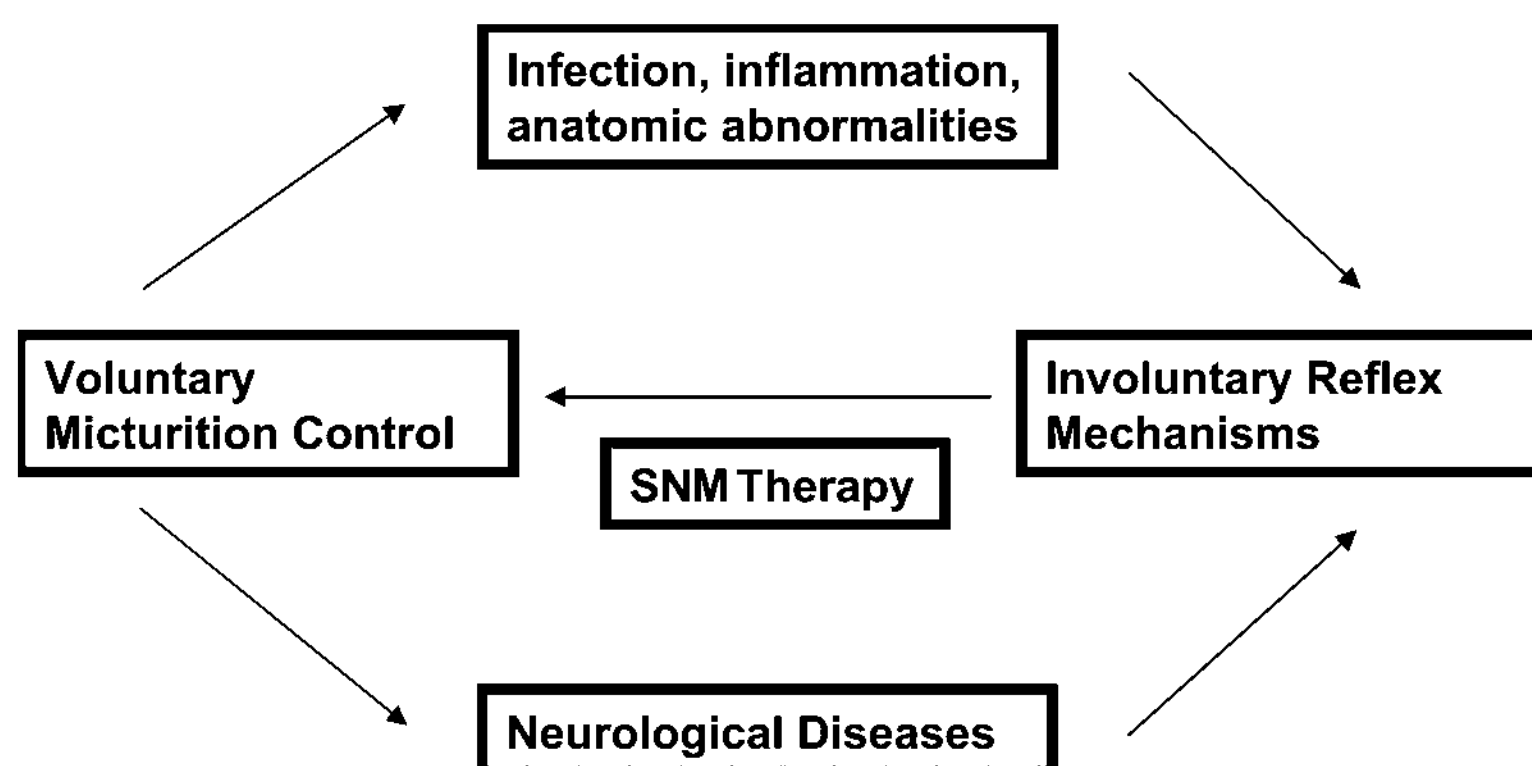

The neuromodulation that we practice today has its roots in the 1960s work of Boyce, Dees, Caldwell, and Nashold, who experimented with various modes of bladder stimulation including a transurethral approach, direct detrusor stimulation, pelvic nerve and pelvic floor stimulation, and finally spinal cord stimulation. The pioneering work of Tanagho and Schmidt in the 1980s demonstrated that the stimulation of the sacral nerve root S3 generally induces detrusor and sphincter

action (11). The U.S. Food and Drug Administration (FDA) approved SNM for intractable urge incontinence in 1997 and for urgency-frequency and nonobstructive urinary retention in 1999. Later labeling was changed to include “overactive bladder” as an appropriate diagnostic category. Since its inception, >40,000 InterStim neurostimulators (Medtronic, Inc., Minneapolis, MN) have been implanted for the three approved indications for SNM of the lower urinary tract (LUT).

### MECHANISMS OF ACTION OF SACRAL NERVE STIMULATION

#### Overactive Bladder

The ability to voluntarily store and evacuate urine is modulated by several centers in the brain. It is thought that patients with overactive bladder may have suffered an insult that effectively unmasks involuntary bladder contractions (Fig. 46.1) (6). SNM of these primitive reflexes may restore normal micturition by suppressing or inhibiting interneuronal transmission in the bladder reflex pathway (6). This inhibition may, in part, modulate the sensory outflow from the bladder through the ascending pathways to the pontine micturition center (PMC), thereby preventing involuntary contractions by modulating the micturition

**FIGURE 46.1** The concept of SNM is to modulate the abnormal involuntary reflexes of the lower urinary tract and restore voluntary control. (Adapted from Leng WW, Chancellor MB. How sacral nerve stimulation neuromodulation works. *Urol Clin North Am* 2005;32:11–18.)

reflex circuit. In clinical practice, SNM improves abnormal bladder sensations, involuntary voids, and detrusor contractions. Interestingly, voluntary voiding is preserved.

---

### Urinary Retention

---

To allow for complete bladder emptying, detrusor contractions must be coordinated with urethral sphincteric relaxation. When the suprasacral pathways that coordinate sphincteric activity are altered, the guarding and urethral reflexes that allow for urine storage without leakage still exist and cannot be turned off. This may result in urinary retention and is seen in certain patients with spinal cord injury and detrusor sphincter dyssynergia. These patients have functional detrusor contractions but are unable to coordinate this with a relaxed urethral sphincter, resulting in urinary retention. Inhibition of the guarding reflexes may improve urinary retention. SNM is postulated to turn off excitatory flow to the urethral outlet and facilitate bladder emptying.

---

### DIAGNOSIS

---

A thorough history will help delineate the nature (acute vs. chronic) and help classify the causes (neurogenic, anatomic, postsurgical, functional, inflammatory, and/or idiopathic) of a patient's LUT symptoms. Physical examination should focus on ruling out treatable causes of incontinence such as stress urinary incontinence and pelvic organ prolapse. Levator tone and function are assessed with rectal and vaginal examination; evidence of high-tone pelvic floor muscle dysfunction is often seen in patients who suffer from both overactive bladder and idiopathic urinary retention. A neurourologic examination should be performed to check for saddle sensation, sphincter tone, and intact bulbocavernosus reflex. Postvoid residual urine volume is determined. Urinalysis and urine culture are routinely performed. Urine cytology should be considered to screen for bladder cancer and bladder carcinoma in situ in those patients who present with refractory symptoms of dysuria and urgency or frequency, especially with coexistent hematuria.

Voiding diaries are invaluable. They provide an objective assessment of symptoms for both initial evaluation and for assessing response to treatment. For patients with overactive bladder, the number of voids and incontinence episodes per 24-hour period, voided volumes, and degree of urgency should be assessed. For patients with idiopathic retention, the amount spontaneously voided versus the catheterized volume per 24-hour period is useful information. Urodynamic studies (UDS) including cystometrogram, pressure-flow studies, and electromyography (EMG) of sphincters and pelvic floor muscles are performed on a selected basis. Many patients without known neurologic disorders can be thoroughly evaluated with the use of a voiding diary and a focused history and physical examination of the pelvis. However, EMG is recommended in suspected cases of neurogenic bladder dysfunction, detrusor sphincter dyssynergia, or Fowler syndrome and may be considered for evaluation of inappropriate pelvic floor muscle behavior. Additionally, urodynamics may be used to rule out treatable causes of urinary incontinence or obstruction.

Cystourethroscopy may be helpful. Urethral strictures and bladder neck contractures or fibrosis can be diagnosed.

Bladder wall trabeculation may help to confirm a clinical suspicion of bladder outlet obstruction or neurogenic pathology.

---

### INDICATIONS FOR SURGERY

---

As yet, there are still no clear predictive factors suggesting who will and will not be helped with SNM. Therefore, all patients with voiding dysfunction, both overactive bladder and idiopathic urinary retention, who are not helped by other measures may be considered candidates. A therapy trial, whether a peripheral nerve evaluation (PNE) or Stage 1 of a two-stage implant, is a minimal-risk, reversible procedure, making it the ultimate predictive test for patient selection (8).

There are several important contraindications to SNM. In patients with anatomic changes such as bony abnormalities of the sacrum, access to the sacral neural foramina may be difficult or impossible. Patients with cognitive impairment rendering them incapable of operating the device or giving appropriate feedback regarding the level and comfort of stimulation are poor candidates. Because of the unknown teratogenic potential of electrical stimulation, it has been considered contraindicated in pregnant women with various voiding dysfunctions. However, women with electrical stimulation devices for pelvic health conditions who become pregnant may simply turn off their devices when considering, and during, pregnancy.

SNM is relatively contraindicated for those patients who have an anticipated need for future magnetic resonance imaging (MRI). The potential hazards of MRI include motion, dislocation, or torquing of the implanted pulse generator (IPG), heating of the leads, and damage to the IPG, resulting in painful stimulation. A recent pilot study from Toronto evaluated eight patients with sacral nerve stimulator devices as they underwent MRI examinations at 1.5 T to study areas outside the pelvis (3). Patients were monitored continuously during and after the procedure. Voiding diaries were collected after the procedure and compared with previous records. No patient experienced painful stimulation during or after the MRI, and there were no changes in perception of stimulation. Furthermore, there were no changes in voiding diaries after the MRI. Until further evidence is collected proving the safety of MRI for this population, we advocate removal of the neuroelectrode lead without removal of the pulse generator prior to elective MRI. Following the MRI procedure, a new neuroelectrode may be placed and connected to the previously implanted and preserved pulse generator.

---

### ALTERNATIVE THERAPY

---

Generally, patients are considered candidates for SNM once they have failed other forms of therapy. For the overactive bladder population, anticholinergics tend to be prescribed first. While still considered experimental, clinical experience with botulinum toxin for the treatment of neurogenic and nonneurogenic overactive bladder is accumulating. As a last resort, bladder augmentation may be considered. Patients with idiopathic urinary retention, particularly when attributable to a hypertonic pelvic floor, should undergo a course of pelvic floor physical therapy with a physical therapist who specializes in treating pelvic floor disorders.

## SURGICAL TECHNIQUE

The procedure consists of two stages: a testing stage or first stage and an implantation stage or second stage. Since its introduction, several modifications have been made in the technology, with resultant changes in the surgical technique.

The most significant of these changes was the shift from peripheral nerve evaluation to the anchored lead staged procedure, and finally to the current tined lead staged procedure. The tined lead was introduced in 2002 and offers the advantage of simplified placement of the stimulation lead through a percutaneous approach without the need for lead anchoring to the fascia, significantly minimizing the invasiveness of the procedure (10). The lead is secured through the action of the tines (Fig. 46.2). Another surgical modification was the movement of the location of the IPG unit from the lower anterior abdominal wall to the posterior gluteal region.

The peripheral nerve evaluation was originally developed to evaluate whether or not patients would respond to SNM before implanting the IPG. Before the inception of the tined lead, implantation required a significant sacral incision and dissection to anchor the lead to the sacral fascia. A less invasive screening test was therefore desirable before committing the patient to permanent implantation. Unfortunately, the PNE lead is precarious, and it is often difficult to replicate placement with the permanent lead and therefore to replicate patient responses. Several reports have confirmed lower response rates and a higher rate of lead migration with the PNE (5). Therefore, after the introduction of the significantly less invasive tined lead, the two-stage implantation approach gained favor. However, the PNE still has proponents because it can be performed in the office setting with local anesthesia, thereby eliminating one trip to the operating room.

### PNE Test Stimulation

The patient is placed prone with slight flexion at the hips to position the sacrum horizontally. A jelly roll or other buttress

**FIGURE 46.2** The tined lead allows for suture-free anchoring to the fascia. (From Medtronic, Inc. © 2006, with permission.)

**TABLE 46.1**

### PATIENT TEST BOX SETTINGS

Rate	15 Hz	
Amplitude	Off	
Rate and pulse width selection switch	Position A	
Pulse width	210 microseconds	
Amp limit	10 V	
Electrode select switches:	0	Minus
	1	Off
	2	Off
	3	Plus

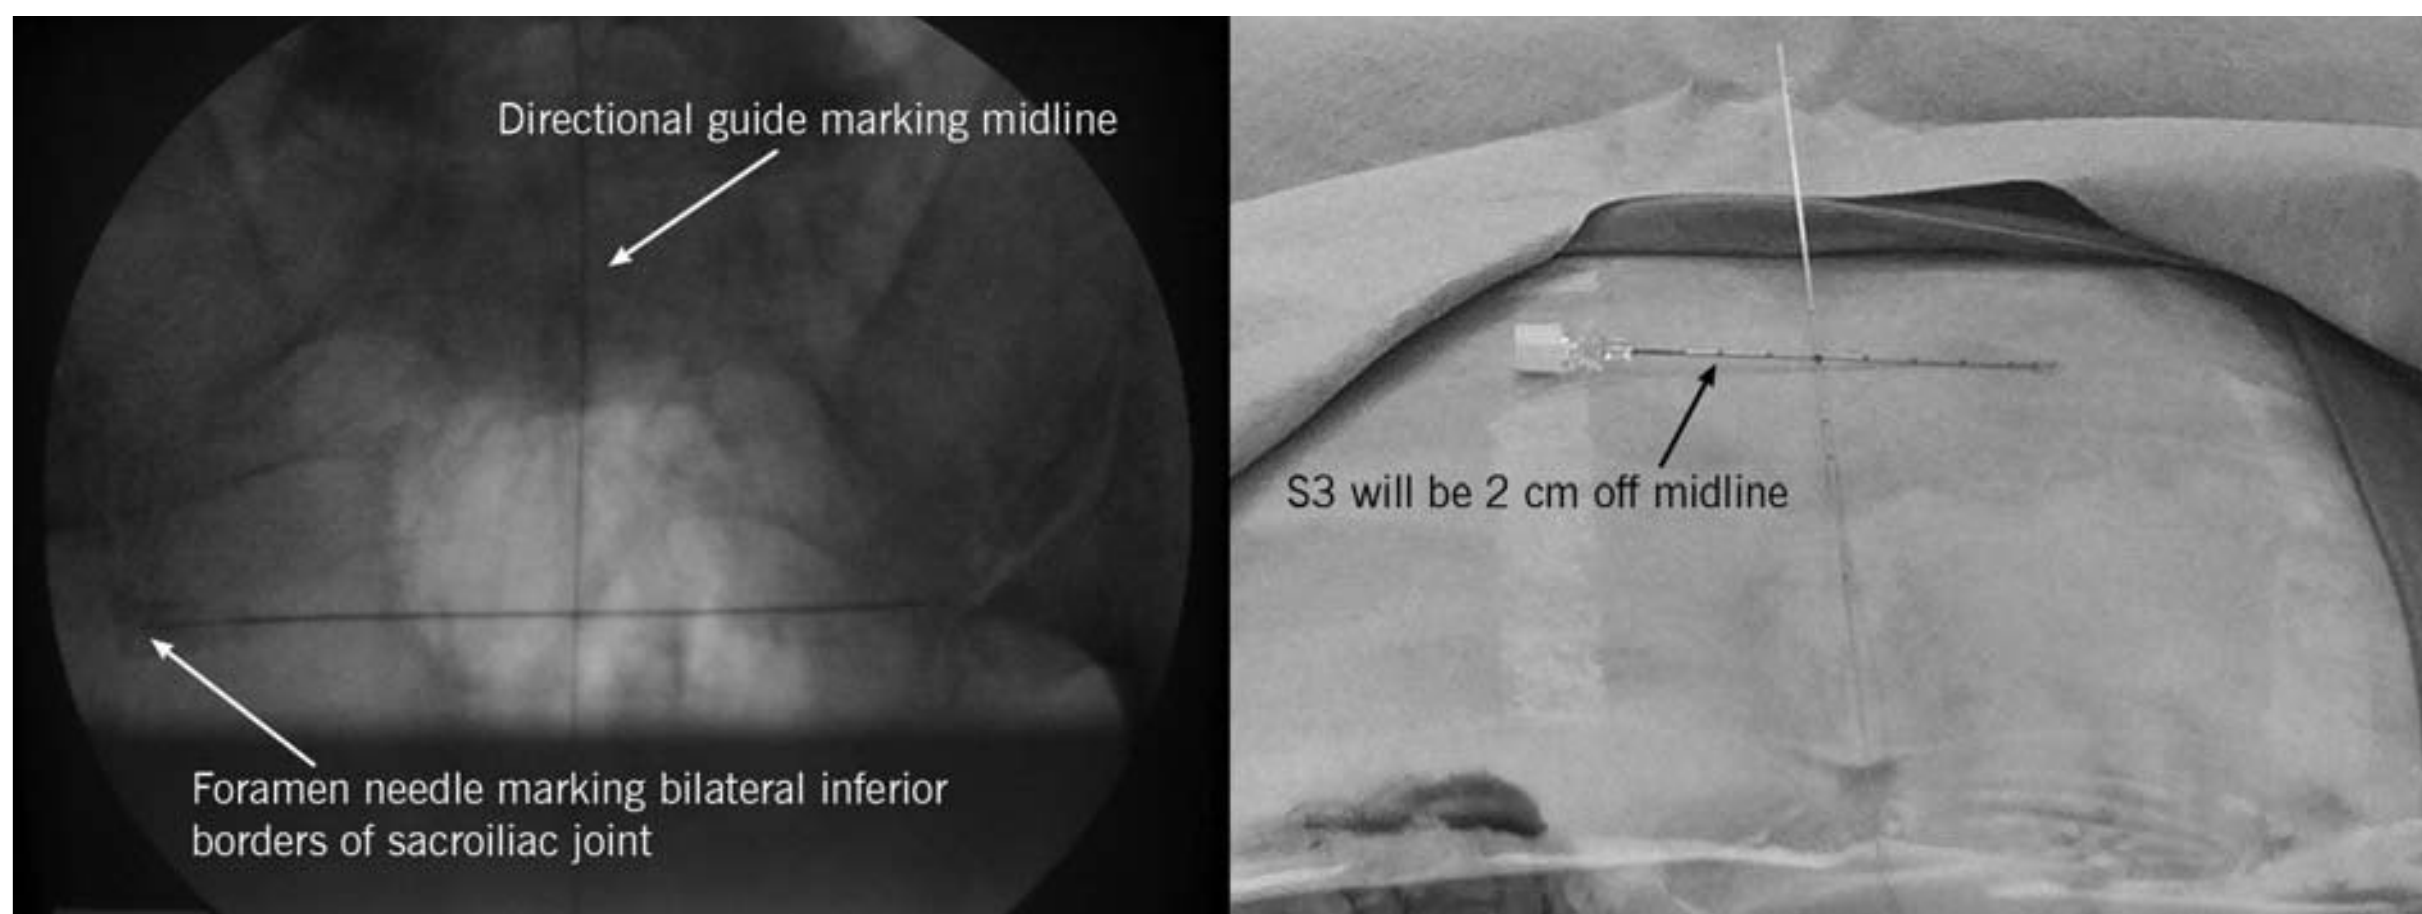

can be used. The sacrum and buttocks are prepared and the patient is draped so that the sacrum, buttocks, and feet are exposed, allowing observation of the bellows and great toe response. The ground pad is placed on the patient's heel or calf. The red plug of the long test stimulation cable is connected to the grounding pad. The black plug is connected to the test stimulation cable and the other end to the test stimulator. The initial settings for the test stimulator can be seen in Table 46.1.

### Locating Sacral Landmarks

There are several methods to locate the S3 neural foramen, the desired location for tined lead placement (Fig. 46.3). Using surface landmarks, the S3 foramen is generally located 2 to 3 cm off the midline on either side approximately 9 to 11 cm cephalad to the tip of the coccyx. If the sciatic notch can be

**FIGURE 46.3** The S3 foramen is the desired location for the lead. (From Medtronic, Inc. © 2006, with permission.)

**FIGURE 46.4** Chai and Mamo's "cross-hair" technique for S3 localization. Fluoroscopic image and surface image of the same patient. The midline is marked by the directional guide, which is placed over the spinous processes of the lower lumbar vertebrae. The foramen needle is placed so that it connects the most inferior border of the sacroiliac joints. The S3 foramina are located approximately 2 cm lateral to the junction of the two lines.

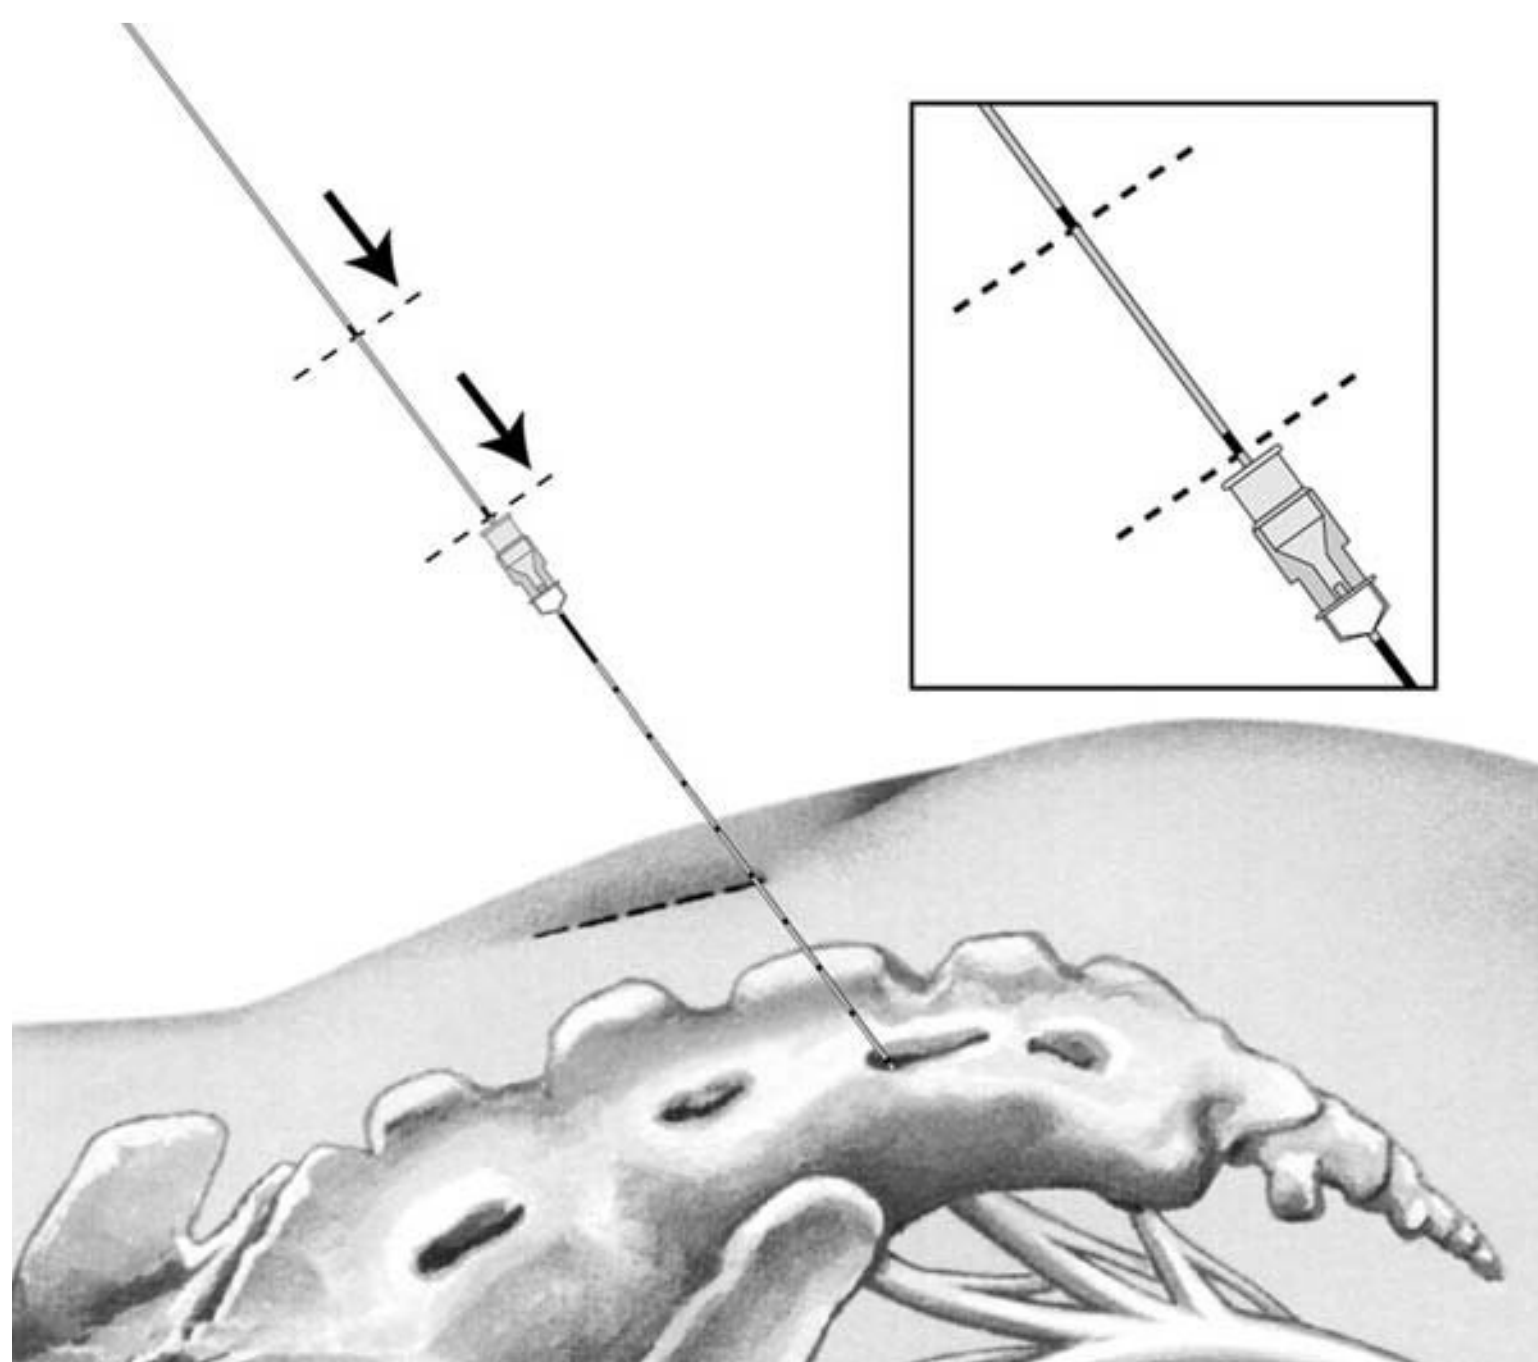

palpated, this provides a useful landmark as well. A line is drawn connecting the sciatic notches bilaterally, and an intersecting line is drawn at the midline of the sacrum. The S3 foramen can be located approximately 1 fingerbreadth, or 2 cm, lateral to the midline of the sacrum along the line connecting the sciatic notches. Less reliably, one can look for the least curved portion of the sacrum by balancing a pen on the sacral crest. This marks the level of the S4 foramen; S3 will be located about 2 cm cephalad to S4.

In 2001, Chai and Mamo (1) introduced the use of the "cross-hair" fluoroscopic technique for S3 localization (Fig. 46.4). An anterior and posterior fluoroscopic image is used to locate the inferior borders of the sacroiliac joints. This is marked with a foramen needle. The directional guide can be used to identify the spinous processes in the midline. A sterile

marker is used to trace a line along the path of both needles, creating a "cross-hair." The S3 foramen can be found approximately 2 cm lateral to the cross-hairs on either side.

#### Inserting the Foramen Needle

After injecting a buffered lidocaine solution into the skin, the subcutaneous layers and bony surface of the sacrum in the vicinity of the selected foramen are anesthetized. Care is taken not to inject anesthetic into the foramen itself as this can anesthetize the nerve intended for test stimulation. The foramen needle comes in two lengths, 3.5 and 5.0 in. After the appropriate needle is selected, it is inserted at the desired site at an angle perpendicular to the bony surface of the sacrum, thus causing it to pierce the skin at approximately a 60-degree angle (Fig. 46.5).

**FIGURE 46.5** A wire is passed through the foramen needle so that the foramen needle can be exchanged for the introducer sheath. Note that the foramen needle is inserted at a 60-degree angle to the skin. (From Medtronic, Inc. © 2006, with permission.)

TABLE 46.2

## SACRAL NERVE RESPONSES

SACRAL NERVE	MOTOR AND SENSORY RESPONSE
S2	Motor: Plantar flexion of the entire foot with lateral rotation and clamp movement of the anal sphincter Sensory: Sensations in the leg and buttock
S3	Motor: Dorsiflexion of the great toe and a Bellows reflex (anal wink) Sensory: Parasthesias or sensation of pulling in the rectum, scrotum, or vagina
S4	Motor: Bellows reflex only Sensory: Sensation of pulling in the rectum only

The operator should walk off the bone by feeling the needle as it drops through the foramen. The J hook of the patient cable is then attached to the black, uninsulated portion of the needle, just below the hub. Beginning at zero, the amplitude of the test stimulator is then slowly increased until the desired response is seen. The nerve is tested for the appropriate motor response: dorsiflexion of the great toe and bellows contraction of the perineal area (Table 46.2). The so-called bellows reflex represents contraction of the levator muscles. A fluttering or tugging sensation in the rectum, vagina, or labia is considered the ideal sensory response.

When the desired response is confirmed, the stimulation lead is placed. After the stylet is removed from the foramen needle, the test lead is threaded through the foramen needle until the depth indicator on the lead is properly aligned with the needle. The distal indicator aligns with the hub of the 3.5-in. needle, and the proximal indicator aligns with the hub of the 5-in. needle. Care must be taken as the lead is delicate and easily damaged. The lead is stimulated once again. After the appropriate response is confirmed, the foramen needle and lead stylet are removed, leaving the lead in place. Once the lead stylet is removed, the lead cannot be repositioned. The lead is taped to the

patient's skin to secure it, leaving the proximal end exposed. The ground pad is relocated to the patient's lower back. The lead is connected to the test stimulation cable and the test stimulator. It should not be left in place for >7 days.

### Stage 1 Tined Lead Placement

For Stage 1, preoperative intravenous antibiotics are given and standard aseptic techniques for the implantation of foreign bodies are implemented. An intravenous dose of either a cephalosporin, vancomycin, or a fluoroquinolone is preferred. Either general anesthesia or monitored anesthesia care (MAC) is used. MAC is preferable as it allows the patient to communicate sensory responses during the procedure. If a general anesthetic is used, no long-acting muscle relaxants should be administered as they can inhibit motor responses. The patient is prone and the buttocks are held apart using wide tape retraction so that the anus is visible during test stimulation. The anus and tape are prepared into the sterile field and then covered with a separate plastic drape until visualization of the anus is required. The patient's feet will also need to be visible during the procedure.

The foramen needle is inserted at a 60-degree angle to the skin, approximately 1 to 2 cm cephalad to the marked location of the S3 foramen. If the patient is obese, the 5-in. needle should be used and the insertion point may need to be even more cephalad. Because the pelvic plexus and pudendal nerve run alongside the pelvis, the needle should be placed just inside the ventral foramen. Fluoroscopy is used to confirm needle position. The nerve is tested for the appropriate motor response. The foramen needle is exchanged for the introducer sheath over the directional guide, and the lead is passed so that the electrodes, numbered 0 (distal) through 3 (proximal), are positioned with electrodes 2 and 3 straddling the ventral surface of the sacrum (Fig. 46.6). Test stimulation is repeated on each electrode and the responses are observed. An S3 response should be noted at a minimum of two of the four electrodes. Once the operator is satisfied with the position, the sheath is removed, releasing the tines that anchor the lead (Fig. 46.6). Confirmation of an S3 sensory response, a sensation of stimulation in the perineum, is not required to confirm proper placement if the correct S3 motor response is observed

**FIGURE 46.6** The foramen needle is exchanged for the introducer sheath over the directional guide, and the lead is passed so that the electrodes, numbered 0 (distal) through 3 (proximal), are positioned with electrodes 2 and 3 straddling the ventral surface of the sacrum. (From Medtronic, Inc. © 2006, with permission.)

(2). However, if a motor response is absent despite what appears to be fluoroscopically appropriate placement, the patient's sedation is lightened and sensory responses are elicited. Patient verification of the correct sensory response can then confirm proper localization. Fluoroscopically appropriate lead placement demonstrates the lead curving cephalad to caudad on the lateral image and with electrodes 2 and 3 straddling the interior portion of the sacrum. The lead should lie medial to lateral on the anteroposterior image.

A 2- to 4-cm incision into the subcutaneous tissues in the upper lateral buttock is made below the beltline, 3 to 5 cm below the superior iliac crest with the outer edge of the incision meeting the posterior axillary line. This will be the site for connecting the permanent lead to the percutaneous extension lead wire. If the screening trial is successful, this connection site will be the site of implantation for the IPG. The permanent lead is transferred to the medial aspect of the lateral buttock incision using the tunneling device. The lead is then connected to the extension wire and the tunneling device is used again to transfer the extension wire from the medial aspect of the incision to an exit point on the contralateral side of the back. The long tunnel created by this transfer reduces the occurrence of infection from the percutaneous exit site of the wire. The extension wire is connected to the test stimulator. The pocket is closed in two layers with a deep, interrupted 2-0 absorbable suture layer and a superficial, running 4-0 absorbable suture layer to close the skin. Patients are able to resume their normal activities immediately but are advised to limit excessive movement, such as during high-impact exercises, for the duration of the trial period.

The external generator can be flexibly programmed for the duration of the intended trial while patients record their symptoms and bladder function in a voiding diary. If there is >50% improvement in the symptoms or voiding function, a Stage 2 procedure is performed.

---

## Stage II

---

At the Stage 2 procedure, the IPG is placed. Fluoroscopy is not required during Stage 2 when a permanent neuroelectrode has been placed for the Stage 1 procedure; however, if a PNE was performed for Stage 1, then fluoroscopic confirmation of the neuroelectrode placement is advised. The buttock incision overlying the lead connections is opened, the percutaneous extension wire is removed, and the extension lead is secured to the permanent lead and subsequently to the IPG. The newer-generation IPG, the InterStim II, is connected directly to the permanent lead without the need for an extension lead (Fig. 46.7). It is smaller than the original IPG but also has a shorter battery life. The IPG pocket should be large enough to accommodate the IPG without tension and deep enough to prevent erosion and provide cosmetic results. The etched side of the IPG faces up when it is inserted into the pocket. The lead should be wrapped around the IPG, not placed on top of the IPG. This protects the lead if the pocket needs to be reopened for revision or IPG replacement. Prior to closing the incision in two layers, impedances should be checked.

Patients are discharged after patient education regarding the test stimulator and with prescriptions for oral pain medication and 1 week of oral antibiotics, either cephalosporins or fluoroquinolones.

---

## COMPLICATIONS

---

The sacral nerve stimulation study group has published several reports on the efficacy and safety of the procedure for individual indications (9). The complications were pooled from the different studies based on the fact that the protocols, devices, efficacy results, and safety profiles were identical. A total of 581 patients were recruited, 219 of whom underwent implantation of the InterStim system. The complications were divided into problems related to percutaneous test stimulation and postimplant-related problems. Of the 914 test stimulation procedures done on the 581 patients, 181 adverse events occurred in 166 of these procedures (18.2% of the 914 procedures). The vast majority of complications were related to lead migration (108 events, 11.8% of procedures). Technical problems and pain represented 2.6% and 2.1% of the adverse events. For the 219 patients who underwent implantation of the InterStim system (lead and generator), pain at the neurostimulator site was the most commonly observed adverse effect at 12 months (15.3%). Surgical revisions of the implanted neurostimulator or lead system were performed in 33.3% of cases (73 of 219 patients) to resolve an adverse event. These included relocation of the neurostimulator because of pain at the subcutaneous pocket site and revision of the lead for suspected migration. Explantation of the system was performed in 10.5% for lack of efficacy. One should consider the fact that at the time, the generator was implanted in the lower abdomen.

Hijaz et al. (5) have presented algorithms for the troubleshooting of SNM problems. Generator site infection is best treated with explanation of the whole system. Despite attempts to salvage some of these patients, follow-up revealed that the infection persisted in all and eventual explantation was inevitable. The troubleshooting algorithm includes the search for causes of (a) pocket (IPG site) discomfort; (b) recurrent symptoms; (c) stimulation occurring in the wrong area of pelvis; (d) no stimulation; and (e) intermittent stimulation.

---

## OUTCOMES

---

The original reported outcomes of SNM for the indications of idiopathic urgency-frequency and urge incontinence were derived from two studies that randomized patients to active or delayed therapy, as well as reports from numerous prospective and retrospective reviews of case series and registry databases.

Schmidt et al. (7) reported on SNM therapy in 76 patients with refractory urge incontinence. During the 6-month study period, at 16 different centers, patients were randomized to active or delayed therapy (control group). Of the 34 patients receiving active SNM therapy, 16 (47%) were completely dry, and an additional 10 (29%) demonstrated a >50% reduction in incontinence episodes.

In a similar study design, Hassouna et al. (4) reported the outcomes of SNM for refractory urgency-frequency conditions in 51 randomized patients. At 6 months patients in the active SNM group showed improvement in the number

of daily voids ( $16.9 \pm 9.7$  to  $9.3 \pm 5.1$ ), volume voided ( $118 \pm 74$  to  $226 \pm 124$  mL), degree of urgency (rank score of  $2.2 \pm 0.6$  to  $1.6 \pm 0.9$ ), and quality-of-life measures. At 6 months post implant, stimulators in the active group were turned off and urinary symptoms returned to baseline values. After reactivation of SNM, sustained efficacy was documented at 12 and 24 months.

In 2007, the results of a 5-year, prospective, multicenter trial confirmed the long-term efficacy of SNM in patients with refractory urge incontinence, urgency-frequency, and retention (12). Seventeen centers enrolled 163 patients, and 152 patients underwent permanent implantation. Voiding diaries were collected annually for 5 years. Study patient retention was fairly good: at 5 years a total of 105 patients completed follow-up and 87 completed the voiding diary. At 5 years after implantation, 68% of patients with urge incontinence, 56% with urgency-frequency, and 71% with retention had successful outcomes, confirming the durability of this therapy.

# CHAPTER 47 ■ SURGICAL TREATMENT OF PELVIC ORGAN PROLAPSE: ANATOMY OF THE PELVIC FLOOR

ARIANA L. SMITH, JA-HONG KIM, AND SHLOMO RAZ

The etiology of pelvic organ prolapse (POP) is multifactorial, with at most 40% of cases being attributable to genetics (1). Other factors that contribute to the development of prolapse include aging, hormonal status, birth and surgical trauma, pudendal neuropathy, elongation or detachment of support, and myopathy. While genetic and environmental effects are being investigated and preventive measures sought, there remain millions of women who have developed or will develop POP in their lifetime.

Understanding pelvic floor anatomy is critical for any pelvic surgeon before undertaking reconstructive surgery. Not only restoring pelvic floor anatomy but also maintaining and restoring appropriate function is essential for successful patient outcomes. Therefore, it is crucial to understand the complex combination of muscles, ligaments, and fascia that act dynamically to provide support to the female pelvic anatomy, including the urethra, bladder, uterus, and rectum. When normal mechanisms of support fail, pelvic floor relaxation and

organ descent occurs. Depending on the compartment affected, symptoms may vary from voiding dysfunction and urinary incontinence to bowel dysfunction and stool incontinence.

Numerous techniques are available for surgical repair of POP, and many of these will be described in upcoming chapters. This chapter will review female pelvic anatomy and musculofascial support, emphasizing the supporting structures that allow normal voiding and defecatory function, as well as the pathophysiology of pelvic floor relaxation, with a description of the various components of POP.

## ANATOMY OF PELVIC SUPPORT

Conceptually, the vaginal canal can be divided into three compartments that have distinct anatomic structures: (i) the anterior compartment, which includes the urethra, bladder neck, and bladder, (ii) the superior compartment, which includes the uterus and cul-de-sac after hysterectomy, and (iii) the posterior compartment, which includes the rectum, anal canal, and perineum. These compartments have functional and anatomic interactions such that the function and support of one compartment depend on intact support of the others. Structurally, the vaginal and pelvic anatomy starts with a framework of bones and ligaments that are lined with fascia and muscles. These structures are intimately related and in some cases are continuations of each other, especially in the case of ligaments and fascia.

### The Pelvic Diaphragm

#### Bones

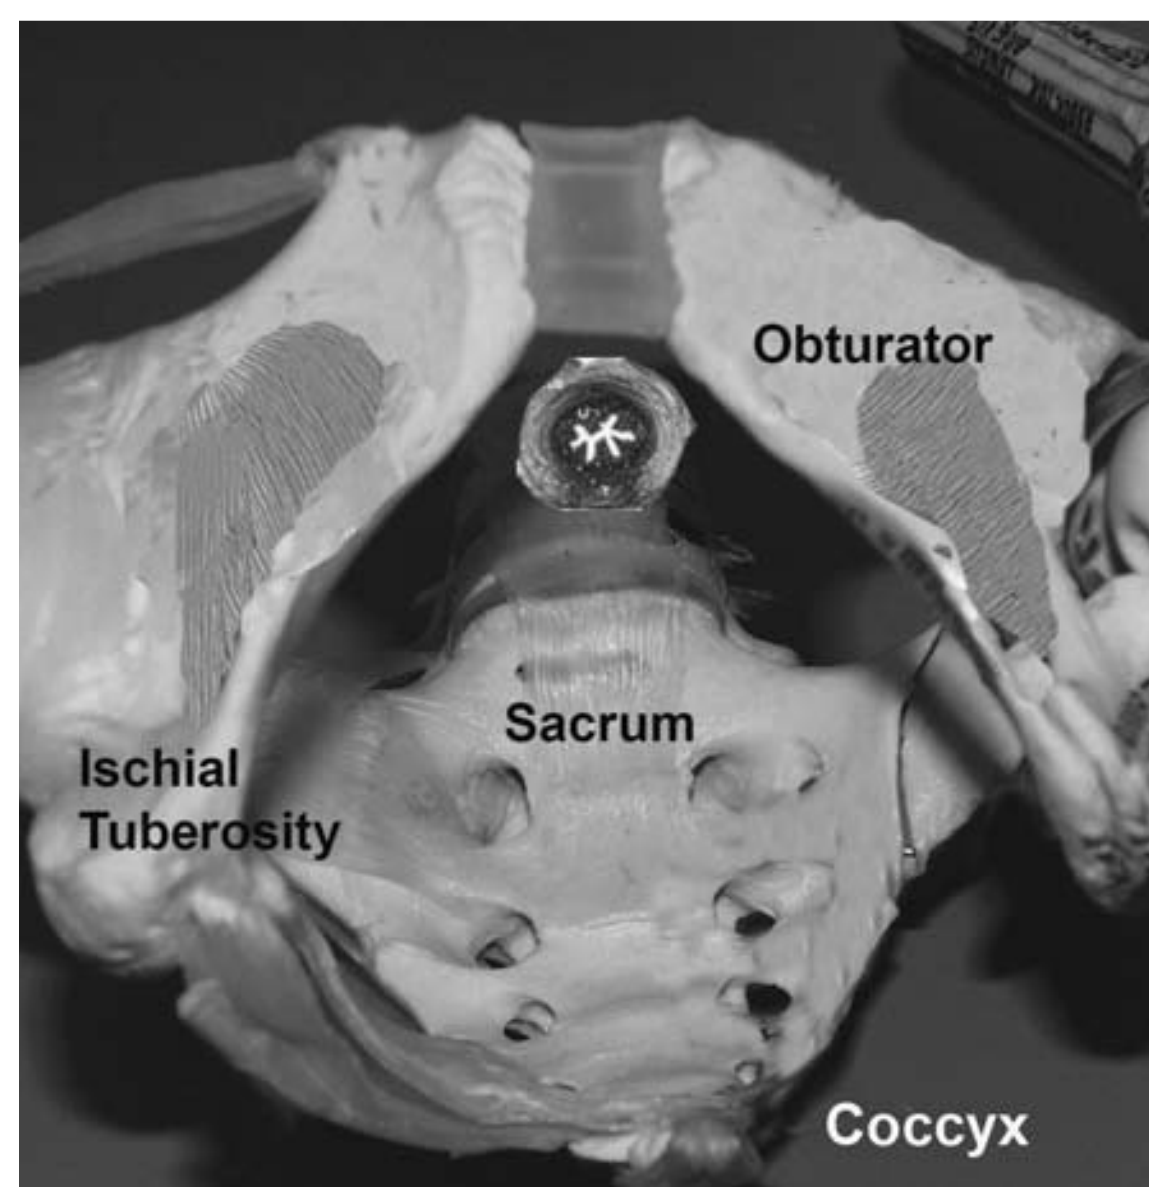

The framework of the pelvic floor is provided by the bony structures, including the pubis, ilium, ischium, sacrum, and coccyx. The pelvic bones create a diamond shape, with the pubic symphysis and coccyx at the apices and the ischial tuberosities dividing the diamond into anterior and posterior compartments (Fig. 47.1). The anterior or urogenital triangle contains the clitoris, urethra, and vaginal vestibule. The posterior or anal triangle contains the anal canal and anal sphincter. The pubic rami, ischial spines, and sacrum are important anchoring points of muscular and fascial structures in the pelvis (2).

#### Ligaments

The name *ligament* has been given to what are truly dense condensations of connective tissue in the pelvis.

**Pubourethral Ligaments.** The pubourethral ligaments anchor the urethra anteriorly to the inferior ramus of the pubic symphysis (Fig. 47.2). They also divide the urethra into proximal and distal halves, with the proximal, intra-abdominal portion responsible for passive, involuntary continence. The midportion, or the striated external sphincter, is responsible for active, voluntary continence. The distal third of the urethra is simply a conduit for urine passage and does not significantly change function when damaged or removed.

**Urethropelvic Ligaments.** The urethropelvic ligaments are a condensation of periurethral fascia that provides anatomic support of the bladder neck and proximal urethra to the

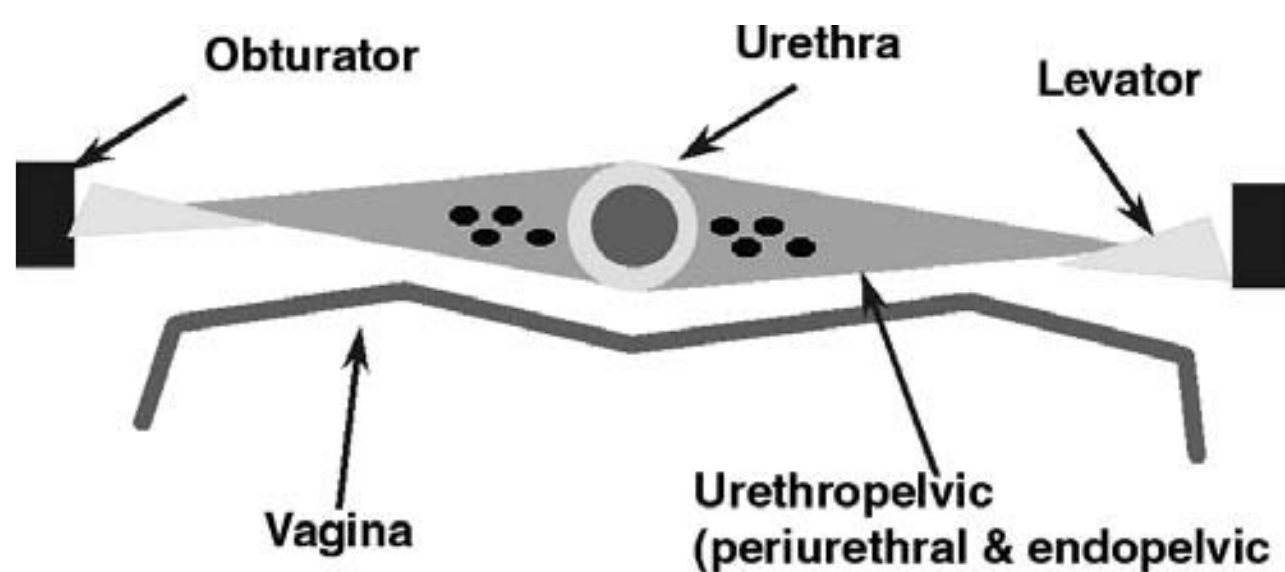

**FIGURE 47.1** The framework of the pelvic floor is formed by the pubic symphysis, pubic rami, and sacrum. The ischial tuberosities divide the pelvic floor into the anterior and posterior compartments. The urethra is shown in the anterior compartment behind the pubic symphysis. The obturator fascia is an important area of anchoring for pelvic support.

**FIGURE 47.2** Abdominal view of the pelvis in a cadaver. The retro-pubic space has been entered from the vaginal side, detaching the urethropelvic ligaments from the lateral pelvic wall and exposing the pubourethral ligament.

lateral pelvic wall (Fig. 47.3). They do so by anchoring the urethra laterally to the arcus tendineus fasciae pelvis (ATFP, see below). The urethropelvic ligaments provide elastic, musculofascial support to the bladder outlet, thereby maintaining passive continence. Voluntary or reflex contractions of the pelvic floor increase the tensile force across these ligaments, enhancing outlet resistance and preventing incontinence. Thus, restoration of these ligamentous structures is critically important in the surgical correction of stress incontinence.

**FIGURE 47.3** Uthropelvic ligaments supporting the urethra to the levator musculature of the lateral pelvic sidewall. In patients with multiple deliveries, the levator musculature is weakened and the ligament is thin, elongated, or detached from the lateral pelvic wall.

**Vesicopelvic Ligaments.** The vesicopelvic ligaments anchor the bladder to the pelvic sidewall. During voluntary or reactive pelvic floor contraction (i.e., contraction of the levator muscles), the ligamentous structures tighten and elevate the bladder, preventing mobility and descent into the vagina. Restoration of these ligaments is important in the correction of anterior wall prolapse, or cystocele.

**Cardinal–Sacrouterine Ligament Complex.** The cardinal ligaments, or ligaments of Mackenrodt, are thick, triangular condensations of pelvic fascia that originate from the greater sciatic foramen and insert into the cervix and vaginal wall. They also extend to the perivesical fascia, providing support to the bladder base (Figs. 47.4 and 47.5). These ligaments contain numerous blood vessels branching from the hypogastrics that supply the uterus and upper vagina (2). The cardinal ligaments fuse posteriorly with the sacrouterine ligaments, which stabilize the uterus, cervix, and upper vagina

**FIGURE 47.4** The vaginal wall has been dissected free to expose the anterior support of the bladder and urethra. The periurethral fascia covers and supports the urethra distally. The perivesical fascia covers the bladder wall from the bladder neck to the cervix. The cardinal ligaments are attached to the cervix in the midline with proximal extensions to the bladder. They provide important support to the bladder base.

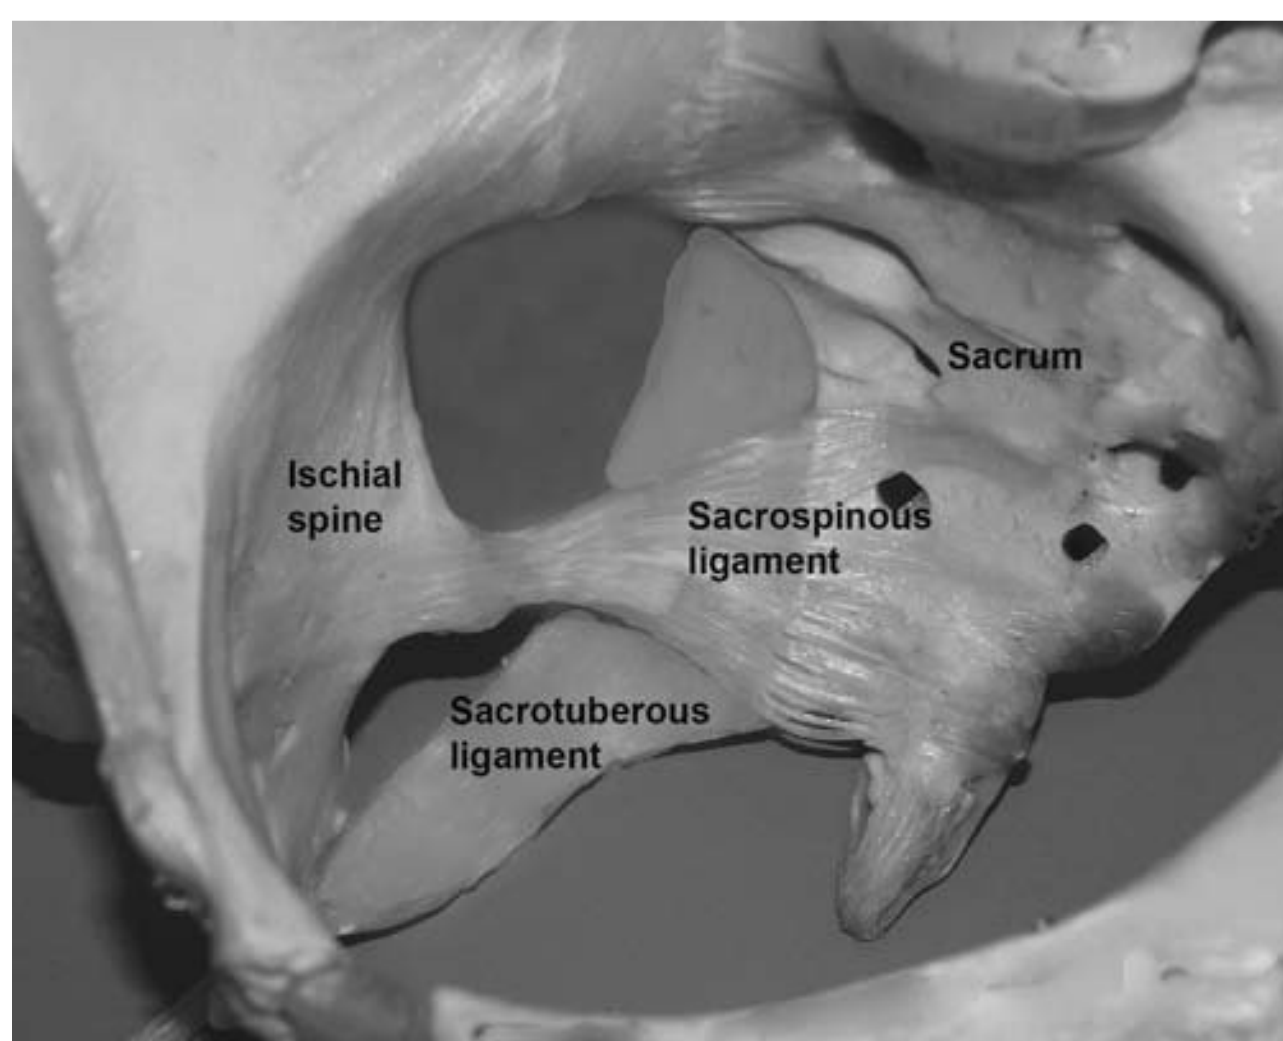

**FIGURE 47.5** Dissection of the bladder wall during repair of grade IV cystocele exposes the cardinal ligaments as they attach to the bladder base.

**FIGURE 47.6** Uterine support and its relations to the bladder and rectum. The cardinal ligaments provide support of the cervix to the lateral pelvic wall.

posteriorly toward the sacrum (3) (Fig. 47.6). The sacrouterine ligaments originate from the second, third, and fourth sacral vertebrae and insert posterolaterally into the cervix and vaginal fornices (4). The trauma of vaginal delivery can cause relaxation of the cardinal-sacrouterine complex and allow descent of the cervix and uterus. Poor surgical technique at the time of hysterectomy may not restore the ligaments to the midline position, thus allowing a wide gap for the bladder to herniate. It is very important to reapproximate the cardinal ligaments in the midline when repairing anterior or posterior wall prolapse.

**FIGURE 47.7** The sacrospinous ligament is an important area of anchoring for vaginal vault suspension.

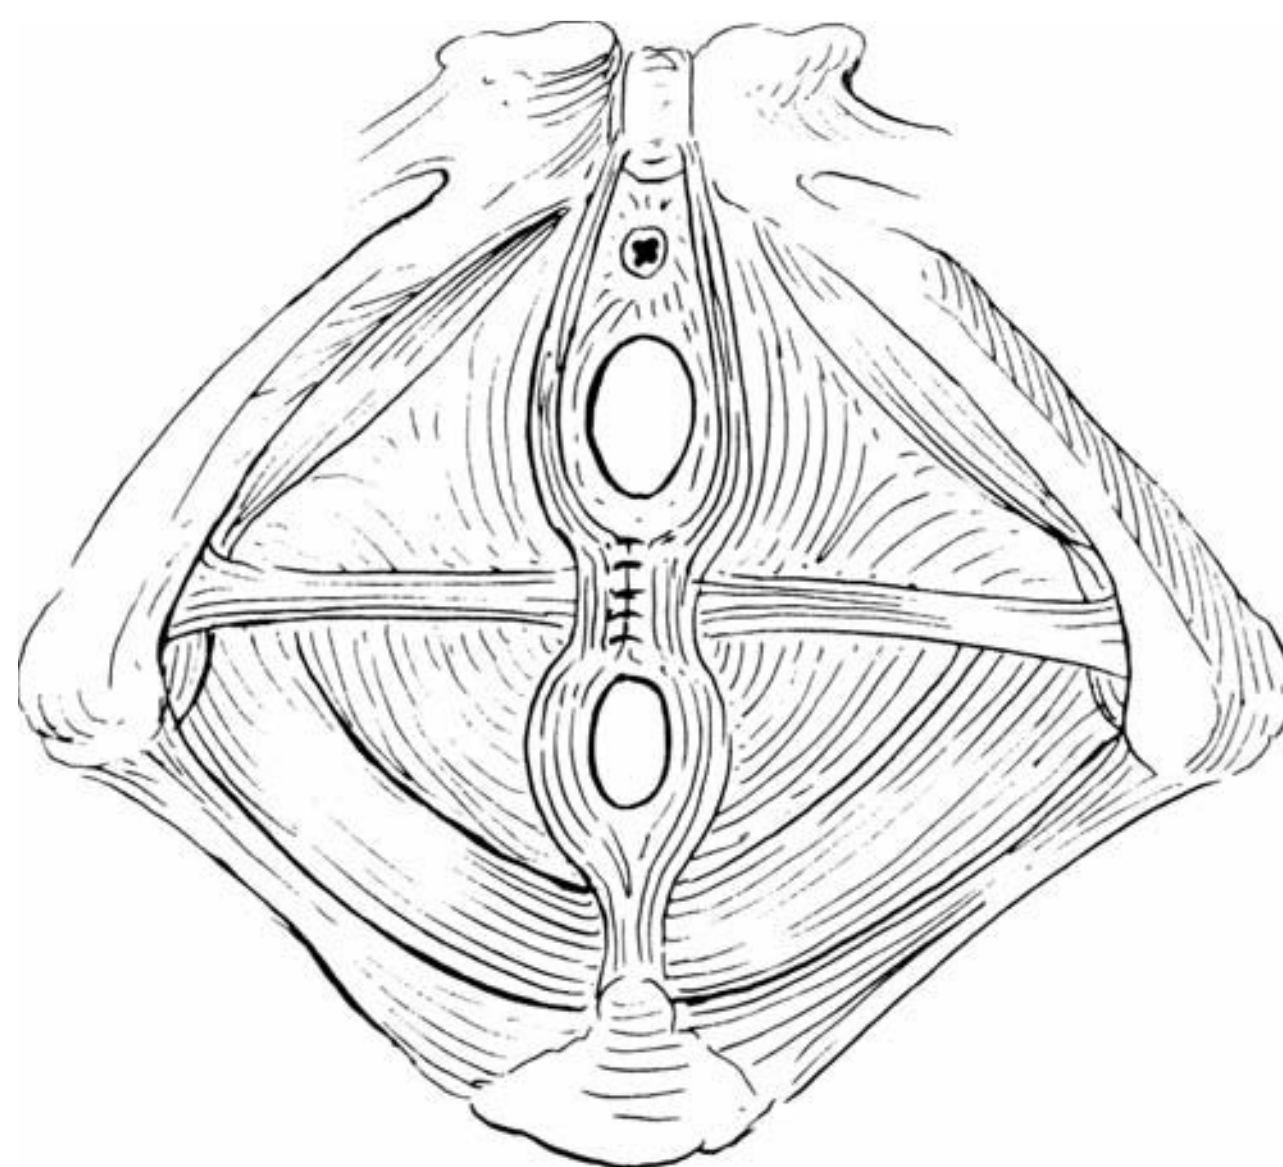

**Broad Ligaments.** The broad ligaments provide additional uterine support superior to the previously named structures. They attach the lateral walls of the uterine body to the pelvic sidewall and contain the fallopian tubes, the round and ovarian ligaments, and the uterine and ovarian vessels. The broad ligaments are covered by an anterior and posterior sheet of peritoneum.

**Sacrospinous Ligaments.** The sacrospinous ligaments span the posterior portion of the pelvic floor, from the ischial spines to the sacrum and coccyx (Fig. 47.7). The coccygeus muscle lies over the top of the sacrospinous ligament and is a very important landmark in vaginal surgery. Cephalad to the coccygeus muscle, the lumbosacral plexus spreads its fibers, which if injured can cause chronic debilitating pain. Lateral to the coccygeus muscle the pudendal nerves and vessels traverse in the canal of Alcock. Also in this area is the ureter, which can be occluded with a suture placed too laterally (5).

**Perineal Body.** The perineal body is a tendinous structure located in the midline of the perineum between the anus and vaginal introitus. It provides a central point of fixation for the transverse perineal muscles, which extend from the ischial tuberosities laterally (6) (Fig. 47.8). The perineal body provides an additional level of support to the posterior vaginal wall and rectum, incorporating the levator ani, bulbocavernosus muscle, and transverse perineal musculature as well as the external anal sphincter. This level of support is elastic in nature, allowing distortion and recoil during childbirth and intercourse.

#### Fascia

Like vaginal ligaments, there are no true vaginal fascias. The structures commonly called fascia are condensations of connective tissue separating the vagina from the urethra, bladder, cervix, or rectum (7). The fascia overlying the pelvic floor musculature plays a critical role in pelvic support. Both sides of the muscle, the abdominal side and the vaginal side, are covered with fascia, and therefore the fascia comprises two components. On the abdominal side it is called endopelvic fascia and represents a continuation of the transversalis fascia.

**FIGURE 47.8** Repair of the perineal body. The bulbocavernosus muscle, the transverse perineal muscles, and the anal sphincter fibers are approximated to recreate the central tendon of the perineum.

**Pubocervical Fascia.** On the vaginal side it is often referred to as the pubocervical fascia, but can be divided into discrete areas of specialization depending on the associated organ it supports (periurethral and perivesical fascia). As a whole, the pubocervical fascia is a trapezoid-shaped continuous sheet of connective tissue support that extends from the pubic symphysis to the cervix and laterally to the ATRP (8). The fascia is fused to the bony scaffold by the cardinal ligaments laterally and the sacrouterine ligaments posteriorly.

**Arcus Tendineus Fasciae Pelvis.** ATRP is a curvilinear condensation of pelvic fascia that arises from the obturator internus muscle and runs from the pubic symphysis to the ischial spines (Fig. 47.9). This tendinous arc of the obturator is the line of insertion of the levator muscles on the obturator fascia. This crucial structure provides musculofascial attachment for the anterior and posterior pelvic organs. It also provides an anchoring point during reconstructive surgery of organs that have descended.

**Periurethral Fascia.** Around the urethra, the periurethral fascia represents two wings of tissue extending from the urethra to the ATRP, fused by the pubourethral ligaments.

**Perivesical Fascia.** Around the bladder, the perivesical fascia extends as wings from the bladder to the ATRP, fused by the vesicopelvic ligaments.

**Prerectal/Pararectal Fascia.** Prerectal and pararectal fascia extends from the cardinal-sacrouterine complex to the perineal body and is sometimes referred to as the rectovaginal septum.

#### Musculature

The striated musculature supporting the pelvic floor is composed of the levator ani muscles and the coccygeus muscles. Together they cradle the visceral contents of the pelvis, providing dynamic support.

**FIGURE 47.9** View of the anterior pelvis. The endopelvic fascia covers the bladder and urethra. The levator musculature is attached to the arcus tendineus fasciae pelvis.

**Levator Ani.** The levator ani has two main components, the pubococcygeus and the iliococcygeus, which are named according to their origin from the pelvic sidewall (9). This broad sheet of muscle extends from the pubic symphysis to the ischial spines and coccyx, taking origin from the ATRFP laterally. These muscle groups have overlying endopelvic fascia that allows direct attachment to the bladder, urethra, vagina, uterus, and rectum to permit active visceral control (Fig. 47.10). These muscles supply support during increases in intra-abdominal pressure, preventing organ descent and more importantly preventing the release of urine and stool (2). The medial fibers of the pubococcygeus muscles are also referred to as the puborectalis muscle or “pullator” because of its role in pulling forward the anal canal and distal vagina, closing the levator hiatus.

**Coccygeus.** The posterior portions of the levator ani, together with the coccygeus muscle, provide a horizontal plate from the rectal hiatus to the coccyx. This plate maintains a normal vaginal and uterine axis. The uterus and proximal vagina, as well as the bladder and rectum, lie horizontally on this plate, preventing their descent. Resting tone of the levator ani and coccygeus, as well as reflex and voluntary contraction, acts to pull the vagina and rectum forward, closing the lumens of these structures. Re-establishing this axis is important for re-establishing normal anatomy and sexual function as well as long-term success in prolapse surgery.

**Levator Hiatus.** The levator hiatus is a U-shaped midline aperture in the levator ani that allows passage of the urethra, vagina, and rectum (Fig. 47.11). These structures are supported by a fascial hammock, the urogenital diaphragm, as they exit the pelvis (10). Fibers from the pubococcygeus enter

**FIGURE 47.10** Pelvic support provided by the levator ani muscles. The levator ani is divided into two main segments: the pubococcygeus and the iliococcygeus. These muscles take origin in the arcus tendineus fasciae pelvis, a thickening of the obturator fascia. The medial portion of the pubococcygeus, the puborectalis, forms a sling around the distal rectum. PR, puborectalis; PC, pubococcygeus; IC, iliococcygeus; O, obturator musculature; TA, tendinous arc.

**FIGURE 47.11** Three-dimensional MRI reconstruction of the levator musculature, bony pelvis, and obturator musculature in a patient with multiple deliveries. The levator hiatus is widened (*arrow*); this represents the distance between the rectal canal and the pubic bone, called the puborectal line.

into the hiatus and surround the urethra and anus, forming the sphincter musculatures.

---

### Areas of Special Interest: Obturator Anatomy

---

Prior to the introduction of the transobturator tape, the obturator anatomy was rarely studied. With the dramatic increase in the number of procedures performed in this area and the arising complications, it is important for all urologists to understand the anatomic landmarks. The adductor longus tendon is a major landmark for trocar passage and protects the patient from injury to the neurovascular bundle. Safe entry and exit zones exist when the patient is properly positioned and landmarks are obeyed. When a sling is placed using this technique, it is important to understand that the mesh sling is placed through the obturator internus muscle via passage of the trocar (Fig. 47.1). Complications are possible as a result of this placement; these include walking difficulty and pain with contraction of the obturator internus muscle.

---

## PATHOPHYSIOLOGY OF PELVIC FLOOR DYSFUNCTION

---

### Mechanisms of Urethral Continence

---

Bladder outlet resistance in women is attained by several factors working together to provide continence at rest and during stress maneuvers. Urethral anatomy, including functional length and elastic closure, is an important determinant of continence. In addition, activity of the muscular pelvic floor with its associated connective tissue elements helps maintain outlet resistance during times of increased intra-abdominal pressure. The anatomic position of the urethra is another factor contributing to continence. Each of these entities will be discussed separately to provide a basis for understanding the pathophysiology of pelvic floor relaxation.

Structural support of the urethra alone is not enough for the maintenance of urinary continence; there are also integral features of the urethra that contribute. The urethra is made up of three functional anatomic components that result in an elastic, dynamic conduit with mucosal coaptation. The urethral mucosa is transitional epithelium with numerous infoldings that allow distensibility and closure with excellent coaptation. Beneath the mucosa is a spongy tissue made up of vascular networks, analogous to the corpus spongiosum in men. Surrounding the spongy tissue is a thin musculofascial envelope, the periurethral fascia, which appears as a glistening, white membrane during surgery. These three components contribute to form a coaptive seal. Surrounding the mucosa are layers of smooth and striated muscle that are part of the sphincter mechanism. These muscles are under both voluntary and involuntary control. When functioning properly, they maintain enough compression, or resistance, of the urethra to prevent leakage of urine.

Both the bladder neck and urethra are normally maintained in a high retropubic position relative to the more dependent

bladder base, creating a valvular effect. The bladder neck and urethra are supported by a musculofascial layer that suspends these structures from the pubic bone and pelvic sidewalls, thereby preventing their descent during increases in intra-abdominal pressure (11). Further, direct transmission of intra-abdominal forces to a well-supported proximal urethra increases its resistance and promotes coaptation (12). Relaxation of the pelvic floor as well as weakening of the urethropelvic ligaments and midurethral complex produces significant posterior and downward rotation of the urethra and bladder neck. This anatomic repositioning of the urethra and bladder neck to a more dependent pelvic position eliminates the valvular effect. Thus, a poorly supported urethra will tend to funnel and open during increases in intra-abdominal pressure. Interestingly, the same mechanism of restoring continence by repositioning the urethra higher than the bladder base and trigone (classic Burch procedure) can produce outlet obstruction in patients who develop a secondary cystocele. This occurs due to a kinking effect when the prolapsing bladder drops further below the suspended urethra.

Essentially, three mechanisms of support maintain continence during increases in intra-abdominal pressure: (i) the backboard effect of urethral support maintained by the periurethral fascia and urethropelvic ligaments, (ii) the valvular effect at the bladder neck, and (iii) the voluntary and reflex contraction of the pelvic floor.

With aging there is a decrease in skeletal and smooth muscle density as a result of atrophy. This can affect the urethral sphincter mechanism as well as the contributing pelvic floor. Continence should therefore be perceived as a dynamic function that changes with age. As a result, surgery for repair should not be viewed as a cure that will last forever, but rather as a treatment. Current methods are not actually curing the defect in urethral function but rather temporizing or treating the symptoms. Therapies aimed at cure are being employed using stem cells to regenerate smooth and striated muscle.

Stress incontinence is just one manifestation of pelvic relaxation. Often other pelvic defects coexist and should be addressed simultaneously.

---

### Cystocele

---

When defects in pubocervical fascia exist, a cystocele develops (Fig. 47.12). Usually the defect is in both the lateral fascia and the midline of the fascia, with also a notable defect in cuff support (13). The defect can be treated by using a trapezoid-shaped piece of mesh and anchoring it to the obturator fascia laterally (via the ATFP), the sacrouterine complex apically, and the bladder neck distally, thus reapproximating the trapezoid-shaped pubocervical fascia. This is usually performed in combination with anterior colporrhaphy, or plication of the pubocervical fascia in the midline. Because of the risk of de novo stress incontinence after cystocele repair, many authors recommend performing a concomitant sling at the time of bladder repair. We agree with this. In fact, there is evidence to support not only a decrease in incontinence, but also a decrease in recurrence of prolapse when a sling is added to the repair (14). It is also important to reapproximate the cardinal ligament complex in the midline to support the bladder base and prevent recurrence.

**FIGURE 47.12** Severe prolapse of the anterior vaginal wall with central and lateral defect. The normal H-shape of the vagina is lost. The lateral walls of the vagina are detached from supporting structures, allowing downward displacement and disappearance of the lateral sulci.

### Rectocele

The posterior vaginal wall has a complex fascial and muscular arrangement that provides support not only to the vagina but also to the rectum, perineum, and anal sphincter. There are four components that contribute to failing posterior support: prerectal/pararectal fascia attenuation, perineal membrane widening, levator hiatus widening, and descent of the levator

plate. Rectocele is a poor name to encompass all of these defects. It is important to address and repair all of these potential weaknesses and avoid segmental repairs—in particular, reinforcing attenuated prerectal and pararectal fascia by plication or with mesh, reapproximating the levator musculature to close the levator hiatus, and rebuilding the perineal body to provide normal introital size and improved support. These measures prevent descent of the organs and the need for secondary surgery.

## RESTORATION OF SUPPORT

The normal vaginal length is approximately 8 to 9 cm, with the ischial spines as a good landmark. The caliber should approximate two fingerbreadths. The axis should be such that the vagina rests on the levator plate in a banana shape, much like its natural position (Fig. 47.13). The proximal half of the vagina is practically horizontal resting over the levator plate. We can see that the axis of the vagina points down to S4–S5 (Fig. 47.14), not to the promontory where sacrocolpopexy is often performed. Suspending the vaginal cuff to this location can allow the formation of other defects, specifically enteroceles and rectoceles. Simply placing the cuff to the sacrospinous ligament restores proper anatomy, allows approximation of the perivesical and perirectal fasciae, and prevents recurrent prolapse. Lateral, anterior, and posterior dissection allows one to obtain good strong tissue for plication of the anterior and posterior vaginal walls. Anteriorly the surgeon must extend dissection to the inferior pubic ramus at the level of the obturator muscle, and posteriorly dissection must be taken to the rectal gutter, the groove between the rectum and the iliococcygeus muscle. The distal vagina is elevated with closure of the perineal defect, allowing achievement of normal introital caliber and shape.

Placement of the vault suspension sutures can be daunting. It is important to understand where it is safe and where it is dangerous to place these sutures. These sutures should be

**FIGURE 47.13** Dynamic MRI in a patient with normal vaginal support. The banana-shaped vaginal curvature is seen. The angulation between proximal and distal vagina (located at the level of the proximal anal canal) points to the insertion of the puborectalis musculature. P, pubic bone; Ur, urethra; PU, pubourethral ligaments; R, rectum; A, anal canal; B, bladder; U, uterus.

**FIGURE 47.14** Vaginal support. The distal vagina is approximately 45 degrees from the vertical axis and the proximal vagina is approximately 10 degrees from the horizontal axis. The angulation between the two areas marks the insertion of the puborectalis muscle, which pulls the vagina anteriorly.

placed in the sacrospinous ligament with the needle pointing downward rather than laterally or superiorly in the direction of other important structures (Fig. 47.7). It is imperative to

avoid going cephalad to the sacrospinous ligament, as the lumbosacral plexus can be injured or trapped with a suture. The ureter can be damaged, as can the pudendal nerve, if the needle is placed laterally. T-shaped soft polypropylene mesh is used to replicate cardinal–sacrouterine support by anchoring the cuff to the sacrospinous ligament.

The importance of a thorough evaluation and complete repair of the whole pelvic floor cannot be overemphasized. Segmental repairs allow exaggeration of pre-existing defects due to functional and anatomic changes. Repair of concomitant prolapse also has an important impact on the outcome of stress incontinence surgery (10). The reverse has also been found to be true: the addition of a sling procedure to anterior colporrhaphy reduces the cystocele recurrence rate by 50% (14). These findings are likely due to the dissipation of intra-abdominal pressure in the setting of POP. With restoration of strong support to the pelvic organs, there is more efficient transmission of abdominal pressure to the urethra and therefore better continence (10). The need to augment support with mesh or biologic fascia is debated. Most experts in the field believe that supporting the patient's weakened fascia can achieve a more durable response.

Regardless of technique, three basic tenets must be obeyed in pelvic reconstruction: (i) restoration of normal vaginal depth, caliber, and axis, (ii) prevention of further POP, and (iii) restoration and maintenance of normal bladder, bowel, and sexual function (7).

## CHAPTER 48 ■ VAGINAL HYSTERECTOMY FOR UTERINE PROLAPSE

JA-HONG KIM, ARIANA L. SMITH, AND SHLOMO RAZ

Hysterectomy is the second most commonly performed surgical procedure in the United States, with 66% of the cases done through the abdominal approach, followed by the vaginal route in 22% and the laparoscopic route in 12% (1). The

most common indications for hysterectomy are uterine fibroids (33%) and menstrual disorders (17%), followed by prolapse (13%) and endometriosis (9%). There is a growing body of evidence has shown that vaginal hysterectomy is the

preferred surgical route due to shorter operative time, fewer postoperative complications, and a shorter hospital stay (2,3). More importantly, it avoids the morbidity of an abdominal incision and offers optimal opportunity to correct and prevent pelvic organ prolapse. Relative contraindications for vaginal hysterectomy include a large uterus in proportion to a narrow introitus, ovarian pathology, previous cesarean delivery, endometriosis, and a history of pelvic inflammatory disease, which may result in extensive scarring in the pelvis, making dissection difficult. The ultimate decision regarding the surgical approach to hysterectomy, however, rests on the surgeon's experience and preference. As a genitourinary surgeon, one should be familiar with the surgical principles and technique of vaginal hysterectomy, as it is a crucial component of female pelvic reconstruction.

This chapter will focus on four major concepts that are important to performing a successful vaginal hysterectomy for uterine prolapse: (i) pertinent female pelvic anatomy as it relates to the pathophysiology of uterine prolapse, (ii) standard evaluation, including a focused history and imaging, (iii) surgical technique, highlighting the principles for vascular control and restoring vaginal support, and (iv) review of potential complications and outcomes.

---

## SURGICAL ANATOMY

---

The female pelvic organs are supported by the dynamic interaction between their connective tissue attachments (ligaments and fascia) and the pelvic floor muscles (levator ani muscle group and coccygeus), which provide a firm yet elastic base on which they rest. Histologically, the term *endopelvic fascia* is used to describe this continuous network of connective tissue that envelops all of the pelvic organs and connects them to supportive musculature and pelvic bones, which is located on the peritoneal side. On the vaginal side, the fasciae acquire different nomenclature and are distinctively named according to their anatomic location and the organ that they support. The thick condensations of the connective tissue are further organized to a trilevel support system that was described by De Lancey as they relate to the pathophysiology of uterovaginal prolapse (4). Level I refers to the fused ligamentous complex in the most cephalad portion (cervix and upper vagina) that maintains vaginal length and horizontal axis. Level II support is provided by the paravaginal attachments along the length of the vagina to the arcus tendineus fasciae pelvis. Level III support describes the most inferior or distal portions of the vagina, including the perineum.

The pear-shaped uterus consists of the corpus and the cervix and lies in the medial axial position, anteverted with the vertical axis of the uterus perpendicular to the axis of the vagina. The corpus or body of the uterus is enclosed between the double-layered broad ligaments, which contain the fallopian tubes, the round and ovarian ligaments, and the uterine and ovarian vessels. No fixed uterine support is provided by the broad ligaments, as demonstrated by its ability to enlarge without restriction during pregnancy. Thus, the main uterine support is provided by the uterosacral and cardinal (Mackenrodt) ligaments, which attach to the cervix from the posterior and lateral sides, respectively. Together, the fused uterosacral–cardinal ligament complex represents level I support and attaches the upper vagina, cervix, and lower uterine

segment to the sacrum and lateral pelvic sidewalls at the piriformis, coccygeus, levator ani, and arcus tendineus. During hysterectomy, these ligaments must be carefully identified and controlled, as they will be incorporated into the vaginal cuff to successfully re-establish proper vault support.

The natural vaginal axis is a banana shape, with the upper third of the vagina lying in a horizontal position and the apex directed towards the lower sacrum (S3–S5). This axis is normally maintained partly by the support of the levator ani and coccygeus muscle group, especially during increased intra-abdominal pressure. Therefore, complete correction of uterovaginal prolapse at the time of hysterectomy should include not only reattachment of the cardinal and uterosacral ligaments to the vaginal vault, but also vault or apical suspension to the area of the coccygeus to re-establish the banana-shaped axis. In the substance of the coccygeus lies a cordlike structure called the sacrospinous ligament, which extends from the ischial spines on each side to the lower portion of the sacrum and coccyx. This sacrospinous ligament provides a consistently strong site for apical fixation that can restore vaginal depth and axis. It is crucial to accurately identify this important structure when placing vault suspension sutures, as the pudendal neurovascular bundle, lumbosacral plexus, and ureters live in close proximity and can be injured during suture placement. Various techniques for vault suspension at the time of hysterectomy have been described in the literature, and a thorough comparison of these procedures is beyond the scope of this chapter. There is no randomized control study that has shown long-term superiority of one technique over the other. In our experience, bilateral fixation of the vaginal cuff to the origin of the uterosacral–cardinal ligament at the coccygeus–sacrospinous ligament complex provides the optimal restoration of vaginal depth and vault support with minimal morbidity. We routinely utilize a piece of soft polypropylene mesh to add strength to the uterosacral–cardinal ligament complex, which is often attenuated in patients undergoing vaginal hysterectomy for prolapse repair.

---

## PATHOPHYSIOLOGY OF UTERINE PROLAPSE

---

Although the exact etiology of pelvic prolapse has yet to be clearly defined, many risk factors have been proposed in the development of prolapse. Bump and Norton (5) categorized these risk factors into four categories: (i) **predisposing** factors are genetics, race, and gender; (ii) **inciting** factors are pregnancy and delivery, surgery, myopathy, and neuropathy; (iii) **promoting** factors are obesity, smoking, pulmonary disease, constipation, and recreational or occupational activities that cause chronic increases in intra-abdominal pressure; and (iv) **decompensating** factors are aging, menopause, debilitation, and medications. Any of the above risk factors can result in attenuation of the uterosacral–cardinal ligament complex or breaks along the endopelvic fascia. Furthermore, muscle atrophy of the levator ani and coccygeus can lead to a wider levator hiatus and a compromise in the excretory function of the bladder and rectum. The loss of uterine support causes the cervix to move anteriorly, and the uterus then begins to shift posteriorly such that the intra-abdominal pressure is then directed on the anterior surface of the uterus. The uterus becomes progressively more retroverted until the axis of the

uterus is essentially vertical. This position allows uterine prolapse to occur (6).

---

## DIAGNOSIS

---

Standard evaluation of the patient with uterine prolapse includes a comprehensive history and physical examination, focusing on urinary and defecatory symptoms, sexual function, reproductive status, and other pelvic pathology. Urinary or bowel symptoms may be present if there is prolapse of other organs. Less commonly, a patient presents because uterine prolapse was incidentally found on routine physical examination. Validated questionnaires measuring symptom severity, impact on quality of life, voiding log, and sexual function can be premailed to allow the patient time to consider her symptoms. An important piece of information in the patient's surgical history is whether the patient had a partial hysterectomy. Often, what is assumed to be uterine descent is only cervical descent resulting from a supracervical hysterectomy. It is also important to ask about any uterine pathology, such as endometriosis, fibroids, and pelvic inflammatory disease, which can influence surgical planning.

Postvoid residual urine volume and urinalysis are obtained for all patients. Urodynamic evaluation is not routinely performed for prolapse patients unless there is a history of stress or urge incontinence, incomplete emptying, obstructive voiding complaints, or bothersome overactive bladder symptoms. For these patients with urinary symptoms, we recommend assessment of the lower urinary tract with a videourodynamic evaluation and office cystoscopy. It is important to recognize that stress incontinence may be masked by the prolapse, which can cause kinking of the urethra. As many patients with prolapse are elderly, detrusor instability secondary to obstruction versus hyperreflexia secondary to an occult neurologic condition must be ruled out in this patient population. Cystoscopy is useful to rule out any intrinsic urethral or bladder lesions that may be contributing to lower urinary tract symptoms.

General, gynecologic, and basic lower neurologic examination should be performed on every woman with prolapse. Occasionally, surgical scars detected on the abdominal examination can provide an important piece of surgical history that was previously unmentioned. The pelvic examination begins with external genitalia inspection for atrophy, discharge, episiotomy scars, and integrity of the perineum. The uterus and cervix is assessed for size, mobility, and any abnormal gross pathology. The anterior, posterior, and apical vaginal walls are examined separately with the aid of a half speculum to assess the presence of other prolapse such as cystocele or rectocele. The size of the introitus and evidence of vaginal stenosis should be noted, as a size disproportion between the uterus and vaginal opening may limit transvaginal delivery of the uterus. Physical examination should be performed both in the supine and standing positions. The severity of prolapse may not be appreciated in the supine position. In both positions the patient needs to perform a Valsalva maneuver to fully elicit the prolapse. The physical examination should be repeated at the time of surgery with the patient under anesthesia. Often, with anesthesia-induced relaxation of the pelvic floor, the degree of uterine descent and other prolapse becomes more pronounced. The screening neurologic examination

**FIGURE 48.1** Magnetic resonance imaging (MRI) of the pelvis. Dynamic MRI of the pelvis demonstrating uterine and bladder prolapse.

should evaluate gross sensory and motor function of both lower extremities, and lumbosacral function. This can be quickly achieved by assessing pelvic floor muscle strength, anal sphincter resting tone, voluntary anal contraction, and perineal sensation.

Imaging of the upper urinary tracts is recommended since patients with uterine prolapse may have associated hydronephrosis. Our preferred imaging modality to assess the presence of hydronephrosis as well as other pelvic pathology is dynamic magnetic resonance imaging (MRI). Dynamic MRI is unrivaled in its ability to characterize pelvic soft tissue, and thereby it can accurately diagnose other uterine and ovarian pathology. It is a relatively simple, noninvasive test that takes only minutes to complete. No contrast is used as the bladder is distinct on T-2 weighted images. Sagittal images are taken of the pelvis with the patient at rest and then performing the Valsalva maneuvers. Uterine or other pelvic organ prolapse is readily identified with this imaging modality (Fig. 48.1).

The Pelvic Organ Prolapse Quantification System (POP-Q) is a commonly used staging system for describing vaginal prolapse and is based on physical examination (7). We classify uterine prolapse based on the dynamic MRI findings. Prolapse is classified in reference to the puborectalis hiatus. The puborectalis hiatus is formed by the puborectalis muscle (the most inferior part of the levator ani) and includes the urethra, vagina, and rectum. The degree of prolapse is measured by 2-cm increments. Mild uterine prolapse is 0 to 2 cm distal to the hiatus, moderate prolapse is 2 to 4 cm, and severe prolapse is >4 cm distal to the hiatus (8).

---

## ALTERNATIVE THERAPY

---

Nonsurgical alternative therapy to hysterectomy and vault suspension for uterine prolapse is no treatment, pelvic floor muscle training, or pessary. These options are reserved for those patients who are deemed poor candidates for surgery. Uterine-sparing procedures can be offered to patients who wish to maintain fertility or have strong opinions regarding sexual and personal identity related to the uterus and cervix. Obliterative procedures, such as colpocleisis, are also viable options for the appropriate patient population.

**FIGURE 48.2** Incision: A circumferential incision is made approximately 1 cm from the cervical os with electrocautery.

## SURGICAL TECHNIQUE

As previously mentioned, vaginal hysterectomy alone is not sufficient to relieve symptoms of uterine prolapse or restore functional anatomy. Thus, every effort must be made to recreate normal pelvic anatomy with adequate support of the vaginal vault and functional depth. These measures include reapproximating the bladder and rectum to close the cul-de-sac and fixing the vaginal apex to the origin of the uterosacral–cardinal ligament at the coccygeus-sacrospinous ligament complex for vault support.

Broad-spectrum prophylactic antibiotics are administered preoperatively. Compression stockings are placed prior to incision to prevent venous thromboembolic events. Following successful induction of anesthesia, the patient is placed in the high lithotomy position. Care should be taken to avoid hyperflexion of the hips, which can result in femoral neuropathy. An iodine-based solution is used to cleanse the skin from the suprapubic area to the posterior perineum. Sutures are used to retract the labia laterally and a weighted speculum is inserted for vault exposure. A Lowsley retractor is used to place a suprapubic tube in every patient undergoing hysterectomy, and the bladder is drained by both urethral and suprapubic catheters. A ring retractor with skin hooks is used to maintain exposure. The cervix is grasped at the 12 o'clock and 6 o'clock positions using Lahey clamps to maintain the axis. A circumferential incision is made at the cervicovaginal junction using electrocautery (Fig. 48.2). The vagina and bladder base is dissected off the cervix for several centimeters. The anterior cul-de-sac is carefully entered using sharp dissection (Fig. 48.3A). Gentle downward traction, visualization of the glistening surface of the uterus, and limiting the dissection to the midline of the uterus help to minimize risk of cystotomy. Once the anterior cul-de-sac is entered, we use electrocautery to extend the incision laterally to allow placement of a Heaney retractor (Fig. 48.3B).

The posterior cul-de-sac is entered similarly, and the peritoneum is opened sharply using curved Mayo scissors (Fig. 48.4). Any adhesions encountered should be lysed with limited sharp dissection to allow placement of another Heaney retractor. If

A

B

**FIGURE 48.3** Exposure of the anterior uterus: Sharp dissection is used to (A) expose the anterior cul-de-sac and (B) place a Heaney retractor.

