The use of testicular-sparing surgery in testicular cancer requires that there be close follow-up for possible recurrence. The best modality for local follow-up is transscrotal ultrasonography. We recommend the first ultrasound to be done 4 to 6 weeks postoperatively, a time when scar tissue has replaced the intraparenchymatous traumatic edema; thereafter, scrotal imaging should be performed at 2-month intervals for the first year to adequately document the developing scar tissue for further follow-up studies (5). In patients who have undergone local radiation therapy postoperatively, periodic ultrasonography can be safely omitted and the patients should be educated to self-palpate the testicle. In patients who have not undergone adjuvant local radiation, periodic ultrasonography should be performed twice annually due to the high risk of local recurrence. In patients who develop a local recurrence, secondary orchiectomy has to be performed and androgen substitution has to be initiated (3–5).

In summary, organ-preserving surgery in patients with testicular germ cell tumors is feasible in patients with bilateral testis cancer or germ cell tumor in a solitary testicle. The procedure should be performed in conjunction with biopsies of the tumor bed and the resection rim and frozen section analysis, as well as a biopsy of the peripheral parenchyma. Follow-up in these patients should be either postoperative radiation of the remaining testicle with 18 Gy or very close follow-up. As this is still a controversial procedure, it may be best performed in a center experienced in the management of testicular cancer.

# CHAPTER 66 ■ RETROPERITONEAL LYMPHADENECTOMY

MICHAEL LEVERIDGE AND MICHAEL A. S. JEWETT

Carcinoma of the testis is the most common malignancy occurring in men aged 20 to 35. Most testicular malignancies are germ cell in origin and are classified as seminoma or nonseminomatous germ cell tumors (NSGCT), with the latter including embryonal carcinoma, teratoma and teratocarcinoma, choriocarcinoma, and yolk sac tumors. Treatment usually begins with radical inguinal orchiectomy to remove the primary tumor and to make a tissue diagnosis. Lymphovascular invasion (LVI) and embryonal carcinoma (EC) are the principal risk factors for metastasis. A staging workup follows. This chapter discusses the indications for retroperitoneal lymphadenectomy in testis cancer and describes the technique in primary and postchemotherapy settings.

---

## DIAGNOSIS

---

The majority of testis cancers are diagnosed following radical inguinal orchiectomy for a painless testicular mass. Less frequently, patients present with a symptomatic testis mass, or signs or symptoms of metastatic disease that lead to a presumptive or pathologically confirmed diagnosis.

The propensity for and the patterns of metastasis in germ cell tumors form the basis of the staging workup and the staging system used to describe the extent of disease. This information will dictate treatment. As the testes originate in utero as intra-abdominal structures, their primary lymphatic drainage, and therefore first metastatic tumor landing site, is to the retroperitoneum. The primary landing zones differ for each testis. Right-sided testis tumors metastasize first to interaortocaval nodes along the route of the supplying vessels, then with decreasing frequency to the precaval, para-aortic, and paracaval nodes (crossover may occur from right to left in the retroperitoneum). Left-sided masses metastasize to the para-aortic nodes, and with decreasing frequency to the precaval and interaortocaval nodal regions (1). Further lymphatic metastasis occurs via the thoracic duct, which may lead to mediastinal or supraclavicular adenopathy. Hematogenous metastatic disease is less common than lymphatic and can originate from the testis or can gain entry to the systemic circulation via the thoracic duct. The lungs are the most common hematogenously seeded sites.

Retroperitoneal nodal staging is based on the number and size of metastatic nodal deposits (2). N0 disease is when the retroperitoneal computerized tomography (CT) imaging is clinically negative with no nodes  $\geq 10$  mm, although normalized nodes along the gonadal drainage may be considered suspicious. N1 disease is when there are fewer than five

enlarged nodes, none  $> 2$  cm. N2 disease involves more than five nodal deposits, or disease between 2 and 5 cm, while N3 disease has a greatest diameter  $> 5$  cm.

The retroperitoneum in patients with germ cell tumors is best examined using CT. Coronal views can be particularly helpful in examining the presence of and extent of disease. Plain films or CT of the chest should be used to assess for metastatic disease to the lungs or mediastinum.

Serum tumor markers are important in the assessment of the patient before and after orchiectomy, as well as in disease monitoring after retroperitoneal or systemic treatment. The serum alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (HCG) are elevated in up to 80% of patients before orchiectomy, and their persistence after removal of the primary tumor may be considered an indicator of metastatic disease, even in the setting of a negative imaging workup. The serum half-lives of AFP and HCG are 5 to 7 days and 24 to 36 hours, respectively, and so serial measurements may be needed until a nadir is reached before determining that markers are persistently elevated.

---

## INDICATIONS FOR SURGERY

---

Primary retroperitoneal lymphadenectomy or lymph node dissection (RPLND) is less widely practiced than it once was but is considered for patients with stage I NSGCT, especially in the setting of adverse pathologic risk factors (presence of LVI and predominant or pure EC) in the primary tumor, as an alternative to surveillance (3). Those without adverse risk factors have a low risk of progression and are generally managed by initial active surveillance. Persistently elevated markers after orchiectomy, with or without nodal metastases, are generally managed with chemotherapy due to a 50% or more risk of systemic metastatic disease beyond the retroperitoneum.

Patients with N1 low-volume disease may also be managed with primary RPLND if markers are very low or normal. If the nodal diameter is  $> 5$  cm in any dimension, or if there are numerous small nodes, these patients have a high likelihood of systemic disease and are managed with primary chemotherapy. The management of nodal disease 2 to 5 cm in axial dimension is controversial, and many centers recommend initial primary chemotherapy as although RPLND provides 50+% control if markers are low or normal.

The most common indication for retroperitoneal lymphadenectomy is in the postchemotherapy setting (pcRPLND). Patients with a residual retroperitoneal mass(es) after primary

chemotherapy for NSGCT are candidates for surgery because of a 50% incidence of viable germ cell tumor or teratoma (which may expand) (4). Histology of the residual mass can determine future treatment, as residual carcinoma is usually an indication for further chemotherapy (5). Residual retroperitoneal disease occurs infrequently after radiation and/or chemotherapy for seminoma, but these patients should be considered for RPLND if resolution does not occur, particularly if a PET scan is positive. These masses tend to disappear slowly after radiation therapy, and so a retroperitoneal mass may be initially closely observed.

---

## ALTERNATIVE THERAPY

---

Surveillance remains a very reasonable alternative for testis cancer patients with a negative staging workup. A recent systematic review of surveillance in stage I germ cell cancer revealed a 28% relapse rate in patients with NSGCT (3), with the implication that RPLND would represent overtreatment in approximately 70% of cases. One percent of the patients in these studies died of testis cancer during follow-up. Recurrence outside of the retroperitoneum will not be prevented by RPLND. These studies of early-stage germ cell tumors have uncovered several prognostic factors relating to the primary tumor that have predictive value regarding risk of relapse. Vascular or lymphovascular invasion is consistently related to increased risk of relapse, as are an increased proportion of embryonal histology, the absence of yolk sac elements, higher local stage (particularly involvement of spermatic cord tissue), and the presence of mature teratoma (3). In patients without adverse risk factors, a stringent surveillance protocol can be followed with 10% to 15% risk of progression, sometimes treatable by RPLND alone. High-risk patients, in our experience, have about a 50% chance of progression, so any treatment will be unnecessary in about 50%. Nonrisk adapted surveillance can be practiced, reserving treatment for those who clearly need it. Surveillance requires frequent assessments with history, physical examination, serum marker measurement, and chest and abdominal imaging. As the majority of relapses occur in the first year of surveillance, visits are undertaken at 2-month intervals for the first 2 years (CT of the abdomen can be done every 4 months), with increasing intervals between assessments afterwards.

There is also evidence for primary chemotherapy for clinical stage I NSGCT, with a relapse rate of 1.5% to 7.0% in the retroperitoneum (6). Indeed, a recent German clinical trial of 382 men randomized to RPLND versus a single cycle of bleomycin, etoposide, and cisplatin suggested an increase in relapse-free survival in the chemotherapy cohort at a median follow-up of 4.7 years (7). The incidence of late relapse and long-term toxicity has not been described.

Chemotherapy and RPLND each have a role in low-volume retroperitoneal adenopathy. False-positive imaging can occur in up to 30% of patients, but with increased size of the retroperitoneal mass there is an increased likelihood that adenopathy represents active tumor. Our practice is to advise primary chemotherapy in those patients with a retroperitoneal mass >5 cm in any dimension, or with elevated markers.

Subfertility affects an increased proportion of testis cancer patients primarily, and it can be further compromised with any treatment of advanced disease. Consideration of sperm banking should be encouraged.

---

## SURGICAL TECHNIQUE

---

### Primary Procedure (No Previous Treatment)

---

The patient is positioned supine, with central venous and epidural lines placed at the discretion of the attendant anesthesiologist. A midline incision is made from the xiphisternum to approximately midway between the umbilicus and pubis, and subcutaneous tissue and fascia are divided (Fig. 66.1A). The fascia adjacent to the xiphisternum is undermined and incised. The falciform ligament may be ligated and divided. A thoracoabdominal incision can also be used, particularly in early-stage left-sided tumors whose primary dissection will be in the para-aortic and interaortocaval areas, but this is rarely done today. The peritoneum is entered and thoroughly explored.

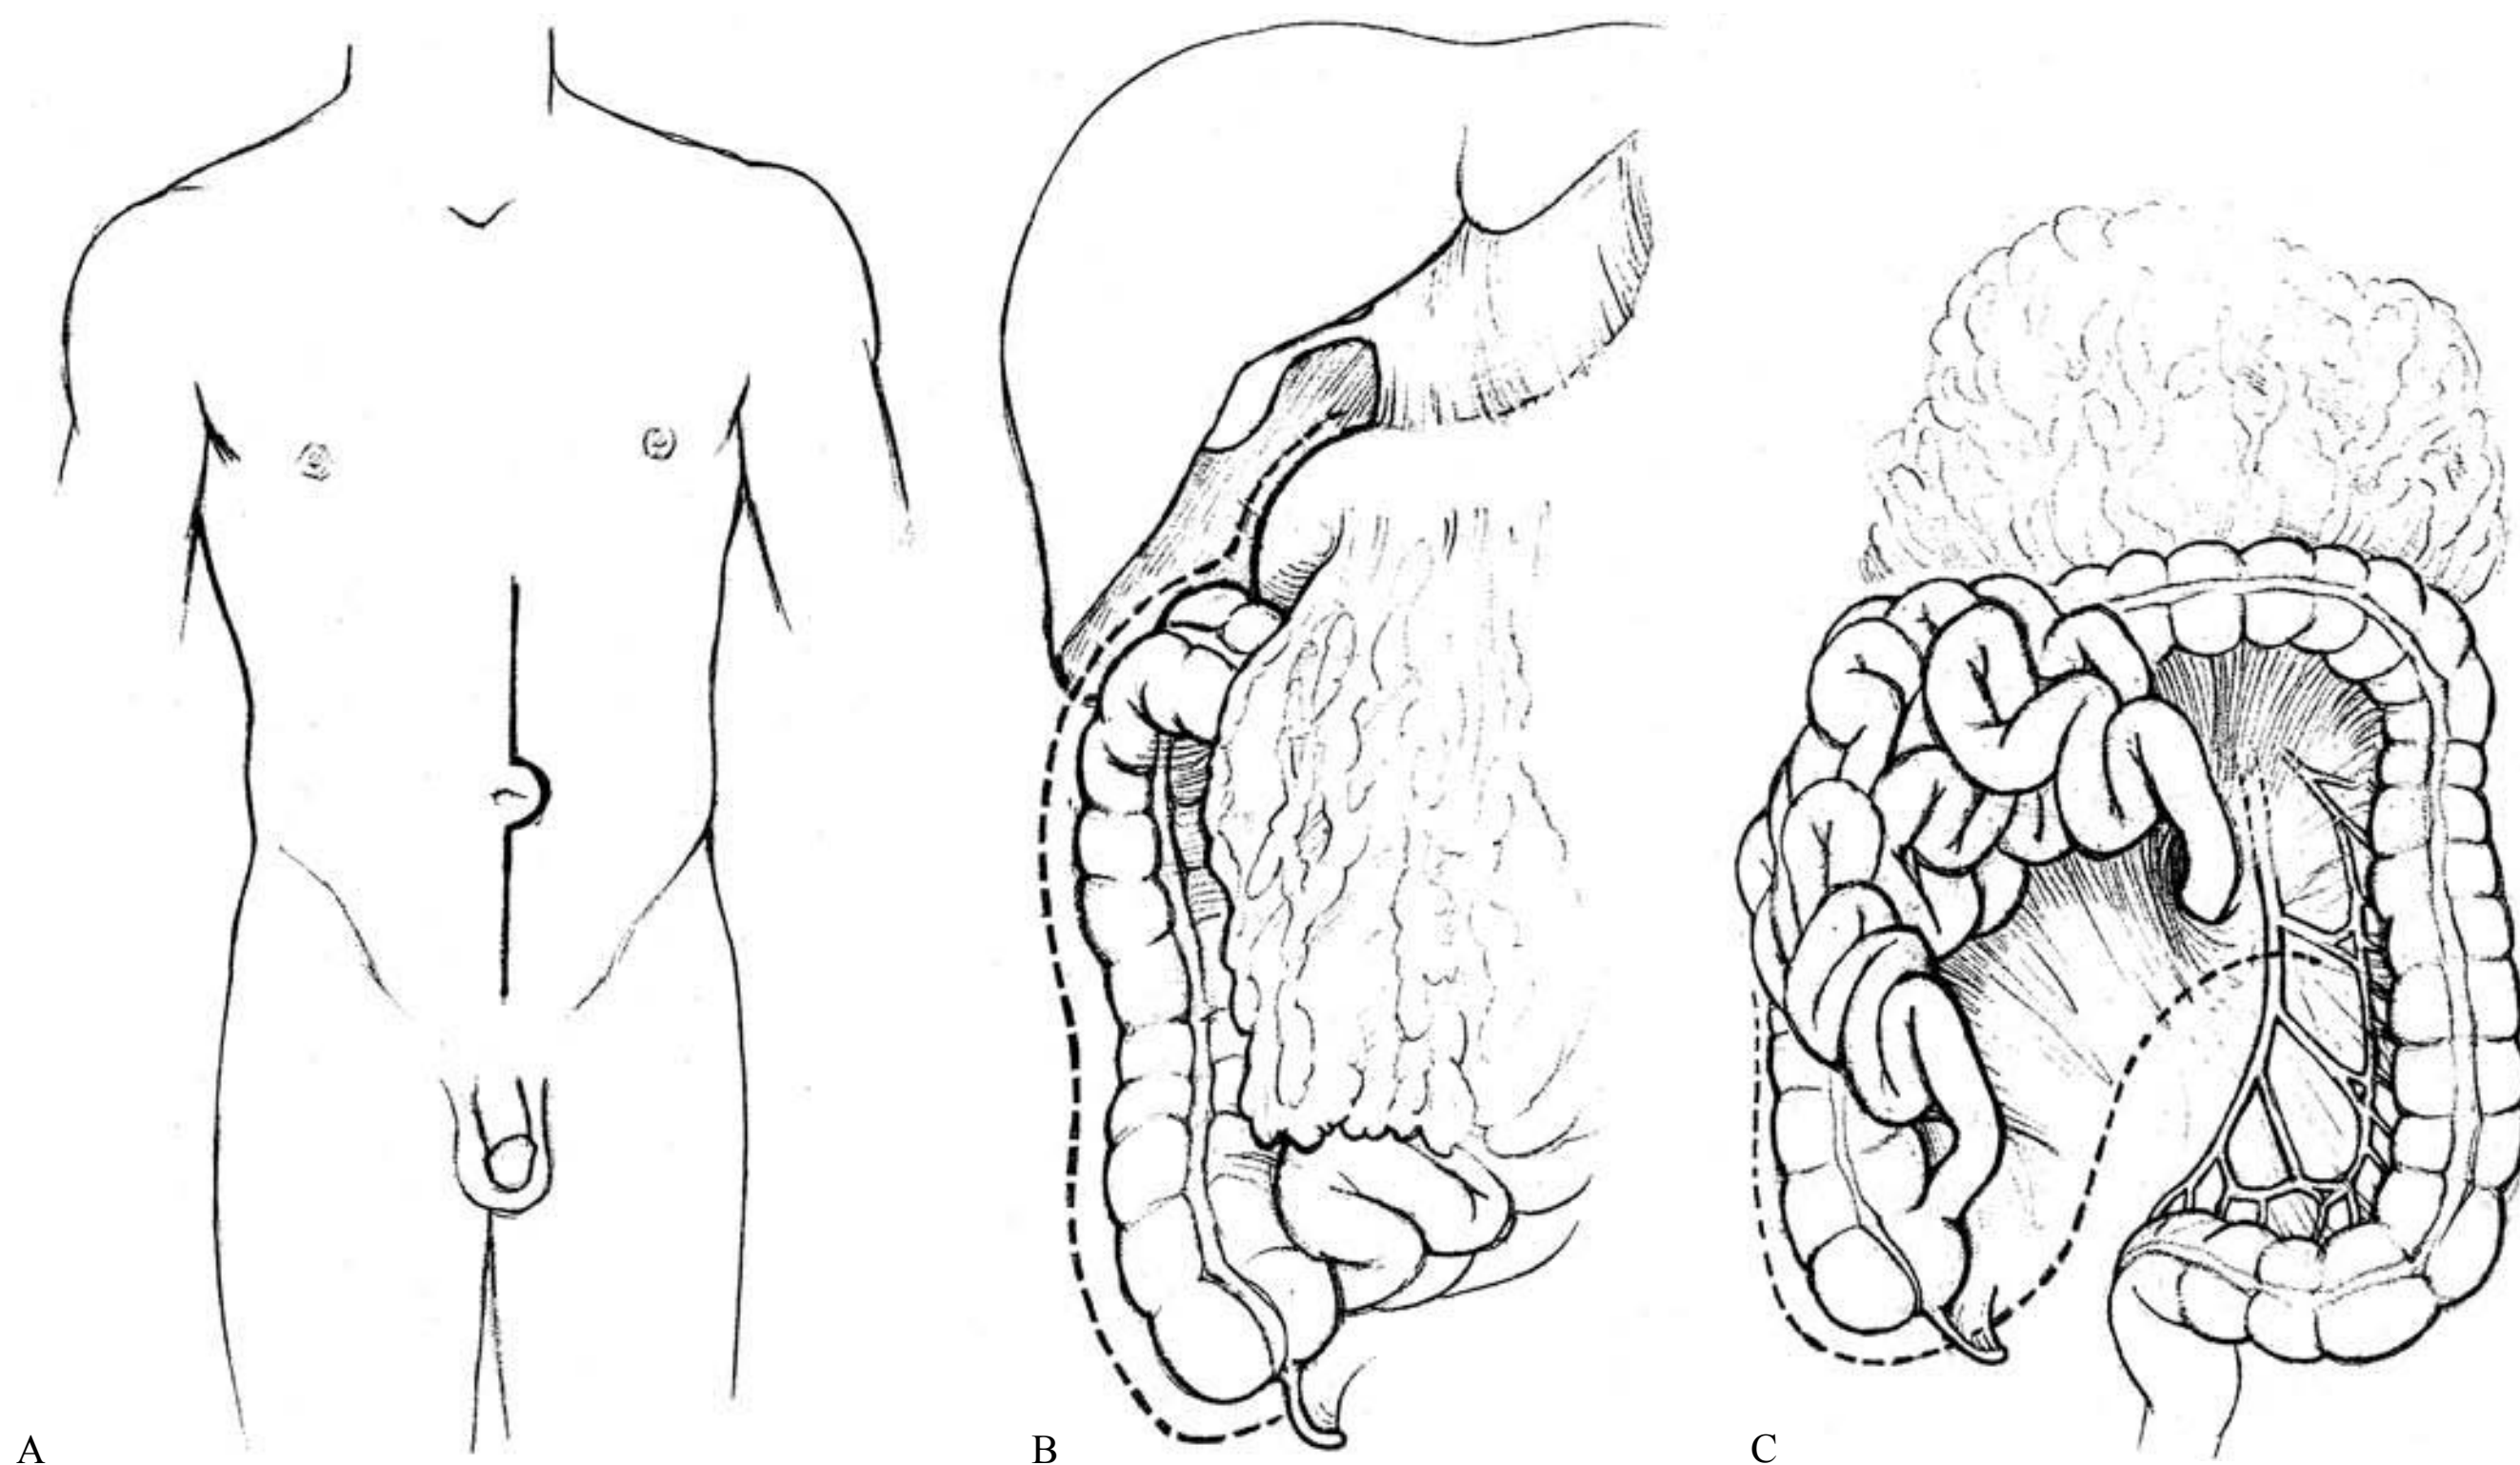

The right colon is reflected medially following the plane anterior to the perinephric fascia (Fig. 66.1B). This dissection can be carried up to the hepatic flexure as needed. The right ureter is identified and protected during the mobilization of the right colon, and it will later constitute the lateral limit of the node dissection. The incision is carried around the cecum, and the posterior peritoneum is incised medially along the root of the small bowel mesentery, ending at the ligament of Treitz (Fig. 66.1C). The right colon and small bowel are then dissected off the retroperitoneum until the left renal vein is visualized and accessible superiorly and the perinephric fascia is evident laterally. The small intestine and right colon are placed in a bowel bag and rotated onto the patient's chest. The inferior mesenteric vein may be ligated and divided to facilitate outward rotation of the pancreas for optimal retroperitoneal exposure, although the left colon can also be taken down. The left renal vein is mobilized and the tissue overlying it is divided, with care to identify and ligate or clip larger lymphatic channels as they may be encountered. The superior margin must be carefully controlled to avoid chylous ascites, as with all superior borders of dissection around the hilum and behind the crura of the diaphragm. The retroperitoneum is now fully exposed to begin the dissection with a clear field of view.

---

### Templates for Dissection

---

Dissection templates in the retroperitoneum are based on the lymphatic drainage patterns of the involved testis. Many surgeons do a full bilateral dissection for all cases, but the initial efforts to achieve nerve sparing without necessarily identifying the nerves intraoperatively lead to defining templates to include the most likely nodes to be involved. For right-sided testis tumors, the upper border of the renal veins marks the superior extent of dissection (Fig. 66.2A). Suprahilar dissections are no longer performed unless there is gross adenopathy in the renal hilum, but in fact, much of the suprahilar tissue is pulled down and removed during a thorough dissection.

**FIGURE 66.1** **A:** Midline incision from xiphoid to symphysis. **B:** Incision of the line of Toldt to allow reflection of the right colon and exposure of the retroperitoneum. **C:** Continuation of line of peritoneal incision around the root of the bowel mesentery.

Paracaval and interaortocaval nodes are removed, as are para-aortic nodes to the level of the takeoff of the inferior mesenteric artery. The nodes along the right common iliac artery are removed to the bifurcation of the common iliac artery. The dissection extends laterally to the right ureter. The upper border of the renal veins is the superior limit of dissection in the left-sided template as well (Fig. 66.2B). Para-aortic nodes are removed with the left ureter as the lateral limit and the bifurcation of the left common iliac artery as the inferior limit of dissection. Interaortocaval nodes are removed above the takeoff of the inferior mesenteric artery. In either case, suspicious or enlarged nodes are indications for a full bilateral dissection (Fig. 66.2C).

In the presence of clinically positive nodes that number less than five, with none larger than 2 cm, similar templates as outlined above may be used. Caveats include the potential for left para-aortic (17%) and left iliac (7%) nodal disease in right-sided tumors, which would not be included in a strict template dissection (8). Two percent of patients will have suprahilal nodal disease in the interaortocaval region. These may be recognized and removed if grossly abnormal, but routine dissection here is not necessary given the low incidence of disease. This additional dissection does not contribute to additional patient morbidity, unless more lumbar vessels are ligated, which may incur a greater incidence of postoperative back pain.

In the setting of more extensive nodal disease, a full bilateral template is indicated (Fig. 66.2C). In this case the superior extent of dissection lies at the origin of the superior mesenteric artery, 1 to 2 cm superior to the renal arteries. The

lymphadenectomy extends laterally to the ureters, posteriorly to the psoas muscle and the anterior spinal ligament, and inferiorly to the ipsilateral midexternal iliac artery and contralateral common iliac artery bifurcation.

### Nerve-Sparing Retroperitoneal Lymph Node Dissection

The postganglionic sympathetic nerves arising from the lumbar sympathetic chains are responsible for seminal emission. Until 1988, they were routinely sacrificed, and many patients lost antegrade ejaculation and therefore fertility. The modification of RPLND allows identification and preservation of these nerves (9). The sympathetic fibers innervating the seminal vesicles and vasa deferentia arise as postganglionic fibers from T12-L3. The sympathetic trunks lie on the medial borders of the psoas muscles bilaterally, lateral to the lumbar vertebral bodies. The right trunk lies posterior to the middle of the inferior vena cava (IVC), and the lateral border of the aorta conceals the left trunk (Fig. 66.3). Their ganglia are rounded or fusiform and of variable size (up to 10 mm). The postganglionic nerves course anteromedially over the aorta, whereupon they form a network of fibers (Fig. 66.4). These nerve fibers condense to form the inferior mesenteric and hypogastric plexuses, which can exhibit variable location despite names approximating adjacent aortic branches. The nerves that connect these plexuses are termed intermesenteric nerves. One rationale for limiting the inferior dissection in a unilateral template to the inferior mesenteric artery origin is to

**FIGURE 66.2** A: Template for right-sided tumor accounting for crossover to left side. B: Template for left-sided tumor. C: Full retroperitoneal dissection.

avoid the ipsilateral hypogastric plexus, which commonly overlies the aortic bifurcation and interiliac angle. The hypogastric and pelvic nerves emanate from these ganglia to course inferiorly and supply the prostate, bladder, urethra, periurethral glands, seminal vesicles, and vasa deferentia.

Dissection begins by incising the tissue on the anterior surface of the IVC in its midline, avoiding transection of obvious nodes. The adipose tissue is dissected medially to expose the left side of the IVC from the left renal vein to the common

iliac vein, with care taken to ligate or cauterize small vessels as they are encountered (Fig. 66.5A). Careful lateral mobilization of the cava is performed, with ligation of lumbar veins as needed (Fig. 66.5B). The right sympathetic chain is encountered posterior to the midline of the IVC (Fig. 66.3). The lumbar veins tend to run medial to the sympathetic chain but may be found lateral to it, or occasionally branching around it. The individual nerves running anteromedially from the ganglia of the chain pass above and medial to the lumbar

**FIGURE 66.3** Relationship between the great vessels and sympathetic trunks.

**FIGURE 66.4** Anatomy of the lumbar sympathetic nerves.

veins, which serve as good landmarks. They can be individually skeletonized from the underlying tissue, which is ultimately mobilized posteriorly and removed superiorly or inferiorly. Dissection may be helped with the use of the Hydro-Jet dissector.

The left ureter is identified across the midline under the inferior mesenteric vessels posterior to the mesocolon. A plane is developed between the inferior mesenteric vessels anteriorly and the retroperitoneal lymphatic and adipose tissue posteriorly. The inferior mesenteric artery occasionally must be sacrificed, and if done should be ligated and cut several centimeters from its origin at the aorta. This allows direct access to the left side. The left ureter is identified in this plane and is mobilized to the perinephric tissue, which can be reflected laterally to identify the psoas muscle. The tissue medial to the ureters and perinephric tissue represents the para-aortic nodal bed (Fig. 66.6). It can be seen above at the level of the left renal vein as well as from below. For right-sided tumors, the left gonadal vein is a marker of the lateral limit of dissection at the renal hilum, but some surgeons sacrifice it and go more laterally to be sure that retrograde tumor cell spread to nodes in this area is removed if present. This tissue is carefully reflected medially to identify the ganglia of the left sympathetic chain, and the postganglionic nerves can be seen coming off to run anteromedially (Fig. 66.3). Fibers from a higher ganglion may be encountered anterior to either renal artery, and they can be difficult to preserve. It is not clear that they are necessary to preserve antegrade ejaculation. Similarly, nerves running along the inferior mesenteric artery are clearly seen but not always preserved with no obvious detriment.

At this point the patient's sympathetic anatomy has been elucidated, and anteromedially coursing fibers from the sympathetic chains are preserved lateral to the aorta. The aorta can now be exposed. Careful dissection along the aorta is then undertaken. The previously identified sympathetic nerves are followed from the side and preserved as they cross in front of the aorta and coalesce into plexuses. The plexuses that condense at and below the inferior mesenteric artery origin form the hypogastric nerves that provide sympathetic innervation to pelvic structures. Careful skeletonization and preservation of these structures allow the complete removal of para-aortic and interaortocaval nodal tissue, as well as tissue overlying the aortic bifurcation, common iliac veins, and sacral promontory, with maintenance of emission and ejaculation. It is our practice to limit inferior dissection to the common iliac artery bifurcation, taking care to preserve the genitofemoral nerves. The remnant ipsilateral spermatic cord is removed, along with as much vas deferens as possible and the spermatic vessels in their attachments to the retroperitoneum.

It is not always possible to preserve all postganglionic nerves, as nodal metastases or tumor masses may involve or lie immediately adjacent to them. Ejaculation does not rely on the preservation of all nerves, and so there should be no hesitation to sacrifice ipsilateral (or even in a limited manner bilateral) nerves to ensure complete removal of disease. The right-sided nerves are generally more prominent and easier to preserve.

At this point the retroperitoneum as defined by the limits of dissection should be clear of all lymphatic and adipose tissue surrounding the aorta and IVC, and postganglionic nerves should be intact beside and overlying the aorta. The contents of the bowel bag are returned to the abdomen. The peritoneum can be reapproximated with absorbable suture. The fascial incision is closed with a running no. 1 suture, with occasional interrupted figure-of-eight sutures. The skin is closed as per the surgeon's preference. Drains and nasogastric

**FIGURE 66.5** **A:** Dissection between the vena cava and aorta. **B:** Retraction of the great vessels allows exposure of the lumbar vessels, which may be ligated.

**FIGURE 66.6** Reflection of the left ureter and adipose tissue.

suction are not routinely used. A urethral catheter is left in if there is an epidural.

### Postchemotherapy Retroperitoneal Lymphadenectomy

There is debate regarding whether patients with a postchemotherapy mass warranting resection should undergo a full bilateral template dissection or if oncologic control with fewer adverse outcomes can be obtained through excision of

the mass and the template as above. Removing the mass alone is not recommended due to the frequent micrometastases in adjacent nodes (10). Recent case series, however, have demonstrated a low retroperitoneal recurrence rate in patients treated with unilateral template postchemotherapy procedures, with excellent maintenance of antegrade ejaculation (11). The postchemotherapy procedure can be complicated by large tumor masses outside of typical templates, which may mandate en bloc nephrectomy, or occasionally resection of significant portions of the aorta or IVC. This has become less common with the reduction in the proportion of cases with active cancer to <10% in current series. Vascular surgery expertise may be required. Small lacerations of great vessels can be repaired with monofilament 5-0 or 6-0 sutures.

It is important to clear the nodal and lymphatic tissue at the upper limits of dissection in particular. The lymphatics are often prominent anterior and behind the right crus of the diaphragm. Nodal tissue may be present behind the right crus and can be removed from below if not overly bulky, sparing the patient a thoracotomy. Similarly, nodal tissue may be present along the course of the ipsilateral gonadal vessels and vas; these structures should be carefully inspected and removed along with any nodal tissue along their lengths.

If the mass is confined and permits, nerve-sparing dissection can be performed in up to 50% of patients. This is particularly difficult where the tumor is adherent to the great vessels, when skeletonization of the nerves is difficult and dissection can appear to be subadventitial. Normal vascular and retroperitoneal anatomy can be distorted, and blood loss can be sudden; therefore, the surgeon and the anesthetist must be experienced.

---

## OUTCOMES

---

---

### Complications

---

Intraoperative complications in primary RPLND are generally confined to damage of the renal vasculature and great vessels. Complication rates are increased in postchemotherapy procedures. If an appropriate plane cannot be developed between the mass and the aorta or IVC, it may be more prudent to resect part of the vessel and primarily close it or employ a vascular graft.

Chylous ascites and lymphocele represent infrequent but potentially serious complications that stress the importance of careful identification and obliteration of lymphatic vessels intraoperatively. Most lymphoceles resolve spontaneously, while some will require percutaneous drainage. They may occasionally exert a mass effect and cause gastrointestinal symptoms, flank pain, or ureteric obstruction.

Pulmonary physiotherapy and early mobilization will limit the incidence of lung complications such as atelectasis and

pneumonia. Patients who have received bleomycin as part of their chemotherapy regimen are at particular risk of pulmonary complications.

Careful and successful sympathetic nerve preservation is effective in preserving antegrade ejaculation and seminal emission.

---

### Results

---

Retroperitoneal lymphadenectomy provides pathologic staging. Patients with low-volume germ cell metastasis in the specimen progress in approximately 30% of cases without adjuvant chemotherapy. Chemotherapy in these patients may be avoided and can be given in the salvage setting in the case of relapse. Alternatively, all patients with pathologically proven retroperitoneal carcinoma may be given adjuvant chemotherapy with excellent cure rates, but 50% or more are treated unnecessarily.

## CHAPTER 67 ■ TORSION OF THE TESTICLE

BLAKE W. MOORE AND HARRY P. KOO

Testicular torsion is a surgical emergency that demands prompt recognition and treatment to preserve testicular function. This condition occurs when the spermatic cord twists upon itself, leading to vascular compromise and a possible testicular loss from prolonged ischemia. The need for timely assessment and intervention is heightened by the fact that hours often elapse between the onset of symptoms and the urologist's evaluation. Despite the continuing advancements in radiologic imaging of the acute scrotum, history and physical

examination consistent with acute testicular torsion are often sufficient to warrant immediate surgical exploration.

Torsion of the spermatic cord has been recognized in all age groups, with the majority of patients presenting during adolescence. The annual incidence of testicular torsion in men under the age of 25 years is estimated to be 1 in 4,000 (1). The peak incidence has uniformly been seen in the 12- to 18-year-old age range (accounting for 65% of all torsions), with a second, much smaller peak in the perinatal period (1,2). A large

**FIGURE 67.1** **A:** Extravaginal torsion, typical of a neonatal testicular torsion. The tunica vaginalis is involved with the twist of the spermatic cord. **B:** Intravaginal torsion, usually seen after the neonatal period, involves the spermatic cord below the reflection of the tunica vaginalis onto the spermatic cord.

study found that 7% of the cases involved an undescended testicle, and it was speculated that testicular torsion was 10 times more common in patients with undescended testes (3). Curiously, a number of investigations have demonstrated unequal laterality, with the left testicle being affected more frequently. Bilateral torsion is said to account for fewer than 5% of all cases (3,4).

Testicular torsion can be classified as extravaginal or intravaginal based on whether the twisting is above or below the reflection of the tunica vaginalis onto the spermatic cord (Fig. 67.1). Extravaginal torsion occurs when the tunica vaginalis is not securely attached to the scrotum, allowing the testis and the tunica vaginalis to rotate as a unit along the longitudinal axis. This variant is virtually always limited to the perinatal population and may take place antenally or postnatally, a distinction that has important prognostic and therapeutic implications. A review by Das and Singer (5) found that 72% of perinatal torsions occur in utero. With *intravaginal* torsion, twisting of the spermatic cord occurs entirely within, but does not involve, the tunica vaginalis. This type of torsion affects patients outside of the perinatal age group, although it has been reported on rare occasion in newborns.

Several anatomic factors contribute to intravaginal torsion. The tunica vaginalis normally covers the anterior surface of the testis and extends varying distances over the epididymis and the spermatic cord. In the “bell clapper” variant, the tunica vaginalis inserts at an abnormally high location on the spermatic cord, causing the testis to be suspended freely within the tunical cavity. The “bell clapper” variant has been seen in 12% of testes at postmortem (6). In addition, the mesorchium may have a narrow attachment onto the testicle, allowing the testis to assume a more horizontal position within the scrotum. These factors contribute to increased testicular motility within the tunica vaginalis and facilitate rotation of the testis about the spermatic cord.

---

## DIAGNOSIS

---

### Perinatal Torsion

---

In the newborn, local and systemic symptoms of torsion may be scarce, delaying presentation and diagnosis. The patient with antenatal torsion may present with a large, firm, painless scrotal mass. Parents may report a swollen scrotum with discolored skin. In postnatal torsion, similar symptoms develop in a newborn with a previously normal scrotal examination. However, torsion that occurs after birth is more likely to cause systemic symptoms such as irritability or lack of appetite. Parents may also note an acute onset of redness and swelling of the scrotum.

In newborns, the physical exam may be the only indicator of testicular torsion. The neonate is usually in no acute distress, though a postnatal onset is more likely to cause general discomfort. An abdominal or inguinal mass may be found in the case of an undescended testis. The scrotal skin may be discolored, ranging from erythematous to blue-black, depending on the degree and duration of torsion. Chronic changes are more frequently seen with antenatal torsion.

---

### Torsion of the Testicle in Children, Adolescents, and Adults

---

Torsion outside of the perinatal population is usually associated with a more acute symptomatology. The classical presentation is described as a sudden onset of severe, unilateral testicular pain, with swelling of the testicle. With time, the patient may complain of swelling and redness of the scrotum.

The most common etiologies of scrotal pain are testicular torsion, torsion of testicular appendage, and epididymitis. Differentiating these disease processes can sometimes be problematic. In general, historical features (fever, nausea/vomiting, dysuria, sexual activity, history of trauma) were not helpful in differentiating testicular torsion from other conditions. In a retrospective review of 90 patients presenting with acute scrotum, the only statistically significant finding from history was that patients with testicular torsion or torsion of testicular appendage had a shorter duration of symptoms (<12 hours) when compared with patients with epididymitis (7).

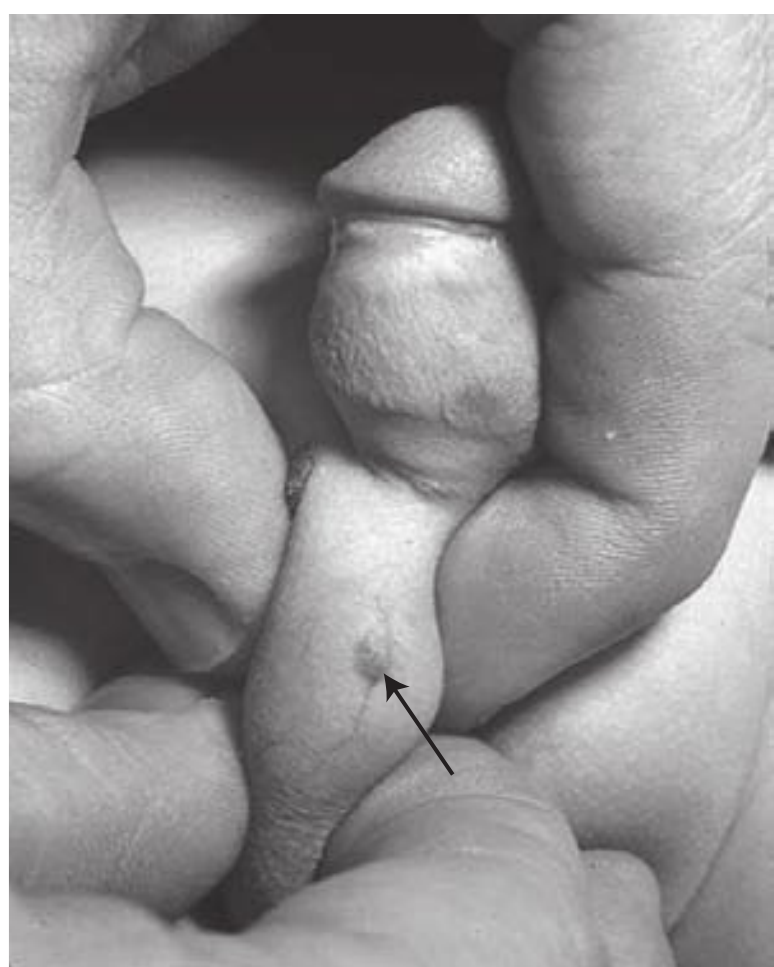

Older patients typically have more acute findings on physical exam. Almost invariably, the testicle will be swollen and exquisitely tender. Scrotal edema and erythema are usually present. In many cases the affected testicle assumes a retracted, horizontal lie. A detectable secondary hydrocele could be found in up to 50% of patients. Loss of the cremasteric reflex is suggestive of testicular torsion, and in several series it was universally absent (6,7). These characteristic findings all point toward an etiology of testicular torsion, but it must be remembered that no single finding is pathognomonic.

---

### Torsion of Testicular Appendages

---

Four testicular appendages have been identified: the appendix testis (hydatid of Morgagni), the appendix epididymis, the paradidymis (organ of Giralde's), and the vas aberrans of Haller. Each of these is susceptible to torsion, but the overwhelming

**FIGURE 67.2** Torsion of appendix testis showing the “blue dot sign” (arrow).

majority of twisted appendages involve the appendix testis. In the pediatric age group, appendiceal torsion is nearly as common as testicular torsion and accounts for 20% to 40% of acute scrotum cases (8). Torsion of a testicular appendage is often characterized by a gradual onset and few systemic symptoms. Early in the course of torsion of the appendix testis, physical examination may reveal a tender mass located at the upper pole of the testicle, sometimes adherent to the overlying skin. In our experience, it has been quite rare to see a small area of ecchymotic skin at the upper pole (“blue dot sign”), which is pathognomonic for torsion of the appendix testis (Fig. 67.2). In almost all cases the testicle has a normal orientation and the cremasteric reflex is intact (4). With time, torsion of the testicle and torsion of an appendage can become clinically indistinguishable. Imaging with Doppler ultrasound frequently shows a hyperechoic mass at the upper pole of a normal-appearing testicle. If the clinician is completely confident in the diagnosis of appendage torsion, the condition can be treated symptomatically. Therapy consists of bedrest, scrotal elevation, and nonsteroidal anti-inflammatory agents as needed. Symptoms should begin to resolve within 1 to 2 weeks as the infarcted appendage is gradually resorbed. If testicular torsion cannot be ruled out with certainty, urgent surgical exploration is needed.

Testicular torsion is a clinical diagnosis and is proven at the time of surgery. Radiologic studies may support the diagnosis, but negative imaging should not preclude exploration when clinical suspicion is high. Nonetheless, diagnostic examinations should be performed when testicular torsion is considered unlikely and the clinician has concluded that the patient has a nonsurgical condition.

Color Doppler ultrasound is widely utilized in the evaluation of scrotal abnormalities and has been studied in patients with testicular torsion. The capacity to view both blood flow and anatomic detail is particularly useful in assessing the scrotal contents and can provide valuable information about other pathologic conditions. Because of the prompt availability, low costs, short duration, and convenience of this examining method when compared with alternative diagnostic tools such as magnetic resonance imaging (MRI) or scintigraphy, sonography has become the primary diagnostic modality in evaluating the acute scrotum (9). Color Doppler ultrasound has been reported to have a sensitivity of 89% to 100% and a specificity

of 97% to 100% in diagnosing testicular torsion (7,9). Lack of intratesticular blood flow and testicular enlargement are characteristic findings. Gunther et al. (9) have noted that central arterial perfusion was a reliable diagnostic parameter to exclude testicular torsion. However, arterial blood flow ceases only after venous obstruction and edema develop, which can lead to a false-negative result early in the torsion. Intermittent torsion may also go undiagnosed. As with many radiographic technologies, interpretation is highly dependent on the experience of the technician or radiologist.

---

## INDICATIONS FOR SURGERY

---

Management of the newborn with testicular torsion is an area of controversy. To understand treatment in this age group, it is important to define the condition as prenatal or postnatal. Torsion that presents acutely *after* birth requires emergent surgical exploration. The nonviable testicle should undergo orchiectomy while evidence of viability should prompt detorsion with orchidopexy. We recommend fixation of the contralateral testis, regardless of the condition of the affected testicle. In the case of bilateral torsion (both prenatal and postnatal), the threshold for performing bilateral orchidopexy should be lower in an effort to preserve testicular function. The most common scenario in the perinatal period is the case of prenatal torsion, in which the baby is found to have chronic changes and a nonviable testicle. These neonates should undergo elective orchiectomy with contralateral testis fixation once anesthesia risk assessment has been stabilized (within 1 to 2 days of diagnosis). Operative risk is a concern, but in a series of 27 patients with perinatal torsion who underwent exploration 2 hours to 2 months after birth, there were no surgery- or anesthesia-related complications (10). Regular follow-up is needed to assess testicular size and pubertal development, and the services of an endocrinologist should be considered when hormonal dysfunction is expected (e.g., bilateral torsion). The option for testicular prosthesis placement in childhood should be discussed with the parents of orchiectomy patients.

The principles of management for patients beyond infancy are similar to those for newborns, though the more acute presentation in the older group provides greater opportunity for testicular salvage. To reiterate, a history and physical exam consistent with testicular torsion demand immediate surgical exploration. Orchiectomy is needed for the nonviable testicle, while a viable testis should be untwisted and fixed to the scrotum. Orchidopexy should be performed to protect the contralateral testicle. Testicular prostheses are available for adults and can be placed during the initial operation or at a later date. Evidence of testicular atrophy should be noted during follow-up visits. Furthermore, it is important to discuss with patients the increased risk of subfertility.

---

## ALTERNATIVE THERAPY

---

Some clinicians recommend that manual detorsion should be attempted. Studies evaluating the success rate for manual detorsion have produced conflicting evidence. Clinicians who adopt this strategy must do so on the premise that it does not substitute for or delay surgery. Because the majority of testes twist inward (right testicle clockwise and left counterclockwise as viewed from the foot of the bed), manual detorsion

should occur in the opposite direction. Nerve block of the spermatic cord can facilitate this maneuver, but it may also conceal the relief of detorsion or the pain of manipulation in the wrong direction. Successful manual detorsion should be followed by immediate surgical exploration.

While currently limited to animal models, medical adjuncts may one day be implemented, along with surgical management, to minimize the sequelae associated with testicular torsion. Pentoxifylline, a methyl xanthine derivative that decreases blood viscosity and platelet aggregation, appears to improve blood flow to both testes and unilateral torsion (11). Nitric oxide has been shown to have a protective effect against histopathologic change in the contralateral testicle, presumably through the regulation of blood flow (12).

---

## SURGICAL TECHNIQUE

---

Aside from the choice of incision, the surgical treatment for perinatal and childhood/adult (intravaginal) testicular torsions is essentially the same. For perinatal torsion, we use an inguinal approach on the affected side. The reason for doing so is that with extravaginal torsion (Fig. 67.3), there is a rare chance that another problem may exist, such as a hernia or tumor, that is best treated superior to the scrotum.

For intravaginal torsion, a vertical midline incision is our preferred approach to explore both testes. Two separate hemiscrotal incisions may also be used with excellent cosmetic results. Following incision to the level of the dartos muscles, the affected testis is moved under the midline incision. The layers of tunicae can be gently separated using a hemostat to minimize bleeding. The final few layers of tunicae are opened in a vertical fashion to expose the testis. A torsed testis usually

**FIGURE 67.3** Exposure of the right spermatic cord and testicle through an inguinal incision reveals a case of extravaginal torsion.

**FIGURE 67.4** Intravaginal testicular torsion in an adolescent.

appears dark blue or black (Fig. 67.4). Following manual detorsion, the testis is inspected for viability. If the viability of the testis is in question, the detorsed testis is wrapped in a warm moist sponge to recover while the contralateral testis is being pexed. If there still remains concern about the viability, a small nick can be made in the tunica albuginea to expose the seminiferous tubules, which should appear dusky to pink.

A nonviable testis should be removed to avoid possible continued symptoms and possible infection and to reduce the possibility of contralateral testicular damage from antisperm antibodies. We routinely do not place a testicular prosthesis at the time of orchiectomy. For the individuals who request a testicular prosthesis, we have performed delayed placement of solid silicone prostheses through a low inguinal incision.

The techniques for fixation of the viable detorsed testis and the contralateral testis still remain debated. Some of the controversy includes fixation with or without eversion of the tunica vaginalis, the use of absorbable or nonabsorbable suture, and fixation at two or three sites on the testis (13–15). We believe that the most important step in the fixation is the eversion of the tunica vaginalis (Fig. 67.5). This step produces two effects: (a) the testis is in an extravaginal position, and thus would not be at risk for intravaginal torsion; (b) everting the tunica vaginalis allows for contact between the tunica albuginea and the dartos. As an additional step, we perform two-point fixation of superior and inferior peritesticular tissue using absorbable (Vicryl) or nonabsorbable (Prolene) sutures.

---

## OUTCOMES

---

### Complications

---

The most significant complication of testicular torsion is infarction of the gonad. This event depends on the duration and degree of torsion and is managed by orchiectomy. A testicle that is viable at the time of surgery may later become atrophic despite orchidopexy, and it must be monitored closely by physical exam. Abnormal semen analysis and contralateral testicular apoptosis are also recognized sequelae following testicular torsion (16,17). Therefore, the risk of subfertility should be discussed with the patient. Although rare, torsion of a previously pexed testicle may occur.

**FIGURE 67.5** Scrotal incision with open tunica vaginalis reveals an intravaginal torsion.

## Results

The primary determinants of testicular viability are the degree to which the spermatic cord twists and the duration of torsion. The literature reports dismal salvage rates in newborns (as low as 5%); however, these accounts do not always distinguish

between prenatal and postnatal torsion. Very few cases of testicular salvage have been reported with an antenatal event. An aggressive approach to postnatal torsion is likely to improve the rate of testicular salvage for this subset of patients, which was 20% in a recent study (10). Long-term assessment of fertility in patients with perinatal torsion is lacking.

Determining the duration of symptoms is easier in patients outside of the newborn age group, for obvious reasons. Workman and Kogan (18) found that patients who underwent surgery within 6 hours of onset had testicular salvage rates of 83% to 97%. This figure dropped to 55% to 85% between 6 and 12 hours of onset, and after 24 hours the salvage rate fell to <10%. These statistics are consistent throughout the literature. Notably, testicular salvage does not necessarily imply normal testicular function. A number of studies have demonstrated that men with testicular torsion are prone to subfertility and abnormalities of the contralateral testicle.

In summary, testicular torsion is a urologic emergency that is diagnosed clinically and treated by immediate surgical exploration. The decision to perform orchiectomy versus orchidopexy of the affected testicle is based on the viability of the testis at the time of exploration. In either case, contralateral orchidopexy should be performed. The anatomic abnormalities that predispose the patient to testicular torsion are well established; however, the mechanisms responsible for long-term testicular dysfunction and contralateral testicular damage are under investigation. Rates of testicular salvage have improved dramatically since the first recorded case of testicular torsion in 1840. With heightened awareness of the signs and symptoms on the part of patients and physicians, along with a better understanding of the pathophysiologic mechanisms, immediate and long-term outcomes of testicular torsion will continue to improve.

# CHAPTER 68 ■ SCROTAL TRAUMA AND RECONSTRUCTION

TIMOTHY O. DAVIES AND GERALD H. JORDAN

The anatomy of the male genitalia is quite complex. In the scrotum, there are multiple fascial layers (Fig. 68.1 and 68.2). From the standpoint of trauma, however, most of the fascial layers are relatively unimportant. The Buck's fascia is related to the deep penile structures and is important in the containment of periurethral processes or the occasional hematoma associated with injury to the corpora cavernosa and/or corpus spongiosum. In the scrotum, the analogous fascia to the Buck's fascia—the external spermatic fascia—is usually uninvolved with scrotal trauma (Fig. 68.2).

Culp (3) has classified injuries to the external male genitalia into five categories: nonpenetrating, penetrating, avulsions, burns, and radiation injuries (both direct and indirect). Nonpenetrating injuries result from either a crushing or sudden

deforming force to the scrotum. These forces can cause severe damage to the internal structures without disrupting the skin. With any nonpenetrating trauma to the scrotum or perineum, one must suspect and rule out injury to the corpus spongiosum and urethra.

## DIAGNOSIS

Penetrating injuries to the genitalia frequently involve the urethra. Most of these injuries require exploration, irrigation, and removal of foreign-body material, if any, with anatomic repair and drainage (Level of Evidence, LOE 4) (4). If there is any suspicion of urethral injury, a retrograde urethrogram

**FIGURE 68.1** **A:** Cross section of the penis illustrating the fascial and structural components of the shaft of the penis. **B:** Sagittal section of the pelvis demonstrating the fascial layers and structural component.

**FIGURE 68.2** **A:** Perineal view of a trauma patient illustrating a hematoma contained by Colles fascia (classic butterfly hematoma). **B:** Same trauma patient illustrating the containment of the hematoma by the extended Colles layer, that is, the fascia lata of the thigh and extending onto the abdomen beneath the Scarpa fascia.

should be performed, and cystoscopy should be performed if further clarification of the injury is required. Saline should be used for irrigation in these cases. Because of the position of the urethra beneath the scrotum and perineum, significant penetrating injuries to the scrotum can also often miss the urethra.

Avulsion injuries of the genital skin most frequently involve the scrotal skin and occur when the patient's clothing becomes entangled in machinery. The loose scrotal tissues ensnare, and as the clothing is ripped off, so is the loose genital skin. These avulsion injuries vary from minimal injuries, which are essentially nothing more than lacerations, to emasculating injuries, which take not only the skin but also the deep structures. Usually, the deep penile structures are not avulsed, as the injury, fortunately, takes only the skin and the dartos fascia/tunica dartos, leaving the underlying Buck's fascia of the penis and the fascial layers surrounding the testicle intact. Occasionally, the testicle ensnares in the skin and is avulsed. In most cases of avulsion, bleeding is not a problem, as the skin and fascia are avulsed in a plane between the fascial structures related to the deep structures and the superficial fascia.

Burns to the genitalia are usually not isolated injuries but reflective of a wider area of body burn. Chemical burns are in general only superficial and involve the skin. Thermal injuries can be deep, but often, even with extensive deep burns proximate to the genitalia, the multiple clothing layers (i.e., underwear and other clothing) can protect the genitalia. Electrical burns disseminate via the deep vascular and neurological structures, and what may appear to be a minimal burn to the skin and scrotum may have significant deep injury associated with it, and this can be devastating. However, usually the deepest burns associated with electrical contact occur at the site of the current inflow and the ground site. These sites are

usually not the genitalia. However, it is not uncommon to have thermal burns in concert with electrical burns, as frequently the clothing is ignited by the electrical spark. Thus, with electrical burns, fortunately, if the genitalia are involved it is usually a more superficial process.

Radiation injuries to the genitalia can occur either from direct exposure to the genitalia or from the effects of radiation on the venous and lymphatic drainage. Now, by and large, we do not see complications of direct radiation to the genitalia, as radiation for penile lesions is rarely undertaken. The secondary effects of radiation, as seen in the scrotum, are usually manifested by chronic lymphedema, lymphangiectasia, and, in some cases, chronic recurring cellulitis.

To this list of traumas must be added the patient who has required significant debridement because of rapidly progressive, multiorganism fasciitis (Fournier's gangrene). Fournier's gangrene is often seen with processes of the anus or rectum, such as missed perianal abscess. Likewise, processes involving the urethra, such as periurethral abscess, can accompany Fournier's gangrene. Many times Fournier's gangrene is associated with other comorbidities, such as diabetes mellitus. Many of these patients present late, and aggressive surgical debridement (LOE 2), while lifesaving, usually leaves a significant defect (4). If the fasciitis is associated with pathophysiology of the urethra and/or anus, then these situations must be managed and resolved before reconstruction (5). Recently there have been descriptions of the use of unprocessed honey to augment or provide an alternative treatment to wide surgical excision. Honey apparently contains antimicrobial agents and enzymes to digest necrotic tissue as well as to promote epithelial growth (6).

Also, in recent years we have seen several patients who have attempted to enhance the size and bulk of their genitalia

**FIGURE 68.3** B-scan ultrasound demonstrating the classic distribution of a scrotal contusion (scrotal wall hematoma). Note the testis displaced anteriorly, with the hematoma contained in the multiple fascial layers of the scrotum.

with the injection of lipid-containing substances such as paraffin or petroleum jelly or inert substances such as silicone. In these cases, one is often confronted with a fulminant cellulitis that must be treated with broad-spectrum antibiotics. Later, one sees a sclerosing granulomatous process that can be troubling to the patients. In some cases, the skin must be excised along with the deeper involved structures, but it is not unusual to be able to excise the deep process and leave the skin that survives either on its random dermal blood supply or, in some cases, on the tunica dartos fasciocutaneous blood supply.

A contusion of the scrotum, that is, scrotal hematoma, can be confused with a fracture of the testicle. The latter injury implies disruption of the tunica albuginea and visceral tunica vaginalis of the testicle. With a scrotal contusion the hematoma usually is noted to be posterior and lateral to the testicle (Fig. 68.3), whereas with fracture of the testicle the parenchyma of the testis is not normal and is often associated with a hematocele (Fig. 68.4). Physical examination remains the cornerstone in the diagnosis of blunt testicular trauma. However, the

**FIGURE 68.4** B-scan ultrasound of a patient with a fracture of the testicle. Note the disrupted parenchymal pattern of the testicle, the hematocele, and the demonstration of extruded seminiferous tubules within the hematocele.

use of ultrasonography in the diagnosis of testicular trauma can be helpful in situations when the physical examination is difficult to perform or interpret. Ultrasonography is the most sensitive and specific imaging technique, with heterogeneity of the parenchyma of the testicle suggestive of testicular rupture (LOE 2) (4). In the presence of penetrating trauma to the genitalia, a retrograde urethrogram is always indicated because of the close proximity to the urethra. In all cases of genital avulsion, other than a simple scrotal avulsion, a complete evaluation of the urethra must be done, along with a rectal examination and possibly flexible sigmoidoscopy.

---

## INDICATIONS FOR SURGERY

---

Exploration of the scrotum is indicated if the patient has sustained either blunt or penetrating injury to the testicle (LOE 3) (4). Scrotal reconstruction is required following complex lacerations and avulsion injuries. If a patient has required excision for chronic cellulitis, lymphangiectasia, and lymphedema, split-thickness skin graft reconstruction of the scrotum is very effective and provides cosmetically very acceptable results. If the lymphedematous process is due to a local process, then often the lateral scrotum and the posterior scrotum are free of the process because the lymphatic drainage is lateral and often uninvolved. In these cases lateral scrotal flap reconstruction is often very effectively employed.

If, however, the process causing the scrotal lymphedema is “systemic” (i.e., Charles’s disease, secondary to pelvic irradiation, etc.), then Split-thickness Skin Graft (STSG) reconstruction is always the best approach. The lymphatics of the skin are carried in the reticular dermis (the deep layer of the dermis). If a thick STSG is used to reconstruct the genitalia, in cases of lymphedema, the lymphedema can significantly recur in the graft. One must be careful of the patient with scrotal lymphedema without “involvement of the penile skin”; following scrotal reconstruction, often the penile skin becomes edematous. Following burn injury to the genitalia, almost always graft reconstruction can be undertaken, and it offers extremely good functional and cosmetic results.

---

## ALTERNATIVE THERAPY

---

Contusions of the scrotum are usually treated with bedrest, analgesia, and scrotal elevation. Scrotal elevation can be accomplished very efficiently with a Bellevue-style (a taped suspensory dressing to elevate the scrotum) bridge or with scrotal support.

---

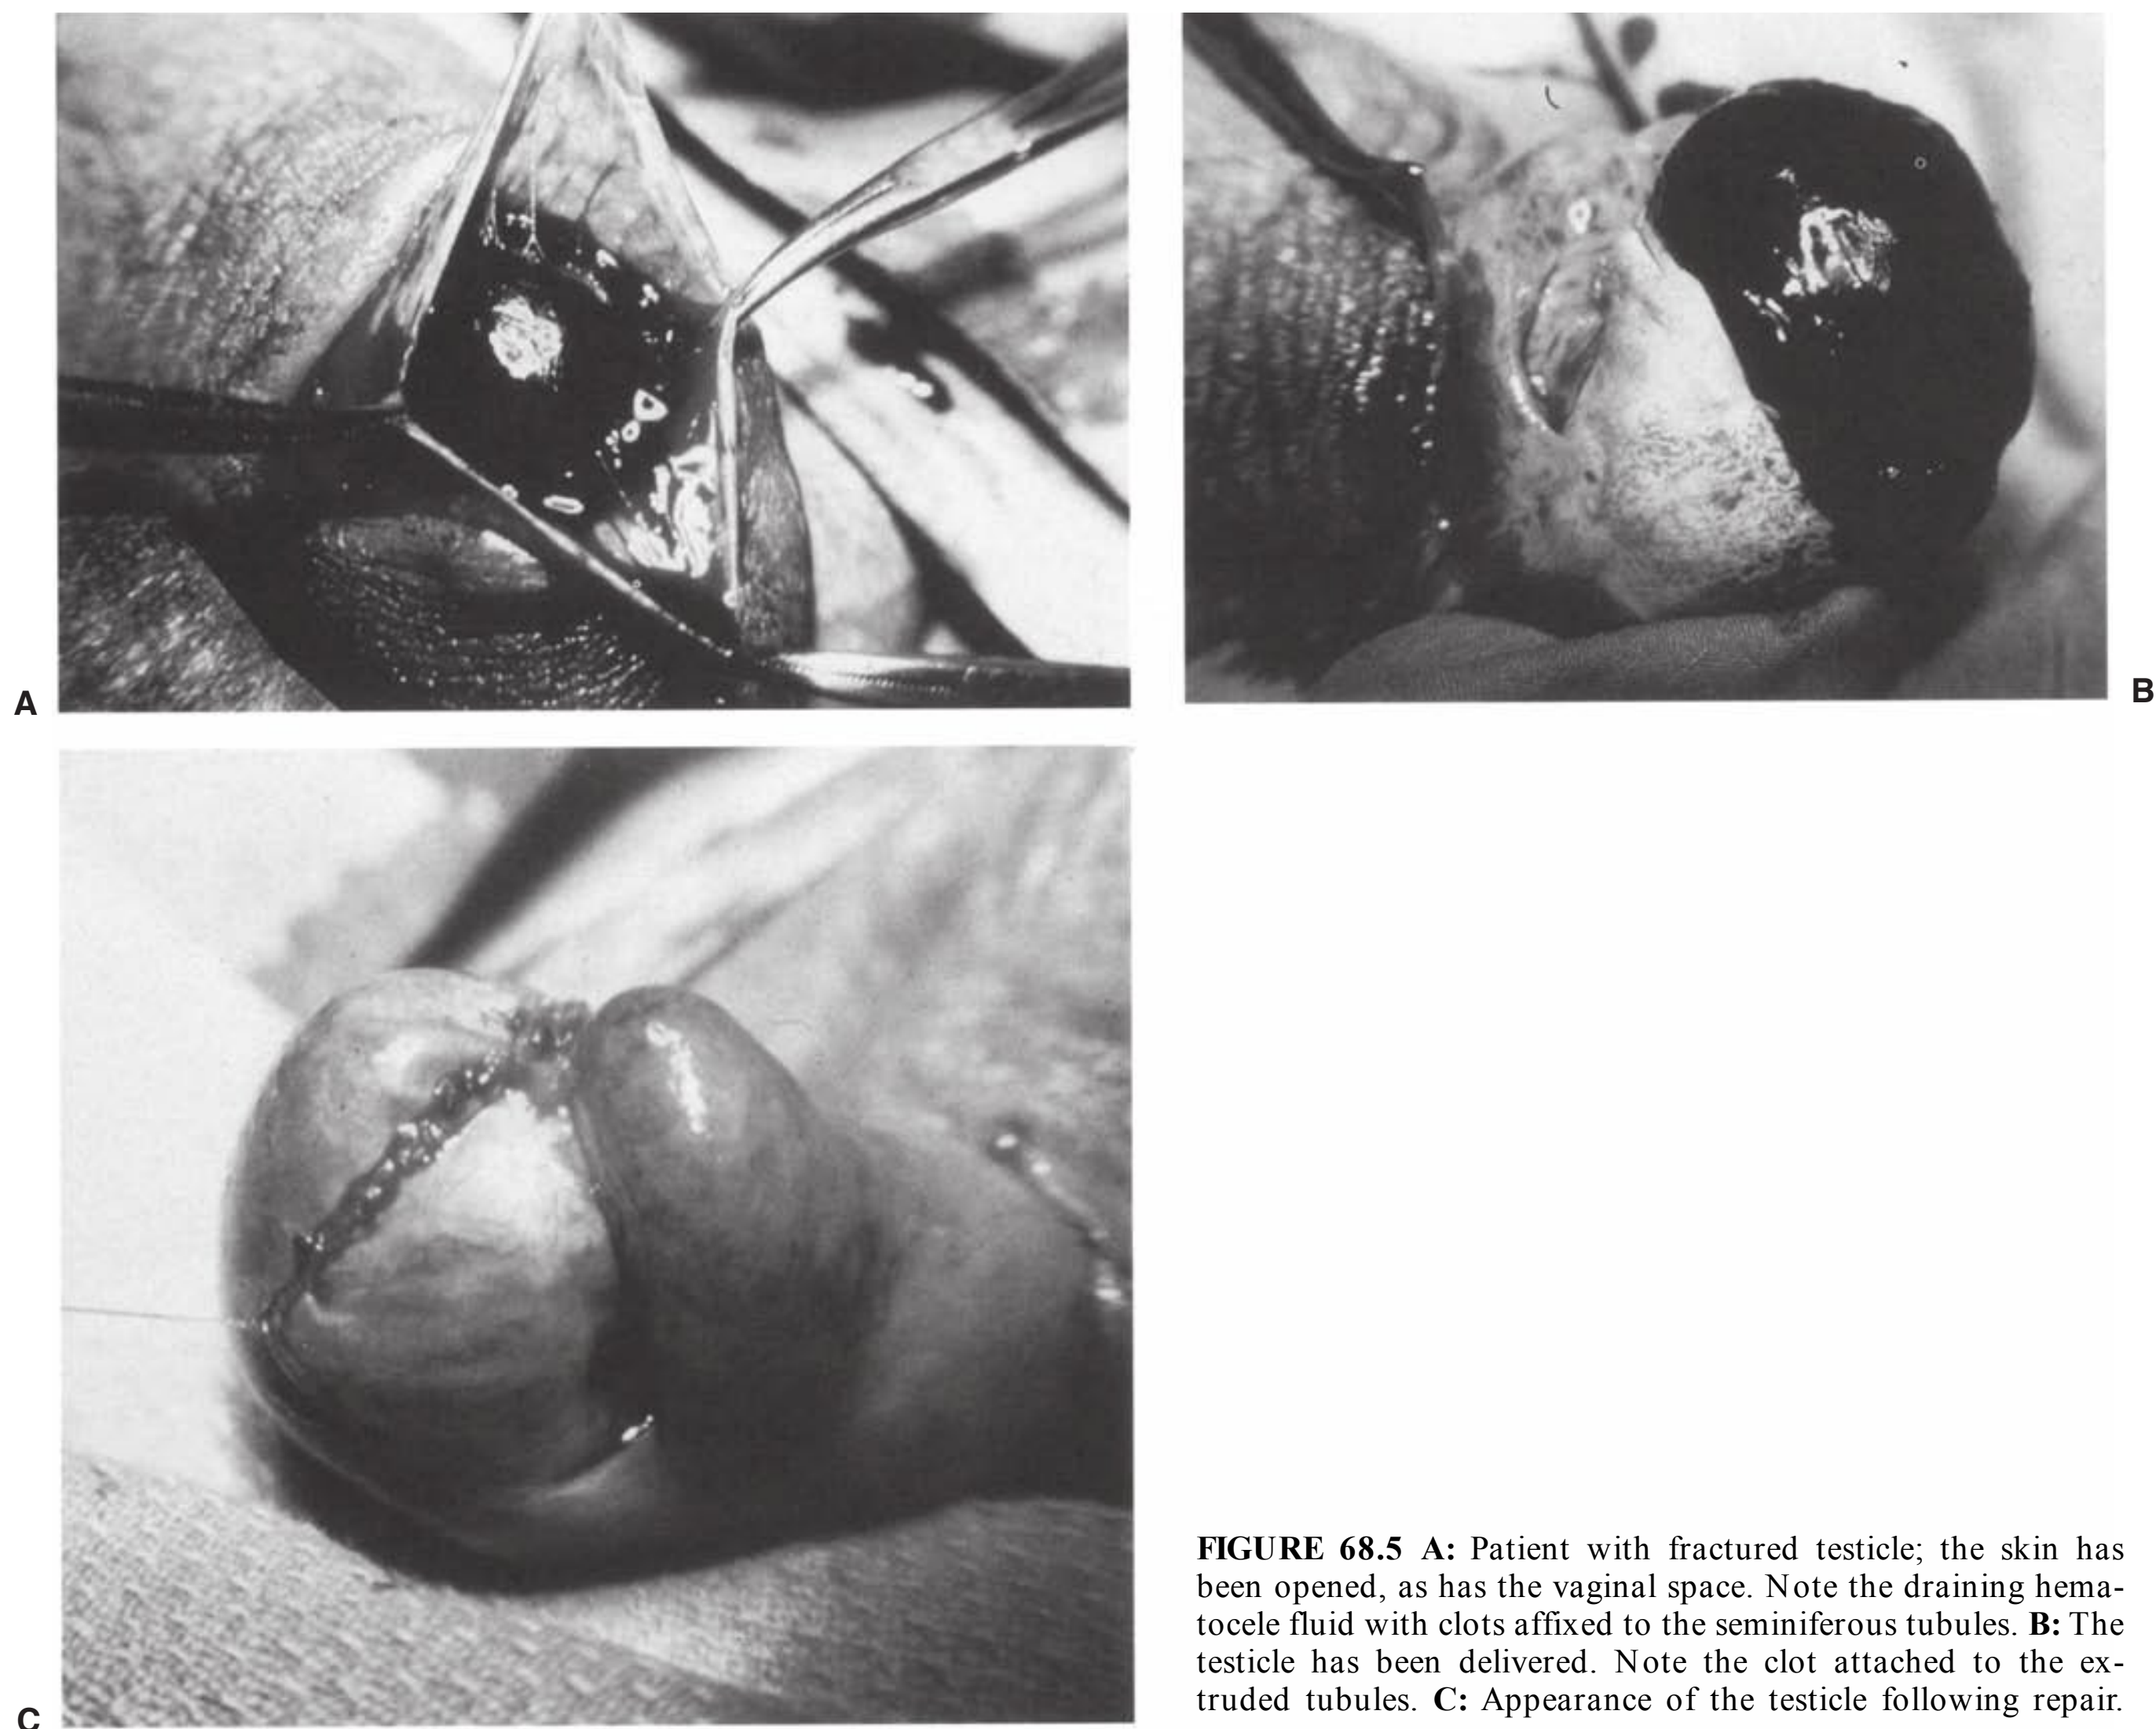

## SURGICAL TECHNIQUE

---

### Scrotal Hematomas and Blunt Testicular Injury

---

There is little to be accomplished in exploring the scrotal hematoma secondary to external blunt trauma, as the hematoma is usually disseminated throughout the highly elastic layers of the scrotum and does not form a drainable hematoma per se (3). On the other hand, if there is a testicular

**FIGURE 68.5** **A:** Patient with fractured testicle; the skin has been opened, as has the vaginal space. Note the draining hema-tocele fluid with clots affixed to the seminiferous tubules. **B:** The testicle has been delivered. Note the clot attached to the ex-truded tubules. **C:** Appearance of the testicle following repair.

injury, exploration and repair of the testicle are indicated (Fig. 68.5). Exploration consists of exposure of the testicle. The space of the tunica vaginalis is opened, the hema-tocele is drained, seminiferous tubules are debrided, and the tunica albuginea is closed. The remaining viable testicular tissue should be salvaged for endocrine function and psychological impact (LOE 2) (4). In the past, polyglycolic (PGA) suture was used; however, now we use polydioxanone suture, although Monocryl is also an option. The parietal tunica vaginalis is left open and is reflected as would have been done for a hydrocele. The scrotum is drained and closed with 3-0 PGA suture, chromic suture, or Monocryl. Alternatively, in cases of testicular fracture secondary to either blunt or penetrating injury, rather than using aggressive debridement and primary closure of the tunica albuginea, one can close the testis with a tunica vaginalis graft or island.

### Penetrating Injuries to the Genitalia

Penetrating injuries have been subclassified as either simple or complicated. By and large, complicated injuries imply

urethral involvement, amputation, or near-total amputation; and with regard to the scrotum they imply amputation of or injury to the testicle, with or without amputation of the overlying scrotal skin (Fig. 68.6). Simple lacerations are managed with primary closure and drainage, if indicated. In the case of amputation of the testicles, testicular microreplantation has been performed, including vasovasostomy, along with reapproximation of the vasculature of the spermatic cord (Fig. 68.7). The testicle is placed, as quickly as possible, in a sterile bag in saline-soaked gauze, and that bag is placed in a second bag filled with saline slush for cold preservation. Unlike amputation of the penis, where successful replantation has been done as long as 18 to 24 hours from the injury, the testicle must be replanted by 6 to 8 hours due to the very high metabolic rate of the testicular tissue.

There can be some difficulty in identifying the vessels in the spermatic cord, although they are somewhat compartmentalized. Identifying the artery proximally is not difficult, and identification of the distal artery in the severed organ can be aided by examining the relationship of the compartments to the vas deferens. Coaptation of the artery and a number of veins is optimal using 9-0 or 10-0 Prolene, depending on the

A

B

C

D

**FIGURE 68.6** **A:** Young patient with complex penetrating trauma to the thigh and genitalia. Retrograde urethrogram, rectal examination, and flexible sigmoidoscopy were normal. The patient's scrotum was explored. **B:** The patient's right testicle is delivered; note the intact seminiferous tubule pattern with virtual complete disruption of the tunica albuginea. **C:** Appearance of the same testicle (*B*) following reconstruction of the tunica albuginea with primary closure. **D:** Appearance of the genitalia with the gunshot wounds debrided and the right hemiscrotum drained. Dr. Michael Coburn, Baylor University, Department of Urology, Personal Communication, (January 16, 2009, Norfolk, Virginia) has assembled a series of patients with similar injuries to that illustrated. In those cases, the testicle was closed with a parietal tunica vaginalis patch. He reports good results with this technique.

size of the respective vessels. Vasovasostomy can be done using 9-0 or 10-0 Prolene or nylon sutures, either with a classic microscopic two-layer technique or a single-layer "tricorn" technique, depending on the surgeon's preference.

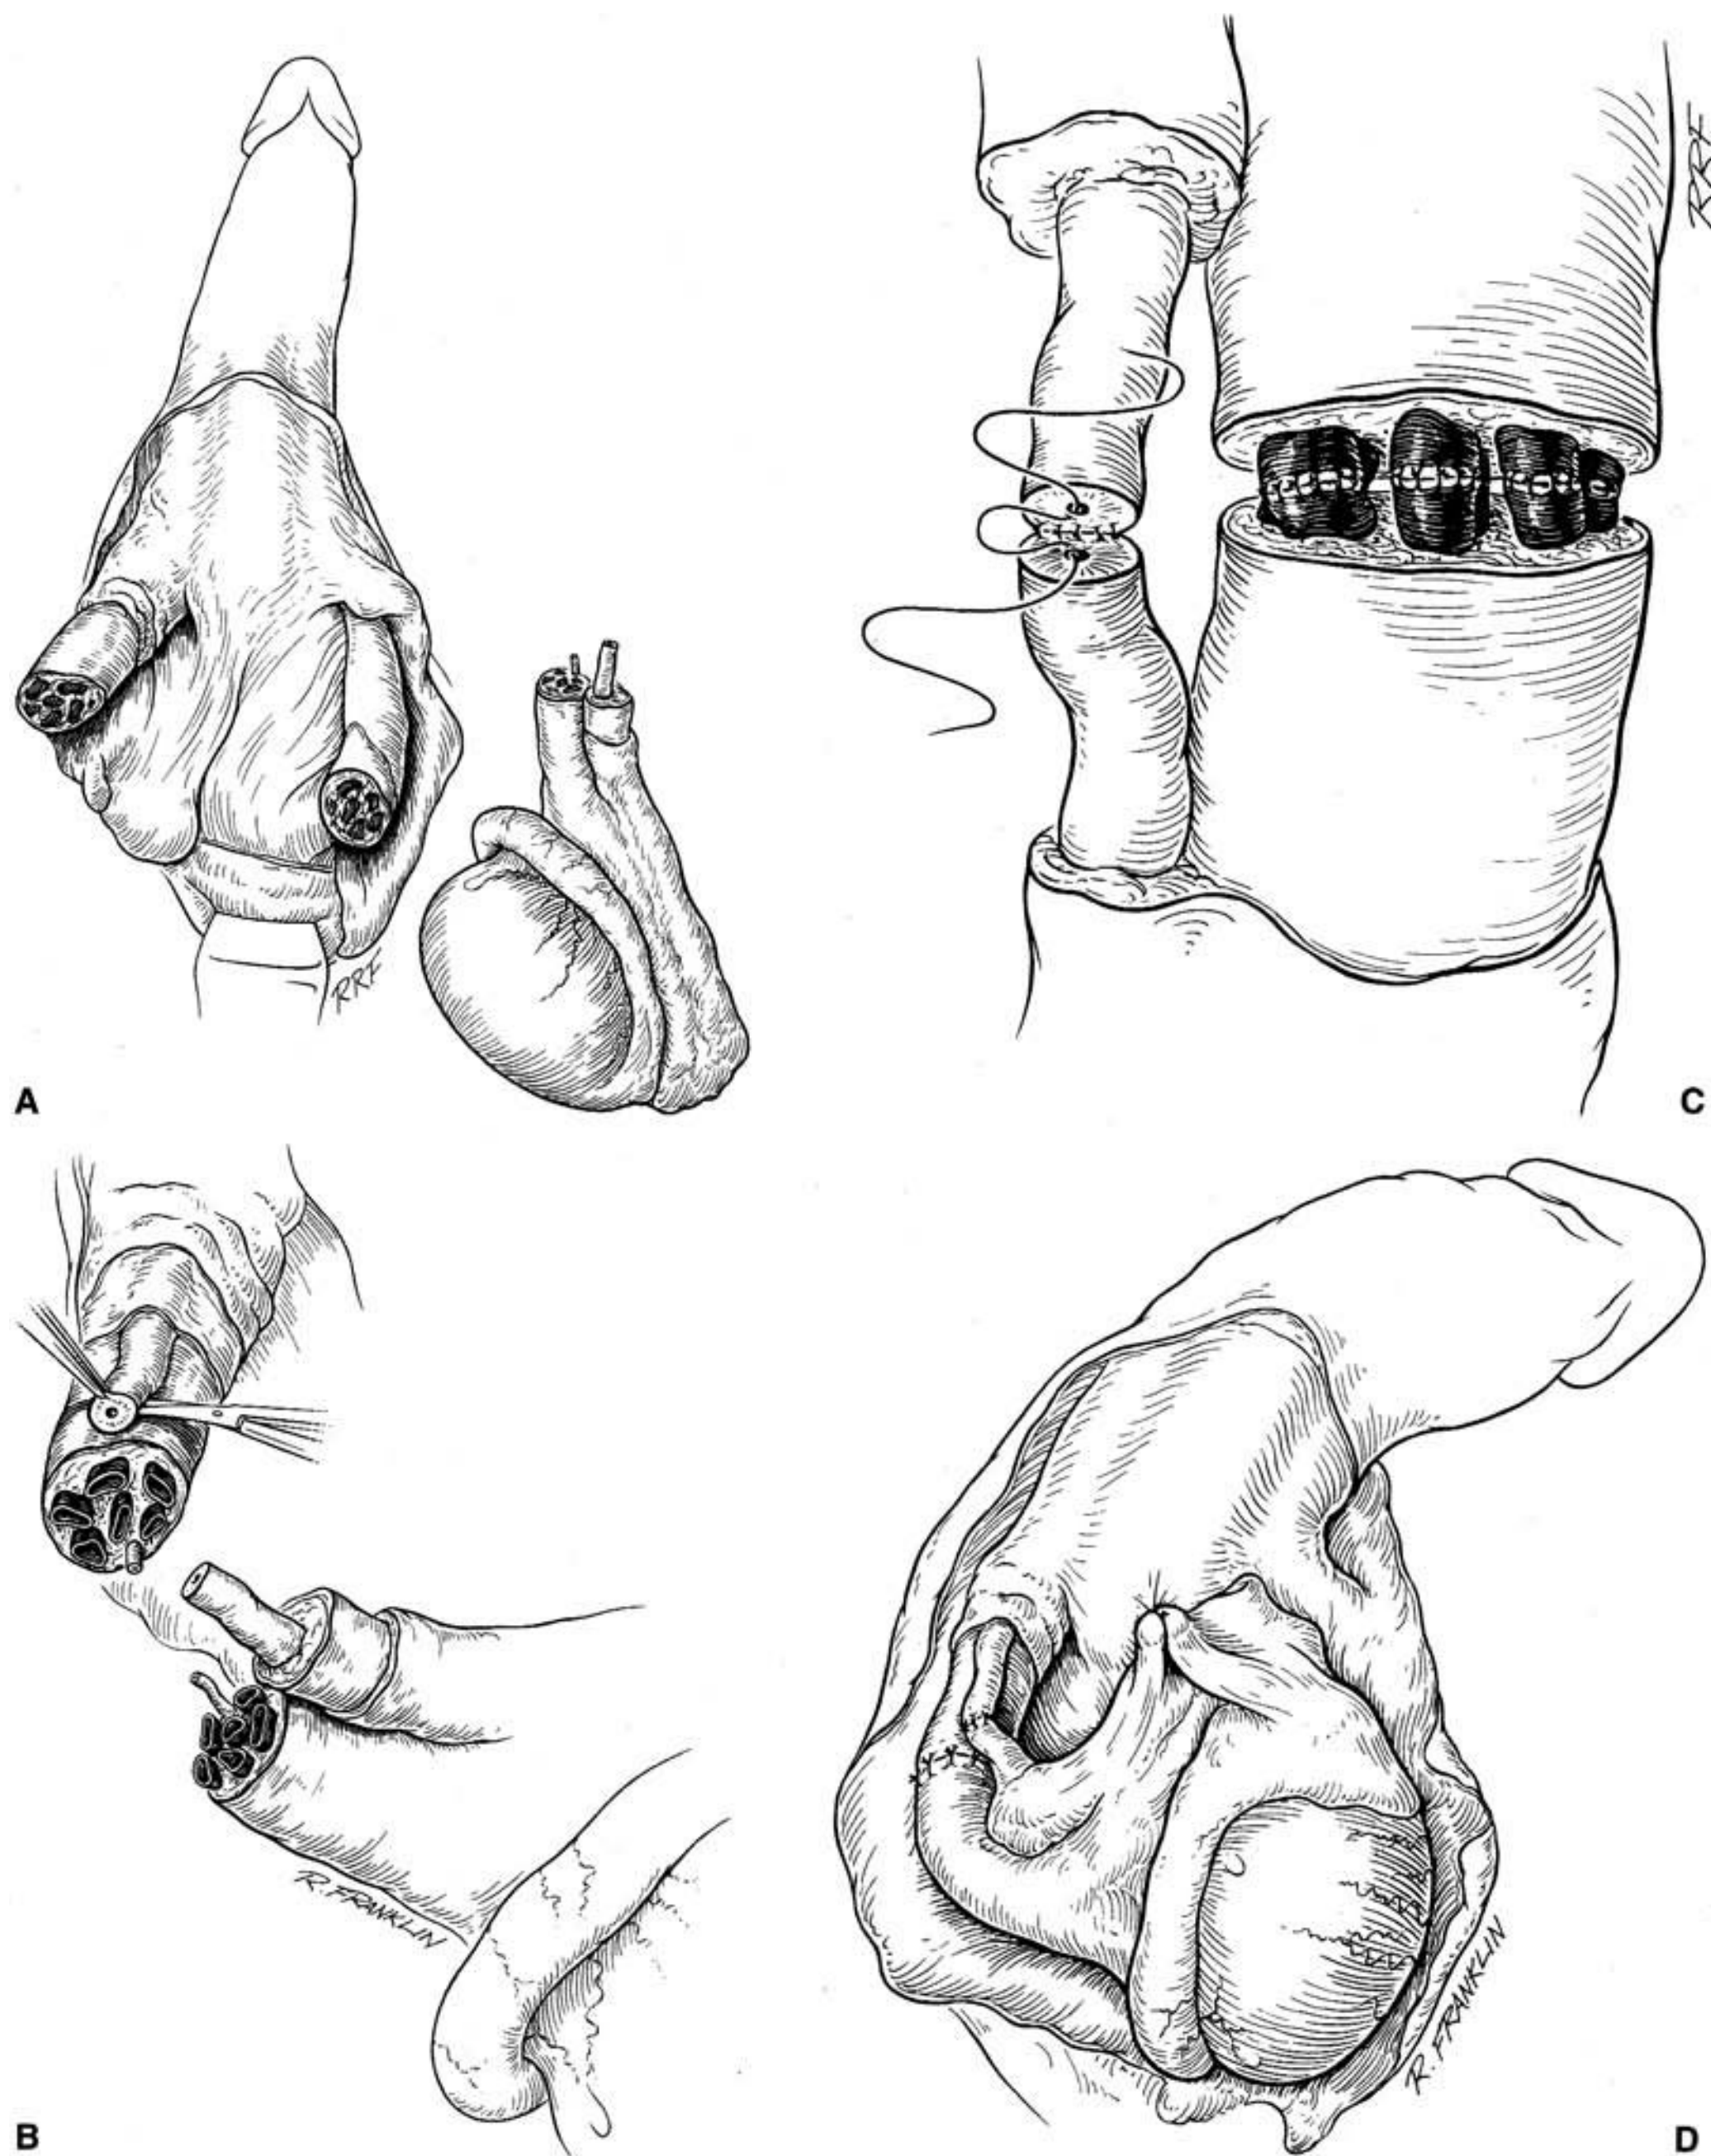

If possible, the testicle should not be covered with a graft but either placed in a thigh pouch and later liberated or, if there is some remaining redundancy of the scrotum, covered primarily with reapproximation of the remaining scrotal tissues.

Obviously, if the patient arrives without his amputated testicle, then hemostasis must be ensured. Usually the vessels are in spasm, but they clearly can come out of spasm later. The

wound should be irrigated and, if contaminated, packed to be closed by secondary intention. If the wound is clean, then primary closure or primary grafting can be performed.

### Avulsion Injuries

Small scrotal avulsions are managed as simple lacerations with either primary or delayed closure and drainage, as would be indicated for any laceration (LOE 3; Fig. 68.8) (4). For larger injuries, the emergency management consists of allowing the

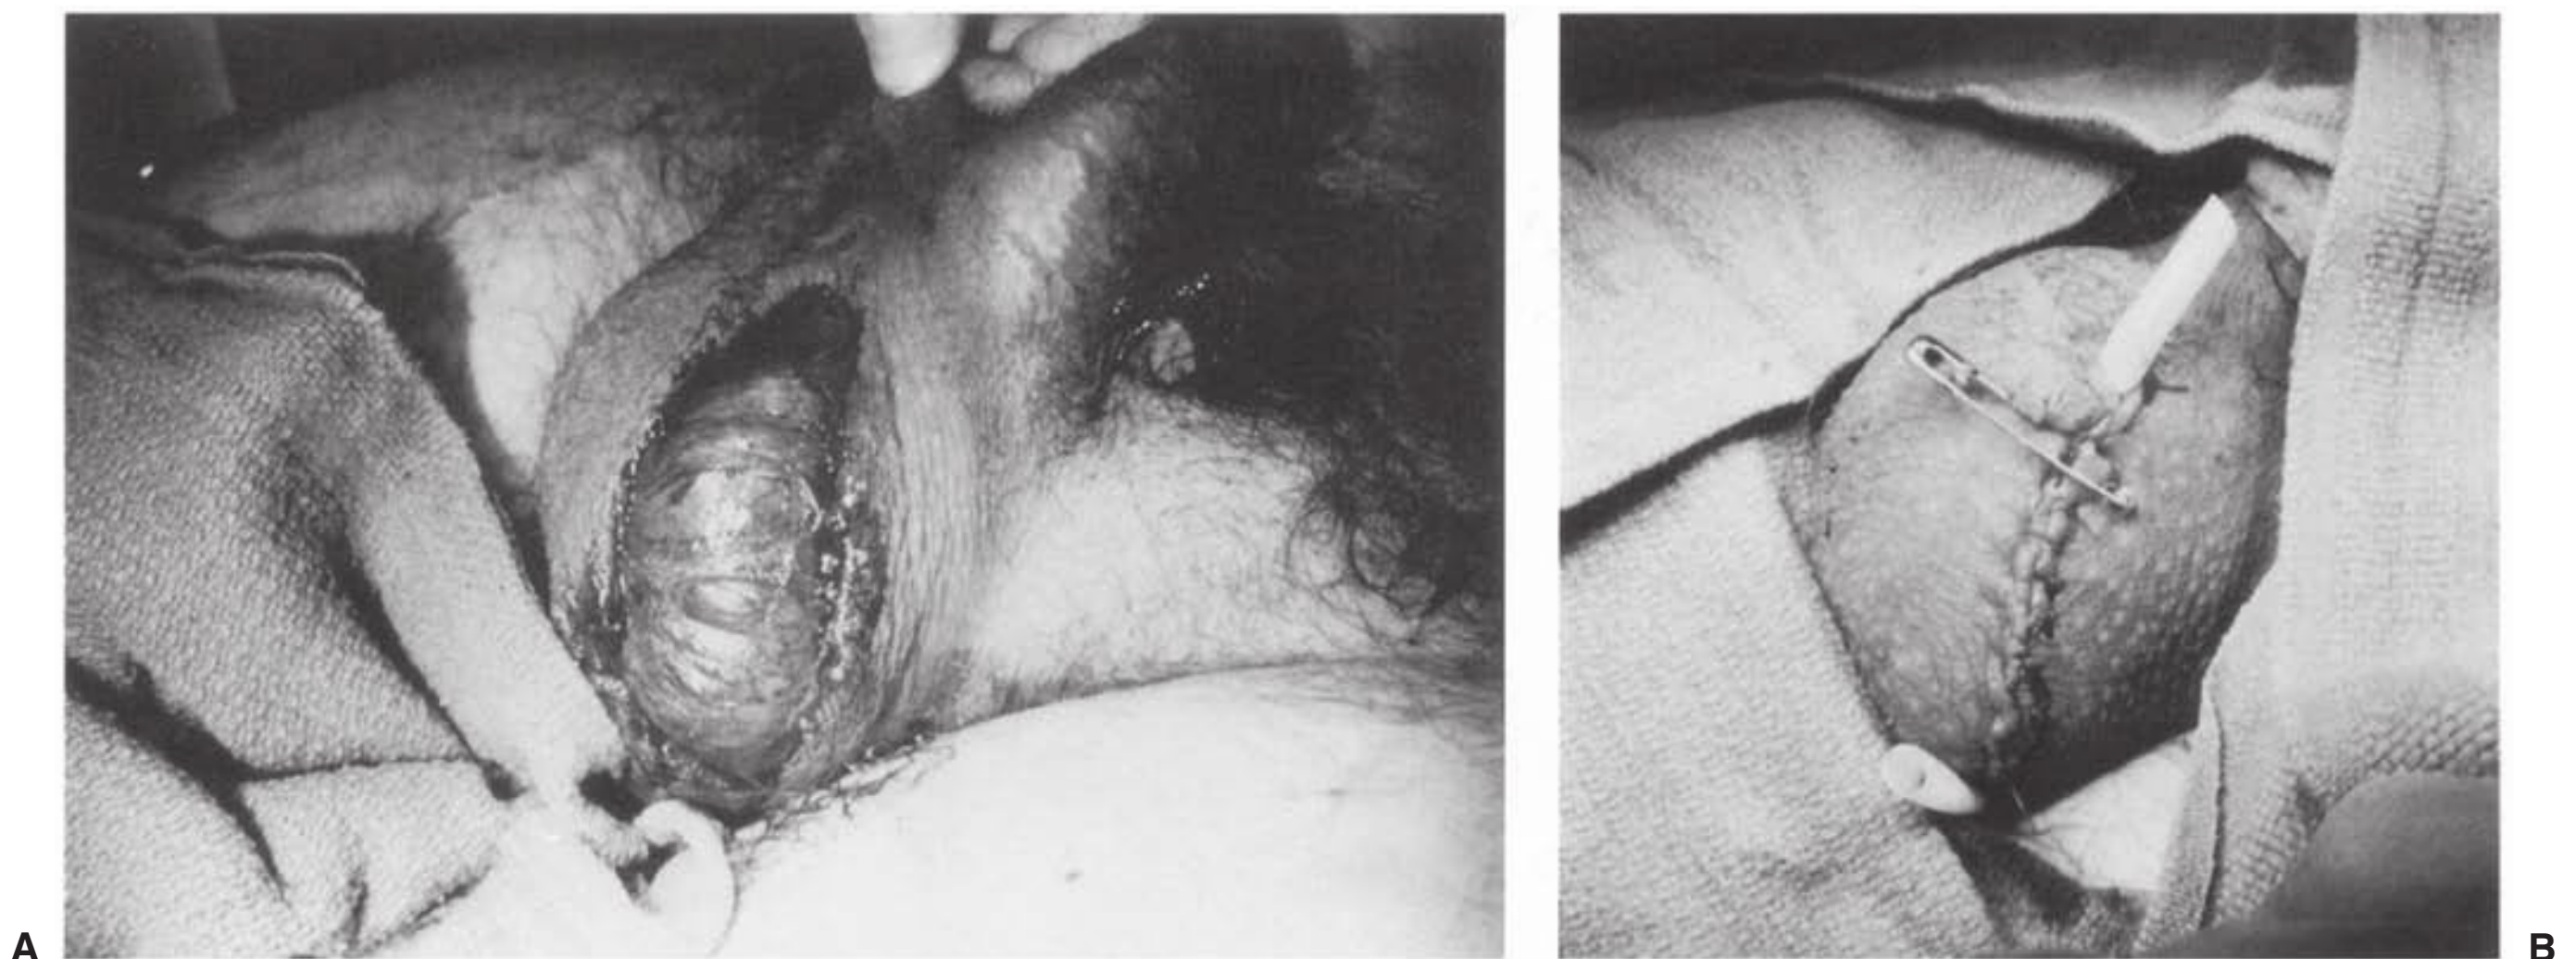

**FIGURE 68.7** **A:** Appearance of a patient following bilateral testicular amputation and scrotal amputation. The patient presented with only his right testicle. The left testicle could not be found at the trauma scene. **B:** The right testicle is reanastomosed to the left (longer) spermatic cord. **C:** Note the appearance of the debrided spermatic cord and the debrided distal spermatic cord going to the testicle. Vasovasostomy was performed with a two-layer microscopic technique. Microscopic coaptation of the spermatic artery and multiple spermatic veins was performed. **D:** Appearance of the replanted testicle before closure of the scrotum.

injury to completely demarcate (Fig. 68.9). The area of the avulsed scrotum should be managed with cold saline packs and observed over 12 to 24 hours. Clear demarcation will occur and allow the surgeon to debride only the tissue that is nonviable. Debridement with closure is then performed (LOE 3) (4).

If a primary closure cannot be accomplished with the remaining scrotal tissue, then the surgeon has several options.

One option is to place the testicles in thigh pouches to be later liberated and later replaced to the area of the scrotum. The preferable option is to perform a primary reconstruction of the scrotum using a mesh split-thickness skin graft. The graft should be harvested 0.016 to 0.018 in. thick and then meshed on a 1.5- to 1.0- meshing template. The testicles must be fixed in position using permanent suture or absorbable suture that is slowly absorbed so that they do not migrate beneath the

**FIGURE 68.8** **A:** Appearance of a left scrotal avulsion injury. The patient was injured in a motorcycle accident in which his trousers were ripped off as he departed the motorcycle. **B:** Appearance after closure. Primary closure is performed with drainage.

graft. The meshing of the graft allows for escape of serum and blood products from beneath the graft, but it also allows the graft to configure to the complex contours of the underlying testicles. The vaginal space is left open, and the parietal tunica vaginalis is reflected to fix the testicle in place. The graft is then applied immediately to the testicles, suturing it to the

surrounding skin. It is the opinion of some authors that grafting directly on the visceral tunica vaginalis or tunica albuginea can lead to a situation where there is chronic testicular pain. This has not been the author's (GHJ) experience. Unless the wound is markedly contaminated, cases so managed have yielded very successful results.

**FIGURE 68.9** **A:** Large avulsion injury of the genitalia. The patient was injured when his clothing was ensnared in the power takeoff mechanism of a tractor. Note the exposed shaft of the penis and the exposed testicles bilaterally. **B:** The appearance after reconstruction with a split-thickness skin graft. The patient was observed for 24 hours, allowing the wounds to demarcate. In this case, both the shaft of the penis and the scrotum were reconstructed with a sheet split-thickness skin graft.

The grafts should be bolstered using Xeroform gauze or one of the other commercially available fine meshed gauzes applied directly to the graft, with Dacron batting soaked in saline and mineral oil placed over the finely meshed gauze. Lately we have favored the use of the high-density polyethylene sheeting (N-Terface, Richardson, TX 75083-2297, Winfield Laboratories, Inc.) to prevent adherence and subsequent graft displacement with bolster removal. The bolster is held in place with 4-0 chromic sutures. Unless there is an associated urethral injury, the patient can be "diverted" with a soft Foley catheter. In patients in whom the avulsion injury extends near to the anus, colostomy may be required. It must be emphasized that local skin flaps are not recommended for primary closure in these cases.

Should the testicles be avulsed, replantation is not an option. During the avulsion injury, the vasculature is stretched before giving way to the force, and the endothelial damage can be significant and unpredictable.

In patients in whom the avulsion injury is tantamount to emasculation, these injuries are often associated with significant injuries to the adjacent tissue. Reconstruction assumes a very secondary position, as these patients require lifesaving steps. The vast majority of these patients will require colostomy, suprapubic cystostomy, and multiple dressing changes over the posttrauma course, and they often present with significant bleeding.

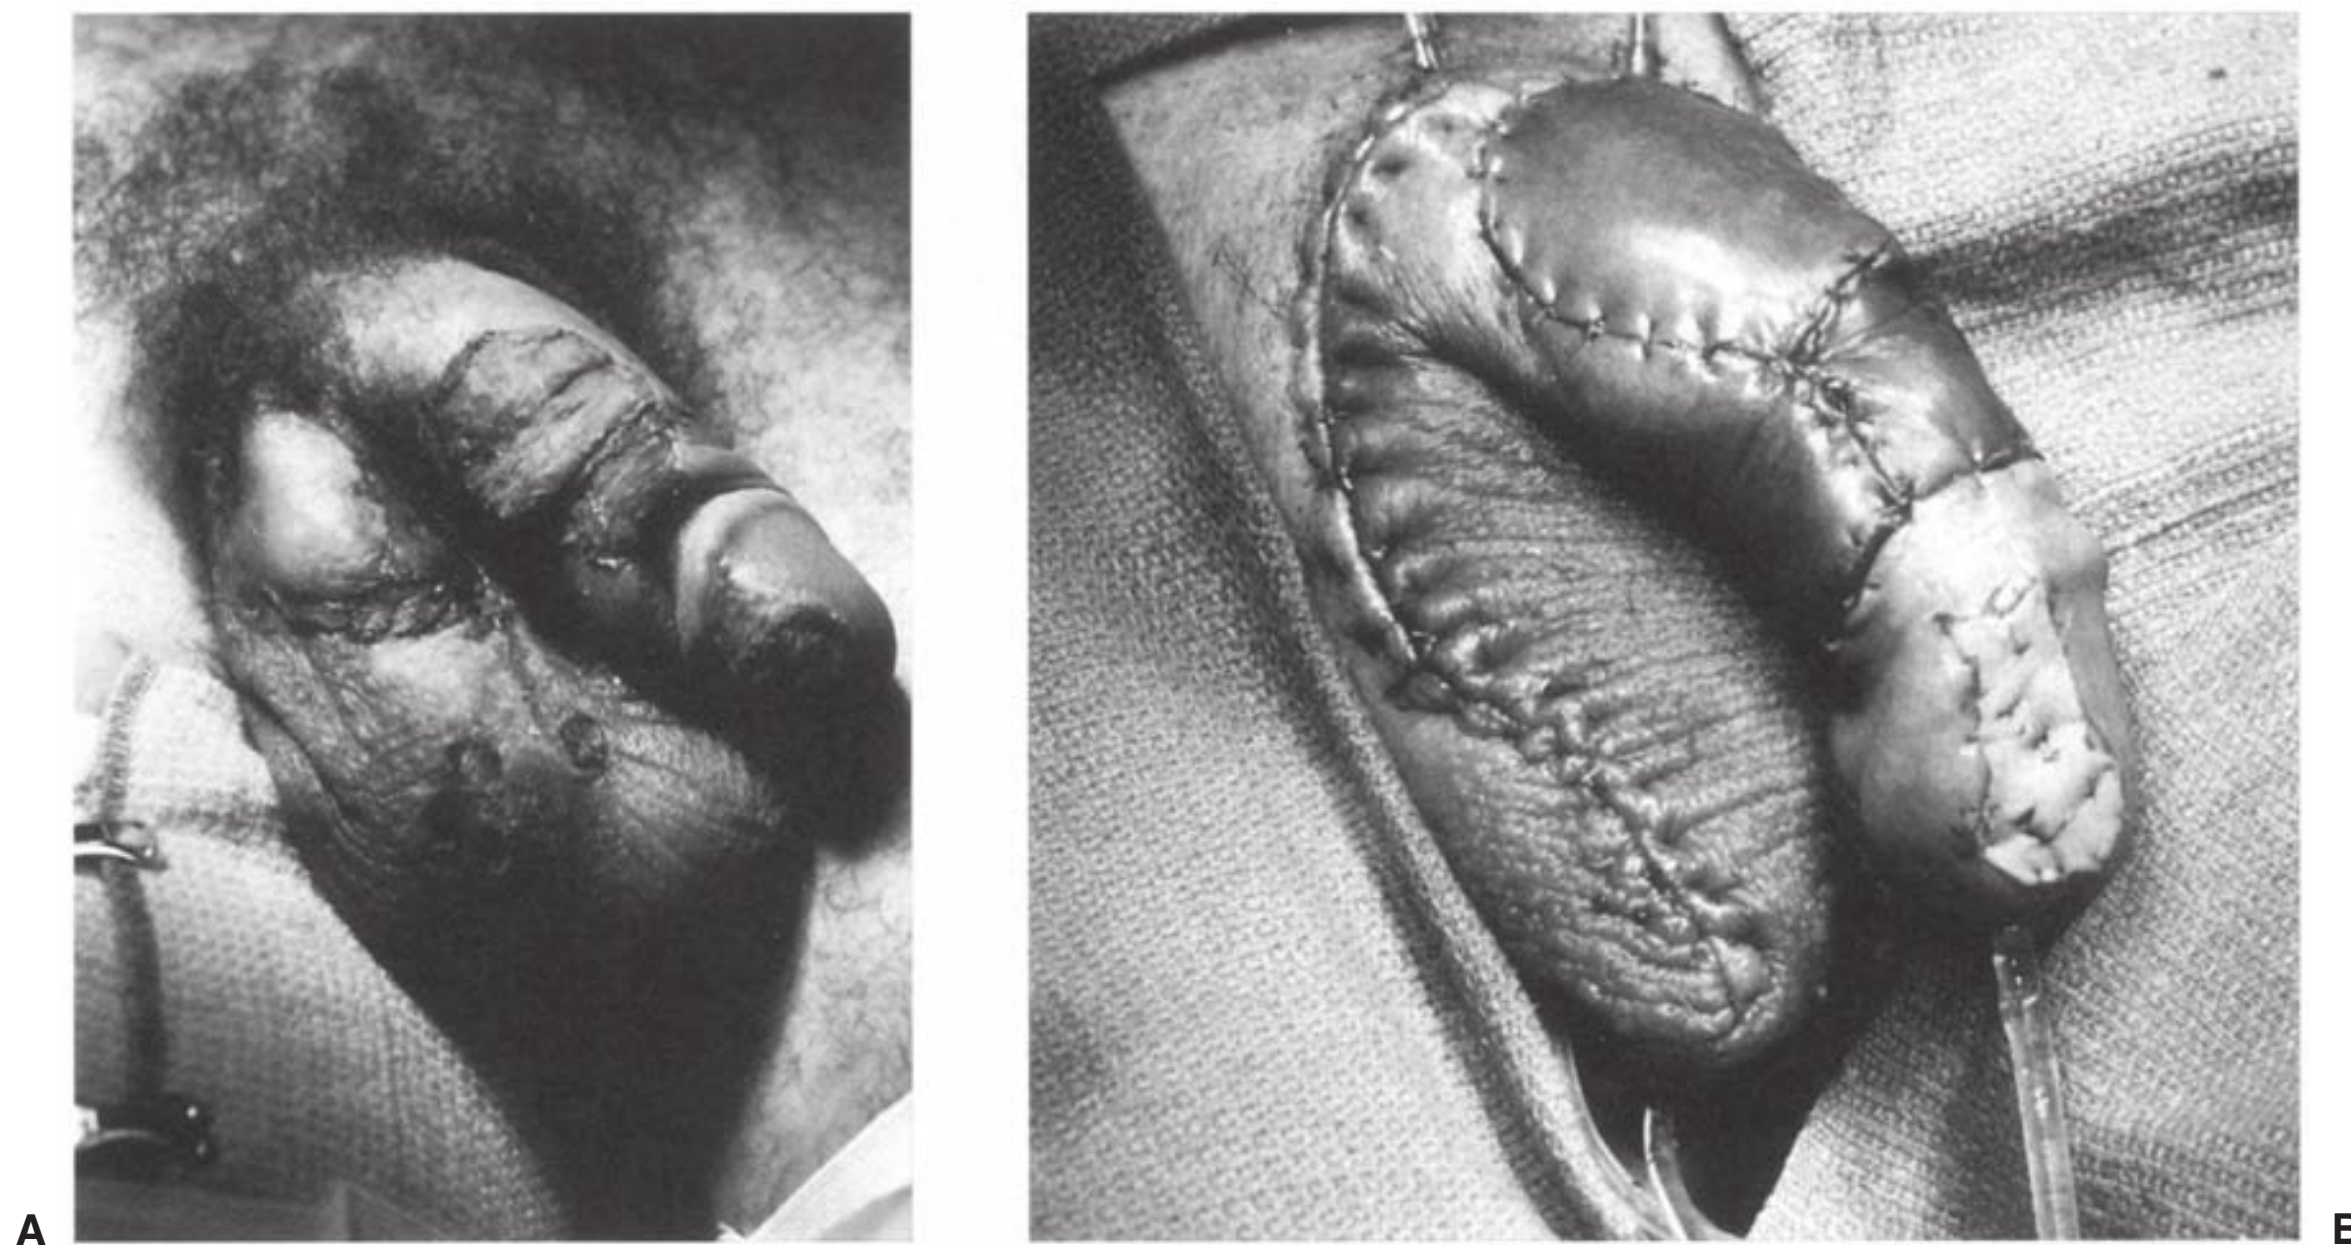

In general, the scrotal skin is highly distensible, and even a small fragment can be expanded to cover a large defect with a good functional result. There has been concern regarding the effect of implantation of the testes in thigh pockets on spermatogenesis, although there are few clinical data to support this concern.

## Genital Burns

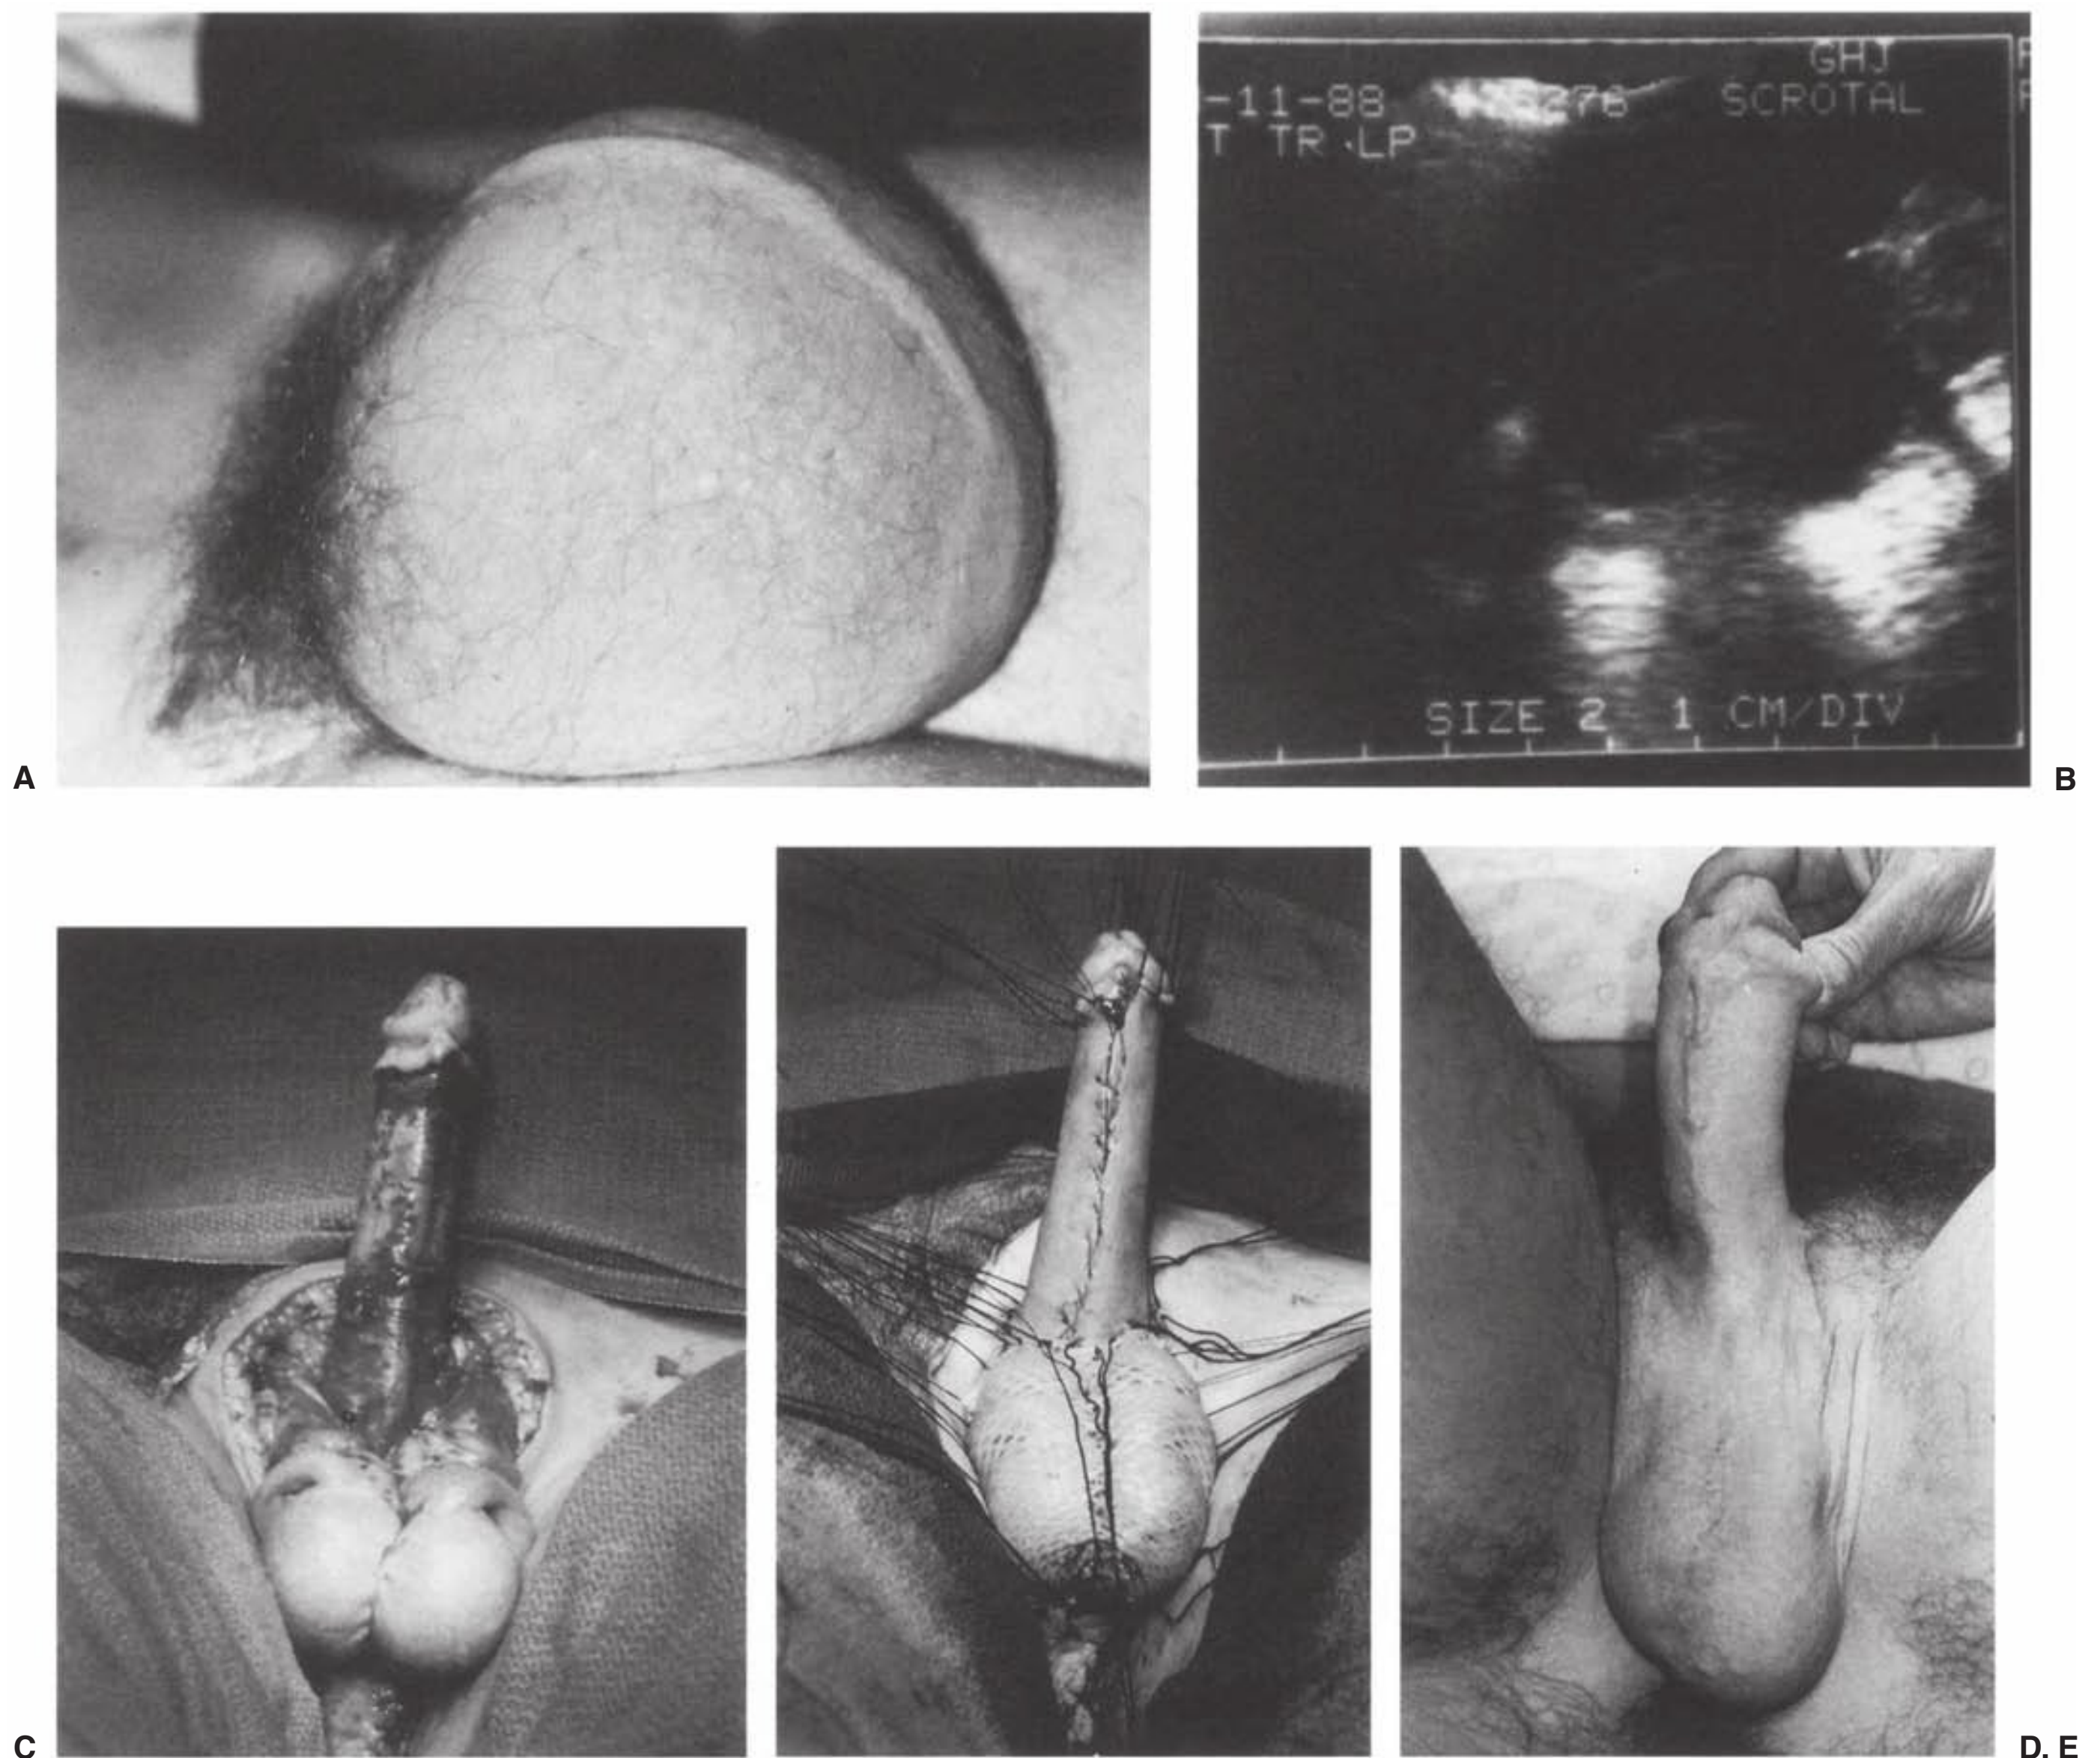

The emergency therapy of genital burns is similar to that for any burn. The scrotum can be dressed, open, with topical antibiotic ointments such as Silvadene, or a closed antibiotic dressing regimen can be used. The integrity of the urethra must be determined when the patient presents. A Foley catheter can be placed in the patient who has burns to his genitalia. If there is evidence of urethral burn, then most would suggest diversion with suprapubic cystostomy. If the burns to the genital and perineal area are extensive, then an occasional patient will require colostomy. If the subscrotal urethra is involved in the burn, no attempt at initial reconstruction should be made. In the case of the infant or young male, the move to a suprapubic tube should be made quickly if the need for a urethral catheter is at all prolonged.

The genital tissues are remarkably vascular. Debridement of the genitalia, in general, should be accomplished carefully. Aggressive debridement should be avoided, as many of the tissues will recover and are nonreproducible. Whirlpools and tank soaks are useful for gentle debridement and cleansing, and they may be done early on, two to three times per day.

Chemical burns rarely involve the structures deep to the skin and are managed with copious irrigation and then as with a thermal burn (LOE 4). If a patient has evidence of an electrical burn to the area of the genitalia, the patient must be observed for 12 to 24 hours and then explored. In electrical burns, the initial management is aimed at debridement, and reconstruction can be offered later as the situation dictates (Fig. 68.10).

**FIGURE 68.10** **A:** The appearance of the genitalia in a patient who was burned in a steam-line accident. Note the burns to the glans, the dorsum of the shaft of the penis, and the right hemiscrotum. **B:** In this particular case, reconstruction of the glans was accomplished with a small split-thickness skin graft. Reconstruction of the shaft of the penis was accomplished with a penile skin island flap; the patient was uncircumcised, and the ventral skin was mobilized to the dorsum. The scrotal burn was completely excised, and primary reconstruction of the right hemiscrotum was accomplished. This particular patient demonstrates all of the possibilities for reconstruction following burn debridement.

**FIGURE 68.11** Appearance of a young man with chronic genital lymphedema following irradiation therapy for Hodgkin lymphoma. **A:** Appearance of the massively lymphedematous scrotum. **B:** B-scan ultrasound demonstrating the large hydrocele. Note the normal testis posteriorly. **C:** Appearance of the genitalia after debridement of the lymphedematous tissue. Note that orchidopexy has been performed. **D:** Immediate appearance following reconstruction of the shaft of the penis with a split-thickness skin graft and reconstruction of the scrotum with a meshed split-thickness skin graft. **E:** Appearance of that same patient 6 months postoperatively. Note the small amount of residual lymphedema of the preputial cuff. Further note the redundant appearance of the scrotal graft.

### Radiation Injuries

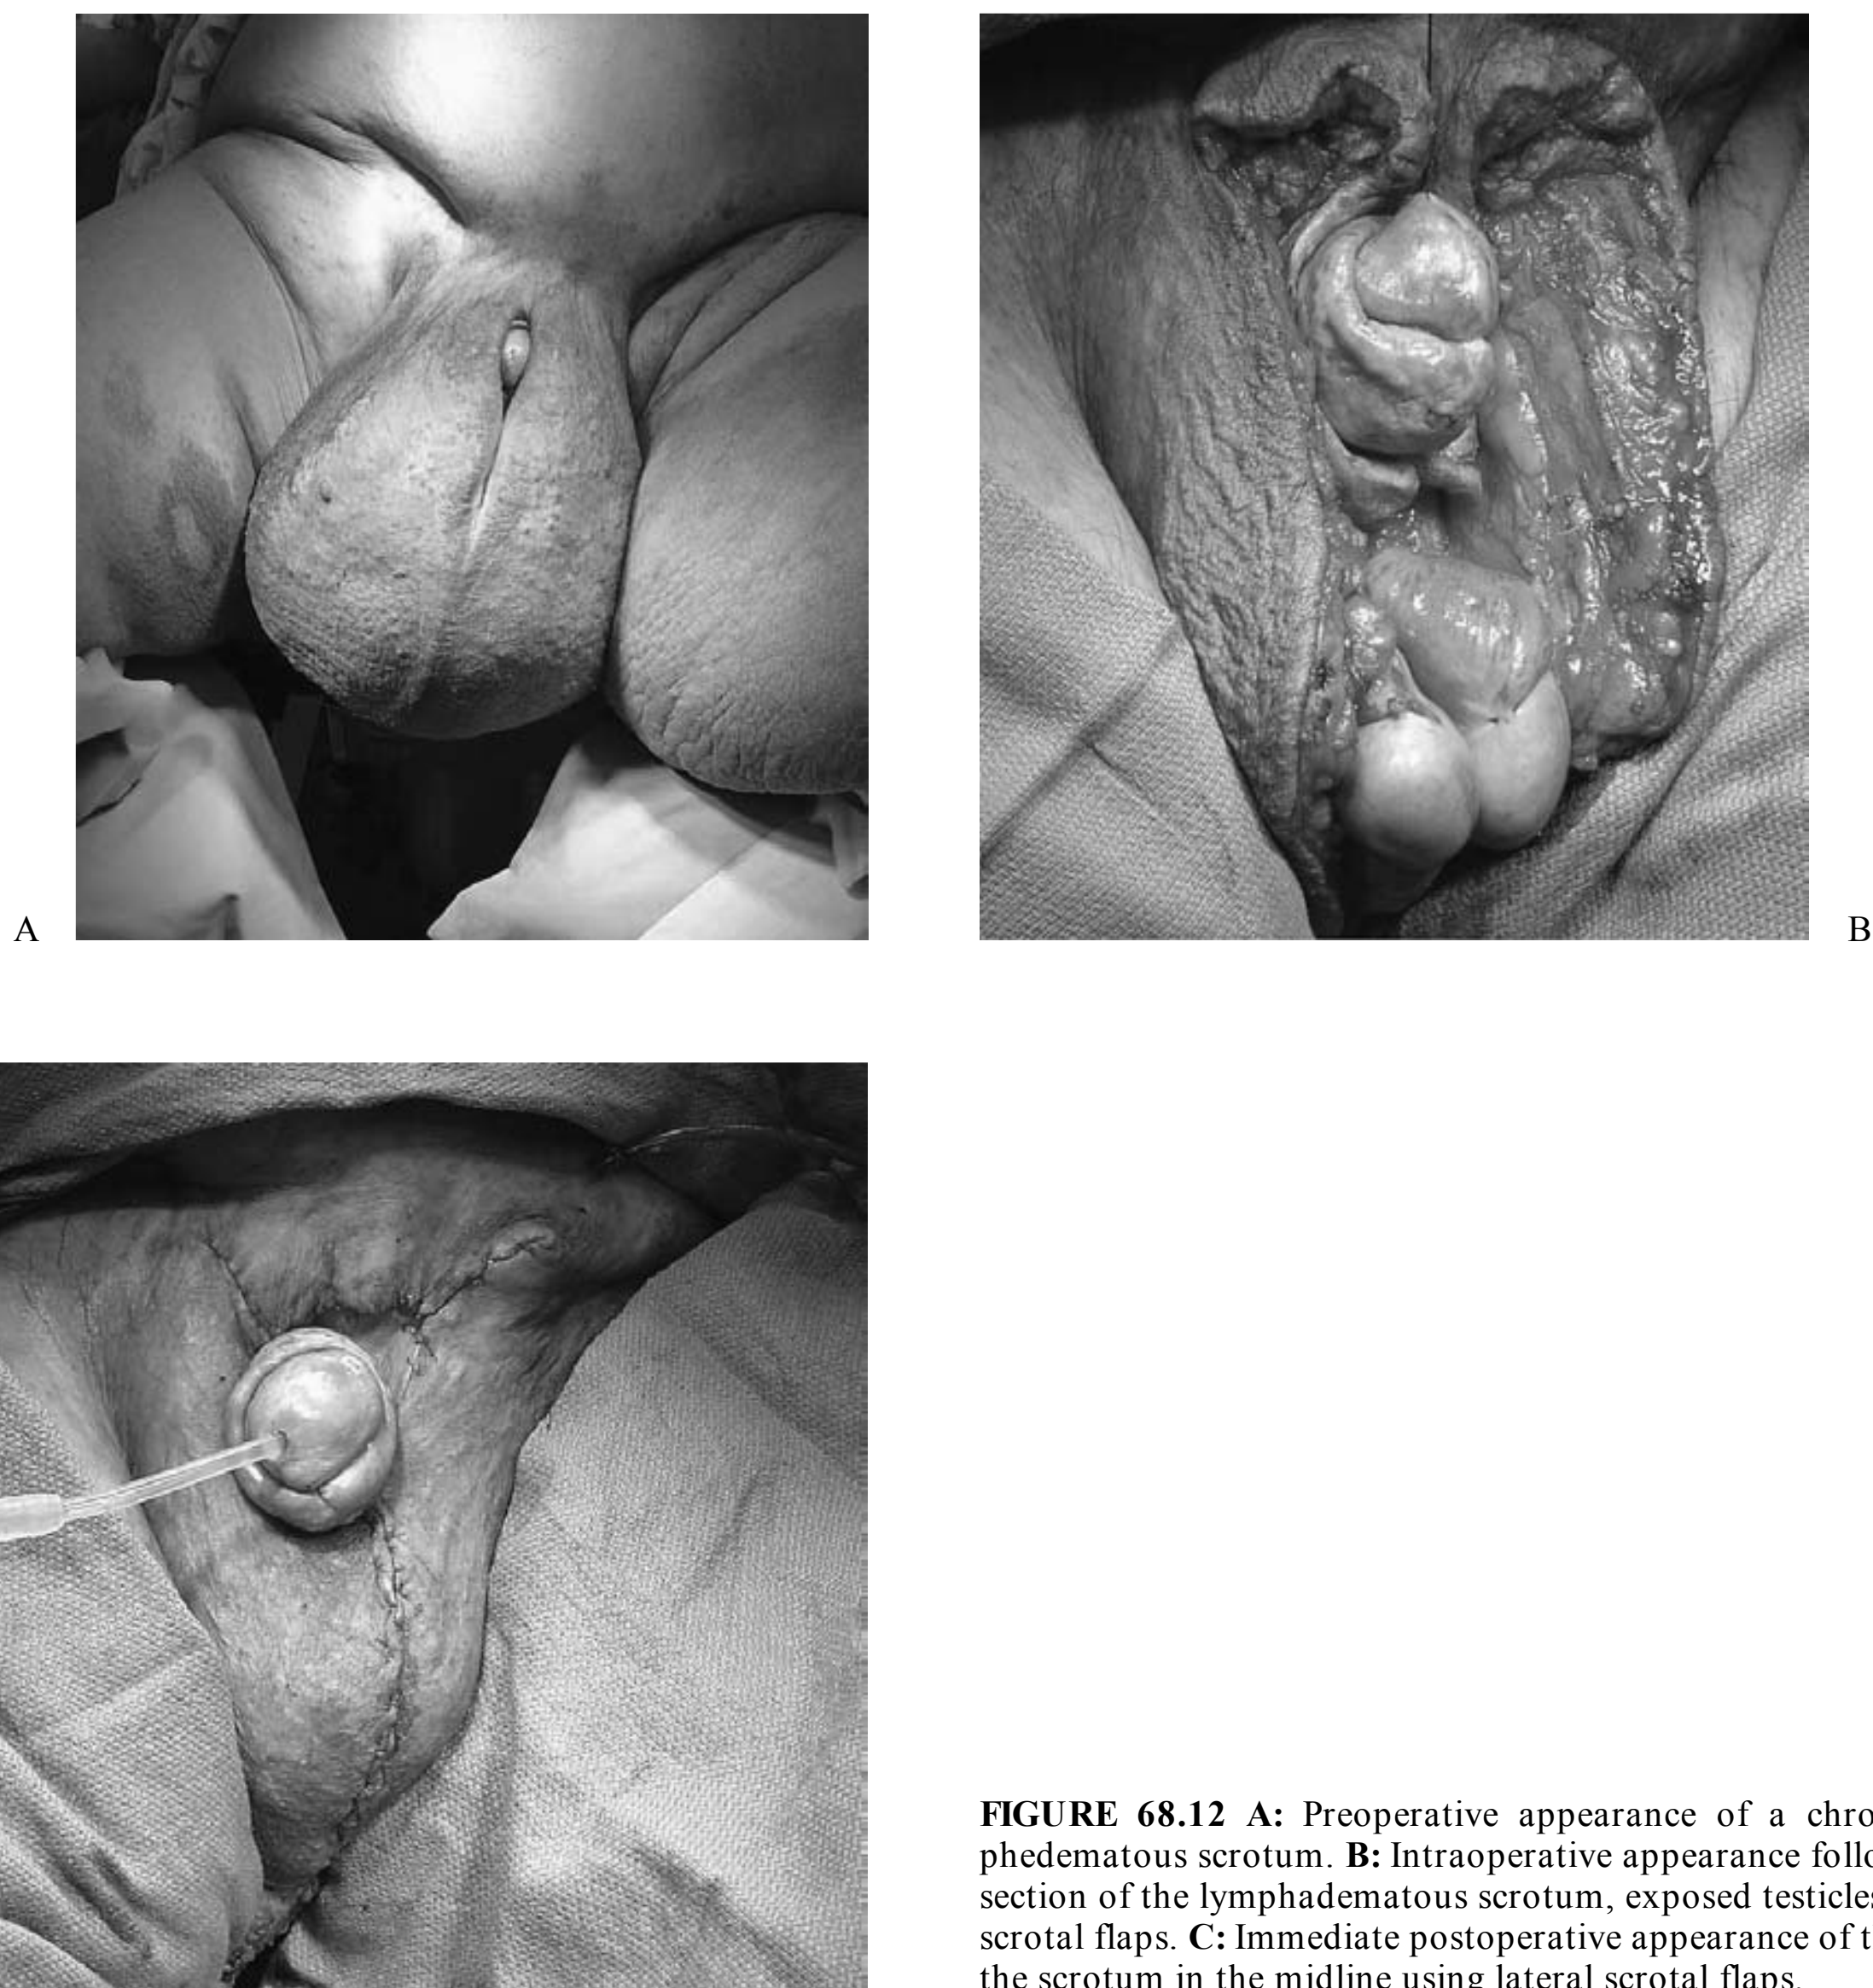

In the case of scrotal lymphedema and recurrent cellulitis, all layers of the scrotum should be excised, to the level of the external spermatic fascia (Fig. 68.11). It is not uncommon for the patient also to have large hydroceles (2).

The vaginal space should be opened and the parietal tunica vaginalis then reflected and incorporated in the orchidopexy. Reconstruction can be accomplished, using split-thickness skin grafts, as already discussed, and on the scrotum these grafts can be meshed as discussed earlier. In addition, the meshing seems to improve the cosmetic result by giving the appearance of the normal scrotal rugations (1). Full-thickness

skin grafts should not be used. The cosmetic results achieved in these patients, so reconstructed, are excellent. The use of lateral scrotal flaps as mentioned previously is worthy of consideration in properly selected patients (Fig. 68.12). Radiated patients in general are not candidates, as the problem is with the “systemic” lymphatic drainage and not just the lymphatics of the skin per se.

### Fournier’s Gangrene

If the primary process has resulted in extensive debridement of the scrotum, the testicles can be placed in thigh pouches with the intention of later replacing the testicles in their normal

**FIGURE 68.12** **A:** Preoperative appearance of a chronically lymphedematous scrotum. **B:** Intraoperative appearance following the resection of the lymphedematous scrotum, exposed testicles, and lateral scrotal flaps. **C:** Immediate postoperative appearance of the closure of the scrotum in the midline using lateral scrotal flaps.

anatomic area and for scrotal reconstruction. The author's (GHJ) preferred approach was described by McDougal and is illustrated in Fig. 68.13. The lateral defects on the thigh can often be closed *per primam* or can be grafted.

For most patients, however, the scrotal excisions do not necessitate placing the testicles in thigh pouches, but instead they can be dressed in the wound (7). These patients often require multiple dressing changes and wet-to-dry debridements. These techniques can be used in combination with negative pressure dressings or vacuum-assisted closure (VAC) devices to reduce the defect size more quickly. When reconstruction is undertaken, the testicles must be fixed in their normal anatomic position. It is my custom to open the parietal tunica vaginalis and reflect it, and, as already described, graft techniques can be utilized to restore the scrotum. Although local flaps can be used, the cosmetic results achieved with local flaps are usually less than optimal in most of these circumstances when compared to reconstruction techniques utilizing split-thickness skin grafts. Interestingly, these mesh split-thickness skin grafts

not only remain supple, but in many cases (as has been shown), will actually become redundant.

---

## OUTCOMES

---

### Complications

---

Complications of scrotal trauma and reconstruction are primarily related to inadequate appreciation of the degree of injury with subsequent necrosis of additional skin. It is important for the surgeon to adequately debride the devitalized skin, which may require more than one trip to the operating room. The failure of a skin graft to take is usually a result of technical errors such as accumulation of fluid under the graft, inadequately prepared graft bed, or continual slippage of the graft over the bed, which does not allow capillary ingrowth.

**FIGURE 68.13** Technique after McDougal for liberation of testicles that have been placed in thigh pouches. Note that the testicles are mobilized with random thigh skin flaps and transposed to the midline to reconstruct the scrotum. The lateral defects can be closed *per primam* or can be grafted.

---

## Results

---

As with most surgical conditions, prompt diagnosis and management of acute testicular injuries is paramount to maintaining testicular function. Burns, avulsion, and radiation

injuries require aggressive debridement of devitalized tissue to minimize infection and to prepare a healthy graft bed. Reconstruction of the scrotal skin, most often performed with meshed STSG, offers excellent graft take and survival with acceptable cosmetic results in closing the resultant defect.

## CHAPTER 69 ■ ANATOMY OF THE PENIS AND SCROTUM

SAM D. GRAHAM, JR.

The penis is composed of three columnar bodies, a pair of which are larger, dorsally located, and extend the length of the penis (Fig. 69.1). These two columnar bodies contain cavernosal vascular tissue and are called the corpora cavernosa.

**FIGURE 69.1** Anatomy of the three corporal bodies comprising the penis.

Proximally the corpora cavernosa taper to form the crus and are attached to the pubic arch. Each corpus is closely applied to the other, separated only by a septum, for most of the distal penis. The corpora cavernosa is supported at its base by the ischiocavernosus muscles, which arise from the inner surface of the ischial tuberosity and are innervated by the perineal nerves.

The third columnar body, the corpus spongiosum, contains the urethra, and the distal end is bulbous, forming the glans penis. The corpus spongiosum is attached proximally to the perineal membrane and at the most proximal portion is larger, forming the bulb.

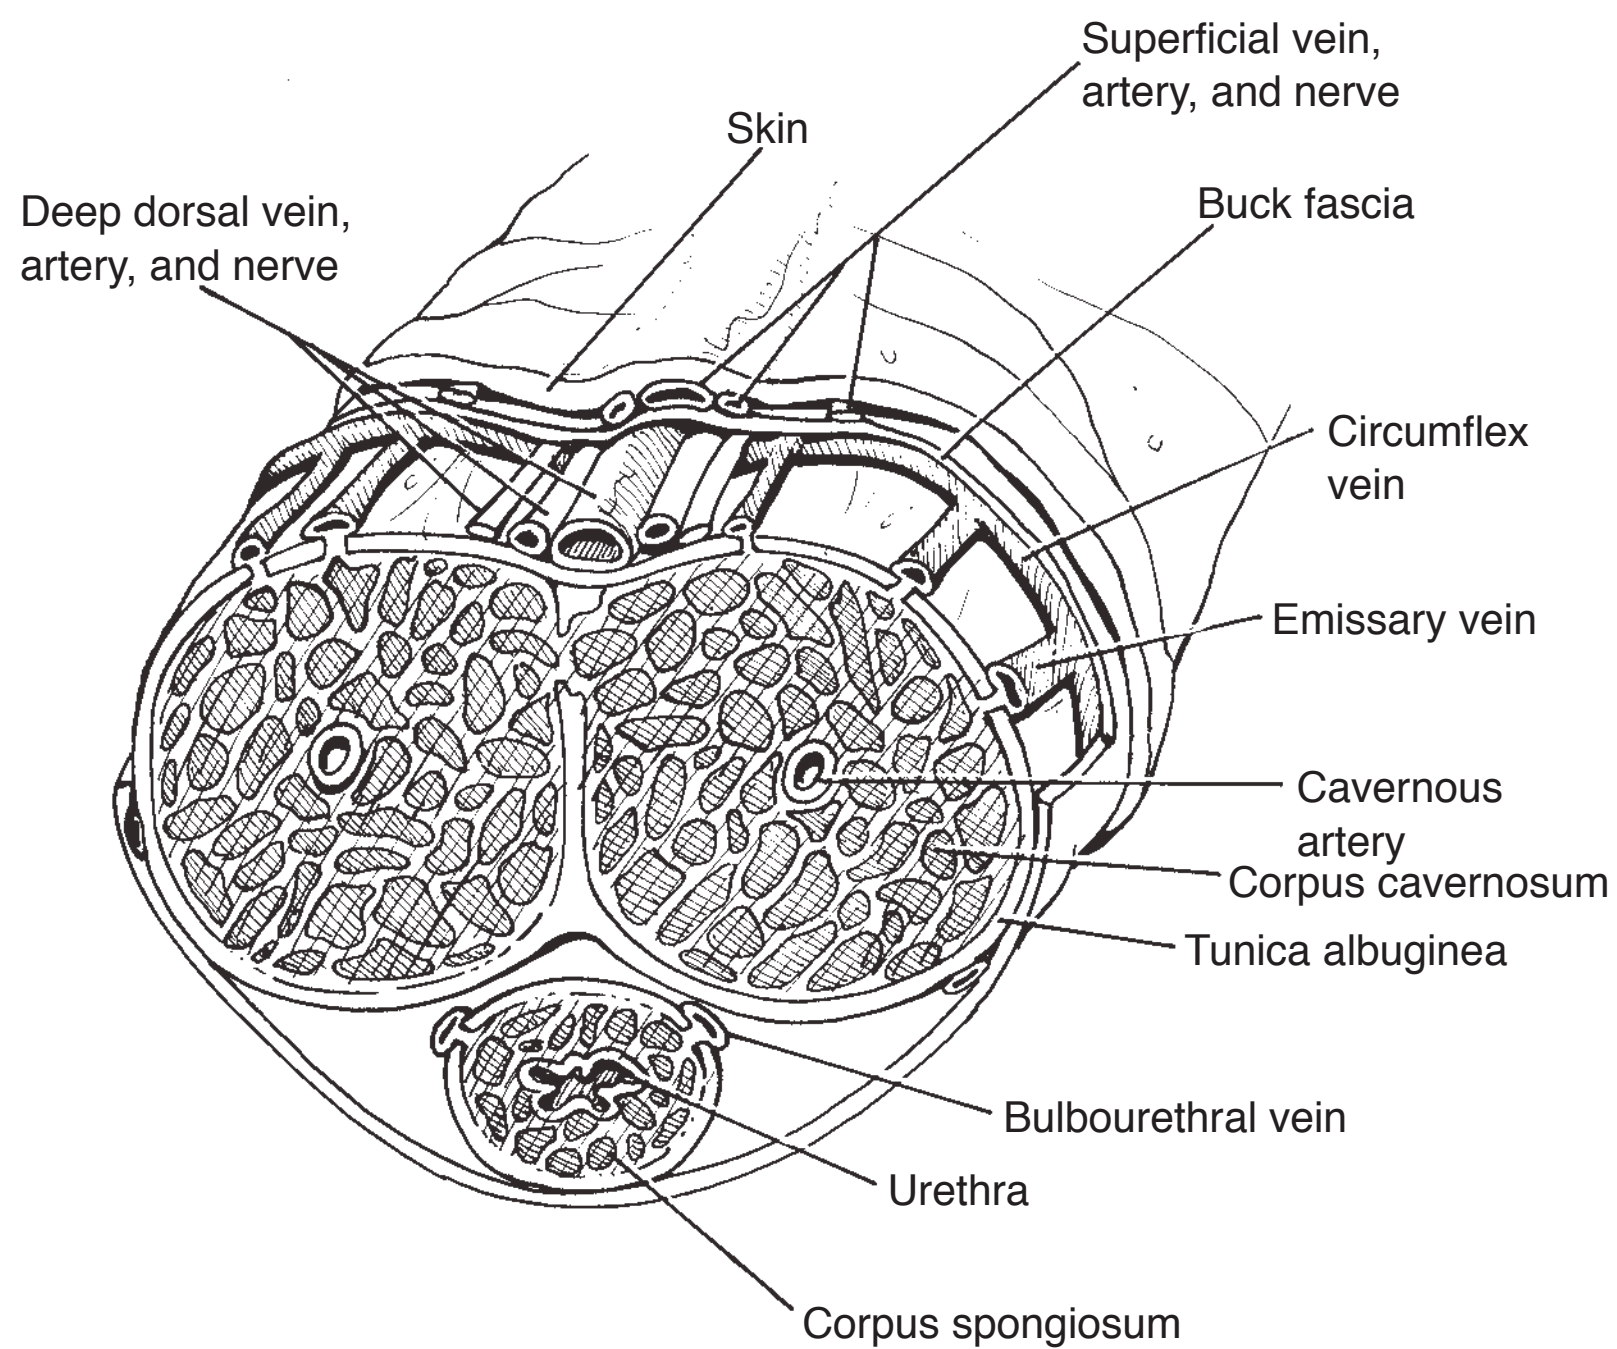

Each of the corporal bodies is encased in its own tunica albuginea, and the three corporal bodies are surrounded by the Buck fascia, which is a continuation of the Colles fascia (Fig. 69.2). The Buck fascia is attached posteriorly to the urogenital diaphragm and anteriorly forms the suspensory ligament. There is little vascular communication between the corpora cavernosa and the corpus spongiosum. There is, however, vascular communication between the two corpora cavernosa via pectiniform septa in the distal corpora.

---

### VASCULAR ANATOMY

---

The superficial penile artery lies between the superficial and Buck fascia and originates from the external pudendal artery, which in turn is a branch of the femoral artery. This artery, along with a corresponding vein, supplies the penile skin and is located between the superficial penile fascia and the Buck fascia. The deep arterial supply arises from the internal iliac artery, which initially branches into the internal pudendal artery and then into the penile artery. As the penile artery exits the urogenital diaphragm, it branches into the bulbourethral, cavernosus, and urethral arteries. The cavernosus artery is the direct supply of the corpora cavernosa. The penile artery continues along the corpora cavernosa as the dorsal artery.

**FIGURE 69.2** Cross section of the penis demonstrating fascial layers as well as vascular and neural anatomy.

The corpus spongiosum is supplied by the bulbourethral artery proximally, circumflex arteries from the dorsal artery along its shaft. The glans is supplied by the dorsal artery. The dorsal artery, the deep dorsal vein, and the dorsal nerve are enclosed within the Buck fascia.

The superficial penile vein drains into the external pudendal vein. The circumflex and deep dorsal veins drain into the plexus of Santorini, as do the crural and cavernosal veins (Fig. 69.3).

## LYMPHATIC ANATOMY

The lymphatics of the penile skin drain into the superficial inguinal and subinguinal lymph nodes. The lymphatics of the glans penis empty into the subinguinal and external iliac nodes. The deep lymphatics drain into the hypogastric and common iliac nodes.

**FIGURE 69.3** Venous drainage of the penis.

# CHAPTER 70 ■ PARTIAL AND TOTAL PENECTOMY IN THE MANAGEMENT OF INVASIVE SQUAMOUS CELL CARCINOMA OF THE PENIS

ANTONIO PURAS BAEZ AND ALEX M. ACOSTA MIRANDA

Squamous cell carcinoma of the penis is an epidermoid tumor arising in the glans or mucosal lining of the prepuce. Its incidence follows a distinct geographic, racial, and socioeconomic distribution. The tumor is age-related, showing an age-specific rate of increase with each decade and having its peak incidence at the fifth and sixth decades (9). An earlier age of onset and a high proportion of younger patients have been reported in areas of high incidence, such as Africa, India, and South America (8). In Puerto Rico the age-adjusted incidence is around 5 per 100,000 men (7), whereas in the United States and Europe it accounts for only 0.4% to 0.6% of all malignancies in men (8).

Although the precise etiology of penile carcinoma remains undetermined, numerous factors have been associated with the risk of developing squamous cell carcinoma of the penis, such as chronic irritation, poor genital hygiene, the presence of an intact foreskin, phimosis, smegma, and viruses.

There is increasing evidence for a sexually transmitted viral etiology in penile cancer. Human papilloma viruses (HPV), especially types 16, 18, 31, and 33, are the most frequently detected types in penile cancer. Other investigators have shown an association between the use of tobacco products and penile tumors. It appears that an enclosed preputial environment associated with poor genital hygiene of the foreskin, chronic irritation, and exposure to certain etiologic agents, such as viruses, smegma, and hydrocarbons, may also play a causative role in the development of this tumor.

---

## DIAGNOSIS

---

Patients with penile carcinoma may present with lesions that are a subtle induration or erythema of the glans or foreskin, a papule, a warty growth, or a large exophytic lesion with purulent discharge and cellulitis. These lesions are usually non-painful, and there is a delay in patient presentation due to self-denial, ignorance, fear, and personal neglect (12).

Penile lesions such as erythroplasia of Queyrat, leukoplakia, cutaneous horn, balanitis xerotica obliterans, condyloma acuminatum, advanced melanoma, and giant condyloma may resemble squamous cell carcinoma of the penis and must be considered in the differential diagnosis.

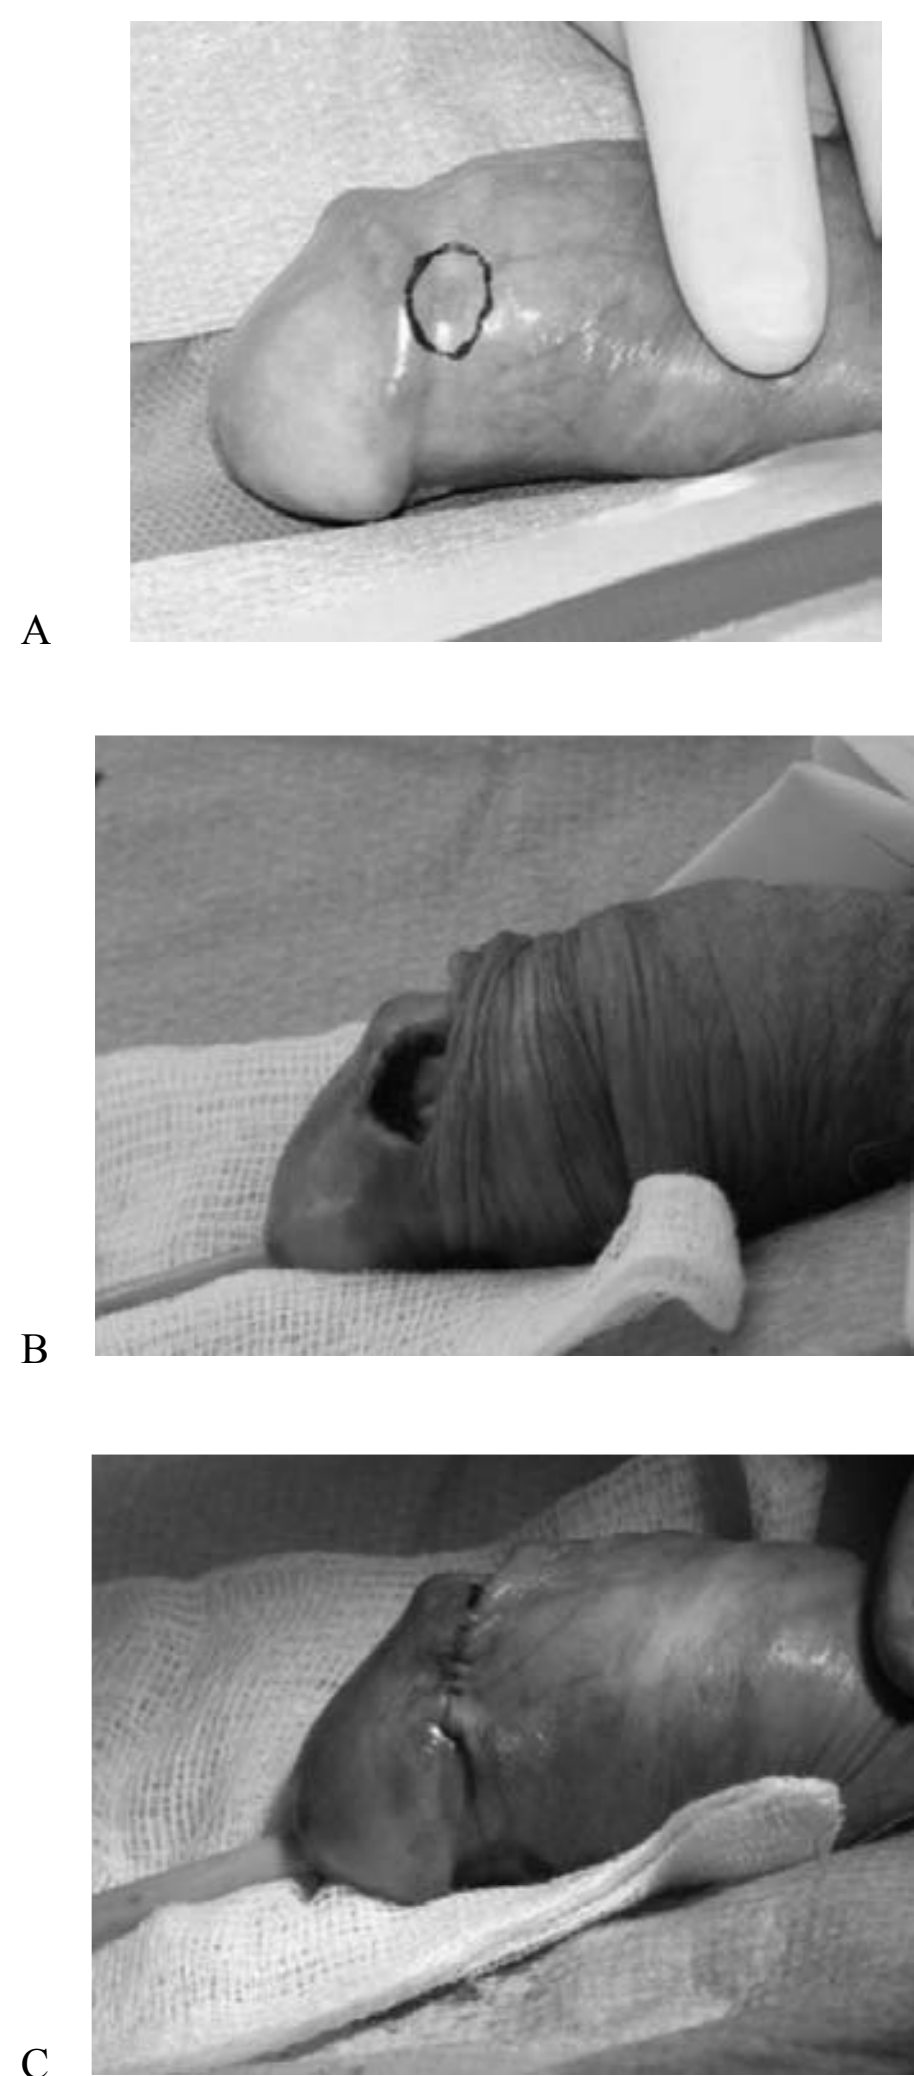

Penile lesions should be examined thoroughly and assessed in regard to location, tumor growth, size, and infiltration of the corporal bodies and urethra. Careful examination of the

inguinal area and pelvis is of extreme importance for staging and assessment of lymph node status. The lesion should be cultured and the patient started on appropriate antibiotic therapy. Any suspicious growth or ulceration should be biopsied, and meticulous pathologic analysis should be done for the depth and type of invasion, the presence of microvascular permeation, and the histologic grade of the tumor prior to initiation of any therapeutic modality.

The definite diagnosis is made by biopsy of the lesion (Fig. 70.1) following appropriate antibiotic therapy. Adequate anesthesia is obtained with 1% local lidocaine, and a 1.5-cm elliptical wedge of tumor tissue is removed (Fig. 70.2). The biopsy should include tumor growth and adjacent neighboring normal tissue to be examined for tumor infiltration. The incision is closed with interrupted 3-0 chromic catgut. We prefer to perform a wedge biopsy as a separate procedure and discuss with the pathologist the tumor grading, type of growth, and presence of microvascular permeation prior to initiation of any definite therapeutic modalities. Patients with tight phimosis who have purulent discharge and a palpable mass or induration concealed underneath the foreskin should be

**FIGURE 70.1** Wedge biopsy of the penile lesion. Biopsy should include tumor growth and adjacent neighboring normal tissue to be examined for tumor infiltration.

**FIGURE 70.2** Wedge biopsy with wide excision at coronal sulcus. **A:** Tumor growth and adjacent normal tissue margins are marked. **B:** Wedge biopsy. **C:** Repaired defect with advancement of penile shaft skin.

managed with a dorsal slit incision, long enough to retract the prepuce and adequately examine and biopsy any suspicious lesion or growth.

Further assessment of local invasion to the corpora and spongiosum can be done with MRI. This radiologic cross-sectional modality has been shown to be highly accurate in the local staging of penile cancer and in surgical planning for the possible institution of conservative surgical treatments over more extensive procedures (5).

## INDICATIONS FOR SURGERY

Survival of patients with carcinoma of the penis depends primarily on the tumor grade, the depth of invasion, and the status of the regional nodes. The primary therapeutic goal in the management of penile carcinoma should be complete tumor excision, regional lymphatic control, and a functional, cosmetic penis. Surgery plays a prominent role in the management and control of the primary lesion. If adequately performed, it will assess the histologic grade, depth, and type of tumor invasion and in many cases can be curative.

## ALTERNATIVE THERAPY

Various nonsurgical therapeutic modalities, including radiation therapy, chemotherapy, and a combination of these, have been used in the treatment of the primary lesion. Penile-sparing procedures such as micrographic excision (Mohs micrographic surgery) and laser procedures have been utilized in other cutaneous malignancies and have been investigated in penile cancer.

Mohs micrographic surgery is a technique of excision of the lesion in thin horizontal layers using microscopic examination of the entire undersurface of each layer and systematic use of frozen sections. Two techniques by which microscopic control of the tumor is achieved have been described. The first technique is a fixed tissue technique in which the tissues are subjected to in situ chemical fixation with zinc chloride paste before excision of successive layers. In the fresh tissue technique, a local anesthetic is injected and the tissues excised in a fresh, unfixed state and examined by frozen section. The fresh tissue technique is recommended for small tumors, whereas for larger infiltrative lesions the fixed technique will provide control of bleeding from the relatively noncontractile vessels of the erectile tissues of the glans and corpora cavernosa. Cure rates for low-stage lesions that are  $<1$  cm in diameter are close to 100%, while cure rates for lesions  $>3$  cm drop to around 50%. It appears that microscopically controlled tumor excision provides an effective treatment alternative for managing some types of penile cancer with good cosmetic results. Complications related to most micrographic surgical techniques are meatal stenosis and disfigurement of the glans.

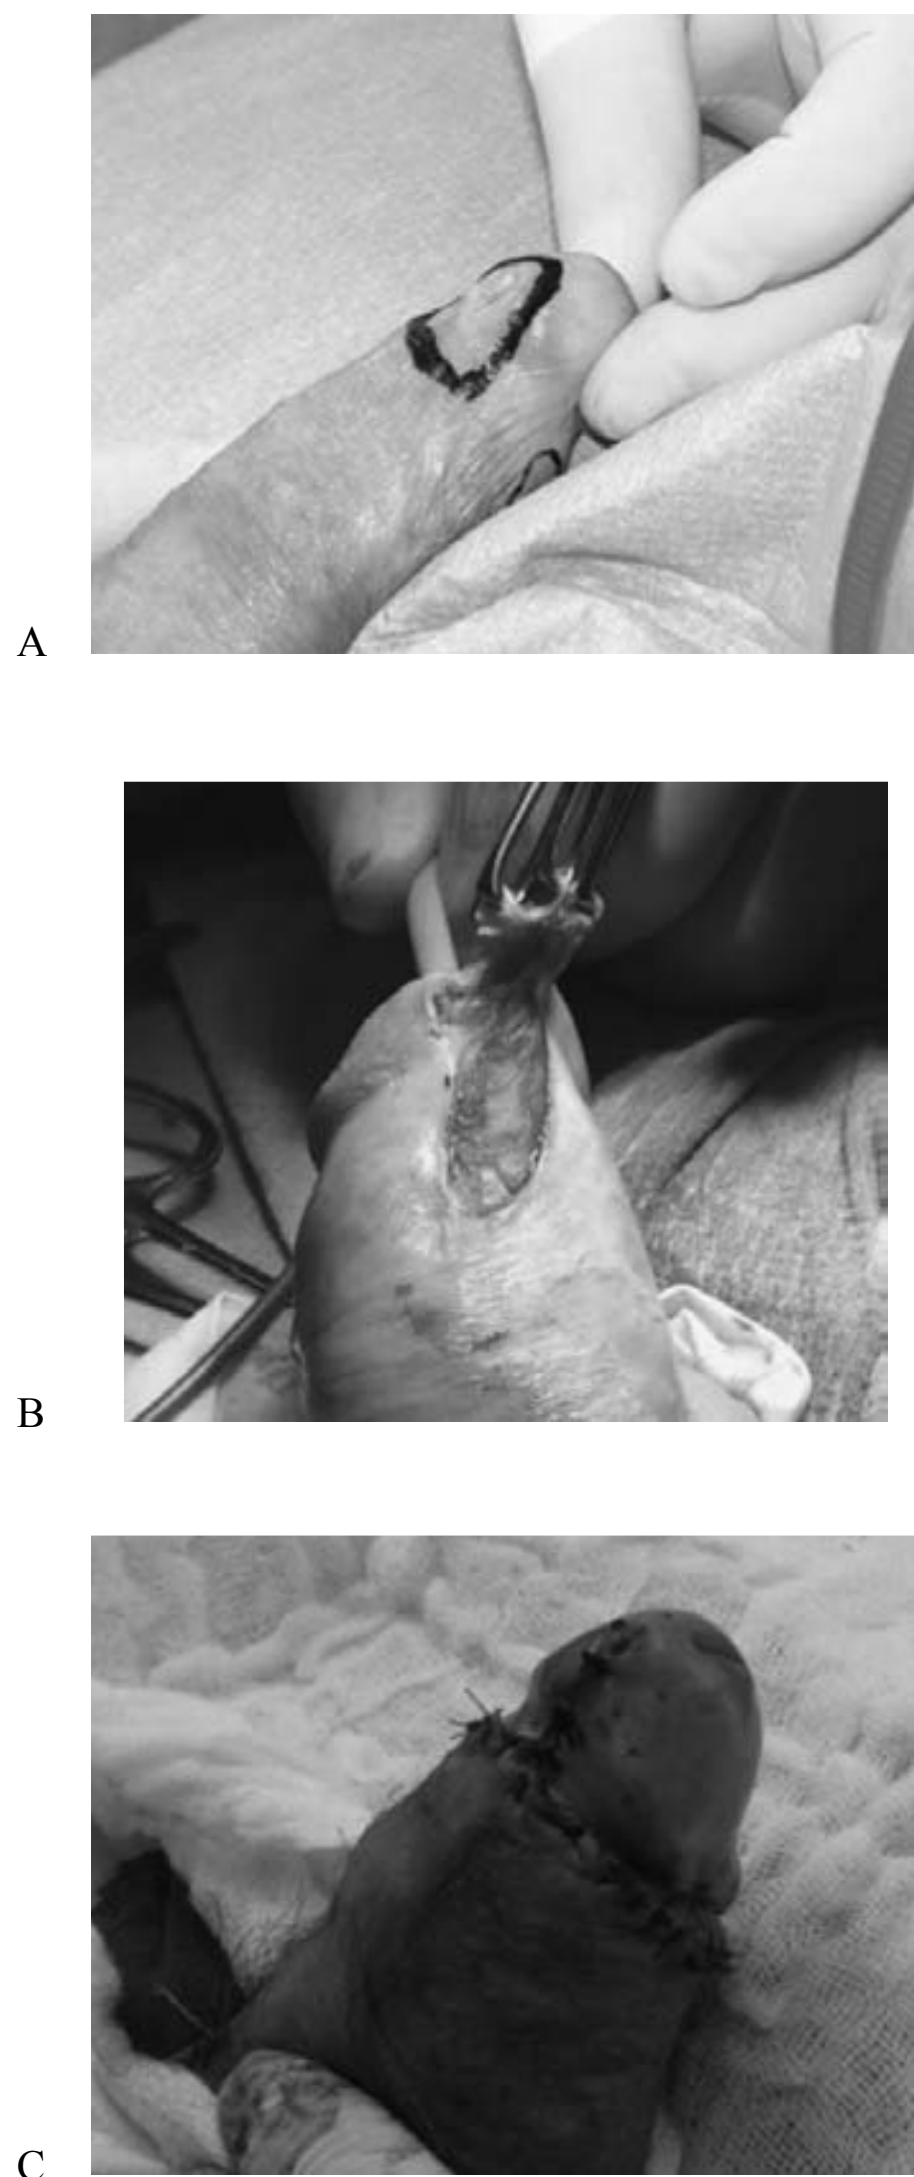

Laser therapy has been used in the treatment of penile carcinoma with highly satisfactory cosmetic results as well as good local tumor control. The major advantage of laser therapy for carcinoma of the penis is the destruction of the tumor with penile preservation and function; it also gives the advantages of destroying tissue, sealing small vessels and nerve endings, and reducing the incidence of postoperative bleeding and pain. The main disadvantage of laser surgery is the difficulty of obtaining histologic documentation and determining the depth of penetration by the tumor; it appears that the site and depth of penetration of the primary lesion correlate with its curability. Bandieramonte et al. (1) were able to resect T1 tumors at the glans penis by using a very short pulse and high peak power at the base of the lesion and at the meatus, providing precise excision of the specimen for histologic examination; however, a 15% recurrence rate was reported.

In a select group of patients with morphologically and anatomically suitable penile cancer with low-grade, low-stage disease, conservative surgical techniques are safe and can provide similar tumor control when compared to conventional, more radical resections. The tumor size, location, and pathologic characteristics should dictate the treatment of the primary penile lesion (2).

## SURGICAL TECHNIQUE

### Circumcision and Glans-Sparing Surgery

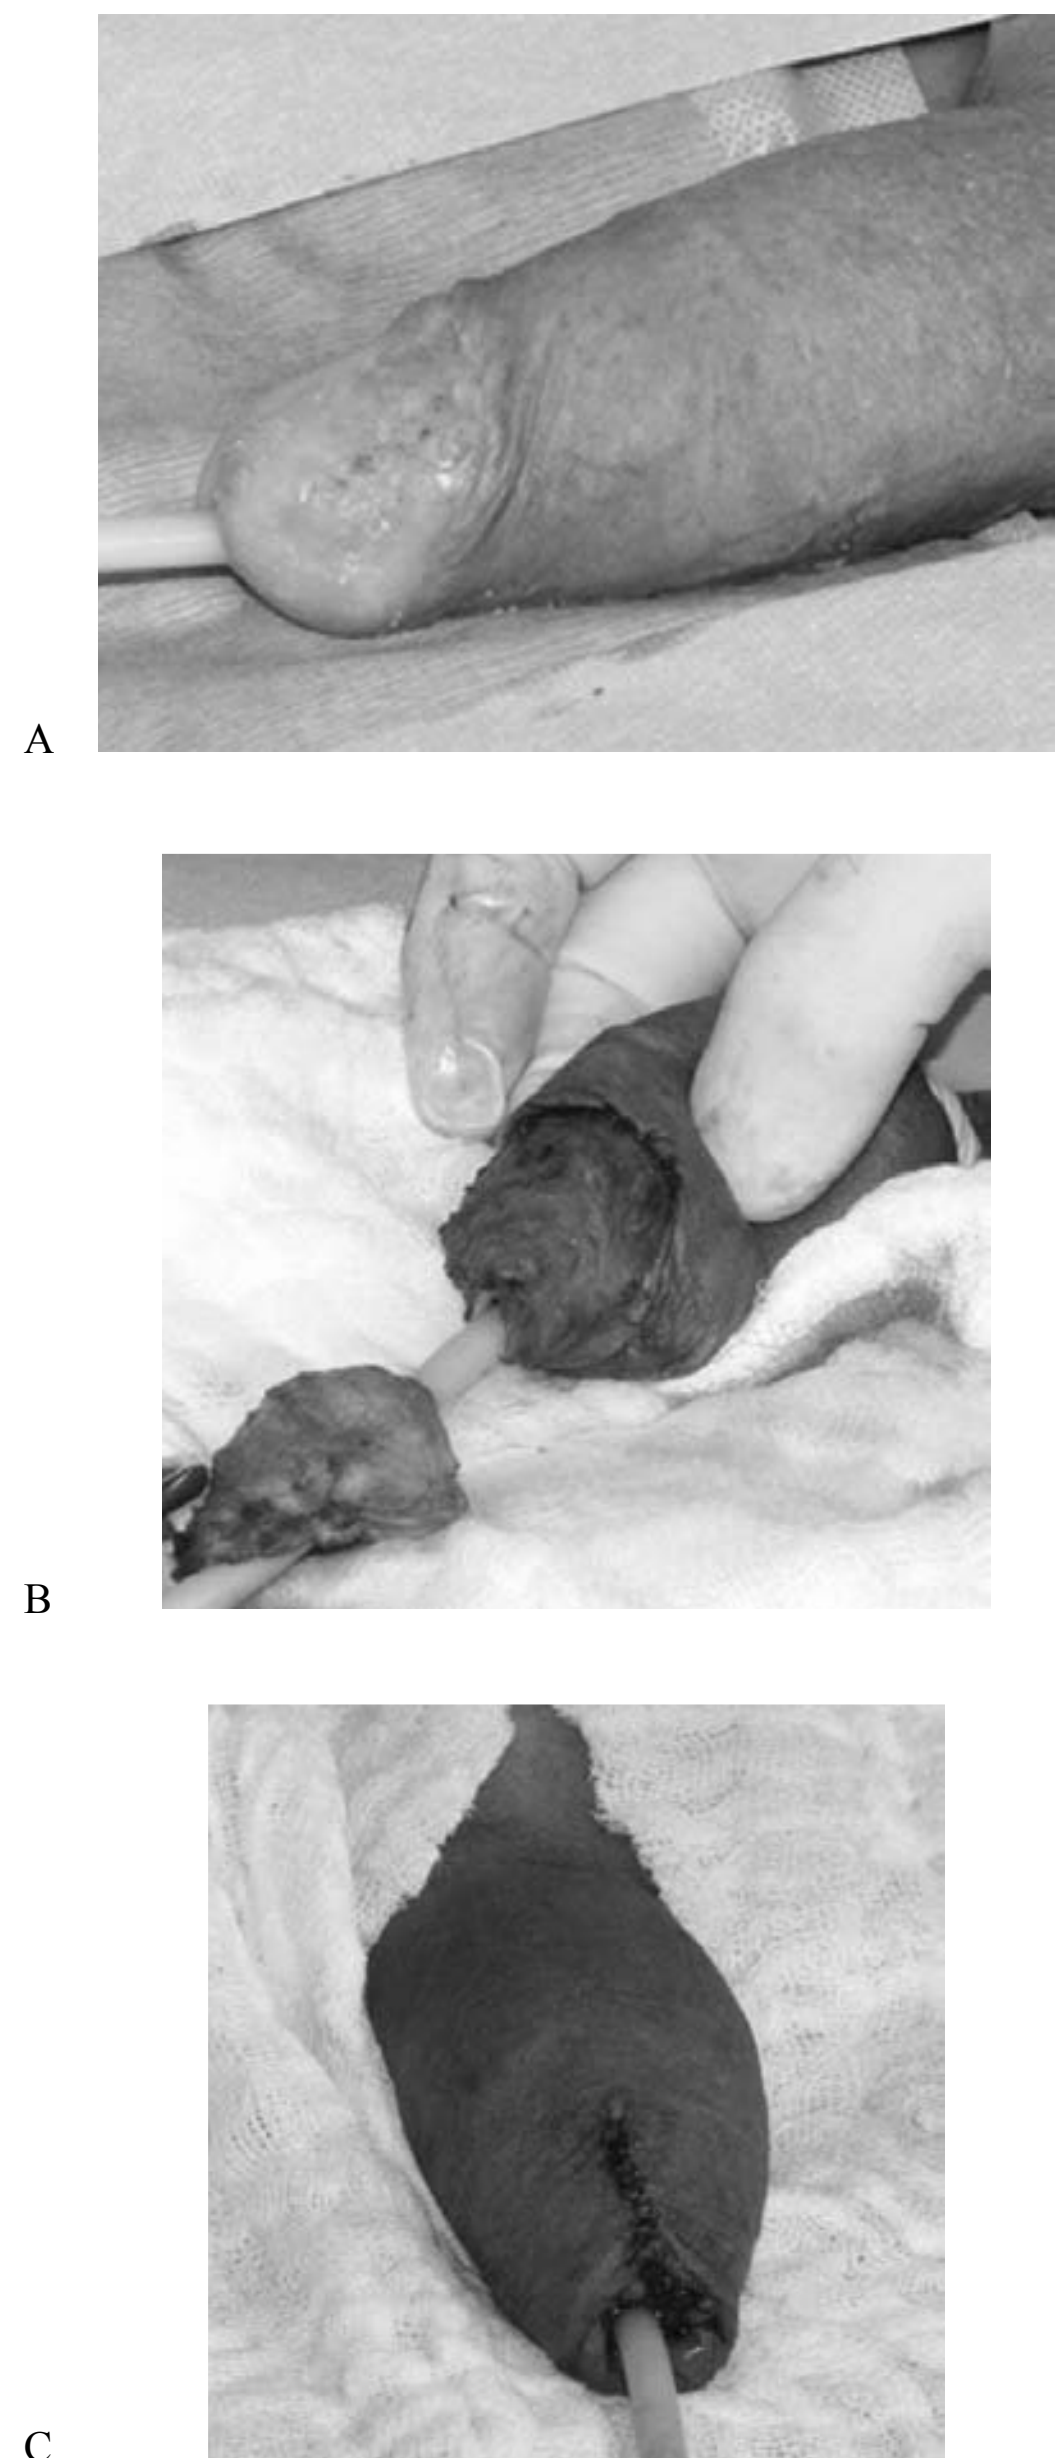

Patients presenting with small lesions involving the prepuce may be adequately managed by wide excision with a 1.5-cm margin. Microscopic examination by frozen section should be

**FIGURE 70.3** Excision of recurrent penile carcinoma at the frenular aspect of glans. **A:** Tumor growth with margins. **B:** Wedge excision with care to avoid damage to urethra. **C:** Repaired defect.

performed to obtain a tumor-free margin due to the high risk of recurrence.

The histopathologic slides should be reviewed with the pathologist with special attention to the patterns of tumor growth, grading, depth of invasion, and microvessel infiltration. Suspicious lesions at the glans or coronal sulcus should be biopsied and proved to be free of tumor. Selected patients with superficial tumors of the shaft can be managed with a wide excision by excising around 2 cm of normal skin. The skin defect can be covered by a full-thickness skin graft, which results in a functional and cosmetically appealing phallus without jeopardizing the cancer control surgical aspects. Small lesions at the glans may be treated with local excision and primary closure of the surgical defect (Fig. 70.3). Glansectomy can result in a very satisfactory cosmetic penile appearance after reconstruction, preserving penile length and function while offering an oncologically safe and effective procedure for patients with glans-confined low-grade squamous cell tumors (Fig. 70.4). In some rare cases large exophytic, low-grade, well-differentiated noninvasive lesions can be managed with organ-sparing surgery with complete disease-free status on

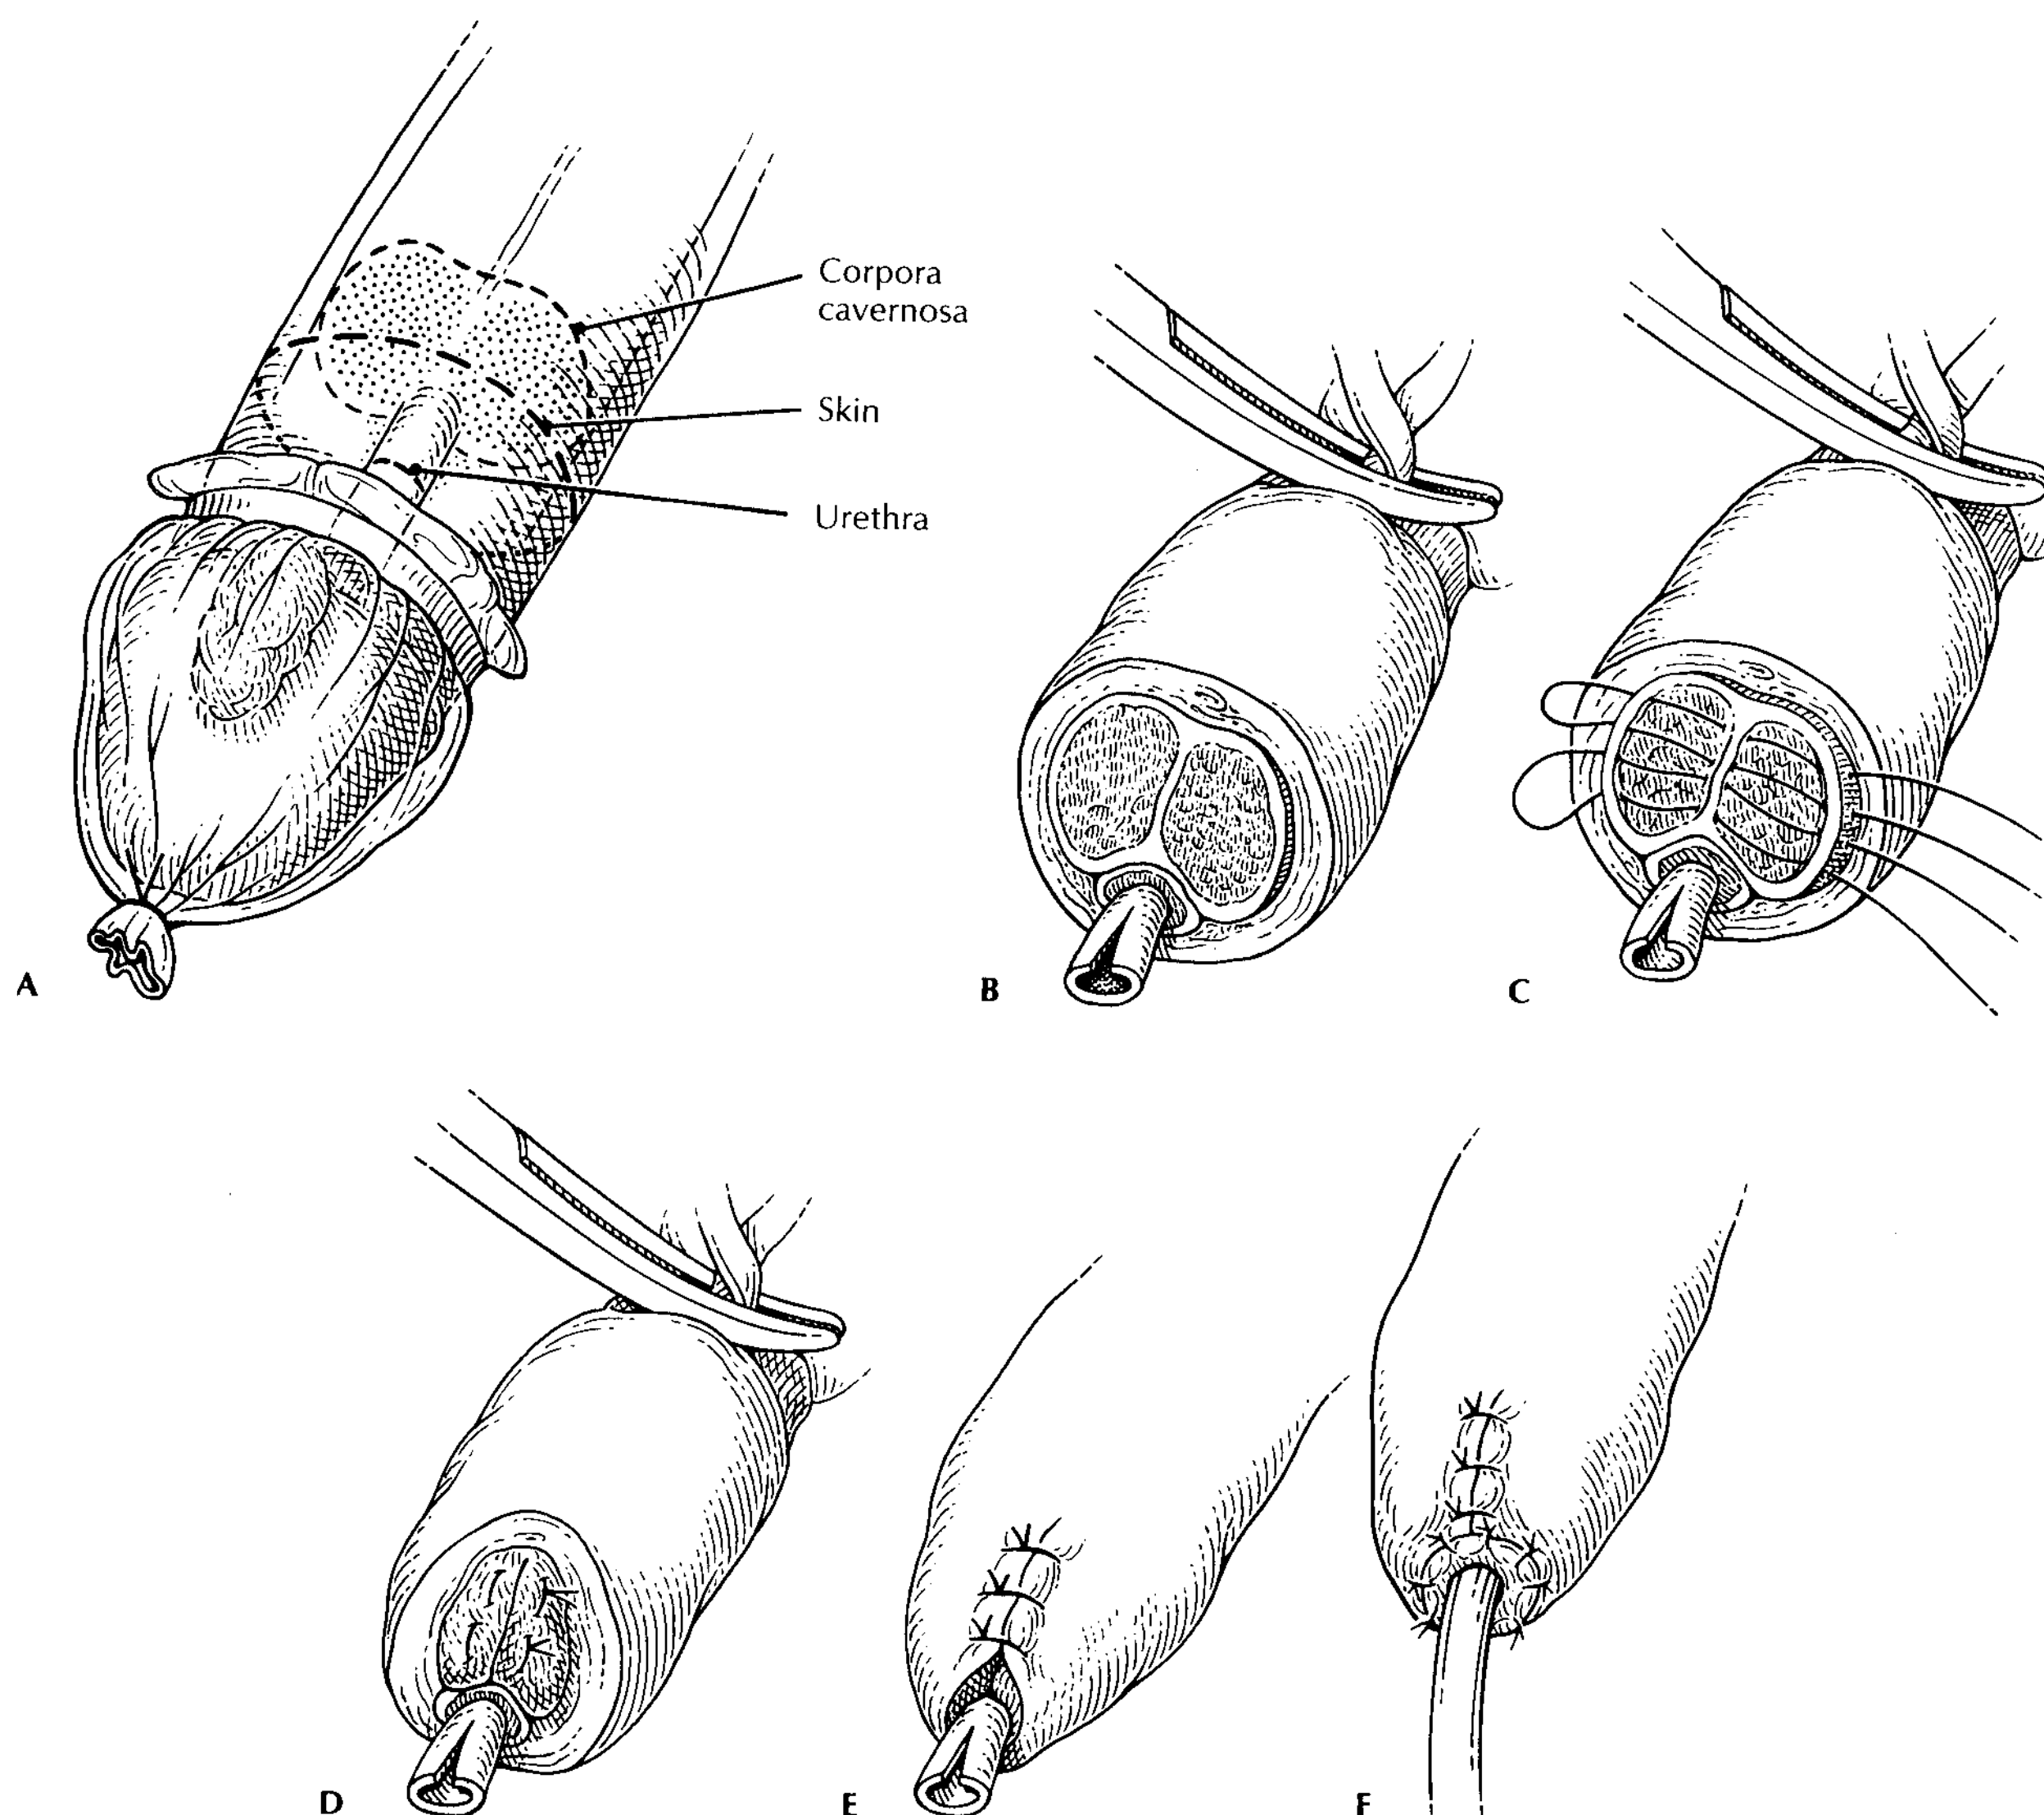

**FIGURE 70.4** Glansectomy. **A:** Patient with recurrent carcinoma of the glans penis following radiation therapy. **B:** Glans is excised with preservation of a 1-cm urethral stump. **C:** Skin is closed longitudinally.

long-term follow-up, but each case must be individualized accordingly.

The incidence of local recurrence may be increased with penile-preserving strategies. This carries a poor prognosis and may represent regional lymphatic spread. With careful patient selection and meticulous follow-up, some patients with invasive penile carcinoma can benefit from penile-preserving surgery.

### Partial Penectomy

Partial penectomy for squamous cell carcinoma of the penis provides excellent local control with a low recurrence rate and acceptable maintenance of urinary and sexual function. Invasive tumors involving the glans and coronal sulcus can be adequately managed by a partial penile amputation excising

**FIGURE 70.5** Partial penile amputation. **A:** A condom catheter is placed over the tumor and a circumferential incision is marked on the skin 2 cm proximal to the lesion. **B:** A 14Fr catheter or 0.25-in. Penrose drain is placed as a tourniquet at the base of the penis. The skin and Buck fascia are incised onto the tunica albuginea. Corpora cavernosa are sharply divided down to the urethra. The urethra is dissected free from the corpus spongiosum, and a 1-cm stump projects distally to the corpora cavernosa. **C:** The urethra is spatulated on its dorsal surface, and the corporal ends are closed with horizontal mattress sutures incorporating the Buck fascia, tunica albuginea, and intracavernosal septum. **D:** The tourniquet is released and adequate hemostasis is obtained. **E:** The dorsal skin is closed longitudinally. **F:** Ventral approximation of the penile skin to the urethra is begun and continued dorsally. The remaining dorsal skin is closed longitudinally.

around 1.5 to 2.0 cm of normal tissue proximal to the margin of tumor infiltration (Fig. 70.5). In most instances, this should leave a functional penis of  $>4$  cm in length, which allows standing micturition and enough rigidity and length for vaginal penetration. Frozen sections of the proximal margins are necessary to confirm tumor-free resection and a recurrence rate of 10% or less. Partial penectomy has consistently been shown to give better oncological results than conservative treatment in the local management of the T1-stage tumor.

The procedure can be performed under local, regional, or general anesthesia. The patient is placed in the supine position. The lesion and urine should be cultured preoperatively and appropriate parenteral antibiotics started prior to the surgical

procedure. The penis is prepared with a povidone-iodine solution and the tumor isolated using a sterile condom or glove that is sutured in place using 3-0 silk sutures. A 0.25-in. Penrose drain or 14Fr Red Robinson catheter is applied as a tourniquet at the base of the penis. A circumferential incision is marked on the skin 1.5 to 2.0 cm proximal to the lesion. The skin is incised circumferentially, and the superficial and deep dorsal veins are divided and ligated using 3-0 silk sutures. The Buck fascia is incised onto the tunica albuginea of the corpora. The corpora cavernosa are sharply divided down to the urethra and the central cavernosal arteries ligated on each side.

The urethra is dissected free from the corpus spongiosum in such a manner that an approximately 1-cm stump projects

distally to the transected corpora cavernosa. The urethral stump and transected corpora are then washed with gentamycin solution. The corporal ends are closed with horizontal mattress sutures of 2-0 Vicryl incorporating the Buck fascia, tunica albuginea, and intercavernosal septum. The penile base tourniquet is then released, and all minor vessels are fulgurated or ligated until adequate hemostasis is obtained. Skin closure can be performed either in the classic longitudinal fashion or using a buttonhole technique in which a flap of dorsal penile skin is left, a crescentic buttonhole incision in the skin flap is made, and this flap is then rotated ventrally toward the urethra. In both techniques the urethra is spatulated dorsally and sutured to the skin using 4-0 Vicryl. The remaining skin is closed using 3-0 Vicryl sutures. A 16Fr Foley catheter is left indwelling to closed straight drainage for 48 hours, and the wound is dressed with triple antibiotic and Vaseline gauze.

---

### Total Penectomy

---

Patients with large, extensive, and infiltrating lesions involving the glans and midshaft of the penis, in which the location precludes adequate excision with a functional residual penile remnant, are managed by total penectomy (Fig. 70.6). The patient is placed on lithotomy position and the lesion is prepared with povidone-iodine solution. Appropriate antibiotic therapy should be started before the procedure according to penile and urine culture results. A condom catheter or sterile glove is secured to the base of the penis with interrupted 3-0 silk sutures. An elliptical incision is made around the base of the penis and extended through the subcutaneous tissues until the surface of the pubis is reached. All vessels and lymphatics are either fulgurated or ligated. The suspensory ligaments of the penis are isolated with a right-angle clamp and divided. The dorsal vein and penile arteries are identified, clamped, ligated, and divided. The penis is then reflected cephalad, the Buck fascia is opened ventrally, and the urethra is dissected free from the corpora cavernosa with sharp and blunt dissection. At the distal bulbar region, the urethra is divided, leaving enough length to reach the perineum. The corpora cavernosa are dissected up to the ischiopubic rami, sutured, and ligated with 2-0 Dexon sutures and then transected. The specimen should be removed with a 2-cm tumor-free margin.

The urethra is dissected to the area of the urogenital diaphragm to obtain an unangulated straight course to the perineal urethrostomy site. The urethra is tagged with 3-0 catgut sutures. A 1-cm ellipse of skin and subcutaneous tissues is removed from the midperineum just midway between the anus and scrotum. A tunnel is developed in the perineal subcutaneous tissue using a curved clamp, and the urethra is drawn into the perineal incision, with care taken to avoid angulations in the urethra. The urethra is then spatulated dorsally, and a V-inlay of skin can be created and anastomosed to the urethra using 3-0 or 4-0 Vicryl. A watertight technique should be used to prevent urinary leakage under the flap. An 18Fr Foley catheter is inserted, and 0.25-in. Penrose drains are left to drain each side of the scrotum. The scrotal incision is closed transversally to allow elevation of the scrotum away from the perineal urethrostomy using a two-layered closure with Vicryl 3-0. Triple antibiotic is placed over the wound incision and around the perineal urethrostomy. A Vaseline gauze, pressure

dressing, and scrotal support are applied for 24 hours. The Penrose drains are usually removed in 48 hours, and the Foley catheter should be removed when the urethrostomy is well healed.

Lesions involving the perineum and anterior abdominal wall may need adjuvant preoperative chemotherapy in an attempt to downsize the tumor. If no adequate response is observed, the patient will need complete removal of the neoplasm, which may result in total emasculation and may require a musculocutaneous flap closure. In some rare instances cystoprostatectomy with urinary diversion will be necessary.

---

## OUTCOMES

---

### Complications

---

The most common complication of partial and total penectomy is meatal stenosis. The V-inlay technique has been used to decrease the stenosis at the urethral opening. Some institutions also advocate the use of a “loop” cutaneous urethrostomy, instead of the classic end cutaneous urethrostomy, during total penectomy, which may better preserve the distal urethral blood supply and thus minimize the tendency for the urethral meatus to develop stenosis. Patients should be aware of this complication and instructed to start self-dilation as soon as they notice a decrease in the urine stream.

Patients with partial and total penectomy suffer serious psychological and physical trauma with major changes in their quality of life. They should undergo psychiatric evaluation and counseling and receive emotional support in which the family and a team of social workers, psychologists, and physicians should take an active role. Some authors have proposed that the classic 2-cm excision margin is not necessary and a more conservative approach might still offer adequate cancer control while providing a more cosmetic and functional penile remnant.

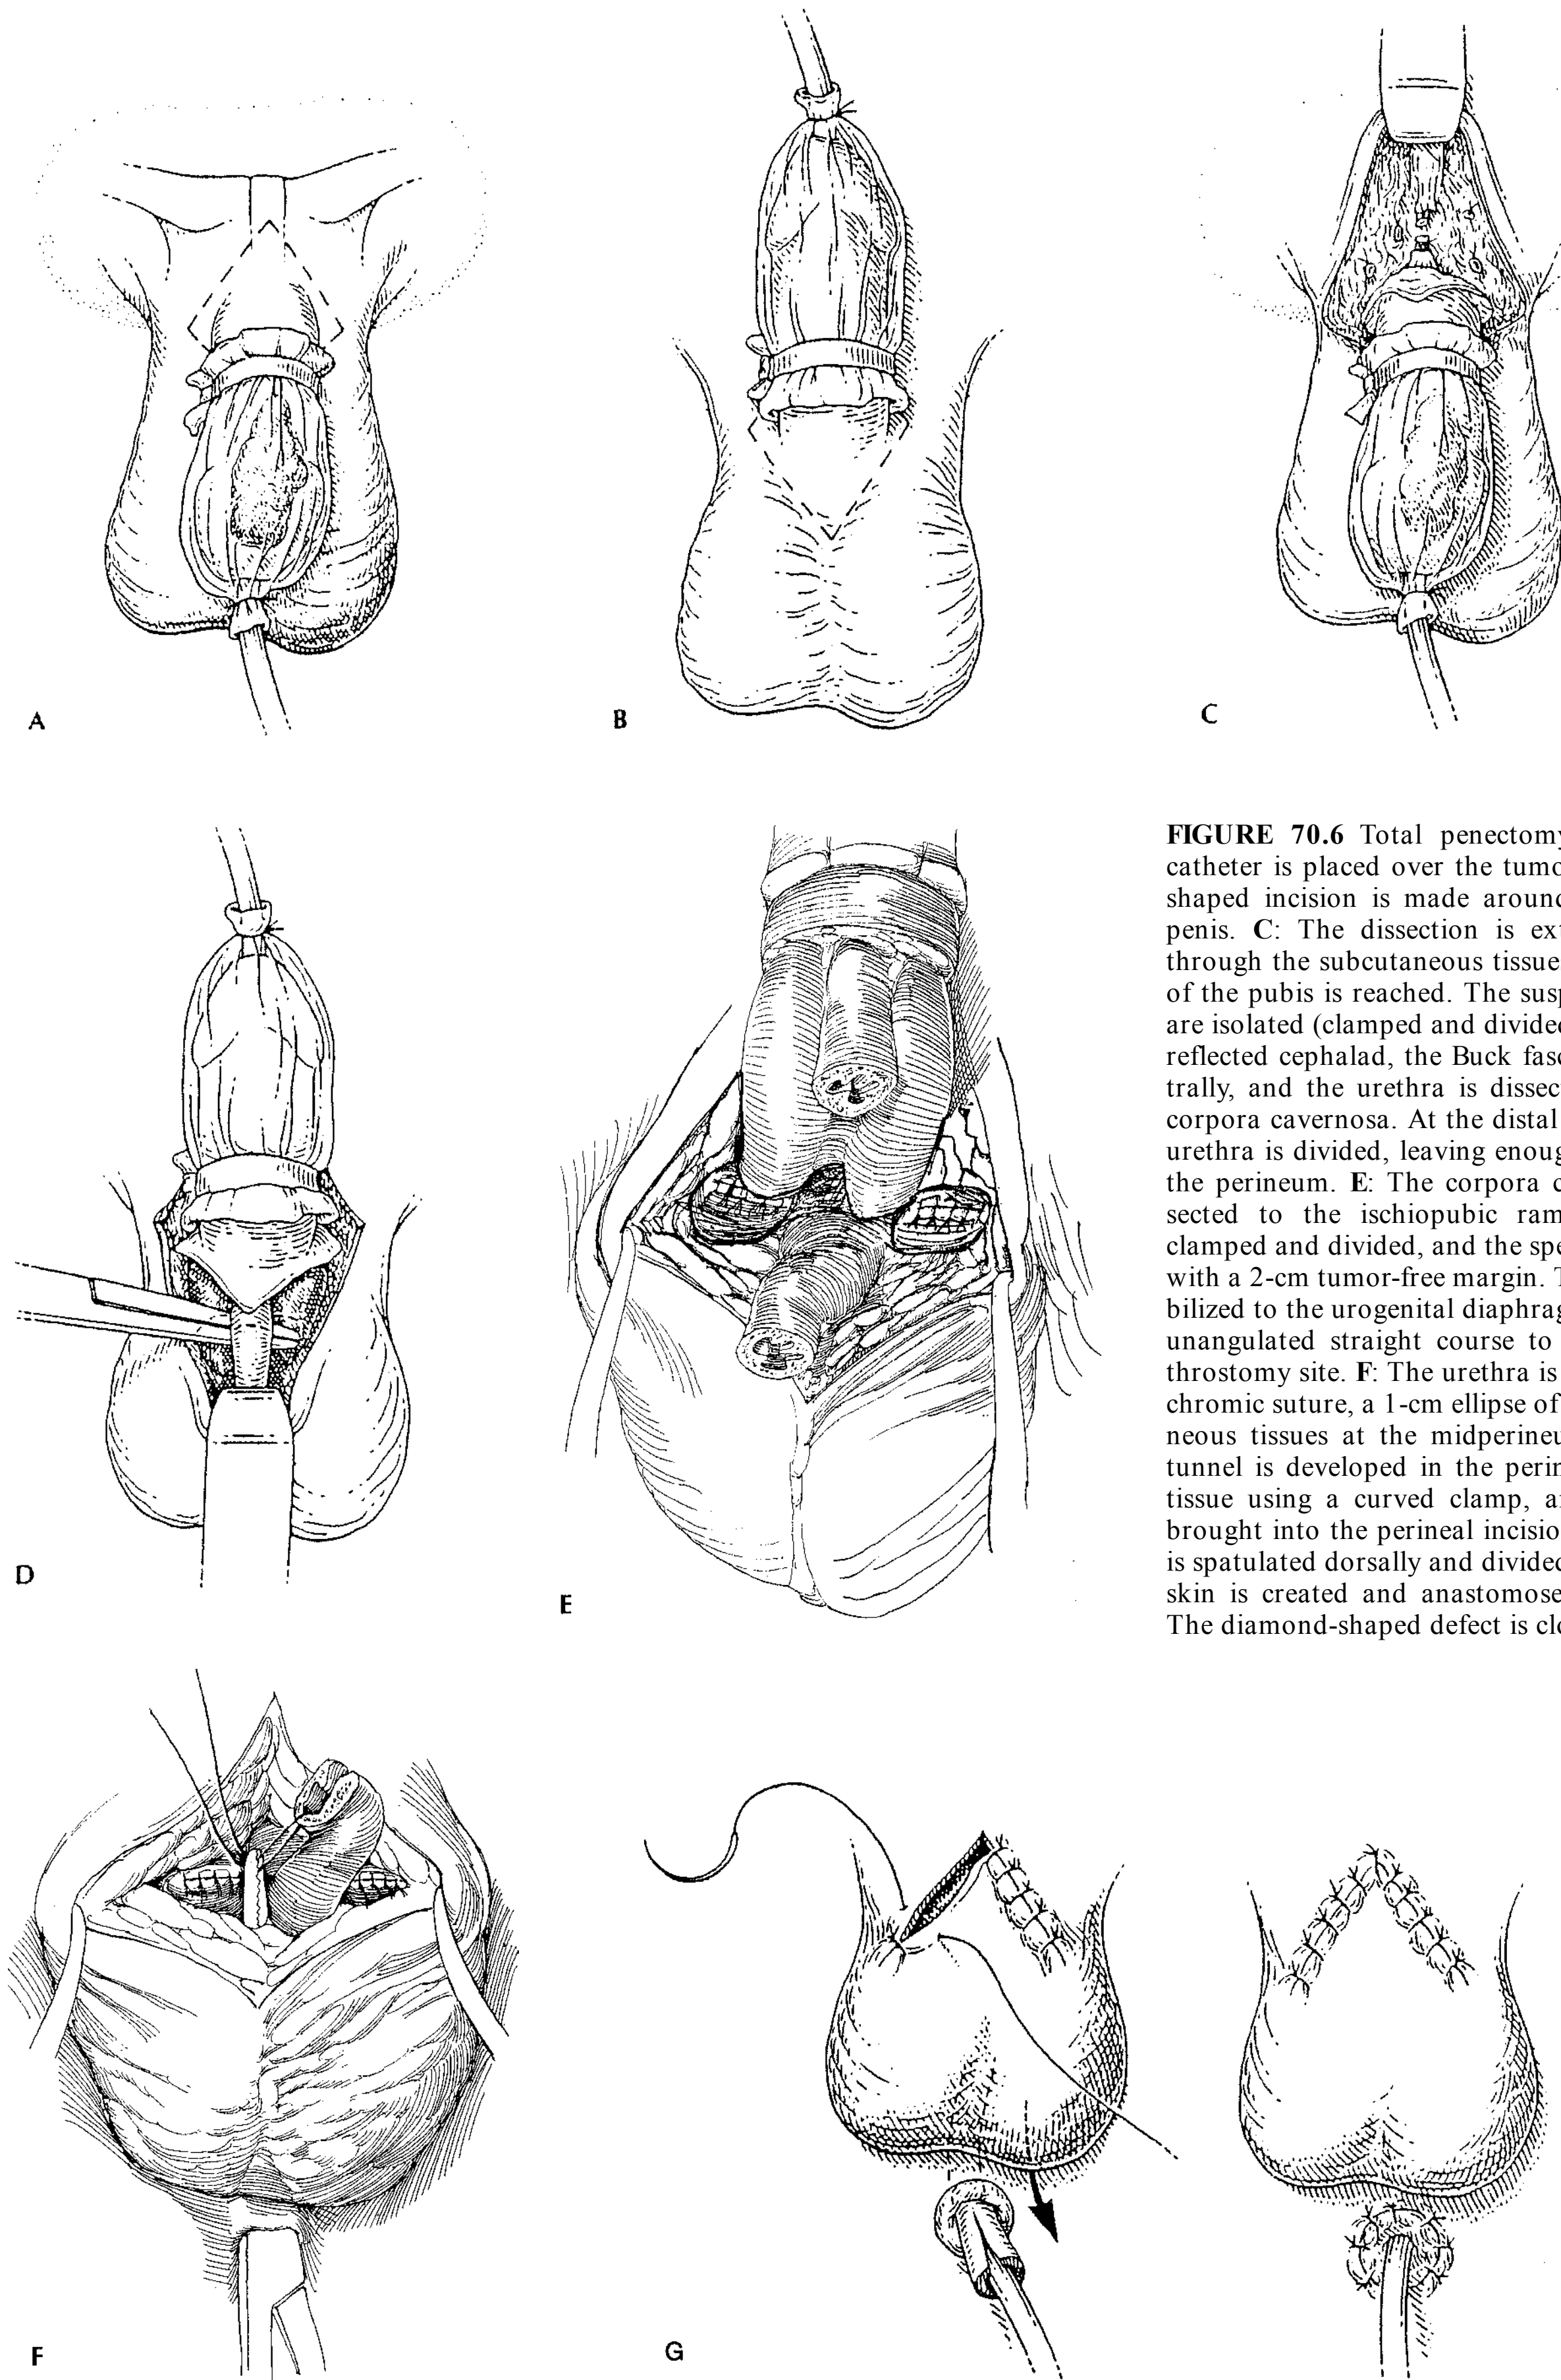

Various techniques for penile reconstruction have been described and include the radial forearm flap and the use of innervated forearm osteocutaneous flaps combined with big toe pulp for reconstruction of the glans. These complex reconstructive procedures require a multidisciplinary approach and are usually performed at specialized referral centers.

---

### Results

---

Surgery plays a prominent role in the treatment and control of the primary lesion in squamous cell carcinoma of the penis. The presence and extent of metastasis to the inguinal nodes are the most important prognostic factors for survival in patients with penile cancer (6). Patients who are at risk or have persistent adenopathy following treatment to the primary lesion should undergo early regional inguinal lymphadenectomy. It has been shown that early resection of lymph node metastases in patients with penile carcinoma improves survival. Histologic grade, stage, and lymphovascular involvement are important parameters for selecting patients for “early” lymphadenectomy. Patients with microscopic disease to the inguinal nodes and well-differentiated tumor are at low risk for developing pelvic lymph node involvement and thus have a good 5-year cancer-specific survival. Survival drops

**FIGURE 70.6** Total penectomy. **A:** A condom catheter is placed over the tumor. **B:** A diamond-shaped incision is made around the base of the penis. **C:** The dissection is extended superiorly through the subcutaneous tissues until the surface of the pubis is reached. The suspensory ligaments are isolated (clamped and divided). **D:** The penis is reflected cephalad, the Buck fascia is opened ventrally, and the urethra is dissected free from the corpora cavernosa. At the distal bulbar region the urethra is divided, leaving enough length to reach the perineum. **E:** The corpora cavernosa are dissected to the ischiopubic rami, the crura are clamped and divided, and the specimen is removed with a 2-cm tumor-free margin. The urethra is mobilized to the urogenital diaphragm to maintain an unangulated straight course to the perineal urethrostomy site. **F:** The urethra is tagged with a 3-0 chromic suture, a 1-cm ellipse of skin and subcutaneous tissues at the midperineum is removed, a tunnel is developed in the perineal subcutaneous tissue using a curved clamp, and the urethra is brought into the perineal incision. **G:** The urethra is spatulated dorsally and divided, and a V-inlay of skin is created and anastomosed to the urethra. The diamond-shaped defect is closed.

significantly in the presence of multiple nodal involvement, pelvic metastasis, and extranodal extension of cancer.

Several investigators have noted a correlation between tumor grade, regional metastasis, and survival. Well-differentiated tumors seldom demonstrate nodal involvement and have a high disease-specific survival. Tumors that exhibit a compact, vertical growth are usually high-grade neoplasms, associated with regional nodal metastasis (3). Slaton et al. (11) evaluated 48 patients with invasive squamous carcinoma of the penis and examined the prognostic factors for lymph node metastasis using univariate and multivariate analysis. These authors concluded that the pathologic stage of the penile tumor, vascular invasion, and >50% poorly differentiated cancer were independent prognostic factors for inguinal lymph node metastasis. These data clearly establish the significance of histologic grade, patterns of tumor growth, depth of invasion, and vascular permeation in predicting regional spread and survival.

Several new techniques are being applied to achieve local and regional lymph node control in patients with penile cancer. Dynamic sentinel lymph node biopsy is a promising technique in evolution that may become an alternative to superficial or modified inguinal dissection techniques with intraoperative

frozen section, which remain the “gold standard” for defining the presence of microscopic lymph node metastases (4).

Sánchez-Ortiz and Pettaway (10) reviewed the M. D. Anderson Cancer Center series and proposed that follow-up regimens should be tailored according to high-risk recurrence stratification factors that include men treated with phallus-sparing strategies such as laser ablation, topical therapies, or radiotherapy; patients with clinically negative inguinal lymph nodes who are managed without lymphadenectomy despite high-risk primary tumors (pT2–3, grade 3, vascular invasion); and those with lymph node metastases after lymphadenectomy. Less rigorous surveillance protocols should be instituted in patients with low-risk primary tumors (pTis, pTa, pT1, grades 1–2) and those with negative inguinal nodes after lymphadenectomy whose primary tumors were managed with partial or total penectomy (10).

Squamous cell carcinoma of the penis, although a rare entity, represents a formidable challenge for the practicing urologist. Every therapeutic modality should be individualized to achieve the ultimate goals of complete tumor excision of the primary lesion, provision of a cosmetic functional penis, and early regional lymph node control.

# CHAPTER 71 ■ INGUINAL LYMPHADENECTOMY FOR PENILE CARCINOMA

SHAHIN TABATABAEI AND W. SCOTT McDOUGAL

Squamous cell carcinoma of the penis tends to spread locally to regional lymph nodes long before distant metastases occur. Approximately 50% of patients have lymph node involvement at presentation. Metastatic spread to the locoregional lymph nodes occurs in a stepwise fashion along the normal route of

penile lymphatic drainage. The disease first spreads to the superficial and deep inguinal nodes, followed by the pelvic nodes (i.e., external iliac and obturator lymph nodes). Although tumor metastasis to the contralateral inguinal nodes is common, pelvic cross-drainage has not been reported.

**FIGURE 71.1** Management of inguinal lymph nodes following primary surgery for carcinoma of the penis. LND, lymph node dissection.

The most important prognostic factors for survival in men with invasive squamous cell carcinoma of the penis are the presence and extent of inguinal lymph node metastasis (1). Although penile carcinoma metastatic to the lymph nodes portends a poorer prognosis, aggressive surgical excision of the involved nodes is associated with increased long-term survival with a possible cure in 30% to 60% of patients with inguinal lymph node metastasis (1,2). This is not true if the tumor has spread to the pelvic lymph nodes, however, in which case there is a <10% survival rate. There is currently no effective chemotherapy for patients with disease beyond the inguinal nodes. Without treatment, patients with metastatic disease die within 2 years.

Until recently, inguinal lymphadenectomy had been associated with significant morbidity (30% to 90%) and up to 3% mortality. Further, previous studies reported up to a 50% false-positive rate in patients with clinically enlarged lymph nodes. These reports have generated considerable controversy regarding the indications for a lymphadenectomy in patients with penile carcinoma.

## DIAGNOSIS

The diagnosis is secured at the time of biopsy and definitive treatment of the primary lesion (Chapter 66). A computerized tomography (CT) scan of the abdomen and pelvis is important for staging the pelvic nodes.

## INDICATIONS FOR SURGERY

In the last two decades, improvements in surgical and perioperative techniques have considerably decreased the complication rates of inguinal lymphadenectomy. In addition, accurate prognostic factors to predict lymph node involvement have been better defined. Therefore, a more proactive approach to treating penile cancer may be taken. Tumor grade and depth of invasion help predict the lymph node involvement (1–3). In

patients with grade 1 squamous cell carcinoma (SCC) of the penis, 24% to 37% may have inguinal lymph node involvement, while almost 82% of patients with grade 3 tumors have positive inguinal lymph nodes (3,4). Patients with carcinoma in situ and verrucous carcinoma of the penis are considered low risk as there is no evidence that these lesions metastasize. Patients with tumor stage T2 or greater (invasion into the corpora) have a 30% to 66% incidence of positive nodes. When stage and grade are combined, those with grade 3 and/or those with stage T2 or greater have an 80% incidence of positive nodes (3).

We advocate early lymphadenectomy in high-risk patients with nonpalpable groin adenopathy (5). Figure 71.1 summarizes our current approach to managing inguinal lymph nodes in these patients. As shown in the algorithm, all patients with penile cancer undergo 4 to 6 weeks of antibiotic therapy before the inguinal lymphadenectomy. It has been shown that most patients with ulcerative, penile SCC have infectious lymphangitis. Inguinal lymphadenectomy in the absence of appropriate antibiotic treatment may significantly increase the risk of complications after the surgery.

Controversies regarding unilateral versus bilateral groin dissection have been resolved by recent data and studies indicating that lymphatic cross-drainage to the contralateral side does occur. Therefore, we strongly recommend bilateral inguinal lymphadenectomy.

The role of pelvic lymphadenectomy and whether the lymphadenectomy should start in the groin or pelvis are also controversial issues. Many studies indicate that involvement of pelvic lymph nodes is an ominous sign, and almost all of these patients succumb to the disease in <2 years. Indeed, the knowledge of pelvic lymph node status has prognostic significance and may change the surgical approach. If the pelvic lymph nodes are positive, the surgical intention will be focused on palliation. In these situations, we still perform inguinal lymphadenectomy, but only on clinically palpable inguinal nodes, to prevent lesions from penetrating through the skin and/or invading into the femoral vessels, which may result in fatal femoral artery bleeding. In these cases, we do not proceed to

contralateral inguinal lymphadenectomy for nonpalpable contralateral nodes. Pelvic lymphadenectomy could also serve as a tool for accurate staging in patients who are candidates for adjuvant or neoadjuvant chemotherapy protocols.

In patients with negative palpable inguinal lymph nodes who are at high risk for inguinal node involvement, several approaches have been proposed to minimize morbidity. These include (a) modified inguinal lymphadenectomy, (b) sentinel lymph node biopsy (SLNB), and (c) intraoperative lymph node mapping (IOLM). Some investigators suggest a modified inguinal lymphadenectomy for the side with nonpalpable inguinal lymph nodes and then radical lymphadenectomy only if the superficial lymph nodes are positive for cancer on the frozen section. This approach differs from radical dissection in four respects: (a) The skin incision is smaller, (b) the lymph nodes lateral to the femoral artery or dorsal to the fossa ovalis are spared, (c) the saphenous vein is preserved, and (d) the sartorius muscle is not transposed. Proponents of this approach point to evidence that there is decreased morbidity without any increase in mortality (6). The main argument against this approach is that it relies heavily on intraoperative frozen section diagnosis of lymph node involvement, which may be inaccurate (7).

Another approach is sentinel node biopsy. Lymphangiograms performed via the dorsal penile lymphatics demonstrate drainage into a specific lymph node center, which is most often located between the superficial epigastric and superficial external pudendal veins. Studies have suggested that the sentinel lymph node is the first site of metastasis and is often the only lymph node involved. Although the concept is intriguing, the location of the sentinel node varies, and therefore clinicians have not found it particularly useful (8).

Based on the experience with breast and melanoma cancers, IOLM of the inguinal nodes has been proposed to address the shortcomings of SLNB. The technique involves injecting a vital blue dye and/or technetium-labeled colloid adjacent to the primary lesion and following its drainage to a specific node in the inguinal region. This node is designated the sentinel node. The goal is to eliminate the anatomic variability of the sentinel node location. Although preliminary results with IOLM are promising, lack of long-term follow-up, as well as the associated learning curve and technical difficulties of the procedure, limits its current use (9). We do not recommend IOLM as a standard approach at this time.

At the present time it seems that because of the unreliability of SLNB and the technical aspects of IOLM and its associated learning curve, superficial lymphadenopathy and modified inguinal lymphadenopathy are considered more informative and accurate for staging and carry minimal morbidity.

---

## ALTERNATIVE THERAPY

---

The value of radiation therapy and chemotherapy is still uncertain. These treatments are currently considered palliative. In patients with positive inguinal lymph nodes, the survival rate is significantly less when treated with radiation therapy than when treated with surgery. Based on the encouraging results of adjuvant radiation therapy in squamous cell carcinoma of the head and neck, some investigators advocate the use of preoperative radiation therapy in patients with large,

fixed regional nodes (>4 cm in size and/or extracapsular extension). In the absence of surgical contraindications (medical comorbidities, patient's refusal, bulky, infected lymphadenopathy with distant metastasis), we are not in favor of inguinal area radiation, as flap viability may be compromised and there is no proven survival benefit in penile cancer. At the present time inguinal radiotherapy is reserved only for inoperable nodes and palliative purposes.

Experience with chemotherapy in penile carcinoma is hampered by a limited number of cases and lack of prospective trials. Cisplatin, iphosphamide, taxol, bleomycin, vincristine, 5-fluorouracil, and methotrexate, as single agents or as combinations, have all been shown to provide a partial response in selected cases. The use of chemotherapy as adjuvant or neoadjuvant therapy may be beneficial, although the optimum chemotherapy regimen remains to be determined.

---

## SURGICAL TECHNIQUE

---

All patients undergo a thorough metastatic workup including abdominal and pelvic CT scan, chest X-ray, and liver function tests. All patients complete 4 to 6 weeks of appropriate antibiotic therapy following excision of the primary lesion and wound closure, to treat any associated infection and decrease the risk of postoperative wound infection. Intravenous antibiotics with appropriate skin flora coverage are administered 1 hour prior to the skin incision. Adequate hydration should be ensured before surgery. Antiembolism stockings and pneumatic compression boots are applied to the lower extremities prior to induction of anesthesia.

---

## SURGICAL ANATOMY

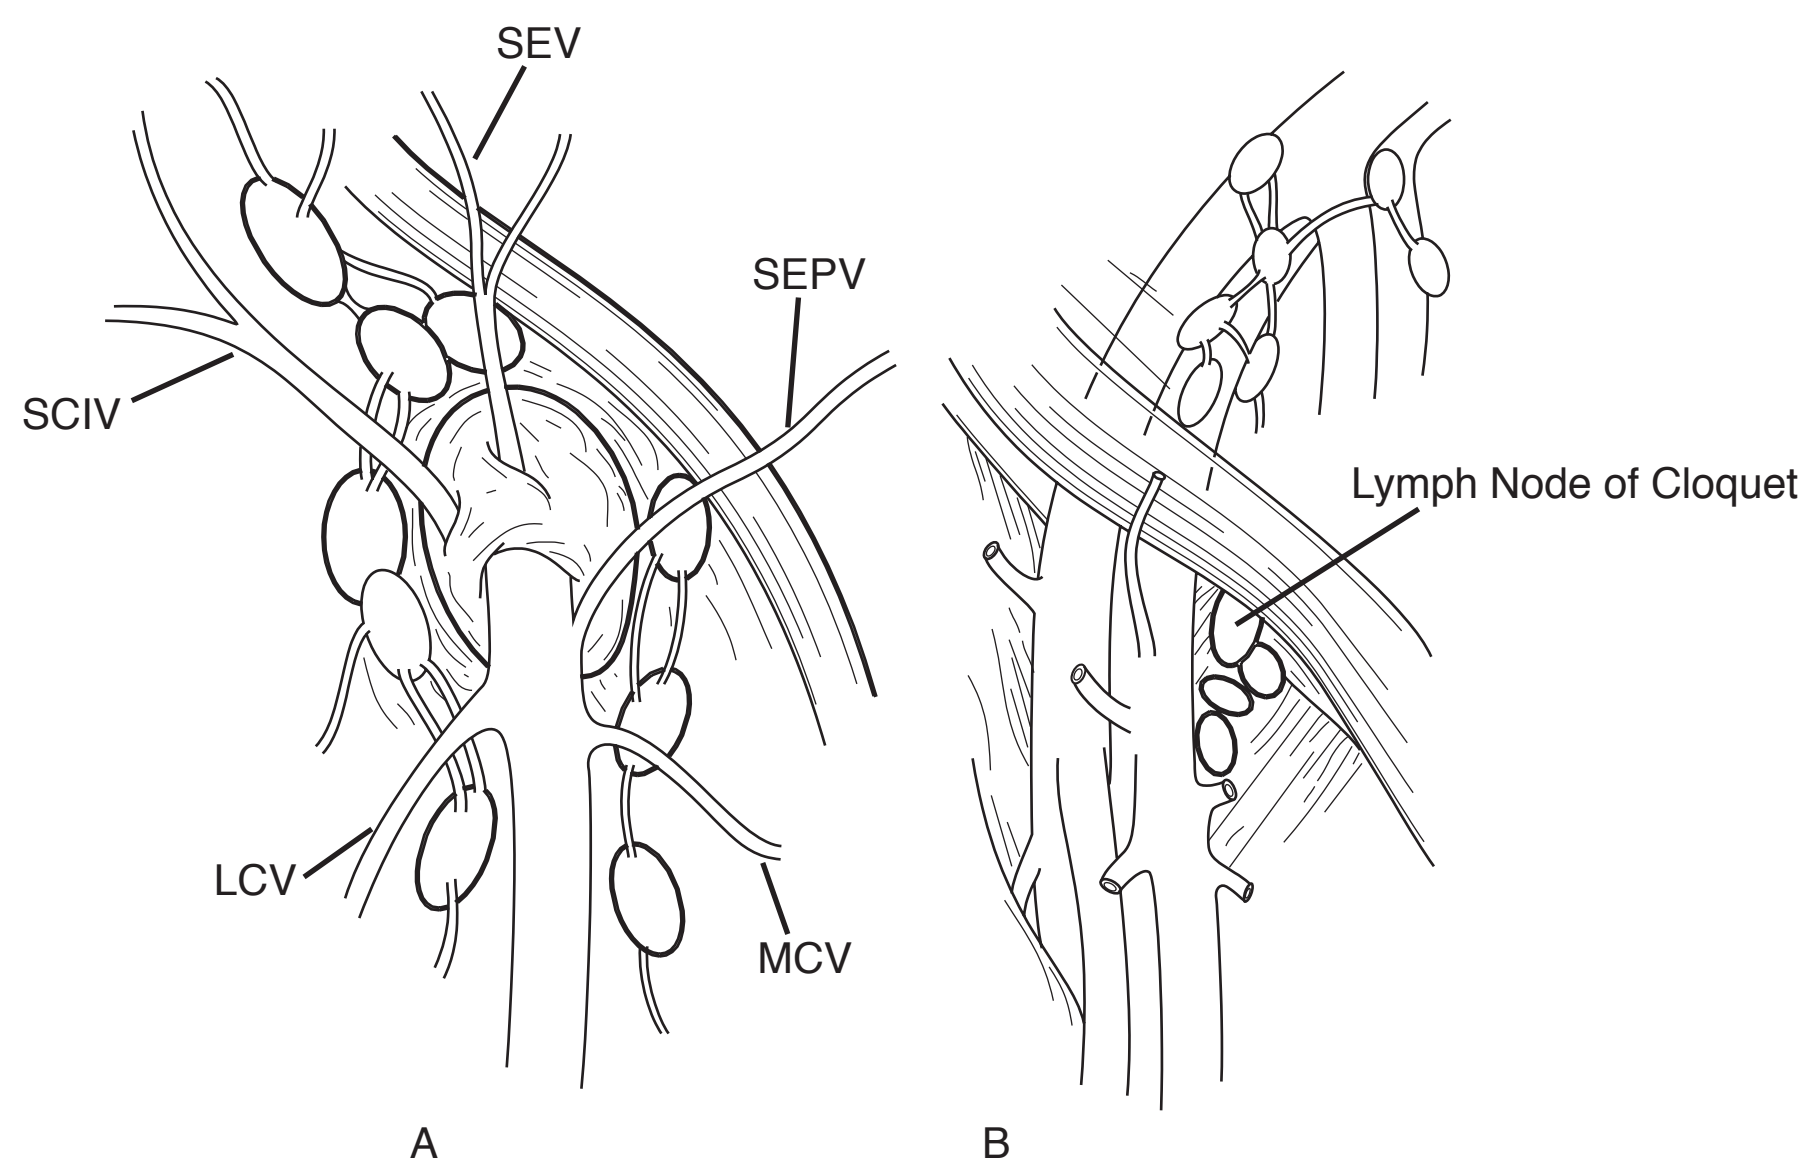

---

The lymphatics of the skin of the penis, scrotum, and perineum drain into the superficial and deep inguinal nodes. The superficial fascia of the thigh (fascia lata) separates the superficial inguinal nodes from the deep nodes. Extensive work by Daseler et al. (10) on inguinal lymph node dissection suggests that five node groups exist in the superficial inguinal area (Fig. 71.2A) (10):

1. Central nodes at saphenofemoral junction
2. Superolateral nodes around the superficial circumflex vein
3. Inferolateral nodes around the lateral (femoral) cutaneous and superficial circumflex veins
4. Superomedial nodes around the superficial external pudendal and superficial epigastric veins
5. Inferomedial nodes around the greater saphenous vein

Overall, 4 to 25 lymph nodes are present in the superficial groups. All of these nodes are situated below the globular fat of the superficial fascia called the Camper fascia.

The deep inguinal nodes are located medial to the femoral vein in the femoral canal (Fig. 71.2B). The most cephalad deep inguinal node, known as the node of Cloquet, is located between the femoral vein and the lacunar ligament. Deep inguinal nodes drain to obturator, hypogastric, and external iliac lymph nodes, which in turn drain to the common iliac and para-aortic nodes.

**FIGURE 71.2** **A:** Superficial lymph nodes and the five tributaries of the saphenous vein: medial (*MCV*) and lateral (*LCV*) cutaneous, superficial external pudendal (*EPV*), superficial circumflex iliac (*SCIV*), and superficial epigastric (*SEV*). These veins should be ligated and the surrounding package removed with preservation of the saphenous vein. **B:** Deep inguinal lymph nodes, which in general number two to four. The most cephalad lymph node is the node of Cloquet.

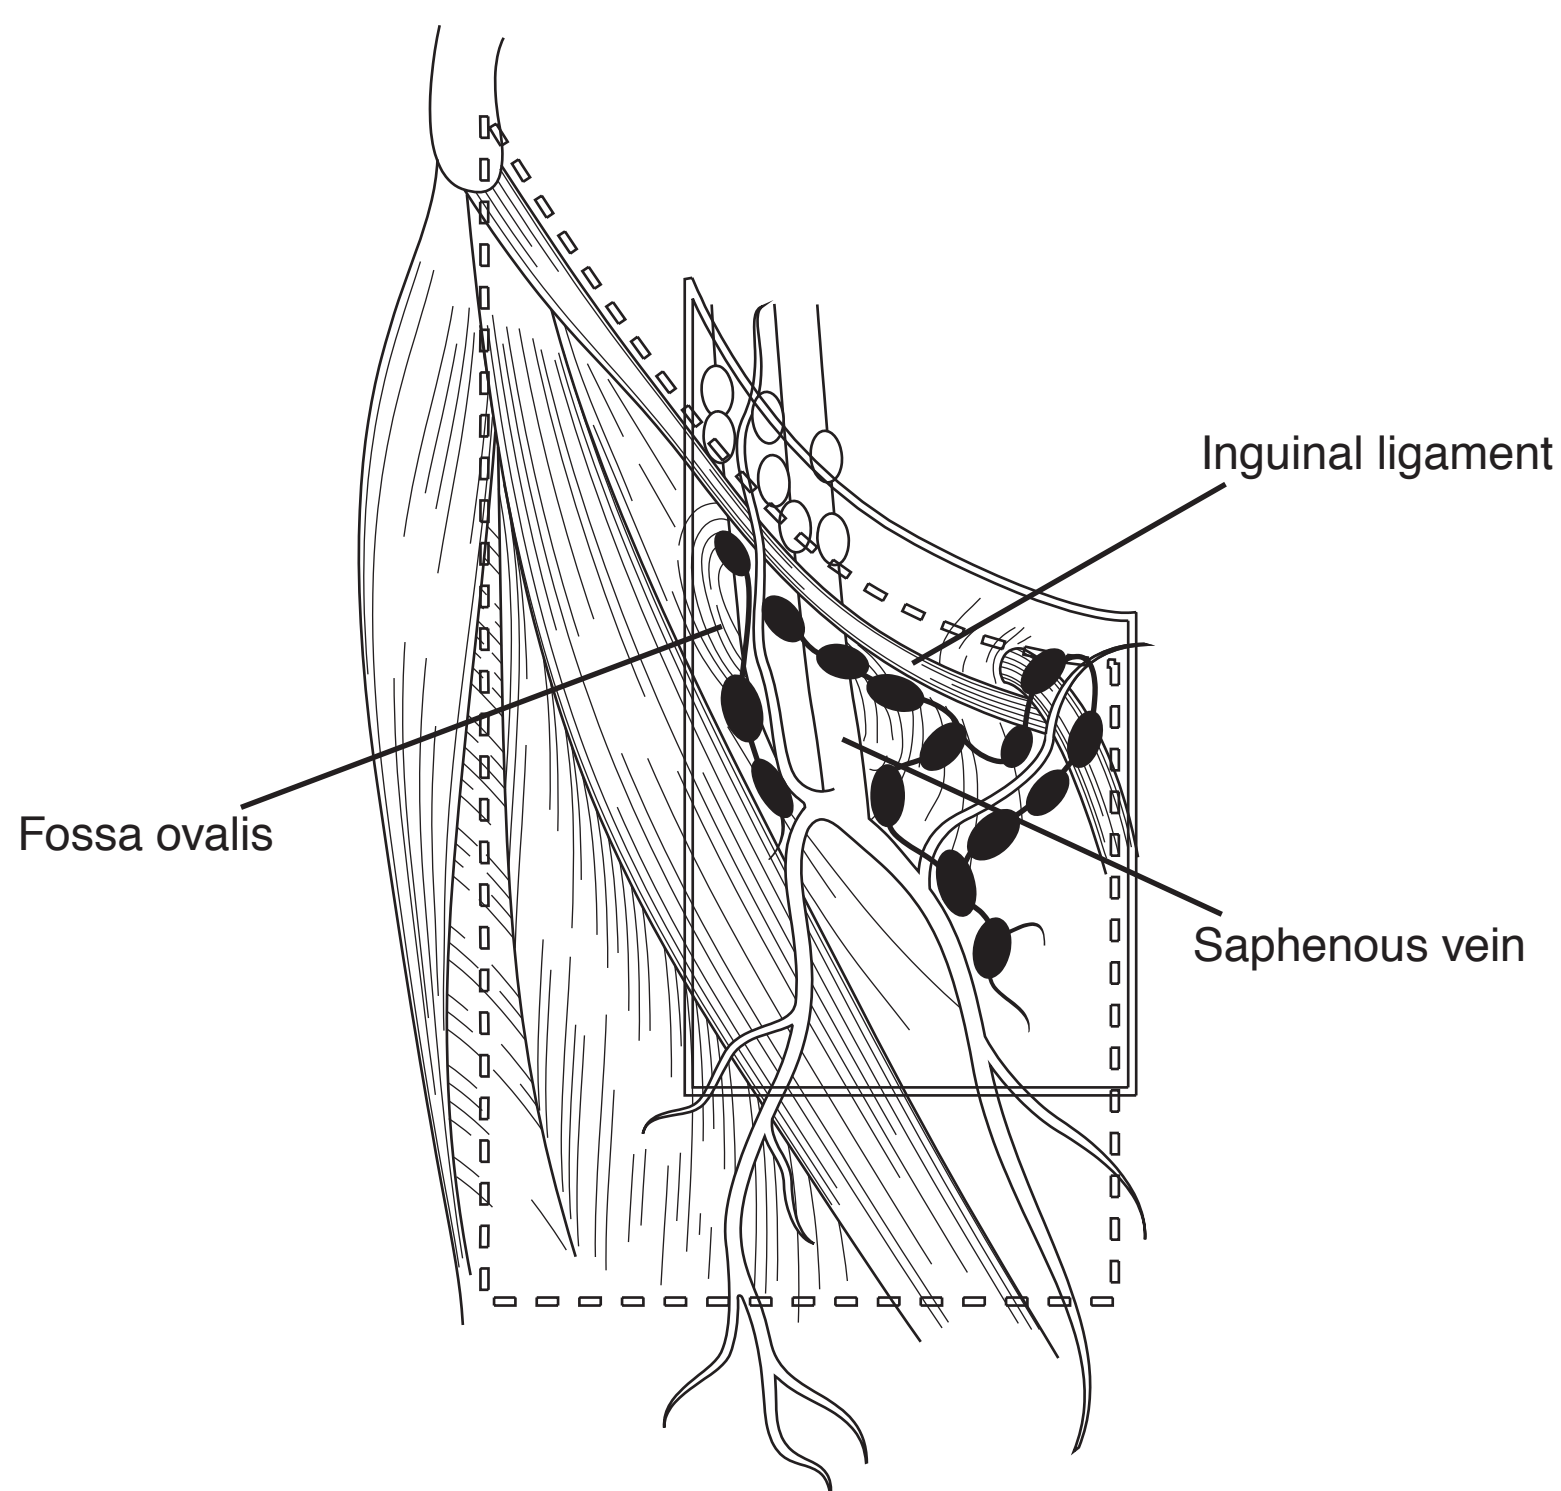

Blood supply to the inguinal skin derives from superficial branches of the femoral artery (i.e., superficial external pudendal, superficial circumflex iliac, and superficial epigastric arteries). Corresponding veins parallel the arteries that join into the greater saphenous vein as it joins the femoral vein at the fossa ovalis. These arteries are ligated in the inguinal lymphadenectomy. Skin flap viability depends on anastomosing vessels within the superficial globular fat of the Camper fascia that track from lateral to medial along the skin lines, parallel to the inguinal ligament. In theory, the transverse skin incision is least likely to compromise blood supply.

### Radical Inguinal Lymphadenectomy

The patient is placed in the supine position with the ipsilateral hip abducted and the ipsilateral knee flexed (Fig. 71.3). The dissection margins for the classic radical inguinal lymphadenectomy cover the area outlined superiorly by a line drawn from the superior margin of the external inguinal ring to the anterosuperior iliac spine (ASIS), medially by a line drawn from the pubic tubercle 15 cm down the medial thigh, and laterally by a line drawn from the ASIS extending 20 cm inferiorly (Figs. 71.3 and 71.4). A line drawn between the inferior end of the lateral and medial margins marks the inferior limit of the dissection. An incision is made 3 to 4 cm inferior and parallel to the inguinal crease over the medial thigh from the lateral to medial limits of the dissection. The femoral vessels should be palpable in the medial aspect of the incision. We have modified this approach to include more tissue above the inguinal ligament—see section entitled “Suprainguinal Dissection in Inguinal Lymphadenectomy” following.

**FIGURE 71.3** The patient is positioned with the hip abducted and knee flexed. The skin incision is demarcated by the line drawn two fingerbreadths below the inguinal crease (classic dissection) or two fingerbreadths above the groin crease.

**FIGURE 71.4** Comparison of limits of dissection of modified inguinal lymphadenectomy (*solid line*) with classic groin dissection (*dotted line*). Note that with the modified groin dissection the dissection is medial to the midpoint of the femoral artery. *Black*, superficial inguinal nodes; *white*, deep inguinal nodes; *gray*, external iliac nodes.

Skin flaps are developed superiorly and inferiorly as the first step of the dissection. Elevation of the skin edges with skin hooks allows dissection within the superficial fatty fascia of the thigh. At the junction of the superficial globular fat and the deeper membranous fat, the tissues are separated. The skin and globular fat are elevated off of the deep membranous fascia and the Scarpa fascia cephalad to a point 4 cm above the inguinal ligament. The skin flaps are protected by gentle elevation with Deaver retractors placed over moist sponges. Inferior traction on the lymphatic package with a small sponge under the left hand provides countertraction to facilitate dissection in the proper plane.

Dissection is carried down through the Scarpa fascia onto the external oblique aponeurosis. The external inguinal ring and emerging spermatic cord are identified medially and retracted as dissection extends to the pubic tubercle. The fat and lymphatics are separated from the spermatic cord and base of the penis medially. Vascular and lymphatic channels are meticulously ligated to prevent postoperative fluid accumulation under the skin flaps. The fatty lymph packet is elevated off of the external oblique fascia to the inferior border of the inguinal ligament (Poupart ligament), where the femoral vessels are identified within the femoral sheath (Fig. 71.5A).

The medial (adductor longus muscle) and lateral (sartorius muscle) borders of the dissection are identified next, and the fascia lata is incised over the muscles. The muscles are traced to their confluence at the apex of the femoral triangle, representing the inferior limit of dissection. The resulting triangular packet of lymphatics and fat needs only to be elevated off its deep margin to complete the dissection. Care must be taken not to retract the adductor longus medially or the sartorius muscle laterally as the dissection will extend too

far caudally (i.e., confluence of the two muscles will be displaced caudally).

The saphenous vein is identified medially and preserved if possible. Although this vessel is by tradition sacrificed during radical lymphadenectomy, this achieves no therapeutic benefit and may increase morbidity. If massive lymphadenopathy exists, however, the saphenous vein should be removed. The femoral sheath is incised over the femoral artery and vein. Medial dissection isolates the lymph node of Cloquet between the Cooper and Poupart ligaments, lateral to the lacunar ligament. The femoral sheath is stripped inferiorly to the apex of the femoral triangle, as the fascia overlying the sartorius and adductor longus is stripped distally. The deep lymph nodes are removed from their location between the femoral artery and vein. The superficial cutaneous perforating arteries and veins are ligated as they are encountered on the surface of the femoral artery and saphenous vein, leaving the intact saphenous to join the femoral vein, in the area of the now absent fossa ovalis. It is important to limit the lateral aspect of dissection along the femoral sheath to the anterior surface of the femoral artery. Dissection laterally on the femoral sheath can injure the femoral nerve beneath the iliaca fascia (deep to the fascia lata), and posterolateral dissection can injure the profunda femoris artery.

When this dissection is complete, the superficial and deep lymphatics are removed together en bloc. The wound is irrigated liberally. The exposed femoral vessels are covered by mobilizing the sartorius from its insertion on the anterior superior iliac spine, transposing it over the vessels, and securing its cephalad margin to the inguinal ligament with 2-0 silk suture (Fig. 71.5B). Blood supply to the sartorius arises from its medial and inferior aspects, and care must be taken to protect

**FIGURE 71.5** **A:** Raised groin flaps and the completed groin dissection. **B:** The sartorius muscle is detached at the anterior superior iliac spine and moved medially, thus providing for coverage of the vessels. **B:** The transferred sartorius muscle is sutured to the inguinal ligament.

these vessels during mobilization. The medial edge of the muscle can be tacked to the adductor longus to ensure coverage of the femoral vein. If pelvic lymphadenectomy has been performed simultaneously, this dissection should join with the distal limit of the pelvic dissection and allow free communication with the pelvis. To prevent herniation, the Cooper ligament should be secured to the shelving edge of the Poupart ligament with permanent suture (2-0 Prolene) without compromising the lumen of the femoral vein.

At this point the wound edges will be inspected for nonviable tissue. Any suspicious area with doubtful vascularization should be excised. Some have suggested giving an ampule of fluorescein intravenously and inspecting the skin edges with a Wood lamp for viability. We have not found this technique to be particularly useful.

A Jackson-Pratt drain is placed beneath the subcutaneous tissue and brought out inferiorly. The skin flaps are tacked to the surface of the exposed muscles with 3-0 chromic sutures and the wound closed with nylon sutures or staples. A light-

pressure dressing is applied for the first 12 hours. Care is taken not to apply excessive pressure, which might further compromise blood supply in the skin flaps.

Parenteral antibiotics are continued for 48 hours and then converted to oral agents. The patient is maintained on bedrest for 1 day and ambulated on the second postoperative day. Deep vein thrombosis (DVT) prophylaxis, that is, thromboembolic stockings or pneumatic compression boots, is crucial. The drain is removed when the patient is ambulatory and drainage is  $<30$  cc per day. Patients are instructed to use thromboembolic stockings for at least 6 months after the surgery. Hospital stockings are converted to fitted compression stockings 1 month postoperatively.

---

### Modified Inguinal Lymphadenectomy

---

The skin is incised transversely 2 cm below the groin crease for a distance of 10 cm. Skin flaps are raised in the same

manner as described previously for a distance of approximately 8 cm cephalad and 6 cm caudally. Cephalad dissection onto the external oblique is performed as in radical lymphadenectomy, and the medial extent of dissection is identical. The lateral dissection is more limited, however. After opening the femoral sheath, dissection lateral to the femoral artery is not performed. The sartorius is not exposed, and dissection inferiorly on the fascia lata and femoral sheath extends only to the caudal edge of the fossa ovalis (Fig. 71.4). The saphenous vein is preserved in the superficial nodal package, and the deep lymphatics below the fascia lata between the femoral vessels and medial to the femoral vein along the adductor longus fascia up to the Cooper ligament are removed. Postoperative management is similar to that for radical lymphadenectomy.

---

### Suprainguinal Dissection in Inguinal Lymphadenectomy

---

As mentioned previously, the primary lymphatic drainage of carcinoma of the penis is to the superficial inguinal region, which is mostly inferior to the inguinal ligament. This is the basis for the surgical approach, and hence for placing the incision inferior to the inguinal ligament.

In a number of cases we have noted that the metastasis from penile carcinoma occurs in lymph nodes above the inguinal ligament. Indeed, in some cases the only involved nodes have been superior to the inguinal ligament. For this reason, we have begun to place the incision above the groin crease (2 cm above the inguinal ligament) with the dissection extending at least to the level of the symphysis pubica, skeletonizing the cord structures and the external oblique medially and extending the incision laterally to the anterior superior iliac spine. The standard groin lymph node dissection is performed caudally.

It is important to encompass the soft tissue above the inguinal ligament as lymphatic drainage from the penis may extend directly to nodes above the inguinal ligament and superficial to the external oblique fascia. There is little additional morbidity in extending the groin dissection to this level, and we have found that skin flap viability is better preserved when compared to incisions placed several centimeters below the groin crease. Although this is slightly more difficult for the most caudal portion of the groin dissection, the decreased need to retract flaps for the dissection of the groin around the femoral vessels at the level of the inguinal ligament likely reduces trauma to the skin. We have found that this extended incision encompasses an area of nodal drainage that may be missed with the standard groin dissection; indeed, in some patients positive nodes would have been missed with a standard groin dissection. Furthermore, we believe that the incision for this extended dissection improves skin flap survival.

---

### Inguinal Reconstruction after Inguinal Lymphadenectomy

---

Large groin defects may be created after inguinal lymphadenectomy for bulky metastatic penile cancer. Many types of flaps have been described and advocated to cover large defects

in the groin, when extensive dissections are required. The goal is to provide muscle bulk to protect the femoral vessels and full-thickness skin for wound coverage. This will allow for the least morbidity postoperatively and the least likelihood of femoral vessel rupture should adjuvant radiotherapy be required. Flaps described to accomplish this purpose have included a tensor fascia lata myocutaneous flap, a gracilis myocutaneous flap, an abdominal rotation flap, a rectus abdominis myocutaneous flap, a deep inferior epigastric artery myocutaneous flap, a thigh rotational skin flap, and a scrotal advancement flap. Most of these reconstructive procedures are performed in collaboration with a plastic or reconstructive surgeon.

Recently, we proposed the use of an abdominal cutaneous advancement flap as an alternative for primary skin closure of large groin defects (11). The procedure involves sartorius muscle transfer for vascular coverage followed by elevation of the ipsilateral abdominal wall, immediately anterior to the underlying rectus and external oblique fascia, cephalad to the level of the umbilicus. This provides enough mobility for closing a gap of up to 12 cm (Fig. 71.6A and B). For patients with larger (up to 20 cm) gaps, a midline incision is made to the xiphoid process and the entire overlying skin and subcutaneous tissue immediately superficial to the rectus abdominis and external oblique muscle are raised on the ipsilateral side of the defect. The flap is then moved caudad to cover the defect (Fig. 71.6C). Jackson-Pratt drains are employed beneath the flap. Postoperative management is similar to that for the standard inguinal lymphadenectomy described previously. The simplicity, lower morbidity, and excellent cosmetic results are the main advantages of this procedure. The technique may be utilized for bilateral groin defects as well. Abdominal scars (paramedian, appendectomy, Gibson, or flank incision) may compromise the blood supply to the flap and are considered relative contraindications to this approach.

---

## OUTCOMES

---

### Complications

---

Skin necrosis, wound infection, vascular injuries, lower-extremity lymphedema, DVT, and death are some of the potential complications. Skin necrosis and wound infection are probably the most feared complications. Older series report up to 30% flap necrosis. Improved understanding of the cutaneous blood supply, avoidance of the vertical skin incision, improved surgical technique, and appropriate use of perioperative antibiotics have resulted in significant reduction in mortality, skin necrosis, and wound infection—to negligible levels—in several recent reports (12).

---

### Results

---

Currently, surgical intervention is the most effective approach to treat SCC of the penis. Early inguinal lymphadenectomy can improve survival in the high-risk patient. Expectant follow-up may be offered to low-risk patients with clinically negative groin nodes who comply with comprehensive, close observation.

# CHAPTER 72 ■ SURGICAL TREATMENT OF PEYRONIE DISEASE

URI GUR AND GERALD H. JORDAN

Peyronie's disease is characterized by the formation of a fibrous lesion within the tunica albuginea of the corpora cavernosa (Fig. 72.1). This lesion or "plaque" is believed to be caused by repetitive microvascular trauma (3). It is proposed that trauma, either acute or chronic, is sustained during intercourse, with subsequent scar formation in susceptible individuals. The plaque's inelasticity results in a functional shortening of the corporal body on the most affected side, resulting in deformity during erection. The incidence of Peyronie's disease has recently been estimated at up to 3% or as high as 7% to 9% of the general male population (9,10).

Patients most commonly present with dorsal curvature. Fortunately, only a small proportion of patients with Peyronie's disease have deformity requiring surgical intervention. Surgical intervention should be regarded as palliation of the deformity only and not as cure.

---

## DIAGNOSIS

---

The diagnosis of Peyronie's disease can usually be made with a focused history and physical examination. On history, it is imperative to elicit the duration of symptoms, the progression of the penile deformity, and the degree of sexual dysfunction. Erectile dysfunction, to some degree, is felt by many surgeons to be almost uniformly present. This may represent the psychological impact incurred from living with a genital deformity but may also be due to several organic causes.

The physical examination should be focused on delineating plaque location, size, and opposing plaque formation (if

present). An attempt to elicit known disease associations such as Dupuytren's contracture or other elastic tissue fibromatosis should be made. Objective evaluation of penile curvature with home-taken photographs of the erect penis, we find, is extremely helpful. Plain radiographs are effective in demonstrating plaque calcification, believed to be a sign of plaque maturity. Plaque calcification is also easily demonstrated with ultrasonography (1). The plaque can be imaged by both CT and MRI, both being unnecessary except for the possibility of using MRI to "stage" the phase of disease for research or study protocol purposes (5), or in a rare patient where the diagnosis is not certain and a concern for a possible malignancy arises.

It is important to evaluate and define the surgical candidate's preoperative erectile function. Prospective surgical patients, at our center, are evaluated with color duplex ultrasound (CDU) in the presence of pharmacologically induced erection. Abnormalities in the resistive index and end-diastolic velocity, at our institution, prompt further testing with dynamic infusion cavernosometry/cavernosography (DICC). In addition, one must determine if acceptable intercourse can be accomplished by enhancement of erectile rigidity alone. In this scenario, patients may be best served with a pharmacologic erection program as an alternative to surgery.

A frank discussion of treatment goals with the couple is imperative. The patient should be assured that the process is not malignant or life-threatening. The goal of surgery is to straighten the penis and maintain erectile function so that satisfactory intercourse can be achieved.

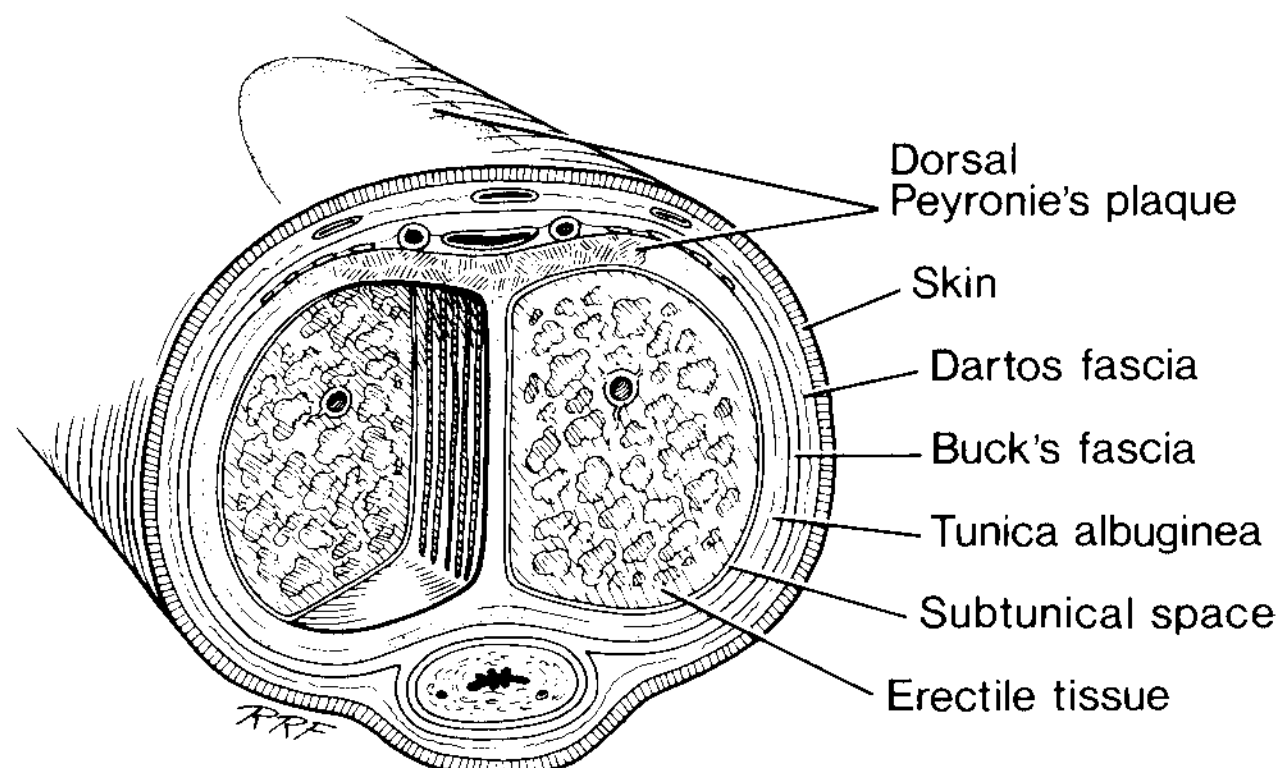

Couples must be aware that pre-existing penile shortening and erectile dysfunction will not be improved by straightening procedures. Rigidity may be improved by straightening the penis, but truly improved erectile function does not occur. Evaluation with a sex therapist can help patients and partners adjust to these new sexual expectations.

---

## INDICATIONS FOR SURGERY

---

Although medical treatments targeting the evolution of scar tissue have largely been unsuccessful, an attempt at treating Peyronie's disease medically may be beneficial for patients prior to surgical intervention, provided the patient is in the immature or active phase of the disease. A surgical candidate must meet certain criteria. First, the disease process must be stable and the "plaque" mature and quiescent. In review, the signs of disease quiescence include unchanged penile deformity for a minimum of 6 months, with the resolution of pain

**FIGURE 72.1** Cross-sectional penile anatomy with dorsal Peyronie's plaque.

associated with erection. Moreover, before surgical intervention most investigators recommend a minimum 12-month waiting period from disease onset. The experienced examiner may recognize the clinical findings of a mature or calcified plaque and could elect to intervene earlier than this arbitrary time period. Once disease stability exists, indications for surgical intervention are penile deformity and/or erectile dysfunction that precludes intercourse.

Three general techniques exist for the surgical management of Peyronie's disease: (a) corporoplasty or plication procedures, (b) plaque incision or excision with grafting, and (c) penile prosthesis insertion with plaque modeling or incision with or without grafting. Many protocols have been published describing the treatment of Peyronie's disease, but the best outcome depends on an individualized approach. Straightening techniques are appropriate for patients with adequate erectile function in whom penile straightening alone will achieve satisfactory intercourse.

Plication procedures involve shortening the tunica albuginea on the side opposite the plaque; this may eventually shorten the penis, but it carries the advantages of being less technically demanding, of involving a more rapid convalescence, and in most series of having a smaller risk of postoperative erectile dysfunction.

Plication or corporoplasty procedures may be the preferred option for ventral curvatures, as historically this subset of patients has demonstrated poor outcomes with grafting procedures. Incision or excision of the Peyronie's plaque with grafting of the corporotomy defect is a more technically complex procedure and may incur a higher risk of postoperative erectile dysfunction. Patients with severe curvature, hourglass deformity, or inadequate penile length are more amenable to incision or excision with grafting over corporoplasty or plication techniques that can further shorten or deform the erect penis. At our institution we prefer the technique of plaque incision with grafting and use this even for severely calcified plaques. However, there are cases where large, extensively calcified plaques may require plaque excision with grafting.

Last, insertion of penile prostheses for Peyronie's disease was once considered a panacea but for most patients is now reserved for those with severe erectile dysfunction. In patients with severe curvature, prosthetic implantation can be done in conjunction with an incision and grafting procedure. Modeling the plaque intraoperatively after prosthesis placement is remarkably successful and often avoids the need for incision. The technique of penile prosthesis insertion is covered in Chapter 74.

---

## ALTERNATIVE THERAPY

---

Medical management includes oral agents, topical agents, with or without delivery modalities, and intralesional injection protocols. Several surgeons are also examining the efficacy of plaque expansion using devices that put traction on the penis. As mentioned, the surgical management of Peyronie disease should be viewed as a palliation of the mechanical effects of the disease rather than a cure. In a patient with erectile dysfunction, with or without curvature, penile prosthesis insertion should be contemplated. Many patients will refuse prosthetic implantation based on personal bias.

**FIGURE 72.2** Dorsal penile curvature with incision marked at the circumcision scar.

---

## SURGICAL TECHNIQUE

---

### Skin Incision

---

The initial skin incision is dependent on plaque location and the procedure to be performed. As previously mentioned, corporoplasty or plication procedures address the aspect of the corpora cavernosa opposite the plaque (most involved aspect), whereas plaque incision or excision techniques approach the plaque directly. The dorsum of the corpora cavernosa is best exposed by a circumferential degloving incision. If the patient has been previously circumcised, then the incision should be performed through the circumcision scar (Fig. 72.2). Approaching the penis through the previous circumcision scar has not been problematic, even when the scar is displaced proximally. The penile shaft is degloved to its base by sharply dissecting the dartos fascia from the underlying Buck's fascia. This maneuver gives good exposure for midshaft and distal lesions. For very proximal plaques or patients with a redundant prepuce, a second peripenile or periscrotal incision may be helpful. After degloving the shaft of the penis, the surgeon delivers it into the counterincision, laying the shaft skin aside and covering it with a warm soaked gauze dressing. This protects the penile skin from trauma until the end of the procedure, when it is returned to the shaft. Ventral exposure can also be achieved through a midline incision on the ventral aspect of the penis, which we prefer, as this results in less postoperative penile edema.

---

### Corporoplasty or Corporoplication Procedures

---

Several techniques have been described to "plicate" the curvature associated with Peyronie's disease. At our institution,

procedures are performed with the patient in the supine position, via a degloving incision for dorsal “plication,” and a midline ventral incision for ventral “plication.”

An artificial erection is created to accurately define the point of maximal curvature using a pressure infuser with 0.9% saline. The use of a tourniquet for control of bleeding or induction of an artificial erection is not favored as proximal curvatures can be concealed. The Buck’s fascia opposite the site of maximal curvature is sharply incised and elevated from the underlying tunica albuginea. Correction of dorsal curvature requires identification of the corpus spongiosum ventrally. For ventral curvature, care must be taken to avoid injury to the dorsal neurovascular structures. Once the tunica albuginea is exposed, “plication” of the corpora can be performed in several ways. Creation of an ellipse corporotomy defect with reapproximation of the corporal edges using 4-0 polydioxanone sutures effectively counteracts the opposing lesion (11). The tunica albuginea may be excised or tucked underneath the corporotomy closure. Correction of curvature can also be achieved by plicating the tunica albuginea by a number of techniques that use nonabsorbable sutures without incising the tunica albuginea (4). One technique of corporoplasty uses the Heineke-Mikulicz technique, which horizontally closes a vertical incision of the tunica (12). Once acceptable straightening is achieved, the penis is closed anatomically in layers, and we place a small-caliber, closed-suction drain superficial to the Buck fascia.

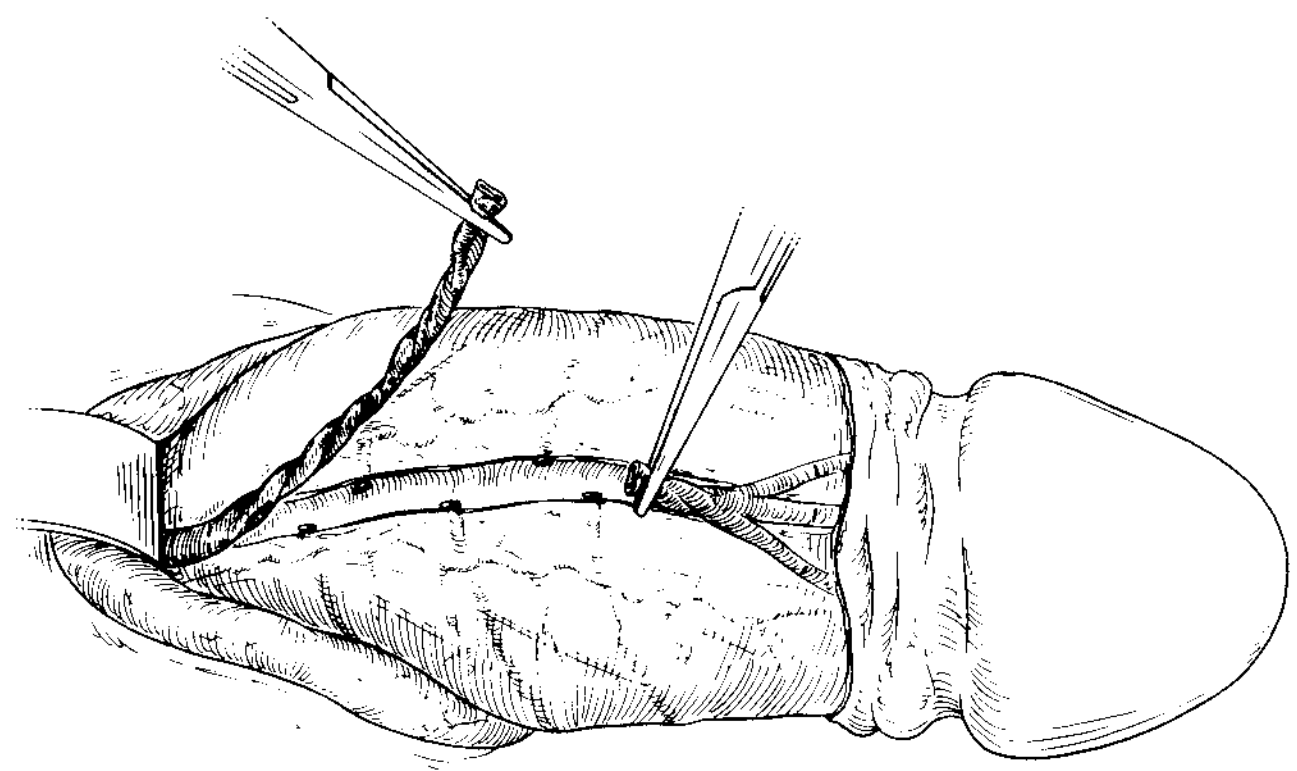

### Plaque Incision and Grafting

After incision and degloving, exposure for the incision of a dorsal plaque requires elevation of the dorsal neurovascular bundle concurrently with the Buck’s fascia. This can be approached by several techniques. One technique involves making bilateral incisions lateral to the corpus spongiosum and then dissecting the Buck’s fascia and the dorsal neurovascular bundle off the lateral and dorsal aspects of the corpora cavernosa. Alternately, a dorsal plaque can be approached through the bed of the deep dorsal vein with a modified vein dissection and excision.

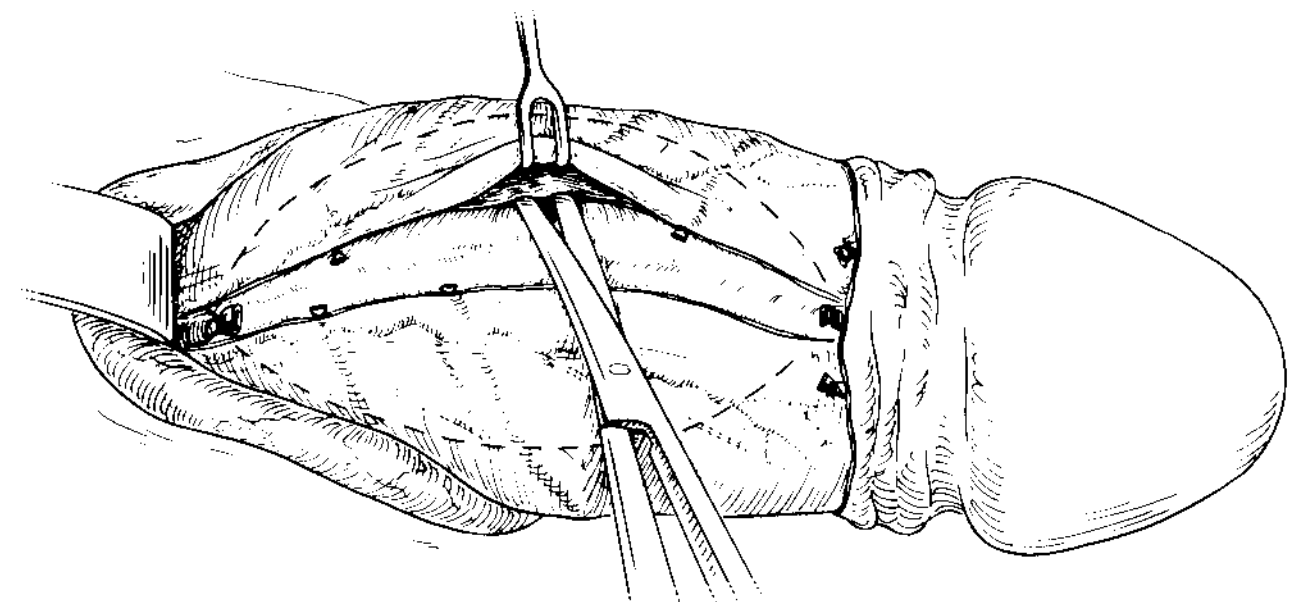

This is done by sharply opening the Buck’s fascia over the path of the deep dorsal vein to the level of the penopubic ligaments (Fig. 72.3). The dorsal vein is elevated and ligated as proximally as possible without detaching the penopubic attachments and then distally to the “trifurcation” of the vein (Fig. 72.4). The circumferential veins are ligated at their junction with the deep dorsal vein. The dorsolateral neurovascular structures are reflected off the tunica albuginea in concert

**FIGURE 72.3** Incision of the Buck’s fascia overlying the dorsal vein after penile degloving.

**FIGURE 72.4** Deep dorsal vein dissection and ligation.

**FIGURE 72.5** Elevation of the Buck’s fascia concurrently with the dorsal neurovascular structures.

with the inner lamina of the Buck’s fascia. The Buck’s fascia is widely mobilized from the base of the penis to the coronal margin and to the lateral aspect of the penis (Fig. 72.5). If necessary, the glans can be partially detached from the tips of the corporal bodies in order to expose distal dorsal plaques. Austoni E and Perovic S, Personal Communication, Peyronie’s Meeting, Washington, DC attended by Dr. Charles J. Devine, Jr., have both advocated penile disassembly for certain patients with Peyronie’s disease; however, the complication rate can be significantly higher. Approaching the dorsal plaque through the bed of the dorsal vein is our favored approach.

Once appropriately exposed, the extent of the plaque can be determined by palpating the surface of the tunica albuginea. After creation of an artificial erection, an H-shaped incision is marked at the point of maximal curvature (Fig. 72.6).

**FIGURE 72.6** An H-shaped incision marked at the point of maximal deformity.

**FIGURE 72.7** Incision of the tunica albuginea.

**FIGURE 72.8** Creation of a square defect in the tunica albuginea. Darting incisions are performed if indentation persists.

Once the incision is created, the “flaps” of the H are elevated and allowed to “slide” (Fig. 72.7). During this maneuver the thickened septal fibers are divided from their attachment to the tunica albuginea. Complete release of all of the thickened fibers appears integral to achieving good straightening. It is not necessary to remove thickened septal fibers, and it is unnecessary and potentially harmful to remove any spongy erectile tissue. A square defect is then created by suturing the flap corners into place with interrupted 4-0 polydioxanone sutures. If an indentation exists after corporotomy, darting incisions are made to allow for expansion of the defect (Fig. 72.8).

After the incision is completed, we measure the corporotomy defect with the penis flexed to ensure accurate graft coverage. The ideal graft material is not known. We have preferentially in the past used dermis at our institution (2). Alternatively, corporotomy defects can be patched with the saphenous vein (8) or the deep dorsal vein with good long-term results. Temporalis fascia, fascia lata, tunica vaginalis, and nonautologous pericardial grafts have also been described, as have small intestinal submucosa (Surgisis Biodesign, Cook Medical Inc., Bloomington, IN) grafts. Recently we have used the Surgisis Biodesign graft at our institution with good outcomes. A recent comparative report (7) was shown to be at least equivalent to the dermal graft. Tunica vaginalis lacks

tensile strength and is best applied to small defects. Prosthetic (e.g., Gore-Tex, silastic) grafts, historically, have tended to fibrose and contract. The authors feel that caution should be used when applying these “grafts” in the absence of concurrent prosthetic implantation.

The dermal graft is obtained from the nonhirsute area of abdominal skin located superior and lateral to the iliac crest (Fig. 72.9). The Surgisis Biodesign graft requires soaking when removed from the package. There is a “fuzzy side” and a smooth side. For no good reason, we have always placed the “fuzzy side” inward. By hyperflexing the penis, the graft is placed approximately 30% larger than the corporotomy defect in all dimensions.

Once tailored, the dermal graft or the Surgisis Biodesign graft is sewn into the corporotomy defect using interrupted 4-0 polydioxanone sutures followed by a running locked 4-0 polydioxanone suture (Fig. 72.10). An artificial erection is performed after graft placement to ensure a watertight suture line and an acceptably straight penis. Any leaks, if present, are oversewn. An obvious disadvantage, as opposed to “off-the-shelf grafts,” is the time necessary for graft harvest as well as donor site morbidity.

We have found that curvature can be corrected with a single incision and grafting in the majority of instances. Some patients will require an additional “touch-up” plication or in the rare case a second incision of the plaque. Incision as opposed to excision limits the size of the applied graft and may be more reliable in preserving erectile function (Dr. Friedhelm Schreiter, International Reconstructive Live-Surgery Congress, Genitourinary Reconstructive Surgeons Meeting, Hamburg, Germany, February 28-March 2, 1999). The penis is closed as described previously for surgical plication. We have also noted that in patients where erect penile length is not equivalent to stretched length, the Surgisis Biodesign graft may be more likely to inadequately correct the curvature as opposed to autografts.

Recently, we have modified our technique of “H incision” in an effort to more efficiently correct the curvature without the need for touch-up plications. The site of maximal curvature is identified and marked. However, a strip of tunica albuginea, a thick cross member of the H, is marked (Fig. 72.11). The H is incised with the flaps elevated and detached from the septal fibers as already described (Fig. 72.12). The strip of the H is excised and the flap sutured as already described (Fig. 72.13). The resulting corporotomy defect is grafted (Fig. 72.14).

## Plaque Excision and Grafting

Plaque excision (vs. incision) may be required in the patient with a severely calcified plaque. In this scenario the plaque is exposed as previously discussed. Prolene stay sutures are used to mark the plaque at the proximal and distal aspects. An incision outlining the plaque is made and the plaque is excised (Fig. 72.15). The corporotomy defect left by plaque excision is converted from ovoid to stellate by creating lateral incisions into the tunica albuginea (Fig. 72.16). Grafting and closure are then accomplished in the same manner as in the technique of plaque incision and grafting. In most cases the calcified plaque can be removed without excising the entire thickness of the tunica, and that is our favored approach.

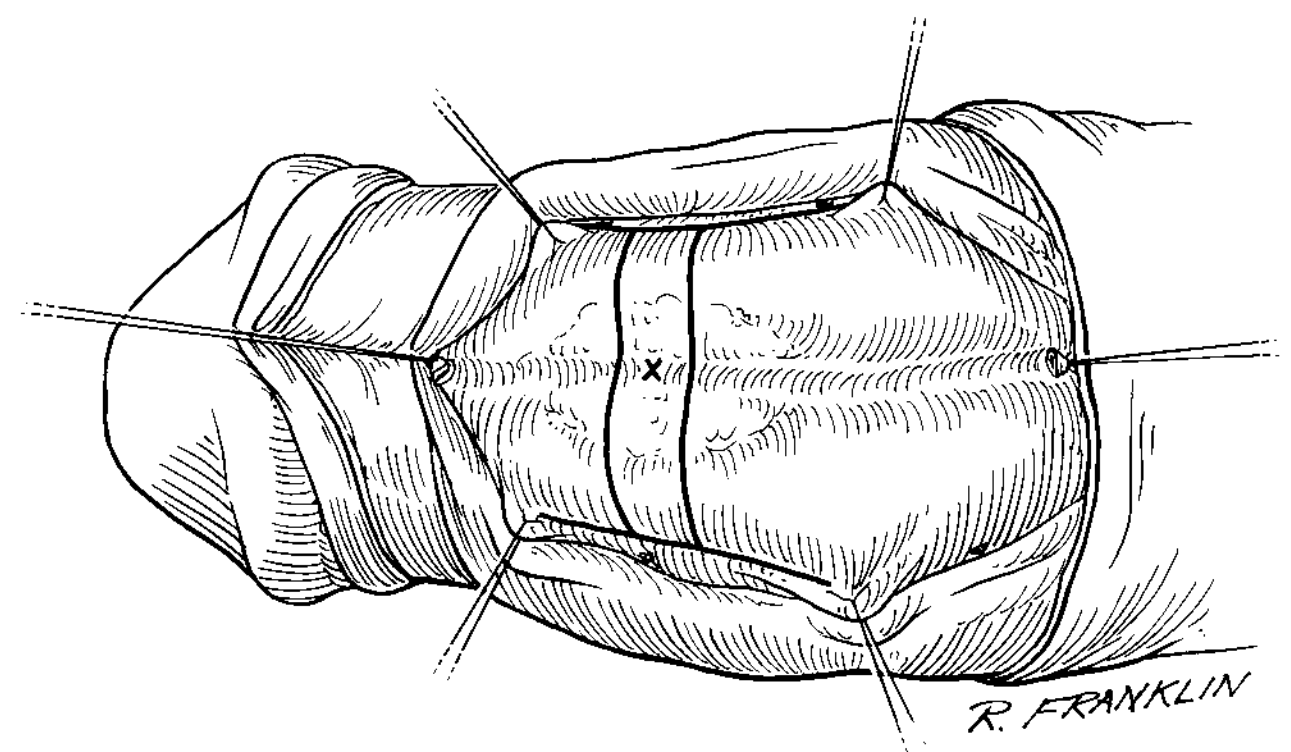

**FIGURE 72.9** Dermal harvest from the nonhirsute skin above the iliac crest.

## POSTOPERATIVE CARE

A loosely applied Bioclusive (Johnson & Johnson Medical Limited, Gargave, Skipton, UK) dressing is used to dress the penis. Mildly compressing Conform gauze dressing (Tyco Healthcare Group LP, Mansfield, MA) is wrapped around the Bioclusive to reduce edema and keep the surgical spaces collapsed around the suction drains. The compressing dressing is

**FIGURE 72.10** Watertight closure of the corporotomy after dermal graft.

**FIGURE 72.11** Modification of the sliding H technique, in which a small strip is excised at the point of maximal curvature. The stitch marks that point. (From Jordan GH. Peyronie's disease. In: Wein AJ, Kavoussi LR, Novick AC, et al., eds. *Campbell-Walsh urology*, 9th ed. Philadelphia: Saunders Elsevier, 2007:818–838, with permission.)

removed in 4 hours and the glans is checked every 30 minutes during this interval. A 14Fr Foley catheter is placed intraoperatively and left for 24 hours. The drains are, in general, removed on postoperative day 1 and the patient is discharged the same day. Erections are suppressed with diazepam and amyl nitrite for a short period postoperatively.

**FIGURE 72.12** The incisions are made; the H flaps are incised and elevated from the underlying erectile tissue. The septal fibers are divided. The septal fibers are detached back to the point of normal tunica albuginea both proximally and distally. This maneuver is extremely important in achieving straightening with this technique. Note the expansion of the corporotomy defect. (From Jordan GH. Peyronie's disease. In: Wein AJ, Kavoussi LR, Novick AC, et al., eds. *Campbell-Walsh urology*, 9th ed. Philadelphia: Saunders Elsevier, 2007:818–838, with permission.)

**FIGURE 72.14** Alternatively, the corporotomy defect can be replaced with a vein graft. Notice that the vein graft is oriented so that the circumferential distensibility allows long axial lengthening. (From Jordan GH. Peyronie's disease. In: Wein AJ, Kavoussi LR, Novick AC, et al., eds. *Campbell-Walsh urology*, 9th ed. Philadelphia: Saunders Elsevier, 2007:818–838, with permission.)

**FIGURE 72.13** The transverse strip is excised; the H flaps are then sutured. The flap can be darted if lateral expansion is needed. (From Jordan GH. Peyronie's disease. In: Wein AJ, Kavoussi LR, Novick AC, et al., eds. *Campbell-Walsh urology*, 9th ed. Philadelphia: Saunders Elsevier, 2007:818–838, with permission.)

After that, erections are felt to be beneficial and integral to good graft healing. Levine (13) and Moncado, Personal Communication at Experts in Urology Conference, London, England, June 12–16, 2007, are using a mechanical stretching device to distend the penis and graft postoperatively and are encouraged that the results seem better.

After 2 weeks, patients are encouraged to have erections but refrain from intercourse. At about 10 to 12 weeks postoperatively, patients may resume sexual intercourse.

**FIGURE 72.15** Excision of Peyronie plaque.

**FIGURE 72.16** Creation of stellate defect after plaque excision.

---

## OUTCOMES

---

A successful reconstructive procedure for Peyronie disease results in a satisfactory straightening of the penis such that any residual deformity does not interfere with sexual intercourse.

A second component of success is preservation of adequate erectile function. In our experience surgical success correlates linearly with preoperative erectile function (6). Patients with good erectile function have a surgical success rate in the range of 85%. Poor preoperative erectile function correlates strongly with a poor surgical outcome, and these patients may be best managed with prosthesis placement. The demonstration of corporal veno-occlusive dysfunction preoperatively seems to correlate strongly with diminished success (i.e., poor preservation of erectile function), particularly with grafting operations.

The ultimate goal of surgery is to resume satisfactory sexual intercourse by correcting penile curvature without further diminishing erectile function. With proper patient selection, surgical correction for Peyronie disease yields reliable results.

---

## COMPLICATIONS

---

Early postoperative complications include hematoma formation, wound infection, and persistent penile edema. Meticulous hemostasis with bipolar cautery, the use of small closed-suction drains, and careful tissue handling can minimize the risk of these complications.

Patients should be informed of the risk of experiencing a change in glanular sensation. This applies predominantly to those patients requiring dissection of the Buck's fascia dorsally. The vast majority of patients recover adequate glanular sensation, and it is unusual for persistent bothersome neuropathies of the glans to occur.

Late and chronic complications may include the risk of a bothersome granuloma ("lump") formation after the use of permanent sutures during a plication procedure. Recurrent disabling curvature is uncommon but may occur. Patients requiring grafting with dermis should be counseled that during the late phase of maturation the graft tends to contract and may be inelastic enough to recreate some of the curvature. Patients can be reassured that this is transient and that straightening will occur when the graft softens.

The most frequently encountered "complication" is that of diminished penile rigidity postoperatively. With plication procedures this occurs in approximately 5% to 6% of patients and with grafting procedures in approximately 12% to 15% of cases. Erectile dysfunction can occur as a consequence of surgery but may also represent the natural history of the patient. Many of these patients benefit from the addition of pharmacologic therapy to enhance their erectile function.

# CHAPTER 73 ■ PRIAPISM

TRINITY J. BIVALACQUA AND ARTHUR L. BURNETT

Priapism is defined as an erectile disorder in which erection persists uncontrollably without sexual purpose. This disorder is likely a result of disturbances in the mechanisms governing erection physiology as it relates to regulatory control of penile detumescence and initiation and maintenance of penile flaccidity. Priapism represents one of the greatest challenges in therapeutic management among erectile disorders. During a single episode of ischemic priapism, blood fails to drain from the corporal sinusoids, resulting in prolonged painful

erection. The pain associated with priapism is perceived to be a consequence of tissue ischemia and increased pressure generated within the corporal bodies. This condition frequently results in erectile dysfunction (ED), and therefore prompt management is indicated. The natural sequelae of untreated ischemic priapism or recurrent stuttering priapism is global penile fibrosis with significant impairments in erectile mechanisms, resulting in an overall rate of ED as high as 59% (1–3).

**FIGURE 73.1** Pie graphs demonstrating the percentage of (A) pediatric (<18 years) and (B) adult (>18 years) patients suffering from priapism.

Ischemic (venous, low-flow) priapism is more prevalent than nonischemic (arterial, high-flow) priapism. Ischemic priapism due to pharmacologic, hematologic, or neurogenic causes is a condition whereby there is a persistent, painful erection characterized clinically by absent cavernous blood flow. Failure to recognize this as an emergency and instigate immediate treatment may lead to corporal tissue ischemia or anoxia, fibrosis, and long-term ED. After 24 hours there is evidence of irreversible smooth muscle cell necrosis, destruction of the vascular endothelium, and exposure of the basement membrane with adherence of thrombocytes (4). Nonischemic priapism commonly follows an episode of trauma to the perineum or genitalia resulting in increased flow through cavernosal arteries, which leads to the formation of arteriocavernous shunts with increased well-oxygenated arterial flow into the cavernous tissue and may not need urgent surgical attention.

Priapism is associated with a number of diverse disease states, and a number of clinical contexts have risk associations for developing the disorder (1,5,6). Etiologic categories include trauma, neurological conditions (multiple sclerosis, spinal cord tumor with compression), hematologic dyscrasias (sickle cell anemia, thrombophilia, and thalassemia), malignancies, intracavernous injection therapy (prostaglandin E<sub>1</sub>, papaverine, and combination therapy), pharmacologic and drug exposure (psychotropic and antidepressant medications, and illicit drugs), and idiopathic circumstances (Fig. 73.1) (1). Urogenital carcinomas can cause priapism either by local invasion and growth into the adjacent tissue or by the hematogenous, lymphatic, or retrograde venous routes. Priapism associated with malignancy may be ischemic secondary to veno-occlusion or nonischemic secondary to high arterial blood flow.

In principle, ischemic priapism consists of an imbalance of vasoconstrictive and vasorelaxatory mechanisms, thus predisposing the penis to hypoxia and acidosis. In vitro studies have demonstrated that when corporal smooth muscle strips are exposed to hypoxic conditions, significant apoptosis results, and alpha-adrenergic stimulation fails to induce corporal smooth muscle contraction (7). Additional pathophysiologic

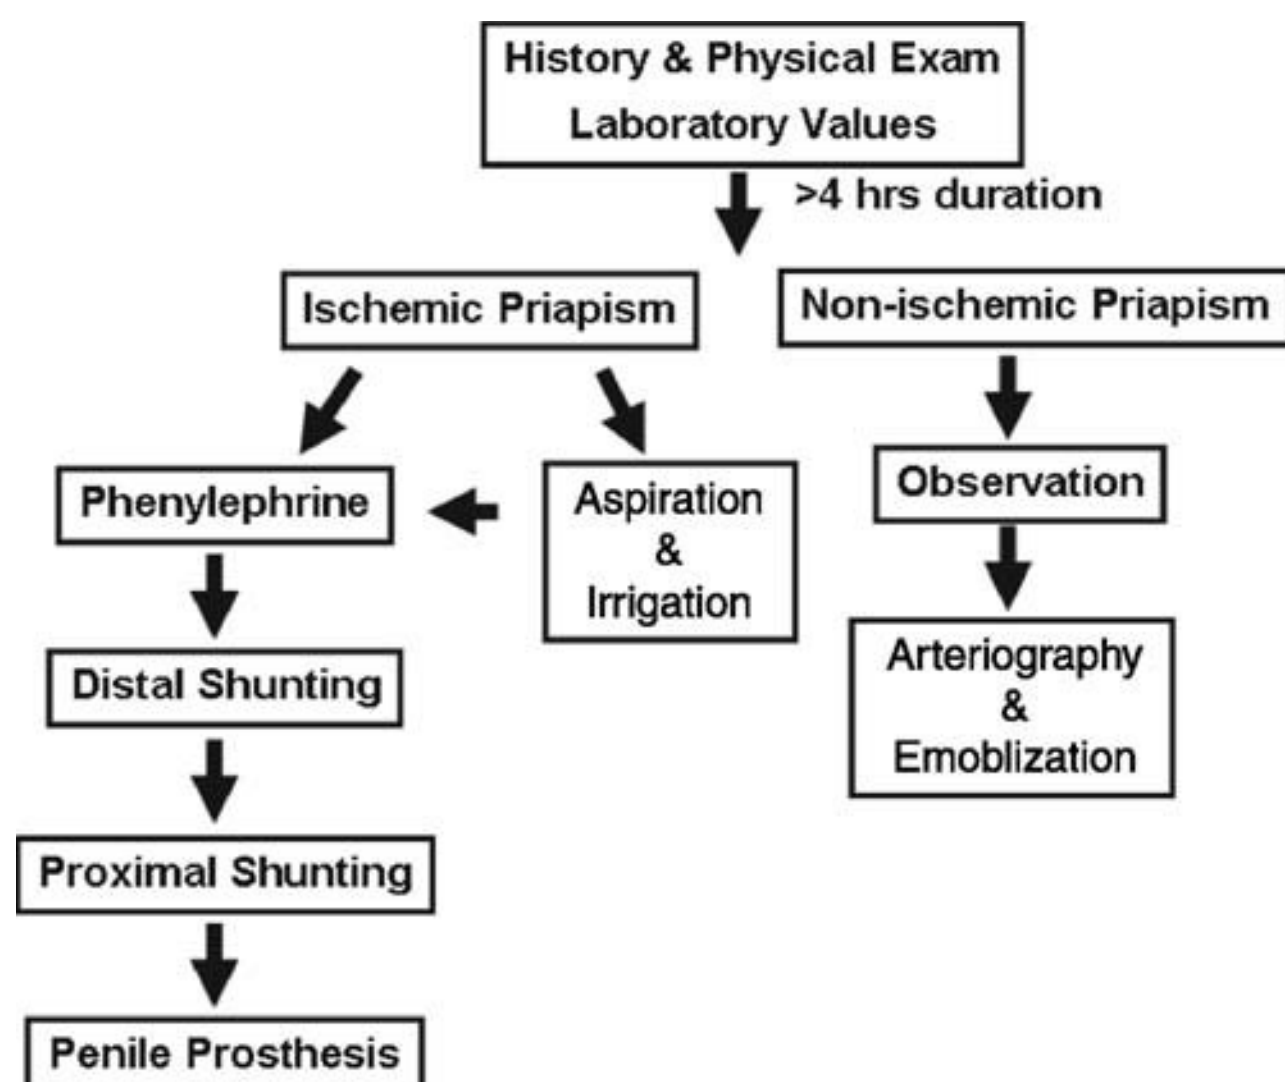

mechanisms involved in the progression of ischemia-induced fibrosis are the upregulation of hypoxia-induced growth factors such as transforming growth factor- $\beta$  (8). Recently, we have shown that recurrent priapism is a manifestation of defective phosphodiesterase type 5 (PDE5) regulatory function in the penis, resulting from altered endothelial nitric oxide and cyclic guanosine monophosphate (cGMP) signaling in the organ and recurrent priapism (9,10).

## DIAGNOSIS

The diagnosis and classification of priapism are based on clinical evaluation, including laboratory tests and corporal blood gas evaluation via aspirated blood directly from the corpora cavernosa. On initial evaluation, patients should have a detailed history and physical examination, with emphasis on possible causative factors (Fig. 73.2). Historical features should include the duration and previous episodes of priapism, a detailed medical and social history to evaluate for hematologic or neurologic conditions, and illicit drug use (cocaine). Physical examination should assess the penis and perineum, inspecting for any neurologic defects and pelvic or penile masses, and checking the perineum for evidence of recent trauma. Laboratory tests should include a complete blood count, reticulocyte count, and sickle cell anemia screen when appropriate, as well as urinalysis and urine toxicology.

Patients with significant sustained penile pain with a rigid penis and soft glans are more likely to have ischemic priapism, whereas patients with nonischemic priapism will have a semi-erect penis without pain. Corporal blood gas analysis will help delineate the type of priapism. Acidotic (pH <7.25, pO<sub>2</sub> <30 mm Hg, pCO<sub>2</sub> >60 mm Hg) penile blood gas indicates ischemic priapism, whereas a blood gas consistent with arterial blood gas (pH >7.4, pO<sub>2</sub> >90 mm Hg, pCO<sub>2</sub> <40 mm Hg) is suggestive of nonischemic priapism. To further determine the type of priapism, color duplex Doppler ultrasound may be

**FIGURE 73.2** Algorithm for the management of priapism. (Adapted from Montague DK, Jarow J, Broderick GA, et al. Members of the Erectile Dysfunction Guideline Update Panel; American Urological Association. American Urological Association guideline on the management of priapism. *J Urol* 2003;170:1318–1324.)

performed to evaluate cavernosal arterial inflow (1,11). No cavernosal artery flow is pathognomonic for ischemic priapism, whereas a ruptured cavernosal artery with unregulated arterial flow and blood pooling may be seen in the non-ischemic form of priapism. After the correct form of priapism is determined, then rapid medical and/or surgical intervention is a necessity. In ischemic priapism, definitive first-line treatment consists of evacuation of blood and irrigation of the corpora cavernosa along with intracavernous injection of an alpha-adrenergic sympathomimetic agent before initiating any surgical treatment (Fig. 73.2). If the diagnosis of nonischemic priapism is confirmed by ultrasound imaging, then embolization of the ruptured cavernous artery angiographically may be indicated after initial observation and supportive therapy (Fig. 73.2).

## INDICATIONS FOR SURGERY

The goal of therapy is to relieve pain and decompress the corporal bodies, thus reducing anoxia and the risk of tissue necrosis or injury. Ischemic priapism of  $>4$  hours warrants decompression of the corpora cavernosa. One can proceed earlier if a patient is in severe pain, but action *must* be taken if 4 hours have elapsed (Fig. 73.2). Typically, if treatment is delayed, tissue injury and risk for development of ED may occur. A dorsal nerve block or local penile shaft block with lidocaine is usually performed. Then, a scalp vein needle (19- or 21-gauge) is inserted directly in the penile shaft for therapeutic aspiration of old blood and injection of alpha-adrenergic agonists (sympathomimetics) (5,6). Hemodynamic monitoring is recommended to monitor potential side-effects, such as hypertension, headache, reflex bradycardia, tachycardia, and cardiac arrhythmia, which may result from medication entry into the systemic circulation. The alpha-1 selective agonist

phenylephrine is preferred for this application since it minimizes the risk of cardiovascular side-effects. Phenylephrine in a dose of 100 to 200  $\mu\text{g}$  is injected via the same needle into the corpora cavernosa and observed for 5 minutes.

If the penis is still rigid, then aspiration of blood and injection of phenylephrine (100 to 200  $\mu\text{g}$ ) is performed until detumescence occurs. If the penis remains tumescent after a reasonable duration and dose escalation of phenylephrine (1 mg of diluted phenylephrine  $>1$  hour), then another Doppler ultrasound can be performed to evaluate the status of cavernosal arterial flow in the penis. Re-evaluation may be warranted at this time because the penis may simply be edematous with restored corporal arterial flow and not in a persistent ischemic state. It is recognized that ischemic priapism of extended durations, that is,  $>48$  hours, is unlikely to resolve with intracavernous injection or irrigation therapy; therefore, surgical shunting should be performed in a timely manner.

## ALTERNATIVE THERAPY

Aspiration or irrigation in combination with intracavernous injection therapy represents first-line therapy in patients with underlying etiologic disorders such as sickle cell anemia and other hematologic disorders, metastatic neoplasia, or other causes having standard treatments. For priapism related to sickle cell disease, medical therapies such as intravenous hydration, oxygenation, alkalization, and exchange transfusion may be performed. However, these interventions should not lead to delays in intracavernous therapies directed at the end organ. The use of antiandrogens or gonadotropin-releasing hormone agonists is successful for the treatment of recurrent stuttering priapism. The use of sympathomimetic intracavernous injection therapy with phenylephrine is also successful in patients with stuttering priapism. The use of other agents such as baclofen and digoxin is less efficacious.

## SURGICAL TECHNIQUE

Surgical management of ischemic priapism represents a surgically created fistula that allows blood to drain from the corpora cavernosa until the penile compartment syndrome has subsided. Ideally, the surgically created fistula will spontaneously close after the priapic event has resolved. Before proceeding to distal corporoglanular surgical shunt procedures, the placement of needles into the corpora cavernosa distally and proximally at the penile crura with the patient in lithotomy position offers an approach for maximally irrigating the corporal bodies. Distal corporoglandular shunts represent the first-line surgical therapy because they are easy to perform and have fewer complications (Fig. 73.2) (1,11,12).

### Corporoglanular (Winter) Shunt

Under local or general anesthesia, a penile-glans block is performed to ensure adequate local anesthesia. The tips of the rigid corpora cavernosa are palpated, and a large biopsy needle

**FIGURE 73.3** Corporoglanular (Winter) shunt. A needle is placed through the glans penis into the corpora cavernosa in order to make multiple core biopsy windows or fistulas between the glans and each corporal body. (Adapted from Burnett AL. Priapism. In: Wein AJ, Kavoussi LR, Novick AC, et al., eds. *Campbell-Walsh urology*, 9th ed. Philadelphia: Saunders Elsevier, 2007:839–849.)

is inserted through the glans into the corpus cavernosum several times (1,11,12). This results in multiple core biopsy windows or fistulas between the glans and each corporal body (Fig. 73.3). Several biopsy core fistulas are necessary to create enough communicating channels to cause detumescence. The puncture site is closed with a figure-of-eight 3-0 chromic suture. The patient is instructed to squeeze the penis every few minutes for the next 12 hours to lessen blood pooling in the penis. If partial (>50%) erection persists, the procedure is repeated or an alternative shunt is used. An adequate result is evidenced by swelling of the glans and detumescence.

### Corporoglanular (Ebbehoj and T-) Shunt

The Ebbehoj shunt procedure involves the use of a no. 11 blade scalpel passed percutaneously several times through the glans into the corpus cavernosum (1,11,12). This results in several larger fistulas between the glans and each tip of the corpus cavernosum. The scalpel blade is inserted into the corpora away from the urethral meatus and pulled back to create an opening in the tunica albuginea between the glans and corporal bodies. A modification of the Ebbehoj shunt is the T-shunt procedure (1,11,12). A no. 10 blade scalpel is placed vertically through the glans penis into the corpus cavernosum. The scalpel is then turned 90 degrees away from the urethra and pulled out. This maneuver creates a T-shaped opening in the tunica albuginea. Both of these shunts can be performed unilaterally or bilaterally if necessary. In theory, this T-shunt should provide a large enough fistula between the corpora cavernosa and spongiosal tissue of the glans for detumescence. Closure of the defects in the glans is performed using 3-0 chromic sutures, especially for the T-shunt.

**FIGURE 73.4** Corporoglanular (Al-Ghorab) shunt. An incision is made dorsally into the glans penis, and portions of the distal corpus cavernosum are excised as a vent for blood drainage. (Adapted from Burnett AL. Priapism. In: Wein AJ, Kavoussi LR, Novick AC, et al., eds. *Campbell-Walsh urology*, 9th ed. Philadelphia: Saunders Elsevier, 2007:839–849.)

### Corporoglanular (Al-Ghorab) Shunt

If the previous percutaneous distal shunts are unsuccessful, then an Al-Ghorab shunt is performed (1). Typically, distal shunts fail because a large enough window between the priapic corpora cavernosa and corpus spongiosum does not exist (Fig. 73.4). This shunt is usually done under general anesthesia in combination with a penile-glans block. A tourniquet is placed around the penis. A 2-cm transverse incision is made on the dorsum of the glans 1 cm distal to the coronal sulcus. A transverse incision is not recommended in the distal penile shaft proximal to the corona because this incision may cut sensory nerves to the dorsal aspect of the glans and possibly cause distal atrophy. The tips of the corpora cavernosa should be separated from the glans and transfixed with 2-0 sutures or grasped with a Kocher clamp so that they will not withdraw during detumescence, and a circular cone segment of tunica albuginea approximately 5 by 5 mm should be sharply excised from each corporal body. Dark blood will drain from the corporal bodies, and once detumescence occurs, then reapproximation of the skin with 3-0 chromic sutures is performed. Care is taken not to obliterate the spongy vascular space of the glans penis.

### Corporospongiosal Shunts

A proximal corporospongiosal shunt is performed in rare circumstances (1,11,12). When distal shunts are unsuccessful or technically unachievable, then a proximal shunt may be performed to re-establish blood drainage and thus produce penile detumescence. However, these surgical maneuvers are often ineffective, lead to significant ED, and have a number of potential complications. For the Quackel or Sacher shunt, the

**FIGURE 73.5** Quackel or Sacher shunt, a proximal cavernospongiosal (corporospongiosal) shunt procedure. Openings are placed in a staggered fashion connecting a cavernosum and spongiosum bilaterally for blood drainage.

patient is placed in lithotomy position and the bulbocavernosus muscle is dissected off the corpus spongiosum. A longitudinal incision or excision of 1-cm-long ellipses of tissue is made in the spongiosal and corporal bodies (Fig. 73.5). Care is taken to avoid incising the urethra, which would result in a fistula. The incisions or excisions are made in close proximity to each other in order to suture the defects together. The walls of the two openings in the spongiosum and corpora are sewn together in a running fashion using 5-0 polydioxanone suture. It may be necessary to perform bilateral shunting procedures if detumescence is not satisfactory. This technique involves staggering positions of the proximal shunts on the spongiosal and corporal bodies to avoid urethral fistulas.

---

### Corporo–Saphenous Vein Shunt

---

The Grayhack shunt is rarely performed due to the technical difficulties of the surgical approach and lack of efficacy and complication rate (1,11,12). For this shunt, an incision is made at the penile base and the tunica albuginea of the corpus cavernosum is exposed. Next, the femoral artery is palpated and an incision is made at the saphenofemoral junction, which is approximately 3 to 4 cm below the inguinal ligament. The saphenous vein is identified and mobilized for a distance of approximately 10 cm distal to the fossa ovalis. The surgeon ligates the vein distally and burrows beneath the skin with the index finger to join the two incisions. An ellipse of tunica albuginea 1.5 by 0.5 cm is excised, and the vein is drawn without tension or torsion into the penile wound; then the vein is

spatulated and anastomosed to the tunica albuginea using a continuous 5-0 polydioxanone suture. A dry dressing is applied, and a standard protocol of intermittent squeezing is recommended.

---

### Corporo–Deep Dorsal Vein Shunt

---

As with the previous two shunts, the Barry shunt is a last resort for a patient with severe priapism refractory to distal shunt maneuvers (1,11,12). With this shunt, a 4-cm skin incision is made at the base of the penis. The superficial or deep dorsal vein is identified, taking care not to injure the dorsal artery or sensory nerves. The vein is ligated distally and divided. The proximal limb is spatulated on its ventral surface and anastomosed to the corpora cavernosa end-to-side in a tension-free manner. The penile skin is replaced and sutured at the base.

---

### Nonischemic Priapism

---

The initial management of nonischemic priapism is observation. The diagnosis is confirmed by detecting high flow or the site of rupture with color duplex Doppler imaging in combination with normal arterial blood gas analysis. Spontaneous resolution of untreated nonischemic priapism occurs in >50% of patients. Therefore, the patient is advised about chances for spontaneous resolution, complication risks after treatment (ED, abscess, neurological sequelae), and lack of significant adverse consequences resulting from delayed therapy for many months. Early presentation of nonischemic priapism can be managed with ice or pressure packing to cause vasospasm and thrombosis of the ruptured artery to efficiently close the fistula. If the fistula does not close, selective angiographic arterial embolization may be needed. This should be performed in concert with interventional radiology. Use of nonpermanent materials is associated with less ED rates postprocedure (5% vs. 39% with permanent substances); therefore, these biomaterials are preferred. If angiographic embolization fails, then penile exploration and direct surgical ligation of sinusoidal fistulas or pseudoaneurysms may be performed with the assistance of intraoperative color duplex ultrasonography.

---

## OUTCOMES

---

### Postoperative Management

---

After shunt procedures the patient should receive perioperative and postoperative antibiotics. It is important to avoid circular pressure dressings that may compromise the shunt and decrease venous drainage. Intermittent manual squeezing and milking of the penis will help keep the shunt open and prevent recurrence of priapism. The penis often still appears partially erect after shunting procedures due to postischemic hyperemia. Color duplex Doppler imaging may be performed to document penile vascular arterial blood flow status if desired after corporoglanular and proximal shunts. Additionally, intracavernosal pressure monitoring may help evaluate the effectiveness of the shunt procedures.

---

## Perspective

---

The most common complication of priapism is complete ED, which has been reported as high as 59% (2,3). The most critical factor in maintaining potency is immediate treatment of men presenting with priapism. Patients treated within 12 to 24 hours will more likely have a favorable response than those with delayed treatment. Patients with prolonged priapism (>36 hours) and recurrent episodes are more likely to suffer ED as a result of impaired smooth muscle function and fibrosis. This group of patients will ultimately proceed to a penile prosthesis because pharmacologic erectogenic therapy will fail. Nonischemic priapism has the best prognosis in the preservation of erectile function.

The Grayhack and Barry shunts are less efficacious in reducing priapism, perhaps due to the small-caliber size of the veins, especially regarding the Barry shunt. These are historical

procedures proposed to alleviate severe priapic events and in practice have not been as successful as expected. Therefore, corporoglanular and corporospongiosal shunt procedures are preferred.

---

## COMPLICATIONS

---

Complications associated with shunt procedures are urethral damage and fistulas, bleeding, purulent cavernositis, skin necrosis, abscess, and pulmonary embolus after the Grayhack procedure. Since most shunts appear to close in time, it is believed that shunting does not cause permanent ED. However, failure of venous shunts to close spontaneously will lead to venogenic ED. Penile vascular dysfunction after shunt procedures may be a direct result of the repeated and prolonged priapism itself with significant fibrosis of the erectile compartments.

# CHAPTER 74 ■ PENILE PROSTHESIS IMPLANTATION

CULLEY C. CARSON

While erectile dysfunction has been described since ancient times, adequate treatment has only been available for the last four decades. The era of implantable devices began with the development of silicone-based prosthetic materials in the late 1960s as a result of the U.S. space program (4). Modern penile prosthetic devices were first developed in the early 1970s when Small et al. (6) along with Scott et al. (5) reported the implantation of penile prosthetic devices into the corpora cavernosa to fill the corpora cavernosa and provide a physiologically functional erection with good cosmetic results. These devices have undergone multiple revisions and redesigns

between the early prosthetic devices and the currently implanted inflatable penile prostheses. Mechanical malfunction rates in these early devices, however, were reported in excess of 60% of cases. Current inflatable prosthetic devices have a far more improved mechanical reliability. These current devices can be divided into semirigid, mechanical, and multiple-component inflatable penile prostheses, of which there are two- and three-piece models available.

The semirigid rod and mechanical prostheses available today are the successors of the devices designed in the 1970s (Table 74.1). These devices, while easier to implant, have few

TABLE 74.1

## AVAILABLE PENILE PROSTHESES

Semirigid rods	Inflatable
AMS 600 (AMS)	700 CX (AMS)
Malleable (Coloplast)	700 LGX(AMS)
Dura II (AMS)	Alpha 1 (Coloplast)
	Ambicor (AMS)

advantages over the newer inflatable devices because infection and mechanical malfunction rates are similar. The semirigid devices consist of a central metal core and a silicone elastomer rod, whereas the mechanical Duraphase implant is a series of disks held in position by a central cable. The latter design facilitates positioning of the implant between uses.

The three-piece inflatable penile prostheses vary in construction from three-layer silicon, Dacron, Lycra, or silicone to a single layer of silicon or Bioflex (Fig. 74.1). Options include girth expansion and/or length elongation. Aneurismal dilatation is rare with both of these cylinder designs, but it has been reported. Similarly, other design changes—including replacement of stainless steel connectors with plastic connectors, addition of nonkinked tubing, single design construction, Teflon cylinder input sleeves, and multiple-layer cylinders—have improved the longevity of these devices. These modifications have decreased mechanical malfunction rates from  $>30\%$  to  $<5\%$ . The most significant recent advance is the coating of three-piece implants to reduce infection risk.

The three-piece inflatable penile prostheses continue to be the most satisfactory prostheses once they are implanted and while they remain functional. These prosthetic devices produce the most natural-appearing erection in girth and length,

**FIGURE 74.1** American Medical Systems' AMS 740CX three-piece inflatable penile prosthesis.

**FIGURE 74.2** American Medical Systems' Ambicor two-piece inflatable penile prosthesis.

with satisfactory rigidity and excellent flaccidity for optimal concealment. They also have advantages for many patients with complex penile implantations because the flaccid position removes pressure from the corporal cavernosa and decreases the possibility of erosion in these highly difficult implantations.

To improve the ease of surgical implantation by removing a portion of the prosthesis placed within the abdominal region, two-piece prostheses were designed (Fig. 74.2). Because these two-piece inflatable prostheses remove the separate reservoir, additional fluid is available either by a larger scrotal pump or a combination of a proximal cylinder and pump reservoir. Although these devices provide adequate erection in many patients, the limited reservoir capacity decreases flaccidity and may, in some patients, diminish rigidity. These prostheses are especially difficult to deflate in patients with small penises and frequently provide inadequate rigidity in patients with longer penises. While less optimal than three-piece devices, these two-piece implants may be ideal for patients in whom reservoir placement is difficult or contraindicated. Such patients as renal transplant recipients and patients who have undergone significant radical pelvic exenteration procedures may benefit from two-piece devices.

---

## DIAGNOSIS

---

The diagnosis of erectile dysfunction can be obtained by history. The clinician should determine whether the erectile dysfunction is situational or constant, whether the degree of dysfunction is partial or total, and also include the details of the relationship with the partner. Any coexisting conditions such as diabetes, vascular disease, smoking, medications (especially steroids, hormones, antihypertensives, or antidepressants), and use of alcohol or drugs should be identified. Physical examination should include the genitalia, including the testes, hair distribution, femoral and distal lower-extremity pulses, and the penis for Peyronie plaques or other abnormalities. Nocturnal tumescence studies, cavernosometry, cavernosography, and penile Doppler are useful in some patients in securing the diagnosis.

## INDICATIONS FOR SURGERY

Although there are a variety of penile prosthesis designs currently available for implantation, not all patients with erectile dysfunction are candidates for penile prosthesis implantation. Penile prostheses are generally the procedure of last resort for those men failing more conservative measures such as oral PDE5 inhibitors, vacuum erection device, urethral alprostadil, and cavernosal injection therapy. For those men in whom penile prostheses are suggested, careful counseling before penile implant procedures will limit many of the problems with post-operative dissatisfaction. Once the discussion and demonstration of penile implant varieties have been carried out, patients can be counseled about the most appropriate penile prosthesis for their individual use. Patients may choose a specific prosthetic type based on their needs and preferences (1). Younger patients with normal manual dexterity and patients who wear stylish, form-fitting, athletic clothing or who shower in public at a health club or other athletic facility often choose a three-piece inflatable penile prosthesis because appearance in the flaccid position is better than with other designs. For these patients, implantation of a semirigid rod penile prosthesis requires a significant lifestyle change, and they are better served with an inflatable-type prosthesis. Similarly, patients with Peyronie disease, secondary implantation, or significant peripheral neuropathy such as occurs in severe diabetes are best served with an inflatable penile prosthesis because interior tissue pressures are diminished between uses and the possibility of extrusion is diminished.

For patients in whom the convenience of inflation and deflation is not important, the risks and mechanical malfunctions may outweigh the disadvantage of a malleable penile prosthesis (Fig. 74.3). Such patients as paraplegics who require an external urinary collection device, those with inadequate manual dexterity, or those with significant obesity may be better served with a malleable penile prosthesis.

## ALTERNATIVE THERAPY

Alternative therapy includes sexual counseling, vacuum erection devices, intracavernosal injection therapy, intraurethral medication, or oral PDE5 inhibitor medications. Less commonly used therapies include penile vascular (arterial or venous) surgery.

**FIGURE 74.3** American Medical Systems' AMS 600 malleable penile prosthesis.

## SURGICAL TECHNIQUE

Surgical implantation of penile prostheses can be carried out using a variety of surgical approaches and incisions. Semirigid and malleable prostheses can be implanted through a distal penile approach. Multiple-piece prostheses, however, can be implanted by the infrapubic or penoscrotal approach. While individual surgeons have a variety of rationales for each of these approaches, there does not appear to be any clear advantage in patient satisfaction or outcome between the two approaches. Patient anatomy may dictate appropriate choice. Patients with previous abdominal surgical procedures where reservoir placement is difficult may be better served with an infrapubic approach, whereas patients with massive obesity may be better approached through a penoscrotal incision. Two-piece devices, because there is no separate reservoir, are best implanted through a penoscrotal incision.

### Distal Penile Approach

A distal penile approach is usually the best approach for insertion of a semirigid or mechanical penile prosthesis. This incision heals well, allows complete corporeal dilation, and facilitates rod placement. After placement of a Foley urethral catheter, a circumcoronal incision is carried out  $>180$  degrees of the subcoronal region of the penis. Dissection is carried down to the layer of the Buck fascia, taking care to avoid the dorsal penile nerves, which course within the Buck fascia. After the Buck fascia is identified, stay sutures are applied to the two corpora through the tunica albuginea lateral to the penile nerves. These longitudinal incisions can be extended as much as is necessary for dilation and cylinder insertion. The corporal dilation is begun with Metzenbaum scissors to establish a track in the corporal tissue. Dilation then follows with Hegar, Brooks, or Dilamezinsert dilators to 9 to 11 cm, depending upon the required cylinder girth (Fig. 74.4). Once the corpora are sized using a Furlow or other dilator, the cylinders can be placed (Figs. 74.5 and 74.6). A small vein retractor can be used to facilitate placement of the distal end of the cylinder. The corporotomy is closed with 2-0 absorbable, synthetic sutures. With noninflatable cylinders, a penile block can be performed and a noncompression dressing is applied.

**FIGURE 74.4** Corporal dilation using Brooks dilators.

**FIGURE 74.5** Prosthesis cylinder loaded onto Furlow inserter and placed into the corporal tunnel.

### Infrapubic Approach

The infrapubic approach allows better visualization of the reservoir placement than the penoscrotal approach. However, because of the proximity of the dorsal neurovascular bundle in the infrapubic approach, injury is possible, resulting in decreased distal penile sensation in some patients. The infrapubic approach is usually carried out with a horizontal incision approximately one fingerbreadth below the symphysis pubica, allowing implantation with an easily concealed incision once the pubic hair regrows (Fig. 74.7). In patients with significant obesity or a previous midline incision, however, a midline incision carried out just to the base of the penis facilitates exposure of the corpus cavernosum and improves ability for corpus

cavernosum dilation. After incision of the subcutaneous tissue, the dissection is continued to the rectus fascia. The rectus fascia is incised horizontally and dissected cephalad for approximately 2 to 3 cm. A midline separation of the rectus muscles is carried out using sharp and blunt dissection. A pouch is created bluntly beneath the rectus muscles to comfortably insert the inflatable reservoir without compression (Fig. 74.8).

**FIGURE 74.7** Infrapubic incision for prosthesis implantation.

**FIGURE 74.6** Placement of proximal cylinder base.

**FIGURE 74.8** Blunt dissection establishes a location for the pump device.

**FIGURE 74.9** Corporotomy incision between two stay sutures, avoiding the dorsal neurovascular bundles.

Dissection is then carried out over the corpora cavernosa. Sharp and blunt dissection is begun on either side of the fundiform ligament identifying the dorsal neurovascular bundle. Note that the dorsal nerves of the penis lie approximately 2 to 3 mm lateral to the deep dorsal vein. Once the Buck fascia has been dissected free from the tunica albuginea, the shiny white tunica albuginea is fixed with traction sutures. A corporotomy incision is then carried out between the traction sutures and the corpora cavernosa entered (Fig. 74.9). The corporotomy incision can be carried out with scalpel or electrocautery. Metzenbaum scissors are then used to carefully initiate the tunneling of the corpora cavernosa, gently spreading the cavernosal tissue both proximally, until the ischial tuberosities and crura of the corpora are encountered, and distally, palpating the glans penis to identify the distalmost aspect of dilation. Hegar dilators from size 9 to 12 or Brooks, Pratt, or Dilamezinsert dilators can be used. If corporeal fibrosis is encountered, Rosillio cavernatomers can be used to dilate to size 12. Once dilation has been adequately carried out bilaterally, the Furlow introducer or Dilamezinsert is used to measure the corpora cavernosal length using a traction suture as a central point of reference. The proximal and distal measurements are added to identify total corporal length and obtain appropriately sized inflatable cylinders. A length slightly less than measurement is usually obtained to permit comfortable positioning of the cylinders. Rear tip extenders of size 0.5, 1.0, 2.0, or 3.0 cm or combinations thereof are placed on the proximal cylinder end to adjust length. Once measurement has been obtained, interrupted sutures can be placed for later corporotomy closure. The advantage to this technique is the elimination of suture needles close to the area of the inflatable cylinder, diminishing the possibility of cylinder damage during corporotomy closure. Other methods of corporotomy closure include running sutures with or without a locking technique. Once the corporotomy sutures are placed, cylinders are positioned in the dilated corpora cavernosa using the inserting tool with distal needle to pull the cylinders into position. Once positioned, it is essential to visualize the cylinder in the corpus

**FIGURE 74.10** Device in place with connections complete.

cavernosum to ensure that there is no kinking and that complete proximal and distal seating has taken place (Fig. 74.10). The corporal incision should be placed proximal enough to allow easy exit of the input tube and minimize contact between the cylinder and input tube. Closure of the corpora cavernosa is carried out with traction on the cylinder placement suture to maintain it in a flat, nonkinking position and ensure adequate seating. Following placement of cylinders and closure of the corporotomy incision, cylinder inflation can be tested by placing fluid in each of the cylinders through the input tubes, gently inflating the prosthesis to identify any abnormalities in position, curvature, or other problems.

A finger is then placed in the most dependent portion of the scrotum lateral to the testicle on the right or left side. The finger is then pushed to the area of the external inguinal ring, and any adipose tissue in this area is dissected free to expose the dartos fascia. The dartos fascia is thoroughly cleaned to allow pump placement. Following development of this subcutaneous pouch for the pump, the pump is positioned in the most dependent portion of the scrotum and temporarily fixed into position using a Babcock clamp. The inflatable reservoir is then placed in the previously constructed subrectus pocket and filled with an appropriate volume of normal saline or water/radiographic contrast media. Before connection, it is important to release pressure on the filling syringe and determine if any backfilling is seen. This backfilling or backpressure may predict autoinflation in the postoperative period. Tubing connection is then carried out using quick connectors or suture tie plastic connectors. The snap-on connectors are used for Mentor prostheses. In a redo prosthesis in which a residual tubing segment is connected to a new device piece, suture tie plastic connectors must be used. The tubing is tailored prior to connection to allow for adequate pump positioning is carried out prior to connection. Shodded clamps are used to compress the tubing, and the ends of the tubing, once tailored, are flushed with inflation fluid to eliminate small particles and blood clots. After the tubing is connected, the adequacy of the connection is tested by gently pulling on the connectors. All shodded clamps are removed and the device is inflated and deflated on multiple occasions to ensure adequate location, placement, and erection.

Following testing, thorough irrigation with antibiotic solution is carried out and the rectus fascia closed with interrupted sutures. The wound is then closed in the standard fashion with

two layers of subcutaneous tissue and a subcuticular skin suture. A dry sterile dressing is applied, a Foley catheter placed if necessary, and an ice pack applied. Suction drains could be used at the surgeon's discretion.

Postoperatively patients are instructed to maintain their penis in a Sutherland position for 4 to 6 weeks. Tight underwear and athletic supporters are not used in an effort to maintain the pump in its most dependent position.

### Penoscrotal Approach

Three-piece inflatable penile prostheses, as well as semirigid and two-piece prostheses, can be implanted by a transverse or vertical penoscrotal incision. This approach has distinct advantages in obese patients and is the most common approach for routine penile prosthesis implantation. Because the penoscrotal approach requires differentiation of the corpora cavernosa from the corpus spongiosum during resection, initial placement of a Foley catheter is necessary for this approach. The incision is placed in the upper portion of the scrotum and is usually horizontal, one fingerbreadth below the penoscrotal junction. The Scott/Lone Star retractor (Lone Star Medical Products, Stafford, TX) facilitates exposure with this incision. Once the skin incision has been carried out, dissection is continued lateral to the corpus spongiosum and urethra to expose the corpora cavernosa. Incision, dilation, and closure of the corpora cavernosa are similar to those described previously for the infrapubic incision, but synthetic absorbable sutures must be used with this approach because the suture line may be palpable postoperatively (Fig. 74.11). Cylinder sizing and placement are as described above. Pump placement is likewise in the most dependent portion of the scrotum just above the dartos fascia, with positioning using a Babcock clamp.

**FIGURE 74.11** Penoscrotal incision with exposure of corpora cavernosa.

**FIGURE 74.12** Reservoir placement with penoscrotal approach.

Dissection for reservoir placements can be carried out with a second separate infrapubic incision but is more commonly performed through the penoscrotal incision (Fig. 74.12). The scrotal skin incision is retracted to the area of the external inguinal ring, and dissection is carried out medial to the spermatic cord. The transversalis fascia is identified and incised sharply using Metzenbaum scissors placed firmly against the pubic tubercle. Dissection is carried out using a combination of sharp and blunt dissection. Dilation is carried out with the index finger after incision of the transversalis fascia and with gentle blunt dissection using a large Kelly clamp. The reservoir balloon is then positioned over the index finger and placed in the perivesical space. Inflation of the reservoir is carried out with care that no backpressure is observed. If refilling of the syringe occurs, the reservoir is removed and reservoir pocket enlargement must be carried out. Once the reservoir is placed and inflated and the tubing is connected as previously described, the device is tested in inflation and deflation (Fig. 74.13). Closure is carried out with a subcuticular suture in the standard fashion. In men with a penoscrotal skin web, the horizontal skin incision can be closed in a midline fashion to enhance functional penile length.

Perioperative antibiotic treatment is critical in diminishing the incidence of perioperative infection and prosthetic removal. The Inhibizone (American Medical Systems, Minnetonka, MN) coating consisting of rifampin and minocycline or the lubricious coating of the Titan implant (Coloplast Inc, Minneapolis, MN), which allows antibiotics to adhere to the Bioflex, has reduced infection risk by threefold. An initial perioperative dosage of an antibiotic agent effective against the most common infectious pathogens should be administered 1 to 2 hours prior to surgery and continued for 24 hours postoperatively. The choice of an aminoglycoside with a first-generation cephalosporin, ampicillin/sulbactam, a cephalosporin alone, vancomycin, or a fluoroquinolone is appropriate for prophylaxis of the most common

FIGURE 74.13 Pump placed for penoscrotal approach.

infections from *Staphylococcus epidermidis*. Patients may be discharged for 7 days of continued antibiotic therapy. The use of antibiotic-coated penile implants, while reducing the incidence of postoperative infection, does not preclude the need for systemic, perioperative antibiotics. The penile prosthesis remains deflated for 4 weeks while healing occurs. Prior to activation, the patient is advised to retract the pump into his scrotum on a daily basis, and tight underwear and athletic supports are avoided to maintain pump position. A return office visit for activation of the device is carried out once discomfort has resolved. Patients are advised to inflate and deflate the device on a daily basis for 4 weeks to allow tissue expansion around the prosthesis. Most patients can then begin use of their device 4 to 6 weeks after implantation.

---

## OUTCOMES

---

### Complications

---

Despite careful counseling, many patients enter penile prosthesis procedures with expectations that cannot be met by penile prosthesis surgery. Decreased penile length compared with the preimplant state, decreased penile sensation, “coolness” of the penis and glans penis, and chronic pain, as well as partner dissatisfaction, are among the complaints patients may voice despite adequate surgical implantation and satisfactory mechanical functioning. Fortunately, these complaints are unusual, and >90% of patients report satisfaction with their prostheses. Many patients who are dissatisfied with their penile

prostheses will benefit from sexual counseling or continued counseling assistance from the implanting surgeon to be sure that they are able to operate the device satisfactorily and understand its use.

Most patients’ dissatisfaction results from difficulty with operation of the device and unrealistic expectations. Preoperative discussions with patients should include the concept that penile prostheses do not create normal erections but only support the penis for sexual activity. Penile prosthesis surgery brings about the ability to resume sexual functioning and vaginal penetration, but decreased penile sensation, length, and engorgement may result. Patients should also be advised that a penile prosthesis will not improve libido or ejaculation. Patients frequently report delayed or difficult ejaculation initially following penile prosthesis surgery. This delay is primarily a result of inadequate preparation, stimulation, and psychological adjustment to the prosthesis. Most patients require 3 to 6 months of prosthesis use with careful attention to presexual stimulation before ejaculation routinely returns to preoperative levels. Because the prosthesis neither improves nor detracts from preoperative ejaculatory ability, patients must be counseled regarding their preoperative ejaculatory ability before prosthesis placement.

The most worrisome postoperative complication is infection, which occurs in fewer than 10% of all patients. Perioperative prosthetic infections can, however, occur at any time in the postoperative period in patients with penile or other prosthetic devices. Patients continue to be at risk for hematogenously seeded infections from gastrointestinal, dental, or urologic manipulations as well as remote infections. Patients must be counseled to request antibiotic coverage if remote infections occur. Most periprosthetic infections are caused by gram-positive organisms such as *S. epidermidis*, but fungi or gram-negative organisms such as *Escherichia coli* and *Pseudomonas* are also common culprits. Severe gangrenous infections with a combination of gram-negative and anaerobic organisms have also been identified and frequently result in significant disability and tissue loss. Patients at increased risk for perioperative infections include diabetics, patients undergoing penile straightening procedures or circumcision with prosthetic implantation, patients with urinary tract bacterial colonization, and immunocompromised patients, such as posttransplant patients. Spinal cord injury patients have also been reported to have a specially increased risk of infections, with rates reported as high as 15%.

Appropriate treatment of periprosthetic infections requires early and immediate identification with institution of parenteral antibiotic therapy and early prosthesis removal (2). Conservative treatment would dictate a healing period of 3 to 6 months followed by repeat prosthesis implantation. Satisfactory results with prosthesis removal, a 5- to 7-day course of antibiotic irrigation, followed by additional replacement has been reported for selected patients. Better long-term results with no additional morbidity can be achieved with the prosthesis salvage technique reported by Mulcahy (4). This technique—which requires removal of the infected implant and vigorous irrigation using solutions of antibiotics, povidone-iodine, hydrogen peroxide, and a repeat of these solutions—is successful in >75% of infected prostheses (2).

The most common complication of penile prosthesis function is mechanical malfunction. Mechanical malfunction has declined from rates as high as 61% to levels below 5% since

the 1970s (3,7). Aneurismal dilation of inflatable cylinders, both American Medical Systems and Mentor, kinks in tubing, reservoir leakage, and pump malfunction have been limited by device modifications. Fluid leak, however, continues to be a problem for many inflatable penile prostheses. These mechanical malfunctions require replacement of the leaking portion of the inflatable portion of the prosthesis. If a nonfunctioning prosthesis has been in place >4 years, however, it is usual practice to replace the entire device to reduce further mechanical malfunction (1).

Semirigid rod penile prostheses are associated with fewer mechanical problems; the most common complication associated with these prostheses is cylinder erosion through skin or urethra. Prosthesis fracture or breakage has been reported, and patients may return 6 to 8 years postimplantation with complaints of decreased rigidity of their semirigid rod, indicating fracture of the central prosthetic cylinder wires. These wire fractures usually cannot be appreciated radiographically unless the prosthesis is put on stretch once it has been explanted. Replacement of these devices is indicated when patients note decreased rigidity. Prosthesis extrusion or erosion

is most common in diabetics and spinal cord injury patients, especially those requiring urinary management with catheter placement or with condom catheter collection devices.

Extrusion can also occur beneath the penile skin distally from vigorous dilation or remotely from trauma or repeated use. These extrusions are characterized by distal penile pain with use. Correction can be carried out with the use of a patch graft, but a better approach is rerouting with no grafting material. Rerouting is associated with less infection and pain and a reduced recurrence rate.

---

## Results

---

Long-term function and use have been confirmed in studies of patients who have had implants as long as 10 years (3). While partner satisfaction notes are few, patients have a >90% satisfaction, and those with functioning devices for >5 years use them 27 times monthly (3). Other studies have confirmed that patient satisfaction is greater than with any other erectile dysfunction treatment modality (1).

# CHAPTER 75 ■ PENILE VENOUS SURGERY

AUDREY C. RHEE, MARK R. LICHT, AND RONALD W. LEWIS

Although the exact incidence of vasculogenic erectile dysfunction (ED) is not known, arterial insufficiency and/or venous leakage of varying etiology probably account for the majority of cases of ED. Sustaining a rigid erection depends on both adequate perfusion pressure of the erectile bodies via arterial inflow and maintenance of intracavernosal pressure by increased venous outflow resistance. The trapping of blood within the expanding corporal bodies during erection by direct compression of subtunical venules as they exit through the tunica albuginea is known as the corporal veno-occlusion mechanism. Venous leak ED refers to the inability of an individual to maintain a rigid erection because of abnormal venous outflow from the corpora cavernosa secondary to failure of the corporal veno-occlusive mechanism. Failure of full expansion of the sinus spaces due to sinus smooth muscle malfunction or replacement with fibrous tissue probably accounts for the majority of veno-occlusive dysfunction. Focal defects in the integrity of the tunica albuginea or congenital or arteriogenic

abnormal venous channels may be a less frequent source of veno-occlusive disorders. In this chapter, we discuss the diagnosis of venogenic ED and detail the surgical correction of this form of ED by penile venous dissection and ligation.

---

## DIAGNOSIS

---

A history and physical examination help identify patients who may have venous leak ED. Patients present with complete loss of erection, decreased penile rigidity, or rapid loss of erection during intercourse. Medication side-effects, significant cardiovascular disease, psychologic disorders, and tobacco use should be excluded as contributing causes of ED. Penile trauma, surgery for priapism or Peyronie disease, and previous endoscopic incision of urethral strictures can all lead to focal defects in the corporal veno-occlusive mechanism (7).

FIGURE 75.1 Penile venous anatomy.

The first diagnostic test that we employ in the diagnosis of venogenic ED is color penile duplex Doppler ultrasonography. This test allows for the evaluation of both penile arterial inflow (peak systolic velocity) and veno-occlusion (end-diastolic velocity), as well as for observing the erectile response to the intracavernosal injection of a vasodilating agent. Our preferred injection agent is 0.25 mL of a Tri-Mix agent (containing 6 mg of papaverine, 0.2 mg of phentolamine, and 2  $\mu$ g of prostaglandin E<sub>1</sub>). Patients with measured end-diastolic velocities  $>3$  cm per second for up to 20 minutes (measured at 5-minute intervals) after the administration of the vasodilating agent despite normal arterial inflow, a peak systolic velocity  $>30$  cm per second, are likely to have venogenic ED (4). Patients who obtain a full rigid erection within 10 minutes of injection that lasts for 30 minutes probably have no clinically significant vascular disease. Our practice is to reinject and to measure values every 5 minutes for 20 minutes if after the first injection the response is not a full erection or not equal to the best attained erection at home. Patients who achieve only tumescence or who rapidly obtain a rigid erection that dissipates within 15 to 20 minutes are suspected of having a venous leak.

Infusion pharmacocavernosometry and pharmacocavernosography are the definitive tests for diagnosing venous leak ED and visualizing the sites of leakage. Knowledge of the anatomy of the venous drainage of the penis is critical in interpreting this study (Fig. 75.1). Two 19-gauge needles are placed into each of the corpora cavernosa. One is connected to a pressure transducer, and the other is connected to an infusion pump with metered delivery rates of heparinized saline. After injection of a vasodilating agent, the need for a flow rate of  $>20$  mL per minute of saline to maintain a rigid erection at an intracorporeal pressure of at least 90 mm Hg is indicative of corporal veno-occlusive dysfunction. A maintenance flow rate between 10 and 20 mL per minute is considered borderline for venous leakage. Others have used lower flows to maintain as diagnostic cutoff. Excessively high maintenance flows ( $>50$  mL per minute) usually indicate massive venous runoff, and these patients do not do well with veno-occlusive surgery (12). Isosmotic contrast material is infused into the corpora at the previously defined maintenance flow rate from cavernosometry, and then Anterior Posterior (AP) and oblique radiographs of the penis are taken (cavernosography). The most common

sites of venous leakage seen in patients with veno-occlusive dysfunction are the deep dorsal vein, the cavernosal veins, and the circumflex veins at the base of the penis. A large amount of drainage into all of these systems is a contraindication to surgery, since these patients do not do well.

## INDICATIONS FOR SURGERY

Patients must meet strict criteria to be selected for venous surgery. Candidates must first have a history that is consistent with venous leak ED, corroborated by color duplex Doppler ultrasonography or intracavernosal test injection findings. Other causes of ED should be ruled out. Normal penile arterial inflow must also be documented in response to an intracavernosal injection agent because patients with concomitant arterial disease often have a poor outcome after venous surgery. Pharmacocavernosometry and pharmacocavernosography must confirm veno-occlusive dysfunction and outline the sites of leakage. Patients should have no medical contraindications to surgery. There is no strict age limit, but we prefer to perform venous surgery on patients  $<65$  years old. Sasso et al. (12) advise veno-occlusive dysfunction for patients  $<50$  years of age.

Patients need to eliminate all tobacco use at least 6 months before surgery. Finally, patients must select venous surgery only after presentation of alternative forms of therapy and discussion of the  $<50\%$  long-term expected success rates ( $>2$  years). We also perform venous surgery in conjunction with penile arterial revascularization in select patients with both focal arterial disease and veno-occlusive dysfunction (8).

## ALTERNATIVE THERAPY

Patients with venous leak ED have other effective surgical and nonsurgical options to consider instead of penile venous dissection and ligation. Some patients with mild to moderate veno-occlusive disorders will respond to oral phosphodiesterase inhibition therapy for ED. Vacuum erection devices create an adequate erection by drawing blood into the penis with negative pressure in the vacuum cylinder tube. An occlusion

band placed at the base of the penis prevents outflow of blood and substitutes for a faulty veno-occlusive mechanism. Self-injection of intracavernosal vasodilating agents at higher doses can often produce a functional erection in patients with mild to moderate venous leak. Patients with severe leakage, however, will most often not respond to injection therapy. Combining self-injection with an occlusion band is also helpful in maintaining an erection in some patients. Implantation of a penile prosthesis effectively replaces the natural veno-occlusive mechanism with a mechanical device capable of producing a sufficiently rigid erection. A short-time high success rate (68.7%) with an embolization of the deep dorsal vein technique was reported in 2000 by Peskircioglu et al. (10). A goal-directed approach is used to help the patient select an appropriate form of therapy.

## SURGICAL TECHNIQUE

Patients receive a dose of intravenous cephalosporin or a fluoroquinolone within an hour before surgery. Surgery is performed under either general intubated or spinal anesthesia. The patient is positioned supine with legs abducted to allow easy access to the perineum. If crural ligation and banding are planned as part of the operative procedure, then a dorsal lithotomy position is preferred. A lighted suction device can facilitate illumination of the deep infrapubic dissection. An intraoperative Doppler probe can be helpful in localizing small arteries in this region. Optical magnification can be used for the dissection, although we do not routinely use it. The operative field is prepared and draped in a sterile fashion from the umbilicus to the perineum, and an 18Fr Foley catheter is placed for the purpose of bladder drainage and facilitating urethral identification during the dissection.

An infrapubic curvilinear anterior peripenile scrotal incision is made with a no. 15 blade (Fig. 75.2). The superior extent of the incision is the inferior border of the pubis, and the

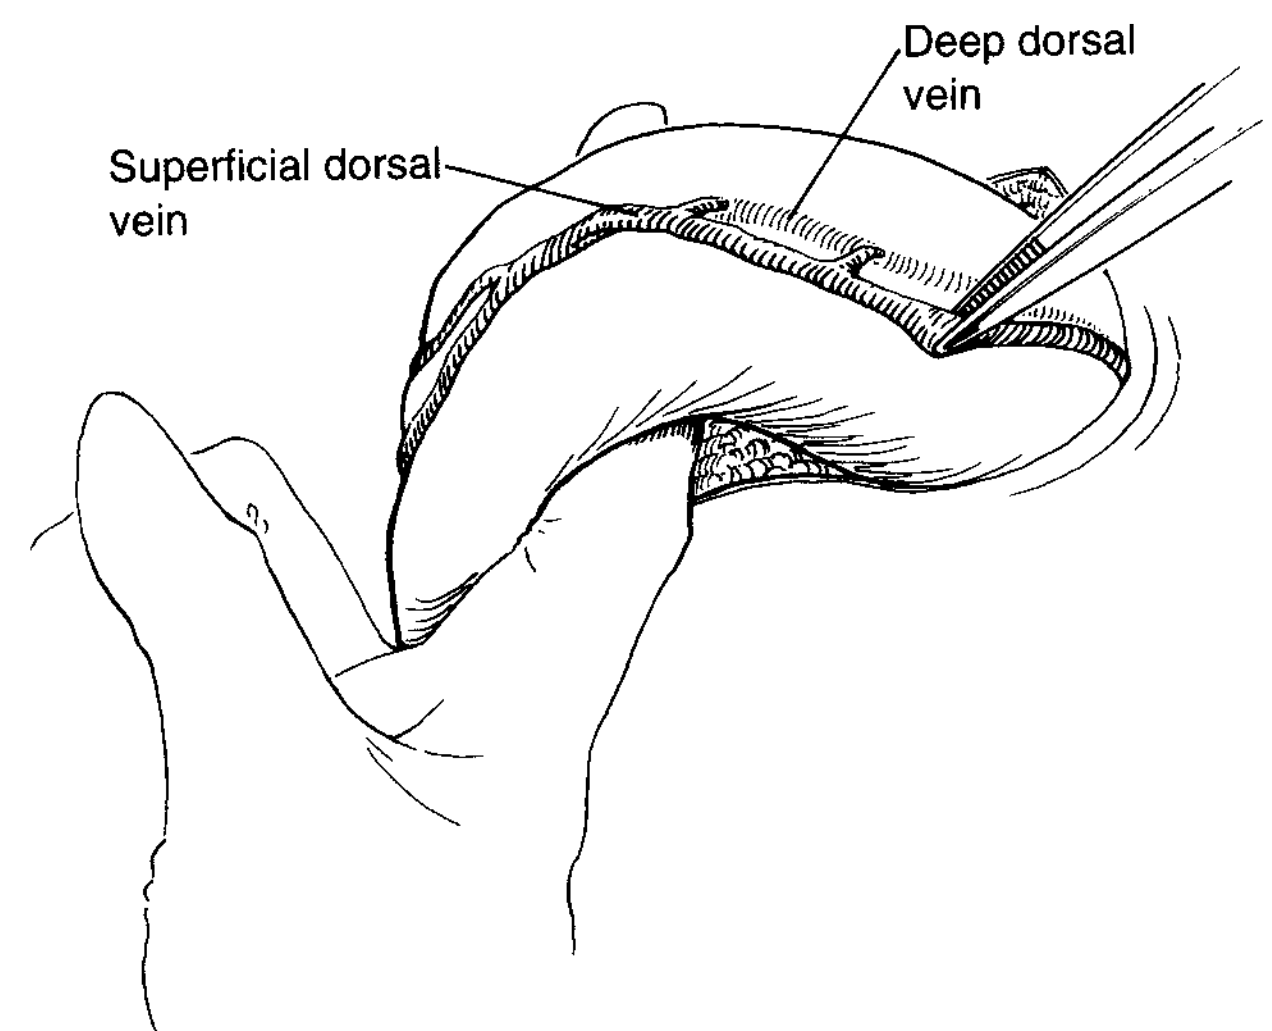

**FIGURE 75.2** Peripenile scrotal incision for penile venous surgery.

**FIGURE 75.3** Inversion of the penile shaft into the wound.

inferior extent is the median raphe of the scrotum below the penile shaft. Superficial tissue is dissected free of the corporal bodies with sharp and blunt dissection. Communicating veins joining the deep and superficial drainage systems are isolated, ligated with 3-0 plain gut sutures, and divided. The penile skin is then inverted into the wound to gain exposure to the superficial and deep venous systems (Fig. 75.3). Any other venous trunks of the superficial system that receive tributaries from the corpora are ligated with absorbable suture material and divided at this time (Fig. 75.4).

A 19- or 21-gauge butterfly needle is placed into the base of the corpus cavernosum and fixed in place to the tunica albuginea with a 3-0 chromic pursestring suture (Fig. 75.5). The cavernosal tissue receives an injection of 30 mg of papaverine (or similar vasodilating agent[s]), followed 10 minutes later by indigo-carmin colored saline (12 mL in 250 mL of saline) to help visualize abnormally effluxing veins. The butterfly needle tubing is clamped for the duration of the procedure and is

**FIGURE 75.4** Ligation of superficial veins with connections to the corpora.

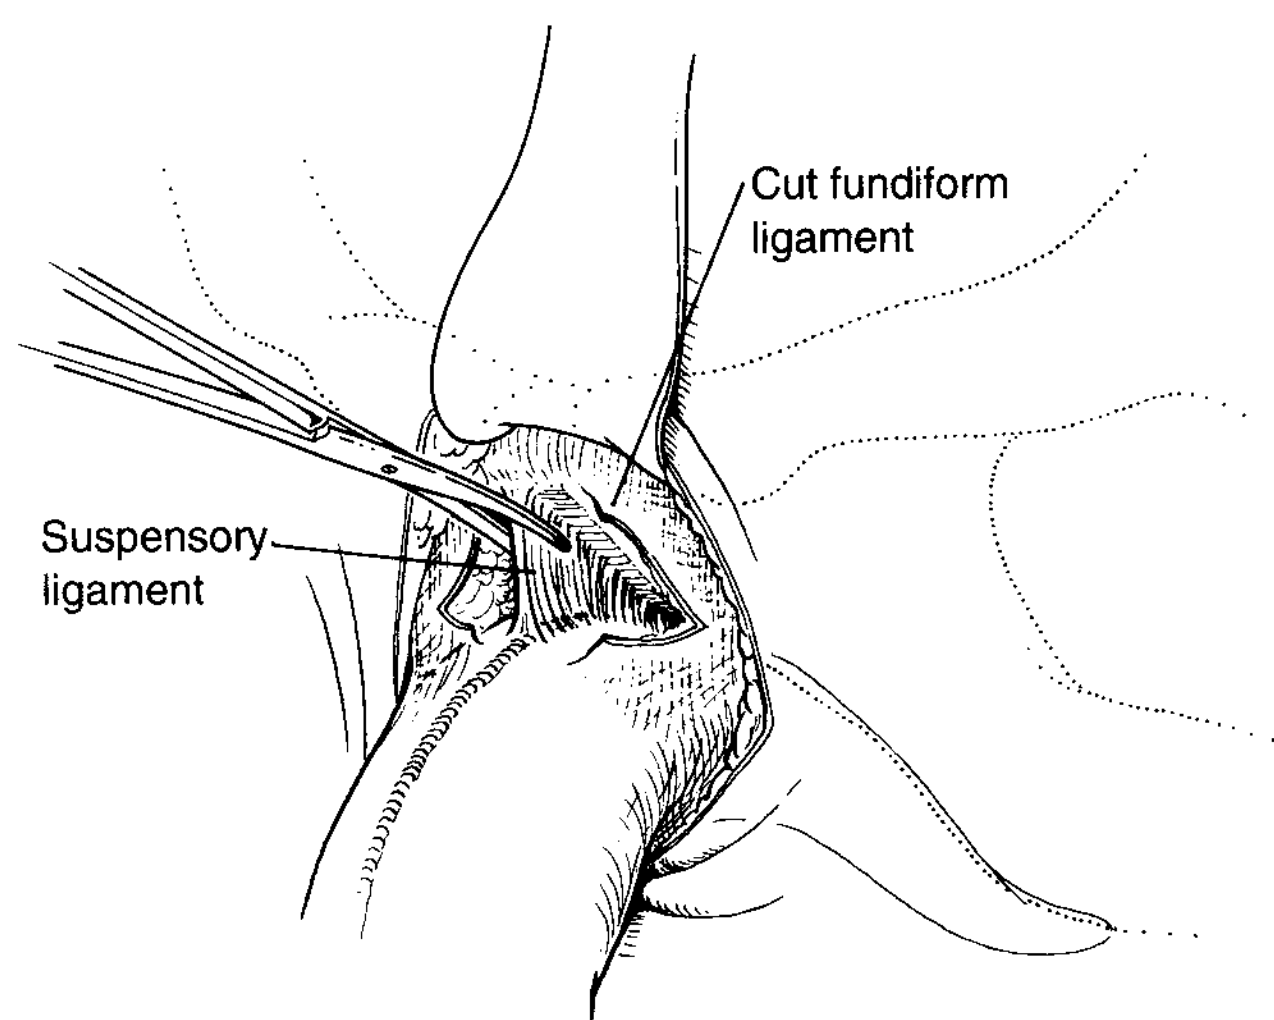

**FIGURE 75.5** Placement of a butterfly needle for intraoperative cavernosometry.

used again after the dissection to perform intraoperative cavernosometry. A 3/8-in. Penrose drain is looped around the penile shaft between the corpora. This allows retraction of the penile skin, allows elongation and stabilization of the penile shaft, and affords exposure for the proximal vein dissection.

The superficial fundiform ligament is identified at the base of the penis and is divided to expose the underlying suspensory ligament. The suspensory ligament is then sharply divided close to the underside of the pubic symphysis (Fig. 75.6). The suspensory ligament must be completely taken down to expose the deep infrapubic region. Care is taken to identify and divide small veins emanating from the underside of the pubis and joining the superficial drainage system as well as veins perforating the Buck fascia to connect the deep and superficial systems at this level. Failure to ligate these vessels can lead to significant bleeding, which can be difficult to control and obscure exposure for the proximal portion of the venous dissection.

Deep in the infrapubic region, the Buck fascia is opened in the midline over the deep dorsal vein. The vein usually has a single large main trunk at this level. The deep dorsal vein is dissected free of the tunica albuginea, ligated with 0 silk ties, and divided (Fig. 75.7). Inferior to the deep dorsal vein, the cavernosal veins can be identified in the penile hilum at this time. They may be divided if they are a major source of leakage. Great care is taken to preserve the cavernosal arteries and nerve trunks that lie lateral to these veins.