**FIGURE 48.4** Exposure of posterior cul-de-sac and sharp entry into the peritoneum.

A

B

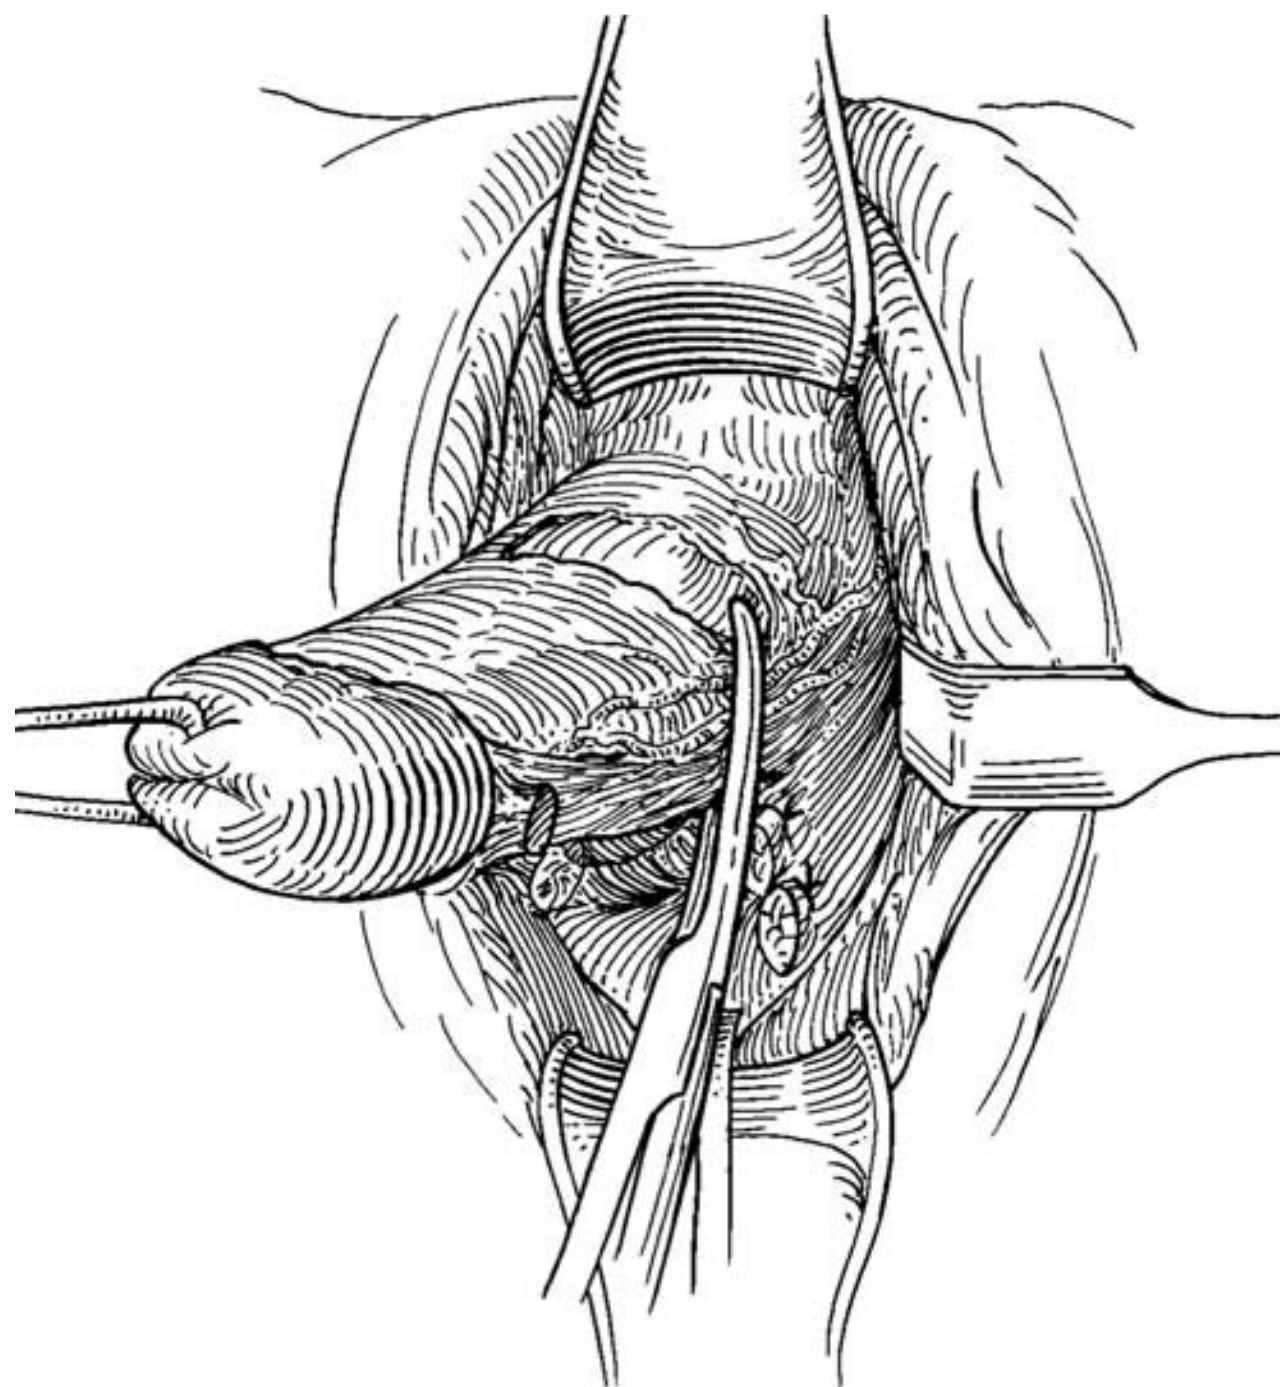

**FIGURE 48.5** Isolation of cardinal–uterosacral ligaments. Right-angle and Phaneuf clamps are used in succession to (A) better delineate the cardinal–uterosacral complex before (B) transection.

difficulty is encountered when attempting to enter the peritoneum, the hysterectomy can be initiated in an extraperitoneal fashion by severing the uterosacral ligament and caudal portions of the cardinal ligament close to the cervix. This maneuver mobilizes the uterus to provide better visualization.

Next, the uterosacral and cardinal ligament complex is divided by placing the cervix on careful traction and passing a large right-angle clamp from the posterior cul-de-sac parallel to the cervix. The right-angle clamp is used to expose the ligament, which is then grasped with a Phaneuf clamp and ligated with electrocautery (Fig. 48.5). The stumps are oversewn with figure-of-eight 0 Vicryl sutures. The ends of the sutures are clamped and secured on the ring retractor. Then the uterine pedicles are carefully identified, isolated, and divided in similar fashion (Fig. 48.6). After the contralateral ligament and pedicles are likewise controlled, the uterus can then be manually everted and brought outside the introitus (Fig. 48.7). Safe entry

A

B

**FIGURE 48.6** The uterine pedicles are carefully identified (A), isolated, and divided (B).

into the anterior peritoneum can be made by placing a finger anteriorly over the uterine fundus to elevate the peritoneum. Electrocautery can then be used to incise the peritoneum overlying the surgeon's finger. The broad ligaments are now ligated as above (Fig. 48.8). If an oophorectomy is not planned, the ovarian attachments are also now divided. The uterus is finally removed. A circular arrangement of the six ligated pedicles and their attached sutures remain (Fig. 48.9).

After hysterectomy, the vault support and vaginal depth must be restored. This is accomplished by obliterating the cul-de-sac to prevent enterocele recurrence and by sacrospinous fixation of the apex to recreate the natural banana shape. To perform this procedure correctly and safely, the surgeon must be familiar with the pararectal anatomy and obtain adequate

**FIGURE 48.7** Eversion of the uterus. After the bilateral cardinal–uterosacral ligaments have been ligated, the uterus is manually everted.

exposure. First, the patient is placed in Trendelenburg position, and two Betadine-soaked laparotomy pads are placed intraperitoneally to pack away the peritoneal contents. Next, the coccygeus–sacrospinous ligament complex is identified by palpating the ischial spine and tracing the taut triangular band of fascia medially and posteriorly as it attaches to the edges of the sacrum. Next, we use two Allis clamps to grasp the area of the future vaginal cuff and apply downward traction toward the coccygeus–sacrospinous ligament complex to determine the extent of the apical prolapse and associated pelvic support defects. If concomitant cystocele still exists after reducing the apical prolapse, we will perform a formal cystocele repair. Otherwise, we will incise an oval shaped soft polypropylene mesh with two arms, which is designed so that the horizontal arms are attached to the corresponding sides of the vaginal cuff (at the uterosacral–cardinal ligament complex). The middle circular portion of the mesh is incorporated extraperitoneally to reinforce the pursestring closure of the cul-de-sac (Fig. 48.10).

The technique of bilateral sacrospinous ligament fixation is challenging due to the difficulty in maintaining good visualization in the deep pelvis through the vagina and the risk of injuring the pudendal vessels, the lumbosacral plexus, and the ureters, which are in close proximity. To optimize this exposure, three retractors are employed: (i) a long-handled Breisky is placed anteriorly to retract the peritoneal contents from descending; (ii) another Breisky or Heaney is used to displace the rectum laterally; and (iii) a Heaney retractor is then carefully placed posteriorly just distal to the tight cordlike coccygeus–sacrospinous ligament complex. We begin by placing a 1-0 Vicryl suture brought from outside the vaginal wall into the peritoneal cavity (in the area of the ligated uterosacral–cardinal ligament complex) (Fig. 48.11). Instruments are switched to a long-handled needle driver and long gastropasty forceps to place that same suture in figure-of-eight fashion in the coccygeus–sacrospinous ligament complex on the corresponding side (Fig. 48.12). The direction of the needle must be horizontal, since one can easily damage the nearby neurovascular structures and ureters. It helps to

A

B

**FIGURE 48.8** Division of the broad ligament. The surgeon's index finger is (A) inserted into the peritoneal cavity and hooked around the broad ligament, which is (B) then ligated in the same fashion as the cardinal–uterosacral ligaments.

carefully palpate and identify the tight cordlike sacrospinous ligament structure in the substance of the coccygeus prior to suture placement. The same suture is then brought through one end of the mesh, then exited through the vaginal wall just above the area of the uterosacral–cardinal ligament complex, and tagged separately. The adjunctive use of mesh is necessary because we cannot rely on the native attenuated connective tissues to suspend the vaginal vault. A second 1 Vicryl suture is placed on the contralateral side in the exact same fashion.

Two pursestring sutures of 1 Vicryl are now placed to close the cul-de-sac. These sutures incorporate the prerectal fascia, the uterosacral–cardinal ligament complex, the broad ligaments, segment of the circular mesh, segment of the circular mesh, and the perivesical fascia (Fig. 48.13). It is important to stay in the midline when incorporating the perivesical fascia to avoid ureteral injury. The pursestring sutures are tagged at this time. The sutures of the previously ligated pedicles of the broad ligaments and the uterosacral–cardinal ligament

**FIGURE 48.9** A circular arrangement of the six ligated pedicles and their attached sutures remain.

**FIGURE 48.10** The oval shaped soft polypropylene mesh with horizontal arms is used to add strength to vault support. The horizontal arms are attached to the corresponding sides of the vaginal cuff (at the uterosacral–cardinal ligament complex). The middle circular segment of mesh is used to reinforce the pursestring closure of the cul-de-sac.

complex are identified on each side and tied in the midline. The pursestring culdoplasty sutures are now cinched and tied. If simultaneous repair of other prolapse is planned, it is now performed. The sacrospinous ligament vault suspension sutures are tied last after any cystocele repair and vaginal cuff closure. It is important to use Allis clamps to grasp and push down the vault to the sacrum while tying down the vault suspension sutures to achieve optimal depth.

Cystoscopy is performed routinely after giving indigo carmine and a bolus of 500 mL normal saline to assess for a healthy jet stream of urine from the ureteric orifices prior to tying down the vault suspension sutures. If there is any question of ureteric injury, the repair is taken down systematically starting with the vault suspension sutures to correct the problem. Vaginal depth is restored when the vault suspension sutures are tied down. Excess vaginal wall is excised before closure with an absorbable suture. Finally, if rectocele is planned, it is

**FIGURE 48.11** A 1 Vicryl suture brought from outside the vaginal wall into the peritoneal cavity in the area of the ligated cardinal–uterosacral complex.

**FIGURE 48.12** The same suture is placed in figure-of-eight fashion in the coccygeus–sacrospinous ligament complex.

performed at this time. A detailed description of rectocele and cystocele repair will not be addressed in this chapter.

---

## OUTCOMES

---

### Complications

---

Hysterectomy is a relatively safe procedure. Intraoperative complications include cystotomy (especially in patients with history of cesarean delivery), ureteral injury, hemorrhage, and gastrointestinal injury, although these complications occur less frequently compared to when the abdominal approach is used (9–11). Interestingly, bladder and ureteral injury occurs less

**FIGURE 48.13** Placement of pursestring culdoplasty sutures. Inside the peritoneal cavity, two 1 Vicryl pursestring sutures are placed to obliterate the cul-de-sacs and approximate the prevesical and prerectal fascia.

commonly with the vaginal approach. By performing routine cystoscopy, we are able to diagnose and address any ureteral injury in a systematic fashion by taking down any offending suture and/or placing a ureteral stent if needed (12).

Complications during and after surgery include infection (cuff cellulitis or abscess), bleeding, urinary retention, rectal injury, bladder injury, mesh erosion, bowel obstruction, fistulas, and ileus. Our patients are discharged on postoperative day 2 with a capped suprapubic tube and instructed to check postvoid residuals. The suprapubic tube is removed when the residuals are  $<50$  mL. Ileus may also occur but usually responds to conservative treatment. Delay in bowel function  $>3$  days should be taken seriously, with appropriate assessment to rule out bowel injury or colonic obstruction (from misplaced vault suspension sutures). Avoiding abdominal incision facilitates early ambulation and fewer respiratory complications. Apical cure rate of uterine prolapse following vaginal hysterectomy range from 88–100% (13). The majority of cases of recurrent prolapse involve only the upper vagina and are asymptomatic. Prolapse that develops following hysterectomy

may be an enterocele that was missed at the time of surgery or, more commonly, that occurred because of insufficient closure and/or support of the cuff. An enterocele may also develop postoperatively if other affected compartments are not repaired. Absence of the normal vaginal axis promotes prolapse of the cuff.

Ureterovaginal and vesicovaginal fistulas occur in 0.09% to 0.5% and 0.6%, respectively, of cases (6). Adequate anterior retraction of the bladder, ligation of the pedicles close to the cervix, and avoidance of lateral placement of the pursestring sutures in the perivesical fascia aid in the prevention of bladder and ureteral injury.

---

## Results

---

In regard to overall postoperative genitourinary function, Roovers et al used validated questionnaires to assess urogenital symptoms and quality of life after prolapse surgery and found improvement in all domains and quality of life following vaginal hysterectomy (14). Sexual function has always been a concern following hysterectomy. Recent data indicate that hysterectomy actually improves sexual functioning and overall quality of life. Rhodes et al. found that following hysterectomy, the occurrence of sexual relations and orgasm increased, while the rates of dyspareunia and low libido decreased (15). Similarly, researchers from the Maine Medical Assessment Foundation concluded that hysterectomy relieved pelvic pain, fatigue, depression, and sexual dysfunction and improved the overall quality of life 1 year after surgery (16).

---

## CONCLUSION

---

All genitourinary and pelvic reconstructive surgeons should be familiar with the relevant female pelvic anatomy and surgical technique of vaginal hysterectomy, which is being performed in increasing numbers in this country. Vaginal hysterectomy is considered the preferred surgical approach for treatment of benign uterine pathology, especially uterine prolapse, since it avoids the morbidities associated with an abdominal incision and has lower rates of bladder and ureteral injury. Successful vault suspension is an integral part of vaginal hysterectomy to restore normal vaginal axis and functional depth.

## CHAPTER 49 ■ CYSTOCELE AND ANTERIOR VAGINAL PROLAPSE

MELISSA R. KAUFMAN, HARRIETTE M. SCARPERO, AND ROGER R. DMOCHOWSKI

Anterior compartment vaginal prolapse, commonly referred to as cystocele (1), is the most common category of pelvic floor relaxation. Anterior defects arise from weakening of the endopelvic fascia and herniation of pelvic viscera into the potential space of the vagina. Compromise of the levator fascia and laxity of pelvic floor musculature both result in structural defects causing loss of pelvic floor support and subsequent formation of anterior compartment prolapse.

The fascia of the levator floor has a primary supportive function for not only the anterior vaginal wall but also the bladder and urethra in composite. DeLancey (2) elegantly described three levels of vaginal support to elucidate the proximal and distal structures involved in pelvic organ biomechanics. The abdominal aspect of this fascia is referred to as the endopelvic fascia, while the vaginal side is termed perivesical fascia at the level of the bladder base and periurethral fascia at the level of the bladder neck. The term *pubocervical* often refers to the combined periurethral and perivesical fascia complex. The vaginal and abdominal components of these fascial sheets fuse laterally at their insertion into the tendinous arch of the obturator internus, formally termed the arcus tendineus fasciae pelvis (ATFP), which forms a pelvic sidewall anchor for these structures.

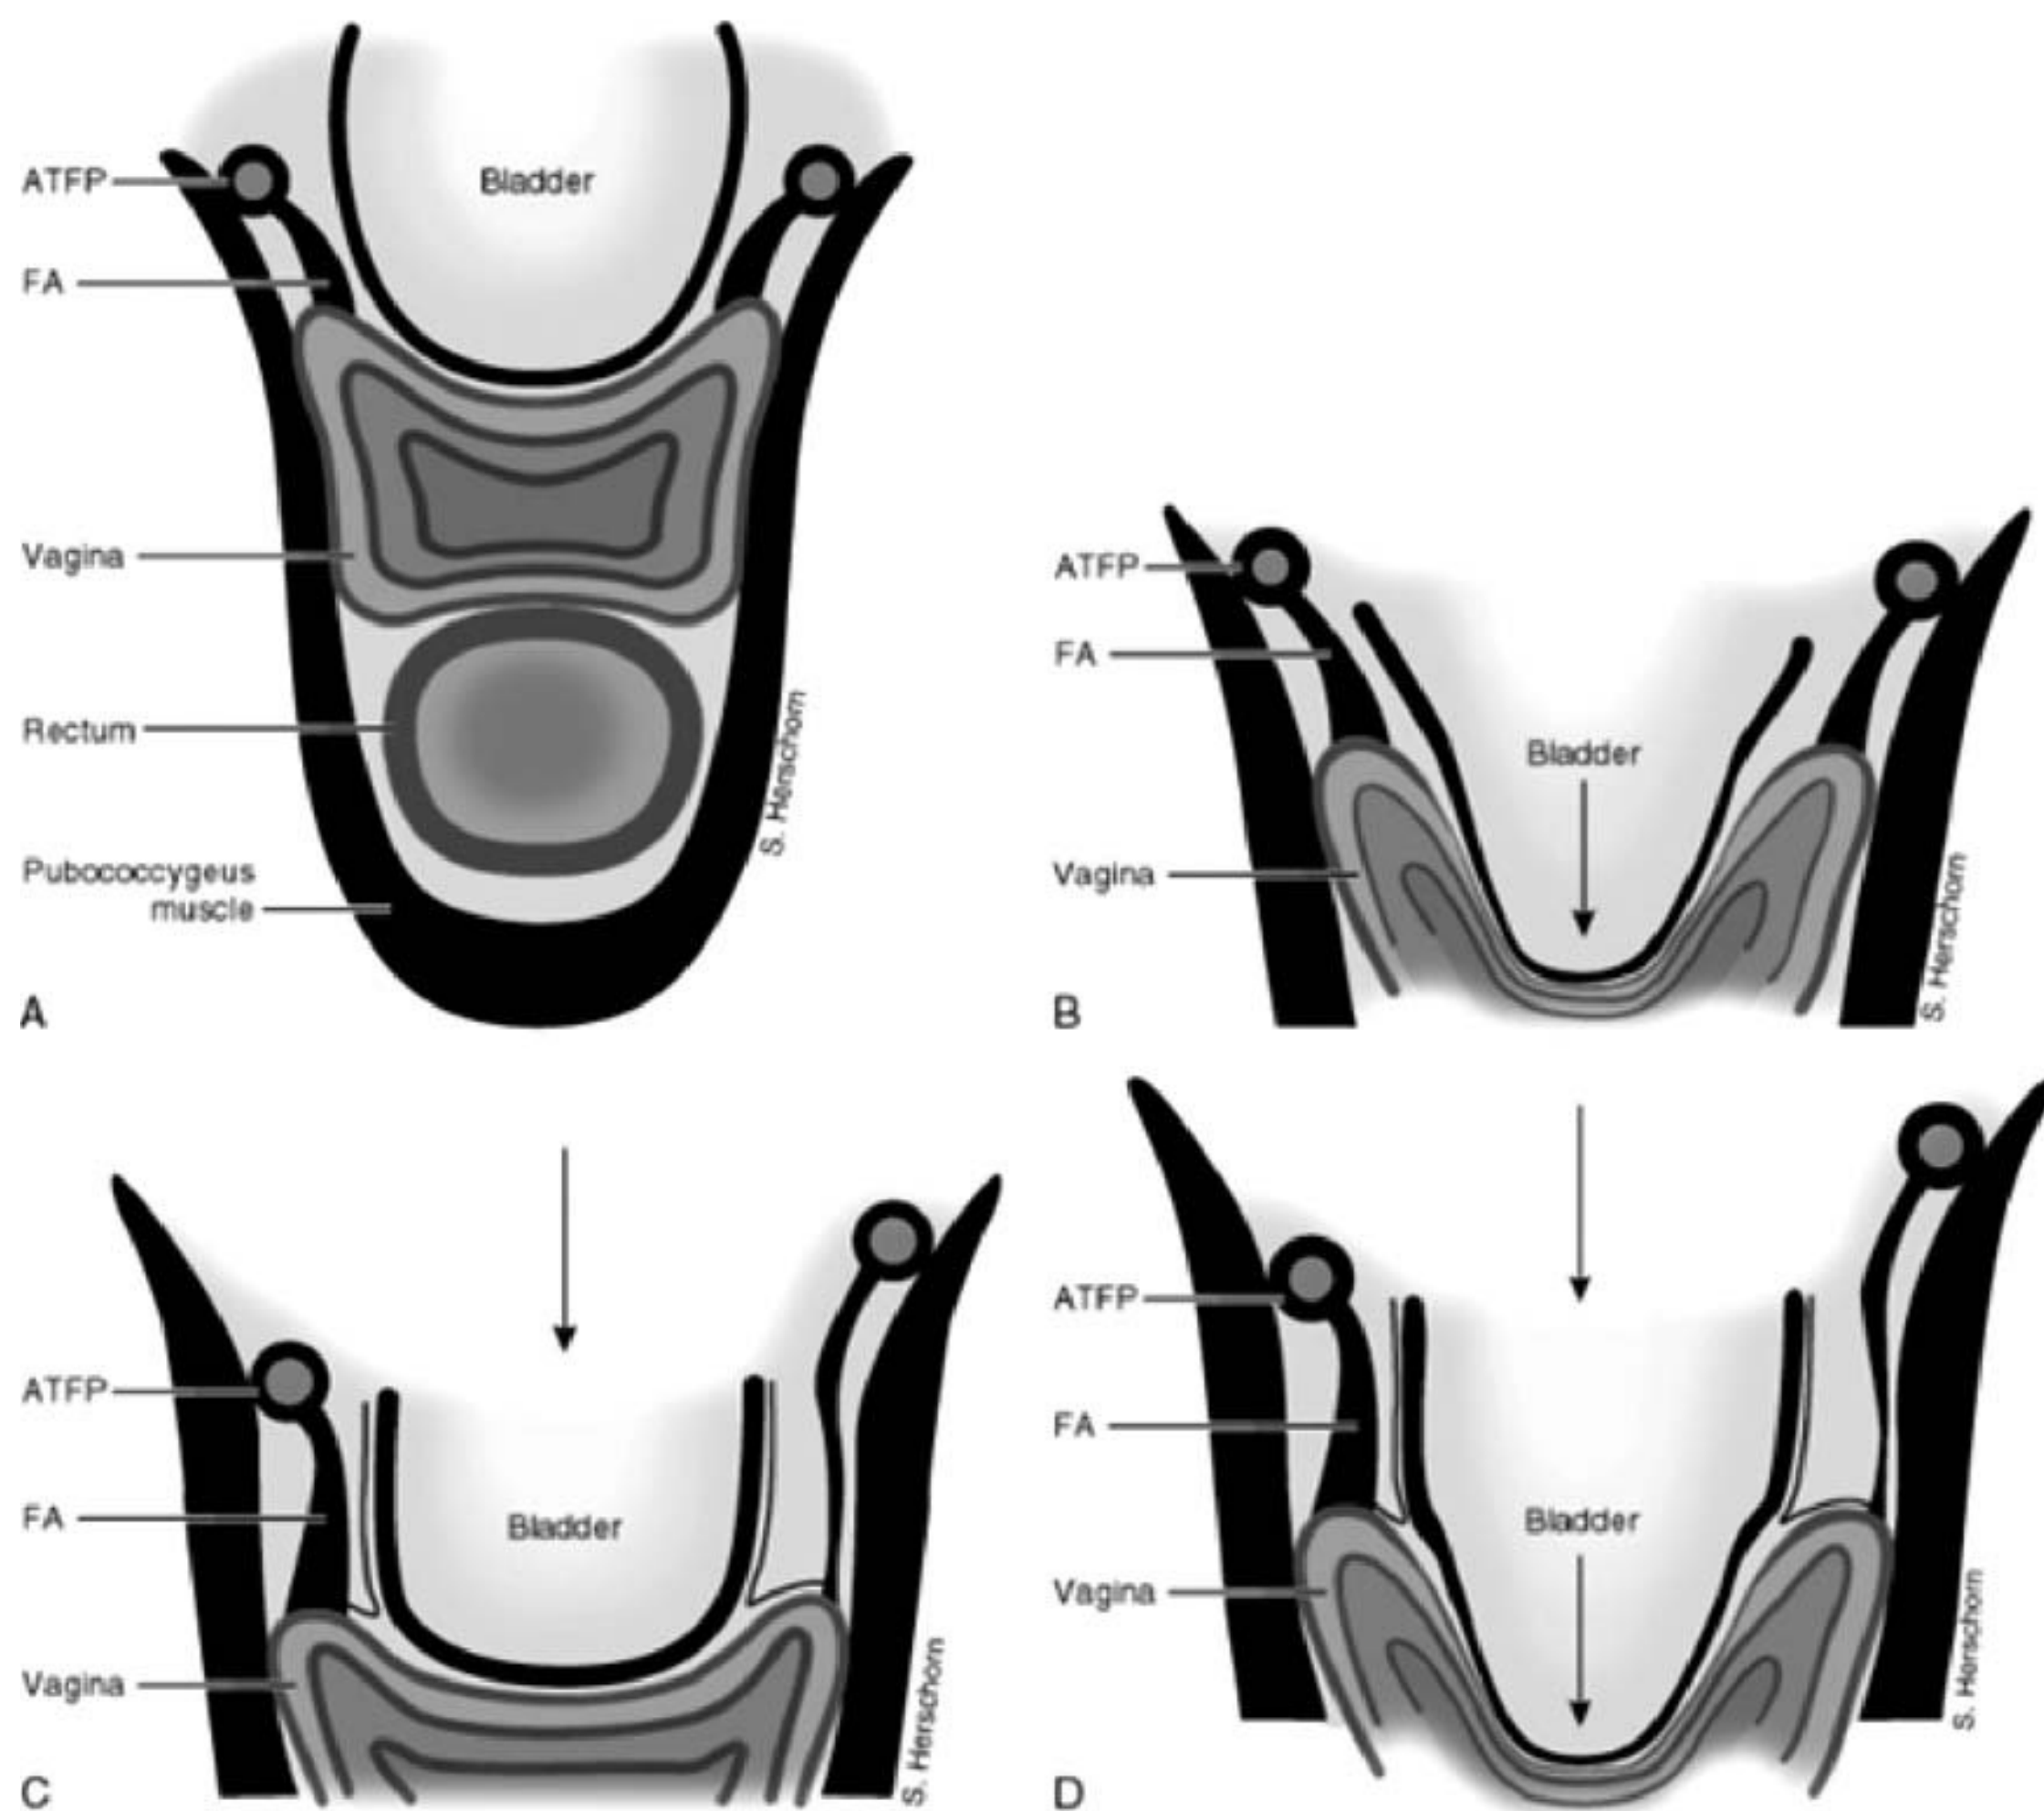

When viewing vaginal support from cephalad to caudad, the uterosacral–cardinal ligament complex supports the upper vagina and cervix and anchors them to the pelvic sidewall (Fig. 49.1). In the midvagina, the vesicopelvic ligament,

composed of endopelvic and perivesical fascia, extends from the ATFP of the pelvic sidewall to the bladder base and anterior vaginal wall. Distally, the urethropelvic ligaments provide support from the urethral meatus to the bladder neck. The ATFP, which is actually a thickened condensation of the obturator internus fascia and endopelvic fascia, provides a lateral insertion for all these structures. Indeed, the sturdy shelf of the ATFP provides a stabilization point for the entire pelvic floor hammock (3,4). Cystocele defects are commonly associated with other forms of pelvic relaxation, namely loss of support of the uterus and vaginal apex resulting in uterine or enterocele vault prolapse and/or loss of posterior compartment support with ensuing perineal relaxation and rectocele as well as functional deficits such as incontinence.

Defects of the anterior compartment may produce either isolated urethral or bladder support defects or a combination of deficiencies of both structures. Loss of structural integrity surrounding the urethra can result in urethral hypermobility without a concomitant cystocele defect being identified. Cystocele defects tend to be more complex and may involve isolated central, lateral, or combination defects (Fig. 49.2). Lateral, or paravaginal, cystoceles result from disruption or separation of the condensation of the vesical pelvic ligament to the arcus tendineus on either side of the vagina. Central defect cystoceles result from attenuation of the pubocervical fascia without compromise of the urethropelvic and vesicopelvic ligaments. Central defect cystoceles are often associated with

**FIGURE 49.1** The vesicopelvic ligament supporting the bladder is composed of endopelvic and perivesical fascia. The cardinal ligaments support the upper vagina and cervix and anchor them to the pelvic sidewall.

**FIGURE 49.2** Defects of the anterior compartment may result in either isolated urethral or bladder support defects or a combination of support defects of both structures. **A:** Cross section demonstrating bladder support to fascial attachments (FA) and the arcus tendineus fasciae pelvis (ATFP). **B:** Central cystocele. **C:** Lateral support defect. **D:** Combined central and lateral anterior prolapse. (Reprinted with permission from Herschorn S. *Vaginal reconstructive surgery for sphincteric incontinence and prolapse*. In: Walsh PC, ed. *Campbell-Walsh Urology*, 9th ed. Philadelphia: Saunders, 2007.)

attenuation of upper vaginal support as well, including loss of cardinal ligament support, which on occasion will manifest as a concomitant enterocele. Isolated central defects actually represent the minority of diagnosed anterior prolapse cases, with the most frequent presentation being a combination cystocele (5). Lateral defects are more numerous and are often associated with urethral hypermobility (6). When combined central and lateral defects are present, more severe degrees of prolapse regularly result.

## DIAGNOSIS

Anterior compartment prolapse produces a diversity of symptoms, including “mass effect” discomfort such as perineal or intravaginal bulge or sensation of a mass in the vagina, stress or urge urinary incontinence, dyspareunia, low back pain, vaginal irritation or bleeding due to excoriation of exposed vaginal mucosa, recurrent urinary tract infections, voiding

dysfunction, and in exceptional cases defecatory symptoms. Women may be required to manually reduce the anterior prolapse for successful voiding. Surprisingly, even large cystoceles can be totally asymptomatic. Profound cystocele defects may be associated with angulation of the proximal urethra by the bladder base, resulting in concomitant incomplete emptying, obstructive voiding symptoms and urinary retention. Severe cystoceles might also precipitate upper urinary tract changes, including hydronephrosis and, rarely, renal failure due to urethral or ureteral obstruction. Smaller cystoceles could be responsible for dyspareunia or incontinence only during sexual activity and, in select individuals, provoke early presentation prior to the onset of pelvic descensus symptoms.

Physical examination of the vagina will demonstrate a mass occupying the anterior vaginal wall from the vaginal apex or cervix, if hysterectomy has not been performed, extending to the bladder neck and/or urethra. If significant pelvic relaxation is present, this anterior prolapse may actually protrude from the vaginal introitus with activity or may

present exteriorized at rest. Vaginal examination with the patient in dorsal lithotomy position with a full bladder is aided by the lower blade of a Graves speculum. The examination should include anatomy at rest and with straining maneuvers to evaluate for stress incontinence, urethral hypermobility, and the degree of anterior prolapse. Examination should also focus on the integrity of the bladder base and presence or absence of defects in the lateral vaginal fornices. Isolated central defect cystoceles will present with a large anterior vaginal wall bulge that blunts the vaginal rugae with preservation of the lateral fornices. However, central cystoceles are often associated with lateral defects with little preservation of the paravaginal support. Unfortunately, physical examination is not particularly reliable or accurate for diagnosis of paravaginal defects (7). With isolated central defects, urethral hypermobility is often not noted; however, this finding is not universal. Lateral cystoceles are usually associated with combined anterior vaginal wall defects and urethral hypermobility. Bimanual examination or placement of an instrument such as a curved ring forceps in the lateral sulci may help reveal paravaginal defects. Evaluation should be repeated in the standing position to discover more subtle defects, to recapitulate the prolapse experienced during daily activity, and to identify concomitant apical or posterior prolapse.

Cystocele grading uses several different taxonomies, with the Baden-Walker being the simplest and most reproducible and the Pelvic Organ Prolapse Quantification System (POP-Q) providing the most descriptive method, often reserved for research protocols (8,9). Vaginal apical examination is crucial to locate the vaginal cuff and identify other forms of prolapse that may be present posteriorly or behind the cuff, such as enterocele and/or high rectocele. The location of the cuff establishes the usual limit of surgical dissection for the vaginal cystocele repair, and recognition of cuff position facilitates evaluation of a concomitant enterocele.

During the pelvic examination, it is imperative to ascertain the presence or absence of urinary incontinence. With significant anterior compartment defects, urinary urgency and urge incontinence from detrusor instability may be identified. The possibility of bladder outlet obstruction should be considered in patients who have undergone a prior incontinence procedure and developed de novo anterior prolapse. In those patients, a hyperangulated or nonmobile urethra with increased urinary residuals and symptoms compatible with outlet obstruction should warrant consideration of urethrolisis prior to or at the time of cystocele correction. Reduction of the prolapse during the vaginal examination with a speculum, packing, or pessary will on occasion unmask occult stress urinary incontinence. Video urodynamic evaluation may be indicated for these patients to best discover any contributing obstructive voiding component, as this patient may experience persistent outlet obstruction postoperatively and should be alerted to the risk of long-term catheterization. Some reconstructive surgeons advocate preoperative videourodynamics for all prolapse patients to assess for bladder dysfunction and provide a baseline for comparison (10). If the prolapse patient possesses additional lower urinary tract symptoms, office cystoscopy may be useful to illuminate concomitant bladder or urethral pathology. In complicated scenarios, dynamic magnetic resonance imaging (MRI) of the pelvis can provide dramatic anatomic information on the type and degree of pelvic organ prolapse and aid in operative planning.

---

## NONSURGICAL THERAPY

---

Optional management strategies for pelvic floor descensus include pelvic floor exercises, physical therapy combined with biofeedback, and behavioral modifications, although efficacy is usually confined to incontinence and not prolapse. The utilization of topical estrogens may augment the symptomatic response to this intervention in those patients who demonstrate vaginal mucosal atrophy and have a component of associated urinary irritative symptoms. Estrogens may also bolster vaginal tissues for improved tolerance of pessaries. A patient with an asymptomatic small cystocele, adequate vesical emptying, and no incontinence does not require surgical intervention.

Large prolapse defects can often be managed effectively with pessary placement. This option should be discussed with all women who experience symptoms of anterior compartment mass effect, as substantive clinical improvement may result. In some women, the use of a pessary may actually unmask occult incontinence and nullify any symptomatic benefit that the device has conveyed.

---

## INDICATIONS FOR SURGERY

---

Surgical intervention is predicated on several factors. Symptoms arising from the anterior prolapse, including incomplete emptying, vaginal mass, perineal prolapse, or the presence of urinary incontinence are the cornerstone indications for repair. The presence of dyspareunia should be carefully considered, as this symptom often coexists with cystocele mass effect complaints. Dyspareunia as an isolated indication for surgery, however, must be judiciously evaluated as the complaint may or may not respond to anatomic correction.

The choice of appropriate technique for operative management of anterior prolapse is based upon the degree and severity of the patient's incontinence, the magnitude of the cystocele, the underlying nature of the fascial defect, and the presence of concurrent voiding dysfunction. Comprehensive surgical planning also includes identification of associated prolapse elements, including enterocele, rectocele, and apical prolapse defects, as well as possible indications for concurrent hysterectomy.

The type of anterior compartment repair is suggested by the preoperatively defined fascial defect, although patients should always be counseled that intraoperative findings may alter the prescribed course of therapy (Table 49.1). Central fascial defects may be managed with a plication type of repair and/or an interposition graft repair with or without concomitant sling, dependent upon the presence of incontinence. Indeed, an isolated central defect repair is rare in the absence of a concomitant stress incontinence procedure.

Lateral defect repairs may be performed with a variety of techniques, including multiple-point suspensions as well as vaginal paravaginal repairs or abdominal paravaginal repairs combined with an incontinence intervention. Severe cystoceles with attendant central and lateral defects require simultaneous stress procedures as well as interpositional graft placement to compensate for complete disruption of the supportive pelvic floor structures.

Lower-grade cystoceles may be effectively repaired by outlet procedures performed at the level of the bladder neck,

including pubovaginal slings and earlier forms of suspensions such as needle suspensions.

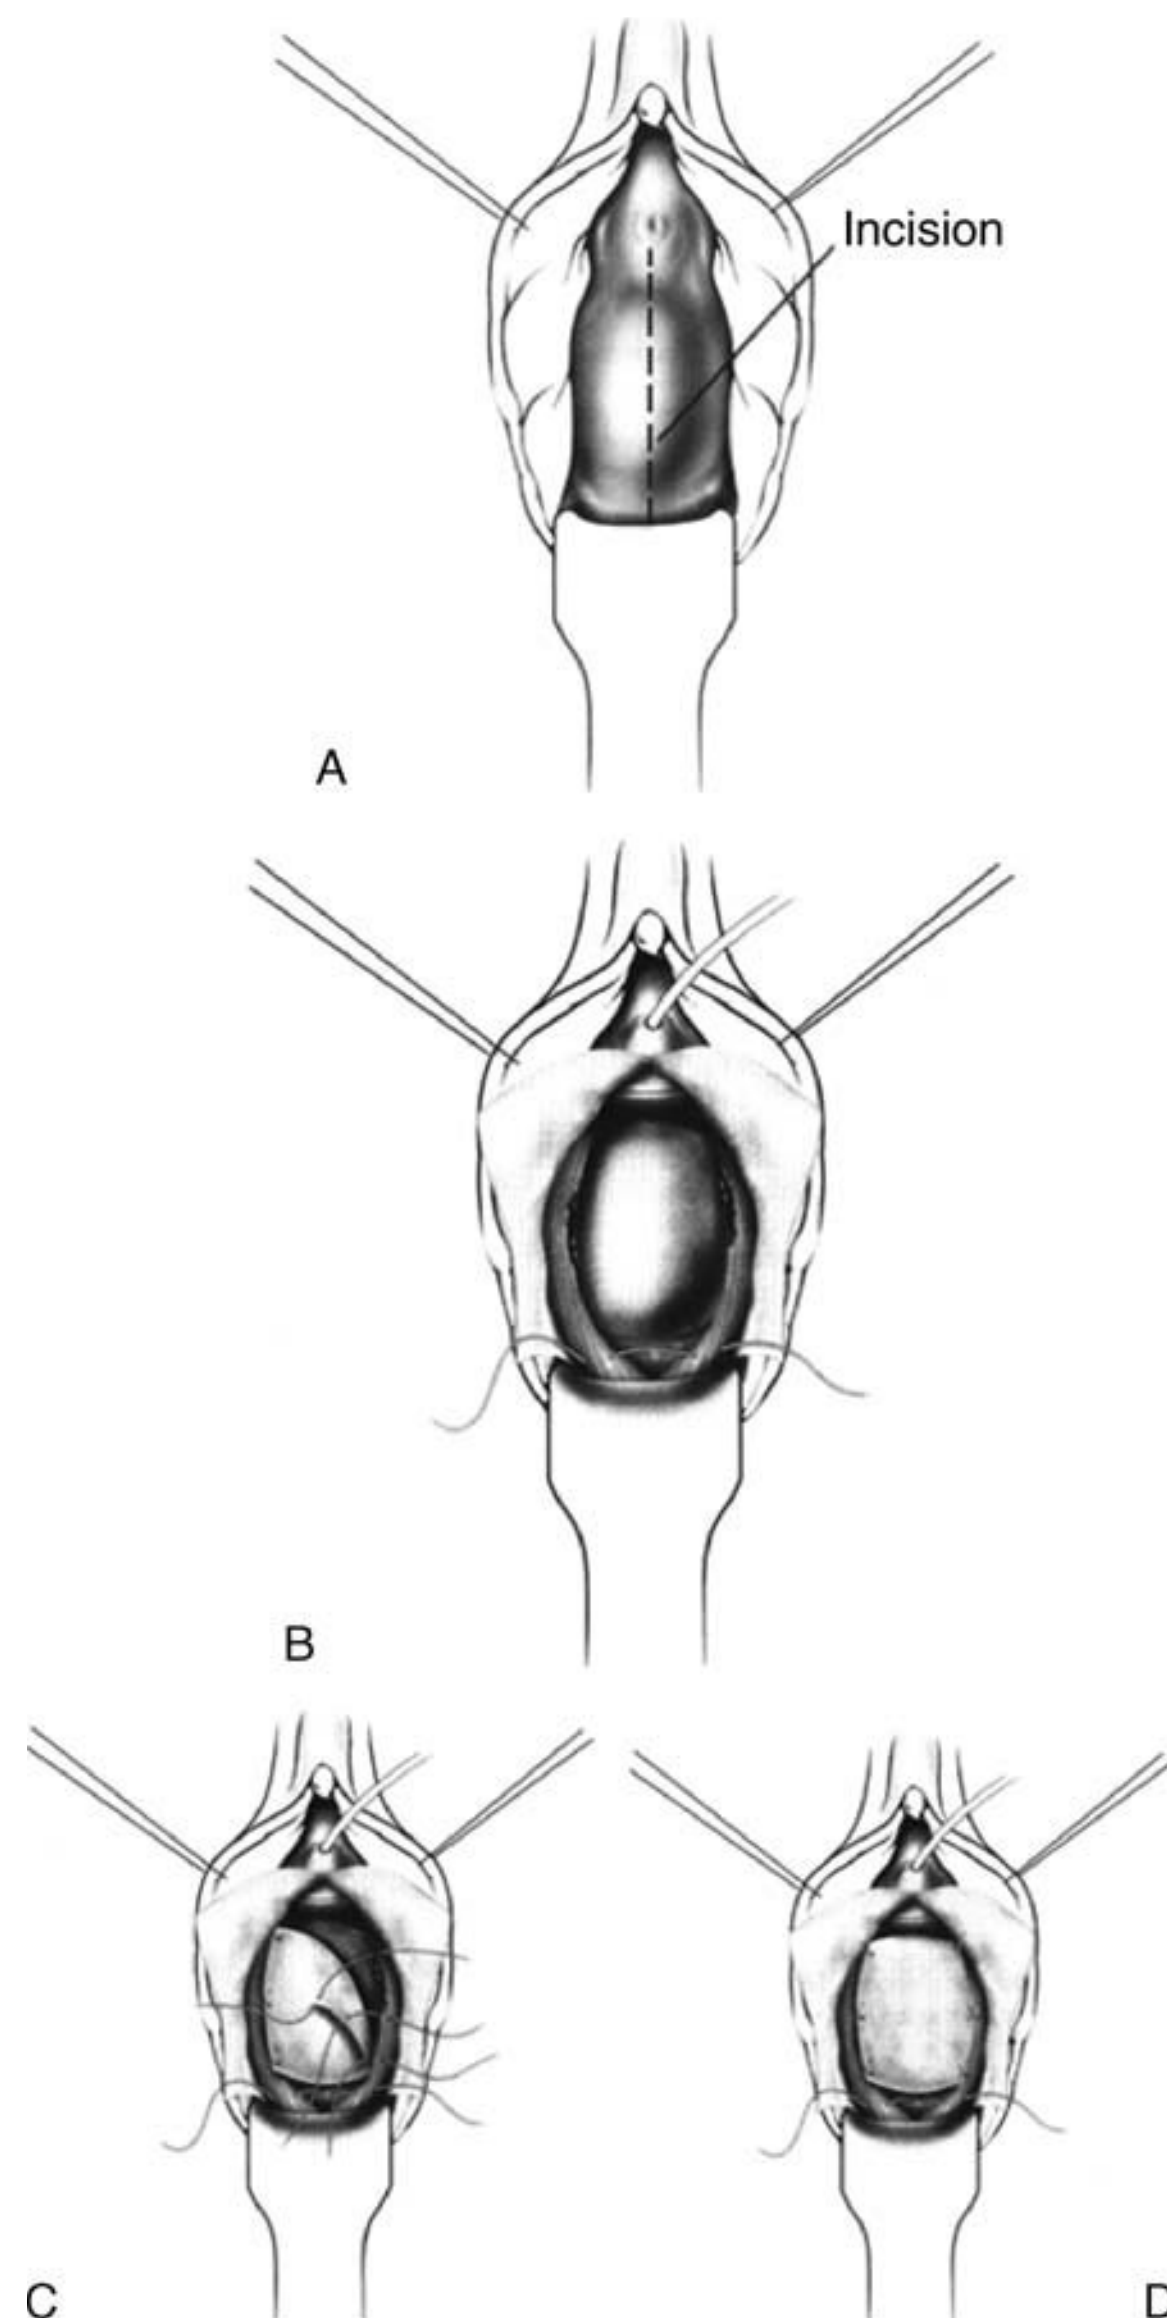

Recent innovative approaches to be discussed below include transobturator techniques for tension-free placement of polypropylene mesh that will accommodate both central and paravaginal fascial deficits and are often accomplished in conjunction with placement of a polypropylene midurethral sling. However, the surgeon must always consider to risks of transvaginal mesh placement and carefully select patients for such procedures.

## SURGICAL TECHNIQUE

### Repair of Combination Defects with Interposition Graft

Simultaneous lateral and central defects with associated urethral hypermobility may be addressed by a combined mesh inlay and pubovaginal sling procedure (Fig. 49.3). The choices for mesh interposition include synthetic, xenograft, autograft of free full-thickness vaginal wall, as well as allograft materials. Long-term data are not yet available to support one material as preferred; however, some evidence exists from experience with alternative slings that may be extrapolated to these inlays (11–13). When considering synthetic materials, polypropylene, polyglactin 910, and polyglycolic acid meshes are all viable choices. Polyglactin 910 and polyglycolic acid materials are conformal, modestly rigid, and, most importantly, eventually degraded and replaced by host fibrosis. Newer knitted filament polypropylene meshes, although permanent, elicit minimal inflammatory response and have pore sizes that allow excellent tissue ingrowth. Allografts that are fresh frozen appear to have poor durability, whereas those that are solvent deactivated or radiated maintain structural integrity, which has translated to increased durability. Dermis xenografts are the most conformal to underlying tissues and are less rigid and relatively less expensive, but some iterations tend to encapsulate as opposed to integrate into the tissue (14).

Defect repair may be approached either with a single-component interposition that serves as both bladder base and urethral support (14) or with a two-component interposition with separate strips of material providing the sling and the anterior compartment repair. The authors favor the two-component method, particularly considering the advent of midurethral tapes for use in cases of urethral hypermobility.

**FIGURE 49.3** **A:** The incision for the interposition graft is made in the midline from the midurethra to vaginal apex. **B:** After completion of dissection and entry into the retropubic space, identification of the cardinal ligament complex and the obturator internus is completed. The area of the cardinal ligament complex on either side is identified and the ligaments are reapproximated to reconstruct the vaginal apex. **C:** The interposition graft is inlaid in the defect. Sutures are placed sequentially in the obturator internus fascia and through the inlay material. **D:** Final repair demonstrating placement of the free graft from the bladder neck to vaginal apex.

Consideration should be given to concurrent stabilization of the vaginal apex with cardinal ligament plication sutures and/or apical suspension to the iliococcygeus muscle fascia or the sacrospinalis ligament. Inlay repairs tackle both central and lateral defects. Further paravaginal defect correction may also be fashioned by suture placement through the vesicopelvic ligaments and subsequent suspension to the anterior rectus fascia.

After appropriate administration of perioperative antibiotics (16) and placement of graded compression stockings and pneumatic compression devices, the patient is placed in hydraulic stirrups in the dorsal lithotomy position. After preparation of the abdomen, perineum, and vagina, the posterior compartment is draped away from the surgical field. However, if the surgeon is concerned that access to the rectum may be required, an adherent drape may be placed for an isolation barrier that will still permit entrance. A weighted speculum and a ring retractor are used for vaginal exposure. A 16Fr indwelling catheter is inserted and the incision delineated on the anterior vaginal wall in the midline extending from the midurethra to the vaginal apex (Fig. 49.3). The anterior vaginal wall overlying the cystocele is infiltrated with 20 to 50 cc of either normal saline or dilute vasoconstrictor for hydrodissection prior to incision with a scalpel. Lateral vaginal flaps are then developed by sharp dissection of the vaginal wall away from the underlying attenuated pubocervical fascia. The appropriate plane is recognized by the glistening white pubocervical fascia, with the vaginal wall itself often noted to be very thin in this plane. Dissection in the incorrect plane is usually associated with significant bleeding and inability to identify the underlying fascia. When placing mesh in the anterior compartment, some authors advocate developing a thicker vaginal flap that preserves some muscularis on the vaginal epithelium to decrease the risk of mesh extrusion. Placement of an Allis clamp on the lateral aspect and supporting the vaginal wall inferior to the clamp with the index finger can facilitate proprioception of the proper plane and substantially aid dissection. Once the dissection of the vaginal wall has been completed to the fornix on either side of the bladder neck, sharp dissection is utilized to enter the retropubic space immediately under the arch of the pubis. This plane is in general avascular and should separate well from the underlying fascial components. In previously operated cases, this space may be difficult to identify and it is important to utilize sharp, shallow dissection in immediate tactile proximity to the arch of the symphysis pubis to avoid inadvertent entry into pelvic viscera such as the bladder and urethra.

After sharp entry into the retropubic space, blunt lateral and anterior dissection is carried out to extend the space, palpate the arcus tendineus and ischial spine, and mobilize the bladder and urethra. Subsequently, dissection is performed to the vaginal cuff in a line parallel to the vaginal vault. During this dissection in posthysterectomy patients, the stump of the uterine arterial complex is commonly encountered, and bleeding may occur due to disruption of remaining vessels. Suture ligation with 4-0 polydioxanone should be contemplated to avoid persistent blood loss during the reconstructive segment of the operation. Cautery should be minimized to avoid devascularization of the underlying tissues. The authors prefer bipolar diathermy for vessel coagulation.

Apical dissection should be meticulous so as to identify any enterocele component; if found, the defect is excised and closed. Apical enteroceles may be small and somewhat obscured by the

bladder base descensus. The uterosacral ligaments can often be identified at this level of the dissection, and when found, plication with a 0 or 2-0 synthetic absorbable suture (SAS) can be performed. For high-grade cystocele, placement of sutures posteriorly in the iliococcygeus muscle fascia will provide further support and stability to the anterior compartment repair. These sutures are then brought through the vaginal apex to be tied at the completion of the procedure, after the vaginal wall has been closed. Once dissection of the retropubic space is completed and it is freely mobile, a pubovaginal sling is placed. The sling may be autologous tissue harvested through a separate abdominal incision, or if a midurethral transvaginal tape is selected, it should be placed through a separate incision following final closure of the anterior repair. For autologous fascial slings, ligature passage needles are directed from suprapubic to vaginal incisions on either side of the proximal urethra and bladder neck with digital guidance. Once placed, cystoscopy is performed to exclude needle entry into the bladder or urethra. Suspending sutures of 0 or 1 polydioxanone are placed through either end of the sling material and the suspending suture is then transposed from vaginal to suprapubic incisions using the ligature carrier. The sling is then affixed to the underlying periurethral fascia with 4-0 SAS. Following these steps, absorbable 1 polydioxanone sutures are placed in the obturator internus fascia at the level of the ATRP in an interrupted manner from the bladder neck to vaginal apex. This step usually requires two to four sutures in sequence. A sheet of graft material is tailored to the dimensions of the defect and affixed to the preplaced sutures in the arcuate internus fascia. The material should be placed loosely under the bladder base from the bladder neck to vaginal apex. Apical relocation sutures are then delivered through the vaginal wall, utilizing a free needle to pass the blunt end of the suture. Next, the vaginal wall is closed with running 2-0 SAS, and in our experience, it is rarely necessary to trim excess vaginal mucosa. If previously brought through the vaginal wall, apical relocation sutures are tied at this juncture.

After completion of the above steps, cystoscopy is again performed to ensure no penetration of graft or sutures into the bladder has occurred, as well as confirming bilateral efflux from the ureteral orifices and assessing the degree of reduction of the prolapse at the bladder base with the inlay material. Sling tension is then set by loosely tying the suspension sutures over two fingers, followed by closure of the suprapubic incision. Vaginal packing impregnated with estrogen cream is placed at the conclusion of the procedure. The vaginal pack is removed 12 to 24 hours postoperatively and the urinary catheter is removed for a voiding trial. If this is not successful, an indwelling catheter is reinserted or clean intermittent catheterization may be instituted. Alternatively, if a suprapubic tube has been placed at the time of surgery, the patient cycles the suprapubic tube during at-home convalescence. Patients are counseled to refrain from lifting over 5 lbs or engaging in intercourse for 6 weeks postoperatively.

---

### Repair of Isolated Central Defect Cystoceles

---

Primary colporrhaphy of isolated central defects with a well-supported, nonobstructive urethra may be performed with plication of the pubocervical fascia (Fig. 49.4). Urethral sphincteric function should be evaluated to determine if a

concurrent sling is indicated. Patient preparation and positioning are similar to the previously described procedure utilizing mesh. The anterior vaginal wall is infiltrated with injectable saline and a single midline incision is formed from the bladder neck to vaginal apex. The anterior vaginal wall is then dissected off the underlying attenuated pubocervical fascia utilizing countertraction with Allis clamps facilitated by the operative finger of the nondominant hand. This technique splays and flattens the tissue, easing dissection and identification of the correct surgical plane. The dissection is continued to the level of perivesical fascia. Once this is reached, the retropubic space is entered and the defect is defined from the introitus to vaginal apex.

Repair commences with reapproximation of the pubocervical fascia with 2-0 interrupted SAS along the base of the bladder from the bladder neck to vaginal apex. The fascial plication effectively relocates the cystocele behind the reconstituted pelvic floor. This repair may be bolstered with absorbable mesh to reduce the cystocele during plication and further strengthen the fascial reapproximation. The cardinal ligaments should also be reapproximated in the midline to secure the apex of the repair. The cardinal ligaments are then corrected with interrupted 2-0 absorbable sutures.

Cystoscopy is performed to ensure that the bladder is intact and ureteral efflux is present. Vaginal closure is then carried out utilizing a running 2-0 absorbable suture.

---

### Vaginal Paravaginal Repair

---

The paravaginal procedure performed through a vaginal incision does not use inlay material, instead exploiting the ATRFP as an anchoring point for sutures placed through the anterior vaginal wall on either side of the bladder base (17). The surgical field is prepared as above with dissection of the retropubic space, which frees the base of the bladder from the pelvic floor. Once the dissection is complete, the bladder base is retracted medially with curved retractors and the ischial spine is palpated. A 1-0 permanent suture is placed into the white line of the ATRFP just distal to the spine. A series of four to six 1-0 sutures are then placed in sequence to the urethrovesical junction. These sutures are then passed through the pubocervical fascia and vaginal wall beneath the bladder base from the bladder neck to the apex of the vagina. These steps are repeated on the contralateral side and then all are tied to reduce the cystocele. Subsequent sutures of 1-0 delayed absorbable material may be used to plicate the vaginal muscularis prior to closure.

---

### Needle Suspension

---

These procedures rely on a sequence of sutures placed through the pubocervical fascia that are then secured to the anterior rectus muscle (18). The authors find these types of procedures are of minimal utility for most patients. Preparation is similar to the previously described inlay repair. Two parallel anterior vaginal wall incisions that extend from the bladder neck to the vaginal apex are created. These incisions are made on either side of the midline in an oblique fashion so as to be able to reflect the lateral wall off the underlying anterior vaginal wall. Once the incisions are completed, sharp dissection is carried out laterally to enter the retropubic space and identify the attenuated edge of the pubocervical fascia. In addition, the loca-

tion of the cardinal ligament complex at the apex of the vagina is identified on either side.

After vaginal dissection has been completed, four or six suspending sutures of 1 polypropylene are placed in the pubocervical fascia in pairs—two proximal at the vaginal apex, two midvaginal, and two distal at the level of the bladder neck. Sutures are placed to incorporate the pubocervical fascia and, at the vaginal apex, the cardinal ligaments. The most distal sutures are placed in the midurethral complex. These sutures are then transferred from the vaginal to the suprapubic incision using specially designed needle carriers. This repair may be augmented with SAS mesh or other inlay materials affixed to the pubocervical fascia with 0 or 2-0 SAS or PDS sutures. The vaginal wall is closed with a 2-0 absorbable suture, and finally the suprapubic incision is irrigated and closed.

---

### Abdominal Repairs

---

The abdominal approach for cystocele repairs is exclusively for lateral defects (5) (Fig. 49.5). This approach yields superb visualization of the lateral defect and surrounding structures. Also, retropubic incontinence procedures or slings may both be performed with this approach (19). Preparation includes positioning the patient in the low lithotomy or frog-leg position so as to have sterile access to the vagina. A lower-abdominal incision is made, either horizontal or transverse.

The retropubic space is entered and developed on either side of the bladder and urethra to identify the obturator internus fascia. This is best performed bluntly, with the suction tip or a sponge stick, so as to sweep the overlying adipose tissue from the underlying structures. The ischial spine is identified and the white line of the ATRFP traced from its origin at the ischial spine to the urethrovesical angle. The fascial defect will often be easily identifiable once this dissection is complete. The surgeon may also place a sponge stick or the nondominant hand in the vagina to displace the vaginal wall superiorly and better demonstrate the edges of the fascial defect.

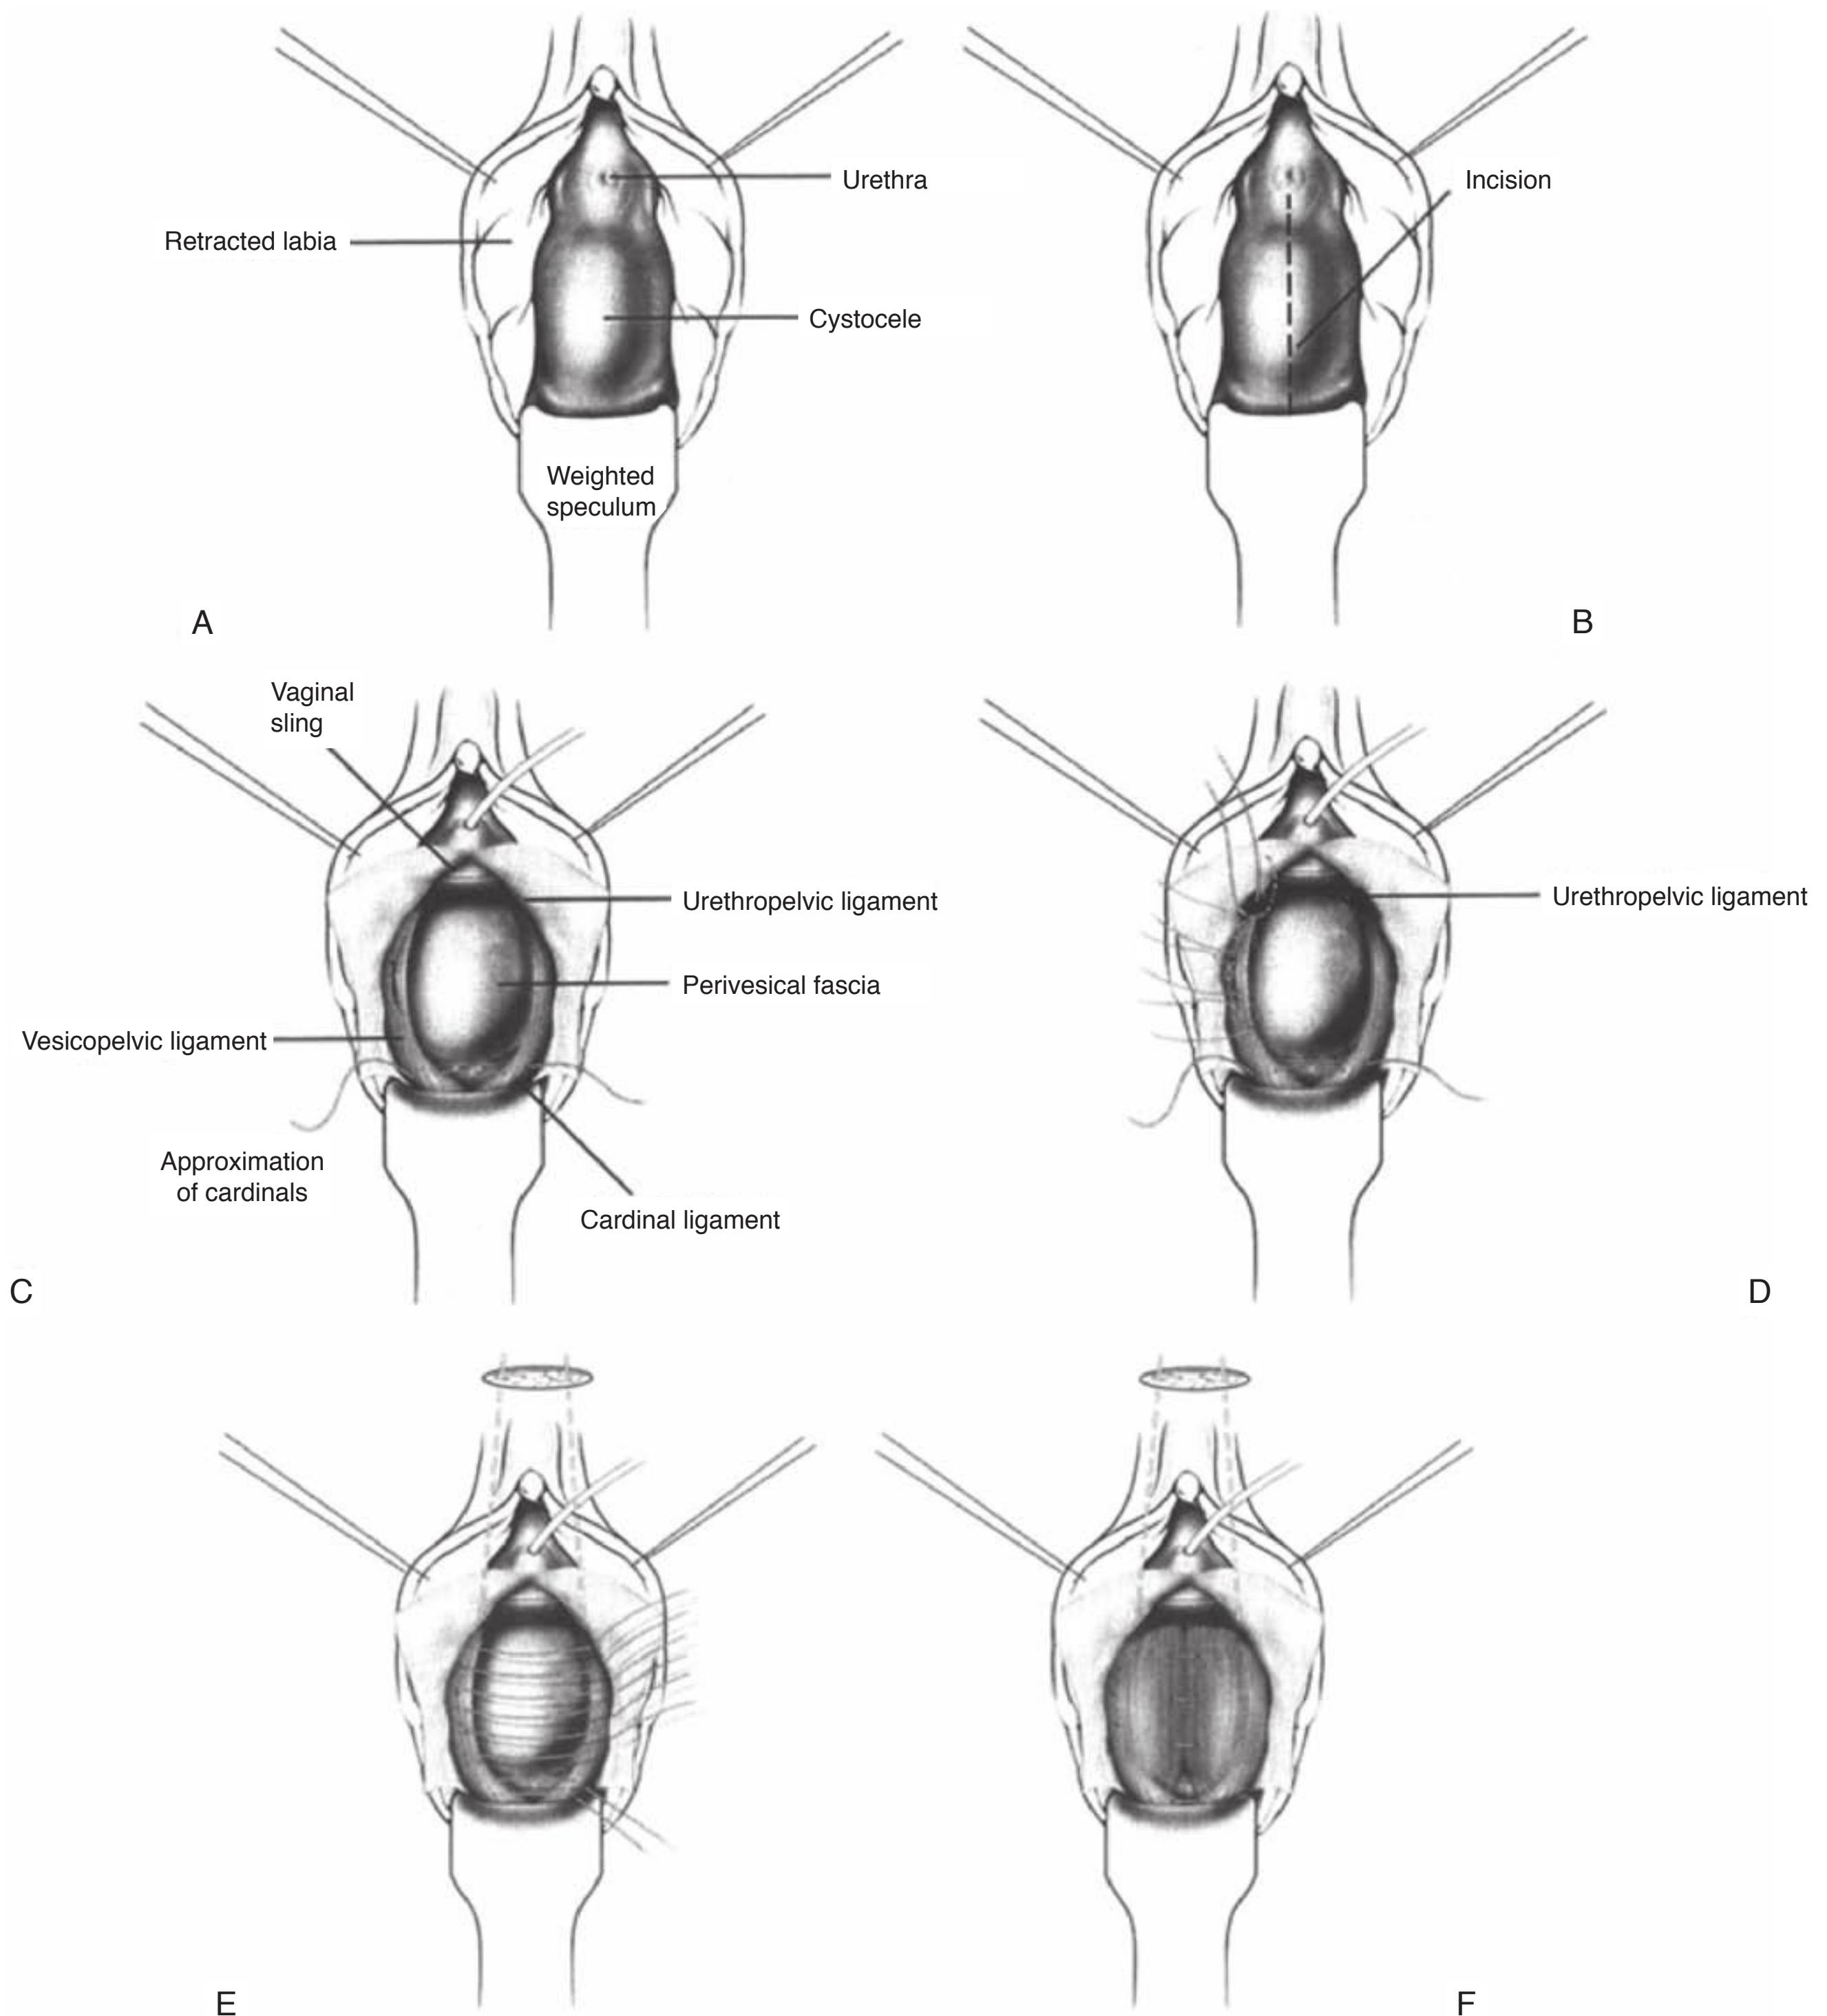

Once dissection is complete, four to six interrupted sutures are placed in the disrupted edges of the defect to reapproximate the obturator internus fascia and the medially displaced pubocervical fascia. After all sutures are placed, they are tied sequentially. Prior to closure of the abdomen, cystoscopy is performed to exclude suture entry into the bladder and confirm ureteral efflux.

---

### Innovative Transobturator Approaches

---

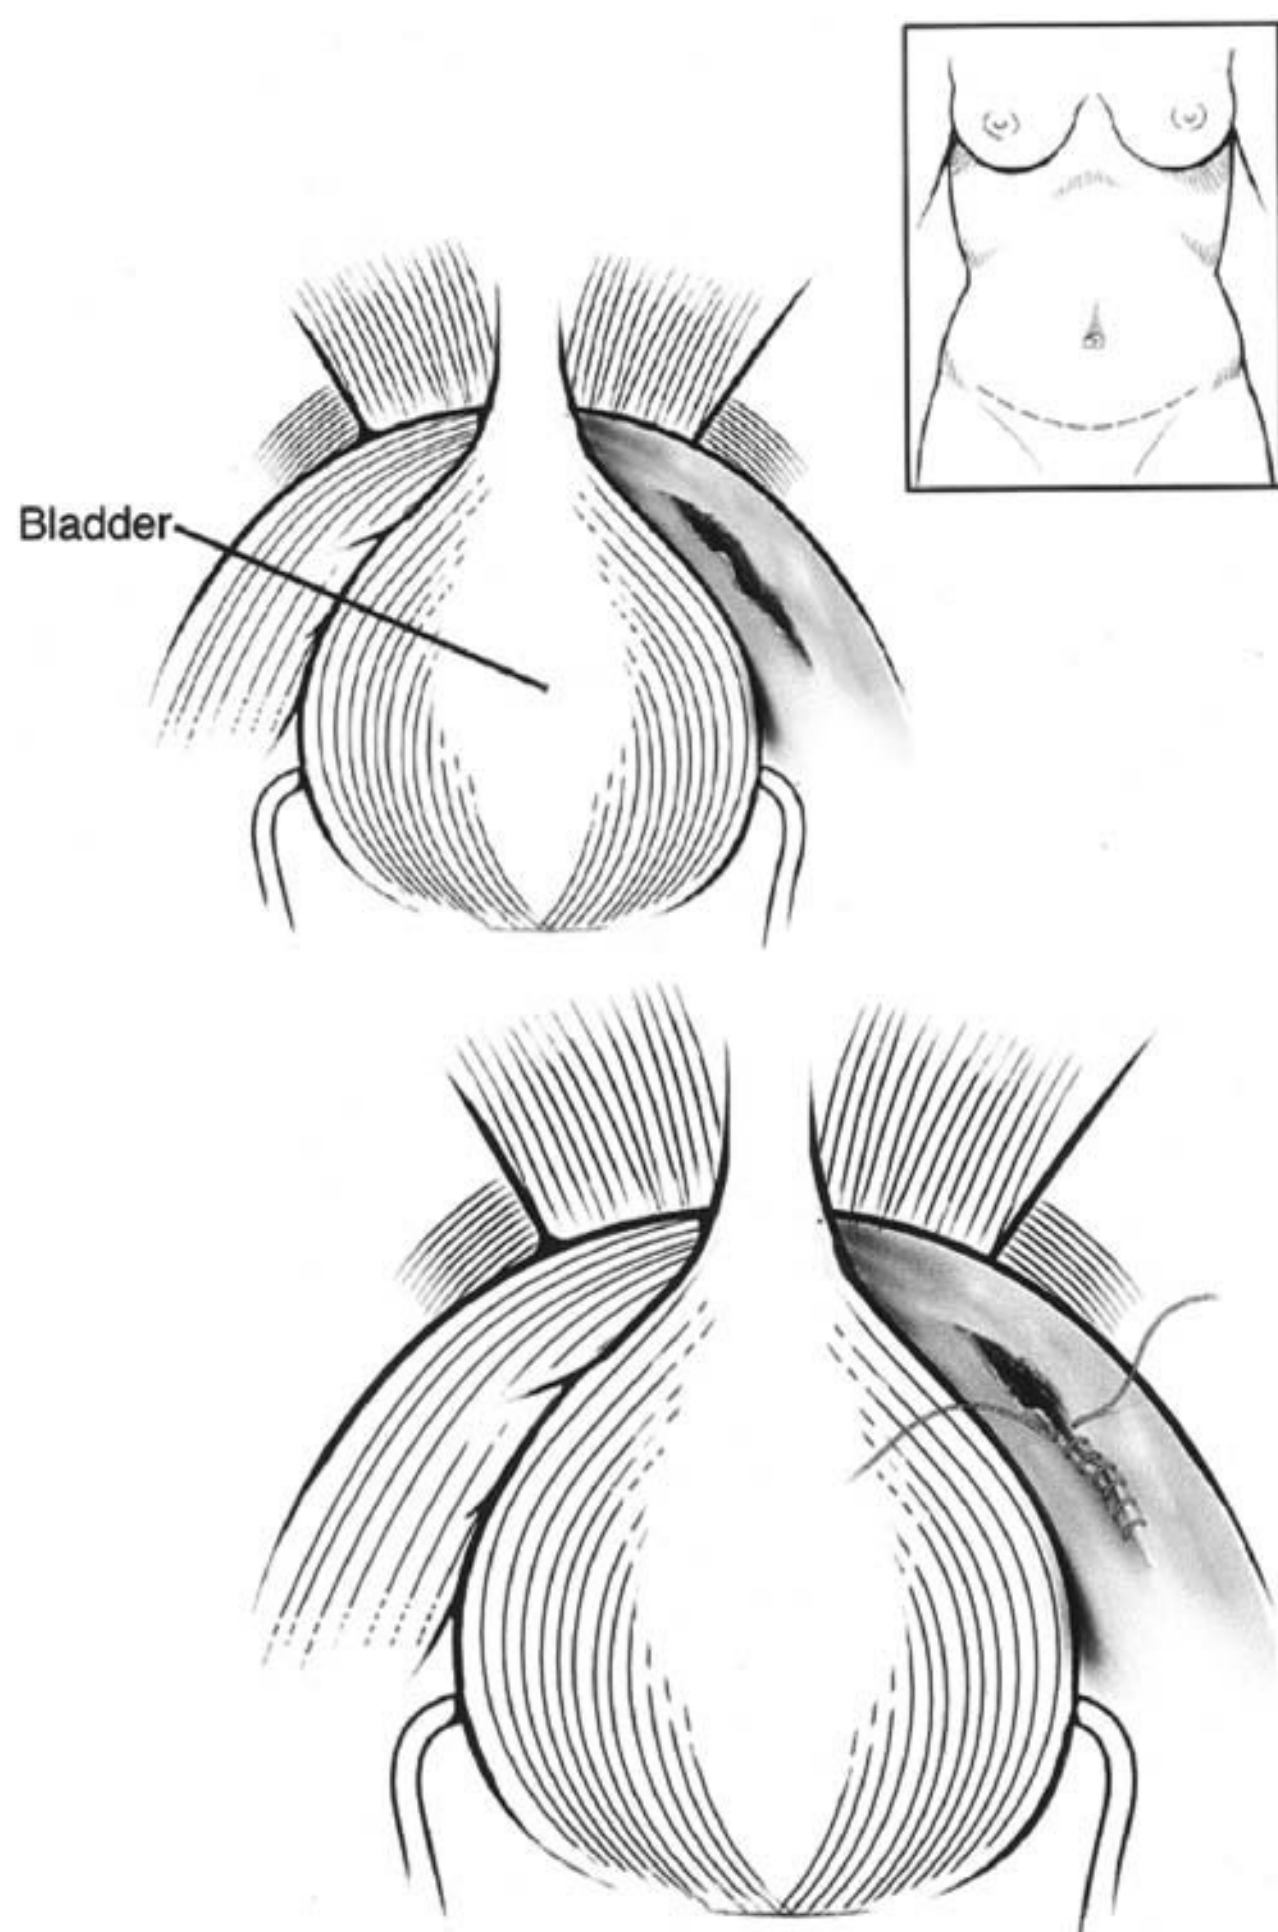

Several comprehensive pelvic organ prolapse systems have recently been released and are gaining substantial acceptance from urologists and urogynecologists for the treatment of cystocele. These mesh-based systems utilize the minimally invasive approach of a vaginal incision with a reproducible, standardized kit allowing simultaneous repair of multiple fascial defects (Perigee, American Medical Systems, Minnetonka, MN; and Anterior Prolift, Gynecare, Somerville, NJ). Current systems allow anchoring of allograft, xenograft, or polypropylene mesh through the obturator foramen and into the ATRFP with specially designed passage devices (Figs. 49.6 and 49.7). The appropriate placement of these supporting materials allows simultaneous repair of both central and lateral defects. Patient

**FIGURE 49.4** **A:** Demonstration of the central cystocele defect with preservation of the lateral vaginal sulci. **B:** A midline incision is created from the midurethra to vaginal apex in the vaginal wall. The retropubic space is developed on either side of the urethra and bladder. **C:** The vesicopelvic ligaments are identified, as are the cardinal ligaments. The cardinal ligament complex is reconstituted in the midline with sutures so as to provide apical support for the repair. **D:** For those repairs involving suture suspension techniques, sutures may be placed throughout the vesical pelvic ligament and transposed from the vaginal to suprapubic area for subsequent stabilization. These steps are repeated on the contralateral side. **E:** In those circumstances where plication alone is performed, sutures are placed across the base of the bladder from the vesicopelvic ligament on one side to the vesicopelvic ligament on the contralateral side and the two structures are reapproximated. **F:** Completion of combined plication repair with needle suspension of the proximal urethra and bladder neck.

preparation and positioning are similar to anterior colporrhaphy, except draping of the operative field must include the medial thigh overlying the obturator foramen. A urethral catheter

is placed and hydrodissection of the anterior vaginal wall performed with saline or a dilute vasoconstrictor prior to creating a midline incision from the bladder neck to the vaginal apex.

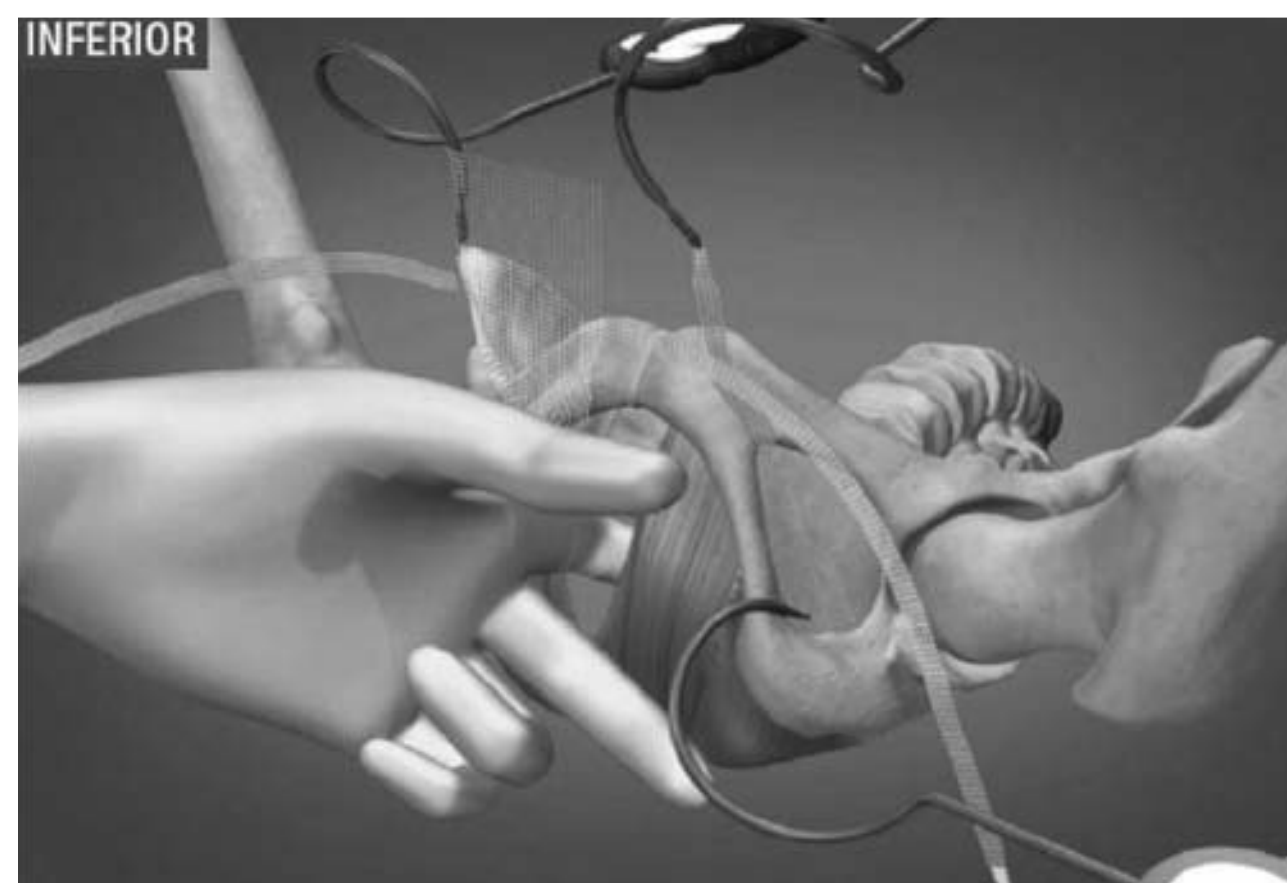

**FIGURE 49.5** Positioning and incision for retropubic repair of lateral cystocele defects. A Pfannenstiel incision is made in the lower abdomen to expose the retropubic space. The dissection exposes the obturator internus fascia, and the fascial defect is identified as seen in the right aspect of the diagram. Using interrupted delayed absorbable or permanent sutures, the disrupted fascial edges are reapproximated. The sutures are placed from the ischial spine to the level of urethrovaginal angle as noted.

Vaginal epithelial flaps are intentionally created so as to be thicker for purposes of graft coverage. Lateral dissection proceeds to the endopelvic fascia, but entry into the retropubic space is not performed. The surgeon must be able to palpate the ischial spine for appropriate placement of the proximal graft arm. External skin incisions are made over the medial border of the obturator foramen and the passage devices are delivered from the outside to the inside of the vaginal dissection with guidance of the surgeon's finger. The distal incision is at the level of the clitoris, and the proximal incision is 2 cm inferior and 1 cm lateral to the clitoral incision. The distal trocar is placed in the ATFP at the level of the bladder neck and the proximal trocar is placed approximately 2 cm distal to the ischial spine. Cystoscopy is performed at this juncture to ensure no violation of the bladder has occurred during dissection or trocar passage. The graft is attached to the passage devices and guided back out of the skin incisions. Tension is set by manipulation of the graft arms and cystoscopy is again performed to ensure bilateral ureteral reflux. The graft is secured proximally

with 2-0 absorbable suture and the vaginal incision closed with 2-0 SAS. Tailoring of redundant anterior vaginal wall skin is not recommended, as redundant mucosa will contract and may provide an additional barrier for prevention of mesh extrusion. Skin incisions may be closed with 4-0 SAS subcuticular sutures or secured with a biologic tissue adhesive. Using a separate

**FIGURE 49.7** Prolift mesh placement with critical landmarks—1 denotes uterosacral ligament, 2 indicates sacrospinous ligament, and 3 overlies the arcus tendineus fasciae pelvis, demonstrating the position of graft anchoring through this fascial condensation. midline incision, a midurethral sling can now be placed for treatment of concomitant incontinence.

---

## OUTCOMES

---

### Complications

---

Significant intraoperative complications occur relatively infrequently with anterior vaginal prolapse repairs. In addition to the general risks of hemorrhage and urinary or soft tissue infections, the most common complication seen with cystocele repair is injury to underlying structures such as the urethra, bladder, and rarely, other pelvic viscera, including bowel. Incidental cystostomy may be repaired with a layered closure with absorbable suture, nonopposing suture lines, and maximization of urinary drainage. Although reported to occur at an incidence of <2%, the prolapse surgeon must always be cognizant of the risk of ureteral damage or obstruction (20). Cystoscopic evaluation intraoperatively should indicate the possibility of ureteral obstruction with nonreflux from one side. Sutures may be removed at this time prior to completion of the procedure. Stenting should be considered only in the case of significant disruption or trauma to the ureteric orifice. Failure to recognize ureteral injury intraoperatively sets the stage for one of the most devastating complications of anterior prolapse repair, namely ureterovaginal or vesicovaginal fistula.

Increasing use of permanent mesh materials for prolapse repair may increase the risk for erosions, infections, sinuses, fistulas, and development of robust vaginal granulation tissue (13,21). Nonabsorbable suture present in the bladder can

result in stone formation or recurrent infections and should be removed and relocated. The use of the transobturator approach has added the variable of leg pain due to inexact placement of trocars during graft insertion. When encountered, this pain may be persistent and quite troublesome.

Postoperative voiding dysfunction may be caused by detrusor instability, urethral obstruction, or recurrence of the cystocele. Resolution of preoperative urgency will occur in up to 63% of patients (22); however, de novo detrusor instability will occur in approximately 5%. Although degrees of urinary retention may occur in patients on a transient basis, prolonged obstruction manifests in <1% of women. Poor or inadequate detrusor contractility may be a reason for incomplete emptying and should be predictable on the basis of preoperative urodynamic evaluation. Clean intermittent catheterization or long-term indwelling catheterization may be indicated in these patients.

Persistent dyspareunia, pelvic pain, or vaginal stenosis may ensue from aggressive plication and/or excision of vaginal mucosa. However, the majority of women appear to have improved dyspareunia after surgery, largely due to resolution or improvement of stress urinary incontinence (23). In those women who had deterioration of sexual function, the majority of cases appear to be associated with simultaneous posterior colporrhaphy (24). Vaginal shortening from inadequate apical reconstruction also may contribute to dyspareunia. Finally, late-onset apical prolapse and enterocele formation may occur due to alterations of the vaginal axis and insufficient repair of the apex. Meticulous attention to apical reconstruction should avert this consequence.

---

## Results

---

Long-term results for these procedures are still undergoing evaluation, and as evidenced by recent meta-analysis, most published studies reflect uncontrolled case series (25). Results should reveal cure of prolapse and remediation of incontinence. Risk factors for operative failure may include advanced age, hormonal depletion, inadequate preoperative identification of all anatomic defects, incomplete surgical reconstruction, or technical failure (26). In addition, obesity, chronic pulmonary disease, bowel dysmotility, and genetic predisposition have also been implicated in surgical failure. Some studies have reported that interpositional grafts convey a significant reduction in prolapse recurrence, with plication repairs demonstrating only a moderate success rates (25,27); however, other authors have found similar objective anatomic outcomes (28).

Vaginal paravaginal repairs have reported failure rates of 3% to 14% at 1 year (29). The six-corner bladder suspension has shown reasonable results at 2 years. Combined repairs have a small associated risk of cystocele and enterocele formation but have been reported to have a 94% success rate for cure of incontinence.

Little data have yet to be published on the transobturator mesh kits, but short-term results appear promising, with up to 95.3% anatomic correction of the anterior compartment, with an acceptable complication profile (30–32). Enthusiasm for these early results must be tempered by emerging reports of exceptional complications possible with extensive transvaginal mesh procedures (33).

## CHAPTER 50 ■ TRANSVAGINAL REPAIR OF APICAL PROLAPSE

KATIE N. BALLERT AND VICTOR W. NITTI

Most women who present with pelvic organ prolapse (POP) have a combination of pelvic floor support defects affecting multiple compartments (anterior, apical, and posterior). In our opinion, the majority of anterior prolapse cases significant enough to require repair have an apical component. In addition, we believe that the high recurrence rate after POP repair may in part be due to failure to adequately address the apical component. For example, Shull et al. (1) demonstrated a

reduced rate of recurrence (by 7%) after vaginal repair of large POP by routine performance of a transverse defect repair.

After hysterectomy, the apical portion of the vagina is supported by sheet-like extensions of the endopelvic fascia that attach it to the pelvic sidewall and levator ani fascia, referred to as the paracolpium (Fig. 50.1) (2). The paracolpium provides two levels of support. Level I, or upper support, “suspends” the vagina, attaching it to the pelvic sidewall. Level II,

**FIGURE 50.1** Level I (suspension) and level II (attachment). In level I the paracolpium suspends the vagina from the lateral pelvic walls. Fibers of level I extend both vertically and also posteriorly toward the sacrum. In level II the vagina is attached to the arcus tendineus fasciae pelvis and superior fascia of levator ani. (From DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol.* 1992;166:1717–1728, with permission.)

or midvaginal support, which includes the pubocervical fascia, “attaches” the midvagina more directly to the pelvic walls, including the levator fascia and arcus tendineus. Damage to mid-level support usually results in anterior and posterior defects, while damage to upper-level support results in apical prolapse, including enterocele and/or vault or uterine prolapse.

## DIAGNOSIS

Prolapse is described in terms of anterior, apical, and posterior as opposed to “cystocele, enterocele, and rectocele.” This is because most cases of prolapse are multicompartmental, and the support of one pelvic structure is dependent on the support of other structures. Second, it is sometimes difficult to tell on physical examination exactly what organs are prolapsed. An enterocele may present as anterior prolapse (usually in conjunction with a cystocele), apical prolapse, posterior prolapse, or a combination, depending on where the break in support is located. It is also important to ascertain if the vaginal vault is prolapsed, as this will affect the type of repair performed.

The extent of prolapse is first evaluated with the patient in the lithotomy position. The presence of urethral mobility, stress incontinence, and anterior, apical, and posterior prolapse should be assessed. The patient should be instructed to cough and perform a Valsalva maneuver to assess the effect of increased abdominal pressure on the prolapse. With the prolapse reduced (manually or with a ring forceps, packing, or pessary), the patient should be asked to cough and perform a Valsalva maneuver to evaluate for occult stress incontinence. To ascertain the full extent of the prolapse, the patient should also be examined in the standing position with one foot elevated on a stool. The degree of prolapse of each compart-

ment may be quantified using a variety of systems. Currently, the Pelvic Organ Prolapse Quantification System (POP-Q) is the most comprehensive (3). Imaging studies, including cystography, defecography, ultrasound, computerized tomography scan, and magnetic resonance imaging, may also be used to help define pelvic anatomy if necessary.

## INDICATIONS FOR SURGERY

In general, the degree of pelvic prolapse and the severity of the symptoms it causes are the main indications for treatment. Low-stage prolapse is often asymptomatic and does not require treatment. Treatment is typically driven by the patient’s symptoms, which may include an uncomfortable feeling of prolapse that may limit activity, obstructive voiding symptoms, and/or constipation. POP may be associated with stress incontinence, which may ultimately drive the patient toward treatment. The patient’s age, general health, performance status, degree of sexual activity, and expectations from treatment will play a role in the type of treatment or surgical procedure performed. Finally, some patients may suffer serious sequelae of prolapse, such as hydronephrosis from ureteral obstruction or urinary retention from urethral obstruction.

## ALTERNATIVE THERAPY

Nonsurgical treatment involves supporting the pelvic floor with a device such as a pessary. Pessaries come in a variety of shapes and sizes and are fit depending on the patient’s size and anatomy and the components of the prolapse. Many women find pessaries a satisfying alternative to surgery that can comfortably control the symptoms of pelvic prolapse, while others are unable to maintain a pessary due to their specific anatomy or cannot use one due to symptoms such as discomfort, bothersome discharge, or bleeding. For those women who do not remove the pessary, regular follow-up (every 1 to 3 months) is necessary so the pessary can be removed, cleaned, and replaced and the patient examined.

## SURGICAL TECHNIQUE

There are several options for surgical management of apical prolapse. Prolapse can be approached vaginally or abdominally depending on its degree, patient characteristics, and desired outcomes. While the focus of this chapter is on transvaginal repair, there are situations where the abdominal approach (either open or laparoscopic) is preferred, such as in young women with vaginal vault prolapse or those with failed transvaginal procedures (4). In the frail elderly population, colpocleisis, in which the entire vagina is closed, may also be considered.

### Transvaginal Enterocele Repair

Transvaginal enterocele repair may be performed either intraperitoneally or extraperitoneally. In cases of large enterocele, we prefer the intraperitoneal approach; however, in cases where the enterocele is small or difficult to find, an extraperitoneal approach may be appropriate. There are several variations of the repair, depending on the degree of prolapse and

**FIGURE 50.2** The vaginal wall is grasped with two Allis clamps and brought outside the vaginal introitus. A midline incision is made. (From Nitti VW. Transvaginal enterocele repair with variations. *Contemp Urol* 1994;6:50–64, with permission.)

whether or not a vault suspension is necessary, yet most variations start with the basic intraperitoneal repair.

The patient is placed in the dorsal lithotomy position. She is prepped, with attention placed on adequately scrubbing the inside of the vagina. If necessary, the labia are retracted with silk sutures. A Scott ring retractor (Lone Star Medical Corp.) is useful in exposing the operative field.

The first step in intraperitoneal repair is to isolate the enterocele sac. This is begun by grasping the prolapsed vaginal wall with two Allis clamps and bringing it outside of the vaginal introitus. A longitudinal incision is made in the vaginal wall along the entire length of the enterocele (Fig. 50.2). The vaginal wall is then carefully dissected away from the underlying pubocervical fascia and enterocele sac. In the initial dissection, care must be taken to stay very superficial and develop the proper plane. This is best accomplished by placing the curve of the Metzenbaum scissors against the vaginal wall. A finger can be placed on the outside of the vaginal wall to stabilize the initial dissection. Once the proper plane is entered, it is usually easy to dissect the vaginal wall away from the underlying enterocele sac. Care taken here will prevent early entry into the peritoneal cavity. The dissection of the enterocele is continued all the way to the neck of the enterocele sac (Fig. 50.3). After the enterocele has been completely isolated, the sac is opened and the peritoneal cavity is entered. At this time, one may see small bowel, omentum, or ovary and fallopian tube in cases where previous hysterectomy without oophorectomy has been performed (Fig. 50.4).

The next step is closure of the enterocele defect or pouch of Douglas. Retraction of the peritoneal contents is best performed using a moist pediatric laparotomy pad and a narrow Deaver or Heaney retractor. Placing the patient in the Trendelenburg position so that abdominal organs fall slightly cephalad assists with this. The enterocele repair begins posteriorly while the abdominal contents are retracted anteriorly

**FIGURE 50.3** Enterocele sac completely dissected to its neck. (From Nitti VW. Transvaginal enterocele repair with variations. *Contemp Urol* 1994;6:50–64, with permission.)

**FIGURE 50.4** The enterocele sac is opened, exposing intra-abdominal contents. (From Nitti VW. Transvaginal enterocele repair with variations. *Contemp Urol* 1994;6:50–64, with permission.)

using the retractor. A no. 1 polyglactac acid (PGA) suture is first placed through the peritoneum and into the prerectal fascia that overlies the rectum (Fig. 50.5). A circumferential closure of the defect is then performed by placing the purse-string suture laterally in the right uterosacral–cardinal ligament complex, anteriorly in the peritoneum overlying the base of the bladder, laterally on the left in the uterosacral–cardinal

**FIGURE 50.5** A Deaver retractor is used to retract abdominal contents so that pursestring sutures can be placed. (From Nitti VW. Transvaginal enterocele repair with variations. *Contemp Urol* 1994;6:50–64, with permission.)

**FIGURE 50.6** Placement of pursestring sutures. (From Nitti VW. Transvaginal enterocele repair with variations. *Contemp Urol* 1994;6:50–64, with permission.)

ligament complex, and finally again posteriorly in the prerectal fascia (Fig. 50.6). After this pursestring suture has been placed, a second one may be placed in the identical structures in close proximity to the first. If one is not going to perform a further vault suspension, it is especially important to incorporate the uterosacral–cardinal ligament complex into the closure, as this will be the main support of the vaginal apex. In addition, care should be taken to place these sutures deep enough to ensure that adequate vaginal depth can be achieved. When an additional apical support procedure is preformed, the main purpose of the pursestring suture is simply to close the peritoneum. After all sutures are placed, the assistant cinches down and places tension on one of the pursestrings while the surgeon ties the other. After this has been tied, the second pursestring (if placed) is tied in a similar manner. The

excess enterocele sac may be excised and the ends oversewn with a 2-0 PGA suture.

Cystoscopy is performed to document that there has been no injury to the bladder. Ureteral injury is ruled out by intravenous indigo carmine. Excess vaginal wall is then excised, and the vaginal wall is closed with a 2-0 PGA suture incorporating deep tissue to obliterate any dead space. Antibiotic-impregnated vaginal packing is placed for 24 hours.

## Enterocele Repair with Vault Suspension

In most cases of enterocele, the vaginal apex is also prolapsed and requires new support. It is also common to have concomitant anterior and posterior defects, and therefore repair of more than one compartment is typically necessary. There are several techniques commonly used to accomplish a transvaginal vault suspension, and the best technique is still debated. We will review nonaugmented repairs, including the McCall culdoplasty, the uterosacral ligament suspension, the sacrospinous ligament fixation, and the iliococcygeus fixation, as well as augmented repairs, including sacrospinous ligament fixation with mesh. Lastly, we will briefly discuss uterine-sparing procedures and the mesh kits that have recently emerged as treatment options for POP.

## Nonaugmented Repairs

### McCall Culdoplasty

In 1957 McCall (5) originally described a technique of posterior culdoplasty used to correct enterocele at the time of vaginal hysterectomy. Several modifications of the procedure have been reported, but the concept remains the same. As described above, retraction of the peritoneal contents is best performed using a moist pediatric laparotomy pad and a narrow Deaver retractor with the patient in the Trendelenburg position. Permanent or delayed absorbable suture can be used for the internal McCall sutures. The suture is passed through one uterosacral ligament approximately 2 cm above its cut edge. Successive passes are then made through the posterior peritoneum, and lastly the suture is placed through the contralateral uterosacral ligament. The suture is not tied, and additional sutures are placed in a similar fashion as needed (Fig. 50.7). After all of the internal McCall sutures have been placed, one or two external McCall sutures are placed using delayed absorbable suture. External McCall sutures are placed through the vaginal epithelium (from outside to inside), through the peritoneum and the ipsilateral uterosacral ligament. Similar to the internal McCall sutures, successive passes are again made through the posterior peritoneum until the contralateral uterosacral ligament is reached. The suture is then passed through the peritoneum and the vaginal epithelium close to the entry point. The internal sutures are each tied, followed by the external sutures, which suspend the vaginal wall at the level of the uterosacral ligaments.

### Uterosacral Ligament Fixation

Suspension of the vaginal vault to the uterosacral ligaments, as described by Shull et al. (1), provides a more natural vaginal axis than the sacrospinous ligament fixation. Without the posterior deflection of the vagina caused by fixation to the

**FIGURE 50.7** Placement of internal McCall sutures. (From McCall ML. Posterior culdoplasty: surgical correction of enterocele during vaginal hysterectomy: a preliminary report. *Am J Obstet Gynecol* 1957;10:595–602, with permission.)

sacrospinous ligament, the risk of prolapse of the anterior vaginal compartment is reduced. Identification of the uterosacral ligaments posthysterectomy can be difficult. Their origin is at the sacrum, and they reflect anteromedially toward insertion at the cervix. After the uterus and cervix are removed, these ligaments meld into the surrounding connective tissue. The optimal site of fixation to the uterosacral ligament is in the intermediate portion of the ligament, which has fewer vital adjacent structures and is a strong fixation site, and tension on this area has little effect on the nearby ureter. The ischial spine can be used to reliably identify the intermediate portion of the uterosacral ligament. Sutures should be placed at the level of the ischial spine, 1 cm posterior to the anteriormost palpable margin of the uterosacral ligament. The uterosacral ligament is very close to the intrapelvic ureter and the ureter can be injured if incorporated by one of the sutures or kinked by traction from a suture. The intraperitoneal approach, however, allows for better visualization and thus better suture placement compared to the visualization in the narrow, deep pararectal space.

A vertical midline incision is made in the vaginal epithelium. The vaginal wall is then carefully dissected away from the underlying pubocervical fascia and enterocele sac and the enterocele sac is entered and the bowel is packed away as described above for transvaginal enterocele repair. The following technique is as described by Shull et al. (1) in 2000, with minor modifications. The remnants of the uterosacral ligaments are identified posterior and medial to the ischial spines at approximately the 4 o'clock and 8 o'clock positions. An Allis clamp can be used to apply traction to the tissue and the uterosacral ligament can be palpated towards the sacrum. Two or three delayed absorbable or permanent (Ethibond) sutures (double-armed) are placed through the uterosacral ligaments on each side. In an effort to minimize ureteral injury, it is recommended that sutures be passed in a lateral-to-medial fashion as the surgeon has better control over the entry point of the needle than its exit point. Central defects in the pubocervical

**FIGURE 50.8** Sutures are placed in uterosacral ligaments bilaterally. One arm of each suture is placed in the pubocervical fascia and the other in the rectovaginal fascia. (From Shull BL, Bachofen C, Coates KW, et al. A transvaginal approach to repair of apical and other associated sites of pelvic organ prolapse with uterosacral ligaments. *Am J Obstet Gynecol* 2000;183:1365–1373, with permission.)

**FIGURE 50.9** Sagittal view of suspensory suture in uterosacral ligament (USL), pubocervical fascia (PCF), and rectovaginal fascia (RVF). (From Shull BL, Bachofen C, Coates KW, et al. A transvaginal approach to repair of apical and other associated sites of pelvic organ prolapse with uterosacral ligaments. *Am J Obstet Gynecol* 2000;183:1365–1373, with permission.)

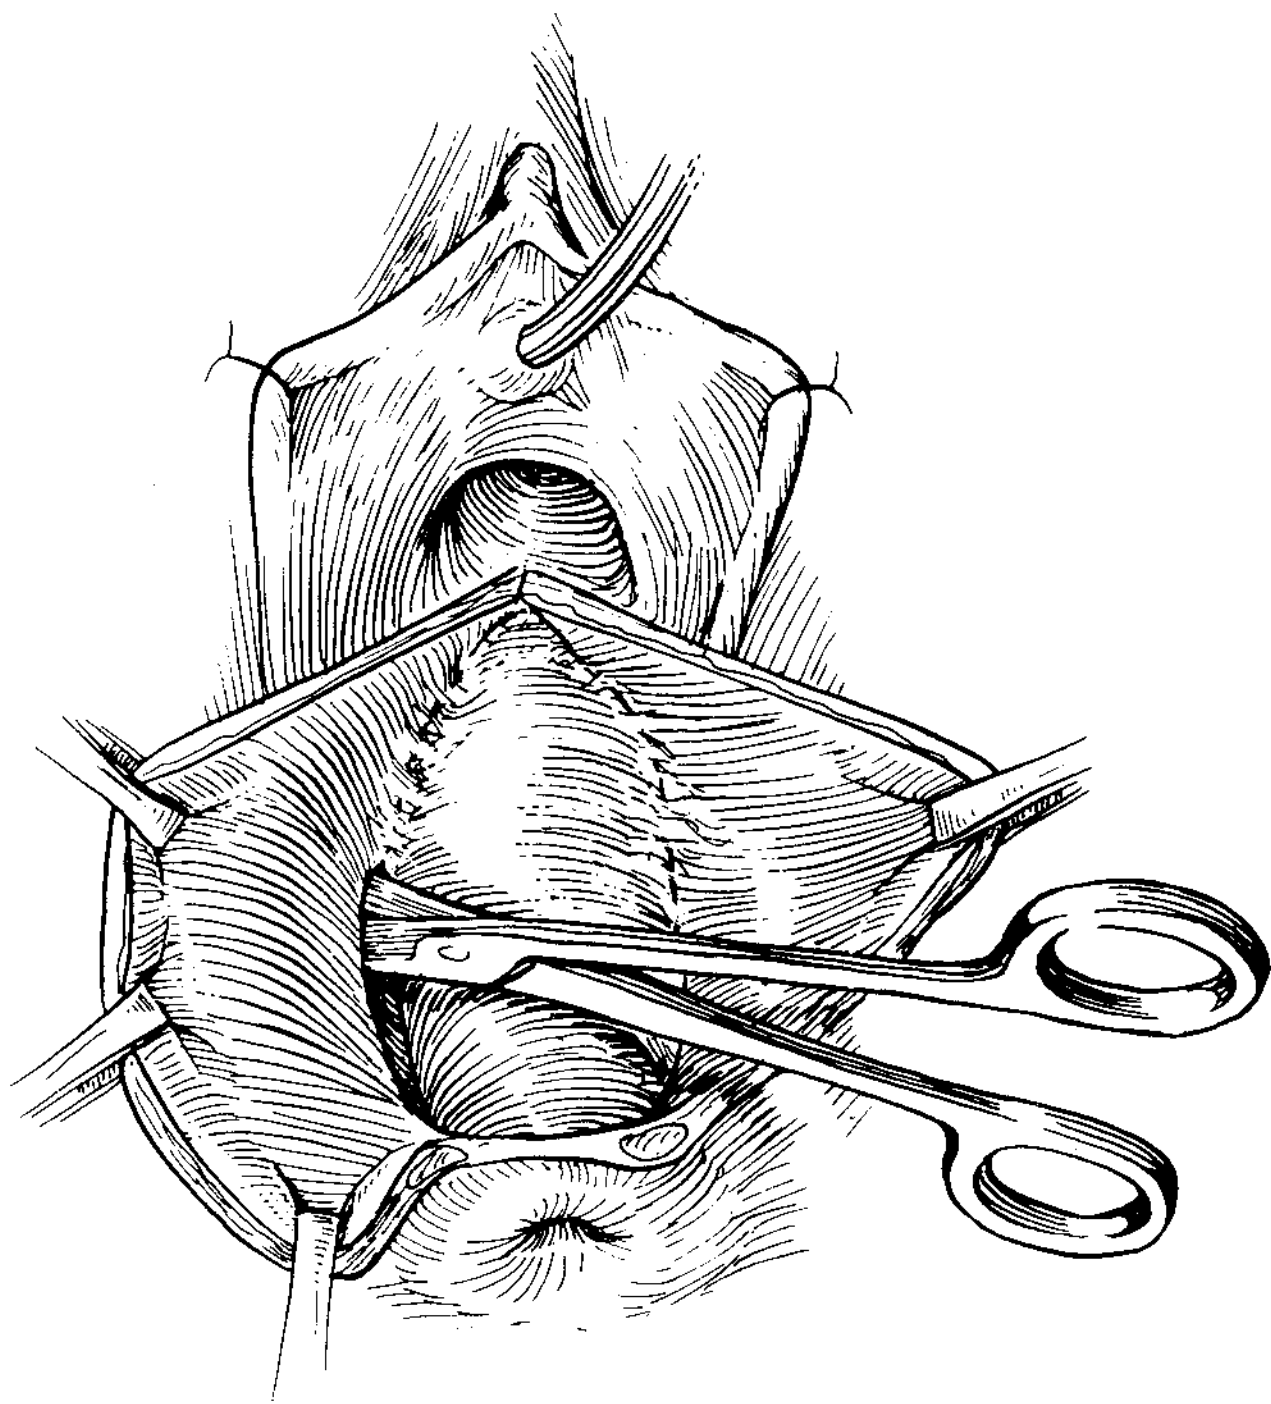

and rectovaginal fascia are repaired by plication. The double-armed sutures are placed through the pubocervical and rectovaginal fascia (Figs. 50.8 and 50.9). The distal remnants of the uterosacral ligaments are then plicated across the midline. The previously placed absorbable suspension sutures may be

placed through the posterior vaginal wall. If one prefers, two permanent sutures and one absorbable suture (to be brought through the vaginal wall) can be used. Intravenous indigo carmine is administered. The vaginal epithelium is then closed as described previously, and the suspension sutures are tied, but left long and tagged. Cystoscopy is performed with indigo carmine as described above, and once ureteral patency is ensured the suspension sutures are trimmed.

### Sacrospinous Ligament Fixation

Sacrospinous ligament fixation is used to correct vault prolapse when the anterior vaginal wall is well supported, or it can be used with simultaneous anterior repair. Vaginal depth and axis are restored by posterior fixation of the vaginal vault to the sacrospinous ligaments. The sacrospinous ligament stretches from the ischial spine to the sacrum and is covered by the coccygeus muscle.

Once the enterocele repair is complete, the posterior vaginal wall must be opened far enough distally to facilitate dissection to the sacrospinous ligament. When a simultaneous rectocele repair is to be performed, the entire posterior vaginal wall is opened through the perineum. After the posterior vaginal wall is incised in the midline, it is gently dissected laterally from the underlying prerectal fascia for a short distance. Next, the sacrospinous ligament must be identified. This is done by penetrating the right or left rectal pillar (pararectal fascia) sharply and entering the pararectal space (Fig. 50.10). Blunt dissection of the pararectal space can be performed with a combination of finger dissection and the use of deep Breisky-Navratil retractors. This dissection is

**FIGURE 50.10** Dissection for sacrospinous ligament fixation. The rectal pillars are sharply penetrated and the pararectal space is entered. The space is widened with blunt dissection to expose the superior surface of the pelvic diaphragm. The sacrospinous ligament can then be palpated and the coccygeus muscle overlying it can be seen. (From Nitti VW. Transvaginal enterocele repair with variations. *Contemp Urol.* 1994;6:50–64, with permission.)

performed until the sacrospinous ligament is palpated and the overlying coccygeus muscle is seen. The Breisky-Navratil retractors will help expose the ligament. Once the ligament is identified, a no. 1 permanent braided suture is placed through the ligament and coccygeus muscle complex 2 cm medial to the ischial spine, which is also identified by palpation. It is important to place the suture in this position to avoid injury to the pudendal nerve and vessels, which run just below the ischial spine. It is also important to include the strong ligament in addition to the overlying coccygeus muscle. These tasks can be made easier by carefully dissecting over the ligament with a spreading motion of the Metzenbaum scissors and with the aid of a Kittner dissector. Visualization of the ligament itself helps avoid incorrect placement of the sutures. Another helpful tool is the Capio transvaginal suture-capturing device (Boston Scientific). This tool allows for placement of the suture and retrieval of the needle in this deep and narrow space with just the depression of a lever on the instrument's end. It has greatly simplified suture placement in our procedures. Tension should be placed on the suture to make certain that it is in the strong ligament. A second suture should be placed adjacent to the first. Each of these sutures is then placed through the vaginal wall, excluding the epithelial layer at the level of the apex, approximately 1 cm apart, and left untied. If a rectocele is present, it is repaired at this time. The apex of the vagina can be directed under finger guidance to the deepest possible portion, where it will be fixed. The vaginal wall is then closed with a running interlocking 2-0 PGA suture, and then the previously placed sacrospinous ligament fixation sutures are individually tied. Antibiotic-impregnated vaginal packing is then placed.

After sacrospinous ligament fixation, recurrences usually occur in the anterior vaginal compartment. This observation has led some investigators to try a modification of the sacrospinous ligament fixation meant to reduce recurrences in the anterior compartment by avoiding the downward deflection of the vagina. The anterior approach to sacrospinous ligament fixation approaches the ligament from the retropubic space and dissection of the ipsilateral paravaginal space from the level of the bladder neck to the ischial spine. Theoretically this approach should reduce postoperative vaginal narrowing and posterolateral deviation of the upper vagina, resulting in improved functional outcome. An additional modification is the bilateral anterior sacrospinous ligament fixation. Bilateral fixation should provide additional support and longevity over a single fixation point and may also increase the area of the vagina over the pelvic floor, improving its ability to withstand increases in intra-abdominal pressure. A limitation of this technique is that not all women have vaginal anatomy that is able to stretch to bilateral ligaments.

### Iliococcygeus Fixation

Iliococcygeus or prespinous fixation for vaginal vault prolapse is yet another method to suspend the vaginal vault, created to address what was considered to be a high rate of anterior compartment prolapse after sacrospinous ligament fixation and damage to the pudendal neurovascular bundle. In an iliococcygeus fixation the vaginal apex is fixed bilaterally to the iliococcygeus fascia using one no. 1 polydioxanone suture. The incision and dissection are carried out posteriorly. The rectovaginal fascia is dissected off the posterior vaginal wall laterally all the way to the pelvic sidewall. The ischial spine

and sacrospinous ligament are identified as a landmark for the iliococcygeus fascia, which will be found anterior to them.

Cystoscopy with indigo carmine is recommended with each of the previous procedures to evaluate for bladder injury and ureteral patency.

### Mesh-Augmented Repairs

The use of mesh at the time of POP repair is becoming increasingly popular. This is in part due to the high incidence of recurrence following primary repair. However, there are minimal long-term safety and efficacy data on graft utilization in pelvic reconstruction.

There are various mesh-augmented repairs described in the literature. In 2004, Shah et al. (6) described a procedure using polypropylene mesh for total pelvic reconstruction. Subsequently, Amrute et al. (7) described their modification, in which a tension-free method is used for the anterior arms of the mesh. A horizontal incision is made at the most dependent portion of prolapsed vagina. Sharp and blunt dissection is performed extraperitoneally towards the ischial spine and sacrospinous ligament bilaterally. Two delayed absorbable sutures are placed bilaterally in the sacrospinous ligament (1 cm medial to the ischial spine) using the Capiro needle driver. The vaginal epithelium is dissected off the bladder sharply, and if necessary the endopelvic fascia is imbricated with absorbable suture. Sharp dissection of the periurethral space is performed superiorly toward the retropubic space. An approximately 6 × 8-cm piece of polypropylene mesh is configured in an H and the anterior arms are sutured to the arms of a BioArc device (American Medical Systems). Using the BioArc needle passers, the anterior arms are passed retropubically through the anterior abdominal wall. The distal edge of the mesh is positioned at the level of the midurethra. Cystoscopy is performed to place a suprapubic tube, the bladder is evaluated to identify injury, and indigo carmine is administered to assess ureteral patency. The sacrospinous ligament sutures are passed through the lateral arms of the mesh and tied down. The sutures are then brought through the posterolateral aspect of the vaginal mucosa. Absorbable sutures are placed as needed to prevent folding and kinking of the mesh. The vagina is then closed in a running fashion.

Our current mesh-augmented repair for patients with severe apical and anterior prolapse includes a simultaneous paravaginal and apical repair using soft polypropylene mesh and involves sacrospinous ligament fixation through an anterior approach. It is a modification of the technique described by Shah et al. (6). The prolapsed anterior vaginal wall is grasped with Allis clamps and infiltrated with 1% lidocaine with epinephrine. A vertical midline incision is made from the area of the bladder neck to the vaginal apex. The vaginal wall is dissected off the bladder and the enterocele sac to the level of the endopelvic fascia. The enterocele sac may be opened and repaired as described above for transvaginal enterocele repair or simply reduced, depending on its size. After repair of the enterocele, the endopelvic fascia is perforated and the space of Retzius entered bilaterally. A Capiro needle driver is then used to place a 2-0 Vicryl suture into the arcus tendineus at the level of the bladder neck and 1 cm above the ischial spine, as well as a PDS suture into the sacrospinous ligament. These sutures are placed bilaterally (Figs. 50.11 and 50.12). A piece of soft

**FIGURE 50.11** Placement of 2-0 PDS suture into sacrospinous ligament using a Capiro needle driver. (From Boston Scientific Corporation, with permission.)

**FIGURE 50.12** Sutures are placed in the arcus tendineus at the level of the bladder neck and 1 cm above the ischial spine as well as into the sacrospinous ligament bilaterally.

polypropylene mesh is then configured in the shape of a trapezoid approximately 5 cm wide at the top, 10 cm wide at the bottom, and 10 cm long (Fig. 50.13). The previously placed Vicryl sutures are then placed in the mesh with the narrow portion corresponding to the level of the bladder neck, the middle portion corresponding to the level of the ischial spines, and the widest portion of the mesh at the level of the sacrospinous ligament. The sacrospinous ligament sutures are tied down first and left long. The sutures 1 cm above the ischial spine and the sutures at the bladder neck are then tied down and cut. The wound is irrigated with antibiotic solution. Cystoscopy after intravenous indigo carmine is then performed to ensure ureteral patency. The sacrospinous ligament sutures are passed through the vaginal wall bilaterally at the vaginal apex, about 2 cm from the midline. The proximal two thirds of the vaginal wall is closed, and then the sacrospinous ligament sutures are tied down. The remainder of the anterior vaginal wall is closed. Sometimes a small amount of vaginal wall is excised prior to completing the closure. We have recently modified our procedure

**FIGURE 50.13** Soft polypropylene mesh configured in the shape of a trapezoid (approximately  $5 \times 5 \times 10$  cm).

to include an anterior colporrhaphy with plication of the pubocervical fascia across midline prior to placement of sutures into the arcus tendineus and sacrospinous ligament. Unfortunately this is not demonstrated in the figures.

### Transvaginal Procedures for Preservation of the Prolapsed Uterus

There has been a recent trend towards uterine-sparing procedures despite limited long-term data. Various vaginal, abdominal, and laparoscopic techniques have been described.

#### Manchester Procedure

The Manchester procedure was originally described in 1888 by Archibald Donald of Manchester, England, and subsequently modified by W.E. Fothergill (8). It is an alternative to vaginal hysterectomy for patients with uterine prolapse, cervical elongation, and nonattenuated uterosacral–cardinal ligaments. A circumferential incision is made around the cervix (similar to the incision for a vaginal hysterectomy). The vaginal epithelium is dissected off the cervix. The cardinal ligament, including the cervical branch of the uterine artery, is clamped, divided, and suture-ligated bilaterally. A portion of the cervix is then amputated with a scalpel. Sturmdorf sutures are placed to invaginate the vaginal epithelium into the cervical os. The previously ligated cardinal ligaments are sewn to the anterior cervical stump. Anterior and posterior colporrhaphy procedures are performed as needed, and the vaginal epithelium is closed.

On occasion, we have performed a uterine-preserving transvaginal mesh-augmented sacrospinous ligament fixation repair. We typically prefer the abdominal approach when preserving the uterus. However, in patients in whom an abdominal approach is not ideal and mild (grade II or less) uterine prolapse exists in the setting of more severe anterior prolapse (a rare situation), this approach may be considered. It is performed in a similar fashion as the above-described sacrospinous ligament fixation. A midline incision is made in the anterior vaginal wall from the level of the bladder neck to the cervix. The dissection is then performed as described

previously. An anterior colporrhaphy is performed, suturing the pubocervical fascia across midline and securing it to the cervix at the most proximal extent. The Capio needle driver is used as described previously to place Vicryl sutures in the arcus tendineus at the level of the bladder neck and just above the ischial spine. It is also used to place a PDS suture in the sacrospinous ligament bilaterally. A  $5 \times 5 \times 10$ -cm trapezoidal piece of polypropylene mesh (same as previously) is fashioned and secured using the previously placed sutures. The mesh is also secured to the paracervical fascia in the midline using Vicryl suture. Cystoscopy is performed prior to passing the previously placed PDS sutures through the vaginal wall just lateral to the cervix. Anecdotally, we have had some success with this procedure, but no long-term data are available.

### Mesh Prolapse Repair Devices

Recently a number of prepackaged mesh kits have been marketed for prolapse repair. These kits include polypropylene meshes with various arms that are anchored by passage through support tissues (including the sacrospinous ligament, iliococcygeus muscle, and arcus tendineus) using insertion trocars. We have very limited experience with these procedures, and there are currently no long-term data regarding their use. Further discussion is beyond the scope of this text.

### OUTCOMES

The results of apical prolapse repair are difficult to evaluate because the definition of success varies between studies and few studies report long-term follow-up. Colombo and Milani (9) found no statistical difference in recurrence of vault prolapse in a retrospective study comparing sacrospinous ligament fixation and McCall culdoplasty (8% versus 3%, respectively). Shull et al. (1) reported “optimal anatomic outcomes” in 87% of patients undergoing uterosacral fixation, while Karram et al. (10) reported that 89% of women expressed satisfaction following the procedure. Success rates ranging from 8% to 97% have been reported for traditional sacrospinous ligament fixation (11,12). Shull et al. (13) and Meeks et al. (14) reported 95% and 96% cure rates following iliococcygeus fixation, while more recently Maher et al. (15) reported equal efficacy when comparing the iliococcygeus fixation to sacrospinous ligament fixation.

There are even fewer data regarding outcomes of mesh-augmented repairs. Amrute et al. (7) reported a 5.2% recurrence rate and a 2.1% rate of vaginal erosion with a mean follow-up time of 31 months.

### Complications

In all the previous procedures, the major risks are bleeding due to vascular injury, nerve entrapment, ureteral injury or kinking, bowel injury, wound infection, and persistent or recurrent prolapse. During placement of the pursestring sutures of an enterocele repair, one must take care not to disturb the ovarian vessels, which lie near the uterosacral–cardinal complexes. The pudendal vessels and nerve, which lie beneath the sacrospinous ligament, are at high risk of injury during

sacrospinous ligament fixation. Pudendal entrapment may occur if sutures are placed too laterally, whereas the sciatic nerve is at risk if the sutures are placed too cephalad. Pelvic and gluteal pain, although usually transient, can occur as a result of injury to the pudendal and sciatic nerves. The intrapelvic ureter is intimately associated with the uterosacral ligaments

but can be injured or kinked by any of the transvaginal vault suspensions. Ureteral injury or kinking in cases of vault suspension has a reported rate of 1% to 11% (10). The anterior vaginal compartment is at highest risk for persistent or recurrent prolapse, but in many cases this prolapse is asymptomatic and does not require reoperation.

# CHAPTER 51 ■ POSTERIOR VAGINAL PROLAPSE REPAIR

LIOR LOWENSTEIN AND ELIZABETH R. MUELLER

Pelvic organ prolapse (POP) is prevalent in the United States, with approximately 200,000 surgeries in women annually (1). An epidemiologic study of a large U.S. northwest health care population suggests that a woman has an 11.1% risk of undergoing POP surgery by the age of 80. Over the next 30 years it is predicted that the number of women seeking care for pelvic floor disorders will increase by 45% (2).

One of the confounding factors in diagnosing and treating POP is that “less than perfect” support of the anterior and posterior vaginal walls is a normal finding in the majority of vaginally parous women. Swift (3) reported on vaginal examination findings of 497 women who presented for their annual Pap and pelvic examination. All women were >18 years of age, with a median parity of two. The incidence of cases in which the leading edge of the most prolapsed segment was 1 cm distal to the hymen or beyond was 52%, with only 6% of women demonstrating no prolapse or perfect support. Likewise, the Women’s Health Initiative hormone replacement clinical trial performed baseline pelvic examinations on 16,616 women with a uterus (4). They found that 41% of

women aged 50 to 79 years had POP on physical examination. The vaginal compartment most frequently associated with the prolapse was the anterior vaginal wall (also known as cystocele) at 34%, followed by the posterior compartment (rectocele, 19%) and uterine prolapse (14%). Parity and obesity were strongly associated with an increased risk for prolapse.

Posterior vaginal wall prolapse is thought to be herniation of the posterior vaginal wall or anterior rectal wall into the lumen of the vagina. Vaginal childbirth is one of the most frequent risk factors associated with prolapse. Labor and vaginal delivery results in damage to the pudendal nerve and disruption of connective tissue and muscular attachments. Denonvilliers fascia, which is fused to the inner layer of the posterior vaginal wall, may be torn during vaginal delivery at its caudal and lateral attachments to the perineal body. Nonobstetric risk factors associated with POP include pelvic surgery, conditions leading to elevated intra-abdominal pressure (e.g., obesity and chronic constipation with excessive straining), inherited connective tissue disorders (e.g., Ehlers-Danlos

and Marfan syndromes), and genetic predisposition. Though menopause is often cited as a risk factor for POP, several researchers have failed to find an association with estrogen status. Suspension of the anterior vaginal wall for incontinence procedures such as the Burch urethropexy is also a risk factor for apical prolapse. This is most likely due to the change in the vaginal axis following the surgical procedure, resulting in abdominal forces being directed over the genital hiatus instead of the posterior levator ani.

The symptoms attributed to POP are numerous and include colorectal and urinary symptoms, dyspareunia, pelvic heaviness, and the protrusion of the vaginal wall beyond the introitus. Bowel symptoms such as constipation, incomplete bowel emptying, straining, splinting to defecate, and anal incontinence are common in women and are often attributed to posterior vaginal prolapse (5). Of all of these symptoms, the most reliable predictor of POP appears to be simply the self-reported presence of a palpable bulge at the introitus. Numerous studies have demonstrated that bowel symptoms do not correlate with the degree of POP or objective measures of anorectal function (6); however, these symptoms may improve following surgical intervention, as we will discuss later.

---

## DIAGNOSIS

---

At our institution, the physical examination of a patient with suspected POP is initially done with the patient in the standing, straining position and the physician seated or kneeling. If a bulge is palpable past the introitus on straining, then we place our fingers in the vagina and determine the extent of the prolapse.

Following the standing examination, the woman undergoes a complete gynecologic examination including bimanual examination in the dorsolithotomy position. The pelvic examination of the vagina (especially the apical segment) can be facilitated by using the lower blade of a Graves speculum. The single blade is placed against the anterior wall and then the posterior wall of the vagina during Valsalva, for the evaluation of the opposing wall and apex. Isolated distal protrusion of the posterior vaginal wall with lack of descent of the vaginal apex represents an isolated rectocele. Often the viscera behind the vaginal wall cannot be accurately determined. For example, prolapse of the posterior vaginal wall and apex in a woman who has had a hysterectomy may be due to small bowel herniation (enterocele) or a defect in the rectovaginal fascia (rectocele). A bimanual straining rectovaginal examination with a finger simultaneously in the rectum and the thumb in the vagina can help distinguish rectocele from an enterocele. An enterocele will often fill the space between the two viscera, while a rectocele will result in no change in the plane.

The two most commonly used systems to document the degree of prolapse are the Pelvic Organ Prolapse Quantification (POP-Q) and the Baden-Walker. The POP-Q consists of nine measurements and describes the topography of the vagina, genital hiatus, and perineal body. The anterior, posterior, and apical compartments are described and the prolapse stage is based on the compartment that is most prolapsed relative to the hymenal remnant. The Baden-Walker grading system is based on the position of the most protruding part of the vagina relative to the hymen and is usually reported as the prolapse grade.

One of the possible explanations for the high recurrence rate in prolapse repairs (~30%) is that concomitant vaginal defects are not recognized at the time of surgery. Apical prolapse may go unrecognized during the supine examination. We evaluated the relationship between the anterior, posterior, and apical compartment in 325 consecutive new patients (7). Thirty-nine percent had a previous hysterectomy and only 3% had a previous anterior, posterior, or apical repair. The vaginal apex (POP-Q point C) strongly correlated with the most prolapsed portion of the anterior vaginal wall, Ba (Spearman  $\rho = 0.835$ ,  $p < 0.001$ ), and moderately correlated with the most prolapsed portion of the posterior vaginal wall, Bp (Spearman  $\rho = 0.556$ ,  $p < 0.001$ ). Of 113 women who had the leading edge of the posterior vaginal wall at the introitus or beyond, a significant amount of concurrent apical prolapse was present (Fig. 51.1).

Radiologic imaging may be indicated more for understanding the cause of defecatory dysfunction than for diagnosing POP. Defecography involves dynamic evaluation of the pelvic floor, providing both structural and functional information. Standardization of the testing and interpretation of defecography is not established, however, and therefore it is not recommended for routine clinical use, although it can be helpful in “high” rectoceles when an enterocele is suspected. Magnetic resonance imaging (MRI) has been used to describe the location of the defects during POP, but we do not routinely use it in our practice.

---

## ALTERNATIVE THERAPIES

---

Asymptomatic patients or women with minor symptoms may report little or no bother as a result of the disorder, and observation or watchful waiting is appropriate. Pelvic floor muscle rehabilitation may be offered despite the lack of data supporting its use to prevent progression.

Mechanical support, such as a pessary, can be used to reduce the POP. Support pessaries are made of silicon or soft plastic and can be offered to women with symptomatic POP who prefer a nonsurgical approach. Other indications include women who are poor surgical candidates because of medical comorbidities, or patients needing temporary relief of pregnancy-related POP or incontinence. In most patients, the pessary can be fitted successfully in one or two office visits. Women with symptomatic improvement are taught to place and remove the pessary at least twice weekly and prior to intercourse and should return every 6 to 12 months. Women who cannot remove the pessary will leave it in continuously and return every 3 months for pessary care. They may benefit from vaginal estrogen cream, unless contraindicated, to reduce the risk of erosion. If vaginal erosion develops, the pessary should be removed and vaginal estrogen cream applied until the erosion is healed. The pessary can then be replaced, although a reduction in pessary size is advisable. Pessaries generally are less effective in supporting the posterior vaginal wall than in apical and anterior vaginal wall prolapse.

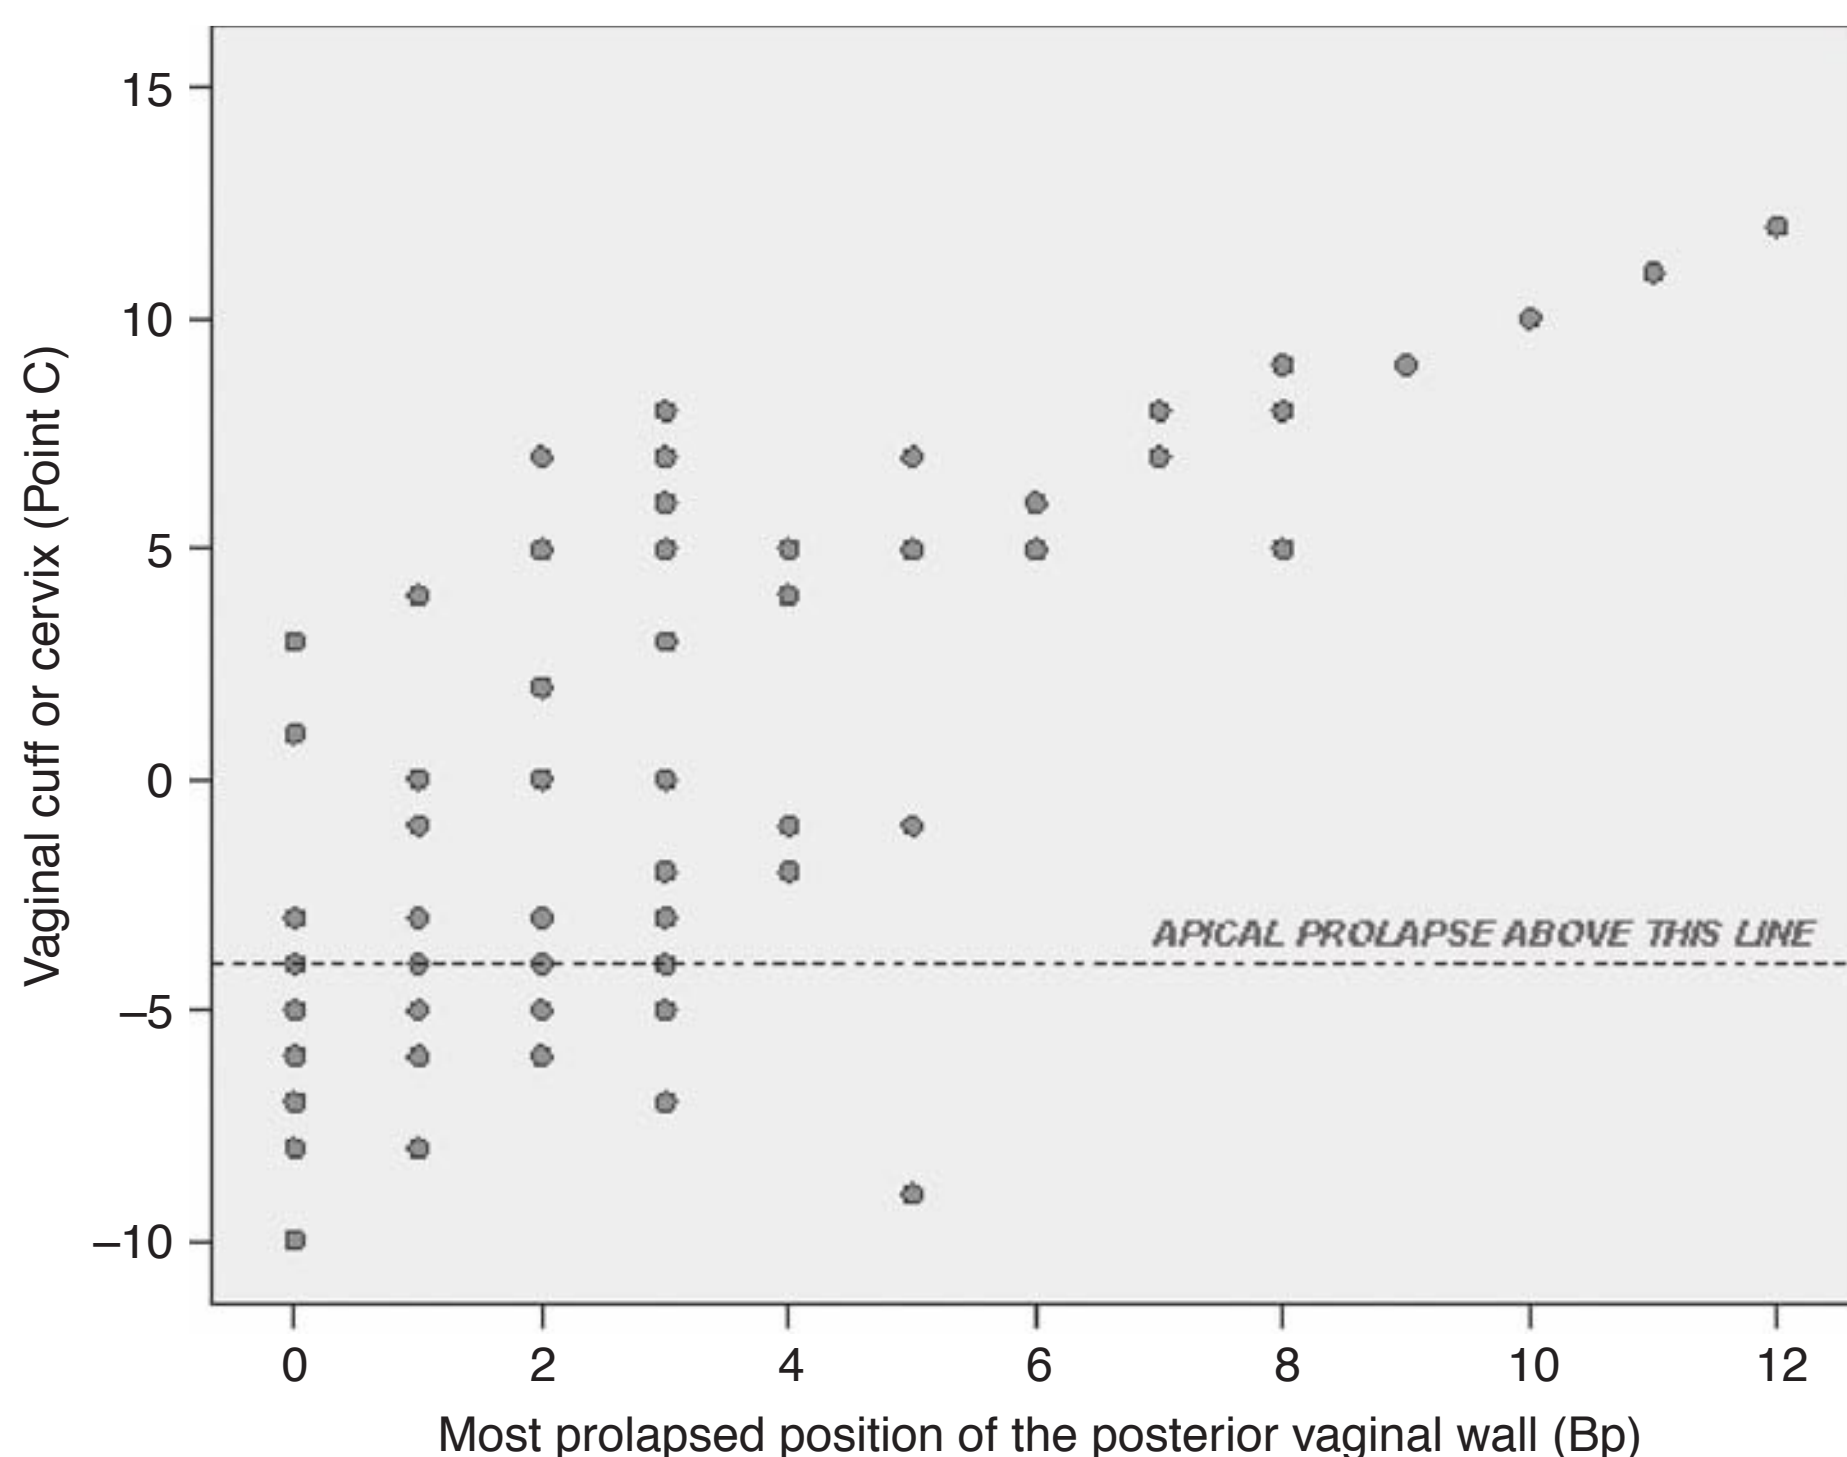

---

## INDICATIONS FOR SURGERY

---

Due to the possibility of postoperative dyspareunia, it is believed that an isolated rectocele should not be repaired unless the patient is bothered by symptoms. Our practice is to refer

**FIGURE 51.1** A scatter plot of the leading edge of the posterior vaginal wall and the vaginal apex in 122 women who had the leading edge of the posterior vaginal wall at the introitus or beyond in a standing straining exam.

the patient to colorectal surgery or occupational therapy for defecation disorders prior to undergoing a procedure for posterior vaginal wall prolapse.

Numerous factors must be considered when counseling patients about the best surgical treatment:

- Surgical route
- Durability
- Recovery time
- Immediate and delayed postoperative complications

## SURGICAL TECHNIQUES

There are three surgical routes that may be used for rectocele repair: abdominal, transanal, and transvaginal. Among the different surgical routes, the transvaginal approach is the most commonly practiced route for the “noncolorectal” surgeon. The abdominal approach is indicated for rare cases when rectocele is associated and repaired with the rectal prolapse. The transanal route was thought to be indicated for cases of small distal rectocele. Today, this is less commonly practiced because of the possible impairment of the anal sphincter as a result of its dilatation during the surgery. Although rectocele repair has been practiced for >100 years, the most effective surgical treatment remains undetermined.

As stated earlier, the position of the vaginal apex or cervix is well correlated to the most prolapsed part of the posterior and anterior vaginal walls in women with POP. When performing sacrocolpopexy, the apical segment is resuspended and the vaginal axis is adequately restored; the anterior and posterior vaginal walls are also restored to a nonprolapsed position without additional anterior or posterior repairs (8).

The following procedures are indicated for women who have a distal defect of the posterior vaginal wall or who are having a concomitant apical suspension.

## Posterior Colporrhaphy

Posterior colporrhaphy is still commonly practiced today by general gynecologists and urologists. Our protocol includes giving 2 g of cefoxitin intravenously at the start of the procedure. Though we find that bowel preparation is often recommended before surgery by our colleagues, this has not been our practice.

Following the administration of general or spinal anesthesia, the patient is positioned in the dorsal lithotomy position with her legs in Yellofin stirrups (Allen Medical Systems). Care is taken to ensure the neural safety and positioning of all four extremities. She is prepped and draped in a sterile fashion and a Foley catheter is inserted.

A bimanual examination is performed to reassess the POP and ensure that the surgical procedures chosen are adequate (Fig. 51.2). A self-retaining vaginal wall retractor such as the Lone Star (Lone Star Medical Products) is placed. Twenty milliliters of 1/200,000 epinephrine/saline solution is injected into the submucosal tissue to aid in the dissection and help with hemostasis. The posterior commissure of the vagina is clamped approximately 2 to 3 cm from the midline on the right and left with Allis clamps. A transverse incision is made in between the two Allis forceps. In cases where perinorrhaphy is performed concomitantly, an additional incision is made in the perineum to remove a triangular piece of skin, allowing exposure of the perineal body, as will be discussed in a later section. A vertical incision is made in the posterior vaginal mucosa from the middle of the transverse incision reaching the apex of the rectocele, which is held by an Allis clamp in the midline (Fig. 51.3). Using a Metzenbaum scissors the vaginal mucosa is dissected from the underlying perirectal fascia using a “snip and push” technique. Once an avascular plane is established, an index finger wrapped with a moist vaginal laparotomy sponge can be used for further dissection, although this technique should be abandoned if significant tissue resistance is met. It is also

**FIGURE 51.2** Rectal examination of a woman with a rectocele. The vaginal apex is 6 centimeters proximal to the hymen but the posterior vaginal wall distal edge protrudes past the introitus when standing. Notice how by placing the nondominant hand's third digit in the rectum, the thumb and index finger can still be utilized by the operating surgeon.

important to do the dissection close to the vaginal wall side to avoid incising the rectum. The dissection is extended upward in the midline to well above the bulge of the rectocele (Fig. 51.4). At this point it is necessary to obtain sufficient hemostasis to identify the anatomic structures.

The surgeon then should insert the nondominant middle finger into the rectum, which allows the thumb and index finger to be available to the surgeon. The bulge is reduced to aid in the identification of the lateral rectovaginal fascia. Care is taken not to incorporate the levator ani (levator plication), since this can result in vaginal distortion, constriction, postoperative pain, and dyspareunia. The rectovaginal fascia is plicated to the midline using a series of interrupted size 0 polyglactin sutures (Fig. 51.5) that are initially tagged and then tied in succession. The distal end of the rectovaginal septum (imbricated rectovaginal fascia) is then attached to the reconstructed perineal body (perineorrhaphy) if this is performed. Any redundant vaginal epithelium that crosses the midline is excised, and the vaginal epithelium is closed with 3-0 poliglecaprone 25 (Monocryl) absorbable sutures (Fig. 51.6).

**FIGURE 51.3** The proximal end of the rectocele is grasped with an Allis clamp and the midline and transverse incisions are marked. Injection of local anesthetic with epinephrine can help with developing a plane.

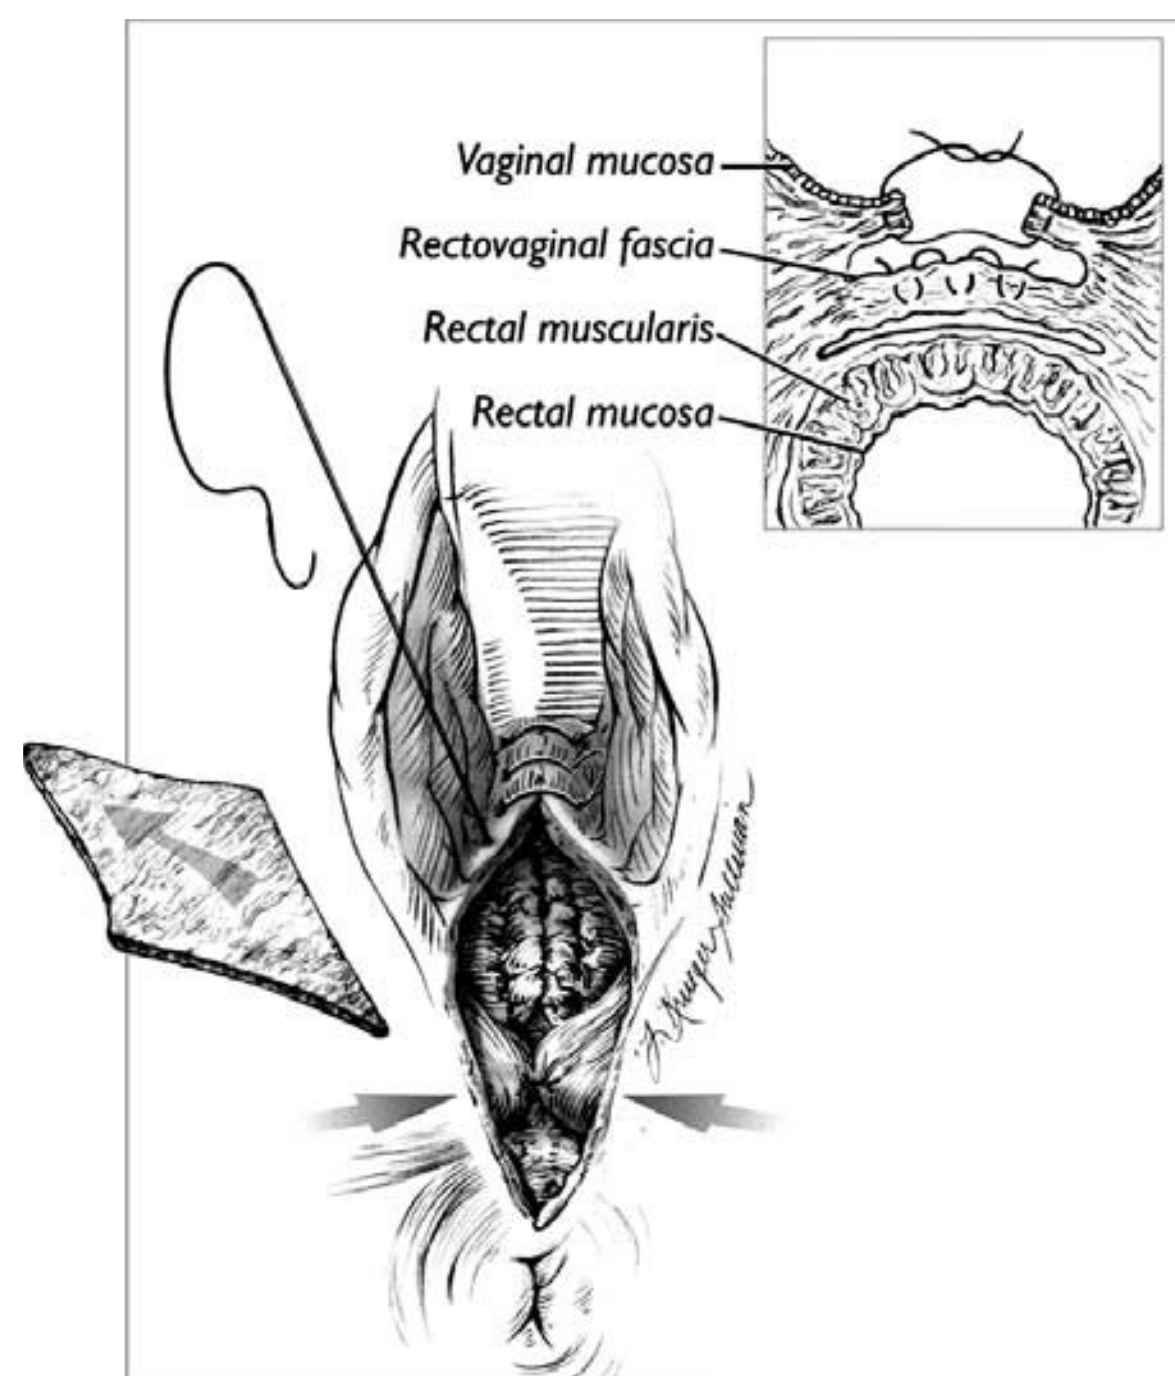

**FIGURE 51.4** The vaginal epithelium overlying the rectocele is dissected off using a "snip and push" technique with Metzenbaum scissors held at a 90° to the vaginal epithelium. The excess epithelium is removed.

### Site-Specific Rectocele Repair

The site-specific repair of rectocele was proposed by Richardson et al. (9) in 1976. This technique is based on Richardson's observations during cadaveric dissection that rectoceles are the result of a specific defect in the rectovaginal fascia.

The initial steps of this procedure are similar to the classic posterior colporrhaphy. The vaginal epithelium is opened and dissected from the underlying rectovaginal fascia. A rectal examination assists in the identification of the edges of the defect, which are grasped with forceps. The defect is repaired with interrupted 0 polyglactin sutures (Vicryl); they are usually placed cranial to caudal, as opposed to the side-to-side placement in a posterior repair. Again, care is taken to avoid

**FIGURE 51.5** The rectovaginal fascia is identified lateral to the rectocele. Absorbable interrupted sutures are placed in the rectovaginal fascia bilaterally. The sutures are tagged and then tied down in succession.

**FIGURE 51.6** Examination of the posterior vaginal wall following the posterior repair.

the incorporation of any healthy muscle that could result in dyspareunia. If indicated, the perineal body is reconstructed. The vaginal epithelium is closed as previously described.

### Reconstruction of the Perineal Body

The perineal body is located between the vaginal introitus and the anus, and attached to it are the following structures: bulbocavernosus muscles, superficial transverse perineal muscles, levator ani muscles, the external anal sphincter, and the rectovaginal fascia (Fig. 51.7). Due to its lateral and superior support there is limited downward movement of the perineal body. Rectoceles that recur or are symptomatic with defecatory disorders may actually be disorders of exaggerated perineal descent due to the detachment of the perineal body to the rectovaginal septum.

Reconstruction of the perineal body starts with placement of Allis clamps on the lateral edges of the posterior commissure of the vagina that also grasp the underlying bulbocavernosus muscles. When brought together in the midline, they

represent the lower edges of the reconstructed introitus. Care must be taken not to overly narrow the introitus especially because the relaxation of the pelvic floor during anesthesia can often lead to miscalculations in the resulting introitus. A triangular piece of vaginal epithelium is removed so as not to damage the underlying superficial transverse perineal muscles (Fig. 51.8). The bulbocavernosus muscles are plicated with midline interrupted size 0 polyglactin sutures (Fig. 51.9) and the epithelium is closed with a running absorbable suture. Preservation of the size of the genital hiatus is important for women who wish to remain sexually active.

### Posterior Repair with Biologic and Synthetic Materials

In an attempt to improve the anatomic cure rates, several variations have been used for correcting the posterior prolapse. The use of synthetic or biologic material as reinforcement or replacement of weak fascia was derived originally from general surgery and has been advocated in gynecologic surgery. The most widely used biologic materials are human freeze-dried cadaveric fascia lata, solvent-dehydrated fascia lata (Tutoplast), porcine dermal graft (Pelvicol), and decellularized human cadaveric dermis (Alloderm, Repliform).

Synthetic materials can be classified as absorbable or permanent. Their use has increased since they were first described in 1995 for the management of stress urinary incontinence and POP. The most commonly used absorbable synthetic graft is polyglactin 910, while polypropylene is commonly used as a nonabsorbable material. Most published data on graft materials are related to incontinence surgery and abdominal colpopexy. There is no standardized method to place the graft. The graft is placed through the vaginal incision as another layer of support after plication of the rectovaginal fascia. Transverse and anteroposterior dimensions of the prolapsed segment are measured. A graft of similar size is placed and secured by delayed absorbable or nonabsorbable 0 sutures. The redundant vaginal mucosa is then excised and the mucosa is closed using an absorbable continuous suture with no tension.

**FIGURE 51.7** Inferior view of the pelvic floor. Superficial perineal muscles and perineal membrane have been removed on the left to show attachments of the levator ani (LA) muscles to the distal vagina, anus, and perineal body.

**FIGURE 51.8** Perineorrhaphy incision. The perineorrhaphy incision is diamond-shaped and only the epithelium is removed. With a finger in the rectum, interrupted sutures are placed lateral to medial (1) with the first pass and then medial to lateral (2) and then tied down.

### Postoperative Care

In our practice, women who have undergone a repair of a posterior vaginal wall defect are admitted to the hospital overnight for pain management and observation. An ice pack to the perineum every couple hours can reduce postoperative edema and pain in women who have had a perineorrhaphy. A voiding trial is typically performed the day of discharge (most often postoperative day 1). A repeat voiding

**FIGURE 51.9** The perineum after three sutures are placed. The genital hiatus has decreased in size and the perineal body is reconstructed.

**FIGURE 51.10** Following the reconstruction of the perineal body, the epithelium is closed using a running absorbable suture. The genital hiatus demonstrated has been constructed for a non-sexually active woman.

trial is performed by a visiting nurse 3 or 4 days later in the patient's home for those who fail initially. Women are discharged home, to return in 2 weeks, with a bowel regimen consisting of fiber, stool softeners, and a "plan" if they have not had a bowel movement for a couple of days. Oral pain medications, including anti-inflammatory agents and narcotics, may be prescribed. We instruct all women that they are limited to no lifting over 10 pounds and "nothing in the vagina" for 6 weeks.

## OUTCOMES

### Results

Despite the fact that transvaginal colporrhaphies have been the preferred surgical procedure for rectocele repair among gynecologic surgeons for over 100 years, there are few data regarding the long-term anatomic success. In different case series, the anatomic cure rate ranges from 76% to 96% for posterior and from 56% to 100% for site-specific defects (10). A recent Cochrane review of surgical management for prolapse reported that transvaginal repair is superior to a transanal approach for posterior vaginal wall prolapse, with a lower recurrence rate (RR 0.28; 95% CI, 0.009–0.64) (11).

Posterior colporrhaphy was found to be effective in alleviating symptoms of vaginal bulge (4–64%), constipation (22–100%), and fecal incontinence (4–36%). Thus, the functional improvement is not always correlated with anatomic success.

Over the past 20 years there have been several case series reporting on the anatomic success of posterior repair with

graft material, with cure rates ranging from 89% to 100% for a follow-up period of 3 to 60 months. Variability of the cure rate can be partially explained by the different definitions and tools used to assess anatomic cure.

---

## Complications

---

The most common immediate complications associated with repair of rectocele are injury to the rectum, constipation, infection, perirectal hematoma, and inclusion cyst. When the rectal lumen is inadvertently opened during dissection of the rectum from the vaginal mucosa, the defect must be closed during surgery. The most important factor is recognition at the time of the injury, as neglected cases may result eventually in rectovaginal fistula. The risk of passing suture through the rectal mucosa is diminished by placing a finger in the rectum at the time of suturing. If a stitch is felt on rectal examination it should be removed transvaginally, not through the rectum.

Constipation should be avoided and is one of the major threats to the success of the surgery; therefore, the problem is best addressed prior to undergoing surgical repair.

Dyspareunia rates of 21% to 27% have been reported following posterior repair (12) and are linked to the levator ani plication that is commonly done. Weber et al. (5) reported similar rates without a plication. Rectocele repairs using synthetic mesh may result in both dyspareunia and *hispareunia*. *Hispareunia* or *partner dyspareunia* is a term we use to describe the pain resulting from penile exposure to the eroded mesh during intercourse. The extent of this phenomenon is unknown.

According to the literature, the rate of erosion via the vaginal route varies from 12% to 30% (13). The true rates of erosion may be higher than reported due to the short follow-up in most studies. The type of mesh used affects erosion rates; however, no synthetic mesh seems to be completely spared from this phenomenon.

Typically, women with mesh erosion present with persistent vaginal discharge or bleeding and possible dyspareunia and require transvaginal trimming of the exposed portion of the mesh. Successful treatment of vaginal mesh erosion with estrogen cream has been reported (13), but in our experience estrogen has not been effective.

# CHAPTER 52 ■ ABDOMINAL SACRAL COLPOPEXY

J. CHRISTIAN WINTERS AND SCOTT DELACROIX, JR.

Pelvic organ prolapse (POP) is a common yet complex medical condition that can significantly impair a woman's quality of life. POP can occur at multiple sites, and therefore the effect of these defects on a woman's symptoms may vary. One of the more complex types of POP is vaginal vault prolapse (VVP), and its incidence is reported to be 18.2% of all women with prolapse (1). In fact, many would suggest that any

descensus of the anterior compartment near the hymenal ring or beyond is associated with VVP. VVP usually occurs as a result of multifactorial muscular and connective tissue disorders that result in weakening of the supporting structures of the vaginal apex—the cardinal and uterosacral ligaments. In most cases this is accompanied by defects elsewhere on the pelvic floor, such as central or lateral cystocele, high or low

rectocele, enterocele, or perineal body laxity. Up to 72% of patients with VVP have been shown to have other pelvic floor defects in some combination (2). For any patient undergoing surgical correction for prolapse, it is paramount to recognize all potential defects prior to surgery. Undiagnosed and untreated vault prolapse will almost always ensure recurrence of a surgically corrected cystocele (1). It has also been demonstrated that an isolated abdominal repair of VVP without addressing concomitant pelvic floor defects may lead to decreased patient satisfaction and the need for secondary vaginal repair.

Finally, there are numerous reports of occult stress urinary incontinence manifesting after vaginal vault prolapse repair (3). There is evidence to support the use of prophylactic anti-incontinence procedures at the time of VVP repair in women with occult stress urinary incontinence (3).

This chapter will discuss the abdominal sacral colpopexy (ASC) for the correction of VVP. One must consider incorporating ancillary vaginal or anti-incontinence procedures with ASC because an untreated symptomatic secondary defect or undiagnosed occult stress urinary incontinence (3) will significantly impair overall patient satisfaction.

## DIAGNOSIS

Patients with VVP will often complain of pelvic pressure, vaginal protrusion, dyspareunia, difficulty walking, and back pain. Bowel and genitourinary symptoms vary from urinary and fecal incontinence to difficult elimination or sexual dysfunction. Patients with severe prolapse may need to manually reduce the prolapse to evacuate the rectum or void. Women with severe prolapse or uterine procidentia may develop recurrent urinary tract infections or hydronephrosis due to angulation of the ureters.

A thorough physical examination is needed to establish the diagnosis of VVP and to demonstrate other pelvic floor defects and/or occult stress urinary incontinence. During the examination every segment of the pelvic floor should be evaluated in a systematic manner—the anterior vaginal wall, the vaginal apex (or cervix), the posterior vaginal wall, and the perineum (Table 52.1).

TABLE 52.1

### COMPARTMENT-SPECIFIC DEFECTS AND FEMALE PELVIC ORGANS COMMONLY AFFECTED

LOCATION	DEFECT
Urethra	Occult stress incontinence Hypermobility
Anterior vaginal wall	Lateral cystocele and/or central cystocele
Vaginal apex	Vaginal vault prolapse
Posterior superior vaginal wall	Enterocele and/or high rectocele
Posterior inferior vaginal wall	Rectocele
Perineum	Incompetent perineal body

The pelvic examination begins with the patient in the lithotomy position, utilizing a Valsalva maneuver. If all areas of the pelvic floor can be assessed in this position, the examination is completed. Urethral mobility can almost always be assessed visually, but in rare equivocal cases, a cotton-tipped applicator test can be performed. In many cases, it will be difficult to assess low-grade or moderate VVP, especially in posthysterectomy patients without the cervix as an anatomic landmark. “Dimples” at the lateral apex of the vagina can sometimes be used to locate the cuff. These dimples usually represent the point of attachment of the uterosacral ligaments. The examiner’s fingers are placed at the vaginal apex. If the fingers descend halfway to the hymeneal ring or further on Valsalva, significant vault prolapse is present. Once again in the supine position, the anterior and posterior compartments are assessed independently. Half of a vaginal speculum is initially used to compress the posterior compartment while the examiner assesses the anterior compartment for abnormal descent. The posterior compartment can then be assessed by replacing the speculum to support the anterior vaginal wall. It is important to distinguish prolapse high along the posterior vaginal wall as either a high rectocele or an enterocele. This can be accomplished by bimanual rectovaginal examination in the supine or standing position to detect enterocele. In an enterocele, there is a defect between the pubocervical fascia and rectovaginal fascia that allows predominantly small intestine to press against the vaginal epithelium. If no enterocele sac is palpated between the rectum and vagina (examiner’s fingers), the defect is most likely a high rectocele. The perineal body should provide definition between the anterior and posterior perineal triangles. Prior episiotomy scars and defects in this area should be noted. In equivocal or difficult examinations where the full extent of the prolapse may not be appreciated, the patient can be evaluated while standing. The Pelvic Organ Prolapse Quantification (POP-Q) can be used as an adjunct to the examination, particularly when performing serial examinations or exchanging data (4).

Lower urinary tract function should be assessed in all patients, whether symptomatic or not. As previously noted, stress urinary incontinence can be unmasked by correction of POP of any type. After reduction of the POP by vaginal packing or pessary, a Valsalva stress test with a full bladder is performed in the standing position. Care should be taken not to falsely support and occlude a hypermobile urethra and thus obtain a false-negative result.

Urodynamic testing is strongly advised to delineate bladder and urethral function. With the prolapse reduced, the examiner assesses for the presence of stress urinary incontinence. If present, the degree of sphincteric deficiency is quantified using abdominal leak point pressures. In addition, urodynamic testing allows the examiner to assess the quality of bladder storage and quantify the contractility of the bladder during emptying. Women with impaired contractility or those who void by abdominal straining may have more difficulty voiding after surgery. These women may need counseling regarding this issue, particularly if an anti-incontinence procedure is performed. These voiding dynamics are easily diagnosed with urodynamic evaluation. Patients with fecal dysfunction, particularly incontinence, may be evaluated with additional studies such as anorectal manometry, transrectal ultrasonography, and an electromyographic latency study. An assessment of sexual function should be performed; one may consider the

use of a validated questionnaire such as the Prolapse and Incontinence Sexual Questionnaire (PISQ-12) (5).

## INDICATIONS

An individualized approach to patients with advanced POP should be undertaken after consideration of multiple factors. The surgeon must consider all site-specific defects present as well as the patient's urinary, bowel, and sexual function. It is of paramount importance to determine the most bothersome symptoms for the patient and to highlight the patient's goals and expectations of treatment. Following this, the patient's general medical condition and other factors are considered when deciding on a management plan.

There is no panacea for POP, as each procedure has advantages, disadvantages, and risks. ASC should be considered an excellent treatment option in the following cases: failed previous vaginal repair; recurrent enterocele and/or VVP; isolated high-grade apical prolapse and/or enterocele; and a younger woman with an active lifestyle who desires to continue sexual intercourse.

In these patients ASC is an excellent choice because it maximizes functional vaginal length and provides a near-normal vaginal axis. As discussed above, other pelvic floor defects and occult stress urinary incontinence can be addressed at the same time.

## ALTERNATIVE THERAPY

Pessary placement is a nonsurgical option that is often unsatisfactory in severe cases of prolapse. In cases of total vaginal prolapse, pessary placement can be impossible. The need for daily cleansing, replacement, discomfort, and vaginal erosion are some of the disadvantages to long-term pessary placement.

A colpocleisis is a safe and effective alternative treatment of POP, especially in elderly patients. It does not preserve normal anatomy and is an option only in a patient not desiring future sexual activity.

Vaginal methods of prolapse repair, including unilateral or bilateral sacrospinous ligament fixation, plication of the uterosacral ligament (McCall) with culdoplasty, or iliococcygeus fascial fixation, are also alternatives to abdominal sacral colpopexy. Sacrospinous ligament fixation will result in significant changes in the vaginal axis and has a higher incidence of anterior compartment defect recurrence and rectal, vascular, or neural complications. Plication of the uterosacral ligament with culdoplasty is difficult in posthysterectomy patients, with a higher potential for ureteral injury. In addition, there is concern regarding the functional integrity of the uterosacral remnant (6). Iliococcygeus fascial fixation will result in vaginal shortening.

## SURGICAL TECHNIQUE

All patients are administered a mechanical bowel preparation preoperatively. Thromboembolic elimination stockings and sequential compression devices are used. Open, robotic-assisted laparoscopic and pure laparoscopic approaches have all been described. The principles of the operation remain the

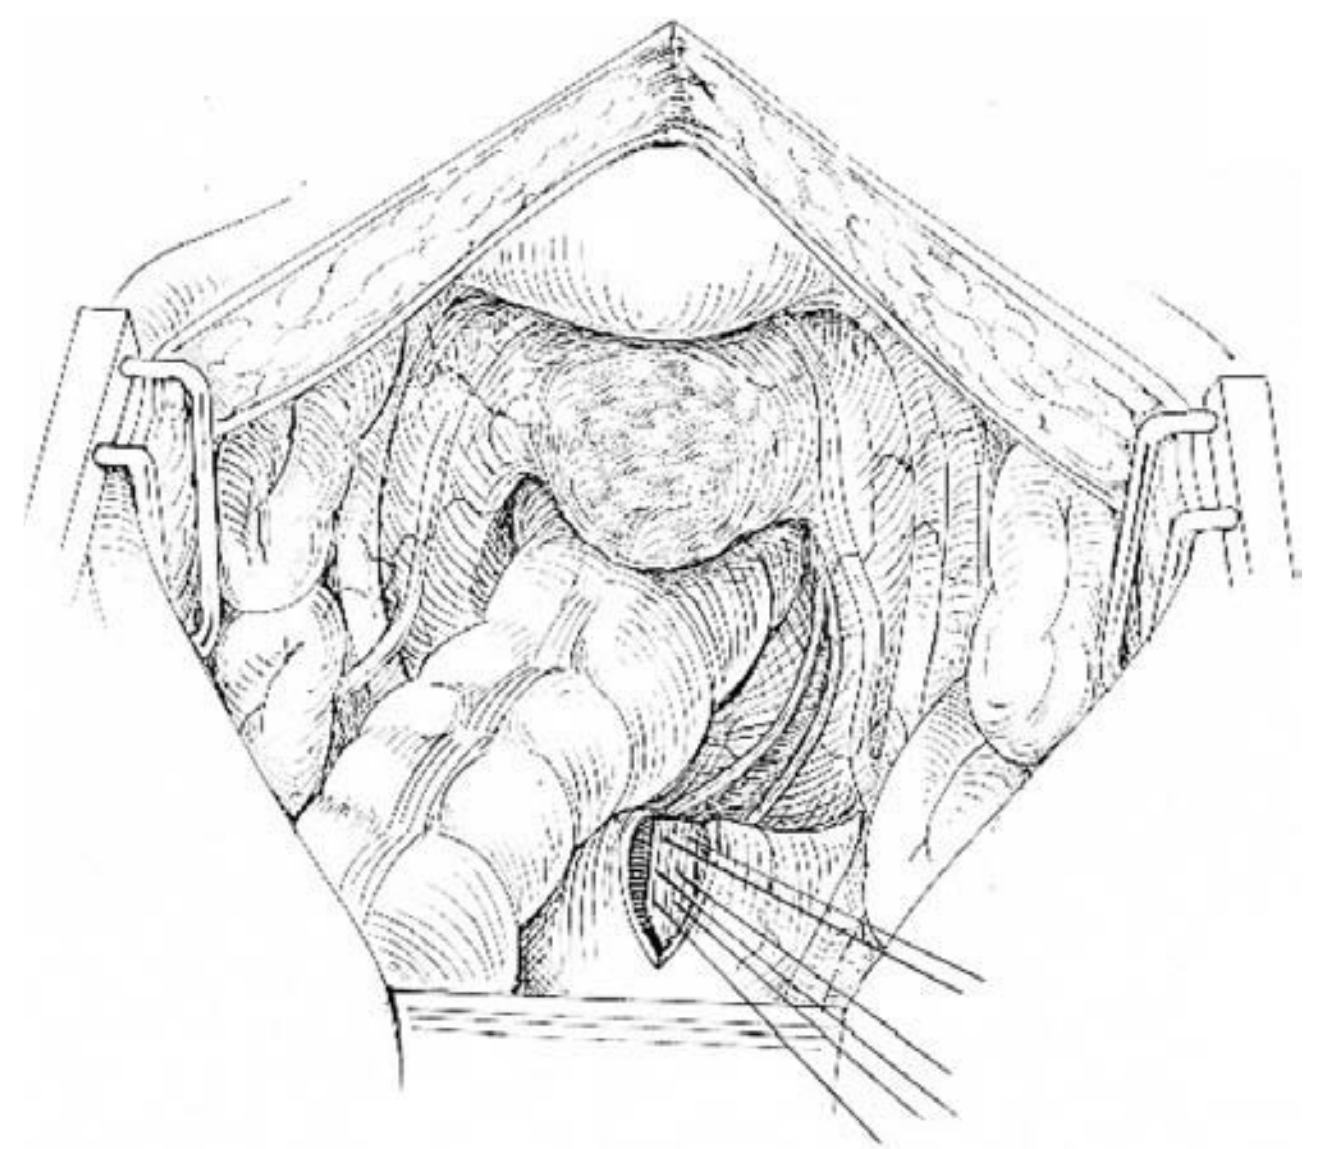

same regardless of approach, and we will describe the open technique of ASC. The critical elements of the operation include:

- Permanent mesh (type I macroporous, monofilament) as graft material
- Secure suture fixation of the graft to the sacral promontory and vaginal cuff
- Complete enterocele reduction and culdoplasty
- Anti-incontinence procedure as indicated

The patient is positioned in the low lithotomy position, providing both transvaginal and transabdominal access. A low midline abdominal incision is preferred by the authors to allow exposure of the sacral promontory. A Pfannenstiel incision may also be chosen in younger patients, although exposure may be slightly more difficult. The following is a description of the operative technique of ASC and abdominal enterocele repair.

Once the incision is made and the peritoneal cavity entered, it is essential to achieve excellent exposure by freeing all adhesions in the pelvis and packing the bowel out of the pelvis above the level of the sacral promontory. Next, an incision is made in the posterior peritoneum over the sacral promontory, extending inferiorly along the right lateral aspect of the rectum (Fig. 52.1). Electrocautery is used when dividing the fatty tissue over the promontory. Diathermy cautery forceps are useful in this dissection. Excessive blunt dissection is avoided in this area as shearing of presacral veins with severe bleeding may occur. Care is taken to avoid the middle sacral vein traversing over the promontory. As the fatty tissue is dissected free, the anterior surface of the sacral promontory is visualized, usually by identification of the anterior longitudinal ligament.

Two or three sutures of no. 0 Ethibond (Ethibond Excel polyester suture; Ethicon Inc., Johnson & Johnson, Somerville, NJ), using a MO-7 needle, or no. 0 Prolene (polypropylene suture material; Ethicon Inc.), using a MO-6 needle, are placed into the periosteum over the sacral promontory (Fig. 52.1).

**FIGURE 52.1** Incision of posterior peritoneum extending into pelvis lateral to rectum. Note secure suture placement into the sacral promontory.

**FIGURE 52.2** Peritoneum over vaginal cuff incised. Note: Dissection is made easier by use of EEA sizer.

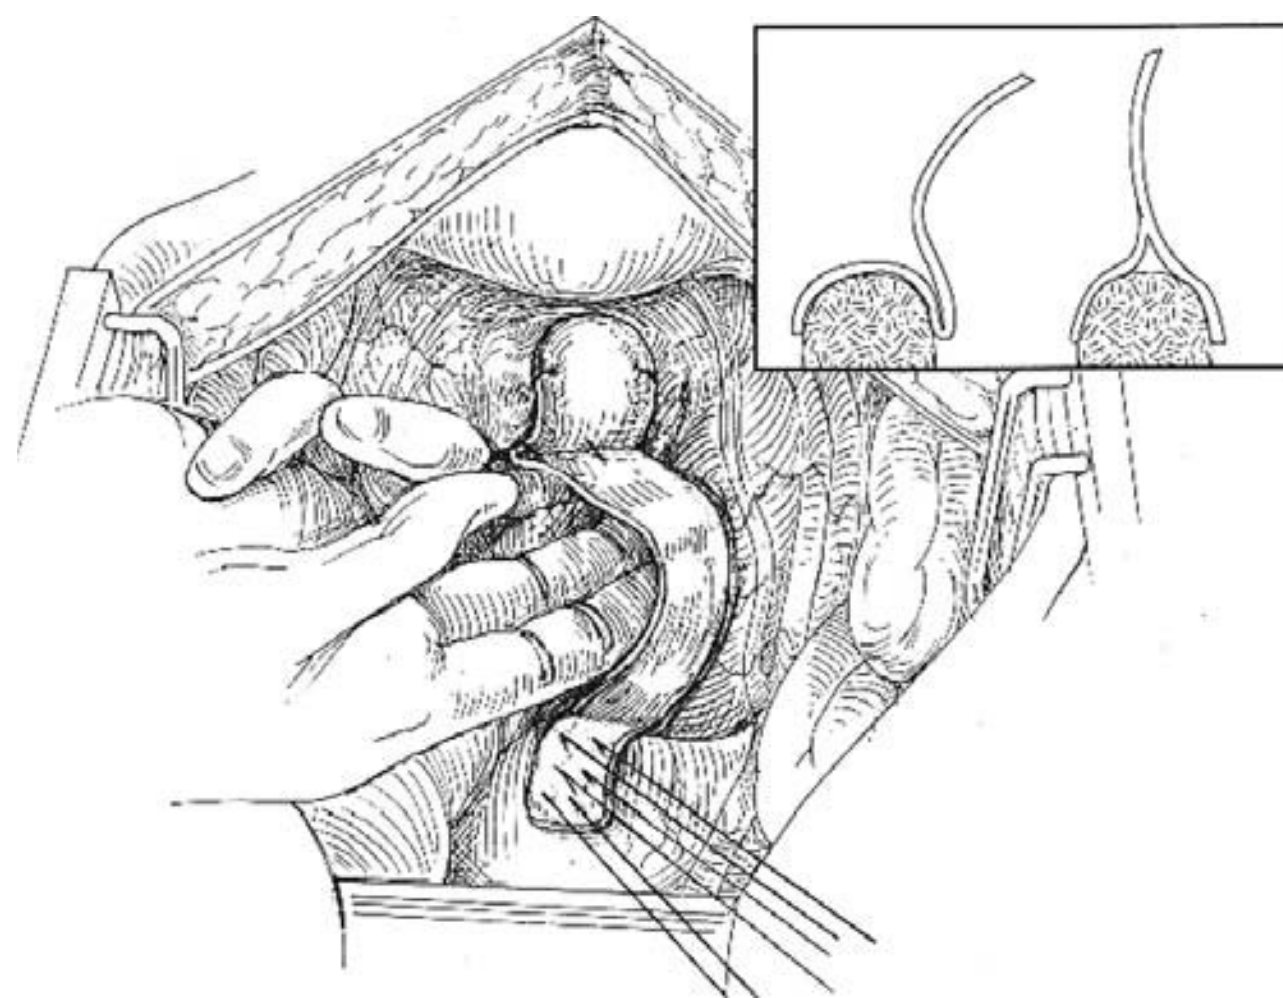

These sutures are safely secured for later placement into the graft. Alternatively, commercially available tacking devices may be used for securing the graft to the sacral promontory.

The peritoneum over the vaginal cuff is excised, and the peritoneum is dissected off the cuff of the vagina (Fig. 52.2). A 2.0-cm-wide segment of graft is sutured to the exposed vaginal cuff using six sutures of 2-0 Ethibond (Fig. 52.3). Monofilament nonabsorbable mesh is recommended (see Outcomes later). The graft is secured to the vagina by folding over the cuff of the vagina and allowing the long end of the graft to exit posteriorly and extend to the sacrum. Alternatively, a T-shaped configuration of the graft may be created. The short arm of the T is placed on the top of the vagina, and the long arm of the T is secured to the lower end of the vagina. The enterocele sutures (Fig. 52.4) are placed into the long arm of the T on the lower side of the vagina.

After placing an obturator in the vagina (large end-to-end anastomosis sizers are useful), the enterocele sac is identified and secured with an Allis clamp. If the enterocele is large, several pursestring sutures or linear 2-0 Ethibond sutures are

**FIGURE 52.3** Intraoperative view: Permanent graft secured to vaginal apex.

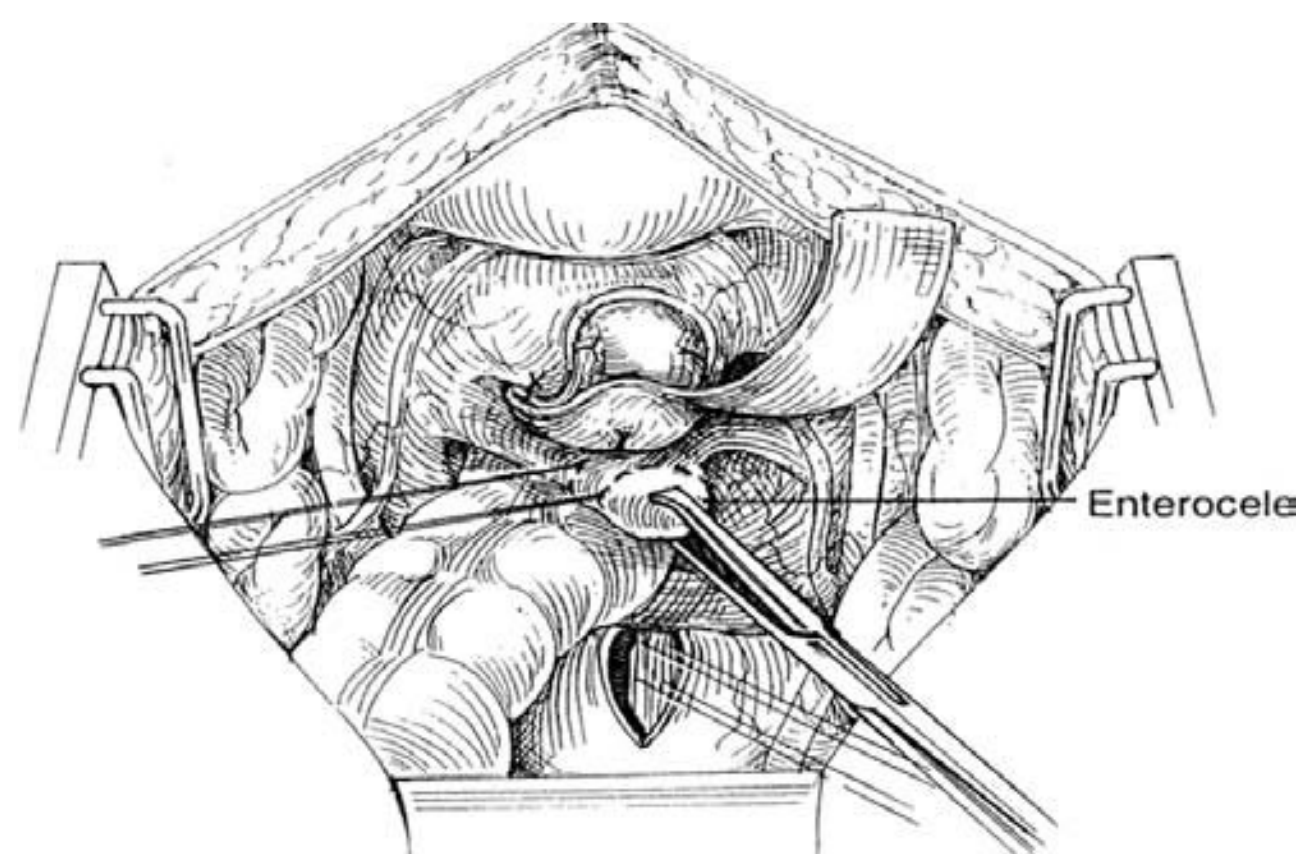

**FIGURE 52.4** Final graft position. Inset shows different methods of graft attachment. Long extension of graft secured posteriorly.

placed into the enterocele sac to obliterate it (Fig. 52.5). This will reduce the cul-de-sac and facilitate the culdeplasty.

A Halban culdoplasty is performed by placing linear sutures (2-0 Ethibond) through the posterior peritoneum and on the outer surface of rectum up to the vaginal cuff (Fig. 52.6). The central sutures are placed through the obliterated enterocele sac to prevent recurrence of enterocele. Upward retraction of the graft will assist in exposing the cul-de-sac. Usually four to six sutures are used to complete adequate cul-de-sac closure. (At this step, the central sutures from the culdoplasty are placed through the long arm of the T, if used.)

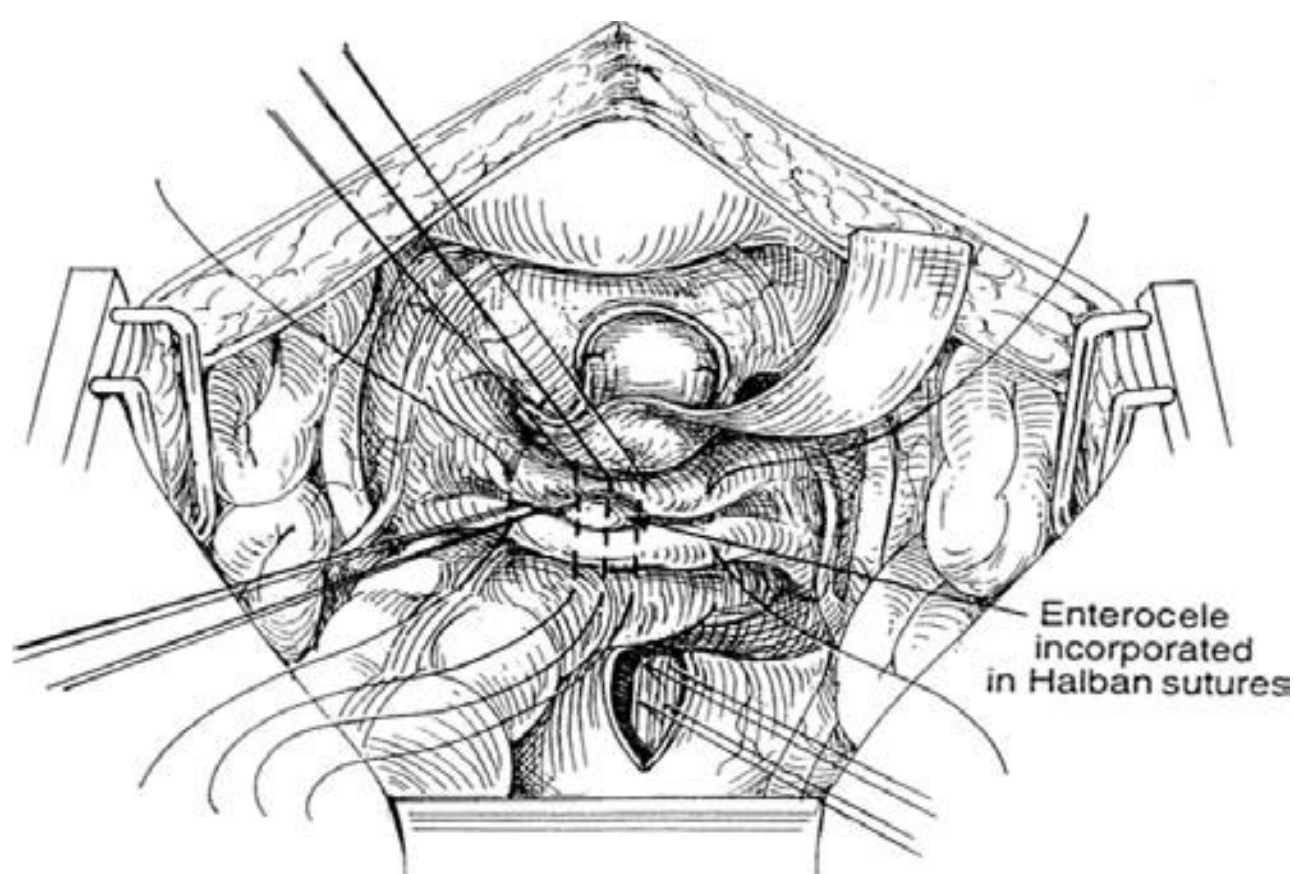

Using the preplaced sutures on the sacral promontory, the graft is secured to the promontory. Care must be taken to avoid excessive tension. Placing the obturator all the way into the vagina but not pushing the vagina upward establishes the proper length of the graft. The graft is placed around the right lateral aspect of the rectum. A space of two fingerbreadths between the graft and the rectum prevents compression of the rectum over the graft (Fig. 52.7). The excessive length of the graft is trimmed after fixation to the sacrum.