**FIGURE 75.6** The suspensory ligament is divided to expose the base of the penis.

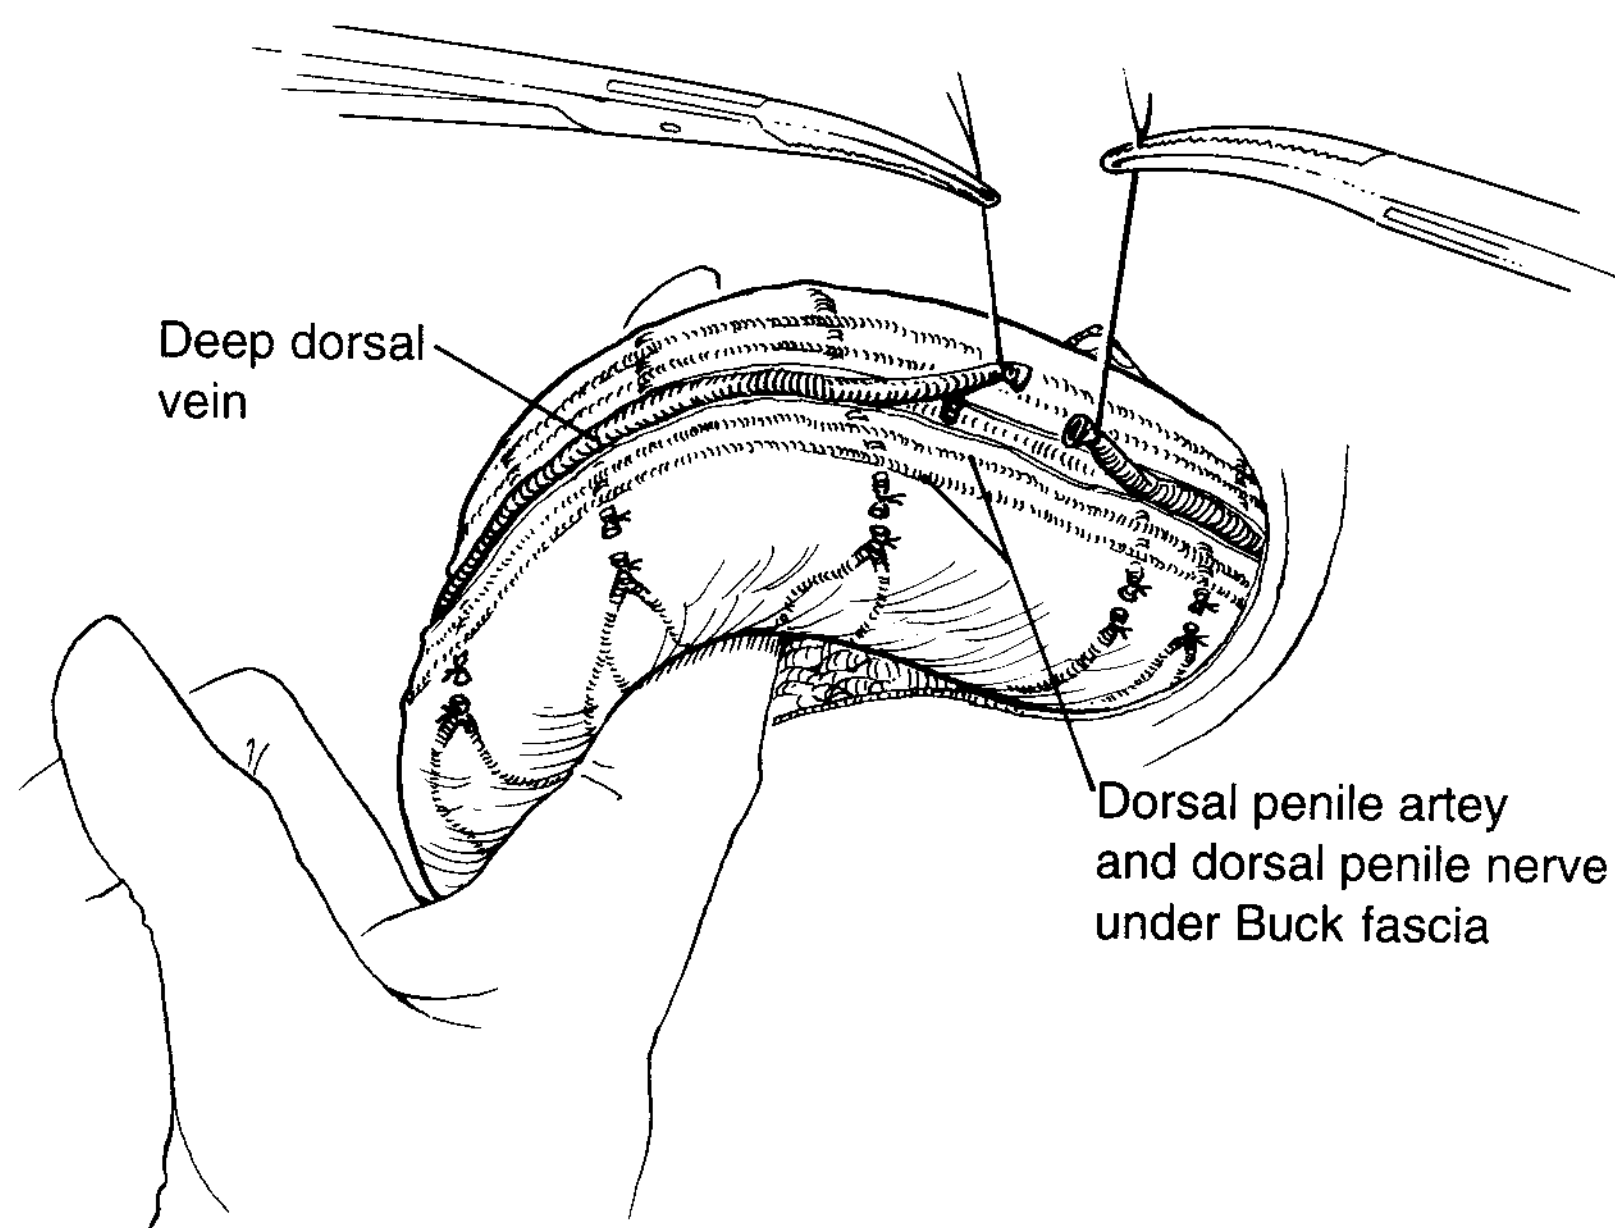

**FIGURE 75.7** Division of the deep dorsal vein in the infrapubic region.

If the deep dorsal vein is a significant source of abnormal penile drainage, then it is dissected from the infrapubic region along the penile dorsal midline under the Buck fascia distally toward the glans. It is important to stay in the midline during the dissection to avoid the laterally located dorsal arteries and nerves. Circumflex and emissary veins encountered on either side of the deep dorsal vein are ligated with 3-0 plain gut sutures and divided (Fig. 75.8). Bipolar electrocoagulation on low setting can be used to cauterize some small vessels along the shaft.

Sometimes the deep dorsal vein is composed of two trunks along the penile shaft, and each must be dissected separately. Dissection continues until several fanning tributaries constitute the deep dorsal vein approximately 1 cm from the glans. Rarely, a large vein arises from the tunica albuginea and penetrates the Buck fascia to join the deep dorsal vein. Ligation of this vein may create a sinusoidal defect in the tunica, which must be closed with a 3-0 chromic figure-of-eight suture ligature. The junction between the corpora cavernosa and the spongiosum is carefully inspected as well, and circumflex veins connecting the two structures are ligated and divided.

After vein dissection and ligation are completed, 30 mg of papaverine or equivalent is injected into the corpora via the butterfly needle, and cavernosometry is performed 10 minutes later. If the abnormal draining veins have been eliminated, then a rigid erection is easily maintained at a flow of saline considerably  $<5$  mL per minute (Fig. 75.9). Following this, the suspensory ligament is reapproximated with a 0 silk suture ligature between the infrapubic periosteum and the penile shaft. A no. 10 Jackson-Pratt fenestrated bulb suction drain is then placed in the wound with the tubing exiting via a separate stab incision lateral to the surgical incision. The Scarpa fascia is closed with a running 3-0 chromic suture, with care taken to approximate equal tissue planes to minimize the chance of scar formation resulting in fixation of the base of the penis. The skin edges are then reapproximated with a running subcuticular 3-0 Monocryl suture. The wound is covered with a standard sterile dressing, and the penis is snugly

**FIGURE 75.8** Division of circumflex and emissary veins on both sides of the deep dorsal vein.

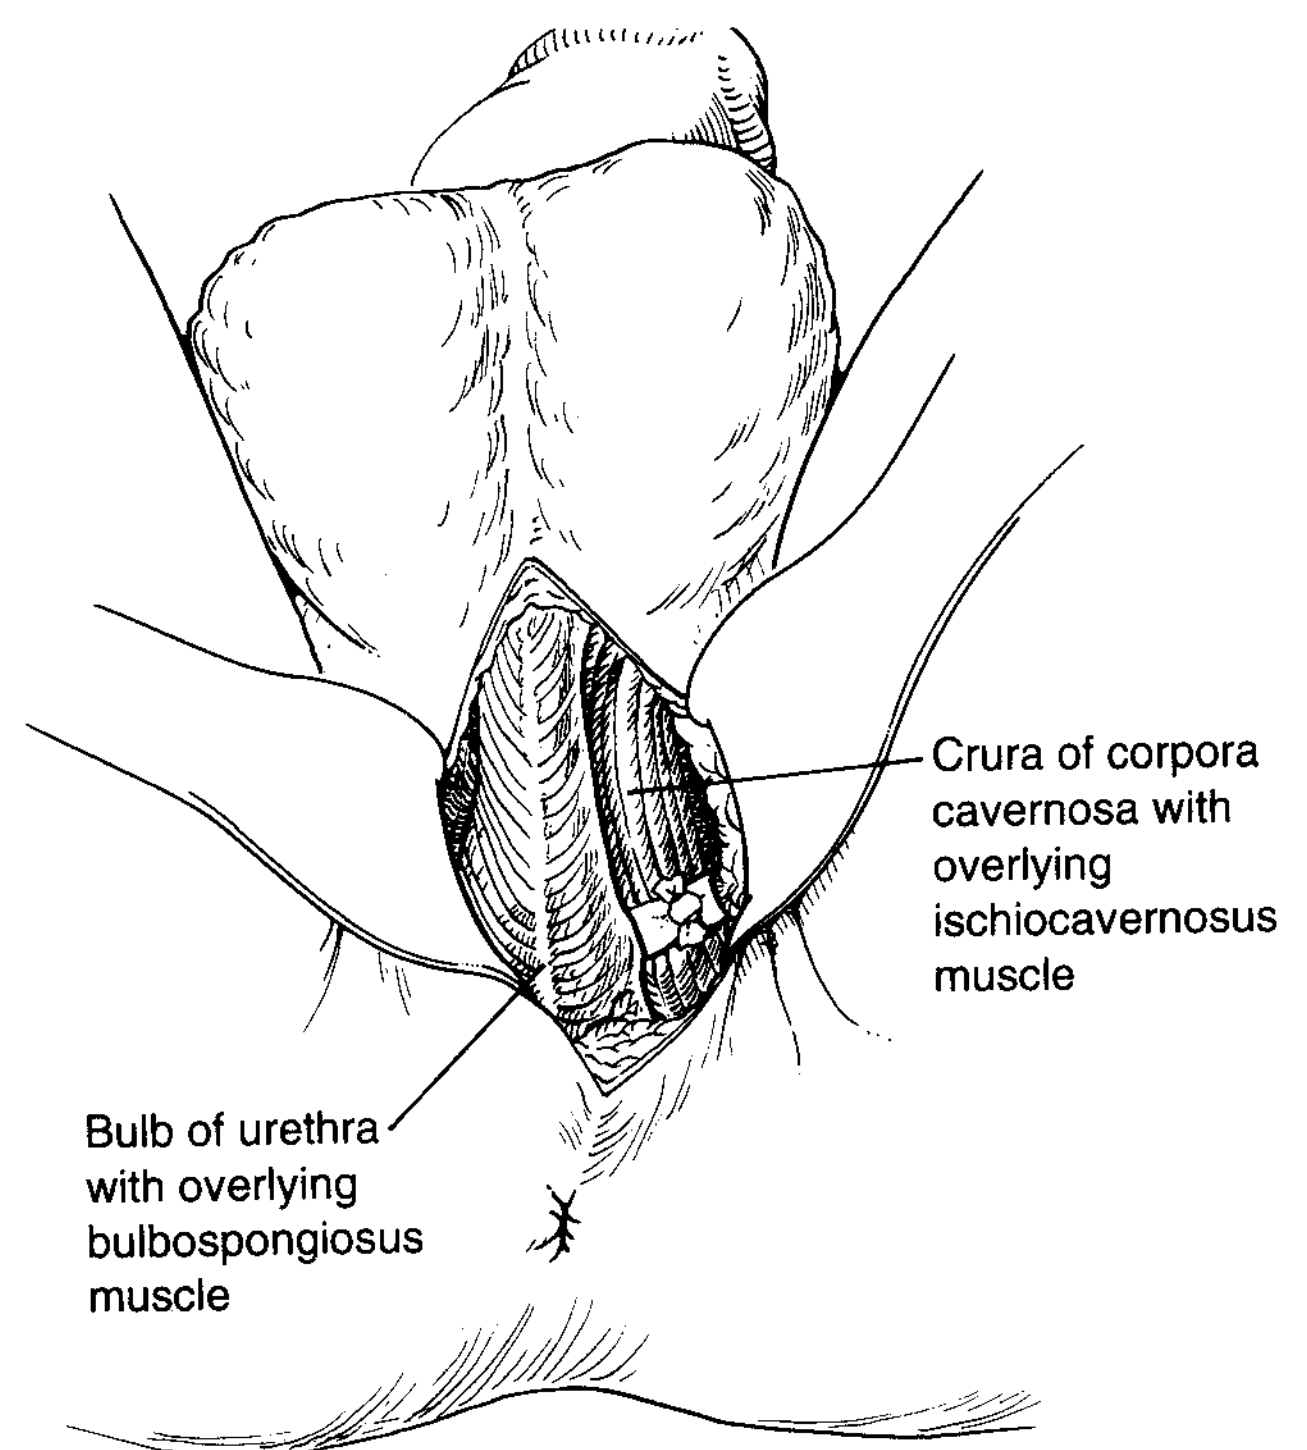

wrapped with a self-adherent Coban wrap. Care is taken to avoid glanular edema from a dressing that is too tight. The Foley catheter and the dressing are removed the day after surgery. The drain is removed as soon as drainage is negligible, usually in 24 to 48 hours. Patients are discharged from the hospital on postoperative day 2 or 3. They are advised against engaging in intercourse for 6 weeks.

### Crural Banding and Other Procedures

If the crural veins are found to be the only source of major venous leakage by cavernosography, we perform a crural banding procedure. The crura are exposed near the bulb of the urethra via a perineal incision, and a 1/4-in. Mersilene ribbon (Ethicon, Inc.) is used to band the crura (Fig. 75.10). Veins

**FIGURE 75.9** Cavernosometry after completion of the dissection confirms correction of the venous leak.

**FIGURE 75.10** Crural banding to correct venous leakage from crural veins.

draining from the edge of the crura are ligated as well. Crural banding is not routinely performed at the time of deep dorsal vein ligation and is usually a secondary procedure. Lue's group described (11) recently published their case series on crural ligation in 11 patients. Cavernosometry and cavernosography were utilized to diagnose these patients with crural leakage. At mean follow-up of 34 months, 9 of 11 patients noted marked improvement in their erectile function.

Another secondary procedure that is rarely employed is spongiosolysis. Via a penile scrotal incision, the corpus spongiosum is

exposed and stripped away from the ventral surface of the corpora cavernosa. All communications between the two structures are ligated or coagulated.

More direct approaches to site-specific areas may be used to treat focal venous outflow abnormalities. These can be due to trauma, previous patent shunts for priapism, Peyronie disease primary or secondary venous outflow sites, or venous leaks secondary to previous stricture repair.

## OUTCOMES

### Complications

Table 75.1 lists the complications that have been encountered after penile venous surgery. Complications can be divided into immediate and long-term. Most patients experience some superficial bruising of the shaft and scrotum. Penile edema is usually moderate and resolves within 2 to 3 weeks. The incidence of penile edema has decreased since our use of a compression dressing and a closed wound drainage system. Painful nocturnal erections often occur for the first 24 to 48 hours after surgery. Infrequently, this may last for longer than 1 week. Wound infection and true hematoma rarely occur. Care taken during the infrapubic portion of the dissection can eliminate the risk of postoperative hematoma.

Despite careful reapproximation of the suspensory ligament after the vein dissection is complete, approximately 20% of patients complain of penile shortening. The amount of perceived loss of length, however, is rarely clinically or functionally significant. Hypoesthesia or numbness of the glans or shaft of the penis is a common occurrence after surgery. Patients who report a loss of sensation often experience a diminished ability to achieve orgasm as well. In most cases, though, penile sensation returns completely within 7 to 9 months. Infrequently, wound scar contractures occur that lead to true penile tethering. In these cases, revision surgery is necessary, consisting of release of scar tissue and skin Z-plasty.

TABLE 75.1

#### COMPLICATIONS OF PENILE VENOUS SURGERY

Immediate
Common
Penile and scrotal bruising
Penile edema
Painful nocturnal erections
Rare
Wound infection
Hematoma
Long-term
Common
Penile shortening
Decreased penile sensation
Decreased ability for orgasm
Rare
Wound scar contractures and penile tethering

## Results

Although individual reports of successful vein ligation procedures date back to the early 1900s, the modern era of penile venous surgery did not begin until the development of accurate and appropriate diagnostic and surgical techniques. A number of surgeons have since reported on the initial and long-term success rates for this procedure. A detailed tabulation of the published results of veno-occlusive surgery for sexual dysfunction has been prepared by the senior author of this chapter (9). Some of these outcomes are discussed in the following paragraphs with also more recent data.

Donatucci and Lue (2) reported on 100 patients operated on between 1986 and 1988. Forty-four patients (44%) had an excellent result, defined as a complete return of spontaneous erections rigid enough for penetration, and 24 patients (24%) noted some improvement in rigidity. All patients were followed for longer than 1 year after surgery. Knoll et al. (5) reported a 46% excellent response to surgery in 41 patients followed for an average of 28 months. Claes and Baert (1) similarly reported a return of normal erectile function in 30 of 72 patients (42%) and a partial response in 23 others (32%). Patients were all followed for >1 year.

Lewis (8) reported on 60 patients, of whom 16 (27%) initially had return of normal erections. Seventeen other patients (28%) experienced improved rigidity and were able to have intercourse with the aid of intracavernosal pharmacologic injections for a combined success rate of 55%. All patients were followed for at least 2 years. Over time, 13 of the 33 patients (39%) who initially experienced a successful result later reported failure of the procedure. Kropman et al. (6) also reported a 40% late failure rate at a mean follow-up of 28 months in 10 of 20 patients who initially experienced a successful result from surgery.

The best long-term results were reported by Sasso et al. (12) in 1999. Seventeen of 23 patients (74%) had normal erections within 1 year of venous ligation surgery, and 12 of 17 maintained normal spontaneous erectile function long-term. The authors describe strict operative selection criteria, including the need to determine a crucial percentage of smooth muscle (>30%) in the corporeal tissue found on preoperative biopsy.

Most recently Hsu et al. (3) have reported a repeat venous dissection and ligation series in 45 men who failed their first meticulous surgery. Long-term successful erections were achieved in 35 of the 45 men (78%), with 4 more obtaining success with the use of prostaglandin E<sub>5</sub> inhibitors and 3 more with intracavernous injection, for a total improved of 91%. They attribute their success in the first and second operation series to meticulous microsurgery ligation of 76 to 125 sites and avoidance of Bovie coagulation and suction.

Several different factors can account for the approximately 40% to 50% immediate failure rate and 75% long-term failure rate of penile venous surgery. Inability to accurately diagnose concomitant arterial disease and less extensive venous dissection probably accounts for many of the early patient failures in the series reported above. With the use of stricter diagnostic inclusion criteria and a more aggressive surgical approach, many of these early failures could have been avoided (3).

Collateralization has limited the long-term success rates of other types of venous surgery as well. Hsu et al. (3) describe most failures as due to residual veins, not recurrent veins. A

final reason for failure is that the ligation of penile veins may not address the true underlying pathologic disorder in many patients. Sinus smooth muscle disease that prohibits the expansion of the tunica albuginea and the subsequent compression of subtunical venules has been postulated as a major

cause of veno-occlusive dysfunction (13). To date, though, no practical test is available to accurately diagnose this entity. Penile venous surgery remains a reasonable surgical option for highly selected patients with venous leak impotence, particularly those with focal or iatrogenic etiology.

# CHAPTER 76 ■ MICROVASCULAR ARTERIAL BYPASS SURGERY FOR ERECTILE DYSFUNCTION

IRWIN GOLDSTEIN AND MARTIN BASTUBA

When a middle-aged or elderly man (age 50 or more years) presents to a physician with complaints of consistent or persistent inability to obtain and/or maintain a penile erection for satisfactory sexual activity, the “new” thinking is that the diagnosis is likely organically based erectile dysfunction. This is especially true if the patient also has a history of diabetes, hypertension, high cholesterol, cigarette smoking, or myocardial infarction (1). This contemporary knowledge represents a shift in understanding; 40 years ago, at the time of Masters and Johnson, most of erectile dysfunction was thought to be psychogenic in origin and sex therapy and cognitive behavior therapy were the primary treatment options. There are widespread data to support an organic vascular pathophysiologic basis of erectile dysfunction in strong association with endothelial dysfunction in older men with vascular risk factors (2).

However, when a young man (age teens to 40 years) presents to a physician with complaints of erectile dysfunction, the “old” thinking still prevails and the diagnosis most likely to be considered is psychogenically based erectile dysfunction. Why do practitioners have such great difficulty accepting the

existence of vasculogenic erectile dysfunction in younger men? Unfortunately, many physicians who evaluate younger men do not seek a history of blunt perineal trauma. Endothelial dysfunction resulting in focal arterial occlusive disease can be associated with a history of blunt trauma (3). Evidence for trauma-associated focal arterial obstructive pathology is well established in the medical literature for several other arterial beds (4). Such arterial beds include the radial artery (construction workers), the axillary artery (crutch-related injuries), and the popliteal artery (football players). The distal internal pudendal, common penile, and proximal cavernosal arteries are susceptible to blunt trauma by virtue of the anatomic relationship to the ischiopubic rami within the Alcock canal. They can be injured during bicycle riding (5) and other sources of straddle injuries such as blows to the perineum during martial arts.

The aim of this chapter is to expand the knowledge concerning microvascular arterial bypass surgery as a therapeutic option for young patients with erectile dysfunction secondary to focal arterial obstructive pathology. Data supporting the existence of traumatic-associated vasculogenic erectile dysfunction and the associated diagnostic and therapeutic paradigm

in young men will be reviewed. The overall goal is to stimulate basic science and clinical research in the management of young men with erectile dysfunction.

---

## ERECTILE FUNCTION PHYSIOLOGY

---

Penile erectile function results following autonomic cavernosal nerve stimulation (6). Nitric oxide synthase (NOS), an enzyme in lacunar space vascular endothelial cells and autonomic cavernosal nerve endings, facilitates the synthesis of nitric oxide (NO) from molecular oxygen and L-arginine. During sexual stimulation, nitric oxide (NO) activates guanylyl cyclase, an enzyme that facilitates the synthesis of the second messenger, cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP). The elevated concentrations of cGMP result in lowered intracellular calcium, thus promoting penile smooth muscle relaxation. Biologic consequences of NO-cGMP relaxation include increased arterial blood inflow, engorgement of the lacunar spaces, lengthening and enlargement of the corporal erectile tissue within the constrained tunica albuginea, and eventual subtunica venule occlusion with increased penile venous outflow resistance and corporal veno-occlusive function (7).

---

## ERECTILE DYSFUNCTION PATHOPHYSIOLOGY

---

The NOS-NO-cGMP pathway is, in part, interfered with by multiple organic pathophysiologies, including hypogonadism, hypothyroidism, and metabolic conditions such as diabetes and reduced insulin sensitivity, metabolic syndrome, low testosterone, elevated body mass index, elevated waist circumference, abnormal lipids, elevated blood pressure, sedentary lifestyle, cigarette smoking, and increased age. Endothelial dysfunction ultimately leads to reduced arterial blood inflow and arterial systolic perfusion pressures during erection (8).

---

### Focal Endothelial Dysfunction Secondary to Trauma-Associated Erectile Dysfunction

---

There is a puzzling resistance to acknowledge that focal endothelial dysfunction may also occur following blunt trauma to the distal internal pudendal, common penile, and proximal arteries. These critical arteries to erectile function lie in close proximity to the hard bony surface, the lateral aspect of the Alcock canal, the ischiopubic rami. Endothelial injuries induced by blunt trauma may be classified as either nondenuded or denuded. While some nondenuded endothelial injuries may spontaneously heal, some progress to frank endothelial dysfunction, increased permeability, and thrombogenicity to eventually, over a variable time period, focal atherosclerosis, focal arterial lumen stenosis, and reduced systolic arterial perfusion pressures. Denuded endothelial injuries that result following blunt trauma to the arterial wall often result in medial smooth muscle cell proliferation, smooth muscle cell migration, myointimal thickening, extracellular matrix production,

and progressive occlusive arterial pathology over time, leading to diminished systolic arterial perfusion pressures and diminished erectile hardness during sexual stimulation.

---

## Bicycle Riding and Erectile Dysfunction

---

Data in the peer review medical literature of an appropriate level of scientific evidence show an association of erectile dysfunction with those who ride bicycles.

Marceau et al. (9) studied a community-based population exceeding 1,700 men 40 to 70 years of age. The odds ratio for men developing moderate to severe erectile dysfunction who acknowledged riding >3 hours per week was 1:72. This analysis was performed where covariates were factored, such as age, energy expenditure, body mass index, cigarette smoking, depression, cancer, high blood pressure, and diabetes.

Schrader et al. (10) published a unique National Institute for Occupational Safety and Health study of bicyclists involving the determination of nocturnal penile tumescence activity as recorded by RigiScan and perineal or nose pressure recorded by specialized pressure-sensitive sheets placed over the rider's saddle. They reported a significant inverse correlation between the magnitude of nose pressure values and the percentage of sleep time in erection. Control subjects exhibited >30% sleep time in erection, whereas those who rode with nose pressures exceeding 1,000 and 2,000 U revealed <20% sleep time in erection.

Dettoni et al. (11) reported on the erectile dysfunction characteristics of several hundred men who performed long-distance bicycle rides. In those men who exceeded 328 kilometers, who complained of current perineal numbness, and who used a saddle with a cutout (which acted to lower surface area contact and increase perineal compressive pressures), a surprising 18% were found at risk for developing erectile dysfunction.

Cohen and Gross (12) studied >30 male cyclists and examined transcutaneous penile oxygen pressures. Compared to values obtained during standing, cyclists who straddled on commercially available saddles with nose extensions such as the Vetta Lite, Terry, and Specialized exhibited significant reductions in transcutaneous penile oxygen pressures.

Leibovitch and Mor (13) performed a literature search of 62 articles in the peer review medical literature on bicycling and genitourinary disorders. They reported that 13% to 24% of bicyclists in the literature claimed erectile dysfunction. They concluded that although bicycling is associated with established cardiovascular benefits, it was a not infrequent cause of injury to the genitourinary system.

Bacon et al. (14) reported that the risk of developing erectile dysfunction among the >20,000 men in the Health Professional Follow-up Study who were healthy and had good or very good erectile function before the study decreased as the subjects reported increasing metabolic energy transfer units (METS) during various exercise forms, including bicycling. The authors also performed a unique multivariate and total physical activity subanalysis of the data by the various exercise forms. The risk of developing erectile dysfunction among healthy participants who had good or very good erectile function before the study (and no prostate cancer) was reduced at the highest tertile of physical activity such as jogging,

running, swimming, tennis, rowing, and squash or racketball. Curiously, there was no risk lowering for bicycle riding.

Goldstein et al. (19) reported in the *Journal of Sexual Medicine* a prospective study recording cavernosal artery peak systolic velocity values using duplex Doppler ultrasound in men who lay supine, sat on the examination table, straddled a saddle, sat on a two-cheek noseless seat, and then lay supine. In all subjects who straddled a saddle, peak systolic velocity values approached zero. All remaining interventions were associated with mean peak systolic velocity values that were not significantly different from each other and that ranged from 20 to 26 cm per second. It was estimated that the compression pressure on the perineum while bearing body weight on a bicycle saddle exceeded 300 mm Hg (15).

Another study published in the *Journal of Sexual Medicine* was performed, for the first time with women bicyclists. This study is being reported because it is likely that blunt perineal trauma causes similar injuries to perineal contents in women. Other than the pudendal artery, critical structures in the Alcock canal in both genders include the pudendal nerve. In this study, female bicyclists were compared to female runners for the value of vibration quantitative sensory testing by biothesiometry. Female bicyclists had significantly lowered sensation in the clitoris, labia, and vaginal introitus compared to runners (16).

An additional study in the *Journal of Sexual Medicine* examined whether noseless bicycle saddles would be an effective intervention for alleviating deleterious health effects, erectile dysfunction, and groin numbness caused by bicycling on the traditional saddle with a protruding nose extension. Ninety bicycling police officers from five metropolitan regions in the United States (Northwest, Southern, Desert West, Midwest, and Southeast) using traditional saddles were evaluated prior to changing saddles and then again after 6 months of using the noseless bicycle saddle. The findings showed that use of the noseless saddle resulted in a reduction in saddle contact pressure in the perineal region. There was a significant improvement in penile tactile sensation, and the number of men who used no-nose saddles and who indicated they had not experienced genital numbness while cycling for the preceding 6 months rose from 27% to 82%. Use of the noseless saddle also resulted in significant increases in erectile function as assessed by the initial evaluation. With few exceptions, bicycle police officers were able to effectively use no-nose saddles in their police work, and 97% of officers completing the study continued to use the no-nose saddle afterward. In summary, for the first time, a prospective study of healthy policemen riding bikes using wider no-nose bike saddles for 6 months revealed improved perineal sensation and improved erectile function. Changing saddles changed physiology (17).

---

## DIAGNOSTIC TESTING

---

The overall goal of microvascular arterial bypass surgery is to create an alternative arterial inflow route around obstructive arterial lesions in the hypogastric-cavernous arterial bed. The specific objective of the surgery is to increase the cavernosal arterial perfusion pressure and arterial blood inflow in patients with vasculogenic erectile dysfunction secondary to pure arterial insufficiency. Young men, without other vascular

risk factors, who have erectile dysfunction of a pure arteriogenic nature represent the ideal patient population for this procedure.

The diagnostic algorithm is aimed at ensuring that this operation is performed on the ideal candidate, that is, one in whom there is erectile dysfunction purely on the basis of arterial insufficiency. All young patients with a history suggestive of trauma-associated impotence (pelvic fractures and perineal trauma) should undergo a comprehensive history, physical examination, and psychologic interview. They should have a routine endocrinologic evaluation to ensure adequate circulating levels of unbound, free testosterone. Duplex Doppler ultrasonography should be performed to provide diagnostic hemodynamic data (cavernosal peak systolic and end-diastolic velocities) and preoperative information such as the presence of communicating branches from the dorsal to the cavernosal artery. Finally, vascular assessment by dynamic infusion cavernosometry should be considered to document the degree of arterial pressure gradients between the brachial artery and the cavernosal arteries and to further evaluate the veno-occlusive function. Following hemodynamic diagnosis, if the patient has pure arterial insufficiency, a selective internal pudendal arteriogram should be performed to confirm the location of the obstructive lesion, most often in the common penile or cavernosal artery(ies), and to select the best inferior epigastric artery (18).

---

## SURGICAL CRITERIA

---

The success of this operation is based on the selection of the correct operative candidate and the microsurgical capabilities of the surgeon. To this end, the following represents a list of criteria to ensure optimum results. The criteria are as follows:

1. The patient's history is characterized by (a) intact libido, (b) a consistent reduction in erectile rigidity during sexual activity, (c) variable sustaining capability with the best maintenance of the rigidity during early morning erections, and (d) poor spontaneity of erections, taking much effort and excessive time to achieve the poorly rigid erectile response.
2. Normal hormonal and neurologic evaluation.
3. Suspicion of arterial insufficiency as evidenced by reduced peak systolic velocity values during duplex Doppler ultrasonography and increased arterial gradients during cavernosal artery occlusion pressure determination using dynamic infusion cavernosometry.
4. Normal veno-occlusive parameters during both duplex Doppler ultrasonography and dynamic infusion cavernosometry.
5. The presence of a distal occlusive lesion in one or both hypogastric-cavernous arterial beds, usually within the common penile artery or cavernosal artery, that is amenable to distal bypass (Fig. 76.1).
6. The presence of an inferior epigastric artery of sufficient length to allow anastomosis to the dorsal artery (Fig. 76.2).
7. The presence of a communication branch(es) between the dorsal artery and the cavernosal artery distal to the occlusion that will allow the inflow of new blood and the development of increased intracorporal pressure.

D

**FIGURE 76.1** The presence of a distal occlusive lesion on selective internal pudendal arteriography in one or both hypogastric-cavernous arterial beds, usually within the common penile artery or cavernosal artery that is amenable to distal bypass, is an inclusion criterion for microvascular arterial bypass surgery.

A

B

**FIGURE 76.2** **A:** An inferior epigastric artery of sufficient length to allow anastomosis to the dorsal artery. **B:** The inferior epigastric artery bifurcates too early to provide sufficient donor artery length. This will place the anastomosis under risk for excessive tension.

## ALTERNATIVE THERAPY

Nonsurgical treatment options for young men with erectile dysfunction include psychotherapeutic, hormonal, pharmacologic, and external device interventions. Surgical treatment options consist primarily of penile prosthesis insertion.

## SURGICAL TECHNIQUE

The patient is placed supine on the operating table and his arms secured next to his body to minimize upper-extremity nerve injuries. As this operation may last in excess of 5 hours, great care must be taken in the positioning and padding of the limbs, in particular the neurovascular points on the upper limbs. Sequential compressive devices are placed around each calf. General endotracheal anesthesia with complete muscle relaxation provides complete skeletal muscle (especially the

rectus muscle) relaxation and facilitates harvesting the donor inferior epigastric artery vessel. The patient's abdomen and genitalia are carefully shaved, prepared, and draped, following which a 16Fr Foley catheter is placed using sterile technique. The patient is given one dose of preoperative antibiotics (cefazolin or vancomycin if penicillin allergic). From a technical standpoint, the operation can be divided into three stages: dorsal artery dissection, inferior epigastric artery harvesting, and microsurgical anastomosis (19).

### Dorsal Artery Dissection

A curvilinear incision is made, in general on the side opposite the planned abdominal incision for the donor inferior epigastric artery harvesting (Fig. 76.3A). The advantages of this incision are that it offers (a) excellent proximal and distal exposure of the penile neurovascular bundle, (b) the ability to preserve the fundiform ligament preventing penile shortening,

A

C

**FIGURE 76.3** **A:** A curvilinear incision is made, in general on the side opposite to the planned abdominal incision for the donor inferior epigastric artery harvesting. The advantages of this incision are that it offers (a) excellent proximal and distal exposure of the penile neurovascular bundle, (b) the ability to preserve the fundiform ligament, preventing penile shortening, and (c) the absence of unsightly postoperative scars on the penile shaft or at the base of the penis. Use of a Scott ring retractor with its elastic hooks maximizes operative exposure of the penis with a minimum of assistance. **B:** The penis is inverted through the skin incision, with care taken to push the glans in fully. **C:** The preselected right or left dorsal penile artery is identified. The course of the appropriate dorsal artery is followed proximally underneath the fundiform ligament, with care being taken to leave the fundiform ligament intact. Blunt dissection is performed under the proximal aspect of the fundiform ligament above the pubic bone toward the external ring.

and (c) the absence of unsightly postoperative scars on the penile shaft or at the base of the penis. Use of a Scott ring retractor with its elastic hooks maximizes operative exposure of the penis with a minimum of assistance.

The incision is made 2 fingerbreadths from the base of the penis, from a point opposite the ventral root of the penis, to the scrotal median raphe. This incision is carried down through the dartos layer using blunt dissection. The ipsilateral tunica albuginea is subsequently identified at the midpenile shaft. With the penis stretched, blunt finger dissection along the tunica albuginea is performed in a distal direction deep and inferior to the spermatic cord structures along the lateral aspect of the penile shaft, avoiding injury to the fundiform ligament.

The penis is then inverted through the skin incision, with care taken to push the glans in fully (Fig. 76.3B). The penis must not be tumesced during this maneuver. If a partial erection is present, an intracavernosal alpha-adrenergic agonist (100  $\mu$ g phenylephrine) should be administered. Blunt finger dissection around the distal penile shaft enables a plane to be established between the Buck fascia and the Colles fascia, and a Penrose drain is secured in this plane.

Exposure of the neurovascular bundle and, in particular, the right and left dorsal penile arteries is now performed. The arteries are usually obvious, located on either side of the deep dorsal vein and surrounded by the dorsal nerves. Isolation of the dorsal penile arteries for such arterial bypass surgery requires limited dissection at this time in the procedure; thus, ischemic, mechanical, and thermal trauma to the dorsal penile arteries may be minimized. To avoid injurious vasospasm, topical papaverine hydrochloride irrigation is applied frequently. In this way, preservation of endothelial and smooth muscle cell morphology during dorsal artery preparation is ensured. This is very critical as the room temperature of the operating room, the use of room temperature irrigating solution, and even the skin incision can induce vasoconstriction, spasm, and possible endothelial cell damage.

The preselected right or left dorsal penile artery is identified. The course of the appropriate dorsal artery is followed proximally underneath the fundiform ligament, with care being taken to leave the fundiform ligament intact (Fig. 76.3C). Blunt dissection is performed under the proximal aspect of the fundiform ligament above the pubic bone toward the external ring. This dissection enables the inferior epigastric artery to pass from its abdominal location to the appropriate location in the penis while simultaneously preserving the fundiform ligament. The penis is placed back in its normal anatomic position and the inguinoscrotal incision is temporarily closed with staples.

### Harvesting of the Inferior Epigastric Artery

A transverse semilunar abdominal incision following Langer lines is the preferred incision. The transverse incision provides excellent operative exposure of the inferior epigastric artery and heals with a more cosmetic scar compared to those observed with paramedian skin incisions. The starting point of the transverse incision is approximately three-fourths of the total distance from the pubic bone to the umbilicus in the midline (Fig. 76.4). It extends laterally along Langer lines for approximately 5 cm. The rectus fascia is incised vertically. The

**FIGURE 76.4** A transverse semilunar abdominal incision following Langer lines is the preferred incision. It extends laterally along Langer lines for approximately 5 cm.

junction between the rectus muscle and underlying preperitoneal fat is identified and the preperitoneal space is entered. The rectus muscle is reflected medially.

The inferior epigastric artery and its two accompanying veins are located beneath the rectus muscle in the preperitoneal plane. The ring retractor is again utilized to optimize operative exposure. It is critical to harvest an inferior epigastric artery of sufficient length to prevent tension on the microvascular anastomosis. Application of topical papaverine is utilized on the inferior epigastric artery throughout the dissection. Thermal injury is avoided using low-current microbipolar cautery set at the minimum level necessary for adequate coagulation, and the vasa vasorum are preserved by dissecting the artery en bloc with its surrounding veins and fat. Dissection of the inferior epigastric is required from its origin at the level of the external iliac artery to a point at the level of the umbilicus.

The transfer route of the neoarterial inflow source is prepared from the abdominal perspective prior to transecting the vessel distally (the penile transfer route has previously been dissected). The temporary scrotal staples are removed and the penis is reinverted. The internal ring on the side of the harvested artery is identified lateral to the origin of the inferior epigastric artery. Using blunt finger dissection through the inguinal canal, a long fine vascular clamp is passed through the fenestration in the fundiform ligament and the external and internal inguinal rings, and a Penrose drain is placed to protect this transfer route.

The donor inferior epigastric artery vascular bundle is transected at the level of the umbilicus between two LigaClips and carefully inspected for any proximal bleeding points. This donor artery should pulsate briskly (Fig. 76.5A). All attachments to the retroperitoneal fat are carefully removed prior to artery transfer as any attachments will diminish donor artery length and place the subsequent anastomosis with the dorsal

**FIGURE 76.5** **A:** The donor inferior epigastric artery vascular bundle is transected at the level of the umbilicus between two LigaClips and carefully inspected for any proximal bleeding points. This donor artery should pulsate briskly. All attachments to the retroperitoneal fat are carefully removed prior to artery transfer as any attachments will diminish donor artery length and place the subsequent anastomosis with the dorsal artery at risk due to excessive tension. **B:** Using blunt finger dissection through the inguinal canal, a long fine vascular clamp is passed through the fenestration in the fundiform ligament and the external and internal inguinal rings, and a Penrose drain is placed to protect this transfer route. The inferior epigastric vascular bundle is transferred to the base of the penis. It should be briskly pulsating and of adequate length.

artery at risk for being made under undue tension. The long fine vascular clamp is brought through the internal inguinal ring again, this time to grasp the end of the transected inferior epigastric artery. The inferior epigastric vascular bundle is transferred to the base of the penis (Fig. 76.5B). It should be briskly pulsating and of adequate length. The origin of the inferior epigastric artery should be inspected for kinking or twisting. Following the achievement of complete hemostasis, closure of the abdominal wound is performed in two layers.

The rectus fascia is closed utilizing a running 0 polyglycolic acid suture, one suture started at either end of the incision. On-Q SilverSoaker catheters, which will stay in place postoperatively for 48 to 72 hours, are placed below and above the rectus fascia, and 0.5% Marcaine is delivered at 2 mL per hour through each catheter (Fig. 76.6A). The skin edges are opposed using 4-0 Monocryl, and Dermabond is applied over the skin incision. On-Q SilverSoaker catheters are secured to the skin temporarily using Steri-Strips (Fig. 76.6B).

**FIGURE 76.6** **A:** On-Q SilverSoaker catheters, which will stay in place postoperatively for 48 to 72 hours, are placed one each below and above the rectus fascia, and 0.5% Marcaine (plain) is delivered at 2 mL per hour through each catheter. **B:** The skin edges are opposed using 4-0 Monocryl, and Dermabond is applied over the skin incision. A

B

**FIGURE 76.7 A:** Prior to the anastomosis, it is appropriate to assess the integrity of the donor inferior epigastric perfusion pressure. Grossly this is assessed by temporarily removing pressure on the gold-plated (low-pressure) aneurysm vascular clamps under minimal tension. The donor artery should exhibit brisk arterial inflow. **B:** Following release of the temporary occluding vascular clamps on the dorsal penile artery, the anastomosed segment should reveal arterial pulsations along its length and retrograde into the inferior epigastric artery. Such an observation implies a patent anastomosis. At this time, the inferior epigastric artery gold-plated aneurysm clamp may be removed. The intensity of the arterial pulsations in the anastomosis usually increases.

### Microvascular Anastomosis

A ring retractor and the associated elastic hooks are utilized once again on the inguinoscrotal incision and the fenestration of the fundiform ligament to gain exposure of the proximal dorsal neurovascular bundle. The pulsating inferior epigastric artery is placed against the recipient dorsal penile arteries, and a convenient location is selected for the vascular anastomosis. The anastomosis is created based on the arteriographic and duplex Doppler ultrasound findings. An end-to-end anastomosis is best under conditions whereby dorsal penile artery communications exist to the cavernous artery. In addition, an end-to-end anastomosis transfers perfusion pressure more effectively than an end-to-side anastomosis with less turbulence.

For intraluminal arterial irrigation, we utilize a dilute papaverine, heparin, and electrolytic solution believed to be capable of inhibiting the early development of myointimal proliferative lesions during surgical preparation.

The appropriate dorsal penile artery segment is freed from its attachments to the tunica albuginea, with care being taken to avoid injury to any communicating branches to the cavernosal artery. Vascular hemostasis of this segment of the dorsal penile artery may be achieved with or gold-plated (low-pressure) aneurysm vascular clamps under minimal tension for the minimal of operating time. The only location where the adventitia must be carefully removed is at the site of the vascular anastomosis, that is, the distal end of the inferior epigastric artery and the free end of the dorsal artery, to avoid causing subsequent thrombosis. If segments of adventitia enter the anastomosis, the patency of the anastomosis is in jeopardy as adventitia activates clotting factors from the extrinsic clotting system. The remaining adventitia should be preserved in the vessels as the vasa vasorum provide a nutritional role to

the vessel wall. The preservation of the adventitia is also important in terms of vessel innervation.

Prior to the anastomosis, it is appropriate to assess the integrity of the donor inferior epigastric perfusion pressure. This is assessed grossly by temporarily removing pressure on the gold-plated (low-pressure) aneurysm vascular clamps under minimal tension (Fig. 76.7A). The donor artery should exhibit brisk arterial inflow. A plastic colored background material is used to aid in vessel visualization under the microscope. An end-to-end anastomosis is performed between the inferior epigastric artery and the dorsal artery using interrupted 10-0 Nylon sutures (single-armed, 100-mm, 149-degree curved needle) under 10 $\times$  magnification. Sutures are usually passed from the outside of the inferior epigastric artery (1 mm from the cut edge) to the inside lumen and then from the inside of the dorsal artery lumen to the outside wall of the dorsal artery (1 mm from the cut edge) and then tied. Usually 15 or more interrupted sutures are used. All sutures used to complete the anastomosis are inserted equidistant from each other to avoid an uneven anastomosis.

Following release of the temporary occluding vascular clamps on the dorsal penile artery, the anastomosed segment should reveal arterial pulsations along its length and retrograde into the inferior epigastric artery. Such an observation implies a patent anastomosis. At this time, the inferior epigastric artery gold-plated aneurysm clamp may be removed. The intensity of the arterial pulsations in the anastomosis usually increases (Fig. 76.7B). On occasion, the application of a small amount of hemostatic material may be needed to aid in promoting hemostasis from suture needle holes in the vessel walls.

After complete hemostasis has been achieved and correct instrument and sponge counts are ensured, closure of the inguinoscrotal incision may begin. The dartos layer is reapprox-

**FIGURE 76.8** After complete hemostasis has been achieved and correct instrument and sponge counts are ensured, closure of the inguinoscrotal incision may begin. The dartos layer is reapproximated using 3-0 polyglycolic acid sutures in a running fashion. The skin edges are opposed using 4-0 Monocryl, and Dermabond is applied over the skin incision. The On-Q SilverSoaker catheters are coiled and secured to the skin with Tegaderm. A compressive scrotal dressing is placed using fluffs and Elastoplast. The Foley catheter is left to closed-system gravity drainage overnight.

imated using 3-0 polyglycolic acid sutures in a running fashion. The skin edges are opposed using 4-0 Monocryl, and Dermabond is applied over the skin incision. The On-Q SilverSoaker catheters are resecured to the skin with Tegaderm. A compressive scrotal dressing is placed using fluffs and Elastoplast. The Foley catheter is left to closed-system gravity drainage overnight (Fig. 76.8).

## COMPLICATIONS

Mechanical disruption of the microvascular anastomosis and subsequent uncontrolled arterial hemorrhage may occur from blunt trauma in the first few postoperative weeks following coitus or masturbation, or from accidents. Abstention from sexual activities involving the erect penis is recommended until 6 weeks postoperatively. Other complications include penile pain and diminished penile sensation from injury to the nearby dorsal nerve. Loss of compliance of the suspensory and fundiform ligaments postoperatively may lead to diminished penile length. Preserving the two ligaments has markedly minimized those complications in our series. Glans hyperemia, once a complication seen when anastomoses between the inferior epigastric artery and the deep dorsal vein (dorsal vein arterialization) were performed, is no longer seen because we no longer perform this kind of anastomosis.

## RESULTS

Microvascular arterial bypass surgery has been performed in this above fashion since 1981. An estimated 1,500 procedures have been performed over >25 years. It is estimated that the

success rate (clinically relevant improvement in erectile function) is approximately 65% to 70%. Since relocating to San Diego, a review has been made of the latest 30 microvascular arterial bypass procedures using postoperative validated outcome scales, ultrasonography, and arteriography. The scores of the International Index of Erectile Function have improved significantly in the total score, the erectile function domain, the desire domain, the orgasm domain, the intercourse satisfaction domain, and the overall satisfaction domain. There has been marked and significant lowering of the sexual distress scale. Postoperative duplex Doppler ultrasonography has confirmed marked increases in cavernosal artery peak systolic velocity. Postoperative selective inferior epigastric arteriograms have been performed that have documented intact arterial anastomoses between the inferior epigastric artery and the dorsal penile artery with subsequent visualization of contrast in the cavernosal artery (Fig. 76.9). Finally, use of On-Q pump delivery of Marcaine for 48 to 72 hours has resulted in significant lowering of postoperative morphine and Percocet while the patients have simultaneously experienced excellent pain relief.

## CHAPTER 77 ■ PENILE TRAUMA

DANIEL I. ROSENSTEIN, ALLEN F. MOREY, AND JACK W. MCANINCH

Trauma to the penis is an uncommon event. Because of the relatively protected position of the penis between the thighs and pubic bone, it is usually able to avoid direct injury from external forces. Nonetheless, penile trauma may arise from both blunt and penetrating injuries. Such injuries present unique and difficult management problems to the urologic surgeon, in particular regarding long-term cosmesis, voiding function, and future potency. Major blunt penile injuries include penile rupture and skin loss from strangulation or degloving injuries. Penetrating penile trauma is usually secondary to stab or gunshot wounds and thus seldom occurs in the absence of associated genital, urethral, or major organ injury, except in the event of bites and self-inflicted wounds. Due to the wide disparity in the causes, diagnosis, and treatment, this chapter is divided into three parts: penile rupture, penile skin loss, and penetrating penile trauma.

---

### PENILE RUPTURE

---

The most common blunt injury involving the penis is rupture of the corpora cavernosa, or penile fracture. This almost invariably occurs when the erect penis is forced to bend in an irregular fashion, such as when it accidentally impinges on the pubis or perineum after slipping out of the vagina during sexual intercourse (11). The remainder of cases are caused by falls

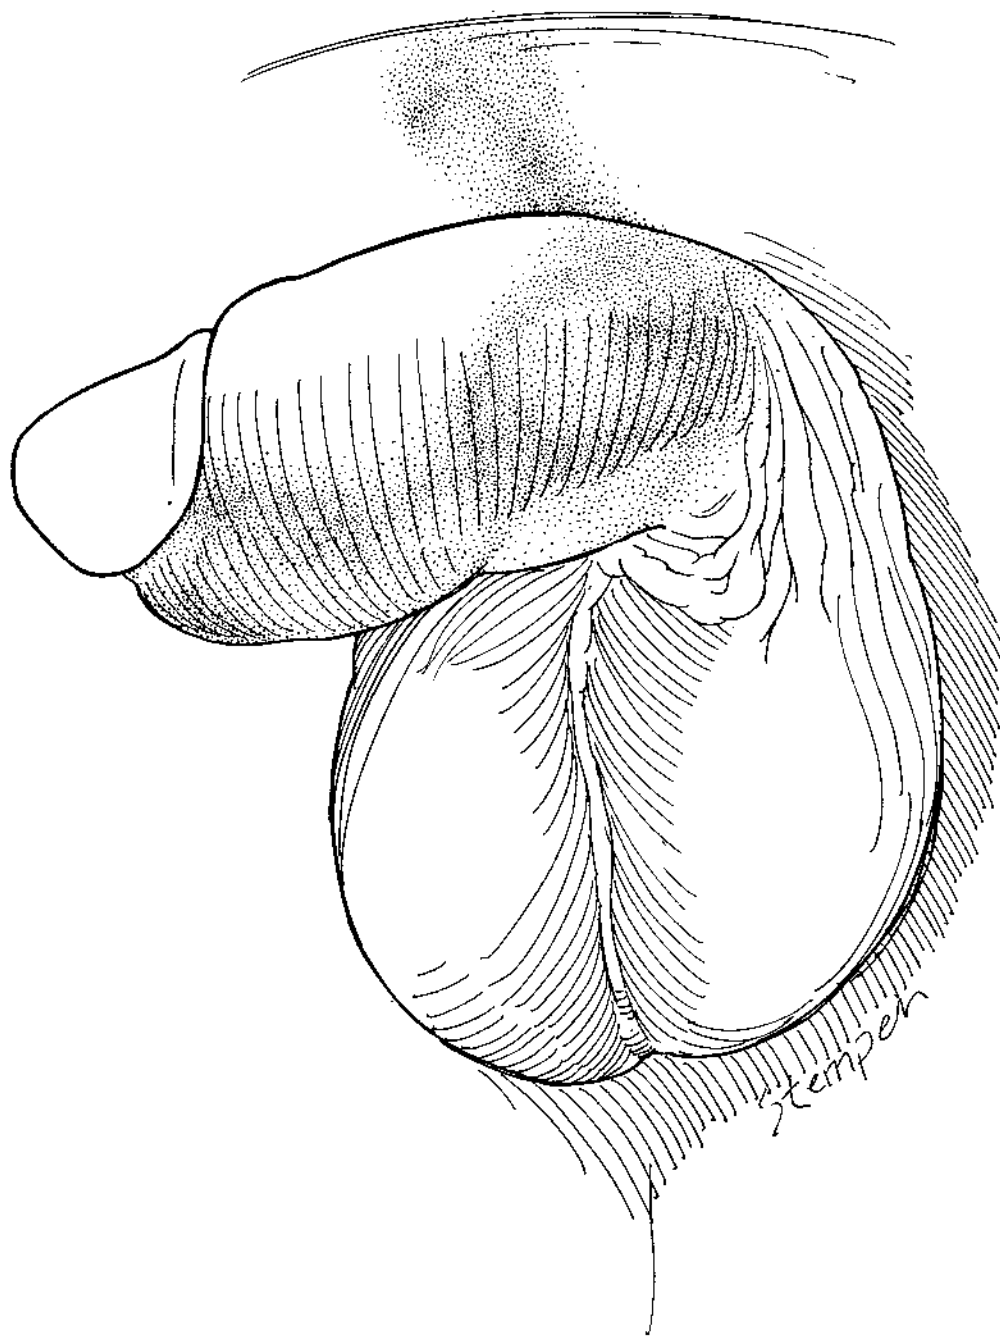

out of bed with an erect penis, masturbation, or manipulation of the erect penis. The patient often reports a cracking or popping noise at the time of injury, leading to immediate detumescence and rapid onset of discoloration and swelling over the site of injury. There is frequently a delay in presentation to the hospital—presumably secondary to patient embarrassment.

---

### Diagnosis

---

The diagnosis of penile rupture is easily made by physical examination along with the appropriate history. Swelling and discoloration may or may not be limited to the penis, depending on the integrity of the Buck fascia. If the Buck fascia is intact, the hematoma will be contained and will not usually spread below the base of the penis, resulting in the typical “eggplant” deformity (Fig. 77.1). However, if the laceration in the tunica albuginea involves the Buck fascia, extravasation will be contained by the Colles fascia and ecchymosis will extend in a “butterfly” distribution over the perineum, scrotum, and lower abdomen. Examination may reveal angulation of the penis away from the side of rupture because of the mass effect of the hematoma. In addition, focal tenderness and a palpable defect in the tunica albuginea may help localize the fracture site. There is often a clot lying over or near the fracture site that corresponds to the site of cavernosal rupture.

**FIGURE 77.1** Fractured penis displaying the pathognomonic “eggplant deformity” with swelling and discoloration extending to the base of the shaft. The penis usually bends away from the side of injury because of the hematoma.

Penile rupture can occur anywhere along the shaft, including the base of the penis, where the corpora are fixed by the penile suspensory ligament. The fracture is typically located at the base of the penis, just proximal to the penoscrotal junction. In general only one corporal body is injured, although both corpora and the corpus spongiosum can be affected depending on the severity of the injury. Most patients are able to urinate normally, but the urologist must maintain a high index of suspicion for urethral injury. Failure to void spontaneously may signify compression of the urethra by hematoma but should lead to evaluation of urethral injury by retrograde urethrography (RUG). Urethral injury occurs in up to one third of cases and usually consists of partial disruption, although complete transection can result (10). RUG is mandatory in all patients with blood at the urethral meatus, hematuria of any extent, or inability to void (11). However, because RUG is easy to perform and provides reliable results, we perform it routinely in all cases of suspected penile rupture. Adjunctive imaging studies in penile fracture (including ultrasound, magnetic resonance imaging, and cavernosography) are usually unnecessary as the clinical picture is frequently adequate to initiate therapy.

### Indications for Surgery

Although penile fractures can be managed nonoperatively, the literature shows a clear advantage to early operative repair (10,11). This approach results in faster recovery, shorter hospital stay, less morbidity, and less long-term penile curvature. The goals of acute exploration are evacuation of the hematoma and primary repair of the laceration.

### Alternative Therapy

Conservative treatment consists of cool compression dressings, anti-inflammatory agents, and sedatives to reduce erections. This results in eventual resorption of the hematoma and scar formation at the site of the tunical rupture.

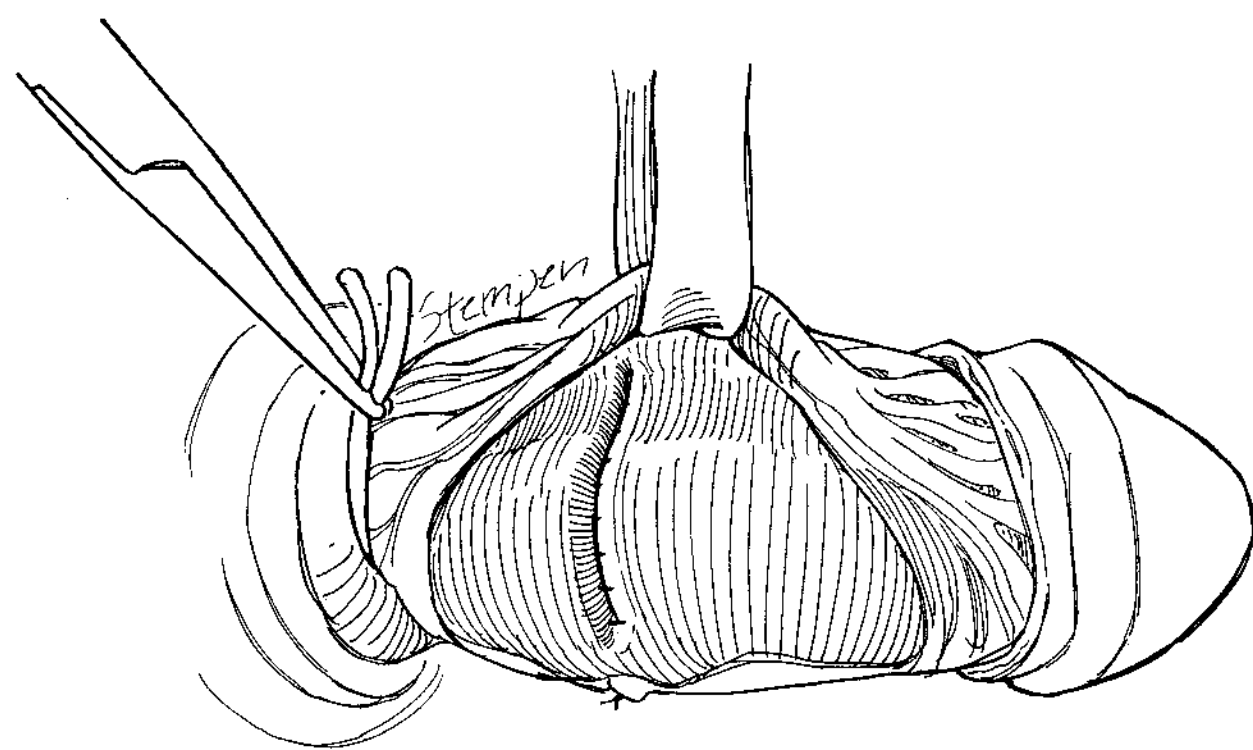

### Surgical Technique

The patient is placed in a supine position and a Foley catheter is placed to facilitate identification of the urethra and urinary drainage. Exposure is usually obtained through a subcoronal circumferential incision, and the penile skin is degloved down to the base. The distal circumferential incision is favored because it allows both exposure of the ruptured corpus and adequate assessment of the contralateral corpus and corpus spongiosum. Alternatively, an incision may be made on the shaft directly over the fracture site. This approach is only useful if the fracture is palpable preoperatively as the corporal bodies may not be easily explored through this incision. Further, the corpus spongiosum cannot be directly inspected via this approach.

Following the circumcising incision, the corpus spongiosum is carefully inspected to evaluate for potential urethral injury. Inspection of the fracture site usually reveals a transverse laceration, between 0.5 and 2.0 cm long, in the tunica albuginea of the proximal penile shaft (4). After evacuation of the hematoma and irrigation, minimal debridement of nonviable wound edges may be necessary before closure with interrupted 4-0 Maxon sutures (Fig. 77.2). The surgeon should not probe the exposed cavernous tissue unnecessarily as this may elicit troublesome bleeding. A tourniquet may be used intraoperatively to control hemorrhage. Lacerations may run directly under the dorsal neurovascular bundle located on the dorsal

**FIGURE 77.2** Identification and repair of penile fracture. A distal circumferential subcoronal incision is made and skin and soft tissue are mobilized off the underlying corporal bodies down to the base of the penis. This maneuver exposes the transverse laceration in the tunica albuginea. The laceration is repaired using interrupted 4-0 Maxon with the knots buried. Exposed corporal erectile tissue should not be probed or explored as this may cause troublesome bleeding.

**FIGURE 77.3** Penile fracture extending beneath dorsal neurovascular bundles. Elevation of the ipsilateral dorsal neurovascular bundle facilitates repair of lacerations and protects these structures from inadvertent injury. Division of the deep dorsal vein in the midline provides access to the correct surgical plane beneath the ipsilateral neurovascular bundle.

surface of the corpora at approximately the 10 and 2 o'clock positions (Fig. 77.3). This necessitates careful dissection of these structures off the corpora to allow a safe, watertight closure. Division of the deep dorsal vein facilitates unilateral dissection of the neurovascular bundle off the underlying corpus cavernosum. The penile skin is then replaced and the subcoronal incision is closed with interrupted 4-0 chromic sutures. If the patient is uncircumcised, the prepuce must be closely monitored for development of subcoronal edema. Postoperatively, a loose compression dressing (Coban) is gently placed, and the urethral catheter may be removed on postoperative day 1. Systemic antibiotics, anti-inflammatory agents, and fibrinolytics are unnecessary. Most patients can be discharged home within 1 to 2 days of surgery. Sexual activity can be resumed at about 4 to 6 weeks. Painful erections may be present in the early postoperative period. Suppression of erections with benzodiazepines or amyl nitrate may provide symptomatic relief.

When urethral transection occurs in the context of penile rupture, we advocate primary repair with interrupted 5-0 or 6-0 Maxon sutures over a 16Fr silicone catheter. In cases of complete urethral transection, additional urinary diversion through a percutaneous suprapubic cystostomy tube may be prudent (11). A voiding cystourethrogram (VCUG) should be carried out at approximately 14 days postrepair to document adequate healing before catheter removal.

---

## Outcomes

---

### Complications

Many patients treated conservatively or with delayed repair have some form of sexual dysfunction, such as painful erection, disabling curvature, or erectile dysfunction secondary to cavernous-venous occlusive disease (1,14). Patients with a missed urethral injury associated with penile fracture are also at risk of periurethral abscess, stricture, and fistula formation.

### Results

Patients who have operative repair within 48 hours of the injury have excellent functional results. In two relatively large studies, none of the patients with early operative repair

experienced impotence, penile curvature on erection, or painful intercourse (4,11).

---

## PENILE SKIN LOSS

---

### Diagnosis

---

Penile skin loss can occur from necrotizing infection, burns, constrictive bands, or degloving injuries from blunt or penetrating trauma. Dog and human bites may also result in considerable penile skin loss. When the skin loss is secondary to infection (e.g., Fournier gangrene), repeated debridement with antibiotics and moist dressing changes must be instituted to prepare the underlying tissue for delayed reconstruction. If the wounds are grossly contaminated, the testes may be placed in subcutaneous thigh pouches with a view toward delayed scrotal reconstruction. Avulsions are most often caused by power tool injuries or motor vehicle accidents, although this injury may rarely be self-inflicted secondary to insertion of the penis into vacuum cleaners and other suction devices (1). Because of the laxity of penile skin, the avulsion usually extends just to the subcutaneous dartos layer, leaving the corporal bodies uninvolved. Immediate repair is frequently possible in cases of traumatic skin loss. If immediate closure is to be attempted, the wound edges must be clean and viable and hemostasis must be excellent to avoid delayed skin necrosis and sloughing.

---

### Indications for Surgery

---

Partial penile skin loss, especially in the distal shaft, is best managed by rotational mobilization of a local skin flap. Primary closure may be appropriate if the defect is short and there is abundant remaining shaft skin. Extensive skin loss, whether from the injury itself or surgical debridement, usually requires tissue transfer for repair. In impotent patients, the penis can be buried under a scrotal flap with the glans left exposed to allow micturition (Fig. 77.4) (5). The penis may be liberated at a later date using the scrotal skin as a graft to cover the previously denuded area. In sexually active patients, a thick (0.016- to 0.018-in.), nonmeshed split-thickness skin graft is used. Thick split-thickness grafts are preferred because they are non-hair-bearing, have minimal contraction, and offer excellent cosmesis and viability. If sexual function is not a concern, a thinner skin graft may be harvested and meshed. The avulsed skin that is still attached on a viable pedicle can be gently washed and reapplied with the knowledge that it may need to be debrided at a later time. Completely avulsed penile skin will usually not survive as a free graft if reapplied to the denuded penile shaft.

---

### Alternative Therapy

---

There are no alternatives to surgery.

---

### Surgical Technique

---

The patient is placed supine and both the genitals and a carefully chosen donor site are prepared into the field. The antero-lateral thigh provides thickness, texture, and color resembling

**FIGURE 77.4** Scrotal tunnel maneuver for penile skin coverage. The penis shaft may be buried beneath a flap of scrotal skin to provide skin coverage, leaving the glans exposed. This is a viable option in older patients who either were impotent before their injury or who have sustained severe associated injuries.

penile skin and is therefore the preferred donor site. Alternatively, the medial or posterior thigh or buttock may be used as a skin donor site. A Foley catheter is placed to prevent postoperative urinary contamination. The shaved donor site is coated with sterile mineral oil, and a Brown or Padgett dermatome (10-cm-wide strip) is used to harvest the graft in an approximately 0.018-in. thickness. The graft is then tailored to fit the defect on the shaft. The donor site may be dressed with fine mesh gauze under slight pressure to ensure adequate hemostasis. Placement of a semipermeable plastic or silicone membrane (e.g., Biobrane) directly against the donor site helps reduce contamination. After about 24 hours, the Biobrane is adherent to the donor site and the redundant edges may be trimmed. This dressing usually falls off spontaneously after 2 weeks.

To prepare the penile shaft for grafting, it must be sharply debrided of all devitalized tissue and any chronic granulation tissue. It is imperative to prepare the recipient site so that the graft will have adequate blood supply. Debridement of the glans should be avoided, but all nonviable skin, including the distal prepuce, should be excised up to the coronal sulcus. Native penile skin distal to the graft will become edematous because of disruption of native lymphatic and venous drainage along the shaft. Hemostasis in the graft bed is essential to prevent hematoma formation under the graft.

Once prepared, the penis is stretched and the graft applied circumferentially around the shaft. The graft seam is placed at the ventral aspect to simulate the appearance of the median raphe (Fig. 77.5). The graft is sutured in place using interrupted 5-0 chromic sutures. Chordee formation has in general not been a problem because the graft will have minimal longitudinal contraction. The graft is secured to itself and along the shaft with interrupted 5-0 chromic sutures. Several 4-0 Vicryl sutures are placed at the proximal and distal graft edges and left long to use as bolster tieover sutures. A Xeroform dressing

**FIGURE 77.5** Penile split-thickness skin graft. A thick (0.016- to 0.018-in.) split-thickness skin graft is applied to the denuded penile shaft. The distal skin is discarded to just beneath the corona when a circumferential graft is indicated. The graft is placed with the seam in the midline ventrally and secured with 5-0 chromic sutures to itself and along the shaft, while 4-0 silk sutures placed proximally and distally are left long to secure a bolster dressing.

is placed directly on the graft. A bolster dressing is then fashioned using mineral oil-soaked cotton and fluffs. The whole dressing is secured in place using the bolster sutures, leaving the glans visible for inspection. To keep the penis in a vertical position, a padded plastic splint is placed around the bolster dressing. This housing may be fashioned out of a 500-cc sterile water container.

Postoperatively, the patient is kept at strict bedrest until the dressing is removed, usually after 5 days, when the Foley catheter is also removed. Immobilization of the penis in the extended position maintained by the bolster is critical for graft survival. Broad-spectrum antibiotics and administration of subcutaneous heparin for deep venous thrombosis prophylaxis are useful adjuncts. We do not routinely administer medications to reduce frequency of erections unless they are painful for the patient. Erections may provide natural tissue expansion, and the grafts usually slide easily along the loose areolar tissue superficial to the Buck fascia. Once the penile dressing is removed, twice-daily sitz baths can be started to enhance epithelialization and reduce bacterial contamination.

---

## Outcomes

---

### Complications

The common causes of early failure of penile skin grafting are infection, shearing forces causing graft separation, and underlying hematoma. It is imperative that the graft bed be free of infected granulation tissue and any necrotic tissue. Shearing forces disrupt the blood supply to the new graft and are prevented by the penile splint and bolster dressing, provided the patient is cooperative with strict bedrest for 5 days. It is critical that the penis be maintained in the extended position within the bolster dressing as this will prevent folding or telescoping of the fresh graft on the penile surface. Hematoma causes failure by creating poor contact between the graft and the recipient bed. It is prevented by ensuring meticulous hemostasis of the graft bed prior to laying the graft in place.

Meshed grafts allow better dissipation of hematoma fluid but are discouraged in potent patients because of their increased degree of contraction.

### Results

Long-term results of reconstruction have been excellent, with successful graft take exceeding 90%. Sensation remains absent in the grafted skin but is retained in the glans and in deeper structures. Potency is unaffected by this type of reconstruction. Most patients have satisfactory intercourse after reconstruction. Cosmetic and functional results of nonmeshed, thick split-thickness penile grafts are superior to either meshed grafts or scrotal flaps.

---

## PENETRATING PENILE TRAUMA

---

Penetrating trauma to the penis is most often caused by firearms but can also result from stab wounds, industrial accidents, self-mutilation attempts, and bites. In all cases, general principles of management include judicious debridement and hemostasis within the wound as well as careful exploration and repair of corporal and urethral injuries. Most civilian penile gunshot wounds are caused by low-velocity missiles, which cause damage only in the path of the bullet. Penetrating penile injuries are a more common genitourinary injury during wartime, possibly because of inadequate genital coverage by protective body armor (12). Associated wounds of the thigh and pelvis are common and may require urgent exploration and repair. Successful treatment of penetrating penile injuries must address and preserve normal voiding, potency, and penile cosmesis.

---

### Diagnosis

---

Genital injury is determined by careful physical examination, with special attention paid to the trajectory of the bullet and initial hemostasis. The finding of a palpable corporeal defect in combination with an expanding penile hematoma or significant bleeding from the entry/exit wound is highly predictive of corporeal injury and should prompt expedient exploration (7). The exam should include a vascular (glanular capillary refill) and penile sensory assessment (9). Urethral injury, which occurs in 25% to 40% of penetrating injuries to the penis, should be excluded with RUG in all cases (6). The triad of no blood at the meatus, absence of hematuria, and normal voiding suggests that there is no urethral injury; however, penetrating trauma can cause urethral injury without clinical signs of damage. Cystography, intravenous pyelography, and scrotal ultrasonography may be necessary to evaluate associated urologic injuries. Cavernosography is rarely indicated in this setting (9).

---

### Indications for Surgery

---

Penetrating injury to the penis most often requires surgical exploration. In addition, patients with unstable major organ injury will be unable to undergo immediate exploration. In these cases, initial treatment consists of hemostasis and packing of major wounds. Penetrating injury causing major skin loss will require tissue transfer for satisfactory coverage, but associated corporal and urethral injuries must be repaired

before the skin grafting. Immediate primary closure or reconstruction should take place only with a clean wound that is in general <8 hours old.

---

### Alternative Therapy

---

Single pellet wounds with small entrance sites and superficial stab wounds in which there is no active bleeding or hematoma may not require surgical exploration (3).

---

### Surgical Technique

---

The operation consists of judicious debridement of devitalized tissue and hemostasis. The wound must be copiously irrigated to remove all foreign bodies, including powder from shotgun pellets and pieces of clothing. Bleeding almost always occurs from a lacerated corporal body but may also be from disrupted superficial veins. The primary objective of surgical exploration is control of corporal bleeding and repair of corporal defects. The corpora are well vascularized, and extensive debridement is usually unnecessary and will hinder future potency. We thus do not recommend extensive exploration of erectile or glanular tissue. Hemostasis is obtained by gentle compression and watertight closure of the tunica albuginea alone, usually with interrupted 4-0 Maxon sutures. Urethral injuries are repaired with 5-0 Vicryl sutures over a silicone catheter. A devitalized urethra must be carefully debrided, and primary repair with a tension-free anastomosis can usually be accomplished. Associated scrotal and spermatic cord injuries are treated with debridement and, if necessary, orchiectomy or ligation of the vas deferens. The skin can be closed primarily unless viable skin edges cannot be approximated. In contaminated wounds or those encountered after 8 hours, immediate skin closure or grafting is not recommended and the wound is packed instead. Once the wound is clean, delayed primary closure, staged reconstruction, or healing by secondary intention may be selected. An important contraindication to debridement and primary closure is the case of massive tissue destruction often associated with close-range shotgun blasts. These should be debrided and allowed to declare themselves in terms of the extent of injury. They may then be repaired in a staged fashion. It appears that longer-range injuries due to shotgun blasts may create multiple low-velocity wounds with less significant blast effect. Carefully selected longer-range shotgun injuries have been successfully managed with immediate debridement and primary repair (13).

Penile bites deserve special mention as they can rapidly progress to severe infection. Wounds should be copiously irrigated and all devitalized tissue debrided. All wounds should be left open and prophylactic antibiotics administered. Antibiotic treatment should cover gram-positive and gram-negative organisms as well as anaerobic gram-negative rods. The most common colonizing organisms in the mouth of a dog include *Pasteurella*, *Streptococcus*, and *Staphylococcus* species (2). Hospitalization with frequent wound inspection and intravenous antibiotics is necessary in those with delayed presentation or with increased risk factors such as steroid use, diabetes, or immunodeficiency syndromes. Close follow-up is mandatory in all outpatients.

---

## Outcomes

---

### Complications

Early complications of penetrating penile trauma include rebleeding and infection. Because the corpora are heavily vascularized, breakdown of repair in the tunica albuginea is rare. A small minority will report superficial sensory loss, pain with erection, and rapid detumescence. Complications attributable to the urethral injury include urethral stricture, periurethral abscess, and urethrocutaneous fistula.

### Results

Excellent functional results can be expected except in those cases of high-velocity injuries where massive tissue destruction has occurred. Most patients report retained potency without penile curvature and with satisfactory cosmetic results (5,8). Patients who develop late penile curvature in the absence of palpable corporeal defects or plaques may have scarring and contraction of the underlying cavernosal tissues and the intercavernous septum (7).

# CHAPTER 78 ■ PENILE REPLANTATION

URI GUR AND GERALD H. JORDAN

Penile amputation is a rare injury in the Western world, arising largely from attempts at self-emasulation or as the result of violent assault. It may also arise secondary to industrial work accidents or as a war injury. Injuries amounting to penile amputation have also been reported as a rare complication of circumcision (5). The largest single series of penile amputation injuries comes from Thailand, where in the 1970s an epidemic of approximately 100 cases was reported (1). In these cases, adulterous husbands had their penises amputated by their humiliated wives while they slept. Unfortunately, only 18 of 100 cases in this series were successfully replanted using microsurgical techniques, as the amputated penis was often rapidly disposed of by the wife. Thus, experience with penile replantation is largely based upon case reports and smaller series. Despite the rarity of this injury, good functional and cosmetic results are routinely attainable using the microsurgical approach to penile replantation.

Psychotic patients who carry out self-emasulation may be broadly divided into two categories. The more common

subgroup includes schizophrenic patients in a decompensated (actively psychotic) state. One study found that 87% of self-emasculating patients were psychotic at the time of injury (3). These patients are usually victims of command hallucinations that coerce the patient to mutilate his genitals.

Because these patients respond well to psychiatric rehabilitation, they are unlikely to repeat an attempt at self-mutilation, provided they remain under chronic pharmacotherapy and surveillance (3,9). Penises should therefore be replanted in a timely manner following amputation, with psychiatric support throughout the patient's admission and probably lifetime. Nonpsychotic patients who self-emasculate are often diagnosed with severe personality disorders. These patients are more difficult to rehabilitate.

While early attempts at penile replantation were frequently fraught with complications including skin and glans slough, the majority of these attempts were successful at salvaging the penis with corporal reapproximation alone. This field was revolutionized in 1976, when two independent groups

described the first successful penile replantations using microvascular techniques (2,11). Since that time, microneurovascular repair has been considered the standard of care in penile replantation and has provided superior results with regard to postoperative sensation, erectile function, and overall graft viability, with durable results in the long term (1).

The remarkable ability of an amputated penile tip to survive even in the absence of penile arterial and venous reanastomosis attests to the unique vascular supply of the penis. It seems that the sinusoidal blood within the corporal bodies sufficiently approximates arterialized parameters, thus adequately nourishing the distal bodies and skin early on without having to depend upon collateral vessel development. Microvascular reanastomosis has further decreased skin and glans slough because the skin may be perfused directly rather than via corporal perforators.

## DIAGNOSIS

The physical diagnosis is obvious with complete loss of the distal penis. As already mentioned, most patients who have self-inflicted wounds will have responded to a command psychosis. Others have severe personality disorders. Thus, the surgery staff must work closely with a psychiatrist for these patients, as the emasculation is only a symptom of the underlying disease. Traumatic amputations either from an assault or industrial equipment will also likely have a postsurgical need for psychiatric evaluation.

All of these patients should be aware of the potential for loss of the penis if replantation is not successful, as well as the potential for erectile dysfunction.

## INDICATIONS FOR SURGERY

Because penile tissue has a remarkable resistance to prolonged ischemia (10), all attempts to replant the penile remnant should be carried out unless the penis has been extremely mutilated. Replantation has been successful despite cold ischemic times of 24 hours or longer. Most patients have sharply lacerated their penises, with clear anatomic structures and vessels often visible both in the stump and the distal portion (Fig. 78.1). The penis should be preserved with the “bag-within-a-bag” technique (Fig. 78.2). This serves to increase ischemic tolerance. The amputated penis is wrapped in saline-soaked gauze in a sterile plastic bag. This bag is then immersed in ice slush. The patient should be kept warm and peripherally vasodilated throughout the procedure as well as in the postoperative period.

## ALTERNATIVE THERAPY

Alternatives are limited, as the alternative is to not reconstruct the penis and thus close the penis and perform a urethrostomy.

One alternative, if microsurgery is not available but the penis is otherwise “replantable,” would be macroscopic approximation of the urethra and corpora. This approach harbors substantial risk for edema, skin necrosis, and sloughing of the glans skin. Often the deeper tissues of the glans survive and will re-epithelialize or can be grafted.

**FIGURE 78.1** The typical appearance of a penile amputation injury. (From Jordan GH, Gilbert DA. Management of amputation injuries of the male genitalia. *Urol Clin North Am* 1989;16:359–367, with permission.)

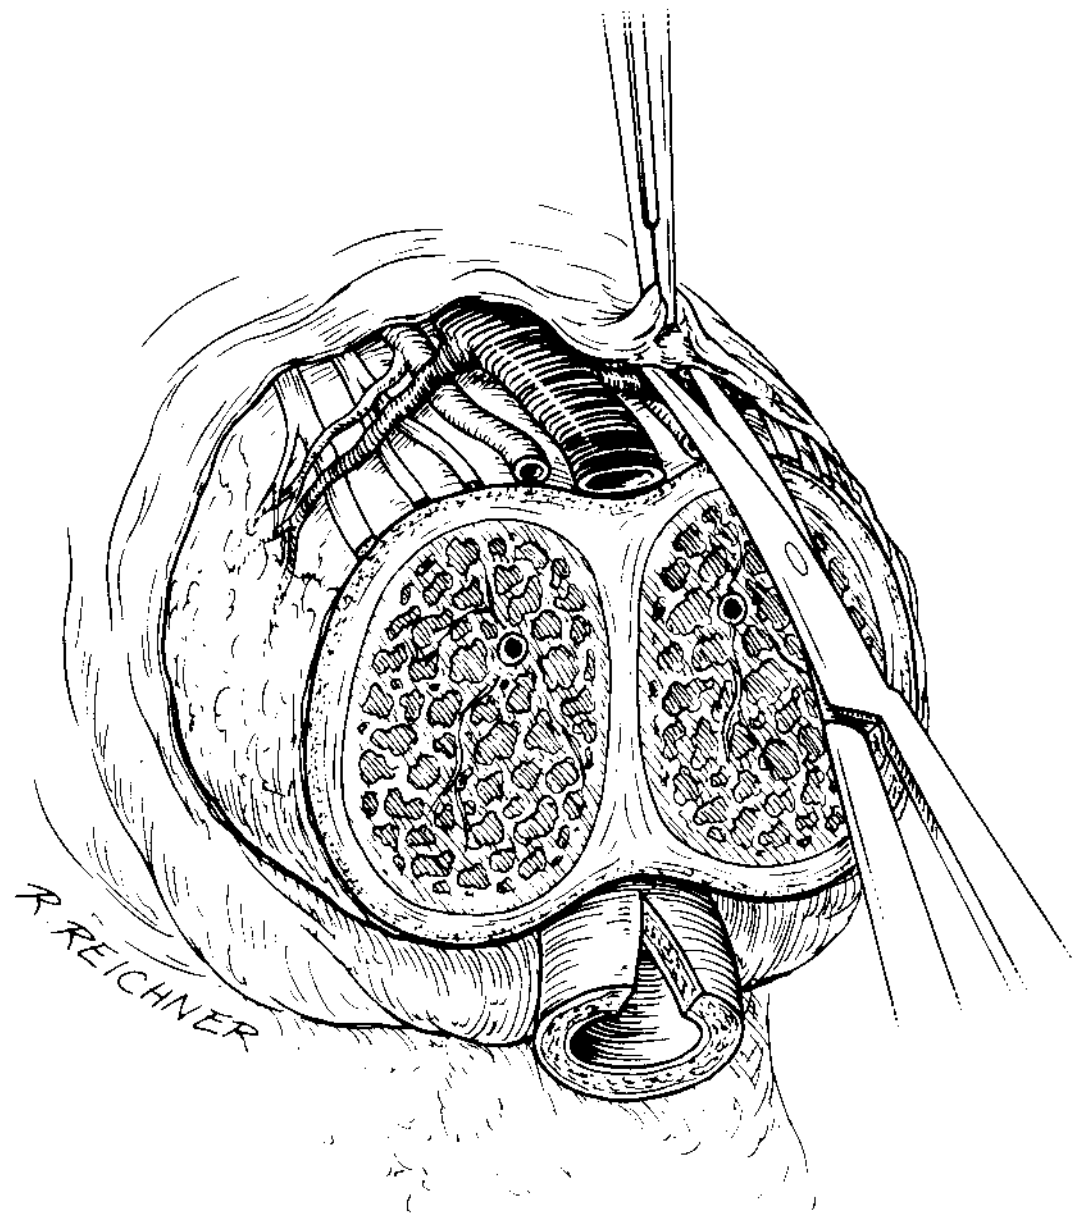

**FIGURE 78.2** Illustration of the bag-within-a-bag technique of organ emergent cold storage. The amputated part of the penis is placed on a saline-soaked gauze sponge, within a sterile (if possible) plastic bag. The plastic bag is then immersed in a second container of iced slush. (From Jordan GH. Initial management and reconstruction of male genital amputation injuries. *Trauma Reconstr Urol* 1996;57:673–681, with permission.)

## SURGICAL TECHNIQUE

Microsurgical replantation is carried out using microsurgical techniques (2), with systematic exploration and debridement of the corporal bodies and dorsal neurovascular structures as necessary (Fig. 78.3).

The urethra should be spatulated and reanastomosed first, as this provides stability to the remainder of the repair. A two-layer repair using 6-0 polydioxanone suture (PDS) or 6-0 polyglactin (Vicryl) for the epithelium followed by 5-0 PDS for the spongy erectile tissue is appropriate. Coaptation of the

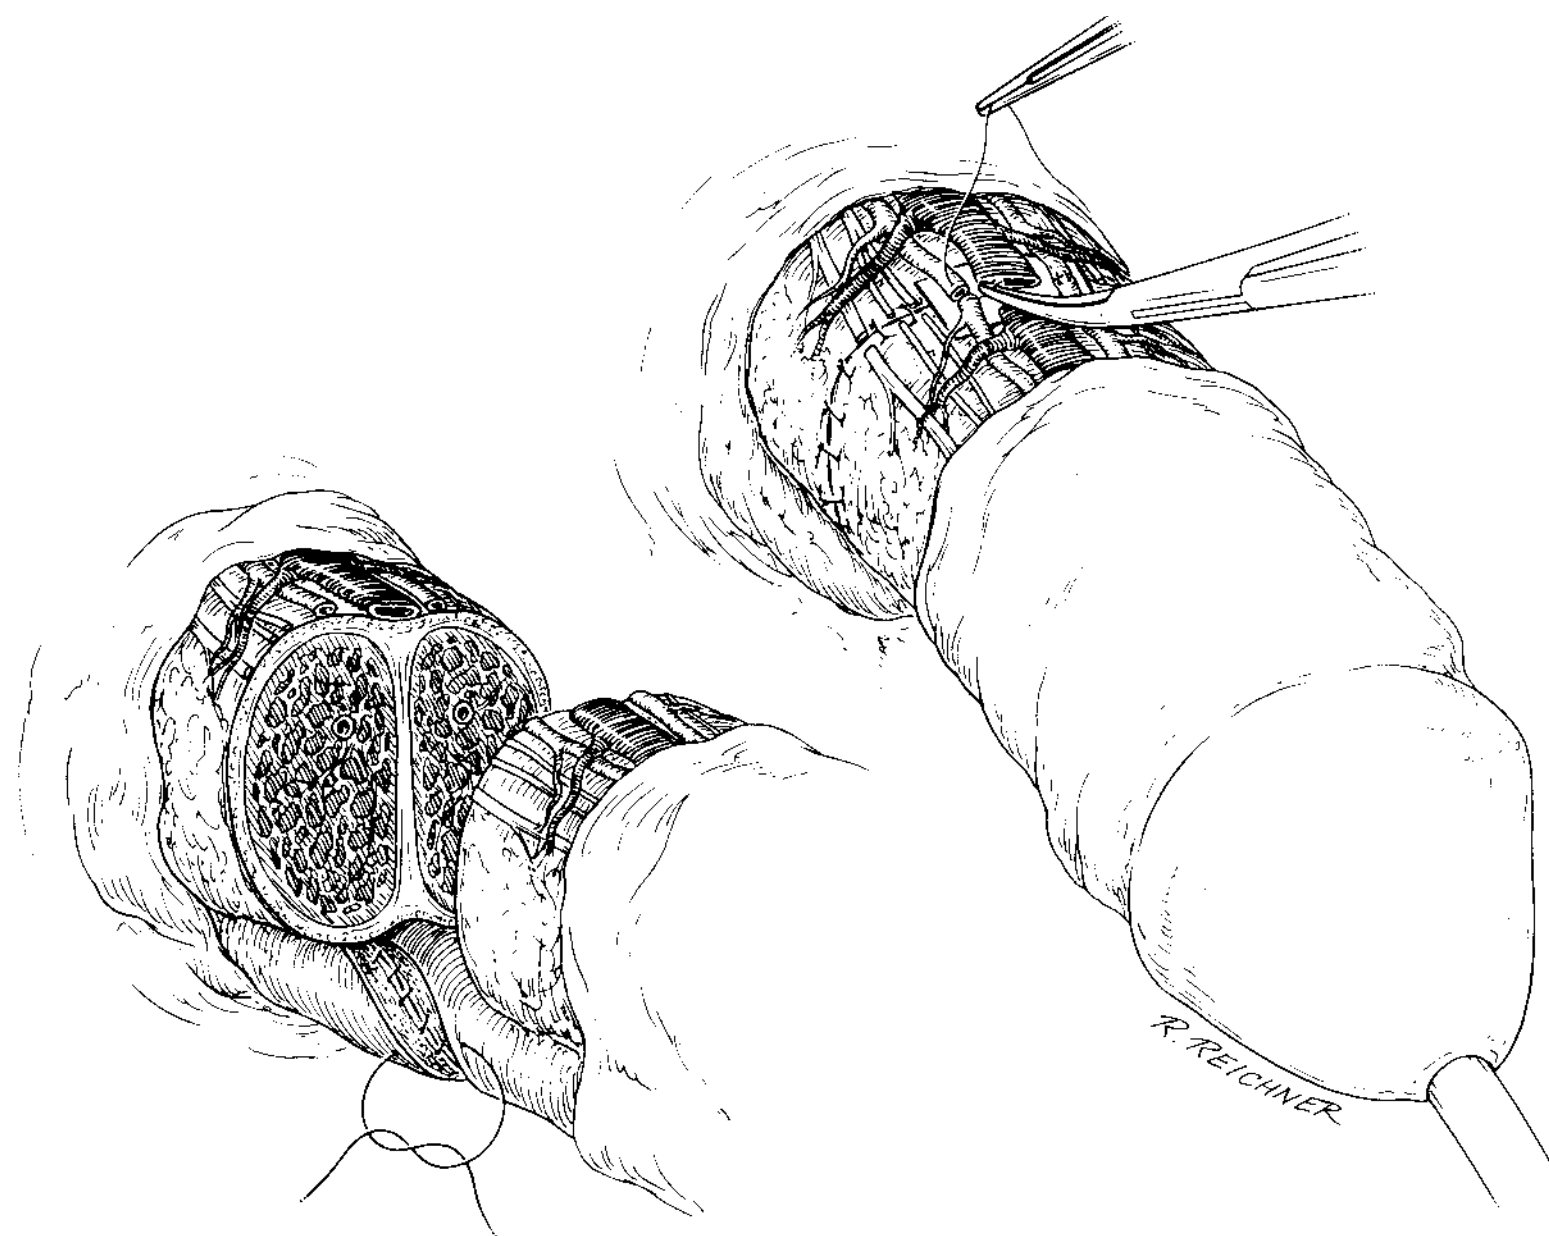

**FIGURE 78.3** The urethra, corpora cavernosa, and dorsal neurovascular structures are exposed and minimally debrided. (From Jordan GH, Gilbert DA. Management of amputation injuries of the male genitalia. *Urol Clin North Am* 1989;16:359–367, with permission.)

cavernosal arteries is difficult and does not seem to offer any advantage (6). The tunica albuginea of the corpora cavernosa should then be meticulously closed with interrupted 4-0 or 5-0 PDS sutures, as this will further provide stability for the microsurgical anastomoses.

The dorsal neurovascular structures are repaired next. Both dorsal penile arteries should be anastomosed using 11-0 nylon or polypropylene (Prolene), and the deep dorsal vein is then repaired with 9-0 or 10-0 nylon or Prolene. Following completion of the vascular anastomoses, the dorsal nerve bundles should be reapproximated with 10-0 nylon. The epineurium of each side should be placed in apposition so that fascicular regrowth is facilitated (Fig. 78.4). For distal injuries, fascicular coaptation may be required. These nerves are branches of the pudendal nerve and are responsible for sensation within the glans. The autonomic cavernous nerves branch proximally within the corporal bodies and are not repaired.

Following completion of the microsurgical anastomoses, the dartos fascia should be reapproximated using 5-0 Vicryl sutures and the skin loosely reapproximated using 5-0 or 6-0 Vicryl sutures. Shaft skin should be preserved if at all possible, as initially questionable skin may appear more viable in the postoperative period (Fig. 78.5). A diverting suprapubic cystostomy catheter should be placed and the urethra stented with a small soft silicone catheter. The penis should be immobilized and elevated to facilitate venous and lymphatic drainage. A subcutaneous suprapubic tunnel technique has been described for protection of the replanted penis in the early postoperative period, in cases where there is not adequate skin for coverage (4).

If the microvascular approach to replantation is technically or otherwise not feasible, the penis should be replanted via corporal and urethral reapproximation. The denuded replanted penis may be buried in the scrotum or a subcutaneous suprapubic tunnel as above, followed by delayed liberation with scrotal skin cover, as described by McRoberts et al. (8), or with grafting. Although penile salvage is usually successful via this technique, it obviously requires a second procedure. Covering the penis with scrotal skin is cosmetically less than optimal,

**FIGURE 78.4** A two-layer spatulated urethral anastomosis is completed. Microvascular coaptation of the dorsal vein, deep dorsal artery, and dorsal nerves is accomplished. (From Jordan GH, Gilbert DA. Management of amputation injuries of the male genitalia. *Urol Clin North Am* 1989;16:359–367, with permission.)

**FIGURE 78.5** Postoperative result. (From Jordan GH, Gilbert DA. Management of amputation injuries of the male genitalia. *Urol Clin North Am* 1989;16:359–367, with permission.)

while grafting the penis provides much more acceptable results. In either case, the shaft sensation will be compromised.

If the amputated penis is absent or too mutilated for replantation, hemostasis should be achieved, followed by spatulation of the neomeatus. The proximal shaft may be buried in the surrounding skin, or the residual corporal stumps may be covered by a split-thickness skin graft. In the unusual circumstance that contamination in the area of the genitalia precludes immediate replantation, temporary ectopic microsurgical implantation (to the forearm) followed by delayed anatomic replantation has been employed successfully (7).

---

## POSTOPERATIVE MANAGEMENT

---

The patient is kept on bedrest for approximately 1 week, with urinary diversion continuing for approximately 3 weeks. During this period, the replanted penis should be closely monitored

with Doppler and observed for signs of skin slough or decreased glans viability. The stenting catheter may be removed at the 3-week postoperative period, with a voiding urethrogram carried out to document the healing of the urethra. The use of daily aspirin in the postoperative period is recommended. More aggressive anticoagulation is usually not warranted but should be addressed on a case-by-case basis.

---

## OUTCOMES

---

Given the uniformly good results of microvascular penile replantation from both cosmetic and functional aspects, this approach should be used if at all possible. If microsurgery is not feasible, macroscopic replantation should still be offered.

---

## COMPLICATIONS

---

The frequency of skin necrosis, glans slough, and urethral complications has been reduced with the microvascular approach to replantation. Edema and congestion are common but are usually of a self-limited nature.

Adjuvant treatment with hyperbaric oxygen in the early postoperative period was reported as possibly advantageous to treat the edematous and/or ischemic replanted penis (12).

As with other “free flaps,” the successful use of medicinal leeches to treat postoperative venous congestion has been reported (9).

Several reports document the return of partial or complete erectile function in the months following the replantation. Patients who fail to achieve adequate return of erections may still respond to pharmacologic erection therapy.

# CHAPTER 79 ■ VARICOCELE: GENERAL CONSIDERATIONS

CARIN V. HOPPS AND MARC GOLDSTEIN

A varicocele is an abnormal dilation of the veins draining the testis, the internal spermatic veins, that can be palpated through the scrotal skin. While varicoceles are present in 15% of the male population overall, they are present in 35% of men with primary infertility and in 81% of men with secondary infertility (3). Varicocele is the most common etiology of male factor infertility, and varicocelectomy (ligation of the internal spermatic veins) is the most commonly performed surgical procedure for men with infertility. Varicocele is associated with decreased testicular volume, impaired sperm quality, and a decline in Leydig cell function (13). Surgical repair of clinical varicocele has been shown to avert further damage to testicular function, improve spermatogenesis, and improve Leydig cell function. Large varicoceles are associated with greater testicular dysfunction than are small varicoceles, and repair of large varicoceles results in greater improvement in semen parameters when compared with repair of small varicoceles (10).

Varicoceles most commonly occur on the left. Whereas the right internal spermatic vein drains into the vena cava, the left internal spermatic vein drains into the left renal vein and therefore is significantly longer than the right vein, resulting in greater transmission of pressure to the pampiniform plexus. Contributing to increased venous pressure is the position of the left renal vein, which crosses anterior to the aorta and posterior to the superior mesentery artery, potentially causing compression of the renal vein, known as the “nutcracker effect.” Retrograde flow of blood into the pampiniform plexus due to incompetent valves within the internal spermatic vein may also contribute to dilation of this venous system.

The pathophysiology by which varicocele impairs testicular function is poorly understood. Of several proposed mechanisms of injury, thermal testicular injury is the hypothesis most supported by animal and human studies. Animal models have demonstrated a clear adverse effect of heat on testicular function. Varicocele is thought to affect thermoregulation of the testis by interfering with the countercurrent heat exchange mechanism within the pampiniform plexus. Although the scrotal location of the testes appears to underscore the importance of temperature regulation, the mechanism by which varicocele causes injury to the testis is likely multifactorial.

---

## DIAGNOSIS

---

Varicocele is diagnosed by thorough examination of the scrotal contents with the patient in both the supine and standing positions. Relaxation of the dartos muscle, facilitated by a warm scrotum (we favor a simple heating pad on the scrotum), is

essential for proper examination of scrotal contents. Grade I varicocele is palpable with Valsalva maneuver only, grade II is palpable in the standing position, and grade III is visually apparent through the scrotal skin as a “bag of worms.” Transscrotal ultrasound is not necessary to diagnose varicocele but may be utilized if physical examination cannot be adequately accomplished or findings on physical examination are equivocal. Internal spermatic vein diameter  $>3$  mm and demonstration of retrograde flow through the vein with Valsalva maneuver on ultrasound are consistent with the diagnosis of clinical varicocele. Varicoceles that do not meet these criteria are defined as subclinical.

---

## INDICATIONS FOR SURGERY

---

Most varicoceles are not associated with infertility, decreased testicular volume, or pain and therefore do not require surgical correction. A clinical varicocele in a patient with abnormal semen parameters should be surgically corrected to reverse the process of progressive and duration-dependent decline in testicular function. Repair of subclinical varicocele has not been shown to confer a benefit to the patient with male factor infertility and is not recommended (4). Varicocele associated with ipsilateral testicular atrophy or with ipsilateral testicular pain that worsens progressively throughout the day, but subsides in the recumbent position, should be repaired as well. Varicocele ligation in adolescents with ipsilateral testicular atrophy has been shown to result in a significant increase in testis volume (5), and therefore surgical correction is recommended in this group. Adolescents with small- to moderate-grade varicoceles in the absence of atrophy are followed with yearly examination to assess testicular growth; the occurrence of diminished growth on the side of the varicocele warrants varicocelectomy. A sound argument could be made for repair of all grade III varicoceles in adolescents to conserve testicular function. Approximately 3% of adolescent males have grade III varicoceles.

---

## ALTERNATIVE THERAPY

---

For men with infertility, abnormal semen parameters, and clinical varicocele, few alternatives to varicocelectomy are available. Currently utilized nonsurgical techniques include percutaneous radiographic occlusion and sclerotherapy. The retrograde percutaneous approach employs cannulation of the femoral vein and placement of a balloon or coil within the internal spermatic vein. Although this technique is associated with preservation of the testicular artery and lymphatics, it has a high

unperformable rate due to difficulty in accessing the internal spermatic vein, and these men ultimately require surgical intervention. Radiographic occlusion is also associated with complications such as migration of embolization material into the renal vein resulting in kidney loss or pulmonary embolization, thrombophlebitis, arterial injury, and allergic reaction to contrast materials. This technique may have a role in the management of varicoceles that persist or recur following open surgical repair to avoid reoperation through scar tissue. Antegrade varicocele occlusion performed by percutaneous cannulation of a scrotal pampiniform vein and injection of a sclerosing agent has been described. This technique is associated with higher performability rates but similar recurrence rates when compared with the retrograde approach, in addition to presenting risk of injury to the testicular artery.

## SURGICAL TECHNIQUE

Ligation of the internal spermatic veins can be approached in several ways. The earliest described technique involved placing an external clamp on the veins through the scrotal skin. Surgical varicocele ligation techniques include retroperitoneal, inguinal or subinguinal ligation, laparoscopic, and microsurgical varicocelectomy.

### Retroperitoneal (Polomo) Approach

The retroperitoneal (Polomo) approach (Fig. 79.1) has the advantage of isolating the internal spermatic veins proximally, near the point of drainage into the left renal vein. At this level, only one or two large veins are present. In addition, the testicular artery has not yet branched and is often sepa-

rate from the internal spermatic veins. A disadvantage to this approach is difficulty in preserving lymphatics due to the poorly accessible retroperitoneal location of the vessels, leading to a higher incidence of postoperative hydrocele. In addition, a high recurrence rate is observed when the testicular artery is preserved due to preservation of the periarterial plexus of fine veins (*venae comitantes*), which may dilate with time and present as the source of recurrence. Parallel inguinal or retroperitoneal collaterals originating at the testis and joining the internal spermatic vein cephalad to the level of ligation, in addition to cremasteric veins that are not ligated, may contribute to recurrence. Intentional ligation of the testicular artery has been suggested in children to minimize recurrence, but in adults who present with infertility, ligation of the testicular artery cannot be recommended as this is unlikely to enhance testicular function.

The patient is placed in the dorsal supine position on an operating table. A horizontal iliac incision equidistant from the umbilicus and anterior superior iliac spine is made (7 to 10 cm, depending on the patient's body habitus). The external oblique aponeurosis is incised obliquely. The internal oblique is split 1 cm off the lateral edge of the rectus abdominis, and the transversus abdominis is incised. The peritoneum is dissected free from the abdominal wall and retracted. The spermatic vessels appear adherent to the peritoneum, making it important to remain close to the peritoneum. Continued dissection along the abdominal wall would lead posteriorly to the psoas muscle. Retraction of the peritoneum allows easy identification of the spermatic veins, and in <10% of cases the spermatic artery is clearly visible, isolated from the rest of the spermatic structures, identified, and preserved.

The remainder of the operation depends on the intraoperative findings. In the case of a single vein and no collateral, the

**FIGURE 79.1** Modified Palomo retroperitoneal approach for varicocelectomy. The internal spermatic vein is found on the posterior aspect of the peritoneum. It is isolated and divided between ligatures.

artery is identified and will only be preserved when it is not accompanied by a plexus of small veins indissociable from the artery. In the case of multiple veins, the collaterals are identified and all vessels from the ureter to the abdominal wall are ligated. Spermatic vessels are in general inspected over a distance of 7 or 8 cm and ligated by braided, permanent suture material.

After verification of hemostasis, the internal oblique, transversus abdominis, and external oblique aponeurosis are reapproximated with absorbable suture. The Scarpa fascia is closed by a resorbable running suture. The skin is closed in subcuticular manner with absorbable suture.

### Inguinal (Ivanissevich) Approach

The incision is made 2 cm above the symphysis pubica (Fig. 79.2). The external oblique aponeurosis is carefully divided to avoid injuring the underlying ilioinguinal nerve. The cord is mobilized and a Penrose drain is inserted beneath the cord and retracted to gain exposure of the cord. The spermatic fascia is then incised and the vessels are identified. Each vein is isolated, doubly ligated with nonabsorbable suture, and transected. Intraoperative Doppler may be utilized to identify the testicular artery. After all collaterals are identified, the external oblique aponeurosis is closed with running absorbable suture and the skin is closed in a subcuticular manner.

### Laparoscopic Varicocele Repair

Laparoscopic varicocele repair is a modification of the retroperitoneal technique with similar advantages and disadvantages. The optical magnification afforded through the laparoscope provides the ability to preserve the lymphatics and the testicular artery while ligating the few internal spermatic

**FIGURE 79.3** Subinguinal approach. The assistant grasps the spermatic cord with a Babcock clamp for elevation of the cord into the wound.

veins present at this level and the venae comitantes adherent to the testicular artery. Laparoscopic technique introduces a unique set of complications, including injury to bowel, intra-abdominal vessels, and viscera in addition to air embolism and peritonitis, all of which are much more serious than those associated with open varicocelectomy.

### Microsurgical Varicocelectomy

Microsurgical subinguinal or inguinal varicocelectomy is our preferred approach to varicocele ligation. The spermatic cord is elevated into the incision (Fig. 79.3), providing excellent exposure, and with use of the microscope providing 6× to 25×

magnification the small periarterial and cremasteric veins can be readily ligated, as can extraspermatic and gubernacular veins when the testis is delivered into the wound (Fig. 79.4). The external and internal spermatic fasciae are carefully opened to expose the vessels (Fig. 79.5). The testicular artery can be

readily identified under the microscope, and preservation of the artery is more likely with enhanced visualization (Fig. 79.6). Lymphatics are also identified and preserved (Fig. 79.7), resulting in a lower incidence of hydrocele postoperatively.

**FIGURE 79.6** A vessel loop is placed around the testicular artery for identification throughout the procedure. The artery has been dissected free of all adjacent veins and lymphatics.

**FIGURE 79.7** A lymphatic measuring 1 mm in diameter is visualized under the microscope and preserved.

## OUTCOMES

### Complications

The most common complication following varicocelectomy is hydrocele formation. The incidence of postoperative hydrocele following the nonmicrosurgical technique ranges from 3% to

33% with an average of 7%. Examination of the hydrocele fluid has shown that the fluid characteristics are consistent with obstruction of lymphatics (12). The effect of a hydrocele on sperm function and fertility is uncertain. Nearly half of postoperative hydroceles require surgical correction due to size. Use of magnification to identify lymphatics and preserve them has nearly eliminated the incidence of hydrocele formation (2,8).

Testicular artery injury is a complication of varicocelectomy. Although the testis also receives blood supply from the cremasteric and deferential arteries, ligation of the testicular artery may result in atrophy and/or impaired spermatogenesis. Microscopic technique facilitates identification and preservation of the testicular artery, minimizing the risk of testicular injury (2).

Varicocele recurrence occurs in periarterial, parallel inguinal, midretroperitoneal, or transscrotal collaterals (6). Parallel inguinal collaterals are missed with retroperitoneal repair. Routine inguinal techniques without optical magnification miss scrotal collaterals and small veins adherent to the testicular artery. The microsurgical approach with delivery of the testis is associated with a varicocele recurrence rate <1% when compared with 9% for nonmagnified inguinal techniques (2,8).

## Results

Varicocelectomy has been found to improve sperm concentration, motility, and morphology with a corresponding increase in pregnancy rate. A randomized controlled trial of surgery compared with no surgery (control group) showed that 60% of men who underwent varicocelectomy initiated a pregnancy within 1 year, whereas pregnancy was achieved in only 10% of those couples in which the varicocele went unrepaired (7). The control group then underwent varicocelectomy, and during the second year of the study 44% initiated a pregnancy. A series of 1,500 men who underwent microsurgical varicocelectomy resulted in 43% pregnancy at 1 year and 69% at 2 years when female factors were excluded (2). Varicocelectomy improves semen parameters sufficiently such that for most couples assisted reproductive techniques (ARTs) are either rendered unnecessary or the type of ART necessary to bypass the male factor is downstaged (1). In addition, up to 50% of men with nonobstructive azoospermia will respond to varicocelectomy with return of sperm to the ejaculate (9). In adolescents, a moderate to large varicocele can be responsible for testicular growth retardation, and early ligation of the varicocele may reverse this process (5). Finally, varicocelectomy can increase serum testosterone levels for infertile men with varicoceles (11).

# CHAPTER 80 ■ HYDROCELE AND SPERMATOCELE

JOHN A. NESBITT

Hydrocele and spermatocele refer to common but abnormal collections of fluid within the scrotum and must be included in the differential diagnosis of scrotal masses. The etiology of each of these masses is different, and both may require surgical intervention for cure. They occur in males of all ages, beginning at birth.

---

## HYDROCELE

---

Hydrocele (from the Greek *hydros* for water and *kele* for mass), literally a watery rupture or water in the scrotum, is an abnormal collection of fluid in the tunica vaginalis that may surround the testicle. The fluid is usually amber and is considered to be an exudate. A small amount of fluid, several cubic centimeters, is normally present around the testicle. This fluid is present between layers of the tunica vaginalis and the tunica albuginea covering the testis. About 0.5 cc of fluid is continuously secreted and reabsorbed by this mesothelial layer daily. Several types of hydroceles exist that may be associated with other pathologic findings, including cancer. The majority of hydroceles occur congenitally, and most of these resolve spontaneously during the first year of life. Acquired hydroceles are found later in life. If due to local inflammation, these hydroceles may resolve as the inflammation resolves. Intervention is usually only required for size or discomfort.

During month 3 of gestation, the gubernaculum traverses the inguinal canal from the internal ring, through the external inguinal ring, and out into the scrotum, pulling with it the parietal peritoneal lining of the abdominal cavity (processus vaginalis). Late in the third trimester, the testis leaves its intra-abdominal location, descends along the same route as the gubernaculum through the inguinal canal, and exits the external ring posterolateral to the processus vaginalis. Normally, the segment of the processus vaginalis lying in the inguinal canal obliterates by the time of birth. A portion of the processus is left within the scrotum closely applied to the testicle. This structure is then termed the tunica vaginalis. Persistence of the inguinal portion of the processus may lead to a patent processus vaginalis, a hernia, or a localized portion of fluid lying within the inguinal canal known as a hydrocele of the cord.

Most acquired hydroceles are idiopathic. However, the clinician must be careful to consider other causes, such as trauma, infection, or testicular tumor, when evaluating a patient. Lymphatic obstruction due to ipsilateral inguinal or pelvic surgery may result in a secondary hydrocele. A common surgical cause for hydrocele is renal transplantation. In this scenario, the spermatic vessels and vas deferens are divided on the ipsilateral side, leading to hydrocele development.

Epididymitis or orchitis may cause an acute hydrocele that usually resolves with the resolution of the inflammation. Tropical infections, such as filariasis, may produce hydroceles where the tunica thickens due to lymphatic obstruction by the parasites. In these cases, the fluid is usually turbid due to chylous drainage secondary to the lymphatic obstruction. It is generally thought that tense hydroceles are caused by lack of reabsorption of the fluid, and the more flaccid type from excess fluid production.

---

## Diagnosis

---

In the pediatric population, hydroceles may present at birth or within the first year of life and are found in about 6% of full-term males. In general, a painless swelling is noticed in the scrotum. The scrotal enlargement may increase or decrease in size if the processus is patent, allowing peritoneal fluid or bowel to enter the scrotum. If the processus is small, only fluid will enter. This persistence of the patent processus allowing the connection from the peritoneal cavity to the scrotum is known as a communicating hydrocele. The change in size may not be apparent to the clinician but will be noticed by the parents.

In acquired hydroceles, the swelling may be accompanied by pain, especially if caused by an inflammatory process. The patient may report an enlargement within the scrotum, a tense sac, or some discomfort within the scrotum that may radiate inguinally or into the ipsilateral flank. The swelling is smooth, confined to the scrotum, and will usually transilluminate if the wall is not too thickened. With somewhat large and tense hydroceles, the testis is not palpable. Because testicular neoplasms may also cause hydroceles, transscrotal ultrasonography is a useful preoperative diagnostic tool for imaging an otherwise inevaluable testicle.

---

## Indications for Surgery

---

Surgical intervention is indicated when the hydrocele is symptomatic either due to discomfort or size impairing daily activity. Hydrocelectomy is inappropriate in the face of a testicular neoplasm.

---

## Alternative Therapy

---

In congenital hydroceles, the treatment is usually observation, unless the patient has an accompanying hernia. This is an important distinction to make because the latter should be

repaired surgically. When the diagnosis is uncertain, some have advocated repair. A period of observation would be appropriate in the absence of other symptoms. Many of these hydroceles will resolve within the first year of life if left untreated.

In acquired hydroceles requiring treatment, the approach is in general considered to be surgical. Various surgical techniques have been described, all of which yield satisfactory results (7). The surgical approach is generally preferred due to the high success and low recurrence rates. Alternative therapies may be considered in symptomatic patients who are poor surgical risks. Hydroceles may be aspirated with some expected temporary pain relief. In addition, a sclerosing agent, such as tetracycline, may be placed within the empty space in an effort to keep the fluid from reaccumulating (2). This treatment has met with mixed results and may be very painful. Other sclerosants have been used, including ethanolamine oleate, polidocanol, sodium tetradecyl sulfate, and phenol. Sclerosing therapy typically requires up to three treatment sessions, and although high success rates have been reported (9), many physicians still reserve this treatment for poor surgical candidates. The recurrence and complication rates associated with sclerotherapy are higher than with the surgical approach, and some side-effects can include infection, impaired fertility, and testicular loss (11). Due to these risks, some authors feel that sclerotherapy is not appropriate for young healthy patients (6).

### Surgical Technique

There are several successful surgical techniques utilized to treat hydroceles. The scrotum is shaved, and, along with the penis, the entire area is cleaned with antiseptic preparation. The approach is usually midline scrotal or transverse between transversely running blood vessels, unless the diagnosis is in question. When neoplasm or hernia cannot be ruled out, the approach should be inguinal. The scrotal incision should be carried down to the tunica vaginalis, where the blue hue of the hydrocele is seen. The hydrocele and testicle may be delivered through the incision. Blunt dissection and use of a surgical sponge will free any surrounding tissue from the hydrocele sac. Once this parietal layer of tunica vaginalis is exposed, one may select the type of procedure to perform. In general, the Lord procedure is suitable for more thin-walled hydroceles, whereas the other described techniques are used with thicker sacs.

#### Andrews Procedure

This technique was described in 1907 by Andrews (1) and is referred to as the “bottle operation.” A 2- to 3-cm incision is made in the hydrocele sac near the superior portion (Fig. 80.1). The procedure may be completed by tacking the cut edges around the cord structures or leaving the everted sac open. A two-layer wound closure is then accomplished with absorbable suture, such as 2-0 or 3-0 chromic, approximating the skin over the dartos layer.

#### Jaboulay or Winkleman Procedure

As described by Jaboulay in 1902 (13), this technique involves delivering the testicle through an incision in the tunica. The majority of the sac is then resected, leaving a small cuff along the border of the testicle. After everting the remnant, bleeding may then be controlled rapidly by a running suture closing

**FIGURE 80.1** The Andrews operation. A small incision is made high in the sac prior to eversion of the sac about the cord.

**FIGURE 80.2** The Jaboulay or Winkleman technique. The redundant sac is excised, leaving enough room to be loosely closed about the cord. A running suture may be used to close the sac and rapidly control bleeding from the free edges.

the free edges around the cord structures (Fig. 80.2). Reapproximation of the edges is done loosely around the cord so as not to compromise the blood supply to the testicle. In another variation of this technique, the parietal tunica vaginalis is resected nearly flush with the testis and epididymis. Electrocautery may be used around the edge to aid in hemostasis, or bleeders may be ligated (Fig. 80.3). The standard two-layer closure is used to close the scrotum.

#### Lord Procedure

In utilizing this plication technique for hydrocelectomy described by Lord in 1964 (8), a small incision is made just large enough to deliver the testis into the field. The parietal layer of the tunica vaginalis is opened without dissection from the dartos layer. With little dissection of the scrotal sac, this procedure is relatively bloodless. Placing the Allis forceps on the cut edges of the open sac allows the testicle to be brought into the wound. Next, the edges are plicated circumferentially with interrupted 2-0 or 3-0 chromic catgut sutures, placing them about 1 cm apart. The bites should be approximately 1 cm as well (Fig. 80.4). As these sutures are tied, the sac will

**FIGURE 80.3** Alternate technique. The sac is excised nearly flush with the testicle, and the epididymis and bleeders are ligated or fulgurated individually.

**FIGURE 80.4** The Lord operation. The testis is extruded through a small incision placed in the middle of the sac, and interrupted placating sutures are placed in a circumferential fashion. The sutures are tied, and the sac will “accordion” into a collar superior to the testicle.

accordion, forming a collar around the testis and epididymis (Fig. 80.4 inset). Wound closure is accomplished as discussed for the other procedures.

#### Inguinal Approach

When a neoplasm is a concern but not definitively diagnosed preoperatively, a Chevassu maneuver may be performed or the Goldstein and Waterhouse modification employed (3). Preservation of the testicle may be accomplished without compromising the cancer operation. Biopsies of the suspicious area may be performed utilizing these techniques and the testicle spared if no cancer is found. These approaches involve exposure through an inguinal incision, clamping the cord with noncrushing clamps, ligating the gubernaculum prior to transection, and cooling the testis with ice slush. The benign testicle is then replaced into the scrotum or a radical orchiectomy performed in the case of malignancy.

In general, any of these procedures may be performed without surgical drainage. When hemostasis is difficult to obtain or the hydrocele particularly large, a small Penrose drain, placed through a separate stab incision in the inferior aspect of the scrotum and left overnight, is useful. This maneuver will also help prevent serous fluid from accumulating in the scrotum postoperatively. Because the scrotum is difficult to dress, fluff dressings held in place by a standard athletic supporter do well in this situation. An ice pack is kept in place for at least 24 hours to help diminish postoperative pain and swelling. Oral analgesics are utilized for several days. Preoperative antibiotics are helpful but not usually continued postoperatively.

---

## SPERMATOCELE

---

A spermatocele (from the Greek *spermatos* for sperm and *kele* for cyst or mass) is a cystic structure arising out of the epididymis, rete testis, or ductuli efferentes. These structures are filled with spermatozoa containing fluid that may be milky. These cysts are usually outside the tunica vaginalis and, as with hydroceles, transilluminate easily. They are frequently seen on scrotal ultrasound as an incidental finding and may be present in as many as 30% of males.

The etiology of most spermatoceles is idiopathic, although trauma, infection, or an inflammatory process within the epididymis or scrotum may precede the development of a spermatocele. It is hypothesized that the epididymal ducts become obstructed, causing proximal dilation. The cause of the obstruction is thought to be the seminiferous epithelium continually shedding immature germ cells that are deposited in the efferent ducts (4).

---

### Diagnosis

---

Because most spermatoceles are asymptomatic, they are usually discovered incidentally on self-examination or on physical examination by a physician. The typical location within the scrotum is cephalad and sometimes posterior to the testicle. However, spermatoceles may arise from any location on the epididymis. These cystic structures are not usually painful, are round, and have distinct borders. The mass is easily separable from the testis. Scrotal ultrasound may be helpful when the diagnosis is uncertain.

---

### Indications for Surgery

---

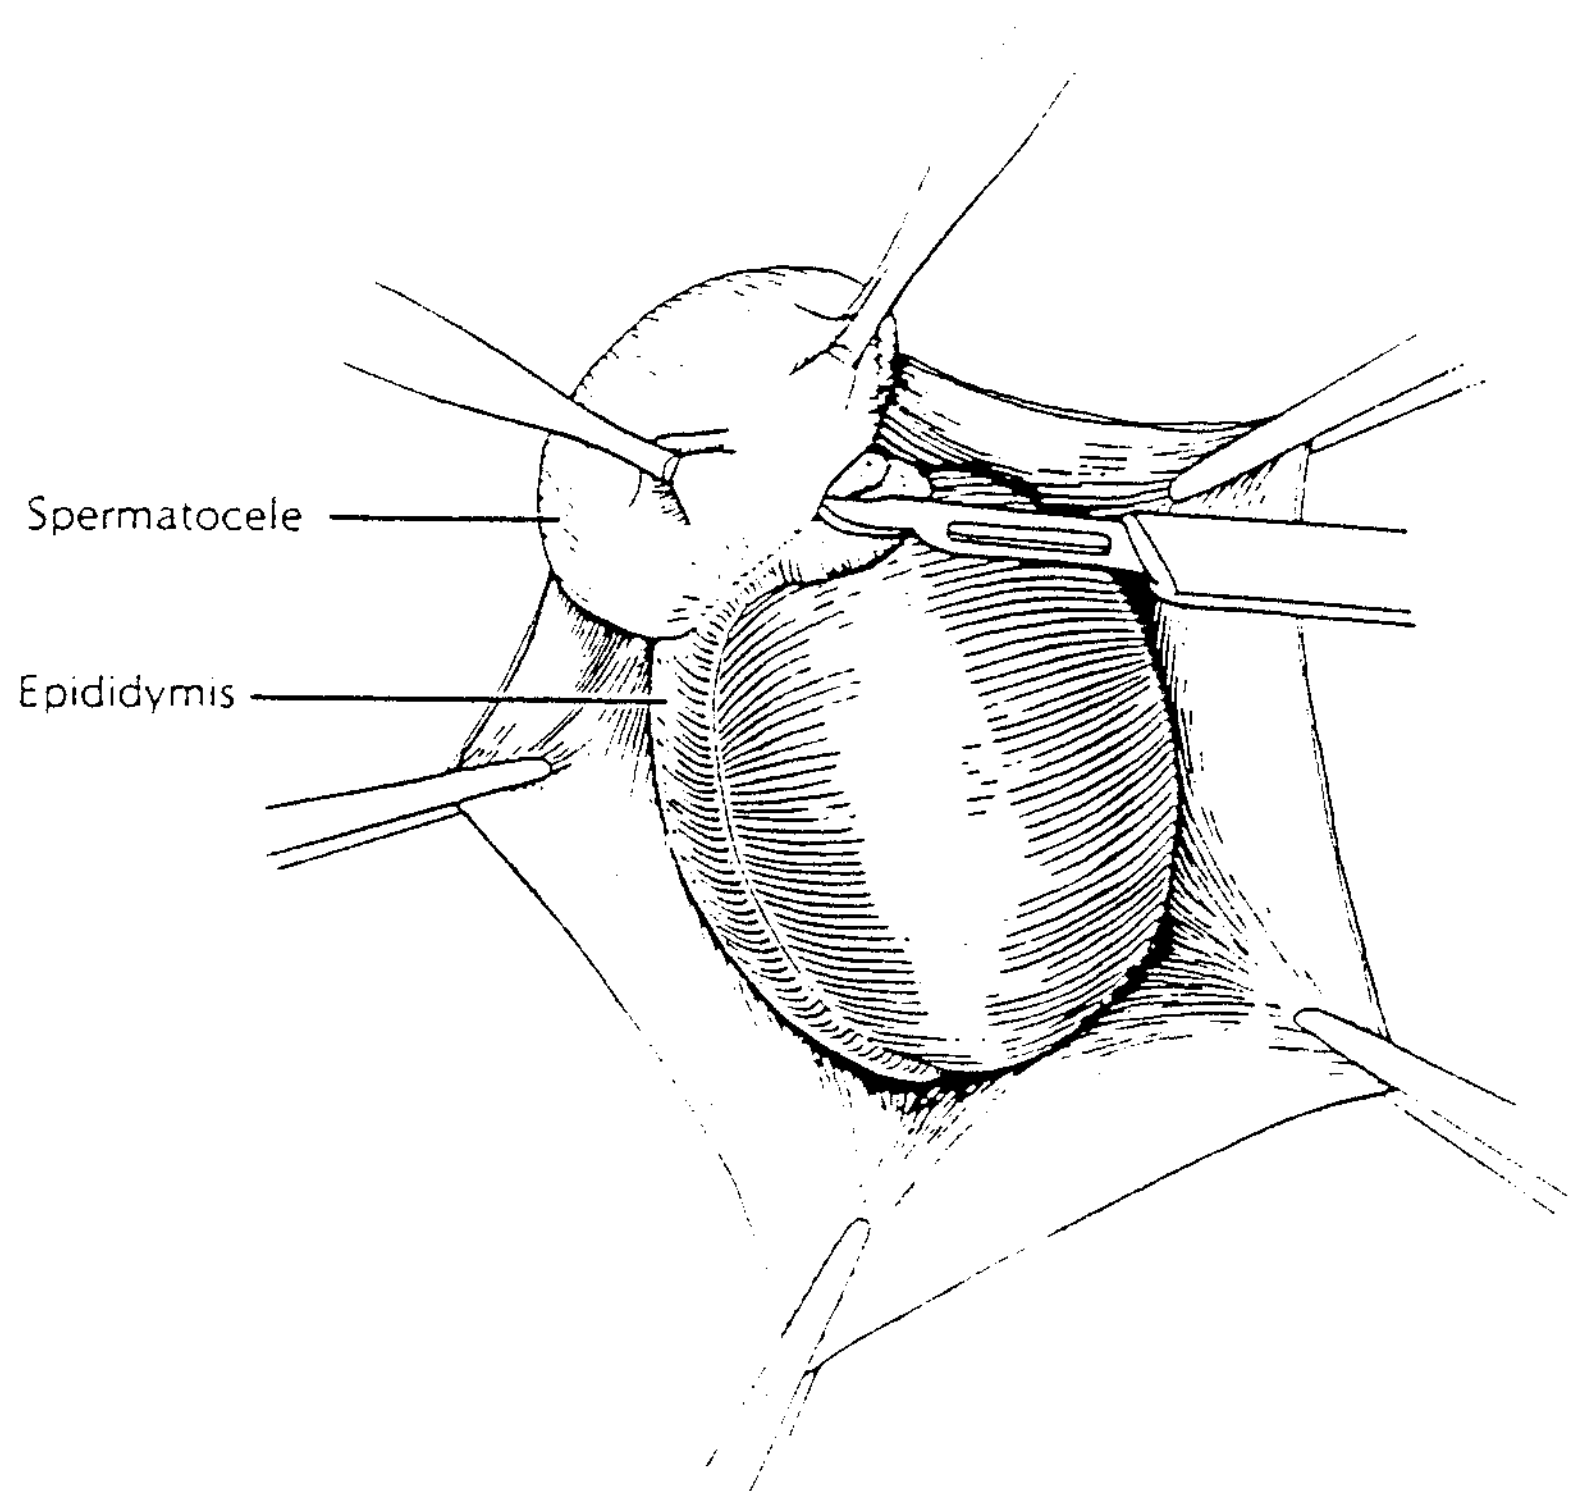

Most spermatoceles do not require intervention. Painful or large, socially embarrassing spermatoceles may require intervention. Surgery should be entertained when there is a question of diagnosis of a potential tumor. Spermatocelectomy should be avoided in men desiring future fertility.

---

### Alternative Therapy

---

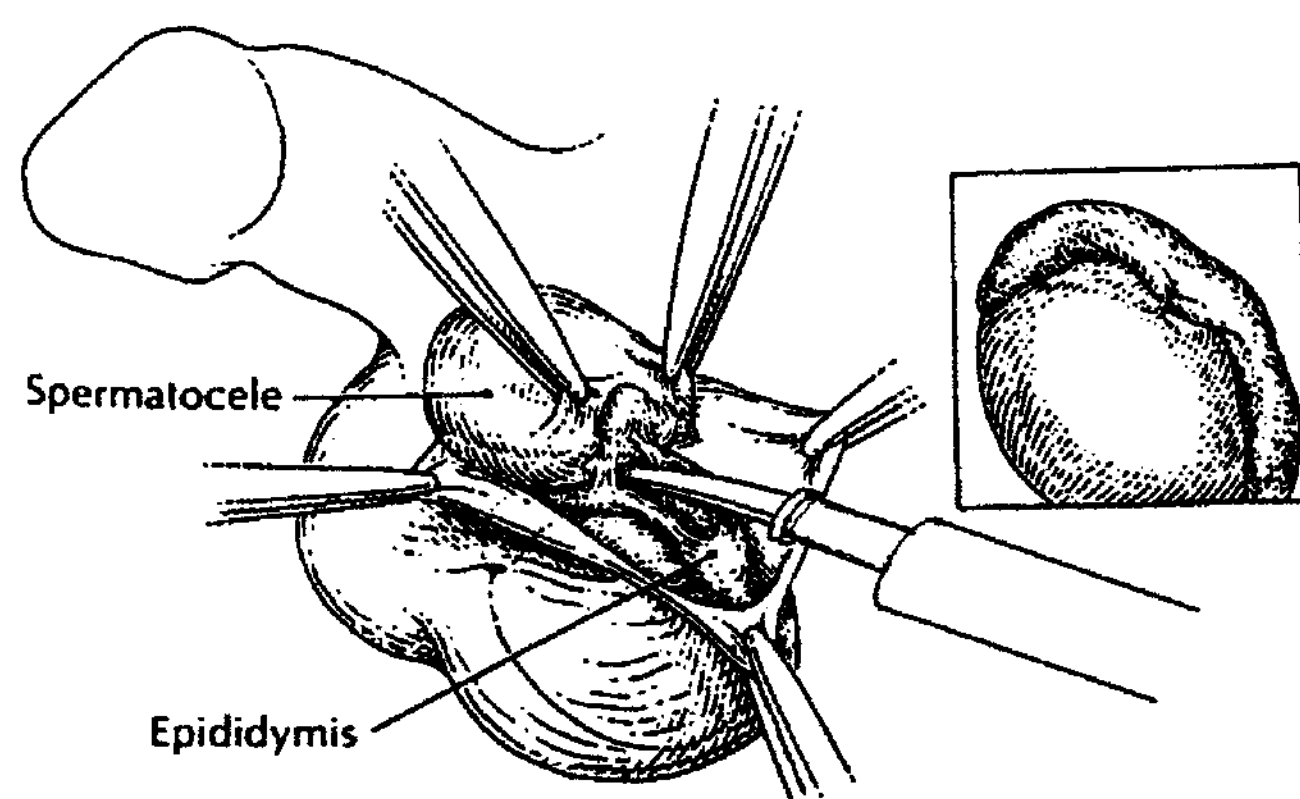

In those requiring treatment, the options are aspiration with the use of sclerosing agents or surgery. Results are similar to those of hydrocele.

**FIGURE 80.5** Spermatocelectomy. The spermatocele is separated from the globus major of the epididymis by sharp dissection and excised.

### Surgical Technique

The spermatocele is approached through the same incision as for the hydrocele. The tunica vaginalis is incised, and the testicle, along with the spermatocele, is delivered into the incision. Utilizing sharp dissection, the cystic structure may be excised or “shelled out” from the epididymis without excessive mobilization of the epididymis or testis (Fig. 80.5). On occasion, an attachment to the epididymis can be identified and ligated or cauterized carefully with minimal trauma (Fig. 80.6).

**FIGURE 80.6** Attachments to the epididymis are identified, ligated, or cauterized with minimal mobility. The epididymal defect is closed with chromic sutures.

Magnification may be of benefit when fertility is a concern. Hemostasis is accomplished with needle tip cautery or chromic ligatures. The edges of the epididymis are reapproximated or a portion of adjacent fascia or tunica may be used to close the epididymal defect (Fig. 80.6 inset). In some cases it may be necessary to resect a portion of the tunica vaginalis to perform a hydrocelectomy in conjunction with this procedure. Wound closure and postoperative management are similar to those for hydrocelectomy.

### OUTCOMES

#### Complications

The usual surgical complications are seen with these procedures. The most common complication is hematoma, usually within the scrotum. In some cases, testicular atrophy or obstruction of the epididymis (12) or vas deferens may occur (5). Bleeding, wound infection, scrotal abscess, and recurrent hydrocele or spermatocele complete the list of possible complications, but they are much less common. There is some evidence that the Lord procedure for hydrocelectomy has fewer of these complications (10).

#### Results

Most patients have a successful outcome with a minimal incidence of recurrence.

## CHAPTER 81 ■ CONGENITAL CURVATURE

TIMOTHY O. DAVIES AND KURT A. MCCAMMON

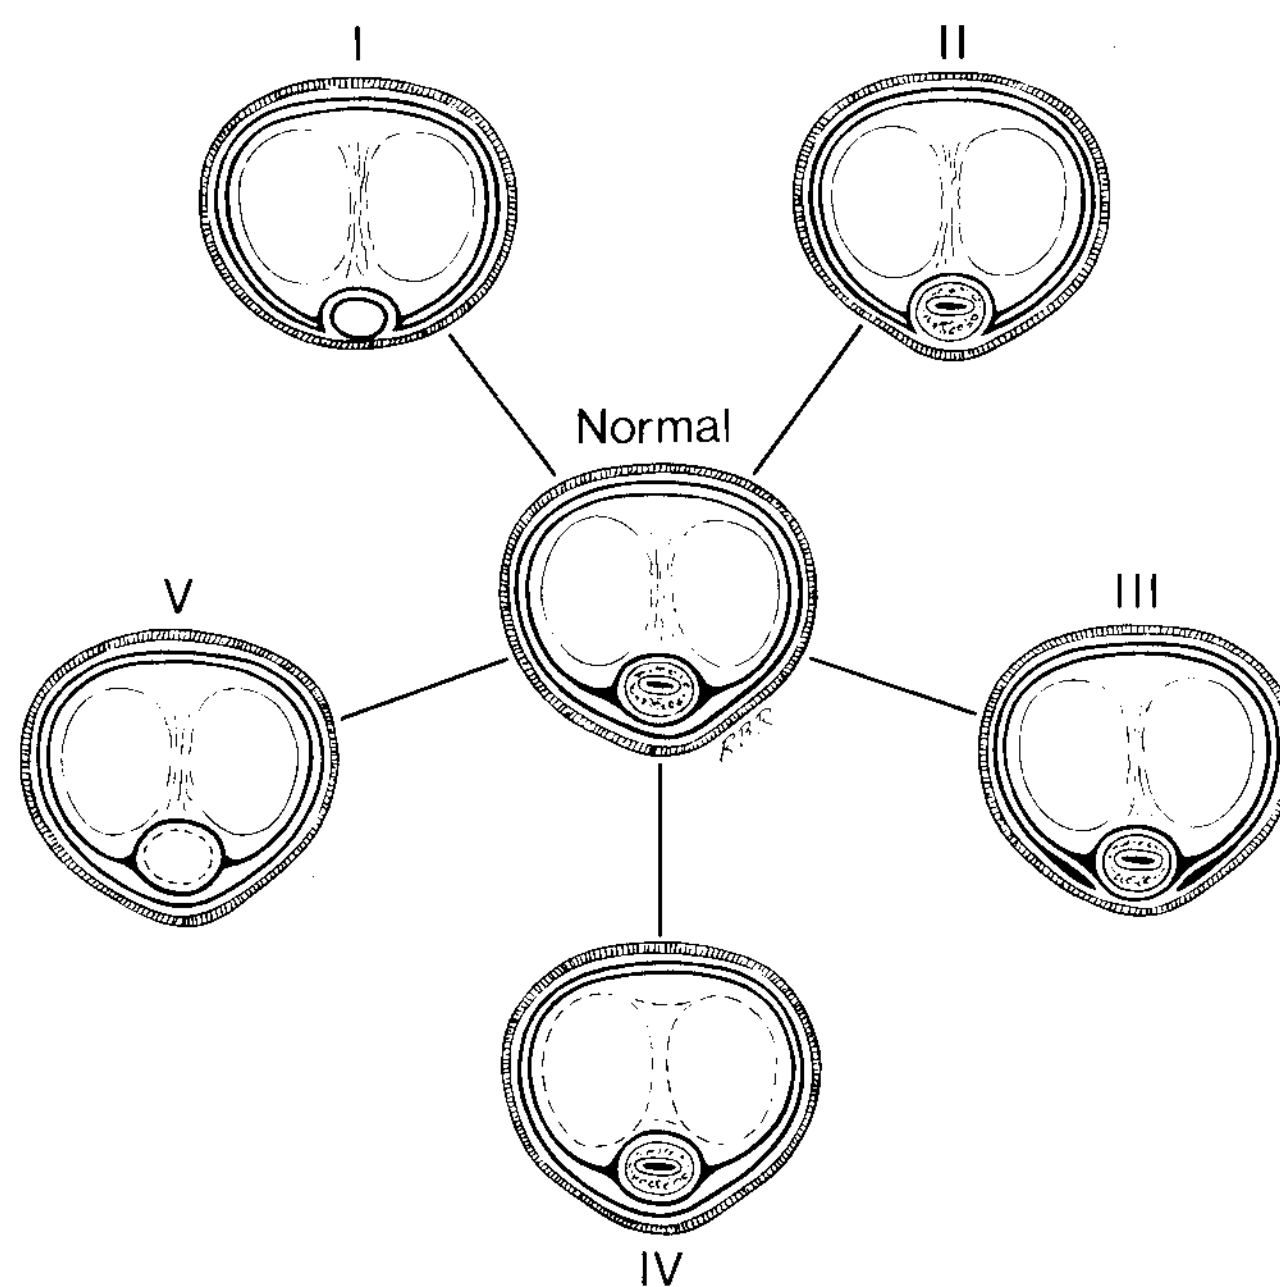

Normal erectile function is not only dependent on normal vascular and neurologic function but also requires elasticity and compliance of all tissue layers of the penis. During tumescence the penis begins to fill with blood and the corporal bodies and tunica albuginea reach their limits of compliance, causing rigidity. Patients with straight erections have normal and symmetrical expansion of the tunica albuginea. Those with curvature have an asymmetrical expansion of one aspect of their penis. This could be due to decreased compliance of one aspect of the tunica or foreshortening of one erectile body.

Patients usually present in their late teens to early 30s. Most men cannot remember their penis being straight and have always assumed their curvature was normal. After puberty and onset of sexual activity, they realize that the curvature impedes normal sexual relations. Some patients also notice that their curvature worsens with puberty. On occasion, a patient will present after the age of 30 either having been sexually active but found sex difficult functionally or psychologically or, less commonly, sexually inactive due to the curvature and the embarrassment he feels.

Penile curvature is described as either congenital or acquired. There is some confusion with the terms *congenital curvature* and *chordee without hypospadias*. Some use these terms interchangeably; however, we do not think they are synonymous. This curvature is associated with abnormalities of the ventral tissue planes or the corpus spongiosum.

Devine and Horton (2) proposed a classification system for congenital penile curvature identifying five separate types of curvature. Types I to III can be collectively termed chordee without hypospadias (Fig. 81.1). This refers to an abnormal development of ventral penile tissue with the patient having a normally placed meatus. For patients with type I, none of the surrounding layers are normal and there is malfusion of the corpus spongiosum. Patients with type II curvature have a dysgenic band of fibrous tissue lateral and dorsal to the urethra, which is believed to have formed from the mesenchyme that would have become the Buck and dartos fasciae. In

type III congenital curvature, the patient's urethra, corpus spongiosum, and Buck fascia are all developed normally. The abnormality in these patients is in the dartos fascia, which has an elastic band that causes the penis to bend sharply. Not infrequently these patients have a large and prominent mons pubis.

**FIGURE 81.1** Cross section of the penis displaying the forms of congenital curvature of the penis. The normal penis is in the center. *Class I:* Epithelial urethra beneath the skin. Dysgenic tissue beneath it represents undeveloped corpus spongiosum, Buck fascia, and dartos fascia. *Class II:* Normal urethra and spongiosum but abnormal Buck and dartos fasciae. *Class III:* Abnormal dartos fascia only. *Class IV:* Normal urethra and fascial layers with abnormal corporocavernosal development. *Class V:* Congenital short urethra (rare). (From Devine CJ Jr, Horton CE. Bent penis. *Semin Urol* 1987;5:252, with permission.)

Type IV curvature is commonly referred to as congenital curvature of the penis by the authors. In type IV penile curvature, development of the urethra, fascial layers, and corpus spongiosum is normal but there is also a relative shortness or inelastic area of the tunica albuginea. Experience with these patients has shown that they have a penis of normal length when flaccid, but when erect the penis may be larger than expected, thought to be due to hypercompliance of the tunica albuginea. Many of these patients will note curvature prior to puberty, but this becomes more accentuated after pubescence and the penile growth spurt that occurs during adolescence.

Type V curvature is the rarest of all types, and some even question whether it exists. This type is known as the congenitally short urethra. The short urethra is not elastic enough or of adequate length, leading to ventral curvature during erections.

---

## DIAGNOSIS

---

All patients should undergo a complete history, including an extensive sexual history and physical examination. Complete examination is done to rule out evidence of subclinical fracture or Peyronie disease, which is obviously rare in the younger patient population. Patients are required to supply photographs of their erect penis for documentation of the curvature. The photographs are beneficial in distinguishing between congenital curvature and chordee without hypospadias. Psychological aspects of the disease also need to be addressed. On occasion, patients are evaluated preoperatively by a certified sex therapist and treated as needed.

Patients with chordee without hypospadias usually present with a ventral or ventral-lateral curvature and are noted to have a penis that is normal or shorter than normal in length. As mentioned earlier, these patients also have noted penile curvature throughout their whole life and may note some progression of the curvature during puberty. Many of these patients have abnormalities of the ventral penile skin. This may be a hooded preputial skin or a high insertion of the penoscrotal skin. The deep ventral tissues of the penis seem to be inelastic to examination and stretch. The inelastic tissue that is palpable is the dysgenic tissue that has replaced the Buck and dartos fasciae.

Some of these patients, because of their curvature and smaller-than-average length, have poor self-images. When identified, these are the patients who benefit from psychological counseling preoperatively.

---

## INDICATIONS FOR SURGERY

---

Patients who have significant enough curvature to impair their sexual function are candidates for surgery. Surgery for chordee without hypospadias is successful in this patient population, with most curvatures repaired in a single procedure. Many times the curvature is corrected by excising the dysgenic tissue on the ventrum of the penis and mobilizing the corpus spongiosum.

---

## ALTERNATIVE THERAPY

---

There are no alternatives to surgery.

---

## SURGICAL TECHNIQUE

---

There are a wide variety of surgical procedures to repair congenital curvature, including incision and plication, incision with grafting, and penile disassembly. Most congenital curvatures are straightened completely with incision and plication.

---

### Incision and Plication

---

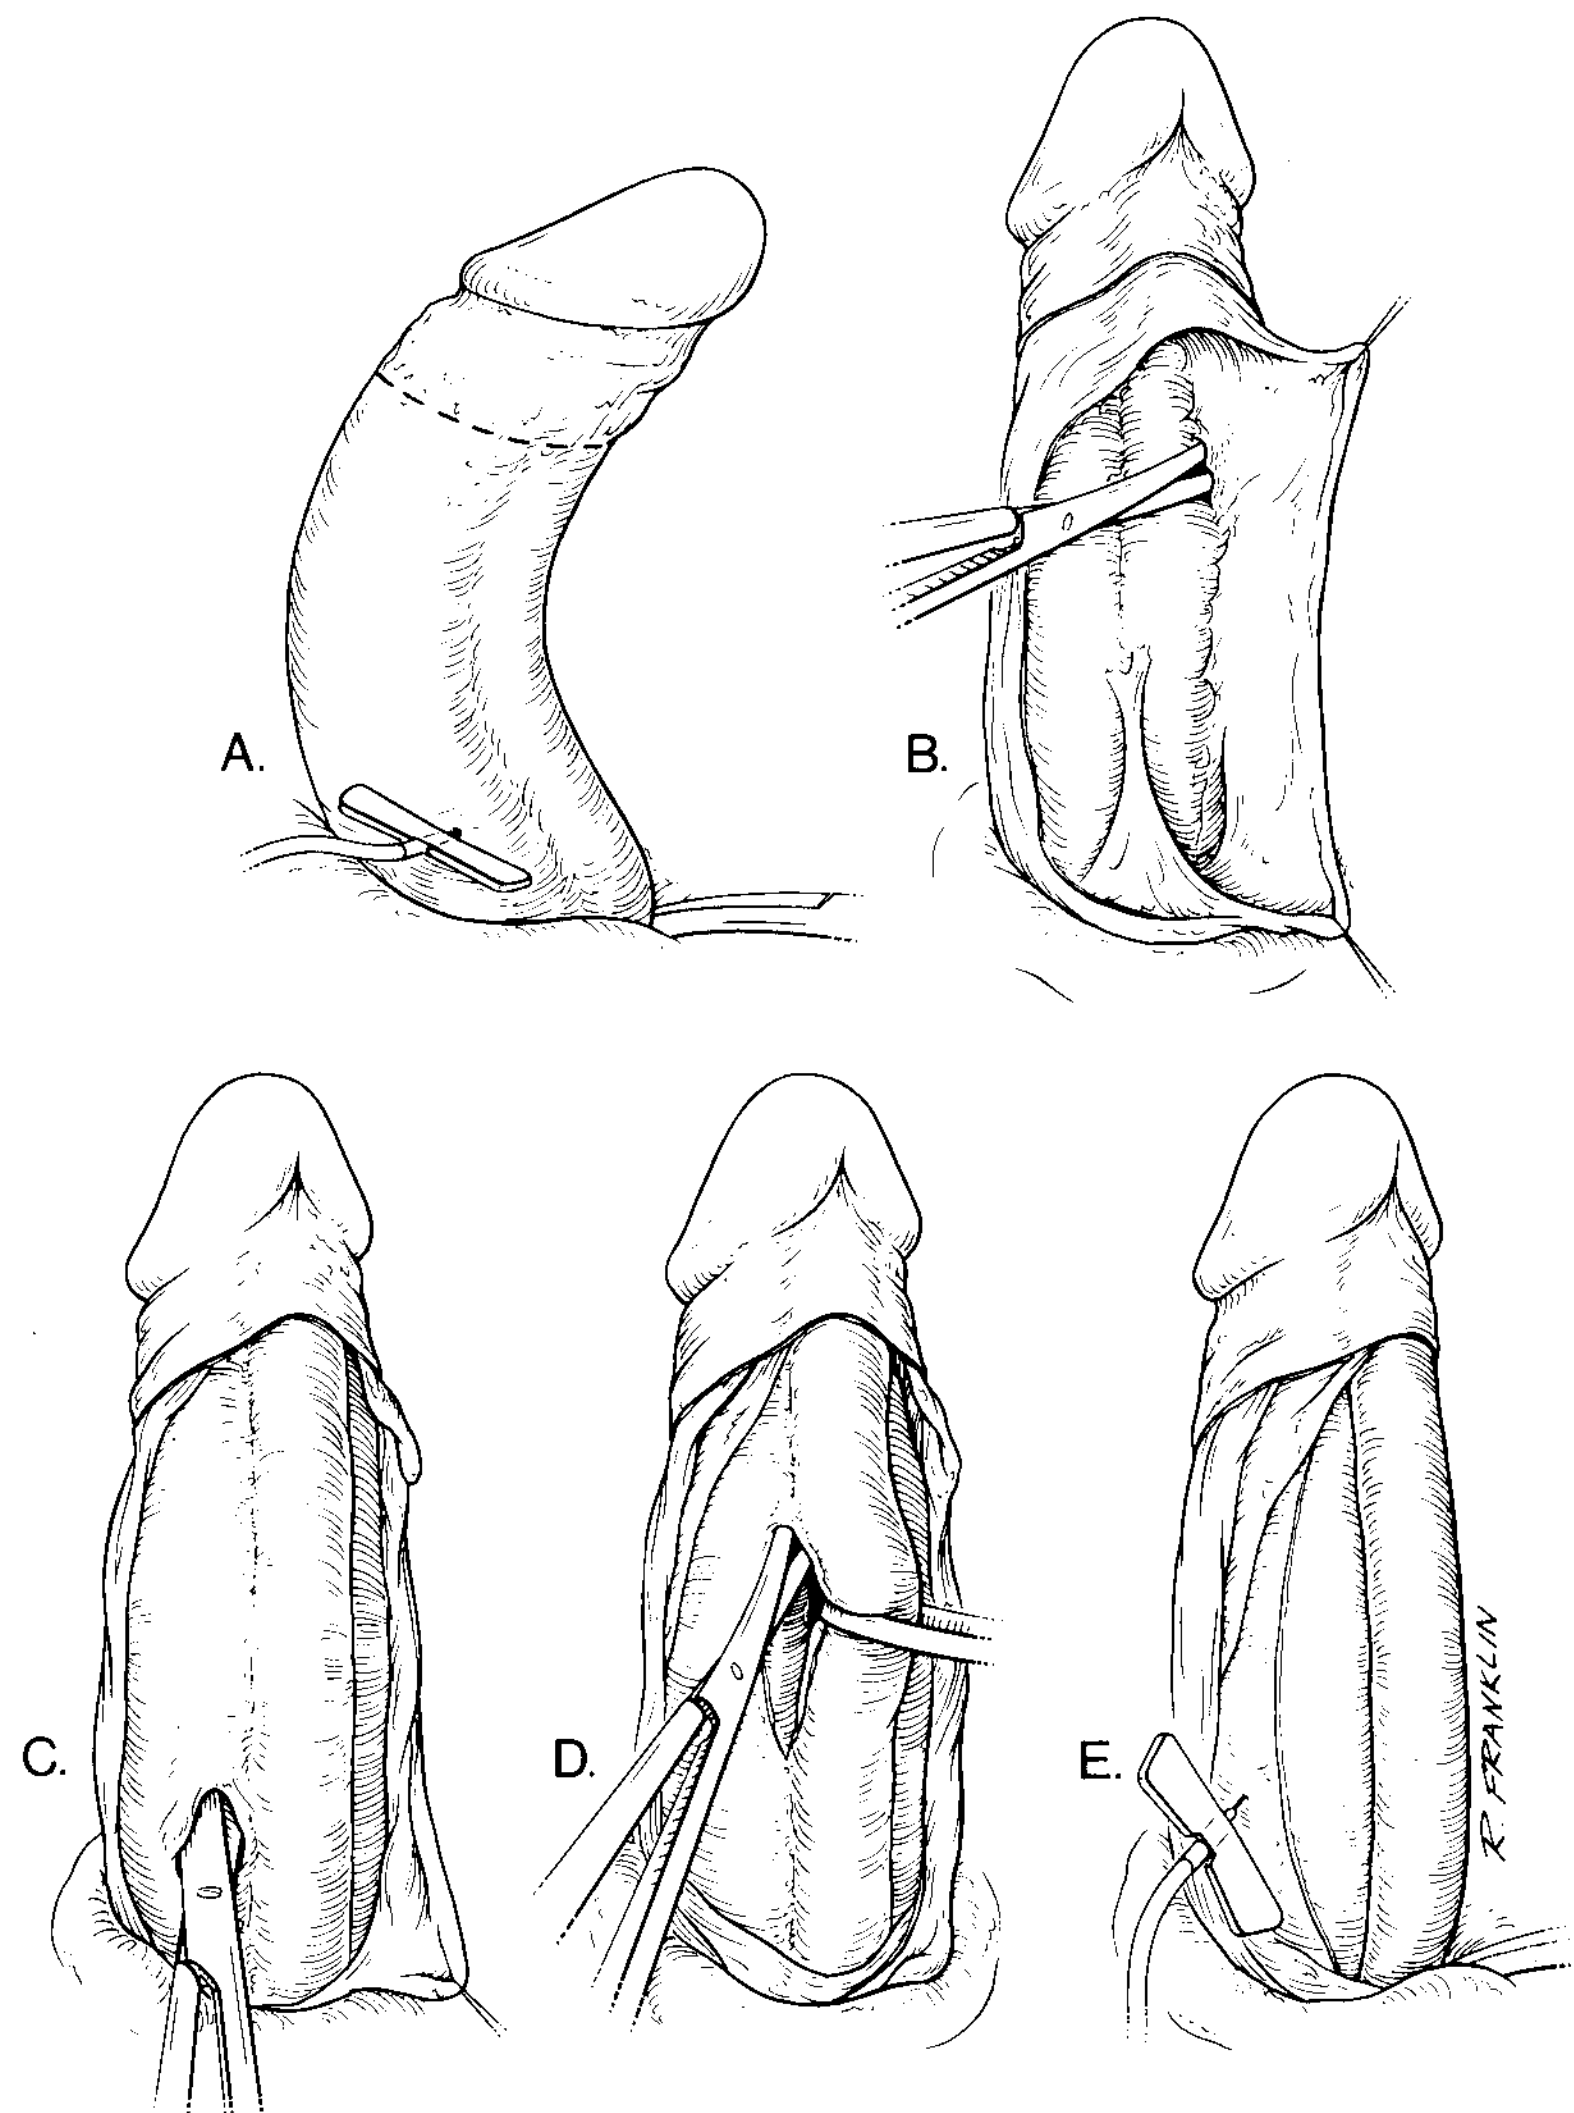

If the patient has been previously circumcised, an incision is made through the circumcision scar. Due to the previous circumcision, there are new patterns of lymph and venous drainage, and an incision proximal or distal to the old scar could lead to marked penile edema. The incision is made down to the superficial layer of the Buck fascia, and the penis is degloved in this plane. Once completely degloved, an artificial erection is created using intravenous normal saline and a high-pressure pump. Perineal pressure may be needed initially, but prolonged pressure is not needed as these patients have normal erectile function. A tourniquet placed at the base of the penis is not recommended as this can mask the proximal extent of curvature.

The artificial erection demonstrates the degree and location of maximal curvature. In patients with ventral curvature, a layer of dysgenic tissue may be noted that includes the Buck and dartos fasciae. This tissue is completely mobilized and excised. Care is taken not to injure the corpus spongiosum, which will need to be detached from the glans to the penoscrotal junction. If injured the urethra is closed primarily. Patients who suffer from a differential elasticity between dorsal and ventral aspects of the corporal bodies may receive some benefit from the excision of the inelastic dysgenic tissue but are rarely straight and often require further maneuvers to straighten the penis. An artificial erection is repeated after this, and if straight the skin is closed (Fig. 81.2).

The options to straighten the penis are to either lengthen the short side with incisions and grafts or to shorten the long side with excisions and/or incisions and plication. In the set of patients for whom penile length is not a major issue, we usually choose to excise and perform plications. The patients recover from plication procedures more quickly, and graft take is not an issue. Although rare, there is a possibility to induce veno-occlusive dysfunction with dermal grafts (Fig. 81.3).

Once it has been determined to proceed with excision of tunica and dorsal plication, the Buck fascia is elevated, incorporating the neurovascular structures via one of two techniques. One approach is to start lateral to the corpus spongiosum and carry the incision medially. The alternative approach is to excise the deep dorsal vein and approach the tunica from the dorsal midline. If done through this approach, after the dorsal vein is excised the inner layer of the Buck fascia is elevated off the tunica, including the dorsal neurovascular structures; this dissection is carried laterally to the corpus spongiosum.

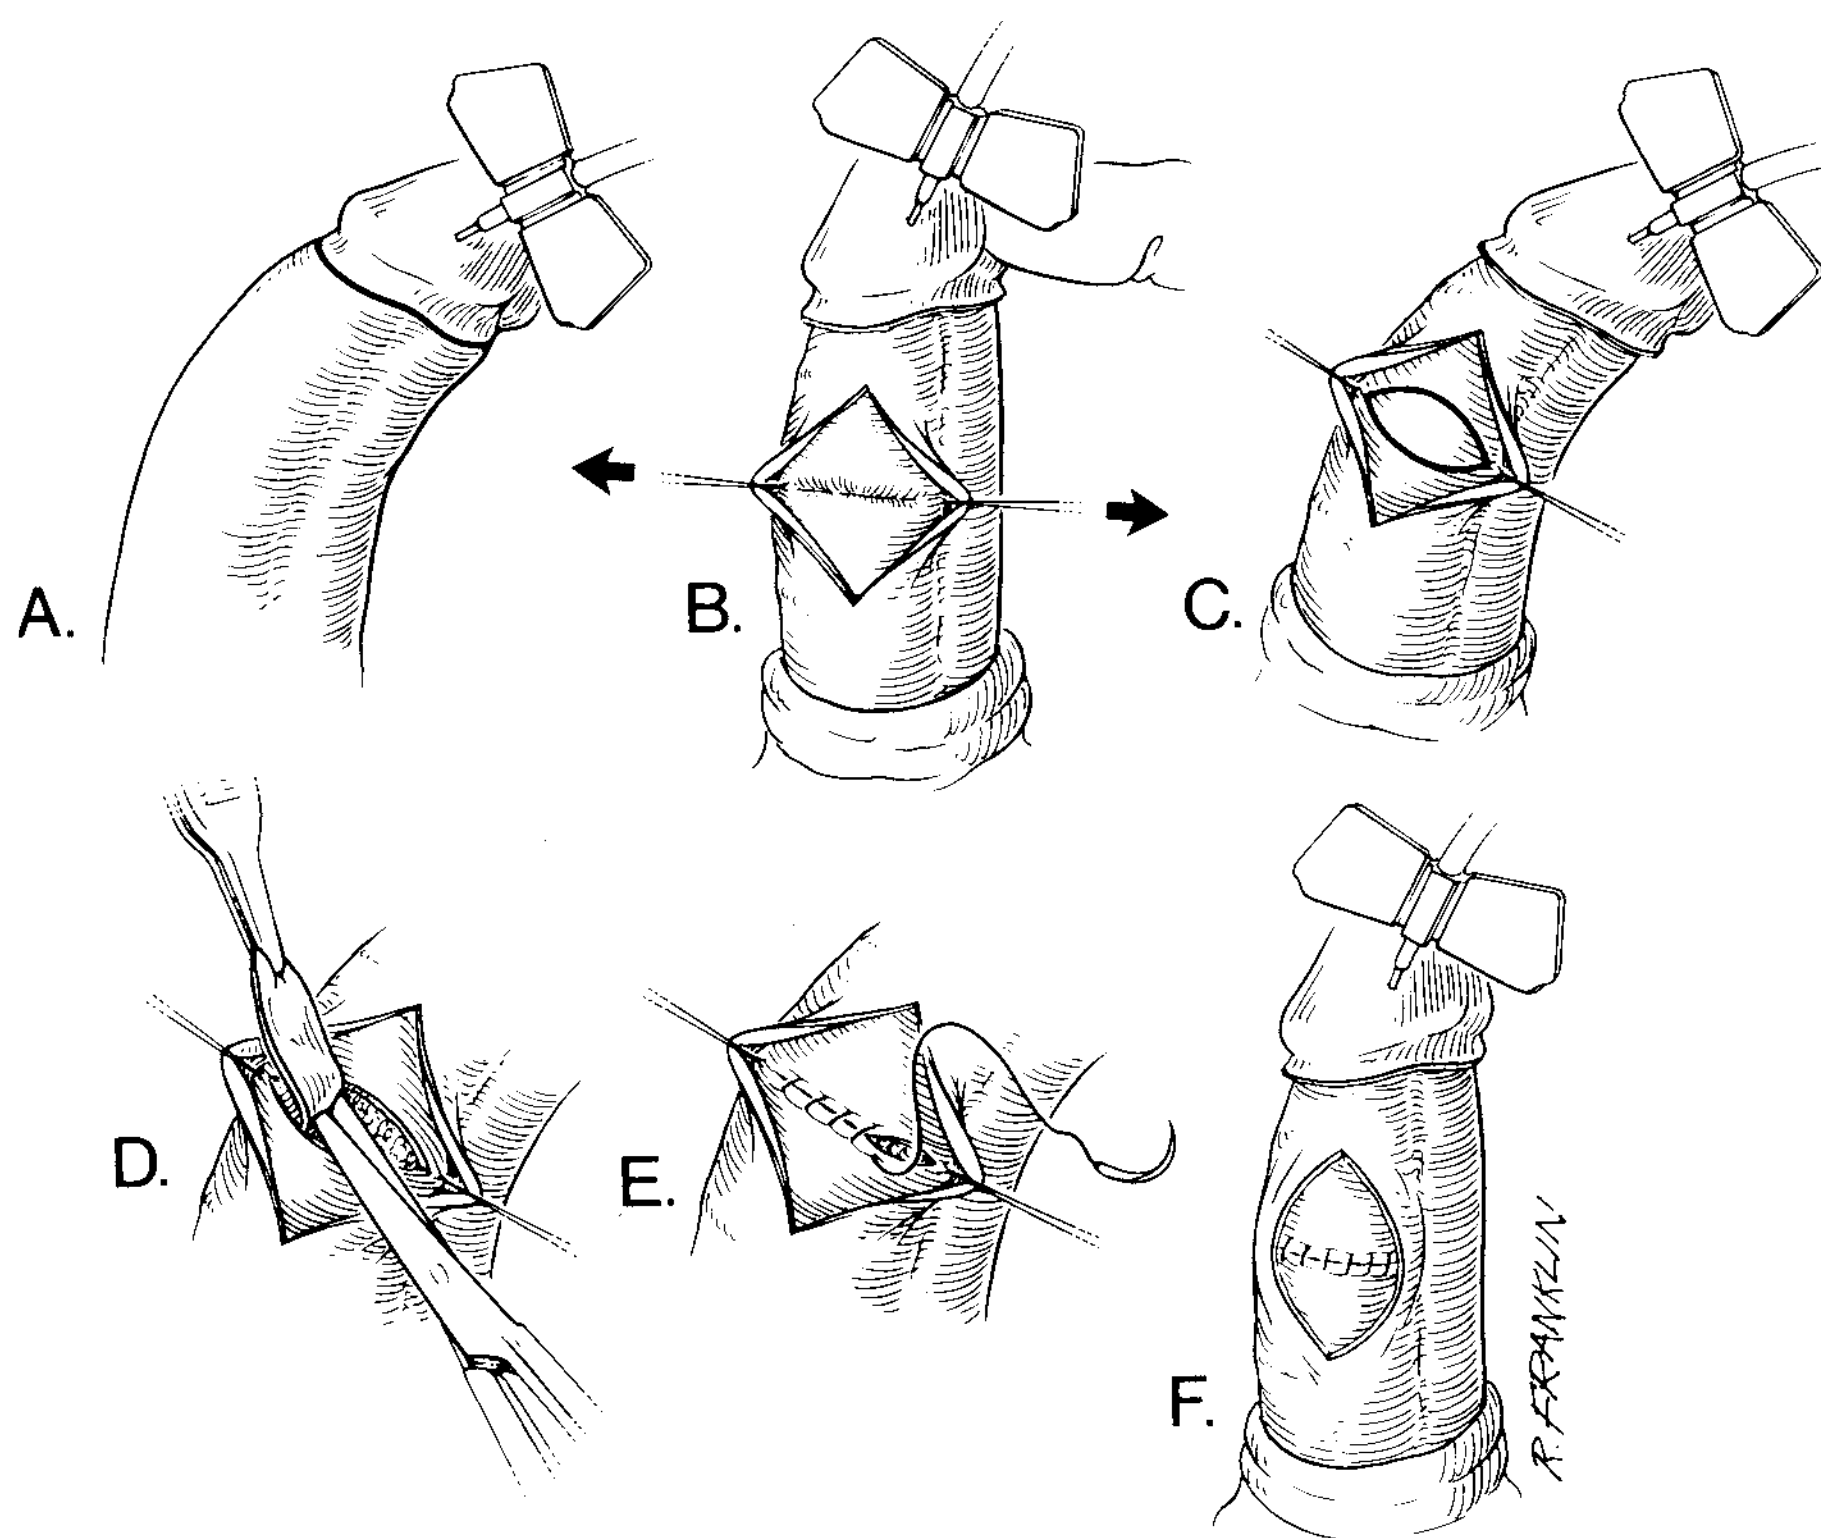

An artificial erection is again performed and the point of maximal curvature identified. The areas of ellipses are identified and marked. Edges of the planned ellipses are apposed with a 3-0 polypropylene (Prolene) suture, and a repeat artificial erection is performed. If this demonstrates adequate straightening, the edges are marked, the suture is removed, and the ellipse of tunica is excised using a sharp scalpel. The

**FIGURE 81.2** Surgery for chordee without hypospadias. **A:** Ventral curvature demonstrated with artificial erection. **B:** Dysgenic dartos fascia is elevated and will be excised. **C:** The dysgenic layer of the Buck fascia is undermined by spreading the scissors. **D:** The inelastic fascia is excised as the corpus spongiosum and urethra are mobilized. **E:** Artificial erection demonstrates correction of the curvature.

**FIGURE 81.3** Surgery for chordee without hypospadias. **A:** A circumcision incision has been made and the urethra has been mobilized by resecting the dartos and Buck fasciae. The needle is in place for an artificial erection. The erection shows continuing chordee. The elastic urethra is not the cause of this curvature. The point of maximum concavity has been marked. **B:** An ellipse of tissue is outlined opposite the point of maximum concavity. As an alternative, two smaller ellipses are shown. **C:** Excision of the ellipse of tunica. Note the tips of the septal strands in the midline. **D:** Closure of the edges of the incision. **E:** Artificial erection revealing a straight penis. When the bend is more complex, ellipses must be excised in other locations. (From Devine CJ Jr, Horton CE. Bent penis. *Semin Urol* 1987;5:4, with permission.)

**FIGURE 81.4** Congenital lateral curvature. **A:** An artificial erection reveals the curvature. The incision to gain access to the potential ellipse of tissue is marked. **B:** The tunica albuginea has been exposed by mobilizing the Buck fascia, and Prolene sutures have been placed at the dorsal and ventral tips of the potential ellipse. While maintaining the artificial erection, tension is established on the two sutures as the penile shaft is straightened. The fold produced in the tunica is marked. **C:** When the penis is relaxed, this mark defines the ellipse of tunica to be removed. **D:** The tunica is excised. **E:** The edges are approximated. **F:** The penis is straight. The Buck fascia and the skin are closed.

underlying erectile tissue is left undisturbed by staying in the space of Smith. Watertight closure is performed with interrupted 4-0 polydioxanone suture (PDS) and a running 5-0 PDS. An artificial erection is performed after each ellipse is excised to determine results. If the penis is not straight, further ellipses are excised to straighten it.

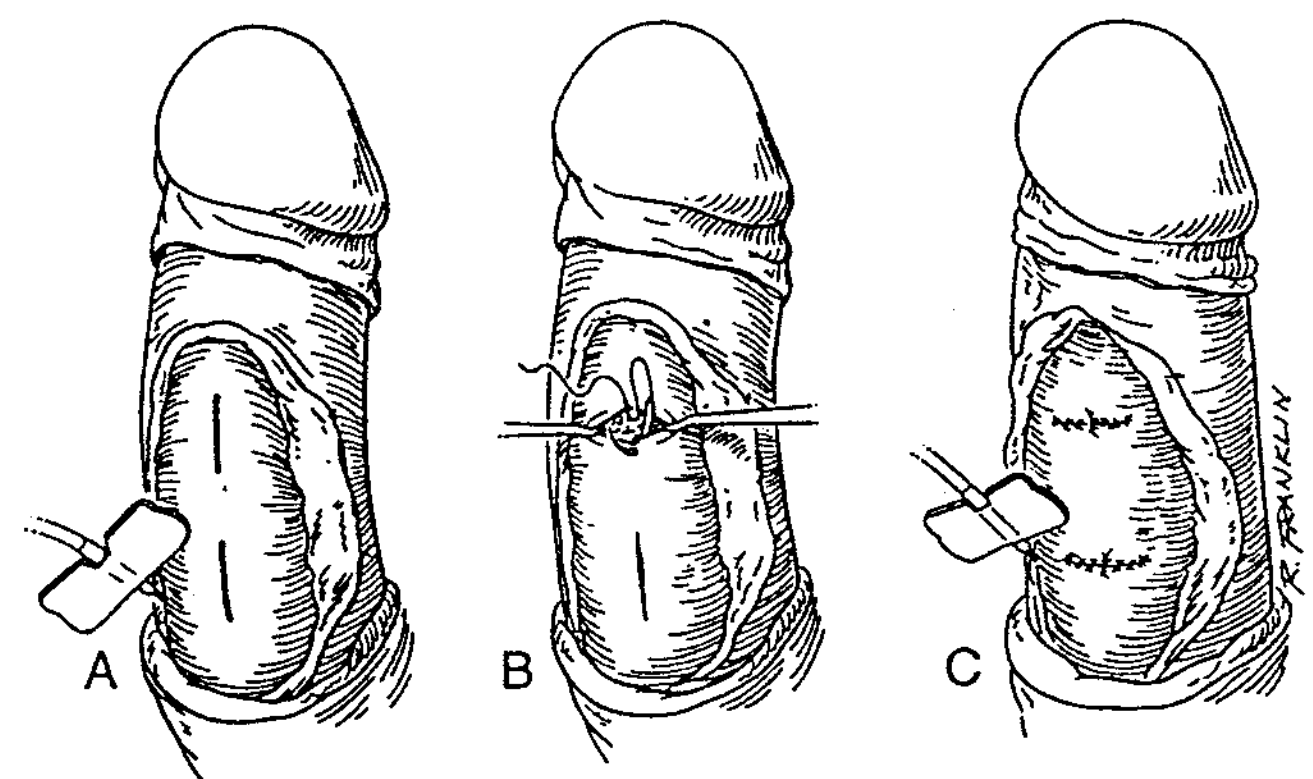

Once straight, the Buck fascia is closed. Two small suction drains are placed superficial to the Buck fascia. The skin is reapproximated with a 4-0 Vicryl suture, and a small Foley catheter is placed overnight. A bio-occlusive dressing is placed. The Foley catheter is removed on postoperative day 1. One drain is removed in the morning as well, and if output is low, the other is removed that afternoon and the patient is discharged from the hospital.

Patients with lateral curvature may have associated ventral curvature or rarely dorsal curvature. On occasion, patients with lateral curvature may only have lateral curvature. In patients with only lateral curvature, this can be approached through a small incision at the maximal point of curvature. After an artificial erection is obtained, the point of maximal curvature is identified and a small incision is made on the contralateral side at the site of maximal convexity. Again, there is minimal dissection of the dorsal neurovascular structures. After 3-0 Prolene sutures are placed, an artificial erection is performed; if straight, ellipses are excised and closed as previously discussed (Fig. 81.4).

Although uncommon, congenital dorsal curvature is usually approached through a circumcising incision. The corpus spongiosum is partially mobilized so that small incisions in the corpora can be placed just lateral to the ventral midline. The techniques used are those previously described, and the postoperative course is similar to that of the patient with ventral curve.

### Yachia Longitudinal Plication

There are other techniques described for the repair of congenital curvature. Yachia (6,7) described a plication procedure using longitudinal incisions in the tunica albuginea that are closed transversely. The long side is therefore plicated without excising tunica. The procedure is similar to that previously described, with an incision through the previous circumcision scar and complete mobilization (Fig. 81.5).

**FIGURE 81.5** Technique after Yachia for correction of curvature, in this case a patient with congenital lateral curvature. **A:** The Buck fascia is reflected, exposing the lateral tunica albuginea. **B:** Longitudinal incisions are created at the area of maximal curvature as demonstrated by artificial erection. **C:** The longitudinal closures are closed transversely, with artificial erection demonstrating good straightening of the penis.

## Multiple Parallel Plication

Multiple parallel plication (MPP) is another technique used in the repair of congenital curvature of the penis without excising any tunica albuginea. In the original description, a pharmacologic agent is used to induce an erection. A circumcising incision is performed, the penis is degloved, and the deep dorsal artery and vein are identified. The dorsal neurovascular bundle does not need to be dissected and freed. Multiple deep plication sutures are placed into the tunica albuginea at the point of maximal curvature between the deep dorsal artery and vein using four to six nonabsorbable 3-0 braided sutures. Some of the sutures may not be fully tied down to prevent overcorrection. For patients with lateral or ventral lateral curvature, the sutures are placed more laterally using the same vertical orientation. When the patient has dorsal curvature, a ventral incision is made and the sutures are placed just lateral to the corpus spongiosum (which does not need to be mobilized).

## Penile Disassembly

Perovic et al. (5) proposed a penile disassembly technique in hopes of avoiding penile shortening with the plication procedures. This technique requires complete disassembly of the penis into its component parts, these being the glans cap with its neurovascular bundle dorsally, the urethra ventrally, and the corporal bodies. Unfortunately, this technique only straightened the penis satisfactorily in 68% of patients, and on occasion a plication procedure was required.

## Chordee without Hypospadias

The corpus spongiosum is rarely the limiting factor in these patients, even if they appear to have obvious abnormalities. The curvature in these patients is due mainly to the inelasticity of the ventral aspect of the corporal bodies. After the dysgenic tissue is excised, if there is residual chordee a small incision can be made in the ventral midline of the corporal bodies after an artificial erection is obtained. The erectile tissue is not entered with this incision, and this allows the ventral tunica to move laterally and noticeably straightens the penis. If this is unsuccessful in correcting the curvature, the dorsal neurovascular structures are mobilized and a small ellipse of tunica is excised and closed as discussed earlier (Fig. 81.6).

Some advocate the use of dermal grafts for patients with chordee without hypospadias, especially in those patients with severe chordee or those with a smaller-than-average penis. This approach does not shorten the penis as a plication procedure would, but there are complications associated with it as well. The major concern with placing a dermal graft is the risk of veno-occlusive dysfunction. This is a known complication when using dermis in adult patients with Peyronie disease. Grafting the corpora cavernosa in any patient has the potential for creating erectile dysfunction. The majority of patients seek surgery as young adults, and the occurrence of erectile dysfunction can be devastating. It is thought that the pediatric patient may not develop veno-occlusive dysfunction because no tunica is excised and a much smaller graft is used than in the adult. No long-term studies have been published following these patients into adult life to determine the risk.

FIGURE 81.6

## OUTCOMES

### Complications

Surgical complications associated with congenital penile curvature surgery are relatively rare. This is in general a healthy population of patients. Complaints of penile shortening and penile irregularity from suture sites are heard. There are also complaints of suture granuloma and sometimes pain at the plication site. Temporary loss of glans sensation has been reported in the past, and there is one report of a patient with permanent loss of sensation. Postoperative erectile dysfunction is extremely rare, and there is one reported case of penile necrosis secondary to a tourniquet; we would not recommend using these.

### Results

The reported success rates of the Nesbitt, Yachia, and incision/plication surgical procedures vary from 85% to 100%. Eight percent of MPP patients were satisfied with their correction, although two of the eight had to undergo a second procedure to correct a residual 15% curvature. All patients did notice the sutures, but only one considered them bothersome.

# CHAPTER 82 ■ RECONSTRUCTION OF THE PENIS FOR COMPLICATIONS OF PENILE ENHANCEMENT SURGERY

GARY J. ALTER

Surgery to enlarge the length and girth of the penis has been developed over the past few decades. These procedures were derived from a combination of plastic surgical techniques and urologic reconstructive pediatric and adult surgical operations (1–4). Penile length is increased by releasing the suspensory ligament of the penis followed by the use of penile weights or stretching devices. The girth is increased by either injecting fat into the dartos fascia or by inserting dermal fat grafts or alloplastic cellular matrix grafts such as AlloDerm. Unfortunately, these procedures are often based on faulty concepts or are not performed meticulously, which has led to many complications. The purpose of this chapter is to outline techniques to reconstruct these unfortunate outcomes.

---

## DIAGNOSIS

---

A patient may present for reconstruction after only a penile lengthening procedure or also with some girth enhancement. An assortment of deformities can occur (6,7).

---

## Penile Lengthening

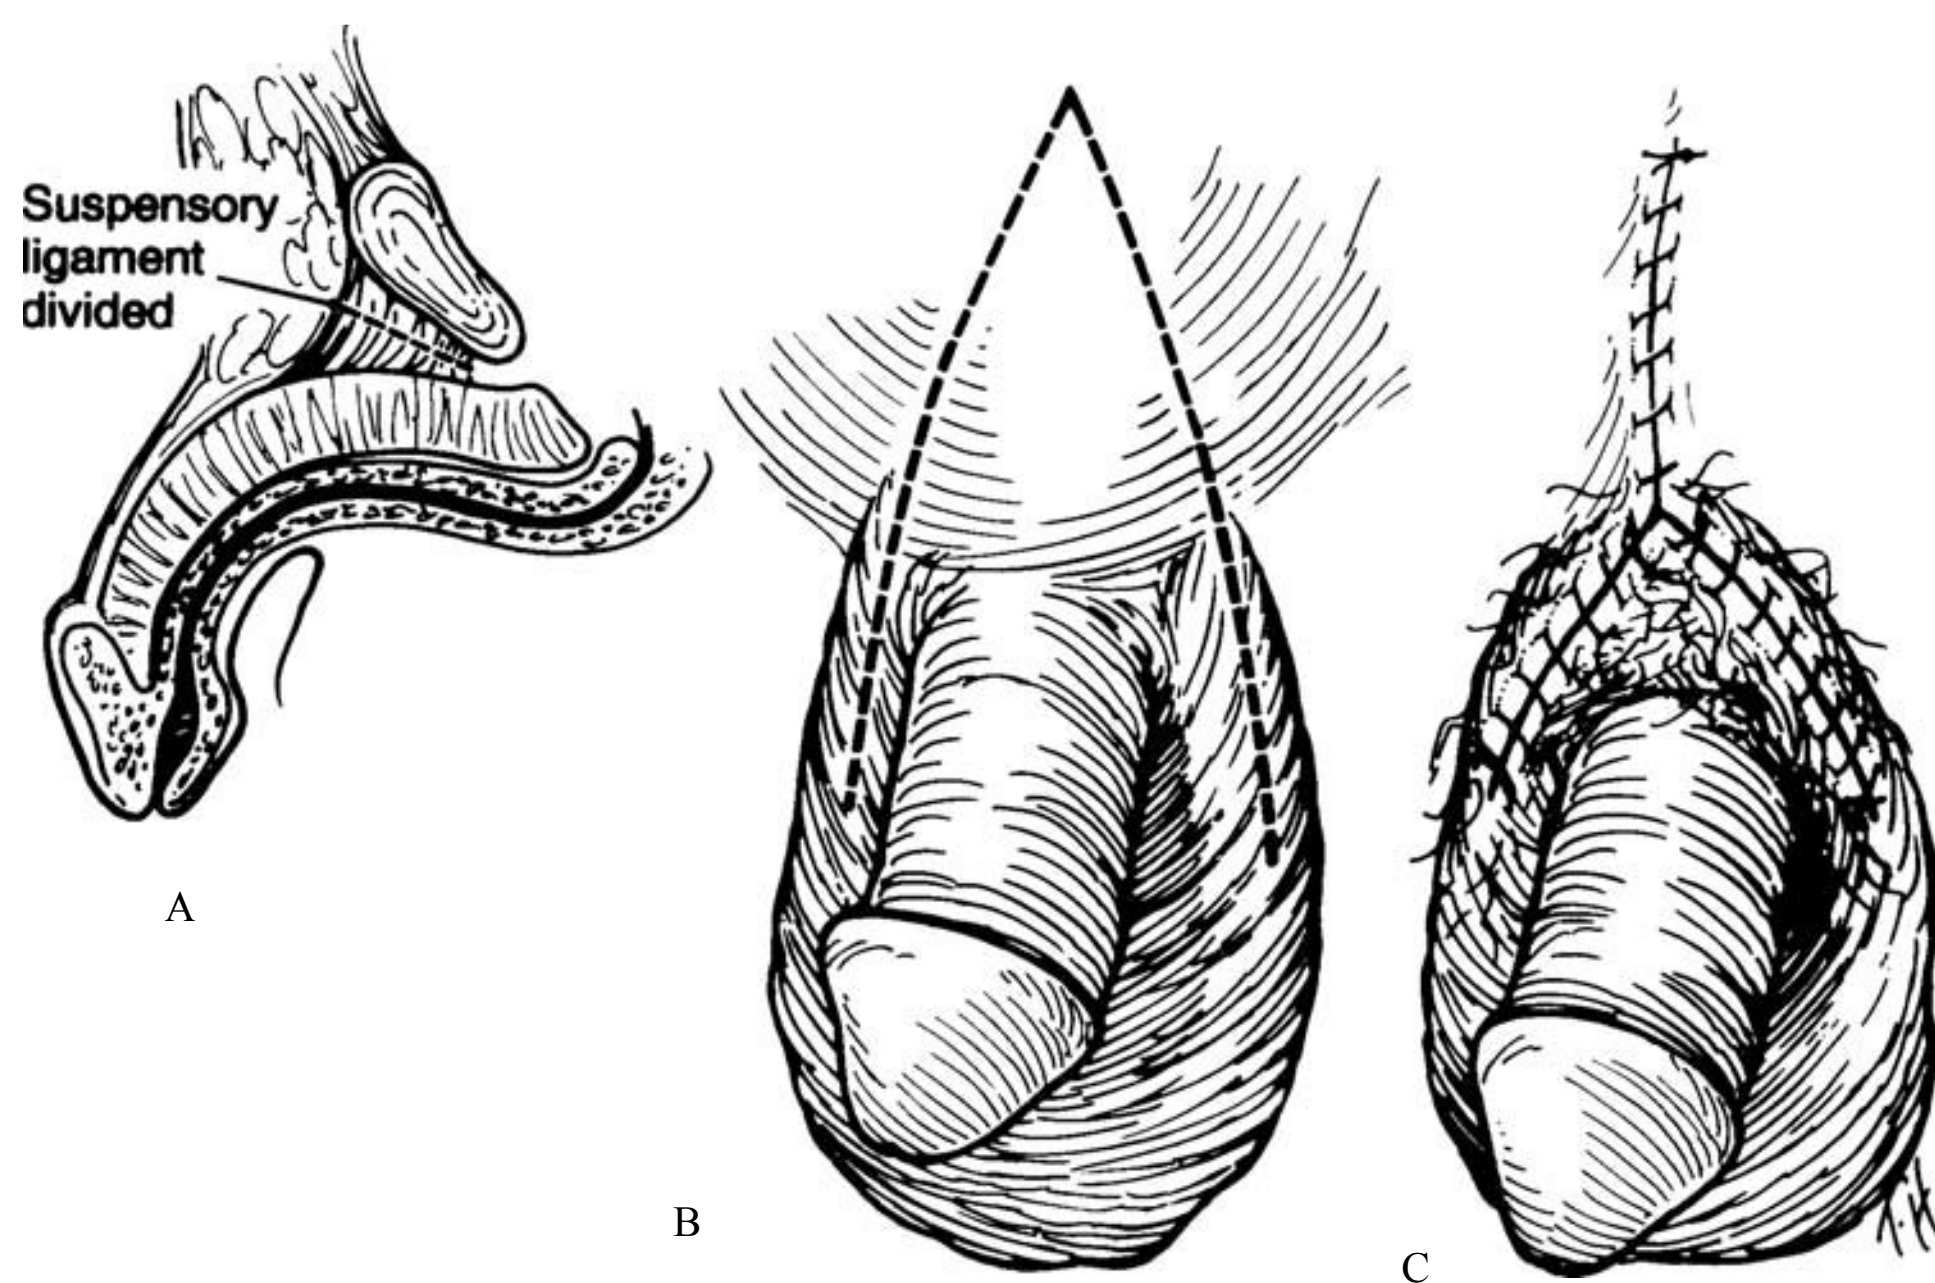

---

Penile lengthening is achieved by releasing the suspensory ligament of the penis and the postoperative use of penile weights or stretching devices (Fig. 82.1A) (6). A small lower transverse pubic incision is usually used, but many surgeons advance infrapubic skin onto the penis using a V-Y advancement flap (Fig. 82.1B and C) (6,8,9). This theoretically increases penile length and gives the penis the appearance of increased flaccid length. This penile length gain is disputed in most cases, and it can cause the penis to appear either longer or shorter in the flaccid state. The V-Y flap is based distally at the penopubic junction, varying from a small (2- to 3-cm) to a large base.

The larger flap encompasses the entire dorsal base of the penis and part of the scrotum, which causes interruption of a significant portion of the proximal penile dartos fascia and skin. The blood supply and lymphatic drainage of the penis are thus partially interrupted, which can cause healing complications such as flap tip loss, poor wound healing with wound dehiscence, and postoperative swelling. Healing problems predispose to hypertrophic or wide scars, which create hairless suprapubic scars and depressions (Figs. 82.2A and 82.3A) (6). The large V-Y flap also advances thick, hair-bearing tissue onto the penis, which frequently creates an unnatural hump at the penile base and the appearance of a low-hanging penis. The penis can appear surrounded by the scrotum (scrotalization) with an overhanging large pubic fat pad, which makes the penis look shorter and hidden. A V-Y flap can also create “dog-ears” at the distal scrotal flap incision. Smaller V-Y advancement flaps cause less frequent problems but have wound and aesthetic complications.

An occasional patient may complain of penile shortening after release of the suspensory ligament. Since there is a dead space between the pubic symphysis and the corpora, it is possible for the corpora to reattach in a shortened position. This dead space can be filled by a proximally or distally based fat flap transposed from the spermatic cord (5). However, most doctors tell the patients to stretch the penis after the release without filling the space.

Penile instability is very rare after suspensory ligament release and usually results from an overly aggressive release of the corporal bodies from the inferior rami of the ischium. If the release is limited to one fingerbreadth on the midline of the pubic symphysis, this will not occur. Dorsal nerve or vessel injuries are prevented by staying directly on the pubic periosteum of the midline of the symphysis with the penis on full stretch and by not releasing the corpora laterally. A mild decrease in the elevation of the erection can occur with release but is not problematic.

**FIGURE 82.1** Method commonly used for penile lengthening that often causes penile deformities. **A:** The suspensory ligament is released. **B:** A large V-Y advancement flap is designed. **C:** The flap is advanced, resulting in hair on the proximal penile shaft, bilateral dog-ears, and a lower-hanging penis.

A

B

**FIGURE 82.2** Patient who had release of the suspensory ligament, a large V-Y advancement flap, and multiple fat injections (same case as in Fig. 82.4). **A:** The deformity shows a low-lying penis, hair on the proximal shaft, bilateral dog-ears at the penoscrotal junction, a shorter-appearing penis, wide pubic scars, and a large amount of fat in the shaft. **B:** Reconstruction after complete reversal of the V-Y advancement flap, correction of V-Y dog-ears, scar revision, selective removal of fat nodules, and contouring of the left side of the penis.

## Fat Injections

Significant complications can occur from autologous fat injections (Figs. 82.2 and 82.3) (6). The penis is a relatively cylindrical structure, so asymmetrical fat absorption can cause severe penile distortion with S-shaped curves, nodules, or liquefied cysts. The larger the amount of fat injected, the greater the chance of deformities. However, a small amount injected may not result in any long-term girth gain. If fat is injected in large amounts, it frequently migrates distally during the initial postoperative period, which causes unsightly fat deposits at the corona. If the fat migrates distally causing penile skin to stretch, and if the patient has a large V-Y flap, then the previously circumcised patient can look uncircumcised. If another

circumcision removes this “excess foreskin,” then there can be inadequate shaft skin to perform a later reversal of the V-Y advancement flap, thus limiting the reconstructive options.

Patients sometimes complain of inadequate rigidity if a large amount of injected fat survives, since the fat bulk overwhelms the corporal erection. Intercourse difficulty can also occur if large fat injections are combined with a large V-Y flap, since a soft penile shaft is combined with loose penile skin.

## Dermal Fat Grafts

Dermal fat grafts are used for girth enlargement by either inserting dermal fat strips into the dartos along the length of the

A

B

**FIGURE 82.3** Patient who had release of the suspensory ligament, a large V-Y advancement flap, and fat injections. **A:** The deformity shows a low-lying penis, hair on the proximal shaft, bilateral dog-ears at the penoscrotal junction, a short-appearing penis, wide pubic scars, and fat in the shaft. **B:** Reconstruction after partial reversal of the V-Y advancement fat, correction of the V-Y dog-ears, scar revisions, and selective removal of fat. Complete reversal of the V-Y flap was not possible due to previous partial loss of a portion of the V-Y flap (Fig. 82.5).

penis or by wrapping sheets of dermal fat around the shaft between the dartos and the Buck fasciae. The grafts are stabilized proximally and distally with sutures to prevent migration. If the grafts do not survive completely and symmetrically, the patient can have fibrosis and firmness. As a result, the patient can complain of loss of penile length, asymmetry, curvature, or firm areas.

---

### AlloDerm

---

The use of AlloDerm for girth expansion was motivated by the unpredictability of dermal fat graft “take” with its cosmetically unappealing donor site scars. Layers of AlloDerm are inserted in a plane above the Buck fascia and stabilized proximally and distally. Theoretically, the AlloDerm is a matrix for the ingrowth of tissue and becomes integrated into the area. However, this does not always occur, so the AlloDerm can be isolated within a capsule. The AlloDerm does not stretch, so the patient may complain of loss of length or curvature. Patients may also complain of an unnatural feel of the penis, migration of the AlloDerm, asymmetry, and visual and palpable deformities. Many cases of infected AlloDerm have occurred, resulting in chronic infections and chronic skin sinuses with or without skin loss.

---

### INDICATIONS AND ALTERNATIVE THERAPY

---

Secondary surgery should not be performed until at least 6 months after the enlargement operation to allow resolution of swelling, revascularization of tissue, and elimination of induration. The patient must prioritize his reconstructive options and be specific as to his desires. He may want only limited fat removal, partial or no V-Y flap reversal, or minimal scar revisions. Additionally, it may not be possible to correct all deformities at one or multiple operations. The operative

plan and probable result are realistically discussed with the patient and often shown while he is standing in front of a mirror. Discussion of expectations and goals is crucial to preventing a hostile patient.

---

### SURGICAL TECHNIQUE

---

Most commonly, patients complain of complications of the large V-Y advancement flap. Usually most of the extensive pubic, penile, and scrotal scars is excised (Figs. 82.2B and 82.4) (6). The defect after the excision of the Y scar is much larger than usually anticipated, with the width of the vertical scar often exceeding 5 cm. Ideally, the V flap is re-elevated to near its original previous location, aligning the hair on the V flap with the pubic hair. This will result in an inverted U closure. Determination needs to be made as to the adequacy of shaft skin so that complete reversal of the flap does not shorten the penis (either real or illusory) and restrict an erection. An artificial erection achieved by intracavernosal injection of Prostaglandin E<sub>1</sub> helps to determine skin adequacy. Penile skin may be inadequate from a previous circumcision or from flap tip loss from the first procedure. If the skin is inadequate, partial V-Y reversal results in a Y-shaped scar with a shorter vertical limb (Figs. 82.3B and 82.5) (6). No restriction of erection should occur by pulling on the erect penis.

The scrotal dog-ears are excised at this time. Prolonged lymphedema or potential skin loss can occur if the skin and dartos fascia at the penile base are completely circumcised while repairing these scars and dog-ears. The method of closure and dog-ear excision is determined by judging the tightness of the penile skin, taking care not to restrict an erection. If the discrepancy of skin occurs from reversal of the V-Y flap, the dog-ear is usually followed along the lateral scrotum. Alternatively, the dog-ear is excised from the midportion of the lateral side of the incision, which creates a lateral dart instead of following the dog-ear around the penile base (Fig. 82.5B) (6).

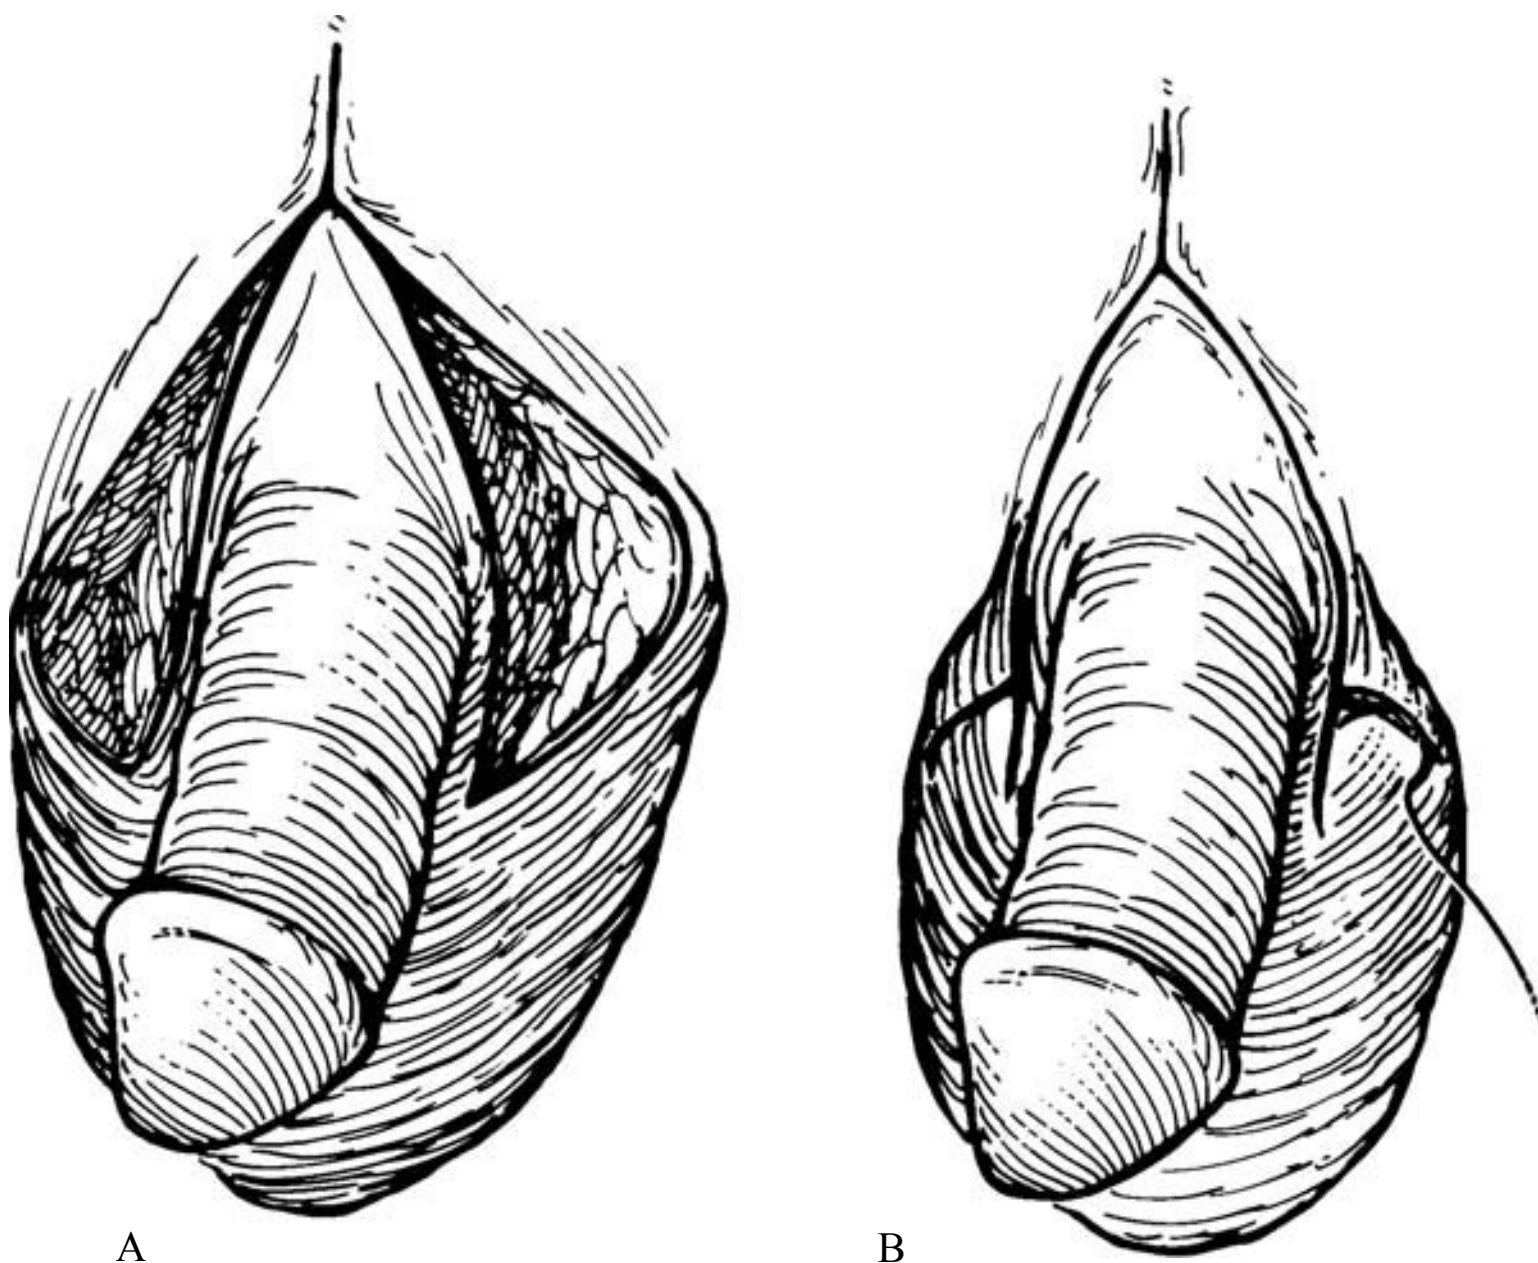

A

B

**FIGURE 82.4** Complete reversal of V-Y flap (same case as Fig. 82.2). **A:** A scar is marked for excision with solid lines. Fat nodules to be excised are marked by dotted lines on the penis. **B:** Complete reversal of V-Y advancement flap, resulting in a semicircular incision line. Hair on the V-Y flap is aligned with the pubic hair. The marked fat nodules were removed.

A

B

**FIGURE 82.5** Diagram of partial reversal of V-Y advancement flap. **A:** The V-Y flap is reversed as much as possible while preserving penile length. A Y-shaped incision line results. **B:** Dog-ears are removed by making lateral darts. They can also be removed by extending the incision along the lateral scrotum.

In order to reduce the risk of redeveloping a hypertrophic scar, closure should be meticulous and without tension. The skin, subcutaneous tissue, and Scarpa's fascia are undermined and then closed in layers. Intra-dermal buried 4-0 Monocryl sutures are placed, and the skin is closed with a subcuticular suture. A suction drain is used. If the upper limb of the vertical incision pulls, then one of two small Z-plasties can be used to release tension and decrease the risk of a restrictive hypertrophic scar contracture. Even with careful closure, the common junction of the V flap with the vertical closure often has minor healing problems. Also, over time, the pulling of the penis on the incision lines usually causes some stretching of the scars.

If complete V-Y reversal is not possible due to restriction of erection and if a significant dorsal flap hump is present,

then the subcutaneous fat on the V flap is conservatively excised to prevent devascularization. This will improve the appearance, but the difference in skin texture and hair growth continues.

The resulting scars are better with the inverted U scar than with the partial V-Y reversal. The reversal and scar revision improve the wide or hypertrophic scars and eliminate the suprapubic concavity. They eradicate the unsightly dorsal penile hump and proximal hair-bearing tissue by redraping the penis with the normal shaft skin and elevating the penis to its normal position. They can also improve or eliminate complaints of penile instability.

Rereleasing the suspensory ligament is performed only if the patient complains of penile shortening. Transposing a fat flap from the lipomatous tissue of the spermatic cord

**FIGURE 82.6** Bilateral fat flaps from the medial spermatic cords are transposed to the midline to fill the dead space at the penile base.

eliminates the dead space between the corpora and pubic symphysis (Fig. 82.6). The fat flap is dissected off of the cord, divided proximally to leave an intact distal random blood supply, and sutured to the periosteum with 3-0 absorbable sutures.

## Infected Fat

The surgeon should remove fat nodules or contour the penile fat through a limited or complete circumcising incision, a medial raphe incision, or part of the previous V-Y or pubic transverse incision. New incisions on the penile shaft are unsightly and unnecessary. Deforming or firm fat deposits are very conservatively removed and then the residual fat is contoured while leaving as much dartos fascia as possible. It is very important not to overresect fat, which will create an unsightly concavity, so resection is performed in very small increments. Large diffuse fat deposits are usually removed through a circumcision incision (Fig. 82.7). Only rarely will a patient want all of the fat removed. Skin necrosis, chronic lymphedema, or skin attachment to the Buck fascia can occur with overly aggressive removal of the dartos fascia. The goal of fat removal is contouring, not complete fat elimination.

If the patient is undergoing V-Y flap reversal, then simultaneous removal of fat nodules or deforming deposits is limited. If large diffuse fat deposits are removed at the same time as V-Y reversal, then further flap disruption and dartos fascia injury decrease the flap vascularity and possibly prolong edema. Fat is removed through a several-centimeter tunnel on one or

both limbs of the distal V-Y incisions without undermining the flap, or through a limited circumcision incision (Fig. 82.8) (6). One side of the penis should be kept relatively inviolate to retain good blood and lymphatic drainage. Degloving of the penis through a circumcision incision and V-Y flap reversal should not be done at the same time. Residual deposits removed at least 6 months later are done through a circumcision, median raphe, or previous incision.

### Dermal Fat Grafts and AlloDerm

The presence of dermal fat grafts and/or AlloDerm creates a different set of problems. Patients complain of penile curvatures, shortening, abnormal texture, chronic infections, and penile distortion. Sometimes patients present after a combination of procedures, such as a V-Y advancement flap and fat injections followed by dermal fat grafts and/or AlloDerm. The graft causing the problems can usually be totally removed through one or a combination of circumcision, median raphe, or pubic incisions. Penile shaft incisions should be avoided. An indurated, scarred graft that is not attached to the Buck fascia can be removed without much difficulty, thereby usually correcting or improving the deformity (Fig. 82.9). However,

**FIGURE 82.9** AlloDerm elevated off the Buck fascia without much difficulty.

patients with penile shortening, penile curvature, or chronic infection caused by graft necrosis and subsequent scar contracture may require a difficult dissection. An extensively fibrotic AlloDerm or dermal graft may adhere to the Buck fascia, so extreme care must be taken not to injure the dorsal neurovascular bundles. Loupe magnification is usually necessary. Removal of the scarred dermal graft may eliminate the deformity, curvature, or penile length restriction, but total return of penile length may not occur due to permanent scarring of the skin or of the dartos or Buck fascia. Under rare circumstances, severe fibrosis may require penile plication. The surgeon should preserve as much dartos fascia as possible during graft removal to prevent skin adherence to the Buck fascia.

A dead space often occurs at the penopubic junction after graft removal. The space must be filled with vascular fat flaps transposed from the medial spermatic cord or other nonadherent vascularized tissue, which will help prevent penile shortening (Fig. 82.6). A closed-suction drain is necessary.

Chronic infections with dermal fat grafts or AlloDerm are often seen. The patient presents with infected sinuses and chronic drainage, erythema, and so forth. Removal of the entire graft is usually recommended. These cases should initially be treated in the short term with antibiotics, but aggressive removal of the dermal grafts and AlloDerm should be done without delay if infection persists. Persistent delay in treatment may complicate the ability of the patient to regain his penile length due to scar contracture of the dartos and Buck fasciae and the skin. These cases can have tragic consequences.

On occasion, dorsal penile skin loss has been seen from both AlloDerm and dermal fat grafts, probably from venous congestion due to stretched dartos fascia and skin combined with a tight dressing. These situations have disastrous consequences. A thick skin graft is needed to maintain the length of the penis or secondary contracture of the wound will cause a short, distorted penis. Unfortunately, the graft has a poor color match, is cosmetically deforming, and may not allow complete length preservation.

The dressing used around the penis after any of these surgeries is crucial to recovery, since it will help prevent hematomas and swelling that can lead to secondary deformities. Any significant fat removal or degloving of the penis usually requires a small closed-suction drain placed through a small pubic stab incision. A thin Duoderm dressing is loosely wrapped around the penis followed by a loose Coban. This dressing is not removed for a minimum of 2 days but frequently longer. It is then replaced with a circumferential loose Tegaderm wrap. Drains are left until they cease draining.

## OUTCOMES

### Complications

Frequently, the patient states that he would just like to return to the appearance of his penis prior to any penile enlargement surgery, but this is usually impossible. Sometimes he just wants to achieve some final girth increase, albeit minor, in order to feel that the enlargement process was not a total loss.

After reversal of the V-Y flap, the patient may have some eventual stretching of the scar so that it does not give the fine line that was present initially. However, there is certainly an

improvement in the scar and elimination of the other V-Y deformities.

Despite careful contouring of injected fat, it is extremely difficult to have a smooth penile contour postoperatively. Residual nodules, lumps, concavities, and convexities are common and certainly expected, but the goal is to minimize them as much as possible. Complete removal of all injected fat is to be avoided if at all possible, since restricting bands can form at the penopubic junction and the skin can attach to the Buck fascia. The surgeon should always try to leave some dartos and fat in order to minimize this possibility. Secondary surgery to repair these bands and attachments is not always successful.

Removal of restricting bands and tissue of the penopubic junction from dermal fat grafts or AlloDerm can still result in erectile restriction at the base of the penis from bands and scar tissue. Postoperatively, tissue reaction at the penopubic junction often requires time and multiple Kenalog injections to soften the palpable bands attached to the corpora and penile skin. These usually soften >6 months. On occasion, a limited release of these recurrent bands needs to be performed. Penile

weights or stretching devices can also be helpful to prevent scar retraction or regain some length.

---

## Results

---

Reconstruction of the complications of these procedures is challenging, requiring an understanding of blood flow, tissue transfer techniques, and plastic surgical principles. These patients are often psychologically devastated when coming for reconstruction, since they started with self-esteem issues that led to their initial penile enlargement operation. Thus, the reconstructions must be done with extreme care in order to regain the patients' penile form and function and psychological health.

The outcome for most patients with reconstruction is usually satisfactory. There is a low complication rate if meticulous technique is used. However, more than one operation is often necessary. The vast majority of these patients are able to resume normal sex lives without being self-conscious after correction of their deformities.

## CHAPTER 83 ■ ILEAL CONDUIT URINARY DIVERSION

MICHAEL C. LEE AND ERIC A. KLEIN

Despite the established role of continent catheterizable and orthotopic voiding urinary diversion techniques, the ileal conduit remains the most common form of urinary diversion performed worldwide. The operation, first described by Bricker in 1950, maintains this popularity in large part because of its applicability to a wide variety of urologic disorders, its tolerability in patients with often significant comorbidities, and its adaptability to almost all patients' anatomic constraints.

---

### DIAGNOSIS

---

The ileal conduit may be constructed as part of a reconstruction following extirpative pelvic surgery, such as radical or simple cystectomy and pelvic exenteration, or as a diversion with the bladder left in situ, such as in cases of neuropathic bladder refractory to conservative management. The clinical evaluation in these patients is therefore directed to their bladder pathology.

---

### INDICATIONS FOR SURGERY

---

Before choosing an ileal conduit, patients should be counseled on all forms of diversion. Comorbidities such as renal insufficiency (serum creatinine  $>2.5$  mg per dL), bowel disease (inflammatory or malignant), extreme obesity, or neurologic illness that prevents the ability to perform self-catheterization may make incontinent diversion a wise choice. While it was suggested in the past that patients with cardiovascular or pulmonary diseases may do better with the shorter, simpler conduit diversions, newer evidence suggests that perioperative morbidity is equivalent with conduit and continent diversions (12).

---

### ALTERNATIVE THERAPY

---

Continent catheterizable or orthotopic voiding diversions are the most common alternatives to conduit diversion. If the aforementioned concerns make conduit diversion preferable to continent diversion, there still exist options regarding the bowel segment to be used and the type of ureteroenteric anastomosis. Jejunal conduits are associated with a higher incidence of metabolic complications, characterized by hypochloremia, hyponatremia, hyperkalemia, and acidosis, but may be the only viable option in certain patients due to previous surgery, irradiation, or concomitant bowel diseases (6).

Colonic conduits, which are thought to be more protective of kidney function by some surgeons due to the ability of colonic conduits to accommodate nonrefluxing anastomoses, may be preferable in children and adults with a longer life expectancy. A transverse colon conduit may be safest in patients who have undergone pelvic irradiation due to its higher intra-abdominal position outside of the radiation field. Another use of colon for conduits is the sigmoid conduit diversion in patients who are undergoing pelvic exenteration, with a transverse colostomy that avoids the potential morbidities of a bowel anastomosis.

Other potential urinary diversions include an ileovesicostomy, which can be used in patients undergoing diversion for reasons other than malignancy and avoids the complications associated with ureteral mobilization and ureteroenteric anastomoses. In patients requiring urinary diversion with life expectancies less than several months, percutaneous nephrostomy tubes should be considered.

---

### SURGICAL TECHNIQUE

---

Most patients can tolerate an at-home preoperative regimen of a clear liquid diet 1 to 2 days before surgery, followed by 4 L of polyethylene glycol or two bottles of magnesium citrate on the afternoon before surgery. Broad-spectrum intravenous antibiotics are given at the time of the surgery. The stoma site should be selected after examining the patient in the supine, seated, and standing positions. To best accommodate an appliance, the site should not be too near the anterior superior iliac spine, costal margin, umbilicus, surgical scars, or skin folds. The usual ideal location is just medial to the linea semilunaris on a line between the umbilicus and the anterior superior iliac spine.

Markedly obese patients may require a higher site to allow them to perform stoma care under direct vision. In instances where there is a question regarding the ideal stoma site, ambulatory trials of pouching candidate sites can help determine the optimal location.

Laparoscopic techniques have been reported for the creation of ileal conduits and have been successfully performed with no reported intra- or postoperative complications (10). However, the open approach remains the standard given the technical difficulty and the need to remove the specimen through a minilaparotomy when performing a concurrent cystectomy.

A low midline incision extending from just above the umbilicus down to the symphysis pubica allows for exposure of the bladder for cystectomy as well as bowel exposure for the conduit portion of the procedure. The patient is positioned

supine. A Bookwalter-type retractor may be used to retract the bowel from the cystectomy field, and then the blades may be repositioned on the abdominal wall for the conduit procedure. The posterior peritoneum is incised at the pelvic inlet above the iliac vessels, where the ureter can be found coursing over the vessels. The ureters are then dissected with care distally and transected as close to the bladder as possible. A lesser degree of proximal mobilization is also usually necessary. During mobilization of the ureter, care should be taken to maintain its blood supply by leaving a generous amount of periureteral soft tissue. The distal ends of the ureters may be clipped to allow dilatation while the ileal conduit is harvested and prepared.

The terminal ileum is then identified and examined. If signs of inflammatory bowel disease, radiation changes, or insufficient mesenteric length are not present, then this segment is in general preferred for conduit formation. The mesentery is examined by transillumination, and the watershed area between the ileocolic artery and the right colic artery is selected for the distal mesenteric incision. This is typically located 15 to 20 cm from the ileocecal valve, and the preservation of this length of terminal ileum suffices to maintain bile salt and vitamin B12 absorption. The bowel incision is continued proximally into the mesentery to allow the distal end to reach the stoma site without tension. Figure 83.1 demonstrates the isolation of the ileal segment.

The mesentery is again transilluminated, and a relatively avascular site is selected for the proximal incision. The optimal length of the conduit differs from patient to patient due to differences in body habitus and the degree of ureteral mobilization. The longest length of conduit should not exceed the distance between the sacral promontory and the stoma site; usually, if there is adequate left ureteral mobilization, a shorter length than this is optimal. If there is any question regarding the length, one should err on the longer side, as redundant conduit is much easier than insufficient conduit to treat intraoperatively. The conduit and its mesentery are positioned caudal to the rejoined bowel and its mesentery.

Standard hand-sewn or staple techniques are then performed to reestablish bowel continuity. The mesenteric window is also closed with a shallow running suture to prevent internal bowel herniation. Care should be taken during closure of the mesenteric window to avoid ligation of the ileal blood supply, which might compromise the healing of the

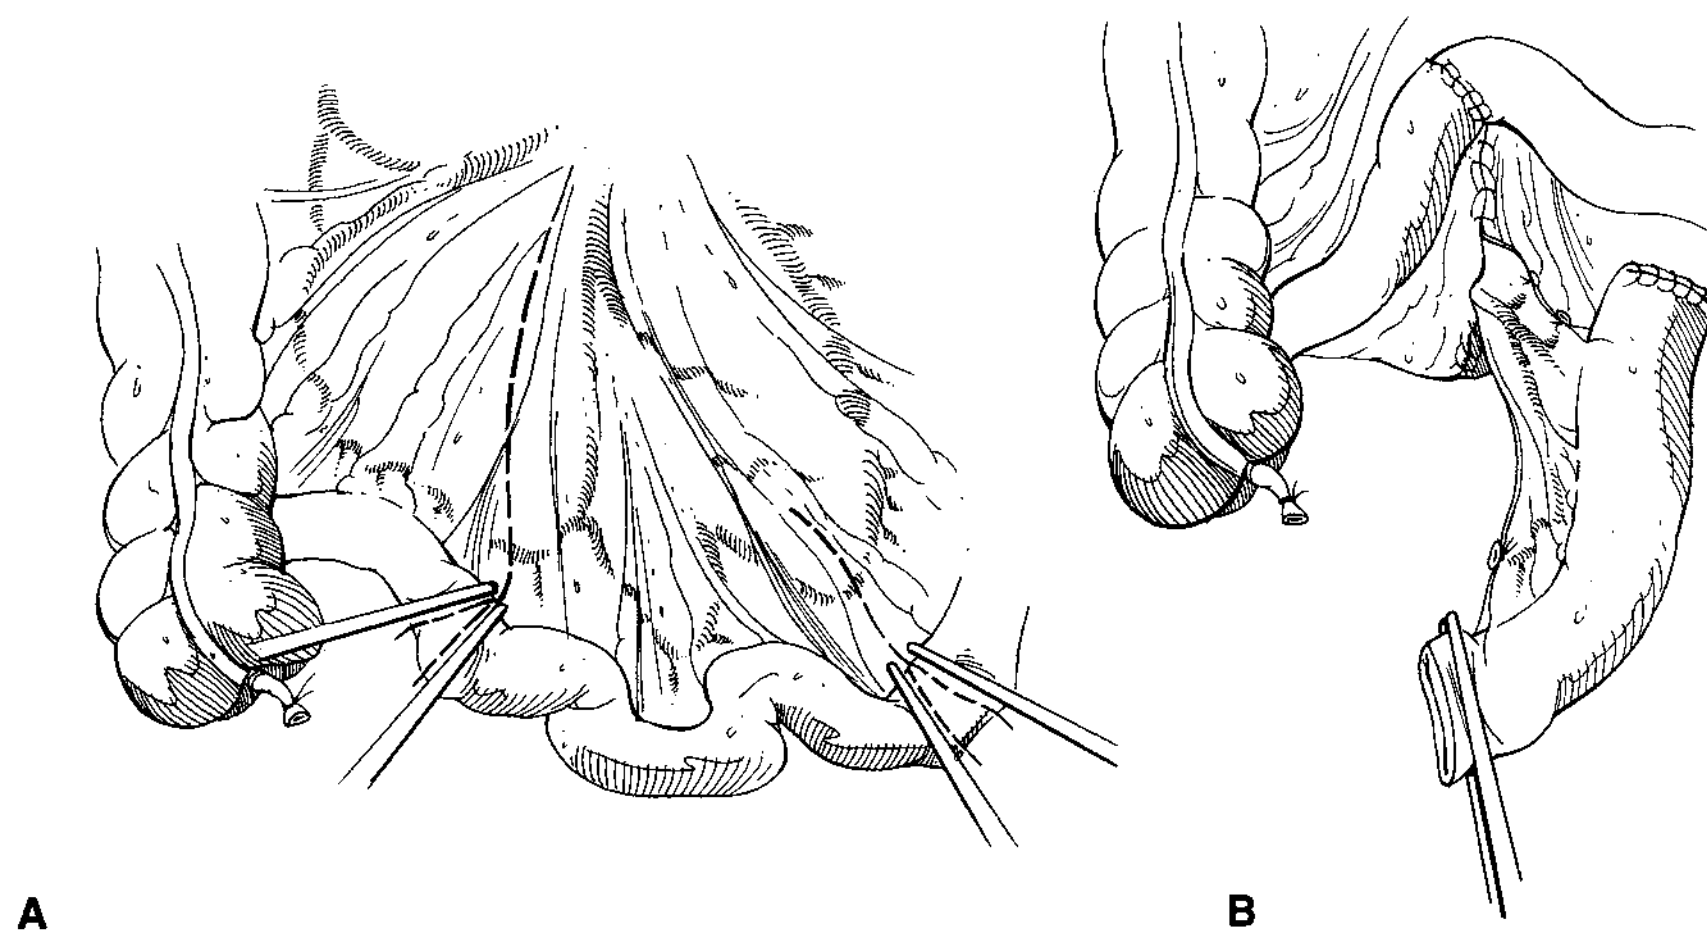

anastomosis. Sterile towels are placed beneath the isolated ileal conduit, which is irrigated free of enteric contents with an antibiotic solution.

At this point in the procedure, either stoma formation or ureteroenteric anastomosis can be performed. This choice is based on surgeon preference. If ureteral stents are to be used, performing the ureteroileal anastomosis first allows for easier antegrade passage of the stent out of the distal end of the conduit. Creating the stoma first provides for more optimal localization of the ureteroileal anastomotic sites and helps direct the optimal level of the sigmoid mesentery through which the left ureter should be passed.

Construction of the stoma begins with the excision of a circular plug of skin around the preselected stoma site. Dissection is carried down to the anterior rectus fascia, and a cruciate incision is made in this layer. A Kelly clamp is passed bluntly through the rectus muscle after palpating for and avoiding the pulsations of the inferior epigastric artery. The Kelly is then spread to create a hiatus that allows the passage of two fingers; this breadth is usually ideal for not compromising the mesenteric blood flow to the stoma while minimizing the risk of parastomal hernia.

In the standard end stoma (“rosebud”) technique, the efferent end of the conduit is grasped and pulled through the abdominal wall defect until the end is 2 to 3 cm above the skin surface. Each of the four tabs of the cruciate incision is then sutured to the bowel serosa, taking care not to pass sutures through the bowel mesentery. Absorbable sutures are then passed through the mucosal edge of the bowel, then the bowel serosa and muscularis deep to the skin edge, and finally through the dermal tissue just deep to the skin edge. Care is taken not to suture the bowel mucosa to the epidermis, as this can lead to mucosal rests that complicate pouching of the stoma. Figure 83.2 shows the technique of suture placement for the end stoma. Four quadrant sutures placed in this manner usually suffice to evert the stoma; additional sutures may be placed for reinforcement.

In obese patients or patients with a short mesentery, a Turnbull loop stoma should be considered. The distal end of the loop is closed with absorbable sutures (if the GIA stapler was used to harvest bowel, no additional closure is needed). An umbilical tape is passed through the mesentery at its border, with the ileum about 3 cm proximal to the end of the conduit. The tape is then grasped and pulled through the

**FIGURE 83.1** **A:** The ideal segment of bowel for the ileal conduit spares the terminal 10 to 20 cm of ileum and should require minimal ligation of mesenteric vessels to harvest. **B:** Once isolated, the conduit mesentery is positioned caudal to the bowel mesentery, which is reapproximated with a running silk suture.

**FIGURE 83.2** The end stoma (“rosebud”) is everted by passing sutures first through a full-thickness bite at the cut edge, then through the bowel serosa at the skin level, and finally through the dermis.

abdominal wall defect. A stomal rod is in general passed through the umbilical tape defect to prevent stomal retraction; this is then sutured in place and left in for 1 to 2 weeks. The blind end of the loop is positioned cephalad, and the loop is opened transversely nearer to the distal limb. The stoma is then matured using eversion sutures in the same manner described for the rosebud stoma. The technique for end-loop stoma formation is detailed in Fig. 83.3.

A long-term follow-up study comparing the results of these two techniques revealed no major differences in outcome (2). Patients with an end stoma had slightly more ischemic complications, while those with the loop stoma required more frequent repair of parastomal hernias, presumably due to the need for a wider aperture in the abdominal wall.

Principles to consider in the creation of the ureteroenteric anastomoses include the maintenance of an adequate distal

ureteral blood supply, the avoidance of tension on the anastomosis, the documentation of malignancy-free status in the distal ureter (if the diversion is performed for cancer), and the avoidance of ureteral kinking. While techniques for nonrefluxing ureteroileal anastomoses have been described (9), the benefits of a nonrefluxing anastomosis have never been conclusively proven. Moreover, these techniques are likely to result in higher rates of anastomotic obstruction and prevent the use of the simple loopogram study in the evaluation of upper tract pathology after ileal conduit formation. Therefore, the freely refluxing end-to-side (Bricker) and conjoined end-to-end (Wallace) techniques remain the most commonly performed and recommended techniques.

In the Bricker technique, the proximal end of the conduit is either left closed if staples were used in the bowel harvest or closed in two layers with absorbable sutures. The left ureter is passed through a hole created in the sigmoid mesocolon. This hole is typically created at the level of the sacral promontory but may be moved cephalad or caudally to avoid ureteral kinking. A site on the conduit where the ureter lies naturally is incised down to the submucosal layer. The submucosa is grasped with forceps, and a small portion is excised along with its mucosa. The ureter is then spatulated, and a single-layer full-thickness anastomosis is performed with 4-0 or 5-0 interrupted absorbable sutures. Prior to closing the anastomosis, silicone ureteral stents may be placed; these can be guided in through the stoma using a Kelly clamp or a copper suction tip. Anchoring sutures through the ureteral adventitia and the bowel serosa may be placed 1 to 2 cm proximal to the anastomosis. Figure 83.4 demonstrates the ideal locations of the ureteroenteric anastomoses using the Bricker technique.

The Wallace technique involves leaving the proximal end of the conduit open. The ureters are spatulated for a distance slightly greater than the conduit diameter. The posterior edges may be joined side-by-side or end-to-end using two running 4-0 absorbable sutures. One suture is then used to join the back walls of the conjoined ureters and the conduit, after

**FIGURE 83.3** Creation of the end-loop stoma. The defunctionalized limb is positioned cephalad.

**FIGURE 83.4** Ideal placement of the vesicoenteric anastomoses using the Bricker technique. The spatulated ureters should pass under the conduit and lie without tension or kinking.

**FIGURE 83.5** The side-to-side Wallace technique creates a widely patent vesicoenteric anastomosis at the “butt” end of the conduit.

which the anterior walls are closed. The side-to-side Wallace technique is detailed in Fig. 83.5. Stents may be passed prior to closure of the anterior wall. This technique allows for the rapid creation of a widely patent ureteroileal anastomosis; its theoretical disadvantage is that a process creating obstruction

of one ureter (recurrent malignancy, anastomotic stricture) is more likely to cause bilateral obstruction.

After performing the ureteroileal anastomosis, the proximal end of the conduit is retroperitonealized by sewing the cut edges of the peritoneum to the conduit. Closed-suction drains (Jackson–Pratt type) are placed in the area of the ureteroileal anastomoses and maintained for the first few postoperative days.

The return of bowel function is the major determinant of the length of the postoperative hospital stay; this is evidenced by similar lengths of hospitalization for urinary diversion procedures with and without cystectomy. Most patients can expect a hospital stay of 6 to 8 days in centers with well-defined clinical pathways (1). Nasogastric decompression is optional. The conduit also experiences an ileus, and its return of peristalsis parallels that of the small bowel; therefore, some surgeons advocate placement of a cut Foley or Rob-Nel catheter to promote conduit drainage in the first few postoperative days. There is no consensus for the optimal length of ureteral stenting (if it is performed at all); the timing of stent removal is left to the discretion of the surgeon. Jackson–Pratt drains are left in place until the drainage is negligible; if drainage persists at high levels several days postoperatively, the drain fluid should be sent for creatinine analysis to rule out a urine leak. If a rod is left under the stoma, this may be removed prior to discharge.

Counseling and teaching by the enterostomal therapist should begin in the preoperative period and continue during the hospitalization. The patient or his or her caregivers should be competent in all aspects of stoma care prior to discharge. Follow-up care is tailored to the individual patient; in most cases, a periodic serum renal profile is indicated. In patients undergoing cystectomy for malignancy, urine cytology should be followed. The upper tracts can be assessed via a loopogram, avoiding the toxicity of intravenous contrast agents.

---

## OUTCOMES

---

### Complications

---

The mortality rates for cystectomy and diversion have steadily decreased over the years since Bricker’s initial description; in a recent series a mortality rate of 0.3% was reported (1).

The most common morbidity causing prolonged hospital stay is ileus (1). This usually resolves quickly with nasogastric decompression; failure to do so after a few days should prompt a diagnostic workup for bowel obstruction. Urine leak at the ureteroileal anastomosis or from the conduit closure and urosepsis are the most common urologic complications of the procedure. Urine leaks can usually be managed successfully with placement of an abdominal drain and percutaneous nephrostomy diversion.

Late complications of ileal conduits are common but usually not severe. Stomal stenosis has been reported in up to 29% of ileal conduits (11); proper stoma construction can decrease this incidence. Definitive treatment includes removal or partial resection of conduit. Parastomal hernias have been reported in 14% of patients with obesity as an independent risk factor (8); stoma relocation may be superior to fascial

repair in these cases. Hyperchloremic metabolic acidosis can occur but is rare in well-functioning conduit; the presence of more than a mild acidosis should prompt an evaluation for obstruction or redundancy of the conduit. Alkalinizing agents (sodium bicarbonate) or chloride transport blockers (chlorpromazine, nicotinic acid) can effectively treat this acidosis. Ureteroileal anastomotic strictures are also uncommon (about 6% in older series); these can be successfully managed with dilation with a cutting balloon (about a 50% success rate), with open surgical repair (76% long-term success) (4), or chronic ureteral stents. The Wallace anastomosis has been reported to have a lower stricture rate than the Bricker (7).

Acute pyelonephritis occurs commonly in patients with ileal conduits (18% of patients) (5). Indeed, bacteriuria can be found in up to three-fourths of ileal conduit urine specimens (5). Most of these can be safely observed without treatment, as patients seem to tolerate this chronic colonization well, and few progress to acute pyelonephritis. Infections with *Proteus* or *Pseudomonas* are associated with deterioration of the upper tracts and should therefore be treated.

Deterioration in renal function occurs in a significant portion of patients undergoing conduit diversion; over the long term, 50% of patients have radiographic evidence of functional deterioration at 15-year follow-up, and up to 7% of patients

can develop renal failure requiring dialysis (5). Renal function should be monitored periodically, and declines in function should alert the clinician to examine for correctable causes of renal dysfunction.

---

## Results

---

The ileal conduit has provided reliable urinary diversion for patients with a variety of underlying illnesses for over 50 years. Continent catheterizable diversions and orthotopic neobladders continue to gain acceptance, and recent studies have focused on quality-of-life outcomes after continent and incontinent diversions. Existing studies are unable to prove that continent reconstruction is superior to conduit diversion (4). Unfortunately, as younger, thinner, and healthier patients undergo continent diversion while older and more frail patients undergo ileal conduit, a real comparison of the quality of life after these procedures will likely never be possible. Still, it is clear that ileal conduit is a simple form of diversion that is well tolerated by most patients and has fewer contraindications than continent diversions. These factors make it likely that the ileal conduit will continue to play a major role in many urologists' practices.

# CHAPTER 84 ■ TRANSVERSE COLONIC CONDUIT

MARGIT FISCH, RUDOLF HOHENFELLNER, RAIMUND STEIN, AND JOACHIM W. THÜROFF

Since the first publication in 1969 (10), the transverse colonic conduit has been increasingly implemented in patients with urologic or gynecologic malignancies and additional radiotherapy (2,9,11,12). With its cranial position outside the irradiation field, it fulfills the requirement of not being irradiated, which is of utmost importance for a segment to be used for urinary diversion. Not only the transverse segment but also the ascending and descending colon can be used, which offers an adaptation to the individual patient's situation. The ascending

and descending colon are located in a retroperitoneal position, as is the sigmoid colon. There are no limitations with regards to short ureters. As part of the colon, the segments offer the option of antirefluxing as well as refluxing ureteral implantation (3,5,8,13) and for positioning of the stoma either to the left or right upper abdomen. In addition, colon can be used either in an isoperistaltic or anisoperistaltic way and is less prone to stoma stenosis than ileum when used for creation of a conduit.

In patients with total damage of the ureters by irradiation or retroperitoneal fibrosis and in patients with recurrent urothelial tumors (7), a direct anastomosis of the conduit to the renal pelvis represents an option (pyelotransverse pyelocutaneostomy) (4).

---

## DIAGNOSIS

---

Preoperatively, an intravenous (IV) urography should be performed to evaluate the upper urinary tract. An enema with water-soluble contrast medium should be done to exclude diverticuli or polyps. The bowel is irrigated with Ringer lactate solution (8 to 10 L) via a gastric tube or oral intake of 5 to 7 L of Fordtran solution. The day before surgery, positioning of the stoma should be done. The best position is in the epigastric region; the attached stoma plate has to be checked in sitting, lying, and standing positions of the patient.

---

## INDICATIONS FOR SURGERY

---

Indications for transverse colonic conduit include urinary diversion in patients with urologic or gynecologic malignancies and irradiation damage of bowel and distal ureters. Other indications are urinary incontinence in patients with radiation cystitis, complex vesicovaginal and rectovesicovaginal fistulas after irradiation, recurrent retroperitoneal fibrosis, Crohn disease, and unsuccessful primary urinary diversion requiring conversion. Complex cases of prostate cancer with a history of irradiation or brachytherapy, recurrent stenosis of the posterior urethra, and/or fistula formation in addition to a small bladder capacity represent rare indications. In patients with recurrent urothelial tumors, anastomosis of the conduit to the renal pelvis allows direct endoscopic access to the calices. Absolute contraindications for the transverse colonic conduit are irradiation of the upper abdomen, previous extensive colon resection, and ulcerative colitis.

---

## ALTERNATIVE THERAPY

---

In young and healthy patients capable of catheterization, a continent transverse pouch (6) represents an alternative.

---

## SURGICAL TECHNIQUE

---

Instruments required include a basic kidney set with additional instruments for intra-abdominal surgery, a Siegel retractor, suction, and a basin containing prepared iodine solution for disinfection. Absorbable monofilament sutures like polyglycolic acid 4-0 are used for closure of the conduit and intestinal anastomosis to re-establish bowel continuity as well as to create the stoma. The ureters are implanted using 5-0 and 6-0 sutures. Intraoperatively, a gastric tube (alternatively gastrostomy), a rectal tube, and a central venous catheter are placed.

Access is gained by a median laparotomy. Both ureters are identified at the points where they cross over the iliac vessels

**FIGURE 84.1** A bowel segment of approximately 15 cm in length in patients with normal weight is selected, respecting the course of the vessels.

and are dissected in the cranial direction. The dissection toward the bladder goes down until the irradiated level is reached. The ureters are cut above the irradiated field where they show good vascularization. There should be capillary arterial bleeding out of the ureteral wall and spontaneous urine efflux. The ureteral stump is ligated, and the cranial end is marked by a stay suture. Depending on the remaining length of the ureters, it is decided which one can be brought to the opposite side by a retromesenteric pull-through. The retromesenteric entrance should be wide enough and the path of the ureter slightly curved in order not to angle or compress it.

A bowel segment of approximately 15 cm in length in patients with normal weight is selected respecting the course of the vessels (Fig. 84.1). The length of the segment depends on the thickness of abdominal wall. Stay sutures outline the segment. Bowel mobilization differs depending on the segment chosen: If the ascending segment is selected, the right colonic flexure is mobilized. The greater omentum is separated from the transverse colon over a distance of 10 to 15 cm starting at the right side. When the descending colon is chosen, the left colonic flexure has to be mobilized, and the left part of the omentum has to be separated from the transverse colon. The selection of a transverse colonic segment makes it necessary to mobilize both the right and left flexure and to completely separate the greater omentum from the transverse colon.

The mesentery of the selected segment is incised lateral to the supplying artery, and the arcade is divided between mosquito clamps and ligated. The fat is dissected from the seromuscularis of the bowel in the area where the segment will be cut, and bleeding vessels are coagulated. The segment is isolated without the use of clamps so that the bleeding out of the ends can be seen. The segment is cleaned using moist sponges.

**FIGURE 84.2** Bowel continuity is reestablished by a one-layer seromuscular suture using polyglycolic acid 4-0, and the mesenteric slit is closed by running suture.

Bowel continuity is re-established by a one-layer seromuscular suture using polyglycolic acid 4-0, and the mesenteric slit is closed by running suture (Fig. 84.2).

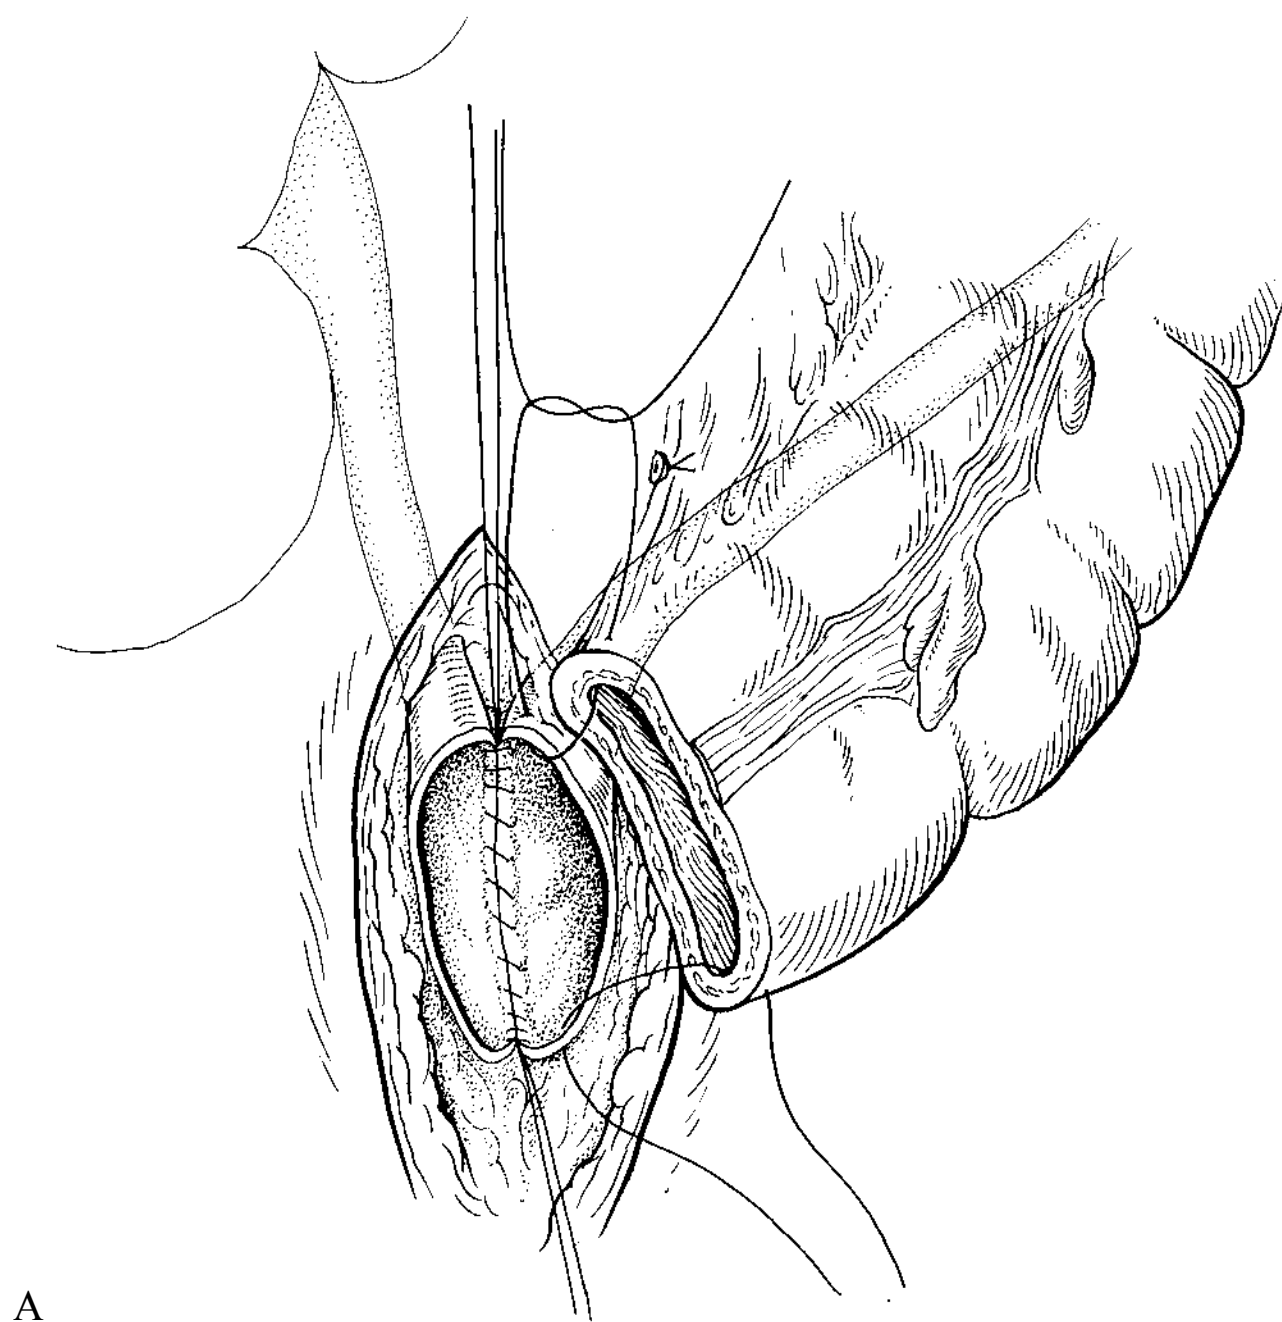

One option for ureteral reimplantation uses the refluxing Wallace technique (13). Both ureters are resected to an adequate length and spatulated over a distance of 3 cm. A stay suture is

placed at the 6 o'clock position and a ureteral stent inserted. The first suture for anastomosis of the medial margins of the ureters is placed at the 12 o'clock position and tied later. The anastomosis is performed by a running suture of polyglycolic acid 5-0. The ureteral stents are fixed to the ureteral mucosa (polyglactin 4-0 with short reabsorption time) and subsequently brought out through the conduit. The ureteral plate is then anastomosed to the oral end of the conduit by two running sutures of polyglycolic acid 5-0 (Fig. 84.3A). When the conduit is positioned on the right side and the left ureter is relatively short, it can be implanted antidromically to the right ureter (like the "crossed hands of a ballerina"; Fig. 84.3B).

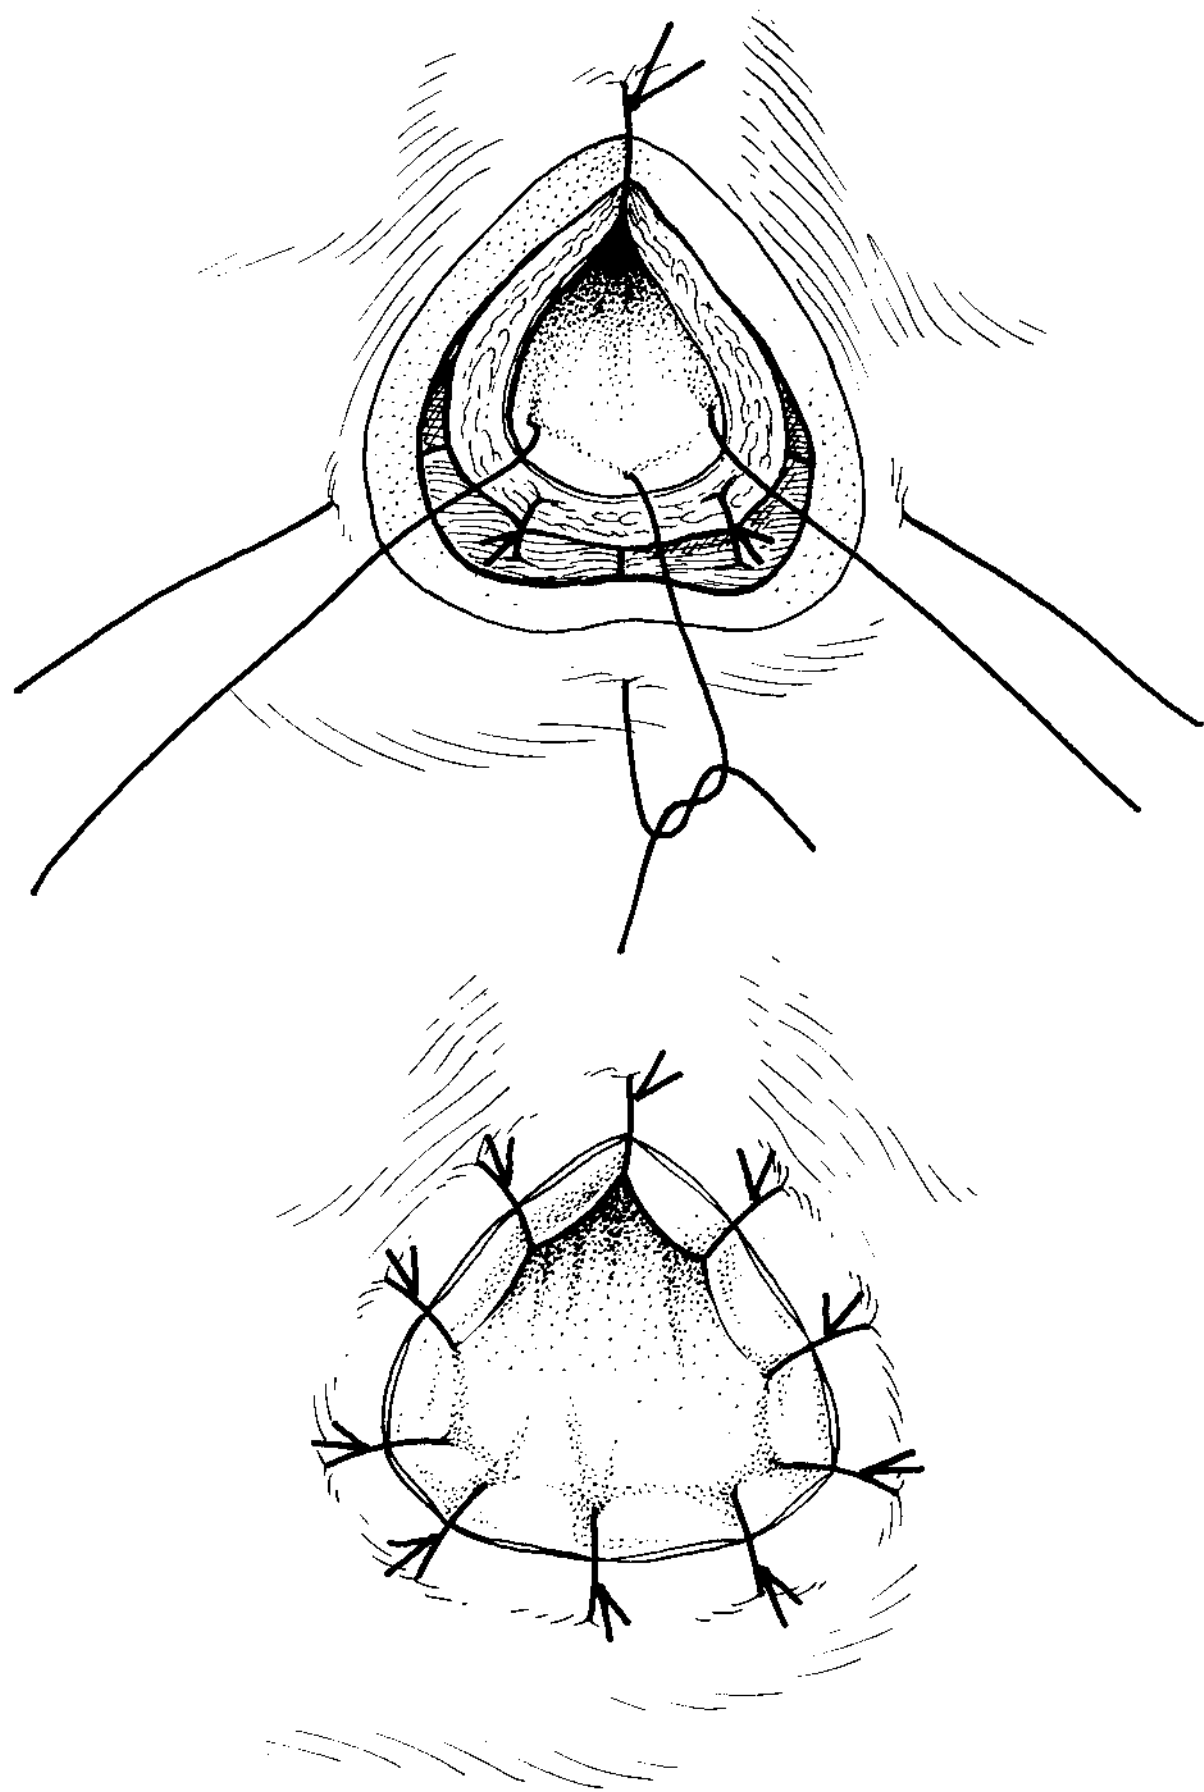

An alternative method of refluxing ureteral reimplantation is a direct implantation using a "buttonhole" technique. The conduit is longitudinally opened in the area of the taenia libera over a length of 3 to 4 cm starting at the oral end. Two stay sutures are placed at the back wall of the conduit. The mucosa in between is excised and the seromuscular layer incised to create an entrance for the ureter. The ureter is pulled through and implanted by two anchor sutures at the 5 and 7 o'clock positions (polyglycolic acid 4-0) and mucomucous sutures (polyglycolic acid 5-0). A stent is inserted, fixed, and led out through the conduit (Fig. 84.4). The contralateral ureter is implanted in the same manner and the conduit closed.

An antirefluxive ureteral implantation can be performed using the Goodwin-Hohenfellner technique (1). The conduit is longitudinally opened over a length of approximately 4 cm starting from the end chosen for ureteral implantation (proximal end preferable). Four stay sutures are placed to facilitate ureteral implantation. A submucosal tunnel is dissected starting from the end of the conduit (tunnel length, 3 to 4 cm). The bowel mucosa at the end of the tunnel is incised, and the ureter is pulled through the respective submucosal tunnel. After spatulation and resection of the ureter to an adequate length, implantation is performed by one anchor suture at the 6 o'clock position, grasping the seromuscularis of the bowel and all layers of the ureter (polyglycolic acid 5-0). The anastomosis is completed by mucomucous single sutures (polyglycolic acid 6-0).

To secure the ureteral implantation, a 6Fr ureteral stent is inserted in each ureter and fixed to the bowel mucosa

**FIGURE 84.3** The ureteral plate is then anastomosed to the oral end of the conduit by two running sutures of polyglycolic acid 5-0. **A:** Classical implantation; **B:** Implantation with left ureter in opposite direction to the right.

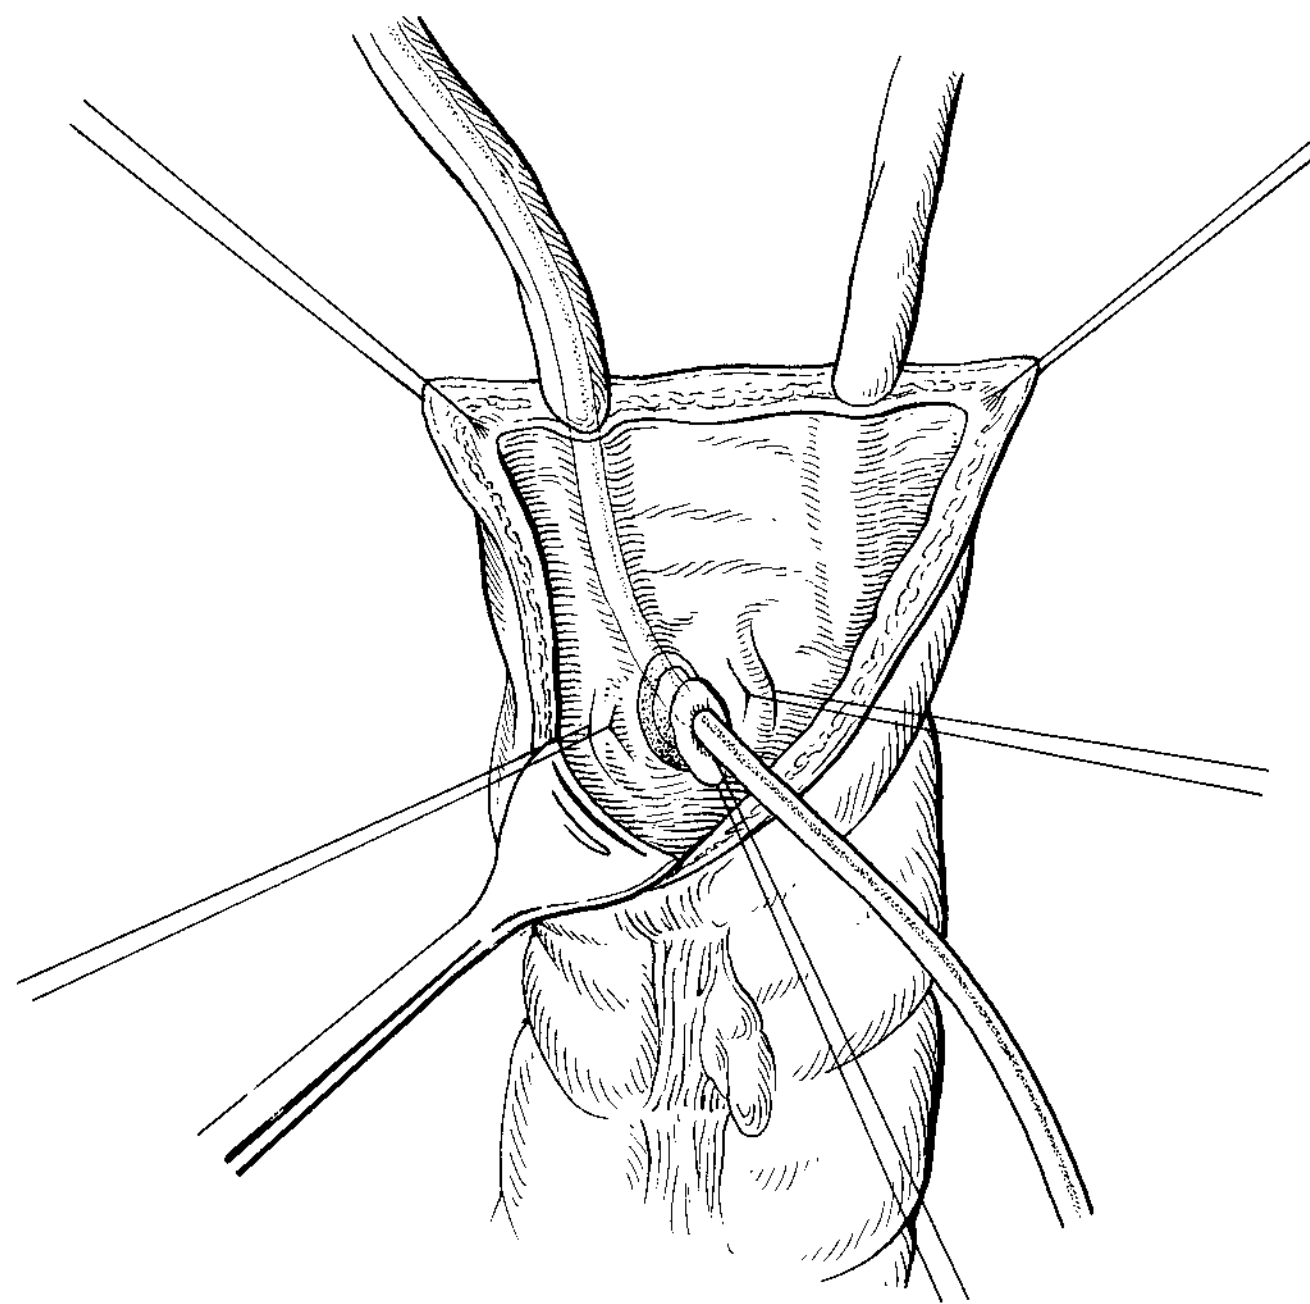

**FIGURE 84.4** The mucosa in between is excised and the seromuscular layer incised to create an entrance for the ureter.

(polyglactin 4-0 with short reabsorption time). For implantation of the second ureter, a second tunnel is prepared beside and parallel to the first; the implantation is done in the same way (Fig. 84.5). Both ureteral stents are led out through the aboral end of the conduit. The proximal ends of the conduit and of the incision line in the area of the taenia libera are closed (single seromuscular sutures, polyglycolic acid 4-0).

A circular area of the skin (approximately 3 cm in diameter) is excised. The abdominal fascia is crosslike incised, and the conduit is pulled through the fascial and the skin opening, together with the ureteral stents, by means of two Allis clamps after having freed the distal end of the conduit of fat and epiploic appendages. The seromuscularis of the conduit is fixed to the abdominal fascia by circular single stitches of polyglycolic acid 3-0, and the oral end of the conduit is anastomosed to the skin by circular single stitches of polyglycolic acid 5-0 everting the stoma (Fig. 84.6).

### Pyelotransverse Pyelocutaneostomy

An extensive bowel mobilization is necessary, including caecum, root of the mesentery, the Treitz ligament, and the right and left colonic flexures (Fig. 84.7A). The omentum majus is

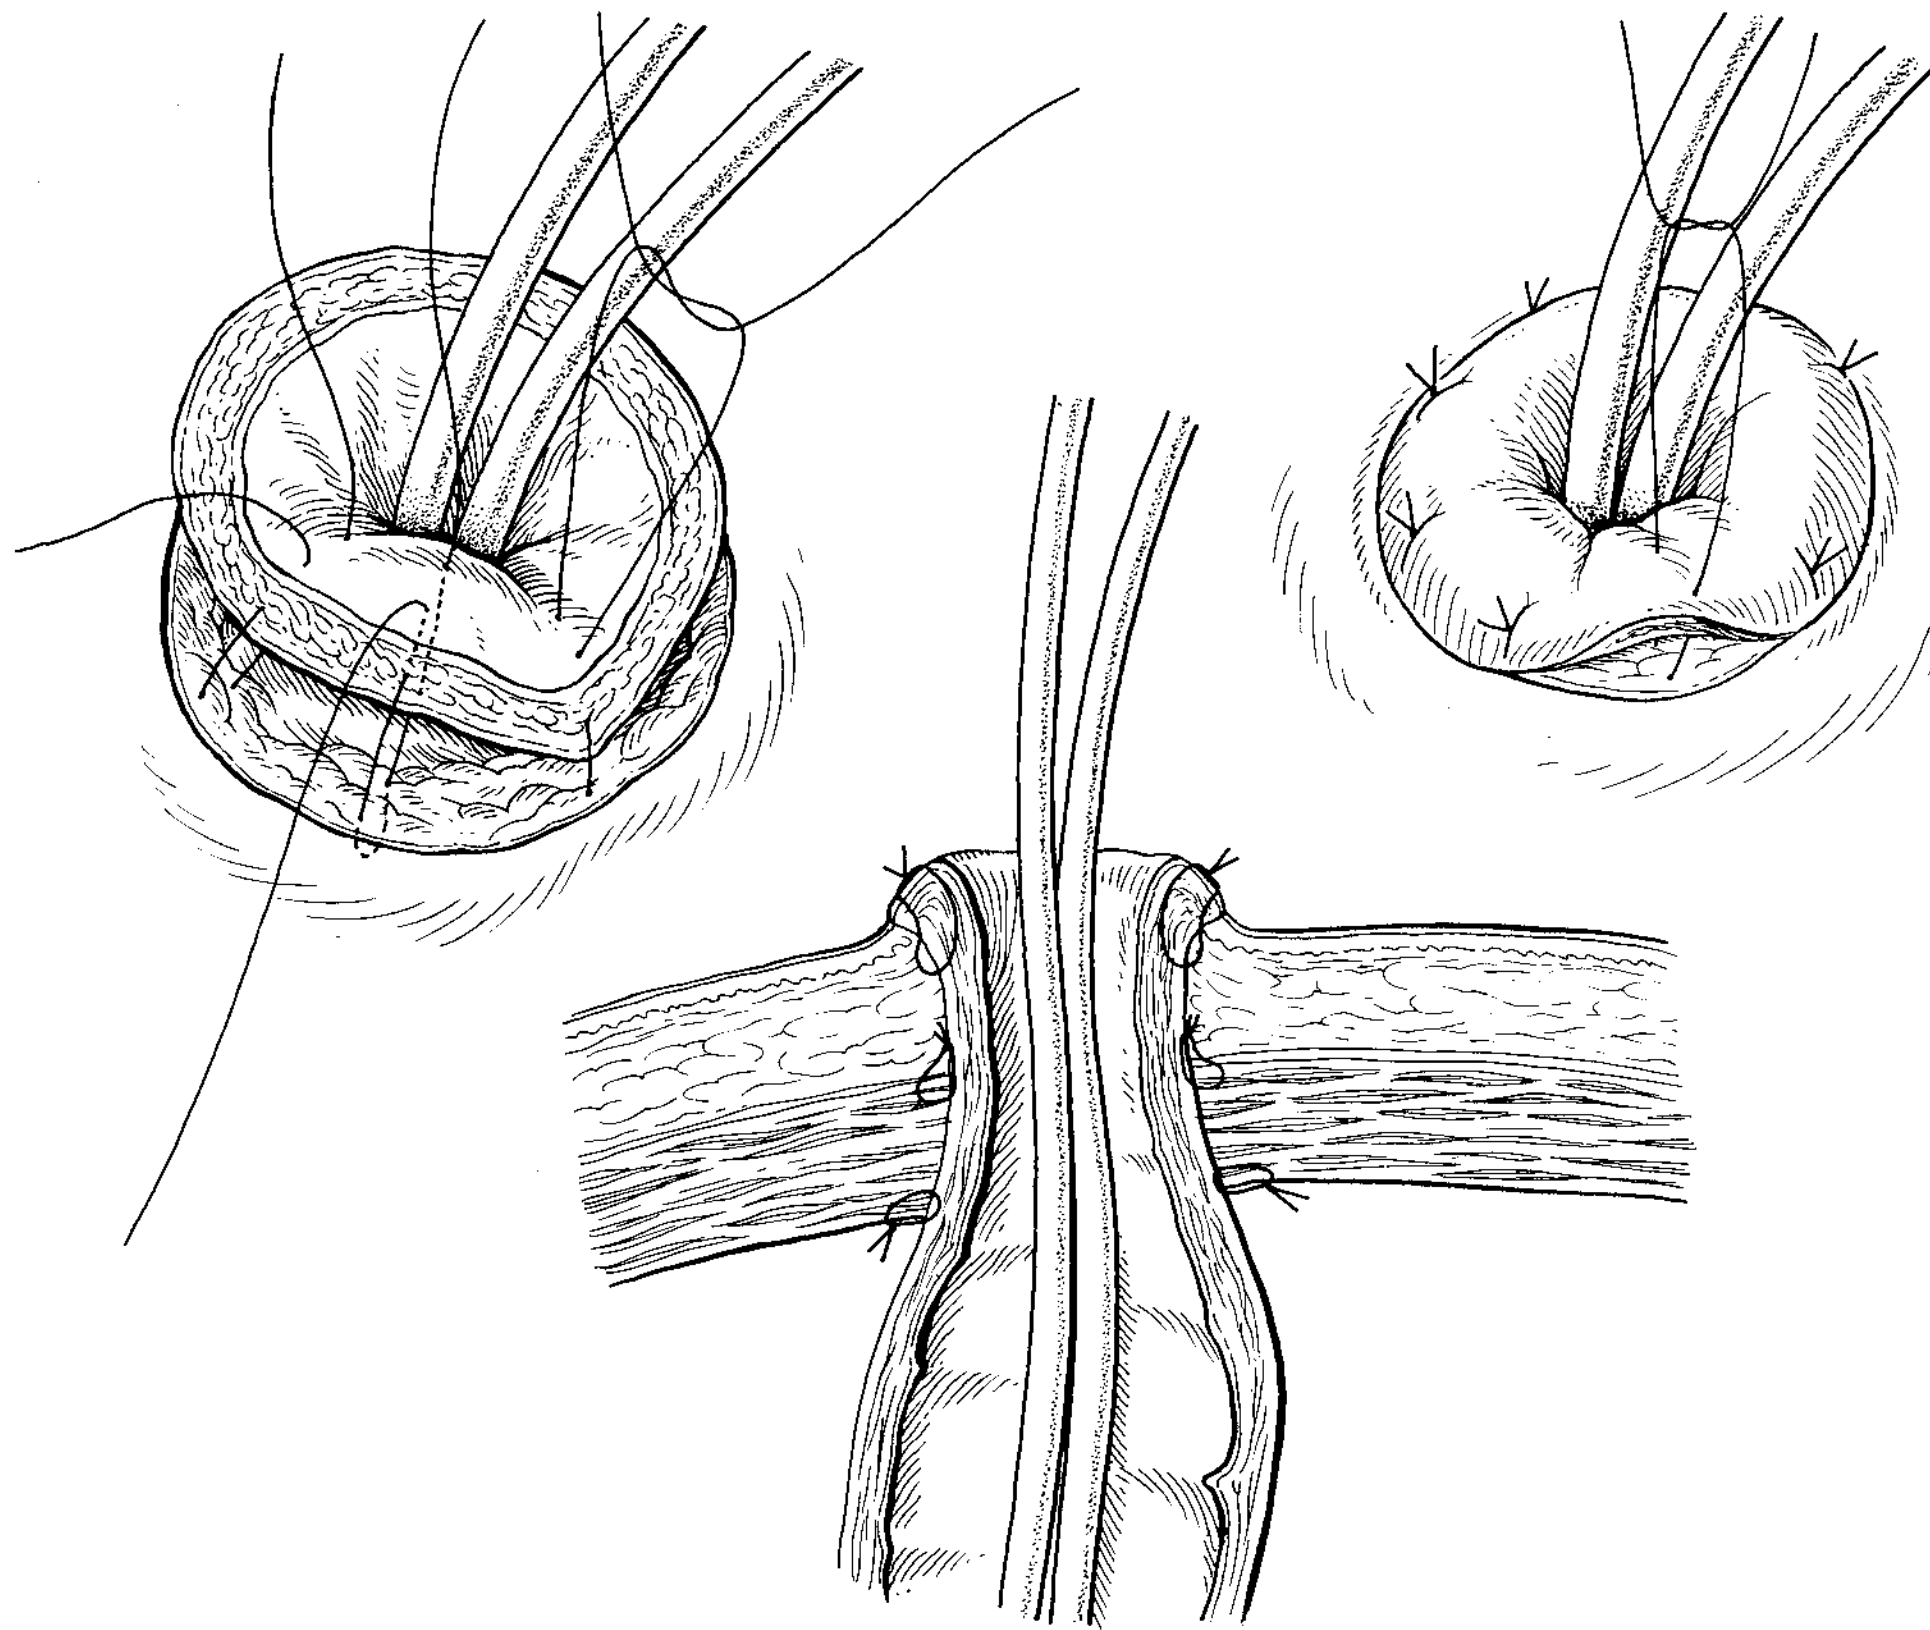

**FIGURE 84.5** For implantation of the second ureter, a second tunnel is prepared beside and parallel to the first; the implantation is done in the same way.

completely dissected from the transverse colon, and the bursa omentalis is opened. The bowel is exteriorized out of the abdomen. The ureters are cut at the ureteropelvic junction, and the renal pelvis is longitudinally spatulated. A transverse colon segment with a length of 25 to 30 cm and an adequate blood supply is isolated (Fig. 84.7B). After having placed a ureteral stent in a calyx of the right kidney, and fixed it within the renal pelvis (using polyglactin 4-0 with short reabsorption time), an end-to-end anastomosis of the right renal pelvis and the distal end of the conduit is performed using two running sutures of polyglycolic acid 5-0. The ureteral stent is led out through the conduit before the anastomosis is completed. The conduit is brought to the left renal pelvis without tension (Fig. 84.7C). Also on this side, a stent is inserted into the kidney, fixed, and led out through the conduit later. For anastomosis of the renal pelvis with the conduit, the wall of the conduit is incised at the taenia libera over an adequate length, and an end-to-side anastomosis of the renal pelvis and the conduit is done by two running sutures of polyglycolic acid 5-0 (Fig. 84.7D). The stoma formation is identical to the standard technique. In patients with a single kidney, the technique is more simple: a direct anastomosis of the spatulated renal pelvis and the oral end of the isolated bowel segment is performed, and the aboral end is led out through an abdominal stoma created as described previously.

### Surgical Tips

Transilluminating the mesentery with a fiberoptic light source visualizes the vessels and facilitates the selection of the segment

**FIGURE 84.6** The seromuscularis of the conduit is fixed to the abdominal fascia by circular single stitches of polyglycolic acid 3-0, and the oral end of the conduit is anastomosed to the skin by circular single stitches of polyglycolic acid 5-0 everting the stoma.

as well as the preparation of the mesenteric slits. When the conduit is positioned on the right side and the left ureter is relatively short, it can be implanted directly to the right ureter (like the crossed hands of a ballerina). This is applicable for the Goodwin–Hohenfellner as well as the Wallace technique. The colonic conduit can be performed so that the urine flow is peristaltic and antiperistaltic and so that the stoma can be alternatively positioned in the right or left upper-abdominal quadrant. For an antiperistaltic application, an extensive mobilization of the Treitz ligament and the descending part of the duodenum becomes necessary; otherwise, compression of the duodenum by the conduit may result. If an isoperistaltic application is preferred, either the right or left colonic flexure can be used for conduit creation. Extraperitonealization of the conduit facilitates revisional surgery, and this can be done through a flank incision. As a result, a transabdominal approach with the need for adhesiolysis can be avoided.

---

## POSTOPERATIVE CARE

---

Antibiotics are given for 5 days. As a standard for postoperative care, parenteral nutrition is continued until bowel contractions appear and then gradually reduced. The gastric tube is removed starting from postoperative day 3 after

clamping. The rectal tube stays for 3 days. Today, fast-track regimes with early removal of the gastric tube and early oral nutrition are being increasingly implemented. Ureteral stents are loosened after day 9 and removed after day 10, beginning on one side with a check of the kidney by ultrasonography on day 11. Then the second stent is removed. An IV urography demonstrates regular kidney function after stent removal.

The acid-base balance should be checked before the patient is discharged. The patient should be taught about all aspects of stoma care.

---

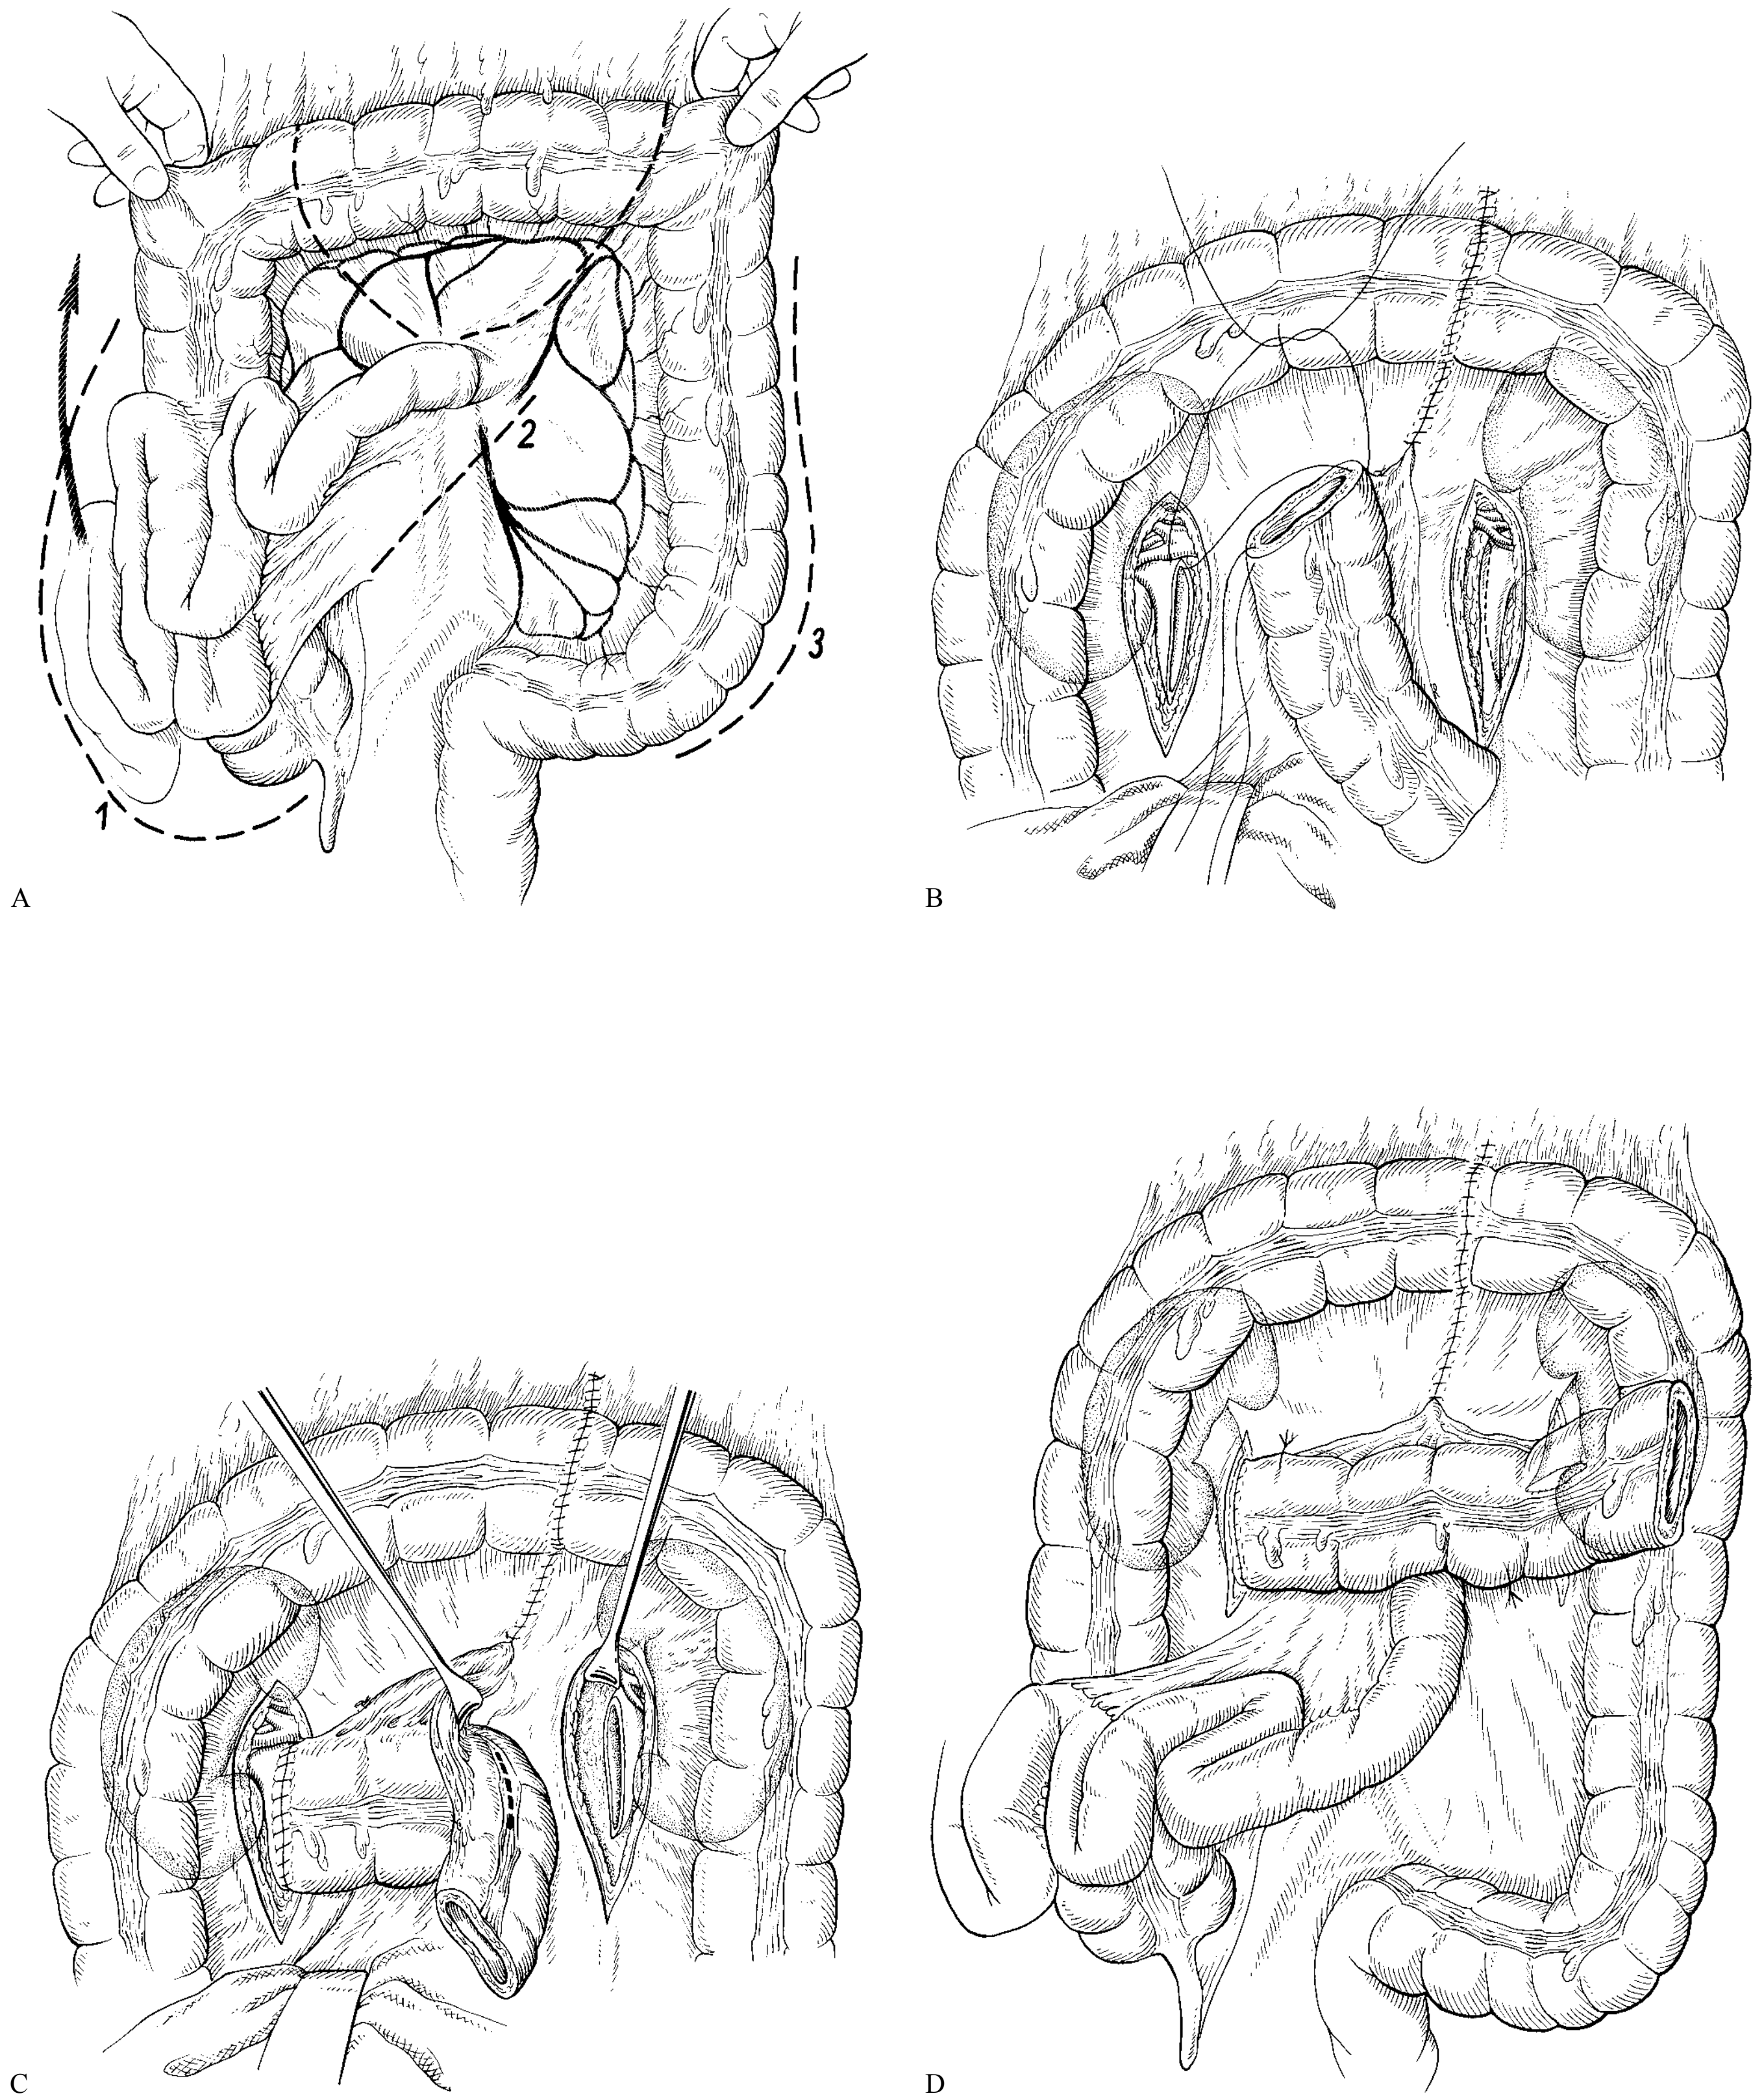

## OUTCOME

---

### Complications and Results

---

At Mainz University, an incontinent diversion using the transverse conduit was performed in 78 patients. Six of the 78 patients developed early complications requiring revision in 3. Forty-nine of the patients were followed for an average of 81 months. Twenty-two of the 49 patients developed a total of 27 complications, and 11 patients required operative intervention. In the long-term follow-up, the status of the upper-tract dilatation improved or remained stable in 85% of the renal units.

**FIGURE 84.7** An extensive bowel mobilization is necessary, including caecum, root of the mesentery, the Treitz ligament, and the right and left colonic flexures.

## CHAPTER 85 ■ MANAGING THE PATIENT WITH ORTHOTOPIC BLADDER SUBSTITUTION

URS E. STUDER AND N. BHATTA-DHAR

Orthotopic bladder substitution approximates the original bladder in both location and function. The goal of lower-urinary-tract reconstruction is to create a reservoir that provides a safe and continent means to store and eliminate urine. Over the last 100 years, bowel has been utilized in various ways for bladder substitution, but only with a recent improved understanding of bowel physiology and Laplace's law (pressure = tension/radius) has bowel been successfully applied.

In the 1980s, orthotopic reconstruction became the procedure of choice in selected male patients. The excellent clinical and functional results achieved subsequently motivated an interest in applying orthotopic reconstruction to women (8). This option is now possible because of an improved understanding of female pelvic anatomy as well as the substantiated low risk of urethral recurrence in women. Specific pathological criteria have allowed clinicians to select appropriate female candidates for orthotopic diversion.

Several different bladder substitutes have been developed, some of which are presented in the following chapters. Each of these bladder substitutes has its own specific advantages and disadvantages. Regardless of the type of substitution, an optimal outcome requires a low-pressure, high-compliance reservoir made of detubularized bowel segments with minimal outlet resistance and a preserved sphincter function.

The critical components to good long-term results with any bladder substitute include not only surgical finesse but also a thorough preoperative evaluation, meticulous postoperative care, and patient compliance. Therefore, this chapter is divided into the preoperative, intraoperative, and postoperative periods followed by a discussion of the necessary long-term management of these patients.

### DIAGNOSIS

A thorough preoperative assessment requires that the following factors be evaluated when determining candidacy for bladder substitution (Table 85.1).

#### Patient Agreement and Mental Status

Perhaps the single most important factor contributing to a successful bladder substitute is the willingness of a patient to comply with indefinite follow-up. Adequate physical dexterity and a thorough understanding of how one's bladder substitute works are mandatory. In addition, ongoing educational reinforcement is necessary for long-term management and success. A dedicated nurse can facilitate the preoperative assessment

TABLE 85.1

#### PREOPERATIVE CHECKLIST

- Patient agreement to indefinite follow-up
- Adequate mental status, dexterity, and mobility
- Serum creatinine of < 1.5 mg/dL
- Liver function within normal limits
- No evidence of significant bowel disease
- No evidence of tumor in the distal urethra, paracollicular, or bladder neck region
- Continence status

and education, as well as be a useful resource as patients become comfortable with their bladder substitutes.

---

### Renal Function

---

The most frequently observed postoperative issues are metabolic acidosis followed by electrolyte abnormalities. The type and severity of these disorders depend on the intestinal segment used, the length of this segment, the time of urine contact with bowel mucosa, and the compensatory renal reserve. While a creatinine level of 1.5 mg per dL is considered the upper limit, some patients with significant creatinine elevations due to primary bladder cancer may recover sufficient function to allow for continent diversion once the obstruction is relieved. Placement of a percutaneous nephrostomy tube in these patients before surgery may provide a better idea of the true renal function (10).

---

### Hepatic Function

---

A bladder substitute candidate must have adequate preoperative liver function. The reservoir's continuous contact with urine permits ammonium to shift through the bowel mucosa and into circulation. A urinary tract infection caused by a urease-splitting organism will further increase the ammonium load. With pre-existing liver disease, hyperammonemia results, which can lead to neurologic decompensation and eventual coma (7).

---

### Bowel Function

---

Since bowel is needed for a bladder substitute, the impact of a prior bowel resection or a diseased or radiated bowel needs to be considered as it relates to malabsorption or diarrhea. The bowel segment used for the bladder substitute itself needs to be free of any pathology. To minimize vitamin B12 deficiency and diarrhea induced by bile acid, the terminal ileum needs to be preserved. Ileal segments of up to 60 cm can be resected in healthy individuals without any significant consequences provided the ileocecal valve is left intact. When >60 cm of bowel is resected, the risk of malabsorption further increases, and it becomes inevitable if >100 cm is used. If the right colon is preserved, an extended length of colon can be resected without significant malabsorptive side-effects because fluid reabsorption occurs predominantly in the right colon, whereas the left colon serves as a conduit.

---

### Paracollicular and Bladder Neck Biopsy

---

Positive biopsies from the paracollicular region in the prostatic urethra or the bladder neck in women (site of bladder substitution anastomosis) indicate a high likelihood of a urethral recurrence. These patients should undergo a primary urethrectomy and be considered for an alternative form of urinary diversion. Prostatic infiltration (superficial or stromal) proximal from the paracollicular site, carcinoma in situ, and multifocal transitional cell cancer confer a higher risk of urethral recurrence (2). However, these findings are not absolute contraindications for a bladder substitution.

---

### Continence

---

Incontinence, especially in female patients, may reflect a poorly functioning rhabdosphincter. These patients require urodynamic evaluation, including a urethral pressure profile, since this may identify an etiology and thereby potential treatment options. Severe incontinence is a contraindication to bladder substitution.

---

## INDICATIONS FOR SURGERY

---

Orthotopic bladder substitution is generally used in patients who are undergoing radical cystectomy for cancer. Patients must meet the preoperative assessment noted in the Diagnosis section.

---

## ALTERNATIVE THERAPY

---

Alternatives to orthotopic bladder substitution include ileal and colon conduits and other continent urinary diversions.

---

## SURGICAL TECHNIQUE

---

---

### Preoperative Period

---

The preoperative evaluation is the same as that for a radical cystectomy: exclusion of metastases and establishment of medical clearance for surgery. Any significant liver, renal, or bowel pathology must also be fully evaluated to determine candidacy for bladder substitution.

The type of bowel preparation depends on the bowel segment needed for the bladder substitute. Colonic bladder substitutes often require a full mechanical bowel preparation with agents such as Glycoprep. For ileal bladder substitutes, a limited bowel preparation with two enemas late in the afternoon before the day of surgery suffices. For this type of substitute, antegrade rinses of the bowel and neomycin-erythromycin intestinal preparations are avoided. In addition, such preparations can increase the risk of fluid imbalances. In the elderly patient, this can produce cardiovascular instability due to intravascular volume depletion as well potentially place the patient in a catabolic state even prior to surgery.

Subcutaneous deep venous thrombosis prophylaxis is started the evening before surgery and continued postoperatively. It is administered in the upper extremity so as to prevent a pelvic lymphocele. All patients receive perioperative and postoperative prophylactic antibiotics. Also, to prevent a deep venous thrombosis of the lower extremities or bronchopneumonia, patients wear stockings and are taught appropriate exercises by a physiotherapist.

---

## INTRAOPERATIVE MANAGEMENT

---

There are certain critical surgical steps that, if adhered to during the cystectomy, will allow for optimal functional results of the bladder substitute (Table 85.2).

TABLE 85.2

## INTRAOPERATIVE CHECKLIST

- Antibiotics and compression stockings
- Anatomical pelvic exenteration with attempt of nerve preservation on the non-tumor-bearing side
- Atraumatic dissection with maximum urethral length preservation
- Preservation of periureteric tissue
- Epidural anesthesia stopped 1 hour prior to bowel length measurement
- Preservation of the ileocecal valve and distal 25 cm of ileum
- Small bowel resection limited to under 60 cm
- Ureterointestinal anastomosis should not be obstructive
- Low-pressure reservoir with transected/opened, cross-folded bowel segments, spheroidal in shape
- Ureteric stents and cystostomy tubes placed through the fatty tissue of the bowel mesentery
- Tension-free anastomosis of the reservoir to the urethra
- The anastomosis of the urethra to the bladder substitute is not to the funnel-shaped end of the reservoir

## Preservation of Pelvic Nerves

In general, nerve sparing should be performed on the non-tumor-bearing side and extensive surgery on the tumor-bearing side. It has been shown that nerve-sparing radical cystectomy does have a positive impact on erectile function and urinary continence after bladder substitute (5). For nerve-sparing cystectomy in men, the nerve fibers in the dorsomedial pedicles lateral to the seminal vesicles as well as the paraprostatic neurovascular bundle have to be spared. The pelvic plexus can be preserved by sectioning the dorsomedial pedicle along its ventral aspect, anterolateral to the seminal vesicles, and terminating the dissection at the base of the prostate. A nerve-sparing prostatectomy must also be performed, which requires a lateral approach with incision of the endopelvic and periprostatic fascia and bunching of the Santorini plexus at the level of the prostate and not distal to it. The dorsolateral neurovascular bundle can be separated from the prostatic capsule. The prostatic apex needs to be approached laterally

directly along the prostatic capsule, and the membranous urethra is delivered sharply out of the donut-shaped prostatic apex to avoid nerve damage on the dorsolateral side of the urethra.

For nerve sparing in women, the vaginal wall dissection at the cervical level is in the anteroventral plane of the vagina, that is, at the 2 or 10 o'clock position. An empty sponge-holding forceps in the vagina helps facilitate dissection along the whitish vaginal wall. It is important to remain in close contact with the whitish wall of the vagina to ensure that the paravaginal venous plexus is hemostatically controlled and resected with the dorsomedial bladder pedicle. The endopelvic fascia is disturbed as little as possible to minimize damage to the intrapelvic branch of the pudendal nerve, which also contributes to urethral innervation.

## Atraumatic Dissection of the Urethra

To obtain maximum urethral length, sharp, atraumatic dissection of the urethra with minimal use of electrocautery at the prostatic apex in men and the bladder neck in women is required. Preservation of the puboprostatic and pubourethral ligaments and incision of the endopelvic fascia, not at its deepest point, but along the bladder neck in female patients, will allow for further urethral stability and improved continence.

## Ureters

The ureters need to be resected at a safe oncologic distance from the bladder, allowing for removal of periureteral lymphatics that may harbor micrometastases. In addition, by removing most of the proximal ureter, ureteral ischemia is precluded and thereby subsequent stricture formation.

When mobilizing the ureters, the periureteric tissue must be preserved, since this contains the ureters' blood supply. This will also help prevent anastomotic strictures. The left ureter is brought without tension to the right side of the abdomen retroperitoneally by crossing the aorta above the inferior mesenteric artery. An antireflux ureteral anastomosis is not required in low-pressure ileal bladder substitutes (11). Another important point is to pass the ureteral stents through the distal tubular wall where their exit sites are covered with mesenteric fat so as to prevent urine leakage when they are removed (Fig. 85.1).

FIGURE 85.1 Placement of cystostomy and ureteric catheters through the fat of the mesentery.

## Bladder Substitute

If small bowel is used for the reservoir, the ileocecal valve and the most distal 25 cm of ileum should be preserved to reduce the associated risk of malabsorption and bile acid–induced diarrhea. One hour prior to bladder substitute construction, administration of anesthetics via the epidural is stopped. This prevents increased muscle tone and activity which results in an artificial shortening of bowel and thereby avoids removal of more bowel than is necessary for reservoir construction.

The reservoir should be spherical to achieve maximum capacity and the lowest possible pressure for the given surface of bowel used. As illustrated by Laplace's law (pressure = tension/radius), intraluminal pressure is low for a given tension, since conversion of a tubular structure into a spherical reservoir increases the radius. Furthermore, the spherical shape obtains maximal capacity while the surface-volume ratio limits the reabsorbing surface and therefore minimizes associated metabolic issues.

It is imperative that the anastomosis of the urethra to the bladder substitute is not to the funnel-shaped end of the reservoir. This error would increase the risk of kinking and obstruction at the anastomotic site, especially when the reservoir is full. To obtain optimal voiding, the anastomosis should sit broadly on the pelvic floor (Fig. 85.2). In addition, all suture material should be absorbable, thereby eliminating any potential nidus for stone formation.

## POSTOPERATIVE MANAGEMENT

During the postoperative period, fluid and electrolyte management predominates; however, it is also important to use this time to educate and encourage patients to become comfortable with their bladder substitute.

### Immediate Postoperative Period

Table 85.3 lists the elements of immediate postoperative care. The suprapubic and transurethral catheters must be flushed and aspirated with normal saline 0.9% every 6 hours. This is needed to prevent mucus buildup, which can block catheters and result in rupture of the bladder substitute. This complication is greatest when bowel activity has resumed but while the catheter is still in situ. Prevention of abdominal distention and return of bowel activity can be accelerated with parasympathomimetic medications (neostigmine) and in smokers with nicotine

TABLE 85.3

#### IMMEDIATE POSTOPERATIVE CHECKLIST

- Deep venous thrombosis prophylaxis
- Catheters irrigated every 6 hours
- Ureteral stents removed day 5 to 7
- Cystogram day 10 with withdrawal of suprapubic tube if no leakage
- Urethral catheter removed 48 hours after suprapubic tube

patches. The ureteral stents should be removed between postoperative days 5 and 7, around the time bowel function returns.

On postoperative day 10 and provided a pouchography documents no evidence of urinary extravasation, the suprapubic tube can be removed. The urethral Foley catheter remains in place for an additional 2 days to provide enough time for the suprapubic tube exit site to heal.

## Management of Patients after Catheter Removal

Management after catheter removal is outlined in Table 85.4. After all drains are removed, any bacteriuria should be managed with antibiotics until the urine is sterile. Infected urine can cause reservoir instability with subsequent urinary incontinence as well as increased mucus production, which can lead to increased postvoid residuals and even urinary retention.

Patients must be carefully instructed on how to void. Initially, they are taught to empty the bladder substitute every 2 hours during the daytime in a sitting position by relaxing the pelvic floor and if necessary by also increasing their intra-abdominal pressure. At night, they should use an alarm clock to void every 4 hours. The adequacy of emptying needs to be monitored postvoid with a straight catheterization and/or ultrasound of the reservoir.

Patients without metabolic acidosis (no negative base excess) or those managed with oral sodium bicarbonate are instructed to retain urine thereafter for 3 hours and later for 4 hours in order to obtain a bladder capacity of up to 500 mL. During this exercise, increased bladder substitute pressures may cause incontinence, but the elevated pressures are required to increase the reservoir's capacity. Therefore, patients are advised not to void when they experience such incontinence; otherwise the bladder substitute will never achieve the desired capacity. It is essential to increase the capacity to approximately 500 cc in order to have low-end fill pressures to ensure urinary continence. With increasing capacity, nighttime continence will improve; on the other hand, a bladder

TABLE 85.4

#### POST-CATHETER REMOVAL CHECKLIST

- Antibiotic prophylaxis with a quinolone following catheter removal for 5 days
- All urinary tract infections must be treated
- Proper voiding technique must be taught
- Ensure reservoir is emptying completely with ultrasound and/or in-out catheterization
- Voids are gradually increased from every 2 hours to every 4 hours (at night with the help of an alarm clock)
- Effective sphincter training must be taught and performed regularly
- Measure daily body weight and correct a negative base excess
- Oral fluid intake of 2 to 3 L/day for the first 3 months
- Ileal bladder substitute patients should increase salt consumption for the first 3 months
- Lifelong regular follow-up

**FIGURE 85.2** A funnel-shaped reservoir to urethra anastomosis must be avoided because of the risk of subsequent kinking and outlet obstruction.

substitute capacity of  $>500$  mL should be prevented. Overdistention of the reservoir will result in a floppy pouch unable to adequately empty, increased residual urine, and the potential for urinary retention.

The time required to achieve continence depends on diligent sphincter training, the age of the patient, and achieving intraoperative neural preservation to the urethra and pelvic floor (if oncologically safe). A postvoid dribble incontinence can be prevented by instructing the patient to milk the urethra at the end of each void (1). Daytime continence rates of up to 90% and nocturnal rates of 80% at 12 months can be achieved (6).

Hypercontinence tends to be a problem primarily for female bladder substitute patients. Having an unobstructed outlet with prevention of kinking of the urethra or reservoir can help avoid this concern (Fig. 85.2). The contribution to sphincter function of the intrapelvic pudendal somatic nerves and autonomic branches of the pelvic plexus has not been fully established, but animal studies have demonstrated a pressure increase in the distal urethra after pudendal nerve stimulation and in the proximal urethra after stimulation of the pelvic plexus (3). This suggests that nerve sparing has functional significance for both continence and voiding ability. Using the female sheep model, Strasser and colleagues (9) found marked degeneration of the smooth muscle cells of the proximal urethra after bilateral denervation of an isolated urethra, which reflects the situation in bladder substitute patients. Thus complete autonomic denervation of the urethra in patients undergoing cystectomy and bladder substitute may result in long-term smooth muscle dysfunction. Absence of the

tonus-regulating function of the autonomic nerves may lead to a dilation or rigidity of the urethra, resulting in intrinsic sphincter deficiency. A denervated proximal urethra may result in ineffective active relaxation and/or kinking during voiding, and thus incomplete emptying, which necessitates self-catheterization.

Urethral length is also important in the genesis of urinary incontinence, as demonstrated by the following formula: continence = urethral length  $\times$  closing urethral pressure (12). In female sheep, Strasser et al. (9) showed that maximal urethral closure pressure was markedly decreased in sheep with denervated urethra (18 cm H<sub>2</sub>O compared to baseline of 49 cm H<sub>2</sub>O). If the autonomic nerves are compromised, closing urethral pressure cannot compensate for a shortened urethral length. Theoretically, after resection of the proximal urethra, patients may not leak with increased intra-abdominal pressure because of the intact pudendal nerve pathway but may leak when walking, particularly with a full bladder, because of reduced functional urethral length. Also, sensory innervations of the proximal urethra may influence urinary continence. Division of these nerves may result in loss of the afferent limb of the external sphincter guarding reflex stimulated by urinary leakage into the proximal urethra.

---

## Metabolic Management

---

After catheter removal, the patient is at an increased risk for metabolic acidosis, particularly if there is residual urine. In fact, this is the most frequent yet most often underdiagnosed

complication associated with bladder substitutes. Jagenburg et al. (4) reported that the iso-osmolality between urine in the reservoir and serum is established within 2 to 6 hours. This explains why, initially, when the urine is hypo-osmolar, the bladder substitute will secrete sodium chloride, resulting in a salt-losing syndrome, hypovolemia, and metabolic acidosis. The resultant dehydration and anorexia may lead to a rapid decrease in body weight; therefore, daily postoperative weight assessment is essential. To prevent this metabolic cascade, patients should increase salt intake (pretzels, chips, etc), primarily because they are also encouraged to consume 2 to 3 L of fluids a day to prevent a metabolic acidosis resulting from highly concentrated acidotic urine (7). With time, the villi will atrophy and this syndrome will become less pronounced.

Both the urologist and the patient should be aware of the symptoms that may arise with a metabolic acidosis (Table 85.5). The base excess can be monitored with a venous blood gas analysis. A negative base excess needs to be corrected. This is usually accomplished with sodium bicarbonate 2 to 6 g daily for ileal bladder substitutes and with potassium citrate for colonic bladder substitutes.

TABLE 85.5

### SYMPTOMS OF METABOLIC ACIDOSIS IN PATIENTS WITH BLADDER SUBSTITUTES

- Fatigue
- Anorexia
- Dyspepsia and heartburn
- Nausea and vomiting
- Weight loss

## OUTCOMES

### Long-Term Follow-up

Meticulous lifelong follow-up is essential for optimal reservoir function and prevention of long-term complications. A suggested schema is illustrated (Table 85.6). A bladder substitute should have no infection, no incontinence, no acidosis, and no

or minimal postvoid residual urine. Intravenous urogram (IVU) and lavage cytology are used to follow the upper tract and urethra, respectively, for recurrences.

Residual urine should be monitored, recognized early, and promptly managed. The most common reasons for residual urine are protrusion of ileobladder mucosa into the urethra,

residual prostatic tissue, and urethral anastomotic strictures. All of these can be managed endoscopically. Permanent indwelling catheters and intermittent straight catheterizations are not adequate therapies and should only be reserved for patients with personal preferences or for nursing purposes.

# CHAPTER 86 ■ ORTHOTOPIC URINARY DIVERSION USING AN ILEAL LOW-PRESSURE RESERVOIR WITH AN AFFERENT TUBULAR SEGMENT

STEPHAN JESCHKE AND URS E. STUDER

An ileal low-pressure orthotopic bladder substitute offers several significant advantages over other forms of orthotopic diversion. One is the ease of surgery, as the operation can be performed by any urologist experienced in performing a radical prostatectomy or a cystectomy and ileal conduit (1). The short ileum segment, approximately 55 cm long, that is used to construct this bladder substitute minimizes intestinal malabsorption. The terminal ileum, as well as the ileocecal valve, is preserved. The reservoir is spherical, achieving a maximum volume-to-surface area ratio with maximum capacity from a given bowel segment (2). Another advantage is the isoperistaltic tubular afferent segment with the end-to-side ureteroileal anastomosis at its proximal end. This allows resection of the distal ureters, including the paraureteral lymphatics, at a safe distance from the bladder cancer and reduces the risk of leaving distal ureters behind that may contain carcinoma in situ. Furthermore, the shorter the ureters are, the better the blood supply at their distal end and the lower the risk of ischemic stricturing of the distal ureter. The peristalsis of the afferent ileal segments acts as a dynamic antireflux mechanism.

In cases of complicated urethral strictures or urethral tumor recurrence, the afferent tubular segment can easily be transformed into an ileal conduit. By slightly modifying this reservoir, one can also use it for bladder augmentation following subtotal cystectomy in patients with benign bladder pathology.

---

## DIAGNOSIS

---

Patients undergoing orthotopic bladder substitution will generally have the diversion as part of a cystectomy for bladder cancer. A full metastatic workup to stage the cancer is important, as well as a cystoscopy to determine the extent of the cancer in the urethra. As is true for all bladder substitutes, specific criteria for selection are related to the disease stage, the renal and liver function, and the patient's willingness to comply with routine follow-up. These criteria are summarized in table 86.1. Adequate renal function as defined by serum creatinine <1.5 mg per dL precludes the need for lifelong bicarbonate supplementation.

TABLE 86.1

**PATIENT SELECTION CRITERIA FOR CONTINENT URINARY DIVERSION**

- Non-metastatic disease
- Negative biopsies from prostatic urethra (m)/bladder neck (f)
- Adequate renal function (serum creatinine  $< 1.5$  mg/dL)
- Normal liver function
- No active inflammatory bowel disease or previous extensive bowel resection
- Physical and mental ability to live with a bladder substitute
- Compliance to routine follow-up

**INDICATIONS FOR SURGERY**

Orthotopic diversion may now represent the procedure of choice in the properly selected patient undergoing cystectomy. However, as with all bladder substitutes, the cancer operation must not be compromised by the orthotopic reconstruction. In addition, the external rhabdosphincter and internal lissosphincter complex and corresponding innervations must be functionally intact. The ileal orthotopic bladder substitute is also particularly well suited for patients in whom the sequelae of ileocecal resection should be avoided.

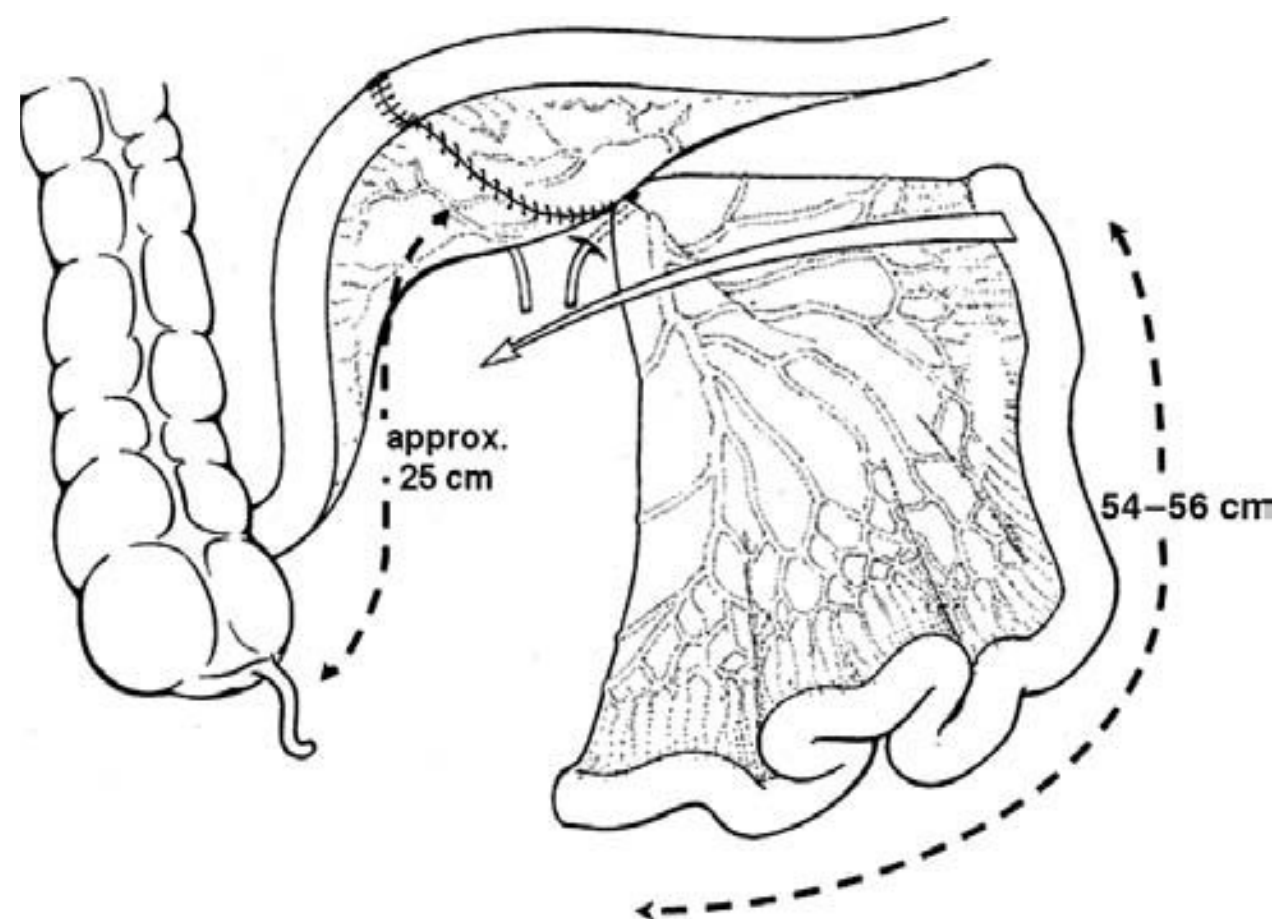

**ALTERNATIVE THERAPIES**

Alternatives to the ileal orthotopic bladder include other forms of diversion, including ileal and colon conduits, continent urinary diversions, and other orthotopic diversions.

**SURGICAL TECHNIQUE****Cystectomy**

Pelvic lymphadenectomy and cystectomy are performed according to standard technique, with slight modifications (3). The external iliac vessels, the obturator fossa, and the hypogastric vessels are freed of all lymphatic, fatty, and connective tissue. Having divided the dorsolateral bladder pedicles containing the superior and inferior vesical vessels along the hypogastric arteries, the pelvic floor fascia is incised and the Santorini plexus is ligated. If possible, the prostatic vessels should be preserved on the non-tumor-bearing side to ensure adequate blood supply to the pelvic plexus and neurovascular bundle.

The ureters are divided where they cross the iliac vessels. This allows en bloc removal of the distal ureters and para-ureteral lymphatic vessels, together with the cystectomy specimen. The dorsomedial pedicle is resected along the pararectal-presacral plane on the tumor-bearing side. Whenever possible, care is taken to preserve the hypogastric fibers and the pelvic plexus situated dorsolaterally to the seminal vesicle on the contralateral non-tumor-bearing side. On this side the dissection along the dorsolateral wall of the seminal vesicle is stopped at the base of the prostate. The Santorini plexus is then divided, and the membranous urethra is transected as close as possible to the apex of the prostate by excavating it

**FIGURE 86.1** The 55-cm-long ileal segment for the bladder substitute is isolated 25 cm proximal to the ileocecal valve. Note the different incision depth of the mesoileum proximally and distally, to preserve the blood supply.

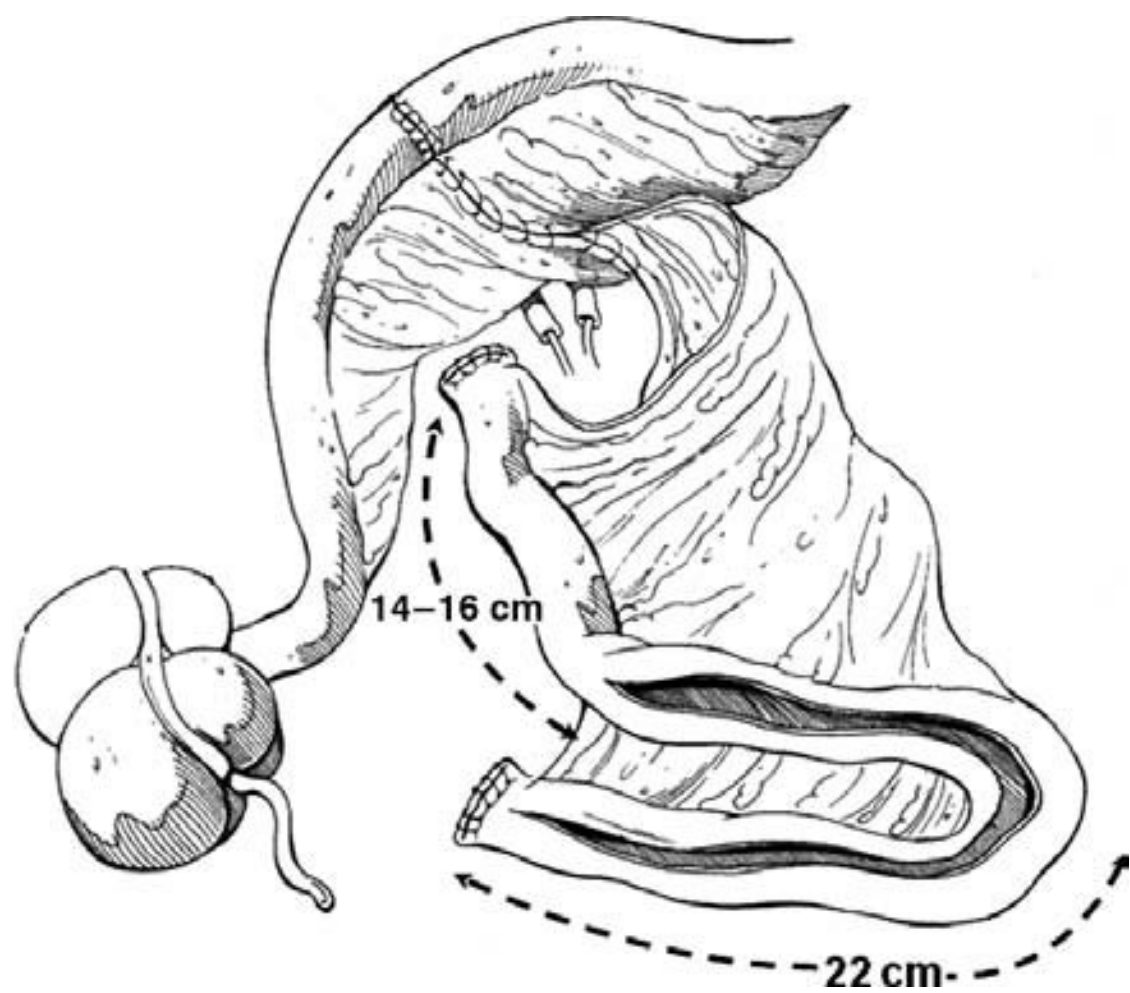

out of the donut-shaped apex. The neurovascular bundles located dorsolateral to the prostate are also preserved on the non-tumor-bearing side.

**Preparation of the Ileum Segment for the Bladder Substitute**

For construction of the reservoir, an ileal segment approximately 55 cm long is isolated 25 cm proximal to the ileocecal valve and bowel continuity is restored (Fig. 86.1). The length of the ileum segment is measured with a ruler in portions of 10 cm along the border of the mesoileum without stretching the bowel. Irritation of the bowel as well as epidural anesthesia with local anesthetics should be avoided since this can increase smooth muscle tone and activity and “shorten” the length of the bowel, which will then be too long after muscle relaxation. The distal mesoileum incision transects the main vessels, whereas the proximal mesoileum incision must be short in order to preserve the main vessels perfusing the future reservoir segment (Fig. 86.1). The mesoileum borders are adapted with a running suture (2-0 polyglycolic acid) in which the mesoileum of the bladder substitute is included (Fig. 86.2). The sutures must be applied superficially, taking care to preserve the blood supply to the bladder substitute. Both ends of the isolated ileal segment are closed by seromuscular running sutures (4-0 polyglycolic acid). The distal end of the ileal segment, approximately 42 to 45 cm long, is opened along its antimesenteric border (Fig. 86.2), leaving a 10- to 12-cm afferent tubular limb for anastomosing the ureters.

**Ureteroileal End-to-Side Anastomosis**

The left ureter is mobilized up to the lower pole of the kidney, with care taken to maintain its surrounding blood supply and thereby prevent ischemia. It is then brought without tension to the right side of the abdomen retroperitoneally by crossing the aorta slightly above the inferior mesenteric artery. Note: If the ureters need to be resected close to the kidney (e.g., if there is carcinoma in situ, compromised vascular supply, or previous radiation history), a longer afferent ileal segment can be harvested

**FIGURE 86.2** Closure of the mesoileum incision. Avoid deep sutures in the area joining the mesoileum of the terminal ileum to the mesoileum of the bladder substitute, in order not to compromise circulation. Transpose the afferent ileal segment as shown by the *arrow*.

to bridge the necessary distance. The ureters are spatulated over a length of 1.5 to 2.0 cm. Incisions (2 cm) are made along the paramedian antimesenteric border of the afferent tubular ileal segment by running sutures using the Nesbit technique in an open end-to-side fashion (Fig. 86.3). The anastomoses are placed paramedial to the antimesenteric border at the most proximal portion of the afferent tubular segment. To prevent bowel ischemia between the ureteral anastomosis, the right ureter is placed approximately 1 cm distal to the left ureter.

The ureters are stented with 7Fr or 8Fr catheters. To prevent dislocation of the catheters, a rapidly absorbable suture (5-0 polyglycolic acid) is placed through the ureter and catheter together 3 to 4 cm proximal to the anastomosis. It is tied loosely, to not compromise the ureteral blood supply. The most distal periureteral tissue is sutured to the afferent ileal segment to remove tension on the anastomosis and to cover it. The ureteric catheters are passed through the wall of the most distal end of the afferent tubular segment, where it is covered by some mesoileum. This provides a “covered” canal in the reservoir wall when withdrawing the ureteric splints 4 to 7 days postoperatively.

**FIGURE 86.3** A ureteroileal anastomosis using a simple end-to-side Nesbit technique with a 4-0 running suture ensures a low stricture rate.

## Construction of the Bladder Substitute and Anastomosis to the Urethra

To construct the reservoir itself, the two medial borders of the opened U-shaped distal part of the ileal segment are oversewn with a single continuous seromuscular layer of 2-0 polyglycolic acid suture (Fig. 86.4). The bottom of the U is folded over between the two ends of the U (Fig. 86.4), resulting in a spherical reservoir consisting of four cross-folded ileal segments. After closure of the lower half of the anterior wall and part of the upper half (Fig. 86.5), the surgeon’s finger is introduced through the remaining opening to determine the most caudal part of the reservoir. At this point, a hole 8 to 10 mm in diameter is cut out of the pouch wall, outside the suture line (Fig. 86.6). Importantly, although it may appear easier to perform, it is imperative that the anastomosis of the urethra to the neobladder is not to the funnel-shaped end of the reservoir.

**FIGURE 86.4** The two medial borders of the antimesenteric opened U-shaped distal ileum segment are oversewn with a single-layer seromuscular running suture. The bottom of the U is folded over and tied between the two ends of the U.

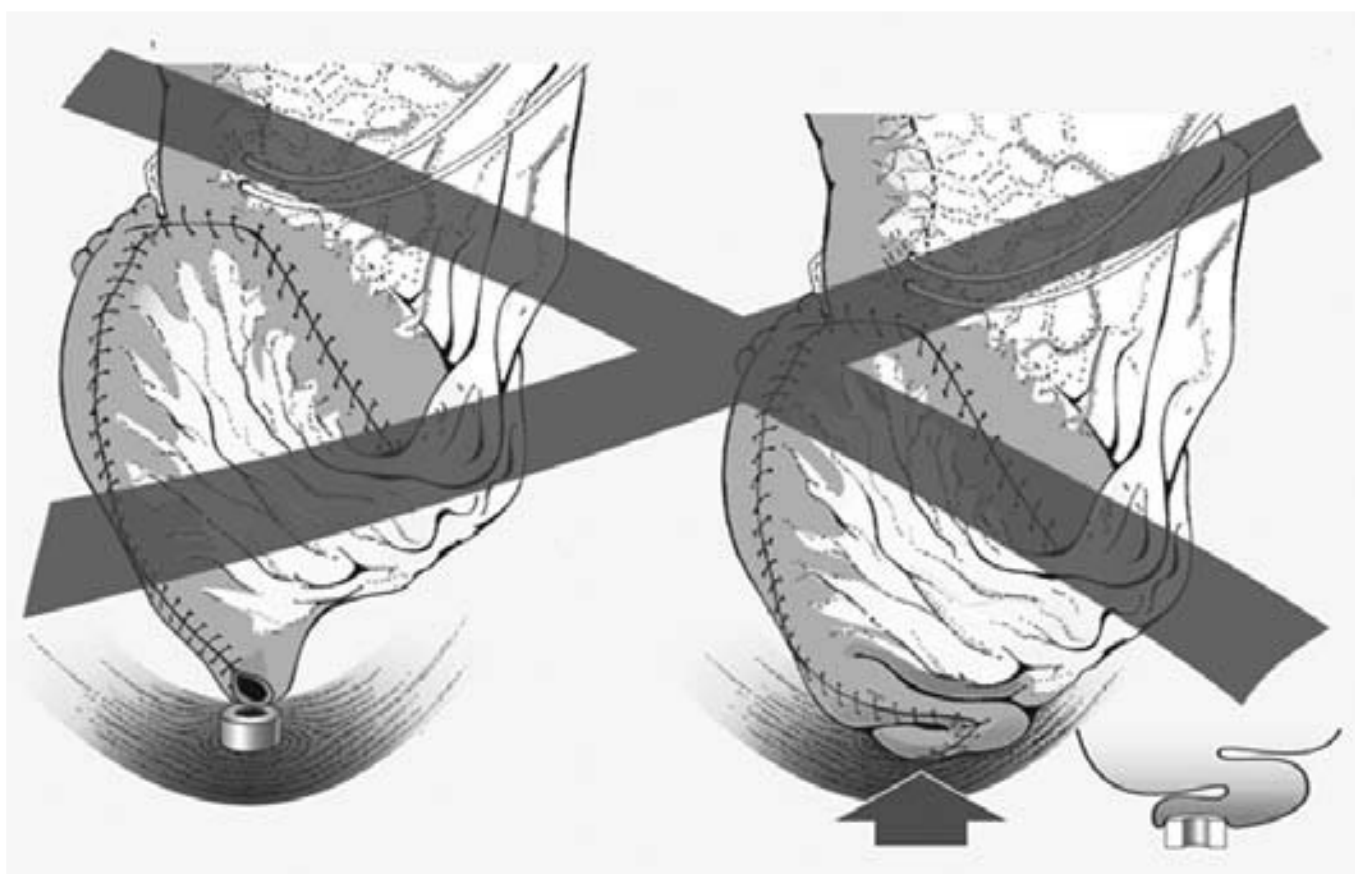

**FIGURE 86.5** The caudal half of the remaining reservoir opening is closed completely, and the cranial half partially by a running seromuscular suture.

**FIGURE 86.6** The surgeon's finger is introduced to determine the most dependent part, and a 8 to 10 mm-diameter hole is excised.

**FIGURE 86.8** Six 2-0 Vicryl sutures anastomose the previously made hole in the bladder substitute to the urethra.

**FIGURE 86.7** Anastomosis of the urethra to the neobladder is not made using the funnel-shaped end of the reservoir.

This error would increase the risk of kinking and obstruction at the anastomotic site when the reservoir is full (Fig. 86.7). To achieve optimal voiding, the anastomosis must sit broadly on the pelvic floor. After placement of a silicone 18Fr Foley urethral catheter, six 2-0 Vicryl sutures anastomose the previously made hole in the bladder substitute with the urethra (Fig. 86.8). Two posterior sutures are passed through the Denonvilliers fascia and medial to the neurovascular bundles, two anterolaterally to them through the lateral portion of the urethra, and two anteriorly, taking only a little of the urethra but also through the ligated Santorini plexus. When the urethral sutures are placed, the needle incorporates 3 to 4 mm of the sphincter but exits at the mucosal edges, thereby bringing them close to the mucosal edges of the reservoir. This minimizes tension on the anastomosis and shortening of the urethral length, and it also reduces the incidence of anastomotic strictures. If necessary, the operating table is now flexed to reduce the distance between the bladder substitute and the urethra. In situations where the mesentery is short and the anastomosis between the reservoir and urethra is under tension, careful superficial incisions of the neobladder mesentery will provide for further length. Sutures are loosely tied to prevent cutting, ischemia, and stenosis. Rarely, to prevent undue traction on the anastomosis, two stitches placed lateral to the urethra can fix the bladder substitute to the pelvic floor.

**FIGURE 86.9** After insertion of a cystostomy tube into the reservoir, the pouch is closed completely.

Before complete closure of the reservoir, a cystostomy tube is passed through the bladder substitute wall and its exit site is covered with mesenteric fat (Fig. 86.9). The cystostomy tube is withdrawn 10 days postoperatively after exclusion of any leakage by a "pouchography." The indwelling catheter is left on continuous drainage for 2 more days before removal to allow for closure of the cystostomy canal in the reservoir wall.

### Surgical Modifications for Obese Patients

An ileal neobladder can successfully be constructed and brought down into the pelvis of obese patients. A measure of whether the reservoir will work in obese patients is if the bowel at 12 cm from the distal harvested end is able to reach the base of the penis. To ensure this will happen, the following steps should be employed. First, extend the distal mesenteric division deeper into the mesentery; this will provide for increased mobility (Fig. 86.10). In addition, unflex the operating table as much as possible, and if necessary make superficial transverse incisions of the serosa. If there is still tension, then, 12 cm from the distal end, transect a vessel proximal to the Riolan arch (Fig. 86.11). Provided collateral vessels are left

**FIGURE 86.10** The distal mesenteric division should be extended deeper into the mesentery.

**FIGURE 86.11** A vessel proximal to the Riolan arch is transected.

on either side, this will not compromise vascular supply to the reservoir.

### Postoperative Care

Critical components to good long-term results include the ability to create a high-compliance, low-pressure reservoir with an adequate continence mechanism, as well as patient compliance and meticulous postoperative care. Ureteral stents are removed 5 to 7 days after surgery. At 8 to 10 days postoperatively and after pouchography documents no evidence of urinary leakage, the cystostomy tube is removed. The Foley catheter remains for an additional 2 days to provide adequate time for closure of the cystostomy tube exit site from the reservoir wall. Although our patients are on antibiotics, all drains are removed as early as possible to prevent infections. After the patient is drain-free, any bacteriuria is treated with antibiotics until the urine is sterile.

Patients are carefully instructed on how to void. Initially, they are taught to empty the pouch every 2 hours during the daytime in a sitting position by relaxing the pelvic floor and

increasing intra-abdominal pressure. At night, they are instructed to use an alarm clock to void every 3 to 4 hours. Initially, the urine is often hypo-osmolar; consequently, the bladder substitute will secrete sodium chloride, resulting in a salt-losing syndrome and therefore hypovolemia and metabolic acidosis. To prevent this series of metabolic events, patients are instructed to consume 2 to 3 L of liquid a day and to increase salt intake, and they are prophylactically placed on sodium bicarbonate (2 to 6 g per day) after ureteral stent removal. These patients are carefully followed with regular assessments of blood gas and body weight.

Patients without metabolic acidosis (no negative base excess) or those managed appropriately with oral intake of sodium bicarbonate are instructed to retain urine for 3 and later for 4 hours in order to obtain a bladder capacity of up to 500 mL. During this exercise, increased pouch pressures may result in incontinence, but the elevated pressures are essential to increase the reservoir's capacity. Therefore, patients are advised to not void when they experience such incontinence; otherwise the bladder substitute will never achieve the desired capacity.

With increasing capacity, nighttime continence will improve; on the other hand, a reservoir capacity of  $>500$  mL should be prevented. Overdistention of the reservoir will result in a floppy pouch that is unable to adequately empty, increased residual urine, and the potential for urinary retention. Residual urine should be monitored, recognized early, and promptly managed. The cause of residual urine needs to be addressed (urethroscopy), and any evidence of outlet obstruction needs to be incised or resected. In addition, bacteriuria should also be appropriately treated. Our patients are followed regularly at every 6 months for 5 years and then at yearly intervals.

---

## OUTCOMES

---

### Complications

---

We recently published our 20-year experience with the ileal neobladder (4). In our experience, early diversion-related complications (within 30 days) occurred in 13% of patients. Pyelonephritis was the predominant complication noted (5.8%). Diversion-related late complications ( $>30$  days) that required rehospitalization were metabolic acidosis, pyelonephritis, and sepsis in 4.4%, 3.9%, and 2.1%, respectively, and urinary retention due to infection and consequent mucus production in 4.5%. Typical late complications requiring surgery were bladder substitute outlet obstruction in 12% and incisional or inguinal hernias in 10%.

---

### Results

---

After 20 years' experience and a median follow-up of 32 months in 482 patients, our results are promising. In this series, 93% could void spontaneously at the last visit, and 90% had daytime and 78% nighttime continence with 3- to 4-hour voiding intervals. The remaining 7% were on intermittent self-catheterization or had an indwelling catheter for nursing home reasons. In addition to the correct performance of the above detailed surgical technique, success with this method of substitution demands meticulous postoperative care and follow-up.

# CHAPTER 87 ■ ILEAL NEOBLADDER

RICHARD E. HAUTMANN

During the last 20 years orthotopic reconstruction evolved from “experimental surgery” over “standard of care at larger medical centers” to the “preferred method of urinary diversion” in both sexes. During the last decade the time-honored conduit has given way to the increasingly frequent use of orthotopic reconstruction.

The goal of patient counseling about urinary diversion should be to find the method that will be the safest for cancer control, has the fewest complications in both the short and long term, and provides the easiest adjustment for the patient’s lifestyle that is supporting the best quality of life. The paradigm for choosing a urinary diversion has changed substantially, and the proportion of cystectomy patients receiving a neobladder has increased at medical centers to 50%.

---

## DIAGNOSIS

---

This procedure is used as an adjunct for reconstruction of the urinary tract, usually following cystectomy. The diagnostic modalities therefore are relevant only to the primary diagnosis that resulted in the plan for the cystectomy. This reconstructive technique is performed following cystectomy, usually for malignant disease. As such, proper diagnostic studies for the underlying disease are important.

---

## INDICATIONS FOR SURGERY

---

The primary determining factor for a neobladder is the patient’s desire for the procedure. The patient needs a certain motivation to tolerate the initial and sometimes lasting inconveniences of the nocturnal incontinence associated with a neobladder. Most patients readily accept some degree of nocturnal incontinence for the benefit of avoiding an external stoma; but not all patients do, and realistic expectations of the functional outcome are essential for both the surgeon and the patient. The psychologically damaging stigma to the patient who enters surgery expecting a neobladder but awakens with a stoma plays an increasing role in today’s surgery.

An absolute contraindication to continent diversion of any type is compromised renal function as a result of long-standing

obstruction or chronic renal failure, with serum creatinine >150 to 200  $\mu\text{mol}$  per L. Severe hepatic dysfunction is also a contraindication to continent diversion. Patients with compromised intestinal function, in particular inflammatory bowel disease, may be better served by a bowel conduit. Absolute contraindications to orthotopic reconstruction are all patients who are candidates for simultaneous urethrectomy based on their primary tumor (1–3). The role of relative contraindications and comorbidity is steadily decreasing. However, some of them—like mental impairment, external sphincter dysfunction, or recurrent urethral strictures—deserve serious consideration.

In many cases, the patient’s main motivation is to “get out of the hospital as soon as possible” and resume normal, rather sedentary activities. Many frail patients undergoing cystectomy will have less disruption of normal activities with a well-functioning conduit than with an orthotopic reservoir associated with less-than-ideal continence. Patients who have no concern about body image may also be better served with an ileal conduit.

In addition to the above contraindications, patients undergoing cystectomy for cancer have concerns regarding completely resecting the cancer versus preserving the rhabdosphincter. One of the initial deterrents to orthotopic diversion is the risk for urethral recurrence of cancer. The best predictor of the risk for urethral disease is the presence and extent of carcinoma in situ (CIS) in the prostatic urethra, ducts, or stroma. If there is diffuse CIS in the ducts and invasion of the stroma, the risk for urethral disease has historically been 25% to 35%, thus discouraging the use of the urethra. Lesser amounts of CIS confer a lesser degree of risk. Our aggressive approach for neobladder diversion relies only on a frozen section of the urethral margin at the time of surgery. A conservative approach would disqualify a patient with any prostatic involvement. In our view, neither multifocal bladder tumors nor CIS of the bladder is an indication for urethrectomy. The frequency of urethral recurrence after orthotopic diversions is much less than anticipated. Increasing experience with orthotopic reconstruction has made patient selection based on tumor stage less restrictive. Should extensive pelvic disease, a palpable mass, or positive but resectable lymph nodes preclude a neobladder because of the high propensity for a pelvic recurrence or distant relapse?

There is no convincing evidence that a patient with an orthotopic diversion tolerates adjuvant chemotherapy less well or that a pelvic recurrence is any more difficult to manage with a neobladder than after an ileal conduit. Patients can anticipate normal neobladder function until the time of death. Nevertheless, our philosophy respects the patient's desire for a neobladder; if the patient is strongly motivated, he or she gets a neobladder. Even though the patient has a poor prognosis and relapse is likely to occur, we still try to construct the diversion he or she wants. However, all patients should be informed that diversion to the skin either by a continent reservoir or ileal conduit may be necessary due to unexpected tumor extent, and there should be an appropriate stoma site marked on the abdominal wall beforehand.

---

## ALTERNATIVE THERAPY

---

The alternatives to orthotopic urinary diversion (neobladder construction) are incontinent cutaneous urinary diversion (percutaneous nephrostomy, pyelostomy, ureterostomy, and bowel conduit urinary diversion), ureterosigmoidostomy, and continent cutaneous urinary diversion. The patient must understand that the choice of a particular form of urinary diversion is primarily a quality-of-life decision and has essentially no impact on the course of the disease necessitating bladder replacement. It is the responsibility of the surgeon who undertakes urinary reconstruction to fully educate the patient about all available forms of reconstruction and their relative benefits and risks. Having been so educated, the patient is prepared to make a truly informed decision.

---

## SURGICAL TECHNIQUE

---

No particular bowel preparation is necessary. Intravenous antibiotic coverage is indicated at the time of surgery. Heparin is given subcutaneously peri- and postoperatively as thrombosis prophylaxis.

---

### Cystectomy

---

Modifications of pelvic lymphadenectomy and the approach to the pelvic ureter are made to allow for optimum ileal neobladder construction (4). Pelvic lymphadenectomy and cystectomy are performed according to standard technique with slight modifications. Ideally, the ileal neobladder anatomically replaces the native bladder (i.e., it is located extraperitoneally in the pelvic cavity) and ileourethral anastomoses are located extraperitoneally. Depending on tumor stage and location, this goal can be easily achieved by the creation of two large peritoneal flaps obtained from the visceral pelvic peritoneum (Fig. 87.1).

---

### Modified Pelvic Lymph Node Dissection Following a Standard Laparotomy

---

Following a standard laparotomy via a lower midline incision, the prevesical space is entered. The space between the bladder and the iliac vessels is opened. The peritoneum is sharply

**FIGURE 87.1** Modified pelvic lymph node dissection has been completed. Ureters are exposed extraperitoneally. The peritoneum over the bladder is bisected to create two large peritoneal flaps for later total extraperitonealization of the ileal neobladder.

dissected from the anterior abdominal wall, from the ileopsoas region, and from the internal ring. The spermatic cord is freed and looped out of the way with a vessel loop. The dissection is carried distally far enough to reach and resect the large medial retrocrural lymph node of Cloquet near the inguinal canal. The surgeon should stop at the circumflex iliac vein and clear the tissue from the posterolateral aspect of the common and external iliac veins. The bladder is retracted medially to dissect in the obturator fossa, and the important nodal tissue and fat are gently pulled out, clearly exposing obturator vessels and nerves. The peritoneum is mobilized bluntly in a cephalad direction to expose the anterior surface of the ureter.

---

### Ureteral Mobilization

---

The standard vertical incision lateral to the sigmoid mesocolon should not be used. The peritoneal sac should be mobilized medially on both sides. The surgeon should continue to locate the ureter extraperitoneally, realizing that it is displaced during exposure because it adheres to the peritoneum (Fig. 87.1). The ureters are mobilized with sufficient peri-ureteral adventitia in a cephalad direction on both sides. A plane is established between the ureter and the lateral pedicles of the bladder. As the ureter and bladder are retracted medially, the lateral pedicle is exposed. Finally, the ureter is clamped distally. Fine-traction sutures are inserted in the proximal surface of the ureter, and it is divided against the clamps with scissors. Then, the ureter is dissected proximally so that about 6 to 9 cm is free.

Depending on tumor stage and location, the bladder is completely extraperitonealized and the peritoneum is bisected over the bladder (Fig. 87.1). If this cannot be done safely, an incision in the peritoneum is made high on the base of the bladder, leaving a peritoneal patch on the posterior bladder wall.

## Approach to the Membranous Urethra in the Male Patient

Urethral preparation with preservation of the continence mechanism is of critical importance when orthotopic diversion is anticipated. Attention to surgical detail is important and deserves special mention. The author believes that the continence mechanism in men may be maximized if dissection in the region of the anterior urethra is minimized. This has led to a slight modification in the technique of the apical dissection in the male patient undergoing orthotopic reconstruction. All fibroareolar connections between the anterior bladder wall, prostate, and undersurface of the pubic symphysis are divided. The endopelvic fascia is incised adjacent to the prostate, and the levator muscles are carefully swept off the lateral and apical portions of the prostate (Fig. 87.2A).

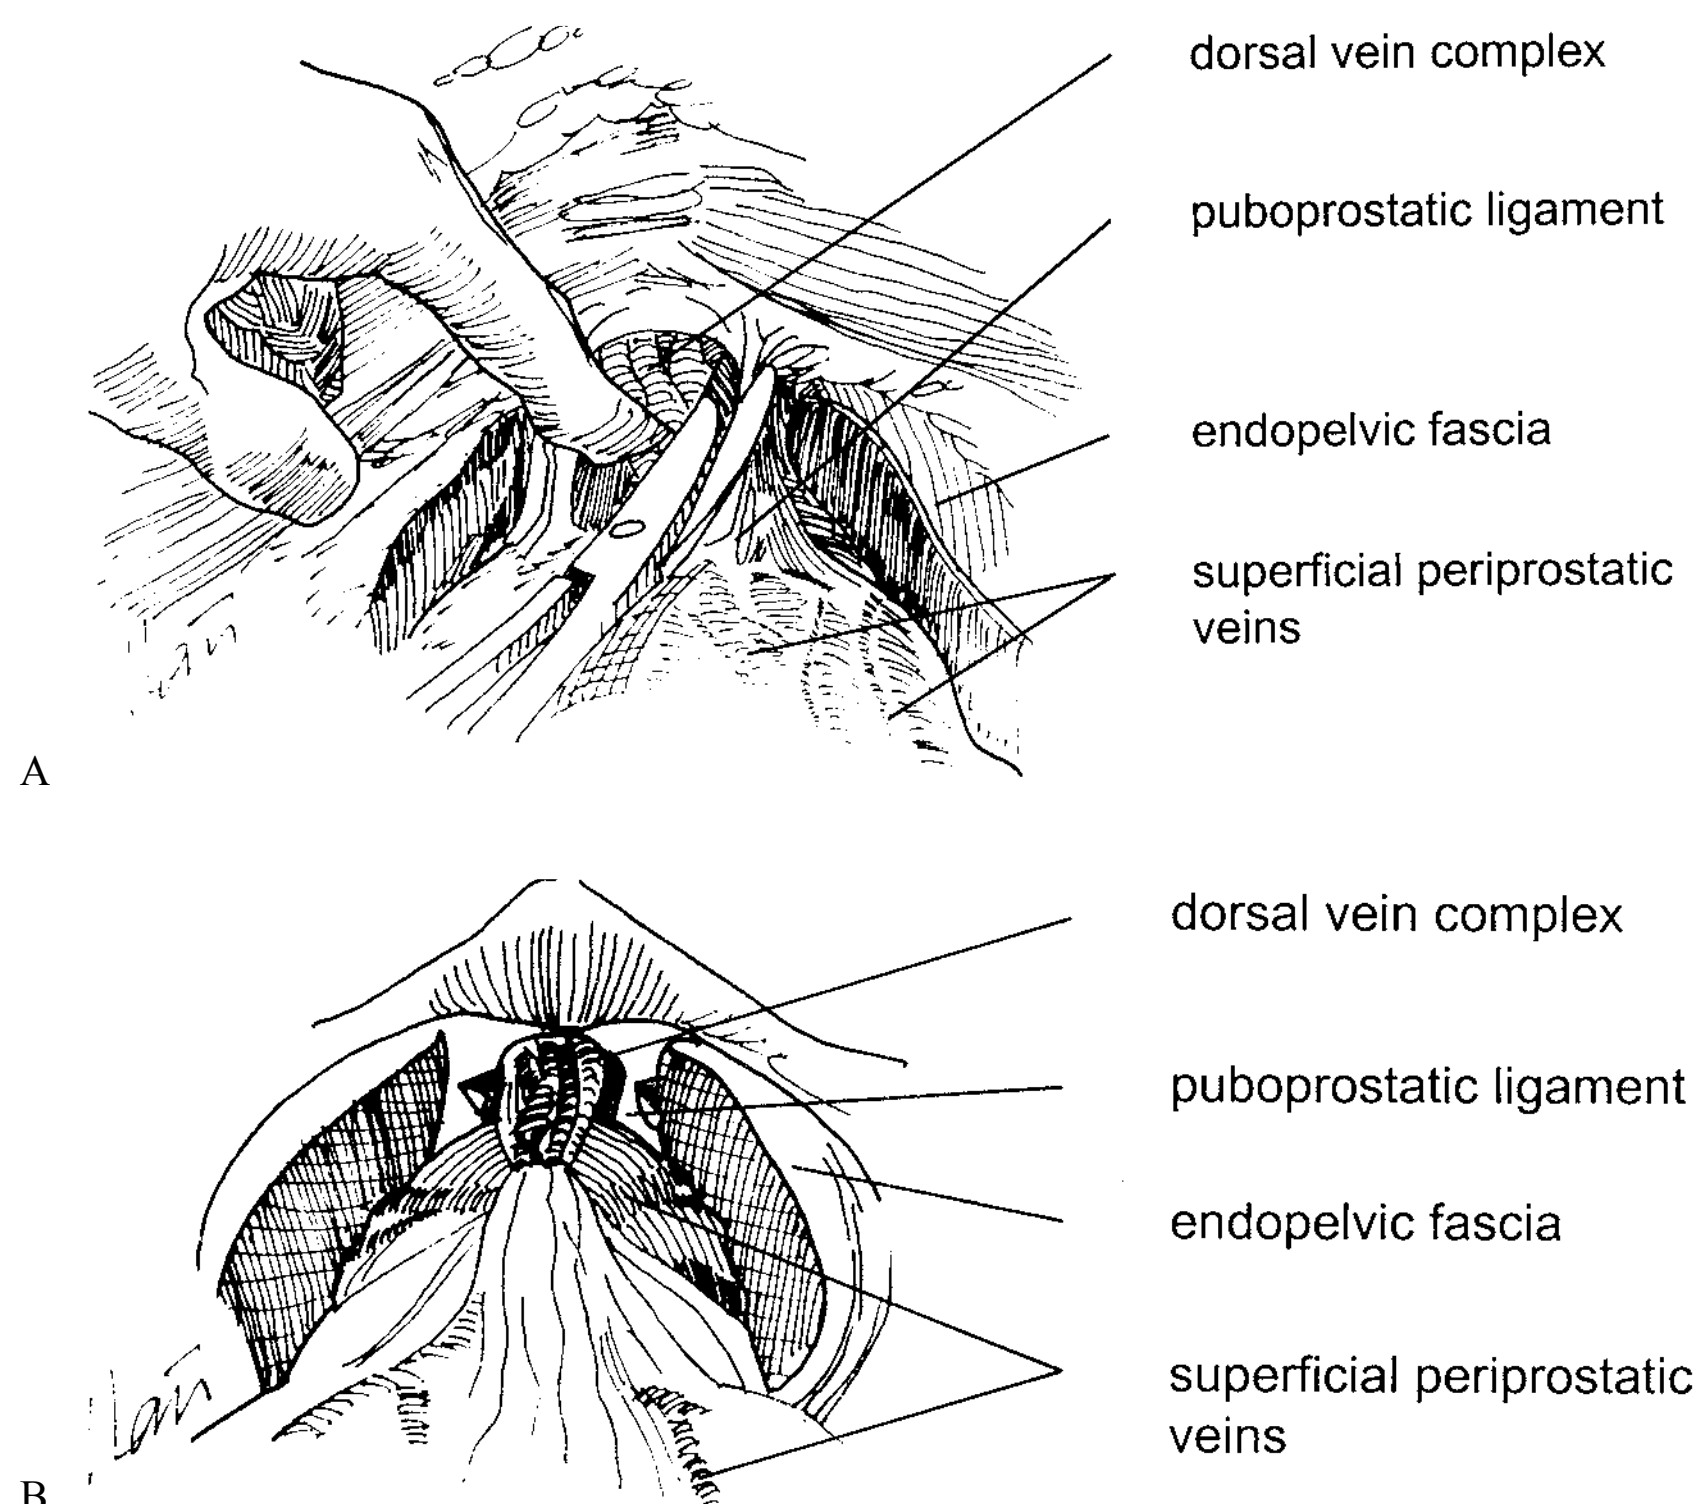

With tension placed posteriorly on the prostate, the puboprostatic ligaments are identified and slightly divided just beneath the pubis and lateral to the dorsal venous complex that courses between these ligaments (Fig. 87.2A). Care should be taken to avoid any extensive dissection in this region. The puboprostatic ligaments should only be incised enough to allow for proper apical dissection of the prostate (Fig. 87.2B). The apex of the prostate and membranous urethra becomes palpable. Several methods can be performed to properly control the dorsal venous plexus. An angled clamp may be passed carefully beneath the dorsal venous complex, anterior to the urethra (Fig. 87.3A and B). The venous complex can then be ligated with a 2-0 absorbable suture and divided close to the apex of the prostate. If any bleeding occurs from the transected venous complex, it can be oversewn with 2-0 polyglycolic acid sutures in a slightly different fashion; the dorsal venous complex may be gathered at the apex of the prostate with a long Allis clamp (Fig. 87.2B).

A 1-0 absorbable suture is then placed under direct vision anterior to the urethra (distal to the apex of the prostate) around the gathered venous complex (Fig. 87.3A and B). This suture is best placed with the surgeon facing the head of the table and holding the needle driver perpendicular to the patient. This maneuver avoids the unnecessary passage of any instruments between the dorsal venous complex and the rhabdosphincter, which could potentially injure these structures and compromise the continence mechanism.