The graft is positioned in the retroperitoneal space by closing the presacral peritoneum over the graft and covering the

**FIGURE 52.5** Isolation of enterocele from above. If enterocele is large, it may be reduced by plicating with pursestring sutures prior to cul-de-sac closure.

**FIGURE 52.6** Halban cul-de-plasty: longitudinal sutures placed to close cul-de-sac.

**FIGURE 52.7** Intraoperative view: graft in final position. Note minimal tension placed on graft material. Incised peritoneum will be closed over graft after securing graft.

graft on the vagina with the superior edge of the peritoneum over the vagina (Fig. 52.8). Stress incontinence procedures (if indicated) are then performed. The patient is then examined to determine if any ancillary prolapse repairs are needed.

---

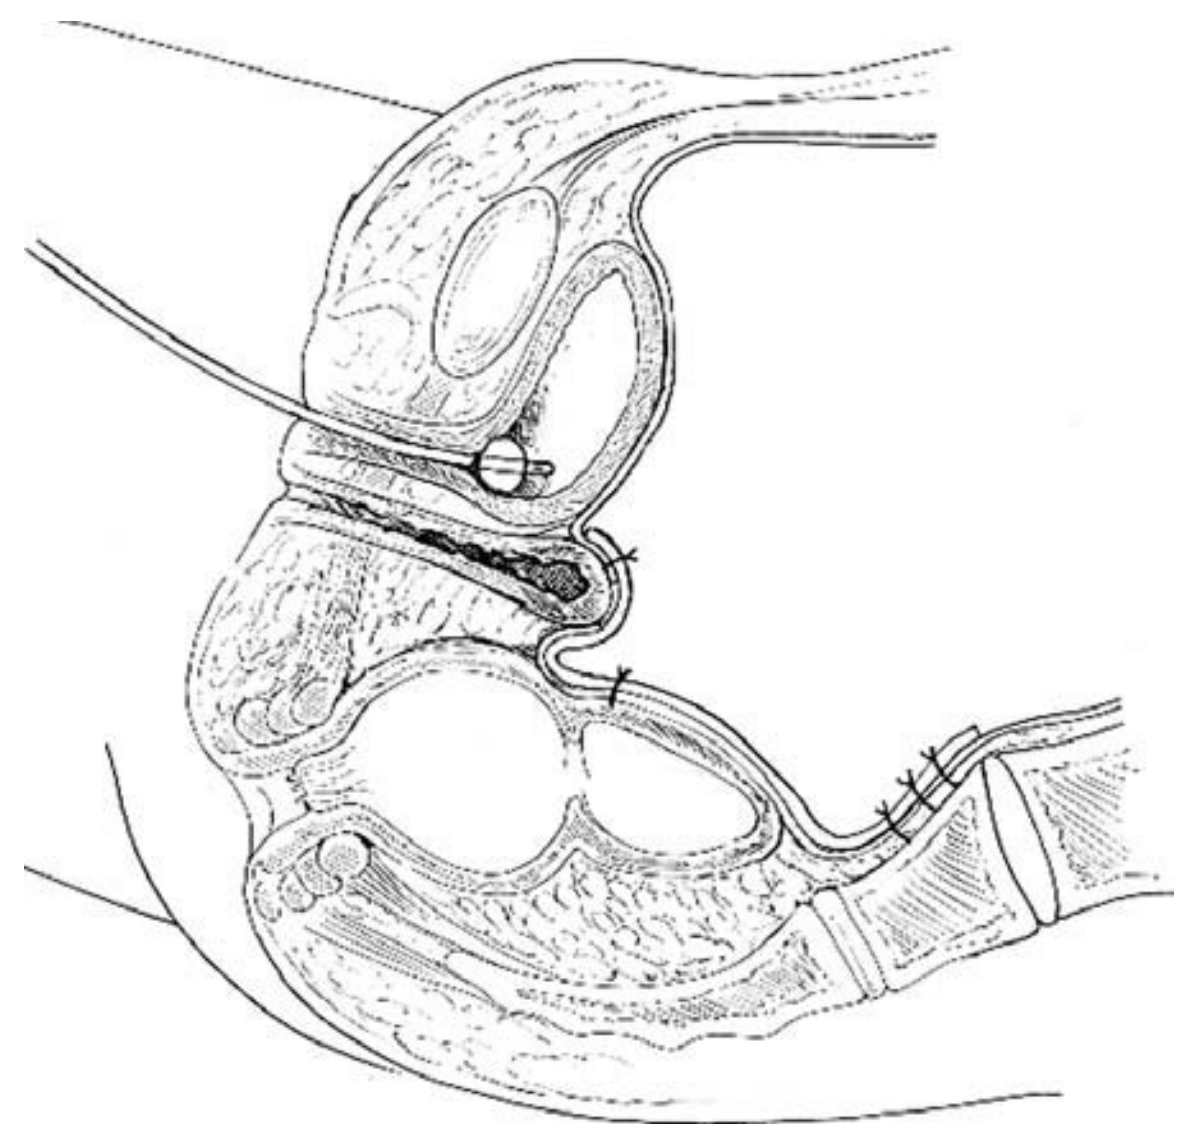

## OUTCOMES

---

### Results

---

In the indicated patient, the goal of pelvic reconstruction is to preserve vaginal depth and normal vaginal axis while repairing POP. This should be done through a procedure with a low

**FIGURE 52.8** Final result. Graft positioned below posterior peritoneum by closing the previously incised peritoneum over the mesh.

complication rate, minimal morbidity, and a low recurrence rate. ASC maintains a functional vagina and restores maximal vaginal length and support by securing the vaginal apex to the periosteum of the sacrum (7). In a comparative study, the vaginal length was longer after ASC compared to sacrospinous fixation (7). The abdominal approach allows excellent exposure to the pelvis and allows complete obliteration of the pouch of Douglas (Halban culdoplasty).

A nonabsorbable monofilament synthetic mesh should be used for fixation during the ASC. In a study by Culligan et al. (8), patients undergoing ASC using either absorbable cadaveric fascia lata graft (Tutoplast) or nonabsorbable monofilament polypropylene were randomized. The objective failure rate for recurrence at any other vaginal site was 14 out of 44 in the fascial group and 4 out of 45 in the mesh group (RR 3.58, 95% CI 1.28–10.03) (9).

There are numerous reports by multiple authors that confirm the success of ASC. Success rates  $>90\%$  have been reported and the durability of this procedure has also been documented (10–12). There are several randomized, prospective trials comparing sacrospinous ligament fixation (SSLF) with abdominal sacral colpopexy (13). In a comparative study between ASC versus vaginal repair, Benson et al. (11) reported a lower success rate with vaginal repair and an equivalent hospital stay between the two groups. Lo and Wang (12) reported on their results of ASC versus SSLF at a duration of 2.1 years: 94.2% success with ASC compared to 80% with SSLF. Maher et al. (10) reported on a comparative study between ASC and SSLF. At 2 years of follow-up, symptoms and anatomic success were equivalent, but asymptomatic failures to introitus and recurrent cystoceles were less after ASC. Overall, vaginal procedures have a higher rate of recurrent anterior defects even when performed in the setting of a concomitant anterior repair (colporrhaphy).

The assessment, determination, and treatment (if present) of occult stress urinary incontinence should be the standard by which patients with significant POP warranting surgical correction are addressed. Brubaker et al. (3) reported the importance of performing simultaneous Burch culposuspension in

women undergoing ASC. In a prospective, controlled trial, 23.8% of women who underwent Burch procedures at the time of ASC reported bothersome stress urinary incontinence compared to 44.1% of women who underwent ASC alone. These findings occurred in women regardless of the presence or absence of occult stress urinary incontinence. This study clearly demonstrates that women undergoing ASC are at significant risk for developing stress urinary incontinence postoperatively, even in the absence of preoperative symptoms. The implications of these findings should be discussed with patients in advance of surgery. However, some patients may have significant obstructive voiding symptoms and no evidence of stress urinary incontinence on preoperative evaluation. A selective approach may be warranted in these patients, with the caveat that a midurethral sling can be placed at a later date with minimal difficulty. In patients who have symptomatic or occult stress urinary incontinence, the authors prefer midurethral sling placement at the time of ASC, due to the common coexistence of intrinsic sphincter deficiency.

Other advantages of ASC include consistent anatomy that is less reliant on deficient pelvic connective tissue, the ability to perform the most definitive enterocele repair via abdominal culdoplasty, and the fact that urologists are comfortable with pelvic surgery. The ASC is a procedure that should be easily incorporated into the surgical repertoire of urologists, providing excellent correction of VVP.

---

## Complications

---

Complications can be divided into intraoperative complications and postoperative complications. In a comprehensive review by Nygaard et al. (13), intraoperative complications included hemorrhage or transfusion (4.4%), cystotomy

(3.1%), enterotomy (1.6%), and ureteral injury (1.0%). Postoperative complications included urinary tract infection (10.9%), wound infection (4.6%), ileus (3.6%), deep venous thrombosis or pulmonary embolism (3.3%), and small bowel obstruction (1.1%). The risk of significant bleeding has been reported from 1.6% to 4.4% and may be controlled with the use of stainless steel thumbtacks (14). Significant hemorrhage can occur from disruption of the presacral vessels. This complication may be reduced when fixation of the graft is performed high on the sacral promontory. Mesh erosion into the sigmoid colon has been reported (15) and is avoided by meticulous placement of the mesh while ensuring an adequate space between it and the sigmoid colon. Erosions are heralded by persistent pain, discharge, irritative voiding symptoms, or infections, and clinicians must be vigilant in follow-up (16). In a recently reported meta-analysis, the rate of mesh erosion into the vagina was reported at 3.4% to 5.4%; the rate may vary depending on the type of mesh used (13,17). Erosions are more prevalent with Teflon or Gore-Tex type of materials and are rare with macroporous, monofilament meshes. The incidence of mesh erosion is increased when performing a sacral colpoproctopexy (15). Concurrent hysterectomy has a theoretical risk of increasing infection or erosion of the graft, given the chance of contamination from vaginal microbes; however, current evidence is contradictory, and no randomized trials have addressed this issue (13). In 60 patients undergoing concomitant hysterectomy using a two-layer closure of the vaginal cuff followed by ASC with synthetic nonabsorbable monofilament mesh, the erosion rate was 0.8% compared to 0% in the 64 patients with a prior hysterectomy (18). In patients undergoing a combined operation, supracervical hysterectomy or a meticulous two-layer imbricated closure of the vaginal cuff can be performed to reduce the risk of mesh erosion at the vaginal cuff.

# SECTION V ■ VAS DEFERENS, SEMINAL VESICLE, TESTIS

MARC GOLDSTEIN

## CHAPTER 53 ■ ANATOMY OF THE EPIDIDYMIS, VAS DEFERENS, AND SEMINAL VESICLE

HOWARD H. KIM AND MARC GOLDSTEIN

The formation of a spermatozoan from precursor cells does not signify its readiness to fertilize an oocyte. It must travel a vast distance and learn fundamentals such as swimming before debuting in the world and laying claim to its female counterpart. Fortunately, the excurrent ductal system of the male reproductive tract provides specialized facilities for this journey, as a nursery, dormitory, finishing school, and test track. The anatomic features that make this system so exquisitely

suited for nurturing and educating sperm also make it vulnerable to injury and malfunction; imagine how easily the elongated single duct of the epididymis is injured or blocked. The components of the excurrent ductal system (Fig. 53.1) can be organized into a logical order, the epic journey of a spermatozoan from its origin at the germinal epithelium to its dramatic exit at the ejaculatory duct with assorted encounters in between.

FIGURE 53.1 A: Front overview of the male excurrent ductal system. B: Side overview.

## EPIDIDYMIS

### Physical Examination

Careful assessment of the epididymides during the physical examination of an infertile patient is as important as the testicular evaluation. The consistency of the epididymis can help differentiate obstructive from nonobstructive causes of azoospermia. A large and turgid feel to the epididymis implies obstruction of sperm outflow, whereas a small and flaccid epididymis indicates a likely problem of spermatogenesis. Tenderness to palpation can indicate the presence of inflammation or infection. Palpation of a cystic structure originating from the epididymis indicates the presence of a spermatocele; aspiration of the cyst fluid revealing sperm confirms the diagnosis. In patients presenting with acute scrotal pain, the presence of a paratesticular or epididymal nodule or “blue dot” and absence of testicular pain help to distinguish testicular torsion from torsion of the testicular appendages.

### Development

The epididymis develops from the portion of the mesonephric duct that was directly associated with the mesonephros; all

mesonephric tubules degenerate along with the mesonephros, except the vasa efferentia, which become highly convoluted tubules (11). In humans, the epididymis is well developed by 16 weeks of gestation, and secretory activity of the epididymal cells has been observed by 25 weeks of gestation (12).

### Anatomy

The epididymis is a single tubule 6 to 7 m in length with the cauda forming half of the length (Fig. 53.2); the long distance provides gametes both time and resources to mature during their travel down the tract (32,34). The rete testis gives rise to 8 to 12 ductuli efferentes that penetrate the tunica albuginea and form the lobules that comprise the caput of the epididymis (34). Anatomically, the epididymis is divided in three parts, the caput (head), the corpus (body), and the cauda (tail). More specifically, the epididymis is composed of the terminal part of the ductuli efferentes, the ductus epididymis, and the initial portion of the vas deferens (34). Each segment of the epididymis features the characteristic size and shape of the ducts, epithelial lining, contractile elements, innervation, and vascularization (34).

The luminal shape on transverse section of the epididymis varies from the irregular stellate shape in the ductuli efferentes to the regular, round, or oval shape in the ductus epididymis to

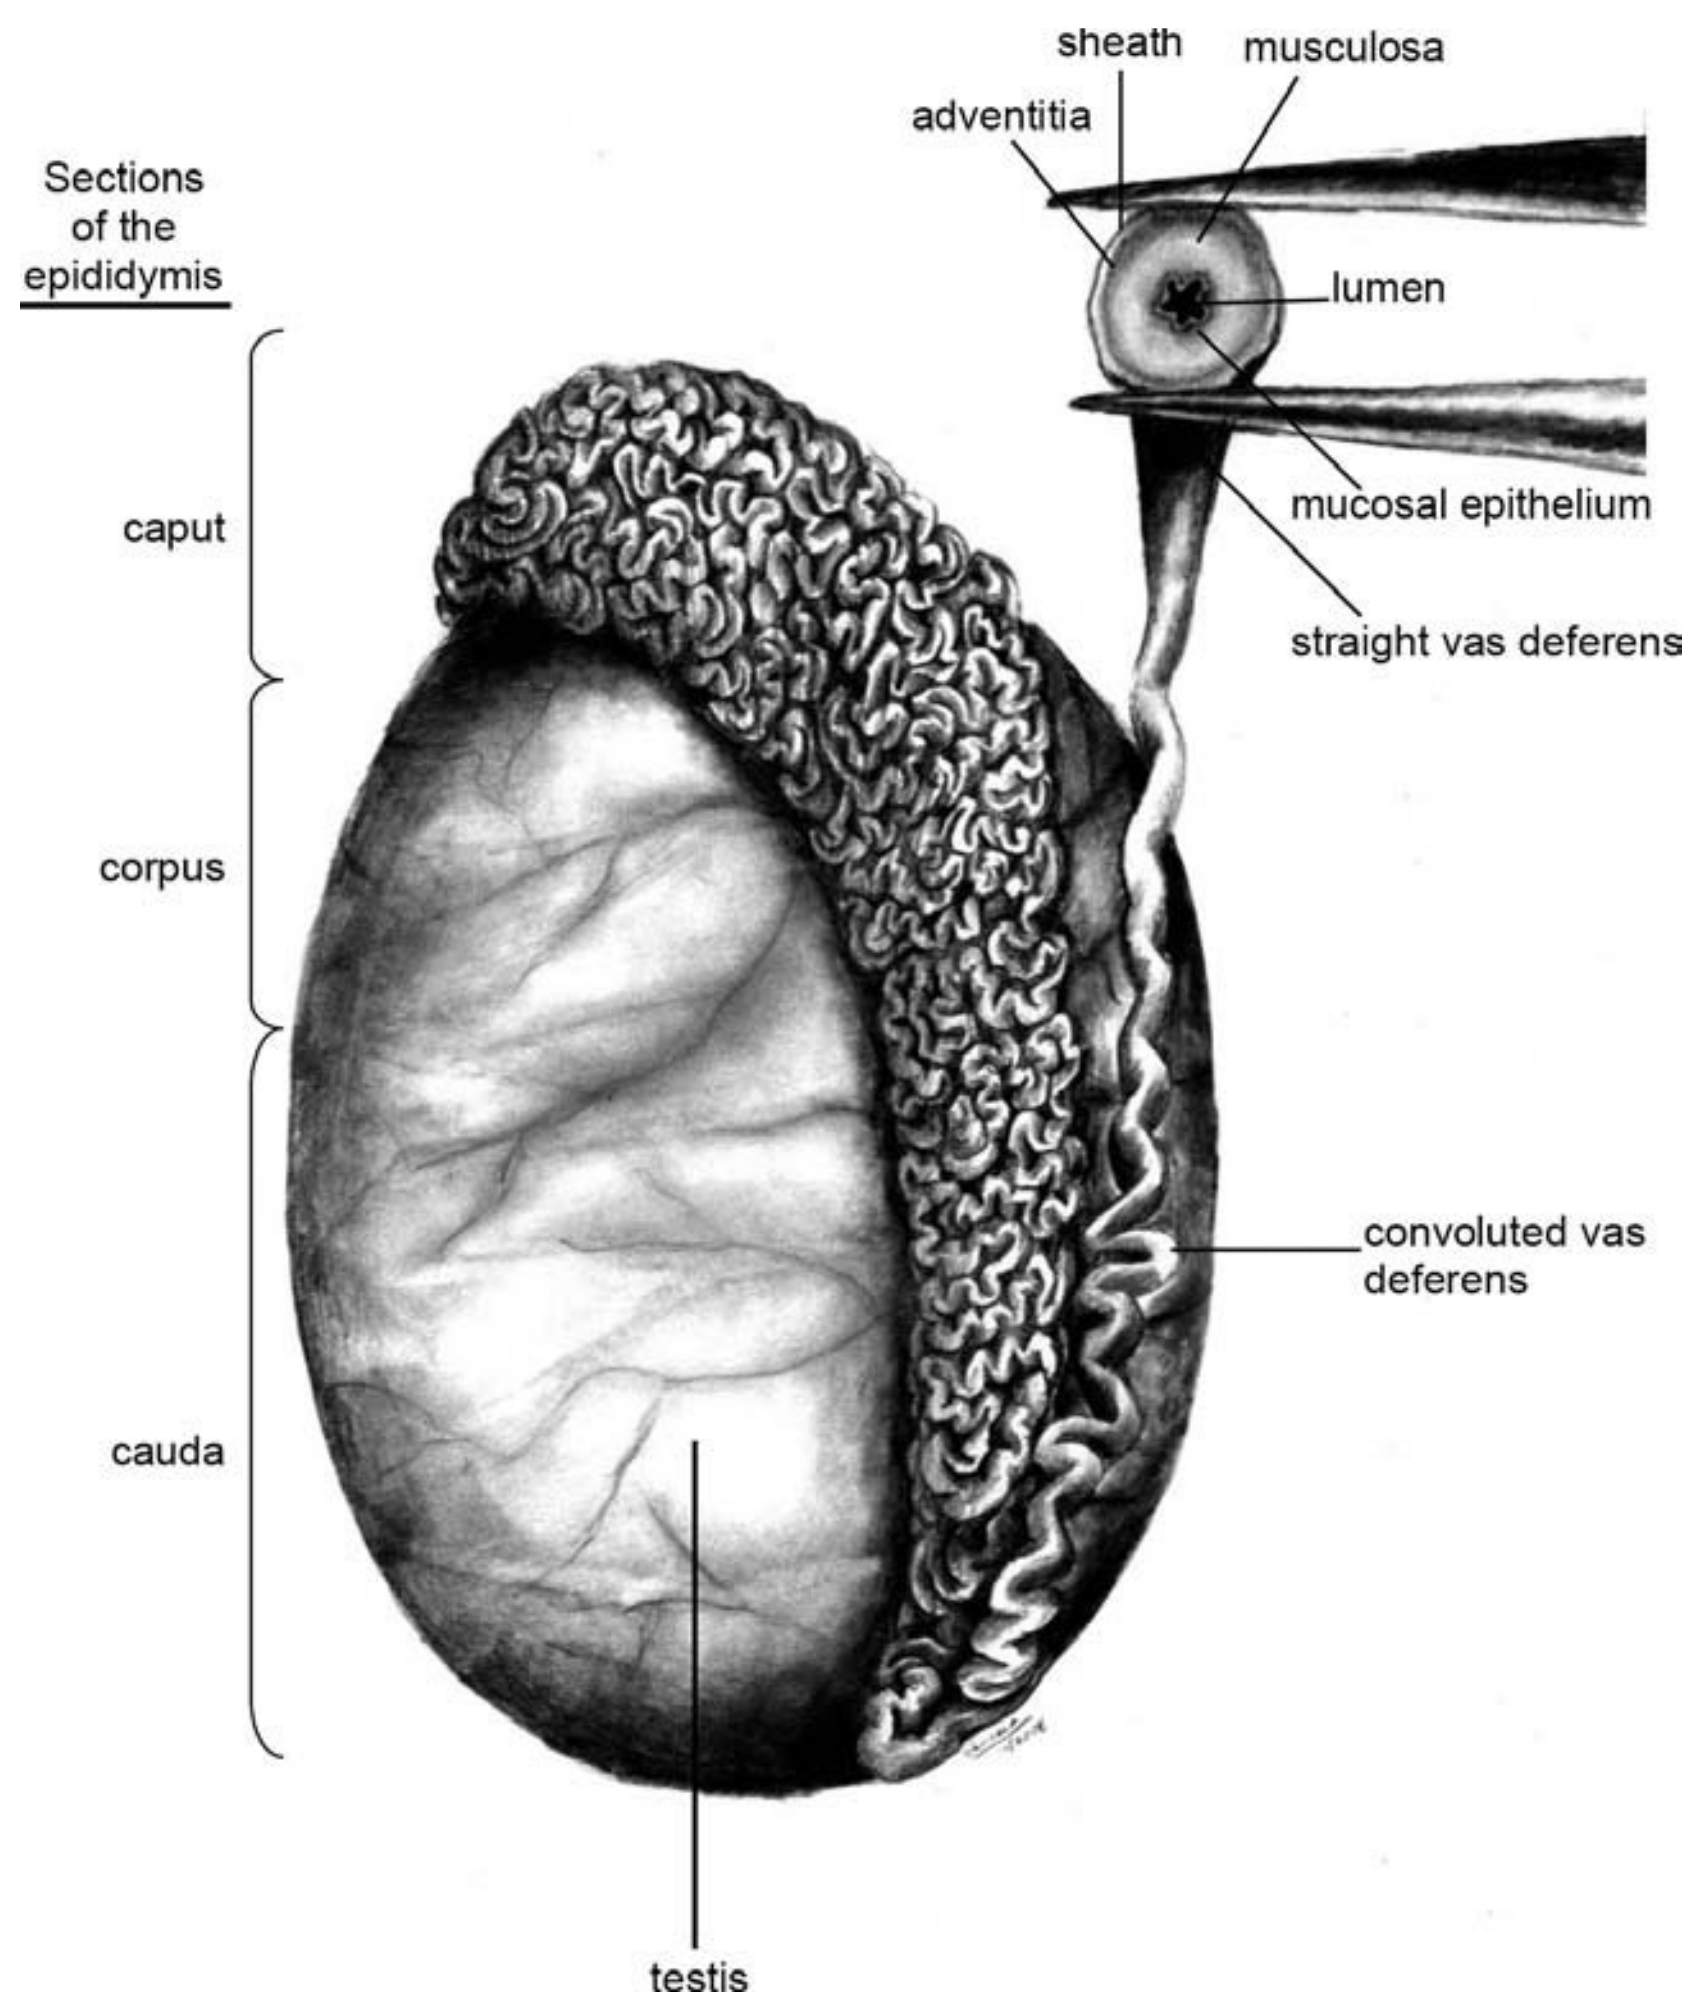

FIGURE 53.2 Epididymis and vas deferens.

the wide irregularity of the cauda epididymis (34). The duct constricts at the caudal section before it widens considerably (34). The luminal shape and size reflect the different function of each segment as well as the different cellular components contained within. The epithelium of the ductuli efferentes is prismatic; at least two cell types, some with cilia and others with microvilli, are gathered according to size in a single layer with their apical poles joined by junctional complexes (34). As variant cell morphologies may reflect adaptations of the same cell, different investigators report different numbers of cell types. The epithelium of the ductus epididymis is a prismatic pseudostratified type with basal and chief cells, among other cell types (34). The epithelial transition from the cauda to the initial portion of the vas deferens is progressive, without striking changes in the cellular organization (34). The sheath enclosing the entire epididymis contains a continuous layer of contractile cells, organized circularly or in a light spiral, with rare longitudinal bundles outside the circular layers (34). In the cauda, the contractile cells are replaced by smooth muscle cells forming three layers, inner and outer longitudinal and intermediate circular, that thicken and continue into the vas deferens (34).

The delicate structure of the epididymis makes it vulnerable to iatrogenic injury. The epididymis may be violated during procedures such as hydrocelectomy, spermatocelectomy, and orchiopexy, especially if the epididymis is adherent to the tunica vaginalis. Furthermore, unlike vascular injuries, which declare themselves immediately with hematoma or ecchymosis formation, epididymal injury may not be evident until the patient later presents for fertility evaluation. Hopps and Goldstein (16) reported the restoration of spermatozoa in the ejaculate in five of six patients following microsurgical repair of iatrogenic epididymal injury from hydrocelectomy. Blockage of the epididymis is not limited to iatrogenic injuries; trauma, infection, inflammation, and even blockage of the vas deferens (i.e., vasectomy) and subsequent increase in intraluminal pressure can result in epididymal obstruction.

### Blood Supply

The epididymis is supplied by the spermatic and funicular vascular pedicles (7). An intra-abdominal branch of the spermatic artery divides to feed the corpus, and an inguinal branch divides to feed the caput (7). The funicular pedicle consists of the deferential artery, which is a branch of the internal iliac artery or from a branch of the internal iliac artery, usually the superior vesical artery, and runs along the vas deferens onto the cauda; and the funicular artery, which starts at the vesicular artery and supplies the vas deferens and the cauda; the funicular artery is thought to be the most important contribution to the main muscular epithelium of the cauda (7). Just as the hypogastric artery is now referred to as the internal iliac artery, the funicular vessel has fallen out of favor and is rarely referenced outside of historical anatomy texts. A more recent description of epididymal blood supply attributes the testicular (internal spermatic) artery as the source of the superior epididymal artery of the globus major of the epididymis and the cremasteric artery as the origin of the inferior epididymal artery of the globus minor of the epididymis (17).

In humans, the testicular vascular and epididymal vascular systems form anastomoses (7); this redundancy is helpful to microsurgions performing vasectomy reversals and other scrotal procedures that can potentially interrupt blood supply to the testis or epididymis. Despite this contact with the testicular

blood supply, the epididymis is generally independent of the testicular vascular network, and there is little direct hormonal exchange by this route, although the direct linkage of the lymphatic drainage of the testis and epididymis allows for passage of testicular hormones into the epididymis (7). The capillary network of the epididymis is much more extensive than that of the testis, with the density of microvessels reflecting the concentration and demands of the specialized epithelial cells (7).

### Innervation

Sympathetic nerve endings are concentrated in the corpus and cauda of the epididymis with progressive density approaching the vas deferens, consistent with their contractile role during ejaculation (34). In the ductuli efferentes and proximal epididymis, the sympathetic nerves form a loose peritubular plexus without penetrating between the cells (34). The distal portion of the epididymis demonstrates intermittent contractions during ejaculation, in contrast to the peristaltic activity of the proximal epididymis (34). Mean transit time of sperm in the epididymis of humans is 12 days (26).

---

### Function

---

In addition to the transport of spermatozoa with smooth muscle contractions, the epididymis stores and facilitates maturation of the spermatozoa. Fluid resorption at the caput epididymis concentrates sperm by 20-fold (9). Turner et al. (33) hypothesized that the dilution of epididymal fluid on ejaculation along with the addition of electrolytes promote sperm motility. Acott et al. (1,4) presented evidence that sperm motility may depend on changes in intrasperm cyclic adenosine monophosphate (cAMP) levels and the binding of a forward motility protein of epididymal origin. The epididymis also synthesizes and secretes proteins thought to be involved in the development of motility and fertilizing capacity (18). Studies in rats have demonstrated reconstruction of membrane glycoproteins of spermatozoa resulting from interactions with epididymal secretory proteins as part of the maturation process (5). The maturation process within the epididymis is dependent on androgens. In a study of the rat epididymis, castration resulted in changes in the ultrastructural organization of the epididymal epithelium and inhibition of secretory function (22). Fertilization with spermatozoa from the caput epididymis is possible, however. Silber (30) performed vasoevididymostomy in 51 patients with blockage at the caput epididymis; pregnancy rates with spermatozoa from the proximal and distal caput were 33% and 50%, respectively.

---

## VAS DEFERENS

---

### Physical Examination

---

The most important aspect of the physical examination of the vasa deferentia is to simply confirm their presence (Fig. 53.3). About 95% of men with cystic fibrosis have congenital bilateral absence of the vasa deferentia (CBAVD) (6). As over 70% of men with CBAVD have mutations in at least one allele of the cystic fibrosis transmembrane conductance regulator (CFTR) gene detectable by routine testing methods, couples with CBAVD wanting to conceive should undergo genetic testing (6).

**FIGURE 53.3** Palpation of the vas deferens on physical examination. (From Goldstein M. Surgical management of male infertility and other scrotal disorders. In: *Campbell's urology*, 8th ed. Philadelphia: WB Saunders, 2002:1532–1587, with permission.)

In addition, abdominal ultrasonography should be performed to assess the man for associated renal anomalies. Schlegel et al. (27) reported 26% of men with unilateral congenital absence of the vas deferens and 11% of men with CBAVD to have renal agenesis. Scrotal ultrasonography is helpful in detecting other urogenital anomalies, such as contralateral ejaculatory duct and epididymal or vasal obstruction in men with unilateral congenital absence of the vas deferens (13).

### Development

The vas deferens is formed by the portion of the mesonephric duct from the mesonephros to the urogenital sinus (11). The vas deferens is taken along with the testis during its descent and inguinal passage; the vas deferens is progressively stretched during this process (11).

### Anatomy

The vas deferens stretches about 45 cm in length as it travels from the cauda epididymis through the inguinal canal to join the seminal vesicle behind the bladder and form the ejaculatory duct that empties into the prostatic urethra (35). The lumen of the scrotal portion averages about 330  $\mu\text{m}$  in diameter. Two distinct histologies divide the vas deferens into the vasal portion, comprising the proximal 40 cm of length, and the ampullary portion, comprising the distal 5 cm (35). The cylindrical vasal portion is 2 to 4 mm in diameter and resembles the cauda epididymis (35). In contrast, the ampulla is dilated and fusiform and resembles the seminal vesicle (35).

The thick, muscular wall (>1 mm thickness) of the vas deferens contrasts with its narrow lumen (0.5 mm) (35).

It is composed of three layers: mucosa, muscularis, and adventitia. The mucosa (60  $\mu\text{m}$  thickness) is lined by a tall columnar epithelium containing chief cells, dark or pencil cells, mitochondrion-rich cells, and basal cells (35). The muscular layer forms >80% of the wall thickness, and the component large smooth muscle cells are arranged in an outer and inner longitudinal orientation with a thick middle circular or spiral layer (35). The adventitia contains blood vessels and nerves (35).

The vas deferens is vulnerable to injury, especially in its course through the inguinal canal. Inguinal hernia repair in both adults and children is an important cause of vasal obstruction. In adults, the vas deferens can become entangled in the synthetic mesh of the hernia repair. In children, the vas deferens can be ligated inadvertently with the hernia sac. The vas is only 1 mm in external diameter before puberty and 2 mm after mid-puberty (24). In a report by Sheynkin et al. (29), 7.2% of 472 men surgically explored for obstructive azoospermia had an iatrogenic injury to the vas deferens. Twenty patients had undergone pediatric inguinal hernia repair, and 10 patients had undergone adult inguinal hernia repair, the two most common etiologies of vasal injury. Overall, vasal injury was secondary to bilateral inguinal hernia repair in 19 patients, to unilateral inguinal hernia repair in 11, to renal transplantation in 2, to appendectomy in 1, and to spermatocelectomy in 1 (29).

### Blood Supply

The blood supply to the vas deferens is derived from the deferential artery, which originates from the internal iliac artery (28). The vas deferens features two distinct vascular networks: the larger vessels of the adventitia provide branches that penetrate the muscularis centripetally to the lamina propria, where a dense capillary network resides in the subepithelium (28). In rat studies, a distinct subepithelial sinusoidal network is seen, and the sinusoidal network is thought to function during ejaculation in increasing intraluminal pressure (14,23,28,31). The deferential artery is surrounded by a dense adrenergic network, and it contracts and relaxes in response to different agonists, demonstrating that it plays an active role in regulating the vasal blood supply (21). Venous drainage occurs via the deferential vein, which travels along the vas deferens to empty into the hypogastric vein (28).

### Innervation

The high density of the adrenergic nerve endings of the distal epididymis continues into the three layers of the vas deferens (28), although it has been noted that adrenergic innervation in humans is less extensive than in other species (2). Cholinergic neurons have also been demonstrated in the vas deferens (28).

## SEMINAL VESICLE

### Physical Examination

Palpation of the seminal vesicles provides important information for urologic specialists in oncology or fertility. Ideally, the former group uses the digital rectal examination of the seminal vesicles to feel for their involvement in prostate cancer and the latter group to collect evidence for ejaculatory duct obstruction in men with azoospermia and low-volume ejaculate. In reality, unless the examiner is blessed with long, slender digits, the seminal vesicles are difficult to reach for adequate

palpation. Although transrectal ultrasonography cannot substitute for the tactile assessment of cancer, infertility specialists fortunately can use this noninvasive test to help diagnose ejaculatory duct obstruction when the seminal vesicles elude the reach of their index fingers. Seminal vesicle dilatation  $>1.5$  cm and other signs, including dilatation of the ejaculatory duct, calcifications within the duct, and the presence of mid-line cysts on transrectal ultrasonography, suggest the diagnosis of ejaculatory duct obstruction. However, transrectal ultrasonography is less accurate than the traditional diagnostic combination of testicular biopsy and vasography (Fig. 53.4).

### Development

The caudal end of the Wolffian duct develops into the seminal vesicle, first as a dilatation, then as an evagination (15). This simple tube branches into a lobular structure during its development, organizing into ducts draining into a principal excretory duct (15). The few differentiated cuboidal cells that line the Wolffian duct during fetal life undergo several modifications with the production of androgens by the fetal testis and are eventually replaced at puberty by a glandular epithelium (15). In humans, the seminal vesicles are relatively undifferentiated during infancy and adolescence and develop their secretory activity between 16 and 18 years of age (3,15).

### Anatomy

The seminal vesicles (Fig. 53.5) are exocrine glands that empty into the ejaculatory ducts (Fig. 53.6). They enrich the sperm with proteins, enzymes, fructose, and other substances, contributing 46% to 80% of the total ejaculate volume (20). As such, the seminal vesicles are designed to optimize their secretory function. The

**FIGURE 53.4** Left vasogram demonstrating contrast in the vas deferens, seminal vesicle, and bladder, indicating patency of the left excurrent ductal system. Residual contrast seen in right seminal vesicle from previously performed right vasogram.

three layers of the seminal vesicle wall include villous mucosa, smooth muscle, and external sheath (10). The mucosa consists of a pseudo-stratified epithelium containing granular columnar cells and ovoid basal cells resting on a basement membrane surrounded by loose connective tissue replete with elastic fibers (10). The histology of the seminal vesicle is identical to that of the ampulla of the vas deferens (10). The epithelium is composed of principal secretory cells, basal cells, and duct cells, which are considered variants of principal cells (3,10). The principal cells metabolize the secretory components of seminal vesicle plasma and are dependent on androgens and other hormones such as prolactin for growth and activation (10).

**FIGURE 53.6** Ejaculatory ducts. (Adapted from Goldstein M. Surgical management of male infertility and other scrotal disorders. In: *Campbell's urology*, 8th ed. Philadelphia: WB Saunders, 2002:1532–1587.)

### Blood Supply

The seminal vesicle receives its blood supply from the internal iliac artery via the vesiculodeferential artery (28). Venous outflow is provided by the prostatic plexus and the inferior vesical plexus, which in turn drain into the internal iliac vein (28).

### Function

The seminal plasma, composed of fluid from the seminal vesicles, prostate, and accessory glands, contains a wide range of substances, including inorganic ions, low-molecular-weight organic molecules such as citrate, reducing sugars, amino acids, and prostaglandins (28). Using a rat model system, Clavert et al. (8) examined the role of the seminal vesicle fluid on fertility. They concluded that seminal plasma prevents agglutination of sperm, stabilizes the sperm cytoplasmic membrane, coats antigens on the sperm surface, forms a coagulum to prevent loss of deposited sperm, and in the female genital tract stimulates smooth muscle activity and inhibits lymphocytic reactions (8).

## ACCESSORY GLANDS

### Prostate

Although an important organ of the male reproductive tract, the prostate is featured in its own chapters and will not be reviewed here.

## Bulbourethral (Cowper) Glands and Urethral Glands

Bulbourethral glands are paired multilobular glands that are located at the penile bulb and empty into the urethra (28). A fibroelastic capsule and a thick striated compressor muscle surround a network of elastic and muscle fibers separated by connective tissue septa (28). A single layer of cuboidal or squamous cells lines the ducts, while mucuslike cells line the glandular alveoli (25,28). The bulbourethral glands receive their blood supply from the artery to the bulb of the penis as well as the internal pudendal artery, the urethral artery, the perineal artery, and the anastomosis of the cystic inferior and internal pudendal arteries (19,28). Motor nerves control the smooth muscle contraction, vascular tone, and secretory activity of the accessory glands (28). Primary innervation of the smooth muscle of the accessory glands is provided by adrenergic fibers arising from the ipsilateral pelvic plexus (28). The vasculature is innervated by a separate system of nerves traveling with the blood vessels (28). Urethral glands or the glands of Littre open into the urethra and, similar to bulbourethral glands, secrete mucus during intercourse.

## SUMMARY

The anatomic features of the epididymis, vas deferens, and seminal vesicle reflect their function. An understanding of the anatomy of the excurrent ductal system facilitates the diagnostic workup and physical examination as well as the surgical management of male fertility disorders.

## CHAPTER 54 ■ SEMINAL VESICLE AND EJACULATORY DUCT SURGERY

JAYI SANDLOW

### SEMINAL VESICLE SURGERY

The seminal vesicles are paired male organs with no female homologue. They develop as a dorsolateral bulbous swelling of the distal mesonephric duct at approximately 12 fetal weeks. The blood supply to the seminal vesicle is from the vesiculodeferential artery, a branch of the umbilical artery. Venous drainage is from the vesiculodeferential veins and the inferior vesical plexus. The seminal vesicles are innervated by

the pelvic nerve and the hypogastric nerve. The hypogastric nerve sends both adrenergic and cholinergic fibers to the seminal vesicles. Lymphatic drainage is via the internal iliac nodes (1).

Primary pathology within the seminal vesicles is rare; secondary lesions are more common. In the past, insufficient imaging methods led to infrequent definition of either primary or secondary seminal vesicle pathology. The use of transrectal ultrasonography (TRUS), computerized tomography (CT), and magnetic resonance imaging (MRI) has improved diagnostic visibility and facilitated the diagnosis and treatment of

seminal vesicle pathology. The necessity of surgical intervention is rare, but indications include congenital cysts with infection and/or obstruction causing infertility, ureteral ectopy into a seminal vesicle with resultant obstruction or dysplasia of the ipsilateral kidney, and primary tumors, either benign or malignant. Surgical access to the seminal vesicles is mostly via routes familiar to the urologic surgeon, but surgery on the seminal vesicles alone (without adjacent organ removal) is a unique challenge.

---

## Diagnosis

---

The normal seminal vesicle on TRUS is an elongated, flat, paired structure between the rectum and the bladder just superior to the prostate and is typically not palpable on digital rectal examination. The diagnosis of seminal vesicle neoplasms can be difficult because they often do not cause symptoms until late in their course. General symptoms that may occur include urinary retention, dysuria, hematuria, or hematospermia. A mass is often palpable above the prostate and is usually not tender. TRUS is usually the next step in diagnosis and may be accompanied by needle aspiration or biopsy for diagnosis. CT or MRI would then be appropriate to stage the patient and may also be used to stage solid lesions within the pelvis, as well as to confirm the hemorrhagic nature of suspicious masses. Because prostate cancer may be mistaken for primary seminal vesicle cancer, serum prostate-specific antigen (PSA), as well as tissue immunohistochemical stains for PSA, should, if positive, help define the prostate as the site of primary malignancy. In infertile patients who present with azoospermia, or in patients with hematospermia or coital pain, TRUS is the initial imaging study. Contrast vasography accurately images the vas deferens and ampullary–seminal vesicle junction but is less reliable than TRUS for seminal vesicle pathology.

---

## Alternative Therapy

---

There are relatively few alternatives to treatment of seminal vesicle masses, unless they are infected. Antibiotics may be utilized in this case. Many of the benign masses are asymptomatic and may be observed. Ejaculatory duct obstruction can also be observed if fertility is not an issue or if the couple desires sperm acquisition with in vitro fertilization.

---

## Indications for Surgery

---

Treatments of conditions of the seminal vesicles alone are limited to (i) transperineal/transvesical aspiration of seminal vesicle cysts or abscesses, (ii) transurethral unroofing of seminal vesicle cysts or abscesses, (iii) laparoscopic or robotic dissection, and (iv) open resection of one or both seminal vesicles.

Most procedures performed on the seminal vesicles are related to radical surgery for the treatment of urethral, prostate, bladder, or rectal cancer. Treatments specific to the seminal vesicle include transrectal aspiration of cysts or abscesses, transurethral unroofing of abscesses and obstructing cysts, and open resection for refractory infections, to excise an ectopic ureter, or to remove benign or malignant masses.

If a solid lesion identified in the seminal vesicle shows no evidence of local spread and is benign on biopsy, treatment is dependent on symptoms. If the patient is asymptomatic, close follow-up consisting of repeat rectal examination and TRUS to determine subsequent growth of the tumor is reasonable. If the mass enlarges or if the patient has symptoms referable to the mass, simple seminal vesiculectomy is advisable. This may be accomplished through one of several routes described below. If the mass is quite large and solid and demonstrates questionable margins, or if the biopsy shows malignant cells, the treatment of choice is quite different. Because fewer than 10 cases of primary tumors of the seminal vesicles have been treated at any one institution, it is difficult to define optimal treatment with any degree of certainty. Radical excision, which usually includes a cystoprostatectomy with pelvic lymphadenectomy, is the treatment of choice unless the tumor is extremely small. This recommendation is based on the extensive nature of the majority of the cancers when detected. The excision may include the rectum (total pelvic exenteration) if it is thought to be invading the surrounding structures. Adjuvant therapy has no proven efficacy, although the only long-term survivors in the literature received radical surgery with subsequent pelvic radiation therapy or androgen deprivation therapy. No chemotherapeutic regimen is known to be efficacious.

---

## Surgery

---

The most useful open surgical methods include transperineal, similar to radical perineal prostatectomy; transvesical, achieved by incising through the posterior bladder wall; paravesical; retrovesical; or transcoccygeal. Over the past decade, the laparoscopic or robotically assisted approaches to benign seminal vesicle lesions have been found to be remarkably direct and associated with much less postoperative morbidity than the open surgical approach (2). The choice of surgical approach, of course, depends partly on the characteristics of the lesion to be treated but probably more on the experience and expertise of the surgeon. For the most part, congenital lesions require an abdominal approach so that the ipsilateral kidney can be dealt with concomitantly, if necessary. Such lesions may be dealt with by laparoscopic or open surgical intervention. Benign lesions may be approached perineally; however, the risk of impotence is high even if a nerve-sparing approach is attempted. Larger benign tumors or cysts are best handled by an anterior abdominal approach, although a transcoccygeal method may be as useful. Again, the transperitoneal or retroperitoneal laparoscopic approach has great merit for such lesions. Patients with malignancy require radical extirpation, which commonly includes cystoprostate seminal vesiculectomy and pelvic lymphadenectomy. This operation is no different from a routine procedure for bladder cancer and, thus, is not described here.

### Preoperative Preparation

Preoperative preparation for laparoscopic, robotic, or open seminal vesicle surgery depends on the extent of the pathology and the planned incision. Transperineal, transcoccygeal, and transvesical approaches should be prefaced by a complete bowel preparation. Most surgeons use a mechanical preparation

with GoLyteLy orally the evening before surgery, followed by the standard antibiotic bowel regimen. Some method to prevent phlebothrombosis in the legs, such as use of intermittent compression stockings during and immediately after surgery, is advisable.

## Surgical Technique

A variety of open surgical approaches to the seminal vesicles have been described, of which the most useful are the transvesical, transperineal, and laparoscopic.

### Transvesical Approach

The transvesical approach to the seminal vesicle has been described by numerous authors (3). A midline extraperitoneal suprapubic incision is made up to the umbilicus, and the rectus muscles are separated on the midline. The space of Retzius is opened by downward displacement of the transverse fascia on the pubis, and an Omni retractor is placed to expose the anterior bladder wall. Care is taken during this dissection not to injure the epigastric vessels on either side of the pubis. The bladder is opened longitudinally approximately 7 to 10 cm, ending 2 to 3 cm away from the bladder neck. Moist 4 × 8 sponges are placed on the bladder wall laterally and at the dome of the bladder, and specialized blades are placed to put the open bladder on stretch. Although it is not necessary, it is preferable to place long 8Fr feeding tubes in the ureters at this point to define the orifices and to help with identification of the subtrigonal ureters to prevent their injury later in the dissection. Using a Bovie cutting stilet, a vertical incision is made through the trigone on the posterior midline approximately 5 cm in length (Fig. 54.1A). Alternatively, a transverse incision just above the bladder neck can be used, but it is not preferred. The vertical incision is deepened through the bladder muscle,

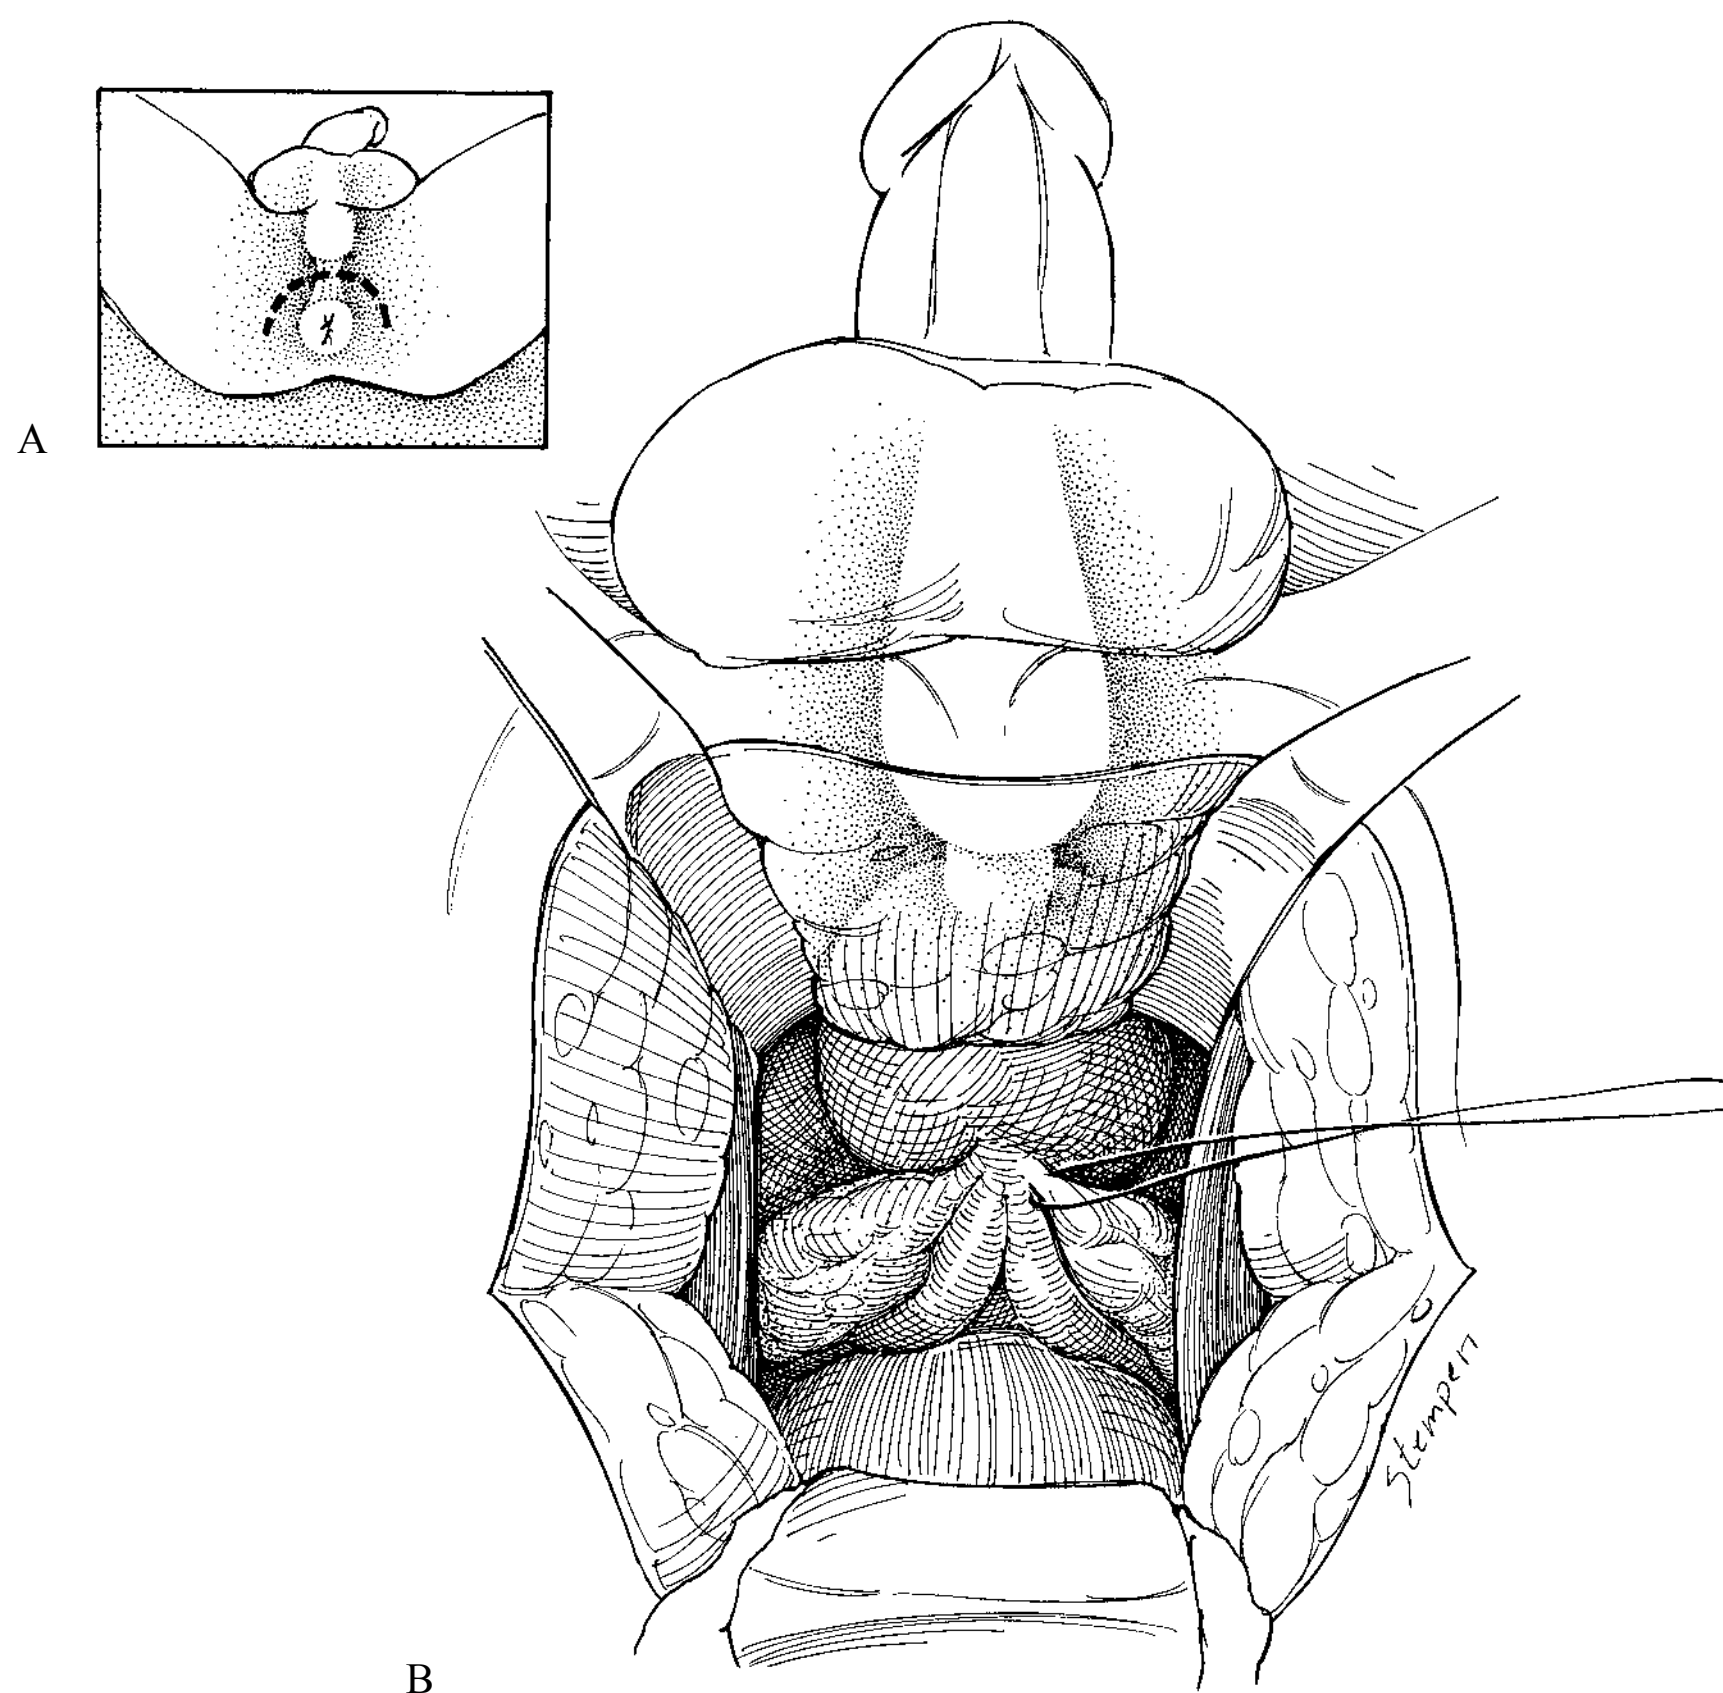

and the ampullae of the vas should be recognized directly beneath the bladder neck. They can be dissected by scissors down to their entrance into the prostate and then either ligated and divided or left intact, depending on the pathology, as described in the perineal approach. Just lateral to the ampullae on the prostate base, the seminal vesicles should be identified and the plane surrounding them entered easily unless there has been prior inflammatory disease (Fig 54.1B). The seminal vesicles should be encircled and dissected completely free. Metal clips should be placed on the vascular pedicle and a 2-0 chromic tie on the distal end at the prostate. A clip is placed across the proximal end of the vas to prevent seminal vesicle contents from obscuring the field, and then the vesicle is transected and removed. If there is a moderate-sized cyst, the dissection is more involved but is usually made simple because the perivesical plane is usually more pronounced. The plane may be very difficult to establish if there was prior vesiculitis, and in this instance the ureteral catheters are a welcome safeguard—care must be taken not to dissect completely through Denonvilliers fascia posteriorly and into the rectum. The posterior bladder incision is then closed with a running 2-0 absorbable suture in the muscle layer, followed by a running 4-0 absorbable suture in the mucosal layer. The ureteral stents and 4 × 8 sponges are removed, a 20Fr urethral catheter is placed, and the anterior bladder wall is closed as the posterior wall was. Suprapubic tube placement is an option but is not necessary. A suction drain is placed through a separate stab incision and positioned in the prevesical space away from the suture line. The urethral catheter is typically removed in 5 to 7 days. This approach is more prone to blood loss and ureteral injury than the perineal approach, but a rectal laceration is much less likely.

### Transperineal Approach

The transperineal approach to seminal vesiculectomy is virtually identical to radical perineal prostatectomy, described in

**FIGURE 54.1** The transvesical approach to the seminal vesicle. **A:** Vertical incision in the trigone to expose the retrovesical seminal vesicle. **B:** Dissection of the vas ampullae and seminal vesicles.

**FIGURE 54.2** The transperineal approach. **A:** U-shaped incision in the perineum with takedown of the central tendon. **B:** Exposure and ligation of the seminal vesicles after incising Denonvilliers fascia.

Chapter 29. An exaggerated dorsal lithotomy position is used to elevate the perineum so that it is parallel to the floor. An inverted-U incision is made in the perineum and the central tendon is divided (Fig. 54.2A). An anterior retractor stretches the rectal sphincter superiorly, allowing visualization of the glistening anterior rectal fascia fibers. The rectourethralis is divided near the prostatic apex and a weighted speculum is placed, dropping the tented rectum. To adequately expose the seminal vesicle, the rectum should be dissected off the posterior surface of the prostate to a point higher than that needed for perineal prostatectomy. Denonvilliers fascia is then incised transversely or in the midline (if nerve-sparing) on the prostate near the base of the seminal vesicles.

Seminal vesicle dissection is facilitated by posterior traction on the prostate provided by placement of a Lowsley retractor in the bladder. Medially, the ampullae and seminal vesicles are apparent after Denonvilliers fascia is incised (Fig. 54.2B). The ampullae can be spared for the excision of a simple seminal vesicle cyst or small tumor but may need to be resected in the setting of cancer or infection. After dissection of the seminal vesicle at the prostatic base, an absorbable tie of 2-0 suture is used to ligate the gland (Fig. 54.2B). Before division of the seminal vesicle, a clip is placed on the cut end of the organ to minimize spillage. An Allis or Babcock clamp is then placed on the freed base of the seminal vesicle to ease the apical dissection. The vascular pedicle at the apex of the gland is usually observed within 1 cm of the tip and is ligated with small metal clips, allowing gland removal. The wound is closed in layers as outlined for perineal prostatectomy. A Penrose drain is left in the area of dissection for 24 hours or until no drainage is

noted. This approach is well tolerated, and patients are usually discharged within 24 to 48 hours of surgery.

#### Paravesical and Retrovesical Approaches

The paravesical incision is used in children, when there is a large unilateral cyst that lies lateral to and above the bladder, and when nephroureterectomy is required. A midline or Pfannenstiel extraperitoneal suprapubic incision is made. The bladder is finger-dissected away from the lateral pelvic sidewall on the affected side. The vas deferens is identified, placed on tension, and dissected down toward the base of the bladder. If the seminal vesicle mass is distended, it should be visible rather quickly as the vas comes close to the bladder posteriorly. Placing a catheter in the bladder and emptying it usually allows the plane between the bladder and the cyst to be readily identified. The plane is incised with scissors, and the seminal vesicle cyst is carefully dissected away sharply. When the tip of the cyst is clearly identified, a 1-0 chromic suture is placed into it to provide traction, making further dissection easier. As the dissection proceeds, it must be remembered that the ureter crosses the vas and must be identified to prevent its injury. In addition, the superior vesicle artery and perhaps the inferior vesicle artery may be sacrificed to gain access to the base of the seminal vesicle. This will cause no harm and should be done without major concern. As the dissection proceeds, the bladder is progressively rolled over medially, and the mass is dissected away from the bladder laterally. The plane is easily maintained with sharp dissection. Any vessels feeding the seminal vesicles should be suture-ligated or metal-clipped. As the prostate is approached, caution must be used

**FIGURE 54.3** The retrovesical approach. **A:** Midline infraumbilical incision. **B:** Incision of the posterior peritoneum over the rectum in the cul-de-sac. **C:** Exposure of the vas ampulla and seminal vesicle behind the bladder.

to stay directly on the mass so as not to injure the neurovascular bundle lying just lateral to the seminal vesicle. At the prostate base, the neck of the seminal vesicle is encircled and ligated with a 2-0 absorbable suture. A clamp is placed across just distal to the tie, and the seminal vesicle is severed. There may be no need to clip the vas. A suction drain is placed in the bed of the seminal vesicle and brought out through a separate stab incision. The wound is then closed in layers. Postoperative care is as previously described, except with this approach, the drain can be removed within 24 hours if there is no drainage, and the urethral catheter can be removed within 24 hours. The patient may be discharged within 2 to 3 days. Complications include ureteral injury and excessive blood loss. If the principles outlined earlier are followed, these are unlikely events.

The retrovesical approach should be considered in patients requiring bilateral excision of small seminal vesicle cysts or benign masses (4). A midline suprapubic incision is made into the peritoneal space (Fig. 54.3A). A catheter is placed, and the urine is evacuated. The reflection of the peritoneum over the rectum at the posterior bladder wall is incised transversely, with care taken not to incise into the rectum (Fig. 54.3B). The bladder is peeled back from the rectum progressively with sharp dissection until the ampullae of the vasa and the tips of the seminal vesicles come into view (Fig. 54.3C). The seminal vesicles are dissected down to the base of the prostate, much as described in the transvesical approach, and the neck of the seminal vesicle is ligated and divided bilaterally. The ampullae are usually not taken unless necessary. A suction drain is left in the area posterior to the bladder and brought out as before.

**FIGURE 54.4** The transcoccygeal approach. **A:** The incision is made over the coccyx and curved along the gluteal cleft. **B:** Denonvilliers fascia is incised deep to the rectum to expose the prostate and seminal vesicles.

Postoperative care is as per the description for a paravesical resection. Complications include rectal injury, bladder laceration, and hemorrhage. In this situation, a rectal injury would be within the peritoneum well above the levator ani muscles. After a two-layer closure as before, strong consideration should be given to placement of omentum over the closure between the bladder base and the rectum, as well as to a temporary colostomy.

#### Transcoccygeal Approach

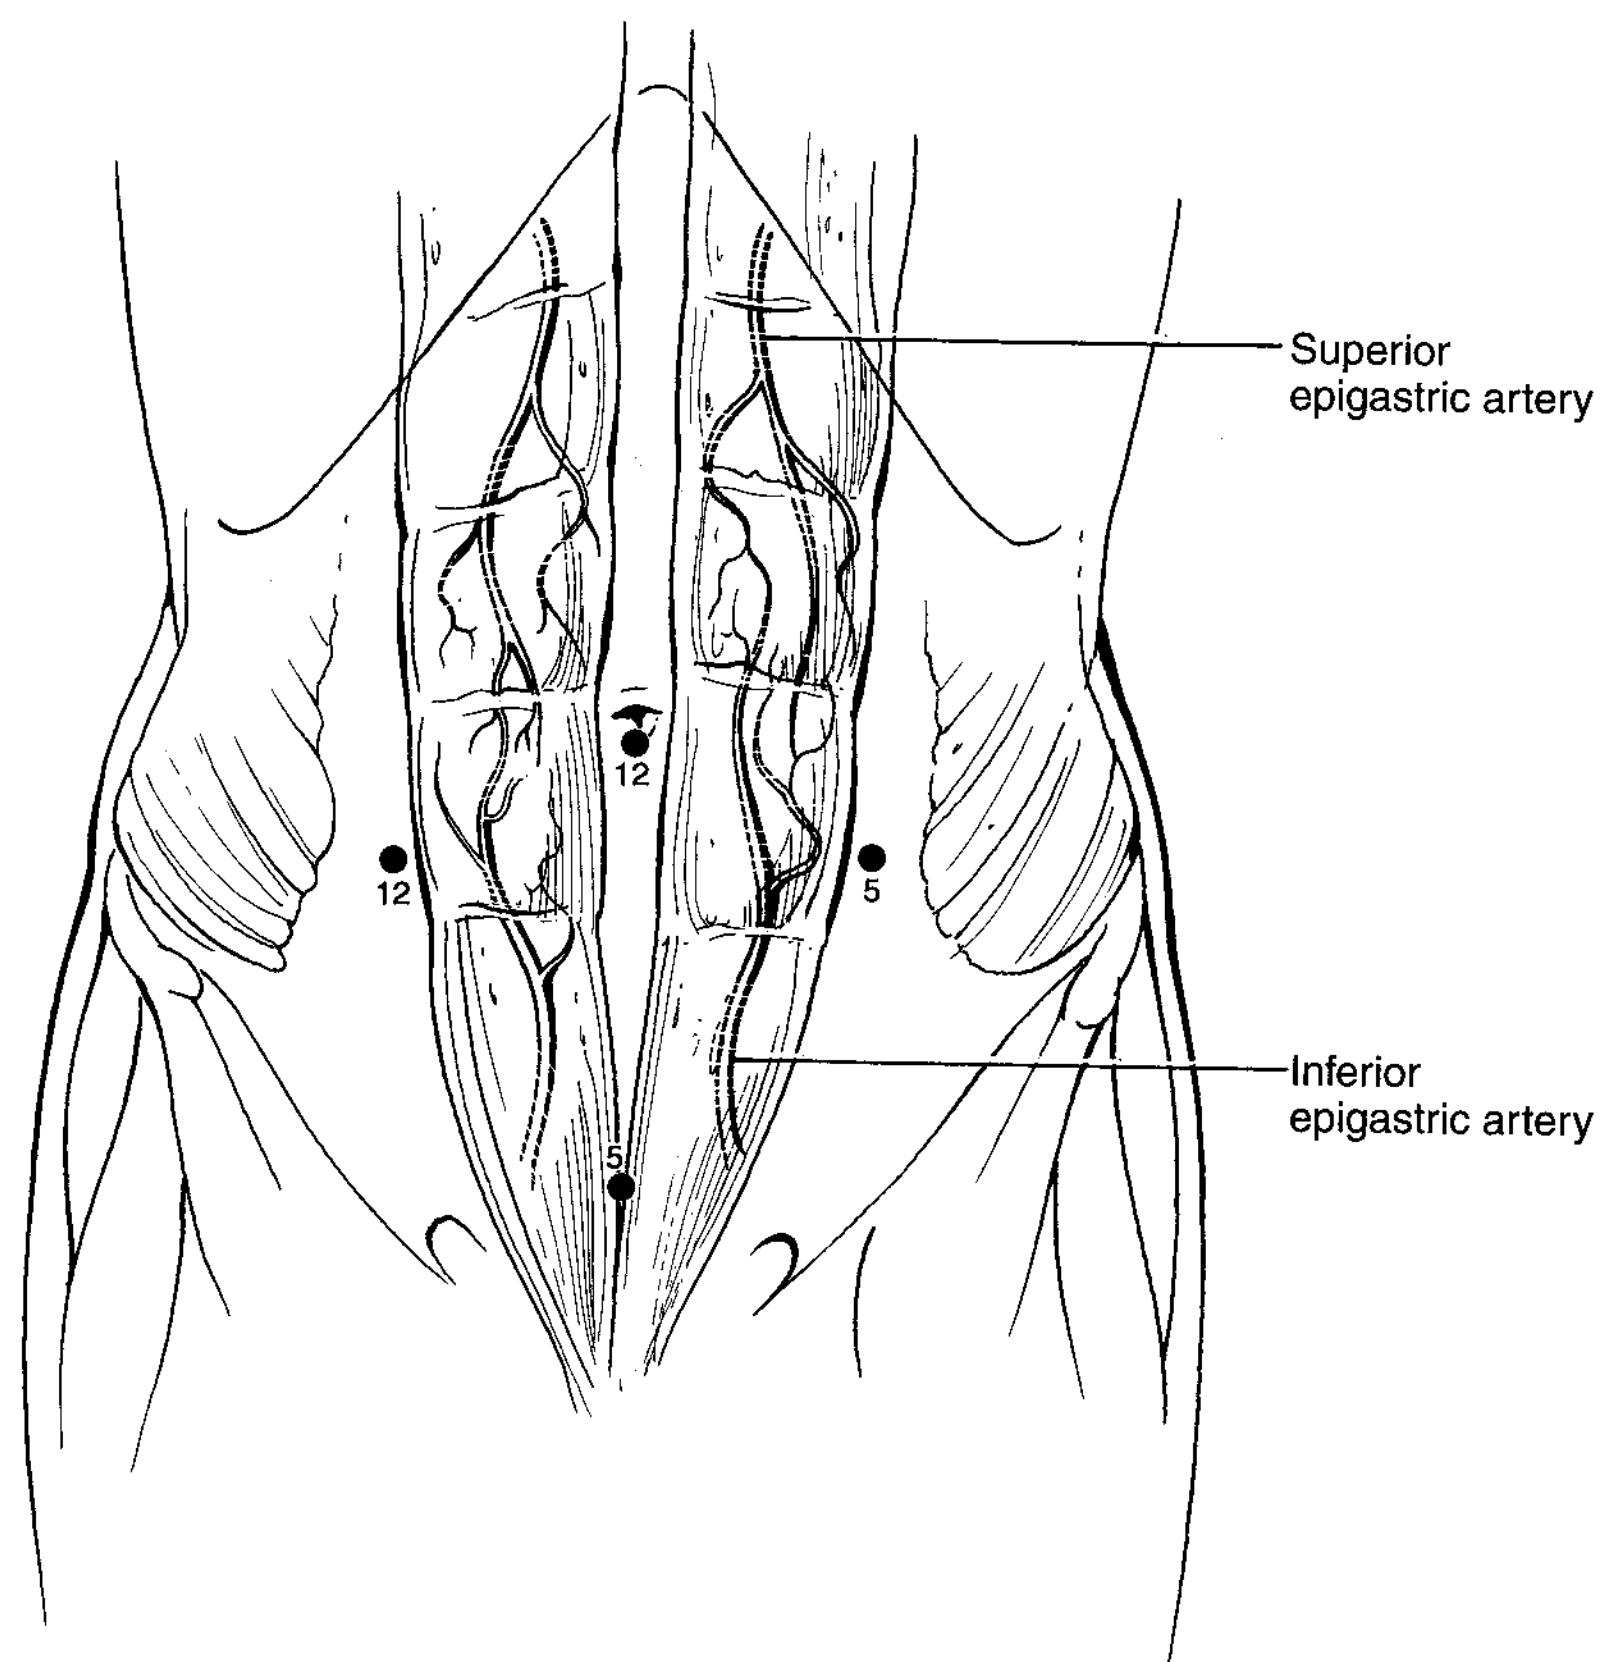

The transcoccygeal approach may not be familiar to most urologic surgeons and is unlikely to be a common choice owing to fear of rectal injury and impotence. In individuals for whom the perineal or supine position may be difficult to maintain, or who have had multiple suprapubic or perineal surgeries, the transcoccygeal approach may be very useful. The patient is placed on the table, ventral side down (prone) and in a relative jackknife position (5). The incision is made in an L shape from midway on the sacrum (10 cm from the tip of the coccyx) and angled at the tip of the coccyx down the gluteal cleft within 3 cm of the anus (Fig. 54.4A). The incision is carried down to the lateral side of the coccyx, which is dissected free from the underlying rectum and eventually totally removed. The gluteus maximus muscle layers are moved aside, and the rectosigmoid is encountered and dissected carefully from the underside of the sacrum. With careful dissection, the lateral wall of the rectum on the side of the lesion is dissected medially from the levator ani muscle and surrounding tissue until the

prostate is encountered. It is possible that the neurovascular bundle will be recognized from this approach. Once the prostate is palpated, dissection of the tissue directly superior to the base on the midline should reveal the ampulla of the vas and, lateral to it, the seminal vesicle (Fig. 54.4B). If difficulty dissecting the rectum away from the prostate is encountered, a finger in the anus via an O'Connor sheath will allow the correct plane to be determined. Dissection and removal of the seminal vesicles should follow the principles outlined previously. A Penrose drain should be left in the area, exiting through a separate stab incision at closure. The rectum should be carefully scrutinized for injury; if any injury is found, it is closed in two layers. The wound is closed in layers as well. Postoperative care does not differ from that previously described; similar to the perineal approach, the patient should have a rapid and easy recovery. The drain should be removed within 2 to 3 days if there is no drainage.

#### Laparoscopic Technique

Most laparoscopic surgery performed on the seminal vesicles has been in conjunction with radical prostatectomy. It is known that dissection of the ampulla of the vas and seminal vesicles is a challenging part of a perineal prostatectomy, and thus prior mobilization of these structures made this easier. Its application for benign seminal vesicle pathology is limited to case reports or small series (2).

Patients are placed supine with the arms carefully padded and tucked in by the sides. Access to the perineum is usually

**FIGURE 54.5** Optimal sites (*black spots*) of access for transabdominal laparoscopic seminal vesicle excision. Numbers represent trocar size in millimeters.

not necessary for benign seminal vesicle pathology, whereas if a laparoscopic or robotic prostatectomy will be performed in addition, the legs are abducted but left straight with the use of an operating table that allows a split-leg arrangement. If possible the low lithotomy position is avoided so as to minimize the risk of lower extremity thrombosis or neuromuscular injury. Patients are carefully strapped to the operating table with wide cloth tape across the chest and thighs as steep Trendelenburg (approximately 20 degrees) is required for deep pelvic laparoscopic visualization. After the patient is prepared and draped, a Foley catheter is inserted into the bladder under sterile conditions. An orogastric tube placed in the stomach is optional.

A transperitoneal approach is preferred for benign seminal vesicle lesions. After establishing a suitable pneumoperitoneum up to 15 mm Hg with the Veress needle placed at the inferior or superior umbilical crease, four laparoscopic ports are usually adequate for seminal vesicle benign pathology excision. These ports, varying from 5 to 12 mm in size, may be placed in a diamond shape (Fig. 54.5) or a horseshoe shape. With the patient in steep Trendelenburg, the peritoneum just anterior to the rectum in the rectovesical pouch (pouch of Douglas) is incised transversely between the two obliterated umbilical ligaments. Large seminal vesicle cysts are usually easily visualized and the dissection is carried close to the seminal vesicles so as to avoid injury to surrounding viscera and the neurovascular bundle. Use of bipolar coagulation is highly recommended over monopolar energy so as to minimize injury to these surrounding structures. The dissection can be completed using laparoscopic scissors and curved graspers using blunt and sharp dissection. The main arterial branch to the tip of the seminal vesicle is easily handled with bipolar coagulation, but

a laparoscopic clip is also a good choice. The seminal vesicle should be dissected caudally down to its juncture with the ampulla of vas and then clipped en bloc. With completion of the dissection, the specimen is placed in an entrapment device (LapSac, Cook Urological Inc., Spencer, IN) or an Endocatch bag (US Surgical, Tyco Healthcare, Norwalk, CT) and extracted through one of the larger laparoscopic ports. Large cysts may be aspirated prior to extraction so as to minimize the specimen size and obviate the need for enlarging the incision. Hemostasis and surrounding visceral integrity are assured and then the laparoscopic ports are closed in the usual fashion.

In select cases, a concomitant ipsilateral nephroureterectomy may be required should an atrophic kidney have an ectopic ureter draining into the seminal vesicle. It is recommended that the laparoscopic nephroureterectomy be performed prior to the seminal vesicle dissection. Thus, the patient would begin the procedure in a modified lateral decubitus position and then the operating table would be rotated so as to bring the patient into a relative supine and Trendelenburg direction. The operative details of laparoscopic nephrectomy for benign disease are described in Chapter 124.

Laparoscopic robotic assistance for surgery of the seminal vesicles has usually been performed in conjunction with radical prostatectomy. The technique, with respect to port placement and approach, is almost identical to the standard laparoscopic route described (6).

Although the transperitoneal laparoscopic/robotic approach to the seminal vesicles offers improved visualization to the seminal vesicles, the latter's close proximity to bladder, rectum, ureter, and neurovascular bundle must be appreciated by the surgeon. Transperitoneal incision in the pouch of Douglas, which is too anterior, may lead to perforation of the

posterior bladder wall. Subtle hints that the surgeon may be dissecting too anterior would be the appearance of the detrusor musculature, which is quite vascular and tends to bleed easily. Should a hole be made in the bladder, it can be repaired laparoscopically or robotically without undue difficulty.

Similarly, the rectal wall may be incised at any point in the seminal vesicle mobilization. Assuming the patient has received a satisfactory bowel preparation, such rectal lacerations may be laparoscopically or robotically repaired in two layers. The anal sphincter is dilated at the termination of the procedure and the patient's diet is advanced slowly. Electrocautery must be used judiciously when in close proximity to the rectum. Use of precise bipolar coagulation is recommended.

The distal ureter runs close to the tip of the seminal vesicle. Any tubular structure that is lateral to the seminal vesicle may be the vas arching upwards towards the internal ring, but it also could be the ureter. The surgeon may easily become disoriented to which ampulla of the vas is being dissected, leading to the dissection shifting too far lateral and possibly injuring or transecting the ureter. Injection of intravenous methylene blue quickly confirms the ureteral injury. Should this unfortunate complication occur, the ureter could possibly be repaired by laparoscopic or robotic suturing. However, a ureterovesical reimplantation may be required and necessitate open surgical conversion. Placement of a double-J ureteral stent following repair is wise, and a pelvic drain is strongly advised in the presence of any bladder, rectal, or ureteral injury that may have occurred during the course of laparoscopic or robotic seminal vesicle dissection.

Finally, the neurovascular bundle is just lateral to the tips of the seminal vesicles. Injury to this structure will impair erectile function and create a serious problem, especially to the potent patient who may be undergoing seminal vesicle excision for benign disease.

Although data are limited for laparoscopic and robotic excision of benign seminal vesicle pathology alone, this approach appears to afford superb visualization with minimal postoperative morbidity and shorter hospitalization compared to the open surgical alternatives (2). In most cases, the seminal vesicle is excised laparoscopically or robotically in conjunction with radical prostatectomy or cystoprostatectomy.

### Endoscopic Treatment

**Transurethral Resection.** If the cyst or abscess is adjacent to the prostate (not in the middle or distal end of the seminal vesicle), it may be possible to unroof the cavity with a deep

transurethral resection into the prostatic substance, just distal to the bladder neck at the 5 or 7 o'clock position. However, urinary reflux, with resultant postvoid dribbling, and infection are potential complications (7). Previous reports have detailed endoscopic treatment of seminal vesicle abscesses using semirigid ureteroscopes, as well as drainage of a seminal vesicle cyst cystoscopically with an incision using a Collins knife (1).

## Outcomes

### Results

Resection of the seminal vesicles for cystic and inflammatory diseases is in general successful, although large case series are rare. Seminal vesicle extirpation for cancer has also been successful, but the rarity of this indication prohibits an accurate assessment of survival and cure rates. Strict categorization of the 100 reported cases of primary seminal vesicle cancer reveals that fewer than 50% are truly primary to the seminal vesicle (8). In general, reconstructive surgery in children using these approaches has resulted in satisfactory outcomes.

### Complications

Each approach to seminal vesicle surgery is associated with unique complications. The relative complication rates with these approaches are outlined in Table 54.1. Limited extraperitoneal rectal injuries can be handled with formal two-layer closure. Rectal injury with the retrovesical approach is intra-abdominal, however, and may require the placement of omentum over the repair or even temporary colostomy. Most bladder injuries can be closed primarily. The most important point about ureteral injuries is their recognition. Most ureteral injuries can be treated adequately with stents for 7 to 10 days.

## EJACULATORY DUCT SURGERY

The ejaculatory ducts are paired, collagenous, tubular structures that commence at the junction of the vas deferens and seminal vesicle, course through the prostate, and empty into the prostatic urethra at the verumontanum. There are three distinct anatomic regions to the ejaculatory duct: the proximal and largely extraprostatic portion, the middle intraprostatic segment, and a distal segment that is incorporated into the lateral aspect of the verumontanum in the prostatic urethra (9).

TABLE 54.1

RELATIVE COMPLICATION RATES OF THE DIFFERENT SURGICAL APPROACHES TO THE SEMINAL VESICLE

Approach	Rectal Injury	Impotence	Bladder or Ureteral Injury	Risk for Blood Transfusion	Other Risks
Other	Moderate	High	Moderate	Moderate	Thromboembolic
Transvesical	Low	Low	High	Low	Fistula
Transperineal	High	High	Moderate	Moderate	Thromboembolic
Para/Retrovesical	Moderate	Low	Moderate	Low	Low
Transcoccygeal	High	High	Low	Low	Low
Laparoscopic	Low	Low	Unclear	Low	Air Embolism

The duct consists of three histologic layers: an outer muscular layer, a collagenous middle layer, and an inner mucosal layer (10). The muscular layer is absent in the distal segment.

### Indications for Surgery

Patients with ejaculatory duct obstruction sufficient to cause coital discomfort, recurrent hematospermia, or infertility should be considered candidates for transurethral treatment. Infertility with duct obstruction can present with low ejaculate volume and azoospermia or low ejaculate volume with decreased sperm density ( $<20 \times 10^6$  sperm per mL) or impaired sperm motility ( $<30\%$  motility). Anatomic findings suggestive of obstruction and lesions located within approximately 1 to 1.5 cm of the verumontanum are usually amenable to transurethral management.

### Diagnosis

Ejaculatory duct obstruction causes infertility in 5% of azoospermia cases. Duct obstruction can result from seminal vesicle calculi, mullerian duct (utricular) or wolffian duct (diverticular) cysts, postsurgical or postinflammatory scar tissue, calcification near the verumontanum, or congenital atresia (7). Classically, this condition presents as hematospermia, painful ejaculation, or infertility with azoospermia. Associated risk factors include evidence of prior urinary tract infection or trauma and perineal pain or discomfort. It is important to discontinue medications that may impair ejaculation. An abbreviated list of these medications is found in Table 54.2. Ejaculatory duct obstruction is suggested by finding enlarged, palpable seminal vesicles on rectal examination. The diagnosis is confirmed by a combination of findings:

1. An ejaculate volume  $<1.0$  mL and a pH  $<7.0$  that contains no sperm or fructose
2. A TRUS demonstration of dilated seminal vesicles ( $>1.5$  cm in width) or dilated ejaculatory ducts ( $>2.3$  mm) in association with a cyst, calcification, or stones along the duct

Recently, high-resolution TRUS has virtually replaced the more invasive vasography for this diagnosis. MRI with endorectal coil is recommended in suspicious cases without TRUS findings as it is excellent for the detection of small cysts. To complete the evaluation for infertility, it is important that the serum follicle-stimulating hormone (FSH) and testosterone levels be normal. Testicular volume should also be normal. A testis biopsy confirming ongoing sperm production may be helpful but is not always necessary.

TABLE 54.2

#### MEDICATIONS ASSOCIATED WITH IMPAIRED EJACULATION

<p>Antihypertensive agents  <math>\alpha</math>-Adrenergic blockers (prazosin, phentolamine)          Thiazides          Antipsychotic agents</p>
---

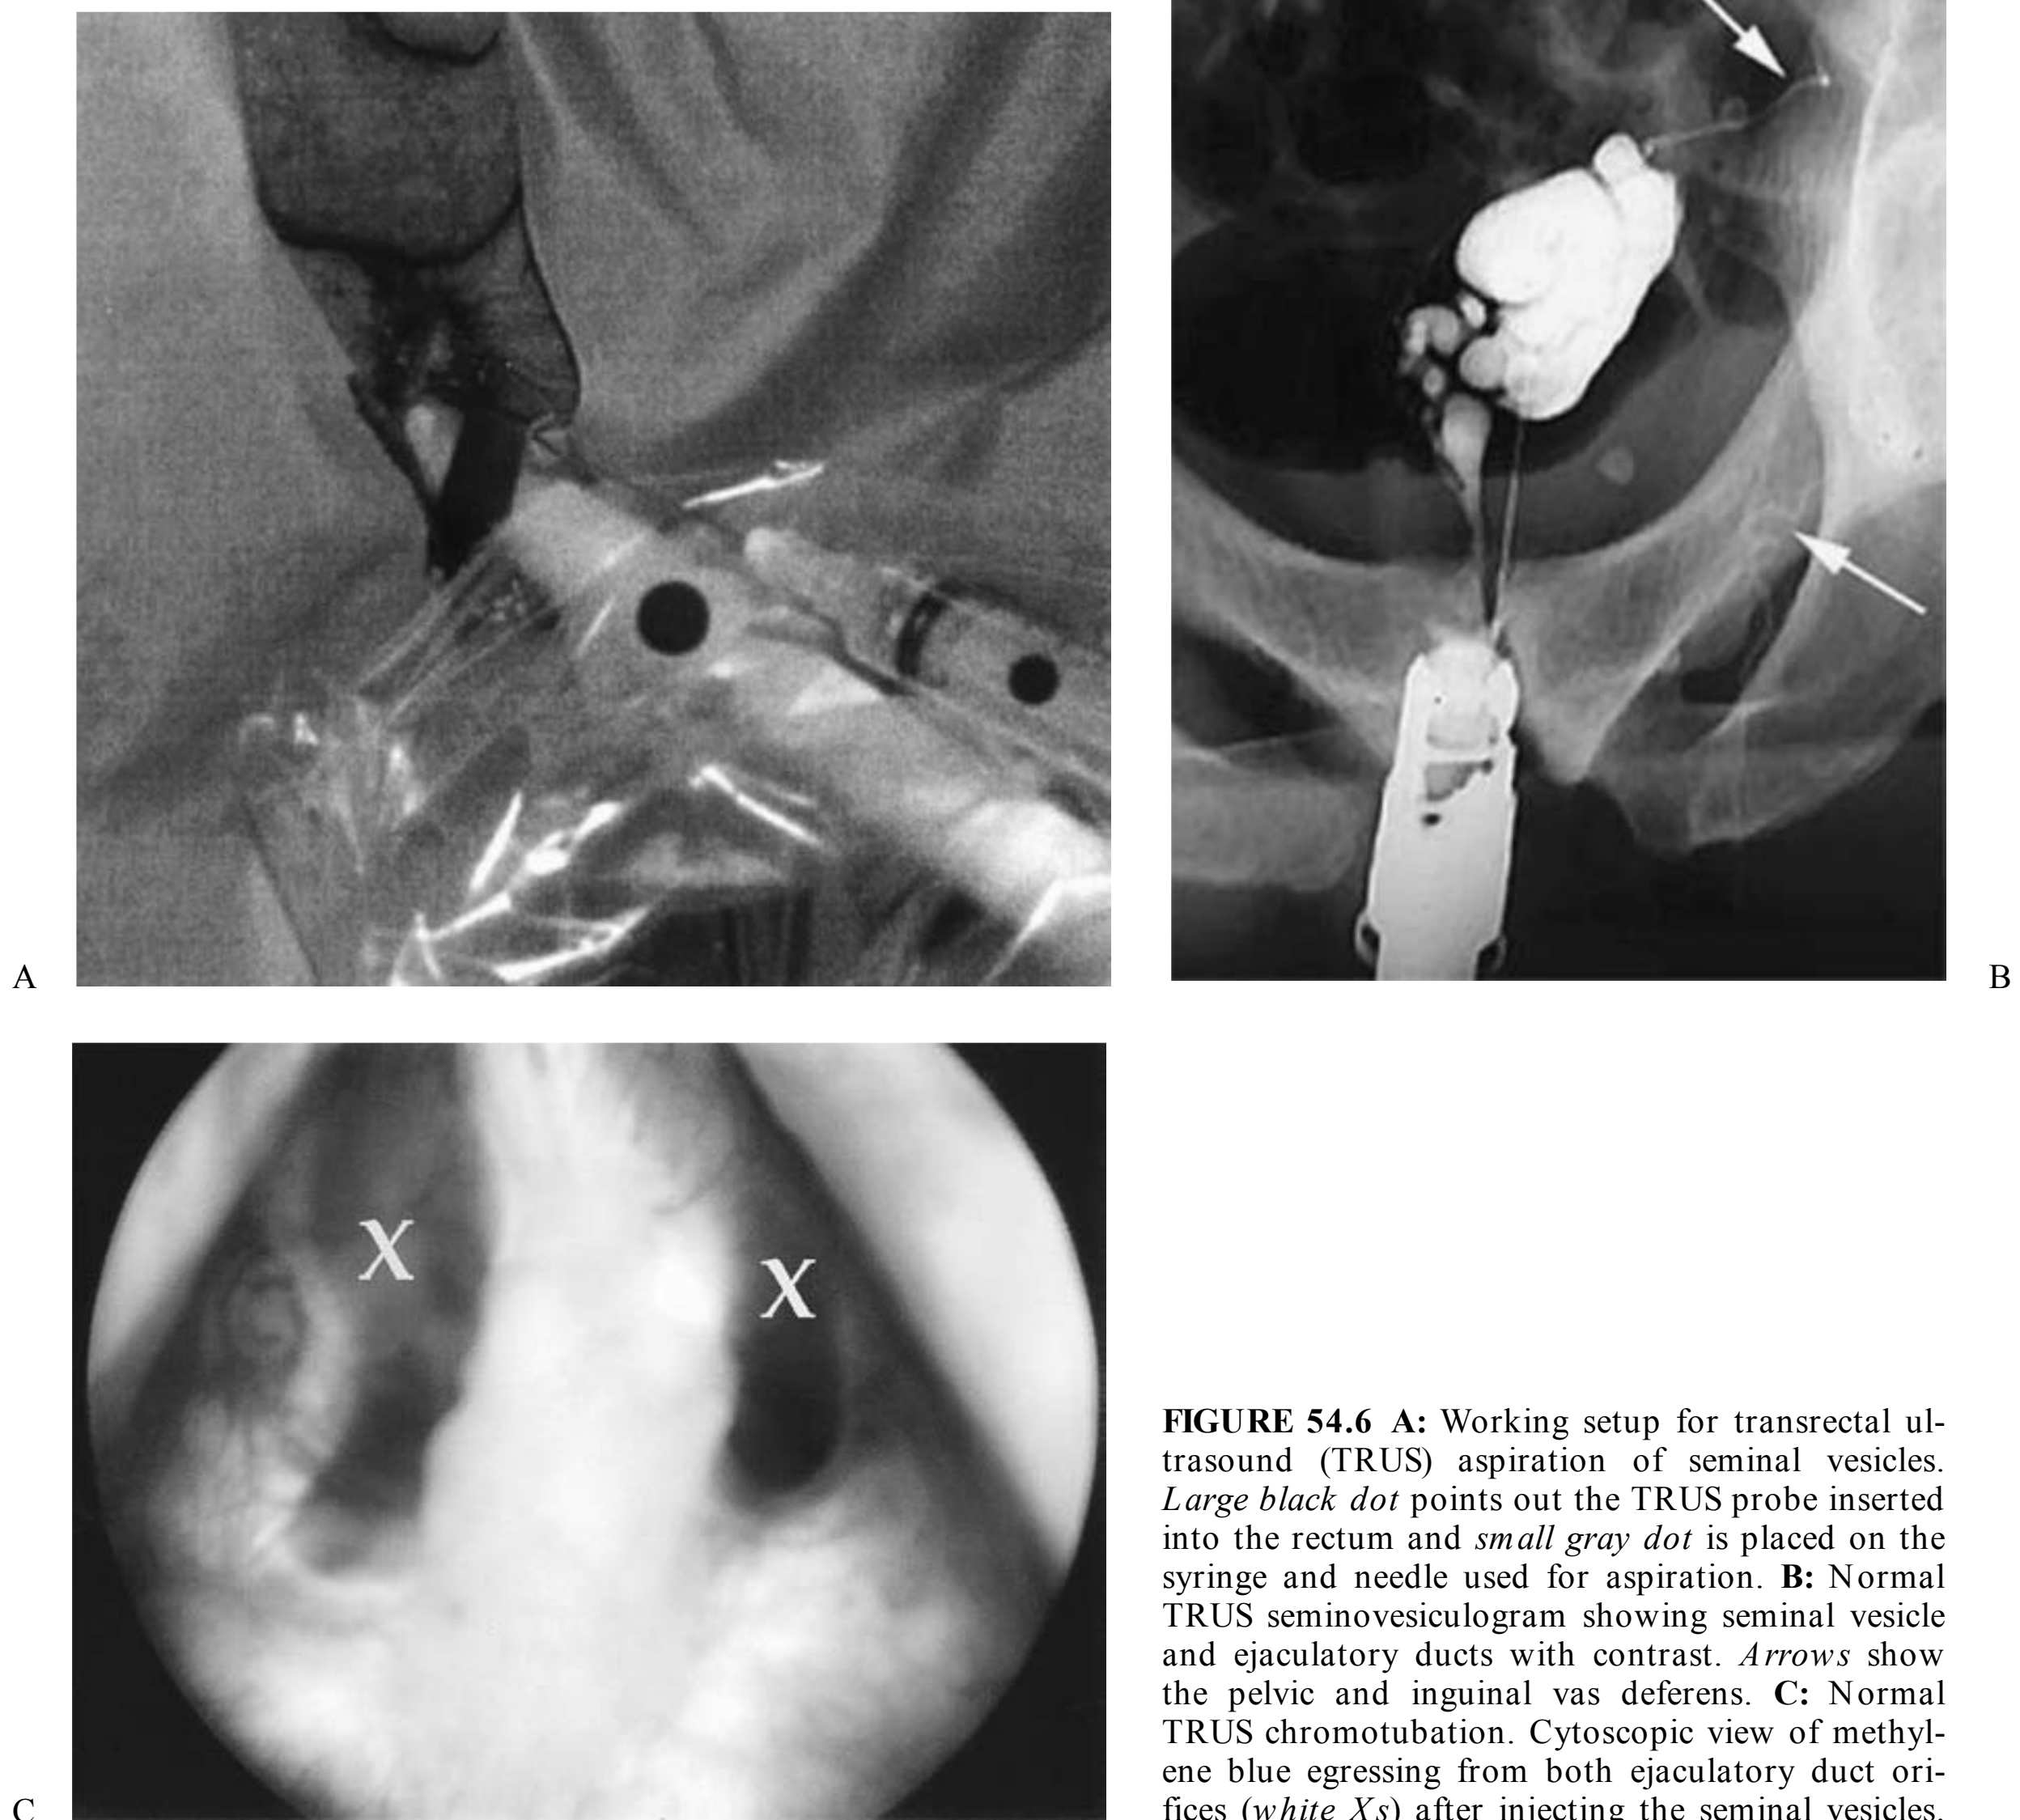

Not all patients with ejaculatory duct obstruction have dilated seminal vesicles, and not all patients with dilated seminal vesicles have ejaculatory duct obstruction. This has led to refinements in diagnostic techniques. Jarow (9) found that seminal vesicle sperm aspiration with TRUS more accurately defined affected patients. With a 30-cm, 21-gauge needle (Williams, Chiba, or oocyte retrieval needle), the seminal vesicles are aspirated transrectally or transperineally during TRUS (Fig. 54.6A). The aspirate is then examined under  $400 \times$  phase microscopy for sperm. The finding of more than three sperm per high-power field is considered positive and suggestive of obstruction. Importantly, the duration of sexual abstinence prior to aspiration can influence the findings. Seminal vesicle aspiration should be performed with  $<24$  hours of sexual abstinence. Despite the fact that aspiration does not anatomically localize the site of blockage or differentiate between physical blockage and functional obstruction, it confirms that spermatogenesis is ongoing and that epididymal obstruction is unlikely.

Injection of nonionic contrast (50% Renografin) into the seminal vesicles after seminal vesicle aspiration, followed by formal radiographic imaging, can be a useful retrograde study of seminal vesicle and vasal anatomy in suspected obstruction (Fig. 54.6B). Also, a good-quality pelvic and inguinal vasogram can be obtained in most patients (Fig. 54.6B). Fluoroscopy or a kidney-ureter-bladder (KUB) plain film is taken after the injection of 5, 10, and 20 mL of contrast to delineate excurrent duct anatomy. Helpful maneuvers include (i) having the patient in the 15- to 30-degree reverse Trendelenburg position for radiographs to “open up” the pelvic outlet and minimize overlying pelvic bone density and (ii) placing a Foley catheter with 5 mL of water in the balloon on slight traction during contrast injection to reduce the spillage of contrast into the bladder that “clouds” the radiograph. As seminal vesiculography is more invasive than simple aspiration, it may require mild intravenous sedation and is best performed at the time of transurethral surgery.

Injection of diluted indigo carmine or methylene blue (1:5 dilution with saline) into the seminal vesicle with TRUS instead of contrast is termed seminal vesicle chromotubation. When performed with cystoscopy it can assess whether or not there is antegrade flow of dye from the seminal vesicle into the prostatic urethra (Fig. 54.6C). In fact, “patency,” with chromotubation, defined by the presence of dye egressing from the ejaculatory duct orifices after seminal vesicle injection, may be the most accurate way to diagnose complete ejaculatory duct obstruction, unilateral or bilateral (11).

### Surgical Technique

Transurethral resection of the ejaculatory ducts (TURED) is performed in the outpatient setting. Following the administration of light general or regional anesthesia and a single dose of a broad-spectrum antibiotic, the patient is placed in the dorsal lithotomy position with a rectal drape (O'Connor). Formal cystourethroscopy is performed. Careful examination is made of the areas lateral to the verumontanum within the prostatic urethra to visualize either ejaculatory duct orifice. A small resectoscope (24Fr) and electrocautery loop are inserted and the verumontanum is resected in the midline (Fig. 54.7). The resection is performed with pure cutting current to minimize cauterization of the delicate ejaculatory ducts. Often several

**FIGURE 54.6** **A:** Working setup for transrectal ultrasound (TRUS) aspiration of seminal vesicles. *Large black dot* points out the TRUS probe inserted into the rectum and *small gray dot* is placed on the syringe and needle used for aspiration. **B:** Normal TRUS seminovesiculogram showing seminal vesicle and ejaculatory ducts with contrast. *Arrows* show the pelvic and inguinal vas deferens. **C:** Normal TRUS chromotubation. Cytoscopic view of methylene blue egressing from both ejaculatory duct orifices (*white Xs*) after injecting the seminal vesicles.

passes of the cutting loop are required to visualize the ejaculatory duct openings within the prostate. This can mean relatively deep dissection in a small prostate gland, a situation that can make even an experienced transurethral surgeon feel uneasy. At the correct level of resection, cloudy, milky fluid can usually be seen effluxing from the opened ducts. After resection, large bleeding blood vessels are lightly cauterized, with care taken to avoid fulguration of the duct openings. Because the area of resection is at the prostatic apex, near both the external urethral sphincter and the rectum, careful and constant positioning of the resectoscope is essential. A finger placed in the rectum can help avoid rectal injuries and assist in keeping the resectoscope tip proximal to the external sphincter. A small Foley catheter is placed for 24 to 48 hours and removed on an outpatient basis. Oral antibiotics are given while the catheter is in place. After such treatment for infertility, intercourse is resumed after 7 days, and a formal semen analysis is checked as early as 2 weeks and then at regular intervals thereafter, until semen quality stabilizes.

Several useful aids can ensure that the resection is performed safely and completely. With an endoscopic needle, the milky ejaculatory duct fluid can be sampled transurethraly during the procedure and inspected with microscopy for sperm. The use of simultaneous, real-time TRUS during the resection is a valuable addition to this procedure. The exact location of the lesion to be resected can be determined by TRUS and the depth of resection continuously assessed during the resection. Similarly, TRUS can be used to guide the instillation of indigo carmine or methylene blue into the seminal vesicles with a long, 20-gauge Chiba needle before the resection. The dye is subsequently visualized on relief of obstruction.

---

## Outcomes

---

### Results

Long-term relief of postcoital and perineal pain after TURED can be expected in 60% of patients (12). Hematospermia has

**FIGURE 54.7** Transurethral resection for ejaculatory duct obstruction. Midline resection of the verumontanum is shown. Lateral and deeper resection may be necessary depending on the site and reason for duct obstruction. (Conceptualized by Paul Stempen)

also been effectively treated with TURED, but the literature on this indication remains anecdotal. There is convincing evidence from several large series of patients treated for infertility that a 20% to 30% pregnancy rate can be expected from TURED (13,14). In one series, men treated for either low-volume azoospermia or low-volume oligoasthenospermia were equally likely (65% to 70%) to show improvements in semen quality after TURED (14). From a recent series, it appears that obstruction due to cysts responds better to TURED than that due to calcification (15).

Several caveats of TURED surgery should be emphasized to the patient preoperatively. Roughly 13% of men treated by TURED for low-volume azoospermia will convert to normal-volume azoospermia. Among these patients, some have evidence of secondary obstruction at the level of the epididymis that requires epididymovasostomy. Epididymal obstruction may reflect the effects of time and blockage on other portions of the delicate male ductal system. Notably, 4% of patients treated for low-volume oligoasthenospermia may become azoospermic after TURED, presumably from scar tissue formation. We now recommend preoperative sperm cryopreservation if TURED is planned for this indication.

## Complications

The expected complication rate from TURED surgery is approximately 20% (7). The most common complications are self-limited hematospermia, hematuria requiring recatheterization, and urinary tract infection. More concerning, but less frequent, are epididymitis and a “watery” ejaculate. High-volume watery ejaculate is presumed secondary to the reflux of urine retrograde through the ejaculatory ducts into the seminal vesicles or into opened cysts, as suggested by the finding of creatinine in the ejaculates of TURED patients. In addition to the social implications of this, the exposure of sperm to urine may impair fertility potential. Several potentially major but rarely reported complications include retrograde ejaculation, rectal perforation, urinary incontinence, and recurrent seminal vesicle infection.

## ACKNOWLEDGMENTS

The author would like to thank Drs. Paul Turek and Howard Winfield for their previous works that contributed to this chapter.

# CHAPTER 55 ■ VASECTOMY

DOUGLAS G. STEIN

As the most dependable method of contraception and one that requires virtually no compliance, vasectomy is an ideal choice for those men who have made a mature, informed decision to have no more children, and especially for men who have difficulty with compliance. As a result, 11% of the U.S. population relies on vasectomy as their primary method of birth control, and the incidence of vasectomy is approximately 500,000 per year in the United States. While it has been noted that vasectomy is the “most common procedure involved in malpractice claims against urologists” (1), vasectomy accounted for only 8 of 469 (1.7%) urology malpractice claims closed with indemnity payment between 1985 and 2004 for one liability carrier in New York (2). So, while urologists need not avoid vasectomy to decrease perceived high liability, they need to be thoroughly versed in the management of men seeking vasectomy.

---

## DIAGNOSIS

---

In most practices, a “consultation visit” includes counseling about vasectomy and a brief physical examination to help determine whether the surgeon and the patient feel comfortable with office vasectomy under local anesthesia or whether, in rare circumstances, general anesthesia in an operating room is indicated for reasons of patient anxiety or features on physical examination that could make vasectomy more difficult in an office setting. Such features include incomplete testicular descent (either untreated or status post orchiopexy); scarring due to prior scrotal surgery; a small tight scrotum; obesity with thick spermatic cords; very thin vasa; large hydrocele, spermatocele, or varicocele; or extreme scrotal hypersensitivity. In this practice of about 2,000 vasectomies per year, general anesthesia is never utilized. Counseling is accomplished online by a personal counseling video, a very informative web page, and a written consent that includes alternatives, potential complications, and pre- and postprocedure instructions. Medical and surgical (prior scrotal conditions and surgeries) histories are reviewed by the physician. Sedatives are not routinely used.

---

## INDICATIONS FOR SURGERY

---

While no strict criteria exist for determining which patient should be offered vasectomy, the Electronic Code of Federal Regulations for sterilization of persons in federally assisted family planning projects (Title 42 CFR, Part 50, subpart B) specifies that the individual be at least 21 years of age and mentally competent when consent is obtained, that consent be obtained with certain procedures, and that 30 days pass between the date of consent and the date of vasectomy.

---

## ALTERNATIVE THERAPY

---

Especially because vasectomy should always be presented as a permanent form of contraception, a full disclosure of alternative contraceptive methods must be a part of informed consent. While condoms are the only other alternative available to men, men should have a thorough understanding of the options available to women, even though these provide less control for the male. When features of the male anatomy (obesity, tight scrotum, thin vasa, or scarring from prior scrotal surgery) would make vasectomy difficult for the vasectomist at his or her skill level, couples considering permanent contraception should be asked to consider tubal ligation for the woman or the opinion of a vasectomist with more experience, as complication rates are lower for vasectomies performed by more experienced vasectomists. While not guaranteed successful, sperm storage should also be considered by vasectomy candidates as an insurance policy that may enable paternity after vasectomy, if vasectomy reversal fails to restore fertility.

---

## SURGICAL TECHNIQUE

---

Nearly all surgical procedures involve three steps: (i) anesthesia, to allow the procedure to proceed without pain, (ii) access, or how the surgeon gets to the target organ, and (iii) technique, how one manages the target organ, the actual vasectomy.

---

### Anesthesia

---

For vasectomy, general anesthesia or heavy intravenous sedation in an operating room setting may be preferred by anxious patients and by surgeons who simply find it easier than using local anesthesia for anxious or technically challenging patients. For young healthy men, the risks are minimal, but the costs may make it prohibitive for men without health insurance coverage.

Most vasectomies are performed in an office setting under local anesthesia. Administration with a needle is the most common and traditional technique, but since 2002, no-needle anesthesia has made vasectomy much more acceptable, especially for men who “just hate needles.”

Needle local anesthesia is accomplished after the scrotum is prepped and draped. A 27-gauge 1.5-inch needle is commonly used to create a skin wheal over the point at which the vas is held beneath the skin (Fig. 55.1). Then the needle is advanced proximally its full length adjacent to the vas in the direction of the external ring. Two mL of anesthetic is injected into the vas sheath as the needle is withdrawn. (A 30-gauge 1-inch needle causes less of a poke but requires more time and strength for injection. The anesthetic can be lidocaine without epinephrine

**FIGURE 55.1** The right vas deferens is manipulated to the midline raphe and anesthetized.

[1% burns a bit <2%] or a mixture of lidocaine and bupivacaine to delay the onset of the mild discomfort that usually occurs on the day of the procedure.) The surgeon then either lifts and injects the other vas or proceeds with the vasectomy on this side, employing the traditional incisional technique or the no-scalpel technique (see below). The contralateral vas sheath is injected similarly, either through the same skin wheal if the vasectomy is to be performed through a single midline opening (preferred) or through a second skin wheal if the surgeon is more comfortable with accessing the vas through separate lateral wall openings.

No-needle local anesthesia for vasectomy involves the use of a jet injector, the most popular of which is the MadaJet (MADA, Inc., Carlstadt, NJ). Use of no-needle local anesthesia has become more widespread, popularized by Weiss and Li (3). The MadaJet (Fig. 55.2) emits an extremely thin 0.1- to 0.2 mL stream of anesthetic (a 50:50 mixture of 2% lidocaine and 0.5% bupivacaine is preferred) strong enough to penetrate the

**FIGURE 55.2** Cocking a MadaJet with an angled head. The release button is at the top.

skin and underlying tissue to a depth of 2 to 5 mm, depending on the factory setting of the particular MadaJet. No-needle anesthesia is administered after the scrotal wall is shaved but before the formal scrotal preparation with povidone-iodine. The vas is lifted into position beneath the skin at the preferred access site (anterior midline or lateral scrotal wall), the overlying skin is prepared with alcohol, the fluted tip of the MadaJet is positioned over the vas (Fig. 55.3), and the release button is pressed to discharge the anesthetic through the skin and around the vas. The procedure is repeated one or two times along the path of the vas at 4- to 5-mm intervals. Medication entry sites are barely visible as minute dots, surrounding which are 2- to 3-mm areas of anesthetized skin. If the right vas is lifted to the midline and injected 2 mm to the left of the median raphe, and if the left vas is then lifted to the midline and injected 2 mm to the right of the median raphe, the patient develops a square of anesthetized skin about 4 to 5 mm on each side centered on the midline and the scrotal septum receives four to six doses of the anesthetic. Through the anesthetized square, the no-scalpel vasectomy (NSV) is performed.

For the occasional vasectomy, needle anesthesia is more convenient unless the surgeon wishes to appeal to those men who “just hate needles.”

**FIGURE 55.3** Positioning a MadaJet with a straight head over the right vas, while it is held beneath the median raphe using a three-finger technique.

## Access

Using the traditional approach, access to the vas is accomplished through a 1- to 1.5-cm horizontal or vertical incision in each lateral scrotal wall or through a single incision in the midline, wherever the vas was previously anesthetized using needle or MadaJet. The vas, held beneath the incision and still within its sheath, is grasped with an Allis or small towel clamp. Then the fibrous tissue around the vas is incised longitudinally with the scalpel, exposing the vas itself, which is then grasped with an Adson forceps, and a section is lifted through the sheath. Surgeons familiar with NSV instruments but more comfortable with an incisional approach often prefer to use the NSV ringed forceps to both secure the vas and lift it from its sheath.

The no-scalpel approach utilizes two special instruments and a three-finger technique (Fig. 55.4). Access to both vasa is via a single small opening in the anterior midline of the scrotal wall (anesthetized with needle- or MadaJet-applied lidocaine), but there is no reason why the same instruments could not be used with lateral wall incisions for surgeons more comfortable with that approach. After the scrotum is prepared with povidone-iodine and draped, needle anesthesia is utilized (see above) or the pinpoint marks in the skin made by the MadaJet are located and the site marked by inserting and gently spreading the tips of the pointy NSV hemostat. Locating the pinpoint MadaJet injection application sites can be difficult in dark-skinned men, so this step and the remainder of the vasectomy may be much easier with the magnification provided by 2 $\times$  optical loupes. The vas, most commonly located on the posterior aspect of the spermatic cord, is swept medially and lifted into position beneath the anesthetized site using a three-finger technique. While the vas is draped over the middle finger and stabilized with the thumb of the nondominant hand, the skin is drawn tightly over it with the index finger of the same hand. The vas is grasped with the NSV ringed forceps (Fig. 55.5). When the overlying skin is thin, the initial grasp incorporates the skin. When the overlying skin is very thick, some surgeons will find it easier to spread the skin and underlying fascia enough to introduce the NSV ringed forceps through this opening and grasp the vas within its sheath. One

**FIGURE 55.5** Held using the three-finger technique, the right vas is grasped with the no-scalpel vasectomy (NSV) ringed forceps.

tip of the pointy NSV hemostat is then introduced into the lumen of the vas and removed. The NSV hemostat is then closed and both tips are introduced into the lumen of the vas at the same spot. The tips are spread to a width twice that of the vas, splitting the vas open longitudinally and spreading all overlying layers. One tip of the NSV hemostat is then used to “hook” the vas (Fig. 55.6) and lift it from its sheath as the ringed forceps is removed. The ringed forceps is then used to grasp one wall of the vas and deliver a 1- to 3-cm loop of it from its sheath (Fig. 55.7).

## Occlusion

Numerous methods for establishing vasal obstruction have been described, and most surgeons employ a combination of luminal cauterization, ligation, division, excision, and fascial interposition with either a suture ligature or hemoclip (4) (Figs. 55.8, 55.9, 55.10, and 55.11). The objective should be very low failure and low complication rates, without removing so much vas, especially in young patients, that vasectomy reversal is rendered extremely difficult. “Early” failure is said to occur when the postvasectomy patient has motile sperm or

**FIGURE 55.4** The three-finger technique for isolating the (A) right and (B) left vas deferens.

**FIGURE 55.6** After the vas and overlying layers are split by spreading with the pointy hemostat, the pointy hemostat is used to hook the vas as the no-scalpel vasectomy (NSV) ringed clamp is released.

significant numbers ( $>100,000/\text{mL}$ ) of nonmotile sperm in the semen 6 months after vasectomy. Recanalization within the tissue between the two severed ends occurs frequently during the 1 to 2 months following vasectomy but usually scars off. Early failure occurs when recanalization does not scar off but rather persists. “Late” failure is the return of motile sperm to the semen of a patient previously diagnosed as azoospermic, an event caused by delayed recanalization and usually discovered as a result of a surprise pregnancy.

**FIGURE 55.11** Cauterization of the abdominal end only (open-ended technique) with fascial interposition over the abdominal end (testicular end left outside sheath) using a hemoclip. (Copyright and courtesy of Barone MA, Irsula B, Chen-Mok M, et al., and the Investigator Study Group. Effectiveness of vasectomy using cautery. *BMC Urol* 2004;4:10, <http://www.biomedcentral.com/1471-2490/4/10>)

There are numerous reviews of surgical techniques (5,6). Ligation without division has a high early failure rate, even when employing a specially designed clip rather than a suture ligature or hemoclip (7). Cauterization without division might be expected to create adequate obstruction by scarring in some patients but is not routinely used because of an anticipated high failure rate, given that cautery and division (without excision of a segment or fascial interposition) resulted in the only failures in a study of the effectiveness of various cautery techniques (4). Early recanalization and failure rates are highest for ligation and excision without fascial interposition and lowest for thermal cautery with fascial interposition (4,8). This is the rationale for the following technique.

### Preferred Anesthesia, Access, and Occlusion Techniques

The no-needle, no-scalpel vasectomy with thermal cauterization and hemoclip fascial interposition is performed as follows. An elastic lasso is applied at the coronal sulcus and an attached hemostat is snapped onto the shirt to keep the penis elevated. Most patients, coached by online instructions and telephone staff, shave the night before so that the skin is not so sensitive to the alcohol used to prepare it for application of the no-needle anesthesia. If needed, the anterior scrotal wall is shaved with a single-edge shaver. No-needle local anesthesia is applied to each vas in turn at a midline location as described previously. The scrotum is then formally prepped with povidone-iodine and draped with a fenestrated 18 × 24-inch drape. If no-needle anesthesia is not used, needle anesthesia is applied as described previously.

After local anesthesia, the no-scalpel technique described previously is utilized to deliver a loop of vas from its sheath (see Fig. 55.7). It is very important that the vas be opened a few millimeters lengthwise to confirm complete penetration of the sheath and to allow grasping of the vas wall with the ringed forceps. The NSV pointy hemostat is passed along the under-surface of the vas at the apex of the loop and gently spread to push the vasal vessels away from a 1- to 2-cm segment of vas

**FIGURE 55.12** The no-scalpel vasectomy (NSV) pointy hemostat is used to spread vessels away from a 1- to 2-cm length of vas.

(Fig. 55.12). At the prostatic end of the segment, a small vasotomy opening is made with one tip of the pointy NSV hemostat (Fig. 55.13). A battery-powered wire loop thermocautery tip is introduced into the upper end and advanced 5 to 10 mm toward the prostate (Fig. 55.14). It is activated just long enough to sear the mucosal lining of the vas so that it will seal off by scarring. If applied too long, causing the full thickness of the wall to blanch, the cauterized segment may slough, negating the effectiveness of cautery in contributing to obstruction of the vas. Then the thermocautery unit or a scissors is used to divide the vas where the vasotomy was made. The prostatic end slips up into the vas sheath and the margins of the sheath are brought together and tented over the buried end with a conventional Halsted hemostat (Fig. 55.15). If there are any bleeding vessels near the sheath margins, these can be included in the hemostat to provide hemostasis. At this point, the testicular end is still secured with the ringed clamp. The hemostat is now brought down to a position below the ringed clamp (toward the foot of the table) and transferred to the nondominant hand. A medium hemoclip is applied to the tissue in the hemostat alongside the testicular end of the vas, drawing the sheath around the testicular end so that it cannot slip back inside. When the hemostat is removed, the clip rotates back cephalad and sits parallel to the testicular end (Fig. 55.16)

**FIGURE 55.13** The no-scalpel vasectomy (NSV) pointy hemostat is used to make a small vasotomy opening in the abdominal end.

**FIGURE 55.14** The tip of a thermocautery unit is introduced into the abdominal end.

**FIGURE 55.15** After the abdominal end is divided, it slips up into the vas sheath and a Halsted hemostat is used to close the sheath margins over the now-buried abdominal end.

so that it will not hang up on scrotal wall fascia as it released back into the scrotum. Be careful that the sheath is not drawn so tightly around the lower end that it indents the surface, compromising blood flow to the segment outside the sheath. Should that end slough, the remaining stump would be inside the sheath, defeating the intent of fascial interposition. An additional hemoclip can be applied for hemostasis if necessary. The ringed clamp on the testicular end is opened and the divided vas ends fall back into the scrotum. The testicular end is not ligated or cauterized, making this an open-ended technique. The same procedure is repeated on the other side.

The patient is instructed to recline on the day of the surgery. Ice packs are recommended by many surgeons to decrease the risk of hematoma formation. On the day after surgery, patients may walk and drive ad lib but should avoid yard work, sports, and heavy lifting. They may shower, then continue use of scrotal supports for 2 more days. Two days after the vasectomy, patients may return to normal activities and sex but should limit aggressive athletic workouts to half of the normal routine to see if they are ready for normal routines thereafter.

**FIGURE 55.16** When the hemostat is removed, the hemoclipped sheath over the buried abdominal end rotates back to its original position.

---

### Follow-Up Semen Analysis

---

If a fresh specimen contains fewer than 100,000 nonmotile sperm per milliliter (1 sperm per 400 $\times$  high-power field with many light microscopes), as will be the case for 95% at 12 weeks, no further testing is necessary, as 99.7% of these cases will achieve azoospermia or rare nonmotile sperm by 24 weeks (4) and the risk of pregnancy with fewer than 100,000 nonmotile sperm per milliliter is extremely low (9,10). If a sample older than 2 hours (motility evaluation not reliable) shows no sperm in 10 high-power fields, which would be fewer than 10,000 sperm per milliliter, no further testing is necessary. If any sperm are seen in 10 high-power fields at 8 weeks, another container or mailer is provided. If sperm are seen at 12 weeks in a second unfresh specimen, evaluation of a fresh specimen is required. Labrecque et al. (8,10) propose a nomogram suggesting that testing be repeated every 4 to 6 weeks and that failure due to “persistent” recanalization (some cases will scar closed) be considered probable only if motile sperm persist over 6 months. When 100,000 or more non-motile sperm per milliliter persist for over 6 months, failure should be considered, but even this is considered overly cautious by some (11,12).

---

## OUTCOMES

---

### Results

---

Using fascial interposition with a hemoclip to bury the testicular end, over the past 16 years and approximately 10,800 vasectomies, four patients (0.04%) experienced early failure (motile sperm at 4 months) and required repeat vasectomies, and four patients (of whom we are aware), again 0.04%, experienced late failure (pregnancy and confirmation of motile seminal sperm or paternity >1 year after azoospermia). Since February 2007, the author has buried the prostatic end of the vas, hoping for an even lower failure rate. As of May 2008 and 2,465 vasectomies with burial of the prostatic end, there has been one early failure (again 0.04%) and no late failures. It is still too early to present a rate of late failures and to determine whether abdominal-end fascial interposition is superior to testicular-end fascial interposition.

## Complications

### Early

Three levels of hematoma are possible: small (2–3 cm) incidental hematomas following needle or no-needle anesthesia will usually resolve within a few days; medium (3–5 cm) hematomas due to delayed bleeding of a weakened small vessel may take 2–3 weeks to resolve; for large (>5 cm) hematomas, surgical drainage should be considered to decrease the duration of morbidity. Reported rates average about 2% but are higher (4.6%) for surgeons who perform few vasectomies (1 to 10 per year) and lower (1.6%) for surgeons who perform many vasectomies (>50 per year). The incidence is lower with NSV (0.3% versus 1.4%), during which tissue is spread for exposure of the vas, than with traditional vasectomy.

Postvasectomy inflammation can occur anywhere from 3 days to years following vasectomy. Patients who have had little discomfort following vasectomy may “out of the blue” develop swelling and tenderness at the vasectomy site or within the epididymis and convoluted vas “upstream” from the vasectomy site. Most cases are unilateral and respond quickly to nonsteroidal anti-inflammatories.

Infection with conventional incisional vasectomy has been reported to occur in 1.4% of cases compared with a rate of 0.1% with NSV (13). The most severe and obvious cases develop into scrotal abscesses that require surgical drainage. There is one published report of lethal gangrene due to beta-hemolytic strep with onset 2 days after vasectomy in a previously healthy young man.

### Late

Sperm granulomas form at the vasectomy site to varying degrees in up to 60% of patients. A granuloma probably forms when sperm leak from the testicular end of the divided vas and cause the inflammation needed for their absorption, typically in the second or third week following vasectomy. This actually vents the congestion and inflammation that often occurs

upstream in the proximal vas and epididymis and may enhance the prognosis for success with a future vasovasostomy. Open-ended vasectomy expectedly reduces the risk of pain due to congestive epididymitis, but paradoxically does not increase the risk of tender sperm granuloma (14) and actually reduces it. For granulomas that are exquisitely tender, most patients will respond to nonsteroidal anti-inflammatories. Some may also respond to an injection of a steroid near the granuloma, but some will require surgical excision.

Chronic pain of the scrotal contents after vasectomy is a syndrome with various names: postvasectomy pain syndrome (PVPS), congestive epididymitis, postvasectomy orchalgia, and chronic testicular pain (15). In two studies conducted 7 to 12 months following vasectomy, 14.7% of men described some degree of chronic discomfort of the scrotal contents; approximately 1% described the pain as “quite severe and noticeably affecting quality of life” (16), and 1% to 2% expressed regret over having had the vasectomy because of pain. Rates were about the same at 10 years following vasectomy, indicating that the incidence does not increase or decrease with time. PVPS is thus defined as intermittent or constant unilateral or bilateral testicular pain for >3 months following vasectomy, severe enough to interfere with daily activities and cause the patient to seek medical attention. There are no predictors as to which patients will develop it, there is no clear-cut etiology, and there is no best treatment. The syndrome is not due to infection, so antibiotics are not helpful. Medical treatment options include nonsteroidal anti-inflammatories, scrotal support, nerve blocks, and tricyclic antidepressants. Surgical treatments include conversion to open-ended vasectomy, vasectomy reversal, epididymectomy, and orchiectomy (15).

Prolonged sexual dysfunction following vasectomy is rare.

Through the years questions have been raised about an association between vasectomy and a variety of subsequently diagnosed disease states, including atherosclerosis, prostate cancer, glomerulonephritis, and primary progressive aphasia. So far, reviews of the initial studies point out methodologic factors, and subsequent studies have not been able to support any association between vasectomy and any disease states (17).

## CHAPTER 56 ■ VASO EPIDIDYMOSTOMY

PETER T. K. CHAN

Azoospermia may be due to bilateral obstruction at any point of the male excurrent ductal system, which comprises the efferent ductules, epididymis, vas deferens, and the ejaculatory ducts. Primary obstructive azoospermia is most commonly due to bilateral obstruction of the epididymides, if the iatrogenic cause of vasal obstruction postvasectomy is excluded. Obstructive azoospermia due to epididymal obstruction can be corrected by microsurgical reconstruction with vasoepididymostomy.

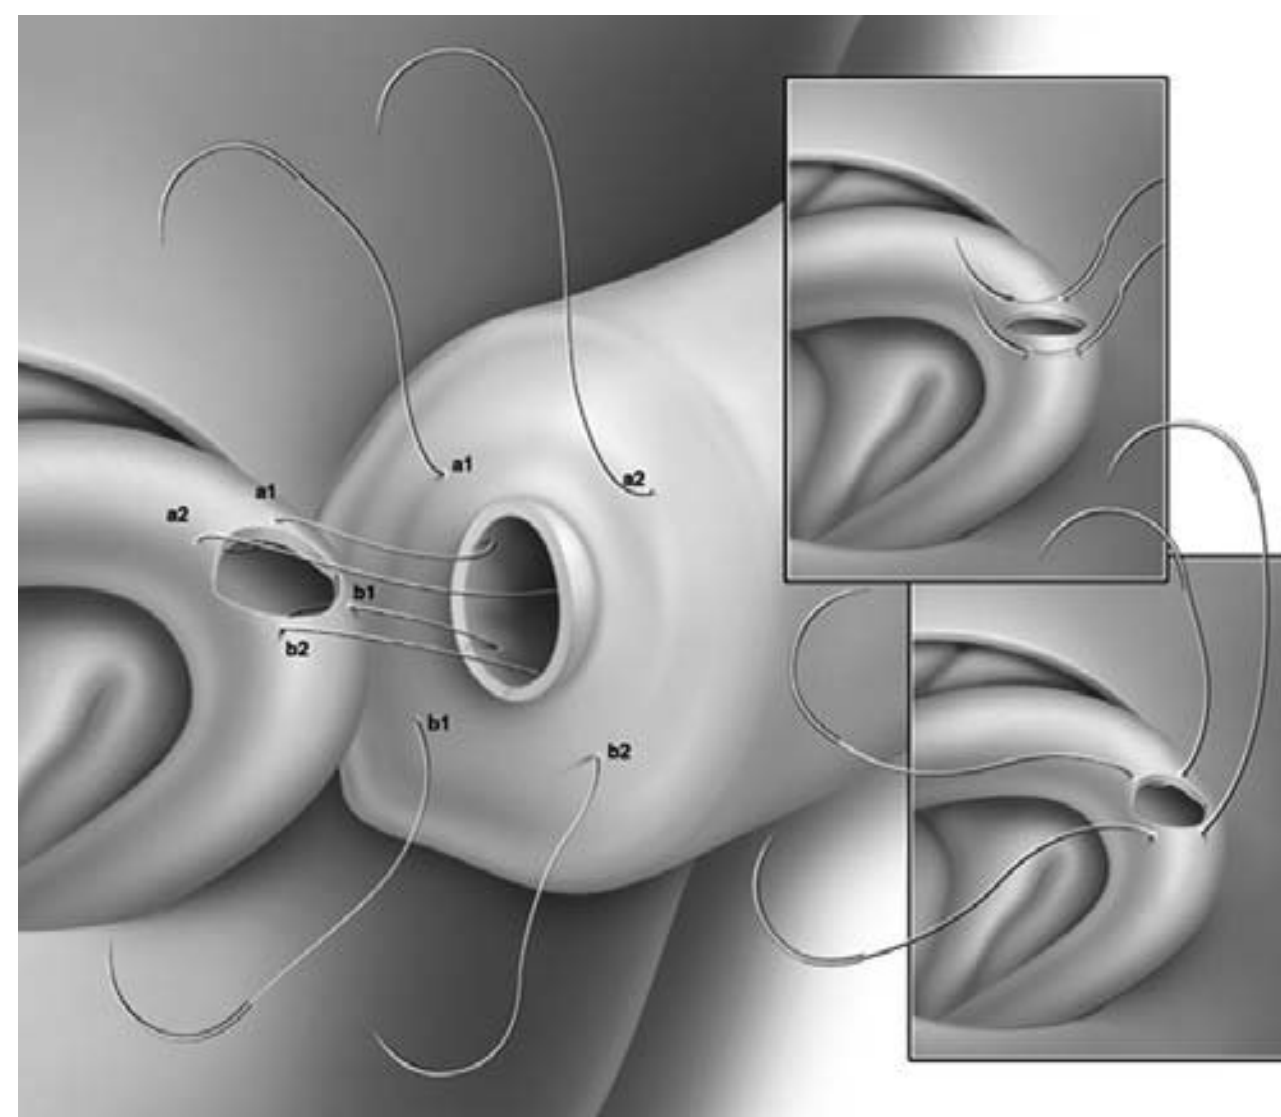

Vasoepididymostomy is considered the most technically challenging operation in male reproductive microsurgery. With the introduction of optical enhancement, microsurgical end-to-end single-tubule anastomosis was introduced by Silber (9) in 1978, and end-to-side anastomosis by Wagenknecht et al. (10) Berger (1) described a tubular intussusception using three double-armed microsutures placed to an epididymal tubule in a triangular fashion (Fig. 56.1). Subsequently, Marmar (7) modified this technique, using only two microsutures placed perpendicularly to the epididymal tubule for the anastomosis (Fig. 56.2). Chan et al. (2,3) reported placing the two microsutures longitudinally to the epididymal tubules, allowing the incision on the tubules to be made longitudinally (longitudinal intussusception vasoepididymostomy [LIVE]) and resulting in a larger lumen of epididymal inflow to the anastomosis.

### DIAGNOSIS

A thorough history and physical examination often provide important clues that can lead to the diagnosis of epididymal obstruction. In North America, by far the most common cause

**FIGURE 56.1** Triangulation intussusception end-to-side vasoepididymostomy. Three double-armed microsutures are placed in a triangulation fashion on the epididymal tubule, which is opened in the center of the triangle formed. The ends of the sutures are placed on the vasal end to complete the anastomosis.

**FIGURE 56.2** Two-needle intussusception vasoepididymostomy. This technique allows the use of two double-armed sutures to provide a four-point fixation on the vasal end for the anastomosis.

of epididymal obstruction is prolonged vasal obstruction after vasectomy. Besides a vasectomy, other history that may suggest an obstruction include previous surgeries, instrumentation, or trauma in the groin, pelvis, scrotum, prostate, or urethra or prior epididymoorchitis. A family history of cystic fibrosis suggests that the patient may be a carrier of mutations in the cystic fibrosis transmembrane conductance regulator gene (congenital bilateral absence of vas deferens with epididymal obstruction).

The physical examination should include a complete examination of the scrotum, vas deferens, testes, and epididymides. Findings suggestive of epididymal obstruction include a vasectomy performed in the proximal convoluted vas, a full epididymis or epididymal cysts with normal testicular volume and texture, and the time since the vasectomy. The presence of a vasal sperm granuloma reduces the risk of epididymal obstruction. Congenital bilateral absence of the vas deferens on scrotal examination represents another finding consistent with obstruction of the excurrent ductal system. Semen analyses demonstrating azoospermia with normal ejaculation volume, pH, and fructose level are consistent with isolated bilateral epididymal obstruction.

The diagnoses of unilateral obstruction and partial epididymal obstruction are difficult to make or confirm, as these patients generally do not present with azoospermia, but rather with infertility with a combination of oligo-, astheno-, and teratospermia. If unilateral or partial epididymal obstruction

is suspected clinically and vasoepididymostomy or other surgical reconstruction of the excurrent ductal system is contemplated, cryopreservation of sperm preoperatively should be considered as it is possible that the semen profile may decline significantly postoperatively if the reconstructive surgery fails.

Epididymal obstruction is generally an intraoperative diagnosis, as suggested by the presence of active spermatogenesis within the testis and the absence of sperm in a patent vas deferens. Although additional evaluations, including cystoscopy and various imaging studies, including scrotal and transrectal ultrasound, computerized tomography, and magnetic resonance imaging, may provide information that is consistent with epididymal obstruction, they are neither sensitive nor specific enough to diagnose epididymal obstruction and are generally not required prior to vasoepididymostomy.

Active spermatogenesis must be confirmed prior to attempting reconstruction of the excurrent ductal system. Confirmation of active spermatogenesis can be obtained through bilateral testicular biopsy performed as an isolated procedure ahead of time. Histologically, the cross section of each seminiferous tubule should have over 20 mature spermatids. Alternatively, cytologic examination of testicular aspiration for spermatozoa intraoperatively prior to vasoepididymostomy may confirm the presence of active spermatogenesis.

---

## INDICATIONS

---

Vasoepididymostomy is indicated in cases of obstructive azoospermia due to epididymal obstruction. Vasoepididymostomy should be performed in epididymal tubules that contain abundant sperm (motile or immotile) or sperm parts (heads and tails). Absence of abundant sperm or sperm parts indicates that the level of epididymal obstruction is located more proximally, where the anastomosis should be performed. Vasoepididymostomy should not be attempted in the absence of vasa, when the vasal gap is too big to be bridged despite appropriate surgical maneuvers for tissue mobilization, or in case of azoospermia due to testicular failure (nonobstructive azoospermia).

---

## ALTERNATIVE THERAPY

---

Besides microsurgical reconstruction with vasoepididymostomy, men with azoospermia due to epididymal obstruction may have sperm retrieved surgically from the epididymides (microscopic [MESA] or percutaneous [PESA] epididymal sperm aspiration) or from the testes (testicular sperm aspiration [TESA] or testicular sperm extraction [TESE]) for intracytoplasmic sperm injection (ICSI) to achieve pregnancy with their partners. With the increasing popularity and availability of assisted reproductive technologies such as in vitro fertilization and ICSI, the safety and efficacy of these technologies have improved significantly in recent years. Particularly for couples in whom the female partners are of advanced reproductive age or have significant female-factor infertility, sperm retrieval combined with ICSI

can be an effective alternative to allow them to conceive as early as possible.

---

## SURGICAL TECHNIQUE

---

A light general anesthesia is preferred. Slight movements are greatly magnified by the operating microscope and may disturb performance of the anastomosis. In the absence of any clinical evidence of complicated obstruction (e.g., multiple previous failure of reconstruction attempts, large vasal gap, significant fibrosis in scrotal structure on physical examination), regional anesthesia with sedation can be employed in cooperative and motivated patients. Appropriate intraoperative intravenous antibiotics should be considered, particularly in cases with a significant past history of infection in the genitourinary tract.

---

### Preparation of the Vas

---

A high scrotal incision (Fig. 56.3) is preferred to allow adequate mobilization of the inguinal portion of the vas to anastomose to the epididymis without any tension. When isolating the vas, its periadventitial sheath should not be stripped off to preserve its blood supply. As the epididymis lies laterally in the posterior aspect of the testis, the vas should be mobilized and isolated lateral to the rest of the spermatic cord to allow a more direct contact with the epididymis for the anastomosis. In patients who had a previous vasectomy, the vas should be transected at the vasectomy site to evaluate whether the testicular vas contains sperm and whether a vasoepididymostomy is indicated. The cut surface of the testicular end of the vas deferens is inspected with the operating microscope under 15 $\times$  to 25 $\times$  magnification. A healthy, white mucosal ring should be seen that springs back immediately after gentle dilation with a 2- to 3-mm microvessel dilator. The muscularis should appear smooth and soft. A gritty-looking muscularis layer indicates the presence of scar/fibrotic tissues. Healthy bleeding should be noted from both the cut edge of the mucosa as well as the surface of the muscularis. If the blood supply is poor or the

**FIGURE 56.3** A high scrotal incision (*solid lines*) for vasoepididymostomy allows to option to extend the incision (*dotted lines*) towards the external inguinal ring (marked by *X*) for mobilization of the abdominal vas to bridge a larger gap for the anastomosis.

muscularis is gritty, the vas should be recut until healthy tissue is found.

In patients with primary epididymal obstruction with no previous vasectomy, the vas is isolated at the junction of the straight and convoluted vas, where it is hemitransected with a 15-degree ophthalmic knife. Transection of the vas at this area will allow the maximal length of straight vas to be preserved to allow a tension-free vasoepididymostomy to be performed. The vasal fluid is sampled and evaluated under light microscopy. The absence of sperm and sperm parts in the vasal fluid indicates epididymal obstruction. On the other hand, the presence of abundant motile sperm indicates the absence of epididymal obstruction, and evaluation of vasal patency distally is essential to identify the location of the obstruction. In this case, the hemitransected vas can be reapproximated with interrupted 10-0 and 9-0 microsutures in two layers.

Patency of the abdominal end of the vas should be confirmed by saline vasogram in which a 24G soft angiocatheter connecting to a syringe containing 1 to 3 cc of saline is used to cannulate the vas. Easy injection of saline towards the abdominal vas confirms patency. If patency is not certain, a dye vasogram using 1 to 3 cc of 1:10 diluted indigo carmine should be performed. After injection of dye, bladder catheterization should review blue or green dye in the urine to confirm patency. If patency is not confirmed, formal vasography with diluted water-soluble radiographic contrast medium can be used to locate the obstruction.

---

### Identification of the Appropriate Epididymal Tubule

---

After confirming that a vasoepididymostomy is necessary and that the abdominal vas is patent and of adequate length, the testis within the tunica vaginalis is delivered outside the wound. A longitudinal incision is made on the anterior aspect of the tunica vaginalis. In long-term epididymal obstruction, a small hydrocele is often noted when opening the tunica vaginalis. The epididymis is then inspected under the operating microscope at 16 $\times$  to 25 $\times$  magnification to select an anastomotic site above the area of suspected obstruction. Often, a discrete yellow sperm granuloma is noted, above which there is indurated epididymis and dilated tubules, and below which the epididymis is soft and the tubules are collapsed.

Selection of the correct level of the epididymal tubule for anastomosis should not be a random event. The diameter of the epididymal tubule increases gradually from caput to cauda. Anastomosing to the larger tubule may result in a higher patency rate. Once a potential epididymal tubule for the anastomosis is identified, a relatively avascular area of the epididymal tunica is grasped with sharp jeweler's forceps and tented upward. A 3- to 4-mm buttonhole is made in the tunica with microscissors to create a round opening that matches the outer diameter of the prepared vas deferens.

If the level of obstruction in the epididymis is not clearly demarcated, choose a tubule distally and puncture it with a 10-0 needle to aspirate epididymal fluid and examine it microscopically. If sperm are not found, proceed in an identical

fashion proximally. Once sperm are identified, seal the puncture with a bipolar cautery and begin the anastomosis a few millimeters proximally along the epididymal tubule. Since the microsutures are to be placed longitudinally, a straight segment of the tubule is more preferable than one that is curved. This would allow the needle bites to run further along the tubule and a longer incision to be made longitudinally between the two needles.

---

### Preparation of the Epididymal Tubule

---

The epididymal tunic covering the tubule is thick and tough. On the other hand, the bare epididymal tubule underneath is thin and delicate, and extra care should be taken to avoid accidentally puncturing it, resulting in leakage of epididymal fluid and collapse of the tubule. After the initial cut on the epididymal tunic, there is often still a thin layer of residual tunic covering the epididymal tubule. Use of indigo carmine on the tissue may enhance visualization of the residual overlying tunic. The residual tunica should be dissected off fully with a combination of sharp and blunt dissection to expose the bare epididymal tubule underneath and to facilitate its intussusception into the vasal lumen when completing the anastomosis.

The vas deferens is drawn up through an opening in the tunica vaginalis and secured in proximity to the anastomotic site with two to four interrupted sutures of 6-0 polypropylene placed through the vasal adventitia and the tunica vaginalis. Care should be taken to avoid taking too deep a bite with the suture; this may result in accidental closure of the vasal lumen, rendering failure of the surgery. The vasal lumen should reach the opening in the epididymal tunica easily, with length to spare. To avoid tension or kinking of the vas, the surgeon should inspect the position and orientation of the vas not only when the testicle is delivered outside, but also when the testicle is placed back into the scrotum. The posterior edge of the epididymal tunica is then approximated to the posterior edge of the vas muscularis and adventitia with two or three interrupted sutures of 9-0 nylon (Fig. 56.4). This is done in such a way as to bring the vasal lumen in close approximation to the epididymal tubule selected for anastomosis. Adequate hemostasis of the vas and the epididymal tunic is essential, as the fluid in the epididymis cannot dissolve blood clot, which may obstruct the anastomosis.

---

### Longitudinal Intussusception Vasoepididymostomy

---

The LIVE procedure is our preferred method of microsurgical vasoepididymostomy as it greatly simplifies the procedure while yielding the highest patency rate among the various alternative techniques that we have employed (4–6). To allow even distribution of the suture points, four microdots are placed with a micro marking pen on the vasal ends to demarcate the exit points of the suture needles to be placed on the vas (Fig. 56.4A). For the anastomosis, we prefer to use 1-inch monofilament 10-0 nylon sutures, double-armed with 70-micron-diameter taper-point needles. Double-armed sutures

**FIGURE 56.4** Longitudinal intussusception vasoepididymostomy (LIVE). **A:** The vas is secured on the edge of the tunica epididymis with two or three 9-0 sutures with its lumen opposing the midportion of the isolated epididymal tubule. **B:** Placement of the two double-armed 10-0 mucosal sutures in a longitudinal fashion on the tubule that is opening with a longitudinal incision between the needles. **C and D:** The sutures are pulled through and placed in an inside-out fashion on the vasal ends. **E and F:** A 9-0 tension-reducing suture is placed to position the vasal lumen in direct opposition with the epididymal lumen prior to tying the mucosal sutures. **G:** When the epididymal tubule is aligned in parallel with the vasal lumen, both mucosal sutures can be tied to their own ends to complete the anastomosis.

allow inside-out placement of the needles on the mucosa, eliminating the need for manipulation of the mucosa and the possibility of back walling. Modification of the LIVE technique for the use of longer double-armed needles or single-armed needles will be described later.

The vas is secured with 9-0 nylon sutures on the edge of the tunica epididymis opening, with the vasal lumen positioned at the center of the selected epididymal tubule. Under the highest magnification of the operating microscope (25× to 40×), the needles of two double-armed 10-0 microsutures are placed longitudinally on the epididymal tubule (Fig. 56.4B). Leave the microneedles in the epididymal tubule until it is ready to be incised longitudinally. Since the diameter of the needle (70 microns) is significantly larger than the suture diameter (17 microns), pulling through the needle will result in leakage of the epididymal fluid. The collapse of the epididymal tubule, along with the impaired visibility from the cloudy epididymal fluid, makes it difficult to place an additional suture or to make a precise opening in the tubule for the anastomosis.

Using a 15-degree ophthalmic knife, the tubule is incised longitudinally between the two needles of the 10-0 sutures (Fig. 56.4B). The epididymal fluid is then aspirated with a 5-microliter micropipette or with a 24G angiocatheter connected to a syringe for aspiration. The fluid is examined for sperm under light microscopy. We generally recommend that the surgeon evaluate the epididymal fluid himself or herself with a bench-top light microscope intraoperatively. This allows a quicker and more accurate answer to be obtained and avoids drying of the slide during transit to a pathologist/cytologist outside the operating room, which may compromise the interpretation.

If motile sperm are found, cryopreservation of the sample should be considered for future use with ICSI should the anastomosis fail. Generally, if the level of the epididymal tubule is carefully selected, the fluid inside is likely to contain sperm or sperm parts. Absence of abundant sperm or sperm parts in the fluid indicates that obstruction is still proximal to the selected segment of tubule and anastomosis should not be performed there.

The needles of the two double-armed 10-0 sutures are then pulled through and placed to the mucosa in the vasal ends in an inside-out fashion through the four microdots (Figs. 56.4C, 56.4D). Depending on whether the selected epididymal tubule for the anastomosis lies parallel (Fig. 56.4) or perpendicular (Fig. 56.5) to the vas, the placement of the needles on the vas may vary.

---

### Completing the Anastomosis

---

To avoid tearing the 10-0 sutures out of the epididymal tubule during tying, it is necessary to position the vas to allow the vasal and epididymal lumina to be in direct opposition to each other. This is achieved by placing a 9-0 tension-reducing suture approximating the epididymal tunic to the vasal sheath prior to tying the 10-0 microsutures (Figs. 56.4E, 56.4F). This 9-0 suture is tied loosely to allow visualization of the anastomosis during tying of the 10-0 sutures. Just prior to tying, the ends of each of the 10-0 sutures should be gently pulled until the opposite end just begins to move. This prevents having a loose loop of suture in the anastomosis and ensures that the epididymal mucosa is plastered against the vasal mucosa

prior to tying. When setting up the anastomosis, in order to achieve the lowest tension possible without kinking the vas, the vasal lumen usually may end up lying parallel (Fig. 56.4) or perpendicular (Fig. 56.5) to the direction of the epididymal tubule. The ends of sutures for tying should be chosen carefully according to the orientation of the vas with respect to the direction of the epididymal tubule. In the setting when the vas and the epididymal tubules are parallel to each other, the two sutures are tied with their own ends on either side of the stay suture (Figs. 56.4F, 56.4G). In the setting when the vas and the epididymal tubules are perpendicular to each other, it is not necessary to push the ends of the 10-0 sutures on the same side of the 9-0 tension-reducing suture to tie. Instead, the two 10-0 sutures can simply be cross-tied to each other (Figs. 56.5B, 56.5C).

The advantages of LIVE include providing a four-point fixation at the mucosal anastomosis using two double-armed microsutures and allowing a larger epididymal lumen to be created with a longitudinal incision on the tubule. A watertight outer-layer anastomosis between the vasal sheath and the epididymal tunic is crucial to avoid leakage of fluid, which can lead to formation of sperm granuloma. We recommend placing 10 to 12 interrupted sutures of 9-0 nylon for the outer layer closure (Fig. 56.5D). Care should be taken to avoid injury to the peripheral epididymal tubules during the placement of needles on the epididymal tunic.

LIVE is a delicate procedure. Errors can occur at several crucial points of the surgery, requiring the anastomosis to be performed more proximally. Examples may include absence of sperm or sperm parts in the epididymal fluid, tearing of the epididymal tubule, or breakage of a mucosal suture. In any of these cases, a new spot more proximally in the epididymis should be identified to redo the anastomosis. The surgeon should not feel frustrated when it is necessary to take down the setup and redo the procedure at a more proximal site. Although it is time-consuming to redo an anastomosis, the extra time is well worth it. Vasoepididymostomy is a delicate operation where the outcome is highly dependant on technical perfection.

---

### Closure

---

After careful hemostasis and copious irrigation of the tissue, the tunica vaginalis should be closed with absorbable sutures and the testis returned intrascrotally in the correct orientation. Care should be taken to avoid any tension when manipulating the testis and spermatic cord after a delicate anastomosis is completed. With careful control of hemostasis, the risk of scrotal edema or hematoma can be minimized and drainage is generally not necessary.

---

### Maneuvers to Gain Extra Length to Bridge a Larger Gap

---

The simplest maneuver that should be attempted first to gain length to bridge a larger gap for the anastomosis is to mobilize the abdominal vas superiorly towards the external inguinal ring. The skin incision may be extended towards the external

**FIGURE 56.5** Longitudinal intussusception vasoepididymostomy (LIVE) when the epididymal tubule lies perpendicular to the vasal lumen. **A:** After pulling through the 10-0 mucosal sutures from the epididymal tubules, they are placed on the vasal end according to the plan for tying. **B:** A 9-0 tension-reducing suture is placed to position the vasal lumen in direct opposition with the epididymal lumen prior to tying the mucosal sutures. **C:** In this scenario, the mucosal sutures can be cross-tied with the end of the other mucosal suture to complete the anastomosis. **D:** Ten to 12 9-0 sutures are placed on the vasal sheath and the tunica epididymis to complete the outer layer of the anastomosis.

inguinal ring to facilitate this maneuver. Care should be taken to avoid stripping the periadventitial sheath to compromise the vasal blood supply. When there is still inadequate length of the vas deferens to reach the dilated epididymal tubule without tension, the cauda and corpus epididymis can be dissected off the testis and flipped up to obtain additional length (Fig. 56.6). To do this, the full depth of the epididymis is encircled with a small Penrose drain at the level of obstruction and, under 8 $\times$  to 16 $\times$  magnification, it is dissected distally off the testis, yielding sufficient length to perform the anastomosis (4). Usually, a surgical plane can be developed between the epididymis and testis, and injury to the epididymal blood supply can be minimized by staying right on the tunica albuginea of the testis. The inferior and if necessary the middle epididymal branches of the testicular artery are doubly ligated and divided to free an adequate length of epididymis. The superior epididymal branches entering the epididymis at the caput are always preserved and can provide adequate blood supply to the entire epididymis. The tunica vaginalis is then closed over the testis with absorbable suture, which prevents drying of the testis and thrombosis of the surface testicular vessels during the anastomosis. The dissected epididymis can remain outside the tunica vaginalis for the anastomosis.

**FIGURE 56.6** The corpus and caudal epididymis can be dissected off from the testis tunica albuginea and brought superiorly to bridge a massive vasal gap.

### Use of Single-Armed Microsutures for Longitudinal Intussusception Vasoepididymostomy

LIVE can be performed using 10-0 single-armed sutures, which are less costly than the double-armed ones (8). The disadvantage is that two of the four needle placements on the vasal end have to be done in an outside-in fashion. Two 10-0 sutures are first placed on the vas in an outside-in fashion. If the selected epididymal tubule lies perpendicularly to the vasal lumen, it is recommended to place the two needles on the two dots on the same side as the dominant hand of the surgeon (Fig. 56.7A). If the selected tubule lies in parallel to the vas, the sutures can be first placed on the two upper microdots and then pulled through the vasal lumen (Fig. 56.7B). Insertion of a 2- to 3-mm microvessel dilated during the outside-in placement of the needle may further decrease the risks of back walling of the vasal lumen mucosa. The LIVE procedure can then be performed in a similar fashion, with the two needles placed on the epididymal tubules where a longitudinal incision is made between the needles. The sutures are then pulled through and placed to the remaining two microdots marked on the vasal end in an inside-out fashion to

**FIGURE 56.7. A:** Placement of single-armed microsutures for longitudinal intussusception vasoepididymostomy (LIVE) when the epididymal tubule is in parallel to the vasal lumen. The *arrows* indicate the placement of the first bites of the two sutures. **B:** Same technique when the epididymal tubule is perpendicular to the vasal lumen. The *arrows* indicate the placement of the first bites of the two sutures when the surgeon is right-handed.

complete the anastomosis. Tying of the two single-armed sutures can follow the same principle as described previously.

### Use of Long Double-Armed Microsutures for Longitudinal Intussusception Vasoepididymostomy

LIVE can be performed using a single long (6-inch) double-armed microsuture. Similar to the use of single-armed microsutures, the disadvantage is that two of the four needle placements on the vasal end have to be done in an outside-in fashion. The two needles at each end are first placed in the vas in an outside-in fashion. If the selected epididymal tubule lies perpendicularly to the vasal lumen, it is recommended to place the two needles on the two dots on the same side as the dominant hand of the surgeon (Fig. 56.8A). If the selected tubule lies in parallel to the vas, the sutures can be first placed on the two upper microdots and then pulled through the vasal lumen (Fig. 56.8B). Insertion of a 2- to 3-mm microvessel dilated during the outside-in placement of the needle may further decrease the risks of back walling of the vasal lumen mucosa.

**FIGURE 56.8. A:** Placement of a long double-armed microsuture for longitudinal intussusception vasoepididymostomy (LIVE) when the epididymal tubule is in parallel to the vasal lumen. The *arrows* indicate the placement of the first bites of the two needles. **B:** Same technique when the epididymal tubule is perpendicular to the vasal lumen. The *arrows* indicate the placement of the first bites of the two needles of the suture when the surgeon is right-handed.

The LIVE procedure can then be performed in a similar fashion, with the two needles first placed on the epididymal tubules where a longitudinal incision is made between the needles. The sutures are then pulled through and placed to the remaining two microdots marked on the vasal end in an inside-out fashion to complete the anastomosis. Since a single double-armed suture is used in this case, suture tying needs to be done only once. Care must be taken to ensure there is no loose loop of suture before tying; otherwise, leakage of epididymal fluid may occur.

---

## OUTCOMES

---

### Results

---

We recently reported our clinical experience of microsurgical LIVE in a series of 72 men with azoospermia due to epididymal obstruction (3). The mean age of the subjects was 39.3 years. The etiologies of obstruction were postvasectomy (69%), infection (22%), iatrogenic (5%), trauma (1%), and idiopathic (3%). The median duration of obstruction was 18.7 years. Previous failed attempts at reconstruction were noted in 38% of patients. Mean follow-up period was 16.3 months.

The patency rate, defined as  $>10,000$  sperm per milliliter of semen at any time postoperatively, was 92%. Early patency was achieved in 73% of subjects at 4 to 6 weeks postoperatively. The median best sperm count was  $12.9 \times 10^6/\text{mL}$ , with a 23% rate of forward motility. The late “shut-down” rate, defined as the percentage of subjects who had sperm postoperatively but later became persistently azoospermic, was 4% at 1 year postoperatively. The median duration of the procedure was 55 minutes per anastomosis.

Among patients with follow-up over 1 year, the natural pregnancy rate was 31%. Median time to achieve natural pregnancy was 15.3 months. An additional 39% of patients

achieved pregnancy with assisted reproduction, all using fresh ejaculated sperm.

---

## Complications

---

Potential surgical complications associated with vasoepididymostomy include wound infection, scrotal edema, hematoma, orchalgia, and persistent epididymal obstruction (surgical failure). Most of these complications are self-limiting and can be managed conservatively. More devastating complications such as ischemic epididymal fibrosis and testicular atrophy may be encountered rarely. The risk of complications increases in patients who have multiple previous unsuccessful reconstruction attempts with a significant extent of tissue fibrosis in the scrotal contents, or in cases where additional dissection is required to mobilize the vas or the epididymis to bridge a larger gap for the anastomosis.

Patients should also be instructed on the various preventive measures, such as avoidance of strenuous physical activities immediately postoperatively, use of an ice pack for wound or scrotal compression to prevent the development of hematoma or edema, and avoidance of ejaculation for up to 4 weeks to minimize the risks of disruption of the anastomosis due to the force of propulsion of the excurrent ductal system from orgasm.

Postoperatively, semen analyses may be performed at 1 month and subsequently every 2 to 3 months. Patients who have motile sperm return to the ejaculate should consider cryopreserving sperm, as initially patent anastomoses may eventually shut down. From our experience with LIVE, the great majority of patients who have a patent anastomosis will have sperm in the ejaculate in the first 6 months. It is rare for patients who have been persistently azoospermic in the first 6 months postoperatively to have the anastomoses open up. Persistently azoospermic men without cryopreserved sperm can opt for a redo vasoepididymostomy or surgical sperm retrieval by various techniques combined with ICSI to achieve pregnancy with their partner.

# CHAPTER 57 ■ VASOVASOSTOMY

MARC GOLDSTEIN AND HOWARD H. KIM

Of the 500,000 men undergoing vasectomy each year in the United States, an estimated 2% to 6% will ultimately seek reversal (1). Despite the proven safety and efficacy of reversal surgery, vasovasostomy is not universally accepted. A significant drawback to vasovasostomy is the variable time interval to recovery of fertile sperm from the ejaculate, which is especially problematic for patients with partners of advanced maternal age. The lack of access to a microsurgeon trained in the vasovasostomy and vasoepididymostomy procedures is another potential limitation. With the widespread availability of assisted reproductive techniques (ART), some have questioned the need for complex reconstructive procedures for postvasectomy infertility.

Microsurgical vasovasostomy was first described in the 1970s by Earl Owen and Sherman Silber. Owen reported a patency rate of 98% in his series of 50 patients (2). Silber noted that normal sperm counts can be achieved in up to 95% of patients (3). This technique has been refined even further since its introduction, and similar, if not better, success rates have been reported recently by dedicated urologic microsurgeons (4). Most cost-benefit analyses have found that reversal procedures are the most efficacious and economical management of postvasectomy infertility (5), even in men with previous failed vasectomy reversal (6), demonstrating that microsurgical reconstruction is an important treatment option in appropriately selected patients.

---

## DIAGNOSIS

---

The preoperative workup for men requesting vasectomy reversal is straightforward. Confirmation of previous natural fertility is often sufficient documentation of spermatogenesis. However, if the patient has never fathered children in the past or if he has obstructive azoospermia without a history of prior vasectomy, further workup is necessary. The workup includes a full history, physical examination, and basic laboratory tests, including a semen analysis, and should be performed in conjunction with evaluation of the female partner. An obstructive etiology such as complications from a previous hernia repair may be revealed in the medical history.

---

## Physical Exam

---

The physical examination provides important clues about the likelihood for successful reversal surgery. Testicular volume and consistency mirror the spermatogenesis status; soft, small testes suggest impaired spermatogenesis, and a testicular biopsy may be necessary prior to reconstruction. An indurated epididymis or an ipsilateral hydrocele may predict the presence of a secondary epididymal obstruction, which would necessitate a vasoepididymostomy.

Physical findings specific to the vasectomy site include the presence of a sperm granuloma and the length of the vasal gap. Sperm granulomas are found in 10% to 30% of men undergoing reversal surgery (7). The presence of a sperm granuloma can serve as a pop-off valve for the efferent ductile system, protecting the epididymis from the detrimental effects of increased intratubular pressure, and increases the likelihood of vasovasostomy being required instead of vasoepididymostomy. A large gap between the obstructed vasal ends may require inguinal extension of the scrotal incision and additional dissection to ensure a tension-free anastomosis.

---

## Laboratory Evaluation

---

A semen analysis with examination of the centrifuged pellet is the primary laboratory test obtained prior to reversal surgery. Up to 10% of patients will have sperm with tails in the centrifuged pellet at a mean of 10 years after vasectomy (8), a finding indicative of likely sperm in at least one has deferens, meaning a vasovasostomy will almost certainly be possible on at least one side with a good overall prognosis for return of sperm to the ejaculate. An elevated level of serum follicle-stimulating hormone (FSH) suggests poor spermatogenesis in men with small, soft testes, which may precipitate further diagnostic workup. In men with elevated serum FSH levels or in men without prior fertility, the serum antisperm antibody assay helps to make a case for obstructive azoospermia with active spermatogenesis (9).

---

## INDICATIONS FOR SURGERY

---

Although an overwhelming majority of vasovasostomies are performed in men with postvasectomy infertility, a significant number of men undergo repair for iatrogenic injury to the vas deferens. In a series of 472 patients surgically explored for obstructive azoospermia, 7.2% had an iatrogenic injury (10). Mode of injury included inguinal hernia repair (more frequently pediatric hernia surgery), renal transplantation, appendectomy, and spermatocelectomy (10). Because these patients often have longer vasal defects, impaired blood supply, and longer obstructive intervals, surgery is usually more challenging technically and outcomes are worse.

---

## Prognostic Factors

---

Several patient and partner factors influence the outcome of reversal surgery and should be considered during the preoperative evaluation. These factors include prior fertility, age at vasectomy, medical and surgical history subsequent to vasectomy,

obstruction interval, and partner's age and fertility status. The chance for successful pregnancy following vasectomy reversal decreases from 56% in patients whose partners are 20 to 39 years of age to 14% in those whose partners are age 40 or older (11). Men with the same partners from before the vasectomy procedure also fare better, perhaps due to proven previous fecundity together and shorter time interval since vasectomy (12). Regarding time interval between the initial vasectomy and subsequent reversal surgery, we found patency and pregnancy rates of 91% and 89%, respectively, for obstruction interval of <5 years and 89% and 44%, respectively, for obstruction interval of >15 years (13). The Vasovasostomy Study Group had similar results: they reported patency and pregnancy rates of 97% and 76%, respectively, for obstruction interval of <3 years, which fell to 71% and 30% for obstruction interval of 15 years or more (14). Finally, as a significant number of reversals actually require vasoepididymostomy on one or both sides, the surgeon must be comfortable with performing both surgeries.

---

## ALTERNATIVE THERAPY

---

Alternatives to vasovasostomy include in vitro fertilization (IVF) with intracytoplasmic sperm injection (ICSI) using retrieved sperm, donor sperm insemination, and adoption. Selecting between vasovasostomy and vasoepididymostomy based on intraoperative vasal fluid findings will be discussed later in this chapter. With the availability of IVF/ICSI, the use of donor sperm or adoption for postvasectomy infertility is rare.

---

## SURGICAL TECHNIQUE

---

### Operating Room Set-up

A two-headed operating microscope with 6× to 32× power magnification is used (Fig. 57.1). Foot pedal controls allow the surgeon to zoom and focus the field of view without interrupting the surgery. The microscope is used for most of the procedure, with the exception of the opening incision and closure. Although the operation can be performed in the standing

**FIGURE 57.1** The operating microscope has two heads for the surgeon and the assistant. Microscope settings are checked before starting the procedure. (All photos courtesy of Marc Goldstein, MD and Philip S. Li, MD)

**FIGURE 57.2** The specially designed micro-surgical chair adjusts for optimal support of the chest and arms.

position, the use of specially designed micro-surgical chairs increases the stability of the surgeon's chest and arms (Fig. 57.2). By standing or sitting on the patient's right side, the right-handed surgeon is in position to place the more difficult abdominal end vasal sutures with the forehand.

---

## Anesthesia

---

Although regional anesthesia can be used for uncomplicated vasovasostomies, general anesthesia is preferred to minimize disruptive motion when placing the delicate anastomotic sutures, especially during complex or prolonged reconstructive procedures. The patient's ability to remain still and the surgeon's experience and comfort level should be considered in selecting the type of anesthesia.

---

## Incision

---

After a dose of intravenous cefazolin and standard surgical preparation of the groin and genitalia in the supine position, the external inguinal ring is marked on both sides (Fig. 57.3). Careful palpation of the vasectomy site helps to determine the level of the incisions, usually high vertical scrotal incisions at

**FIGURE 57.3 A:** The right surgical incision is marked over the scrotal skin. The external inguinal ring is marked with an X. The incision is at least 1 cm away from the penis.

**FIGURE 57.3 B:** The skin incisions for both sides are marked.

least 1 cm lateral to the base of the penis for optimal cosmetic results. The incision should be long enough to allow delivery of the testis; the tunica vaginalis should be kept intact to optimize exposure of the vas deferens (Figs. 57.4–6). The incision may be extended toward the external ring if a high vasectomy or large vasal gap is encountered. Alternatively, if the site of vasal disruption is even higher, such as in the case of inguinal obstruction secondary to herniorrhaphy, an inguinal incision is

**FIGURE 57.4** The skin incision is made with a #15 blade.

**FIGURE 57.5** Electrocautery is used for the underlying dartos layer.

**FIGURE 57.6** The testis is delivered into the field, with the tunica vaginalis intact.

preferred. Incision through the scar from the previous surgery usually leads directly to the obstruction. Even if the epididymis needs to be exposed, the testis can be delivered through the inguinal incision or through a separate scrotal incision.

### Exposure of the Vasa Deferentia

Adequate exposure of the vas deferens is critical for achieving a tension-free anastomosis (Fig. 57.7). To preserve the blood supply of the vas deferens, the correct dissection plane must be achieved along the vasal sheath; venturing too close to the sheath endangers the periadventitial vasal blood supply, whereas straying too far away from the sheath jeopardizes the testicular artery. Injury to the testicular artery can result in testicular atrophy, as the deferential artery likely has been disrupted during the previous vasectomy. The operating microscope should be used for this dissection with at least 10 $\times$  power magnification to provide adequate visualization and to minimize risk of injury to the vessels. After gentle blunt dissection of the vas deferens, two Babcock clamps are placed above and below the obstructed segment (Fig. 57.8). Finding the proper dissection plane can be facilitated by transilluminating the sheath with the operating light (Fig. 57.9). A curved mosquito clamp is used to puncture this space at two points on either side of the vasectomy site (Fig. 57.10), and two quarter-inch Penrose

**FIGURE 57.7** Blunt dissection with a gauze-covered finger releases the vas deferens from the surrounding tissue.

**FIGURE 57.8** Two Babcock clamps are placed along the length of the vas deferens.

**FIGURE 57.9** Transilluminating the tissue surrounding the vas deferens by bringing the operating light low helps to identify the correct dissection plane.

**FIGURE 57.10** The plane between the vas deferens and the surrounding tissue is pierced with a Crile clamp.

drains are pulled through to serve as handles to traction the vas deferens while gently separating the surrounding tissue with both blunt and sharp dissection with small fine Metzenbaum scissors (Fig. 57.11).

Length is more difficult to achieve on the abdominal portion of the vas deferens. Several maneuvers can be used to achieve

A

B

**FIGURE 57.11** **A:** Quarter-inch Penrose drains are brought through the two openings made by transillumination. **B:** Using traction on the Penrose drains, the vas deferens is released using both blunt and sharp dissection.

additional length when a long vasal gap is encountered. Blunt dissection with the index finger through the external inguinal ring can release the abdominal vas deferens almost to the level of the internal inguinal ring without opening the external oblique aponeurosis. Distally, the convoluted vas deferens can be dissected from the epididymal tunica (Figs. 57.12 and 57.13). Up to 6 cm of additional length can be achieved with

**FIGURE 57.12** The vas deferens is freed distally to the level of the convolutions.

**FIGURE 57.13** The convoluted vas deferens is fully exposed.

these techniques. Another 4 to 6 cm can be released by further dissection of the epididymis from the testis, up to the level of the caput epididymis. Again, the blood supply must be carefully preserved. Finally, the Prentiss maneuver can provide up to 10 cm of vasal length when used in combination with the other techniques.

### Preparation of the Vasa Deferentia

The obstructed segment, along with any associated vasectomy clips or sperm granuloma, is excised, first on the testicular side using an ultrasharp knife and a slotted 2-mm, 2.5-mm, or 3-mm-diameter nerve-holding clamp (Accurate Surgical & Scientific Instruments Corp., Westbury, NY). The slotted nerve-holding clamp allows for a perfect 90-degree transection (Figs. 57.14 and 57.15). Under 15 $\times$  to 25 $\times$  magnification, three distinct layers—the mucosa, muscularis, and adventitia—can be visualized. The mucosa should be white and elastic and the muscularis smooth and supple. Evidence of bleeding at each layer demonstrates a healthy blood supply. If the blood supply is in question, or if the muscularis appears gritty and fibrotic, additional transections should be made until the appearance of healthy tissue (Fig. 57.16). The deferential artery and vein are ligated with 6-0 Vicryl. The micro-bipolar coagulation forceps, set at 2.5 to 3.5 watts, help control the smaller bleeders, but care should be taken to avoid thermal injury to the mucosa.

**FIGURE 57.14** The slotted nerve-holding clamp and the ultrasharp knife help to make perfect 90-degree transections of the vas deferens.

**FIGURE 57.16** An unhealthy segment of vas deferens demonstrates white, avascular vasal layers surrounded by fibrotic scar tissue.

### Examination of Vasal Fluid

The testicular end of the vas deferens is milked and a touch-prep is made using a glass slide (Fig. 57.17). The fluid is mixed with a drop of lactated Ringer's solution and a cover slip is placed. The slide is immediately examined under 40 $\times$  power magnification using a separate microscope setup (Fig. 57.18).

**FIGURE 57.17** A touch-prep of the vasal fluid is made by blotting the freshly cut testicular portion of the vas deferens onto a glass slide.

**FIGURE 57.18** A separate microscope setup should be used to examine the vasal fluid under 40 $\times$  magnification.

In its review of vasectomy reversal, the Practice Committee of the American Society for Reproductive Medicine (ASRM Guidelines) graded the sperm quality of vasal fluid as follows: grade 1, mainly normal motile sperm; grade 2, mainly normal nonmotile sperm; grade 3, mainly sperm heads; grade 4, only sperm heads; and grade 5, no sperm (15). Vasovasostomy is a

good option for grades 1 through 4. If no sperm are found in the vasal fluid (grade 5), the gross appearance of the vasal fluid can help in deciding between vasovasostomy and vasoepididymostomy (Table 57.1). Cloudy, water-soluble fluid indicates the best chance for the eventual return of sperm to the semen, and thick, white, greasy toothpaste-like material indicates the worst prognosis (Fig. 57.19). Although a standard algorithm has not been established, the general recommendation is to proceed with vasovasostomy if sperm are identified in the vasal fluid or if the quantity of the fluid is copious and watery. Vasoepididymostomy should be considered if the vasal fluid is absent or if the quality of the fluid is thick, white, and creamy. If no fluid can be expressed for evaluation, the testicular end of the vas deferens is barbitaged with 0.1 mL of saline using a 24-gauge angiocatheter sheath, and the resultant fluid is examined (Fig. 57.20). In the presence of large sperm granulomas, the testicular end of the vas is minimally dilated with very little or no luminal fluid; barbitage with milking often expresses a small amount of fluid with sperm.

The abdominal end of the vas deferens is similarly transected and inspected. The lumen is gently dilated with a microvessel dilator and about 1 mL of saline is injected with a 24-gauge angiocatheter sheath to confirm patency. In assessing patency of the testicular and abdominal ends of the vasa deferentia, the surgeon must consider the left and right sides

**FIGURE 57.19** A thick, greasy, “toothpaste” consistency indicates a poor prognosis for sperm in the vasal fluid.

**TABLE 57.1**

#### EVALUATION OF VASAL FLUID

Gross appearance	Microscopic appearance	Grade	Indicated surgery
Copious, cloudy, thin, water soluble	Sperm with tails	1, 2	Vasovasostomy
Copious, creamy yellow, water-soluble	Many sperm heads, occasional sperm with short tails	3, 4	Vasovasostomy
Scant fluid, sperm granuloma present	Barbitage fluid with sperm	1–5	Vasovasostomy
Copious, crystal clear, watery	No sperm	5	Vasovasostomy
Scant, white, thin fluid	No sperm	5	Vasoepididymostomy
Copious, thick, white, toothpaste-like, water-insoluble	No sperm	5	Vasoepididymostomy
Dry	No sperm	5	Vasoepididymostomy

Typical intraoperative findings on vasal fluid evaluation and the recommended procedure for each finding are listed.

**FIGURE 57.20** If the vas deferens is “dry,” a 24-gauge angiocatheter sheath is used to barbitage the lumen with saline.

together, with the fundamental principle that one good anastomosis is superior to two tenuous connections. For example, if a right epididymal obstruction and a left abdominal vas blockage are encountered, a single crossed vasovasostomy should be performed. Specifically, crossed vasovasostomy should be considered in the following circumstances: (i) unilateral inguinal obstruction of the vas deferens with an atrophic contralateral testis, or (ii) obstruction or aplasia of the inguinal vas or ejaculatory duct with a contralateral epididymal obstruction. Although this technique requires opening of the scrotal septum, it is much easier than an inguinal vasovasostomy.

### Anastomosis of the Vasa Deferentia

In preparation for the anastomosis, the two ends of the vas deferens are stabilized without tension using a microspike approximating clamp (Fig. 57.21) (16). A tongue blade encased in a 1-inch Penrose drain serves as a platform for suturing (Fig. 57.22). The entire setup is brought up through a slit in a rubber dam (Fig. 57.23); the rubber dam provides a contrasting field for the black sutures and prevents the sutures from adhering to tissue.

**FIGURE 57.21** The microspike approximating clamp stabilizes the two ends of the vas deferens for suturing.

**FIGURE 57.22** A tongue blade wrapped with 1-inch Penrose drain provides a platform for suture placement.

**FIGURE 57.23** A rubber dam prevents sutures from sticking and getting lost in the surrounding tissue.

### The Microdot Technique for Multilayer Microsurgical Vasovasostomy

A microtip marking pen (Devon Skinmarker Extra Fine #151, Devon Industries, Buffalo, NY) is used to make six equidistant dots on the face of each transected vas deferens; the dots of one vasal end should mirror those of the other end to prevent twisting or distortion of the anastomosis (Fig. 57.24). The dots are made at the 1, 3, 5, 7, 9, and 11 o'clock positions on the muscularis, roughly halfway between the adventitia and the mucosa. This blueprint ensures precise suture placement and a watertight closure even with markedly discrepant luminal diameters.

Six monofilament 10-0 nylon double-armed sutures with 70-micron-diameter taper-point needles (Sharp, Surgical Specialties Corp., Reading, PA, or Ethicon, Inc., Somerville, NJ) are placed, starting with the three anterior positions (Figs. 57.25 and 57.26). Each suture begins within the lumen and exits at the dot; this inside-out placement of the sutures minimizes mucosal manipulation and reduces the risk of backwalling. The mucosal lumen can be stained with indigo carmine and gently dilated with the microvessel dilator as needed to facilitate suture placement (Fig. 57.27). Although methylene blue causes an immediate reduction in sperm motility and

A

B

**FIGURE 57.24** **A:** The microdots are made on the clock face of each cut vasal end using a microtip marking pen. **B:** The microdots should be symmetrical and mirror the corresponding side. Note the size discrepancy of the two vasal ends, with the larger dilated testicular end resulting from occlusive pressure.

**FIGURE 57.25** The placement of the 10-0 nylon mucosal sutures is guided by the microdots. Additional fine-tuning of the suture placements can be made at the surgeon's discretion.

should be avoided in reversal surgery, indigo carmine may be used (17). Each suture should include a small amount of mucosa and one third to one half of the muscularis, and the same amount of tissue should be included on each side. After the three anterior mucosal sutures are tied, two monofilament 9-0

**FIGURE 57.26** Three anterior mucosal sutures are placed and tied.

**FIGURE 57.27** Visualization of the mucosal edge is improved with the application of indigo carmine.

**FIGURE 57.28** Monofilament 9-0 nylon deep muscularis sutures are placed in between the three anterior mucosal sutures.

nylon deep muscularis sutures are placed in between these three, without including the mucosa, and tied (Fig. 57.28).

The vas deferens is rotated 180 degrees and the remaining three mucosal sutures are placed in a similar fashion (Fig. 57.29). Before the final mucosal suture is tied, the vasal lumen is irrigated with heparinized lactated Ringer's solution to discourage clot formation. Four deep muscularis sutures are placed between the recently placed mucosal sutures for a circumferential two-layer closure. Four to six monofilament 9-0

A

B

**FIGURE 57.29** **A:** The vas deferens is rotated 180 degrees for placement of the remaining sutures. **B:** The sutures are placed in the same sequence as on the other side.

nylon sutures placed between the deep muscularis sutures within the adventitia constitute the third closure layer. Finally, the vasal sheath is reapproximated with six interrupted 8-0 nylon sutures, which protects the anastomosis from tension and enhances vascularization across the anastomosis (Fig. 57.30).

Chances for a successful operation are optimized by following the basic principles of anastomotic surgery, including mucosa-to-mucosa approximation of healthy well-vascularized tissue

**FIGURE 57.30** The vasal sheath is reapproximated with 8-0 nylon sutures, covering and protecting the anastomotic sutures.

with minimal handling using atraumatic technique. The anastomosis should be leak-proof and tension-free. As sperm are highly antigenic, leakage at the anastomosis can develop into a sperm granuloma and provoke an inflammatory reaction, potentially leading to failure of the vasovasostomy (18). Tension on the anastomosis may result in late stricture and failure after an initial period of sperm in the ejaculate.

### Special Circumstances

If unhealthy tissue or blood supply results in cutback of the testicular portion of the vas deferens to the convoluted segment (Fig. 57.31), anastomosis to the convoluted portion of the vas deferens follows the same principles as for the standard anastomosis, with a few additional considerations. A perfect 90-degree transection must be achieved; the convoluted segment is even more vulnerable to an oblique cut, resulting in insufficient mucosa and muscularis on one side. The surgeon must resist the temptation to unravel the convoluted segment lest the maneuver compromise the blood supply. Instead, additional length can be achieved with careful dissection of the vas deferens away from the epididymal tunica. During the suturing, taking too-large bites of the convoluted segment increases the risk for perforation of adjacent convolutions. In a series of 48 patients undergoing vasectomy reversal

A

B

**FIGURE 57.31** **A:** If additional length is necessary, the convoluted segment is carefully dissected free. **B:** The vasal cut is made at the juncture of the straight and convoluted portions.

**FIGURE 57.32** After closure, the nonscrotal portion of the incision is reinforced with adhesive skin-closure strips.

involving the convoluted vas deferens, the patency and natural pregnancy rates were 88% and 48%, respectively, comparable to outcomes with the standard technique (19).

In a less frequently encountered scenario, significant shortage of vasal length during a crossed vasovasostomy may warrant a testicular transposition. This maneuver takes advantage of the superior length of the spermatic cord to the vas deferens. Tension on the vas deferens is relieved by simply moving the testes to the contralateral hemiscrotum through an opening in the septum.

---

### Closure

---

After the four-layer anastomosis, the dartos layer is approximated with interrupted 4-0 Monocryl followed by a subcuticular skin closure with 5-0 Monocryl (Fig. 57.32). Penrose drains may be necessary with extensive dissection (Fig. 57.33); as reversal surgery is performed on an ambulatory basis, explicit instructions are given to the patient for self-removal the following day.

---

### Postoperative Care and Follow-Up

---

Bacitracin ointment and sterile gauze dressing are applied to the closure, followed with fluff-type gauze and a snug-fitting

**FIGURE 57.33** Penrose drains exiting the dependent portion of the scrotum provide wound drainage for cases involving extensive dissection.

athletic supporter. The supporter should be worn at all times, even at nighttime, for 6 weeks. Thereafter, the supporter is worn during athletic activity until pregnancy is achieved. Light activity may be resumed in 3 days and heavy activity in 3 weeks. The patient is instructed to avoid sexual activity and ejaculation for 4 weeks. Hydrocodone with acetaminophen and a nonsteroidal anti-inflammatory drug are used for postoperative pain management. Semen analyses are obtained at 1, 3, and 6 months after surgery and every 6 months thereafter.

---

## OUTCOMES

---

---

### Results

---

In our published series of 194 consecutive cases, patency was achieved in 99.5% of cases when sperm were found in the vasal fluid on at least one side at the time of surgery (4). The pregnancy rate in the first 100 cases was 54%, which increased to 64% when female factor infertility was excluded (4). Pregnancy rates were 82% to 89% for obstructive intervals of 0 to 15 years but significantly lower, 44%, with obstructive intervals >15 years (13). Persistent azoospermia beyond 6 months after surgery is an indication of likely immediate surgical failure. Late failure after initial patency were observed in 12% of men by 14 months after surgery, an event usually preceded by progressive loss of motility on semen analyses, followed by decreasing sperm counts (20). Because of the possibility for late stricture formation, we recommend cryopreservation of semen specimens when motile sperm are found in the ejaculate.

Failure of vasectomy reversal may be due to unrecognized epididymal obstruction and compromised anastomosis, among other causes. With patency and pregnancy rates of 67% and 30%, respectively, repeat vasectomy reversal surgery remains a viable option (21). Prognostic factors for successful initial vasectomy reversal also apply to repeat procedures.

---

### Complications

---

Vasovasostomy is a safe procedure with a low risk for significant complications. Although hematoma formation is the most common acute complication of vasectomy reversal surgery, only seven small hematomas occurred in our series of 2,100 cases (unpublished data). All resolved in 6 to 12 weeks without intervention. No wound infections occurred. Sperm granulomas, which often precede eventual obstruction, formed in about 5% of our patients (unpublished data). In an animal study, sperm granulomas were present in 99% of failed anastomoses in rats undergoing vasovasostomy (18).

---

### Cost-Benefit Analyses

---

To address the comparative utility of reversal surgery and ART, several cost-benefit analyses have been performed. Pavlovich and Schlegel (5) reported a cost per delivery after vasectomy reversal of \$25,475 with a delivery rate of 47%, whereas the cost per delivery after sperm retrieval and ICSI was \$72,521 with a delivery rate after one cycle of ART with sperm retrieval of 33%. Furthermore, a systematic review of

four cost-benefit analyses comparing these two approaches also reported results favoring vasectomy reversal surgery (22). Another study found the cost of microsurgical epididymal sperm aspiration with ICSI/IVF to be 2.4 times higher than vasectomy reversal, even in men with previous failed vasectomy reversal (6).

Vasovasostomy is a safe and cost-effective management option for postvasectomy infertility. Although the average interval until pregnancy after successful microsurgical reconstruction is 12 months, reversal surgery has significant advantages over ART: the normal partner avoids treatment and

subsequent children are possible without the need for further intervention. The ASRM Guidelines recommend the use of microsurgical reconstruction if the obstructive interval following a vasectomy is <15 years and no female fertility risk factors are present (15). The use of ICSI with sperm retrieval is recommended if advanced female age (>37 years of age) or fertility factors requiring IVF (e.g., tubal disease) are present, if the chance for success is greater with this technique, or if the couple prefers this method for financial or other reasons (15).

# CHAPTER 58 ■ MICRO SURGICAL VARICOCELECTOMY

ARMAND ZINI AND ZIV MAIANSKI

A varicocele is an abnormal dilation of the pampiniform plexus of the testis. It is reported that 35% to 40% of infertile men have a palpable varicocele (dilated testicular veins), whereas the prevalence of a varicocele in the general male population is about 15% (1,2). Despite extensive study, the exact mechanism by which varicocele influences fertility remains unclear. Various theories continue to be discussed, such as abnormal testicular temperature regulation with elevated scrotal temperature, reduced perfusion of the affected testicle due to venous stasis and backflow of toxic substances of either adrenal or renal origin, and changes in the testicular endocrine milieu (2).

The effect of varicocelectomy on male fertility is also controversial (3,4). Uncontrolled studies have generally shown improved semen quality and pregnancy outcome after surgery (3). On the other hand, the results of randomized, controlled studies of varicocelectomy for clinical varicocele are equivocal (4,5). Nonetheless, varicocelectomy remains a commonly treated condition in men with infertility in North America (6). The benefit of varicocele repair must be balanced by the risk associated with the procedure itself. Therefore, it is important to select the procedure with the highest success and lowest complication rate.

---

## DIAGNOSIS

---

Varicoceles develop during early adolescence, at which time they usually produce no symptoms. Therefore, in the adolescent, the detection of a varicocele is by routine physical examination of healthy individuals. In contrast, in the majority of adult cases, the patient is referred to the urologist following a poor semen analysis. On occasion the patient may provide a history of dull scrotal ache or heaviness upon prolonged standing or exertion.

The physical examination should be performed in a warm room. The patient should be examined in the standing and supine positions, before and after a Valsalva maneuver. Careful palpation of the pampiniform plexus and measurement of testicular size (preferably by a standard orchidometer) are essential. The Valsalva maneuver can provoke engorgement of the plexus. Long-standing varicocele can induce a reduction in volume of the affected testis, usually the left one.

Varicoceles can be classified into one of three grades based on physical examination:

1. Grade I: small, palpable, following Valsalva maneuver only
2. Grade II: moderate, clearly palpable but not visible
3. Grade III: large, visible enlargement of the pampiniform plexus

Scrotal ultrasound including Doppler is a valuable tool to confirm the physical findings when the clinical exam is difficult (e.g., in obese men, when there has been prior scrotal surgery, or when the testicle has a high scrotal position) and for objective measurement of testicular size.