After the complex has been ligated, it can be sharply divided with excellent exposure to the anterior surface of the urethra (Fig. 87.4). Once the venous complex has been severed, the suture can be used to further secure the complex. The suture is then used to suspend the venous complex anteriorly to the periosteum to help re-establish anterior fixation of the dorsal venous complex and puboprostatic ligaments. This may enhance recovery of continence. The anterior urethra is now exposed. Regardless of the technique, the urethra is then incised 180 degrees, just beyond the apex of the prostate (Fig. 87.5). Six 2-0 polyglycolic acid sutures are placed in the urethra circumferentially, carefully incorporating only the mucosa and submucosa of the striated urethral sphincter muscle anteriorly. The urethral catheter is clamped and divided distally. Two sutures are placed, which should incorporate the rectourethrales muscle posteriorly or the caudal extent of the Denonvillier fascia (Fig. 87.6). Following this, the posterior urethra is divided and the specimen is removed.

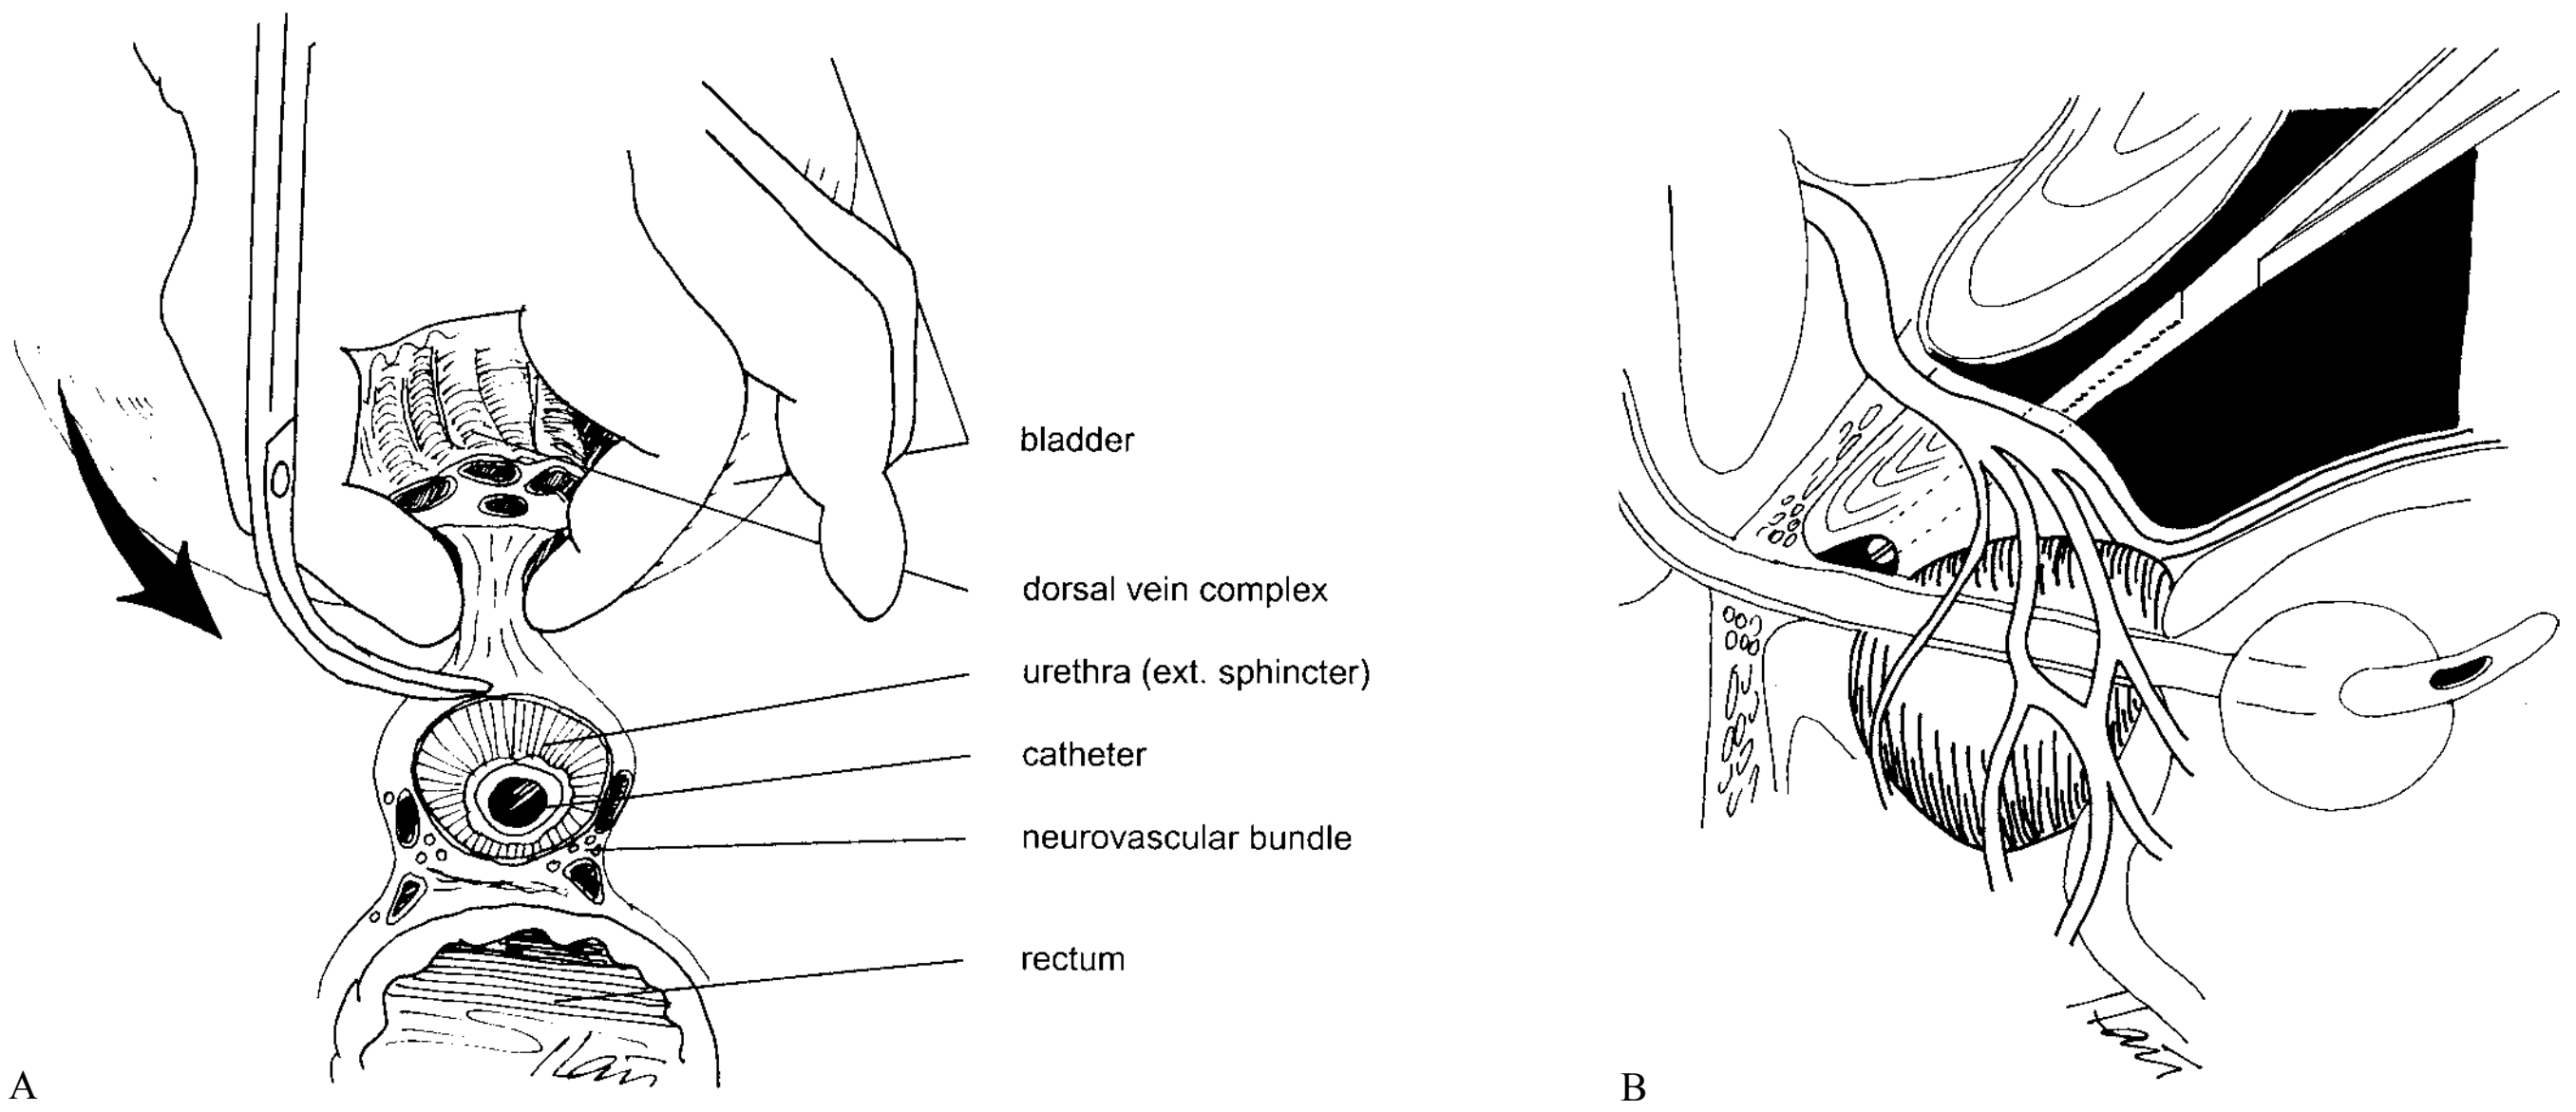

## Construction of the Reservoir

The light behind the mesentery should be adjusted, and a 60- to 70-cm-long ileal segment should be selected 10 to 20 cm proximally from the ileocecal valve (6,9,10). Spasticity of the

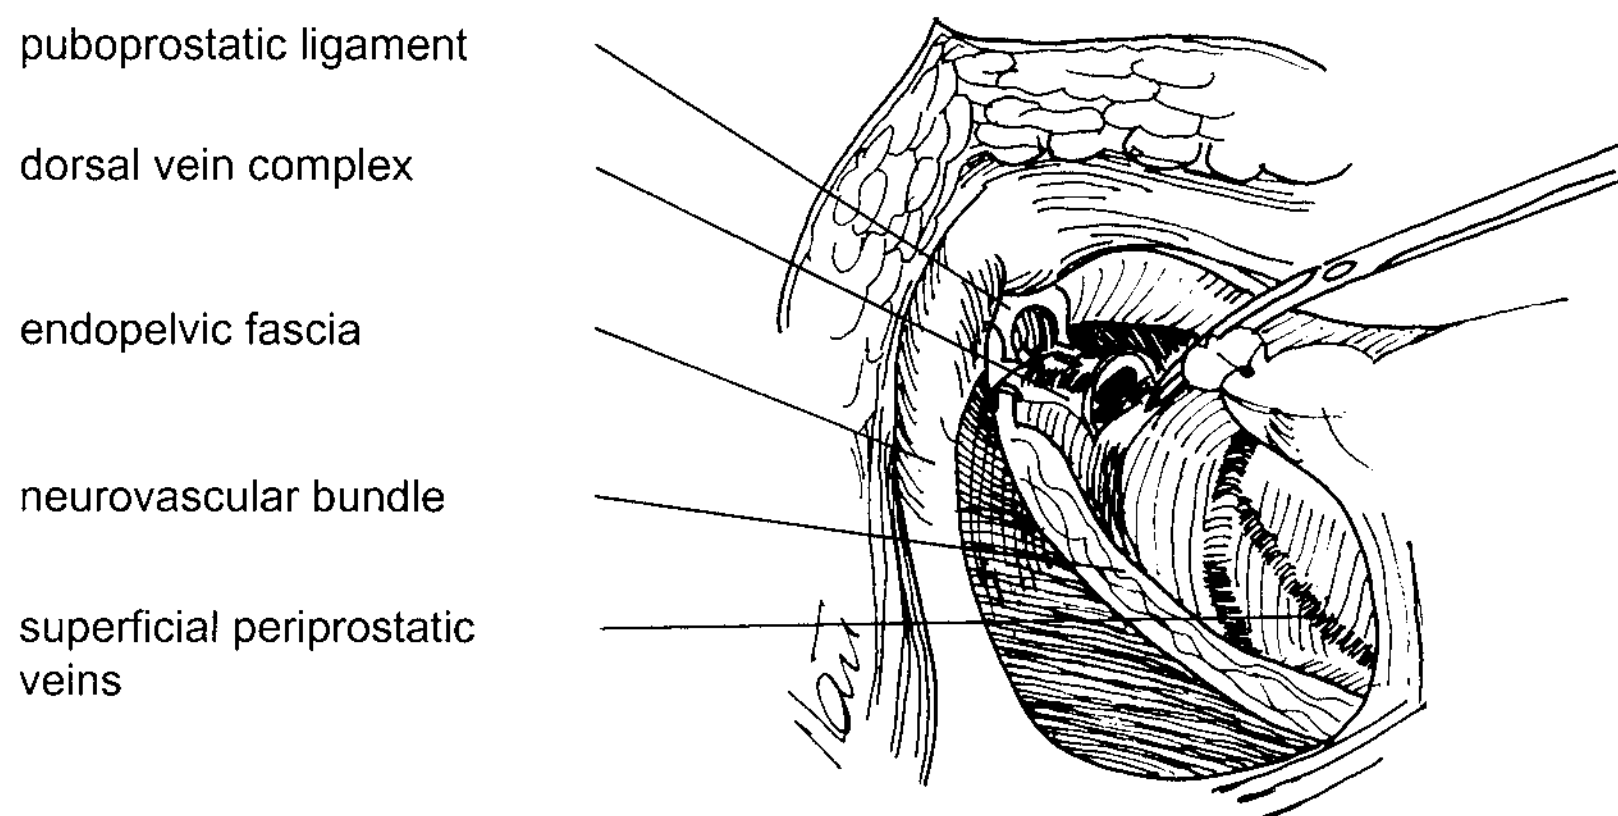

**FIGURE 87.2** **A:** The endopelvic fascia adjacent to the prostate is incised. Note that care should be taken not to perform excessive dissection along the pelvic floor levator musculature, which could injure the innervation to the rhabdosphincter. The puboprostatic ligaments are slightly divided, providing excellent exposure to the apex of the prostate and the membranous urethra. **B:** The dorsal venous complex should be gathered with an Allis clamp near the apex of the prostate or with a stitch.

**FIGURE 87.3** **A:** The dorsal venous complex may be controlled by carefully passing a clamp between the venous complex (anterior) and the urethra (posterior). **B:** A suture is carefully placed anterior to the urethra and around the gathered venous complex.

**FIGURE 87.4** The venous complex is divided. The previously placed suture can then be used to further secure the dorsal venous complex if any bleeding occurs. The complex is then fixed anteriorly to the periosteum.

**FIGURE 87.5** The anterior urethra is incised 180 degrees just beyond the prostate apex.

**FIGURE 87.6** Placement of urethral sutures and division of the posterior urethral wall.

**FIGURE 87.7** Selection of the ileal segment with an appropriate vascular supply and antimesenteric incision of ileum, except for the small chimneys on both sides of the W and the intended site of the ileourethral anastomosis (broken line).

bowel or a thick, short mesentery may lead to more bowel than necessary, thus increasing the reservoir capacity. It is helpful to place two temporary stay sutures at the intended resection lines. They can be moved several times if necessary. The most dependable part of the segment should be long enough to reach the top of the symphysis pubica in the skin level. That point should be marked with a suture. This maneuver guarantees that the reservoir will reach the urethral remnant without difficulty. The distal division of the mesentery along the avascular region between the ileocolic artery and the terminal branches of the superior mesenteric artery should extend to the base of the mesentery to provide maximum mobility and sufficient length to reach the membranous urethra. The proximal incision of the mesentery is made as short as possible to provide maximum vascular supply to the ileal segment. The ileum is then divided between bowel clamps. A standard bowel anastomosis is performed and the mesenteric trap is closed. The isolated bowel segment is thoroughly cleaned or rinsed with saline or an iodine solution (Fig. 87.7).

Four lengths of ileum are arranged in the shape of a W with 3- to 5-cm-long chimneys on each side of the W using five to six Babcock clamps. Other than the two chimneys, the bowel is opened on the antimesenteric border except for a 5- to 7-cm section centered around the marking suture, which is opened to close to the antimesenteric border to create a U-shaped flap. Two to 3 cm from the tip of that flap, a buttonhole of all layers is excised from the ileal plate. An ileal plate is formed by sewing together the cut edges of the antimesenteric borders of the W using 2-0 synthetic absorbable sutures (SASs) on a straight needle (Fig. 87.8).

A 22Fr catheter is placed through the buttonhole. For the actual anastomosis, six previously placed double-armed sutures using 3-0 SAS in the urethra are used. The inner sutures are passed through the neobladder outlet in the ileal plate without grasping the ileum, and the corresponding outer sutures grasp the entire ileal wall 5 to 8 mm lateral to the neobladder outlet (Fig. 87.9). This guarantees a wide, ideal, funnel-shaped

**FIGURE 87.8** W-shaped reconfiguration of the intestinal segment after detubularization and asymmetrical incision of the ileal wall at the site of the anastomosis to the urethra, forming a U-shaped flap.

anastomosis so that mucosa is in direct contact with urethral epithelium. Next, under gentle traction on the transurethral catheter, the ileal plate is manipulated down to the urethral remnant and the knots are tied inside the bowel (Fig. 87.10). The cut edges of the 5- to 7-cm U-shaped flap are sewn together over the catheter. The lower third of the anterior wall of the neobladder is closed, beginning inferiorly with interrupted 3-0 SAS (Fig. 87.11).

**FIGURE 87.9** Ileourethral anastomosis, anterior view.

In 10% of patients, the ileourethral anastomosis may cause some difficulties. Some or all of the following tricks are helpful to overcome this dilemma (Fig. 87.12A and B): loosening the retractor, straightening the operating table, removing the sacral cushion, neutralizing the extended position of the patient, bringing up the perineum with a sponge stick, freeing the cecum and descending colon as in retroperitoneal lymph node dissection (RPLND), moving up the neobladder outlet to the tip of the U-shaped flap, or performing an end-to-end anastomosis after tubularization of the U-shaped flap (Fig. 87.13). Any incisions into the mesentery of the neobladder should be avoided. The neobladder mesentery should not be pulled roughly to the pelvic floor.

### Refluxing Ileoureteral Anastomosis

Controversy exists about the importance of an antireflux mechanism, and the benefits are not easy to define in adults undergoing urinary diversion. It is clear that the need for reflux prevention is not the same as in ureterosigmoidostomy conduit

or continent diversion. The rationale for implanting the ureters in an antireflux fashion into orthotopic bladder substitutes or continent reservoirs is to prevent the upper urinary tract from retrograde hydrodynamically transmitted pressure peaks and from ascending bacteriuria. However, the routine of antireflux ureter implantation into intestinal urinary reservoirs was born in the era before the creation of designated low-pressure reservoirs. Reflux prevention in neobladders is even less important than in a normal bladder because there are no coordinated contractions during micturition and there is a simultaneous pressure increase in neobladder, abdomen, and kidney pelvis during the Valsalva maneuver. Using nonrefluxing techniques, the risk of obstruction is at least twice that following a direct anastomosis, irrespective of type of bowel segment used, and half of these strictures require secondary procedures.

Since 1996 we have been using a freely refluxing, open, end-to-side ureteroileal anastomosis, which is the simplest small-bowel surgery and which has reduced our stenosis rate from 9.5% to 1.0%. Further advantages of this chimney modification are the extra length to reach the ureteral stump, the

**FIGURE 87.10** Lateral aspect of the ileourethral anastomosis. The sutures are tied from inside the ileal bladder.

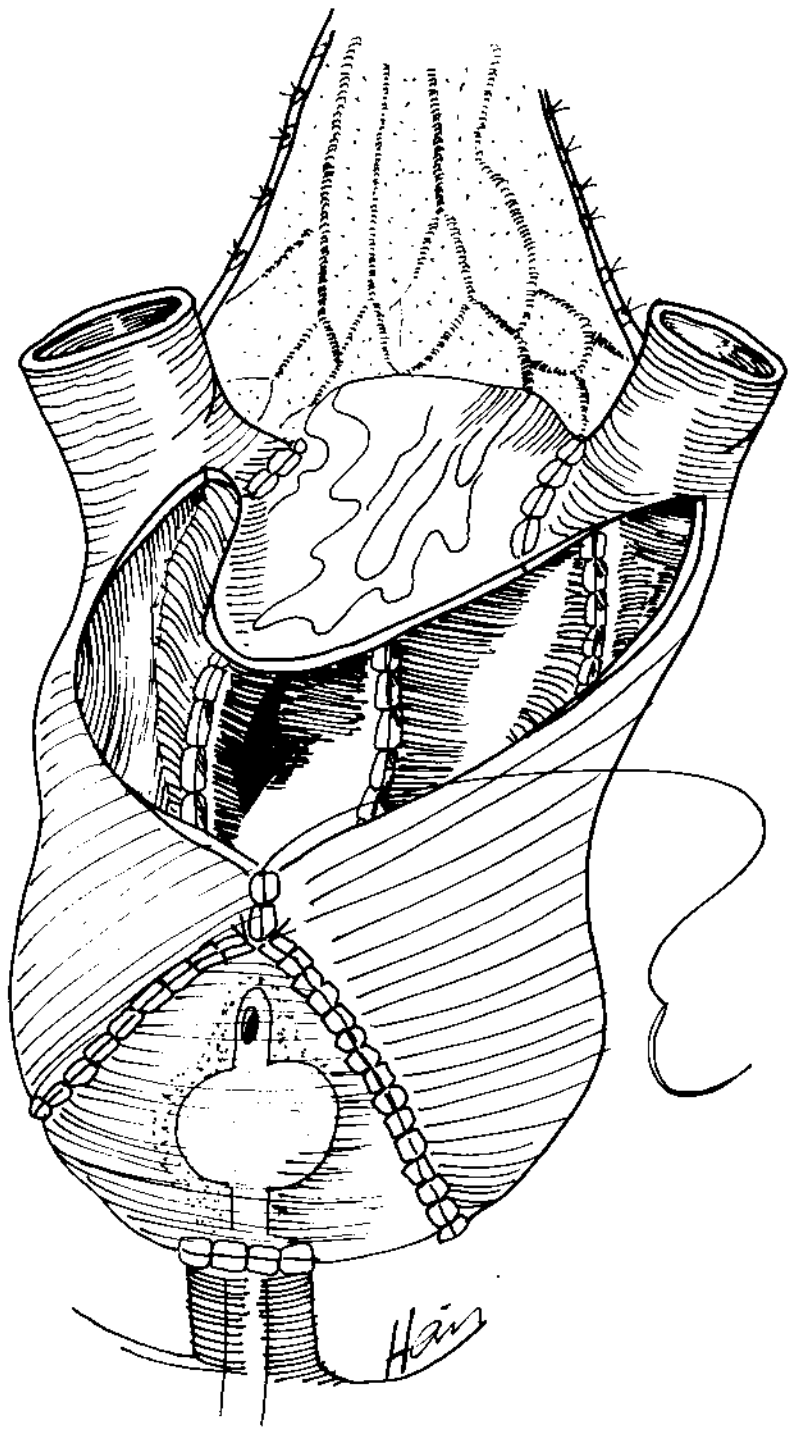

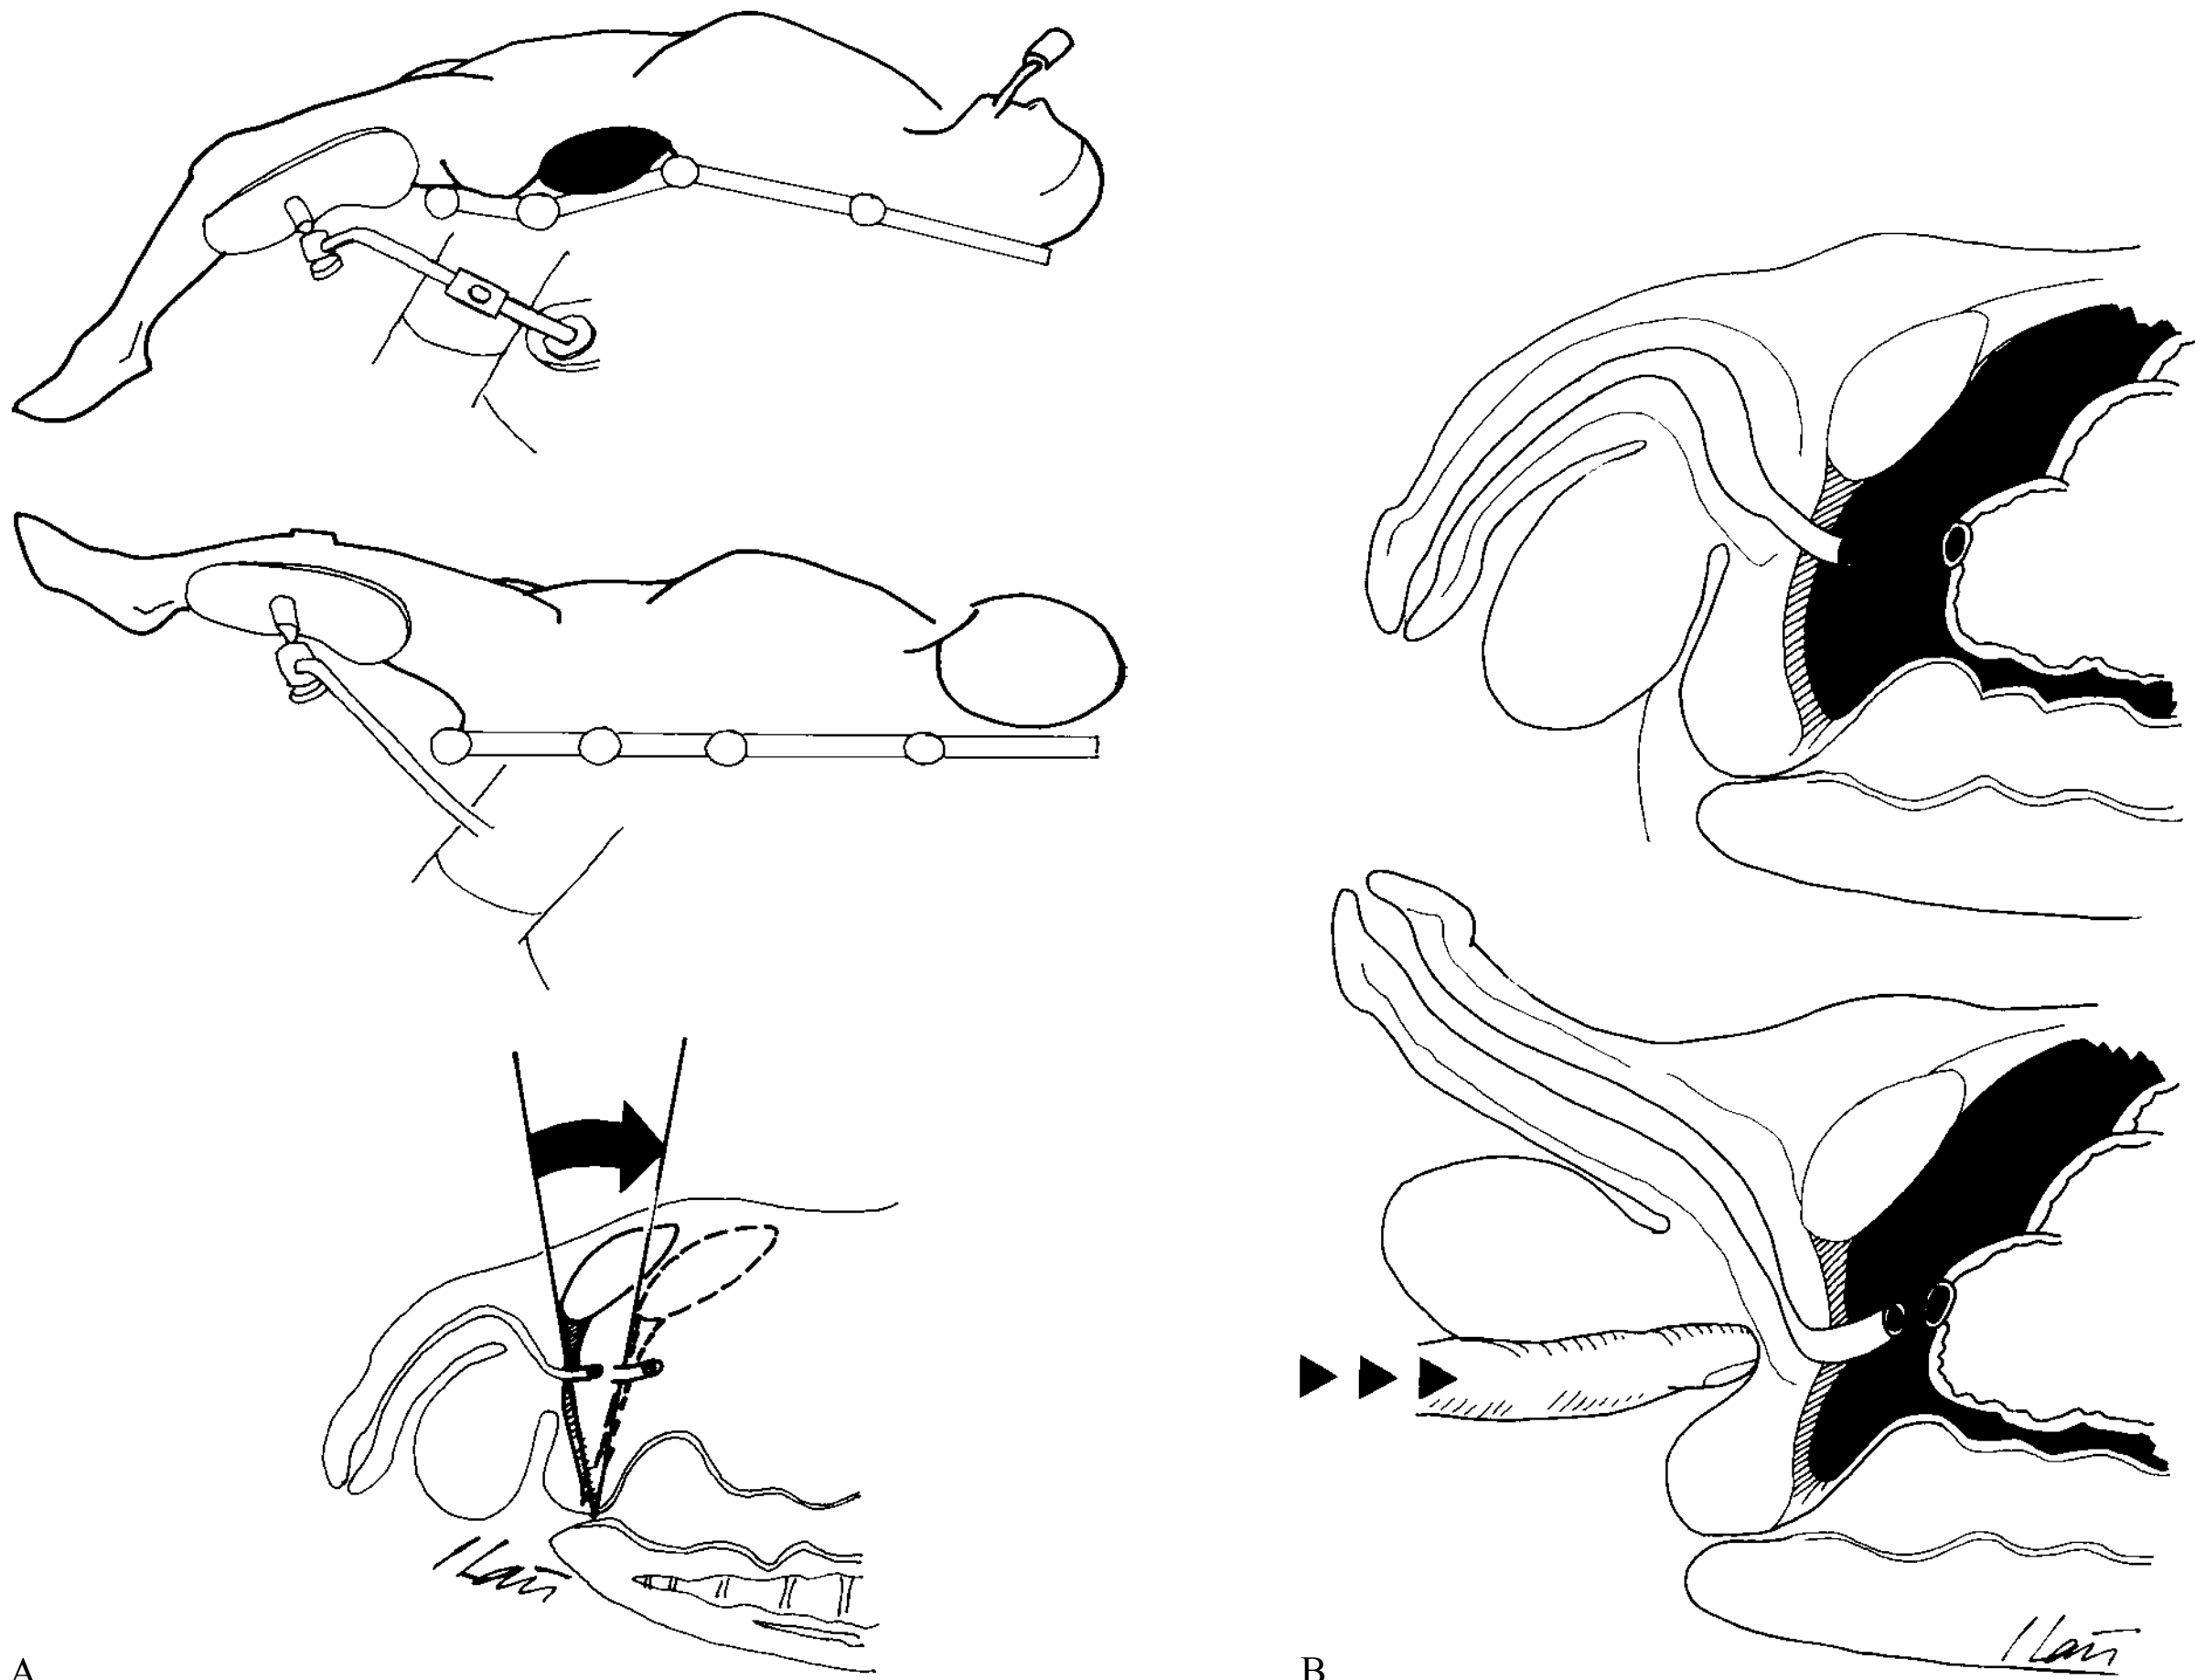

FIGURE 87.11 Closure of reservoir.

ease of surgery far outside the pelvic cavity, a tension-free anastomosis, no risk of ureteral angulation with neobladder filling, and a simplified flank access for revisional surgery.

On each side, the ureters are trimmed as appropriate for their chimney (Fig. 87.14). The ureterointestinal anastomosis can be done extraperitoneally above the common iliac vessels using a Bricker or Wallace (our choice) technique without competing with the bowel mesentery for an anastomotic site (Fig. 87.14). After appropriate ureteral stents are placed, they are brought through the anterior neobladder suture line. The remaining anterior neobladder wall is closed in a T shape with running 3-0 SASs. No cystostomy tube is placed. Two 20Fr silicone drains are placed into the small pelvis.

Using the two large peritoneal flaps from the visceral pelvic peritoneum, this goal can easily be reached (Fig. 87.1). Both flaps are sewn together, except for the portion where the mesentery of the neobladder runs through them. The peritoneal cavity is closed in a standard fashion (Fig. 87.15). Alternatively, the flaps can be sewn to the posterior wall of the neobladder.

Excessive mucus production of the ileal bladder may rarely cause a problem by obstructing the urethral catheter in the postoperative course. Therefore, the ileal bladder is rinsed via the cystostomy with 50 to 100 mL of saline twice a day, starting on postoperative day 5. Routinely, the ureteral stents are removed between postoperative days 7 and 14.

A

B

FIGURE 87.12 Methods to get the ileal neobladder to the pelvic floor. **A:** Changing the extended position of the patient to slightly supine and removing the sacral cushion rotate the pelvic floor upward. **B:** Pushing up the perineum with a sponge stick or finger approximates the urethral remnant and neobladder.

**FIGURE 87.13** Moving the neobladder outlet closer to the tip of the U-shaped flap of ileal plate. If this still does not allow tension-free anastomosis, one should tubularize the U-shaped form and perform direct (end-to-end) anastomosis.

As soon as the urine is in contact with the ileal bladder mucosa, reabsorption of urine electrolytes may occur. Therefore, the base excess is checked at weekly intervals for the first 4 weeks and monthly thereafter. Approximately 50% of all patients need temporary alkalinizing therapy.

The urethral catheter is removed between postoperative days 14 and 21, after a cystogram has demonstrated complete healing of the ileourethral anastomosis. Rarely, there is still leakage from the anastomosis. When this occurs, it is treated by prolonged catheter drainage until the leak has closed spontaneously.

---

## OUTCOMES

---

### Complications

---

The complications of both continent catheterizable reservoirs and orthotopic bladder substitutes in the hands of the most experienced surgeons have been considered in detail (4,7,8).

**FIGURE 87.14** Refluxing ileoureteral anastomosis using chimneys of a 3- to 5-cm afferent limb on each side.

**FIGURE 87.15** Completely extraperitoneal localization of the neobladder as well as ileourethral and ileoureteral anastomoses.

Reoperation for early complications overall occurred in 3% of continent catheterizable reservoirs and 7% of orthotopic bladder substitutions. Reoperation for late complications overall occurred in about 30% of continent catheterizable reservoirs

and in 13% of orthotopic bladder substitutions (4,7,8). We believe that the morbidity of orthotopic bladder substitutes is actually similar to, or lower than, the true rates of morbidity after conduit formation, contrary to the popular view that conduits are simple and safe.

There are several new complications unknown during the conduit era, including incisional hernias, as a consequence of the Valsalva maneuver: neobladder-intestinal and neobladder-cutaneous fistulas, mucus formation, and neobladder rupture. The secretion of mucus can be dramatically increased.

Spontaneous late rupture of neobladders is a rare but potentially life-threatening complication. In the majority of cases it is secondary to acute or chronic overdistention and bacterial infection. Other factors are minor blunt abdominal trauma or urethral occlusion. Chronic ischemic changes of the neobladder's wall, possibly facilitated by detubularization and the variability of the mesenteric circulation, are additional factors that lead to perforation. The rupture site is typically the upper part of the right side of the reservoir. This is the most mobile part of the reservoir and undergoes the most marked distention during overfilling, which may constitute an additional factor for perforation in this location. There is no reliable procedure to establish the diagnosis. Cystography is misleading in three of four patients with neobladder rupture. A high index of suspicion and early aggressive operative treatment in patients suspected of having a neobladder rupture are instrumental in providing a successful outcome. Prevention of neobladder rupture comprises careful monitoring of neobladder

emptying. Physicians must be aware of the risk of rupture. Patients must be encouraged to void regularly, especially at bedtime, and perform clean intermittent self-catheterization to avoid chronic reservoir overdistention. In the event of anesthesia, proper bladder drainage should be performed.

---

## Results

---

In some studies, perioperative death occurred in 3% of patients. Neobladder-related early and late complications occurred in 15% and 23% of patients, respectively. Neobladder-related early and late abdominal reoperation rates were 0.3% and 4%, respectively. Perioperative neobladder-unrelated early complications were observed in 33%, and 12% of patients required operative treatment. Late postoperative complications unrelated to the neobladder occurred in 12% of patients, and 5% required open surgical revision. Ninety-six percent of patients voided spontaneously, 4% performed clean intermittent catheterization in some form, and 1.7% performed regular intermittent catheterization. Thirty percent to 40% of women required some form of intermittent catheterization to completely empty their neobladder (6–8). Daytime and nighttime continence was reported as good by 96% and satisfactory by 95% of patients. Unacceptable daytime continence requiring more than one pad per day occurred in only 4% of patients, and only 5% were wetting more than one pad per night.

# CHAPTER 88 ■ THE PADUA ILEAL BLADDER

FRANCESCO PAGANO AND PIERFRANCESCO BASSI

The Padua ileal bladder (VIP, or “vescica ileale Padovana”) was developed as a practical application of the concepts expressed by Camey (3), Bramble (2), Kock (5), and Hinman (4) for the construction of a urinary reservoir employing an intestinal segment: detubularization, reconfiguration, and search for a spherical pouch of adequate capacity.

Large and small bowel nondetubularized segments used as bladder substitutes have been shown to generate significant intraluminal pressures (4,5) and subsequently cause urinary incontinence and/or renal failure. Disrupting directional peristalsis by opening the antimesenteric border of the bowel (detubularization) and folding (reconfiguration) has been

proven to significantly decrease intraluminal pressure by making ineffective the bowel contractions. However, a single folding of the intestinal detubularized segment incompletely suppresses the peristaltic activity, as Kock demonstrated: a double folding is necessary for this aim (5). As a consequence, the double-folding Kock principle is the gold standard in constructing a spherical reservoir from a cylindrical bowel segment.

The capacity and the intraluminal pressure of a reservoir also depend on the geometric configuration, as demonstrated by Hinman (4) with geometric considerations: the larger the radius, the larger the volume. From the surgical standpoint, this explains why the double folding produces the largest volume from the same initial intestinal length. Coupling the double folding with the spherical configuration also offers a relevant feature: at the same endoluminal pressure, the larger diameter accommodates a larger volume, according to the Laplace and Pascal laws.

---

## GOALS

---

Following the above-mentioned principles, the functional requirements of the Padua ileal bladder were identified in 1990 (6): adequate capacity (300 to 500 mL), low-pressure storage phase (<40 cm of water), no reflux to upper urinary tract, daytime and nighttime continence, and voluntary as well as easy and complete voiding “per urethram.” An intestinal reservoir respecting these requirements should allow the long-term preservation of renal function and provide a reliable control of continence and voiding with satisfactory patient acceptance.

Further features have also been considered. Because urine absorption throughout the intestinal wall is unavoidable, the shortest intestinal segment must be selected to minimize secondary metabolic disorders. An easy-to-perform and quick procedure with a short learning curve is considered highly desirable. Last but not least, from the oncologic standpoint, the neobladder must not interfere with the natural history of the disease and the related treatment(s).

---

## DIAGNOSIS

---

Normal renal function is compulsory: however, a dilated upper urinary tract(s) per se does not represent a contraindication to the procedure. A normal urethral closure pressure, evaluated by the urethral pressure profile and the tumor site far from the trigone and the posterior bladder wall, is requested in female patients. To benefit from the procedure, the patient must have intelligence, maturity, and motivation.

---

## INDICATIONS FOR SURGERY

---

Any patient, male or female, who is a candidate for a conduit diversion is potentially suitable for bladder substitution as long as an adequate ileal segment is available. Surgical indications include bladder cancers, neurogenic bladder, congenital abnormalities, and refractory interstitial cystitis. From the oncologic standpoint, the only contraindication is a positive urethral margin biopsy: patients with locally advanced

bladder cancer (T3 to T4) or with nodal involvement and candidates for adjuvant systemic chemotherapy are also suitable for the procedure.

---

## ALTERNATIVE THERAPIES

---

Other urinary diversions, including ileal and colonic conduits, continent urinary diversions, and other forms of orthotopic bladders, are possible alternatives. The patient's health, motivation, and desires, together with the abdominal anatomy, will determine the optimal diversion.

---

## SURGICAL TECHNIQUE

---

### Cystectomy

---

In men, the membranous urethra is managed as in radical prostatectomy and is incised as close as possible to the prostatic apex to preserve the distal urethral sphincter. In selected patients, the nerve-sparing cystoprostatectomy can be performed.

In women, the ureters are dissected and divided distally and the uterine vessels ligated and divided. The peritoneum is circumferentially incised just below the vaginal fundus. The uterus is lifted posteriorly, and the plane between the anterior vaginal wall and bladder is developed toward the bladder neck (Fig. 88.1). In this phase the bladder vessels are ligated and divided with respect of the autonomic nerves that originate from the pelvic plexus and run along the lateral vaginal wall toward the urethra. The bladder neck is identified by filling the catheter balloon to 20 cc and using a slight outward traction. Before the bladder neck incision, a Satinsky clamp is cranially placed to avoid the spilling of urine and tumor cells. The urethral margin is sent for pathological evaluation.

Thereafter the uterus with the ovaries is removed and the vaginal fundus accurately sutured. A 2- by 15-cm strip of

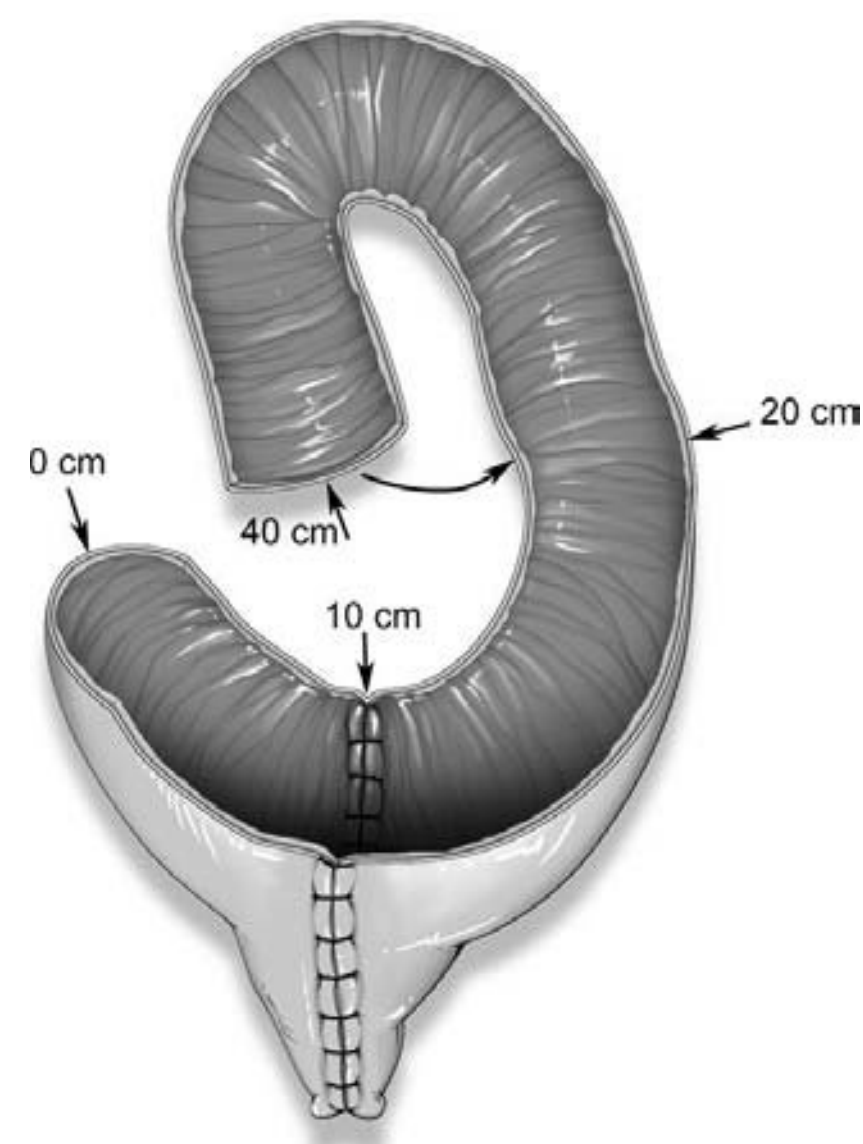

FIGURE 88.1 Creation of lower funnel

**FIGURE 88.2** Detubularization and reconfiguration (scheme).

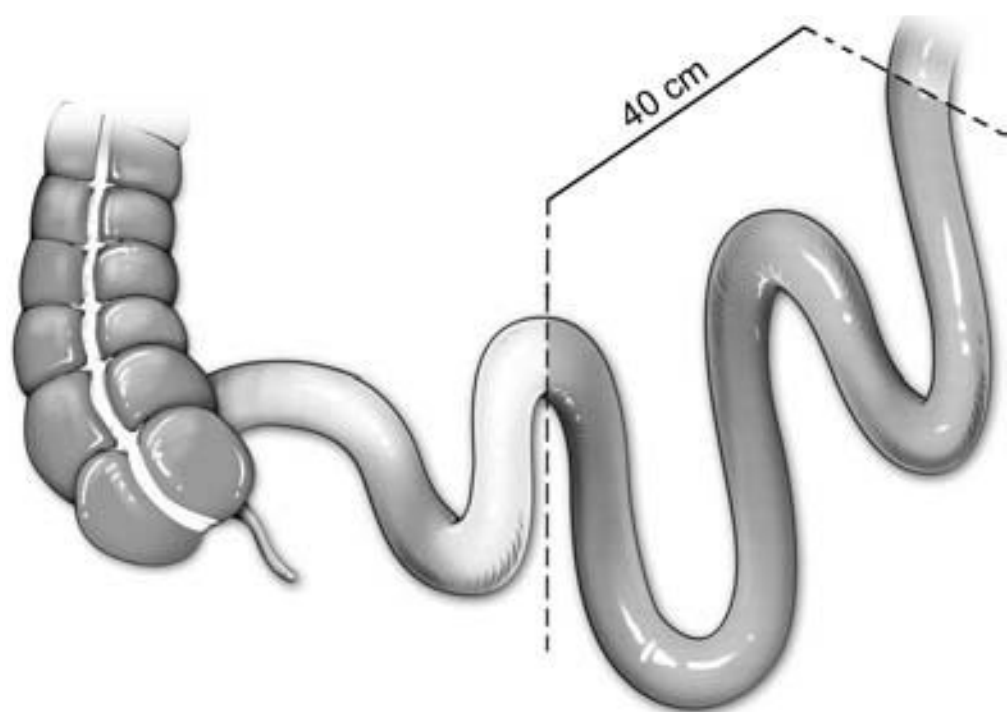

**FIGURE 88.4** First folding maneuver.

abdominal fascia is dissected from the laparotomic incision and bilaterally fixed to the sacrum promontory with non-absorbable sutures and to the vaginal fundus with 2-0 polyglactin sutures, respectively (Fig. 88.2).

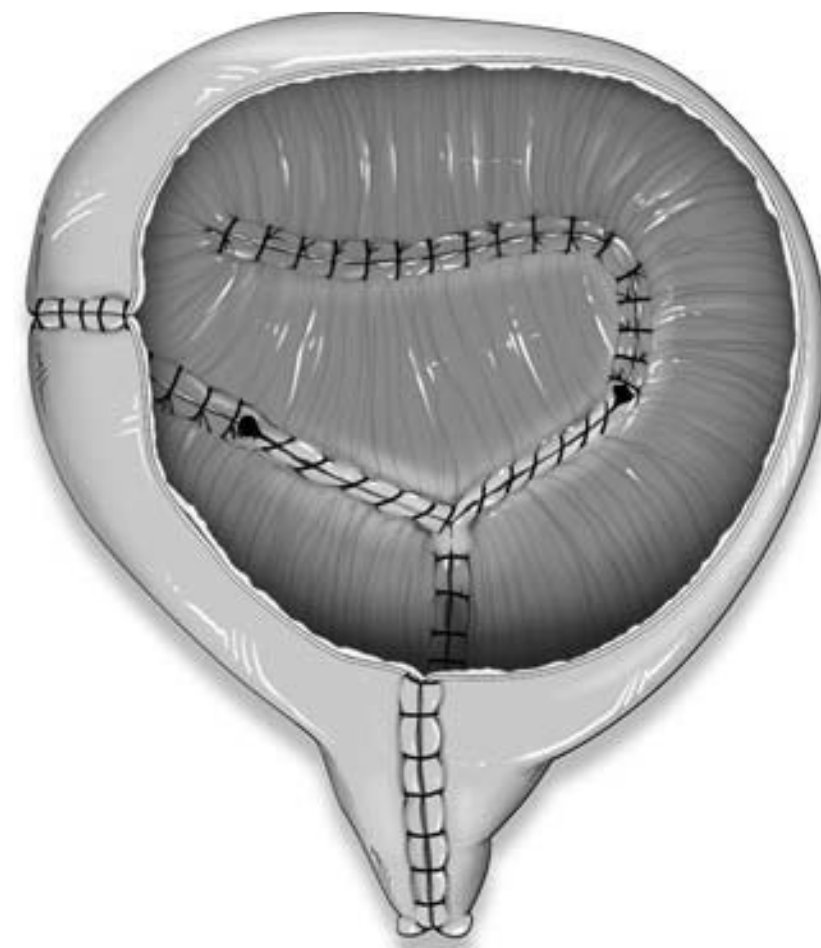

### Creation of the Padua Ileal Bladder

A 40-cm ileal segment is isolated, starting at a convenient point 15 to 20 cm proximal to the ileocecal valve (Fig. 88.3). The distal (aboral) mesenteric incision is deepened at the level of the ileocolic artery to obtain better mobility and to allow a tension-free urethrointestinal anastomosis. On the contrary, the proximal (oral) mesenteric incision can be short because it does not contribute to the mobility of the reservoir. The intestinal continuity is restored by an end-to-end anastomosis with surgical staplers.

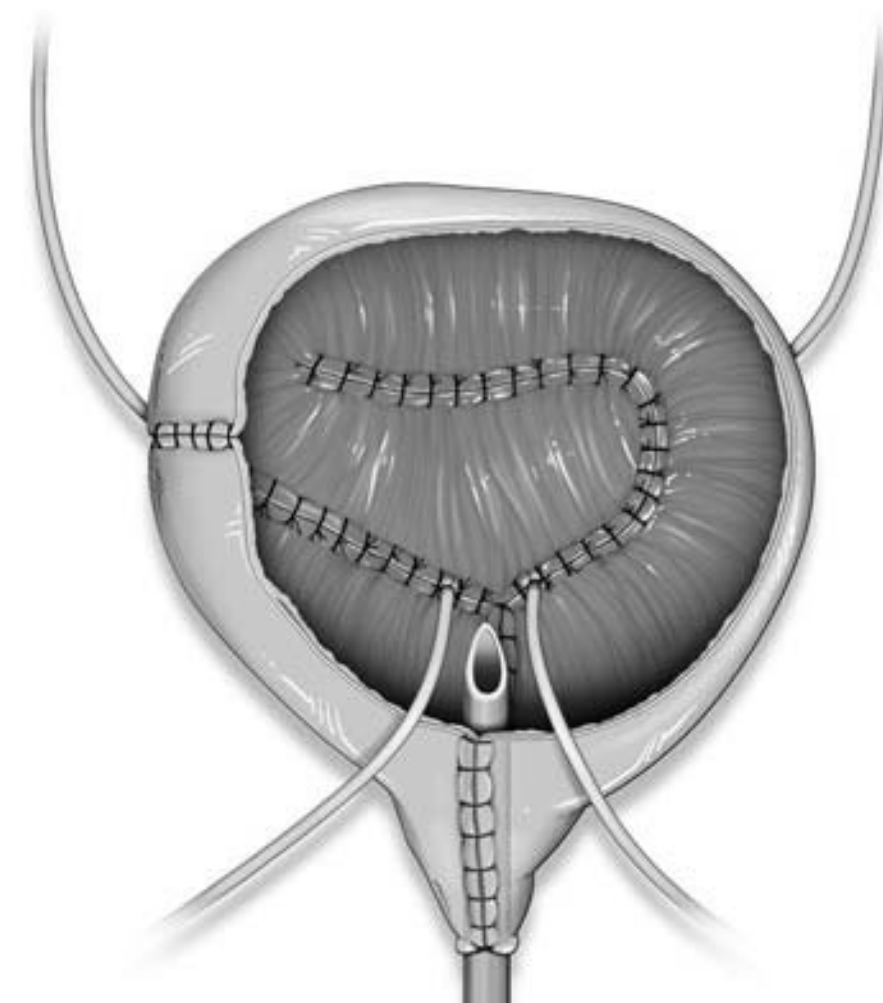

The entire ileal segment is split open along the antimesenteric border (Fig. 88.4). A lower funnel is created by means of two running sutures, posteriorly and anteriorly, about 5 cm in length in order to make the urethrointestinal anastomosis easier and tension-free (Fig. 88.5). The ileal anastomotic hole is placed at the lowest edge of the funnel: the eversion of the ileal mucosa in the anastomotic hole is recommended. Medially, the proximal loop is folded on itself in a reversed U shape, and the inner opposite borders are sutured side to side to create an upper ileal cup (Fig. 88.6).

**FIGURE 88.3** Isolation of a 40-cm segment of distal ileum.

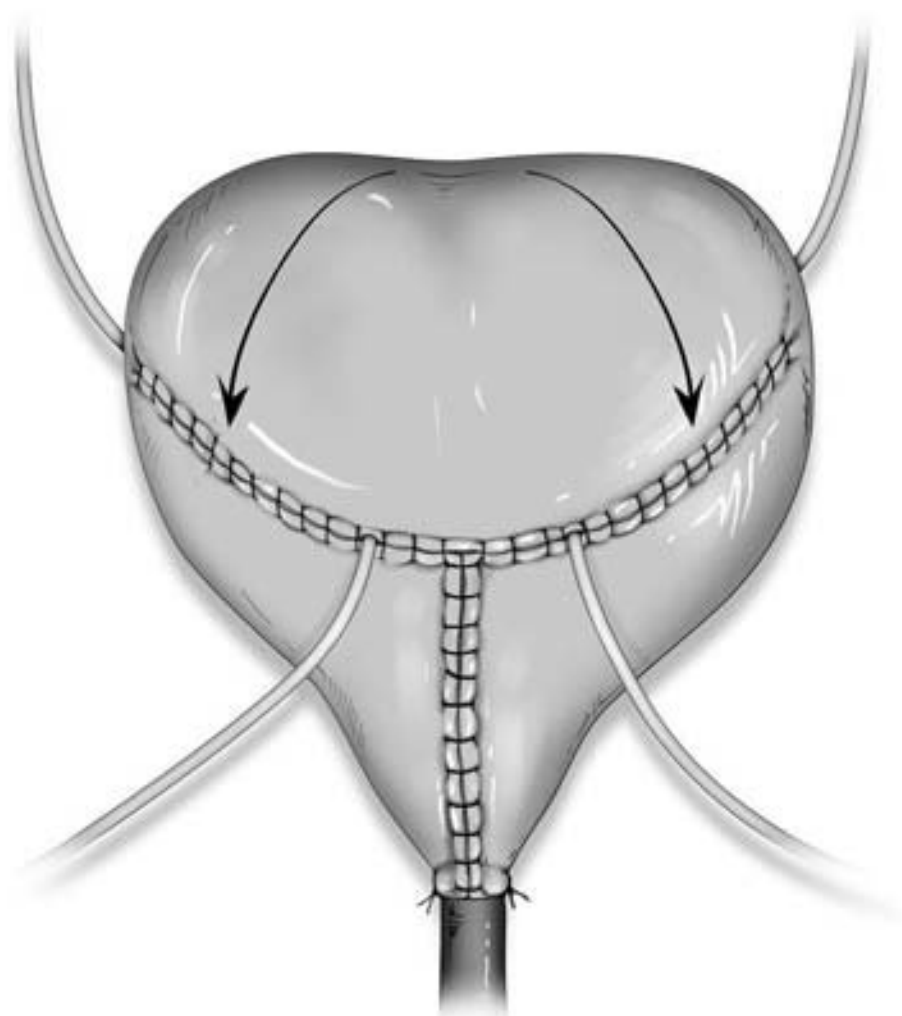

**FIGURE 88.5** Ureteral reimplantation: serous-lined intestinal troughs.

**FIGURE 88.6** Ureteral reimplantation: final view.

**FIGURE 88.7** Second folding maneuver and final view.

The ureteroileal anastomosis with serous-lined extramural reimplantation according to the Abol-Eneim and Ghoneim technique (1) is carried out bilaterally. The edges of two medial intestinal flaps are joined by a running through-and-through suture of 3-0 polyglactin, resulting in the creation of two oblique serous-lined intestinal troughs (Fig. 88.7). The left ureter is brought medially through a suitable mesenteric window in the left mesocolon, providing a downward smooth curve without kinking. Each ureter is then laid into its corresponding trough. A mucosa-to-mucosa anastomosis between the stented (6Fr) and spatulated end of the ureter and the ileal flaps is performed using 4-0 polyglactin suture. The implanted ureters are then covered by approximation and an interrupted 3-0 polyglactin suture is inserted.

When appropriate, a direct non-antirefluxing ureteroileal anastomosis is performed monilaterally or bilaterally: in this case the neobladder is also fixed with 3-0 polyglactin sutures to the ipsilateral psoas muscle. The ureteral stents are fixed to the pouch mucosa close to the ureteral hiatus and secured to their exits (made by stabbing through the anterior wall of the reservoir) using a 4-0 polyglactin suture. The urethroileal anastomosis is performed with six to eight 3-0 polyglactin sutures.

The closure of the reservoir is completed at the anterior aspect by folding downward the upper edge of the ileal cup to obtain a spherical reservoir. A running suture of 3-0 polyglactin is employed for all the suturing of the reservoir. The reservoir is drained by a transurethral 22Fr or 24Fr hematuria catheter.

Parenteral alimentation is supplied until normal bowel function resumes. Wide-spectrum antibiotics are given for 7 days; then quinolones are administered orally as long as the

pouch catheter stays in. The rectal and the gastric tubes are left in place for 3 to 4 days or until bowel contractions begin. The ureters are drained by 6Fr to 8Fr or more stents and are removed after 10 days. Radiologic evaluation of the pouch is performed after 12 days. Special attention is paid to train the patient to completely empty the reservoir by abdominal straining and simultaneous perineal relaxation and to develop alternatives to the normal voiding desire.

---

## OUTCOMES

---

### Results

---

The Padova small bowel neobladder procedure was first performed in 1987 (6). Since its first applications, some changes have been sequentially introduced to simplify and shorten the procedure. Initially, the sequence was as follows: ileourethral anastomosis, detubularization, lower funnel, ureteral reimplantation according to the LeDuc technique, posterior reconfiguration, and anterior reconfiguration. The length of the ileal segment was progressively reduced from between 50 and 60 cm to 40 cm. Recently the sequence of maneuvers has been established as follows: detubularization, construction of the lower funnel, posterior reconfiguration, bilateral ureteral reimplantation, incomplete anterior reconfiguration, ileourethral anastomosis, complete reconfiguration, and extraperitonealization of the reservoir. This sequence allows the surgeon to perform the major part of the procedure on the surface of the surgical field, thus reducing the operative time (at present about 2 hours). Because of the unsatisfactory rate of ureterointestinal anastomosis stenoses (7), the LeDuc ureteral reimplantation technique has been abandoned and favorably replaced with the serous-lined extramural reimplantation according to the Abol-Eneim and Ghoneim procedure (1). The procedure can be easily performed in women with satisfactory functional results provided the vaginal axis is respected by a colpexy.

---

## CONCLUSIONS

---

The Padua ileal bladder (VIP, or “vescica Ileale Padovana”) is a simple, quick procedure with a short learning curve for the urologist who is accustomed to performing radical cystoprostatectomy, ileal conduit, and antireflux procedures. The procedure provides both sexes a good-capacity, low-pressure, nonrefluxing, and continent reservoir by employing only a 40-cm ileal segment in both men and women. The procedure can be easily customized according to anatomical and oncologic needs.

# CHAPTER 89 ■ THE T-POUCH ILEAL NEOBLADDER

JOHN P. STEIN AND DONALD G. SKINNER

The goals of urinary diversion have evolved from simply diverting the urine and protecting the upper urinary tracts. Contemporary objectives of urinary diversion should also include a form of reconstruction that provides a safe and continent means to store and eliminate urine, with efforts to improve the quality of life of the patient requiring cystectomy (6). Currently, four reasonable options regarding lower-urinary-tract reconstruction exist: (a) an incontinent cutaneous diversion: the ileal or colon conduit; (b) a continent cutaneous reservoir, requiring catheterization of a cutaneous stoma; (c) a continent rectal reservoir, with storage and elimination of urine via the rectum; and (d) the orthotopic bladder substitute (neobladder), with reconstruction to the native intact urethra.

The evolution of urinary diversion and lower-urinary-tract reconstruction over the past 60 years has been remarkable. Progress should be attributed to advances in medical and surgical improvements but should also be credited to thoughtful and creative surgeons looking to improve upon existing forms of urinary diversion. In 1950, Bricker (2) introduced the ileal conduit, which established a technically simple and reliable form of urinary diversion. The ileal conduit remains even today a commonly performed urinary diversion and a standard to which other forms of urinary reconstruction are compared. Concurrent with Bricker's introduction of the ileal conduit, Gilchrist (3) independently reported on a continent cutaneous form of diversion utilizing the ileocecal valve as the continence mechanism and the terminal ileum as a catheterizable stoma. For various medical reasons, Gilchrist's ileocecal reservoir garnered little support, and the technically simpler Bricker ileal conduit became the urinary diversion of choice for the next several decades.

The concept of a continent cutaneous urinary diversion was eventually reintroduced and popularized in the early 1980s, revolutionizing urinary diversion to a continent cutaneous form of diversion (4). Although patients were relieved from the issues of an external collection device, catheterization of the continent abdominal stoma was required. The continent cutaneous urinary diversion was considered a step forward and an improvement on the standard ileal or colon conduit. These continent reservoirs, however, are technically more challenging, take significantly longer to construct, and are associated with a reoperation rate, particularly the efferent catheterizable limb. Despite the benefits of the continent cutaneous reservoir over an ileal conduit, these aforementioned issues even today have limited the widespread application of this form of urinary diversion.

A natural progression from the continent cutaneous urinary diversion was the orthotopic bladder substitute (neobladder) connected directly to the native intact urethra

(6). The orthotopic neobladder resembles the original bladder in location and function. An orthotopic form of reconstruction eliminates the need for a cutaneous stoma and a cutaneous collection device, and it relies on the patients' intact rhabdosphincter continence mechanism (external striated sphincter muscle), thus eliminating the need for intermittent catheterization in most cases and the often plagued efferent limb of the continent cutaneous reservoir. Voiding is effectively accomplished by concomitantly increasing intra-abdominal pressure (Valsalva) with relaxation of the pelvic floor musculature.

Orthotopic reconstruction was initially applied to carefully selected male patients in the mid 1980s with excellent clinical and functional results (6). The positive experience in men subsequently stimulated interest in applying orthotopic reconstruction to women (7). After neuroanatomical dissections provided a better understanding of the continence mechanism in women and defined pathologic guidelines allowed for proper patient selection from a cancer perspective in women, orthotopic reconstruction was subsequently and successfully applied to women in the early 1990s. The majority of both male and female patients undergoing cystectomy today are appropriate candidates for orthotopic reconstruction (6).

From 1982 to 1997, the primary form of urinary diversion at the University of Southern California (USC) was the continent Kock ileal reservoir (Kock pouch) (4,5). The intussuscepted nipple valve provided the continence and antireflux mechanism in the Kock ileal reservoir. The principles of the continent Kock ileal reservoir (cutaneous and orthotopic forms) are sound; however, complications can occur (8). Most complications associated with the Kock ileal reservoir relate to the intussuscepted limb, either the antireflux (afferent limb) or the continent catheterizable (efferent limb) nipple.

A review of our large experience at USC with the Kock ileal reservoir subsequently revealed a 10% complication rate associated with the afferent intussuscepted antireflux nipple in over 800 patients (including the continent cutaneous and orthotopic Kock ileal reservoir) (8). The three most common complications associated with the intussuscepted afferent nipple include (a) stone formation (associated with exposed staples that secure the afferent nipple valve), seen in 5%; (b) afferent nipple stenosis (thought to be caused by ischemic changes resulting from the mesenteric stripping required to maintain the intussuscepted limb), seen in 4%; and (c) extussusception (prolapse of the afferent limb), seen in 1% of patients. Although the majority of these afferent nipple valve complications (60%) can be managed with endoscopic techniques, they nonetheless may result in some morbidity. Approximately 3% of all patients undergoing a continent

Kock ileal reservoir will require an open surgical revision to repair an afferent nipple complication (8).

The need to improve upon the intussuscepted Kock nipple valve became increasingly obvious. Based on reports from Ghoneim's group in Mansoura, Egypt, employing a ureteral serous-lined, extramural tunnel (1), as well as our initial experience with the Mitrofanoff appendiceal subserosal tunnel at USC, we subsequently developed and reported our initial experience with a flap-valve technique called the "T-mechanism" (9). The T-mechanism is a versatile technique that can be applied as an antireflux mechanism as well as a continent mechanism in a cutaneous reservoir (10). Since 1997, we have utilized the T-mechanism as an important modification to the Kock ileal reservoir (11).

The T-mechanism was first successfully incorporated as the afferent antireflux limb of an orthotopic reservoir (T-pouch) (9,11) and subsequently into an afferent antireflux and efferent continence limb of a cutaneous reservoir (double-T-pouch) soon after (10). We believe the flap-valve T-mechanism has eliminated the complications associated with the intussuscepted nipple valve while maintaining an effective antireflux or continence mechanism. The surgical technique of the orthotopic T-pouch ileal neobladder will be described herein.

## DIAGNOSIS

Indications for an orthotopic diversion are related to a functional loss of the bladder for either benign or malignant causes. In the United States, the most common cause is related to bladder cancer requiring radical cystectomy. All diagnostic tests are related to the underlying disease and indication for cystectomy.

## INDICATIONS FOR SURGERY

Any patient who is an appropriate candidate for orthotopic diversion may undergo this procedure. If a patient has a history of bladder cancer, the authors recommend intraoperative frozen section analysis of the proximal urethra. If there is no

evidence of tumor on this biopsy and no other contraindications exist, an orthotopic diversion is performed.

## ALTERNATIVE THERAPY

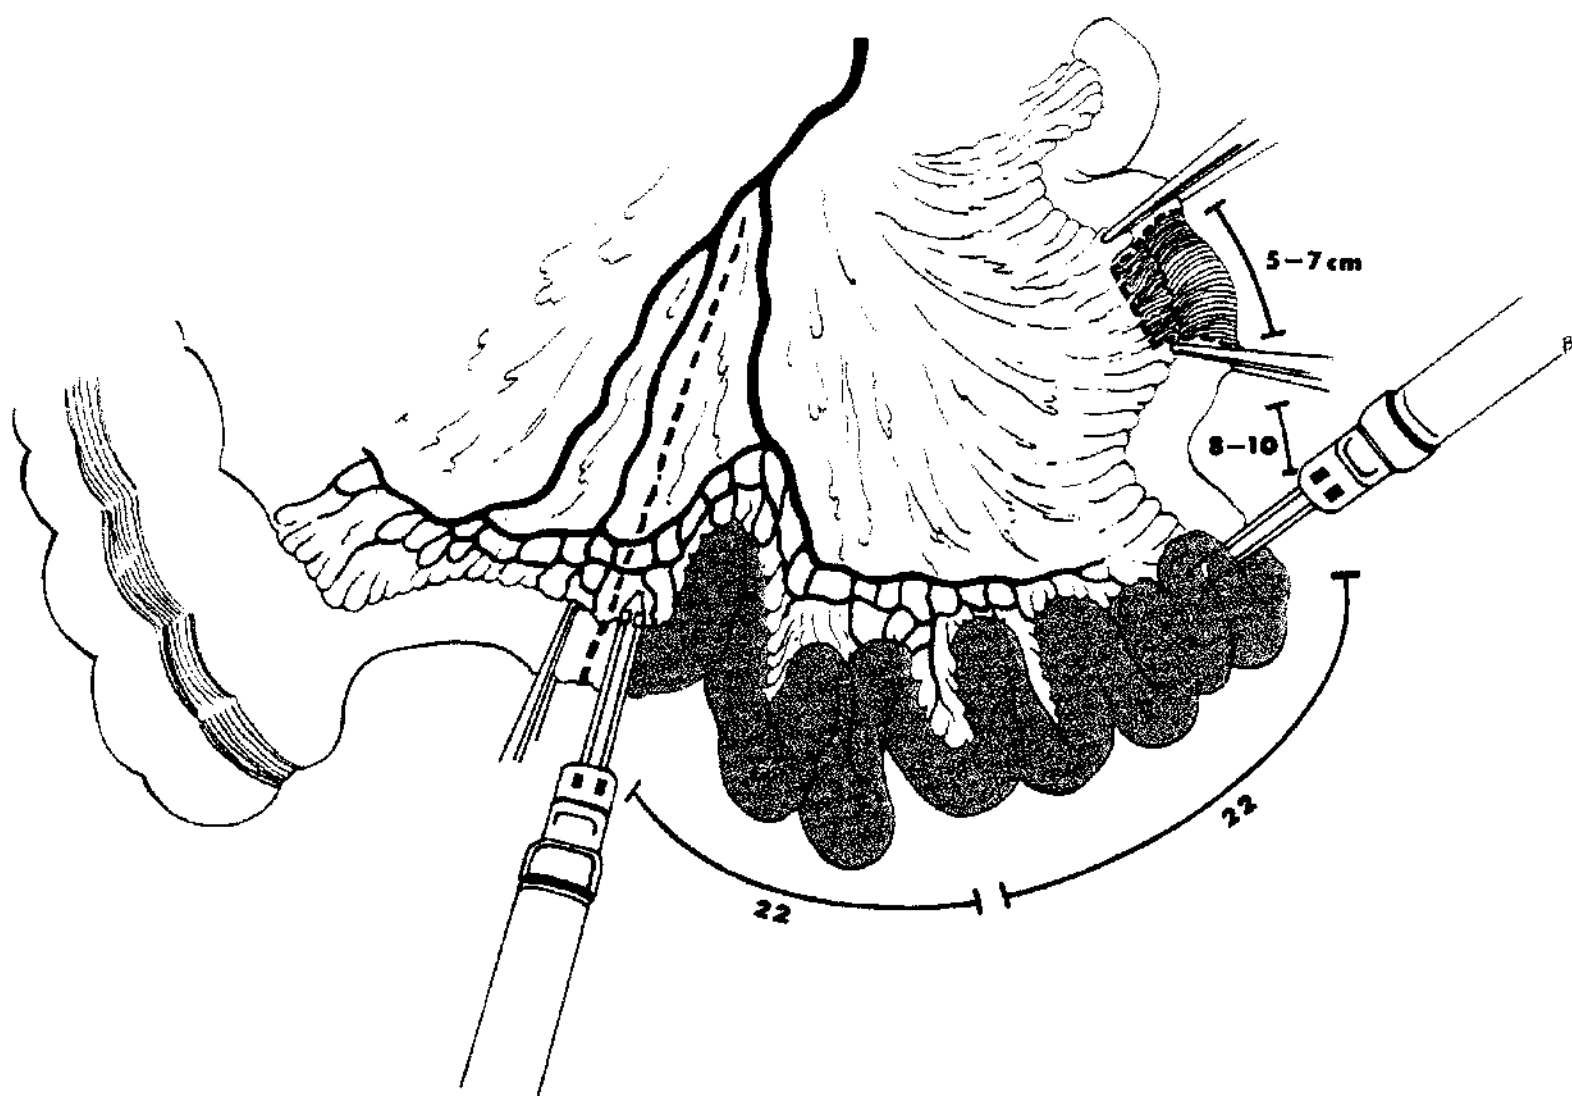

Other forms of urinary diversion may be performed, including various incontinent reservoirs (ureterostomy, conduits), continent cutaneous reservoirs, continent rectal reservoirs, and other orthotopic neobladders.

## SURGICAL TECHNIQUE

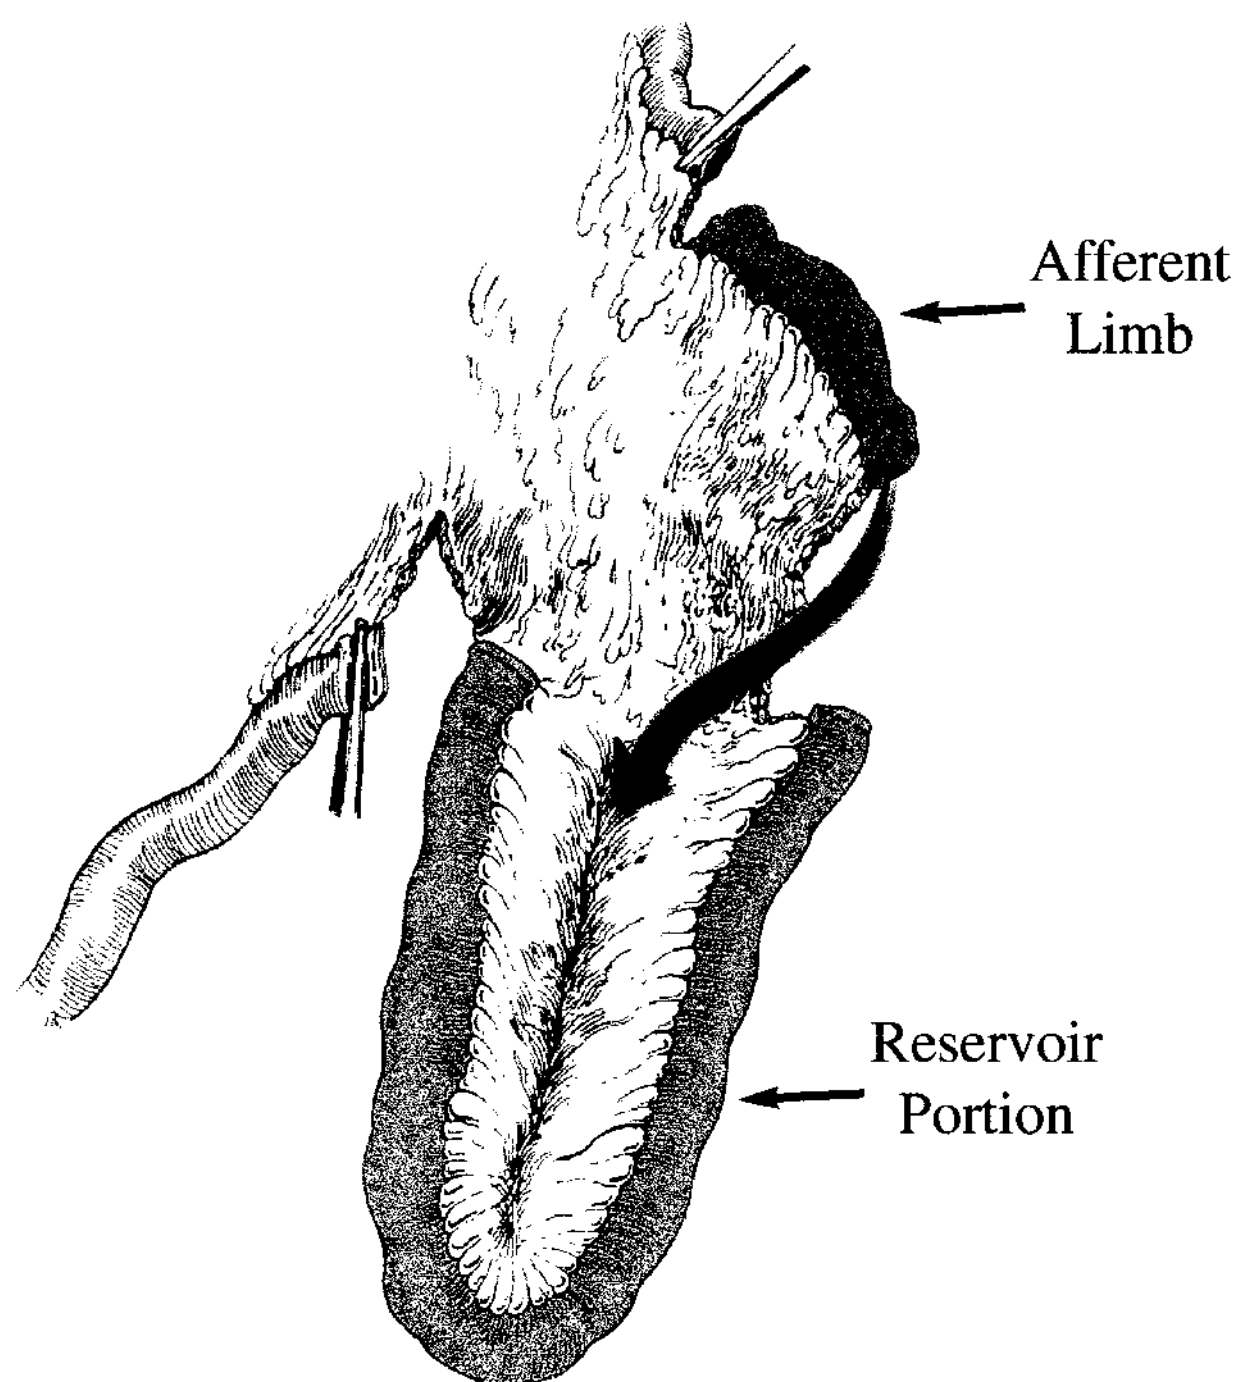

The terminal portion of the ileum is used to construct the orthotopic T-pouch ileal neobladder (Fig. 89.1). The distal mesenteric division is best made along the avascular plane of Treves between the ileocolic artery and terminal branches of the superior mesenteric artery. This division extends deep into the avascular portion of the mesentery, which is essential for adequate mobility of the reservoir. The proximal mesenteric division, however, is short and provides a broad vascular blood supply to the reservoir. In addition, a small window of mesentery and a 5- to 7-cm portion of small bowel most proximal to the overall ileal segment are discarded. This helps ensure mobility to the pouch and small bowel anastomosis.

The T-pouch reservoir is created from a 44-cm segment of distal ileum placed in an inverted V configuration. Each limb of the V measures 22 cm. A proximal 8- to 10-cm segment of ileum (afferent limb) is used to form the afferent antireflux T-mechanism. Note: If ureteral length is short or compromised, a longer afferent ileal segment (proximal ileum) may be harvested to bridge the ureteral gap.

The ileum is divided between the proximal afferent ileal segment and the 44-cm ileal segment that will form the reservoir portion of the neobladder. The mesentery between these ileal segments does not need to be incised; this could potentially compromise the blood supply to the afferent limb. There is generally adequate mobility of the afferent ileal segment, which will ultimately be advanced into the serous-lined ileal trough formed by the base (cephalad) of the two adjacent 22-cm segments of ileum.

**FIGURE 89.1** Designated segments of terminal ileum for construction of the orthotopic T-pouch ileal neobladder. Note that the distal mesenteric division is made between the ileocolic and terminal branches of the superior mesenteric artery, which extends into the avascular plane of the mesentery. In addition, a small window of mesentery and a 5- to 7-cm segment of most proximal small bowel is discarded to allow mobility to the pouch and small bowel anastomosis.

**FIGURE 89.2** The T-pouch is constructed from an isolated 44-cm ileal segment (laid out in an inverted V configuration) that forms the reservoir portion of the pouch, and a proximal 8- to 10-cm segment of ileum to form the antireflux limb. The mesentery between the afferent ileal segment and the proximal portion of the 44-cm ileal segment is carefully incised (2 cm) with preservation of the major vascular arcades. Note the serous-lined ileal trough created at the base of the two 22-cm ileal segments where the afferent limb will be advanced (*arrow*).

The proximal end of the isolated afferent ileal segment is closed with a running Parker-Kerr suture of 3-0 chromic, and a third layer of interrupted 4-0 silk sutures. A standard small bowel anastomosis is performed to re-establish bowel continuity, and the mesenteric trap is closed.

The isolated 44-cm ileal segment is then laid out in an inverted V configuration, with the apex of the V lying caudally toward the feet and with a suture marking a point between the two 22-cm adjacent segments of ileum (Fig. 89.2). The opened end (base) of the V is directed in a cephalad manner toward the head. Note the serous-lined ileal trough formed at the base of the 44-cm segment.

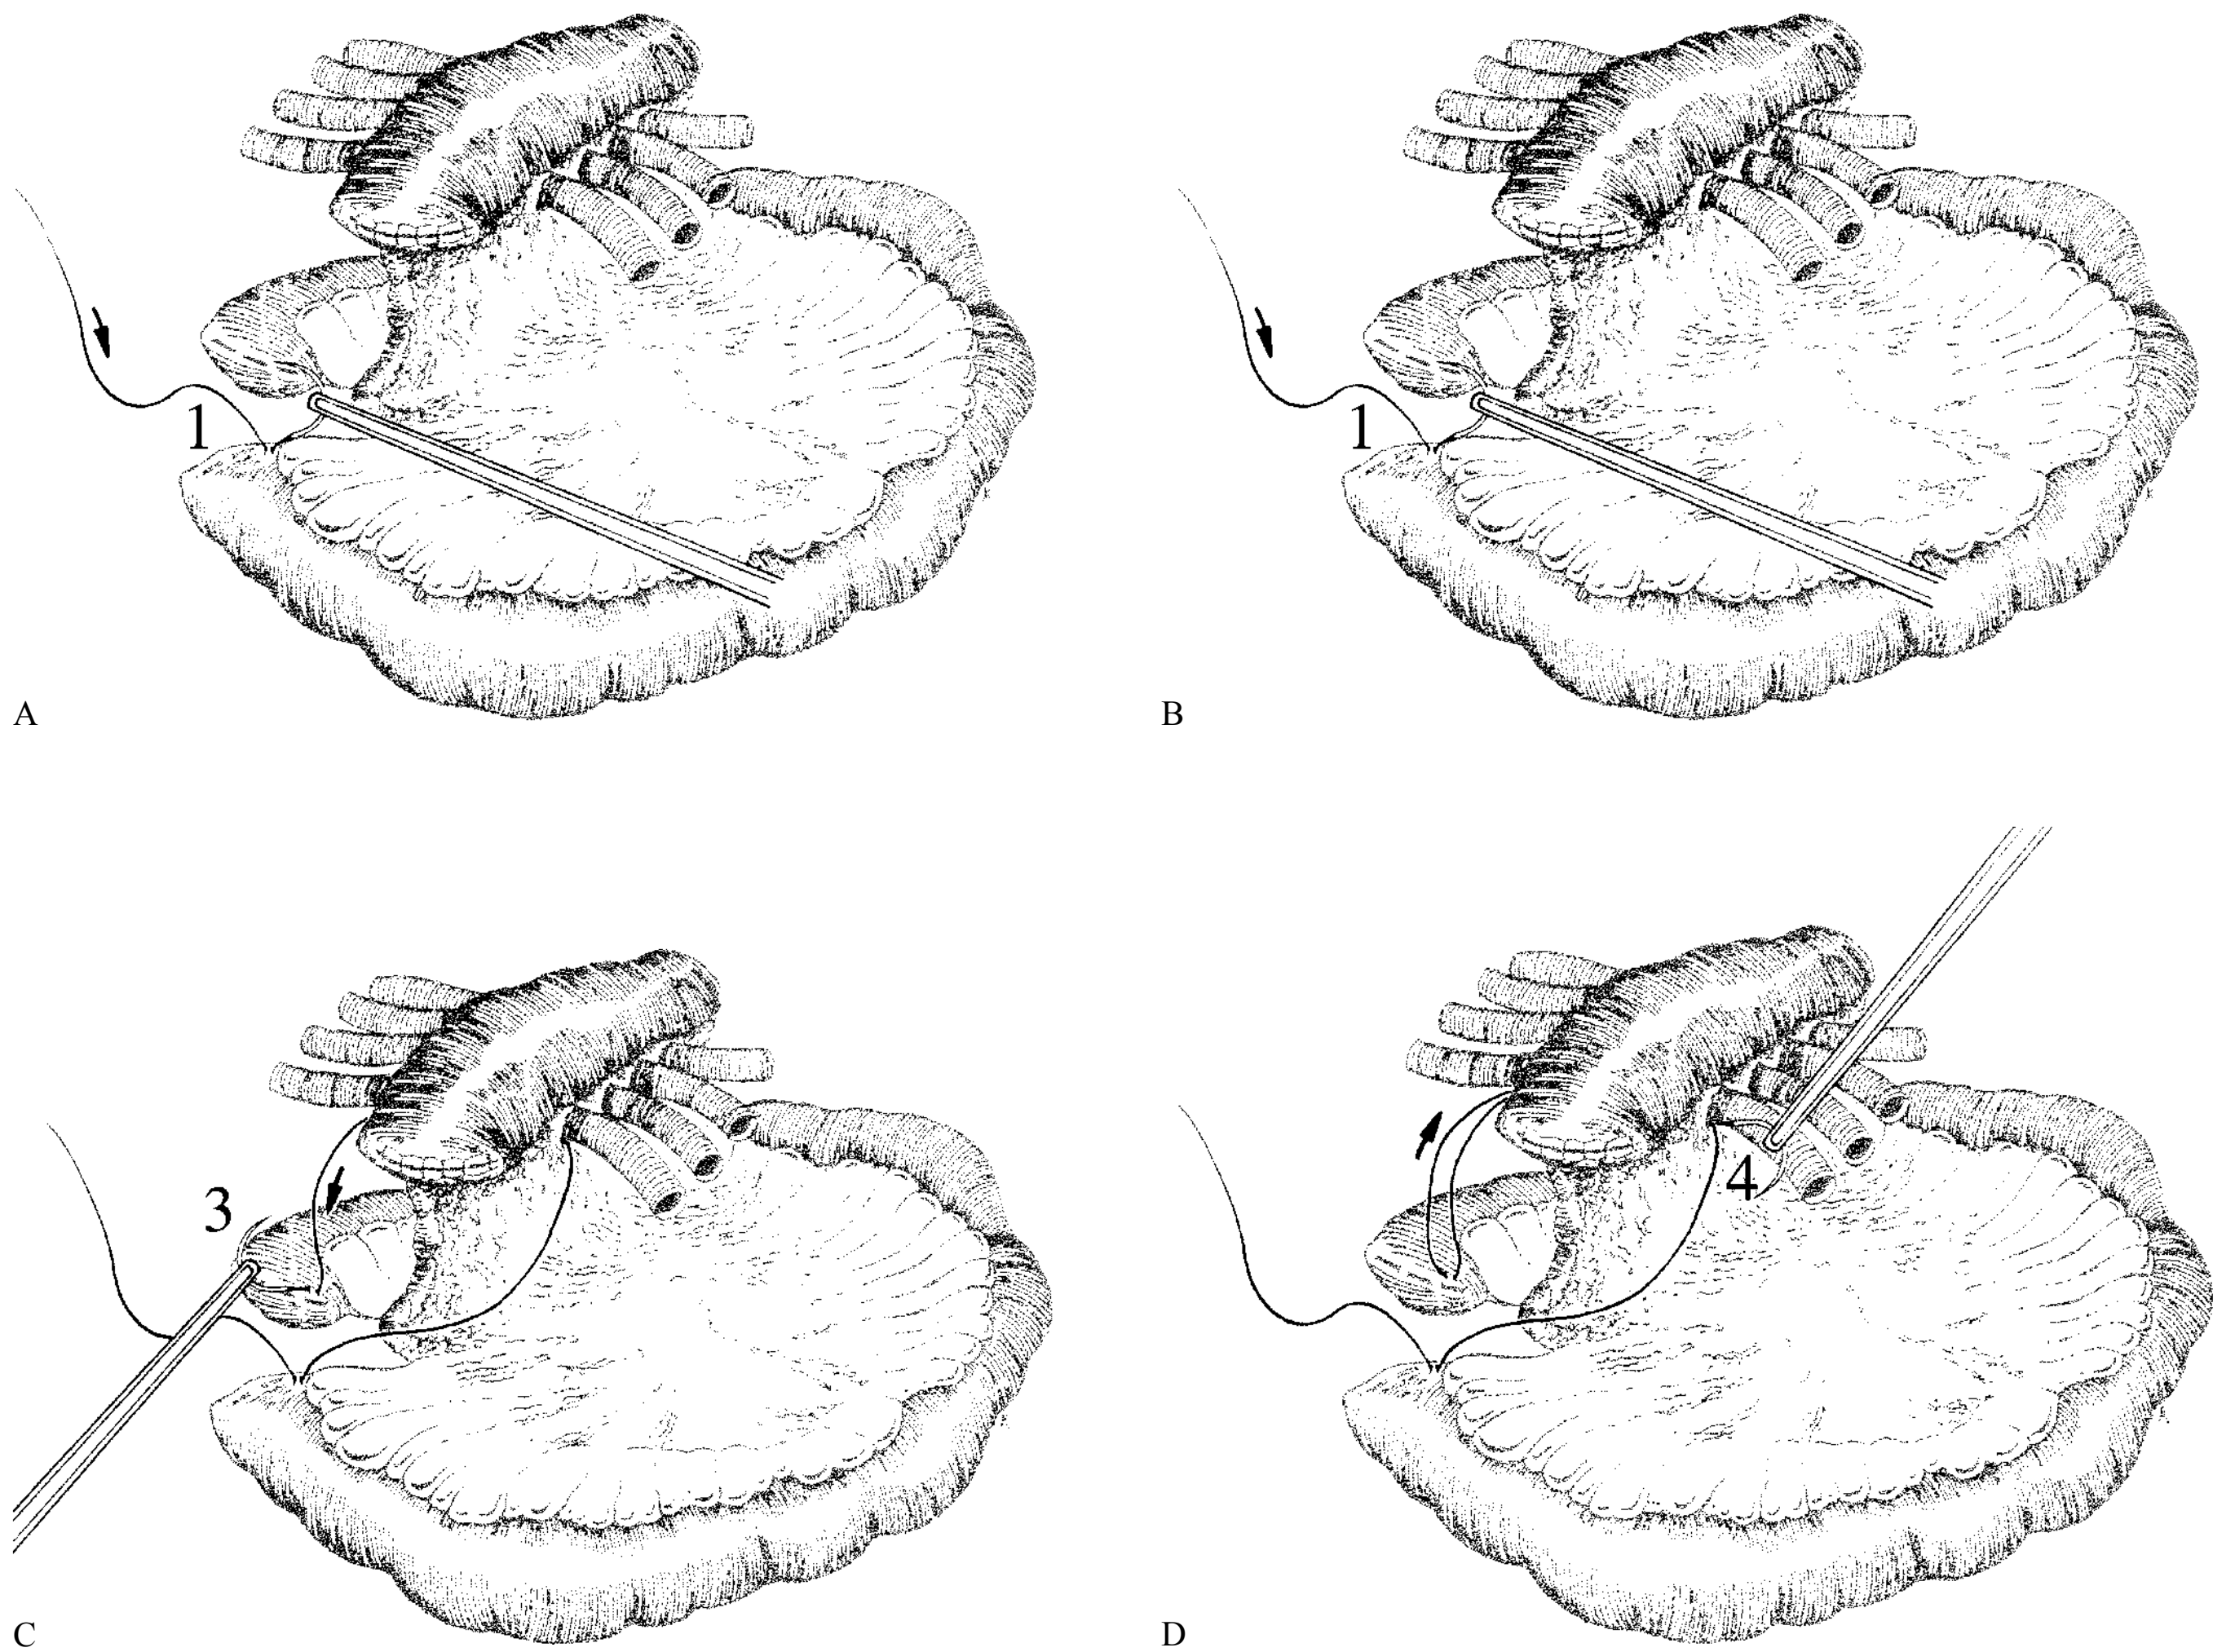

The antireflux (flap-valve) T-mechanism is then created by anchoring the distal 4 cm of the afferent ileal segment into the serous-lined ileal trough formed by the two adjacent 22-cm ileal segments. First, mesenteric windows of Deaver are opened between the vascular arcades (carefully excising mesenteric fat adjacent to the serosa of the ileum, which facilitates the development of these mesenteric windows) for 4 cm proximal to the distalmost portion of the isolated afferent ileal segment (Fig. 89.3). Preserving these arcades (blood vessels) maintains a well-vascularized afferent limb and allows permanent fixation of this portion of the limb into the serous-lined ileal trough with complete preservation of the mesentery and blood supply. Note: Placement of small Penrose drains through each mesenteric window helps identify and facilitates passage of suture through each window.

Next, a series of 3-0 silk sutures are then used to approximate the serosa of the two adjacent 22-cm ileal segments at the base of the V. Note: These sutures are passed through the previously opened windows of Deaver in the afferent ileal limb. This will anchor the 4-cm segment of afferent limb into the serous-lined ileal trough. Specifically, a silk suture is placed into the seromuscular portion of the bowel (adjacent to the mesentery) at the base (most cephalad portion of the V) of one of the 22-cm ileal segments (Fig. 89.4A). The suture is then passed through the most proximal window of Deaver opened in the afferent ileal limb (Fig. 89.4B) and placed in a corresponding seromuscular site of the bowel (next to mesentery) of the adjacent 22-cm ileal segment (Fig. 89.4C). The suture is brought back through the same window of Deaver and tied down (Fig. 89.4D). Generally, two to three silk sutures are placed within each window of Deaver to ensure that the back wall of the reservoir (serous-lined ileal trough) is anchored and does not separate. This process is repeated through each individual window of Deaver until the distal 4 cm of the afferent segment is permanently fixed in the serous-lined ileal trough. We have found that placement of small (1/4-in.) Penrose drains through each window of Deaver facilitates passage of the silk suture back and forth through the mesentery without difficulty. The Penrose drains are systematically removed as the afferent limb is fixed within the serous-lined ileal trough.

In our early experience with the T-pouch, the previously anchored portion of the afferent ileal segment (distal 4 cm) was consistently tapered on the antimesenteric (anterior) border over a 30Fr catheter (Fig. 89.5). Tapering this portion of the

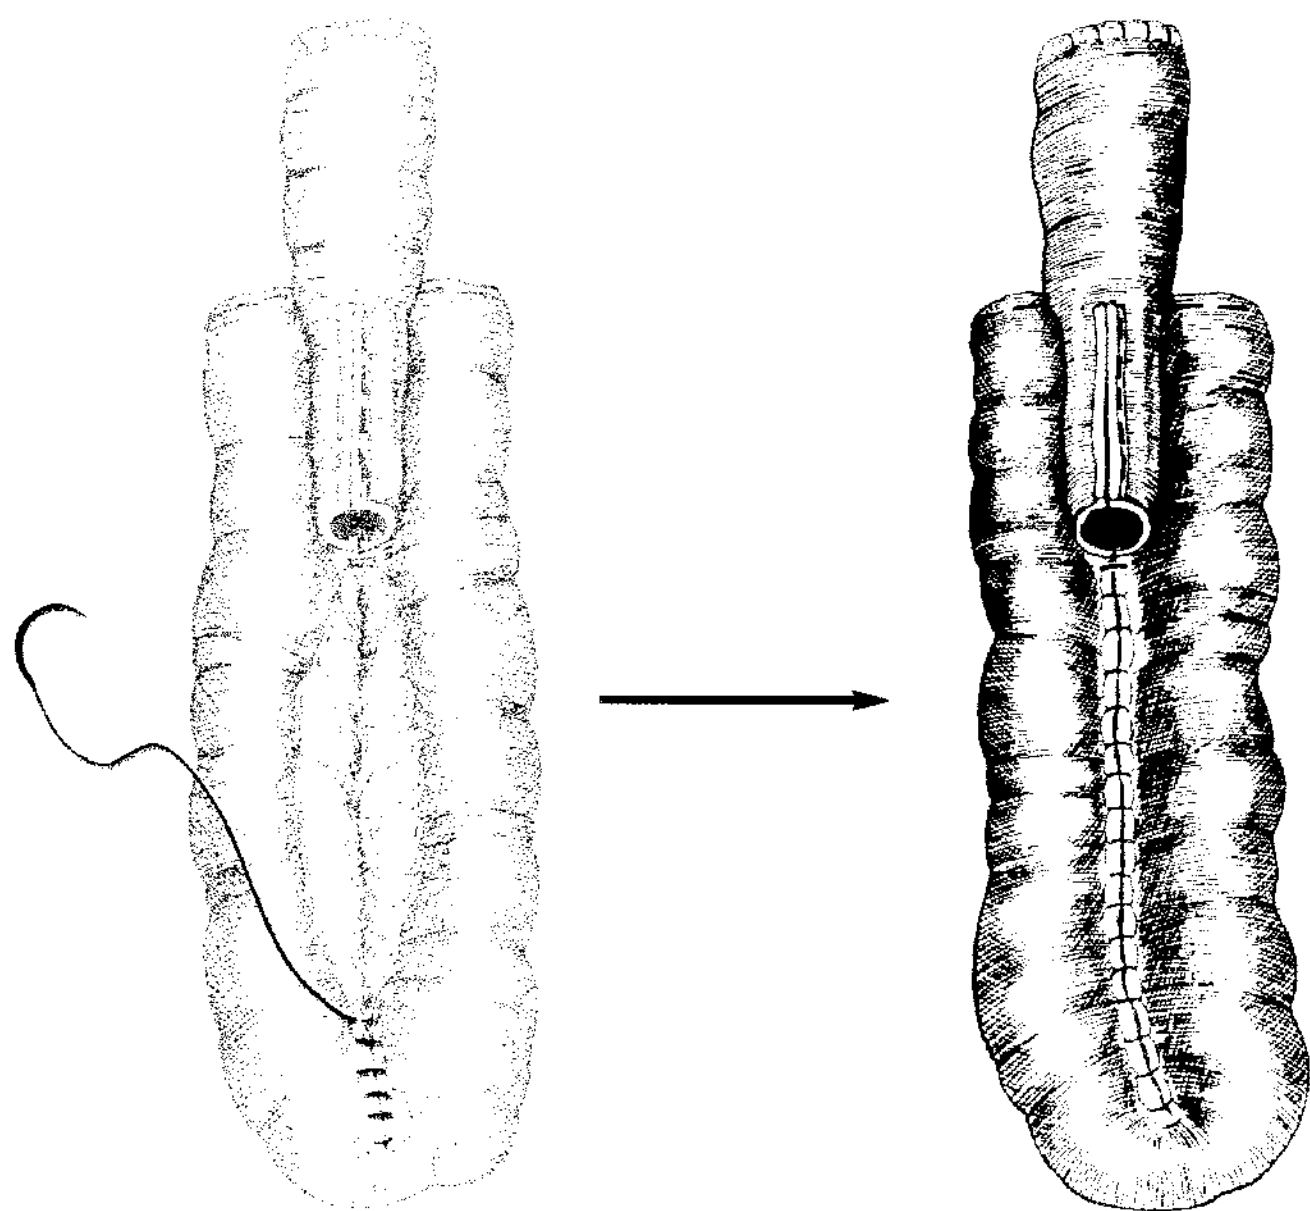

**FIGURE 89.3** Creation of the antireflux mechanism. First, four mesenteric windows of Deaver are opened (adjacent to the serosa of the ileum) at the distal 4 cm of the isolated afferent ileal segment. Placement of small Penrose drains through each mesenteric window helps identify and facilitates passage of suture through each (*insert with arrows*). The distal 4 cm of the afferent segment will be anchored into the serous-lined ileal trough formed by the base of the two adjacent 22-cm ileal segments.

**FIGURE 89.4** **A:** A series of interrupted silk sutures are used to approximate the serosa of the base of the two adjacent 22-cm ileal segments. Note that these sutures are brought through the windows of Deaver, facilitated by the use of the Penrose drains. After the silk suture is passed through the window of Deaver (**B**), it is placed in a corresponding site on the adjacent 22-cm ileal segment (**C**). **D:** This suture will then be brought back through the same window of Deaver and tied down.

**FIGURE 89.5** The previously anchored distal 4-cm afferent ileal segment is tapered over a 30Fr catheter on the antimesenteric border. Since the initial description of the T-pouch, we now selectively taper the afferent limb only in those cases where there is clearly a large diameter of ileum.

**FIGURE 89.6** The two 22-cm ileal segments are joined by a running 3-0 polyglycolic acid continuous suture. Note that this suture is placed adjacent to the mesentery and runs from the apex up to the ostium of the afferent ileal segment. The serosa of the two 22-cm ileal segments is reapproximated.

afferent ileal segment reduces the bulk and lumen of the afferent limb and facilitates later coverage of the anchored afferent limb with ileal flaps. In addition, this tapering of the afferent limb increases the ratio of the tunnel length to the lumen diameter, theoretically providing a more effective flap-valve mechanism. However, we have found that with longer follow-up this tapering may contribute, in a small percentage of patients, to some narrowing and even stenosis at the ostium. Currently, tapering of the afferent limb on the antimesenteric boarder is only performed when the ileum has an obviously large diameter.

After the distal 4 cm of the afferent ileal segment has been anchored into the serous-lined tunnel, the remaining portions of the adjacent 22-cm ileal segments are approximated together with a side-to-side 3-0 polyglycolic acid suture. This suture line simply reapproximates the two ileal limbs and is placed adjacent to the mesentery (Fig. 89.6). This can be performed in a running or interrupted fashion.

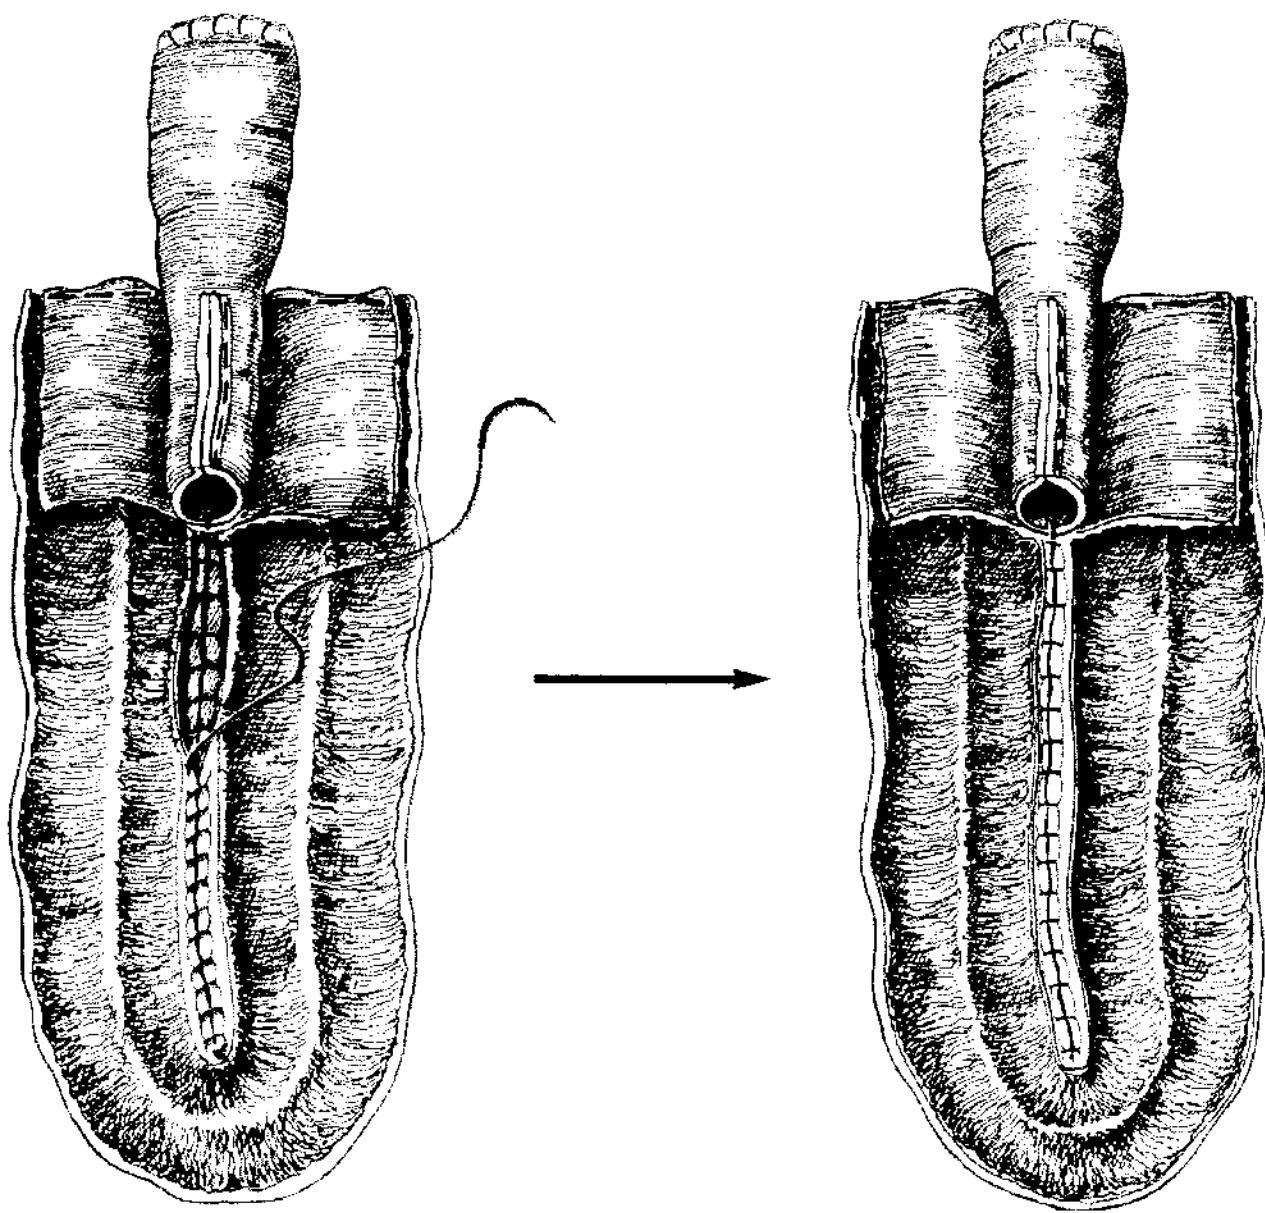

Next, starting at the apex of the V, the ileum is opened immediately adjacent to the previously placed serosal suture line using electrocautery. This incision is carried upward toward the ostium of the afferent limb where the afferent limb is anchored (Fig. 89.7A). Once this incision reaches the level of the afferent ostium, the incision is then extended directly lateral to the antimesenteric border of the ileum and carried upward (cephalad) to the base of the ileal segment. An incision is made in similar fashion on the contralateral 22-cm ileal segment (Fig. 89.7B). Once completed, these incisions provide wide flaps of ileum that will ultimately be brought over and cover the anchored afferent ileal segment to create the antireflux mechanism in a flap-valve technique (Fig. 89.7C).

The previously incised ileal mucosa is then oversewn with two layers of a running 3-0 polyglycolic acid suture starting at the apex and running upward toward the ostium of the afferent limb (Fig. 89.8). Once the ostium of the afferent limb is reached, the running suture is tied. An interrupted mucosa-to-mucosa anastomosis is then performed between the ostium of the afferent ileal limb and the incised intestinal ileal flaps with 3-0 polyglycolic acid sutures (Fig. 89.9). The mucosal edges of the ileal flaps are then approximated over the tapered portion of the afferent ileal limb (4 cm) with a running suture in two layers (Fig. 89.10). This suture line completes the posterior wall of the reservoir and creates the effective flap-valve T-mechanism: the serous-lined ileal antireflux limb.

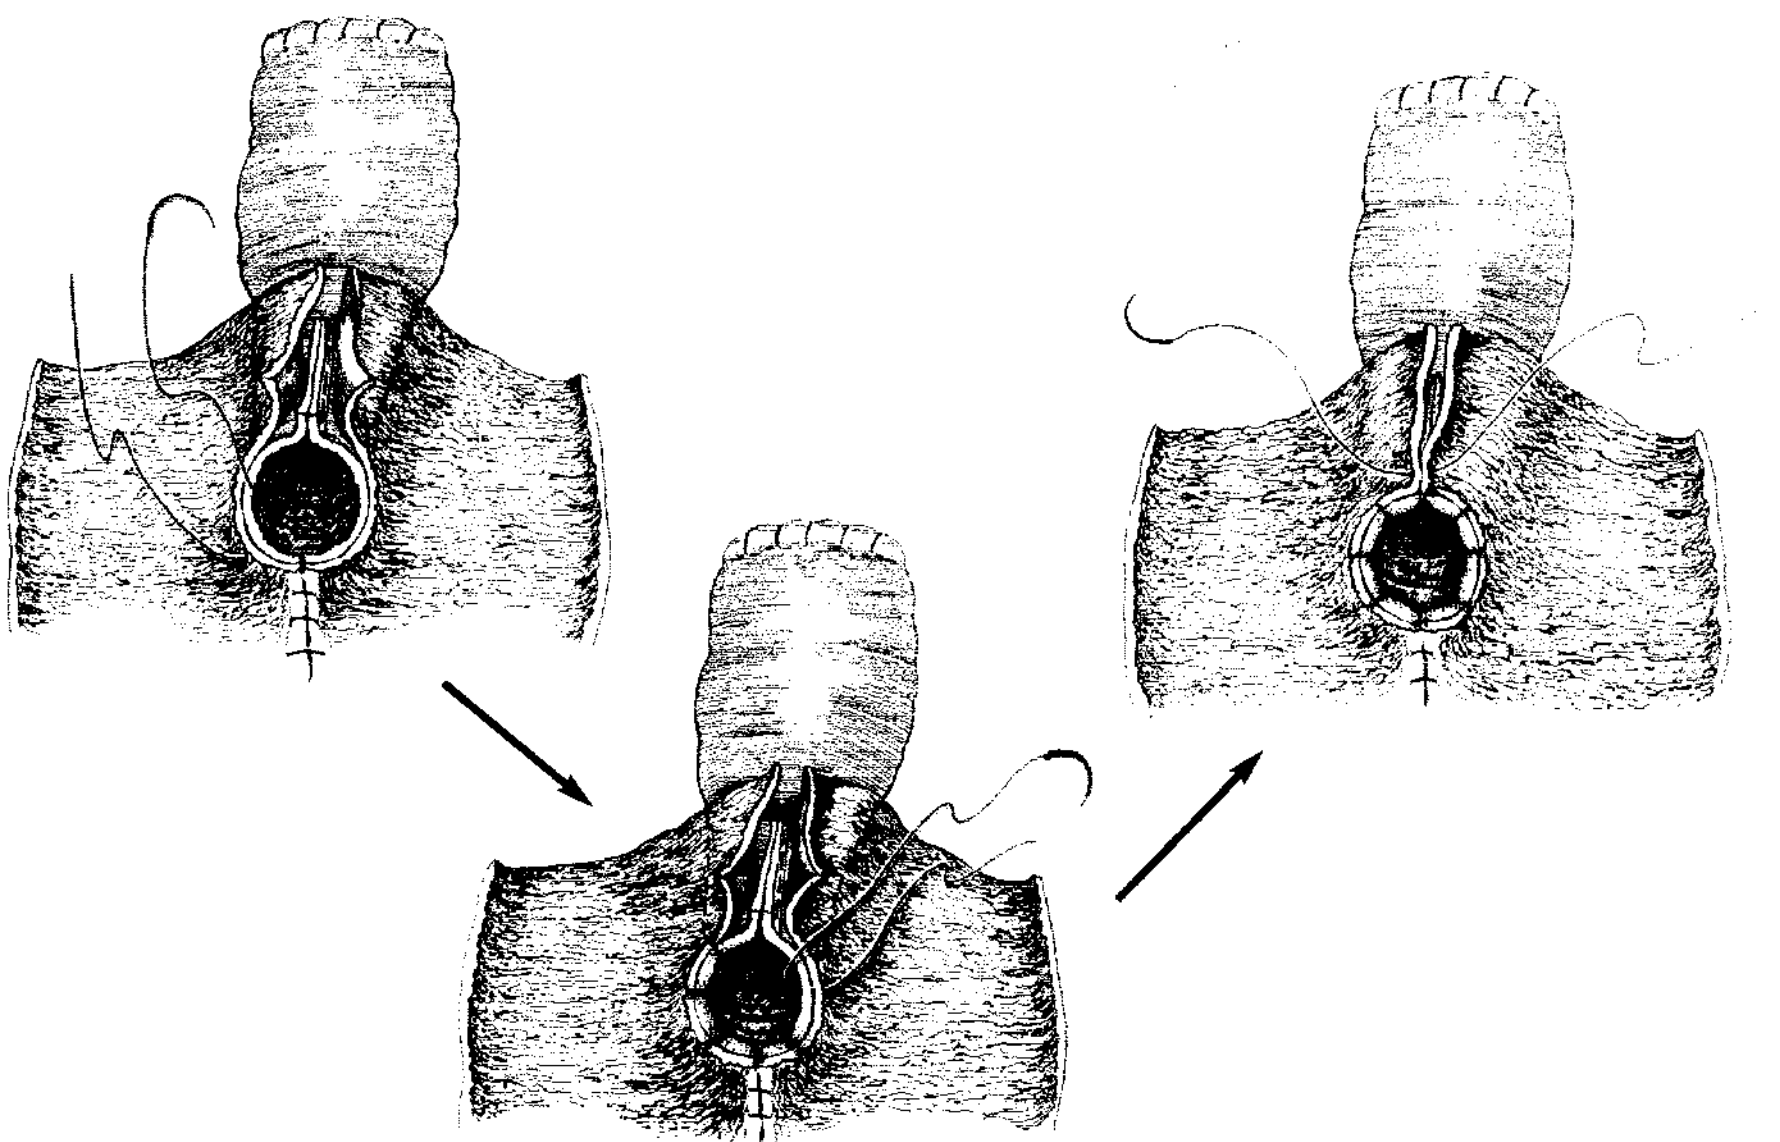

The reservoir is then closed by folding the ileum in half in an opposite direction to which it was opened (Fig. 89.11). This effectively creates a low-pressure, high-capacity urinary reservoir. The anterior wall is closed with a running, two-layer 3-0 polyglycolic acid suture that is watertight (Fig. 89.12). This anterior suture line is stopped just prior to the end of the

**FIGURE 89.7** **A:** The two 22-cm ileal segments are opened immediately adjacent to the serosal suture line beginning at the apex and carried upward to the ostium of the afferent segment. Note: Once this incision reaches the ostium, it is then directed lateral (to the antimesenteric border) and cephalad to the base. The *dotted line* depicts the incision line. **B:** Completing the incision of the bowel. **C:** The incision provides wide flaps of ileum that can easily be brought over and that cover the tapered distal afferent ileal segment to form the antireflux mechanism in a flap-valve technique.

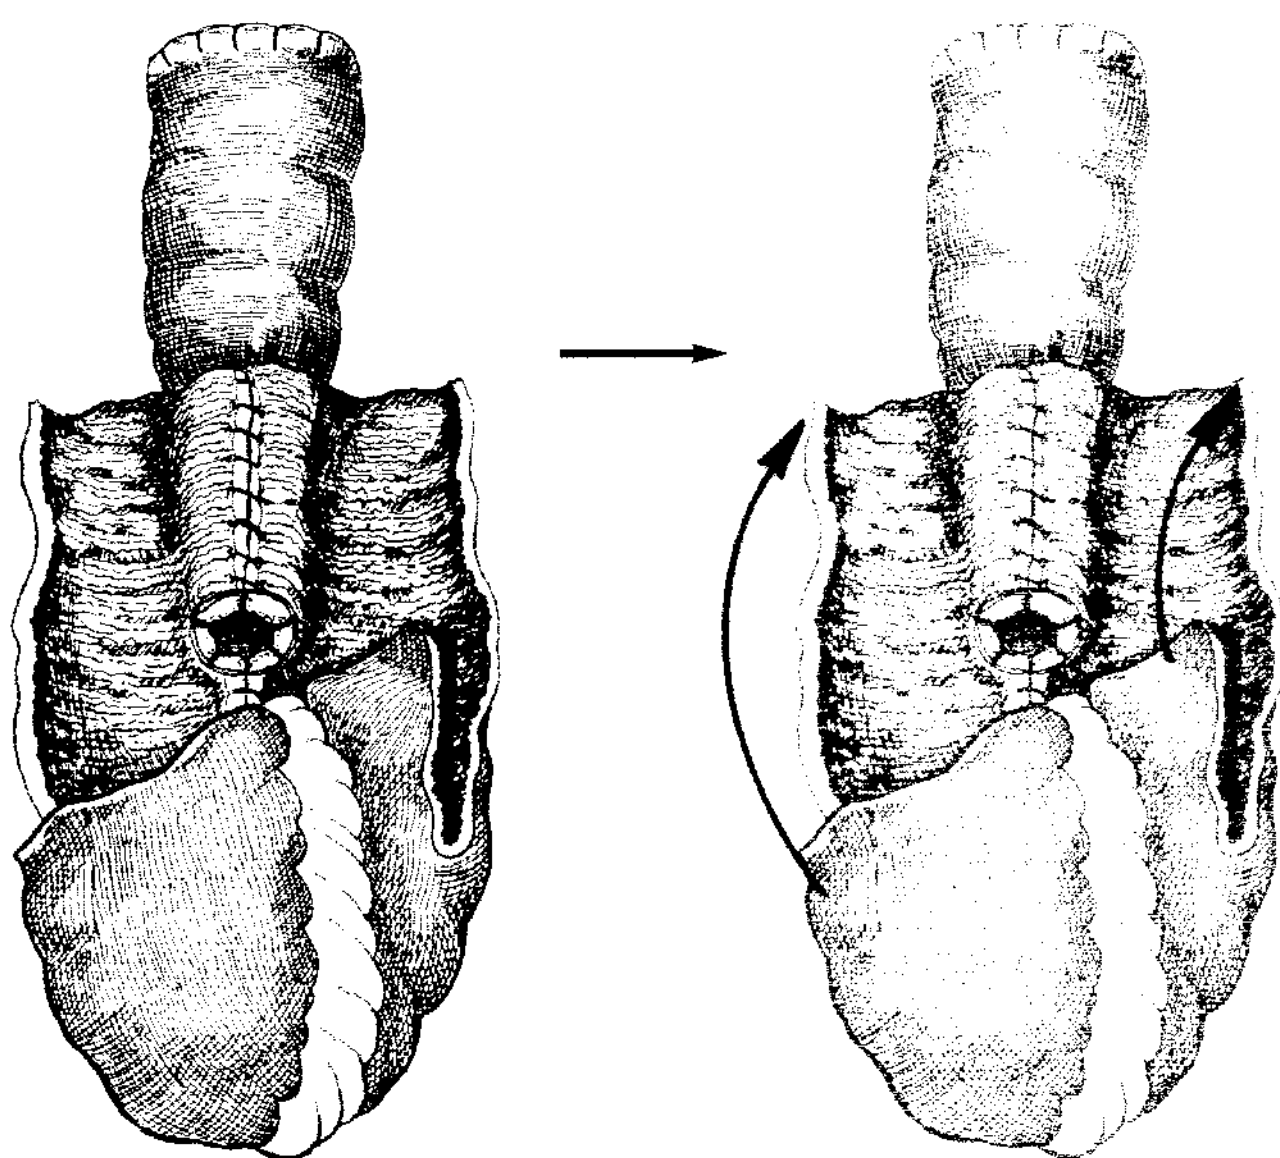

**FIGURE 89.8** The incised ileal mucosa is oversewn in two layers beginning at the apex and continuing toward (cephalad) the ostium of the afferent ileal segment.

**FIGURE 89.9** A mucosa-to-mucosa, ileal-to-ileal anastomosis is performed between the ostium of the afferent segment and the edges of the ileal flaps. Note that this is performed with interrupted 3-0 polyglycolic acid suture with completion of the ileal-to-ileal anastomosis.

**FIGURE 89.10** **A:** The mucosal edges of the ileal flaps are brought over the tapered distal portion of the afferent ileal segment. **B:** Completion of the posterior suture line covering the afferent segment with the ileal flaps. Note: This will exclude the staple line from the reservoir.

**FIGURE 89.11** The T-pouch is folded (*arrows*) and closed in the opposite direction to which it was opened. This manner of folding will create a low-pressure, large-capacity spherical reservoir.

right side to allow insertion of an index finger. This is the most mobile and dependent portion of the reservoir and will later be anastomosed to the urethra.

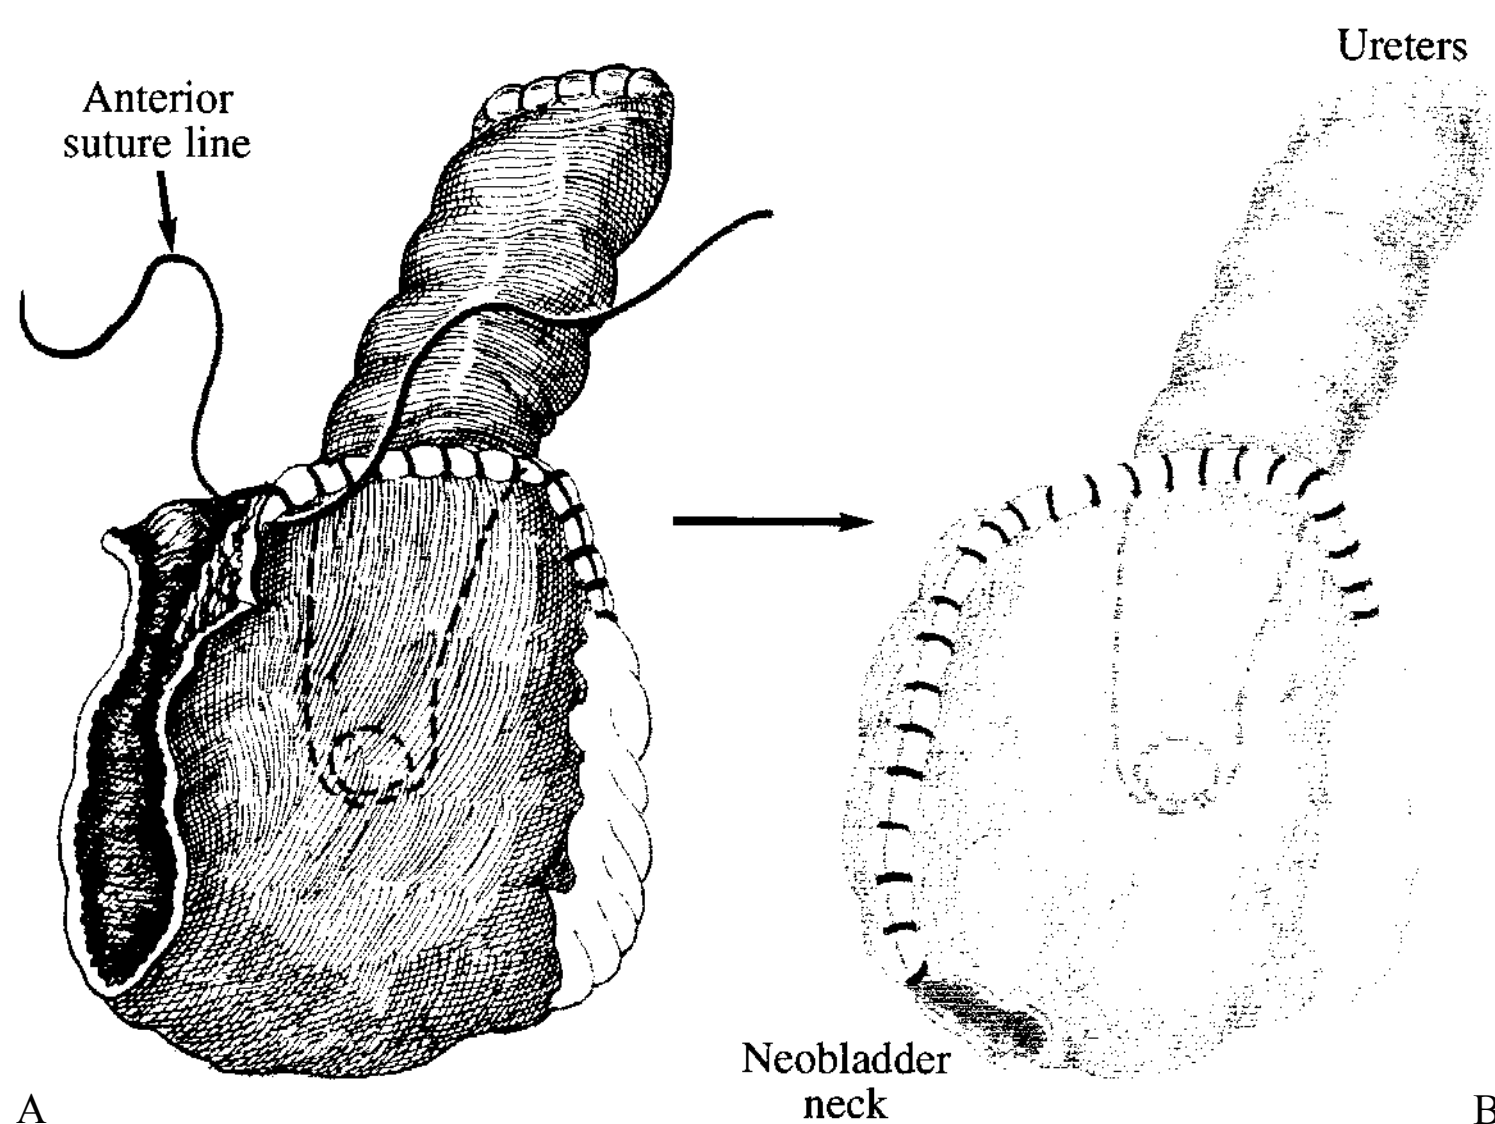

Once the pouch has been closed, each ureter is spatulated and a standard, bilateral end-to-side ureteroileal anastomosis is performed to the proximal portion of the afferent limb using interrupted 4-0 polyglycolic acid suture. These anastomoses are stented with no. 8 infant feeding tubes that are directed from the ipsilateral renal pelvis (kidney), across the ureteroileal anastomosis through the afferent limb into the reservoir and out the neourethra. A 24Fr hematuria catheter is placed per urethra to provide adequate drainage of the

reservoir, and the ureteral stents are secured to the end of the urethral catheter with a 3-0 nylon suture. This step facilitates removal of the stents at approximately 3 weeks along with the urethral catheter. A tension-free mucosa-to-mucosa urethroileal anastomosis is performed.

## OUTCOME AND COMPLICATIONS

From November 1996 through May 2000, 209 patients (169 men [79%], 40 women), with a mean age of 69 years (range, 33 to 93 years) underwent an orthotopic T-pouch ileal neobladder following cystectomy (11). The indication for cystectomy included bladder cancer in 198 patients (95%). The median follow-up for the entire cohort is 33 months (range, 0 to 69 months). Data were analyzed according to perioperative mortality, early (within 3 months) and late diversion-related and diversion-unrelated complications, radiographic evaluation of the upper urinary tract and urinary reservoir, and determination of renal function.

Three patients (1.4%) died during the perioperative period. A total of 63 (30%) early complications occurred, including 53 (25%) diversion-unrelated and 10 (5%) diversion-related. The most common early diversion-unrelated complication was dehydration (10 patients). The most common early diversion-related complication was urine leak in 6 patients. There were no early complications directly related to the antirefluxing T-limb. Late complications occurred in a total of 66 (31%) patients, including 30 (14%) diversion-unrelated and 38 (17%) diversion-related. The most common late diversion-unrelated complication was incisional hernia in 16 patients. Of the 38 late diversion-related complications, the most common were pouch calculi in 17 patients and ureteroileal obstruction in 9 patients. The only late complication directly related to the T-limb was afferent ostial stenosis seen in 4 patients, 3 of whom received adjuvant pelvic radiation.

**FIGURE 89.12** **A:** The anterior suture line is completed with two layers of a continuous 3-0 polyglycolic acid suture. Note that the anterior suture line is stopped just short of the right side to allow insertion of an index finger, which will be the neourethra. **B:** Completion of the T-pouch. Note that the most mobile and dependent portion of the reservoir will be anastomosed to the urethra following the ureteroileal anastomosis to the proximal portion of the afferent limb.

A total of 181 patients had radiographic evaluation of the upper urinary tract, including 162 (90%) with a normal radiographic study or evidence of decompression postoperatively. An abnormal upper-tract study was seen in 18 patients (10%), including 9 patients with ureteroileal obstruction and 4 with afferent T-limb stenosis. Gravity cystography of the neobladder was normal in 143 of 158 (90%) evaluable patients. Reflux was seen in 15 patients (10%). Renal function as determined by serum creatinine was stable or improved in 96% of patients.

Good daytime and nighttime continence was reported in 87% and 72% of evaluable patients, respectively. Overall, 75% of patients completely voided, while 25% required some form of intermittent catheterization to completely empty their neobladder, including 20% of men and 43% of women.

---

## DISCUSSION

---

The development of orthotopic reconstruction was a significant improvement in the evolution of urinary diversion. The importance of preventing the reflux of urinary constituents following orthotopic reconstruction is a controversial subject and remains a topic of significant debate. The authors have been, and continue to be, strong proponents of reflux prevention in patients undergoing lower-urinary-tract reconstruction. It is emphasized that the complications or risks associated with incorporating an antireflux mechanism (i.e., obstruction) should not outweigh the theoretical advantage of reflux prevention. To meet this end, we have been diligent to critically evaluate our antireflux techniques and continually improve upon existing ideas and methods. This evaluation process has subsequently stimulated a change from the intussuscepted nipple of the Kock pouch to the development of the flap-valve T-mechanism, incorporated as an antireflux limb in the orthotopic T-pouch ileal neobladder as well as a rectal reservoir (9,11). This technique provides an effective antireflux mechanism without the complications associated with the intussuscepted nipple. Furthermore, the T-mechanism has been successfully applied as a catheterizable continent mechanism in cutaneous reservoirs, as discussed elsewhere (10).

Many antireflux techniques exist today. The inclusion of an antireflux mechanism in the chronically infected, continent cutaneous reservoir (requiring intermittent catheterization) is still thought to be important and not a source of considerable debate. With increasing popularity and further application of the low-pressure orthotopic reservoir, the issue of reflux prevention has regained attention. Studer and associates (12) advocate a long (20-cm), dynamic, isoperistaltic ileal segment as an afferent limb of an orthotopic neobladder reservoir. Proponents of the isoperistaltic afferent ileal limb argue that radiographic evidence of reflux in a sterile, low-pressure reservoir may not have the same importance and clinical consequence. Furthermore, the complications of late stenosis from the various antireflux techniques could potentially outweigh their theoretical advantage of protecting the upper urinary tract. Others, however, argue that antireflux procedures are not only theoretically inherent in humans but are also critical to preserve or maintain renal function and important in all forms of lower-urinary-tract reconstruction, even orthotopic diversion. Reasons include the fact that patients, even with an orthotopic neobladder, may have colonized bacteriuria. The

unexpected patient who requires intermittent catheterization to completely empty the neobladder (which is unpredictable) can also be expected to have colonized bacteriuria with the risk of upper-tract deterioration.

Reflux prevention following orthotopic diversion may become more important as the comprehensive therapy (medical and surgical) for pelvic malignancies improves and patients' life expectancy increases following exenteration and urinary diversion. This may then place patients at further risk for renal deterioration in the future. Subsequently, several novel antireflux mechanisms have been developed to improve on existing techniques and to eliminate or reduce the complications associated with previous antireflux mechanisms, particularly obstruction (9,11). Longer follow-up will be required to accurately evaluate the isoperistaltic afferent limb, as well as these more recent antireflux techniques, to determine if reflux prevention in patients undergoing orthotopic diversion is truly necessary.

From 1982 to 1997, we incorporated the intussuscepted nipple valve as an antireflux mechanism in all forms of continent urinary diversion at USC and as an efferent continence mechanism in patients undergoing a cutaneous Kock ileal reservoir (4,5,7). The basic surgical premise and structural characteristics of the Kock ileal reservoir are sound: a low-pressure, large-capacity reservoir, employing an antirefluxing and continent nipple valve. The Achilles heel of the Kock ileal reservoir, however, remained the intussuscepted nipple valve. Despite several surgical modifications to improve upon the construction of the intussuscepted nipple valve, there remained complications and a reoperation rate (8). The intussuscepted nipple valve needed to be improved.

The so-called T-mechanism is a flap-valve technique that can be applied as an antireflux and continence mechanism in lower-urinary-tract reconstruction (9–11). In general, all flap-valve techniques rely on the dynamic principle that the channeled segment (appendix, ureter, intestine) is fixed and tunneled along the inner wall of the reservoir. As reservoir filling occurs, the channeled segment is compressed against the wall of the pouch and continence or reflux prevention is achieved. This technique is based on similar principles for reimplantation of the ureter into the bladder. Keys to success of the flap-valve technique include an appropriate ratio of tunnel length to lumen diameter. Furthermore, the back wall of the reservoir must be sufficiently capable to allow compression of the tunneled channel as the pouch fills.

The unique aspect of the T-mechanism (antireflux and continence) is the ability to create a reliable and effective flap-valve system. Maintenance of the vascular arcades (opening the windows of Deaver) provides complete preservation of the mesentery and blood supply to the entire limb, thus eliminating problems with ischemia or stenosis of the bowel segment. Permanent fixation of the limb into the serous-lined ileal trough should also eliminate issues associated with prolapse or extussusception of the limb. Importantly, no exposed metallic staples exist within the reservoir, which should reduce the incidence of stone formation, typically associated with exposure of metallic foreign bodies to urine. Furthermore, if necessary, the proximal portion of the afferent limb can be easily lengthened when there is shortened or compromised ureters. A longer proximal afferent segment may be harvested to bridge any ureteral defect and maintain a tension-free ureteroileal anastomosis.

Several technical points regarding the specifics of the construction of the flap-valve T-mechanism (antireflux, continence) deserve mentioning. An effective afferent antireflux valve can be created from 4 cm of ileum anchored within the serous-lined ileal trough. Permanently anchoring the portion of ileum in the serous-lined ileal trough is critical to fix the limb and prevent any valve slippage or prolapse. In addition, the silk sutures used to anchor the valve (passed through the windows of Deaver) should be placed adjacent to the mesentery and should incorporate a generous portion of the seromuscular ileum to prevent separation of the serous-lined ileal trough. This trough forms the so-called “backboard” (posterior wall to the reservoir) of the flap-valve technique, which is critical to antireflux prevention as the reservoir fills. Placement of two to three sutures within each window of Deaver should prevent separation of this trough.

The antimesenteric tapering of the valve was initially described and performed on all patients with this technique. Tapering the afferent limb over a 30Fr catheter was effective in preventing reflux of urinary constituents and in protecting the upper tracts in patients undergoing an orthotopic T-pouch

ileal neobladder (11). This effectively increases the ratio of the tunnel length to the lumen diameter and has provided an excellent efferent continence mechanism. However, several patients (2%) with longer follow-up developed some narrowing of the ostium and even stenosis that may be attributed to either some postoperative radiation to the reservoir or possibly to the antimesenteric tapering. We subsequently tapered the T-limb only in those patients with a large ileal diameter and have found that it does not appear to compromise the antireflux mechanism; to date, we have not observed any further issues with stenosis of the afferent limb.

The flap-valve T-mechanism in the T-pouch provides an effective and reliable antireflux mechanism. The long-term results of the T-pouch are yet to be determined; however, the initial and intermediate results have been promising. Furthermore, we believe that this technique can be easily learned with a little experience. The T-mechanism is a very versatile flap-valve technique that can also be applied as a continent mechanism in a cutaneous reservoir (double-T-pouch). We believe that reconstructive surgeons interested in lower-urinary-tract reconstruction should understand this concept and technique to broaden their surgical armamentarium.

## CHAPTER 90 ■ COLONIC ORTHOTOPIC BLADDER SUBSTITUTION

JOACHIM W. THÜROFF AND LUDGER FRANZARING

Orthotopic bladder substitution can be realized from ileum only or from colonic segments either alone or in combination with small bowel segments as a composite reservoir. The rationale of using large bowel for urinary diversion is based on anatomical and functional considerations. Surgical creation of

a urinary reservoir from bowel segments generally means transformation of a cylinder into a sphere. The length of bowel to be excluded from the intestinal tract for formation of a reservoir of a given capacity depends only on bowel diameter. Since in the volume formula of a cylinder ( $V = \pi r^2 \cdot l$ ) the

radius determines the volume by its second power, the wider the bowel diameter, the less the bowel length required. Thus, large bowel with its wider diameter can contribute a significant capacity to a continent reservoir while excluding only a short length of a functional segment.

Physiologically, fat-soluble vitamins such as vitamin B12 and folic acid as well as biliary acids are absorbed from the entire ileum, but not from colon. Consequently, possible malabsorption syndromes are related only to resection of ileum but not to colon resection. The critical length of ileum resection is >40 cm, at which the risk of secondary malabsorption syndromes starts to increase. These facts should influence choice of bowel segments for reservoir formation in favor of reducing the length of ileum segments for a composite reservoir or of avoiding ileum entirely in an all-colon reservoir.

However, the large bowel is less distensible than small bowel. Although at first this may be regarded as a disadvantage, it may be advantageous, specifically for spontaneous evacuation of an orthotopic bladder substitute in the long run. Intestinal urinary reservoirs start their life at a surgically determined volume that increases over time by gradual distention. During this process, large bowel segments have the advantage that the longitudinal arrangement of taeniae prevents the development of a decompensated substitute megacystis as has been described for ileum reservoirs. In addition, large bowel segments, especially cecum and ascending colon, offer several alternatives for safe and effective antirefluxive ureteral implantation.

The downsides of using large bowel for creation of an orthotopic reservoir have to be weighed against the advantages of large capacity, less malabsorption, less overdistention, and reliable antireflux techniques.

First, many urologic surgeons are not familiar with large bowel surgery and feel uncomfortable with it, specifically when mobilizing the large bowel and performing the bowel anastomosis after resection of the segments for the urinary reservoir. However, generous mobilization of segments as well as rotation of segments may be required to allow a tension-free transposition as an orthotopic reservoir in patients with a deep true pelvis. Surgical techniques using large bowel may also be more time-consuming because adhesions with the greater omentum have to be freed and the bowel anastomosis after exclusion of the segments for urinary diversion has a significantly larger circumference to be sutured than in a small bowel anastomosis.

Finally, the use of large bowel segments may have functional sequelae as well. All reservoirs that use the ileocecal segment and thus require resection of the ileocecal valve may allow retrograde colonization of the ileum if the ileocecal valve is not reconstructed by an antirefluxing technique of the ileoascendostomy anastomosis.

The different techniques of constructing an orthotopic reservoir, either from large bowel only or in combination with small bowel segments as a composite reservoir, refer to the very same principles of continent urinary diversion: detubularization and spherical reconfiguration. Thus, the success of orthotopic bladder substitution is not confined to selection of small bowel segments; good results have been reported with the ileocecal segment, the right colon, and the sigmoid colon. However, in general, large bowel segments have physiologically decreasing capacity and compliance from proximally to distally, while wall tension and pressure are increasing at the

same time. This translates into higher capacity and lower pressure of the cecum and ascending colon as compared to the descending and sigmoid colon. The surgical technique of the Mainz ileocecal pouch as described following in detail may in this context serve as a general example of construction of an ileocolonic composite pouch.

However, one single technique of continent urinary diversion does not fit all patients and all pathologies. Thus, modern concepts of intestinal urinary diversion require surgical versatility instead of stereotypic repetition of fixed surgical strategies.

---

## DIAGNOSIS

---

The scope of diagnostic studies is determined by the underlying disease because of which the native bladder has to be substituted. For continent urinary diversion as compared to incontinent diversion, the most important assessment is renal morphology and function. Grossly dilated upper urinary tracts may not drain as well into a continent urinary reservoir as into a conventional zero-pressure conduit diversion. Every intestinal urinary reservoir reabsorbs hydrogen and chloride ions. The resulting metabolic acidosis is generally balanced by respiratory compensation and by an increased renal secretion. As a consequence, renal reserve must be sufficient as judged by a glomerular filtration rate better than a minimum of 50% of the age-related normal global renal function.

The intestinal tract must be evaluated in order to avoid surgical or postoperative problems. Concerning patient history, special attention must be paid to inflammatory bowel disease, prior abdominal surgery or radiation, and related abnormalities of stool and defecation. When large bowel segments are used for continent diversion, contrast enema or colonoscopy are mandatory to exclude asymptomatic diverticulosis or tumors of the large bowel.

---

## INDICATIONS FOR SURGERY

---

The indications for a colonic orthotopic bladder substitute or a composite reservoir of ileum and colon are not different from those for ileal orthotopic bladder substitution. However, in patients with neurogenic bowel and anal sphincter incompetence, any change in stool consistency secondary to bowel resection bears the risk of worsening pre-existing anal incontinence. Another aspect of all forms of orthotopic bladder substitution, specifically in women, is the risk of urinary retention requiring emptying of the reservoir by intermittent catheterization. Thus, the willingness and ability to perform intermittent self-catheterization have to be determined and possibly practiced preoperatively. This is of special importance in women, patients with neurogenic bladder, and children. Generally, children can perform intermittent self-catheterization of the urethra from about 6 years of age.

---

## ALTERNATIVE THERAPY

---

Alternatives to orthotopic bladder substitution with colonic segments are orthotopic ileal neobladders. Alternatives to continent orthotopic bladder substitution are continent cutaneous

urinary diversion (e.g., Mainz Pouch I, Indiana Pouch) or continent anal urinary diversion (Mainz Pouch II). Alternatives to continent urinary diversion are incontinent conduit diversions (ileal conduit, sigmoid conduit, transverse colonic conduit).

---

## SURGICAL TECHNIQUE

---

The day before surgery the bowel is cleansed either by oral administration with 4 to 6 L of a hyperosmotic nonabsorbable solution (e.g., macrogol) or by irrigation with 8 to 10 L of isotonic saline with a total of 50 mval of potassium chloride added through a nasogastric tube. After irrigation, serum electrolyte concentrations have to be checked and, if necessary, intravenously substituted.

During surgery, the small and large bowel segments that have been excluded for construction of the intestinal urinary reservoir are intubated with a Foley catheter and antegradely flushed with saline until the irrigation fluid turns out clear before they are opened antimesenterically. Perioperative parenteral antibiotic therapy with broad-spectrum antibiotics should include antianaerobic activity. The antibiotics are administered 1 hour before surgery and continued until the fifth to seventh postoperative day.

The patient is positioned supine on the operating table. Radical cystoprostatectomy should adhere to the same principles as radical prostatectomy: that is, to preserve maximum urethral length and, if possible and indicated, to preserve the neurovascular bundles.

For ileocecal orthotopic bladder substitution, the cecum and ascending colon are mobilized beyond the right colonic flexure. Extended mobilization is helpful for later sliding the pouch easily into the small pelvis.

Ten to 15 cm of cecum and ascending colon and about 20 to 30 cm of distal ileum are marked by stay sutures and isolated from bowel continuity. An ileoascendostomy is accomplished either as a sutured single-row, dual-layer (seromuscularis), running end-to-end anastomosis after antimesenteric spatulation of the ileum for adjustment of bowel diameter or as stapled mechanical end-to-side anastomosis of ileum to ascending colon using EEA and TA-55 staplers. The isolated ileocecal segment is intraoperatively irrigated with isotonic saline for further cleansing.

Ascending colon, cecum, and ileum are split open at their antimesenteric borders. The posterior wall of the pouch is completed by side-to-side anastomosis of the ascending colon with the terminal ileal loop and of the latter with the next proximal segment. The anastomosis is performed by single-row, all-layer running sutures of 4-0 polydioxanone with a straight needle. The still open pouch is slid into the small pelvis. For bladder substitution to the bladder neck (benign disease), the pouch is anastomosed with the posterior bladder wall using single-row, all-layer running sutures of 4-0 polydioxanone. For bladder substitution to the urethra after cystectomy, a small vertical buttonhole incision is made at the lowest aspect of the cecal pole and the opened mucosa is everted with a few 5-0 absorbable stitches before anastomosis to the membranous urethra is performed by eight interrupted sutures of 4-0 glykonat (Fig. 90.1). Alternatively, the ileocecal pouch may be created by using GIA staplers with reabsorbable staples (Fig. 90.2).

The ileocecal segments may also be used for creating an orthotopic pouch in the “Le Bag” technique (Fig. 90.3). The right colonic pouch is constructed from cecum and ascending colon (Fig. 90.4). The blood supply of ileocecal reservoirs is based on the ileocolic artery, which always allows tension-free anastomosis to the urethra, specifically if a 180-degree counterclockwise rotation of the pouch around the “insertion” of the ileocolic vessels is performed. In right colonic pouches, with additional blood supply from the right colonic artery, reaching down to the urethral stump may sometimes be more difficult. The blood supply of the sigmoid colon is from the inferior mesenteric and superior rectal arteries (Fig. 90.5). Sigmoid reservoirs thus always easily reach down to the urethral stump (Fig. 90.6).

---

## Ureteral Implantation

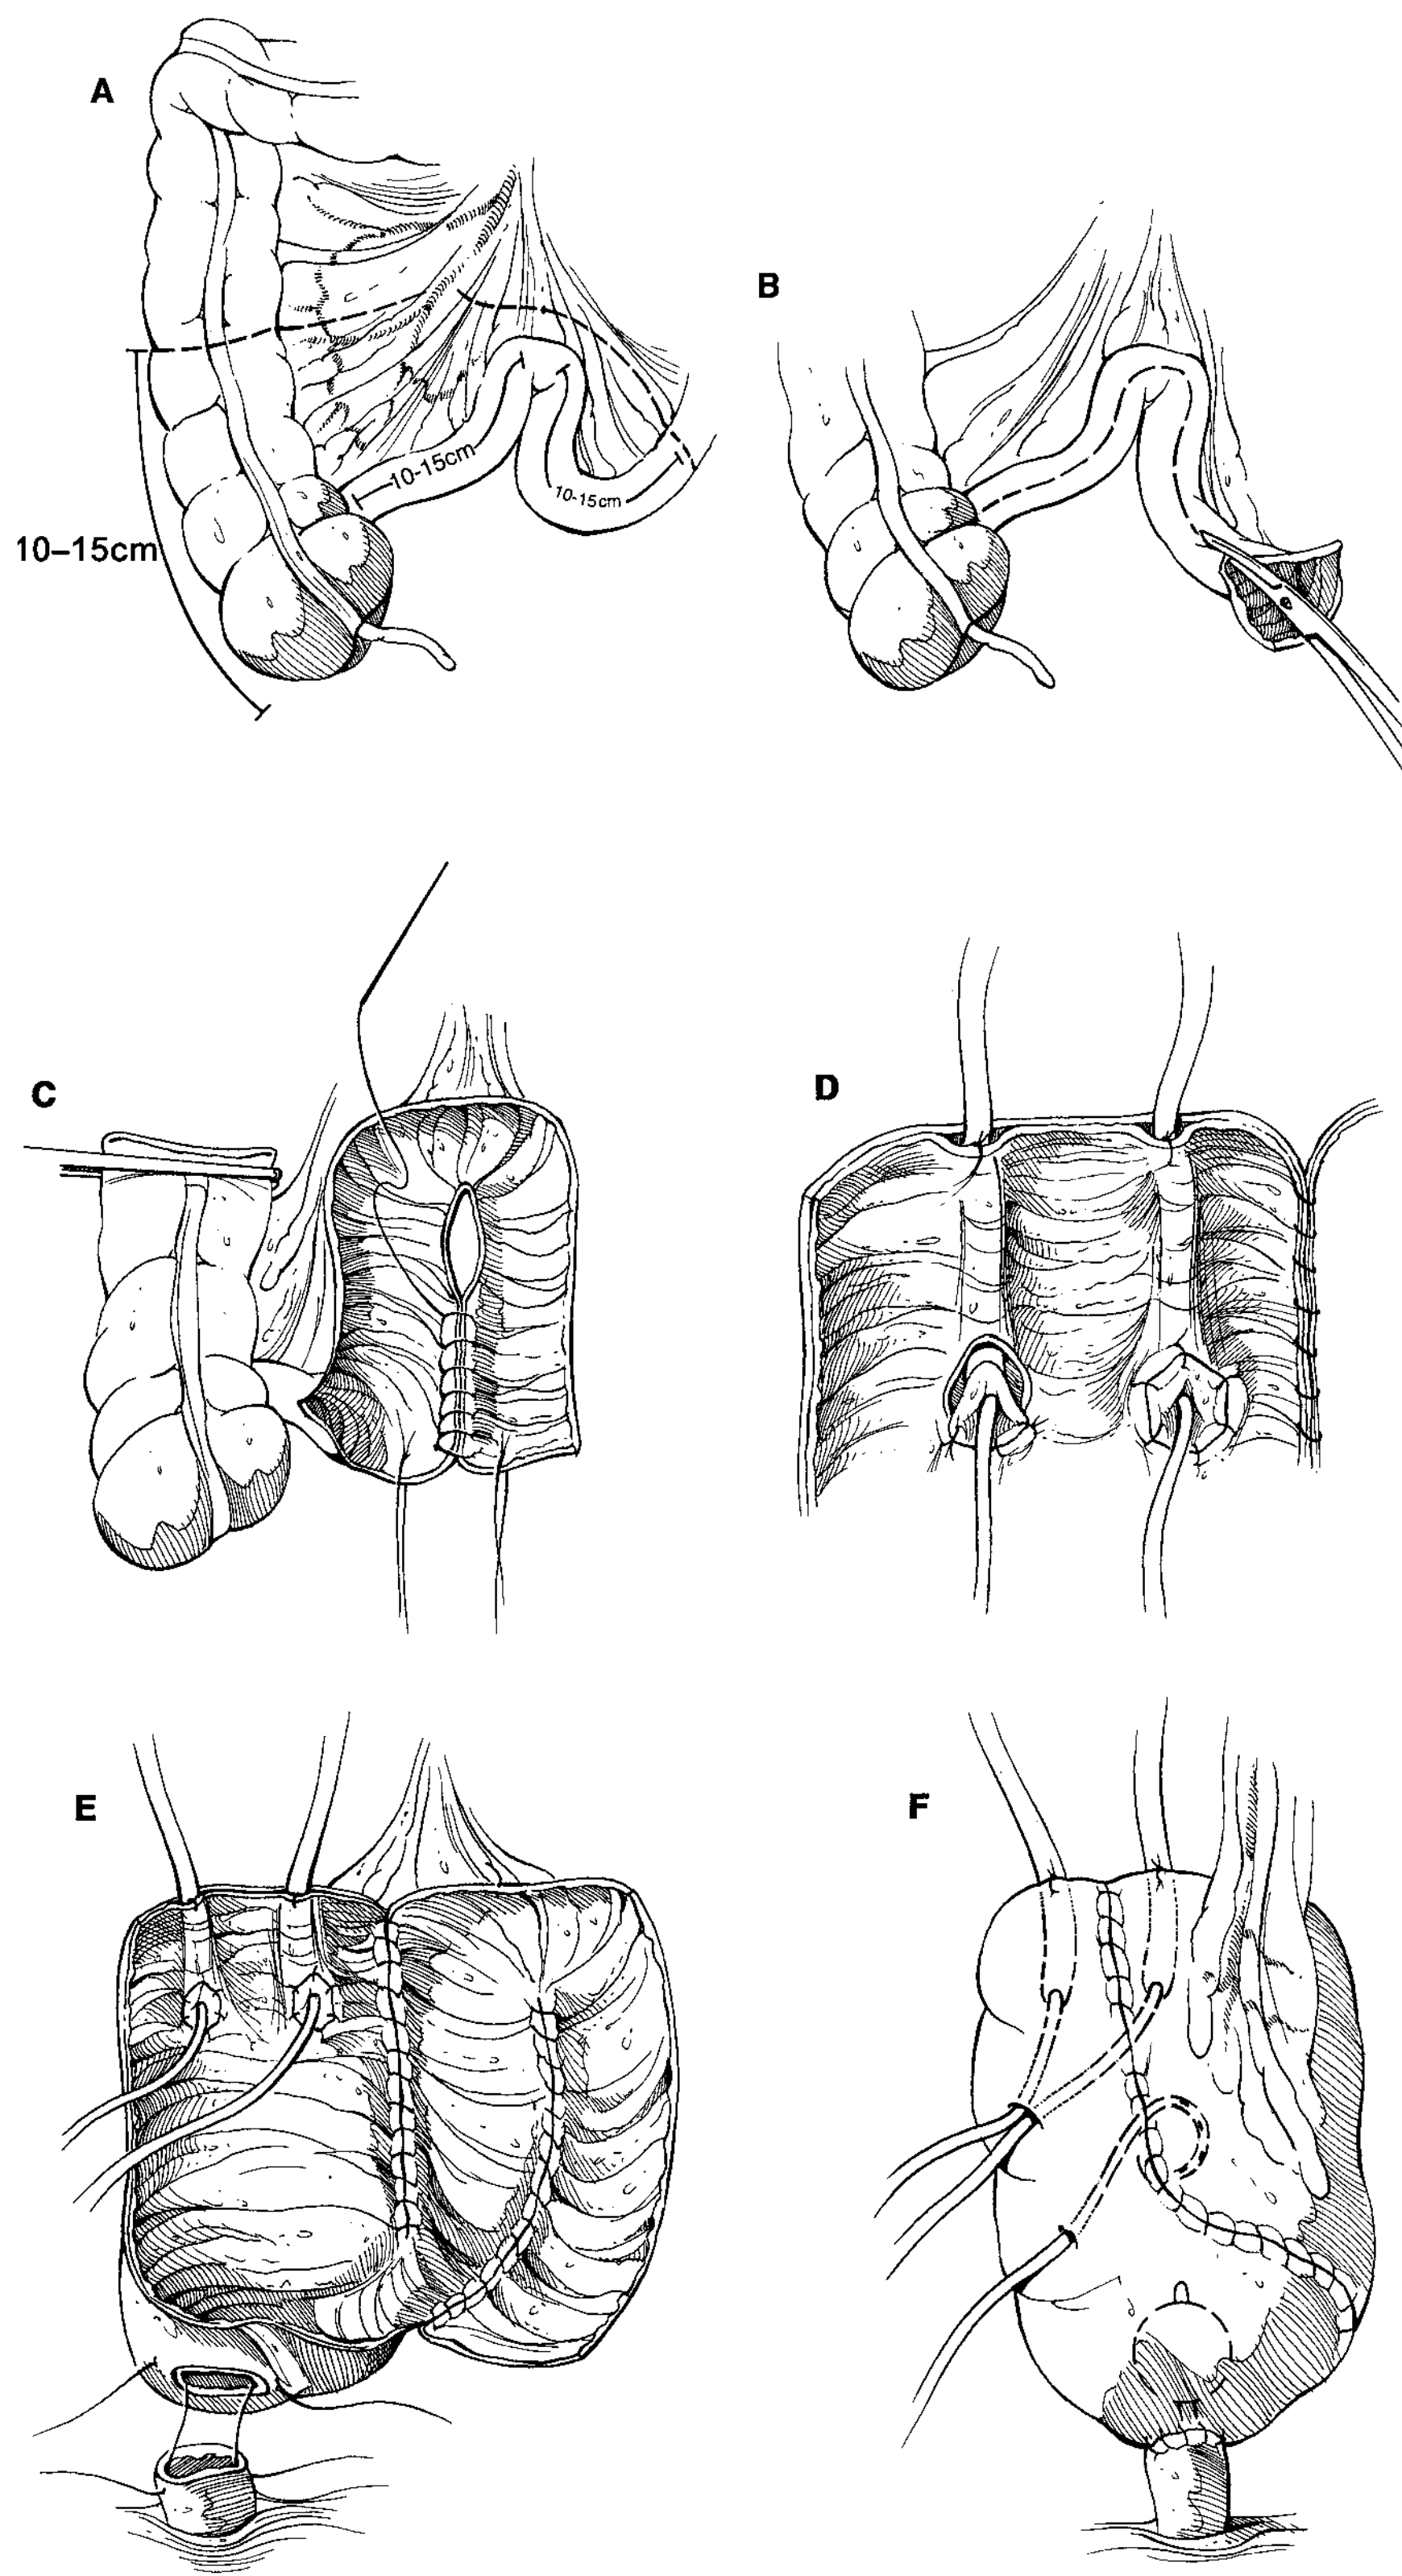

---

A variety of techniques reflects the surgical challenge to create an antireflux mechanism without obstruction of the ureter. This challenge may be heightened by a number of pathological conditions in the individual patient. Ureters may be dilated, fibrotic, or ischemic secondary to obstruction, previous surgery, or irradiation. Bowel segments may be altered from inflammation, dilatation, or ischemia secondary to inflammatory bowel disease, previous surgery, or irradiation. Mechanical factors (e.g., position changes of the reservoir) or biochemical factors (e.g., effects of urine on the ureteral adventitia or on the intestinal mucosa) may have long-term effects on the whole system.

The rationale of implanting the ureters by an antirefluxive technique into an orthotopic bladder substitute is to protect the upper urinary tracts from retrogradely transmitted pressure peaks and from ascending bacteriuria. However, the standard technique of antirefluxive ureteral implantation into large bowel was conceived from ureterosigmoidostomy, which means diverting urine into a high-pressure reservoir. The debate about the necessity of antirefluxive ureteral implantation into orthotopic low-pressure reservoirs is still not concluded. One argument is that, in contrast to most forms of continent cutaneous diversion, orthotopic reservoirs have the pop-off valve of urethral incontinence when overfilled. Another argument is a supposedly lower bacterial contamination rate as compared to reservoirs that require intermittent catheterization. Nevertheless, antirefluxive ureterointestinal reimplantation is still the method of choice for colonic reservoirs. A variety of surgical techniques is based on different antireflux mechanisms, which have been described, although two general types exist. In one type, the ureter itself is part of the antireflux mechanism, while in the other a bowel-derived antireflux mechanism is interposed between ureter and reservoir.

In any case, for implantation of the ureters into cecum or ascending colon, the left ureter has to be brought into the right retroperitoneum behind the mesentery of the descending colon as for ileal conduit diversion.

Antirefluxive ureteral implantation techniques in which the ureter becomes part of the antireflux mechanism mostly follow the “flap-valve” principle: An oblique entry of the ureter into the reservoir is created with a “tunnel” course that allows transmission of the reservoir pressure onto the ureter and against the seromuscularis of the reservoir. This pressure transmission passively compresses the ureter with rising reservoir pressures. The most frequently utilized principles to

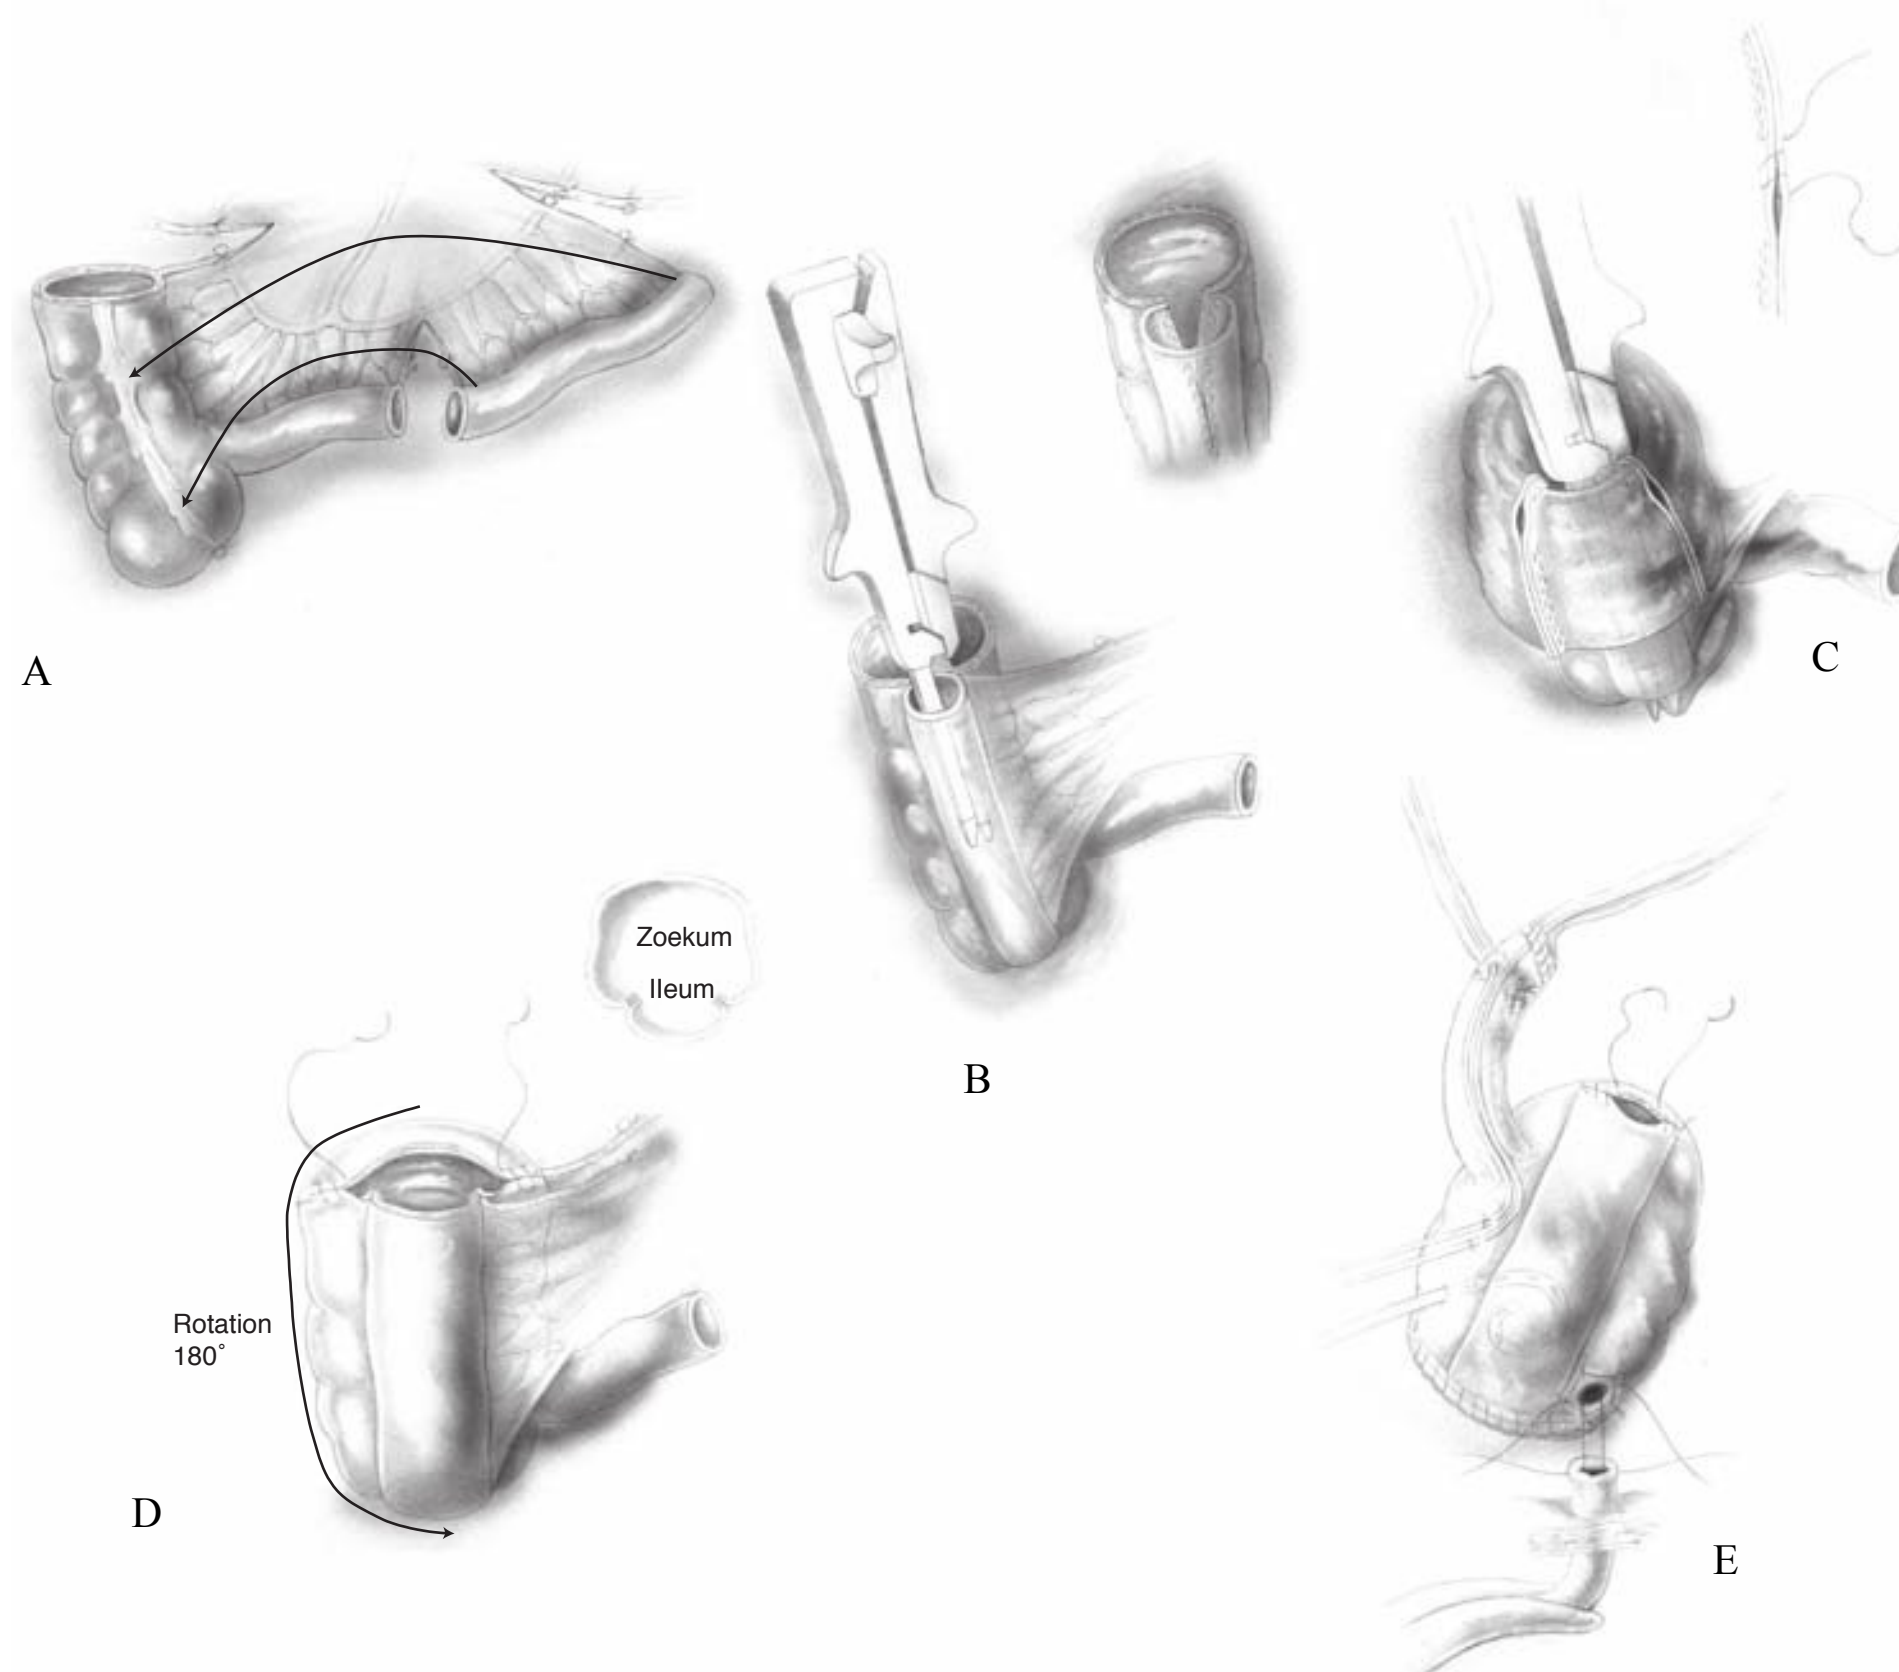

**FIGURE 90.1** Construction of the Mainz ileocecal reservoir. **A:** Isolation of the ileocecal segment consisting of 20 to 30 cm of ileum and 10 to 15 cm of cecum and ascending colon. **B:** Antimesenteric opening of the intestinal segments. **C:** Detubularization and reconfiguration of the ileal segment. Note: The ileocecal valve may be left intact. **D:** Submucosal tunnel implantation of the ureters in “open-end” technique into the colonic segment. The term *open end* describes the ureters entering the submucosal tunnel from the resection margin. **E:** Completion of the posterior wall of the pouch by anastomosing the medial margin of the colonic segment to the right margin of the ileal plate. The lowest part of the pouch is anastomosed to the urethra. **F:** Completion of the anterior wall of the pouch by anastomosing the lateral margin of the colonic segment to the left margin of the ileal plate. Drainage of the pouch is secured by a transurethral Foley catheter and a percutaneous pigtail pouchostomy catheter.

transmit the reservoir pressure to the ureter are the submucosal tunnel technique and the seromuscular extramural tunnel technique.

In the submucosal tunnel technique, both ureters are implanted into the colon with a 2- to 3-cm submucosal tunnel.

Ureters are anchored with 6-0 glykonat sutures to the muscularis of the bowel wall, and the neo-orifices are established by 6-0 glykonat or 7-0 polyglycolic acid ureteromucosal sutures.

The most common technique of interposition of an antirefluxive mechanism between the urinary reservoir and the ureters

**FIGURE 90.2** Construction of an ileocecal reservoir utilizing reabsorbable staples. **A:** Isolation of the ileocecal segment comprising 15 cm of large bowel with 10 cm of preterminal ileum and an additional 15 cm of ileum. **B:** Alignment of cecum or ascending colon and the separated segment of 15 cm of ileum and one-step antimesenteric opening and side-to-side anastomosis of the large bowel segment and the ileal segment, with the GIA-75 (Autosuture) stapler applying on either side two rows of polyglycolic absorbable staples (copolymer Lactomer). **C:** Eversion of the pouch wall and second stapler application (a third application in the very same way may be required). Gaps between the staple lines are closed with a running 4-0 polydioxanone suture (*insert*). Note: The 10-cm terminal preterminal ileum remains intact. **D:** The cranial aspect of the pouch is closed with a running seromuscular 4-0 polydioxanone suture. Then the pouch is rotated 180 degrees counterclockwise. **E:** At the most dependent aspect of the pouch, a vertical buttonhole incision is performed and the pouch is anastomosed to the urethral stump. The left ureter is pulled into the right retroperitoneum above the inferior mesenteric artery, and the ureters are anastomosed to the terminal ileum in an end-to-end (left ureter) and end-to-side (right ureter) technique.

is to take advantage of the antireflux function of the ileocecal valve. The cecum with the ileocecal valve is incorporated in the pouch, and the ureters are anastomosed in an end-to-side (Nesbit) or spatulated end-to-end (Wallace) technique to the terminal preterminal ileum. Thus, the flow of urine is directed from the ureters into the pouch through the ileocecal valve.

The ureters are intubated with 6Fr or 8Fr stents, and a 10Fr pouchostomy pigtail catheter and a 20Fr transurethral Foley balloon catheter are inserted into the reservoir. The closure of the anterior wall of the pouch is completed in the same way as described previously. However, at the site of a submucosal ureteral tunnel implantation, the pouch is closed by mucosal sutures only to prevent ureteral obstruction at the entry. A 20Fr gravity drain is placed each into the small pelvis and at the ureteral implantation site.

The ureteral stents are removed at day 10 and 11. The transurethral catheter is removed at day 12 when a pouchogram has ruled out extravasation. Residual urine is checked via the pouchostomy catheter when patients void spontaneously. The

pouchostomy catheter is removed at residual urine volumes <50 mL. In neurogenic cases, patients are instructed in intermittent catheterization.

---

## OUTCOMES

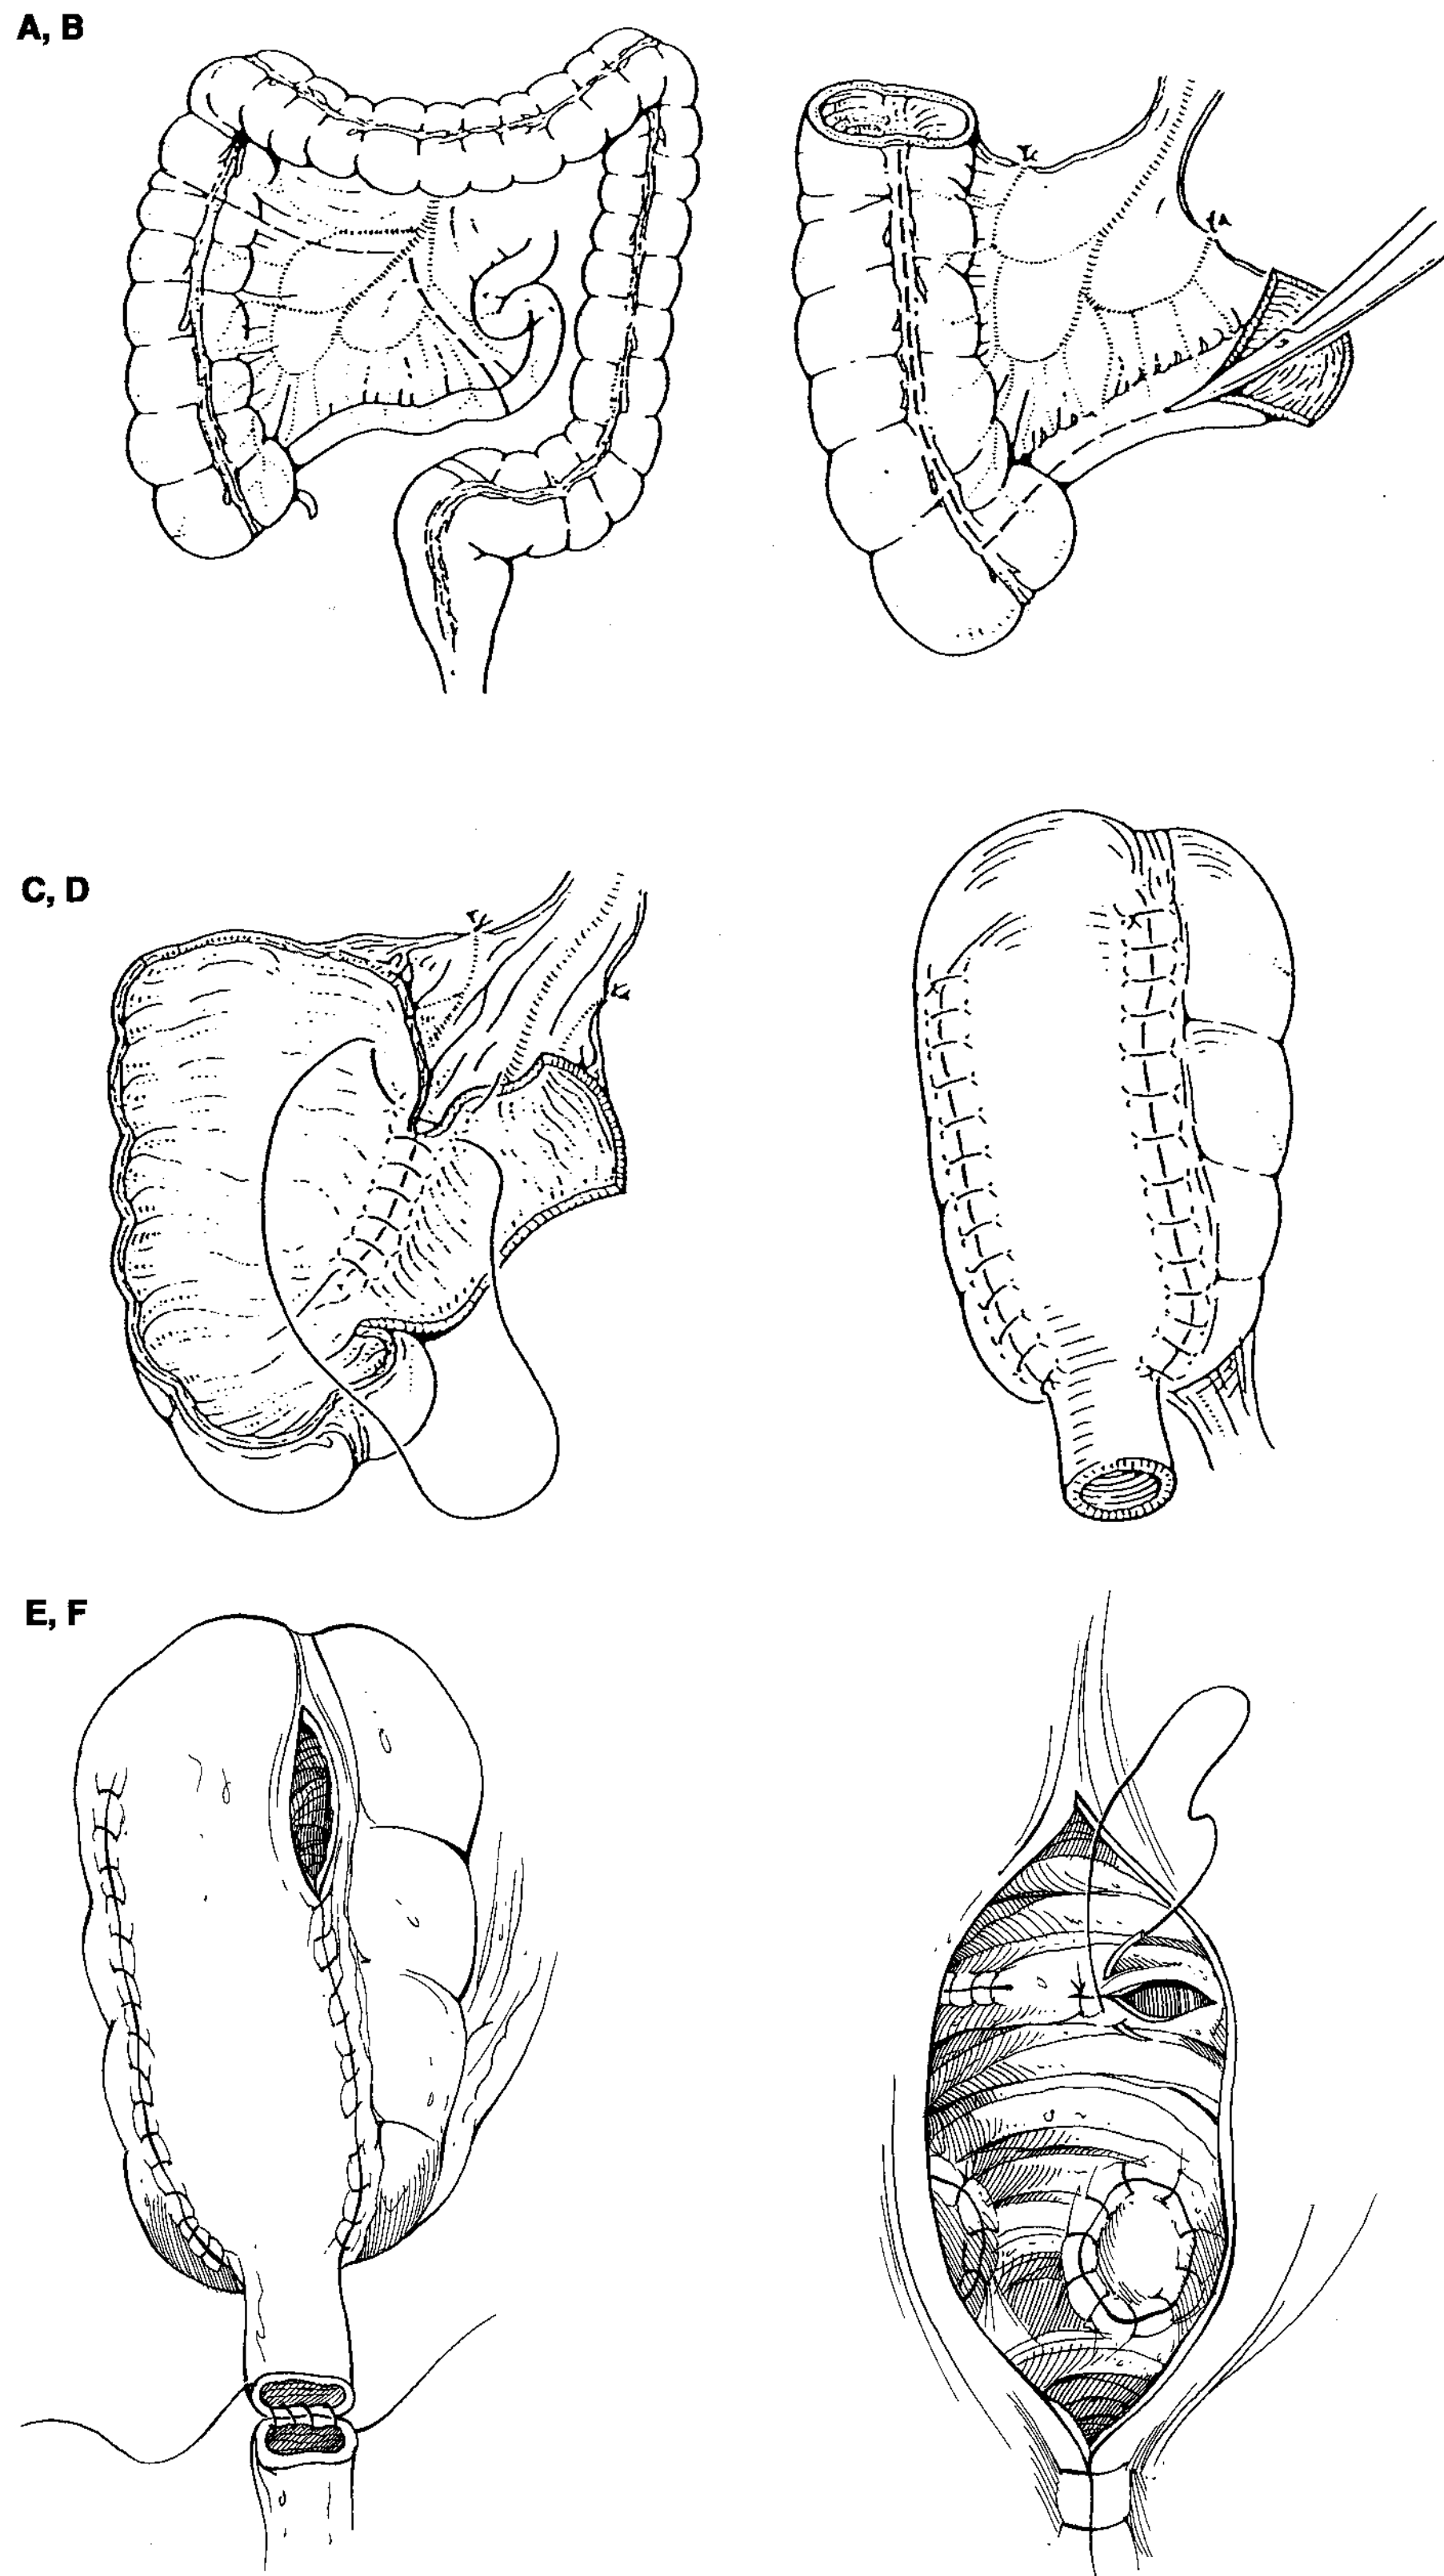

---

### Complications

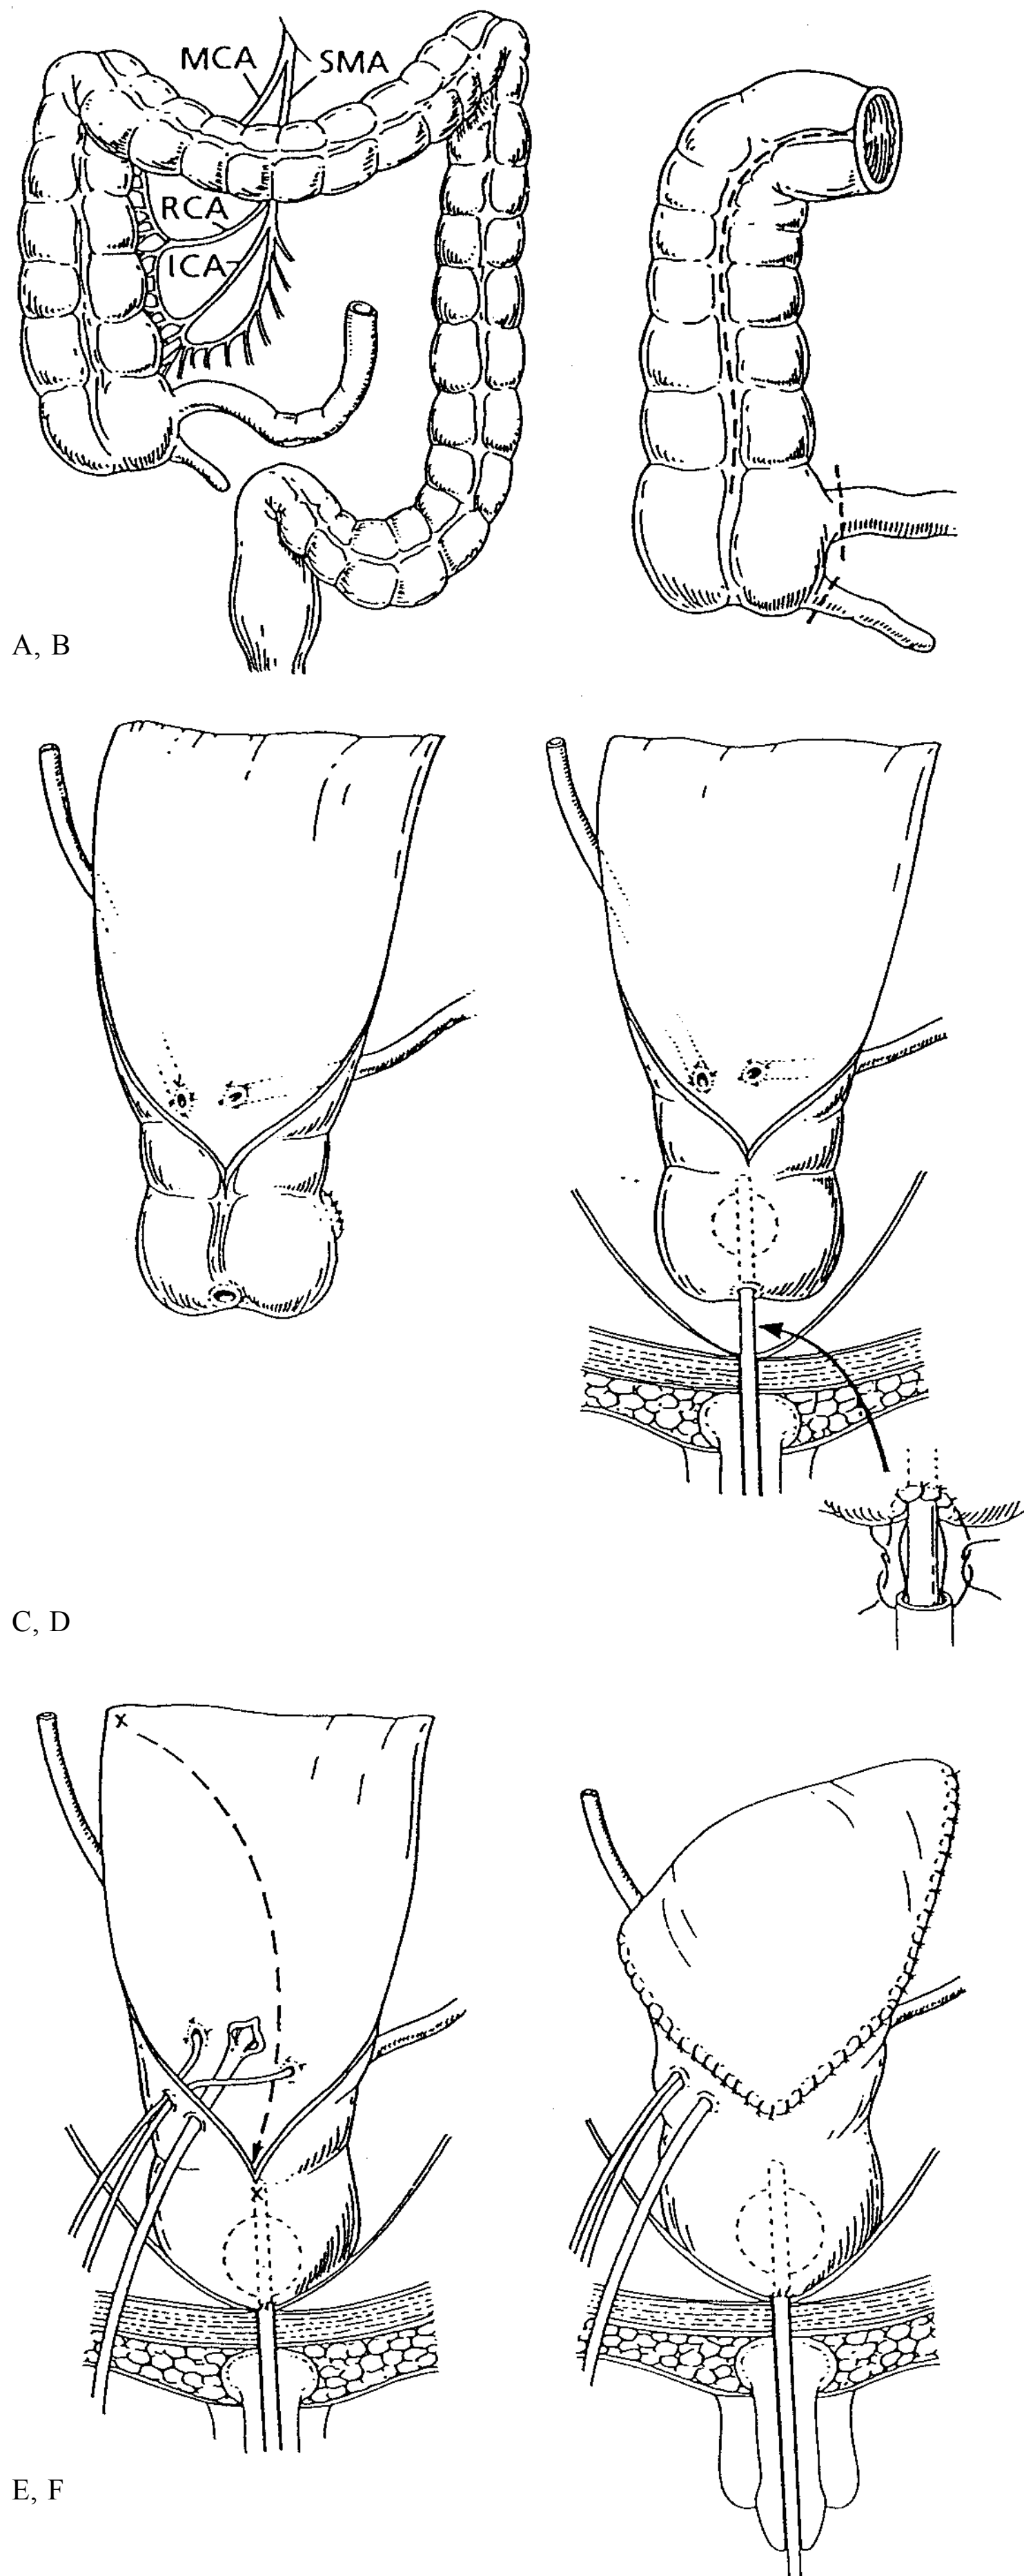

---

In the early postoperative months, nonperistaltic contractions of the bowel segments of a Mainz pouch do occur but subside spontaneously with increasing capacity of the pouch. For persistent inadequate compliance or persistent contractions of the pouch, antimuscarinics can be used for pharmacotherapy.

About 60% of patients postoperatively have an asymptomatic metabolic acidosis as judged by blood gas analysis (base excess below  $-2.5$ ), which is balanced prophylactically by oral alkali substitution (sodium/potassium citrate/bicarbonate).

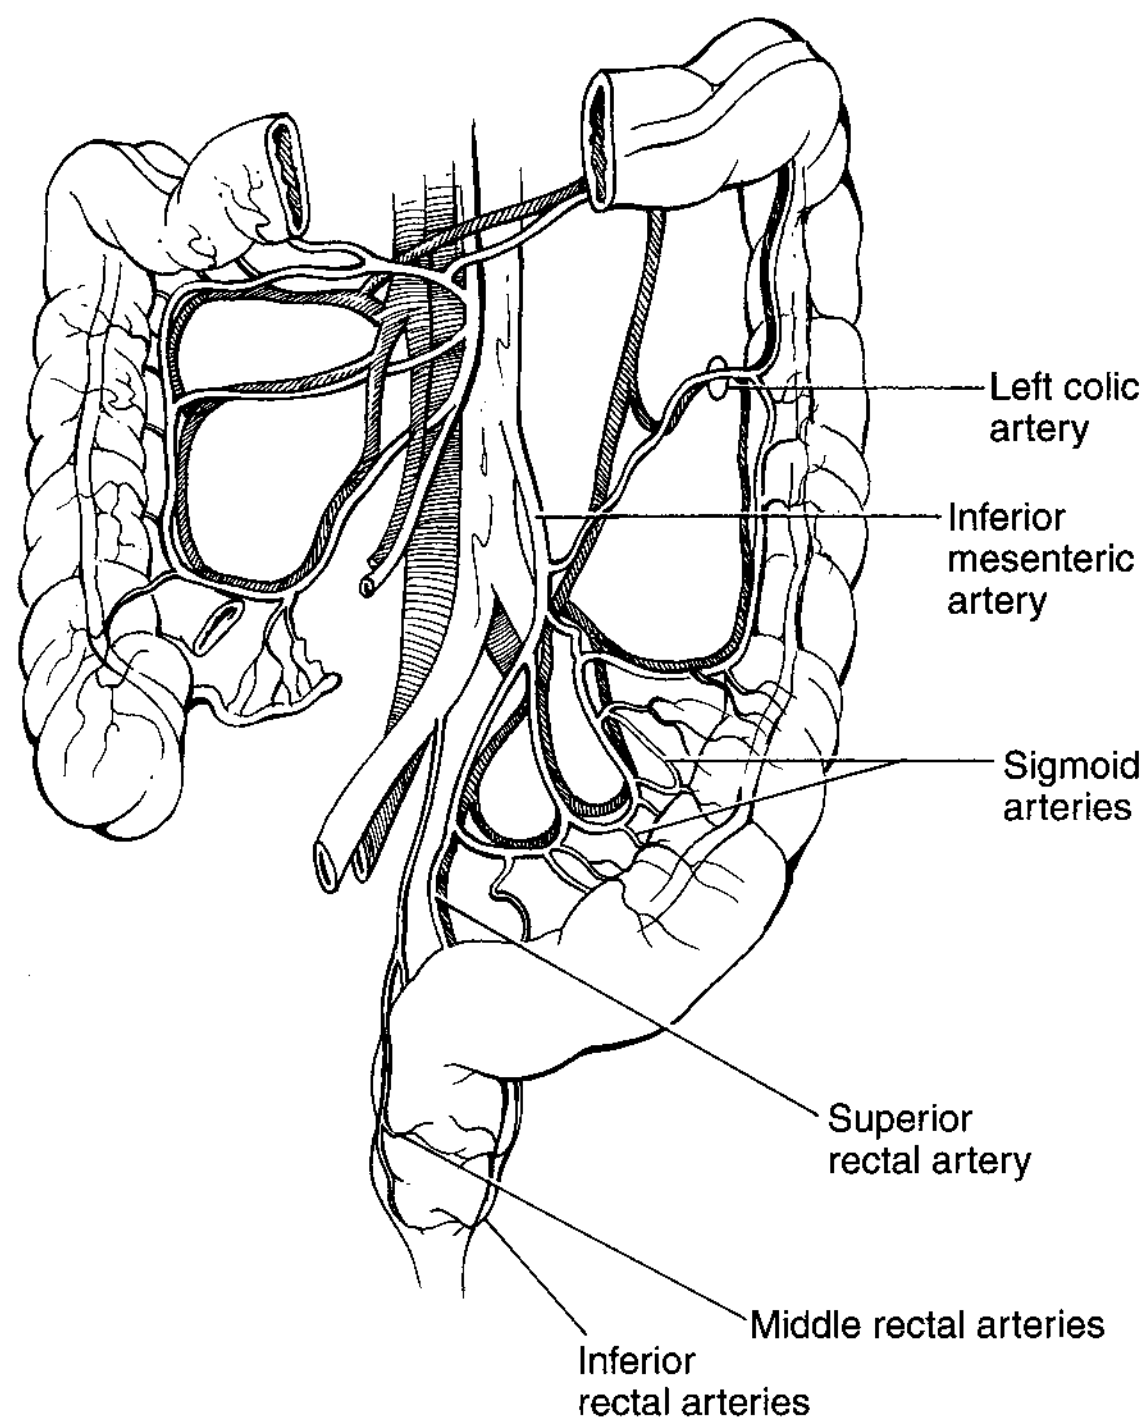

**FIGURE 90.3** “Le Bag” procedure. **A and B:** Isolation of the ileocecal segment and antimesenteric opening, leaving the oral end of the ileal segment intact. **C and D:** Detubularization and reconfiguration of the segments into a pouch. A 180-degree counterclockwise rotation brings the oral intact ileum segment down to the urethra. **E:** Ileourethral anastomosis with the oral end of the ileal segment. **F:** Antirefluxive submucosal tunnel ureter implantation through two separate incisions of the posterior pouch wall (buttonhole technique).

**FIGURE 90.4** Construction of a right colonic reservoir. **A and B:** Isolation of a colonic segment consisting of cecum, ascending colon, and the right colic flexure. **C and D:** Opening of the segment through the taenia libera, leaving the cecum intact and anastomosing it to the urethra. **E and F:** The ureters are anastomosed into the colonic segment utilizing the “buttonhole” submucosal implantation technique. This technique describes the ureters entering the submucosal tunnel via a buttonhole incision into the posterior wall of the pouch. Reconfiguration is completed by folding the open cranial segment over the caudal segment and anastomosing both lateral margins.

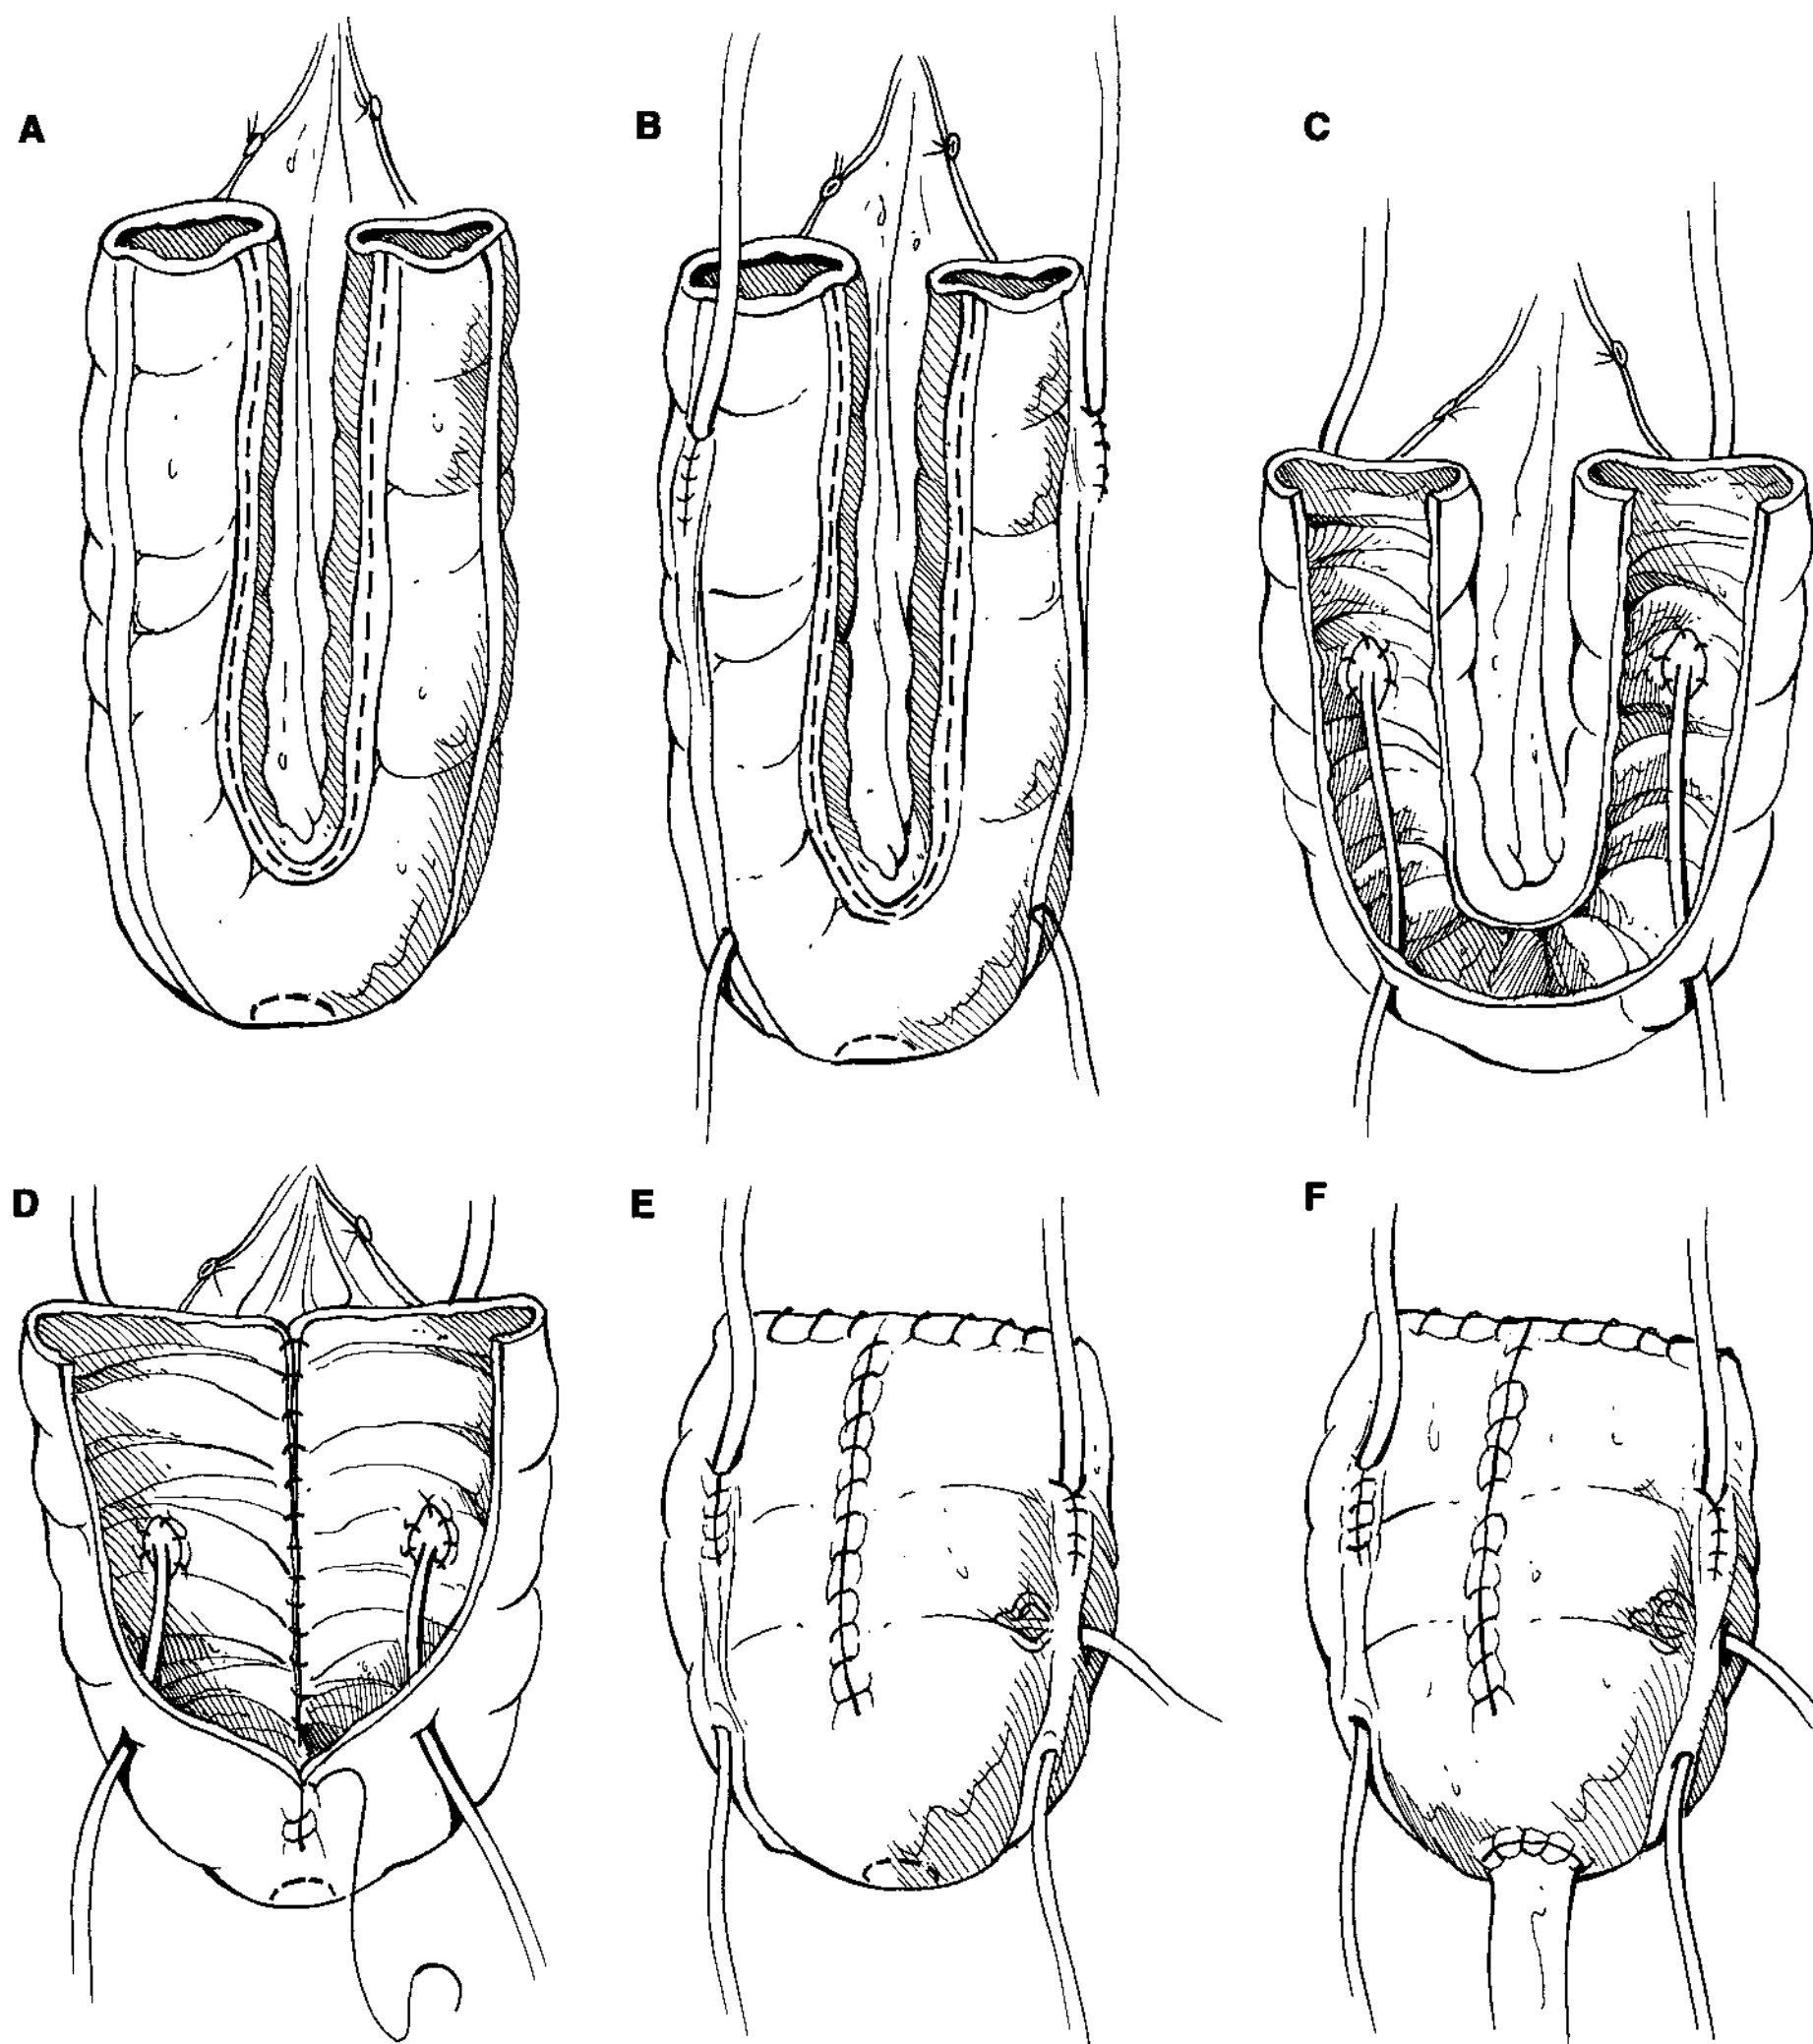

**FIGURE 90.5** Vascular supply of the left colon and rectosigmoid.

At present, the risk of secondary malignancies cannot be comprehensively determined. Follow-up examinations must include renal ultrasound and/or intravenous pyelogram, blood gases, and, starting from the fifth postoperative year, pouchoscopy and evaluation of serum cobalamin.

## Results

In general, the outcome criteria for orthotopic bladder substitution by intestine are (a) the function and morphology of the upper urinary tracts, (b) frequency during day and night, (c) continence, and (d) ability to void spontaneously. However, one has to keep in mind that especially continence and the ability for spontaneous micturition may significantly be influenced by the type and quality of surgery preceding the orthotopic substitution itself. Related factors are, for example, preparation of the bladder neck and urethra, sparing of the autonomous nerves, and measures to prevent pouch displacement or kinking. Therefore, functional results attributed to specific kinds of reservoirs actually rely on more factors than the segment(s) of intestine chosen. For ileocecal reservoirs, a ureterointestinal obstruction rate of up to 7% is reported. Continence rates for ileocecal reservoirs vary between 75% and 88% during the day and 67% during the night (6,11). Continence rates for sigmoid colon reservoirs are significantly lower, at 50% (11).

**FIGURE 90.6** Construction of a sigmoid colon reservoir (Reddy). **A:** Isolating a segment of about 30 cm of sigmoid colon. **B:** Submucosal tunnel ureteral implantation. **C and D:** Detubularization, U-shaped reconfiguration of the segment, and side-to-side anastomosis of the back wall of the pouch. **E and F:** Completion of the anterior wall of the pouch and anastomosis to the urethra.

# CHAPTER 91 ■ CONTINENT CATHETERIZABLE RESERVOIR MADE FROM ILEUM

HASSAN ABOL-ENEIN AND MOHAMED A. GHONEIM

A substantial number of techniques have been described for the creation of continent cutaneous urinary reservoirs. For construction of such systems three elements are required: a low-pressure compliant reservoir, an antirefluxive ureterointestinal anastomosis, and a continent stoma that allows easy catheterization.

To create a reservoir with high capacity at low pressure, various segments of bowel have been utilized: the ileum, the ileocolonic region, the ascending colon, and the transverse colon. Regardless of the selected bowel segment, detubularization and double folding are basic prerequisites to achieve this goal.

A reliable antirefluxive ureterointestinal anastomosis is necessary, since bacteriuria is a constant feature in these systems and results from intermittent catheterization. The technique employed should provide a unidirectional but nonobstructed flow. The antirefluxing mechanism should not be at the expense of a higher incidence of obstructive complications.

Hinman (7) classified continent outlets into four categories according to the mechanism of their action. These included an antiperistaltic ileal segment (6); imbricated or tapered ileal segments resulting in passive tubular resistance (11); outlets using the pressure equilibration principle, including an ileal spout valve (3), flutter valve (4), inkwell hydraulic valve, intussusception nipple (5), or ileal servomechanism sphincter (8); and flap valves, which are created by the incorporation of tubular structures within the wall of the reservoir, such as the

appendix (10), fallopian tubes (12), parts of ileum (13), or tubularized cecal segments (9). Multiplicity of techniques implies that none is optimal. Many of the above techniques rely on an inert or even unphysiologic mechanism, and problems and malfunctions soon appear.

In our proposed technique, we have utilized the ileum for construction of the low-pressure reservoir and a serous-lined tunnel to provide an antirefluxive mechanism (1) as well as to create a reliable continent outlet (2).

---

## INDICATIONS FOR SURGERY

---

Any patient who requires bladder replacement is a potential candidate for this operation. The indications of continent cutaneous urinary diversion include the following:

1. Pelvic malignancies: In patients for whom cystectomy is indicated for bladder cancer or those requiring an anterior pelvic exenteration for other pelvic malignancies.
2. Benign indications: These include neuropathic bladders when conservative measures fail, extensive urethral strictures with damaged urethral sphincter, contracted bladders with compromised urinary continence, complex urinary fistulas affecting the sphincteric mechanism, and some cases of bladder exstrophy with failed attempts of primary repair.

- Urinary conversion: Conversion from other types of urinary diversion, such as ileal conduits in young healthy patients, for patients who develop isolated urethral recurrence following radical cystectomy and orthotopic bladder substitution, and in some cases of ureterosigmoidostomy suffering from intractable metabolic acidosis.

---

## PATIENT SELECTION AND EVALUATION

---

Suitable candidates should have reasonable manual dexterity. Motivation to carry out clean intermittent catheterization at regular intervals is necessary. Furthermore, a good prognosis might be expected if the indication to diversion was a pelvic malignancy. Patients who are unfit for prolonged surgery and those with a history of previous bowel resection, short bowel syndrome, or heavily irradiated bowel are among the contraindications for this procedure. Patients with impaired renal function (serum creatinine equal to or  $>1.8$  mg per dL and or creatinine clearance equal to or  $>40$  mL per minute) are unsuitable candidates since metabolic acidosis would be inevitable.

---

## ALTERNATIVE THERAPY

---

Alternative techniques of urinary diversion should be discussed with the patient when orthotopic bladder substitution or continent cutaneous reservoirs are contraindicated or unfeasible. These include conduit diversion and anal sphincter-controlled bladder substitutes. The potential postoperative complications, changes in future lifestyle, and long-term sequelae should be clearly explained to the patients.

---

## SURGICAL TECHNIQUE

---

### Preoperative Preparation

Since the small bowel is utilized, no specific preparation is necessary. The only requirement is fasting overnight with administration of intravenous fluids to ensure good hydration. Patients with histories of thromboembolic disease or varicose veins should receive a prophylactic dose of heparin (5,000 U subcutaneously) the night before the operation and every 12 hours thereafter until ambulation. Compression leg stockings are also advised. Although the intention is to use a concealed umbilical stoma, a stoma therapist should examine the patient and determine a suitable site for an abdominal stoma. A parenteral broad-spectrum antibiotic is given just before induction of anesthesia and continued postoperatively for 3 days.

---

### Operative Technique

---

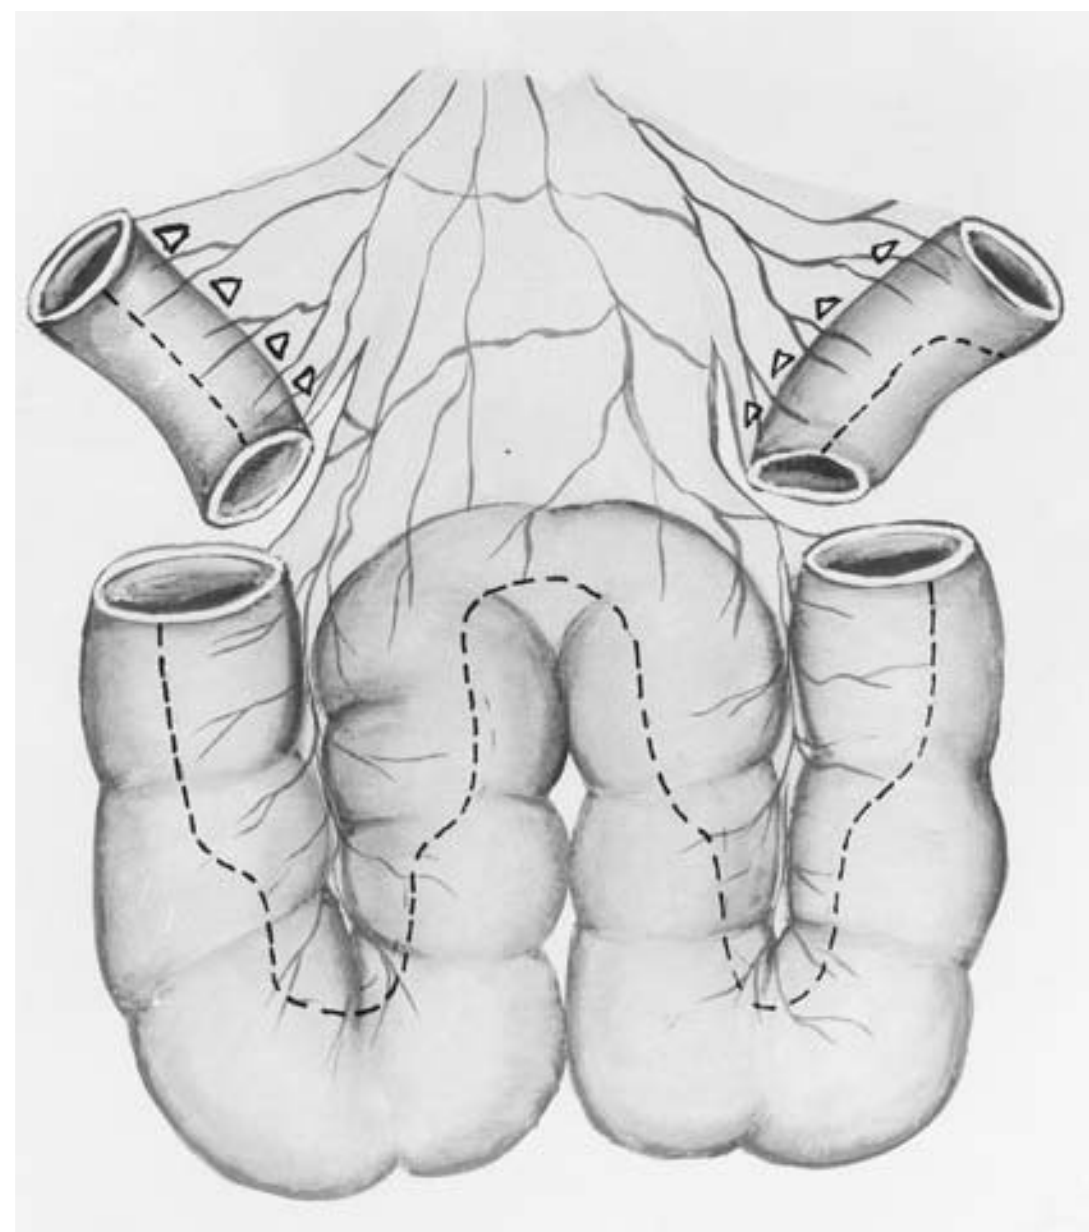

The patient is put in the supine position with a Trendelenburg tilt. Slight flexion of the knees will further help in the relax-

ation of the abdominal muscles, facilitate retraction, and provide wider exposure. If total urethrectomy is planned, the patient is put in a slight lithotomy position for access to the perineum. The surgical area to be sterilized and draped extends from the lower chest down to the upper thighs.

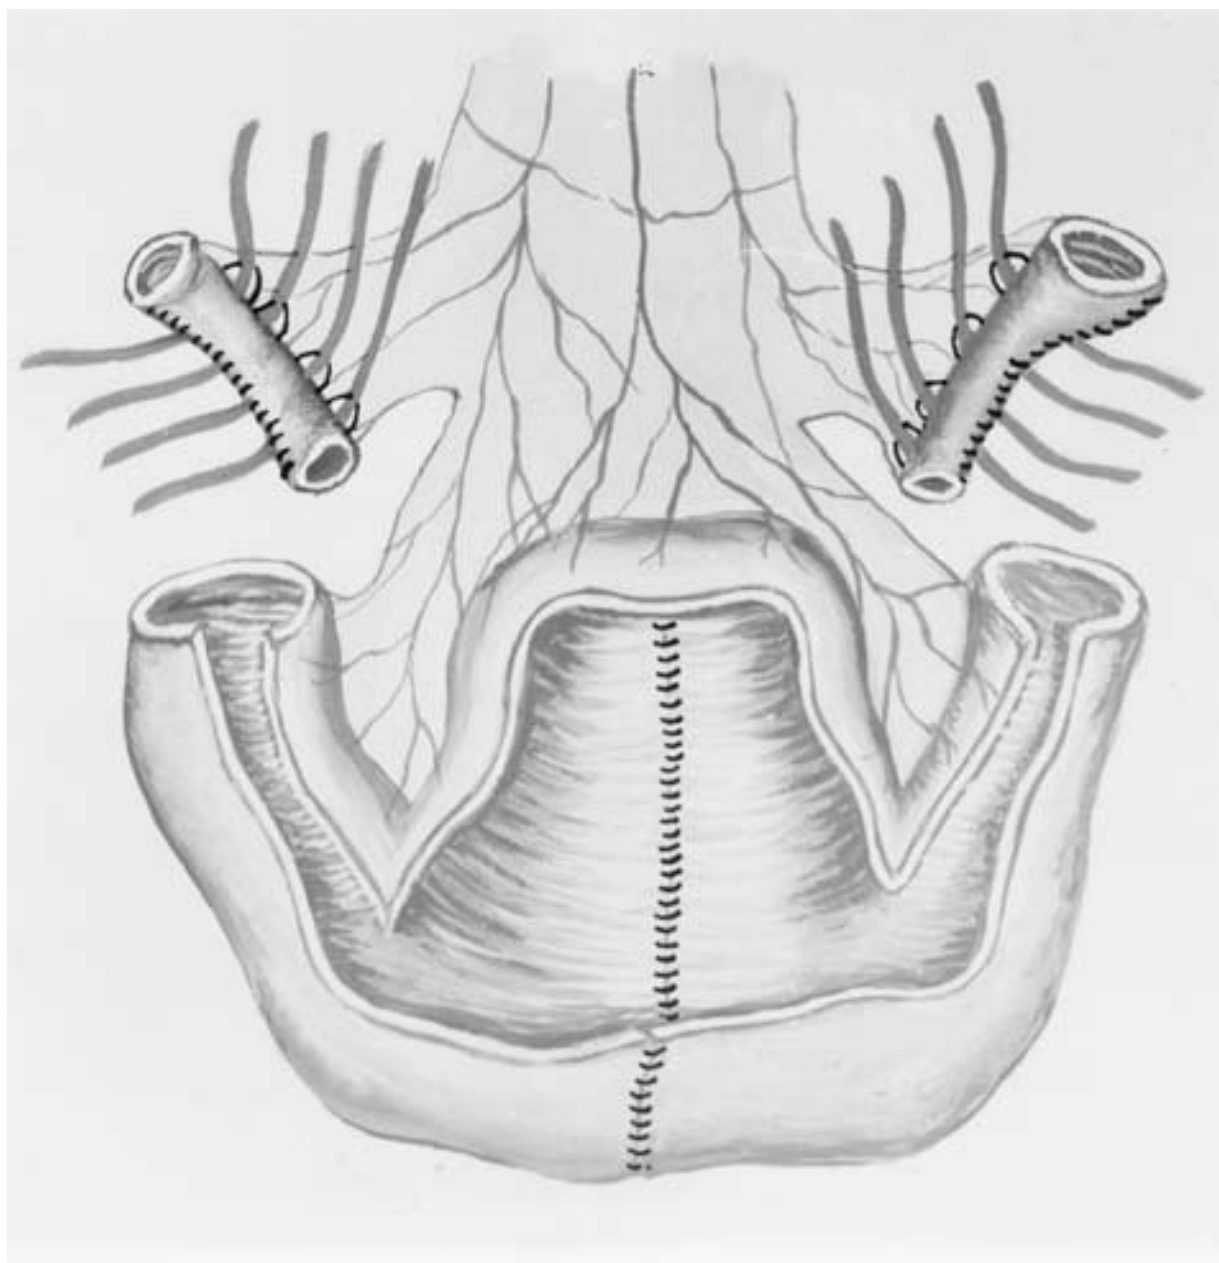

A midline incision from the pubis inferiorly to a point halfway between the umbilicus and xyphoid process of the sternum superiorly is generally employed. The incision is encircling the umbilicus by 2 to 3 cm to the left.

The bowel is examined, and a 60-cm-long segment of the terminal ileum is isolated. Backlight transillumination of the mesenteric attachment greatly helps the identification of the arterial arcades supplying the selected segments. The bowel is divided 15 to 20 cm proximal to the cecum in the avascular window of Treves between the ileocolic artery and the terminal branch of the superior mesenteric artery. The ileum is divided proximally in a suitable avascular plane between the superior mesenteric arcades. Continuity of the bowel is re-established by end-to-end anastomosis. The use of an automatic stapler or a hand-sewn technique is a matter of surgeon's preference. The isolated bowel segment is subsequently subdivided into three parts. The middle 40-cm segment is used for construction of the reservoir, the 10-cm oral segment is used for creation of the antireflux mechanism, and the distal 10-cm caudal segment is used for creation of the outlet valve (Fig. 91.1). Great attention is paid to preserving an adequate blood supply for the oral and caudal small bowel segments.

The middle segment is arranged in a W configuration, and its antimesenteric border is incised by a diathermy knife. The edges of the two medial flaps are joined by a single layer of continuous 3-0 polyglactin sutures. The two lateral limbs are left to serve as serous-lined troughs. The oral and caudal short

**FIGURE 91.1** A 60-cm-long ileal segment is isolated; the 40-cm middle segment is arranged in a W configuration and used for construction of the body of the reservoir, the 10-cm oral segment is used for the antireflux mechanism, and the caudal segment is used for the outlet valve.

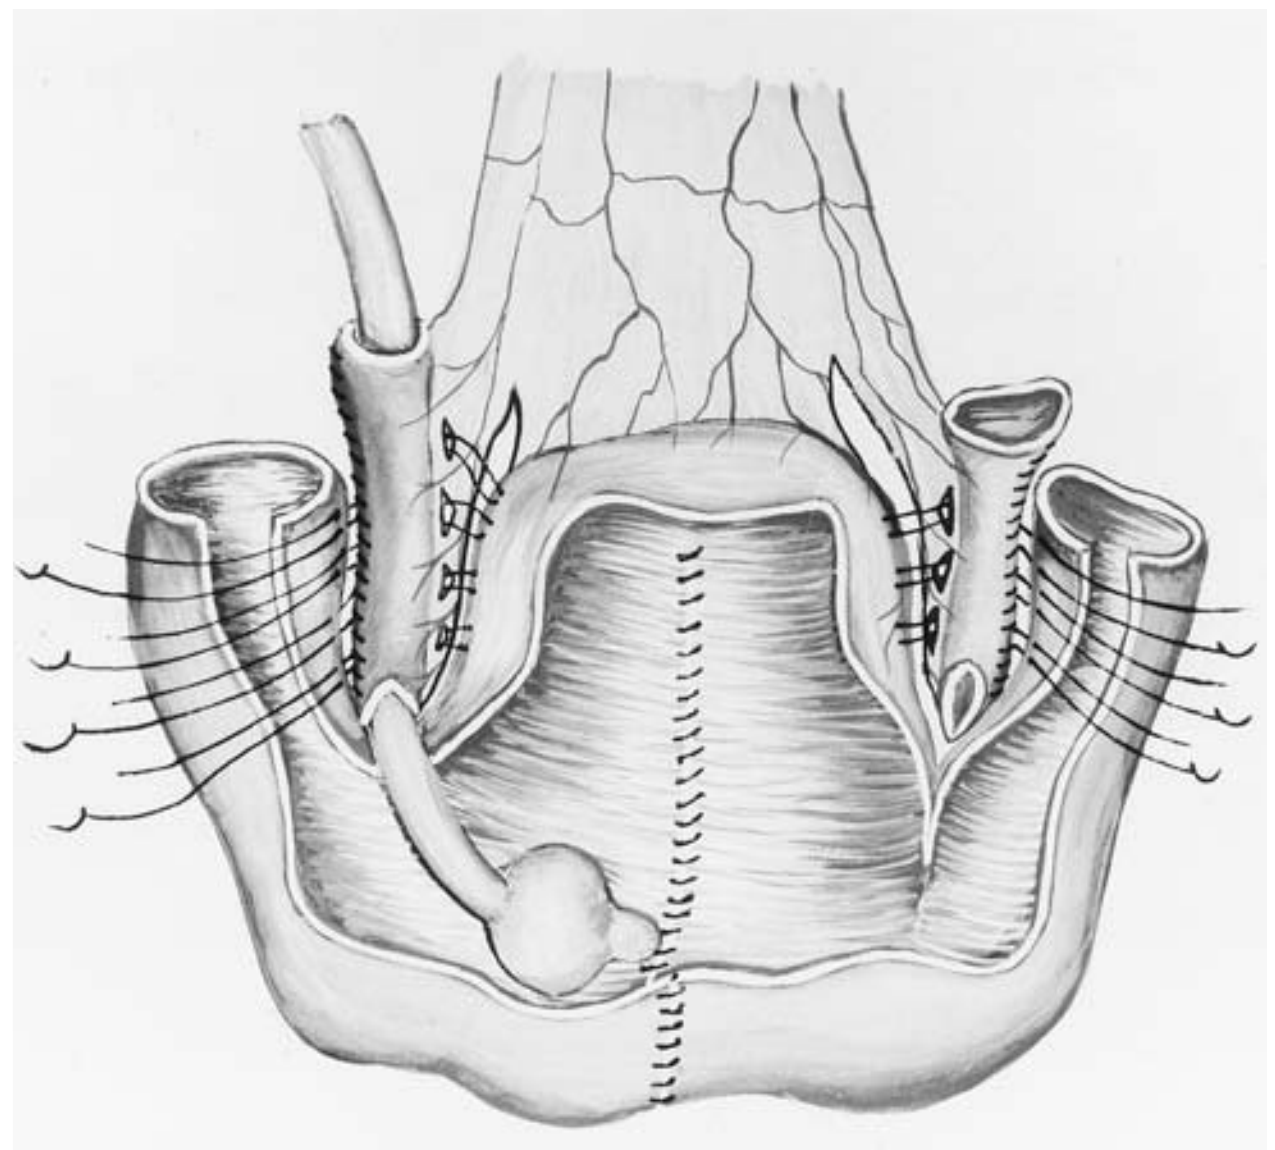

**FIGURE 91.2** The bowel segment is incised at the antimesenteric border. The medial flaps are approximated with continuous 3-0 polyglactin sutures. The oral and caudal segments are tapered around a 20Fr catheter. The proximal one-third of the inlet segment is kept untapered. The created mesenteric windows are marked by a strip of vessel loops.

segments are tapered around a 22Fr catheter. Bowel tapering could be performed either by simple excision and hand-sewn technique or by using a one-step technique with an automatic gastrointestinal stapler. The proximal one-third of the inlet segment is kept untapered for ureteral anastomosis. Three to four small mesenteric windows close to the mesenteric border are created in between the arterial arcades supplying these segments. Each mesenteric window is marked by a small strip of rubber vessel loop. This step will facilitate easy passage of sutures through the mesenteric window (Fig. 91.2).

Each tapered segment is inlaid in its corresponding serous-lined trough. The two adjacent limbs of each trough are approximated using 3-0 silk seromuscular suture passing through the mesenteric windows and guided by the inserted strips of vessel loops. The tapered ileal segments are fixed and embedded within the serous-lined extramural troughs. Thus, the bulky mesentery of the embedded segments is excluded behind the pouch (Fig. 91.3). The spatulated distal ends of the tapered segments are anastomosed to the tunnel flaps, and the ileal trough is closed in front of the embedded segment using interrupted 4-0 polyglactin sutures (Fig. 91.4).

Two soft siliconized 8Fr to 10Fr stents are threaded through the inlet segment and secured in place by 4-0 chromic gut sutures. The pouch plate is then closed by approximation of the most lateral ileal flaps anteriorly and to the shoulder flap between the inlet and outlet segments (Fig. 91.5).

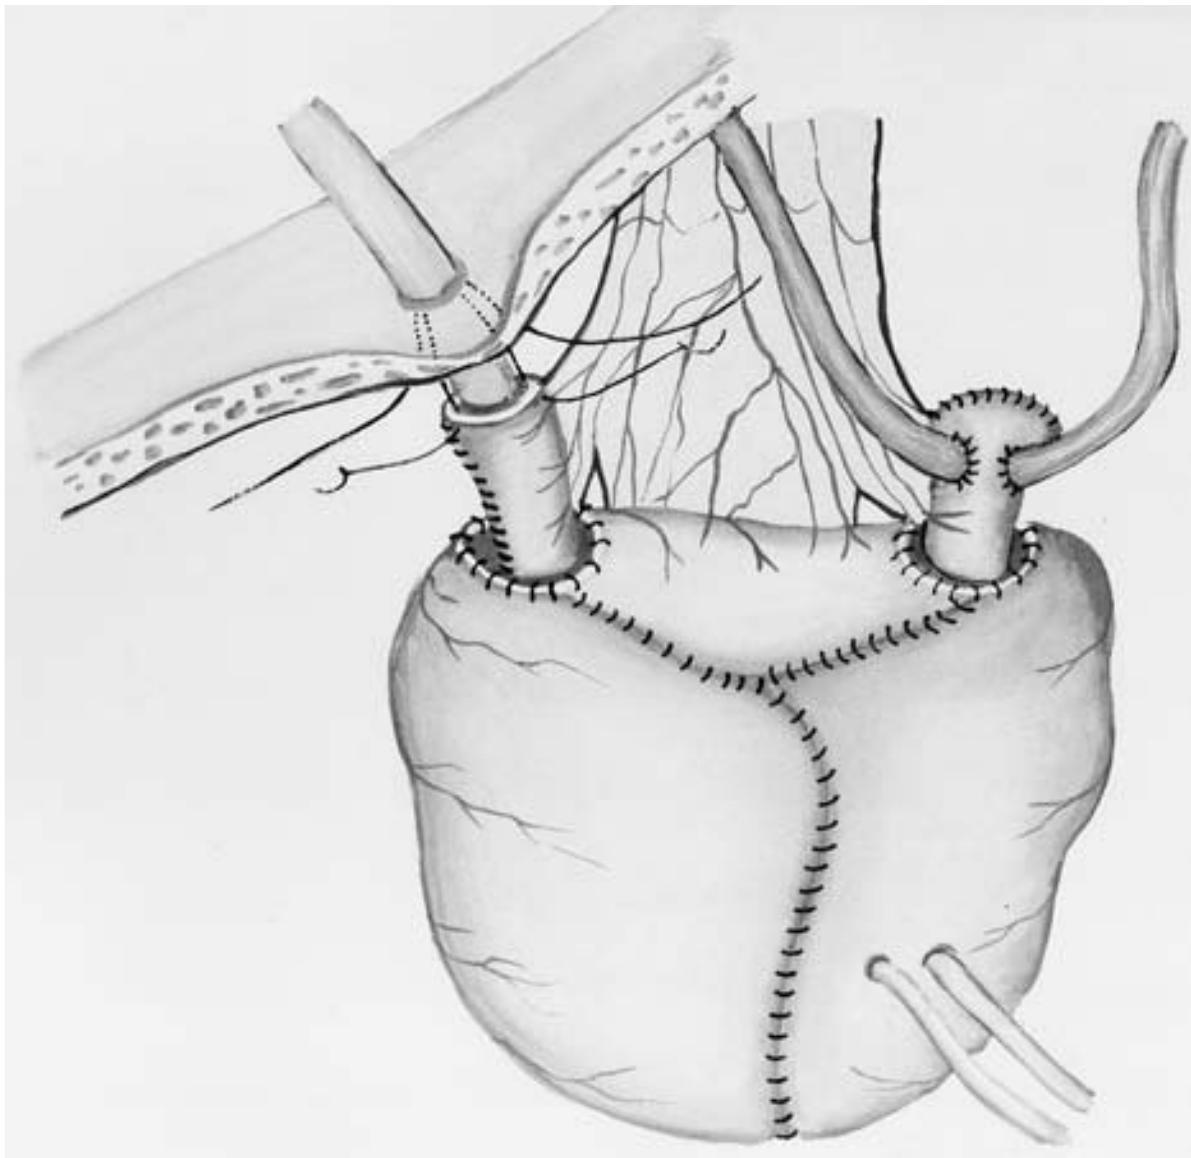

The skin of the umbilical funnel is raised and separated from the underlying rectus fascia in the midline. A fascial cruciate incision is made that can admit a 20Fr to 24Fr catheter. The invaginated umbilical skin funnel is identified and a suitable button hole is excised. The distal end of the outlet segment is

**FIGURE 91.3** The tapered ileal segments are fixed and embedded within the serous-lined extramural troughs. The bulky mesentery of the embedded segments is excluded behind the pouch.

**FIGURE 91.4** The spatulated distal ends of the tapered segments are anastomosed to the tunnel flaps, and the ileal trough is closed in front of the embedded segment using interrupted 4-0 polyglactin sutures. Two siliconized stents are threaded through the inlet segment.

**FIGURE 91.5** The pouch plate is closed by approximation of the most lateral ileal flaps anteriorly and to the shoulder flap between the inlet and outlet segments.

**FIGURE 91.6** The edge of the outlet is fixed to the edge of the umbilical skin funnel using interrupted sutures including the rectus fascia.

pulled through the rectus fascia aperture. The edge of the intestinal outlet is fixed to the edge of the umbilical skin funnel using interrupted monofilament 4-0 or 3-0 monocril sutures including the rectus fascia (Fig. 91.6).

The body of the reservoir wall around the outlet segment is then fixed to the inner aspect of the abdominal wall. Attention is paid to avoid twisting and/or angulation of the outlet segment. This would avoid difficulties in catheterization later.

The reservoir is drained by an 18Fr to 20Fr Foley balloon siliconized catheter fixed through the stoma.

Both ureters are prepared and oriented toward the inlet segment according to the final position of the pouch. The left ureter is passed from left to right through a high, wide enough mesenteric hole created in the left mesocolon. The right ureter comes from right to left in front of the common iliac artery behind the mesentery of the pouch. Tension-free, widely spatulated, stented implantation of the ureters into the inlet segment is then performed. A Wallace, Nesbit, or end-to-end anastomosis could be utilized according to surgical needs, using 4-0 or 5-0 polyglactin sutures.

The ureteral stents are exteriorized through the anterior wall of the reservoir to which they are secured. This will provide almost a dry reservoir during the healing stage.

The pelvic cavity is drained by two 18Fr fenestrated tubes. Only straight gravity drainage is used. Gastric drainage is established using either a nasogastric tube or open gastrostomy.

### An Alternative: Utilization of the Appendix

If the appendix is suitable to serve as an outlet, the ileocecal junction is mobilized sufficiently to ensure a tension-free implantation of the appendix. The appendix is mobilized and detached at its base. The isolated appendix is cut and spatulated at its tip. The lumen is then dilated up to 16Fr to 18Fr using straight dilators. Four windows are created in the mesoappendix. The windows are labeled by rubber vessel loops. The appendix is embedded in the serous-lined trough as described previously (Fig 91.7).

**FIGURE 91.7** The appendix is isolated and spatulated at its tip. Four windows are created at the mesoappendix. The appendix is fixed and embedded in the serous-lined trough as previously described.

---

## POSTOPERATIVE CARE

---

Parenteral fluids are maintained until bowel habit resumes. Prophylactic antibiotics are given routinely for 5 days. Low-molecular-weight heparin is given for 10 days. The draining tubes are removed when the drainage ceases. The reservoir is irrigated with 30 to 60 mL of normal saline every 8 hours to prevent mucus retention. The ureteric stents are removed after 10 to 12 days postoperatively. The pouch is drained for 21 days before training by intermittent catheter clamping. All patients start self-catheterization 2 days before discharge from the hospital. A 2-hour interval is allowed in week 1, which is increased gradually until the pouch matures. By the end of week 6 most of the patients evacuate the pouch every 4 to 5 hours.

---

## OUTCOMES

---

### Complications

In our experience with 101 patients, early complications were observed in 15%. These included urinary leakage (2%), pelvic collections (8%), ureteroileal obstruction (1%), ileus (3%), and wound complications (3%). Small nonsymptomatic pelvic collections need no treatment. Sizable and/or infected symptomatic ones are usually treated by ultrasound-guided needle aspiration with or without an indwelling tube drain. None of these pelvic collections required open drainage. Urinary leakage was an infrequent complication in our series (2%). This complication was due to pouch perforation during catheterization training. Prolonged pouch drainage was required for an additional 2 weeks until healing of the injury occurred. Early evidence of ureteroileal obstruction was observed in one patient. Antegrade fixation of a double-J stent was done for 6 weeks. The stent was removed by pouchoscopy carried out through the umbilical stoma. Gastrointestinal and wound complications were similar to those for other urinary diversion procedures.

Late complications included stomal stenosis at the skin level with catheterization difficulties in 6% of the patients. Two-thirds of them had an appendix stoma. Half of these patients required revisional surgery to widen the mucocutaneous

stenotic area using a wedge skin flap technique. In one child it was impossible to pass a catheter into the pouch due to overdistention resulting in angulations of the outlet tract. Under ultrasound guidance, percutaneous insertion of a pig-tail catheter was carried out. Once the pouch became empty, outlet catheterization again was easy. Rupture of the pouch was observed in one patient following blunt abdominal trauma. Laparotomy was necessary, and the pouch tear was adequately repaired. Pouch stones were observed in 5% of the patients. All of them were amenable for endoscopic manipulations, but one patient required open pouchlithotomy. The incidence of upper-tract dilatation due to anastomotic stricture was minimal (1%); the stricture was treated by antegrade balloon dilatation. One patient required left nephroureterectomy 3 years following cystectomy due to a renal pelvis tumor. Gravity pouchography demonstrated reflux in three patients (3%). Reflux was asymptomatic in all, and the patients were kept on prophylactic antimicrobial suppressive therapy. None of the operated patients developed metabolic acidosis. All patients were advised to use oral alkali therapy.

---

## Results

---

Patients regained their normal lifestyle once healing was completed. Ninety-five percent of our patients were completely dry day and night. The catheterization interval was every 4 to 5 hours during daytime and every 1 to 2 hours at night. The average capacity at 6 months postoperatively was  $550 \pm 130$  mL.

Five patients (5%) had a frequently wet stoma due to failure of the continence mechanism. Two patients were revised. One underwent revision of the continent outlet, and augmentation ileopouchoplasty was required to increase pouch capacity in the other. Two patients preferred frequent catheterization to avoid leakage. The remaining patient fixed a collection device during nighttime and refused further intervention.

Patients have to understand that they have a neobladder constructed from the bowel and that this bladder is different from the native one. The usual desire to micturate and the familiar micturition mechanism no longer exist. However, all patients with a dry, continent outlet stoma enjoy an excellent lifestyle, normal social activities, an accepted body image, and personal satisfaction.

# CHAPTER 92 ■ CONTINENT CATHETERIZABLE RESERVOIR MADE FROM COLON

HUBERTUS RIEDMILLER AND ELMAR W. GERHARZ

Over the past 15 years there has been an increasing interest in alternatives to the Bricker ileal conduit as a form of urinary diversion. A wide range of techniques are currently available, including orthotopic bladder substitution and continent cutaneous and rectal bladder diversion. The current body of published literature is insufficient to conclude that there is a superior form of urinary diversion in terms of evidence-based medicine. It is quite clear, however, that not all patients are candidates for one type of diversion. The best results are obtained when a comprehensive concept is tailored to the individual patient at a high-volume center with experience in all major types of diversion techniques (4).

---

## DIAGNOSIS

---

The most common indication for continent cutaneous diversion is a bladder replacement after anterior pelvic exenteration for malignant disease, followed by functional or morphologic bladder loss for other reasons. Diagnostic modalities therefore should be directed at the underlying pathology and definitive treatment.

---

## INDICATIONS FOR SURGERY

---

Despite the recent trend toward orthotopic substitution, continent catheterizable urinary reservoirs remain a good form of diversion. Whereas previous or synchronous urethral transitional cell carcinoma (TCC) is an absolute contraindication to urethral preservation, the role of multifocality, associated carcinoma in situ and of bladder neck and prostatic involvement on urethral recurrence is less well defined. In these cases, continent cutaneous diversion is still a safe alternative in the appropriate patient.

Advanced age (>70 years) with its physiologic deterioration of sphincter competence is another relative contraindication for orthotopic reconstruction; older patients who are otherwise physically fit may well benefit from a continent cutaneous reservoir.

Whenever the native sphincter mechanism is lacking, destroyed, or dysfunctional or urethral catheterization is painful or technically impossible, cutaneous diversion is the only alternative to modified ureterosigmoidostomy and ileal loop. As a salvage procedure in failed exstrophy reconstruction, in other complicated congenital abnormalities of the urinary tract, in neurogenic bladder dysfunction (wheelchair-bound myelomeningocele patients), and in patients with intractable urinary incontinence, severe pelvic traumas, and complicated

fistulas, continent cutaneous reservoirs provide excellent results even in extremely complex cases.

Until recently, renal transplant patients were excluded from the benefits of continent urinary diversion. Several authors have, however, reported encouraging experiences with kidney transplantation into continent urinary intestinal reservoirs as a planned two-stage procedure in patients with functional or morphologic bladder loss (see below) (9).

Other factors to consider when deciding on the type of urinary diversion include patient age, prognosis of underlying disease, comorbidity, urinary and anal sphincter competence, manual dexterity, renal function and upper-urinary-tract configuration, and subjective criteria (motivation, compliance, expectation of social support, emotional capability of dealing with clean intermittent catheterization). Patient priorities are considered whenever medically justifiable and technically feasible.

Contraindications of continent urinary diversion include impaired renal function with serum creatinine >2 mg per L, inflammatory bowel disease, large bowel malignancy, or previous history of multiple bowel ablative procedures, with or without a history of diarrhea.

---

## ALTERNATIVE THERAPY

---

Alternatives to catheterizable colonic reservoirs include pouches made from ileum (Kock), ileal or colonic conduits, classic and modified ureterosigmoidostomy (e.g., sigma-rectum pouch/Mainz pouch II), or orthotopic neobladder (Camey II, Kock, Hautmann, Studer).

---

## SURGICAL TECHNIQUE

---

While there is a broad consensus among reconstructive urologists regarding detubularization and spheric reconfiguration of bowel as a basic principle in the creation of a low-pressure, high-capacity reservoir, the issues of reflux prevention (afferent limb) and continence (efferent limb) are more controversial. The still-growing number of techniques described for achieving continence in urinary reconstruction indicates that a universally applicable procedure with a low complication rate has not yet evolved. The principal methods for construction of a continence mechanism depend on the formation of a nipple valve, utilization of the ileocecal valve, or construction of a flap valve. Among the different techniques, the versatile Mitrofanoff principle (6) has acquired significant popularity, predictably providing continence and allowing easy catheterization in >90% of cases. In 1990, Riedmiller et al. introduced

the Mitrofanoff theme to the ileocecal reservoir, significantly facilitating the Mainz pouch procedure (8,12).

When performing a Mitrofanoff, the method of attaching the appendix to the reservoir (reversed, in situ: imbricated, embedded, unaltered), the location of the stoma (umbilicus, lower abdomen), and appropriate alternatives are controversial. It is known that the success of the Mitrofanoff principle is not dependent upon the underlying pathologic condition, the type of tube and its possible peristalsis, the type and configuration of the reservoir, or the patient's age, but rather on the maintenance of a pressure gradient between channel lumen and the reservoir. It is therefore the availability of the required material and the simplicity of a technique that determine its popularity. Recent variations of the Mitrofanoff theme have aimed at its simplification and at reduction of long-term complications.

## Ileocecal Pouch (Mainz Pouch I)

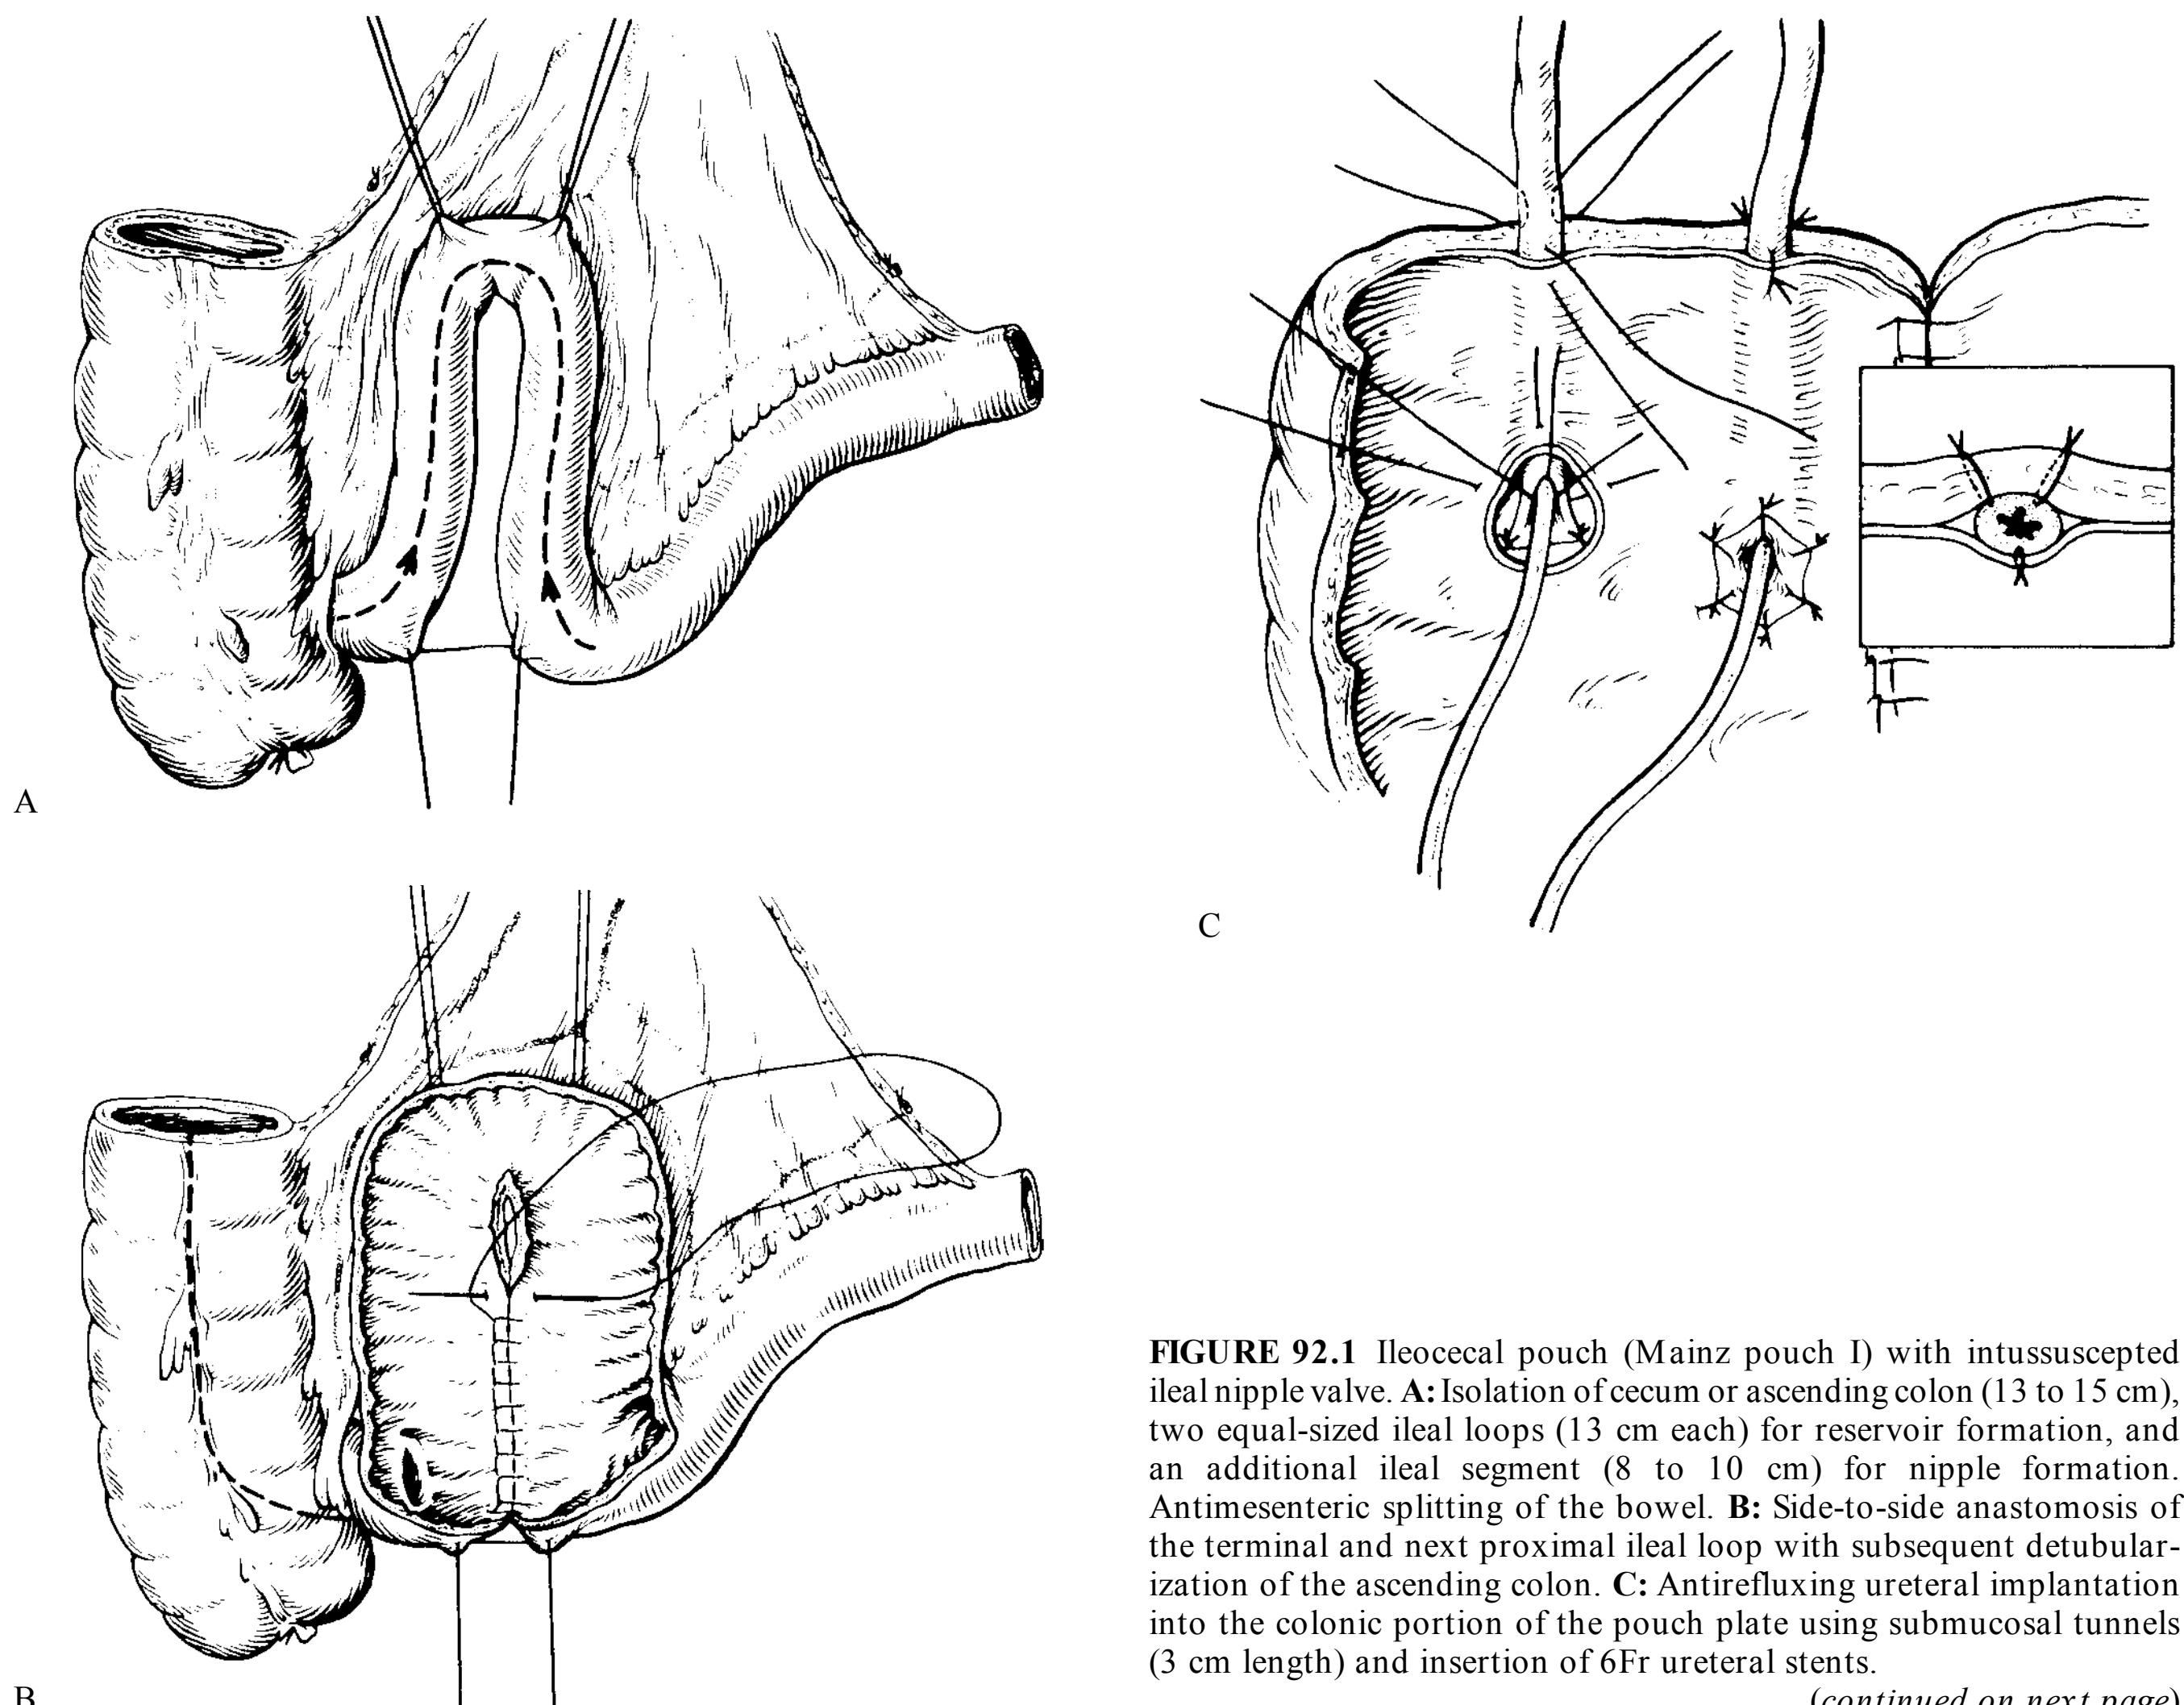

### Intussuscepted Ileal Nipple

After mobilization of cecum, ascending colon, and the right colonic flexure, the mesentery is divided between the right colic and the ileocolic arteries. A 13-cm segment of cecum and ascending colon is isolated along with two equal-sized limbs

of distal ileum. If the vermiform appendix is absent, as in cloacal exstrophy, completely obliterated, immobile, insufficient in diameter and length, or has been removed beforehand, we usually isolate an additional portion of ileum measuring 8 to 10 cm (Fig. 92.1A). While the latter is left tubularized, the remaining bowel segment is split antimesenterically. These three opened bowel loops are folded in the form of an incomplete W, and their posterior aspects are sutured to one another to form a broad posterior plate (Fig. 92.1B). Both ureters are implanted into the large bowel segment of the pouch plate, forming submucosal tunnels for reflux prevention (Fig. 92.1C).

The midportion of the intact ileal segment is freed of its mesentery up to a distance of 4 to 5 cm to allow its intussusception (Fig. 92.1D and E). One row of staples is applied to stabilize the intussusception itself (Fig. 92.1F). Thereafter, the intussuscepted nipple is pulled through the intact ileocecal valve and two additional rows of staples are applied to attach the nipple to the ileocecal valve. After the mucosa has been removed from the rim of the intussuscepted nipple and the colonic aspect of the ileocecal valve, their circumferences are sewn together with a running suture.

The bowel is then folded on itself in a side-to-side fashion, thus creating a low-pressure, high-capacity reservoir. Ureteral stents (6Fr or 8Fr) and a 10Fr pouchostomy are led through

**FIGURE 92.1** Ileocecal pouch (Mainz pouch I) with intussuscepted ileal nipple valve. **A:** Isolation of cecum or ascending colon (13 to 15 cm), two equal-sized ileal loops (13 cm each) for reservoir formation, and an additional ileal segment (8 to 10 cm) for nipple formation. Antimesenteric splitting of the bowel. **B:** Side-to-side anastomosis of the terminal and next proximal ileal loop with subsequent detubularization of the ascending colon. **C:** Antirefluxing ureteral implantation into the colonic portion of the pouch plate using submucosal tunnels (3 cm length) and insertion of 6Fr ureteral stents.

the abdominal wall at separate sites. The entire pouch is rotated to bring the efferent limb to the region of the umbilicus. A small button of skin is removed from the depth of the umbilical funnel. The pouch is carefully attached to the posterior fascia with interrupted nonabsorbable sutures to prevent the pouch from rotating and kinking. The efferent limb is then connected to the umbilical funnel with interrupted absorbable sutures. In the absence of an umbilicus (as in the case of exstrophy), it is created by tubularizing a V-shaped cutaneous flap and connecting it to the appendicular stump (12).

A vigorous washout regimen is started early in the postoperative course. Ureteric stents are removed after 10 to 14 days. Clean intermittent catheterization is usually started at the end of the third postoperative week after leakage and reflux have been ruled out by pouchogram.

### Appendix Stoma

If the appendix is present and can be dilated to accommodate a 16Fr to 18Fr catheter, it is ideally our first choice as the efferent segment for construction of a continence mechanism. In this case, a 15-cm segment of cecum and ascending colon is isolated along with two equally sized limbs of distal ileum (12 to 13 cm each). The lower 5 cm of the cecum (cecal pole) is left tubularized and intact. The seromuscular layer of the intact cecal pole is divided along the tenia down to the mucosa in a manner analogous to the Lich-Gregoir procedure for vesicoureteral reflux (Fig. 92.2A). By careful dissection of the seromuscular tissue, a broad submucosal bed (5 cm) is created for the appendix. The appendicular mesentery is freed of its

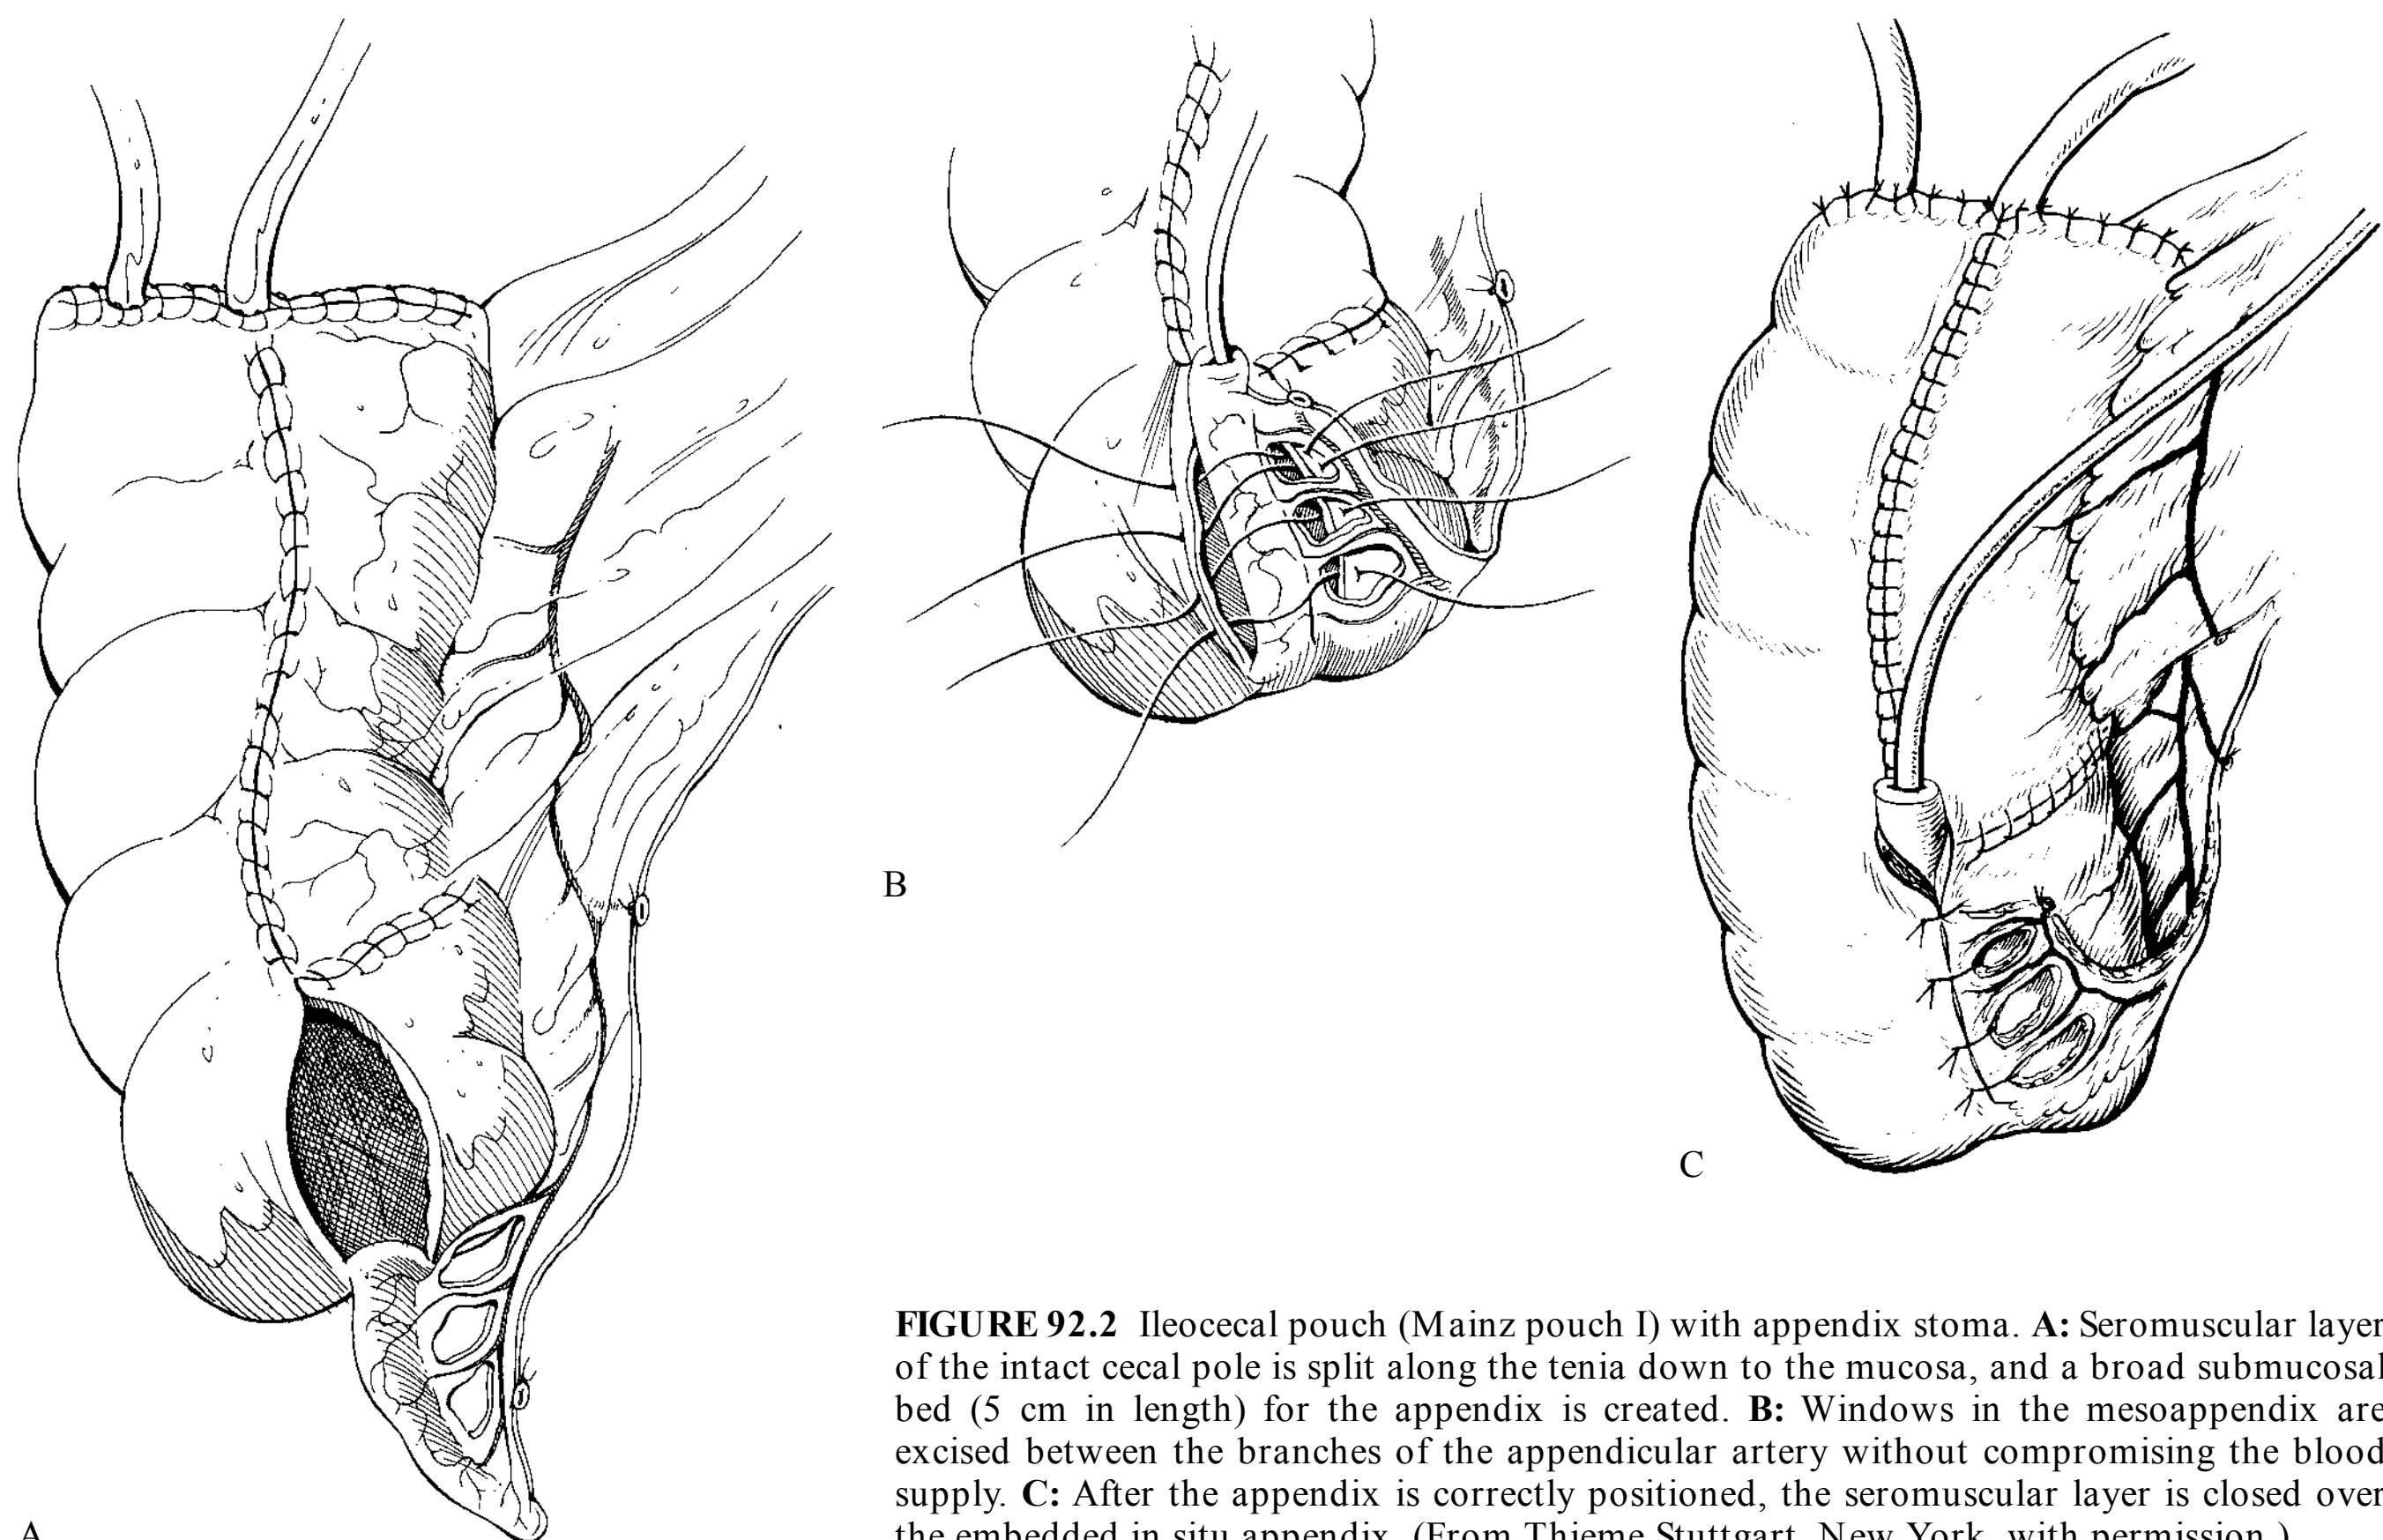

excessive fatty tissue. Windows in the mesoappendix are excised between the branches of the appendicular artery without compromising the blood supply (Fig. 92.2B). Anatomic variations of the appendicular artery have to be respected, and an additional branch of the anterior or posterior cecal artery supplying the base of the appendix should be preserved. After the appendix is correctly positioned, the seromuscular layer is closed over the embedded in situ appendix with interrupted 4-0 polydioxanone sutures. A short mobile portion of the distal appendix remains for the creation of the appendicoumbilical stoma (Fig. 92.2C). Formation of the pouch plate, the ureterointestinal anastomosis, and the attachment to the umbilicus follows the same procedure as that for a pouch with an intussuscepted nipple (8).

### Alternative Techniques for Construction of Continence Mechanism

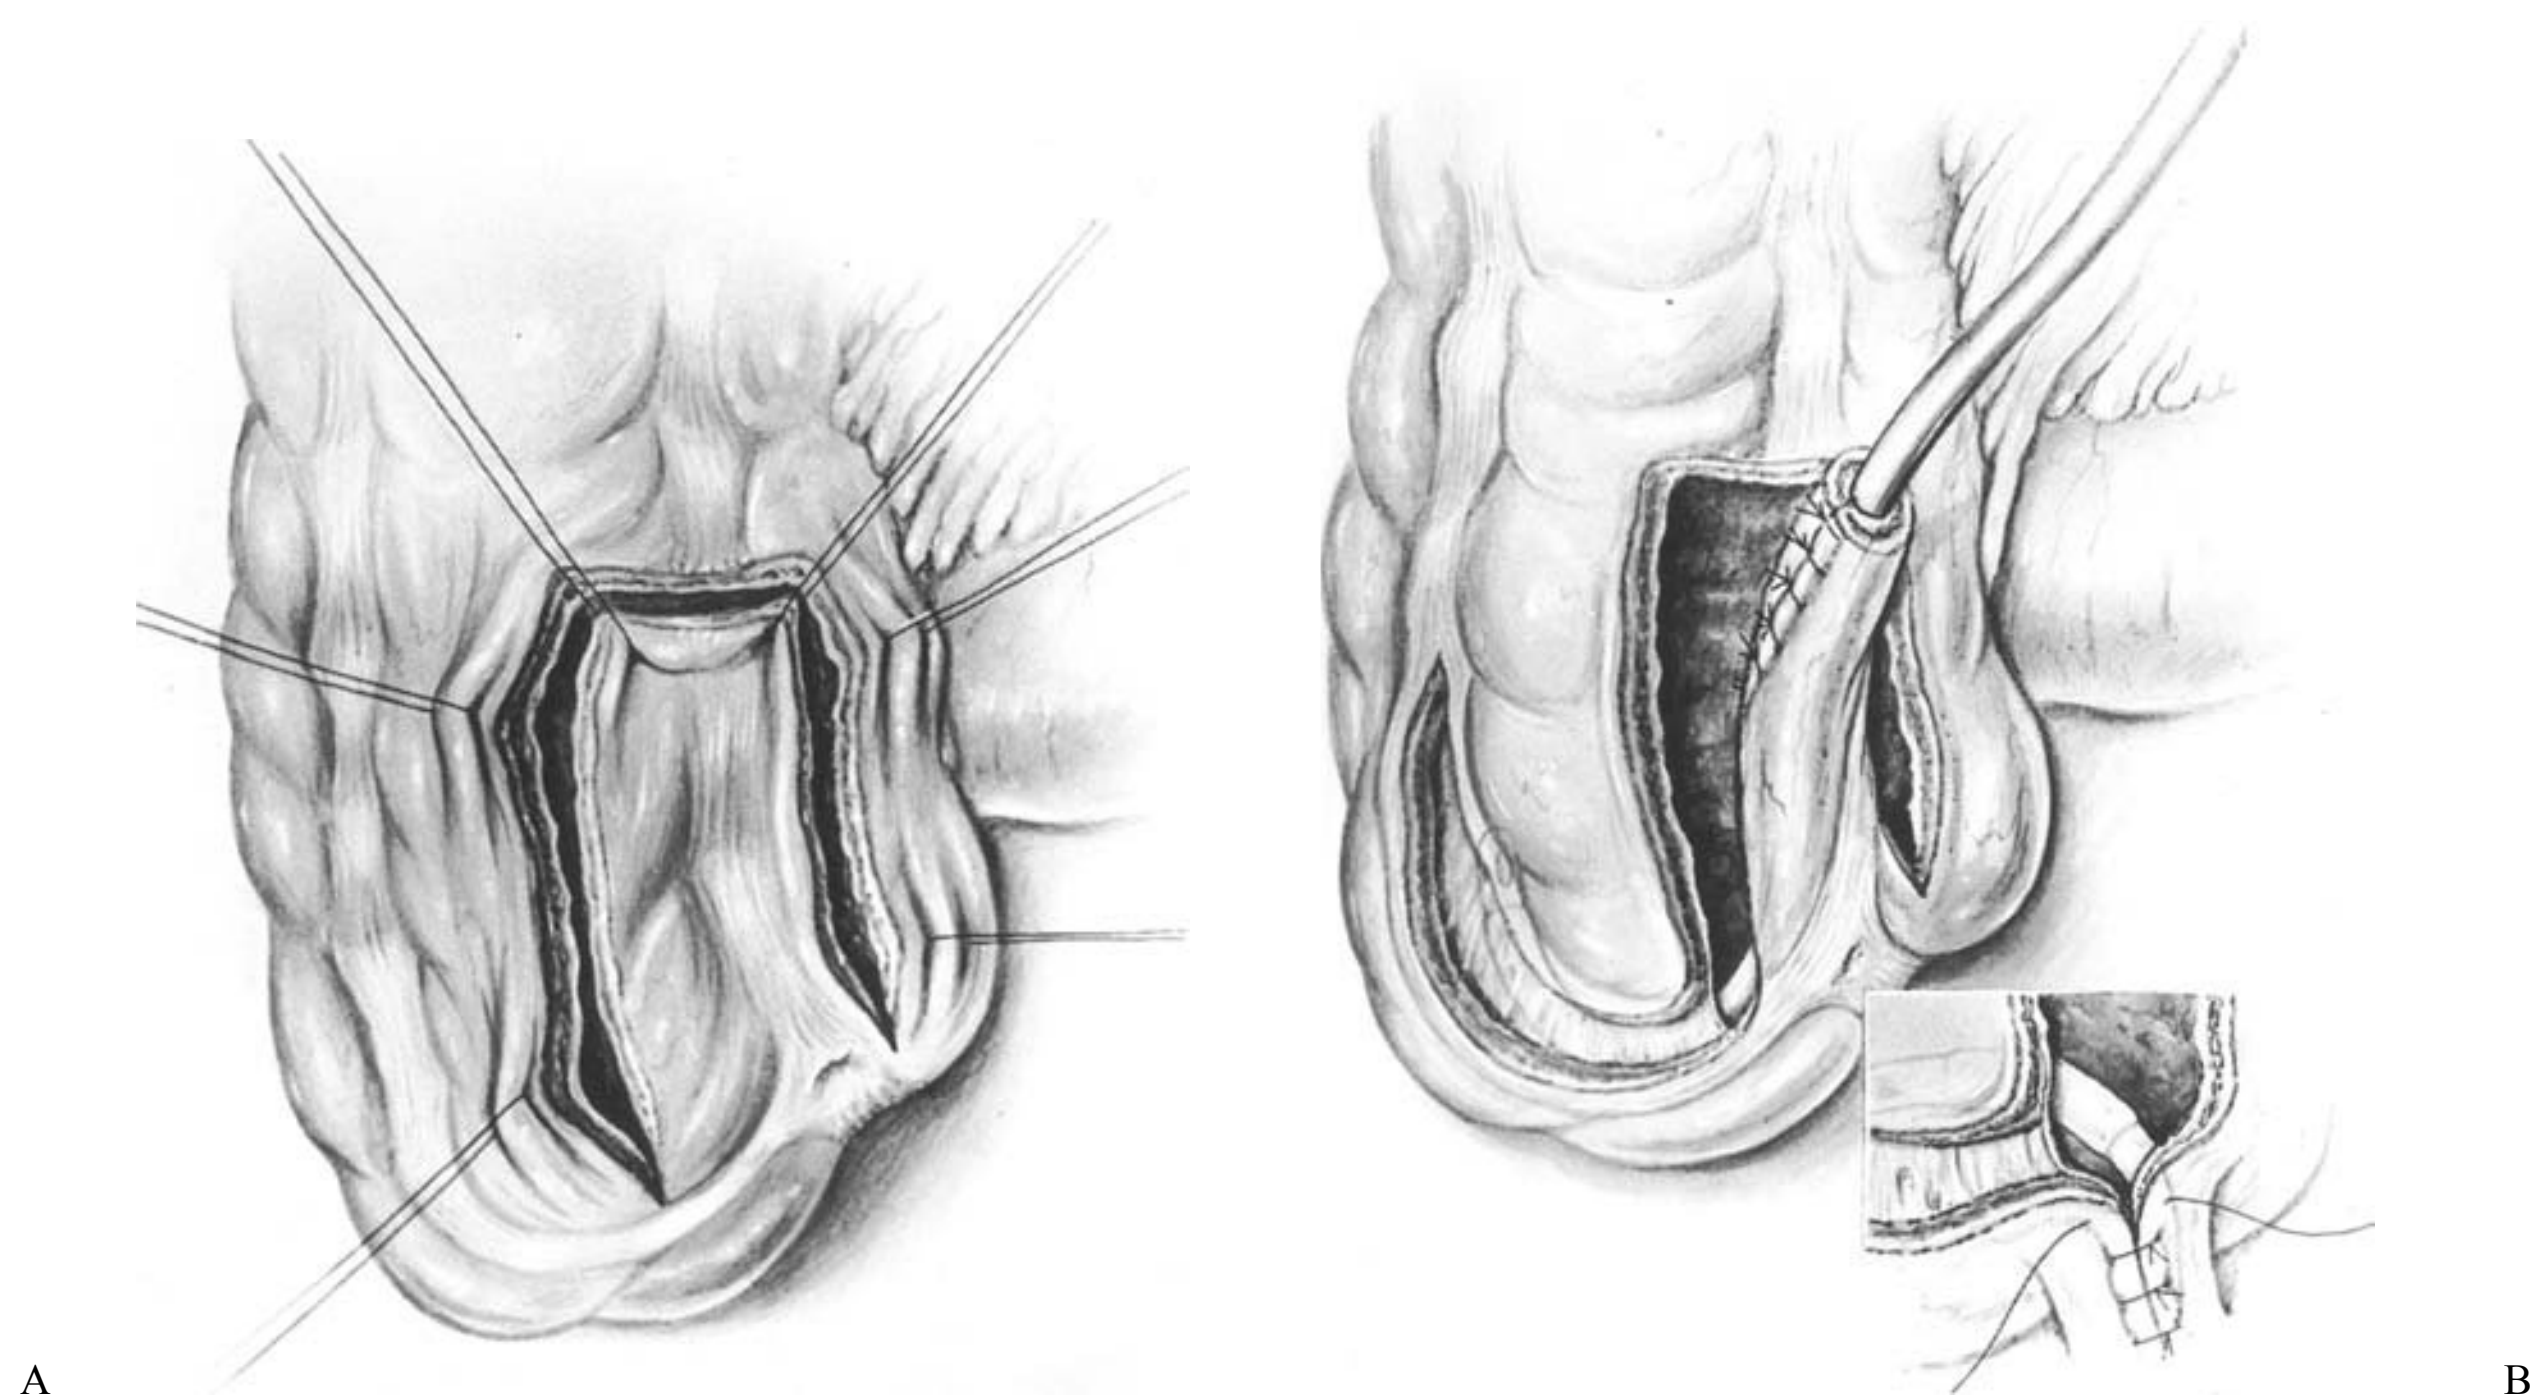

More recent alternative techniques use a small-caliber conduit fashioned from the cecal wall. One technique uses a full-thickness tube lined by mucosa (Fig. 92.3) and the other a seromuscular tube lined by serosa (Fig. 92.4) (5). Other authors have described transversely retubularized ileum (Fig. 92.5) to create a tunneled access into the right colon (7).

### Alternative Techniques for Ureteral Implantation

In dilated, irradiated, or otherwise compromised ureters, ureterointestinal anastomosis may be performed according to a technique that has been described by Abol Enein and Ghoneim (serous-lined extramural tunnel) (Fig. 92.6) (1).

**FIGURE 92.2** Ileocecal pouch (Mainz pouch I) with appendix stoma. **A:** Seromuscular layer of the intact cecal pole is split along the tenia down to the mucosa, and a broad submucosal bed (5 cm in length) for the appendix is created. **B:** Windows in the mesoappendix are excised between the branches of the appendicular artery without compromising the blood supply. **C:** After the appendix is correctly positioned, the seromuscular layer is closed over the embedded in situ appendix. (From Thieme Stuttgart, New York, with permission.)

(From Thieme Stuttgart, New York, with permission.)

### Right Colon Pouches with Intussuscepted or Tapered Terminal Ileum

Several other authors use the ileocecal region in continent cutaneous urinary diversion. In contrast to the Mainz technique, they employ the ileum for construction of the continence mechanism but not for creation of the reservoir itself. Other colon pouches using nipple valve configuration for the continence mechanism include modifications from many other centers and differ from one another by only a few features, predominantly related to the technique employed for stabilizing the nipple valve. For example, in the “Tiflis” technique, the continence mechanism is created by tapering and submucosally embedding the terminal ileum (Fig. 92.7) (2).

#### Indiana Pouch

Between 25 and 30 cm of cecum and ascending colon and 8 to 10 cm of terminal ileum are isolated (10). The entire colonic segment will be detubularized by incising it along its antimesenteric surface. If an appendix is present, it is removed at this time. Reconfiguration of the opened bowel segment by folding the cephalad end down to the apex of the antimesenteric incision allows the creation of a spheric reservoir (Fig. 92.8A). For construction of the efferent limb and continence mechanism, metal staples are applied sequentially to narrow the efferent limb over a 12Fr straight catheter (Fig. 92.8B). Any excess antimesenteric ileum is then removed. The last row of staples is placed at an angle to prevent stapling into the wall of the cecum. After narrowing the efferent limb, the ileocecal

valve area is plicated with five to seven Lembert stitches of 3-0 silk suture (Fig. 92.8C). Care is taken to avoid having the sutures enter the lumen of the bowel. Each Lembert suture is progressively wider than the last. This has the effect of narrowing the ileocecal valve by wrapping cecal wall over the angled staple line. The tightness of the plication sutures is tested by passing an 18Fr catheter through the efferent limb. Once the efferent limb and continence mechanism have been completed and a Malecot catheter has been placed as a cecostomy tube in the dependent portion of the cecum, the reservoir is closed. Both ureters are led in such a manner as to allow alignment with a tenia. A tenial incision is made for each ureter. The ureter is cut obliquely or spatulated, and the site for the ureteral orifice is created by incising the bowel mucosa. The ureteromucosal anastomosis is performed with interrupted sutures of 5-0 synthetic absorbable monofilament material. The tenia is reapproximated over the ureter with a nonabsorbable 5-0 suture.

#### Colon Pouch (Mainz Pouch III)

Between 15 and 17 cm of transverse colon and either ascending [transverse-ascending pouch (TAP)] or descending colon [transverse-descending pouch (TDP)] (Fig. 92.9A) are required to create a pouch of adequate capacity (350 to 400 mL). Complete mobilization of the right or left colic flexure should be performed to gain adequate colon length for the pouch. The greater omentum is dissected from the transverse colon from right to left in the TAP and vice versa in the TDP. The bowel segment is detubularized antimesenterically, leaving 5 to 6 cm of the oral or aboral end intact for construction of the efferent limb. The terminal segment is tapered over a

A

B

C

**FIGURE 92.4** Seromuscular bowel flap tube. **A:** U-shaped incision ( $3 \times 5$  cm) of seromuscular layer at lower pole of cecum and transverse incision of mucosa (0.5 cm) at the oral end of flap for insertion of 18Fr Foley catheter into lumen of reservoir. **B:** Tubularization of seromuscular bowel flap over 18Fr Foley catheter. **C:** Suturing of anterior circumference of seromuscular tube to margin of mucosa (*inset*). (From Thieme Stuttgart, New York, with permission.)

18Fr silicone catheter, thus creating a neoappendix (Fig. 92.9B). The mucosa is sewn with polyglycol suture and the seromuscular layer with a nonabsorbable running suture. Easy insertion of the catheter is important, as a shrinkage of approximately 30% has to be allowed for. After the pouch plate is created, antirefluxing ureterointestinal implantation according to Goodwin is performed on both sides of the suture line (Fig. 92.9C). For refluxing ureteral implantation, about  $1 \text{ cm}^2$  of the bowel mucosa is excised and the seromuscular layer is incised in the shape of a cross. After anchor sutures at the 5 and 7 o'clock positions are placed, a watertight anastomosis with 5-0 Monocryl sutures is performed. Ureteral stents and a

10Fr pouchostomy are led through the abdominal wall at separate sites.

The pouch is closed and the efferent segment is established. Windows are dissected in the mesentery of the tapered colon between the vessels. The efferent limb is then placed in the suture line, and the seromuscular layer of the anterior wall is approximated through the windows in the mesentery (Fig. 92.9D). Our favorite technique comprises isolation of a short segment of jejunum or ileum, which is tapered over a 18Fr Foley catheter and embedded submucosally after incising the tenia of a tubularized portion of the colonic segment. Sutures are led through windows in the ileal mesentery (Fig. 92.10).

**FIGURE 92.5** Yang-Monti technique. **A:** An ileal segment 2.0 to 2.5 cm long is excised and opened longitudinally about 1 cm from mesentery. **B:** The resulting pedicled rectangle (2 × 6 to 7 cm). **C:** Retubularization in transverse direction using interrupted sutures (4-0 chromic catgut or 5-0 polydioxanone), resulting in a small-caliber tube (neoappendix) that is divided by mesentery into a short branch (stoma formation, anastomosis with umbilical funnel) and long branch (for submucosal embedding). (From Thieme Stuttgart, New York, with permission.)

The umbilicointestinal anastomosis is performed in the same fashion as in the ileocecal pouch. Finally, the reservoir is attached to the abdominal wall. The greater omentum is used to cover pouch and bowel. Ureteric stents are removed after 10 to 14 days. Clean intermittent catheterization is started 3 weeks postoperatively (11).

## COMPLICATIONS

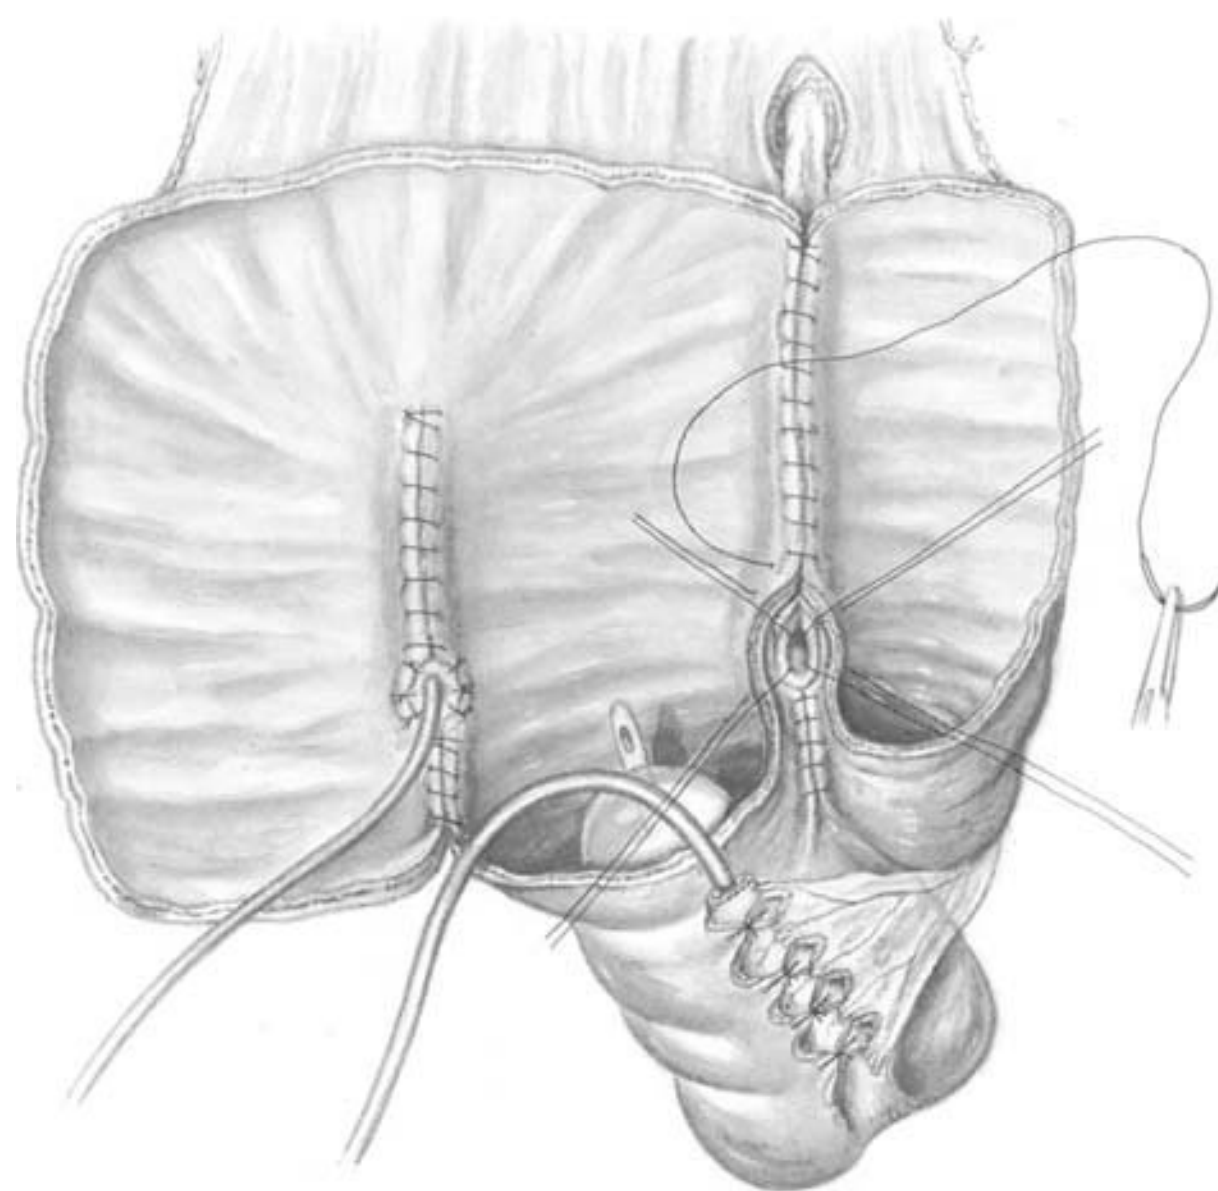

While continence using the appendix, once established, is durable with late-onset failure of 1% to 2% at about 4 years, stomal stenosis is seen in between 8% to 28% of patients,

depending on the length of follow-up. Although stenosis represents a minor technical problem, the subsequent inability to insert the catheter is a distressing complication with potentially serious consequences in patients in whom the Mitrofanoff channel is the only route of evacuation. In these cases the reservoir must be immediately emptied percutaneously, which is facilitated by fixation of the pouch to the abdominal wall.

Skin stenosis may be dilated, incised, or repaired by open surgery, carefully removing fibrotic tissue. According to our experience, dilatation alone seldom produces a lasting improvement. We therefore tend to intervene early. Although revisions are usually successful, prevention of

A

B

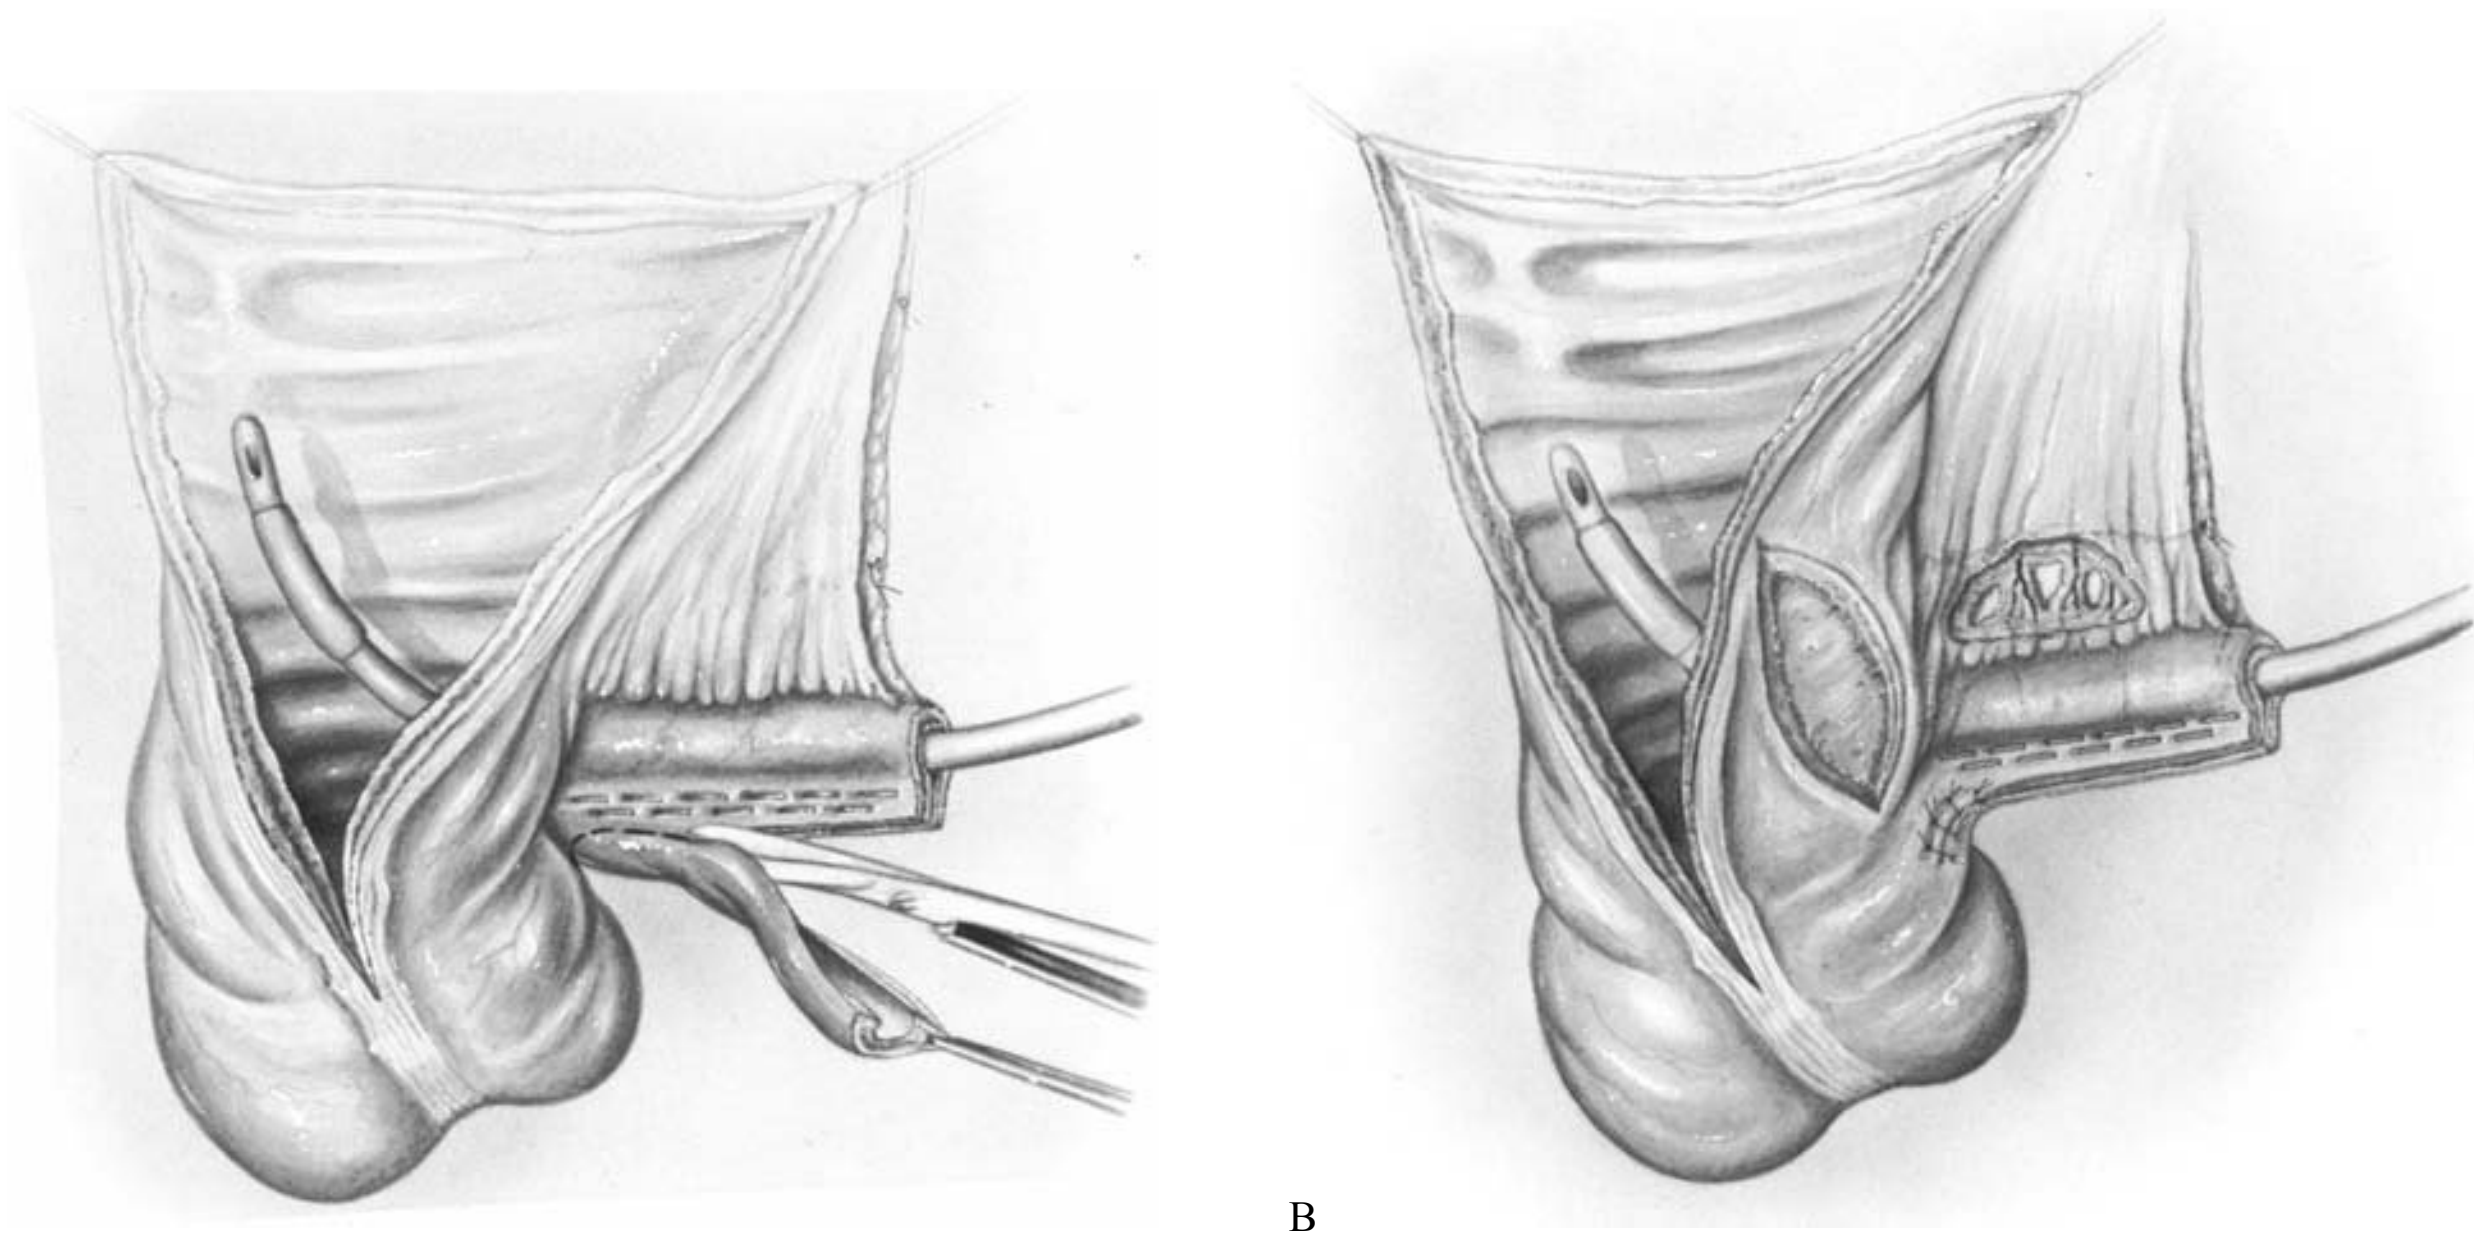

**FIGURE 92.6** Ileocecal pouch (Mainz pouch I) with serous-lined implantation of ureters. **A:** In contrast to the original technique, the pouch plate is not created by anastomosing the edges of detubularized bowel segments, but by creating two serous-lined extramural troughs. **B:** The ureters are placed into the serous-lined tunnels and covered by approximating the margins of the detubularization. (From Thieme Stuttgart, New York, with permission.)

stenosis is desirable. Stomal stenosis can be avoided by incorporation of a V-shaped flap of umbilical funnel into the spatulated appendix. To prevent recurrence, we have developed a cone-shaped metal dilator. Its effective length was designed to cover only the known critical segment of the channel. Directly before inserting the catheter for evacuation of the reservoir, the stoma is gently dilated for a few minutes once or twice daily. A similar effect might be produced by occasionally leaving the catheter in the pouch at night.

Metabolic complications are due to either reduction of the absorptive bowel capacity through functional loss of those segments required for reservoir construction or the highly

unphysiologic exposure of the reconfigured bowel to urine. Factors that affect solute absorption include the size and segment of bowel used, the time of retention of urine, the concentration of the solutes in the urine, renal function, and the pH and osmolality of the fluid (3).

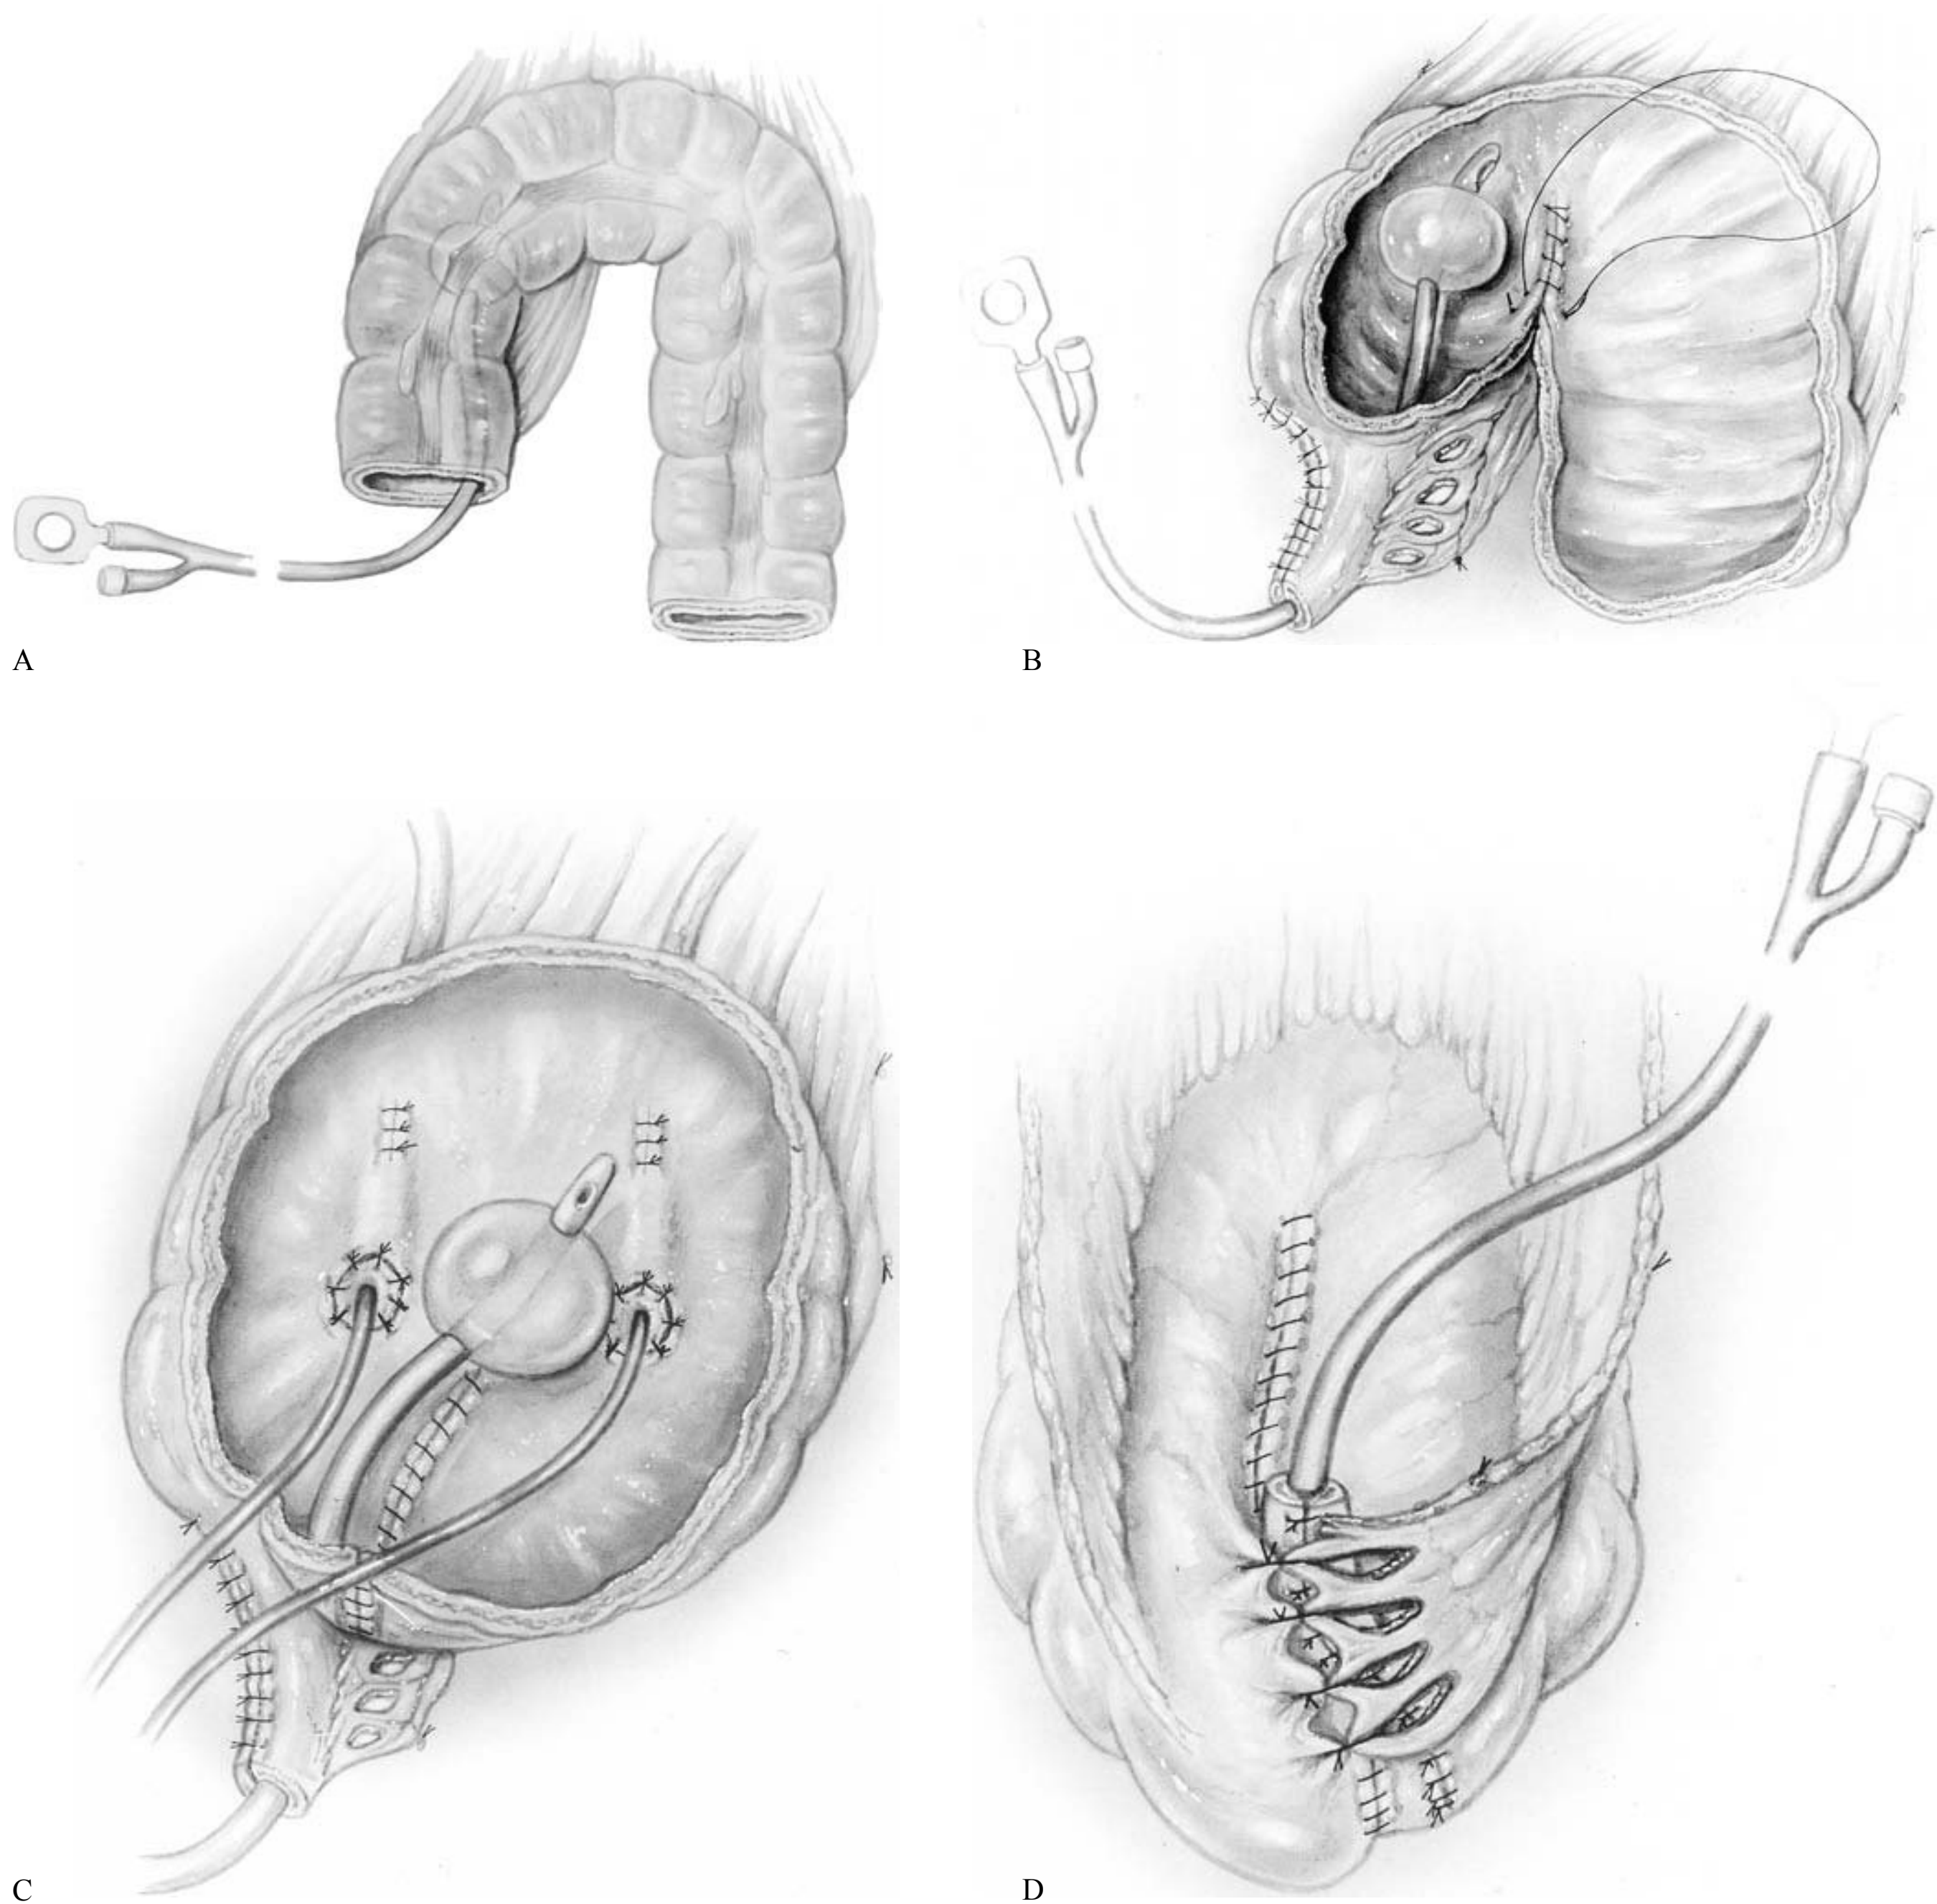

The most common consequence of intestinal urinary diversion is metabolic acidosis. Depending on definition, diagnostic modality, reservoir characteristics, renal function, and length of follow-up, it has been reported in 20% to 100% of patients after ureterosigmoidostomy, bladder substitution, and continent diversion using ileal and/or colonic segments. There is no proven effect on either bone absorption or childhood growth and development.

**FIGURE 92.7** Tiflis pouch. **A:** Tapering of terminal ileum over a 18Fr Foley catheter with removal of excessive bowel wall. **B:** Incision of seromuscular layers of the cecum adjacent to the terminal ileum in preparation for submucosal embedding. **FIGURE 92.8** Indiana pouch. **A:** The cephalad end of the detubularized right colon segment is folded caudally to the apex of the antimesenteric incision. A Malecot catheter is placed in the dependent portion of the cecum prior to closing the reservoir. **B:** A stapler is used to trim away the excess bowel wall of the ileal segment (tapering). **C:** A total of five to seven Lembert sutures are placed to plicate the ileocecal valve.

**FIGURE 92.9** Colon pouch (Mainz pouch III) with tapered colon as efferent limb. **A:** About 15 to 17 cm of nonirradiated large bowel is isolated for reservoir creation. The oral end with a Foley catheter is used for construction of the efferent limb. **B:** The colonic segment is detubularized and the pouch plate is formed. The oral end is tapered over an 18Fr Foley catheter and windows are made in the mesentery. **C:** The ureters are attached to the posterior pouch wall through a submucosal tunnel. **D:** Pouch formation is completed by closing the anterior wall. The efferent segment is embedded serosa-to-serosa by sutures led through mesenteric windows. (From Thieme Stuttgart, New York, with permission.)

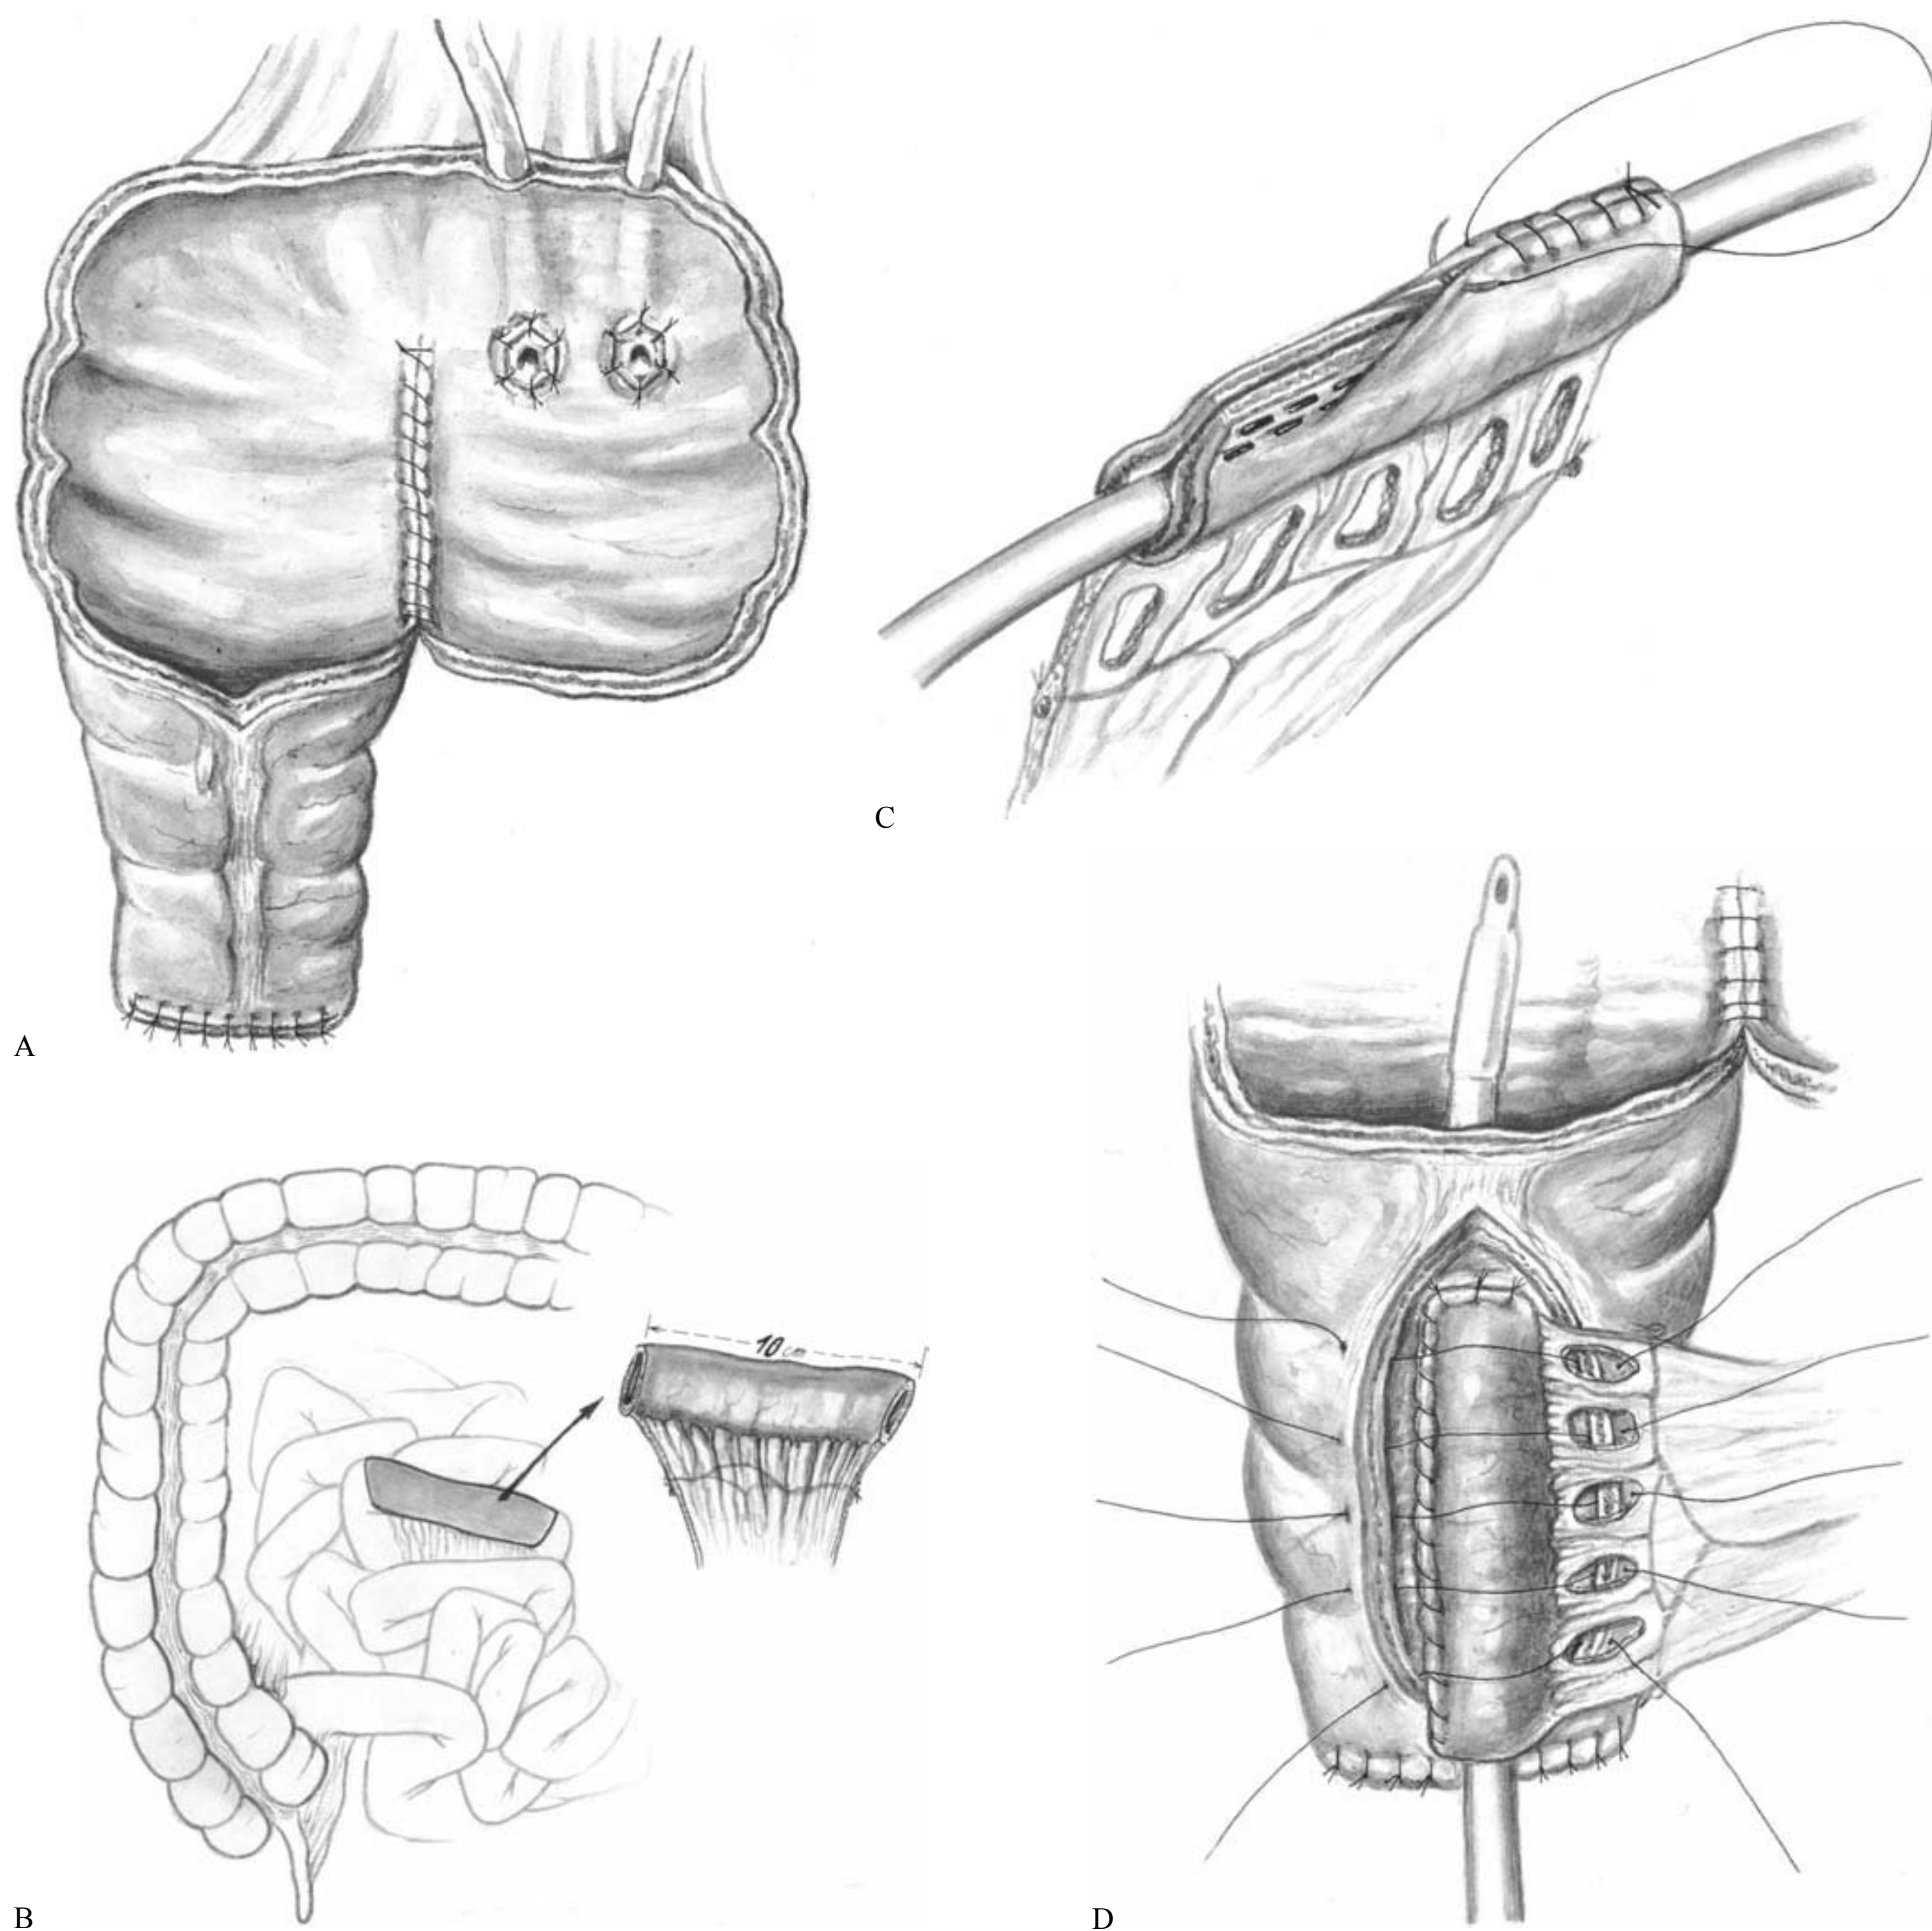

Intestinal urinary reservoirs have an increased propensity to form urinary calculi, predominantly in the lower tract, that tend to recur with an increasing incidence over time. Risk factors include the presence of foreign material (e.g., staples), recurrent and chronic infection, the composition of the urine, mucus production, urinary stasis, and noncompliance with irrigation and catheterization regimes.

Spontaneous rupture or perforation during catheterization has been reported after bladder augmentation, after

orthotopic ileal and ileocolonic bladder replacement, and in continent cutaneous reservoirs 4 weeks to >5 years after surgery.

Hypovitaminosis is a well-studied sequela of bowel resection, particularly of vitamin B12, in which patients may develop irreversible neurologic disease following an unrecognized deficiency. Substitution of vitamin B12 is simple and even less expensive than regular analysis. Empirical supplementation should therefore be considered.

**FIGURE 92.10** Colon pouch (Mainz pouch III) with tapered small bowel as efferent limb. **A:** The oral end of the large bowel segment is closed and left intact. **B:** A 10-cm jejunal or ileal segment is isolated with careful preservation of its mesenteric pedicle. **C:** The ileal segment is tapered over an 18Fr Foley catheter, trimming away the excess bowel wall. The tube is formed using a running suture. Windows are created in between the vasculature of the mesentery. **D:** Submucosal embedding of tapered ileum after incision of seromuscular layer of the tenia of the intact colonic segment. Sutures are led through mesenteric windows. (From Thieme Stuttgart, New York, with permission.)

## OUTCOMES

Between 1985 and 2005, a continent cutaneous ileocecal reservoir was created in 977 patients in two high-volume tertiary referral centers (Departments of Urology, Johannes-Gutenberg-University Medical School at Mainz, Bavarian Julius-Maximilians-University Medical School at Würzburg, Germany) (12), reflecting the learning curves of numerous

surgeons. The mean age of the patients at the time of surgery was 47.8 years. The most common indication for urinary diversion was bladder replacement after anterior exenteration for pelvic malignancies (69.9%), followed by morphologic or functional bladder loss due to various benign conditions. Mean follow-up was 91.1 months (4.3 to 220.2 months). The vast majority of ureterointestinal anastomoses were performed using a submucosal tunnel [1,470 renal units (RU)]. In 419 patients, the in situ appendix could be embedded submucosally

to form a Mitrofanoff type of continence mechanism (43%), while an intussuscepted ileal nipple valve was established in 491 patients (50%). In 56 patients the outlet was created by using other techniques (Figs. 92.3, 92.4, 92.5). Stoma stenosis was the most frequent outlet-related complication, affecting 161 out of 839 patients (19.2%). A reintervention was necessary in 93 of 396 patients (23.5%) with appendix stoma and in 68 of 443 patients (15.3%) with an intussuscepted ileal nipple. While stoma-related complications in patients with appendix stoma could be treated successfully by minor outpatient procedures in the vast majority of cases, management of nipple complications more often required open revision such as refixation of the nipple in the ileocecal valve or at the fascia. Creation of a new outlet became necessary because of ischemic outlet degeneration in 11 patients, including 8 with an appendix stoma and 3 with a nipple valve.