Abnormalities in semen analysis include a decrease in sperm concentration and motility and an increase in abnormal morphologic forms classically described as “stress pattern.” However, none of these seminal findings are specific to varicocele.

---

## INDICATIONS

---

The indications for repairing varicoceles in adolescents include the following:

1. Palpable left varicocele with associated ipsilateral testicular atrophy (with the volume of the left testis being at least 20% less than that of the right)
2. Palpable varicocele with abnormal semen analysis results
3. Large symptomatic (painful) varicocele
4. Bilaterally palpable varicocele with testicular atrophy

Although prophylactic treatment of adolescent varicocele (for prevention of future infertility) is not recommended, it is important to follow untreated patients, since no test can predict whether an adolescent will be fertile or infertile.

Based on the Best Practice Policies for Male Infertility of the American Urological Society (5), varicocele treatment should be offered to the male partner of a couple attempting to conceive when all of the following are present:

1. A varicocele is palpable.
2. The male partner has one or more abnormal semen parameters or sperm function test results.
3. The couple has documented infertility.
4. The female partner has normal fertility or potentially correctable infertility.

In addition, testicular pain associated with varicocele (in the absence of other pathology), psychological concern regarding future fertility, and cosmetic reasons are all relative indications. Varicocele repair is not indicated in men with normal semen analyses or a subclinical (nonpalpable) varicocele.

---

## ALTERNATIVE THERAPY

---

Several approaches exist for varicocelectomy, including retroperitoneal and inguinal open techniques, microsurgical inguinal and subinguinal approaches, laparoscopic repairs, and radiographic embolization. The microsurgical varicocelectomy, low inguinal or subinguinal, as first described by Marmar et al. (7), is preferred by many urologist and male infertility experts because it is associated with a higher success rate and lower morbidity than nonmicrosurgical techniques (8,9).

The subinguinal approach is associated with less operative and postoperative pain than the inguinal approach because, with the former technique, the external oblique aponeurosis is not opened. However, the subinguinal approach is more challenging owing to the greater number of vessels (arteries and veins) encountered at the subinguinal level compared to the inguinal canal.

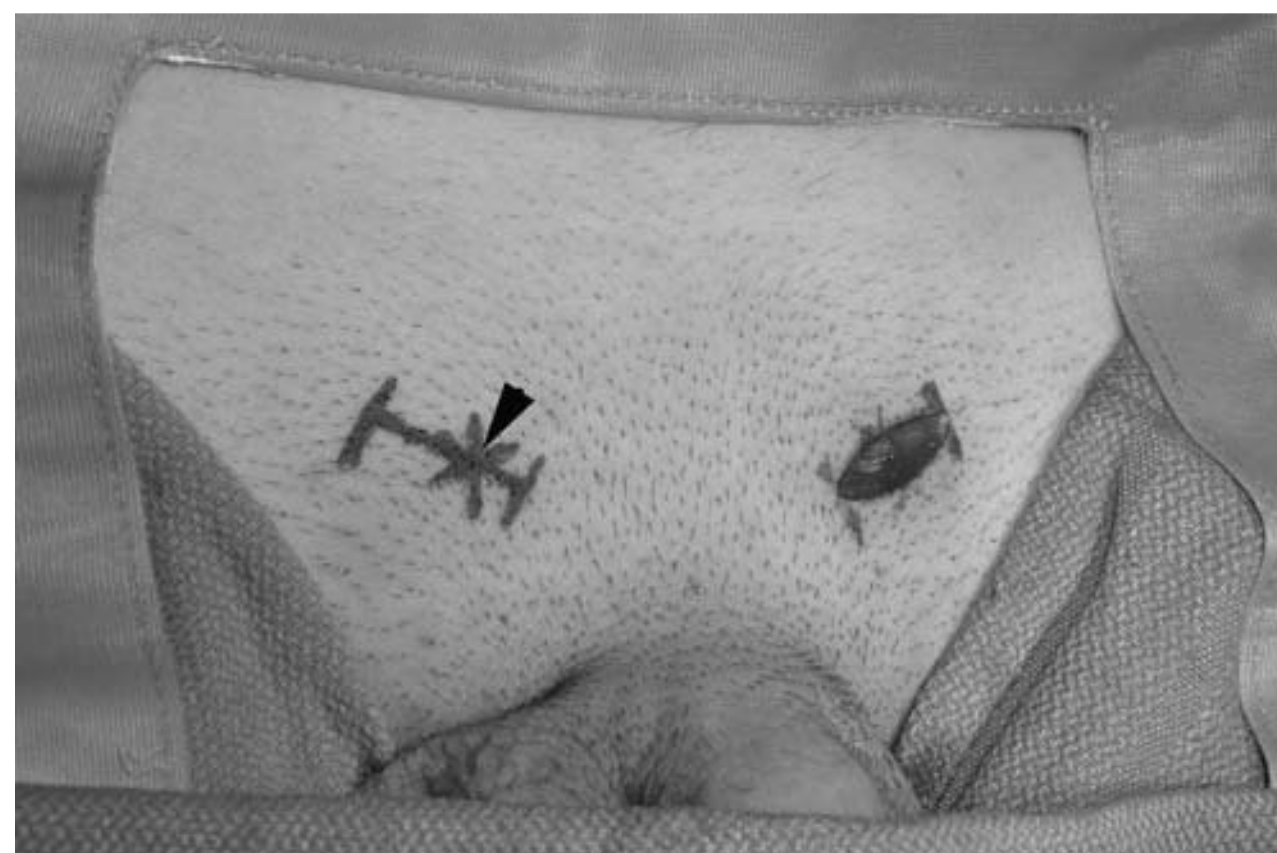

---

## SURGICAL TECHNIQUE

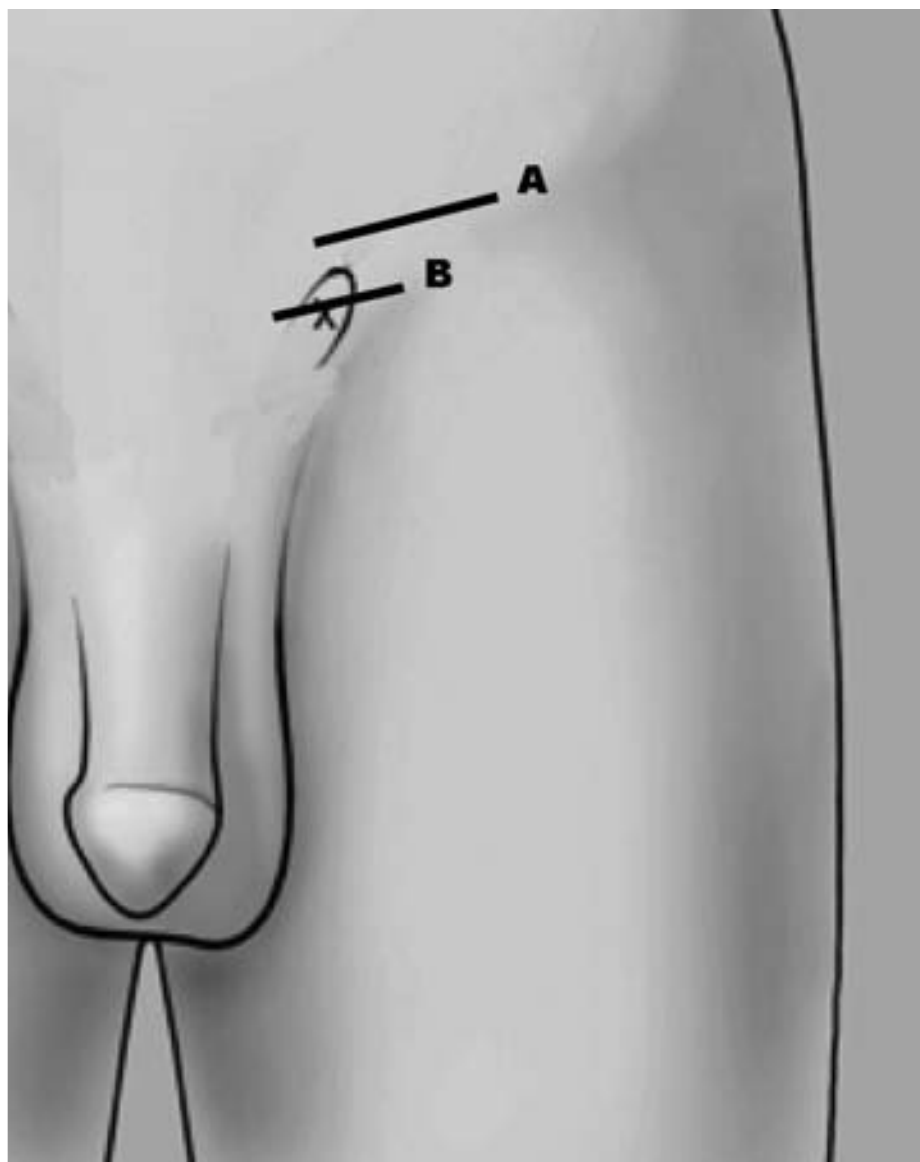

---

For the subinguinal approach, optical magnification is mandatory to avoid injury to the testicular artery and lymphatic vessels. For a better cosmetic result in the case of bilateral varicocelectomy, we recommend marking the incision sites (Fig. 58.1). The inguinal area is prepared and draped in the standard sterile way.

We start with a 2- to 3-cm oblique skin incision centered over the external inguinal ring, as previously described (Fig. 58.2) (8). The incision is deepened through the Camper and Scarpa fasciae by lifting these layers with a mosquito clamp and dividing the tissue with monopolar electrocautery. The spermatic cord is exposed by placing two small Richardson retractors at the extremities of the incision and by sliding a finger along the course of the spermatic cord, starting at the

**FIGURE 58.1** The position of the right and left subinguinal incisions (approximately 2.5 cm long) for microsurgical varicocelectomy. The arrowhead points to the location of the right external inguinal ring.

**FIGURE 58.2** Illustration demonstrating the location of the inguinal (*A*) and subinguinal (*B*) incisions for microsurgical varicocelelectomy (the position of the external inguinal ring is shown).

**FIGURE 58.3** The spermatic cord is grasped with the Babcock clamp and delivered through the incision.

external ring and ending at the upper scrotum. The cord is then grasped with a Babcock clamp (Fig. 58.3), delivered, and placed over a large (1-in.) Penrose drain. During this maneuver, care is taken to spare the ilioinguinal nerve and the genital branches of the genitofemoral nerve. The testicle is then delivered through the wound by gently pulling on the cord and pushing the testicle cephalad. Once the testicle is delivered, the gubernacular veins and external spermatic perforators are exposed, clipped, and divided (Fig. 58.4).

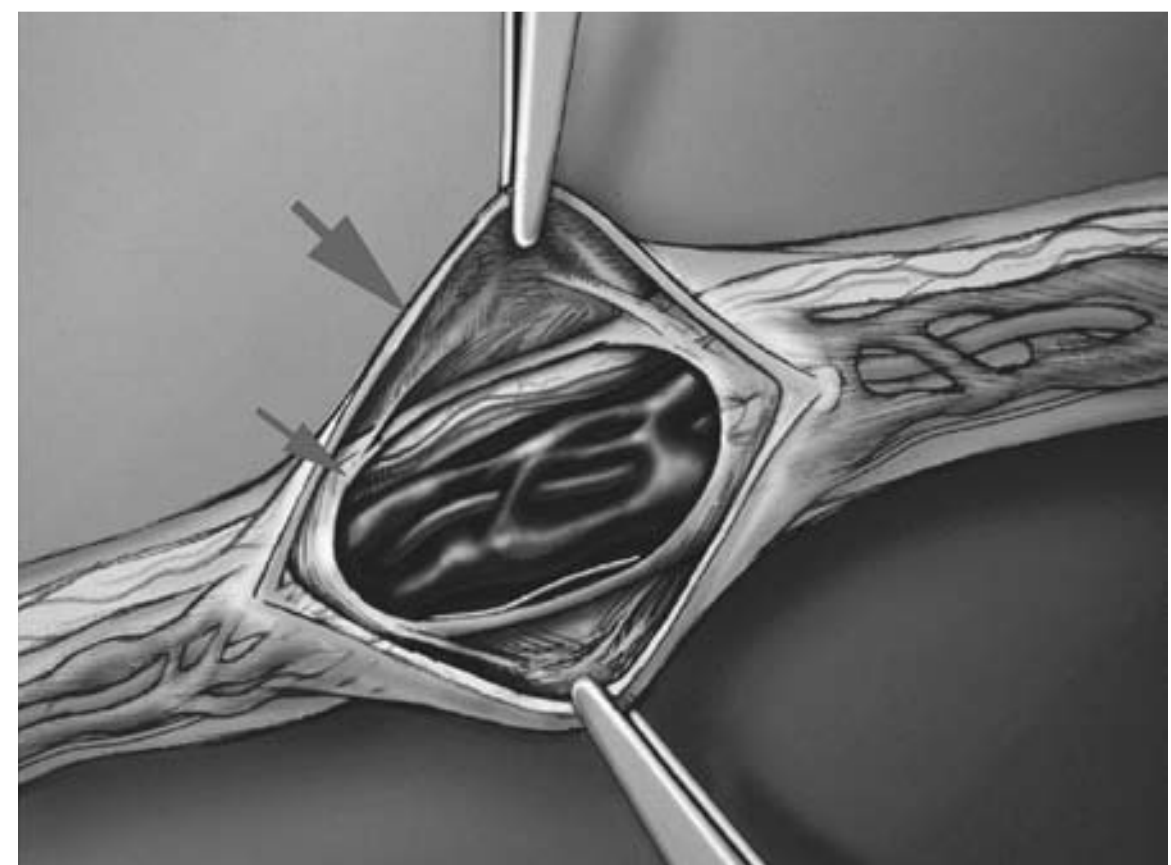

The testicle is returned to the scrotum, and the spermatic cord is elevated on a large Penrose drain. The microscope is then brought into the operating field and the cord examined under  $8\times$  to  $15\times$  magnification. The external and internal spermatic fasciae are gently lifted (Fig. 58.5) and incised in the direction of the fibers using the monopolar electrocautery.

**FIGURE 58.4** The testicle is delivered through the subinguinal incision. The spermatic cord (*small arrowhead*) and the gubernaculum (*large arrowhead*) are depicted.

**FIGURE 58.5** The external spermatic fascia is lifted with two smooth forceps in preparation for longitudinal incision of this fascia.

**FIGURE 58.6** Illustration demonstrating the spermatic cord after longitudinal incision of the external (*large arrow*) and internal spermatic fasciae (*small arrow*).

The internal spermatic vessels are exposed and examined (Fig. 58.6).

To simplify the procedure and protect the vas deferens and its vessels from potential injury during subsequent cord dissection, we first create a window between the internal spermatic vessels and the external spermatic fascia such that the internal

**FIGURE 58.7** The spermatic cord is divided into two packages with a 1-in. Penrose drain between (a) the contents of the internal spermatic fascia (*large arrowhead*) and (b) the remainder of the cord, including the vas deferens and cremasteric fibers (*small arrowhead*).

spermatic vessels are separate from the external spermatic fascia and its associated structures (cremasteric fibers, external spermatic vessels, vas deferens and its vessels) (10). A second Penrose drain is then introduced between the internal spermatic vessels and the external spermatic fascia and its associated structures (Fig. 58.7).

We first dissect the contents of the internal spermatic fascia (lying on top of the most superficial Penrose drain). Subtle pulsations will usually reveal the location of the underlying internal spermatic artery(ies). Once identified, the artery is dissected free of all surrounding veins by blunt dissection using a microsurgical needle driver and is then encircled with a 2-0 silk ligature for identification. Care is taken to also identify and isolate a number of lymphatics (usually three to six channels), and these are also encircled with a 2-0 silk ligature. All internal spermatic veins are clipped or ligated (with 4-0 silk) and divided. At the end of the first dissection, the cord is skeletonized such that only the identified artery(ies) and lymphatics are preserved.

We then elevate and dissect the contents of the external spermatic fascia (lying between the two Penrose drains). The vas deferens and its associated vessels are readily identified and preserved. Any cremasteric artery is also preserved. The remaining cremasteric fibers and veins are ligated and cut, thus skeletonizing the cord. At the completion of varicocelectomy, the cord should contain only the testicular artery or arteries, vas deferens and associated vessels, and spermatic cord lymphatics. The wound is irrigated with 1% Neomycin irrigation, and the Scarpa and Camper fasciae are closed with a single 3-0 chromic catgut suture. The incision is infiltrated with 0.5% Marcaine solution with epinephrine, and the skin is closed with a running 4-0 Vicryl subcuticular closure reinforced with Steri-Strips. A dry sterile dressing is applied.

---

## OUTCOME

---

Several publications have addressed the efficacy of varicocelectomy as a treatment for male infertility. In general, varicocelectomy is associated with an improvement in several sperm

parameters and with pregnancy rates in the range of 40% to 60% (3). However, most of these studies are retrospective, nonrandomized, and heterogeneous (3). Several recent reviews have critically examined the results of randomized, controlled trials of varicocelectomy. When all randomized trials are evaluated (including studies of subclinical varicocele and those of men with normal semen parameters), the data do not support the practice of varicocelectomy for male infertility (4). However, in North America, it is not common practice to treat subclinical varicoceles and/or men with normal semen parameters (6). In a recent analysis including only randomized studies of clinical varicoceles with abnormal semen parameters, the data support the practice of varicocelectomy for male infertility (5).

Most studies of adolescents with varicocele indicate that varicocelectomy has a beneficial effect on testicular function. In general, surgery is indicated in boys with testicular atrophy and/or abnormal semen parameters. Controlled studies indicate that at follow-up evaluation (1 to 15 years), varicocelectomy is associated with higher sperm parameters and higher testicular volumes than no treatment (11,12).

---

## COMPLICATIONS

---

There are three complications specific to varicocelectomy:

1. Hydrocele formation. This complication is believed to be due to ligation of lymphatic channels. The postoperative incidence of hydrocele is significantly lower with microsurgical surgery (0% to 0.69%) than it is with the retroperitoneal approach (7% to 9%), laparoscopic ligation (12%), or conventional inguinal varicocelectomy (3% to 30%) (8,9). Hydrocele repair (hydrocelectomy) is indicated for the management of a large, symptomatic (painful) hydrocele.
2. Recurrence. This generally results from incomplete ligation of collateral venous channels. The recurrence rate associated with microsurgery (<2%) is significantly lower than that with the retroperitoneal (15% to 25%), inguinal (5% to 15%), and laparoscopic approaches (5% to 15%) (8,9). This complication can be corrected by a repeat surgical procedure or by radiographic embolization. However, a redo varicocelectomy is often technically challenging and may pose a greater risk of complications (e.g., testicular atrophy, hydrocele).
3. Testicular ischemia and atrophy. These are a result of injury to the testicular artery. The incidence is likely very low owing to the collateral vasculature (vasal and external spermatic arteries) supplying the testicle.

---

## SUMMARY

---

The use of the operating microscope during varicocelectomy allows for better identification (and preservation) of the testicular artery and lymphatic channels and for complete ligation of small collateral venous branches. Therefore, microsurgical varicocelectomy reduces the potential for complications to a minimum and, as such, is considered superior to nonmicrosurgical varicocelectomy (inguinal or subinguinal). However, microsurgical varicocelectomy, particularly the subinguinal approach, remains a technically challenging procedure that requires microsurgical expertise.

# CHAPTER 59 ■ TESTIS BIOPSY AND TESTICULAR SPERM EXTRACTION (TESE)

PETER N. SCHLEGEL

Testicular biopsy may serve as a diagnostic or therapeutic procedure, or both. Testicular biopsy is indicated for the classification of azoospermia as obstructive (where normal sperm production is documented on biopsy) or nonobstructive (where sperm production is markedly abnormal). For azoospermic men, testicular sperm extraction (TESE), a surgical procedure involving retrieval of one or more samples of testicular tissue, may procure spermatozoa that can be used for successful treatment with assisted reproduction. Whereas testicular biopsy was previously used only to document normal sperm production prior to possible reconstruction of reproductive tract obstruction, men with impaired sperm production (serum follicle stimulating hormone [FSH] more than three times normal levels) may be candidates for testis biopsy or TESE.

---

## TESTIS BIOPSY

---

A testis biopsy is performed to document the level of sperm production. It is used to determine whether obstruction is present for an azoospermic man with palpable vasa deferentia. Testis biopsy can also provide some diagnostic information for men with nonobstructive azoospermia. Since a single biopsy samples very little of the testis, it may not definitively determine if sperm are present in any area of the testis for men with nonobstructive azoospermia. Only men with a serum FSH less than three times the upper limit of normal levels will have normal sperm production. Azoospermic men with small or soft testes are highly unlikely to have sperm production,

but some of these men have limited foci of spermatogenesis that can provide sperm for assisted reproduction. All men (that we have evaluated) with congenital absence of the vas deferens, normal serum FSH levels, and normal-volume (>15-cc) testes had sperm production, obviating the need for biopsy. If performed for diagnostic purposes, biopsy should be performed on both testes, since substantial differences in sperm production may be present without a palpable difference in the testes. Up to 10% to 15% of men will have a substantial difference in sperm production in the two different testes.

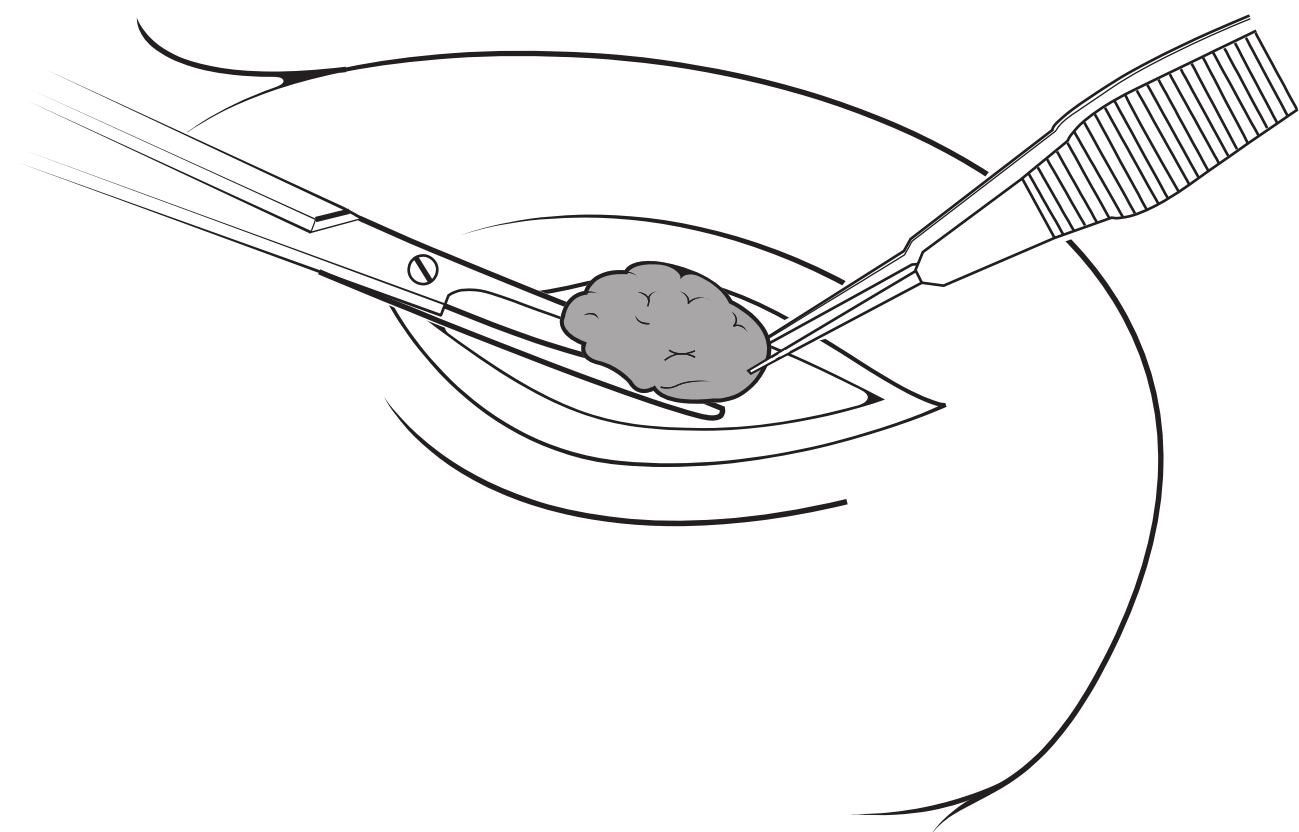

A second relative indication for testis biopsy is for the evaluation of azoospermic men with presumed abnormal production. These men with nonobstructive azoospermia (NOA) will typically have soft or small testes and an elevated FSH level. Although these patients are not expected to have completely normal production and reproductive tract obstruction, in selected cases sperm may be retrieved from the testis and used with assisted reproduction (intracytoplasmic sperm injection; ICSI). A biopsy may be of value in providing some prognostic information on which patients are candidates for ICSI. Unfortunately, a diagnostic biopsy is performed randomly and evaluates only a limited number of the hundreds of highly coiled seminiferous tubules within the testis. Subsequent attempts at sperm retrieval are dependent on finding the most advanced spermatogenic pattern of production in the 600 to 800 tubules present within each entire testis. An initial, random diagnostic biopsy that demonstrates at least one spermatozoon predicts the subsequent finding of sperm on attempted TESE in 80% to 95% of patients. The observation of at least germ cells (spermatogonia or spermatocytes) on diagnostic

biopsy predicts subsequent sperm retrieval with TESE for about 50% of patients. In all cases, the chance of sperm retrieval is determined by the most advanced pattern of sperm production on diagnostic biopsy, not the predominant pattern. For men who have only tubules with Sertoli cells in their lumen, the chance of sperm retrieval from another area of the testis is at least 35% to 40%. Therefore, the prognostic value of a diagnostic biopsy in NOA is limited.

Diagnostic information on the status of spermatogenesis is most reliably determined on evaluation of a thin-sectioned stained fixed tissue specimen. Specimens for tissue evaluation can be obtained by open biopsy, needle biopsy, or, occasionally, fine needle aspiration. Given the potential inadequacy of needle biopsy or fine needle aspiration, with its attendant risks to the vasculature of the testis, the open biopsy technique is preferable. The biopsy should be performed prior to reconstruction (rather than simultaneous to vasoepididymostomy) in most cases, so that a definitive analysis of sperm production is possible on fixed sections prior to further exploration. In addition, vasography is superfluous at the time of biopsy and should be avoided because of the risk of vasal injury or stricture.

### Technique

For open biopsy, the procedure may be done under local or general anesthesia. The testis must be accurately positioned with the scrotal skin tightly stretched over the testis, and the epididymis must be secured in a posterior position. A 1-cm incision is made transversely over the midportion of the testis (Fig. 59.1). The incision is carried out down to the tunica vaginalis. Cutting through this tunic is confirmed intraoperatively by the release of a small amount of clear fluid, expressed from within the space of the tunica vaginalis. A stay suture is placed through a nonvascularized region of the testis, preferably in a superior, medial, or lateral position. Nonreactive suture such as nylon or polypropylene is preferred. Optical loupes or an operating microscope may help identify vessels under the tunica albuginea, limiting the risk of injury to the testicular blood supply. A 0.5-cm incision is made through the tunica albuginea with a sharp no. 11 blade or a fine ophthalmic knife. A small sample of seminiferous tubules should extrude easily through this incision. If a sample is not easily delivered, the incision may not be long or deep enough. Excessive pressure to extrude tubules may adversely affect the architecture of the

**FIGURE 59.1** Technique for open testicular biopsy.

specimen. The sample should be cut off sharply and placed directly into Bouin solution or buffered glutaraldehyde. The use of formalin is avoided because of the deleterious effects that it has on tubular architecture. A “wet prep” of the cut seminiferous tubular surface or a “squash prep” of a separate piece of tubules on a glass slide, bathed with lactated Ringer solution and compressed with a cover slip, can be immediately examined under the microscope. The presence of sperm alone does not guarantee obstruction; however, only men with motile sperm are highly likely to have distal obstruction.

The tunical levels and the skin should both be closed to encourage hemostasis. Generous injection of 0.25% bupivacaine into the tunica vaginalis space and the subcutaneous areas provides excellent local anesthesia postoperatively.

### “Quick Prep” Cytologic Evaluations for Men with Presumed Obstruction

Since introduction of the testis biopsy as a diagnostic tool by Hotchkiss (3) and Charney (4), a variety of refinements in technique have been proposed to improve its usefulness. The role of a testis biopsy is to evaluate spermatozoal production and, indirectly, the presence or absence of reproductive tract obstruction. Since formal testis biopsy requires fixation, embedding, and staining of specimens for interpretation, biopsy and reproductive tract reconstruction must occur at different times. Quantitative analysis of testicular sperm production is possible by counting the number of mature spermatids per round tubule, as described by Silber and Rodriguez-Rigau (5). Several techniques have attempted to provide additional information or “quick analysis” from testis biopsy specimens.

#### Technique: Touch Prep

The touch prep (testicular touch imprint) is a cytologic smear of fluid from the cut surface of testicular parenchyma. The touch prep is performed during testis biopsy by taking a clean glass slide and placing it on the cut surface of seminiferous tubules after obtaining a specimen for permanent section. The slide is applied to the cut surface in several areas and immediately cytofixed with a commercial spray or 95% ethyl alcohol. The smear is subsequently stained via the Papanicolaou technique. Identification of individual spermatogenic cells as well as mature spermatozoa is possible. The most important role of the touch prep is to differentiate between late maturation arrest and complete spermatogenesis. Late maturation arrest may be difficult to assess on biopsy, since mature sperm with tails are uncommonly seen on the thin slice of a histologic slide, and quantitation of spermatozoal production is usually inferred from the number of mature spermatids present on fixed testis biopsy specimens. Quantitation of spermatozoa on touch prep allows direct evaluation of whether late maturation arrest may be present. Detection of fully formed testicular sperm morphology is also possible. A diagnosis of late maturation arrest spares the patient unnecessary scrotal exploration and even possible partial epididymectomy in a futile attempt at reconstruction.

Little published data exist regarding the frequency of late maturation arrest or the sensitivity (or specificity) of the touch prep technique. If late maturation arrest is very uncommon and false-positive results occur with the touch prep, then it is possible that more patients may be denied reconstructive microsurgery than are benefited by diagnosis of late maturation

arrest. Certainly, the touch prep can be of great value when late maturation arrest is suspected.

#### Technique: Wet Prep

A wet prep is performed after the standard biopsy specimen has been atraumatically transferred into Bouin solution. For the wet prep, a small additional piece of testis is placed on a clean glass slide with Ringer lactate, and the tissue is compressed under a glass cover slip. Analysis of this specimen can be performed immediately in the operating room. The presence or absence of sperm is documented, and the motility of sperm can also be evaluated.

The presence or absence of sperm is not very predictive of the findings on fixed permanent sections, but the presence of sperm motility may be of importance. A review of 100 consecutive testis biopsy and wet prep evaluations at Cornell indicated that histology (complete spermatogenesis) and cytology (presence of sperm on wet prep) were concordant in only 81% of biopsies. However, the presence of motile sperm had a 100% positive predictive value for the presence of reproductive tract obstruction. For the 18 cases where motile sperm were present, it would have been safe to proceed with microsurgical reconstruction of the reproductive tract. The converse is not applicable; the absence of motile sperm did not predict the absence of obstruction. In fact, 47 out of 65 men (72%) with obstruction did not have motile sperm present on wet prep.

Further data collection will be helpful to fully evaluate the relevance of sperm motility on wet prep examination during testis biopsy. Based on the data available, the presence of motile testicular sperm is highly suggestive of the presence of distal obstruction.

---

### Summary: Testis Biopsy

---

Testis biopsy is a diagnostic technique to assess spermatogenesis. It is most useful to determine whether obstruction is the cause of azoospermia. It is possible to take additional tissue during this diagnostic procedure that can be frozen for subsequent therapeutic trials of assisted reproduction. Cytologic evaluation, performed concurrently with standard testicular biopsy, may provide important adjunctive information. Touch prep techniques allow for the detection of late maturation arrest, not evaluable on fixed permanent sections. Touch prep techniques allow for evaluation of the presence of sperm within the seminiferous tubule, without removing an additional piece of testicular parenchyma. The wet prep technique allows an evaluation of sperm motility. The presence of sperm motility appears to be highly indicative of the presence of obstruction. Further information regarding the frequency of late maturation arrest and the endurance of the predictive value of wet prep sperm motility is needed. At present, cytologic techniques should best be considered adjuncts to, not a replacement for, careful evaluation of fixed permanent testicular biopsy specimens.

---

## SPERM RETRIEVAL FOR ASSISTED REPRODUCTION

---

It had long been thought that sperm exiting the testis lack maturity, motility, and fertilizing capability and that transit through the epididymis is essential to the acquisition of these

features. ICSI has changed our view of the functional capacity of testicular spermatozoa; these sperm are now routinely used to effect pregnancies using in vitro fertilization (IVF) with ICSI. In the unobstructed setting, sperm quality improves as the spermatozoa travel from caput to cauda epididymis; however, this is not true in the obstructed setting. In reproductive tract obstruction, improved motility is seen in sperm retrieved from the areas of the epididymis closer to the testis (caput) compared to the distal end of the epididymis (cauda). In contrast, sperm from the cauda region of an obstructed epididymis are in advanced stages of degeneration and necrosis. Normal sperm are absent or rare, whereas macrophages filled with phagocytized sperm remnants or sperm with blunt or coiled tails are seen in abundance. This finding is often referred to as “inverted motility.” Therefore, in some cases, it is possible that better sperm quality can be found in the testis.

Although it has long been thought that sperm exiting the testis are immature and incapable of fertilization, this holds true only in the unobstructed system. In obstruction, better-quality sperm can be found proximally, in the rete testis, vasa efferentia, or caput epididymis, and the more distal (cauda) epididymis is the site of sperm degeneration. These factors should be taken into account during any attempt at sperm retrieval.

---

### Nonobstructive Azoospermia: Heterogeneity of Sperm Production

---

It has previously been shown that human testicular histology is heterogeneous; that is, there can be small foci of abnormal spermatogenesis adjacent to normal seminiferous tubules. The converse of this previously casual observation is now the cornerstone of treatment for men with nonobstructive azoospermia. Successful sperm retrieval is possible in most TESE attempts in men with nonobstructive azoospermia, despite diagnostic testis biopsy specimens showing predominantly maturation arrest or Sertoli cell-only. The ability to retrieve sperm from the testes of men with nonobstructive azoospermia is independent of testicular size and FSH level but dependent on the most advanced level of spermatogenesis identified. All standard parameters of testicular evaluation (testicular volume, FSH, inhibin B levels) evaluate overall function of the testis. Since sperm retrieval and pregnancy are dependent on finding sperm in just one small focus of the testis, the only predictor of successful treatment is the most developed region of the testis, not the predominant pattern of testicular histology, overall testicular volume, or FSH. These observations suggest that nearly all cases of male factor infertility can potentially be treated.

---

### Intracytoplasmic Sperm Injection

---

Without question the most significant advance in the treatment of male infertility has been the technique of intracytoplasmic sperm injection or ICSI. The procedure involves the deposition of a single sperm directly into the oocyte cytoplasm with a micropipette. The advantages of this technique are that it bypasses all oocyte barriers so that even severely abnormal spermatozoa can successfully fertilize as long as the spermatozoon is viable. At this point, ICSI has been applied successfully to obstructive and nonobstructive azoospermia with fresh and thawed spermatozoa obtained from the epididymis and testis.

**FIGURE 59.2** Technique of fine needle aspiration of testis.

As ICSI has been more widely applied, it has become evident that female factors, not male, present the primary limitations to ICSI success in couples unable to achieve a pregnancy.

### Percutaneous Testicular Sperm Aspiration

As mentioned above, it was previously thought that sperm retrieved from the testis were incapable of fertilization. However, it is now well established that testicular sperm can be used effectively with ICSI, although the cytogenetic abnormality rate is higher in testicular than in epididymal or ejaculated sperm. Although testicular sperm retrieval has been reported in cases of obstructive azoospermia after epididymal aspiration attempts failed, the primary indication for open testicular sperm retrieval today should be for sperm acquisition in nonobstructive azoospermia.

Testicular sperm can be recovered using fine needle aspiration (FNA), percutaneous biopsy, or an open technique. The technique of percutaneous fine needle aspiration of the testis was initially described as a diagnostic procedure in azoospermic

men. In this procedure, the testis is stabilized between the surgeon's thumb and forefinger and a needle is inserted along the long axis of the testis. The needle is withdrawn slightly and redirected in order to disrupt the testicular architecture. The procedure is repeated until adequate testicular material has been aspirated. A Franzen needle holder can be used to provide negative pressure for needle aspiration (Fig. 59.2).

### Percutaneous Testicular Biopsy (PercBiopsy)

A technique of percutaneous biopsy of the testis has also been described. A 15-gauge biopsy gun with a short (1-cm) excursion is used to retrieve testicular tissue (Fig. 59.3). Anesthesia is achieved with a spermatic cord block, and multiple biopsies can be obtained through a single entry site. The patient may be prepared for this procedure by the topical application of local anesthetic as EMLA cream (Astra-Zeneca Pharmaceuticals, Worcester, MA). The core needle provides better sperm yield than fine needle aspiration and is relatively simple to use.

**FIGURE 59.3** Technique of percutaneous testicular biopsy (PercBiopsy).

---

## Testicular Sperm Extraction

---

Testicular sperm retrieval using an open biopsy technique (TESE) is rarely, if ever, indicated for men with obstructive azoospermia. The procedure is more invasive and is not needed in obstructive azoospermia to allow sperm retrieval. If an open procedure is performed, then our experience is that over 99% of men (184 out of 185) with obstructive azoospermia will have approximately  $100 \times 10^6$  or more sperm retrieved from the epididymis with microsurgical epididymal sperm aspiration (MESA). Sperm retrieval from the epididymis is far more efficient than testicular biopsy extraction in that it provides better sperm yield and motility when compared to that obtained with TESE in obstructive azoospermia. This provides sperm quantities sufficient for a virtually unlimited number of ICSI attempts. If testicular sperm retrieval is planned because of patient preference or if microsurgical expertise is not available, then PercBiopsy is the recommended approach.

---

## Nonobstructive Azoospermia

---

Testicular access is required for sperm retrieval in nonobstructive azoospermia since pockets of sperm production are limited and evaluation of large areas of the testis or multiple biopsies are usually needed to retrieve sperm. Although testicular fine needle aspiration has been used to retrieve spermatozoa in azoospermic men, documentation of its effectiveness is lacking for men with nonobstructive azoospermia. Two controlled studies have shown that open biopsy has a substantially higher yield of sperm for men with nonobstructive azoospermia (1,2). An alternative approach is to perform testis biopsies with intentional cryopreservation. However, this approach may lead to unnecessary biopsies, since up to 35% of “azoospermic” men will have sperm found with careful examination of the ejaculate on the day of planned simultaneous TESE-ICSI. In addition, sperm “retrieved” from the testis and frozen may not survive the freeze-thaw process in nonobstructive azoospermia. Moreover, multiple biopsies may be needed to retrieve sperm in men with nonobstructive azoospermia, and a simultaneous biopsy-by-biopsy analysis is required with careful analysis by an experienced embryologist. A microsurgical approach to TESE is presented herein.

---

## Microdissection Testicular Sperm Extraction (MicroTESE)

---

Microsurgical TESE offers the advantages of improved yield of spermatozoa per biopsy, less tissue removal (and less risk of testicle loss), and improved identification of blood vessels within the testicle, minimizing the risk of vascular injury and loss of remaining functional areas of the testis.

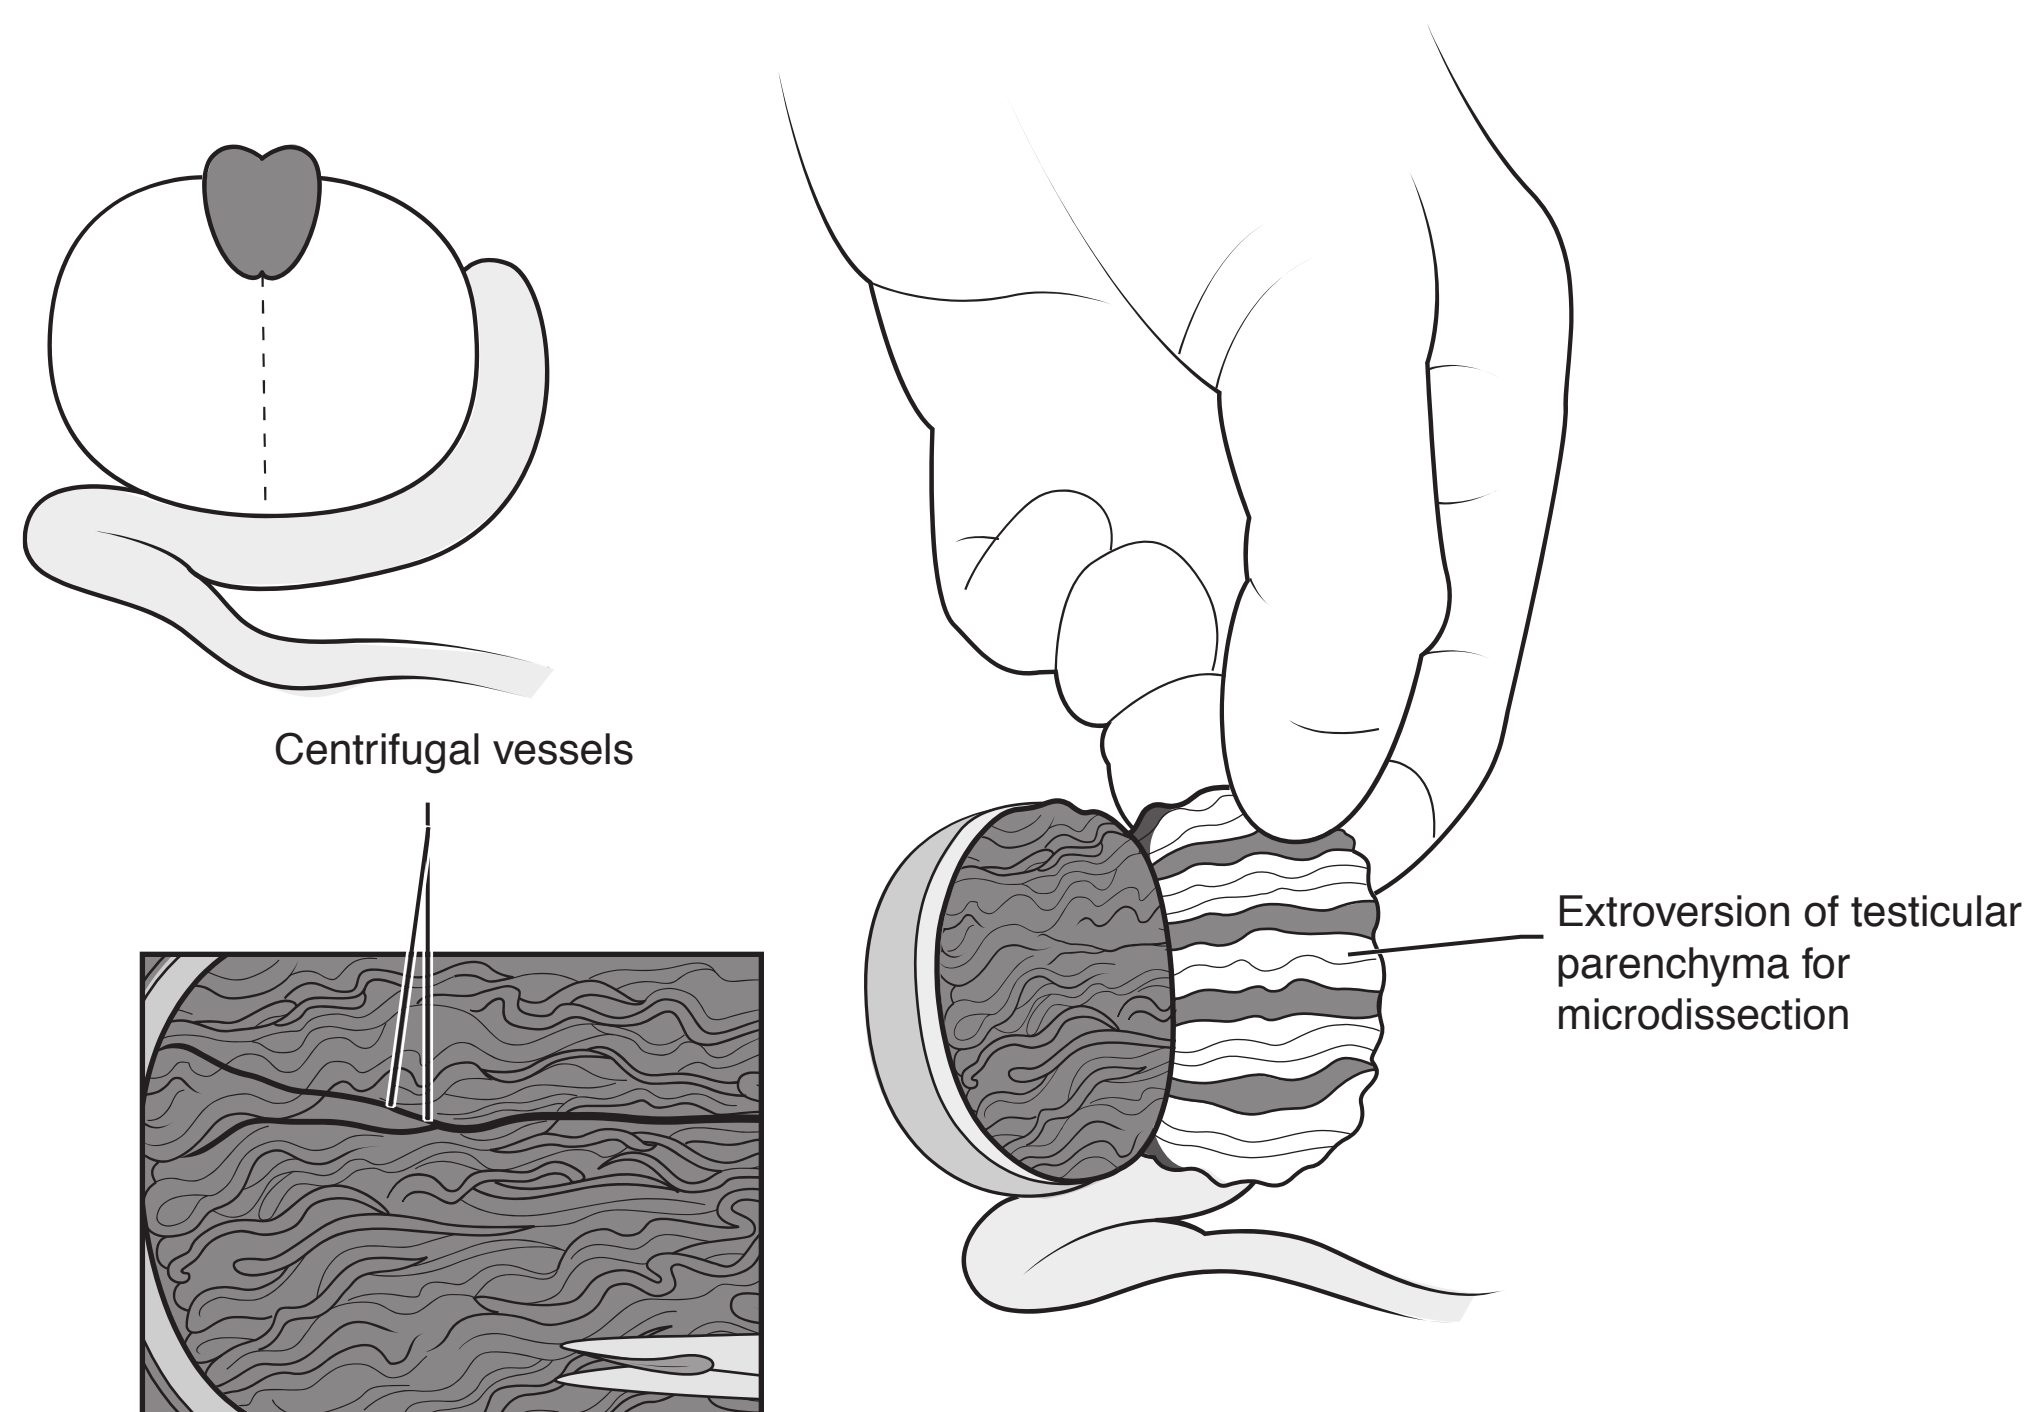

On the day of, or preferably on the day before, oocyte retrieval, scrotal exploration is performed through a median raphe incision under local or general anesthesia, and sperm are retrieved using an open technique. In order to confirm accurate identification of the testis, observe all testicular vessels, and avoid any injury to the epididymis, delivery of the testis is routinely performed.

Testicular blood vessels under the tunica albuginea are identified with  $6\times$  to  $8\times$  optical magnification. An avascular

region near the midportion of the medial, lateral, or anterior surface of the testis is chosen, and a generous incision in the tunica albuginea is created with a 15-degree ultrasharp knife, avoiding any capsular testicular vessels. With this approach, direct visualization of large areas of the testis can be achieved, which allows for either large sample biopsies or microdissection. Since the incision is directed at an avascular region, the sperm retrieval procedure is less traumatic than multiple “blind” biopsies. The testis is opened widely to allow direct examination of all areas of testicular parenchyma. Dissection between the tubules is also needed to view tubules that are not exposed with the initial approach (Fig. 59.4). The microdissection technique that we have applied allows the removal of tiny (2 to 3 mm; 3- to 5-mg volumes) of testicular tissue with improved sperm yield (1). The tubules containing sperm can often be identified visually under an operating microscope after opening the testis, when approximately  $10\times$  to  $15\times$  magnification is used to assist the biopsies. The tubules containing sperm production are directly identified based on their large size and white color. If all tubules appear uniform at high power magnification, then dissection is performed to allow access to other regions of the testis. Finally, if no sperm have been seen in microdissected samples, additional searching throughout testicular tissue is done, avoiding the centrifugal testicular vessels that course parallel to and between the septae that separate seminiferous tubules.

The excised testicular tubular segments are placed in buffered human tubal fluid or a similar culture medium supplemented with 6% Plasmanate. Isolation of individual tubules from the mass of coiled testicular tissue is achieved by initial dispersal of the testis biopsy specimen using scissors, preferably in a small Petri dish. Additional dispersion of tubules is achieved by passing the suspension of testicular tissue through a 24-gauge angiocatheter. Individual tubules may also be evaluated directly in the embryology laboratory immediately prior to ICSI, but the evaluation of sperm in the operating room during TESE provides critical information to the surgeon to determine how much dissection and/or removal of tissue is necessary.

Intraoperatively, a “wet prep” of the suspension is preferably examined under phase-contrast microscopy at  $200\times$  power in the operating room. If no spermatozoa are seen, then (a) additional samples of tissue are obtained through the same tunical incision, (b) the remainder of the testis is examined by evaluating the exposed regions of testicular tissue and (c) exposure of deeper tubules is effected by dissecting between the septae and everting the testicular tissue, and then (d) examination of the contralateral testis is performed if no sperm have been found. The sperm extraction process is complete when sperm are reliably identified in the wet preparation of a biopsy specimen. Otherwise sperm extraction attempts are stopped when all areas of the testis have been examined. Care must be taken to preserve vessels between and within the septae of the testis that contain the tubules. Additional incisions beyond the initial wide incision should be avoided, as they could adversely affect the blood supply to the testis. Operating through a limited incision may not allow the surgeon to adequately control bleeding within the testis. Not only does this potentially obscure the testicular tissue, but the scar tissue that develops within the testis postoperatively is primarily caused by postoperative bleeding within the testicle. Therefore, meticulous hemostasis with bipolar cautery during the procedure is important.

**FIGURE 59.4** Exposure during microdissection testicular sperm extraction (TESE).

Subsequent processing of the testicular tissue suspension, including mechanical disruption and/or additional enzymatic digestion of the specimens, is performed in the IVF laboratory. Aliquots of tissue can also be processed for cryopreservation.

### Results of TESE for Nonobstructive Azoospermia

We have done microdissection TESE on over 865 men with nonobstructive azoospermia. Sperm retrieval rates for azoospermic men are 63%. Once sperm are obtained, the testicular sperm will fertilize 55% of oocytes injected using the ICSI technique. Clinical pregnancies (fetal heartbeat seen on ultrasound) are obtained during 48% of successful sperm retrieval attempts for couples with nonobstructive azoospermia. Ongoing or delivered pregnancies occurred for 43% of successful attempts at sperm retrieval.

No etiology of azoospermia provided an absolute predictor for the presence or absence of sperm within the testes, except for the presence of complete deletions of the AZFa or AZFb regions of the Y chromosome. (Testicular volume and serum FSH levels did not predict sperm retrieval.) Sixty-four attempts at sperm retrieval-ICSI have been made where the man had testicular failure because of prior chemotherapy treatment. Sperm were obtained in 53% of attempts, slightly more

commonly in men previously treated with platinum-based regimens for germ cell tumor (73%) than in men treated for lymphoma with cytoxan-based regimens (48%). Of 91 attempts at sperm retrieval for men who have Klinefelter syndrome (47, XXY; nonmosaic), sperm were found for 68% of men, and clinical pregnancy (fetal heartbeat on ultrasound) was achieved in 43% of cases once sperm were retrieved.

### Summary: Sperm Retrieval

Sperm retrieval for use with the advanced form of assisted reproduction, ICSI, is now possible for many men with nonobstructive azoospermia. Men with azoospermia may have unique genetic defects, such as Y chromosome microdeletions, that should be evaluated prior to an attempt at conception. In obstructive azoospermia, several options exist to allow for sperm retrieval rates approaching 100%. In nonobstructive azoospermia, TESE is required and sperm retrieval is less certain. At the Weill Cornell Medical Center, 63% of couples with nonobstructive azoospermia have sperm retrieved from the testis with TESE, and 48% of couples achieved a clinical pregnancy using testicular sperm in nonobstructive azoospermia. Since some couples will not have sperm retrieved with TESE, the use of frozen donor spermatozoa as backup should be discussed with couples prior to simultaneous TESE-ICSI attempts.

# CHAPTER 60A ■ EPIDIDYMAL SPERM ASPIRATION

CIGDEM TANRIKUT AND MARC GOLDSTEIN

Obstructive azoospermia is the blockage of the male reproductive tract resulting in complete absence of sperm in the ejaculate. Up to 40% of azoospermic patients undergoing fertility evaluation will have an obstructive etiology (4). Fortunately, cases of obstructive azoospermia now comprise the most treatable of male factor problems owing to the development of advanced reproductive techniques: in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI).

Obstruction may be either congenital or acquired, occurring along any point of the male excurrent ductal system: epididymis, vas deferens, or ejaculatory duct. Congenital causes of obstructive azoospermia include congenital absence of the vasa deferentia and idiopathic epididymal obstruction. Acquired reasons for reproductive tract obstruction include prior vasectomy, previous genitourinary tract infection, iatrogenic injury related to prior surgery, and a history of pelvic or scrotal trauma. This chapter focuses on common techniques used in the setting of obstructive azoospermia to surgically extract sperm from the epididymis for use with a concurrent IVF-ICSI cycle or for purposes of cryopreservation for future IVF-ICSI cycles.

---

## DIAGNOSIS

---

Azoospermia in a man with normal-volume testes ( $\geq 20$  cc) and normal serum follicle stimulating hormone (FSH  $< 8.0$  U per L) suggests an obstructive etiology. If neither vas deferens is palpable on physical examination, obstructive azoospermia is due to congenital bilateral absence of the vasa deferentia (CBAVD), a reproductive tract anomaly associated with cystic fibrosis. Men with genetic mutations of the cystic fibrosis transmembrane conductance regulator (CFTR) gene may lack segments anywhere from the epididymis to the seminal vesicle, with resultant obstructive azoospermia (2,11). Screening for the CFTR gene mutation should be performed in the patient as well as in his partner, and genetic counseling should be provided.

Patients with obstructive azoospermia due to vasectomy will be apparent upon obtaining patient history. If physical examination reveals normal testicular volume and FSH is in the normal range, no further evaluation is warranted prior to proceeding with sperm extraction.

In patients with suspected or known obstructive azoospermia presenting with testis atrophy and/or elevated FSH, a testis biopsy may be considered to confirm normal spermatogenesis, proceeding with concurrent epididymal or testicular sperm extraction if sperm are identified.

---

## INDICATIONS FOR SURGERY

---

Although many postvasectomy patients are candidates for microsurgical reconstruction via vasovasostomy or vasoepididymostomy (see Chapters 56 and 57), not all such patients are willing or able to undergo reconstruction. Obstructive azoospermia related to blockages of the epididymides or vasa deferentia, regardless of etiology, may be addressed via surgical sperm retrieval followed by IVF-ICSI.

---

## ALTERNATIVE THERAPY

---

Surgical alternatives to epididymal sperm extraction in men with obstructive azoospermia include testicular sperm extraction via a variety of methods (see Chapter 59). Sperm obtained from men with chronically obstructed reproductive tracts usually have poorer motility and decreased fertilizing capability as compared with ejaculated sperm. The use of ICSI is essential to achieve optimal results with either epididymal or testicular sperm; thus the female partner must be willing and able to go through with an IVF cycle if surgically extracted sperm are to be used. Other alternatives about which the couple should be counseled include the use of donor sperm or adoption.

---

## SURGICAL TECHNIQUE

---

Sperm may be retrieved from the epididymis using either microsurgical or percutaneous techniques (Table 60A.1). Microsurgical epididymal sperm aspiration (MESA) can be performed on the same day as the partner's oocyte retrieval or at a separate time interval prior to oocyte retrieval with cryopreservation of procured sperm. Percutaneous epididymal sperm aspiration (PESA) does not often yield numbers of sperm sufficient to allow for cryopreservation and, therefore, should be performed synchronously with egg retrieval. Regardless of when sperm aspiration is performed relative to oocyte retrieval, it is imperative that an intraoperative sample be assessed under phase-contrast microscopy by a qualified embryologist to assess the quality of the sample.

In patients with obstructive azoospermia, sufficient quantities of sperm are generally obtained from aspiration on one side; however, the patient should be counseled that a bilateral procedure may be necessary.

TABLE 60A.1

## COMPARISON OF MESA AND PESA

	ADVANTAGES	DISADVANTAGES
<b>Microsurgical epididymal sperm aspiration (MESA)</b>	<ul style="list-style-type: none"> <li>• Lower risk for complications, less risk for spermatic cord or epididymal damage</li> <li>• Large numbers of sperm may be obtained and cryopreserved in multiple aliquots during single procedure</li> </ul>	<ul style="list-style-type: none"> <li>• General anesthesia preferred</li> <li>• Requires microsurgical skills</li> <li>• More expensive</li> <li>• Longer recovery</li> </ul>
<b>Percutaneous epididymal sperm aspiration (PESA)</b>	<ul style="list-style-type: none"> <li>• No microsurgical skill required</li> <li>• Local anesthesia ± sedation</li> <li>• Can be done in office</li> </ul>	<ul style="list-style-type: none"> <li>• Higher risk of complications, including hematoma, pain, and vascular injury to testes and epididymis</li> <li>• Variable success in obtaining sperm</li> <li>• Smaller quantity of sperm obtained than with MESA</li> </ul>

### Microsurgical Epididymal Sperm Aspiration (MESA)

MESA is most easily performed with the patient under general anesthesia, although spinal or local anesthesia may be used. The patient is supine on the operating table and anesthesia is induced. The scrotum is shaved and sterilely prepared and draped. A longitudinal median raphe or transverse hemiscrotal incision is made. The testis is delivered through the incision to gain direct access to the epididymis. The operating microscope is brought into the field at this time. The surgeon's non-dominant hand is used to hold the testicle while stabilizing the epididymis between the thumb and index finger. Under the operating microscope at 10× to 15× magnification, the microtipped bipolar forceps are used along the longitudinal plane of the epididymal tunic to create an avascular plane. The tunic is incised gently using a 15-degree ophthalmic microknife, taking care not to violate the underlying epididymal tubules. Hemostasis is attained using the bipolar cautery. A dilated epididymal tubule is selected and isolated, then incised with the microknife (Fig. 60A.1A). In an obstructed epididymis, sperm within the more caudal aspect tend to be of poorer quality, and better-quality sperm are usually found within the body or head of the epididymis, so the tubule should be selected accordingly. The epididymal fluid is touched to a sterile glass slide, a drop of saline is added, a cover slip is placed, and then the fluid is immediately examined under a bench microscope. When motile sperm are identified, a dry micropipette (5 μL; Drummond Scientific Co., Broomall, PA) or a standard hematocrit pipette is placed adjacent to the effluxing epididymal tubule (Fig. 60A.1B). Using an in-line syringe for aspiration is not recommended, as the negative pressure generated may disrupt the delicate epididymal mucosa. Sperm-containing fluid will be drawn into the pipette by simple capillary action (5). Two pipettes may be used simultaneously in order to expedite sperm recovery. The highest rate of flow is observed immediately after incising the tubule. Sperm quality progressively improves after the initial washout. Gentle compression of the testis and epididymis

using the thumb and index finger or a smooth-tipped microforceps enhances flow from the incised tubule. With patience, 25 to 50 μL of highly concentrated epididymal fluid can be recovered, containing approximately 75 million sperm. This is diluted in multiple aliquots of 2 to 3 mL of human tubal fluid medium, such that there are approximately 5 million sperm per milliliter. Those specimens not used immediately for IVF-ICSI are cryopreserved for possible future use. If no sperm or immotile sperm are obtained at the initial incision site or the quantities acquired are inadequate, additional incisions are made more proximally along the epididymis or even at the level of the efferent ductules until motile sperm are obtained.

Once adequate quality and quantity of sperm are attained, the tubular incisions may be closed using 10-0 Prolene or bipolar cautery. After ensuring meticulous hemostasis, the edges of the epididymal tunic are reapproximated using a 6-0 or 8-0 nonabsorbing monofilament suture in a running fashion. The testis is reduced into the hemiscrotum, and the scrotal incision

**FIGURE 60A.1** Microsurgical epididymal sperm aspiration. **A:** Selection and isolation of dilated tubule (10× magnification). **B:** Aspiration of sperm into micropipette by capillary action (15× magnification).

is closed in layers in standard fashion. Fluffed gauze and an athletic supporter are placed on the patient prior to waking from anesthesia.

---

## Percutaneous Epididymal Sperm Aspiration

---

Percutaneous epididymal sperm aspiration (PESA) is a simpler method of obtaining epididymal sperm that does not require microsurgical experience (1). It may be performed under local anesthesia via spermatic cord block, with or without the use of intravenous sedation. After initiation of anesthesia and sterile preparation and draping of the scrotum, the testis is stabilized manually with the nondominant hand or by the assistant. The surgeon grasps the epididymis between thumb and index finger. A small (21- or 22-gauge) needle is percutaneously inserted into the epididymis, and an attached syringe containing a small amount (approximately 0.1 cc) of human tubal fluid is used to gently aspirate fluid from the epididymis. A small amount of this fluid is assessed under a bench microscope to confirm the presence of sperm and ascertain motility. Multiple punctures may be required to obtain sufficient sperm-containing fluid. If no sperm are retrieved, as occurs in at least 20% of sperm retrieval attempts (6), then one must proceed with MESA, testis biopsy, or testicular aspiration.

Given that the numbers of sperm retrieved with PESA are often not sufficient to allow for cryopreservation, repeat procedures may be warranted for multiple IVF cycles. In addition, there is a risk for the development of scrotal hematoma or injury to the epididymal or testicular vessels given the blind nature of this procedure.

---

## OUTCOMES

---

### Complications

---

Complications after either procedure are infrequent and include wound infection, scrotal hematoma, epididymal scarring, and injury to the spermatic cord vasculature, possibly

leading to testis atrophy and impaired testis function. Scrotal exploration is rarely indicated for management of any of these complications. Given the blind nature of PESA, the risks of hematoma, scarring, and spermatic cord injury are higher than those associated with MESA.

---

## Results

---

An experienced microsurgeon can retrieve sperm from the epididymis via MESA in over 99% of patients with obstructive azoospermia (7,10). Similar success rates are possible even if previous scrotal procedures have been performed or if extensive scarring is present. If the entire epididymis is obliterated from prior surgery or infection, the efferent ductules of the testis can still be exposed by reflection of the caput epididymis; one should be able to aspirate sperm from at least one of these tubules.

Reported sperm extraction rates via PESA are somewhat lower than those reported for MESA, averaging about 80% (3). The ability to cryopreserve sperm obtained from men with obstructive azoospermia can help alleviate concerns regarding coordination of sperm extraction with oocyte retrieval, as well as offer the possibility of avoiding repeat sperm extraction if good quantities of motile sperm are obtained at the initial extraction. No clearly identified differences in outcomes between the use of fresh or cryopreserved and thawed sperm have been demonstrated (9).

Using surgically extracted epididymal sperm warrants IVF with ICSI to accomplish oocyte fertilization. Successful fertilization rates using ICSI in conjunction with surgically retrieved epididymal sperm are approximately 72% (8). Fertilization and pregnancy rates for both MESA and PESA are comparable. Of critical importance for successful outcomes, however, is the collaborative effort of the urologist along with the embryology team and reproductive endocrinologist.

# CHAPTER 60B ■ EPIDIDYMECTOMY

DAVID M. NUDELL AND LARRY I. LIPSHULTZ

The epididymis is a complex tubular network that connects the testicular efferent ducts to the vas deferens. In total, the single epididymal tubule measures 3 or 4 m. In its coiled form, the epididymal tubule is contained within the tunica vaginalis of the epididymis, creating a crescent-shaped organ intimately attached to the posterolateral aspect of the testis. The epididymis is anatomically divided into caput, corpus, and cauda regions (head, body, and tail, respectively) (Fig. 60B.1). While there are histologic differences in the delicate epididymal tubule between these regions, there are no gross and discrete dividing lines between the regions. The blood supply to the caput and body of the epididymis arises from a division of the testicular artery. The cauda epididymis is usually supplied by a branch of the vasal artery, but rich anastomotic connections usually exist. The epididymis functions primarily in sperm transport and maturation.

**FIGURE 60B.1.** Sagittal section of the testis and epididymis. The epididymis is seen attached to the posterolateral aspect of the testis. The efferent ducts (vasa efferentia) of the testis consist of 10 to 20 channels draining individual lobes of the testis into the globus major of the epididymis. The epididymal tubule gradually gains more smooth muscle components as it progresses toward the vas deferens, which is seen exiting the inferior, most distal aspects of the epididymis.

---

## DIAGNOSIS

---

This procedure is performed rarely, and the diagnostic steps are individualized to each patient.

---

## INDICATIONS FOR SURGERY

---

Currently, epididymectomy is done more commonly for complex epididymal cystic disease, chronic scrotal pain, or postvasectomy pain syndromes. Other indications are for abscess or chronic infections of the epididymis.

---

## ALTERNATIVE THERAPY

---

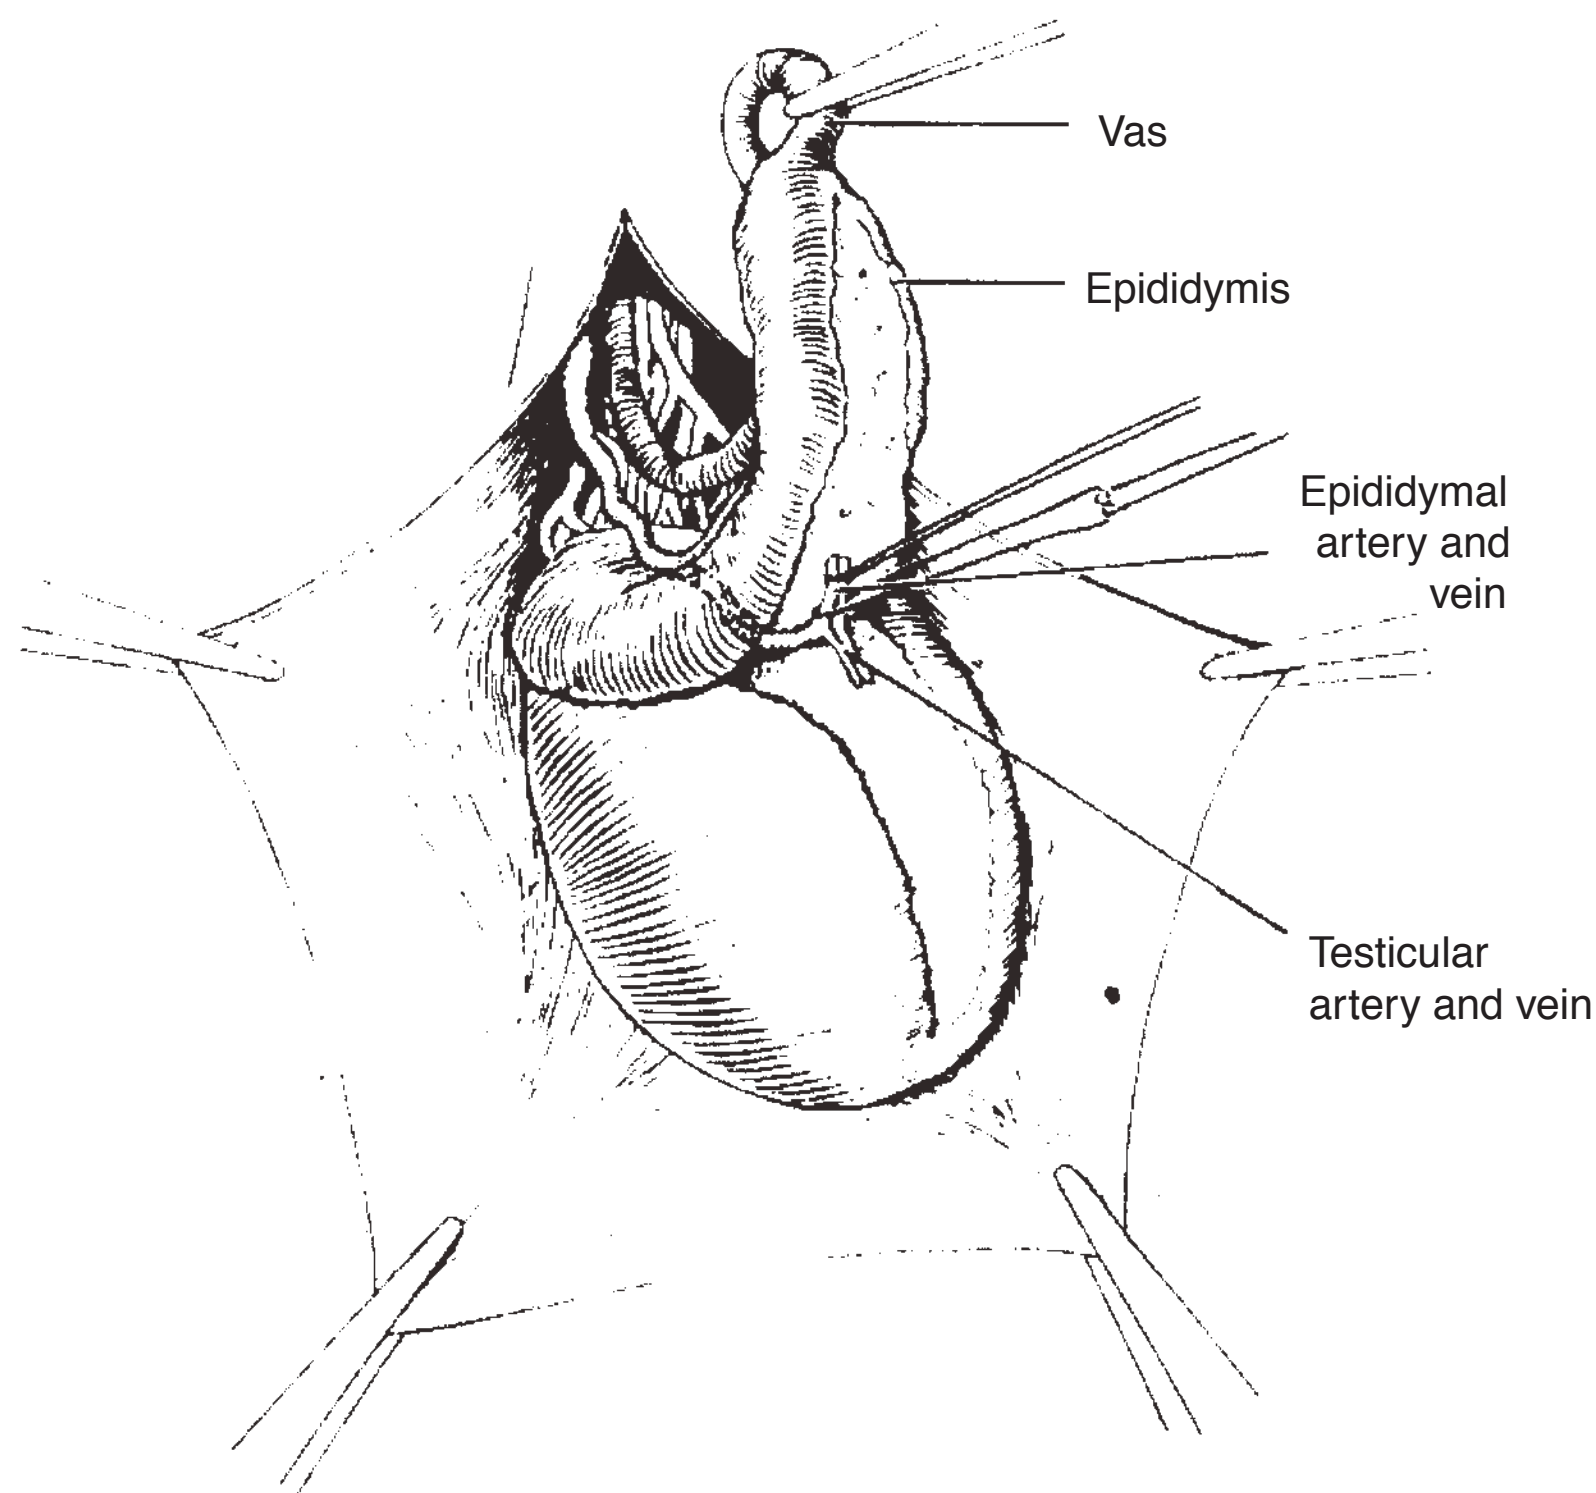

Surgical removal of all or part of the epididymis is done uncommonly, especially with the availability of broad-spectrum antibiotics. In the past, most cases were performed for abscess, chronic infection, or tuberculosis of the epididymis. In cases of scrotal abscess, the epididymis may be removed in an attempt to save the testis from overwhelming orchitis (1). If tuberculosis is suspected, it is critical to obtain appropriate cultures at the time of surgery.

---

## SURGICAL TECHNIQUE

---

After administration of appropriate antibiotics if necessary, either general or local anesthesia is induced. If local anesthesia is used, a generous cord block and infiltration of the skin overlying the incision will be adequate. A transverse scrotal incision is made that is just large enough to deliver the testis, epididymis, and distal vas deferens. The initial incision may be carried down through the tunica vaginalis without extensive dissection of the plane between the tunica vaginalis and dartos muscle layer. This will allow delivery of the intravaginal contents. Often, the distal vas deferens can be accessed in this way as well. If extensive scarring or infection has occurred, it may be necessary to dissect the tunica vaginalis free of the dartos muscle layer due to dense adhesions. In these cases, sharp dissection of the testis and epididymis from the undersurface of the tunica vaginalis will usually be necessary as well. In cases performed for postvasectomy pain, it is important to remove the epididymis and vas all the way up to and including the vasectomy site or sperm granuloma (2). If performed for other reasons, the vas may be divided and ligated at the junction of the convoluted and straight vas with an absorbable suture. In

**FIGURE 60B.2.** Drawing demonstrating the correct plane of dissection during epididymectomy. The main spermatic cord structures are seen posterior and medial as they enter the testis. Injury to these structures can be avoided by dissecting only the plane between the epididymis and testis, which will usually contain only epididymal blood supply. The vascular pedicle to the epididymis may be encountered in the dissection plane between the testis and epididymis. The exact location of this blood supply can be variable.

patients with complex cystic disease, it is critical to ascertain the desire for future fertility. If fertility is still desired, epididymectomy should be avoided. If surgery is necessary in this situation, the larger cysts should be removed from the epididymis individually with the use of an operating microscope to avoid epididymal tubular obstruction.

After the vas is divided, it is dissected back to the vasoepididymal junction and dissection begun in the plane between the epididymis and the testis (Fig. 60B.2). Optical loupe magnification can be helpful in maintaining the correct plane and avoiding injury to the testis or spermatic cord vessels. The dissection is done sharply with fine Iris-type scissors and Bovie cauterization. The epididymis is grasped between the thumb and index finger of the nondominant hand and elevated off the testis as the dissection progresses from inferior to superior. The epididymal artery may be encountered midway up the dissection of the epididymis, but its exact location may be variable. If encountered, the artery should be ligated. The main spermatic cord blood supply containing the testicular artery will usually be found medial and posterior to the dissection in the region of the head or proximal body of the epididymis (Fig. 60B.2). In cases where the normal anatomy is distorted, it is important to avoid dissection into the spermatic cord, as this will lead to testicular infarction and subsequent atrophy. The most superior attachment of the epididymis to the testis consists of the testicular efferent ducts. These can be ligated with a single absorbable suture or cauterized. At this point, the specimen can usually be removed intact.

After the area is irrigated, the epididymal bed is inspected closely for bleeding. Vessels can be cauterized or ligated with small, absorbable sutures. The edges of the tunica along the bed of the epididymis should be approximated with several absorbable sutures for further hemostasis and to prevent leakage of testicular sperm from the efferent ducts. If extensive

dissection has been performed or purulent material was encountered, a drain should be left in place that exits in a dependent fashion. Otherwise, the tunica vaginalis is closed with a running absorbable suture followed by closing the dartos layer and skin with interrupted or running absorbable sutures.

---

## OUTCOMES

---

### Complications

---

Complications of epididymectomy include hematoma formation, orchitis, skin infection, chronic pain, and infertility. Inadvertent injury to the spermatic cord during a difficult dissection may lead to testis atrophy.

---

### Results

---

The results of epididymectomy vary with the indications for surgery. In patients with complex, symptomatic cystic disease, patient satisfaction is usually high following surgical removal (3). In patients with chronic orchalgia, epididymectomy has produced poor results, with around 50% improvement rates in several series (3–5). This may not be surprising given the high incidence of perineural fibrosis found in the pathology specimens from patients undergoing epididymectomy for pain syndromes (2). However, in well-selected patients, satisfaction as high as 90% has been obtained (5). Poor predictors of success include pain extending into the groin region, failure to alleviate pain following a well-placed spermatic cord block, and normal appearance of the epididymis on preoperative ultrasound (5). Selective denervation of the spermatic cord may be

another alternative to epididymectomy for chronic pain syndromes (6). This technique involves skeletonizing the spermatic cord surgically, leaving only the vas deferens, a few lymphatic channels, and the testicular artery intact. This procedure is best accomplished through a subinguinal incision with the use of an operating microscope. The long-term results of this relatively new approach remain to be determined.

For patients with postvasectomy pain syndromes, epididymectomy results have been mixed. In general, about 50% of patients report long-term satisfaction and prevention of ongoing pain following epididymectomy (2). As mentioned, it is important in these cases to include the vas deferens up to and including the vasectomy site in the surgical specimen.

Epididymectomy is performed most commonly for complex cystic disease, chronic pain syndromes, postvasectomy pain syndromes, and nonhealing infections. There are slight but important differences in the technique used for each of these indications. For example, during epididymectomy performed for postvasectomy pain syndromes, excision of the proximal vas up to and including the vasectomy site is necessary. This is not necessary in patients with cystic disease or with idiopathic orchalgia. In patients with cystic disease who desire fertility, epididymectomy should be avoided and the larger cysts, if necessary, should be removed microsurgically. In patients with infection, it is important to obtain appropriate intraoperative cultures and insert a dependently directed drain.

# CHAPTER 61 ■ EJACULATION INDUCTION PROCEDURES: PENILE VIBRATORY STIMULATION AND ELECTROEJACULATION

DANA A. OHL, SUSANNE A. QUALLICH, JENS SØNKSEN, NANCYL BRACKETT, AND CHARLES M. LYNNE

Anejaculatory infertility is a relatively uncommon etiology of failure to conceive, but in certain patient populations, this condition may be the most common cause of infertility. Men with anejaculatory infertility have dysfunction of some portion of the normal ejaculatory reflex system, preventing the emission of semen during normal sexual activity. These neuroanatomic components of the ejaculatory response include (a) penile dorsal nerves carrying efferent sensory stimuli to the spinal cord at S2–4; (b) descending pathways from the brain to carry cerebral input down to the ejaculatory center at T10–L2; (c) ascending pathways from S2–4 to coordinate sensory input at T10–L2; (d) sympathetic outflow at T10–L2, carried via the sympathetic chain, the inferior mesenteric plexus, and pelvic sympathetics, ending in the walls of the ejaculatory organs, the seminal vesicles, vas deferens, prostate, and bladder neck, to effect seminal emission and bladder neck closure; and (e) pudendal nerves to stimulate the periurethral skeletal muscle, to create the projectile phase of the reflex. Stimulation of the brain and genitalia results in a coordinated response culminating in emission of sperm and seminal plasma into the urethra, followed shortly by rhythmic contractions of the

periurethral muscle against a tightly closed bladder neck, resulting in projectile expulsion of semen from the urethra.

There are several types of ejaculatory dysfunction, including premature ejaculation, retrograde ejaculation, and anejaculation. Men with premature ejaculation and retrograde ejaculation are not appropriate for penile vibratory stimulation (PVS) and electroejaculation (EEJ), favoring other treatment algorithms. Candidates for ejaculation induction procedures are those men who are unable to initiate a normal ejaculatory reflex due to neurologic conditions. The most common cause seen in practice is spinal cord injury (SCI), due to the fact that SCI men are able to ejaculate only 10% to 20% with normal coitus (8). Other etiologies include surgical sympathectomy from retroperitoneal lymph node dissection, aortic surgery, or perirectal dissection, diabetic neuropathy, transverse myelitis, multiple sclerosis, and spinal bifida. In these neurologic conditions, segments of the normal neuroanatomic structures are nonfunctioning, leading to absence of seminal emission. In uncommon cases, anorgasmia from a psychogenic source may be a reason to utilize ejaculation induction procedures.

---

## DIAGNOSIS

---

The diagnosis of anejaculation is made primarily by history. Certainly in individuals with the profound neurologic conditions mentioned previously, such as spinal cord injury, there is little mystery as to the source of their infertility. The history needs to capture other risk factors, such as prior surgery, a diagnosis of diabetes, and any neurologic symptoms that may indicate an occult condition. In individuals who are relatively neurologically intact, such as a diabetic neuropath, a history of normal orgasm sensation, without seminal fluid emitted per urethra, is key. One needs to inquire for signs of retrograde ejaculation, such as cloudiness in the urine immediately after ejaculation. In men with psychogenic anorgasmia, which tends to be lifelong, the history may be more problematic, as these men may have never experienced a normal orgasm. The clinician may need to have the man describe in detail the events that occur during sexual activity to determine if the man is experiencing orgasm or not.

There are few diagnostic tests necessary in most men prior to a trial of an ejaculation induction procedure. Information about spermatogenesis can be indirectly obtained with a serum follicle stimulating hormone (FSH) level and by finding a normal testicular volume on physical examination. If the FSH is elevated, a testis biopsy might be indicated. If there is a question of retrograde ejaculation, postorgasm urine is examined to look for sperm. In men with retrograde ejaculation, or those with peripheral neuropathy (diabetic neuropathy or surgical sympathectomy), a trial of sympathomimetic agents may induce antegrade ejaculation, thus preventing the need for ejaculation induction. Finally, prior to performing procedures on men with anejaculation, a fertility evaluation of the female partner ensures that a suitable recipient for assisted reproductive techniques (ARTs) is available.

---

## INDICATIONS FOR EJACULATION INDUCTION PROCEDURES

---

Men with anejaculation who wish to induce a pregnancy in their female partners are candidates for PVS or EEJ. These procedures are not aimed at restoring sexual function, but merely serve as a method to retrieve sperm that might be used for ARTs. Indeed, many men find these procedures uncomfortable. Therefore, the goal of using PVS and EEJ is procreation.

Penile vibratory stimulation is useful in men who are anejaculatory from SCI. Since this procedure requires an intact ejaculatory reflex arc, men with peripheral neuropathies and those with incomplete lesions are suboptimal candidates. PVS has a higher success rate in SCI men with complete lesions, lesions above T8, upper motor neuron characteristics (spastic), and intact bulbocavernosus and hip flexion reflexes. The success rate markedly drops off with the lower levels of injury associated with lower motor neuron injury characteristics. However, because of the relative noninvasiveness of PVS compared to EEJ, it is reasonable to attempt PVS in all SCI men prior to attempting EEJ.

EEJ is utilized for SCI men who fail PVS and in all other etiologies of anejaculation. However, cost analysis of the results of EEJ with ARTs has led to the recommendation

that non-SCI men rarely should undergo EEJ (7). In men with normal sensation, a general anesthetic is needed to perform EEJ, and the added cost of the anesthetic changes the cost-effectiveness calculations. Although it may still be reasonable to utilize EEJ in the non-SCI population, the clinician needs to strongly consider the alternative procedures noted below.

---

## ALTERNATIVE THERAPIES

---

The goal in ejaculation induction procedures is to obtain sperm to be used in ARTs. Therefore, the choice of ART is dependent on the sperm quality delivered by the ejaculation induction procedure. For instance, if a procedure delivers sperm with  $>10$  million total motile sperm (TMS), then a simple ART procedure, such as intrauterine insemination (IUI), will have a reasonable chance of a pregnancy. However, if the TMS is between 1 and 10 million, then standard in vitro fertilization (IVF) will be necessary to give reasonable pregnancy rates. If the TMS drops below 1 million sperm, intracytoplasmic sperm injection (ICSI) in conjunction with IVF is necessary to give reasonable pregnancy rates. Finally, in an SCI man who exhibits exceptional semen quality with PVS, patient-directed PVS procedures in the home setting, followed by patient-directed vaginal insemination, may result in pregnancy.

In general, ejaculation induction procedures are aimed at utilizing IUI in an attempt to optimize cost-effectiveness. If IUI is determined not to be cost-effective as compared to IVF, the advantage of ejaculation induction is lost. In fact, when analyzing the effectiveness of EEJ when coupled with IUI in men without SCI, the increased cost of the required anesthetic changes the analysis to favor proceeding directly to the more costly IVF procedure, based on pregnancy rates and the cost of the procedures (7). Since there are methods other than EEJ to deliver adequate numbers of sperm for IVF, these procedures merit discussion.

In men who require an anesthetic to perform EEJ, it is cost-effective to bypass the EEJ procedure and go directly to sperm aspiration procedures (described elsewhere in this book), in conjunction with IVF, and ICSI of the partner's oocytes (7). However, some IVF clinics proceed directly to sperm aspiration procedures in all men, without consideration of PVS or IUI, even for SCI subjects. The authors disagree with this algorithm, based on cost-effectiveness analysis (5).

Finally, a discussion of options in the anejaculatory patient would not be complete without mentioning the possibility of donor artificial insemination and adoption. This information is discussed with the couple, but the subjects themselves need to decide whether to forego attempts at conception with the male partner's sperm and use these techniques.

---

## TECHNIQUES

---

---

### Penile Vibratory Stimulation

---

Penile vibratory stimulation depends on an intact reflex arc to be successful. The general idea is that the penis is overstimulated with a carefully designed vibrator, overcoming the ejaculatory reflex threshold. Sensory input is carried via the dorsal

nerves into the sacral cord. These impulses then ascend into the ejaculatory center at the thoracolumbar cord, where sympathetic fibers carry a signal to the ejaculatory organs, causing them to contract. Since a complete ejaculatory reflex is elicited, there is also coordination of bladder neck closure during emission to prevent retrograde ejaculation, as well as pulsatile rhythmic contraction of the periurethral muscles, causing, in turn, pulsatile projectile ejaculation. The neurophysiologic events that occur during PVS are indistinguishable from a normal ejaculatory reflex, other than the fact that it is not associated with sexual activity, as well as the lack of sensation and control of the SCI subject.

The choice of the vibrator directly impacts ejaculation success rates. A study performed by Sønksen et al. (9) found that ejaculation rates when utilizing a vibrator with amplitude of 1.0 mm was only 32% in a cohort of SCI men. When challenging the same group of men with a vibrator with peak-to-peak amplitude of 2.5 mm, the ejaculation rate was 91%. In this study, amplitudes of commercially available vibrators were measured, and it was found that manufacturers' specifications were highly inaccurate and were not dependable enough to make choices in the types of devices to be used for patients. These observations led to development of a commercially available device produced with medical indication standards and FDA approval for use in ejaculation induction procedures in SCI men (Fig. 61.1). The authors recommend that this FDA-approved device be used in clinical PVS.

The initial PVS should be done in the clinic setting to ensure that there are no complications. PVS can be performed on a treatment table or with the patient remaining in his wheelchair. Although retrograde ejaculation is very uncommon with PVS, it is prudent to catheterize the bladder prior to the first procedure and again immediately after the procedure to check for sperm in the bladder. Catheterization must be done with a plastic catheter with nonsporicidal lubricant. If after the first procedure it is determined that no retrograde ejaculation is present, subjects will characteristically not develop this over time, and the catheterization may be omitted from future procedures.

**FIGURE 61.1** The FertiCare vibrator (Multicept APS, Copenhagen, Denmark) is the only device approved by the FDA for the purpose of penile vibratory ejaculation.

A

B

**FIGURE 61.2** Different SCI patients will respond to different stimulation positions. **A:** Placement of the vibrator head at the frenulum. **B:** Placement of the vibrator head on the dorsum of the glans penis.

An automated blood pressure cuff is used to monitor blood pressure during the procedure, in case autonomic dysreflexia with extreme blood pressure increase occurs in response to the stimulation. SCI men with lesions above T6 are prone to dysreflexia. In such patients, consideration must be given to prophylactic administration of sublingual nifedipine 10 to 20 mg. Autonomic dysreflexia is discussed in more detail in the “Complications” section of this chapter.

The vibrator is placed on the patient's penis to deliver the stimulation. In most subjects, the stimulation area most likely to result in a positive response is the frenulum, although there is individual variation that can be sorted out with trial and error (Fig. 61.2).

The vibrator is placed on the penis with an initial amplitude of 2.5 mm and a frequency of 100 Hz. Enough pressure to get the device close to dampening is used to ensure delivery of an adequate power of vibration. The stimulation is applied until ejaculation occurs, or for a total of 3 minutes. If no ejaculation is reached within 3 minutes, there may be sensory fatigue and a rest period is indicated. One can resume stimulation

again after a rest period of 1 minute, with consideration given to increasing the amplitude in half-centimeter increments up to 4.0 mm at maximum.

During stimulation, characteristic muscular responses can be seen and can give clues to the operator that ejaculation may be imminent. With application of the vibrator, abdominal and periurethral muscle contractions are typical. Piloerection is also common. When ejaculation is near, there is tonic contraction of leg and abdominal muscles, followed by rapid release and spastic, sometimes jerking, contractions of the muscles, coincident with the actual ejaculation process. If the vibration is discontinued just prior to ejaculation when such premonitory signs are seen, the complete reflex will continue without interruption. Discontinuation at this time may limit blood pressure rise in those prone to dysreflexia and may also prevent overstimulation and sensory fatigue, allowing multiple stimulations to be successful. If multiple attempts are made, one can continue with another stimulation period after a rest period of 1 minute (2).

An assistant is responsible for ensuring that the ejaculate is collected in a sterile specimen container. The assistant can also be very helpful in ensuring the comfort of the patient and watching for complications. Such assistance in monitoring for complications ensures having another set of eyes on the blood pressure monitor and checking verbally with the patient for any symptoms of dysreflexia, such as headache.

After the procedure, most patients feel quite well. There may be a general reduction in reflex activity that may lead to limitation of spasticity and bladder activity. The blood pressure of those who have received prophylactic nifedipine should be measured after assuming the sitting position.

---

## Electroejaculation

---

Rectal probe EEJ has been used in animal husbandry quite regularly for some time. The first use in men with spinal cord injury was reported in 1948 (4), but no pregnancies from electroejaculated sperm were reported until the 1970s. Further isolated reports ensued for many years until Bennett refined the procedure and presented a series of United States pregnancies from EEJ of SCI men (1).

Historically, it was assumed that EEJ worked via direct stimulation and contraction of the ejaculatory organs. However, recent research has shown that the electrical stimulation appears to initially cause high-pressure contraction of the pelvic floor and periurethral muscles, leading to a partially coordinated reflex with seminal emission and contraction of the bladder neck and rhythmic, although somewhat disorganized, contractions of the periurethral muscles, leading to expulsion of semen (11). Although there are many components of the reflex that are similar to PVS, the less organized reflex response leads to incomplete coordination and the likely possibility that some of the ejaculate will be emitted in a retrograde fashion.

Since retrograde ejaculation is a distinct probability, it is important to prepare the patient to limit toxicity of the sperm-urine contact. The authors favor limitation of fluid intake in order to limit urine production during the procedure. Subjects are instructed to take ½ teaspoon of sodium bicarbonate 12 hours and 2 hours prior to the procedure to alkalinize the urine. In SCI men with recurrent urinary tract infections,

consideration is given for a short course of prophylactic antibiotics. To clear the rectum of feces, SCI men are instructed to perform their normal bowel evacuation the night before the procedure. Non-SCI men are instructed to empty the rectum with the assistance of an enema.

Although most non-SCI men should not undergo EEJ, there may be compelling reasons to proceed. These may include evidence of very high sperm production, increasing the chance of an IUI success; or religious objections to IVF, necessitating the use of IUI. In non-SCI men, EEJ is a very painful procedure and must be performed under anesthesia. General anesthesia has been the most common modality in practice. The discussion of the procedure that ensues will assume that the subject is an SCI man, who does not require anesthesia.

There is only one device that is FDA-approved for EEJ of SCI men. This is the Seager unit. Virtually all modern experience with EEJ has been with this machine. The unit consists of a central power generator and cords that may be attached to a variety of rectal probes. The central unit has a stimulation counter and a read-out of probe temperature so that overheating may be monitored. There is a heat sensor fail-safe that cuts power to the unit if temperature rises to unsafe levels. The EEJ equipment setup and additional supplies are shown in Fig. 61.3.

EEJ is performed on the treatment table. The patient begins supine, and an automated blood pressure cuff is applied to monitor for dysreflexia. In those prone to dysreflexia, consideration is given for prophylactic sublingual nifedipine, 10 to 30 mg. Since EEJ is capable of providing a very noxious stimulus that can create a dysreflexia situation in prone individuals, subjects are instructed to inform the staff if a headache or palpitations arise.

The bladder is catheterized in all EEJ cases, due to the propensity for retrograde ejaculate (Fig. 61.4). Five to 20 mL of a sperm-friendly medium from the assisted reproduction lab is instilled into the bladder (Fig. 61.5). A plastic catheter with nonspermicidal lubricant is used for the pre- and post-procedure catheterizations to limit sperm toxicity.

The subject is then turned into the lateral decubitus position (Fig. 61.6), and rectoscopy is performed to ensure that no lesions are seen (Fig. 61.7). If significant inflammation is seen due to bowel program activity or colitis, the procedure should be canceled for the day and rescheduled. Any inflammatory condition of the colon will only be made worse by running electrical energy into the area.

The probe is inserted far enough into the rectum such that the limit of the plastic is located just at the anal sphincter (Fig. 61.8). The electrodes should be completely internalized inside the rectum. The conductive characteristic of the rectal mucosa allows efficient flow without much heat generation. However, if the electrodes are applied externally to the skin, the very high resistance of the skin will cause significant heat release and put the patient at risk for perineal burn. The electrodes are positioned anteriorly, facing the ejaculatory organs.

Electricity is delivered in waves of increasing voltage. The first stimulation is 2.5 to 5.0 V and is increased by 2.5 to 5.0 V per stimulation. The degree of rectal contact and individual characteristics lead to differences in resistance, such that with the same voltage, differences in electrical flow (milliamperes) may be seen. In general, a guideline of a maximum delivery of 1,000 mA at peak stimulation should be used, and that is usually seen with a voltage delivery of 30 to 35 V (Fig. 61.9).

B

C

**FIGURE 61.3** Electroejaculation equipment. **A:** Sigmoidoscope and rectal probe. **B:** Additional equipment, including plastic catheters, non-spermicidal lubricant packets, media for instillation into the bladder, basin for draining the urine, and specimen containers for the antegrade and retrograde specimens. **C:** Seager Model 14 Electroejaculator. Meters give voltage and current delivery, stimulation count and time, and probe temperature. The central rheostat is turned by the operator to alter voltage.

**FIGURE 61.4** The bladder is emptied prior to electroejaculation.

**FIGURE 61.5** Sperm-friendly medium is instilled into the bladder in anticipation of retrograde ejaculation.

**FIGURE 61.6** The lateral decubitus position allows access for insertion of the rectal probe and access to the penis for retrieving antegrade ejaculate.

**FIGURE 61.7** Rectoscopy is performed before and after the electrical stimulation.

**FIGURE 61.9** The operator is maintaining probe position with the right hand, while moving the rheostat on the machine to alter voltage delivery.

A

B

**FIGURE 61.8** Rectal probe insertion. **A:** The well-lubricated probe is placed into the rectum. **B:** Final probe position with the electrodes completely inside the sphincter. The electrodes are positioned facing anteriorly.

Waves are delivered with a relatively rapid rise to the chosen voltage for that stimulation, held for 5 seconds, and then abruptly cut off. During the time of electrical silence, the ejaculatory response develops over a few seconds, and ejaculation actually occurs during the silent phase. In the past the standard thinking was to leave an electrical baseline of 100 mA, never reaching zero again. However, the change from the older technique to the one described above has led to a significant reduction in the percentage of retrograde ejaculate (3,6).

During stimulation, there can be significant abdominal and leg muscle contractions. Piloerection can be seen also, and this also may indicate an adequate level of stimulation. In the electrically silent period between contractions, and during ejaculation, visible contraction of the perineal and periurethral muscles may be seen, again attesting that adequate stimulation is being given.

An assistant holds a cup over the penis to ensure that any antegrade ejaculate is collected (Fig. 61.10). Since ejaculate

**FIGURE 61.10** The assistant is maintaining the position of the urethral meatus inside the specimen container to collect the antegrade ejaculate.

**FIGURE 61.11** Following electrical stimulation, the subject is once again catheterized to retrieve the retrograde fraction of the ejaculate.

may be retained in the urethra, gentle milking on the underside of the urethra in an antegrade fashion may help in the expulsion. The assistant can also aid in monitoring the blood pressure and any patient complaints of dysreflexia.

When no more fluid is expelled following a stimulation cycle, or if probe temperature reaches 39.5°C, the procedure is terminated. The probe is removed and rectoscopy performed again to ensure that no burn, bleeding, or perforation is seen. The subject is then catheterized again to extract the postejaculation urine (Fig. 61.11). A plastic catheter is used to avoid sperm adhering to it, and nonspermicidal lubricant is used, for obvious reasons. After extraction of bladder contents, the bladder is irrigated with the sperm-friendly medium for complete removal of retrograde ejaculate. Both specimens are submitted to the laboratory for analysis and processing (Fig. 61.12).

Similar to PVS, patients feel quite well after EEJ, and they may also feel a reduction in skeletal muscle and bladder spasticity for 12 to 24 hours after the procedure.

**FIGURE 61.12** The specimens from a typical EEJ procedure include a small-volume antegrade ejaculate and a larger-volume retrograde fraction.

---

## OUTCOMES

---

In SCI men, PVS is approximately 60% successful in inducing an ejaculatory response. The best results are seen in men with spasticity, in those with lesions above T8, and in those with intact bulbocavernosus and hip flexion reflexes, where ejaculation rates can be as high as 90%. EEJ, however, is nearly universally successful in causing seminal emission.

Unfortunately, the sperm quality from PVS and EEJ in SCI men is poor. This includes abnormalities of gross semen parameters and abnormal sperm function. Typically, sperm numbers are high, but motility and viability are very low. Other abnormalities seen include poor overnight survival, decreased ability to penetrate cervical mucus, and lower fertilizing capability, as compared to control sperm. This limits the success rates in series of men attempting conception.

Sperm obtained from ejaculation induction procedures are sent to the assisted reproductive laboratory for processing by standard preparation techniques. The specimens can be utilized for IUI or IVF, depending on the couple's situation and the sperm quality. The largest series of EEJ coupled with ARTs demonstrated an IUI cycle fecundity of 11% per cycle and 35% per couple. A single attempt of EEJ coupled with IVF gave a 43% pregnancy rate (7).

In men with exceptional semen quality, couples may be taught to perform PVS at home and do vaginal insemination. In a series of men in Germany, Denmark, and the United States, 73 of 169 couples had a pregnancy (43%). Ninety-nine pregnancies in these 169 couples were achieved (10).

---

## COMPLICATIONS

---

Autonomic dysreflexia is a phenomenon seen in higher spinal cord lesions. When a noxious stimulus is delivered, such as EEJ, the initial response is for the sympathetic nervous system to raise the blood pressure. Regulatory mechanisms including vascular baroreceptors give rise to modulation of the response from brainstem centers. The sympathetic outflow responsible for the blood pressure rise is located below T6. Therefore, in a man with a spinal cord injury above T6, the brainstem centers cannot communicate with the sympathetic outflow, leading to an autonomous, and unchecked, response. Therefore, the periphery is responding to the noxious stimulus with extreme rises in blood pressure, without normal control mechanisms stopping this reflex response.

EEJ and PVS are efficient stimuli that can induce dysreflexia. In susceptible subjects, dangerous rises in blood pressure can be seen, resulting in a risk for stroke. Blood pressure monitoring is essential in men with T6 or above lesions. Prophylactic nifedipine is highly successful in limiting the risk of extreme blood pressure rise during the procedures (12).

Specific minor complications from PVS may include skin swelling or bruising, discomfort from muscle contraction during the procedure, and urinary retention in reflex voiders due to limitation of reflex activity following the procedure.

There have been very rare reports of rectal injury or burn from EEJ, which is obviously a major complication, but the incidence is extremely low. Patients may also experience some discomfort during the procedure and temporary urinary retention, as in PVS.

# CHAPTER 62 ■ ANATOMY OF THE TESTIS

HOWARD H. KIM AND MARC GOLDSTEIN

A working knowledge of anatomy is vital for all surgeons, but it is perhaps especially critical for male reproductive urologists. In addition to knowing which nerves and lymphatics to avoid injuring during surgery and which collateral blood supply to depend on when a particular blood vessel is transected, the infertility specialist must understand the surgical anatomy in the context of spermatogenesis and reproductive physiology. Fortunately, the male reproductive anatomy has clinically relevant physical examination findings that facilitate the commitment of major principles to memory.

---

## INTRODUCTION TO MALE REPRODUCTIVE SYSTEM

---

### Physical Examination

---

Although representing only a minor subset of infertile men, endocrine disorders are often associated with characteristic findings on physical examination and are generally treatable with hormonal manipulation. Physical assessment of the hypothalamic-pituitary-gonadal (HPG) axis begins as soon as the infertile patient disrobes for the examination. Body habitus and secondary sex characteristics such as body hair distribution provide clues to disruption of the HPG axis and its potential role in the fertility status of the patient. For example, men with Kallmann syndrome or hypogonadotropic hypogonadism (HH) can present with delayed pubertal development or midline defects such as anosmia and cleft palate. In Kallmann syndrome, the olfactory axons fail to establish connections with the developing olfactory bulb during development, resulting in problems with gonadotropin-releasing hormone (GnRH) secretion. GnRH neurons use olfactory nerve migration for their own travel to the forebrain (12).

Other disorders, such as androgen-insensitivity syndromes, can present with impaired secondary sex development or infertility.

---

## Hypothalamic-Pituitary-Gonadal Axis

---

Reproductive hormones are controlled by the hypothalamus, which releases GnRH in a pulsatile fashion, on average every 90 to 120 minutes from its preoptic and arcuate nuclei (Fig. 62.1). GnRH stimulates the anterior pituitary to release luteinizing hormone (LH) and follicle stimulating hormone (FSH). LH in turn stimulates the production of testosterone by Leydig cells, while FSH supports spermatogenesis in Sertoli cells. Both androgens and estrogens feed back to inhibit LH release, and inhibin, produced by the Sertoli cells, decreases FSH release.

---

## TESTIS

---

### Physical Examination

---

The physical examination of an infertile man reveals a wealth of information. Body habitus is assessed. Late closure of the epiphyses due to lack of adequate testosterone results in an arm span that exceeds height, or a pubis-to-foot distance that exceeds pubis-to-crown distance by  $>5$  cm. Gynecomastia, feminized body habitus, and sparse male hair distribution complete the picture characteristic of either HH or Klinefelter syndrome. Evaluation of the scrotal contents is the centerpiece of the examination. A scrotum warmed with a heating pad to relax the dartos muscle and a securely private room optimize patient comfort and subsequently yield

**FIGURE 62.1** Hypothalamic-pituitary-gonadal axis. *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone; *FSH*, follicle stimulating hormone.

a superior examination. The testes should be checked for size and consistency. Testes measure 15 to 25 cu cm in volume (45) and 4.5 to 5.1 cm in longitudinal length (60) in young healthy men. Testes decrease in size with age (27). Size directly correlates to spermatogenesis, as seminiferous tubules comprises 80% of testicular volume (5). Although a variety of devices are available for testis size measurement, including calipers, punched-out orchidometers, and scrotal ultrasonography, we prefer the standard Prader orchidometer for quick and easy assessment of testis volume. Assessment of testis consistency is equally important. A soft, mushy feel to the testis implies diminished spermatogenic capacity. Taken together, size and consistency help differentiate nonobstructive from obstructive causes of azoospermia.

### Development

Primordial germ cells migrate from the yolk sac to the genital ridge of the mesonephros, where they join somatic cells to form the primary epithelial or medullary cords (55). The testes arise from the primordial germ cells at 7 to 8 weeks of development (25) under the direction of the SRY gene of the Y chromosome (58). The component cells of the testis, Leydig and Sertoli cells, begin production of testosterone and müllerian

inhibiting substance/antimüllerian hormone (MIS/AMH), respectively (65). AMH transcription is regulated by many transcription factors, including steroidogenic factor 1 (SF-1), SRY HMG box related gene 9 (SOX9), Wilms tumor 1 (WT1), and a zinc finger transcription factor (GATA-4) (11). Testosterone preserves the wolffian duct, and MIS/AMH induces degeneration of the adjacent müllerian duct (23). The wolffian duct of the regressing mesonephros combines with the developing gonad to form the epididymis, ductus deferens, ampulla, and seminal vesicles (55).

### Descent

The developing testis is anchored by two ligaments, the cranial suspensory ligament and the caudal genitoinguinal ligament or gubernaculum (23). Although we have an incomplete understanding of the mechanism of testicular descent, the process can be conceptualized as occurring in three simplified steps: nephric displacement, transabdominal movement, and inguinal passage. In the first stage, occurring about gestation day 55, the gubernaculum and the wolffian and müllerian ducts pull the gonad posteriorly as the metanephros moves anteriorly into the space recently vacated by the mesonephros (15). As the abdominal cavity of the fetus enlarges, the gonad

maintains its proximity to the inguinal canal by dynamic changes to the suspensory ligaments. Under hormonal control, the gubernaculum enlarges and the cranial suspensory ligament regresses, facilitating descent (24) at 8 to 15 weeks of gestation (23). Testosterone induces regression of the cranial suspension ligament (61), whereas gubernacular development depends on insulinlike hormone 3 (Insl3) produced by the Leydig cell (13,43). At 25 to 35 weeks of gestation (23), the gubernaculum pushes through the inguinal canal, leading the testis outward into its final position (55). Calcitonin gene-related peptide (CGRP), found in the sensory branches of the genitofemoral nerve, appears to control gubernacular growth and direction of migration (23,68). The process ends with the regression of the gubernaculum (66).

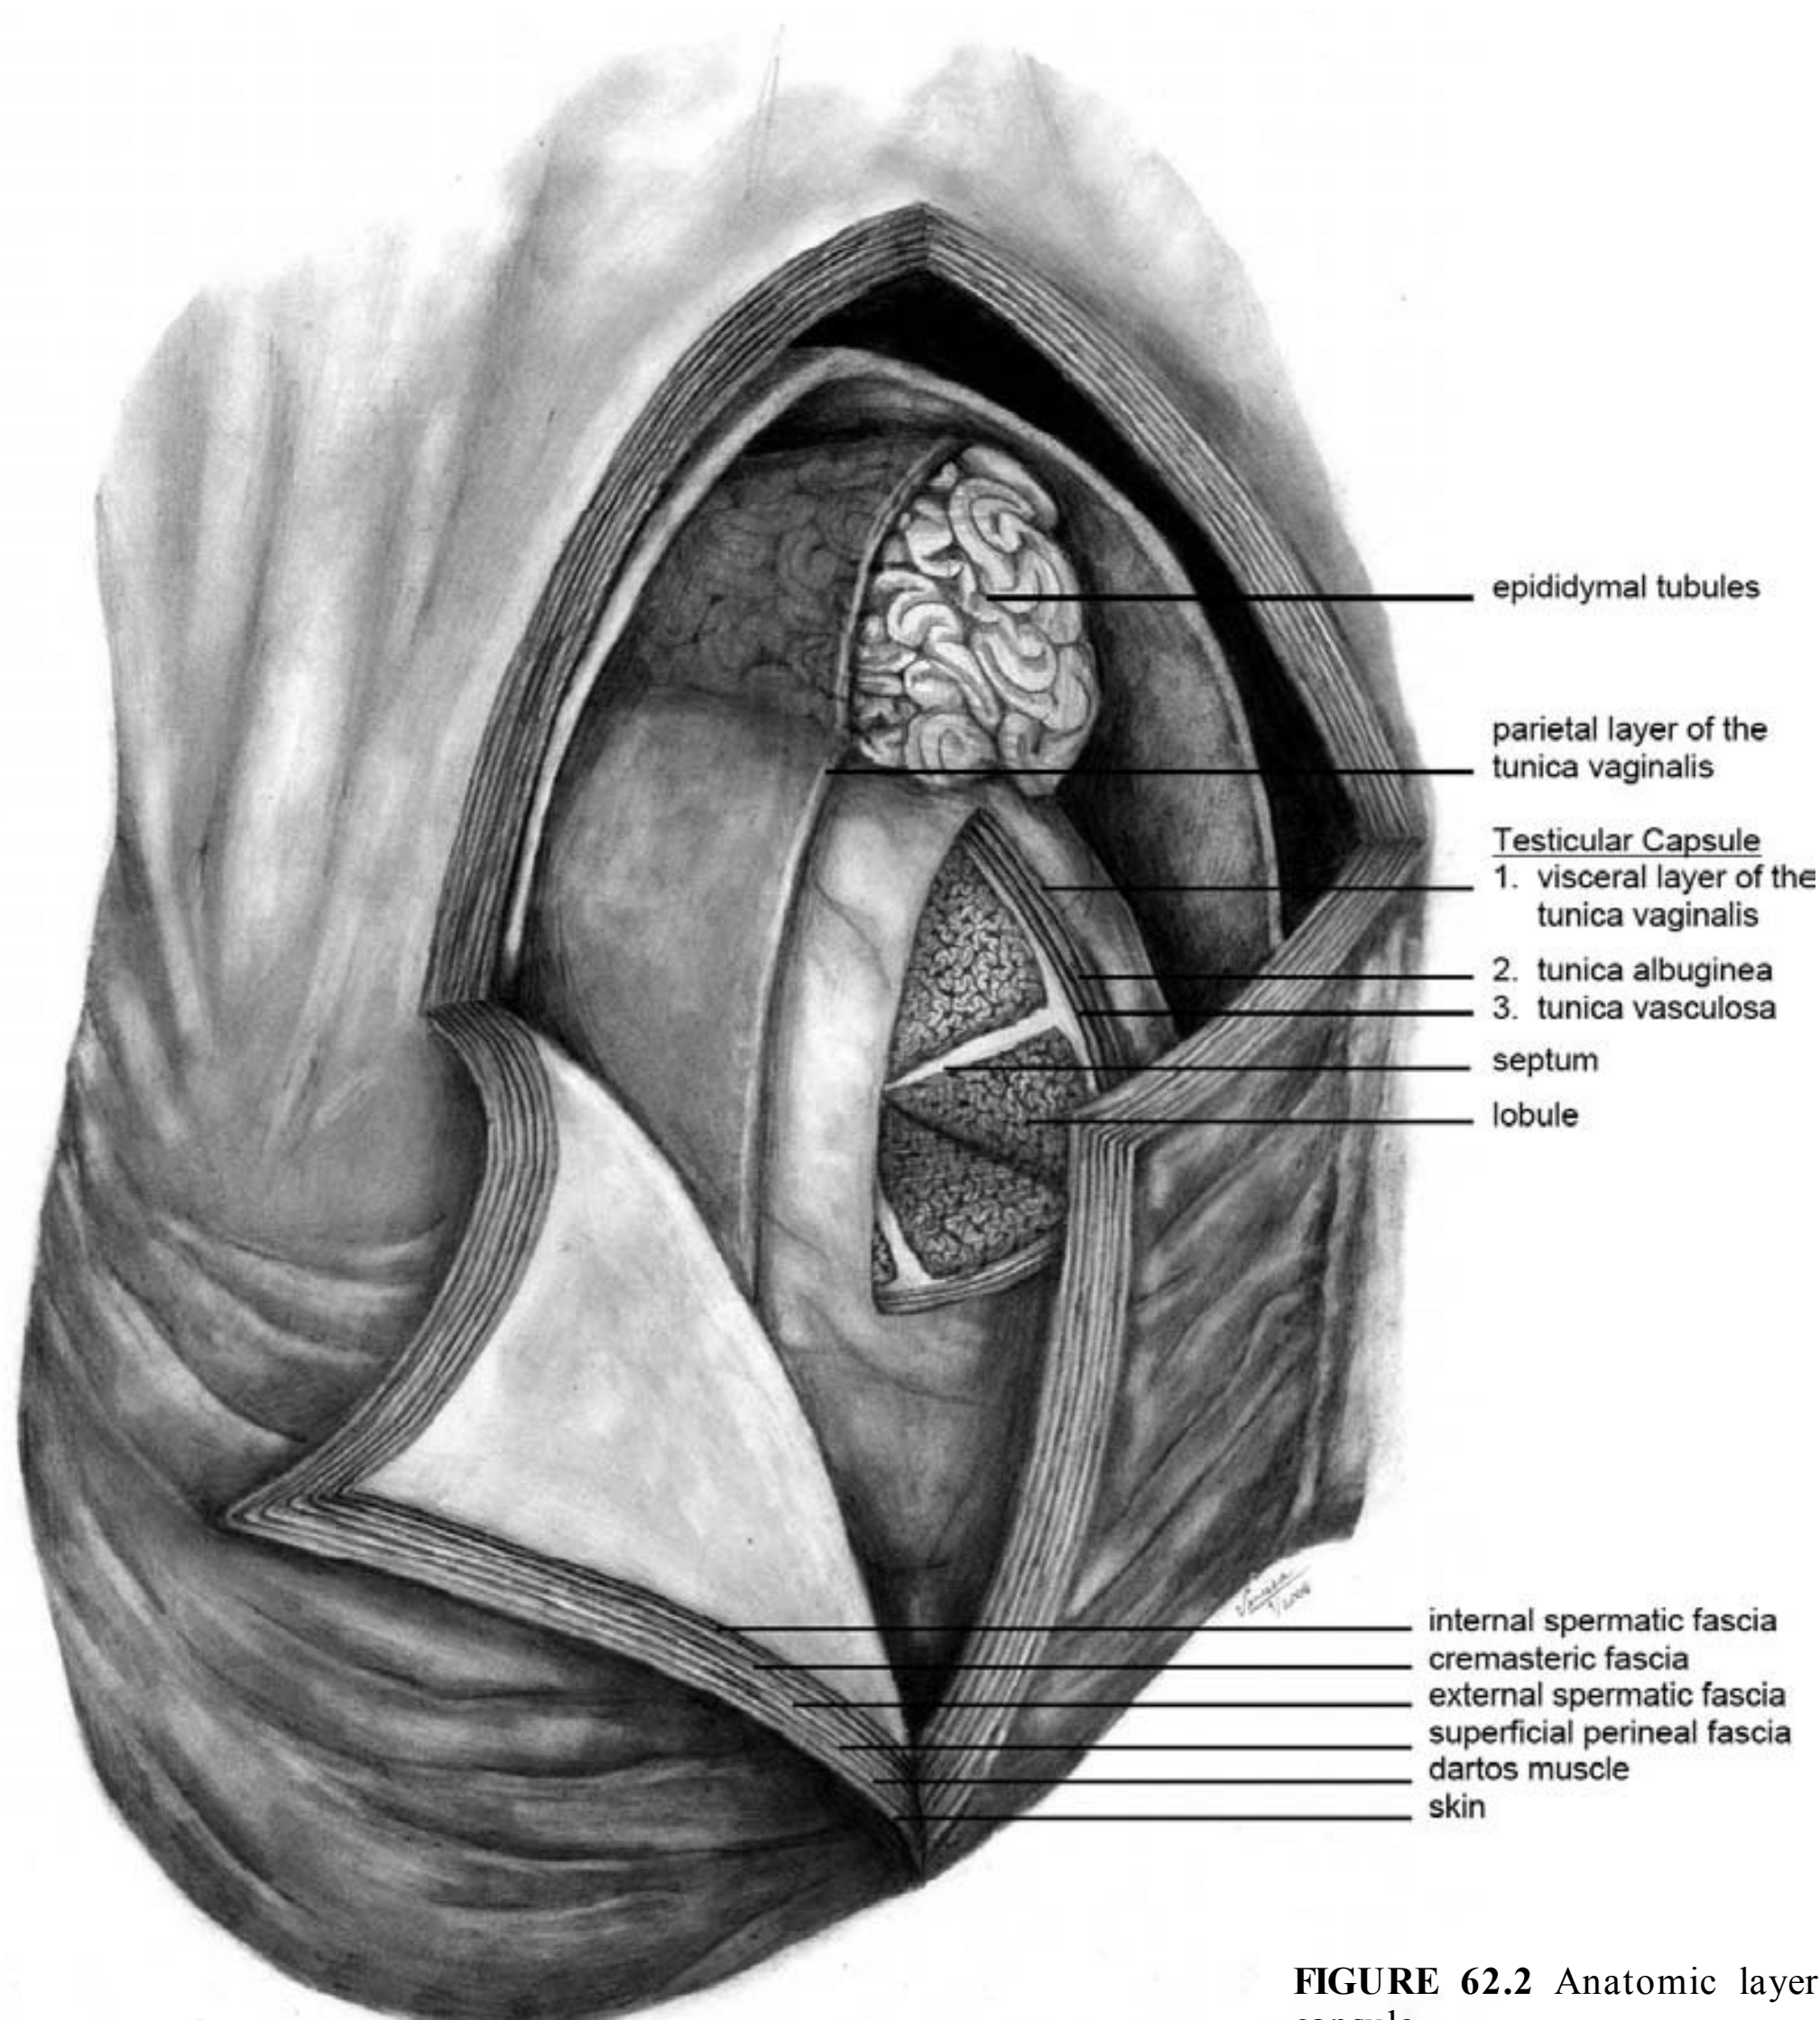

### Capsule

Medical students are all too familiar with the seven layers of the scrotal wall: skin, dartos muscle, superficial perineal fascia, external spermatic fascia, cremasteric fascia, internal spermatic fascia, and the parietal layer of the tunica vaginalis (Fig. 62.2).

But not many know that the testicular capsule consists of more than just the tunica albuginea. The testicular capsule is distinctly separate from the scrotal layers and is composed of its own three layers: the visceral layer of the tunica vaginalis (an outer thin serous layer composed of attenuated mesothelial cells), the tunica albuginea (a fibrous membrane, composed of collagen fibers and fibroblasts, that forms the bulk of the capsule), and the tunica vasculosa (a thin, delicate areolar layer with occasional networks of tiny blood vessels) (9). The tunica albuginea forms septations that separate the testis into lobules; the blood supply travels along these septations (9). Along the posterior border of the testis, the tunica albuginea thickens to form the mediastinum testis, which houses the channels of the rete testis and the initial portions of the vasa efferentia (Fig. 62.3) (9). Contractility of the testicular capsule (49) may be involved in the regulation of blood flow into the testis (53).

### Blood Supply

The internal spermatic or testicular, deferential, and external spermatic or cremasteric arteries are the major blood supply

**FIGURE 62.2** Anatomic layers of the scrotal wall and testicular capsule.

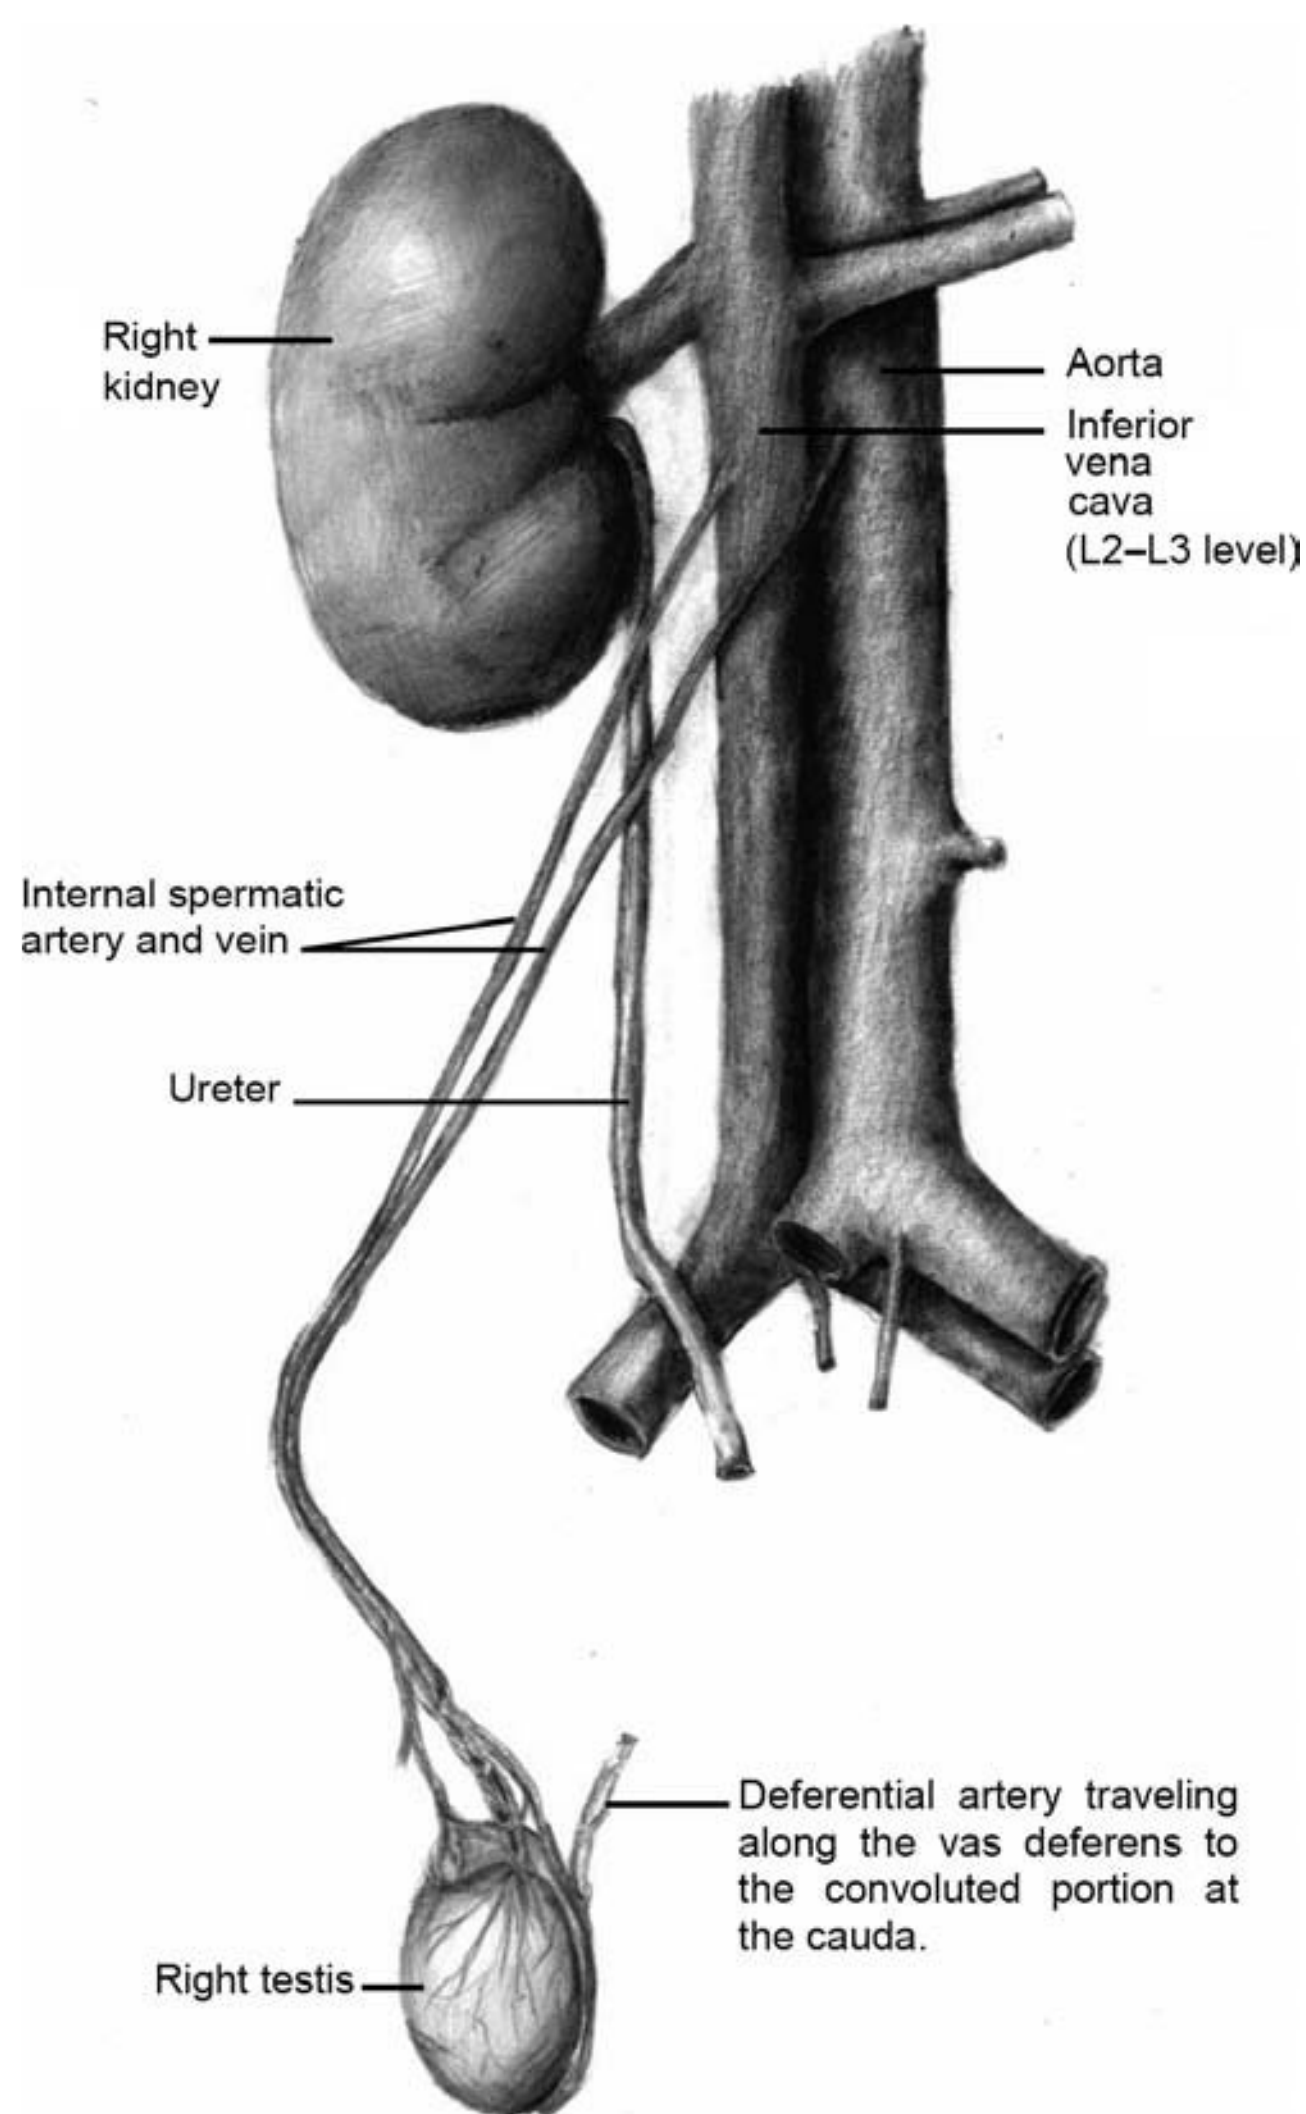

FIGURE 62.3 Overview of testicular anatomy.

to the testis (Fig. 62.4) (18). The internal spermatic artery arises from the aorta at L2-3, just below the origin of the renal arteries, and travels over the psoas major muscle, the ureter, and the genitofemoral nerve (41). The right testicular artery also lies anterior to the inferior vena cava and posterior to the third part of the duodenum, the right colic artery, the ileocolic artery, the root of the mesentery, and the terminal ileum; the left testicular artery lies posterior to the inferior mesenteric vein, the left colic artery, and the lower descending colon (41). The artery enters the spermatic cord as a single vessel before branching several times, sometimes as high as the internal inguinal ring (34). Studies have noted that the testicular artery often has one to three branches supplying the upper and lower poles of the testis (41).

Despite variant views on testicular blood supply, the predominant understanding is that the arteries supplying the parenchyma arise on the free border and run up toward the mediastinum before turning and branching out into the parenchyma (54). The testicular arteries penetrate the posterior aspect of the tunica albuginea and send parenchymal branches anteriorly as they travel inferiorly. Large branches also cover the inferior pole of the testis. The medial and lateral aspects of the midtestis have relatively fewer arterial branches compared to the anterior and inferior aspects (53). Color Doppler ultrasonography with point spectral analysis has demonstrated the low vascular resistance of the testis, in contrast to the high vascular resistance of the epididymis and peritesticular tissues (39).

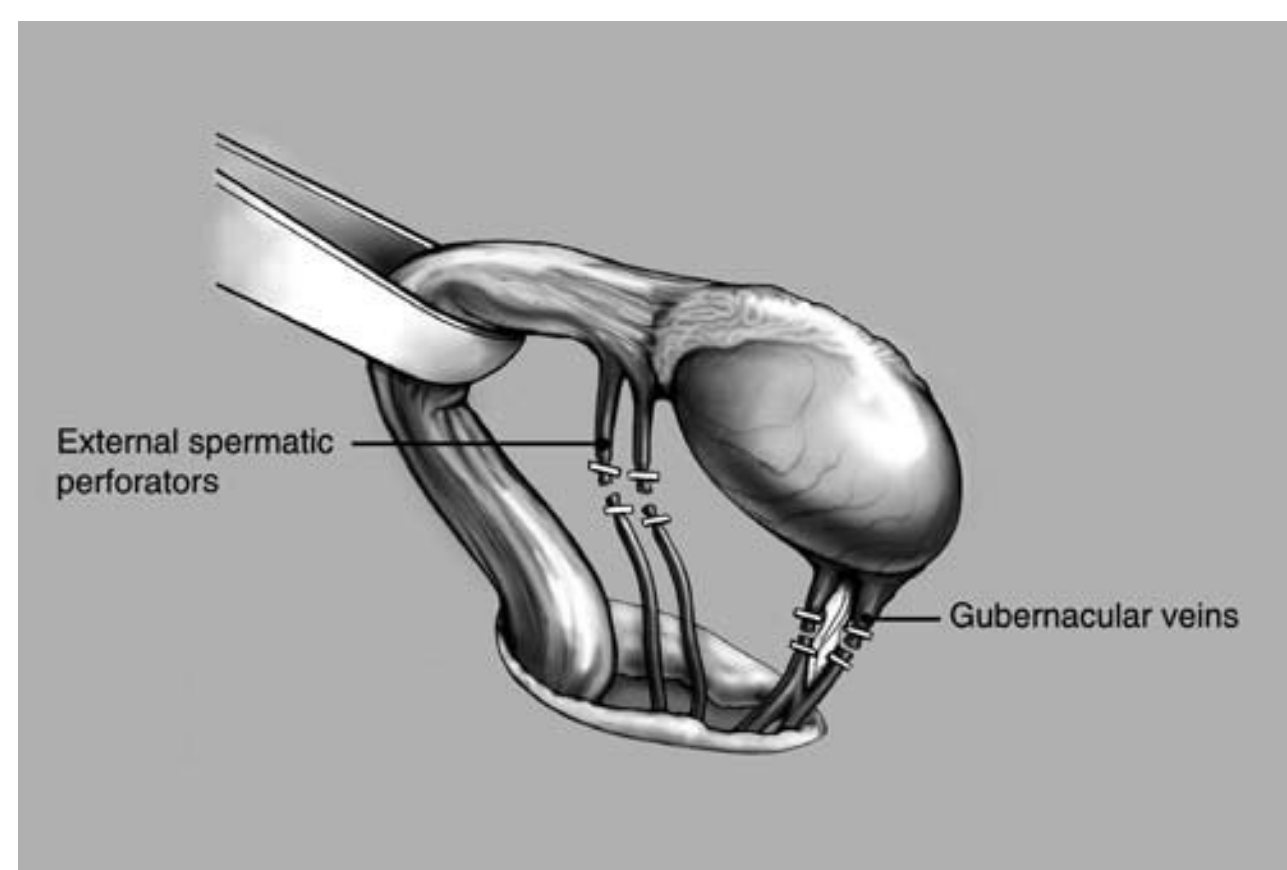

The deferential artery branches from the inferior vesical artery and travels along the vas deferens in the spermatic cord to the convoluted portion of the epididymis at the cauda (34). The cremasteric artery forms off the inferior epigastric artery and travels superficially in the cremasteric fascia and tunica vaginalis to widely cover the surface of the testis and spermatic cord (34). Large-caliber anastomotic channels between the testicular and deferential arteries have been demonstrated in 87% of human testes specimens (34). The deferential artery forms its anastomosis at the cauda epididymis, whereas the testicular artery forms its anastomosis by a branch anywhere from near the internal inguinal ring to the tunica albuginea (34). The cremasteric artery has contributed to the anastomosis in 50% of the specimens studied (34). The relative contributions of each artery to the overall blood supply can be estimated by noting their diameters; Harrison and Barclay (18) and Harrison (17) reported that the sum of the cremasteric and deferential diameters was equal to the diameter of the testicular artery in one third of the cases. The diameter of the testicular artery is equal to or greater than the sum of the deferential and cremasteric artery diameters in 57.5% of cases (47). Raman and Goldstein (47) point to the Poiseuille law ( $Q = \pi \alpha^4 P / 8 \eta L$ ), in which the rate of blood flow through a vessel ( $Q$ ) is related to the fourth power of the radius ( $\alpha$ ), the difference in blood pressure at the two ends ( $P$ ), the viscosity of blood ( $\eta$ ), and the length of the vessel ( $L$ ); because of the fourth power of the radius, blood flow of a large vessel is greater than that of two smaller vessels whose combined

**FIGURE 62.4** Testicular blood supply. Not pictured: cremasteric artery.

diameter equals that of the larger vessel. Raman and Goldstein (47) concluded that the testicular artery contributes significantly more to the testicular blood supply than the combined flow of the deferential and cremasteric arteries. This fact may be relevant in procedures involving ligation of the testicular artery with dependence on collateral blood flow, such as non-artery-sparing laparoscopic varicocelectomy. Although several studies have reported no testicular atrophy in adults and adolescents who had their testicular arteries ligated during varicocelectomy (29,38,59), other studies have demonstrated significant sequelae of testicular artery ligation (30,44,57).

The layout of the testicular blood supply has important implications for several urologic procedures. In the surgical management of cryptorchidism with intentional ligation of the testicular artery, manipulation of the vas deferens should be minimized to preserve the deferential artery (34). Also, the testicular artery must be ligated above the origin of its anastomotic branch to take advantage of collateral circulation from the other arteries (34). Even venous drainage plays a significant role in the surgical anatomy of the testis. Deferential veins provide the only outlet for venous drainage following

**FIGURE 62.5** Varicocelectomy. In addition to ligation of the internal spermatic veins, external spermatic and gubernacular veins must be identified and clipped to prevent varicocele recurrence. (From Goldstein M. Surgical management of male infertility and other scrotal disorders. In: *Campbell's urology*, 8th ed. Philadelphia: WB Saunders, 2002:1532–1587, with permission.)

varicocelectomy (Fig. 62.5). If the patient simultaneously or subsequently undergoes vasectomy, the deferential venous drainage may be compromised. Lee et al. (35) advocate microsurgical technique to avoid this outcome of insufficient venous drainage when performing both vasectomy and varicocelectomy in the same patient. In another example of relevant surgical venous anatomy, the importance of gubernacular veins and their contribution to varicocele has been debated. Although Ramasamy and Schlegel (48) reported no benefit of testicular delivery and ligation of gubernacular veins when performing varicocelectomy, Murray et al. (42) found presumed scrotal collaterals in 7% of recurrent varicoceles.

Knowledge of the layout of the testicular blood supply minimizes the risk for significant bleeding and compromise of the arterial supply during surgical sperm retrieval (51). The branches of the testicular artery are vulnerable to injury with their superficial course beneath the tunica albuginea. In one study, significant arterial blockage resulted from placement of a traction suture through the lower pole of the testis (26). Each septal compartment created by the tunica albuginea encapsulates at least one centrifugal artery with surrounding seminiferous tubules (53). Mostafa et al. (41) divided the testis into three vascular zones: the rich vascular areas comprising the upper pole, mediastinum testis, and posterolateral segments; the moderate vascular area of the middle third of the lateral surfaces; and the poor vascular areas of the anterior border and anterolateral surfaces.

The location of the testes outside the main body cavity makes them vulnerable to traumatic injury and torsion. Within the body, the long distance of travel across several anatomic planes by the internal spermatic artery and the other structures of the spermatic cord, as well as their delicate nature, exposes them to iatrogenic injury. Spermatic cord structures, including the testicular artery, may be injured during an inguinal hernia repair. In adults, the use of mesh for hernia repair can involve the spermatic cord with inflammation or direct obstruction. In children, the fine structures of the spermatic cord can be ligated inadvertently along with the hernia

sac. The testicular artery and lymphatics may be compromised during varicocelectomy. Even with microsurgical technique, accidental artery ligation has occurred in approximately 1% of 2,102 cases (4). Of these, 5% resulted in testicular atrophy; the low incidence of morbidity was attributed to the preservation of the cremasteric and/or secondary testicular arteries (4).

Venous channels run independent of arteries, draining into surface veins of the tunica albuginea or into a central vein near the mediastinum; these veins feed the pampiniform plexus (54). Lymph fluid of the testis and epididymis travels in the spermatic cord to the lumbar or para-aortic lymph nodes (40,55).

---

### Countercurrent Heat Exchange

---

The control of blood flow to the testis is a complex collaboration of many factors, including nervous and hormonal control, temperature, and posture (54). As for all organ systems, blood flow is critical for testicular function and its effects on the system as a whole. Beyond the importance of flow rate to the inflow of oxygen and nutrients, the delivery of androgens to the body relies on testicular blood flow (54). Furthermore, the countercurrent heat exchange system of the testicular vasculature has been widely discussed in the context of varicocele pathophysiology. The arteries are intimately intermingled with the veins along the spermatic cord with the surrounding pampiniform plexus (64), allowing for efficient heat exchange and cooling of the testis. As a result of this mechanism, the blood entering the testis is 2°C to 4°C lower than rectal temperature (1), and intratesticular temperatures are 3°C to 4°C lower than rectal temperature (32).

---

### Blood–Testis Barrier

---

The relative isolation of the testis fluid is attributed to the blood–testis barrier formed by inter–Sertoli cell tight junctions (63). Lipid solubility, not molecular size, is the main determinant of substance entry into the testis fluid, although glucose and testosterone are two substances that enter more rapidly than expected (55). The barrier is established at puberty, and once formed is resistant to disruption (55). Efferent duct ligation and subsequent distention of the seminiferous tubules is one way to disrupt the barrier (55). The blood–testis barrier may serve to optimize tubular conditions for meiosis, and the immunological isolation of the testis fluid may be a secondary benefit (55). Men with failure of the barrier (i.e., men having undergone vasectomy) can form antibodies against their own spermatozoa (55). Holash et al. (21) hypothesized that testicular microvessels form part of the blood–testis barrier. They reported several markers of barrier properties, such as glucose transporter and P-glycoprotein, in testicular microvessels analogous to brain microvessels. They also found intertubular Leydig cells adjacent to microvessels to express the astrocyte markers glial fibrillary acidic protein, glutamine synthetase, and S-100 protein; astrocytes help to maintain barrier features in brain microvessels (21).

Sperm cells must travel from the basal compartment to the adluminal and luminal compartments. Two theories exist to explain how spermatocytes cross the blood–testis barrier

during the course of spermatogenesis. In the “zipper” theory, tight junctions at the basal domain of Sertoli cells break down to allow passage of spermatocytes as new tight junctions are formed behind them (37). In the “repetitive removal of membrane segments” theory, stress created by spermatocytes alters tight junction fibrils (37).

---

### Innervation

---

No somatic nerves supply the testis. Scrotal and spermatic branches of the genitofemoral and ilioinguinal nerves as well as sympathetic fibers along the testicular artery mediate testicular pain (19). The genital branch of the genitofemoral nerve innervates the cremaster muscle and scrotal skin, and a branch of the ilioinguinal nerve innervates the skin of the upper scrotum and base of the penis. Spermatic cord traction during scrotal surgery may even activate peritoneal stimulation (62). Autonomic innervation is provided by the superior spermatic nerve and the inferior spermatic nerve (14). The superior spermatic nerve originates from the celiac and aortic plexuses and travels along the testicular vessels to form the major nerve supply of the testis (14). Sympathetic fibers originate in thoracic segments 10 and 11, whereas the parasympathetic fibers come from the vagus nerve (14). The inferior spermatic nerve travels with the ductus deferens and through the epididymis to innervate the lower pole of the testis (14). Sympathetic fibers originate in the inferior mesenteric and hypogastric plexuses, and parasympathetic fibers branch from the pelvic nerve (14). Evidence from animal models indicates that the nerve supply to the testis helps regulate its endocrine function. However, the precise function of testicular innervation in humans remains unclear.

Testicular pain is a common referral for urologists and can be secondary to infection, inflammation, trauma, varicoceles, hydroceles, and other causes. Orchialgia can be acute or chronic, and it is best treated by addressing the underlying disorder, such as varicoceles. As another example, vasectomy reversal can alleviate postvasectomy pain syndrome. However, the etiology of chronic testicular pain remains unknown in up to 25% of patients even after extensive workup (8). For these men, treatment ranges from psychological support to medication, from regional nerve blocks to surgery (36). Inguinal orchiectomy is one option, providing complete pain relief in 75% of patients in one study (8). In another study, however, orchiectomy failed in 80% of patients (6). Understanding the innervation of the testes and scrotum can help to target surgical management. Levine and Matkov (36) reported microsurgical denervation of the spermatic cord, including branches of the ilioinguinal and genitofemoral nerves and autonomic fibers, to provide complete pain relief in 76% and partial relief in 9%. Heidenreich et al. (19) reported a 96% complete response rate.

---

### Seminiferous Tubules

---

The seminiferous tubules contain the germinal epithelium. They form the bulk of the testis, with 15 to 25 m of length per gram of tissue in humans (3,55). As the testis declines in size with age, there is a corresponding shortening of the

**FIGURE 62.6** Normal spermatogenesis showing several cellular associations (stages) in a seminiferous tubular cross section. *Sb1*, round spermatid; *Sc* and *Sd2*, elongated spermatids; *II*, secondary spermatocyte; *P*, pachytene spermatocyte; *Z*, zygotene spermatocyte; *G*, spermatogonia; *S*, Sertoli cells (hematoxylin and eosin, magnification 1,000 $\times$ ). (From Jow WW. Testis biopsy. In: Goldstein M, ed. *Surgery of male infertility*. Philadelphia: WB Saunders, 1995:15, with permission.) Inset: Exaggerated, schematic illustration of the blood–testis barrier formed by tight junctions of Sertoli cells.

seminiferous tubules (33,55). The tubules are a series of convoluted loops with their two ends opening into the rete testis; they are further organized into about 300 lobules, with one to four tubules per lobule (55). The tubular wall has four layers: an internal noncellular layer or basement membrane, an internal cellular or intralamellar layer containing smooth muscle cells, an external noncellular layer similar to the internal noncellular layer, and an external cellular layer organized from cells of the intertubular mesenchyme (7). This flexible wall regulates the entry of fluid and substances and may contribute to the transport of spermatozoa with rhythmic peristaltic contractions (7).

## Germinal Epithelium

### Germ Cells and Spermatogenesis

A cross-sectional view of a seminiferous tubule demonstrates the wall with basement membrane enclosing Sertoli cells and sperm cells at various stages of development. Spermatogenesis involves three distinct processes: mitotic renewal of constituent stem cells, called spermatogonia; meiotic halving of the chromosomal number of the sperm product; and structural development of the mature spermatozoan (10). Spermatogenesis begins near the basement membrane, and the cells migrate toward the lumen as they develop, a process facilitated by the Sertoli cells (10).

Spermatogonia (2N) have significant contact with the basement membrane of the seminiferous tubule. They are classified as type A dark, type A pale, and type B based on their appearance on electron microscopy (10). Cells undergoing meiosis are identified as spermatocytes. In meiosis I, the diploid primary spermatocyte (2N becomes 4N with DNA replication),

which has duplicated its DNA, forms two haploid secondary spermatocytes (2N). In meiosis II, the chromatids of each chromosome of the secondary spermatocyte divide to form spermatids (1N). In transforming the spermatid into a spermatozoan, spermiogenesis involves multiple steps, including acrosome formation, nuclear changes, neck and tail formation, and reorganization of the cytoplasm (10).

### Supporting Cells

In addition to the germ cells, supporting cells, also called follicular cells, small epithelial cells, or indifferent cells, reside in the seminiferous tubules (7). These somatic elements originate from the coelomic cells of the gonadic crests and organize into sex cords shortly after sexual differentiation (7). The supporting cells increase their numbers by mitosis prior to spermatogenesis, and they gradually convert to Sertoli cells with the onset of spermatogenesis (7).

### Sertoli Cells

Sertoli cells are polymorphous and highly cohesive (7). The size and shape of Sertoli cells vary over the course of the seminiferous epithelial cycle (7). The shape has been described as a short body adjacent to the basement membrane with multiple sheetlike cytoplasmic projections extending toward the lumen, the form of these projections altered by surrounding germ cells (10). Each Sertoli cell spans the basement membrane to the tubular lumen and encloses clusters of germ cells (Fig. 62.6).

The seminiferous epithelial cycle refers to the simultaneous development of several germ cell generations within the seminiferous tubule, in which the cycles of different generations are coordinated (7). In humans, the duration of the seminiferous epithelial cycle is 64 days (20), and the duration of spermatogenesis is 74 to 76 days (56).

The Sertoli cell has many functions. The Sertoli-Sertoli tight junctional complexes effectively separate the exterior and interior compartments of the seminiferous epithelium (2). The Sertoli cell also secretes numerous products, including inhibin, androgen-binding protein (ABP), testicular transferrin and ceruloplasmin (iron and copper transport proteins), plasminogen activators, and growth factors (2). It even produces and metabolizes steroid hormones, although on a much smaller scale than Leydig cells (2). The secretory capacity of the Sertoli cell is bidirectional, which means it can secrete into both the tubular lumen and the interstitium and systemic circulation (67). In addition to supplying nutrition, adhesion, and transport functions to cells undergoing spermatogenesis, Sertoli cells may regulate apoptosis of germ cells (46). Sertoli cell function is regulated primarily by FSH and testosterone, although other substances, such as insulin, glucagon, calcitonin, estrogens, other steroid hormones, and vitamins, play a supporting role (2). Surrounding cells such as germ cells, Leydig cells, and myoid cells interact with the Sertoli cell by cell-cell contacts and paracrine factors (2). The Sertoli cell population is a major determinant of testicular size along with germ cells (2). The ratio of germ cells to Sertoli cells is estimated at 16:1 (2,67).

---

### Interstitial Tissue

---

The interstitium surrounding the seminiferous tubules is composed of loose fibrous connective tissue and a network of blood vessels, nerves, and lymphatics. The interstitial tissue also contains cells including fibroblasts, reticular cells, macrophages, plasma cells, lymphocytes, mast cells, and epithelioid cells called Leydig cells (22).

### Leydig Cells

Organization of the Leydig cell within the interstitium varies by species, but in humans Leydig cells form small aggregations near blood and lymphatic vessels (10). LH stimulates the production of androgens by the Leydig cell through several mechanisms, including acceleration of synthesis of the proteins

involved in steroidogenesis and augmentation of cholesterol transport to and within the mitochondria (16). Leydig cells communicate extensively with Sertoli cells and germ cells via paracrine regulation of testicular function (50). There are two generations of Leydig cells in humans: fetal and adult. Fetal Leydig cells originate from undifferentiated mesenchymal cells at 8 weeks of gestation and regress starting at 14 weeks (5). Adult Leydig cells are evident at puberty (5). The gradual decline in plasma testosterone with advancing age correlates with age-related attrition of Leydig cells (28) or may possibly be due to alterations in LH function and oxidative damage to proteins involved in steroidogenesis (69).

### Rete Testis and Efferent Ducts

The rete testis is a network of anastomosing channels located at the testicular hilum along the epididymal edge of the testis (55). Cells lining the rete testis vary from squamous to columnar and are joined near the lumen by specialized junctions (55). The rete testis is closely associated with the testicular artery at the surface of the testis (55). Sperm and fluid flow from the rete testis and travel through efferent ducts to reach the epididymis (55). These ducts are lined with principal and ciliated cells (55). Although these cells have minimal secretory capacity, the ciliated cells may be involved with fluid resorption (55). In contrast to the rete testis, the efferent ducts are bathed by a dense subepithelial capillary bed (31).

---

## SUMMARY

---

Our current knowledge of male reproductive anatomy and physiology is a culmination of research spanning more than a century. Recent advances in molecular techniques have revealed some of the underlying mechanisms, such as cell signaling, involved in spermatogenesis and development of the reproductive tract. This chapter reviewed the basic anatomy of the testis, a simplified framework that can be filled in with future developments in the field.

## CHAPTER 63 ■ SIMPLE ORCHIECTOMY

BRETT S. CARVER AND SHERRI M. DONAT

Simple orchiectomy involves the removal of one or both testes at the distal spermatic cord, usually through an anterior transscrotal approach, although it has also been described through a suprapubic approach (9). It is used in the treatment of benign intrascrotal processes and as a method of androgen ablative therapy in patients with advanced prostate cancer.

Among men in the United States, prostate cancer is the most commonly diagnosed malignancy, with 186,320 new cases projected to be diagnosed in 2008 and approximately 28,660 deaths attributed to it (1). Since Huggins and Hodges (7) first demonstrated the therapeutic benefit of hormonal ablation in the treatment of advanced prostate cancer, bilateral scrotal orchiectomy has been commonly utilized as a means of removing the testosterone-producing tissue, thereby bringing serum levels to castrate levels. Although it has been by tradition used only for treatment in patients with advanced or metastatic disease, it is currently being evaluated for patients with presumed localized disease in both neoadjuvant and adjuvant settings to determine if it has any benefit in decreasing the chance of local or systemic recurrence and improving survival when used in combination with the traditional monotherapies of surgery or radiation (4).

---

### DIAGNOSIS

---

The initial diagnosis of prostate cancer is usually made through a combination of digital rectal exam, prostate-specific antigen level, patient symptoms, and transrectal ultrasound-directed biopsy, although it is on occasion found incidentally on transurethral resection for obstructive benign disease. Advanced disease may involve lymph nodes, bone, or, less commonly, visceral or soft tissue lesions and may be documented by physical examination, elevated prostatic acid phosphatase levels, abnormal bone scan, computerized tomography scan, magnetic resonance imaging, plain film bone survey, or chest X-ray. Lymph node involvement may be determined by biopsy of enlarged nodes seen on imaging studies or unexpectedly during the pelvic lymph node dissection for a radical prostatectomy.

Benign intrascrotal processes such as epididymal orchitis or devitalization of testicular tissue by trauma or torsion are diagnosed by physical examination, patient symptoms, nuclear testicular examinations, color Doppler ultrasonic examinations, and/or surgical exploration. In general, inflammatory processes show increased flow on both nuclear scans and Doppler flow studies and processes causing devascularization show decreased or no flow on nuclear and Doppler flow studies. However, if there is any question as to whether an acute scrotum represents a testicular torsion versus an epididymal orchitis, it should be surgically explored immediately to answer the question and render the appropriate treatment.

---

### INDICATIONS FOR SURGERY

---

The primary indication for bilateral scrotal orchiectomy is advanced prostate cancer requiring hormonal ablation as treatment. Other indications for simple orchiectomy include benign intrascrotal disorders such as a traumatic injury to the testis requiring partial or complete removal of the devitalized tissue, testicular necrosis following prolonged torsion, and severe epididymal orchitis that is refractory to antimicrobial therapy.

Malignant diseases of the testes, such as suspected germ cell tumor, should never be managed with a simple orchiectomy through a transscrotal approach. Suboptimal approaches to testicular neoplasms, including scrotal orchiectomy and transscrotal biopsy, can alter the normal lymphatic drainage of the testis and increase the burden of therapy for the patient (3). A meta-analysis of 206 cases of scrotal violation reported a local recurrence rate of 2.9%, compared to 0.4% for patients treated with inguinal orchiectomy, but no difference in systemic relapse or survival were appreciated (3). Therefore, if there is any suspicion of testicular cancer, a radical orchiectomy through an inguinal incision should be performed.

---

### ALTERNATIVE THERAPY

---

There are now several agonist analogues of gonadotropin-releasing hormone that inhibit the pituitary gonadal axis, resulting in the downregulation of luteinizing hormone-releasing hormone receptors and subsequent decrease in gonadotropin secretion. These are equally effective in achieving hormonal ablation and provide an alternative to orchiectomy in patients for whom the psychological implications of the surgery are too great (4); however, the cost effectiveness of surgery is certainly superior to that of chemical castration. While the use of bilateral orchiectomy for the management of metastatic prostate cancer has declined with the implementation of gonadotropin-releasing hormone agonists or antagonists, a recent study demonstrated that, with changes in Medicare reimbursement, the rates of surgical castration have increased over recent years (14).

Alternatives to the total removal of the testis and epididymis have been explored and include subcapsular orchiectomy and subepididymal orchiectomy (2,6,8,12). These give the cosmetic effect of a testis being present but also achieve the therapeutic goal of androgen ablation. There has been some controversy (10) over the efficacy of subcapsular orchiectomy since it was first described in 1942 by Riba (12); however, multiple modern studies have demonstrated its efficacy and suggest that any residual testosterone production is most likely a result of incomplete removal of the intratesticular contents (2). Testicular prostheses are also available for use in

patients who desire a better cosmetic result, and these may be placed in either the tunica vaginalis or within the tunica albuginea (13). Kihara and Oshima (8) have also described an epididymal-sparing orchiectomy with insertion of a pedicled fibrofatty tissue graft to preserve scrotal cosmesis after bilateral orchiectomy. This type of procedure may be complicated by epididymitis, which can be minimized by performing a vasectomy at the time of the procedure (6). Advantages of a fibrofatty tissue graft over implants or prostheses are that there are no risks of developing autoimmune disorders and rupture or migration complications.

---

## SURGICAL TECHNIQUE

---

### Simple Orchiectomy

---

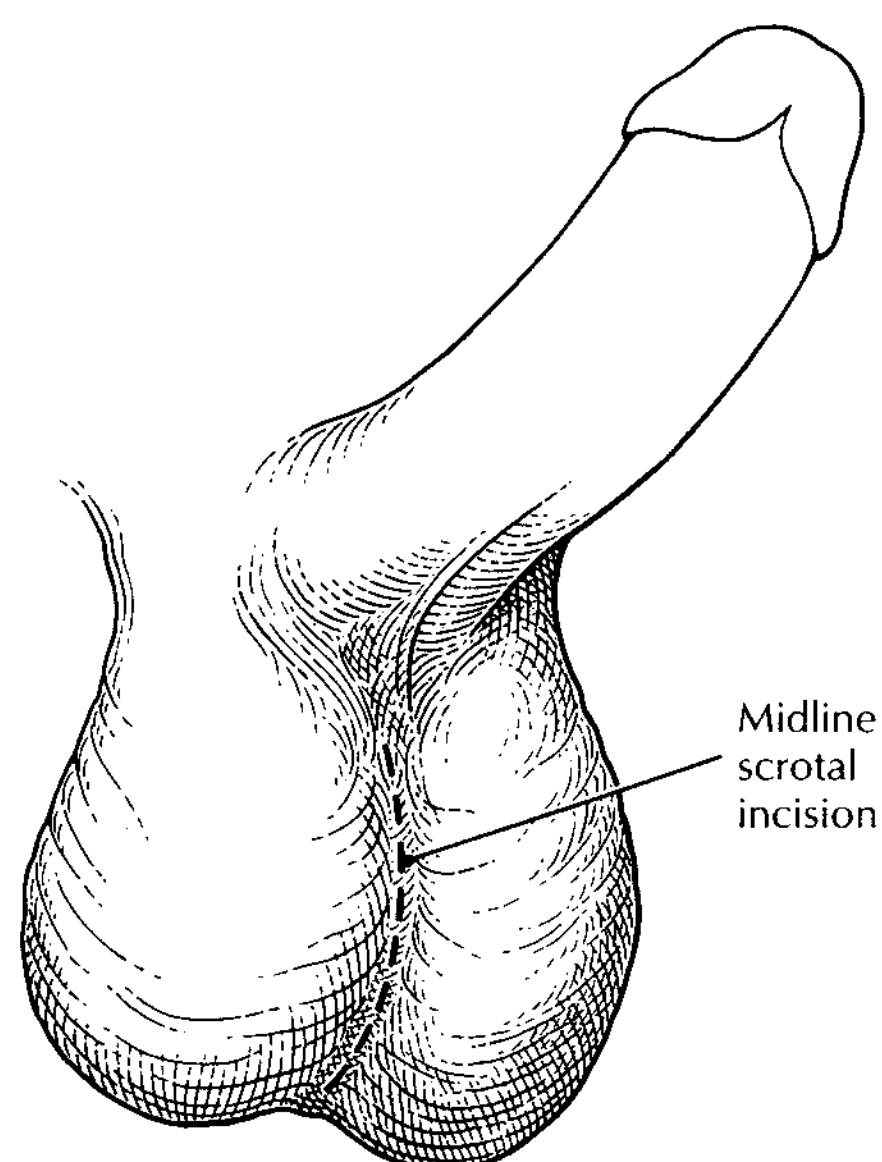

This procedure may be performed with local, regional, or general anesthesia. Local anesthetic sensory blockade is obtained by infiltrating the spermatic cord in the region of the vas deferens in the high scrotum just below the pubic tubercle with a 0.5% bupivacaine solution. Care must be taken to ensure that the block is not injected intravascularly by drawing back on the syringe prior to injecting the medication. The same solution is then injected subcutaneously at the site of the anterior scrotal incision. Sensory blockade should then be tested by pinprick before the beginning of the procedure.

---

### Scrotal Approach

---

The anterior scrotal wall is shaved to remove existing hair, and the scrotum and genitalia are prepared in a sterile manner. A 2.5- to 3.0-cm midline incision is made just through the skin along the median raphe in the anterior scrotal wall using a no. 15 blade scalpel while the assistant pushes a testicle toward the incision between his or her thumb and index finger so that the testicle lies directly under the incision (Fig. 63.1). By electrocautery, the incision is then carried down through

**FIGURE 63.1** A midline scrotal incision over the median raphe allows access to both testes.

**FIGURE 63.2** The vas deferens is ligated separately from the vascular structures of the cord. The vascular structures are double ligated with both a free tie proximally and a suture ligature distally using 0 Vicryl.

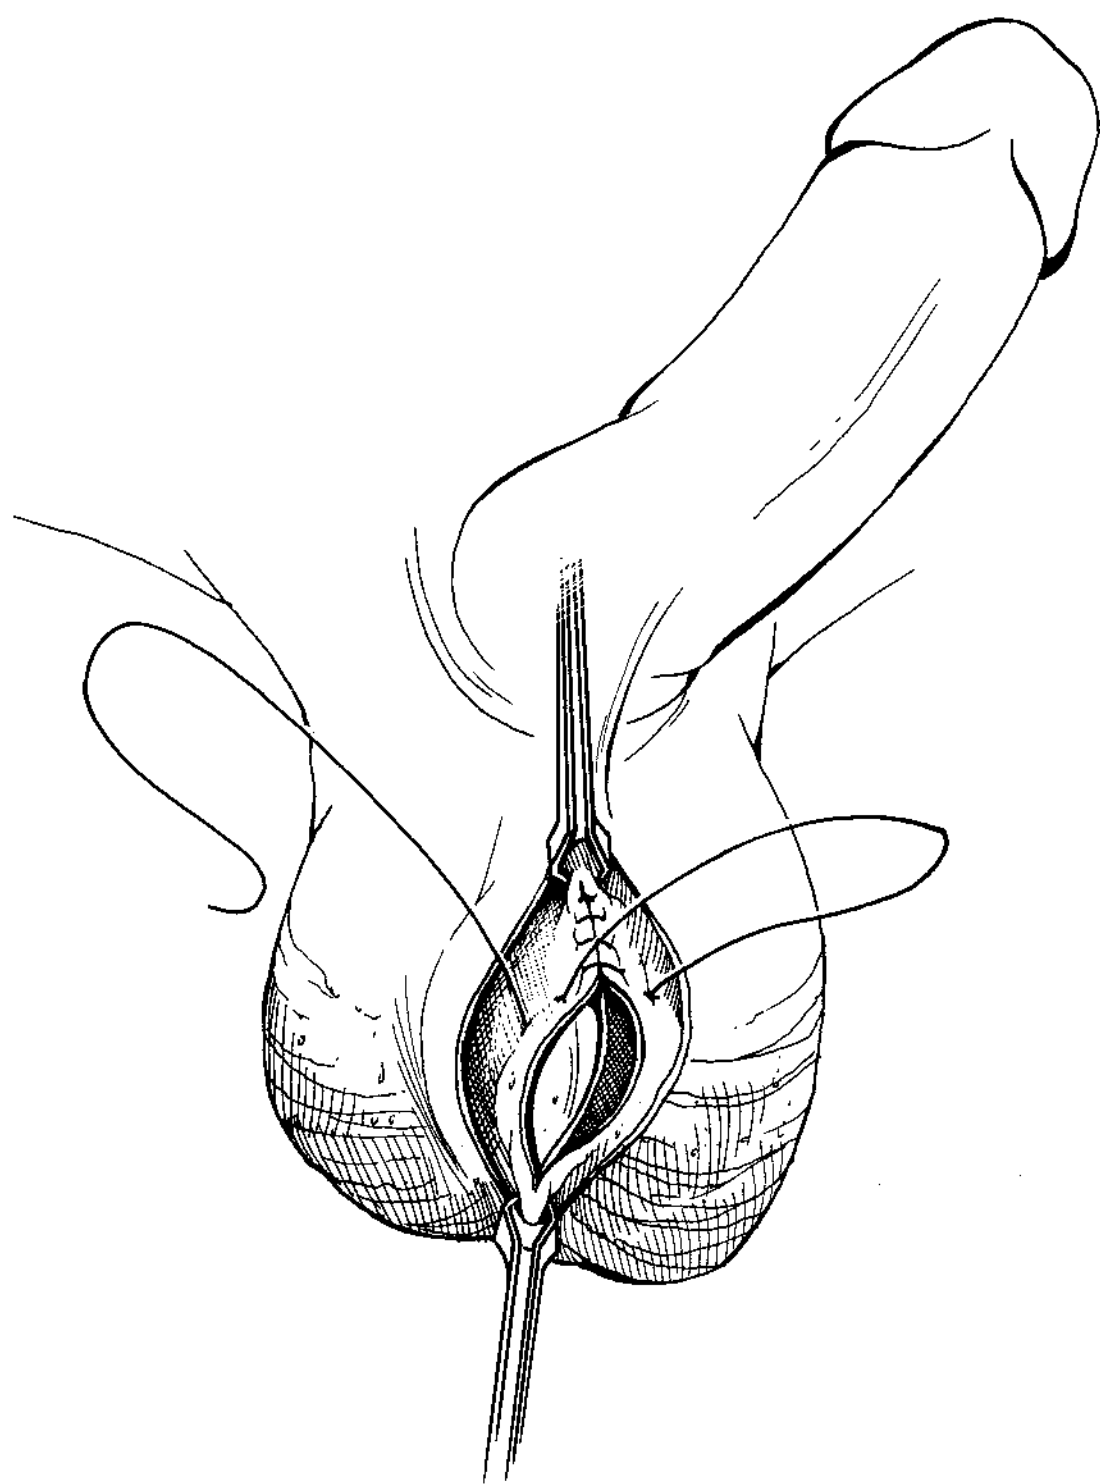

the dartos and cremasteric layers until the parietal portion of the tunica vaginalis is incised directly over the testis. This is usually evidence by a gush of fluid from the peritesticular space. The incision in the tunica vaginalis is lengthened in both directions far enough to allow exposure of the entire testicle through the wound. The surrounding tunics are freed from the spermatic cord by a combination of blunt and sharp dissection. Meticulous hemostasis may be obtained in each layer as it is entered with electrocautery. Once the spermatic cord is isolated, the vas deferens is separated, doubly clamped, divided, and ligated with 2-0 Vicryl ties (Fig. 63.2). The remainder of the cord structures may be divided into one or more bundles and are doubly clamped on the proximal side and singly clamped on the distal side. Once divided, the proximal portion of the cord is ligated with a 0 Vicryl free tie behind the most proximal clamp, which is then removed, and a 0 Vicryl suture ligature is placed just distal to the free tie (Fig. 63.2). Before the cord is released to retract proximally, the tunics, dartos, and subcutaneous areas are again inspected for hemostasis. Once this is felt to be adequate, the cord is allowed to retract and attention is turned to the opposite testicle. It is then removed through the same midline incision in the same manner. This leaves two openings in the tunica vaginalis and dartos layers, which are separated by a median septum. These deep layers are then closed in one layer using a 3-0 Vicryl running suture. Allis clamps are placed at either end of the median septum to facilitate the exposure (Fig. 63.3). The skin is then closed with interrupted 3-0 chromic sutures and a gauze dressing is applied. Drains are not required but can be considered if there is doubt about hemostasis. Compression or turban dressings may also be used if there is concern over postoperative hemostasis or edema.

---

### Suprapubic Approach

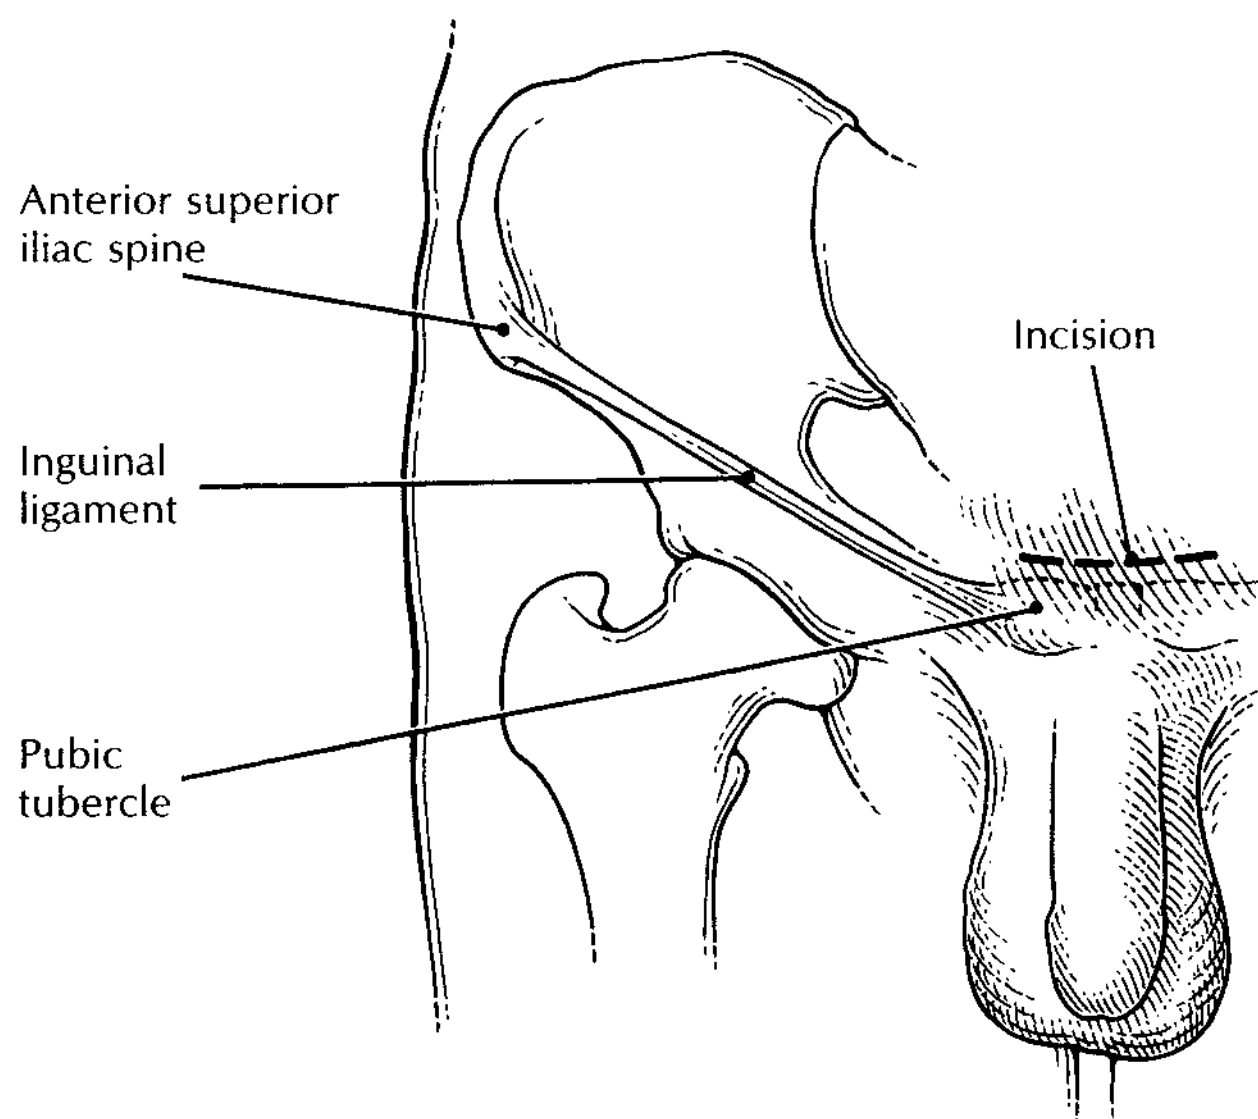

---

This approach is advantageous in patients in whom one wants to avoid a scrotal incision and/or place testicular prostheses at the time of the orchiectomy. The patient again is placed in the supine position and the suprapubic area is shaved. A

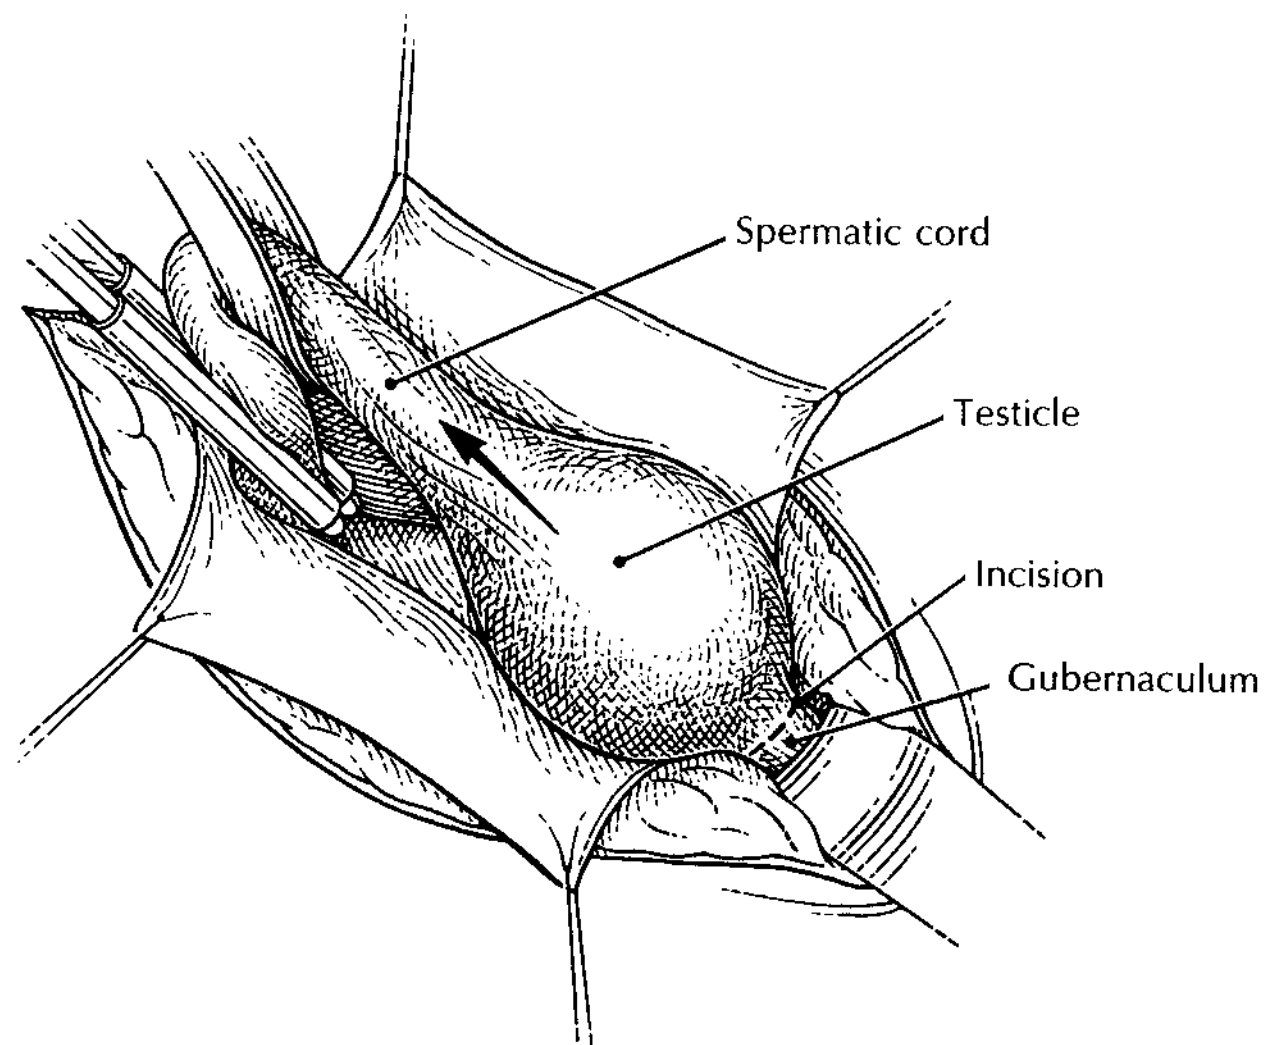

**FIGURE 63.3** Closure of the deep layers of the scrotum, including the dartos musculature and testicular tunics laterally and the midline septum in one running layer.

4- to 5-cm transverse incision is made in the midline approximately 2 to 3 cm above the pubic symphysis (Fig. 63.4). This is extended down through the subcutaneous tissues to the level of the rectus fascia using electrocautery. The subcutaneous tissue is then swept bluntly toward the external inguinal ring, exposing the distal spermatic cord, which is then isolated just distal to the ring in the upper scrotum (Fig. 63.5). Right-angle retractors are helpful to obtain exposure during this dissection by moving the incision toward the side being worked on. The spermatic cord is looped with a Penrose drain and the

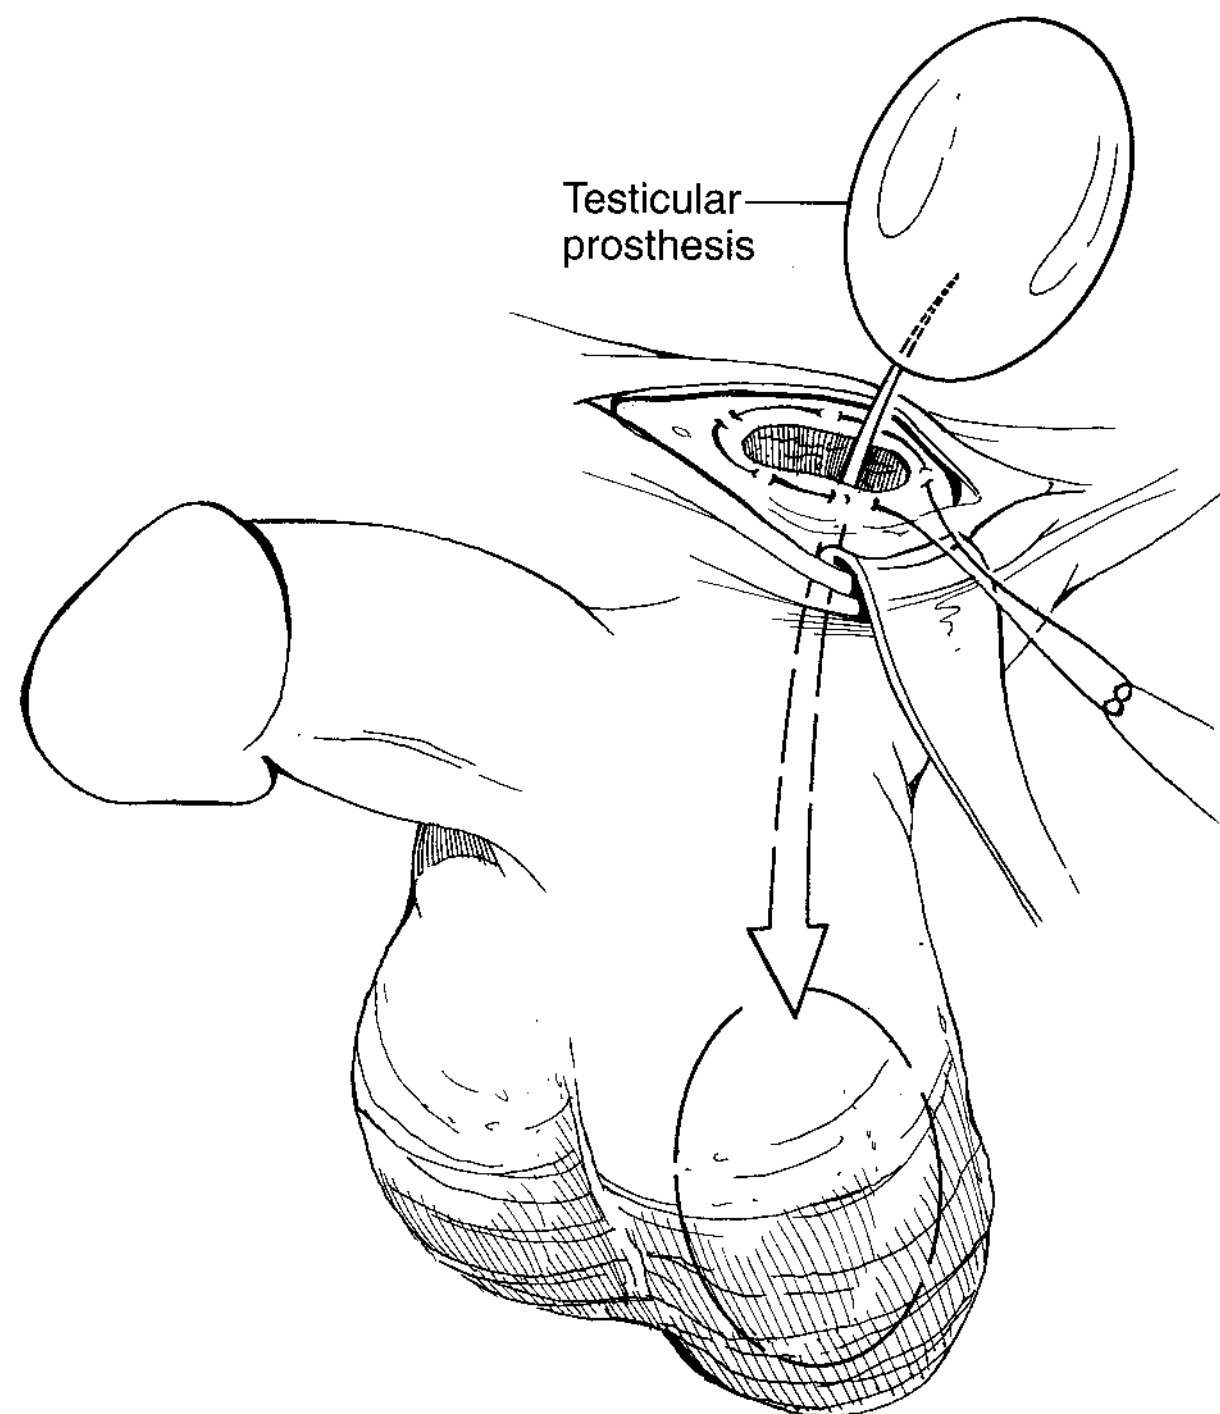

**FIGURE 63.4** A midline suprapubic incision 2 to 3 cm above the pubis allows access to both testes at a level just below the external ring.