Continence was reported in 96% of the patients with an appendix stoma and in 89.5% of patients with a nipple valve.

Calculus formation was observed in 22 out of 396 patients (5.6%) with an appendix stoma and in 48 out of 443 patients (10.8%) with an intussuscepted ileal nipple.

Ureteral complications are mostly due to anastomotic stricture. Of 1,422 renal units with ureterointestinal reimplantation by submucosal tunnel, 93 (6.5%) developed obstruction at the anastomotic site. Of those, 74 renal units were reimplanted by open surgical revision, and 7 renal units were treated endoscopically by balloon dilatation, incision with the cold knife, or ureteral stent implantation. Eleven renal units had to be removed because of renal deterioration.

In 17 patients with an absent or dysfunctional lower urinary tract, a continent urinary reservoir was created in preparation for renal transplantation (9). In a recent update, follow-up ranged from 3 months to 15 years after kidney transplantation, with serum creatinine values documented between 0.9 and 2.0 mg per dL.

## CHAPTER 93 ■ URETERO SIGMOIDO STOMY: MAINZ POUCH II

MARGIT FISCH, RUDOLF HOHENFELLNER, JÖRG SCHEDE, AND JOACHIM W. THÜROFF

Since the introduction of internal urinary diversion 140 years ago by Simon (11), >60 modifications of ureterosigmoidostomy have been published. It remained the method of choice for urinary diversion until the late 1950s, when electrolyte imbalance and secondary malignancies arising at the ureteral implantation site were described. However, with increased follow-up, secondary malignancies were later reported in all other forms of urinary diversion using bowel (2). The development of new absorbable suture material, modern ureteric stents, antibiotics, and alkalinizing drugs has solved many of the traditional shortcomings of ureterosigmoidostomy and has rekindled the interest in this technique.

At this time continence became a more important issue. Frequency and urgency were often observed, and nighttime

incontinence was reported to be high (7,10). Urodynamic investigations showed that bowel contractions with a pressure rise in the bowel/reservoir are responsible for the incontinence (7,10). By interrupting the circular contractions (antimesenteric opening of the bowel and reconfiguration), a low-pressure reservoir can be created, thus improving continence rates and protecting the upper urinary tract. The era of low-pressure anal reservoirs began.

Kock was the first to apply these principles to ureterosigmoidostomy: By an antimesenteric opening of the rectosigmoid and augmentation by an ileal patch, a low-pressure reservoir was created (10). To avoid metabolic disorders, a valve mechanism cranial to the augmentation was formed by invagination of the sigmoid colon. A temporary colostomy was needed

to protect the invagination, and the advantage of the low-pressure reservoir was, however, tempered by the complexity of the operative procedure. Reports on similar techniques of augmenting the sigmoid segment with either ileal or ileocecal segments followed.

At the Mainz Medical School, a more simple but equally effective operative procedure for the creation of a low-pressure rectal reservoir was developed, in which the sigmoid-rectal pouch was based on Kocher's description in 1903 (5,6). Although the standard technique describes ureteral implantation into the sigmoid-rectal pouch, the submucous tunnel represents an excellent implantation technique for normal undilated ureters with a low risk of stenosis or reflux. It is, however, associated with an increased complication rate when dilated or thick-walled ureters are present. For these ureters the serosa-lined extramural tunnel as published by Abol-Enein and Ghoneim represents an alternative (1). The technique was first described for the ileal neobladder but is also applicable for the sigmoid-rectal pouch. More recently, modifications of the original technique have been described with good results. With the increased interest in minimally invasive procedures, the technique of the sigmoid-rectal pouch, as with radical cystectomy and urinary diversion, can be completely performed endoscopically (12). The bladder specimen can even be removed transanally through the opened rectosigmoid during pouch creation, thus avoiding an additional incision. Today the techniques of low-pressure anal reservoirs have completely replaced classic ureterosigmoidostomy.

## DIAGNOSIS

The anal sphincter function can be checked by a *water tap enema* (perianal instillation of 200 to 300 mL saline, which the patients should keep for at least 3 hours) and a *rectodynamic investigation* (no incontinence during measurement; anal sphincter profile: resting closure pressure  $>60$  cm H<sub>2</sub>O, closure pressure under stress  $>100$  cm H<sub>2</sub>O). The upper tract should be normal as proven by renal ultrasound and intravenous urography or renal function study. An enema with water-soluble contrast medium should be performed to exclude any rectal or sigmoidal anomalies.

## INDICATIONS FOR SURGERY

The sigmoid-rectal pouch is suitable for primary urinary diversion, revision of ureterosigmoidostomy, and conversion of incontinent diversion. The procedure is indicated in patients with functional or actual loss of the urinary bladder. Our main indications are urinary diversion in patients with bladder exstrophy and incontinent epispadias or after radical cystectomy for bladder cancer. The sigmoid-rectal pouch also has been used for treatment of complex ureterovaginal and vesicovaginal fistula. It presents an excellent method of urinary diversion, especially for countries in which catheters or any stoma appliances are difficult to obtain. A competent anal sphincter is a prerequisite for the sigmoid-rectal pouch, as it is for ureterosigmoidostomy. There should be no renal insufficiency (creatinine maximum 1.5 mg per dL) or liver dysfunction.

Contraindications are an incompetent anal sphincter, irradiation of the pelvis, diverticulosis of the sigmoid

colon, polyposis, liver dysfunction, and a serum creatinine  $>1.5$  mg/dL.

## ALTERNATIVE THERAPY

Alternatives to the sigmoid-rectal pouch are any other forms of urinary diversion, including bladder substitution, continent cutaneous urinary diversion, and conduit diversion.

## SURGICAL TECHNIQUE

For bowel preparation, oral administration of 4 to 7 L Fordtan solution can be used on the day before the operation (alternatively, 8 to 10 L of Ringer lactate solution via a gastric tube). Metronidazole in combination with a cephalosporin (alternatively, piperacillin sodium) and an aminoglycoside is given at the beginning of surgery. A gastric tube or gastrostomy and a rectal tube are placed. For parenteral nutrition a central venous catheter has to be inserted.

### Classical Ureterosigmoidostomy

After a median laparotomy, the peritoneum is incised lateral to the descending colon and the left ureter is identified. A peritoneal incision is made on the contralateral side lateral to the ascending colon and the right ureter identified. Both ureters are dissected, respecting the longitudinal vessels running inside the Waldeyer sheet. The dissection is extended caudally to the ureterovesical junction. The ureters are cut as distal as possible, and stay sutures are placed at the 6 o'clock position. The ureteral stumps are ligated.

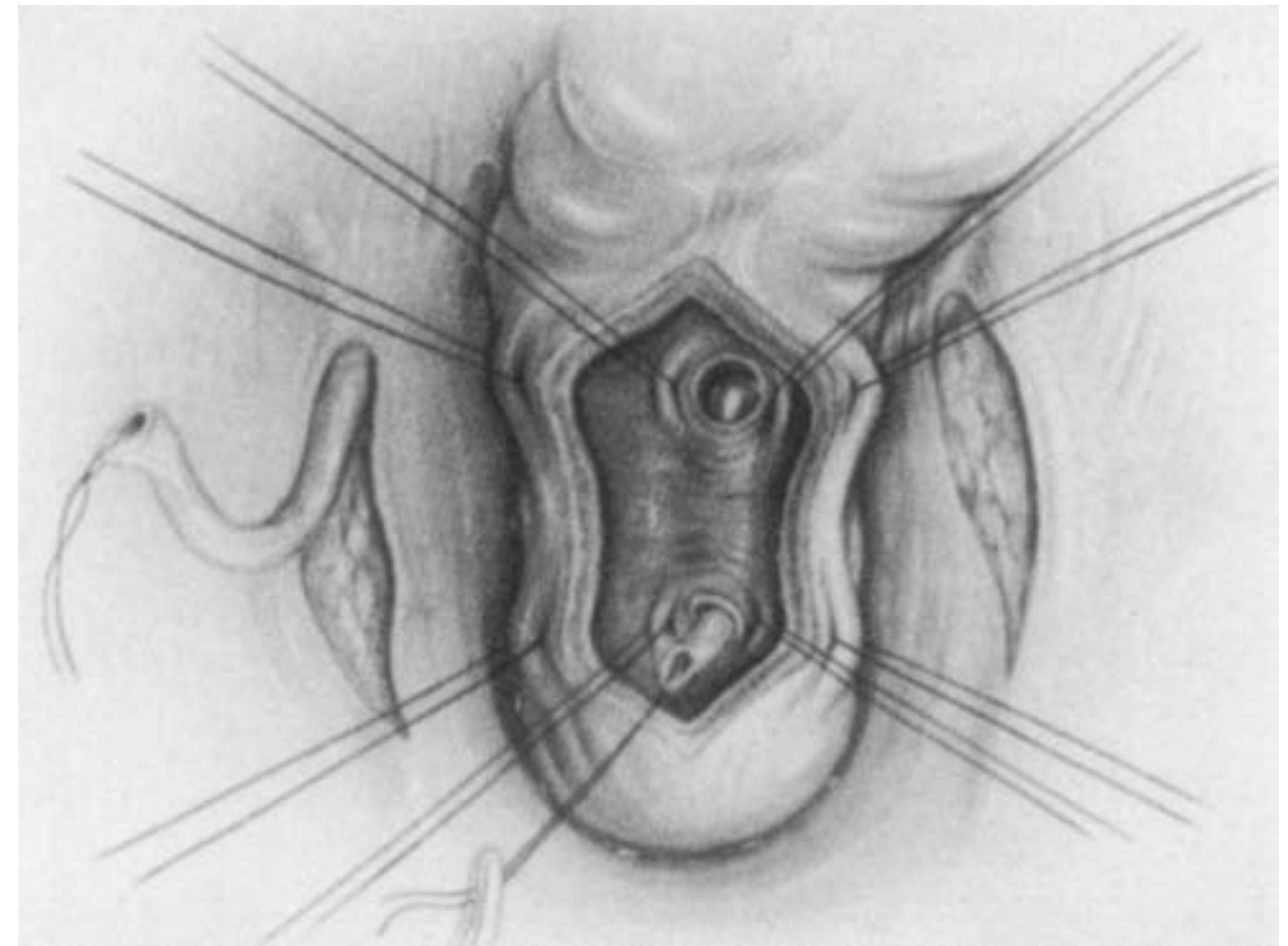

The colon is slightly elevated at the rectosigmoid junction by four stay sutures. After opening of the sigmoid colon over a length of 4 cm by an incision of anterior teniae, four mucosal stay sutures are placed in the mucosa of the posterior aspect of the sigmoid (Fig. 93.1). The bowel mucosa is incised between

**FIGURE 93.1** Open transcolonic ureterosigmoidostomy: Both ureters have been cut at its entrance into the bladder and mobilized. The sites of the planned ureteral implantations in the posterior sigmoid wall are outlined by stay sutures.

**FIGURE 93.2** After incision of the mucosa and a buttonhole type of excision of the posterior bowel wall site, the ureter is to be brought through the intestinal wall; a subperitoneal tunnel is modeled bluntly from this point to the left incision in the peritoneum. The curved clamp is advanced precisely below the peritoneum

**FIGURE 93.3** The ureter has been pulled into the bowel and through a submucosal tunnel reaching from the proximal to the distal stay sutures.

the proximal stay sutures, and a buttonhole type of excision of posterior bowel wall is performed. A straight or slightly curved clamp is advanced through the opening, and a tunnel is created by blunt dissection below the visceral peritoneum of the mesosigmoid (Fig. 93.2). The ureter is pulled into the lumen of the intestine. After creation of a submucosal tunnel of about 3 cm in length, the ureter is threaded through this tunnel, avoiding torsion of the ureter (Fig. 93.3). The anterior wall of the ureter is spatulated for a length of 1 cm. For the

ureterointestinal anastomosis, an anchor suture is placed at the 6 o'clock position grasping intestinal mucosa and musculature (5-0 polyglactin), and the anastomosis is completed by several ureteromucosal single stitches (6-0 polyglactin). A 6Fr silastic stent is inserted into the ureter and fixed to the mucosa by a polyglactin 4-0 suture (Fig. 93.4). The contralateral ureter is implanted about 3 cm lateral and either proximal or distal to the first anastomosis using the same technique (Fig. 93.5). The ureteral stents are inserted into the rectal tube

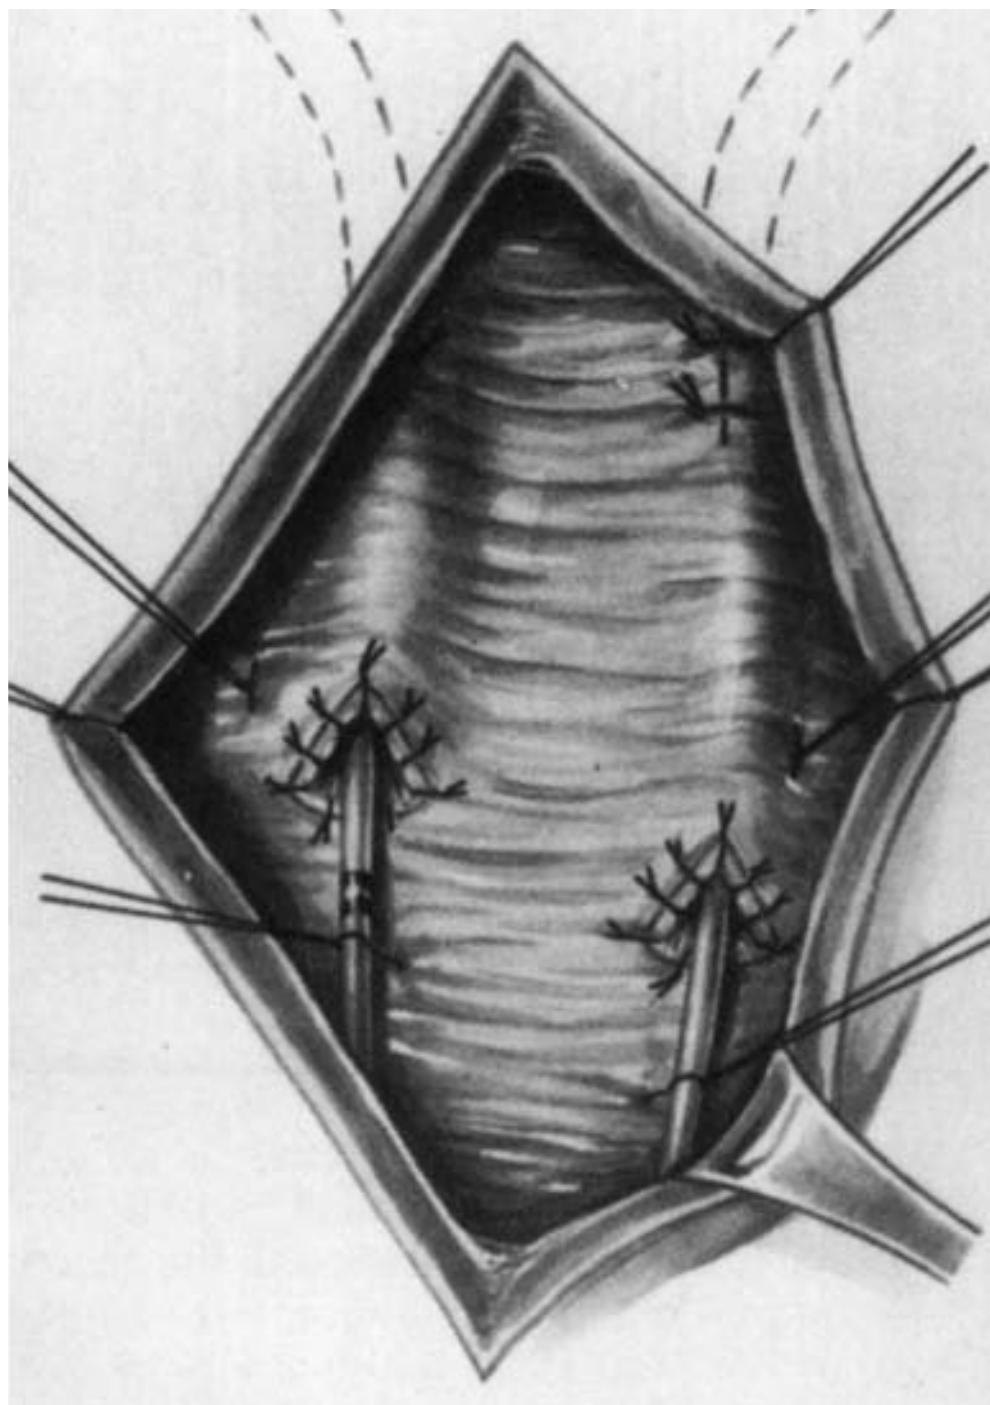

A

B

**FIGURE 93.4** Spatulation of the anterior wall of the ureter (A) and ureteromucosal anastomosis between ureter and intestinal wall. The ureter is stented (B).

**FIGURE 93.5** Identical implantation of the right ureter 3 cm lateral and proximal or distal of the first anastomosis.

and pulled out through the anus. Thereafter, the rectal tube is reinserted.

The anterior sigmoid colon is closed in one layer using interrupted sutures of 4-0 polyglactin or in two layers using running sutures (5-0 polyglactin for the mucosa and 4-0 polyglactin for the seromuscularis). The peritoneal incisions are closed. At the end of the operation separate fixations of the rectal tube and ureteral stents to the skin of the anus are performed (nonabsorbable material).

### Sigmoid-Rectal Pouch (Mainz Pouch II)

Access is gained by a median laparotomy as for ureterosigmoidostomy. The rectosigmoid junction is identified and two stay sutures are placed. The peritoneum is incised lateral to the descending colon and the left ureter is identified. Another peritoneal incision is made lateral to the ascending colon and the right ureter is identified. Both ureters are dissected down to the ureterovesical junction, respecting the longitudinal vessels running inside the Waldeyer sheet. The ureters are cut as distal as possible, stay sutures are placed at the 6 o'clock position, and the ureteral stumps are ligated.

For creation of the pouch, the intestine is opened at the anterior tenia starting from the rectosigmoid junction over a total length of 20 to 24 cm distal and proximal of this point (Fig. 93.6). By placing two stay sutures in the middle of the incision at the right side of the opened rectosigmoid, the intestine is positioned in a shape of an inverted U. The posterior wall of the pouch is closed by side-to-side anastomosis of the medial margins of the U using two-layer running sutures of 4-0 polyglactin for the seromuscular layer and 5-0 polyglactin for the mucosa (Fig. 93.7).

The left ureter is pulled through retromesenterically above the inferior mesenteric artery from the left to the right side

**FIGURE 93.6** Identification of the rectosigmoid junction.

(Fig. 93.8). For ureteral implantation, four mucosal stay sutures are placed parallel right and left to the medial running suture. The mucosa is incised, and the seromuscular layer is excised between the two cranial stay sutures to create a wide buttonhole type of opening as an entrance of the ureter into

**FIGURE 93.7** Opening of the rectosigmoid at the anterior tenia starting from the rectosigmoid junction over a total length of 20 to 24 cm distal and proximal of this point. Side-to-side anastomosis of the medial margins of the cut bowel edges by two-layer closure using running sutures of absorbable synthetic suture material (4-0 for the seromuscular layer and 5-0 for the mucosa).

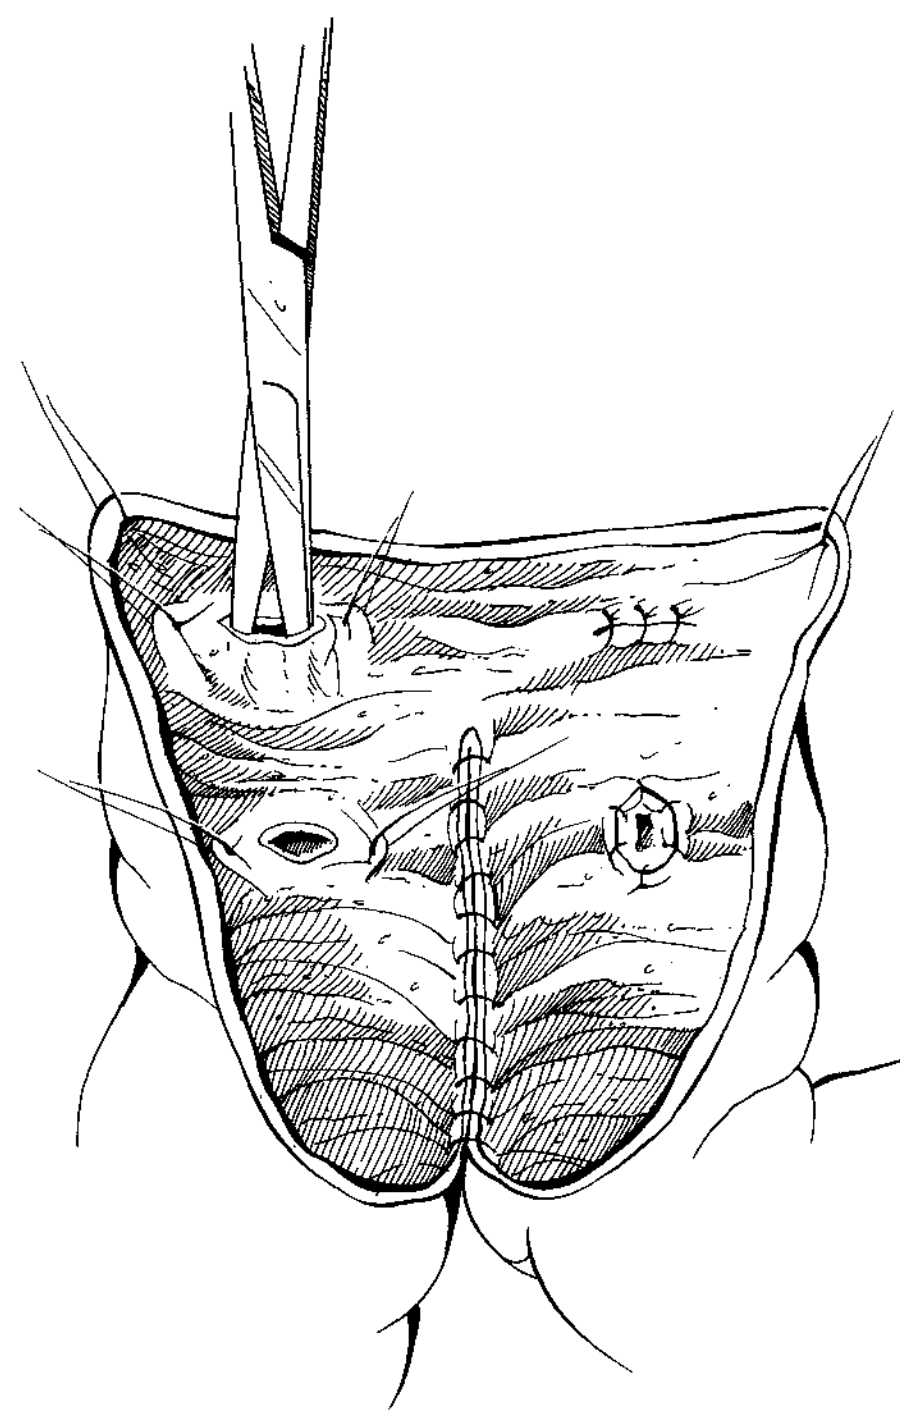

**FIGURE 93.8** The left ureter is pulled through retromesenterically to the right side.

the pouch. The dissection of the submucous tunnel starts from this incision downward over a length of 2.0 to 2.5 cm. The mucosa is incised at the distal end of the tunnel and the ureter is pulled into the tunnel. After having resected the ureter to an adequate length, implantation is completed by placing an anchor suture at the 6 o'clock position (5-0 polyglactin) and several interrupted ureteromucosal sutures (6-0 polyglactin). The cranial mucosal incision is closed by a running suture with polyglactin 4-0, which has a short reabsorption time. The contralateral ureter is implanted in the same manner (Fig. 93.9). Next, 6Fr ureteral stents are inserted into the ureters and are pulled out through the anus with the rectal tube, which is afterwards reinserted. The pouch is fixed to the anterior longitudinal band at the sacral promontory in the region of the proximal end of the posterior medial running sutures by two Bassini sutures of 3-0 nonabsorbable suture material (Fig. 93.10). Closure of the anterior pouch wall is performed in two-layer sutures (5-0 polyglactin for the seromuscular and 4-0 polyglactin for the mucosal layer). Alternatively, single-layer closure using interrupted stitches can be used (Fig. 93.11). The peritoneal incisions are closed and the anastomotic site of the pouch is covered by omentum. The rectal tube and the ureteral stents are separately fixed to the skin of the anus (nonabsorbable material).

### Serosa-Lined Extramural Tunnel Ureteral Implantation

Mobilization of the bowel includes the left colonic flexure (in cases of a short sigmoid segment). Dissection of the ureters is identical to the standard technique (Fig. 93.12). An S-shaped

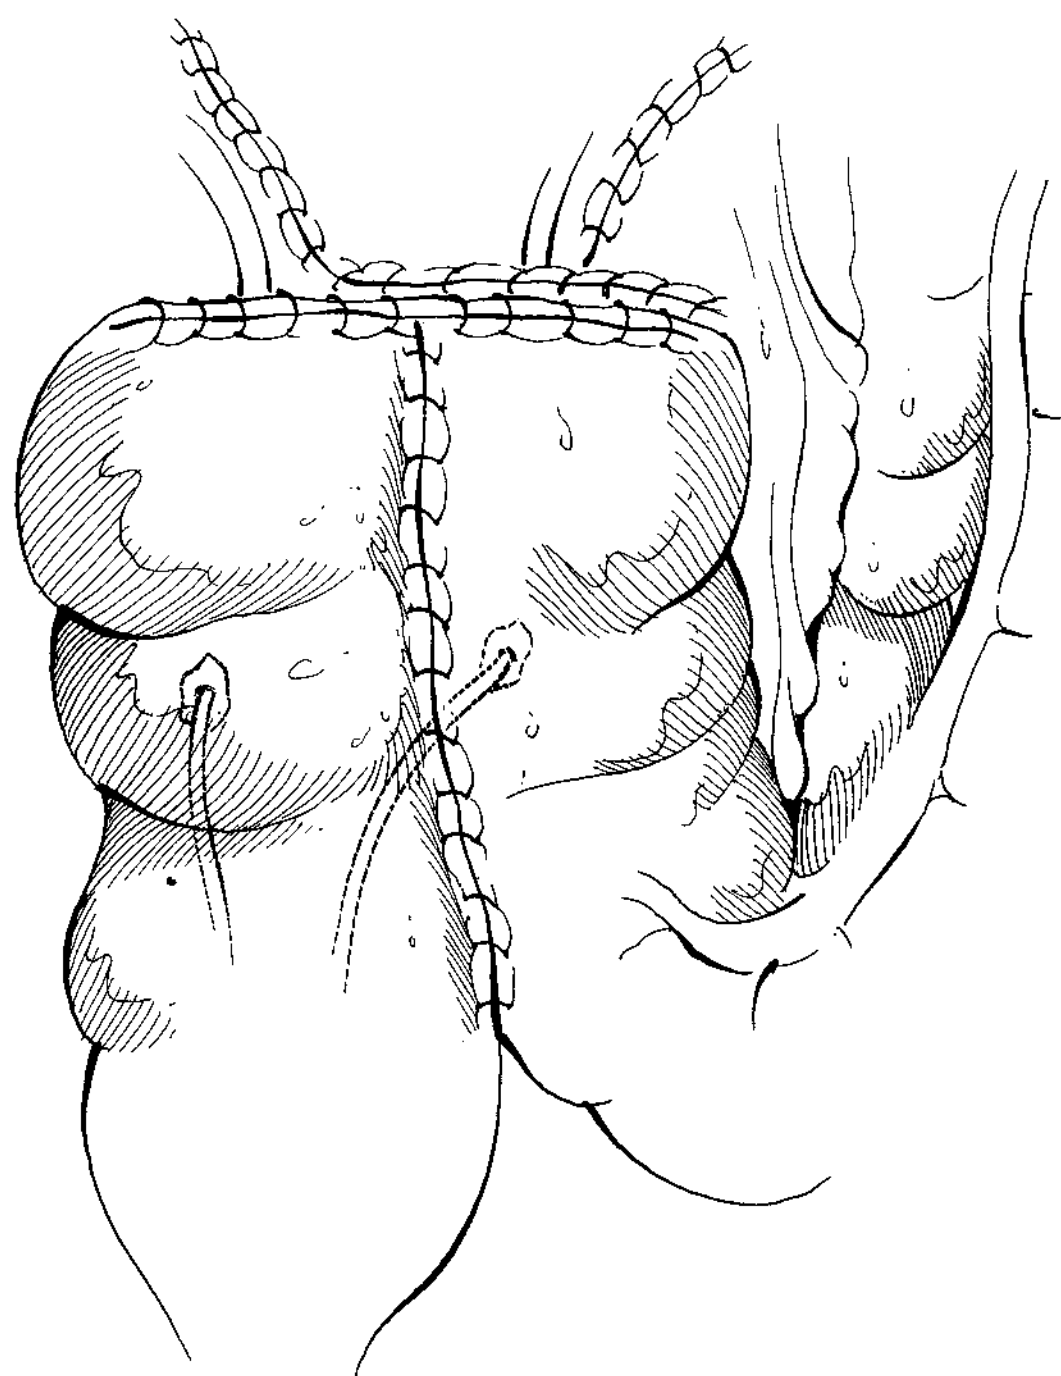

**FIGURE 93.9** The left ureter is pulled through retromesenterically to the right side.

sigmoid segment is outlined by stay sutures, with each limb of 10- to 12-cm length, resulting in a total length of 30 to 36 cm (Fig. 93.13). After antimesenteric opening of the S-shaped sigmoid colon (Fig. 93.14) in the area of the anterior tenia, a

**FIGURE 93.10** After a 6Fr stent is inserted in each ureter, which are pulled out through the anus with the rectal tube, the pouch is fixed to the anterior longitudinal band of the spine in the region of the proximal end of the posterior medial running sutures by two Bassini sutures.

**FIGURE 93.11** Closure of the anterior pouch wall by seromuscular single stitches with 4-0 absorbable synthetic suture material. Closure of the peritoneal incisions.

**FIGURE 93.13** S-shaped sigmoid segment is outlined by stay sutures. The length of each segment is 10 to 12 cm, starting at the rectosigmoid junction (standard technique), adding another segment of 10 to 12 cm of ascending colon.

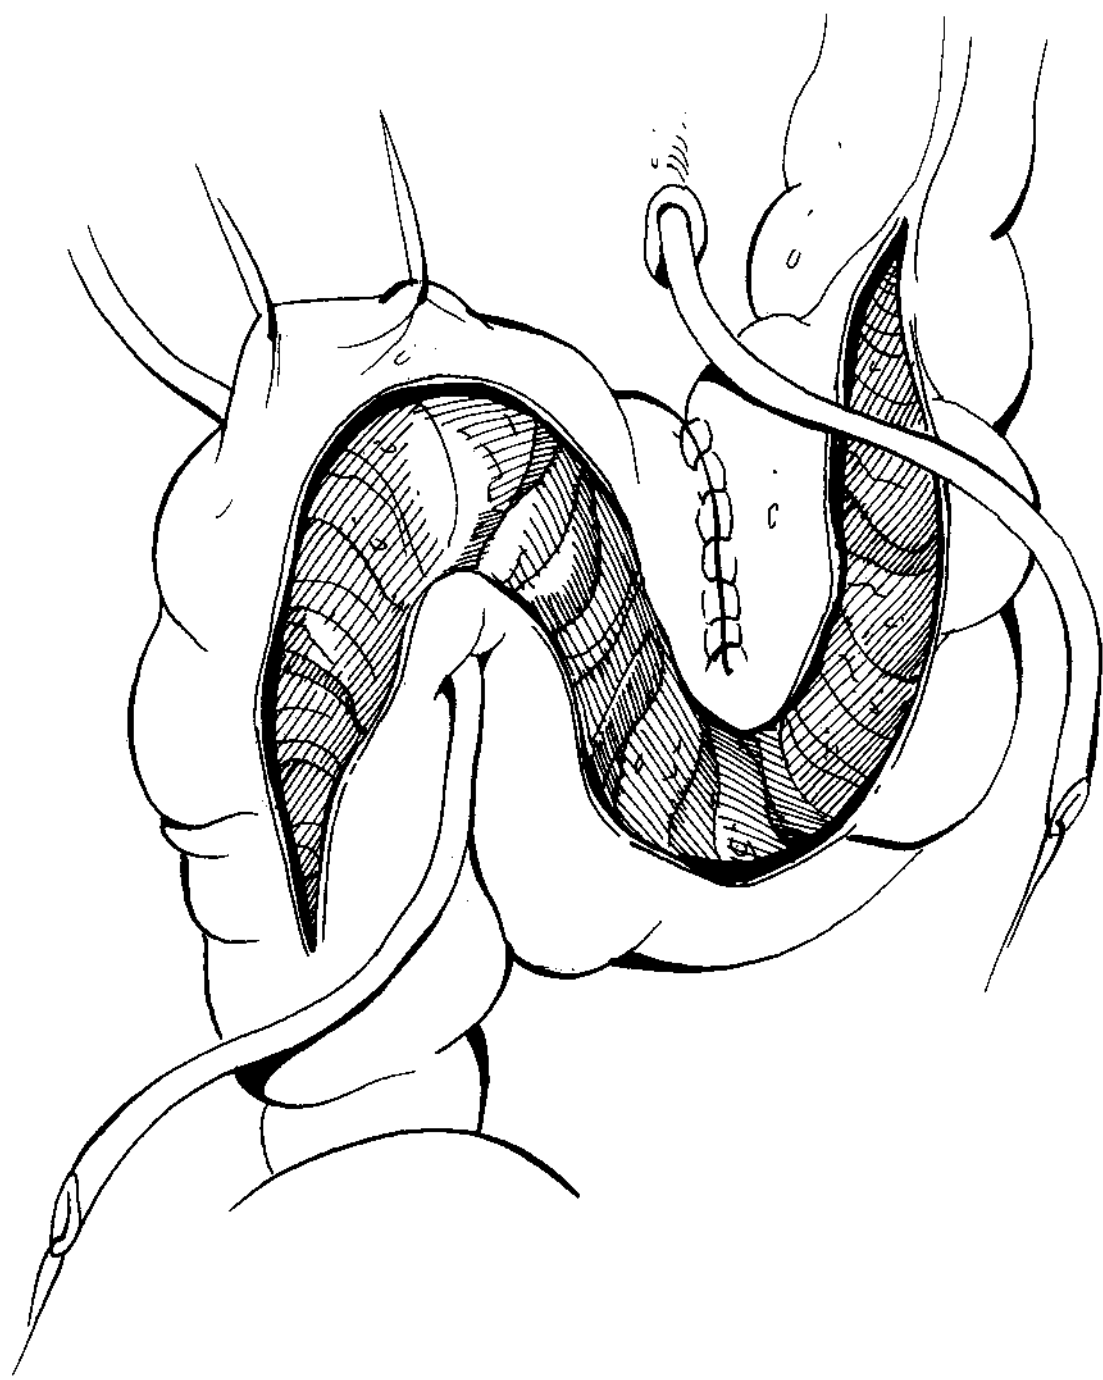

**FIGURE 93.12** Right and left paracolic incision; identification and dissection of the ureters.

side-to-side adaptation of the seromuscularis of both limbs is obtained by single-stitch sutures close to the mesentery (non-absorbable suture), thereby creating two serosa-lined channels. On the right side an entrance for the right ureter is left at the cranial aspect of the running suture. The mesentery cranial to the left running suture is incised and the left ureter pulled through. The ureters are placed in their respective channels (Fig. 93.15), and the cut edges of the bowel are sutured above

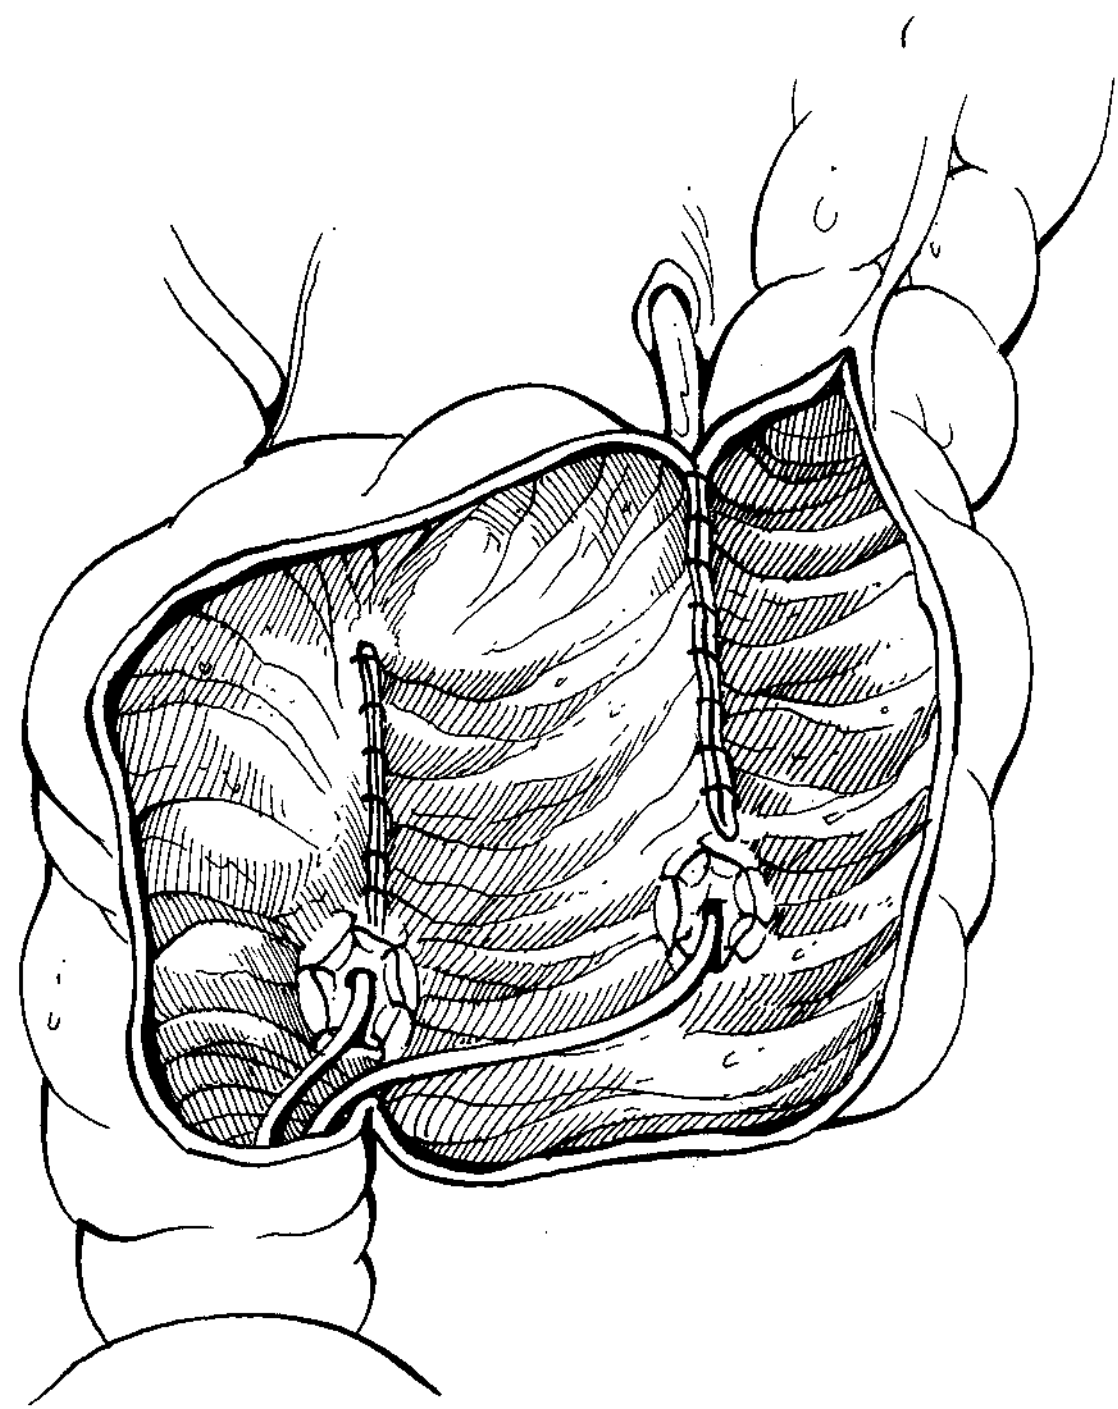

**FIGURE 93.14** The marked segments are opened in the area of the anterior tenia. Excision of a mesenteric window for pull-through of the left ureter.

the ureter with a running suture incorporating all layers, thus converting the channel into a tunnel. The length of the tunnel should be four times the diameter of the ureter. For implantation, the ureter is cut at its required length and spatulated.

**FIGURE 93.15** Side-to-side adaptation of the seromuscularis of the limbs of the S by two interrupted sutures close to the mesentery (4-0 nonabsorbable suture), thereby creating two serosa-lined channels. On the right side, an entrance for the right ureter is left at the cranial aspect of the running suture and the ureter is pulled through. One ureter is placed in each channel created between the segments of the S.

**FIGURE 93.16** Ureteral implantation in the area of the continuous suture line. Insertion of ureteral stents.

Four anchor sutures are placed at the 11 and 1 o'clock and the 5 and 7 o'clock positions through all layers of the ureter as well as all layers of the bowel wall (4-0 polyglactin). Ureteromucosal sutures are placed in between the anchor sutures to complete the anastomosis (5-0 polyglactin) (Fig. 93.16). Two ureteral stents are inserted and pulled out through the anus with the rectal tube after having been fixed to the bowel mucosa (4-0 polyglactin). The anterior pouch wall is closed by interrupted seromuscular sutures (4-0 polyglactin) (Fig. 93.17).

### Surgical Tricks (Sigmoid-Rectal Pouch)

When the anastomosis reaches deep down to the rectum, it is easier to suture the pouch starting caudally, as the deepest point of the anastomosis is the most critical part and can be reached more easily at the beginning of the anastomosis.

To facilitate fixation of the pouch to the promontory, one sutured end of the dorsal running suture can be pulled through dorsally outside of the pouch and be tightened with the fixation suture placed in the anterior band at the promontory.

A Bassini needle facilitates placement of the fixation suture through the anterior band of the spine.

During ureteral implantation, sufficient spatulation of the ureters is of utmost importance to avoid a nipplelike protrusion of the ureters.

To drain an incidental hematoma of the submucous tunnel, the mucosa covering the tunnel can be selectively incised at different points.

**FIGURE 93.17** The stents are pulled through the anus and the pouch is closed.

The S-shaped sigmoid-rectal pouch as created for the ureteral implantation via a serosa-lined tunnel has an ideal and stable position within the pelvis; therefore, no fixation to the promontory is needed.

---

## OUTCOMES

---

Of utmost importance for the outcome is patient selection. A functioning anal sphincter is a prerequisite. Also important are technical details such as ureteral implantation, side-to-side anastomosis by two layers, and the fixation at the promontory (classical technique).

Between 1990 and 1999 a sigmoid-rectal pouch was performed in 123 patients (94 adults and 29 children). Mean age was 44 years (10 months to 73 years). Indications were malignancy ( $n = 92$ ), bladder exstrophy and incontinent epispadias ( $n = 26$ ), trauma ( $n = 4$ ), and sinus urogenitalis ( $n = 1$ ). A total of 102 of the 123 patients were followed, with a mean follow-up of 46.2 months (1 to 9 years). Eight patients died during follow-up due to their primary malignant tumor; another 2 died unrelated to the underlying disease. Eleven were lost to follow-up. Four early pouch-related complications were encountered: two dislodged ureteral stents requiring temporary nephrostomy and one ileus treated by operative intervention. One patient developed severe complications as a result of anastomotic leakage from a pouch fistula requiring revision and colostomy. Stenosis at the ureteral implantation site was the most common complication (7%, or 14 renal units). Eleven renal units required surgical reimplantation. During follow-up, pyelonephritis was observed in 3% of patients. Ninety-nine of the 102 patients were completely continent postoperatively; nighttime continence was 95%. The majority of the patients (70 out of 102, or 69%) used alkalinizing drugs to prevent metabolic acidosis.

Between 1991 and 2004 a total of 38 children with a mean age of 5 years underwent a Mainz pouch II procedure. Of these, 33 had bladder exstrophy or incontinent epispadias. In 14 children (37%) urinary diversion was performed after failed primary reconstruction. Thirty-five children could be followed, with a mean follow-up of 112 months (range 5 to 147). All children were continent during daytime, but 3 (8.6%) suffered from nighttime incontinence requiring pads. Six children (15.8%) had developed pyelonephritis, mostly with stenosis of the ureterointestinal anastomosis. Reimplantation

of the ureter was required in 10 of 69 renal units (14.4%), in 10.1% due to stenosis, and in 4.3% due to reflux. Early alkali supplementation was initiated in 24 (69%). No secondary malignancies were observed during follow-up.

Concerning quality of life, the Mainz pouch II serves as a satisfying continent urinary diversion for both sexes. No statistically significant differences in functional and symptom scales or global health status were detected between males and females. All scales but diarrhea showed good results, and the outcome was comparable to health-related quality of life in a reference population (4).

---

## COMPLICATIONS

---

The main complication is stenosis at the ureterointestinal anastomosis. The incidence in our series was 7% in the whole collective and 10% in the children. Hadzi-Djokic et al. (8) reported a stenosis in 11 out of 220 patients. Hammouda (9) used the serosa-lined extramural tunnel as well as the submucosal tunnel for ureteral implantation in 95 patients and found reflux in 1.6% of renal units and stenosis in 5.3%. Balloon dilatation and endoscopic incision of the stenosis have been described to treat ureterointestinal anastomosis; however, we would recommend open revision with reimplantation.

Pyelonephritis is described in our series (3,8,9) with an incidence of 3.0% to 15.8% and should be treated with antibiotics. Only those patients with recurrent pyelonephritis and a decrease in split renal function require ureteral neoimplantation.

About two-thirds of patients will develop an acidosis with a negative base excess. Early correction (starting from a base excess of  $-2.5$ ) with alkali supplementation is recommended to avoid further complications, especially in children. Incontinence is a rare complication but can be disastrous. In severe forms a conversion to another form of urinary diversion is required.

To discover secondary malignancies early, endoscopy is recommended starting from the fifth postoperative year.

# CHAPTER 94 ■ PALLIATIVE URINARY DIVERSION

BURKHARD UBRIG AND STEPHAN ROTH

The word *palliative* derives from the Latin *palliare*, which means “to cover with a coat.” The term *palliative therapy* implies the impossibility of cure. The main goal of palliative urinary diversion is the control or the prevention of symptoms caused by incurable diseases of the urinary tract, usually cancer. In addition to bladder and prostate cancer, advanced cervical, ovarian, breast, or colorectal cancer may interfere with the urinary tract.

Typical symptoms of locally progressive pelvic cancer with impairment of the urinary bladder include urgency, pelvic pain, pyocystitis, recurrent gross hematuria, ileus, and fistulas (e.g., vesicovaginal, vesicorectal, cloacal) that may severely compromise quality of life. In a broader sense, palliative treatment for ureteral obstruction may also be considered in this chapter.

---

## DIAGNOSIS

---

Diagnosis of incurable pelvic cancer is based on the diagnosis of metastatic disease or local infiltration of adjacent pelvic structures and organs. Diagnostic studies may depend upon the underlying pathology. In general, the detection of distant and locoregional metastases will be achieved with common imaging procedures: computed tomography and/or magnetic resonance imaging and bone scan. Urethrocystoscopy, rectal digital examination, and bimanual palpation of the pelvis by the experienced pelvic surgeon aid in local staging of the primary tumor and reveal important information on resectability.

---

## INDICATIONS FOR SURGERY

---

There are no prospective studies that compare bladder-preserving strategy versus palliative cystectomy in locally advanced bladder cancer. However, the clinical course of patients with advanced muscle-infiltrating bladder cancer under a bladder-preserving strategy is often dismal. In a recent study, 24 patients with muscle-infiltrating bladder tumor (mean age 81 years) were treated with bladder preservation for a mean 22.6 months (7). All complained of frequency, urgency, and severe nocturia. The mean hospital readmission rate was eight times per patient. Salvage cystectomy was required in 11 of 24 cases, in 7 alone because of recurrent macrohematuria. Major complications that might have been prevented with early cystectomy were ileus in three cases and an enterovesical

fistula in one. All patients in whom the bladder was preserved complained of severe symptoms that reduced the quality of life of their remaining life span (7).

Radical cystectomy with urinary diversion is nowadays a routine procedure with acceptable risk in many urologic departments. Recent reports have proven the feasibility of radical cystectomy with acceptable morbidity and mortality also in octogenarians (5). There is some evidence that radical cystectomy itself, if performed with minimal blood loss and in a time-efficient manner, does not decisively increase the morbidity of the palliative urinary diversion (8,11).

Therefore, in most palliative patients with acceptable surgical risk and good motivation for surgery, radical cystectomy with urinary diversion will be the most suitable option. Nevertheless, the decision will be made on an individual basis between the urologic surgeon and his or her patient. In some borderline cases the risk of the surgical approach is considered too high, either because of a poor general health condition (American Society of Anesthesiologists (ASA) score 3 and 4) or because the operation cannot be considered due to advanced age and limited life expectancy.

---

## ALTERNATIVE THERAPY

---

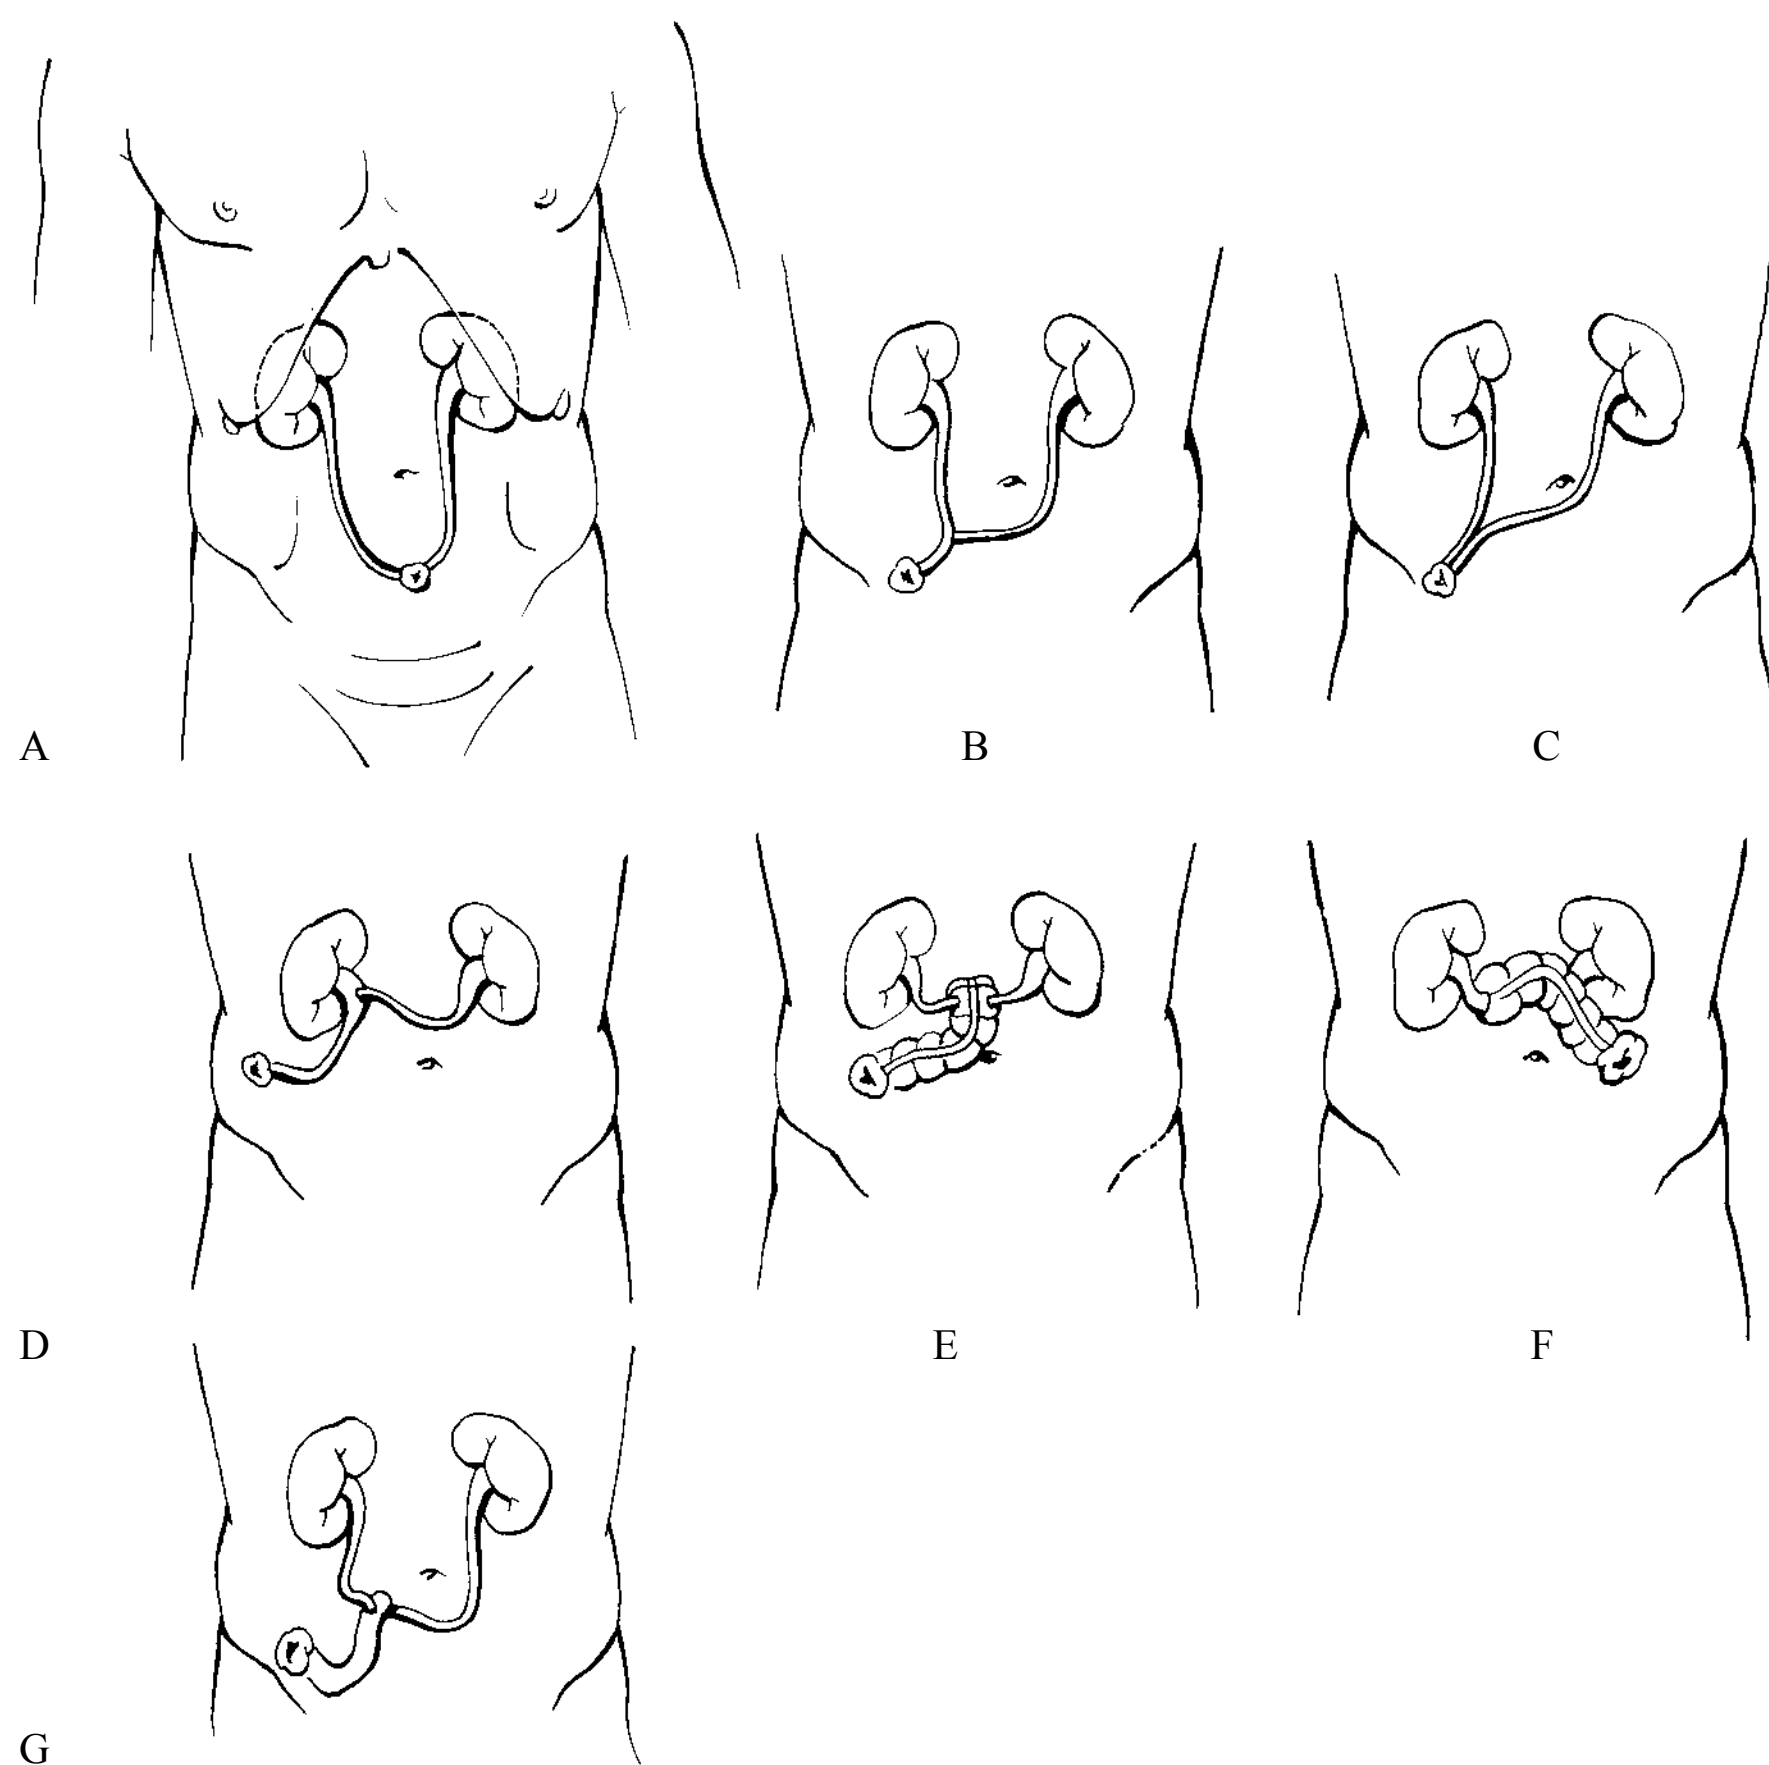

In most patients with locally advanced pelvic cancer, cystectomy or complete pelvic exenteration is the standard option. In a select group of patients with high surgical risk, frozen pelvis, and a short residual life expectancy, supravescical diversion without exenteration may be a viable option that results in good symptom control (12). Indications are infrequent, and results of this strategy have rarely been reported in the literature. Further alternatives to radical cystectomy with urinary diversion are observation, repeated transfusions, or indwelling catheters, depending upon the underlying disease process.

---

## SURGICAL TECHNIQUE AND OUTCOMES

---

Palliative urinary diversion will usually be performed with the lowest risk options that are acceptable to the patient. Continent orthotopic or cutaneous diversion will be considered if the patient is suitable and motivated. It may take 3 to 12 months before continence and an acceptable quality of life are attained (4). The presence of (completely resectable)

**FIGURE 94.1** Supravascular urinary diversion. **A–D:** Cutaneous ureterostomy with **(A)** median or **(B)** lateral stoma, **(C)** transureteroureterostomy, and **(D)** pyeloureteral anastomosis. **E and F:** Transverse colon conduit, with **(F)** anastomosis to the pylon; **(G)** ileal conduit.

nodal disease does not preclude the placement of an orthotopic bladder substitute (4). In general, conduits will often be preferred in palliative situations. Some patients for whom palliation is the goal may be very poor surgical candidates. Therefore, in these select cases, less elaborate techniques such as cutaneous ureterostomy or nephrostomy placement may also be considered.

### Ileal Conduit

Assuming adequate surgical risk and life expectancy, an ileal conduit is the first choice of many urologists in a palliative situation. Ostomy care is relatively easy, and patients may return to normal activity soon after discharge (Fig. 94.1). An ileal conduit should not be used in patients with short bowel syndrome or inflammatory small bowel disease and in those who have had high-dose radiation to the ileum. The small intestine and ureters are usually within the radiation portals for treatment of pelvic malignancy and may evidence long-term sequelae. Impaired healing of gut anastomosis and scarring with stricture formation of the ureterointestinal anastomosis may occur.

### Sigmoid Colon Conduit

The sigmoid colon is a viable alternative to ileum if the latter cannot be used for conduit construction (see above). However,

it should not be used if diseased, if exposed to radiation, or if the internal iliac arteries have been ligated with the rectum still in place. This last condition might lead to rectal sloughing because of compromised rectal blood supply (10). The stoma will usually be placed in the lower left abdominal quadrant (Fig. 94.1).

### Transverse Colon Conduit

The transverse colon is not within the radiation portals commonly used for pelvic malignancies, such as cervical cancer. The blood supply via the middle colic artery is usually ample (10). Indications for the use of transverse colon for conduit construction may be marked radiation fibrosis of the ureters or impaired ureteral mobilization because of frozen pelvis or periureteral lymph nodes. The ureterointestinal anastomosis can be accomplished with very short ureteral stumps. Also, anastomosis with the renal pelvis is feasible (Fig. 94.1). The perioperative mortality rate has recently been reported at 3% (10).

### Bilateral Cutaneous Ureterostomy with Single Stoma

In patients for whom major gut surgery is not advisable, cutaneous ureterostomy is an alternative to transintestinal diversion (Fig. 94.1); operative time is short, and renal function is

not a selection factor, while paralytic ileus rarely occurs. Construction of a single stoma in the lateral or midline position is generally feasible and ensures easy care with minimal patient discomfort. Occasionally, though, excessive obesity, extensive paraureteral lymph node involvement, or frozen pelvis makes construction of a single stoma impossible.

Stoma construction is of critical importance. Stomal stenosis rates of 50% and more have been reported (10). Distal spatulation of the ureteral end and plastic augmentation with a V-shaped skin flap as proposed by Rodeck should be considered (8). Stomal stenosis results mainly from ischemia of the distal ureteral end with consequent sloughing and fibrosis. Also, postoperative tension or hyperplastic epithelium at the ureterocutaneous anastomosis may play a role. Firm fixation of the anastomosis to the skin and healing by first intention are essential. The following different techniques have been proposed. Both ureters are guided to the skin and anastomosed with each other and the stomal skin (Fig. 94.1). This can be done by passing one ureter to the contralateral side through the retroperitoneum and behind the descending colon (8). Alternatively, in slender patients, the ureters may be mobilized completely extraperitoneally, led around the peritoneal sac, and conjoined in the midline. An infraumbilical stoma can then be formed (12).

---

### Transureteral Cutaneous Ureterostomy

---

One ureter is retroperitoneally led to the other side and anastomosed to the contralateral ureter end-to-side (e.g., with 5-0 Monocryl). This ureter will be guided through the abdominal wall and anastomosed to the skin.

---

### Transureteropyelocutaneous Ureterostomy

---

Alternatively, the collecting systems of both renal units have been connected with a high ureteral or pyeloureteral anastomosis (Fig. 94.1). Operative mortality was 1.75%; severe late complications occurred in 10.5%. The most frequent problems arose from the nephrostomy and from stenoses of the ureteropelvic or ureteral anastomosis (9).

---

### Percutaneous Nephrostomy

---

Percutaneous nephrostomy is another alternative for supravescical diversion. The advantages are the relative ease with which these can be placed under local anesthesia, but the drawbacks are the need for continuous replacement due to encrustation as well as the propensity for these to become dislodged. Bilateral nephrostomies are sometimes badly tolerated, and usually only the renal unit with better function should be diverted by nephrostomy.

To prevent further flow of urine downstream, additional occlusion of the ureter may sometimes be necessary. Transection and ligation of the ureter with nonabsorbable material may be performed. This may be accomplished by a small flank incision or laparoscopically. If feasible, a unilateral cutaneous ureterostomy may be the better alternative in such cases.

Several percutaneous techniques to obliterate the ureteral lumen have been proposed: butyl-2-cyanoacrylate, detachable balloons, liquid polyacrylonitrile, butyl-2-cyanoacrylate and lipiodol with adjuvant balloon catheter occlusion, electrocautery, and nylon and silicone occlusion devices. Some nephrostomy devices for transient closure of the ureteral lumen have been reported, including modified nephroureteral catheters and balloon occlusion devices. None of these methods has gained wide acceptance.

---

### Defunctionalization of the Contralateral Unit

---

If only one kidney is diverted and urine continues to flow downstream from the contralateral kidney, it may be necessary to defunctionalize the latter. Some palliative patients are poor candidates for nephrectomy. In a previously obstructed hydronephrotic kidney with significant parenchymal reduction, ligation and transection of the ureter will usually result in long-term success. Postinterventional paralytic ileus and some pain may be expected during the first postoperative days.

However, in unobstructed kidneys, ligation of the ureter should not be done because of significant pain and spontaneous ureteral recanalization. Usually renal arterial embolization will be considered. Excellent results to stop urine production from the kidney have been reported with transcatheter ablation with a mixture of ethanol and contrast agent and a combination of sponge and coil plugging of the proximal artery: Out of 20 patients, urinary flow ceased after 2 days in 18 patients; 2 required a second session. The authors propose epidural anesthesia, which may also be used in the first 2 postoperative days for pain control. Transient postinterventional paralytic ileus and fever may be expected (1).

---

## PALLIATIVE TREATMENT OF URETERAL OBSTRUCTION

---

Common causes of malignant compression of the ureterovesical junction and the prevesical ureter are bladder, prostate, and cervical cancers. Malignant obstruction of the mid- or upper ureter is usually caused by metastatic lymphatic spread as from metastatic breast cancer, lymphatic disease, colon cancer, and cancers of the female internal genitalia. However, even years after radiation therapy, newly arising ureteral obstruction may represent long-term sequelae of radiation and not tumor recurrence.

Indications for treatment should be considered very carefully. Septic episodes, with accompanying persistent pain, are rare in malignant ureteral obstruction if there has been no retrograde endoscopic manipulation. The insertion of a regular double-J stent or a nephrostomy will result in repeated consultations to change the catheters, sometimes under general anesthesia. Any measure carries the risk of infection or dislocation. Many patients are in critical condition, and quality of life should be the main treatment goal.

**FIGURE 94.2** Endourologic techniques for treatment of malignant ureteric obstruction. **A:** Ureteral stent. **B:** Two parallel ureteral stents. **C:** Metal stent. **D:** Nephrostomy tube. **E:** Extra-anatomic prosthetic bypass.

In patients with unilateral ureteral obstruction and sufficient function of the contralateral kidney, one should generally abstain from therapy; however, if nephrotoxic chemotherapy is planned or life expectancy exceeds 1 to 2 years, intervention may be indicated. In patients with bilateral ureteral obstruction and impending renal failure, it is usually sufficient to stent, divert, or bypass only one renal unit (usually the one with better function). In some patients, however, it may be preferable to abstain from any treatment at all. The use of the below-mentioned techniques assumes normal bladder function. Otherwise, suprav vesical diversion may be discussed.

Retrograde stenting with replaceable double-J stents is often considered the first-line option for relieving ureteral obstruction (Fig. 94.2). Transurethral resection will sometimes be necessary to find the ureteral orifice or intramural ureter hidden in the tumor. In these situations prior antegrade placement of a guide wire or antegrade placement of the stent itself may be very useful. Specific drawbacks of double-J stents are irritative bladder symptoms, stent obstruction, and encrustation—necessitating repeated changes (intervals range from 6 weeks to 6 months, but can be much shorter) and stent migration.

Under conditions of extrinsic compression, hard polyurethane stents are recommended over soft silicone to ensure patency of the stent lumen. Specially developed “tumor stents” are available.

### Two Double-J Stents

Extensive compression from the tumor may lead to malfunction and obstruction of conventional double-J stents. Liu and Hrebinko (6) used two 4.7Fr double-J stents passed simultaneously over guide wires when drainage with a single ureteral stent had failed. The increased stiffness of two stents

reduces kinking and luminal compression, and the potential space between the stents likely preserves flow around as well as through them (Fig. 94.2).

### Metallic Mesh Stents

Metallic mesh stents such as the Wallstent have been used with limited success. Epithelial hyperplasia and tumor ingrowth through the mesh have been reported to result in recurrent ureteral obstruction. These stents are virtually unremovable. An alternative might be nickel-titanium shape-memory alloy stents that occupy only the obstructed ureteral segment. These are soft and malleable at 10°C and regain their shape when reheated to 55°C. The tendency to form encrustations is apparently low (3).

### Extra-anatomic Pyelovesical Prosthetic Bypass

In 1992 Desgrandschamps and colleagues introduced their technique of pyelovesical bypass with a composite prosthesis (internal diameter, 18Fr; external diameter, 28.5Fr), and Jabbour et al. (2) reported long-term results with 35 prosthetic ureters in 27 patients, 22 with malignancies. Minor early and late complications were noted in 5 and 3 patients, respectively. No encrustations of the inner silicone lumen were noted, although asymptomatic bacteriuria sometimes was. The 5 surviving patients (4 with renal transplants, 1 with retroperitoneal fibrosis) were followed from 34 to 84 months (mean, 47 months), and the authors found no encrustation, kinking, or obstruction (2). Alternatively, single- or multiple-piece stents with small diameters (7Fr to 11Fr) have been used. Recent data from this work group suggest that quality of life

**FIGURE 94.3** Combined reconfigured colon segments for incontinent diversion of solitary kidney. **A, B:** A 6-cm segment is excised from the ascending or descending colon. The segment is split in the middle and the rings are opened antimesenterically. When reconfigured, the tube produced will be approximately 18 cm long, suitable for incontinent urinary diversion. **C:** Pyelocolocutaneostomy in a solitary kidney.

in patients with unimpaired bladder function may be better than with conventional nephrostomy tubes.

### Transverse Retubularized Colon Segments

In selected patients, transverse reconfigured colon segments may be used successfully to reconstruct extensive ureteral defects (Figs. 94.3 and 94.4). The successful use of a combination of two such segments has been described to divert solitary kidneys in palliative situations (11). In patients with renal insufficiency or a history of irradiation, this technique may be superior to the use of ileum. An advantage of the colon is its immediate proximity to the ureters bilaterally and its position outside the radiation portals for treatment of pelvic malignancy. Nevertheless, unreconfigured colon has not been widely recruited for ureteral replacement because of its wide diameter: Its large volume when replacing long defects could result in metabolic or septic complications. Surgical access is via flank or pararectal incision, and intraperitoneal surgery is minimal. The colonic segments are taken immediately proximal to the ureteral defect, necessitating little mobilization of the mesenteric pedicle. Metabolic consequences have not been described and should be absent or low, as only minimal amounts of intestine need be isolated (11).

**FIGURE 94.4** Interposition of a reconfigured colon segment to repair an extensive ureteral defect.

## CHAPTER 95 ■ NEUROBLASTOMA

W. ROBERT DEFOOR, JR., PRAMOD P. REDDY, AND CURTIS A. SHELDON

Neuroblastoma represents the most common extracranial malignant solid neoplasm of infancy and childhood and the most common intra-abdominal malignancy in the newborn. The biological, genetical, and morphological characteristics of this neoplasm demonstrate heterogeneous behavior. These tumors have a varied clinical course, with reports of spontaneous regression and tumor maturation from malignant to a benign histological form. However, in many cases the disease is progressive (1,2) and exhibits a wide spectrum of morphological differentiation, ranging from primitive (neuroblastoma) to well differentiated (ganglioneuroma), or between these two extremes (ganglioneuroblastoma).

The clinical incidence is approximately 1 in 8,000 to 10,000 children. There are approximately 500 new cases diagnosed each year in the United States; 90% occur in children <7 years old. Cervical and mediastinal lesions tend to present in younger patients (<1 year of age) and tend to have a better prognosis. Neuroblastoma is slightly more common in boys than in girls, with a ratio of 1.2:1, and has been described in familial settings (2). Infants presenting with the following four clinical conditions have a higher incidence of neuroblastoma than the general population: Beckwith–Wiedemann syndrome, Hirschsprung disease, fetal alcohol syndrome, and fetal hydantoin syndrome.

---

## DIAGNOSIS

---

The clinical presentation of neuroblastoma is varied and dependent upon the site of the primary tumor, the presence of metastatic disease, the age of the patient, and the production of metabolically active substances. Vasoactive tumors can present with hypertension. The catecholamine urinary metabolites, vanillylmandelic acid (VMA) and homovanillic acid (HVA), are elevated in >80% of patients with a neuroblastoma. An increased VMA/HVA ratio is associated with a better prognosis in localized disease. Other elevated metabolic products can include lactate dehydrogenase (LDH) >1,500 IU/mL, serum ferritin >142 ng/mL, and serum neuron-specific enolase (NSE) >100 ng/mL; these are associated with a poor prognosis.

At least 50% of children with neuroblastoma will have metastatic disease, including spread to the cortical bone, bone marrow, liver, and skin, at the time of initial presentation. Initial evaluation of a child with a suspected neuroblastoma includes random urine for VMA and HVA, chest radiograph, ultrasound of the abdomen, computed tomography (CT) or magnetic resonance imaging (MRI) body scans, radioisotopic bone scan, I<sup>131</sup>-metaiodobenzylguanidine (MIBG) scan, bone marrow aspirate/biopsy from multiple sites, and *N-myc* oncogene

TABLE 95.1

**EVANS STAGING SYSTEM**

Stage of Tumor	Description of Stage
I	Tumor confined to the organ of origin
II	Tumor extends beyond organ of origin but does not cross the midline; unilateral lymph nodes may be involved
III	Tumor extends across the midline; bilateral regional lymph nodes may be involved
IV	Distant metastases (skeletal, other organs, soft tissues, distant lymph nodes)
IV-S	Stage I or II with remote disease confined to one or more of the following sites: liver, skin, or bone marrow, but without evidence of bone cortex involvement

From Evans AE, D'Angio GJ, Randolph J. A proposed staging for children with neuroblastoma. *Children's Cancer Study Group A. Cancer.* 1971;27:374–378, with permission.

copy number of tumor. Serum LDH, ferritin, and NSE are also obtained.

---

## Staging Systems

---

Multiple staging systems have evolved in the management of neuroblastoma. The Evans–D'Angio staging system (Table 95.1) consists of a clinical assessment that describes the initial tumor distribution and incorporates whether the tumor crosses the midline (3). The International Neuroblastoma Staging System (INSS) incorporates many of the important criteria from each of these three staging systems and includes initial tumor distribution as well as its surgical resectability (Table 95.2) (4). The most useful histologic classification is the system described by Shimada (5). This system utilizes the mitosis karyorrhexis index (MKI) of nuclear fragmentation. This system divides the tumors into age-related favorable and unfavorable histologic categories based on whether the tumor exhibits a stroma-rich or stroma-poor appearance (Table 95.3).

---

## INDICATIONS FOR SURGERY

---

The management of patients presenting with neuroblastoma varies with the extent of disease at the time of diagnosis, the age of the patient, and the staging criteria used. If the patient

TABLE 95.2

## INTERNATIONAL NEUROBLASTOMA STAGING SYSTEM

Stage of Tumor	Description of Stage
1	Localized tumor confined to the area of origin. Complete gross excision, with or without microscopic residual disease. Identifiable ipsilateral and contralateral lymph nodes that are microscopically negative.
2-A	Unilateral tumor with incomplete gross resection. Identifiable ipsilateral and contralateral lymph nodes that are microscopically negative.
2-B	Unilateral tumor with complete or incomplete gross excision. Positive ipsilateral regional lymph nodes. Identifiable contralateral lymph nodes that are microscopically negative.
3	Tumor infiltration across the midline with or without regional lymph node involvement. Unilateral tumor with contralateral lymph node involvement or midline tumor with bilateral regional lymph node involvement.
4	Dissemination of tumor to distant lymph nodes, bone marrow, bone, liver, or other organs (except as defined in Stage 4-S)
4-S	Localized primary tumor as defined for Stage 1 or 2 (Stage 2-A or 2-B), with dissemination limited to the liver, skin, or bone marrow

From Brodeur GM, Seeger RC, Barrett A, et al. International criteria for diagnosis, staging, and response to treatment in patients with neuroblastoma. *J Clin Oncol*. 1988;6:1874–1881, with permission.

TABLE 95.3

## SHIMADA PATHOLOGIC CLASSIFICATION

	Favorable Histology	Unfavorable Histology
Stroma rich	Well-differentiated, intermixed appearance	Nodular appearance
Stroma poor		
Age <18 mo	Mitosis karyorrhexis index (MKI) < 200/5,000	MKI < 100/5,000
Age 18–60 mo	MKI > 100/5,000	MKI > 100/5,000
	Differentiating	Undifferentiated
Age >5 yr	None	All

Shimada H, Ambros IM, Dehner LP, et al. The International Neuroblastoma Pathology Classification (the Shimada system). *Cancer*. 1999;86:364–372, with permission.

has stage I or II disease (with favorable histology), then surgical resection alone can be undertaken with reasonable success. A multimodal approach utilizing chemotherapy, radiation, and surgery is used for advanced disease (stages III and IV).

Surgical intervention (“second-look” laparotomy) after open biopsy is usually performed 13 to 18 weeks after chemotherapy has been administered. During this procedure, surgical resection and dissection may appear to be somewhat easier, especially around vital structures and major blood vessels, because chemotherapy usually makes the tumors smaller and firmer. This rubbery consistency also decreases the risk of rupture and spillage of the tumor that might otherwise be encountered. Intraoperative radiation (IORT) may be utilized and is helpful in reducing the exposure to normal adjacent structures. In advanced-stage tumors radiation therapy is delivered to the tumor bed and regional lymph nodes.

### Neonatal Observation Protocol

For neonatally detected adrenal tumors that are thought to be localized neuroblastoma, an option for close observation without surgical intervention has been proposed. This is based on the experience that many of these lesions may regress or

mature spontaneously, and the majority of persistent tumors have favorable biological activity, with a 95% 4-year survival. In addition, there are significant surgical risks of ablative surgery in small or preterm neonates. Consequently, some centers have adopted a “wait-and-see” strategy of management for those detected from prenatal screening. However, each case should be evaluated thoroughly and carefully, with any possible benefit balanced against the morbidity of the diagnosis (6).

### SURGICAL TECHNIQUE

In cases of very large tumors where resection of adjacent organs or intestine might be required, a mechanical bowel preparation is reasonable. The procedure is performed with the patient in a supine position. The patient should be given prophylactic antibiotics (broad-spectrum cephalosporin). Depending on the location and size of the tumor, the surgeon can choose between three different incisions: (a) transverse transperitoneal–supraumbilical incision (for primary tumor of the retroperitoneum), (b) bilateral subcostal chevron incision (for large tumors), or (c) thoracoabdominal incision (for upper abdominal and/or large tumors).

The retroperitoneum is entered by incising the posterior peritoneum along the white line of Toldt. The colon is reflected medially to expose the retroperitoneum. For left-sided tumors the spleen and pancreas are displaced upward and medially. For tumors on the right side the various peritoneal attachments of the liver can be divided to improve exposure. In children with locally metastasizing disease it is sometimes necessary to perform en bloc excision of adjacent organs (i.e., ipsilateral kidney, spleen). Neuroblastomas typically have a friable pseudocapsule; therefore, during dissection it is useful to think of the surgery as aimed at dissecting the patient from around the tumor to decrease the risk of tumor spillage.

Vascular control should be achieved early in the procedure. These tumors often invade the tunica adventitia of large blood vessels; therefore, special care should be taken to identify and spare the blood supply to important visceral structures such as the branches of the celiac axis and superior mesenteric artery. The venous drainage of these tumors is usually constant, with right-sided tumors draining directly into the inferior vena cava. Left-sided tumors drain into the left renal vein and subdiaphragmatic venous tributaries. Regional lymph nodes should be sampled to complete the surgical staging. Once the tumor has been resected, the margins of the tumor bed should be marked with titanium clips to guide radiation therapy. A liver biopsy is indicated if there is clinical or imaging suspicion of disease within the liver; an effort should be made to biopsy the involved area.

In some instances it is not possible to perform primary resection of the tumor; in these cases a wedge biopsy of the tumor should be obtained for histopathological and genetical analysis. Neuroblastoma tissue should be rushed to the lab for processing in a fresh state. Following a good response to chemotherapy, the residual tumor may be successfully removed at a “second-look” procedure (7).

---

### Laparoscopic (Minimally Invasive) Procedures for Neuroblastoma

---

Minimally invasive surgery (MIS) procedures are accepted as a safe alternative to open surgery. Its use in children has been increasing rapidly as evidenced by a growing body of literature. The theoretical benefits include decreased surgical stress, decreased postoperative morbidity, decreased use of narcotic analgesics, reduced time to initiation of enteral nutrition, and improved cosmetic appearance. Most importantly, the earlier recovery may reduce the time to initiation of adjuvant therapy. Previously, MIS techniques were reserved for biopsy prior to planned multimodal therapy in diffuse disease; however, there are several contemporary reports in the literature that have described MIS, including the use of the surgical robot, as a safe alternative to open surgery for excision of small localized primary lesions. This has not gained widespread international acceptance; thus, the following discussion is limited to the technique of laparoscopic biopsy.

General anesthesia is induced and the patient undergoes endotracheal intubation. An orogastric or nasogastric tube and urethral catheter are placed. The patient is then positioned in a 45-degree lateral decubitus position. The use of the open Hasson technique is strongly recommended for initial umbilical trocar placement (5 to 12 mm) to lower the risk of visceral or vascular injury associated with the Veress needle

technique. A pneumoperitoneum is created, with the pressure maintained at around 12 mm Hg. Two 3- or 5-mm ports are then placed under laparoscopic vision. The retroperitoneum is then dissected using electrocautery and/or a Harmonic Scalpel (Ethicon Endo-Surgery, Ohio).

On the right side, the retroperitoneum may be entered by a transverse incision in the posterior peritoneum to expose the inferior vena cava and the region of the adrenal gland. When operating on a left-sided lesion, the colon should be mobilized; this is achieved by incising the posterior peritoneum along the line of Toldt from the splenic flexure to the pelvic rim. The major vessels surrounding the tumor, such as the inferior vena cava and the renal vein and artery and the adrenal vessels, are mobilized by blunt dissection; this dissection should begin medially and proceeds laterally. Vascular control may be obtained at this time prior to proceeding with the biopsy or excision of the mass.

Once the tumor surface has been adequately exposed, a Tru-cut biopsy of the tumor can be obtained by passing the biopsy needle through one of the 5-mm ports or directly through the abdominal wall and performing the biopsy under visualization. Hemostasis is then obtained. It is recommended that an incisional biopsy be obtained when possible as this minimizes the chances of sampling error and provides the surgical pathologist with adequate quantities of tissue. The tissue specimen is placed in a laparoscopic bag and removed through the umbilical port. The defect may be cauterized, but to achieve complete hemostasis, an absorbable hemostatic agent may be applied to the surface of the tumor. The fascial defect left by the ports is closed with an absorbable suture, and the skin edges are approximated. Some authors advocate that the fascial defect in 5-mm and smaller ports does not require closure because the risk of visceral herniation is low (8). No drains are left at the end of the procedure. To avoid port site recurrence, high-dose adjuvant chemotherapy is given as soon as possible.

---

## OUTCOMES

---

### Results

---

Modern chemotherapy has conferred improved survivability upon many pediatric neoplasms (e.g., Wilms tumor); however, in the case of neuroblastoma chemotherapy has had no such effect. Although a demonstrable initial tumor response is achieved in 70% to 80% of patients, current chemotherapeutic protocols have not effectively increased the cure rate in patients with neuroblastoma. The main purpose of chemotherapy in the management of children with stage II or higher-stage neuroblastoma is to reduce the size of the tumor (permitting surgical excision), to clear the bone marrow of tumor cells, and possibly to produce histological maturation of the tumor.

Figure 95.1 shows a coronal view from an MRI scan of a solitary tumor adjacent to the lower pole of the right kidney. The patient was treated with surgical excision alone and remained free from relapse. Figure 95.2 shows the microscopic pathology from the same mass consisting of small round blue cells typical of neuroblastoma. Patients such as this with Evans stage I or II with favorable histology (low-risk) neuroblastoma do not

**FIGURE 95.1** Coronal MRI scan of a 1-year-old girl found to have a left pararenal mass on a screening ultrasound after a urinary tract infection.

**FIGURE 95.2** Microscopic view of lesion excised from patient in Figure 95.1 showing small round blue cells consistent with neuroblastoma.

require adjuvant chemotherapy if the tumor can be surgically excised. Patients with stage II to IV disease and poor prognostic biological factors (intermediate- to high-risk neuroblastoma) should be treated with multiagent chemotherapy, including a combination of carboplatin, doxorubicin (Adriamycin), cyclophosphamide, and etoposide (VP-16) (9).

Clinical experience has demonstrated that neuroblastoma is a radiosensitive tumor. Tumor shrinkage and symptomatic pain relief are often observed after radiation treatment. In patients with advanced neuroblastoma, lymph node metastases, and/or incomplete surgical resection of the primary tumor, chemoradiotherapy appears to improve long-term disease control as compared to chemotherapy alone (10,11). Radiation

therapy protocols include delivery of hyperfractionated radiotherapy (2,100 cGy at 150 cGy twice daily). The final setting for external beam treatments is a total body irradiation given as part of a preparative regimen for autologous bone marrow transplantation. IORT is being used to treat patients with advanced-stage disease. Initial reports demonstrate a low complication rate with IORT and a 38% 3-year survival rate in patients with stage IV disease.

The age of the patient and the stage of the disease at the time of diagnosis were the two main independent variables determining the prognosis of children with neuroblastoma. The worst survival data were observed in patients older than 1 year, with stage IV disease, and with metastases to cortical bone (12). Over the years a number of factors have become available to the clinician managing these patients to help determine the prognosis of the individual patient. These factors are presented in Table 95.4. Patients with neuroblastoma detected by urinary screening for VMA and HVA in Japan have a survival rate of 96%, suggesting that most of these tumors spontaneously regress and do not present with clinical disease (13). The intrinsic properties of the tumor itself appear to be the greatest determinant of the eventual outcome of the patient with neuroblastoma. Survival data from the Children's Cancer Group neuroblastoma protocols are presented in Table 95.5 (13).

---

### Surgical Complications

---

Among the potential complications of open surgery are vascular injuries that may occur during dissection of the tumor. Others complications include injury to adjacent intraperitoneal organs (e.g., splenic injury, pancreatic injuries), lymphatic leak, brachial plexus injury related to patient positioning, and acute renal failure (secondary to spasm of the renal artery). MIS complications include hypercapnia, hypothermia, surgical emphysema, and electrosurgical complications. Others are gas embolisms, tension pneumothorax, complications of surgical access, Veress needle injury to blood vessels or bowel structures, access failure, bleeding/vascular injury, and visceral injuries. Port site neoplastic recurrences have also been described.

---

### CONCLUSION

---

Neuroblastoma is a common pediatric malignancy that remains an enigma because of the high variability in its natural history and behavior. Information on prenatally detected cases and the infant screening programs have clearly demonstrated that some tumors spontaneously regress and may be managed with close observation. A better understanding of the factors influencing tumor regression, tumor differentiation, and tumor–host immunorelations will improve our ability to identify and aggressively treat patients at risk for a poor outcome (14). This knowledge may also allow a decrease in treatment-related morbidity in patients with low-risk tumors. Ongoing clinical trials utilizing retinoic acid and gene therapy may result in the development of additional tools in the clinical armamentarium to better treat neuroblastoma and further improve the prognosis of these patients (15).

# CHAPTER 96 ■ WILMS TUMOR

SARAH CONLEY AND MICHAEL L. RITCHEY

Wilms tumor, or nephroblastoma, is the most common solid tumor of childhood. It represents approximately 6% of all childhood cancers in the United States and is the most common primary malignant renal tumor of childhood. The incidence of Wilms tumor is 1 in 10,000 children, with a new case rate of approximately 500 annually in the United States. The incidence has remained stable for the past several decades and is equal among boys and girls (1). The mean age at diagnosis for unilateral Wilms tumor is 36.5 months for boys and 42.5 months for girls. The age of peak incidence for bilateral tumors is lower for both sexes: 29.5 months for boys and 32.6 months for girls.

Most cases of Wilms tumor are sporadic; however, there are certain phenotypical syndromes associated with Wilms tumor (2). These syndromes are divided into overgrowth and non-overgrowth categories. Examples of overgrowth syndromes include Beckwith–Wiedemann syndrome, Perlman syndrome, Sotos syndrome, and Simpson–Golabi–Behmel syndrome. Examples of non-overgrowth syndromes include isolated aniridia, trisomy 18, WAGR syndrome (Wilms tumor, aniridia, genitourinary malformations, and mental retardation), Bloom syndrome, and Denys–Drash syndrome. Wilms tumor is also associated with isolated genitourinary anomalies such as hypospadias, cryptorchidism, and renal fusion. Less than 2% of Wilms tumor cases show familial patterns of inheritance.

The identification of the relationship between Wilms tumor and WAGR syndrome led to the discovery of genes associated with Wilms tumor. The WT1 gene located on chromosome 11p13 encodes a transcriptional factor that serves both tumor-suppressive and developmental regulatory functions (2). Nonmutated WT1 is critical in the early embryogenesis of the genitourinary system. WT1 mutations are present in up to 15% of patients with unilateral Wilms tumors (3). Another genetical mutation associated with Wilms tumor has been designated the WT2 gene, located on chromosome 11p15. Loss of heterozygosity (LOH) at this locus is associated with Beckwith–Wiedemann syndrome.

LOH at chromosome 16q and/or 1p occurs in up to 20% of Wilms tumors (4). These have been shown to be associated with an increased risk for tumor relapse and mortality. In National Wilms Tumor Study (NWTS)-5, patients with stage I or II favorable-histology Wilms tumor (FHWT) and LOH of either 1p or 16q had an increased relative risk of relapse and death compared to patients lacking LOH at either locus. The risks of relapse and death for patients with stage III or IV FHWT were increased only with LOH for both regions.

Nephrogenic rests (NRs) are foci of primitive metanephric tissue that persist into infancy and are found in 1% of infant postmortem kidneys. The presence of NRs in up to 44% of kidneys removed for Wilms tumor suggests that they

represent precursor lesions in children genetically predisposed to Wilms tumor. NRs are categorized as either perilobar or intralobar based on their anatomical location within the kidney. Perilobar NRs are observed in kidneys harboring Wilms tumors with WT2 locus deletions, whereas intralobar NRs are more often observed in those with WT1-associated tumors (5). The presence of multiple NRs in the nontumoral portion of a Wilms tumor kidney has been shown to be a risk factor for development of metachronous tumor in the contralateral kidney.

---

## DIAGNOSIS

---

More than 90% of children with Wilms tumor present with an asymptomatic abdominal mass discovered incidentally by a family member or physician. The mass may be extremely large relative to the size of the child and is not necessarily confined to one side. Approximately 20% of children with Wilms tumor have hematuria at diagnosis. Gross hematuria warrants further evaluation to rule out tumor extension into the collecting system (6). Other symptoms include fever, anorexia, and weight loss in 10% of patients. Rarely children may present with acute abdominal pain from tumor rupture into the peritoneal cavity or bleeding within the tumor. A persistent varicocele in the supine position or hepatomegaly may be reflective of inferior vena caval obstruction from tumor thrombus. Atrial thrombus may present as hypertension or congestive heart failure.

The preoperative laboratory evaluation of a child with an abdominal mass should include a complete blood count, liver enzymes, and serum electrolytes, including blood urea nitrogen, creatinine, and calcium. There is an 8% incidence of acquired von Willebrand disease in patients newly diagnosed with Wilms tumor. Coagulation studies, including prothrombin time and partial thromboplastin time, may be normal in the presence of von Willebrand disease. This defect can be corrected preoperatively with the administration of 1-desamino-8-D-arginine-vasopressin (DDAVP).

The first radiographic study usually obtained in children with an abdominal mass is an abdominal ultrasound, which can differentiate between solid and cystic masses. Real-time ultrasonography of the renal vein and inferior vena cava (IVC) can evaluate for the presence of tumor thrombus in children with renal tumors. If this study is inconclusive, magnetic resonance (MR) imaging is an excellent modality to assess for venous tumor extension. All patients should undergo computed tomography (CT) of the abdomen and pelvis with oral and intravenous contrast or MR of the abdomen and pelvis with gadolinium. These imaging modalities allow for improved

preoperative planning by evaluating for extrarenal spread of disease, the relationship of the tumor to adjacent visceral structures, and the presence of synchronous tumors in the contralateral kidney. Preoperative chest CT is performed to rule out pulmonary metastases.

## INDICATIONS FOR SURGERY

There have been tremendous advances in survival with adjuvant therapy, but surgery remains an integral part of the multimodal approach to treatment of Wilms tumor. Primary radical nephrectomy is the procedure of choice for the majority of patients with unilateral Wilms tumor. Nephron-sparing surgery is preferred for children with bilateral tumors. It may be considered for some children with syndromes known to be at high risk for development of Wilms tumor, particularly if these patients are found to have small tumors on screening studies (7). There are reports of laparoscopic nephrectomy in children with unilateral nonmetastatic Wilms tumor who received preoperative chemotherapy (8). However, the role of laparoscopy prior to chemotherapy may be limited because of large tumor size and risk of intraoperative spillage. Histopathology and tumor stage have been demonstrated to be the key determinants of prognosis in patients with Wilms tumor. Tumor grade is the most important prognostic factor. Assignment of tumor stage (Table 96.1) is based on intraoperative and pathological findings.

The International Society of Pediatric Oncology (SIOP) advocates preoperative chemotherapy for all patients with Wilms tumor regardless of the extent of disease. Preoperative treatment can produce dramatic reduction in the size of the

primary tumor, facilitating surgical excision. The SIOP trials have demonstrated that the incidence of tumor rupture is lower after preoperative therapy (9). There is no survival advantage over a primary surgical approach.

The Children's Oncology Group (COG) recommends preoperative chemotherapy in children with bilateral tumors, tumors inoperable at surgical exploration, or IVC extension above the hepatic veins. All other patients are recommended to undergo primary excision of the tumor. This allows precise staging of patients with modulation of treatment for each individual, thereby decreasing the intensity of treatment when possible while maintaining excellent overall survival.

## SURGICAL TECHNIQUE

The recommended surgical approach for Wilms tumor is through a transperitoneal transabdominal incision. An extraperitoneal flank incision should be avoided because it does not allow for proper staging. A generous transverse abdominal incision allows for inspection and exploration of the abdominal cavity. The patient is placed in a supine position with mild flexion of the lumbar spine to facilitate the exposure of retroperitoneal structures. The incision is made approximately two fingerbreadths above the umbilicus beginning in the midaxillary line on the side of the neoplasm. The extent to which the incision is extended across the midline will vary with the size of the tumor and amount of exposure needed. The incision may be extended into a thoracoabdominal approach by continuing through the bed of the ninth or tenth rib, if necessary. The muscle layers are divided sequentially to facilitate exposure. The peritoneal space should be opened carefully. The tumor may compress the colon and/or small bowel against the anterior abdominal wall, inadvertently resulting in enterotomy. A thorough exploration of the abdomen is performed. The peritoneal cavity is assessed for evidence of preoperative tumor rupture and peritoneal implants. The liver is carefully examined, as liver metastases may not be identified on preoperative imaging studies. An assessment of tumor extent is performed next, including palpation of the IVC and assessment of regional lymphadenopathy, perinephric extension, and tumor mobility.

In the past, formal exploration of the contralateral kidney was routinely performed in children with presumed unilateral Wilms tumor to rule out synchronous bilateral tumors.

Imaging has improved dramatically over time and very few small contralateral lesions will be missed on preoperative imaging. Long-term outcomes in these cases are favorable (10). Contralateral renal exploration is no longer recommended if preoperative CT or MR demonstrates a normal kidney.

Following exploration of the abdominal cavity, the colon is reflected medially by incising the white line of Toldt. The colonic mesentery is mobilized, with care taken to preserve the colonic vessels that may be draped over the tumor. The colon can then be retracted medially to expose the renal vessels (Fig. 96.1). For right-sided tumors, the posterior peritoneum can be incised up to the base of the mesentery. This will allow reflection of the entire colon and small bowel, which provides excellent exposure of the retroperitoneal vessels. Early ligation of the renal vessels before manipulation is ideal. The renal vessels are identified and encircled individually with vessel loops.

TABLE 96.1

### STAGING SYSTEM OF THE CHILDREN'S ONCOLOGY GROUP

Stage	Characteristics
I	The tumor is limited to the kidney and completely excised. The renal capsule is intact and the tumor was not ruptured prior to removal. There is no residual tumor. The vessels of the renal sinus are not involved.
II	The tumor extends beyond the kidney, but is completely excised. There is regional extension of the tumor (i.e., penetration of the renal capsule, extensive invasion of the renal sinus). Extrarenal vessels may contain tumor thrombus or be infiltrated by tumor.
III	Residual nonhematogenous tumor confined to the abdomen: lymph node involvement, tumor spillage either before or during surgery, peritoneal implants, tumor beyond surgical margin either grossly or microscopically, or tumor not completely removed.
IV	Hematogenous metastases (lung, liver, bone, brain, etc.) or lymph node metastases outside the abdominopelvic region are present.
V	Bilateral renal involvement at diagnosis

**FIGURE 96.1** Descending colon retracted medially after incising of the line of Toldt and mobilizing of the mesocolon off the anterior surface of the tumor.

The artery can be identified with careful retraction of the vein. The renal vein and IVC should be carefully palpated for the presence of Wilms tumor thrombus, which occurs in 4% and 0.7% of patients, respectively. Prior to ligation of the vessels, the contralateral renal vessels and superior mesenteric artery are identified to avoid injury to these structures. Large tumors can significantly distort vascular anatomy. The renal vessels are then doubly ligated and divided. The renal artery should be ligated prior to the renal vein in order to avoid distention of the vein, which can dislodge the ligature. Early ligation of the artery also decreases the theoretical risk of tumor dissemination.

An alternative for management of the renal vein is to place a Satinsky clamp on the vena IVC just proximal to the insertion of the renal vein. This maneuver can be valuable when the vein is short or if there is tumor extension beyond the renal vein. The tumor thrombus is gently milked back prior to placement of the Satinsky clamp. The renal vein is then divided and the venous stump is oversewn with continuous 5-0 Prolene in two layers (Fig. 96.2).

If tumor thrombus is present in the IVC, additional surgical exposure is warranted. Both proximal and distal vascular control is necessary. For minimal thrombus extension below the level of the hepatic veins, the inferior edge of the liver can be retracted to expose the infrahepatic vena cava. For a tumor that extends more cephalad, mobilization of the liver is required. Division of the triangular and coronary ligaments of the liver allows rotation and exposure of the retrohepatic vena cava. Additional exposure can be gained by dividing the lesser hepatic veins. The contralateral renal vein and infrahepatic IVC are controlled with vessel loops. The vena IVC is then vertically incised just medial to the entrance of the renal vein. If the

thrombus is free floating, it is manually extracted at this point. In many cases, the thrombus is adherent to the wall of the IVC. A Fogarty or Foley balloon catheter can be passed beyond the level of the hepatic veins, then inflated. The catheter is then pulled inferiorly, thus displacing the adherent thrombus into the cavotomy. The vena IVC is allowed to fill by releasing the vessel loops on the distal cava and contralateral renal vein. This will displace the air from within the IVC. The cavotomy is then clamped with a Satinsky clamp and oversewn with a continuous 5-0 Prolene suture (Fig. 96.3). In rare instances, tumor thrombus invades the wall of the IVC, precluding thrombectomy, and this may necessitate partial resection of the IVC.

Patients with IVC extension above the level of the hepatic veins or atrial thrombus remain a difficult surgical challenge. Pretreatment with chemotherapy is usually done. If this fails to shrink the thrombus or if a primary surgical approach is chosen, the procedure may require cardiopulmonary bypass and benefit from a combined abdominothoracic approach with a pediatric cardiothoracic surgeon. Suprahepatic or atrial involvement is best approached through a median sternotomy. This can be performed in conjunction with a subcostal incision or a midline abdominal incision required for nephrectomy.

After the vessels are controlled, a dissection plane is established outside of the fascia of Gerota by sharp and blunt dissection. The perforating vessels can be quite large and should be ligated individually. Gentle manipulation of the tumor should be emphasized. Wilms tumors are very soft and may easily rupture, leading to tumor spill and an increased risk of local recurrence (11).

The ureter is palpated to rule out intraureteral extension before it is divided as distally as possible (6). Formal lymph

**FIGURE 96.2** Mobilization of left-sided Wilms tumor by blunt dissection after ligation and division of the (A) renal artery and (B) vein.

node dissection is not required, but all suspicious lymph nodes should be biopsied. Lymphatic tissue in the renal hilum and adjacent precaval and preaortic areas is generally removed with the specimen. Failure to sample lymph nodes will mandate increased therapy due to an increased risk of local recurrence secondary to incomplete staging (11). After extraction of the intact tumor, the wound is copiously irrigated and hemostasis is assessed. Drains are not routinely placed unless a portion of the pancreas or liver has been resected. The displaced colon is replaced in the tumor bed.

### Bilateral Tumors

Synchronous bilateral Wilms tumor occurs in 4% to 6% of patients with Wilms tumor (12). Children with bilateral Wilms tumors should not undergo initial radical nephrectomy; rather, they should receive preoperative chemotherapy with the goal of tumor shrinkage and renal preservation. Children treated with preoperative chemotherapy will have

more renal units preserved. This is important because the risk of renal failure in patients with bilateral disease approaches 15% at 15 years posttreatment (13).

The proposed COG protocol for patients with bilateral Wilms tumor recommends 6 weeks of chemotherapy prior to surgery. Tumor response is evaluated with CT or MR after 6 weeks.

Patients with tumors amenable to renal-sparing procedures can proceed with surgery. If there has not been a good response, biopsy of the tumor(s) is recommended to determine the histology. Additional chemotherapy is then given, but all patients should proceed to surgical resection within 12 weeks of starting therapy.

At the time of definitive surgery, partial nephrectomy or wedge excision of the tumor is preferred, but only if it will not compromise tumor resection and if negative margins can be obtained. The kidney with the lower tumor burden is addressed first. If complete excision of tumor from this kidney can be performed leaving a viable and functioning kidney, then surgery of the contralateral kidney with more extensive

**FIGURE 96.3** Surgical technique to manage tumor extension through the renal vein. **A:** Tumor extension into the vena cava (limited to the infrahepatic level). **B:** After exposure of the vessels, the infrarenal vena cava and contralateral renal vein are controlled with vessel loops and the vena cava is incised vertically at the intersection with the renal vein. **C:** A Fogarty catheter is passed superior to the tumor thrombus and the balloon is inflated. **D:** The vena cava is flushed of air and a Satinsky clamp is placed to allow closure of the cavotomy.

tumor involvement is done. Enucleation of the tumor may be considered in lieu of a formal partial nephrectomy. This will usually be considered for large centrally located tumors where removal of a margin of renal tissue would compromise the vascular supply to the kidney. Even when very large bilateral masses remain after initial chemotherapy, a high percentage of children can be successfully managed with renal-sparing surgery (14). It is easy to underestimate the amount of renal parenchyma that can be salvaged due to compression by the

tumor; therefore, renal-sparing surgery should be entertained in all patients.

---

## POSTOPERATIVE CARE

---

All clinical trials for children with Wilms tumor strive to tailor treatment to individual risks for tumor recurrence and reduce the overall morbidity of treatment. The latter will allow

TABLE 96.2

## RECOMMENDED THERAPY ON CHILDREN'S ONCOLOGY GROUP PROTOCOLS

Stage/Histology	Radiotherapy	Chemotherapy
Stage I FHWT <2 y, <550 g	None	None
Stage I FHWT, >2 y or >550g	None	Regimen EE-4A
Stage II FHWT	None	Regimen EE-4A
Stage I or II FHWT and LOH 1p, 16q	None	Regimen DD-4A
Stage III FHWT, no LOH 1p, 16q	Yes	Regimen DD-4A
Stage I–III focal AHWT	Yes	Regimen DD-4A
Stage I diffuse AHWT	Yes	Regimen DD-4A
Stage III or IV FHWT and LOH 1p, 16q	Yes	Regimen M
Stage IV FHWT pulmonary metastases		
Lesions resected at diagnosis	Yes	Regimen DD-4A
Lesions resolve after 6 weeks chemo	None	Regimen DD-4A
Lesions persist after 6 weeks chemo	Yes	Regimen M
Stage IV FHWT nonpulmonary metastases	Yes	Regimen M
Stage II or III diffuse AHWT	Yes	Regimen UH-1
Stage IV diffuse AHWT (no measurable disease)	Yes	Regimen UH-1
Stage IV focal AHWT	Yes	Regimen UH-1
Stage I CCSK	None	Regimen I
Stage II or III CCSK	Yes	Regimen I
Stage IV CCSK	Yes	Regimen UH-1
Stage I–III MRT	Yes	Regimen UH-1
Stage IV MRT	Yes	Regimen UH-2
Stage IV AHWT (measurable disease)	Yes	Regimen UH-2
Regimen EE-4A: Pulse-intensive AMD plus VCR (18 weeks) Regimen DD-4A: Pulse-intensive AMD, VCR, and DOX (24 weeks) Regimen M: VCR, AMD, DOX, alternating with CYCLO and ETOP (24 weeks) Regimen UH-1: CYCLO, carboplatin, ETOP alternating with VCR, DOX, CYCLO (30 weeks) Regimen I: VCR, DOX, CYCLO alternating with CYCLO, ETOP (24 weeks) Regimen UH-2: VCR, DOX, CYCLO alternating with CYCLO, carboplatin, ETOP and VCR, irinotecan (30 weeks) FHWT, favorable-histology Wilms tumor; LOH, loss of heterozygosity; AHWT, anaplastic-histology Wilms tumor; CCSK, clear cell sarcoma of the kidney; MRT, malignant rhabdoid tumor of the kidney; AMD, dactinomycin; VCR, vincristine; DOX, doxorubicin; CYCLO, cyclophosphamide; ETOP, etoposide.		

clinicians to reduce treatment-related side effects. Current treatment recommendations of the COG are listed in Table 96.2 (3,15). All renal tumors are eligible for enrollment in COG protocols, including renal cell carcinoma and congenital mesoblastic nephroma.

There are several study arms grouped by risk for recurrence (very low, low, standard, and high). The COG will again examine the role of surgery-only treatment for patients with stage I FHWT weighing <550 g and age <2 years. Children with stage I or II FHWT and LOH of 1p and 16q will undergo treatment with vincristine (VCR), dactinomycin (AMD), and doxorubicin (DOX) without radiotherapy. Patients with stage III FHWT disease without LOH of 1p and 16q are treated with VCR, AMD, and DOX and irradiation of the flank or abdomen. The COG will evaluate a response-based approach for management of children with pulmonary metastases. Those with resolution of the pulmonary lesions on chest CT after 6 weeks of chemotherapy will not be given whole-lung irradiation and will be treated with VCR, AMD, and DOX. Patients who do not have resolution of the pulmonary lesions by week 6 will receive more intensive chemotherapy and pulmonary irradiation. Children with stage I to III focal anaplastic histology Wilms tumor

(AHWT) and stage I diffuse AHWT are treated with AMD, VCR, DOX, and abdominal irradiation. Patients with stage II, III or IV (no measurable disease) diffuse AHWT, stage IV focal AHWT, stage IV clear cell sarcoma, and stage I to III malignant rhabdoid tumor will be treated with a new chemotherapy regimen to try to improve overall survival.

---

## OUTCOMES

---

### Complications

---

The most common intraoperative complication of nephrectomy for Wilms tumor is bleeding. Major vascular injuries and injury to other organs are less frequent. Following surgery the most common complication is small bowel obstruction, which occurs in about 5% of patients. The surgical complication rate of nephrectomy for Wilms tumor has declined over the past three decades.

Preoperative chemotherapy may influence surgical complication rates by producing tumor shrinkage. In a report from SIOP,

nephrectomy performed after 4 or 8 weeks of chemotherapy was associated with an overall surgical complication rate of 5% (16). A prospective comparison of complications in patients enrolled in the NWTS-5 and the SIOP-93-01 trials demonstrated that the overall complication rate for the SIOP patients was 6.4% compared to 9.8% in NWTS-5 patients (17). There was a much lower incidence of intraoperative tumor spill in the SIOP patients (2.2%) than the NWTS-5 ones (15.3%).

A mortality rate of 0.5% related to surgical complications was reported from NWTS-3. However, a higher intraoperative mortality rate of 1.5% has been reported from other centers. The latter may reflect that intraoperative deaths may not be reported to the cooperative groups since study enrollment occurs after surgery. Factors that have been associated with an increased risk for surgical complications are higher tumor stage, tumor size >10 cm, incorrect preoperative diagnosis, thoracoabdominal incision, intracaval tumor extension, and resection of other visceral organs.

## Results

The overall prognosis for children with FHWT is excellent as a result of multimodal therapy. Common sites of recurrence are the lungs, liver, and renal fossa. Tumor histology and clinical stage are the most important predictors of outcome. There is an increased risk for local recurrence in the setting of unfavorable histology and intraoperative tumor rupture (11). Omission of lymph node biopsy also correlates with recurrence and is attributed to understaging. Preventing local recurrence is important as the survival after abdominal recurrence is poor. Current trials continue to refine chemotherapeutic regimens to improve survival, in particular for higher-risk populations with unfavorable histology. The use of biological factors to further stratify patients for therapy may further advance survival and minimize late effects of treatment.

## CHAPTER 97 ■ RENAL FUSION AND ECTOPIA

ROSS M. DECTER

Abnormalities of renal position and fusion predispose to infection, hydronephrosis, stone disease, and, in some instances, neoplasia. Although clinical problems associated with these anomalies present infrequently in urological practice, an understanding of the deviations from standard urological techniques required to address them is important.

The ureteral bud branches from the wolffian duct and extends toward the metanephric blastema during the fourth and fifth weeks of gestation. The ureteral bud induces the metanephric blastema to form the functioning kidney. The exact mechanism of renal ascent is not known, but during normal development the kidneys ascend and rotate. The renal

**FIGURE 97.1** Three common variants of blood supply in horseshoe kidney. **A:** Single renal arteries arising from the aorta. **B:** Multiple aortic arteries. **C:** Multiple aortic and iliac arteries.

pelvis rotates from its initial anterior position 90 degrees toward the midline until it reaches its final medial position. Migration and rotation occur simultaneously between the fourth and eighth or ninth weeks of gestation. The blood supply to the kidney is derived from successively higher levels of the aorta and its branches during ascent.

The most common anomaly of renal position is malrotation: incomplete rotation of the kidney to its final position. The renal pelvis in a malrotated kidney in general lies anterior to the parenchyma, as opposed to its normal medial location. Simple malrotation of a normally positioned kidney is often an incidental finding. The pyelocaliceal systems of malrotated kidneys are morphologically abnormal, but functionally they usually drain without impairment. Malrotation occurs occasionally in orthotopically positioned kidneys, and it is commonly observed in ectopic kidneys.

Close approximation of the two proliferating renal blastemas prior to significant ascent is a normal embryological finding (1). If there is any disturbance of separation of the closely approximated renal blastemas, fusion anomalies of the kidneys may develop.

The most common fusion anomaly is the horseshoe kidney. The horseshoe kidney in general ascends until the upper border of the isthmus is at the level of the inferior mesenteric artery. Horseshoe kidney occurs in 1 in 400 to 1 in 1,800 births (2). There is a male predominance for the condition (3). The fusion in horseshoe kidney almost always occurs at the lower poles; cases of upper pole fusion are recorded rarely (3). The isthmus of the horseshoe kidney lies just below the inferior mesenteric artery at the L4 vertebral level. The blood supply to these kidneys is variable (Fig. 97.1).

Crossed–fused ectopia is the second most common fusion anomaly. This abnormality occurs when the developing kidney crosses from one side to the other during its ascent or when the ureteral bud from one side crosses to the contralateral side and induces abnormal development of that metanephric blastema. Crossed ectopia with fusion may occur in a variety of forms (Fig. 97.2). Although crossed ectopia occurs most frequently with fusion, the anomaly may occur without fusion (Fig. 97.3).

An ectopic kidney lies outside of the normal position in the renal fossa. The kidney, in simple ectopia, in general lies in the ipsilateral retroperitoneal space at a position that is lower

than normal (Fig. 97.4). In crossed ectopia, the kidney crosses the midline and is frequently fused to its contralateral mate. The autopsy incidence of renal ectopia is about 1 in 1,000 cases, and the condition often is totally asymptomatic (4). Reviews of renal ectopia show that the left kidney is affected slightly more frequently than the right. Ectopic kidneys occur bilaterally around 10% of the time, and the most common position of the ectopic kidney is in the pelvis. Pelvic ectopia was reported in about 55% of patients in one series of ectopic kidneys; crossed–fused ectopia occurred in 27%; lumbar ectopia occurred in 12%; non–crossed–fused ectopia occurred in 5% of patients; and a thoracic kidney was recorded only 1% of the time (4). Rarely, a solitary pelvic kidney occurs. This kidney suffers the risk of injury during pelvic surgical procedures and on occasion has been reported as an unusual cause of giant hydronephrosis.

Ectopic kidneys are smaller than their orthotopically positioned mates (5). The blood supply to the pelvic kidney, the most common of the ectopic kidneys, is variable. The arterial supply may arise from the distal aorta or bifurcation, the ipsilateral common iliac, or the hypogastric vessels. In general, the lower the kidney is in its pelvic location, the greater the likelihood that multiple arterial vessels will supply it (6).

---

## DIAGNOSIS

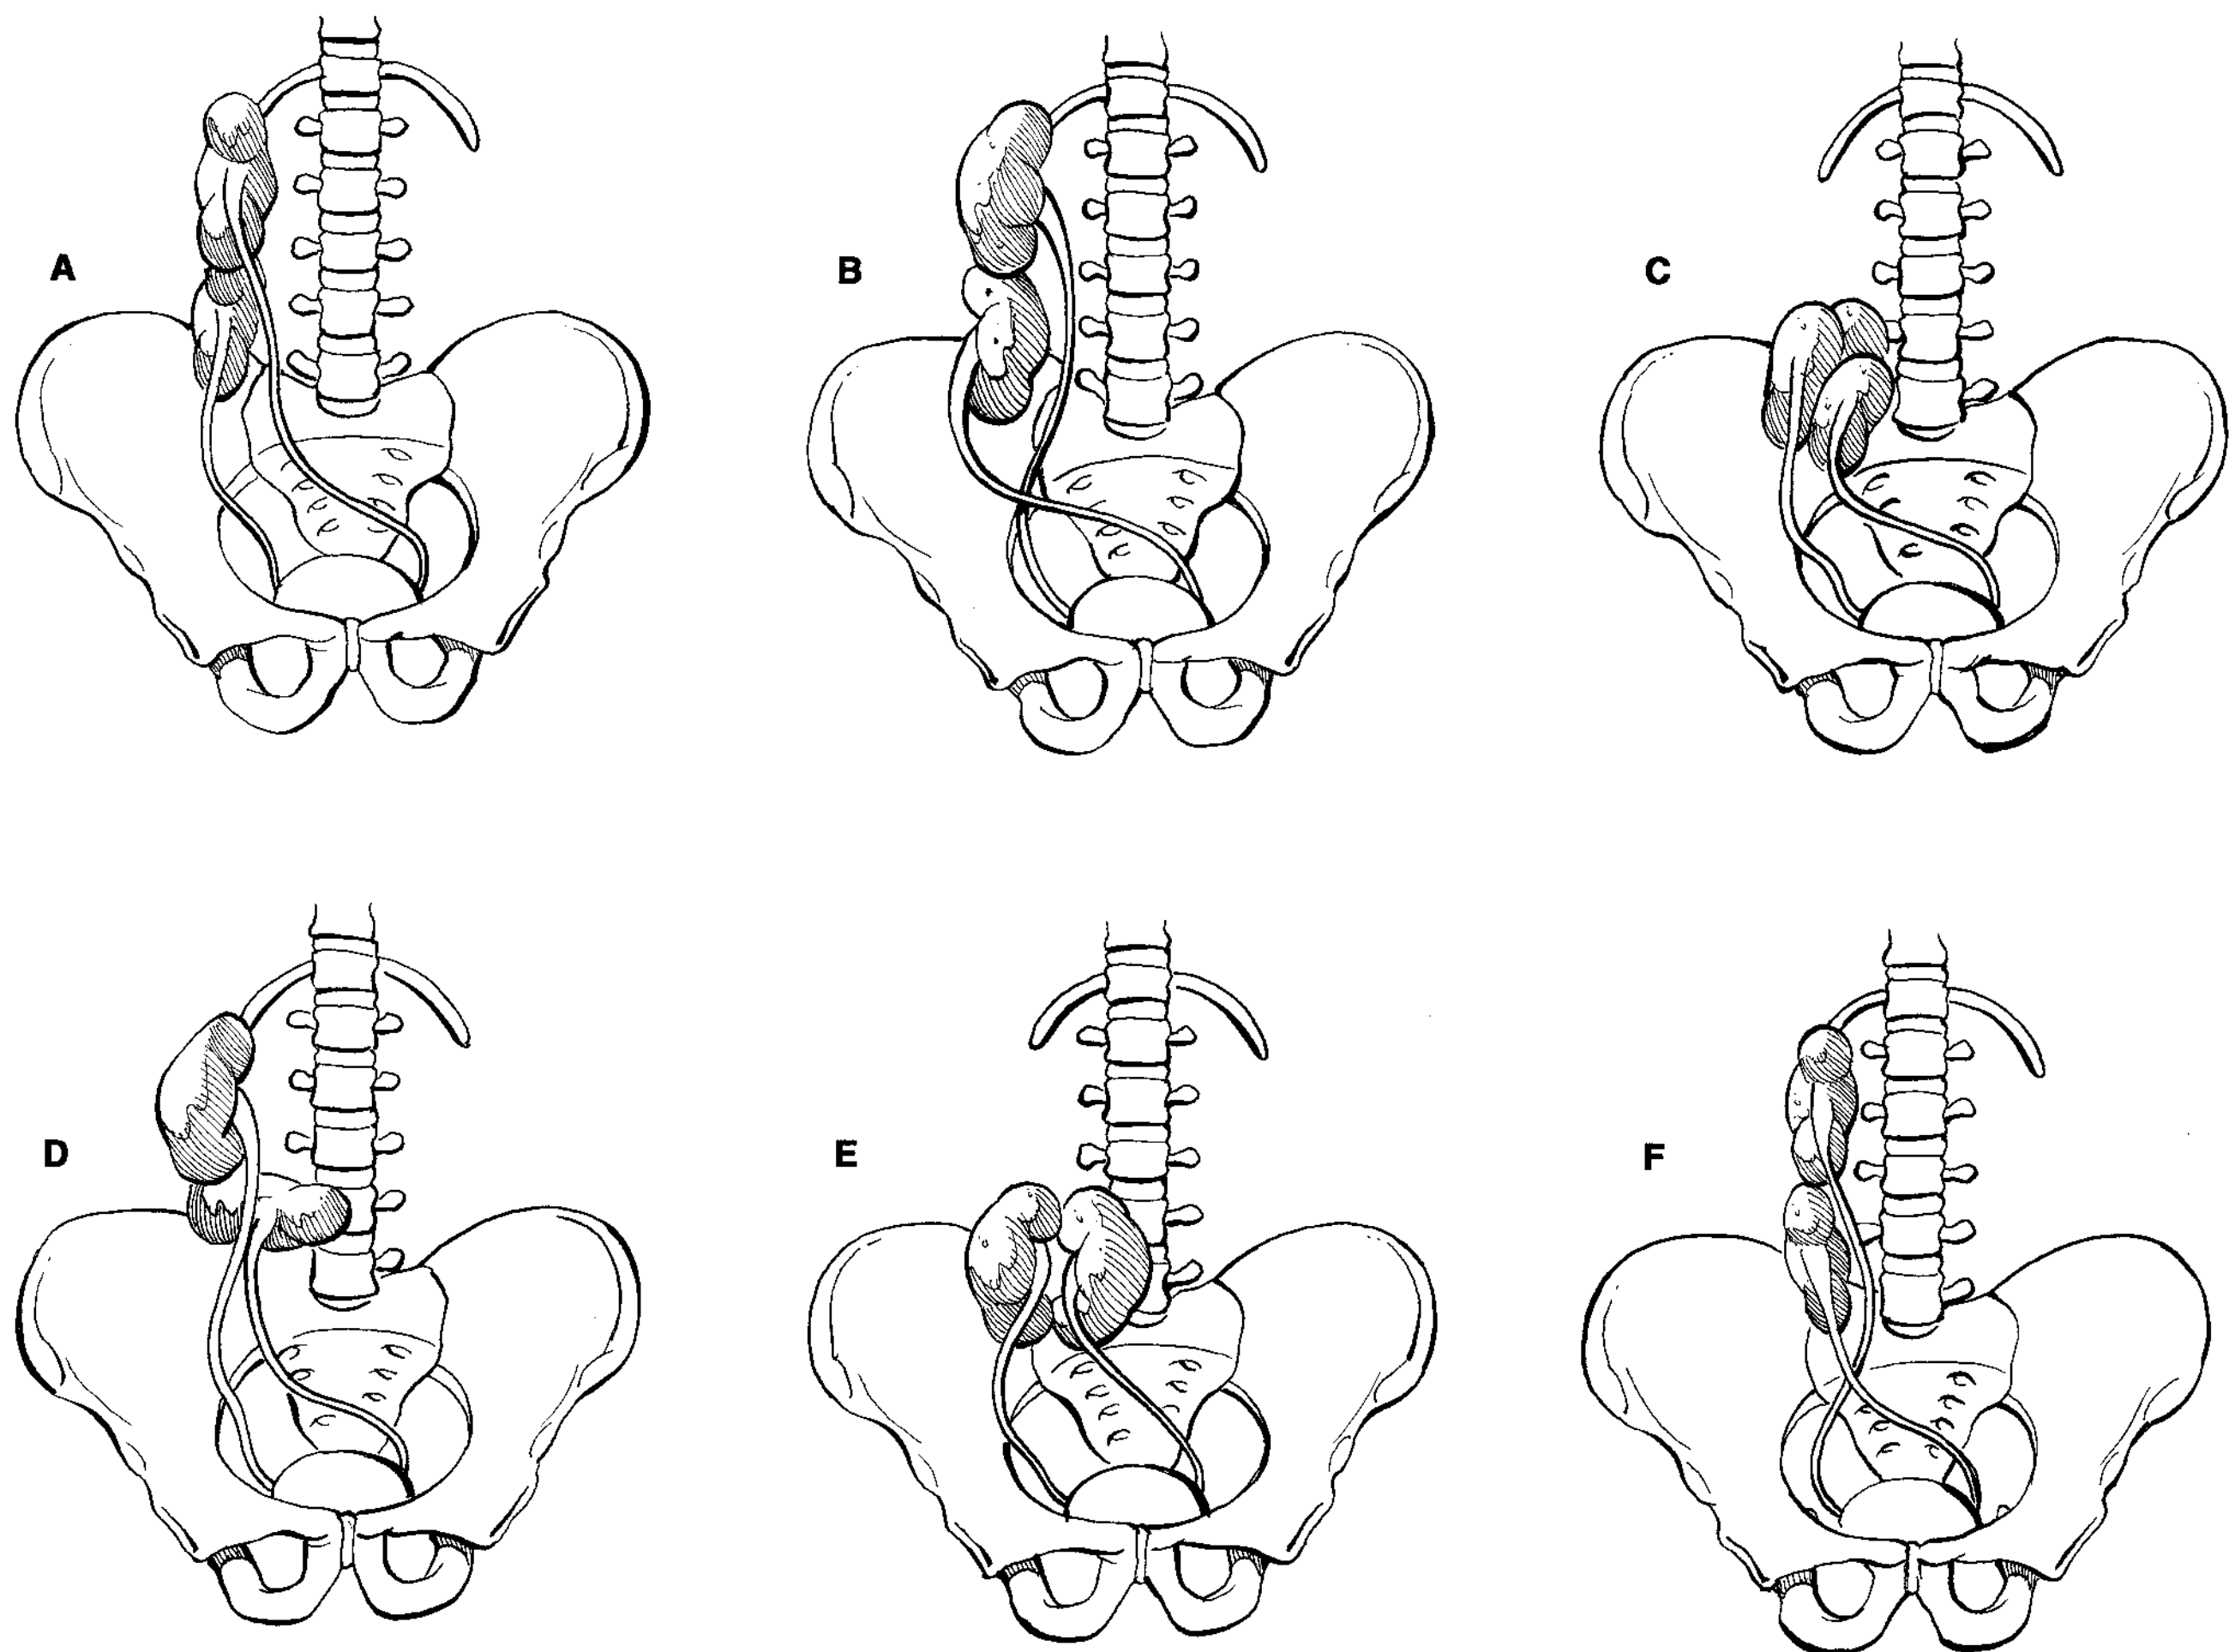

---

### Horseshoe Kidney

---

Historically, 25% to 33% of patients with horseshoe kidneys who survived beyond the newborn period were asymptomatic (3). The advent of prenatal ultrasound screening makes it likely that an even larger proportion of these kidneys are asymptomatic. Patients with symptoms typically present with urinary tract infections (about 50% of the time), an abdominal mass, hematuria, or abdominal pain (approximately 10% each).

The initial diagnostic evaluation in children is usually a renal ultrasound (RUS), and many patients subsequently have intravenous pyelography (IVP) or computed axial tomography (CT). Many adults have an IVP as their initial study. The intravenous pyelographic features of the horseshoe kidney are typical. The renal axis is abnormal, being either vertically

**FIGURE 97.2** Six types of crossed renal ectopia with fusion. **A:** Ectopic kidney superior. **B:** Sigmoid or S-shaped kidney. **C:** Lump kidney. **D:** L-shaped kidney. **E:** Disk kidney. **F:** Ectopic kidney inferior. (Modified from McDonald JH, McClellan DS. Crossed renal ectopia. *Am J Surg* 1957;93:995.)

orientated or tilted laterally. The renal pelvis tend to be located anteriorly and the ureters course ventral to the isthmus. The lower calices are oriented caudally or even medially as opposed to laterally. Kidneys with fusion anomalies are subject to a high incidence of vesicoureteral reflux, variably reported between 20% and 50%. Voiding cystourethrography (VCUG) is therefore mandated during the evaluation of children with a horseshoe kidney.

The diagnosis of a ureteropelvic junction (UPJ) obstruction in a horseshoe kidney is straightforward when the patient's symptoms lead to a RUS, IVP, or CT that reveals significant pyelocaliectasis. In other instances, with less severe dilation, and especially when there is coexistent stone disease, we find the diuretic renal scan a valuable adjunct in assessing the drainage of these systems and assessing whether the hydronephrosis is functionally significant.

### Ectopic Kidney

Patients with a symptomatic ectopic kidney frequently present with a urinary tract infection, or the ectopic kidney is discovered in the evaluation of abdominal pain. The workup of a palpable abdominal mass and the discovery of the abnormal renal

position during the evaluation of other anomalies each account for the diagnosis in about 20% of cases. Hematuria, incontinence, renal insufficiency, and nephrolithiasis are less common presenting complaints. It is important to emphasize that the majority of patients with ectopic kidneys are asymptomatic.

The evaluation in children is usually by RUS, while older patients will in general have an IVP or CT scan. The ectopic kidney can be difficult to detect on the IVP because the pyelocaliceal system often overlies the bony pelvis. Functional evaluation of the ectopically positioned kidney is routinely performed with a renal scan. Ectopic kidneys have a high incidence of associated vesicoureteral reflux, so a VCUG should be a routine part of the evaluation of these patients.

### INDICATIONS FOR SURGERY

The indications for surgical intervention in the ectopic or horseshoe kidney are similar to those in a normally positioned kidney. Pyeloplasty is required in patients with symptomatic UPJ obstruction or when the evaluation suggests that the abnormality at the UPJ may affect ultimate renal function. Symptomatic stone disease needs to be addressed using open, endoscopic, or extracorporeal techniques. If the evaluation

**FIGURE 97.3** Types of crossed renal ectopia. **A:** Fused. **B:** Nonfused. **C:** Solitary. **D:** Bilateral. (Modified from McDonald JH, McClellan DS. Crossed renal ectopia. *Am J Surg* 1957;93:995.)

**FIGURE 97.4** Location of lumbar and pelvic ectopically positioned kidneys in relation to the normally positioned kidney.

of infections in a horseshoe kidney reveals vesicoureteral reflux, operative management, either subureteral injection of Deflux or ureteral reimplantation, may be mandated if the reflux is of high grade, if it persists, or if prophylaxis fails to prevent infection.

---

## ALTERNATIVE THERAPY

---

The alternative to surgical intervention for reflux is nonoperative management, usually consisting of observation either with or without antibiotic prophylaxis.

Surgery is the only viable option for patients with significant UPJ obstruction, significant stones, and tumors.

Endopyelotomy has been utilized to treat UPJ obstruction in horseshoe kidneys. The initial results of endopyelotomy performed in adults by experienced surgeons are encouraging; however, we currently prefer pyeloplasty as the initial procedure for UPJ obstructions in children.

---

## SURGICAL TECHNIQUE

---

### Pyeloplasty

---

Pyeloplasty is the most common open procedure performed on the horseshoe kidney. Division of the isthmus with nephropexy had been considered to be an important part of

the procedure, but recent experience suggests that isthmus division or symphysiotomy is rarely necessary in the correction of UPJ obstruction. Pyeloplasty may be performed either open or laparoscopically. Laparoscopic procedures can be accomplished with or without robotic assistance. Although laparoscopic pyeloplasty is becoming more widely practiced, we still favor open surgery in abnormally positioned kidneys.

The surgical exposure of the horseshoe kidney can be achieved through a midline transperitoneal, anteriorly positioned flank extraperitoneal, or transverse transperitoneal approach. We prefer the transverse transperitoneal exposure as it seems to provide the widest exposure with a cosmetically acceptable scar. We perform a retrograde ureteropyelogram at the time of pyeloplasty so we can position the incision accurately. The incision generally extends from the anterior axillary line on the affected side to the midline several centimeters below the umbilicus. It can be extended laterally in either direction if necessary. For a right-sided UPJ obstruction, the posterior peritoneum may be incised medial to the inferior mesenteric, then inferior and laterally along the small bowel mesentery around the cecum, and up along the line of Toldt. The small bowel and cecum can then be reflected upward out of the operative field and packed in the upper abdomen. For a left-sided UPJ obstruction, the sigmoid colon may be mobilized if necessary to afford better exposure. Exposure is maintained with a ring retractor.

Repair of UPJ obstruction in the horseshoe kidney can be performed by a Foley Y–V-plasty or a dismembered pyeloplasty. Although the Foley Y–V repair is nicely suited to the typical high-insertion obstruction seen in horseshoe kidneys (Fig. 97.5D), we prefer the dismembered technique because it provides more flexibility. During the conduct of the pyeloplasty, care must be taken to avoid inadvertent division of small vessels to the parenchyma and excessive dissection of the ureter or pelvis. As much adventitial tissue is left on the ureter as possible, and no vessels to the ureter are sacrificed unless their division is necessary to provide for adequate mobilization.

After the proximal ureter and renal pelvis are adequately exposed using sharp dissection, two stay stitches of 5-0 chromic are positioned in the ureter just below the UPJ (Fig. 97.5). The ureter is divided between these stitches and carefully mobilized. A pelvic flap is then created by orienting a wide-based inverted-V-shaped incision on the renal pelvis, with the apex of the inverted V at the UPJ. The flap is designed such that it will provide a dependent portion of pelvis for the anastomosis. It is important that the base of the V be wide to avoid ischemia of the flap. The flap is opened with tenotomy scissors and the tip is trimmed minimally to smooth the point of the V. The ureter is then positioned so the length and position of the spatulation can be judged. The spatulation is positioned on the posterior aspect of the ureter using Potts scissors such that the ureter will not be twisted when it is laid on the dependent pelvic flap. It is critical that the flap and the spatulated ureter are approximated in a tension-free fashion. If the repair is performed under tension, an anastomotic stricture may result. It is also important that the upper ureter or anastomosis are not compressed by any of the renal vessels, as they may obstruct the repair (7). The anastomosis and dissection are performed with the aid of  $2.5\times$  optical magnification. We perform the anastomosis using 7-0 Vicryl in younger children and 6-0 Vicryl in adolescents.

The fact that the ureter is dismembered and freely mobile allows the surgeon to position it so that the ureteral spatulation can extend into a relatively wide portion of the ureter and simultaneously the ureter can be oriented to avoid torsion or redundancy that might kink the ureter distal to the repair. The anastomosis in the dismembered pyeloplasty seems technically easier than the Foley Y–V because the ureter is not fixed at two points.

We begin the anastomosis at the heel, suturing the most dependent portion of the V-shaped incision to the apex of the ureteral spatulation. The initial portion of the anastomosis is performed using interrupted sutures, in general one at the apex and two on either side of the apex. Each stitch must be precisely positioned to avoid postoperative leakage and/or compromise of the lumen. After the apex is anastomosed, the remainder of the pyeloplasty is performed using a running locking 7-0 Vicryl suture up one side of the spatulated ureter and then up the other side. Prior to complete closure, the patency of the anastomosis is tested by passing a 5Fr and 8Fr feeding tube through the repair. No stent or diversion is in general employed in children. A Penrose drain is positioned near the anastomosis and made to exit through a separate stab wound. The abdominal wall closure is performed using running 3-0 or larger PDS. We close the skin with a subcuticular pull-out stitch of 3-0 Prolene. Most children are discharged the day after surgery. The skin suture is removed between 6 and 8 days postoperatively and the drain is removed at that time if drainage is minimal.

---

## Ureterocalicostomy

---

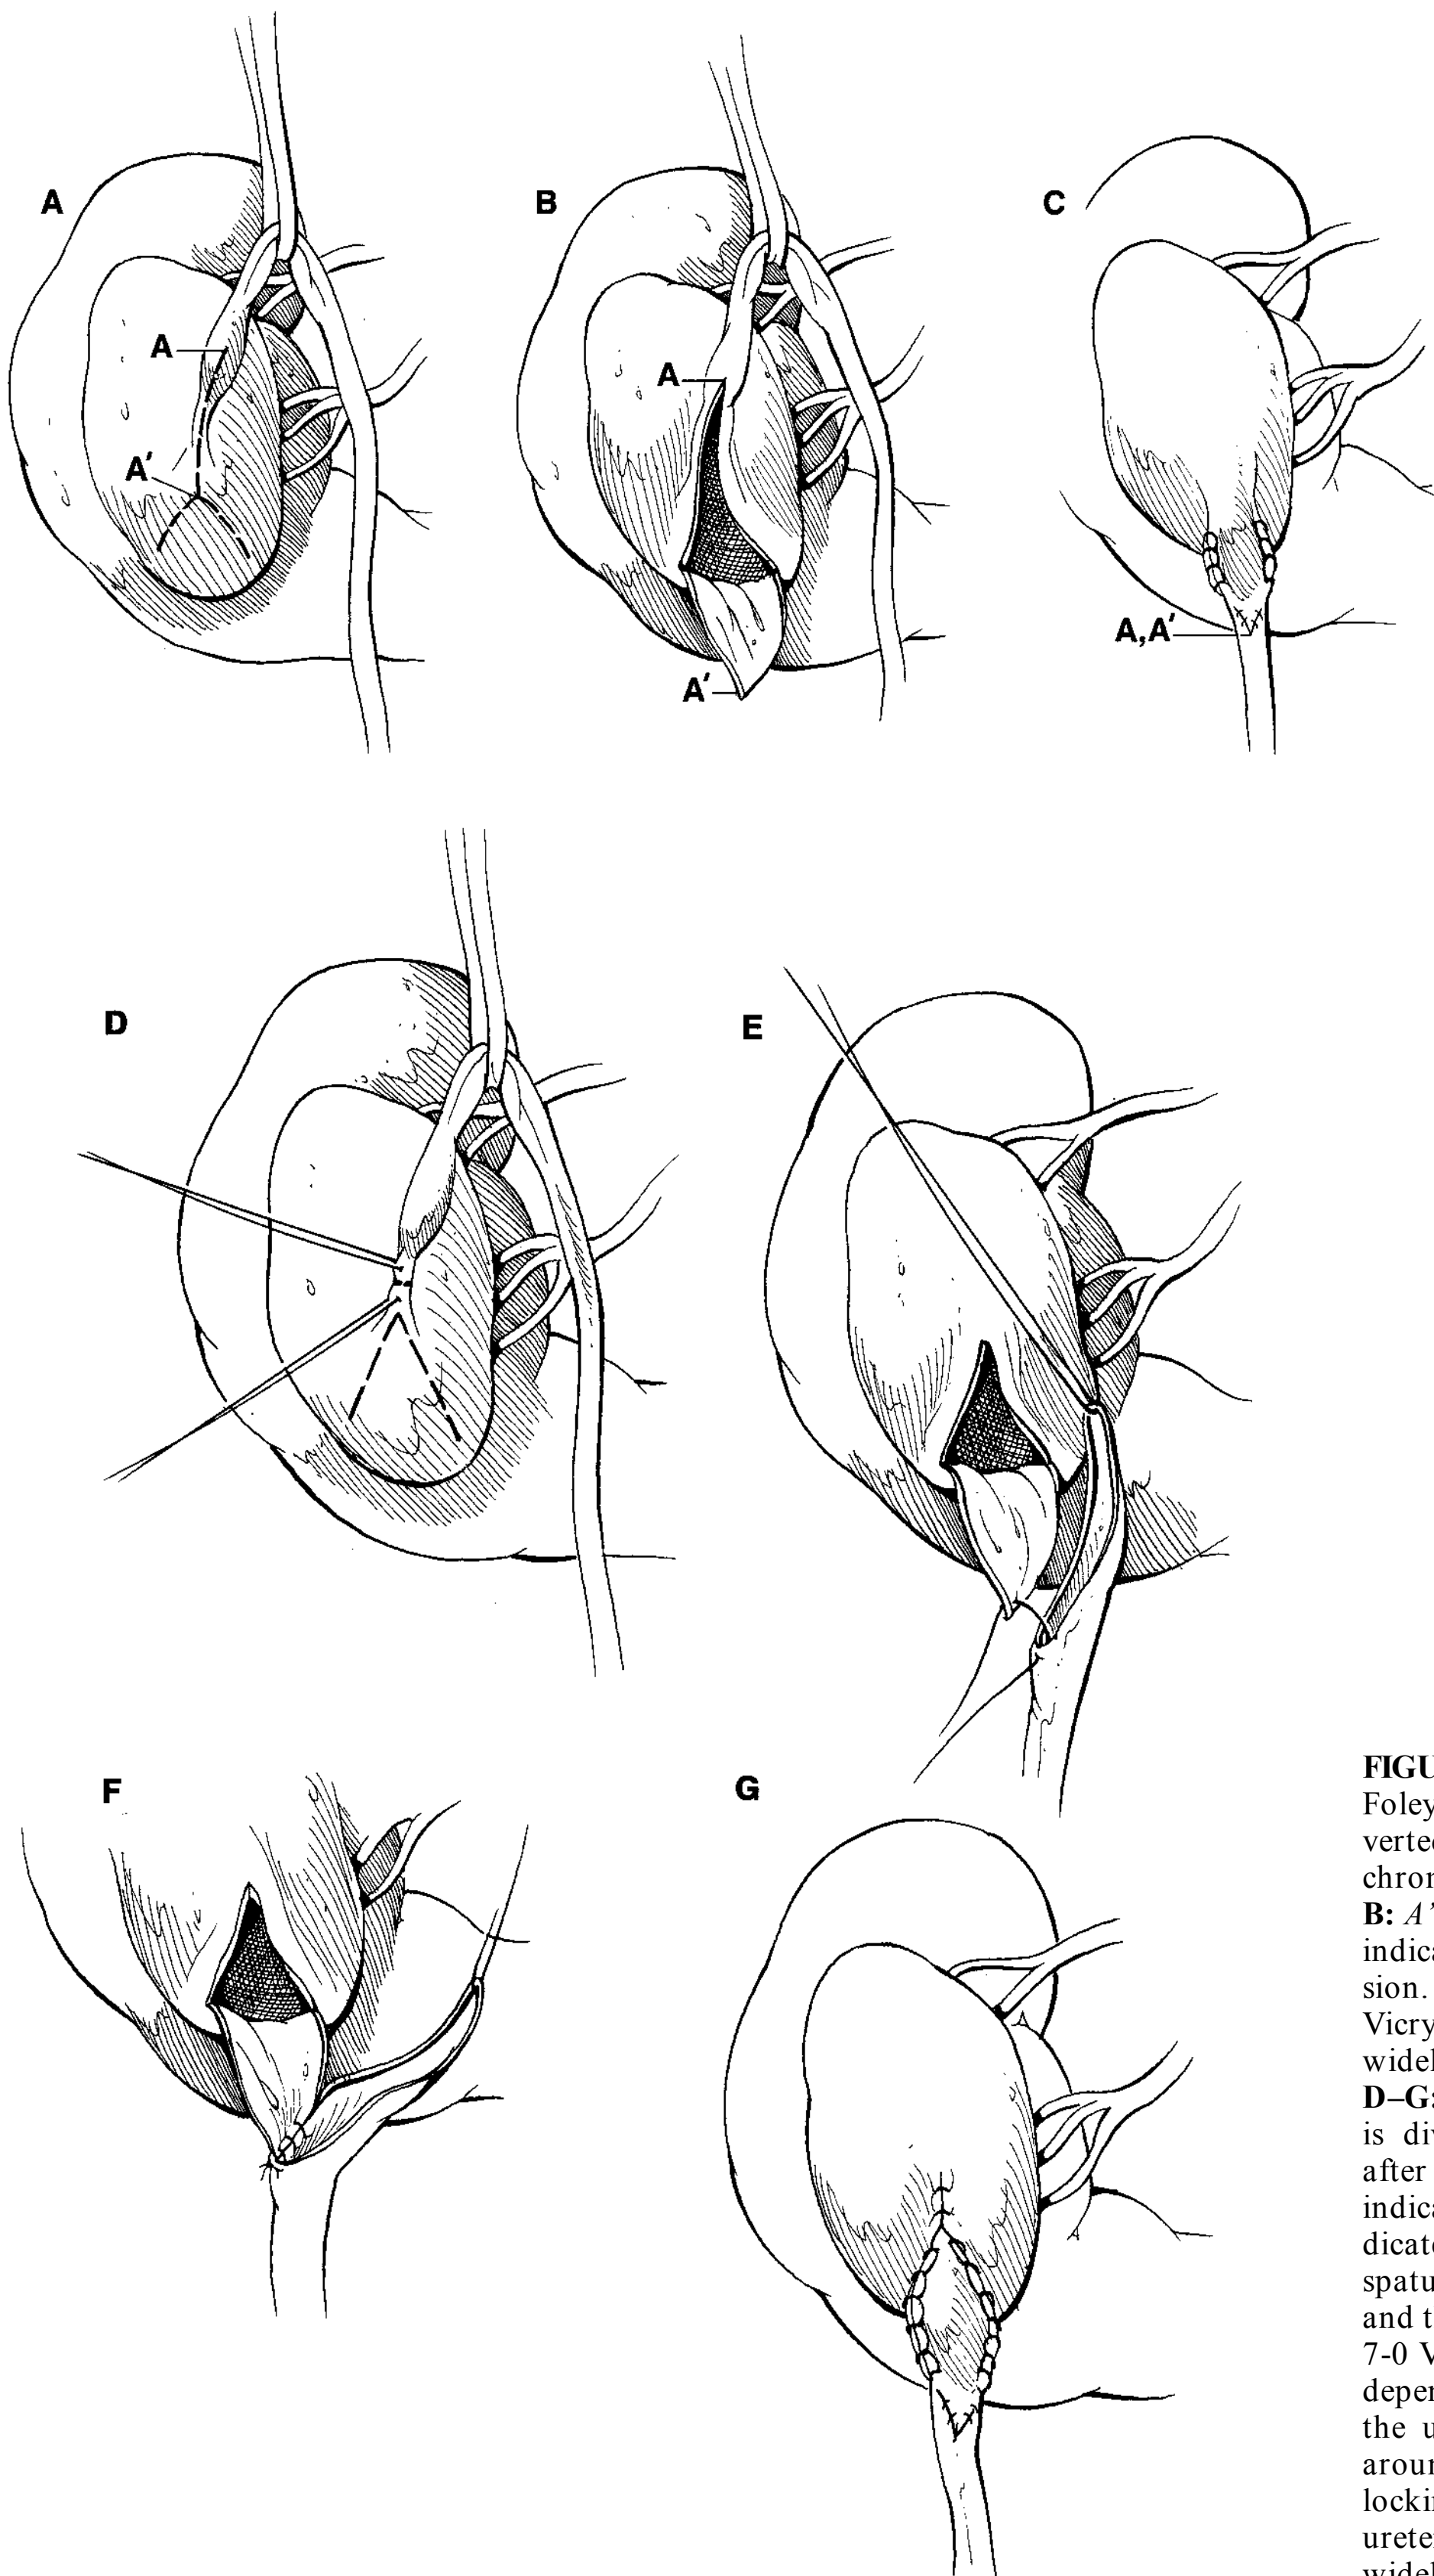

A ureterocalicostomy is usually performed to salvage a failed prior pyeloplasty, but it should be considered as the primary procedure for UPJ obstruction when there is a small intrarenal pelvis or in other instances with significant lower-pole caliectasis and thin overlying parenchyma (7) (Fig. 97.6). The ureter is carefully separated from the pelvis as described above, and if feasible a pyelotomy is performed. We find that a finger inserted into the open renal pelvis and positioned in the lower pole calyx aids in the dissection. The parenchyma over the dilated lower-pole calyx is incised with electrocautery; the capsule is incised and the parenchyma resected to allow adequate exposure of the calyx. Hemostasis is achieved using cautery and/or sutures of 4-0 chromic through the edge of the resected parenchyma. The ureter is spatulated and the anastomosis between the ureter and the opened calyx is performed as described in the figure. We divert the urine by using a nephrostomy tube (a 10Fr or 12Fr Malecot catheter) and either a ureteral stent (usually a 5Fr feeding tube) or a double-J stent. A ureterocalicostomy as it would appear in a horseshoe kidney is shown in Figure 97.7.

---

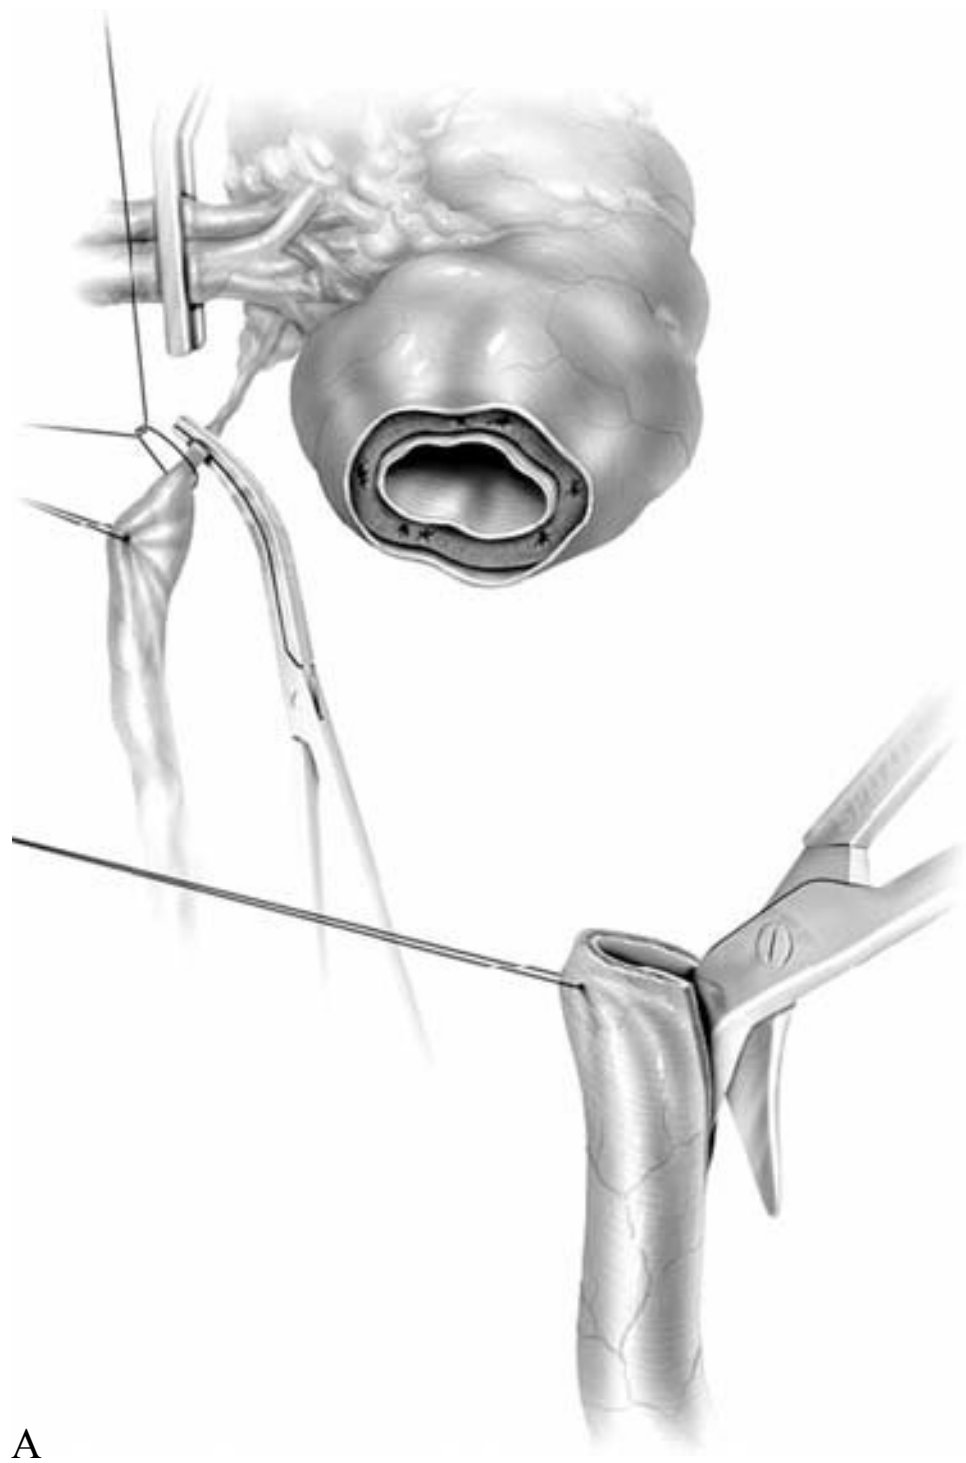

## Surgery for Tumors

---

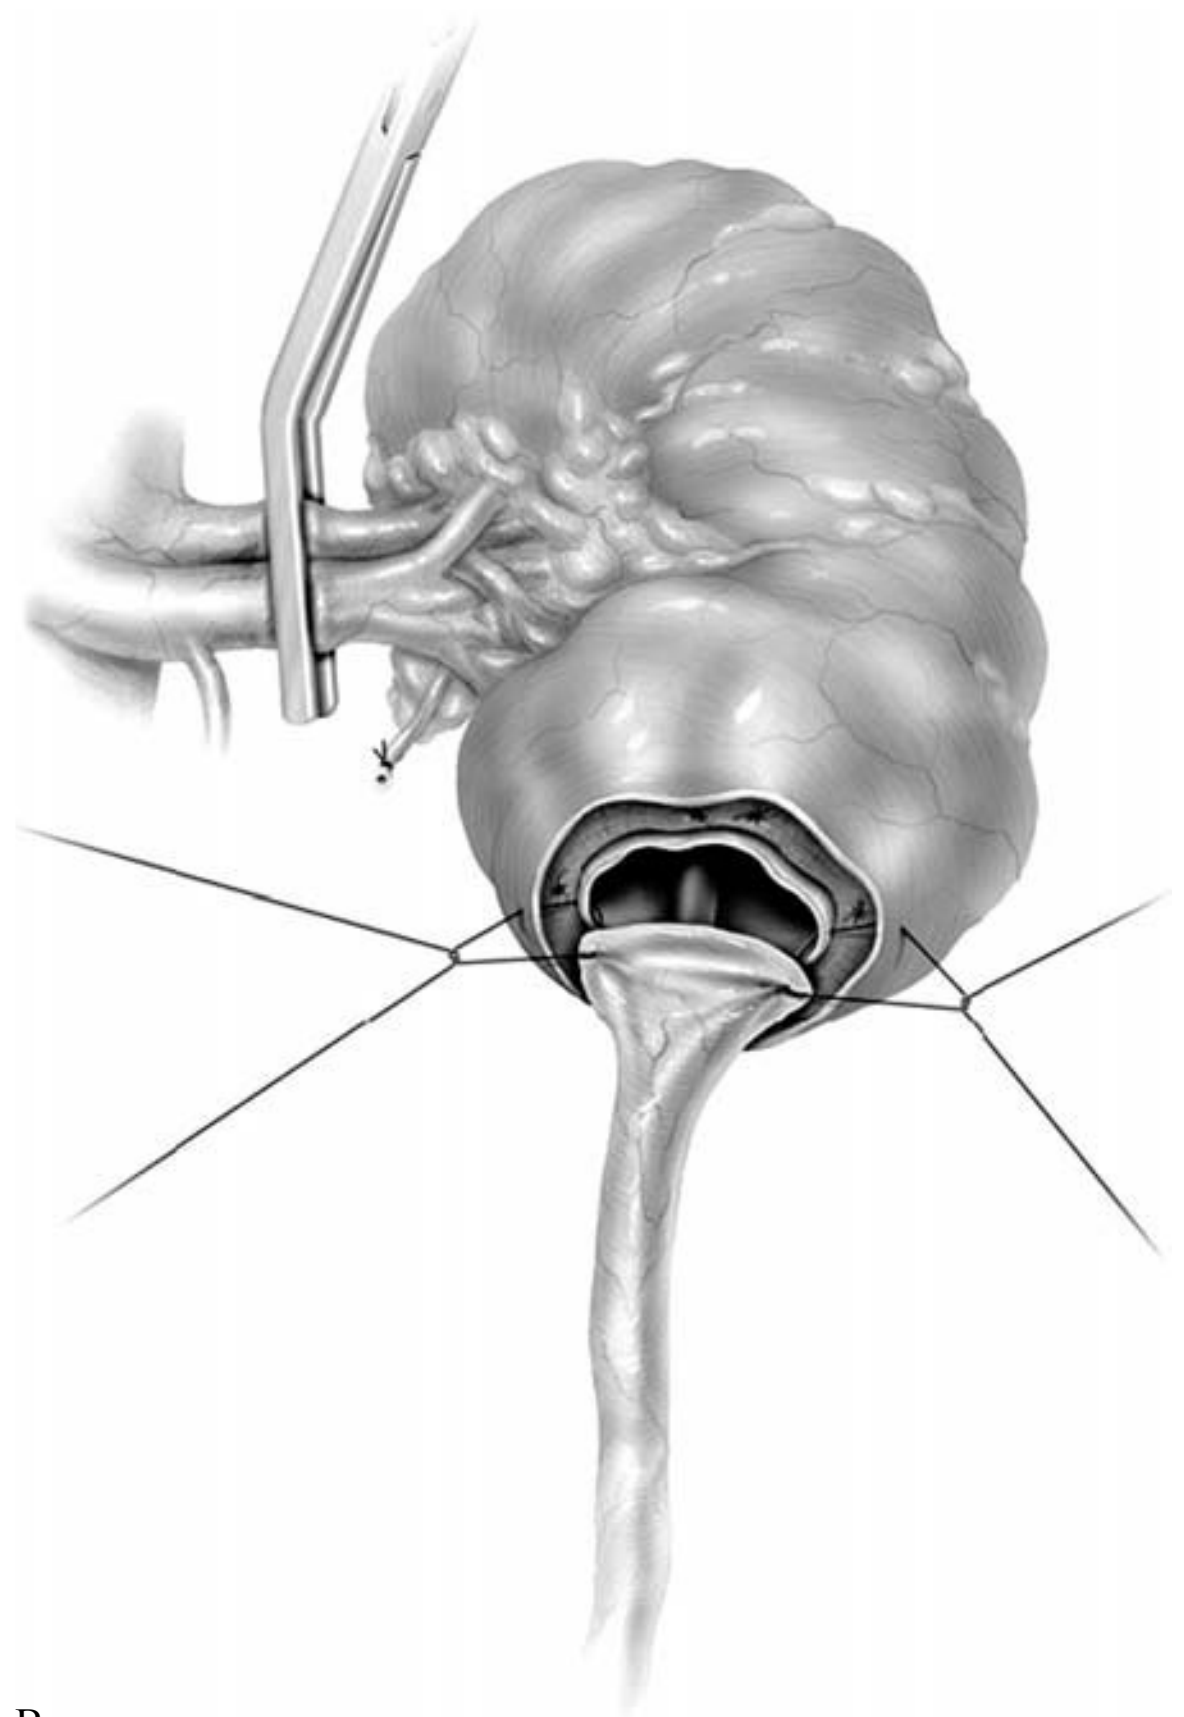

Renal cell carcinoma and renal pelvic tumors are reported in horseshoe kidneys (12). Wilms tumor occurring in a horseshoe kidney represented 0.48% of tumors in the National Wilms Tumor Study; this incidence is about twice that expected in the general population (8). When Wilms tumor involves a horseshoe

Thin cortex over the dilated lower pole calyx has been excised and hemostasis achieved. **B:** The spatulated ureter is anastomosed to the open lower-pole calyx. The sutures of 4-0 chromic catch the capsule, calyx, and ureter (the end of a double-J stent is visualized in the pelvis). **C:** The anastomosis is completed with interrupted sutures. A nephrostomy tube (not visualized) should be used. The surgeon may irrigate through the nephrostomy tube to ensure a watertight repair. **D:** Place one or two nephropexy sutures to obviate kinking of the repair. Replace the perirenal fat and place a perinephric drain. (Modified from Steffens J, Humke U, Haben B, et al. Open ureterocalicostomy. *BJU Int* 2008;101(3):397–407.)

**FIGURE 97.7** **A:** Horseshoe kidney with prior failed pyeloplasty; note the dilated intrarenal collecting system. **B:** After ureterocalicostomy, dependent drainage has been achieved. (Modified from Kay R. Ureterocalicostomy as a salvage procedure. *Urol Times* 2001;April:34.)

kidney, the involved portion of the kidney and isthmus are generally resected in the course of removal of the tumor. If the tumor occurs in the isthmus, some authors have recommended bilateral lower-pole heminephrectomy. If the Wilms tumor is bilateral at presentation, management is the same as for bilateral Wilms tumors in orthotopically positioned kidneys.

Tumor surgery of the horseshoe kidney deserves special mention because excision of the involved kidney will necessitate division of the isthmus. If the isthmus is composed of a band of fibrous tissue, it can be readily divided using cautery; however, if it is functioning parenchyma, it must be carefully

addressed to avoid excessive blood loss and necrosis of the remaining parenchyma, with the risk of secondary bleed and urinary fistula. The area must be carefully dissected and arteries to the isthmus sequentially occluded with bulldog clamps to assess the line of demarcation. Once this line is established, the capsule is divided sharply and the parenchyma divided. Bleeding from the cut parenchyma is controlled with 4-0 chromic sutures. Any exposed calices are closed with running locking 4-0 or 5-0 chromic sutures, and the capsule and parenchyma are closed with carefully positioned horizontal mattress sutures of 2-0 chromic (Fig. 97.8).

**FIGURE 97.8** Division of the isthmus of a horseshoe kidney with a right-sided renal tumor. The isthmus blood supply is from the left iliac. **A:** After identification of the line of demarcation, an incision is made around the capsule of the isthmus. **B:** The capsule is peeled back. **C:** The parenchyma of the isthmus is transected in a wedge fashion to facilitate closure. **D:** Horizontal mattress sutures of absorbable 2-0 material are used to close the parenchyma for hemostasis. **E:** The capsule is closed over the parenchyma with a continuous absorbable suture.

---

## Stone Surgery in the Horseshoe Kidney

---

Pyelolithotomy had been utilized in past decades to clear calculi from horseshoe kidneys, but currently, percutaneous and extracorporeal techniques are employed almost exclusively. Extracorporeal shock-wave lithotripsy (ESWL) in the horseshoe kidney has not enjoyed the success rate that it provides in orthotopically positioned kidneys. Most series note the requirement for an increased number of shocks, an increased need for retreatment, and a somewhat decreased stone clearance rate in horseshoe kidneys compared to stones in normally positioned kidneys. One series recorded a 73% stone-free rate in horseshoe kidneys using ESWL after multiple treatments (9). One of the reasons for difficulties treating stones with ESWL is that the anterior position of the stone makes it harder to position the stone at the F2 focus; often, the surgeon will have to employ the blast path to try to fragment the stone. Some investigators have used prone positioning to overcome this problem.

After appropriate CT planning, percutaneous access to the horseshoe kidney is best achieved using an upper-pole posterior calyx. Stones in any calyx can be managed through this access, although often a long nephroscope and flexible instrumentation are required (10,11). Reports comparing ESWL of stones in horseshoe kidneys to percutaneous nephrostolithotomy conclude that the percutaneous technique provides superior stone clearance rates (10).

When calculus disease complicates obstruction of the UPJ in a horseshoe kidney, the stone is removed at the time of pyeloplasty. In these instances, there may be considerably more reaction around the pelvis and ureter, so the use of a nephrostomy tube and ureteral stent is prudent. An antegrade study can be performed 10 to 12 days postoperatively prior to nephrostomy tube removal to confirm drainage through the UPJ and integrity of the repair.

---

## Surgical Options for the Ectopic Kidney

---

The ectopic kidney can be affected by any of the processes that occur in a normally positioned kidney. Overall, the evaluation and surgical management of these conditions will follow the lines of those discussed with horseshoe kidney. Reflux, if it mandates operative treatment, is addressed by a standard ureteral reimplantation or, alternatively, subureteral injection of a bulking agent.

On occasion, one has to address the problem of a failed pyeloplasty in a patient who has an ectopic pelvic kidney. Ureterocalicostomy is one alternative in management of this problem; another is the use of a pyelovesicostomy. Pyelovesicostomy has been performed in renal transplant recipients after ureteral loss due to ischemia and/or rejection and has proven to be a viable salvage procedure.

---

## OUTCOMES

---

---

### Complications

---

Complications of pyeloplasty, such as prolonged urine leakage and poor anastomotic drainage, occur somewhat more frequently in horseshoe kidneys than in normal kidneys. The risk of renal ischemia caused by damage to an aberrant vessel is increased in the horseshoe or ectopically positioned kidney.

---

### Results

---

Pyeloplasty in the horseshoe kidney is in general a successful procedure. A higher rate of complications was experienced in the era when division of the isthmus was employed.

# CHAPTER 98 ■ TRANSURETERO URETEROSTOMY

H. GIL RUSHTON

Ureteral surgery and various conditions, including trauma, stricture, neoplasm, or a previous failed surgical procedure, can render a ureter inadequate for successful ureteroureterostomy or ureteroneocystostomy. Transureteroureterostomy (TUU), first described by Higgins (1) in the 1930s, has gained increased prominence in pediatric urology as a method to compensate for a lacking or defective distal ureter. In some cases, bridging the midureter to the contralateral ureter TUU may salvage a renal unit, especially in cases when an ipsilateral psoas hitch and/or Boari flap are insufficient to accomplish this task. In other situations, TUU can be performed as a salvage procedure following previous failed ureteral surgery (2,3). More recently, TUU has been employed in complex reconstructive procedures that entail harvesting of the distal donor ureter for alternative purposes, including augmentation ureterocystoplasty or as a continent catheterizable conduit (2).

---

## DIAGNOSIS

---

In the majority of cases in pediatric urology, TUU is employed as part of a planned reconstruction. The preoperative workup requires thorough assessment of bilateral renal function and drainage, knowledge of the anatomy of both the donor and recipient ureters, and careful evaluation of bladder function. Differential renal function and drainage are the most objectively determined by preoperative MAG-3 renal scintigraphy. Sonography can aid in determining the presence and severity of hydronephrosis. Contrast imaging with intravenous, retrograde, or antegrade pyelography may be necessary in select cases when detailed anatomic definition of the ureters is required. Contrast voiding cystography is the best modality to assess for the presence of vesicoureteral reflux, which when present provides a “free” retrograde ureteropyelogram. In cases involving children with abnormal or neuropathic bladder function, preoperative urodynamics is required to evaluate bladder capacity, compliance, and emptying.

Less commonly in children than in adults, initial recognition of a ureteral injury requiring a TUU occurs intraoperatively during resection of a tumor or during exploration for trauma. Fortunately, in the majority of these cases one can usually anticipate a normal recipient ureter and bladder.

---

## INDICATIONS FOR SURGERY

---

The primary goal of a TUU is to reestablish nonobstructive, nonrefluxing drainage of the ureter. Historically, TUU in children has been performed either to salvage a failed ureteral

reimplantation or in conjunction with cutaneous ureterostomy for urinary diversion (4–6). Because TUU requires only one ureter for reimplantation, this procedure was commonly employed in the 1980s for urinary undiversion of conduits or in the construction of continent urinary reservoirs (3,7). In the majority of these cases, TUU was used simultaneously with reimplantation of the recipient ureter, many of which required tapering or tailoring, frequently with a psoas hitch and/or bladder augmentation. TUU has also been used as an adjunct to reimplant procedures complicated by an abnormal bladder, which precludes reimplantation of more than one ureter, or as a salvage procedure for failed ureteral reimplantation surgery (3). More recently, indications for TUU have been broadened to allow for harvesting the distal donor ureter to construct a continent ureteral conduit for clean intermittent catheterization or for unilateral ureterocystoplasty in cases where there is sufficient ureteral dilatation (2).

Ureteral reconstruction with TUU may not be possible if there is insufficient donor ureter (approximately one-half the original length) for a tension-free anastomosis. Any disease process that has the potential to affect contralateral renal function or drainage is also a contraindication, such as retroperitoneal fibrosis, high-dose radiation therapy, calculus disease, recurrent pyelonephritis, and urothelial malignancy. Although size disparity between ureters has been regarded as a relative contraindication in the past, successful TUU has been accomplished by use of a longer vertical ureterotomy in the recipient ureter to accommodate a larger-caliber donor ureter (3,5,7).

---

## ALTERNATIVE THERAPY

---

Other procedures to be considered in lieu of TUU include ureteroneocystostomy with a psoas hitch or Boari flap, nephropexy to allow ureteroneocystostomy or ureteroureterostomy, ileal substitution, and autotransplantation. Other alternatives to TUU include mitigating or temporizing procedures such as cutaneous ureterostomy, pyelostomy, nephrostomy drainage, and ureteral stenting. Nephrectomy should also be considered in cases of marginal donor renal function.

---

## SURGICAL TECHNIQUE

---

The patient is placed supine with such options as kidney rest elevation, retroflexion of the surgical bed, and Trendelenburg positioning to enhance retroperitoneal exposure. A midline vertical incision is usually made in the abdomen, extending

**FIGURE 98.1** Transureteroureterostomy (TUU) approached by two incisions in the posterior peritoneum. **A:** Schematic diagram of left-to-right TUU. **B:** The donor ureter is approximated to the vertical ureterotomy on the anteromedial aspect of the recipient ureter. **C and D:** The anastomosis is begun at the apex and is extended to the posterior aspect of the TUU, using either running or interrupted absorbable sutures. **E and F:** The anterior aspect of the anastomosis may be performed over a catheter or feeding tube removed prior to the last stitch. **G:** Completed TUU in situ.

from just above the umbilicus to the pubic symphysis. However, in cases of distal TUU following a failed reimplantation, a Pfannenstiel incision may be sufficient. A choice of exposure approaches is then available.

### Transperitoneal Approach

Wide transperitoneal exposure is indicated in cases that require complex adjunct procedures such as tapered reimplantation of the recipient ureter or bladder augmentation, as well as when there is a long segment of diseased distal donor ureter. This approach would also be preferred when a high TUU is necessary for the distal donor ureter to be used as a continent catheterizable channel or for augmentation of the bladder.

The bowel is packed and retracted superiorly to allow for further dissection. Once the ureters have been visualized as

they pass over the iliac vessels, two options for opening the retroperitoneum have been described (8): (a) two 5-cm vertical incisions may be made over the ureters where they cross the iliac vessels, creating a window on each side (Fig. 98.1), and (b) wider retroperitoneal exposure can be achieved through a single curved incision that opens the retroperitoneum from over the left distal ureter, extending across the midline along the small bowel mesentery and cecum, and up the right side along the line of Toldt (Fig. 98.2). This technique allows for more extensive mobilization of the bowel in an upward direction.

Once the ureters are adequately exposed, the retroperitoneal tunnel is created by blunt dissection beneath the posterior peritoneum, anterior to the great vessels and superior to the inferior mesenteric artery (IMA). The angle between the aorta and IMA may kink or even obstruct the donor ureter. The position of the IMA should therefore be noted and

**FIGURE 98.2** Approach for single curvilinear incision in the posterior peritoneum to mobilize the bowels and mesentery and expose the retroperitoneum.

avoided in calculating the path of the donor ureter to the contralateral retroperitoneum. Rarely, it may be necessary to ligate the IMA to prevent donor ureteral compression.

### Retroperitoneal Approach

This technique provides the benefit of preventing complications associated with intraperitoneal procedures. The author prefers this approach for a more distal TUU, which requires less mobilization of the donor ureter. Other authors have also described this method as a viable alternative to the transperitoneal approach (9). Most commonly, this approach would be used in salvage procedures for failed ureteral reimplantation.

After the transversalis fascia is incised, the extravascular space is mobilized on each side of the bladder. The ureters are identified crossing beneath the obliterated umbilical arteries. After dividing these vessels with Vicryl or silk ties, the peritoneal sac is retracted superiorly to further expose the retroperitoneum. The peritoneal sac may also be reflected medially to expose the area of interest.

Once adequate exposure of the ureters has been achieved, blunt finger dissection is then used to create an ample retroperitoneal tunnel. In cases of a low TUU using a retroperitoneal approach, the tunnel is created beneath the posterior peritoneum just superior to the posterior wall of the bladder and anterior to the sacral promontory.

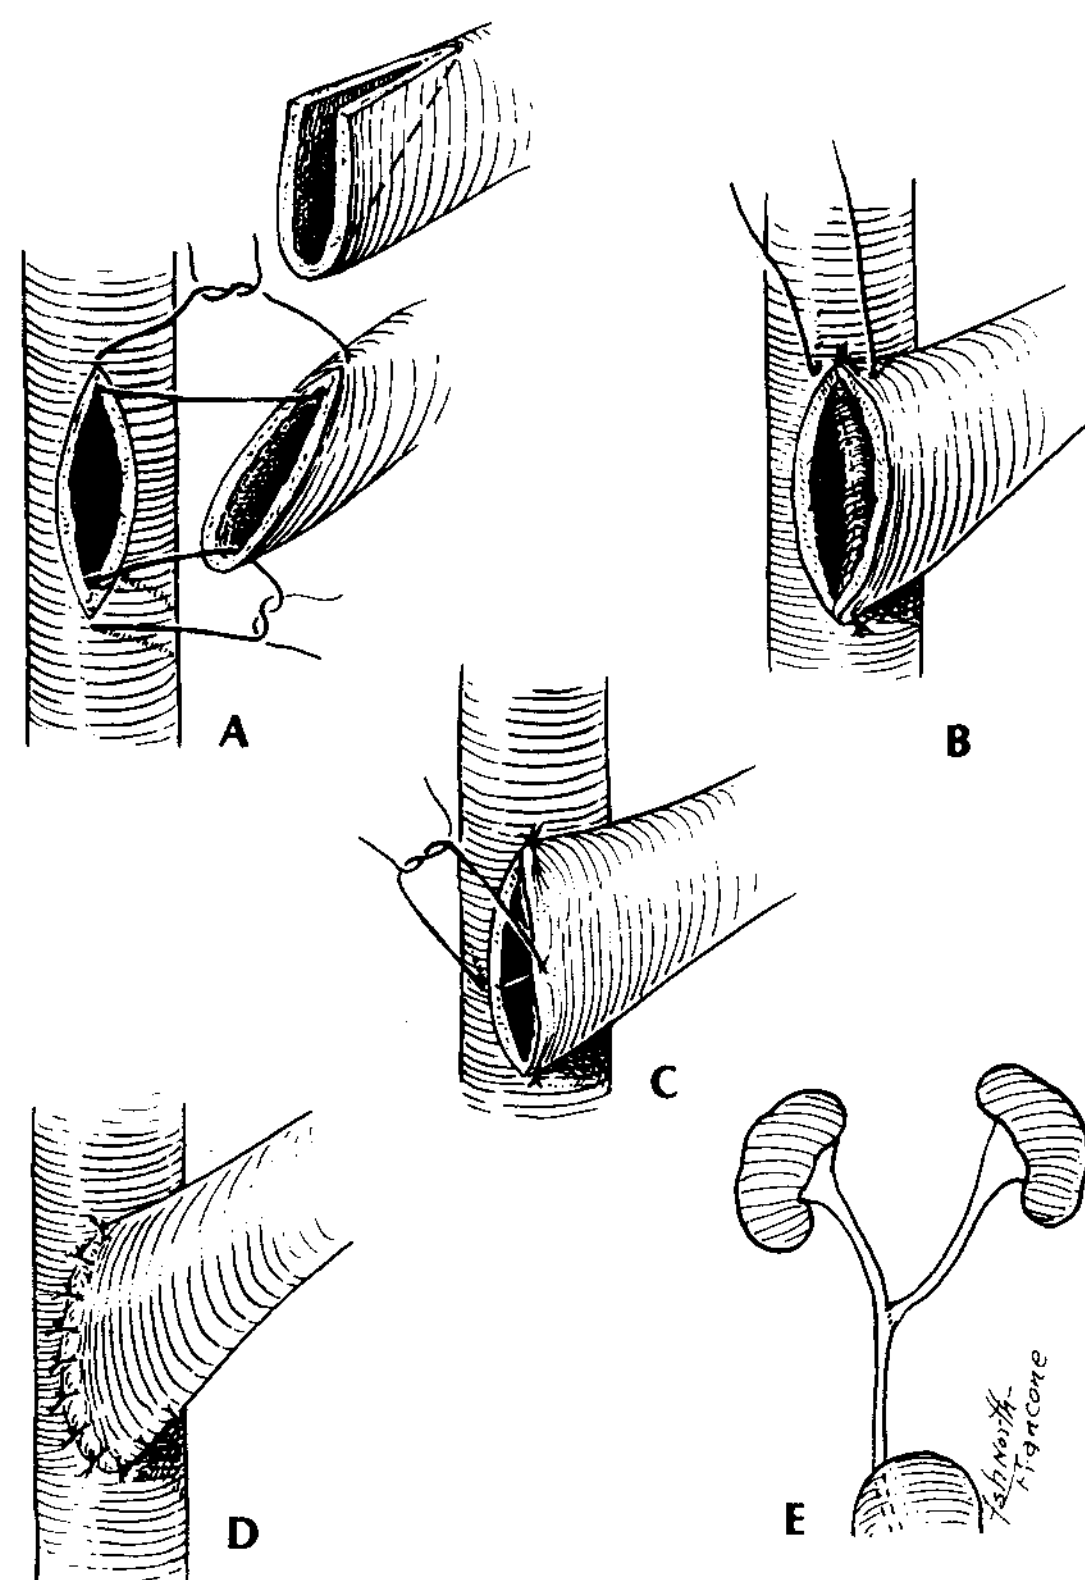

### TUU

Adjunct procedures required for the recipient ureter, such as tapering and reimplantation, should be undertaken prior to the anastomosis of the donor and recipient ureter. For a standard TUU, mobilization of the donor should be sufficient to create a tension-free anastomosis. Because preservation of blood supply is essential for the success of TUU, great care is

taken to avoid unnecessary disruption of the adventitia. The ipsilateral gonadal vessel may be tied off with a 3-0 silk suture to provide even greater mobilization with adventitial preservation. If even greater donor ureteral length is necessary, the donor kidney may be gently mobilized, moved inferiorly, and pexed to the psoas muscle using interrupted 3-0 Vicryl or 3-0 polydioxanone sutures.

After dividing the donor ureter as distal as possible, a long tagged 4-0 chromic or Vicryl suture is then placed on the most distal aspect of the divided donor ureter to allow the ureter to be brought through the retroperitoneal tunnel. A right-angle clamp can then be passed from the recipient to the donor side to grasp the stay suture on the donor ureter and pull the donor ureter through the tunnel. Care must be taken to avoid twisting or kinking of the ureter, and the ureter should reach easily to the other side without tension.

With respect to the recipient ureter, mobilization should be minimized. To enable touch-free manipulation of the recipient ureter, stay sutures consisting of 4-0 or 5-0 chromic may be placed in the recipient ureteral adventitia, superior and inferior to the intended area of anastomosis. A vertical ureterotomy at least 1.5 cm in length on the anteromedial wall of the recipient ureter is then performed at the site of the anastomosis. The donor ureter is then spatulated to accommodate the recipient ureterotomy. However, spatulation may not be necessary if the donor ureter is sufficiently dilated. The anastomosis is performed using interrupted (Fig. 98.3) or running 4-0 or 5-0 absorbable

**FIGURE 98.3** Transureteroureterostomy (TUU) anastomosis performed with interrupted absorbable sutures. **A and B:** After aligning the distal donor ureteral lumen and recipient ureterotomy, apical sutures are placed and tied. **C:** Subsequent intervening interrupted sutures are placed halfway between previously placed sutures. **D:** Completed anastomosis. **E:** Schematic diagram of completed TUU.

sutures, beginning with the superior and inferior apices, followed by the approximation of the more posterior wall of the anastomosis. At this juncture, a ureteral catheter or infant feeding tube may be helpful in some cases to facilitate the anterior wall anastomosis. This tube may be removed just prior to the final anastomotic stitch (Fig. 98.1).

The use of an indwelling ureteral stent is mandatory only when the recipient ureter distal to the anastomosis has been altered in some fashion, such as in reimplantation. A 5Fr or 8Fr feeding tube or a double-J stent may be used. In addition, nephrostomy drainage of the recipient ureter may be employed if extensive mobilization or tapering of the recipient ureter and/or kidney is required to complete the reconstruction (3). In all cases, it is vital to drain the retroperitoneal space using either a Penrose or closed-suction drain. Furthermore, with the transperitoneal approach it is recommended to close the posterior peritoneum to avoid drainage of urine into the peritoneal cavity. Finally, a suprapubic catheter or urethral catheter should be placed to keep the bladder decompressed, as an overly distended bladder in the early postoperative period may stress the TUU anastomosis.

Approximately 2 months postoperatively the patient should undergo a renal sonogram and/or a diuretic renal scan to assess drainage and/or renal function. Depending on the results, imaging may be repeated in 3 to 9 months until a trend of progression has been established. Renal function by creatinine measurements should also be followed, particularly if these levels were elevated preoperatively.

---

### Laparoscopic Approach

---

Laparoscopic TUU has recently been described in children (10). The patient is initially placed in the lithotomy position under general anesthesia for cystoscopy and retrograde pyelogram with stent placement, wire placement, or both in the normal recipient ureter. The patient is then placed supine and re-draped. After gaining periumbilical access to the peritoneal cavity, working ports (3 to 5 mm) are placed under laparoscopic vision in the hypogastrium and in the right and left flank. The position is adjusted according to patient size, at the level of the umbilical line and above for infants and older children, respectively. The patient is placed in the Trendelenburg position with the donor ureter side elevated 30 to 45 degrees and the surgeon standing on the opposite side.

The donor ureter is identified at the pelvic brim. The peritoneum is incised and the ureter is dissected distally as close to the bladder as possible, with special care not to damage the vas deferens in male patients. The distal ureter is ligated with an absorbable suture and divided in an oblique fashion. Proximal mobilization of the donor ureter is performed, preserving the periureteral tissue and its vascularization. The surgical table is then turned to elevate the side of the recipient ureter, and the surgeon changes position to the other side. The recipient ureter is exposed at the same level while incising the peritoneum. A tunnel under the rectosigmoid mesentery is created with blunt dissection, bridging the two peritoneal windows.

Once enough space is developed to accommodate the donor ureter free of external compression it is transposed, pulling it

through the retroperitoneal tunnel with an atraumatic grasper or a stay suture. If the donor ureter was under tension, further proximal mobilization is performed. Care is taken to avoid twisting or kinking of the donor ureter as it enters the retroperitoneal tunnel. A longitudinal ureterotomy at the medial aspect of the recipient ureter is performed to match the lumen of the donor ureter using laparoscopic sharp KOH Ultramicro suture scissors. The indwelling stent is identified and left in place. The anastomosis is carried out with running 5-0 absorbable monofilament sutures. An abdominal drain is left in the proximity of the anastomosis and exteriorized through one of the port sites. The Foley catheter is removed on postoperative day 2, and the drain is subsequently removed once the patient has voided and urine leakage is ruled out. The double-J stents are removed 2 to 4 weeks postoperatively.

---

## OUTCOMES

---

### Complications

---

Postoperative complications include urinoma, pyelonephritis, prolonged anastomotic drainage, and stricture (11). The risk of any of these complications is heightened by tenuous ureteral blood supply from excessive mobilization or from previous radiation (12). Patients with neuropathic or abnormal bladders may be more at risk for developing new vesicoureteral reflux or distal ureteral stenosis in cases that involve reimplantation of the recipient ureter (13). Early anastomotic obstruction leading to persistent drainage may be initially treated conservatively with placement of a double-J ureteral stent or percutaneous nephrostomy.

Late complications include small-bowel obstruction, but only in cases involving the transperitoneal approach. A TUU performed in the context of neoplasm may suffer from late ureteral obstruction. Subsequent stone disease can potentially obstruct the common segment, rendering the patient anuric and mandating emergent percutaneous nephrostomy drainage. Rarely, compression of the donor ureter by the IMA can develop years after TUU if precautions to avoid the artery during donor ureter tunneling were not taken. However, despite potential problems and the possible need for reoperation, several series have shown that TUU anastomotic revision is rarely, if ever, necessary. Also, donor renal loss due to chronic infection or obstruction has proven infrequent, with rates ranging from 0% to 6% (2,3,5). Recipient kidney loss is even less common, reportedly occurring only after extensive mobilization required in complex reconstructions (3,7).

---

### Results

---

Numerous studies have shown excellent results after TUU. Damage to the recipient kidney and ureter has rarely been observed, and successful preservation of both renal units occurs in >90% of cases. TUU performed in the correct setting, with meticulous attention to maintaining ureteral blood supply and a tension-free anastomosis, is clearly an important component of the urologist's repertoire of reconstructive ureteral surgery.

# CHAPTER 99 ■ PYELOPLASTY

EVAN J. KASS AND KEVIN M. FEBER

Ureteropelvic junction (UPJ) obstruction is a common etiology for hydronephrosis in the neonate and young child. UPJ obstruction has been classically divided into intrinsic, extrinsic, and secondary causes. The most common etiology in an infant is an intrinsic adynamic or atretic segment of ureter that inhibits urine exiting from the renal pelvis (1). This restriction to urine flow can lead to varying degrees of renal pelvic dilation and renal damage. Less common causes of intrinsic obstruction include valvular mucosal folds and persistent fetal ureteral convolutions. Extrinsic obstruction is most often the result of periureteral fibrous bands or aberrant lower-pole vessels. Rarely, severe vesicoureteral reflux with periureteral scarring can be a cause of secondary UPJ obstruction.

---

## DIAGNOSIS

---

Historically, most cases of UPJ obstruction were diagnosed in older children who presented with symptoms of flank pain, urinary tract infection, hematuria, and abdominal mass. The widespread utilization of prenatal ultrasound has allowed earlier identification of UPJ pathology in newborns. Children with hydronephrosis persisting on a postnatal ultrasound routinely should have a voiding cystourethrogram to exclude reflux as a possible etiology. When no reflux is present a MAG-3 renogram with Lasix washout allows objective measurement of renal function and drainage. Whitaker antegrade perfusion studies are no longer routinely performed. The natural history of most children with antenatally detected hydronephrosis is usually benign. Operative intervention is in general reserved for patients demonstrating increasing hydronephrosis, worsening renal function, pain, urinary tract infection, or other symptoms. The role of the Lasix washout half-time remains controversial (2).

---

## INDICATIONS FOR SURGERY

---

The indications for pyeloplasty at our institution encompass the following: (i) severe hydronephrosis (Society for Fetal Urology grade III or IV) postnatally and a diuretic renogram of the affected side with <40% differential kidney function and no response to furosemide; (ii) worsening hydronephrosis on serial ultrasound studies; (iii) symptomatic UPJ obstruction with intermittent flank pain; (iv) loss of relative renal function (>10% on serial scans of the affected kidney); or (v) a persistent obstructive half-time on serial diuretic renograms in a child with severe hydronephrosis.

---

## ALTERNATIVE THERAPY

---

Any procedure for correction of UPJ obstruction must satisfy four criteria first described by Foley in 1937: (i) formation of a funnel at the UPJ, (ii) dependent drainage, (iii) watertight anastomosis, and (iv) tension-free anastomosis (3). The Anderson–Hynes dismembered pyeloplasty is the most widely used procedure today and is in general applicable regardless of the etiology of obstruction. Access to the UPJ can be achieved from several incisions, including anterior extraperitoneal, flank, and dorsal lumbotomy. These approaches allow excellent exposure to the renal pelvis with minimal morbidity to the child. Anterior transperitoneal incisions are rarely used due to the increased morbidity associated with intraperitoneal bowel manipulation and the possibility of secondary bowel obstruction.

Ureterocalicostomy is another option for children with massive hydronephrosis or those who have failed primary pyeloplasty. A Foley Y- or V-plasty is indicated when there is a

**FIGURE 99.1** Dismembered pyeloplasty. **A:** The renal pelvis is incised, redundant tissue excised, and the ureter divided distal to the atretic segment. **B:** The ureter is spatulated and brought to the most dependent portion of the pelvis. **C:** The remaining pelvis is closed with running sutures.

UPJ obstruction secondary to a high insertion of the ureter, which is often found in patients with horseshoe kidney.

The refinement of more minimally invasive technologies has allowed correction of UPJ obstruction with minimal operative morbidity. Antegrade and retrograde endopyelotomy procedures have been successful in older children with UPJ obstruction (4). This technique, however, is associated with decreased success rates and an increased risk of intraoperative and postoperative bleeding.

Laparoscopic and robotic-assisted pyeloplasty procedures are evolving techniques to correct UPJ obstruction. In expert hands, success rates following laparoscopic repairs approach results seen with open pyeloplasty (5). Decreased hospital stay and analgesic requirements have been reported in children undergoing the transperitoneal or retroperitoneal approach with or without robotic assistance (6,7). The drawbacks of the laparoscopic and robotic techniques include increased operative time, expensive surgical instruments that may not be available at all centers, and the need for proficiency in laparoscopic surgery. Although laparoscopic and robotic-assisted pyeloplasty procedures have been gaining popularity, open pyeloplasty with optical magnification continues to be the gold standard, with established long-term results.

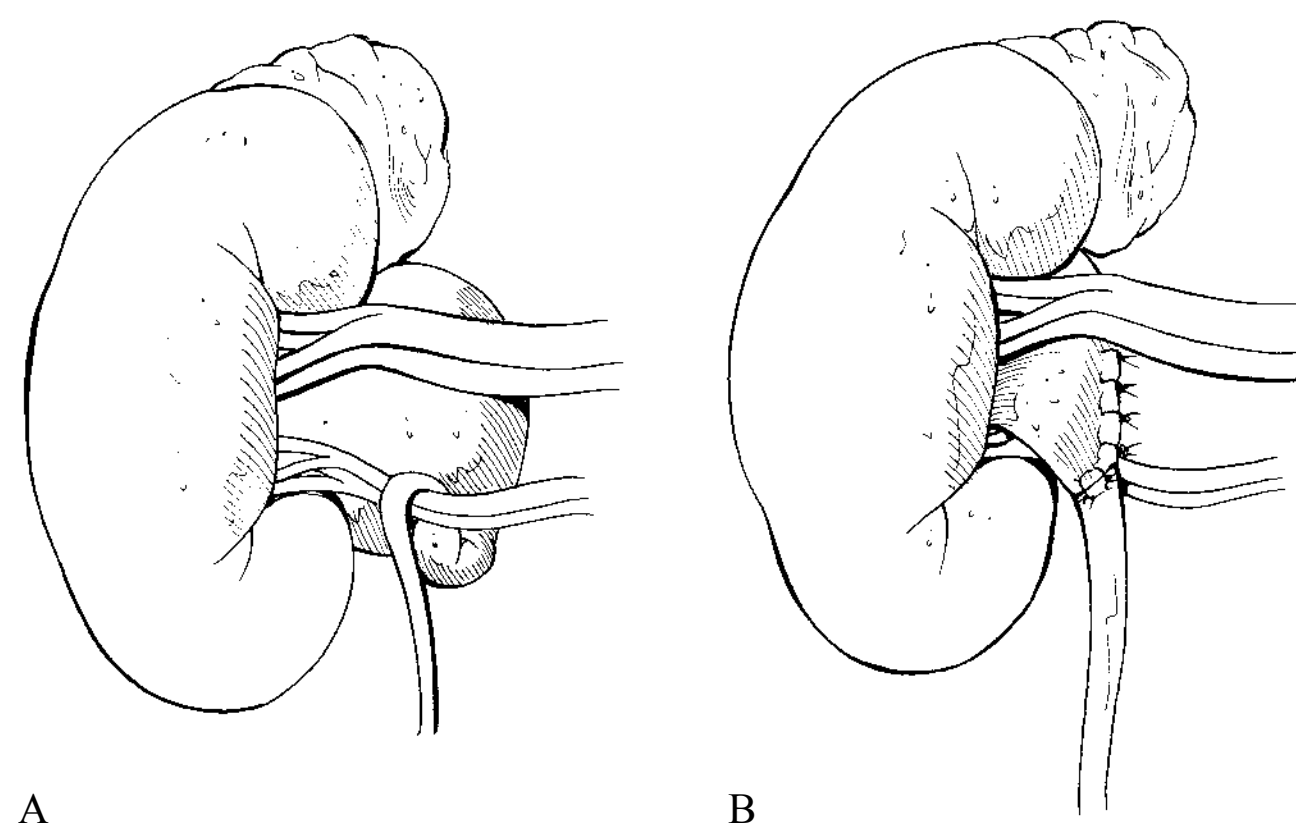

## SURGICAL TECHNIQUE

The patient is placed in the flank position and flexed with the use of rolled towels and/or table flexion with elevation of the kidney rest. We make a transverse incision starting just medial to the angle of the 12th rib and carry it anteriorly. The subcutaneous tissues and musculofascial layers are opened with electrocautery. The lumbodorsal fascia is then divided, the peritoneum is mobilized medially, and the fascia of Gerota is opened.

The lower pole and entire renal pelvis are sharply dissected to identify the UPJ to determine the cause of the obstruction. Care is taken in dissection to preserve the blood supply in the periureteral tissues and ureter. Stay sutures are placed just cephalad to the UPJ and in the ureter to minimize handling of

the tissues. The renal pelvis is incised circumferentially, decompressing the obstructed collecting system (Fig. 99.1). The proximal ureter is mobilized using the stay suture distal to the obstructing segment to facilitate handling, and the atretic portion is excised. The renal pelvis is trimmed of redundant tissue, the ureter is spatulated for 2 cm, and a 5Fr feeding tube is placed in the ureter. The ureter is then anastomosed to the most dependent portion of the renal pelvis using 7-0 interrupted PDS sutures, and the feeding tube is removed. Optical magnification with a 3.0 to 4.5  $\times$  loupe facilitates precise suture placement. Alternatively, 7-0 running sutures can be used, but in infants we prefer interrupted sutures to decrease the purse-string effect and subsequent narrowing of the anastomosis. Care is taken to ensure there is no twisting or kinking of the anastomosis. The remainder of the trimmed upper renal pelvis is closed with a running 6-0 polydioxanone suture.

If the UPJ obstruction is secondary to an accessory lower-pole vessel, the divided ureter is brought anterior to the vessel and anastomosed to the pelvis (Fig. 99.2). Pelvic tailoring is often required in this correction as well.

**FIGURE 99.2** Dismembered pyeloplasty with accessory vessels. **A:** Vessels causing ureteral compression and hydronephrosis. **B:** Anastomosis performed anterior to crossing vessels. Pelvic tailoring as needed.

The placement of intraoperative stents and/or nephrostomy tubes remains controversial, and we do not use either routinely. Whereas some of the early pyeloplasty descriptions used both internal and external drainage, many authorities now believe routine stenting is unnecessary. Stents are indicated in children with poor renal function, those undergoing repeat pyeloplasty, those with a solitary kidney, and those requiring extensive renal pelvic tailoring (4). Disadvantages of percutaneous nephrostomy tubes and ureteral stenting include patient discomfort and need for drain removal either in the office or under a second anesthetic. A 0.25-in Penrose drain is placed in the perirenal space and brought out through a separate, more caudal incision. The musculofascial layers are closed using 3-0 Vicryl. The subcutaneous tissues are closed using 4-0 plain sutures and the skin is reapproximated with 5-0 Monocryl in a subcuticular fashion.

Postoperatively the patient is kept on intravenous antibiotics until the drain is removed, usually on postoperative day 1 or 2. We routinely administer ketorolac 0.5 mg/kg intravenously for the first 48 hours. We have found that it provides excellent pain relief, with the majority of children requiring no parenteral narcotic. Children are typically discharged within

24 hours of surgery. A follow-up ultrasound is done at 3 to 4 weeks postoperatively. If a stent was placed at the time of pyeloplasty, it is removed in 4 to 6 weeks.

---

## OUTCOMES

---

### Complications

---

Most children do very well postoperatively. Significant bleeding, infection, or other morbidity is uncommon. Urinary leakage from the anastomosis can occur and usually resolves spontaneously. When leakage persists or when hydronephrosis increases postoperatively, a ureteral stent can be placed in either an antegrade or retrograde fashion.

---

### Results

---

We have found that dismembered pyeloplasty has been shown to successfully relieve pelvic obstruction in >95% of cases.

## CHAPTER 100 ■ MEGAURETER

J. CHRISTOPHER AUSTIN AND DOUGLAS A. CANNING

Megaureter, or wide ureter, is an unusual congenital anomaly of the urinary tract. We define megaureter as a ureter that is 8 mm or greater in diameter. Megaureter is classified into three categories: (a) refluxing megaureter, (b) obstructed megaureter, and (c) nonobstructed, nonrefluxing megaureter. Urologists further subdivide megaureters into primary and secondary types, with the secondary types resulting from an abnormality such as posterior urethral valves, high-volume vesicoureteral reflux or neuropathic bladder resulting in higher detrusor pressure, or less commonly an acquired condition such as external compression of the ureter from a mass lesion. Primary megaureters, in contrast, are isolated abnormalities of the ureter or ureterovesical junction resulting in a wide ureteral lumen.

Prior to the widespread use of screening prenatal ultrasonography, most children with megaureters presented with urinary tract infection, flank pain, urolithiasis, abdominal mass,

or hematuria. Today, most cases are detected in asymptomatic infants with hydroureteronephrosis in utero. This earlier presentation has led to changes in the approach to management.

The pathophysiology of obstructive megaureters lies not within the dilated ureter but in the distal nondilated segment. This segment of ureter fails to effectively propagate the wave of peristalsis as it descends down the ureter. This segment is not usually narrowed compared with the normal ureter. When the bolus of urine is propagated to the aperistaltic segment, only a portion of the urine passes into the bladder; the remainder is reflected back up the ureter in a yo-yo fashion. This causes the characteristic appearance of the ureter with fusiform dilation affecting the distal ureter more severely. When the amount and force of the bolus are sufficiently large that it dilates the entire ureter and reaches the renal pelvis, hydronephrosis may develop as well.

---

## DIAGNOSIS

---

Differentiating an obstructed megaureter from a nonrefluxing, nonobstructed megaureter can be difficult. These ureters demonstrate a spectrum of severity rather than separate conditions. The diagnostic workup depends on the presenting signs and symptoms and may vary from patient to patient. For the child with prenatal hydronephrosis, the usual evaluation includes a renal/bladder ultrasound, a voiding cystourethrogram (VCUG), and a renal scintigram (renal scan). Hydroureteronephrosis is identified with the renal ultrasound. The dilated ureter is usually visible in the pelvis and is often posterolateral to the bladder. If the ureter is dilated beyond the level of the trigone, an ectopic ureter may be present rather than a primary megaureter. The VCUG separates children with refluxing megaureters from those without reflux. The renal scan in the newborn should be performed with mercaptoacetyl triglycine (MAG-3) with diuretic washout. The scan will estimate the relative function of each kidney and measure the effectiveness of renal clearance of radiotracer from the collecting system. In the past, the  $t_{1/2}$  (time required for half of the radiotracer to clear from the renal pelvis) had been used as an indicator of obstruction. However, in practice, the use of the  $t_{1/2}$  alone to estimate obstruction is not always reliable. Because the clearance is variable based on the patient's prestudy hydration level, age, renal function, and response to the diuretic, we prefer to follow trends in the relative renal function, reserving surgery for those with increasing  $t_{1/2}$  or decreasing relative renal function.

In children who are symptomatic, the presenting symptom determines the workup. Hematuria, rarely noted in children with megaureter, is normally evaluated initially with a renal/bladder ultrasound. The finding of hydroureteronephrosis should be followed by a renal scan or intravenous pyelogram. If there is suspicion of renal or ureteral stone, a noncontrast computed tomography scan should be performed. The renal scan may be required to provide a baseline estimate of relative renal function.

If the anatomy is unclear, magnetic resonance (MR) imaging or MR urography may be useful in distinguishing primary megaureters from ectopic ureters. If there is impaired function of the affected kidney and the child is undergoing surgical correction, cystoscopy should be performed at the beginning of the reconstructive procedure to evaluate the position of the ureteral orifice. The orifice is normally positioned in an obstructed megaureter. If an ectopic ureter is present, the trigone on the affected side will be distorted and the ectopic orifice will not be located at the trigone.

---

## INDICATIONS FOR SURGERY

---

Relative indications to proceed with surgical repair include poor initial relative function (<40% of differential renal function by renal scan), progressive hydronephrosis, decreasing function (>10%) in serial renal scans, persistent severe hydroureteronephrosis, bilateral megaureters, or the development of symptoms such as pain or urinary tract infection localized to the side of the megaureter. In some cases, we consider infants with a poorly functioning kidney for alternative

approaches to primary repair, given the infant's small, thin-walled bladder and the technical difficulties of reimplanting a hydronephrotic ureter into the infant bladder. Options in this case include a staged reconstructive approach with temporary diversion to an end-cutaneous ureterostomy, construction of a refluxing ureteral reimplantation, or, rarely, diverting pyelostomy should be given consideration instead of primary surgical repair (1,2).

We usually operate on children with megaureter who present with symptoms of intermittent flank pain or urinary tract infection. Prior to surgery, we evaluate the child for voiding dysfunction. Rarely, children develop a secondary megaureter from high-pressure bladder storage that is transmitted to the ureter and renal pelvis. Ureteral dilation can be detected in association with neuropathic bladder dysfunction, posterior urethral valves, or severe voiding dysfunction. Appropriate treatment of the posterior urethral valves or the bladder dysfunction may result in improvement or resolution of ureteral dilation. Failure to recognize bladder dysfunction before planning surgery leads to persistent obstruction or postoperative vesicoureteral reflux.

---

## ALTERNATIVE THERAPY

---

Because most patients are asymptomatic and identified as part of an in utero ultrasound, most children with primary megaureters do not require surgical correction. Ureteral dilation does not always equal obstruction. Dilation in some boys and girls may represent the residuum of in utero obstruction that has resolved. The long-term experience at the Children's Hospital of Philadelphia has been that the majority of children with megaureter maintain renal function and ureteral dilation often improves with time. In a series of 27 children with megaureters treated conservatively with a mean follow-up of 6.8 years, hydronephrosis completely resolved in 53% and was improved or stable in the rest. Only 10% of patients required surgical correction, while 90% were followed with serial radiologic studies. A single patient from this cohort developed progression of hydronephrosis and diminished function at age 14 (3). Likewise, in a series of 53 patients with 67 megaureters, only 17% required surgery for poor initial function or progressive loss of function; in addition, the dilation completely resolved by ultrasound in 34% (4). These two series suggest that the majority of megaureters can be managed conservatively. Because of the rare risk of late decompensation, children with persistent hydronephrosis require extended follow-up.

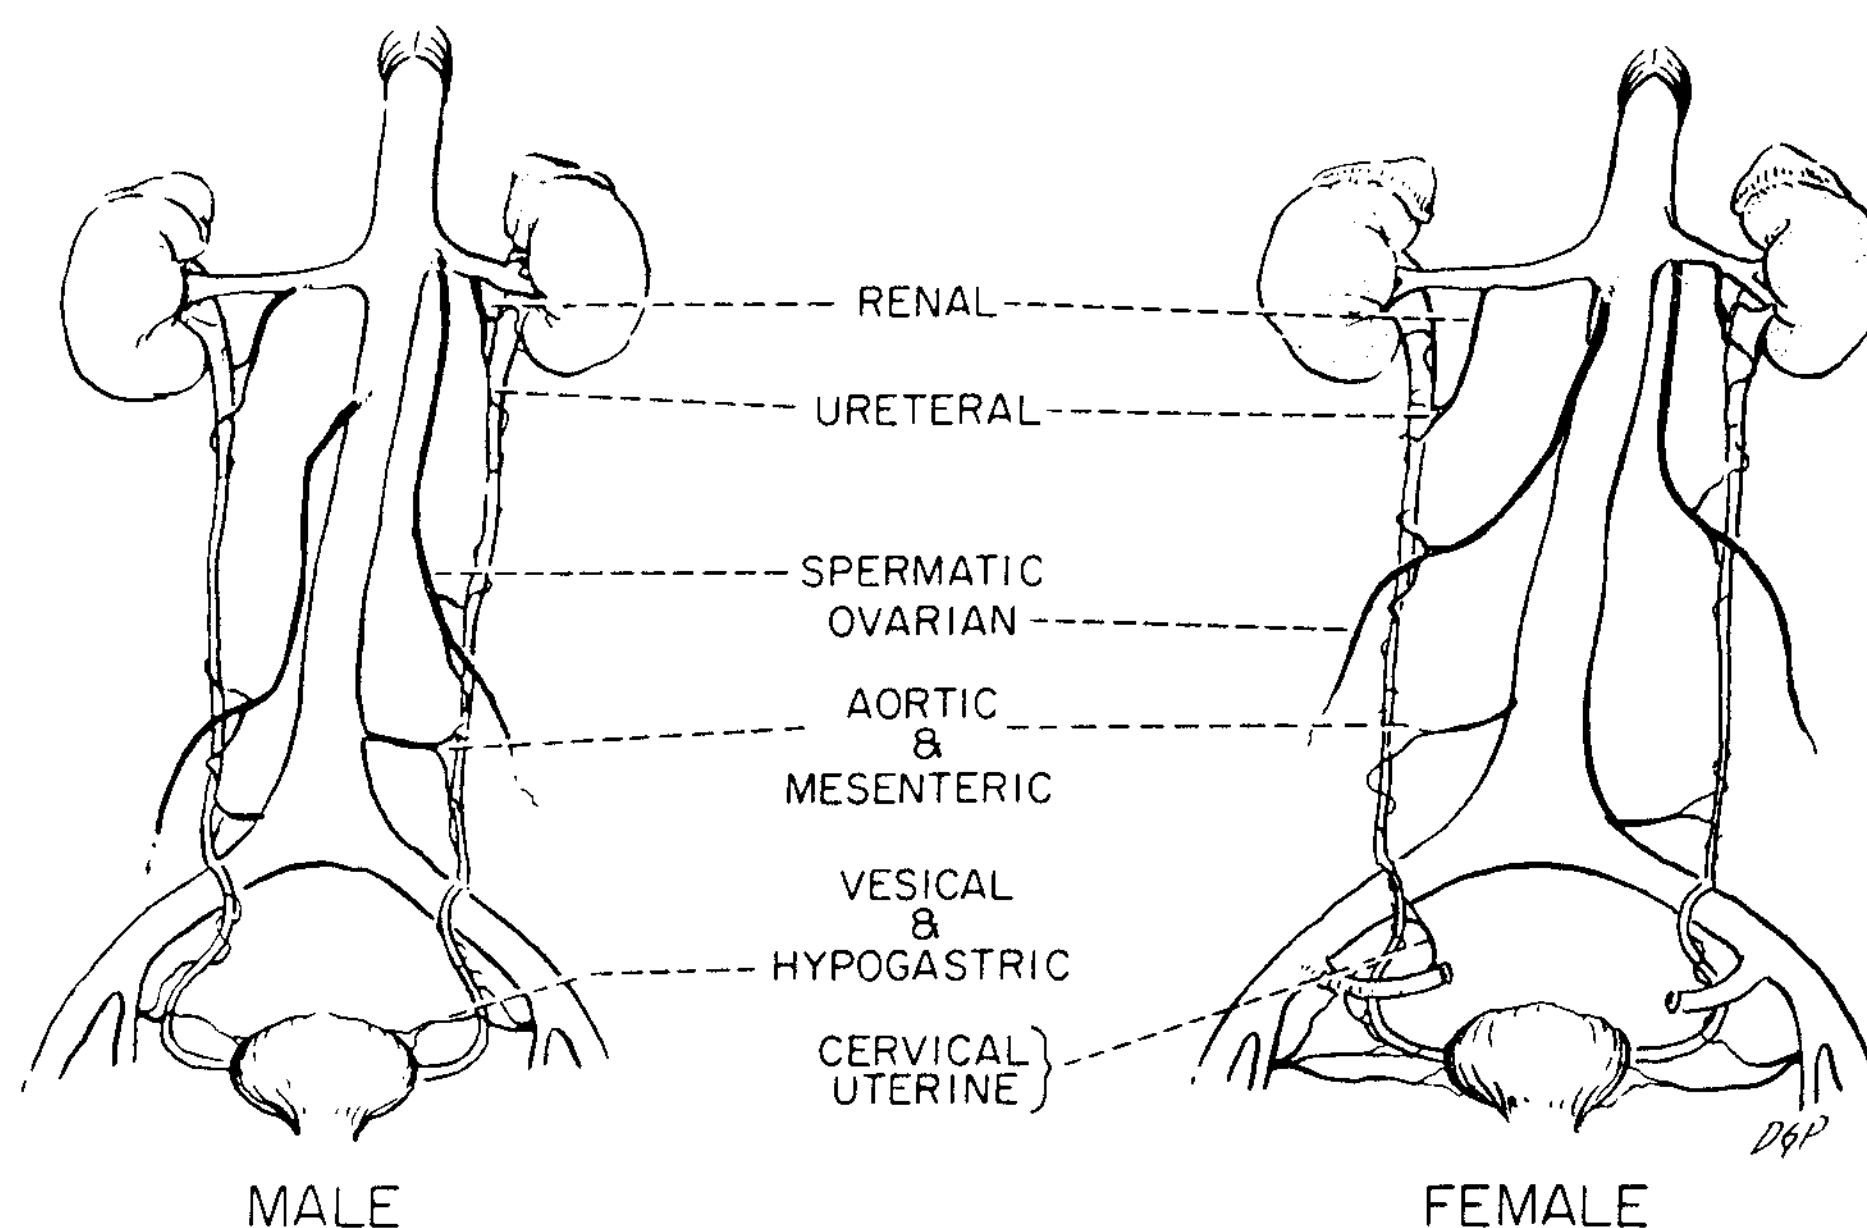

---

## SURGICAL TECHNIQUE

---

The surgical correction is similar for refluxing and obstructed megaureters. Obstructed megaureters have a distal ureteral segment of variable length with a normal or narrowed caliber that does not contract normally and should be excised. Refluxing megaureters are dilated to the level of the ureterovesical junction. Distal segment excision is not always required.

The child is positioned supine on the operating room table. In boys, the lower abdomen and genitalia are fully prepared and draped. Females are placed in a mild frog-legged position

**FIGURE 100.1** Major arterial supply to the ureter. It is not necessary to sacrifice any medially based blood supply for primary megaureter repair.

with gel bolsters under the knees to permit intraoperative access to the urethra if needed. The bladder may be left full during the initial surgical exposure. A Pfannenstiel incision is made in the abdominal skin crease. The rectus fascia is opened along the course of the incision and the flaps of fascia are elevated off the muscle superiorly to just below the umbilicus and inferiorly to the pubis. The rectus muscles are separated in the midline. The space of Retzius is entered, exposing the bladder.

### Intravesical Approach

At this point, depending upon the surgeon's preference, the dissection of the ureter begins either intravesically or through an extravesical exposure. It has been our preference to begin intravesically. The bladder is opened via a midline cystotomy. The bladder dome is packed with damp sponges and a Dennis–Brown retractor is placed to provide exposure of the trigone. A 5Fr feeding tube is passed up the ureter and secured at the orifice with a 4-0 suture. The urothelium surrounding the orifice is divided using electrocautery. With the mucosa divided circumferentially, the ureteral catheter is gently pulled to expose the medial and inferior attachments of the trigonal musculature. These attachments are divided with electrocautery. At this point the dissection proceeds to carefully divide the muscular attachments of the ureter through the plane of Waldeyer's sheath. This dissection will free the distal ureter, which should have a normal or narrowed caliber. The surgeon should recognize the blood supply of the ureter, as shown in Figure 100.1. As the dissection proceeds more proximally, the blood supply of the ureter originates from medial branches of the hypogastric (male) or cervical (female) arteries. These vessels should be preserved, as should the longitudinal blood supply, by taking care to prevent dissection too close to the ureteral wall. When the ureter is free from its detrusor attachments, the

mobilization should proceed extravesically. The ureter at this point can be passed through the bladder wall, and the dissection proceeds more proximally. When the dilated region of the ureter is reached, dissection should continue until an adequate length for reimplantation has been mobilized, again paying attention to the previous outlined principles for preserving the blood supply. An ischemic distal ureter may lead to fibrosis and obstruction.

At this point the surgeon must decide whether to taper the ureter. In general, if the lumen of the ureter is significantly larger than 16Fr it should be tapered prior to reimplantation. There are two techniques used to taper the size of the ureter: (a) excisional tapering and (b) tapering by folding. We will review the three most commonly used procedures. The goal of tapering is to provide a distal ureter with a small enough diameter that postoperative vesicoureteral reflux will be prevented with a reasonable length of intramural tunnel. The tapering needs to extend for only a short distance beyond the bladder wall rather than the whole length of the ureter. The dilation of the proximal ureter should improve postoperatively with the relief of obstruction and/or reflux. The decision to perform an excisional versus a folding technique depends on the preference of the surgeon and the size and thickness of the ureter. Folding a very dilated, thick wall ureter will create a large amount of bulk, making the creation of the submucosal tunnel difficult. In general, the taper should not be aggressive. In a bladder that functions well, reflux is less hazardous than persistent obstruction.

Excisional tapering (Fig. 100.2) begins with carefully examining the ureter. Without twisting the ureter, the surgeon observes the pattern of blood supply to the ureter. In most cases, the longitudinal ureteral vessels are predominately along the medial aspect of the ureter. Usually, the excised segment of ureter is taken from the opposite side along the lateral border. The distal nondilated ureteral (aperistaltic) segment is excised. A 16Fr catheter is passed up the ureter. With this

**FIGURE 100.2** A and B: The wedge of ureter to be excised is secured with Allis or Hendren clamps. C: The outlined segment of ureteral wall is excised sharply. D and E: The ureter is closed in two layers. Distally, interrupted sutures are placed to allow for trimming of the end of the ureter at the time of reimplantation.

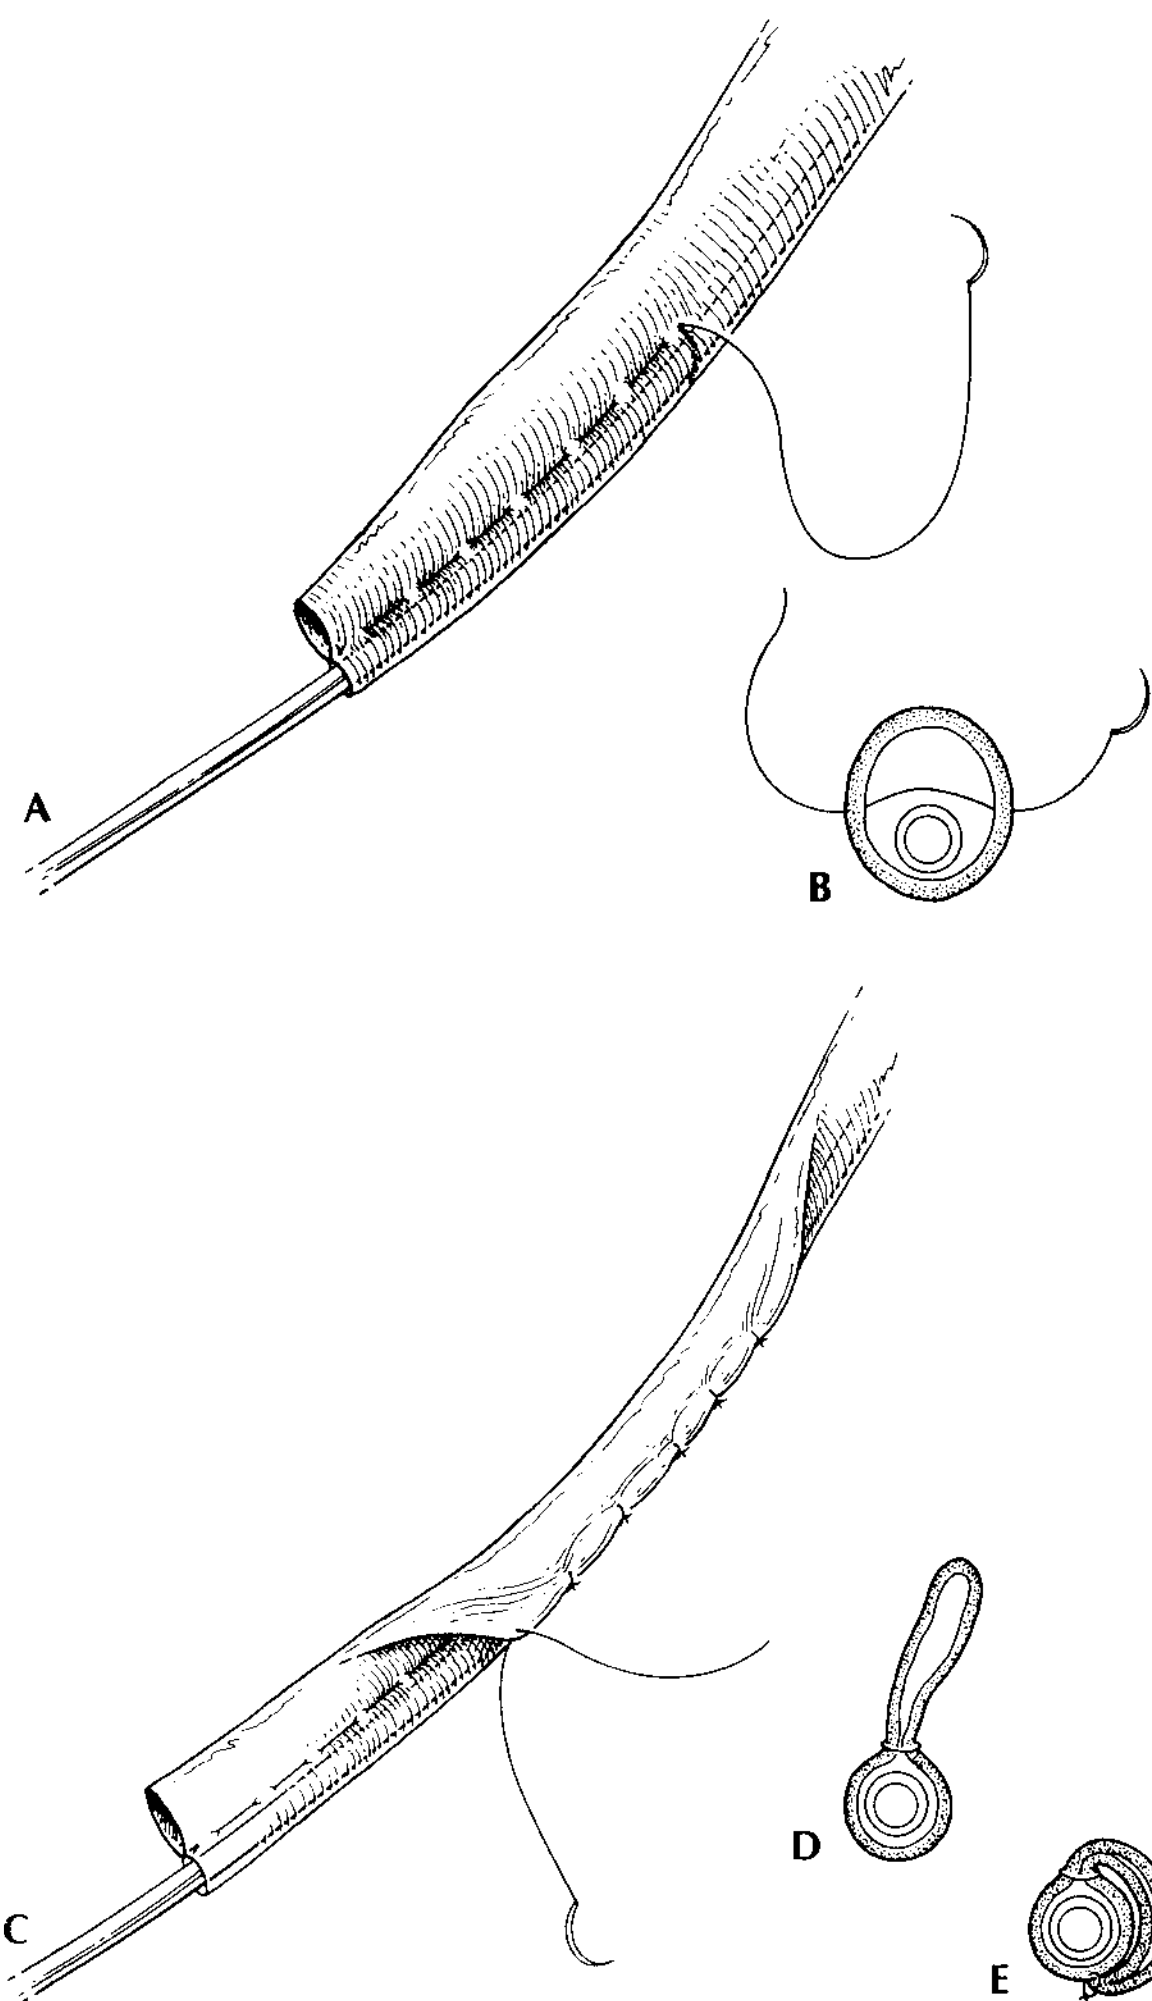

in place, the wedge to be excised is identified and outlined. Aggressive tailoring may result in obstruction. The process of excising and suturing the ureter will result in considerable contraction of the ureteral lumen. The tailored segment should gradually widen as the ureter is reconstructed

proximally. The ureter is then closed. The mucosa and the muscularis of the ureter are closed with absorbable interrupted or running fine suture. A second layer if desired may incorporate the muscularis and adventitia with a series of interrupted absorbable fine sutures. The ureter is then reimplanted in a cross-trigonal fashion. If possible, the suture line should be positioned facing the detrusor muscle to prevent the development of a ureterovesical fistula and reflux. The 12Fr catheter is replaced with a 5Fr or 8Fr feeding tube or a double-J stent. The advantage to leaving an open-ended ureteral catheter is that a retrograde ureteral study can be performed postoperatively to demonstrate ureteral drainage, and the catheter can be removed in the office. The internal stent is easy to care for and leaves the patient free of external tubes; however, it requires a general anesthetic for removal. All tapered reimplants should be stented, regardless of which type of stent is used.

There are two techniques commonly employed for tapering by ureteral folding: (a) Starr plication and (b) the Kaliscinski technique. Both techniques are similar to excisional tapering with regard to the length of ureter to be narrowed and the choice of the segment of the wall based upon the intrinsic blood supply. Starr plication (Fig. 100.3) reduces the diameter of the ureter by infolding the ureteral wall with interrupted Lembert sutures of 5-0 polyglyconate or polydioxan. The tapering begins proximally and gradually reduces the caliber of the ureter until the diameter approaches that of the 12Fr catheter. Care should be taken to ensure the wedge of folded ureter stays in the same position of the ureteral wall as you proceed distally and does not spiral from lateral to medial as the sutures are placed more distally. The ureter is reimplanted with the plication sutures facing the detrusor muscle as was described with excisional tapering. The Kaliscinski technique (Fig. 100.4) begins with a running horizontal mattress suture of 5-0 or 6-0 chromic that runs the length of the segment to be tapered, creating a defunctionalized wedge of ureter that is then wrapped around the ureter and secured posterior with interrupted absorbable sutures. The ureter is reimplanted with the imbricated segment against the muscularis. Again, ureteral stents are placed in both repairs as with excisional tapering.

**FIGURE 100.3** A: Starr plication of the ureter suture to infold the ureter. B: Cross section to show placement of Lembert-type sutures. C: Cross section after ligation of sutures.

**FIGURE 100.4** Kaliscinski technique of ureteral imbrication. **A:** Placement of cobbler's stitch to exclude a major portion of the ureteral lumen. **B:** Same in cross section. **C:** After ligation. **D:** Excluded portion of the ureter is folded over and wrapped around the intubated ureter. **E:** Final appearance in cross section.

### Extravesical Approach

Several authors have reported good results with the extravesical approach to megaureter repair (5,6). We avoid this technique in bilateral megaureter. In cases of bilateral megaureters, a high rate of voiding dysfunction postoperatively has been reported that may require intermittent catheterizations for a period following surgery. A Foley catheter is placed at the beginning of the procedure. The catheter may be attached with a Y-connector for intraoperative filling and emptying. The ability to regulate the bladder volume aids in the dissection. The incision and initial approach is identical as for the intravesical approach until the bladder is exposed. The dissection then proceeds into the lateral extravesical space. The obliterated umbilical artery is divided to expose the ureter. The ureter is carefully dissected free and encircled with a vessel loop. The ureter is dissected distally to the ureterovesical junction. With the bladder full, a detrusorotomy is made in a line extending from the bladder neck cephalad and circumscribing the detrusor adjacent to the ureter. The length of the incision should be 3 to 4 cm.

The ureter is freed from all detrusor attachments, keeping the mucosal attachments intact. The edges of the detrusor incision are then dissected free of the urothelium to form flaps that can be closed over the ureter. If the urothelium is perforated during the dissection it can be repaired with 6-0 or 7-0 chromic. The most distal region is ligated and the ureter divided proximal to the ligature. The aperistaltic segment of the ureter is resected. The dilated ureter is then tapered as necessary. An indwelling stent is placed if the ureter is tapered. The bladder is partially emptied and the ureter is then directly anastomosed to the urothelium at the distal apex of the detrusorotomy using 5-0 absorbable sutures. With this accomplished, the distal ureter is fixed to the detrusor with 5-0 polyglyconate horizontal mattress sutures at the apex. The detrusor is then closed over the ureter with 4-0 polydioxan sutures. The hiatus should be approximated, but not closed too tight. A Foley catheter is left indwelling postoperatively and a Penrose drain is placed during closure.

### Staged Approach

Although repair of megaureters has been performed safely in newborns and young infants, there is a reasonable concern about reimplanting a markedly dilated ureter into the thin bladder wall of an infant (1,7). In some infants where severe dilation and diminished relative function (<35%) exists, end-cutaneous ureterostomy is a good alternative to reimplantation with tapering (7). The infant bladder often empties with high pressure, and postponing the definitive reimplantation while decompressing the obstructed ureter may reduce complications. In this case an end-cutaneous ureterostomy (technique presented in Chapter 93) is performed and the distal stump is resected. This provides reliable decompression of the kidney and allows for improvement in the degree of ureteral dilation prior to reimplantation. In some cases the ureterectasis recovers enough to avoid the need for tapering. In addition, if the initial function is poor and the kidney fails to recover following decompression, a nephrectomy rather than reimplantation may be preferred. This temporary measure will allow the reimplantation to be delayed until the infant is older. The takedown of the ureterostomy and ureteral reimplantation is usually done when the child is 12 to 18 months old and can be performed intravesically or extravesically.

### POSTOPERATIVE CARE

A Foley catheter is usually left in place for 24 to 48 hours. The external stent is left in place for 10 to 14 days. Children are discharged from the hospital on prophylactic antibiotics. Contrast injection of external stents at low pressure by gravity infusion with antibiotic coverage is performed to document drainage. If there is not prompt drainage around the stent, it is left for another 10 to 14 days and the study is repeated. Internal stents are removed 4 to 6 weeks postoperatively. Patients are evaluated with a renal ultrasound 1 month after surgery or stent removal. If hydronephrosis is not improved, a renal scan should be obtained. A VCUG and renal scan should be performed 3 months after surgery, and the ultrasound is repeated at 1 year.

---

## OUTCOMES

---

---

### Complications

---

The most common complication related to surgery for megaureters is new or persistent reflux. This complication is more common when the surgery is performed for refluxing megaureters than for obstructed megaureters. Management options include observation with prophylaxis, endoscopic injection, and surgical revision. Obstruction is a rare complication, with reported rates of 0% to 4% (4,5,7). It should be initially evaluated endoscopically as on occasion a synechia has been reported to narrow the orifice. Strictures can be assessed by retrograde pyelography. Initial management with dilation and

stenting may be successful, but failures will require an open revision.

---

### Results

---

Most series report success rates >90% (1,7–9). In a series of infants treated with reimplantation, 20% had reflux postoperatively; however, with time a few patients had spontaneous resolution of their reflux, lowering the rate to 12.5% (10). Extravesical reimplants had rates of postoperative reflux similar to intravesical rates (12%). When performed bilaterally for megaureters, two thirds of patients treated with extravesical reimplantation required intermittent catheterization for a period of 1 to 4 months (5).

## CHAPTER 101 ■ PRUNE BELLY (TRIAD) SYNDROME

DAVID B. JOSEPH

Triad syndrome—the clinical association of a thin flaccid abdominal wall, undescended testes, and bladder hypertrophy with hydroureters—was originally described in 1895 by Parker (1). Shortly thereafter, Osler presented a similar constellation of findings in a child he described as having the appearance of “a wrinkled prune” (2). From that point, “prune belly” has unfortunately become synonymous with this syndrome. This clinical manifestation is also known as the Eagle–Barrett syndrome and the abdominal muscular deficiency syndrome. By classic description, the triad syndrome occurs in boys. However, 5% of patients are girls presenting with similar physical findings, with the obvious exception of the gonadal abnormality. The incidence of triad syndrome occurs in 1 of every 30,000 to 50,000 live births. Most cases are sporadic, although a familial occurrence has been described (3).

Approximately three quarters of children with classic triad syndrome will have other associated anomalies. Urethral abnormalities, including atresia and megalourethra, have been reported but are not required as part of the triad. Urethral atresia is usually associated with a patent urachus. The most common skeletal abnormality is a thoracic deformity resulting in a protruded upper sternum, depressed lower sternum, and splayed ribs. Other less frequent skeletal deformities include talipes equinovarus, congenital hip dislocation, calcaneus valgus, polydactyly, syndactyly, arthrogryposis, scoliosis, and lordosis. Intestinal malformations are noted in approximately one third of children and most often are due to defective fixation or malrotation of the midgut. Cardiac atrial or ventricular septal defects, patent ductus, and teratology of Fallot have been reported in approximately 15% of children (3).

## DIAGNOSIS

The diagnosis of triad syndrome can be established in utero with fetal sonography. However, similar findings can be seen in a fetus with posterior urethral valves or the megacystis–megaureters syndrome. Close inspection for thinned or absent abdominal wall musculature should hedge the differential diagnosis to that of the triad syndrome. In utero diagnosis allows for a planned neonatal investigation. Triad syndrome is often obvious at birth with the pathognomonic physical findings of a loose, lax, wrinkled abdominal wall; flared chest; and undescended testes.

Several classifications of the triad syndrome have been established based on severity and initial clinical presentation. There is no single classification system that incorporates the total spectrum of this syndrome. For practical purposes, children can be grouped into severe, moderate, or mild presentations. With a severe presentation, survival is often limited by significant respiratory compromise due to pulmonary immaturity and dysplasia, as well as extensive renal dysplasia, resulting in a Potter-like syndrome. Children described with moderate involvement have combined renal and respiratory insufficiency, mandating close observation and early intervention to minimize the sequelae of pulmonary and renal compromise. The combination of increased bilateral renal echogenicity on sonography, chronic urinary tract infections (UTIs), and a nadir serum creatine of  $>0.7$  mg/dL are prognostic for renal failure (4). Monitoring of the urinary system is necessary to prevent progressive renal deterioration due to stagnation of urinary flow, UTIs, and possible urinary tract obstruction. Urinary tract reconstruction may play an important role in limiting long-term morbidity. Children with mild involvement do not suffer from respiratory or renal compromise. While long-term follow-up is necessary, operative intervention is often limited to orchiopexy and abdominal wall reconstruction.

A team approach consisting of a pediatric urologist, neonatologist, nephrologist, pulmonologist, and cardiologist is required to maximize the outcome. The initial cardiorespiratory status of the neonate must be established. The baby should undergo a chest X-ray and, when indicated, cardiac sonography. Urologic evaluation commences with abdominal sonography and a baseline chemistry profile. Both the upper and lower urinary tract should be assessed. Attention should be placed on the degree of hydronephrosis, the volume of renal parenchyma, and its echogenicity. Often, there will be a disproportionate degree of distal ureteral dilation and megacystis compared to dilation of the proximal ureter and kidney. On occasion, a marked transition of ureteral dilation is noted. If the infant is clinically stable with normal renal function and is voiding per urethra or draining through a patent urachus, further diagnostic testing can be placed on hold.

Children with renal insufficiency require further imaging to differentiate renal dysplasia and stagnant urine flow from true obstruction. The MAG-3 renal scan has limitations in the newborn period but still provides the most objective data. The voiding cystourethrogram can assess vesicoureteral reflux and the effectiveness of bladder emptying. The neonate with triad syndrome and hydroureteronephrosis is susceptible to bacteriuria and can quickly become symptomatic. Bacteriuria is often

**FIGURE 101.1** A: Scaphoid megalourethra. Corpora spongiosum (CS) is deficient throughout the ventral aspect of penile urethra. Corpora cavernosum (CC) is normal. B: Fusiform megalourethra. Both corpora spongiosum and cavernosum are deficient. Glans (gl) is normal in both variants.

persistent and difficult to clear. Therefore, it is of utmost importance that any invasive lower urinary tract imaging be performed in a sterile environment, with the child receiving pre- and postprocedural antibiotics.

Megalourethra has been classified as scaphoid and fusiform (Fig. 101.1). The more common scaphoid defect is confined to the penile portion of the corpus spongiosum, resulting in a variable length of massively enlarged ventral, anterior urethra similar in appearance to a saccular diverticulum. The fusiform variety encompasses a defect of the corpus spongiosum and deficiency of one or both of the corpus cavernosum, resulting in circumferential ballooning of the urethra and generalized penile flaccidity. Megalourethra is usually an isolated defect but can present with upper urinary tract changes, including hydronephrosis, vesicoureteral reflux, and renal dysplasia. It has been reported to occur with the triad syndrome, which may represent a continuation of the abnormal mesodermal theory of development related to the triad syndrome.

## INDICATIONS FOR SURGERY

Each child presents with a unique constellation of problems resulting in its own set of considerations and requires individualized care (5). Therefore, no one treatment plan is appropriate for all children. In general, operative management can be divided into three broad areas: reconstruction of the urinary system, reconstruction of the abdominal wall, and transfer of the intra-abdominal testes to the scrotum.

---

## Urinary Tract Reconstruction

---

Controversy surrounds the need for aggressive urinary tract reconstruction. Early aggressive operative intervention for all children is countered by the fact that renal dysplasia may be inherent, thus preventing any intervention from improving the functional status. In addition, imaging studies depicting significant hydronephrosis do not always correlate with obstruction or the potential for symptoms, and hydronephrosis by itself does not mandate reconstruction. Urinary tract reconstruction is beneficial in a child who has a component of obstructive uropathy and has been shown to have improved renal function with decompression of the urinary system. Reconstruction is also of benefit in the child who has progressive hydronephrosis associated with increasing renal compromise and in the child who has recurrent symptomatic UTIs due to stagnant urine flow.

Urinary diversion plays an initial temporary role in the management of acute renal failure or sepsis. Often, children with urethral atresia or obstruction will present with a patent urachus, effectively emptying their lower tract. Infants with associated posterior urethral abnormalities resulting in obstruction or poor bladder decompression, who are not candidates for intermittent catheterization, benefit from a vesicostomy. A vesicostomy, however, may not adequately drain the upper urinary tract due to a relative obstruction of the ureter at the level of the bladder or poor urinary transport secondary to a highly compliant, adynamic ureter. Vesicostomy should be undertaken only when bladder catheterization has been shown to be effective. Otherwise, temporary diversion of the upper urinary tract will be required. Nephrostomy tube drainage is helpful to stabilize an acute problem but its long-term effectiveness is limited, resulting in a need for a more formal upper urinary tract diversion. There is a theoretical advantage in performing upper tract diversion as proximal as possible. This should maximally relieve stress to the kidney and limit stagnation of urine in a dilated tortuous ureter. However, there is often a disproportionate degree of distal versus proximal ureteral dilation that can prevent easy access of the proximal ureter.

It is compelling to perform a reduction cystoplasty during urinary reconstruction in a child with triad syndrome. However, long-term follow-up has not shown an objective advantage (6,7). With time, the bladder will often regain its large size and lose its tone, resulting in inadequate emptying. For these reasons, it is not practical to proceed with reductive cystoplasty as the primary indication for urinary reconstruction. If a large, poorly contracting bladder results in inadequate urinary emptying, intermittent catheterization would be a more appropriate form of initial management. However, when undertaking formal upper tract reconstruction and ureteral tailoring, reductive cystoplasty is practical and may provide limited improved bladder emptying.

---

### Reconstruction of the Abdominal Wall

---

Several techniques have been devised to maximize the cosmetic benefits of abdominal wall reconstruction in children with triad syndrome. There is evidence indicating that the muscular defect is more pronounced centrally and caudally. Initial reconstructive efforts were based on removal of this

abnormal tissue. While the appearance of the abdomen was improved, it was not ideal and resulted in a transverse incision and loss of the umbilicus. Monfort described preservation of the umbilicus, and others have added various modifications (8–10). Based on this approach, abdominal wall reconstruction now allows for an excellent cosmetic and functional outcome (11). The benefit of abdominal wall reconstruction is dependent on the degree of abdominal wall laxity. The timing for this procedure should be based on the need for other operative intervention. If it is obvious that the child will not require upper urinary tract reconstruction, abdominal wall reconstruction can be undertaken at any time. If, however, there is the potential for upper urinary tract reconstruction, abdominal wall reconstruction should be deferred until the time of that intervention.

---

### Orchiopexy

---

The timing for orchiopexy can be individualized based on the child's need for urinary reconstructive surgery. If urinary reconstructive surgery is required, orchiopexy can be performed at the same time. If urinary reconstructive surgery is not required, then the timing and approach are variable. Placement of the testes within the scrotum is important for maintaining hormone function, allowing for pubertal development and sexuality, but unfortunately fertility is not improved (12). Biopsies of testes have shown a Sertoli-cell-only feature prohibiting future fertility.

---

### Urethral Reconstruction

---

Correction of the megalourethra is dependent on presenting symptoms of urinary dribbling and/or urinary infections. Most often operative correction is undertaken because of the unusual appearance of the megalourethra. Urethral tapering is an appropriate treatment.

---

## ALTERNATIVE THERAPY

---

Alternative therapy relates to conservative medical management and observation. The floppy abdominal wall and poor musculature can be supported with use of an elastic corset.

---

## SURGICAL TECHNIQUE

---

---

### Vesicostomy

---

A vesicostomy is placed between the symphysis and umbilicus. A 2- to 3-cm incision is made down to the rectus fascia. A triangular segment of fascia is removed, which will help limit problems of stenosis. The rectus is separated, the space of Retzius is entered, and the dome of the bladder is identified along with the urachus and umbilical ligaments. The bladder is opened in this region to decrease the risk of prolapse. The bladder wall is secured to the rectus fascia with 4-0 polyglactin sutures and the bladder epithelium is approximated to the skin with 4-0 chromic gut.

## Distal Cutaneous Ureterostomy

When there is minimal proximal dilation, a low distal cutaneous ureterostomy provides adequate decompression with relief of stagnated urine flow and stabilization of renal function. The ureter can be approached from a small (2.5-cm) incision placed in a lower inguinal location. The muscles are split to enter the retroperitoneum. The ureter may have the appearance of bowel due to its large size. When in doubt, a 21-gauge needle should be passed, aspirating contents to confirm urine. Once confirmed, the ureter is opened at the level of the obliterated umbilical artery. The size of the ureter usually prevents postoperative stenosis, allowing for either an end or loop ureterostomy. An advantage of distal diversion is noted at the time of definitive urinary reconstruction: the proximal urinary system will have remained uncompromised, allowing for easier mobilization and greater flexibility when tailoring the ureter.

## Ureteral Reconstruction

When definitive primary urinary reconstruction is necessary, the initial approach to the ureter can be extravesical. The ureter is isolated at the level of the bladder and proximal dissection ensues. If there is an obvious transitional phase noted on imaging between the dilated distal ureter and the normal proximal ureter, the dissection should be continued proximal to the transition point. During dissection, the adventitial tissue surrounding the ureter is preserved to prevent devascularization. All of the distal ureter is excised when there is adequate length for the proximal ureter to be reimplanted in the bladder in a standard fashion or with the assistance of a psoas hitch.

If total proximal and distal ureteral tailoring is necessary due to massive dilation, full mobilization of the ureter will be required. This can be accomplished via a retroperitoneal

approach, but in most children it is helpful to enter the peritoneum and reflect either the descending or ascending colon along the white line of Toldt. The dilated ureter is often exceedingly redundant and tortuous. Straightening of the ureter without devascularization is required. The functional capability of the ureter for peristalsis and transmission of urine into the bladder parallels the degree of hydroureter. Therefore, ureteral tapering may enhance urinary flow into the bladder. Multiple techniques exist for ureteral tailoring, including ureteral imbrication and formal ureteral excision as with any megaureter (Fig. 101.2). Ureteral imbrication is appropriate for marginally dilated ureters. But, when massive ureteral dilation is present, which is usually the reason for reconstruction, formal excision is preferred, eliminating the bulky tissue that results from the large imbricated ureter.

The ureter is tapered loosely over either a 10Fr or 12Fr catheter, depending on the child's age and size. The excised ureteral segment may need to take an unconventional course to preserve adequate blood supply to the tailored ureter. If a large, redundant renal pelvis is present in association with a dilated proximal ureter, a reduction pyeloplasty should be performed in line with the ureteral excision. Preservation of the proximal ureteral blood supply is mandatory.

After excision, the ureter and renal pelvis are closed in a two-layer technique using absorbable sutures. The first running suture line is 5-0 or 6-0 chromic gut, polydioxanone, or polyglactic acid, directly apposing the mucosa and muscularis of the ureter. The second layer reapproximates the adventitial tissue using the same suture material. Both running layers are discontinued a few centimeters from the distal end of the ureter. The very distal portion of the ureter is closed with interrupted sutures. This allows for excision of the distal ureter without interruption of the running suture line. Enough ureteral length should be preserved to allow for a tunneled antirefluxing ureteroneocystostomy in all cases. A ureteral stent will remain for 5 to 10 days postoperatively.

**FIGURE 101.2.** **A:** The tortuous dilated ureter is carefully straightened without compromising blood supply. The redundant portion is excised and the remaining distal segment tapered if necessary. **B:** Ureteral folding over a 10Fr or 12Fr ureteral catheter. **C:** Formal ureteral tapering with excision and closure. *Note:* The continuous running closure stops 1 to 2 cm from the end of the segment, followed by interrupted suture placement, allowing for excision of the distal end of the ureter without compromising the running closure.

**FIGURE 101.3** Reduction cystoplasty. **A:** The dome of the bladder, including any urachal remnant, is removed. **B:** A 2- to 3-cm mucosal strip is then removed from one portion of the bladder. **C and D:** The bladder is closed with overlapping suture lines.

## Reduction Cystoplasty

Reductive cystoplasty should include the urachus and the majority of the dome of the bladder (Fig. 101.3). A 2- to 3-cm strip of mucosa is removed from one side of the bladder wall, allowing for a reinforced overlapping suture line. The bladder is closed in three independent layers using a running suture of 3-0 chromic gut, polydioxanone, or polyglactin acid. A suprapubic tube is inserted for postoperative monitoring regarding the effectiveness of bladder emptying.

## Abdominal Wall Reconstruction

The Monfort approach begins with a midline incision from the tip of the xiphoid process carried inferiorly, circumscribing the umbilicus, leaving an adequate umbilical island of tissue, and ending at the symphysis pubis (Fig. 101.4). A full-thickness skin flap is created bilaterally, elevating the subcutaneous fat from the underlying fascia. The dissection is continued laterally to the anterior axillary line. Often, there will be variability and asymmetry of muscular development. Care must be taken not to enter the peritoneum while mobilizing the skin flaps, in particular in areas where the fascia is relatively thin. An incision is then made lateral to the superior epigastric artery through the fascia, entering the peritoneum. The incision is continued lateral and parallel to the course of the superior and inferior epigastric arteries from the costal margin to the symphysis pubis. The fascia is then elevated and the contralateral superior and inferior epigastric arteries are identified. A

second parallel incision is made lateral to these arteries. The central fascial bridge with the umbilical island is now supported by both sets of epigastric arteries. The two lateral incisions provide excellent exposure for orchiopexy and major urinary tract reconstruction when required.

At the time of abdominal closure, the lateral fascia wall is secured to the central fascial strip with a running 2-0 or 3-0 polyglactin suture. The lateral fascia can be scored with the cautery along the intended suture line to enhance adherence. The edge of the lateral fascia is then overlapped and secured in the midline with figure-of-eight suture placement using 2-0 or 3-0 polyglactin sutures. This pants-over-vest closure provides additional ventral support. Two flat 7Fr suction drains are placed between the fascia and the subcutaneous space. The skin flaps are then tailored, removing the excess, allowing for a midline and periumbilical closure. The skin flap is closed in multiple layers, securing the subcutaneous tissue with 4-0 plain gut sutures. The epithelial edge is reapproximated with a running subcuticular suture of 4-0 or 5-0 polyglactin. The drains remain in place for 2 or 3 days for decompression of the dead space. An alternative laparoscopic-assisted approach may allow for improved abdominal wall plication and simultaneous orchiopexy (13).

## Orchiopexy

The testicle is usually found closely associated with a dilated distal ureter and should be released from the ureter in order to determine whether it can be delivered into the scrotum without

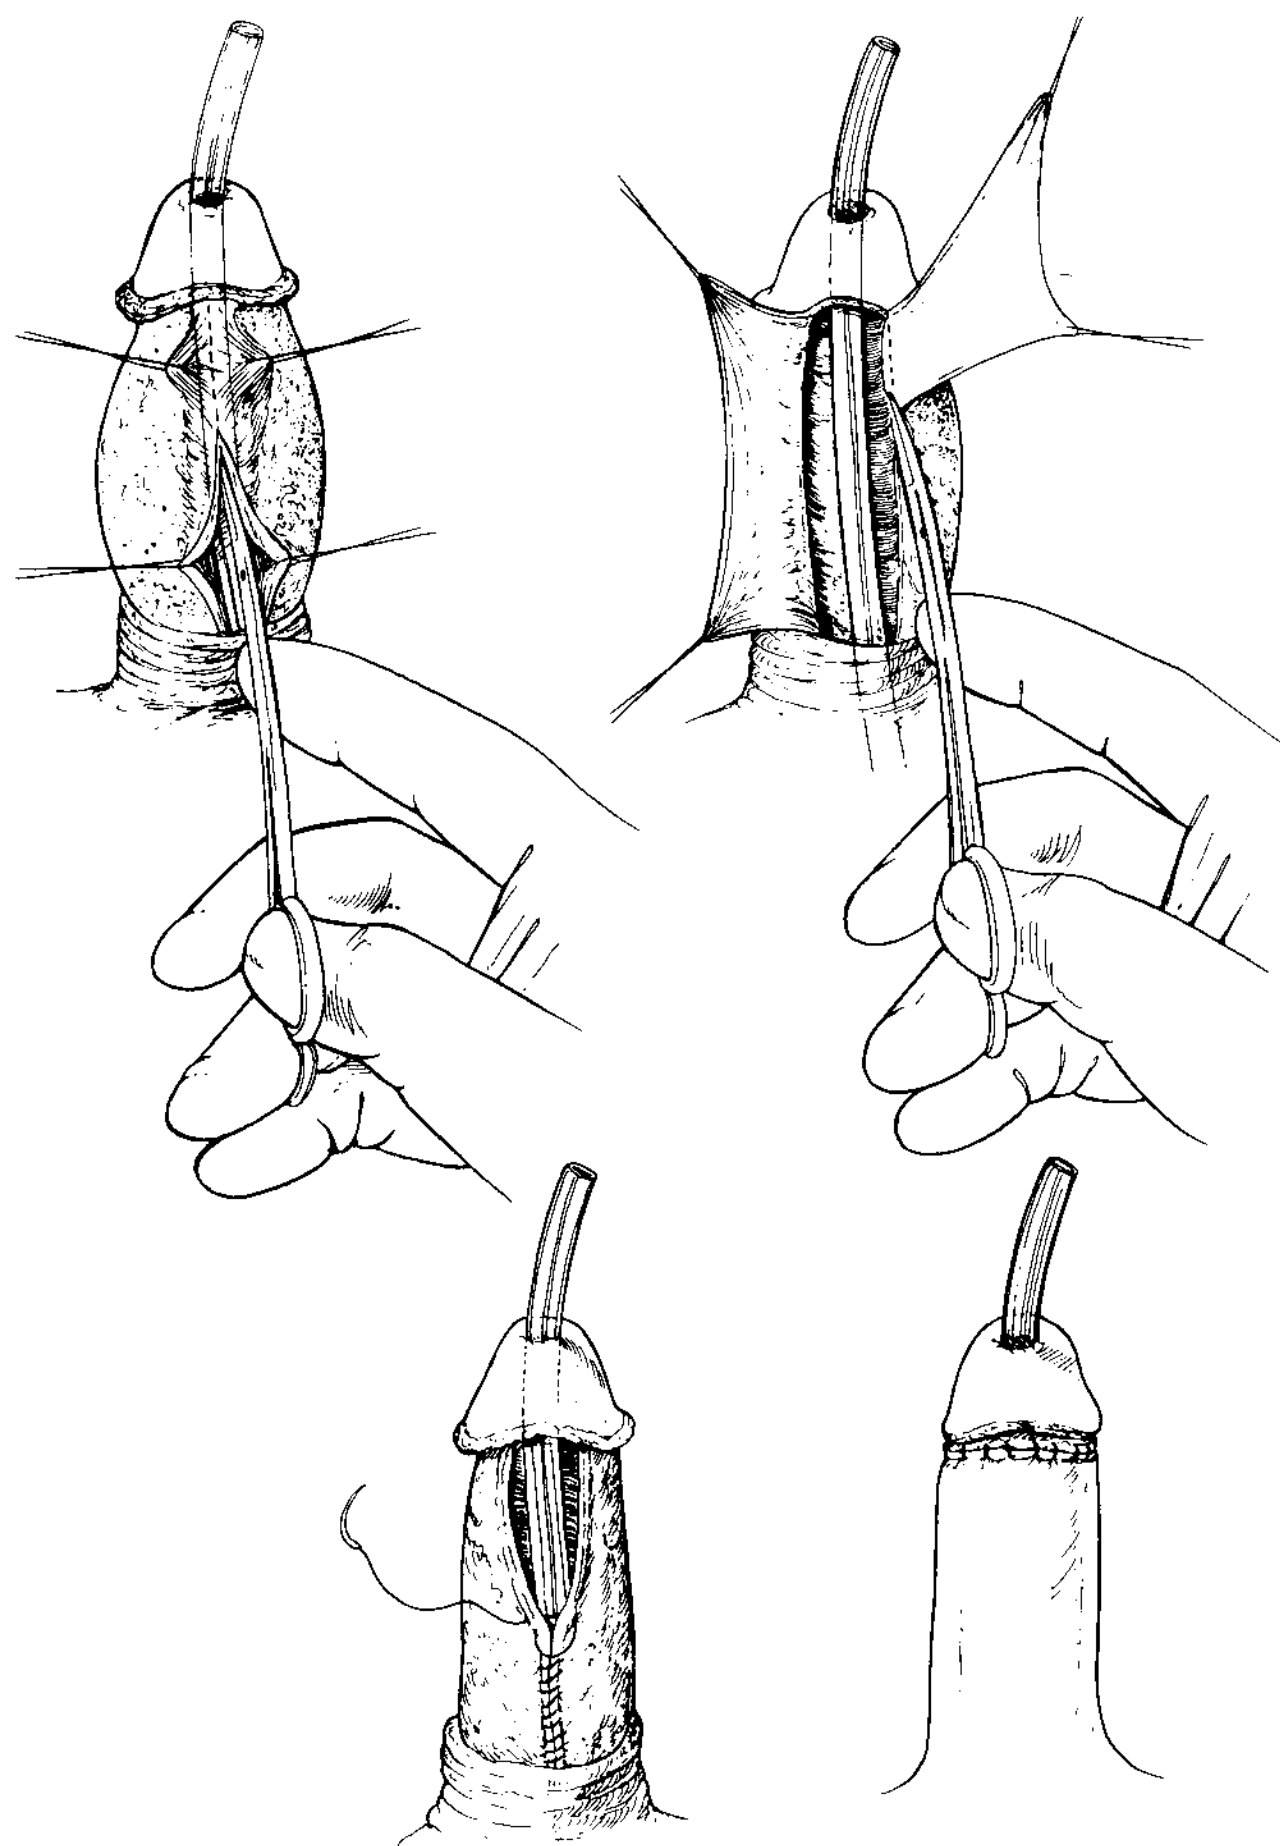

**FIGURE 101.4** **A:** An incision is begun at the xiphoid, circumscribing the umbilicus, and carried down to the pubis. **B:** Skin flaps are then elevated, dissecting between the subcutaneous fat and the fascial layer. The lateral extension is the anterior auxiliary line. **C and D:** The umbilicus is supported by the central fascial bridge. Incisions will be made into the peritoneum lateral to the epigastric vessels. The central fascial bridge is easily manipulated to allow for excellent intra-abdominal exposure. **E:** At the time of closure, a line is scored on the peritoneal surface of the fascia. **F:** The central fascial strip is then secured laterally to the scored fascia line with a running suture of 2-0 or 3-0 polyglactin. **G:** The lateral fascia is then secured in the midline above and below the umbilicus with 2-0 or 3-0 polyglactin. Centrally, the fascia is secured directly to the umbilicus. This allows for an overlapping reinforced fascial wall closure. Subcutaneous tissue is closed with 3-0 or 4-0 plain gut and the skin with a running subcuticular 4-0 or 5-0 polyglactin suture.

sacrifice of the gonadal artery. If orchiopexy is undertaken early, particularly within the first 6 months of life, there is often adequate vascular length to deliver the testicle directly into the scrotum without transection of the gonadal artery (5). After the testicle is separated from the ureter, an incision is made in the peritoneum lateral to the gonadal artery and directed to the internal ring. A second incision medial to the gonadal vessels is made in the peritoneum and continued caudally along the course of the vessels and vas deferens. It is important not to disrupt the vascular supply of the peritoneal pedicle running on both sides of the vas deferens. If it becomes apparent that the testes will not reach into the scrotum after mobilization, the gonadal artery is sacrificed to obtain adequate length for the testicle to be delivered in the scrotum, as described by Fowler and Stephens (14). The blood supply to the testes is maintained by the vasal artery and small anastomotic channels within the

peritoneal flap. A tunnel is then made into the scrotum and an incision placed inferiorly in the scrotum to create a dartos pouch. A clamp is passed from the scrotum to the inguinal canal. The testicle is grasped, pulled down through the tunnel, and delivered to the scrotum. Care must be taken not to twist or place the peritoneal pedicle on tension. If desired, the testicle can be secured to the dartos tissue with a 5-0 polydioxanone suture. When the orchiopexy is approached as an independent procedure it can be undertaken laparoscopically.

### Urethral Reconstruction

Urethral reconfiguration is most effective by formal excisional tapering, as described by Nesbitt (Fig. 101.5). An incision is made in line with the previous circumcision or beneath the

**FIGURE 101.5** Nesbitt reduction urethroplasty for megalourethra. **A:** The urethra is opened vertically in the midline, followed by excision of the lateral redundant tissue (**B**). **C:** Reconstruction is carried out over a 12Fr catheter using two layers of running suture. **D:** The penile skin is reapproximated to the coronal margin circumferentially.

coronal sulcus if the patient is uncircumcised. The penile shaft skin is then mobilized to the base of the penis. The anterior urethral wall is usually thin and poorly supported, and care needs to be taken to prevent inadvertent entrance into the urethra. The urethra is split in the midline ventrally. The redundant portion of the urethra is excised and the urethra is reapproximated over a 10Fr or 12Fr catheter, depending on the child's age. The urethra is closed in two layers using 6-0 or 7-0 polydioxanone or polyglactic acid sutures. The glanular urethra is usually patent and the reconstruction is limited to the penile shaft. Because of poor development of the spongiosum it may be difficult to achieve additional tissue for a second layer of coverage. The penile shaft skin is then secured to the coronal tissue with 6-0 chromic sutures. A urethral stent or catheter is placed for 7 days. The penis is dressed with the personal technique used for a hypospadias repair.

A variant of megalourethra is the "megameatus with an intact prepuce" (MIP). This is corrected using standard hypospadias techniques (Fig. 101.6). The glans is infiltrated with a mixture of 1:200,000 epinephrine for hemostasis. Parallel incisions are made lateral to the urethral plate and extended into the glans, creating two glanular wings. The incisions are continued along the shaft of the penis and connected beneath the urethral meatus. The urethra is then tubularized over an 8Fr, 10Fr, or 12Fr catheter using 6-0 or 7-0 polyglactic or polyglycolic acid sutures. The glans is closed in the midline, reapproximating the deep tissue with 6-0 Vicryl and the epithelium with 6-0 chromic. The penile shaft skin is brought up and the excess

excised and then reapproximated to the coronal ring. A urethral stent or catheter can be positioned for 7 days, depending on the length of the defect. The penis is dressed as above.

---

## OUTCOMES

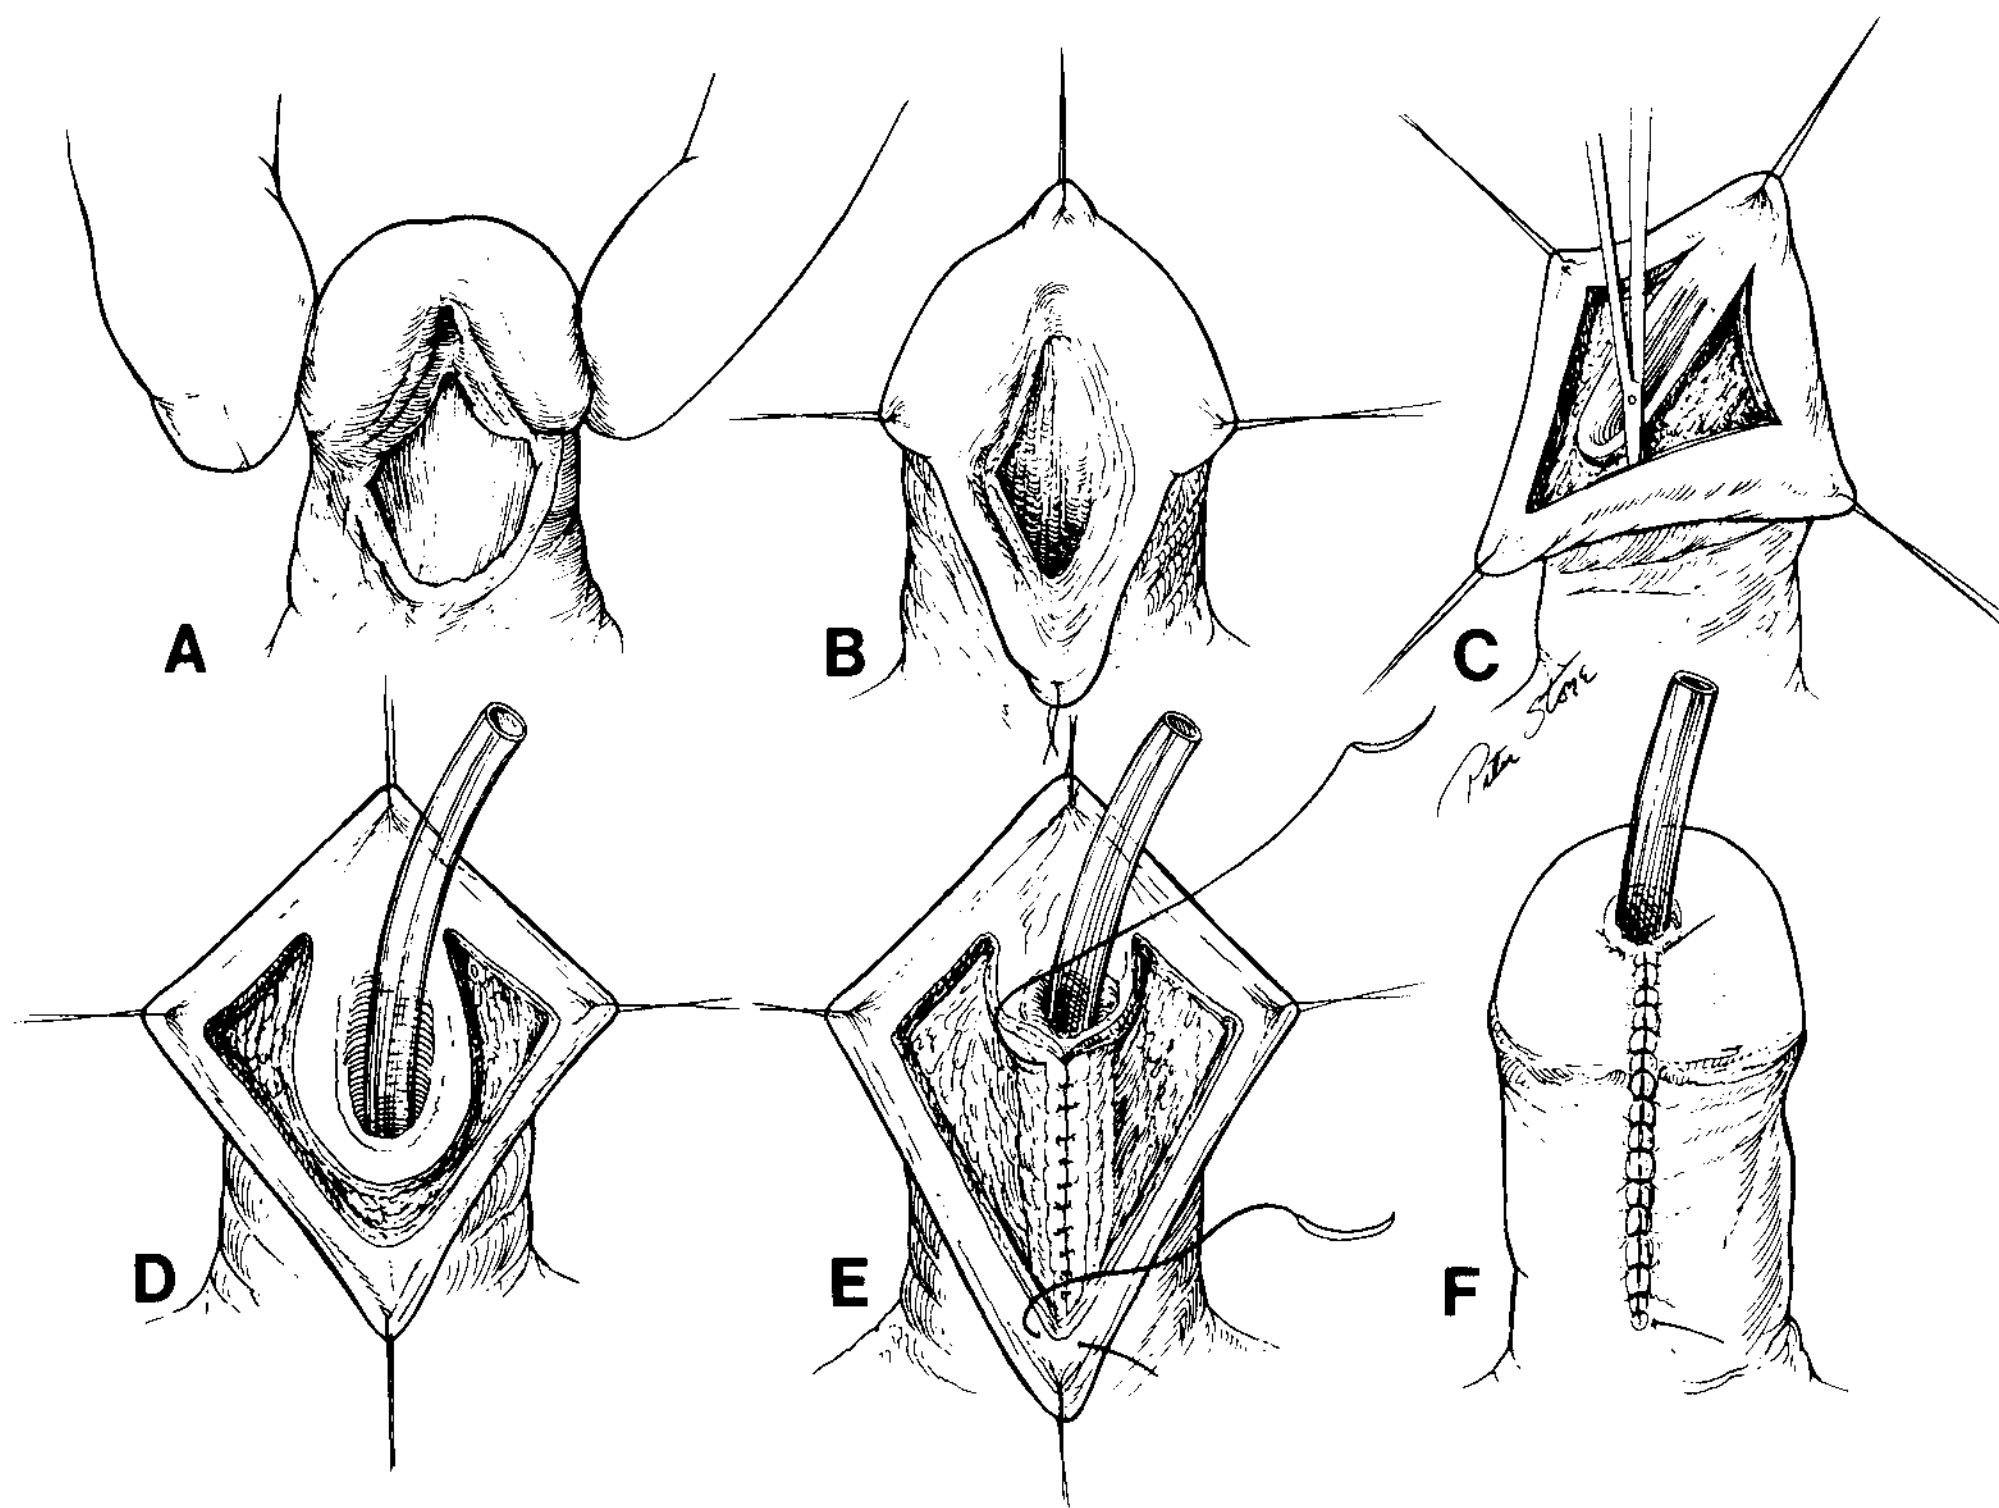

---

### Complications

---

Ureteral devascularization resulting in ischemia and subsequent obstruction can occur if attention has not been paid to the ureteral blood supply. The risk of bowel obstruction is present as in any intra-abdominal procedure. Testicular ischemia and atrophy due to a single-stage Fowler–Stephens procedure has been reported to occur in 30% of children. This can be decreased with a staged approach (12). More importantly, ischemia may be prevented with early orchiopexy, eliminating the need for sacrificing the gonadal vessels.

The cosmetic appearance following urethral tapering is good and limited only by any residual corpora cavernosa deficiency. Postvoid dribbling can be abolished and the risk of urinary infections due to stagnant urine can be diminished. The most common complication is that of a urethral fistula due to limited spongiosum tissue for a multiple-layer closure. The circumferential degloving of the penis with subsequent reapproximation of the penile shaft skin to the corona will limit fistula formation. The greatest risk for a fistula is located at the level of the ventral coronal sulcus.

**FIGURE 101.6** A: Pyramid procedure for repair of the megameatus with intact prepuce variant of hypospadias. B and C: Stay sutures are placed and the urethra is mobilized sharply. D and E: The urethra is tubularized in a two-layer technique. F: Subcutaneous glandular tissue is reapproximated and the skin closed.

## Results

The results of urologic reconstruction can be very gratifying in the initial postoperative period, in particular the cosmetic appearance of the abdomen and improvement in upper urinary tract drainage. Voiding function may become more effective due to the benefits of abdominal wall reconstruction and reduction cystoplasty (11). However, with time there can be an increase in both bladder size and ureteral dilation. This is often due to ineffective voiding and is independent of bladder

reduction. For those reasons, long-term follow-up of the urinary tract is required. Patients should be prepared for the potential need for intermittent catheterization. Because of normal sensation, children are often unwilling to cooperate with urethral catheterization. Placement of an appendicovesicostomy should be considered if catheterization appears to be a realistic possibility at the time of urinary reconstruction. An appendicovesicostomy provides excellent access to the bladder in a normally sensate child.

# CHAPTER 102 ■ CHILDHOOD RHABDOMYOSARCOMA

HSI-YANG WU AND HOWARD M. SNYDER III

The management of rhabdomyosarcoma (RMS) remains the most controversial topic in pediatric urological oncology. While all agree that a combination of surgery, chemotherapy, and radiotherapy is best, the optimal timing and extent of the three treatment modalities remain unclear. It is useful to remember three key points: (i) chemotherapy cures microscopical disease, (ii) residual mass does not equal disease, and (iii) radiotherapy renders pathology very difficult to read.

Twenty percent of RMS cases involve the bladder, prostate, vagina, or paratesticular area. The incidence of RMS peaks between ages 2 to 4 and ages 15 to 19. The tumor is nonencapsulated, grows rapidly, and spreads to regional lymph nodes as well as hematogenously. The Intergroup Rhabdomyosarcoma Study (IRS) Group initiated studies in the United States in 1972 to achieve better survival with less morbidity. The Children's Oncology Group (COG) has taken over responsibilities for these trials, and is currently investigating new chemotherapeutic options such as irinotecan (1). Patient survival, which was only 40% to 73% prior to chemotherapy, has improved to 86% in IRS IV with VAC (vincristine, dactinomycin, and cyclophosphamide) (2). During the same time, the surgical approach has changed from initial exenterative surgery to organ-preserving surgery following chemotherapy. The functional bladder salvage rate has risen from 25% to approximately 60% with this change in management.

RMS consists of small, blue, round cells, arising from undifferentiated mesoderm, with a microscopical appearance of spindle cells resembling fetal skeletal muscle. Embryonal pathology accounts for 90% of genitourinary RMS cases. Embryonal pathology is more favorable than alveolar pathology, which tends to occur in extremities. Sarcoma botryoides ("bunch of grapes") is a polypoid form of embryonal pathology.

## DIAGNOSIS

Bladder and prostate primaries present with urinary retention and gross hematuria and tend to be located at the trigone and bladder neck. Often, determining the organ from which the tumor arose can be difficult. Vaginal primaries present with vaginal bleeding or an introital mass and tend to occur on the anterior vaginal wall. Paratesticular primaries present with a painless scrotal mass. The preoperative evaluation can be carried out with ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI) (T2 weighting). The retroperitoneum is best evaluated with CT or MRI. Metastatic workup is completed with a chest X-ray, liver function tests, bone scan, and bone marrow biopsy.

TABLE 102.1

### PREOPERATIVE STAGING

T1: Confined to organ of origin, a:  $\leq 5$  cm, b:  $> 5$  cm  
T2: Extension or fixed to surrounding tissue, a:  $\leq 5$  cm, b:  $> 5$  cm  
N0: Regional nodes clinically negative  
N1: Regional nodes clinically positive  
Nx: Unknown  
M0: No distant metastasis  
M1: Metastasis present  
Stage I: Vaginal and paratesticular RMS, any T, any N, M0  
Stage II: Bladder/prostate RMS, T1a or T2a, N0 or Nx, M0  
Stage III: Bladder/prostate RMS, (T1a or T2a) and N1, M0, OR (T1b or T2b), any N, M0  
Stage IV: Any tumor with M1

TABLE 102.2

### POSTOPERATIVE GROUPING

Group 1: Localized disease, completely excised, no microscopical residual  
A: Confined to site of origin, completely resected  
B: Infiltrating beyond site of origin, completely resected  
Group 2: Total gross resection  
A: Gross resection with microscopical local residual  
B: Regional disease with involved lymph nodes, completely resected with no microscopic residual  
C: Microscopical local and/or nodal residual  
Group 3: Incomplete resection or biopsy with gross residual  
Group 4: Distant metastases

The IRS studies included both preoperative staging and postoperative grouping (2) (Tables 102.1 and 102.2). The IRS I–III studies grouped patients based on completeness of resection, introducing biases (shifting patients from group 1 to group 3) that are not seen with the use of the tumor–node–metastasis (TNM) system in IRS IV and V.

## INDICATIONS FOR SURGERY

During the initial procedure, adequate tissue for a definitive diagnosis should be obtained and, if possible, one should remove the tumor without removing the affected organ (with the exception of paratesticular RMS, where the testis is

removed with the tumor inguinally). If excision is not possible, primary chemotherapy should be given. In follow-up staging, a biopsy is needed during the “second-look” operation because residual mass does not always represent tumor: the cancer can involute more rapidly than the supporting stroma. Definitive surgery aims to do a good radical but pelvic-organ-sparing operation if possible. If microscopical residual disease is found, it is treated with brachytherapy or external-beam radiotherapy. Exenteration is reserved for patients who fail this protocol of chemotherapy, conservative surgery, and radiotherapy. In Europe, the approach is to give primary chemotherapy without initial local control (radiotherapy or surgery) and offer local therapy based on the initial chemotherapy response (3).

---

## ALTERNATIVE THERAPY

---

The use of surgery or radiotherapy as definitive local control remains a difficult choice. In favor of radiotherapy, it has been remarkably successful in decreasing the need for radical surgery to achieve a cure. However, the difficulty with radiotherapy and bladder RMS is that because the tumors tend to be located at the bladder neck, even the lowest dose (41 Gy) that the radiation oncologists are willing to deliver may significantly risk urinary continence. Current attempts at limiting radiation toxicity to adjacent organs involve both conformal radiotherapy and brachytherapy. The long-term risk of radiation vasculitis, which is inevitably progressive, as well as possible bony pelvis deformity in these children is another issue to consider. Therefore, one must sometimes weigh whether preserving a bladder without an outlet is better than removing the bladder entirely (4). The final issue is that postradiation artifact makes subsequent biopsy very difficult to interpret, so it would make sense to delay radiation until the patient is free of gross disease.

---

## SURGICAL TECHNIQUE

---

For bladder and prostate RMS, we will summarize the surgical options available after the initial biopsy has shown RMS, the patient has received chemotherapy, and the choice has been made to use surgery to achieve local control. For vaginal and paratesticular RMS, we will review the overall surgical approach starting with the initial resection.

---

### Bladder

---

The approach to partial or total cystectomy is similar to that for muscle-invasive transitional cell carcinoma (see Chapters 23 and 24). We will highlight the technical points that are unique to the management of bladder RMS.

The initial step after opening the abdomen is to examine the retroperitoneum. While we do not perform a full retroperitoneal lymphadenectomy because there is no therapeutic benefit, any suspicious lymph nodes along the vessels between the obturator fossa and the renal veins are removed. The next step is to properly stage the tumor by obtaining multiple frozen-section biopsies of the bladder around the area of the tumor. If these are negative and the tumor is

amenable to partial cystectomy with a 2- to 3-cm margin, then the bladder does not need to be entirely removed. RMS is a nonencapsulated, infiltrative tumor, so adequate margins are necessary.

If the tumor extends down the urethra, then the symphysis should be split to gain better access. After completing distal dissection of the urethra, the symphysis is closed with long-term absorbable sutures. With this improved exposure, it is also possible to perform a nerve-sparing dissection (see Chapter 33), although follow-up potency data are not yet available. The placement of brachytherapy catheters for after-loading (to treat microscopical positive margins if needed) should be considered.

Following cystectomy, we have often placed Dexon mesh across the abdomen to hold the intestines out of the pelvis at the level of the sacral promontory. This is done by attaching it to the sacral promontory and wrapping it around the sigmoid. This serves to prevent adhesion of the bowel to the raw surface of the pelvis until it has re-epithelialized, and if postoperative radiation is necessary for microscopical residual disease it limits the exposure of the bowel to the radiation field. Currently, pelvic exenteration is reserved for patients who have failed both chemotherapy and radiotherapy and who have tumors that invade both the bladder and the rectum.

The final surgical decision is whether to proceed with continent urinary reconstruction at the same time. We have taken the approach that it is not necessary to perform the reconstruction at the same time unless the patient is both motivated and able to perform clean intermittent catheterization to drain a urinary reservoir. For younger patients who are not ready to manage a urinary reservoir, we have either brought up the remaining bladder plate with ureterovesical junctions intact as a vesicostomy or performed low end-cutaneous ureterostomies, with the ureters placed side by side as a single stoma on the abdomen.

---

### Prostate

---

The approach is similar to that for localized prostatic adenocarcinoma (see Chapter 33). Again, no follow-up on nerve-sparing procedures is yet available. Splitting the symphysis is useful as it is essential to remove the urethra to the midbulbar level, and the placement of brachytherapy catheters for after-loading (to treat microscopical positive margins if needed) should be considered.

---

### Vagina

---

The patient is placed in the lithotomy position and the pelvis and vagina are prepared. For the initial resection, vaginoscopy is helpful in defining the limits of the tumor. Stay sutures and a small weighted vaginal speculum are helpful for exposure, as is a headlight for vision. Sharp excision of the tumor is carried out, staying away from the external sphincter, urethra, and bladder neck. The vaginal mucosa is closed with interrupted absorbable sutures. Hysterectomy is rarely carried out because uterine tumors are rare and tend to present in older girls (>10 years old).

---

## Paratestis

---

The testis and adnexa are removed via inguinal orchiectomy (see Chapter 62). Frozen section of the proximal cord should reveal no tumor. The key step is to avoid making a scrotal incision for a solid paratesticular mass because, while chemotherapy often cures residual disease, some cases have required hemiscrotectomy due to tumor infiltration. Retroperitoneal lymph node dissection is carried out for all boys with stage I disease older than age 10, regardless of the findings on abdominal CT. The technique is identical to that used for retroperitoneal involvement by testicular tumors (see Chapter 63). Again, sympathetic nerve-sparing techniques can be used to maintain ejaculation, but no follow-up data are currently available. For boys under age 10, the retroperitoneum is imaged by CT or MRI, and if there is no gross disease then retroperitoneal lymph node dissection is not performed. Chemotherapy has been shown to adequately clear microscopical disease (30% to 40% incidence).

---

## Postoperative Decisions

---

Review of the pathology may reveal persistent rhabdomyoblasts in a patient who has received as much chemotherapy as can safely be given. Currently, there is debate concerning the malignant potential of these cells, which represent matured rhabdomyoblasts (5). Normally, resection of the involved organ is carried out. If this would require destruction of a functional bladder, observation with frequent radiological follow-up may be an option to consider.

---

## OUTCOMES

---

---

### Results

---

#### Bladder and Prostate

Bladder and prostate RMS has a 2.5:1 male predominance. IRS III included intensified chemotherapy (dactinomycin, etoposide) and 6 weeks of radiotherapy, increasing the functional bladder salvage rate from 25% to 60%. The initial procedure consists of percutaneous, endoscopic, or transrectal biopsy of the mass, followed by chemotherapy. In IRS IV, VAC was shown to be as effective as two other three-drug regimens (VIE/VAE: ifosfamide, etoposide) (2). On a “second-look” procedure, half of patients were managed with biopsy, 30% had partial cystectomy, 13% had cystoprostatectomy, and the remainder had either cystectomy or prostatectomy alone (6). For persistent disease, group 2 was treated with 41 Gy and group 3 was treated with 50 Gy. At 24 weeks, a third operative evaluation was performed with consideration for exenteration. Patients with embryonal pathology had an 83% 3-year failure-free survival, compared to 40% in those with alveolar pathology. All patients with group 4 (metastatic) prostate disease died. Renal function, as assessed by serum blood urea nitrogen and creatinine, was normal in 95%, although 29% of patients had abnormal renal scans (7). Bladder function (as assessed by questionnaire) was normal in only 40% of patients (6).

In a larger international series, 48% of patients underwent biopsy alone, 30% had partial cystectomy, and 21% had complete cystectomy. Of male patients, only 24% underwent prostatectomy. Bladder function was normal in 69% of patients treated with biopsy alone and 73% of patients who underwent partial cystectomy. Neither of these series utilized urodynamic studies to fully evaluate bladder function. Renal function was abnormal in 40% of patients, and bowel function was abnormal in 13% (8).

#### Vagina

Surgery and chemotherapy cure most cases of vaginal RMS. In the overall IRS I–IV experience, 42% of patients were treated with surgery and chemotherapy, 19% required additional radiotherapy, 21% were treated with biopsy and chemotherapy alone, and 12% were managed with biopsy, chemotherapy, and radiotherapy (9). In IRS IV, only 19% of patients required wide excision of the tumor. Primary treatment with VAC chemotherapy is usually successful, and a biopsy 8 to 12 weeks after chemotherapy is recommended. Pelvic lymph node dissection is not necessary. Radiotherapy should be used only for persistent disease or relapse (10). Rhabdomyoblasts on biopsy are evidence of chemotherapy response, and therefore further chemotherapy, instead of resection, is the proper treatment (5).

#### Paratestis

Paratesticular RMS has two peak incidences: in the 3- to 4-month-old boy and in the teenager. Scrotal ultrasound will confirm the paratesticular primary, which should then be resected along with the testis in a radical inguinal orchiectomy. Serum  $\beta$ -human chorionic gonadotropin and  $\alpha$ -fetoprotein levels should be obtained to confirm that the mass is not a testicular primary. Thirty percent to 40% of patients will have metastases to the retroperitoneum. The biological activity of the tumor is different between the neonate and the teenager (90% vs. 63% failure-free survival at 3 years). In previous studies, all patients underwent retroperitoneal lymph node dissection (RPLND) (2). However, Olive et al. (11) showed in 1984 that of 19 patients with clinical stage I disease, 17 were cured with adjuvant chemotherapy alone. This showed that chemotherapy can clear microscopical retroperitoneal disease, making RPLND unnecessary. In IRS IV, RPLND was not recommended, leading to a significant understaging of disease and a decrease in failure-free survival rates because patients with negative CT scans did not receive radiation. Thirty percent of those patients who were clinically stage I and over at 10 years of age required retreatment. Because the outcome for stage I disease in those under 10 years of age was so good in IRS IV, those patients who are <10 years old and have stage I disease and negative abdominopelvic CT are treated with VA (vincristine, dactinomycin) only in IRS V, whereas all patients with stage I disease who are 10 years or older undergo RPLND regardless of CT findings. Group 2 tumors (positive lymph nodes on pathology) are treated with radiotherapy and VAC. The 3-year failure-free survival rate was 81% for group 1 tumors overall, but those patients >10 years old had only a 63% survival rate (2).

---

## Complications

---

The majority of patients have acute toxicity from the chemotherapy: 90% developed myelosuppression, 55% developed

significant infections, and renal toxicity was seen in 2% (2). Most relapses occur within 3 years of initial diagnosis (12). Late recurrences can occur in patients who are treated with chemotherapy alone. Of 883 patients, 10 developed a secondary cancer. Patients with pre-existing renal abnormalities were at a higher risk of death (5% vs. 1%). Relapse in group 3 patients (incomplete resection) was associated with a 22%

chance of 3-year survival, compared to 41% in group 1 or 2 patients (localized disease or total gross resection) (2). Twenty-nine percent required sex hormone replacement and 11% were shorter than expected (4). If radiotherapy has been used, there is an increased risk of a secondary neoplasm, often another sarcoma, in the radiation field.

## CHAPTER 103 ■ VESICOURETERAL REFLUX

MARK R. ZAONTZ

Considering that vesicoureteral reflux (VUR) was first recognized during the time of Galen (150 A.D.), not much progress was noted until the beginning of the 20th century. Young (1) and later Sampson (2) noted that those patients with both normal ureterovesical junction and ureteral path through the bladder did not have VUR. It was not until the 1950s that the strong relationship between VUR and pyelonephritis was recognized by Hutch (3). His work demonstrated the pathologic anatomy that underlies VUR and led to successful surgical correction of this entity. His pioneering work was also instrumental in making the voiding cystourethrogram (VCUG) part of the evaluation in patients with urinary tract infection (UTI) as well as hydronephrosis.

Until the 1980s, the treatment for reflux was largely surgical, with cure rates approaching 98%. However, multicenter studies have shown that lower grades of reflux had high spontaneous resolution rates and these patients could be followed at least initially with medical management using prophylactic antibiotics and yearly reassessment. Higher grades of reflux are associated with a higher incidence of renal scarring and lower rates of spontaneous resolution.

Surgical correction of reflux may not prevent progression of reflux nephropathy when present, although corrected reflux in

general prevents new renal scarring. Reflux in the presence of sterile urine in general does not cause renal damage, although reflux in the presence of UTI can lead to renal scarring.

Boys in general present with higher reflux grades than girls of the same age, but boys also have a higher spontaneous resolution rate than girls. Studies showing that circumcised boys with low grades of reflux rarely get UTIs or related morbidity have led to a nonoperative algorithm in this group of patients.

Reflux is commonly linked with voiding dysfunction in children. Recent evidence using urodynamics and biofeedback techniques has shown high spontaneous cure rates for refluxing children with concomitant voiding dysfunction. Conversely, children with significant voiding dysfunction have higher failure rates from conventional surgery than those with normal bladder function.

Sampson (2) in the early 1900s proposed a flap-valve mechanism for the ureterovesical junction that was corroborated by Gruber (4), who found that those ureters with shorter intravesical segments were more prone to have reflux and therefore have a defective flap-valve mechanism. Stephens and Lenaghan (5) added that the deficiency of the intravesical ureter's longitudinal muscle with or without a deficiency in ureteral tunnel length was also responsible for the reflux

phenomenon. From a surgical perspective we have learned that a 5:1 ratio of ureteral tunnel length to ureteral lumen diameter is necessary to prevent reflux.

While most cases of reflux are congenital in nature and considered primary reflux, increased intravesical pressure due to anatomic bladder outlet obstruction or functional causes such as neuropathic bladder/voiding dysfunction may lead to what is termed secondary reflux.

## DIAGNOSIS

Today, thanks in great part to common antenatal screening, reflux is often diagnosed prior to the development of a urinary infection and, as a result, pyelonephritis may be avoided by promptly beginning prophylaxis just after delivery. Presenting symptoms in neonates may include malaise, fever, vomiting, diarrhea, or failure to thrive. Toddlers and young children may have more typical symptoms, such as fever, frequency, urgency, dysuria, foul-smelling urine, incontinence, or abdominal and/or back discomfort.

It is critical that a urine culture be obtained in all cases of suspected UTI. A urinalysis alone is unacceptable as it only alludes to the presence of UTI and at best is only 80% accurate in diagnosis. Radiographic evaluation is indicated after the first UTI in boys of any age and in all preadolescent girls. Further, any girl with a febrile infection or recurrent UTIs should be studied regardless of her age. Workup for UTI should include an ultrasound of the kidneys and bladder as well as a VCUG. In cases where screening is needed for siblings or children of known refluxers, a renal ultrasound and nuclear cystogram (NVCUG) for girls and a fluoroscopic VCUG for boys is recommended. Recently, there has been discussion of alternative initial evaluation of the first febrile UTI by performing a  $^{99m}\text{Tc}$ -labeled dimercaptosuccinic acid (DMSA) scan to see if the kidney has been engaged in the infection. If the scan is negative, then a VCUG can be obviated.

However, a second febrile UTI would still warrant a VCUG. Once reflux is diagnosed, it is graded according to the International Study Classification (Fig. 103.1) (6). This system is based on the radiographic appearance of the ureter and collecting system during a VCUG. Follow-up studies are in general done using nuclear cystography at yearly intervals to assess the resolution or progression of reflux.

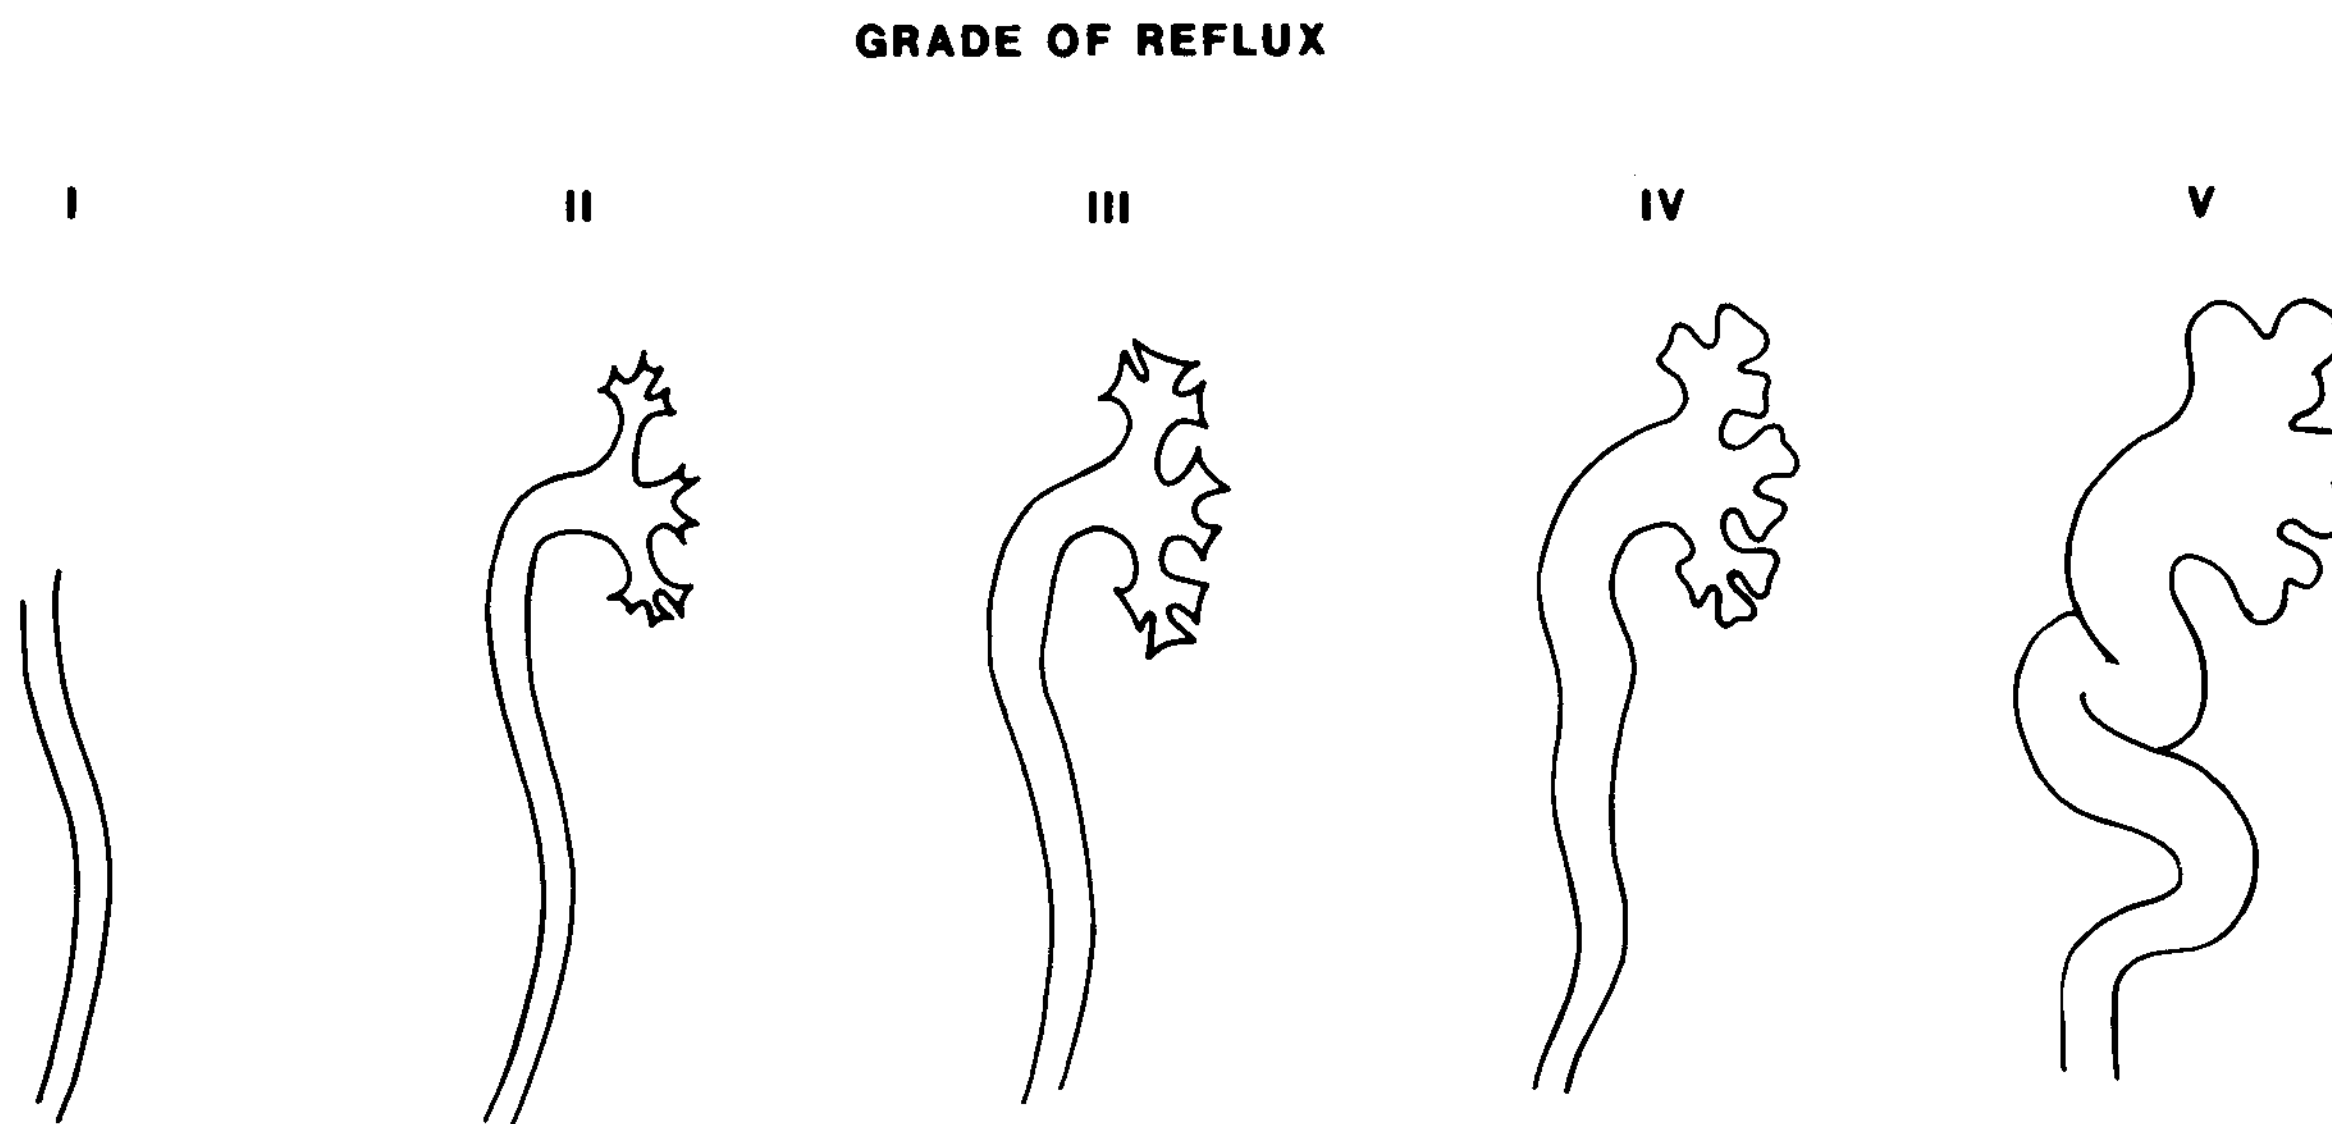

Ultrasound appears to be relatively accurate in determining the presence or absence of renal scars in low-grade reflux patients. However, in those with higher-grade reflux a "normal" renal ultrasound may miss significant renal scarring. The DMSA scan is to date the best available study to assess focal pyelonephritis and renal scarring.

Cystoscopy has little value in predicting the presence or cessation of reflux based on ureteral orifice configuration or location. Factors such as tunnel length or the presence of incomplete versus complete duplication anomalies will guide the surgeon to choose an appropriate technique, open or endoscopic.

## INDICATIONS FOR SURGERY

Indications for surgical correction of VUR include an older patient, higher grade of reflux, presence of renal damage, non-compliance with prophylaxis, and the family's concerns with respect to repeated invasive testing and long-term prophylaxis. Findings from the International Reflux Study lend support toward surgical intervention in grade III and IV refluxers, with the majority of these patients failing to resolve their reflux (7). Other studies have supported these findings, with rates of resolution of reflux ranging from 10% to 33% in patients with grade IV reflux (8,9). Surgery is in general recommended for grade V reflux because of the low likelihood of spontaneous resolution.

Girls should not be allowed to go into puberty with reflux due to the increased risk and morbidity of pyelonephritis during pregnancy. Recurrent breakthrough urinary infection

**FIGURE 103.1** International classification of vesicoureteral reflux. Grade I, into the nondilated ureter; grade II, into the pelvis and calices without dilation; grade III, mild to moderate dilation of the ureter, renal pelvis, and calices with minimal blunting of the fornices; grade IV, moderate ureteral tortuosity and dilation of the pelvis and calices; grade V, gross dilation of the ureter, pelvis, and calices and loss of papillary impressions and ureteral tortuosity.

while on adequate antibiotic prophylaxis is the sine qua non for surgical intervention because otherwise these children are at high risk for renal damage.

---

## ALTERNATIVE THERAPY

---

There are several factors that must be taken into consideration for appropriate management: reflux grade, presence/degree of renal scarring, patient age, presence or absence of bladder outlet obstruction, compliance of the patient/family on prophylactic antibiotics, ability to remain infection-free while on prophylaxis, and presence/absence of associated voiding dysfunction. Reflux may spontaneously resolve, and the peak time for resolution is between 5 and 7 years of age. The lower the grade of reflux, the higher is the likelihood for spontaneous resolution. Unilateral reflux is statistically more likely to resolve than bilateral reflux. Medical management consists of antibiotic prophylaxis, usually a sulfa-based compound or nitrofurantoin at bedtime. In addition to antibiotics, bladder training in cases of dysfunctional voiding is instituted. This is designed to improve bladder emptying at regular intervals, obviate bladder-sphincter dyssynergia, and have minimal postvoid residual. This may require a variety of teaching aids and the use of pharmacotherapy such as anticholinergics and/or alpha antagonists. In addition, urodynamics and biofeedback may be used in selected cases. Equally important is to improve bowel function/evacuation in the presence of constipation.

---

## SURGICAL TECHNIQUE

---

Once the decision is made for surgical intervention, there are a myriad of operative procedures available depending on one's preference and comfort level. The existing techniques are divided into endoscopic, extravesical, intravesical, a combination of intravesical and extravesical approaches, and laparoscopic correction.

---

### Endoscopic Surgery

---

Teflon was the first bulking agent used for endoscopic correction of reflux. Although the results were encouraging, later studies showed that there was migration of the Teflon particles to the lung, lymph nodes, and brain as well as the finding of granuloma formation; this resulted in the search for more biocompatible bulking agents (10). These have included both autologous agents (fat, blood, human collagen, bladder muscle cells, and ChondroGEL) and nonautologous agents (silicone, BioGlass, polyvinyl alcohol, and dextranomer microspheres). Deflux (dextranomer microspheres) is at present approved by the U.S. Food and Drug Administration for use as a bulking agent. Endoscopic surgery technique for reflux will be discussed in another chapter.

---

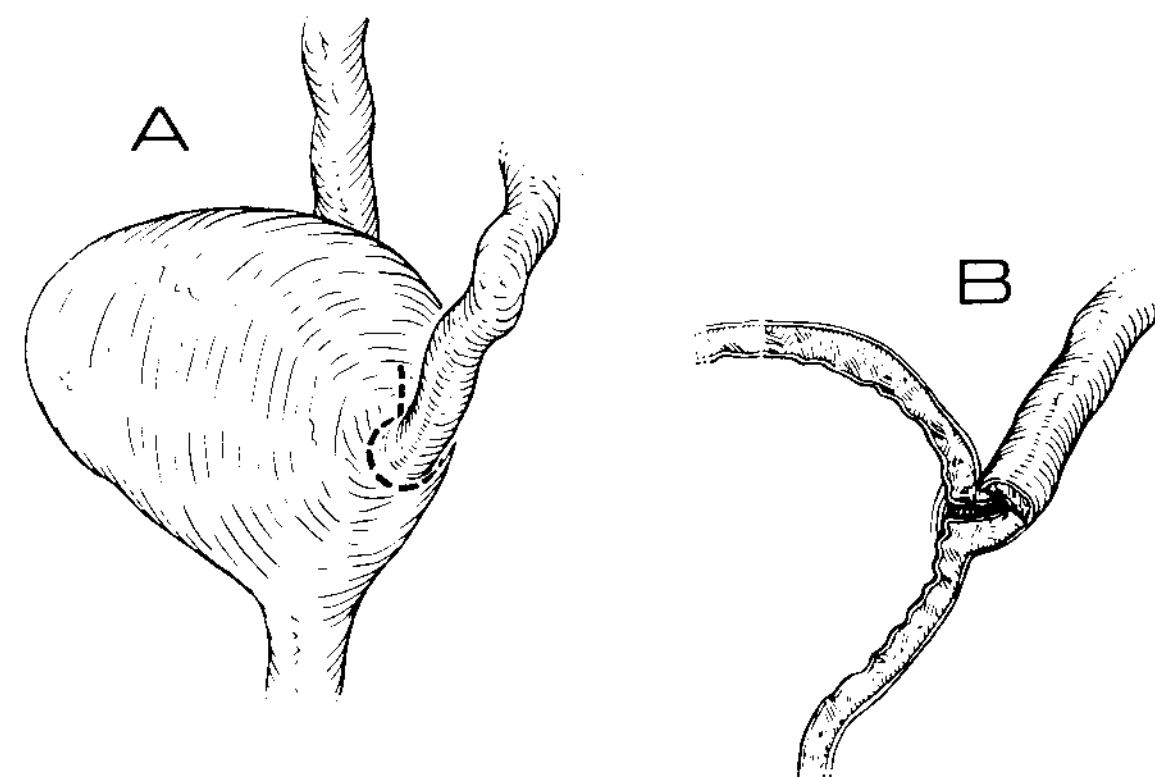

### Extravesical Approach

---

Lich (11) and Gregoir (12) in the 1960s separately developed the extravesical approach to correct reflux. Further modifications of this approach have yielded success equal to that of the

intravesical techniques (13). The benefits of this procedure are several: (a) The surgery is performed outside of the bladder mucosa and as such avoids gross hematuria and irritable postoperative voiding problems such as urgency symptoms and bladder spasms, (b) catheter drainage of the bladder is brief, (c) wound drains are avoided, and (d) ureteral stents are eliminated. A further advantage of this technique is that hospital stay is brief, averaging 1.5 days in my hands, thus decreasing overall hospital costs.

Prior to the incision, after the patient is prepared and draped, the bladder is catheterized and the bladder filled to about one third to one half of its estimated capacity with sterile saline. This allows for easier dissection when separating the detrusor muscle from the mucosa. The bladder may be further filled or emptied depending on the surgeon's preference during the procedure. The surgical procedure for detrusorrhaphy begins similarly to the intravesical approach with a Pfannenstiel incision. A Dennis-Browne retractor is then placed over moistened gauze pads and the bladder is carefully mobilized and rotated anteromedially, exposing the appropriate perivesical space. Care should be taken to avoid entering the peritoneum during this maneuver. Placing an appropriate-sized Deaver retractor to help keep the rotated bladder in place will greatly facilitate locating the obliterated hypogastric vessel. This vessel is tied off with 3-0 polyglycolic acid suture and the most lateral tie is clamped to help expose the ureter, which lies just beneath this vessel. In cases of bilateral detrusorrhaphy, the obliterated hypogastric vessel need not be tied off but simply recognized for ease of finding the underlying ureter. This minimal dissection technique, as well as limiting the dissection of the extravesical submucosal tunnel, may help prevent significant nerve denervation and avoid postoperative urinary retention. The ureter is carefully mobilized and encircled with a vessel loop (Fig. 103.2). The ureter is freed up to its entry point into the bladder. During this maneuver the Deaver retractors may need to be reset such that the ureter is in the middle of the operative field throughout the procedure. A tennis racket incision is made around the ureteral detrusor hiatus and deepened until the ureter is only attached to its connection with the mucosa. The incision is then extended such that a 3- to 5-cm trough is created. All vessels encountered during this dissection are tied off with 4-0 or 3-0 polyglycolic acid suture. Dissection carefully proceeds down to the mucosa and great care is exercised to avoid making a rent in the bladder

**FIGURE 103.2** **A:** After ureteral mobilization, detrusor is incised (*dotted lines*) at level of ureteral hiatus. **B:** Sagittal section demonstrates ureteral hiatus.

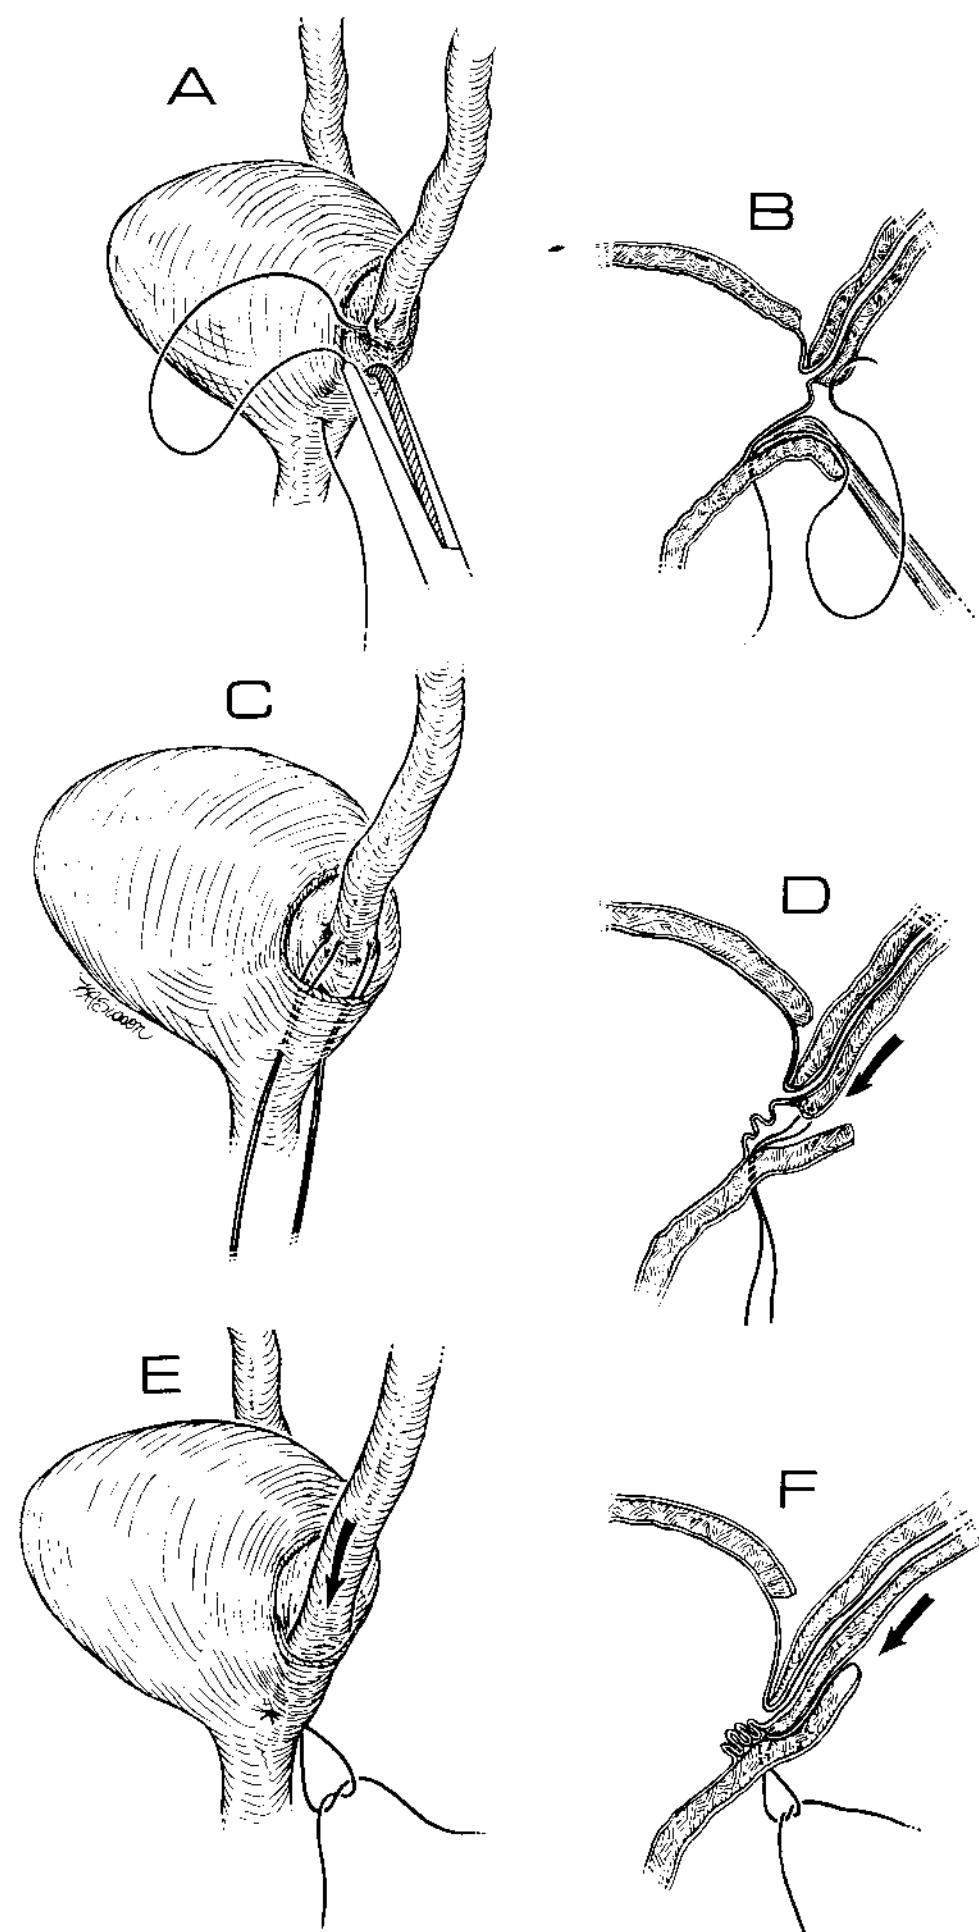

**FIGURE 103.3** Ureter contiguous with detrusor mucosa (arrowheads).

(Fig. 103.3). If this occurs, immediately close the defect with the 6-0 chromic catgut. Place stay sutures of 3-0 polyglycolic acid on the detrusor edges to facilitate dissection of the mucosa off the detrusor muscle. The mucosal dissection should be generous enough to allow the ureter to easily sit in the newly created trough and permit the detrusor muscle to be closed over the ureter without tension. Prior to this step, further dissection is performed toward the bladder neck beyond the distalmost detrusor incision to allow placement of the advancement sutures. Once completed, the ureteral orifice is advanced on the trigone toward the bladder neck with a pair of “vest-type” sutures of 4-0 chromic catgut (Fig. 103.4). The first limb of the sutures is through the detrusor (outside/in). The sutures enter the detrusor at the distal limit of the trigonal musculature and exit in the plane between the mucosa and detrusor. The second limb of the suture is through the ureteral muscle, and the final limb of the suture is back through the detrusor (inside/out). Tying the pair of vest sutures advances and anchors the ureteral orifice distally and creates a new longer submucosal tunnel. The remaining detrusor defect is closed over the ureter in two layers; the first is a running layer and the second is an interrupted Lembert suture, both using 4-0 polyglycolic acid suture. Care must be exercised to avoid making the ureteral hiatus too snug. The exit point for the ureter should be able to admit a hemostat between the detrusor and the ureter easily (Fig. 103.5). No perivesical drains or ureteral stents are used, and the Foley catheter is removed the following morning.

Complete and incomplete ureteral duplication may also be approached extravesically. Cystoscopy at the time of surgery is recommended to visualize the ureteral orifice location with respect to location and proximity to each other as well as distance to the bladder neck. This information will aid in determining if detrusorrhaphy is feasible or if another technique is more appropriate.

Finally, as we continue to push the envelope into minimally invasive procedures, the extravesical technique can also be approached in selected patients via a small transverse inguinal incision to achieve access to the ureter. In these cases, I find it advantageous to first cystoscope the patient and pass a temporary ureteral stent up the refluxing ureter to aid in initial

**FIGURE 103.4** **A:** Bladder mucosa is elevated off bladder wall muscle and vest-type sutures are placed. **B:** Sagittal section shows suture passing between undermined mucosa and detrusor. **C:** Alignment of vest sutures after placement. **D:** Sagittal section demonstrates appropriate positioning of sutures. **E:** Tying vest sutures advances and anchors ureter onto trigone. **F:** Sagittal section of ureteromeatal advancement.

identification. The procedure is otherwise essentially the same as already described, although some institutions are obviating the advancement portion of the procedure, making this technique that much simpler.

### Intravesical Approach

One of the earlier and still highly popular and successful techniques to correct reflux is the Politano–Leadbetter approach (14). This procedure is performed entirely intravesically and avoids mobilization of the bladder as seen in the extravesical approach. Once the bladder is exposed via the technique described for the extravesical approach, it is opened in the midline between 3-0 chromic catgut stay sutures. The bladder is packed with moist 4 × 8-inch gauze pads to allow superior retraction of the bladder and easier exposure of the ureteral orifices. This is further facilitated with the placement of a Dennis–Browne retractor with the curved blades actually within the bladder over moist sponges. The ureteral orifice is identified and intubated with a 5Fr feeding tube and secured with 4-0 or 5-0 silk sutures to allow tenting of the ureter by pulling on the feeding tube. As with all intravesical repairs the ureter is mobilized in similar fashion (Fig. 103.6). An incision is made to score the mucosa around the orifice. This can be done with a scalpel, tenotomy scissor, or, as I prefer, the cutting current of the Bovie, which

provides a precise incision. Carefully, using long tenotomy scissors, vascular forceps, Kittner dissector, a right-angle clamp, and judicious use of the cautery unit, the muscular attachments to the ureter are taken down. As the dissection proceeds proximally, I have employed the use of a number 3 Freer elevator along the posterior surface of the ureter, which further aids in mobilization. It is critically important to stay outside of the adventitia of the ureter to avoid devascularization during its dissection. As the peritoneum is encountered, it is generously swept back off the ureter to avoid injuring the bowel during the relocation of the ureter. A hernia retractor or a very thin Deaver helps to better expose the peritoneum and extravesical attachments to the ureter. Take care in the male patient to avoid injury to the vas deferens.

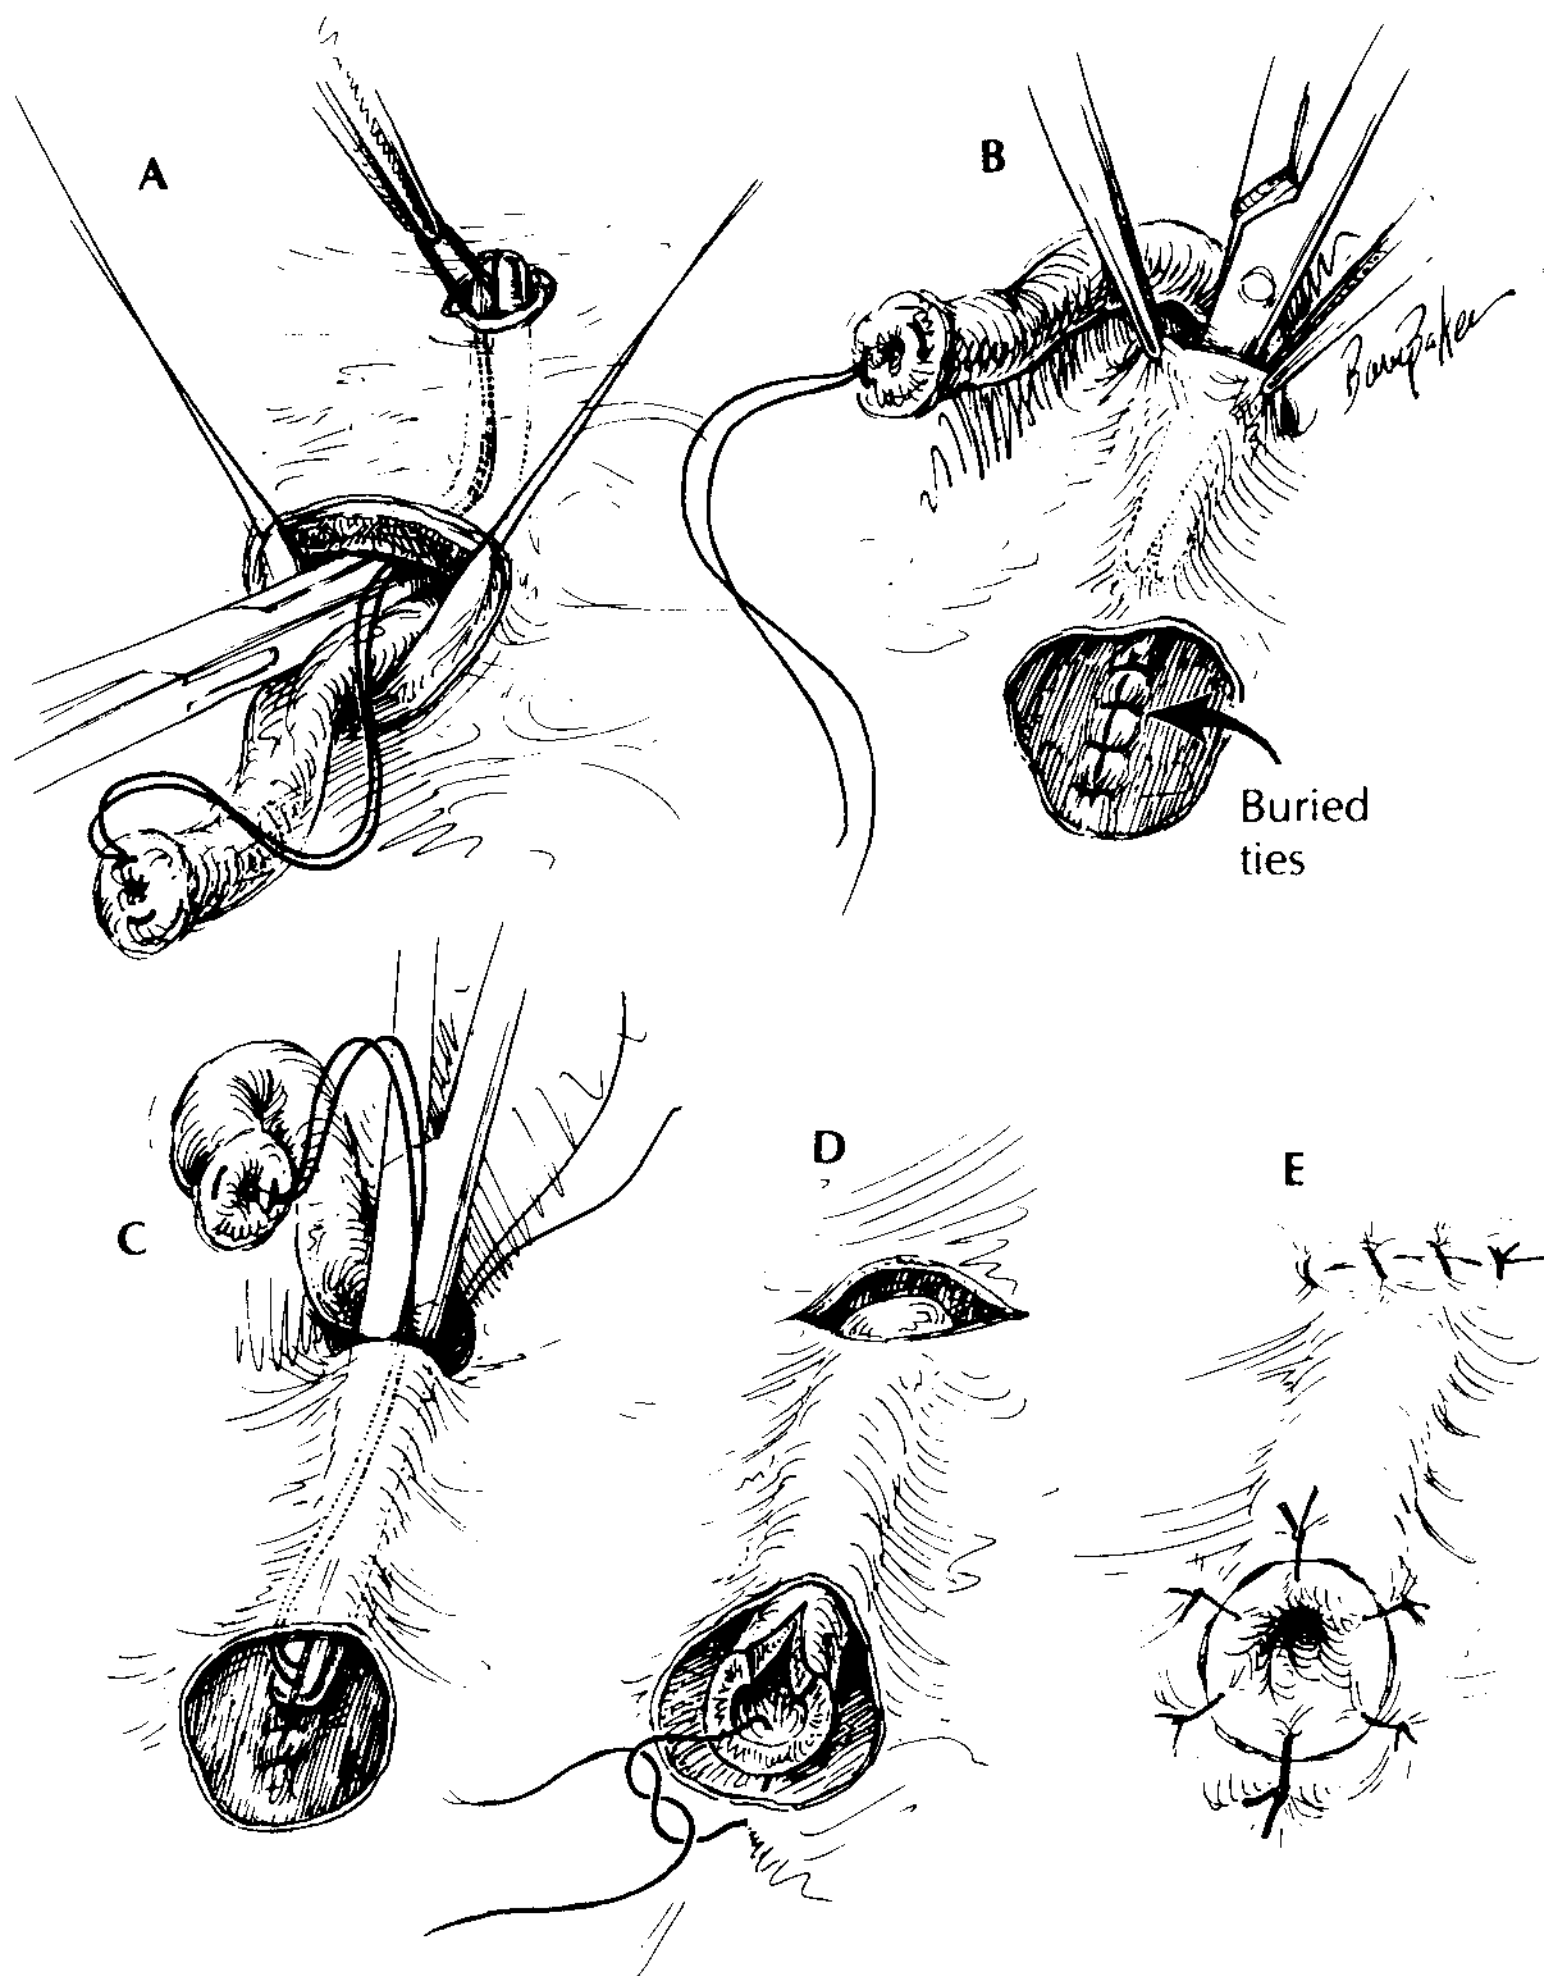

After completion of ureteral mobilization, the surgeon may choose one of several procedures to complete the ureteral reimplantation. The Politano–Leadbetter repair employs a suprahiatal approach (Figs. 103.7 and 103.8). A submucosal tunnel is created from the old hiatus superiorly, long enough to achieve a 5:1 ratio of submucosal tunnel to ureteral diameter. I like to use 135-degree blunt-tip Metzenbaum scissors to facilitate this maneuver and avoid tearing the bladder mucosa. Once the desired tunnel length is achieved, the new hiatus is developed by making a small incision directly on top of a right-angle clamp. Using a stay suture or the feeding tube, the mobilized ureter is passed from the old hiatus to the new

**FIGURE 103.6** Intravesical mobilization of ureter. **A:** Low transverse incision. **B:** A 3.5Fr or 5.0Fr polyethylene tube and traction suture. **C:** Incision around meatus with mucosal cuff using long-handled knife. **D:** Cutting and blunt dissection of muscle of superficial trigone. **E:** Extravesical mobilization with right-angle clamp and Kittner dissector.

**FIGURE 103.8** Politano–Leadbetter repair and details of ureteral reimplant. **A:** The ureter is brought through the new hiatus, and the old hiatus is closed with interrupted absorbable suture. **B:** The ureter is brought through the new tunnel (**C**), spatulated if necessary (**D**), and sewn in place with interrupted absorbable suture (**E**).

**FIGURE 103.9** Glenn-Anderson repair. (From Walker RW. Vesicoureteral reflux. In: Gillenwater JY, Grahhack JR, Howards SS, et al., eds. *Adult and Pediatric Urology*, vol 2. St. Louis: Mosby-Year Book, 1996, with permission.)

hiatus, care being taken to avoid twisting, kinking, or angulating the ureter as well as avoiding the peritoneum. The old hiatus is repaired with 4-0 chromic catgut. The ureter is then brought through the new tunnel. The old meatus is then trimmed up and spatulated if necessary. The distal and posterior lip of the ureter is anchored first with a deep suture of 4-0 or 5-0 chromic catgut to the mucosa and muscular layers of the bladder. The remaining anastomosis is performed with the same suture for a mucosal-to-mucosal approximation. Leaving a ureteral stent is at the surgeon's preference. In general, I assess how the urine output appears from the reimplanted ureteral orifice. If there is copious drainage, I do not leave a stent. If I am uncomfortable with urine drainage or there is significant edema at the orifice, a stent is left and brought out through a separate stab wound in the bladder and secured there with a chromic catgut suture. Then, a separate stab wound is made to bring the stent out through the skin and secured there with 4-0 nylon. Likewise, if I have to taper the ureter a stent is left in place for 4 to 7 days postoperatively. I close all bladders in three layers using running 4-0 chromic catgut for the mucosa, muscularis, and seromuscular layers. This has allowed me to avoid leaving any perivesical drains when the ureters are not stented. A Foley catheter remains in the bladder for 1 or 2 postoperative days.

The Glenn-Anderson procedure (Fig. 103.9) (15), in comparison to the Politano-Leadbetter, is an infrahiatal repair and develops a submucosal tunnel toward the bladder neck (Fig. 103.10). It is in particular advantageous when there is good distance between the native ureteral orifice and the bladder neck such that an appropriate tunnel length can be obtained. Adequate mobilization of the ureter is paramount to achieve satisfactory success rates. If the tunnel length appears too

**FIGURE 103.10** Glenn-Anderson repair: details of ureteral reimplantation. **A:** Tunnel made toward bladder neck. The ureter is brought through the tunnel (**B**) and sewn in place (**C**). An alternative, similar to the Mathison technique, allows enlargement of hiatus (**D**) and results in longer repair (**E and F**).

short on initial inspection, moving the hiatus more superiorly will allow for satisfactory tunnel creation. Advantages of the Glenn–Anderson technique are that the entire procedure is done under direct vision and it creates a relatively straight tunnel with an easily catheterized ureter.

The transtrigonal approach (Cohen) (16) is similar to the Glenn–Anderson procedure with the exception that the ureter is transposed across the trigone (Fig. 103.11). This is in particular useful in small-capacity and neurogenic bladders where an appropriately long tunnel is critical to success. The ureteral course created is an extension of the natural direction of the ureter; thus, it carries a low risk of ureteral kinking and

obstruction. If bilateral reimplant is necessary, it is important to create separate tunnel paths for each ureter. Always remember to close the hiatus with absorbable 4-0 chromic catgut. Leave enough room for a hemostat or right-angle clamp to be interposed between the ureter and the approximated detrusor muscle to avoid obstruction at the hiatus. A potential disadvantage of the Cohen technique is the difficulty of ureteral access postoperatively. These patients may need percutaneous access for any future procedures.

## Ureteral Duplication

Determining whether the ureteral duplication is complete or incomplete guides operative considerations. In the absence of a ureterocele, an intravesical complete duplication can be approached extravesically as well as intravesically. The key to intravesical surgery is to mobilize the duplicated ureters as one unit because their blood supply at the bladder level is intertwined within a common sheath (Fig. 103.12). This will avoid unnecessary devascularization. The technique chosen for reimplant can be any of the intravesical repairs mentioned. In cases of a complete duplication, an ipsilateral ureteroureterostomy is an attractive alternative. In situations where there is an associated ectopic ureter with a salvageable renal moiety, separate ureteral tunnels should be created.

One tip that I have found useful to aid in freeing up the ureter and also with submucosal dissection for all of the intravesical techniques is the use of 1% lidocaine (Xylocaine) with a 1:100,000 epinephrine solution. This is injected periureterally at the orifice and along the proposed subepithelial tunnel using a 26-gauge needle. This minimizes bleeding and provides ease of dissection in a readily defined plane.

## Intra–Extravesical Approach

The Paquin technique (Fig. 103.13) (17) is a commonly used repair and has the advantage over the Politano–Leadbetter approach of doing the complete procedure under direct vision, thus avoiding the potential risk of peritoneal injury. The approach to the ureter is extravesical, similar to that described in detrusorrhaphy. When the ureter is mobilized to the level of the detrusor hiatus, a right-angle clamp is used to clamp the ureter and then the distal stump is oversewn after the ureter has been divided using polyglycolic acid suture. Alternatively, the bladder may be opened in the midline and the ureteral orifice circumscribed and mobilized from within the bladder. The ureter should be intubated with a 5Fr or 8Fr feeding tube and secured with a suture prior to mobilization. The ureter is then passed extravesically, taking care to avoid the peritoneum, which should be swept off the posterior lateral bladder wall. If ureteral tailoring is warranted, it is performed at this point of the procedure. If a longer tunnel is needed and ureteral length is suspect, consider a psoas hitch at this time as well (Fig. 103.14). Using two fingers inside the bladder, bring the bladder up to the psoas muscle tendon, where it should sit under no tension. Place interrupted figure-of-eight sutures of heavy chromic or polyglycolic acid from the tendon of the psoas to the bladder wall just lateral to where the new ureteral hiatus will be situated. Avoid the genitofemoral nerve running along the psoas muscle during this

**FIGURE 103.11** Cohen technique of ureteral reimplantation. Cross-trigonal tunnel, with the stippled area (A) sewn in place with interrupted sutures (B). C: Bilateral reimplants easily accomplished. (From Walker RW. Vesicoureteral reflux. In: Gillenwater JY, Grayhack JT, Howards SS, et al., eds. *Adult and Pediatric Urology*, vol 2. maneuver. Likewise, the vas deferens in boys and the fallopian tubes in girls must be protected.

A submucosal tunnel is created as described for the Politano–Leadbetter repair. The ureter is brought through the new hiatus, under the subepithelial tunnel, and secured in its new location. Care is taken to avoid twisting or kinking the ureter as it is brought back intravesically. As with all of the intravesical techniques, after the final ureteral anastomosis is complete, a 5Fr feeding tube should easily pass up through the reimplanted ureter to the kidney.

### Laparoscopic Repair

The modern era of laparoscopy has brought forth many new and innovative techniques. These new procedures have been designed to decrease morbidity and hospital costs as well as speed patient recovery. Among these is the laparoscopic extravesical ureteral reimplant. Designed to emulate the Lich–Gregoir repair, this repair is at present utilized in few centers specializing in laparoscopic technique. This particular repair requires two surgeons and can be performed intraperitoneally or retroperitoneally. The technique for intraperitoneal access has been well described. In the pediatric population, access to the peritoneum should be performed using an open technique. I do this using the 10-mm Hassan trocar to avoid intraperitoneal injury. Once the pneumoperitoneum is created, three other trocars are placed. A second 10-mm trocar (instruments) is placed 1 to 5 cm above the infraumbilical site (camera) on the opposite side of the refluxing ureter in the midclavicular line. Two 5-mm trocars are placed in the left and right midclavicular lines at the level of the anterior superior iliac spine for dissecting instruments and retraction.

The operating room table is rotated away from the refluxing side to shift the peritoneal contents and bladder away from the operative location. The peritoneum is incised over the iliac vessels, where the obliterated hypogastric artery is recognized. The ureter is identified (Fig. 103.15), grasped with a Babcock-type instrument, and tented up to allow dissection and mobilization of the ureter for 3 or 4 cm proximal to its detrusor insertion. This will allow placement of the ureter within a trough that is to be created. Next, using electrocautery the muscle layer of the bladder is incised for approximately 3 cm proximal to the ureterovesical junction. Spreading carefully with scissors will expose the mucosa. Dissection continues for the length of the tunnel until the mucosa bulges throughout the incision. The ureter is placed in the trough and the detrusor edges are approximated and the ureter is advanced with a fixation suture at the distalmost part of the trough. The remaining detrusor defect is closed over the ureter with either absorbable polydioxanone suture or staples. A Foley catheter is left overnight.

At present, laparoscopic correction of reflux takes longer than traditional repairs and the incisions made are actually more unsightly than the single lower-abdominal incision done for open surgery. The instruments used are more costly. As a whole, the laparoscopic repair is not yet as cost-effective as either open surgery or endoscopic correction.

### POSTOPERATIVE CARE

The patient stays on prophylactic antibiotics until reflux has been shown to be resolved. An ultrasound of the kidneys and bladder is usually done 4 to 6 weeks after surgery to assess for occult hydronephrosis and hydroureter. Assuming

**FIGURE 103.15** Laparoscopic reimplant. **A:** Ureteral mobilization. The obliterated umbilical artery is identified and traced distally until the ureter is seen. The ureter is grasped gently and the periureteral tissue dissected bluntly toward the ureterovesical junction. **B–D:** Creation of bladder wall trough. Bladder wall is incised with electrocautery 3 cm proximal to the ureterovesical junction. Muscle fibers are gently cut and spread. Dissection is complete when mucosal tissue bulges outward. **E:** After placing the ureter in the trough-grasping instruments, the superior aspect of the bladder wall is wrapped around the ureter and a suture placed proximally, immobilizing the ureter in the trough (*left*). Remaining sutures are placed throughout the length of the tunnel (*right*). **F:** Completed repair. (From Atala A, Keating M. Vesicoureteral reflux. In: Walsh PC, Retik AB, Wein A, et al., eds. *Campbell's Urology*, vol 2. Philadelphia: WB Saunders, 1997, with permission.)

the ultrasound is normal, a follow-up VCUG or nuclear cystogram is performed 3 months later to assess the surgical result. If reflux is no longer present, I routinely repeat a renal ultrasound 1 year later to make sure that anatomically all is well. Should known renal scarring be present, then yearly urinalysis, blood pressure measurements, and periodic ultrasounds are recommended.

---

## OUTCOMES

---

### Complications

---

Fortunately, the success rates for open surgery to correct reflux approach 98% for nondilated ureters and those with normal bladder function. In cases with dilated ureters, significant voiding dysfunction, neuropathic bladder, and anatomic conditions such as prune belly syndrome and posterior urethral

valves, the success rates diminish somewhat. Previously unrecognized bladder and bowel dysfunction is the most common cause of postoperative problems and needs to be vigorously addressed. The most common complication is persisting reflux on the operative side or contralateral reflux of a previously nonrefluxing ureter. In most cases observation is the treatment of choice as the vast majority of these patients will have spontaneous resolution of reflux within 1 year. Always look for voiding or bowel dysfunction in any case of persistent reflux. If the recurrent reflux is high grade, then most likely there was a technical failure such as not creating a long enough tunnel or insufficient ureteral mobilization. These cases frequently require reoperation. Always treat any voiding problems first.

Ureteral obstruction is fortunately a rare complication of reflux surgery and frequently is transient in nature, resulting from postoperative bladder spasms, edema, or blood clots. Hence, it is not unusual to see some mild renal or ureteral dilatation in the first few weeks after surgery on sonography.

Should problems persist, ureteral stenting or percutaneous nephrostomy will help temporize the situation until resolution occurs spontaneously or surgical reimplantation is performed. Higher-grade obstructions usually present with a variety of symptoms such as flank pain, fever, nausea, vomiting, and ileus. These are due to angulation, obstruction at the hiatus, extravasation (of a tapered ureter), or ureteral ischemia with resultant stricturing. Urinary diversion or stenting is paramount in these situations and redo reimplantation required. If the remaining ureter is too short to reimplant in the standard fashion, consider a psoas hitch or a transureteral ureterostomy.

Bladder diverticula are usually the result of a defect in the closure of the muscular hiatus at the original procedure. If the diverticula is wide-mouthed and drains well in the absence of

obstruction or reflux, then observation is all that is needed. In the presence of ureteral pathology or poor drainage of the diverticula, surgical correction is necessary.

---

## CONCLUSIONS

---

Surgical management of VUR is highly successful if performed for the right indications and if one adheres to the proper principles of good surgical technique. There are a myriad of corrective techniques available, each with their respective advantages and disadvantages. It is up to the individual surgeon to decide what works best in his or her hands after analyzing the available information on the respective patient.

# CHAPTER 104 ■ ENDOSCOPIC TREATMENT OF VESICOURETERAL REFLUX

WOLFGANG H. CERWINKA AND ANDREW J. KIRSCH

Approximately 1% of children are diagnosed with vesicoureteral reflux (VUR), a condition that promotes pyelonephritis and may lead to renal scarring and hypertension. VUR is one of several treatable risk factors, such as dysfunctional elimination, in the development of urinary tract infection (UTI). The goal of VUR treatment is to prevent pyelonephritis and to preserve renal function. Antibiotic prophylaxis is initiated in most children irrespective of VUR grade. Surgical management, indicated in cases of breakthrough UTIs and/or persistence of VUR, comprises ureteral reimplantation and endoscopic injection. In 1981 endoscopic

injection for VUR was introduced as an investigational method and the first clinical experience was published in 1984 (1,2). Over the last 20 years, injection techniques, injectable agents, and consequently treatment success rates have significantly improved (3). The success rate of outpatient endoscopic treatment of VUR approaches that of open ureteral reimplantation and offers considerable advantages to patients and parents such as lower morbidity (e.g., pain, scar), fewer complications, and reduced cost. Consequently, an apparent trend from reimplantations toward injection treatments has been observed over the last several years.

---

## DIAGNOSIS

---

VUR is diagnosed by nuclear cystography or voiding cystourethrography (VCUG) and graded from I to V. This grading system bears clinical significance not only for spontaneous resolution, but also for treatment method and outcome. VCUGs performed with a single cycle of filling and voiding show false negatives in approximately 20%; for improved sensitivity, cyclic VCUGs consisting of three voiding cycles are recommended. VCUG as a means to detect VUR is indicated in various clinical scenarios. The current guidelines recommend VCUGs for children of both sexes and all ages after the first febrile UTI or subsequent UTIs if the previous VCUGs did not demonstrate VUR. Approximately 40% of children with febrile UTIs are subsequently diagnosed with VUR. Children who experience recurrent febrile UTIs without evidence of VUR by VCUG may suffer from occult VUR. It is conceivable that despite negative conventional VCUG, occult VUR is clinically significant. One method to diagnose occult VUR is the positional instillation of contrast cystography (PICC). The tip of the cystoscope is positioned at the ureteral orifice and contrast instilled at full flow with a pressure of 80 cm of water. A patient is designated PICC-positive if contrast is seen in the ureter, without the need to grade occult VUR. An alternative approach for the diagnosis of occult VUR is hydrodistention of the distal ureter, thus avoiding the use of contrast and ionizing radiation. The degree of hydrodistention was shown to correlate with the presence of occult reflux. VCUGs are recommended in patients with multicystic dysplastic kidneys because of the condition's association with contralateral VUR in 15% to 20%. Antenatal hydronephrosis, even when it resolves postnatally, will be associated with VUR in 20%. Screening siblings or parents implies a 30% to 65% chance of VUR. VUR may be incidentally discovered by a VCUG obtained for reasons other than febrile UTIs, such as posterior urethral valves, patent urachus, or suspected bladder rupture. The obligation to diagnose VUR in asymptomatic patients (no history of febrile UTIs, prenatally diagnosed hydronephrosis, sibling screening) has been questioned because the natural history of asymptomatic VUR may be benign and treatment not necessary.