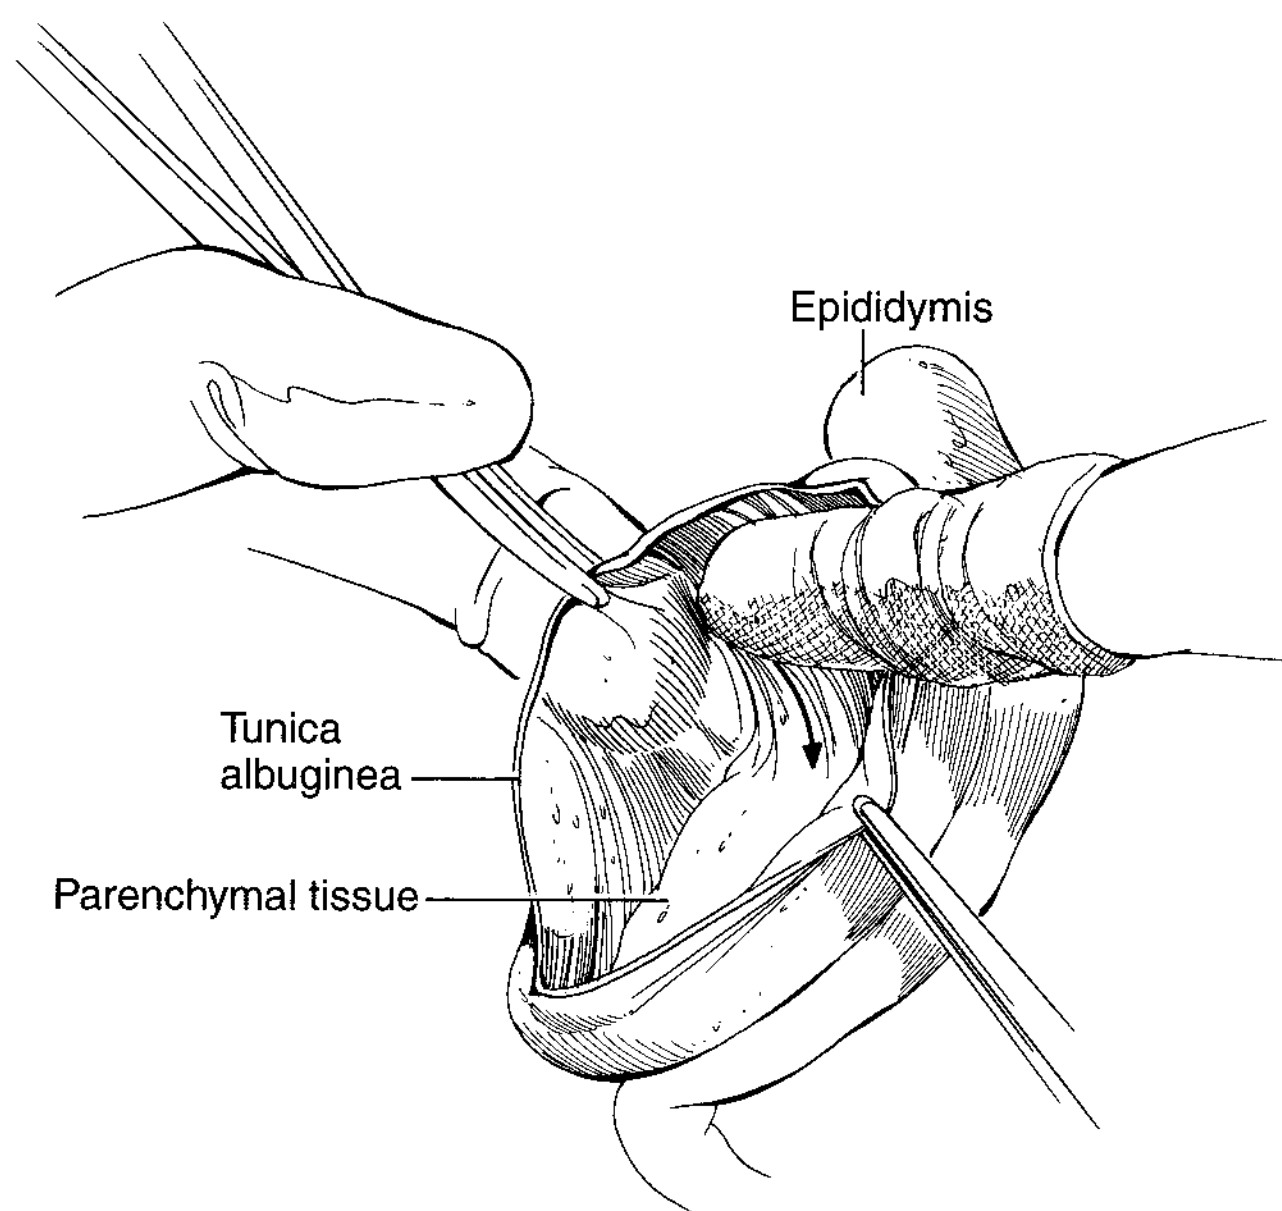

**FIGURE 63.5** Isolation of the cord with a Penrose drain. Division of the gubernaculum allows complete mobilization of the testis from the scrotum.

testicle is delivered into the wound by placing upward pressure on the scrotum and testicle, with simultaneous upward traction on the cord with the Penrose drain. The gubernaculum is then divided, which mobilizes the testicle (Fig. 63.5). The vas deferens and spermatic cord are then divided as previously described. If testicular prostheses are desired, they are then placed into the empty scrotum after adequate hemostasis is ensured, and a pursestring suture of 3-0 silk is used to close the neck of each hemiscrotum (Fig. 63.6). The Scarpa fascia is closed with 3-0 Vicryl suture, and the skin is closed with a 4-0 Vicryl subcuticular suture reinforced with benzoin and Steri-Strips.

**FIGURE 63.6** If a prosthesis is desired, it is placed into the empty hemiscrotum. To prevent migration, a pursestring suture is used to close the neck of the hemiscrotum, eliminating the need for an anchoring suture.

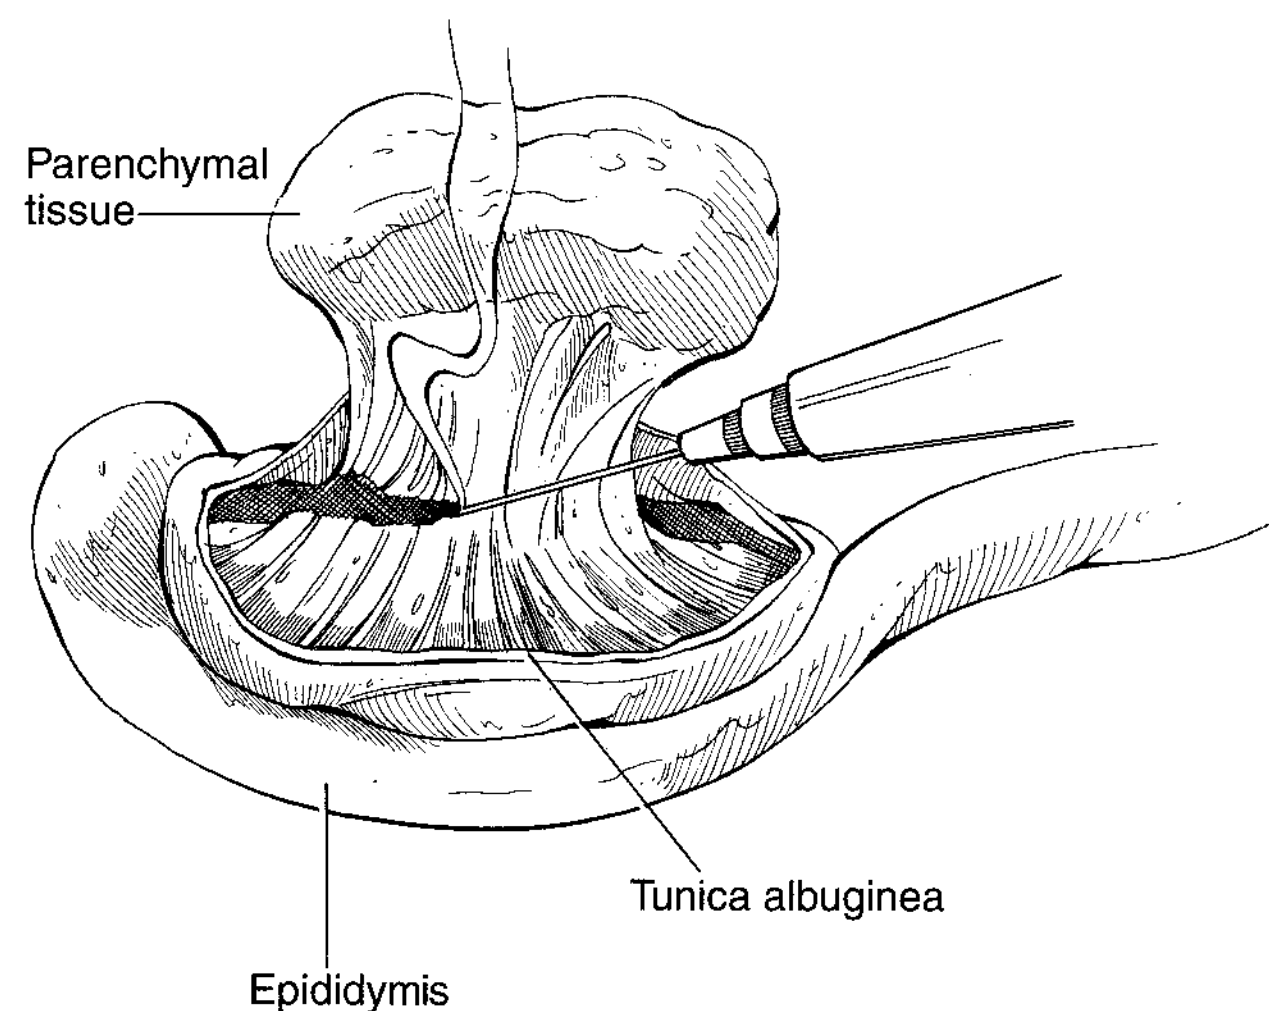

**FIGURE 63.7** The tunica albuginea is opened in midline opposite the epididymis and the contents are swept bluntly to the midline attachment.

### Subcapsular Orchiectomy

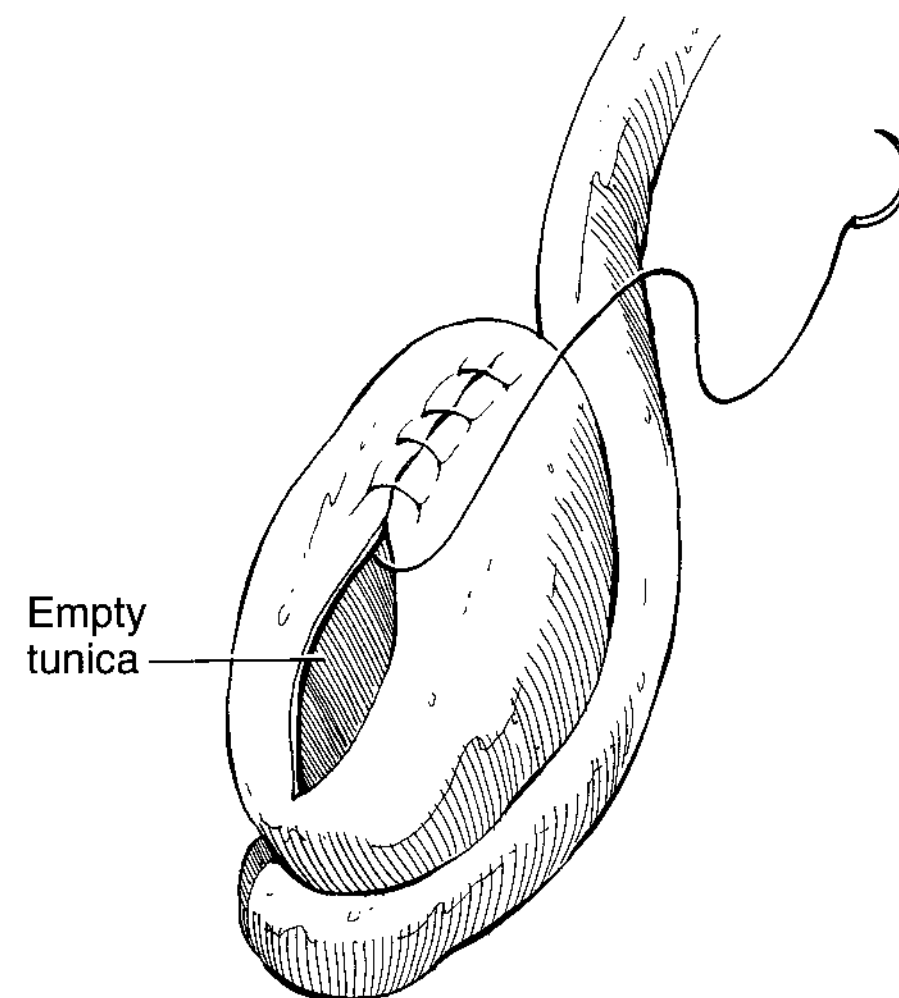

This approach is used in patients who desire the cosmetic effect of testicles being present without the use of testicular prostheses. The operation is approached through the anterior scrotum as previously described (Fig. 63.1). Once the testicle is delivered to the wound, the tunica albuginea is opened in midline in a cephalad-to-caudad fashion. Hemostats are placed on the edges of the capsule to provide traction, and an index finger is placed behind the capsule to invert it (Fig. 63.7). This maneuver facilitates the removal of the parenchymal contents, which are swept to the midline using a gauze sponge. The midline attachment of the parenchyma is divided using electrocautery, and the remainder of the interior capsule is cauterized to ensure hemostasis and complete destruction of all testicular parenchyma (Fig. 63.8). This technique has also been described using a CO<sub>2</sub> laser (15). The tunica albuginea is then closed using a running 3-0 Vicryl suture (Fig. 63.9) and the residual testicular tunics, adnexa, and cord are returned to the scrotum. The deep layers of the scrotum are closed in one layer as previously described, as is the skin (Fig. 63.3).

### Subepididymal Orchiectomy

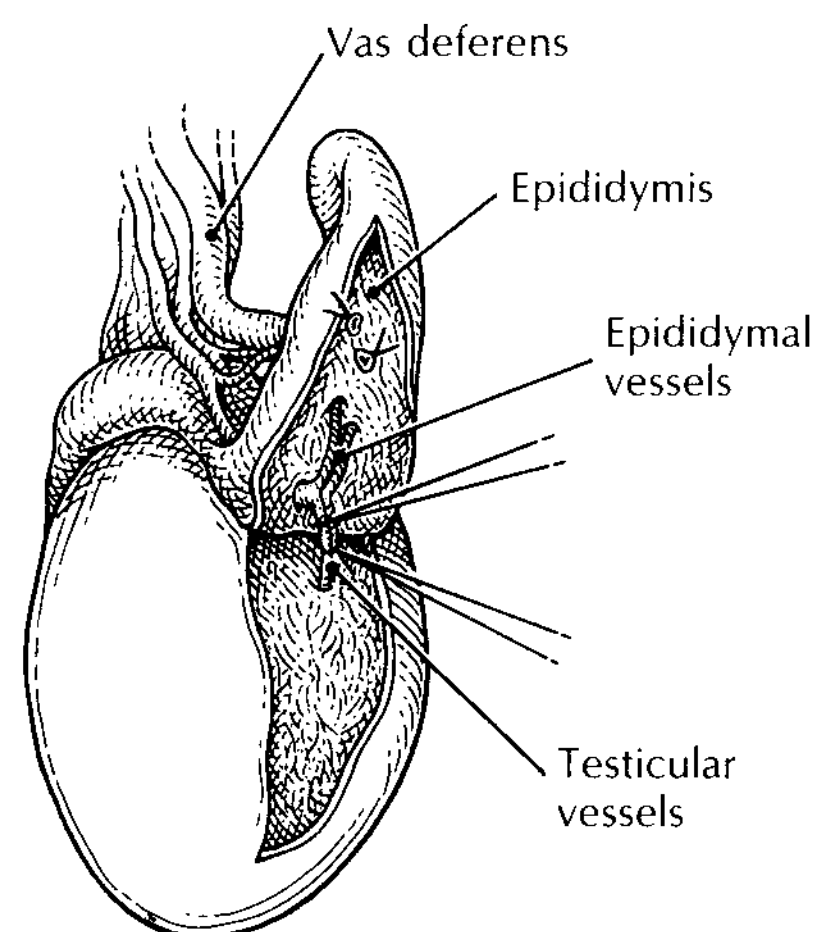

This is another procedure offered as an alternative to simple scrotal orchiectomy for a more acceptable cosmetic result. Again, the initial exposure to the testicles is the same as previously described for the anterior scrotal approach (Fig. 63.1). Once the testicle is delivered to the wound, a vasectomy is performed including double ligation and division to minimize the possibility of postoperative epididymitis (6). A line of dissection between the cleavage plane of the testis and the epididymis is utilized (Fig. 63.10). Dissection is started at the head of the epididymis, and the epididymal tissue is clamped for hemostasis. Care must be taken to secure the spermatic artery entering the testis at a point between the midportion and the tail of the epididymis. The clamped epididymal tissue is ligated using a

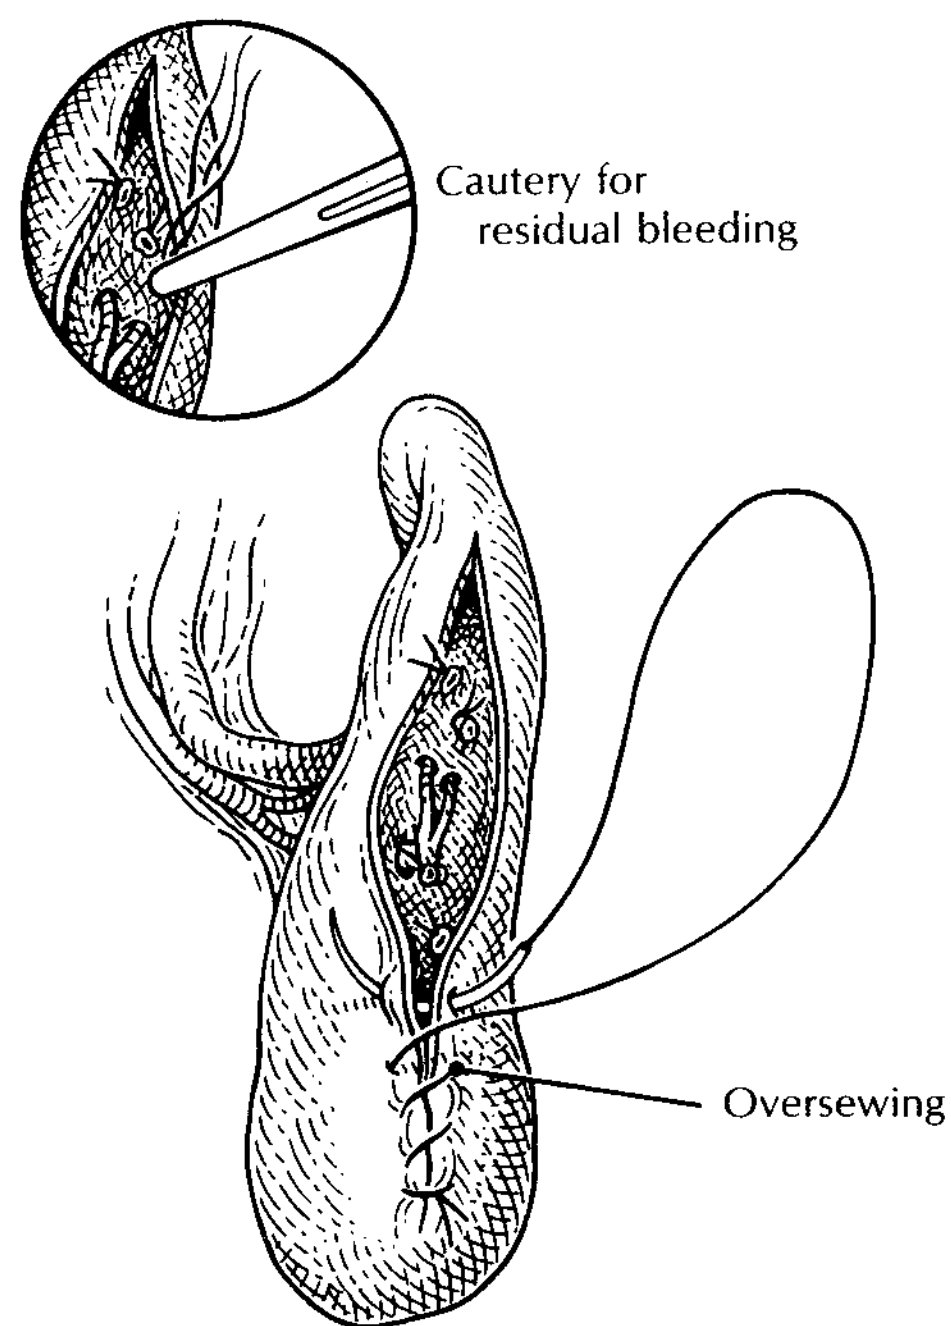

**FIGURE 63.8** The parenchymal tissue is then removed at its midline attachment with electrocautery and the internal surface of the capsule is cauterized.

**FIGURE 63.9** The tunica albuginea is reapproximated with a running 3-0 Vicryl suture.

**FIGURE 63.10** Dissection of the testis from the epididymis, ligating the epididymal side over clamps with Vicryl suture.

**FIGURE 63.11** After removal of the testis and further hemostasis with electrocautery, the tunica of the epididymis is closed over the raw surface using a running suture.

3-0 Vicryl suture. Meticulous hemostasis is then obtained using electrocautery, and a running 3-0 Vicryl suture on a tapered needle is used to approximate the edges of the tunica albuginea over the raw surface of the epididymis (Fig. 63.11). The remaining spermatic cord and epididymis are replaced into the scrotum, which is closed as previously described.

---

## OUTCOMES

---

### Complications

---

Complications can include infection, hematoma, edema, and the inadvertent removal of a testicular neoplasm through the scrotal approach. Of these, hematoma can be a significant problem because of the distensible nature of the scrotum,

which prevents any tamponade effect. Re-exploration with evacuation of the hematoma and placement of a drain may be required but can be ineffective when the bleeding dissects subcutaneously in the dartos layer. This has led to the development of several preventative measures to achieve adequate compression of the area postoperatively, including turban-type dressings or compression of the scrotal wall over a gauze bolster as described by Oesterling (11). These techniques should not be substituted for being meticulous in obtaining hemostasis at the time of the procedure.

Infection, depending on the degree of severity, is managed by incision and drainage of any abscess pockets. This is followed by local wound care, which may include wet-to-dry dressing changes, sitz baths, and whirlpool with debridement of any devitalized tissue. Antibiotics can be used in cases where there is induration only and no abscess to drain or in combination with the incision and drainage procedure if needed. If antibiotics are used, they should be directed by the results of wound cultures.

If a testicular neoplasm has been inadvertently removed through a scrotal approach, the remaining inguinal spermatic cord should be removed, as well as a wide excision of the scrotal scar. The hemiscrotum should also be removed if there was any known tumor spillage during the transscrotal procedure. This usually results in cure rates similar to those for conventional initial radical inguinal orchiectomy (5).

---

## Results

---

The effectiveness of scrotal orchiectomy in terms of achieving adequate hormonal ablation in patients with prostate cancer can be easily determined by measuring serum testosterone levels postcastration, which are reduced by approximately 90%. Castrate levels of testosterone have reportedly been achieved by 2 and 15 hours after surgery (2,4). Prostate-specific antigen levels, patient symptoms, and patient survival may be followed to determine the procedure's effectiveness in terms of disease control. Side-effects may include loss of libido, impotence, and hot flashes.

**For benign intrascrotal processes such as epididymal orchitis unresponsive to antibiotics, or devitalized tissues secondary to torsion or trauma, simple orchiectomy is curative.**

# CHAPTER 64 ■ INGUINAL ORCHIECTOMY

DAVID A. SWANSON

Testicular tumors are relatively rare (only 2 to 3 cases per 100,000 men; an estimated 8,090 new cases in the United States in 2008) (8). When they occur, 94% are germ cell tumors and the rest are tumors of the gonadal stroma and secondary tumors of the testis. In black men throughout the world, germ cell tumors occur infrequently, but because they do occur, this diagnosis cannot be excluded on the basis of race alone. Although the etiology of testicular tumors is not known, there is a relatively high association (reported in up to 12% of tumors) with a history of cryptorchidism; in 20% of such cases, the tumor is in the normally descended testis. Orchidopexy does not prevent the subsequent development of tumor; it simply makes the diagnosis easier to establish. Carcinoma in situ (CIS) is also known to be associated with cryptorchidism, and data support the hypothesis that at least some, if not all, germ cell tumors originate as CIS (7).

---

## DIAGNOSIS

---

Most testicular tumors present as a palpable nodule or painless swelling of the testis, often discovered incidentally by the patient or his sex partner. The differential diagnosis of a testicular mass includes tumor, epididymitis, and epididymoorchitis (the two most common diagnoses other than cancer), torsion (the diagnosis of which also requires surgery), and, less commonly, hernia, hydrocele, spermatocele, varicocele, hematoma, and hemocele. The patient with cancer may complain of a dull ache or sense of heaviness. Acute onset of pain is relatively rare and usually indicates bleeding within the tumor or associated epididymitis. Signs and symptoms may be secondary to metastatic spread.

When careful bimanual examination of the testis reveals an intratesticular mass, with or without an associated epididymal mass or tenderness, testicular tumor must be suspected. A transscrotal ultrasound is a widely available, rapid, sensitive, noninvasive, and inexpensive way to determine whether there is a solid mass within the tunica albuginea (12). Color Doppler ultrasound might on occasion help differentiate testicular torsion. Magnetic resonance imaging can also demonstrate the presence of an intratesticular mass but has no established advantage over a careful physical examination plus ultrasound exam. With rare exceptions, all solid masses within the testis should be considered malignant until proven otherwise, and all require surgical intervention.

Patients with testicular tumors commonly have elevated tumor markers, in particular  $\beta$ -human chorionic gonadotropin and  $\alpha$ -fetoprotein. However, the presence of normal marker levels does not exclude malignancy, and there is in general no advantage to waiting for the marker results before operating,

although blood should always be drawn for these tests before orchiectomy (12).

---

## INDICATIONS FOR SURGERY

---

The presence of an intrascrotal mass that cannot be clearly localized to outside the tunica albuginea is sufficient indication for surgical exploration through an inguinal approach. Although a sense of urgency is appropriate, it is not necessary to consider inguinal orchiectomy an emergency procedure; it can be scheduled during regular operating hours.

---

## ALTERNATIVE THERAPY

---

For the patient who has equivocal findings on physical examination and ultrasound that make the diagnosis of epididymitis tenuous, a short course of antibiotics may be tried. If there is no prompt improvement (<10 to 14 days), or if the serum tumor markers are elevated, inguinal exploration should be performed. Although radical (inguinal) orchiectomy is standard therapy for a solid lesion within the tunica albuginea, partial orchiectomy might be appropriate in the patient with a solitary testis or bilateral testicular masses or in the patient whose preoperative evaluation makes the diagnosis of an epidermoid cyst of the testis highly likely (3,5,6,11). The selection criteria, technique, and results of organ-sparing surgery of the testis are presented in Chapter 65.

---

## SURGICAL TECHNIQUE

---

Although regional anesthesia is acceptable, general anesthesia is preferred because of the short duration of the surgery and the possible reflex response to traction on the testicle and cord. With the patient in the supine position, and after adequate anesthesia, the lower abdominal wall, penis, and scrotum are cleaned with a surgical scrub and draped in a sterile fashion so that the palpable testicular mass and ipsilateral hemiscrotum are accessible in the surgical field. By tradition, an oblique skin incision is made approximately 2 cm superior to the inguinal ligament and parallel to that ligament, extending approximately 8–10 cm laterally from just above the pubic tubercle to a point overlying the external inguinal ring. I prefer a more horizontal incision, extending approximately 5 to 8 cm from one fingerbreadth above the superior aspect of the external inguinal ring laterally toward the internal inguinal ring, which might be slightly more cosmetic (Fig. 64.1).

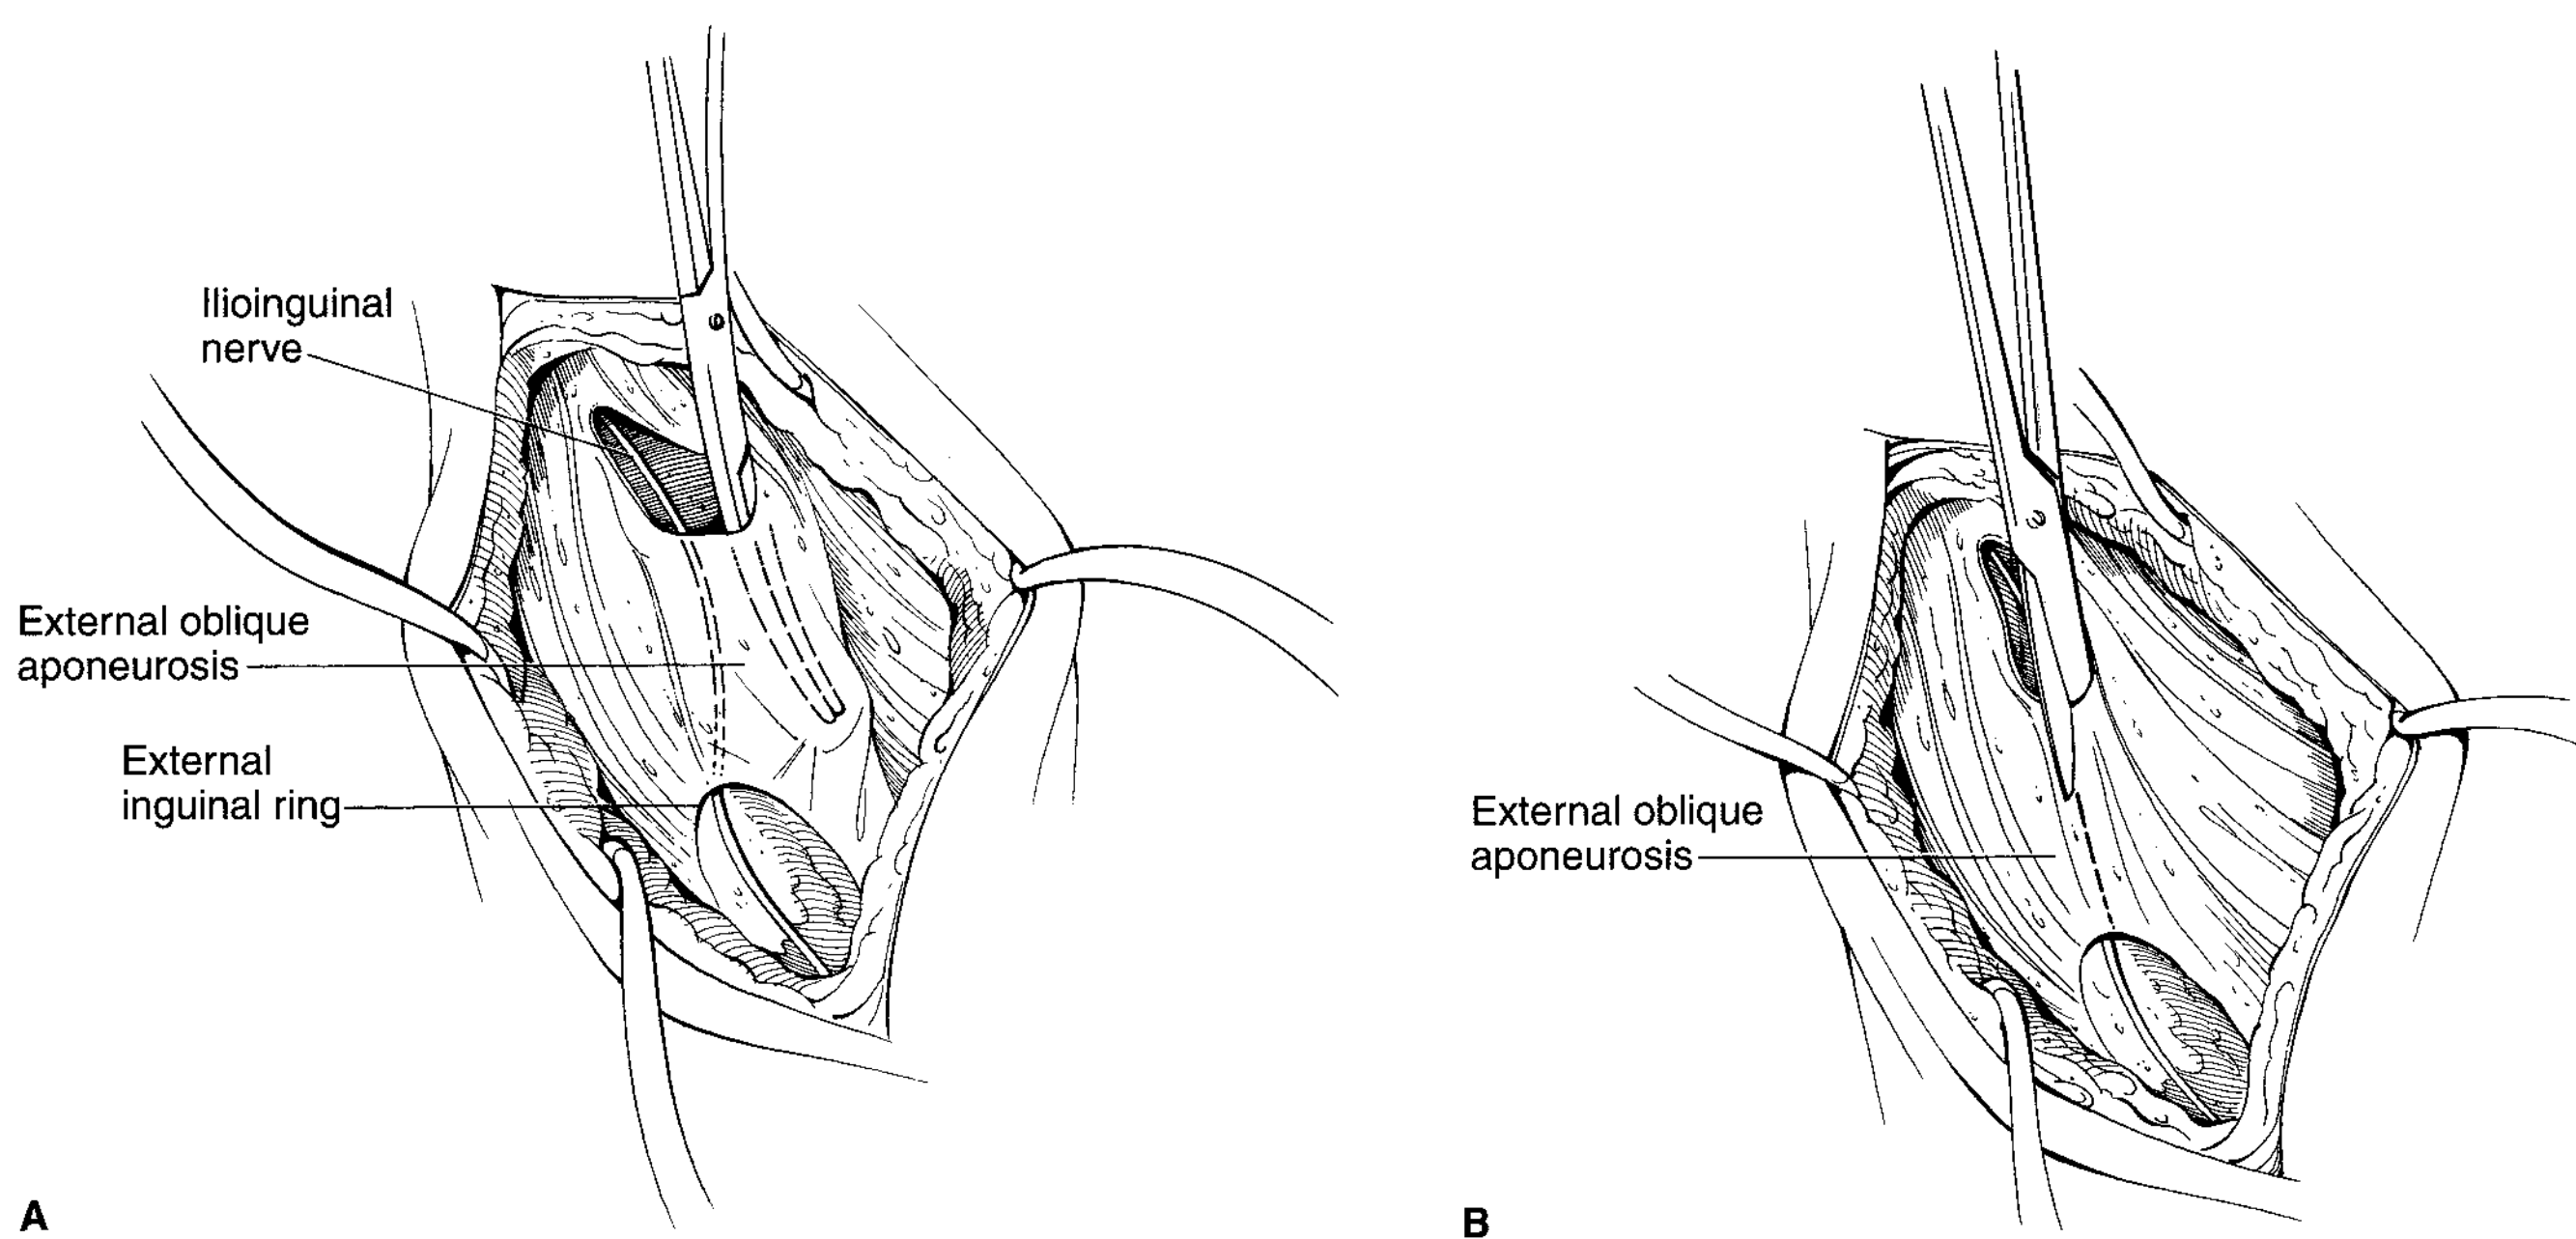

**FIGURE 64.1** An almost horizontal incision from just cephalad to the external inguinal ring laterally almost to the internal ring provides adequate exposure and an excellent cosmetic result. Alternatively, the incision may be made parallel to the inguinal ligament.

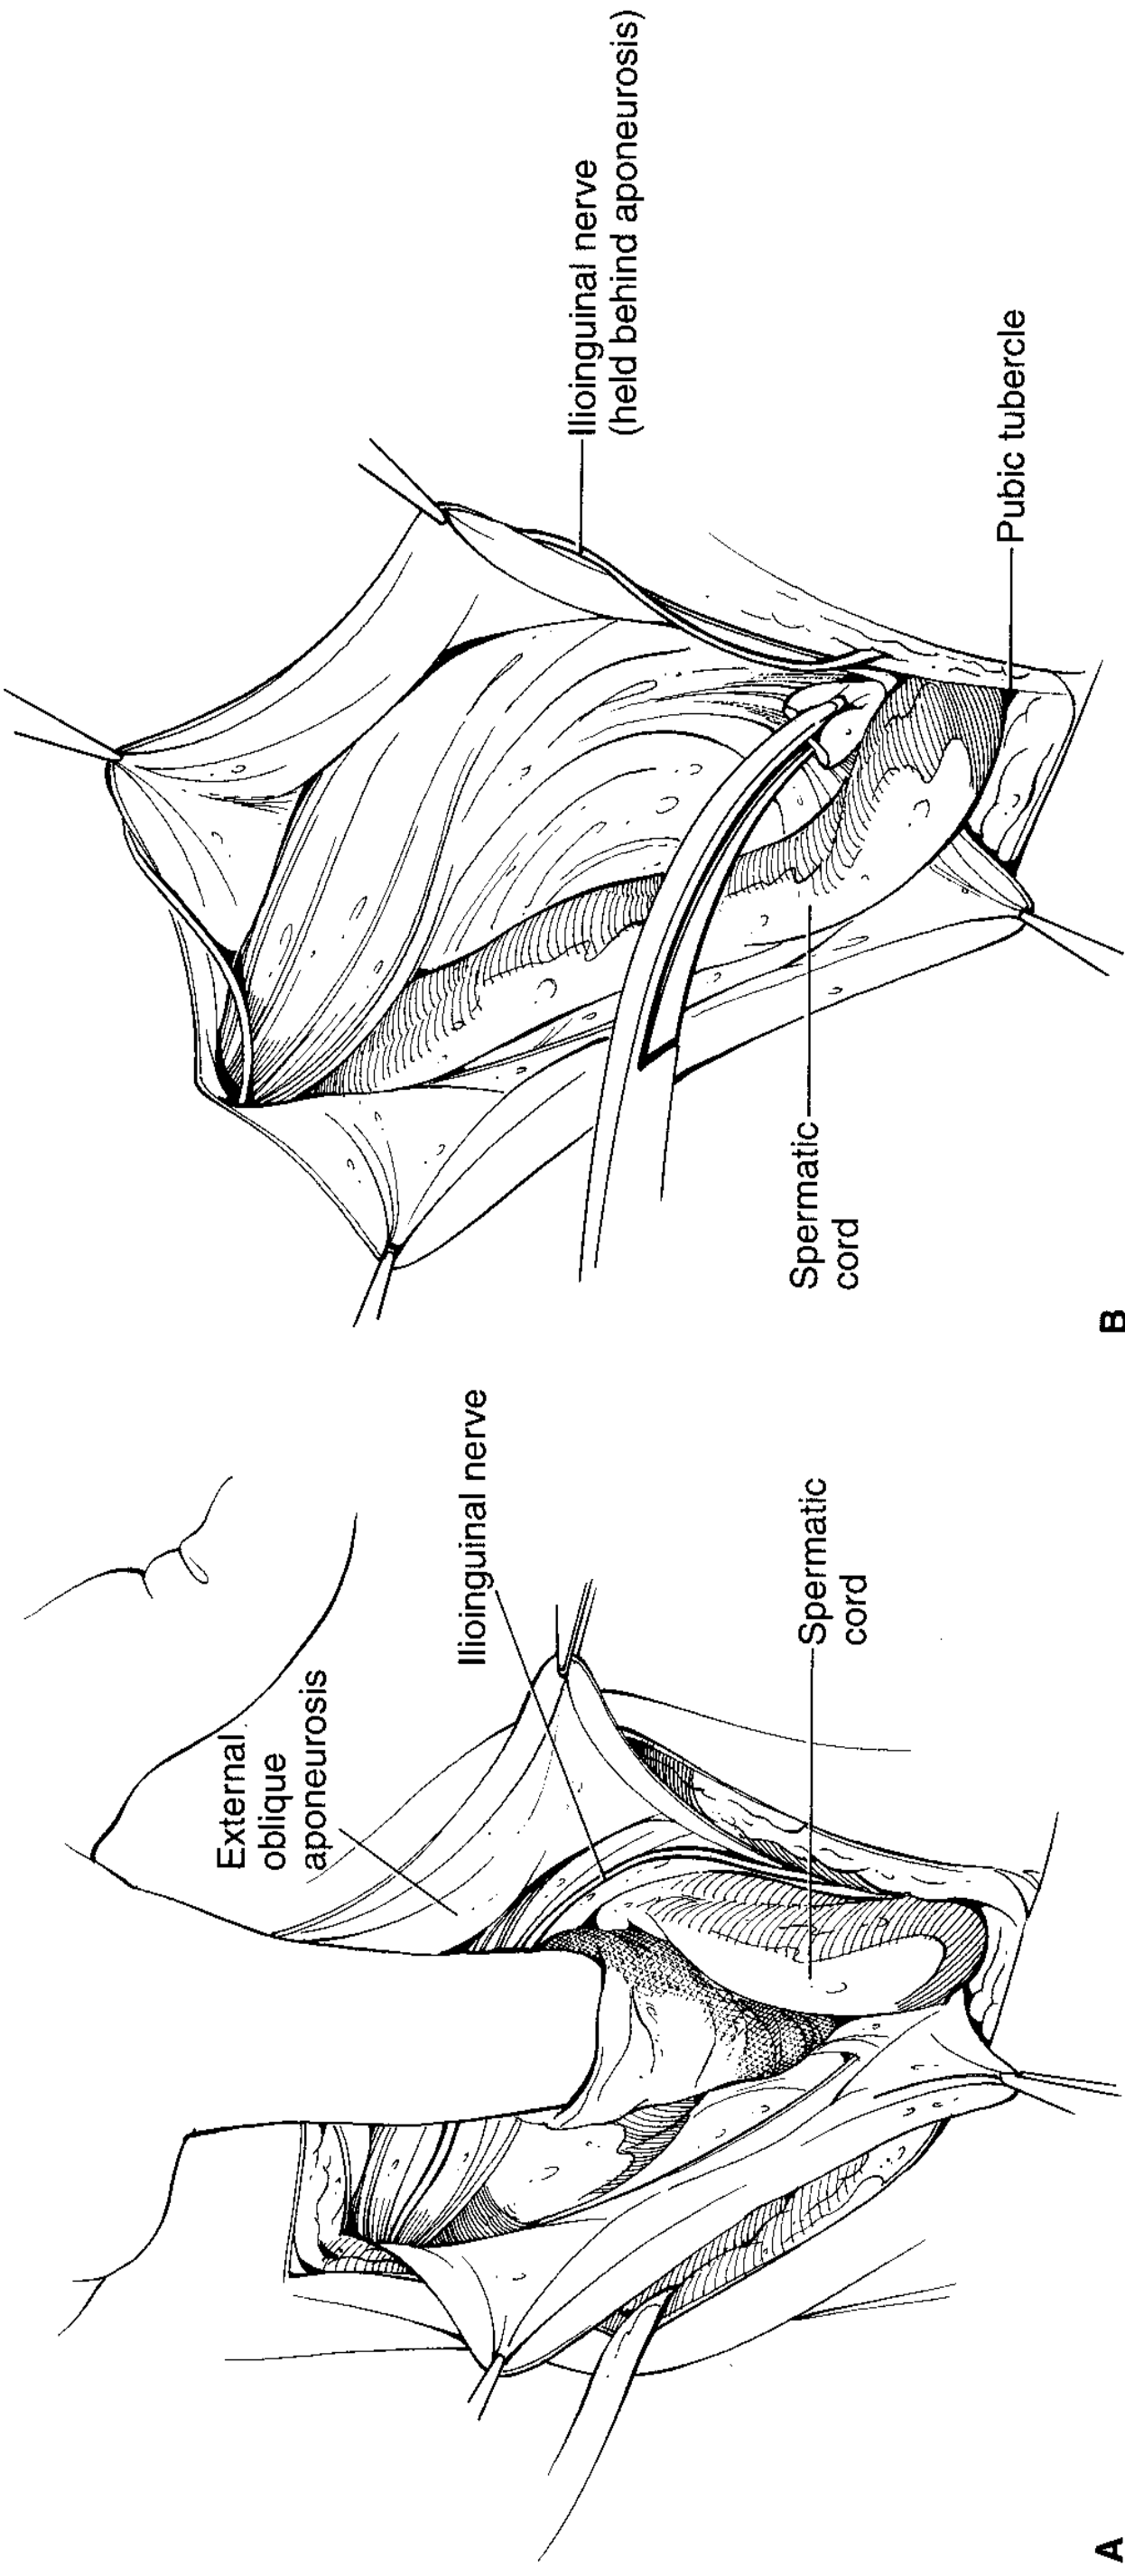

The incision with the knife or electrocautery should be deepened through the subcutaneous tissue until the external oblique aponeurosis is reached. There are usually one or two significant veins that traverse this incision. They should be isolated and secured with hemoclips or 3-0 plain or chromic catgut sutures before being cut. When the external oblique aponeurosis is cleaned sufficiently to be well visualized, it is helpful to place one or two small self-retaining Gelpi (or similar) retractors in the wound to improve exposure. Next, the

scalpel is used to make a small incision in the external oblique aponeurosis midway between the internal and external inguinal rings, in the direction of its fibers. Metzenbaum scissors are inserted through this opening, and the closed scissors are pushed with slight upward pressure underneath the aponeurosis to the external inguinal ring and then laterally toward the internal ring (Fig. 64.2A). This helps ensure that the ilioinguinal nerve will not be cut during the next step, which is to push the partially opened Metzenbaum scissors from the point of incision into the external inguinal ring and then laterally toward the internal ring as required, thus splitting the aponeurosis and opening the roof of the inguinal canal (Fig. 64.2B). Careful inspection will usually reveal the ilioinguinal nerve, which should be freed up carefully by blunt and sharp dissection for the length of the incision. It can then be retracted out of the surgical field by passing two small hemostats underneath the nerve, grasping the superior edge of the aponeurosis, and retracting it in a cephalad direction. It may also help to grasp the inferior edge of the aponeurosis and retract it as well to fully expose the inguinal canal.

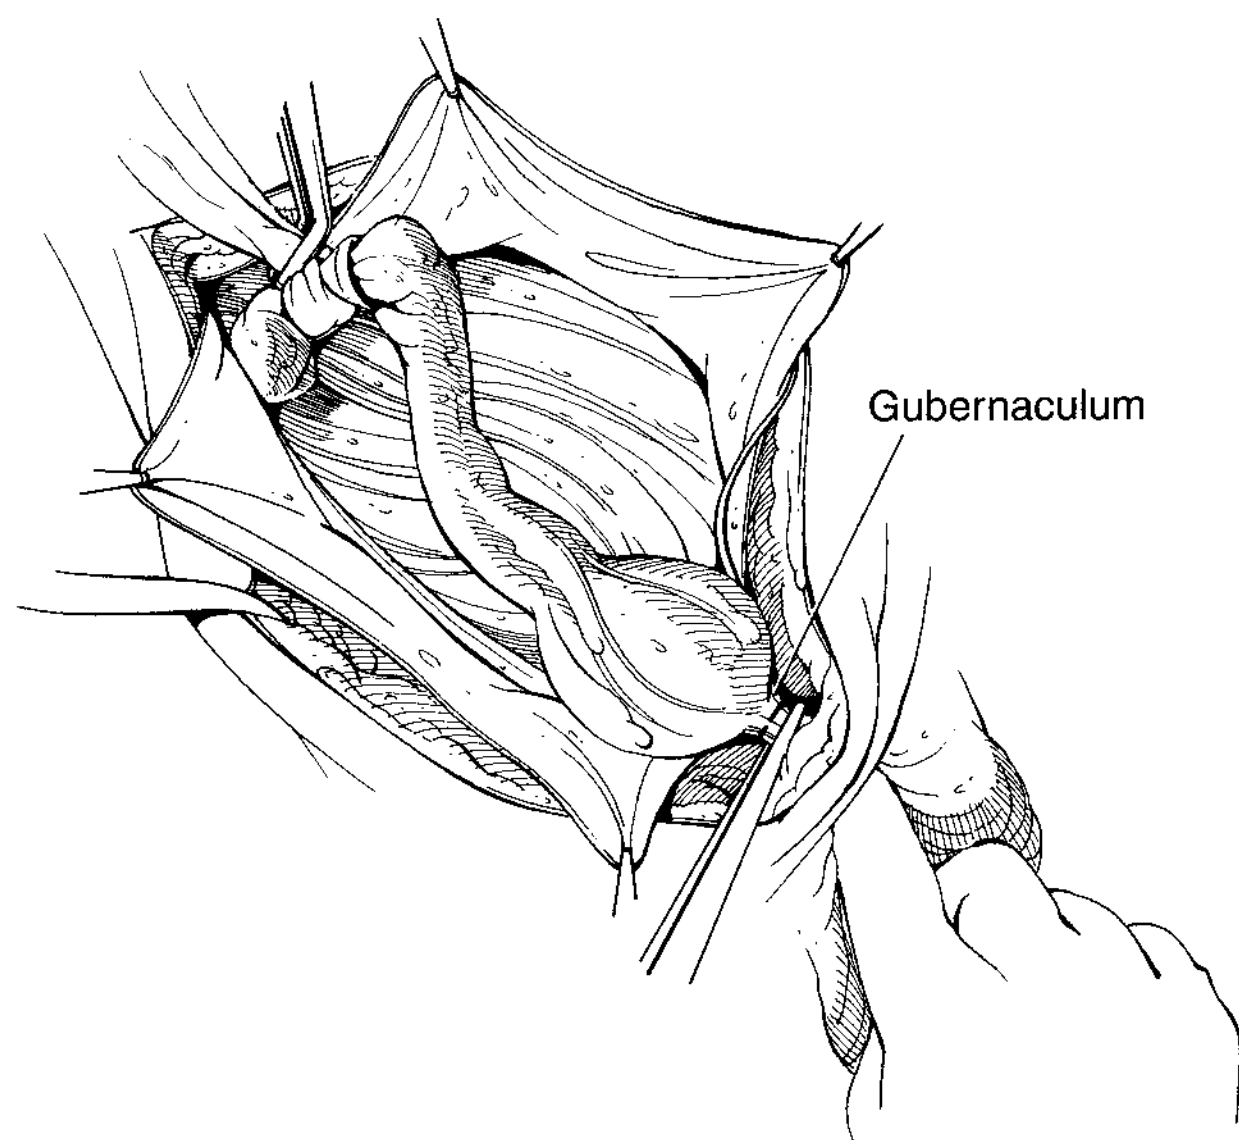

This will expose the spermatic cord, although it may not appear distinct because of the cremasteric muscle fibers surrounding the cord, which merge into the internal oblique muscle. Using a gauze sponge wrapped around the fingertip (Fig. 64.3A) or a peanut (Kittner) sponge (Fig. 64.3B), the plane between the spermatic cord and the floor of the inguinal canal is bluntly developed until it can be encircled with a thumb and forefinger. It is usually easiest to both initiate the dissection and completely encircle the cord at the level of the pubic tubercle. Once it is ascertained that all components of the cord are included, the operator should pass a 0.5-in. Penrose drain around the cord (Fig. 64.3C), elevate it with gentle traction, and free up the cord laterally to the internal

**FIGURE 64.2 A:** The external oblique fascia is entered and tented up over the length of the inguinal canal before cutting to help ensure that the ilioinguinal nerve is not injured. **B:** The external oblique fascia is incised over the spermatic cord, and the incision is extended into the external ring.

**FIGURE 64.3** **A:** The spermatic cord is bluntly mobilized from the inguinal ligament and floor of the inguinal canal with a finger wrapped with a gauze sponge, starting near the pubic tubercle. **B:** The blunt dissection is performed superiorly and inferiorly to the cord and may be facilitated by using a peanut sponge. **C:** When the entire spermatic cord is free, a 0.5-in. Penrose drain is passed around the cord.

**FIGURE 64.4** The Penrose drain is encircled twice around the cord just distal to the internal ring and clamped to act as a tourniquet. A finger outside the scrotum helps push the testis into the surgical field. The gubernaculum is clamped and cut, and the scrotal side of the gubernaculum is tied.

ring using predominantly blunt dissection, although some sharp dissection may be required. Care should be taken in approaching the internal ring that the inferior epigastric vessels are not injured, and the spermatic cord should be inspected carefully to ensure that an indirect inguinal hernia, which could contain bowel or bladder, is not present. At this point, the spermatic cord should be occluded firmly with either a soft rubber-shod clamp or, as I prefer, a 0.5-in. Penrose drain encircled twice around the cord, tightened in a tourniquet fashion, and secured with a Kelly or right-angle clamp (Fig. 64.4). The operator should be sure to leave enough spermatic cord distal to the internal ring to permit it to be double-clamped later without first removing the tourniquet.

It is now possible to mobilize the testis from the scrotum and through the opened external inguinal ring into the inguinal canal and surgical field. Upward pressure on the external skin of the hemiscrotum and testis, coupled with gentle traction on the spermatic cord, will in general define the circumferential fibromuscular attachments that need to be cut or, better, electrocoagulated to completely free up the testis (Fig. 64.4). Great care should be taken not to rupture the mass and spill tumor contents. At the most inferior aspect of the testis, there may be a well-defined gubernaculum that needs to be clamped and cut, being careful to exclude scrotal skin, and tied with 2-0 or 3-0 chromic catgut.

At this point, the surgeon should isolate the testis and spermatic cord, now free to the level of the internal ring, with sterile towels and carefully inspect the testis. If the diagnosis is still in doubt, the surgeon may open the tunica vaginalis and expose the tunica albuginea of the testis. If doubt still persists, which should happen only rarely, a small incision may be made in the tunica albuginea to permit insertion of a finger for palpation of the testicular parenchyma. If all of these maneuvers fail to exclude tumor, the surgeon should

**FIGURE 64.5** The spermatic cord is triple-clamped just distal to the internal ring (two clamps proximal and one distal to the Penrose tourniquet) and cut after careful inspection of the testis, which has been isolated from the surgical field on a sterile towel.

proceed with radical orchiectomy rather than risk returning a testis with tumor to the scrotum. I want to emphasize that it is only rarely necessary to open even the tunica vaginalis and far more rare to open the tunica albuginea or perform a biopsy.

To complete the orchiectomy, the spermatic cord should be double-clamped at the level of the internal ring and proximal to the Penrose tourniquet with two Kelly or heavy right-angle clamps; a third clamp is added to occlude the cord just distal to the Penrose tourniquet (Fig. 64.5). The surgeon then transects the cord and removes the testicle, with attached spermatic cord, from the surgical field. The cord is tied behind the most proximal clamp with a 0 silk tie, and a suture ligature of 0 silk is placed behind the most distal clamp. One of the two sutures should be left long for later identification of the stump of the cord if a retroperitoneal lymph node dissection is performed. Some surgeons prefer to tie the cord in two portions, separating the spermatic vessels and the vas deferens, and double-tying both portions of the cord. In either case, after the cord is securely tied, it should be allowed to retract through the internal ring into the retroperitoneum.

Next, the surgeon should carefully inspect the entire floor of the inguinal canal as well as the scrotal compartment by everting the scrotal wall into the surgical field with upward external pressure on the most dependent portion of the hemiscrotum. All sites of bleeding, even tiny ones, should be controlled with electrocautery and then irrigated with sterile water. It is prudent to perform a final inspection for complete hemostasis at this point before closure. Closure begins with careful inspection of the inguinal floor. If it seems weak, it can be reinforced with several interrupted sutures in a standard hernia repair. If not, the ilioinguinal nerve should be released and the external oblique aponeurosis closed with interrupted 2-0 silk or 2-0 Prolene sutures, placing the sutures at varying

**FIGURE 64.6** The stump of the cord retracts back through the internal ring into the retroperitoneum; one suture is left long. The external oblique fascia is closed with interrupted sutures placed at varying distances from the cut edge and completely closing the external ring.

distances from the aponeurotic edge to prevent a linear tear and taking care to exclude the ilioinguinal nerve (Fig. 64.6). The closure should begin at the level of the internal ring and extend medially as close to the pubic tubercle as possible because there is no longer any reason to have an external inguinal ring. A drain is not necessary or advisable. The wound should be irrigated once again and the skin incision closed with clips or with a running subcuticular suture of 4-0 Vicryl or Monocryl. The wound is covered with a dry sterile dressing and the scrotum is gently compressed with either fluffed gauze sponges held in place with an athletic supporter or by gently wrapping the scrotum with a loosely applied turban dressing of Kling, Kerlix, or Coban. An ice pack should be avoided because it has little impact on swelling and is a source of considerable discomfort.

Patients may resume a regular diet and ambulation when completely awake and may be discharged. Most patients require oral narcotic analgesics for pain control for several days.

---

## OUTCOMES

---

### Complications

---

Many would consider the most serious complication to be scrotal violation, which in the past required hemiscrotectomy and now requires irradiation to the scrotum (for seminoma). In truth, little data demonstrate reduced survival following scrotal contamination (9,10). Nonetheless, there is virtually no reason why the testis should be approached transscrotally if the diagnosis of possible testicular tumor has been even considered. At the least, a transscrotal approach prevents early control of venous outflow in the cord before manipulation of the tumor, leaves spermatic cord behind, potentially alters lymphatic drainage of the testis, risks tumor contamination

of the scrotum (10), and may preclude consideration of surveillance as a treatment option, although this has been challenged (1).

The most common actual complication is probably an intrascrotal hematoma. Because the scrotum is such an expansile organ with loose areolar tissue beneath the dermis, bleeding may continue because of a lack of tamponade, and the resulting hematoma may grow quite large. These scrotal hematomas usually become organized and quite firm and may even raise the question of residual or recurrent tumor. Nonetheless, if the hematoma does not become infected (which would require surgical drainage), it can almost always be followed expectantly and will eventually regress. Ideally, this complication should be prevented. The depths of the inguinal canal and entire inner surface of the scrotal wall should be thoroughly and compulsively inspected and electrocoagulated to ensure hemostasis. The surgeon can facilitate this, as described earlier, by everting the scrotal wall with a finger positioned on the most dependent portion of the external scrotal wall. After hemostasis appears adequate, the surgeon should irrigate with sterile water and inspect again. Although the turban dressing used in bilateral orchiectomy, which completely collapses the scrotum, is not possible, it is possible to use a modified turban dressing that is wrapped firmly enough to collapse the hemiscrotum ipsilateral to the orchiectomy but not so tight as to cause pain because of pressure on the remaining testis.

It is also possible to get a retroperitoneal hematoma if the ligature(s) on the spermatic cord pull off or if there is an injury to one of the inferior epigastric vessels. Although rare, retroperitoneal hematoma and other potential complications have prompted one team of clinicians to advocate orchidectomy at the external ring (low cord) instead of at the internal ring (high cord) (2). Nonetheless, despite an absence of apparent increase in relapse rate with this alternate surgical approach, they present no data to show fewer complications and no proven advantage to a quicker operation or to leaving the inguinal floor intact. In the absence of such data, this approach is not recommended (4). Retroperitoneal hematoma can be prevented virtually always by a properly tied ligature with adequate length of spermatic cord distal to it so it cannot slip off. A suture ligature on the spermatic cord offers an additional measure of security. Injury to the epigastric vessels can be avoided by careful dissection of the proximal spermatic cord at the level of the internal inguinal ring. This complication is usually discovered incidentally at the time of further staging evaluation with a computed tomography scan, although an unexplained and occult blood loss may prompt investigation. If bleeding has stopped when the problem is discovered, it does not require specific treatment; the hematoma should ultimately be reabsorbed.

---

## Results

---

Properly performed inguinal orchiectomy with the spermatic cord taken at the level of the inguinal ring is potentially curative if the tumor is still confined to the testis. Except for treatment of a complication, reoperation is virtually never required, although additional surgical procedures may be performed later to remove regional lymph nodes.

# CHAPTER 65 ■ ORGAN-PRESERVING SURGERY IN TESTICULAR TUMORS

AXEL HEIDENREICH

Testicular germ cell tumors (TGCTs) are the most common neoplasms in young men, with bilateral simultaneous and sequential tumors arising in 2% to 3% of patients. Bilateral orchiectomy is still recommended as the gold standard treatment; it results in infertility, lifelong dependency on androgen substitution, and psychological distress due to castration at a young age. Because most testicular cancer patients are going to be longtime survivors with modern therapeutic approaches, long-term morbidity should be omitted whenever possible; cure of cancer might only be achieved if quality of life following therapy can be restored to pretreatment levels. Considering these quality-of-life issues, organ-sparing surgical approaches have been developed in patients with bilateral testicular cancer or in selected patients with a germ cell tumor arising in a solitary testicle.

---

## DIAGNOSIS

---

The diagnosis of testicular cancer is usually made by the appearance of a mass in the testicle that on ultrasonography appears solid or appears to have some cystic components (2). Serum markers, including  $\beta$ -human chorionic gonadotropin and  $\alpha$ -fetoprotein, are routinely drawn prior to surgery.

---

## INDICATIONS FOR SURGERY

---

Patients in whom preservation surgery is contemplated should have enough testicular parenchyma for maintaining physiological testosterone synthesis, which requires that the diameter of the tumor should not exceed 2 cm (3,7). Preoperative serum testosterone and serum luteinizing hormone (LH) levels should be in the normal range. Elevated LH levels in the presence of

normal testosterone levels indicate compensated Leydig cell insufficiency. These patients bear a high risk to develop hypogonadism with the need for androgen substitution following surgery. In addition, a semen analysis should be obtained to assess fertility and to discuss the option of cryopreservation (3,5). Also, testicular ultrasonography must be performed preoperatively because this usually represents the imaging modality of choice to assess the intratesticular location and diameter of the tumor. Scrotal magnetic resonance imaging appears only to be necessary if there is more than tumor suspected or if there is a very high suspicion for a benign testicular lesion (6).

---

## ALTERNATIVE THERAPY

---

The alternative to testicular-sparing surgery is bilateral orchiectomy, which will require lifelong hormonal replacement. Other problems associated with bilateral orchiectomy include infertility and the psychological impact of the procedure on the patient, who is usually a young male.

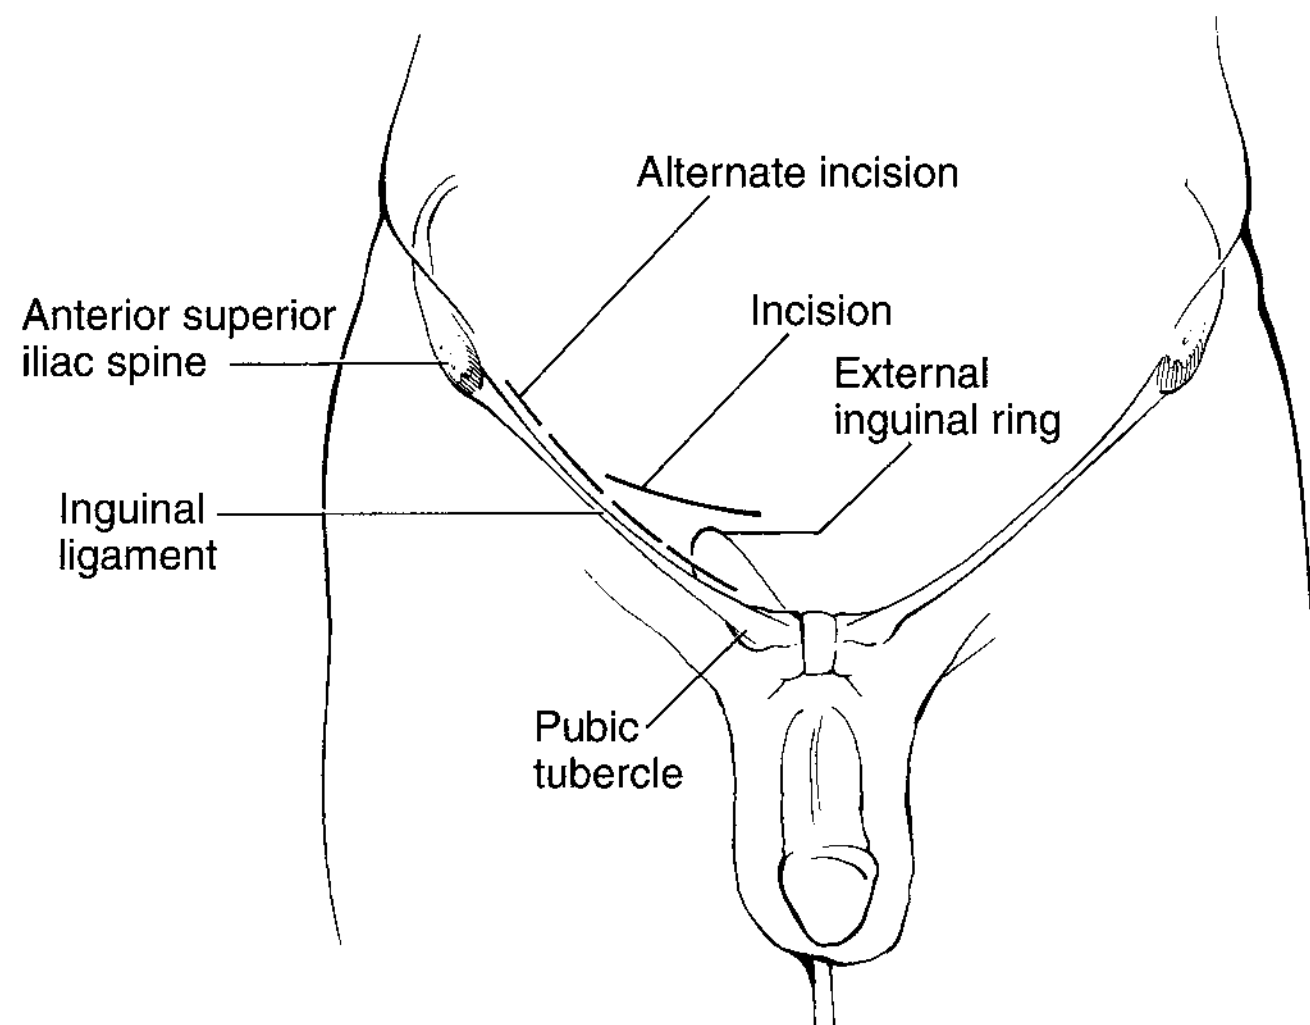

---

## SURGICAL TECHNIQUE

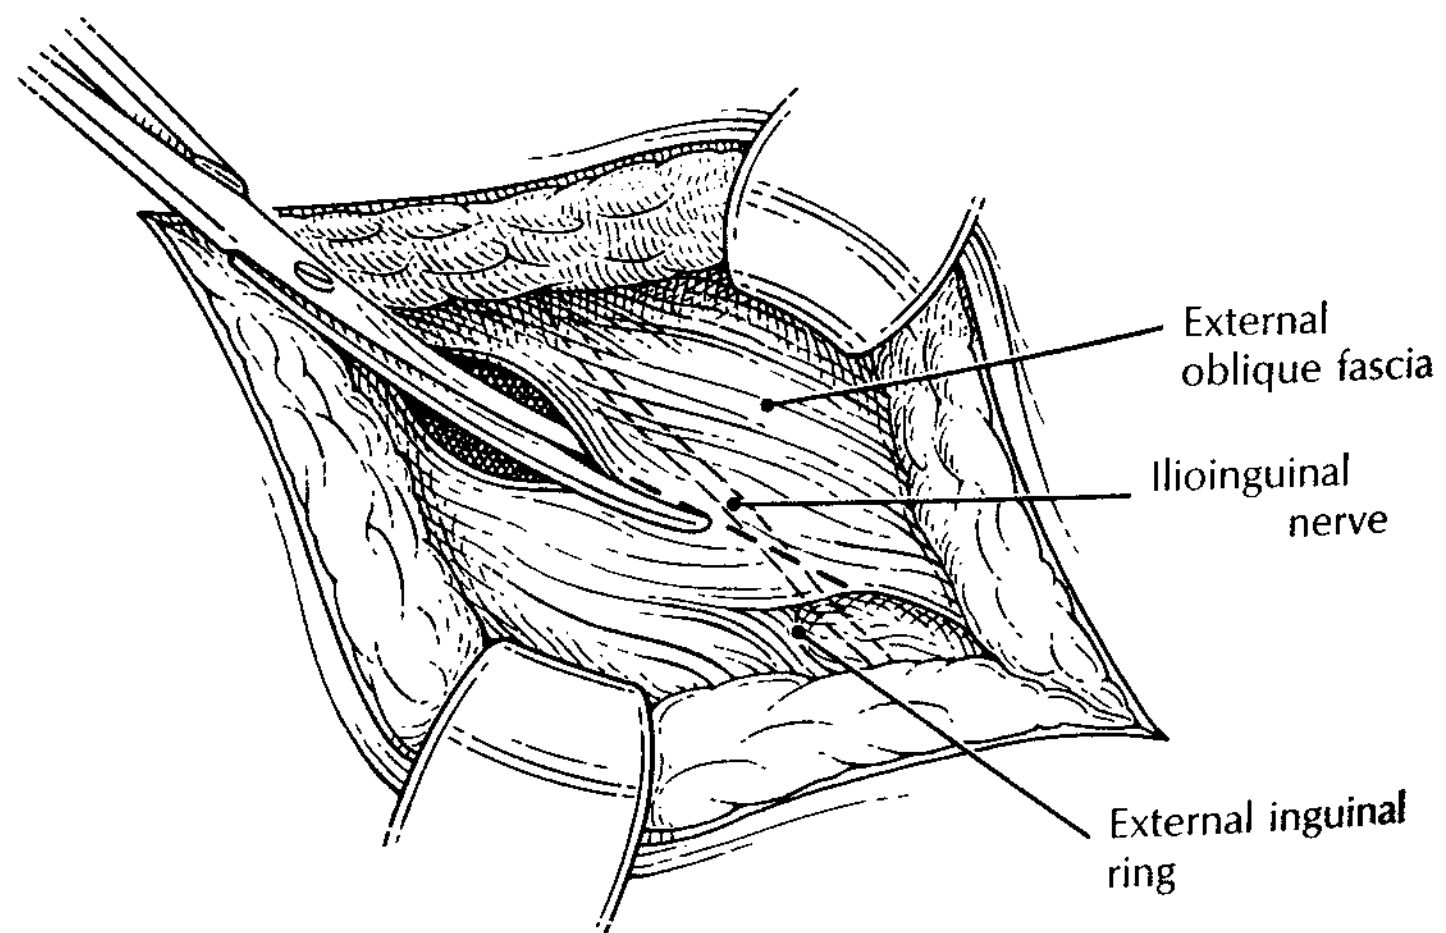

---

An inguinal approach is chosen with the skin incision being made about two fingerbreadths above and parallel to the inguinal ligament (Fig. 65.1). The incision extends from the external inguinal ring cephalad for about 5 cm and is carried down to the external oblique fascia (Fig. 65.2). Care is taken not to injure the ilioinguinal nerve, which runs laterally just underneath the fascia.

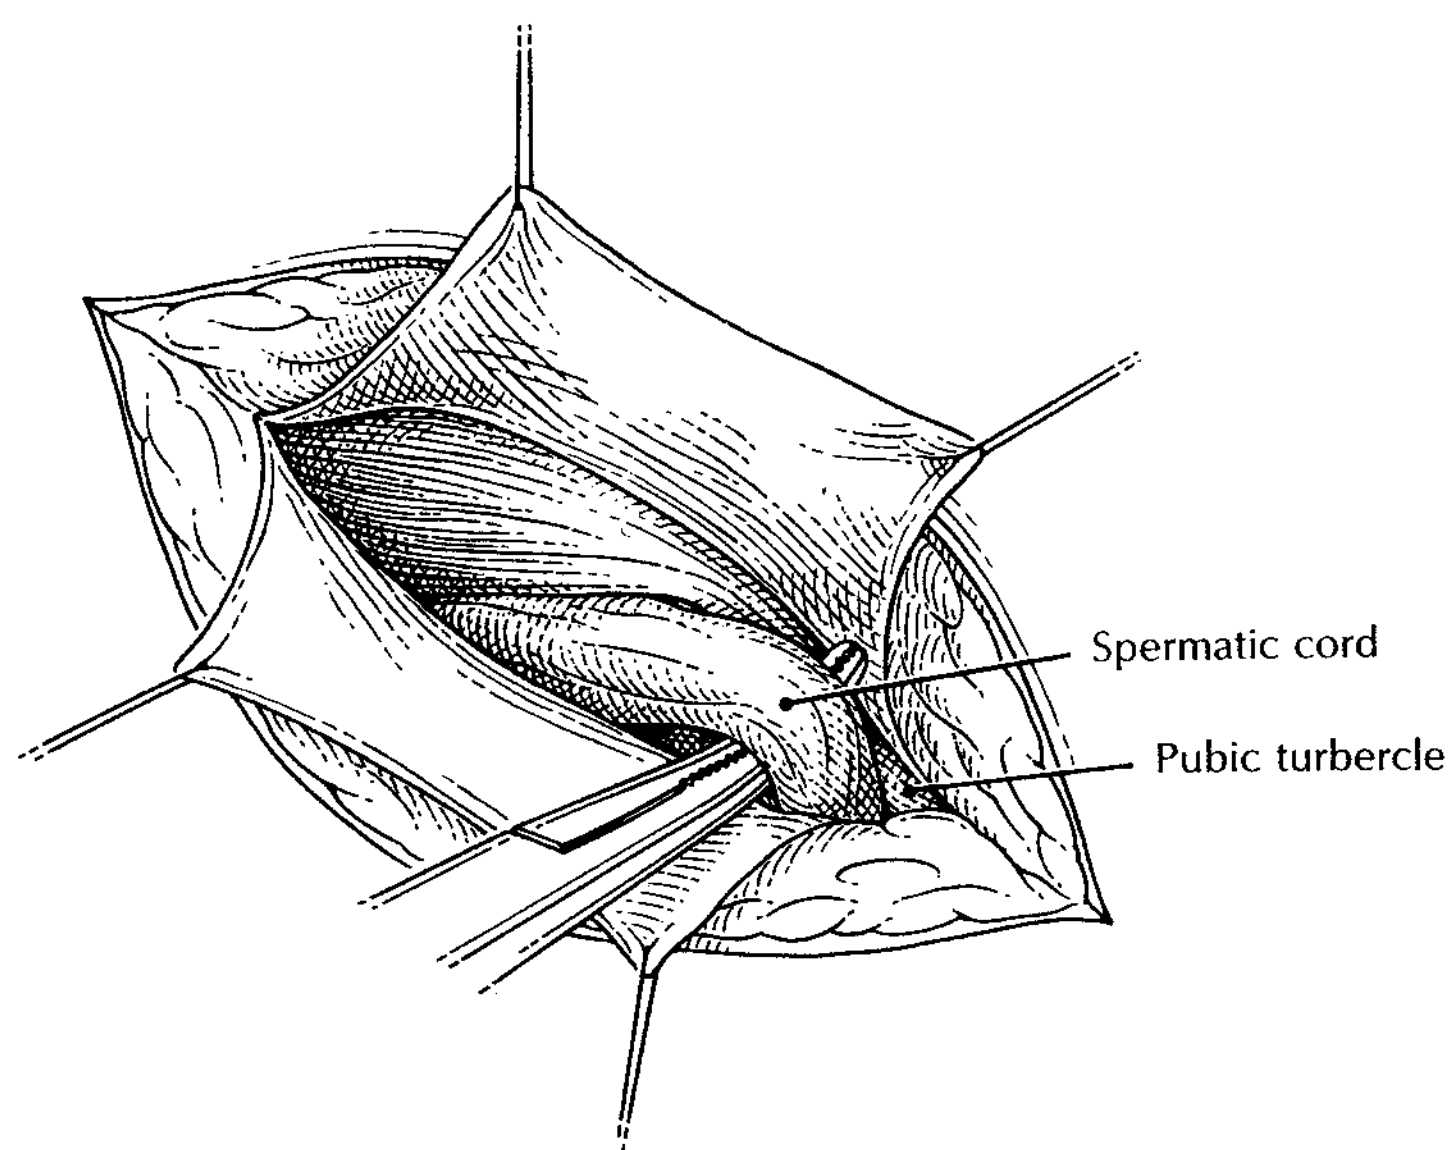

The spermatic cord is identified and isolated at the level of the pubic tubercle (Fig. 65.3), secured with a half-inch Penrose

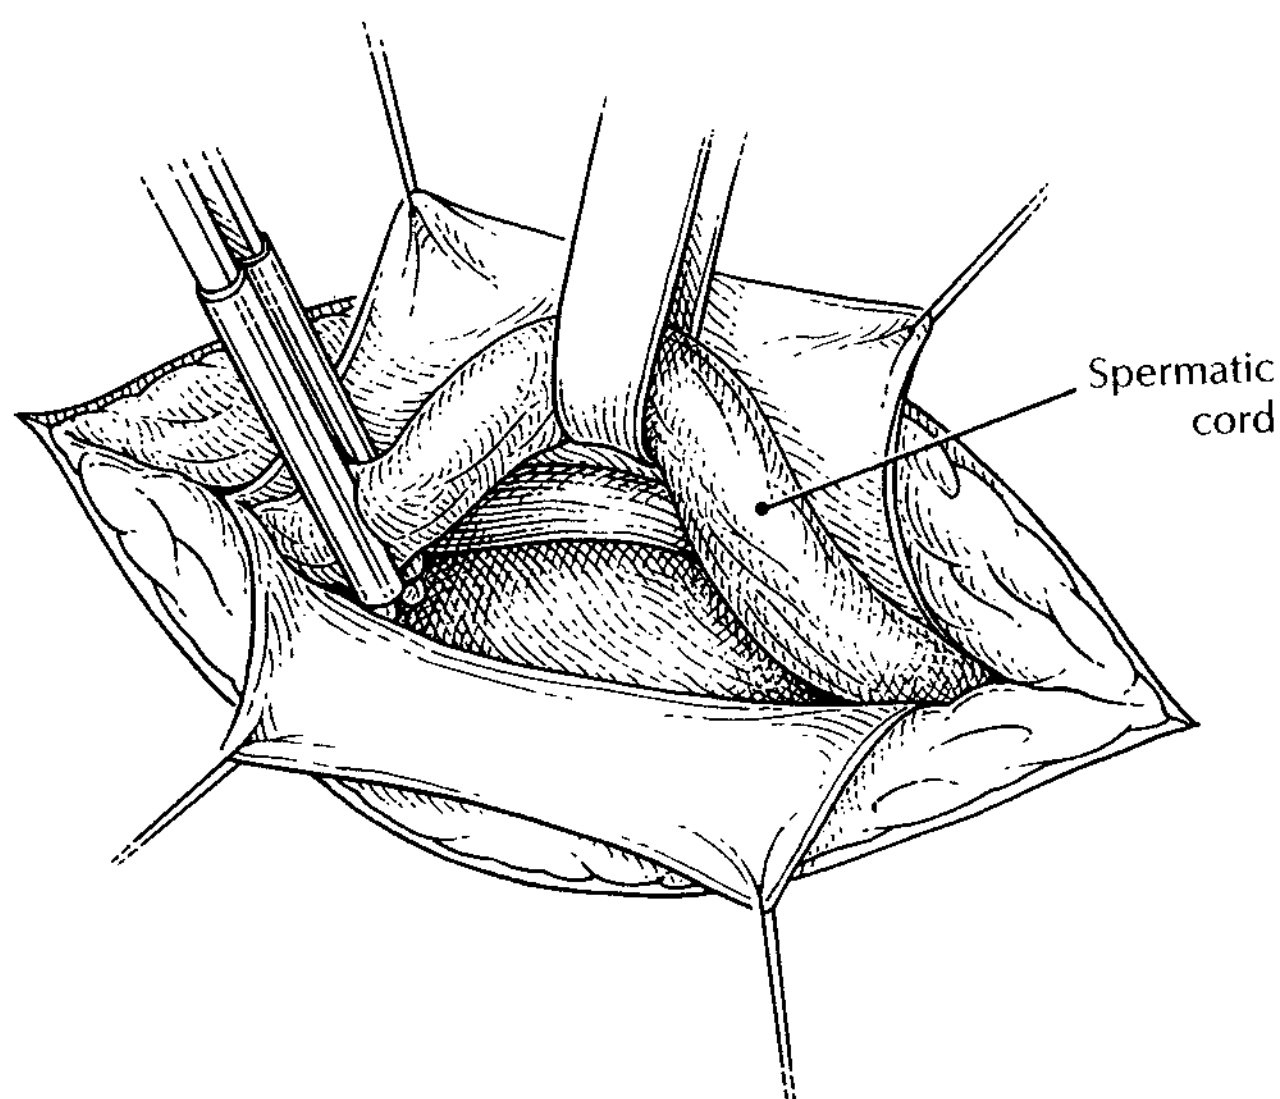

**FIGURE 65.1** Inguinal incision for exploration of the testicle in relation to anatomic landmarks of the groin.

**FIGURE 65.2** Incision of the external oblique fascia and its close relationship to the ilioinguinal nerve.

**FIGURE 65.3** Delivery of the spermatic cord after the external oblique fascia has been opened.

**FIGURE 65.4** Mobilization of the spermatic cord up to the internal inguinal ring; the cord may be cross-clamped if desired.

drain, and mobilized back to the internal inguinal ring (Fig. 65.4). As in the case of radical orchiectomy, the spermatic cord might be cross-clamped with a rubber-shod clamp prior to delivering the testicle in the operating field. In this scenario, all following manipulations should be performed under cold ischemia by placing the testicle in crushed ice.

On the other hand, it is also possible to deliver the testicle into the operating field without cross-clamping the spermatic cord; we know that simple tumor cell shedding will not result in an increased frequency of distant metastases unless the tumor cells harbor molecular characteristics enabling them to adhere to the vascular endothelium, invade adjacent organs, and induce neovascularization. The testicle is delivered by slight traction on the spermatic cord and inversion of the scrotum; the gubernaculum is divided between two clamps and suture-ligated with 3-0 silk ties (Fig. 65.5).

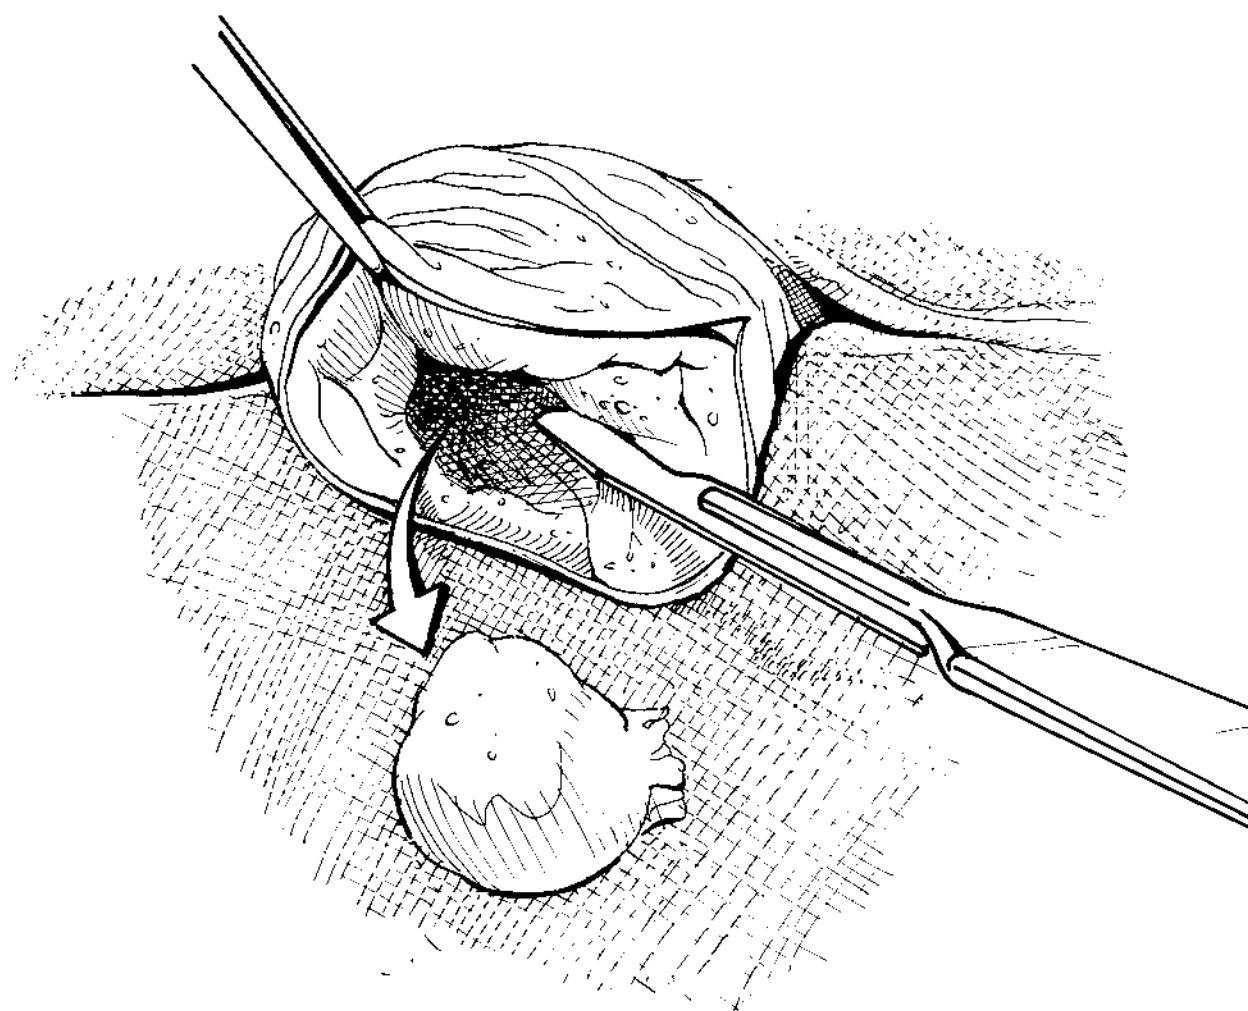

**FIGURE 65.5** The testicle is delivered, and the gubernaculum may be divided and suture-ligated.

**FIGURE 65.6** Incision of the tunica albuginea just above the testicular tumor.

The operating field is draped with laparotomy pads, and the tunica vaginalis is opened anteriorly; depending on the size and the intratesticular location of the tumor, it might be located underneath the tunica albuginea by simple palpation. In the presence of small testicular lesions, intraoperative ultrasonography with a 7.5-MHz scanner might be used for visualization and detection (1).

The tunica albuginea is incised just above the tumor (Fig. 65.6); because small testicular lesions usually present with a pseudocapsule, the surrounding testicular parenchyma can be scraped away with the blade of a scalpel (Fig. 65.7). Following the enucleation procedure, four additional biopsies are taken from the tumor bed to exclude tumor infiltration (Fig. 65.8), and all specimens are sent for frozen section examination (FSE). At least in our hands, FSE has turned out to represent a reliable technique to differentiate between benign and malignant tumors. Another biopsy is taken from the peripheral testicular parenchyma, fixed in Bouin or Stieve solution, and sent for pathohistologic analysis to exclude associated testicular intraepithelial neoplasia. After careful bipolar coagulation of small intratesticular blood vessels, the tunica albuginea is closed with a 4-0 Vicryl running suture

**FIGURE 65.7** The tumor is surrounded by a firm pseudocapsule.

**FIGURE 65.8** Additional quadrant biopsies following the enucleation procedure.

**FIGURE 65.9** Running suture of the tunica albuginea.

(Fig. 65.9), the tunica vaginalis is closed with a Vicryl 3-0 running suture, and the testis is replaced in the scrotum, taking care not to twist the spermatic cord. A formal orchidopexy for the testis is not necessary. The skin is closed with an absorbable, intracutaneous running suture; usually, no drains are placed. Postoperatively, the patient should receive potent analgesics and antiphlogistics to reduce uncomfortable testicular pain.

---

## OUTCOMES

---

### Complications

---

Potential complications include hemorrhage and loss of the testicle. Eighty-five percent to 92% of patients have maintained adequate androgen levels (5).

---

### Results

---

The initial study with a limited number of patients showed a 5-year survival rate of 92% and the maintenance of physiological testosterone serum levels in 92% without the need for androgen substitution (5). These findings resulted in the German Testicular Cancer Study Group criteria for proper patient selection, surgical technique, and follow-up based on the review of a large patient cohort with a median follow-up of >8 years. The disease-free survival rate was 99%, local recurrences developed in 5.5%, and normal testosterone serum levels were maintained in 85% of the patients.