The “top-down approach” in the management of UTI attempts to distinguish clinically significant from insignificant VUR by evaluating kidneys for pyelonephritis and/or scarring with DMSA scans performed within weeks of the onset of acute pyelonephritis. A positive DMSA scan is an indication for VCUG and consequently 50% of “unnecessary” VCUGs can be avoided. However, many patients suffering from the significant morbidity of recurrent febrile UTIs without detectable renal injury are missed. At this time, this approach is rarely used and should be considered investigational until long-term data become available.

While VCUGs and nuclear cystographies both apply ionizing radiation to a field that includes the gonads, in cases of prolonged nonoperative management of VUR, nuclear cystography is often preferred because it utilizes a lower radiation dose. Magnetic resonance voiding cystourethrography (MRVCU) became a potential alternative to conventional VCUG with the advent of near real-time magnetic resonance fluoroscopy. In comparative studies, MRVCU demonstrated inferior sensitivity (76%) and specificity (90%) to conventional VCUG and has limitations, such as incomplete voiding

of some infants and young children secondary to sedation. Although technically feasible, it seems unlikely that MRVCU will gain widespread acceptance.

---

## INDICATIONS FOR SURGERY

---

Endoscopic treatment using Deflux is U.S. Food and Drug Administration (FDA) approved for VUR grades II to IV in single or duplex ureters and for cases of initial endoscopic treatment failure; however, it has been applied to all VUR scenarios. While open ureteral reimplantation may be a good treatment option after failed injection therapy, endoscopic treatment has been successfully employed after failed ureteral reimplantation (Table 104.1). Current evidence does not suggest that antireflux surgery of any means reduces the incidence of renal scarring or end-stage renal disease. Valuable goals of VUR treatment are to prevent UTIs, particularly pyelonephritis, to avoid long-term antibiotic prophylaxis, and to reduce the need for distressing VCUGs and radiation exposure. Proponents of the endoscopic approach will argue that decreasing the incidence of UTIs is the main goal of therapy. Recurrence, while possible, may occur in the absence of symptoms and be viewed as subclinical, similar to an individual with VUR diagnosed after a sibling screen or for fetal hydronephrosis. Proponents of the open surgical approach will argue that ureteral reimplantation provides a permanent cure of VUR and is worth the increased morbidity to achieve this goal. In terms of reducing the risk of UTI, endoscopic treatment may achieve this goal as well as or better than open surgery, and there are no long-term data on the radiographic results of open surgery (4,5).

The indications for ureteral reimplantation and endoscopic treatment are with few exceptions identical and include persistent VUR after a period of observation, new renal scarring, breakthrough UTIs, and poor compliance with antibiotic prophylaxis. When surgical options are discussed with parents, a significant preference for endoscopic treatment becomes apparent (6,7). While endoscopic injection has focused on the treatment of primary VUR, it was largely avoided for cases of complex VUR (i.e., VUR associated with functional or anatomic abnormalities such as neurogenic bladder or megaureters). In general, endoscopic treatment is emerging as the treatment modality of choice for VUR, whereas ureteral reimplantation remains reserved for cases of failed injection therapy, significant anatomic abnormalities (e.g., large paraureteral diverticula, ectopic ureters, megaureters), and surgeon's or parents' preference.

---

## ALTERNATIVE THERAPY

---

Most patients diagnosed with VUR are started on antibiotic prophylaxis irrespective of grade. Antibiotic prophylaxis may be continued for several years until VUR resolution or significant grade reduction or if it is deemed clinically insignificant. The presumed benefits of antibiotic prophylaxis, prevention of pyelonephritis, and avoidance of surgery have been challenged by recent studies demonstrating increased bacterial resistance and failure to protect against UTIs. Observation off antibiotics was consequently proposed as an alternative management option. However, at the current time, observation protocols in young patients who are at risk for renal injury (<4 years of age)

or who have shown a propensity for recurrent pyelonephritis should be considered investigational.

Treatment of concomitant dysfunctional elimination (i.e., constipation and/or voiding dysfunction) reduces the risk of UTIs in patients with VUR. Surgical intervention comprises open ureteral reimplantation (extravesical and intravesical), laparoscopic ureteral reimplantation, and endoscopic treatment. Ureteral reimplantation has a success rate of 95% to 99% for grade I to IV and 80% for grade V VUR. Persistent or recurrent VUR after surgical treatment may be treated in an identical fashion or with an alternative method (i.e., reimplantation or endoscopic injection). A second injection was shown to be highly successful in patients after initial endoscopic treatment failure (90%); however, a third injection in general yields low success (34% to 50%) and is not recommended. Older patients with persistent VUR and no other risk factors (e.g., worsening VUR grade, renal scarring, dysfunctional elimination) often remain asymptomatic and may be taken off antibiotic prophylaxis (8). However, parents should be warned of the risks of pyelonephritis and its associated morbidity that may be seen during sexual activity and pregnancy.

## SURGICAL TECHNIQUE

Numerous injectable bulking materials have been utilized and abandoned over time in search of a nonimmunogenic, noncarcinogenic, biocompatible, and biodegradable agent. Teflon, the first bulking material used for the treatment of VUR, was abandoned in pediatric urology in the United States because of the material's propensity to migrate to distant organs and to form granulomas; however, carcinogenesis of Teflon has not been reported. Silicone also demonstrates distant migration and granuloma formation. Its carcinogenic potential has been controversial but is most likely unsubstantiated. Glutaraldehyde cross-linked bovine collagen demonstrates a lower degree of absorption as compared to native collagen and can cause allergic reactions even in patients with a negative skin test. Several new bulking agents are currently under investigation, such as inorganic materials and autologous tissue. The latter is nonimmunogenic; however, cell harvest and/or cell culture are time-consuming and expensive.

Dextranomer/hyaluronic acid copolymer (Deflux) is easy to inject and is biodegradable with stable implant volume, and its relatively large particle size prevents distant migration. It has been used as an injectable material in pediatric urology since 1995 and is currently the first-choice injectable agent due to its safety and efficacy (9). Deflux implants in animal tissue were shown to undergo time-dependent histopathological changes. The initial phase was dominated by an ingrowth of granulation tissue, a foreign body giant cell reaction, and the formation of a surrounding capsule. In the later phase, cellular elements became largely replaced by a collagen-rich matrix, whereas the capsule remained unchanged. These findings were confirmed in patients who had failed endoscopic injection and proceeded to ureteral reimplantation. Besides biological properties, cost of bulking agents, and surgeon's experience, the choice may ultimately depend on approval by administrative agencies, such as the European Medicines Agency or the FDA.

The endoscopic method currently achieving the highest success rates is the double hydrodistention implantation technique (HIT) (Fig. 104.1). The patient is placed in the low dorsal lithotomy position and antibiotic prophylaxis is given. Cystoscopy is performed with a pediatric cystoscope equipped with an offset lens. An offset lens permits direct passage of the needle in line with the ureter without bending the needle. The bladder is filled to less than half capacity to permit visualization of the ureter and avoid tension within the submucosal layer of the ureter secondary to overdistention. Hydrodistention (HD) is performed with the tip of the cystoscope placed at the ureteral orifice (UO) and a pressured stream is achieved by placing the irrigation bag approximately 1 meter above the bladder on full flow. HD of the distal ureter serves two purposes: it allows visualization of the intraureteral injection site and assessment of treatment progress (i.e., ureteral coaptation). The needle is passed into the UO and inserted at

**FIGURE 104.1** Endoscopic treatment of vesicoureteral reflux (double HIT technique). **A:** Proximal intraureteral injection. **B:** Coapted intramural ureter. **C:** Distal intraureteral injection. **D:** Coapted ureteral orifice.

**FIGURE 104.2** Needle placement algorithm for the endoscopic treatment of vesicoureteral reflux. The double hydrodistention implantation technique uses sites 1 and 2; site 3 (subureteric injection of Teflon) is rarely used.

the mid-ureteral tunnel at the 6 o'clock position. Sufficient bulking agent is injected to produce a bulge, which initially coapts the detrusor tunnel, while a second implant within the most distal intramural tunnel leads to coaptation of the UO (approximately 1 to 1.5 mL). Rarely, if the two intraureteric submucosal injections (double HIT method) fail to coapt the ureter, a classic STING (supraureteric injection of Teflon) is needed to achieve coaptation. The latter two injection sites are used more commonly in complex or redo cases (Fig. 104.2). HD is performed after each injection to monitor treatment progress; when HD ceases to dilate the UO, appropriate coaptation has been achieved.

In general, all procedures are performed on an outpatient basis and all patients receive preoperative antibiotic prophylaxis, which is continued until resolution of VUR has been confirmed. Radiographic success is defined as grade 0 VUR on a postoperative VCUG, 1 to 6 months after a single treatment. Patients are then followed clinically on an annual basis to determine clinical success and recurrence.

## OUTCOMES

Outcome of endoscopic treatment for VUR has been evaluated in several large series (Table 104.1). Most studies included both primary and complicated cases of VUR. Interpretation of and comparison among these studies are confounded by different inclusion criteria (e.g., with or without complex VUR, grade I, grade V), varying lengths of follow-up, definitions of success, and single versus multiple injections. Nevertheless, most current series report cure rates of >85%. Age, gender, and bilaterality of VUR have not been shown to predict treatment outcome. While the STING technique yields lower success rates with higher grades of VUR, the HIT method achieves similar outcomes across all VUR grades up to grade V. Endoscopic treatment of complicated VUR has been evaluated in smaller series and success rates vary significantly depending

**FIGURE 104.3** Retractable injection needle guide (Injekt, Cook Urological, Spencer, IN). A: Flexible wire is placed into the ureter and the needle is advanced submucosally. B: Depth gauge allows needle advancement in 1-mm increments.

on the associated pathologies (Table 104.1). In general, cure rates for complex cases of VUR are lower than for primary VUR. Treatment of VUR associated with neurogenic bladder or voiding dysfunction was shown to yield acceptable outcomes. Endoscopic injection has been successfully employed in patients who failed either ureteral reimplantation or initial injection. Injection after failed reimplantation or second injection will be curative in most instances, whereas a third injection has been shown to be far less successful (10). Refluxing ureters of transplanted kidneys in symptomatic patients may be treated endoscopically. Although this approach is curative in only half the cases, it represents an attractive alternative to open surgery in the setting of immune compromise and reduced wound-healing properties. VUR associated with anatomical abnormalities (e.g., duplex ureters, paraureteral diverticula, and ureteroceles), previously thought to be contraindications for endoscopic treatment, was recently shown to be amenable to injection treatment.

There are many factors that may affect the success of the procedure. Preoperative (i.e., patient selection), intraoperative (i.e., injection technique, injected volume), and postoperative variables have been shown to correlate with treatment outcome. Postoperatively, failures may result from Deflux displacement

(implant migration), disruption (mucosal breach), or dissolution (decrease in implant volume). Success may be improved with the HIT method when performed by an experienced surgeon familiar with the subtleties of the technique. New technologies will continue to improve the success of endoscopic injection. For example, a prototype of a new retractable injection needle guide (Injekt, Cook Urological, Spencer, IN) has been developed to reproduce the double HIT method and reduce the learning curve (Fig. 104.3). New biologic injectable agents are also under study.

---

## COMPLICATIONS

---

In comparison to ureteral reimplantation, endoscopic VUR treatment offers major advantages to patients and parents. The procedure generally lasts <15 minutes and is performed on an outpatient basis. While cure rates are approaching those of open ureteral reimplantation, significant complications are rare. Endoscopic treatment entails greater patient convenience, lower morbidity (e.g., pain, abdominal scar), and reduced cost (11). Consequently, a significant parental preference for endoscopic treatment is evident (6,7). A recent study demonstrated that both patients and parents viewed injection therapy as the least bothersome aspect of VUR treatment, followed by antibiotic prophylaxis and VCUG (5).

The most common complications following endoscopic treatment of VUR are new contralateral VUR (2.3% to 17.3%) and treatment failure. Less than 4% of children complain of flank pain or emesis several hours after the procedure and all respond to analgesics. Gross hematuria, urinary retention, or febrile UTIs have not been observed. The most significant potential complication of endoscopic treatment for VUR includes a 0.6% risk of ureteral obstruction (12). Factors that may increase the risk of obstruction include bladder dysfunction and markedly dilated ureters. Patients with recurrent VUR often remain asymptomatic, and those without risk factors for pyelonephritis such as young age, voiding dysfunction, or significant history of UTIs may be taken off antibiotic prophylaxis (8).

# CHAPTER 105 ■ URETEROCELES

RICHARD N. YU, CHESTER J. KOH, AND DAVID A. DIAMOND

Ureteroceleles are congenital cystic dilations of the intravesical submucosal ureter. They are more commonly found in female children and are almost exclusively diagnosed in whites. Approximately 10% of these children have bilateral ureteroceleles. Ureteroceleles may be “orthotopic” and contained entirely within the bladder, or “ectopic” and partially situated at the bladder neck or urethra. An orthotopic ureterocele is typically associated with a single collecting system, while an ectopic ureterocele is usually associated with the upper-pole moiety of a kidney with complete ureteral duplication.

## DIAGNOSIS

Increasingly, ureteroceleles are diagnosed by prenatal ultrasonography, which can demonstrate both the intravesical cystic dilation as well as the corresponding hydronephrosis. These patients should undergo a comprehensive postnatal urological evaluation and be placed on prophylactic antibiotics, which may help to prevent future urinary tract infections (UTIs) (1). However, for many children the diagnosis of ureterocele is made only after a UTI or urosepsis. Ureteroceleles can also present as a palpable abdominal mass, usually representing a hydronephrotic kidney, or as a vaginal mass, which represents prolapse of an ectopic ureterocele. Large ureteroceleles may even lead to obstruction of the bladder neck or of the contralateral ureteral orifice, which may result in bilateral hydronephrosis.

In general, ultrasonography is the first radiological study obtained in diagnosing ureteroceleles. In addition to the intravesical cystic dilation, ureteroceleles are usually seen with duplex collecting systems, with the ureterocele being associated with hydronephrosis of the upper-pole moiety.

A voiding cystourethrogram (VCUG) is essential in the evaluation of the patient with a ureterocele because of the high incidence of concomitant ipsilateral and contralateral vesicoureteral reflux. In addition to the reflux, VCUG can demonstrate the size and location of the ureterocele.

Currently, the dimercaptosuccinic acid (DMSA) renal scan provides the most precise estimates of the differential renal function between each kidney, as well as of the associated upper pole’s contribution to the overall renal function. DMSA scans may even detect lower-moiety abnormalities that may not have been demonstrated by ultrasonography (2).

Intravenous urography (IVU) is less commonly used in the modern evaluation of ureteroceleles. However, in cases of unusual urinary tract anatomy IVU may be helpful in the delineation of previously undefined anatomy. Severe hydroureteronephrosis

associated with a ureterocele may lead to lateral deviation of the upper pole away from the spine.

## INDICATIONS FOR SURGERY

The goals of surgical treatment should be the preservation of renal function, elimination of obstruction and reflux, prevention or elimination of infection, and maintenance of urinary continence (3) while minimizing surgical morbidity. The main factors to consider in developing an individual treatment plan should be patient age, patient’s clinical presentation, ureterocele size and anatomy, presence of reflux and UTI, and function of the involved renal segments.

## ALTERNATIVE THERAPY

The anatomy and clinical presentations of children with ureteroceleles vary widely. Therefore, each child should have an individualized treatment plan as no single method of surgical repair is appropriate for all cases. Table 105.1 lists some therapeutic options for patients with ureteroceleles.

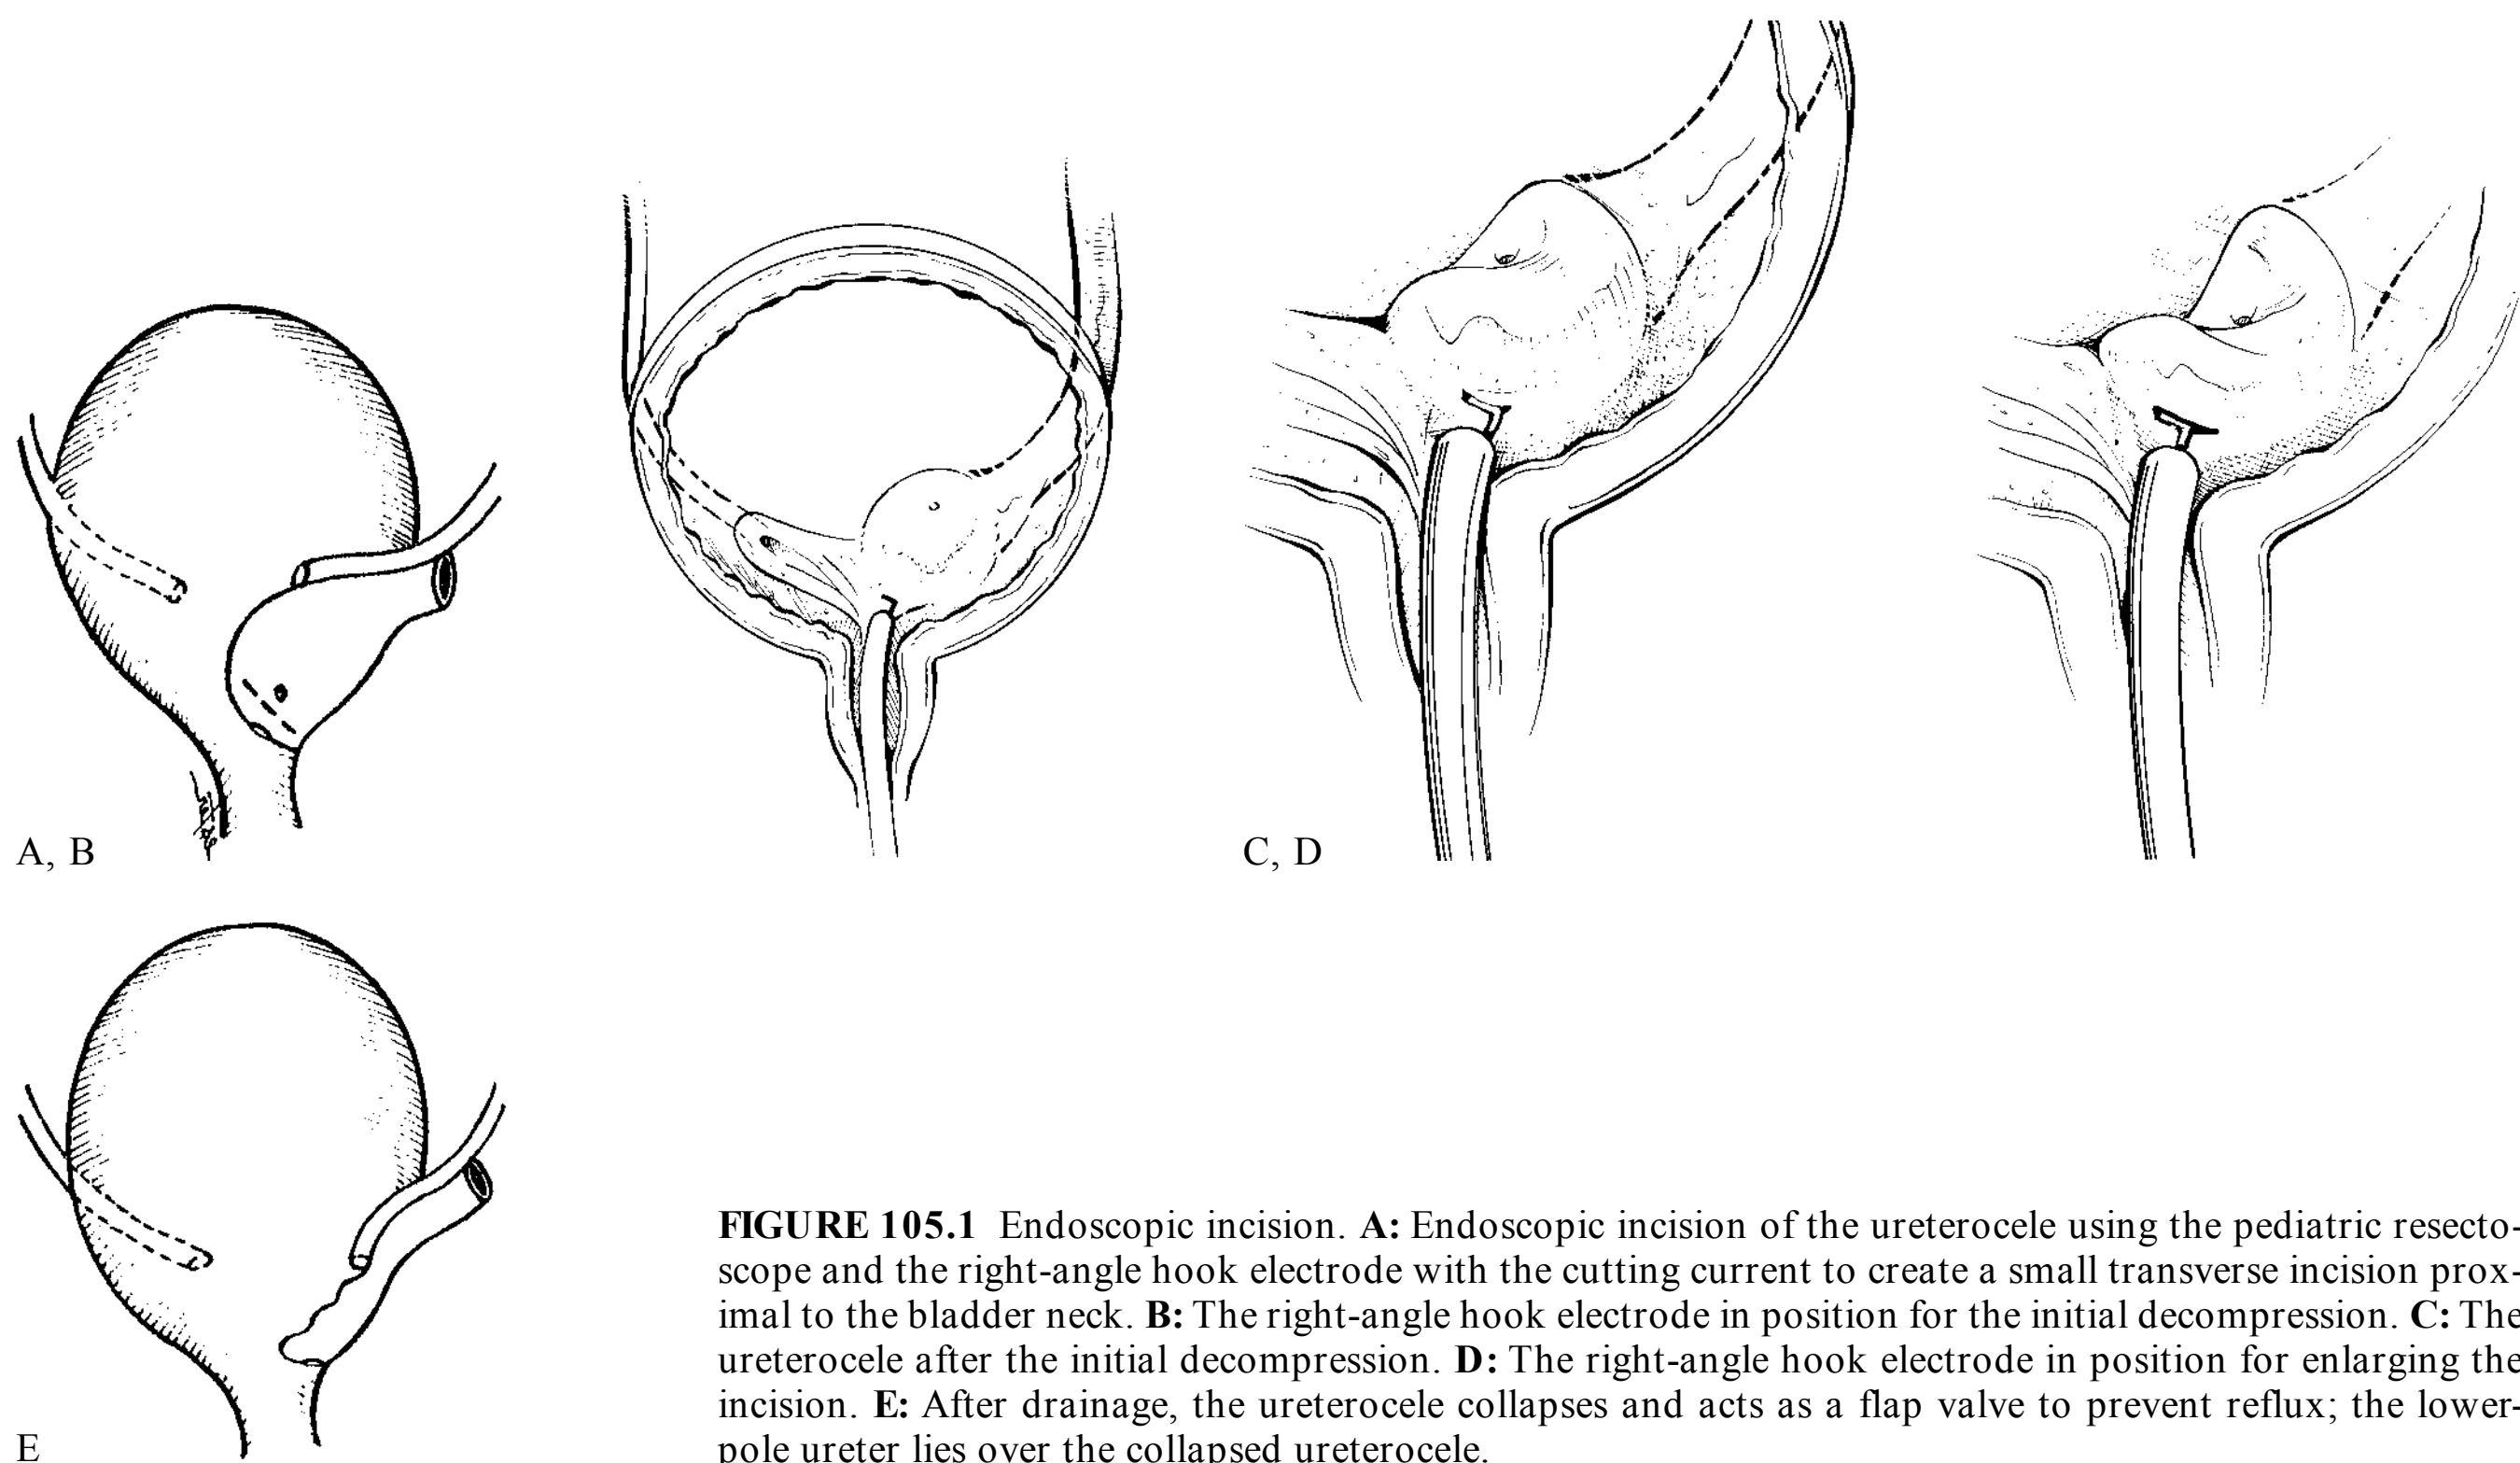

## SURGICAL TECHNIQUE

Techniques that preserve functional upper-pole moieties are listed below. However, in many instances the upper pole has little to no contribution to the overall renal function and upper-pole ablative techniques, also described below, may be indicated.

TABLE 105.1

### URETEROCELE THERAPEUTIC OPTIONS

Upper-pole preservation
Endoscopic incision of the ureterocele
Complete lower-tract reconstruction (excision of ureterocele with ureteral reimplantation)
Ureteroureterostomy/ureteropyelostomy
Upper-pole ablation
Upper-tract approach (upper-pole nephrectomy and partial ureterectomy)
Complete reconstruction

**FIGURE 105.1** Endoscopic incision. **A:** Endoscopic incision of the ureterocele using the pediatric resectoscope and the right-angle hook electrode with the cutting current to create a small transverse incision proximal to the bladder neck. **B:** The right-angle hook electrode in position for the initial decompression. **C:** The ureterocele after the initial decompression. **D:** The right-angle hook electrode in position for enlarging the incision. **E:** After drainage, the ureterocele collapses and acts as a flap valve to prevent reflux; the lower-pole ureter lies over the collapsed ureterocele.

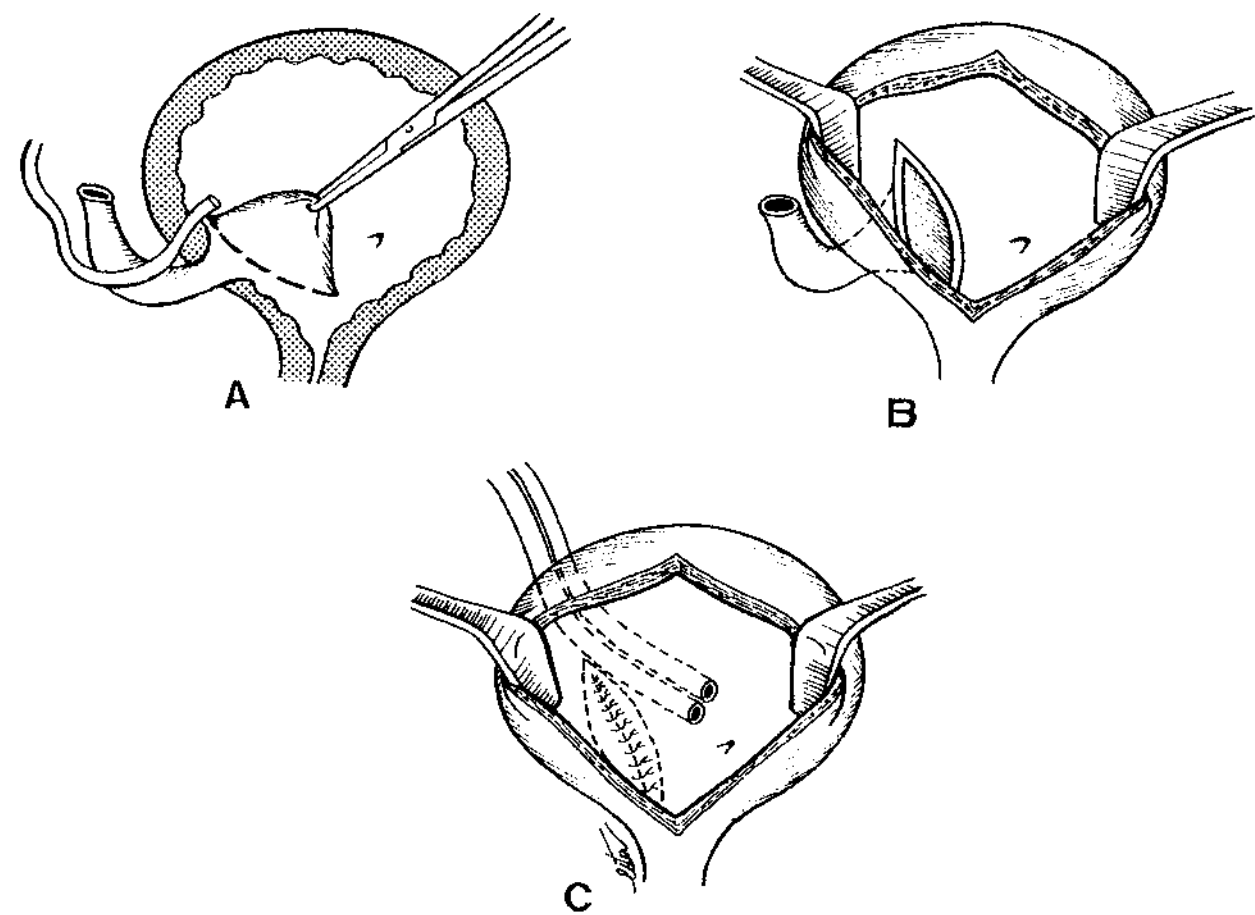

## Upper-Pole Preservation

### Endoscopic Incision of the Ureterocele

The goal of endoscopic incision of ureteroceles is to decompress the ureterocele in a minimally invasive manner while minimizing the risk of postincision vesicoureteral reflux and the need for further urinary tract reconstruction (4). This technique can be used in infants if infant-sized endoscopic equipment is available and should be used to drain obstructive urinary systems in any ureterocele patient with urosepsis. Blyth et al. recommended the use of a 3Fr Bugbee wire electrode (using the cutting current) to incise the roof of the ureterocele through its full thickness near its base and proximal to the bladder neck (5). A new unobstructed intravesical ureteral orifice will be created, and the roof of the collapsed ureterocele can act as a flap-valve mechanism to prevent reflux. While the Bugbee electrode has been a widely utilized instrument for ureterocele puncture, it has limitations, primarily that following initial decompression enlargement of the puncture site is difficult. Therefore, we prefer to use the pediatric resectoscope and the right-angle hook electrode with the cutting current, which allows one to make a clean transverse incision and enlarge it by placing the hook into the original incision and withdrawing under vision (Fig. 105.1). Magnification with the use of video projection helps improve the accuracy of the incision. Making the incision as distal and as close to the bladder neck as possible should reduce the risk of postoperative reflux into the corresponding ureter. The adequacy of the incision can be confirmed by the presence of a jet of urine from the ureterocele or by visualization of the urothelium inside the ureterocele. The major advantage of the endoscopic incision is that it can be done on an outpatient basis, without the need for hospitalization.

### Complete Lower-Tract Reconstruction (Excision of Ureterocele with Ureteral Reimplantation)

For excision of the ureterocele and common sheath reimplantation of upper- and lower-pole ureters, a Pfannenstiel incision is made and the bladder is opened (Fig. 105.2). The lower-pole and contralateral ureters are intubated with 5Fr feeding tubes, and multiple circumferential stay sutures are placed. A circumferential incision is made around the perimeter of the ureterocele with electrocautery and the wall of the ureterocele and its

**FIGURE 105.2** Complete lower-tract reconstruction. **A:** After the bladder is opened, multiple circumferential stay sutures are placed around the ureterocele to assist with the excision. **B:** All ureters should be intubated with 5Fr feeding tubes for identification of the ureters during the dissection. **C:** After excising the ureterocele, the posterior bladder wall is repaired with running 3-0 absorbable sutures and the ureters are reimplanted into a generous tunnel.

associated upper-pole ureter are dissected away from the thinned posterior muscular wall of the bladder, incorporating the lower-pole ureter in the dissection. All attempts should be made to avoid injury to the sphincteric mechanisms at the bladder neck during the distal dissection of the ureterocele. The upper- and lower-pole ureters are dissected as a common sheath to avoid injury to the blood supply of both ureters. After excising the distal ureterocele, the dilated upper-pole ureter often requires tapering. The thin posterior bladder wall is repaired by imbrication of adjacent muscle with running 3-0 absorbable sutures to provide sufficient muscle backing for the reimplanted ureters. An unoperated portion of the bladder floor is selected and the ureters are reimplanted as a common sheath into a generous ureteral tunnel.

#### Ureteroureterostomy/Ureteropyelostomy

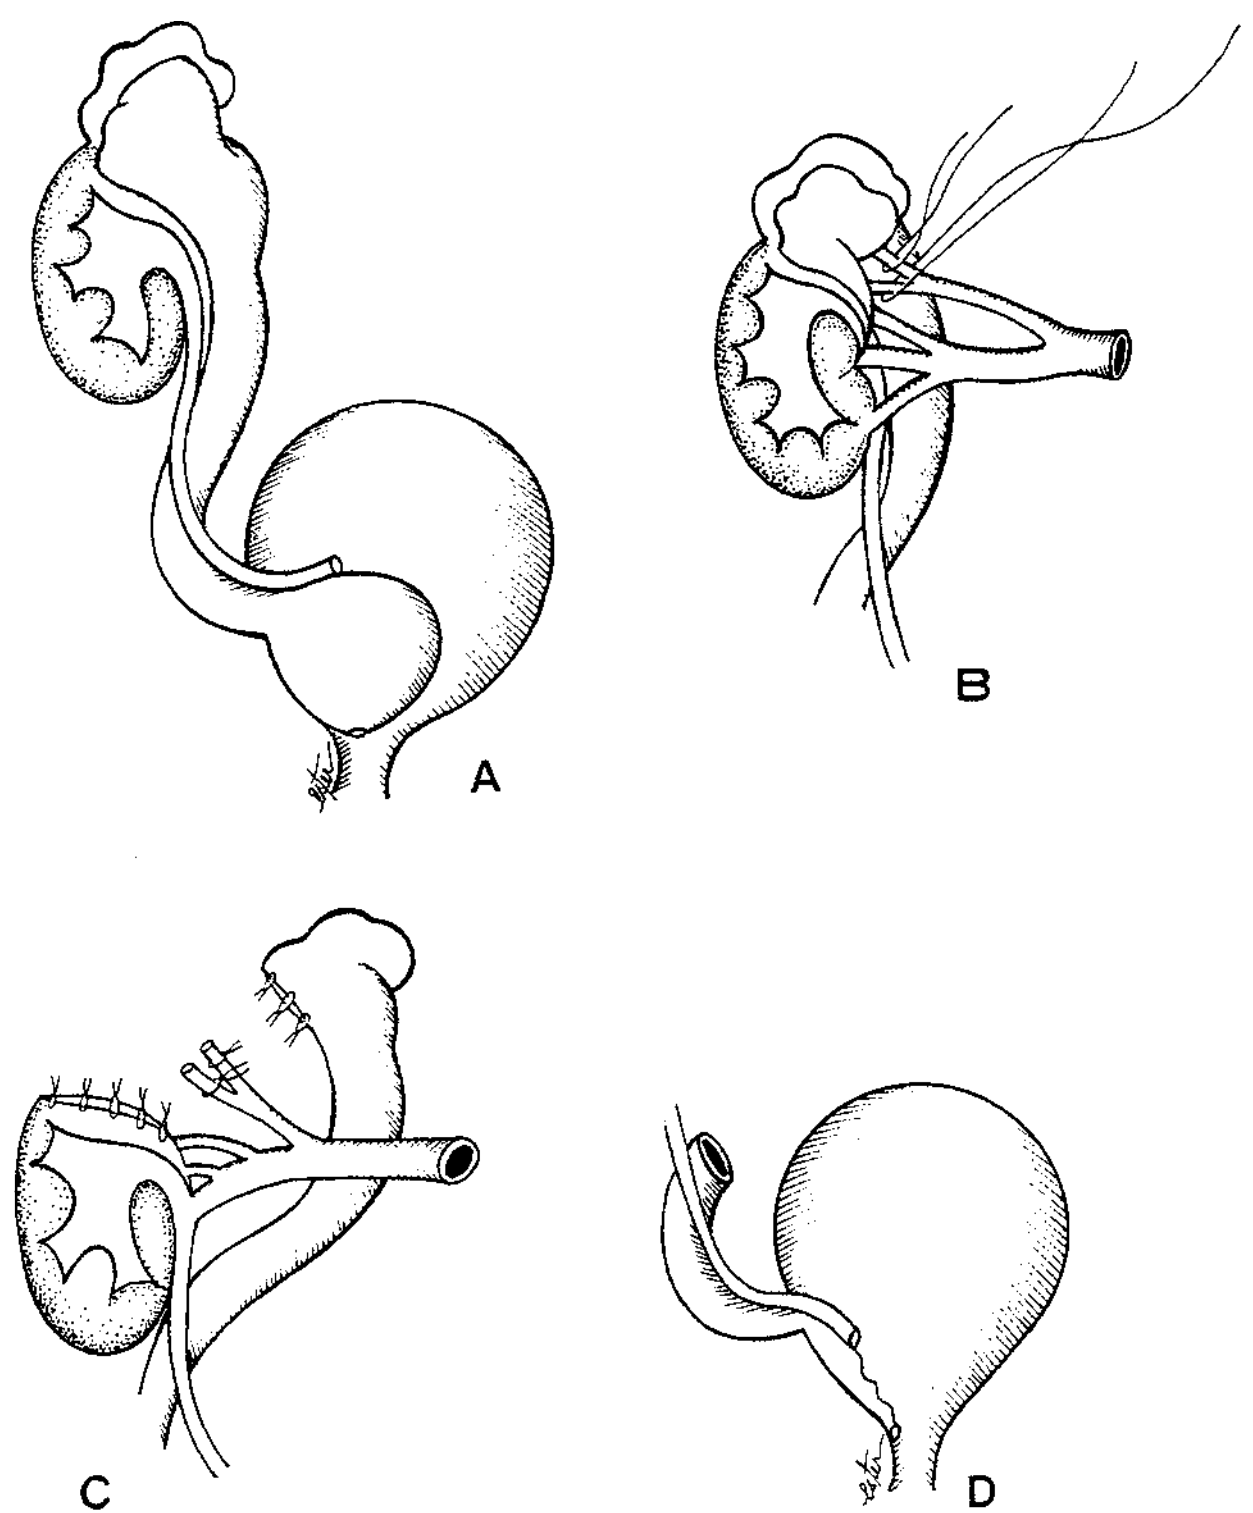

In upper urinary tract anastomotic techniques, the dissection of the upper tracts should be kept to a minimum, and mobilization should be directed toward the upper-pole ureter, so that distortion of the adjacent lower-pole ureter can be avoided. Because the upper-pole ureter is usually larger than the lower-pole ureter, generous spatulation of the ureters during ureteroureterostomy may be necessary for an optimal end-to-side anastomosis. Furthermore, a feeding tube should be passed distally into the ureterocele to decompress it.

### Upper-Pole Ablation

#### Upper-Tract Approach (Upper-Pole Nephrectomy and Partial Ureterectomy)

In many cases, the upper pole associated with the ureterocele has minimal or no contribution to the overall renal function. The upper-tract approach (upper-pole nephrectomy and partial ureterectomy) should lead to the relief of obstruction, prevention of recurrent infection, and resolution of the reflux that is present in about half of these patients. This approach should result in the decompression of the ureterocele, hopefully with resolution of the ipsilateral lower-pole reflux, because the trigone will be returned to a more normal configuration. This usually eliminates the need for lower-tract reconstruction with a potentially difficult bladder neck and urethral dissection (3).

For the upper-pole heminephrectomy, we suggest the use of the flank or laparoscopic approach, which offers superior access to the upper-pole vessels. With either approach, care should be taken to avoid excessive traction upon the kidney to avoid damage to the viable lower pole. In many cases, the upper pole resembles a dysplastic nubbin, and early division of the upper-pole ureter with upward traction on the proximal portion of the transected ureter usually helps in the definition and manipulation of the upper pole (Fig. 105.3). After the upper-pole vessels are sequentially ligated, demarcation of the upper-pole parenchyma should become apparent. We recommend the use of a no. 15 blade or electrocautery around the upper-pole parenchyma, which usually results in a wedge-shaped defect. During the dissection of the upper-pole parenchyma, the plane of dissection should remain as close as possible to the upper-pole ureter to avoid injury to the vascular supply of the lower-pole ureter. After the upper-pole nephrectomy, the wedge-shaped defect is closed with interrupted 3-0 chromic sutures in a vertical mattress fashion to achieve effective hemostasis.

**FIGURE 105.3** Upper-pole partial nephrectomy and partial ureterectomy. **A:** This procedure is commonly used for a duplex system with a nonfunctioning upper pole and minimal or absent ipsilateral reflux. **B:** The upper-pole ureter is transected early after a stay suture has been placed proximally. Upward traction on the proximal portion of the transected ureter assists in the manipulation of the upper pole during the partial nephrectomy. **C:** After removal of the upper pole, the wedge-shaped kidney defect is repaired with 3-0 chromic sutures in a vertical mattress fashion. **D:** This approach should result in the decompression of the ureterocele, with the return of the trigone to a more normal configuration.

### Complete Reconstruction

In certain instances, a complete reconstruction may be indicated where both an upper-tract repair and a lower-tract reconstruction are performed via separate incisions in a single stage. These situations include the presence of high-grade reflux into the ipsilateral lower-pole ureter or the presence of lower-pole reflux associated with a large, everting ureterocele and a nonfunctioning upper pole. Depending on the amount of upper-tract function, either an upper-pole nephrectomy with partial ureterectomy or a ureteropyelostomy (as described above) is performed for the upper-tract repair. Lower-tract reconstruction is also performed, which involves excision of the ureterocele with reimplantation of the ureters as a common sheath, as previously described.

## OUTCOMES

### Complications

Excision of the ureterocele with ureteral reimplantation achieves the goal of upper-tract drainage. However, the disadvantage of this approach is the morbidity associated with bladder surgery,

including hematuria, bladder spasm, and catheter drainage. Extensive distal dissection also carries the risk of bladder neck and sphincteric injury, which may jeopardize urinary continence (6).

---

## Results

---

Endoscopic incision of the ureterocele may be the only surgical procedure required for many patients. For infants, endoscopic incision may be used as a temporizing measure that achieves early decompression. Secondary surgery, if necessary, can be performed electively when the child is older. If the ureterocele is orthotopic, one can expect high rates of decompression and low rates of de novo reflux and the need for secondary procedures (7). On the other hand, ectopic ureteroceles are associated

with a high rate of secondary surgery and a significant incidence of postoperative reflux after endoscopic incision. Therefore, patients with ectopic ureteroceles may be best served by more definitive reconstruction, even those <1 year of age (8).

The upper-tract approach, which includes upper-pole nephrectomy and partial ureterectomy, is usually reserved for the patient with an upper pole that provides little or no contribution to the overall renal function and mild or absent ipsilateral reflux. This approach has the advantage of avoiding the lower-tract complications noted previously.

For patients who are at significant risk for requiring a second procedure with some of the approaches detailed previously, such as those patients with large, ectopic ureteroceles or high-grade ipsilateral reflux, complete upper- and lower-tract reconstruction in a single stage has the advantage of expediency (9).

# CHAPTER 106 ■ URACHAL ANOMALIES AND RELATED UMBILICAL DISORDERS

LESLIE T. MCQUISTON AND ANTHONY A. CALDAMONE

During bladder development, the urogenital sinus is initially contiguous with the allantois. When the lumen of the allantoic duct becomes obliterated, the urachus remains, connecting the bladder to the umbilicus (Fig. 106.1A,B). It continues to elongate as the fetus grows. The urachus is a muscular tube, with a length ranging from 3 to 10 cm and a diameter of approximately 8 to 10 mm, that extends from the dome of the bladder to the umbilicus. It has three distinct tissue layers: (a) an epithelial-lined lumen with cuboidal or transitional epithelium, (b) an intermediate connective tissue layer, and (c) an outer smooth muscle layer. In the adults, the urachus lies between two layers of umbilicovesical fascia along with the umbilical ligaments and the remnants of the obliterated umbilical arteries. This fascial investment tends to contain the spread of urachal disease between the peritoneum and transversalis fascia (Fig. 106.1C).

The urachus normally closes or involutes at approximately 32 weeks' gestation, and urachal anomalies in general represent an abnormality in this process. These anomalies are characterized as patent urachus, urachal cyst, urachal sinus, and urachal diverticulum (Fig. 106.2) (1). Of these anomalies, urachal cysts (45%) and sinuses (37%) are the most commonly identified (2).

---

## DIAGNOSIS

---

In general, the diagnosis of urachal anomalies requires clinical suspicion and a thorough physical examination. Further evaluation in patients with periumbilical drainage should include a sinogram, and those with a periumbilical mass should undergo

**FIGURE 106.1** **A:** At 9 weeks of gestational age showing the allantois extending into the body stalk. **B:** At 3 months' gestation, the urachus connects to the dome of the bladder. **C:** The urachus persisting as the median umbilical ligament in the adult.

ultrasonographic imaging. A voiding cystourethrogram may be required in only selected patients (2,3).

Complete failure of the urachal lumen to close results in an open connection between the bladder and the umbilicus. Patients present with umbilical leakage of urine and often a protruding tissue mass (Fig. 106.3). The leakage may be more obvious during times of increased intra-abdominal pressure such as crying, coughing, or straining. The fluid may be analyzed for urea and creatinine to confirm its urinary quality. Two factors thought to contribute to a persistent patent urachus are bladder outlet obstruction and failure of the bladder to descend into the pelvis (4,5). With regard to bladder outlet obstruction, distal urinary obstruction is thought not to be the only causative factor because normally the urachus closes developmentally before the urethra becomes tubularized (6). In addition, only 14% of patients with patent urachus demonstrate bladder outlet obstruction clinically, and it is uncommon for a patent urachus to be associated with posterior urethral valves. The diagnosis may be

confirmed with a sonogram, although a voiding cystourethrogram may be more useful because it may rule out bladder outlet obstruction concurrently. Alternatively, methylene blue or indigo carmine may be instilled in either the bladder or the umbilical opening and detected in the umbilicus or bladder, respectively. The differential diagnosis for patent urachus includes patent omphalomesenteric duct, urachal sinus, omphalitis, granulation of a healing umbilical stump, and infected umbilical vessel.

Segmental or incomplete closure of the urachal lumen may result in the formation of a urachal cyst (Fig. 106.4). The cyst usually forms in the proximal or lower third of the urachal remnant near the bladder (7). Usually, the cyst is lined with transitional epithelium and filled with serous fluid, but mucinous contents have been described. In general, urachal cysts are small and asymptomatic. Symptoms such as pain, redness with localized swelling, and tenderness below the umbilicus may occur with infection and may be accompanied by chills, fever, irritative voiding symptoms, hematuria, and pyuria.

**FIGURE 106.2** The four types of abnormalities involving the urachus. **A:** Complete patency to the umbilicus. **B:** A blind-ending urachal sinus open at the umbilicus but not complete to the bladder. **C:** A urachal cyst without communication to either the umbilicus or the bladder. **D:** Simple diverticulum from the dome of the bladder.

**FIGURE 106.3** Patent urachus.

**FIGURE 106.4** Abdominal ultrasound that demonstrates an infected urachal cyst.

Alternatively, symptoms may arise as the result of mass effect due to a large urachal cyst. These patients present with a sensation of abdominal fullness or pain, a mass, or irritative voiding symptoms due to compression of the bladder. Diagnosis is most easily confirmed by ultrasound or computed tomography (CT).

Incomplete closure of the urachus may also result in a urachal sinus. This may be the result of a urachal cyst that extended either to the bladder or to the skin for drainage. Some urachal sinuses may alternate and at first drain at the umbilicus and then later into the bladder. Presenting symptoms may include periumbilical redness and tenderness with intermittent drainage, umbilical irritation or granulation tissue, or symptoms of urinary tract infection. Clinical suspicion of a urachal sinus may be confirmed by a sinogram or ultrasound. A cystogram may show an irregular area at the dome of the bladder. Cystoscopy may demonstrate an inflamed area at the dome that may extrude purulent drainage.

A urachal diverticulum results from failure of closure of the urachus adjacent to the bladder, leaving a wide-mouth diverticulum at the dome of the bladder. The urachal diverticulum may or may not be associated with bladder outlet obstruction, as has been often reported in patients with prune belly syndrome. In general, aside from treatment for any coexisting bladder outlet obstruction, the urachal diverticulum requires no specific management as it usually drains well.

Omphalomesenteric disorders may be confused with urachal anomalies. The omphalomesenteric duct is a fetal structure that connects the yolk sac and the gut. Incomplete closure of this tubular structure may lead to a patent omphalomesenteric duct, an omphalomesenteric sinus, or an omphalomesenteric cyst. A patent duct may be characterized by the drainage of intestinal fluid or fecal material. A sinogram should demonstrate a connection to the gastrointestinal tract.

Malignant lesions of the urachus are rare; however, the cancer risk does increase with advancing adult age (8). The most common sign of urachal cancer is hematuria. Patients may also present with a suprapubic mass, abdominal pain, irritative voiding symptoms, or mucus in the urine. The diagnosis may be made by identification of a filling defect at the dome of the bladder with calcifications on intravenous urogram or cystogram, CT, and cystoscopy with transurethral biopsy. Adenocarcinoma is the most common malignancy; however, sarcoma and transitional cell carcinoma have been reported (9).

---

## INDICATIONS FOR SURGERY

---

Surgical management is central to the treatment of urachal anomalies with the exception of infants under 6 months of age, in whom the anomalies may resolve spontaneously, and the wide-mouth diverticulum, which in general requires no treatment (10). In the patient with a persistently patent urachus beyond 6 months of age, surgical excision is recommended because of the risk of recurrent infections, stone formation, and persistent umbilical drainage, excoriation, and pain.

Urachal cysts that are symptomatic due to size or infection also merit surgical treatment. Incidentally discovered small, asymptomatic urachal cysts may be excised at the time of discovery or watched for the development of symptoms or progressive enlargement. With infected cysts, initial antibiotic

therapy with possible drainage followed by delayed excision may be required. Similarly, in the case of the urachal sinus initial treatment should focus on the eradication of any infection before excision is undertaken.

Treatment of urachal malignancy follows the principles of treatment for any malignancy of the bladder and is discussed elsewhere in this book.

---

## SURGICAL TECHNIQUE

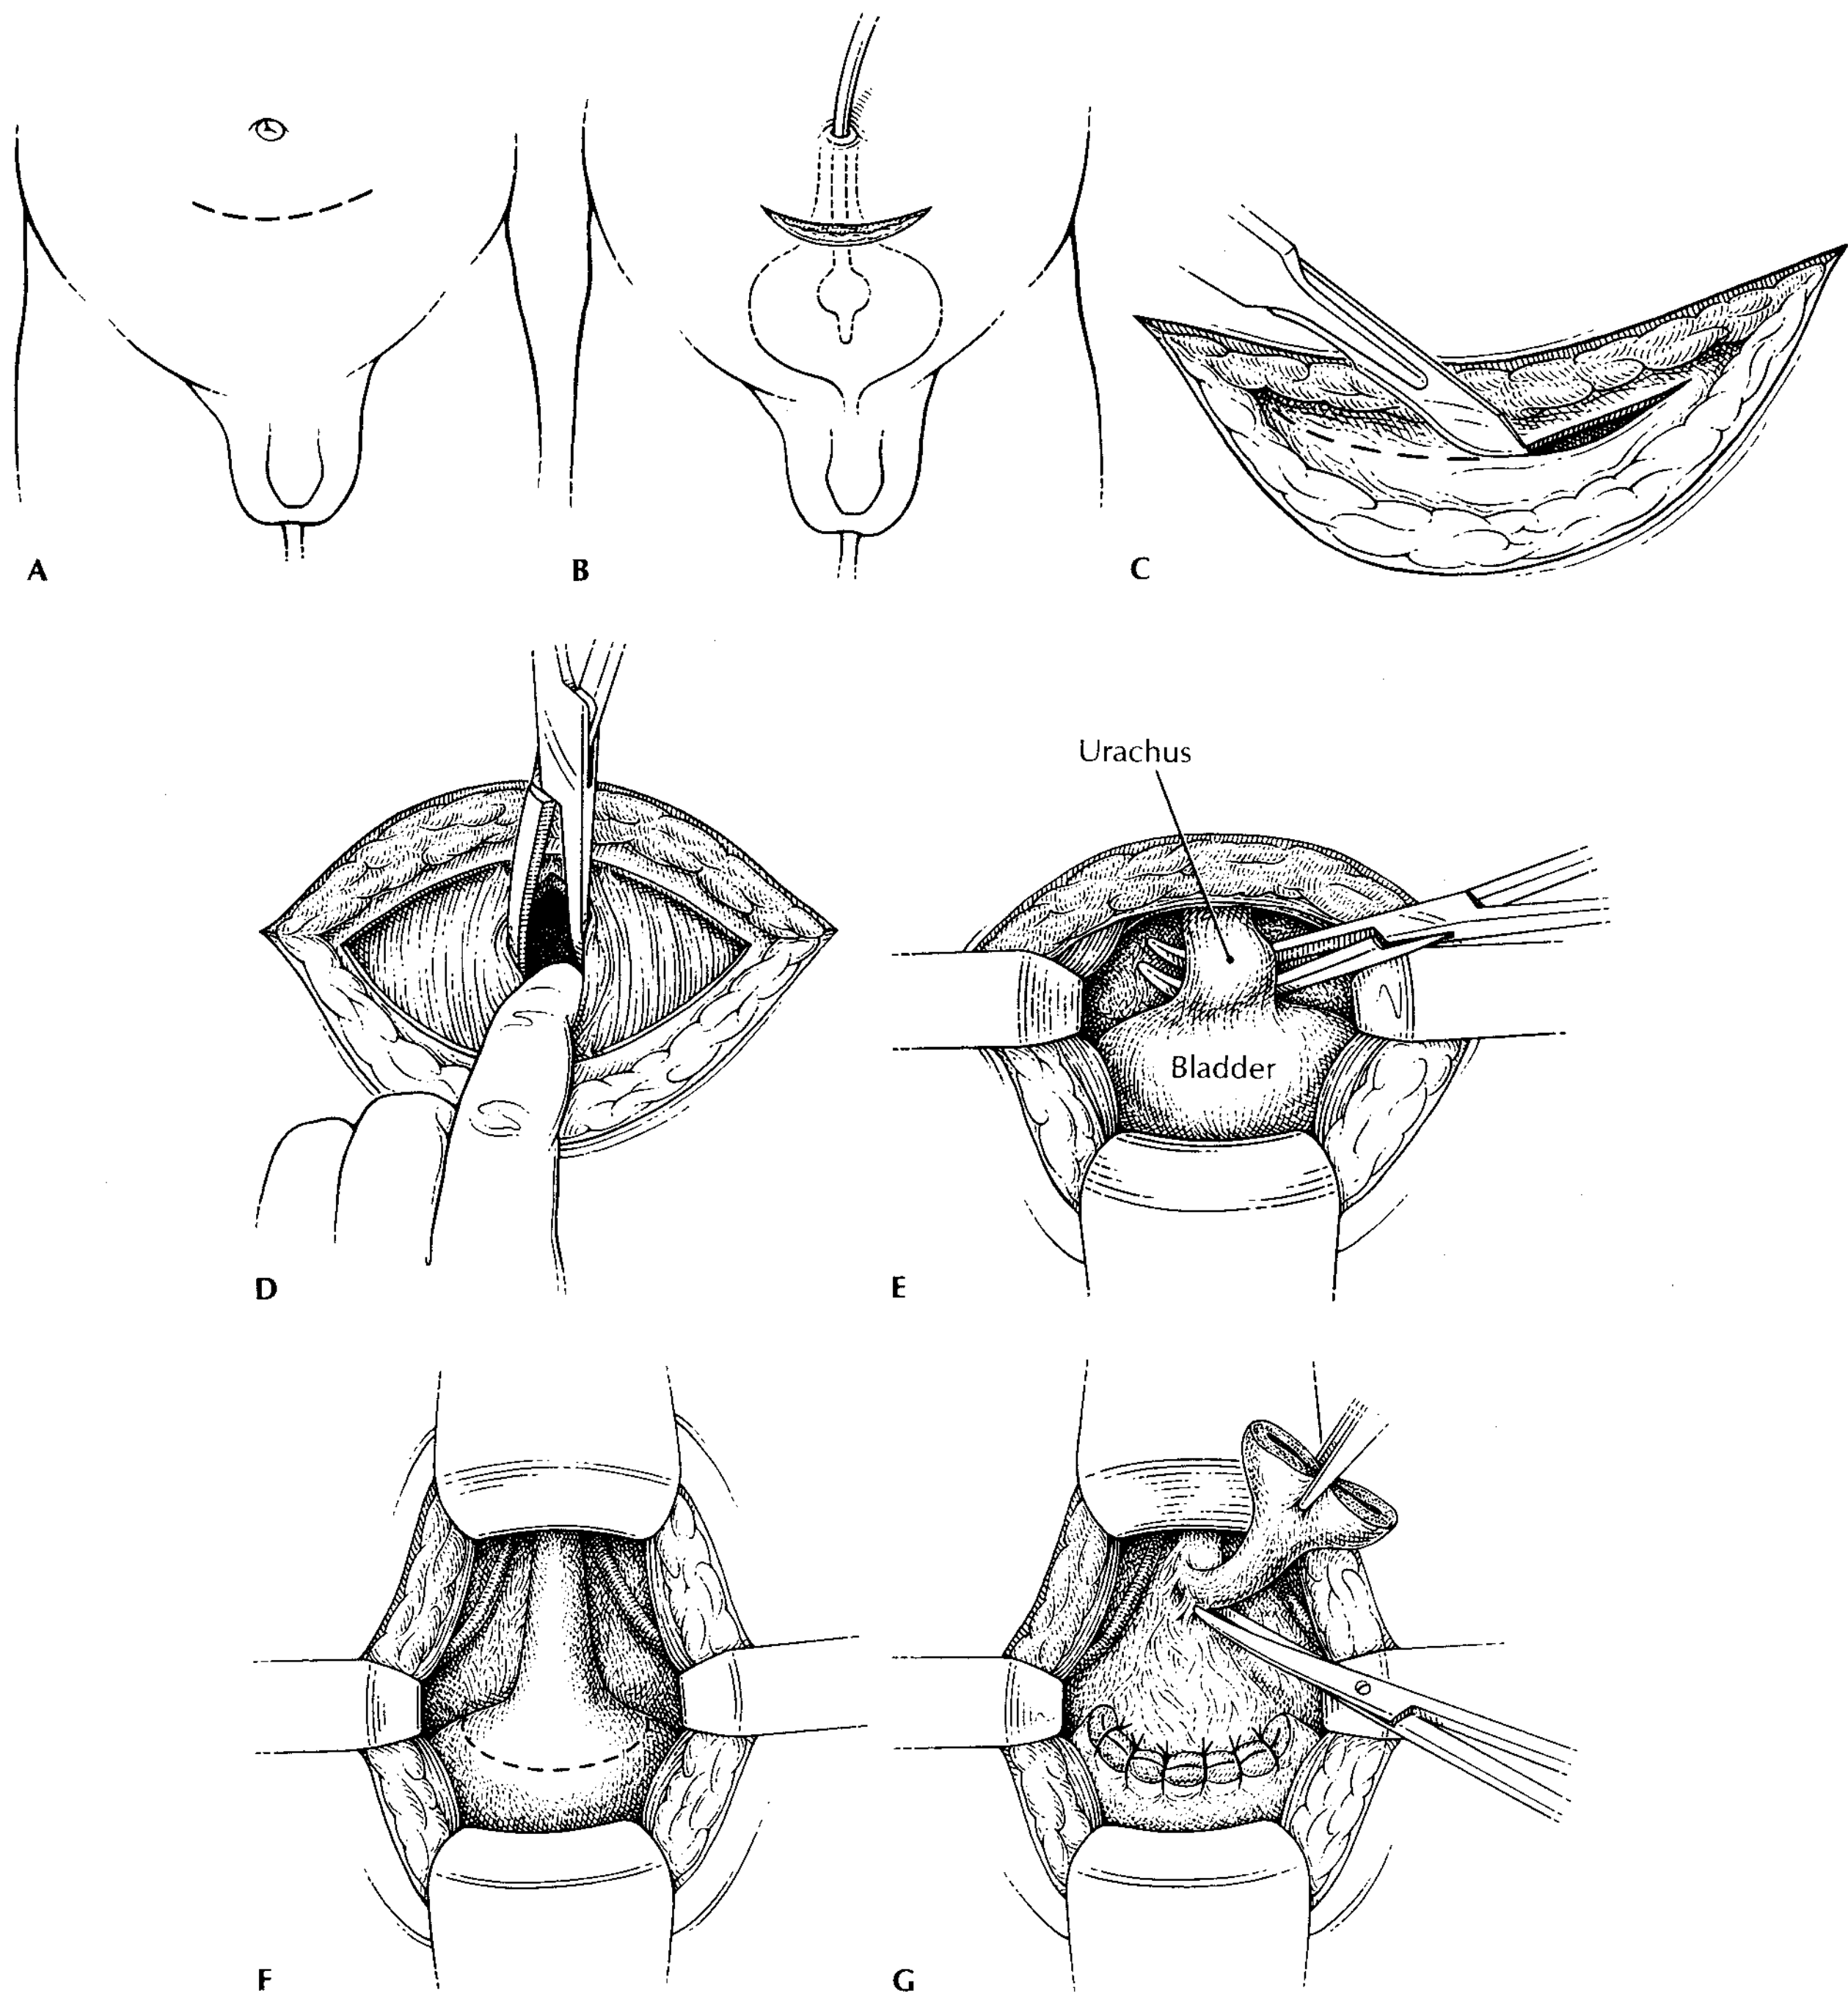

---

For the patent urachus, urachal cyst, alternating urachal sinus, or urachal diverticulum requiring correction, the patient is placed in a supine position. If possible, a small catheter, guide wire, or probe is placed through the patent urachus (Fig. 106.5). If nothing will pass, the tract may be stained with methylene blue for later identification. A Foley catheter should be placed in the bladder and the bladder distended with sterile saline to bring the anterior bladder wall up to the abdominal wall and, in doing so, push the peritoneum cephalad.

The urachus may be approached via a vertical midline incision or a transverse infraumbilical incision one-half to two-thirds the distance from the symphysis pubis to the umbilicus. Although the transverse infraumbilical incision will result in excellent exposure, alternatively a vertical midline incision along the course of the urachus may be more direct and can allow for extension to the umbilicus in a cosmetic fashion, should this be required because of difficulty in procuring the umbilical end of the urachus or for any additional necessary procedures. The rectus fascia is opened and the dome of the bladder is identified. The urachus is identified and isolated. Once the proximal portion of the urachus is delineated, it is resected along with a small cuff of bladder to prevent a residual diverticulum. The bladder is then closed in two layers. Dissection then proceeds toward the umbilicus. The operation is facilitated by identifying the proper plane of dissection between the peritoneum posterior to the urachus and the posterior rectus fascia, which is anterior to the urachus. In this same plane will lie the obliterated umbilical arteries, which may be ligated proximally on the bladder wall or distally at the umbilicus.

Infected urachal remnant structures, such as urachal cyst or sinus, may present a more challenging dissection. In fact, it is sometimes advisable to drain a large infected urachal cyst initially percutaneously and allow a period for antibiotic therapy to reduce the local inflammation. Smaller infected urachal cysts or sinuses, however, can be managed safely as a single procedure. With these infected remnants, it may be impossible to dissect the urachus away from contiguous structures. For instance, a larger portion of the bladder may need to be removed with the infected urachal cyst. Similarly, one may find it impossible to separate the infected cyst or sinus from the underlying peritoneum. One should be extremely careful in identifying adherent loops of bowel that may have been involved in the inflammatory process and could easily be injured.

Once the urachus is completely dissected distally it is excised or ligated at its obliterated point. The goal is to remove all urachal tissue and leave the umbilicus intact. If an umbilical hernia is present, it may be corrected concurrently. A catheter may be left in the bladder and a drain in the prevesical space postoperatively at the surgeon's discretion.

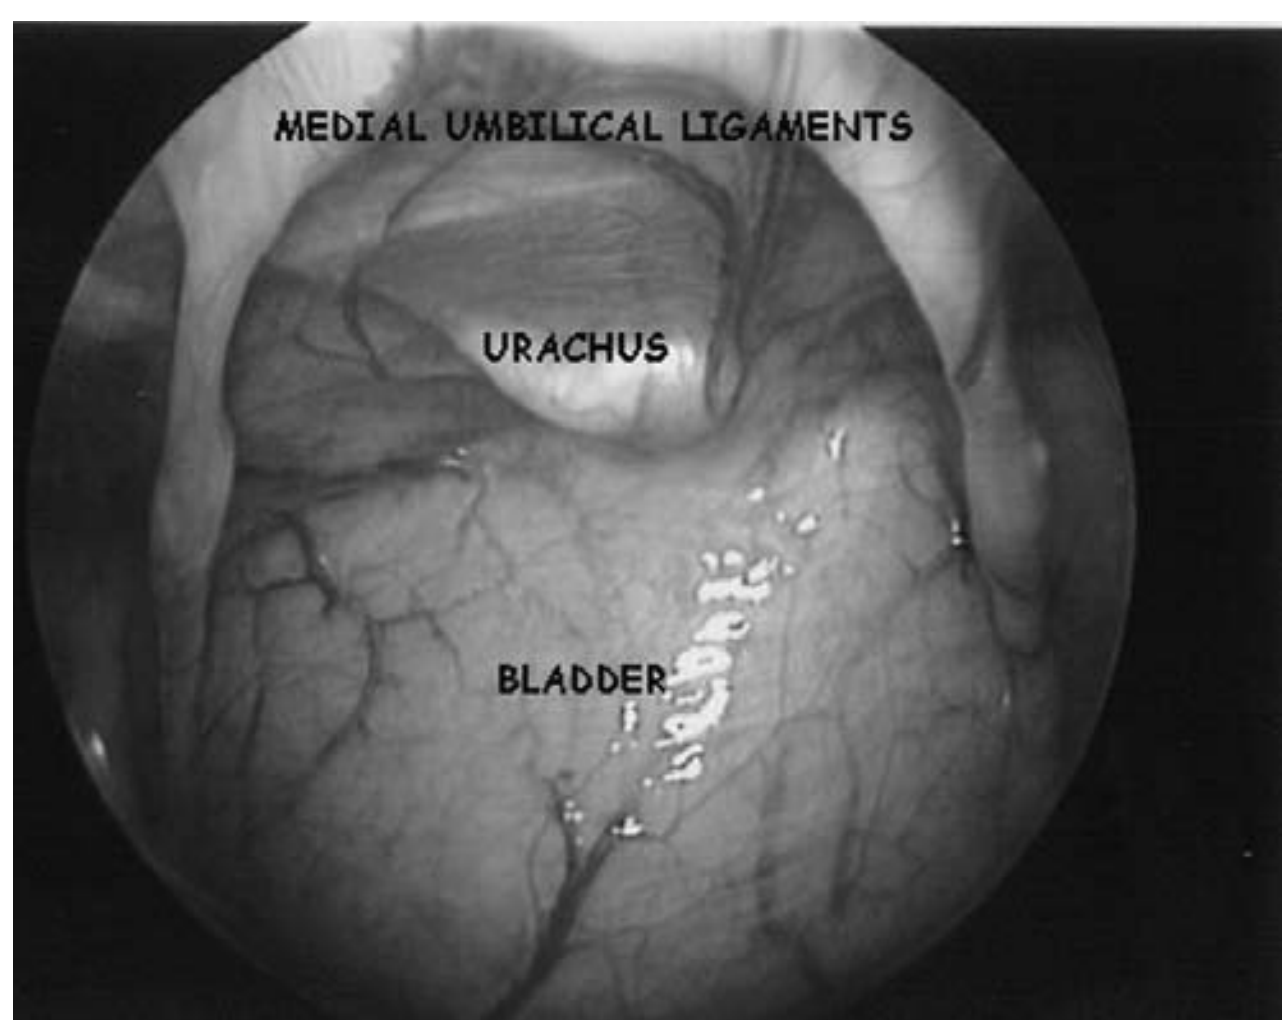

**FIGURE 106.5** **A and B:** Typical transverse infraumbilical approach to the urachus. The catheter through the urachus can aid in identification of a patency. **C and D:** The fascia is divided transversely and the rectus muscle is parted in the midline, remaining preperitoneal. **E:** The urachus or urachal remnant can be separated from the peritoneum and identified in its proximal and distal extent. **F and G:** The urachus is resected with a cuff of bladder and the bladder closed in a watertight fashion. The urachus is removed completely out to the umbilicus if necessary.

For the urachal sinus draining at the umbilicus, dissection is begun by circumscribing the sinus, again with the goal of preserving as much of the umbilicus as possible. The obliterated umbilical arteries are ligated as they are encountered. The tract is dissected to its termination and excised, and the area is drained because the sinus tract is usually infected.

An alternative to open surgical treatment is laparoscopic treatment. Laparoscopic treatment, including robotic treatment,

has been reported in both children and adults with excellent visualization and access to the urachal remnant (Fig. 106.6) (11,12). Port placement may vary by surgeon preference; however, in general, the first port is placed using open Hasson technique in the midline halfway between the umbilicus and the xiphoid process, and two additional ports are placed under direct vision on each anterior axillary line just above the umbilicus, creating an angle of approximately 45 degrees between

**FIGURE 106.6** Typical view of the bladder and urachus during laparoscopy with a 30-degree telescope, showing the urachus, bladder, and medial umbilical ligaments.

the working ports. The procedure then follows the principles as outlined previously for open surgery.

---

## OUTCOMES

---

### Complications

---

Postoperative complications include persistent urinary drainage, which can be managed by prolonged bladder catheter drainage, and infection, which is generally superficial and responds well to antibiotic therapy. With laparoscopic procedures, the reported complications are most often port-related, and therefore, open Hasson technique for initial port placement is recommended.

# CHAPTER 107 ■ VESICAL NECK RECONSTRUCTION

JOHN C. POPE IV AND JOHN H. MAKARI

Prior to toilet training, the functions of the lower urinary tract include storage of urine at low pressure and good emptying. The result is protection of the upper tract and avoidance of urinary tract infection. Adequate outflow resistance is not necessary during that time, but is eventually critical to achieve urinary continence, another ultimate function of the lower tract. Congenital anomalies resulting in inadequate outflow resistance, and thus failure to achieve urinary continence, can in general be divided into two groups based on pathophysiology. In the first group there is an anatomic or developmental abnormality where the bladder outlet is malformed and incapable of providing adequate resistance. This group would include patients

with bladder exstrophy, bilateral single ectopic ureters, persistent cloaca, and rarely an extensive ureterocele. In the second, more common, group involving neurogenic dysfunction, the outlet is normally developed from an anatomic standpoint, but abnormal neurologic control results in inadequate function.

---

## DIAGNOSIS

---

When urinary continence is not achieved in children, the critical evaluation is video urodynamic study of the bladder and outlet. Parameters that need to be evaluated include sphincteric

function, outflow resistance, detrusor function, and bladder compliance.

Monitoring of external urinary sphincter activity is helpful during studies of storage and emptying. Perineal surface electrodes are most widely used to evaluate the activity; however, in children with neurogenic dysfunction who tolerate placement, a concentric needle electrode or dual electrodes placed through a 25-gauge needle increase accuracy.

The functional length and pressure of the external sphincter are important and can be measured with urethral pressure profilometry. This measurement is technically challenging in a small child and there are no adequate standard nomograms for urethral pressure profilometry to use in pediatric patients. Continuous monitoring of the urethral pressure during filling in the area of maximum resistance may demonstrate an etiology of incontinence. Some surgeons also use leak point pressure to evaluate outflow resistance during passive filling and performance of Valsalva maneuvers. Simultaneous fluoroscopic observation is advantageous.

Detrusor function should be evaluated by the cystometrogram, synergistic relaxation of the external sphincter on electromyography, urinary flow rate, and measurement of postvoid residual urine. Bladder compliance should also be evaluated with the detrusor pressure measured as the bladder is filled with warm saline or contrast (37°C) at a rate equal to or <10% of estimated or known bladder capacity. Such filling minimizes irritation of the bladder, which may artifactually increase bladder pressure. Other artifacts that affect the measurement of compliance such as urinary infections or low urethral resistance should be eliminated to obtain the best results.

Before reconstructive surgery on the bladder is considered, the status of the patient's upper urinary tract should also be evaluated. Standard evaluation includes renal ultrasonography and serum electrolytes, including creatinine. If hydronephrosis is present, renography should be obtained to rule out obstruction. Vesicoureteral reflux should be sought on voiding cystourethrography, often at the time of video urodynamic evaluation. Any upper-tract obstruction or reflux should be corrected at the time of lower urinary tract reconstruction.

Unfortunately, no test ensures that a patient will be able to void spontaneously and empty well after outlet reconstruction with or without bladder augmentation. All patients must be prepared to perform clean intermittent catheterization before considering reconstruction. The native urethra should, therefore, be examined for the ease and discomfort of catheterization.

---

## INDICATIONS FOR SURGERY

---

If urinary continence is not achieved at an appropriate age in patients with congenital anomalies, and the patient has failed behavioral regimens such as timed voiding, had urodynamics, and failed all medical regimens and other conservative therapies (e.g., intermittent catheterizations), then surgical intervention should be considered. It is critical to ensure that the bladder is a compliant storage reservoir prior to any reconstructive procedure on the lower urinary tract. Increasing outflow resistance in the presence of inadequate bladder capacity would put the patient at significant risk for upper-tract deterioration and febrile urinary tract infection. Determining the commitment of the patient and family to achieve a good result

with reconstructive surgery, including a willingness to perform intermittent catheterization if necessary, is critical.

---

## ALTERNATIVE THERAPY

---

In few areas of reconstructive urology are there as many choices to consider as for bladder neck repair and as little consensus as to which repair is appropriate for a given patient or setting. One reason for the variety of choices is the wide range of patients and problems for which the procedures are used. In some cases, the procedure to increase outflow resistance may logically be chosen based on particular patient considerations, but the experience and confidence of the surgeon with a given technique also may play a significant role in the choice.

Conceptually, techniques to increase outflow resistance may be considered as one of two general types. The first set of repairs is used to improve the function of the native outlet, while the second set is designed to repair the anatomy and functionally alter the outlet. Several procedures that may provide benefit and are occasionally used include urethral suspensions, injection of bulking agents, artificial sphincters, and obliteration of the bladder neck.

One of the first bladder neck repairs to function in such a manner was the urethral suspension described by Marshall, Marchetti, and Krantz and since modified by numerous surgeons. While these procedures have been successful in treating stress urinary incontinence among neurologically normal female patients, they have had minimal effect and are rarely indicated for pediatric patients with congenital anatomic anomalies of the outlet or neurogenic dysfunction.

Recently, transurethral injection of bulking agents has been tried to improve the function of the existing outlet. Initially, the use of polytetrafluoroethylene and later, the use of bovine collagen were reported. More recently, the availability of dextranomer/hyaluronic acid copolymer has renewed interest in injection therapy for increasing bladder outlet resistance and for correction of sphincteric incontinence. Injection therapy is relatively simple and avoids any incision, but has met with limited results for significant outlet anomalies (1). Further, the durability of this approach is a concern, as declining rates of dryness and/or improvement are observed even years after treatment (2). Injection therapy may, however, be useful after primary repairs in patients who have some persistent incontinence (2,3).

The most definitive procedure to improve the function of the outlet as it exists is placement of an artificial urinary sphincter. This group of procedures would seem appropriate for patients with a normal or near-normal outlet from an anatomic standpoint and to have little role for patients with significant anatomic anomalies such as bladder exstrophy or bilateral single ectopic ureters.

The ultimate procedure to increase outlet resistance is division of the bladder neck. Effective closure requires extensive mobilization of the bladder and bladder neck away from the urethra with interposition of omentum between. It must be accompanied by construction of a continent abdominal wall stoma for bladder catheterization and effectively moves the reconstruction into the realm of continent urinary diversion. Division of the bladder neck has in general been reserved for complex patients who have failed multiple prior procedures to effectively increase outflow resistance; however, it may be performed in select patients as primary definitive management.

Extremely high success rates have been reported for both primary or secondary management when the previous principles are followed (4).

## SURGICAL TECHNIQUE

### Fascial Sling for Bladder Neck Suspension

In adults, fascial slings may be performed transvaginally, and a small patch of fascia is secured with suspension sutures. In pediatric patients with congenital anomalies, fascial slings have in general been placed from above, often at the time of bladder augmentation. Before placement, the pelvic floor is cleared of overlying fatty tissue and a 2-cm incision made through the endopelvic fascia on either side of the bladder neck and proximal urethra (Fig. 107.1A). This area may be identified by palpation of a transurethral catheter and balloon seated at the bladder neck. Using blunt dissection, a plane is developed between the bladder neck and vagina in girls or rectum in boys (Fig. 107.1B). This plane may at times be more easily developed from the cul-de-sac by dissecting behind the bladder and ureters from above. With a difficult dissection it may be useful to open the bladder, in particular if bladder augmentation is planned.

Once the proper plane is developed and the appropriate length of graft determined, a rectus abdominis fascial strip 1 cm in width and appropriate in length is harvested. The fascia may be taken in either a vertical or horizontal fashion depending on the initial incision. Fascia from other sites has been utilized but requires a second incision. Autologous cadaveric tissue or biodegradable scaffolds may also be used.

All of the grafts are in general brought through the rectus muscle and anterior rectus fascia on either side and approximated to the anterior rectus fascia using permanent sutures (Fig. 107.1C). If long enough, the two limbs of the sling may also be approximated to each other superficial to the fascia. In patients with stress incontinence, the sling is placed tightly enough to maintain the proximal urethra and bladder neck in the appropriate anatomic position. Too snug of placement in such a setting may impede spontaneous voiding. When used for patients with neurogenic dysfunction who will not rely on spontaneous voiding, the sling may be pulled up more tightly to improve compression of the bladder neck and proximal urethra. If intermittent catheterization will be performed postoperatively through the native urethra, intraoperative catheterization should be repeated frequently to make sure the fascial sling is not placed so tightly as to impede catheterization.

A

B

C

**FIGURE 107.1** Pubovaginal sling. **A:** The endopelvic fascia is cleared of fatty tissue and a 2-cm incision made on either side of the urethra. A Foley catheter through the urethra may be palpated for identification of the urethra and bladder neck. **B:** The plane between the posterior urethra and anterior vagina is carefully developed using a right-angle clamp. **C:** A fascial strip 1 cm wide is passed through the anterior rectus fascia and rectus muscle lateral to the midline incision. It is secured on the left to the anterior fascia. The sling is then passed behind the bladder and will be brought through the right rectus muscle and fascia to be secured at the proper tension.

## Young–Dees–Leadbetter Bladder Neck Repair

Often done after bladder exstrophy closure, the procedure is typically performed through a lower midline incision. For patients with epispadias who do not require augmentation, the reconstruction may be done through a Pfannenstiel incision. The anterior bladder is opened. This incision is carried as far distally into the proximal urethra as possible. Splitting of the intersymphyseal band with subsequent closure may allow closure and tapering of the proximal urethra. Virtually all exstrophy patients require antireflux surgery, and typically the ureteral hiatus is initially quite low in the bladder. The ureters are mobilized and reimplanted into the bladder 3 to 4 cm more cephalad in location. Typically, the ureters are reimplanted with a cross-trigonal technique, although the tunnels may even be angled upward in a cephalad direction from the new hiatus. A 12- to 15-mm-wide strip of mucosa is preserved in the posterior midline of the urethra and bladder trigone for reconstruction of the neourethra. Parallel incisions through mucosa are made on either side of this strip and the triangles of trigone mucosa on either side are excised (Fig. 107.2A). Submucosal infiltration of

dilute epinephrine in those two areas may aid in excision and decrease bleeding. The midline strip of mucosa and the subsequent neourethra are typically made 4 to 6 cm long, depending on how much proximal urethra is exposed and reconstructed. The midline strip is tubularized over an 8Fr catheter using absorbable sutures to approximate the edges. This tubularization may be done with interrupted or running absorbable sutures but should be tension free (Fig. 107.2B). Small portions of the adjacent superficial muscle of the trigone may be included with the mucosa for strength. The closure is easier to begin distally and finished cephalad. The lateral flaps of trigone muscle are then wrapped over the neourethra in an overlapping fashion. To do so without tension, the muscle must be incised transversely at the cephalad margin of the mucosal excision. One flap of muscle is wrapped over the neourethra and approximated to the underside of the other muscle flap using interrupted, absorbable mattress sutures. The second flap of muscle is then wrapped over the first and approximated to the outside of the muscle, again with absorbable sutures (Fig. 107.2C). A soft urethral catheter is left in place during healing but should be secured so as to avoid tension on the neourethra. Ureteral stents or catheters are often left in place because of potential edema. The bladder is closed in two layers.

**FIGURE 107.2** Young–Dees bladder neck repair. **A:** The trigone mucosa is incised to leave a posterior, central strip of mucosa 15 mm wide. The triangles of mucosa on either side are excised. The ureters have previously been reimplanted in a more cephalad position. **B:** The central mucosa strip is tubularized using a running absorbable suture. **C:** The lateral trigone muscle flaps are closed in an overlapping fashion around the neourethra. **D:** After completion of the bladder and urethral closure, several pairs of suspension sutures secure the urethra and bladder to the underside of the intersymphyseal band and lower abdominal wall.

**FIGURE 107.3** Leadbetter modification of Young–Dees–Leadbetter bladder neck repair. **A:** Full-thickness parallel incisions are made through the trigone mucosa and muscle, leaving a central strip 15 mm wide. **B:** The mucosa of the neourethra is tubularized using a running absorbable suture. The muscle is then closed. The lateral flaps of trigone are left in continuity with the bladder.

If bladder augmentation is required, the bladder should be closed to itself for a short distance from the urethra prior to applying the bowel segment. A clear demarcation between the neourethra and bladder can often be seen after closure. Care should be taken that there is effective closure of the urethra and bladder at this junction. The bladder may tend to kink over the urethra at that level, and the neourethra and new bladder neck should be suspended to the undersurface of the intersymphyseal band and lower abdominal wall using several pairs of sutures as described for the Marshall–Marchetti–Krantz procedure (Fig. 107.2D).

Alternatively, Leadbetter described full-thickness, parallel incisions through the trigone mucosa and muscle on either side of the central strip. These incisions, again made 12 to 15 mm apart, are started distally at the old bladder neck and continued in a cephalad direction for 4 to 5 cm (Fig. 107.3A). The central strip of mucosa is tubularized with interrupted or running absorbable sutures. The muscle of the central strip is closed as a second layer. If the incision through the muscle is made slightly wider than on the mucosa, the muscle may be approximated in an overlapping manner but to a lesser degree than that described by Young and Dees. The lateral triangles of full-thickness trigone are left in continuity with the bladder and included in that closure (Fig. 107.3B).

### Kropp Urethral Lengthening Procedure

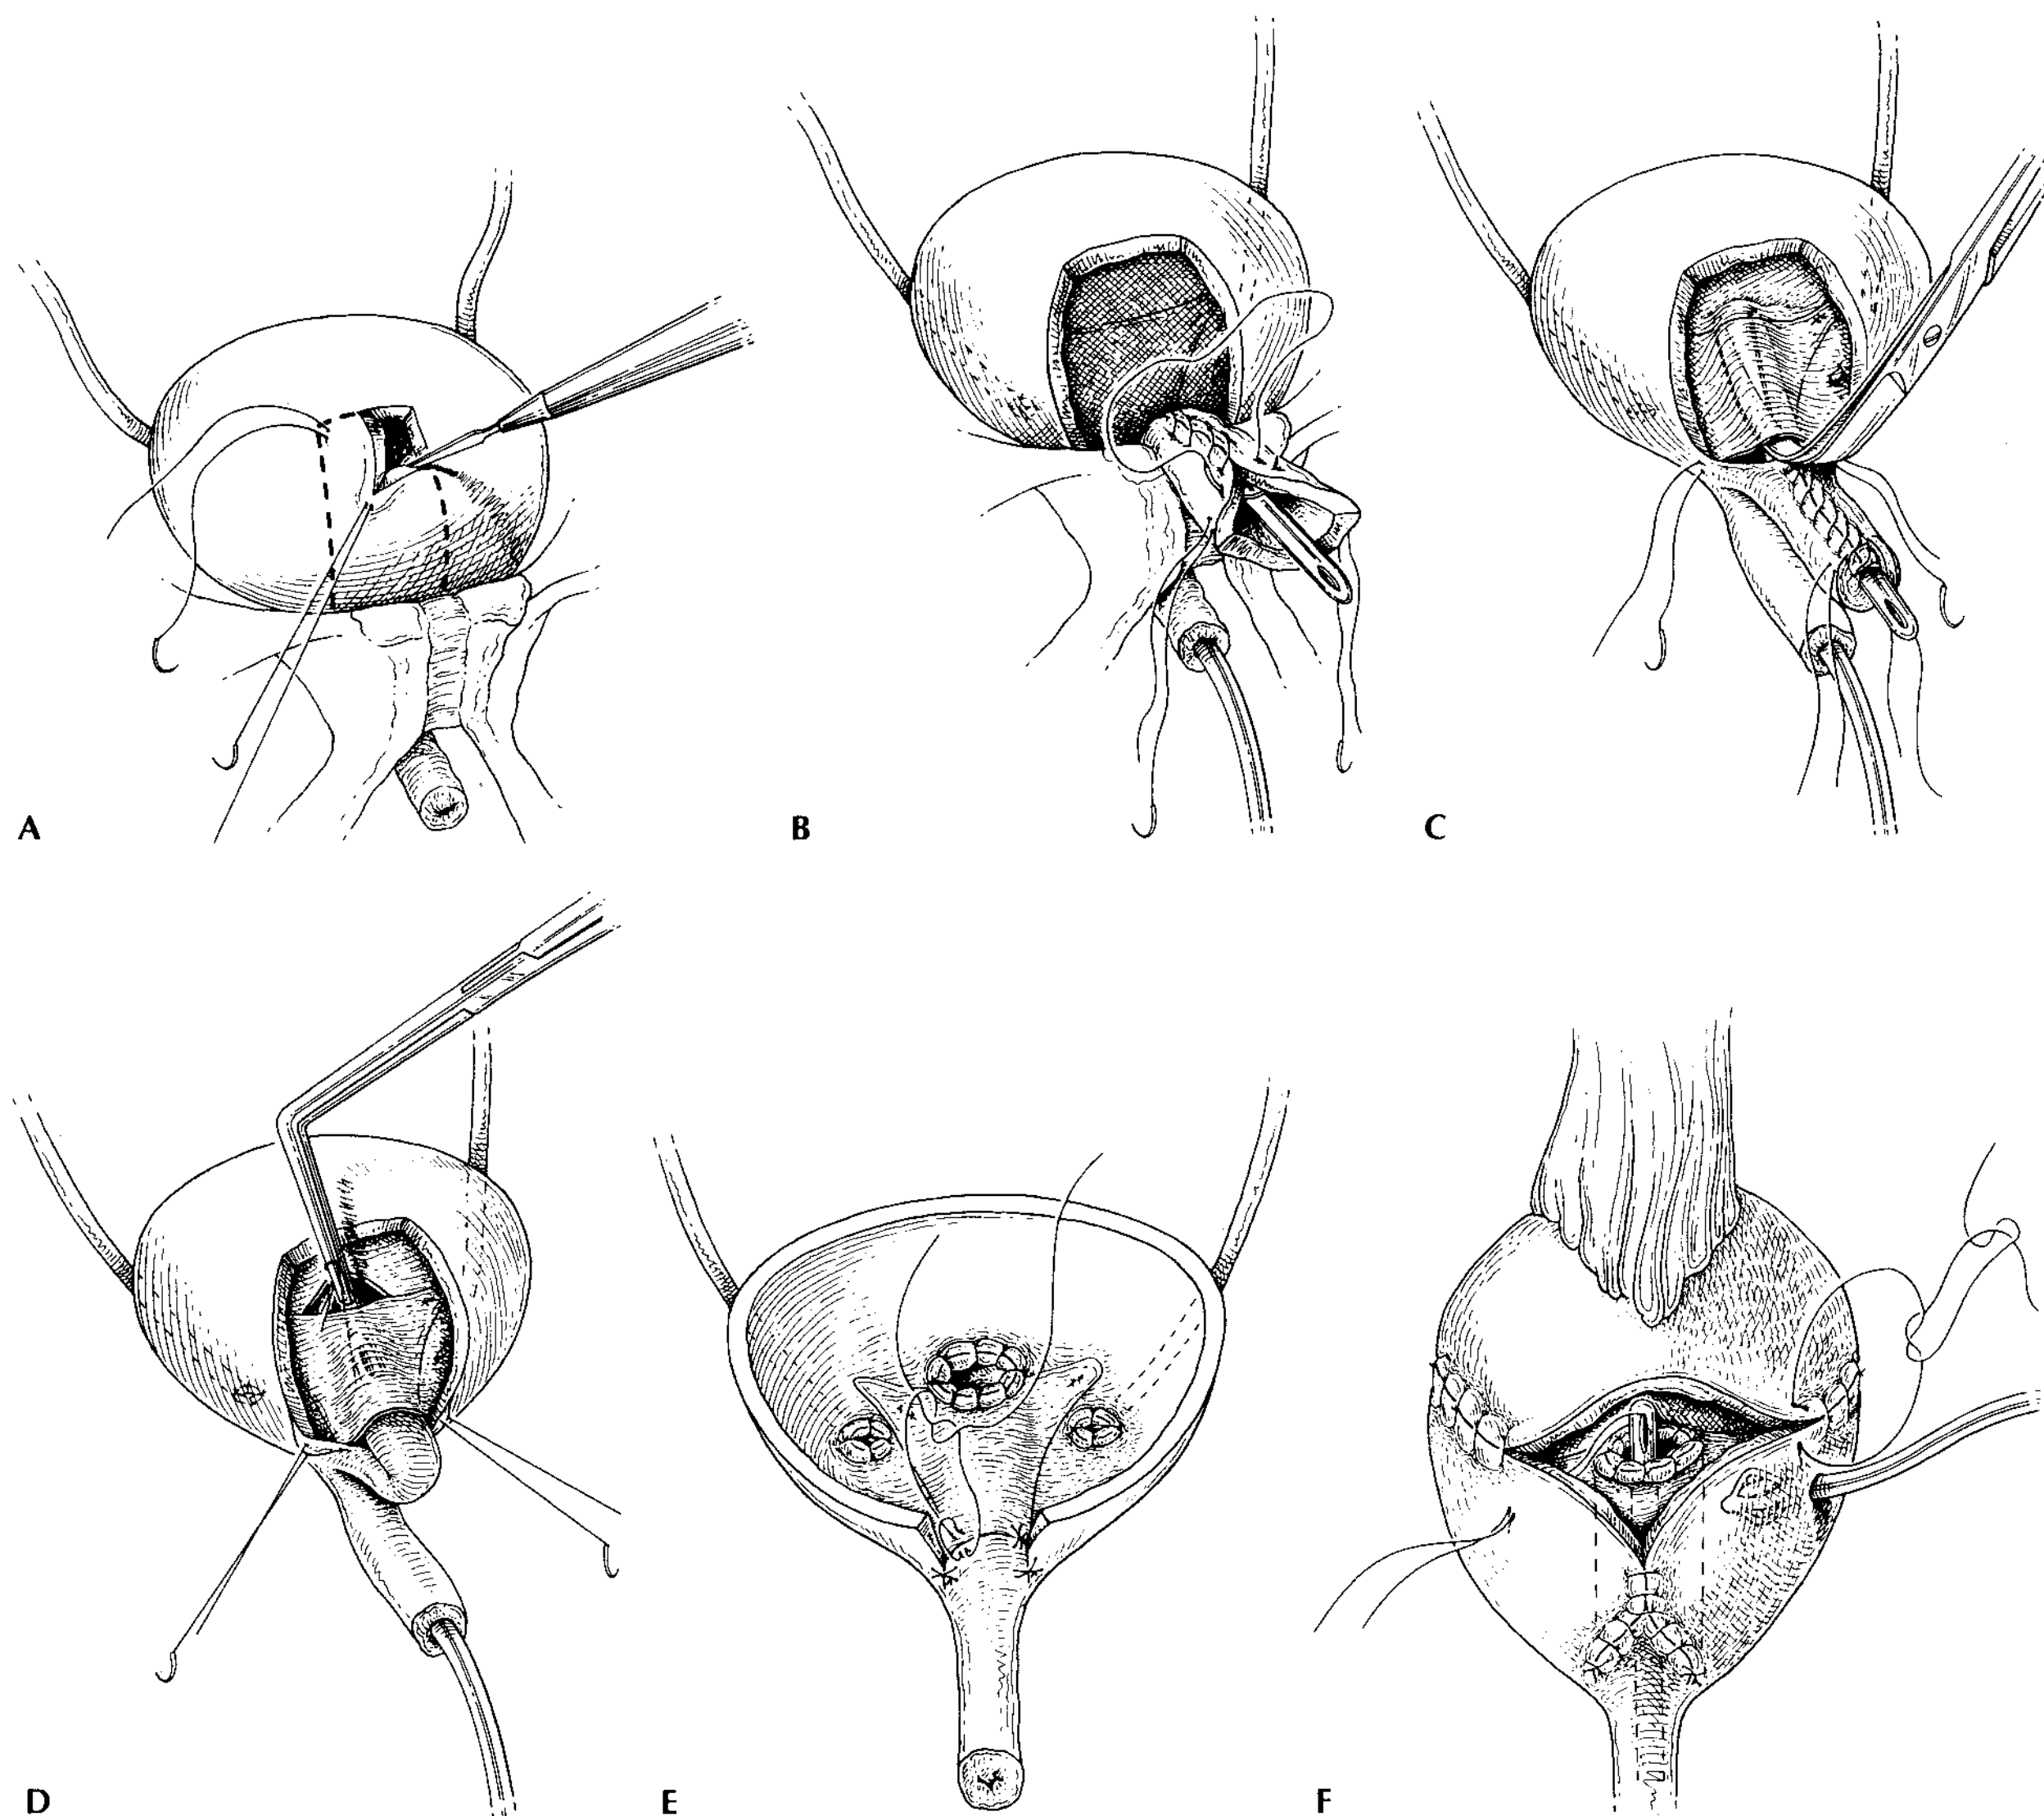

The bladder is exposed through a lower midline incision and the bladder neck is identified by palpation of a catheter placed through the urethra. A rectangular, full-thickness strip of anterior bladder is marked and incised. This strip is based at the bladder neck and should be left in continuity with the urethra (5). The incised strip measures 6 cm in length and 2 cm in width (Fig. 107.4A). Stay sutures placed at the cephalad corners of the strip aid in mobilization. The bladder cephalad to the strip is opened in the midline. After anterior incision, the catheter is pulled over the pubis to expose the posterior bladder neck. This allows identification of the ureteral orifices, which are catheterized. If reflux is not present and the space

between the orifices is adequate for urethral tunneling, ureteral reimplantation may not be necessary. The ureteral stents are often left in place for 4 to 5 days due to edema. Posterior incision of the mucosa at the bladder neck is performed using cutting current with the electro-surgical cautery to completely separate the neourethra from the bladder at the mucosal level. Further dissection through the posterior muscle in the midline is performed to allow smooth tubularization of the neourethra. Posterolateral musculoadventitial tissue at the 5 and 7 o'clock positions is left intact so that the bladder remains anchored in a caudal position. This eventually ensures that the tubularized neourethra reaches well into the bladder lumen to achieve an effective flap valve.

The anterior bladder flap in continuity with the urethra is tubularized by approximating the mucosa and then the muscle with continuous absorbable sutures (Fig. 107.4B). This closure is again begun distally and continued in a proximal or cephalad direction.

A submucosal tunnel is developed from the posterior bladder neck to a position several centimeters above the interureteric ridge (Fig. 107.4C). The more cephalad portion of this tunnel is easily developed from above and the more distal or caudal portion is typically developed from the bladder neck (Fig. 107.4D). This tunnel must be made wide enough that the neourethra can be brought through in a nice smooth course. Care must be taken that there is no kink whatsoever at the entrance of the neourethra into the bladder at the area of the old bladder neck. Any kinking at that level will result in difficult catheterization.

Alternatively, the mucosa in the posterior midline may be incised for the entire length for the proposed tunnel. The mucosa on either side is then mobilized to create a wide trough into which to place the urethra. The mucosa from either side is then approximated to the adventitia of the neourethra and will eventually grow to cover it completely. The tubularized neourethra should not be redundant in length relative to the submucosal tunnel to minimize the risk of difficult catheterization. If necessary, excess length may be excised. The proximal end of the neourethra is approximated to the bladder mucosa at its orifice with interrupted absorbable suture (Fig. 107.4E).

**FIGURE 107.4** Kropp procedure for urethral lengthening. **A:** A 6 × 2-cm flap of anterior bladder is mobilized in continuity with the urethra. **B:** The flap is tubularized. **C:** The posterior mucosa is incised transversely at the bladder neck and a tunnel created for the neourethra from the old bladder neck to a position above the interureteric ridge. **D:** The neourethra is brought through the tunnel, taking care that it does not kink. Note that the posterolateral musculo-adventitial tissue is intact and keeps the bladder anchored distally. **E:** The proximal end of the neourethra is trimmed flush with its orifice in the bladder. The end is approximated to the vesical mucosa circumferentially. **F:** The bladder is carefully closed distally by approximating the bladder muscle and mucosa to the adventitia of the neourethra. The neourethra extends well into the lumen of the bladder to create an effective flap valve. Bladder augmentation is performed when necessary.

Distally, the lateral and anterior bladder is securely approximated to the adventitia and muscle of the urethra (Fig. 107.4F). This closure should be performed as distally as possible on the urethra to avoid foreshortening of the tunnel within the bladder. Ease of catheterization through the neourethra should be tested at each step of reconstruction and any problems addressed when noted. If augmentation of the bladder is necessary, the incision is extended and the peritoneal cavity entered. A short segment of distal bladder should be closed to itself up from the urethra prior to placing the segment for augmentation. A soft urethral catheter is left in place per urethra during healing. The catheter should be secured so as to avoid any pressure on the reconstructed urethra. The catheter is usually

left in place for 4 to 6 weeks during healing, often with a suprapubic cystostomy tube as well. After a static cystogram demonstrates no leakage and good healing, self-catheterization may begin.

---

### Pippi Salle Urethral Lengthening Procedure

---

In an effort to achieve the effective flap valve created with the Kropp procedure while decreasing the risk for problems with catheterization, Salle et al. (6) described a modification for urethral lengthening. The anterior bladder wall flap is used as an

**FIGURE 107.5** Pippi Salle procedure for urethral lengthening. **A:** A full-thickness, anterior bladder flap  $5 \times 1$  cm is marked and incised. Parallel incisions through the trigone mucosa posteriorly leave a central strip of similar length and width. **B:** The lateral trigone mucosa is mobilized to cover the neourethra. The mucosa of the anterior flap is approximated to the edge of the central mucosal strip using a running absorbable suture. **C:** The muscle of the anterior flap is approximated to the superficial trigone muscle on either side of the mucosal closure. **D:** The lateral mucosa is closed over the neourethra. **E:** The distal bladder is closed to itself and carefully to the urethra. **F:** Bladder augmentation is performed when necessary.

onlay and eventually contributes half of the circumference of the neourethra. Therefore, a full-thickness anterior bladder flap  $5 \times 1$  cm is mobilized in continuity with the bladder neck (Fig. 107.5A). One millimeter of mucosa on either side is excised to avoid overlapping suture lines. Two parallel incisions through the mucosa of the trigone are made so as to leave a central strip of mucosa 8 to 10 mm in width and 5 cm in length. The lateral trigone mucosa on either side is mobilized to eventually close over the neourethra. The mucosa of the anterior flap is approximated to the midline strip of trigone mucosa using a running absorbable suture started distally (Fig. 107.5B). The muscle of the anterior flap is approximated to the superficial muscle on either side of the central mucosa

(Fig. 107.5C). The trigone muscle on either side of the posterior mucosal strip may be incised superficially to provide an edge to which to sew the muscle of the anterior flap. Closure of the lateral mucosa of the trigone over the reconstructed neourethra creates a flap valve and a neourethra with an intact posterior wall (Fig. 107.5D,E). Distally, the muscle and mucosa of the bladder neck are approximated to the lateral and anterior adventitia and muscle of the neourethra as distally as possible. Proximally, the neourethra should extend well into the lumen of the bladder to create an effective flap-valve mechanism for continence. The neourethra and ureters are often stented temporarily in a manner similar to that described for the Kropp procedure (Fig. 107.5F).

---

## OUTCOMES

---

In the pediatric population, fascial slings have been used most extensively in patients with neurogenic sphincter incompetence. Long-term success with slings in that population has varied greatly, from 40% to 100%. Success rates have varied so much that it is not clear that any particular modification of the sling configuration results in any difference in terms of continence. Fascial slings have been used more extensively and with better results in girls with neurogenic dysfunction, in whom the continence rate may reach 75% (7). The primary factor predictive of success has been concomitant enterocystoplasty to ensure a compliant bladder. Placement does not in general interfere with the ability to perform intermittent catheterization, which is usually necessary in the patient population.

The Young–Dees–Leadbetter bladder neck repair has been used most commonly in the classic staged reconstruction for bladder exstrophy. Continence with spontaneous voiding has been achieved in up to 80% of patients with exstrophy and may be even higher for patients with epispadias (8). Other authors have reported a lower continence rate, and even among patients considered dry, clinical and urodynamic problems related to poor emptying may exist (9). When used for patients with neurogenic dysfunction and denervated sphincter muscle, the procedure initially resulted in continence in approximately 25% of patients, but the rate can be improved to almost 70% if combined with bladder augmentation (10,11). Due to the high percentage of additional procedures required, the repair has in general fallen out of favor for patients with neurogenic dysfunction. Reliable catheterization through the urethra after a Young–Dees–Leadbetter repair may be difficult.

The urethral lengthening procedures have primarily been used in boys with neurogenic bladder dysfunction. Using the technique described by Kropp, continence has been achieved in 75% to 90% of such patients (5,12). Difficulty with catheterization has been reported in 40% of male patients in some series, although that incidence may be lowered when the posterior urethra is not totally transected (12). Because of

concerns about the potential problem with catheterization, some surgeons prefer routine construction of a continent catheterizable stoma (13). A significant incidence of new reflux has been apparent in some series using the Kropp technique (13). Using the modification by Salle et al., less trouble with catheterization in male patients has been noted, although continence rates have not been quite as high (14,15). Urethrovesical fistula and partial necrosis of the intravesical neourethra have on occasion resulted in incontinence after the repair, and widening the base of the anterior flap at the level of the bladder neck may decrease those problems.

---

## Complications

---

Relatively common clinical problems after bladder neck reconstruction include urinary tract infection and bladder stones. Both may occur in exstrophy patients after Young–Dees–Leadbetter bladder neck repair due to poor emptying (9), but they are even more common among patients with neurogenic dysfunction requiring intermittent catheterization, in particular if bladder augmentation has been performed. The urethral sling and the artificial urinary sphincter possess unique complications that are related to their periurethral placement or mechanical and synthetic characteristics. Urethral erosion, although the rate is low with fascial slings and 5% to 15% with artificial urethral sphincters, is most commonly related to infection. Erosion is a leading cause for permanent failure of the artificial urinary sphincter. Additionally, mechanical problems or tissue atrophy at the cuff lead to artificial urinary sphincter revision rates of approximately one in four in modern series (16).

It is important to perform routine surveillance for hydronephrosis of the upper urinary tract with ultrasonography after any form of bladder neck repair. This is particularly true among patients with neurogenic dysfunction if they have not undergone bladder augmentation. Even if the bladder appeared adequate prior to outlet reconstruction, up to one quarter of patients may develop bladder hostility after an increase in outlet resistance, which may silently threaten the kidneys (17).

# CHAPTER 108 ■ SURGERY FOR POSTERIOR URETHRAL VALVES

ROSALIA MISSERI AND KENNETH I. GLASSBERG

A posterior urethral valve (PUV) is the most common cause of congenital bladder outlet obstruction in boys. It is associated with a dilated posterior urethra, poor urinary stream, and incomplete bladder emptying. Bilateral hydronephrosis of varying degrees is almost always present and frequently accompanied by vesicoureteral reflux and/or bladder diverticula.

---

## DIAGNOSIS

---

With the widespread use of antenatal ultrasound, PUVs are often diagnosed prenatally. The condition is suspected in utero when a male fetus is found to have bilateral hydronephrosis and a thick-walled bladder that does not empty completely on sonography. In addition, there may be a keyhole deformity noted on sonography. This is noted when a dilated bladder and posterior urethra is seen. In severely affected fetuses, oligohydramnios, pulmonary hypoplasia, and Potter syndrome may occur. Newborns may present with abdominal masses representing a distended bladder or hydronephrotic kidney, dry diapers, nonspecific gastrointestinal symptoms, respiratory distress, or urinary ascites. Younger boys usually present with urinary tract infection, respiratory distress, abdominal distention, sepsis, or azotemia, while older boys may present with dysfunctional voiding symptomatology, incontinence, poor urinary stream, urinary tract infections, or hematuria.

If a PUV is suspected in an infant, prophylactic antibiotics should be initiated and the bladder should be drained with a 5Fr or 8Fr feeding tube securely taped in place with a clear transparent dressing. Positioning is best confirmed with an abdominal radiograph as the tube may coil in the dilated posterior urethra. The feeding tube is left in place until a voiding cystourethrogram (VCUG) is obtained to make the diagnosis. In patients with severe hydronephrosis and/or azotemia, the catheter should be left in place until the azotemia resolves/stabilizes and hydronephrosis improves.

The VCUG of a boy with a PUV will reveal a posterior urethra that appears dilated, often taking on a “shield shape” or squared-off appearance. The bladder neck is often clearly demarcated and may appear as a thick collar, and the urethra distal to the obstruction will appear less full than normal (Fig. 108.1).

---

## INDICATIONS FOR SURGERY

---

Today, most valve ablation is accomplished transurethrally. Some controversy still exists as to what to do once the bladder has been drained with a catheter (Fig. 108.2). For severe

**FIGURE 108.1** Voiding cystourethrogram of newborn with posterior urethral valves. Note the dilated posterior urethra and bladder diverticulum.

hydronephrosis, some report better long-term outcomes when these infants are temporarily diverted, while most feel that primary valve ablation is the treatment of choice (1). For those who believe temporary diversion is best, many methods of vesical and suprapubic diversion of the obstructed bladder exist.

---

## ALTERNATIVE THERAPY

---

There is no effective alternative to surgical therapy.

---

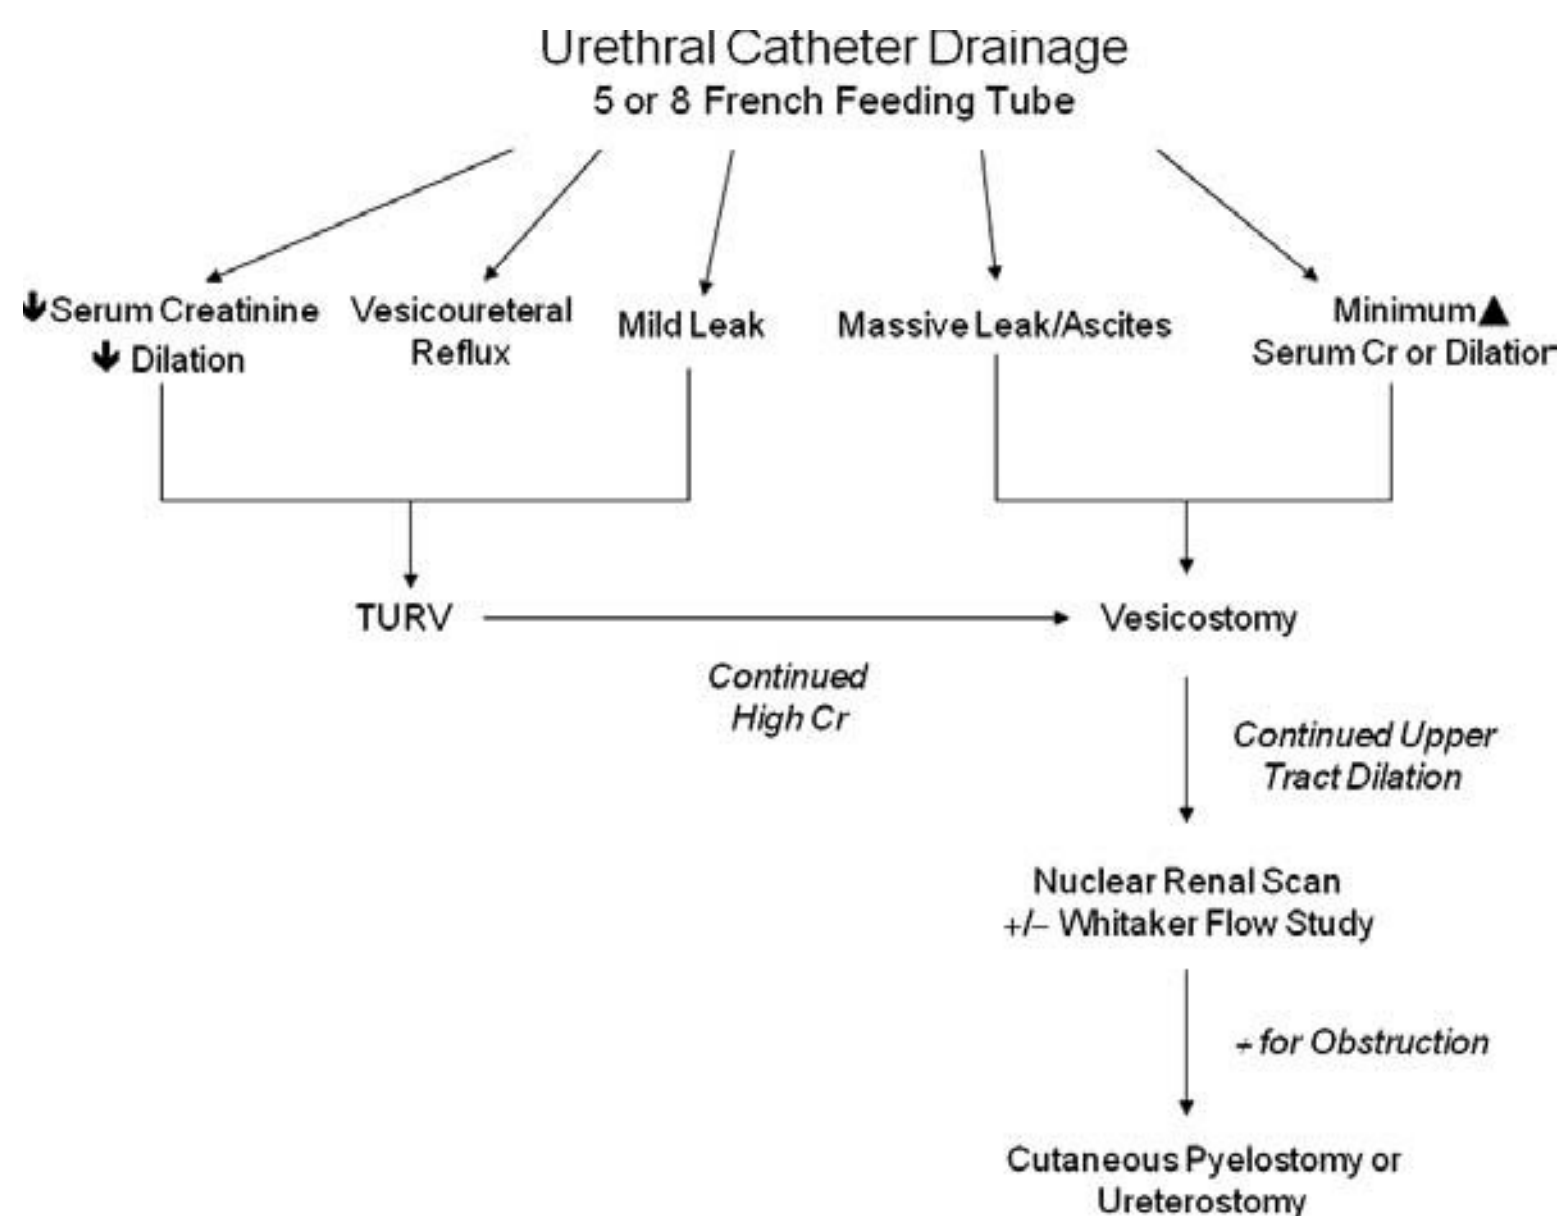

## SURGICAL TECHNIQUE

---

### Transurethral Valve Ablation

---

Valve ablation is most commonly accomplished transurethrally. The size of the infant's fossa navicularis usually limits the size of cystoscope that may be used. Typically, a 7.5Fr or 8.5Fr scope is used in infants, while a larger scope may be used in older children. The cystoscope should be well lubricated and advanced under direct vision. Gentle dilation of the distal urethra may be required to advance the cystourethroscope. With the bladder full and applying gentle suprapubic pressure, the valve leaflets are more easily seen coming off the verumontanum and extending distally to fuse anteriorly (Fig. 108.3). The goal of valve ablation is to disrupt the leaflet, hence destroying the obstruction.

**FIGURE 108.2** Proposed management of posterior urethral valves.

**FIGURE 108.3** Cystoscopic appearance of type 1 posterior urethral valve.

A PUV may be ablated or incised in several ways. It may be ablated using a 3Fr Bugbee electrode through a cystoscope. Alternatively, the wire insert of a 3Fr ureteral catheter with the distal end connected to electrocautery may be used. Once in position the wire is advanced and pushed into the valve at the 5 and 7 o'clock positions while employing a cutting current of 20 to 25 W. (Note that power settings may vary from machine to machine.) When using cautery care must be taken to ensure that thermal energy is targeted at the valves alone. This may be particularly useful if the infant resectoscope is too large for the child's urethra.

Using a small pediatric resectoscope, the valves are incised with a right-angle hook, loop electrode, or hook-shaped cold-knife. When using a loop electrode, a narrow, more oblong loop is preferable to a wider, more circular loop. Some debate exists as to the best location for valve incision. Williams et al.

(2) preferred incising at the 12 o'clock position, while Gonzales (3) advocated cutting at the 4, 8, and 12 o'clock positions. However, most prefer incising at the 4 to 5 o'clock and 7 to 8 o'clock positions using a hook-shaped cold knife or with the cutting current set at 20 to 25 W pure cut.

Lasers such as the neodymium:YAG have also been employed for PUV ablation. Additional methods of PUV ablation have also been described for use in patients with small-caliber urethras. With the advent of smaller scopes, perineal urethrotomy is now rarely necessary for valve ablation. Zaontz and Firlit (4) have described percutaneous antegrade ablation of PUV as well as antegrade incision of PUV in infants with small-caliber urethras.

Once the valves are endoscopically ablated the bladder should be cystoscoped to evaluate for diverticula, trabeculations, and the appearance of the ureteral orifices. A full stream should be noted at the end of the procedure while applying gentle pressure to the suprapubic area. A small urethral catheter is left in place for 1 to 2 days following the procedure or until an elevated creatinine nadirs. A VCUG may be performed after the catheter is removed to assess the success of the procedure. Timing of the VCUG is determined by the surgeon based on his or her confidence in the adequacy of ablation. A VCUG and urodynamics or preferably videourodynamics should be delayed no  $>6$  to 8 weeks after ablation. If there is suspicion of inadequate ablation or continued obstruction, "second-look" cystoscopy with ablation of residual leaflets should be considered. If the child is found to have diminished compliance or detrusor hyperactivity, anticholinergic therapy should be considered. Anticholinergic therapy may also be instituted immediately after valve ablation or prior to closure or reversal of vesical or suprapubic diversion.

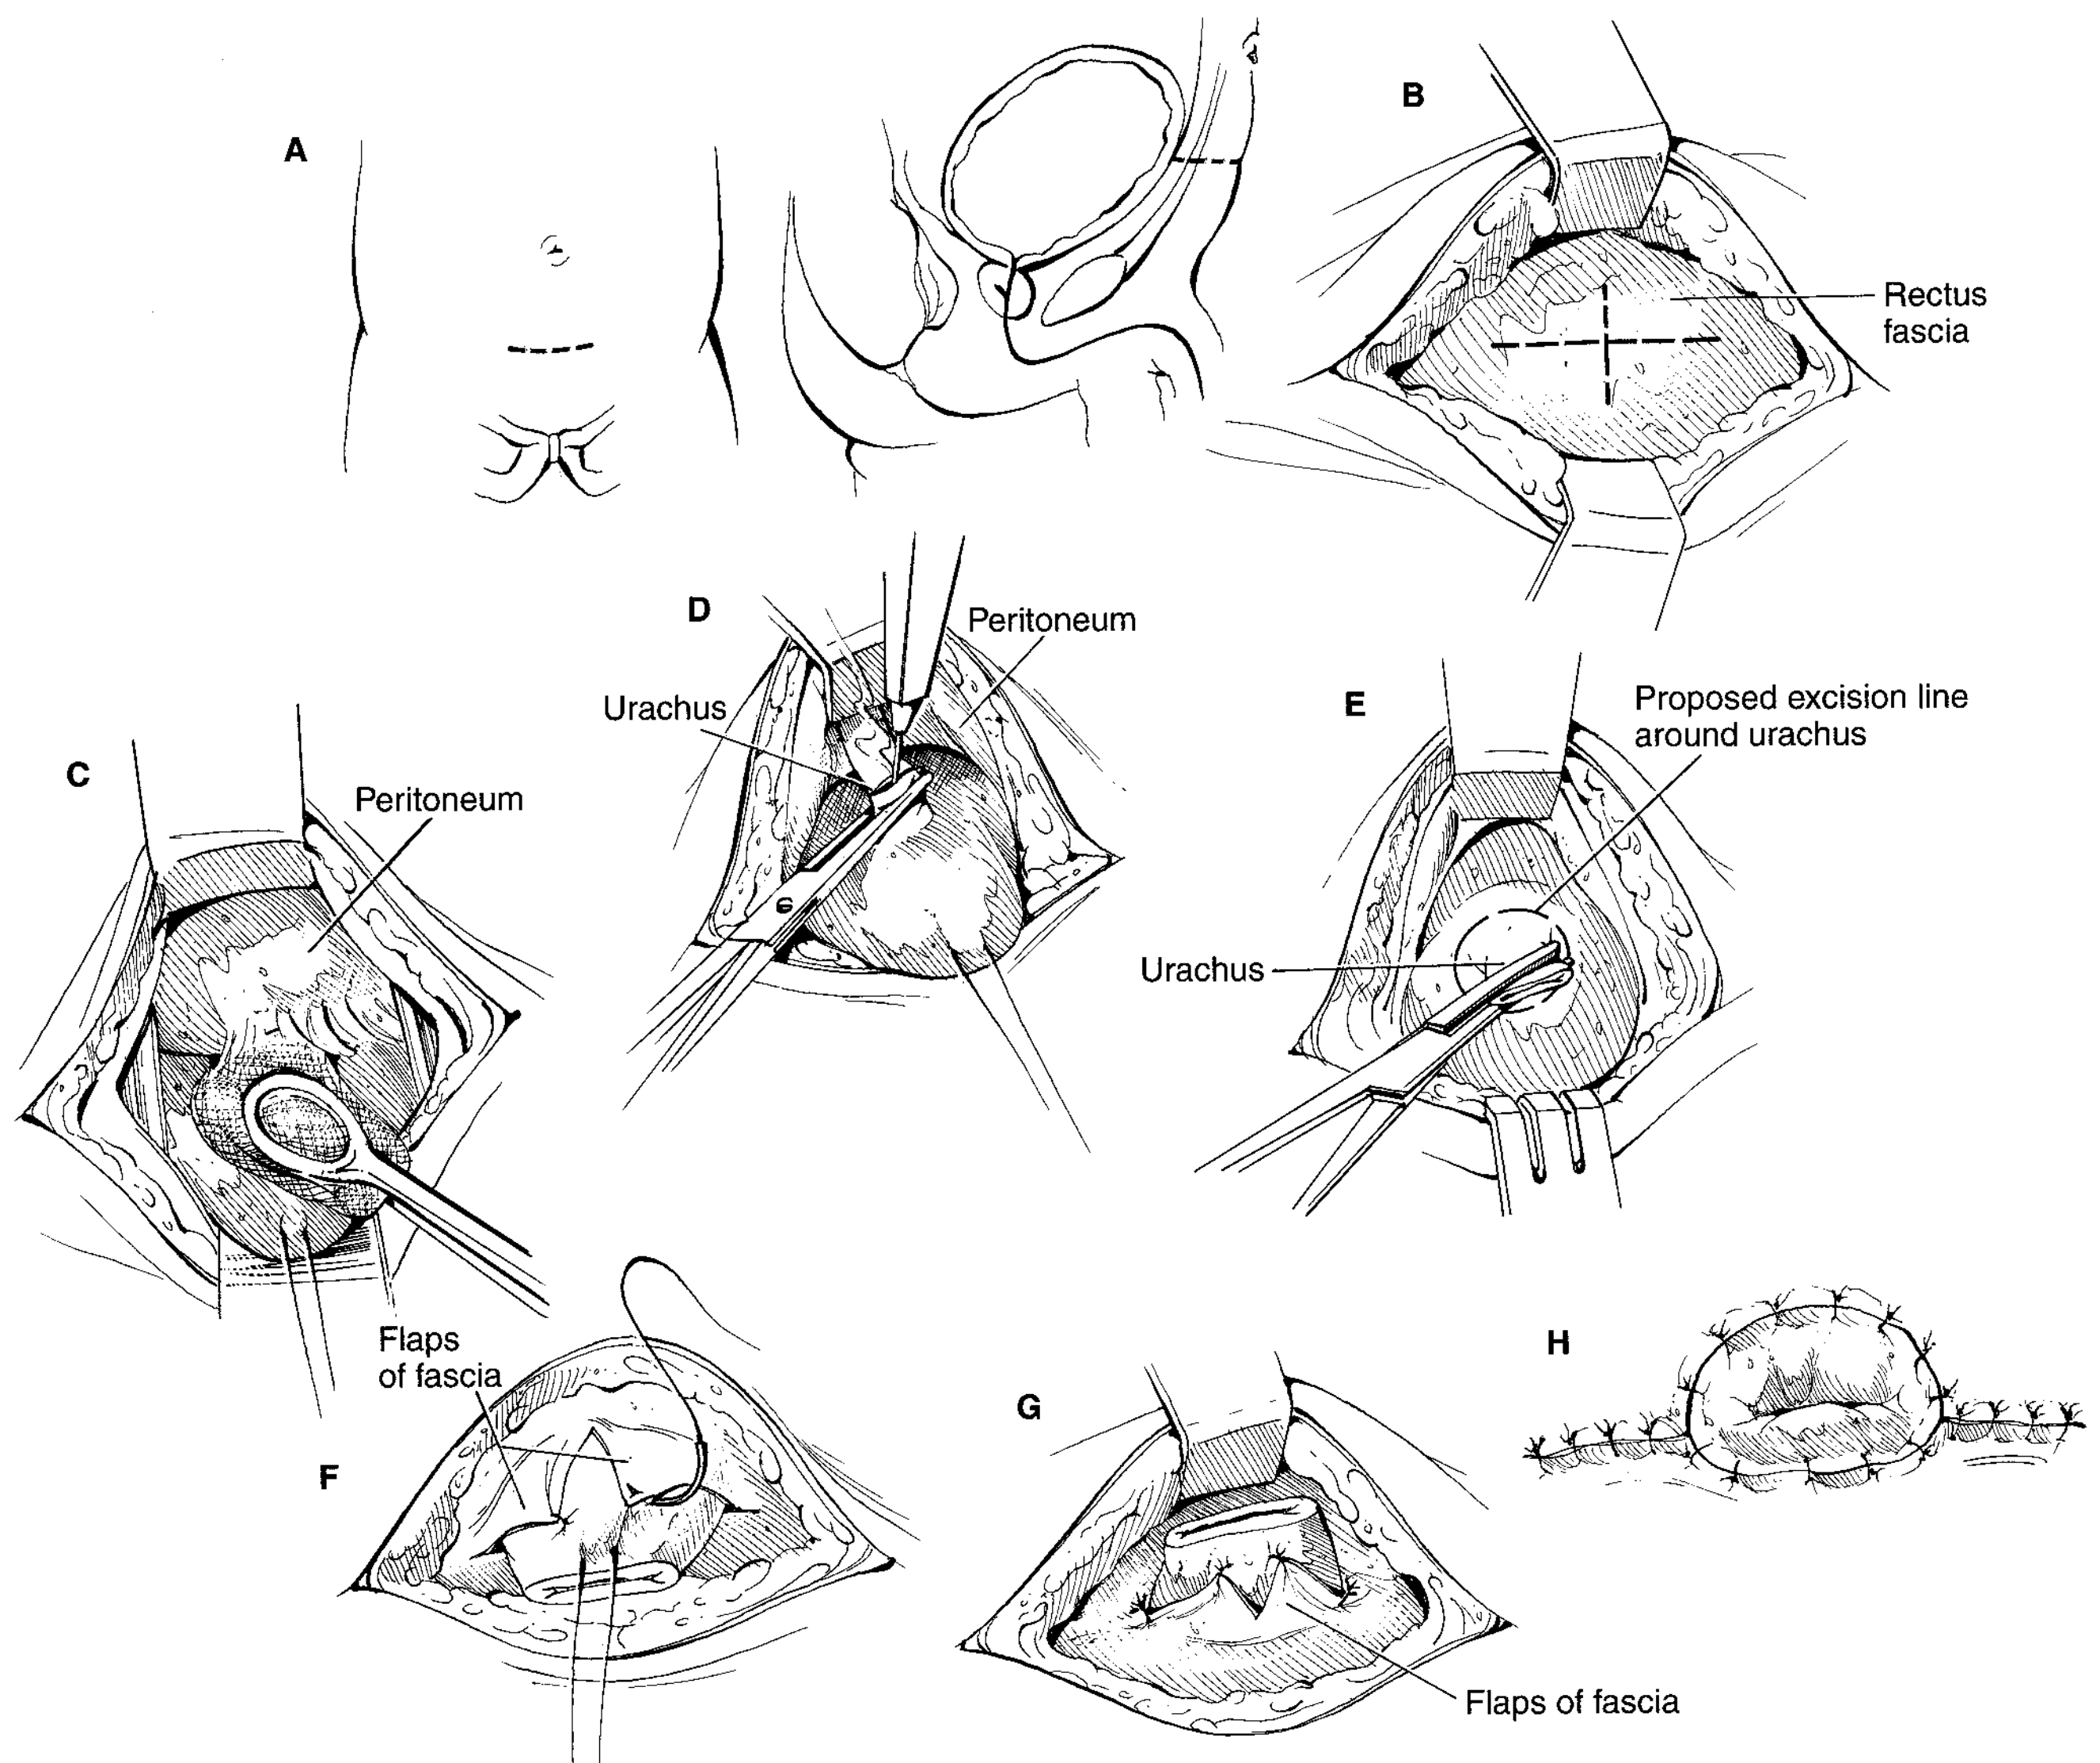

## Vesicostomy

While most patients with PUV are treated with primary valve ablation, a vesicostomy may be useful in neonates whose urethra will not accommodate a cystoscope or in those whose creatinine rises despite adequate valve resection.

With the patient in the supine position the lower abdominal skin is prepared and draped in the typical fashion. The procedure is more easily performed with a full bladder. A 2-cm transverse incision is then made midway between the pubic symphysis and umbilicus. The rectus fascia is exposed and a 2 × 2-cm cruciate incision is made. Alternately, a triangle or circle of rectus fascia measuring 2 cm may be excised. One must remember that the size of the fascial opening ultimately determines the caliber of the stoma. The rectus muscles are then retracted laterally, exposing the bladder. A 3-0 suture is placed near the dome of the bladder and used for traction. Using the traction suture the bladder is mobilized superiorly. The peritoneum is gently swept off the superior aspect of the bladder. Additional cephalad sutures may be placed in a stepwise fashion to help bring the dome into the surgical field. Care is taken to avoid the peritoneal contents. With gentle traction one should be able to visualize the urachus or obliterated hypogastric artery.

The vesicostomy may be created in one of two ways. In the first method, a stay suture is placed proximal to the urachus. The urachus is then transected and excised. In the second method, the portion of the bladder cephalad to the urachal remnant is used as the site for the vesicostomy. The bladder is incised and the fascial edges are sewn to the outer bladder wall using 3-0 or 4-0 polyglactin sutures approximately 0.5 to 1 cm from the opening created in the bladder. The vesicostomy should be calibrated to 24Fr or large enough to allow passage of the surgeon's fifth digit. If the fascial defect is too large, interrupted 3-0 polyglactin sutures may be used to narrow the opening. The edges of the detrusor are then sewn to the skin using 4-0 polyglactin sutures in an interrupted fashion. If the skin incision is wider than the stoma created, the skin is approximated with a suture of choice (Fig. 108.4).

The decision to close a vesicostomy should be made only once bladder dynamics have been assessed and a plan for

**FIGURE 108.4** Blocksom vesicostomy. **A:** A 2-cm transverse incision is made midway between the pubic symphysis and umbilicus. **B:** A 2 × 2-cm cruciate fascial incision is made. **C:** Using the traction suture the bladder is mobilized superiorly. The peritoneum is gently swept off the superior aspect of the bladder. **D:** The urachus is incised and the bladder is further mobilized. **E:** The urachus is excised. **F and G:** The outer bladder wall is sewn to the edges of the incised rectus fascia. **H:** The edges of the detrusor are sewn to the skin. (Modified from Belman AB, King LR. Vesicostomy: useful means of reversible urinary diversion in selected infant. *Urology* 1973;1:208–213.)

permanent therapy has been devised. Ultimately, the timing of closure is dictated by the surgeon's philosophy. Some believe an empty bladder becomes a contracted bladder, while others close vesicostomies just prior to the expected time of potty training.

Initially, an adequate-size balloon catheter is placed into the stoma of the vesicostomy. With the balloon inflated, an elliptical skin incision is made around the stoma. The subcutaneous and perivesical tissues are dissected circumferentially around the vesicostomy. Next, 3-0 chromic stay sutures are placed through the bladder wall approximately 1 cm cephalad and 1 cm caudad to the stoma. The skin and protruding portion of the bladder are excised. The previously placed catheter is removed and a urethral catheter is placed for bladder drainage. The bladder defect is then closed in two layers: a running 4-0 chromic suture is used to reapproximate the bladder mucosa, followed by interrupted or running 3-0 polyglactin or chromic sutures as a second layer. The remainder of the wound is closed in a standard fashion.

## Supravesical Diversion

### Cutaneous Pyelostomy

The decision to proceed with a supravesical diversion remains controversial, and it is rarely used. To safely perform a cutaneous pyelostomy, the renal pelvis should be sufficiently dilated to avoid tension on the renal pelvis as it is pulled toward the abdominal wall. A dilated renal pelvis also ensures that dissection can be carried out away from the ureteropelvic junction (UPJ).

The renal pelvis may be approached in several ways, including a dorsal lumbotomy or a subcostal extraperitoneal approach. A surgeon may use the approach he or she is most comfortable with. Despite the limited exposure that a dorsal lumbotomy incision affords, it is excellent for visualization of the renal pelvis and upper ureter. The procedure avoids a muscle-splitting incision and may produce less postoperative pain.

After the patient is intubated, he should be placed in the prone position on the operating room table. Cushions should then be placed under the chest and just superior to the anterior superior iliac spines. The landmarks include the 12th rib superiorly, the iliac crest inferiorly, and the lateral border of the sacrospinalis medially. A vertical incision with or without a slight curve at its distal end is made approximately one-third to one-half the distance between the 12th rib and the iliac crest. Alternatively, an oblique incision may be made along the Langer lines (Fig. 108.5). Care should be taken to avoid

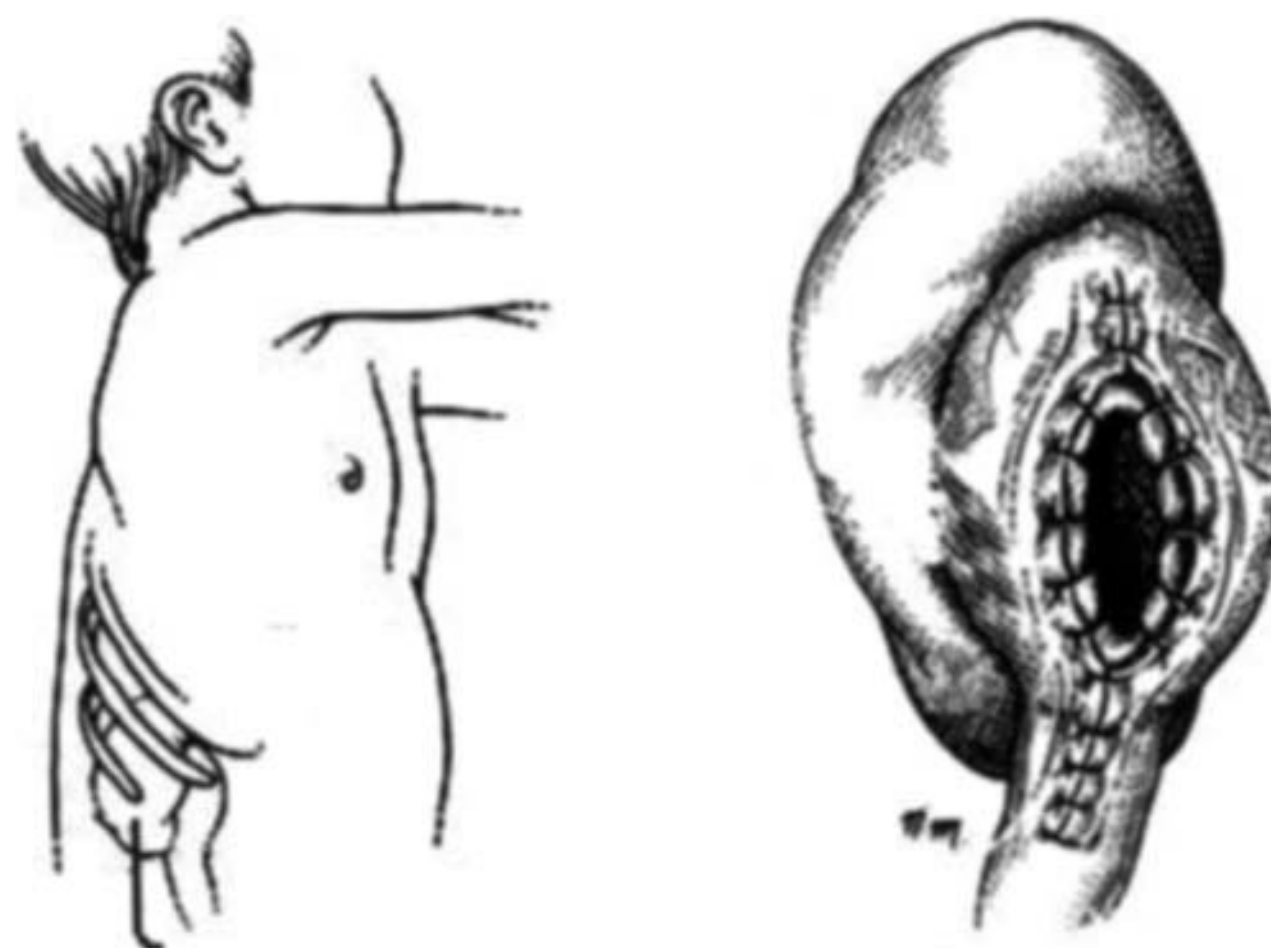

**FIGURE 108.5** Positioning for dorsal lumbotomy and possible skin incisions. The *solid line* represents our incision of choice; the *broken line* represents a suitable alternative.

**FIGURE 108.6** Fascial incision through lumbodorsal fascia lateral to the sacrospinalis and quadratus lumborum, avoiding the division of muscles.

injuring the subcostal neurovascular bundle. The lumbodorsal fascia is exposed by elevating the skin and subcutaneous tissues for about 3 cm on either side of the incision so that a vertical fascial incision may be comfortably made. The posterior layer of the lumbodorsal fascia is incised vertically 2 cm lateral to the midline. The sacrospinalis muscle is then retracted medially. This exposes the middle layer of the lumbodorsal fascia, which is incised at the lateral border of the quadratus lumborum. Retracting the quadratus lumborum medially, the anterior layer of the lumbodorsal fascia is exposed (Fig. 108.6). This layer and the transversalis fascia are then incised between the subcostal and iliohypogastric nerves. The perinephric fat should then be in view. The kidney should be located in the superomedial part of the wound.

Once the fascia of Gerota is entered, the dilated renal pelvis is identified and rotated anteromedially. The surgeon must assess if the pelvis can comfortably reach the skin. If not, a very proximal portion of the ureter may be brought out to serve the same purpose. Care should be taken to avoid dissection near the UPJ so as to avoid the possibility of a future UPJ obstruction. Two 3-0 chromic traction sutures are placed on the posterior aspect of the renal pelvis away from the UPJ. Using a scalpel a 3-cm incision is made. The full thickness of the renal pelvis is sutured to the posterior corner of the skin incision using multiple interrupted 4-0 polyglactin sutures (Fig. 108.7). The pyelostomy should be calibrated to approximately 20Fr to avoid future stenosis or prolapse. Once the planned procedure

**FIGURE 108.7** Cutaneous pyelostomy (sutures at the skin level).

has been performed, the posterior layer of the lumbodorsal fascia is reapproximated with 3-0 polyglactin sutures and the skin is then closed with either a subcuticular suture or skin staples.

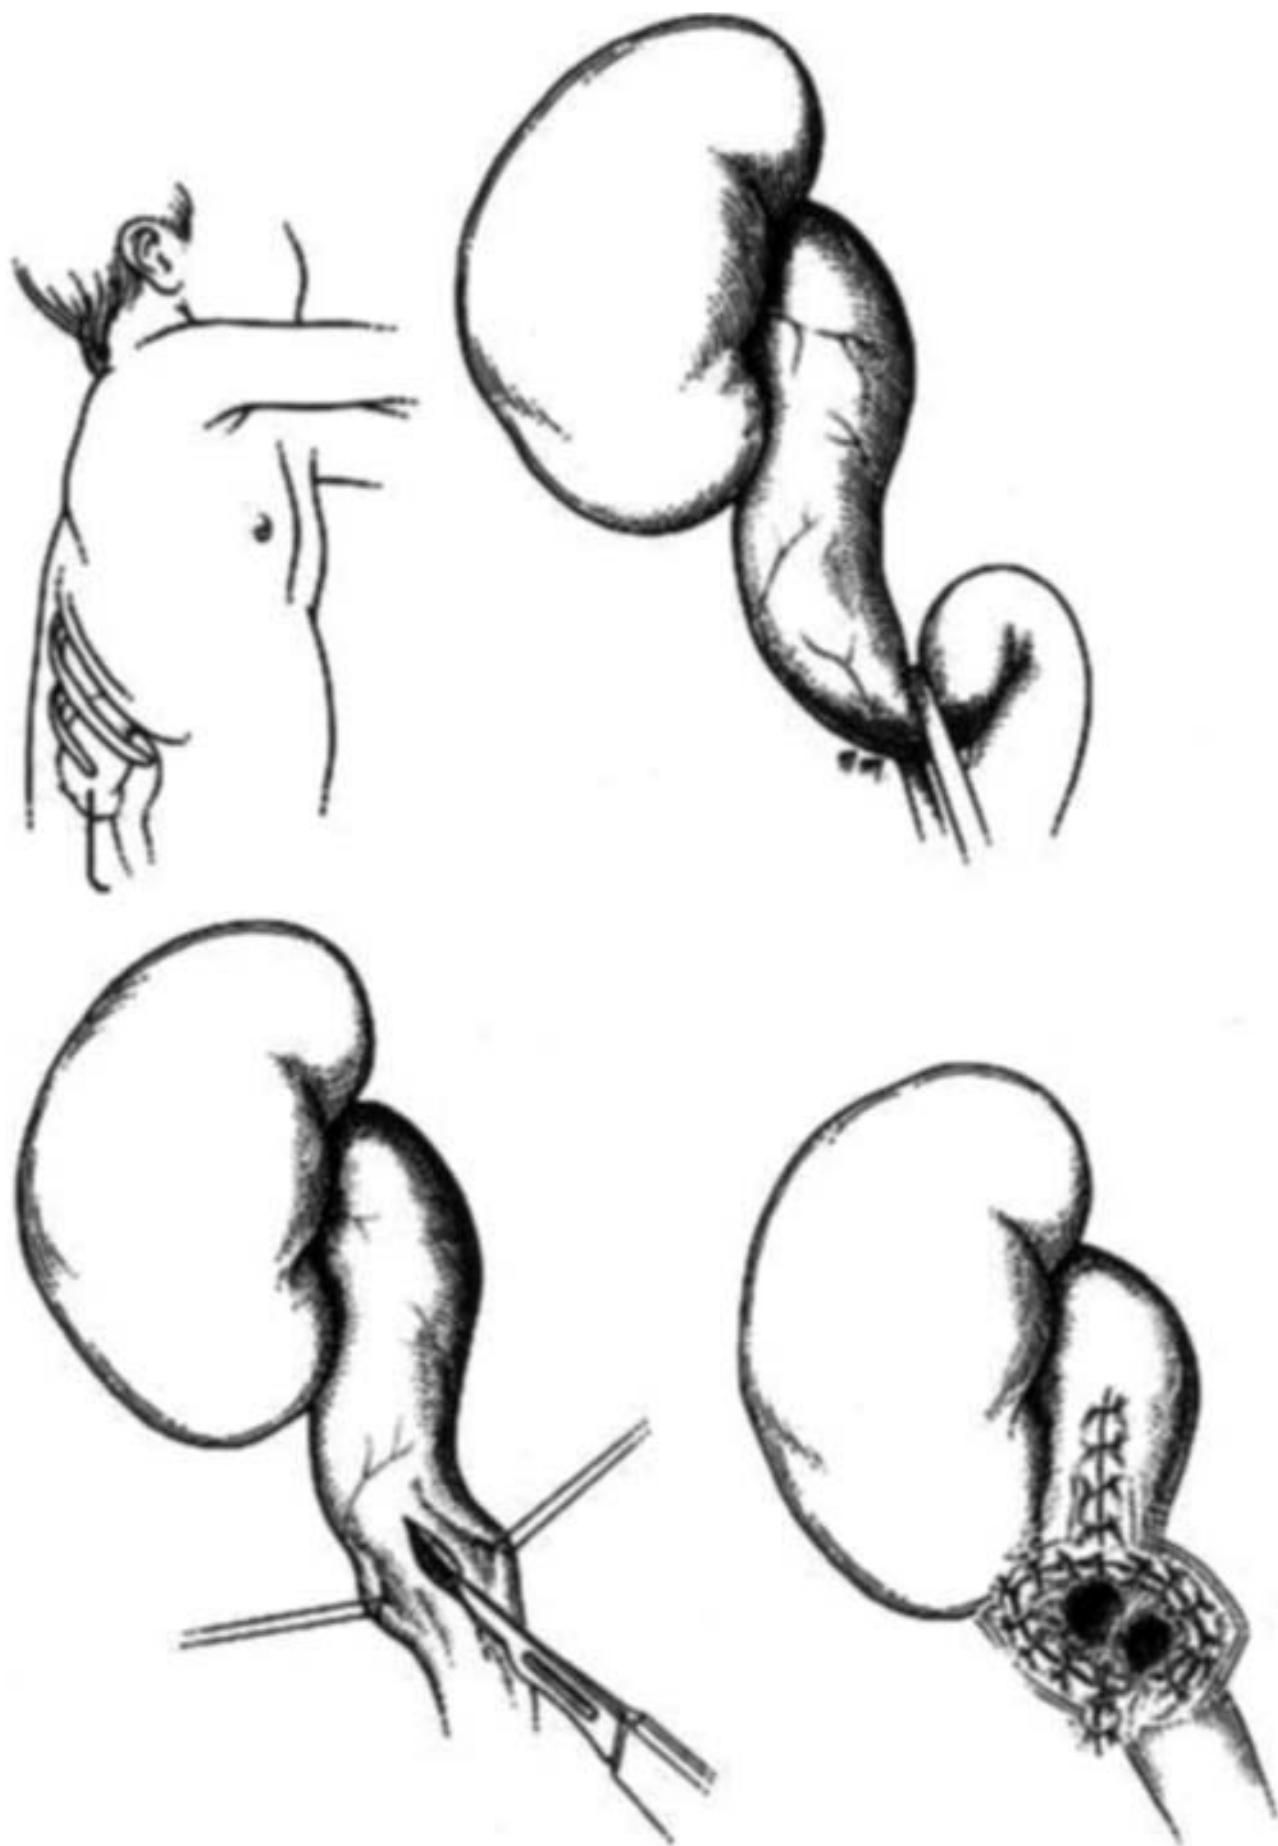

### High Cutaneous Loop Ureterostomy

This method is typically employed when the renal pelvis is not large enough for a cutaneous pyelostomy to be performed. The initial steps for a high cutaneous ureterostomy are similar to that for a cutaneous pyelostomy. The ureter is brought to skin level. Two 4-0 polyglactin sutures are placed in the upper ureter approximately 5 mm from each other. Using a scalpel a 2-cm vertical ureterotomy is created. The abdominal musculature is closed on either side and behind the loop of ureter. Care is taken to avoid strangulating the ureter. The incised ureteral margins are sewn to the skin using interrupted 4-0 polyglactin sutures. The final product is a double-barreled ureteral stoma (Fig. 108.8).

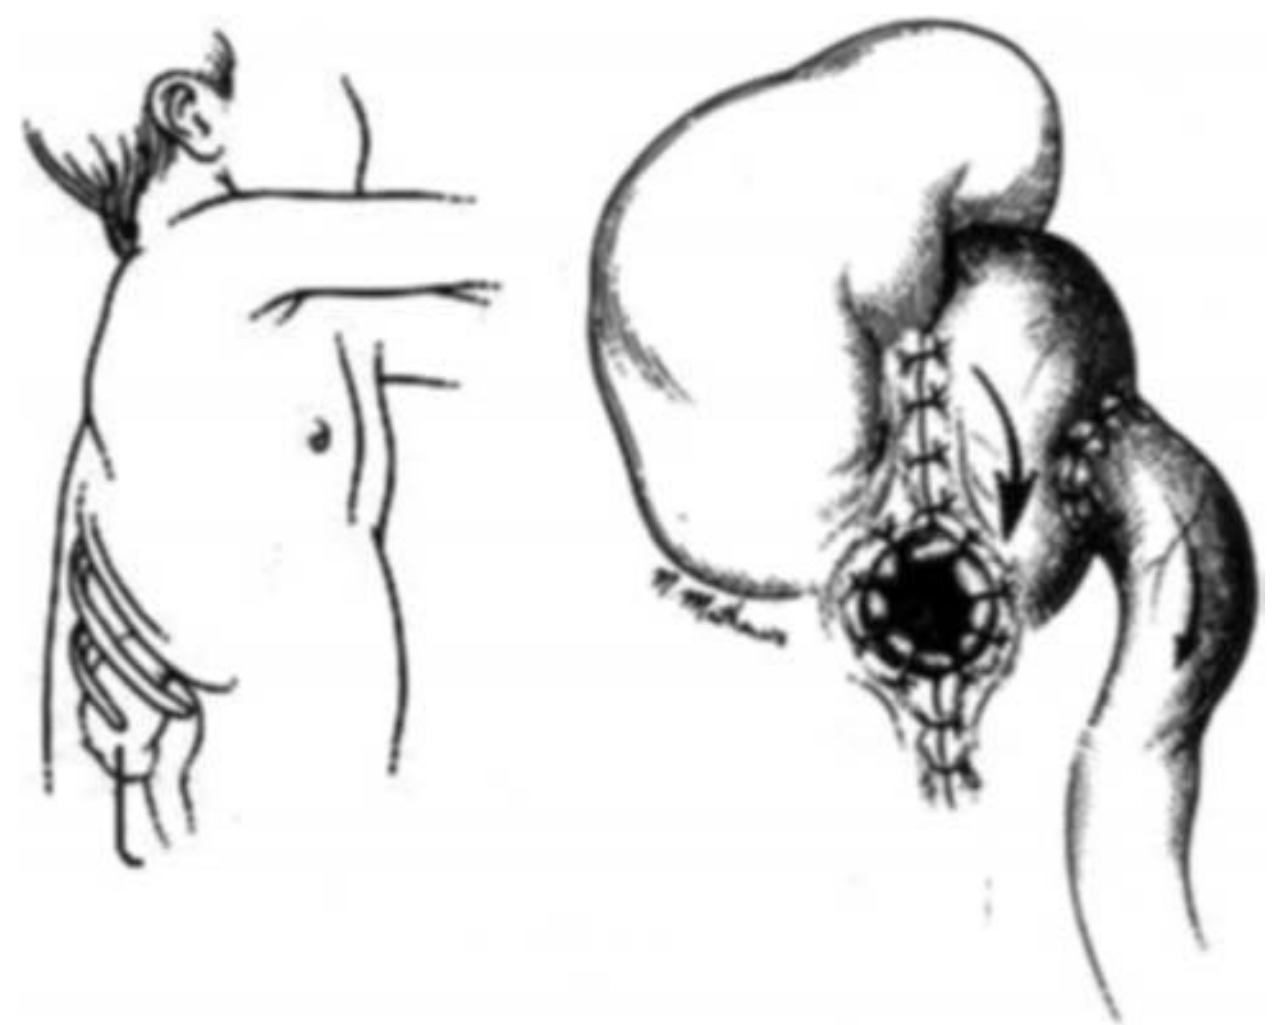

Loop ureterostomies maintain continuity of part of the ureter, therefore decreasing the likelihood of disruption of ureteral blood supply and possibly making closure of the ureterostomy simpler.

### Pelvioureterostomy-en-Y (Sober Loop Ureterostomy)

The Sober Y ureterostomy allows some urine to drain into the bladder, thus avoiding a completely defunctionalized bladder that may eventually become contracted (5). It is not

**FIGURE 108.8** Loop cutaneous ureterostomy (sutures at the skin level).

**FIGURE 108.9** Pelvioureterostomy-en-Y (Sober ureterostomy).

the procedure of choice in critically ill patients as it is more extensive and time consuming than other forms of diversion, and it is best used in patients with redundant tortuous ureters. The ureter is mobilized from the level of the kidney to the level of the true pelvis. The ureter is divided at a point where the lower ureteral segment comfortably reaches the renal pelvis. The upper ureter that remains in continuity with the renal pelvis is brought out to the flank caudad to the flank incision. The proximal end of the lower portion of the transected ureter is anastomosed to the renal pelvis. This is done in an end-to-side fashion after creating a pelviotomy at a point that will not cause ureteral kinking. The anastomosis is performed using a 6-0 or 7-0 polyglactin suture in a running fashion (Fig. 108.9). The flank incision is closed in the standard fashion. A small Penrose drain may be temporarily placed. Initially, most urine will drain via the ureterostomy. Over time, increasing amounts of urine will drain into the bladder.

### End Cutaneous Ureterostomy

To successfully perform a cutaneous ureterostomy, the ureter must be sufficiently thick-walled and dilated. Preservation of the ureteral blood supply is essential. The ureter should be approached extraperitoneally via either a low abdominal incision or a Gibson incision. The ureter should be carefully dissected from the level of the sacral promontory to the bladder with care to avoid stripping the ureter's adventitia. Once dissected, a thick vessel loop or Penrose drain should be placed around the ureter. One should estimate whether the ligated ureter will comfortably reach the anterior abdominal wall at the right or left lower quadrant. Once satisfied with this, the ureter is clamped and cut. The distal segment is ligated using a 3-0 polyglactin suture. A 3-0 polyglactin stay suture is placed on the cut end with care to avoid the ureter's medial blood supply (Fig. 108.10).

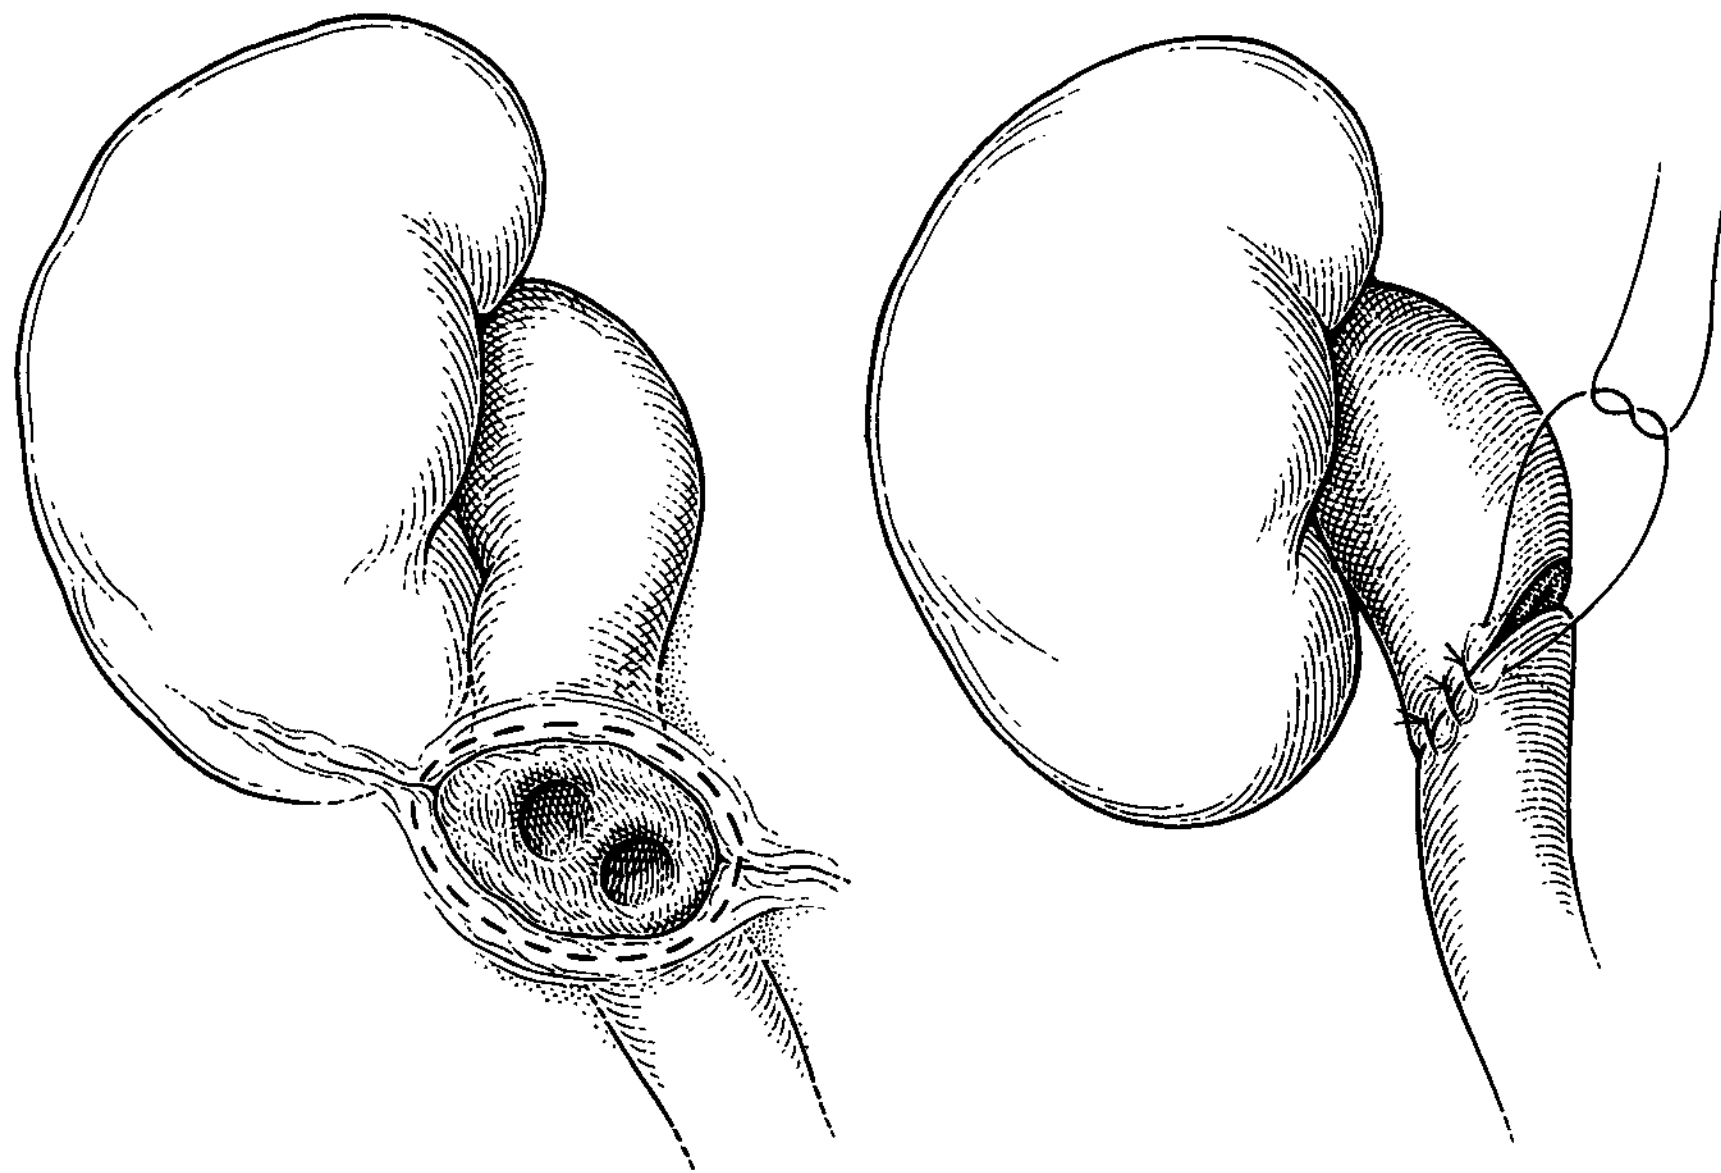

The cutaneous stoma is then created. Stomas should be placed in the right or left lower quadrant for ease of stomal fit in the event an appliance will be used. Once the site of the stoma has been determined, a V-shaped incision is made and taken down through the subcutaneous tissues and rectus sheath. Using the previously placed stay suture, the ureter is gently brought through the incision. If the ureter seems

**FIGURE 108.10** End ureterostomy (sutures at skin level). (From Indiana University School of Medicine, Office of Visual Media, with permission).

stretched, additional mobilization may be necessary. The ureter is then spatulated medially to avoid its blood supply. The apex of the spatulated ureter is then sewn to the apex of the skin incision using a 4-0 polyglactin suture. The ureter is then sewn to the other angles of the skin incision and additional sutures are placed circumferentially.

Bilateral end ureterostomies may be brought to the midline or either lower quadrant. The medial wall of each ureter is incised approximately 3 cm. The apexes of the incised ureters are sewn to each other using a two-armed 5-0 polyglactin suture. The incised walls of the ureters are then sewn to each other in a running fashion.

**FIGURE 108.11** Takedown of loop cutaneous ureterostomy.

### Closure of Supravesical Diversions

To close a cutaneous pyelostomy, an elliptical skin incision is made around the stoma. The portion of pelvis that has been exteriorized is trimmed so that healthy renal pelvic edges may be approximated. Using a 6-0 polyglactin suture in a running fashion the renal pelvis is closed in a transverse fashion. The UPJ should be inspected to ensure that no kinking has occurred secondary to pyelostomy closure.

To close a loop ureterostomy, an elliptical skin incision is made in the skin surrounding the stoma. The proximal and distal ureteral segments are adequately mobilized. The fibrotic exposed portions of the ureter are excised, while trying to maintain the continuity of the ureter's back wall and blood supply. The remaining ureteral margins are then spatulated and closed in a transverse fashion using a 6-0 polyglactin suture (Fig. 108.11). Again, one must ensure that no angulation or narrowing of the ureter has occurred. A temporary indwelling ureteral stent may be placed to bridge the anastomosis.

A Sober ureterostomy may be reversed by excising the stoma at the skin level along with the limb of ureter used to create the cutaneous ureterostomy. The dissection is taken down to the level of the renal pelvis. The defect in the renal pelvis is closed using a 6-0 polyglactin suture in a running watertight fashion.

---

## OUTCOMES

---

### Complications

---

Cutaneous vesicostomies may be complicated by early or late prolapse of the dome or posterior bladder wall in up to 17% of patients. To prevent prolapse the most cephalad portion of the bladder or the urachus should be used as the site for the vesicostomy. By employing this portion of the bladder, the peritonealized part of the dome becomes immobilized, decreasing the risk of prolapse. The stomal opening itself should be no larger than 2 cm. The final stoma should calibrate to 24Fr. Excessive mucosal eversion should not be mistaken for

prolapse. Despite its appearance, no intervention is necessary for excessive eversion.

If the vesicostomy does not appear to be draining well and there is evidence of large amounts of residual bladder urine or large amounts of urine are voided by urethra, the suspicion of stomal stenosis should be raised. Stomal stenosis rates of 3% to 12% have been reported (6). The stenosis may be secondary to a small fascial opening or excessive tension on the vesicocutaneous anastomosis. Continuous drainage of urine into a diaper commonly may lead to peristomal dermatitis. Prolonged, severe dermatitis may ultimately lead to stomal stenosis. This can be prevented by air drying the skin or applying topical ointments used for diaper rash. Fungal superinfections may occur and are treated with antifungal creams and powders.

Some infants, particularly those with persistent vesicoureteral reflux, may have recurrent urinary tract infections despite patent vesicostomy and small bladder residuals. These children may benefit from intermittent catheterization through their vesicostomies.

The most common complication associated with pyelostomy is chronic skin irritation and dermatitis. As in other forms of diversion, chronic bacteriuria is also common. Less common complications of pyelostomy include stomal stenosis and prolapse of the renal pelvis. Chronic bacteriuria has been found in approximately two thirds of patients with ureterostomies and is the most common complication in this group. Stomal stenosis occurs in 11% to 70% of patients undergoing end cutaneous ureterostomies (7). The incidence of stenosis and obstruction is related to the caliber of the ureter used as well as the type of stoma created. Chronic skin irritation may also result in scarring and stenosis.

---

## Results

---

Despite the ease of performing a vesical diversion and its effectiveness in relieving bladder outlet obstruction, controversy exists regarding both its necessity and ultimate effects on bladder function (1,3).

---

## ANTERIOR URETHRAL VALVES

---

Anterior urethral valves occur 10 times less frequently than posterior urethral valves and may be located anywhere along the anterior urethra. In most cases, an anterior urethral valve is actually a congenital urethral diverticulum with the lip of the diverticulum preventing antegrade flow of urine. The bulging diverticulum may further obstruct the urethra by compressing the lumen. These children present with symptoms similar to those with a PUV, including varying degrees of hydronephrosis; however, many also present with penile ballooning. As with PUV, the diagnosis is also made on VCUG. A renal ultrasound should be performed to complete the evaluation. Cystourethroscopy may miss the valve due to the retrograde flow of fluid during the procedure.

The obstruction is relieved endoscopically. The distal lip is incised using a hook or right-angle wire electrode. If unsuccessful, the diverticulum may be excised and the urethra reconfigured. Staged urethroplasty may be the best treatment option when faced with a large urethral diverticulum. Management of the hydronephrosis would be similar to that in a patient with a PUV.

# CHAPTER 109 ■ HYPOSPADIAS

LAURENCE S. BASKIN

Hypospadias is defined by three major anatomic defects: (i) the abnormal location of the urethral meatus, (ii) penile curvature, and (iii) abnormalities of the foreskin. The objective in treating patients with hypospadias is to reconstruct a straight penis for normal coitus and place the new urethral meatus on the terminal aspect of the glans to allow a forward-directed

stream. There are five basic steps for a successful hypospadias outcome: (i) orthoplasty (straightening), (ii) urethroplasty, (iii) meatoplasty and glanuloplasty, (iv) scrotoplasty, and (v) skin coverage. These various elements of surgical technique can be applied either sequentially or in various combinations to achieve a surgical success (1).

**FIGURE 109.1** Location of the hypospadias meatus. Glandular, midshaft, scrotal, and perineal.

---

## DIAGNOSIS

---

### Meatal Abnormalities

---

Hypospadias is characterized by an abnormality in location and configuration of the urethral meatus (Fig. 109.1). The urethral meatus may be ventrally placed just below a blind dimple at the normal meatal opening on the glans or so far back in the perineum that it appears as a “vaginal” hypospadias. Most patients present with the urethral meatus somewhere between these extremes. The meatus is encountered in a variety of configurations in form, diameter, elasticity, and rigidity. It can be fissured in both transverse and longitudinal directions or can be covered with delicate skin. In the case of the megameatus intact prepuce, the distal urethra is enlarged, tapering to a normal caliber in the penile shaft. Often, there is an orifice of a periurethral duct located distal to the meatus that courses dorsal to the urethral channel for a short distance. It is blind ending and does not communicate in any way with the urinary stream. The periurethral duct corresponds with the sinus of Guérin or the lacunae of Morgagni. Unless these ducts are inadvertently closed, leading to a blind-ending epithelial pouch, they are of no clinical consequence.

---

## Skin and Scrotal Abnormalities

---

The skin of the penis is radically changed as a result of the disturbance in the formation of the urethra. Distal to the meatus, there is often a paucity of ventral skin, which may contribute to penile curvature. The frenulum is always absent in hypospadias. Vestiges of a frenulum are sometimes found inserting on either side of the open navicular fossa.

The skin proximal to the urethral meatus may be extremely thin, so much so that a catheter or probe passed proximally is readily apparent through a tissue-paper thickness of skin. When it is present, it abrogates the use of perimeatal skin flaps in repairs.

The urethral plate extending from the hypospadiac meatus to the glanular groove may be well developed. Even with a meatus quite proximal on the shaft, this normal urethral plate is quite elastic and typically nontethering. Artificial erection demonstrates no ventral curvature in these situations. A normal urethral plate may be incorporated into the surgical repair. However, if the urethral plate is underdeveloped, it will act as a tethering fibrous band that bends the penis ventrally during artificial erection. When this fibrous chordee tissue is divided, the penis will frequently straighten.

Normally, the genital tubercle should develop in a cranial position above the two genital swellings. The penis may be caught between the two scrotal halves and become engulfed with fusion of the penoscrotal area. The boundary between the penis and the scrotum may be formed by two oblique raphes that extend from the very proximal meatus to the dorsal side of the penis.

---

## Penile Curvature

---

The curvature of the penis is caused by deficiency of the normal structures, most commonly on the ventral side of the penis. It has been labeled *chordee*; however, this term implies a strand of connective tissue stretched like a cord between the meatus and glans, which is rarely found in practice. Penile curvature can be from skin deficiency, a dartos fascial deficiency, a true fibrous chordee with tethering of the ventral shaft, or deficiency of the corpora cavernosa on the concave side of the penis (2).

There are occasional reports of other penile anomalies that represent variations of the embryologic defect causing hypospadias. They can be characterized as a defect in the course of the urethra, such as congenital urethral fistula, and a group characterized by curvature of the penis without hypospadias, or so-called chordee without hypospadias.

---

## SURGICAL TECHNIQUE

---

### Hypospadias Training

---

Success is directly related to the experience of the surgeon. For a successful result in hypospadias repair, the penile tissues must be handled with great care. Experience in mobilizing and rotating skin flaps is needed, as are the minutiae involved in plastic surgical techniques. It is not enough to review pictures and follow descriptions; training in the techniques is essential. Knowledge of a few methods is not enough, because the one used must be the best for the individual situation of the child.

A pediatric urology fellowship is the appropriate place to become competent in hypospadias surgery.

---

## Preoperative Evaluation

---

Because hypospadias is an isolated anomaly, the entire genitourinary tract does not require evaluation. The absence of one gonad, perineal hypospadias, severe chordee, or a bifid scrotum suggests a disorder of sex development and requires genotypic evaluation. If both gonads are not palpable, consider the possibility of congenital adrenal hyperplasia in a phenotypic female.

---

## Age for Operation

---

Select a time between 6 and 9 months for surgery. At this age the infants are also easiest to manage, are not walking and remain in diapers. Babies appear to have fewer bladder spasms and require smaller doses of pain medication. They do not seem to remember the surgery as teenagers and adults. Parenteral testosterone may be administered to increase the size of the penis and especially the size and vascularity of the prepuce should it be needed for proximal and perineal hypospadias repair. Give 25 to 50 mg intramuscularly, repeated once or twice at 3-week intervals, before the operation.

---

## Outpatient Repair

---

An uncomplicated hypospadias operation can be done without hospital admission. Parents and children should visit the surgeon sometime before the date of surgery for history taking and examination, as well as for instructions in feeding and preoperative care. The surgeon and nurse should give considerable support to the parents because of their need to know what to expect. At this visit surgeons can explain the procedure, hand out suitable booklets describing details, and obtain informed consent. They can also review the postoperative catheter care and medications.

---

## Nerve Block

---

A caudal nerve block placed by the anesthesia team is an excellent form of postoperative pain control. A good alternative is a penile nerve block. To place a penile nerve block in an infant, use 3 to 4 mL of 0.5% long-lasting bupivacaine mixed with 1% of quick-acting lidocaine. Inject it at the base of each crus just below the notch of the symphysis, or vertically in the midline deep to the notch of the symphysis, with a 1-1/2-inch 25-gauge needle. When placed at the beginning of an operation it will reduce the amount of general anesthesia required and will provide anesthesia that will last well into the postoperative period.

---

## Surgical Hints

---

### Hemostasis

For hemostasis use 1% lidocaine with 1:100,000 epinephrine and inject it through a 27-gauge needle within the glans and the area of abortive spongiosum. Wait 7 minutes for it to act. This

vasoconstrictor will reduce the bleeding during the dissection, but if the operation is prolonged beyond 90 minutes, rebound vasodilation can be expected. Remember that halothane anesthesia sensitizes the heart to catecholamines, thus promoting arrhythmias. Avoid electrocoagulation as much as possible; if it is necessary, use a bipolar cautery or touch a monopolar cautery to only the forceps unit set at a low current. Once the skin flaps are applied, bleeding improves, and a pressure dressing will usually ensure hemostasis. On rare occasion the use of a tourniquet that is typically used for artificial erections can facilitate hemostasis.

### Artificial Erection

To induce a saline-induced erection, place a sterile rubber band around the base of the penis and snug it with a hemostat. Introduce a 25-gauge butterfly needle into the corpus cavernosum. Gently distend the penis with injectable normal saline solution; avoid overdistention. Maintain the erection during evaluation of the chordee. After the chordee has been corrected, create a second erection to check penile alignment.

### Local Urinary Diversion in Children

Diversion of urine away from the suture lines has always been a problem in children because any indwelling tube, particularly one terminating in a balloon, induces bladder spasms that force urine around it into the repair. This disrupts the suture line and leads to formation of fistulas. Besides, the lumen of a balloon catheter is small compared to that of a straight catheter, especially a plastic one.

Many techniques have been tried to minimize these problems with diversion. The simplest method for infants, one that combines stenting with drainage, is to insert a fine silicone tube, such as 6Fr peritoneal shunt tubing or neurosurgical tubing with its wand-like end, into the bladder through the urethra and fasten the end to the glans in one or two places with nonabsorbable sutures.

Alternately, place a 6Fr Kendall catheter of soft Silastic, with a Luer-loc at the end, to prevent internal migration and to allow irrigation. Whatever intubation system is used in infants, collect the urine in a double diaper. For older boys use a urethral balloon catheter; tape it to the abdomen so that it cannot disturb the ventral glans repair. Drainage should be continued for 4 to 7 days for distal and penile shaft repairs and 7 to 10 days for more severe hypospadias repairs.

---

## Dressings

---

Apply a dressing to immobilize the area, to reduce edema, and to prevent the formation of a hematoma. Use transparent and permeable absorbent plastic film (Tegaderm or OpSite) applied over Telfa or tincture of benzoin. Let the catheter drain into an outer diaper. The dressing may be removed in 2 to 3 days after a few warm baths at home. Once the dressing has been removed use petroleum jelly on the diaper to keep the repaired penis from sticking, typically for 4 to 5 days.

---

## Setup for Operation

---

### Instruments

Select instruments designed for delicate handling of tissues. A reasonable list would include loupe magnification, genitourinary

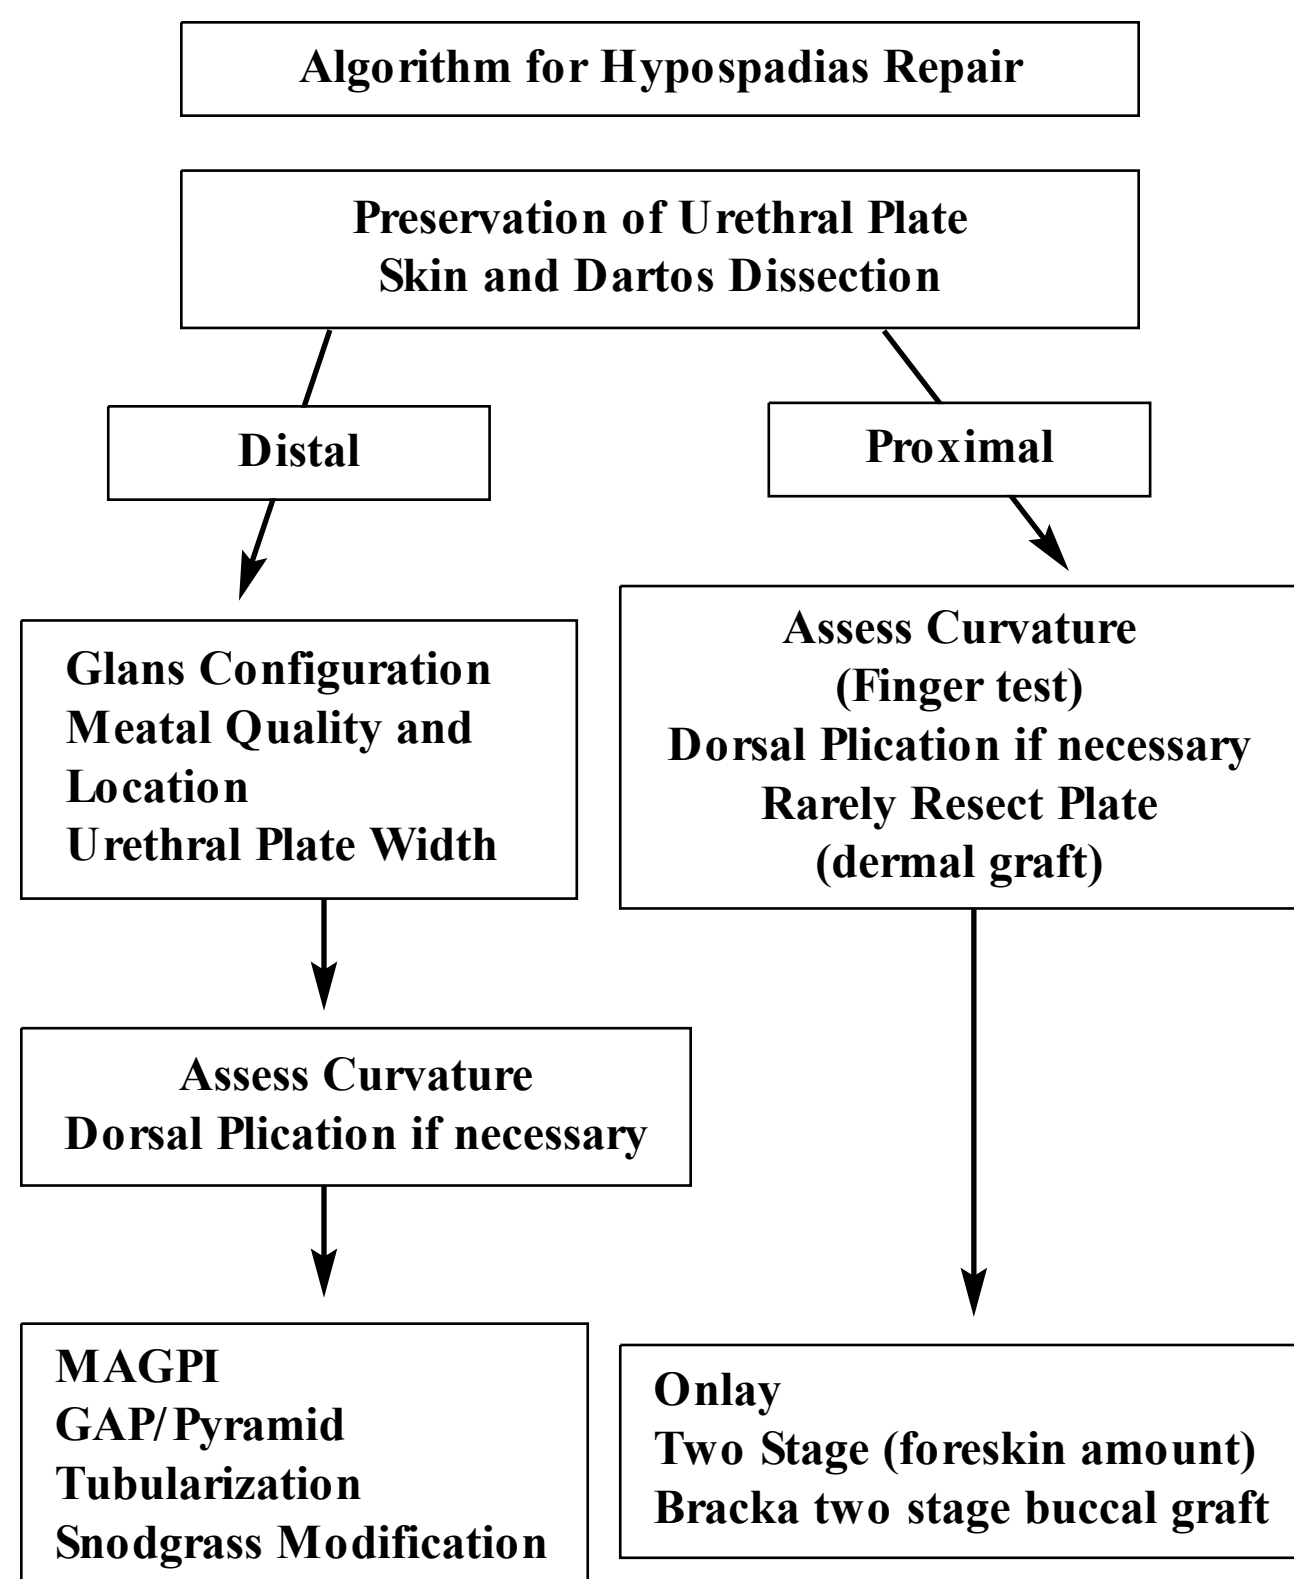

FIGURE 109.2 Algorithm for hypospadias repair.

fine and microsurgery sets, microsurgical knife (Weck), toothed and nontoothed forceps (Adson), fine Allis clamps, fine clamps, two pairs of Bishop–Harmon forceps or 0.5 platform forceps, sharp small tenotomy scissors, iris scissors, microtip Castroviejo scissors, microtip Castroviejo needle holders, plastic needle holders and ring retractor (Scott/Lone Star), and hooks. Also have available bougies á boule, 5Fr and 8Fr infant feeding tubes, rubber bands, a marking pen, a 25-gauge butterfly needle and syringe, and a hand-held Bovie, or an ophthalmic electrocautery. Have fine sutures of appropriate sizes and types at hand but unopened—for example, 5-0 Prolene on a C-1 tapered needle for glans traction, 7-0 PDS and Vicryl for urethroplasty, and 6-0 PDS for the skin.

### Selection of the Operative Technique

Figure 109.2 presents an algorithm for the reconstruction of hypospadias. A tried-and-true approach is to start each repair by preserving the urethral plate, dissecting the skin to the penile scrotal junction, and assessing for the presence of penile curvature. If curvature is not present or is mild to moderate and amenable to dorsal plications, then a one-stage approach is typically successful. The specific repair is now dependent on the meatal configuration and the surgeon's preference (1).

#### Meatal Advancement and Glanuloplasty

The hypospadiac penis that is amenable to meatal advancement and glanuloplasty (MAGPI technique) is characterized by a dorsal web of tissue within the glans that deflects the

urine from either a coronal or a slightly subcoronal meatus (3). Once the patient is asleep, the urethra itself must have a normal ventral wall, without any thin or atretic urethral spongiosum. The urethra also must be mobile so it can be advanced into the glans (Fig. 109.3).

#### Glans Approximation Procedure

The glans approximation procedure (GAP) is applicable in a small subset of patients with anterior hypospadias who have a wide and deep glandular groove (4). These patients do not have a bridge of glandular tissue that typically deflects the urinary stream, as seen in patients who would be more appropriately treated with the MAGPI procedure. In the GAP procedure, the wide-mouth urethra is tubularized primarily over a stent (Fig. 109.4). Ventral glanular tilt, meatal retraction, and splaying of the urinary stream can result from the inappropriate use of the MAGPI technique in these circumstances.

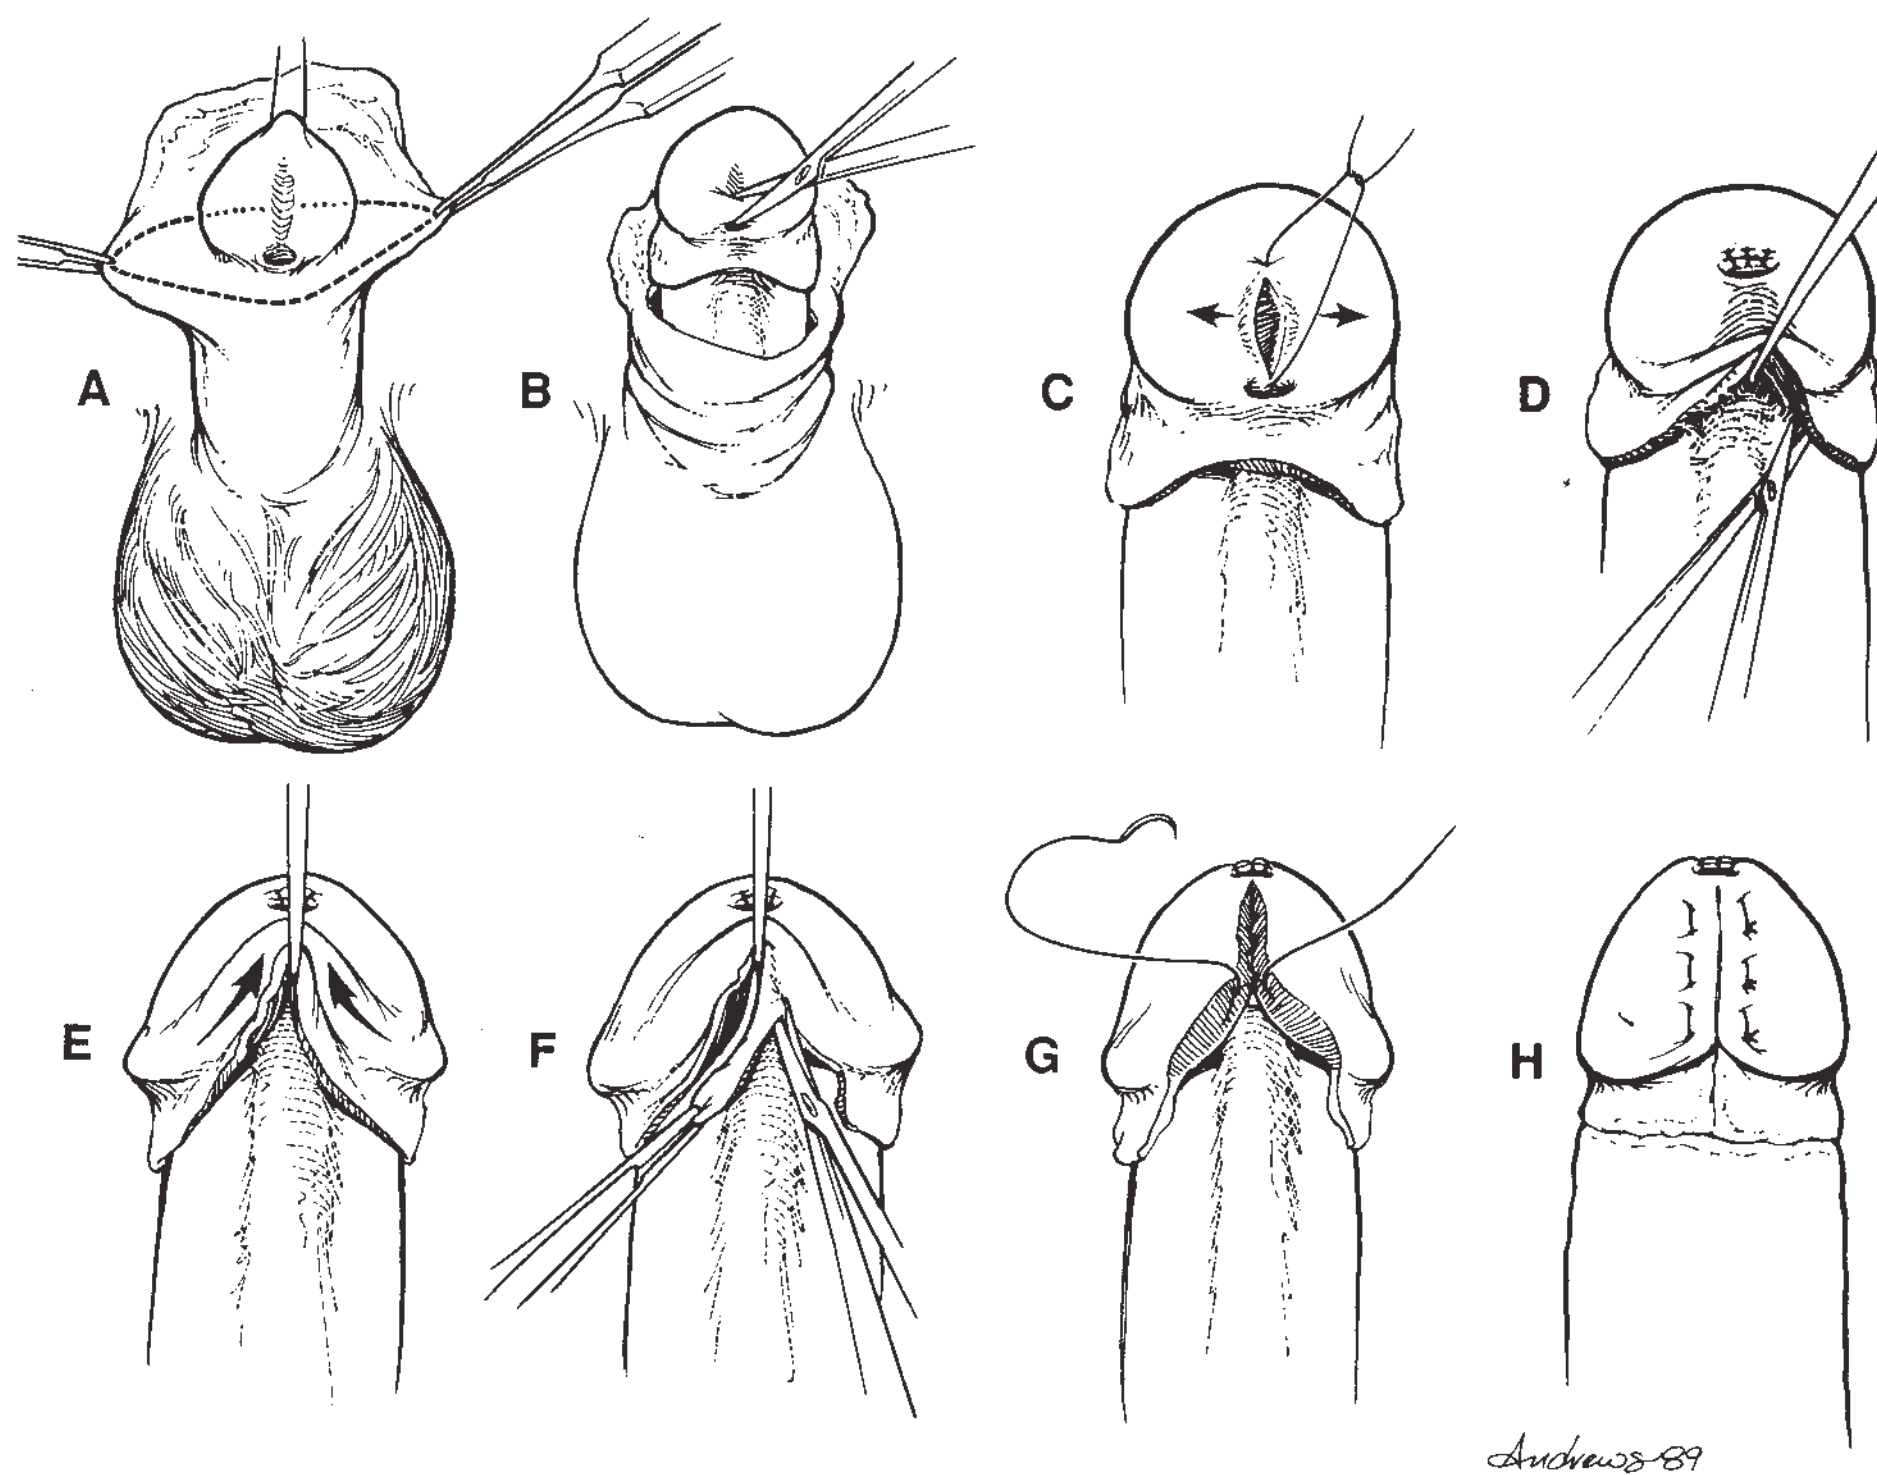

#### Tubularized Incised Plate Urethroplasty (Snodgrass)

Historically, if the urethral groove was not wide enough for tubularization in situ, such as in the GAP or Thiersch–Duplay procedure, then an alternative approach such as the Mathieu or, for more severe hypospadias, a vascularized pedicle flap was performed. Recently the concept of the incision in the urethral plate with subsequent tubularization and secondary healing has been introduced by Snodgrass (5) (Fig. 109.5). Short-term results have been excellent, and this procedure is enjoying extensive popularity. One appealing aspect is the slit-like meatus that is created with the dorsal midline incision. More recently, this technique has been applied to more posterior forms of hypospadias. Theoretically, there is concern about the possibility of meatal stenosis from scarring as occurs in patients with urethral stricture disease, where direct-vision internal urethrotomy often leads to recurrent stricture. However, reports of meatal stenosis have been rare. In hypospadias, the native virgin tissue with excellent blood supply and large vascular sinuses seems to respond to primary incision and secondary healing without scar. The tubularized incised plate (TIP) urethroplasty is conducive to preservation of the foreskin (6). To preserve the foreskin the incision is made only on the ventrum; therefore, patients with significant penile curvature are not candidates for this procedure. A three-layer closure of the prepuce prevents foreskin fistulas. The fact that the foreskin cannot be used as a de-epithelialized flap theoretically increases the chance for urethra fistula.

### Treatment of Posterior Hypospadias

#### The Urethral Plate

Duckett has popularized the concept of preservation of the urethral plate, which is now standard practice for anterior as well as more severe posterior hypospadias surgery (7,8). The urethral plate serves as the dorsal urethral wall, and the ventral urethra is created by a vascular onlay flap of tissue from the inner prepuce. Extensive experience has shown that the urethral plate is rarely the cause of penile curvature. The concept of preserving the urethral plate yet undermining the plate and exposing the corporal bodies with the idea that chordee

**FIGURE 109.3** Meatal advancement with glanduloplasty (MAGPI) procedure. Note the proximal location of the initial circumcising incision in relation to the urethral meatus (A). The dorsal meatotomy is as shown (B and C). The glans is then detached from the lateral margin of the corpus spongiosum and the side of the corpora cavernosa (D). The edge of the glans on either side that will be approximated ventrally is identified (E). The triangle of skin between these two points and the urethral meatus is excised completely (F). Dissection must stay right on the skin because the urethra here is usually thin and easily entered. Excising this skin allows exposure of the glans tissue which can now be reapproximated into a conical shape to complete reconstruction with the meatus in a terminal position (G and H).

**FIGURE 109.4** Glans approximation procedure (GAP) hypospadias technique. A: Initial incision. B: Exposure of the glans mesenchyme by de-epithelialization of tissue, which is critical for a two-layer glans closure, allowing for good support of the urethroplasty. C: Tubularization of the neourethra, followed by glans closure. D: The completed repair. (Reproduced with permission from Grossfeld J, O'Neill J, Coran A, Fonkalsrud, E. *Pediatric Surgery*, 6th ed. Elsevier, 2006.)

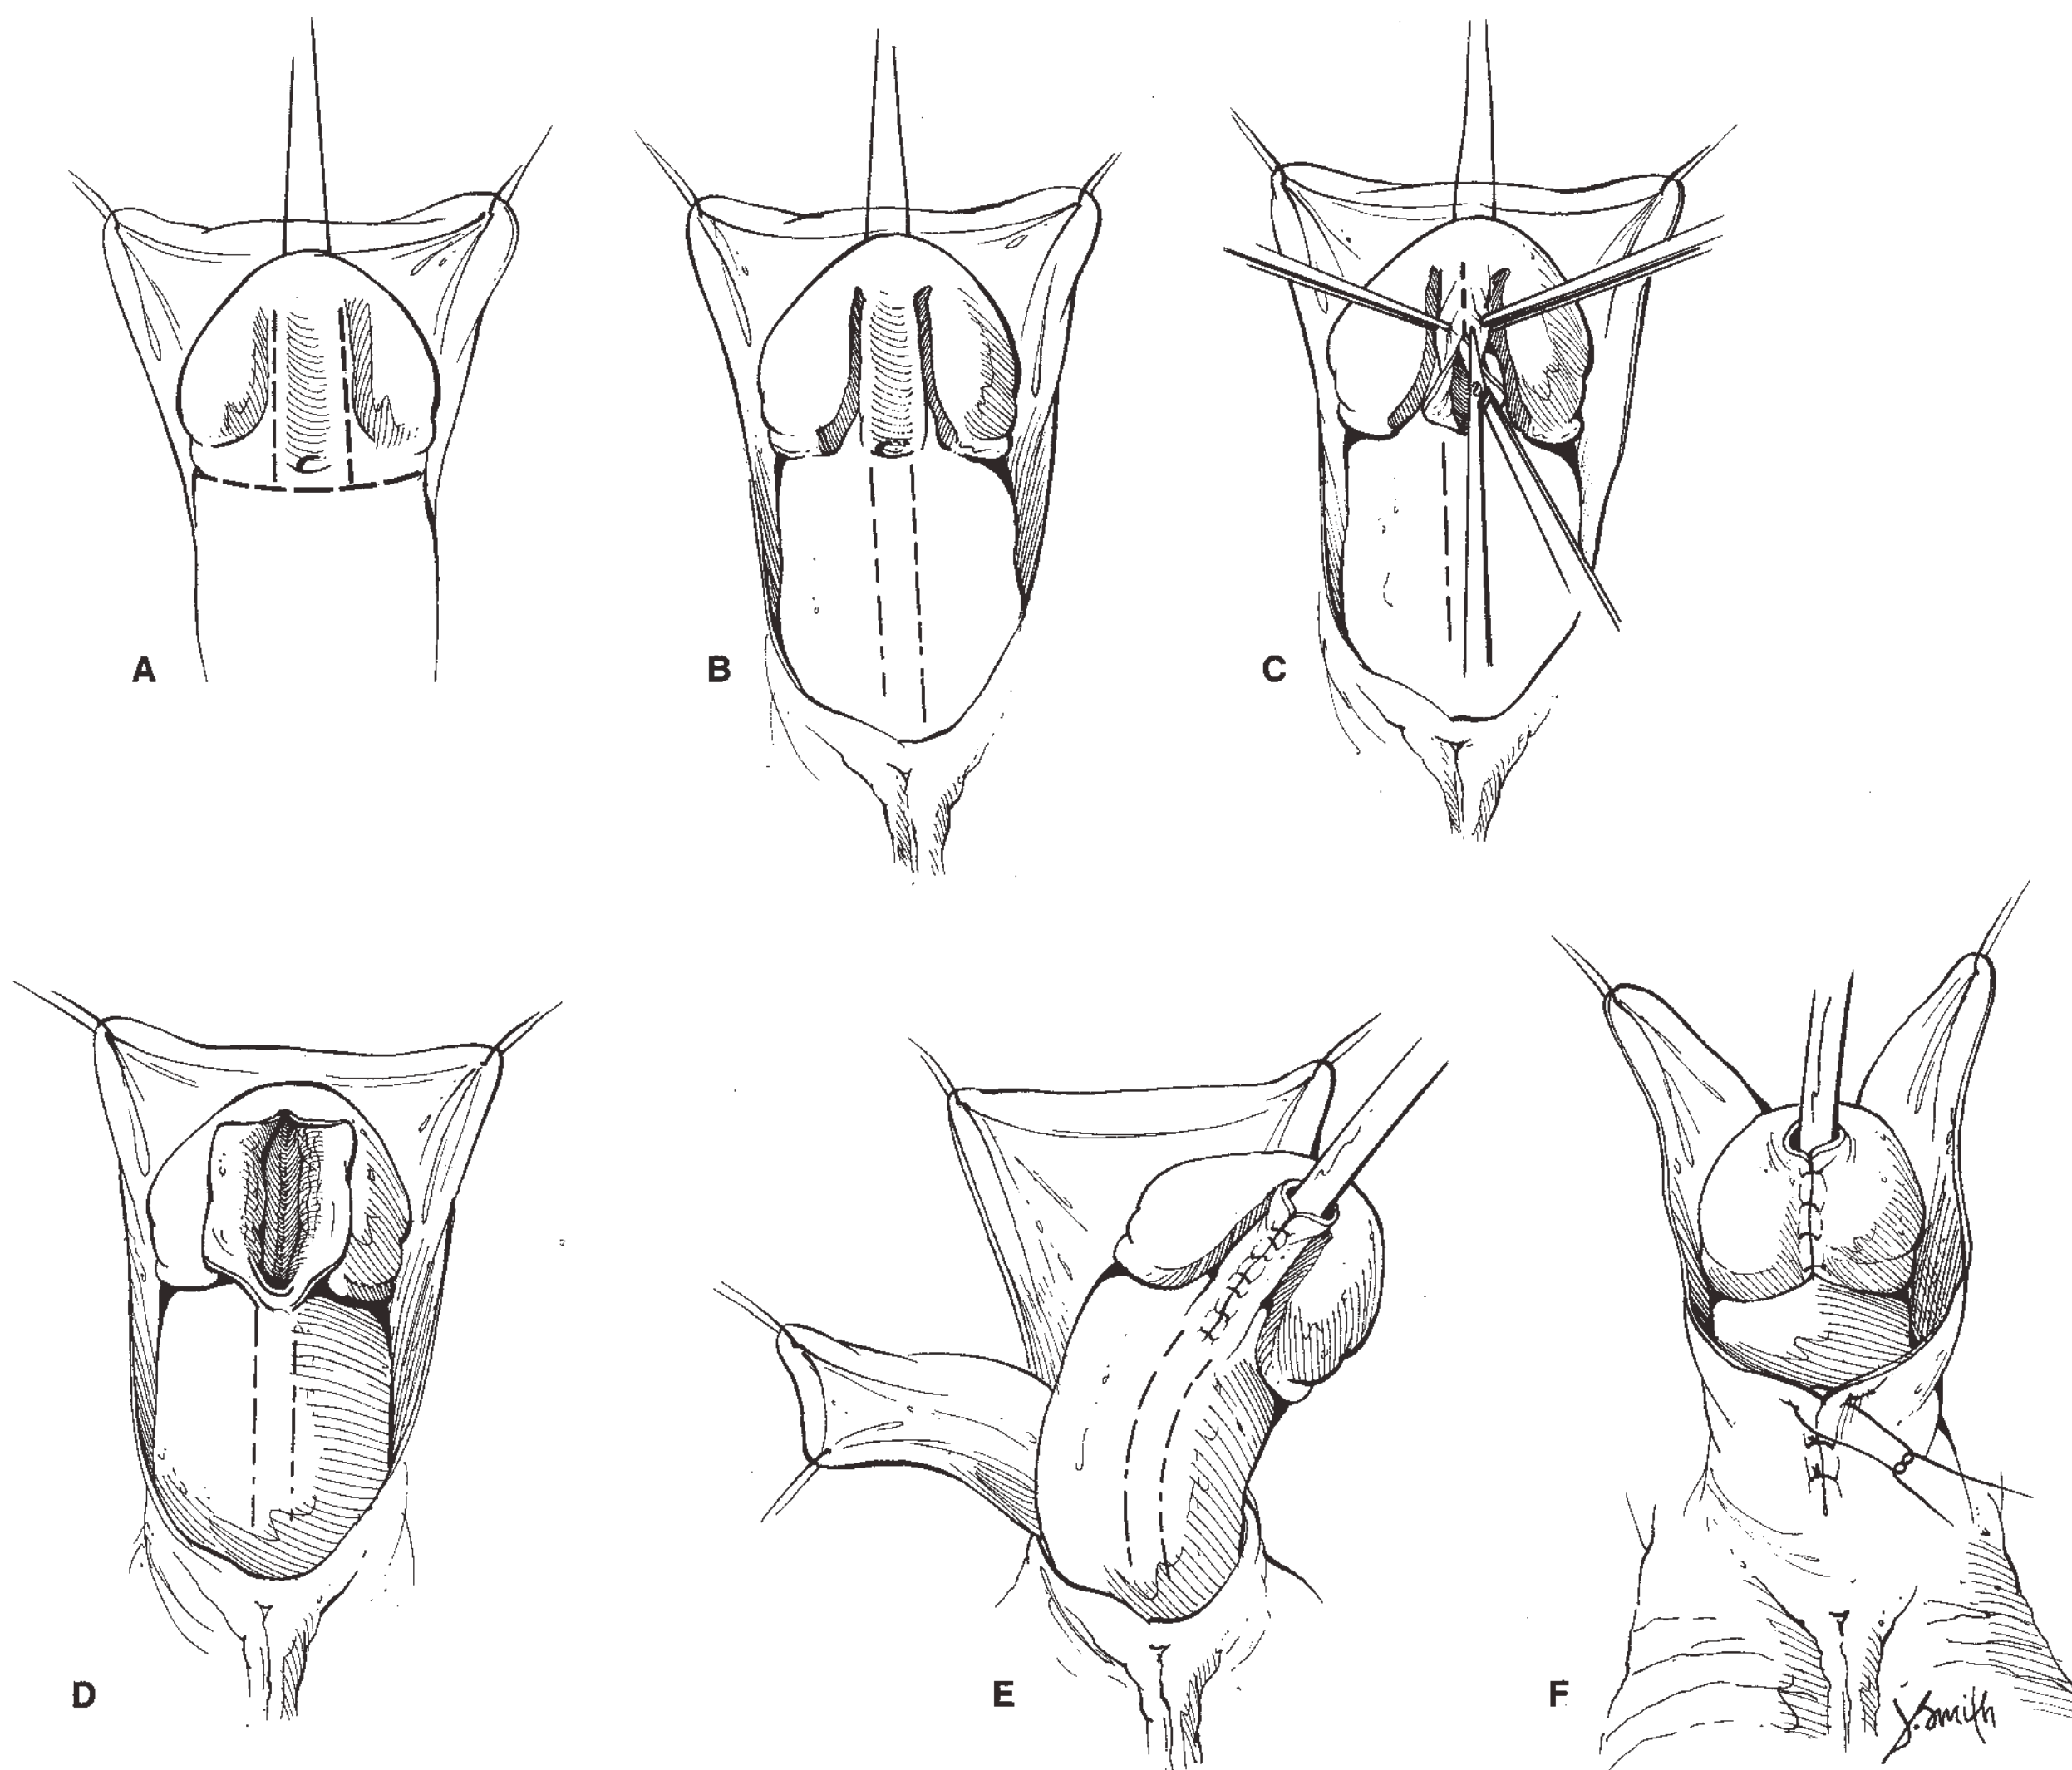

tissue could be released has not held true. In fact, careful anatomic studies have shown an extensive network of blood vessels supplying the urethral plate in the hypospadiac penis, and lifting of the urethral plate defeats the purpose of preservation by violating this intricate blood supply (9). At present, in the majority of cases of posterior hypospadias, including perineal hypospadias, the urethral plate can be preserved and a vascularized flap used in an onlay fashion. In the rare case when the urethral plate needs to be resected, a two-stage technique can be employed (see below).

#### Onlay Island Flap

The blood supply to the hypospadias preputial tissue is reliable and easily delineated. The abundance of cutaneous tissue on the dorsum of the penis is vascularized in a longitudinal fashion. For posterior hypospadias, all cases are approached by initially leaving the urethral plate intact. This includes patients with and without penile curvature. This technique can be applied to penile shaft as well as scrotal and perineal hypospadias. The intact dorsal plate essentially avoids complications of proximal stricture, and the excellent blood supply has decreased the fistula rate to approximately 5% to 10% for all cases of onlay island flap hypospadias repair (Fig. 109.6) (7). Long-term results with the onlay island flap have been very durable. For very severe hypospadias, the prepuce can be designed in a horseshoe style to bridge extensive gaps.

#### Two-Stage Hypospadias Repair

An alternative approach for severe hypospadias is to transfer the dorsal prepuce to the ventrum after correction of penile curvature (Fig. 109.7). In severe cases the urethral plate may need to be resected to correct chordee. Dermal grafting may be required, and performing a urethroplasty on top of the healing graft is not suggested. Byars flaps can be rotated from the dorsum, setting up ventral coverage for subsequent

**FIGURE 109.5** Tubularized, incised plate (TIP) urethroplasty. **A:** *Horizontal line* indicates circumscribing incision to deglove penis. *Vertical lines* show junction of urethral plate and ventral glans. **B:** Parallel incisions separate urethral plate from glans. **C:** Midline incision of urethral plate from meatus to granular tip. **D:** Incision has widened and deepened the urethral plate. **E:** Plate tubularized over 6Fr stent. Dorsal subcutaneous tissues are rotated ventrally to cover the repair. **F:** Midline closure of glans wing, mucosa collar, and ventral shaft skin.

urethroplasty (10). The second stage is performed at least 6 months after the first stage. To facilitate the urethroplasty within the glans, during the first stage dorsal skin is tucked within the glans wings. Subcutaneous secondary coverage of the reconstructed urethra is performed to prevent fistula.

#### Bracka Buccal Two-Stage Repair

For patients with prior surgery or with severe hypospadias, Bracka has described a buccal free graft two-stage repair (11). In the first stage the penis is straightened and the scarred urethra is discarded (Fig. 109.8). Buccal mucosa is harvested from either the cheek or lip and grafted to the prepared bed (12). Extensive quilting of the graft is performed to prevent hematoma from lifting off the buccal mucosa. During the first stage, glans wings are mobilized in preparation for the creation of a slit-like meatus during the second stage. The second-stage urethroplasty is undertaken at least 6 months after

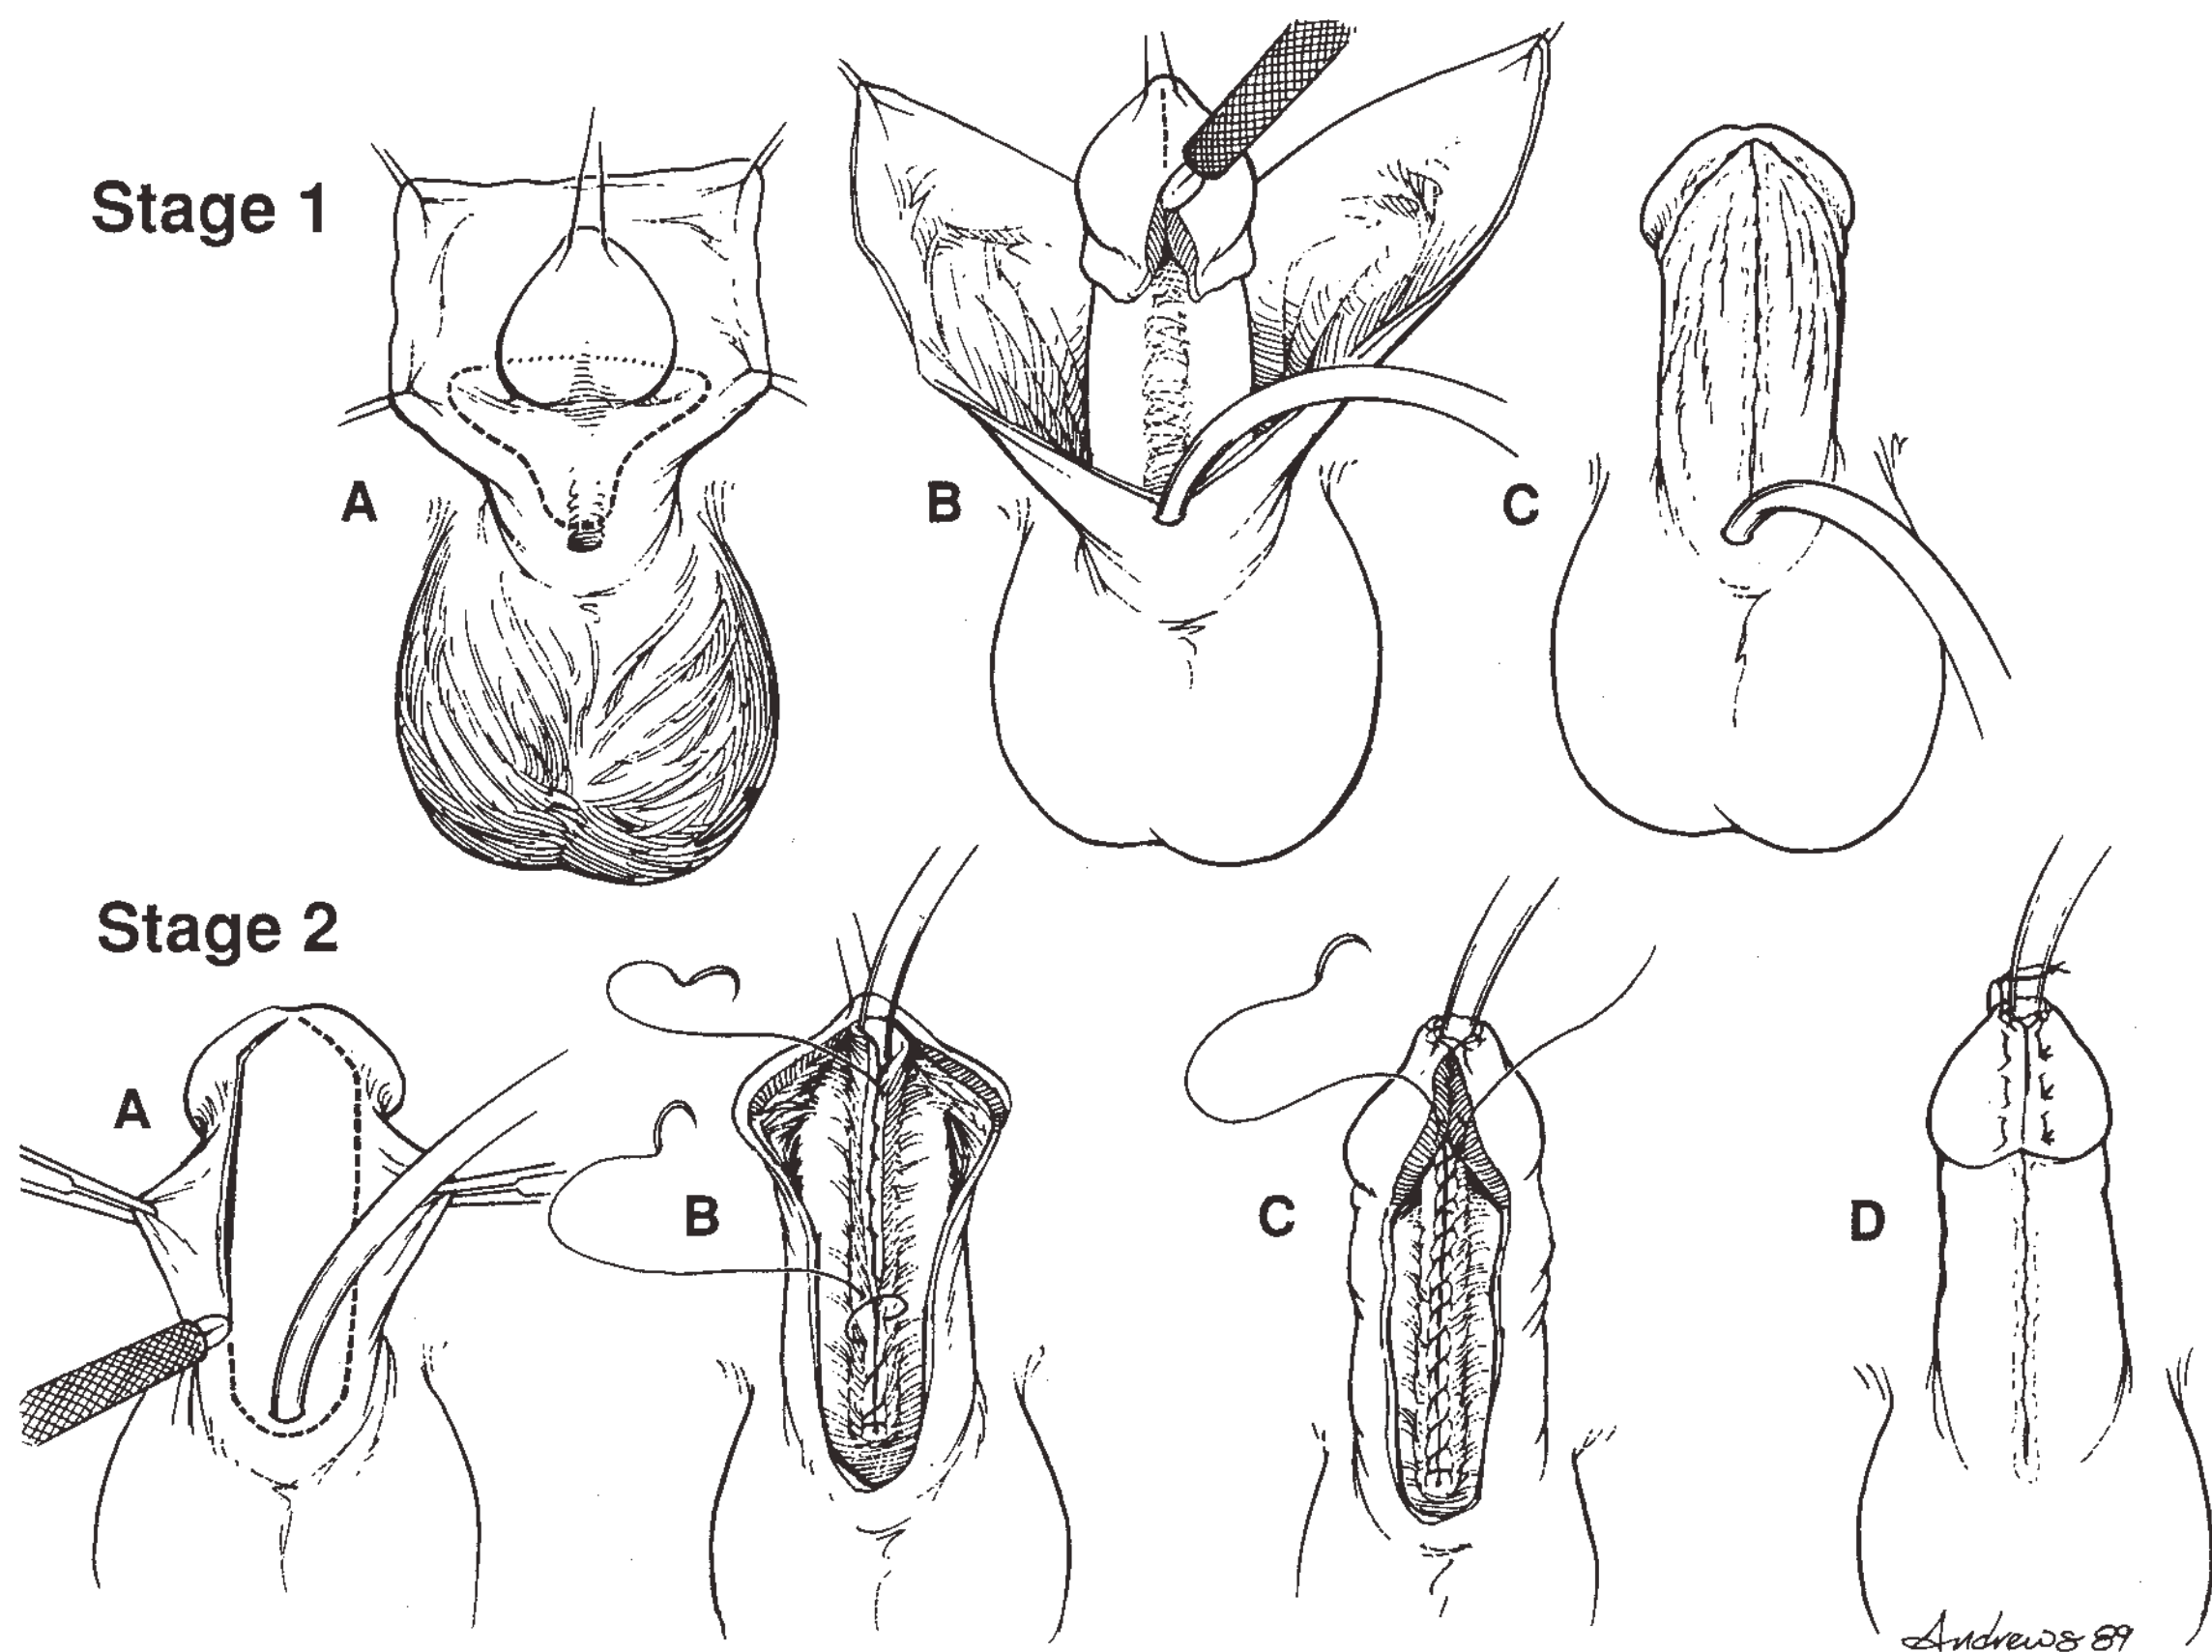

the first stage. In the second stage excess buccal tissue is trimmed off the glans, setting up a two-layer glans closure. The buccal mucosa is rolled into the new urethra and subcutaneous tissue is used for secondary coverage.

#### Penile Curvature (Chordee)

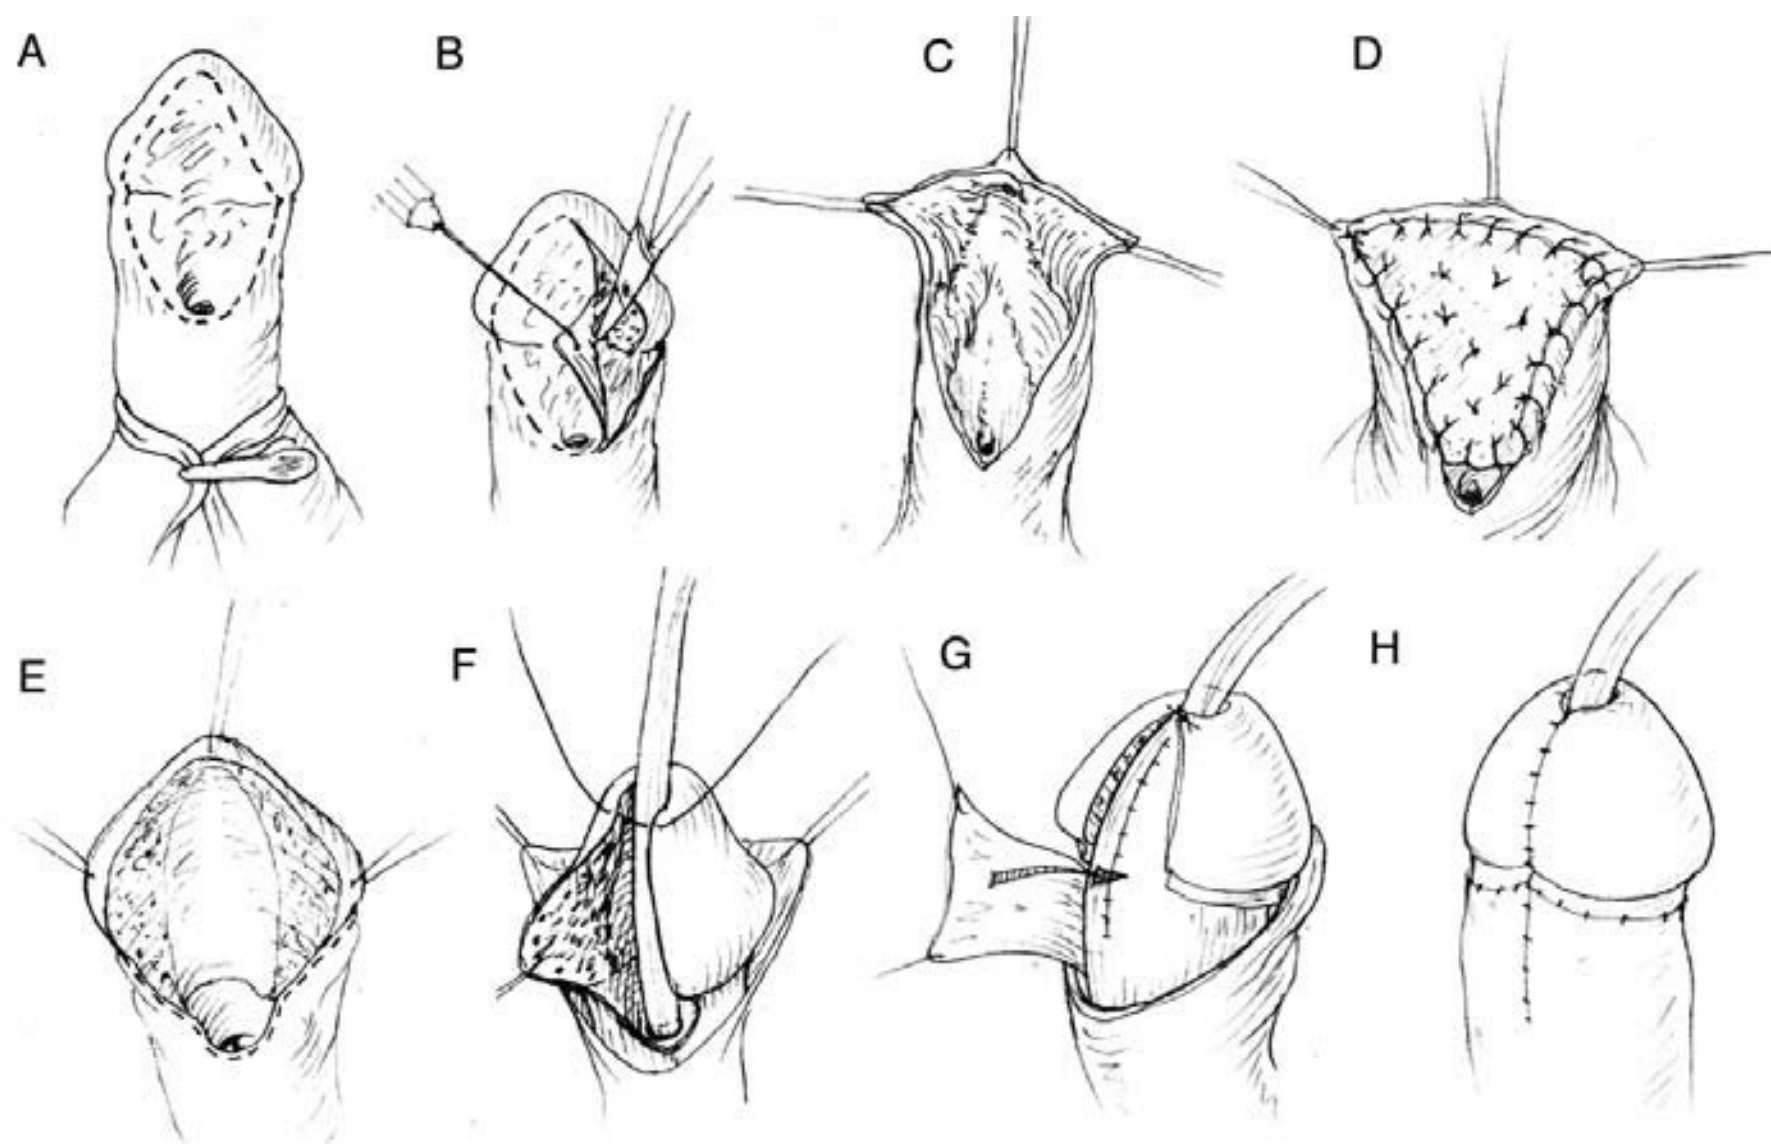

Correction of penile curvature has also evolved along with the concept of preservation of the urethral plate. Based on anatomic studies of the human fetal penis, a simpler approach placing dorsal midline plication sutures in the nerve-free zone at 12:00 is now advocated (9). The midline dorsal plication avoids the need for mobilization of the neurovascular bundle (Fig. 109.9). The midline plication can be applied to mild and moderate to severe degrees of curvature. If more than two rows of plication sutures or greater than four permanent sutures are

**FIGURE 109.6** Onlay island flap **A:** Penile hypospadias. **B:** Preservation of the urethral plate and rectangular outline of the onlay flap. **C:** Onlay of preputial island flap onto urethral plate.

**FIGURE 109.7** Two-stage repair. Stage 1: The unfolded foreskin is brought out to the tip of the incised and mobilized glanular wings (**B**). Delicate sutures reapproximate the skin in the midline and fix the skin to the corpora cavernosa (**C**). Stage 2: A sufficient strip of skin is outlined (**A**). Dissection of the shaft skin is lateral and away from the neourethra (**B**). Two layers of inverting sutures are used to close the neourethra (**B**). If the prepuce has been positioned sufficiently distal at the first stage, a normally positioned meatus with good ventral glandular support can be achieved (**C**). Any excess shaft skin is excised, but the dartos layer is preserved (de-epithelialization) to drape across the neourethral suture line (**D**).

**FIGURE 109.8** Schematic two-stage Bracka buccal hypospadias repair. First stage: **A:** Patient with a midshaft hypospadias and a paucity of available skin after multiple previous hypospadias repairs. **B:** Resection of scar tissue. **C:** Mobilization of glans wings. **D:** Buccal free graft quilted into the resected scar. Second stage after 6 months of healing. **E:** Exposure of glans mesenchyme and trimming of buccal graft for subsequent urethroplasty. **F:** Urethroplasty. **G:** Secondary de-epithelialized pedicle coverage of the urethroplasty. **H:** Two-layer glansplasty and completed repair. (Reproduced with permission from Grossfeld J, O'Neill J, Coran A, Fonkalsrud E. *Pediatric Surgery*, 6th ed. Elsevier, 2006.)

**FIGURE 109.9** Midline dorsal plication technique. In this technique, plication sutures are placed in the tunica albuginea in the 12 o'clock position, which is free of both nerves and vascular structures. This technique involves a minimum amount of manipulation to the penis. It is not necessary to incise into the corporeal body or extensively mobilize the fascia of Buck. A maximum of two rows of parallel plications at the 12 o'clock position can be placed for correction.

necessary, then an alternative approach such as complete resection of the urethral plate and possible dermal grafting should be considered. During artificial erection, if the chordee cannot be corrected with your “finger,” the midline dorsal plication is not advised.

### Postoperative Problems

Bladder spasms not only cause the child to move about in response to pain, but also force urine through the repair. Give analgesics and antispasmodics, such as oxybutynin (Ditropan). Recommend a suitable diet, because the antispasmodic regimen

may result in constipation and lead to straining and urine leakage.

Bleeding is an infrequent problem. A compressive sandwich dressing will resolve the problem in all but the rare patient. In selected cases, give a broad-spectrum antibiotic such as trimethoprim (Septra) or a cephalosporin, and continue it for a few days after the tubing has been removed. Should postoperative erections in older boys become a problem, use amyl nitrate ampules or diazepam sedation to reduce them.

See the patient 6 weeks and 1 year after the repair. Re-evaluate after potty training and at puberty to confirm patient satisfaction and the absence of fistula, stenosis, diverticulum, recurrent chordee, and cosmetic issues.

## OUTCOMES

Results today, cosmetically and functionally, are better than those in the past. The use of a one-stage hypospadias repair at an early age with a low complication rate encourages our current positive outlook for this condition. Curvature correction with the aid of an artificial erection is extremely important for ensuring satisfactory sexual function. With the placement of the urinary meatus at the tip of the glans, the infertility potential has been improved unless the patient has other coexisting testicular problems. Evidence shows that the neourethra grows with the child, and subsequent repairs are seldom necessary.

Early hypospadias repair with minimal hospitalization helps to avoid separation anxiety and castration fears. We can now counsel parents confidently that there is an excellent outlook for a good cosmetic, functional, and emotional result in boys with all degrees of hypospadias.

### Complications

Complications occur after 10% to 30% of hypospadias operations. These include meatal retraction, urethrocutaneous fistula formation, meatal stenosis, urethral stricture, development of a

diverticulum (sometimes with hair, followed by stones), and persistent chordee. Of these, strictures, fistulas, and urethral diverticula account for most of the late problems. These complications should be managed at least 6 months from the time of the initial surgery.

---

## PRACTICAL CONCLUSIONS

---

Hypospadias should be repaired within the first year of life, preferably at 4 to 6 months of age. Pain control and catheters seem better tolerated and the baby's lack of mobility simplifies postoperative care.

A terminal slit-like meatus should be the goal, with or without preservation of the foreskin, depending on parental

preference. Preservation of the urethral plate creates the best possible chance to recreate normal urethral anatomy by incorporating the abortive spongiosum into the repair. Midline dorsal plication is safe and effective for the correction of penile curvature in the majority of patients (placing more than two rows of sutures is a sign that another technique, such as dermal grafting, is indicated). In the small percentage of patients who require resection of the urethral plate, a two-stage approach is generally warranted. Vascularized pedicle onlay flaps are successful in primary and redo hypospadias surgery. De-epithelialized vascular flaps should be used as a second layer for all urethroplasties. Patients with a paucity of skin are best managed with the Bracka two-stage buccal repair. Coronal fistulas require a redo glansplasty.

Surgical volume correlates with successful outcomes.

# CHAPTER 110 ■ COMPLETE PRIMARY REPAIR FOR EXSTROPHY

RICHARD W. GRADY

Bladder exstrophy is a congenital anomaly that has characteristic external physical manifestations; the diagnosis of exstrophy is usually made immediately after birth, although it can be detected antenatally. The anterior portion of the bladder and/or urethra and abdominal wall structures are deficient, and the pubic symphysis is widely separated from the midline in the exstrophy anomalies (Fig. 110.1); the bladder and urethra are herniated ventrally. The exstrophic defects are typically found in isolation; other organ systems are only infrequently affected. However, children with exstrophy typically have an anteriorly located anus. Female genital anatomy is altered, with a more vertically oriented vaginal opening after closure and a wider and shorter vagina than normal. The anterior component of the penis is also foreshortened in males compared to the general population.

---

## DIAGNOSIS

---

In some situations, the diagnosis may be made antenatally, although many affected fetuses are not suspected to have exstrophy before birth (1). In Gearhart's review of 29 antenatal studies of 17 children born with exstrophy (2), only 3 were identified before delivery despite the presence of findings to suggest the diagnosis. Ultrasonography can reliably detect exstrophy before the twentieth week of gestation (2,3). The absence of the bladder is a hallmark of exstrophy. Ultrasonographic findings of exstrophy also include a semi-solid mass protruding from the abdominal wall, an absent bladder, a lower abdominal protrusion, an anteriorly displaced scrotum with a small phallus in male fetuses, normal

**FIGURE 110.1** Initial dissection, inferior view. *Dashed lines* indicate lines of dissection. Note that the lines of dissection proceed around the umbilicus and superior to it. The line of dissection also extends subcoronally around the ventral aspect of the penis. See Fig. 110.2 for another view of the initial lines of dissection.

kidneys in association with a low-set umbilical cord, and an abnormal iliac crest widening.

Subtle findings such as low umbilical cord insertion and the location of the genitalia will only be seen if the fetus is examined in a sagittal alignment with the spine (4). Because exstrophy affects the external genitalia, the diagnosis is easier to make in males than in females. Iliac crest widening can also be seen during the routine prenatal evaluation of the lumbosacral spine that is performed to evaluate for myelomeningocele. The iliac angle will be about 110 degrees rather than the 90 degrees that is normally seen (4). Since urine production is normal for these fetuses, amniotic fluid levels should be normal.

Prenatal diagnosis allows optimal perinatal management of these infants. The infants can be delivered near a pediatric center equipped to treat babies with this unusual anomaly. Of equal importance, antenatal diagnosis also allows the parents the opportunity to discuss early management of the patient. The early counseling should include the expertise of a pediatric urologist experienced in the treatment of bladder exstrophy. Patients with exstrophy can have a satisfactory long-term outcome and life expectancy with appropriate management.

---

## INDICATIONS FOR SURGERY

---

Exstrophy anomalies are nonlethal; children with exstrophy can survive untreated into adulthood (5). However, significant morbidity exists with these conditions if they are left untreated, including total urinary incontinence, bladder and kidney infections, skin breakdown, and tumor formation in the bladder plate. The surrounding skin around the exposed exstrophic bladder is often inflamed secondary to urine contact dermatitis, loss of skin integrity from constant wetness,

and secondary infection. In contrast, when these patients receive effective surgical and medical treatment, they can lead productive, healthy lives with minimal morbidity from their underlying urologic abnormality.

---

## SURGICAL TECHNIQUE

---

Primary goals for exstrophy reconstruction include preservation of kidney function, urinary continence, low-pressure urinary storage, volitional voiding, and functional and cosmetically acceptable external genitalia. Secondary goals for reconstruction include minimization of urinary tract infections, adequate pelvic floor support, minimization of the risk for malignancy associated with the urinary tract, minimization of the risk for urinary calculi, and adequate abdominal wall fascia.

Surgical reconstruction of exstrophy and epispadias represents one of the most significant challenges for physicians who specialize in the urologic care of children. Over the last 15 years, a novel surgical reconstructive approach has been developed for the exstrophy-epispadias complex. In the late 1980s Mitchell (6) devised an anatomic approach that integrated epispadias and exstrophy repair. This operation evolved out of a technique developed for the treatment of epispadias: the complete penile disassembly technique. By employing this technique, the surgeon permits the tissue deformation in exstrophy to return more closely to an anatomically normal position. We have used this approach exclusively for the surgical treatment of newborns with exstrophy since 1990. This operation or its principles are also useful in some reoperative repairs or delayed repairs for exstrophy.

---

## Preoperative Care

---

After delivery, to reduce trauma to the bladder plate, the umbilical cord should be ligated with silk suture rather than a plastic or metal clamp. A hydrated gel dressing may be used to protect the exposed bladder from superficial trauma. This type of dressing is easy to use, keeps the bladder plate from becoming desiccated, and stays in place to allow handling of the infant with minimal risk of trauma to the bladder. Plastic wrap is an acceptable alternative. Dressings should be replaced daily, and the bladder should be irrigated with normal saline with each diaper change. A humidified air incubator may also minimize bladder trauma.

We routinely use intravenous antibiotic therapy in the pre- and postoperative period to decrease the risk for infection following reconstruction. We also perform preoperative ultrasonography to assess the kidneys and to establish a baseline examination for later ultrasonographic studies. Preoperative spinal sonographic examination should be considered if sacral dimpling or other signs of spina bifida occulta are noted on physical examination.

---

## Operative Considerations

---

Ideally, the primary exstrophy closure is performed in the newborn period. We routinely use general inhalation anesthesia. However, nitrous oxide should be avoided during primary closure as it may cause bowel distention, which decreases

surgical exposure during the operation and increases the risk of wound dehiscence. Some advocate the use of nasogastric tube drainage to decrease abdominal distention in the postoperative period, but we do not routinely use it postoperatively. We do routinely place an epidural catheter to reduce the inhaled anesthetic requirement during the operation. Tunneling the catheter may reduce the risk for infection if it is left in for prolonged periods after surgery.

For patients older than 3 days or newborns with a wide pubic diastasis, we perform anterior iliac osteotomies. Osteotomies assist closure and enhance anterior pelvic floor support, which may improve later urinary continence.

Factors that appear to be important in the operative period include use of osteotomies in selected cases and for newborn closures >48 hours after birth to decrease the tension on the repair, ureteral stenting and bladder drainage catheters placed intraoperatively for use in the postoperative period to divert urine, avoidance of abdominal distention, and use of intraoperative antibiotics.

## Complete Primary Repair for Exstrophy Surgical Technique: Boys

After standard preparation of the surgical field, we place transversely oriented traction sutures into each of the hemiglans of the penis. We then mark the lines of dissection (Figs. 110.1 and 110.2). Care is taken in marking these lines to exclude dysplastic tissue at the edges of the exstrophic bladder and bladder neck. This is particularly important at the bladder neck, where dysplastic tissue left in the continuity may impair later bladder neck function. Following this, we place 3.5Fr umbilical artery catheters into both ureters and suture them in place with 5.0 chromic sutures. Bladder polyps are removed prior to beginning the dissection, since these will act as space-occupying lesions after the bladder is reconstructed (Fig. 110.2). Initial dissection begins superiorly and proceeds inferiorly to separate the bladder from the adjacent skin and fascia, since it is usually easiest to identify tissue

**FIGURE 110.2** View of lines of dissection from above. The urethral dissection is carried along the lateral aspect of the urethral plate.

planes in this location. We use tungsten fine-tip electrocautery (Colorado tip) during this dissection to reduce blood loss. The umbilical vessels may be ligated if necessary. We also incise the periumbilical skin circumferentially at this time. The umbilicus will be moved superiorly to a more anatomically normal location and will be later used as the location to bring out the suprapubic catheter (Figs. 110.3 and 110.4).

### Penile/Urethral Dissection

Traction sutures placed into each hemiglans of the penis aid in dissection at this point in the operation (Fig. 110.2). The sutures will rotate to a parallel vertical orientation (Fig. 110.5) because the corporal bodies will naturally rotate medially after they are separated from the urethral wedge (urethral plate plus underlying corpora spongiosa). We begin the penile dissection along the ventral aspect of the penis as a circumcising incision (see line of dissection in Fig. 110.1). This step precedes dissection of the urethral wedge from the corporal bodies because it is easier to identify the plane of dissection above the Buck fascia ventrally (Fig. 110.6). The Buck fascia is deficient or absent around the corpus spongiosum; as the dissection progresses medially to separate the urethra from the corpora cavernosa, the plane shifts subtly from above the Buck fascia to just above the tunica albuginea. It is important to recognize this. Failure to adjust the plane of dissection will carry the dissection into the corpus spongiosum; this will result in excessive, difficult-to-control bleeding during the deep ventral dissection of the urethral wedge from the corporal bodies.

Applying methylene blue or brilliant green to the urethra can help identify the plane between urothelium and squamous epithelium. We routinely inject surrounding tissues with 0.25% lidocaine and 1:200,000 U per mL epinephrine to improve hemostasis. This may assist the dissection. Shallow incisions are made laterally along the dorsal aspect of the urethra to begin the dissection (Fig. 110.7). Sharp dissection is required to develop the plane between the urethral wedge and the corporal bodies. Careful dissection will preserve urethral width and length. This is particularly important because the urethra is often too short to reach the glans penis once the bladder has been moved into the pelvis.

Careful lateral dissection of the penile shaft skin and dartos fascia from the corporal bodies will avoid damaging the laterally located neurovascular bundles on the corpora of the epispadic penis. The lateral dissection on the penis should be superficial to the Buck fascia because of the lateral location of the neurovascular bundles in the epispadic penis.

### Complete Penile Disassembly and Deep Dissection

Once a plane is established between the penis and the urethral wedge (Fig. 110.8), the penis may be disassembled into three components: (a) the right and (b) left corporal bodies with their respective hemiglans and (c) the urethral wedge (urothelium with underlying corpora spongiosa). This is done primarily to provide exposure to the intersymphyseal band and to allow adequate proximal dissection. We have found that the easiest plane of dissection to completely isolate the corporal bodies is proximal and ventral (Fig. 110.9). The plane of dissection should be carried out at the level of the tunica albuginea on the corpora. After a plane is established between the urethral wedge and the corporal bodies, this dissection is carried distally to separate the three components from each other (Fig. 110.10). Complete separation of the corporal bodies

**FIGURE 110.3** The exposure for deep dissection is optimal after complete separation of the corporal bodies. It is crucial to adequately divide the inter-symphyseal band (*inset*) to allow the bladder and urethra to move posteriorly.

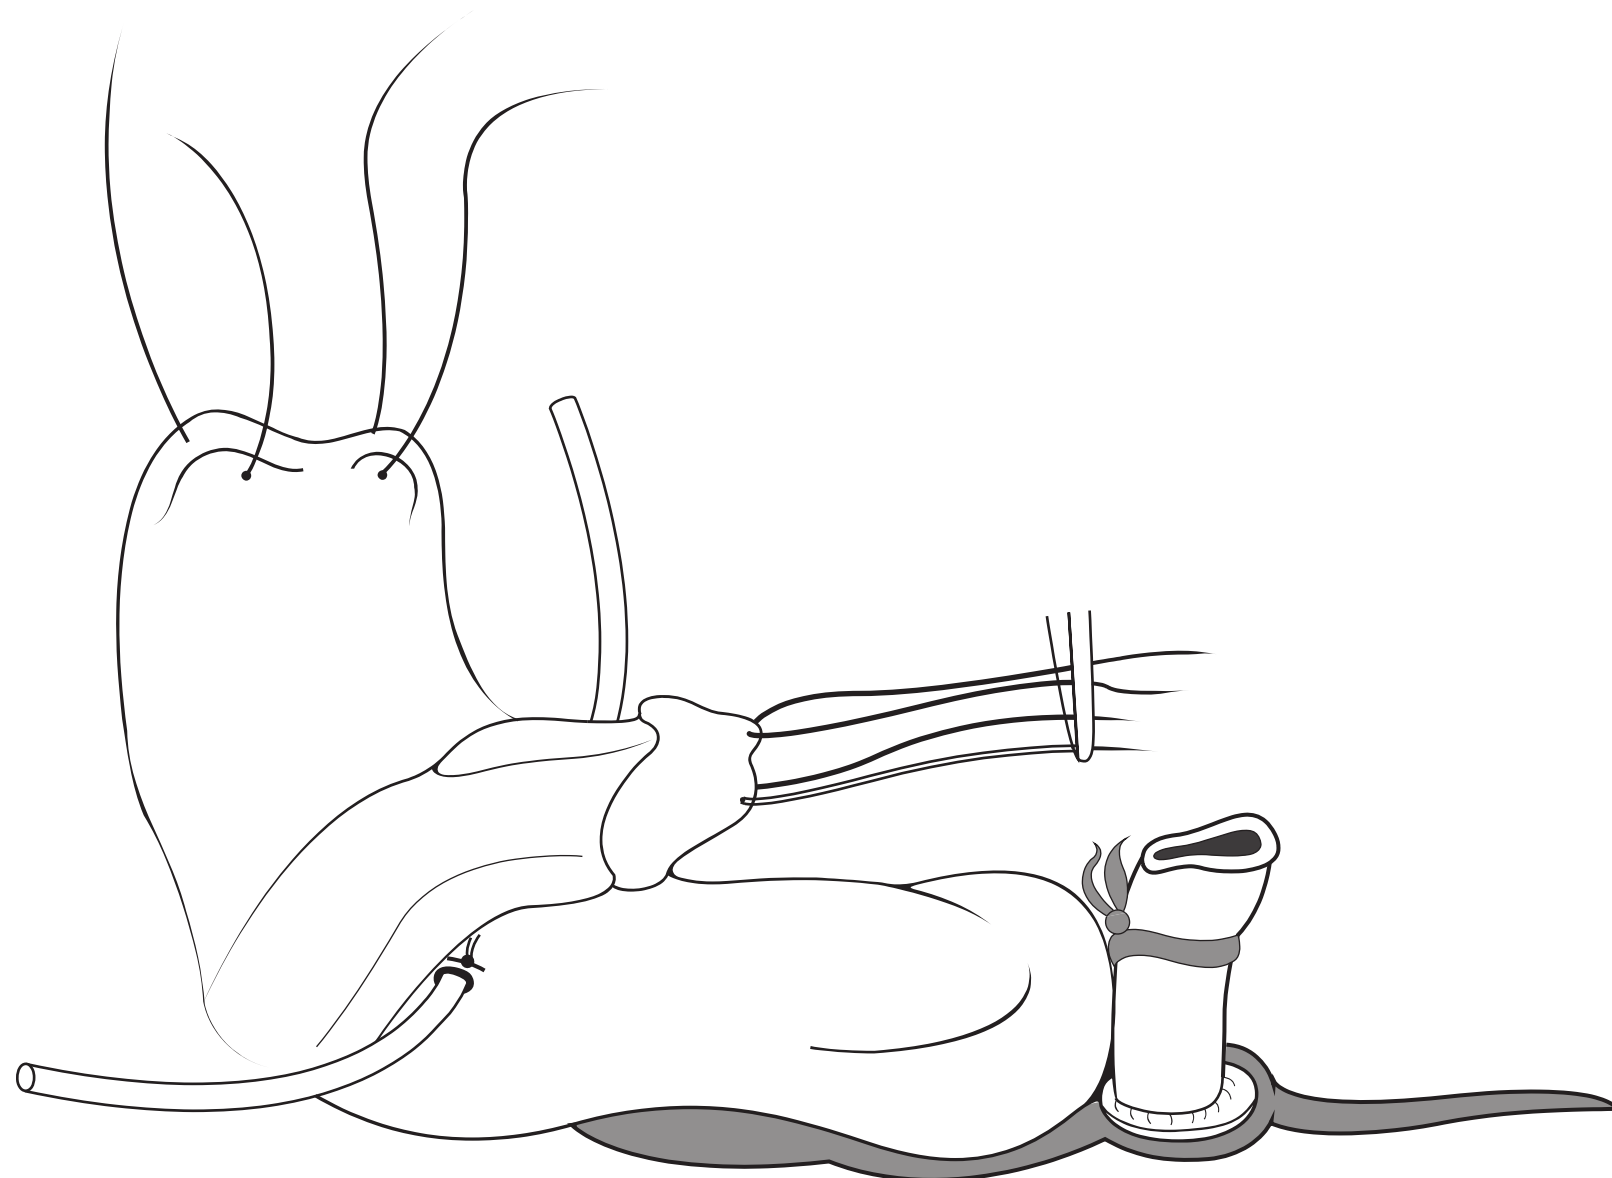

**FIGURE 110.4** To adequately cover the penis dorsally, Z-plasty incisions may be necessary. We also employ tacking sutures dorsally (*inset*).

**FIGURE 110.5** The urethra and bladder are reapproximated in a two-layer closure.

increases exposure to the pelvic diaphragm for deep dissection. The corporal bodies may be completely separated from each other because they exist on a separate blood supply (Figs. 110.9 and 110.10). It is important to keep the underlying corpora spongiosa with the urethra; the blood supply to the urethra is based on this corporal tissue, which should appear wedge-shaped after its dissection from the adjacent corpora cavernosa. The urethral/corpora spongiosa component will

**FIGURE 110.6** Ventral dissection is initiated most easily below the glans with a circumcising incision. The dissection may be carried proximally.

later be tubularized and placed ventral to the corporal bodies. Paraexstrophy skin flaps should not be used with this technique because this maneuver will place the blood supply to the distal urethra at risk. Because the bladder and urethra are moved posteriorly in the pelvis as a unit (with a common proximal blood supply), division of the urethral wedge is counterintuitive to the intent of the repair. In some cases, a male patient will be left with a hypospadias that will require later surgical reconstruction. The urethra and corporal bodies do not always have to be separated; occasionally the urethra is long enough and the bladder mobile enough to preserve the connection between them while still effectively carrying out the deep pelvic dissection that is integral to this repair.

After separating the components distally, the urethral dissection is carried proximally to the bladder neck. Exposure to the pelvic diaphragm is optimized by complete separation of the urethra and corporal bodies (Fig. 110.10). This creates the surgical exposure to perform the deep incision of the intersymphyseal band required to move the bladder and urethra posteriorly. When dissecting the urethral wedge from the corporal bodies medially, the dissection plane is on the tunica albuginea of the corpora cavernosa (Fig. 110.9). This medial dissection should be carried down through the intersymphyseal band (the condensation of anterior pelvic fascia and ligaments) (Fig. 110.3 inset).

Deep incision of the intersymphyseal band posterior and lateral to each side of the urethral wedge is absolutely necessary to allow the bladder and bladder neck to achieve a posterior position in the pelvis. This dissection should be carried until the pelvic floor musculature becomes visible. Failure to adequately dissect the bladder and urethral wedge from these surrounding structures will prevent posterior movement of the bladder in the pelvis and create anterior tension along the urethral plate.

### Primary Closure

Once the intersymphyseal band is adequately incised and the bladder and urethral wedge are adequately dissected from the surrounding tissues, the bladder and urethra can be

**FIGURE 110.7** The urethra is dissected from the corporal bodies. This plane of dissection is developed from both a ventral and lateral perspective using sharp dissection.

reapproximated. This portion of the repair is straightforward and anatomic. To provide urinary drainage, we place a suprapubic tube and bring it out through the umbilicus. We then perform a primary closure of the bladder using a three-layer closure with monofilament absorbable suture (i.e., Monocryl and Vicryl). The urethra is tubularized using a two-layer running

closure with monofilament and braided absorbable suture (Fig. 110.5). Because of the previous deep dissection, we can position the tubularized urethra ventral to the corpora in a tension-free fashion. If the urethra cannot be positioned ventrally without creating tension, it is likely that a deeper incision is required into the intersymphyseal band and pelvic fascia.

**FIGURE 110.8** Disassembly of the corporal bodies from the urethra and corpora spongiosa (the urethral wedge) can often be most easily begun at the position depicted here. The dissection is carried distally to completely separate the glans penis.

**FIGURE 110.9** Perineal view of complete disassembly. Notice depth of dissection.

**FIGURE 110.10** The urethra and corporal bodies are separated distally to allow deep dissection of the pelvic floor musculature.

We reapproximate the pubic symphysis using two no. 1 polydioxanone interrupted sutures placed in a figure-of-eight fashion. Knots are left anteriorly to prevent suture erosion into the bladder neck (Fig. 110.11). The rectus fascia is reapproximated using an interrupted or running 2-0 polydioxanone suture (PDS). We also place interrupted 6-0 PDSs along the dorsal aspect of the corporal bodies to reapproximate them (Fig. 110.12). We provide penile skin coverage by using either a primary dorsal closure or reversed Byars flaps if needed. The skin covering the abdominal wall is reapproximated using a two-layer closure of absorbable monofilament suture.

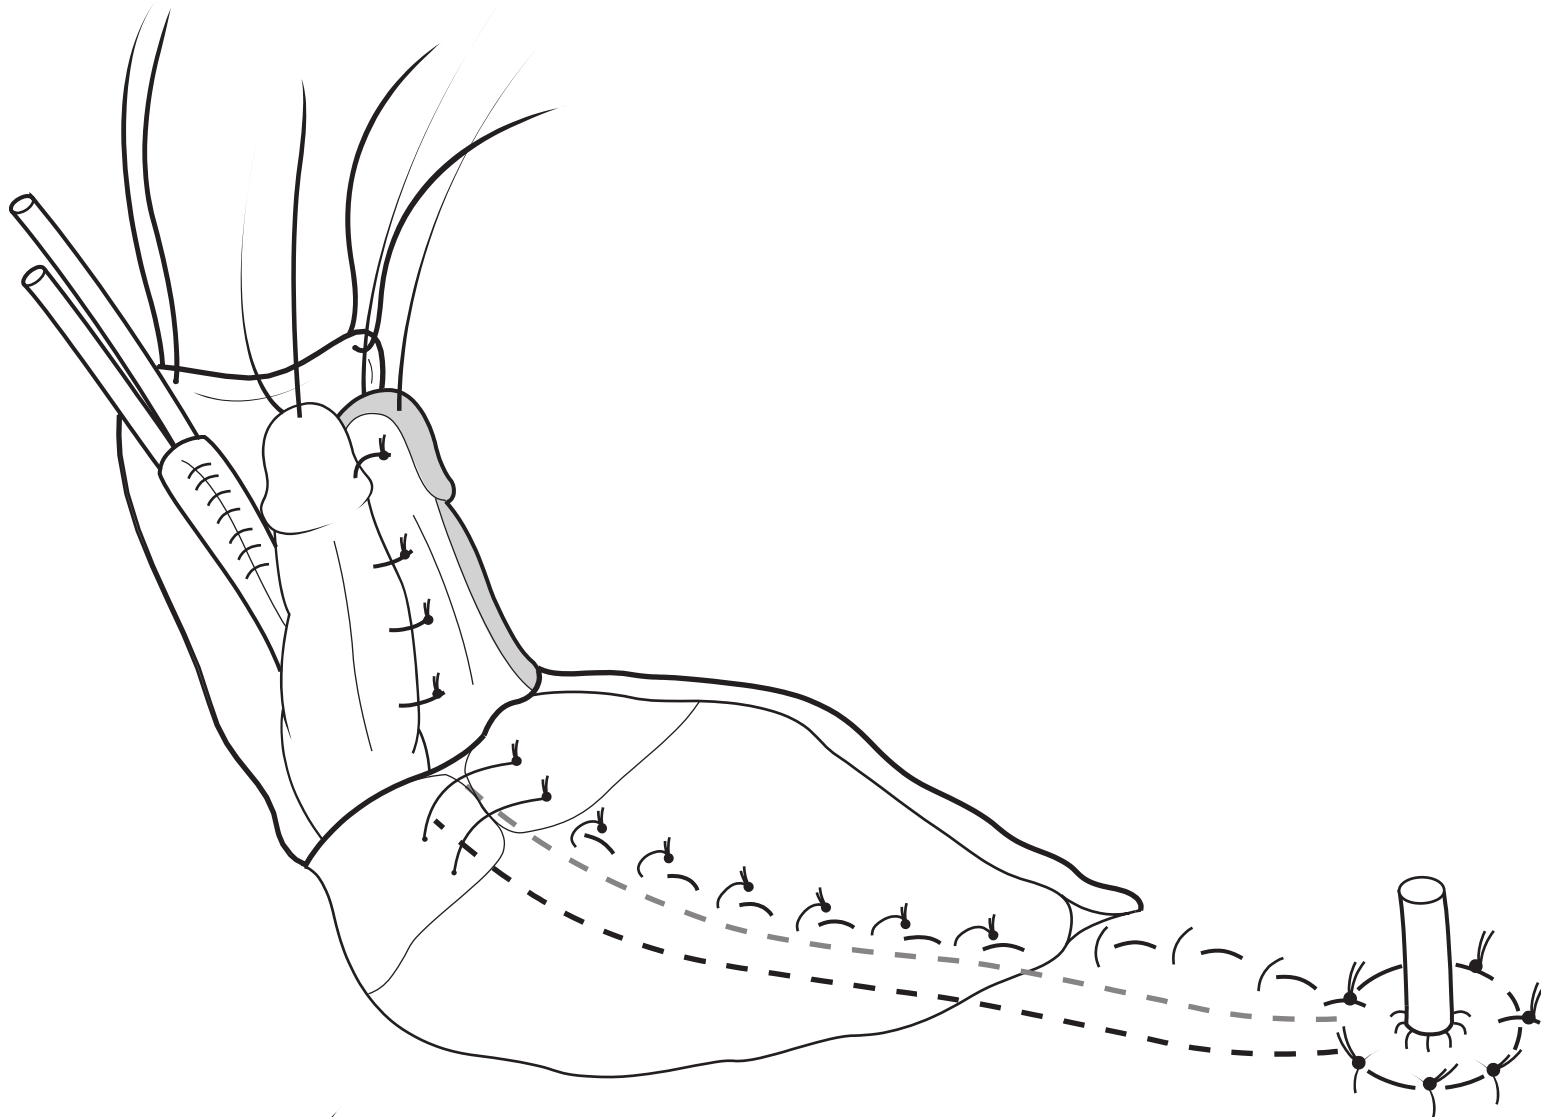

The corporal bodies will rotate medially with closure (Fig. 110.11). This rotation will assist in correcting the dorsal deflection and can be readily appreciated by observing the new vertical lie of the previously horizontally placed glans traction sutures. Occasionally, significant discrepancies in the dorsal and ventral lengths of the corpora will require dermal graft insertion to correct chordee.

If there is adequate urethral length, the urethra may be brought up to each hemiglans ventrally to create an orthotopic meatus (Fig. 110.12). We reconfigure the glans using interrupted mattress PDSs followed by horizontal mattress sutures of 7-0 monofilament suture to reapproximate the glans epithelium. The neourethra is matured with 7-0 braided polyglactin suture similar to our standard hypospadias repair. When needed, we also perform glans tissue reduction to create a conical-appearing glans and to eliminate the furrow between the glans halves. Tacking sutures are placed ventrally and dorsally to prevent penile shaft skin from riding over the corporal bodies and “burying” the penis (Figs. 110.4 and 110.13).

In our hands, the urethra lacks enough length to reach the glans in about half the cases. In this situation we mature the urethra along the ventral aspect of the penis to create a hypospadias. This can be corrected at a later date as a second-stage procedure (7). We often leave redundant shaft skin ventrally in these patients to assist in later penile reconstructive procedures.

**FIGURE 110.11** After the bladder and urethra are reconstructed, these structures will move posteriorly. The urethra will assume a more normal anatomic position. The pubic symphysis is reapproximated with two figure-of-eight sutures.

**FIGURE 110.12** The corporal bodies will rotate medially so that the neurovascular bodies are located medially. The suprapubic tube can be brought out through the umbilicus. The umbilicus is moved superiorly to a more normal anatomic location.

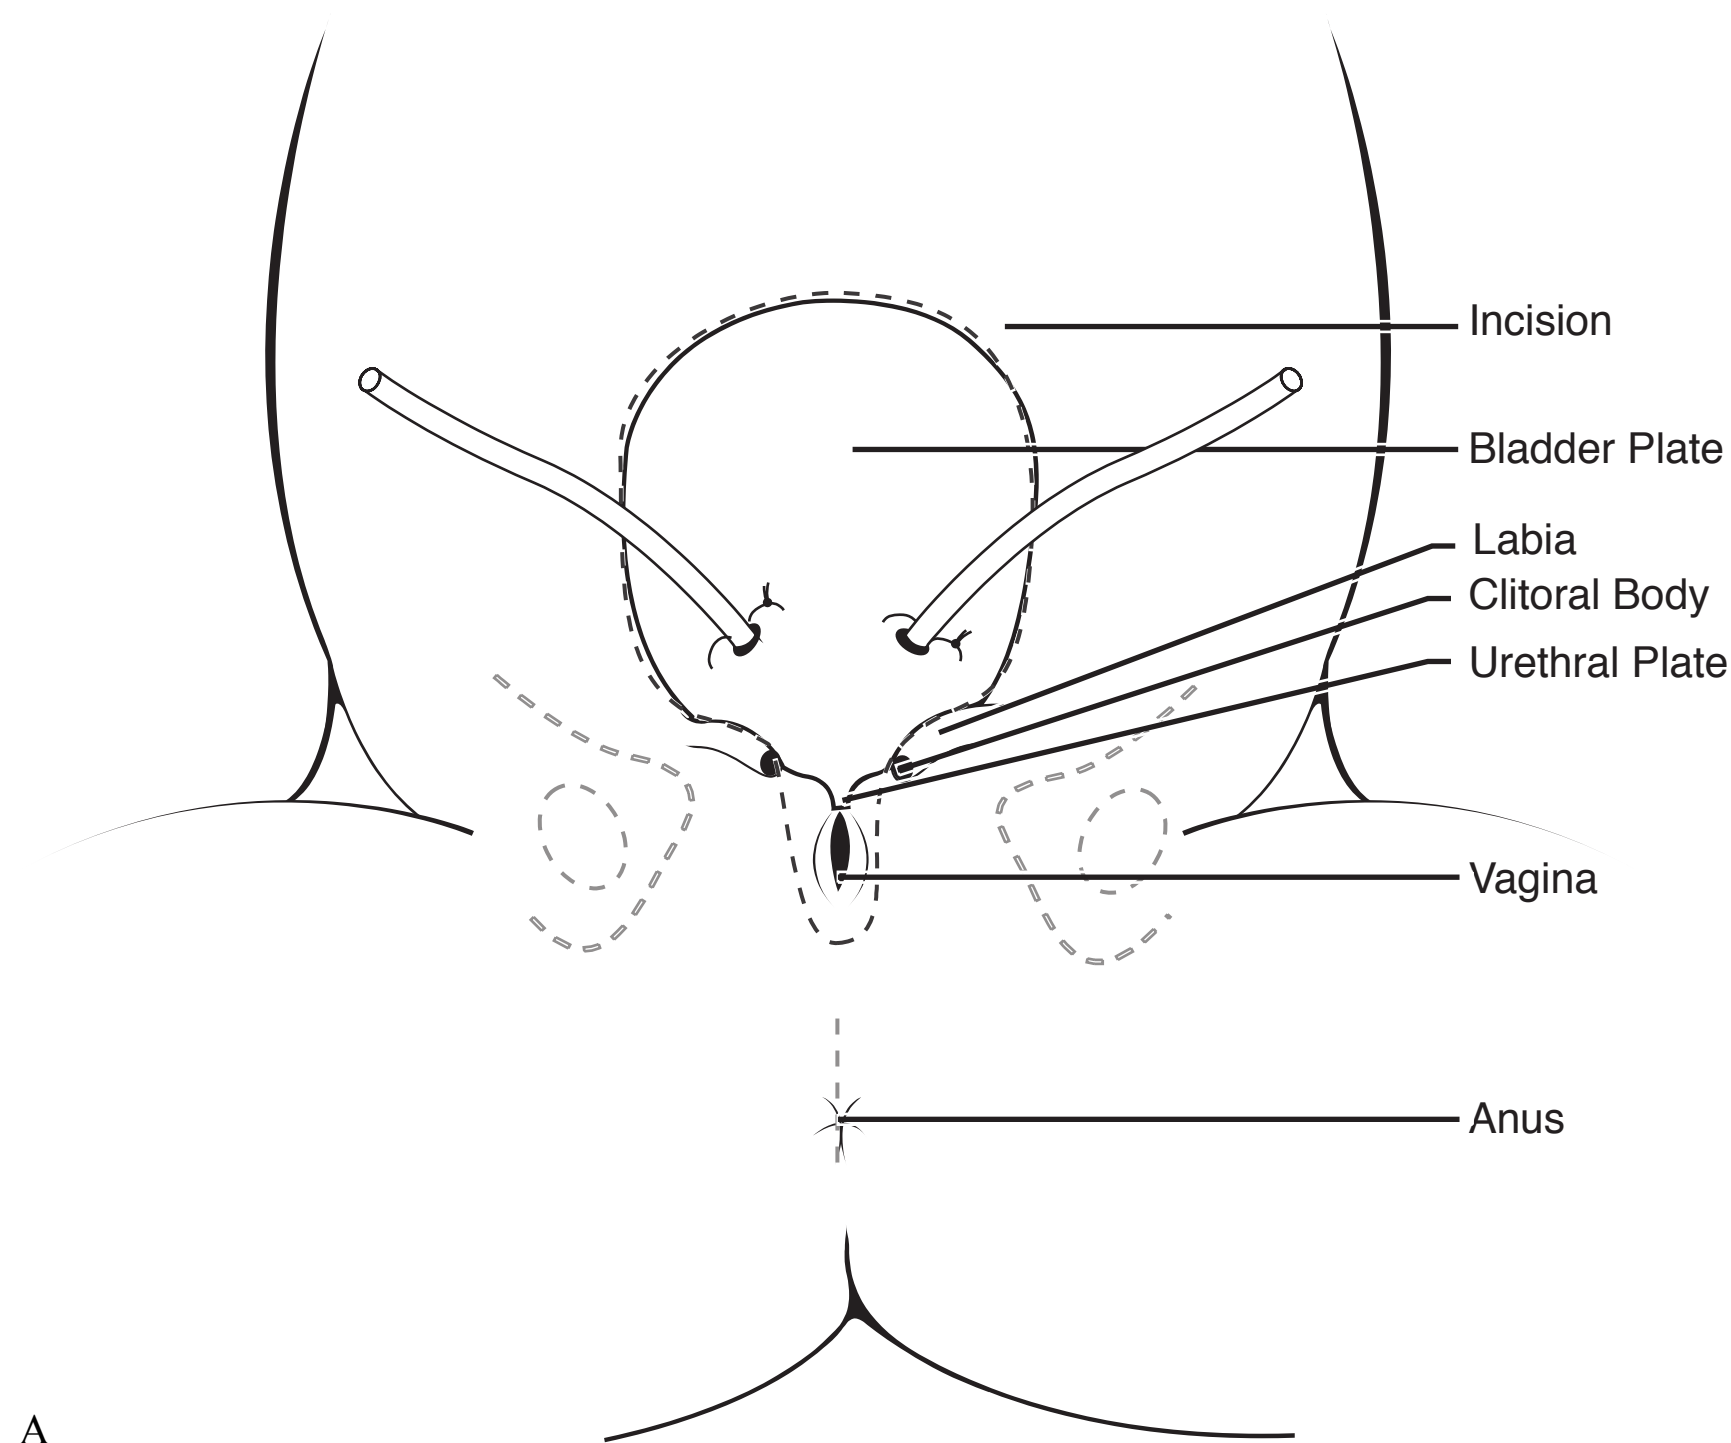

**FIGURE 110.13** The ventral shaft skin is secured to the base of the penis to prevent the penile shaft skin from riding over the body of the penis. The ureteral catheters are brought out through the urethra.

## The Primary Repair Technique: Girls

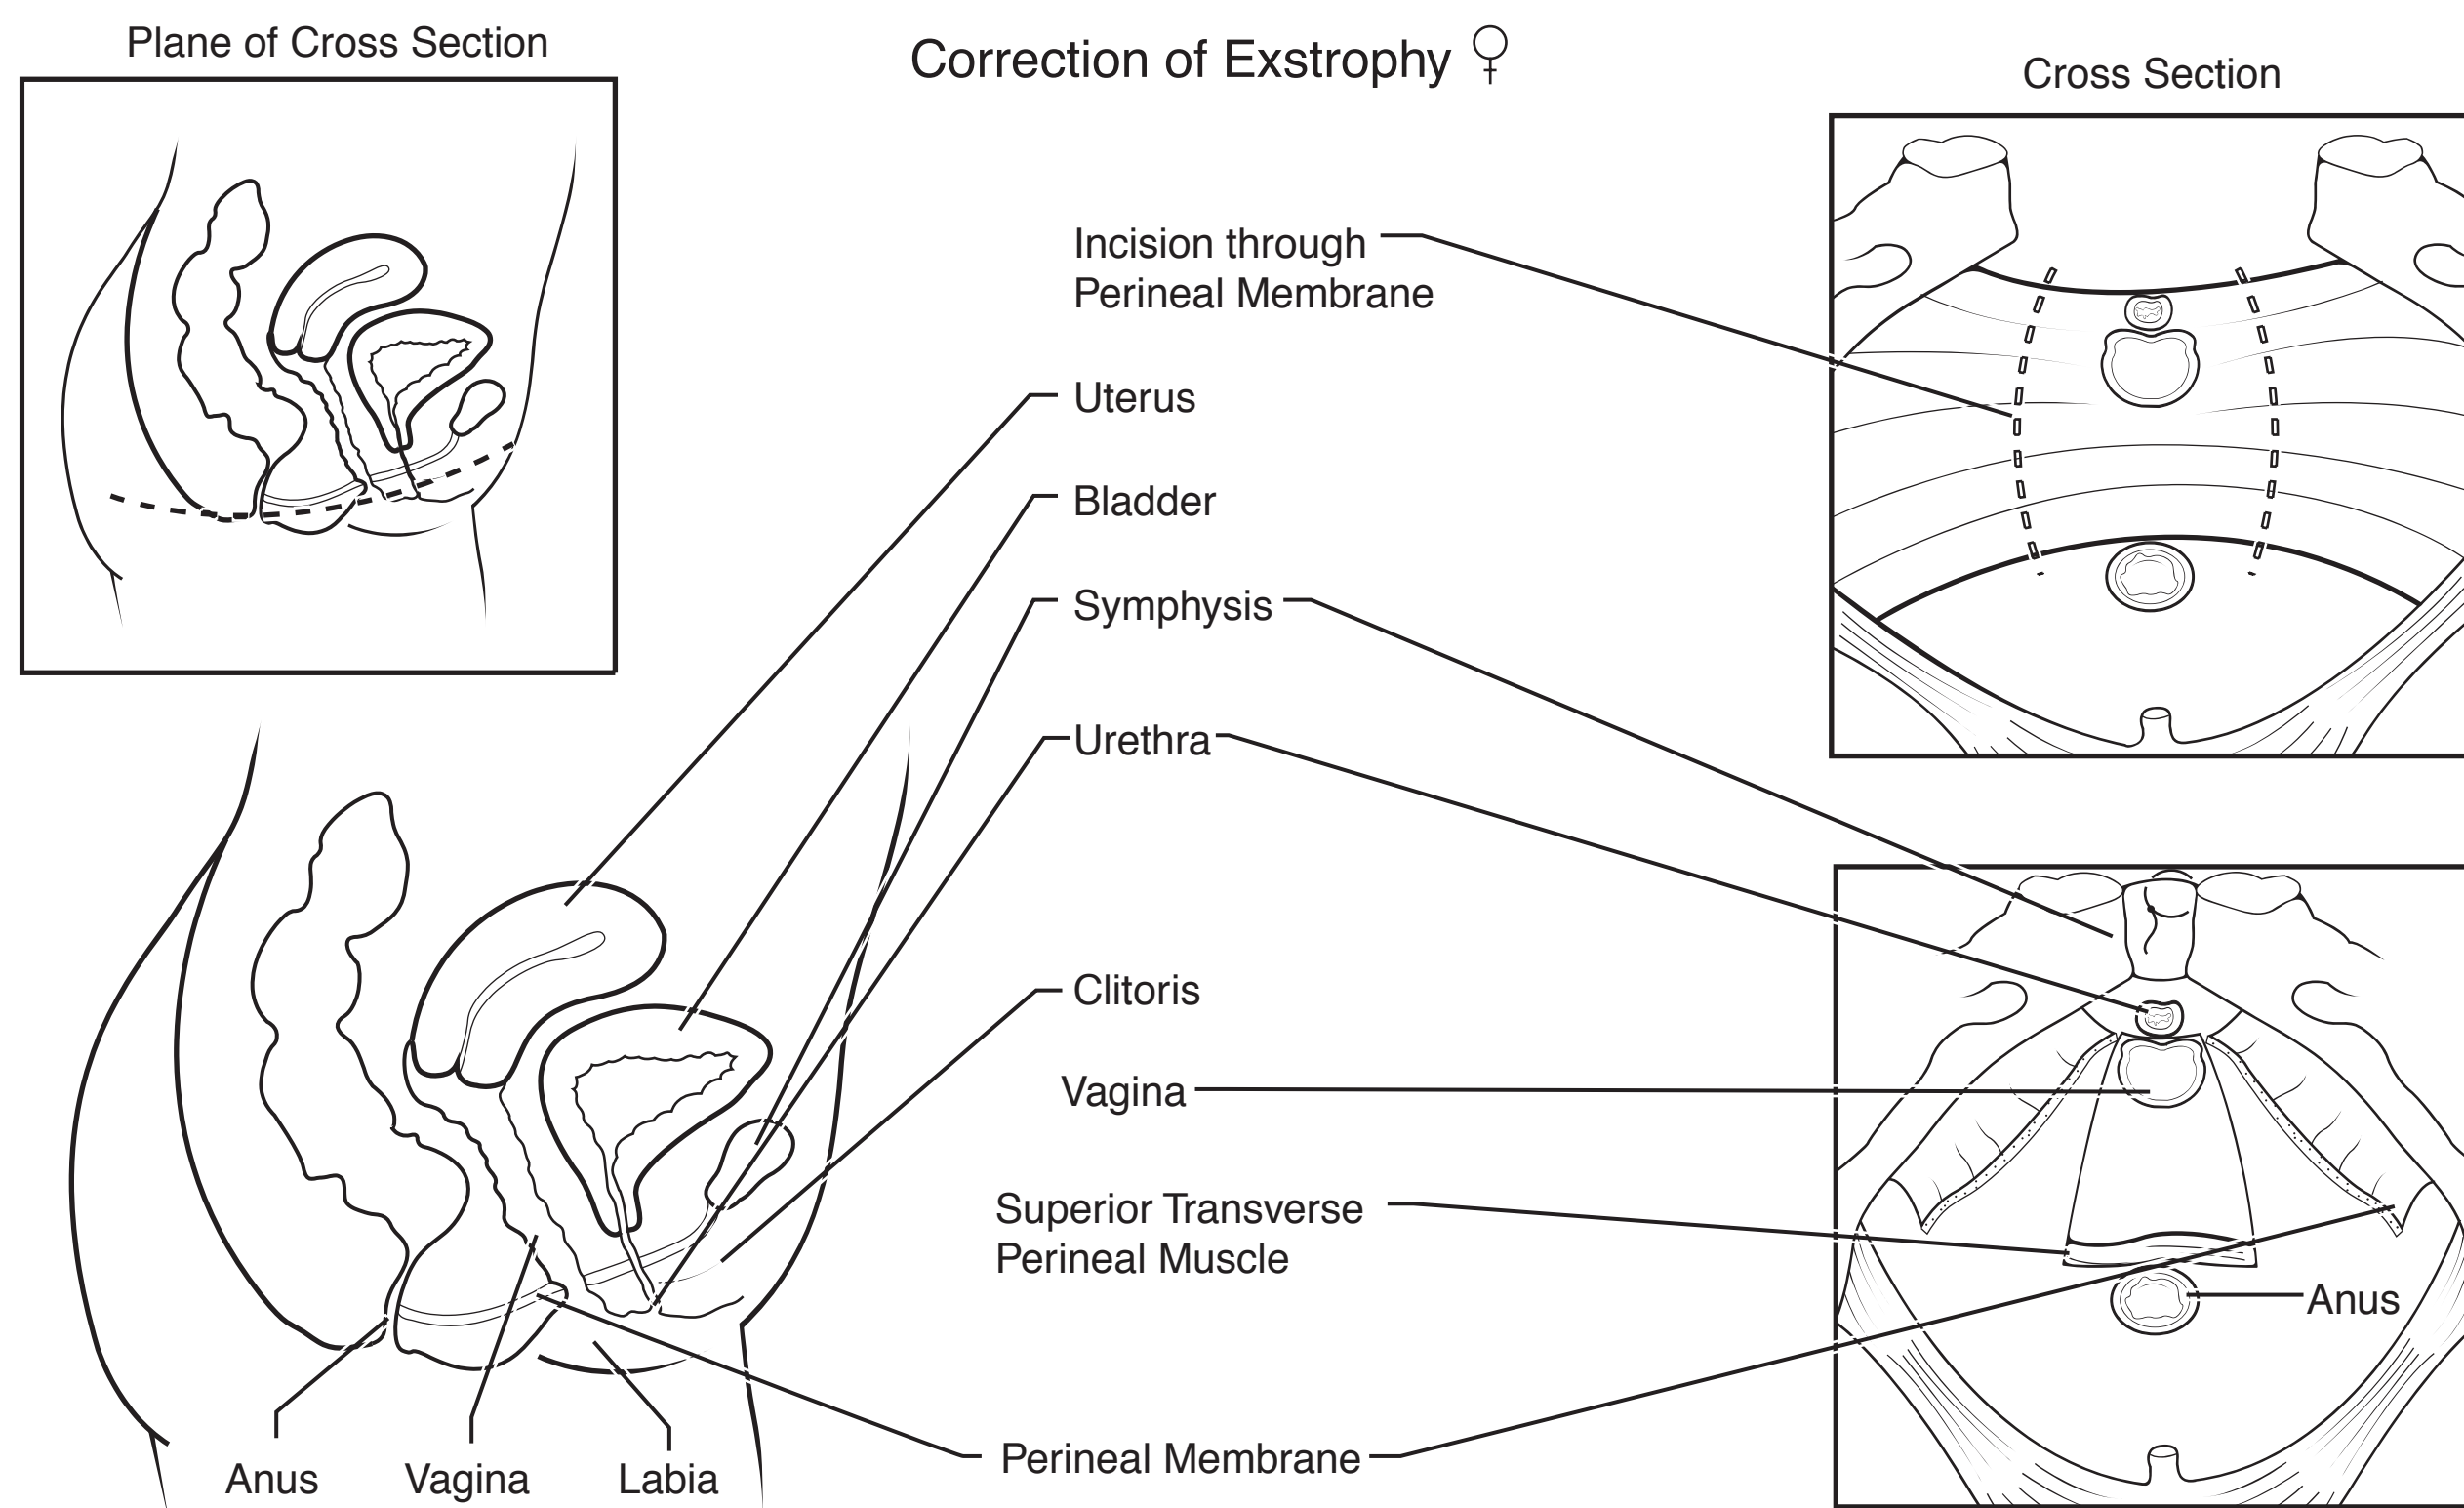

The principles of this single-stage technique are similar in boys and girls. After preoperative antibiotics are given, the patient is prepared and draped in a sterile field. We mark the planned lines of incision (Fig. 110.14) with the bladder neck, urethra, and vagina mobilized as a unit. We perform this dissection with a tungsten-tip electrocautery (Colorado tip) to minimize tissue damage while achieving hemostasis. The appropriate plane of dissection is found anteriorly along the medial aspect of the glans clitoris and proceeds posteriorly along the lateral aspect of the vaginal vault (Fig. 110.15). The vagina is mobilized with the urethra and bladder neck. Dissection along the vaginal wall extends quite laterally. Placement of a hemostat in the vaginal vault will help with retraction to identify the plane of dissection. The urethra and bladder neck should not be dissected from the anterior vaginal wall, as this will compromise the blood supply to the urethra. During the posterior

lateral dissection, the intersymphyseal band will be encountered and should be deeply incised to allow the urethra and bladder neck to move posteriorly. The posterior limit of the dissection is reached when the pelvic floor musculature is exposed and the bladder, bladder neck, and urethra can move into the pelvis without tension.

Following adequate dissection, the vagina, urethra, and bladder neck are moved posteriorly using a Y-V plasty if the vagina is anteriorly located (Fig. 110.16). The urethra is then tubularized using a two-layer closure of absorbable suture. Prior to the urethral closure, we routinely place a suprapubic tube to provide postoperative urine drainage. The pubic symphysis is reapproximated using two figure-of-eight no. 1 PDSs (Fig. 110.17). Osteotomies may be necessary when a wide pubic diastasis prevents a low-tension reapproximation of the pubic symphysis or if the patient is older than 48 to 72 hours old. We use anterior iliac osteotomies in these situations. The rectus fascia can then be closed in the midline. We

**FIGURE 110.14 A:** Schematic diagram of lines of incision for complete primary repair of a female infant with bladder exstrophy. This concept has been applied to the repair of female epispadias in the adjacent photograph (B), demonstrating lines of incision for an infant girl with epispadias. Note the posterior extent of dissection to allow movement of the vagina, bladder neck, and urethra as a unit posteriorly.

**FIGURE 110.15** The plane of dissection lies adjacent to the urethra and vaginal vault (*dashed lines in upper right cross-sectional view*).

**FIGURE 110.16** The intersymphyseal band is incised laterally (*white arrows*) to allow the urethra, bladder, and vaginal vault to move posteriorly as a unit.

**FIGURE 110.17** The pubic symphysis is reapproximated (*arrow*). With adequate dissection, the pubic symphysis can be reapproximated with minimal compressive effects on the urethra and bladder.

mature the neourethra with 5-0 Vicryl sutures and reapproximate the bifid clitoris by denuding the parts medially so that they fuse together after suturing with 7-0 Maxon suture (Fig. 110.18). The labia majora should be advanced posteriorly to the perineum at this time as well. A Z-plasty skin closure aids in skin closure. A simplified monsplasty technique described by Pippi-Salle et al. (8) provides a satisfactory aesthetic result to the introital area and can be applied at the time of the primary repair.

### Adjunctive Aspect of Repair

Inguinal hernias are commonly associated with exstrophy in both male and female patients. The majority of these hernias occur indirectly. They arise as a consequence of enlarged internal and external inguinal rings combined with compromised fascial support and lack of obliquity of the inguinal canal. In a review of patients from the Toronto Sick Children's Hospital,

**FIGURE 110.18** Final reconstruction demonstrates apposition of the labia and clitoral bodies. Denuding the epithelium on the clitoris medially improves the cosmetic results postoperatively.

56% of classic male exstrophy patients and 15% of classic female exstrophy patients developed inguinal hernias over a 10-year period (9). The authors recommended that these hernias be repaired at the time of primary bladder closure to prevent incarcerated hernias, which could affect up to 50% of these patients in the first 2 years of life. Reinforcement of the transversalis and internal oblique fascia during hernia repair decreases the incidence of later direct inguinal hernias. Umbilical hernias, as a contiguous defect with the bladder plate, also uniformly occur with exstrophy and are repaired at the time of the primary repair.

## POSTOPERATIVE CARE

The patient must be immobilized to decrease lateral stresses on the closure after the primary reconstructive procedure for exstrophy. A number of options exist for this purpose. We prefer to use a spica cast for 3 weeks to prevent external hip rotation and to optimize pubic apposition, which can facilitate early discharge and home care (Fig. 110.19). Modified Buck traction has been used by many groups with success. A posterior

**FIGURE 110.19** Use of a spica cast postoperatively to immobilize the pelvis and prevent hip abduction.

lightweight splint can be used in newborns when the child is out of traction to maintain hip adduction. We have stopped using Buck traction because spica casts are easier for the families to care for at home. External fixation devices have also been used with success (10). Fixator pins for these devices should be cleaned several times a day to reduce the chance for infection. Internal fixation may be necessary in older patients.

Because of the high incidence of vesicoureteral reflux, we prescribe low-dose suppressive antibiotic therapy for all newborns after bladder closure. This is continued until the vesicoureteral reflux is corrected or resolves spontaneously. Some surgeons perform neoureterocystostomies at the time of initial closure. The success of this approach has not been reported.

Postoperative factors that appear to directly impact the success of initial closure include postoperative immobilization, use of postoperative antibiotics, ureteral stenting catheters, adequate postoperative pain management, avoidance of abdominal distention, adequate nutritional support, and secure fixation of urinary drainage catheters.

## OUTCOMES

### Complications

Complications can occur with this form of exstrophy closure. The most commonly reported complication is urethrocutaneous fistula formation (at the penopubic angle dorsally) in males. These fistulas will often close spontaneously. They may initially be managed conservatively by providing urinary diversion via catheter drainage. If the fistula does not close after conservative management, the bladder and urethra should be examined cystoscopically for the possibility of obstruction at the bladder neck or urethra.

Other complications have been reported following a primary reconstructive technique. These include atrophy of the corpora cavernosa and urethra. These complications can occur if the blood supply to the corporal bodies or urethral wedge is damaged during dissection or during closure (11). Similar complications have been described following the initial stage of a staged reconstruction (12). In experienced hands, such complications are unusual and underscore the importance of involving surgeons experienced in the surgical management of these patients in their care.

If a child develops chronic bladder and kidney infections following exstrophy closure, he or she should be evaluated for possible outlet obstruction. We routinely maintain our patients on suppressive antibiotic therapy because of the high incidence of vesicoureteral reflux in this population.

### Results

Since 1989 we have performed this operation for 36 children with the exstrophy-epispadias complex in a prospective fashion. This series represents a treatment group who underwent the CPRE technique to construct classic bladder exstrophy ( $n = 31$ ) or proximal or female epispadias ( $n = 5$ ). Twenty-three of these children underwent this operation in the first 48 hours of life. Mean follow-up for the original group of patients that we reported in 1999 is 85 months. Mean follow-up for the entire series is 68 months.

Daytime continence with volitional voiding was achieved in 77% of boys and girls 4 years old or older. Primary urinary continence was achieved by 18% of boys and 36% of girls without the need for bladder neck reconstruction. Complications occurred in 13% of the children in the entire series; 81% of the children demonstrated mild or no hydronephrosis following this operative technique (13).

Hammouda (14) reported a series of 33 cases. They achieved continence in 72% of the patients with minimal complications, mirroring the results at our institution. Hammouda (14) has also used the complete penile disassembly technique for 42 patients with excellent functional results.

Borer et al. (15) at Boston Children's Hospital have performed detailed urodynamic studies for 23 children with exstrophy who have been closed using the complete primary repair technique. In a comparison with patients closed using a staged approach, these children demonstrated universal bladder stability, bladder capacities within the expected range, and normal sphincter electromyogram (EMG) activity, suggesting no neuromuscular compromise of the pelvic floor. Further, magnetic resonance imaging studies in this group suggest that urinary control is improved as pelvic floor anatomy becomes more normal in appearance (16).

## CHAPTER 111 ■ BLADDER EXSTROPHY AND EPISPADIAS

THOMAS E. NOVAK AND JOHN P. GEARHART

Bladder exstrophy is a rare, severe congenital defect that affects the lower urinary tract, genitalia, abdominal wall, and pelvis. The reported incidence ranges from 1:10,000 to 1:50,000 live births, with boys being affected five to six times more frequently than girls (1). Bladder exstrophy is usually an isolated defect, and in its classic form, associated chromosomal abnormalities or defects of the central nervous system, heart, and digestive tract are extremely uncommon.

Until the middle of the 19th century, bladder exstrophy was treated primarily nonsurgically. Early forms of repair focused on abdominal wall closure using skin flaps for partial reconstruction, leaving a fistula to attach a urinal for dryness. Trendelenburg recognized that pubic reapproximation would not only prevent prolapse of the reconstructed bladder but also be crucial to achieve continence. Although his theoretical

assumptions were correct, his surgical efforts were not successful (2). Early failures lead to an abandonment of interest in primary closure with a shift toward urinary diversion. In 1942, Hugh Hampton Young performed the first successful primary closure of a female exstrophy patient (3). Although similar reports about continent, primary closures were published in the same era, the numbers were small and most surgeons were not able to reproduce these favorable results. Both Jeffs (4) and Cendron (5) published their description about successful staged anatomic reconstruction in the mid-1970s, and their pioneering work set the standard for the modern staged repair of exstrophy (MSRE). Grady and Mitchell (6) subsequently developed the complete primary repair of exstrophy (CPRE), in which the primary closure is combined with a complete penile disassembly and epispadias repair.

While older techniques have evolved and alternative approaches have been developed, the primary objectives of modern exstrophy management remain consistent:

1. Secure closure of the abdominal wall, pelvis, bladder, and urethra
2. Reconstruction of a functional and cosmetically acceptable penis in the male and external genitalia in the female
3. Urinary continence, preferably via urethral voiding, with preservation of renal function

The complex embryology and genetics of exstrophy are not well understood. A number of theories have been proposed, which include premature rupture of the cloacal membrane, arrested mesenchymal ingrowth, and failure of cranial yolk sac progression during development (1). In its classic form, bladder exstrophy describes the condition in which an exteriorized bladder template develops in association with a diastasis of the pubic symphysis. This pubic separation results in characteristic genital and pelvic abnormalities. The pubic diastasis is found in association with foreshortened, externally rotated anterior pubic rami and a wide pelvic inlet. The perineum is short and broad and there is anterior displacement of the anus. The appearance of the genitalia varies by gender. In boys, the urethra lies in an epispadiac position, splayed open on the dorsal surface of the corporal bodies. The pubic diastasis results in corporal shortening and severe dorsal chordee. The testes are usually descended, but inguinal hernias are extremely common (especially in boys). In girls, the pubic diastasis results in an absence of a mons pubis, with a bifid clitoris and lateral displacement of the labia. Girls usually present with a bifid clitoris and a short vagina that often has a stenotic orifice. In isolated epispadias, which can be viewed as the least severe form of exstrophy, the bladder is closed and covered by a normal abdominal wall, but the pubic separation and genital abnormalities persist. Degrees of epispadias vary in a manner analogous to hypospadias from the very proximal “complete” epispadias in which the urethra is open through the bladder neck, to minor distal variants. A number of other exstrophy variants have been described (7).

---

## DIAGNOSIS

---

The definitive diagnosis of bladder exstrophy is made by recognition of the characteristic physical examination findings at the time of birth. Diagnosis by prenatal ultrasound is becoming more common with advances in sonographic techniques. Ultrasound findings include an absence of bladder filling, an anterior abdominal mass, a low-set umbilicus, abnormal widening of the iliac crests, and an anteriorly displaced scrotum with a small phallus in male fetuses (8). The differential diagnoses include cloacal exstrophy, omphalocele, and gastroschisis. Children with a prenatal diagnosis of exstrophy should be delivered at term via cesarean section. The principal implication of prenatal diagnosis of exstrophy is that most parents will seek early counseling regarding the nature of the disease and will temporarily relocate, if necessary, to a center with experience in exstrophy management. Some parents ultimately decide to terminate their pregnancies. The regionalization of complex surgical care such as that required for exstrophy patients is the subject of current debate and outcomes research.

---

## INDICATIONS FOR SURGERY

---

Historically, some children with bladder exstrophy have survived without surgical reconstruction. As mentioned previously, the earliest attempts at treatment focused on providing a suitable drainage apparatus that would help to manage chronic wetness and odor. Because of the rarity of the condition, it is unlikely that a prospective study will ever compare observation to reconstruction. The importance of treating this condition, however, can be inferred from several studies that have investigated the profound negative impact of urinary incontinence and sexual dysfunction on quality of life and social and psychological well-being (9,10). Furthermore, it is known that chronic exposure of the exposed bladder mucosa to the environment results in painful ulceration and metaplastic and ultimately neoplastic changes (11). It seems reasonable to conclude that all children with exstrophy deserve surgical treatment and that every attempt should be made to deliver this to even underprivileged populations whose medical capabilities are deficient.

---

## ALTERNATIVE THERAPY

---

### Urinary Diversion

---

A number of different urinary diversion techniques have been used historically with success in the management of exstrophy/epispadias (12). Although incontinent conduits are rarely indicated in contemporary pediatric practice, reconstructive urologists should be comfortable with their construction. Ureterosigmoidostomy was the first successful continent diversion performed in an exstrophy patient, and continence rates without the need for intermittent catheterization are very good (13). The role of ureterosigmoidostomy has decreased with the application of anatomic reconstructions, but it is still used in some centers today. The Mainz II pouch is a modification of the ureterosigmoidostomy that reconfigures the sigmoid into a theoretically lower-pressure reservoir, thereby promoting continence and renal preservation (12). Long-term concerns over the potential for malignancy at the ureterocolonic anastomosis and renal deterioration are cause for ongoing postoperative surveillance. Urinary diversion remains an important salvage approach in children who fail anatomic reconstruction.

---

### Anatomic Reconstruction

---

The modern staged repair of exstrophy will be described in detail as performed at Johns Hopkins. Alternate anatomic reconstructions have been proposed and are used in some centers. Grady and Mitchell developed the one-stage closure in the newborn period, which combined primary closure of the bladder, urethra, abdomen, and pelvis with epispadias repair using the complete penile disassembly technique. Proponents of CPRE believe that this approach will promote bladder growth and better continence outcomes by initiation of bladder cycling early on (6). Schrott (14) describes bladder closure, ureteral reimplantation, epispadias repair, and bladder neck reconstruction in the newborn period, applying the same technique to even older children without osteotomies. Primary newborn exstrophy closure followed by subsequent combined bladder

neck reconstruction and epispadias repair has been described by Baka-Jakubiak (15). The combination of bladder closure with modified Cantwell–Ransley epispadias repair has been reported in a series of delayed and secondary exstrophy closures (16).

---

## SURGICAL TECHNIQUE

---

### Preoperative Considerations

---

A type and screen with baseline complete blood count and coagulation studies should be obtained. A plain film of the pelvis allows for precise measurement of the pubic diastasis. A baseline renal/bladder ultrasound is recommended to establish the presence of both units and for purposes of later comparison. The use of cross-sectional imaging (computerized tomography/magnetic resonance imaging) is investigational. The umbilical cord should be ligated with a heavy silk suture. If a plastic cord clamp was used initially, this should be changed in order to prevent it from irritating the bladder mucosa. Likewise, the bladder template should be kept moist with periodic saline irrigation and covered with either a hydrated gel or Saran-type dressing. Petroleum-based gauze dressings are discouraged as they may dry and denude the mucosa when removed. Latex precautions are recommended as many of these children will develop latex sensitivity or allergy later in life.

---

### Timing and Staging

---

Modern staged closure has defined strict criteria for the selection of patients suitable for this approach. The technique includes early bladder, posterior urethral, and abdominal wall closure, usually with pelvic osteotomy in the newborn period, subsequently followed by an early epispadias repair at 6 months of age after intramuscular testosterone stimulation. Around age 4 to 5 years a competent bladder neck is reconstructed along with bilateral ureteral reimplantation, when adequate bladder capacity is reached and the child demonstrates the maturity necessary to participate in a postoperative voiding program (17).

Successful initial bladder and posterior urethral closure is the most important factor for achieving eventual urinary continence and sufficient bladder capacity. The primary objective in initial, functional closure is to convert the bladder exstrophy into a complete epispadias with incontinence with balanced posterior outlet resistance that preserves renal function but stimulates bladder growth. The size and the functional capacity of the detrusor muscle are ultimately the most important determinants of success (18). In the presence of a small, fibrotic bladder template without elasticity or contractility, the operation should be deferred until adequate template growth has taken place. If sufficient size is not reached 4 to 6 months after birth, alternative options should be considered. Inguinal hernia repairs should be considered early if the closure is delayed in order to guard against incarceration during this time interval.

The role of pelvic osteotomy performed at time of initial closure ensures a tension-free approximation of the bladder, posterior urethra, and abdominal wall, placement of the urethra deep within the pelvic ring, enhancing bladder outlet resistance, and finally aligning the large pelvic floor muscles to support the bladder neck. Usually, osteotomies are not needed in the patient <72 hours old with malleable pubic bones that are easily

brought together in the midline by medial rotation of the greater trochanters. However, if the pubic bones are >4 cm apart or unable to be reapproximated without tension, osteotomies are mandated to ensure a secure closure.

---

## Osteotomy

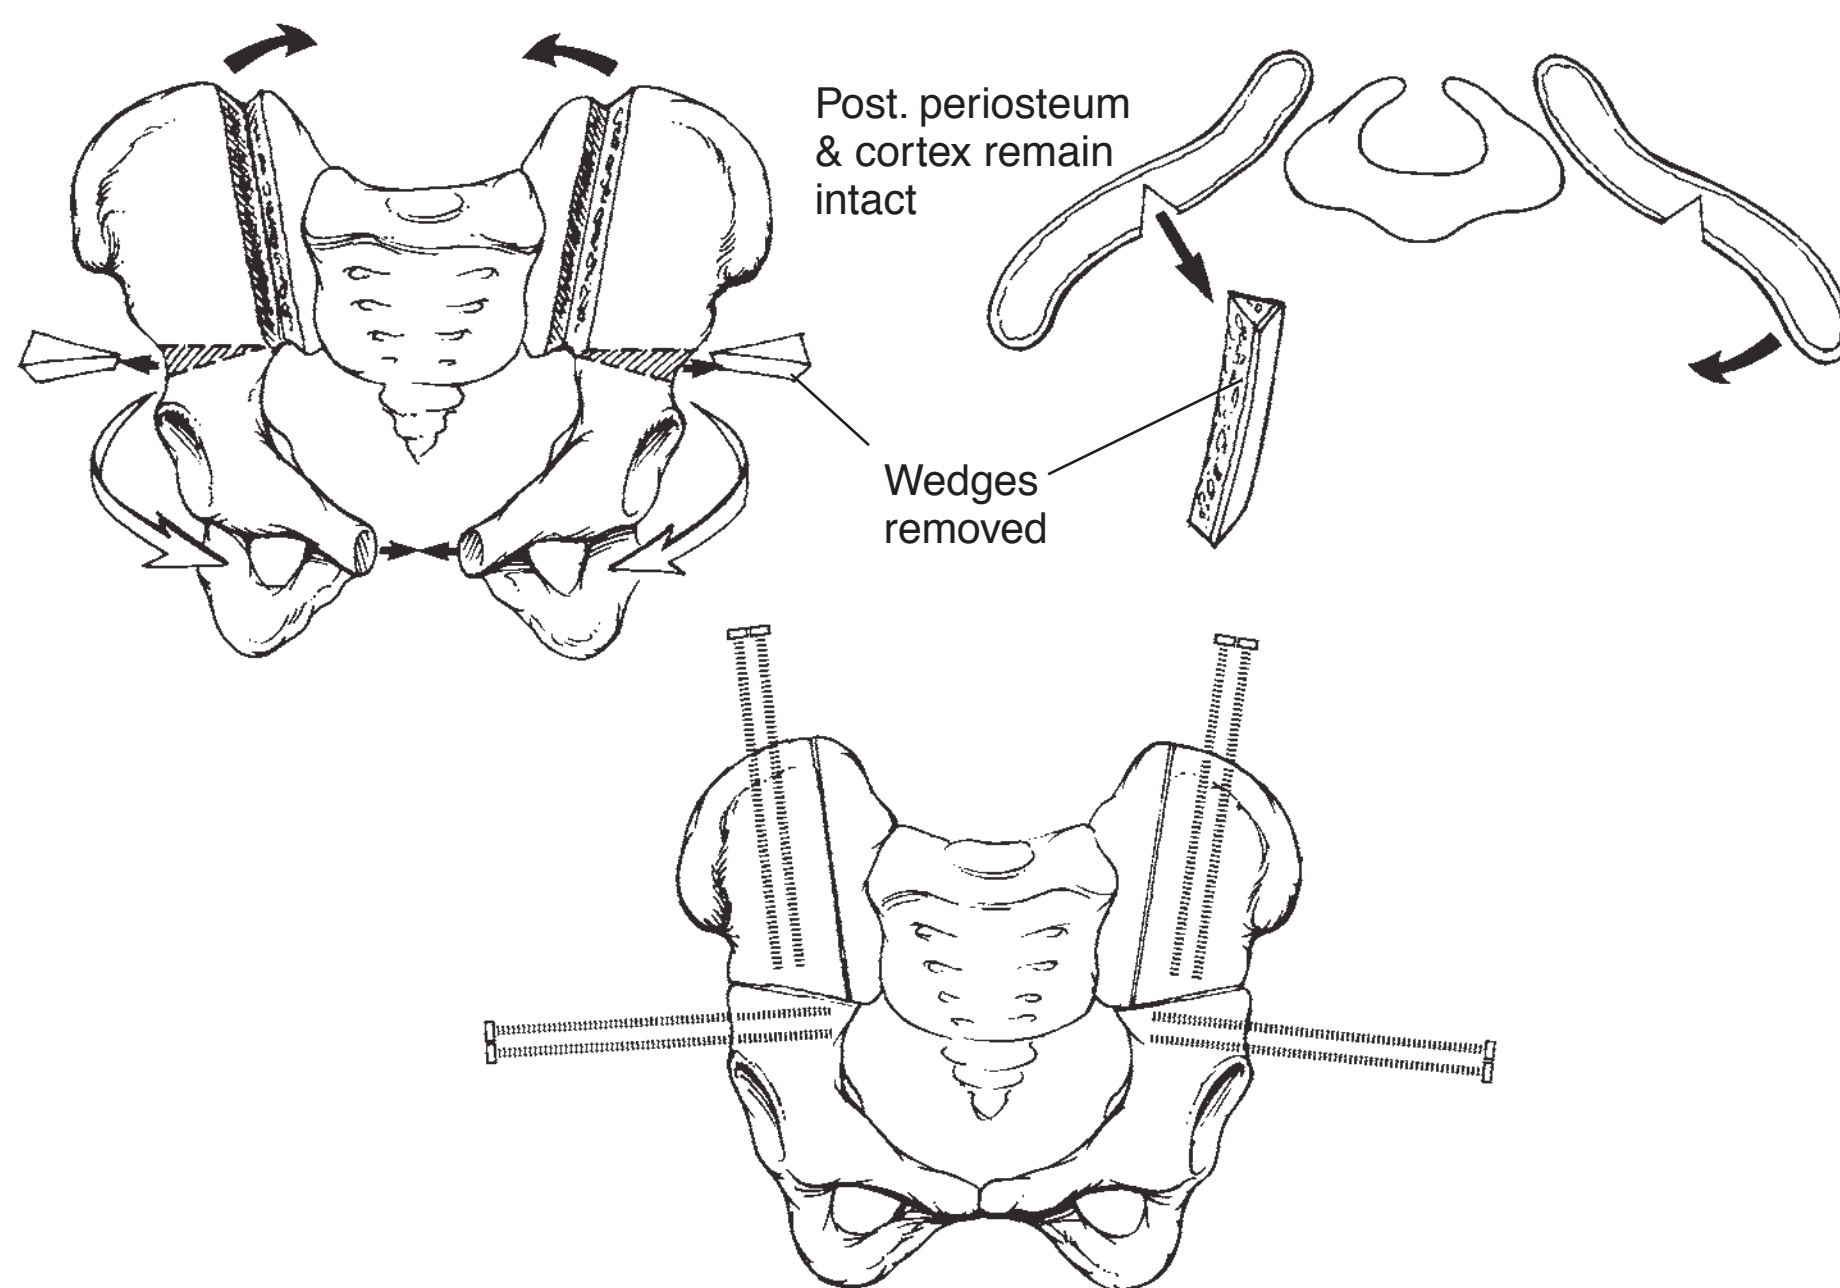

---

The bilateral anterior innominate and vertical iliac osteotomy has been used in our institution because it has numerous advantages over the posterior approach. The patient is placed in a supine position, preparing and draping the lower body below the costal margins and placing soft absorbent gauze over the exposed bladder. The pelvis is exposed from the inferior wings inferiorly and the pectineal tubercle and posteriorly to the sacroiliac joints. The periosteum and sciatic notch are carefully elevated and a Gigli saw is used to create a transverse innominate osteotomy exiting anteriorly at a point halfway between the anterosuperior and the anteroinferior spines (Fig. 111.1). This osteotomy is created at a slightly more cranial level than that described for a Salter osteotomy to allow placement of external fixator pins in the distal segments. Also, the posterior ileum may be incised from the anterior approach in an effort to correct the deformity more completely. This is important because anatomic studies have shown that the posterior portion of the pelvis is also externally rotated in patients with exstrophy, and as patients age they lose the elasticity of their sacroiliac ligaments. An osteotome is used to create a closing wedge osteotomy vertically and just lateral to the sacroiliac joint. The posterior iliac cortex is kept intact and used as a hinge (Fig. 111.2). Two fixator pins are placed in the inferior osteotomized segment and two pins are placed in the wing of the ilium superiorly. Radiographs are obtained to confirm pin placement, soft tissues are closed, and the urologic procedure is performed. At the conclusion of the exstrophy closure, external fixators are applied between the pins to hold the pelvis in a correct position.

Radiographs are taken 7 to 10 days postoperatively. If the diastasis has not been completely reduced, the right and left sides can be gradually approximated using the fixator bars over several days. Light longitudinal Buck skin traction is used to keep the legs still. The patient remains supine in traction for approximately 4 weeks to prevent dislodgement of tubes and destabilization of the pelvis. The external fixator is kept on for approximately 6 weeks, until adequate callus is seen at the site of osteotomy. The pins are removed under light sedation at the bedside. Postoperatively, newborns undergoing closure without osteotomy are immobilized in modified Bryant traction for 4 weeks with the hips in 90 degrees of flexion.

Staged pelvic closure in the setting of an extreme (>8 cm) pubic diastasis has been described with good results in a series of children with both classic and cloacal exstrophy. In this approach, osteotomies are performed in conjunction with interfragmentary pin placement during the initial procedure. The pelvis is then gradually reduced under sedation at the bedside over the next several weeks, and ultimately the pubis is secured with an interpubic stainless steel plate that is placed at the time of bladder and urethral closure (19).

The use of spica casting and mummy wrapping for immobilization following exstrophy closure has been described. In our experience, these techniques are associated with higher rates of complications and inferior surgical outcomes and are

**FIGURE 111.1** Combined transverse anterior innominate and anterior vertical iliac osteotomies with pin placement and preservation of the posterior periosteum and cortex. (Drawings by Timothy Phelps after Leon Schlossberg. ©2002 Brady Urological Institute, with permission.)

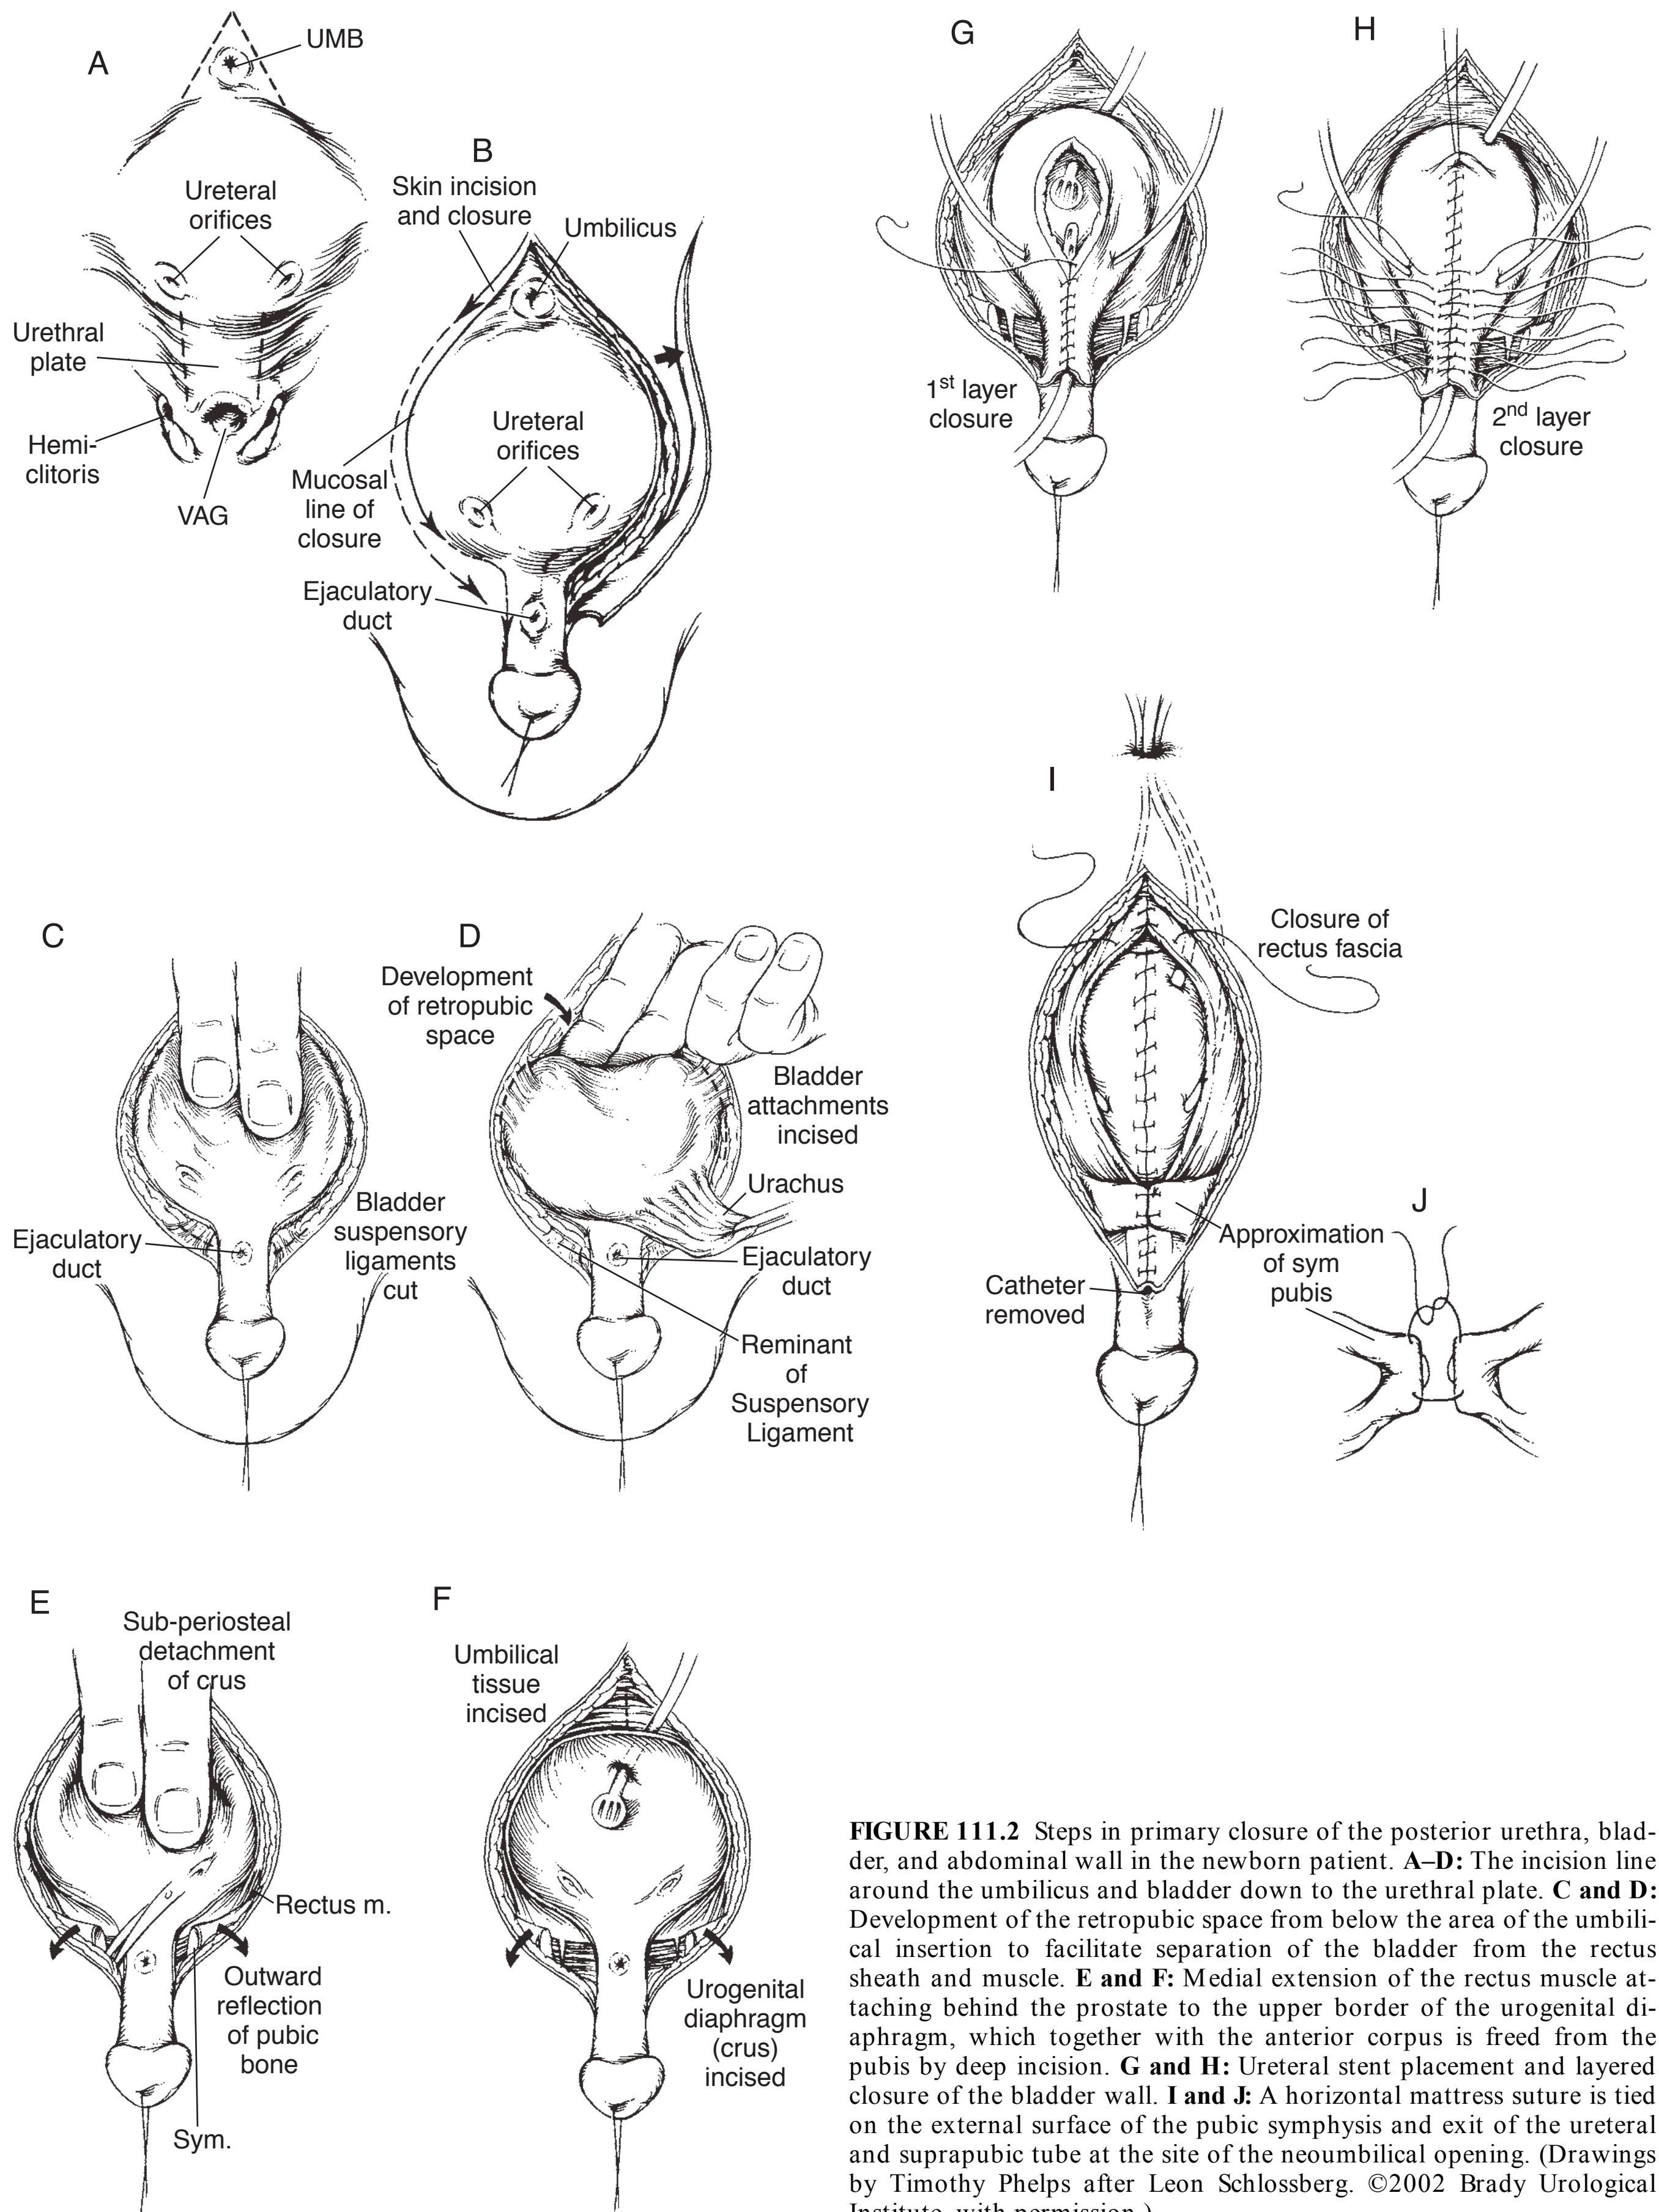

not recommended (20). Okubadejo (21) reviewed the orthopedic complications of exstrophy management in 624 patients from Johns Hopkins: 26 complications were noted (4%), of which four were identified as being specifically caused by traction.

### Bladder, Posterior Urethral, and Abdominal Wall Closure

The various steps in primary bladder closure are illustrated in Figure 111.2. A strip of mucosa 2 cm wide, extending from the distal trigone to below the verumontanum in the boy and to the vaginal orifice in the girl, is outlined for prostatic and posterior urethral reconstruction (Fig. 111.2A). With the advent of the modified Cantwell–Ransley epispadias repair, the urethral plate should not be incised unless the length of the urethral groove from the verumontanum to the glans is so short that it interferes with eventual penile length and produces dorsal angulation. In this situation, the urethral groove is lengthened. Figures 111.2B to 111.2D show marking of the incision from just above the umbilicus down around the junction of the bladder and the para-exstrophy skin to the level of the urethral plate. The appropriate plane is entered just above the umbilicus and a plane is established between the rectus fascia and the bladder (Fig. 111.2E,F). The umbilical vessels are doubly ligated and incised and allowed to fall into the pelvis. The peritoneum is taken off the dome of the bladder, to be deeply placed into the pelvis at the time of closure. The plane is continued caudally down between the bladder and rectus fascia until the urogenital diaphragm fibers are encountered bilaterally. With electrocautery, these urogenital diaphragm fibers between the bladder neck, the posterior urethra, and the pubic bone are taken sharply down to the levator hiatus in their entirety (Fig. 111.2F). A double-pronged skin hook can be inserted into the pelvic bone and pulled laterally to accentuate the urogenital diaphragm fibers. If this maneuver is not performed adequately, the vesicourethral unit will be brought anteriorly with pelvic closure in an unsatisfactory position for later reconstruction.

If the decision is made to transect the urethral groove, then it is cut distal to the verumontanum with continuity maintained between the thin, mucosa-like non-hair-bearing skin adjacent to the posterior urethra and bladder neck and the skin and mucosa of the penile glans. Flaps in the area of thin skin are subsequently moved distally and rotated to reconstruct the urethral groove, resurfacing the penis dorsally. The corporal bodies are not brought together because later Cantwell–Ransley epispadias repair requires the urethral plate to be brought underneath the corporal bodies. If the urethral plate is left in continuity, it must be mobilized up to the level of the prostate to create as much urethral and penile length as possible. Apparent penile lengthening is achieved by exposing the corpora cavernosa bilaterally and freeing the corpora from their attachments to the suspensory ligaments. After the urogenital diaphragm is completely incised bilaterally, freeing the bladder neck and urethra well from the pubis, the mucosa and muscle of the bladder and the posterior urethra well onto the penis are closed in the anterior midline (Fig. 111.2G). The resulting orifice should be easily passed by a 12Fr sound, creating enough resistance to aid in bladder adaptation and prevent prolapse but not too much to cause outlet resistance altering the upper tracts. A second layer is closed if possible (Fig. 111.2H). Bladder drainage is achieved using a suprapubic nonlatex Malecot catheter for 4 weeks. The urethra is not stented to prevent necrosis. Ureteral stents are left in place for 10 to 14 days, until swelling goes down.

By applying gentle pressure over the greater trochanters bilaterally, the pubic bones are approximated in the midline. A horizontal mattress suture of no. 2 nylon is placed between the fibrous cartilages of the pubic rami and tied anteriorly to the pubic closure to avoid the neourethra (Fig. 111.2I,J). A second stitch is placed caudal to the insertion of the rectus fascia if possible for added support. Should the sutures work loose or cut through the tissues during subsequent healing, the anterior placement of the knot of the horizontal mattress suture ensures that it will not erode through into the urethra. A V-shaped flap of abdominal skin at a point corresponding to

**FIGURE 111.2** Steps in primary closure of the posterior urethra, bladder, and abdominal wall in the newborn patient. **A–D:** The incision line around the umbilicus and bladder down to the urethral plate. **C and D:** Development of the retropubic space from below the area of the umbilical insertion to facilitate separation of the bladder from the rectus sheath and muscle. **E and F:** Medial extension of the rectus muscle attaching behind the prostate to the upper border of the urogenital diaphragm, which together with the anterior corpus is freed from the pubis by deep incision. **G and H:** Ureteral stent placement and layered closure of the bladder wall. **I and J:** A horizontal mattress suture is tied on the external surface of the pubic symphysis and exit of the ureteral and suprapubic tube at the site of the neoumbilical opening. (Drawings by Timothy Phelps after Leon Schlossberg. ©2002 Brady Urological Institute, with permission.)

the normal position of the umbilicus is tacked down to the abdominal fascia, and the drainage tubes exit this neoumbilicus.

Postoperatively, before suprapubic tube removal the bladder outlet is calibrated to ensure free passage of urine. Repeated ultrasound examinations are obtained before discharge and every 3 months to check for upper-tract dilatation and residual urine. Continuous, prophylactic antibiotic therapy is advised to prevent upper-tract infection from ureteral reflux. Yearly gravity cystograms under anesthesia are performed to receive quality information about reflux and, more importantly, bladder capacity. For successful continent procedures a minimal bladder capacity of 100 cc is needed (18). An increase in bladder capacity is seen after epispadias repair, which is why the bladder neck procedure is performed after the urethral reconstruction.

---

### Epispadias Repair

---

Four key concerns have to be addressed: (a) a functional and cosmetically pleasing penis, (b) correction of dorsal chordee, (c) urethral reconstruction, and (d) penile skin closure and glandular reconstruction. In patients undergoing delayed repair or reclosure, a combined epispadias/exstrophy closure using the modified Cantwell–Ransley repair is possible.

The modified Cantwell–Ransley repair is begun by placing a nylon suture through the ventral glans for traction. A meatal advancement and glanuloplasty incorporated (MAGPI) incision is made in the urethral plate distally and closed with 6-0 polyglycolic sutures in a transverse fashion to flatten the distal urethral plate and advance the urethra to the tip of the phallus (Fig. 111.3A). The reconstructed neourethra will be in excellent glandular position once the wings are closed. Next, incisions are made over two parallel lines marked previously over the dorsum of the penis that outline an 18-mm-wide strip of urethral mucosa extending from the prostatic urethral meatus to the tip of the glans (Fig. 111.3A). Triangular mucosal areas of the dorsal gland are excised adjacent to the urethral strip, and thick glandular flaps are constructed bilaterally. Lateral skin flaps are mobilized and undermined.

A Z-incision of the suprapubic area permits exposure and division of the suspensory ligament and old scar tissue from the initial exstrophy closure. The ventral skin is taken down to the level of the scrotum (Fig. 111.3B). Care is taken to preserve the mesentery to the urethral plate, which arises proximally and extends upward between the corpora as a blood supply to the urethral plate. The corpora are dissected ventrally on the surface of the Buck fascia. The plane is followed closely bilaterally until one exits on the dorsum of the penis between the corpora spongiosum and the corporal body (Fig. 111.3C).

After placement of loops, the urethral plate is dissected just on the corporal bodies to the level of the prostate and the glans, respectively (Fig. 111.3D). Care is taken to leave the most distal 1-cm attachment of the mucosal plate to the glans intact. The neurovascular bundles are dissected free from the corporal bodies only if rotating the corpora over the urethra does not straighten the penis. The urethral strip is closed in a linear manner from the prostatic opening to the glans over an 8Fr silicone stent with 6-0 polyglycolic sutures. Afterward, the corporal bodies are incised at the point of

maximal curvature, leaving a diamond-shaped defect (Fig. 111.3E). The corpora are then closed over the neourethra with two running sutures of 5-0 polydioxanone (PDS), with the adjacent areas of the diamond sutured to each other (Fig. 111.3F). The now ventrally placed urethra is secured in place with further 5-0 polyglycolic acid sutures between the corpora, especially at the coronal level (Fig. 111.3G–I). The glans wings are subcuticularly closed with 5-0 and the glans epithelium with 6-0 polyglycolic acid. Finally, the ventral skin is brought up and sutured to the ventral edge of the corona, while the flaps provide coverage of the dorsum. The skin as well as the Z-plasty at the base of the penis is reapproximated with interrupted 5-0 or 6-0 polyglycolic acid sutures (Fig. 111.3J,K). The silicon stent is secured and left for 10 to 12 days.

In girls the mons and external genitalia are reconstructed at the time of initial exstrophy closure. The bifid clitoris is denuded medially and brought together in the midline, along with labia minora reconstruction, creating a fourchette.

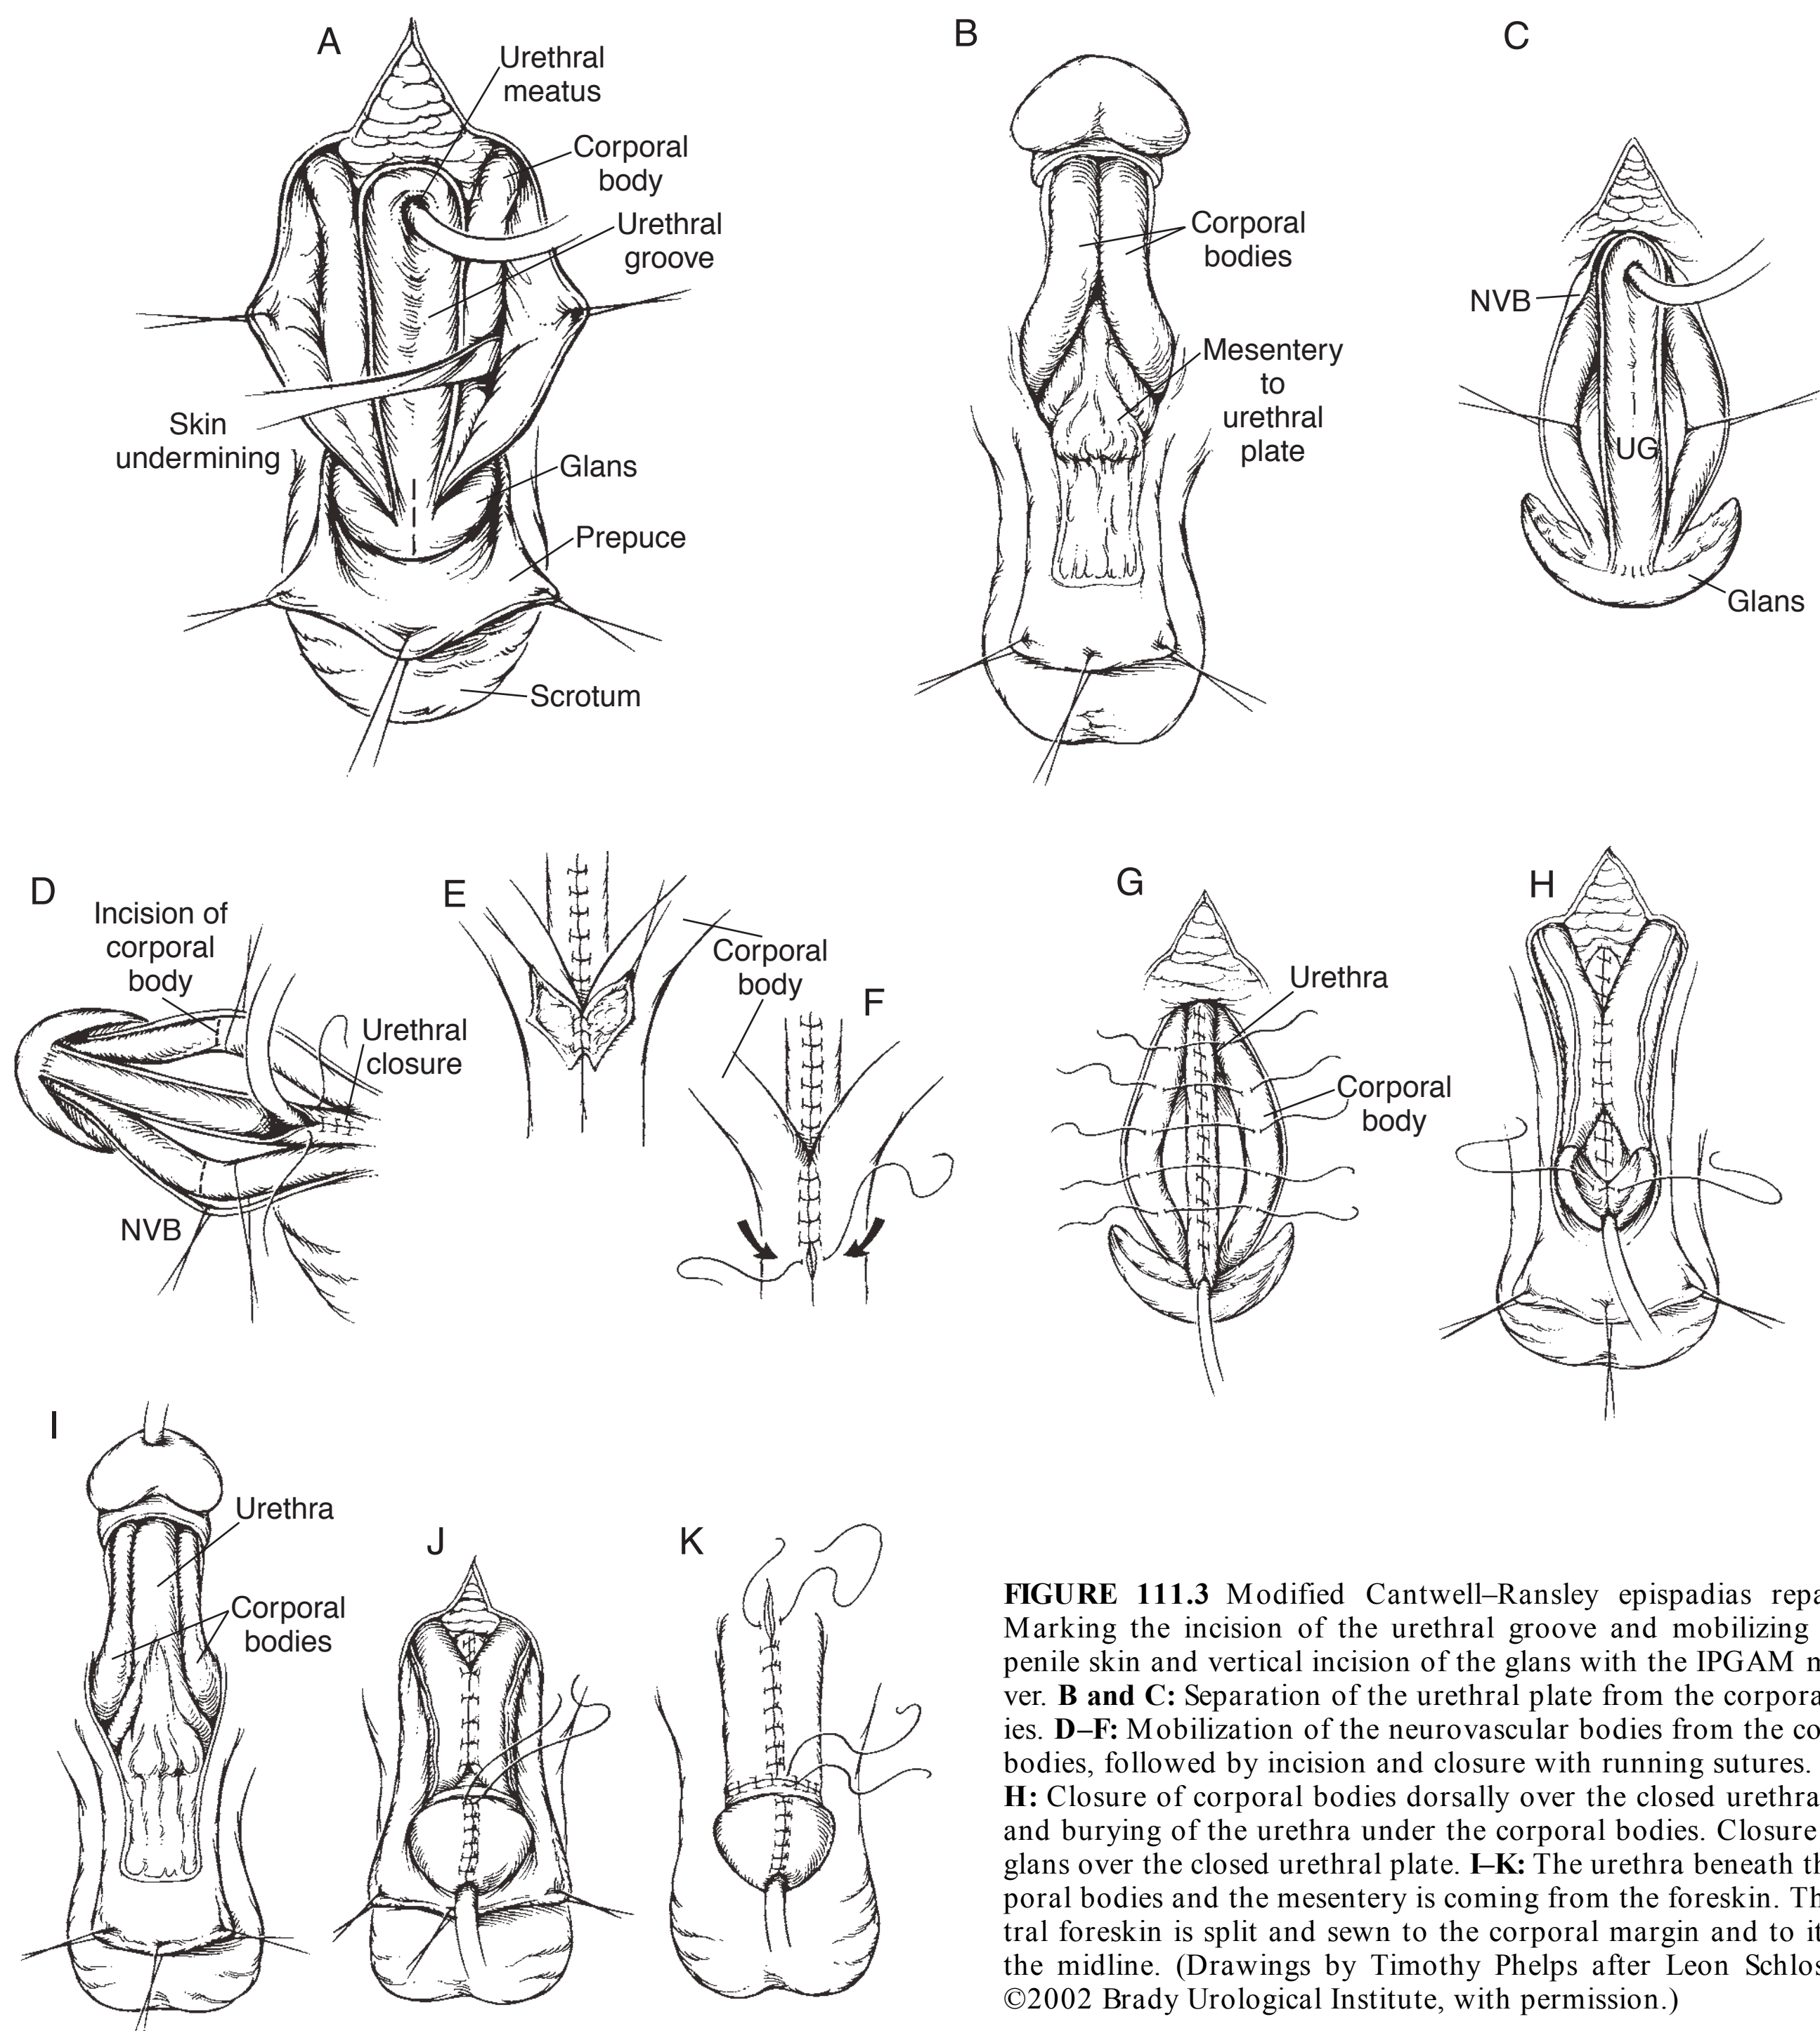

Postoperatively it is critical to control pain and bladder spasms to prevent urine extravasation and fistula formation. This is best achieved by preoperative placement of a caudal epidural catheter and the administration of anticholinergic medication. At the time of discharge, the postoperative plastic occlusive dressing is left intact and the patient is supplied with oral broad-spectrum antibiotics, pain medications, and antispasmodics.

---

### Continence and Antireflux Procedure

---

The bladder is opened through a transverse incision at the bladder neck with a vertical incision (Fig. 111.4A). Figure 111.4 depicts a Cohen transtrigonal ureteral reimplantation or a cephalotrigonal reimplantation for either moving the ureter across the bladder above the trigone or, if the ureters are too low, moving them on the upper aspect of the trigone (Fig. 111.4B). The modified Young–Dees–Leadbetter procedure is begun by selecting a posterior strip of mucosa 15 to 18 mm wide and 30 mm long that extends from the midtrigone to the prostate or posterior urethra (Fig. 111.4C). The bladder muscle lateral to the mucosal strip is denuded of mucosa and sponges, soaked in 1:200,000 epinephrine, and applied to control bleeding for better visualization. Tailoring of the muscle triangles is aided by multiple small incisions on the free edge bilaterally that allow the area of reconstruction to assume a more cephalic position (Fig. 111.4D). A transverse, full-thickness muscular incision is not performed as described in the original Young–Dees–Leadbetter procedure because there is a significant risk of denervation and ischemia for the bladder neck. The edges of the mucosa and underlying muscle are closed with interrupted sutures of 4-0 polyglycolic acid (Fig. 111.4E). The adjacent denuded muscle flaps are overlapped and sutured firmly in place with a 3-0 polydioxanone to provide reinforcement of the bladder neck and urethral reconstruction (Fig. 111.4F,G). Two or three of the overlapping sutures are left long, brought through the rectus fascia, and tied as bladder suspension to elevate the bladder neck (Fig. 111.4G). An 8Fr urethral stent may be used during construction but is removed afterward. Exposure is essential for the creation of a continent bladder neck. Therefore, if visualization of the posterior urethra is problematic, the

**FIGURE 111.3** Modified Cantwell–Ransley epispadias repair. **A:** Marking the incision of the urethral groove and mobilizing of the penile skin and vertical incision of the glans with the IPGAM maneuver. **B and C:** Separation of the urethral plate from the corporal bodies. **D–F:** Mobilization of the neurovascular bodies from the corporal bodies, followed by incision and closure with running sutures. **G and H:** Closure of corporal bodies dorsally over the closed urethral plate and burying of the urethra under the corporal bodies. Closure of the glans over the closed urethral plate. **I–K:** The urethra beneath the corporal bodies and the mesentery is coming from the foreskin. The ventral foreskin is split and sewn to the corporal margin and to itself in the midline. (Drawings by Timothy Phelps after Leon Schlossberg. ©2002 Brady Urological Institute, with permission.)

intrasymphyseal bar has to be cut and afterward approximated with 0 PDS nylon sutures. In this case the child should be immobilized postoperatively.

The ureteral stents are removed after 10 to 12 days and the suprapubic catheter is clamped after 3 weeks, for no longer than 1 hour for the first time. After residual-free voiding is achieved, the suprapubic catheter is removed. The patient is followed up with frequent bladder and renal ultrasounds in the first few months.

---

## OUTCOMES

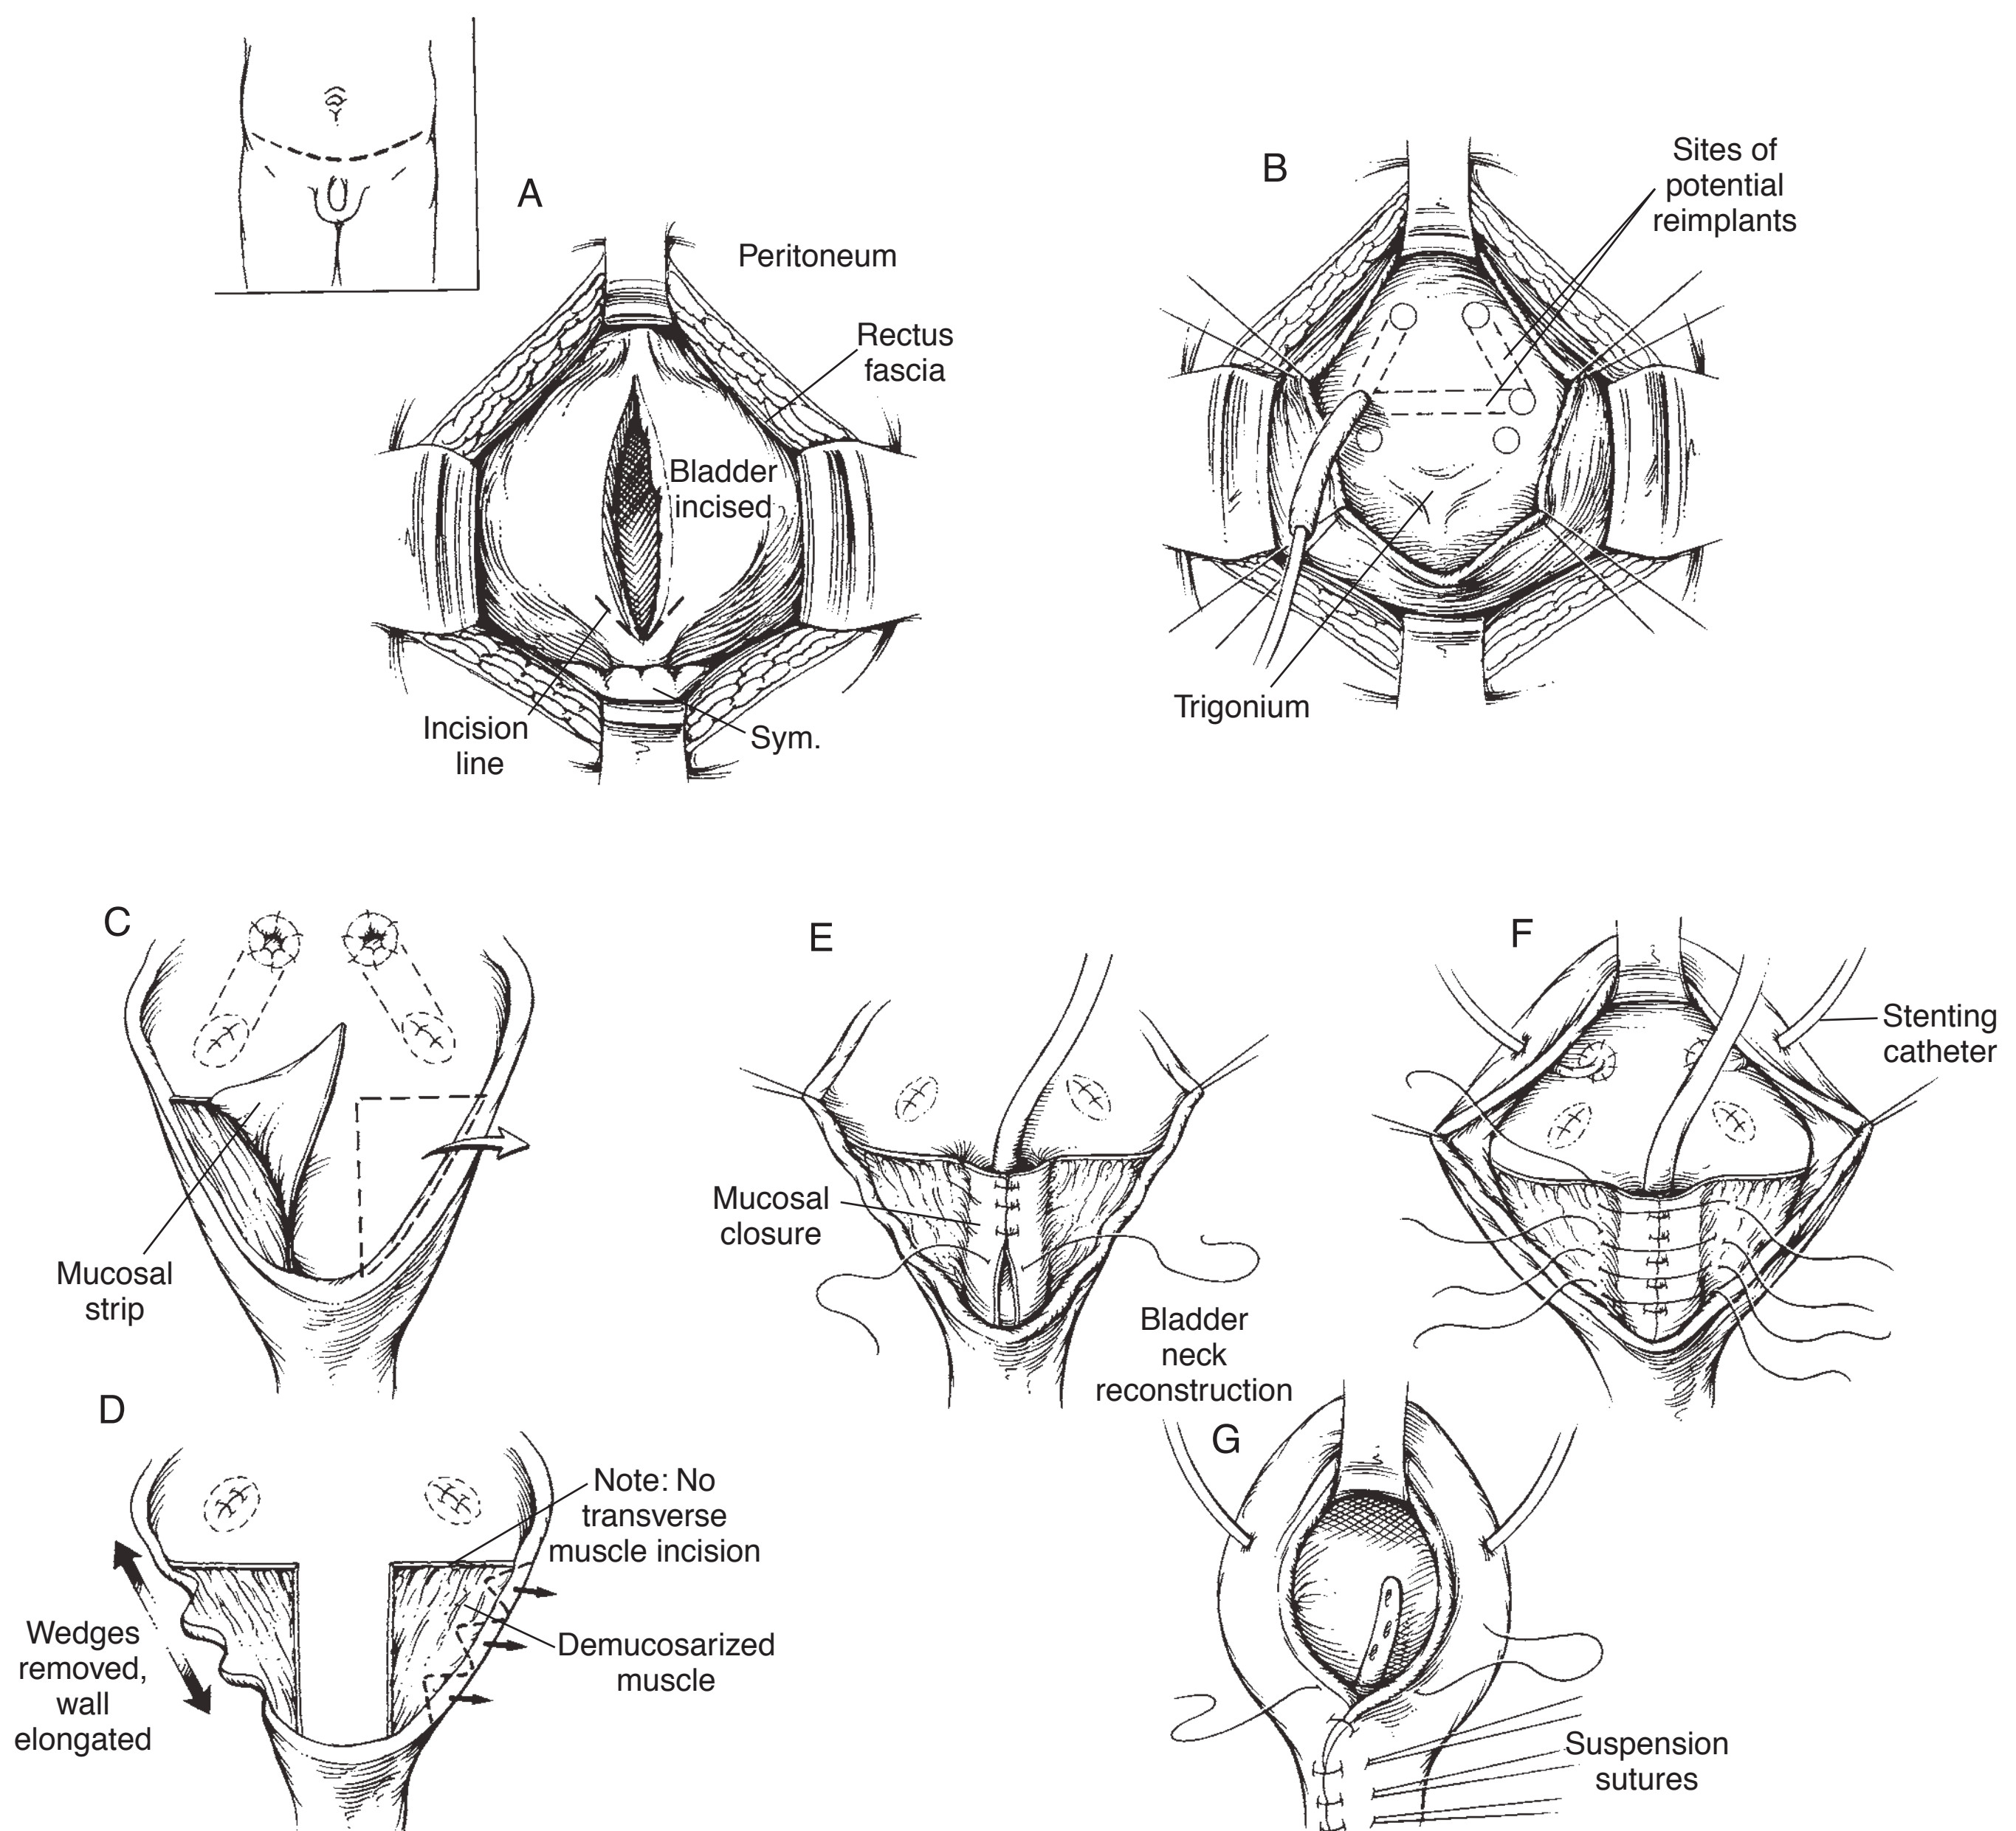

---

### Complications

---

Failure of the closure is marked by dehiscence, prolapse, or outlet obstruction. It is possible that these complications are underreported secondary to patients changing surgeons following an initially undesirable outcome. Osteomy is recommended at the

**FIGURE 111.4** Modified Young-Dees-Leadbetter bladder neck repair. **A:** Vertical bladder incision with transverse extension distally. **B and C:** Ureteral mobilization for ureteral reimplantation. **C-E:** Use of mucosal trigone strip to form the bladder neck and prostatic urethra. Lengthening of the denuded muscle triangles by several incisions. Note: No transverse muscle incision. **E-G:** Double-breasted closure and exact suture placement of the bladder neck reconstruction. The bladder neck and urethra are unstented at the end of the operation. (Drawings by Timothy Phelps after Leon Schlossberg. ©2002 Brady Urological Institute, with permission.)

time of secondary closure in all cases. Outlet obstruction may develop early following removal of the urethral catheter. Surveillance of residual volumes and upper-tract dilation with ultrasound is important following removal of the urethral catheter and prior to removing the suprapubic tube. The development of pyelonephritis is likewise a cause for evaluation of the bladder outlet following primary closure. In some cases, calibration and temporary catheter replacement are sufficient. We prefer to calibrate under anesthesia with a cystoscope because this allows for precise catheter placement if needed.

The incidence of urethrocutaneous fistulas following Cantwell-Ransley epispadias repair is 19% at 3 months (22). Some of these will close spontaneously. The majority, however, will require operative repair as an outpatient procedure. Residual chordee is a common indication for revision surgery, usually as an adolescent, prior to becoming sexually active.

It is clear that the bladder needs time to adjust to the increased resistance added by the reconstructed bladder neck. Bladder spasms and detrusor instability are expected and should be treated with oral anticholinergics. The biggest

challenge of the child and the parents after bladder neck reconstruction is the initiation of a voiding trial. If the child cannot void, an 8Fr catheter is placed under anesthesia and left in place for 5 days and the voiding trial is initiated again. Ultimately, if the child is not dry for a period of 3 hours during the day within 12 months of the operation, the bladder neck reconstruction has failed. Multiple options are available for these children to achieve future continence, but few will void through their urethra.

---

## Results

---

The success or failure of the initial closure is highly associated with long-term functional results. Bladders that dehiscence or prolapse and require repeat closure are not likely to grow and reach the capacity needed for bladder neck reconstruction. In a review of 23 patients with one or more failed closures, we found that only 6 children reached sufficient capacity for bladder neck reconstruction, with a success rate of 50% (23). The use of osteotomy in conjunction with pelvic and lower extremity fixation has produced the best success rates at our institution and is recommended for all closures beyond the first 72 hours of life (i.e., delayed or secondary closures) (20). A recent presentation of long-term outcomes from the Seattle Children's experience with CPRE reported dehiscence in 2 of 41 patients closed primarily and during the newborn period (24). In a comparable group of 194 primary MSRE closures at Johns Hopkins, 63 of which had simultaneous osteotomy, there were 4 failures (2 dehiscence and 2 prolapse) (25). Interpretation of continence rates requires consideration for the definition applied and the manner in which the child voids/empties. The ultimate goal remains continence, day and night, with volitional voiding and stable renal function. Daytime dry intervals vary in the literature from 1 to 3 hours. "Social" continence refers to an adequate daytime dry interval with bedtime wetness. The use of catheterizable stomas, with or without bladder augmentation and additional outlet procedures such as artificial urinary sphincters, slings, or bladder neck, should likewise be noted when reviewing published continence rates. Chan et al. (26) reported complete and social continence rates of 77% and 91%, respectively, with urethral voiding following bladder neck repair in children treated exclusively at Johns Hopkins. Preoperative bladder capacity measured under anesthesia appears to be the primary determinant of success in these patients. Patients with capacities >100 mL are good candidates for modified Young-Dees-Leadbetter procedures (18). A small number of children have been reported to attain

continence following CPRE without additional surgery at the bladder neck. Comparable continence outcomes of children undergoing CPRE with subsequent Mitchell bladder neck repair have been recently reported (24). Like the MSRE, the results of bladder neck repair following CPRE appear to be related to a successful primary closure, and in one report this was highly associated with the use of osteotomy (17). There are a number of options for salvage procedures in patients who fail bladder neck repair. Ultimately, however, several series have reinforced the fact that very few of these children will obtain continence with volitional voiding (27,28). Uppertract dilation following exstrophy closure is common, as most of these children have significant degrees of vesicoureteric reflux. Long-term poor renal outcomes are uncommon following ureteral reimplantation at the time of continence surgery in the MSRE.

It is important to differentiate between functional and cosmetic outcomes of genitoplasty. Cosmetic outcomes rely on subjective patient interpretation. From a cosmetic standpoint, VanderBrink (29) recently reported a 92% esthetic satisfaction rate in 65 male patients undergoing genitoplasty for exstrophy/epispadias. Nineteen revision procedures were required to obtain this outcome. The majority of these cases were treated with a Cantwell-Ransley technique. From a functional standpoint, prospective studies of sexually active adults are needed to ascertain this long-term outcome. North et al. (30) recently reported International Inventory of Erectile Function (IIEF-15) and Female Sexual Function Inventory (FSFI) scores for a group of adult exstrophy males and females, respectively. When compared to controls, adult males with exstrophy reported similar scores for erection, orgasm, desire, and satisfaction. Females, on the other hand, had poor sexual satisfaction and lower scores when compared to controls in all FSFI domains. The reason for this gender dichotomy is not clear.

---

## CONCLUSION

---

The modern treatment of bladder exstrophy can be quite successful in experienced hands. A successful initial closure can place the child on the road to eventual continence and volitional voiding, while failed closures are likely to result in a less satisfactory outcome that often involves augmentation or continent diversion. These surgeries should be performed in exstrophy centers if at all possible in order to give the child born with this major birth defect the best chance at a good quality of life.

## CHAPTER 112 ■ CONGENITAL ANOMALIES OF THE SCROTUM

SEAN T. CORBETT AND DAVID R. ROTH

Isolated congenital anomalies of the scrotum, including inclusion cysts, the bifid or hypoplastic scrotum, penoscrotal transposition, and webbed penis, are unusual. Most often these anomalies are found in association with other abnormalities: penoscrotal transposition and bifid scrotum with hypospadias, bifid scrotum and scrotal ectopia with exstrophy, and scrotal hypoplasia with cryptorchidism. When these anomalies occur in conjunction with other genital abnormalities, the scrotum can be surgically repaired with excellent results at the time of the procedure to correct the primary anomaly. It is important, however, that neonatal circumcision be avoided in boys with genital anomalies because the prepuce may be required for reconstruction of the penis and its presence will allow greater flexibility for the surgeon.

---

### DIAGNOSIS

---

The diagnosis of scrotal congenital anomalies is made by physical examination. Rarely do these anomalies occur as solitary lesions, and the patient should be appropriately evaluated for associated anomalies. The physician should examine the scrotum for its relative position to the penis, rectum, and median raphe. The appearance of the scrotum should be noted with attention to symmetry and distribution of its rugations. The testes, penis, urethra, and rectum should be inspected to ensure that they are normal.

---

### INDICATIONS FOR SURGERY

---

Timing of the surgical repair of urogenital anomalies is important with regard to feasibility of the surgery, safety of the surgery to the patient, and the psychological impact of the anomaly and surgery. Because congenital scrotal anomalies do not interfere with urinary function, repair can be scheduled at the time that is most appropriate for the infant and most convenient for parents and physicians. Technically, from the surgeon's point of view, there is little to be gained by delaying surgery beyond the child's fourth to sixth month because by that time the genitalia have developed to sufficient size for easy reconstruction. With optical magnification and the standardization of fine sutures, excellent results can be expected even in the very young child. In addition to the degree of scrotal development, the safety of anesthetics has always been a concern in determining the minimum age at which an operation seems appropriate. However, as a result of the proliferation of specially trained and dedicated pediatric anesthesiologists, the anesthetic complication rate has reached a nadir at approximately 3 months of age. To delay repair beyond that time is no longer necessary in centers dedicated to pediatric surgery.

Psychological concerns limit the opposite end of the time spectrum (1). The child's anxiety concerning hospitalization, gender identity, and subsequent sexual development

must be considered. If genital surgery is performed before the child is 18 months of age, he neither remembers the surgery nor associates the experience with an abnormality of his penis or scrotum. Therefore, a window (4 to 18 months) exists for surgery, limited on the younger side by both anesthetic and technical concerns and on the older side by memory and psychological issues. Parents need to determine a time during that 14-month period that is best for their schedules. Because most of these surgical repairs require only external relocation of skin, they usually can be performed on an outpatient basis and only rarely with a hospital stay of a single night. A further consideration is that it is easier for parents to care postoperatively for a boy who is younger and not yet walking.

Certain technical points are relevant to all of these operations and warrant mentioning. For instance, optical magnification has proved to be very useful. Several companies now make loupes in powers of  $2.5\times$  to  $4.5\times$  that practitioners have found to be invaluable when performing delicate surgery on the genitalia. Also helpful are the fine (6-0 to 8-0) absorbable (plain, chromic) sutures, which are excellent materials with which to repair a child's scrotum. They do not have to be removed and are absorbed quickly, so skin tracks are unlikely to form. The use of tissue expanders for progressive skin dilatation, as in the cases of hypoplastic/absent scrotum, has offered a viable alternative to myocutaneous flaps, which often result in a poor cosmetic result in the pediatric population. Finally, prophylactic antibiotics are seldom necessary in uncomplicated cases with the prepubertal child.

## ALTERNATIVE THERAPY

There are no alternatives to surgical correction of the congenital anomaly. On the other hand, nontreatment is an option, and reconstructive surgery can be delayed until the boy can participate in the decision to proceed. The psychological advantage of earlier surgery would need to be weighed against the importance of allowing the youngster to be involved in the decision-making process.

## SURGICAL TECHNIQUE

### Bifid Scrotum

Isolated bifid scrotum is rare. When it occurs, the corpus spongiosum appears to be continuous with a prominent median raphe of the scrotum, a fibrous band that separates and divides the scrotum into two individual parts. Surgical reapproximation of the two hemiscrotums can be achieved after excision of the fibrous midline band. The underlying urethra must be preserved and allowed to fall away from the dense band. This requires mobilization of each hemiscrotum to the extent that it can be elevated and moved medially to the midline. Closure is accomplished in at least two layers. Deep absorbable sutures allow fixation and reconstruction of the midline. Fine absorbable sutures should be used to close the skin. In general, interrupted simple sutures are used, but a running subcuticular closure may also be utilized.

**FIGURE 112.1** A: In the moderately severe case of penoscrotal transposition, the phallus is circumscribed and freed of supporting tissue. An incision is made cephalad to the base of the phallus. B: The penis can then be brought back through the new opening and the skin sutured about it. The original opening is then sewn closed.

## Penoscrotal Transposition

Various degrees of penoscrotal transposition exist, ranging from the complete form, in which the scrotum is actually anterior and cephalad to the base of the penis, to incomplete forms, in which the penis emerges from the center of the scrotum, and the milder forms, in which only the superior edges of the scrotum lie anterior to the penis. For correction of the anomaly, the two hemiscrotums are mobilized, swept inferiorly and medially, and sutured together. It may be necessary to transpose the penis cephalad to the scrotum. This can be achieved by using a skin bridge (Fig. 112.1) or by dividing the abnormal scrotum in its midline cephalad and caudal to the phallus and swinging both halves below the penis (Fig. 112.2) (2). Some authors suggest leaving a segment of skin intact cephalad to the penis to avoid jeopardizing the vascularity and lymphatic drainage of the penile shaft skin. Other authors advocate the creation of a

**FIGURE 112.2** A: In the more severe case of penoscrotal transposition, each hemiscrotum is circumscribed. B: Once each side is freed to rotate caudally and medially the two portions are sewn together. Some authors suggest leaving a bridge of skin cephalad to decrease the possibility of a vascular insult.

**FIGURE 112.3 A and B:** In the mild case of penoscrotal transformation, a V-shaped wedge of ectopic scrotal skin is excised. **C:** The defect is then closed, thereby eliminating the ectopic scrotal skin.

suprapubic buttonhole through which the penis can be delivered (3,4). For less severe cases of penoscrotal transposition, the wedge of ectopic scrotal skin is removed and the resultant defect closed, thereby eliminating the problem (5). This approach is most appropriate when there is incomplete mild penoscrotal transposition (Fig. 112.3). The penoscrotal angle can be recreated by anchoring sutures applied to the underlying fascia and corresponding skin. Fixation of the penopubic angle can also be performed in a similar fashion. The anchoring sutures may have the additional benefit of stabilizing penile length (6,7).

### Scrotal Hypoplasia

Scrotal hypoplasia is almost always restricted to boys with cryptorchidism. A limited course of androgen stimulation (testosterone enanthate 2 mg/kg intramuscularly) will induce scrotal development and enlargement in addition to increasing penile length and glans circumference (8). This allows easier surgical placement of either a testis or prosthesis in the poorly developed scrotum at the time of inguinal surgery for the undescended testis. The hormonal treatment should be undertaken only in conjunction with either an orchiopexy or placement of a testicular prosthesis because the effects of the testosterone are temporary; if the scrotum is not distended, it may revert to its hypoplastic appearance. In severe cases of scrotal hypoplasia or the rare case of congenital scrotal agenesis, tissue expanders may be used as another alternative where there is inadequate space for the testis or prosthesis. The expanders can be used to progressively dilate the scrotum to an adequate size (3). Placement of a testicular prosthesis before puberty is not routinely advocated as these children will outgrow their prosthesis and need a larger size at a later date.

### Scrotal Ectopia

Although less common than either scrotal transposition or a bifid scrotum and usually associated with cloacal exstrophy, scrotal ectopia on occasion is found in the otherwise normal

child (9). The ectopic scrotal tissue can be found on the inner aspect of the thigh or caudal and inferior to the external inguinal ring. Often, the ipsilateral testis can be found within the ectopic tissue. Correction is accomplished by relocating the ectopic tissue, by way of a flap or graft, or by utilizing the normally positioned contralateral hemiscrotum as a reservoir for both gonads and discarding the ectopic tissue (10). The latter can be accomplished by stretching local tissue either primarily or after pretreatment with parenteral testosterone enanthate (2 mg/kg intramuscularly). The ectopic scrotal tissue in that case can then be excised.

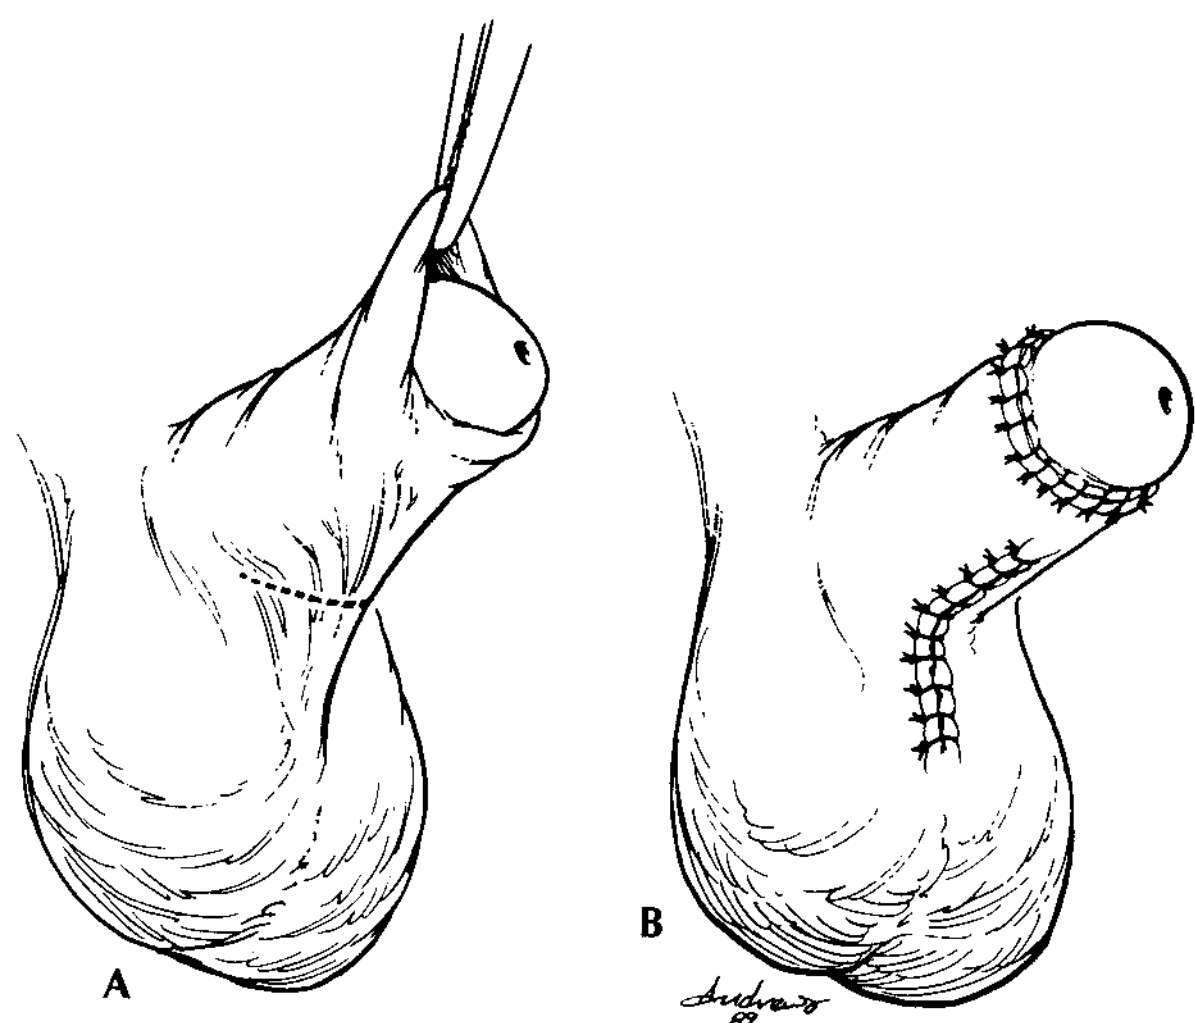

### Webbed Penis

In boys with a webbed penis, scrotal skin is tethered to the ventrum of the penile shaft. This tethering produces a web of skin stretching from the penis to the scrotal base. The webbed penis causes no problem during childhood. However, as the scrotal skin is hair-bearing, future intercourse could be difficult or uncomfortable. Therefore, a webbed penis should be corrected during infancy. A modified circumcision can often correct the defect. The circumcision incision is brought more distal than normal on the ventrum, thereby preserving all penile shaft skin possible in that location. After the inner preputial skin is excised, the additional length on the ventrum allows the scrotum to fall away from the glans and penis. If necessary, skin from the dorsum can be mobilized and swept ventrally to provide additional shaft skin (Fig. 112.4). A second type of repair can be performed by incising the web transversely and closing it longitudinally, thereby separating the penis from the median raphe of the scrotum. A circumcision should be considered at the same time because it facilitates the approximation of the skin (Fig. 112.5).

In more severe cases of webbed penis, a U-shaped incision is made about the phallus (11). This releases the penis from the dependent scrotum. Flaps are developed to allow ventral closure of the penis with fine absorbable sutures. The scrotum is closed in a side-to-side manner (Fig. 112.6). In a manner

**FIGURE 112.4** In the mildly webbed penis, a modified circumcision may be all that is required. With the ventral incision made at the phimotic band, the ventral skin can be repositioned to cover the penile shaft appropriately.

**FIGURE 112.5** In the moderately webbed penis, the defect can be repaired by (A) transversely incising the web and (B) closing it longitudinally. As in the mild cases, a modified circumcision incision with preservation of all the ventral skin can be helpful in recovering the penile shaft.

similar to cases of penoscrotal transposition, the penoscrotal angle can be recreated by the placement of anchoring sutures securing the skin to the underlying fascia.

---

### Scrotal Inclusion Cysts

---

Midline scrotal inclusion cysts are in general dermatoid in origin and can be managed by local excision (12). However, care must be taken not to confuse these with the sinus associated

**FIGURE 112.6** A: In a severely webbed penis, an incision is made between the penis and scrotum. B: Skin flaps are elevated in all directions so that the surgical defect can be closed. C: A two-layer closure is used to stabilize and approximate the skin and underlying tissues.

with an imperforate anus. Both are located in the median raphe and can be multiple. Because cysts can lead to calculi formation or infection, local excision should be considered.

---

## OUTCOMES

---

### Complications

---

Complications from these surgeries are in general uncommon. Superficial infections can be treated with antibiotics.

---

### Results

---

The cosmetic results of this surgery are usually excellent.

# CHAPTER 113 ■ PEDIATRIC CRYPTORCHIDISM, HYDROCELES, AND HERNIAS

KENNETH G. NEPPLE AND CHRISTOPHER S. COOPER

Between 3% and 5% of full-term boys are born with an undescended testicle. Often associated with the undescended testicle is a patent processus vaginalis that predisposes to hydrocele and hernia formation. The urologist treating the infant with an undescended testicle must therefore be familiar with the anatomy (Fig. 113.1) and operative techniques employed in treating this common condition. This familiarity assists with orchiopexy and hydrocele and hernia repair.

## CRYPTORCHIDISM

Cryptorchidism includes the strict definition of a hidden or nonpalpable testicle as well as a testicle that is undescended but palpable in the inguinal canal. True undescended testicles stop along the normal path of descent into the scrotum. They may remain in the abdominal cavity (least common), in the

**FIGURE 113.1** Anatomy of inguinal orchiopexy. **A:** Relationship of the vas deferens, spermatic vessels, and processus vaginalis to investing fascial layers. The transversalis fascia is contiguous with internal spermatic fascia. **B:** With tension applied to the cord (arrow), the orientation of the fibers of the intermediate stratum investing the retroperitoneal spermatic cord is changed so that fibers become parallel to cord structures. Freeing the vas and vessels from this investing fascia is the most important step in achieving distal testicular displacement. (From Hutcherson JC, Cooper CS, Snyder HM III. The anatomical approach to inguinal orchiopexy. *J Urol* 2000;164:1702–1704, with permission.)

inguinal canal (canalicular), or just outside the external ring (suprascrotal, most common). Testes may also pass through the external ring and then be located ectopically, most commonly in a superficial inguinal pouch. The incidence of undescended testicles increases from 3% to 5% in full-term infants to 30% in premature infants. Low birth weight has also been shown to be a predictor of cryptorchidism, independent of gestational age. Most of these testicles descend within the first 6 months of life, and by 1 year of age the prevalence is 1%. The left testicle is affected more often, and 1% to 2% of children with cryptorchidism will have both testicles affected. Twenty percent of boys who present with cryptorchidism have one nonpalpable testis. Of nonpalpable testes, 20% are intra-abdominal, 40% are canalicular, scrotal, or ectopic testes, and 40% are atrophic or absent.

---

### Diagnosis

---

The diagnosis of cryptorchidism relies on the physical examination. Absence of an identifiable testicle with ultrasound, computed tomography, or magnetic resonance imaging does not prove testicular agenesis and therefore does not alter the need for surgical exploration. The testicular examination in the infant and young child requires two hands and patient relaxation. One hand is placed near the anterior superior iliac spine and the other on the scrotum. The first hand is swept from the anterior iliac spine along the inguinal canal to gently express any retained testicular tissue into the scrotum. Placing soap on the fingertips of the palpating hand may improve the sensitivity of palpation. A true undescended or ectopic inguinal testis may slide or “pop” under the examiner’s fingers during this maneuver. A low ectopic or retractile testis will be felt by the second hand as the testis is milked toward the scrotum by the first hand. To distinguish a retractile testicle, the testicle is brought into the scrotal position; holding it in place for at least 1 minute fatigues the cremaster muscle. After this maneuver, a retractile testicle remains in the scrotum, whereas an ectopic or undescended testis immediately springs out of the scrotum. If a testis cannot be palpated in the inguinal canal or the scrotum, or in the typical ectopic sites, evaluation for a nonpalpable testis must be performed.

A child with bilateral nonpalpable testes should undergo hormonal evaluation for testicular absence (1). Elevations in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) and absence of detectable müllerian inhibiting substance (MIS) suggest testicular absence (2). Testicular absence is confirmed by a negative human chorionic gonadotropin (HCG) stimulation test. The HCG stimulation test is performed by the administration of intramuscular HCG (2,000 IU per day for 3 to 4 days) (3). Raised gonadotropin levels (FSH and LH) *and* a lack of a testosterone rise from HCG indicate bilateral absent testes and a formal surgical exploration is not necessary. When one or both components are lacking or there is detectable MIS, surgical exploration is warranted.

---

### Indications for Surgery

---

Treatment of the undescended testicle offers the possibility of improved fertility, correction of patent processus vaginalis, prevention of testis torsion, and improvement in body image.

There is controversy whether orchiopexy decreases the risk of malignancy, but placement of an undescended testicle in the scrotum assists physical examination of the testis. Because histologic changes related to fertility occur in the undescended testicle as young as 1 year of age and spontaneous descent rarely occurs after 6 months of age, the optimal time for surgical correction is around 6 months of age.

Almost 90% of undescended testes have an associated patent processus vaginalis. If a patient with cryptorchidism presents with an incarcerated or strangulated inguinal hernia, repair at the time of presentation along with orchiopexy should be undertaken. Otherwise, the hernia should be repaired at the time of orchiopexy. Occult inguinal hernia in patients with untreated undescended testis can present at any time with the typical symptoms or complications, including incarceration.

---

### Alternative Therapy

---

Hormonal therapy is an option in the treatment of cryptorchidism because the condition may be related to hypogonadotropic hypogonadism. HCG is the only hormone approved for use in the treatment of cryptorchidism in the United States. Side effects of administration of HCG include enlargement of the penis, growth of pubic hair, increased testicular size, and aggressive behavior during administration. The likelihood of success with hormonal therapy is greatest for the most distal undescended testes or for testes that have been previously descended (4). Some suggest that hormonal therapy is effective only for retractile and not truly undescended testes (5). Although hormonal therapy may not be effective in achieving testicular descent, it may improve fertility in cryptorchid boys (6).

---

### Surgical Technique

---

Prior to any surgical intervention, the patient is re-examined while under anesthesia because on occasion a retractile testicle descends under anesthesia or a previously nonpalpable testicle becomes palpable. A bimanual examination with a finger in the rectum may permit detection of an intra-abdominal testicle. For a palpable testicle an open inguinal approach is performed. For the nonpalpable testicle in a child a laparoscopic approach is preferred, but an open inguinal approach may be performed.

#### Inguinal Orchiopexy

Preoperative antibiotics (cefazolin 25 mg/kg) are administered and operating loupes can be used for magnification. A 3- to 4-cm incision along the lines of Langer is made in a groin crease one third of the way between the pubic tubercle and the anterior superior iliac spine (Fig. 113.2). The incision is carried through subcutaneous fat and the fascia of Scarpa to the level of the anterior aspect of the inguinal canal using Metzenbaum scissors. Overlying fat and fascia are cleared off the external oblique fascia to its lateral shelf. An ectopic testicle may be visualized exiting through the external ring. The external ring is visualized and the anterior aspect of the inguinal canal is incised by nicking the fascia with a scalpel blade. An incision placed too far medial makes cord

**FIGURE 113.2** Incision for left orchiopexy.

identification more difficult, while an incision too far lateral makes fascia closure more difficult. Metzenbaum scissors with the tips facing upward are inserted into the nick and used to spread the adjacent tissue away while taking care to identify and protect the underlying ilioinguinal nerve. The roof of the inguinal canal is then opened along the course of its fibers downward toward and through the external ring. The spermatic cord is identified and elevated and dissected free of the anterior cremaster fibers using blunt dissection and DeBakey forceps. If no cord structures are identified, attention is turned to the level of the internal ring, and by application of abdominal pressure and retraction in the internal ring frequently a testicle may be identified just inside the internal ring. If no testicle is identified, the peritoneum is opened and a search is made for either a testicle or a blind-ending vas and vessels (see below). Blind-ending spermatic vessels must be identified to confirm absence of a testicle as a blind-ending vas does not guarantee testicular absence.

After identification of the testicle and spermatic cord in the canal, the gubernaculum is divided sharply after placement of 4-0 Vicryl sutures. Placement of a hemostat on the proximal end for traction provides a means of manipulating the testicle and cord structures safely. Care must be taken at this point to avoid a long-looped vas deferens that sometimes extends distally. Elevation of the cord permits blunt sweeping dissection of the inferior cremaster fibers proximally to the level of the internal ring. By placing a retractor in the internal ring and pulling the cord and attached peritoneum medially, the surgeon gains access to the retroperitoneal space along the lateral aspect of the internal ring, which is enveloped in the endopelvic fascia. The cord and peritoneum may then be swept anterior and medial with blunt dissection in the retroperitoneal space.

The intermediate stratum, an extension of connective tissue that envelops the spermatic vessels and vas deferens in the retroperitoneum, is located between the inner striatum (connective tissue of the peritoneum) and the outer striatum (transversalis fascia). As the vas joins the vessels in the inguinal canal, the

**FIGURE 113.3** Isolation of cord structures during orchiopexy.

fibers of the intermediate stratum attenuate and the structures (vas, vessels, processus vaginalis) are enveloped by the internal spermatic fascia, which is an extension of the transversalis fascia from the floor of the inguinal canal. To free the remaining anterior and medial retroperitoneal attachments to the spermatic vessels and vas deferens, the internal spermatic fascia must be divided, allowing separation of the processus and contiguous peritoneum from the vas and vessels and complete access to the retroperitoneum (Fig. 113.3).

With a nonpatent processus vaginalis, a hemostat providing anterior traction on the tip of the peritoneal reflection permits dissection of the underlying cord from the internal spermatic fascia binding it to the peritoneum. With a patent processus vaginalis, the posterior cord is exposed, the internal spermatic fascia is swept off the cord structures, and the processus vaginalis is freed to the level of the peritoneum. The processus vaginalis is incised and the edges can be held and the processus can be flattened and readily dissected from the underlying cord. The processus is twisted and ligated at the level of the peritoneum with a 3-0 or 4-0 Vicryl suture.

The anterior and medial retroperitoneal attachments to the cord may be approached by placing a retractor anterior to the vessels in the internal ring, allowing the bands of the retroperitoneal fascia to be bluntly dissected from the vessels to obtain increased cord length. The beginning of the retroperitoneum is marked by the divergence of the vas medially and inferiorly. The circumferential dissection of the vessels can be extended in the retroperitoneum up to the level of the renal hilum if the need arises to gain additional cord length so the testicle can reach the scrotum without tension. True skeletonization of the vas and vessels should be avoided as this can lead to testicular atrophy. The limiting factor on length is most often the spermatic vessels rather than the vas deferens (Fig. 113.4). To gain additional length a Prentiss maneuver can be performed by using a right angle to puncture through the floor of the inguinal canal near the pubic tubercle and then passing the testicle directly under the transversalis fascia towards the scrotum, in effect moving the course of the vessels toward the midline with alignment of the internal and external rings.

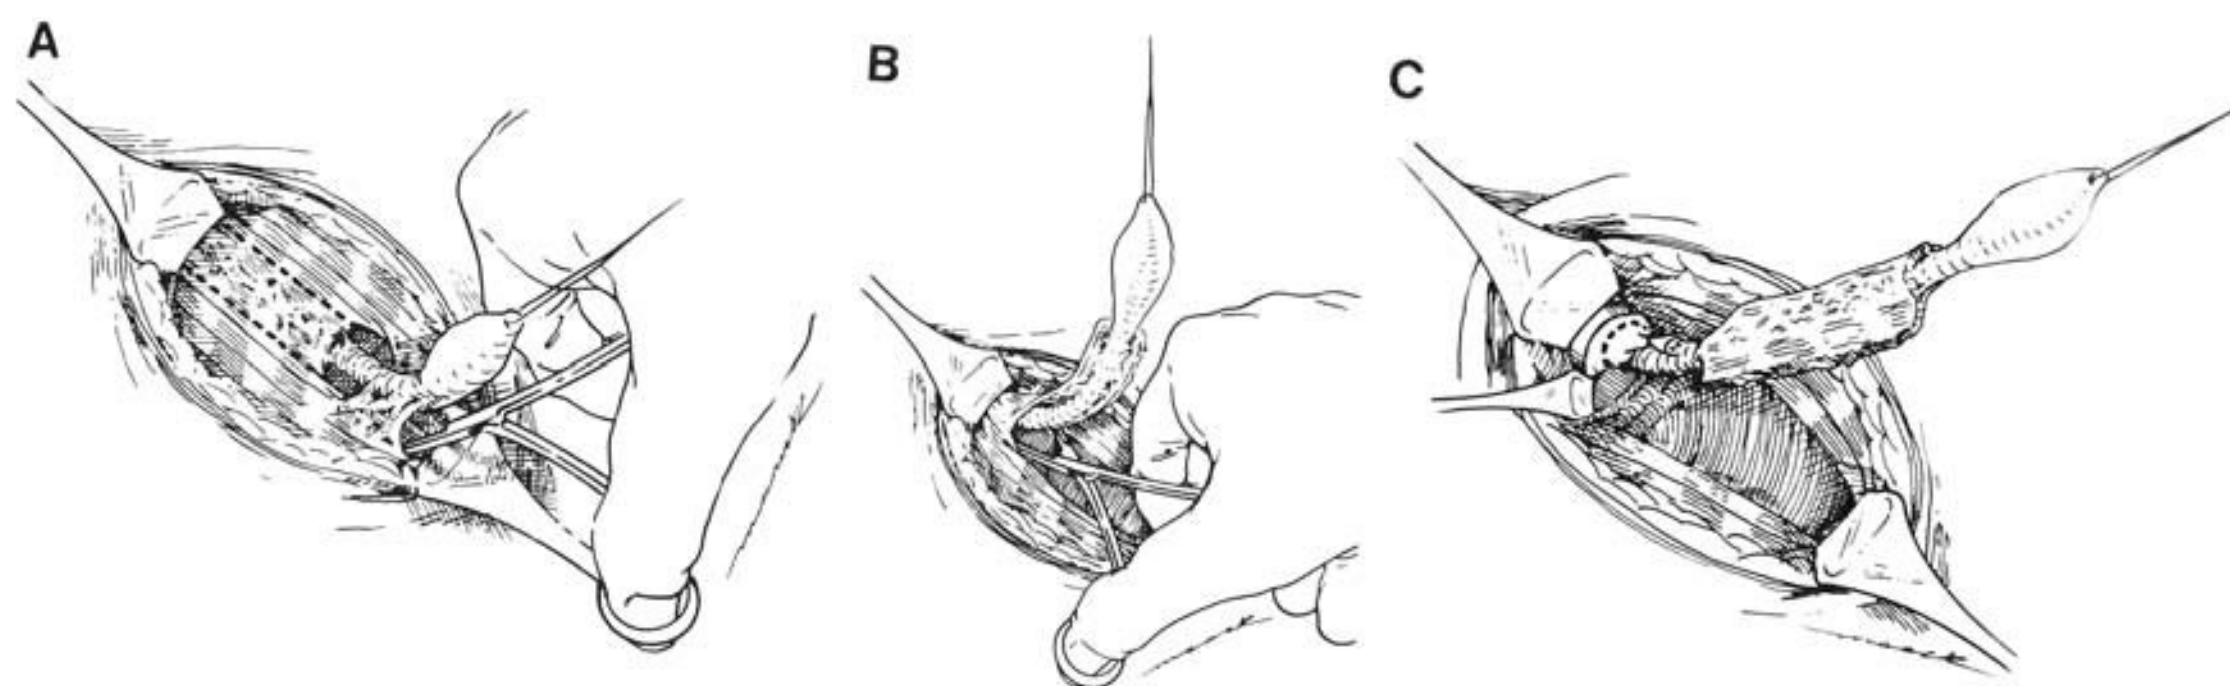

With an absent testicle, blind-ending vas and vessels may be encountered in the inguinal canal. The tubular structures in the canal must be traced proximally to the internal ring, where the divergence of the vas and vessels helps the surgeon positively identify the spermatic vessels. With identification of blind-ending spermatic vessels, no further exploration for a

**FIGURE 113.4** After dissection, adequate spermatic cord length is demonstrated.

testis is indicated. However, a blind-ending vas deferens is not sufficient reason to stop the exploration because there are patients with a wide separation of the vas and an intra-abdominal testis. When no spermatic cord structures are identified in the inguinal canal, the dissection is carried to the internal ring and into the retroperitoneum. If no structures are identified, the peritoneum is opened and the testicle or blind-ending spermatic vessels are sought.

Repeat inguinal exploration for a failed orchiopexy is associated with scar tissue surrounding the testicle and spermatic cord causing adherence to the underside of the external oblique fascia. Following the inguinal incision, the testicle should be identified and freed from surrounding scar tissue. Once this is accomplished, the cord can usually be freed along its posterior aspect extending through the inguinal canal. No attempt is made to dissect the cord from the scar extending along its anterior surface and the overlying external oblique fascia. By cutting the fascia along the medial and lateral sides of the cord and then connecting these incisions above the internal oblique muscle, a strip of fascia is left attached to the cord as described by Cartwright et al. (Fig. 113.5). The peritoneum may then be opened and the spermatic vessels freed as described above. At the peritoneal level there is rarely any significant scar tissue.

**FIGURE 113.5** Reoperative orchiopexy demonstrating external oblique fascial incisions lateral and medial to the cord structure. The adherent scar tissue is dissected with the spermatic cord and no attempt is made to dissect the spermatic cord from the scar. (From Cartwright PC, Velagapudi S, Snyder HM III, et al. A surgical approach to reoperative orchiopexy. *J Urol* 1993;149:817–818, with permission.)

**FIGURE 113.6** Incision for subdartos pouch.

#### Scrotal Fixation (Subdartos Pouch)

Multiple methods have been described for fixing the testis to the scrotum, although the subdartos pouch is our preferred method because it avoids transparenchymal sutures. Following a transverse incision in the hemiscrotum (Fig. 113.6), a pocket for the testicle is created by dissecting the scrotal skin superiorly and inferiorly from the adherent underlying dartos using Ragnell orchiopexy scissors (Fig. 113.7). Care must be taken not to develop the pouch too lateral or too inferior because this could result in an ectopic testis location. The testicle is exposed by opening the tunica vaginalis. A testicular biopsy is not routinely indicated. Once adequate cord length has been obtained, the testicle is passed down from the inguinal incision using a hemostat attached to the gubernaculum. The testicle is brought through the dartos and placed in the pouch, taking care to avoid any torsion of the cord. For additional security, the inlet

**FIGURE 113.7** Creation of dartos pouch using Ragnell orchiopexy scissors.

into the pouch may be narrowed with a single polyglycolic acid suture at a diameter less than that of the testis but not so narrow as to compromise the blood supply of the testis. A small portion of the parietal tunica vaginalis or spermatic cord adventitia is incorporated into this stitch for further fixation. The use of an absorbable suture may heighten the inflammatory reaction around the testis and create a greater degree of scarring and fixation. The scrotal skin is then closed with subcuticular sutures (Fig. 113.8). For the inguinal incision, the fascia is closed

**FIGURE 113.8** Successful orchiopexy shows both testes in the scrotum.

with interrupted 3-0 Vicryl suture, taking care not to close the external ring too tightly, followed by closure of the subcuticular tissue with 4-0 Vicryl and skin with absorbable suture. For postoperative pain control, anesthesia can administer a caudal block, or a local nerve block with 0.25% Marcaine can be performed by the surgeon just prior to closure.

### Transperitoneal Orchiopexy

Open transperitoneal orchiopexy has been in large part replaced by laparoscopic exploration. In cases where an open approach is undertaken, an incision is made transversely or in the midline with subsequent intraperitoneal exploration. The spermatic vessels may be dissected free from their attachments cephalad to the level of their origin/insertion. With intra-abdominal testicles, this dissection should leave a broad leaf of peritoneum attached to the vas deferens along the medial aspect in case transection of the spermatic vessels is required (see below). A new external inguinal ring is created lateral to the pubic tubercle to provide the most direct route into the scrotum.

Despite a high retroperitoneal dissection, some testicles may not reach a scrotal location due to short spermatic vessels. Often, these testicles can be identified after opening the peritoneum by applying traction to the testicle and observing minimal caudal displacement and no redundancy in the spermatic vessels. In this case the surgeon must consider either bringing the testicle down as low as possible, with an anticipated reoperative orchiopexy in 6 to 12 months, or Fowler–Stephens orchiopexy, with transection of the spermatic vessels with immediate or secondary orchiopexy. A Fowler–Stephens bleeding test involves occluding the spermatic vessels for 5 minutes with atraumatic bulldog clamps and then incising the tunica albuginea toward the testicular upper pole and watching for testicular bleeding. If there is adequate bleeding a Fowler–Stephens orchiopexy is performed by ligating the spermatic vessels while a broad-based medial pedicle of peritoneum and the vas deferens are mobilized. This procedure relies on collateral blood flow to the testicle from the vas deferential artery, a branch of the inferior vesical artery, and cremasteric vessels, which branch off the inferior epigastric artery. Spermatic vessel ligation should not be done for a failed previous inguinal orchiopexy or when the vas has been skeletonized during initial orchiopexy because the collateral blood supply along the vas deferens will have been compromised and is unreliable.

An alternative is the staged testicular vessel transection orchiopexy, which involves ligation at the initial stage without mobilization to provide time for vasal collateral blood supply development. After several months, at the second stage the vessels are divided and the testicle is brought into a scrotal location after a dissection similar to that described above. A final option that is rarely utilized is testicular autotransplantation with anastomosis to the inferior epigastric artery and vein by an experienced microvascular surgeon.

### Scrotal Orchiopexy

The high transscrotal incision for testicular mobilization including ligation of an associated inguinal hernia through one incision has been applied to primary and secondary cryptorchidism, although the increased technical difficulty of inguinal herniorrhaphy and concern for gaining adequate cord length through this approach have limited its popularity. The

scrotal approach may be especially suited to ectopic or ascended testes, including those that have failed prior orchiopexy. Bassel et al. (7) recently reported that scrotal incision orchiopexy was highly successful in a select group of children with palpable undescended testis that can be brought down following induction of anesthesia to the scrotum with caudal traction by the surgeon. The processus vaginalis is dissected free of cord structures and, if patent, then high suture ligation is performed. An alternative procedure is a low scrotal incision, with addition of an inguinal incision if a patent processus is encountered. A scrotal incision is made and blunt dissection is used to expose the processus vaginalis. The processus is opened and then the testis is delivered. The processus is probed and, if patent, an inguinal incision is made.

---

## Outcomes

---

### Complications

Retraction is the most common complication of orchiopexy and usually occurs secondary to an incomplete initial dissection and tension on the testicle. It is possible that some cases of retracted testicle after an orchiopexy occur because of dislodgement of the testis from the scrotum. To prevent this possibility, straddle toys are avoided for at least 3 weeks following the operation.

The most significant complication is testicular atrophy, which occurs in 1% to 2% of cases of orchiopexy, while complete devascularization of the testis is rare. The dissection of the testicular vessels and/or postoperative swelling and inflammation can result in ischemic injury with subsequent testicular atrophy. The failure rate with orchiopexy is 8% for distal undescended testes and 26% for intra-abdominal undescended testes (8). Other potential complications include ascent of the testis requiring reoperative orchiopexy, infection, bleeding, ilioinguinal nerve injury, or damage to the vas deferens.

### Results

Successful therapy, as defined by a viable testis positioned in the scrotum, is dependent on the preoperative anatomic position of the testis. Success rates are 74% for the abdominal testis, 87% for canalicular, and 92% for those distal to the external ring. Success rates for various operative techniques are 89% for the standard inguinal orchiopexy, 67% for Fowler–Stephens, 77% for staged Fowler–Stephens, 81% for transabdominal, 73% for two-stage, and 84% for microvascular (9). All of these results suggest an advantage to maintaining intact vessels where possible.

Paternity rates among men who had attempted to father children were 65%, 90%, and 93% in men with bilateral cryptorchidism, unilateral cryptorchidism, and normally descended testicles, respectively (10). If only one testis is undescended, the sperm count will be subnormal in 25% to 33% and the serum FSH concentration will be slightly elevated (11, 12). The presence of these abnormalities suggests that both testes are abnormal, perhaps congenitally, although only one fails to descend. If both testes are undescended, the sperm count usually will be severely subnormal and the serum testosterone may be reduced (12).

---

## HYDROCELE/HERNIA

---

A hydrocele consists of a collection of fluid in the tunica vaginalis around the testicle. In children this is almost always found in association with a patent processus vaginalis that permits flow of peritoneal fluid into the tunica vaginalis (communicating hydrocele). An indirect inguinal hernia forms when bowel or any other tissue from the abdominal cavity protrudes into the patent processus vaginalis. Between 0.8% and 4.4% of newborns and up to 30% of premature infants have an inguinal hernia. Boys are six times more likely than girls to have a hernia and right-sided hernias occur twice as frequently as left-sided hernias, with bilateral hernias occurring about 10% of the time.

---

## Diagnosis

---

Children with a hydrocele or hernia present with swelling in the groin and scrotum/labia. This swelling can be persistent or intermittent and may not be observed by the physician. Often, it is noted by the parents only when the child is crying or straining and the intra-abdominal pressure is elevated. In this case, the diagnosis depends on a reliable history from the parents describing the intermittent groin and scrotal swelling. Older children may be examined while standing and performing a Valsalva maneuver to increase the intra-abdominal pressure. Rarely children will present with large abdominoscrotal hydroceles that cross the internal inguinal ring and contain an intra-abdominal component resulting in a palpable abdominal mass.

With increasing size of the hydrocele, the testicle becomes more difficult to palpate and often is not palpable. Usually, a hydrocele becomes narrow at the level of the internal ring and the examiner is able to detect this narrowing and get above the swelling. With a hernia, the swelling extends through the internal ring. The fluid in a hydrocele sac will transilluminate; however, bowel can also be transilluminated, making this a nonspecific finding for either a hydrocele or a hernia. Ultrasonography may help define the testicle and rule out any testicular pathology, as well as help differentiate a hydrocele from a hernia.

---

## Indications for Surgery

---

The majority of infant hydroceles resolve by 18 months of age as the patent processus obliterates. If a hydrocele persists beyond 18 months, then it is unlikely to undergo spontaneous resolution and surgical treatment is indicated. When the fluid in a hydrocele sac is easily reduced, it suggests the size of the patent processus vaginalis is larger than with a hydrocele that does not have easily reducible fluid. This examination finding and a history of waxing and waning size of the hydrocele may serve as an indication for surgical correction before 18 months of age.

A healthy child presenting with an incarcerated hernia should undergo attempts at manually reducing the hernia. This may require sedation and placement of the child in the Trendelenburg position. Once the hernia is reduced, surgical correction should be performed within the next several days

because an inguinal hernia will not resolve spontaneously and the child is at risk for repeat incarceration. If the hernia is not reducible, an emergent operation should be performed. Preterm infants with a reducible hernia may be observed during their stay in the intensive care unit until they are thought to be medically stable enough to undergo a surgical procedure.

Because of the high incidence of a contralateral patent processus, some surgeons routinely explore the contralateral groin during hernia surgery. We do not routinely explore the contralateral groin as there is only a 20% chance of developing a clinical contralateral hernia. Some physicians will perform laparoscopy through the hernia sac and examine the contralateral inguinal ring to determine if a contralateral groin exploration and hernia repair is required, and others will perform a pneumoperitoneum and feel for crepitation in the contralateral groin as an indication to operate on this side.

---

### Alternative Therapy

---

There are no alternative therapies.

---

### Surgical Technique

---

A similar inguinal incision is made for indirect hernias or communicating hydroceles as previously described in surgical technique of inguinal orchidopexy. After the inguinal canal is opened, the cremaster fibers may be spread off the anterior aspect of the spermatic cord. The bulging shiny hernia sac or patent processus vaginalis, which is typically located anterior and medial, is identified and grasped with a hemostat. By elevation of the hernia sac the cord is brought up and freed from surrounding cremaster attachments, permitting the surgeon's finger to be placed beneath the entire spermatic cord and hernia sac. Extensive dissection of cremasteric fibers need not be performed. The sac is teased off the underlying cord by breaking apart the internal spermatic fascia that encases the cord structures and the hernia

sac. As this is done, the cord structures are separated from the hernia sac by passing a hemostat from lateral to medial and spreading at a 90-degree angle to separate cord from hernia sac. When the cord structures are completely freed, the sac is transected and then dissected up to the internal inguinal ring. It is important to identify the internal spermatic fascia and break this down so that when the sac is twisted and ligated, the cord structures will not become incorporated.

The hernia sac is twisted and high ligation is performed with two 4-0 Vicryl sutures and divided close to the level of the internal ring. The distal sac or hydrocele is then delivered along with the testicle into the wound, and the sac is opened down to the level of the testicle, taking care not to injure the cord structures. The authors routinely evert and sew the hydrocele sac behind the cord or testis in a Bottle technique with an absorbable suture to prevent the possible reformation of the hydrocele. Repair of the dilated internal inguinal ring may be required and is accomplished by approximation of the transversalis fascia to itself at the level of the internal ring, taking care not to strangulate the cord. The conjoined tendon may also be sutured to the shelving edge of the inguinal ligament. The testicle is then drawn back into the scrotum with traction on the scrotal skin and gubernaculum. The external oblique aponeurosis and wound are then closed with 3-0 Vicryl suture as described above.

---

### Outcomes

---

#### Complications

Recurrence or persistence of the hernia or hydrocele may occur if the patent processus is not well ligated. Injury to the underlying spermatic and/or vas deferens vessels may result in testicular atrophy. Displacement of the testicle to an extrascrotal location may occur after surgery. To prevent this complication, every hydrocele and hernia repair should be concluded by confirmation of the testis location in its normal dependent scrotal position.

# CHAPTER 114 ■ LAPAROSCOPIC MANAGEMENT OF THE UNDESCENDED TESTICLE

DANIELLE D. SWEENEY, MICHAEL C. OST, AND STEVEN G. DOCIMO

Cryptorchidism is defined as the absence of a testicle; one that is not present in the scrotum, or one that cannot be manipulated into the scrotum on physical examination. These testicles may be truly absent, due to agenesis or intrauterine torsion, or more commonly, they may have not completed their normal path of descent into the scrotum. This condition is reported in 3.4% to 5.8% of full-term boys, and the incidence decreases to about 1% at year one of life (1). Cryptorchidism is reported to be bilateral in 10% of cases (2).

Of the boys diagnosed with cryptorchidism, as many as 20% will have a nonpalpable testis (3). In this subset of patients, testicles may be absent, intra-abdominal, or within the inguinal canal (canalicular). Prior to the 1970s, surgical management of the nonpalpable testicle consisted of inguinal exploration with extension of the dissection into the peritoneum if a testis, nubbin, or blind-ending vessels could not be identified. However, Cortesi (4) described using diagnostic laparoscopy for nonpalpable testis in 1976, revolutionizing the diagnosis and surgical management of the undescended testicle. This technique has become the gold standard for the diagnosis of the intra-abdominal testis, and in urology for its surgical management.

---

## PREOPERATIVE ASSESSMENT

---

Upon the initial evaluation, a thorough history and physical examination must be obtained. Antenatal as well as maternal history for the use of gestational steroids or hormones should be elicited, as well as the birth history and physical examination at the time of delivery. The presence of palpable gonads, hypospadias, genital surgery, or inguinal herniorrhaphy should be noted, as well as a family history of cryptorchidism or other urologic syndromes.

A careful physical examination in a nonthreatening, warm environment, with warm lubricant, is crucial to identifying a subtle but palpable testicle. In children with a referral to a urologic specialist for an undescended testicle, approximately 80% will have a palpable testicle on examination (5). Contralateral testicular size should be documented to assess for compensatory hypertrophy in cases of nonpalpable or atrophic testis.

---

## DIAGNOSTIC ASSESSMENT

---

In general, radiographic imaging in the evaluation of cryptorchidism is not cost-effective or warranted. Radiologic testing, including inguinal/abdominal ultrasound, magnetic

resonance imaging or magnetic resonance angiography, herniorrhaphy, venography, and arteriography, has been shown to have limited value in detection or localization of nonpalpable testicles (5,6). Even when a good examination is not obtained in the office setting, examination under anesthesia at the time of surgical exploration is generally more cost-effective than preoperative radiographic imaging (7). Surgical intervention, either open or laparoscopic, has been the only modality proven to accurately diagnose, localize, and concurrently treat the nonpalpable testicle (7). Hormonal therapy has been used to promote testicular descent; however, this is best reserved for those with bilateral nonpalpable testis and is unlikely to be cost-effective in those with unilateral cryptorchidism (8). In patients with bilateral nonpalpable testicles and a phenotypically male appearance, it is very important to rule out congenital adrenal hyperplasia and other intersex conditions.

---

## SURGICAL INTERVENTION

---

---

### Timing of Surgery

---

Optimal timing of surgery should be prior to the child's second birthday, and ideally between 6 and 12 months of age, since spontaneous testicular descent has been noted as late as 4 to 6 months of age. The overall goals of orchiopexy are to preserve testicular function and fertility, to relocate the testicle to the scrotum for easier neoplasm examination, and to prevent testicular torsion and trauma. In some cases, there is a psychological benefit of relocating the testicle to its anatomically correct position.

At birth, the undescended testis has been shown to have normal histology; however, delayed germ cell development has been described in the older infant, and this appears to be progressive over time. Histology correlates with testicular position, with worse features seen in higher testicles.

Early surgical intervention has been shown to improve testicular growth (9) and adult Leydig cell function (10). In children over the age of 2, the decision to perform an orchiopexy versus orchiectomy is based on the risks and benefits of the testicle to the individual. In prepubertal children the usefulness of androgen production must be considered, especially in cases of a solitary testicle. In postpubertal presentation of the undescended testis, sperm are rarely noted (11) and the testes are at significant risk for malignant change, leading some authors to recommend orchiectomy in all healthy, postpubertal cryptorchid males under 50 years of age (12).

---

## Diagnostic Laparoscopy

---

The indications for diagnostic and therapeutic laparoscopy are identical to the goals of open surgical management: to determine if a testicle is present and viable, and if so, to relocate the testicle into the scrotum. Historically, laparotomy was performed to localize an intra-abdominal testis or diagnose blind-ending vessels if cord vessels were not observed on initial inguinal exploration. This was most often accomplished with a high inguinal (i.e., Jones incision) or Pfannenstiel incision. It is now standard practice at most centers to proceed with diagnostic laparoscopy when the testicle is nonpalpable. Approximately 10% of boys with nonpalpable testis are found at the time of diagnostic laparoscopy to have blind-ending vessels, indicating the absence of testicular tissue (7).

During diagnostic laparoscopy for the nonpalpable testis, there are three scenarios that may be encountered. If blind-ending vessels and vas deferens are present proximal to the internal ring, a vanishing testis is diagnosed and no further action is required. If the vessels and vas deferens are present and appear to enter the internal ring, then inguinal or scrotal exploration is warranted. The final scenario includes the presence of an intra-abdominal testis, which can be located in a variety of positions. At this point the surgeon will need to assess which therapeutic modality is the most appropriate for treatment.

Recent studies report blind-ending cord structures or an intra-abdominal testis found during laparoscopic evaluation of nonpalpable testis between 31% and 83% of the time (7,13). Barqawi et al. (13) reviewed 27 patients who had undergone previous negative inguinal exploration and reported that 67% had a viable intra-abdominal or inguinal testicle. Cisek et al. (7) reported that laparoscopic findings precluded unnecessary abdominal exploration in 13% of cases and that the typical surgical incision for inguinal exploration would have left the surgeon compromised in 66% of the cases. In many of these patients, diagnostic laparoscopy can eliminate the need for further exploration or facilitate open or laparoscopic orchiopexy.

Ultimately, the decision to proceed with an inguinal or laparoscopic abdominal exploration depends on the surgeon's confidence in the physical examination. However, the evidence clearly suggests that if an initial open inguinal exploration is inconclusive, laparoscopic exploration should be the next step in the diagnosis and treatment of the nonpalpable testis. Our current protocol is to perform an examination under anesthesia. If any tissue suggestive of a scrotal nubbin is felt, then open scrotal exploration is performed. If this is negative or inconclusive, only then do we perform laparoscopic exploration.

---

## Laparoscopic Orchiopexy

---

The driving force behind the success of laparoscopic orchiopexy has been the need to improve upon the technique of open orchiopexy for the high undescended testis. In a meta-analysis of open orchiopexy techniques, Docimo (14) reported success rates by type of procedure (inguinal 89%; Fowler–Stephens 67%; staged Fowler–Stephens 77%; trans-abdominal 81%; two-stage 73%; microvascular 84%) and concluded that the high failure rates left significant room for improvement. Bloom (15) started the era of therapeutic laparoscopy with clip ligation of the spermatic vessels in preparation for an open second-stage Fowler–Stephens orchiopexy.

Jordan and Winslow (16) extended the technique to introduce laparoscopic orchiopexy. Lindgren (17) reported a 93% success rate in the treatment of 44 nonpalpable testes in 36 patients with no evidence of testicular atrophy. In a large multi-institutional analysis, Baker et al. (18) reported excellent success rates superior to that of historical open orchiopexy and no significant difference in success or complication rates between low- and high-volume centers. When compared to open orchiopexy, laparoscopic orchiopexy is a successful approach with low risk in the management of the impalpable, undescended testicle.

During diagnostic laparoscopy for nonpalpable testis, if a testicle is present, it is evaluated for size and location. If the testicle appears to be atrophic or grossly abnormal, then orchiectomy should be considered. If the testicle appears relatively normal, the ability to mobilize it to the scrotum is assessed, based on the distance of the testicle to the internal inguinal ring and redundancy of the spermatic vessels.

Deciding whether to perform a single-stage procedure leaving the vessels intact or to perform a one- or two-stage Fowler–Stephens procedure has been challenging since no specific set of criteria has been determined. As part of the decision-making process, intraoperative measurement of the distance between the testis and the internal ring, observation of the cord anatomy, or assessment of the ability of the intra-abdominal testicle to reach the opposite inguinal ring after dissection can be helpful. Baker et al. (18) reported the incidence of testicular atrophy after primary laparoscopic (2.2%), one-stage Fowler–Stephens (22%), and two-stage Fowler–Stephens (10%) orchiopexy. When counseling preoperatively, parents or guardians should be aware of the approximately 8% to 25% risk of testicular atrophy associated with performing an orchiopexy regardless of operative technique (14). Ultimate “success” of laparoscopic orchiopexy will therefore be measured by maintenance of the testicle in proper scrotal position without evidence of atrophy. Equally important is avoiding the rare complications possible during this laparoscopic procedure. In light of this, it is critical to know the different steps that will maximize successful outcomes.

### Diagnostic Laparoscopy Technique

Prior to obtaining access, re-examination of the patient in an anesthetized state is essential. Approximately 18% of boys with a previously nonpalpable testis will have a palpable testis when examined under anesthesia (7). In the instance of a unilateral nonpalpable testicle, assessment of the size and length of the contralateral testicle may be helpful in predicting if the intra-abdominal testicle is present. A contralateral palpable testicle length exceeding 2 cm and an average volume exceeding 2 cc for example, have been cited as being predictive of monorchia in over 90% of cases (19), although not reliably enough to forgo exploration.

An open dialogue with the anesthesia team is essential. Inhaled NO<sub>2</sub> should be avoided in order to avoid bowel distention, and an oral gastric tube should be inserted to maximize visualization in the abdomen. After induction of general anesthesia, the patient is secured to the bed in the supine position with his arms tucked, and the legs are placed in a slightly abducted position. The patient is secured to the bed with wide tape at the level of the chest and low thigh. Care is taken to place the tape without tension over the chest and legs and not to restrict ventilation. Adequate space should

**FIGURE 114.1** Preferred setup for a left single-stage laparoscopic orchiopexy. A 5-mm radial dilating trocar is placed at the umbilicus. Two 3-mm working ports are placed lateral to the rectus muscles just inferior to the umbilicus. Care is taken to avoid injury to the epigastric vessels. In the event a larger port is needed to accommodate a clip applicator, a 5-mm trocar would be used on the contralateral side to ligate the testicular vessels. A 10-mm scrotal port is placed in the final stage of the case when the mobilized intra-abdominal testicle is delivered into the scrotum.

also be left for access to the scrotum. Securing the child to the table permits Trendelenburg or laterally rolled positions. When preparing and draping the patient, plan for an open procedure and drape accordingly. In the sterile field an appropriately sized Foley catheter is placed. Figure 114.1 demonstrates the preferred setup and trocar placement for performing a laparoscopic orchiopexy.

Access into the peritoneum is achieved in an open fashion at the umbilicus. Blind access for pneumoperitoneum with a Veress needle or trocar is less commonly used in the pediatric population as an overly compliant abdomen may increase the risk of injury to intra-abdominal structures. It is our preference to use the Bailez technique for open access (20), modified to employ the use of a radially dilating trocar. In our current technique a 2-0 Vicryl suture is placed in the umbilicus to provide continual anterior tension. A 3-mm hidden infraumbilical incision is made in the skin and a scissor is then used at an approximately 15- to 20-degree angle cephalad to cut through the umbilical fascia into the underlying adherent peritoneum. Alternatively, the rectus fascia and underlying peritoneum may be entered sharply at 90 degrees under direct vision.

For the umbilical camera port, we utilize a 5-mm radially dilating trocar to accommodate a 5-mm camera with a 0-degree lens. The child is placed in Trendelenburg position and the abdomen is insufflated at 1 to 2 liters/minute to a pressure of 10 to 12 cm H<sub>2</sub>O. A general survey of the abdomen is undertaken, inspecting the underlying bowel for injury that might have occurred during port placement. Next, attention is focused on the evaluation of the pelvis. If an instrument is needed to aid in the inspection, a 3-mm port is placed on the ipsilateral side of the nonpalpable testis, lateral to the rectus and just caudal to the umbilicus. An atraumatic 3-mm instrument may then be used to sweep bowel cephalad. Placement of

an additional 3- or 5-mm trocar on the contralateral side (lateral to the rectus and just caudal to the umbilicus) is reserved for the need of an additional working port or use of a 5-mm clip applicator. Clinical circumstances in which this would be necessary include if an atrophic nubbin is to be excised, and if a viable testicle is found far from the internal ring and a staged Fowler-Stephens orchiopexy is to be performed.

In the case of a unilateral undescended testicle, the internal ring of the descended testicle is examined first to gain an appreciation of the anatomy. Possible findings on inspecting the affected side of the “nonpalpable” testicle may include blind-ending vessels, cord structures entering the internal ring, or an intra-abdominal testis. Note the status of the processus vaginalis: most undescended testicles are associated with a patent processus.

### Blind-Ending Testicular Vessels

Blind-ending gonad vessels indicate a “vanishing” testicle. This is the result of in utero testicular torsion that is either an intra-abdominal or intrascrotal event. Vessels will have a “horse tail” appearance; they diverge, do not exit the internal ring, and do not supply obvious testicular tissue (Fig. 114.2). If found during exploration, no further investigation is needed and the procedure is terminated. It is important to note that the finding of a blind-ending vas deferens during laparoscopy is insufficient to conclude the absence of testicular tissue. Further cephalad inspection toward the aortic origin of the gonadal vessels is then necessary.

### Cord Structures Entering the Internal Ring

Cord structures may be visualized entering a closed internal ring or a patent processus vaginalis (open ring) (Fig. 114.3). In the instance of a closed internal ring, a groin or scrotal exploration may be performed (Fig. 114.4). If a patent processus vaginalis is present, the laparoscope may be used to inspect the inguinal canal antegrade. Alternatively, gentle manual retrograde pressure can be placed over the inguinal canal in an attempt to push groin contents (viable testicle versus nubbin) intra-abdominally. In the instance of a nubbin or

**FIGURE 114.2** Finding blind-ending and divergent testicular vessels (A) is evidence of a vanishing testicle. The sole finding of a blind-ending vas (B) is insufficient evidence to conclude that there is absence of ipsilateral testicular tissue.

**FIGURE 114.3** Laparoscopic view of a left patent processus vaginalis (hernia) with normal cord structures exiting the internal rings. Left groin exploration revealed a high viable intracanalicular testicle. Inguinal orchiopexy with hernia sac ligation was performed.

testicular remnant, laparoscopic orchiectomy is performed. This is accomplished by either clipping or dividing the cord contents or using a 5-mm instrument designed to seal and divide smaller vessels (i.e., LigaSure or Harmonic Scalpel). The specimen is grasped and removed from the contralateral 5-mm port. This incision can be widened as needed by spreading the fascia with any clamp while under direct vision from the camera port.

## INTRA-ABDOMINAL TESTIS

There are three minimally invasive reconstructive options to address an intra-abdominal testicle: (i) primary laparoscopic orchiopexy, (ii) one-stage laparoscopic Fowler–Stephens orchiopexy, and (iii) two-stage laparoscopic Fowler–Stephens orchiopexy. Laparoscopic orchiectomy is reserved for an intra-abdominal nonviable testis (atrophic nubbin) or a testis that cannot be brought into the scrotum based on an extreme ectopic location (retrovesical, pararenal, pararectal), limiting blood supply length. Older children (>10 years of age) found to have an intra-abdominal testis may be better served with a laparoscopic orchiectomy, provided the contralateral testicle is

intrascrotal. Although an intra-abdominal testicle may remain hormonally active indefinitely, spermatogenic potential tends to decline after 18 months.

The initial measured distance of the testicle from the internal ring will determine which laparoscopic approach should be utilized and is therefore a predictor of success rates. “Peeping testes” or those located in close proximity to the internal ring (<2 cm away) can usually be mobilized into the scrotum in a single stage without dividing the testicular vessels (Fig. 114.5). It is important to counsel parents that intra-abdominal ectopic testes and those located >2 cm from the internal ring are at increased risk for surgical failure.

## SINGLE-STAGE LAPAROSCOPIC ORCHIOPEXY

In 1991, Bloom (15) reported using laparoscopy to ligate the testicular vessels in the first stage of a Fowler–Stephens approach. Jordan and Winslow (16) further advanced the role of laparoscopy as a therapeutic modality when they reported the first laparoscopic orchiopexy. There have been many subtle variations described for performing this procedure (21).

### Establishing a Peritoneal Pedicle Flap

Following abdominal access, insufflation, and additional trocar placement, as outlined above, attention is focused on the ipsilateral testicle and internal ring. Figure 114.6 demonstrates the surgical “map” needed to mobilize a triangular flap of peritoneum demarcated by the testicular vessels laterally and vas deferens medially. The preliminary goal is to create two continuous peritoneotomies parallel to the testicular vessels and vas in order to mobilize the testicle on a well-vascularized peritoneal pedicle.

The testicle, epididymis, and extent of vasal descent distally into the inguinal canal are evaluated. It is critical from the onset to define the gubernacular attachments and identify a long-looping vas, if present. Scissors are used in the preliminary dissection. Care must be taken not to activate cautery in proximity to the vessels and vas. The first peritoneotomy is made lateral to the testicular vessels at the most proximal position. The incision is directed toward the internal

**FIGURE 114.4** Bilateral closed processus vaginalis with normal cord structures exiting the internal rings. This morbidly obese 8-year-old boy underwent exploratory laparoscopy for a “nonpalpable” left testicle. The findings on diagnostic laparoscopy of cord structures exiting the left internal ring proceeded to a left groin exploration. A high viable intracanalicular testicle was found and open orchiopexy was performed.

**FIGURE 114.5** Bilateral intra-abdominal “peeping” testicles at the internal rings in a 6-month-old with nonpalpable gonads. Bilateral single-stage laparoscopic orchioepexies were performed.

ring. Often after the first incision, pneumoperitoneum will diffuse into the plane between the peritoneum and pelvic side wall. In this regard, CO<sub>2</sub> can aid in isolating the peritoneum to be dissected.

The second line of dissection will again begin at the level of the internal ring distally but will parallel the vas medially. Care is taken not to injure the iliac vessels and ureter that lie beneath the vas. It is also critical that dissection is not performed within the distal triangular area enclosed by the gonadal vessels and vas (Fig. 114.7). Critical collateral microvasculature within this flap will flow from the vasal artery to the testicle and should be maintained if possible. This is especially relevant if a single-stage Fowler–Stephens orchioepexy is performed; dividing the testicular vessels and interrupting collateral blood flow will invariably lead to testicular atrophy. Widely mobilizing the peritoneal flap laterally and medially leaves only the distal gubernacular attachments. A window is created distally, allowing the gubernaculum to be divided while visualizing the course of the vas deferens. An

indication that dissection has maximized the flap length is that the testicle can reach the contralateral internal ring without tension. The ipsilateral ring is not closed since there is not an increased risk for a clinically significant hernia to develop. The patent processus is ablated by the peritoneal incisions, division of the gubernacula, and, if necessary, incision of the anterior peritoneum. Subsequently, peritoneal regrowth obliterates the previously patent tract.

### Creating a Neinguinal Hiatus and Testicular Delivery into the Scrotum

Various methods to deliver the testicle into the scrotum have been described. It is our belief that the testis may be most safely and effectively delivered to the scrotum using 2- or 3-mm instruments and a radially dilating trocar system (22). A 12-mm ipsilateral scrotal incision is first made and a subdartos pouch is created. A 2-mm laparoscopic grasper is placed through the ipsilateral 3-mm lateral trocar directed toward the scrotal incision. Care is taken to place the instrument over the pubis and between the medial umbilical ligament and epigastric vessels. The surgeon’s free hand should palpate the pubic area and scrotal incision to ensure the instrument is being guided over the pubis and through the scrotal incision. After the instrument is passed through the scrotum, the Foley catheter is checked for hematuria. A bladder injury, which is very rare, would most likely occur during this step of the procedure. Proper placement of the instrument in the position described above should minimize the risk of this complication (Fig. 114.8). The step sheath is then passed onto the end of the 2- or 3-mm instrument ex vivo and brought through the scrotum. The 5- or 10-mm trocar obturator, depending on the size of the testicle, is then inserted, creating the neinguinal hiatus. A locking grasper is introduced into the abdomen through the scrotal trocar and the testicle is grasped at the gubernaculum and then delivered into the scrotum (Fig. 114.9). It is imperative for the surgeon to personally monitor the tension on the cord during scrotal delivery so the vessels are not avulsed.

**FIGURE 114.6** A left intra-abdominal testicle in an 8-month-old boy at the internal ring. The *dark lines* represent where peritoneotomies are made parallel to the testicular vessels (lateral) and vas deferens (medial) in order to mobilize the testicle on a vascularized peritoneal pedicle flap. The insert shows the same landmarks when a nonpalpable intracanalicular testicle is milked into the abdomen and then mobilized via laparoscopic orchioepexy.

A

B

**FIGURE 114.7** After lateral mobilization, medial dissection follows the course of the vas deferens (A). Collateral paravasal blood supply to the testicle is visualized. Cephalad traction following release of the distal gubernacular attachments (B) demonstrates the extent of the peritoneal flap and clarifies the boundaries where the neoinguinal hiatus is to be created between the inferior epigastric vessels and the medial umbilical ligament.

### Gaining Additional Cord Length and Securing the Testicle

After delivering the testicle into the scrotum, if there is tension and/or additional length is needed, further dissection can be carried out laterally and cephalad toward the kidney. In most instances the cord length will still be inadequate and additional maneuvers are required. An option at this point is to divide the peritoneum overlying the testicular vessels to provide extra cord length and release any remaining tension (Fig. 114.10). If incising the peritoneum has not helped, consideration can be given to dividing the testicular vessels, therefore performing a one-stage Fowler–Stephens orchiopexy. The contralateral 3-mm port must be upsized to a 5-mm port in order to accommodate a clip applicator. Consideration must be given to

**FIGURE 114.8** During delivery of the testicle into the scrotum, the bladder edge (arrows) is at risk for perforation. The risk is increased if the neoinguinal hiatus is not created anterior to the pubis and lateral to the medial umbilical ligament. Following delivery of the testicle medial to the ligament in a right laparoscopic orchiopexy, there was concern that the bladder was perforated (A). Filling the bladder demonstrated no evidence of a leak (B). After delivery of the testicle through a 12-mm scrotal trocar in the final stage of a left laparoscopic orchiopexy, there is little concern of a bladder injury. The neohiatus was created in a plane lateral to the medial umbilical ligament and medial to the epigastric vessels (C).

the higher risk of testicular atrophy after a one-stage Fowler–Stephens maneuver.

When the testicle lies tension-free in the scrotum, the orchiopexy can be completed (Fig. 114.11). The testicle is harnessed in the dartos pouch and the scrotal skin is closed by any of the preferred technique(s) utilized by the surgeon.

A

B

C

D

**FIGURE 114.9** Delivering the testicle into the scrotum requires developing a neohiatus (A–C) to facilitate passage of the testicle, epididymis, and cord structures into the scrotum without resistance. This technique minimizes the risk of an avulsion injury (D).

A

B

**FIGURE 114.10** Delivering the testicle into the scrotum provides the traction and assistance of a “third arm.” If there is tension and/or additional length is needed, further dissection can be carried out laterally and cephalad. The peritoneum overlying the testicular vessels (A) may also be divided (B) to release tension and provide extra cord length.

**FIGURE 114.11** Antegrade view of a left neoinguinal hiatus created between the inferior epigastric vessels (A) and the medial umbilical ligament (B). The testicle is fixed to the scrotum after maximal length on the cord has been reached without residual tension.

### Closure and Exiting the Abdomen

The abdomen is surveyed a final time and the pneumoperitoneum pressure is lowered. Any occult bleeding should be identified and addressed at this time. While maintaining pneumoperitoneum, the two lateral ports are removed sequentially and inspected for bleeding. The fascial layers of these trocar sites are closed with 2-0 Vicryl sutures through the fascia. The laparoscopic view is maintained on the port sites during closure to ensure that it is airtight and free of any intra-abdominal contents (i.e., bowel or omentum). Through the umbilical port the pneumoperitoneum is evacuated. Larger tidal volumes given by the anesthesiologist and mild abdominal pressure help with the expulsion of CO<sub>2</sub>. The umbilical trocar and camera are removed while inspecting for bleeding.

Final fascial stitches are placed in the umbilical port, the skin is closed, and dressings are applied.

## SECOND-STAGE FOWLER–STEPHENS PROCEDURE

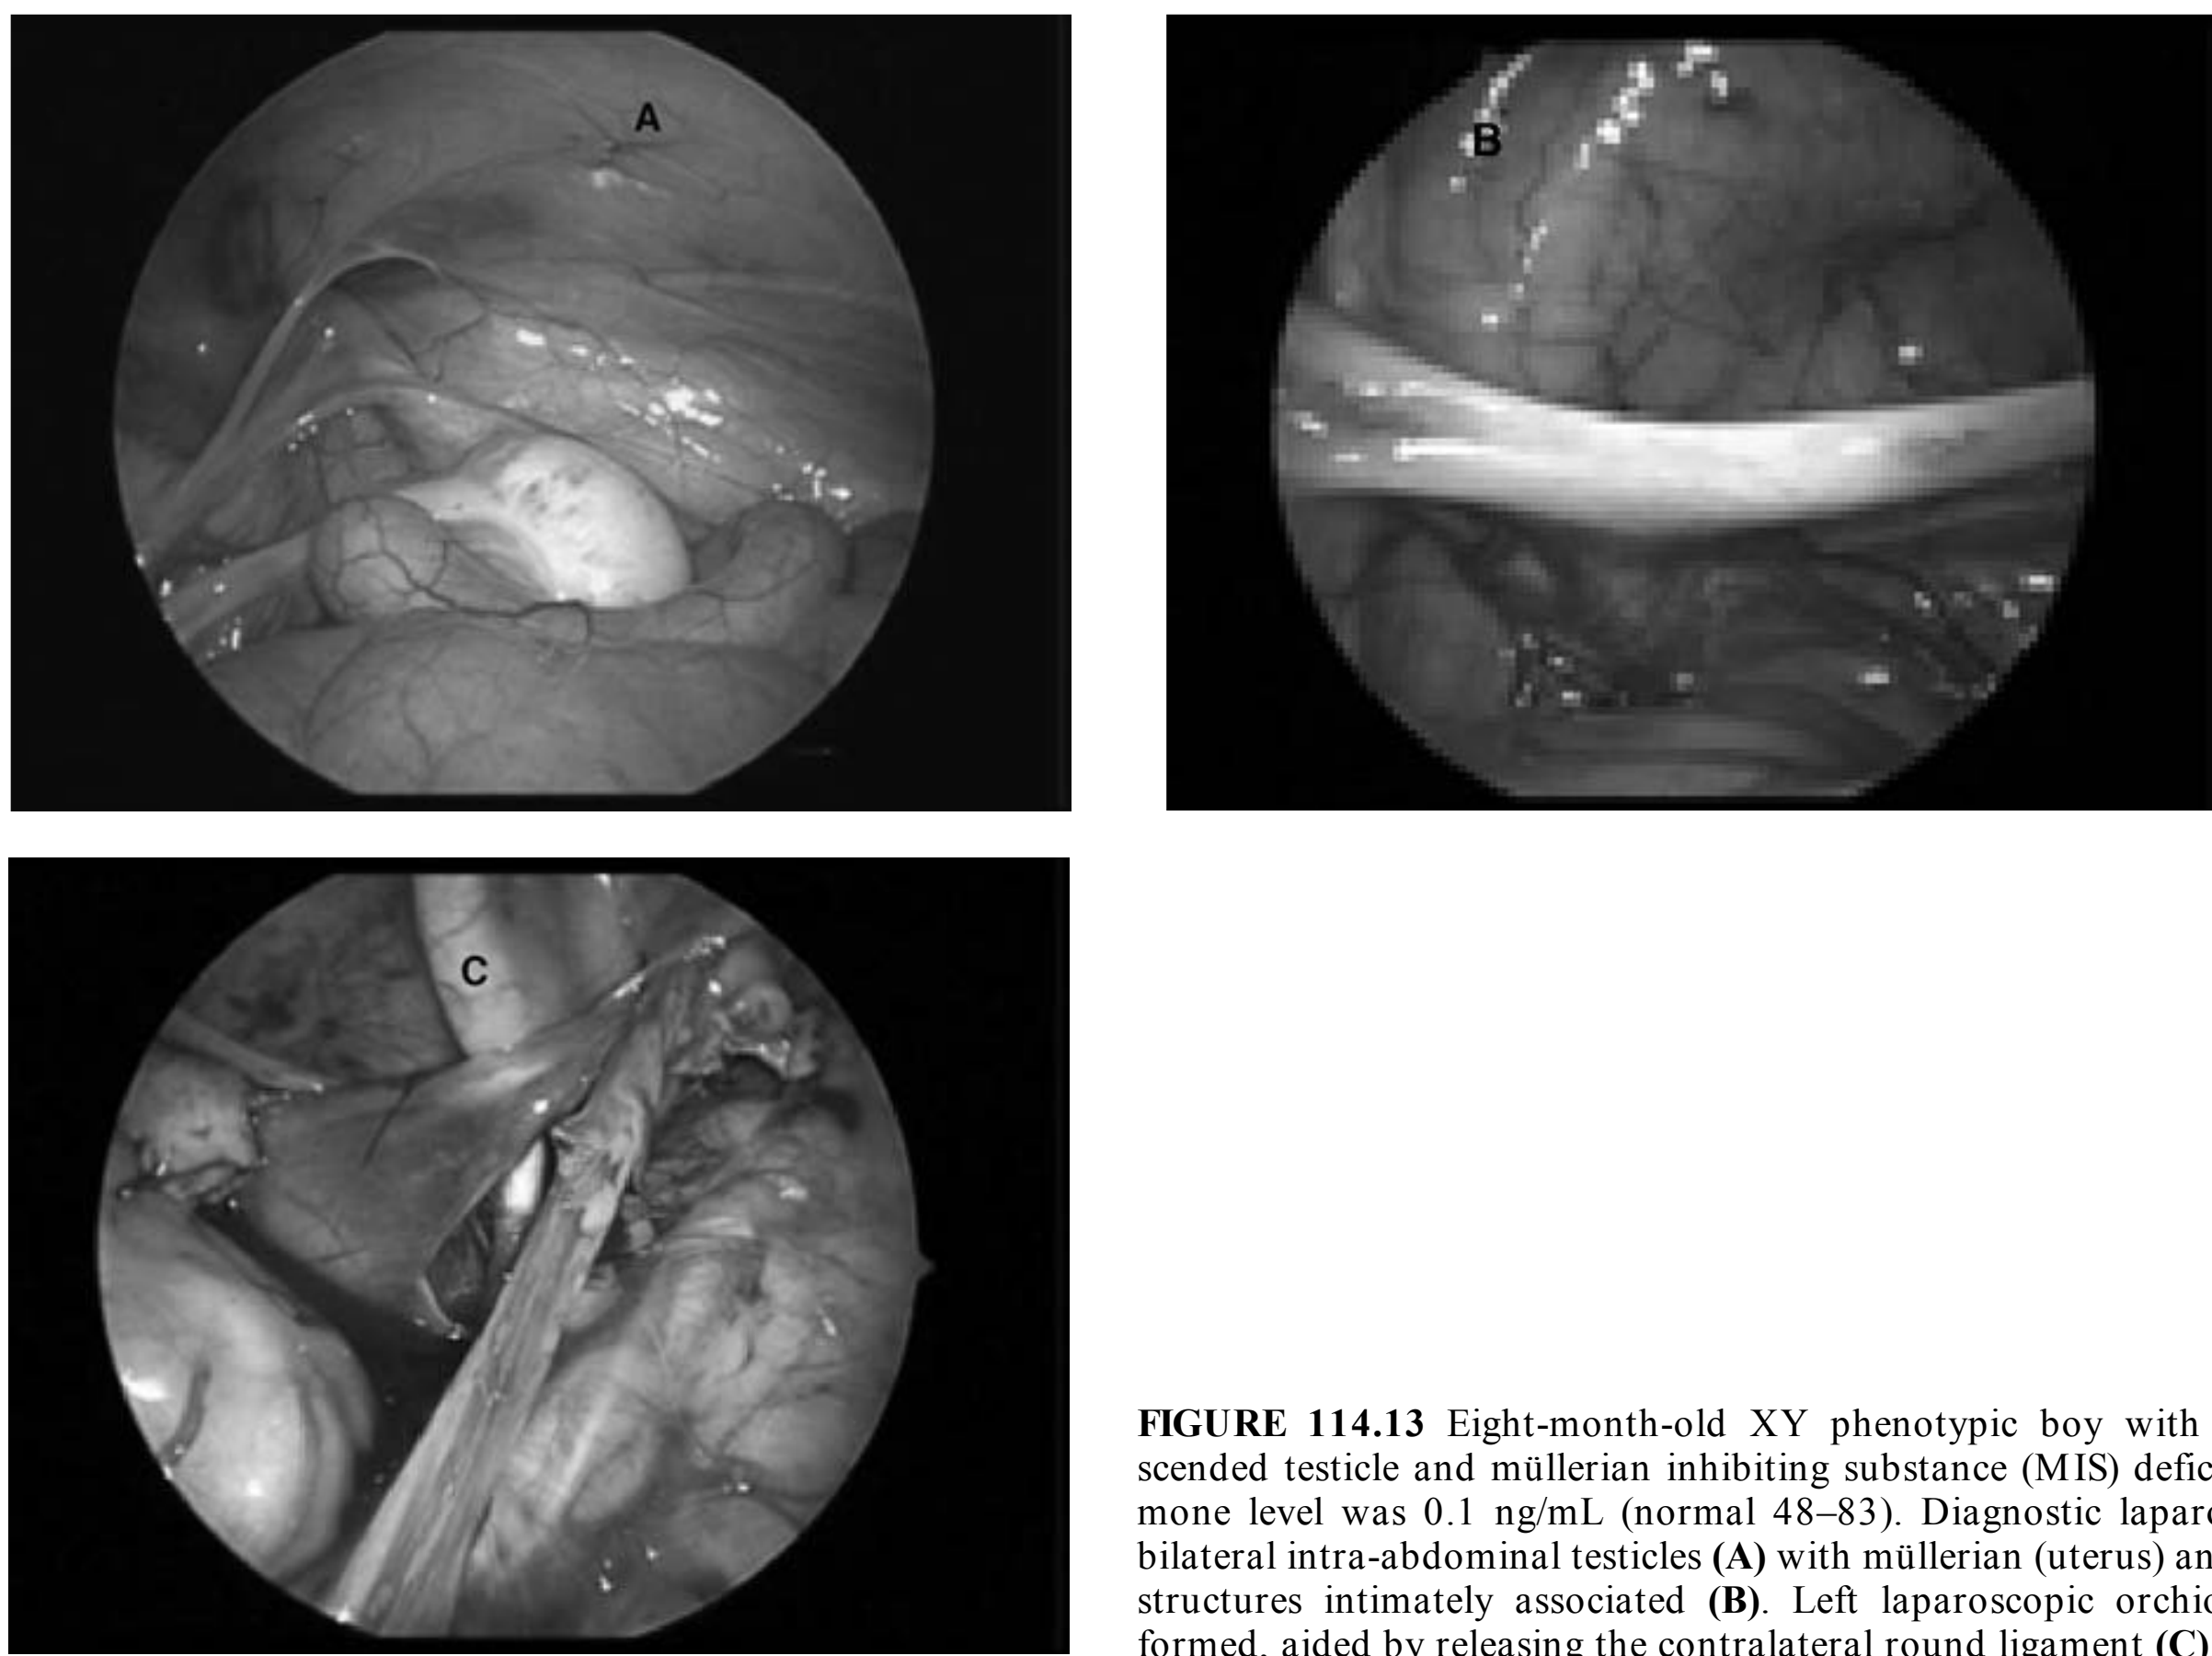

As a general rule, the further the intra-abdominal testicle lies from the internal ring (i.e., >2 cm) the higher the likelihood that a staged procedure is necessary. Staging the procedure will enable delivery of the testicle into the scrotum without tension and at a decreased risk for atrophy. This may be accomplished by ligating the testicular vessels by using a 5-mm stapler through the contralateral port (Fig. 114.12). A laparoscopic second-stage Fowler–Stephens orchiopexy will be performed approximately 6 months later, when collateral blood flow from the deferential artery has matured.

## BILATERAL NONPALPABLE TESTES AND LAPAROSCOPIC ORCHIOPEXY

Bilateral nonpalpable testicles in a newborn should raise the suspicion of an intersex condition, especially with coincidental genital ambiguity (i.e., proximal hypospadias). Other possibilities include bilateral anorchia or bilateral intra-abdominal testis. It is urgent to institute a workup to rule out life-threatening intersex conditions such as congenital adrenal hyperplasia (CAH). Once an intersex disorder has been excluded, endocrine studies, including a human chorionic gonadotropin (hCG) stimulation test and or serum müllerian inhibitory substance (MIS), will be useful in differentiating anorchia from bilateral nonpalpable testis (23). Regardless of such laboratory findings, however, exploratory laparoscopy will be needed for a gonadal biopsy, gonadectomy, or orchiopexy (Fig. 114.13). Bilateral laparoscopic orchiopexies can be performed simultaneously or at separate procedures, depending on perceived risk of atrophy.

**FIGURE 114.12** A right intra-abdominal testicle in a 9-month-old boy was found >2 cm from the internal ring. The testicular vessels were clipped in the first stage of a two-stage Fowler–Stephens reconstruction. Note that clips are applied without dissecting the peritoneal attachments free from the vessels.

**FIGURE 114.13** Eight-month-old XY phenotypic boy with bilateral undescended testicle and müllerian inhibiting substance (MIS) deficiency. MIS hormone level was 0.1 ng/mL (normal 48–83). Diagnostic laparoscopy revealed bilateral intra-abdominal testicles (A) with müllerian (uterus) and wolffian (vas) structures intimately associated (B). Left laparoscopic orchiopexy was performed, aided by releasing the contralateral round ligament (C).

---

## COMPLICATIONS

---

Complication rates in contemporary series of adult laparoscopic procedures range from 12% to 16% (24). Although the same issues reported in the adult literature are experienced in children, there is little published information regarding laparoscopic complication rates in the pediatric population, particularly in the urologic literature. However, the number of complications associated with laparoscopic orchiopexy compares quite favorably to that of an open approach. In a large multi-institutional review, Baker et al. (18) reported a major complication rate of 3.0% and a minor complication rate of 2.0%. Major complications that have been reported include acute testicular atrophy, bowel perforation, cecal volvulus, vascular injury, bladder perforation, ileus, laceration of the vas, testicular vessel avulsion, and wound dehiscence/infection.

The prevention of complications associated with laparoscopy starts with proper positioning and padding to reduce the risk of neuromuscular injuries. Although injuries are less likely to occur with pelvic laparoscopy, extremes in table positioning are often necessary. Close attention to placement of straps and/or tape and adequate padding should limit positioning-related injuries. As in adults, abdominal visceral injuries related to access are encountered; however, an understanding of the unique anatomic aspects of the pediatric abdominal wall can decrease these risks. The pediatric abdomen requires less force for entry, so penetration injury to the abdominal viscera can easily occur. The smaller pediatric

working space also sets up the potential for injury to the visceral structures from the laparoscopic working elements.

For this reason, open peritoneal access has been associated with fewer complications than when a Veress needle is used. As previously mentioned, we prefer to gain access using an open technique. Surgical planning and an appreciation for the anatomic landmarks within the pelvis will aid in avoiding complications. During testicular mobilization, care must be taken to avoid injury to the vas, testicular, femoral, and iliac vessels and the ureter. When mobilizing the vas on the medial aspect of the peritoneal flap, these structures lie directly posterior and medial (Fig. 114.14). In general, complications can be limited by careful intra-abdominal mobilization, using cautery in short bursts, and execution of meticulous technique. The laparoscopic approach facilitates this by allowing extensive and high retroperitoneal mobilization of the testicular vessels in an atraumatic manner.

Today the learning curve for pediatric laparoscopy is decreasing as trainees are entering the field with far more laparoscopic experience gained during general urology residency.

---

## CONCLUSIONS

---

Laparoscopic orchiopexy is now commonplace in the pediatric urologist's armamentarium, since evolving from a diagnostic procedure to the surgical treatment of choice when managing the intra-abdominal testicle. The option of what type of procedure to be performed is reflective of the intra-abdominal positioning of the testicle and its distance from the internal

**FIGURE 114.14** Pelvic view during a right laparoscopic orchiopexy. During medial mobilization of the vas deferens, the cord structures (*arrow*) are held cranially and laterally. Care must be taken not to injure the iliac vein (**A**), iliac artery (**B**), or ureter (**C**), which lie immediately posterior to the mobilized peritoneal flap.

ring. Success rates for these techniques are comparable to or better than those reported in open series. Maintaining a mobilized testicle on a wide peritoneal flap free from tension is the key to maintaining scrotal position and minimizing the

risk of testicular atrophy. Although there is a learning curve associated with this minimally invasive technique, it is surmountable.

# CHAPTER 115 ■ PEDIATRIC LAPAROSCOPIC PYELOPLASTY

PASQUALE CASALE AND WALID A. FARHAT

Historically, open pyeloplasty has been the standard treatment for congenital or acquired ureteropelvic junction (UPJ) obstruction in adults and children, with overall success rates of 90% to 100% (1). Although endopyelotomy and retrograde dilation are alternative methods of managing UPJ obstruction in children (2), the success of these two procedures is inferior to that reported for conventional dismembered pyeloplasty (3). Advances in technology have enabled the introduction of laparoscopic and robot-assisted laparoscopic pyeloplasty over the last few years.

Laparoscopic pyeloplasty was introduced in adults in 1993 (4). In the initial reports, the operative time ranged from 3 to 7 hours, but the procedure has gradually gained in popularity and acceptance, with a reported success rate of over 95% (5).

---

## DIAGNOSIS

---

Approximately 1% of prenatal ultrasounds detect hydronephrosis in the fetus. In 50% of these cases, UPJ obstruction causes the condition. UPJ obstruction is more common in male patients and affects the left kidney more often than the right. About 10% to 30% of cases occur in both kidneys (bilaterally) (6). Congenital abnormalities are the most common cause of UPJ obstruction in children. The condition often results from an abnormality in the muscles that surround the UPJ, causing an intrinsic narrowing. It may also be caused by an abnormality in the structure or position of the ureter, such as a high insertion onto the renal pelvis. Lower-pole renal blood vessels crossing over the ureter can cause an obstruction as well. Other etiologies are compression of the ureter caused by inflammation, retroperitoneal fibrosis, kidney stones, or scar tissue from previous surgery to correct UPJ obstruction. Symptoms are typically seen in older children but can be seen in infants; they include back or flank pain, hematuria, failure to thrive, flank mass, and pyelonephritis.

Neonatal patients are evaluated for the obstruction using renal ultrasound and diuretic renography. Magnetic resonance urography is also an option, and a voiding cystourethrogram (VCUG) might be utilized to rule out vesicoureteral-associated reflux.

---

## INDICATIONS

---

The indications for laparoscopic pyeloplasty are similar to those for an open pyeloplasty and include increasing hydronephrosis, progressive deterioration of renal function, recurrent urinary tract infection, and persistent pain. The

introduction of refined instrumentation and more experience with intracorporeal suturing allows reconstructive laparoscopy to be implemented in the pediatric population, with multiple techniques of pyeloplasty described in the literature (7). One of the earliest descriptions of the transperitoneal Anderson–Hynes laparoscopic pyeloplasty in pediatric patients by Tan (8) recommended that it should not be performed in children <6 months of age. The advent of improved 3-mm instrumentation and laparoscopic telescopes has allowed better suture manipulation and visualization, making it feasible even in infants <6 months of age (9). The key point to performing a laparoscopic pyeloplasty in the infant is based on the geometry of the patient's body habitus. A triangle is constructed utilizing the umbilicus as the apex, with the remaining points being lateral to the ipsilateral rectus muscle subcostal and at the level of the anterior superior iliac spine.

Yeung et al. (10) reported their initial experience with retroperitoneal laparoscopic pyeloplasty in 13 children, 1 requiring open conversion. The mean operative time was 143 minutes (range 103 to 235 minutes). El-Ghoneimi (11) reported on 50 retroperitoneal laparoscopic pyeloplasties in children aged between 22 months and 15 years. Conversion to open surgery was necessary in four cases due to technical difficulties during suturing. Mean hospital stay was 2 days, and return to full activities occurred within 5 days of surgery. The longer time needed for the retroperitoneal approach is almost certainly related to the limited working space, which renders suturing more difficult.

As laparoscopic pyeloplasty is technically challenging, this procedure was initially restricted to those medical centers with advanced laparoscopic surgeons, and long-term outcome data are still being evaluated. With increasing experience, however, laparoscopic pyeloplasty in children is more commonly being considered as the initial treatment for UPJ obstruction. This procedure maintains the benefits of the endoscopic approaches, including decreased postoperative pain, short hospitalization, and reduced postoperative recovery time, while demonstrating success rates comparable to those of the conventional open approach (12,13).

---

## ALTERNATIVE THERAPY

---

Open pyeloplasty remains the gold standard, with a high success rate for a flank, dorsal lumbotomy, or anterior muscle-splitting incision. Proponents have shown that this procedure can be done without an indwelling ureteral stent and with simple percutaneous drainage.

Endopyelotomy and retrograde dilation are also alternative methods of managing UPJ obstruction in children. Endopyelotomies are performed in the same fashion as in adults either by a percutaneous approach or ureteroscopically in a retrograde manner. The long-term success rate of endopyelotomy is less than with the standard open or laparoscopic approaches (8,9). Retrograde dilation has virtually no role in pediatrics due to its high failure rate, requiring a subsequent procedure (14).

## SURGICAL TECHNIQUE AND STEPS

Initial cystoscopy and ureteric stenting is left to the discretion of the surgeon and may not be necessary (10,15). An indwelling Foley catheter is placed to gravity drainage.

Positioning of the patient is crucial as it facilitates optimal ergonomics for the surgeon and increased access to the operative space. For both a transperitoneal and retroperitoneal approach, the patient is placed in a lateral or semilateral decubitus position in close proximity to the posterior edge of the table. The table is flexed, the kidney rest is elevated, appropriate padding is applied, and the patient is secured with 2-inch tape and a safety belt. An option for the retroperitoneal approach described by Yeung et al. (10) is a modified semi-prone position with the left flank up or a 45-degree right lateral decubitus position (for right-sided obstruction) to allow the subsequent ureteropelvic anastomosis using the right hand (for a right-handed surgeon). Another option utilized for the transperitoneal approach is to place the patient supine with a slight 30-degree rotation of the ipsilateral side. The patient is then secured to the table with 2-inch silk tape (Fig. 115.1). The table can then be rotated as needed after visualization of the intraperitoneal field. This approach can be utilized on the left side, allowing the colon to stay lateral to the left kidney so a transmesenteric window is unobstructed.

### Retroperitoneoscopic Approach

Appropriate placement of the trocars is of the utmost importance, and three or four laparoscopic ports are inserted at the surgeon's discretion. Retroperitoneal access is achieved through the first trocar incision, which is 15 mm long and

**FIGURE 115.1** Supine positioning for transperitoneal approach in left-sided and bilateral cases.

**FIGURE 115.2** Port placement for retroperitoneal approach.

10 mm from the lower border of the tip of the 12th rib (Fig. 115.2). Our preferred method to achieve access to the retroperitoneal space is that the Gerota fascia is approached by a muscle-splitting blunt dissection, then opened under direct vision. A working space is created by gas insufflation dissection, and the first trocar is fixed with a pursestring suture applied around the deep fascia to ensure an airtight seal. Another approach to create the retroperitoneal space is a modification of Gaur balloon technique to dissect the retroperitoneum. Two index fingers of a powder-free surgical glove are placed one inside the other and ligated onto the 5/10-mm trocar sheath. The dissection is then performed by instilling 500 mL of warm saline through the insufflation channel of the trocar. After completed dissection, the trocar is reinserted without the balloon and pneumoretroperitoneum is established (maximum pressure 12 mm Hg, or age dependent). A 5- or 10-mm 0-degree telescope is inserted through the first trocar. A second 3-mm trocar is inserted posteriorly near the costovertebral angle, while the third 3-mm trocar is inserted 10 mm above the top of the iliac crest at the anterior axillary line. To avoid transperitoneal insertion of this trocar, the working space is fully developed and the deep surface of the anterior wall muscles identified before the trocar is inserted. The insufflation pressure is <12 mm Hg and the flow rate of CO<sub>2</sub> is progressively increased from 1 to 5 L/min.

The kidney is approached posteriorly, the Gerota fascia is incised parallel to the psoas muscle, and the perirenal fat is dissected to reveal the lower pole of the kidney, in which the renal pelvis is first identified and then mobilized. The UPJ is identified and minimally dissected to free the UPJ from connective tissue, and small vessels are divided after bipolar electrocoagulation. The anterior surface of the UPJ is cleared to identify any polar crossing vessels. In order to dissect the UPJ adequately with minimal trauma, stay sutures of 5-0 Prolene are placed at the UPJ for easy manipulation (Fig. 115.3).

The traction sutures not only help to mobilize the UPJ but also facilitate the alignment of the ureter to the trocar axis so that spatulation and suturing are easily accomplished.

Once complete dissection of the UPJ is done, the renal pelvis is partly divided by scissors at the most dependent part,

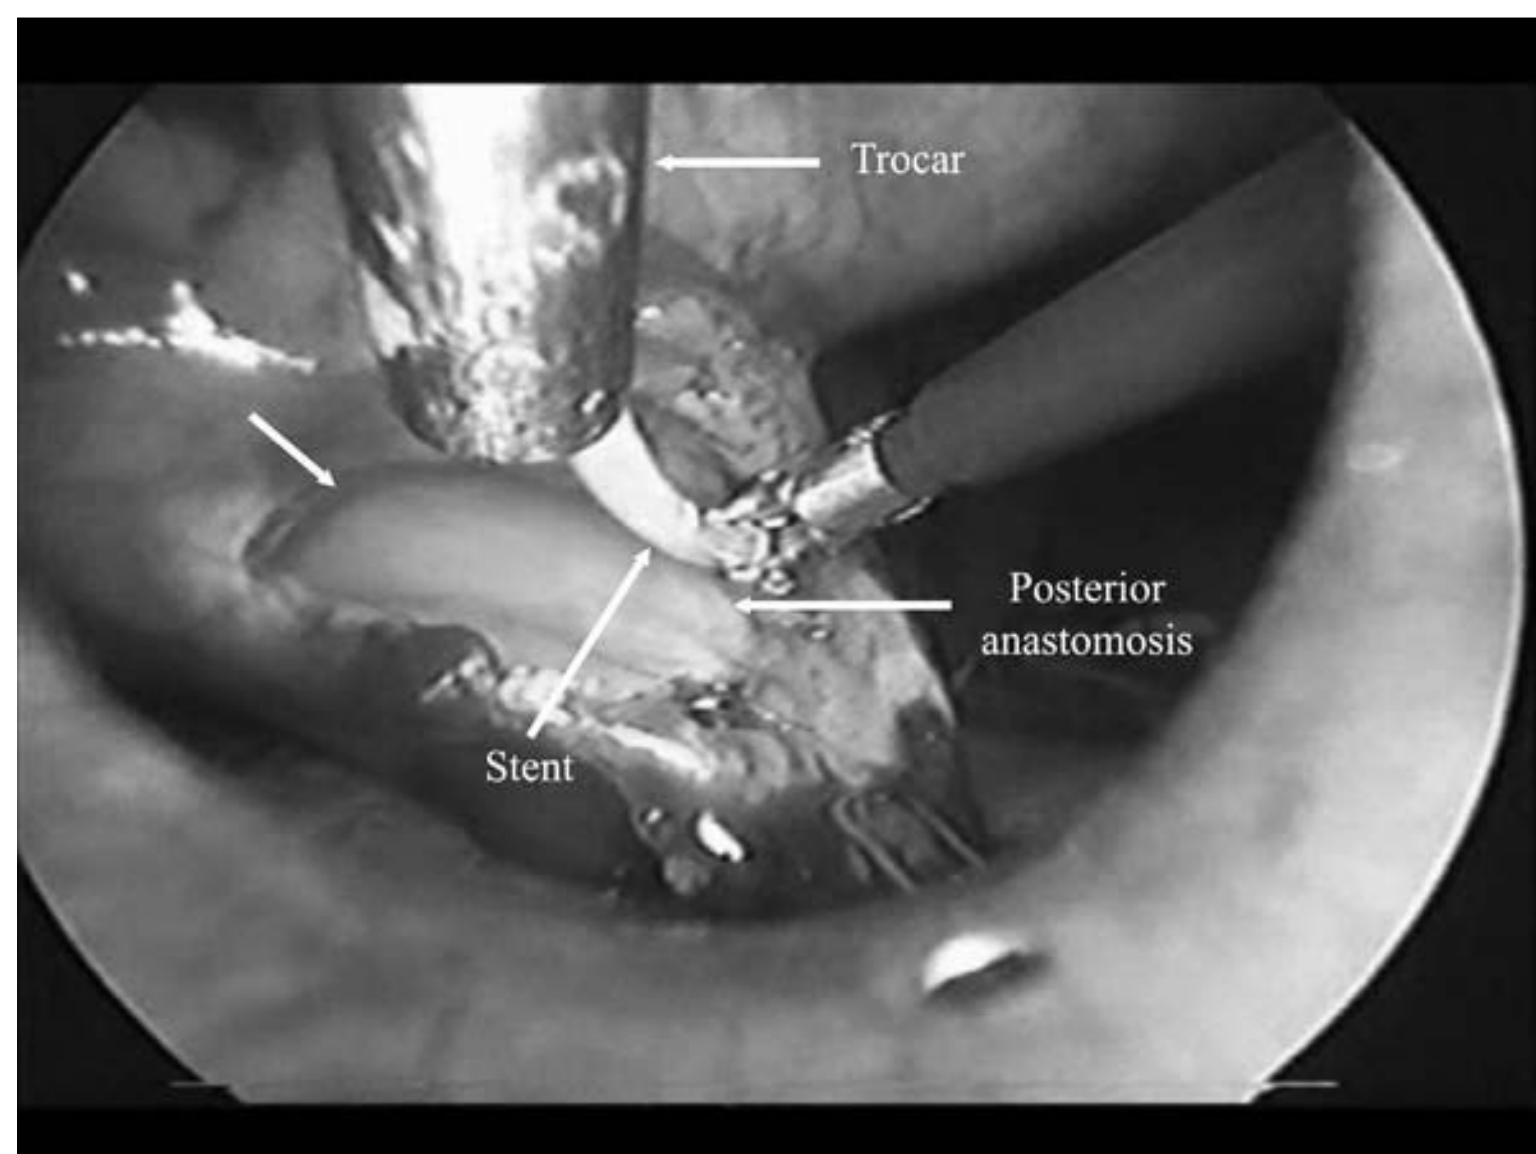

**FIGURE 115.3** Retroperitoneal view of 5-0 suture as a hitch stitch at the right UPJ.

and then the ureter is partly divided and spatulated. At all times, the anterior surface of the kidney is left adherent to the peritoneum so that the kidney is retracted medially away from the anastomosis. Nevertheless, if inadvertent dissection of the kidney anteriorly is performed, a fourth trocar (3 mm) is inserted lateral to the lumbosacral muscles near the iliac crest to facilitate medial retraction on the kidney.

The pelviureteric anastomosis begins using 6-0 polydioxanone sutures and a tapered 3/8 circular needle. To facilitate passage of the needles through the 3-mm trocars, needles may be flattened out in the shape of a ski and lubricated. The first suture is placed from the most dependent portion of the pelvis to the most inferior point or vertex of the ureteric spatulation. In the initial few cases, the suture is tied using the intracorporeal technique with the knots placed outside the lumen. In order to facilitate the suturing part of this procedure, two 6-0 undyed polydioxanone sutures 6 cm in

length were tied together and one was colored utilizing a surgical marker, thus eliminating a cumbersome step of tying intracorporeally. Once the ureter is approximated to the pelvis, the UPJ is maintained on traction and the suture line stabilized. Once half of the anastomosis is accomplished, a 4.7Fr polyurethane ureteral stent is inserted through the suture line to the bladder at the end of the anterior-layer reconstruction. Our preferred method for this is through a percutaneous placement of a 12Fr angiocatheter; however, the stent can also be inserted through the costovertebral trocar (Fig. 115.4). To ascertain the position of the stent in the bladder, retrograde filling of the bladder with methylene blue saline is done. The stent remains indwelling for 4 to 6 weeks. Perirenal drainage in the form of a Penrose drain is used. The Foley catheter is left in situ in all patients for 24 hours after surgery. Prophylactic antibiotics (third-generation cephalosporin) are routinely prescribed.

**FIGURE 115.4** Retroperitoneal view of the double-pigtail ureteral stent inserted through a trocar traversing the ureter antegrade.

## Transperitoneal Approach

The first trocar is placed at the umbilicus either through a small open technique or after insufflation with a Veress needle. Utilization of 3- or 5-mm trocars depends on the patient size. In patients under a year of age, 3-mm trocars are sufficient. However, in any age group, 5-mm trocars with 3-mm instrumentation have been proven the easiest for suture passage in our experience. The abdomen is insufflated with low pressures and high flow to accommodate for suture passage and potential loss of pneumoperitoneum. A 3- or 5-mm 0-degree telescope is inserted through the first trocar. A second trocar is inserted subcostally lateral to the ipsilateral rectus muscle, while the third trocar is inserted 10 mm above the top of the iliac crest lateral to the ipsilateral rectus muscle. A transmesenteric window is performed if the UPJ obstruction is on the left kidney. If the UPJ obstruction is on the right, the colon is mobilized to expose the UPJ (Fig. 115.5).

The UPJ is identified and mobilized as just described above for the retroperitoneal approach with stay sutures and a hitch stitch. The hitch stitch is placed through the anterior abdominal wall, traversing the renal pelvis, then back through the anterior abdominal wall. It is held in place with a clamp to allow traction control to lift and relax the pelvis as necessary. Once complete dissection of the UPJ is done, the renal pelvis is partly divided by scissors at the most dependent part, and then the ureter is partly divided and spatulated.

The anastomosis and percutaneous stent placement are performed as described in the previous section on retroperitoneoscopic pyeloplasty (Fig. 115.6). The stent remains indwelling for 4 weeks. No perirenal drainage is used. The Foley catheter is left in situ in all patients for 24 hours after surgery. Prophylactic antibiotics (third-generation cephalosporin) are routinely prescribed until the catheter is removed. The patients are placed on prophylactic antibiotics until the stent is removed.

**FIGURE 115.5** Transperitoneal view of right lower-pole crossing vessels.

## Special Considerations

Although various reconstructive methods of laparoscopic pyeloplasty such as dismembered or Y-V-plasty have been reported, it remains to be determined which methods are most appropriate for which cases of obstruction. For instance, when an aberrant crossing vessel is identified, the polar vessel is dissected and dismembered pyeloplasty is performed to enable the UPJ transposition. After placing the stay suture, the ureter is completely divided and the UPJ and pelvis are delivered anterior to the vessels with the help of the stay suture. In some retroperitoneoscopic cases when we encounter a long segment of obstruction that precludes the creation of a tension-free anastomosis, we perform a

**FIGURE 115.6** Completed posterior anastomosis and stent in place. The stent was placed percutaneously after completion of the posterior anastomosis as described.

**FIGURE 115.7** Concomitant stone extraction. Note the insert showing the ureteroscopic view seen during the procedure. The stone is extracted with a basket through an accessory port.

transperitoneal laparoscopic approach, and a Y–V-plasty can be performed more readily. A concomitant caliceal or renal calculus that cannot be easily accessed via a laparoscopic procedure is not an absolute contraindication if access to the stone is possible using ureteroscopy through one of the access trocars (Fig. 115.7).

## OUTCOMES

Although controversy still goes on concerning which laparoscopic approach to choose (i.e., transperitoneal or retroperitoneal), arguments to advocate one approach over another are more theoretical than true evidence-based criteria. We believe that surgeons who have started with laparoscopic nephrectomy using a retroperitoneal approach will be able to naturally extend the indications to pyeloplasty without changing their habits. Nevertheless, the longer time needed for the retroperitoneal approach is probably related to the limited working space, which makes suturing more difficult.

It is true that the gold standard of pediatric open renal surgery is the retroperitoneal approach and that minimal invasive surgery should follow the same rules (16). The major advantage of the retroperitoneoscopic approach is that it provides a direct access to the UPJ without interference with intra-abdominal structures. Furthermore, the complication of urine leakage would be better tolerated in the retroperitoneal space than in the intraperitoneal cavity. However, in our experience with the transperitoneal approach with stenting, the rate of urinary leakage from the anastomosis into the abdominal cavity has disappeared.

Laparoscopic pyeloplasty in children has been demonstrated to be feasible and to have satisfactory results (8,11,16,17). Although there are only a few published series on the long-term outcomes to date, the short-term data suggest that outcomes are similar to those of open pyeloplasty in children (11,12).

When comparing the gold standard open approach to the laparoscopic approach (16), the mean operative time was significantly shorter in the open surgery group versus the laparoscopy group (96 minutes [range 50 to 150] versus 219 [range 140 to 310],  $p < 0.0001$ ). On the other hand, the mean postoperative use of analgesics and hospital stay were less in the laparoscopy group. The major disadvantage of the laparoscopic approach is that it is clearly a technically challenging and lengthy surgical procedure because of the high proficiency required for intracorporeal suturing. Although automated devices that facilitate suturing (18) are available, the need for accurate suture placement and unavailability of small sizes for pediatric application preclude their use. Development of novel alternatives to suturing, such as fibrin glue and laser welding, may enhance the utilization of the laparoscopic approach; however, the results with these methods alone have not yet matched the success of conventional sutures in providing adequate tensile strength of the anastomosis (19).

## Complications

Potential complications include bleeding, wound infection, hernia at the port site, thermal damage to tissues or organs, trocar or insufflation needle damage to viscera or vessels, persistent leakage of urine, stent migration, reobstruction (transient and persistent), and urinary tract infection with stent in place.

## CONCLUSIONS

Reports on the retroperitoneal approach in laparoscopic pyeloplasty are less common, despite wide use of this approach in laparoscopic nephrectomy. In our experience, the retroperitoneal approach has been difficult in the following scenarios: (i) children under 15 kg with extremely large renal pelvis and (ii) previous violation of the retroperitoneal space. For a relatively long obstructed UPJ segment associated with a hydronephrotic extrarenal pelvis, several flap pyeloplasty techniques, such as a Culp–Deweerd spiral, Scardino–Prince vertical flap, and a dismembered tubularized renal pelvic wall flap described by Kaouk et al., have been performed (19).

The level of difficulty of manipulation certainly increases in the retroperitoneal space, but we believe that difficulty of manipulation in the retroperitoneal space can be overcome with improvement in operative skill, especially in ambidextrous suturing technique. This approach has some advantages. First, it can avoid dissemination of urine into the peritoneal cavity. Second, it can theoretically minimize the risk of injury to intraperitoneal organs.

The success rate of laparoscopic pyeloplasty is equal to that of conventional open pyeloplasty. Transperitoneal and retroperitoneal approaches are reported to have comparable outcomes (11). We believe that laparoscopic dismembered pyeloplasty for UPJ obstruction in infants is technically possible and that an indwelling stent is helpful but not mandatory.

# CHAPTER 116 ■ PEDIATRIC LAPAROSCOPIC NEPHRECTOMY AND PARTIAL NEPHRECTOMY

GLENN M. CANNON, JR., AND RICHARD S. LEE

Since the initial description of a laparoscopic heminephrectomy in a 14-year-old by Jordan and Winslow in 1993 (1), a large amount of literature has been devoted to laparoscopic renal ablative surgery in children. With its decreased length of stay, decreased postoperative opioid requirements, improved cosmesis, and equivalent operative times to open surgery, laparoscopic nephrectomy and partial nephrectomy have become widespread procedures in pediatric urology. In a cost analysis from the United Kingdom, the laparoscopic approach to nephrectomy in children was 54% less expensive than the open approach (2). Currently, robotic systems such as the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, CA) are being utilized for more complex reconstructive procedures such as partial nephrectomy. Future research will determine its utility as compared to conventional laparoscopy.

---

## DIAGNOSIS

---

Children with prenatal or postnatal hydronephrosis and/or febrile urinary tract infection are often imaged with renal ultrasound, voiding cystourethrogram (VCUG), and possibly radionuclide renal scanning. If there is no evidence of vesicoureteral reflux (VUR), nuclear renography is performed to determine if there is significant obstruction and/or salvageable function. If a clinically significant nonfunctioning renal

moiety (e.g., <5% to 10% function by dimercaprosuccinic acid study) is identified, nephrectomy or partial nephrectomy may be considered. Further imaging is usually not warranted, unless there is a history of a continued day and night wetting and possible ureteral ectopia. In these instances MRI urography may be beneficial. In cases of a renal mass, abdominal CT or MRI is typically obtained to further delineate the mass. In all cases, particular attention should be paid to vascular anatomy, the presence and appearance of the contralateral kidney, the presence and appearance of the ipsilateral and contralateral adrenal glands, and any degree of lymphadenopathy.

---

## INDICATIONS FOR SURGERY

---

Indications for laparoscopic nephrectomy or partial nephrectomy in children include nonfunctioning kidney, upper- or lower-pole moieties with duplicated collecting systems, or renal mass. Typical causes include obstruction, reflux, or ureteral ectopia. Symptoms can possibly include pain, hypertension, infections, or stone formation. Laparoscopy can also be applied when bilateral nephrectomy is required of nonfunctioning kidneys causing hypertension, infections, or nephrotic syndrome prior to renal transplantation. Removal of potentially malignant renal masses is not usually approached in a laparoscopic fashion in children.

## ALTERNATIVE THERAPY

Open nephrectomy or partial nephrectomy is the alternative to a laparoscopic approach. Percutaneous renal ablative procedures such as cryogenic and radiofrequency ablation are not performed in children. An open procedure may be considered if the kidney is large or extensive intra-abdominal adhesions are present. Retroperitoneal laparoscopy can be considered if there is a history of previous abdominal surgery, and transperitoneal laparoscopy can be considered if there is a history of retroperitoneal open surgery.

## SURGICAL TECHNIQUE

The following descriptions refer to laparoscopic partial nephrectomy in children. Specific mention is made when the steps of the procedure differ from the performance of a complete nephrectomy. Otherwise, the steps are identical. Although ultimately the surgical approach will be chosen by an individual surgeon's comfort level and experience, Borzi and Yeung (3) proposed selecting an approach based on the specific type of procedure performed. Reporting an experience of 179 laparoscopic procedures, they recommended a posterior retroperitoneal approach for isolated renal excision without extended ureterectomy, a lateral retroperitoneal approach for complete ureterectomy or access to horseshoe and pelvic kidneys, and a transperitoneal approach when complete moiety excision with lower urinary reconstruction is planned.

### Transperitoneal Approach

Preoperatively, patients receive a clear liquid diet for 24 hours and a rectal suppository the night before surgery. Depending on surgeon preference, cystoscopy is performed prior to the start of the partial nephrectomy. A ureteral stent can be placed in the nonfunctioning moiety to assist in identification if necessary. A bladder catheter and orogastric tube are placed.

The affected side is elevated by a 30-degree wedge, and the patient is carefully secured to the operating table. The table is rotated to flatten the patient's abdomen. With the patient's abdomen flat, transperitoneal port access is gained using either a Veress needle or with the modified Hasson technique. A camera port (12 mm) is placed at the umbilicus (Fig. 116.1). A second port is placed superior to the umbilicus in the midline approximately 10 cm from the umbilical port. A third working port (5 or 8 mm) is positioned at the anterior superior iliac spine laterally at a 45-degree offset and 10 cm from the umbilical port. If necessary, a fourth 5-mm port is placed. The fourth port is often helpful in right-sided cases to lift the liver edge and expose the upper pole of the kidney. The table is angled to raise the affected side into a 60-degree flank position. If the da Vinci Surgical System is utilized, the robot is positioned on the ipsilateral side of the patient and angled over the shoulder. The three robotic arms are then engaged to the laparoscopic ports. A 30-degree lens is used in the down position.

The kidney is exposed by medial reflection of the colon. The ureter from the nonfunctioning moiety (or the single ureter for a complete nephrectomy) is identified and mobilized as distally as the iliac vessels. The nonfunctioning ureter is

**FIGURE 116.1** Port placement for a left-sided laparoscopic nephrectomy and partial nephrectomy.

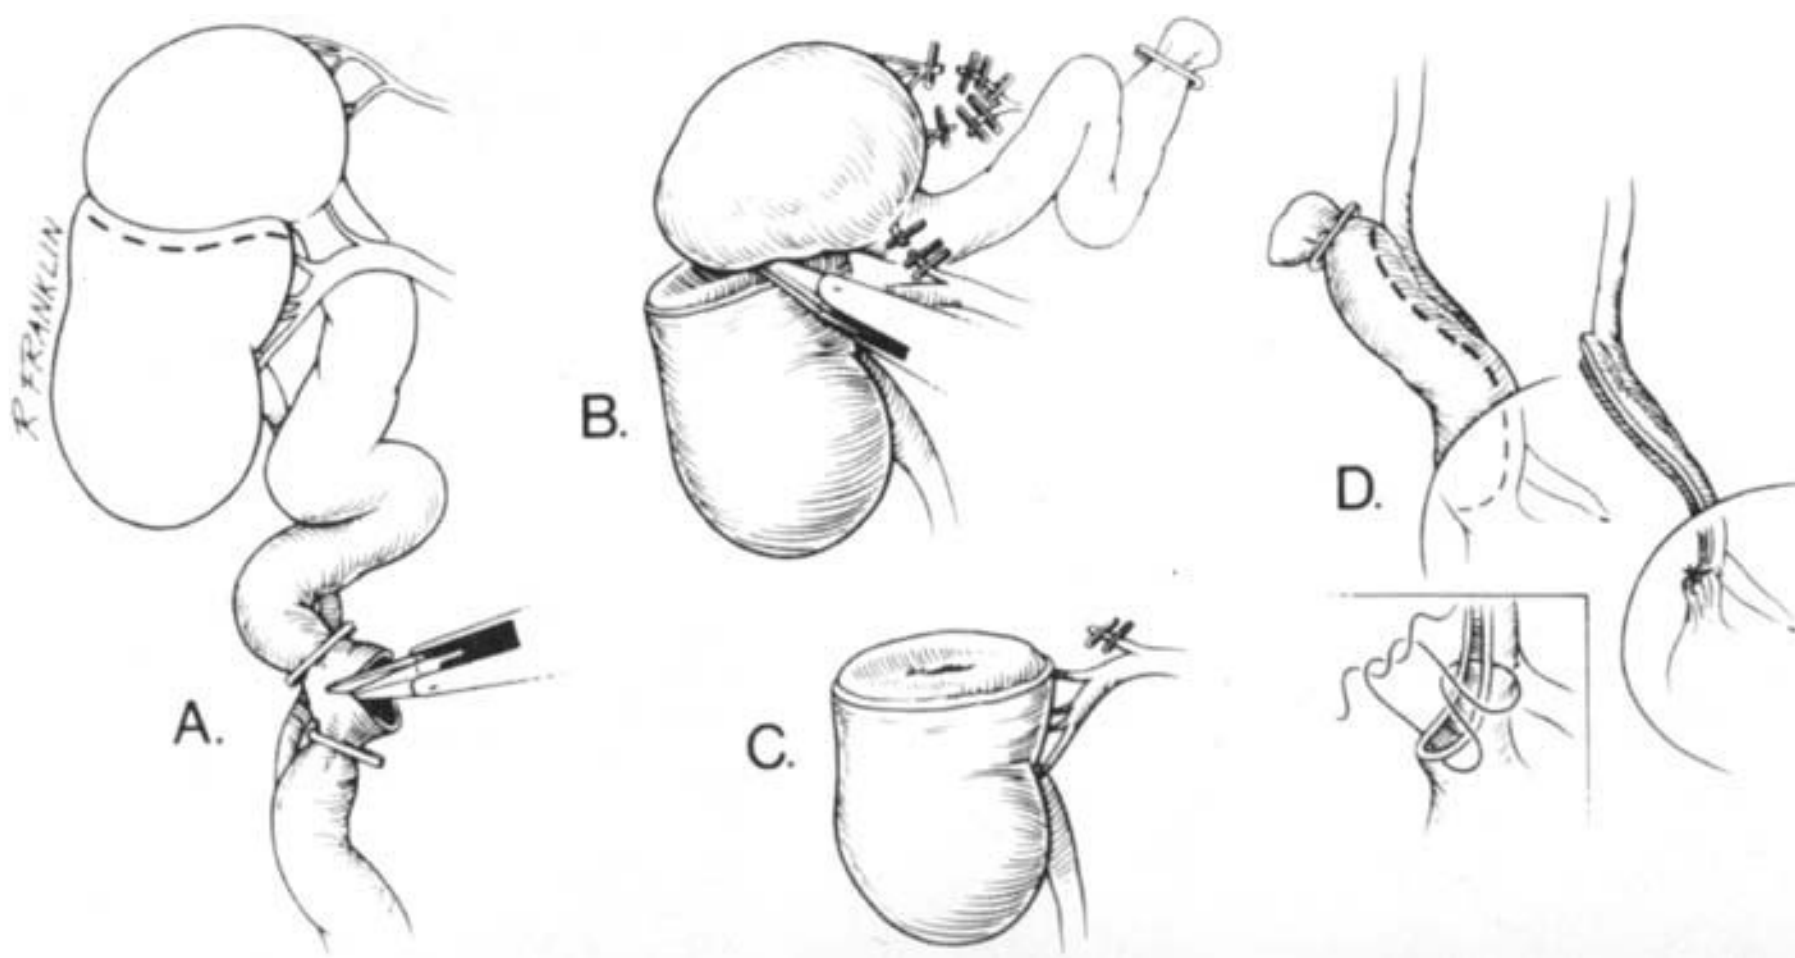

divided. If there is no VUR the distal end can be left open. If there is VUR, the distal ureter is ligated with an absorbable stitch. The affected pole is manipulated by using the divided proximal ureter as a handle (Figs. 116.2 and 116.3).

The proximal nonfunctioning ureter is mobilized and passed posterior to the main renal hilum. During this mobilization, the nonfunctioning ureter is dissected away from the remaining ureter by mobilizing the adventitia of the nonfunctioning ureter toward the remaining ureter. This maneuver is critical to preserve the blood supply of the remaining ureter.

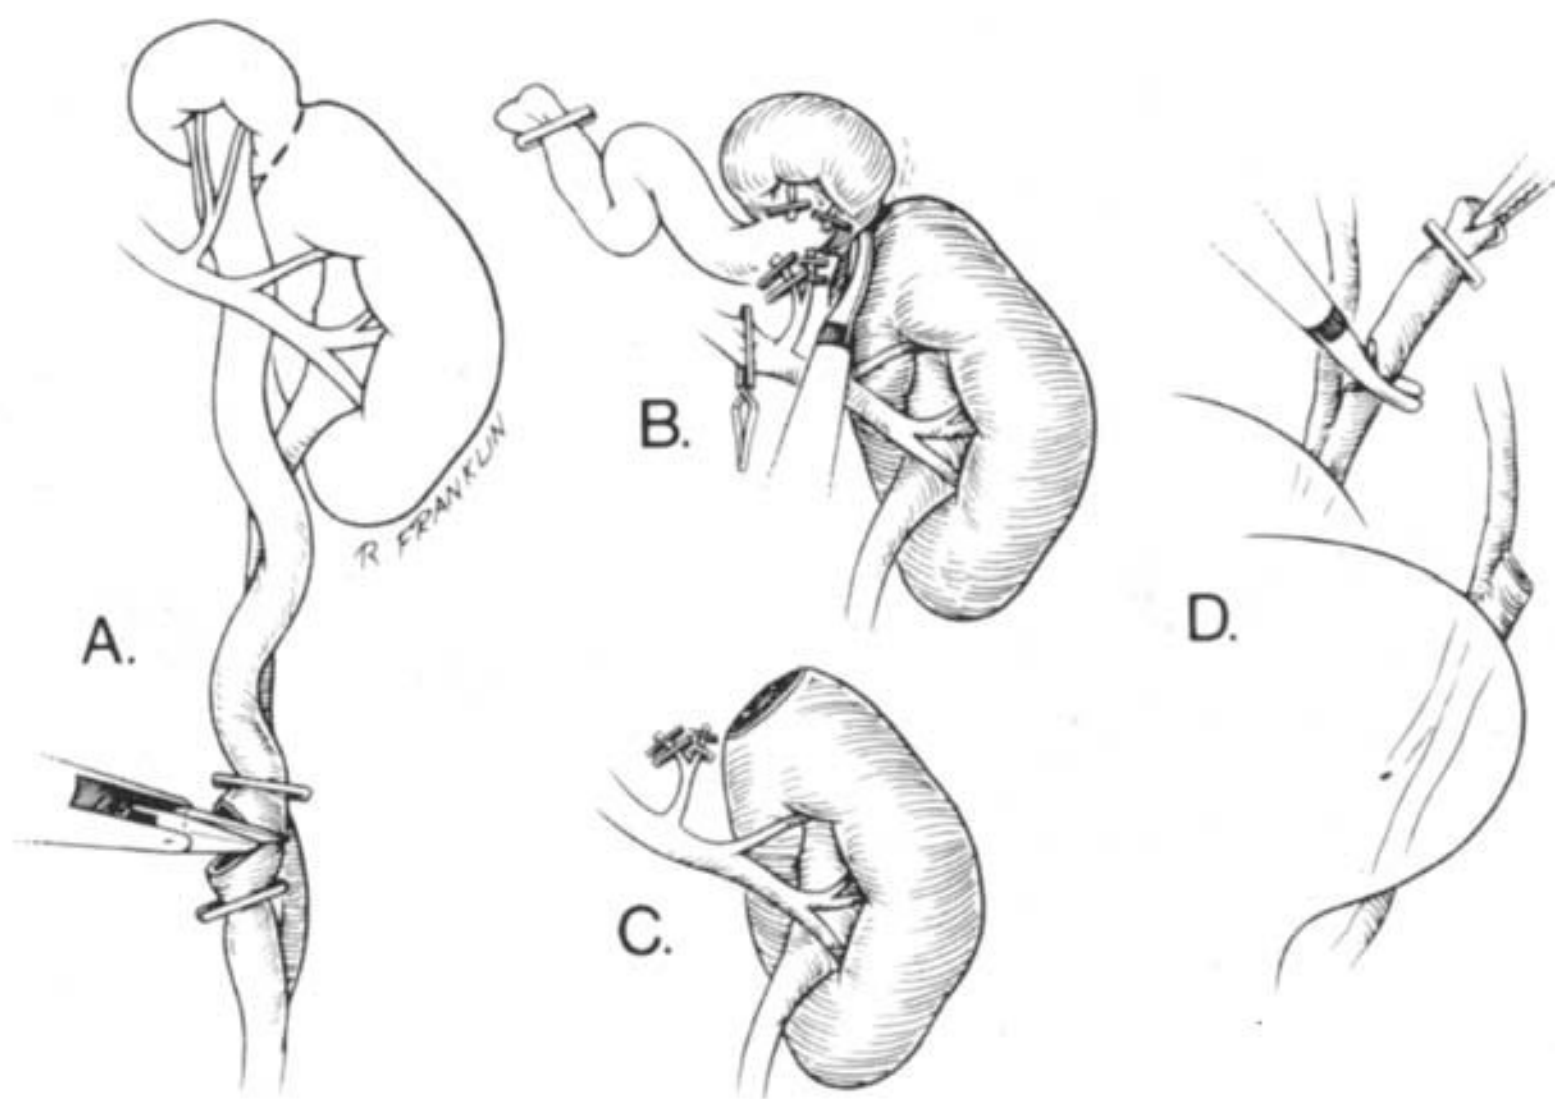

The nonfunctioning ureter is mobilized to the kidney and the Gerota fascia is opened. The ureter is passed posterior to the main renal hilum. Suprahilar, cephalad traction on the ureter should provide access to the upper-pole (nonfunctioning) hilum. If the blood supply is not clearly identified, laparoscopic bulldogs may be placed on the presumed upper-pole vessels. A clear demarcation between the upper and lower pole should be visible. The upper-pole vessels are clipped and divided. The renal pelvis of the nonfunctioning moiety is separated from the normal parenchyma using blunt dissection to better identify the demarcation between the functioning and nonfunctioning moiety. Large hydronephrotic moieties can be opened to help delineate the separation between the upper and lower pole. The nonfunctioning moiety is excised using electrocautery or the harmonic scalpel along the line of vascular demarcation. Any collecting system injuries to the remaining pole should be closed with an absorbable suture. Perirenal fat is used as a bolster prior to closing the cut surface of the remaining moiety with 4-0 absorbable monofilament suture.

If a complete nephrectomy is to be performed, after the ureter is divided and Gerota fascia open, the renal vessels are dissected and divided using clips or an endovascular stapler. The kidney is mobilized and removed.

After inspection for hemostasis, a retroperitoneal drain is placed and the specimen is removed through the camera port. If

**FIGURE 116.2** Laparoendoscopic right upper-pole partial nephroureterectomy. **A:** The ureter is clipped and divided in the region of the midureter. **B and C:** The ureter has been dissected from beneath the main renal pedicle and the upper-pole vasculature has been clipped. The hydronephrotic cap is dissected off with the parenchyma minimally divided. **D:** The ureter is left attached as the remaining wall of the ureter is dissected and ligated at the bladder wall.

**FIGURE 116.3** Laparoendoscopic left upper-pole partial nephroureterectomy. **A:** The ureter is clipped and divided in the region of the midureter and dissected in a rostral direction. **B and C:** The upper-pole segmental vessels are clipped and the cap of the kidney allowed to demarcate. The plane of amputation is marked, an endoscopic bulldog is applied to the major pedicle, and the upper-pole cap is amputated. **D:** The ureter is dissected in a caudal direction to the point of the common vascularity and there amputated with the stump left open.

a complete nephrectomy is performed, a drain is typically not placed. Local anesthetic is injected into the port sites. Most patients, if not all, do not require epidural analgesia. The bladder catheter is removed on the first or second postoperative day, depending on whether further bladder work is required. The drain is removed when there is minimal drainage. The patient is discharged when comfortable with diet and oral analgesics.

### Retroperitoneal Approach

Retroperitoneal access to the kidney can be obtained by either a prone or a flank approach. The posterior prone retroperitoneal approach has been recommended for children with end-stage renal disease who may require immediate peritoneal dialysis (4). In the prone approach, initial retroperitoneal access is gained at the costovertebral angle using an open technique. Balloon inflation to 15 to 20 mm Hg of pressure is utilized to dissect and create the retroperitoneal space. Working ports are placed under direct vision inferior to the camera port and just above the iliac crest (Fig. 116.4). In this position, the kidney will move anterior by gravity, thereby exposing the hilar vessels. The psoas muscle is identified as a landmark. During nephrectomy, exposure and dissection of the hilum are performed first

**FIGURE 116.4** Port placement for right-sided prone retroperitoneal laparoscopic renal surgery.

with subsequent identification and division of the ureter. In partial nephrectomy, minimal mobilization of the remaining vessels and moiety should be performed to prevent vasospasm of the remaining moiety. The affected vessels should be divided and

the nonfunctioning moiety removed as in the transperitoneal approach. The ureter is used as a handle to manipulate and isolate the affected moiety. Collecting system injuries should be closed appropriately, and the edges of the remaining moiety may be sutured together for further hemostasis. A retroperitoneal drain is typically left in place.

The flank approach is similar except that the working space is developed with the camera port just below the tip of the twelfth rib. The working ports are placed along a transverse line with the camera medially and laterally after dissection of the peritoneum from the anterior abdominal wall. The remainder of the procedure is identical to that of the prone approach.

---

## OUTCOMES

---

Janetschek et al. (5) presented the first series of pediatric laparoscopic heminephrectomy. In 12 cases, 7 upper renal poles were removed for ectopic refluxing megaureter and obstructive ureteroceles. Five lower poles were removed for reflux nephropathy. Their blood loss was minimal (10 to 30 mL), there were no complications, and mean operative time was 222 minutes. Horowitz et al. (6) later reported a series of 14 laparoscopic upper-pole heminephrectomies with a mean operative time of 100 minutes.

To assess for potential benefits of laparoscopic renal ablative surgery over open procedures, Robinson et al. (7) retrospectively compared 22 consecutive partial nephrectomies of which 11 were performed laparoscopically and 11 performed open in a nonrandomized fashion. Although the mean operative time was significantly longer for the laparoscopic group (200 minutes vs. 114 minutes), there was no difference in mean hospital stay. Patients in the laparoscopic group had a significantly lower opioid requirement than the open group. Piaggio et al. (8) compared intraperitoneal laparoscopic partial nephrectomy to an open retroperitoneal approach. They noted that length of hospitalization was shorter in the laparoscopic group and stated that the procedure is feasible even in infants under 6 months of age.

Success in laparoscopic partial nephrectomy has also been reported via a retroperitoneal approach. Castellán et al. (9) also reported their experience utilizing both transperitoneal and retroperitoneal heminephrectomy. Their overall complication rate was 10%, which included urine leak, pneumothorax, urinary tract infection, and hypertension. Lee et al. (10) performed an age-matched comparison of pediatric patients undergoing retroperitoneal laparoscopic partial nephrectomy to

open surgery. Compared to open partial nephrectomy, the laparoscopic approach was eventually associated with equivalent operative times, significantly shorter length of stay, and less postoperative opioid requirements.

---

## COMPLICATIONS

---

The most severe complication that can occur during laparoscopic nephrectomy and partial nephrectomy is a major vascular injury. This is most likely to occur during trocar insertion or during the hilar dissection. Trocar injuries may be prevented by using an open approach. Meticulous attention must be paid during the hilar dissection. The vascular anatomy needs to be clearly defined prior to division of the renal vessels. When endovascular staplers are utilized, the surgeon must confirm that only the renal vessels are included within the stapler.

Other complications can include bowel injury, bleeding, infection, or urine leak resulting in urinoma formation. Bowel injuries can occur with inadvertent trocar placement or during dissection secondary to instrument handling or electrocautery misuse. Urine leaks are often discovered by elevated postoperative drain output. They are often managed with bladder decompression, with or without ureteral stent placement. Asymptomatic postoperative retroperitoneal fluid collections can be observed. Symptomatic retroperitoneal fluid collections may require percutaneous drainage and assessment for creatinine. A late complication that can occur is loss of function in the ipsilateral remaining moiety, eventually resulting in hypertension or worse loss of the moiety. If severe, this may require completion nephrectomy. This complication may be prevented with meticulous dissection and minimal mobilization of the hilum and kidney of the functioning moiety to prevent any intimal vascular injury or vasospasm.

As experience with laparoscopic nephrectomy and heminephroureterectomy increases, operative time and estimated blood loss can improve. Yucel et al. (11) retrospectively reviewed their experience with laparoscopic ablative renal surgery performed by one surgeon over a 6-year period. In the fourth year of their experience, they noted a statistically significant improvement in operative time for laparoscopic nephrectomy and in estimated blood loss for laparoscopic heminephroureterectomy. They concluded that their experience should continue to encourage pediatric urologists to perform laparoscopic renal surgery.

# CHAPTER 117 ■ UROGENITAL SINUS AND CLOACAL ANOMALIES

JEFFREY A. LESLIE AND RICHARD C. RINK

Anomalies of the urogenital sinus occur on a spectrum ranging from a mild distal communication between the urethra and vagina to a very complex confluence between the urethra, vagina, and rectum. For this last-mentioned complex group a distal common channel for all of these structures drains to a single perineal opening (Fig. 117.1A). The clinical presentation of this single opening results from persistence of the cloaca and is essentially a severe urogenital sinus abnormality with a high imperforate anus (Fig. 117.1B). In addition to a more bizarre and diverse internal anatomy, patients with cloacal anomalies have a high incidence of other serious midline congenital anomalies. Important elements of baseline evaluation and surgical management of urogenital sinus and cloacal anomalies are discussed in detail in this chapter.

Urogenital sinus abnormalities (no rectal involvement) in general occur in one of two forms: pure urogenital sinus anomalies and females with disorders of sexual development (DSD, formerly known as intersex) conditions. The latter group is much more common. In these children surgical management must address not only the urinary and vaginal communication but also the virilization of the clitoris and labia.

---

## DIAGNOSIS

---

The majority of children with urogenital sinus abnormalities are detected at birth due to genital ambiguity. The initial evaluation in this group of children requires a team approach to gender identification with appropriate rapid chromosomal and endocrinologic studies. The history and physical examination are often helpful in establishing a correct diagnosis. Congenital adrenal hyperplasia (CAH) secondary to 21-hydroxylase deficiency is by far the most common etiology. Some children may be identified antenatally on ultrasound by noting a fluid-filled mass (distended vagina) posterior to the bladder and indeterminate genitalia. Persistence of the cloaca is suspected in utero when large fluid-filled pelvic structures are noted associated with bilateral hydronephrosis, oligohydramnios, and ascites. A 46 XX karyotype is found. Hydrometrocolpos due to retention of urine and secretions results in upper-tract distention, and ascites occurs due to retrograde flow through the genital tract into the peritoneum. The rectum and bladder may also be filled with urine, giving rise to the other fluid-filled structures.

Prematurity and multiple congenital defects are common in children with cloacal anomalies. Initial evaluation of these children should therefore include medical stabilization and evaluation for midline abnormalities. Abdominal distention is

A

B

**FIGURE 117.1** **A:** Urogenital sinus. The confluence of the vagina with the urethra is near the bladder neck and thus “high.” A Fogarty catheter is in the vagina. **B:** Cloacal anomaly with the urethra, vagina, and rectum all exiting a single perineal opening.

common and may result in respiratory embarrassment. Cardiac, renal, and upper gastrointestinal anomalies and spinal dysraphism are frequently identified. Although these infants are uniformly female, ambiguity of the genitalia may occur and should be investigated. A single perineal opening is noted anteriorly, and the anus is absent. The perineum is in general flat with variable amounts of labial tissue mounded around the anterior orifice. Occasionally, a prominent phallic structure is found. The buttocks are often poorly developed, and the sacrum may be deficient on abdominal plain film.

Renal ultrasound reveals anomalies of number and fusion. Magnetic resonance imaging (MRI) clarifies the complex pelvic relationships, evaluates the structural quality of the sphincter complex, and defines the anatomy of the lumbosacral spine and distal spinal cord. A gender assignment committee is convened to determine gender identity. The child must be stabilized. Genitography is of utmost importance to help determine the anatomy (i.e., length of common sinus, location of vaginal confluence, status of bladder, presence or absence of vesicoureteral reflux, or vaginal duplication). Patients with cloacal anomalies will show communication between the urogenital tract and rectum, and vesicoureteral reflux is commonly identified. Ultrasonography of the pelvis and kidneys is also of help to identify the uterus, ovaries, and any vaginal distention, or, in the case of cloacal anomalies, it may reveal hydronephrosis or increased echogenicity suggestive of renal dysplasia. The adrenal glands in CAH may be prominent with a cerebriform appearance. MRI of the pelvis is an excellent tool to determine pelvic anatomy and note the presence of lumbosacral spinal cord anomalies that may be present.

Pure urogenital sinus anomalies are in general not detected early because of normal external genitalia. These patients are usually found at puberty with hydrometrocolpos or difficulty with tampon insertion. Some children are identified earlier with incontinence and urinary tract infection (UTI) from urine pooling within the vagina. Those with pure urogenital sinus anomalies are also more likely to have other organ system abnormalities than those with a urogenital sinus associated with DSD.

---

## INDICATIONS FOR SURGERY

---

It is important for the reader to understand that there is a great deal of controversy surrounding feminizing genitoplasty. There are proponents of (a) very early neonatal reconstruction, (b) delayed postpubertal reconstruction (this usually involves vaginoplasty), and (c) no surgery unless the patient requests it. There are obvious advantages and disadvantages to each of these approaches. All children with genital ambiguity should be evaluated promptly by a gender assignment team consisting of a neonatologist, geneticist, endocrinologist, pediatric urologist, and psychiatrist who are all working with and for the child and family. For the purposes of this presentation we will assume that the family and gender assignment team agree to proceed with surgery. It is our belief that early reconstruction is most appropriate with all three steps (clitoroplasty, vaginoplasty, and labioplasty) completed in a single stage. A revisional vaginoplasty is often needed at puberty due to stenosis of the introitus, which should be conveyed to the parents preoperatively. This is usually a minor procedure. In the rare situation of the very small and very high vagina, it may be

more appropriate to postpone the vaginoplasty until the child is pubertal. Delayed postpubertal vaginoplasty, however, could easily be done by the same techniques described in this chapter.

---

## DECOMPRESSION THERAPY

---

While most of those with a urogenital sinus undergo reconstruction in the first few months, the complex nature of cloacal anomalies and their high incidence of other congenital defects, may necessitate a delay in formal reconstruction while the child is stabilized. Certainly, temporary diversion of the gastrointestinal tract by colostomy is essential, and decompression of the urinary tract may be required. This may be done by clean intermittent catheterization, but if this is not adequate, a temporary cutaneous vesicostomy may be necessary. Rarely a vaginostomy is needed, but this is a last resort as it tethers the vagina to the abdominal wall, making later vaginoplasty difficult. In the current era of Malone antegrade continence enema (MACE appendicocostomy) procedures to achieve fecal continence, nearly all will ultimately undergo complete reconstruction, including a rectal pull-through.

---

## SURGICAL TECHNIQUE

---

All children with a very high vaginal confluence or a cloacal anomaly receive a polyethylene glycol electrolyte solution bowel preparation and prophylactic parenteral antibiotics preoperatively. Those with a low to midlevel confluence receive only a preoperative enema and broad-spectrum antibiotics.

Endoscopy is performed with the child in the lithotomy position. This is one of the most important steps in reconstruction, as it defines the level of vaginal confluence and allows identification of any other lower genitourinary pathology, such as vaginal duplication, ectopic ureter, and so forth. We believe that the distance of the vagina from the bladder neck is the most critical aspect and dictates the type of vaginoplasty. Endoscopy also allows placement of a Fogarty catheter into the vagina, which is left indwelling with the balloon inflated. Correct placement is confirmed by repeating endoscopy. The Fogarty balloon will aid in identification of the vagina during the reconstruction. A separate small Foley catheter is passed into the bladder.

Historically, urogenital sinus surgery has been performed with the child in the lithotomy position. While this position is acceptable, we have found it much easier to prepare the entire lower portion of the body circumferentially to allow access to the abdomen and perineum and to allow the child to be supine or prone (Fig. 117.2A and B). The supine portion of the procedure is done with the child "frog-legged," with the buttocks elevated on towels. This position dramatically improves visualization for the surgical assistants. By far the most common group of patients with a urogenital sinus anomaly to require surgical reconstruction is the group with congenital adrenal hyperplasia, who have not only a urogenital sinus but also virilization of their external genitalia. This includes clitoral hypertrophy, absence of the labia minora, and anteriorly placed labia majora. Therefore, most patients will undergo clitoroplasty, labioplasty, and vaginoplasty.

A

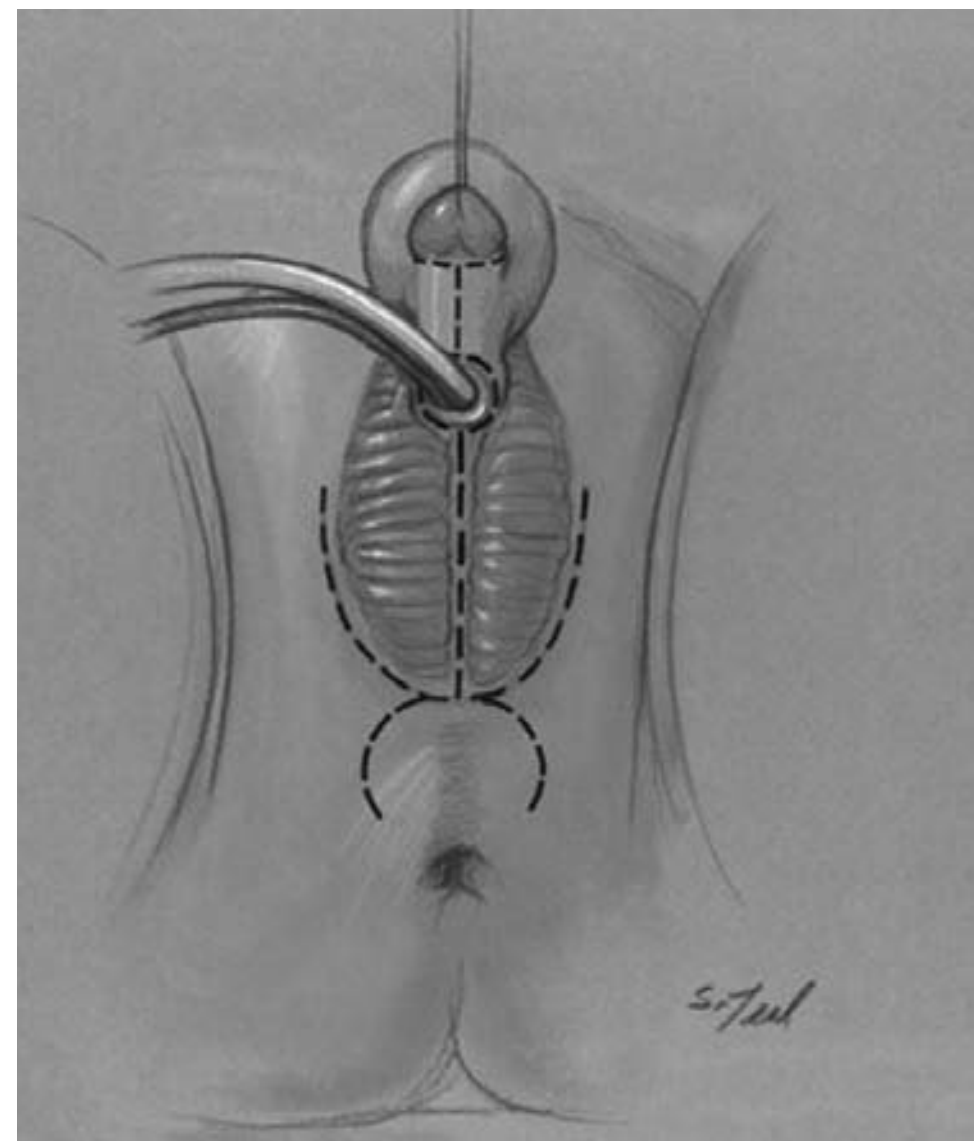

B

**FIGURE 117.2** Total lower body preparation. **A:** Supine position allows access to perineum and abdomen. **B:** Child has been rotated prone, allowing access for a posterior sagittal approach.

### Clitoroplasty

In cases of genital ambiguity the operation begins with placement of a traction suture in the glans clitoris. Using a skin scribe, the proposed incisions are outlined as shown in Fig. 117.3. Historically, a very wide-based inverted U-shaped perineal flap has been created. Improved cosmesis occurs, however, if the flap has a narrower base similar to an omega, avoiding the appearance of a triangular introitus. After injecting 0.5% lidocaine with 1:200,000 epinephrine subcutaneously along the proposed suture lines, the clitoroplasty is begun. The initial incision is carried out dorsally well proximal to the glans to preserve the inner preputial layer for a clitoral hood. The entire clitoris is degloved by creating a plane between the Buck's fascia and the dartos circumferentially. Ventrally, the incision is carried around the urogenital sinus meatus. The rounded apex of the perineal flap should extend to near the meatus. This flap is elevated with its underlying subcutaneous and adipose tissue to expose the urogenital sinus. Dorsally, the suspensory ligament is divided and the

**FIGURE 117.3** Proposed initial incisions. Notice the omega-shaped perineal flap. The meatus is encircled.

bifurcation of the corporal bodies is exposed ventrally. With the entire clitoris now exposed, a tourniquet is placed at its base. A vertical ventral midline incision is made along the entire length of each corporal body to the glans (Fig. 117.4A). The erectile tissue is exposed and excised, with care taken not to injure the Buck's fascia, the tunica albuginea, the neurovascular bundle, or glans. This is performed bilaterally from the glans to the level of the bifurcation (Fig. 117.4B). The proximal end of each corporal body is oversewn with 4-0 polyglycolic acid sutures to prevent bleeding. With the Buck fascia folded, the glans is now secured to the corporal stumps with 4-0 polydioxanone sutures. We had previously sutured the glans to the pubis but found that this technique prevents appropriate concealment of the glans. At times the glans is quite large, but one should resist aggressive glans reduction. If any reduction is done, it should only occur on the ventral aspect of the glans to prevent loss of sensation (1).

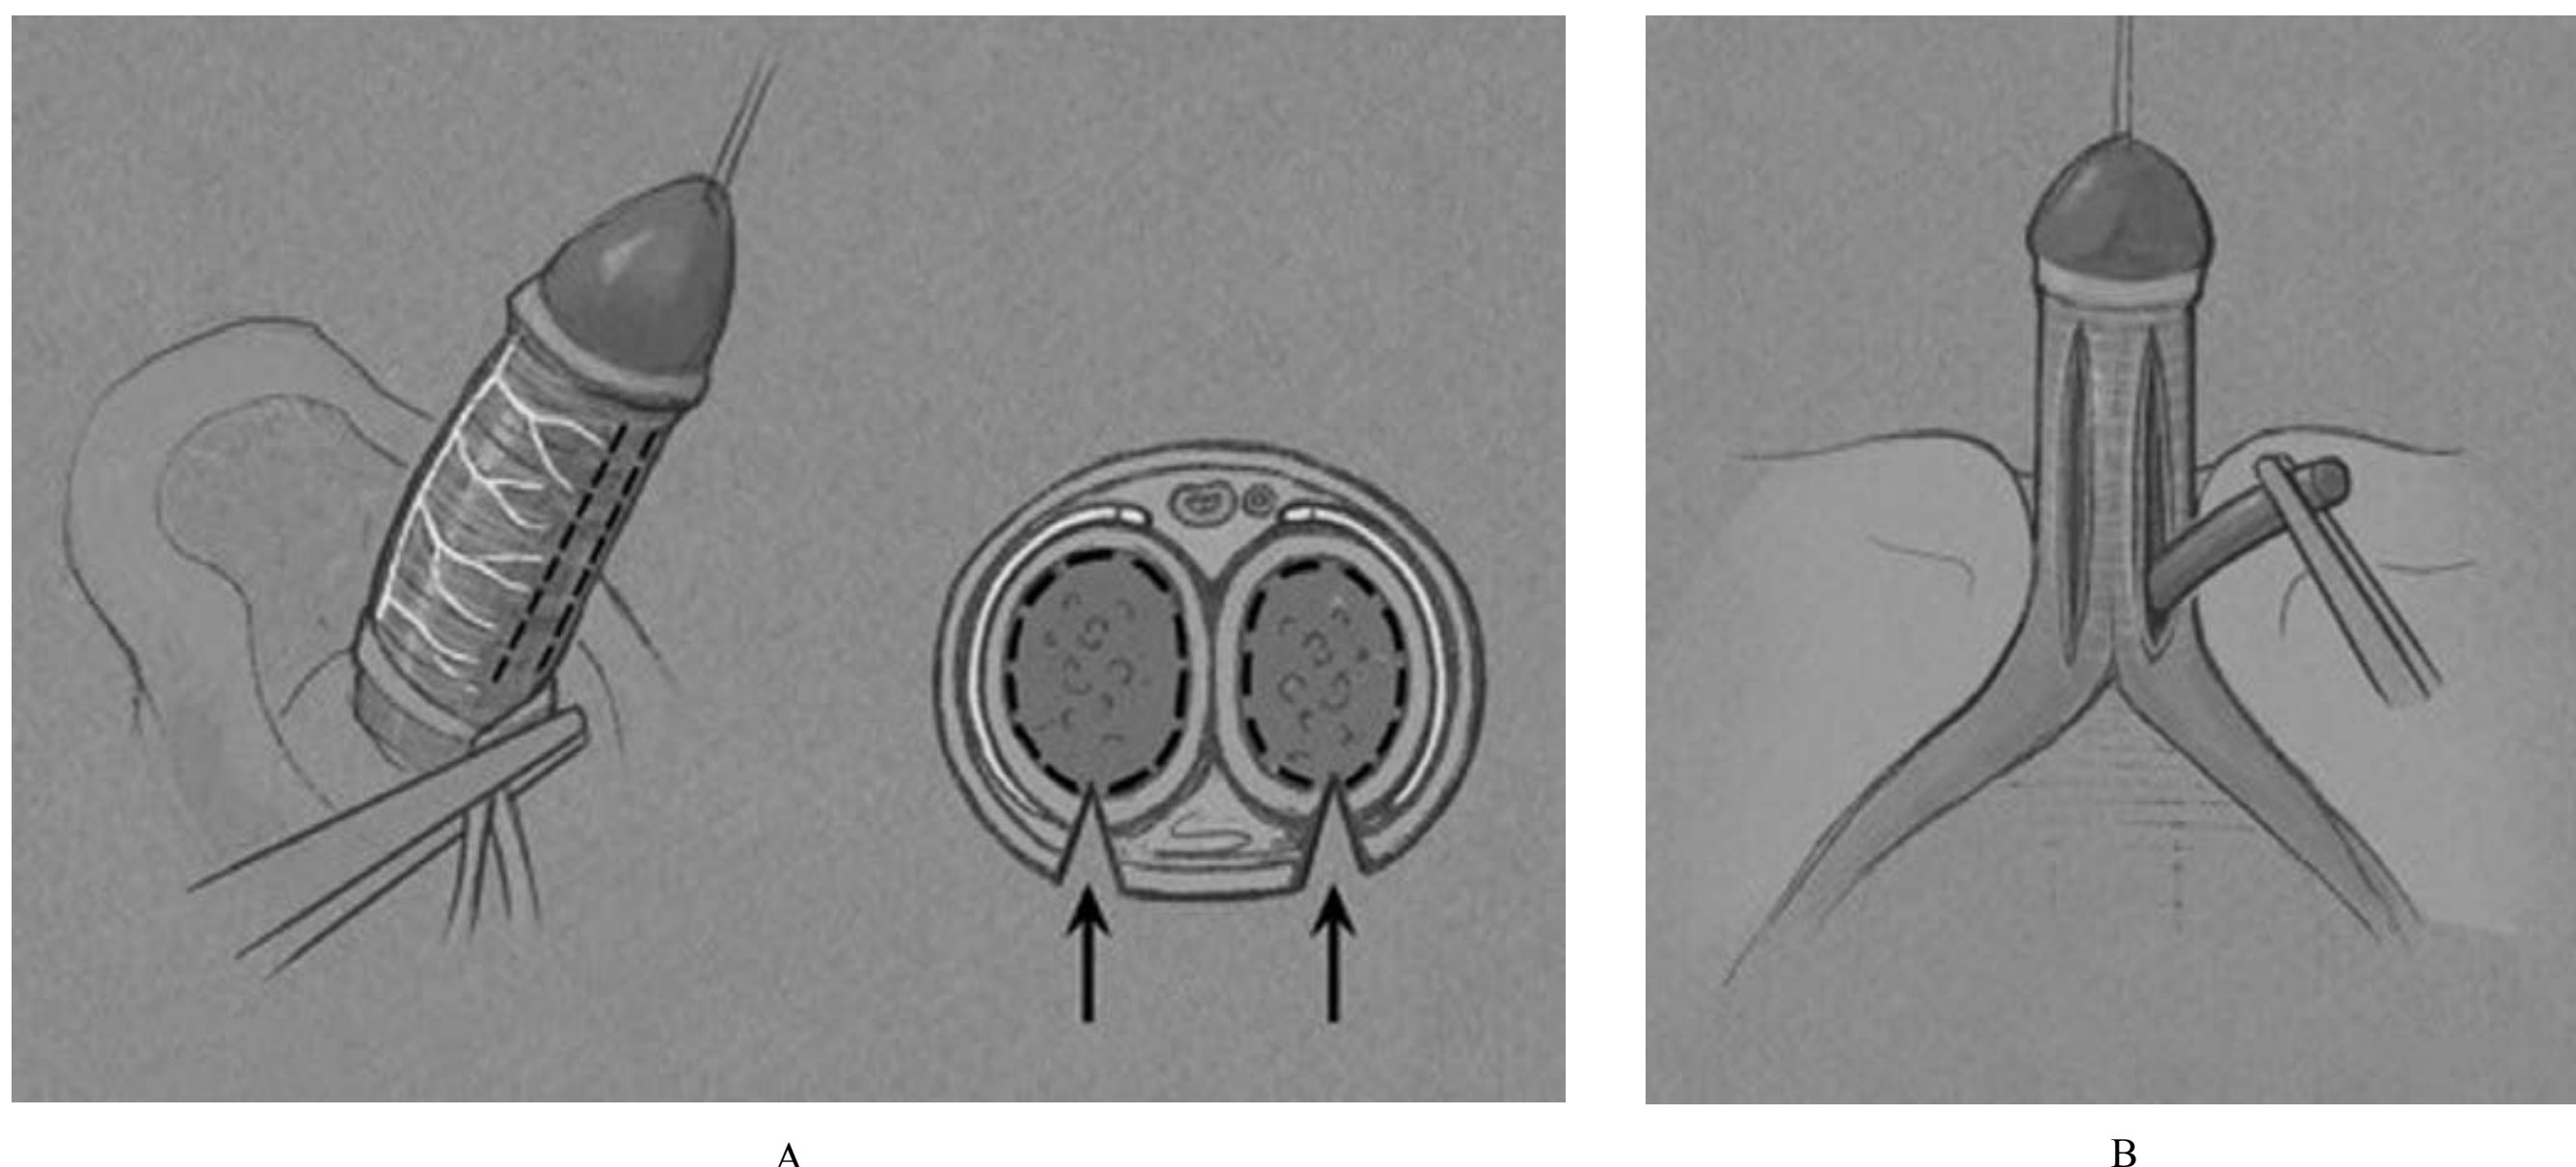

### Vaginoplasty

The most complex component of reconstruction of the urogenital sinus is the vaginoplasty. While multiple techniques of vaginal reconstruction have been described, they all fall in general into four types: (a) cut-back vaginoplasty, (b) flap vaginoplasty, (c) pull-through vaginoplasty, and (d) vaginal replacement. The type of vaginoplasty is determined by the location of the confluence between the vagina and the common urogenital sinus.

The *cut-back vaginoplasty* is applicable only for minor labial fusion and is in fact contraindicated for any true urogenital sinus anomaly. In this procedure the sinus is opened with a midline vertical incision that is then closed transversely in a Heineke-Mikulicz fashion. It is of historical significance only and will not be addressed further.

#### Low Vaginal Confluence

For the low confluence a *flap vaginoplasty* is performed. This procedure leaves the vagina in the same anatomic location but

**FIGURE 117.4** Clitoroplasty. **A:** The longitudinal incisions must be ventrally placed to avoid injury to the neurovascular supply. **B:** The erectile tissue is removed. There is no excision of any of the tunic, and the neurovascular pedicles are never manipulated.

opens the sinus to provide a larger common opening for the urethra and vagina. It is contraindicated in patients with a high vaginal confluence. The previously elevated perineal flap must be long enough to allow a tension-free anastomosis to the normal-caliber proximal vagina. Redundancy of the flap, however, will create a lip of tissue at the introitus. The exposed ventral aspect of the sinus is opened in the midline, and the incision is carried through the narrowed distal one third of the vagina into the normal-caliber proximal vagina. It is very important to open into the normal-caliber vagina to prevent later vaginal stenosis. It is also noteworthy that the flap vaginoplasty does not change the vaginal location or confluence but merely exposes the vagina by widely opening the introitus. Because the anterior and lateral aspects of the vagina are untouched, stenosis is less common.

#### High Vaginal Confluence

If the vaginal confluence is near the bladder neck, a flap vaginoplasty is contraindicated, as it will result in severe female hypospadias with urine pooling. Deep spatulation of the sinus and posterior vagina may permanently open and injure the sphincteric mechanism. Therefore, a *pull-through vaginoplasty* is required, which allows a complete separation of the vagina from the sinus. The sinus is closed in layers to create a urethra, and the vagina is brought to the perineum. In this technically demanding procedure, the vagina is completely separated from the sinus. The dissection of the anterior wall of the vagina from the urethra and bladder neck is the most difficult part of the procedure, and if not done with care and excellent exposure it may result in injury to the urethra or sphincteric mechanism. The initial portion of this procedure is identical to the flap vaginoplasty. It is important to expose the entire posterior wall of the vagina by dividing the bulbospongiosus muscle and sweeping the rectum posteriorly. The sinus is opened in the midline until the Fogarty balloon is exposed in the vagina. At this time we rotate the patient to the prone position and elevate the posterior wall of the vagina with a

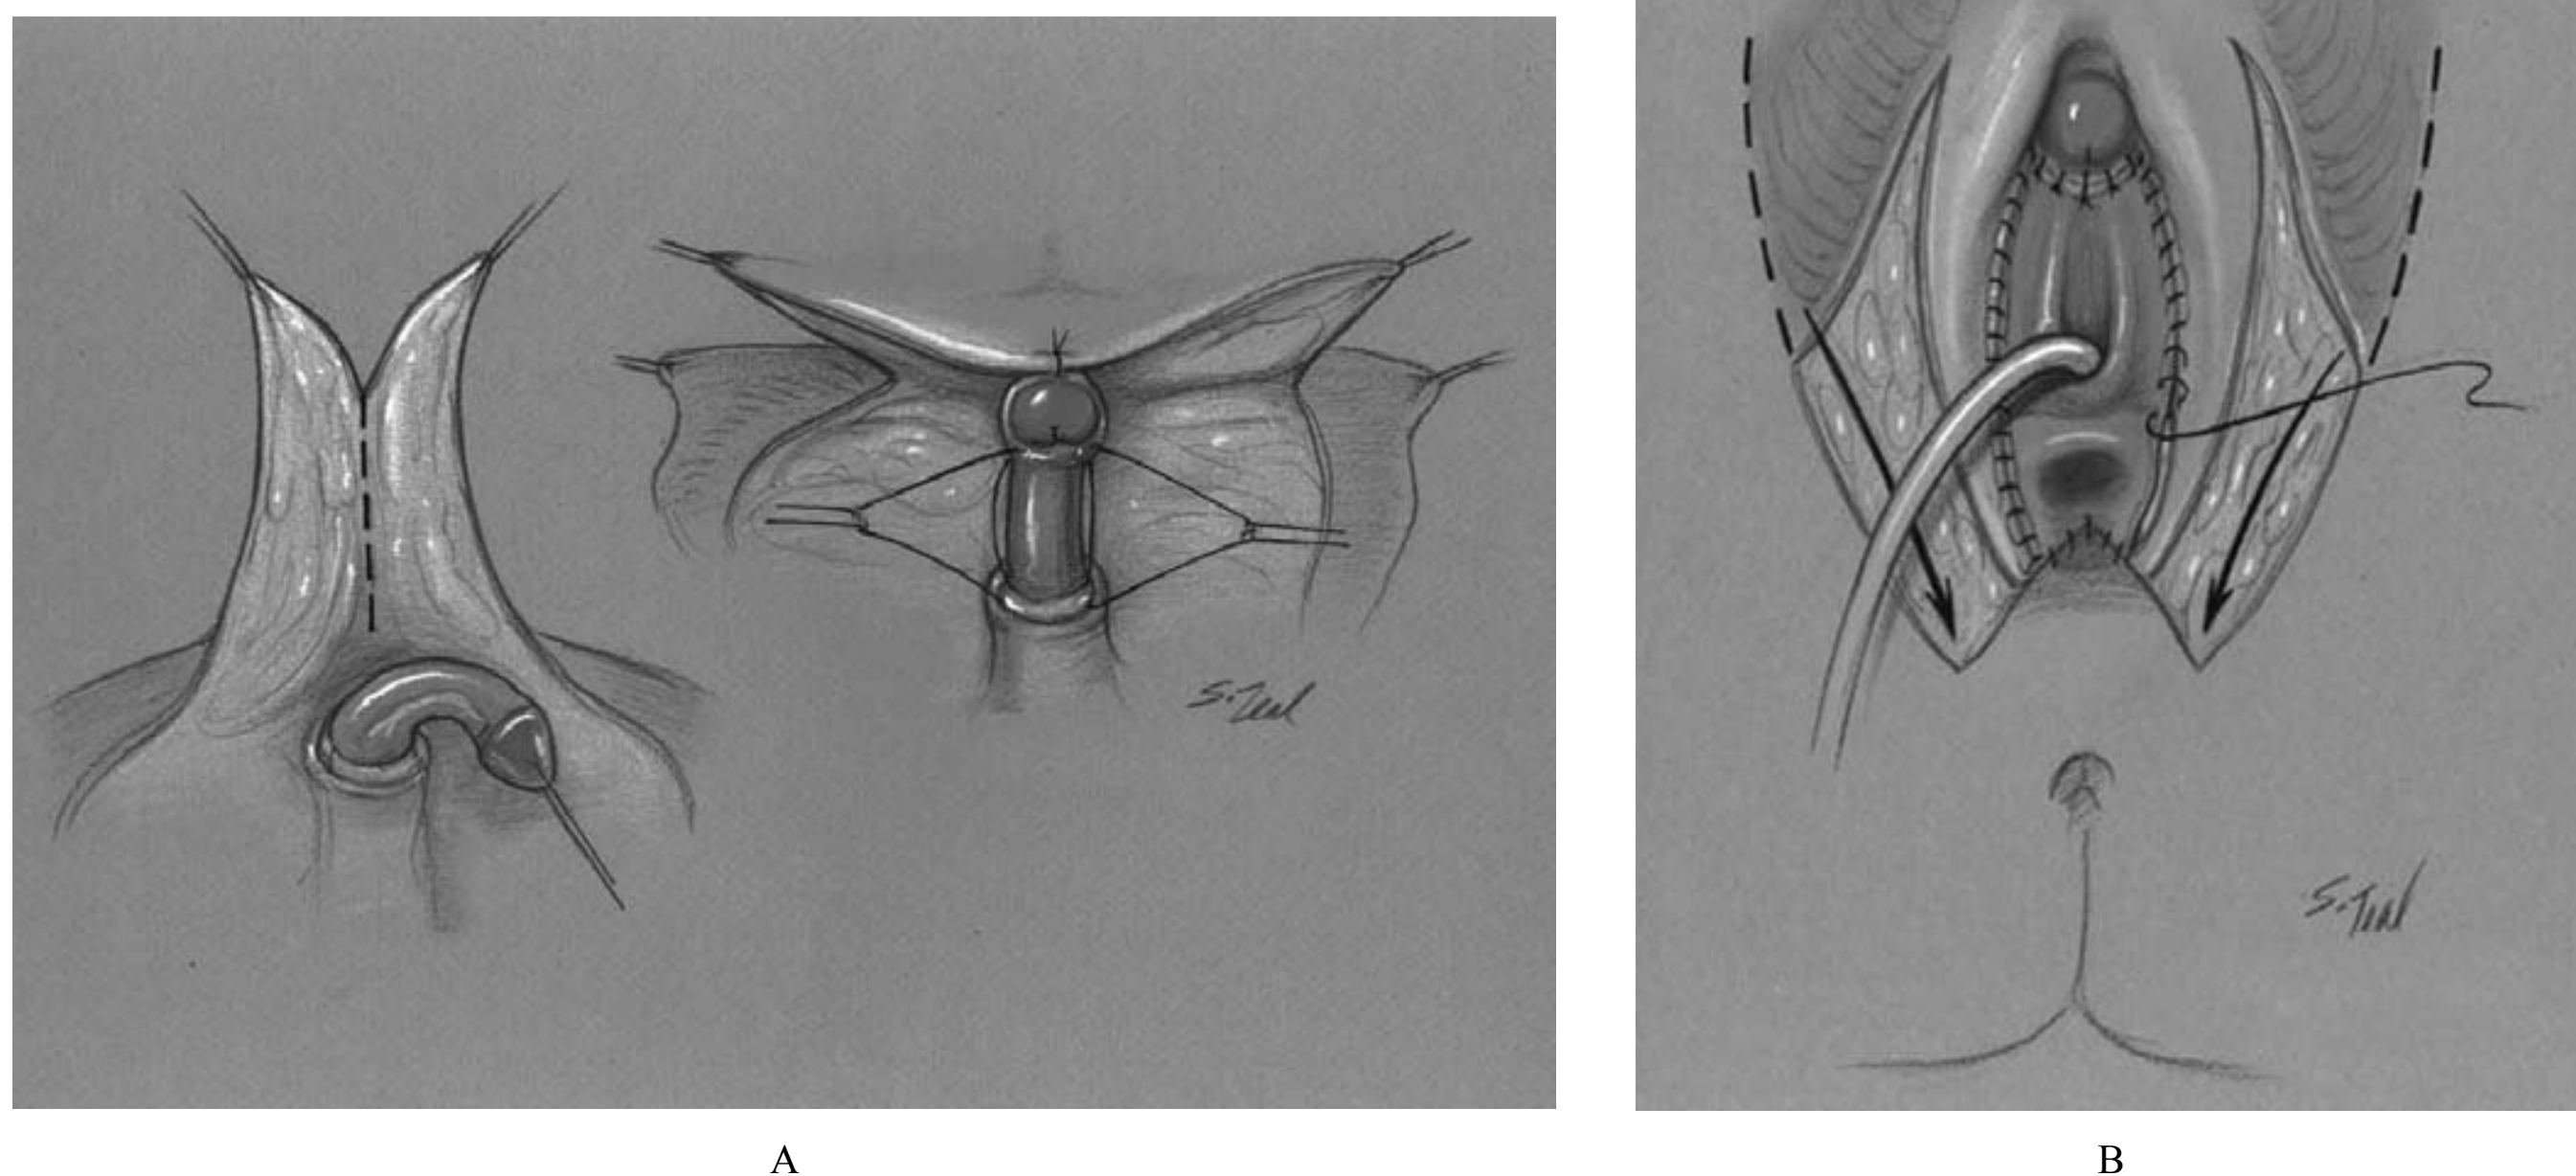

malleable retractor, providing excellent exposure of the anterior wall of the vagina and its confluence with the urethra (2). Stay sutures on the vagina are very helpful. With the vagina separated from the urethra and sinus, the opened sinus is closed in layers over a catheter, allowing the sinus to become the urethra. Unfortunately, “pull-through” is at times a misnomer: Even following complete circumferential vaginal mobilization, the vagina may not reach the perineum. In these situations the perineal flap will create the distal posterior vaginal wall and the anterior wall can be created by either a preputial or labial flap. In extreme situations, bowel interposition may be required to create the distal vagina. A Penrose drain is left in the vagina, and the Foley remains in the urethra.

#### Labioplasty

Having completed the clitoroplasty and vaginoplasty, only the labial reconstruction remains. The phallic skin is unfurled and divided in the midline longitudinally (similar to Byar flaps), stopping short of the base to allow a clitoral hood (Fig. 117.5A). These skin flaps are now sutured in place inferiorly along either side of the vagina to create labia minora. The anteriorly displaced labia majora are mobilized posteriorly by making lateral incisions in a Y-V fashion (Fig. 117.5B). The mobilized labia majora are now sutured to the labia minora and to the apex of the perineal flap. This step moves the labia posteriorly to their normal location on either side of the vagina.

#### Cloacal Anomalies

Surgical management of children with cloacal anomalies occurs in several important steps, but the formal reconstruction is best performed in a single stage. Neonates require early diverting colostomy. Hendren (3) prefers a right colostomy to leave adequate distal length and an intact blood supply for

**FIGURE 117.5** **A:** The phallic skin is divided in the midline and used to create labia minora. The incision should stop well short of the base to allow creation of a clitoral hood. **B:** Y-V plasty of the labia majora moves the labia inferiorly to place the urethra and vagina between the labia in a more normal location.

subsequent rectal pull-through. A long distal colonic segment, however, can allow persistent retention of urine in the mucus fistula and result in refractory hyperchloremic metabolic acidosis. Preliminary mapping of the anorectal sphincter complex provides prognostic information for future rectal pull-through.

Decompression of the genitourinary tract is performed during endoscopic investigation of the cloacal anatomy. Inspissated mucus and meconium debris are drained. Because the bladder neck and vagina are often closely related, the vagina passively retains voided urine. If vaginal voiding is a problem, intermittent catheterization of the common channel will allow decompression, with the catheter most likely entering the vagina rather than the bladder. Poor emptying is suspected in children with persistence of hydronephrosis postnatally. Alternatively, if the common channel is narrow and more urthrallike, it can be opened distally to facilitate voiding. If the above measures fail, cutaneous vesicostomy is performed. Cutaneous vaginostomy allows free drainage but tethers the vagina anteriorly and complicates the subsequent vaginoplasty.

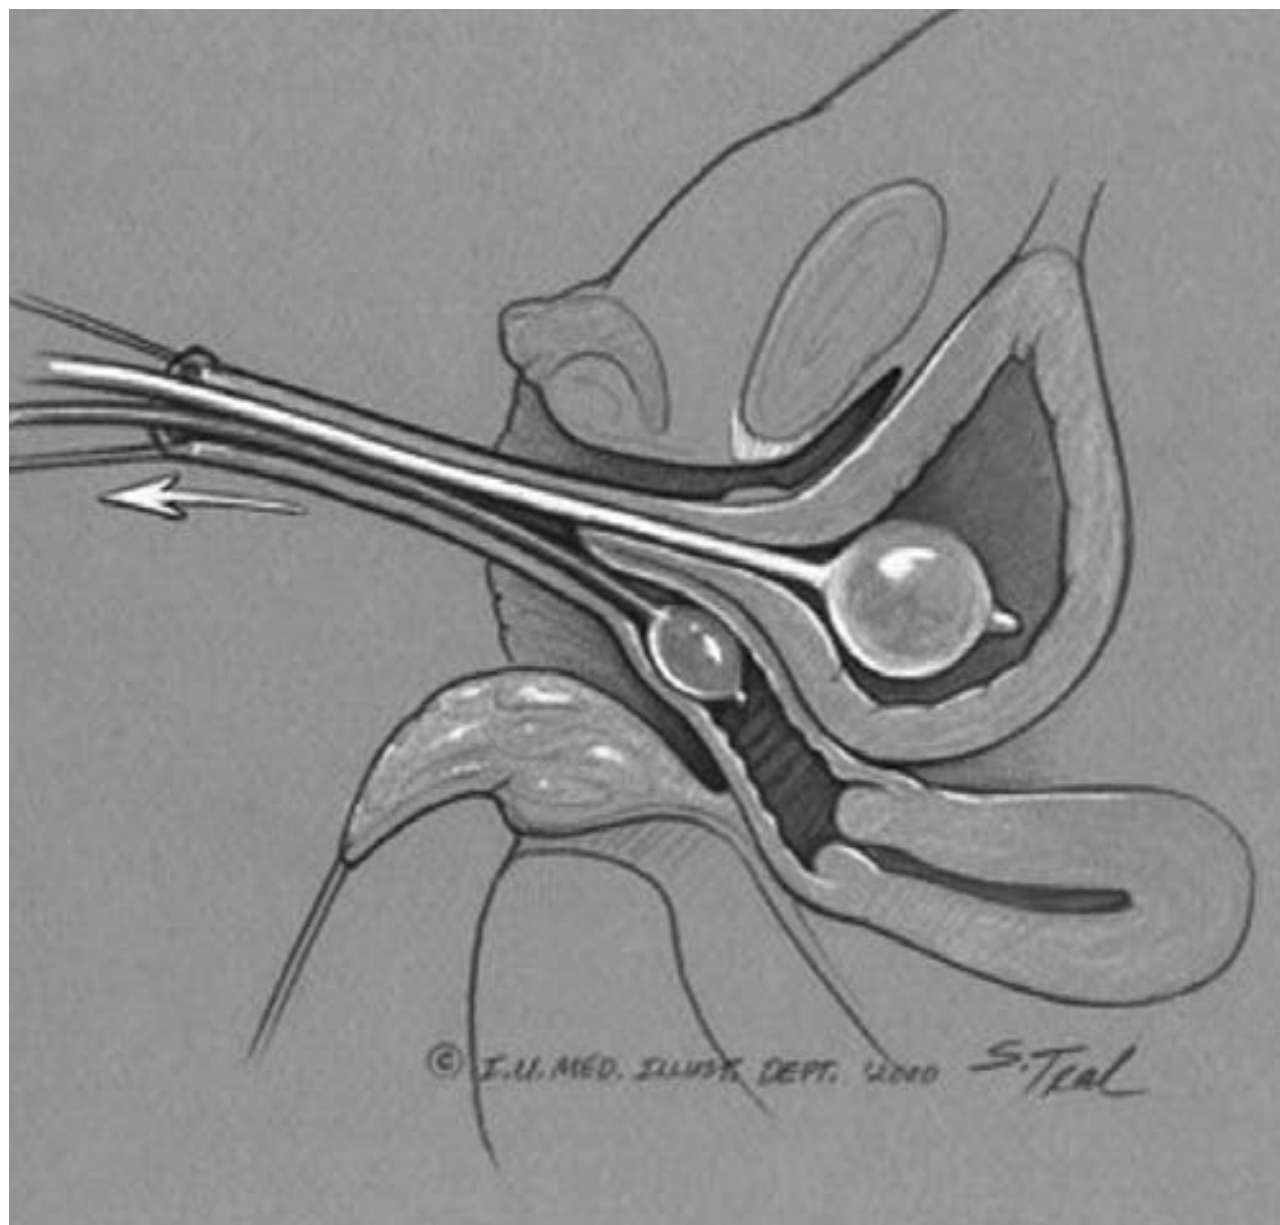

Severe anomalies of other organ systems should be corrected early. Other urinary tract abnormalities that may compromise long-term renal function should be addressed. Colonization of the urinary tract is common, but symptomatic infections mandate aggressive therapy. Assuming that all other congenital issues have been satisfactorily addressed, formal repair of the cloaca with the Peña posterior sagittal anorectovaginourethroplasty (PSARVUP) is planned for 6 to 12 months of age. This demanding procedure should be completed in a single stage, capitalizing on the virgin tissue planes for both anorectal and urogenital reconstruction.

The initial preparations for repair of the persistent cloaca are similar to those described above for the high-confluence urogenital sinus. After a circumferential lower-body preparation and endoscopic placement of Fogarty catheters in the

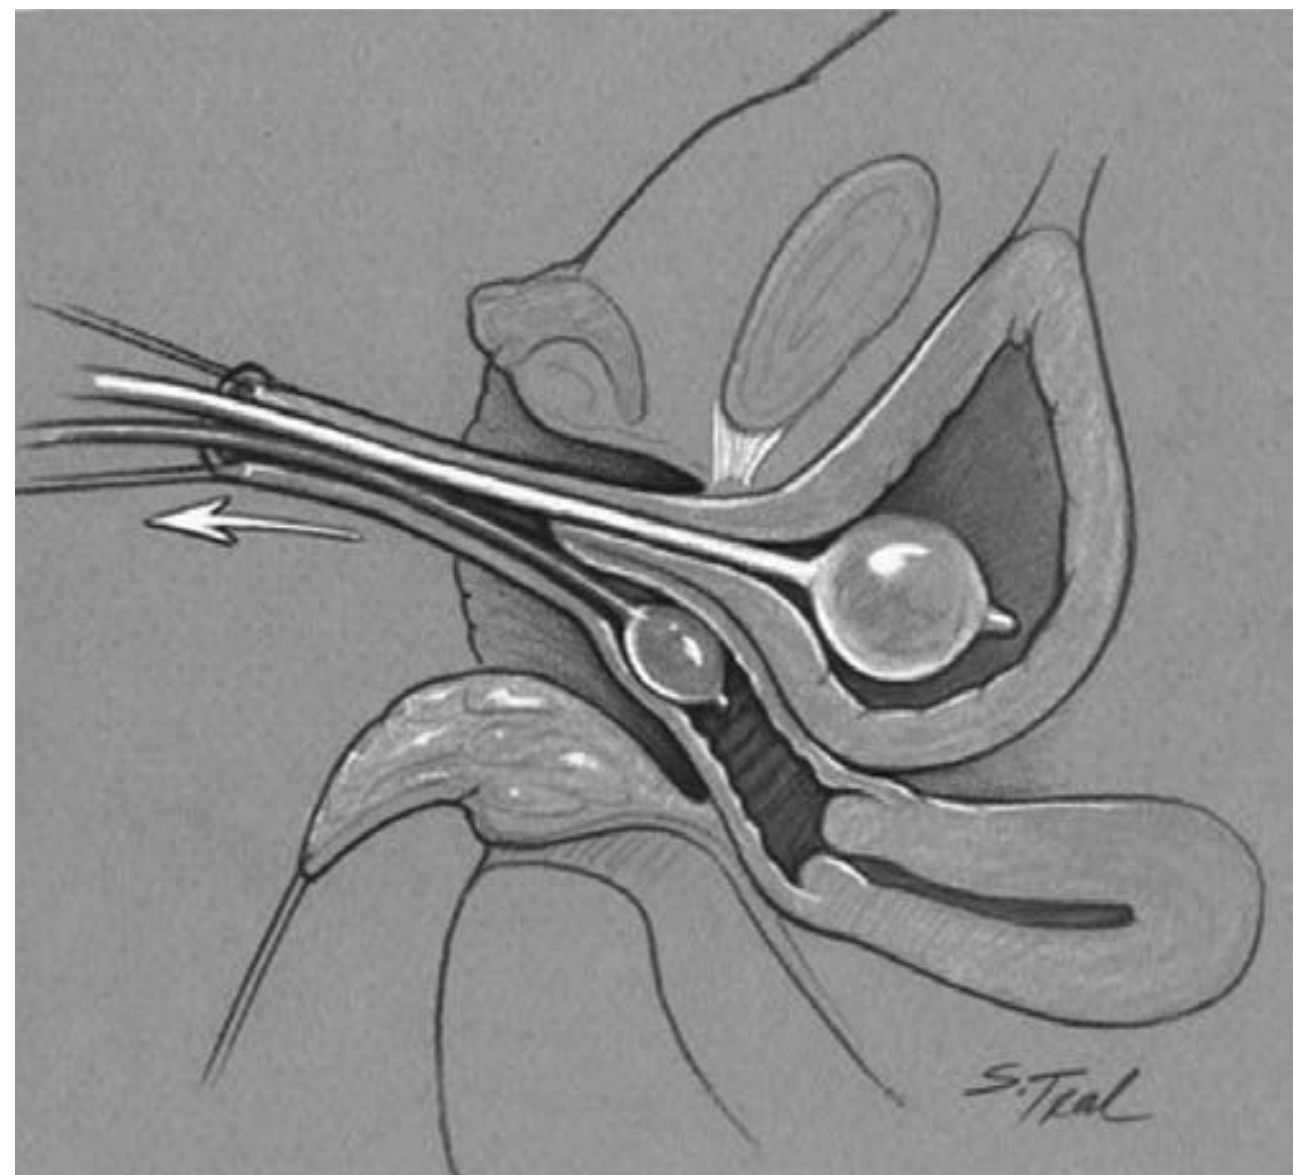

vagina(s) and rectum and a Foley catheter in the bladder, the patient is placed prone on the chest and pelvic rolls. The sphincter complex is stimulated, and the optimal positions for the anus, perineal body, vagina, and urethra are marked. The perineum is incised in the midline from the tip of the spine to the posterior margin of the single perineal orifice. The sphincteric muscles are split in the midline and tagged to facilitate subsequent reconstruction. The rectal communication is sharply dissected off the common channel, and the distal colon is mobilized for pull-through. Occasionally abdominal exploration is required to achieve adequate rectal mobilization. At this time the entire urogenital system is circumferentially mobilized toward the perineum by the Peña technique of *total urogenital mobilization*. Even if this maneuver cannot bring the vagina to the perineum, it does improve exposure to the confluence for completion of a pull-through vaginoplasty. Duplicate vaginas are often encountered and are combined by division of the vertical septum. Vaginal agenesis or atresia requires bowel interposition for vaginoplasty, and again this is best performed at the time of rectal pull-through and urethroplasty.

### Total and Partial Urogenital Mobilization

*Total urogenital mobilization (TUM)*, described by Peña in 1997 (4), entails complete circumferential dissection of the intact urogenital sinus, urethra, and vagina from the pubis (Fig. 117.6A). This was originally proposed for cloacal anomalies but has since been often applied to those with a urogenital sinus only. TUM allows the midlevel vagina to be moved to the perineum easily, thus avoiding a *pull-through* vaginoplasty, and while the high-confluence vagina may still require a *pull-through* vaginoplasty, the separation of the vagina from the urinary tract is much more easily performed.

A

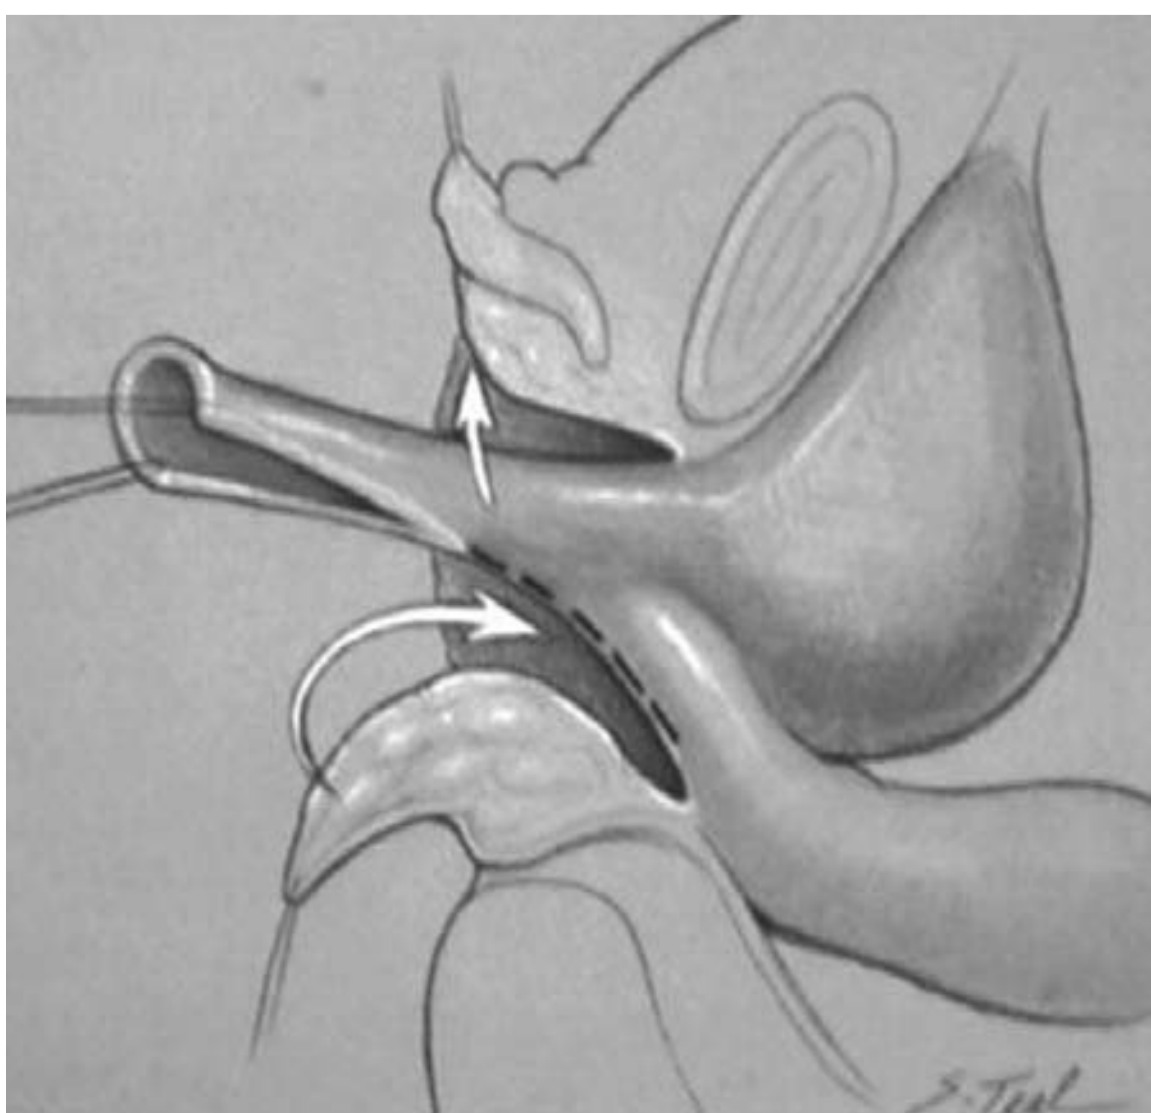

B

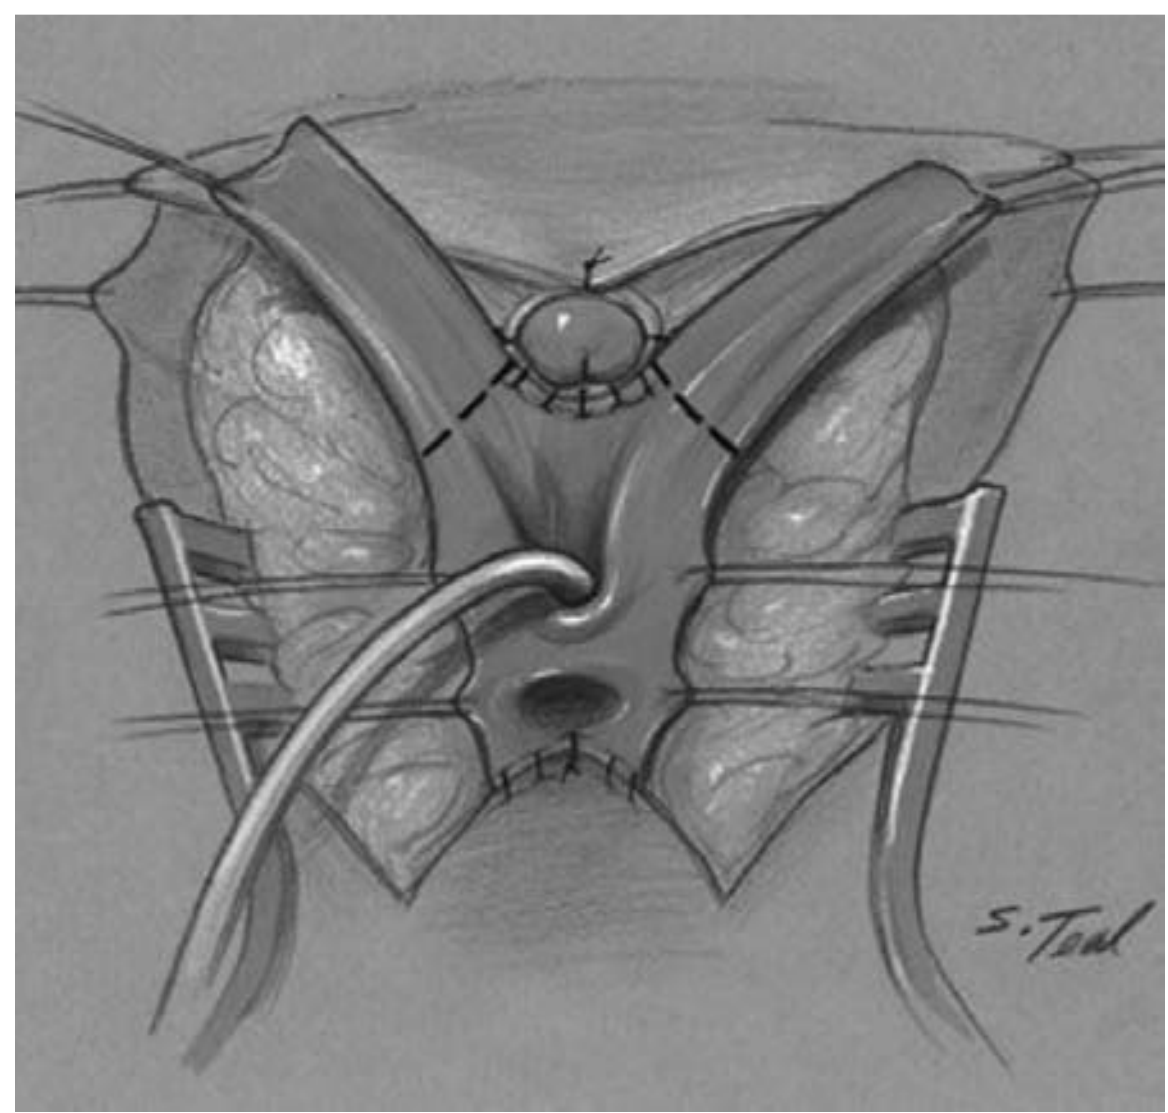

**FIGURE 117.6** **A:** Total urogenital mobilization. Complete circumferential mobilization of the intact sinus with the dissection well above the pubis. **B:** Partial urogenital mobilization. The anterior dissection ceases at the pubourethral ligament.

The initial incisions are similar to those described previously, but the urogenital sinus is mobilized intact off the corporal bodies and is carried out between their bifurcation through the pubourethral ligament. At this time the dissection is continued posteriorly in the midline, separating the rectum from the posterior wall of the vagina. The Fogarty balloon within the vagina is palpated, and an incision is made into the vaginal wall posteriorly near the confluence. If the vagina reaches the perineum, no further dissection is performed and instead partial urogenital mobilization (PUM) is used. In Peña's original description the mobilized sinus was amputated, but Rink et al.

(5) have shown that this is important tissue to save for the reconstruction. If the vagina does not reach the perineum, then the sinus is mobilized between the corporal bifurcation and off the pubis (TUM). When these avascular attachments from the pubis are divided, the sinus moves toward the perineum. If the sinus is near the perineum, we still believe a flap vaginoplasty should be performed to prevent vaginal stenosis. The redundant sinus is then split ventrally to create a mucosa-lined vestibule (Fig. 117.7A and B) (6). Recently, we described splitting the sinus laterally to create a posterior vaginal wall (Fig. 117.8) (7). This is also a form of *flap vaginoplasty*, but

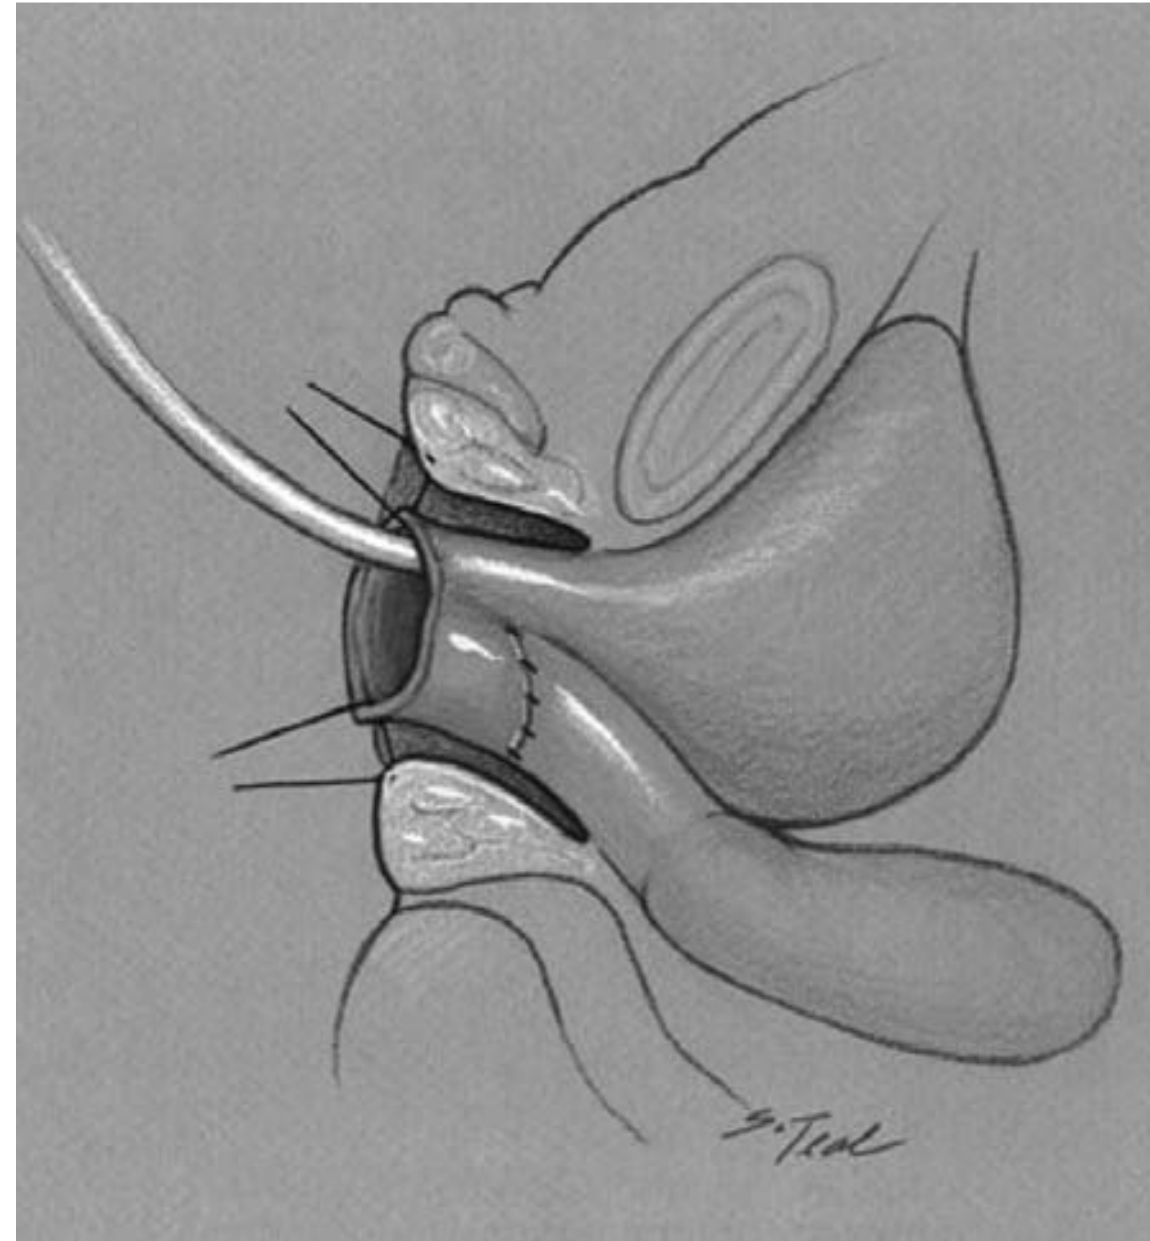

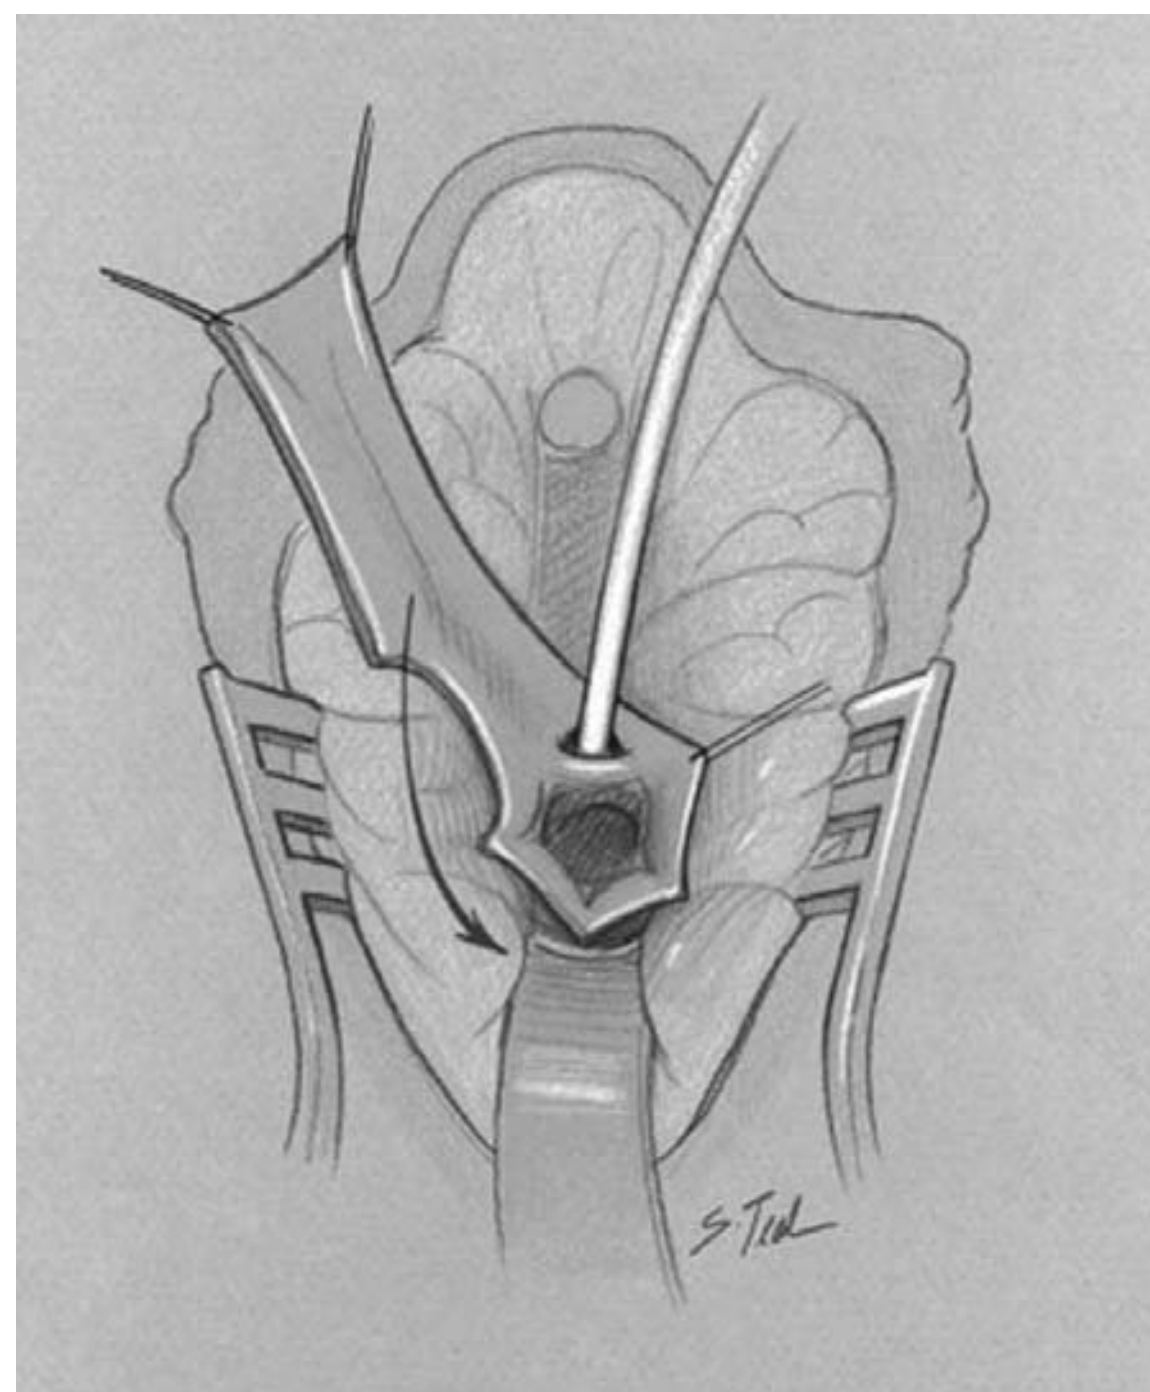

A

B

**FIGURE 117.7** Low confluence with flap vaginoplasty. **A:** The mobilized sinus is opened on the ventral side. **B:** The opened sinus provides a mucosal-lined vestibule.

**FIGURE 117.8** The mobilized sinus is split laterally to allow rotation of the flap to create a posterior vaginal wall.

the posterior flap is native urogenital tissue rather than perineal skin. If the vagina is high following the TUM, then the vagina is separated from the sinus as described previously for a pull-through vaginoplasty. This vaginal separation is again more easily achieved by placing the patient prone over chest rolls. The mobilized sinus is split dorsally, and the opened sinus is rotated to create an anterior vaginal wall (Fig. 117.9).

Due to concerns for potential sphincteric injury from aggressive retropubic dissection, Rink et al. (8) described *partial urogenital mobilization* (PUM). In the PUM, the dissection anteriorly ceases at the pubourethral ligament (Fig. 117.6B). We believe this procedure is less risky yet still allows use of the

mobilized tissue for improved cosmesis and function as described previously for the TUM. In the majority of urogenital sinus anomalies, PUM is adequate to exteriorize the vagina when combined with a flap vaginoplasty.

---

## OUTCOMES

---

This is a time of widespread evaluation of all aspects of feminizing genitoplasty. There is little agreement on any component, including the timing of the procedure or even the necessity of some aspects, such as clitoroplasty. While virtually

**FIGURE 117.9** The sinus is opened dorsally for a pull-through vaginoplasty and rotated to create an anterior vaginal wall.

all surgeons believe they achieve excellent cosmetic results, blinded studies have questioned this. Unfortunately, there are few data available on long-term results from current surgical techniques. There is debate about both the psychological aspects of having genital surgery and the psychological aspects of not having the surgery and growing up with genital ambiguity. Clitoroplasty is controversial, as no one knows if it is a clinical problem to have an enlarged clitoris, and there remains a concern that even modern techniques may alter sensation. Should the parents make the decision about early surgery, or should it be postponed until the patient can decide? If the latter, then what are the social implications of growing up with ambiguous genitalia? Virtually all agree that the vagina must be exposed to allow egress of menstrual fluid, but when this should be done remains controversial. Early TUM results are promising, and incontinence does not seem to be a problem in children who are otherwise neuroanatomically normal. And while the procedure is technically easier, the long-term results may show that sphincteric injury with incontinence or stress incontinence from moving the bladder neck

inferiorly occurs with unacceptable frequency. Early PUM results are similarly promising. All neurologically normal children older than 2 who have undergone PUM in our hands are dry and voiding (9). Long-term data are lacking, of course, as these techniques are relatively new and have been applied mainly to young girls. These issues are complex and will only be solved by long-term prospective multi-institutional studies. We believe that virtually all CAH patients can be treated with a PUM technique, avoiding the more aggressive TUM.

From an anatomic and cosmetic standpoint, surgical reconstruction of cloacal anomalies is now satisfactory in the majority of cases. Unfortunately, the functional success of the urinary and rectal elements of the reconstruction also depends upon sacral nerve function and the quality and innervation of the sphincteric complexes. The bladder neck and intrinsic sphincter may be inherently deficient with a high confluence. No natural plane exists between the bladder neck or trigone and the vagina, and therefore the continence mechanism may be further compromised as the vagina is dissected off the bladder neck. The external sphincter may also be congenitally deficient or may be injured during reconstruction. Due to abnormal sacral nerve function, these patients may require intermittent catheterization or further reconstruction, such as outlet resistance enhancement or augmentation cystoplasty, to achieve continence (9).

Outcomes of vaginoplasty in cloacal anomalies are as reported with the high-confluence urogenital sinus. Total urogenital mobilization appears to reduce the incidence of stenosis and the need for a pull-through procedure, although long-term pubertal follow-up is pending. Introital revision may be required at puberty after vaginoplasty in infancy.

One of the most important issues in functional outcome after repair of a persistent cloaca is the long-term preservation of renal function. Many of these children have congenital renal dysplasia related to vesicoureteral reflux and/or in utero infravesical urinary tract obstruction. Persistent postnatal hydronephrosis should be aggressively addressed with diversion if necessary. Chronic renal failure may occur even in the fortunate subset of patients who achieve a normal nadir creatinine in infancy (10). This is usually due to abnormal lower-urinary-tract dynamics. Therefore, even after apparently successful lower-urinary-tract reconstruction, these patients require urodynamic evaluation and vigilant monitoring to prevent upper-urinary-tract deterioration due to silent bladder dysfunction.

# CHAPTER 118 ■ SURGERY TO CORRECT AMBIGUOUS GENITALIA (46XX DISORDER OF SEXUAL DEVELOPMENT)

ANTHONY J. CASALE

*Ambiguous genitalia* and *intersex* are historical terms used to describe a congenital condition where the appearance of the genitalia is neither classically male nor female. Modern nomenclature has been proposed to replace the old, and this group of disorders is now described as disorders of sexual development (DSD). The condition affects both external genitalia (phallus, labia, scrotum, and introitus) and internal reproductive structures (vagina, urethra, urogenital sinus). In these cases there is usually a conflict between the genetic sex, gonadal sex, and apparent gender as based on genital appearance. The genital appearance may be gender neutral and give little indication of the genetic or gonadal sex. On the other hand, the genitalia may have an appearance more consistent with the opposite gender, as with females with severely virilized congenital adrenal hyperplasia (CAH). When patients with these conflicts reach adulthood they face significant hurdles in both reproduction and sexual activity.

The historical goal of surgery for ambiguous genitalia has been to provide the child with genitalia that have the appearance of and are functional as either male or female gender and that are consistent with the genetic and gonadal sex when possible. *Feminizing genitoplasty* is the term used to describe a series of surgical procedures designed to create classic female genitalia from a truly ambiguous genital state. This surgery has usually been applied to female patients with partially masculinized genitalia, and in those cases surgery brings the genetic, gonadal, and genital sex back into alignment. Rarely, this surgery has been used to reassign the gender of genetic and gonadal male patients with what was felt to be inadequate phallic tissue to the female gender. It is this later group of patients who have had more difficulties with gender dissatisfaction, and their experience has brought the principle of gender assignment under question. This chapter will discuss the technical aspects of feminizing genitoplasty.

Society dictates that the appearance of the infant's genitals and therefore its apparent gender is the subject of great and urgent interest for the immediate and extended family and friends, making ambiguous genitalia a cause of intense concern and confusion for all. It is this powerful interest that has driven physicians and families to treat the condition as an emergency, even though there are often no immediate health risks. The historical approach to this issue has been to assign gender based on several factors, including the potential for reproduction, the technical limits of surgical reconstruction (i.e., our limited ability to create a male phallus without adequate corpora), and the belief that gender was determined by genital

appearance and role assignment in childhood. The validity of this approach has recently been questioned and is the subject of widespread study at this time. At present, intrauterine and postpartum androgen exposure of the central nervous system seems to be the dominant factor in determining gender identity. Exactly how to reliably measure the gender of the brain remains an unsolved question.

Genital ambiguity is a result of an abnormality in sexual determination resulting from a defect in genetic, gonadal, or genital tissue differentiation and has been classified historically into four categories: female pseudohermaphrodite (now called 46XX DSD), male pseudohermaphrodite (46XY DSD), mixed gonadal dysgenesis (sex chromosome DSD), and true hermaphrodite (ovotesticular DSD). Female genital reconstruction, also called feminizing genitoplasty, is restricted to female pseudohermaphrodite (46XX DSD), mixed gonadal dysgenesis (sex chromosome DSD), and true hermaphrodite (ovotesticular DSD) individuals who have the potential to have normal female sexual function. CAH is a form of 46XY DSD and is by far the most common condition causing ambiguous genitalia. CAH is responsible for over 70% of cases of ambiguous genitalia and the vast majority of patients treated with feminizing genitoplasty.

Candidates for feminizing genitoplasty have two distinct problems: (i) the fusion of their internal reproductive system with the urinary tract as a urogenital (UG) sinus with a single external orifice and (ii) the virilization of the external genitalia, with fused labioscrotal folds and clitoral enlargement. The internal anatomy can cause problems by pooling of urine within the vagina and uterus and inadequate vaginal drainage for secretions and menses. There is no adequate external vaginal orifice for sexual intercourse. Infants with a UG sinus may present with urinary infection or an abdominal mass from a poorly drained vagina or uterus. Today many present on prenatal ultrasound screening that reveals a dilated bladder, vagina, or upper urinary tract. The external genitalia are a concern primarily for sexual function and the potential psychological damage that may result from gender ambiguity.

There have been great advances in the surgical technique of feminizing genitoplasty over the past half-century, resulting in more normal appearance and sexual function. Despite apparently successful surgery, some adult patients have expressed profound dissatisfaction with their childhood genital reconstruction and gender. Because of this concern, more long-term outcome studies that include all patients with these rare conditions must be undertaken in order to understand the most

**FIGURE 118.1** This intersex female patient demonstrates labial/scrotal fusion and a hypertrophied phallus with a distal urogenital sinus opening.

appropriate management of these complex patients. The challenge of these studies is to make them comprehensive in surveying medical, sexual, and psychological health.

The first task for the physician faced with a child with intersex is to correctly diagnose the underlying condition responsible for the appearance of the genitalia. A team including a pediatric urologist, pediatric endocrinologist, neonatologist, and either pediatric psychologist or psychiatrist provides the best approach for this complex process.

The first step in diagnosis is a thorough physical examination. The initial caregivers in the nursery are usually alerted to the possibility of gender ambiguity if the phallus is small or curved and if the labioscrotal folds are partially fused (Fig. 118.1). The pediatric urologist should then document the length and diameter of the phallus and the position and number of external perineal openings, including the position of any potential urogenital orifices as well as the rectum. The state of fusion of the labioscrotal folds and their location are important, as is the presence or absence of palpable gonads. The presence of a palpable gonad almost always is consistent with male gender. Hyperpigmentation of the labioscrotal skin is common in cases of CAH. The blood pressure should be measured carefully because of the threat of hypertension with CAH.

Chromosomal studies should be sent immediately. In the immediate newborn period the presence of functioning testicular tissue can be determined by measuring serum testosterone, which is elevated in the first few days of life. CAH is diagnosed by finding elevated plasma levels of 17-hydroxyprogesterone and androstenedione and urine levels of pregnanetriol and 17-ketosteroids. CAH can be a life-threatening condition because adrenal insufficiency commonly causes salt wasting leading to hyponatremia and hyperkalemia and could result in lethargy, vomiting, and eventual hypotension.

Imaging studies of the infant should include a pelvic ultrasound looking for the presence of a uterus and retrograde injection of contrast into the UG sinus (genitogram) to identify the presence of a vagina and uterus. The uterus can usually be

**FIGURE 118.2** Pelvic ultrasound demonstrates the uterus in the midline position posterior to the urinary bladder.

identified on pelvic ultrasound of the newborn as a 1-cm solid midline mass just posterior to the bladder (Fig. 118.2). The uterus can often be identified on a genitogram with a cervical impression outlined by the contrast in the vagina.

During the initial investigation the family is advised to delay naming the child and reporting the child's gender to others until the gender is established, and to state only that the child had some developmental problems that need to be investigated. It is during this period that the gender assignment team should carefully educate and counsel the family about the nature of their child's problem and the limitations and potential inherent in the exact condition. The family should be prepared to face the options of therapy, including reconstructive surgery, so that when the diagnosis is clear they can make an informed decision. This is a difficult and often painful process for both family and team, and it is critical that every option be explored and discussed with the family and that this counseling is documented in the medical record.

There are actually two decisions to be made by the parents: the gender that they will raise the child and whether to have reconstructive surgery. Gender decisions have always been considered urgent, while surgical reconstruction decisions may be made later as long as there is not a health concern because of inadequate drainage of urine. The medical team must explain the surgical options, including advantages, risks, and potential complications of delaying surgery, performing the external genital reconstruction (clitoroplasty), and performing the internal genital reconstruction (urogenital sinus repair).

---

## TIMING OF SURGERY

---

Once the decision for feminizing genitoplasty has been made, the timing of the procedure is of some importance. In cases of CAH, glucocorticoid and mineralocorticoid replacement therapy will diminish androgen production by the adrenal and lead to partial reversal of the clitoral hypertrophy. For this reason the external genital surgery should be delayed until at least 6 months of age. In some cases hormone replacement therapy decreases the size of the clitoris so that surgery on this structure is not necessary. Since most complaints about

childhood genital surgery involve dissatisfaction with clitoral reconstruction, most surgeons have currently limited this surgery to the most extreme cases of enlargement and with the family's clear support. Some surgeons have refused to perform clitoral reconstructive surgery altogether. The decision about clitoral reconstruction is the most difficult issue to face in the care of these children and must be considered carefully by the family and medical team.

Some surgeons prefer to delay reconstruction of the internal structures until adolescence if the child does not have problems with urine retention and urinary tract infections because historically patients who had reconstruction early in life might require a secondary procedure at adolescence to correct vaginal stenosis. On the other hand, those children who have early reconstruction need only dilations or simple revisions of the vagina at adolescence, in contrast to the child who delays the major reconstruction until later in life. We prefer to do a complete reconstruction at 6 months of age and explain to the family that a second minor procedure may be needed later.

---

## PREOPERATIVE EVALUATION

---

Each child suspected to have ambiguous genitalia should have a complete anatomic, endocrine, and genetic evaluation. A karyotype is necessary not only to determine the correct genetic sex but to look for other chromosomal errors that may be present. A complete endocrine evaluation should focus on potential gonadal function as well as concerns related to the endocrinopathy of CAH.

A comprehensive definition of the anatomy is imperative in planning for and accomplishing the reconstruction. The upper urinary tract should be imaged with ultrasound and, if the kidneys are not normal, a diuretic (Lasix) renal scan. The lower urinary tract should be imaged with a retrograde genitogram (Fig. 118.3). This is performed by placing a catheter in

**FIGURE 118.3** Genitogram demonstrates confluence of the urethra anteriorly and vagina posteriorly. Note cervical impression at the apex of the vagina and contrast within the cervix.

the most distal portion of the UG sinus and injecting contrast while imaging from the anterior, lateral, and oblique perspectives. This gives the surgeon important information about the length of the UG sinus, the point of confluence of the vagina and urethra, and their relative lengths and position within the pelvis. The level of this confluence, either high (UG sinus over 3 cm) or low (UG sinus <3 cm), ultimately determines the surgical approach. Further imaging of the pelvic organs may be necessary in complex cases and can be done with magnetic resonance imaging or computerized tomographic scanning with good visualization.

Finally, an examination under anesthesia is needed, including cystoscopy and vaginoscopy. It is often easier to measure the length of the UG sinus and determine the height of the confluence with the scope than with imaging. The length of the UG sinus can be measured by placing the tip of the scope at the point of confluence and marking the scope at the level of the external meatus. When the scope is withdrawn, the length of the UG sinus is estimated by measuring the distance from the mark on the barrel to the tip of the scope. These measurements of the UG sinus, vagina, and urethra, along with the position of the confluence of all three, are important in order to plan what techniques may be necessary for repair.

---

## SURGICAL POSITIONING

---

Most of the surgery for ambiguous genitalia can be performed in the lithotomy position. The lithotomy position is ideal for the clitoroplasty and reconstruction of the labia and introitus. The lithotomy position, however, does not always provide adequate exposure of the higher forms of urogenital sinus. Hendren and Atala (1), Peña (2), and Rink and Adams (3) have demonstrated the superior exposure provided by the posterior prone approach to the pelvic organs. We follow Hendren's recommendations to prepare the patient circumferentially while applying sterile wrapping to the lower legs to allow the patient to be turned from the lithotomy to the prone position as necessary during the operation. It is wise to have all positioning options available for this challenging surgery. Surgery usually begins in the lithotomy position and the clitoroplasty is done first, followed by the vaginoplasty, and finally the labioplasty.

---

## SURGICAL TECHNIQUE

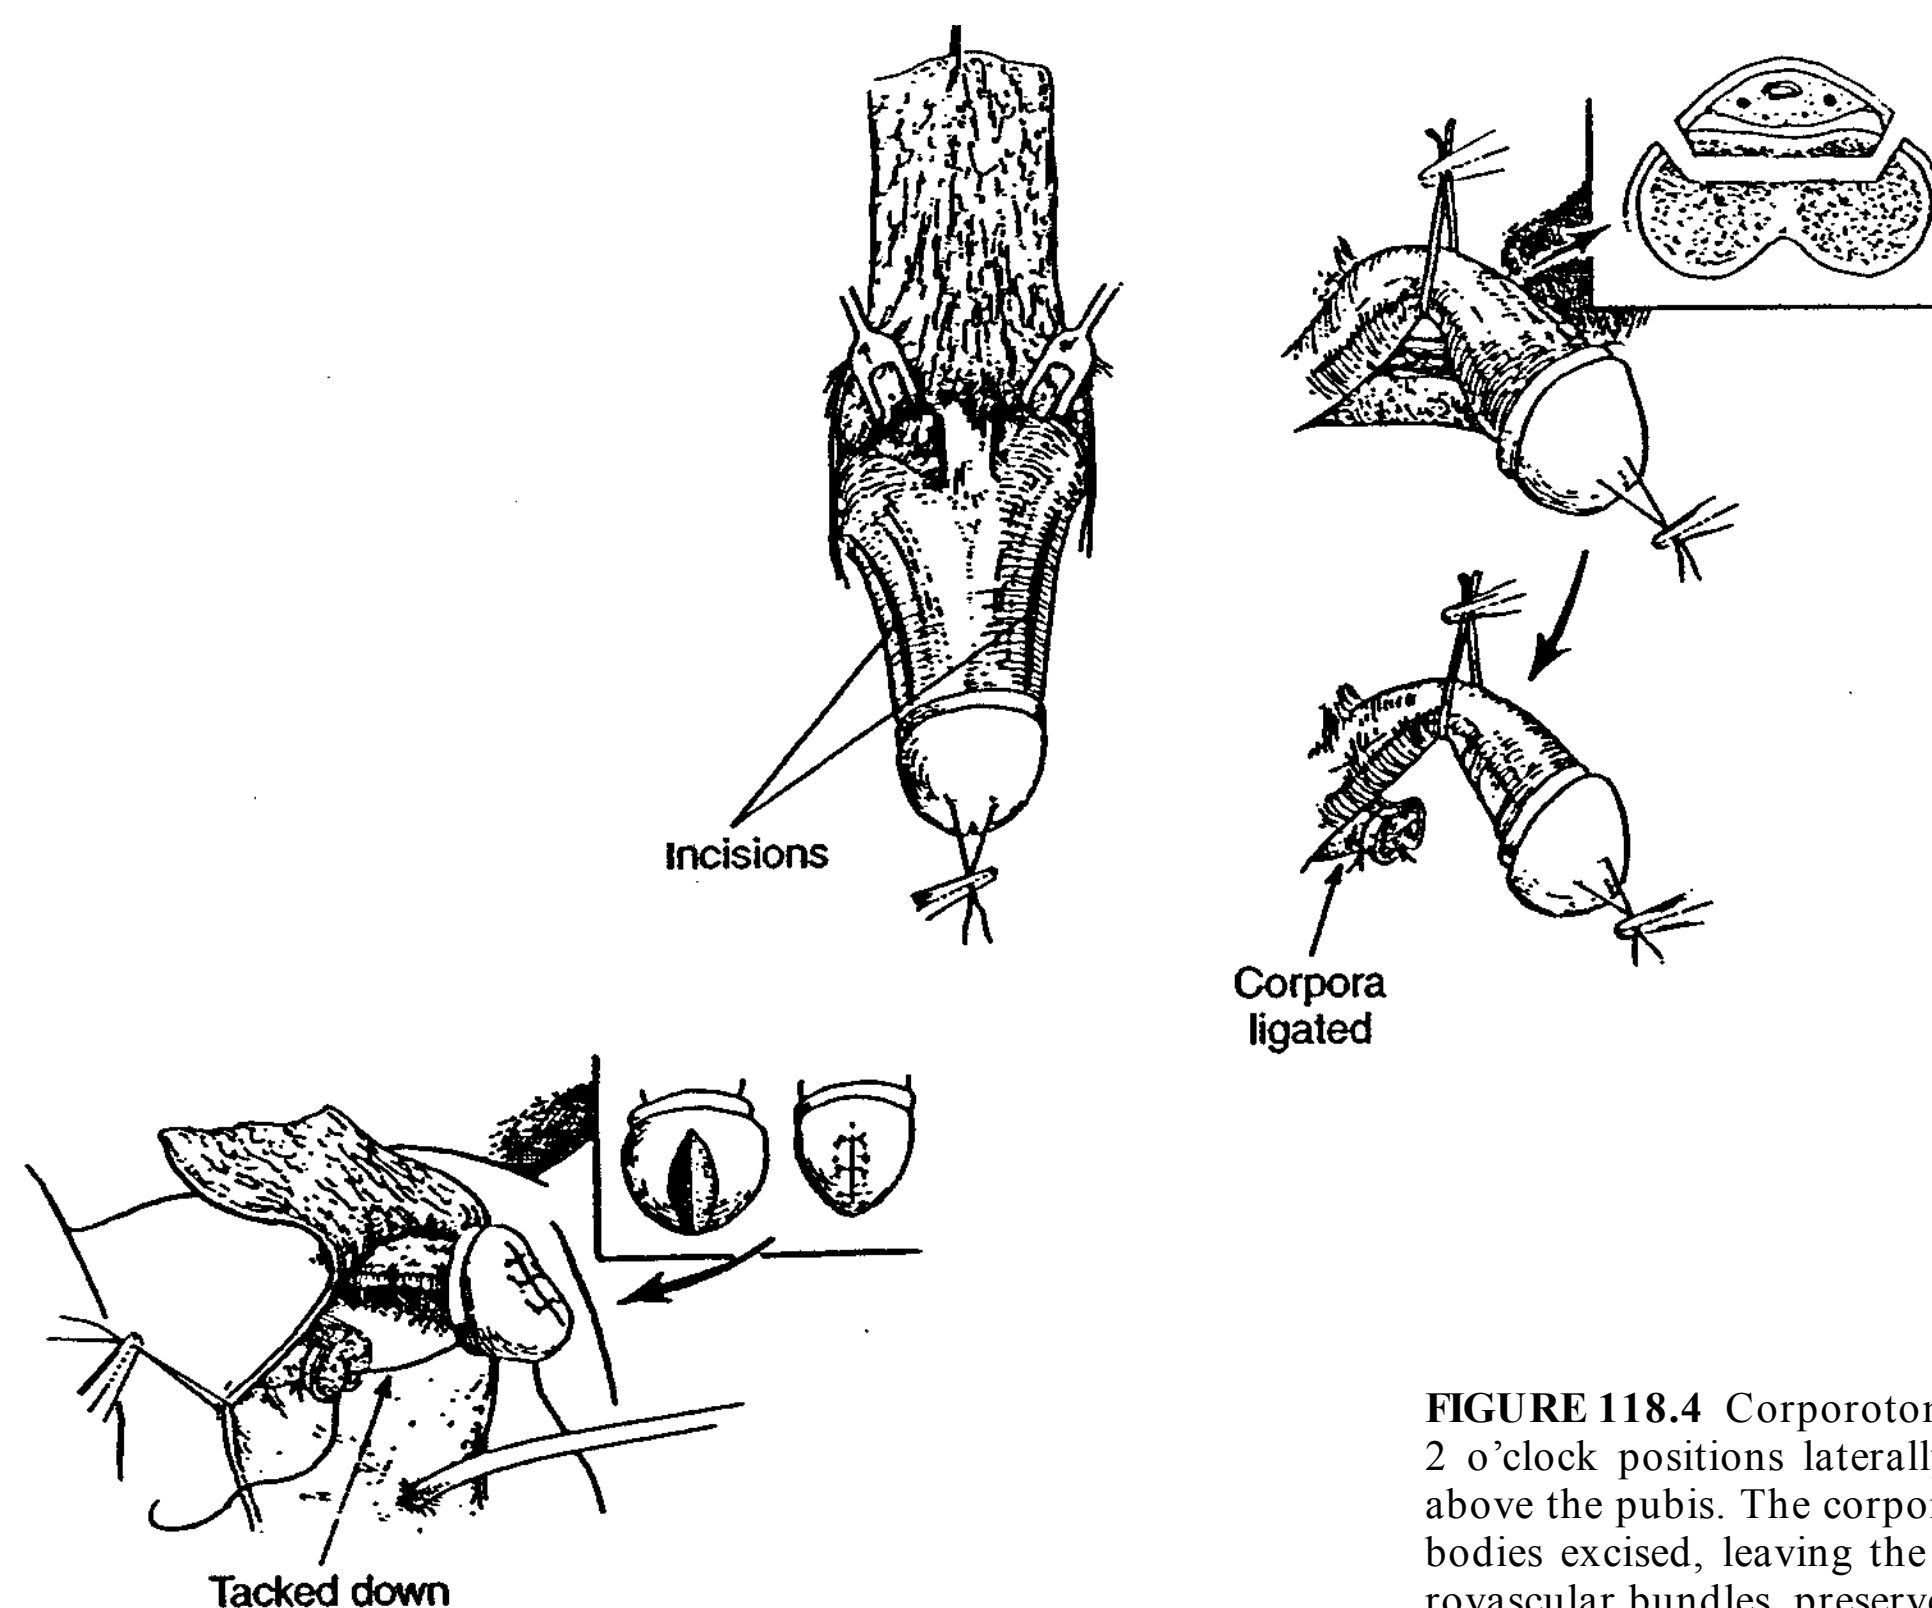

---

### Repair of the External Genitalia

---

#### Clitoroplasty

Once the decision has been made to surgically reconstruct the clitoris, the goal of clitoroplasty is to reduce the size of the enlarged clitoris to one that is within the range of normal for females. Modern clitoroplasty developed after Mollard et al. (4) realized that the erectile tissue of the corpora was primarily responsible for the large size of the organ and that it caused problems during sexual engorgement. The glans clitoris must be preserved for sensation, but the corpora should be shortened. Mollard mobilized the neurovascular bundle that supplied the glans and excised the corpora from the level of their union at the pubis to the distal tip. He then sewed the glans

**FIGURE 118.4** Corporotomy incisions are extended from the 10 and 2 o'clock positions laterally from just below the corona to 0.5 cm above the pubis. The corporal bodies are ligated at their base and the bodies excised, leaving the dorsal strip of fascia, including the neurovascular bundles, preserved with the glans.

back to the stumps of the corpora cavernosa, resulting in a functional clitoris that could become engorged to an appropriate size and was sensate. The dissection of the neurovascular bundle is somewhat difficult and can potentially lead to compromise of the nerves or infarction, so we prefer a variant of the Mollard procedure that was described by Gonzales and Fernandes (5).

A circumferential incision is made on the clitoris just proximal to the coronal sulcus and the clitoris is degloved from skin and subcutaneous tissue. The urethral plate and rudimentary corpus spongiosum may be divided distally and dissected with the subcutaneous tissue or just mobilized from the corpora cavernosa while leaving it attached both proximally and distally. We prefer to divide the urethral plate from the glans during this dissection. Incisions are made in the tunica albuginea of the corpora at the 2 and 10 o'clock positions using needle-point electrocautery. These incisions are extended and joined across the ventral aspect of the corpora at the subcoronal level distally and 0.5 cm above the pubis proximally (Fig. 118.4). The dorsal tunica albuginea (including the enclosed neurovascular bundle) is dissected from the erectile tissue and remaining tunica of the corpora. The erectile tissue bodies and their ventral and lateral fascia can be dissected from the dorsal fascia and excised. A 4-0 polyglycolic acid suture can be used to ligate each corporal body at its base. The rim of fascia on the glans can be sewn to the fascia on the stumps of the corpora with 4-0 suture to reseat the glans and stabilize it. The dorsal fascia, which contains the neurovascular bundle, is allowed to fold under the skin cranial to the glans. The urethral plate, which was previously separated from the glans, can now be shortened and partially split in the midline to flatten the introitus and to shorten the distance from the vagina to the clitoris (Fig. 118.5).

**FIGURE 118.5** The urethral plate is used to shorten the distance between the clitoris and the vagina, producing a more normal introitus.

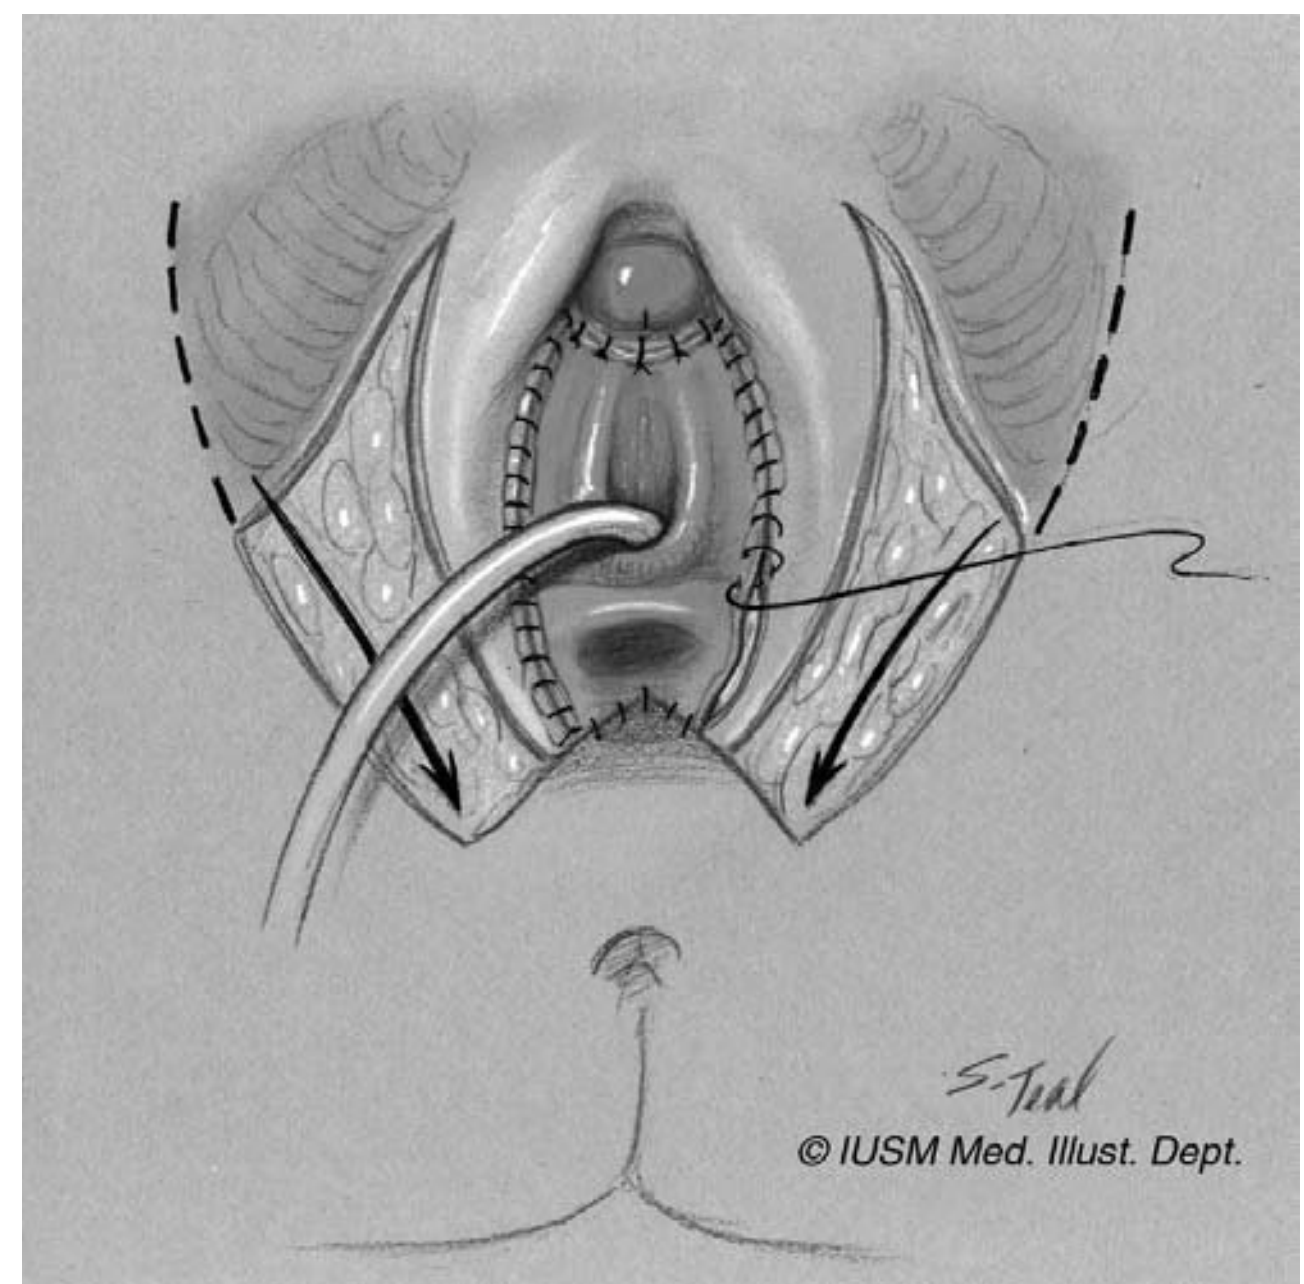

The glans clitoris is often quite large, and several procedures have been described to reduce its size. We have preferred not to decrease the overall size of the glans but instead to conceal some of the dorsal glans with the glans hood. A small patch of the dorsal glans epithelium at the base can be excised, leaving the erectile tissue intact, and the glans hood can be sewn to this area and allowed to fold over the remainder of the glans. This leaves the glans with its full erectile capability, leaves it accessible, and covers it appropriately with a skin hood.

### Labioplasty

The goal of labioplasty is to create a normal-appearing and normal-functioning female perineum and introitus. The shaft skin and dorsal prepuce of the clitoris can be utilized to form the labia minora and to fashion a clitoral hood. The original skin incision had degloved the clitoris and left all skin based on the dorsal pedicle. This skin can then be split in the midline for approximately two thirds of its length (Fig. 118.6). At the proximal end of the incision a transverse incision is made and curved proximally at each end for a few millimeters to develop a flap that is used for the clitoral hood. The two long sides of the shaft skin are folded to form long, thin, vertical two-sided flaps that will form the labia minora. The horizontal central flap is folded under itself to form a two-sided hood for the clitoris. The clitoral hood is sewn to the base of the dorsal aspect of the clitoris and around each side to the approximate 3 and 9 o'clock positions. Each of the three flaps is sewn into shape using 5-0 absorbable suture.

**FIGURE 118.6** The dorsal preputial skin is split in the midline and reconfigured to create a clitoral hood.

**FIGURE 118.7** The dorsal preputial skin flaps are mobilized laterally and advanced toward the vagina. There, they are sewn to the lateral edge of the urethral plate as a labial flap. The labioscrotal folds are then sewn to the lateral edge of the labia minora to form labia majora.

The labia minora are created with the two lateral strips of shaft skin. They are dissected on their pedicles to allow them to extend to the vagina or midperineum (Fig. 118.7). They are then sewn to the lateral aspect of the urethral plate, which now lies in the midline between vagina and clitoris. A three-way stitch is used to fasten the labia minora to the introitus and to narrow their base so that they maintain their character and their base does not spread and flatten. The labioscrotal folds are then sewn to the labia minora to form the labia majora. All sutures are absorbable 4-0 and 5-0, and while some suture lines can be created using a running 5-0 suture, any point of potential tension, such as at corners, should be fixed with an interrupted 4-0 skin suture.

## Repair of the Urogenital Sinus

### Low-Confluence Urogenital Sinus

The goal of urogenital sinus reconstruction is to create separate functional openings for the urinary and genital tracts. The low-confluence UG sinus has a long urethra and vagina that join near the perineal surface, resulting in a short common channel or sinus (Fig. 118.8). There are two good options for managing these anomalies. John Lattimer introduced the posterior flap vaginoplasty in 1964, and it is still a useful technique.

A U-shaped incision is made in the perineum with the open end facing caudally and the proximal point at the orifice of the UG sinus. This incision isolates a posteriorly based skin flap (Fig. 118.9). This flap was originally designed to be wide-based but it needs to be no wider than half of the circumference of the proposed vagina (a 1- to 1.5-cm flap in infants). The excellent blood supply of the tissue allows a narrower flap, which results in a more normally functional and cosmetic introitus.

**FIGURE 118.8** This illustration demonstrates a low-confluence urogenital sinus with a short common urogenital sinus channel draining the urinary bladder and vagina.

Once the skin flap is isolated, it is mobilized from the deeper tissue and folded back to expose the caudal wall of the UG sinus (Fig. 118.10). A fine-tipped hemostat can be placed in the orifice and the sinus split using electrocautery in the midline to the level that exposes the confluence of the sinus vagina and urethra. The vagina is split as deep as the apex of the posterior skin flap will reach. With a catheter in the urethra, the posterior skin flap is sewn in position starting at the apex and using interrupted absorbable 4-0 sutures. This advancement of the flap into the sinus and vagina both widens the introitus and the vagina and reorients the vagina into a more vertical position, improving passive drainage (Fig. 118.11).

The other option for the low UG sinus is a limited total urogenital mobilization (TUM) technique as described originally by Peña (2). This is a relatively simple technique and is initiated by a circumferential incision around the UG sinus

orifice (Fig. 118.12). This dissection is continued around the sinus while providing constant traction on the sinus with multiple stay sutures. The entire sinus vagina and urethra can then be mobilized caudally, delivering the confluence of the urethra, vagina, and sinus to the level of the perineal skin (Fig. 118.13). Peña originally described this technique for use in cloacal reconstruction and stressed that the dissection must extend high in the pelvis, but this is not always necessary in the low-confluence UG sinus. The dissection can be considered complete when the confluence is at the level of the perineum.

If the vagina and urethra reach the appropriate level and are wide enough to be functional, then the distal UG sinus can be amputated and discarded (Fig. 118.14). If the vagina is too narrow, the posterior wall of the vagina can be split and a posteriorly based perineal skin flap can be inserted to widen it.

### High-Confluence UG Sinus

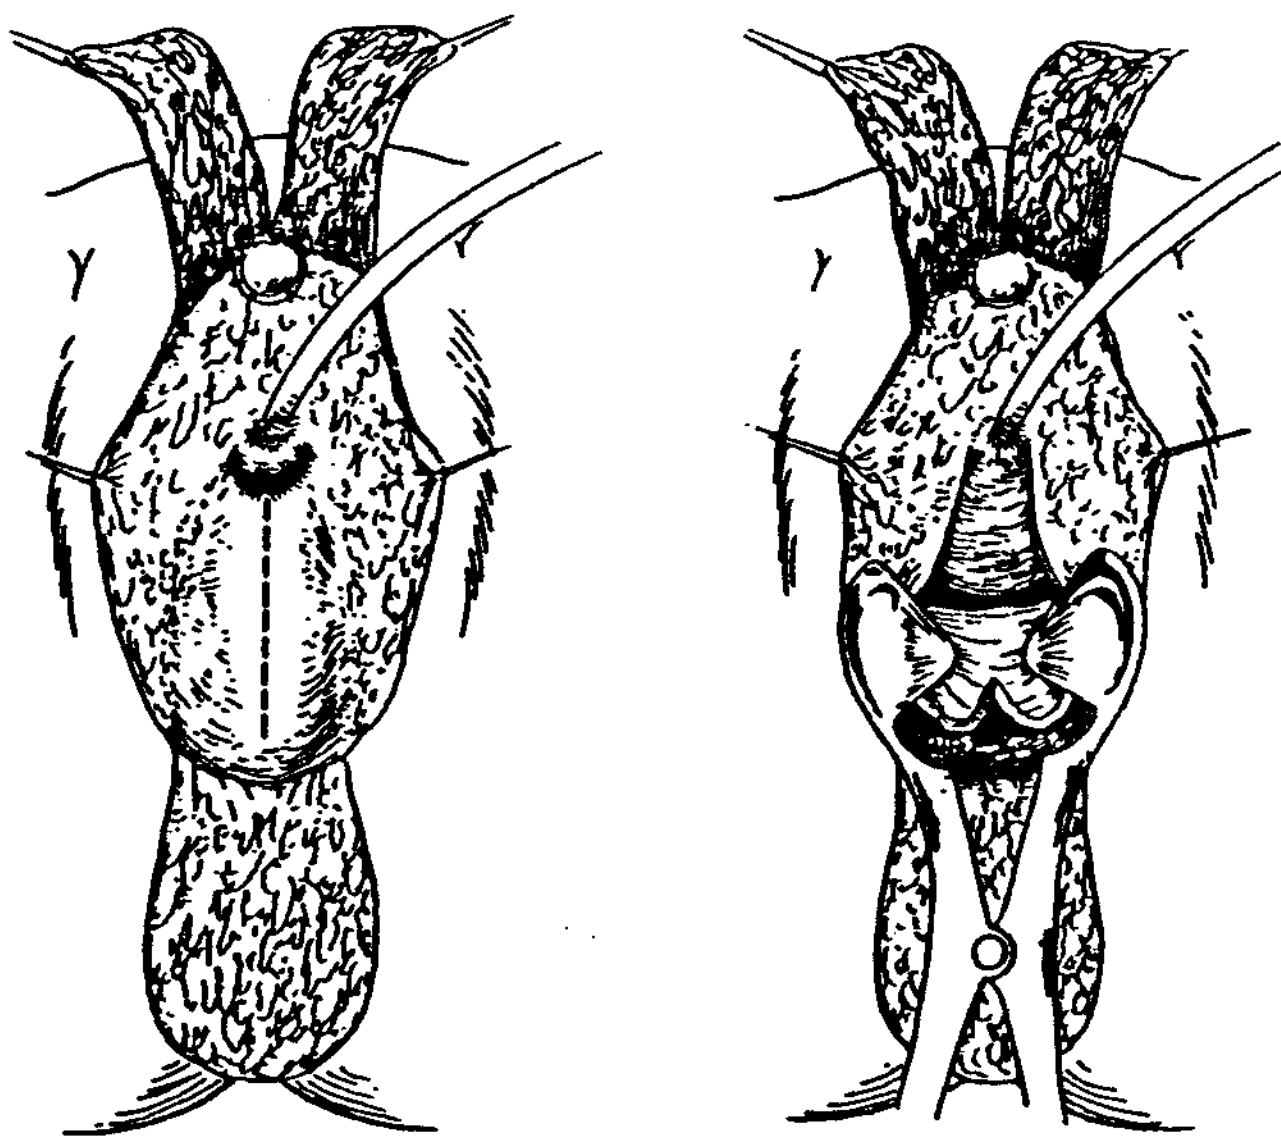

The high-confluence UG sinus with a short urethra and vagina and a long common urogenital sinus channel is much more of a challenge to reconstruct because of the position of the confluence high within the pelvis and the relative lack of suitable tissue for reconstruction. In this condition the urethra and vagina are short and tethered far from the introitus by soft tissue attachments within the pelvis.

Early attempts to repair these children were made using techniques that were more suitable for low-confluence variants, and this fact may explain many of the poor surgical results now apparent in older patients. The posterior flap repair, which was very useful for less severe cases, did not provide enough length to reach the high confluence and left the child with a short, hypospadiac urethra and inadequate tissue to reconstruct the vagina to the introitus. Hendren pioneered the dissection separating the bladder and vagina, allowing the vagina to be advanced toward the perineum. This dissection between the urinary and genital tract is very difficult and can result in vesicovaginal fistula and bladder dysfunction. Even with the vagina completely dissected from the posterior bladder, it often would not reach the perineum, and the gap was bridged with complex skin flaps that were sometimes less than ideal.

Peña's TUM procedure is a perineal-based approach that is based on circumferential dissection of the UG sinus, vagina,

**FIGURE 118.9** Inverted-U incision produces a posterior-based perineal skin flap used to reconstruct the posterior wall of the vagina.

**FIGURE 118.10** The caudal portion of the urogenital sinus is exposed by deflecting the perineal skin flap inferiorly. The sinus can then be mobilized intact or split in the midline ventrally to the level of the vagina in a very low-confluence case.

and urethra and advancement of these structures toward the perineal surface. This approach leaves the child with a urethra of normal length by lowering the bladder and vagina in the pelvis. The TUM also lowers the proximal vagina and uterus in the pelvis, allowing the vagina to be reconstructed with less outside tissue. The TUM has become an important tool in the reconstruction of children with UG sinus, particularly those with a high confluence.

The initial circumferential dissection around the UG sinus is performed just as with the lower-confluence variant. Multiple stay sutures are placed and the dissection can be performed in the lithotomy position. Unlike the lower-confluence UG sinus, those who have a high confluence need much more extensive dissection to allow the vagina to come close enough to the perineum for satisfactory reconstruction. The dissection usually must reach the level of the pubis both anterior and posterior to the UG sinus.

If the vagina and urethra reach the appropriate level and are wide enough to be functional, then the distal UG sinus can be amputated and discarded (Fig 118.14). This is usually not the case, however, and the distal vagina is usually too narrow. In this case the vagina can be divided from the sinus, dissected away from the urethra and bladder, and split in the midline dorsally. The mobilized sinus can also then be split in the midline dorsally and the sinus can be folded back on itself ventrally and advanced into the vagina as a flap to widen the vagina. If the vagina is still too narrow, the posterior vaginal wall can be split as well and a posteriorly based perineal skin flap can be inserted (Fig. 118.11). The TUM has allowed UG sinus reconstruction and minimized the need to perform the difficult dissection between bladder and vagina.

We prefer to approach the child with high UG sinus as an individual who may need various techniques for successful repair. The options are TUM, mobilization of the vagina from the urethra/bladder, and various flaps to augment the vagina from either the UG sinus tissue or perineal skin. The less severe cases may need only TUM and a posterior skin flap, while the most severe cases need all techniques in order to have a successful outcome.

Dressing and drains are strictly up to the surgeon and the difficulty of the procedure. A simple genitoplasty may need only antibiotic ointment or, at most, overnight catheter drainage. More complex procedures always merit catheter drainage of the bladder, and complex vaginoplasties may be aided with a vaginal Penrose drain or in some cases a pressure dressing of fluffed gauze and elastic tape crisscrossing the perineum. Some surgeons believe in keeping these patients in bed and relatively immobile for 48 hours, but we often allow them to move about at will and to be held by their mother immediately after surgery.

---

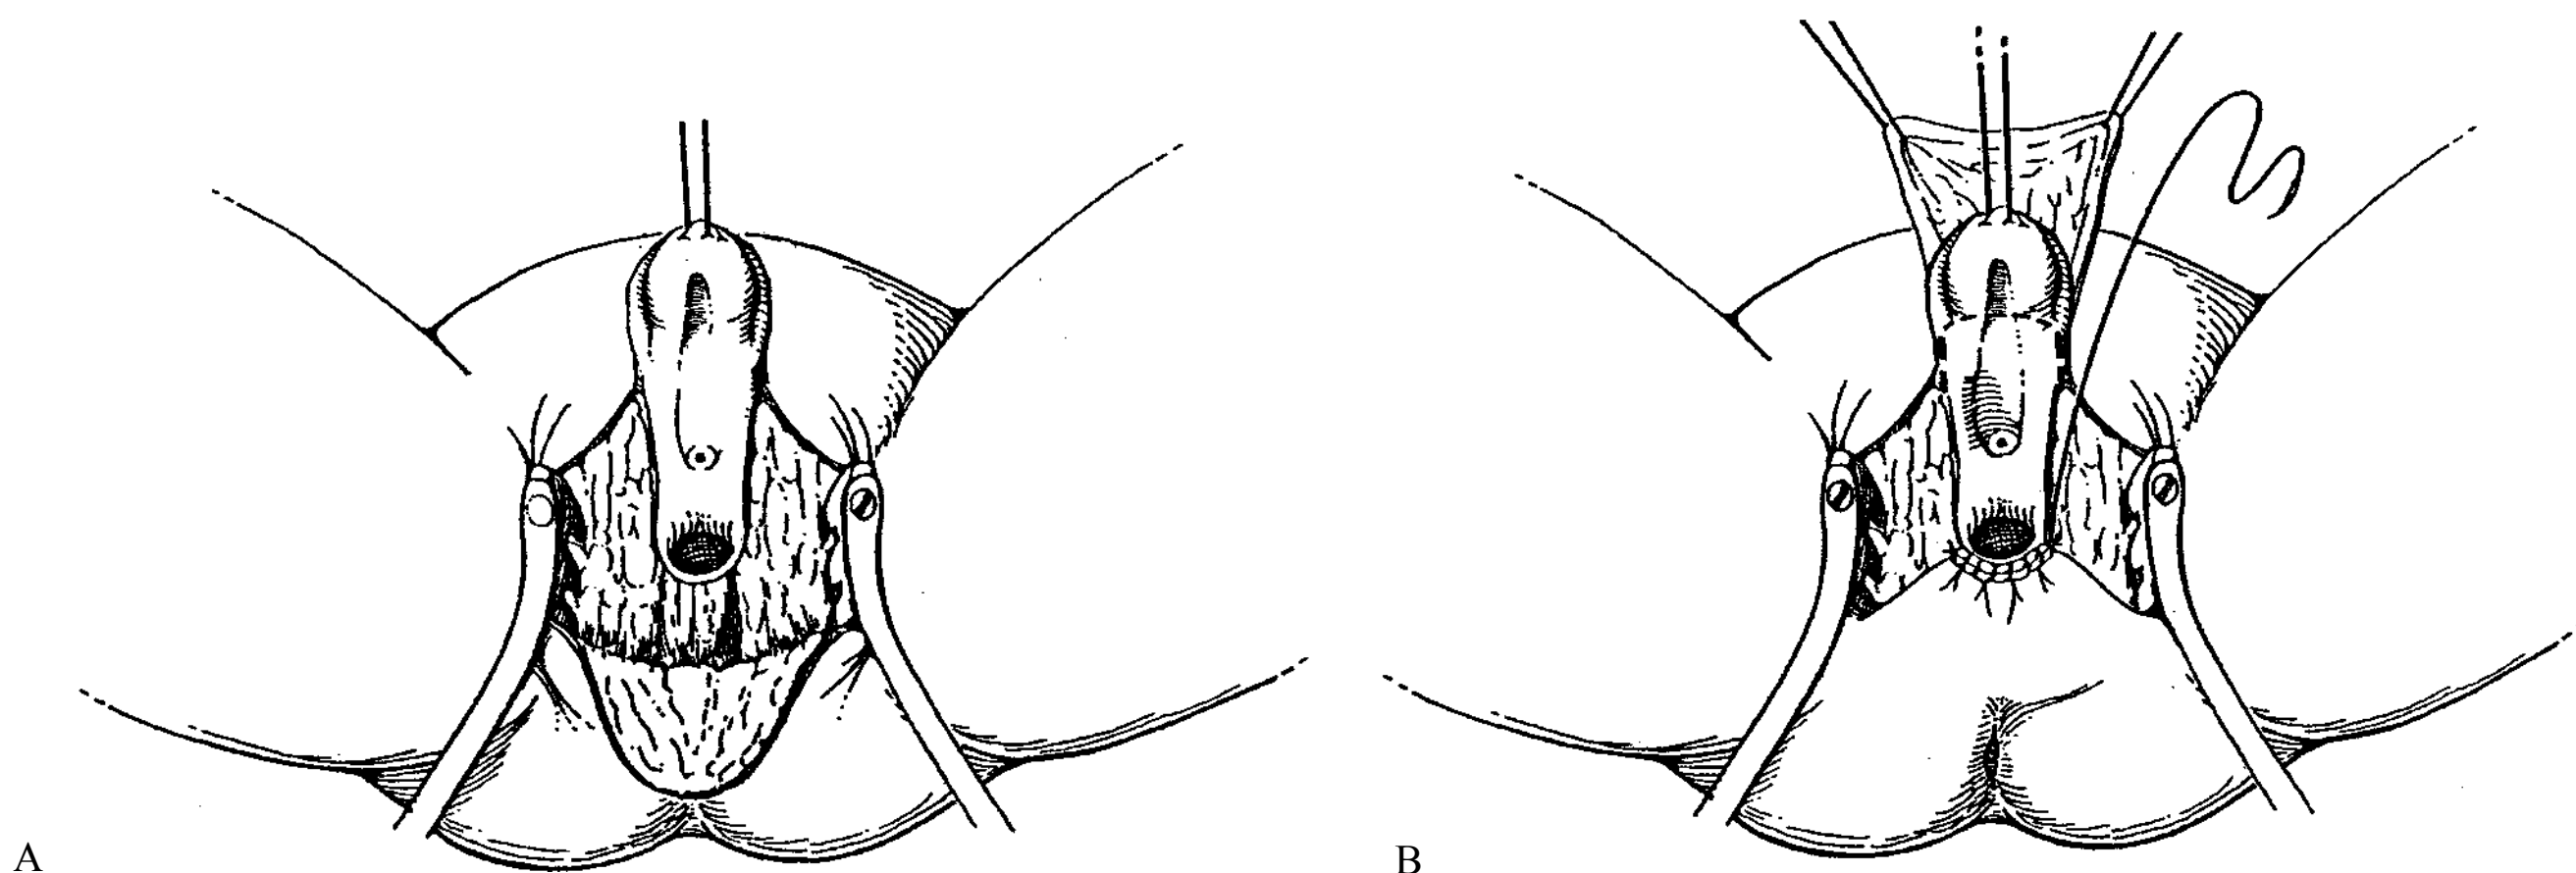

## OUTCOMES

---

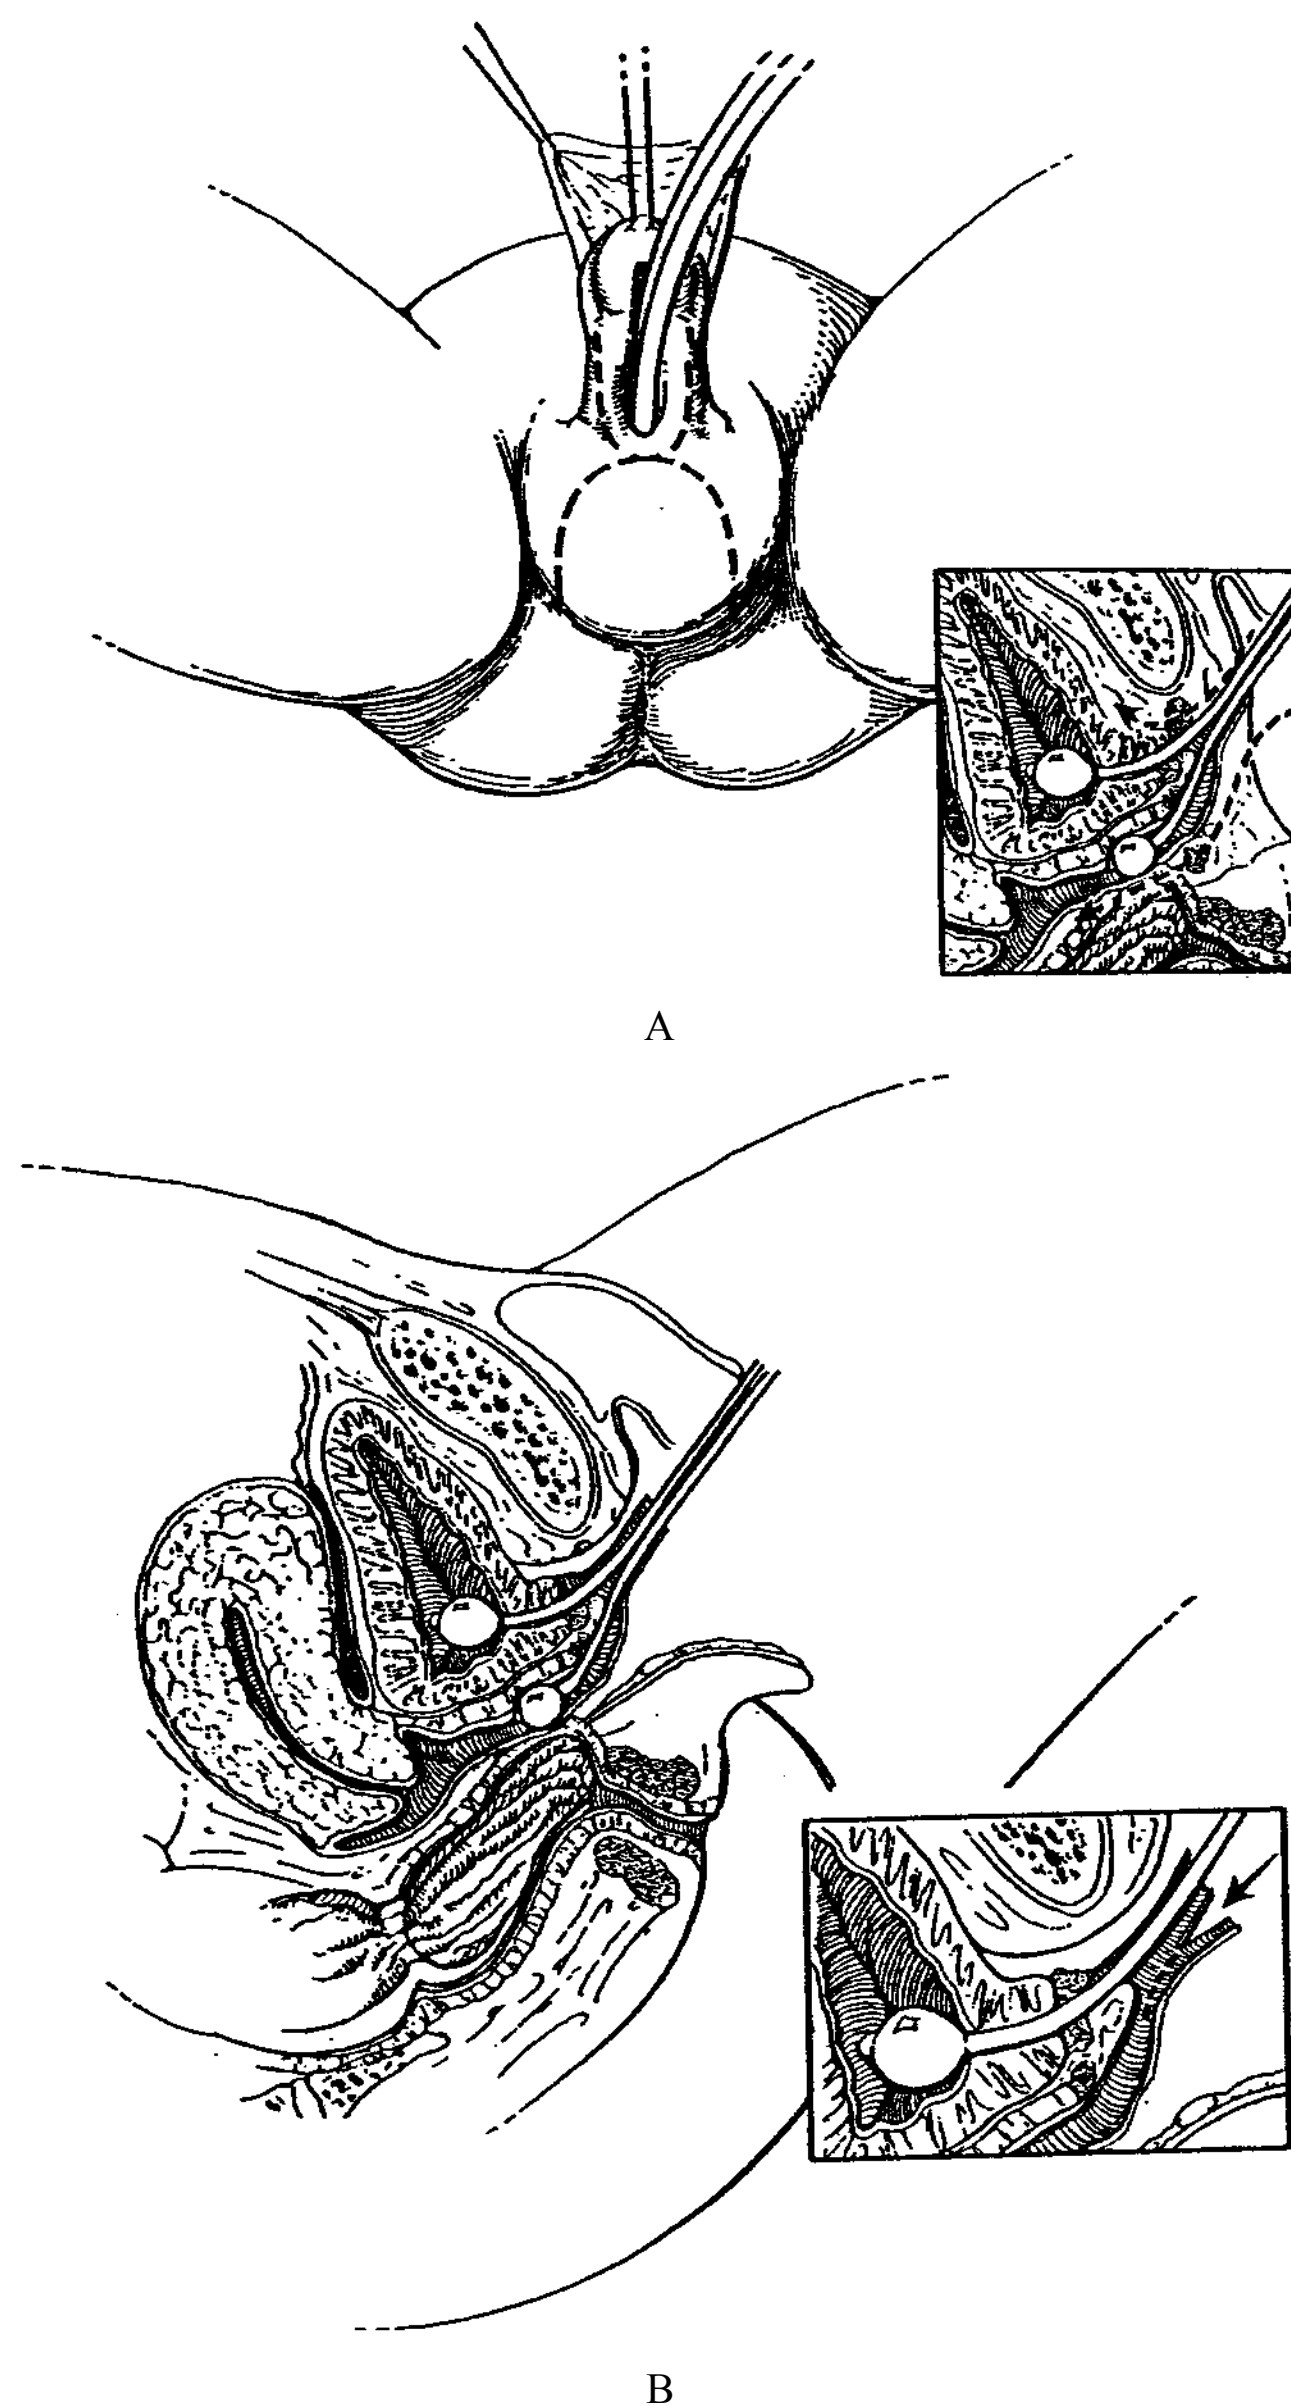

### Complications

---

The most common complication of genitoplasty is bleeding, both immediate and delayed. The tissue is very vascular and the use of injected dilute epinephrine during the procedure may be helpful. Late bleeding may originate from the corpora

**FIGURE 118.11** Advancement of the perineal skin flap widens the posterior wall of the introitus and reorients the vagina in a more vertical plane.

**FIGURE 118.12** Total urogenital sinus mobilization (TUM) for the urogenital sinus begins by circumferential dissection around the common channel. With cranial dissection the entire sinus can be mobilized and delivered to the level of the perineal skin. If the vagina reaches the perineum easily, the excess sinus can be amputated. If the vagina is narrow, it can be split in the midline posteriorly and the posterior perineal skin flap inserted as part of the posterior vaginal wall.

cavernosa or vaginal wall and can usually be controlled with pressure dressing. Pressure dressing must be carefully applied since it is possible to cause vascular compromise of the glans clitoris in the immediate postsurgical period.

The neurovascular pedicle of the glans clitoris can be injured during the original dissection. This potential injury is minimized by leaving the entire dorsal fascia, including the bundles, intact during and after dissection. Infections in the urine or wound are also possible but uncommon. It is not unusual to find a small dehiscence of the wound at the posterior apex of the labial incisions due to tension from movement. These heal without surgical intervention. They can be bathed normally and dressed with antibiotic ointment. The skin stress

**FIGURE 118.13** Total urogenital sinus mobilization for the high urogenital sinus requires a more extensive circumferential cranial dissection that takes down all the attachments to the pubic bone.

in this area is the prime reason to close with longer-lasting absorbable sutures.

## Results

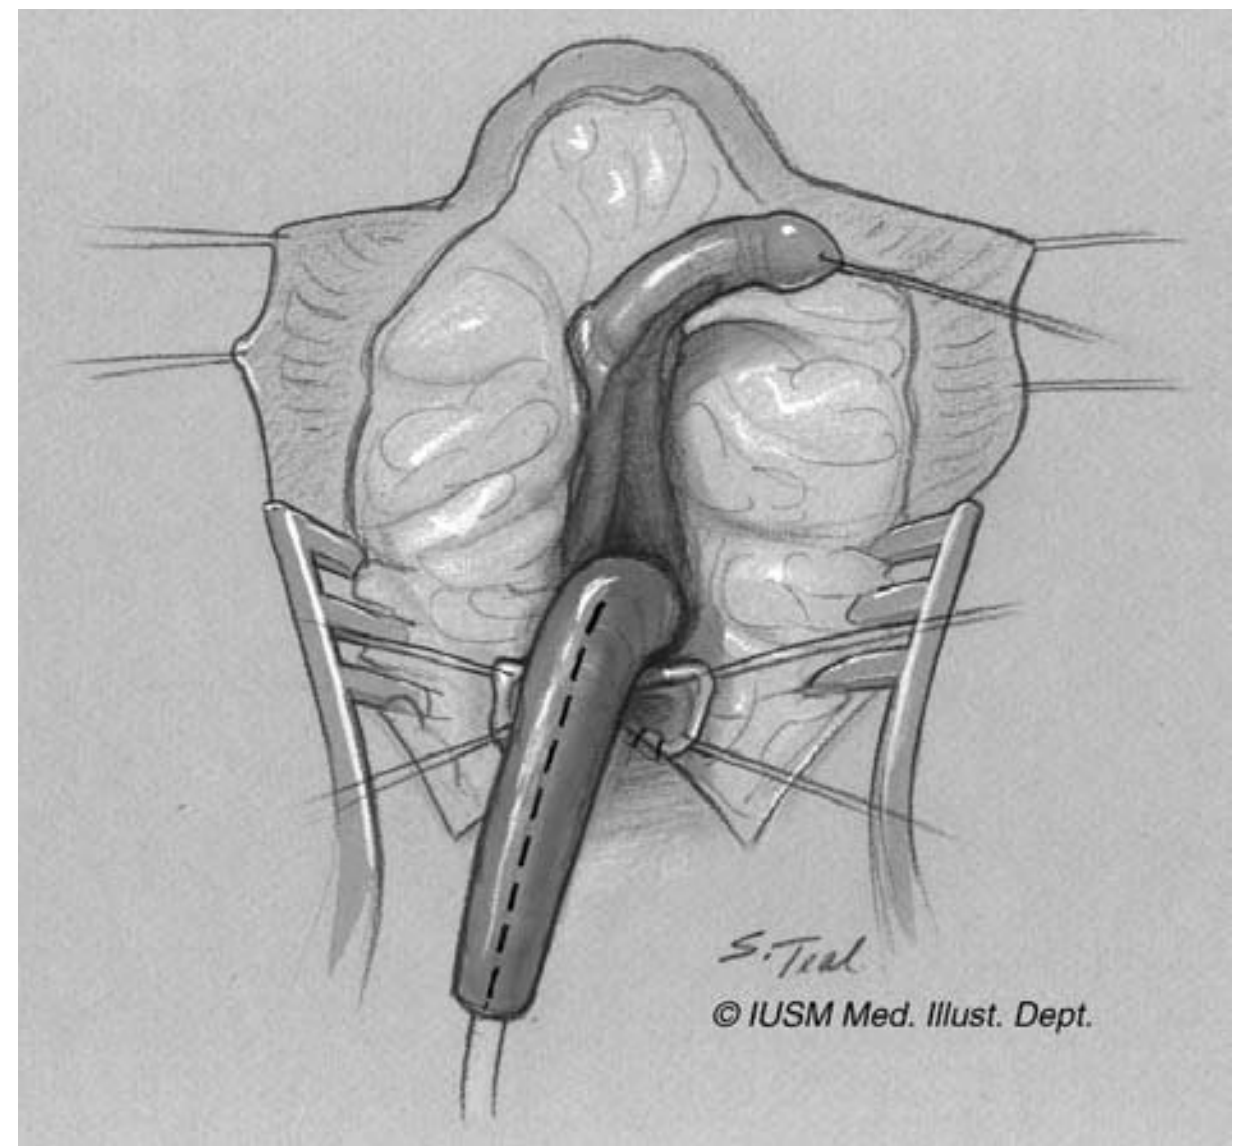

At this time surgical results are consistently good in terms of appearance and potential for function. There are, however, few long-term outcome data for feminizing genitoplasty, and the studies that have been done are, by necessity, evaluating the surgical technique that was in fashion 25 years ago. The techniques have improved, and while we can see superior cosmetic and functional results in young children and adolescents treated more recently, we still need to observe and evaluate these patients as they mature.

The question of gender assignment is one of great importance and intense study at this time. While it is necessary to learn from our patients, we must learn from all of them and not focus on only those who have been dissatisfied with their treatment. We now know that gender identity is much more complex than to be dependent on genital appearance and gender roles. While we must continuously re-evaluate our management of these difficult problems, we should not lose faith in the ability of surgery to create urogenital structures that can function normally and have an appearance consistent with the classic norm of the human body. Feminizing genitoplasty, like all surgery, has demonstrated that the most difficult question remains the choice of the correct procedure for the proper patient.

# CHAPTER 119 ■ CIRCUMCISION

IRENE M. MCALEER AND GEORGE W. KAPLAN

Currently about 1.2 million newborn boys in the United States are circumcised annually, making circumcision probably the most commonly performed surgical procedure on boys or men (1,2). The incidence of circumcision in the United States is highest in whites (88%) and less frequent in African Americans (73%) and Hispanics (42%) (2). The frequency of newborn circumcision is much lower in other countries, such as Canada (35%) and Australia (10%), and is generally much <8% in Europe and most parts of Asia (1).

## DIAGNOSIS

No diagnostic studies are needed preoperatively. Comorbidities, such as excessive prematurity, inherited or transient bleeding disorders associated with infancy, and congenital abnormalities of the skin such as epidermolysis bullosa and of the penis such as exstrophy, hypospadias, penoscrotal webbing, or micropenis, would all mitigate against circumcision, particularly routine newborn circumcision (Fig. 119.1).

## INDICATIONS FOR SURGERY

Circumcision is often performed in the neonatal period, infancy, or childhood for cultural or religious reasons and is also performed after the newborn period, when phimosis, paraphimosis, balanoposthitis, or sexually transmitted diseases are

**FIGURE 119.1** Webbed penis with paucity of shaft skin.

more prevalent. Medical benefits to the boy circumcised in infancy include reduced urinary infections in infancy (3), decreased incidence of sexually transmitted disease (2,4,5), and marked reduction in the incidence of penile carcinoma (6), but these benefits must also be weighed against the risks of the procedure: bleeding, infection, and poor outcome (7).

The American Academy of Pediatrics in 1999 (8) concluded that there were benefits from neonatal circumcision but the benefits gained did not warrant universal routine circumcision. Conversely, there are some opponents who feel that neonatal circumcision is never warranted (9).

Recently, with the increased incidence of human immunodeficiency virus (HIV) in sub-Saharan Africa of epidemic proportions, where over 90% of HIV-positive men in Africa acquire the virus through vaginal intercourse, clinical trials of adult male circumcision in large groups of men have found a reduced risk of >50% in the populations studied (Kenya, Uganda, South Africa). Even though the risk behavior of the circumcised men was no different from the uncircumcised men, the risk of contracting HIV was substantially decreased (2,5). In the uncircumcised man, the inner preputial skin has more Langerhans cells with densely concentrated CD4 receptors needed by HIV for entry into the body than do the glans, outer preputial skin, or penile shaft skin; as a result, the inner preputial skin, which is retracted and telescoped during intercourse, facilitates HIV entry into the body (2,5).

Because circumcision is so common, there are a number of misguided ideas and practices that have crept into American medical practice leading to some circumcisions being done for reasons that are not completely medically sound. At birth the prepuce, in over 90% of infants, is fused to the glans and is not retractable. As studied by Gairdner in 1949 (10), the foreskin progressively retracts on its own with age, so that only 10% of 3-year-olds will have nonretractable foreskins, and Oster et al. (11) found that only 1% of 17-year-olds will not have retractable foreskins. It is not necessary for parents or physicians to retract the prepuce as retractability occurs with penile growth, erection, and smegma formation; the smegma that forms will generally spontaneously be discharged from under the prepuce and does not need to be removed. Balanoposthitis is not a mandatory indication for circumcision in children as the prepuce in that area of the penis after such an episode will be permanently separated from the glans and should not produce recurrences of balanoposthitis. Forcible retraction of the prepuce causes the child pain and can produce paraphimosis or a dense cicatrix and perhaps subsequent balanitis xerotica obliterans (BXO) (Fig. 119.2).

Phimosis becomes pathologic when the opening of the foreskin develops a tight cicatrix usually caused by BXO. According to Shankar and Rickwood (12), BXO represents the one absolute indication for circumcision. BXO is a chronic dermatologic

**FIGURE 119.2** Photo of pathologic phimosis due to balanitis xerotica obliterans.

condition, analogous to lichen sclerosus et atrophicus, of the glans and prepuce but can also involve the meatus and the anterior urethra, especially if the glans is extensively involved (13).

Most of the series where BXO is reviewed have found that most of the patients affected are older boys, primarily those whose ages range from 5 to 15 years old (12–15). Previously, it was thought that the incidence of BXO was relatively rare in boys (range from 0.6% to 6%) (12,15), but recent reviews have shown that the BXO occurs more frequently in boys than previously reported. Circumcision is thought to be about 96% curative of BXO, but it is concerning that in more obese boys, especially those with prominent pubic fat, more severe disease is prevalent and recurrent (13).

---

## ALTERNATIVE THERAPY

---

Observation, intermittent medical treatment for balanoposthitis, and dorsal slit are common alternatives to circumcision. Recently the use of topical steroid creams, typically 0.1% triamcinolone or 0.05% betamethasone cream (16–18), to the preputial opening for about 4 to 8 weeks has successfully treated phimosis and obviates the need for circumcision in 85% to 87% of boys reported to be using the steroid preparations.

Paraphimosis occurs when the prepuce is retracted behind the glans penis and, because the preputial orifice is tight, becomes trapped in this position after it is retracted, with resultant swelling of the glans that prevents its reduction. If untreated, paraphimosis can lead to infection, significant penile swelling and pain, and occasionally loss of penile tissue. The edema can often be reduced by injecting hyaluronidase into the edematous tissue, thereby allowing for easier reduction of the paraphimosis. Many healthcare providers are unlikely to inject anything into such a swollen and painful penis, so an easy and effective treatment for the paraphimotic edema

**FIGURE 119.3** Photo of paraphimosis with topical granulated sugar.

is to place granulated sugar over the swollen penile tissue, with a resultant osmotic gradient pulling the fluid out. Another alternative to reduce swelling is the application of ice (Fig. 119.3). The paraphimosis is reduced by grasping the penis between the second and third fingers of both hands and pulling the shaft skin distally while simultaneously applying cephalad pressure with both thumbs. If this maneuver is unsuccessful, a dorsal slit is necessary to open the phimotic constriction ring. Circumcision can be performed after the inflammation and edema have resolved and should not be attempted at the time that the acute paraphimosis is present.

---

## SURGICAL TECHNIQUE

---

The goal of the operation is to remove an adequate amount of the prepuce such that the glans is exposed and balanoposthitis, phimosis, BXO, and paraphimosis are prevented. Too much or too little skin should not be removed, as the former can tether the penis and on occasion produce chordee, while the latter may produce continued risks of phimosis or paraphimosis.

All circumcisions should take place with an anesthetic: during the newborn period, local anesthesia with 1% lidocaine is generally used with or without topical anesthesia (EMLA 2.5% to 2.5% lidocaine–prilocaine). EMLA should be used cautiously as methemoglobinemia can occur in newborns. In older children and adolescents, general anesthesia is usually used. The penis is cleaned and draped and the foreskin retracted by taking down all the adhesions between the glans and the inner preputial skin. If a dense phimosis prevents this retraction, a dorsal slit may be necessary as a preliminary maneuver by placing one blade of a straight clamp inside the preputial sac in the dorsal midline (ensuring that the blade is not within the urethral meatus) and then placing the other blade on the outer skin. The clamp is closed and left in place for a few minutes, crushing the tissue and producing temporary hemostasis, and then the crushed area is incised with scissors. Marking the coronal ridge (as seen through the shaft skin) in ink helps identify where to place the circumferential incision about the shaft skin. In the adult or older child the proposed line of incision in the inner preputial sac is marked with ink about 3 to 4 mm below the coronal sulcus.

**FIGURE 119.4** **A:** An incision is made on the shaft. **B:** A second incision is made below the coronal sulcus. **C:** Removing the excessive preputial skin. **D:** The wound edges are coapted and sutured together.

A common method of excising the prepuce, called a “sleeve technique,” is performed by incising the two previously marked lines of incision circumferentially about the penis and dividing the tissue between the layers. Hemostasis is secured generally with judicious use of cautery, although vessels can also be individually ligated. The skin and the inner preputial epithelium are then coapted with fine absorbable sutures (Fig. 119.4).

Alternatively, an older method involves putting the prepuce on stretch by applying a hemostat to the dorsal and ventral aspects of the preputial orifice. The area of the shaft skin previously marked as overlying the coronal ridge is pulled forward beyond the tip of the glans and a straight clamp is applied, taking care to ensure that the glans is not included in the clamp. The prepuce distal to the clamp is amputated with a knife, the clamp is removed, hemostasis is secured, and the skin edges are coapted.

With the advent of synthetic tissue adhesives such as Dermabond (2-octyl cyanoacrylate, Ethicon), circumcisions can be performed quickly and safely with good cosmetic results in most children with minimal surgical time, few if any sutures required, and minimal tissue handling, thereby decreasing postsurgical swelling and possibly postsurgical pain (19).

### Dermabond Circumcision

Either a typical sleeve circumcision is performed or a Gomco clamp is used to prepare the tissue for the adhesive, which is applied directly to the apposed penile shaft and coronal skin

edges. Acceptable surgical results have been obtained as long as the skin edges are closely approximated and the adhesive is not extensively used on subcutaneous tissue (Fig. 119.5).

### Neonatal Circumcision

In newborns, circumcisions performed without anesthesia previously were common. However, local anesthesia using an agent such as lidocaine or bupivacaine as a dorsal penile block or, more importantly, a ring block at the base of the penis can alleviate most of the pain experienced by the newborn at the time of the circumcision. The anesthetic dose must be adjusted for the weight of the patient.

In newborns, circumcision is in general accomplished using some type of device. The common devices in use in the United States are the Gomco clamp, the Plastibell, and the Mogen clamp. The methodology for the Gomco clamp and Plastibell is similar. After local anesthesia has been provided and the skin cleansed, the area of the coronal ridge is marked as previously described, followed by a dorsal slit being performed. The Gomco device has three parts—a bell of variable size that fits over the glans, a plate, and a screw that completes the assembly. After the dorsal slit is performed and all the adhesions are released, the bell is then placed over the glans; a safety pin placed through the distal corners of the previously incised prepuce that keeps the edges aligned may be helpful. Then the plate is placed over the glans, the shaft skin is pulled up until the marked area can be seen emerging from the hole in the

**FIGURE 119.5** Photo of circumcision using 2-octyl-cyanoacrylate (Dermabond).

plate, and then the screw is placed and tightened. The device is left in situ for several minutes and the prepuce distal to the plate is then excised with a knife. Electrocautery must never be applied to the Gomco device, as this has resulted in total necrosis of the penis. The device is then removed, reversing the order in which it was applied. By loosening the screw, the plate can be disengaged from the bell and removed. The cut skin edges of the penis are then gently teased over the edge of the bell to ultimately remove the bell and complete the circumcision; rarely are sutures needed for hemostasis for this type of clamp circumcision (Fig. 119.6).

The Plastibell follows the same principles as the Gomco device. After the bell is applied, a heavy string is tied over a groove at the base of the bell at the level of the previously marked area on the shaft. The distal prepuce is then excised. The stem distal to the bell is snapped off, leaving a plastic ring under the inner preputial epithelium. In roughly 1 week, the skin distal to the ligature sloughs and the ring comes off spontaneously.

The Mogen clamp is a clothespin-like device, and the methodology of its application is akin to the older open surgical method described above. After the skin is cleansed and the area of the coronal ridge as seen through the shaft skin is marked with ink, the adhesions between the glans and the

**FIGURE 119.6** Gomco circumcision. **A:** Line of incision for dorsal slit. **B and C:** Application of the device. **D:** Excision of the prepuce.

**FIGURE 119.7** Traumatic amputation of portion of glans from Mogen clamp circumcision.

inner prepuce are lysed with a blunt probe. It is usually not necessary to perform a dorsal slit when using the Mogen clamp. The prepuce is pulled distally and the clamp applied, taking care to ensure that the glans is not included in the clamp. The clamp is closed and left in situ for a few moments. The prepuce distal to the clamp is excised and the clamp is removed. This type of clamp device is the easiest to use by those first performing neonatal clamp circumcisions, but it is the one most likely to have associated complications, typically partial or complete amputation of the glans if the glans is inadvertently enclosed in the clamp and cut when the tissue in the clamp is incised (20) (Fig. 119.7).

---

## OUTCOMES

---

### Complications

---

Occasionally complications do occur, but most are minor and rarely portend a bad result. Bleeding is the most frequent complication and occurs in approximately 0.1% of cases. Most episodes of bleeding are minor and respond to pressure alone. Some require cautery or suture for control, particularly in the area of the frenulum. Most infections are minor and superficial, manifested by redness and occasionally purulence at the circumcision site that usually responds to local wound care. A common complication of neonatal circumcision is meatal stenosis, probably produced by a chemical meatitis from ammoniacal urine exposure on the tip of the penis while the patient is still wearing diapers. Serious complications, fortunately, are rare but include recurrent phimosis, wound separation, major tissue loss, concealed penis, skin bridges between the shaft and the glans, inclusion cysts, urethrocutaneous fistula, and loss of some of the glans or, extremely rarely, all of the penis.

---

### Results

---

A circumcision should remove a sufficient amount of the prepuce so that the glans is exposed, significantly reducing the risk of developing phimosis, paraphimosis, BXO, or balanoposthitis.

# CHAPTER 120 ■ AUGMENTATION CYSTOPLASTY IN CHILDREN

HANS G. POHL

*Dedicated to W. H. Hendren, M.D., whose creative use of intestine in urologic reconstruction I have been honored to observe.*

Neuropathicity, bladder outlet obstruction, or embryologic abnormalities may result in a bladder too small or too overactive to provide normal storage of urine. The goal of augmentation cystoplasty in the pediatric patient is to provide a sufficiently capacious reservoir that stores urine at low pressure and as a result improves urinary continence and prevents upper urinary tract deterioration.

## DIAGNOSIS

Evaluation should include imaging of the upper tracts, urodynamic evaluation and evaluation of the bladder outlet, and urine culture. In the child with no prior history of bowel resection or gastrointestinal comorbidity, it is in general not necessary to evaluate the intestinal tract. However, radiologic imaging is essential with intestinal atresia, intestinal malrotation, and imperforate anus because it is likely that anatomic abnormalities or prior surgical intervention would obviate the use of specific bowel segments.

## INDICATIONS FOR SURGERY

The majority of pediatric patients requiring augmentation cystoplasty have small-capacity, noncompliant, or overactive bladders as a result of neuropathicity (from myelodysplasia or traumatic spinal cord injury) or myogenic failure (from posterior urethral valve). Occasionally, augmentation cystoplasty is

required in order to provide adequate bladder volume in cases of classic exstrophy, cloacal exstrophy, and cloacal malformations. Bladder dysfunction should initially be treated with anticholinergic medications and clean intermittent catheterization (CIC) in an effort to diminish uninhibited bladder contractions, improve compliance, and provide regular and effective bladder emptying. When urodynamic evidence exists that nonoperative measures have failed, augmentation cystoplasty is indicated. Intravesical storage pressure that has been demonstrated to be  $>40$  cm H<sub>2</sub>O is the most robust indication for augmenting the bladder. Incontinence and urinary tract infections, with or without vesicoureteral reflux (VUR), are associated symptoms that may benefit from enterocystoplasty. However, a thorough evaluation is warranted in order to ascertain what type of augmentation to perform and whether a secondary procedure is indicated in addition to enterocystoplasty to provide continence and/or prevent upper tract deterioration. Since the combination of urinary infection, detrusor hyperreflexia, and VUR poses a significant risk for renal scarring, antireflux surgery should be considered at the time of augmentation cystoplasty when reflux is high grade or recurrent symptomatic urinary infection has occurred. However, reimplanting ureters into a thick-walled bladder is challenging technically and has been associated with postoperative ureteral obstruction, leading some to consider augmentation without ureteral reimplantation. When children with neuropathic bladders and VUR have undergone augmentation cystoplasty alone, VUR has resolved or been significantly downgraded without the need for reimplantation even in high-grade VUR (1) (Table 120.1). If bladder outlet surgery is entertained in conjunction with enterocystoplasty, the incontinence procedure should be performed prior to opening the peritoneal cavity in order to minimize insensible fluid loss.

## ALTERNATIVE THERAPY

Alternatives are either continued medical management or urinary diversion.

## SURGICAL TECHNIQUE

Preoperative preparation must include a thorough review of the anticipated goals of the surgery with the parent and patient, when he or she is an older child or adolescent. During this meeting, the family's ability to comply with the postoperative care of a bladder augmented with bowel must be assessed. When CIC has been performed preoperatively, the postoperative catheterization and irrigations are more readily adhered to (2). Urinary infection, bladder calculi, or perforation may result when routine emptying and augment cleansing are not performed regularly. Table 120.2 outlines the most common complications of augmentation cystoplasty in the early and late postoperative period.

There is no ideal segment of bowel for augmentation cystoplasty; each has a set of characteristics that are advantages or liabilities depending on the clinical scenario (Table 120.3). It should be noted that none of these complications are seen following ureterocystoplasty, making it the ideal tissue for bladder augmentation. However, it is a procedure ideally performed in a patient with a severely dilated ureter that subtends a nonfunctioning kidney.

Bowel cleansing is typically performed prior to augmentation cystoplasty (Table 120.4). While expedited bowel cleansing protocols (or complete omission) are replacing standard regimens in adults, there are few studies in children demonstrating

TABLE 120.2

### TYPES OF COMPLICATIONS FOLLOWING PEDIATRIC AUGMENTATION CYSTOPLASTY

Preoperative Counseling and Informed Consent
Bleeding (pelvic hematoma)
Infection (more common after colonic than ileal anastomosis)
Small bowel obstruction
Urinary leak
Ureteral stricture
Vesicoureteral reflux
Bladder calculi
Metabolic abnormalities
Poor somatic growth
Hematuria–dysuria syndrome
Excoriation around stoma site

a significant benefit in the absence of preoperative bowel cleansing. Considering that the majority of children who will undergo augmentation cystoplasty have ventriculoperitoneal shunts that are prone to infection, there appears to be a rationale to continuing the practice of preoperative clean-outs (3).

The patient is positioned supine on the operating table. General anesthesia with endotracheal intubation is mandatory; however, if no spinal abnormality exists that contraindicates the use of an epidural catheter, consideration should be given to regional anesthesia as well. The surgical field is prepared and draped from the xiphoid process inferiorly,

TABLE 120.3

### COMPARISON OF GASTROINTESTINAL SEGMENTS IN PEDIATRIC AUGMENTATION CYSTOPLASTY

	Advantages	Disadvantages
<b>Ileum</b>	Most compliant Less mucus	Diarrhea Vitamin B <sub>12</sub> deficiency Short mesentery Hyperchloremic acidosis Poor muscle backing
<b>Sigmoid</b>	Readily mobilized Easily implanted Good muscle backing	Unit contractions Lower compliance Mucus Hyperchloremic acidosis perforation risk
<b>Ileocecal</b>	Valve as antireflux/continence mechanism Good-capacity reservoir Constant blood supply	Diarrhea Not always available Contractile
<b>Stomach</b>	Short gut/radiation Chloride pump Minimal mucus Fewer infections Ease of implantation Good muscle backing	Hypochloremic alkalosis Rhythmic contractions Hematuria–dysuria

including the genitalia. A Foley catheter is inserted urethrally. A midline incision is created beginning at the symphysis pubis and extending superiorly toward the umbilicus. Retraction can be provided by an Omni or Bookwalter retractor. In order to avoid the insensible loss of heat and water from peritoneal surfaces, it is recommended that any concomitant procedures on the bladder or bladder neck be performed through a limited incision that does not enter the peritoneal space.

When a continent diversion is not planned, a midline cystotomy suffices to prepare the bladder for augmentation. Ureteral reimplants can be easily performed at this point (Fig. 120.1). However, when a continent catheterizable stoma is planned, either a paramedian or transverse cystotomy should be considered since these incisions create bladder flaps that facilitate the creation of a long submucosal tunnel for the appendix or ileal tube. Regardless of the bladder incision

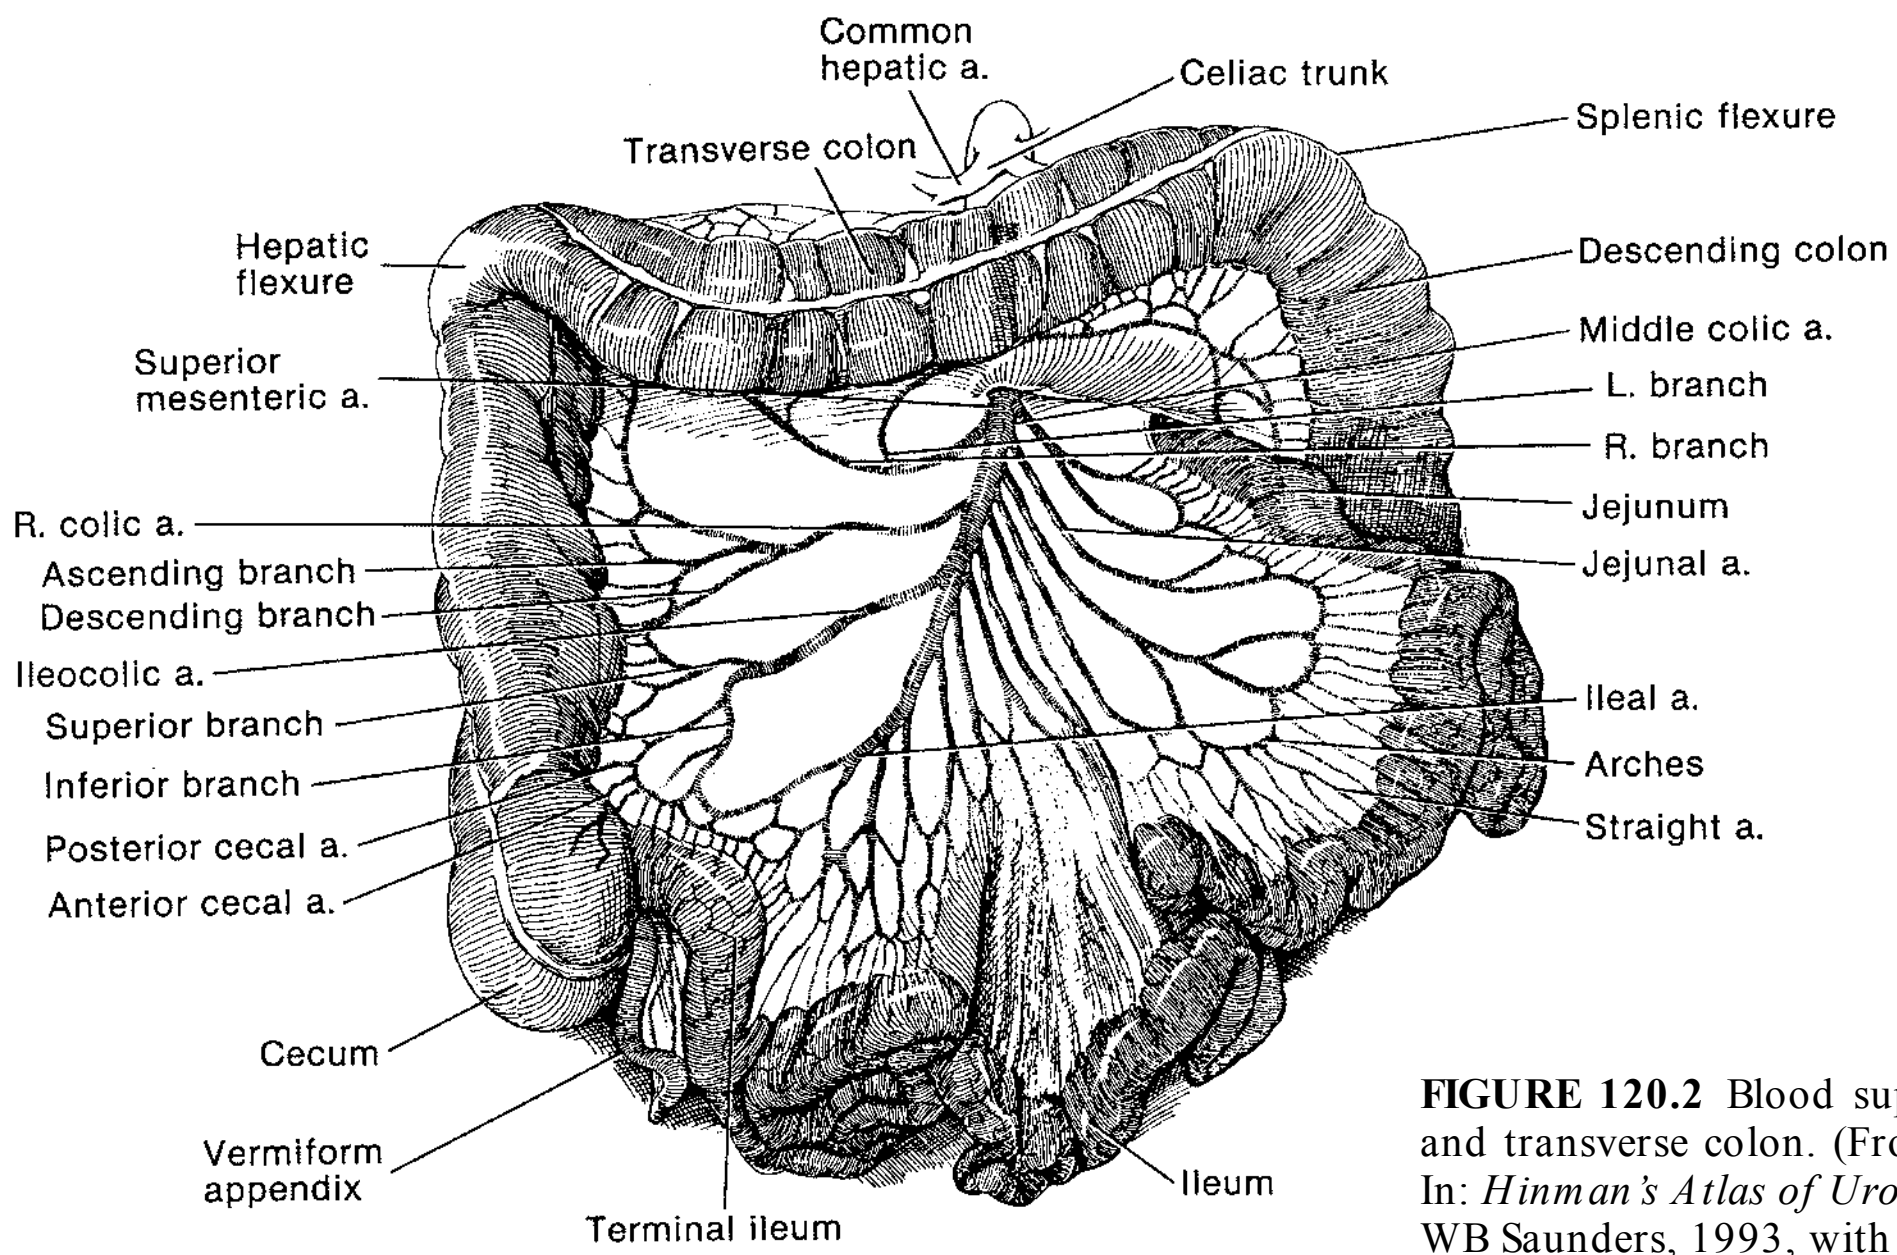

created, it must be sufficiently long to open the bladder widely. If the cystotomy is too short, the augmented segment may behave as a diverticulum, thus facilitating urinary stasis and stone formation. Once the bladder has been prepared, the midline incision is carried above the umbilicus and the peritoneum is entered.

### Ileocystoplasty

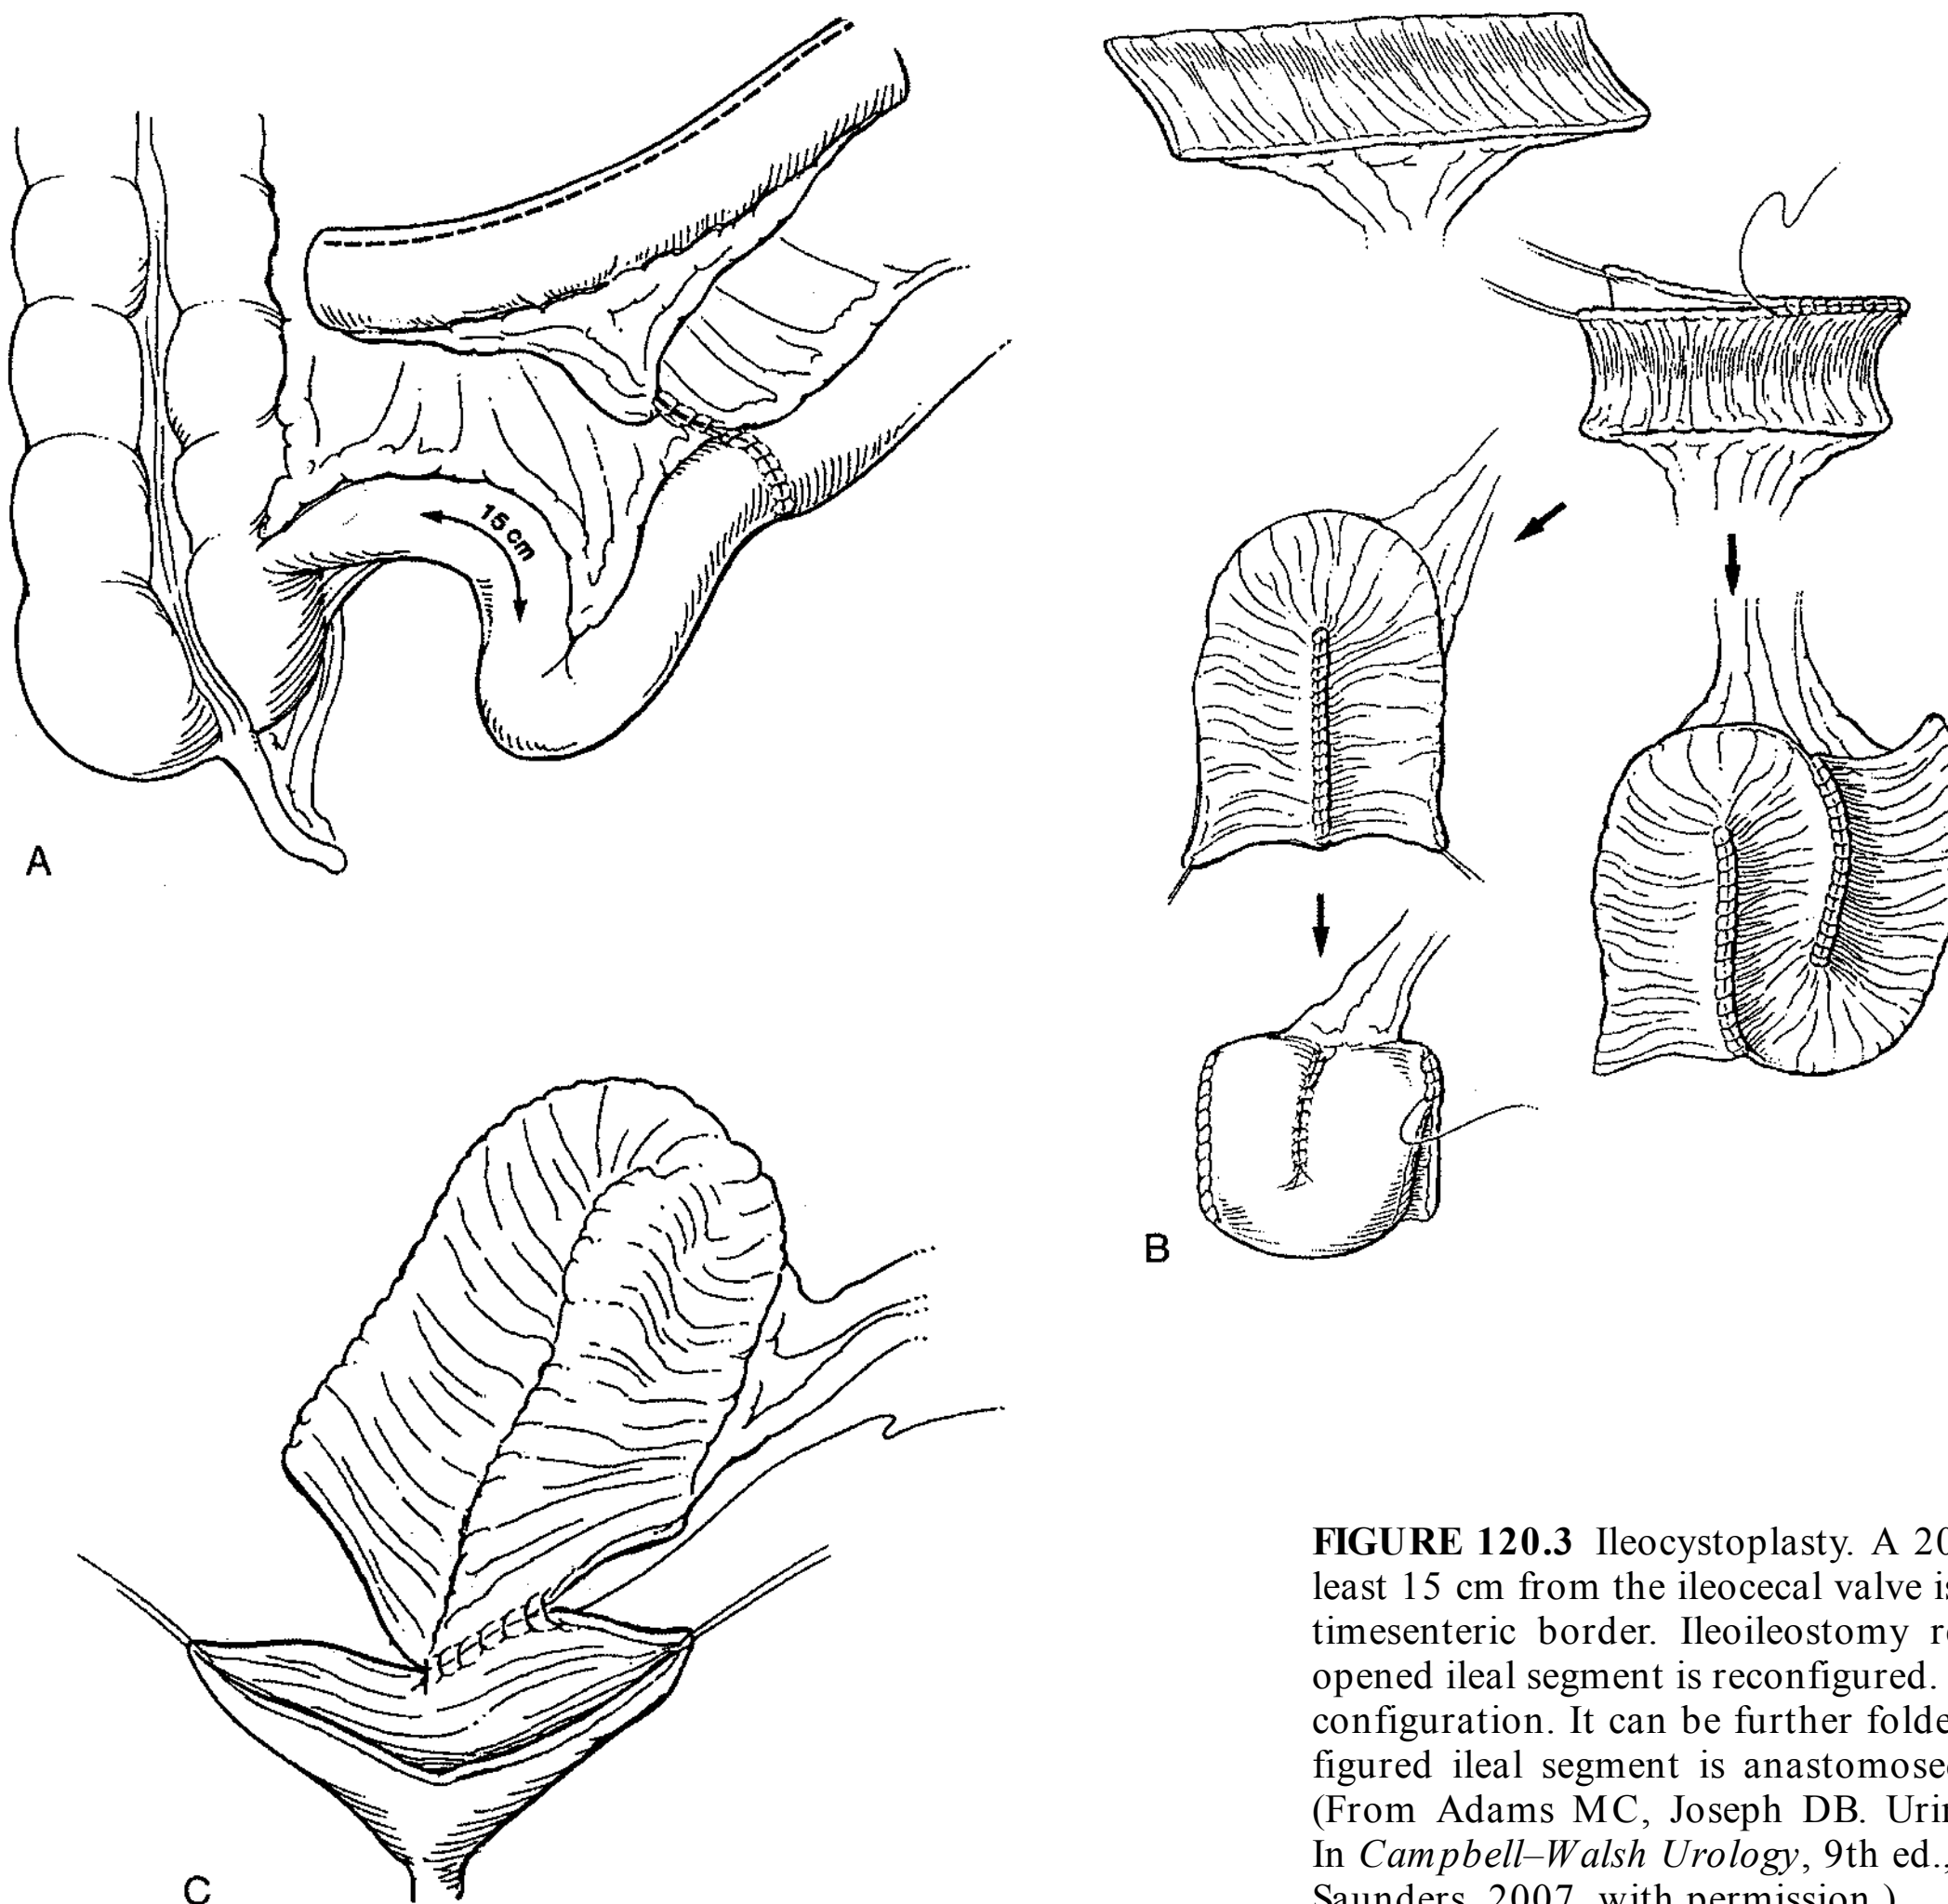

Ileum is by far the most popular segment used for bladder augmentation. The segment, 20 to 25 cm long, is based on a pedicle that is supplied by branches of the superior mesenteric artery and that is sufficiently mobile to be brought into the pelvis (Fig. 120.2). On occasion an abnormally thick, fatty, or short mesentery can limit mobility of the vascular pedicle, thus necessitating extensive division of the mesentery posteriorly. The terminal 15 to 20 cm of ileum, as measured from the ileocecal valve proximally, is spared in order to retain bile salt absorption, thus preventing steatorrhea and vitamin B<sub>12</sub> deficiency (Fig. 120.3). The portion of ileum to be used is measured and 5-0 silk sutures are used to mark the proximal and distal limits of resection. Prior to dividing the mesentery, the vascular supply to the isolated segment should be observed by transillumination and the proposed incisions in the mesentery marked. Beginning at the mesenteric border of the bowel, the mesentery is divided between pairs of fine hemostats and the vascular arcades are ligated with 5-0 silk suture ties. The bowel is then divided between atraumatic bowel clamps that have been applied at the proximal and distal limits of resection. Once the ileal segment reaches into the pelvis without tension on the vascular pedicle, no further mesenteric division is needed. An ileoileal anastomosis is performed cephalad to the isolated ileal segment and the mesenteric trap is closed. The bowel clamps are removed and a thorough lavage of the ileal segment is performed with sterile saline. The segment is folded 180 degrees and the adjoining serosal surfaces are sutured with 4-0 PGA. The antimesenteric border of the ileal segment can then be opened using scissors or the cutting current

**FIGURE 120.1** A: Preparation of the bladder for “clam” augmentation cystoplasty. B: Sagittal incision is made to create two bladder flaps.

**FIGURE 120.2** Blood supply to the jejunum, ileum, and ascending and transverse colon. (From Hinman F Jr, ed. *Gastrointestinal tract*. In: *Hinman's Atlas of Urosurgical Anatomy*, Chapter 6. Philadelphia: WB Saunders, 1993, with permission.)

**FIGURE 120.3** Ileocystoplasty. A 20- to 40-cm segment of ileum at least 15 cm from the ileocecal valve is removed and opened on its antimesenteric border. Ileoileostomy reconstitutes the bowel. **B:** The opened ileal segment is reconfigured. This can be done in a U, S, or W configuration. It can be further folded as a cup patch. **C:** The reconfigured ileal segment is anastomosed widely to the native bladder. (From Adams MC, Joseph DB. *Urinary reconstruction in children*. In *Campbell-Walsh Urology*, 9th ed., Chapter 124. Philadelphia: WB Saunders, 2007, with permission.)

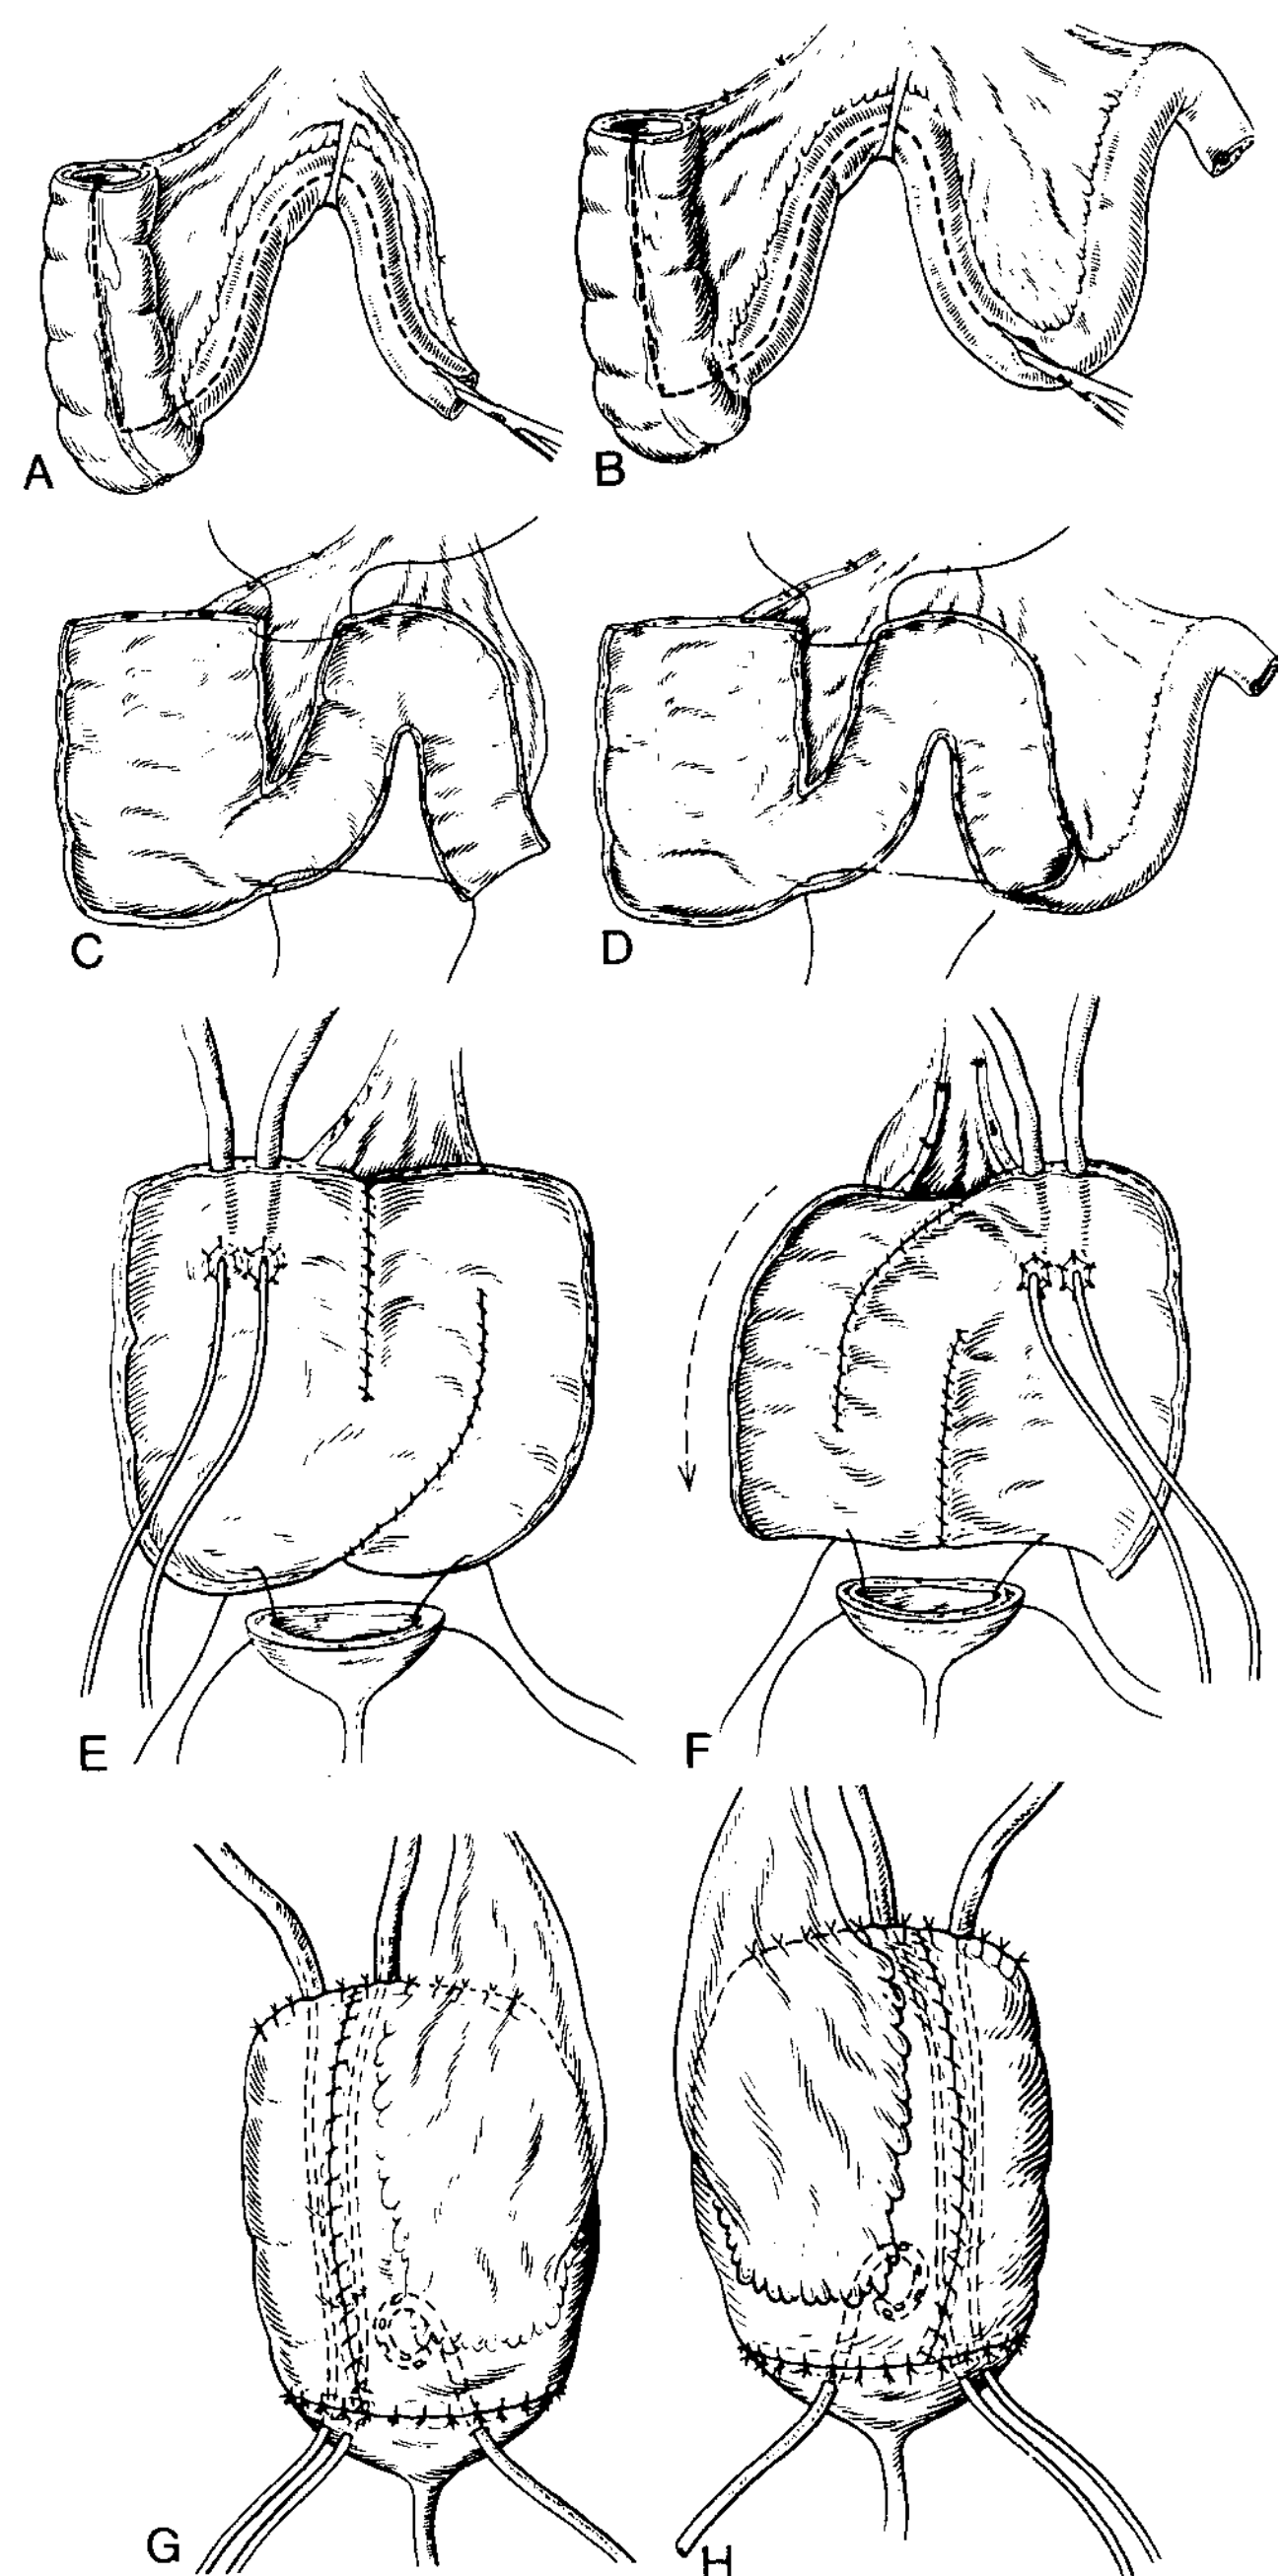

with little concern for bleeding, which usually ceases spontaneously. An optional second suture line is created by placing 4-0 PGA through the full thickness of the bowel wall in a continuous fashion. Once the ileal cap has been formed, it is anastomosed to the opened bladder beginning at the most posterior portion of the bladder incision. Hemostatic clamps may be left on the short ends of the tied sutures in order to identify the most posterior limit of the anastomotic line, thus facilitating placement of the second, reinforcing suture layer between the serosal surfaces of the bladder and ileum. A suprapubic catheter is placed through the bladder wall prior to completion of the first anastomotic closure.

### Right Colocystoplasty and Mainz Enterocystoplasty

Enterocystoplasty with a segment of ascending colon is based on vascular supply from the ileocolic artery (Fig. 120.2). Dissection begins at the inferior edge of the cecum and progresses cephalad along the line of Toldt, the peritoneal reflection lateral to the right colon. At the hepatic flexure, the hepatocolic ligament must be divided. Next, the omental attachments to the colon are divided and the omentum is packed into the left upper quadrant with moist laparotomy sponges. The ascending colon is divided at the watershed between the ileocolic and right colic arteries, approximately midway between the cecum and hepatic flexure. The ileum is divided close to the ileocecal valve. An ileocolonic anastomosis is performed and the mesenteric trap is closed. If the appendix will not be used to create a continent catheterizable stoma, an appendectomy is performed at this point. The bowel is folded 180 degrees and the serosal surfaces are sutured with 4-0 PGA. The bowel is incised along its antimesenteric border and the edges are sutured full thickness with 4-0 PGA placed in a continuous fashion. The resulting colonic plate is folded once again. This time the full-thickness suture line is placed first and reinforced with a second continuous line of 4-0 PGA. The resulting cup is inverted and anastomosed to the bladder opening as described for the ileocystoplasty. An alternative approach that has gained wide popularity is the Mainz augmentation, in which 15 to 30 cm of terminal ileum is isolated in continuity with the right colon and detubularized, anastomosed to each other, and sutured to the cystotomy (Fig. 120.4).

### Sigmoidocystoplasty

Since the diameter of the sigmoid is much greater than that of the ileum, a shorter segment is necessary in order to perform a successful augmentation cystoplasty. The isolated segment derives its blood supply from the sigmoid branches of the inferior mesenteric artery (Fig. 120.5). A mesenteric incision is created proximally and distally and bowel clamps are applied to minimize fecal soiling. The sigmoid is divided and a sigmoidosigmoidostomy performed lateral to the mesentery of the isolated segment (Fig. 120.6). It is advisable for each surgeon to standardize the side where he or she performs the sigmoidosigmoidostomy in the event that reoperation is necessary in the future. Two methods are available for anastomosing the bowel segment to the bladder. In the first, the proximal and

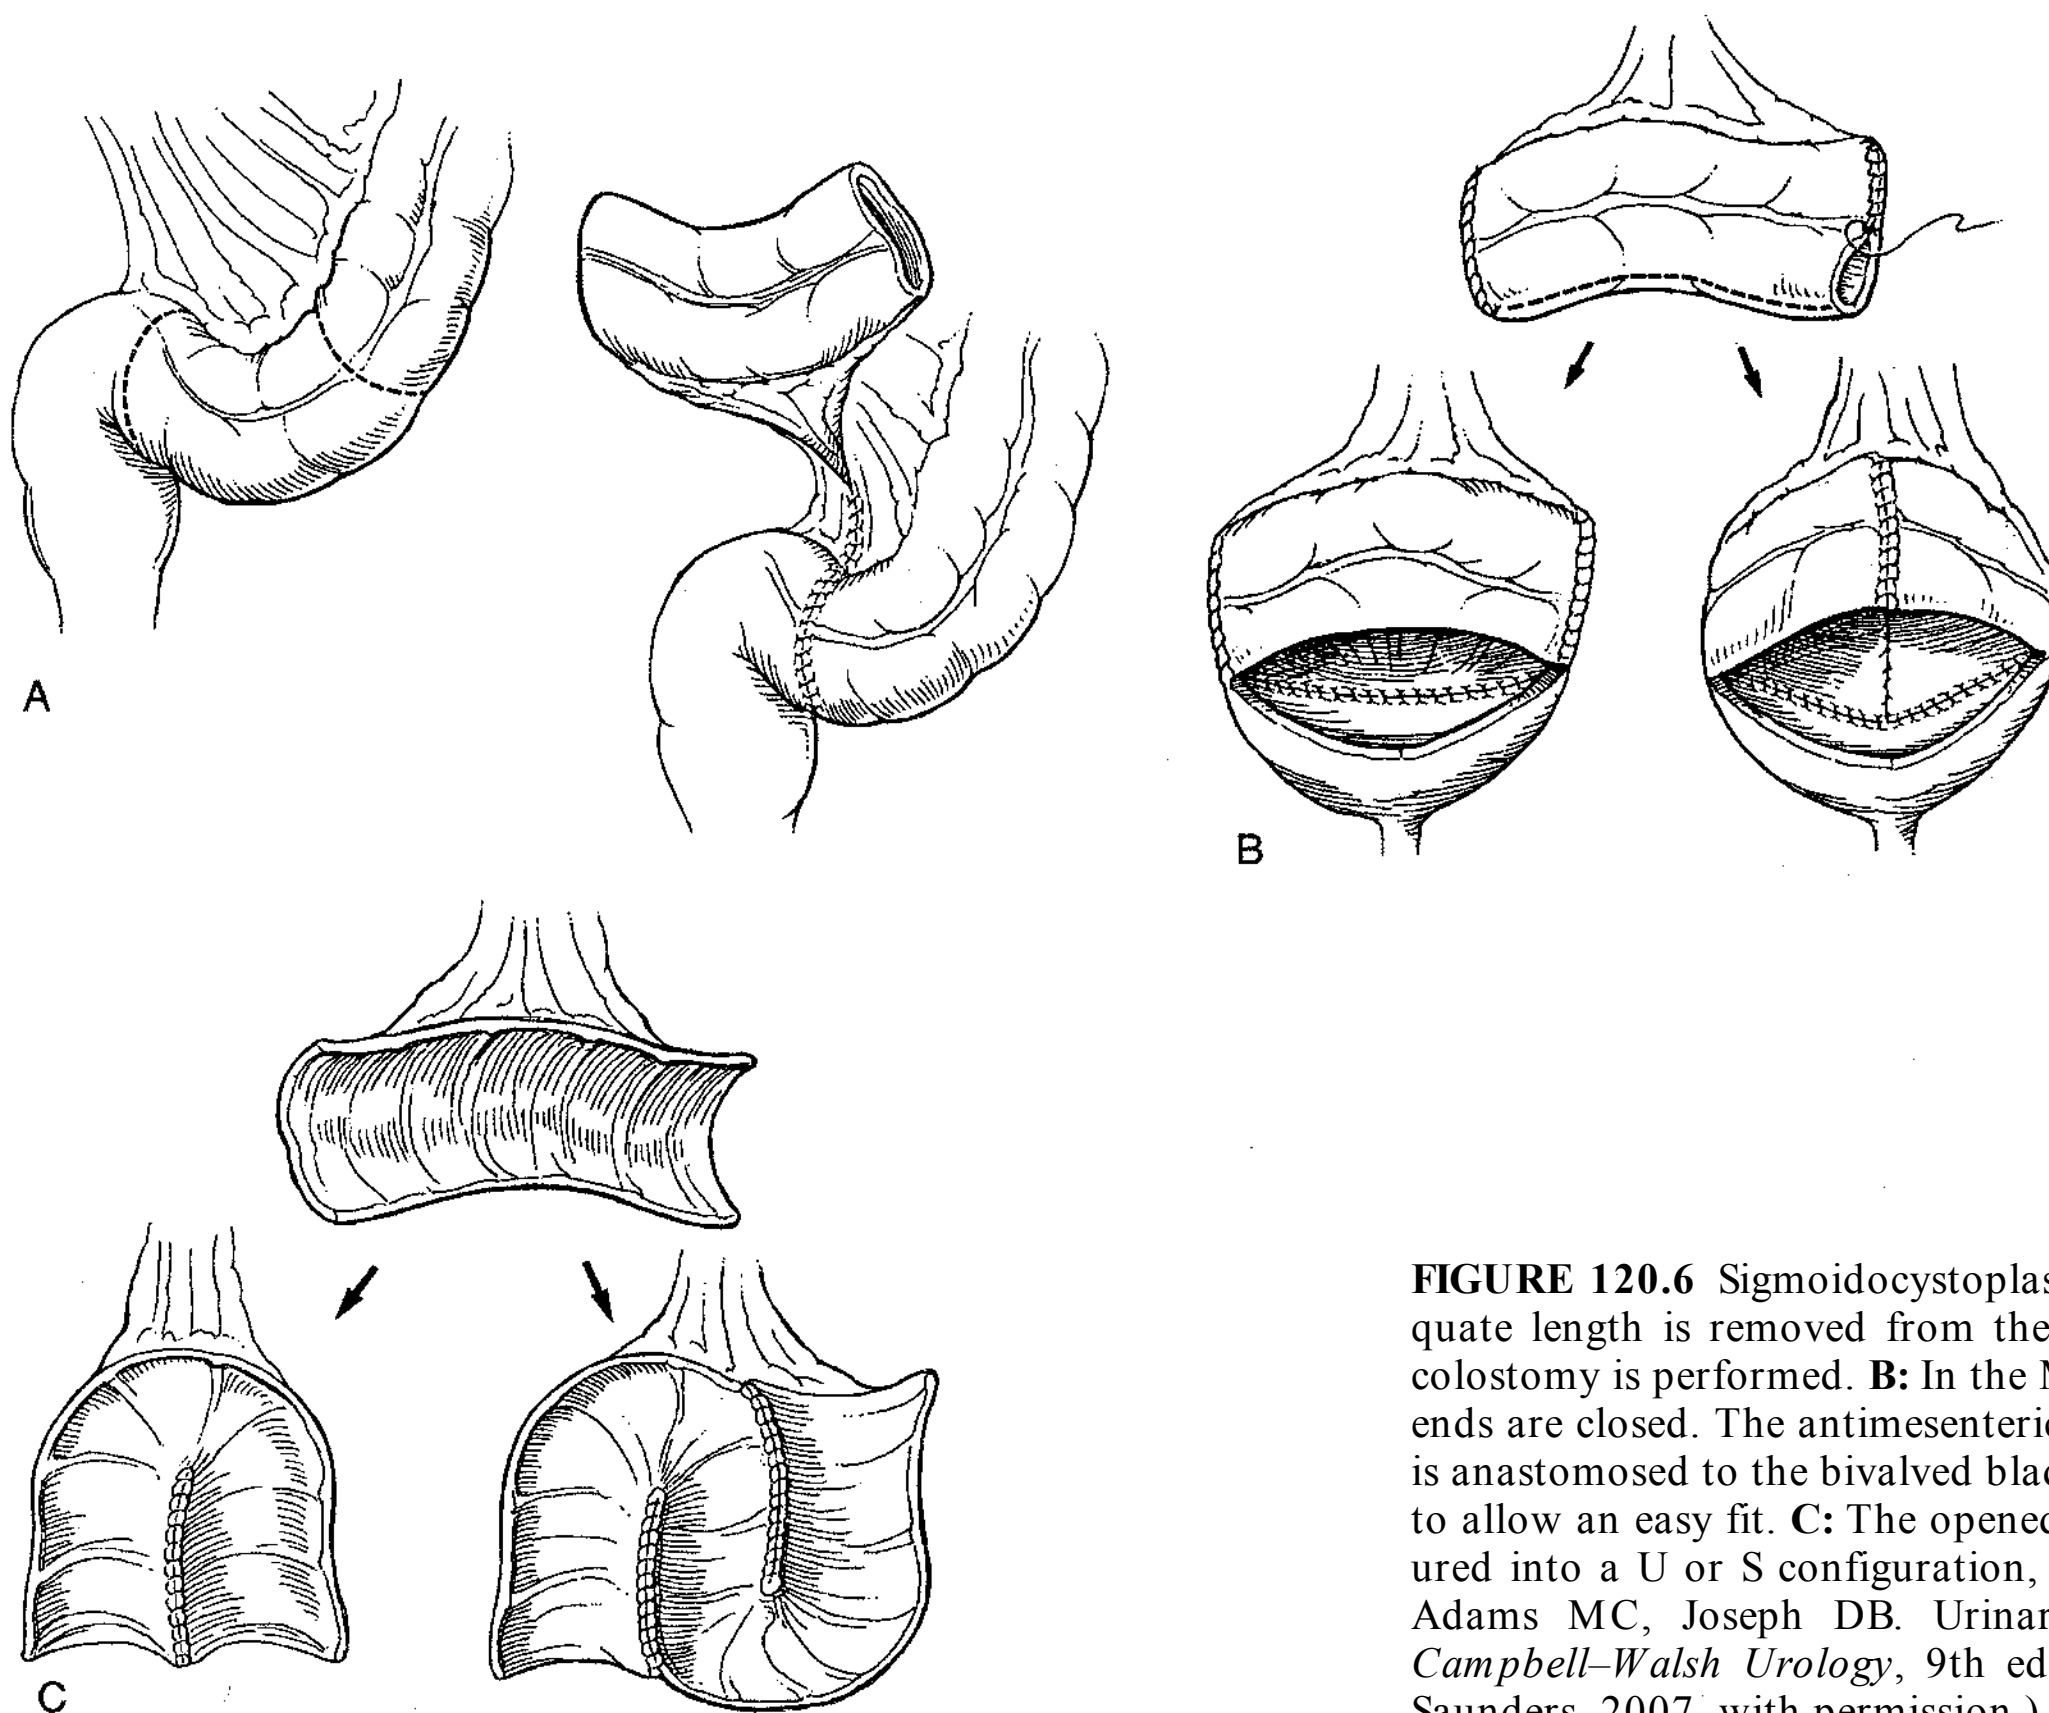

**FIGURE 120.4** Mainz ileocecocystoplasty. **A and B:** The ileal segment is twice the length as the cecal segment. **C and D:** It is opened on the antimesenteric border. **E and F:** The ureters can be opened into the opened cecal segment if necessary. **G and H:** The ileocecal segment is anastomosed to the native bladder. (From Thuroff JW, et al. The Mainz pouch. In: King LR, Stone AR, Webster GD, eds. *Bladder Reconstruction and Continent Urinary Diversion*. Chicago: Year Book, 1987, with permission.)

distal ends of the segment are closed and the bowel is opened along its antimesenteric border and sutured to the bladder opening. In the second, the bowel is opened along its antimesenteric border first, then folded 180 degrees into a U shape prior to suturing it to the bladder. The latter method likely disrupts the high unit contractions of the sigmoid more than the first; however, it requires that a greater length of sigmoid be isolated.

**FIGURE 120.5** Blood supply to the descending and sigmoid colon and rectum. (From Hinman F Jr, ed. *Gastrointestinal tract*. In: *Hinman's Atlas of Urosurgical Anatomy*, Chapter 6. Philadelphia: WB Saunders, 1993, with permission.)

**FIGURE 120.6** Sigmoidocystoplasty. **A:** A sigmoid segment of adequate length is removed from the gastrointestinal tract and a colocolostomy is performed. **B:** In the Mitchell technique, the two opened ends are closed. The antimesenteric border is incised and the segment is anastomosed to the bivalved bladder. It may be rotated 180 degrees to allow an easy fit. **C:** The opened sigmoid segment can be reconfigured into a U or S configuration, which may lower pressure. (From Adams MC, Joseph DB. *Urinary reconstruction in children*. In *Campbell-Walsh Urology*, 9th ed., Chapter 124. Philadelphia: WB Saunders, 2007, with permission.)

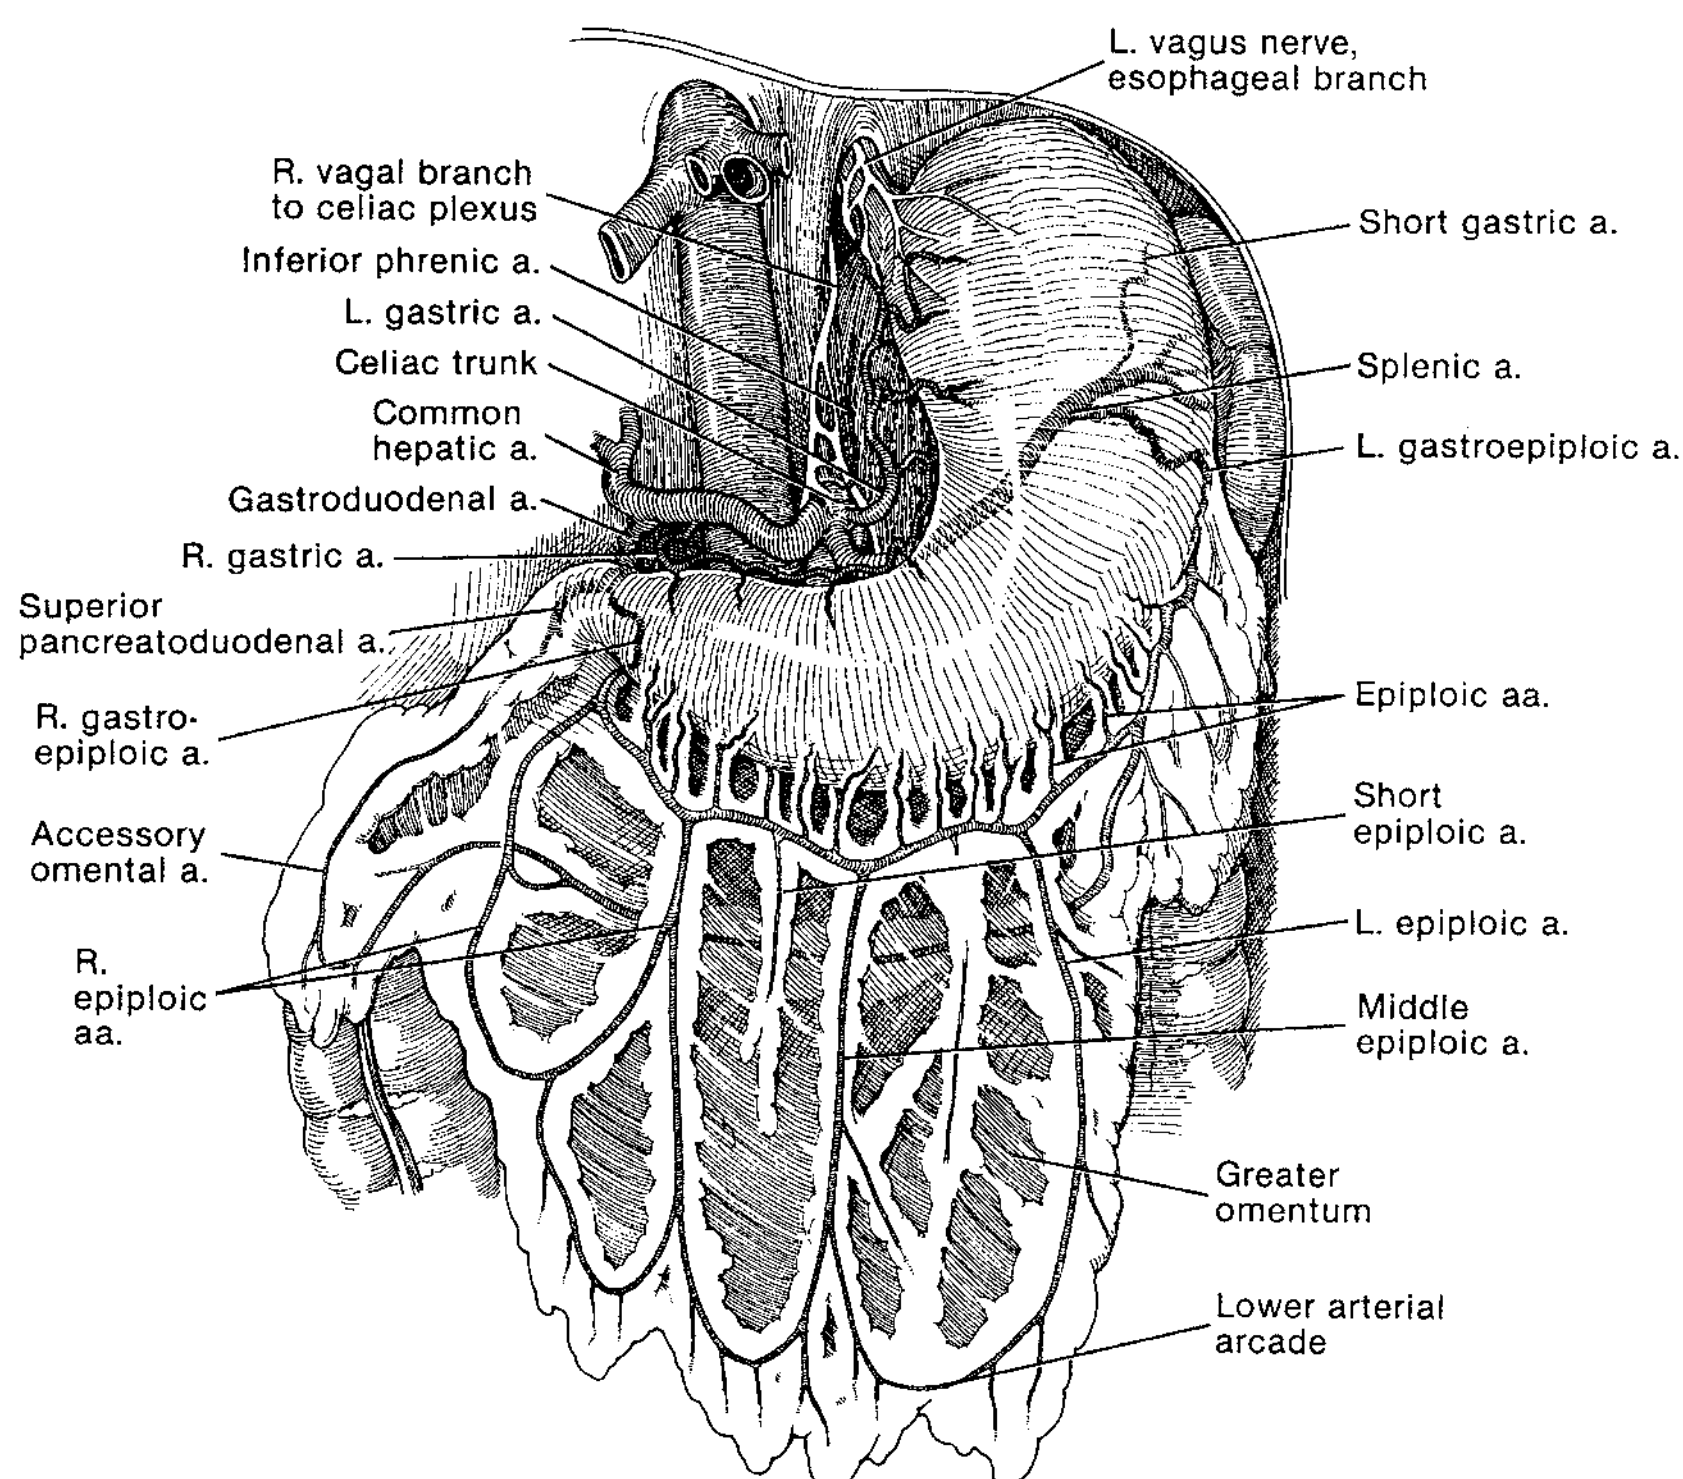

## Gastrocystoplasty

The bladder may be augmented with a gastric segment derived from either the antrum or the body of the stomach. When antral gastrocystoplasty is performed, the enteric stream is reconstructed using a Billroth I anastomosis (gastroduodenostomy). This procedure is now rarely performed in children because resection of the antrum has been associated with delayed gastric emptying, gastric dumping syndrome, and feeding difficulties. Currently, most surgeons prefer the use of the stomach body instead. A segment between 10 and 20 cm is marked along the greater curvature of the stomach and drawn as a rhomboid that extends toward the lesser curvature, ending 1 cm from the edge so as not to interrupt branches of the vagus nerve. Two arterial supplies exist to the greater curvature of the stomach: (i) the right gastroepiploic artery, derived from the right gastric artery, and (ii) the left gastroepiploic artery, from the splenic artery (Fig. 120.7). If the right gastroepiploic artery is chosen, the gastric segment should be obtained from higher on the greater curvature, lower if based on the left (Fig. 120.8). The gastroepiploic arteries supply the stomach with anterior and posterior branches that must be divided before the segment can be excised from the stomach. Atraumatic intestinal clamps are applied in parallel at the proposed incision sites on the stomach. Alternatively, an intestinal stapling device can be used to divide the stomach; however, the staples must be removed later. The vascular pedicle must be retroperitonealized in order to prevent internal hernia formation. A window is created in the transverse mesocolon that accepts the gastric augment and its vascular pedicle. The segment is passed posterior to the mesocolon and exits a second window that has been created in the small bowel mesentery

inferiorly. If the vascular pedicle is too short, additional branches between the gastroepiploic artery and the stomach must be divided. The stomach is sutured to the bladder beginning along the posterior aspect of the cystotomy.

## Ureterocystoplasty

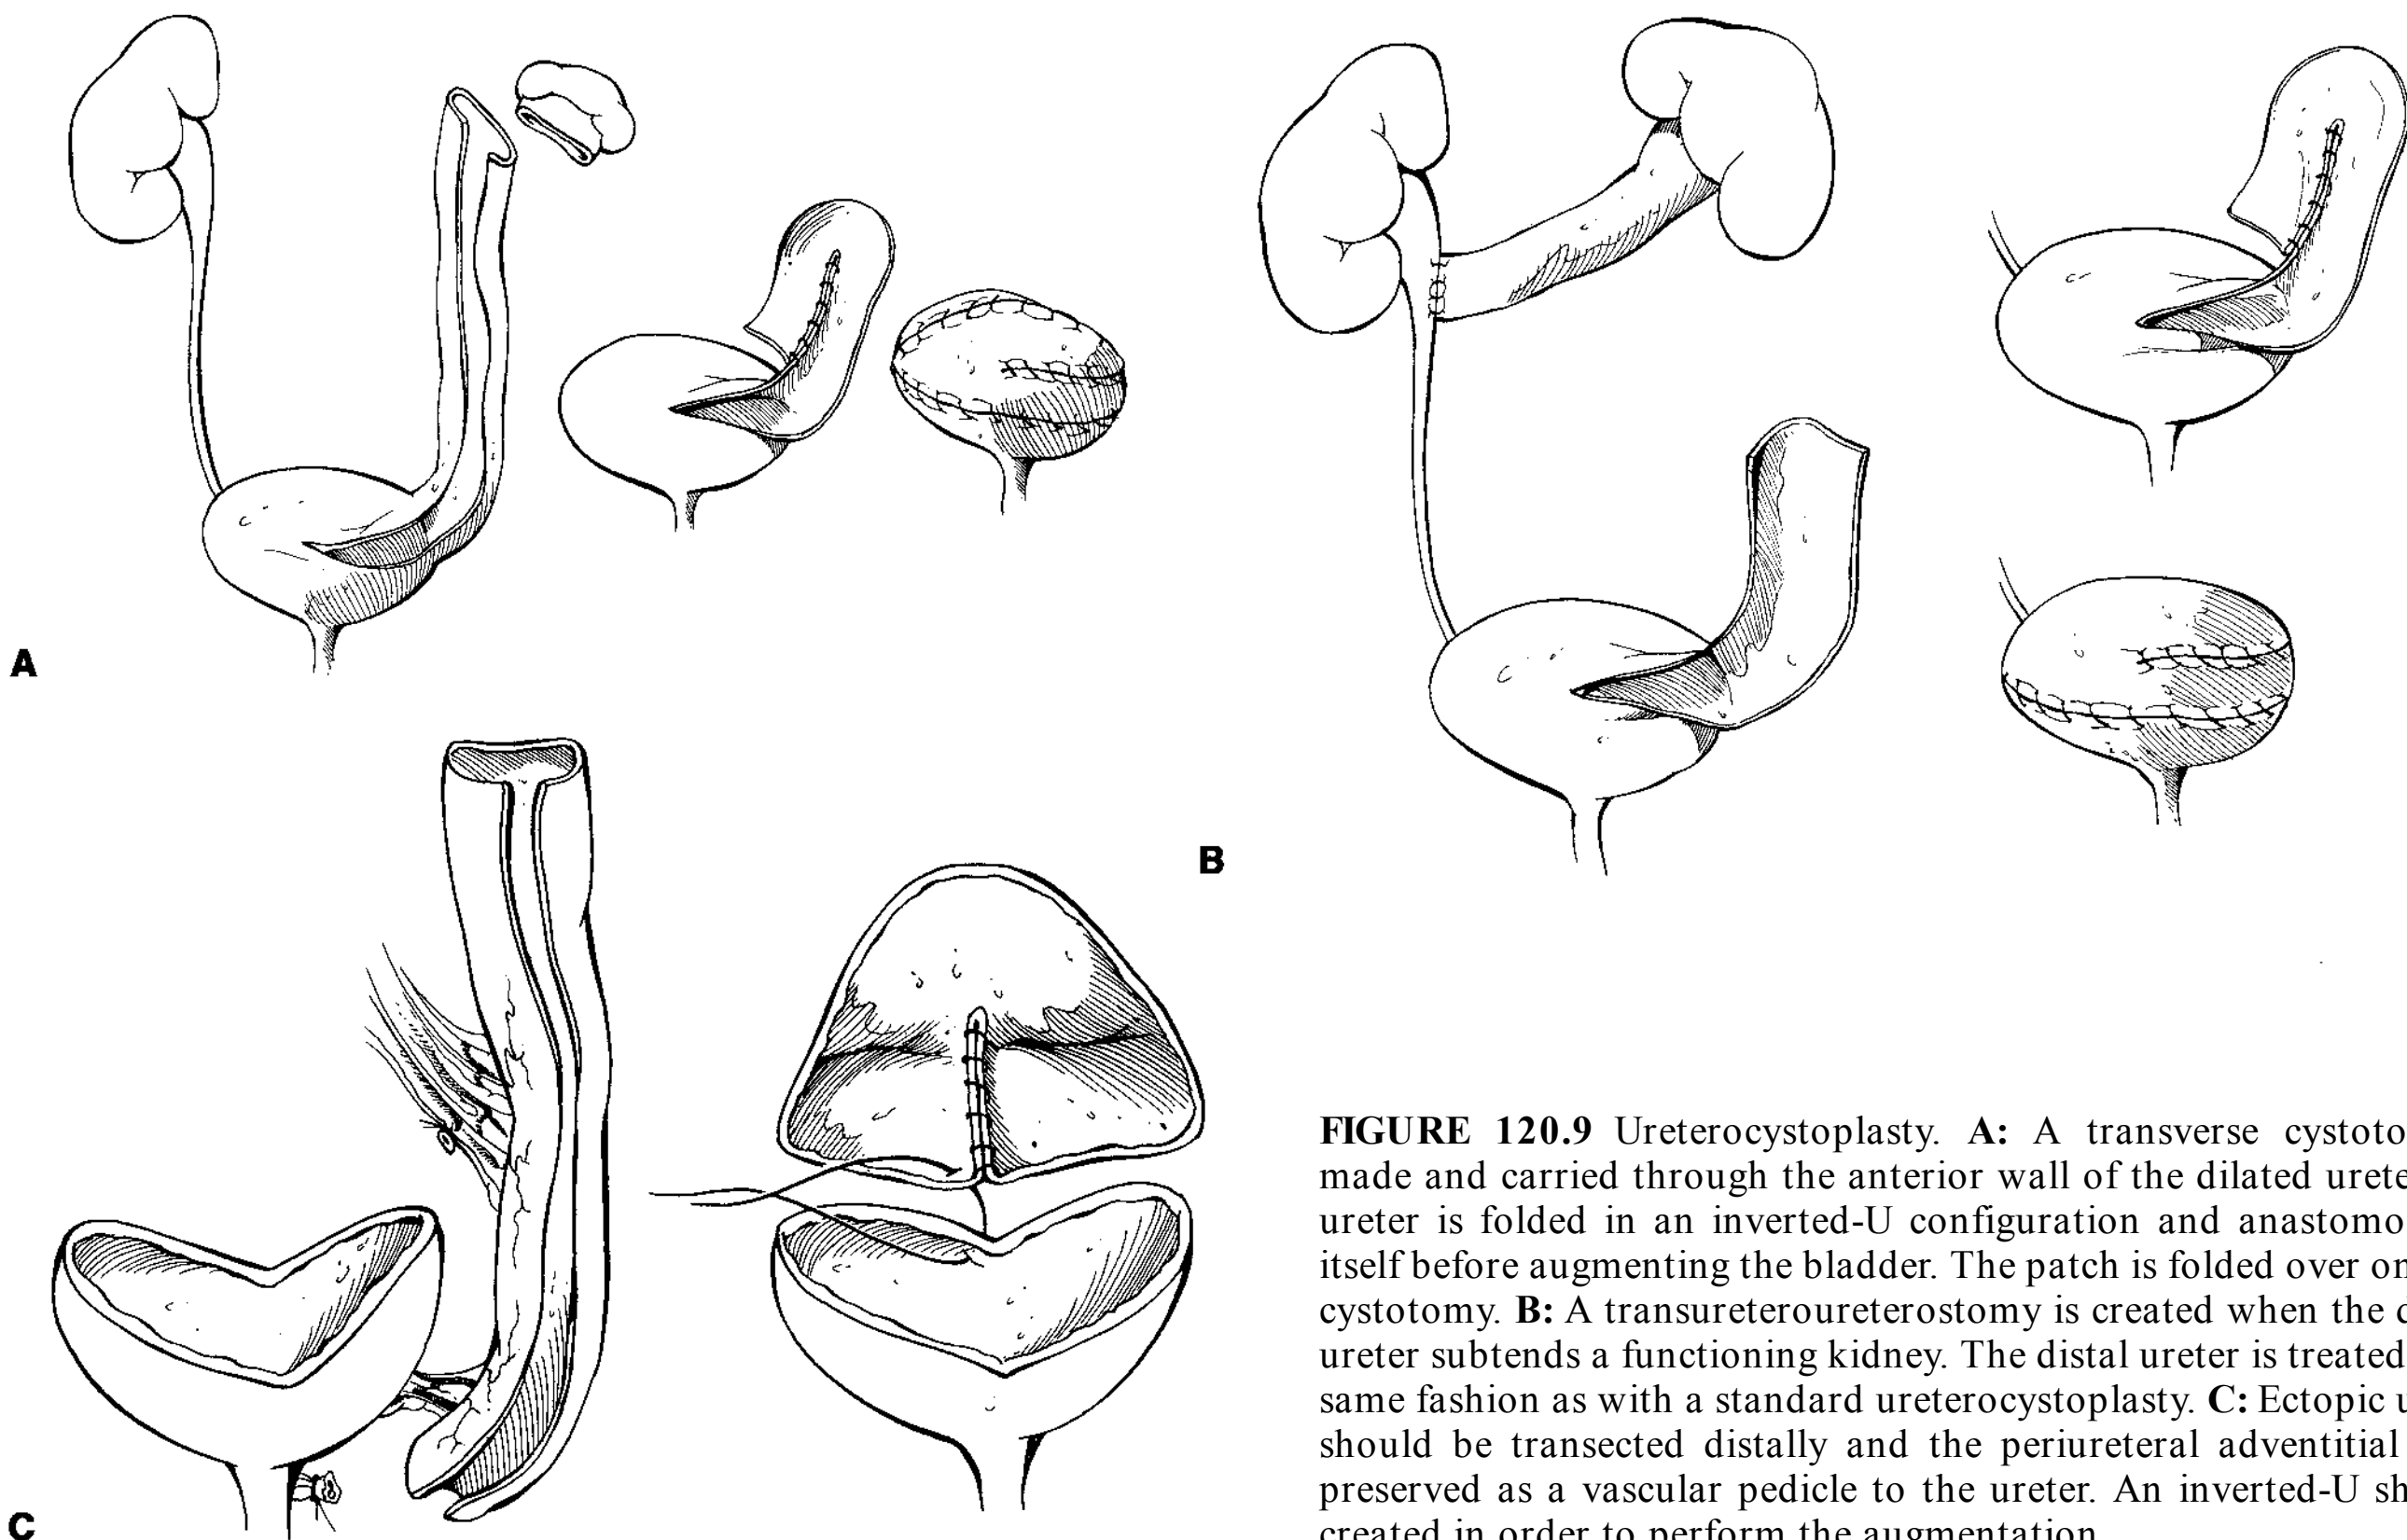

Unlike enterocystoplasty, ureterocystoplasty does not require a midline transperitoneal incision. The entire procedure can be performed retroperitoneally through a flank incision, to perform the nephrectomy and harvest the proximal portion of the ureter, and a Pfannenstiel incision, through which the augmentation is performed. Only a midline incision should be considered when two functioning kidneys exist, since a transuretero-ureterostomy will be required in order to re-establish continuity of the upper urinary tract after the distal ureter has been harvested (Fig. 120.9). Following the nephrectomy, careful mobilization of the ureter from its retroperitoneal location includes dissection of all surrounding adventitia away from the peritoneal lining toward the ureter itself. The ureter is then passed into the pelvis. A midline cystotomy is created such that the posterior portion of the incision includes the ureterovesical junction. The ureter, too, is incised along its anterior aspect. A spherical reservoir can be created by folding the proximal end of the ureter toward the cystotomy in an inverted U and suturing the adjoining edges of the ureter to itself. The remainder of the anastomosis between the ureter and the bladder is performed as in enterocystoplasty, beginning at the posterior aspect of the cystotomy and proceeding in an anterior fashion. Drainage tubes are placed through the native bladder muscle tissue.

**FIGURE 120.7** Blood supply to the anterior aspect of the stomach and greater omentum. (From Hinman F Jr, ed. *Gastrointestinal tract*. In: *Hinman's Atlas of Urosurgical Anatomy*, Chapter 6. Philadelphia: WB Saunders, 1993, with permission.)

**FIGURE 120.8** Gastrocystoplasty using the body of the stomach. **A:** A gastric segment of the body is mobilized on the right gastroepiploic artery. The left vessel may also be used; neither vessel as a pedicle should be free-floating through the peritoneum. **B:** A longer gastric segment along the greater curvature with a wider apex provides more surface area for augmentation. **C:** The gastric segment is anastomosed to the bivalved bladder with the mucosa inverted. (From Adams MC, Joseph DB. Urinary reconstruction in children. In *Campbell-Walsh Urology*, 9th ed., Chapter 124. Philadelphia: WB Saunders, 2007, with permission.)

**FIGURE 120.9** Ureterocystoplasty. **A:** A transverse cystotomy is made and carried through the anterior wall of the dilated ureter. The ureter is folded in an inverted-U configuration and anastomosed to itself before augmenting the bladder. The patch is folded over onto the cystotomy. **B:** A transureteroureterostomy is created when the dilated ureter subtends a functioning kidney. The distal ureter is treated in the same fashion as with a standard ureterocystoplasty. **C:** Ectopic ureters should be transected distally and the periureteral adventitial tissue preserved as a vascular pedicle to the ureter. An inverted-U shape is created in order to perform the augmentation.

---

## Urinary and Abdominal Drainage Following Augmentation Cystoplasty

---

If an incontinence procedure has not been performed, an appropriately sized urethral Foley catheter is used. However, since the retention balloon can cause pressure necrosis of the bladder neck following incontinence procedures, some surgeons would instead use a Robnel catheter or Silastic feeding tube, which may be secured with 3-0 silk sutures passed through the bladder and abdominal wall and tied over a cotton bolster. Additionally, a suprapubic Malecot catheter should be placed through a separate incision in the native bladder and brought out through the anterior abdominal wall. It is advised that this tube in particular be secured with 3-0 nylon sutures, since it will remain until after a cystogram has demonstrated a healed anastomosis and the patient is successfully catheterizing the reconstructed bladder, approximately 3 weeks. Irrigation with sterile saline should be instituted on postoperative day 3 in an effort to cleanse the newly augmented bladder free of the copious amounts of mucus that the enteric segments produce. A closed-system vacuum drain is employed briefly following surgery and removed when minimal peritoneal drainage exists. In patients with ventriculoperitoneal shunts, cerebrospinal fluid can be confused for persistent urinary drainage; it can be discriminated by its lower creatinine level than urine.

---

## OUTCOMES

---

### Gastrointestinal Effects

---

The two most likely gastrointestinal complications following augmentation cystoplasty in children are diarrhea and vitamin B<sub>12</sub> deficiency (each in up to 23%). Small bowel obstruction may occur in approximately 3% of patients and is no more likely with any one particular segment of bowel. Gastrocystoplasty is associated with a greater risk for small bowel obstruction as a function of the difficulty in retroperitonealizing the vascular pedicle to the gastric patch. The potentially free-floating pedicle can permit internal herniation of bowel loops that in later stages compromises vascularity to the gastric patch itself.

Diarrhea, a complication most often found following the use of the ileocecal valve (up to 23%), may also be seen after standard ileocystoplasty, although less frequently (11%). For this reason, use of the ileocecal valve is not advocated when other segments will serve just as well. The sigmoid, for instance, dilates and lengthens as a consequence of constipation, thus affording the surgeon a more redundant segment with which to augment. An additional advantage of sigmoid is its proximity to the bladder.

Vitamin B<sub>12</sub> deficiency can be avoided by limiting the length of small bowel harvested and in particular by preserving the terminal 20 cm of ileum, the major site of B<sub>12</sub> absorption. Ileocecal augmentation cystoplasty carries a greater risk for vitamin B<sub>12</sub> deficiency (23%) as compared with standard ileocystoplasty (11%), yet one is unlikely to encounter this deficiency at all since in the majority of circumstances a limited portion of nonterminal ileum is employed.

---

## Metabolic Effects

---

### Ileocystoplasty and Colocystoplasty

Despite the incorporation of intestine into the urinary tract, its absorptive and secretory capacity is retained: chloride, ammonium, hydrogen ions, and organic acids are readily absorbed and bicarbonate ions are secreted into the urine. The resultant hyperchloremic metabolic acidosis is driven by the absorption of ammonium ions that are followed by chloride in an attempt to maintain electroneutrality. Acidosis is rarely seen in patients with normal renal function, and any measurable increase in serum chloride and decrease in serum bicarbonate is subtle. Mild cases of metabolic acidosis can be managed with oral sodium bicarbonate (1 to 3 mEq/kg/day) with the goal being an increase in serum bicarbonate to a value >20 mEq/L. Severe acidosis requires intravenous administration of bicarbonate, usually as dextrose 5% with one-quarter normal saline and 50 mEq/L of sodium bicarbonate. Hyperchloremic metabolic acidosis may occur following augmentation with ileum, cecum, colon, or sigmoid but is most common following sigmoidocystoplasty.

Use of jejunum is associated with a pattern of metabolic derangement distinct from any other segment of bowel: a hypochloremic, hyponatremic, hyperkalemic metabolic acidosis. For this reason, it is recommended that jejunum not be used in pediatric augmentation cystoplasty, especially when renal function is poor.

As a consequence of the net secretion of chloride and hydrogen ions across the gastric mucosa, augmentation with stomach results in a hypochloremic metabolic alkalosis in 3% to 24% of the patients. This effect can be used to advantage in patients with renal dysfunction and acidemia, who will demonstrate decreased serum chloride and increased serum bicarbonate following gastrocystoplasty. In those patients whose renal dysfunction is characterized by a concentrating defect, gastrointestinal illness with vomiting can precipitate significant alkalosis that must be treated with intravenous fluid containing sodium chloride. Milder cases can be treated with oral salt supplementation, or inhibitors of histamine-2 (i.e., cimetidine) or the gastric acid H<sup>+</sup>/K<sup>+</sup> ATPase pump (omeprazole). It has also been reported that alkalosis occurs in the absence of gastrointestinal illness and may still be severe enough to require resection of a portion of the gastric segment. Alternatively, addition of ileum may balance the metabolic abnormality.

---

### Bladder Compliance

---

The immediate goal of augmentation cystoplasty should be that intravesical storage pressure decreases well below the threshold of 40 cm H<sub>2</sub>O, thus averting progressive upper tract deterioration. Although any gastrointestinal segment can provide a sufficiently compliant augment if it is very long and fully detubularized, most authors agree that, for a given length of bowel, ileum provides the greatest compliance of any segment. Of 323 patients who had undergone enterocystoplasty in one large review, 6% required an additional augmentation because of persistently elevated intravesical pressure. Colocystoplasty and gastrocystoplasty patients were 10 times more likely to need a repeat procedure as compared with those having undergone an ileocystoplasty (4).

---

## Urinary Tract Infection

---

Regardless of the segment chosen, persistent bacteriuria is common following augmentation cystoplasty, occurring in up to 95% of patients. The Indiana group reported symptomatic urinary tract infection in 23% of ileocystoplasties, 17% of colocolocystoplasties, 13% of cecocolocystoplasties, and only 8% of gastrocystoplasties, which suggests that bacterial colonization may be impeded by the reduced urine pH in bladders augmented with stomach (5). Symptomatic cystitis may be more likely when CIC is performed sporadically and incompletely or when mucus and stones serve as a nidus for colonizing bacteria.

---

## Calculi Formation and Mucus Production

---

The reported incidence of bladder calculi has ranged between 8% and 52% of patients following augmentation cystoplasty, yet the occurrence of bladder calculi may not be a specific complication of augmentation cystoplasty (6,7). Instead, poor patient compliance with CIC, colonization with urea-splitting bacteria, and the presence of mucus to serve as a nidus for the aggregation of salts may be the trifecta that results in calculus formation. By virtue of lesser mucus production and bacteriuria than either ileum or colon, stomach is least likely to be associated with bladder calculi. Mucus production from ileal segments does decrease over time as a result of villous atrophy, a feature not characteristic of colonic epithelium.

---

## Bladder Perforation

---

Perforation is the most serious complication of augmentation enterocystoplasty, and patients may present critically ill despite few localizing signs and symptoms. The condition should immediately be suspected when an augmented patient presents with fever and abdominal pain no matter how mild the

symptoms; shoulder pain secondary to diaphragmatic irritation from urine in the peritoneal cavity has also been reported. Which gastrointestinal segment carries the greatest risk of perforation is debatable (8). Any child is potentially at risk irrespective of the segment used. The underlying etiology for all perforations is believed to be ischemia within the bowel wall as a consequence of either overdilatation from infrequent emptying or high-pressure contractions or even reconfiguration by detubularization (9).

Patients suspected of having bladder perforation should undergo fluid resuscitation and receive intravenous broad-spectrum antibiotics and Foley catheter drainage while the evaluation is underway. A standard cystogram may miss up to 33% of bladder perforations; therefore, computerized tomography cystograms are advocated. While some have successfully employed nonoperative management, surgical exploration with resection of necrotic tissue and primary closure of the defect should be performed in a gravely ill patient, or when the patient fails to improve during nonoperative management (10).

---

## Hematuria–Dysuria Syndrome

---

This syndrome, occurring in 9% to 70% of patients who have undergone a gastrocystoplasty, presents with perineal pain, dysuria, hematuria, and skin excoriation around either the urethral meatus or the stoma of a catheterizable channel (11). A recent study of 10 children with hematuria–dysuria identified a positive correlation between the presence of infecting *Helicobacter pylori*, reduced urine pH, and the presence of symptoms following gastrocystoplasty (12). The authors recommend evaluating all patients who are under consideration for a gastric augment for the presence of *H. pylori* and treating the infection before performing surgery. Oral therapy with histamine-2 or H<sup>+</sup>/K<sup>+</sup> ATPase blockers should be helpful in symptomatic patients. If prolonged catheterization is anticipated, then bladder irrigations should be performed with a sodium bicarbonate–containing solution.

# CHAPTER 121 ■ THE MITROFANOFF PROCEDURE IN PEDIATRIC URINARY TRACT RECONSTRUCTION

MARK P. CAIN

The Mitrofanoff principle offered a major advancement to continent urinary reconstruction for children and adults. Earlier innovations—including clean intermittent catheterization (CIC), bladder augmentation, and a variety of bladder neck tightening procedures—created the foundation that made continent bladder reconstruction possible. The technically difficult problem was creating a bladder outlet that was tight enough to ensure continence but wide enough to allow reliable catheterization over a lifetime. In addition, many of these patients have physical disabilities that prevent easy access to the urethra, making independent urethral catheterization challenging. The concept of a continent catheterizable abdominal channel was introduced by Paul Mitrofanoff in 1980 (1) and has since been widely adopted as an integral part of urinary tract reconstruction for continence in most pediatric centers worldwide. This principle involves creation of a flap-valve continence mechanism for a conduit that is tunneled into a low-pressure urinary reservoir that can then be catheterized and emptied via an abdominal stoma (Fig. 121.1).

There are multiple surgical options for creating the Mitrofanoff channel. Appendicovesicostomy has by tradition been used because of the availability and the reliable blood supply, adequate lumen for catheterization, and supple muscular wall. Long-term follow-up has shown that appendicovesicostomy provides a durable channel with minimal late complications (2,3). In the absence of a suitable appendix, or in conditions where the appendix is used for an alternate procedure (such as for a Malone antegrade continence enema [MACE channel]), there are several other options that have been described. The most reliable alternatives have been the Monti–Yang ileovesicostomy, ureterovesicostomy, and continent bladder tube.

---

## DIAGNOSIS

---

The Mitrofanoff procedure can be performed with essentially any underlying bladder pathology. The most frequent diagnosis for children undergoing the procedure is neuropathic bladder, usually due to myelomeningocele. This procedure has also been described for reconstruction in patients with exstrophy–epispadias, cloacal anomalies, prune belly syndrome, posterior urethral valves, and other conditions. Although many of these children will require a bladder outlet procedure to provide urinary continence, some will have an intact and continent bladder outlet and the Mitrofanoff channel will provide an alternative to urethral catheterization. This is especially

**FIGURE 121.1** Umbilical Mitrofanoff stoma allowing catheterization in the sitting or standing position.

useful in wheelchair-bound patients who cannot access their perineum independently and also in patients with normal urethral sensation, in whom catheterization can be traumatic both physically and psychologically.

---

## INDICATIONS FOR SURGERY

---

In the past, the primary indication for bladder reconstruction was for upper urinary tract preservation. In the era of aggressive use of anticholinergics and intermittent catheterization in young patients, the more common indication for a Mitrofanoff channel is for urinary continence and convenient, independent bladder management for the patient. All patients should undergo a

trial of CIC to demonstrate that they are reliable and able to comply with a daily routine prior to bladder reconstruction.

## ALTERNATIVE THERAPY

The most common alternative to continent bladder reconstruction with a Mitrofanoff stoma is anticholinergic therapy with clean intermittent urethral catheterization. With careful attention to catheterization schedules and fluid intake, social dryness can be achieved in many patients with neuropathic bladder and other underlying bladder pathology without the need for surgical intervention.

Less frequently used alternatives are long-term incontinent cutaneous vesicostomy and conduit urinary diversion. Although these are both considered suboptimal in the era of continent urinary reconstruction, there will be a subset of patients who are unable to care for themselves because of physical, mental, or psychosocial problems, and the incontinent diversion provides a safer long-term option for these patients.

In the rare patient with a completely nonusable bladder, a continent urinary reservoir with a continent catheterizable channel is another alternative.

## SURGICAL TECHNIQUE

All patients are admitted the day before surgery for intravenous antibiotics to sterilize the urinary tract and for a mechanical and antibiotic bowel preparation. This is particularly important for patients with ventriculoperitoneal shunts, who have a risk of shunt infection. Potential sites for stomal location should be determined preoperatively, with the patient in the sitting and supine position.

Surgical exposure is usually obtained through a midline transabdominal incision that is carried around the umbilicus to leave enough fascia to close the abdomen without compromising an umbilical stoma. A lower transverse Pfannenstiel incision will also allow adequate exposure for both bladder augmentation and the Mitrofanoff stoma in thin patients. Laparoscopy has been used to assist in mobilization of the appendix and colon, allowing a smaller abdominal incision to complete the reconstruction without compromising exposure.

### Appendicovesicostomy

The right colon is mobilized beyond the hepatic flexure to allow maximal freedom of the appendiceal mesentery. If the appendix is retrocecal in location it is mobilized carefully from the cecal attachments with extra caution to avoid injuring the appendiceal artery, which is a branch of the ileocolic artery (Fig. 121.2). In some cases there is significant peritoneal inflammation due to the presence of a ventriculoperitoneal shunt, and the peritoneal incision must be carried medial to the ileocecal valve to adequately mobilize the appendix. When the length of appendix is inadequate, it can be extended by incorporating a segment of distal cecum as described by Cromie et al. (4). Prior to detaching the appendix, the bladder is mobilized to ensure that the bladder and appendix can easily reach the chosen site for the abdominal stoma without tension. The bladder is then opened to the left of the midline for a right

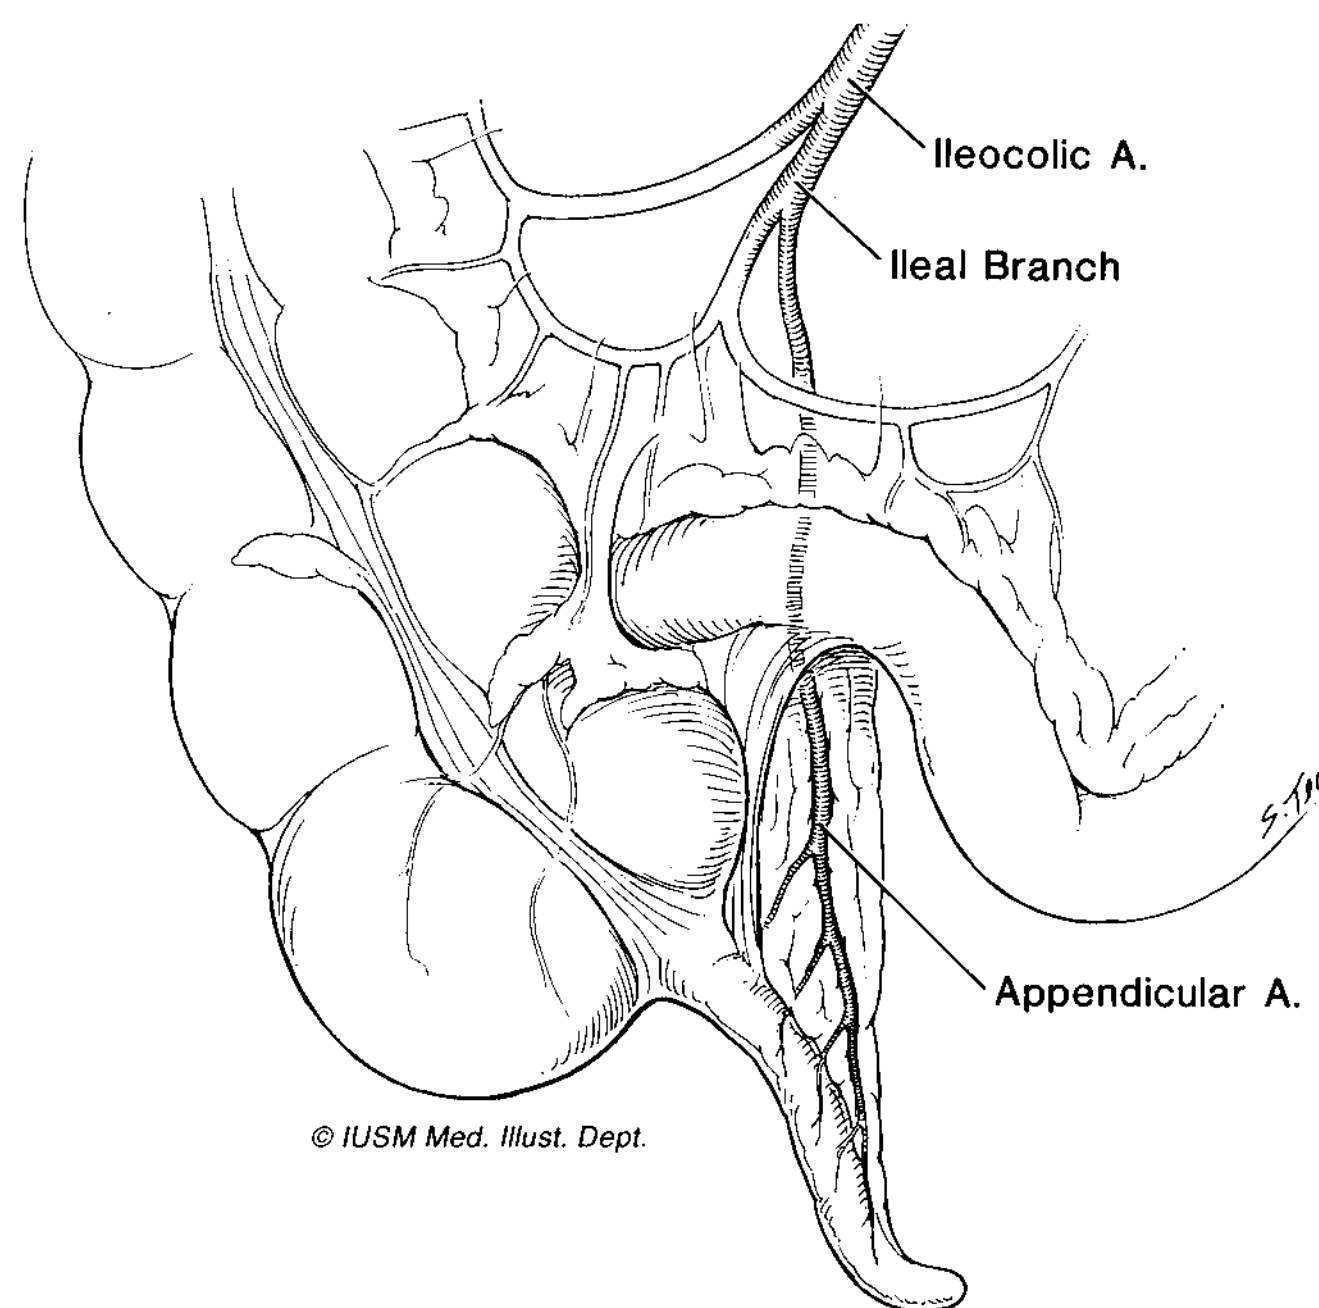

FIGURE 121.2 Vascular anatomy of appendicular artery.

lower-quadrant appendicovesicostomy or in a wide U-shaped anterior bladder incision for an umbilical stoma. The appendix is detached from the cecum either sharply or with a stapling device, and the cecum is closed with absorbable and permanent sutures. The mesentery to the appendiceal artery can be freed from the cecal mesentery to allow complete mobilization of the appendix if needed (Fig. 121.3). The terminal end of the appendix is then opened and irrigated with antibiotic solution, and a 12Fr catheter is passed to ensure that the appendix has an adequate lumen. If necessary the appendix can be gently dilated with serial sounds. If bladder augmentation is to be performed, the segment of bowel is isolated,

FIGURE 121.3 The mesentery to the appendix can be mobilized carefully, taking care not to injure the appendicular artery.

harvested, and reconfigured appropriately. If an additional segment of intestine is required for the Mitrofanoff (e.g., Monti–Yang) channel, it can be harvested simultaneously. The site of the bladder hiatus is then selected, again ensuring that it can easily reach the posterior abdominal wall fascia without tension. The site of the hiatus is opened wide enough to allow the appendix to pass without any tension, and a vessel loop is passed through the hiatus for traction. A submucosal bladder tunnel is then created using sharp dissection. Placing several traction sutures on the bladder to flatten out the posterior bladder wall facilitates this dissection. The orientation of the tunnel should be directed away from the bladder outlet and trigone to prevent painful catheterization postoperatively. The tunnel length should be at least 2.5 cm in length. It is occasionally helpful to inject 1:200,000 epinephrine along the path of the submucosal tunnel to facilitate the dissection and minimize bleeding. The terminal end of the appendix is then passed through the bladder hiatus and submucosal tunnel. The appendix is spatulated and secured distally with two 4-0 absorbable sutures incorporating full-thickness bites of the appendix and detrusor muscle and mucosa. The remainder of the anastomosis is completed using 4-0 or 5-0 absorbable sutures, securing the bladder mucosa to the appendix. The appendix is also secured at the level of the bladder hiatus using several 4-0 absorbable sutures. The channel is catheterized with a 12Fr or 14Fr catheter to ensure that it passes easily across the hiatus and submucosal tunnel. The stomal site is then selected, taking care to ensure that the bladder hiatus can reach the posterior fascia without tension. A U-shaped (umbilical) or V-shaped skin incision is made at the stomal site, and the flap is freed sharply to the level of the fascia. A cruciate incision is made in the fascia and widened to allow passage of an index finger. The appendix is then brought through the fascial opening and the appendiceal/bladder hiatus is secured to the posterior fascial wall using 3-0 absorbable sutures, taking care not to angulate or compress the appendiceal mesentery (Fig. 121.4). This maneuver ensures a short, straight extravescical appendix channel. The cecal end of the appendix is then spatulated on the antimesenteric side, and if there is redundant appendix it is amputated. The stomal anastomosis is secured using interrupted 4-0 absorbable sutures (Fig. 121.5).

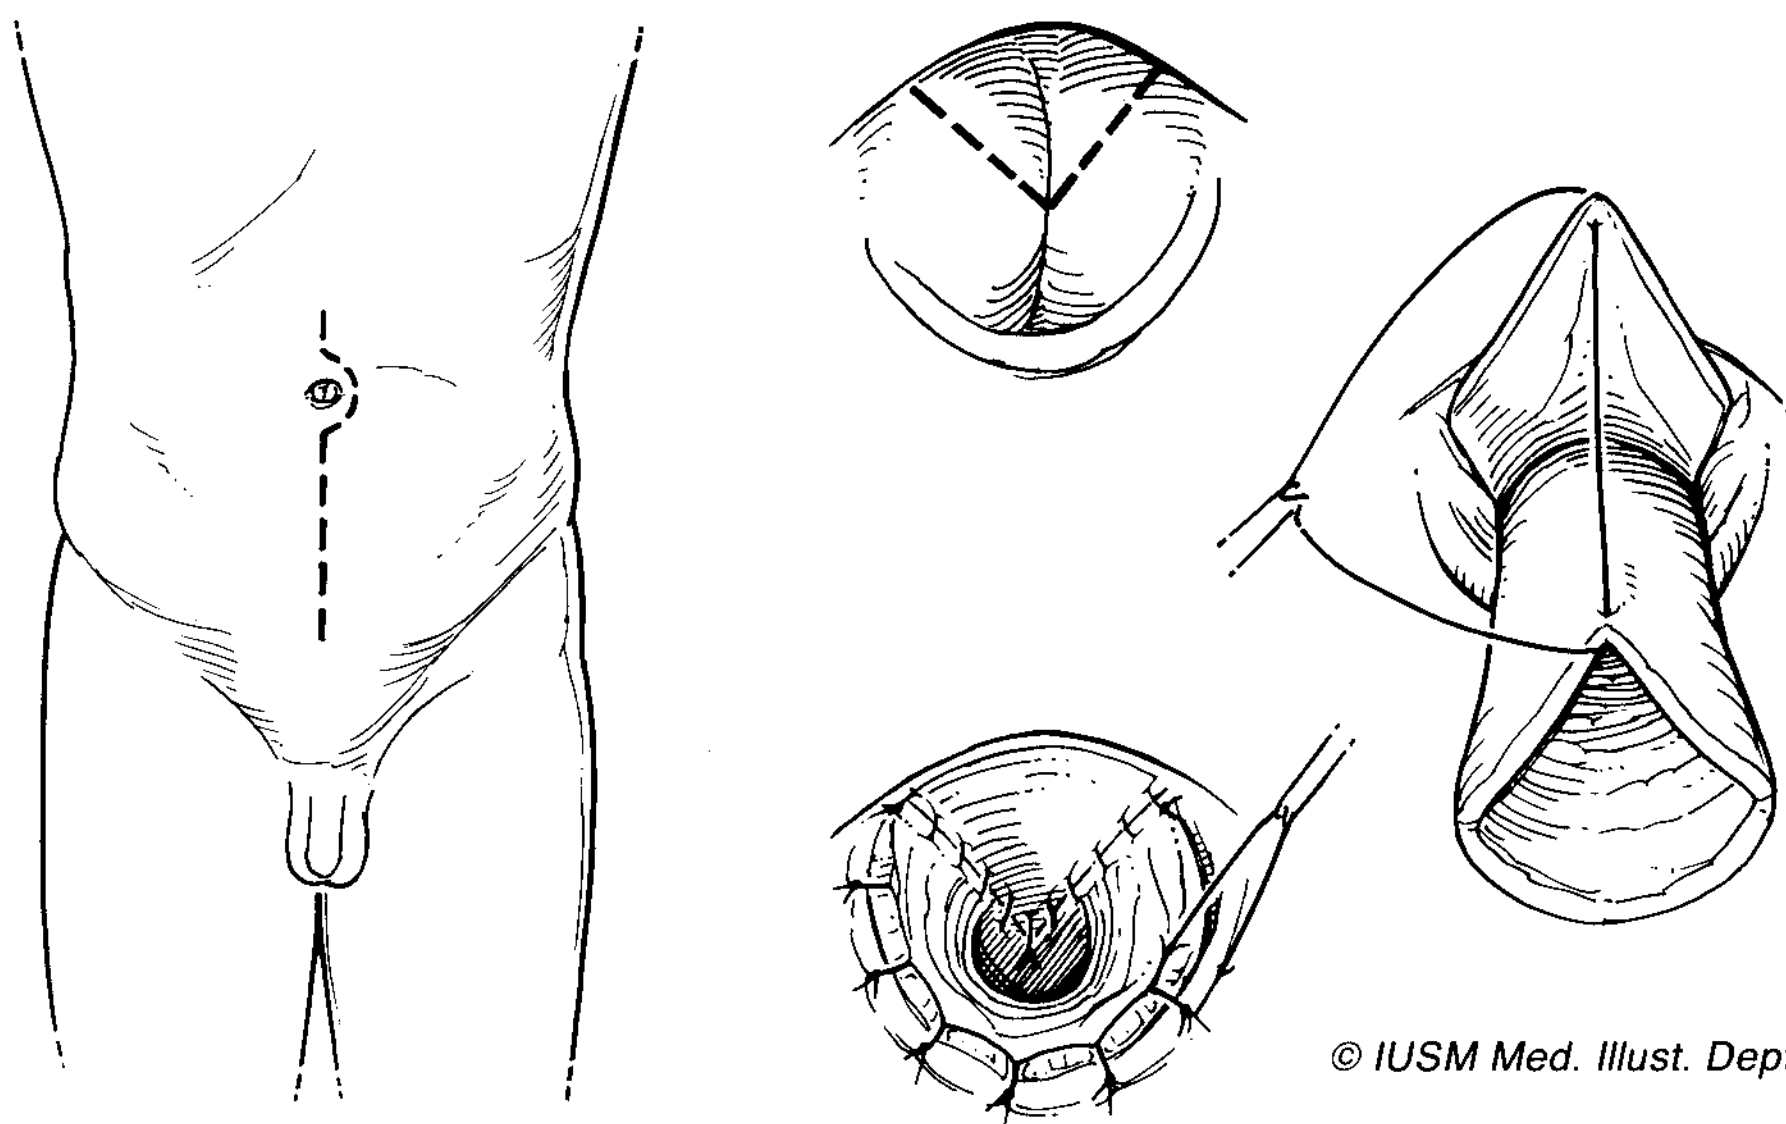

**FIGURE 121.4** The bladder is secured to the posterior abdominal fascia to avoid redundancy in the extravescical channel, which can be a source of late catheterization problems.

The stoma is then catheterized multiple times with the bladder both distended and empty to ensure that there is no angulation in the channel. A 12Fr catheter is left indwelling for 3 weeks before initiating intermittent catheterization.

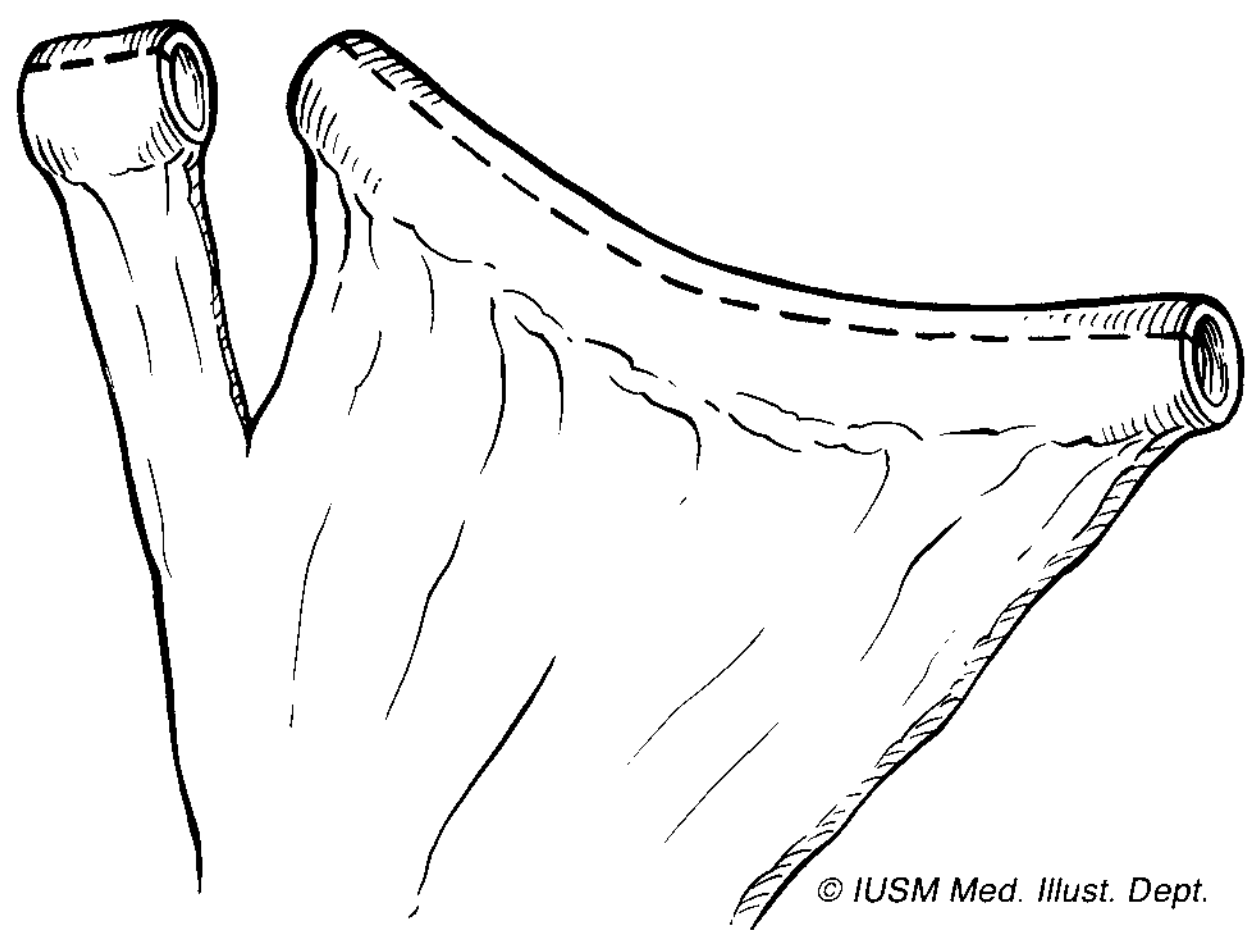

When both Mitrofanoff and MACE channels are indicated, and the appendix is of adequate length to create both channels, it can be split, with the majority of the mesoappendix left intact with the Mitrofanoff segment, basing the blood supply to the appendiceal stump off the cecal artery. In some cases the appendix is too short to use for both channels, but in this circumstance the appendix can still be used for both channels, utilizing one of the described stapling techniques to extend the appendix into the cecum for the MACE channel (5,6).

### Monti–Yang Ileovesicostomy

The concept of retubularized ileum as a replacement for the appendicovesicostomy was introduced in 1997 (7,8), and it has quickly become the ideal alternate to appendix as a choice for the Mitrofanoff channel. Large series with longer follow-up have confirmed the equivalent outcomes for the Monti–Yang channel and appendicovesicostomy (9). The growing indications for and use of the MACE channel have led to

**FIGURE 121.5** The skin stoma is completed by securing the wide-based V flap of skin into the spatulated channel.

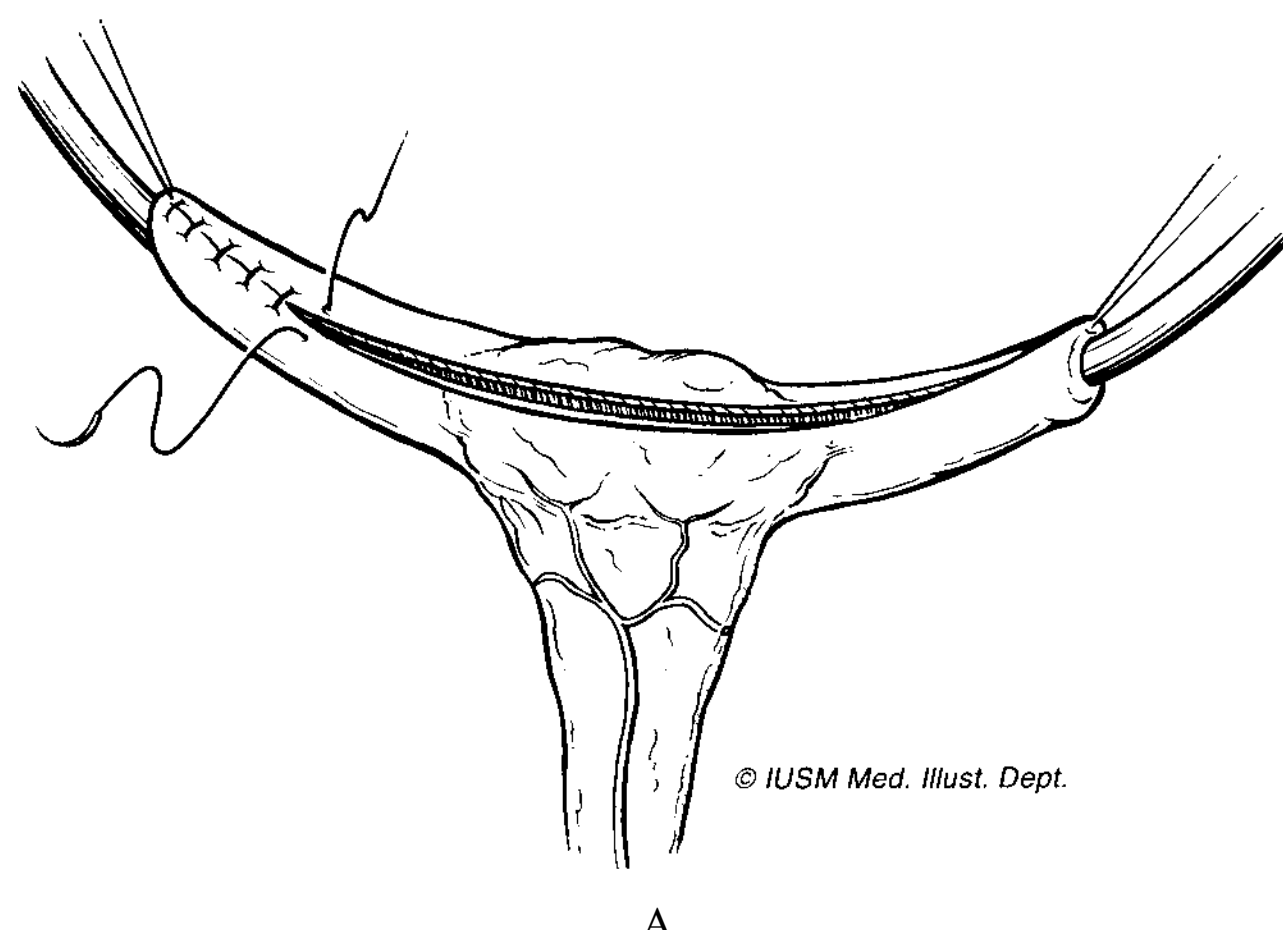

**FIGURE 121.6** A 2.5- to 3-cm segment of ileum is harvested, distal to the segment of intestine to be used for augmentation (if indicated).

preservation of the appendix for the appendicocostomy stoma and the need for alternatives for a bladder channel. Because many of the children will also undergo bladder augmentation at the time of reconstruction, the Monti–Yang channel can be easily constructed from a segment of the bowel harvested for augmentation.

A 2.5- to 3-cm segment of intestine is harvested with a well-vascularized segment of mesentery (Fig. 121.6). If ileal augmentation is planned, the Monti–Yang segment can be easily harvested from the distal end of the segment with a shared mesentery. The ileal segment is opened on the antimesenteric side (Fig. 121.7). It can be opened slightly off the midline to provide a longer segment for implanting into the bladder. The opened segment is then retubularized transversely in two layers over a 14Fr catheter. The bowel mucosa is approximated with running 5-0 or 6-0 absorbable sutures and the muscular layer is closed with running or interrupted 4-0 absorbable sutures (Fig. 121.8). The stomal end is not closed initially, providing wide spatulation of the antimesenteric side of the tube for later stomal anastomosis. The technique of implanting the tube into the bladder and creating a stoma is identical to that for appendicovesicostomy (Fig. 121.9). The Monti–Yang tube can be created out of any segment of intestine with good results. If there is inadequate bladder volume for creation of a submucosal tunnel,

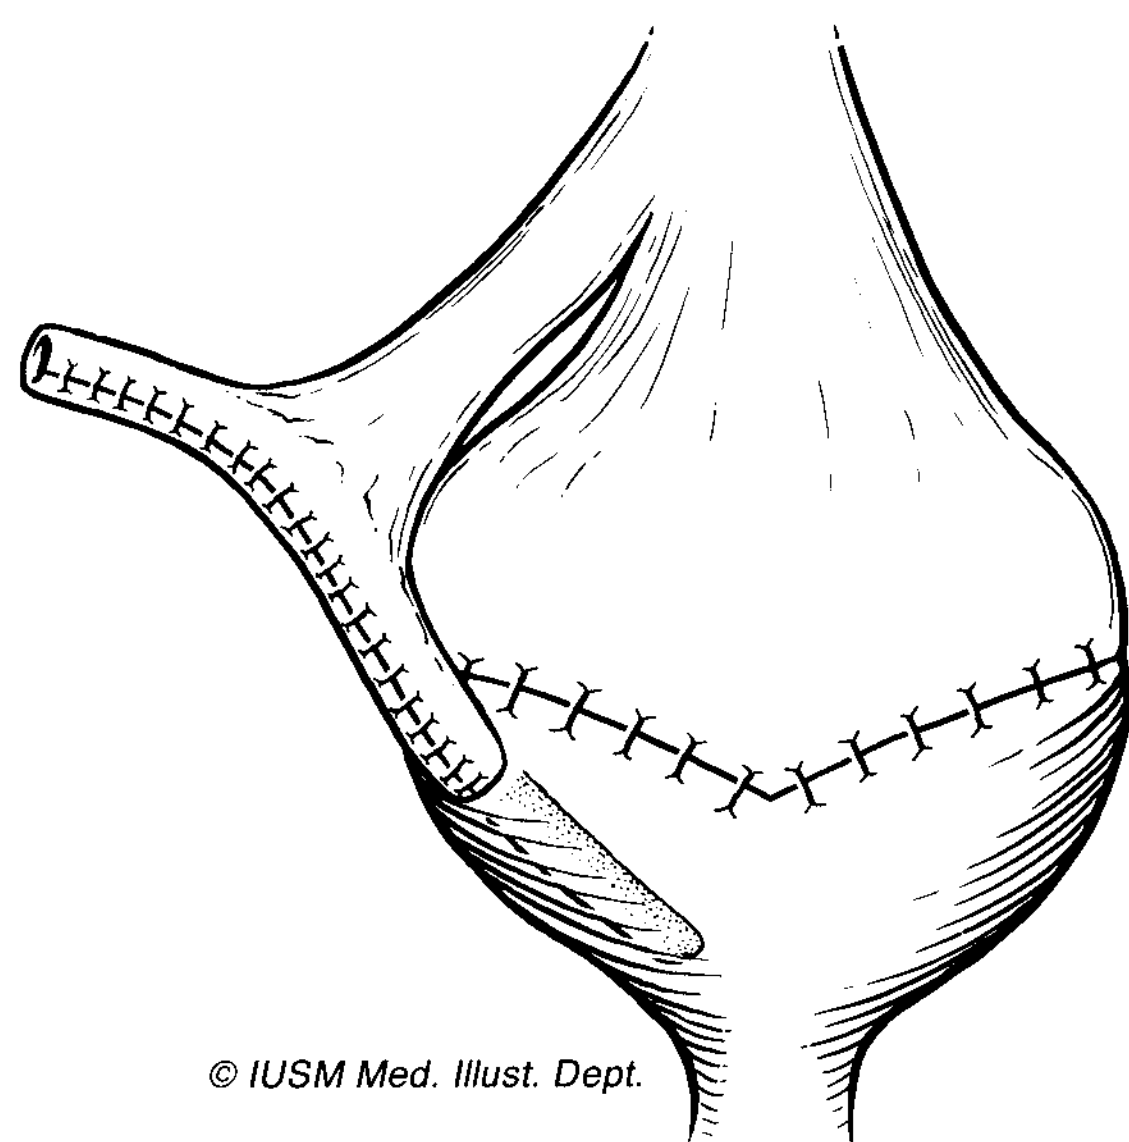

**FIGURE 121.7** The Monti segment is detubularized on the antimesenteric side. This incision can be between the 9 and 12 o'clock positions depending on the desired length of intravesical tunnel.

**FIGURE 121.8 A:** The channel is closed with two layers of absorbable sutures. The stomal end is either closed with interrupted sutures or not closed to allow adequate spatulation at the skin stoma. **B:** Operative photo of completed Monti channel.

the tube can be implanted into a segment of bowel using an extravesical technique. Care must be taken to secure the entire tunnel length to the posterior fascial wall to prevent breakdown of the thin muscular backing during repetitive bladder filling, with the potential for late incontinence. A 12Fr catheter is left across the channel for 3 weeks before initiating intermittent catheterization. The Monti channel can also be used for the MACE channel, with two channels created side by side (Fig. 121.10).

When the Monti channel does not provide adequate length for the extravesical section to reach the abdominal stomal site without tension, then two Monti tubes can be reconfigured and connected (the “double Monti”). This can provide a longer limb to reach the skin stoma but also introduces additional postoperative complications of diverticulum, angulation, and perforation at the anastomosis of the two channels (10). To avoid this complication, Casale (11) described a long ileovesicostomy technique using a single piece of bowel to create a channel 10 to 14 cm in length. This technique involves a 3.5- to 4-cm segment of bowel that is isolated on its mesentery and divided into two equal segments for approximately 80% of the bowel circumference, leaving the two segments attached on the

mesenteric side. The two loops of intestine are opened close to the mesentery on opposite sides, allowing the bowel to unfold in opposite directions, creating a long flat plate of intestine that can be retubularized after trimming the redundant lateral edges. Late follow-up has demonstrated comparable results between the Monti and Casale-Monti, with the exception of slightly higher open revision rates for the longer spiral Monti placed

in the umbilicus, presumably due to extravesimal channel elongation and tortuosity over time and development of a perihatal diverticulum (Fig. 121.11) (12).

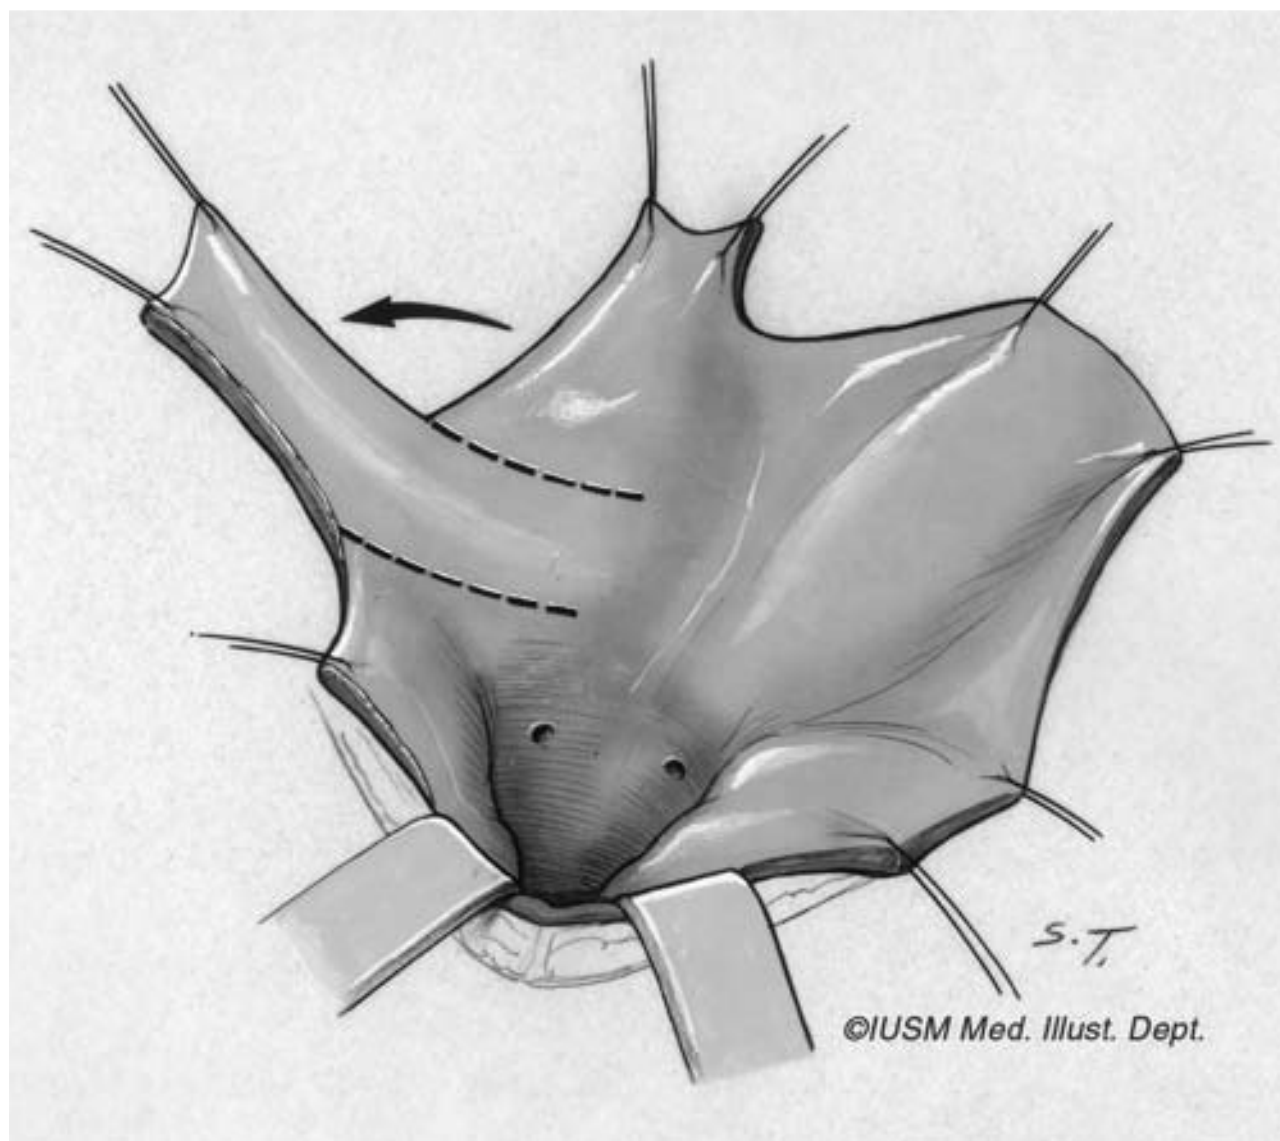

## Continent Vesicostomy

Small subsets of patients require creation of only a catheterizable bladder channel without bladder augmentation or other intra-abdominal procedures. These patients are good candidates for extraperitoneal continent vesicostomy. The largest reported experience is using the procedure described by Cain and Rink (13) utilizing an intravesical submucosal-mucosal-lined tunnel to create the continence mechanism. This procedure has been successfully used with a variety of underlying bladder pathologies.

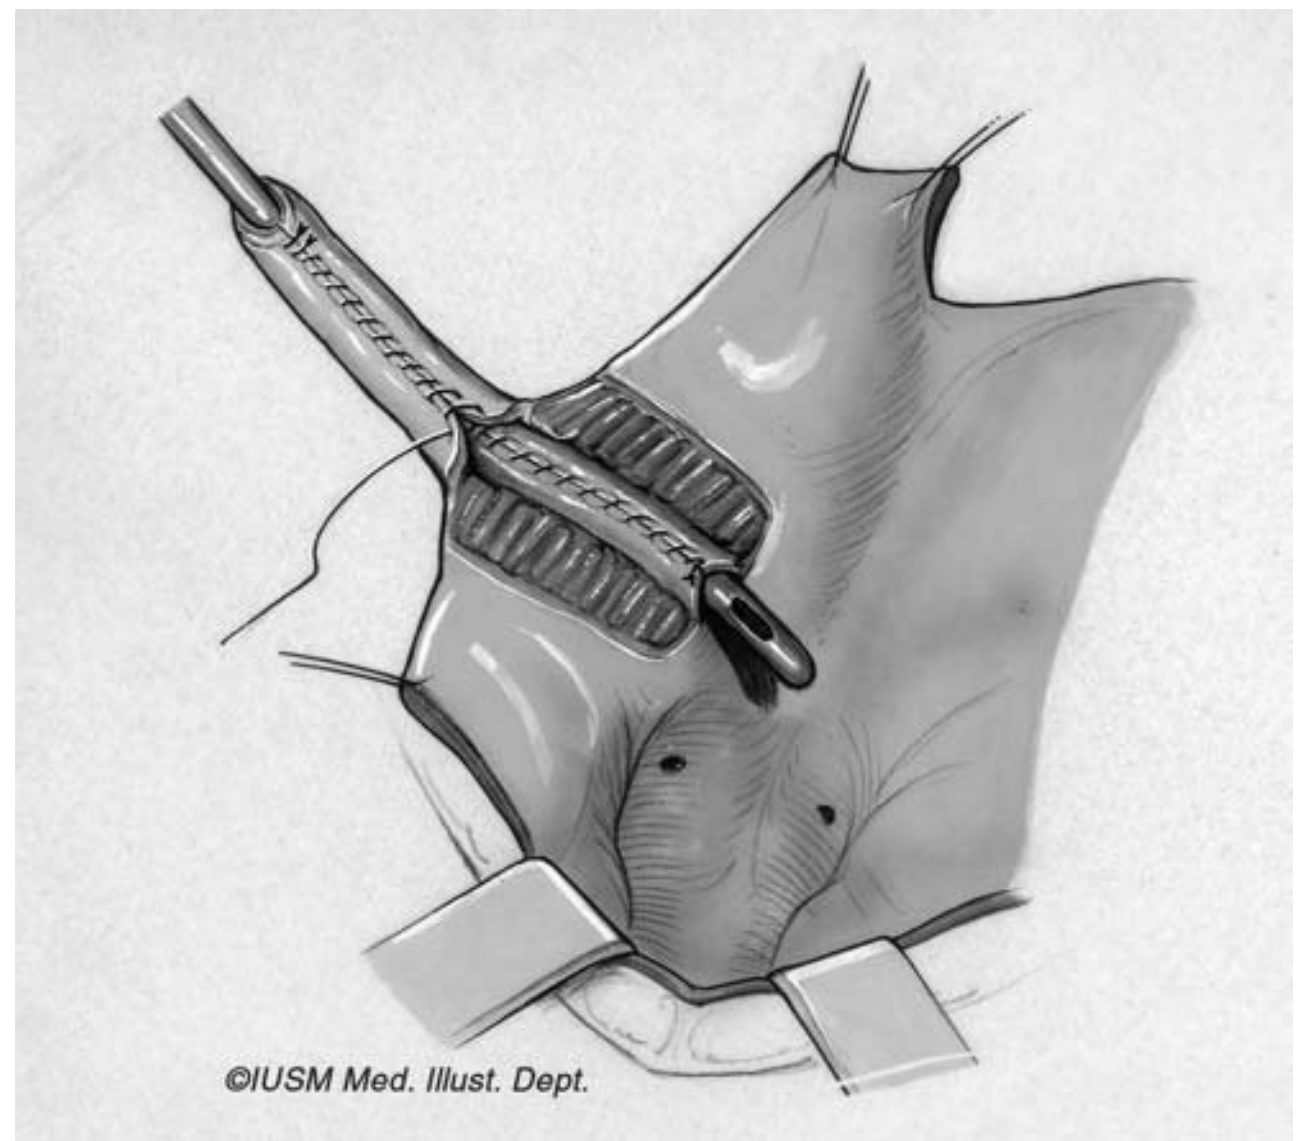

The bladder is opened to allow creation of either a midline or lateral full-thickness bladder flap (Fig. 121.12A). Incisions are extended intravesically, leaving a 2.5-cm plate of mucosa. The mucosa is sharply dissected off the underlying detrusor muscle laterally and medially to allow tension-free mucosal closure (Fig. 121.12B). The intra- and extravesimal mucosal tube is created over a 14Fr catheter with running 6-0 absorbable suture (Fig. 121.12C). The detrusor muscle of the extravesimal portion of the tube is then closed with 4-0 absorbable sutures (Fig. 121.12D). The continence mechanism is then created by closing the lateral edges of the bladder mucosa over the mucosal tube using running 5-0 absorbable suture (Fig. 121.12E). The stoma can be created in either the lower abdomen or umbilicus. An indwelling 12Fr catheter is left in place for 3 weeks.

## Ureterovesicostomy

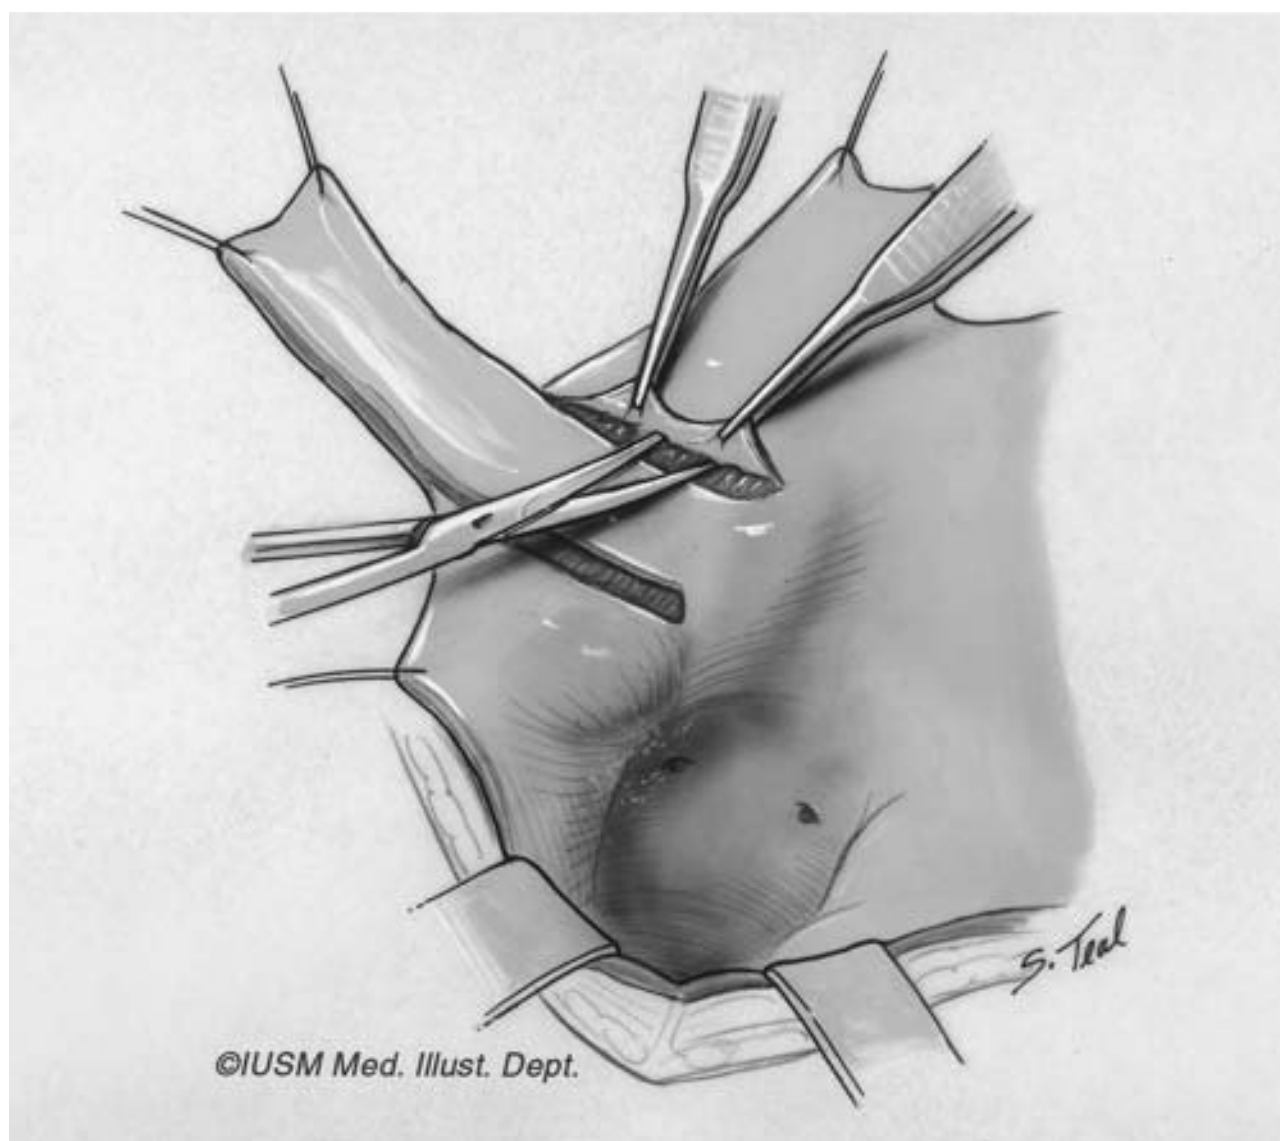

The ureter can be used as a catheterizable channel but has been less popular than bowel channels due to the additional upper urinary tract reconstruction required and the higher risk of skin stenosis and stomal leakage (14,15). When there is a unilateral nonfunctioning kidney with a nonrefluxing distal

**FIGURE 121.12** **A:** A 2.5-cm full-thickness bladder tube is harvested with adequate length to reach an abdominal stomal site. **B:** Intravesical mucosal incisions are made, leaving a 2.5-cm mucosal strip. The mucosal incisions should extend approximately 2.5 cm into the bladder. The lateral mucosal edges are mobilized sharply. **C:** The mucosal channel is closed using running 6-0 suture. **D:** The detrusor muscle of the extravascular portion of the bladder tube is closed with running 4-0 suture. **E:** The lateral mucosal edges are closed over the intravesical mucosal tube to create the continence mechanism.

ureter, a ureteral channel should be considered, but this unfortunate situation should be avoidable in the present era of careful management of these patients from early in life. Several reports have also documented successful distal ureteral reimplantation at the time of the ureterovesicostomy. Obviously, careful mobilization of the ureter to prevent proximal and distal stenosis is an important technical factor.

---

## OUTCOMES

---

### Complications

---

Potential complications of the Mitrofanoff channel are listed in Table 121.1. The most common complication is stomal stenosis, occurring in 10% to 20% of channels in most series. The continent vesicostomy has a much higher rate of stenosis than either appendix or Monti–Yang channels. A short period of passive catheter dilation for 7 to 10 days will avoid the need for surgical intervention in some patients. If necessary, revision of the stoma with a well-vascularized flap of skin is usually successful to manage significant stenosis.

Difficulty catheterizing the channel can occur secondary to angulation, perforation/false passage, or stenosis of the channel. Initially this should be treated conservatively with endoscopic placement of an indwelling catheter for 1 to 2 weeks. On

**TABLE 121.1**

#### COMPLICATIONS OF MITROFANOFF CHANNEL

Shunt infection
Abdominal abscess
Painful catheterization
Prolapsed stomal mucosa
Peristomal hernia
Wound dehiscence/infection

occasion reoperation will be necessary, and the patient and surgeon should be prepared to replace the entire tube if required.

Complications will usually occur within the first year but may occur many years after construction of a Mitrofanoff channel, and long-term follow-up with these patients is mandatory, especially when the Mitrofanoff channel is the sole means to empty the bladder (2,16).

---

### Results

---

Most large series have reported long-term success in up to 96% to 98% of Mitrofanoff channels (2,17). Because appendicovesicostomy has been used since the initial description of the procedure, there are better long-term data for this specific procedure, which has been shown to be durable over long periods of intermittent catheterization. We recently reported our results using the Monti–Yang channel in 199 consecutive patients, achieving 97% success with an average of 3 years of follow-up, which was identical to our experience with appendicovesicostomy (9). Because of the short continence zone required with the mucosal flap-valve technique for continent vesicostomy, there has been nearly 100% success with this procedure with respect to stomal continence.

Failure to obtain continence can be due to an inadequate submucosal tunnel, a fistula into the Mitrofanoff tube, breakdown of the muscular backing to the submucosal tunnel (especially when implanted into a bowel segment), or poor bladder compliance/high intravesical pressure. In many instances, the underlying problem will be the bladder, and any patient with a failed Mitrofanoff should undergo repeat urodynamic studies of the bladder and a trial of anticholinergics. We have had good success with reimplanting a previously constructed channel at the time of secondary bladder augmentation when the initial Mitrofanoff channel has failed because of changing bladder dynamics.

## CHAPTER 122 ■ BASIC PRINCIPLES OF LAPAROSCOPY: TRANSPERITONEAL, EXTRAPERITONEAL, AND HAND-ASSISTED TECHNIQUES

GAURAV BANDI AND LEONARD G. GOMELLA

Laparoscopic surgery is being increasingly utilized for management of urologic conditions that were traditionally managed by open surgery (1–3). Chapters 124 to 136 include laparoscopic procedures commonly performed by urologists in the United States. This chapter provides the foundation for any laparoscopic procedure and describes techniques to enter the intra- or extraperitoneal space, insufflate, place viewing and access ports (including hand-assist devices), and exit the abdomen. This chapter outlines the basic laparoscopic techniques and principles utilized for the other laparoscopic procedures described in this edition, including robotically assisted procedures.

---

### INDICATIONS FOR SURGERY

---

Laparoscopy provides a minimally invasive approach to many standard open surgical procedures. Benefits to laparoscopic intervention may include reduced analgesia, shorter hospital stay, faster return to normal activity, and enhanced cosmesis.

**Absolute contraindications** to transperitoneal laparoscopy include inability to tolerate general anesthesia or pneumoperitoneum (i.e., severe cardiac or pulmonary disease), intestinal obstruction and/or substantial distention, massive hemoperitoneum or hemoretroperitoneum, generalized peritonitis, abdominal wall infection, uncorrectable coagulopathy, or advanced intra-abdominal malignancy. **Relative contraindications** include morbid obesity, prior abdominal or pelvic surgery, large abdominal wall hernias, marked organomegaly, and pregnancy. This list, in general, also applies to extraperitoneal and hand-assisted laparoscopic procedures. Contraindications to extraperitoneal laparoscopy also include prior surgery or inflammation in the extraperitoneal space.

---

### ALTERNATIVE THERAPY

---

All patients undergoing laparoscopic surgery should be informed of the alternate approaches available (including open surgery and nonsurgical approaches) and the team's experience with the specific procedure. The patient must also be informed that the procedure may be terminated or converted to

a hand-assisted or an open approach due to failure to progress or management of complications at any point during the intraoperative or postoperative course. Patients often view laparoscopic surgery so favorably that they may expect to have no discomfort and immediately return to full activities. The patient must understand that interventional laparoscopy is still a surgical procedure with some of the inconveniences and complications associated with any operation. The patient needs to be aware of both complications unique to laparoscopy (e.g., fatal gas embolism, problems owing to hypercarbia, postoperative crepitus, pneumothorax, electrosurgical bowel injury) and procedure-specific complications (e.g., adjacent organ injury).

Although transperitoneal laparoscopy can be performed for the majority of urologic procedures, significant complications, such as bowel or vascular injuries, can occur when utilizing the transperitoneal approach. Extraperitoneal laparoscopy decreases the risk of visceral and vascular injury and may decrease the incidence of shoulder-tip pain, trocar site hernias, postoperative ileus, and adhesions, thereby resulting in slightly more rapid postoperative recovery. It is also associated with decreased alteration in cardiac and pulmonary function and may be especially beneficial in patients with previous transperitoneal surgery. Limitations to the extraperitoneal approach include limited working space, unique anatomic orientation, and a steeper learning curve. Excessive fat in the extraperitoneal space may obscure the anatomy, especially in the retroperitoneum. The limited retroperitoneal working area requires accurate placement of secondary ports and may make entrapment of large masses and intracorporeal suturing difficult. Although there is some evidence to suggest that there may be more CO<sub>2</sub> absorption in the extraperitoneal space, in general it can be managed by aggressive ventilation.

Hand-assisted laparoscopy was devised in part to overcome the learning curve of conventional laparoscopy. Hand-assisted laparoscopy has now been applied to many surgical scenarios and has been reported to provide many of the same advantages as “pure” laparoscopy in terms of patient recovery and morbidity (4,5). The hand-assisted approach can offer some additional benefits over pure laparoscopic techniques: it allows tactile feedback, it may facilitate dissection in challenging cases, it may reduce operative times, the hand is a more facile retractor and dissector than standard rigid instruments, and specimens can be easily removed intact. Hand-assisted

laparoscopy bridges the gap between standard open skills and advanced laparoscopic skills and may be important for training purposes as the ability to perform rapid hand exchanges is possible. Drawbacks of hand-assisted laparoscopy include the creation of a more noticeable (albeit small) incision, the potential for a slower recovery than pure laparoscopy, and the increased risk of wound-related complications.

---

## SURGICAL TECHNIQUE

---

### Patient Preparation

---

Careful patient selection and identification of possible relative and absolute contraindications are vital to a successful outcome of any laparoscopic procedure. A meticulous past history and physical examination are the initial steps in patient evaluation for possible laparoscopic surgery following the same criteria established for any other significant open surgical procedure. Patients with severe chronic obstructive pulmonary disease and significant cardiac histories should undergo further evaluation. Serum type and screen are sufficient for diagnostic laparoscopy or procedures associated with a low chance of major hemorrhage (e.g., varicocelelectomy). More extensive laparoscopic procedures (e.g., nephrectomy, prostatectomy) may require type and hold or type and ready depending on the surgeon's experience. For extraperitoneal laparoscopic surgery, no bowel preparation is needed. For transperitoneal laparoscopic procedures, a light mechanical bowel preparation can be given in an effort to decompress the bowel. Usually, a clear liquid diet and a Dulcolax suppository or half a bottle of magnesium citrate the day before the procedure is sufficient. A full mechanical and antibiotic bowel preparation should be considered if one anticipates encountering dense intra-abdominal adhesions or if the surgery involves entering the bowel.

The role of each operating room personnel (including surgeon, assistants, nurses, anesthesiologist, and other support staff) should be clearly defined and established for each laparoscopic case. Detailed information on laparoscopic instrumentation is available elsewhere, and specific instrumentation may be needed for the growing list of specialized procedures (6). The positioning of the monitors depends on the type of the procedure to be performed. For pelvic surgery, a single monitor at the foot is usually sufficient; for procedures such as nephrectomy and adrenalectomy, monitors on either side of the bed are recommended. All equipment must be fully functional and in operating condition before any laparoscopic procedure is started. A separate tray with open laparotomy instruments must be ready for immediate use in the event of complications or problems necessitating conversion to open surgery.

Positioning of the patient depends primarily on the laparoscopic procedure to be performed. Careful attention to detail during patient positioning, including adequate padding of bony prominences and securing the patient to the table, is critical for table repositioning during the procedure and avoiding neuromuscular complications. Advances in padding and table-mounted accessories have enabled the use of newer devices (e.g., gel pad, lateral support, bean bag), which, when used

appropriately, can markedly decrease the incidence of iatrogenic neuromuscular injuries.

General endotracheal anesthesia is essential for interventional laparoscopy. Nitrous oxide anesthesia is discouraged as it may cause bowel distention. An orogastric tube and a Foley catheter should be placed prior to any transperitoneal laparoscopic surgery to decompress the bowel and bladder, respectively, thereby decreasing the chance of injury during insufflation and initial trocar placement and facilitating visualization during surgery. Deep venous thrombosis prophylaxis can be achieved by utilizing pneumatic compression stockings or by administration of subcutaneous heparin preoperatively. The field should always be prepared widely should there be need to convert to an open procedure. In some procedures it is of advantage to extend the preparation to the knees and to drape the external genitalia into the surgical field to ensure access to the urethra for instrumentation (e.g., prostatectomy, cystectomy).

---

### Transperitoneal Access: Closed Technique

---

Initial pneumoperitoneum can be established using a Veress needle for most transperitoneal laparoscopic procedures and for many hand-assisted procedures. The Veress needle has a spring-loaded, blunt-tipped obturator to help prevent injury. The site of Veress needle entry depends on the position of the patient and the type of the procedure performed. With the patient in supine position, the patient is placed in the 10- to 20-degree Trendelenburg position and the entry into the abdominal cavity can be performed at the inferior or superior margin of the umbilicus. The umbilicus is the central point of the peritoneal cavity, making it an ideal observation site. Here, the abdominal wall is only two layers thick (fascia and peritoneum) and easy to traverse percutaneously (Fig. 122.1). If the patient is in a lateral decubitus position, then the Veress needle is passed two fingerbreadths medial and two fingerbreadths superior to the anterior superior iliac spine. Other potential insertion sites when the patient is either supine or in a lateral decubitus position are the Palmer point (i.e., subcostal in the midclavicular line on the right side) and the corresponding site on the left side.

Placement of the Veress needle into the abdominal cavity is a blind procedure with potential for injury to the underlying structures. If the patient has undergone prior surgery, open entry using the Hasson technique is considered the safest method (see following). A small incision is made at the Veress needle entry site. The abdominal wall can be elevated by grasping the periumbilical area with a sponge or with towel clamps. These maneuvers may raise the umbilicus up and away from the intestines but, more importantly, stabilize the abdominal wall. The needle is grasped like a dart along the shaft to limit its excursion into the abdominal cavity, with the angle of entry directed slightly caudad into the pelvis. Two distinct "pops" are felt as the needle passes through the fascia and peritoneum. It is important to traverse the layers of the abdominal wall in a near-perpendicular fashion to avoid "bouncing off" the peritoneum and remaining in the preperitoneal space. The umbilicus lies directly over the right iliac vessels, just below the aortic bifurcation at L4-L5 (Fig. 122.1). Deep penetration with the needle directly posteriorly could produce vascular injury.

**FIGURE 122.1** The Veress needle is most often placed at the inferior or superior aspect of the umbilicus. The needle is directed into the hollow of the pelvis, below the bifurcation of the great vessels.

Once the needle is in the peritoneal cavity, confirmatory tests are performed prior to insufflation, although none is foolproof. These include:

1. *Color test*: Aspiration of colored (red, yellow, green, brown) or malodorous fluid suggests improper placement.
2. *Drop test*: Apply a drop of saline inside the hub of the needle and lift the abdominal wall. If in proper position, the drop will enter the abdomen due to the negative intraperitoneal pressure.
3. *Advancement test*: If the needle has truly just entered the peritoneal cavity, then the surgeon ought to be able to advance the needle 1 cm deeper without the tip meeting any resistance.
4. *Modified Palmer test*: Inject 10 mL of saline into the needle and attempt to aspirate. Inability to aspirate suggests the fluid has dispersed into the abdomen and the needle is in correct position.
5. *Initial pressure reading*  $< 8$  mm Hg. The insufflator is turned on with no flow to obtain a pressure reading.
6. *A decrease in pressure with elevation of the abdominal wall.*

If perforation of a viscus occurs, the needle should be removed and discarded. A new needle may then be inserted at another location or the surgeon may choose to obtain open access using the Hasson technique (see detailed in a later section). Once insufflation has been completed and the primary trocar has been introduced, the injury can be examined with the laparoscope and a decision made as to the appropriate management. If blood appears, the Veress needle should be withdrawn slightly. Its positioning should be retested, the

pneumoperitoneum established, and the injury inspected for possible repair. Because of the small size of the Veress needle, the majority of these injuries do not require open operative intervention.

Once proper needle placement is verified, CO<sub>2</sub> insufflation should be started at a “low flow” (1 L/min) to maintain a pressure of  $< 8$  mm Hg. A high initial pressure with a low flow suggests improper needle placement. Once insufflation is underway, the abdomen should be observed to assure that a symmetrical pneumoperitoneum is developing. Monitor the insufflation by percussion over the liver, noting the characteristic dull echo tone that indicates proper insufflation. If the distention appears correct and 0.5 L has entered the abdomen, increase to “high flow” (usually  $> 2$  L/min). Initially, the abdomen is insufflated to 15 to 20 mm Hg to provide maximum distention and assist with atraumatic placement of the early trocars. An adult abdomen will typically require 3 to 6 L of CO<sub>2</sub> to create an adequate pneumoperitoneum, while children may require as little as 1 to 1.5 L. The working pressure should be decreased to 12 to 15 mm Hg after all trocars are placed to limit barotrauma.

If preperitoneal insufflation occurs, an attempt can be made to open the peritoneum with laparoscopic scissors and guide the tip of the trocar beneath it. CO<sub>2</sub> gas is then insufflated into the true peritoneal cavity, compressing the preperitoneal gas. Alternatively, evacuation of the preperitoneal space with a needle and syringe and reinsertion of the needle at the same or another site (i.e., superior umbilical position) may be attempted. Simply compressing the abdomen will disperse the CO<sub>2</sub> within the preperitoneal space. Open access (Hasson technique) can be used if these techniques are unsuccessful.

**FIGURE 122.2** Primary shielded trocar is held with a finger along the shaft to limit the depth of entry of the trocar.

### Primary Trocar Placement

Once the pneumoperitoneum is established, the Veress needle is removed and the primary (laparoscope) trocar is inserted. Nondisposable and disposable trocars are available. The trocar designation refers to the size of the instrument that can be inserted into the trocar and not the overall diameter of the trocar. Sizes range from 3 to 20 mm in diameter and 5 to 15 cm in length. A 5- or 10-mm trocar is used in adults to allow passage of the laparoscope. The incision site used for the Veress needle should be enlarged and the subcutaneous tissue spread to the fascia using a hemostat. The skin incision should be sufficient to allow the trocar to pass without resistance. Press the end of the trocar on the skin to create an impression that serves as a guide for the size of the incision. Insert a trocar with firm, steady pressure and a gentle twisting movement. A finger can be held along the shaft to serve as a brake from pushing the trocar in too far (Fig. 122.2). Pressure should be applied using the arm and elbow only. Direct the trocar toward the site of interest within the peritoneum to avoid torque from the abdominal wall during the rest of the case (Fig. 122.2). The abdominal wall can be lifted and stabilized with hemostats (Fig. 122.3).

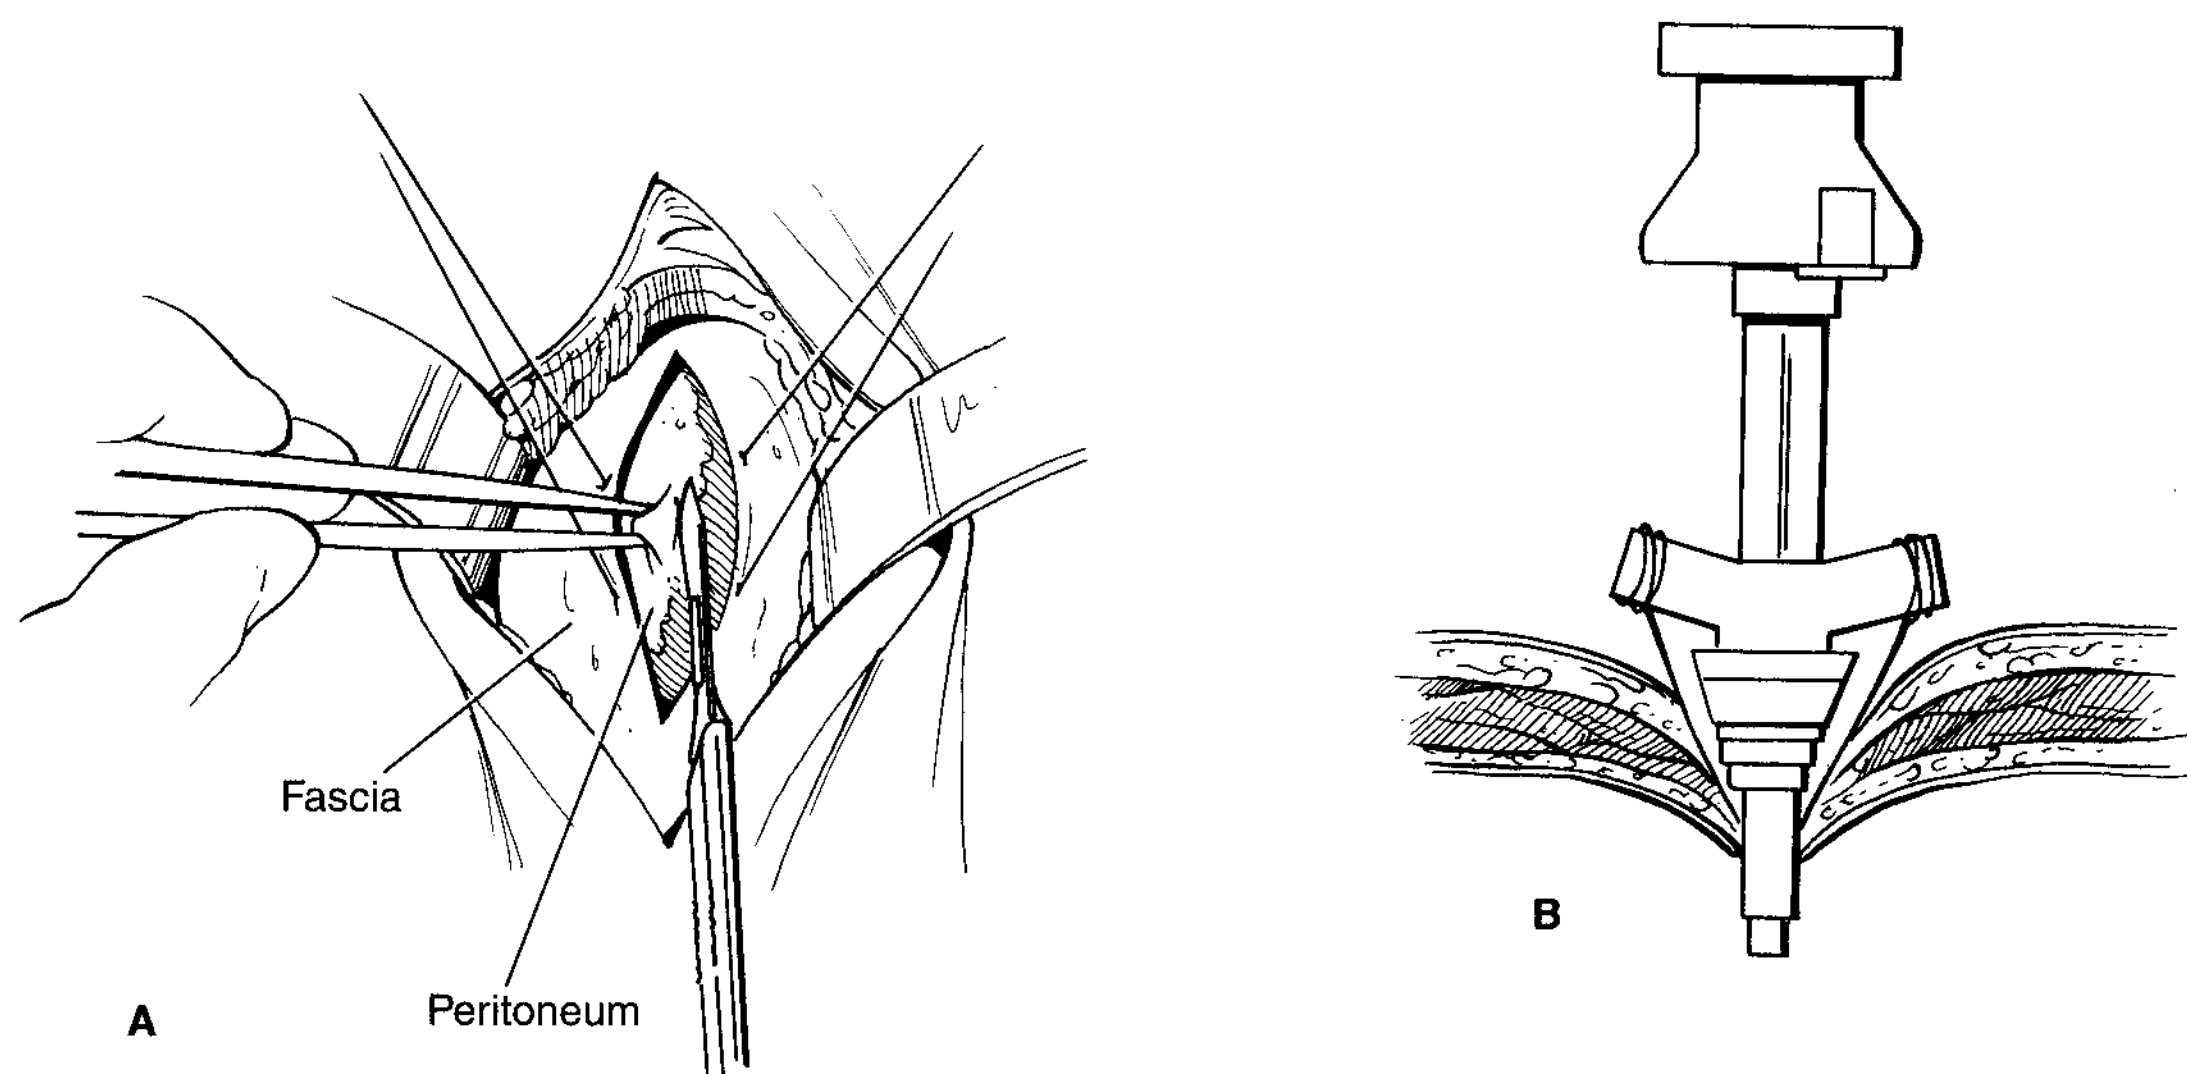

Noncutting dilating trocars and visualizing trocars have largely replaced the bladed/sharp-tipped and shielded metal trocars. After the skin incision is made, the laparoscope is placed into one of the visualizing trocars. Using pressure, a gentle twisting motion penetrates the layers of the abdominal wall, monitored under direct visualization of the tip through the laparoscope. The stopcock on the trocar can be left open during insertion, causing a rush of gas to escape (“whoosh test”), suggesting intraperitoneal placement. The CO<sub>2</sub> insufflator is connected to the stopcock on the trocar and insufflation is resumed. Working pressure of the pneumoperitoneum

is 10 to 12 mm Hg, but an initial pressure of 15 to 20 mm Hg is needed until all the trocars are placed to ensure a “tense” pneumoperitoneum. White-balance the camera and explore the abdomen to assess for possible injury by the Veress needle or trocar. The chance of a serious injury at the time of the insertion of the primary trocar is much greater than with the Veress needle.

Lens fogging is caused by passage of the room-temperature laparoscope into the warm, humid abdomen. As the laparoscope warms during the procedure, fogging becomes less

**FIGURE 122.3** The abdominal wall can be stabilized with towel clips placed on either side of the umbilicus during primary trocar insertion.

**FIGURE 122.4** A: Open laparoscopy using the Hasson technique. The peritoneum is entered under direct vision. B: A blunt-tipped Hasson-style trocar is secured using the stay sutures.

problematic. Fogging can be reduced by heating the laparoscope before insertion in warmed sterile saline, applying antifogging solutions, and limiting the time the scope is removed from the abdomen. If fogging or debris covers the lens, it can be wiped on a clean bowel; touching fat or a blood-tinged surface may leave a film on the laparoscope. The contact time on the tissue should be limited as the laparoscope tip can become quite warm. Heated circuits connected to the insufflation tubing and newer laparoscope systems with imaging or heating chips at the distal end can also reduce this fogging.

### Transperitoneal Access: Open “Hasson” Technique

Many surgeons use this as the primary access for all patients. Open access (Hasson technique) is also useful both for correcting preperitoneal insufflation and in the patient at high risk for multiple adhesions. The advantage is that entry into the peritoneal cavity is under direct vision, minimizing the risk of injury; however, it requires a larger incision and increases the chances of port-site gas leakage during the procedure.

An infraumbilical incision is made and two stay sutures are placed through the fascia on either side. The fascia and peritoneum are directly visualized and opened (Fig. 122.4A). After visual and digital confirmation of entry into the peritoneal cavity, the stay sutures are repositioned and the Hasson cannula is advanced through the incision into the peritoneal cavity. The stay sutures are either attached to the cannula to hold it in position (Fig. 122.4B), if needed, or secured with hemostats for use during closure. Insufflation tubing is attached to the Hasson-style trocar, and immediately “high flow” can be selected.

### Secondary Trocar Placement

The number, size, and sites of the secondary trocars depend on the procedure to be performed, the patient’s anatomy, and the

surgeon’s preference. The secondary trocars should be oriented toward the surgical site to provide tension-free maneuverability of the laparoscopic instruments. Their configuration should be planned so that neither the tips nor handles of the cannulas cross or come into close contact with one another, respectively (“crossing swords” and “rollover”), such that adequate working space is provided for all instruments to be used during a particular procedure. A general rule is to place secondary trocars in the midline or at least 8 cm from the midline in adults to avoid the rectus sheath (Fig. 122.5). If the rectus muscle is penetrated by a trocar, there is an increased risk of bleeding. Trocar placement for specific procedures is noted in the appropriate chapters that follow. At least one larger secondary trocar (10 or 10/11 mm) is usually placed to allow the passage of needles and larger instruments such as a linear endovascular stapler and clip appliers and to allow removal of specimens. Extended-length trocars are available if patients have particularly thick abdominal walls.

The placement of secondary or “working” trocars can be carefully monitored externally and internally to reduce the risk of injury. After full pneumoperitoneum is achieved, the selected site for the secondary trocar is gently pushed with the index finger while the site is observed through the laparoscope. The room is darkened and the light from the laparoscope is used to transilluminate the anterior abdominal wall to confirm that there are no underlying vessels or bowel. A skin incision of appropriate diameter to accommodate the trocar is made. It is useful to spread the subcutaneous tissue down to fascia with a clamp until the impression of the clamp tip is visible on the peritoneum. The trocar is introduced with the same technique described for the primary trocar except that the progress into the abdomen is followed on the monitor. Newer trocars have intrinsic stability threads that limit accidental removal. Suturing trocars to the skin using a heavy silk tether to prevent accidental removal during the case may be needed occasionally. The robotic surgical systems have specific trocars that should be used that mechanically connect to the robotic arm to allow control of the instrument more precisely.

**FIGURE 122.5** Secondary trocars should be placed in the midline (linea alba) or at least 8 cm from the midline to avoid injury to the rectus or the epigastric vessels.

## Trocar Removal

At the end of the procedure, the pneumoperitoneum should be lowered to 5 mm Hg or less to observe for any bleeding that may have been tamponaded by the working pressure. A brief survey of the abdomen should verify that there was no injury outside the operative field. Trocar sites should be examined prior to and after removal of the sheaths for bleeding or herniation. During trocar removal and fascial closure, bowel can become trapped along the trocar pathway. Trocar removal and suturing should always be observed laparoscopically; 10 mm and larger trocars require fascial suturing in adults.

Fascial closure can be accomplished by a variety of techniques. A 0 or 2-0 absorbable suture (i.e., Vicryl) on a small curved needle (i.e., CT-3 or UR-6) can be used to close the fascia externally. Fascial edges are grasped with either a toothed forcep or Scanlon clamps. Army-Navy retractors facilitate exposure. Laparoscopic closure needles (i.e., Endo Close, US Surgical, Norwalk, CT) are also available that are similar to a Stamey-style needle. A free 0 or 2-0 absorbable suture is engaged and passed percutaneously along the side of the trocar, through the fascia, and into the abdominal cavity using laparoscopic guidance. (Note: If stability threads were used to secure the trocar, they may interfere with passage of the closure device. Release the thread and slide it out of the incision while maintaining the trocar in the abdominal cavity.) The end of the suture is held with a laparoscopic grasper while the spring-loaded end is depressed to release the suture (Fig. 122.6). The closure device is then passed on the opposite side of the trocar, with the free end of the suture placed in

the end of the needle using laparoscopic guidance. Once engaged, the device is withdrawn with the attached end of the suture. The trocar is removed and the ends of the suture are tied from the outside using laparoscopic control. Another

**FIGURE 122.6** One technique to close the trocar site uses a device such as the Endo Close fascial closure needle. Here, the 2-0 absorbable suture has been passed into the abdomen alongside the trocar. The suture is grasped and the needle is withdrawn and passed on the opposite side of the trocar.

closure method utilizes the Carter-Thomason suture-passing device (Inlet Medical, Eden Prairie, MN). A suture guide (5 or 10 mm) device is placed into the trocar site and the suture-passing device is loaded with a 2-0 absorbable suture and the suture passed inside. The suture is released, the needle is placed in the opposite hole, and the suture is retrieved and removed through the opposite guide hole. The guide is removed and the suture is tied from outside the body.

After fascial sutures have been placed in all 10-mm port sites, each 5-mm port is removed under endoscopic control at 5 mm Hg pressure. Then each of the non-endoscope-bearing 10-mm ports can be removed under endoscopic control, and the fascial suture can be tied and the closure inspected endoscopically. The final 10-mm port is removed with the endoscope in place to assess for any bleeding along the tract. In this manner, each port is visually assessed for any bleeding at 5 mm Hg, thereby precluding the possibility of removing a port and missing an injured vessel. After removal of all ports, the CO<sub>2</sub> is allowed to pass out passively through the 5-mm port sites. This will reduce postoperative shoulder pain due to diaphragmatic irritation from the CO<sub>2</sub> gas. If pneumoscrotum is present, this should also be manually decompressed at this time.

The skin site should be thoroughly irrigated prior to closure. Herniation is most often associated with trocars larger than 10 mm, and when it does occur it is often due to a wound infection rather than improper fascial closure. Skin sites are closed with either subcutaneous sutures reinforced by Steri-Strips or with a skin adhesive.

## RETROPERITONEAL LAPAROSCOPY

This is often called “retroperitoneoscopy” and is used most often for renal and adrenal procedures. Following the usual preparation for transperitoneal laparoscopy, the patient is placed in a standard flank position. A 2-cm transverse skin incision is made just anterior to the tip of the 12th rib in the midaxillary line. An alternate site for the skin incision is the triangle of Petit approximately two fingerbreadths above the anterior superior iliac spine (Fig. 122.7). The posterior layer of the thoracolumbar fascia is identified and two stay sutures are positioned. The flank muscles are split to the anterior thoracolumbar fascia; two additional stay sutures are positioned. The anterior layer of thoracolumbar fascia is incised and the retroperitoneal space is entered. Index finger palpation of the belly of the psoas muscle posteriorly and the Gerota fascia-covered inferior pole of the kidney anteriorly confirms proper entry into the retroperitoneal space (Fig. 122.8). The index finger is employed to digitally create a space in this precise location and to sweep the peritoneum away anteriorly.

Simple extraperitoneal insufflation will cause the CO<sub>2</sub> gas to track along fascial planes and will not develop the extraperitoneal space. Balloon dissection of this space is the key to performing any procedure in this area. Gaur was the first to describe balloon distention of the extraperitoneal space using a simple device consisting of a surgical glove finger mounted on a red rubber catheter secured with a silk tie (7,8). Several commercially available trocar-mounted balloons are now available. An advantage of these devices is that the inflation

**FIGURE 122.7** For retroperitoneal procedures, the initial trocar is placed (A) 1 to 2 cm from the tip of the 12th rib or (B) in the triangle of Petit, 1 to 2 cm above the anterior superior iliac spine. Additional ports can be placed as needed between the posterior and anterior axillary lines.

and distention of the space can be laparoscopically monitored through the clear balloon. The degree of balloon dilation varies with the patient’s body habitus: 1 to 1.2 L of normal saline or room air is average in adults. The balloon is kept inflated for 5 minutes. After balloon removal a blunt-tipped trocar is inserted into the retroperitoneum. Visualization of the psoas muscle confirms proper balloon dilation of the retroperitoneum. The peritoneal envelope may be further mobilized with sweeping motions of the laparoscope. If difficulty is encountered mobilizing the peritoneum, an operating laparoscope can be used to pass a blunt-tipped dissector into the retroperitoneum.

The secondary ports can then be inserted under manual or laparoscopic control. For manual port placement, the laparoscope and cannula are removed and the index finger of the left hand (for a right-handed surgeon) is introduced into the retroperitoneum. An “S-shaped” retractor is inserted into the

**FIGURE 122.8** Technique of trocar-mounted balloon dissection of the retroperitoneal space.

retroperitoneum in such a manner that it lies immediately in front of the finger (i.e., the retractor is cradled by the finger). The fingertip mobilizes and retracts the peritoneum away from the abdominal wall; the S-retractor prevents inadvertent trocar injury to the surgeon's finger. With the surgeon's right hand, the secondary trocars are inserted under bimanual control, with the aim being to introduce the trocar onto the

S-shaped retractor. Secondary trocars are placed based on the procedure to be performed. Typical placement for retroperitoneal procedures is demonstrated in Figure 122.7. No trocars are positioned behind the posterior axillary line.

## PELVIC EXTRAPERITONEAL LAPAROSCOPY

Bladder neck suspension, hernia repair, radical prostatectomy, and pelvic lymph node dissection can be approached through the pelvic extraperitoneal space. Patient preparation and positioning are identical to transperitoneal laparoscopy.

A vertical skin incision is made 1 to 2 cm below the inferior umbilical crease to avoid the confluence of the anterior and posterior rectus sheaths at the umbilicus. For procedures such as bladder neck suspension where lateral exposure at the level of the iliac vessels is not needed, the incision is made in the midline about one-third the distance below the umbilicus, between the umbilicus and pubis. The tissues are spread with a clamp to the anterior rectus sheath. Two absorbable 0 (i.e., Vicryl) stay sutures are placed in each side of the midline. Next, the anterior rectus sheath is incised along the linea alba between the sutures. The two bellies of the rectus muscle are separated by blunt dissection to expose the posterior sheath and a finger is passed behind the rectus and above the posterior sheath. Blunt finger dissection is carried out in a caudal direction until the area of the pubis symphysis is reached. At this distal location, the fascia transversalis is punctured with the fingertip, and gentle side-to-side digital dissection is performed in the prevesical space, posterior to the pubic bone. A balloon dilator lubricated with sterile jelly is inserted in this predeveloped space and distended to create an adequate working space. Balloon dilation effectively displaces the prevesical fat and reflects the peritoneum cephalad (Fig. 122.9). The balloon is left inflated for several minutes, deflated, and inflated a second time. The balloon is initially inflated in the midline and then reinflated on either side to further expand the working area. The balloon is removed and a 10-mm Hasson-style cannula or a Bluntport is placed. The extraperitoneal space is insufflated with CO<sub>2</sub> at 15 mm Hg to facilitate secondary trocar

**FIGURE 122.9** Technique of trocar-mounted balloon dissection of the preperitoneal space.

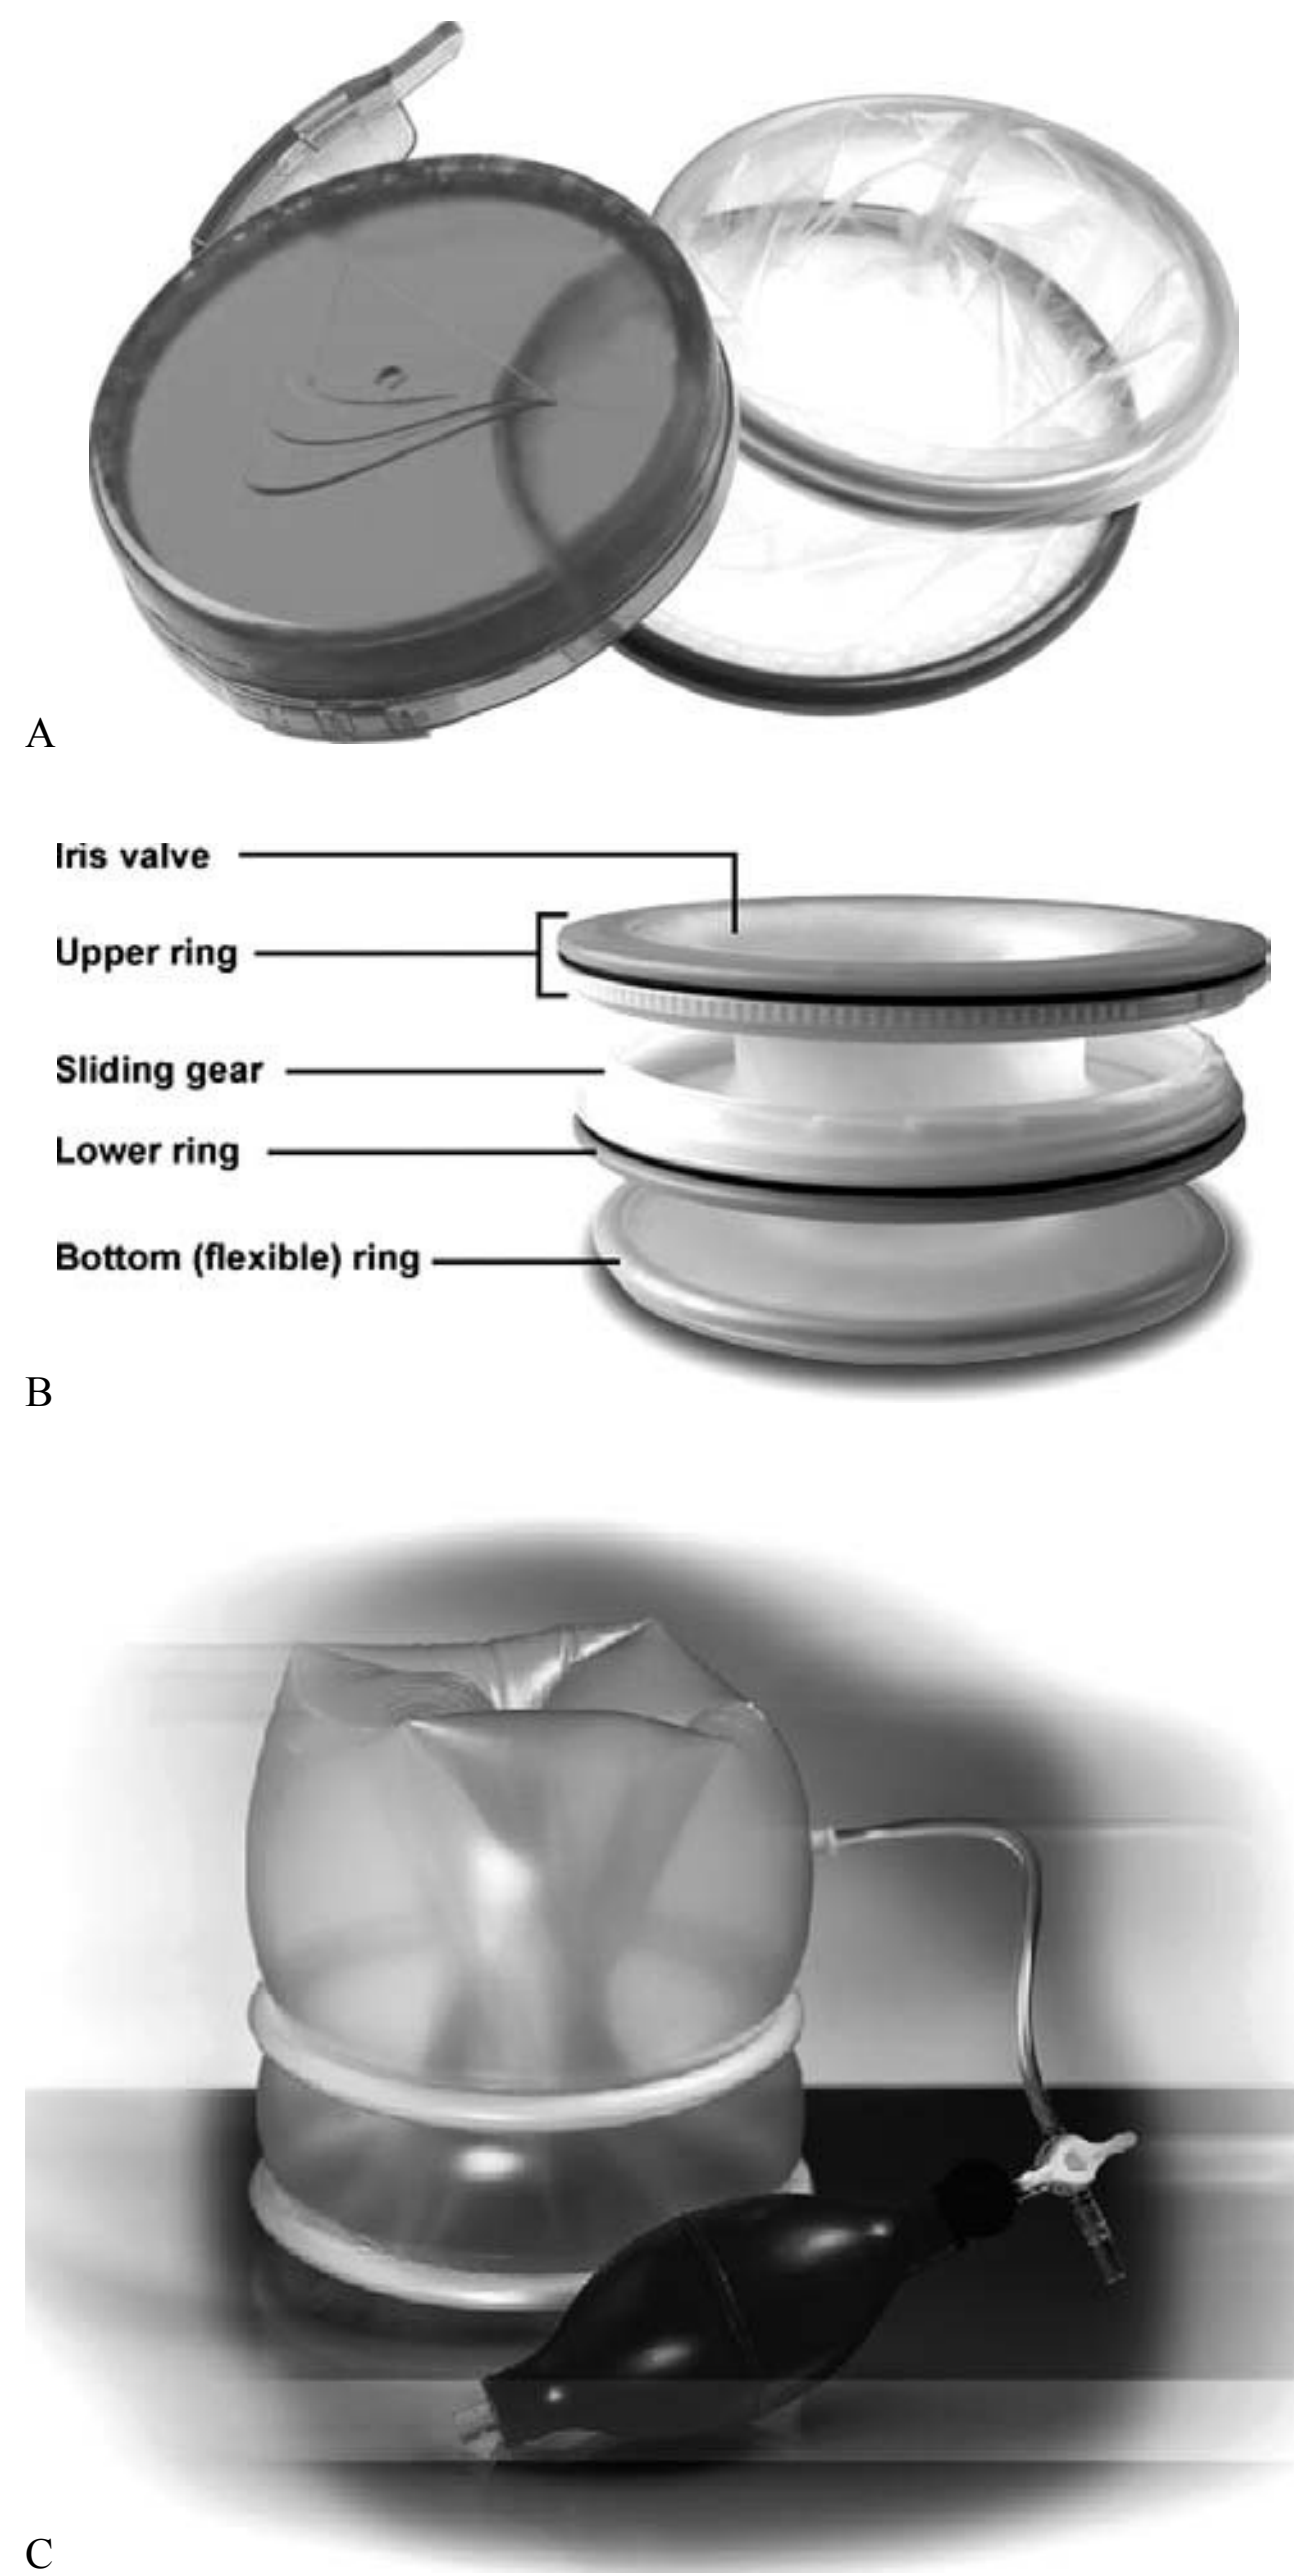

placement. Inspection of the preperitoneal space usually confirms adequate dissection of the prevesical space.

Additional trocars are placed under direct vision using a triangular, diamond-, fan-, or W-shaped configuration. Ensure that the lateral trocars do not traverse the peritoneal cavity and they are beyond the peritoneal reflection. Unlike with retroperitoneoscopy, the occurrence of a peritoneotomy during extraperitoneoscopy may interfere with the performance of subsequent extraperitoneal dissection, and conversion to a transperitoneal technique may be required. After the secondary trocars are placed, pneumoextraperitoneum is reduced to 10 to 12 mm Hg for the remainder of the procedure as prolonged high-pressure insufflation may cause tracking of the gas into the subcutaneous tissues.

## HAND-ASSISTED LAPAROSCOPY

Hand-assisted laparoscopy usually begins with the creation of an open incision that is approximately equal in length (in cm) to the surgeon's glove size, avoiding the use of a "blind" Veress needle access. The exact positioning of the incision depends upon the planned procedure, the body habitus of the patient, and surgeon preference (see subsequent chapters for details). The most common sites for hand-port placement include midline, subcostal, and lower quadrant incisions. Once the peritoneal cavity has been entered, the inside surface of the anterior abdominal wall is inspected for the presence of adhesions, which can be taken down sharply. After the hand-assist device is placed, a blunt cannula is passed through the hand-assist device and the abdomen can be insufflated at a high flow rate. Alternatively, a Veress or Hasson pneumoperitoneum may be initially established, and the hand-assist device can then be placed under endoscopic monitoring. After pneumoperitoneum is attained, the surgeon's nondominant hand is passed into the abdomen and additional secondary ports can be rapidly and safely placed using the intra-abdominal hand to palpate the tip of the trocar and hence guide its entry into the abdomen. Use of brown gloves and Ioban (3M, St. Paul, MN) "sticky drape" is recommended to decrease glare and to waterproof the surgeon's hand respectively. A sterile, water-soluble lubricant applied to the back of the surgeon's hand ensures smooth entry and exit through the hand-assist device.

Recent advances in hand-assist devices have made these instruments easier to place and more comfortable for the surgeon. The newer devices rely on compression against the peritoneal surface and body wall to remain in position. The GelPort (Applied Medical, Rancho Santa Margarita, CA) employs a sleeve that is passed into the abdominal cavity and pulled out through the incision. An inner ring holds the sleeve in place. The sleeve is then rolled on an outer ring that rests on the anterior abdominal wall. The GelPort covering is then attached to the outer ring. The entire two-piece system (Fig. 122.10A) is relatively easy to assemble once the incision has been established in the abdominal wall. The Lap Disc (Ethicon Inc., Cincinnati, OH) consists of three rings connected by a silicone membrane (Fig. 122.10B). The lower and middle rings bridge the abdominal wall, while the upper ring rotates on the middle, acting as an iris to seal the device around the surgeon's hand. The Omniport (Advanced Surgical Concepts, Wicklow, Ireland) is a balloon-like device that anchors itself as one piece across the abdominal wall (Fig. 122.10C). The inflated device

**FIGURE 122.10** Devices for hand-assisted laparoscopy. **A:** The third-generation two-piece GelPort is relatively easy to assemble and provides an adequate seal around the surgeon's wrist while minimizing fatigue. **B:** The Lap Disc consists of three rings connected by a silicone membrane. The lower and middle rings bridge the abdominal wall, while the upper ring rotates on the middle, acting as an iris to seal the port around the surgeon's hand. **C:** The Omniport hand-assist device.

also creates a seal between itself and the surgeon's wrist. The device has a smaller footprint (12 cm), but it must be deflated and reinflated each time a hand is exchanged, which loses the pneumoperitoneum.

Prior to beginning the dissection, laparotomy pads can be preplaced into the abdominal cavity and used to blot any bleeding during the dissection. It is, of course, imperative to remove these pads prior to exiting the abdomen, and a helpful reminder system should be created with the rest of the operating

room staff instead of relying solely upon sponge counts. Exiting the abdomen should be carried out with the secondary sites being closed under direct visualization through a port placed in the hand-assist device. The hand site is closed in the standard fashion.

---

## PEDIATRIC LAPAROSCOPY

---

Most principles of adult laparoscopy can be applied to the pediatric population, with the following exceptions:

1. In younger children, the bladder is an intra-abdominal structure, requiring more care with lower abdominal trocar placement.
2. The peritoneal membrane is loosely attached to the abdominal wall, making it potentially difficult to pass a Veress needle. Many authors advocate an open access technique for *all* children.
3. The total CO<sub>2</sub> to insufflate the abdomen is in general 1 to 3 L. Pressures should be kept lower than in adults (8 to 10 mm Hg).
4. The 5-mm trocars are commonly used in children and the sites *must* be sutured at the end of the case.
5. Many standard laparoscopic instruments will be either too large or long for pediatric procedures, thereby requiring specialized equipment.

---

## POSTOPERATIVE MANAGEMENT

---

Patients undergoing limited laparoscopic procedures like varicocelectomy and diagnostic laparoscopy may be discharged the same day. More extensive procedures may require a short hospital stay. Orogastric tubes are removed in the operating room but may be left in longer if bowel surgery was performed. The Foley catheter is removed either while the patient is still in the operating room (pneumoperitoneum <2 hours) or later in the day or the next morning (pneumoperitoneum >2 hours) unless a prostatectomy or cystectomy was performed. Antibiotics are continued over 24 hours and laboratory values are obtained in a standardized manner postoperatively. The patient ambulates within 12 hours of surgery and pneumatic compression stockings are utilized for deep venous thrombosis prophylaxis until the patient is fully ambulatory.

Depending on the procedure, clear liquids can be given after the effects of anesthesia have cleared. Diets can then be advanced as tolerated. For more extensive procedures (i.e., nephrectomy), it may be necessary to advance the diet more slowly. Parenteral analgesia is given as needed on the day of surgery and is usually replaced by oral pain medication on the first postoperative day. The requirement for postoperative analgesics is usually minimal; excessive pain should raise the suspicion of a complication. Patients should be advised that delayed postoperative bruising is on occasion encountered.

---

## OUTCOMES

---

Outcomes for contemporary laparoscopic interventions are reviewed for each specific procedure in the appropriate chapter.

---

## Complications

---

Although a Veress needle injury of a major blood vessel, bladder, or gastrointestinal tract can be managed expectantly, significant perforation with a trocar should be managed by immediate laparotomy and repair. The trocar and sheath should be left in place while opening the abdomen. In selected instances, laparoscopic repair may be appropriate but often requires significant advanced skills.

Vascular injury within the abdominal wall, especially the inferior epigastric vessels, can be managed by a through-and-through suture placed on a bolster using a Stamey-style needle or laparoscopic closure device; it is removed after 24 to 48 hours.

Anesthetic problems can be caused by the absorption of CO<sub>2</sub> or the physiologic effects of the pneumoperitoneum. Both the intra- and extraperitoneal surfaces can readily absorb CO<sub>2</sub> and this may cause hypercarbia. End-tidal CO<sub>2</sub> monitoring by the anesthesia team can often identify this problem before it becomes clinically significant. Increasing the minute ventilation, use of positive end-expiratory pressure, and reduction of intra-abdominal pressure to 10 mm Hg can usually keep the blood CO<sub>2</sub> levels in a safe range. High intra-abdominal pressure (prolonged periods above 15 to 20 mm Hg) can lead to barotrauma. The initial sign may be hypotension owing to decreased cardiac output secondary to an acute drop in venous return caused by compression of the vena cava. High pressures can also result in subcutaneous emphysema that can exacerbate hypercarbia, and on occasion cause pneumomediastinum and pneumothorax. The surgeon should desufflate the abdomen, and once the hemodynamic changes have been reversed, reinitiate the pneumoperitoneum at 10 mm Hg. Transient oliguria may occur in patients with increased intra-abdominal pressures, and the urge to aggressively hydrate the patient should be avoided.

Life-threatening gas embolism is rare and most often caused by direct insufflation of CO<sub>2</sub> gas into a vessel by the Veress needle. Subtle collection of CO<sub>2</sub> gas in the venous system through an open vessel can rarely occur. The first sign of intravascular insufflation is acute cardiovascular collapse. The diagnosis is usually made by the anesthesiologist based on an abrupt increase of end-tidal CO<sub>2</sub> accompanied by a sudden decline in oxygen saturation and then a marked decrease in end-tidal CO<sub>2</sub>. Sometimes, a “millwheel” precordial murmur can be auscultated. The treatment is immediate cessation of insufflation and prompt desufflation of the peritoneal cavity. The patient is turned into a left lateral decubitus position and hyperventilated with 100% oxygen. Advancement of a central venous line into the right heart with subsequent attempts to aspirate gas may rarely be helpful.

In a recent review of 2,775 diverse urologic laparoscopic procedures, the current overall complication rate was 22.1% and the mortality rate was 0.07%. Transfusions were required in 4.7% of procedures, while open conversion was necessary in only 2.7% (9). The majority were identified in the postoperative period (79%) and were classified as minor (72%). Although each individual procedure had its own characteristic profile of complications, the four most commonly identified complications were vascular injuries (2%), postoperative bleeding requiring blood transfusion (1.8%), ileus that prolonged hospital stay >48 hours (1.6%), and wound infection (1%).

Laparoscopic surgery can be more technically demanding and time-consuming than open surgical intervention. Proper patient selection, formal training, the surgeon's experience,

and working with others who are involved with laparoscopic surgery appear to be the best determinants for a successful outcome in urologic laparoscopy (10).

# CHAPTER 123 ■ LAPAROSCOPIC PELVIC AND RETROPERITONEAL LYMPH NODE DISSECTION

HOWARD N. WINFIELD AND WILLIAM J. BADGER

The gold standard for accurate lymph node assessment in both prostate and testicular cancer continues to be lymphadenectomy. While imaging modalities such as computerized tomography (CT) and magnetic resonance imaging (MRI) may detect moderate- to large-volume metastatic disease, many microscopic or small lymph node metastases are not identified with the current limitations of CT and MRI sensitivity (1). With continued refinements in laparoscopic and robotic instrumentation and techniques, the gold-standard lymphadenectomy can be performed with equal efficacy and decreased morbidity when compared to the open approach.

---

## LAPAROSCOPIC PELVIC LYMPH NODE DISSECTION

---

Laparoscopic pelvic lymph node dissection (L-PLND) for staging of prostate cancer was first described in 1991 by Schuessler et al. (2). Recently, the importance of pelvic lymphadenectomy has been questioned for patients undergoing radical prostatectomy. The arguments against pelvic lymphadenectomy include stage migration, an increasing percentage of patients with a low prostate-specific antigen (PSA) level and tumor stage, and the practice of omitting lymphadenectomy in low-risk patients (PSA <10 ng/mL and/or Gleason score <7). In patients with high-risk prostate cancer (clinical stage T2c, serum PSA level >10 ng/mL, and Gleason score >7), however, there is an approximately 38% risk of lymph node metastasis (3).

---

### Diagnosis

---

L-PLND is an additional diagnostic procedure considered after definitive diagnosis of prostate cancer through biopsy or transurethral resection of the prostate.

---

### Indications for Surgery

---

L-PLND is now rarely indicated as an independent staging procedure for prostate cancer. L-PLND should be considered in patients with clinical stage T2b or T3a cancer of the prostate whether surgery or radiation therapy is being considered; stage T1b cancer with Gleason sums of 7 or more; PSA levels >20 ng/mL; or suspicious lymph nodes visualized on CT that are not amenable to guided needle biopsy. Additionally, patients scheduled to undergo perineal prostatectomy, brachytherapy, external-beam radiotherapy, or laparoscopic/robotic prostatectomy who have a risk of node positivity >25% should undergo pretreatment L-PLND or simultaneous L-PLND.

Malignancies other than prostate cancer may be staged with L-PLND, including bladder, urethral, and penile cancers. Patients with transitional cell carcinoma of the bladder with an enlarged pelvic lymph node on imaging may undergo L-PLND if the lymph node is inaccessible to other minimally invasive biopsy techniques (CT-guided biopsy). In patients with urethral and penile cancers, sampling of enlarged pelvic nodes may confirm the presence of metastatic disease and

guide the treatment course. Patients with metastatic disease may proceed directly to chemotherapy and avoid the morbidity of radical surgery, which would inadequately treat the underlying disease.

Patients with inability to tolerate general anesthesia or pneumoperitoneum, morbid obesity, numerous previous abdominal or pelvic surgeries, or large aortic or iliac aneurysmal disease are not considered good candidates for any laparoscopic or robotic surgery.

### Alternative Therapy

Open pelvic lymphadenectomy historically has been the gold standard for lymph node removal. CT or MRI scanning can be utilized in combination with percutaneous biopsy for sampling of enlarged lymph nodes.

Some authors advocate an extended PLN dissection in patients with carcinoma of the prostate. This dissection reaches above the bifurcation of the common iliac artery and includes all external iliac, obturator, and hypogastric lymph nodes. A recent series reported that 45.5% of the detected metastases were exclusively located outside of the typically sampled obturator fossa (4). Others advocate the use of radioisotope-guided sentinel lymph node dissection. In one series of this approach, 71.4% of the detected metastases were exclusively located outside of the typically sampled obturator fossa (5). Both the extended lymph node dissection and sentinel lymph node dissection can be performed laparoscopically.

### Surgical Technique

Preoperative counseling should include a discussion of the risks, benefits, and alternatives to L-PLND. Although impractical to list all possible complications, the most common injuries should be mentioned, as well as the risk of conversion to an open procedure. Informed consent should be obtained and documented.

On the day prior to surgery, the patient takes only clear fluids by mouth. This preparation helps to maintain good hydration as well as decompress the bowel to aid in pelvic intraoperative exposure. All patients receive a single dose of intravenous antibiotics within 30 minutes of incision. Antiemebolic pneumatic compression boots are placed and

**FIGURE 123.1** Split-leg operating table (Maquet) allows abduction of the legs without the need for lithotomy.

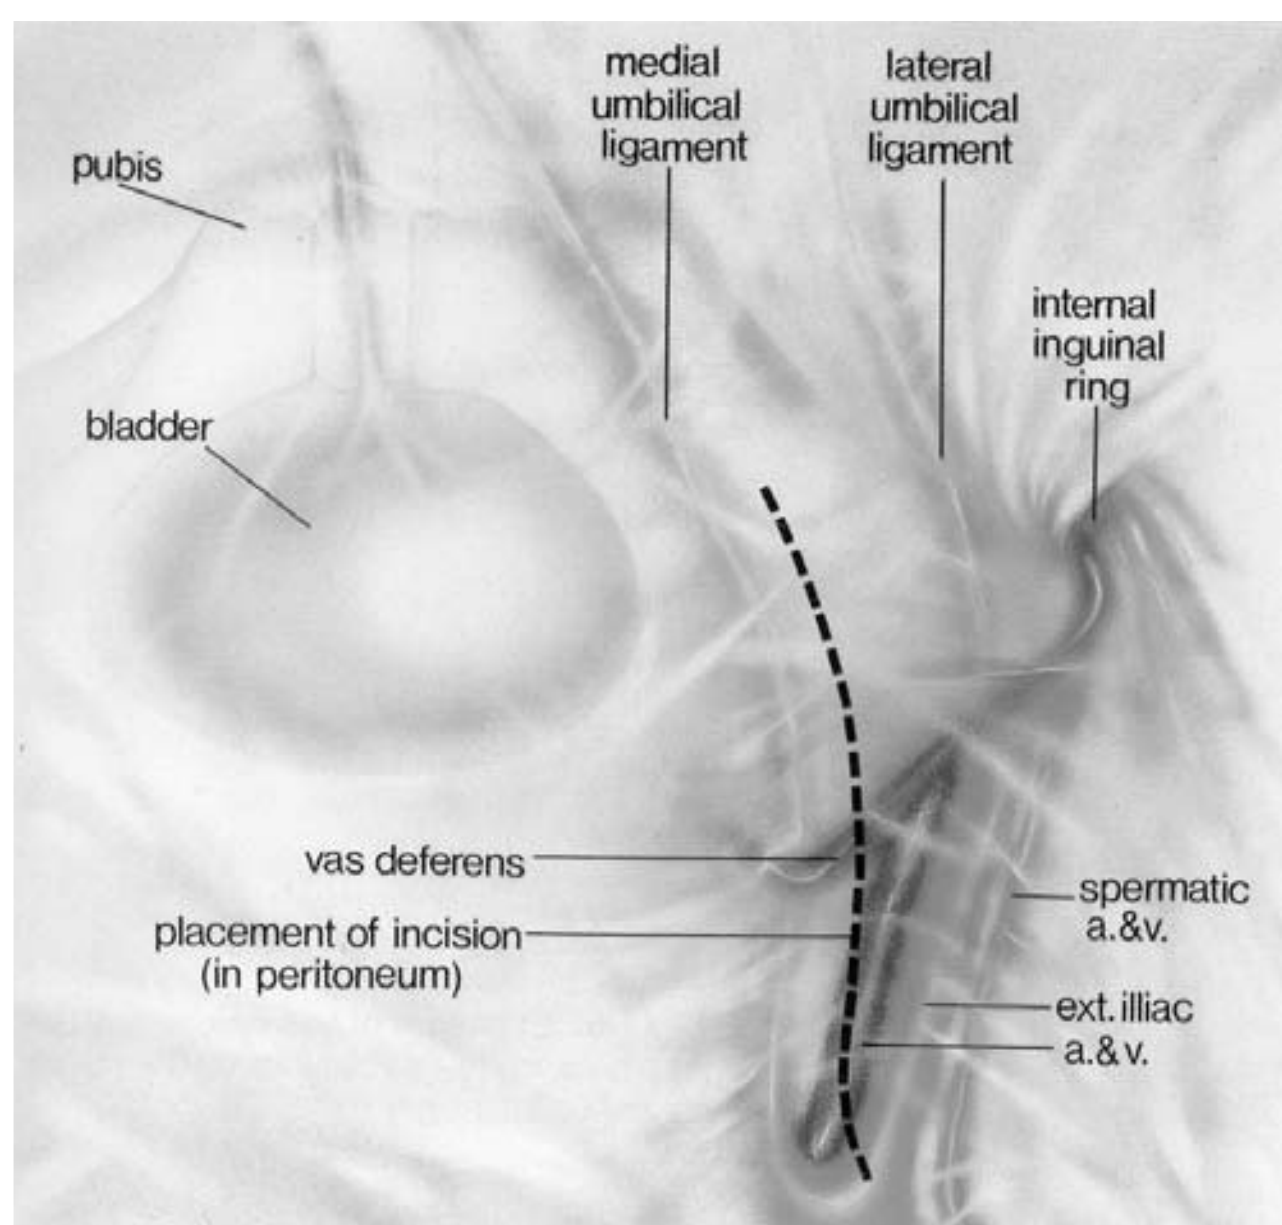

activated throughout the procedure. After adequate anesthesia is obtained, a Foley catheter and orogastric tube are placed in the bladder and stomach, respectively. Patients are placed in the supine position with well-padded arms tucked at the side. We utilize a split-leg operating table (Maquet), which allows abduction of the legs but without the need for lithotomy (Fig. 123.1). With this approach, the assistant may stand between the patient's legs during L-PLND. A padded chest strap is used to secure the patient to the table as the Trendelenburg position will be required.

### Transperitoneal Approach

Pneumoperitoneum is achieved by insertion of a Veress needle at the superior or inferior crease of the umbilicus, and carbon dioxide is insufflated to an initial pressure of 20 mm Hg. A 10/11-mm trocar sheath unit can then be placed by enlarging the Veress needle puncture site. Alternatively, the open Hasson technique can be utilized at the same location to obtain pneumoperitoneum. Immediate laparoscopy with a 10-mm or 5-mm 30-degree lens should be performed to rule out iatrogenic injuries. Two options for trocar configuration include a four-trocar diamond-shaped configuration or a five-trocar inverted-U-shaped configuration as in laparoscopic radical prostatectomy (Fig. 123.2). After all laparoscopic ports are placed,

**FIGURE 123.2** **A:** The standard diamond configuration for trocar placement with the laparoscope placed in the subumbilical position. **B:** The horseshoe configuration is useful for obese patients.

**FIGURE 123.3** The initial peritoneal incision is made between the obliterated umbilical artery (medial umbilical ligament) and the internal inguinal ring. (From Gomella LG, Kozminski M, Winfield HN, eds. *Laparoscopic Urologic Surgery*, 1st ed. Philadelphia: Raven Press, 1994:117, with permission.)

pneumoperitoneum is decreased to 15 mm Hg and the patient is placed in 15-degree Trendelenburg with upward lateral rotation of the side to be operated. The combination of Trendelenburg and lateral rotation allows the loops of bowel to fall away from the area of dissection over the iliac/obturator regions. Any bowel adhesions should be carefully mobilized to facilitate the dissection. On the left side it is not uncommon to require takedown of the sigmoid flexure as it often protrudes toward the internal inguinal ring. The posterior peritoneal membrane is incised longitudinally and immediately lateral to the medial umbilical (obliterated umbilical) ligament from the pubis to the bifurcation of the iliac vessels (Fig. 123.3). The incision is directed just medial to the pulsating external iliac artery. The vas deferens will be exposed after the posterior peritoneum is incised. The vas deferens should be isolated, coagulated, and divided. It should be noted that the ureter is closely approximated to the peritoneum at, or just proximal to, the bifurcation of the common iliac artery.

The fibrolymphatic tissue adherent to the external iliac vein is elevated and dissected from the anterior and medial aspect of the vein. The incised edge of the lymph node packet is grasped and retracted medially, and a relatively avascular plane between the lymph node packet and lateral pelvic sidewall is identified and dissected bluntly. Any small perforating vessels are identified, controlled with bipolar cautery, and divided. Dissection is carried proximally to the iliac bifurcation and distally to the pubis. By retracting the lymph node packet medially, the obturator nerve and vessels can be identified and avoided. After securing the distal extent of the lymph node packet, the packet is then retracted cranially to separate it from the obturator vessels and nerves. Hemoclips or bipolar cautery is used to control lymphatics and vessels at the most proximal and distal extent of the dissection. The lymph nodes can usually be removed as a single packet and extracted either through the 12-mm trocar or by placing them in the entrapment sack.

### Extraperitoneal Approach

A 2-cm infraumbilical incision is made and carried through the rectus and transversalis fascia. Stay sutures are placed in the incised rectus fascia and a preperitoneal plane is digitally enlarged. A balloon inflation device is inflated to 800 to 1,000 mL, then deflated and removed. A Hasson-type or balloon cannula is inserted and secured. Carbon dioxide is insufflated to 15 mm Hg to allow for the remaining port placement. Care should be taken to avoid traversing the peritoneal membrane to prevent intraperitoneal insufflation leakage and possible bowel injury. After the port placement under visual or digital guidance, the procedure proceeds as described previously for the transperitoneal L-PLND. Ensuring careful lymphostasis with the extraperitoneal approach is essential to prevent the risk of postoperative lymphocele formation due to the lack of a peritoneal window to vent lymph fluid leakage.

### Complications

Most complications related to pelvic lymph node dissection are either a consequence of trocar placement or vascular injury. An accessory obturator vein is often encountered arising from the distal aspect of the external iliac vein. When present, this vessel must be controlled and divided, or avoided, when managing the distal extent of the lymph node packet. Dissection deep to the obturator nerve can result in bleeding from the obturator vessels. Bleeding from the obturator vessels can be managed using a hemoclip or bipolar electrocautery, but bleeding from the iliac vessels can be more difficult to manage laparoscopically. Pressure to an iliac vessel injury should be applied immediately and maintained for several minutes, along with the use of hemostatic agents such as oxidized regenerated cellulose or fibrin sealants. Bleeding from a small venous injury may be controlled with this maneuver, but for a larger injury an attempt can be made to secure the opening with either hemoclips or sutures. Prompt conversion to open surgery and repair may be required if these attempts are unsuccessful.

Great care must be taken to avoid undue traction, electrothermal injury, or transection of the obturator nerve throughout the procedure. Avoid accidental injury to the obturator nerve by identifying its course before application of hemoclips on vessels or lymphatics.

Postoperative lymphocele and deep venous thrombosis are the two major morbidities associated with open PLND. With L-PLND, postoperative lymphoceles are less common (6). A transperitoneal laparoscopic approach allows continuous drainage of lymphatic fluid into the peritoneal cavity in the event of a lymphatic leak. Regardless of the approach, however, lymphatic fluid loculations have been reported. Deep venous thrombosis is relatively uncommon after L-PLND owing to the steep Trendelenburg position and avoidance of venous compression of the iliac veins that can occur when using a fixed retractor system during open surgery. One comparative study found a lower total complication rate with L-PLND (0%) compared with open PLND (21%) (7).

Despite the excellent outcomes of L-PLND, the true indications for L-PLND continue to decrease, primarily due to advances in prostate cancer screening with a shift toward earlier diagnosis and lower-stage and -grade disease.

## LAPAROSCOPIC RETROPERITONEAL LYMPH NODE DISSECTION

Due to its minimally invasive approach, laparoscopic retroperitoneal lymph node dissection (L-RPLND) may be part of a new treatment paradigm for patients with clinical stage I nonseminomatous germ cell tumors. L-RPLND offers a highly accurate and reliable method of evaluating the presence and extent of retroperitoneal lymph node metastases. Refinements in laparoscopic surgical technique and instrumentation have allowed for the performance of this minimally invasive procedure with low morbidity.

### Indications for Surgery

The use of RPLND primarily involves patients found to have nonseminomatous germ cell tumors, as 20% to 30% of these patients with clinical stage I disease may have retroperitoneal lymph node metastases. Of more concern are patients with stage T2 to T4 primary tumors, evidence of lymphovascular invasion, and embryonal cell carcinoma, who are in general believed to be at an even higher risk of retroperitoneal and systemic relapse (8–10). Although the literature is replete with controversy concerning the use of chemotherapy versus RPLND, surgery is often advocated as a staging, and possibly curative, procedure for such patients. Under these circumstances RPLND is performed in a unilateral template fashion to preserve antegrade ejaculation. L-RPLND has been used as an alternative to open RPLND in this select patient group. However, upon pathologic confirmation of metastatic disease following L-RPLND, patients are then upstaged and given chemotherapy in most series. Thus, the therapeutic effectiveness of L-RPLND alone in such cases is untested. As such, L-RPLND should currently be considered a diagnostic procedure. However, used as such, this minimally invasive procedure aids in identifying patients with pathologic stage I nonseminomatous testis tumors who can safely be spared chemotherapy. L-RPLND is also utilized in stage IIa and IIb patients to demonstrate lymph node metastasis prior to administering chemotherapy. The general indications for L-RPLND are shown in Table 123.1.

### Alternative Therapy

Alternative treatment approaches for patients with stage I nonseminomatous germ cell tumors include open RPLND, chemotherapy, and active surveillance.

TABLE 123.1

#### INDICATIONS FOR LAPAROSCOPIC RETROPERITONEAL LYMPH NODE DISSECTION

- Clinical stage I, IIa, and IIb nonseminomatous testicular cancer
- Negative testis tumor markers
- No absolute contraindications to laparoscopic surgery
- Residual isolated abdominal or pelvic mass after chemotherapy in the presence of negative testis tumor markers

## Surgical Technique

On the day prior to surgery, the patient undergoes a mechanical bowel preparation, which includes a clear liquid diet and one gallon of GoLYTELY. Type and cross-matching is done for two units of blood. Janetschek et al. (11) also recommend that a low-fat diet be started 1 week prior to and continued for 2 weeks after surgery to minimize chylous ascites. The patient should have nothing by mouth after midnight on the night prior to surgery.

RPLND for patients with stage I nonseminomatous germ cell tumors involves either right- or left-sided template surgery, depending on the testis involved with disease. Nerve-sparing templates are now used, which yield virtually a 100% chance of maintaining antegrade ejaculation (Fig. 123.4) (12). Surgery for each template will be described.

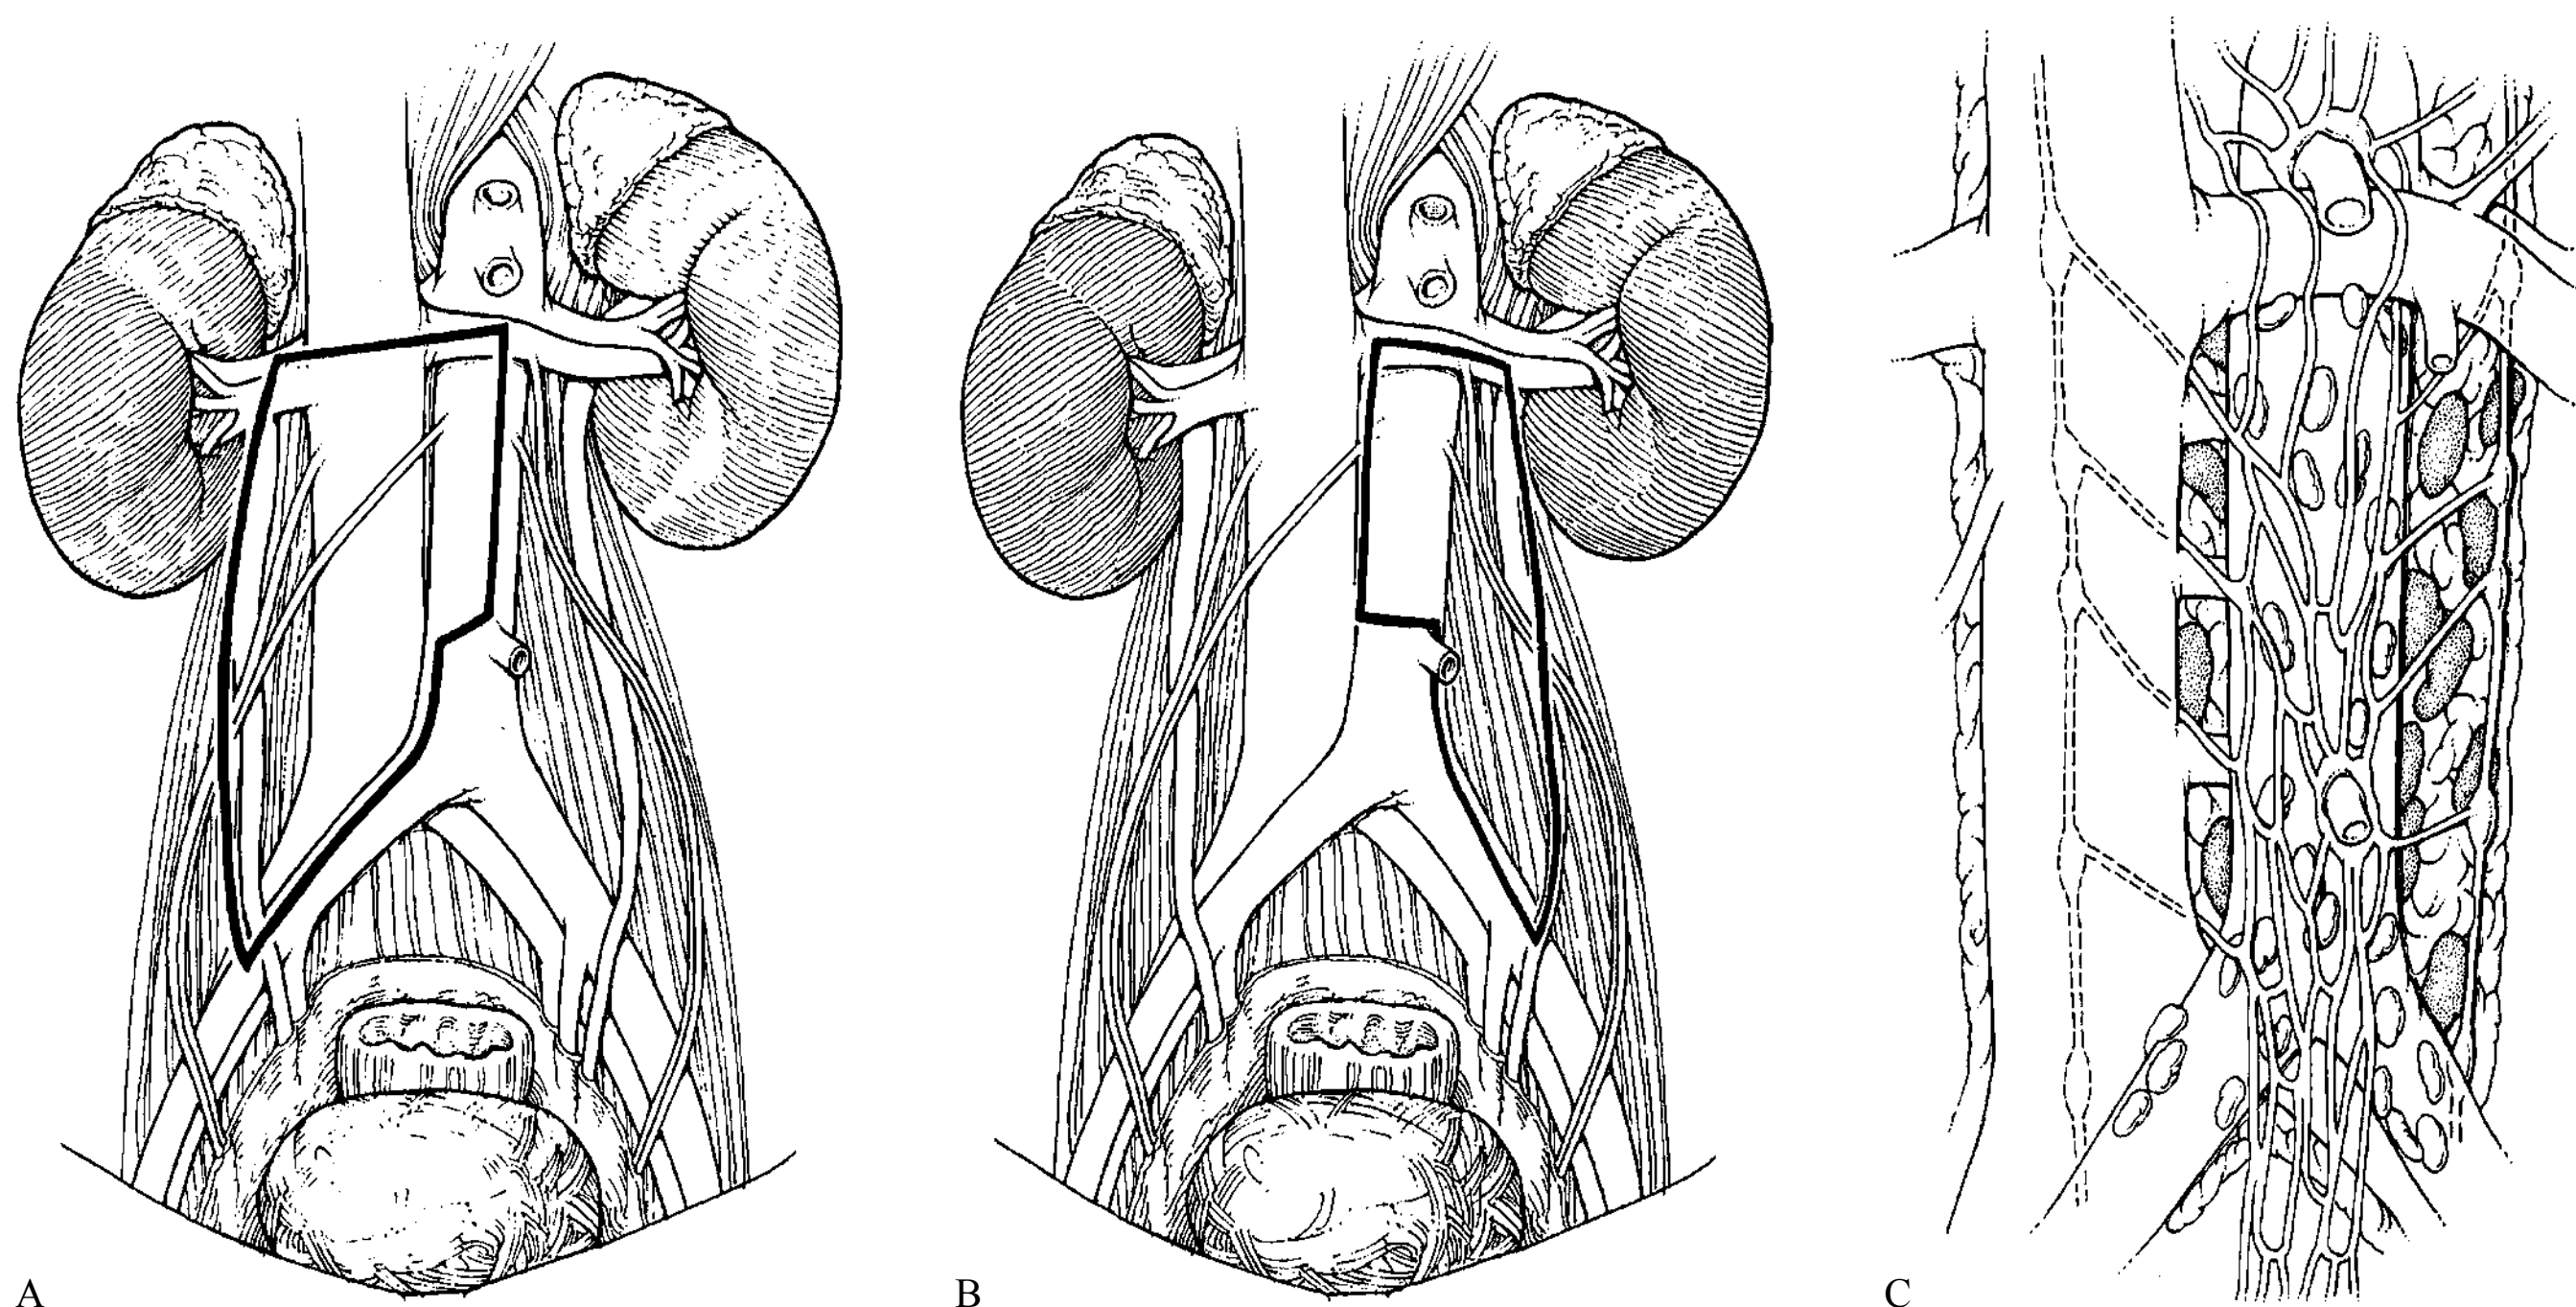

### Transperitoneal Approach

**Right-Sided Template.** The patient is positioned on the operating table with the right side elevated 45 degrees upward. This allows for both supine and lateral decubitus positioning as needed. Trendelenburg or reverse Trendelenburg positioning can then be used as indicated. In general, trocar ports are 5 to 12 mm and placed in a midline vertical arrangement (Fig. 123.5).

The initial step in L-RPLND is to gain wide exposure of the retroperitoneum. Dissection is begun along the white line of Toldt from the level of the cecum to the hepatic flexure. Cephalad, this incision is carried above the level of the transverse colon and lateral to the duodenum (Kocher maneuver) along the vena cava up to the level of the hepatoduodenal ligament.

The duodenum and the head of the pancreas are further mobilized medially until the anterior surfaces of the vena cava, aorta, and left renal vein crossing the aorta are completely exposed. The peritoneal incision is also carried laterally around the liver toward the triangular ligaments, allowing for medial and superior retraction of the liver. This mobilization is necessary to ensure adequate exposure of the inferior vena cava and renal vessels. Inferiorly, the incision is extended along the spermatic vessels to the level of the internal inguinal ring. Dissection is also extended around the cecum and upward along the root of the mesentery, allowing for medial mobilization of these structures. At this point, the dissection has exposed the entire right-sided template. This template includes all preaortic tissue between the left renal vein and the inferior mesenteric artery, the interaortocaval nodes, and all tissue on the ventral and lateral surfaces of the vena cava extending laterally to the ureter. The template is bounded superiorly by the right renal vessels and inferiorly where the ureter crosses the iliac vessels. The template extends posteriorly to the level of the lumbar vessels. There is recent evidence to suggest that dissection posterior to the lumbar vessels within the template is not necessary in clinical stage I patients as no tumor was found in any patients undergoing laparoscopic lymphadenectomy that included this region (12). However, this finding requires corroboration by further studies.

After the entire template has been exposed, dissection is begun inferiorly where the spermatic vessels enter the internal inguinal ring. Typically, one should identify a nonabsorbable stitch, left at the time of radical orchiectomy, that signifies the

**FIGURE 123.4** **A:** Template for right modified nerve-sparing retroperitoneal lymph node dissection (RPLND). **B:** Template for left modified nerve-sparing RPLND. **C:** Anterior view of retroperitoneal sympathetic fibers. △ = 5 mm port for left L-RPLND in anterior axillary line.

**FIGURE 123.5** Trocar placement for transperitoneal laparoscopic retroperitoneal lymph node dissection. (From Clayman RV, ed. *Laparoscopic Urology*. St. Louis, MO: Quality Medical Publishing, 1993:272–308, with permission.)

distal margin of this dissection. The testicular vein is then dissected up to its insertion into the vena cava. Careful dissection is required where the spermatic vein joins the inferior vena cava to prevent inadvertent disruption and bleeding. The testicular artery is clipped and transected where it crosses the inferior vena cava.

Next, the lymphatic tissue overlying the great vessels is dissected free. The lymphatic tissue on the anterior surface of the inferior vena cava is divided, and the anterior and lateral surfaces of the inferior vena cava are dissected free of lymphatic

tissue from the level of the renal vessels going inferiorly to where the ureter crosses the iliac vessels. It is important that the left renal vein has already been clearly identified and exposed to prevent injury to this structure during this part of the dissection. The lymphatic tissue overlying the common iliac artery, starting at the level where the ureter crosses it, is dissected free, moving in a cephalad direction until the origin of the inferior mesenteric artery is reached. Cephalad to this artery, the lymphatic tissue is divided toward the lateral border of the aorta so that all tissue anterior to this vessel is freed

and included with the specimen. If not already done so, during this part of the dissection the testicular artery is clipped at its insertion into the aorta. This dissection is continued cephalad until the right renal artery, traversing the interaortocaval space, is identified, which marks the superior border of the template. The interaortocaval lymphatic tissue is now excised, with its posterior border being the level of the lumbar vessels. Great care must be taken with retraction of the great vessels as vascular injury may result in hemorrhage that is difficult to control by laparoscopic means. Lumbar vessels may need to be sacrificed to ensure retrieval of all lymphatic tissue. All sympathetic nerve fibers should be spared, if possible. With the medial and superior borders of the template freed, attention is paid to the lateral border along the ureter. After the ureter has been identified, all lymphatic tissue medial to it is freed, beginning where the ureter crosses over the common iliac artery and proceeding cephalad to the level of the renal vessels, where the most cephalad portion of the dissection has already been completed. The posteriorly located lumbar vessels may also be encountered during this portion of the dissection. They should be clipped and divided only when needed to facilitate removal of lymphatic tissue. At this point the lymphatic packages are completely free. They are placed in a specimen bag and removed. Obvious tumor or suspicious fibrolymphatic tissue should be sent for pathologic frozen-section interpretation. The colon and duodenum are then repositioned to their normal anatomic positions.

**Left-Sided Template.** The patient is placed on the operating table with the left side elevated 45 degrees upward. All other aspects of positioning and port placement (except now for left-sided dissection) are similar to that as described for right-sided dissection. Dissection is begun by incising the white line of Toldt on the left side, from the splenic flexure to the pelvic brim. The incision is extended distally along the spermatic vein all the way to the internal inguinal ring, where a nonabsorbable stitch, left at time of radical inguinal orchiectomy, should be identified. Superiorly, the dissection is carried medially around the splenic flexure just below the edge of the spleen. At this point the colon is mobilized medially until the entire anterior surface of the aorta is exposed. The entire length of the spermatic vein, from the renal vein to the internal inguinal ring, is dissected free and removed. The left renal vein is identified and freed along its anterior and inferior surface at this point of the dissection. The ureter, which defines the lateral border of the dissection, is then identified. All lymphatic tissue is dissected free from the ureter from the level of the renal hilum to where the ureter crosses the common iliac artery. Then, starting where the ureter crosses (the inferior border of the template) the common iliac artery, all lymphatic tissue is dissected free from the lateral surface of this blood vessel. From here the dissection is continued cephalad along the lateral surface of the aorta to the level of the inferior mesenteric artery. This artery is preserved during this dissection. Cephalad to the inferior mesenteric artery all lymphatic tissue on the anterior and lateral surfaces of the aorta is removed. Dissection is continued in this manner up to the level of the renal vein. All lymphatic tissue associated with the renal vein is now dissected free. If there is a lumbar vein inserting into the posterior surface of the renal vein it must be divided to dissect free all lymphatic tissue. As a final step, the lymphatic package is dissected free posteriorly. The lymphatic tissue is separated

from the lumbar vessels. The lymphatic package is then removed.

---

### L-RPLND for Stage II or III Disease after Chemotherapy

---

L-RPLND has in general been performed only in a unilateral fashion, and there is only limited experience of L-RPLND being performed for stage II or III tumors after chemotherapy. In such cases L-RPLND may be performed when there has been a good response to chemotherapy where only smaller tumors/masses (5 cm or less) remain, and tumor markers have returned to normal. In such cases, dissection is carried out in a similar fashion as described for the unilateral templates involved but focusing primarily on resection of the residual tumor mass. Those with experience in such cases have noted that, due to chemotherapy, although tissue planes are more difficult to identify, mobilization of the bowel and identification of the tumor is possible. Due to the desmoplastic reaction typically seen after chemotherapy, careful dissection is required as tumor/residual tissue may be adherent to blood vessels. Janetschek et al. (11) noted that teratomas are usually well delineated, but other types of tumor-free residual tissue may be adherent to surrounding venous structures. All vascular branches from the tumor must also be carefully dissected out, clipped, and transected.

---

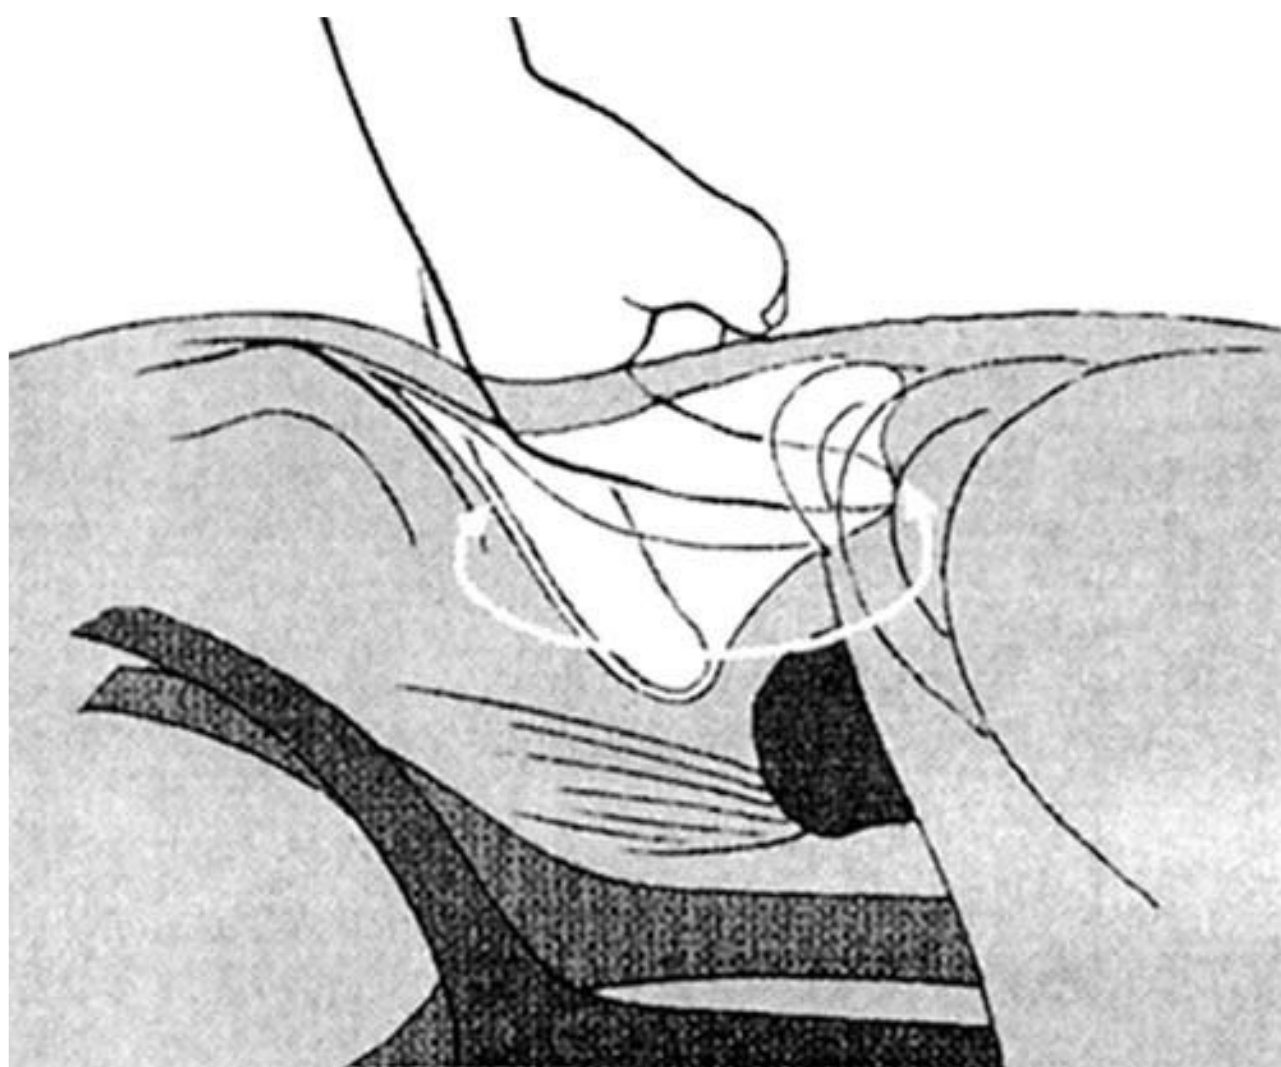

### Retroperitoneal Approach

---

Since the introduction of the balloon dissecting technique by Gaur, the laparoscopic retroperitoneal approach has been used for a variety of urologic procedures. Rassweiler et al. (13) reported use of this technique for L-RPLND in 17 cases. This technique differs from transperitoneal L-RPLND in how access and exposure are obtained. The essential features of this technique include placing the patient in the flank position without Trendelenburg. On the side of dissection a small incision (<2 cm) is made in the lumbar (Petit) triangle between the 12th rib and the iliac crest. Blunt dissection is then used to identify the peritoneal membrane and create the retroperitoneal space (Fig. 123.6). The retroperitoneal space can be expanded by use of either balloon dilating devices (commercial or homemade), or through further dissection with the surgeon's finger. Surgeons who develop the retroperitoneal space with finger dissection place the secondary ports under digital guidance before placing a 12-mm port through the initial incision. When the retroperitoneal space is developed with a balloon dilating device, a 10-mm trocar is placed through the existing incision. Placement of secondary trocars is then performed under laparoscopic guidance (Fig. 123.7). Once the laparoscopic ports are in place and pneumoretroperitoneum is stable, a wide longitudinal incision of the fascia of Gerota is created for optimal exposure of the retroperitoneum. L-RPLND is then performed using the same template and landmarks as described for transperitoneal L-RPLND.

Use of this approach for L-RPLND, to date, is limited. Authors with considerable experience with retroperitoneoscopy reporting on use of this technique classified retroperitoneal L-RPLND as difficult. Others have described extraperitoneal L-RPLND by an anterior approach.

**FIGURE 123.6** Blunt dissection of retroperitoneal space with index finger pushing peritoneum medially; the working space is created between the lumbar aponeurosis and renal (Gerota) fascia. (From Janetschek G. Laparoscopic retroperitoneal lymph node dissection. *Urol Clin North Am* 2001;28:107–114, with permission.)

**FIGURE 123.7** Port placement for laparoscopic retroperitoneal lymph node dissection (L-RPLND). Surgeon stands at the backside. *Port I*, 12 mm for laparoscope; *port II*, 10 mm for right hand of surgeon; *port III*, 5 mm for left hand; *port IV*, 5 mm for assistant.

## POSTOPERATIVE CARE

In an otherwise uncomplicated case, the orogastric tube may be removed at the end of the operation. Ambulation is initiated on the following morning, after which time the indwelling urethral catheter and pneumatic compression stockings may be discontinued. Diet is advanced on postoperative day 1. After the first 24 hours oral analgesics ordinarily suffice for pain control.

## OUTCOMES

### Complications

The predominant approach to L-RPLND has been by a transperitoneal route. The data presented here relate to

L-RPLND performed by this technique. Potential complications associated with L-RPLND most often relate to intraoperative hemorrhaging. Other complications specifically related to this procedure include lymphocele formation and chylous ascites. The cumulative major (0.7%) and minor (7.8%) complication rates (intraoperative and postoperative) of this minimally invasive procedure are reasonable. Patients undergoing L-RPLND are likely to experience fewer pulmonary complications than those undergoing open surgery by midline or thoracoabdominal incisions. Janetschek et al. (11) noted the presence of chylous ascites in 21% of patients who underwent L-RPLND for persistent stage IIb tumor/mass. The authors believe that this complication is not related to surgical technique, as all lymphatic tissue was clipped, but rather to the brief time to oral intake after L-RPLND compared to open RPLND. All such cases resolved with conservative measures (low-fat/medium-chain triglyceride diet). In the hands of experienced laparoscopists, complications specifically related to laparoscopy, such as bowel injury due to trocar insertion or intraoperative manipulation, are less likely.

The largest contemporary series reported that only 3 of 103 patients required conversion to an open surgery because of injury of a small aortic branch, the renal vein in a horseshoe kidney, and a left renal vein ventral to the aorta in one patient each (12). There were four intraoperative vascular complications, including lacerations of the vena cava, renal vein, and a lumbar vein. The authors noted that three of the vascular complications were laparoscopically controlled with compression, clips, and fibrin glue; a left renal vein injury was controlled by laparoscopic suturing. Minor postoperative complications included asymptomatic lymphocele in three patients, genitofemoral nerve irritation in one patient, and a single spontaneously resolving retroperitoneal hematoma. Normal antegrade ejaculation was reported in 100 (97%) patients.

## Results

A summation of the worldwide experience with L-RPLND is shown in Table 123.2 (high-volume centers with 10 or more reported procedures). Review of 311 patients with follow-up for an average 44 months revealed 1 (0.3%) local recurrence and 12 (3.9%) distant recurrences; the solitary local recurrence occurred in the contralateral surgical field (12). Positive lymph nodes were demonstrated in 80 (25.7%) patients, and they were subsequently treated with chemotherapy. A 3.5% open conversion rate is reasonable for this complex procedure. Antegrade ejaculation was maintained in 99%. Longer follow-up of a larger number of patients is still needed to assess the diagnostic efficacy of this procedure.

A major point of discussion relating to L-RPLND is whether this procedure is simply a diagnostic procedure or may also be considered therapeutic. As the vast majority of patients found to have retroperitoneal tumors at the time of L-RPLND received adjunctive chemotherapy, it is not possible to determine the potential therapeutic efficacy of this procedure. L-RPLND has been used in a therapeutic fashion for a limited number of patients who underwent chemotherapy and had a persistent retroperitoneal mass. Janetschek et al. (11) described a group of 59 patients (stage IIb, 43 patients; stage IIc, 16 patients) who underwent chemotherapy, had persistent retroperitoneal mass, and subsequently underwent

L-RPLND. These patients all had normalization of tumor markers and a reduction of tumor size after chemotherapy. Of these patients, 21 had mature teratomas, 36 had necrosis and fibrosis only, 1 had active tumor, and 1 had seminoma. The one patient with active tumor received two additional cycles of chemotherapy and has remained disease-free. One

patient with stage IIb disease had recurrence at 24 months outside of the surgical margin that was excised laparoscopically; the node contained only mature teratoma. L-RPLND is believed to be therapeutic in the 18 patients with mature teratoma. At a mean follow-up of 35 months, there have been no relapses in this group.

# CHAPTER 124 ■ LAPAROSCOPIC NEPHRECTOMY AND PARTIAL NEPHRECTOMY

JAMES A. BROWN

Standard transperitoneal and retroperitoneal laparoscopic nephrectomy (LN) were first performed in 1990, and their partial nephrectomy (PN) counterparts followed in 1993 and 1994 (14). Hand-assisted laparoscopic nephrectomy (HALN) was subsequently introduced in 1997.

Equivalent 5-year cancer cure rates combined with decreased morbidity and recovery time have made LN the current standard of care for surgically treating renal malignancies in industrialized countries. Laparoscopy is also the standard today for performing nephrectomy for benign disease. While open partial nephrectomy (OPN) remains the standard of care, laparoscopic partial nephrectomy (LPN) is increasingly being performed at high-volume medical centers of laparoscopic surgical excellence, and at these centers outcomes approach those of OPN. However, concerns regarding warm ischemia time, control of hemorrhage, urinary extravasation, complications, and difficulties in technique training and propagation have promoted ongoing and wide-ranging refinements to the LPN procedural technique.

---

## DIAGNOSIS

---

Renal masses are identified during radiologic imaging of patients with hematuria or abdominal or flank discomfort. Additionally, patients are increasingly identified incidentally. Tumors are typically characterized and staged using abdominopelvic computerized tomography (CT) or magnetic resonance imaging (MRI) scan and chest radiography. Preoperative blood work includes metabolic panels including serum creatinine, liver function studies, alkaline phosphatase, and calcium. If the latter two studies are elevated or if the patient has bone pain or other evidence of metastases, a bone scan will be performed. Brain imaging is selectively obtained in patients with cerebral symptoms or evidence for metastasis. Nuclear renography is utilized in patients with renal insufficiency or if there is concern regarding the function of the contralateral kidney.

---

## INDICATIONS FOR SURGERY

---

Simple nephrectomy is indicated for benign conditions such as chronic pyelonephritis, nephrosclerosis, multicystic dysplastic kidney, postrenal transplantation or renovascular hypertension, reflux or obstructive nephropathy, and symptomatic acquired renal cystic or autosomal dominant polycystic kidney disease (ADPKD). Radical nephrectomy is indicated for tumors worrisome for malignancy.

Almost all nonfunctioning kidneys and stage T1 and T2 tumors can be removed laparoscopically. Hand-assisted laparoscopy (HAL) is a viable alternative for any case where nephrectomy or PN is indicated. HALN is a particularly useful alternative for urologists with limited laparoscopic surgical experience. Additionally, HALN may be advantageous compared to standard LN in cases of donor nephrectomy, nephroureterectomy, tumors >10 cm, and severe perinephric scarring secondary to prior surgery or infection (e.g., xanthogranulomatous pyelonephritis). Difficult standard laparoscopic operations can be converted to HAL rather than open procedures by the surgeon comfortable with HAL.

Hand-assisted LPN (HALPN) and LPN have differing advantages and disadvantages. LPN minimizes incision length and morbidity. It further allows for more facile suturing and needle handling. HALPN has the advantage of allowing for tumor palpation, which may increase surgeon comfort during tumor excision. It further allows for the selective performance of polar PN with hand compression rather than hilar clamping. In this situation, HALPN may minimize the overall renal injury from the procedure, and if a positive surgical margin occurs, a repeat resection might be performed with less risk for additional renal impairment (5). This is not the case after LPN or HALPN using hilar clamping.

---

## ALTERNATIVE THERAPY

---

Open radical nephrectomy (ORN) and OPN may be performed. Cryoablation (CA) and radiofrequency ablation (RFA) are also therapeutic alternatives, particularly for patients who are elderly or who have significant medical comorbidities, hereditary forms of renal cancer, or multiple tumors. These ablative procedures can be performed percutaneously with CT or MRI guidance and laparoscopically. Tumor enucleation may be considered in patients with severe renal insufficiency, a solitary kidney, multiple tumors, or a tumor in a difficult location (e.g., central, hilar). Lastly, observation alone may be reasonable for patients with small tumors, cystic masses, advanced age, or poor health.

---

## PATIENT PREPARATION

---

A formal bowel preparation is not routinely performed, but a clear liquid diet the day before surgery augmented by a Dulcolax suppository or an oral saline cathartic (e.g., magnesium citrate or Fleet Phospho-Soda) is often employed. One gram of cefazolin (Ancef) is administered preoperatively.

Deep venous thrombosis prevention with subcutaneous heparin (5,000 U 2 hours prior to procedure and continued every 12 hours postoperatively until the patient is ambulatory) and/or pneumatic compressive stockings are used.

---

## PATIENT POSITIONING

---

Under general anesthesia, intravenous access and endotracheal intubation are obtained with the patient supine. Orogastric and Foley catheters are inserted to decompress the stomach and bladder. The patient is then placed in a modified (30- to 70-degree) lateral decubitus position, with the umbilicus over the break in the table. For retroperitoneoscopic procedures, the patient is placed in or closer to the true lateral decubitus position. An axillary roll is placed, the table is flexed as necessary (usually minimally compared with open flank surgery), and a bean bag or padding is positioned to support the buttocks and flank. Pillows are placed between the flexed lower and straight upper leg. The upper arm rests on a well-padded arm board (or pillows) without tension on the brachial plexus. Three-inch tape is used to secure the patient around the hips, shoulders, and thighs to ensure stability when rolling the table to facilitate bowel retraction (Fig. 124.1).

---

## SURGICAL TECHNIQUE

---

### Transperitoneal Radical or Total Nephrectomy

---

#### Access

Although various insufflation techniques can be used, most urologists use a Veress needle. It is commonly inserted at the level of the umbilicus lateral to the ipsilateral rectus muscle. The abdomen is insufflated to 15 mm Hg. Some surgeons prefer a pressure of 20 mm Hg during the trocar placement. Typically a 10- or 12-mm trocar is placed lateral to the rectus at the level of the umbilicus using a visual obturator trocar (e.g., Visiport, AutoSuture or Optiview, Ethicon Endo-Surgery). Once the peritoneum has been entered, the intraperitoneal contents are inspected for injury or adhesions. Trocar site placement varies significantly based on surgeon preference and patient body habitus. Most surgeons prefer

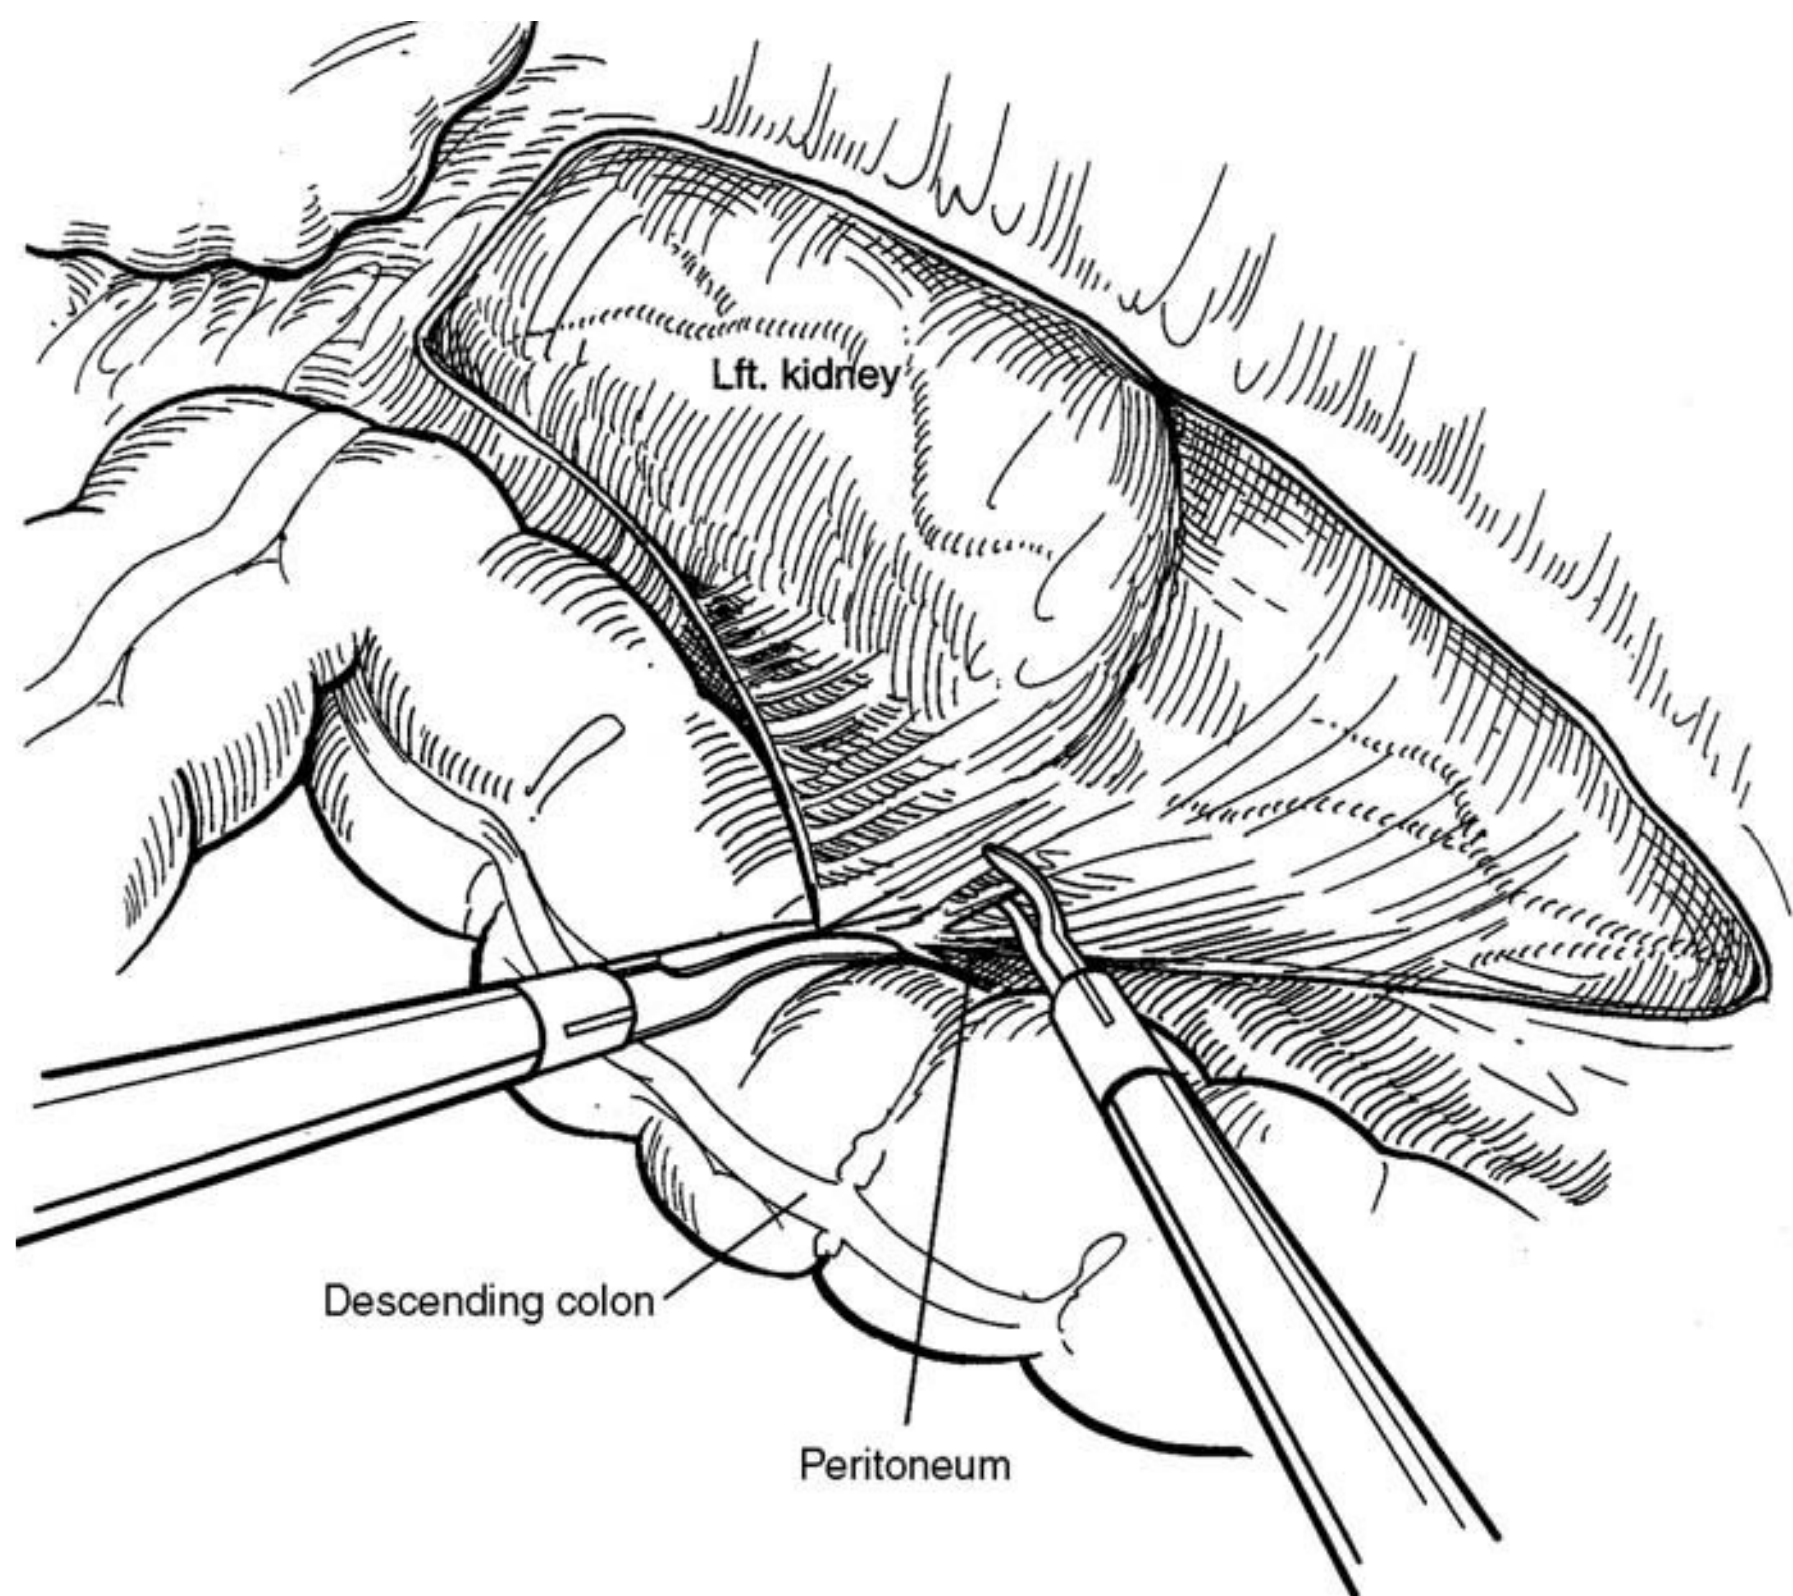

**FIGURE 124.1** The patient is placed in a modified (70-degree) lateral decubitus position, with the umbilicus over the break in the table. (From Figure 11.3 in Bishoff JT, Kavoussi LR, eds. *Atlas of laparoscopic retroperitoneal surgery*. Philadelphia: WB Saunders, 2000, with permission.)

the laparoscope (“camera”) port positioned between the working ports, which is the author’s preference. Some place it caudad to the working ports. Many surgeons use a 30-degree laparoscope placed through an umbilical port, with working ports widely spaced in the subxiphoid midline and the far lateral abdomen (anterior axillary line, umbilical level), creating a 90-degree angle in relation to the umbilical trocar. Other surgeons place the working ports closer to the umbilical trocar, keeping them at least 10 cm apart. Others reduce the angle of the working ports in relation to the umbilicus to approximately 60 to 70 degrees, creating a trocar “diamond” configuration. Alternatively, one can use a 0-degree laparoscope placed through a trocar lateral to the rectus muscle and just cephalad to the umbilicus, with the working ports shifted slightly cephalad and laterally, respectively, to maintain at least 10-cm or five-fingerbreadths distance between trocars. A 5-mm trocar is often placed in the far lateral (anterior to posterior axillary line) position for retraction, and another 5-mm trocar is often placed below the xiphoid process for right-sided procedures to elevate the liver using a locking grasper attached to the lateral abdominal wall. Obese patients or patients with protruberant abdomens will need to have the trocars shifted laterally to maintain effective working angles into the retroperitoneum.

#### Reflection of the Colon

The ipsilateral ascending or descending colon must be mobilized to gain access to the kidney and renal hilum. The parietal peritoneum is first incised medial to the line of Toldt, approximately 1 cm lateral to the mesenteric fat lying lateral to the colon. This incision is carried from the iliac vessels to the level of the spleen (left) or liver (right). Atraumatic graspers are used in the nondominant hand to provide counter-tension, and a hook electrode, Endoshears (scissors), or harmonic scalpel is used in the dominant hand to perform the dissection. Endoshears are particularly useful when dissecting in close proximity to bowel and when tissue planes are relatively avascular. Selective use of monopolar cautery through the instrument or use of a bipolar grasper in the nondominant hand allows for an efficient and elegant dissection by an experienced surgeon. Conversely, the harmonic scalpel excels at maintaining hemostasis when tissue planes are more vascular, and it is an excellent blunt-tipped dissection tool. Less experienced surgeons and surgeons in training may find the harmonic scalpel an easier tool to master. For left-sided procedures, many surgeons advocate carrying the peritoneal incision above the spleen laterally, allowing the spleen to fall medially with the pancreas and colon. Others prefer to carry the peritoneal incision through the phrenicocolic ligament to the spleen but then carry the dissection medially, leaving the spleen suspended on a “hammock of peritoneum caudad to the spleen and extending to the left abdominal sidewall,” (Fig. 124.2). The splenophrenic attachments are left intact while the splenocolic and then renocolic fascial attachments are divided in layers until the descending colon is fully mobilized medially and the left gonadal vein is visible.

For right-sided procedures, the peritoneum just lateral to the ascending colon is divided and carried to the level of the liver. This peritoneal incision is also carried medially, staying approximately 1 cm away from the lateral border of the colonic hepatic flexure. This incision then proceeds cephalad to approximately 1 cm below the liver and back laterally

**FIGURE 124.2** Mobilization of the colon using medial traction to demonstrate and divide attachments. (From Figure 4.8 in Bishoff JT, Kavoussi LR, eds. *Atlas of laparoscopic retroperitoneal surgery*. Philadelphia: WB Saunders, 2000, with permission.)

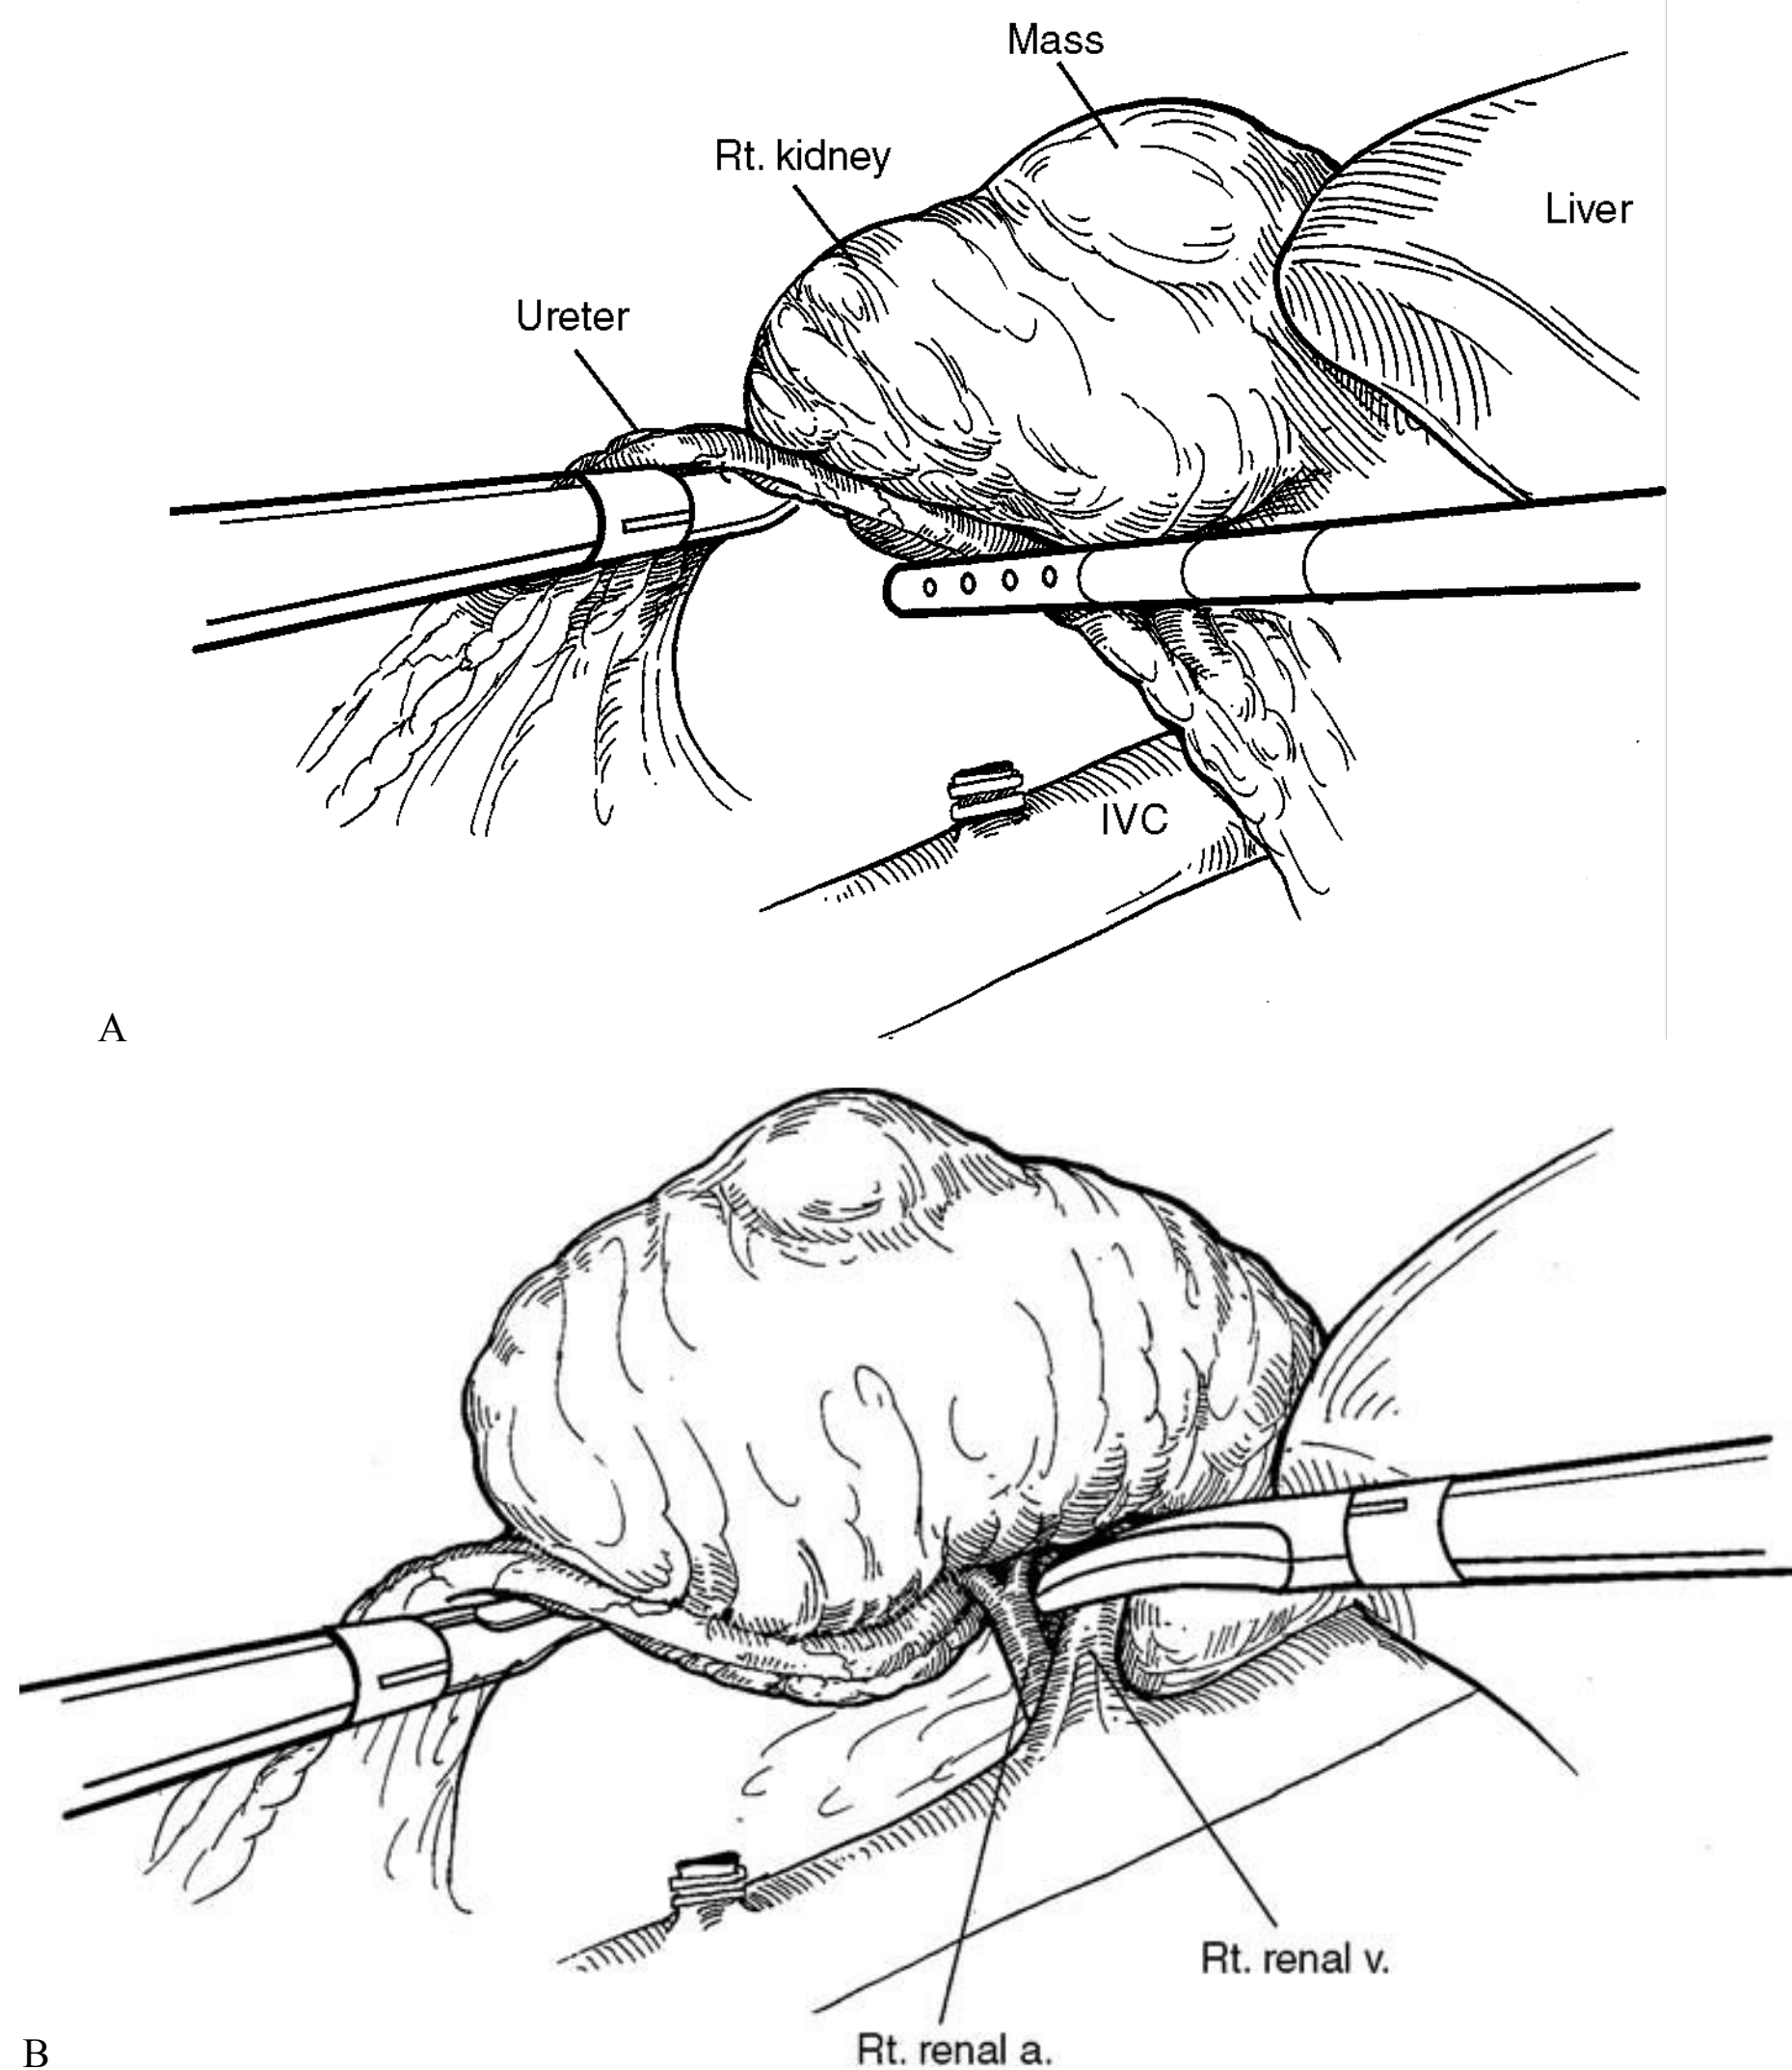

along the inferior surface of the liver to the sidewall. This approach will leave a wedge-shaped area of peritoneum covering the anterior aspect of the right kidney (Fig. 124.3). Once the ascending colon is mobilized medially, the duodenum is subsequently identified and a fascial incision is made approximately 1 cm lateral to its second stage. A Kocher maneuver is performed to move the duodenum medially. Third, the inferior vena cava (IVC) is exposed by incising the fascia and dissecting along its lateral border. For both left- and right-sided procedures, care is taken to preserve the lateral attachments of the kidney to prevent it from falling medially, inhibiting dissection of the renal hilum and the medial aspect of the Gerota fascia.

#### Gonadal Vein Dissection

Once the colon is fully mobilized, the gonadal vein is identified. Many urologists find the gonadal vein to be the “gateway” for initiating the nephrectomy portion of the procedure and carrying the dissection to the renal hilum. For left-sided nephrectomies, the fascia overlying the gonadal vein is divided and this dissection is carried cephalad to the renal vein. Care must be taken to dissect anterior to the gonadal vein to prevent injuring small gonadal venous tributaries or hilar vessels. The harmonic scalpel is useful for dividing these fascial attachments and maintaining hemostasis. This will allow for exposure of the anterior aspect of the left renal vein and subsequently the adrenal vein. The adrenal vein may be dissected using the harmonic scalpel or a gently curved dissector (e.g., Maryland). It is subsequently cauterized (e.g., with a paddle bipolar instrument), clipped (e.g., with Hem-O-Lock clips), and divided. The gonadal vein is then divided 1 to 2 cm below the renal vein in a similar fashion. It is included with the

**FIGURE 124.3** Diagram of the right-sided nephrectomy demonstrating the wedge-shaped configuration. The numbers refer to the three distinct levels of dissection along the medial aspect of the kidney: colon, duodenum, and inferior vena cava.

**FIGURE 124.4** Elevation of ureter and tail of the Gerota fascia (A) to allow dissection to and exposure of renal vessels (B). (From Figures 5.8 and 5.9 in Bishoff JT, Kavoussi LR, eds. *Atlas of laparoscopic retroperitoneal surgery*. Philadelphia: WB Saunders, 2000, with permission.)

radical nephrectomy specimen, particularly for large and lower-pole tumors. For right-sided procedures, the fascia over the gonadal vein may similarly be divided along the course of the vein up to its junction with the IVC. The right gonadal vein may, particularly for large tumors, be divided and removed with the specimen. Conversely, the dissection can be made just lateral to the right gonadal vein for smaller mid- and upper-pole tumors. The plane of dissection between the gonadal vein and the tail of the Gerota fascia (containing the ureter) is developed, and the latter is elevated anterolaterally (using a laparoscopic Kitner, atraumatic grasper, or suction device) to allow dissection to the renal hilum via an inferoanterior approach (Fig. 124.4).

#### Dissection of Ureter and Tail of the Gerota Fascia

For right-sided procedures, the ureter and tail of the Gerota fascia are elevated anterolaterally and the dissection carried along the gonadal vein to the IVC cephalad and to the iliac vessels caudad. For left nephrectomies, the dissection of the ureter and medial tail of the Gerota fascia is often performed

after dividing the left adrenal and gonadal veins, if a true radical nephrectomy is to be performed. The adrenal gland and gonadal vein are spared when performing a simple nephrectomy or in select cancer patients. The tail of the Gerota fascia is mobilized medial to the gonadal vein from the renal hilum to the iliac vessels.

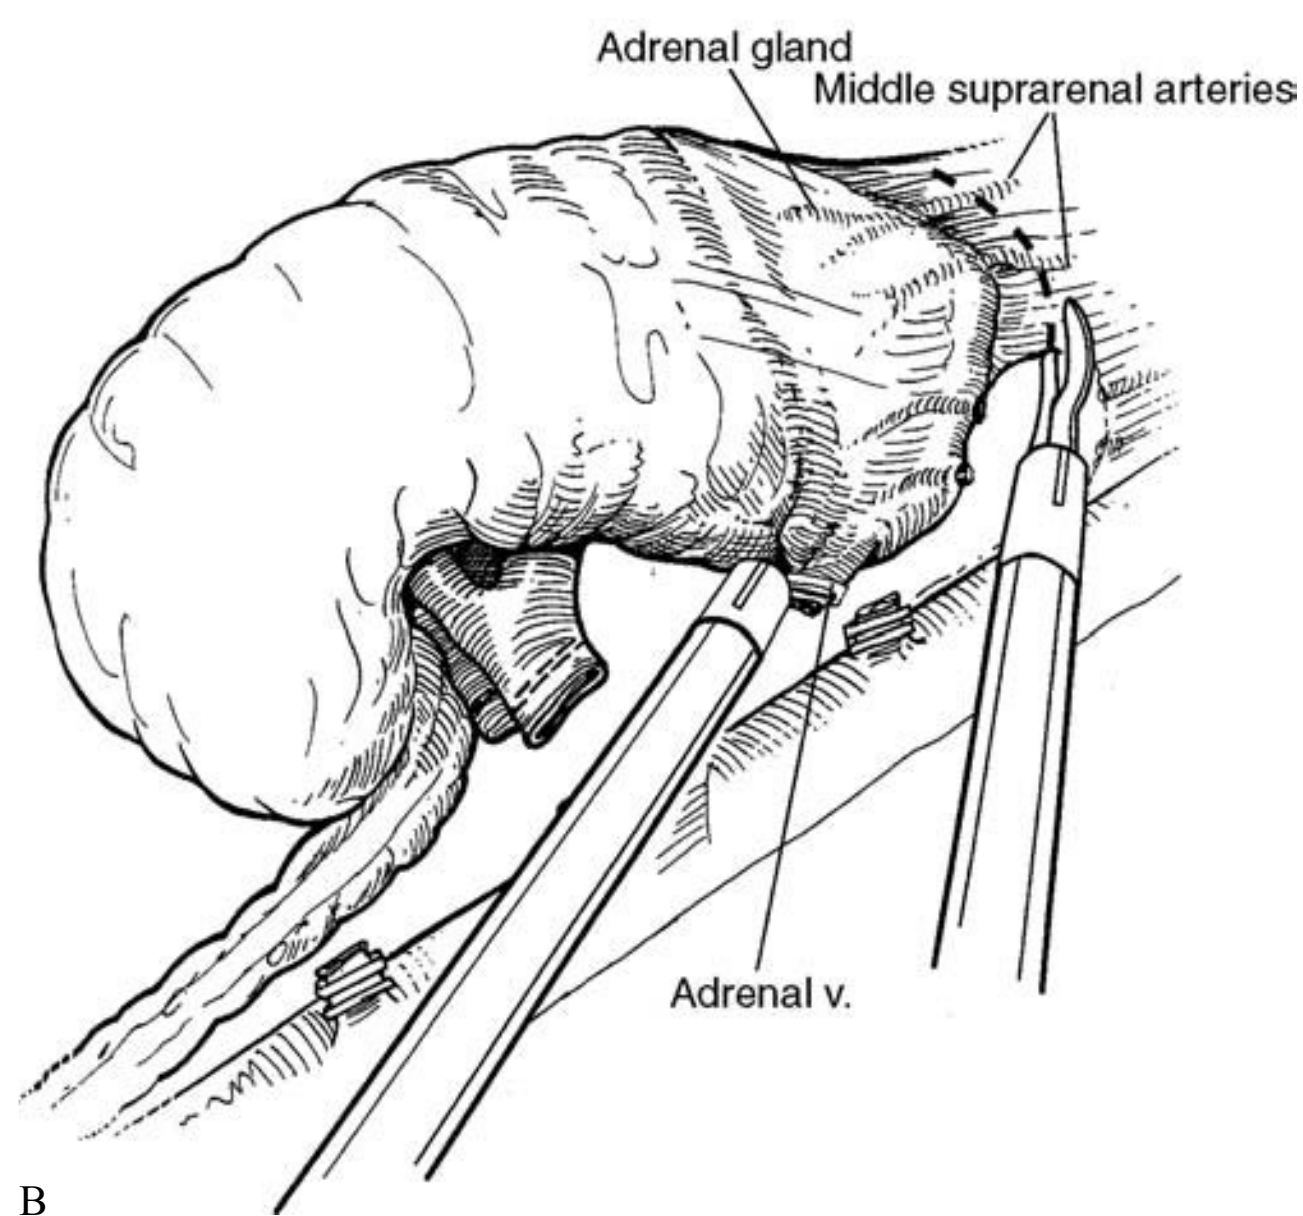

#### Securing the Renal Blood Vessels

Firm anterolateral elevation of the lower pole is critical in order to facilitate dissection of the hilum. This is accomplished by placing a laparoscopic Kitner or atraumatic grasping instrument under the tail of the Gerota fascia, the ureter, and the lower pole and lifting to the abdominal sidewall. With the hilum on tension, a harmonic scalpel, suction instrument, hook electrode, dissector (e.g., Maryland), or Endoshears can be used to dissect out the renal artery and vein and any necessary tributaries (e.g., lumbar or accessory vessels). Lymphatic vessels and fascial attachments inferior to and occasionally encasing the renal artery must be divided bluntly or sharply. Once adequate vessel exposure (at least a 1- to 2-cm space) is

created, an endovascular gastrointestinal anastomosis (GIA) stapler is used to divide first the renal artery and then the vein. Alternatively, a series of at least three Hem-O-Lock clips may be applied to the renal artery, dividing it approximately 1 cm lateral to the clips. In cases of severe perihilar fibrosis or if individual vessel isolation is difficult, en bloc endovascular GIA stapler division of both the artery and vein simultaneously is effective (17). Hilar side branches (gonadal, adrenal, lumbar, and accessory) may be ligated and divided in a variety of ways. Cauterization with either the LigaSure device or three overlapping deployments of a standard paddle bipolar cautery is effective. Standard titanium or locking polymer Hem-O-Lock clips may be used. The author favors sequential paddle bipolar cauterization of the vessel and placement of a Hem-O-Lock clip on the stay side of the vessel if it won't be in the path of the endovascular GIA stapler when dividing the renal vessels.

### Upper-Pole Isolation

Once all hilar vessels have been divided, the dissection is carried superiorly. For right radical nephrectomies (RNs), the adrenal vein must be identified, ligated, and divided. Hem-O-Lock clips, preferably two on the stay side, or an endovascular GIA stapler may be used. The remaining suprarenal attachments and middle suprarenal arteries are divided with the harmonic scalpel or stapler (Fig. 124.5). A similar dissection can be performed for left RNs, separating the adrenal from the aorta and diaphragm. Alternatively, for simple nephrectomies and selectively for small, non-upper-pole renal tumors (with a normal ipsilateral adrenal gland on preoperative abdominal CT or MRI imaging and intraoperative exam), the adrenal gland can be spared by placing the kidney on caudad traction and dividing the attachments between the adrenal gland and upper pole, staying adjacent to the adrenal. At this point, if it hasn't been performed previously, the ureter

B

**FIGURE 124.5** Adrenal gland excision with a right radical nephrectomy specimen. (From Figure 5.14B in Bishoff JT, Kavoussi LR, eds. *Atlas of laparoscopic retroperitoneal surgery*. Philadelphia: WB Saunders, 2000, with permission.)

is clipped and divided and any remaining posterior or lateral attachments are divided by rotating the kidney as necessary.

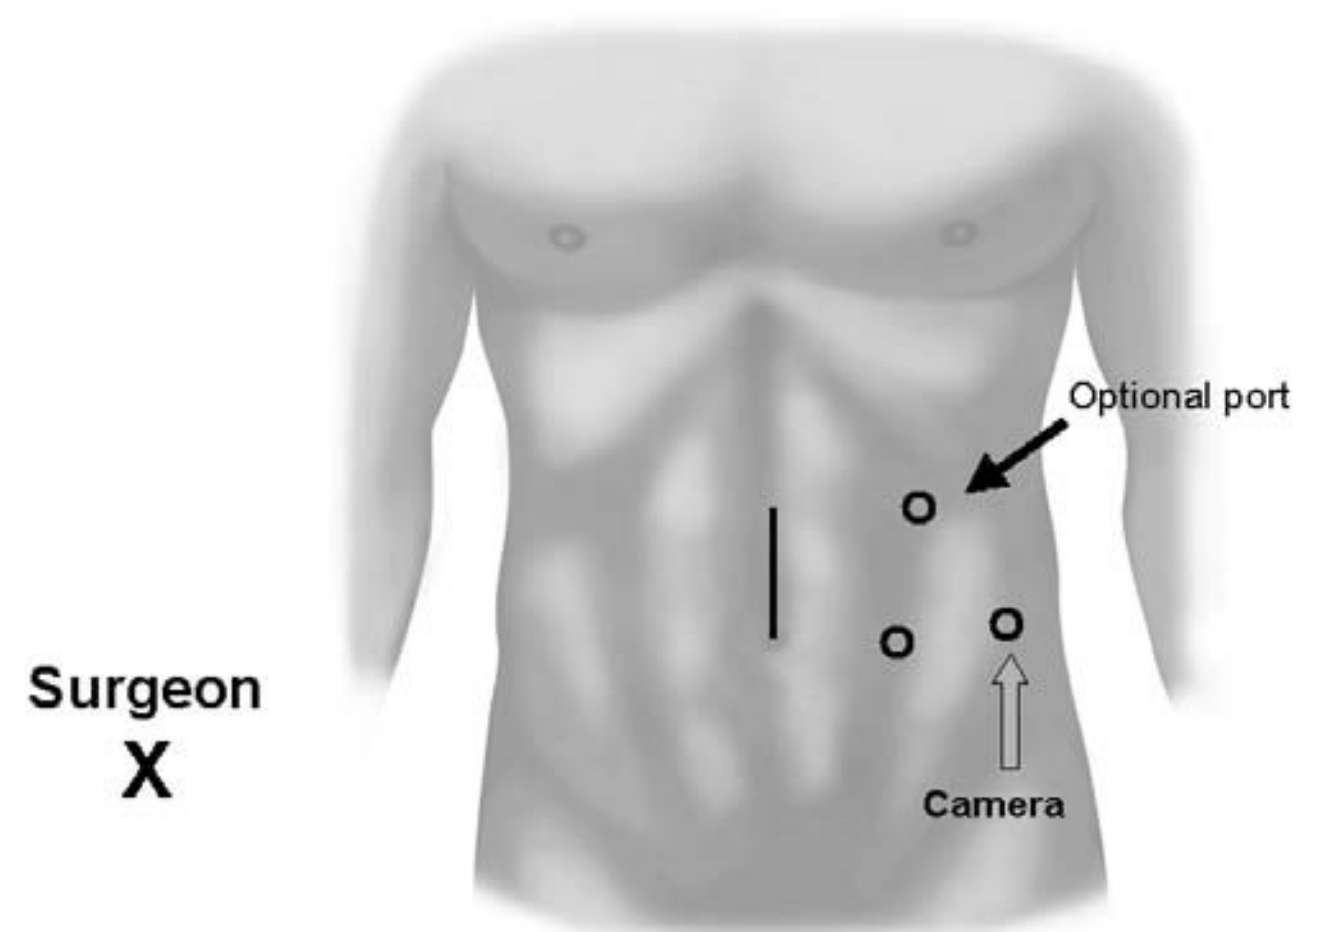

### Organ Entrapment

Benign kidneys may be morcellated in a durable entrapment sac, but malignant kidneys should be removed intact. The risk for tumor spillage and the loss of histologic staging information virtually always outweigh the morbidity benefits of minimizing the extraction incision. The kidney is placed into a deployable entrapment sack (e.g., Endocatch II, US Surgical) and then brought out through an incision extended from a 12-mm trocar site. Alternatively, the specimen may be removed through a Pfannenstiel incision. Trocar sites larger than 5 mm should have a fascial closure suture (e.g., interrupted 0 Vicryl) placed prior to specimen extraction. The Carter-Thomason device facilitates placement of these fascial sutures.

## Hand-Assisted Laparoscopic Nephrectomy

### Access

For left HALN, a 7-cm supraumbilical midline incision is made extending into or skirting the umbilicus. It is useful to place a 0 Vicryl suture through the anterior rectus fascia and peritoneum at the midline of the incision bilaterally in order to elevate the abdominal wall to facilitate placement of the intraperitoneal portion of the laparoscopic hand port (e.g., GelPort, Applied Medical; or Lap Disc, Ethicon Endo-Surgery). These current third-generation devices have a narrower base than their predecessors, facilitating subsequent placement of trocars in slender patients. With a 0-degree laparoscope placed through a 12-mm trocar within the device, the peritoneum is inspected for adhesions. Under direct vision or under fingertip control, 12-mm trocars are then placed lateral to the rectus muscle (midclavicular line) and also approximately two fingerbreadths off the tip of the twelfth rib (anterior axillary line). Both trocars are positioned at the level of the hand port device (Fig. 124.6). A 5-mm trocar is

**FIGURE 124.6** Hand-assisted laparoscopy port placement for left renal surgery. An optional 5-mm trocar may be placed cephalad (shown) or caudad to two 12-mm trocars placed at the level of the hand port or umbilicus.

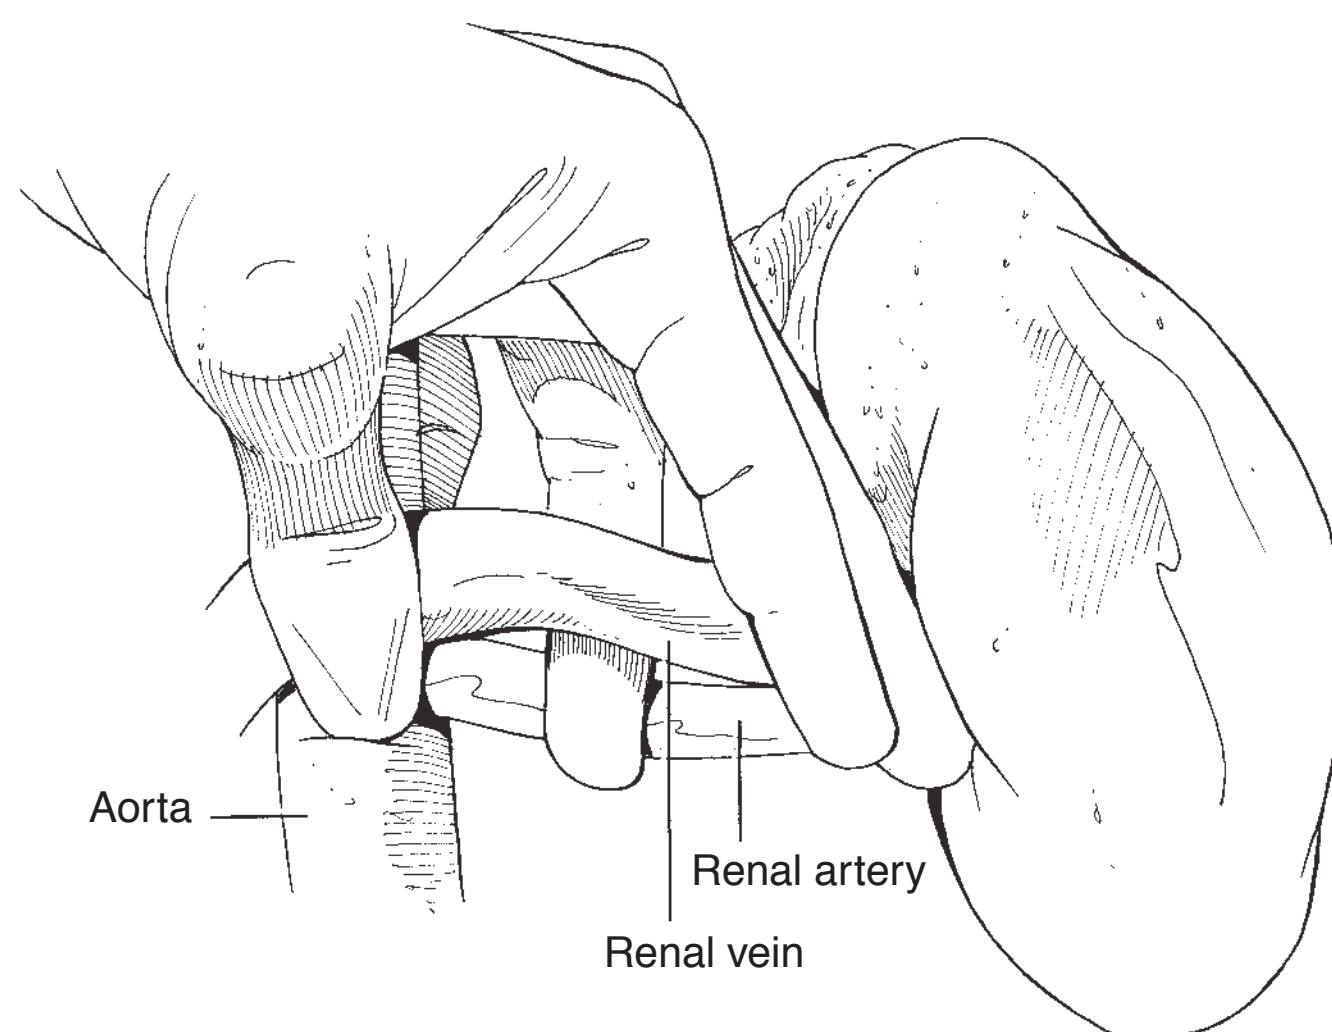

selectively placed in the left lower quadrant, approximately 10 cm below the 12-mm trocars or along the costal margin, to use for retraction.

Right-sided HALN procedures may be performed by the left-handed or ambidextrous surgeon with ports placed in a mirror image fashion to the left-sided procedure. Alternatively, the hand port may be placed in the right lower quadrant through a 7-cm muscle-splitting incision. It may also be moved further caudad in the midline using a paraumbilical incision. This will allow room for placement of the laparoscope and the working and liver retraction trocars in the upper right quadrant and abdominal midline, cephalad to the hand port.

### Procedure

A damp laparotomy sponge, useful for hemostasis, is initially carried into the abdomen while inserting the hand. The obvious and only significant difference between HALN and standard LN is the use of the hand for palpation and retraction. Some standard laparoscopic urologic surgeons find the HAL technique cumbersome and find that their hand is “in the way.” They are able to use retraction instruments more effectively than an intraperitoneal hand. Conversely, expert HAL surgeons become adept at utilizing their intraperitoneal hand in ways that gain them additional exposure beyond what they can obtain with standard laparoscopic instruments. Initially, the colon is reflected using a harmonic scalpel or Endoshears, while providing medial bowel traction with the fingertips. The hand is then placed in a “C-shaped” configuration while operating within the central space between the fingers and thumb.

For a left HALN, fingertips provide gentle tension and countertension, respectively, on the spleen or kidney and colon while the splenicocolic and then renocolic attachments are divided. As the bowel is increasingly mobilized, it may be elevated anteriorly with the hand to facilitate separation of the colonic mesentery from the anterior aspect of the Gerota fascia. The gonadal vein and subsequently renal vasculature are dissected and handled as described for LN. The back of the wrist and hand assist with retraction of the colon to expose the hilum. The fingertips flatten and provide simultaneous cephalad, lateral, and inferomedial tension, facilitating renal vessel dissection and division. The lower pole, ureter, and tail of the Gerota fascia are elevated anteriorly by placing the index and middle fingers posteriorly and lifting anteriorly. The fourth finger may be placed cephalad to the renal vein to further rotate the renal artery into view (Fig. 124.7). Palpation is used to confirm location of the aorta and renal artery or arteries. The remainder of the procedure is accomplished in a similar fashion to standard LN. A simpler, less expensive entrapment sack (Cook Urologic, Spencer, IN) is introduced for specimen extraction. It is unrolled on top of the spleen with the posterior opening of the sack flattened across the body wall using the fifth fingertip to fixate it medially and a grasping instrument to hold it laterally. The third and fourth fingers of the intraperitoneal hand hold the anterior aspect of the sack open, and the thumb and index finger “feed” the kidney into the sack. The neck of the sack is tightened and the specimen is removed through the hand port incision. The incision may be extended as necessary for specimens too large to pass. The retroperitoneum is irrigated and

**FIGURE 124.7** Finger and hand position during left renal hilar dissection.

the incisions are closed. The midline hand port incision is closed with interrupted figure-of-eight no. 1 absorbable monofilament sutures (Maxon or polydioxanone).

Right HALN may be performed using a mirror image technique, with the right hand placed within the peritoneum, or the right-handed surgeon may place the left hand in the abdomen. The procedure is accomplished as described for the standard right LN technique, using the hand to provide tension and countertension. The surgeon will often facilitate the hilar dissection by lifting the lower pole anteriorly with a retractor. This will free up the hand to encircle and flatten the hilum, palpating and placing the artery and vein on stretch. This will promote rapid isolation and division. The adrenal gland may be palpated, as can the hilar lymphatics and the liver. The HALN technique is particularly useful if significant perihilar lymphadenopathy is present and for very large tumors impinging on either the IVC or aorta, where a safe dissection plane may be difficult to identify with standard laparoscopy. The subcutaneous tissues are injected with a mixture of 0.25% Marcaine and 1% lidocaine prior to approximating the subcuticular layer with 4-0 Monocryl suture. Sterile bandages are applied to the trocar sites. Injecting these sites prior to port placement may provide additional analgesic benefit. The hand port incision is covered with a small gauze dressing and Tegaderm and the trocar sites with sterile bandages.

## Retroperitoneal Nephrectomy

### Access

A 2-cm incision is made just below the tip of the twelfth rib in the midaxillary line. A Kelly clamp is used to separate the subcutaneous fat and expose the flank musculature. The muscle is bluntly divided, and the underlying thoracolumbar fascia is pierced to enter the pararenal fat of the retroperitoneum. “S” type or Army-Navy retractors are used for exposure, and a fingertip is inserted and rotated 360 degrees in order to

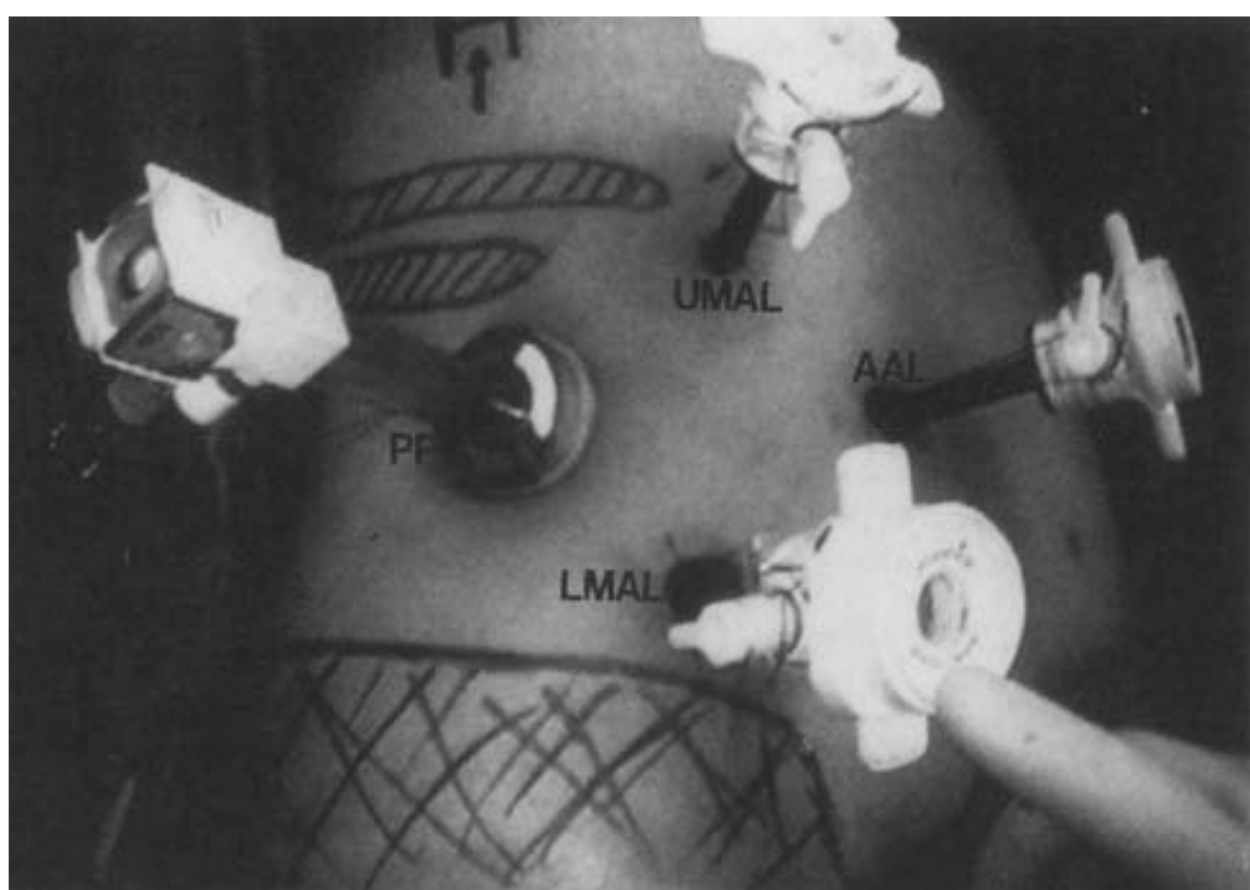

palpate the psoas muscle and confirm an appropriate retroperitoneal location. A balloon dilator is introduced and filled to 800 cc with room air. During insufflation, a 10-mm laparoscope may be introduced to view the dissection. A 10-mm blunt-tipped cannula is introduced with 30 cc of air in the balloon (US Surgical). After tightening the outer ring sponge to compress the balloon against the inner abdominal wall, the retroperitoneum is insufflated to 15 to 20 mm Hg. Of note, some surgeons alternatively make the incision midway between the iliac crest and the tip of the twelfth rib in the posterior axillary line. Additionally, a visual obturator trocar with a 10-mm 0-degree laparoscope may be used instead to enter the retroperitoneal space. Entry must be at a 10-degree anterior angle. Angling too far posteriorly will injure the quadratus or psoas musculature, whereas too anterior of a trajectory may allow entry into the peritoneum or cause colon injury.

### Procedure

After obtaining retroperitoneal entry, blunt dissection is performed using only the scope. Anteriorly, the peritoneum is swept medially, exposing the transversalis fascia. Once peritoneal dissection off the abdominal wall is complete, accessory ports are placed in the upper and lower midaxillary line and a 5-mm trocar is placed in the anterior axillary line (Fig. 124.8). Some surgeons eliminate the lower midaxillary line port (three-port approach), while others maintain this trocar and add another anterior to it (five-port approach).

If balloon dilation was effective, the kidney should be displaced anteriorly. The psoas muscle is cleaned of fat and the dissection is carried cephalad and medially until the pulsating renal artery is visualized. The Gerota fascia is incised and the renal hilum is dissected, clipping the artery and stapling the vein with the endovascular GIA stapler. For left-sided nephrectomy, the posterior ascending lumbar vein may be encountered prior to viewing the artery. It should be dissected,

**FIGURE 124.8** Port placement during right retroperitoneoscopic renal surgery. The primary port (*PP*) is inserted by the open (Hasson) technique caudad to the tip of the twelfth rib. The 12-mm lower midaxillary line (*LMAL*) port is placed 2 to 3 cm cephalad to the iliac crest. The 5-mm anterior axillary line (*AAL*) port is placed at the level of the *PP*. The 5-mm upper midaxillary line (*UMAL*) is placed near the tip of the eleventh rib. Care must be taken to avoid transpleural placement of this trocar.

clipped with Hem-O-Lock clips, or cauterized and divided. Circumferential dissection of the Gerota fascia is performed. On the right side, cephalad dissection will lead to the adrenal vein, which will be clipped or cauterized and divided. The adrenal vein will also typically be divided during left nephrectomy. The ureter is doubly clipped and divided, followed by division of the remaining retroperitoneal attachments. The specimen is entrapped in a deployable sack and removed through the initial port site by extending the incision horizontally anterior to the tip of the twelfth rib. Morcellation of benign kidneys can be performed in an impermeable sack (e.g., LapSac, Cook Urologic, Spencer, IN).

The peritoneal cavity may be entered during anterior dissection of the Gerota fascia, but it does not necessitate conversion to a transperitoneal technique. Conversion to a transperitoneal laparoscopic or open flank nephrectomy approach can be performed in difficult cases. Similar to the transperitoneal technique, the retroperitoneum is inspected for hemostasis with CO<sub>2</sub> pressure at 3 to 4 mm Hg prior to end of the case. The port sites will not require fascial closure but are irrigated, and the skin is closed with 4-0 subcuticular suture.

### Transperitoneal Partial Nephrectomy

Access and renal exposure are similar to transperitoneal LN. The renal hilum is identified. At this point the operation will vary somewhat, depending on the PN technique that is employed. In most instances, the renal artery and vein are carefully dissected. The Gerota fascia is then opened horizontally across the anterior midpole, and the perirenal fat is reflected off the capsule. Some surgeons open the Gerota fascia along the lateral margin of the kidney. Fat is reflected until the tumor is visualized and then exposed, leaving it covered with fat. Endoshears or the harmonic scalpel is used to separate the fat from the capsule, with care taken not to get subcapsular. Intraoperative sonography is performed, if available, to assess the depth of the tumor and rule out additional tumors.

The major challenges of laparoscopic nephron-sparing surgery are difficulty performing regional hypothermia (cold ischemia), difficulty maintaining hemostasis if hilar clamping is avoided, and difficulty completing the procedure within a 30-minute warm ischemic period. Previously, numerous techniques were used in an effort to perform simultaneous tumor resection and hemostasis. These included the use of electrocautery, the Cavitron ultrasonic surgical aspirator, the endovascular GIA stapler, the argon bean coagulator, topical agents, ultrasonic energy, microwave thermotherapy, and cable tie compression (32). A 5- to 10-mm rim of normal parenchyma is marked by scoring the renal capsule with electrocautery using the hook electrode. The excision is initiated by dissecting perpendicularly into the kidney along the pyramidal lines. A meticulous effort is made to avoid dissecting too superficially into the pseudocapsule or the tumor itself. The tumor is removed with a 5-mm to 1-cm margin of normal parenchyma. The parenchymal defect is inspected to ensure hemostasis, and if necessary the closure is augmented with adjuvant coagulation (e.g., argon beam) or topical agents (e.g., fibrin glue). These nonhilar clamping PN techniques

have been only partially effective in preventing perinephric hemorrhage. They are currently used only selectively, by some surgeons, on polar or very exophytic tumors. More recently, most surgeons have moved toward an LPN technique more closely mimicking the OPN technique, including hilar clamping and parenchymal closure. Although efforts have been made to replicate the regional hypothermia caused by ice slush in open surgery, this has been difficult in the laparoscopic setting due to the technologic and logistical difficulties involved. Efforts to cool the kidney during laparoscopy are further hindered by the flow of room temperature CO<sub>2</sub>.

Currently, surgeons typically clamp both the renal artery and vein with laparoscopic bulldog clamps, and without cold ischemia rapidly resect the tumor with laparoscopic scissors. This approach causes less tissue distortion than the use of the harmonic scalpel, bipolar cautery, or “hot scissors” (which are ineffective at preventing bleeding or urine leakage) and allows for a more accurate inspection for a positive surgical margin or an opening into the collecting system. Most surgeons attempt to close large (>5mm) urothelial defects with figure-of-eight absorbable sutures (e.g., 4-0 Monocryl). Lapra-Ty clips (Ethicon, Cincinnati, OH) are used by some to speed this process. An interrupted sutured closure of the capsule, often bolstered, is then performed over a Surgicel or Gelfoam sponge (Fig. 124.9). The closure is often augmented by hemostatic agents (e.g., Tisseel or FloSeal) placed directly into the defect or impregnated in the Gelfoam. A roll of Surgicel may also be placed into the defect prior to reapproximating the

**FIGURE 124.9** Resection bed of a right upper-pole tumor. Fibrin glue-impregnated Gelfoam is placed into the defect. Pledged interrupted sutures are then used to reapproximate the renal capsule.

capsule. Pledgets of numerous materials, including fat, surgical wrapped Gelfoam, and Gore-Tex (W.L. Gore and associates) have been used. The author has also found bovine pericardium to be effective. The bulldog clamps are released and hemostasis assessed. The retroperitoneum is irrigated and aspirated. If hemostasis is adequate at an insufflation pressure of <5 mm Hg, then the perinephric fat is reapproximated. It may be sutured or held in position with clips. A closed system drain (e.g., Jackson-Pratt) is placed outside of the Gerota fascia and away from the renal parenchymal closure. The specimen is placed in a deployable entrapment sack if not done previously and extracted. The incisions are closed.

## Hand-Assisted Laparoscopic Partial Nephrectomy

The access and renal exposure are similar to HALN. The main disadvantages of HALPN compared to standard laparoscopic PN are that a 7-cm incision is virtually never required to extract the specimen, it may be risky to provide hemostatic control with hand compression alone, and suturing “one-handed” may be difficult. There is further concern regarding increased renal damage due to “intermittent” vascular occlusion, which may occur with hand compression alone. HALPN proponents claim that this technique more closely mimics what many urologic oncologists do during OPN. The hand is used for tumor palpation during tumor excision and may be selectively used to provide hemostasis without hilar clamping. In this situation, the interpolar and opposite polar blood flow will likely be maintained throughout the case, and overall renal recovery and function are likely better. Another advantage is the relative ease of ice slush application through the hand port if hilar clamping is used.

Intraoperative sonography may be used during HALPN to confirm the findings of palpation. The margins of dissection are marked and the specimen excised sharply, using the hand to carefully retract and palpate the tumor during the process. For exophytic polar lesions, a “fibrin glue bandage” of Gelfoam impregnated with Tisseel fibrin sealant (Baxter U.S.) may be used. Prior to this, argon beam coagulation may be used as an adjunct to promote hemostasis. This can be applied through a 5-mm trocar with periodic venting of increased pressure. The “bandage” can be “welded” to the capsule with the argon beam. An unfurled Surgicel dressing may be draped over the “bandage” and around the kidney. The specimen is sent for frozen section analysis to confirm negative margins.

For central or hilar tumors, vascular clamping is employed, and an interrupted parenchymal closure over a “fibrin glue bandage” or rolled Surgicel, similar to the closure described for LPN, is utilized. For both LPN and HALPN, ureteral stents may be positioned in the renal pelvis at the initiation of the case to allow for injection of methylene blue to assess for urothelial defects. The need for this and further the need to close urothelial openings prior to closing the renal parenchyma/capsule has been questioned, and the author does not place a ureteral stent prior to PN and only closes large ( $\geq 5$ -mm) urothelial gaps that occur under hilar clamping control. Once hemostasis is ensured and the specimen removed through the hand port, the incisions are closed.

---

## Retroperitoneoscopic Partial Nephrectomy

---

Access and renal exposure are as described in the description of retroperitoneoscopic nephrectomy. This technique is typically performed only by true LPN experts when treating small posterior renal tumors. Hilar dissection and clamping are performed selectively. Excision of the tumor is performed as described for transperitoneal LPN with negative margins confirmed and the defect covered with a fibrin glue bandage if shallow (cortex) or closed with interrupted capsular/parenchymal sutures if deeper (e.g., into the renal medulla). Of note, the limited space within the retroperitoneum makes suturing difficult, and most laparoscopic surgeons prefer to perform LPN transperitoneally. The specimen is entrapped in a deployable sack and removed, followed by hemostasis confirmation, drain placement, and closure.

---

## POSTOPERATIVE CARE

---

Postoperative care is similar regardless of the laparoscopic approach, and, with the exception of drain placement for PN, it is similar for nephrectomy and PN patients. Ketorolac (Toradol) 15 mg every 6 hours as requested is typically prescribed for 36 hours. Oral narcotics are made available if necessary. A clear liquid diet is resumed immediately and advanced as tolerated. The patient ambulates on postoperative day 1 and is typically discharged in the evening or the following morning. Parenteral antibiotics are discontinued on postoperative day 1. Oral analgesics are prescribed upon discharge. Dulcolax suppositories are given as necessary for postoperative constipation, and patients are discharged taking a stool softener (e.g., Colace). For PN, the drain is removed when the volume has decreased to <60 to 100 mL per day. If a question exists regarding a urinary leak, a drain fluid creatinine level is obtained.

---

## OUTCOMES

---

---

### Laparoscopic Nephrectomy

---

In order for LRN to replace ORN as the standard of care, it has to provide equal cancer control with improved patient morbidity and convalescence at comparable operative efficiency. While the latter two issues have been well demonstrated, the remaining most important question is that of long-term cancer control. Several series have now reported overall 5-year disease-free and cancer-specific survival rates for both LRN and HALRN at or over 90%. All have confirmed that the oncologic efficacy of LRN and HALRN is equivalent to that of ORN (8,10,16,26).

In 2007 the Cleveland Clinic reported a 5-year 81% overall and a 90% cancer-specific survival for their LRN cohort compared to a 6-year 79% overall and 92% cancer-specific survival for their ORN cohort. The mean tumor size was 6 cm (5.8 and 6.2 cm,  $p = 0.44$ ). Blood loss and operative times were lower in the LRN cohort (8). Other recent studies have continued to demonstrate that perioperative outcomes,

including operative time, blood loss, postoperative analgesia requirements, length of hospital stay, and duration of convalescence, largely favor LRN. However, postoperative convalescence varies widely in patients undergoing laparoscopic kidney procedures. A randomized controlled single-center trial comparing laparoscopic (transperitoneal) with open (flank) simple and radical nephrectomy demonstrated similar, rapid operative times (105 and 93 minutes,  $p = 0.4$ ) in both groups (Burgess) (7). Blood loss, complications, and mortality rates were also similar. The LRN cohort had less postoperative pain returned to normal activity 20 days earlier.

---

## Laparoscopic Partial Nephrectomy

---

In 2006 researchers from Johns Hopkins retrospectively reviewed and reported on 143 stage T1 N0 M0 patients who underwent LPN (85) or OPN (58) between 1996 and 2004, with a mean follow-up of 40  $\pm$  18 months (25). They observed 5-year 91.4% disease-free and 93.8% actuarial survival rates in the LPN cohort and 97.6% and 95.8% rates, respectively, in their OPN cohort. They reported that survival analysis revealed no significant differences and that midrange oncologic results were comparable for pT1 N0 M0 tumors. The Cleveland Clinic subsequently reported their 5-year follow-up outcomes in 2007 (18). One final surgical margin in 37 cancer cases was positive. A single local recurrence (2.7%) and no distant recurrences were identified. Overall and cancer-specific survival rates of 86% and 100%, respectively, were observed. Median serum creatinine levels increased from 0.9 mg per dL preoperatively to 1.0 mg per dL postoperatively. They concluded that these excellent results are comparable to OPN and that LPN is an established alternative at their center. Despite these promising results, they acknowledge that OPN remains the standard of care for small, resectable, solid renal masses and that LPN is an evolving standard.

What then is the current standard LPN technique in this evolving process? The Cleveland Clinic proposed in 2005 that preoperative ureteral catheterization, laparoscopic renal ultrasonography, en bloc renal hilar vascular pedicle clamping, tumor excision with cold Endoshears, pelvicalyceal suture repair, and parenchymal closure over Surgicel bolsters with application of a biologic hemostatic agent and selective use of ice slush for renal hypothermia in cases with anticipated long warm ischemia times is the standard. Others have challenged that a ureteral catheter is not necessary with experience for tumors <4.5 cm and that suture renorrhaphy is not necessary if the renal sinus or collecting system is not entered, given that fibrin glue products will provide adequate hemostasis (3,15). Recently, the Cleveland Clinic group also stated that omitting bolster renorrhaphy may be reasonable, even for select central tumors (33).

---

## COMPLICATIONS

---

---

### Laparoscopic Nephrectomy

---

Laparoscopy is the current surgical standard for routine simple and radical nephrectomy due to equivalent cancer control and complication rates with decreased patient morbidity and

convalescence. Even when laparoscopic nephrectomy has been expanded to treat complex situations, equivalent or nearly equivalent low complication rates have been observed. It is now not only feasible but increasingly reasonable for an experienced laparoscopic surgeon to selectively use LN to treat patients with large stage T2 tumors, stage pT3b tumors, hilar lymphadenopathy, kidneys needing autotransplantation, bilateral renal tumors, horseshoe kidneys, autosomal polycystic kidney disease (ADPKD), xanthogranulomatous pyelonephritis, profound obesity, and even level II caval thrombi (30). Although da Vinci (Intuitive, Sunnyvale, CA) robotic-assisted laparoscopic surgery has little role in routine LN, it may have a future role in certain complex procedures, such as caval thrombectomy.

Technologic malfunction may cause surgical complications and is an important area of concern for laparoscopic surgery. Recent complications secondary to malfunction of polymer self-locking (Hem-O-Lock) clips are an example (21). Bleeding, delayed exploration, and even death were reported in several patients undergoing LN. The Hem-O-Lock clip is thus no longer recommended for laparoscopic donor nephrectomy renal vessel ligation. This will hopefully stimulate the future development of an inexpensive and improved vessel-grasping and ligating clip.

Of importance, complications do occur at an increased rate during a surgeon's initial learning curve. Improvements in training and skills distribution throughout the urologic community are therefore needed. Although LN has made great inroads into the academic centers, its adoption into private, community practice has lagged behind (1). Laparoscopic-naïve open renal surgeons currently in practice need to remember that a significant time investment in retraining is required to work through an approximately 20-case learning curve (6). It is also critical that new technology does not inappropriately supersede a more appropriate operative procedure, as is highlighted by concerns that LRN may be inappropriately replacing PN in the treatment of small renal tumors (22). Lastly, reassessment of the complications and morbidity of techniques as they evolve is necessary. It is possible that future developments in open and HAL surgery, such as minimization of incision lengths, alteration of incision locations, and improved analgesia, may minimize current LN advantages and warrant re-evaluation of the appropriate role of various surgical procedures. Also, future expansion of indications for nephron-sparing renal surgery could diminish the role of LRN.

---

## Laparoscopic Partial Nephrectomy

---

Whereas equivalent LRN and ORN complication rates are now commonplace, the same is not true for LPN. In 2002 the Cleveland Clinic reported that LRN had morbidity advantages over OPN, but OPN had the long-term renal function advantage (20). The following year, they reported that LPN has a greater positive surgical margin rate (3% versus 0%,  $p = 0.1$ ) and intraoperative complication rate (5% versus 0%,  $p = 0.02$ ) than OPN (12). Subsequent efforts have been made to demonstrate the utility and safety of LPN. Feasibility and near-equivalent outcomes have been demonstrated in obese patients, centrally located and hilar tumors, solitary

kidneys, cystic masses, pT2–pT3b tumors, and kidneys with multiple tumors or renal arteries. Retroperitoneoscopic PN has also demonstrated equivalent outcomes, but it is considered a more difficult operation than transperitoneal PN due to decreased working space.

In a John Hopkins University series, a 15% overall conversion rate of LPN to LRN (13.6%, 35 patients) and LPN to open surgery (1.6%, 4 patients) was observed among 257 operations started as LPN (27). A fourfold increased rate of conversion was noted in patients over 70 years old or with tumors >4 cm. In a review of the Cleveland Clinic's first 200 LPN cases, one third (66) had complications (28). These included a 9.5% (19) hemorrhage and a 4.5% (9) urine leakage rate, 8 of which required double-J stent placement with (2) or without (6) percutaneous drain placement. Two (1%) patients required open conversion and 4 (2%) reoperation. In a subsequent report, a 1.7% renal artery pseudoaneurysm rate in 345 cases was observed, and all 6 patients were effectively treated with percutaneous embolization. Similar LPN complication rates have also been reported from other centers. Importantly, Gill et al. (13) reduced their hemorrhagic complication rate from 12% to 3% by applying gelatin matrix thrombin sealant (FloSeal) to the PN defect prior to sutured renorrhaphy over a Surgicel bolster. They addressed urinary extravasation by running the defect bed with 2-0 Vicryl and testing the repair with gentle injection of indigo carmine through a ureteral catheter. A more recent 200-case series of LPN at the Cleveland Clinic had a complication rate approaching the level observed with OPN (31).

Despite improvements, there remain four principal concerns with LPN: (a) controlling hemostasis, (b) obtaining negative margins (particularly during the learning curve), (c) avoiding lengthy (>30 minutes) warm ischemic times and renal injury, and (d) treating large, complex, or centrally located tumors.

Regarding hemorrhage, the more central or endophytic the tumor, the greater the risk (5). Upper-pole tumors may also create hemostasis challenges. Numerous efforts to prevent bleeding can be categorized as follows: (a) improvement in PN defect closure, (b) energy application, (c) use of hemostatic agents or glues, and (d) superselective embolization prior to LPN. The first category includes use of Lapra-Ty or Hem-O-Lock clips and temporary defect packing. The second category includes use of a saline-irrigated KTP laser, water jet, TissueLink floating ball monopolar device, and radiofrequency coagulation prior to PN. Examples of the third category are gelatin matrix thrombin (FloSeal), fibrin gel (Tisseel), bovine serum albumin (BioGlue), cyanoacrylate glue (Glubran), and autologous fibrin glue.

In a review of positive surgical margins, Breda et al. (4) identified a 2.4% overall rate in 855 U.S. and European LPN procedures. However, surgeons in their initial 30 cases of LPN or HALPN may have positive margin rates  $\geq 10\%$  (23). Fortunately, a large combined review from centers of excellence demonstrated that a positive margin does not necessarily indicate residual disease (25). Nevertheless, efforts to prevent positive margins during LPN should continue.

Warm ischemia >30 minutes has historically been considered detrimental to renal recovery. Recent studies have found that up to 60 minutes may be well tolerated by the human

kidney, and a review of LPN patients at Johns Hopkins observed no significant relationship between warm ischemia and creatinine change and no statistically significant increase in serum creatinine postoperatively (2). There is, however, contradictory evidence that the renal damage caused by warm ischemia >30 minutes is only partially reversible. A Cleveland Clinic study observed increased risk of renal dysfunction with warm ischemic times >30 minutes, advanced age, or pre-existing azotemia (9). Porcine studies have found that clamping the renal artery was beneficial in protecting the kidney only during OPN but not during LPN. Importantly, efforts to identify a practical method of creating laparoscopic renal hypothermia have been numerous, yet none have become widely utilized. “On demand” hilar clamping has been recently proposed, and efforts to address this problem will undoubtedly continue.

Given the complexity of standard LPN, surgeons have developed innovative approaches, such as the use of suspension traction sutures, to facilitate tumor exposure, dissection angles,

and defect closure (24). As expected, several groups have investigated the potential of da Vinci robot-assisted LPN. Surgeons from the National Institutes of Health successfully treated 14 complex tumors including hilar location (5), endophytic (4) and multiple tumors (3) with robotic LPN (29). It is possible that the da Vinci robot will, like robotic prostatectomy, decrease the learning curve, allow for more facile suturing and tumor excision, and greatly increase the propagation of this procedure into the urologic community.

In conclusion, LN is the current standard of care in many industrialized countries. LPN outcomes now closely approach those of OPN at elite centers. However, even at these centers, OPN remains the gold standard due to shorter ischemic times, slightly better retained renal function (99.6% versus 97.9% at 3 months), reduced postoperative complications, and decreased subsequent procedures (11). The eventual fate of LPN hinges upon how well future technologic and procedural modifications address these concerns and how well renal tumor ablative procedures perform over the long term.

# CHAPTER 125 ■ LAPAROSCOPIC NEPHROURETERECTOMY

SCOTT G. HUBOSKY AND MICHAEL D. FABRIZIO

Malignant urothelial tumors of the upper urinary tract account for about 5% to 10% of all renal tumors and 5% of all urothelial tumors. These lesions are relatively rare and have an observed peak incidence of 10 per 100,000 per year (1). The most common location of these lesions is the renal pelvis, followed by the distal ureter, the midureter, and finally the proximal ureter. Tumors of the renal pelvis are almost twice as common as tumors in the ureter. Bilateral involvement of malignant urothelial tumors of the upper urinary tracts occur in 2% to 5% of spontaneous cases. Upper tract lesions are seen in 2% to 4% of patients with primary urothelial carcinoma of the bladder.

---

## DIAGNOSIS

---

Hematuria and dysuria are the most common symptoms. Often flank pain is present in those with upper tract obstruction, but sometimes asymptomatic hydronephrosis is seen. Patients presenting with ureteral stricture in the absence of overt benign etiologies should be seriously considered for ureteroscopy and biopsy. However, a filling defect is the usual initial finding on a dedicated upper tract imaging study. Rarely, patients will present with urosepsis and hydronephrosis necessitating percutaneous nephrostomy tube placement. An antegrade nephrostogram can also demonstrate filling defects consistent with upper tract tumors (Fig. 125.1). Biopsy

**FIGURE 125.1** Antegrade nephrostogram demonstrating a filling defect in the renal pelvis. This patient presented with urosepsis and hydronephrosis.

is suggested since filling defects are nonspecific findings and because tumor grade will dictate the management strategy.

---

## INDICATIONS FOR SURGERY

---

Many variables, including tumor size, location, and grade and extent of disease, need to be considered before choosing a surgical therapy. Additionally, the functional status of the renal unit in question as well as the presence or absence of a contralateral kidney will help guide management decisions. Kidneys with cortical thinning and marginal functional status are likely better treated with nephroureterectomy. Patients with solitary renal units may choose conservative renal-sparing strategies and accept lower cancer-free rates in order to avoid the morbidity associated with dialysis following nephroureterectomy (2). Absolute contraindications for laparoscopic nephroureterectomy include uncorrected coagulopathies, active untreated abdominal wall infection, or significant hemoperitoneum. Relative contraindications include a history of multiple abdominal surgeries or locally advanced disease, both of which may require conversion to open surgery.

---

## ALTERNATIVE THERAPY

---

Radical nephroureterectomy is considered the gold-standard therapy for malignant lesions of the upper urinary tracts. This entails removal of the kidney within the fascia of Gerota along with the entire length of ipsilateral ureter, including en bloc resection of the intramural ureter and ureteral orifice with surrounding bladder cuff. More conservative alternatives exist and were initially reserved for patients in whom nephroureterectomy would be contraindicated, such as patients with solitary kidneys, renal insufficiency, or significant comorbidities. Endoscopic procedures such as ureteroscopy and percutaneous nephroscopy can be considered for those patients with low-grade, low-stage malignancies who are willing to undergo rigorous surveillance schedules. With high 5-year survival rates in patients with low-grade tumors, the utilization of ureteroscopy (3) and percutaneous nephroscopy (4) has been extended to patients with low-grade, low-stage disease with a normal contralateral kidney. Radical nephroureterectomy remains the mainstay of treatment for high-grade disease. Many advocate this approach even in patients with solitary kidneys, although others accept percutaneous or ureteroscopic procedures and cite the benefit of avoiding dialysis morbidity against lower

disease-specific survival rates. Urologists who treat upper tract urothelial lesions were surveyed about how they treat high-grade lesions in a solitary kidney. Among those responding, 34% favored a nephroureterectomy with the subsequent need for dialysis, while 30% and 27% chose to treat the patient with ureteroscopy or percutaneous resection, respectively (5). Although not curative, endoscopic options are attractive in order to minimize gross hematuria and obstruction in these patients in an effort to improve quality of life. Clayman et al. (6) reported the first laparoscopic nephroureterectomy (LNU) in 1991. In stark contrast to open nephroureterectomy (ONU), which requires either two separate incisions or a single lengthy incision, early series of both LNU and hand-assisted laparoscopic nephroureterectomy (HALNU) very quickly showed a benefit with respect to length of hospital stay, narcotic requirement, and convalescence (6–8). Short- and intermediate-term oncologic outcomes for LNU and HALNU have shown equivalence to ONU, and recently long-term oncologic outcomes with median follow-up of 74 months (range 60 to 148 months) have shown a 5-year disease-specific survival of 68%, comparing well with many ONU series (9). An admitted limitation of this retrospective case series was a small patient population ( $n = 39$ ), and other large series must be reported before definitive equivalence is determined.

## SURGICAL TECHNIQUE

Just as in ONU, it is useful to consider separate approaches for the kidney and the distal ureter in LNU. There are multiple acceptable laparoscopic approaches to the kidney that have been described, including transperitoneal, retroperitoneal, and hand-assisted techniques. The choice of technique for renal excision is based primarily on the surgeon's preference and training. All three approaches have the important advantage of avoiding a flank incision or an upward extension of a midline incision. HALNU can be used primarily or as an alternative to standard laparoscopic technique if advanced or bulky disease is present.

Multiple options exist for excision of the distal ureter, and currently no consensus has been established as to the optimal method (Table 125.1). Despite the diverse list of options for

TABLE 125.1

### DESCRIBED TECHNIQUES FOR DISTAL URETERAL EXCISION TO ACCOMPANY LAPAROSCOPIC NEPHROURETERECTOMY

- Open approach (intravesical or extravesical approach)
- Pure laparoscopic approach with stapling of distal ureter and bladder cuff (8)
- Transvesical laparoscopic detachment and ligation technique (17)
- Transurethral resection of ureteral orifice (TURUO)
- Intussusception
- Extravesical en bloc distal ureterectomy with bladder cuff during hand-assisted laparoscopic nephroureterectomy (28)
- One-port transvesical endoscopic cuff technique (26)
- Robot-assisted laparoscopic nephroureterectomy (29)

TABLE 125.2

### CONSIDERATIONS IN SELECTING A METHOD FOR DISTAL URETERECTOMY

- Opportunity for complete excision of distal ureter and bladder cuff
- Location of primary tumor and any other synchronous upper tract lesions
- Presence of any synchronous bladder tumors
- Presence of pelvic lymphadenopathy
- History of pelvic radiation
- Body habitus
- Safety of the contralateral ureteral orifice
- Need for patient repositioning

techniques available, one clear principle shared by all authors is the absolute need to completely resect the entire ipsilateral ureter with a cuff of bladder. Earlier studies demonstrated upwards of 30% recurrence rates when remnants of ureter are left behind after incomplete nephroureterectomy for upper tract urothelial carcinoma (10).

In addition, other factors must be considered in choosing a technique for the distal ureter (Table 125.2). The presence of synchronous bladder tumors mandates maintenance of a closed system and precludes transvesical placement of instruments or formal cystotomy to expose the trigone. Ideally, transurethral resection of bladder tumor (TURBT) should be performed at a separate setting in order to clear the bladder of any overt tumors. Knowledge of the primary tumor location in the upper urinary tract is also critical for surgical planning. The presence of tumor in the distal or intramural ureter typically leads to an open distal ureterectomy with either an intravesical or extravesical approach. The need for repositioning and safety of the contralateral ureteral orifice must also be considered.

## Transperitoneal Laparoscopic Radical Nephroureterectomy

The authors prefer a transperitoneal conventional laparoscopic approach, which allows for a larger working space, while the retroperitoneal approach usually allows for faster access to the hilum.

Preoperative evaluation should include a computerized tomography (CT) urogram to define the location of the upper tract lesion, to evaluate for any existing lymphadenopathy or overt local disease extension, and to define the anatomy of the renal vasculature. It is our preference to have biopsy information about the lesion in question, which also allows an opportunity to evaluate and treat any synchronous bladder tumors. Additional preoperative workup includes chest radiography, serum electrolytes, complete blood count, liver function tests, and coagulation studies. No formal bowel preparation is instituted, but magnesium citrate solution is given the day before surgery and the patient is asked to stay on a diet of clear liquids that day as well.

After the adequate administration of general anesthesia, an orogastric tube and Foley catheter are placed. This helps

to minimize any inadvertent trocar injuries to distended viscera. Spontaneous compression boot devices and intravenous antibiotics are given prior to induction. The patient is placed in a modified decubitus position with the operative side up and propped 30 to 45 degrees from the horizontal plane. A blanket roll is placed under the shoulders and hips in order to help support this position. An axillary roll is also placed at this time. The top of the patient's iliac crest should align with the top of the kidney rest on the operating room table. The table is then flexed about 20 to 30 degrees in order to help maximize the space between the costal margin and the anterior superior iliac spine. The ipsilateral arm is brought across the torso and supported either with pillows or preferably an elevated arm rest. The contralateral arm is placed on the usual arm board perpendicular to the operating table. Pillows are placed between the legs. The downside leg is flexed at the knee and all pressure points must be adequately padded. The patient is then carefully secured to the table with 3-inch tape at the level of the shoulders, hips, and legs just above the knees. This position is then checked for stability.

Access to the peritoneal cavity is achieved with a Veress needle placed in the area of the ipsilateral midclavicular line between the umbilicus and the anterior iliac crest. Alternatively, the Veress needle can be placed just superior to the umbilicus and pointed in the cephalad direction. Gentle injection of saline and failure to aspirate any abdominal contents through the needle help ensure that no bowel or vascular structures have been entered. Carbon dioxide insufflation is commenced and opening pressures should be <10 mm Hg until the abdomen is symmetrically distended. Insufflation is maintained at a pressure of 15 to 20 mm Hg for the case.

Typically a three-port technique is employed, with the occasional additional 5-mm port added as necessary to help with retraction (Fig. 125.2). After pneumoperitoneum is achieved, a 1-cm incision is made in the midclavicular line at the level of the umbilicus. A 10- to 12-mm port is inserted with the use of a zero-degree 10-mm laparoscopic lens. This allows for direct visualization of the initial port placement and the peritoneal cavity is easily identified upon entry. The abdominal contents are surveyed. The second 10- to 12-mm port is placed at the umbilicus using a periumbilical incision. Finally, the third port is placed between the umbilicus and the xiphoid process. For right-sided cases an additional 5-mm port is added just off the tip of the 12th rib to allow for upward retraction of the liver. If colonic retraction is necessary, an additional 5-mm port can be placed in the midline between the umbilicus and the pubic symphysis.

## Left Laparoscopic Radical Nephroureterectomy

The 10- to 12-mm umbilical port is used to place a 10-mm, 30-degree laparoscope, and the surgeon works with instruments through the lateral and subxiphoid ports. Many electro-surgical ligation devices are available, but we prefer to use monopolar electro-surgical scissors and a 10-mm LigaSure device. Alternatively, the harmonic scalpel is also useful. Laparoscopic bipolar forceps are very useful in controlling small points of bleeding, especially around the hilum.

Initial survey of the abdominal contents will allow identification of vital structures, including the colon, spleen, and iliac vessels. The kidney, although not directly visible, is easily palpable with the laparoscopic instruments. Laparoscopic DeBakey instruments are very useful in providing counter-traction and help in identification of the white line of Toldt. A combination of sharp and blunt dissection is utilized to reflect the colon from the splenic flexure down to the level of the internal ring. This includes division of the phrenocolic and splenorenal ligaments. Division of splenophrenic ligaments allows for upward retraction of the spleen and better exposure to the anterior surface of the kidney. Once the colon is mobilized, the colorenal ligaments are easily identified. The colonic mesentery must be dissected free from the anterior surface of the fascia of Gerota. A subtle color difference in the fat of these two structures is appreciable and helps direct the surgeon to the correct plane of dissection. Mesenteric fat is a lemon-yellow shade, while the fat around the fascia of Gerota is more of a pale-white color. Division of the colorenal ligaments must be achieved in order to expose the renal hilum. Dissection of these ligaments usually proceeds from inferiorly to superiorly.

Next the psoas muscle is identified off the lower pole of the kidney, and the psoas tendon is usually easily recognized. Within the confines of retroperitoneal fat the gonadal vein and ureter should be identified. The ureter is now secured, with care to leave surrounding adventitia for adequate achievement of a good surgical margin. At this point in the dissection, the ureter can be traced as inferiorly as possible, which will facilitate later complete distal ureterectomy with bladder cuff excision. After this is achieved, attention can be returned to the renal dissection.

Careful elevation of the ureter allows for upward retraction of the undersurface of the kidney, lower pole, and hilar structures. Tracing the gonadal vein superiorly helps identify the inferior aspect of the renal vein. Just as in open surgery, a

**FIGURE 125.2** Port placement for laparoscopic nephroureterectomy. The camera is placed in the umbilical port and the surgeon works through the other two ports, making use of triangulation to optimize visualization and ergonomics. To better access the distal ureter, an additional port can be placed in the midline between the umbilicus and pubic symphysis.

split-and-roll technique is employed by gently grasping the surrounding adventitia, pulling away from the vein and carefully splitting the adventitia with laparoscopic scissors in order to expose the anterior surface of the vein. Once the anterior surface is exposed, hilar fat around the vein must be carefully dissected out. This is achieved by gently grasping surrounding adventitia and hilar fat with a laparoscopic DeBakey grasper, which provides excellent countertraction and allows one to sweep the edge of the vein free with a blunt suction-irrigator device. Ultimately, all tributaries of the left renal vein can be carefully dissected out this way, including the gonadal, lumbar, and adrenal veins. The laparoscopic DeBakey should be able to be easily placed behind any vein prior to its division. The 10-mm LigaSure device provides for safe division of the gonadal, adrenal, and lumbar veins without the use of clips. This allows for easier future placement of the Endo-GIA vascular stapling device across the main renal vein without having to consider the avoidance of surrounding clips. Some surgeons feel the 10-mm LigaSure device is too large or cumbersome to secure some of the left renal vein tributaries, and this is sometimes the case, especially with the lumbar vein. In this event, the tributaries can be taken with clips, as described by many authors. Of the tributaries of the left renal vein, the gonadal is usually encountered and taken first, followed by the lumbar vein. If adrenalectomy is planned, then the adrenal vein should be taken as well.

Once the renal vein is mobilized and its tributaries are divided as needed, the renal artery is usually identified just posterior and superior to the vein. Gentle upward traction of the kidney allows for identification of the renal artery from a posterior position. A combination of sharp and blunt dissection is used to free the edges of the artery, and ultimately this structure is taken with a 10-mm endoscopic GIA stapler with 2.5-mm or 2.0-mm staples. The vein is taken in a similar fashion.

After hilar division, the kidney can be retracted superiorly and any remaining posterior or lateral attachments are divided. If the adrenal gland is being taken, then superior medial attachments are carefully taken down with either an endo-GIA stapler or the LigaSure device. Care must be taken to avoid the tail of the pancreas. The kidney should be freed from all attachments at this point and should still remain with the ureter intact and attached.

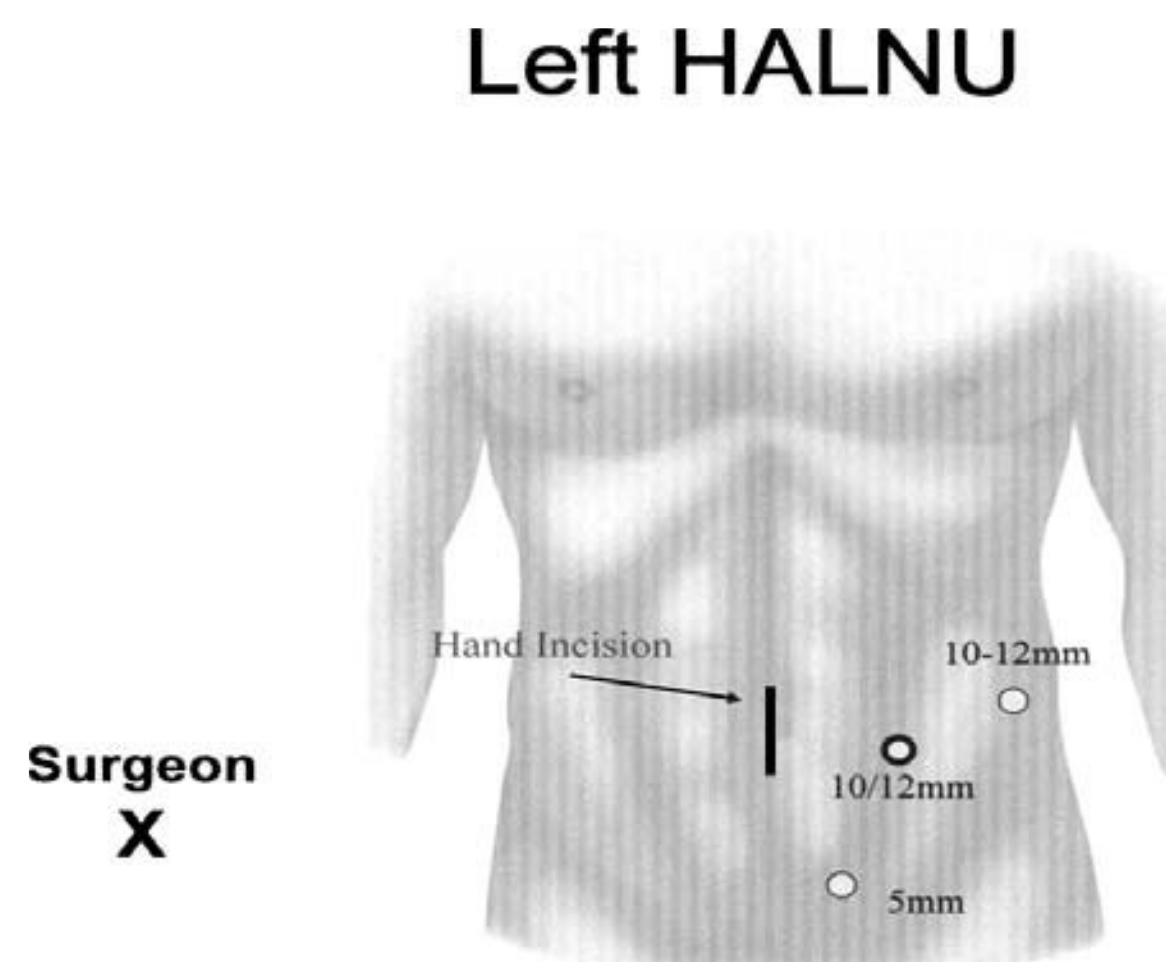

### Right Laparoscopic Radical Nephroureterectomy

Laparoscopic port placement is essentially a mirror image of the right side. An additional 5-mm port is almost always needed to help with retraction of the liver. This additional port is well placed just off the tip of the 12th rib. Care must be taken not to place this additional port too close to the iliac crest, as this will limit the ability to point the trocar in the necessary cephalad direction. Once the liver is retracted anteriorly, the upper pole of the right kidney is easily seen and the ascending colon is easily swept medially after taking down the white line of Toldt. Great care must be taken to identify and avoid the duodenum, which is readily seen after the colon is mobilized. We strongly advocate performance of a laparoscopic Kocher maneuver with cold laparoscopic scissors. A laparoscopic DeBakey grasper is very helpful in providing countertraction for the overlying adventitia anterior to the

duodenum. The duodenum is easily swept medially once the overlying adventitia is carefully incised. The inferior vena cava is readily identified once the duodenum is dissected free. With upward traction of the posterior portion of the kidney, the renal vein is identified and dissection is similar to that for the left side.

### Hand-Assisted Laparoscopic Nephroureterectomy

Hand-assisted laparoscopy greatly facilitates LNU due to the versatility of the approach in addressing the distal ureter and the fact that the hand speeds ureteral mobilization, especially in cases of inflamed or adherent ureters. Many HALNU series have been reported in the literature and demonstrate good oncologic control and safety parameters (7,11–13). The hand port not only allows for the nephrectomy portion of the case but is also used in performing complete ureteral dissection with excision of bladder cuff. The port placement for left HALNU is shown in Figure 125.3. In a left-sided case, the surgeon inserts the left hand with use of any of the available hand ports. This is done through a 7-cm midline incision that starts at the umbilicus and extends downward. This is slightly lower than the midline incision used for hand-assisted laparoscopic nephrectomy (HALN). A 10- to 12-mm port is placed just lateral to the rectus muscle at the level of the hand port, and this supports the laparoscope. A second 10- to 12-mm port is placed about two fingerbreadths anterior to the tip of the 12th rib. In a left HALNU, the surgeon uses the right hand to operate the laparoscopic instruments. After the nephrectomy portion of the case, the opposite hand is placed in the hand port position and attention is turned toward the distal ureter. The left hand is then used to operate laparoscopic instruments as the ureter is dissected down to the bladder hiatus. An additional 5-mm port can be placed in the midline below the hand port to aid in medial retraction of the bladder. The intracorporeal hand allows for multidirectional ureteral traction until the ureter is followed all the way down to the bladder. Under direct vision the bladder is entered superiorly and medially to the ureteral orifice. The Foley

**FIGURE 125.3** Port and hand-assist device placement for left hand-assisted laparoscopic nephroureterectomy.

catheter balloon should be readily visible, as should be the contralateral ureteral orifice. The cystotomy can be left open or sutured closed. The entire specimen is then removed in an entrapment sack through the midline hand incision. In addition to this method, the midline hand incision can be extended down to the pubic symphysis if the surgeon prefers an open approach to distal ureterectomy. This results in a midline incision from the umbilicus to the pubic symphysis, which may be considered large by many laparoscopic surgeons but is still well tolerated and much less invasive than two separate incisions or a midline incision spanning the distance from xiphoid to pubic symphysis.

## Surgical Approaches to the Distal Ureter

There is no clear consensus for the ideal minimally invasive approach to the distal ureter during LNU or HALNU. No prospective randomized trials exist comparing the various techniques, and the number of cases is relatively small, making level 1 evidence unavailable. Numerous retrospective surgical series have been published and many make use of different techniques as the specific patient situation dictates. Perhaps the consensus should be that no single technique is ideal in every situation.

In choosing a technique, the location of the primary tumor and any other synchronous tumors must be known. While many distal ureteral techniques will be successful for tumors in the renal pelvis or proximal ureter, they may be completely inappropriate for tumors located primarily in the distal ureter (Fig. 125.4). The following descriptions are of the most popular techniques found in the current literature.

### Open Approach

An open approach to the distal ureter is still considered the gold standard from an oncologic viewpoint. It is probably the most appropriate technique when the primary lesion is in

**FIGURE 125.4** Computerized tomography scan demonstrating a distal ureteral tumor in the left intramural ureter, thus confirming the importance of acknowledging tumor location.

the distal ureter. The approach is versatile and can be combined with a conventional laparoscopic renal excision, whether performed via the transperitoneal or retroperitoneal route. It can also be performed in concert with HALNU. The presence of an open incision is acceptable by most who perform LNU or HALNU due to the preference for intact specimen removal, which is essential in determining the need for adjuvant chemotherapy in higher-stage disease.

During LNU or HALNU the ureter should be dissected as inferiorly as possible, which is usually at least to the level of the iliac vessels. If HALNU is being performed, then the midline hand incision should be extended to the pubic symphysis. If conventional LNU is performed, then a variety of options are available, including a lower midline incision, a Pfannenstiel incision, or a Gibson incision. If there is difficulty with ureteral dissection laparoscopically, then a Gibson incision may be used, which can be extended to reach the upper mid- to proximal ureter if needed. If a partial flank position is employed for the LNU, the lower abdominal incision can be fashioned by merely rotating the table, thus avoiding the need for patient repositioning.

Access to both the peritoneal cavity and retroperitoneum is possible through the three incisions mentioned above and is utilized depending on the approach to the kidney. Once the ureter is identified, it should be clipped distal to the primary tumor to minimize downward migration of any tumor cells. As the ureter is followed into the pelvis, the vas deferens or round ligament will be encountered and should be taken. It is possible to spare the vas deferens in young men, although this can compromise exposure. Classic open descriptions of distal ureterectomy direct the surgeon to isolate and divide the superior vesicle artery as it crosses the ureter (14). The medial umbilical ligament should also be identified and divided to maximize exposure to the distal ureter as it enters the detrusor.

In order to resect the bladder cuff and ureteral orifice, an intravesical or extravesical approach can be employed. If the intravesical route is chosen, an anterior cystotomy is performed with the bladder full. The trigone and ureteral orifice are readily visualized. A 5Fr feeding tube can be inserted into the affected ureteral orifice and stitched to the surrounding bladder urothelium. This allows for upward and radial retraction of the intraluminal ureter as the urothelium is scored with needle-tip electrocautery. The intramural ureter is identified and resected out of the surrounding detrusor muscle until perivesical adipose tissue is seen. The kidney, ureter, and bladder cuff are then completely removed en bloc through the skin incision after being placed in an entrapment sack. The resected ureteral orifice can be closed through the bladder in layers with absorbable suture. Finally, the anterior cystotomy is closed in layers, also with absorbable suture. A Jackson-Pratt drain is placed in the perivesical space. No suprapubic tube is necessary, and a Foley catheter is kept in place for 4 days and then removed after a cystogram is performed. The main advantage of an intravesical approach is complete visualization of both the affected and contralateral ureteral orifices. This lends to complete resection of the intramural ureter with bladder cuff and safe preservation of the contralateral orifice. A closed system is not maintained, however, and a cystoscopy should be done prior to nephroureterectomy to ensure no synchronous bladder tumors are present.

An extravesical approach can also be used in which the distal ureter is dissected free of detrusor down to the

ureterovesical junction. With upward traction on the ureter, the ureteral orifice is stretched away from the urothelium of the bladder and a right angle is clamped down. The ureteral orifice is then transected and the posterior bladder oversewn. The advantage of this technique is maintenance of a closed system and avoidance of anterior cystotomy. The disadvantages are potentially difficult exposure, predisposing to incomplete resection of the affected intramural ureter, and no direct visualization of the contralateral ureter, which may be inadvertently resected or sewn over. The administration of indigo carmine to the patient intravenously after sewing over the posterior cystotomy can give reassurance of the status of the contralateral ureteral orifice if blue urine is seen in the Foley collection bag.

#### Pure Laparoscopic Approach with Stapling of Distal Ureter and Bladder Cuff

This technique involves conventional laparoscopic nephrectomy with extended dissection of the ureter deep within the pelvis. An additional lower midline abdominal port is required to complement those traditionally placed in a triangular fashion for nephrectomy (15). The umbilical port always supports the camera. During kidney and proximal ureteral dissection, the upper midline and lateral ports are used. The lower midline and lateral ports are utilized during mid- and distal ureteral mobilization. Dissection is performed until the entire intramural ureter is made extravascular. Ultimately, a GIA endovascular stapler with an articulating head is used to come across the ureterovesical junction while the ureter is placed on upward tension (Fig. 125.5). This separates the distal ureter from the bladder and simultaneously closes the bladder. Morcellation has been performed in cases with proximal lesions or low-grade disease. Alternatively, the specimen can be placed in an entrapment sack and removed through a small incision.

Cystoscopic unroofing was initially described with this technique using a flexible cystoscope and Bugbee electrocautery (8). The Bugbee was used to score around the ureteral orifice and a portion of the intramural ureter. Some accounts of this technique involve using a 5-cm-long ureteral dilating balloon placed in the intramural ureter. Cautery then incises the intramural ureter over the balloon in the 12 o'clock position up to but not through the ureterovesical junction. After extensive distal ureteral dissection, the ureter is retracted upward, putting the intramural ureter and orifice on stretch. A laparoscopic endo-GIA stapler is fired across the detrusor, incorporating the intramural ureter and orifice with the specimen. Simultaneous flexible cystoscopy can be performed to ensure safety of the contralateral ureteral orifice. According to the authors, after an extravascular recurrence, they modified the technique to perform unroofing of the ureteral orifice after nephrectomy and staple ligation of the distal ureter. More often than not, an orifice is seen cystoscopically and unroofed until a staple line is seen, which is then coagulated with a rollerball electrode. Using a porcine model, the authors verify that viable cells are definitely found within the staple line of the bladder. They also report no recurrences of urothelial carcinoma within their series, which has up to 13 years follow-up. Furthermore, no stone formation has been noted after a mean of 27 months of follow-up on the titanium staples, which remain in contact with urine. The authors concede that if urothelial carcinoma is known to be present in the distal ureter, then an alternative strategy such as open distal ureterectomy is warranted (16).

**FIGURE 125.5** Pure laparoscopic nephroureterectomy with distal ureter and bladder cuff taken with stapling technique. Articulating heads on the stapler and upward traction on the ureter allow for optimal placement.

#### Transvesical Laparoscopic Detachment and Ligation Technique

This technique was developed at the Cleveland Clinic in 1999 and requires formal cystoscopy in the dorsal lithotomy position prior to LNU. With a full bladder and a rigid cystoscope viewing the inside of the bladder, two 5-mm balloon-tipped laparoscopic ports are placed suprapubically into the bladder from above (17,18). A 2-mm endoloop is inserted through one of the suprapubically placed trocars from above. Through the cystoscope, a 5-mm ureteral catheter is placed through the endoloop and into the affected ureteral orifice. A grasper is placed through the second suprapubic port to provide traction on the ureteral orifice while a Collins knife is used to score the affected orifice and intramural ureter. When perivesical adipose tissue is exposed, the ureteral catheter is removed just after the endoloop is secured around the dissected intramural ureter. No formal closure of the bladder is performed, and the Foley catheter is left for 2 weeks.

Possible advantages include intact en bloc excision of the intramural ureter under direct vision and observation of the endoloop tie. Disadvantages include the need for repositioning,

fluid extravasation with suprapubically placed laparoscopic ports, and a significant learning curve. The authors of this technique admit it should not be used when there is distal or intramural ureteral tumor or active bladder tumors. Additionally, they advise caution in morbidly obese patients and those with a history of pelvic radiation.

#### Transurethral Resection of Ureteral Orifice (TURUO) (Pluck Technique)

This technique involves aggressive transurethral resection around the ureteral orifice until adipose tissue is seen. This is done prior to LNU, at which point the distal ureter is then plucked out of the bladder using upward traction on the ureter. Every attempt is made to clip the ureter as soon as possible to avoid urine draining down the ureter and into the retroperitoneum. The bladder is typically not closed. This procedure has fallen out of practice by most due to the concern of leaving a portion of intramural ureter after the pluck maneuver. Also, tumor seeding of the retroperitoneum has been reported after this maneuver (19). TURUO should also not be performed in the setting of distal, intramural, or perimeatal lesions and is best avoided in patients with active bladder lesions.

## OUTCOMES

In the 1990s various urologic procedures for cancer treatment were adapted to a laparoscopic form in the endeavor to provide equivalent cancer control with less morbidity via smaller incisions. This has definitely been the case with LNU. Early case series reported on the feasibility of the procedure and reported mostly perioperative data and short-term oncologic results. As multiple laparoscopic series have matured we now have intermediate and some long-term data with respect to cancer outcomes (Table 125.3). The series with the longest follow-up for LNU has a median follow-up of 100 months, with a range of 60 to 148 months (20). In this series 26 patients were followed and the distal ureter was addressed either with TURUO or with an open approach if distal ureteral tumors were present. The authors report 72% cancer-specific

survival at 7 years, which they compared to a contemporary open series showing 82% cancer-specific survival at 7 years. There was no statistical difference in survival between the two groups. A larger series has also been recently reported in which 39 patients were followed for a median of 74 months (range 60 to 148 months), and 68% cancer-specific survival was noted at 5 years (9). Of note, 80% of these patients had high-grade disease preoperatively. These series show equivalent cancer control with respectable follow-up and compare well to ONU series in the literature (21,22).

Complications are seen in LNU and HALNU that are common to other laparoscopic renal procedures. A recent meta-analysis of reported complications during various laparoscopic renal procedures identified 56 published series each containing at least 20 patients (23). Among these renal procedures were LNU and HALNU. Access-related complications occurred in <0.5%. Intraoperative complications included hemorrhage in 1.4%. Bowel injury, solid organ injury, diaphragmatic injury, and neuromuscular injury were all seen in <0.5% of cases. Postoperative complications included ileus in 1.5%, deep vein thrombosis in 0.7%, and bowel obstruction and incisional hernia in <0.5%. Among the various laparoscopic renal procedures reviewed, LNU ranked highest in both frequency for neural injuries from positioning and for postoperative complications. This is not entirely surprising, given that LNU can be a relative lengthy procedure and is usually performed in elderly patients with multiple comorbidities.

An obviously distressing complication of LNU is that of laparoscopic port site seeding. Fortunately this is a rare occurrence, and there are seven reported cases, which represent an approximately 1.6% incidence (24). The majority of these cases have been high-grade disease in which the specimen was extracted without an entrapment sack or the sack was ruptured during specimen removal. In one case, a ureteral stent placed previously during ureteroscopic biopsy was seen extruding from the renal pelvis during subsequent LNU (25). The authors cautioned against overly aggressive ureteroscopic biopsy, although no evidence of retroperitoneal recurrence was seen.

TABLE 125.3

### ONCOLOGIC RESULTS OF CONTEMPORARY LAPAROSCOPIC AND OPEN NEPHROURETERECTOMY SERIES

Series	<i>n</i>	Method	Distal Ureter	Cancer-Specific Survival	Median Follow-up (mo)	Local Recurrence Rate
Muntener 2007 (9)	39	LNU	Stapling, open	68%	74	5%
Bariol 2004 (20)	26	LNU	Open, TURUO	72%	100	4%
Matin 2005 (27)	60	LNU	TDL, stapling, open	85%	23	7%
Chung 2007 (7)	39	HALNU	Open	89%	48	3%
Wolf 2005 (13)	54	HALNU	TURUO, TEC	94%	12	8%
				86%	24	
				80%	36	
Bariol 2004 (20)	40	ONU		82%	96

## CHAPTER 126 ■ LAPAROSCOPIC RENAL PROCEDURES: RENAL CYSTECTOMY, BIOPSY, AND NEPHROPEXY

CHAD A. LAGRANGE AND STEPHEN E. STRUP

Laparoscopic surgery has become the standard of care for many renal procedures. The benefits of laparoscopic renal surgery, including less postoperative pain, shorter hospitalization, and quicker recovery, have led surgeons to apply this technique to many different types of renal procedures. Renal pathology such as renal cyst disease and nephroptosis, which were historically performed using an open approach, can be effectively treated in a laparoscopic fashion. In addition, procedures traditionally performed percutaneously, such as renal biopsy, can be performed laparoscopically, which may offer

the advantages of increased effectiveness and decreased risk in certain high-risk patients.

### LAPAROSCOPIC RENAL CYSTECTOMY

Simple cysts are the most common lesions of the kidney. It is estimated that 50% of the adult population have renal cysts. The incidence of cysts increases with age; simple renal cysts

occur with an incidence of at least 20% by age 40 years and 33% by age 60 years (1).

## Diagnosis

The diagnosis of renal cysts was traditionally made during intravenous urography with tomography. Today, ultrasound (US) and computerized tomography (CT) are the principal diagnostic tools, and most cysts are incidental findings. Occasionally, a patient with a very large simple cyst may present with vague abdominal or flank discomfort and fullness on physical examination. However, most patients are asymptomatic.

The sonographic criteria for simple cysts are absence of internal echoes, increased through-transmission of sound, and a sharply defined simple wall. On CT, simple cysts are sharply marginated, nonenhancing, and clearly demarcated from surrounding renal parenchyma with no calcifications. The attenuation values should be in the range of water ( $-10$  to  $+20$  Hounsfield units). On magnetic resonance imaging (MRI), simple cysts appear as round, homogenous, and low intensity (dark) on T1-weighted images and increased intensity (bright) on T2-weighted images.

## Indications for Surgery

Occasionally, patients who present with flank pain are discovered to have no other etiology on radiographic evaluation for their complaint either than a large simple cyst, and they may be candidates for therapy. Large parenchymal cysts or peripelvic/parapelvic cysts can also cause obstruction leading to pain. Depending on the symptoms, size, site, location, presence of infection, and suspicion of malignancy, the following renal cystic disorders can be managed laparoscopically:

1. Renal cystic masses (i.e., Bosniak type IV, cystic renal cell carcinoma): laparoscopic nephrectomy or partial nephrectomy
2. Indeterminate cystic masses (i.e., Bosniak type II or III): laparoscopic exploration and management
3. Bosniak type I and II renal cysts, large ( $>10$  cm) and symptomatic: laparoscopic cystectomy, decortication, or marsupialization
4. Renal hydatid cysts: same as above
5. Peripelvic or parapelvic cysts: same as above
6. Autosomal dominant polycystic kidney disease (ADPKD): cyst decortication

## Alternative Therapy

Aspiration and injection of sclerosing agents is a safe and effective solution. This is usually the initial course of management for symptomatic renal cysts. Aspiration of cysts may also prove to be a diagnostic maneuver to examine the effect on the patient's symptoms, and if the cyst and pain recur then the relationship between the two is solidified. Reported success rates of cyst aspiration and sclerosis range from 75% to 97%, with complication rates between 1.3% and 20% (2,3).

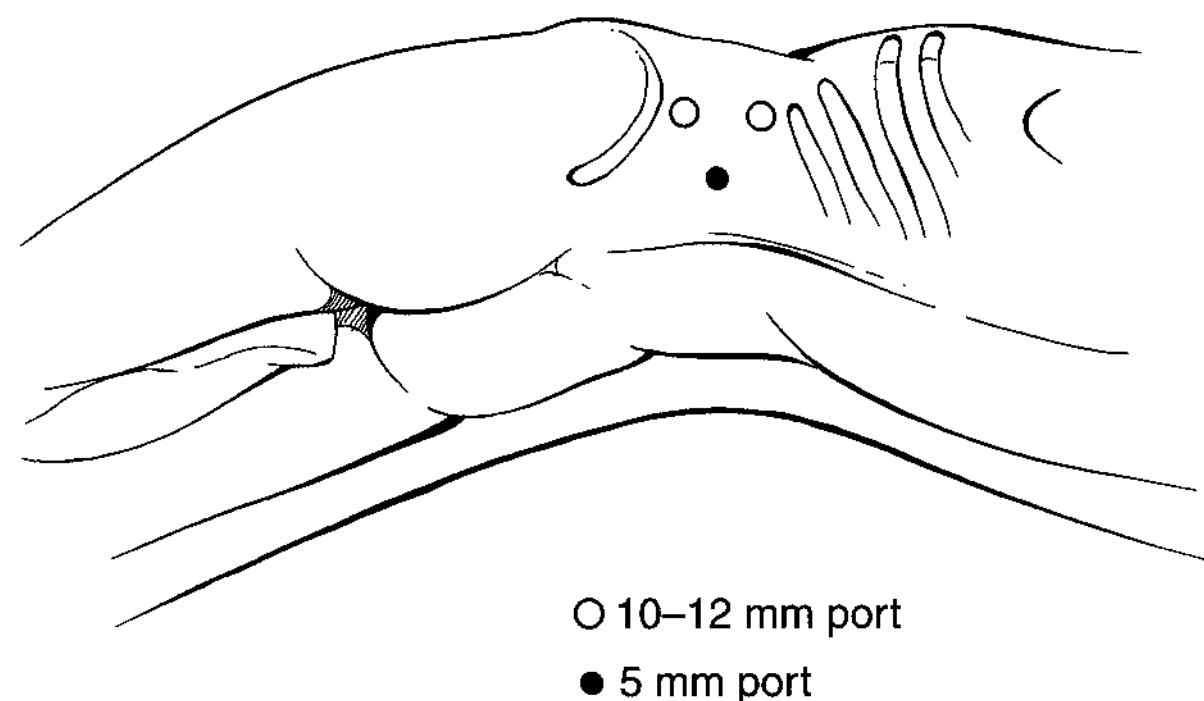

Another alternative is open surgical marsupialization, which can be performed when more conservative approaches fail or laparoscopic surgery is contraindicated.

## Surgical Technique

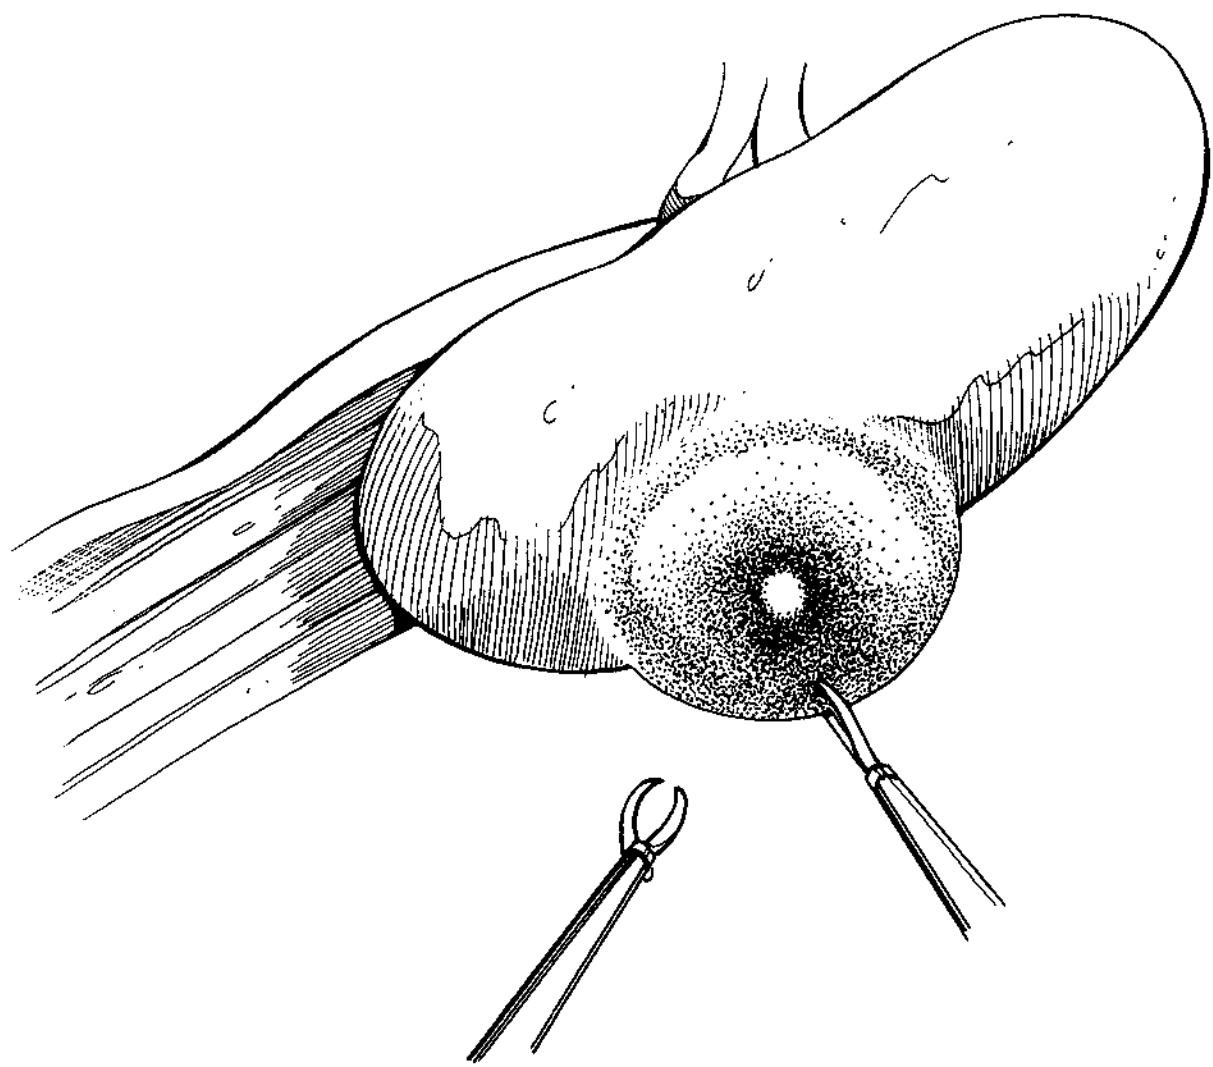

### Retroperitoneal Approach

Standard positioning and preparation are carried out with the patient in the flank position. Port placement is depicted in Figure 126.1. A 1.5-cm incision is made at the tip of the 12th rib and dissection is carried down to the lumbodorsal fascia, which is then pierced with a tonsil clamp to enter the retroperitoneal space. Finger dissection is then performed along the psoas muscle to mobilize the posterolateral aspect of the kidney. A 10- to 12-mm visual balloon dissector trocar is then placed and the space is dilated. The dilating balloon is then removed and a blunt-tip balloon trocar is placed. Pneumoretroperitoneum is established to 15 mm Hg and a 5-mm trocar is placed in the posterior axillary line below the 12th rib. A third trocar is inserted approximately two finger-breadths above the iliac crest in the anterior axillary line. Laparoscopic ultrasound may be used in cases where cysts are difficult to locate. An additional instrument for dissection and countertraction of large cysts can be placed via a 5-mm trocar midway between the iliac crest and the 12th rib in the posterior axillary line.

Once the cyst is exposed from beneath the perinephric fat, the fluid is aspirated and sent for cytology. A gallbladder needle or Orandi-type needle can be used to accomplish the aspiration. The free wall of the cyst is then excised with dissecting scissors, harmonic scalpel, or hook and sent for pathologic analysis (Fig. 126.2). The wall should be incised as close to parenchyma as possible without entering the parenchyma. The parenchymal base of the cyst is then examined for evidence of neoplastic change using cup biopsy forceps to perform frozen-section analysis. The edges of the cyst are cauterized and hemostasis is verified after the pneumoretroperitoneum has been lowered to 5 mm Hg. The argon beam coagulator can be used to quickly paint over any raw bleeding surfaces of parenchyma or cyst wall. If the argon beam coagulator is used, care should be taken to vent the entering argon gas to prevent overpressure and barotrauma.

**FIGURE 126.1** Port placement for retroperitoneoscopic kidney surgery, such as nephropexy, renal cystectomy, and biopsy.

**FIGURE 126.2** Renal cyst exposed and ready for excision.

Fibrin glue with or without oxidized cellulose can be applied for refractory areas of bleeding.

#### Transperitoneal Approach

The transperitoneal laparoscopic approach is ideal for treating anterior renal cysts, either simple or multiple. The usual technique is laparoscopic marsupialization. This technique has also been reported to treat symptomatic ADPKD (4). Under general anesthesia, with the patient in a 45-degree lateral flank position, pneumoperitoneum is established at the umbilicus. A 10-mm port is placed under laparoscopic visualization lateral to the umbilicus on the affected side in the lower quadrant. A third 5-mm trocar is placed in the midline halfway between the xiphoid process and umbilicus. A fourth trocar may be necessary for retraction in some cases and can be placed either in the lower midline or close to the xiphoid in the midline. The colon is reflected medially and the fascia of Gerota is incised. The perinephric fat around the cyst is dissected cleanly. In cases of polycystic disease, the kidney must be entirely mobilized inside the fascia of Gerota. Once again, the cyst fluid can be aspirated with a needle and sent for cytology. The cyst can then be unroofed as detailed above and its walls and base carefully inspected. Then, a portion of the cyst wall may be attached to the mobilized edge of peritoneum with either a clip or suture to ensure communication with the peritoneal cavity and decrease the likelihood of recurrence.

If the cyst is extremely large, another technique is to fashion a window using dissecting scissors. Retroperitoneal fat or omentum can then be packed into the cyst, thus making it unnecessary to remove a large amount of cyst wall. If during any cyst unroofing, excision, or marsupialization there is concern that the collecting system has been entered, indigo carmine can be administered intravenously or a preoperative ureteral catheter can be placed in complex cases for retrograde irrigation with methylene blue. No drains are necessary postoperatively.

#### Results

In most cases, a transperitoneal laparoscopic approach is used. Mean operative time is 89 to 164 minutes in most series, with a mean blood loss of <100 mL (5,6). Procedures performed on peripelvic cysts tend to be more complicated, with longer operative times and higher blood loss. Length of stay in the hospital averages 1 to 2 days.

#### Complications

Bleeding is always a possible complication of laparoscopic renal cystectomy. However, this has not been noted in the several reported series. Reaccumulation of cyst fluid is uncommon, ranging from 3% to 4% (5,6). This can occur when the window fashioned in the cyst wall reapproximates. Nieh and Bihrlé (7) demonstrated that the use of fat was helpful in maintaining the patency of the marsupialization window. Other rare complications include prolonged ileus, delayed hemorrhage, urinary fistula, and nerve paresthesia.

### LAPAROSCOPIC KIDNEY BIOPSY

Renal biopsy is an invaluable diagnostic procedure for determining the etiology of renal dysfunction. While percutaneous renal biopsy has been proven to be safe and effective, some clinical circumstances mandate the use of other techniques for obtaining kidney biopsies.

#### Diagnosis

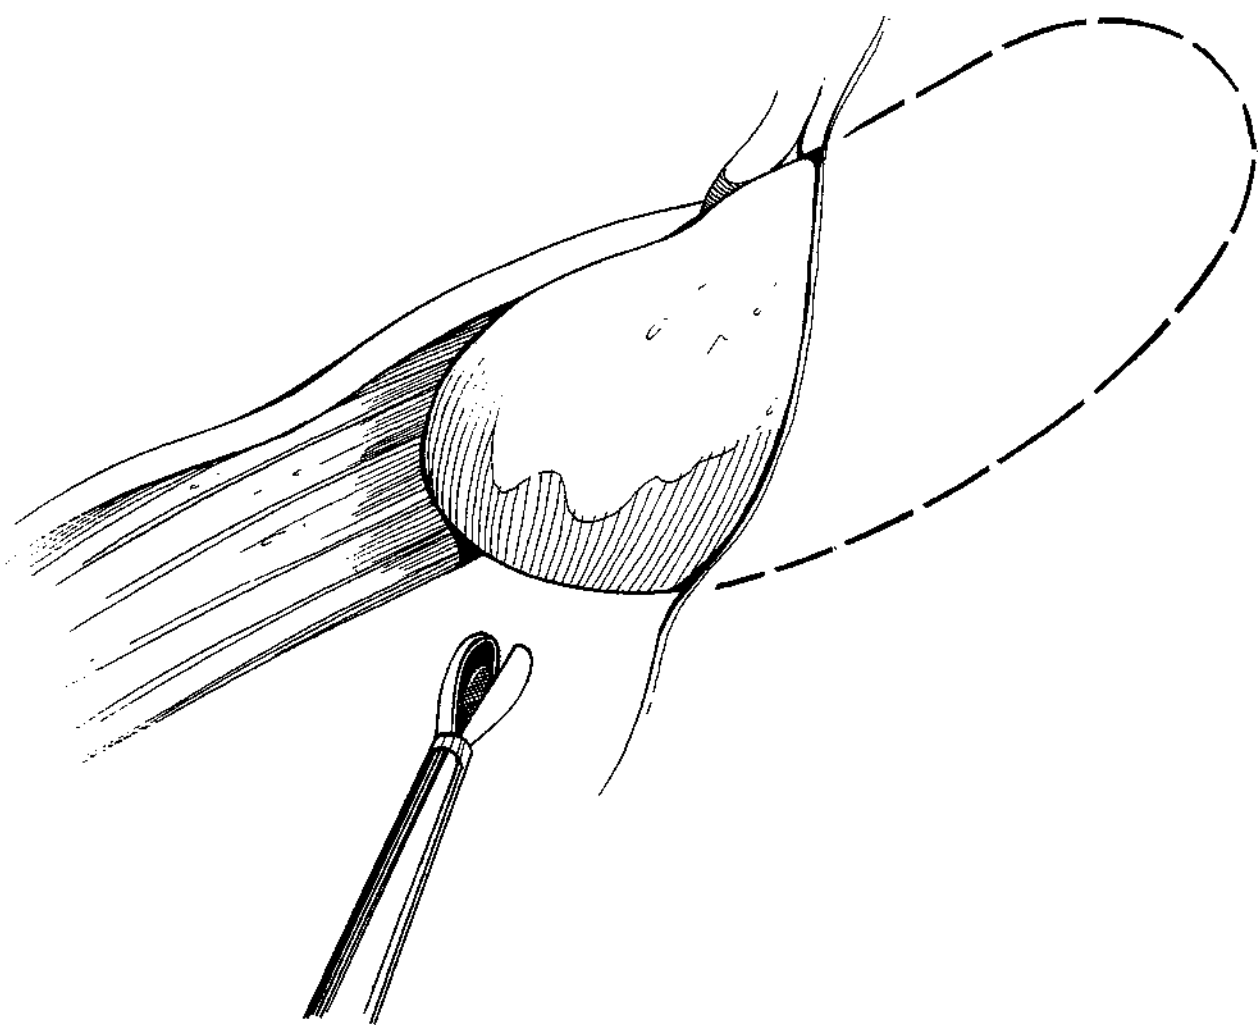

Renal biopsy is most often performed by nephrologists in a percutaneous fashion. The indication is usually hematuria, proteinuria, or renal insufficiency, especially when a glomerular pathology is suspected.

#### Indications for Surgery

US-guided percutaneous kidney biopsy is the most common technique performed. Improved imaging techniques such as US and CT and smaller-gauge biopsy devices have further reduced the contraindications to percutaneous (“blind”) renal biopsy. However, some clinical circumstances such as severe hypertension, bleeding diathesis, anticoagulation, morbid obesity, and difficult renal anatomy dictate the use of more controlled access and better visualization of the kidney during biopsy. Hence, laparoscopic renal biopsy can be of great clinical value.

#### Alternative Treatments

As mentioned, percutaneous needle biopsy by US or CT guidance is the most common method of performing kidney biopsy. Open kidney biopsy through a subcostal or dorsal lumbar incision can also be performed.

**FIGURE 126.3** Lower pole of kidney exposed with spoon forceps or cold-cup biopsy forceps used to take biopsy.

---

### Surgical Technique

---

Preoperative US, CT, or MRI can help characterize the kidney and better identify its location to adjacent structures during surgery. The procedure is ideally performed through a retroperitoneal approach. Patient preparation and positioning are identical to that described for laparoscopic retroperitoneal cystectomy (Fig 126.1). However, in many cases only a camera port and single instrument port are necessary. Minimal blunt dissection through the perinephric fat to expose the lower pole of the kidney is then performed. Laparoscopic US may be necessary in some cases to identify the lower pole of the kidney. Cold-cup biopsy forceps or spoon forceps are used to obtain several samples of tissue, and these are sent to the pathologist for frozen-section analysis to confirm adequate tissue sampling (Fig. 126.3). A large-core Tru-cut-type biopsy needle can also be passed through a trocar or percutaneously to obtain the sample.

Hemostasis can be achieved with electrocautery or an argon beam coagulator, and if necessary the sites can be packed with oxidized cellulose (8). The retroperitoneal pressure should then be lowered to 5 mm Hg and the biopsy sites and dissected space examined for hemostasis. The port-site fascial defects can be closed with Vicryl suture or left open since the procedure is exclusively retroperitoneal.

Most patients can be discharged the same day or within 24 hours. However, many patients have coexisting medical problems that may require longer stays.

---

### Outcomes

---

Adequate tissue samples are obtained in 96% to 100% of patients in the largest reported series. The mean operative time and estimated blood loss is between 90 and 123 minutes and 25.9 and 67 mL (8,9). The majority of patients are discharged from the hospital within 24 hours.

---

### Complications

---

Overall, complications related directly to the procedure are rare because of the direct visualization of the biopsy site for hemostasis and accurate tissue sampling. The reported incidence of delayed bleeding after laparoscopic renal biopsy is 3% to 4% (8,9). Other less common complications are related to visceral injury during access to the retroperitoneum or inadvertent biopsy of other organs.

---

## LAPAROSCOPIC NEPHROPEXY

---

Nephroptosis is a condition of great historical interest. It is classically defined as descent of the kidney  $>5$  cm (or two vertebral bodies) when moving to the upright position. The condition is much more common in female patients and more commonly affects the right kidney, but it can be bilateral in up to 20% of cases. Most patients are thin women. Nephroptosis may be an incidental finding and should be treated only when associated with symptoms. Pain is believed to be a result of acute obstruction and/or renal ischemia upon standing due to the hypermobile kidney.

---

### Diagnosis

---

Historically, the diagnosis of symptomatic nephroptosis was limited to symptomatology and physical examination. Currently, many diagnostic modalities are available. An intravenous pyelogram with the patient in the supine and standing position is the initial test. The hypermobile kidney will descend in the upright position and might become hydronephrotic. Color Doppler ultrasonography with measurement of resistive indices (RI) in the supine and upright position may also be helpful. A reduction in RI may be seen when moving from the supine to upright position, signifying a decrease in renal perfusion (10). A nuclear renal scan in the sitting position is useful in detecting an obstructive pattern after renal descent, as well as diminished blood flow to the kidney when the patient is erect. However, some facilities may not have the proper nuclear imaging systems to perform upright scans.

---

### Alternative Therapy

---

Laparoscopic nephropexy has become the procedure of choice for the correction of nephroptosis. Open nephropexy and its variants are also options.

---

### Surgical Technique

---

The surgical management of nephroptosis is controversial and variable. Many historical options exist, ranging from pexy and slings to other organs, ligaments, or the 12th rib. Current techniques usually employ suture fixation to the

**FIGURE 126.4** Nonabsorbable sutures placed through renal capsule and then psoas fascia on upper pole of kidney (medially, superiorly, and laterally).

psoas and/or quadratus lumborum fascias. In general, the techniques require complete mobilization of the kidney inside the fascia of Gerota down the renal capsule, with sutures placed directly through the fascia.

A transperitoneal approach is the most commonly reported access. The patient is positioned in full flank position, unless performing bilateral nephropexy, in which the patient is positioned supine and the bed tilted side to side to access each kidney. A three-port midline approach is generally used. The kidney is completely mobilized inside the fascia of Gerota and the fascia of the psoas muscle is identified. The operating table is then moved to a head-down position, which causes the mobile kidney to be positioned as cephalad as possible. Beginning at the upper pole, three interrupted nonabsorbable 3-0 sutures are then placed along the lateral margin of the kidney (upper, middle, and lower) through the renal capsule and then through the psoas fascia (Fig. 126.4). Care should be taken not to place the sutures too deeply into

the renal parenchyma to prevent bleeding. In addition, the genitofemoral nerve running along the psoas fascia should not be entrapped. Intracorporeal suturing can be simplified by the use of Lapra-Ty clips (Ethicon Endosurgery, Cincinnati, OH) to secure sutures instead of tying knots.

The retroperitoneal laparoscopic approach provides a direct route to the kidney and may be useful in patients with prior intra-abdominal surgery. However, working space is sometimes limited, making complete kidney mobilization difficult. Creation of the retroperitoneal space is performed as previously described, and nephropexy proceeds as described above. The procedure can be performed on an outpatient basis or the patient may be admitted for 24-hour observation. Follow-up erect and supine radiographic studies are generally performed in 6 to 12 weeks.

---

## Outcomes

---

Success rates are quite high for laparoscopic nephropexy and are comparable to historical open series. Resolution of symptoms occurred in 80% to 100% of patients in published laparoscopic nephropexy series (11–13). Correlation of resolution of symptoms with resolution of renal descent on postoperative imaging appears high. In one series of 31 retroperitoneoscopic nephropexies, complete symptom resolution was present in 83% of patients and 87% of patients had no evidence of persistent renal descent on radiographic studies postoperatively (14).

---

## Complications

---

The most feared complication is failure to resolve symptoms. However, as noted above, failure is uncommon. Other complications include bleeding from the renal parenchyma and postoperative ileus.

# CHAPTER 127 ■ LAPAROSCOPIC ABLATION OF SMALL RENAL MASSES

ILIA S. ZELTSER AND DAVID E. MCGINNIS

As a result of the widespread use of cross-sectional imaging techniques, most incidentally discovered renal tumors are small and locally confined and represent a low-stage renal cell carcinoma (T1a) (1). Long-term oncologic outcomes of open partial nephrectomy have demonstrated that these small tumors (<4 cm) can be treated with nephron-sparing techniques with cancer control outcomes that are equivalent to those of radical nephrectomy (2). Since the development of laparoscopic partial nephrectomy (LPN) in 1993, several centers of excellence have successfully utilized this technique to treat small renal masses. In fact, recent data of the 5-year outcomes of LPN revealed disease-free survival rates of over 90%, with minimal compromise of renal function (3).

Yet despite the excellent outcomes of nephron-sparing surgery (NSS), the widespread adoption of this technique by the urologic community outside of the centers of excellence has been slow. A recent survey of the Surveillance, Epidemiology, and End Results (SEER) registry showed a significant underutilization of NSS in the treatment of small renal masses. Only 42% of the tumors <2 cm were treated with NSS in the 2000–01 time period, and for the treatment of tumors 2 to 4 cm, NSS was employed in a mere 20% of cases (4). The significant technical difficulty of LPN may be responsible for this trend. Furthermore, as compared to open partial nephrectomy, LPN is associated with a longer renal ischemia time and a higher urologic complication rate, even in the most experienced hands.

Thermoablative technologies were introduced to minimize the morbidity of partial nephrectomy, particularly in infirm, elderly patients with multiple comorbidities. Cryoablation (CA) and radiofrequency ablation (RFA) are the two most commonly used energy sources, and both can be applied percutaneously or laparoscopically. The main limitation of in situ ablation is that the tumor is not excised and therefore the pathologic confirmation of complete tumor removal is lacking. Instead, the adequacy of ablation is confirmed by the absence of tumor enhancement on follow-up imaging. Despite this limitation, excellent midrange oncologic efficacy of both CA and RFA has now been demonstrated.

---

## DIAGNOSIS

---

Renal malignancy is suspected when a solid renal mass is visualized on renal ultrasound, computerized tomography, or magnetic resonance imaging. Diagnosis is usually established when a clear enhancement of the lesion is seen during the nephrographic phase following administration of an intravenous contrast agent. Cystic lesions of the kidney are suspected to have

a high malignant potential when they exhibit coarse calcifications, thick outer wall, irregular shape, thickened internal septations, and enhancing mural nodules (Bosniak category III and IV lesions).

---

## INDICATIONS FOR SURGERY

---

Laparoscopic renal ablation is generally indicated for the treatment of suspicious renal masses measuring 4 cm or less in diameter (T1a lesions). Treatment of larger tumors would also be considered for patients with solitary kidneys, renal insufficiency, inherited renal carcinoma syndromes with multiple synchronous renal tumors, and bilateral disease.

Irreversible coagulopathy is the only absolute contraindication to laparoscopic RFA and CA. Large tumors, cystic tumors, and those located in the renal hilum or adjacent to the pelvis or ureter are relative contraindications. Laparoscopic ablation is also relatively contraindicated in patients who are unable to tolerate abdominal insufflation. A transperitoneal laparoscopic approach may be relatively contraindicated in patients who have multiple adhesions secondary to previous abdominal surgery or a history of peritonitis, but a retroperitoneal approach may be considered in these cases. Both RFA and CA can be used to treat exophytic as well as completely endophytic renal masses. Care should be taken to make sure that endophytic lesions to be treated laparoscopically can be well visualized by ultrasound, since they may not be visible on the surface of the kidney. If an endophytic lesion is not visible on ultrasound, then it is not a candidate for laparoscopic ablation. Selection of the approach (intraoperative versus retroperitoneal versus percutaneous) depends on the tumor location, the patient's health status, and the surgeon's expertise. Laparoscopic ablation is generally preferred for anterior and lateral tumors or tumors excessively close to vital structures (e.g., bowel, spleen, major vessels, collecting system), although even posterior tumors can be treated following adequate mobilization of the kidney or a retroperitoneal approach.

---

## SURGICAL TECHNIQUE

---

### RFA Mechanism of Action

---

RFA utilizes a monopolar alternating electrical current with the frequency within the radio segment of the electromagnetic spectrum. The current flows between the grounding pad and the RFA probe. Heat is generated as a result of ionic agitation

of the tissue around the probe, and cell death is achieved when the temperature within a tumor and a small rim of the surrounding tissue rises over 60°C. High temperatures produce occlusion of the microvasculature and destruction of the cellular cytoskeleton, causing tissue ischemia and impaired DNA replication and ultimately resulting in a predictable zone of coagulation necrosis around the RF electrode (5).

Based on the type of the feedback loop modulating energy delivery to the probe, there are two types of RF generators: impedance-based (Valleylab, Boulder, CO, or Boston Scientific, Natick, MA) and temperature-based (RITA Medical Systems, Mountain View, CA). The feedback loops are designed to prevent an overly rapid tissue heating, which would produce charring and increase tissue resistance, thus decreasing the ablation zone.

### Cryotherapy Mechanism of Action

Cell death secondary to rapid severe freezing occurs by several mechanisms. Extracellular ice formation results in movement of water out of the cell and leads to changes in intracellular pH, protein denaturation, and mechanical disruption of the plasma membrane followed by intracellular ice formation. Delayed tissue effects are due to the injury to the microvasculature resulting in tissue hypoxia, endothelial cell damage, edema, platelet aggregation, and thrombosis, culminating in coagulative necrosis (6). Recently, apoptosis and gene-regulated cell death were identified as another mechanism of tissue disruption following freezing (7). It is generally accepted that a temperature of  $-20^{\circ}\text{C}$  must be achieved to ensure cytotoxic effects of CA. It is not clear whether passive thawing between freezing cycles has greater tissue effects than active rapid thawing. However, it is generally accepted that a double freeze-thaw cycle with ice-ball extension beyond the tumor margin should be utilized in clinical practice (8). Cryoablation probes range from large 5-mm probes to 3.4-mm probes to currently available 1.47-mm needles (Galil Medical, Yokneam, Israel, or Endocare, Irvine, CA). Smaller probes were designed to allow for a nontraumatic placement through the body wall and the renal capsule, more precise tumor targeting, and minimal bleeding following cryoprobe removal. The third-generation machines utilize argon for freezing and helium for active thawing.

Routine laboratory studies are obtained and include serum electrolytes, creatinine, liver function tests, and coagulation profile. Urine culture is sent, and culture-specific antibiotics are started in those with positive cultures. A chest radiograph and an electrocardiogram are performed per the discretion of the anesthesiologist. Patients taking aspirin, clopidogrel (Plavix), warfarin (Coumadin), large doses of vitamin E, or other anticoagulation agents are instructed to discontinue them 5 to 7 days prior to the intervention, although they may resume them immediately after RFA or at the surgeon's discretion after CA. A parenteral antibiotic with good coverage of skin flora is given within an hour of starting the procedure.

### Laparoscopic RFA

A transperitoneal approach is utilized for anterior and upper-pole tumors. The retroperitoneal approach is reserved for

lateral and posterior lesions when percutaneous RFA is not possible or available. Basic laparoscopic techniques are described in Chapter 123.

1. After antiembolic stockings are placed and general anesthesia is induced, the bladder is drained with a Foley catheter and the patient is positioned in the modified flank position for the transperitoneal approach and in the standard flank position when retroperitoneal RFA is planned.
2. For transperitoneal ablation, the abdomen is insufflated with a Veress needle or via a Hasson technique, and three transperitoneal laparoscopic trocars are placed in the same configuration as for a laparoscopic nephrectomy. Access to the retroperitoneal space can be obtained using a visual obturator trocar or an open technique where a surgeon's finger is inserted through a 10-mm incision at the tip of the 12th rib and the plane over the psoas muscle is bluntly developed. The retroperitoneal space can be enlarged with a dilating balloon or bluntly developed with sweeping motions of the laparoscope.
3. For transperitoneal ablations, the dissection starts with incising the white line of Toldt as the colon is reflected medially off the fascia of Gerota. Obviously, this step is not required during a retroperitoneal approach.
4. The fascia of Gerota is opened and the perinephric fat is dissected off the renal capsule to identify the tumor. Dissection of the opposite side of the kidney is also performed to create a space for ultrasonic confirmation of probe placement.
5. Laparoscopic renal ultrasound is then used to define tumor margins. Ultrasound is critical in defining the margins of partially or completely endophytic renal tumors.
6. The location on the abdominal wall allowing the most perpendicular path of the probe to the tumor is identified. The probe is inserted through the abdominal wall and the kidney is then manipulated so that the probe enters the lesion at a right angle to the most exophytic point of the tumor. The probe is inserted into the tumor and the tines are deployed to encompass a diameter extending 5 to 10 mm beyond the visualized margin of the tumor. Tine placement is confirmed with laparoscopic ultrasound (Fig. 127.1).

**FIGURE 127.1** Example of the tines being deployed from the end of an radiofrequency ablation probe.

TABLE 127.1

**RADIOFREQUENCY ABLATION PROTOCOL  
UTILIZING STARBURST XL (RITA) PROBE**

Tumor Size	Length of Treatment Cycle (min)	Number of Cycles
<1 cm	3	1 or 2
1–2 cm	5	2
2–3 cm	7	2
3–4 cm	8	2

From: Ogan K, Jacomides L, Dolmatch BL, et al. Percutaneous radiofrequency ablation of renal tumors: technique, limitations, and morbidity. *Urology* 2002;60(6):954–958.

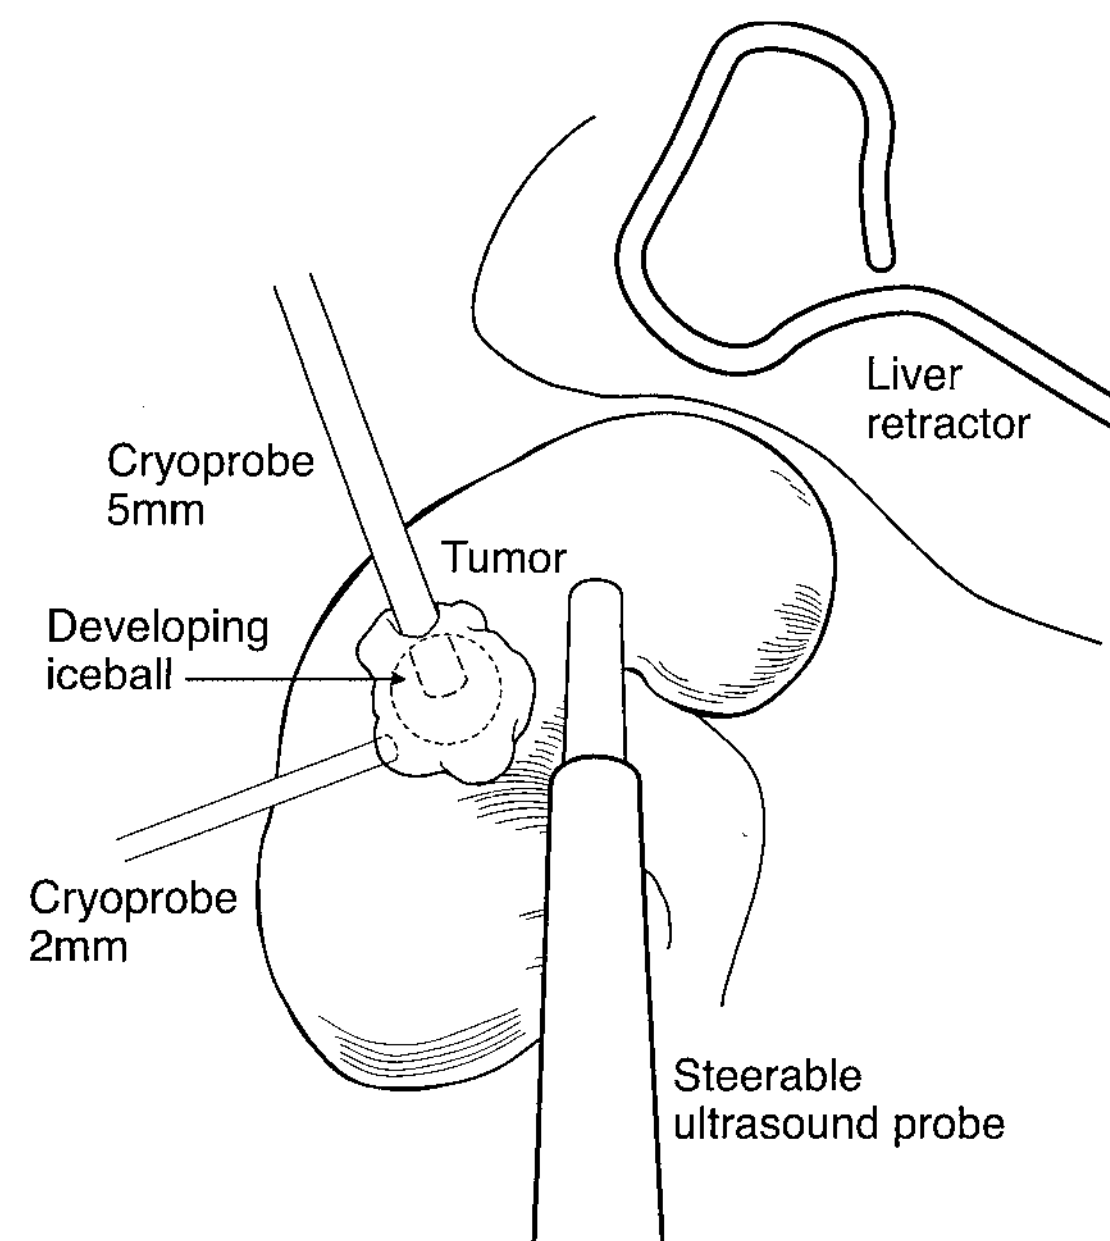

7. Two cycles of RFA are performed. The duration of each ablation cycle is determined by the size of the tumor (Table 127.1).
8. Once ablation is completed, the probe is removed and biopsies of the tumor with a laparoscopic 5-mm toothed biopsy forceps are taken. Performing the biopsy following rather than before the ablation minimizes bleeding, reduces the potential for tumor seeding, and provides adequate tissue sample for accurate diagnosis.
9. The biopsy site on the surface of the kidney is examined: usually no or minimal bleeding results. Mild bleeding can be controlled by application of FloSeal (gelatin–thrombin matrix, Baxter, Deerfield, IL) hemostatic sealant; however, occasionally argon beam or electrocautery coagulation may be needed.
10. Colon is replaced in its normal anatomic position and the incised edges of peritoneum are approximated with clips or intracorporeal suturing. The abdomen is desufflated and the trocars are removed.
11. The postoperative care is the same as for a laparoscopic nephrectomy.

Patients are followed with contrast-enhanced computerized tomography or magnetic resonance imaging. Successful ablation is confirmed by the absence of contrast enhancement within the tumor and a narrow rim of normal parenchyma. It is important to emphasize that the RFA lesion will persist on the follow-up scans, although it may contract slightly. Endophytic lesions may retract from the renal parenchyma, with a narrow rim of fat infiltrating the margin.

### Laparoscopic Cryoablation

Steps 1 through 5 are identical to those of laparoscopic RFA.

6. Once the tumor is localized and its margins are defined, core needle biopsies or the tumor are taken. The ideal path for the cryoprobe is determined based on the path of the biopsy needle. The biopsy needle is passed through a laparoscopic trocar to limit the theoretical risk of tumor seeding. For tumors 2 cm or less, a single 4.8-mm probe is positioned centrally within the tumor and the proper location is confirmed with ultrasound (Fig. 127.2). For

**FIGURE 127.2** During laparoscopic transperitoneal cryoablation a 5-mm diamond flex triangle retractor (Genzyme Surgical) can be used to retract the liver while the ultrasound and laparoscope are used to visualize the procedure.

larger lesions three 1.47-mm probes are triangulated within the tumor so that the resulting ice balls overlap and encompass the tumor margins.

7. Two freeze–thaw cycles are performed and freezing is continued until the ice ball extends about 5 mm to 1 cm beyond the tumor margin. Extension of the ice ball is monitored continuously with ultrasound. Temperature monitoring may be utilized as well to ensure uniform tumor destruction. Eighteen-gauge thermocouples may be placed within the tumor or at the tumor margin, and temperatures below  $-20^{\circ}\text{C}$  must be registered to ensure uniform cell death.
8. After the second thaw cycle, the cryoprobes are removed and FloSeal or Endoavivene plug (Davol, Cranston, RI) may be applied into the puncture sites to help with hemostasis. To avoid tumor cracking, complete thawing of the tumor must be achieved before the probe is removed.
9. Colon is replaced in its normal anatomic position and the incised edges of peritoneum are approximated with clips or intracorporeal suturing. The abdomen is desufflated and the trocars are removed.
10. The postoperative care is the same as for a laparoscopic nephrectomy.

Radiographic appearance of successful CA shows lack of gadolinium or intravenous contrast enhancement within the cryolesion, although a small rim of enhancement may be seen on early scans. This rim gradually disappears and is thought to represent reactive changes in the area of sublethal injury and interstitial hemorrhage along the periphery of the cryolesion. Following cryoablation, some cryolesions will demonstrate gradual reduction in size, with a mean decrease in diameter of 75% at 3 years.

TABLE 127.2

## SELECTED OUTCOMES OF LAPAROSCOPIC RADIOFREQUENCY ABLATION (RFA) AND CRYOABLATION (CA)

Study	Modality	Access	No. of Tumors	Follow-Up (mo)	Radiographic Recurrence
Cestari et al., 2004 (12)	CA	Laparoscopy	37	>6	0/35
Stein and Kaouk, 2007 (13)	CA	Laparoscopy	66	>60	3/66 5-year CCS, 98%
Wen and Nakada, 2006 (14)	CA	Laparoscopy	57	12.5 (1–42)	2/57
Park et al., 2006 (10)	RFA	Laparoscopy	39	26 (12–36)	0/39
Hwang et al., 2004 (15)	RFA	Laparoscopy	15	12 (11–57)	1/24

Note: CCS, cancer specific survival.

## OUTCOMES

Excellent midrange oncologic efficacy of both cryoablation and RFA has now been demonstrated. Gill et al. (9) showed a 98% cancer-specific survival in 51 patients undergoing laparoscopic CA for a unilateral sporadic renal tumor. In a subset of patients with a median follow-up of 6 years, they demonstrated a 5-year overall survival of 80%. Low tumor recurrence rates have also been shown in multiple other series of laparoscopic CA, yet these had shorter follow up (Table 127.2). With a mean follow-up of 25 months, Park et al. (10) demonstrated a 98.5% cancer-specific survival and a 92.3% overall survival in 78 patients (94 renal masses) treated with percutaneous and laparoscopic RFA. Stern et al. (11) compared the intermediate-term outcomes of patients with clinical T1a renal tumors who were treated with NSS by partial nephrectomy or RFA. All patients had at least 2 years of follow-up (the mean [range] follow-up for the partial nephrectomy and RFA groups was 47 [24–93] and 30 [18–42] months, respectively). The overall actuarial disease-free probability for the partial nephrectomy and RFA groups, respectively, was 95.8% and 93.4% ( $p = 0.67$ ). This initial 3-year actuarial analysis showed that RFA for cT1a renal tumors has comparable oncologic outcomes to partial nephrectomy; however, longer-term data are not yet available. It is notable that tumor seeding in surgical incisions or puncture sites has not occurred in any of the series published to date.

## COMPLICATIONS

Current evidence indicates that both renal RFA and CA have low morbidity and are associated with few complications, most of which are minor. In a multi-institutional study, Johnson et al. (16) found a complication rate of 11.1% in 271 patients undergoing renal RFA and CA. Complications occurred after 14.4% of CA cases and 7.6% of RFA cases, with the most common being paresthesia or pain at the percutaneous probe insertion site for both modalities. Major complications in the RFA group included ileus, ureteropelvic junction obstruction requiring a delayed nephrectomy, and a urinary leak. Significant hemorrhage necessitating a transfusion and an open conversion were the major complications of CA. One patient with poor overall health, obstructive pulmonary disease, congestive heart failure, and pulmonary

histoplasmosis died following RFA secondary to aspiration pneumonia. The death was not attributable to the ablation technique, but rather to the patient's overall poor health. In the subgroup of 90 laparoscopic procedures, 3.3% of the complications were attributable to the laparoscopic technique, 4.4% were attributable to the ablation procedure, and one was iatrogenic.

Clinical experience with CA has also shown low complication rates and minimal morbidity. In 56 patients undergoing laparoscopic CA, Gill et al. (17) reported two major and two minor complications. The major complications included a splenic hematoma managed conservatively in one patient and heart failure in another. A pleural effusion and herpetic esophagitis were the minor complications. CA had a minimal impact on renal function. The preoperative and postoperative creatinines were comparable in both the entire study group and the subset of patients with a solitary kidney. Even in 13 patients with a pre-existing renal insufficiency, no significant change in renal function occurred following CA.

In a series of 37 patients undergoing laparoscopic CA, three patients were found to have bleeding complications secondary to renal fracture (12). Perinephric hematomas were seen in two patients and gross hematuria developed in one; all three patients were managed conservatively. Interestingly, this was the first series to show delayed ureteropelvic junction obstruction resulting from CA. This patient was treated successfully with a pyeloplasty at 8 months after CA.

Cryoinjury to the pancreas has been reported in a single patient undergoing retroperitoneal laparoscopic CA (18). The injury was not apparent intraoperatively, and the patient had a delayed presentation with abdominal pain and guarding. Computerized tomography revealed cryoinjury to the pancreas. Abdominal exploration showed no bowel injury, and drains were placed around the pancreas. The patient recovered without further morbidity.

Laparoscopic RFA and CA are promising technologies and can be utilized effectively to treat small renal masses. They require less technical expertise than laparoscopic partial nephrectomy and appear to have lower morbidity and adequate cancer control in the intermediate term. Careful patient selection and meticulous technique are critical to achieving oncologic results comparable to those of partial nephrectomy, which remains the gold-standard therapy for small renal masses. Prospective long-term results of ablative therapy for renal masses are eagerly awaited.

# CHAPTER 128 ■ DONOR NEPHRECTOMY: LAPAROSCOPIC TECHNIQUES

ERIK P. CASTLE, RAFAEL NUNEZ, COSTAS D. LALLAS, AND PAUL E. ANDREWS

Renal transplantation represents one of the most significant developments in surgery. It has had a markedly positive effect on the survival of patients with end-stage renal disease. The limiting factor has continued to be the number of organs available for transplantation. Deceased donor donation rates have remained relatively stable, and the waiting list has continued to grow—from 47,830 in 2001 to 70,501 in 2006, according to the United Network of Organ Sharing Data Registry (2007).

Living kidney donation stands as an immediate solution to the organ deficiency. The disincentives of living renal donation can be attributed, in part, to concerns by the donor regarding the operation, the length of hospitalization, the prolonged recuperation period, morbidity, and mortality. Laparoscopic donor nephrectomy (LDN) offers better cosmesis, decreased length of stay, and shortened convalescence, decreasing the disincentives of living donation.

---

## DIAGNOSIS

---

Individual candidates for living donation are usually between 18 and 70 years of age, without an absolute upper age limit (1). A medical and surgical evaluation is mandatory to accept a living kidney donor (1). The report by the Amsterdam

Forum on the care of the live kidney donor set a standard for the evaluation of potential kidney donors (2,3). This report details the following variables that are important for donation: renal function, blood pressure, obesity, dyslipidemia, urine analysis of protein and blood, presence of diabetes, stone disease, malignancy, urinary tract infections, determination of cardiovascular risk, assessment of pulmonary issues, smoking cessation, and alcohol abstinence. A three-dimensional computerized tomography (CT) scan is also necessary to evaluate the vascular and collecting system anatomy of the living kidney donor candidate (1).

---

## INDICATIONS FOR SURGERY

---

LDN places healthy individuals at risk of morbidity and mortality to benefit the recipient; however, these risks must be minimized. This distinct practice raises ethical concerns and confers a special character to the indications of surgery. The growth of related and unrelated living kidney donation increases the concerns regarding a variety of issues that are unique to organ donation. Such issues include donor psychological status, motivation, and social aspects (4). Ethical issues of emotional and financial rewards must be addressed. In a recent study, Rodrigue et al. (5) found that in 132 programs

across the United States, the presence of financial reward, active substance abuse, and active mental health problems presented complete psychosocial contraindications to donation. To identify healthy and stable individuals, social and psychological evaluation of live kidney donors is needed. Guidelines for such evaluations had been an issue, until recently when they were standardized by the United Network for Organ Sharing, the American Society of Transplant Surgeons, and the American Society of Transplantation (4).

---

## ALTERNATIVE THERAPY

---

Open-flank nephrectomy and hand-assisted donor nephrectomy are alternative approaches (6). The procedures are essentially the principles of donor nephrectomy described below, combined with the early use of the hand port as described for laparoscopic hand-assisted nephrectomy (Chapter 125). Less morbid open techniques such as the “mini-nephrectomy” and “mini-incision nephrectomy” use a smaller incision (an average of 10.5 cm) and can reduce morbidity and hospital length of stay compared to a more traditional open approach (6–8). Preliminary work has also been performed using single-port transumbilical access for donor nephrectomy.

---

## SURGICAL TECHNIQUE

---

### Patient Preparation and Positioning

Patients undergo standard workup and clearance by the transplant nephrology team. All donors undergo rigorous medical and psychological evaluation. In addition to standard laboratory evaluations, CT is obtained in all patients. Contemporary imaging hardware and software allow for complete evaluation of the urinary tract within prospective donors. The renal parenchyma, collecting system, and vascular structures are evaluated in axial, coronal, and sagittal planes. Three-dimensional reconstructive applications can also provide 360-degree rotational views of the vascular and collecting systems.

The kidneys are inspected carefully for nephrolithiasis, masses, cysts, aberrant vasculature, and variant anatomic formations. Although single arteries, veins, and ureters are desirable, it is not uncommon to encounter multiple arteries, early branching of vessels, circumaortic and preaortic renal veins, duplicated collecting systems, and renal calcifications. The three-dimensional reconstructive CT allows us to determine the optimal kidney for donation. We do not hesitate to utilize the right kidney if there is a contraindication for the left. Many times the right side offers the transplant surgeons better arterial anatomy.

All patients are given standard preoperative intravenous antibiotics 30 to 60 minutes before incision. Aggressive volume infusion of normal saline is started in the preoperative area, with most patients receiving between 3.5 and 4.0 liters of fluids by the time they arrive to the operative suite. Patients are induced under a general anesthetic with endotracheal intubation. An orogastric tube and urethral catheter are inserted.

Patients are positioned using a “modified flank” technique (Fig. 128.1A). A 10-pound sandbag or “bump” is placed under the mattress on the anticipated operative side. The hips are turned and the “bottom” leg is bent at the knee, with the

A

B

**FIGURE 128.1** A: Positioning for a laparoscopic donor nephrectomy using a modified flank technique. B: “Sling position” of the ipsilateral arm for a right-sided donor.

“top” leg kept relatively straight. The arm on the contralateral, nonoperative side (down side) is placed on an arm board with standard orientation 90 degrees to the table. An axillary roll is not used or needed with this modified positioning as the patient is not in “full flank” and stress is not placed on the contralateral axillary neurologic or vascular structures. The patient is secured to the bed with copious use of 3-inch silk tape wrapped around the patient and bed circumferentially at the level of the nipples, hips, and knees. This secure taping is done before the ipsilateral (up side) arm is positioned.

The ipsilateral arm is finally positioned on the patient’s chest using the “sling position” (Fig. 128.1B). This is a natural ergonomic orientation as one might encounter in patients

wearing slings following clavicular fracture. The elbow is flexed to 30 degrees, almost as if placing the hand on the patient's heart. This allows for the arm to be cephalad to the costal margin. The arm is placed on soft foam and taped only mildly to prevent movement either into the anesthetic or operative fields. It is important not to overly adduct the shoulder with this arm as one might see when using an arm board across the field. Let the upper arm stay in line with the ipsilateral, axillary side of the body. The overadduction may seem optimal but it actually allows for the arm to end up in a less natural state and can even be intrusive to the surgeon by being a bulky structure in the cephalad portion of the operative field.

## General Technique

Utilizing a transperitoneal technique, access can be obtained one of two ways. A Veress needle or Hasson technique can be used. Alternatively, if the kidney is to be removed via an infraumbilical incision (midline or Pfannenstiel), then a hand port may be used from the beginning (dashed lines in Figs. 128.2 and 128.3). Although we use a GelPort for kidney extraction, we

**FIGURE 128.2** Port placement for right-sided laparoscopic donor nephrectomy. *Dotted lines* represent the extraction incisions.

**FIGURE 128.3** Port placement for left-sided laparoscopic donor nephrectomy. *Dotted lines* represent the extraction incisions.

**TABLE 128.1**

### RECOMMENDED INSTRUMENTS FOR LAPAROSCOPIC DONOR NEPHRECTOMY

- Harmonic scalpel
- Suction irrigator
- One nonlocking atraumatic grasper
- One locking atraumatic grasper
- GelPort
- Laparoscopic articulating endovascular stapler (2.5-mm vascular loads)
- Laparoscopic camera and lens (0 and 30 degrees)
- Laparoscopic clip applier (10 mm)
- Laparoscopic ports, dilating (12 mm × 2, 5 mm × 2)

employ conventional pure laparoscopic techniques during dissection. The hand port can be placed at the start of the operation to obtain the pneumoperitoneum if desired and may allow rapid placement of ports. Instruments can also be passed through the GelPort as another working site (Table 128.1). Basic laparoscopic techniques are presented in Chapter 122.

Port positioning for the primary three ports (camera and two working ports) is similar for both the right (Fig. 128.2) and left (Fig. 128.3) sides. The two working ports are placed in a subcostal position in the midclavicular line. The camera port is placed 5 cm medial to the midclavicular line between the two working ports. All ports are above the level of the umbilicus, with medial-to-lateral triangulation. A fourth accessory port is often used and placement is dependent on which side is being operated on. On the right side the accessory port is placed in the epigastric/subxiphoid region as a standalone liver retractor (Fig. 128.2). On the left side (Fig. 128.3), we place the accessory port in a more flank orientation to serve as a bowel retractor and retract the left colon medially for optimal medial dissection of the renal vein, adrenal vein, renal artery, and preaortic area. An alternative placement of this retraction port is to utilize a trocar through the GelPort.

## Medications

One of the goals during LDN is to maximize diuresis of the donor renal unit, as volume status and diuresis are generally felt to be associated with better early function of the transplanted kidney. As was discussed above, patients are infused with large volumes of intravenous fluids to expand the intravascular space and maximize renal perfusion. Healthy donors should be able to tolerate the 3- to 4-liter volume load preoperatively and should be diuresing once they arrive to the operating room. To continue the aggressive filtration and diuresis, two separate doses of mannitol are given throughout the laparoscopic dissection. The first dose of 12.5 g is given once the pneumoperitoneum is established. The second dose is given 30 minutes into the dissection. Furosemide is also given (20 mg) toward the end of the renal dissection. In most cases, the hope is to achieve a urinary output of 300 to 500 mL per hour during surgery.

Although not a part of every transplant protocol, we use heparin prior to extraction. The patient is given a 3,000-unit dose of heparin 5 minutes before anticipated stapling of the hilum and extraction. Once the kidney is removed and passed off to the receiving transplant team, 30 mg of protamine sulfate can be infused to reverse the anticoagulant effect of heparin if desired. The use of heparin and protamine has been part of our protocol for over 500 cases and we have yet to experience a deleterious effect attributable to either drug.

### Left-Sided Donor Nephrectomy

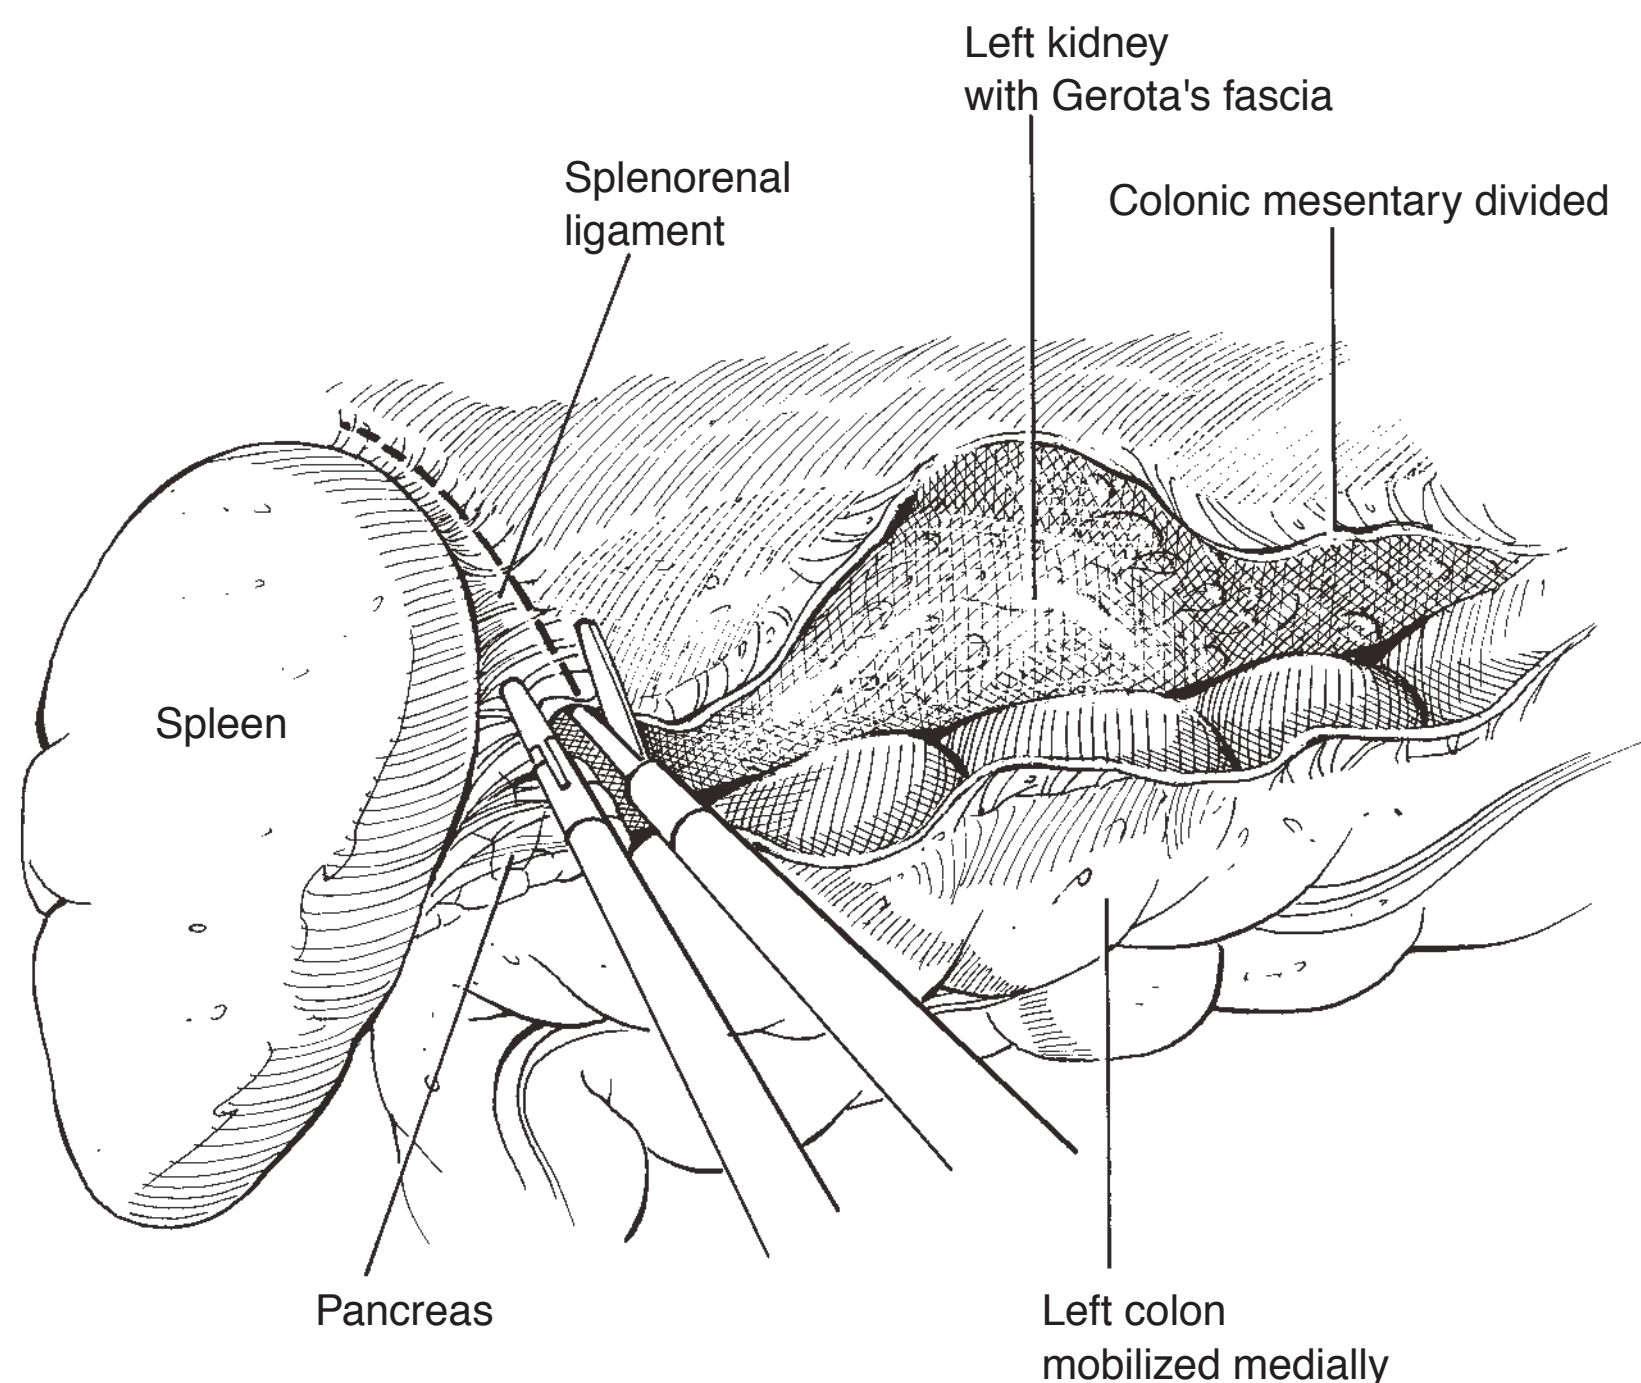

Once the pneumoperitoneum is established, the procedure is begun by incising 2 to 3 cm lateral to the left colon. The incision is carried caudal to the pelvic brim, with care taken to avoid the gonadal vessels and internal ring in male patients. The cephalad incision is carried toward the ipsilateral shoulder lateral to the spleen. Incising lateral to the spleen allows the splenic flexure of the left colon and spleen to fall medially as a unit (Fig. 128.4). This provides excellent exposure of the upper pole. Once the colon is freed from its lateral attachments, the atraumatic locking retractor is inserted via the flank port or GelPort to retract the colon medially. Blunt dissection should be used to identify the gonadal vein and ureter as a package and they are retracted anterolaterally. The gonadal vein should be retracted along with the ureter, as it orients the surgeon to the location of the hilum and renal vein. Utilizing a combination of blunt and careful harmonic scalpel dissection, the dissection is carried cephalad toward the renal hilum. Most of the medial attachments, lymphatics, and areolar tissue can be divided with the harmonic scalpel.

The dissection should be kept medial along the lateral border of the aorta to allow for medial exposure of the renal

hilum. With the gonadal vein retraction, the medial aspect of the renal vein can be easily identified and lumbar tributaries can be identified. The lumbar vein(s) should be bluntly dissected and divided with a single endovascular staple load. With the lumbar vein(s) taken, the renal artery can be exposed and better visualized. Blunt dissection with the suction irrigator will expose the takeoff of the left renal artery.

The dissection can then be carried to the superior margin of the renal vein. The bowel grasper can be moved more cephalad on the left colon, exposing the superior border of the renal vein and the adrenal gland. If more venous length is desired, the adrenal vein can be bluntly dissected and divided with another endovascular staple load. Care must be taken to work in a medial-to-lateral orientation to avoid inadvertent injury to the superior mesenteric artery, as now the dissection is being performed cephalad to the renal vein and renal artery. Blunt and harmonic scalpel dissection can be used to mobilize the fascia of Gerota on the superomedial aspect of the kidney. By dissecting the fascia of Gerota medially at this point, the adrenal gland and its attachments should fall medially off the kidney. The dissection is then carried around the upper pole of the kidney.

Once the inferior, medial, and upper-pole attachments are dissected free from the kidney, the kidney is attached only by the renal vasculature, the lateral attachments, and the ureter. Any remaining dissection of the renal hilum can be performed to maximize vascular length. The lateral attachments of the kidney are divided within the fascia of Gerota. The dissection is begun at the inferior margin of the kidney and lateral to the ureter. The periureteral tissue is not violated so as to preserve all vascularity of the gonadal vein and ureteral complex. The dissection is carried along the lateral border of the kidney within the fascia of Gerota, resulting in a defatting of the kidney if possible. The dissection is carried cephalad to the incised attachments superiorly. The gonadal vein can then

**FIGURE 128.4** The cephalad incision is carried to the ipsilateral shoulder. Dividing the colonic mesentery to rotate the colon medially will develop a plane between the spleen and the fascia of Gerota. The line of dissection is carried between the two organs to allow the colon, spleen, and pancreas to fall medially. The incision of this plane continues cephalad and medial until the stomach is visualized.

**FIGURE 128.5** A goal of laparoscopic donor nephrectomy is to provide a good length of artery and vein on the kidney side.

be dissected and ligated at the pelvic brim. The vein is ligated with laparoscopic clips and divided. The ureter is also ligated and divided, usually at the level of the iliac vessels. The goal is to maximize the length of the artery and vein to assist the transplanting surgeon in a successful vascular anastomosis (Fig. 128.5).

After 3,000 units of heparin have been infused for 3 minutes, the renal artery is taken with a single endovascular staple load. The renal vein can then be similarly taken with an endovascular staple load. In cases of a wide vein, a 45-mm-long staple load can be employed. In most cases, optimal retraction is achieved with pure laparoscopic instruments; in other cases, a hand can be placed in the abdomen through the hand port for retraction. Once the kidney is extracted and passed off, 30 mg of protamine sulfate can be infused. The renal fossa and staple lines are inspected. The adrenal gland should also be inspected, as in some cases there can be some venous ooze from its lateral edge. Hemostatic maneuvers with tissue sealant, clips, or pressure can be employed if needed.

The ports can be removed under direct vision with the pneumoperitoneum down to 5 mm Hg. The extraction is closed with running suture of the surgeon's choice. The ports can be closed with an endoscopic closing device if desired. If dilating ports are used, these can be left open. In our series, we close the 10-mm and 12-mm dilating ports at the external fascial level with a 0 Vicryl UR-6 needle and S-retractors, as herniation has been reported in the literature. Skin edges can be closed based on the surgeon's preference. Wounds can be infiltrated with a local anesthetic of the surgeon's choice, typically lidocaine or bupivacaine.

### Right-Sided Donor Nephrectomy

Pneumoperitoneum is established and ports are placed in the previously described orientation. It is noted that the right colon is not as intrusive and falls medially much more easily than on the left side. The liver is retracted superiorly by placing a locking grasper through the epigastric/subxiphoid port and clamping the underside of the right upper abdomen. The

locking retractor should allow for the liver to be maintained in a cephalad fashion without the need to hold the retractor.

The dissection is begun by incising 3 cm lateral to the right colon. This dissection is carried caudal to the pelvic brim. Care is taken to avoid the gonadal vein in men and the possibility of encountering a retrocecal appendix. The dissection is then turned cephalad and along the superomedial surface of the kidney. The duodenum will be encountered and can be bluntly dissected in a medial direction. Often it is easier to "kocherize" the duodenum after the ureter is retracted anterolaterally.

The ureter and its surrounding attachments should be retracted anterolaterally. It is very important to identify the gonadal vein and dissect it medially away from the ureteral package so as not to inadvertently avulse it from the vena cava. With the ureteral retraction, the dissection is carried superiorly toward the hilum along the lateral border of the vena cava. During this portion of the dissection, the duodenum may need to be bluntly dissected medially and its superior attachments incised with the harmonic scalpel. With the renal vein identified, the dissection is carried posterior to the vena cava and renal vein. With careful blunt dissection, the right renal artery should be dissected, and it should be carried as far behind the vena cava as possible. If any lumbar veins are encountered, they can be clipped and divided to allow for greater "rolling" of the vena cava. The dissection is then carried along the cephalad border of the renal vein following the superolateral margin of the right kidney.

The lateral attachments of the kidney can be divided with the harmonic scalpel starting at the inferolateral margin of the lower pole. Once again, care is taken to preserve all the periureteral tissue. With the kidney completely dissected, the ureter can be clipped and divided distally as for the right-sided procedure. When taking the renal vessels, the same endovascular stapler can be used. It has been our experience that adequate venous length can be obtained with articulation of the stapler and lateral retraction of the kidney. The kidney is extracted and passed off and protamine is given as described earlier for the left side. Closure is the same as the left side.

### Key Points

1. It is the authors' practice to avoid using clips near or around the hilum unless necessary. If a vessel cannot be taken with the harmonic scalpel, then we take it with a stapler. Staples can cross other staple lines. If clips are caught within a stapler, the results can be disastrous!
2. The gonadal vein should be retracted with the ureter on the left side. It is a "pathway" to the left renal vein.
3. The lumbar veins should be divided on the left side to give additional length. These should be taken with a stapler to avoid problems with clips at the hilum and the use of staplers.
4. There is often a tendency to work too lateral and not close enough to the aorta or vena cava. Staying close to the great vessels allows for maximizing vascular length and facilitates hilar dissection.
5. A standard articulating endovascular stapler will suffice for both sides. Avoiding heroic measures to obtain 2 to 3 mm of venous length will prevent complications for an otherwise healthy patient such as a kidney donor.

6. We recommend attempting to close 12- and 10-mm ports at the fascial level in patients whose body habitus is amenable, even if dilating ports are used.

---

## OUTCOMES

---

A major point of contention is the comparison of open versus laparoscopic donor nephrectomy. In a recent review, Shokeir (9) evaluated 69 studies referent to LDN and open donor nephrectomy (ODN). Within this comprehensive review, seven reports were randomized controlled trials (RCTs). All RCTs concluded that LDN provides equal graft function at 1 year, equal rejection rate, equal urologic complications, and equal patient and graft survival. Analgesic requirements, pain data, hospital stay, and time to return normal activities favored the laparoscopic approach significantly. This report also compares reported mortalities. A total of 11 deaths in the LDN cohorts and 10 deaths in the ODN cohorts were reported. A trend toward higher estimated blood loss was found in the open group. Reports of postoperative complications were also reviewed. Gastrointestinal problems (bowel injury, bowel obstruction, internal hernia, and pancreatitis) were more common with LDN, while pulmonary complications (atelectasis, pneumothorax, pulmonary congestion, and hypoxia) as well as thrombotic complications (deep vein thrombosis, thrombophlebitis, and pulmonary embolism) were more common with ODN. Another aspect to be considered when taking into account outcomes and complications of LDN is the absence of a uniform system to classify them. In order to best address this concern, it is necessary to develop a standardized classification and a nationwide donor registry to determine global complications and long-term outcomes rather than short reports at single institutions (10).

Also important is the report of 15 graft losses directly related to the technical aspect of LDN. It is difficult to say, but this may be related to the learning curve of LDN over the years, and long-term outcomes will have to be compared. It is important to consider that the complications and outcomes in LDN have a tendency to be experience-dependent. Through the analysis of the learning curve, different studies have shown that the incidence of complications tends to diminish as the surgeon becomes more experienced (9–12).

In our own series of over 500 LDNs, we have carefully followed our early and long-term patient and graft outcomes. We have previously reported our results after our initial 200 patients (13,14). Overall complication rates have ranged between 12% and 14%, with only 1.5% of the complications being major complications. Our technique and experience have evolved since 1999, when we were doing the dissection with conventional laparoscopic technique and placing the kidney in a specimen retrieval bag. Since then, we have developed a technique of pure conventional laparoscopic dissection with kidney extraction through a hand port as described previously.

We have found that having the hand port in place before actual extraction has decreased our extraction time to a mean of 1.16 minutes. With a short extraction time, the overall warm ischemia time is kept to a minimum. We continue to do pure laparoscopic dissection as techniques have allowed us to be ready to extract and pass off the specimen in under

50 minutes. With our mean operative times down to under 90 minutes, we are able to keep the anesthesia time short for our healthy donor patients.

Another concern with LDN is the manner in which the vessels are ligated and divided. There are numerous reports of ways to “maximize” venous and arterial length. We have been using the laparoscopic articulating endovascular GIA in all 500 patients (left- and right-sided) without direct technical consequence to our transplant colleagues. We feel that the stapler is a reliable, safe, and efficient way to manage the artery and vein. By eliminating extra steps and tools such as clips and/or directly cutting on a clamp requiring vascular suturing, we feel donor safety is preserved. One must remember that the kidney donor patient is an otherwise healthy person, and his or her well-being and best interests should be of the utmost importance.

---

## Complications

---

With an estimated 12% to 14% overall complication rate and a major complication rate of approximately 1.5%, patients must be fully informed of all possible outcomes. As with any surgery, there are risks of bleeding, pain, infection, incisional hernia, deep venous thrombosis, pulmonary embolus, pneumonia, and cardiac risks. These have the same incidence as one would expect in any healthy patient undergoing general anesthesia and laparoscopic renal surgery. Table 128.2 outlines the specific risks of laparoscopic donor nephrectomy.

As with any laparoscopic procedure, there is always the possibility of open conversion. The decision to convert most often reflects good judgment and in and of itself is not a complication. The act of converting should not be considered a complication, as open surgery is the standard to fall back to and not an adverse approach. The surgeon always has the option to convert to open nephrectomy and should have all instruments necessary for open surgery. The incision most often made is a subcostal incision connecting two or more ports if possible. In most cases conversion is due to ongoing hemorrhage or failure to progress secondary to adhesions.

In addition to open conversion, other potential complications inherent to the laparoscopic nature of the operation include pneumothorax, port herniation, and trocar injuries. These should be managed in the standard fashion. The pneumothorax is often not associated with an air leak, so observation or immediate percutaneous drainage is all that is often needed. Port herniation should be treated with return to the operating room for laparoscopic reduction. Trocar injuries to underlying structures should be identified and repaired immediately. In the event of bowel injury during access to the abdominal cavity, the standard of teaching has been to abort the procedure. Although ileus is rare with laparoscopic surgery, it is most often treated with simple bowel rest, ambulation, and observation.

One of the more devastating complications is a vascular complication within the renal hilum. With the U.S. Food and Drug Administration having recalled the Weck Hem-O-Lok L Polymer Ligating Clips (Weck Closure Systems, Research Triangle Park, NC), it is a contraindication for its use in renal hilar control. Nevertheless, failure of the endovascular stapler

TABLE 128.2

**RISKS SPECIFIC TO LAPAROSCOPIC DONOR NEPHRECTOMY**

- Need for open conversion
- Pneumothorax
- Port herniation
- Trocar injuries
- Ileus
- Stapler malfunction resulting in hemorrhage
- Clip malfunction
- Injury to the spleen or liver
- Lymphocele
- Degloving injury to the kidney
- Testicular pain/epididymitis

is a rare but possible event, as well as with clips. This complication is usually identified immediately as significant hemorrhage will be encountered. Venous bleeding can often be controlled with direct compression (laparoscopic or digital through the GelPort), increase of the pneumoperitoneum to 20 mm Hg, and laparoscopic suturing techniques. Arterial bleeding from the main renal artery due to stapler or clip malfunction is particularly difficult to control laparoscopically. Simply put, if vascular control cannot be obtained with laparoscopic maneuvers, one should convert and use standard open techniques. The same applies to injuries to surrounding structures such as the spleen. Although newer hemostatic glues and sealants are available, some splenic lacerations and injuries will not stop bleeding. If use of hemostatic agents fails, splenectomy may be needed and can be performed laparoscopically or open, depending on the surgeon. Injuries to the liver are often

minimal and most often can be managed with hemostatic applications of glues, sealants, or even argon beam coagulation.

Lymphocele is a known complication of donor nephrectomy. This is often due to the disruption of lymphatic channels within the hilum as well as injury to the cisterna chyli. Although rarely seen with donor nephrectomy as it is often performed transperitoneally, it is still a reported complication. If an area walls off and does not communicate with the peritoneum, it can result in a lymphocele even in transperitoneal cases. Often drainage, percutaneous or open, is all that is needed. If it results in chylous ascites, then diet modification to medium-chain fatty acids is required. Management would be similar to retroperitoneal lymph node dissection patients who suffer this complication.

Degloving injuries to the transplanted renal unit are possible. This usually occurs in cases where there is very adherent perinephric fat and a hand is being used in the dissection. This can be avoided if direct incision of surrounding attachments, splenorenal ligaments, and overlying fat is done directly with pure laparoscopic techniques. It is easy to get “heavy-handed” during manual dissection to expedite an operation. If this degloving injury does occur, it has little consequence for the donor but will have to be addressed by the recipient team, as it can increase the risk of bleeding in the recipient. Often back-table repair of stripped renal capsule or intraoperative application of tissue sealants is used.

Finally, in male patients undergoing left LDN, left testicular pain and/or left epididymitis/orchitis has been reported postoperatively. This is a consequence of taking the left gonadal vein during the procedure. The patients will report an “ache” and fullness in the left hemiscrotum. This is usually self-limiting and should be managed with anti-inflammatories and scrotal elevation. In cases where an infectious etiology is suspected due to urethral catheterization, antibiotic treatment for 3 to 4 weeks is appropriate.

# CHAPTER 129 ■ LAPAROSCOPIC AND ROBOTICALLY ASSISTED PYELOPLASTY IN ADULTS

KRISTOFER R. WAGNER AND THOMAS W. JARRETT

After the first successful reconstructive procedure was performed by Kuster in 1891, a variety of procedures (open and minimally invasive surgeries) have been described for management of the obstructed ureteropelvic junction (UPJ). Laparoscopic pyeloplasty was first described in 1993 by Schuessler et al. (1) as a less invasive means of reconstructing the UPJ under direct visualization. This approach preserves the principles of open pyeloplasty and offers maximal flexibility in reconstruction without the associated morbidity of a large flank incision. The learning curve for laparoscopic suturing and prolonged operative times initially prevented more widespread utilization of the technique. More recently, use of robotic technology has facilitated the transition for some surgeons and may lead to decreased operative time.

---

## DIAGNOSIS

---

The diagnosis of UPJ obstruction in general can be made by intravenous urogram or diuretic renal scan. Preoperative computerized tomography may be helpful in identifying patients with a crossing vessel who are being considered for an endopyelotomy procedure. Retrograde pyelography has an important role in confirmation of the diagnosis and for exact delineation of the obstruction. This can usually be performed in conjunction with the procedure.

---

## INDICATIONS FOR SURGERY

---

Laparoscopic pyeloplasty is effective for all types of UPJ obstruction but should be strongly considered in instances where a less invasive procedure is less likely to be successful. Such situations include severe hydronephrosis, crossing vessels, strictures >2 cm in length, failed previous endoscopic procedures, concomitant renal stones, renal ptosis, and poor renal function.

---

## ALTERNATIVE THERAPY

---

Open pyeloplasty has been considered the gold-standard intervention for correcting UPJ obstruction, with a success rate exceeding 90% (2,3), but it is associated with significant postoperative morbidity related with open flank surgery. Several minimally invasive endoscopic procedures for treatment of UPJ obstruction have been developed to minimize the postoperative

morbidity. Direct-vision endopyelotomy via percutaneous antegrade or retrograde approaches yields a lower early success rate of 66% to 90% when compared to open pyeloplasty and may have even lower long-term success rates (4–6). We do not use the fluoroscopic cautery-wire (Acucise, Applied Medical, Rancho Santa Margarita, CA) technique for UPJ repair.

---

## SURGICAL TECHNIQUE

---

The patient is admitted the same day of surgery. After antibiotic administration and induction of general anesthesia, an orogastric tube is inserted and sequential compression devices are placed on the lower extremities. The patient is initially positioned supine (frog-leg position for women and supine for men). Using a flexible cystoscope, angle-tipped glide wire, and 5Fr open-ended catheter, a retrograde pyelogram is performed with C-arm fluoroscopy to confirm the diagnosis and demonstrate the exact site and nature of the obstruction. A 7Fr 28-cm (double-pigtail) stent is placed and correct position confirmed with fluoroscopy. A longer-than-usual stent is used to minimize the possibility of stent displacement out of the bladder during surgical manipulation of the UPJ. In men, the glide wire can be resheathed and prepared into the operative field. The stent can then be placed later with the flexible cystoscope after the back wall of the anastomosis is completed. This avoids the interference with the proximal stent curl while suturing the back wall. In women, access to the urethra is problematic, and it is preferable to place the stent preoperatively. A Foley catheter is inserted before the patient is placed in a 45-degree lateral decubitus position. This position minimizes potential neuromuscular complications that may occur with the 90-degree flank position and is illustrated in previous chapters. A roll is placed under the ipsilateral shoulder and down to the ipsilateral pelvis to keep the operative side elevated and stable. It is not necessary to place an axillary roll, flex the operating table, or elevate the kidney rest. The ipsilateral arm is placed across the chest and the contralateral arm is placed on an arm board abducted 90 degrees from the table with stacked pillows and folded blankets between the arms. Care is taken to protect all pressure points with foam. The lower knee is bent slightly, and the ipsilateral leg is kept almost straight with pillows or foam placed between them to prevent pressure ulcers and neurologic injury. Foam and wide cloth tape are placed across the upper shoulder and arm and across the hip to secure the patient to the operating table. The table is tested tilting maximally to the left and right. The entire

abdomen and flank from the xiphoid to the pubis is shaved carefully and then scrubbed.

### Trocar Placement

Laparoscopic pyeloplasty is performed by the transperitoneal approach. Pneumoperitoneum is established by inserting a Veress needle lateral to the rectus border or into the umbilicus. After an insufflation pressure of 15 mm Hg is established, three midline trocars are placed (Fig. 129.1). The umbilical trocar is 10 mm to allow use of a 10-mm 30-degree laparoscope. The remaining trocars are placed two fingerbreadths above the symphysis pubis and 8 cm above the umbilicus. Trocars are either 5 or 12 mm, depending on surgical side (right or left) and dominant hand of the surgeon. The larger trocar would be placed in the dominant hand of the surgeon to allow for passage of the needle driver and/or Endostitch device during the repair of the UPJ.

The surgeon operates from the opposite side of the affected renal unit and uses the supra- and infraumbilical trocars as the working ports. The assistant or the robot arm (AESOP) stands on the same side of the operating table as the surgeon and manipulates the camera by the umbilical port.

The table is rotated with the ipsilateral side up, and the lateral peritoneal reflection overlying the kidney is incised along the white line of Toldt from the upper pole to approximately 3 cm below the lower pole. The renocolic ligaments are then divided sharply and the colon is retracted medially with a

**FIGURE 129.1** Trocar placement for transperitoneal laparoscopic pyeloplasty.

sweeping motion, further exposing the retroperitoneum. On the right side, a Kocher maneuver may be necessary to mobilize the duodenum off the medial aspect of the kidney.

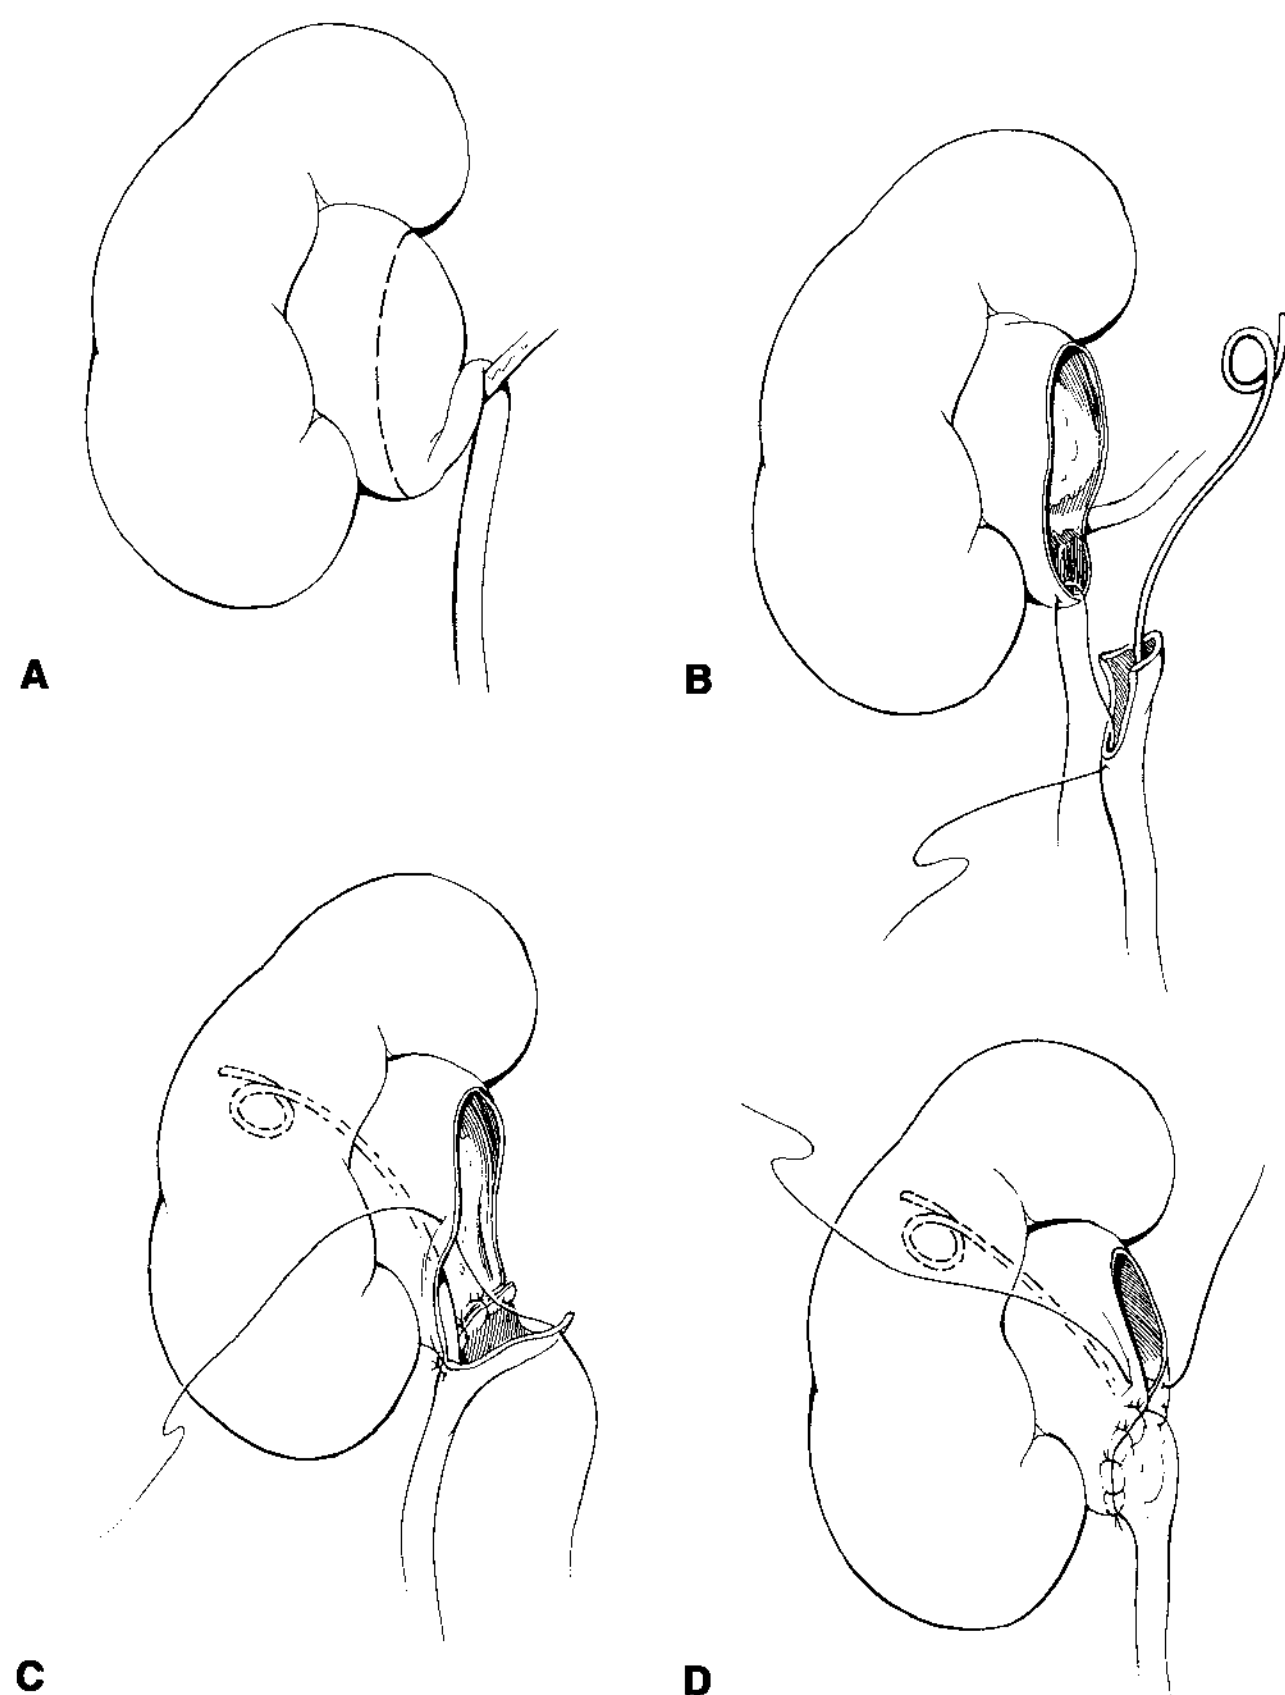

The ureter is identified just medial to the lower pole of the kidney and usually lies lateral and posterior to the gonadal vessels. Gentle palpation of the indwelling stent confirms the structure to be the ureter. A plane between the psoas muscle and the ureter is created using gentle sweeping motions and the ureter is dissected cephalad until the UPJ is identified. It is important to dissect the ureter with its adjacent tissue attached to maximize the blood supply. The ureter should be skeletonized only in the area of the UPJ for delineation of the anatomy.

It is frequently useful to place a 4-0 absorbable suture through the anterior renal pelvis as a stay suture to aid in retraction and fixation during dissection and repair. This suture may be passed through the abdominal wall, renal pelvis, and back through the abdominal wall using a Keith needle. It is secured outside the abdomen using a hemostat to adjust tension on the suture. Extra attention should be made for lower-pole crossing vessels, which can be damaged with overzealous dissection. In the presence of crossing vessels, the renal pelvis and ureter are carefully dissected free so that the ureter can be easily transposed anteriorly as needed. The ureter and renal pelvis are then mobilized as needed to allow for a subsequent tension-free repair. At this point the surgeon must commit to the type of repair to be used depending on the nature of the UPJ obstruction. Any renal calculi can be removed with a combination of direct extraction using forceps through the pyelotomy or with the aid of a flexible cystoscope passed through the upper trocar.

### Anderson–Hynes Dismembered Pyeloplasty

Dismembered pyeloplasty is our preference in most clinical circumstances (Fig. 129.2). It is especially preferable with crossing vessels and a large redundant renal pelvis. Scissors are used to transect the UPJ, taking care not to damage the ureteral stent. The renal pelvis is first incised circumferentially above the area of stenosis, and the stent is then delivered through this incision. The initial pyelotomy is made on the medial aspect of the renal pelvis and cephalad to the UPJ. This results in a “handle” of tissue that can be used to manipulate the ureter. The posterior wall is transected, thus completely freeing the ureter from the renal pelvis. The proximal ureter is spatulated on the lateral aspect using laparoscopic scissors, with attention not to spiral the incision. When a crossing vessel is present, the ureter must be transposed anteriorly to these vascular structures prior to reanastomosis to the renal pelvis. A reduction pyeloplasty is performed at this point when necessary.

Next, 4-0 absorbable stay sutures are placed at the apex of the spatulated ureter and then through the most dependent portion of the reduced renal pelvis. They are tied using intracorporeal techniques. This suture is then used in a running fashion to approximate the posterior portions of the renal pelvis and ureter. Sutures can be placed using the freehand technique or the Endostitch device (Fig. 129.3) (7). The medial portion of the proximal ureter used as a handle is excised. The proximal curl of the stent is placed back into the renal pelvis or upper pole calyx and the anterior portion of the anastomosis is completed using the same technique. The cephalad portion of the pyelotomy is sutured with

**FIGURE 129.2** Anderson-Hynes dismembered pyeloplasty technique.

continuous 4-0 absorbable sutures using the Endostitch or freehand technique. Care is taken to avoid incorporating the stent into the sutures.

### Foley V-V Pyeloplasty

The Foley Y-V pyeloplasty (Fig. 129.4) may be considered in the absence of crossing vessels when there is a small renal pelvis or a high ureteral insertion into the renal pelvis. Using laparoscopic scissors, a wide-based V-shaped flap is constructed from the anterior pelvis. The proximal ureter is spatulated anteriorly. Using 4-0 absorbable sutures, the apex of the V-flap is sutured to the apex of the spatulated ureteral incision and tied intracorporeally with the Endostitch or freehand techniques. The lower wall is completed first using the Endostitch to place the sutures, and the anastomosis is completed with sutures that are placed from the apex out toward the upper pelvis.

### Fenger Nondismembered Pyeloplasty (Heineke-Mikulicz)

The Fenger pyeloplasty (Fig. 129.5) may be considered for a short stenotic segment in the absence of crossing vessels or a high insertion. The principle of this procedure is a longitudinal incision and transverse closure. This technique has the potential advantage of a shorter operative time because fewer intracorporeal sutures are needed. A longitudinal incision is made with laparoscopic scissors from the renal pelvis distally

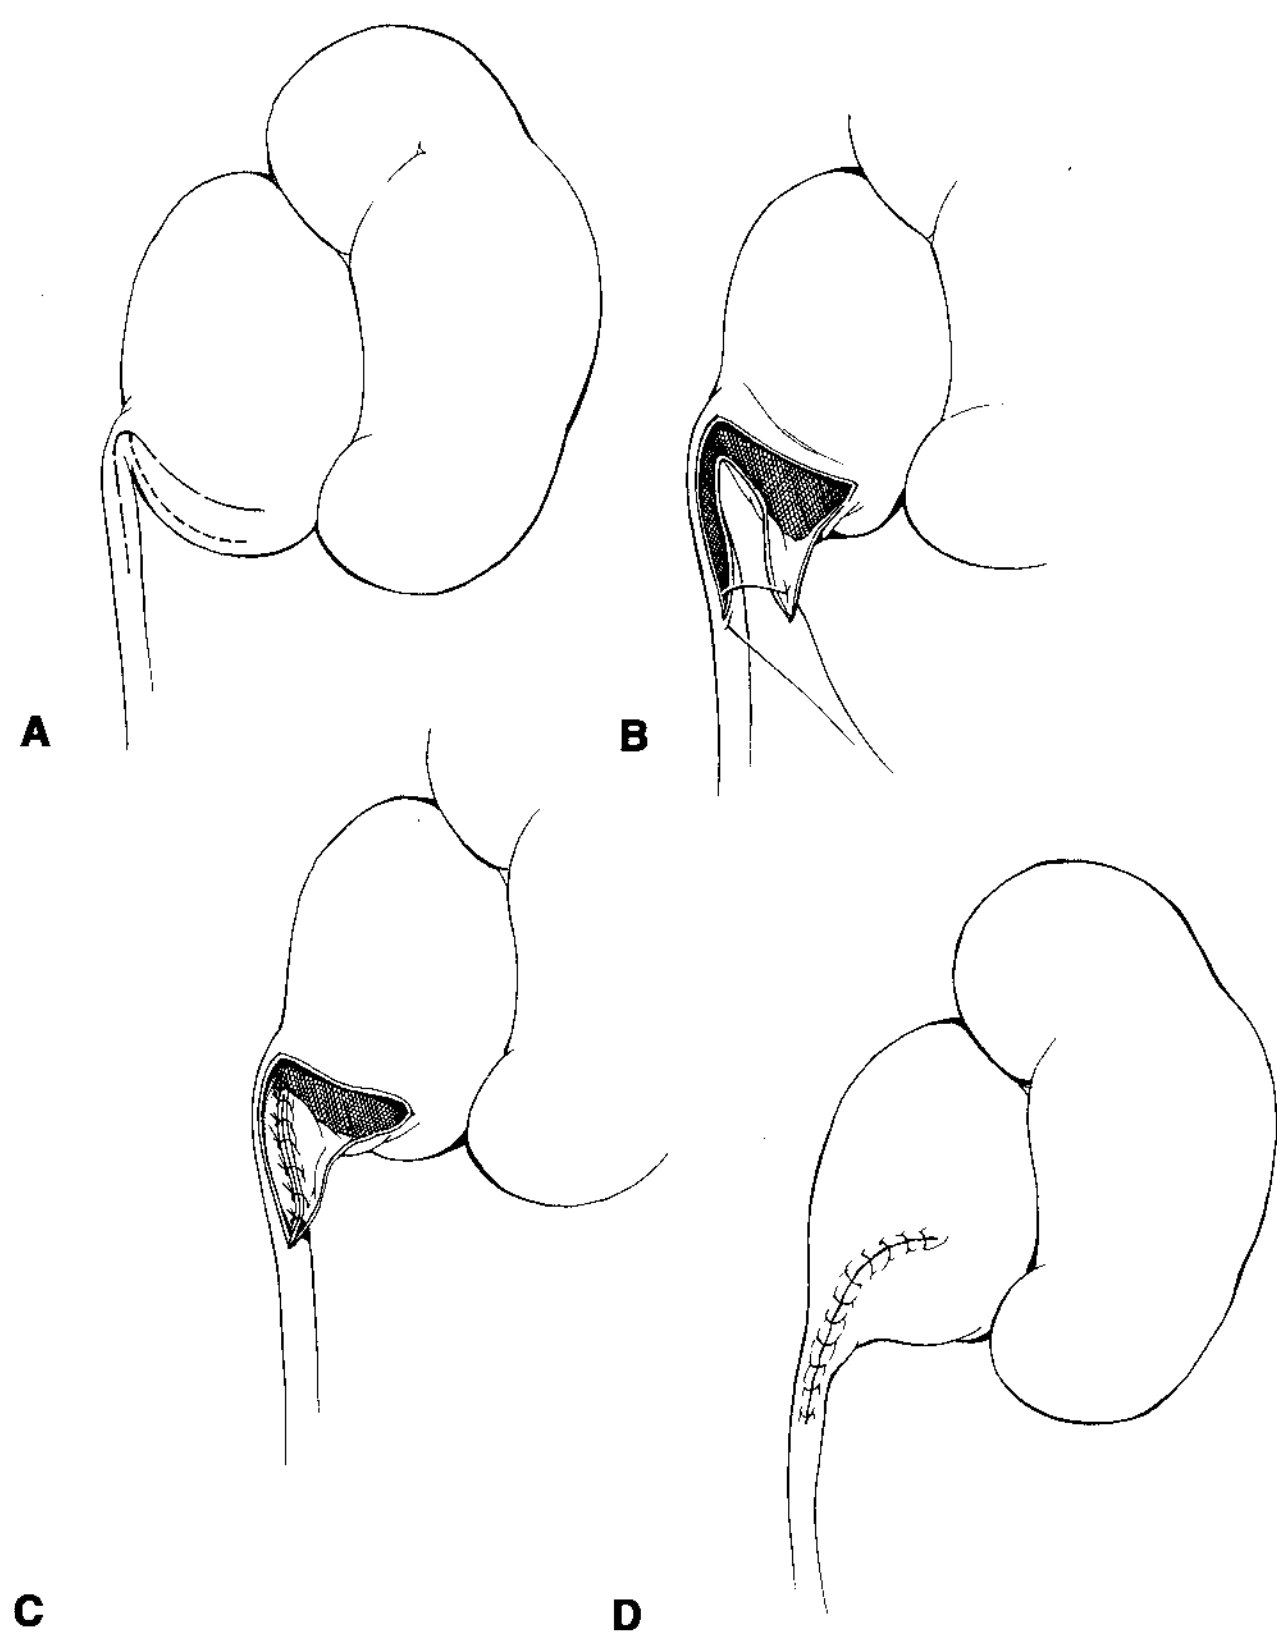

**FIGURE 129.3** Endostitch device.

to 1 to 2 cm below the UPJ segment. The initial pyelotomy incision, just above the UPJ, can be made with a laparoscopic knife or scissors. The longitudinal incision is then closed transversely in a Heineke-Mikulicz fashion over the stent using one continuous 4-0 absorbable suture.

### Additional Salvage Maneuvers

Additional maneuvers may be necessary in cases where a long (>2 cm) stricture is present or the anastomosis is under tension. This is more likely in cases of secondary UPJ obstruction

**FIGURE 129.4** Foley Y-V pyeloplasty technique.

**FIGURE 129.5** Fenger nondismembered pyeloplasty (Heineke-Mikulicz) technique.

or those with previous failed treatment. In these cases, it is critical to assess the UPJ and stricture length prior to transecting the UPJ. It may be necessary to create a vertical or spiral flap of renal pelvis to reconstruct the UPJ and gain adequate length. Mobilization of the entire kidney inferiorly may also provide a few centimeters of additional length. In redo salvage situations with a very long stricture, a laparoscopic ureterocalicostomy or ileal ureter might be necessary.

After the chosen anastomosis is completed, fibrin glue may be used to help seal the anastomotic site. Then, the pneumoperitoneum pressure is dropped to 5 mm Hg and the operative sites are examined for bleeding. After hemostasis is adequately obtained, a small closed-bulb suction drain

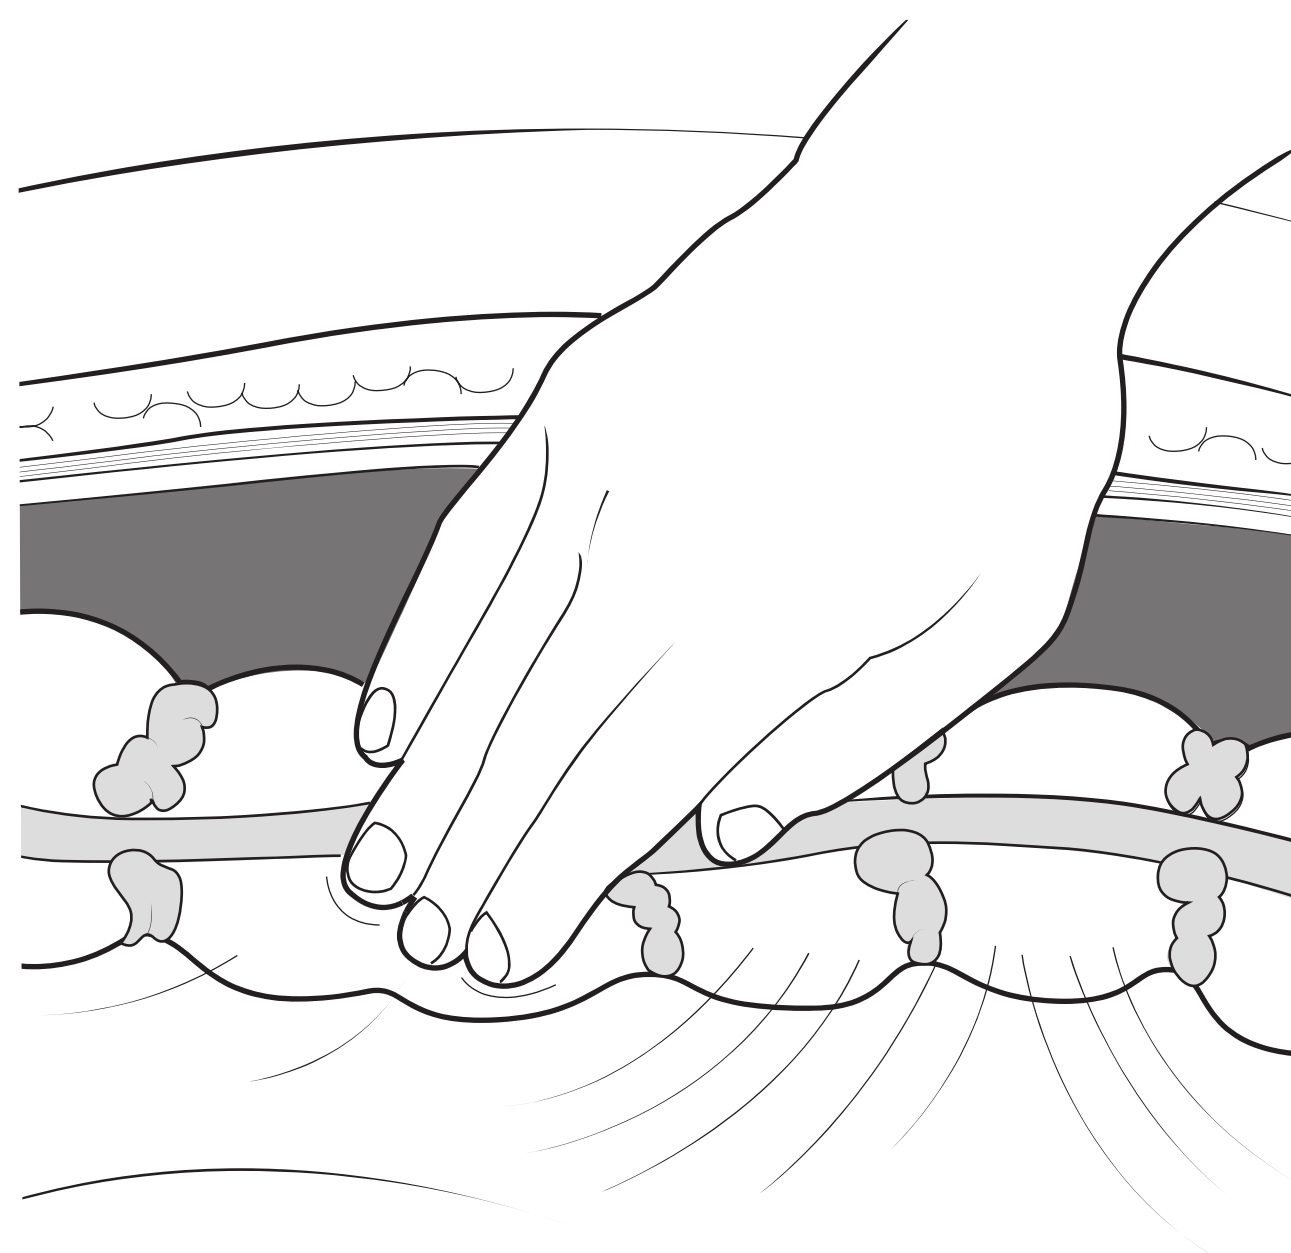

(Jackson-Pratt) is positioned carefully in the retroperitoneum to lie adjacent to the newly completed anastomosis but never in direct contact. The drain is brought out through a small stab incision in the posterior axillary line and then secured with a 3-0 nylon suture. All trocars are then removed under direct vision. The abdominal fasciae of all 10/12-mm port sites are closed with interrupted 0 absorbable sutures using the Carter-Thomason closure device. The CO<sub>2</sub> pneumoperitoneum is removed to decrease postoperative shoulder irritation. The drain is connected to bulb suction. The skin incisions are closed with subcuticular 4-0 polyglactin sutures and adhesive skin tape.

### Transmesenteric Approach

The transmesenteric approach may offer advantages of decreased operative time and ileus in appropriately selected cases. This approach is primarily useful in left-sided cases because the splenic flexure lies cephalad to the UPJ (Fig. 129.6A). It is technically feasible in cases with a laterally displaced colon and relatively thin mesentery. This anatomic situation is more frequently encountered in pediatric cases or in thin women. Instead of mobilizing the colon medially, a longitudinal window is created in the mesentery over the UPJ, taking care to avoid mesenteric vessels (Fig. 129.6B). A stay suture through the abdominal wall is most useful to elevate the renal pelvis and UPJ from the mesenteric window. From this vantage point, the proximal ureter and renal pelvis are dissected and the repair of choice is performed as described above.

### Robot-Assisted Laparoscopic Pyeloplasty

The da Vinci robotic surgical system (Intuitive Surgical, Sunnyvale, CA) offers several advantages over standard

**FIGURE 129.6 A:** Laterally displaced left colon, suitable for transmesenteric approach.

**FIGURE 129.6 B:** Transmesenteric technique with stay suture through abdominal wall.

laparoscopic pyeloplasty. Additional magnification (10 $\times$ ), three-dimensional stereoscopic vision, motion scaling, and tremor filtering provide an increased level of precision in dissection and reconstruction. In particular, suturing time may be decreased with the use of the da Vinci system. The patient is positioned as described previously for laparoscopic pyeloplasty. Trocar placement includes a 10/12-mm trocar at the umbilicus for the camera and two 8-mm robotic trocars, one in the midline 8 cm above the umbilicus and one in the lower quadrant lateral to the rectus border (Fig. 129.7). An additional 5- or 10-mm port is placed in the lower midline to allow the assistant to pass suture and provide suction and retraction. Mobilization of the colon and exposure of the UPJ are performed using standard laparoscopic instrumentation as described previously. The robot is then docked, with the patient side cart approaching the patient's back at a 45-degree angle from the ipsilateral shoulder toward the umbilicus (Fig. 129.8). The camera arm and two working arms reach across the patient's abdomen and angle back toward the ipsilateral upper quadrant. The 30-degree down-angled da Vinci scope is connected to the camera arm. The Maryland forceps and Potts scissors are used to transect the UPJ. The articulating Potts are particularly useful to precisely spatulate the ureter and tailor the renal pelvis. The robotic needle drivers are then used to perform the reconstruction as described previously. Robotic surgeons should be familiar with standard laparoscopic suturing techniques to avoid open conversion in the event of a robot malfunction.

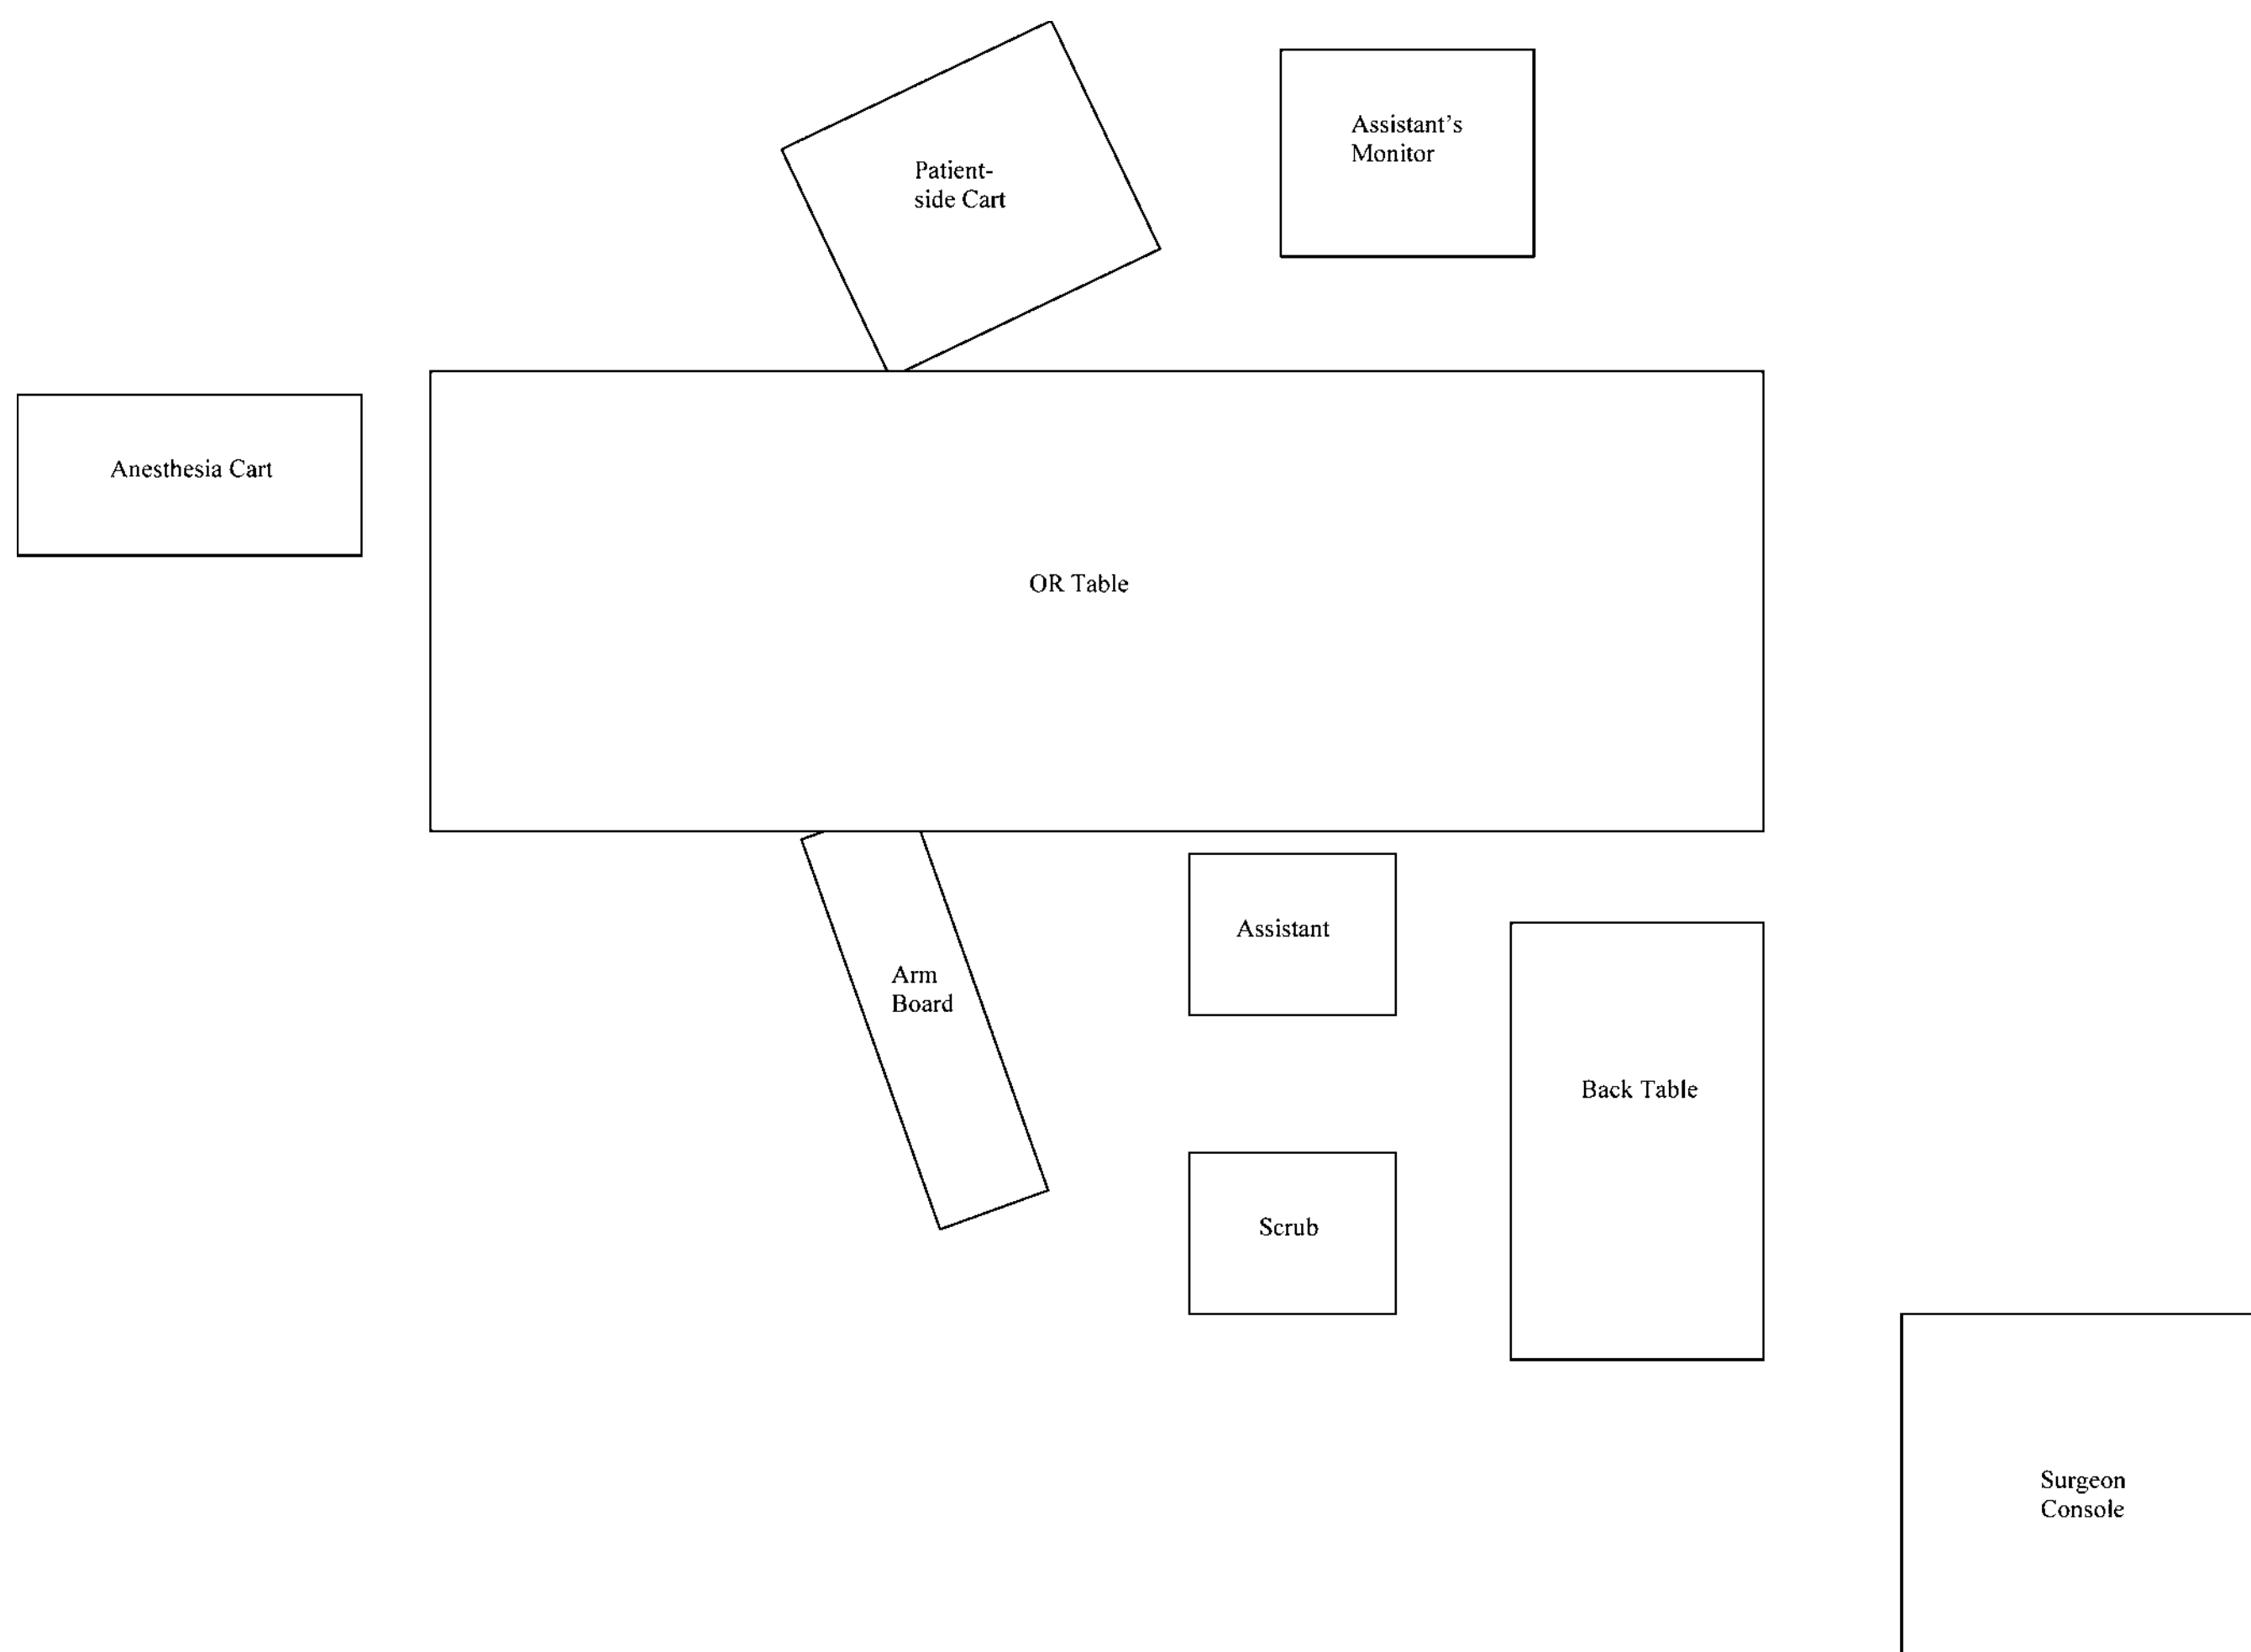

### Postoperative Care

The orogastric tube is removed just before extubation. On the ward, vigilant records of outputs must be kept to dictate drain management. The Foley catheter is removed on postoperative day 1 or 2 if the drain fluid output is consistently  $<30$  to 50 cc per 8 hours. A drain fluid creatinine is obtained if output is

**FIGURE 129.7** Trocar placement for right-sided robot-assisted laparoscopic pyeloplasty.

greater than this. Following removal of the Foley, the retroperitoneal drain outputs must be monitored for increased output. If the outputs increase, the Foley should be replaced until they drop to acceptable levels. The retroperitoneal drain may be removed when the drainage is negligible after the Foley removal, which is usually postoperative day 2. In some cases, patients are sent home with the drains in place if they have met all other criteria for discharge.

**FIGURE 129.8** Room setup for left-sided robot-assisted laparoscopic pyeloplasty.

A clear liquid diet is started on postoperative day 1 and advanced following the passage of flatus. The intravenous antibiotics are continued for 24 hours, and then switched to an oral agent. The ureteral stent is removed in the office in 6 weeks. The anastomosis is then radiologically re-evaluated with an intravenous urogram or renal nuclear scan 6 weeks after stent removal unless the patient has recurrent symptoms. A follow-up diuretic renal scan is obtained at 6 months postoperatively and compared with the previous study. Thereafter, an intravenous urogram or a renal scan is obtained at yearly intervals.

## OUTCOMES

Laparoscopic pyeloplasty retains the benefits of open pyeloplasty while minimizing the morbidity of incisional trauma. This approach should be considered especially in those instances where endopyelotomy is contraindicated or has compromised results. Such situations include severe hydronephrosis, renal ptosis with renal kinking, poor renal function, strictures longer than 2 cm, concomitant nonobstructing renal stones, and crossing lower-pole vessels. The major disadvantage of the laparoscopic approach is the learning curve. The technique requires not only laparoscopic expertise but also experience with intracorporeal suturing and tying.

Results have been excellent and are comparable to open pyeloplasty. In a series of 100 consecutive laparoscopic pyeloplasty cases from the Johns Hopkins Hospital, 96% were successful with a mean radiographic follow-up of 2.2 years (8). Fifty-six of 100 patients were found intraoperatively to have lower-pole crossing vessels and thus underwent dismembered pyeloplasty. In patients with calculi, concomitant laparoscopic pyeloscopy with extraction of the stones was performed. A French multicenter study examined 55 retroperitoneal laparoscopic pyeloplasty cases and found that 95% of cases were successfully completed laparoscopically; all patients were pain-free and radiographically unobstructed by 3 months (9). The overall complication rate was 12.7%. Complications in seven patients included hematoma in three, urinoma in one, severe pyelonephritis in one, and anastomotic stricture in two, requiring open pyeloplasty at 3 weeks and delayed balloon incision at 13 months, respectively.

The largest comparative series between laparoscopic and open pyeloplasties was reported on a retrospective series of 42 patients who underwent laparoscopic pyeloplasty and 35 who underwent open repair with regard to outcome and complications (10). Follow-up was up to 22 months in the laparoscopic group and 58 months in the open series. The complication rate for the laparoscopic group was 12% (five patients) while the open group had 11% (four patients). No

significant difference in pain-free rates between both groups was observed (laparoscopic 62%, open 60%). Objective success was based on radiographic findings. Radiologic failure was observed in one patient in the laparoscopic group (within 24 hours after the stent was removed) and in two patients in the open group.

Gettman et al. (11) reported the first robot-assisted laparoscopic pyeloplasty series in six patients and compared them to a control group of six standard laparoscopic pyeloplasties. Operative time and suturing time were significantly decreased in the robotic group and the objective success rate was 100%. A recent multi-institutional series from several hospitals in New York City included 35 patients, with mean operative time of 216 minutes and suture time of 63 minutes (12). Mean hospital stay was 2.9 days, and objective success rates were likewise excellent (94%) with mean follow-up of 7.9 months.

Laparoscopic pyeloplasty is a feasible but technically demanding procedure. This surgical technique maintains the advantages of open reconstruction of the UPJ while decreasing

the morbidity due to a large flank incision. The increased availability of laparoscopic training and robot-assisted technology has led to acceptable procedure times. Moreover, longer follow-up has shown durable success rates comparable to open surgery.

---

## Complications

---

All complications of abdominal laparoscopy are possible, and injury to adjacent organs should be considered when the clinical situation is deteriorating. The most common complications are usually due to persistence of urinary leak or urinoma. The possibility of urinoma requiring revision of drains can be minimized with vigilant placement at the time of surgery. Most controlled urinary leaks can be managed as an outpatient with continued suction drainage with or without a Foley catheter. Most will close with time. Failure to drain the urine or urinoma requires either percutaneous or surgical drainage.

# CHAPTER 130 ■ LAPAROSCOPIC ADRENALECTOMY

ARVIN K. GEORGE AND LOUIS R. KAVOUSSI

Since Gagner et al. first described laparoscopic adrenalectomy in 1992, this approach has become the preferred technique in the surgical management of most adrenal lesions (1). Laparoscopic adrenalectomy demonstrates the classical benefits of minimally invasive surgery, with multiple studies supporting reduction in postoperative pain, analgesia requirements, and postoperative morbidity with equivalent functional outcome when compared with traditional open surgery. Advances in minimally invasive surgical techniques have generated the development of multiple approaches to adrenalectomy, including transperitoneal, retroperitoneal, transthoracic/transdiaphragmatic, and most recently robot-assisted surgery. The benign nature of the majority of adrenal disease, combined with the deep retroperitoneal location of

the adrenal gland, has lent itself ideally to the laparoscopic removal of lesions.

---

## INDICATIONS

---

Laparoscopic adrenalectomy is a definitive surgical treatment modality for the broad spectrum of adrenal disease. It has been proven safe and effective in the management of benign functioning and nonfunctioning adrenal conditions as well as the majority of malignant neoplasms (Table 130.1). As surgeon experience has increased, the contraindications to the laparoscopic approach have decreased. In the hands of a proficient and practiced surgeon, contraindications have

TABLE 130.1

**INDICATIONS FOR LAPAROSCOPIC ADRENALECTOMY**

Benign	Malignant
Primary aldosteronism (adenoma/hyperplasia)	Adrenocortical carcinoma
Cushing disease or Cushing adenoma	Solitary adrenal metastases
Pheochromocytoma	
Adrenal cyst	
Myelolipoma	
Incidentaloma/adenoma with >3 cm of growth over time with serial imaging	

TABLE 130.2

**CONTRAINDICATIONS TO LAPAROSCOPIC ADRENALECTOMY**

General	
Poor cardiopulmonary status	
Uncorrected coagulopathy	
Specific	
<i>Relative contraindications</i>	<i>Absolute contraindications</i>
Tumor size >6 cm	Tumor with local invasion
Obesity	Tumor with venous thrombus
Previous abdominal/retroperitoneal surgery	Regional nodal involvement
	Malignant/uncontrolled pheochromocytoma

become relative, and the advantages of minimally invasive techniques have afforded urologists the opportunity of a more aggressive approach in treatment (Table 130.2).

**DIAGNOSIS**

Evaluation generally begins with serum and urine chemistry to distinguish between functioning and nonfunctioning tumors. More specific investigations, combined with the clinical presentation, assist in isolation of a specific pathology when present (Table 130.3). Imaging with computerized tomography (CT) or magnetic resonance imaging (MRI) is an integral step in preoperative assessment, as it provides detailed characterization of adrenal lesions. The presence of significant retroperitoneal and periadrenal fat allows for ready identification of the gland. CT may help delineate malignant versus benign lesions based on their attenuation characteristics, with accuracy approaching 90% in suspected adrenal disease. MRI has a reported sensitivity and specificity of 89% and 99%, respectively, with adenomas exhibiting a lipid-rich composition in distinction to the lipid-depleted nature of nonadenomatous lesions. Intraoperative ultrasound can elicit detailed information regarding internal acoustic appearance, tumor size, extent of invasion if present, and adjacent anatomy. Its use is a defined element in adrenal-sparing surgery and can assist in cases where it is difficult to distinguish the periadrenal fat from the gland proper. Progress in imaging techniques and their interpretation has increased diagnostic accuracy and they are an essential adjunct in determining diagnosis, operability, and surgical approach.

**ALTERNATIVE THERAPY**

Alternative treatment for adrenal lesions include conventional open surgery via a transabdominal or retroperitoneal approach, radiofrequency ablation (RFA), and cryoablation (2).

RFA provokes local ion agitation and heat, inducing coagulative tissue necrosis. In one recent study Mayo-Smith and Dupuy (3) demonstrated the successful treatment of hormonally active tumors and small (5 cm) solitary adrenal metastases/adrenocortical carcinoma. RFA's use is currently limited to patients who are not surgical candidates. Munver et al. (4) described the first case of cryoablation as an adrenal-sparing procedure for hyperaldosteronism, with subsequent reduction in the need of antihypertensives postoperatively. RFA and

TABLE 130.3

**DIAGNOSIS OF ADRENAL LESIONS**

Primary aldosteronism	Plasma aldosterone concentration (PAC) >15 ng/dL Plasma renin activity (PRA) <1 ng/mL/hr Aldosterone-to-renin ratio >20–30 (PAC:PRA) Sodium loading with 24-hour urine aldosterone >12 µg/24 hr Adrenal vein sampling with lateralizing ratio >5
Cushing syndrome	24-hour urine free cortisol Low-/high-dose dexamethasone suppression with cortisol >5 µg/dL Plasma ACTH level >50 pg/mL is ACTH-dependent
Pheochromocytoma	24 hour serum/urine catecholamines Plasma fractionated metanephrines <sup>131</sup> I methiodylbenzylguanidine (MIBG)/octreotide scintigraphy
Radiologic imaging with CT/MRI is essential in the diagnosis of all adrenal lesions.	

adrenal cryoablation show potential as less invasive surgical alternatives for small lesions and adrenal-sparing procedures in patients who are not ideal surgical candidates (4). The current experience as described in the literature is limited and further evaluation of such alternative therapies is needed.

---

## SURGICAL TECHNIQUES

---

The transperitoneal approach is preferred by most surgeons due to the greater working space and familiarity of anatomic landmarks. Retroperitoneoscopic adrenalectomy is generally considered by the more experienced surgeon but may prove useful in patients with adhesions and/or obesity. Thoracoscopic adrenalectomy was described by Gill et al. (5) for the treatment of select patients with adrenal pathology and significant abdominal and retroperitoneal scarring from previous surgery through access via the virgin thoracic cavity and transdiaphragmatic approach. The introduction of robotic technology in the minimally invasive arena has proven to be a successful alternative to other surgeries with specific benefits. Robotic systems aid in eliminating surgeon fatigue, tremor and provide a three-dimensional visualization of the operative field. However, they represent a more costly option to the healthcare system and additional training by the surgeon. A prospective trial of laparoscopic versus robot-assisted adrenalectomies failed to show significant benefit in the latter (6). The study demonstrated that robot-assisted adrenalectomy is a feasible alternative to standard laparoscopic surgery with appropriate robotic experience. Further studies of robotic adrenalectomies are needed to show functional advantage or demonstrate cost-effectiveness. Ultimately the choice of surgical technique is dependent on surgeon experience, the patient's past surgical history, and preoperative findings.

---

### Preoperative Considerations

---

Prior to operative intervention, metabolic abnormalities associated with hormonally active tumors must be addressed to optimize the patient for surgery. Hypertension and hypokalemia seen with aldosteronomas are managed with spironolactone. The patient should be maintained normoglycemic with cortisol-secreting adenomas, and stress-dose steroid administration must occur perioperatively. The

preoperative management of pheochromocytomas requires special consideration, as inadequate blockade of circulating catecholamines can trigger hypertensive crises secondary to anesthesia or intraoperative manipulation. Patients should receive 14 days of blockade with phenoxybenzamine hydrochloride titrated to control blood pressure. Additional blockade may be indicated if arrhythmias persist or prior treatment proves insufficient.

A mechanical bowel preparation is recommended the night prior to surgery. Parenteral intravenous antibiotic prophylaxis is given prior to incision. Invasive monitoring via arterial lines and central venous lines is performed as indicated. A urinary Foley catheter allows for bladder decompression and intraoperative urine output assessment. Pneumatic compression stockings are placed on the lower extremities bilaterally to help prevent deep venous thrombosis.

---

### Transperitoneal Laparoscopic Adrenalectomy

---

The patient is placed in the 45-degree modified flank position and secured with silk tape; all bony pressure points are padded prior to the initial incision. The ipsilateral arm can be folded across the chest or placed in an arm rest (Fig. 130.1).

Three or four ports may be used for laparoscopic instrumentation. Initial access is obtained at the lateral margin of the ipsilateral rectus at the level of the umbilicus. A Veress needle is inserted and with CO<sub>2</sub> insufflation, intra-abdominal pressure is increased to 20 mm Hg. This is replaced with a 12-mm laparoscopic port into which a 30-degree lens laparoscope is introduced. The remaining trocars are placed under direct vision at the ipsilateral rectus and costal margin, and anterior axillary line and costal margin. An additional 2-mm port just below the xiphoid process allows for use of locking graspers that assist with cephalad retraction of the liver on the right side (Fig. 130.2). Pneumoperitoneum can be subsequently reduced to 15 mm Hg for the remainder of the operation.

---

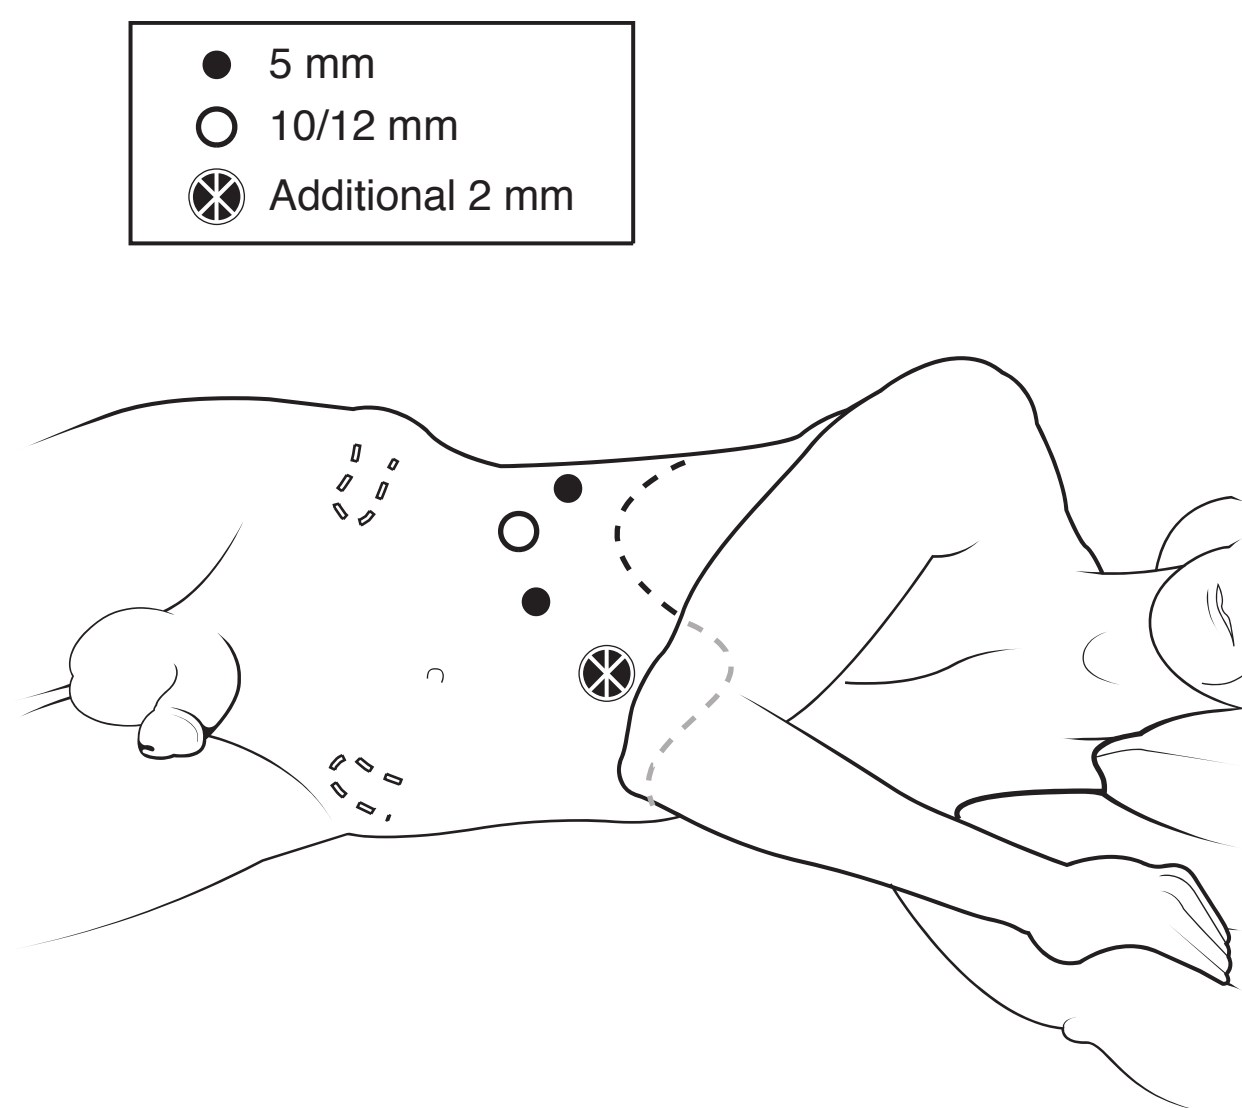

### Transperitoneal Left Adrenalectomy

---

Adrenal exposure begins with incising the line of Toldt with endoscopic scissors/electrocautery, which allows for medial mobilization of the splenic flexure and descending colon

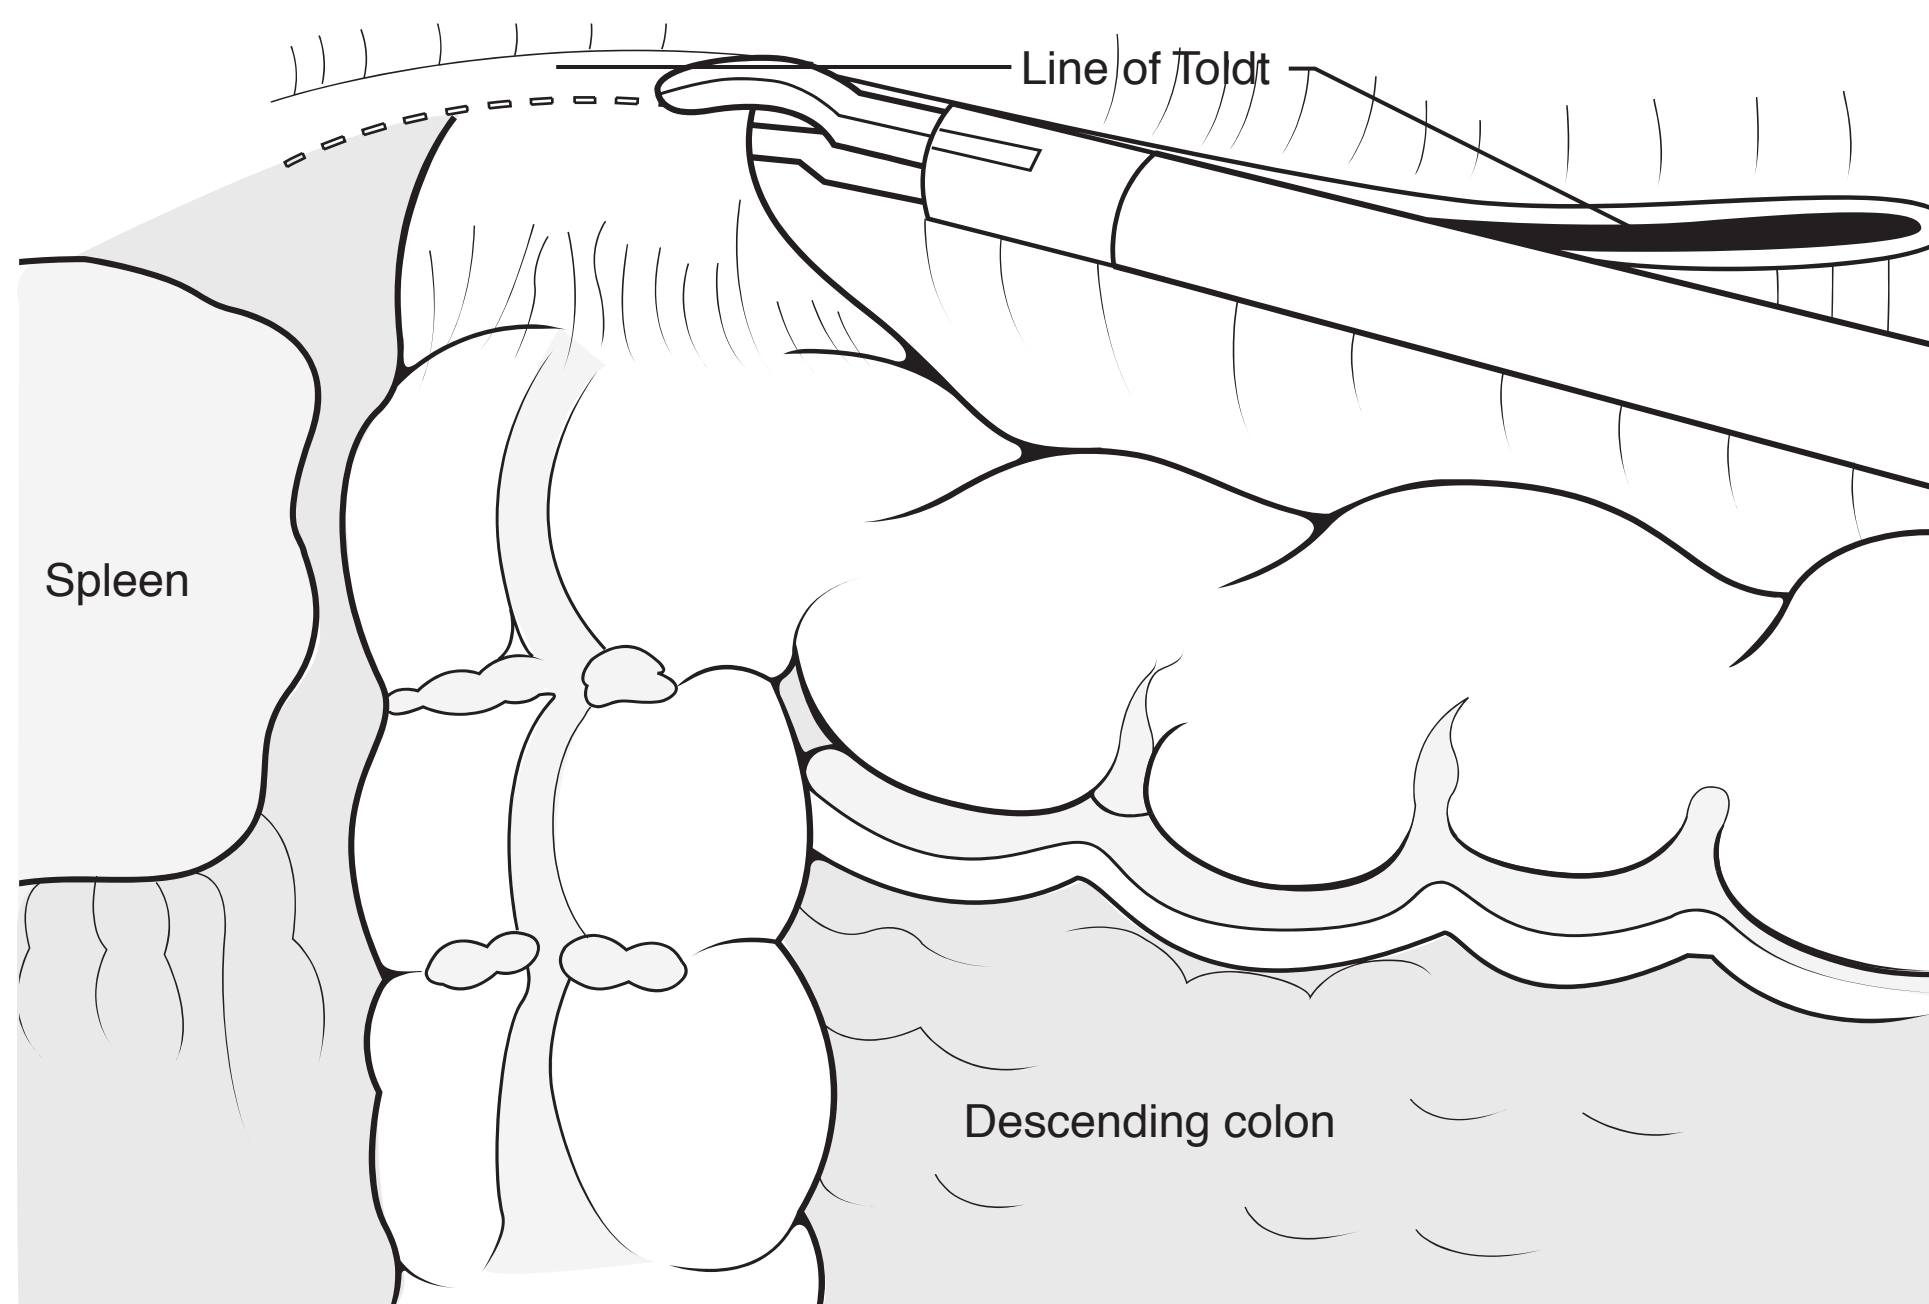

**FIGURE 130.1** Laparoscopic transperitoneal adrenalectomy. Patient is positioned in the modified or full flank position for transperitoneal and retroperitoneal approaches respectively. All bony pressure points are adequately cushioned and the patient is secured in position with silk tape.

**FIGURE 130.2** Laparoscopic transperitoneal adrenalectomy. The primary port site is located at the lateral margin of the ipsilateral rectus muscle at the level of the umbilicus. Secondary ports are placed in the anterior axillary line/ipsilateral rectus near the costal margin. An auxiliary port may be necessary at the xiphoid for retraction of the liver on the right side, as illustrated.

(Fig. 130.3). The splenocolic and lienorenal ligaments are divided and the spleen is mobilized medially to expose the adrenal in the retroperitoneal space (Fig. 130.4). The fascia of Gerota is opened at the upper pole of the kidney and the periadrenal fat is visualized. Dissection is continued to develop the plane between the tail of the pancreas and the renal hilum. The adrenal vein is identified emptying into the renal vein. The adrenal vein is clipped and divided with a minimum of two clips on the medial aspect (Fig. 130.5). Early ligation prevents systemic insult of catecholamines associated with adrenal manipulation and limits the potential for tumor micrometastases. Superiorly, care is taken to control contributions of the inferior

**FIGURE 130.3** Transperitoneal left adrenalectomy. Initial exposure begins with incising the white line of Toldt with endoscopic scissors/electrocautery, which allows for gravity-assisted medial mobilization of the splenic flexure and descending colon.

phrenic artery to the adrenal. Larger vessels may be clipped and transected or coagulated with the harmonic scalpel. The adrenal gland is freed from its lateral and inferior attachments with gentle inferior traction on the kidney, at which point renal artery branches to the adrenal can be seen and controlled (Fig. 130.6). The adrenal gland and periadrenal fat are then placed in a laparoscopic retrieval bag and delivered through the largest port site (Fig. 130.7). The surgical field is examined at 5 mm Hg for adequate hemostasis. Finally, the fascial layer of the 12-mm port site is repaired with absorbable suture and laparoscopic exit is completed in standard fashion.

### Transperitoneal Right Adrenalectomy

Initial exposure of the adrenal gland begins with cephalad elevation of the liver, which may be completed with a fan retractor or self-retaining locking graspers. The peritoneum is incised at the upper pole of the kidney, close to the liver edge, and the peritoneotomy is extended medially toward the inferior vena cava. At this stage the adrenal gland should be readily visible and retracted laterally to expose the renal vein (Fig. 130.8). It is clipped proximally and distally with two clips on the caval side and divided. Dissection is completed with lateral retraction and elevation of the adrenal to allow mobilization of its superior, medial, and inferior attachments. Careful control of supplying vessels is achieved with hemostatic clips or the harmonic scalpel. The free specimen is then placed in a laparoscopic retrieval bag and delivered through the largest port site. The final steps are completed as described with the left side.

### Retroperitoneal Laparoscopic Adrenalectomy

The patient is positioned in the lateral decubitus position, stabilized with an inflatable beanbag, and secured and protected

**FIGURE 130.4** Transperitoneal left adrenalectomy. The lienocolic and lienorenal ligaments are divided to expose the adrenal in the retroperitoneal space.

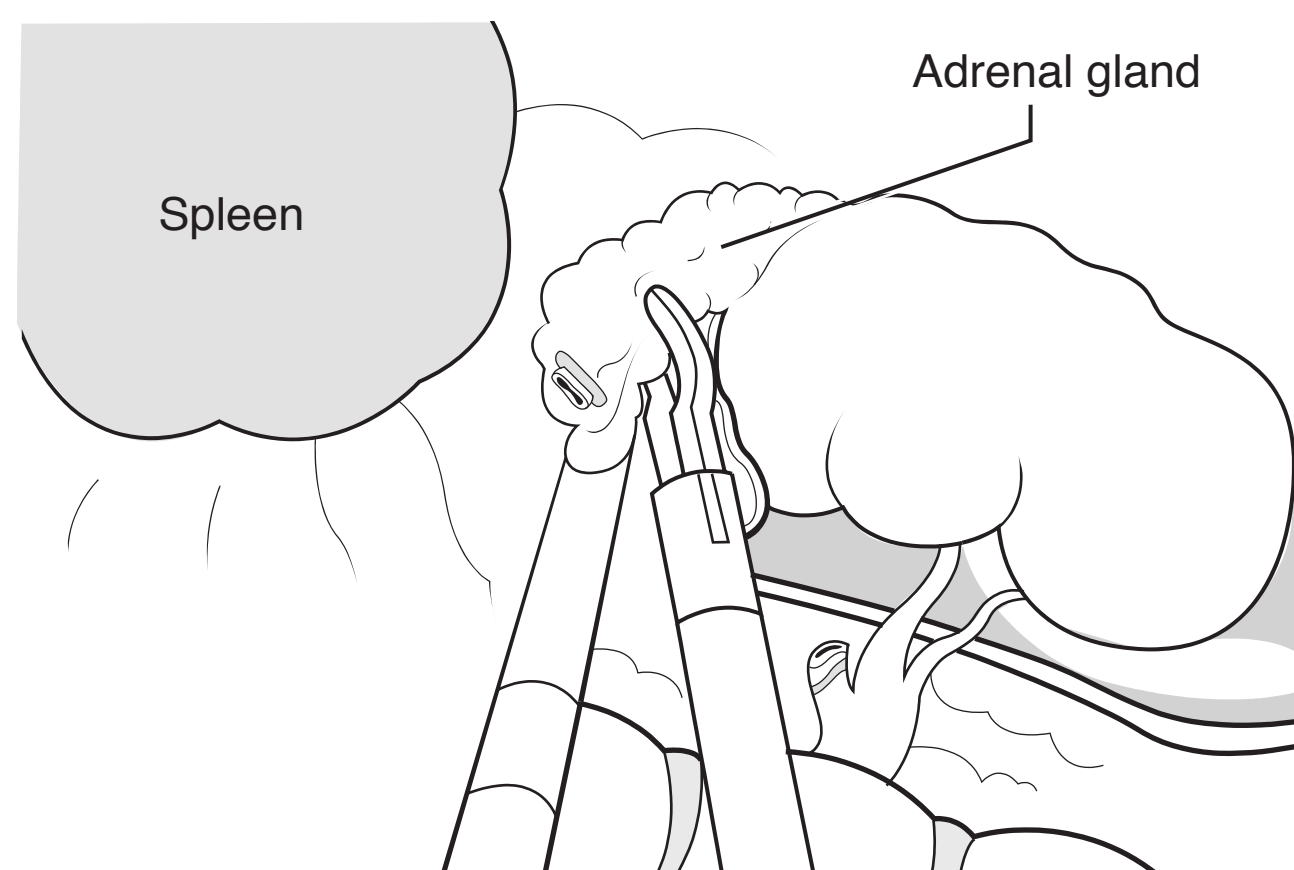

as described for the transperitoneal approach. The table is flexed to maximize the operative working space.

A 12-mm transverse skin incision is made at the tip of the twelfth rib. The flank muscles are split until the thoracolumbar fascia can be palpated (Fig. 130.9). The fascia is opened and a finger is inserted to allow digital dissection and to develop the retroperitoneal space. A balloon dilator is introduced

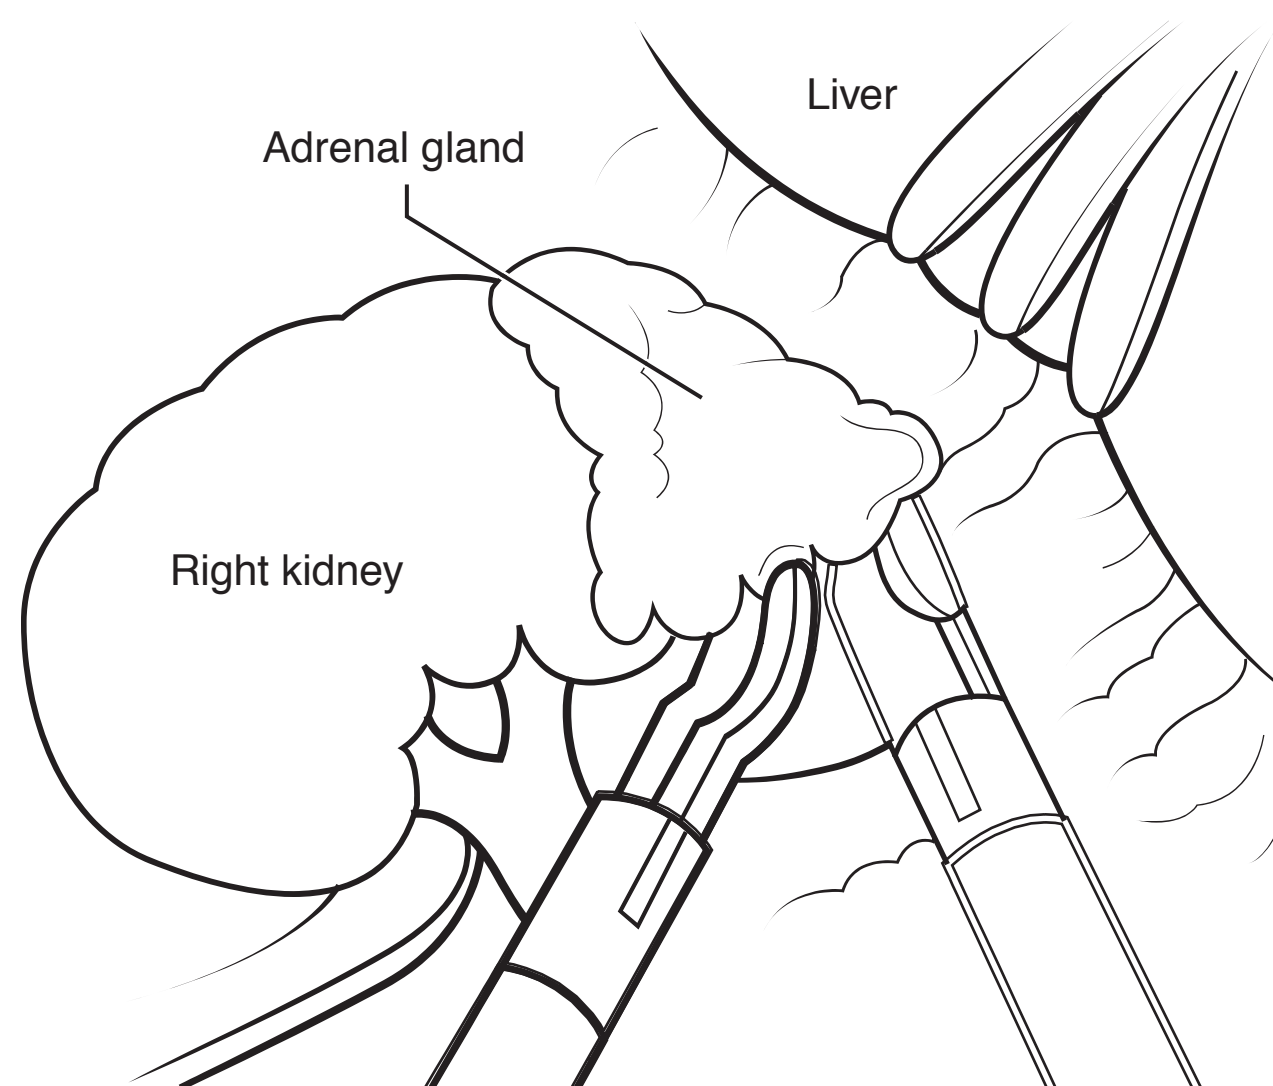

into the retroperitoneum and inflated to 800 cc. The dilator may then be repositioned more cephalad and reinflated to enable access/vision between the posterior adrenal outside the fascia of Gerota and the diaphragm (Fig. 130.10). The dilator is replaced with a balloon-tipped trocar and sealed against the abdominal wall, and CO<sub>2</sub> pneumoretroperitoneum is created to 15 mm Hg. Under direct laparoscopic visualization with a

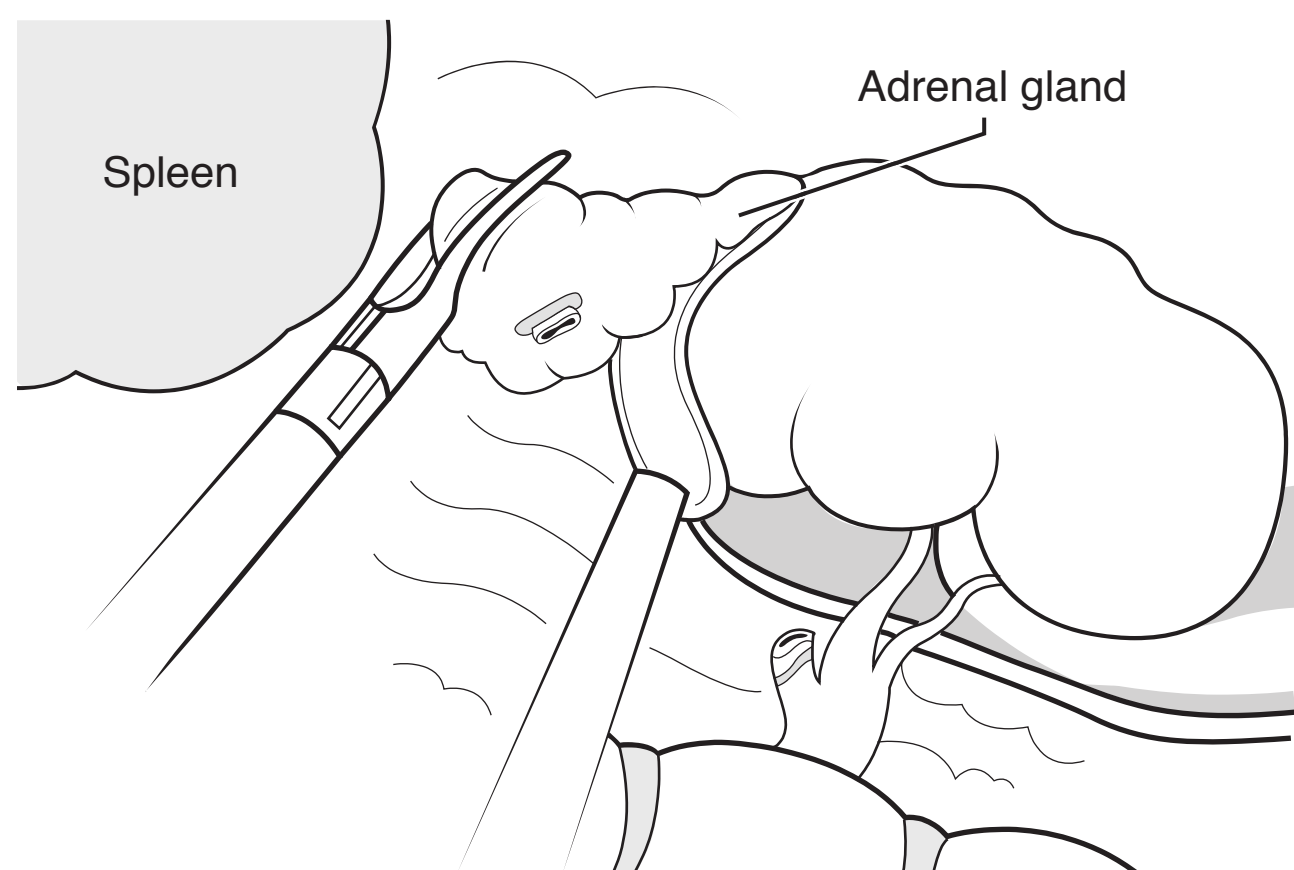

**FIGURE 130.5** Transperitoneal left adrenalectomy. The left adrenal vein is ligated with two clips on the side of the renal vein and sharply divided.

**FIGURE 130.6** Transperitoneal left adrenalectomy. The avascular plane between the adrenal and renal upper pole is developed, and care is taken to control the arterial contributions from the aorta, renal, and inferior phrenic arteries.

**FIGURE 130.8** Transperitoneal right adrenalectomy. After identification of the renal hilum, superior dissection along the inferior vena cava will demonstrate the short, horizontally lying adrenal vein.

**FIGURE 130.7** Transperitoneal left adrenalectomy. The freed specimen is placed in a laparoscopic retrieval bag and removed via the primary port site.

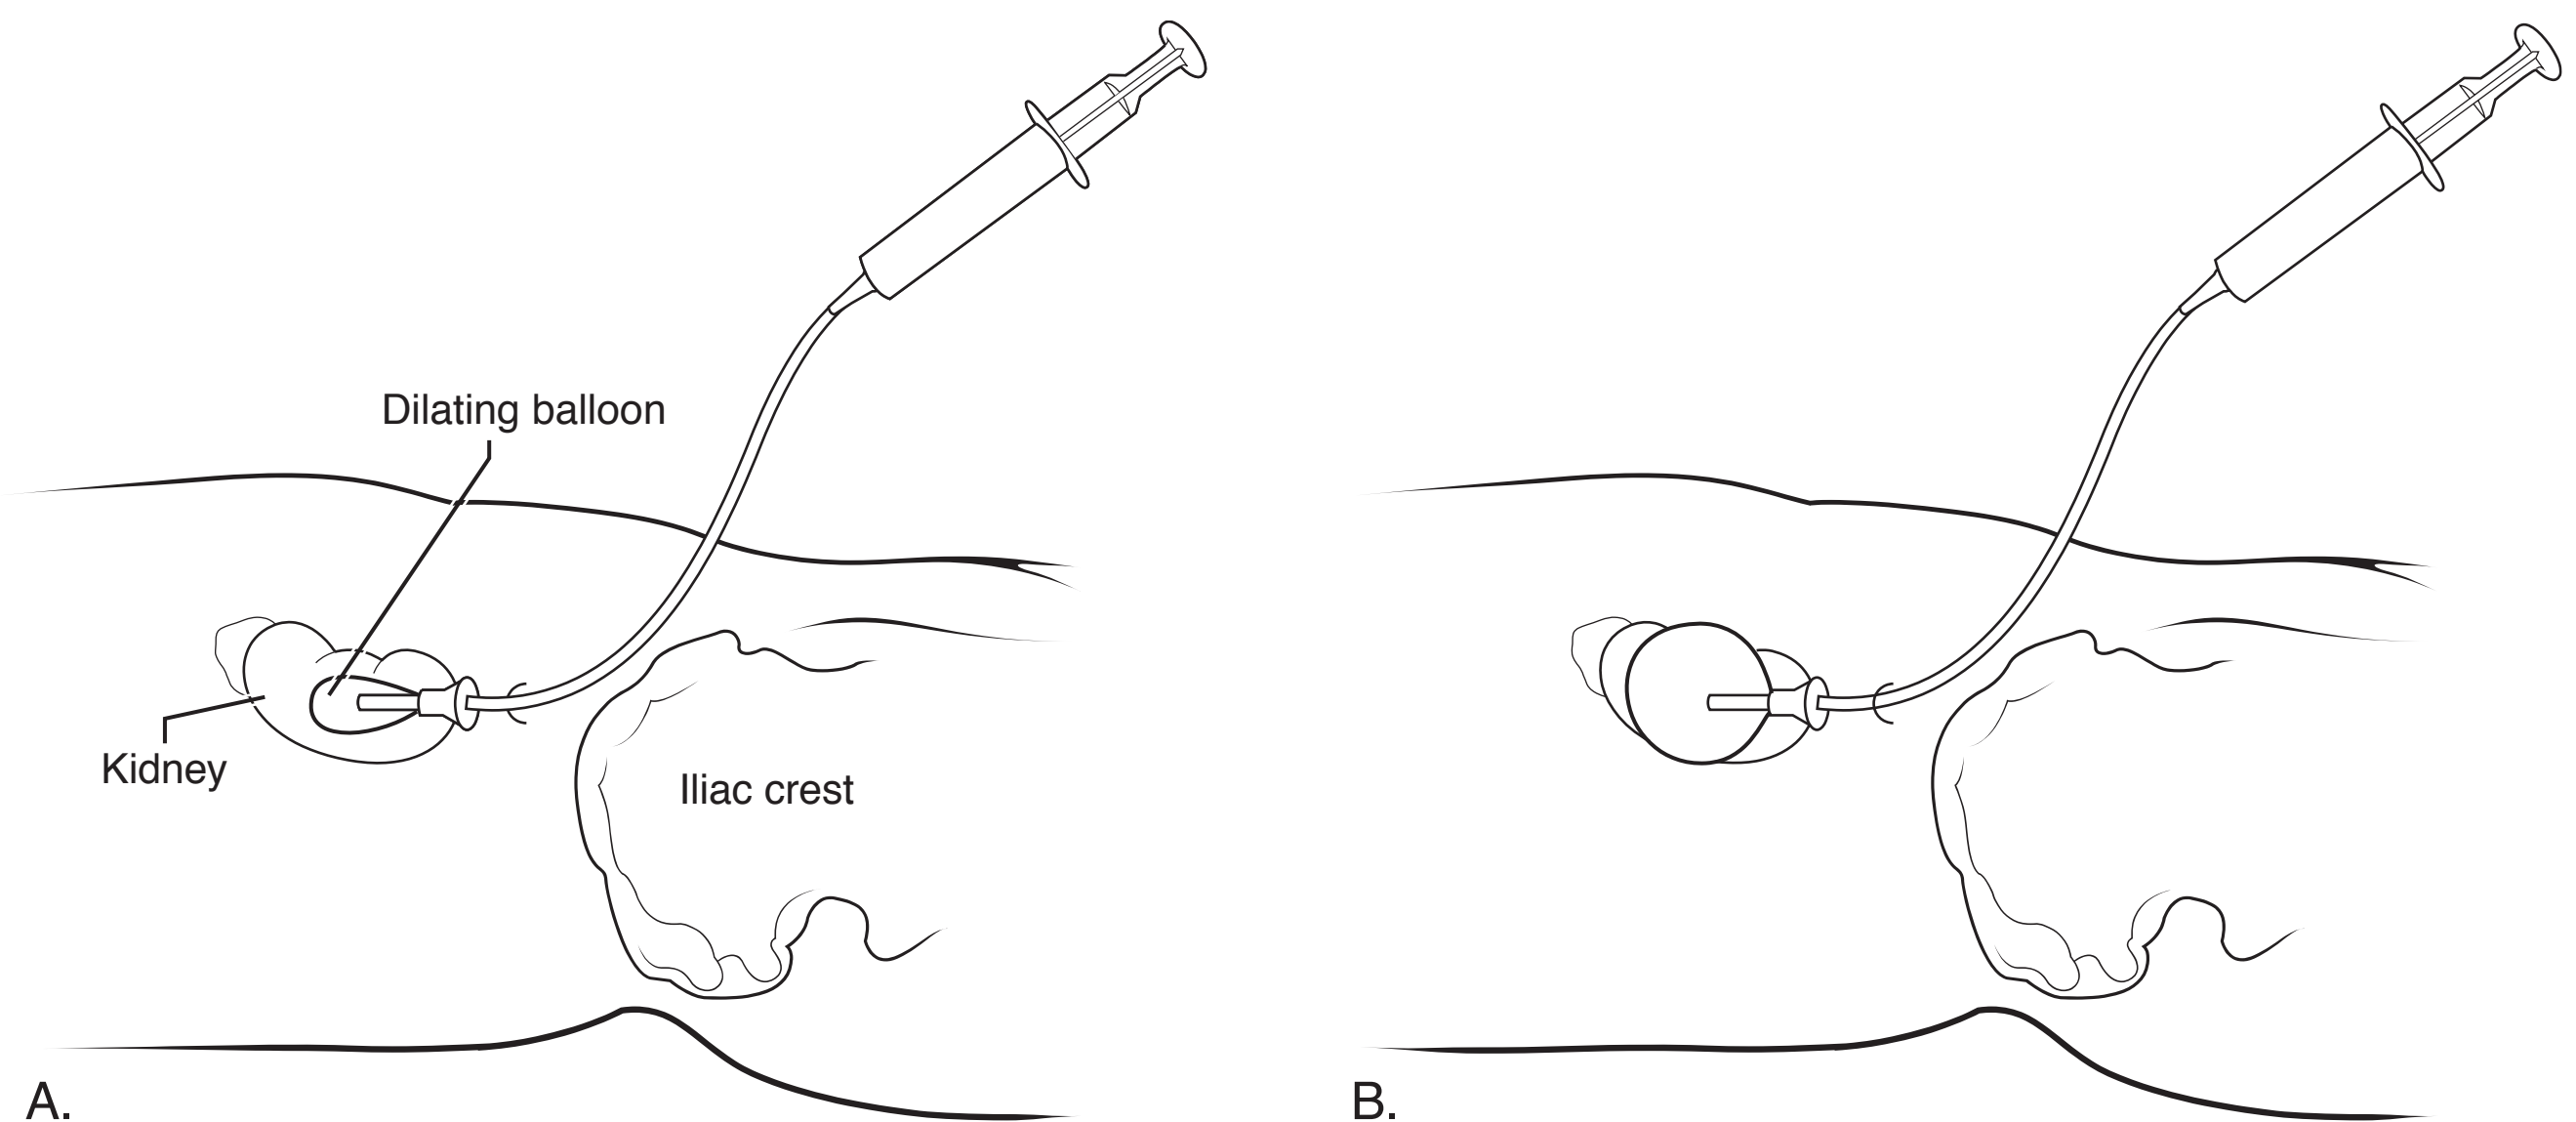

**FIGURE 130.9** Laparoscopic retroperitoneal adrenalectomy. Primary port placement is at the tip of the twelfth rib. Additional ports are placed under direct laparoscopic vision in the midaxillary line above the iliac crest and the inferior border of the twelfth rib, where it meets the paraspinal musculature.

30-degree lens laparoscope, an additional port is placed above the iliac crest in the midaxillary line. The final port is placed at the inferior border of the twelfth rib where it meets the paraspinal musculature. The anatomic landmarks are identified to ensure localization of the adrenal before mobilization is begun. These include the psoas muscle posteriorly, the fascia of Gerota anteriorly, and the diaphragm superiorly (Fig. 130.11). On the left side the pancreas lies medially, whereas in the right it is the liver. Pneumoretroperitoneum is subsequently maintained at 12 mm Hg for the remainder of the operation.

### Retroperitoneoscopic Left Adrenalectomy

An initial 1.5-cm incision is made transversely along the fascia of Gerota toward the renal upper pole with hook cautery. The perirenal fat is cleaned from the adjacent structures. The plane between the upper pole and adrenal gland is identified and developed with superior retraction of the adrenal and inferior

**FIGURE 130.10.** Laparoscopic retroperitoneal adrenalectomy. A balloon dilator is inserted into the retroperitoneum and inflated to 800 cc. It may be repositioned superiorly and reinflated to maximize exposure and working space before creation of CO<sub>2</sub> pneumoretroperitoneum.

**FIGURE 130.11.** Laparoscopic retroperitoneal adrenalectomy. Prior to incision of the fascia of Gerota, identification of the anatomic landmarks confirms adequate localization and access to the adrenal. On the right the liver lies medially, whereas on the left it is the tail of the pancreas.

retraction of the kidney. Dissection is continued medially toward the renal hilum, and exposure of the left renal vein facilitates isolation of the adrenal vein arising from the inferomedial border of the gland. The adrenal vein is clip-ligated with two clips on the side of the renal vein and divided. The adrenal is dissected free from the psoas posteriorly and the diaphragm superiorly with ligation of adrenal branches of the inferior

phrenic vessels, which may obscure the operative field if not controlled appropriately. Aortic branches arising medially are controlled in a similar fashion with the harmonic scalpel or hemostatic clips. The anterior surface of the adrenal is mobilized from the overlying peritoneum, and the free specimen can then be placed in a laparoscopic retrieval bag for removal via the primary port site.

---

## Retroperitoneoscopic Right Adrenalectomy

---

Initial access in retroperitoneal right adrenalectomy is similar to the left side. After incision of the fascia of Gerota and clearance of perirenal fat, the vena cava is readily visualized. Dissection is continued superiorly along the cava until the adrenal vein is encountered. The adrenal vein draining from the posteromedial portion of the gland is shorter and more horizontal than its left-sided counterpart and consequently should be approached with caution to avoid tearing. The vein is ligated and divided as previously described. The adrenal is then freed from its remaining attachments with meticulous control of multiple supplying vessels from the aorta, renal hilum, and inferior phrenic artery. Adrenalectomy is then completed as described on the left side.

---

## OUTCOMES

---

Numerous studies have illustrated the safety and efficacy of Endoscopic adrenal surgery. Laparoscopic surgery has produced excellent outcomes in hormonally active lesions. Adrenalectomy for aldosteronomas effectively reduces blood pressure in the majority of patients, with long-term cure in 33% to 60% of patients. Patients with subclinical Cushing syndrome showed improvement in glucose control, blood pressure, and obesity following laparoscopic adrenalectomy. Initial concerns regarding laparoscopic treatment of pheochromocytoma and complications which have potential to increase catecholamine release including pneumoperitoneum have been dismissed; one study even described a reduction in intraoperative hypertensive events (35% versus 63%) has been described (7). Controversy also exists regarding the laparoscopic treatment of adrenal malignancy. The increased incidence of malignant tumors >6 cm requires careful consideration in surgical approach. Small organ-confined lesions (<6 cm in size) are amenable to laparoscopic excision, but case reports in the literature have even described the feasibility of radical adrenalectomy with en bloc adrenal vein tumor thrombectomy. The current role of laparoscopic adrenalectomy must be tailored to each individual patient without compromising patient safety and ensuring optimal surgical technique with minimal complications (8).

There are several clinical benefits of performing laparoscopic versus open adrenalectomy. Assalia and Gagner (9) demonstrated reduced blood loss (154 versus 309 mL), complication rate (10.9% versus 35.8%), and hospital stay (2.9 versus 7.2 days) when comparing laparoscopic and open surgeries. Additionally this study demonstrated that laparoscopic surgery utilized less analgesia and had improved cosmesis. These key characteristics translate into increased patient satisfaction as compared to open surgery. Operative times for laparoscopic adrenalectomy are generally longer; this is largely dependent on surgeon experience and has been shown to equilibrate with increased number of cases completed (10). The transperitoneal approach is more often employed by urologists due to familiarity with laparoscopic technique and anatomic landmarks. A prospective randomized study by Rubenstein et al. (11) showed no significant disparity in perioperative morbidity or operative time, emphasizing that the choice of laparoscopic approach lies primarily with the surgeon's comfort with the procedure coupled with the clinical characteristics of the individual case.

---

## Complications

---

The largest meta-analysis of complications in laparoscopic and open adrenalectomy, by Brunt (12), reported overall complication rates of 10.9% and 25.2%, respectively. Bleeding was the most common complication associated with laparoscopic surgery. Organ injury, including splenic injury requiring splenectomy and pancreatic, diaphragmatic, and large bowel injury, was also decreased. The greatest reduction in morbidity was seen in the incidence of wound (0.6% versus 3.1%), pulmonary, and infectious complications. Thromboembolic phenomena were predominant in obese patients and those with prolonged operative times. The mean conversion rate to open surgery was 3.6%; conversion was most often secondary to intraoperative bleeding, although large tumor size, adhesions, and malignancy with local invasion were also commonly cited reasons. The mean combined mortality rate for laparoscopic adrenalectomy in an analysis of 2,550 cases was 0.2%, and though slightly less than open surgery, the difference has not proven significant. Patients undergoing adrenalectomy for hormonally active tumors must be followed carefully postoperatively, as contralateral adrenal suppression can result in metabolic derangements requiring replacement of electrolytes, mineralocorticoids, or glucocorticoids.

# CHAPTER 131 ■ LAPAROSCOPIC AND ROBOTIC RADICAL PROSTATECTOMY

COSTAS D. LALLAS AND EDOUARD J. TRABULSI

The driving force behind the development of a minimally invasive radical prostatectomy was certainly patient satisfaction and quality of life. Accordingly, the first laparoscopic radical prostatectomy (LRP) was performed in 1991 (1). Although the benefits to the patient were readily apparent for LRP, the technical challenges and difficult learning curve were also broadly recognized, paving the way for a facilitator for this procedure: robotic technology.

Robotically assisted laparoscopic (radical) prostatectomy (RALP) has made an enormous, albeit controversial, impact on the treatment of prostate cancer. Although different robotic platforms have been described in the literature, the da Vinci Surgical System (Intuitive Surgical, Sunnydale, CA) has quickly monopolized the market. Like other robotic surgical systems, the da Vinci system operates in a master-slave relationship with the surgeon, with motions being translated in a filtered, nonparadoxical fashion. The surgeon sits remotely from the surgical field but does require an assistant at the bedside for instrument changes, retraction, and suction. The setup is ergonomic, and unlike with the physically taxing LRP, most surgeons can easily accomplish multiple RALPs in a given day. Other direct advantages of RALP over LRP include more degrees of freedom of motion, enabled by wristed instruments, as well as nonparadoxical versus paradoxical movements and three-dimensional versus planar, two-dimensional visualization. To date, four different generations of the da Vinci system have been released, with the latter three having four arms (as opposed to three) and the latest model boasting telestration, which aids in teaching and proctoring, and high-definition visualization.

Opponents to RALP consistently cite the market- and patient-driven acceptance of this procedure without any long-term follow-up. Additionally, some maintain that the lack of tactile feedback afforded by the minimally invasive prostatectomy is disadvantageous when evaluating for induration, palpable nodules, and delineation of the proximity or involvement of the neurovascular bundles by cancer. Finally, several believe that the cost of RALP places it at a distinct disadvantage relative to other, more traditional approaches. At our institution, we have completely converted over from LRP, the last of which we performed 3 years ago, to RALP, with the relative ease and consistently positive patient outcomes of the latter procedure being the main reasons. Since RALP stands firmly on the shoulders of LRP, we describe both procedures, with particular focus on our technique and published outcomes of RALP.

---

## DIAGNOSIS

---

Adenocarcinoma of the prostate is typically diagnosed through routine medical screening, which includes a digital rectal examination and a test for serum prostate specific antigen (PSA). An abnormal digital rectal examination, elevated PSA level, or PSA velocity should prompt a transrectal ultrasound-guided biopsy of the prostate. Once the diagnosis of cancer is made, the patient should undergo appropriate staging preoperative counseling, and treatment options should be thoroughly discussed.

A computerized tomography of the abdomen and pelvis and a radioisotope bone scan are traditionally performed on all patients who are evaluated for prostate cancer. These studies have been questioned for patients with low-risk features. MRI with endorectal coil is performed in some centers for local staging but is not widely used.

---

## INDICATIONS FOR SURGERY

---

Men with clinically localized prostate cancer who choose surgical treatment are candidates for this procedure. All patients who are evaluated for prostate cancer at our institution are evaluated in a multidisciplinary setting with urologic oncology, radiation oncology, and medical oncology (2). Preoperative tumor parameters are inputted into the Kattan preoperative nomogram to evaluate for risk of extracapsular extension, seminal vesicle invasion, and metastatic disease. Once patients have chosen RALP, they are medically cleared if deemed necessary and their bladder outlet and ureteral orifice location is evaluated by cystoscopy. Patients are excluded if their life expectancy is  $<10$  years or their American Society of Anesthesiologists (ASA) score is  $>4$ , indicating that they have severe comorbidities. Morbid obesity (Body Mass Index  $>45$ ) is a relative contraindication, as these patients may not be able to tolerate Trendelenburg positioning with pneumoperitoneum for an extended period of time. Previous radiotherapy for pelvic malignancy is a contraindication for RALP or LRP. Prior intra-abdominal surgery is not a contraindication, but patients who have undergone prior pelvic procedures or extensive intra-abdominal surgery are counseled that their likelihood of conversion to standard open radical retropubic prostatectomy is elevated. Nerve-sparing or non-nerve-sparing technique is based on the surgeon's preference, which is based on the clinical parameters of the individual patient.

---

## ALTERNATIVE THERAPY

---

Treatment options for clinically localized prostate cancer include observation, brachytherapy, external beam or proton radiation therapy, cryotherapy, and radical prostatectomy. Radical prostatectomy includes retropubic, perineal, laparoscopic, and robotically assisted laparoscopy.

---

## SURGICAL TECHNIQUE

---

The steps involved in the pure laparoscopic and robotically assisted radical prostatectomy employing the more popular transperitoneal approach are quite similar. One of the most significant differences is the use of robotic instrumentation versus the use of standard laparoscopic instruments. Critical to the success of these procedures is a well-trained and coordinated operating room staff with familiarity of the instruments and devices needed for these complex procedures.

On the day prior to surgery, patients are placed on a clear liquid diet and are given a gentle mechanical bowel preparation with one bottle of oral magnesium citrate as well as a Fleet enema per rectum. Two large-bore intravenous lines and an arterial line, if necessary, are placed. A broad-spectrum

A

B

**FIGURE 131.2** Port placement for laparoscopic prostatectomy. Five ports are utilized.

intravenous antibiotic (cephalosporin such as Ancef) is given 1 hour prior to incision, and all patients receive Lovenox 40 mg subcutaneously prior to surgery for venous thromboembolism (VTE) prophylaxis. Once intubated in the operating room, patients are placed in a low lithotomy position using Allen stirrups. The arms are tucked at the patient's side using 3-in. cloth tape, and the patient's shoulders, elbows, wrists, and neck are padded (Fig. 131.1). An orogastric tube is placed, and the anesthesia staff are also instructed to limit the intravenous fluids given, to avoid overresuscitation. Typically, we recommend 7 mL per kg intravenous fluids per hour for the entire case (approximately 500 mL per hour or 1.0 to 1.5 L per case.

---

### Laparoscopic Prostatectomy (LRP)

---

After a pneumoperitoneum has been established, five trocars are placed. The first 12-mm trocar is placed at the level of the umbilicus (Fig. 131.2). This can be placed by using an optical port, employing an open technique, or gently applying pressure to the 12-mm trocar and introducing it into the abdomen. We use a 0-degree lens throughout the procedure and inspect the abdominal cavity after placement of our first trocar. Our next two 12-mm trocars are placed just lateral to the rectus on the right-hand and left-hand sides, respectively. These 12-mm trocars are placed 2 to 4 cm inferior to the umbilicus. Finally, two 5-mm trocars are placed off the anterior iliac spine on the right-hand and left-hand sides, respectively. Thus a total of five ports are utilized throughout the procedure (Fig. 131.1). The patient is now placed into extreme Trendelenburg position.

If available, the Aesop (Computer Motion, Inc., Goleta, CA) is placed on the right side of the table and controls the 0-degree laparoscope and camera through the umbilical port. Otherwise the assistant holds the camera. The assistant stands on the right side and the surgeon stands on the left. A fan retractor is useful in the right 12-mm port to retract the bowel. The cul-de-sac and the vas deferens are identified on both the

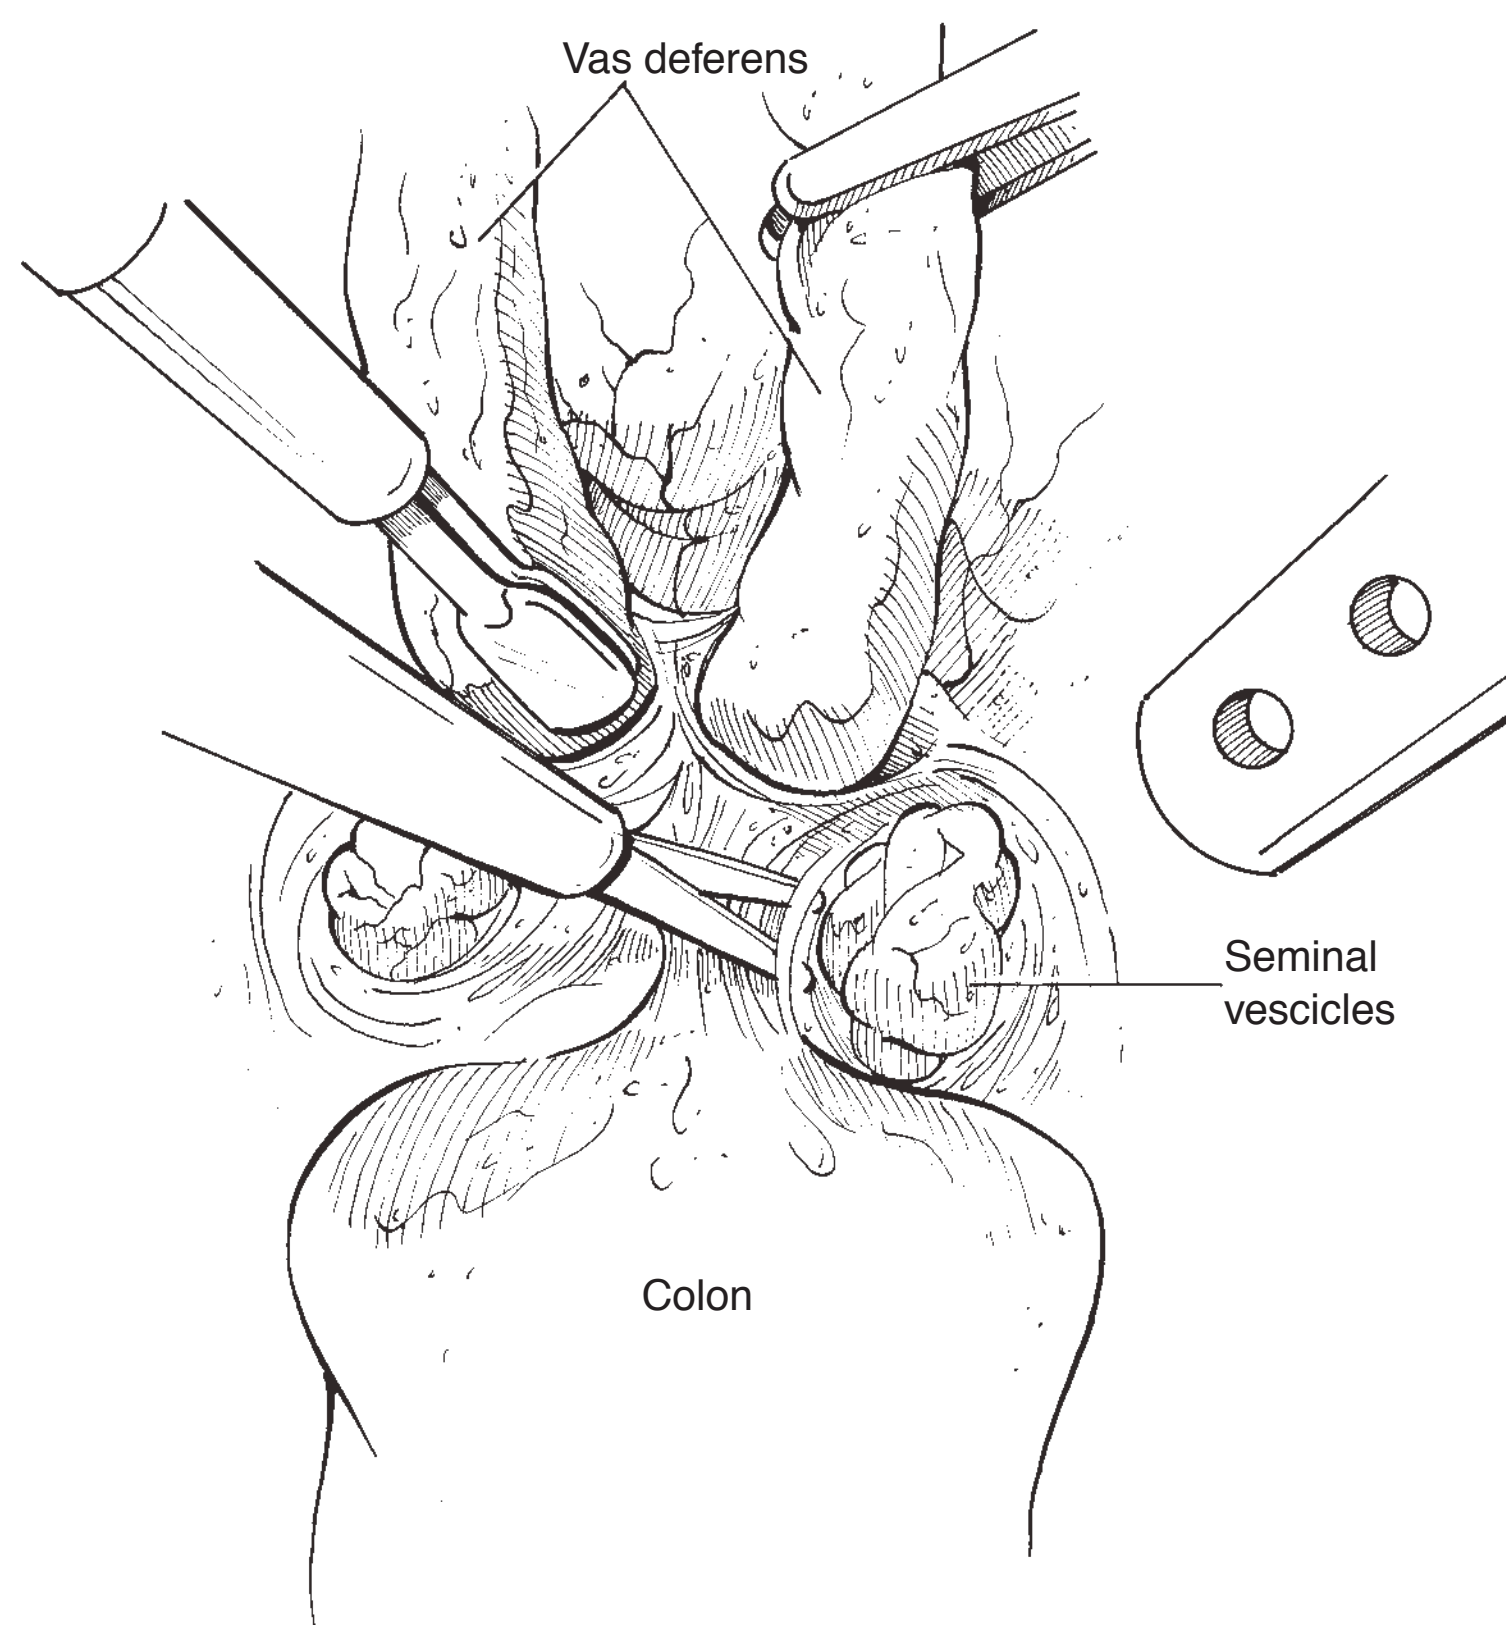

**FIGURE 131.3** Scoring the peritoneum along the vas deferens into the cul-de-sac.

right- and left-hand sides at the level of the internal ring. The peritoneum is scored in a line along the vas deferens down to the cul-de-sac (Fig. 131.3). This incision is carried down to the second peritoneal fold in the cul-de-sac, and the vas deferens is

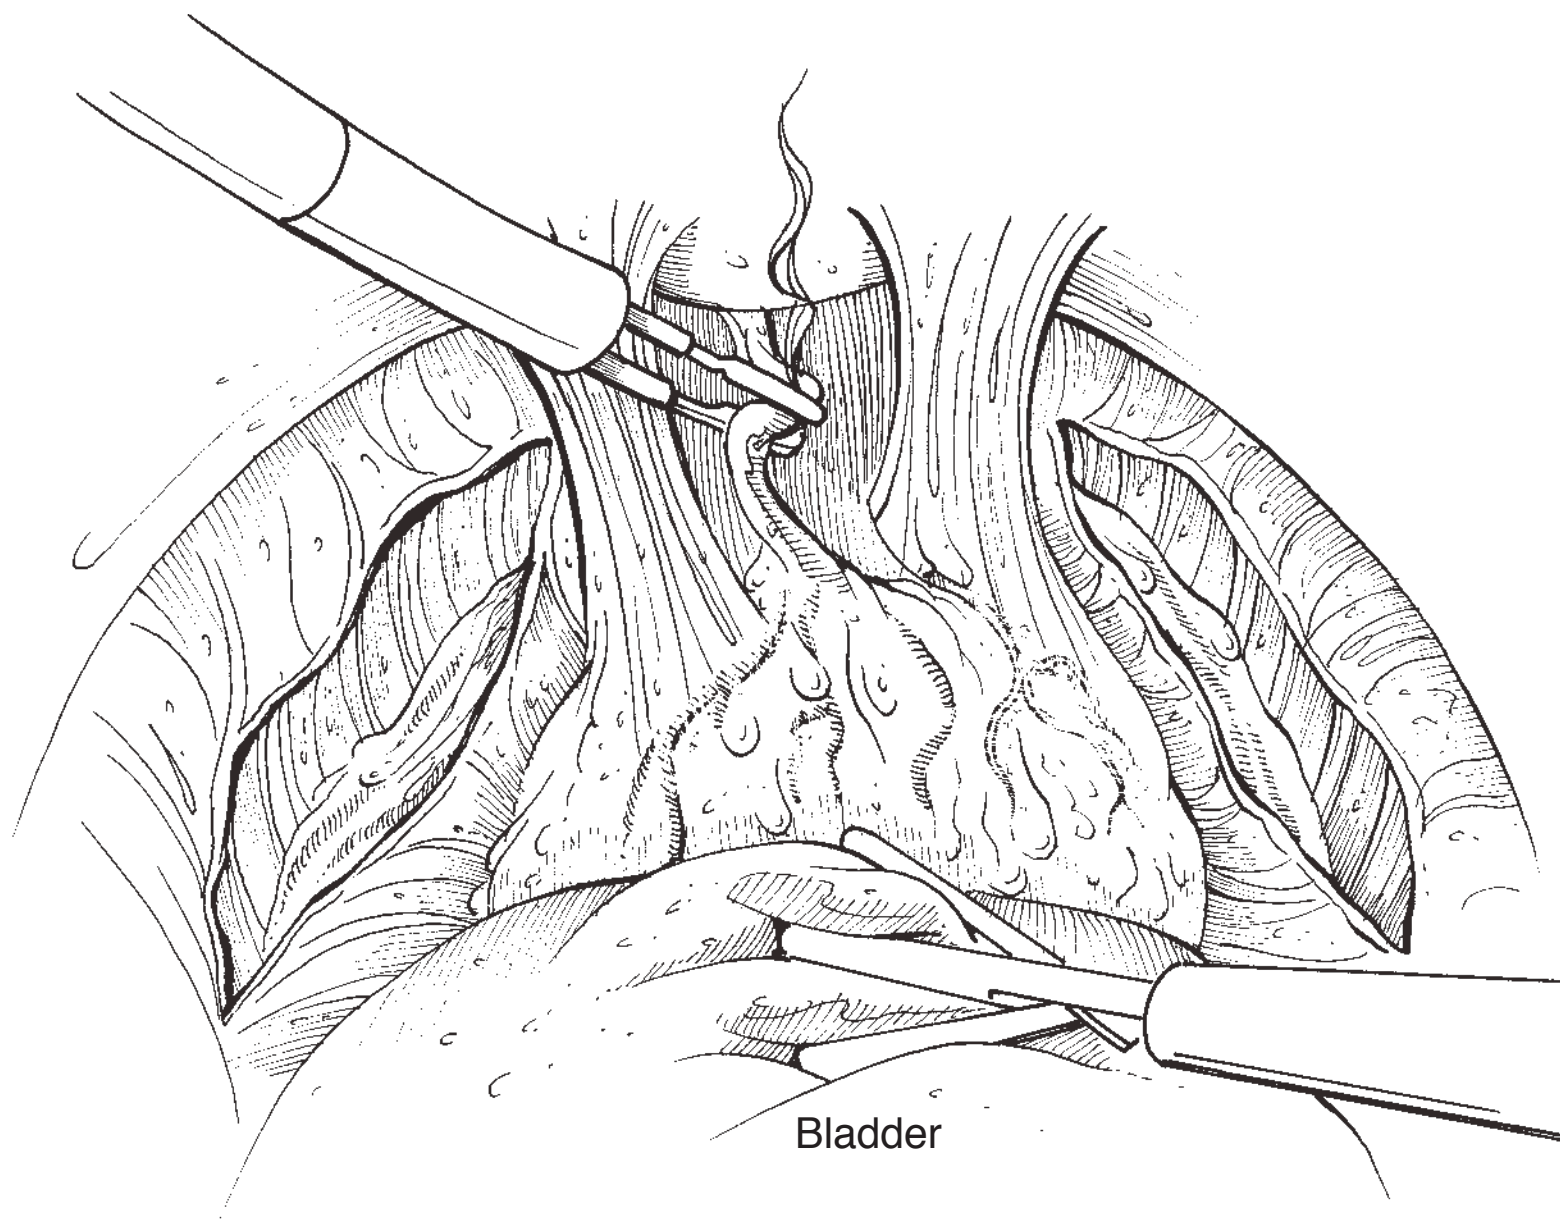

skeletonized bilaterally down to the seminal vesicles. The vas is pulled anteriorly with a grasper through the 5-mm right-sided port (Fig. 131.4), and the assistant uses the irrigator-aspirator through the 12-mm right-sided port. The seminal vesicles are dissected using a combination of sharp and blunt dissection to their tips (Fig. 131.4). With retraction on the seminal vesicles, the Denonvilliers fascia is incised to create a plane between the prostate and rectum. The perirectal adipose tissue should be clearly identified. A rectal bougie can be manipulated to confirm the exact location of the rectum.

The bladder is filled with 200 cc of saline, and using the bipolar cautery and laparoscopic scissors through the left-sided ports, the lateral aspect of the bladder is dissected off the anterior abdominal wall by connecting the points between the incised median and umbilical ligaments and the lateral peritoneal reflection (Fig. 131.5). The bladder is emptied and now has been mobilized. The endopelvic fascia is incised bilaterally, the fatty tissue overlying the prostate is dissected with bipolar cautery, and the superficial dorsal vein is cauterized using the bipolar forceps (Fig. 131.5). The puboprostatic ligaments are sharply divided. The deep dorsal vein complex is ligated with a CT-1 needle loaded with 0 Vicryl suture. The needle is slightly straightened before being passed through the right 12-mm port on a laparoscopic needle driver. A laparoscopic grasper is used from the left 12-mm port site. The dorsal vein complex is identified, and a suture is passed around it with a figure-of-eight suture passed anterior to the urethra and posterior to this deep venous dorsal complex (Fig. 131.6). The suture is tied intracorporeally, and the dorsal vein complex is secured but not divided at this point.

The prostatic base is divided from the bladder neck and is a more challenging part of the procedure. A coagulating scissor

**FIGURE 131.4** The vas deferens is lifted anteriorly by the assistant and the seminal vesicles are dissected free.

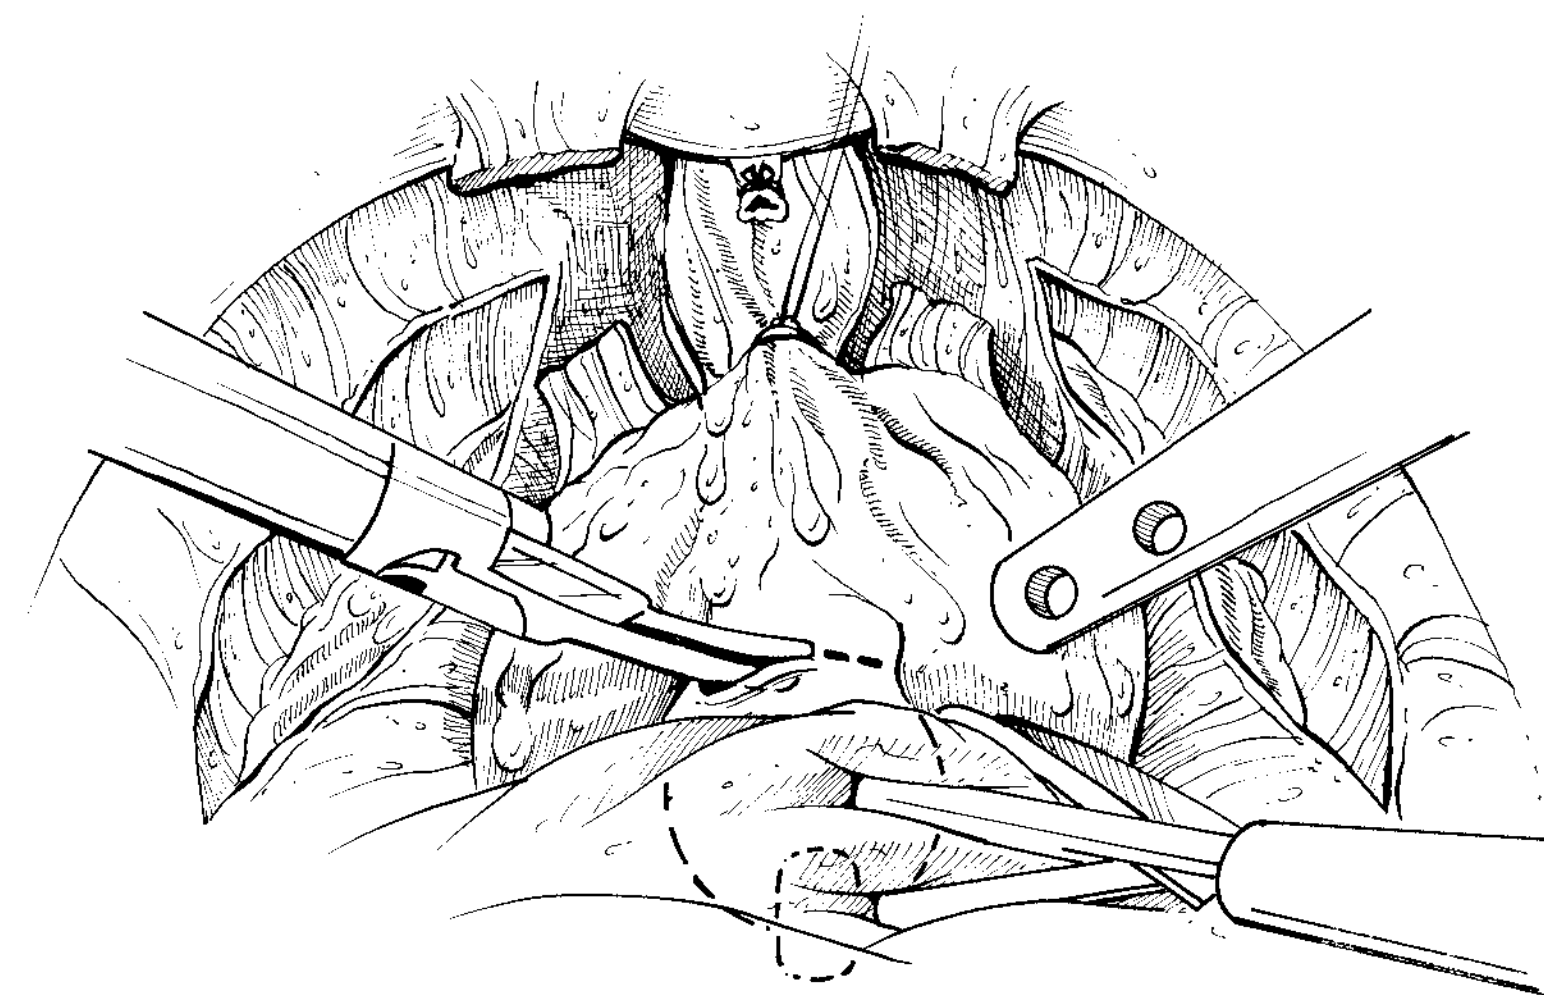

**FIGURE 131.5** The bladder is freed off the anterior abdominal wall by incising the umbilical ligaments and lateral attachments.

**FIGURE 131.6** The endopelvic fascia is incised and the dorsal vein complex identified. The deep dorsal vein complex is ligated using a 0 Vicryl suture on a CT-1 needle.

or curved harmonic scalpel can be used. The assistant retracts the bladder from the right 12-mm port and, using a 5-mm irrigator-aspirator, outlines the Foley catheter balloon down toward the level of the prostatic base. The prostatic base is divided from the bladder neck (Fig. 131.7). The detrusor fibers are often seen, and bladder is entered and the Foley identified. The balloon is deflated, and the assistant retracts the Foley catheter cephalad using a grasper from the right 5-mm port site (Fig. 131.8). The posterior bladder mucosa is scored and carried through the posterior surface of the prostate (Fig. 131.9). The seminal vesicles and vas previously dissected are brought anteriorly and grasped by the assistant using the laparoscopic 5-mm grasper.

If a nerve-sparing approach is attempted, a right-angled dissector with sharp dissection as needed can be used through the right 12-mm port site to free the neurovascular bundle on the lateral surface of the prostate prior to dividing the dorsal venous complex. The assistant lifts the seminal vesicle anteriorly, and the vascular pedicle can be divided with the harmonic

**FIGURE 131.7** Division of the anterior bladder neck and prostatic base using the harmonic scalpel.

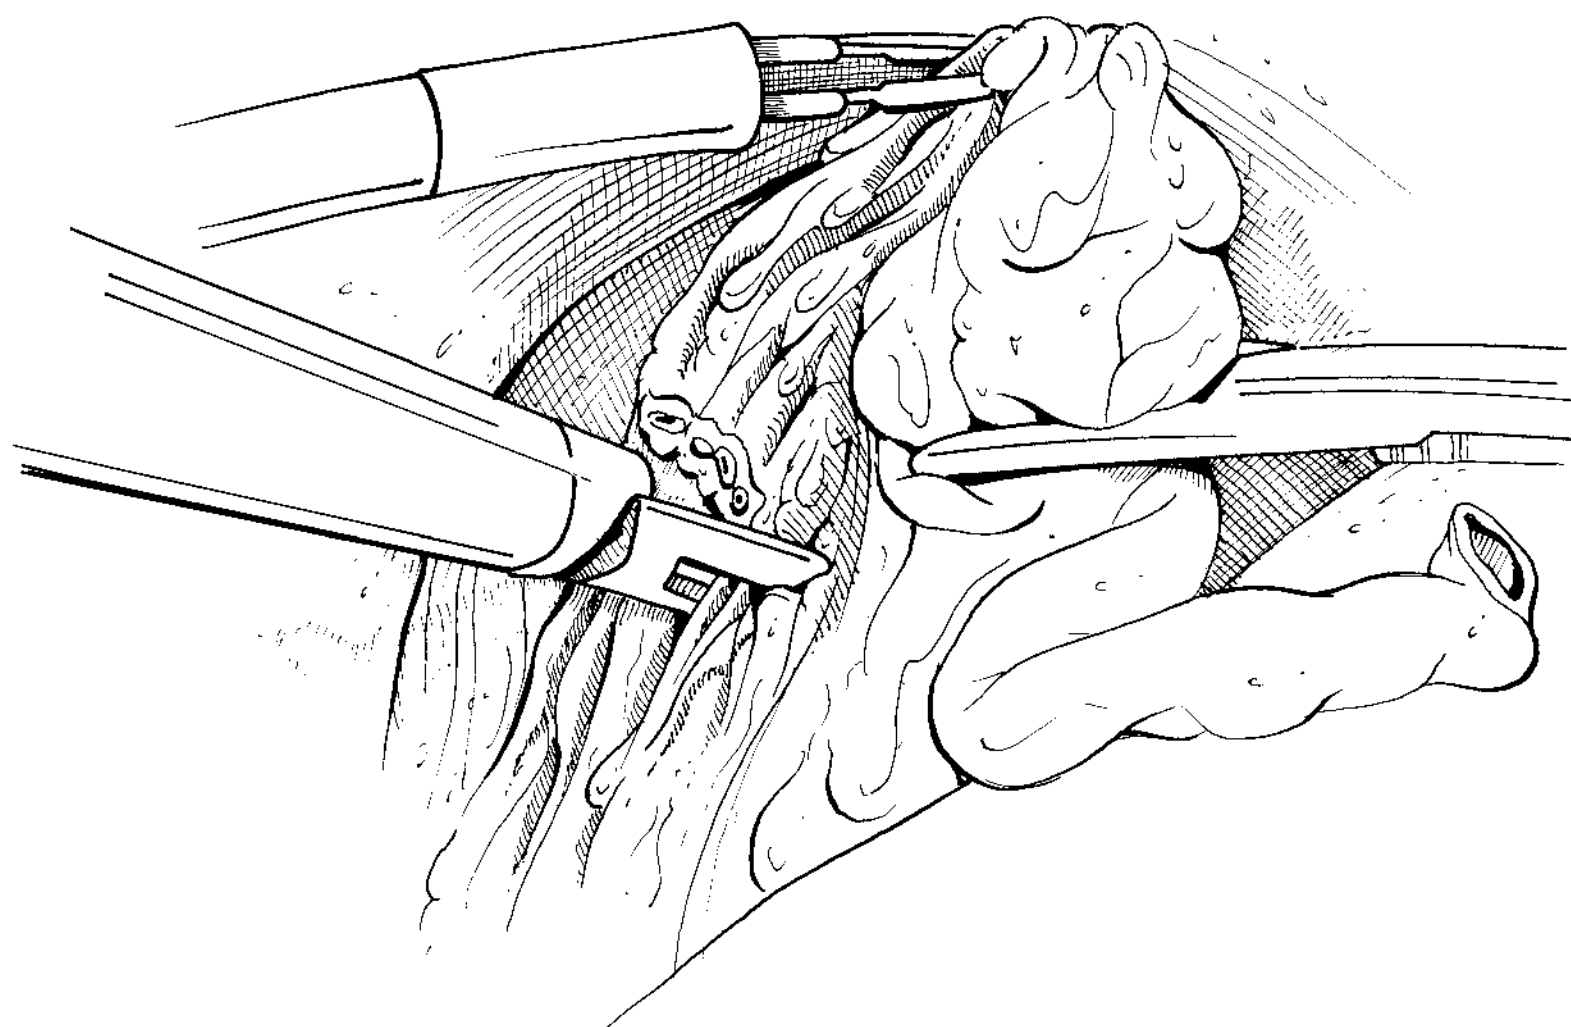

**FIGURE 131.8** The Foley catheter is grasped and the dissection of the bladder neck continues posteriorly.

scalpel or locking clips. Sharp dissection frees the remaining reflection of endopelvic fascia of the prostate laterally (Fig. 131.10).

With a non-nerve-sparing technique, the assistant grasps the seminal vesicle, lifting anteriorly, and the surgeon divides the entire vascular pedicle and neurovascular bundle with the harmonic scalpel, working toward the apex of the prostate.

The prostate is attached posteriorly by the rectourethralis muscle and the urethra. The dorsal vein complex is sharply incised and the apical notch of the prostate developed. The anterior urethra is now sharply divided, exposing the catheter, which is retracted, and the posterior urethra is divided (Fig. 131.11). The assistant provides cephalad retraction by grasping the base of the prostate in order to allow maximum exposure of the urethra. The rectourethralis muscle is sharply

**FIGURE 131.10** Sharply dissecting the neurovascular bundle of the lateral aspect of the prostate.

**FIGURE 131.9** Division of the posterior bladder neck and identification of the previously dissected seminal vesicles and vas deferens.

incised, and the prostate can be rolled to both the left- and right-hand sides to facilitate the exposure. The specimen having been placed into the left lower quadrant, the pelvis is irrigated and any bleeding controlled.

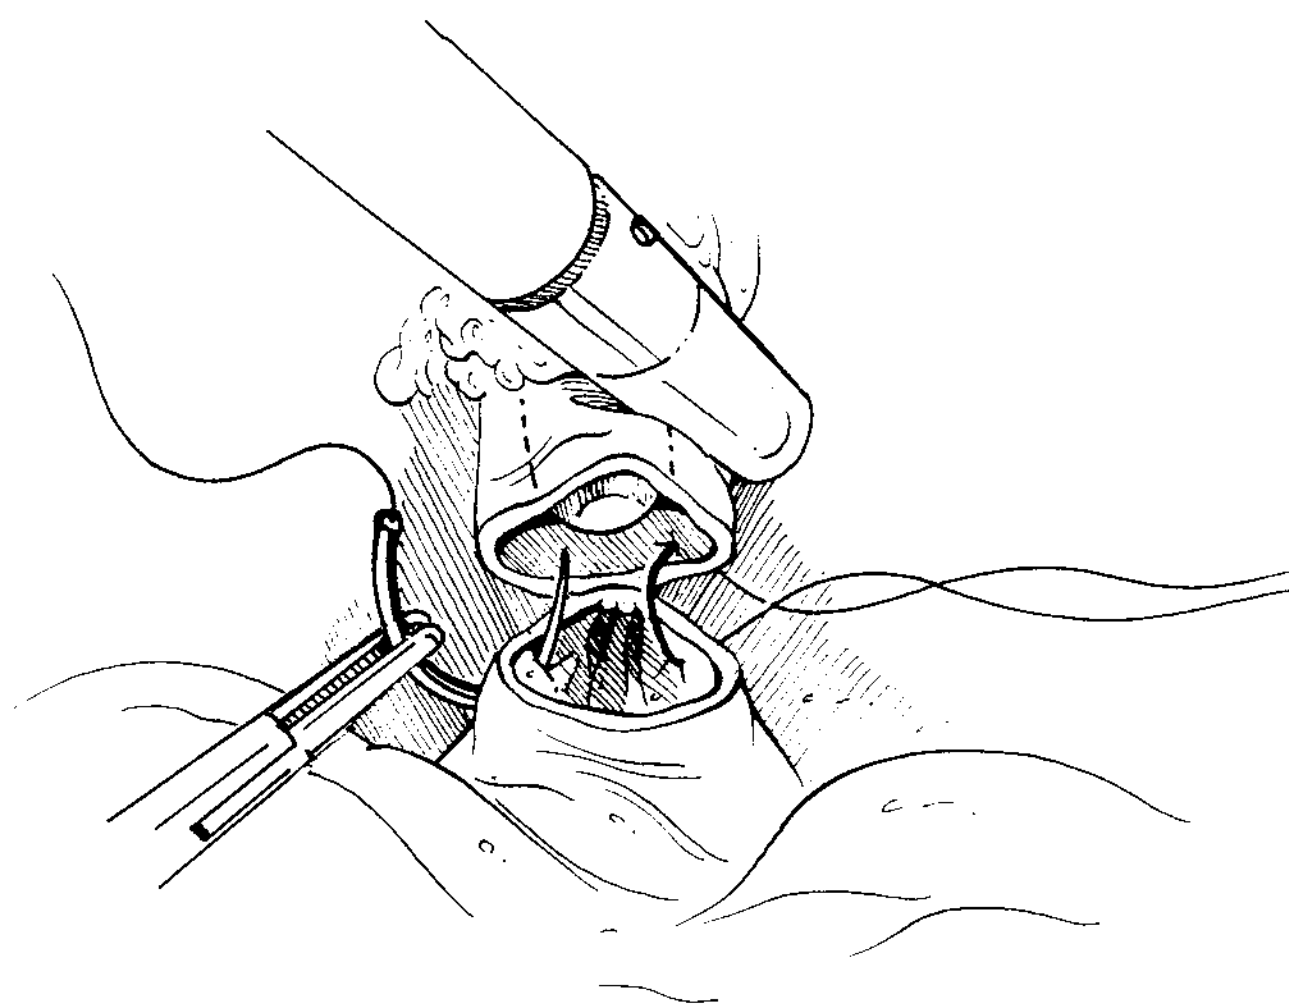

If there are concerns about the location or injury to the rectum, a rectal bougie is useful. If necessary, a 20Fr Foley catheter can be placed in the rectum and the pelvis filled with saline. Air is injected into the Foley catheter to identify any injury.

The bladder neck is identified, and the ureteral orifices are observed for efflux of urine. A urethral sound is placed, and apical margins may be sent for frozen section if needed. The urethrovesical anastomosis is begun (Fig. 131.12). Bladder neck reconstruction can be performed anteriorly using a 2-0 Vicryl suture on a UR-6 needle, and the bladder neck can be reconstructed by placing a suture through the anterior portion of the bladder neck in interrupted fashion.

Using a 2-0 Vicryl suture on a UR-6 needle through the right 12-mm port, the anastomosis is begun by placing a stitch through the posterior bladder neck from outside the bladder. The needle is grasped, and, using the right 12-mm port, the

**FIGURE 131.11** Division of the anterior urethra.

**FIGURE 131.12** Urethral anastomosis beginning with the posterior sutures.

posterior stitch on the right side of the urethra is placed. Next, a second suture is introduced through the left 12-mm port, and, in similar fashion, the posterior bladder neck is sutured outside-in followed by the posterior urethra inside-out. Thus the knots are tied on the outside of the bladder. Alternatively, the two-armed suture technique as described for robotic prostatectomy using two 3-0 Monocryl sutures tied together can be used (see below). The table is reflexed and the bladder is reapproximated to the urethra. The posterior bladder can be grasped from the right side and held in place while the sutures are tied intracorporeally.

The anastomosis is completed. Using the 2-0 Vicryl suture, the sutures are placed circumferentially from either the right or left 12-mm port as determined by the patient's anatomy. Occasionally, it is necessary to place a back-handed suture from the left-sided 12-mm port. The sutures are tied intracorporeally. The remaining anterior sutures can be placed. Typically, the left-sided anterior bladder neck and the urethral sutures are placed through the right 12-mm port and vice versa. This allows more effective needle positioning. A new

18Fr to 20Fr Foley catheter is placed under direct visualization prior to completing the anastomosis, and the final anterior sutures are tied intracorporeally. The bladder is tested by instilling 60 cc of saline, and if a leak is detected, another suture can be placed. Generally seven to eight sutures are used for the urethrovesical anastomosis. The right 5-mm port site incision is extended to accompany a 10-mm Endocatch device (Auto Suture, Norwalk, CT). After the Endocatch is deployed, the accompanying needles and prostate with accompanying seminal vesicles and vas deference are delivered into the bag. The bag is closed and brought through the right 5-mm port site. The external oblique fascia and muscle are incised with electrocautery and the bag removed. This small incision is closed, the abdomen is reinsufflated, and then a Jackson-Pratt drain is placed through the left 5-mm port. Ports are closed in standard fashion and the Foley is left to gravity.

### Robotically Assisted Laparoscopic Prostatectomy (RALP)

Pneumoperitoneum is established up to a pressure of 15 mm Hg in a midline supraumbilical location, and a 12-mm trocar is placed at this site. After blind placement of the midline camera trocar (12 mm), an additional 12-mm, three 8-mm, and one 5-mm port are placed under direct vision in the patient's lower abdomen and pelvis. The initial 12-mm port is always placed 1 to 2 cm cephalad to the umbilicus. Two 8-mm robotic working ports are placed at the apex of a triangle that is 10 cm lateral to the top of the umbilicus and 15 cm from the pubic symphysis. The third 8-mm robotic working port is placed at least 8 cm laterally from the one on the patient's left-hand side, and it must be at least two fingerbreadths off of the anterior superior iliac spine. The 12-mm assistant port is placed at least 8 cm laterally from the 8-mm robotic working port on the patient's right-hand side, and it must be at least two fingerbreadths off of the anterior superior iliac spine, mirroring the 8-mm port on the contralateral side. The 5-mm assistant port is placed 5 to 6 cm directly cephalad to the 8-mm robotic working port (Fig. 131.13). Prior to docking the robot, the patient is placed in a steep Trendelenburg position.

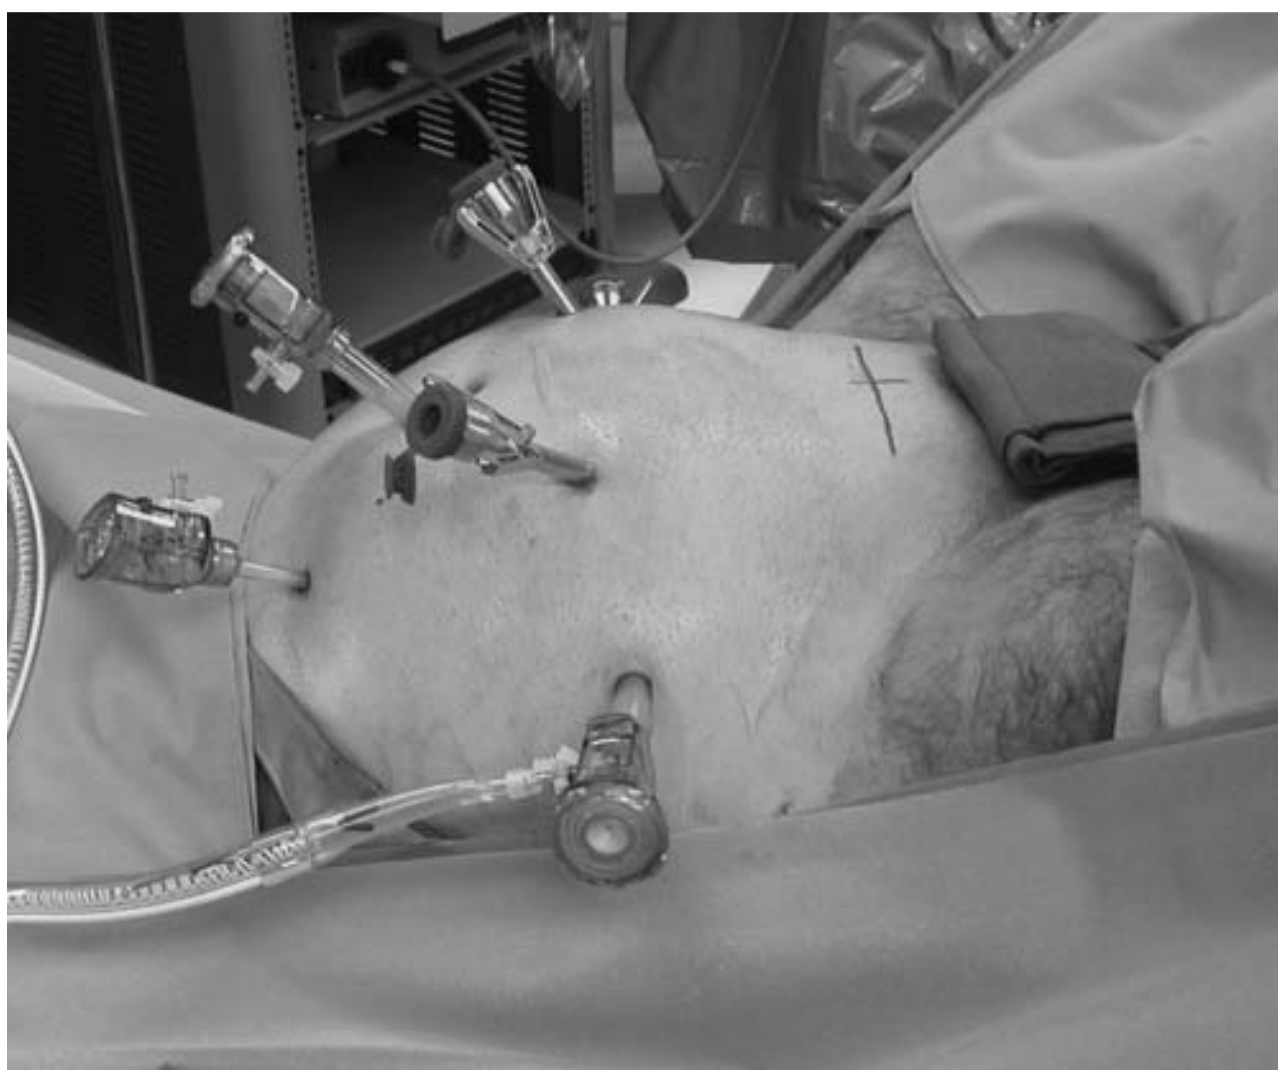

Once the robot is docked, instruments are next inserted into the patient and connected to the robot (Fig. 131.14). Both a monopolar and a bipolar electrocautery instrument are used concomitantly, and the fourth arm (if available on the robot) is equipped with a grasping forceps. A 0-degree lens is used for the entire procedure.

The initial report of LRP described an intraperitoneal approach, with the surgeon first dissecting the vasa deferentia and seminal vesicles through the pouch of Douglas (Fig. 131.15). Next attention was turned anteriorly, incising the urachus and medial umbilical ligaments to enter the space of Retzius, and proceeding in an antegrade fashion (Fig. 131.16) (1). This intraperitoneal approach was advocated by surgeons at the Montsouris Institute in Paris, who also used an initial dissection posterior to the bladder (3). As experience with LRP grew, the posterior approach was abandoned by some surgeons who discovered that the vasa and seminal vesicles could be adequately dissected once the bladder neck had been divided. Once surgeons were comfortable with dissection of the vasa and seminal vesicles at this point of the operation, some turned to an extraperitoneal approach.

**FIGURE 131.16** Beginning intraperitoneal anterior dissection.

The extraperitoneal approach in LRP or RALP places the urologic surgeon who is used to the anatomy of the radical retropubic prostatectomy (RRP) in familiar territory. In this procedure, the preperitoneal space is first bluntly dissected with either a finger or a balloon prior to insufflation. By staying out of the peritoneum altogether, theoretical risks such as small bowel injury from trocar placement, traction, or electrocautery are avoided, and the concerns of bowel stasis or ileus due to a urine leak are minimized. Additionally, this approach would have a hypothetical advantage in those patients who have undergone prior intra-abdominal surgery. Head-to-head comparisons between the two approaches show little difference with regard to intraoperative and postoperative parameters, and it is our opinion that the approach ultimately should be determined by the surgeon. At the Jefferson Kimmel Cancer Center, we use exclusively an intraperitoneal approach and, as we become more comfortable with the procedure, have extended our patient selection to include those individuals who have undergone prior intra-abdominal procedures; these patients currently represent 5% of our overall experience. We have had no small bowel injuries in these patients, nor have we had to convert any of these procedures to an open radical retropubic prostatectomy. Residents and fellows actively participate in the robotic program.

---

### Posterior Dissection

---

The original description of the LRP and subsequent RALP included dissection posterior to the bladder to identify the vasa deferentia and seminal vesicles prior to dissecting the bladder off of the anterior wall (1,3). As noted, this approach has become less popular with RALP as the procedure has evolved. However, this initial posterior approach remains an important innovation and can be utilized in patients in whom the posterior dissection of the bladder neck may pose a challenge. Such patients are those who have had a prior transurethral prostatectomy (TRUP) or other procedure for benign disease, those with a very large (>80 g) or small (<20 g) prostate, or those with a large median lobe. By dissecting posterior to the seminal structures and exposing the posterior surface of the prostate, the rectum is released posteriorly, thus minimizing one of the main concerns of this part of the procedure. In fact, we regularly teach this approach to our trainees so that it will be in their armamentarium for a RALP.

---

### Incising the Endopelvic Fascia

---

Another derivation of the radical retropubic prostatectomy that has been incorporated into both the LRP and RALP is incision of the endopelvic fascia prior to ligating the dorsal venous complex and dissecting the neurovascular bundle and apex of the prostate. With regard to this portion of the procedure, Stolzenburg et al. (4) have recently reported on 1,300 cases of a completely extrafascial endoscopic prostatectomy, with intermediate follow-up showing oncologic and functional results equivalent to most laparoscopic and robotic large series. In this technique, the endopelvic fascia is left intact and dissected with the neurovascular bundle. The dorsal venous complex is taken at the end of the procedure, prior to dividing the urethra. This method has

anatomic merit, given the fact that the endoscopic prostatectomy (both LRP and RALP) is an antegrade procedure, and theoretically the endopelvic fascia, which is intimately related to the apex of the prostate, does not have to be violated until the end of the procedure. Additionally, this approach may have positive implications on nerve sparing, given the fact that a healthy amount of tissue is left over the neurovascular bundle, limiting the possibility of thermal spread and traction injury.

There are situations, however, when early dissection of the endopelvic fascia can be beneficial. Especially for the novice, after the endopelvic fascia has been divided, the lateral margin of the prostate becomes evident. This can be of particular use when identifying the margins of the bladder neck, which is one of the more challenging portions of the RALP. Additionally, in a patient with a large pubic osteophyte or an anteriorly positioned prostate, incision of the endopelvic fascia and the adjacent puboprostatic ligaments can drop the prostate into the pelvis, facilitating the apical dissection and the vesicourethral anastomosis.

---

### Bladder Neck Dissection

---

Antegrade division of the bladder neck in LRP and RALP remains one of the most frustrating parts of this procedure for trainers and trainees alike. At Jefferson, there are several points that we reinforce with our residents and fellows in order to guide them through this part of the procedure:

1. Use the posterior dissection for those patients in whom the posterior bladder neck may pose a problem (see above).
2. Always incise the endopelvic fascia in order to visualize the lateral borders of the prostate as they form the bladder neck.
3. Place the bladder on tension using either the fourth arm or an assistant to see where the bladder drapes over the prostate (the prostatovesical junction).
4. Have the assistant “bounce” the Foley balloon on the bladder neck to help identify the area for initial dissection.
5. Limit the use of electrocautery during dissection so that the tissue planes do not become obscured by char.
6. After incising the anterior bladder neck to reveal the Foley, deflate the balloon and raise the catheter anteriorly with either the fourth arm of the da Vinci or an assistant.
7. When initially dividing the posterior bladder neck, incise full thickness through the detrusor muscle.

In patients whose biopsy indicates minimal disease at the prostatic base, a bladder neck–preserving procedure can be performed by peeling the bladder off of the prostate anteriorly (an *anterior peel*) (Fig. 131.17). The resulting bladder neck can be well approximated to the distal urethra for the anastomosis. Additionally, this method can be employed to dissect out a median lobe and still keep the bladder neck diameter adequate for the anastomosis without having to taper it. In contrast, patients at high risk for involvement of the base of the prostate with cancer should have a wide excision of the bladder neck with circumferential frozen section biopsies when indicated. In this subset of patients, reconstruction of the bladder neck is necessary (Fig. 131.18).

**FIGURE 131.17** Demonstration of anterior peel.

**FIGURE 131.18** Dissection posterior to the median lobe.

### Dissection of the Vasa Deferentia and Seminal Vesicles

Recent evidence from cadaveric dissections has demonstrated the intimate proximity of the tips of the seminal vesicles and the pelvic plexus ganglions that feed the neurovascular bundles (NVB) (5). This report stated that the NVB may be particularly vulnerable to thermal, electrical, and/or crush injury during dissection of these structures. For this reason, we believe it prudent to avoid excessive traction or gratuitous electrocautery during dissection in this region.

### Prostatic Pedicles and Neurovascular Bundles

Since the advent of minimally invasive prostatectomy, there has been a new interest in the anatomy and, more importantly, the preservation of the NVB. One of the more pioneering of these innovations is the contention by Menon et al. (6) that the nerves responsible for erections are not only located at the posterolateral border of the prostate but also course through the lateral prostatic fascia toward the anterior surface of the

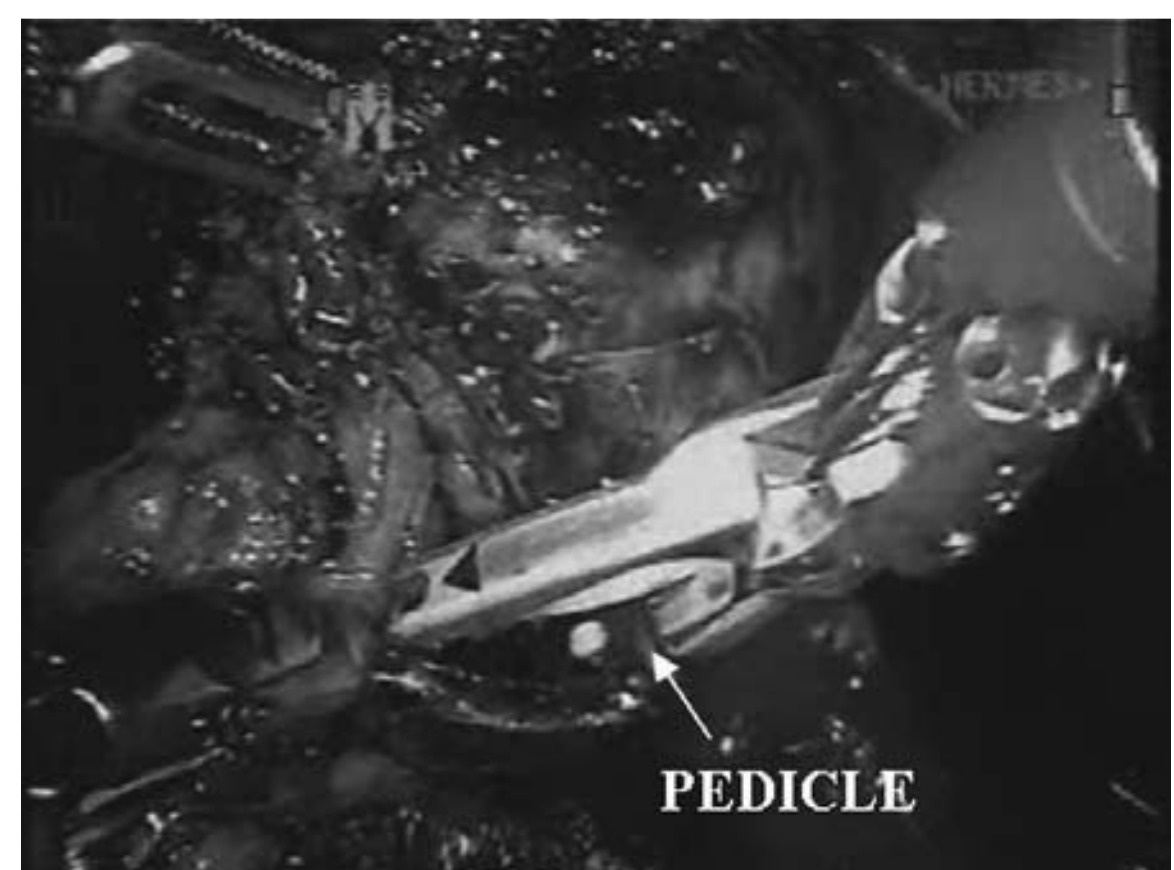

**FIGURE 131.19** Athermal nerve sparing. *NVB*, neurovascular bundle.

prostate. Menon contends that men who undergo the preservation of these nerves, in addition to the traditionally described NVB, are at a distinct advantage when being evaluated for long-term erectile function after nerve-sparing RALP.

To set up the NVB for dissection, we first incise the posterior Denovilliers fascia to expose perirectal fat and the posterior surface of the prostate. To preserve the NVB, we adhere to traditional tenets: avoidance of electrocautery and minimization of traction (Fig. 131.19). Vascular pedicles are thus controlled in an athermal fashion. One tool that we have found useful for this is the robotic Hem-O-Lock (Weck, Research Triangle Park, NC) clip applicator. This instrument contains Endowrist technology and therefore can articulate in the pelvis with 6 degrees of freedom, allowing the surgeon to place clips at difficult angles and minimizing the importance of the assistant (Fig. 131.20).

In contrast to nerve-sparing procedures, there has been some controversy as to the efficacy of minimally invasive prostatectomy in treating patients with high-risk disease. By stratifying our patients according to the D'Amico classification (7), we preoperatively counsel those patients who are high risk to undergo a wide prostate dissection, including removing all tissue enveloped by the lateral prostatic fascia, including bilateral NVB, and taking a wide bladder neck, as well as an extended lymph node dissection at the end of the procedure. In such patients, vascular pedicles are controlled with bipolar electrocautery.

**FIGURE 131.20** Placing robotic Hem-O-Lock clip.

## Dorsal Venous Complex and Distal Urethra

We routinely ligate the dorsal venous complex (DVC) at the end of the procedure, after releasing the NVB and prior to dividing the last attachments, the distal urethra and rectourethralis muscle. A 2-0 Vicryl suture on an SH needle is used to ligate the DVC in either a simple or figure-of-eight fashion. We changed our timing of ligating the DVC from the beginning until the end of the procedure for two principal reasons. The first is the fact that RALP is an antegrade, as opposed to retrograde, procedure. We believe that one of the reasons urologists are quick to ligate the DVC early is a holdover from the retropubic procedure. Since converting to the end of the case, we have not seen an increase in blood loss or transfusion rates. Our most important reason for switching, however, was that we wanted to change our apical dissection in the hope of minimizing positive apical margins in our pT2 specimens. After reviewing the margin status of our first 130 cases, we noted a positive margin rate of 14% on pT2 specimens (15 out of 109), with the majority of those being apical (60%). We analyzed a video of these cases and noted that when we ligated the DVC at the beginning of the procedure, the apex of the prostate was not completely mobile, and we frequently placed the suture too proximal and close to the prostate. When we divided the DVC, at the end of the case, we were precariously close to the prostatic apex, leading to a positive margin. By ligating the DVC at the end of the case, we have already separated all other attachments, making the prostate extremely mobile, and we can clearly visualize the DVC in its entirety as we place the suture (Fig. 131.21). Additionally, we divide both puboprostatic ligaments, thus functionally lengthening the DVC so that the suture can be set more distally. With these adjustments, we have realized a significant decrease in our overall pT2 positive margin rate and our incidence of positive apical margins.

After dividing the DVC, the last attachments are the distal urethra and rectourethralis muscle. We leave a Foley catheter in place when approaching the distal urethra to help identify it better. When dividing the urethra, we do so without electrocautery and enter it approximately 2 to 3 mm distal to the apex of the prostate (Fig. 131.22). This technique prevents us from inadvertently entering the apex, another modification

**FIGURE 131.21** Placing the dorsal venous complex (DVC) suture.

**FIGURE 131.22** Dividing the distal urethra.

that we believe has improved our margin rate. Fortunately, this modification has not compromised continence rates in our patient population.

After the remaining attachments are divided, the prostate is placed in a laparoscopic entrapment bag and brought to the extreme lateral aspect of the field.

## Pelvic Lymph Node Dissection

All patients who undergo a RALP at our institution also receive a bilateral pelvic lymph node dissection. We feel that this represents a sound oncologic practice with prognostic and treatment implications that is standard for RRP but has been deleted by many robotic surgeons. It adds approximately 5 to 10 minutes to the operation, and morbidity is minimal. Our dissection is within the obturator fossa, using the external iliac vein as our superior landmark with the obturator nerve posterior and the pelvic sidewall lateral. We routinely take the Cloquet node and leave accessory obturator vessels intact. For high-risk patients, we extend the superior limit of our dissection to the bifurcation of the common iliac artery. All vessels are neatly skeletonized. We have found that the exceptional visualization provided by minimally invasive technology clearly identifies the anatomy and lymphatic tissue in this area. All lymphatics are secured with bipolar electrocautery. We have had no symptomatic lymphoceles and no complications related to this portion of the procedure. Each lymphatic packet is sent separately to surgical pathology for permanent analysis.

## Vesicourethral Anastomosis

The one portion of RALP in which there appears to be relative uniformity in technique is the vesicourethral anastomosis. Prior to the anastomosis, the bladder neck is tapered to approximate the diameter of the urethral aperture using 2-0 Vicryl suture in figure-of-eight knots. We prefer to perform this anteriorly *and* posteriorly, administering indigo carmine intravenously to help identify the ureteral orifices.

Like others, we have adopted the Van Velthoven one-knot, two-suture method (8). We use two 3-0 Monocryl sutures, one dyed and one undyed, on SH needles and tie them to one

**FIGURE 131.23** Starting the anastomosis at the bladder neck.

another, leaving 7 in. of suture length on each. Both sutures are started on the bladder neck at 5 o'clock (Fig. 131.23), and one is placed to the side while the other is run from urethra to bladder neck in a counterclockwise direction in an in-to-out, out-to-in fashion, respectively, to provide mucosal apposition. The assistant slides the catheter along the distal urethra and provides perineal pressure as needed. After three suture throws are placed in the bladder neck, the bladder is parachuted down with constant tension on the suture to seat the posterior plate of the anastomosis. At this point, the catheter should be able to passively slide into the bladder. This suture is then continued in a running fashion to the 12 o'clock position, and then is held on tension by the fourth arm or by the assistant. The other suture is next run in a mirror-image fashion clockwise around the bladder neck. The ultimate bladder neck stitch on both sides is placed in-to-out to end on the outside of the bladder. Ten to 11 passes are made in total. Prior to tying the two sutures together, a fresh 18Fr Foley catheter is placed under direct vision (Fig. 131.24) and 10 cc of sterile water placed in the balloon. This technique is notably different from what has been described with the LRP, in which interrupted sutures are typically placed. Many believe that the colossal challenge and frustration of intracorporeal suturing and tying deep in the pelvis is the reason that many surgeons have converted to RALP. The anastomosis is tested after tying the sutures using 180 cc saline to ensure its integrity.

**FIGURE 131.24** Visualization of catheter before final completion of urethral anastomosis.

---

## Retrieval of Specimen and Completion of Surgery

---

A suction drain is placed under direct vision at the end of the procedure through the fourth arm port. The robot is next undocked and the specimen bag delivered through the camera port, which is opened at the fascial level as needed. This incision is closed in three layers, and all other incisions are closed with a subcuticular suture.

---

## Postoperative Care and Discharge

---

Patients are sent to the recovery room on intravenous fluids, antibiotics, and pain medication. A 1-L fluid bolus is typically given intravenously at the end of the procedure because of the fluid restriction during the case. Patients are encouraged to ambulate the night of surgery and are started on oral liquids the first night after surgery. During the first postoperative day, patients receive a clear liquid diet for breakfast and regular food for lunch, and they are aggressively ambulated. The majority of patients are then discharged after lunch on the first postoperative day. The catheter is removed the week after surgery (7 to 10 days), depending on the quality of the anastomosis.

---

## OUTCOMES

---

Perioperative, oncologic, and functional outcomes of large ( $\geq 200$  patients) published series of RALP are listed in Tables 131.1 to 131.4. In each table, the benchmark LRP experience of the first 1,000 patients treated at the Montsouris institute is also included (3,9). (Table 131-4 includes potency data from this group which were reported in a separate manuscript). The major advantage of minimally invasive prostatectomy in the perioperative period appears to be a decreased blood loss, which is directly or indirectly related to most of the parameters listed in Table 131.1. Decreased blood loss to the patient leads to fewer transfusions and shorter convalescence, but decreased blood loss to the surgeon means improved visualization in a relatively dry field, which can have short- and long-term implications on outcomes. Long-term data, however, remain lacking with regard to this procedure, although early indicators, such as surgical margin status, are promising. The ultimate role of RALP in the surgical treatment of prostate cancer and its relationship to the standard of care remain to be seen, although the early impact of this technology has been significant.

---

## COMPLICATIONS

---

Reported complications and rates for both LRP and RALP are similar and range from 1.5% to 20.0% in large series for major perioperative complications (e.g., hemorrhage, bowel injury, urine leak, and deep venous thrombosis/pulmonary embolus/myocardial infarction (DVT/PE/MI)) (9,10). At our institution, we have found our complication rates to be similar to what has been reported for RALP in the literature. Of note, of our first 400 pure robotic cases, we have documented 5 cases of hemorrhage requiring blood transfusion (1.3%), 3 bowel injuries (0.8%), 6 clinical urine leaks (1.5%), and 3 DVTs (0.8%), for an overall major perioperative complication rate of 3.5%.

## CHAPTER 132 ■ LAPAROSCOPIC MANAGEMENT OF LYMPHOCELES

SEAN P. HEDICAN AND STEPHEN Y. NAKADA

Lymphoceles are localized encapsulated collections of lymphatic fluid created by disruption of lymphatic vessels that can occur following renal transplantation or other procedures during which lymphatic channels are transected in the pelvis or retroperitoneum. The incidence of asymptomatic lymphoceles following renal transplantation or combined kidney pancreas transplantation has been reported to be as high as 20% (1). Contributing factors in transplant patients include episodes of rejection, cytomegalovirus infections, and post-transplantation reoperations (2,3).

Disruption of the lymphatics in the closed space of the pelvis following limited extraperitoneal pelvic lymph node dissections has also led to localized lymphoceles in patients being treated for prostate cancer, with a reported incidence of 0.5 to 10% (2,4,5). Significant contributing factors to the formation of the lymphoceles include the administration of low-dose heparin (6), prior radiation, presence of metastases, surgical technique, and the extent of the dissection (5). The majority of these pelvic lymphoceles remain clinically asymptomatic. Lymphoceles have also been described following retroperitoneal procedures such

as nephrectomy, retroperitoneal lymph node dissections for testis cancer, or aortic surgery.

## DIAGNOSIS

Asymptomatic lymphoceles are usually discovered incidentally at the time of renal allograft ultrasound (Fig. 132.1) or computerized tomographic (CT) imaging of the abdomen and pelvis (Fig. 132.2) performed for unrelated indications. They appear as a single or septated chamber with Hounsfield unit characteristics and echotexture consistent with fluid located in the region of the renal allograft or adjacent to the iliac vessels.

These structures can be difficult to differentiate from a urinoma unless an ongoing urine leak can be documented via contrast or radionuclide imaging. In the case of a urinoma, aspiration and analysis of the fluid will demonstrate a creatinine value elevated above corresponding serum values (7). The creatinine value on the fluid aspirated from a lymphocele will be equivalent to serum. Hematomas and abscesses usually contain fluid with a higher echogenicity on ultrasound

**FIGURE 132.1.** Ultrasound images of a large lymphocele containing low echogenic fluid extending below and medial to the transplant kidney.

A

B

C

**FIGURE 132.2.** Computerized tomographic images demonstrating the transplant kidney in the right lower quadrant and the inferior and medial location of lymphocele **A:** Note the close proximity of the adjacent iliac vessels containing calcified atherosclerotic plaque. **B:** Extension of the lymphocele at its greatest dimension and the cephalad extent of the bladder appearing medially. **C:** Compression of the lateral wall of the bladder by the medial extent of the lymphocele.

examination, with an increased nonenhanced density on CT imaging (8). The presence of signs and symptoms of an infection in association with a high-density fluid collection, often with mild enhancement of thickened walls or surrounding tissue stranding, usually denotes an abscess. The diagnosis is confirmed and therapeutic intervention often begins with percutaneous drainage or aspiration of purulent material (2).

## INDICATIONS FOR SURGERY

The primary indication for a lympholectomy (surgical unroofing or marsupialization of a lymphocele) is symptoms related to its mass effect. The reported incidence of symptomatic lymphoceles following renal transplantation ranges from 3%

to 7% (9,10). Symptomatic lymphoceles after pelvic lymphadenectomy following radical retropubic prostatectomy are rare, and the majority remain asymptomatic and resolve spontaneously. Symptoms necessitating surgical drainage and unroofing include labial, scrotal, or lower extremity swelling, deep venous thrombosis with or without pulmonary embolism, a sensation of pelvic fullness, and irritative voiding complaints due to compressive effects on the bladder or rectum (5). Renal transplant dysfunction secondary to ureteral obstruction with associated hydronephrosis versus direct compressive effects on the allograft has also been reported. A review of indications for surgery in transplant recipients demonstrated that 69% were performed for local symptoms, 14% for graft dysfunction, and 17% for both (9). Ureteral obstruction following pelvic lymphadenectomy for prostate cancer is extremely rare (5).

---

## ALTERNATIVE THERAPY

---

Prior to the first reported case of laparoscopic lymphocelectomy in 1991 by McCullough et al. (11), the treatment of choice for a symptomatic lymphocele was open transperitoneal marsupialization, with a reported complication rate of 4% and a recurrence rate of 15% on review of 129 patients undergoing open lymphocelectomy (10). This method is still utilized for complex lymphoceles that are multiseptated and lying in a difficult-to-access lateroposterior or lateroinferior position relative to the allograft. Lymphoceles located in these locations have also been shown to be associated with a higher incidence of conversion from a laparoscopic to open surgery as a result (12). Infected lymphoceles requiring extensive evacuation and washout of purulent debris, excision of all septations, and drain placement also support the use of an open extraperitoneal approach (2,3).

Similar to symptomatic renal cysts, aspiration of lymph fluid alone via a percutaneous approach is associated with a 75% to 100% incidence of lymphocele recurrence. These results are not significantly improved by insertion of a percutaneous drain. The use of sclerosing agents instilled into the lymphocele cavity has been reported to increase the likelihood of successful ablation to approximately 85% to 90% (3). Sclerosing agents vary depending upon the series, but the use of alcohol, tetra- or doxycycline, povidone-iodine, and fibrin sealant have all been reported (3,13). It should be noted that this treatment usually requires multiple instillations that can last as long as 45 days (3). The use of this approach is contraindicated for complex multiseptated lymphoceles due to incomplete drainage and inability to introduce sclerotic agent into all chambers (13). Sclerotic agents are also best avoided when the ureter contacts one of the walls of the lymphocele due to the concern that the inflammatory response induced could result in periureteral fibrosis and ultimate transplant ureteral obstruction. Infected lymphoceles likewise should not be treated with aspiration and sclerosis even when utilizing antibiotic agents, as this can lead to persistence and even aggravation of the infection.

Adani et al. (14) utilized an outpatient technique for draining persistent lymphoceles into the peritoneal cavity in seven patients via intraperitoneal placement of a two-cuff Tenckhoff dialysis catheter with the fenestrated end in the peritoneum and the other end in the lymphocele cavity, with the body of the catheter tunneled subcutaneously with the cuff secured to

the fascia. This approach was felt to be especially applicable for lymphoceles in locations not readily accessible to transperitoneal window creation. The catheters were removed 6 months later, with no signs of recurrence after removal in two patients with at least 1 year of follow-up.

---

## SURGICAL TECHNIQUE

---

---

### Preoperative Preparation

---

Patients are placed on a clear liquid diet beginning at noon the day prior to their procedure and are also instructed to drink a bottle of magnesium citrate in an effort to cleanse the bowel. Decompression of the bowel aids in visualization during the operation and improves the speed of bowel recovery. On call to the operating room, the patient is administered a single dose of an appropriate intravenous broad-spectrum antibiotic. Patients on long-term steroid immunosuppressive therapy may require supplemental stress dosing per the anesthesia team. Compressive knee or thigh-high stockings (TED hose) and sequential compression devices are applied to the lower extremities to reduce the risk of deep venous thrombosis formation. Hair is removed from the area of the operative field, including the pubic region and lower abdomen, using an electric shear.

---

### Patient Positioning

---

The operating table should be equipped with a kidney rest and allow flexion/deflection and full Trendelenburg positioning. A 3-inch foam pad mattress is placed on the operating table, followed by a full-size gel pad to aid in securing the patient. Prior to transferring the patient from the transport bed to the operating table, 70% isopropyl alcohol can be used to cleanse the back to remove body oils and debris to establish secure traction between the patient and the gel pad without the use of shoulder bars, chest tape, or straps. Alternatively, any of the other aforementioned securing methods can be utilized. Following intubation of the patient, an orogastric tube is inserted to decompress the stomach, and nitrous oxide should be avoided to prevent bowel distention and to reduce the risk of creating a combustible environment when electrocautery is being utilized. The patient should be positioned with the umbilicus at the region of the kidney rest to allow flexion of the table with slight kidney rest elevation to increase the distance between the umbilicus and the pubic symphysis, assisting in spacing of the trocars.

The Foley catheter should be inserted on the operative field after preparing and draping to allow access for filling and decompressing the bladder, which may assist in localization of the lymphocele. Male patients are placed supine on the operating table. Female patients should be positioned in low lithotomy using Allen stirrups to allow adequate access to the urethral meatus. Alternatively, slight frog-leg positioning can be utilized in nonobese female patients. If the legs are not secured in stirrups, tape can be placed across the upper thighs and a strap across the lower legs to secure them in position.

The arms are protected in eggcrate foam and tucked at the sides using either a split draw sheet or Plexiglas arm sleds. When arm sleds are utilized, care must be taken to avoid disruption of the securing Velcro on their insertion, as this holds the 3-inch foam mattress in place and can lead to its dislodgement

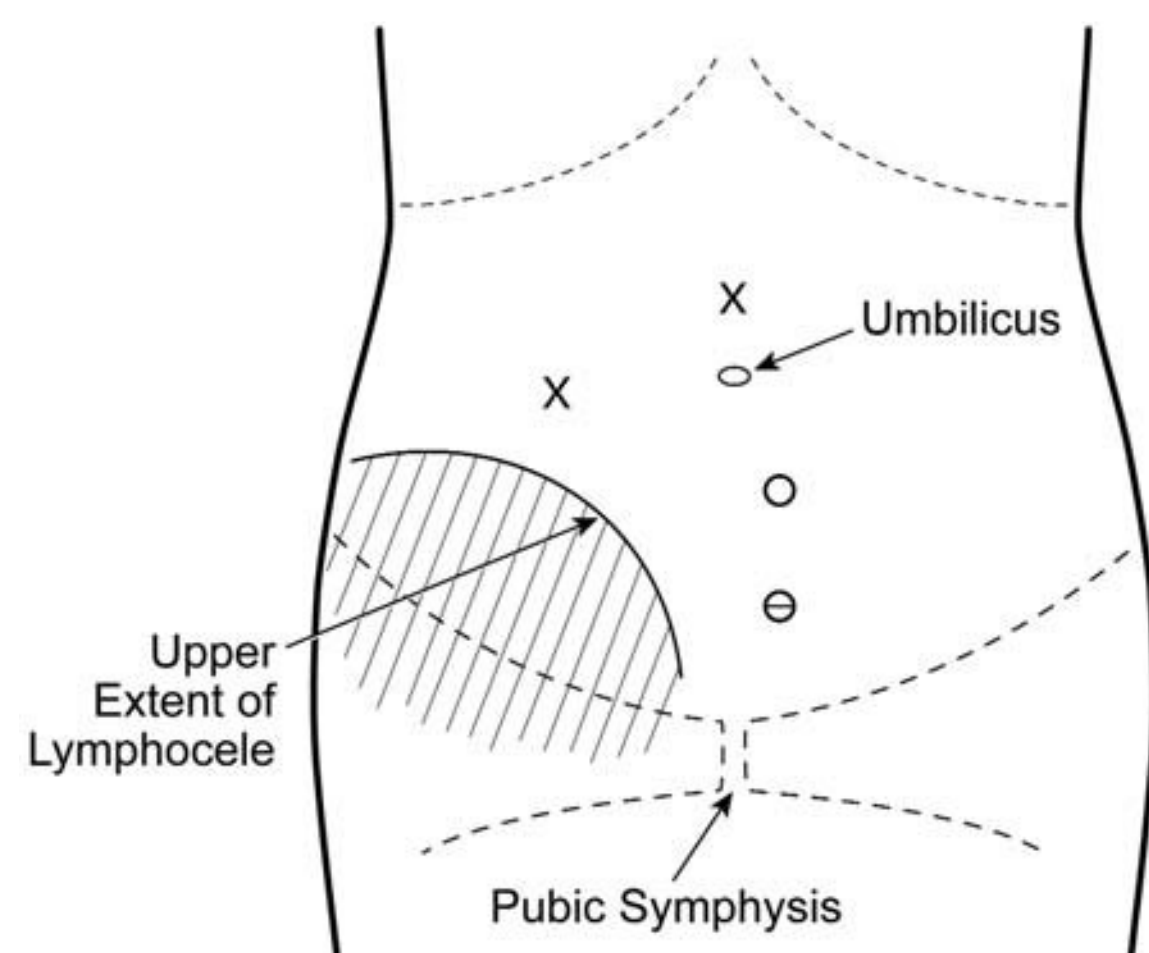

and inadvertent patient movement on deep Trendelenburg positioning. Although it is rarely required, the security of the patient's position should be tested in full Trendelenburg tilt prior to preparation and draping. A wide surgical skin preparation should be performed to include the genitals for sterile Foley catheter insertion and adequate exposure to allow adequate trocar spacing and conversion to an open operation if necessary. A standard wide-aperture laparoscopic drape can be utilized when patients are not placed in stirrups; otherwise, standard cystoscopy legging and aperture drapes are utilized after four-towel draping of the abdominoperineal region. The aperture can be enlarged to give adequate exposure to the lower abdomen.

### Establishing Peritoneal Access and Trocar Configuration

Access to the peritoneum can be obtained utilizing a closed needle (Veress) puncture technique or an open direct vision (i.e., Hasson cannula) method. A 1-cm supraumbilical incision is made through the skin and the underlying dermis using a combination of scalpel and electrocautery incision for insertion of the initial port. If the lymphocele is extremely large, extending to or above the level of the umbilicus, this centrally located port can be moved in a cephalad direction to ensure that the port enters approximately a hands-breadth above the upper extent of the lymphocele. Transabdominal ultrasound can be used to assist in port placement or the extent of the lymphocele estimated by counting CT scan slices above and below the umbilicus to predict its location. The underlying soft tissues are bluntly dissected down to fascia using a sharp clamp.

Initial pneumoperitoneum is created as described in Chapter 123. The insufflation pressure set point should be placed at 15 mm Hg, and once this pressure level is obtained, a visual introducing trocar (e.g., Optiview, Ethicon Endo-Surgery, Cincinnati, OH) is used to insert a 10/12-mm port via the previously made periumbilical incision. The 0-degree 10-mm laparoscope is inserted into the Optiview and can be used to visualize each layer of the abdominal wall as it is traversed using a back-and-forth twisting motion until full entry into the peritoneal cavity is confirmed. Once the visual introducing port has been inserted, the 0-degree lens is exchanged for a 30-degree lens to allow a greater range of visualization angles.

Two additional working ports are then placed, adjusting their position depending upon the location of the lymphocele. In general, a 5-mm working port is inserted a hands-breadth down from the supraumbilical port just lateral to the midline on the side contralateral to the lymphocele. If the distance between the umbilicus and the pubic symphysis is sufficient to allow placement of two ports separated by a hands-breadth without entry into the bladder, the third port (5 mm) can be placed below the second port in the midline. This also requires that the lymphocele is not exceptionally large and that the patient is not morbidly obese (Body Mass Index <35). In general, placement of this port a hands-breadth lateral to the midline just below the level of the umbilicus on the side ipsilateral to the lymphocele is preferred. In the standard trocar arrangement, a 10-mm port can be utilized to allow lateral camera positioning if desired during the case (Fig. 132.3). Alternatively, a 5-mm port can be utilized if a 5-mm laparoscope is available.

**FIGURE 132.3.** Recommended port configuration for right laparoscopic lymphocelelectomy. X, 10/12-mm port; O, 5-mm port; ⊖, alternative 5-mm port.

The surgeon stands on the side opposite the lymphocele and the assistant and scrub personnel stand on the ipsilateral side across from the primary surgeon. The monitor and tower or boom arm containing the insufflation unit, light, and camera source are positioned at the foot of the patient. The patient is placed in Trendelenburg positioning to the extent necessary to liberate the bowel off the area of dissection, and the table is airplaned slightly toward the operating surgeon.

### Identification of the Lymphocele

After release of any overlying bowel or omental adhesions to the lower quadrant of interest, the lymphocele can be identified as a bluish-black pelvic structure if thin-walled. The overall appearance can vary significantly, and when the wall is thickened, differentiation from the bladder can be difficult (Fig. 132.4A). Depending upon its location, other surrounding vital structures, such as the transplant or native ureter or iliac vessels, can also be incorporated into one or more of the walls of the lymphocele. Methods to assist in identification and differentiation from the bladder have been described, including distention followed by decompression of the bladder with sterile saline. The bladder can also be filled with indigo carmine or methylene blue-stained saline and a laparoscopic aspirating needle can be inserted into the identified structure presumed to be the lymphocele (Fig. 132.4B). This is confirmed to be the lymphocele if the aspirated fluid does not contain blue-tinged fluid (15).

A similar but opposite method to assist in the identification of the lymphocele has also been described. This involves outlining the lymphocele using transabdominal ultrasound and percutaneous needle puncture with aspiration followed by injection of the lymphocele with dilute methylene blue-tinged saline. This results in staining of the walls of the lymphocele, allowing confirmation of the structure prior to unroofing by laparoscopic needle aspiration with return of blue-tinged fluid (2,15). Once the lymphocele is entered, the blue staining of the chamber assists in identification of its extent and the amount of unroofing required.

**FIGURE 132.4.** Laparoscopic view of right lower quadrant lymphocele adjacent to a renal transplant. **A:** Thick-walled appearance making differentiation between the indigo carmine–containing bladder and lymphocele difficult. **B:** Laparoscopic aspiration needle inserted into the lymphocele, yielding clear fluid. **C:** Lymphocele unroofing begins utilizing an electrocautery hook. **D:** Final appearance of wide-mouthed peritoneal aperture created in the lymphocele.

### Excision of the Lymphocele

Once the lymphocele is identified, cold or cautery shears, a cautery hook (Fig. 132.4C), or a harmonic scalpel can be utilized to unroof the lymphocele, incising through the area of the wall that appears to be the thinnest portion of the structure in a direction parallel to the presumed course of the transplant ureter. After the initial incision, care should be taken to inspect the wall to make sure that structures such as the renal allograft ureter or pelvis, native ureter, or bladder are not injured in the process. In general, only the portion of the wall in contact with the peritoneum is excised, and any of the contained loculations are disrupted bluntly and the walls excised. Although stenting of the transplant ureter can be performed to help in its identification, this can be technically challenging. In a large multi-institutional retrospective study, 81 patients underwent laparoscopic marsupialization, and none of the ureters were stented prior to the

laparoscopic surgery, yet no ureteral injuries occurred (3). The wall of the lymphocele can then be excised from the central incision to the edge of the thin region of the wall using the laparoscopic instruments to ballot the area to help judge its thickness and the likely involvement of surrounding structures. The excision is then carried out circumferentially until the entire exposed region of the lymphocele is excised (Fig. 132.4D). Once the segments are excised, they can be removed via the 10/12-mm port or cut into strips prior to removal if they are too large to fit through the port. The specimen is visually inspected, and if any concerning elements are identified, such as portions of ureter, these can be confirmed via frozen section analysis, allowing intraoperative management. If the excised region of the lymphocele is small (<4 cm) due to the presence of surrounding vital structures, and this results in a deep-chambered cavity with a narrow aperture, then consideration should be given for placement of an omental wick.

---

## Placement of Omental Wick

---

Hsu et al. (3), in their large multi-institutional review of laparoscopic lymphocelelectomy, reported that omental interposition was utilized in only 14% of the 81 reported cases and “was not considered to be an essential pre-requisite for long-term success.” It was the reported practice of the lead author of the study to utilize an omental tag only if it could be “readily transposed and affixed to the lymphocele window.” In theory, use of native vascularized tissues to maintain patency of the unroofed portion of the lymphocele will facilitate continued patency and peritoneal drainage of the lymphatic fluids.

The omental interposition graft is usually established using the most distal tip of the omentum, which is isolated; if necessary the omentum can be divided in a craniocaudal direction to facilitate mobilization. Major vasculature should be left in place, and typically extensive dissection to the margin of the stomach is not required. Once the omentum can be readily affixed to one of the internal walls of the fenestrated lymphocele, several sutures on a small (e.g., RB-1) needle or tacking titanium clips are placed to secure the tip of the mobilized omentum near the base of the lymphocele. Needles for laparoscopic suturing should be introduced and removed via one of the 10/12-mm trocars to prevent their entrapment in the valve mechanism of the port. If the camera port is the only 10/12-mm trocar being utilized for the procedure, this may require switching to a 5-mm laparoscope to use via one of the working ports to allow needles to be introduced into the peritoneal cavity.

In more complex cases of difficult-to-reach lymphoceles, where an omental wick may not be expected to maintain durable patency, laparoscopic marsupialization with placement of peritoneal dialysis catheters cabled together has been utilized to maintain continued lymphoperitoneal flow (16).

---

## Postoperative Care

---

The patient's postoperative diet is advanced as tolerated and the Foley catheter is removed once the patient is able to ambulate. In male patients with a history of voiding dysfunction, the Foley catheter is left indwelling until the first postoperative day, and several scanned postvoid residual volumes are evaluated following its removal to ensure adequate bladder emptying. Intravenous pain medication is transitioned rapidly to oral analgesics once the patient is tolerating clear liquids. Laboratory studies are kept to a minimum and individualized depending upon the patient's clinical condition. In general, hemoglobin/hematocrit levels as well as a blood urea nitrogen

(BUN) and creatinine (Cr) testing are performed the morning following the operation. If significant lower extremity edema or transplant ureteral obstruction occurred preoperatively due to the lymphocele, then more careful postoperative electrolyte and fluid management may be required.

Discharge criteria include toleration of a regular diet, passage of flatus, and pain adequately controlled on oral analgesics. Typically patients are ready for discharge within 24 hours of the procedure; however, the mean hospital stay in a large reported review series was 1.5 days (3).

---

## OUTCOMES

---

In a multi-institutional study of 81 patients, Hsu et al. (3) noted a lymphocele recurrence rate of 6% over an average of 27 months of follow-up after laparoscopic marsupialization. This compares favorably to the 0% to 15% recurrence rate following open lymphocelelectomy reported in the literature (10,15). In a comparison of a group of patients treated with laparoscopic lymphocelelectomy to a contemporary group of patients treated via an open approach, Gill et al. (2) reported a statistically significant reduction in blood loss (34.6 versus 117.3 mL), more rapid resumption of oral intake (0.9 versus 2.5 days), shorter hospital stay (2 versus 6.1 days), and more rapid convalescence (2.2 versus 6.9 weeks), respectively. A \$7,400 reduction in total hospital costs has also been reported for laparoscopic versus open lymphocelelectomy, largely due to the significant reduction in hospital stay (12). It is important to note that more contemporary case series would likely reflect trends toward shorter hospital stays for both of these approaches.

---

## Complications

---

The reported incidence of complications in one of the largest series of laparoscopic lymphocelelectomy was 5% intraoperatively and 4% postoperatively (3). This compares favorably to the 0% to 12% complication rate reported following open lymphocelelectomy (2,12,15). One of the most frequently occurring intraoperative complications noted by Melvin et al. (15) was division of the transplanted ureter, which occurred in 7% of their cases. Several methods have been employed to prevent this complication, including ureteral stent placement and insertion of a lighted fiberoptic stent.

The reported incidence of open conversion was shown to be 0% to 36% (12,15). Risk factors for conversion of a laparoscopic to an open approach include prior operations, multiple fluid collections, and unfavorable location of the lymphocele.

## CHAPTER 133 ■ LAPAROSCOPIC BLADDER PROCEDURES: RADICAL CYSTECTOMY, PARTIAL CYSTECTOMY, URACHAL EXCISION, DIVERTICULECTOMY

SEBASTIEN CROUZET, GEORGES-PASCAL HABER, AND INDERBIR S. GILL

---

### LAPAROSCOPIC RADICAL CYSTECTOMY

---

Radical cystectomy is the treatment of choice for high-risk, recurrent, superficial, and invasive cancer of the urinary bladder. This procedure is traditionally performed through an open midline incision. Radical cystectomy is curative for most patients who have localized disease, with 5- and 10-year recurrence-free survival rates approaching 70% (1,2).

Laparoscopic radical cystectomy (LRC) is an attractive minimally invasive alternative to conventional open radical cystectomy, as it faithfully duplicates technical aspects of open surgery yet is associated with decreased blood loss (3,4). In reconstructing the ileal conduit or neobladder, an open-assisted approach is preferable to a purely intracorporeal technique for the following reasons: the operating time is shorter than a pure laparoscopic approach, bowel-related complications are fewer, and the advantages of a laparoscopic approach to cystectomy are preserved and it is technically simpler to perform (5,6).

---

#### Diagnosis

---

The diagnosis and staging of muscle-invasive bladder cancer are addressed elsewhere in this book.

---

#### Indications

---

Patients with organ-confined high-risk superficial or invasive bladder cancer are candidates for LRC. Our current contraindications include computerized tomographic evidence of bulky primary tumors, extravesical spread, or gross lymphadenopathy, frozen pelvis due to previous surgery or

inflammatory pathology, fixation of the bladder to surrounding structures and pelvic wall on bimanual palpation, and uncorrected bleeding diathesis. Morbid obesity and previous pelvic radiation can significantly complicate the technical performance of LRC. Previous aortoiliac vascular surgery and endovascular stenting can make the ureteric dissection challenging.

---

#### Alternative Therapy

---

Bladder-preserving protocols utilizing external beam and chemotherapy are available for those who may not be considered for radical cystectomy.

---

#### Surgical Technique

---

##### Patient Preparation

A thorough preoperative evaluation is necessary, including cardiac and medical clearance. Antiplatelet agents should be discontinued at least 1 week before surgery. Anticoagulant discontinuation may necessitate bridging to heparin perioperatively. Mechanical bowel preparation includes a clear liquid diet and 4 L of polyethylene glycol on the afternoon before surgery. A stoma site is marked before LRC for all patients by a stoma therapist. Broad-spectrum intravenous antibiotics (usually a third-generation cephalosporin and metronidazole) are administered at induction. As such, the patient preparation is the same as for open surgery.

##### Procedure

The patient is secured on the operating table in the low lithotomy position, with both arms adducted and secured to the table, thus allowing access to the patient's perineal area and

rectum. All pressure points are meticulously padded. Sequential compressing stockings are applied. The operating table is placed in a steep Trendelenburg position and the patient is prepared from the nipples down to the mid thighs, including the genitalia. A warming blanket covers the upper chest and shoulders. The patient is draped in a sterile fashion using leggings and a special laparoscopy drape. An 18Fr Foley catheter is inserted from the operative field after sterile preparation and draping of the patient.

The surgeon stands on the left side of the patient, while the first assistant stands opposite the surgeon on the right side of the patient. The scrub nurse/technician stands between the legs of the patient and has the instrument table behind him or her. If necessary, a second assistant stands to the left of the surgeon. Two camera monitors are positioned 20 to 30 cm above each outstretched foot of the patient, in direct line of sight of the surgeon and the first assistant. Other laparoscopic essentials such as the insufflator, light source, camera console, recording equipment, and electrocautery are located on a ceiling-mounted boom that is situated behind and to the left of the first assistant. A suction unit is placed just below the boom. An ultrasonic scalpel and bipolar electrocautery unit is placed behind the second assistant.

A 1.5-cm vertical incision is made in the midline about 2.5 cm above the umbilicus; this incision will later be incorporated into the midline incision for the open bowel work. A 2-mm Miniport (Autosuture, Norwalk, CT) is inserted into the abdomen through this incision and CO<sub>2</sub> pneumoperitoneum is created to 15 mm Hg. We prefer to use a 2-mm Miniport to obtain initial access rather than a Veress needle, as it allows a higher gas flow rate and occasional direct inspection of the peritoneal cavity with a 2-mm laparoscope in case of doubt.

A 12-mm primary port is placed through the supraumbilical incision, and a 10-mm 0-degree laparoscope is introduced. Four secondary ports are inserted under vision. A 12-mm right upper port is placed at the previously marked stoma site and is inserted through the belly of the right rectus muscle, carefully avoiding the right inferior epigastric vessels under clear visualization. For ileal conduit diversion, the stoma will be constructed at this site during the "open" part of the operation. Three other secondary ports are placed: a 5-mm left upper port at the lateral edge of the left rectus muscle just below the level of the umbilicus, and a 5-mm port placed 2.5 cm medial and cephalad to each anterior superior iliac spine.

The surgeon typically uses the right-hand 12-mm port and the left pararectal 5-mm port. The first assistant drives the camera through the midline 12-mm port and simultaneously uses the 5-mm right lateral port for suction and/or retraction.

If a patient has had previous abdominal surgery, we prefer initial access through the spatially most distant quadrant, often the left upper quadrant, as most patients with previous surgery have scars either in the midline or in the right half of the abdomen.

Upon initial inspection the surgeon must identify five important landmarks:

1. The medial umbilical ligaments
2. The peritoneal folds overlying the ureters close to the bladder
3. The vasa on each side
4. The posterior cul-de-sac of the rectovesical pouch
5. The iliac vessels

These allow precise orientation during the procedure and expeditious dissection.

### Mobilization and Division of the Ureters

We first identify the peristaltic right ureter as it crosses the iliac vessels at the pelvic brim. Using J-hook electrocautery, the peritoneum is incised along the anterior aspect of the ureter and dissected linearly and distally to the visible peritoneal fold overlying the ureter as it enters the bladder. When circumferentially mobilizing the ureter from the pelvic brim down to the vesicoureteric junction, it is important to maintain an adequate cover of periureteric fatty tissue. Close to the vesicoureteric junction, the superior vesical artery and the vas deferens are visualized crossing the ureter. These are mobilized away from the ureteric surface to obtain maximum ureteric length and do not routinely need division at this point. If antegrade ureteric dissection proves difficult, the peritoneum of the ureteric fold can be incised closer to the bladder and the incision continued in a cephalad direction up to the pelvic brim.

The right ureter is clipped with Hem-O-Lok clips at the vesicoureteric junction and divided such that there are two clips on the bladder side and one on the distal ureter. The two clips on the bladder side of the transected ureter serve as critical landmarks during the subsequent dissection, as they provide a readily identifiable visual clue during transection of the lateral pedicles. The single clip on the cut end of the proximal ureter allows its hydrodistention, which facilitates later ureteroenteric anastomosis. A terminal ureteric biopsy is sent for frozen section analysis. The left ureter is mobilized similarly. Some patients have significant sigmoid adhesions, which might require lysis to allow identification of the left ureter.

### Retrovesical Dissection

The retrovesical space is now dissected. To achieve this, it is essential to tautly retract the sigmoid colon proximally out of the pelvis to facilitate visualization of the cul-de-sac. We use a 2-0 polypropylene suture on a straight Keith needle inserted into the abdomen directly through the skin in the left hypochondrium. This suture is anchored through two selected appendices epiploicae of the most prominent part of the sigmoid colon and brought back out through the abdominal wall in the left hypochondrium, where it is held taut with a hemostat. This simple maneuver efficiently and tautly retracts the sigmoid colon out of the pelvis, obviates the need for an assistant to do so, and provides an excellent view of the operative field.

The ureters have already been mobilized and transected, and the lateral peritoneum of the rectovesical pouch is already divided. The two lateral peritoneotomies are now joined across the midline. It is important that the peritoneotomy across the cul-de-sac be created quite distally, such that it is only 1 to 2 cm anterior to the surface of the rectum. Often there is a subtle transverse peritoneal fold at this location (we refer to it as the "second peritoneal fold"). This plane is now developed between the vasa and seminal vesicles anteriorly, and the anterior surface of the rectum posteriorly. The vessels supplying the seminal vesicles are controlled, and bilateral vasa and vesicles are maintained en bloc with the bladder. Continued dissection brings the posterior layer of the

Denonvilliers fascia into view, which is incised with cold Endo-shears to reveal the yellow prerectal fat posterior to the prostate. This is an important landmark guiding the posterior dissection, the plane of which must remain between the prostate anteriorly and the prerectal fat posteriorly to minimize chances of rectal injury.

### Lateral Dissection and Control of Vascular Pedicles

The parietal peritoneum lateral to the medial umbilical ligaments is incised from the vas deferens as it crosses the pelvic brim toward the peritoneotomy across the rectovesical cul-de-sac. The vasa are clipped and divided at the pelvic brim. The space between the bladder and the lateral pelvic wall is now developed bluntly, retracting the bladder medially away from the iliac vessels and the obturator nerve. As the bladder is still anteriorly attached to the abdominal wall, this allows the lateral pedicles to be clearly identified bilaterally. The lateral pedicles are now divided with a laparoscopic stapler. Once again, the two clips on the bladder end of the transected juxtavesical ureters serve as critical landmarks for the anteromedial limit of resection; the laparoscopic stapler is deployed just posterolateral to these clips. Usually two or three cartridge firings are necessary on each side to control the entire width of the lateral pedicles down to the endopelvic fascia on either side.

The posterior pedicles are now visualized coursing from just lateral to the rectum toward the urinary bladder (Fig. 133.1). These are controlled with the stapler or divided between sequentially applied Hem-O-Lok clips. Usually only the cephalad part of the posterior pedicles can be controlled at this stage; their caudal aspect is addressed after releasing the bladder from the anterior abdominal wall and completing the anterior dissection. At this point the dissection is close to the anterolateral surface of the rectum. An assistant's finger in the rectum can provide guidance in avoiding rectal injury.

### Anterior Dissection

A liberal inverted-U incision is made with the J-hook electrocautery, starting lateral to each medial umbilical ligament, with the limbs of the U joined anteriorly across the midline at the umbilicus. The urachus and medial umbilical ligaments are

**FIGURE 133.1** Stapling of the bladder pedicles.

divided just caudal to the umbilicus. The bladder is released from the anterior abdominal wall; care is taken to protect the inferior epigastric vessels as they course up from the external iliac vessels to enter the posterior rectus sheath.

The space of Retzius is developed behind the pubic bone. Areolar tissue is dissected away to expose the anterior surface of the prostate and the endopelvic fascia on each side. The endopelvic fascia is incised down to the region of the dorsal venous complex. The superficial dorsal vein is coagulated and divided with the bipolar forceps. Fat overlying the anterior surface of the prostate is cleared off with the bipolar forceps. The puboprostatic ligaments are divided with cold Endo-shears.

### Transection of Dorsal Vein Complex and Membranous Urethra, Specimen Entrapment

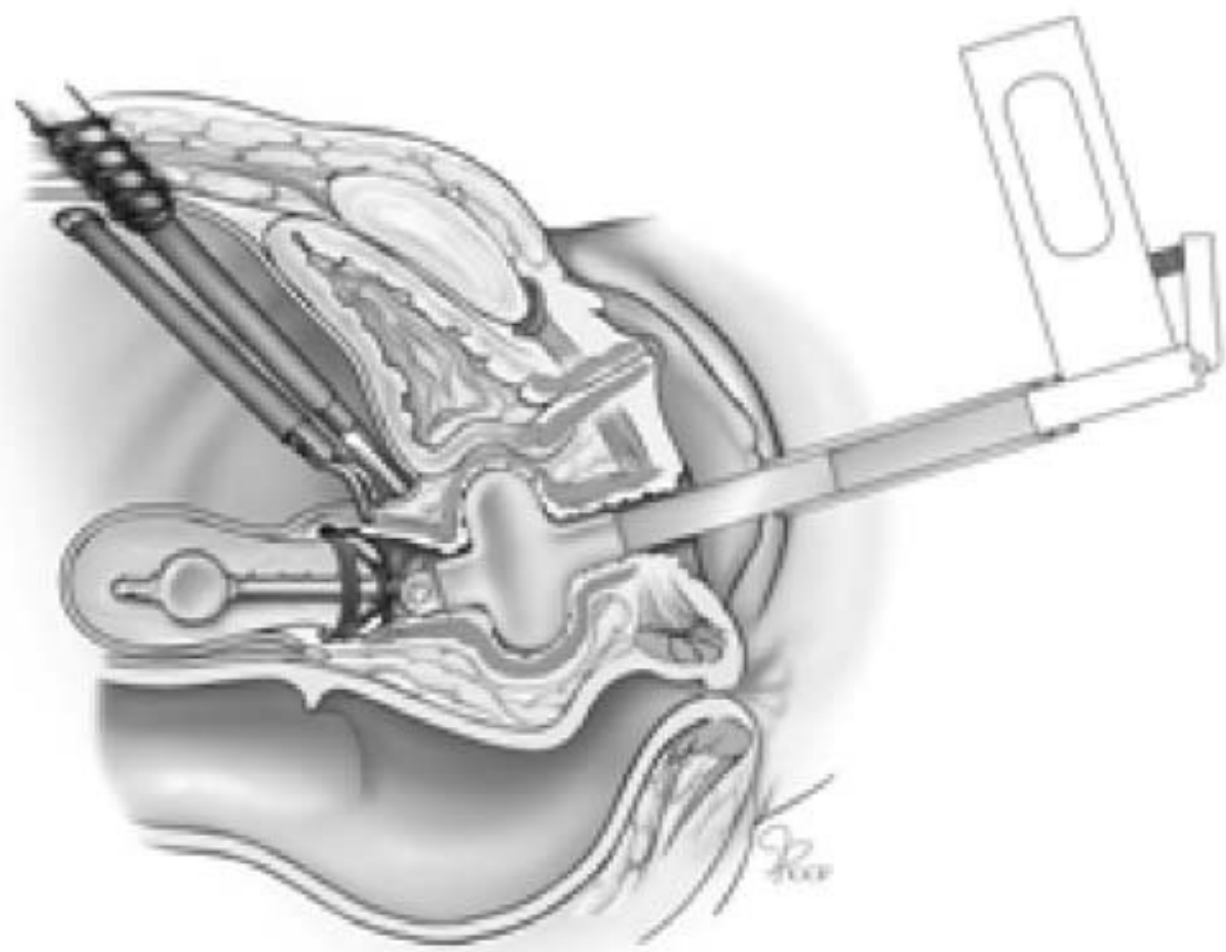

The dorsal venous complex (DVC) is now transected with a laparoscopic stapler. Often an additional suture of 2-0 polyglactin on a CT-1 needle is necessary to secure complete hemostasis of the DVC. The membranous urethra is transected with cold Endo-shears, the catheter is removed, and the urethra at the prostate apex is immediately occluded with a 2-0 polyglactin suture on a CT-1 needle to prevent local spillage of urine. The remaining posterior pedicles are clipped and divided. The remaining posterior attachments of the prostate apex are divided and the freed specimen is entrapped in an Endocatch II bag. The mouth of the bag is transiently retrieved outside a port site, double-ligated to prevent any spillage, and returned into the abdomen.

### Modifications for Cystectomy in Women

Once the ureters are clipped and divided, the uterus is anteverted by the RUMI uterine manipulator (Cooper Surgical, Trumbull, CT) and the sigmoid is retracted as described above (Figs. 133.2 and 133.3). The infundibulopelvic ligaments are transected with a laparoscopic stapler. With the uterus still anteverted and the adnexa retracted anteriorly, the peritoneum over the apex of the posterior fornix is scored transversely with the laparoscopic J-hook. The cervical cup aids in identifying the posterior fornix. The remaining posterior dissection and the vaginal incision are made after preparing the DVC.

**FIGURE 133.2** Modification for cystectomy in the female patient.

**FIGURE 133.3** Modification for cystectomy in the female.

The lateral pedicles are transected with laparoscopic staplers and the bladder is dropped in the usual fashion. The DVC is suture-ligated with a 2-0 polyglactin suture on a CT-1 needle.

Attention is now returned to the posterior dissection. With the uterus anteverted, a transverse incision of the posterior vaginal fornix is completed at the previously scored site. The vaginal incision is extended distally on either side of the urethra, excising a narrow central strip of vagina en bloc with the bladder specimen.

Using a perineal approach, the external meatus and distal urethra are circumferentially cored out using electrocautery. After removing the RUMI manipulator, the distal urethra and an underlying strip of anterior vaginal wall are dissected free by the transvaginal approach. The specimen is delivered en bloc through the vagina. The vagina is reconstructed by combined perineal and laparoscopic suturing before proceeding with urinary diversion (7).

#### Modifications for Nerve-Sparing Cystectomy in Men

Once the ureters are divided and posterior dissection commences, care is taken to stay closely along the surface of the seminal vesicles, as the neurovascular bundles run lateral to the apical tip of the vesicles distally toward the prostatovesicular junction. Thermal energy is avoided in the vicinity of the bundles. The plane of dissection is closer to the bladder and further from the rectum. The bundle on either side is dissected away with cold Endo-shears, and hemostasis is secured with Hem-O-Lok clips. This is in contrast to the non-nerve-sparing technique, in which a laparoscopic stapler is used for en masse transection of the lateral pedicle more posterolaterally, closer to the rectum, and at a considerable distance from the bladder. During the anterior dissection, the endopelvic fascia is maintained intact, and the lateral pelvic fascia is incised high on the prostate to drop the bundles posteriorly. The DVC is divided with a laparoscopic stapler, exposing the membranous urethra. The bundles on either side are released from the prostate apex using cold Endo-shears, and the urethra is divided. The remainder of the operation proceeds in the usual fashion. Intraoperative real-time transrectal ultrasound guidance is of help during nerve-sparing cystectomy, as it can confirm the location of and

blood flow in the neurovascular bundles during and after the procedure (8).

#### Modifications for Reproductive Organ-Sparing Cystectomy in Women

In carefully selected, sexually active young women with low-grade organ-confined disease, a more limited approach can be used. Precise dissection of the bladder away from the uterus and vagina is critically important. The uterus is retroverted, the bladder is identified, and the peritoneum on the anterior surface of the uterus is incised transversely using a J-hook. With the bladder now retracted anteriorly, dissection is performed along and close to the anterior surface of the uterus, developing this avascular plane. Typically dissection proceeds smoothly until the cervix is reached, where adhesions are often dense. At this point extreme care is taken not to thin the vaginal wall or the bladder. This dissection is carried distally down to the bladder neck, which is the end point of posterior dissection. Anterior dissection is now performed and the lateral pedicles are divided with a stapler. The urethra is prepared in the usual fashion. As the vagina is not opened, the specimen is entrapped in an Endocatch II bag.

#### Extended and High-Extended Lymphadenectomy

We perform pelvic lymph node dissection after the LRC. The lateral limit of the dissection is the genitofemoral nerve and the medial limit is the obturator nerve. The distal limit is the inguinal ligament and the proximal limit is the aortic bifurcation. The technique mimics the “split-and-roll” technique used during open surgery. Right lymphadenectomy is performed first. The fibroareolar tissue lateral to the genitofemoral nerve is divided, exposing the iliopsoas muscle. The tissue packet is dissected en bloc off the surface of the iliopsoas muscle and swept medially, dissecting behind the iliac vessels down to the obturator nerve. Tissue anterior to the external iliac artery and vein is then individually split longitudinally using the J-hook, skeletonizing the vessels circumferentially. The external iliac vein typically appears flat at standard pneumoperitoneum pressures. Occasionally, pneumoperitoneum pressure might need to be decreased to 5 mm Hg to facilitate identification of the external iliac vein.

Cephalad dissection along the common iliac artery is facilitated by the fact that the transected ureter has already been mobilized away during the LRC procedure. The circumferentially mobilized common iliac artery is retracted with a vessel loop to retrieve the posterior fibrofatty lymphatic tissue distal to the aortic bifurcation. The internal iliac artery is carefully mobilized, taking care to avoid injury to the internal iliac vein. The released tissue packet is rolled medially posterior to the mobilized iliac vessels, delivering it into the pelvis. Dissection along the medial aspect of the packet separates it from the previously identified obturator nerve. Distally, the tissue packet is clipped and transected at the inguinal ligament (Fig. 133.4).

More recently, we have performed a high-extended pelvic lymph node dissection by dissecting the anterior surface of the aorta and vena cava up to the inferior mesenteric artery; the para-aortic, preaortic, interaortocaval, precaval, and pericaval lymphatic fatty tissue is excised. The aortic bifurcation and the presacral area are also dissected.

Care must be taken to avoid cutting into any enlarged lymph nodes to minimize the risk of tumor spillage. The

**FIGURE 133.4** Extended node dissection.

lymphadenectomy specimen is immediately entrapped in an Endocatch bag, avoiding contact with adjacent tissues. Lymphadenectomy is then performed on the left side in similar fashion (9).

### Urinary Diversion

As mentioned previously, our current preference is to perform this part of the procedure through a 6- to 8-cm midline incision. The three specimens (bladder and two lymphadenectomy specimens) in their separate bags are removed through this incision. The pelvis is carefully inspected to confirm good hemostasis. An ileal conduit or ileal neobladder is fashioned in the usual manner, essentially at or near skin level.

If an ileal conduit is made, the stoma is fashioned at the site of the right-sided 12-mm port. This port site is further expanded and a stoma is fashioned in the usual manner. A 10-mm Jackson–Pratt drain is placed in the pelvis and a 24Fr Foley catheter is placed in the pelvis through the urethra. The balloon of this catheter is inflated to 50 mL and placed on traction for 24 to 48 hours. The abdominal incision is then closed in layers using looped polydioxanone sutures for the fascial layer and 4-0 subcuticular polyglactin for the skin. The 5-mm port sites are closed with 4-0 subcuticular polyglactin.

For the ileal neobladder, the pouch is completed and closed, and the most dependant aspect is defined and a small enterotomy made. This site is tagged with a polyglactin suture and later used for the urethral anastomosis. The ureteric stents and suprapubic tube are brought through separate openings in the anterior wall of the pouch and secured with chromic gut pursestring sutures. The pouch is irrigated to confirm watertight integrity. It is then dropped into the pelvis, one port is reinserted under direct vision, and the abdominal wall is closed in layers as described above. The pneumoperitoneum is then re-established and the other laparoscopic ports are reinserted. The urethrovvesical anastomosis is completed laparoscopically using a running preknotted double-arm suture of 2-0 poliglecaprone 25 and 2-0 polyglytone 6211 on a UR-6 needle over a 22Fr Foley catheter, akin to the technique used for urethrovvesical anastomosis during laparoscopic radical prostatectomy. Two 10-mm Jackson–Pratt drains are

placed in the pelvis through the left and right lateral 5-mm port sites. The ureteric stents are brought out through the left pararectal 5-mm port site. The suprapubic tube draining the pouch is brought out through the right 12-mm port site. The abdominal cavity is extensively irrigated before closure, and this can be done efficiently using this combined approach.

### Pure Laparoscopic Ileal Conduit and Orthotopic Neobladder

The technique for the pure laparoscopic ileal conduit replicates the open procedure with a few minor modifications (6). A 15-cm segment of ileum is isolated using two applications of an Endo-GIA stapler, and the mesentery is also divided with this stapler. The isolated segment is dropped posteriorly. Ileoileal continuity is restored intracorporeally using an application of the Endo-GIA stapler, followed by another application of the Endo-GIA stapler to close the defect. The proximal end of the conduit is imbricated using a running absorbable suture and the mesenteric window is closed with interrupted suture. The stoma is then fashioned, allowing the conduit to be stretched by gravity, thereby improving exposure of the proximal end in preparation for anastomotic suturing. The left ureter has been brought through a mesenteric defect to the right side of the retroperitoneum. The distal ends of the ureters are spatulated and two separate “Bricker” anastomoses are performed using interrupted sutures.

Briefly, 55 to 65 cm of ileum is isolated and ileoileal continuity is restored intracorporeally as described above. The excluded segment is irrigated and detubularized along its antimesenteric border, keeping the proximal 10 cm intact as an isoperistaltic afferent limb. The posterior neobladder plate is created by continuous intracorporeal suturing and the apex of the posterior neobladder plate is circumferentially sutured to the posterior urethra to complete the urethroileal anastomosis. The anterior neobladder wall is then closed and a 22Fr Foley catheter is placed. Finally, the ureters are implanted into the afferent segment using a technique identical to that for the ileal conduit anastomoses (Fig. 133.5).

### Postoperative Care

The neobladder is gently irrigated with 50 mL of saline every 4 hours to prevent mucous plugging of the catheters. Intravenous fluids and antibiotics are continued until bowel function is regained. Diet is gradually advanced and antibiotics are switched to the oral route. The ileoureteric stents are removed in 1 week after a negative intravenous urogram. The Jackson–Pratt drains are removed sequentially, as per the decrease in their output. The urethral Foley catheter and suprapubic catheter are removed at 10 to 12 days after a normal cystogram.

### Outcomes

In the past consecutive 50 LRC procedures (38 men, 12 women) with a urinary diversion performed extracorporeally through a 5- to 6-cm minilaparotomy at our center, the mean operative time was 6.3 hours and mean blood loss was 363 mL. Twelve percent of patients required blood transfusion, time for first oral intake was 3.4 days, and time to ambulation was 3.0 days (Table 133.1).

This group was compared to a contemporary cohort of 50 open radical cystectomy procedures (34 men, 16 women)

**FIGURE 133.5** Pure laparoscopic orthotopic neobladder.

with urinary diversion. There were no significant differences between the groups with respect to mean patient age (66 versus 67;  $p = 0.61$ ), Body Mass Index (27 versus 26;  $p = 0.50$ ), comorbidities, history of prior abdominal surgery and operative indications. Tumor was organ-confined ( $\leq$  pT2N0), non-organ-confined (pT3-4N0), and lymph node positive (pTanyN+) in 66%, 28%, and 6% of the LRC patients and 62%, 20%, and 18% of the open surgery patients, respectively, with no significant differences between the groups ( $p = 0.15$ ) (see Table 133.1) (10,11).

## PARTIAL CYSTECTOMY, URACHAL EXCISION

The urachus is a vestigial fibrous cord derived from involution of the allantois that extends from the bladder apex to the umbilicus and forms the median umbilical ligament. Urachal remnant is a rare congenital anomaly, with an incidence of 2:300,000 in infants and 1:5,000 in adults. Traditional surgical management of benign urachal disease involves the radical excision of all anomalous tissue with or without a cuff of bladder tissue via the open approach (12). Urachal carcinoma

accounts for <0.5% to 2% of all bladder tumors and approximately 40% of vesical adenocarcinomas.

Patients with resectable tumors traditionally underwent en bloc cystoprostatectomy and wide excision of the urachus and umbilicus. Extended partial cystectomy and umbilectomy provide survival rates comparable to those of radical cystectomy (13). The surgical approach has leaned more toward bladder sparing because published reports have not shown an advantage compared to radical surgery (14).

## Surgical Techniques

### Urachal Adenocarcinoma

Patient preparation, positioning, and port placement are similar to those previously described for LRC. The only variation is the placement of the camera port 3 cm above the umbilicus.

The peritoneal and preperitoneal tissue between the medial umbilical ligaments is dissected free of the transversalis fascia. The dissection must include an extensive resection of the peritoneum lateral to the two medial umbilical ligaments, which defined the lateral limits, the posterior sheath of the rectus muscle of the abdomen to the arcuate line and the muscle

**TABLE 133.1**

### CLEVELAND CLINIC EXPERIENCE WITH LAPAROSCOPIC RADICAL CYSTECTOMY

	Laparoscopic radical cystectomy	Open radical cystectomy	p
Operative time (hr)	6.3 ± 0.26	5.3 ± 0.28	0.01
Blood loss (cc)	363 ± 259	801 ± 684	0.0004
Transfusion	12%	40%	0.001
Ileus	18%	28%	0.21
Oral intake (days)	3.4 ± 1.1	4.2 ± 2.1	0.05
Minor postop complications	18%	22%	0.62
Major postop complications	8%	6%	0.69
Ambulation (days)	3.0 ± 1.6	3.4 ± 3.3	0.63
Hospital stay (days)	8.0 ± 3.2	8.7 ± 2.9	0.27
Lymph nodes on final pathology (n)	14.8 ± 7.0	15.8 ± 7.1	0.58
Positive surgical margins	2%	6%	0.29

fibers of the rectus muscle below it, the extraperitoneal fat in the space of Retzius as the anterior limit, the urachus up to the umbilicus superiorly, sparing the umbilical skin.

The bladder is distended with 200 mL normal saline to facilitate the mobilization and dissection. The junction of the solid tumor with the bladder is determined on the anterior aspect by inflating and deflating the bladder, and a cystotomy is made. The excision of the bladder dome is performed with a 2-cm margin of normal mucosa. The specimen is enclosed within the Endocatch bag and placed in the right iliac fossa. The bladder is closed in two layers using absorbable sutures.

Bilateral extended pelvic lymphadenectomy is performed as described in the laparoscopic cystectomy section. The three specimens (the resected tumor and two lymphadenectomy specimens) are removed in separate bags through the supraumbilical port.

### Urachal Remnants

The patient is placed in a supine position and a Foley catheter is inserted in the bladder. Three trocars are generally used: the 12-mm camera port is placed in the midline above the umbilicus and two trocars (5 and 12 mm) are placed on either side, lateral to the rectus muscle. There are several other possible trocar placements as well (15).

The medial umbilical ligaments are clipped and divided. The peritoneal and preperitoneal tissue between the medial umbilical ligaments is dissected free of the transversalis fascia. Dissection is carried along the preperitoneal plane toward the umbilicus, surrounding the cyst. The cephalic side of the lesion is ligated at the umbilicus and divided. The umbilicus is usually not excised. The bladder is filled via the urethral catheter and the cuff is removed. The specimen is placed in a laparoscopic bag and removed by the 12-mm port site. The bladder defect is closed with laparoscopic suturing using 4-0 and 3-0 suture.

## BLADDER DIVERTICULECTOMY

A bladder diverticulum is a herniation of the bladder mucosa as a result of bladder outlet obstruction. The surgical treatment of benign prostatic hyperplasia associated with a symptomatic

bladder diverticulum classically consists of diverticular ablation by open surgery and relief of the prostatic obstacle (16). An endolaparoscopic approach combining laparoscopic diverticulectomy with transurethral resection of the prostate (TURP) is statistically superior to open surgery in terms of blood loss, postoperative hospital stay, and analgesic requirement.

### Surgical Technique

The patient is first placed in the lithotomy position and a standard TURP is performed with meticulous hemostasis. A holmium laser TURP is preferred because of its hemostatic properties. A ureteral catheter is inserted if the diverticulum is close to the ureter. A 10Fr Foley catheter is placed in the diverticulum and the balloon is inflated with 20 to 25 mL normal saline. The neck of the diverticulum is occluded with a gentle traction. Another 14Fr irrigation catheter is placed in the bladder. The patient is moved into the supine position with 15-degree Trendelenburg. A 10-mm supraumbilical midline incision is made for the camera port. An extraperitoneal space is created by using an atraumatic laparoscopic balloon. The preperitoneal space is inflated up to 12 mm Hg. Two 5-mm working ports are inserted in both iliac fossae and a 12-mm port is placed in the suprapubic area. The bladder is mobilized anterolaterally, and the diverticulum is identified after inflating it selectively with normal saline through a Foley catheter. The diverticulum is then circumferentially dissected until its neck is identified. Sharp transection of the diverticulum directly at its neck is performed over the Foley catheter. The neck is then closed in two layers with 3-0 absorbable running sutures, and a watertightness test is performed with bladder irrigation. The resected diverticulum is removed through the 10-mm port. A 14Fr suction catheter is placed in the perivesical space through the 5-mm port.

The laparoscopic procedure can also be carried out via a transperitoneal approach. The drain is removed postoperatively after 48 hours of dryness. The bladder catheter is removed on the 10th postoperative day after confirmation of watertight healing with a negative cystogram.

# CHAPTER 134 ■ LAPAROSCOPIC BLADDER NECK SUSPENSION

RICHARD W. GRAHAM

The first modern advance in the surgical treatment of female urinary incontinence was described by Dr. Victor Marshall along with his colleagues Drs. Marchetti and Krantz (1). The Marshall-Marchetti-Krantz procedure was based on the concept that the loss of the angle of bladder neck juncture combined with the bladder neck protruding through the pelvic floor muscles was the cause of stress urinary incontinence (SUI). His idea was to place stitches next to the bladder neck and sew these stitches to the periosteum. This would elevate the bladder neck and might provide a permanent solution for the incontinence from the scar formation. The initial results were excellent, though complications included osteitis pubis and some patients with permanent retention. Most of Dr. Marshall's patients did not void for weeks; he often stated that if the patient voided before 6 weeks that the procedure would not last (private communication). Subsequent procedures and modifications have been tried, none with perfect results.

In the early 1990s we started to investigate laparoscopic surgery as a minimally invasive technique in urology. The initial strategy was to copy open techniques, improving them by using higher magnification with more light and CO<sub>2</sub> insufflation to lift the abdominal wall and compress the bowel at the same time.

Our initial experience was very encouraging, and later experience of over 600 cases seems to echo this success (2). In a head-to-head trial with open sling procedures at our institution, the laparoscopic procedure showed superior outcomes and fewer adverse outcomes.

---

## DIAGNOSIS

---

The evaluation and selection of patients for any type of treatment for stress urinary incontinence is key to the outcome. The group of patients we want to focus on are the female patients with hypermobility of the bladder neck who have good sphincter control.

The patient's history is one of the most important parts of the preoperative and diagnostic evaluation, which should assess the duration of the problem, time of onset, and cofactors such as whether the problem occurred after pregnancy or at the beginning of menopausal symptoms. In the latter group medical management is usually tried first, and watchful waiting may be appropriate. Other important factors include whether the woman is sexually active, whether the incontinence is mixed, how many pads she is wearing, what induces the leakage, and whether there are signs of intrinsic sphincter deficiency. In considering surgery, it is important to know if there are other pelvic problems associated with the

incontinence (cystocele, rectocele, other forms of vaginal prolapse) and whether the patient is obese or has other risk factors for surgery, including chronic bronchitis, prior radiation, extensive varicose veins (we have seen large venous plexi in the space of Retzius), neurologic issues, or diabetes.

The physical examination should be detailed. Often associated with SUI are vaginal defect issues that need to be repaired at the time of surgery. Is there good estrogenation of the vagina and perivaginal areas? What is the status of her uterus? We perform the Marshall test. (We have patients cough with a full bladder and then watch their urinary leakage. Next we apply digital pressure to the periurethral tissue to watch the leakage stop; if it does not, then we re-evaluate the situation.) We check the rectal tone as well.

Cystoscopy is performed in all patients to assess the urethra and bladder. It is important to note urethral length and angulation of the bladder, urethra, and possible cystocele. (We have noted that releasing the veins at the midline of the bladder neck may increase the length of the urethra by a small portion without a laparoscopic bladder neck suspension [LBNS], as Dr. Marshall noted in his experience with open procedures.) Additionally, the estrogenation of the urethra provides us clues to proper treatment. The cotton-tipped swab test may be of some benefit here as well.

Finally, we feel that urodynamics can be a major help in ascertaining the patient's overall incontinence picture and profile. Her leak point pressures, volume capacity, and other measures help guide our decisions to her care. Videourodynamics are now part of our evaluation as well in helping determine the three-dimensional anatomy and function of the patient.

---

## INDICATIONS FOR SURGERY

---

The indication for surgery for us is based on a paradigm of clinical evaluations and is based on what we feel will work best for the individual. We like to begin with medical therapy. We start with local estradiol therapy if the patient can tolerate it and there are no contraindications. Our experience has shown us that a poorly estrogenized patient can have excellent responses to the cream alone. We tend to limit the local treatment to <4 g a week (one fingertip of cream). Other noninvasive treatments will include biofeedback, begun a month after starting local estrogen. Failure to respond to noninvasive management in a patient with diagnosed SUI is the primary indication for surgery.

We have found that prior pelvic surgery may restrict the available space for suturing retropubically, so we may perform an LBNS using a ProTac (Tyco Healthcare Group, Norwalk,

CT) and polypropylene mesh system to achieve our goal of suspension as opposed to using permanent Gore-Tex (WL Gore and Associates, Flagstaff, AZ) sutures. If other procedures are necessary at the same time, and these are open procedures (total abdominal hysterectomy), then we will opt for open techniques, often using a ProTac and mesh again.

If the patient has morbid obesity, a previous kidney transplant, history of radiation, significant bronchitis, or requires vaginal surgery at the same time, we may decide to use a trans-obturator sling instead of an LBNS, as this patient may require more support. We have had fairly good experience with this procedure as well as with the TVT and feel most comfortable with this direction. We have seen two erosions with the TVT, and the chance of urinary retention or the need of later urethrolysis may be higher with a sling, but that is the balance we use (3).

## ALTERNATIVE THERAPY

There have been many operations described for SUI. The anterior colporrhaphy by H. A. Kelly was felt to be a significant achievement in its day for SUI and was subsequently improved upon by others. The initial success rate quoted of 92% was not able to be reproduced over time, and subsequent years showed a reduction in success rates. This seems to be the trend in many operations for the treatment of SUI.

Each technique has its own inherent advantages and disadvantages. There are many studies quoted as alternative surgical techniques with superior success rates, often with small numbers of patients with fewer than 5 years' experience (4). Many of the larger series of composite studies are with numerous surgeons at multiple institutions with variable skills and experience. So sorting out what is the best technique and alternatives can be a challenge in itself. The standard operations through the years have been primarily retropubic procedures with excellent results initially that tend to have a percentage of failing over time. Additionally, suburethral slings of variable materials seem to be mentioned throughout the literature at this time, first described by Goebel in 1910 using a piece of pyramidalis muscle. Now various ways of placement are being used, and the way these materials are now attached appears to be the latest trend.

Nonsurgical options include adult diapers, which are more popular worldwide than surgery. The cost is enormous, and the satisfaction with this alternative is dependent upon the user.

Biofeedback and behavioral modification have had great success in some series as well. One can never rule this approach out as a primary option in the patient's health care. It does require constant attention even after the initial therapy has been taught, as the muscles will atrophy if not stimulated and the problem will return (5). In a similar physical therapy realm, electrical stimulation of the nerves and muscles, both directly through vaginal devices and indirectly through nerve stimulation products, has been used with mixed results (6).

Sometimes the best alternative is the placement of a permanent Foley catheter to keep the bladder empty. There are a significant group of patients with macerated skin who are not candidates for corrective repairs of their condition, either because surgery won't help or for other reasons.

## SURGICAL TECHNIQUE

The patient is prepared and draped in the lithotomy position, arms by her side, with the vagina prepared as well. Needed materials are listed in Table 134.1. A 16Fr Foley catheter is placed in the bladder after the patient is draped, and 30 cc of water is placed in the balloon. The surgeon stands at the patient's side, on the left side if the surgeon is right-handed. A 1.0- to 1.5-cm incision is made lateral to the umbilicus. With a pair of Metzenbaum scissors, the fat is split down to the external oblique fascia. Using 1-cm "S" retractors, the fat is held back and the fascia grasped with a Kocher clamp, and a 1.0- to 1.5-cm cut is made in the external oblique fascia superior to the clamp. This cut is in a medial/lateral direction. Using a 0 Vicryl UR-6 needle, the stitch is placed on the inferior edge of the fascia and the clamp removed. Next the muscle fibers are split in a longitudinal direction and the "S" retractors placed deeper into the wound to hold back the muscle fibers. The posterior sheath is exposed. Next a Tyco/US Surgical PDB 1000 dissecting balloon is lubricated and placed into the space (Tyco Healthcare, Norwalk, CT). The balloon is gently slid to the posterior sheath, and the retractors are then removed.

Using a zero-degree 10-mm laparoscope inside the dissector, the apparatus is carefully slid into the space of Retzius (Fig. 134.1). One should see muscle above the balloon and fascia below. If bowel is seen, then the peritoneum has been violated and there is no need to expand the balloon. If all is intact, the balloon is slowly expanded with about 45 pumps with the hand pump (Fig. 134.2). The apparatus is removed after all the air in the balloon has been released.

Then a Tyco's blunt port is placed into the wound (Fig. 134.3). The tip is gently placed such that it abuts the posterior fascia. Then 25 cc is placed in the balloon port and the foam cuff brought down to the skin. The retroperitoneal space is then

TABLE 134.1

### MATERIALS NEEDED FOR LAPAROSCOPIC BLADDER NECK SUSPENSION

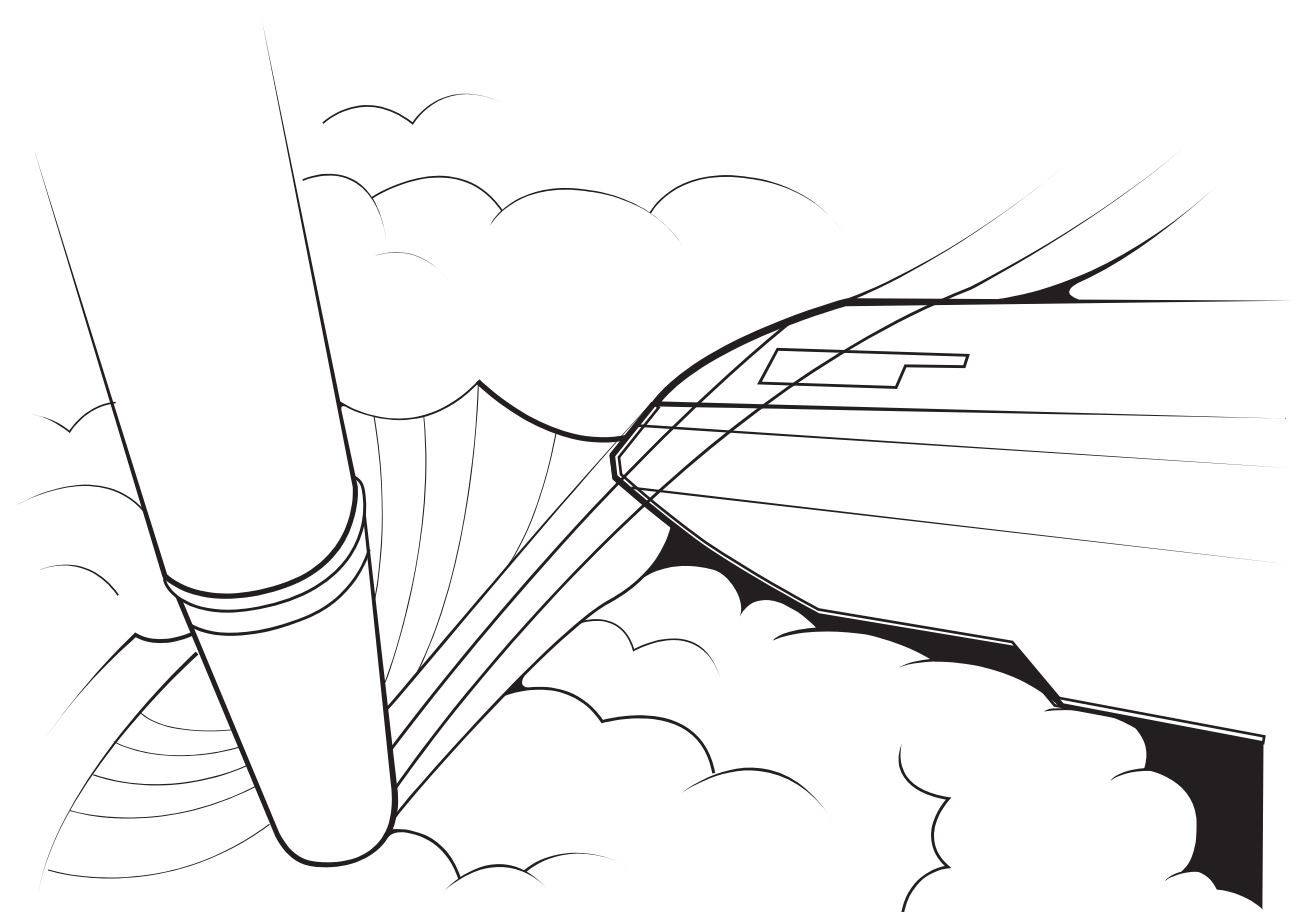

- 16Fr Foley catheter
- Two 1-cm "S" retractors
- One Kocher clamp
- Metzenbaum scissors
- One 0 Vicryl suture UR-6
- AutoSuture PDB 1000 dissecting balloon
- AutoSuture 10-mm blunt/balloon port
- AutoSuture ProTac 5 mm
- 5-mm laparoscopic port/10-mm laparoscopic port
- One dissector 5 mm
- Polypropylene fine woven mesh—need two pieces cut 1 cm by 10 cm
- 30 cc sterile water to fill balloon
- 4-0 Monocryl suture
- One ampule of Dermabond
- 5-mm clip applier on standby
- Suction irrigator on standby
- Preoperative antibiotics; we usually use Ancef
- Zero-degree 10-mm laparoscope

**FIGURE 134.1** From the periumbilical incision, the balloon dissector is passed into the space of Retzius over the posterior fascia.

**FIGURE 134.2** The balloon dissector is insufflated with the pump for 45 compressions in order to create the space for CO<sub>2</sub> infusion.

**FIGURE 134.3** The blunt port is placed in the periumbilical incision, above the posterior fascia when the balloon dissector is removed. The space of Retzius is then insufflated to a pressure of 15 mmhg.

inflated with CO<sub>2</sub> to a pressure of 15 cm. The 10-mm scope is placed in the port. One uses the scope to follow the posterior fascia to the space of Retzius. Sometimes one needs to point the end of the scope up to go over the posterior sheath.

Once into the space, the surgeon looks for signs of bleeding, injuries, and so forth. If all is clear, a 5-mm port is placed

**FIGURE 134.4** The clip applicator is introduced to clip the vessels above the anterior bladder neck. This allows some lengthening of the bladder neck once these vessels are cut, and helps to better identify the bladder neck urethral junction.

below the pubic hair line, midline into the space of Retzius. Since the bladder has been decompressed, this should enter into the space easily. If there has been prior surgery, the port can be placed laterally to midline, being careful not to hit the subumbilical artery just below the lateral rectus muscle.

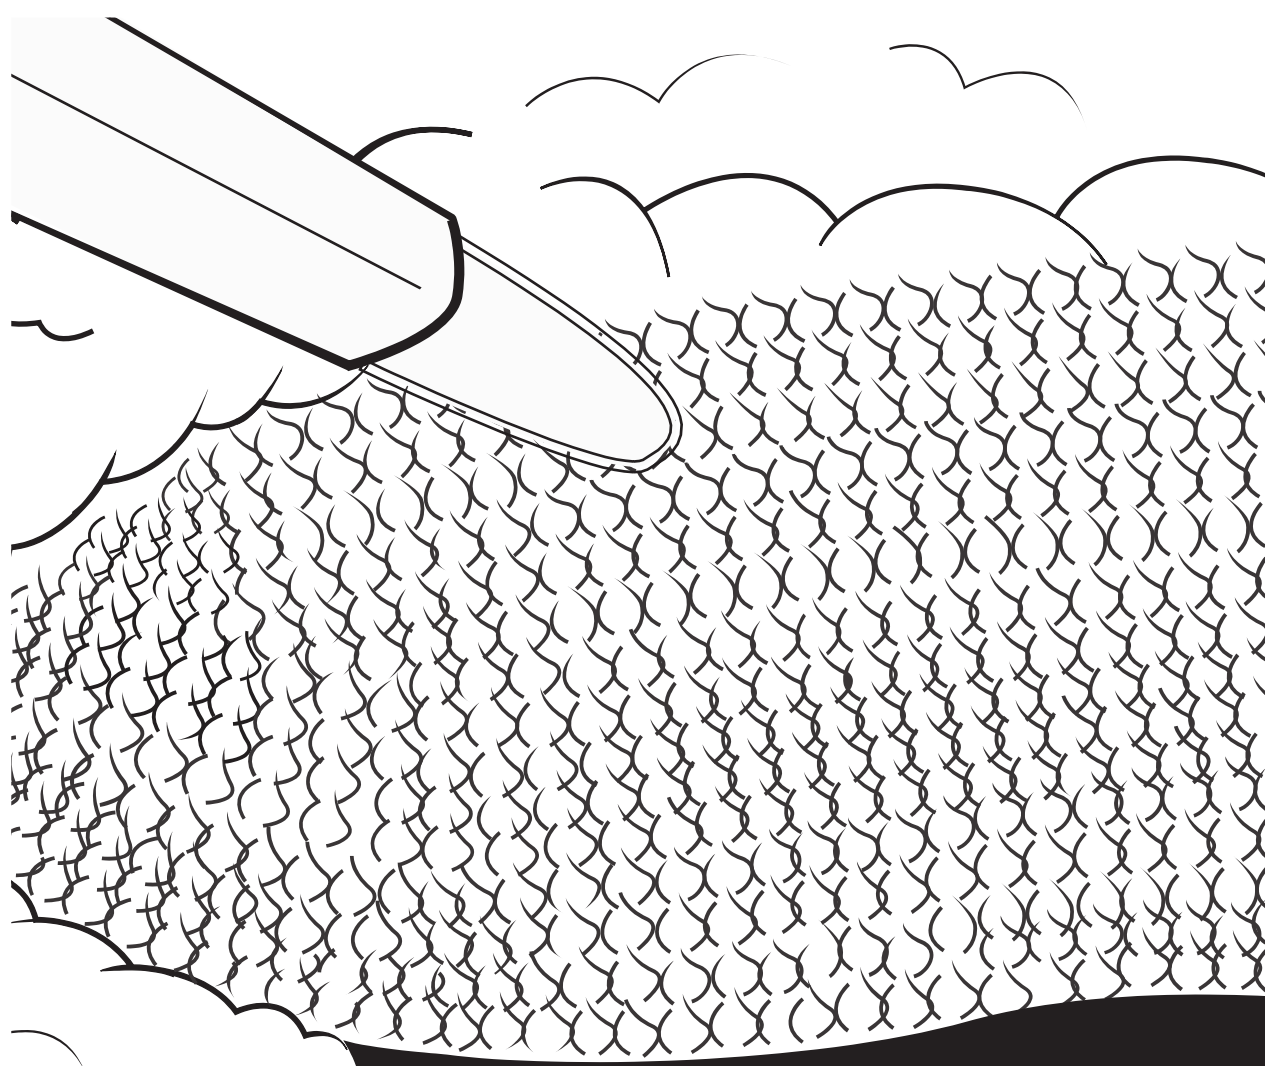

Using the surgeon's dissector of choice through the 5-mm port, the fat must be dissected off the bladder neck, the Cooper ligament, and the fascia lateral to the bladder neck. Once the fat has been removed, it is critical that the bladder neck be exposed. If there is a small vessel midline above the bladder neck extending from the anterior wall toward the bladder, it should be clipped with a small clip so the bladder neck is truly exposed (Fig. 134.4). With 30 cc in the balloon, one can see where the bladder neck joins the urethra.

The surgeon's left hand is placed into the vagina (right hand if the surgeon is left-handed), and the balloon is palpated. Under the scope one ought to be able to see the fascia lift up where the surgeon's finger is. Then using a piece of polypropylene fine woven mesh, a 10-cm by 1-cm strip is attached to a dissector (Fig. 134.5). The camera is removed and cleaned while the piece of mesh is gently placed down the camera port into the space of Retzius. Note: one has to aim somewhat anteriorly so as not to perforate the posterior fascia.

The camera is placed back in the trochar. A dissector is placed in the 5-mm port. The mesh is identified, and one end of the rectangular piece is laid down on the fascia lateral to the left bladder neck, where the surgeon's finger is waiting. The dissector is removed and a ProTac is placed in the 5-mm port. Five tacs are used to secure the mesh to the fascia (Fig. 134.6). The ProTac is removed and a dissector placed in the 5-mm port. The mesh is pulled toward the left Cooper ligament, the ProTac is reintroduced, and while the mesh is held under some tension the ProTac fires 5 tacs, attaching the mesh to the Cooper ligament. The procedure is repeated on the right side, such that there is a piece of mesh on either side of the bladder neck attached to the sides of the pelvis (Fig. 134.7).

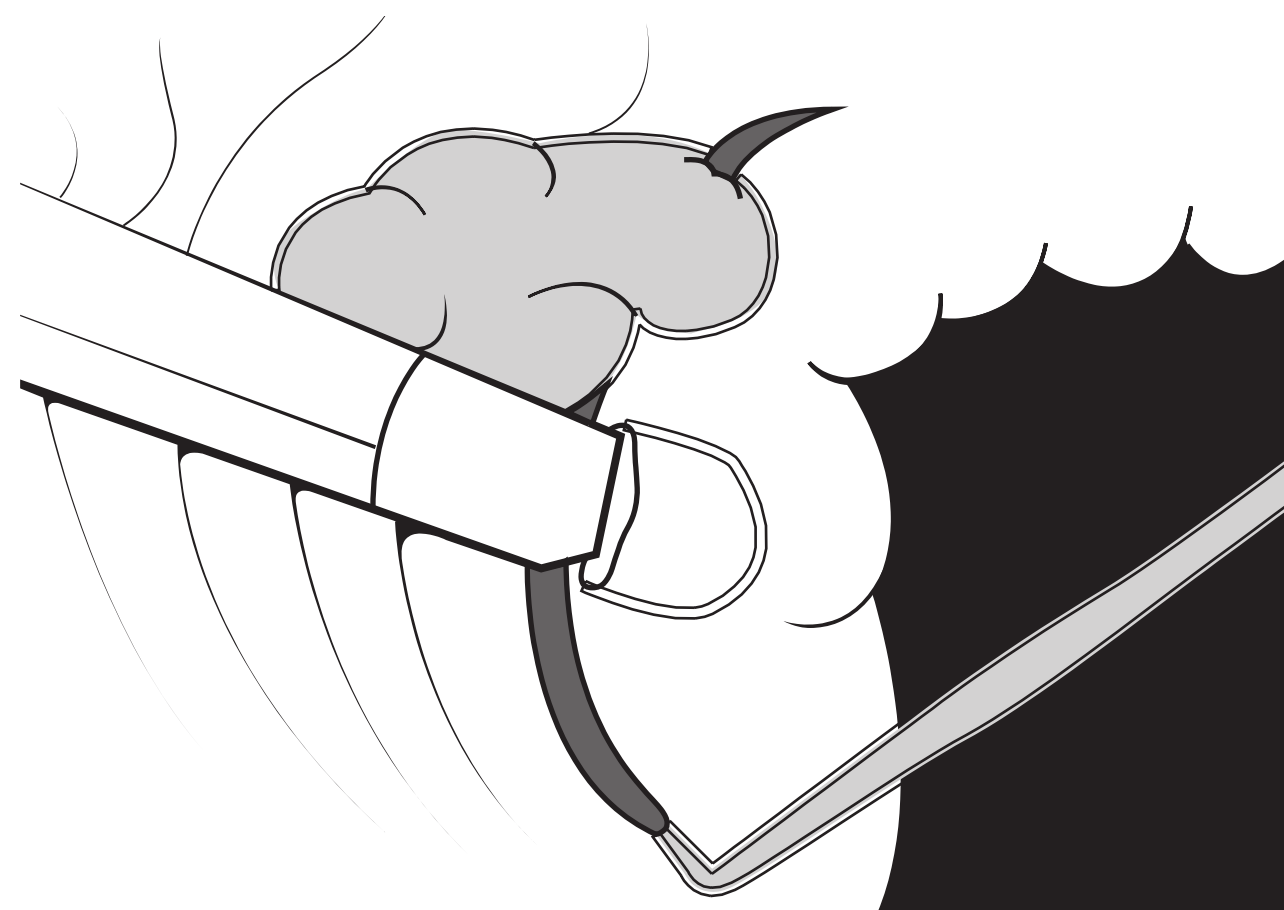

**FIGURE 134.5** While the index finger is placed at the bladder neck, the pro tac is used to fire 5 tacs on top of the mesh toward the underlying finger engaging the periurethral fascia. Then the other end of the mesh is placed on Cooper's ligament where 3 tacs are fired through the mesh into Cooper's ligament, securing the suspension.

**FIGURE 134.6** The mesh is then placed on Cooper's ligament and attached with 3–5 protacs.

**FIGURE 134.7** Here mesh has been attached on both sides with stabilization of bladder neck.

**FIGURE 134.8** A bladder neck suspension here with Gortex suture being sewn into the periurethral fascia at the level of the bladder neck.

**FIGURE 134.9** The gortex suture is first placed in the bladder neck then sewn to Cooper's ligament.

If there is no bleeding or any complications, the gas is emptied out of the pelvis after the 5-mm port is removed under direct vision. Next, the blunt port is removed after deflating its balloon. The fascia is closed with the 0 Vicryl and the wound infiltrated with 0.5% Marcaine without epinephrine. The skin edges are closed with 4-0 Monocryl, and Dermabond is placed over the two small incisions. The Foley balloon is deflated and then refilled with 5 cc of sterile water.

The alternative to using the ProTac system is to use Gore-Tex sutures (Figs. 134.8 and 134.9). Multiple sutures are placed in the same location as the tackers and mesh (Fig. 134.10). The advantage of the Gore-Tex suture is that there is no postneuralgia syndrome from the tacs (in over 600 procedures, we have had 4 cases in which we replaced the mesh and tacs with suture).

The patient is usually discharged the same day or 23 hours postoperatively. The Foley catheter is left in for 2 days. The patient is advised against vaginal intercourse or heavy lifting for 6 weeks.

**FIGURE 134.10** Usually multiple gortex sutures are used on both sides.

**FIGURE 134.11** After the bladder neck is suspended, one can examine the bladder with a flexible cystoscope to inspect the work.

## OUTCOMES

### Complications

Intraoperative complications happen in a very small percentage of people in our experience and in other series (9). The most obvious would be bleeding from the dissection balloon, which has never been an issue for us.

Over 40% of our patients have had previous surgery in the area, and the bladder is encased in significant scar. Our experience is that sometimes the dome of the bladder is densely adhered to the symphysis pubica, and in the process of freeing up the bladder neck, the bladder can be opened. The key for repair of such an opening is to free up the entire area prior to repairing the hole. We place a 2-0 Vicryl suture at each lateral edge of the wound and alternate working the sutures to the middle. This is especially helpful when there is a lot of adipose tissue on the bladder as well. We leave the Foley catheter in for 5 days.

With this technique our experience has been that postoperative retention is rare (<1%). Our Foley catheters are left in for 48 hours to be sure that the patients do not have to return in the middle of the night with urinary retention. If the retention continues, we instruct the patient on intermittent catheterization till the problem resolves. Urethrolisis is a very rare occurrence, and in the few people we explored we found that the mesh was not attached to the sidewall at all. Interestingly, the scar reaction was around the bladder neck. The bladder neck was elevated and suspended by the scar itself (Fig. 134.11). So we lysed the scar, not the mesh.

We have had one erosion of the sidewall mesh into the bladder, which happened several years after the surgery. This was removed laparoscopically and the bladder closed without sequelae.

We expect that some of the patients will develop some urinary frequency, which usually resolves in a few weeks, though

**TABLE 134.2**

### RESPONSE TO QUESTION “DO YOU LEAK WHEN YOU COUGH, LAUGH, OR SNEEZE?”

Follow-Up Interval	Laparoscopic Bladder Neck	Raz
1 Month	140/158 (89%)	70/83 (84%)
6 Months	121/144 (84%)	41/66 (62%)
12 Months	104/129 (81%)	40/67 (60%)
24 Months	47/69 (68%)	22/43 (51%)
36 Months	23/34 (68%)	4/17 (24%)
48 Months	4/6 (67%)	1/5 (20%)

some may have prolonged overactivity and should be treated medically.

## Results

Our initial success rate for the surgery was 93% to 94% as assessed by patient questionnaires. Long-term follow-up (>2 to 4 years) shows stabilization in the 68% range. We performed a prospective head-to-head study comparing 330 LBNSs versus 200 open sling procedures and found a significant superiority in success and complication rate with the LBNS in a 4-year period.

The LBNS appears to be a viable alternative in the quest for continence control in women with SUI. There are other procedures available, each with its advantages and disadvantages. With the very low complication risk, extremely low sling erosion rate, and minimal bladder hyperactivity and misery rate of the LBNS in our hands, we have returned to it and turned away from suburethral slings.

# CHAPTER 135 ■ MISCELLANEOUS LAPAROSCOPIC UROLOGIC PROCEDURES: CALCULUS, VARICOCELE, URETEROLYSIS

GORDON L. FIFER AND RAJU THOMAS

---

## CALCULUS DISEASE

---

One can duplicate the traditional open surgical approaches in appropriately selected patients using laparoscopic techniques. One should, however, gain experience with the common laparoscopic procedures and be comfortable with these prior to tackling these less common or unusual procedures.

The advent of endourology in the late 1970s has transformed the practice of urology. U.S. Food and Drug Administration approval of extracorporeal shock wave lithotripsy (ESWL) in 1984 marked a significant paradigm shift in the treatment of urinary tract calculus disease, moving away from open surgery to less invasive techniques. In modern urologic practice, open stone surgery now accounts for <5% of all procedures performed to treat urolithiasis (1,2).

---

### Diagnosis

---

Imaging with computerized tomography (CT) is the standard today for the identification of urolithiasis. Less commonly, excretory urography, retrograde pyelography, or ureteroscopy is the diagnostic method.

---

### Indications

---

Technologic advances in the design of endourologic instruments, including ureteroscopes, nephroscopes, baskets, and lithotriptors, including the holmium laser, have all contributed to the great success of minimally invasive stone

therapy. Yet infrequent cases exist in which endoscopic or ESWL treatment either has failed or has low expectations for success, and in such cases surgical stone removal remains a viable option.

Since the introduction of laparoscopic surgery in the early 1990s, urologists have recreated virtually every open stone surgical procedure using laparoscopic techniques. Appropriate patient selection is crucial to ensure that a given patient is amenable to laparoscopic management of such calculi. The presence of a large impacted stone is one indication for a laparoscopic approach (3). Although laparoscopy is infrequently utilized for management of urolithiasis, this technique is invaluable when really indicated, providing a minimally invasive approach to managing select cases of urolithiasis (2,4,5).

---

### Alternative Therapy

---

As noted, ESWL, ureteroscopic, or percutaneous techniques are the preferred standard for the management of urolithiasis. Open ureterolithotomy is another alternative to the laparoscopic approach.

---

### Surgical Technique

---

The precise location of the stone must certainly be identified with preoperative imaging. Helical CT scanning provides detailed anatomic information. The planned approach for appropriate trocar placement will depend on the location of the stone and can be categorized as either *upper*, which includes

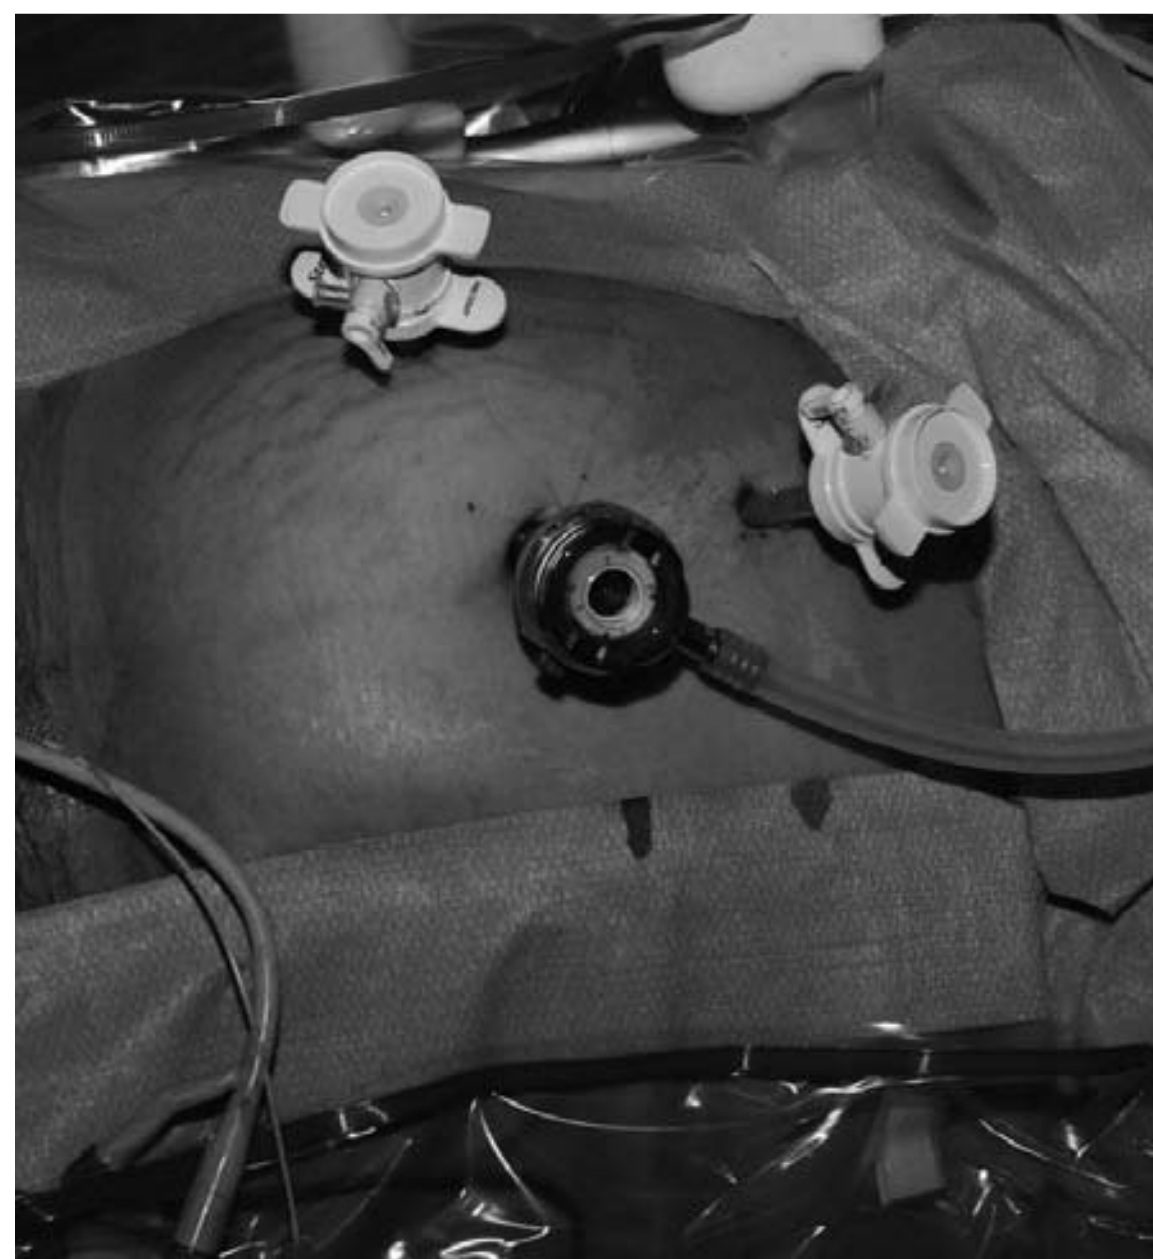

**FIGURE 135.1** X-ray shows a very large calculus (*arrow*) impacted in the upper portion of the right ureter.

calculi in the renal pelvis and the upper ureter (above the pelvic brim) (Fig. 135.1), or *lower*, for calculi in the ureter distal to the pelvic brim.

Placement of a ureteral stent is often required to manage large or impacted stones. To facilitate intraoperative placement of a ureteral stent, cystoscopy with ureteral catheterization should be performed at the onset of the case. If a guide wire can be manipulated past the stone, this will aid the stent placement; if a wire cannot bypass the stone, an open-ended ureteral catheter is advanced up to the level of the stone. This provides a conduit for passing a wire after the stone is removed and may help identify the ureter during the laparoscopic dissection portion of the procedure. A urethral Foley catheter is placed to drain the bladder and a suture used to secure the ureteral catheter, both of which are prepared into the operative field during laparoscopy.

#### For Upper Stones

The patient is placed in a modified lateral recumbent position with the ipsilateral side elevated with a bean bag or kidney rest. The patient is secured to the operating room table with 3-inch silk tape across the chest, waist, and legs. A test airplane roll of the table is performed to ensure the patient is adequately secured. The abdomen is entered with either the Veress needle or the Hasson method, at the surgeon's discretion. Port placement is similar to that used for pyeloplasty, with the camera port placed at the umbilicus. The two operating ports can be placed either in the midline, superior and inferior to the umbilical port, or lateral to the midline and 45 degrees to either side of a "line" from the camera port toward the renal pelvis or ureteral stone location (1). The axis of balance is a line joining the camera trocar to the location of the calculus. The accessory or working trocars are placed with this axis in mind (Fig. 135.2).

**FIGURE 135.2** Patient positioned for right laparoscopic ureterolithotomy. The camera is placed in the umbilical trocar. This configuration can also be used for laparoscopic right ureterolysis, also described in this chapter.

The colon is reflected along the white line of Toldt and is allowed to fall medially, aided by airplane rolling the bed, if needed. The ureter is identified and traced to the renal pelvis or until the stone is encountered. For a ureteral stone, since the proximal ureter is usually dilated or tortuous, placement of vascular tape or a vessel loop around the ureter proximal to the stone can help prevent proximal stone migration. The ureter or renal pelvis is opened with either shears or a laparoscopic scalpel handle (Aesculap, Center Valley, PA). The stone should be removed in one piece when possible and may have to be extracted with the use of an Endocatch bag at the end of the procedure. A guide wire can be placed retrograde through the preplaced ureteral 5Fr open-ended catheter, followed by placement of a double-pigtail ureteral stent. The incision in the ureter or pelvis is closed laparoscopically with a 4-0 polyglactin suture (continuous or interrupted) and a closed suction drain is left in place until output subsides.

#### For Lower Stones

For stones in the lower portions of the ureter, the patient may be left in a supine position. The peritoneum is again entered at the choice of the surgeon with the camera port placed at the umbilicus. The axis between the camera trocar and the stone is marked, and the two operating ports are then placed under direct vision on either side of the body just lateral to the rectus muscles. The surgeon stands on the contralateral side of the patient and begins the dissection at the level of the bifurcation of the common iliac vessels. The ureter is followed proximally or distally until the stone is located. The surgical procedure proceeds in a similar fashion as described above. For stones located in the midureter, the colon may need to be mobilized for exposure, which may be assisted by a gentle airplaning of the table to the contralateral side.

### Postoperative Management

The Foley catheter is left in place for 48 hours to maintain a low-pressure drainage of the urinary tract. This will expedite removal of the peri-incisional drain. The ureteral stent can be removed with the use of a cystoscope in 2 to 4 weeks.

### Outcomes

This procedure is not commonly performed and is practiced more commonly outside the United States. Success rates of over 94% are reported (6).

### Complications

All standard laparoscopic surgical complications are possible, including infection, bleeding, and conversion to an open surgical procedure. Prolonged urinary leakage and urinary stricture are possible.

## LAPAROSCOPIC VARICOCELE LIGATION

Dilation of the pampiniform plexus of veins draining from the testicles is encountered in up to 15% of the general male population and in 40% to 70% of men undergoing evaluation for infertility. Laparoscopic varicocele ligation closely resembles the retroperitoneal approach first described by Palomo in 1948 (7).

### Indications for Surgery

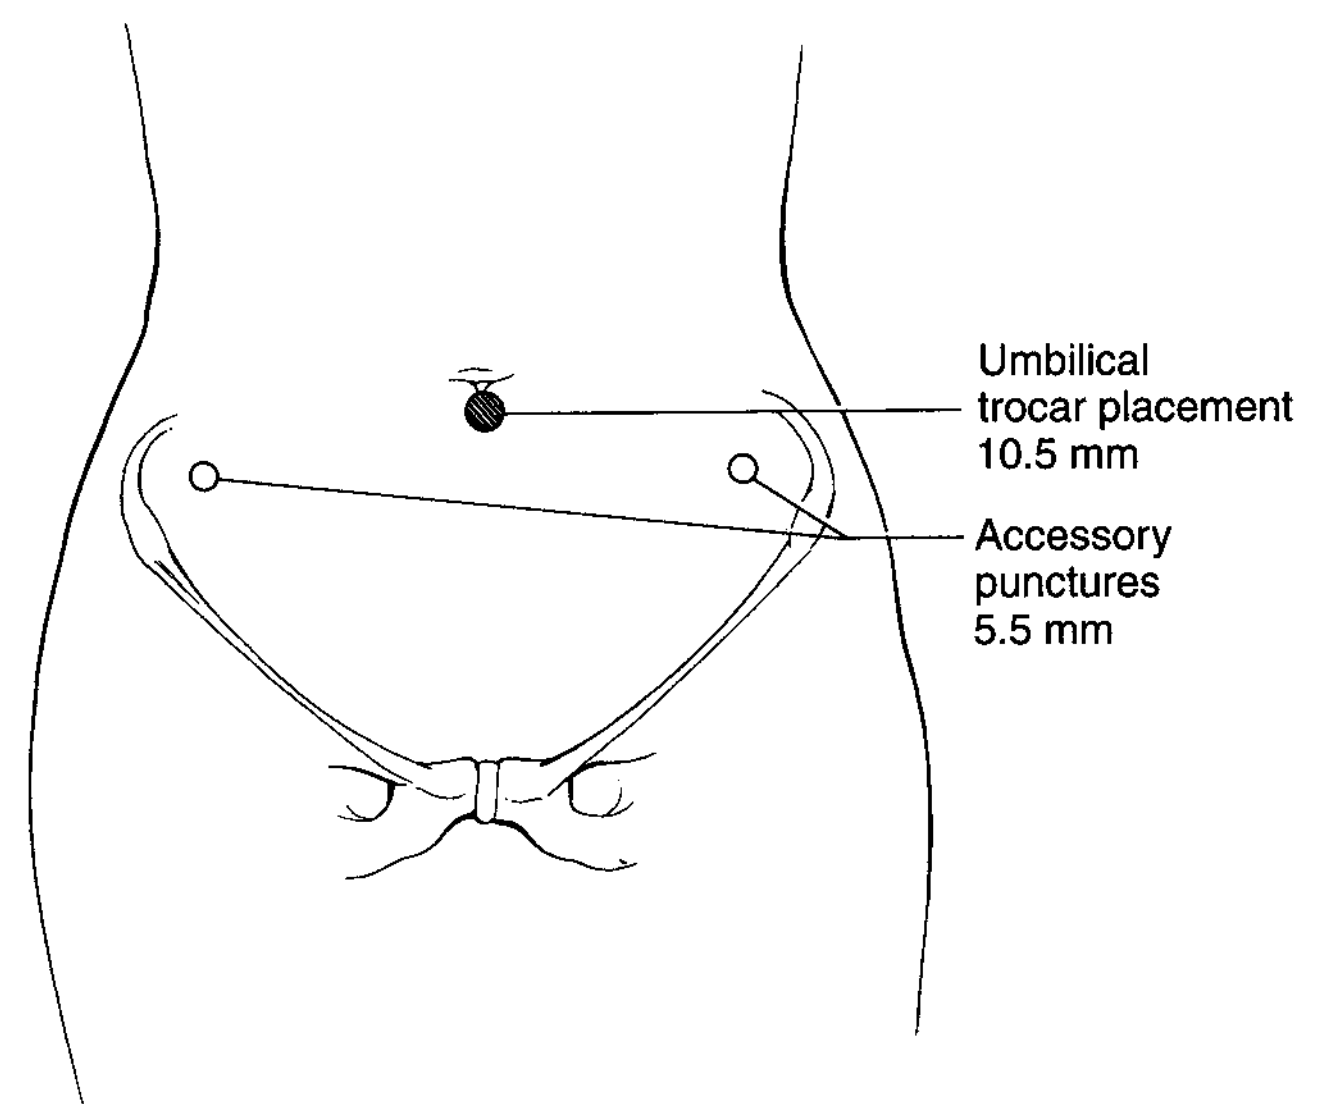

Indications for surgical correction include infertility with poor-quality semen, decrease in testicular size, and chronic pain or discomfort from a large varicocele. A failed previous attempt at retroperitoneal repair is a contraindication to laparoscopic varicocele ligation. The ultimate choice of varicocele ligation method is determined by surgeon preference and experience as well as patient-specific factors.

### Alternative Therapy

Several different surgical techniques have been described with inguinal (Ivanissevitch), subinguinal microscopic (Marmar-Goldstein), and open retroperitoneal or high ligation techniques (Palomo) approaches. Microscopic techniques are becoming more commonly used to reap the benefits of a less invasive procedure and reduced incidence of hydrocele. Embolization of the dilated veins is sometimes utilized.

### Surgical Technique

Most surgeons utilize the transperitoneal approach, with some reports of successful laparoscopic extraperitoneal varix ligation. The patient is placed in a supine position and the peritoneum entered at the umbilicus with either the Veress needle or Hasson technique. After creation of pneumoperitoneum, the table is rotated, and the additional operative trocars are placed under direct vision.

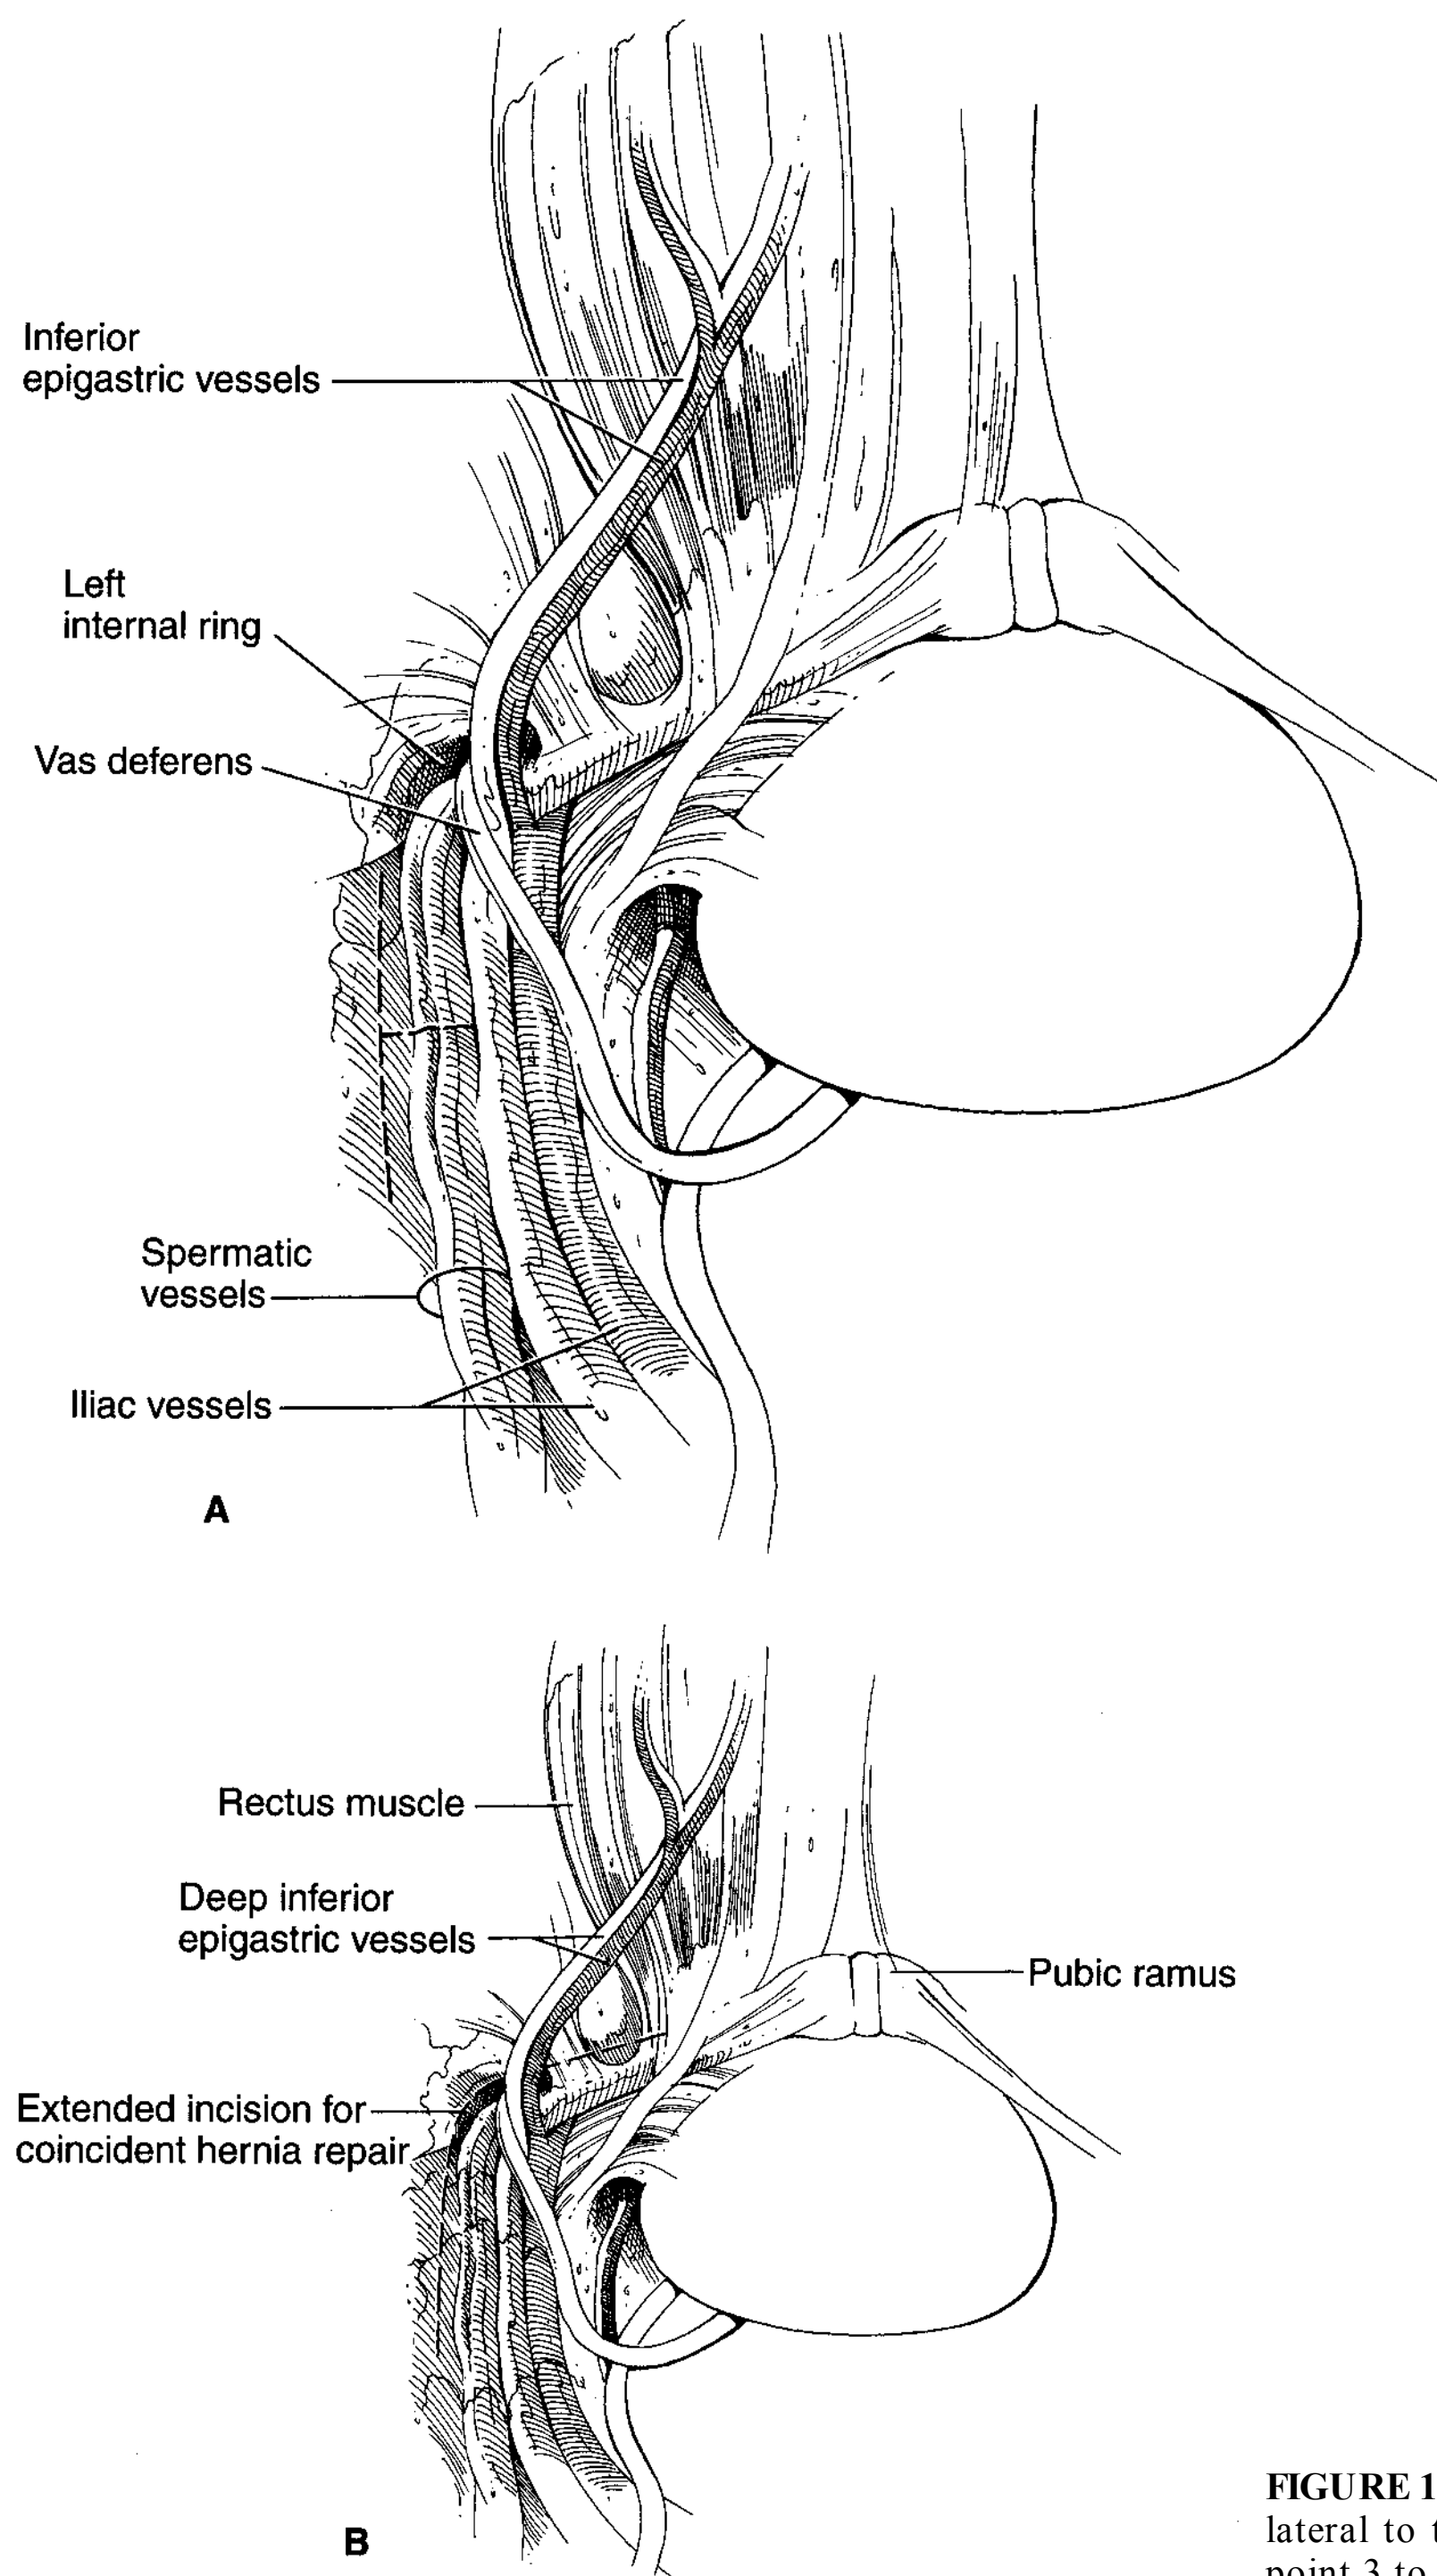

**FIGURE 135.3** Appropriate position of trocars for varix ligation. The array of trocars is used in either left or bilateral varix ligation. The sub-umbilical trocar is either a Hasson cannula for open laparoscopy or a standard trocar inserted following Veress needle insufflation. The operating trocars are 5.5 mm when a 5-mm clip applicator is available or 10 mm when one must rely upon a 10.5-mm hemoclip applicator.

Two separate trocar templates exist. The first places one port just inferior to the umbilicus and lateral to the rectus muscle on the ipsilateral side, with the second port infraumbilical in the midline. The second template places both operative trocars just lateral to either edge of the rectus muscle and slightly inferior to the umbilicus. The latter allows for bilateral procedures to be performed if necessary (Fig. 135.3).

Once the ports are placed, attention is turned to the internal inguinal ring, and the nearby iliac vessels, vas deferens, and medial umbilical ligament are all identified (Fig. 135.4). If the colon obscures the internal ring, it should be mobilized by incising the line of Toldt or placing the patient in slight Trendelenburg position. The magnification afforded by the laparoscope aids in the visualization of the spermatic vessels running beneath the peritoneum.

The peritoneum is incised lateral to the spermatic cord (Fig. 135.4) and the testicular artery and veins are dissected free. If identified, the testicular artery should be preserved. Use of electrocautery should be restricted so as not to cause thermal injury to the artery. The use of papaverine liquid over the vessels will assist in dilation of the artery, subsequent pulsations, and easier identification of the artery. The intraoperative laparoscopic Doppler probe is helpful to identify the artery. Arterial preservation is not a requirement. The cremasteric and deferential collateral circulations are not jeopardized by the laparoscopic approach and are usually sufficient to maintain the viability of the testicle. The dissection and ligation is described in Figures 135.5 to 135.7. The vessels may be ligated with titanium clips, the endovascular stapler, or intracorporeal knot tying. After ligation, they are transected, completing the procedure. Alternatively, a bulk ligation of the cord with a 2-0 silk or stapler can be performed without regard to preserving the artery. It may be useful to divide the cord into smaller packets without regard to the spermatic artery preservation.

If scrotal emphysema is present, we eliminate it with brief compression before final port removal. Standard laparoscopic

**FIGURE 135.4** A 3- to 5-cm incision through the peritoneum is made lateral to the spermatic vascular bundle; it extends cephalad from a point 3 to 5 cm above the internal ring.

closure techniques are followed. Patients are discharged on the day of surgery without restrictions in physical activity.

### Outcomes

Operative times vary based upon extent of operation (unilateral or bilateral), complexity of repair (artery sparing takes longer than artery sacrifice), and laparoscopic experience (novice takes longer than expert). With experience, non-artery-sparing procedures will last 15 to 30 minutes

and artery-sparing procedures will last 45 to 60 minutes. A randomized trial comparing open to laparoscopic varix ligation revealed similar outcomes in terms of efficacy and complications, but advantages in terms of pain and recovery time (8). Results indicate that spermatic arterial ligation did not influence response and did not result in testicular atrophy.

### Complications

Due to the age group involved, perioperative complications are very rare. Potential complications include bleeding, a need

**FIGURE 135.5** The entire spermatic vascular bundle is mobilized from the underlying psoas muscle. A combination of sharp and blunt dissection facilitates separation of the spermatic vessels from surrounding tissues. One should avoid deep dissection in order to spare the underlying genitofemoral nerve crossing anterior to the psoas muscle.

to convert to an open procedure, infection, testis atrophy or loss, and failure to correct the varicocele. Even with successful correction of the varicocele (i.e., absence of a palpable varix at 6 months following surgery), signs and/or symptoms that prompted the operation (orchalgia, oligoasthenospermia) may persist.

## LAPAROSCOPIC URETEROLYSIS

Ureteral stenosis or strictures can be caused by a variety of intrinsic as well as extrinsic causes. Thus, ureteral strictures can be caused iatrogenically, such as post-ureteroscopy or following other surgical procedures in close proximity to the ureter. Stenosis may also be secondary to conditions such as retroperitoneal fibrosis (RPF) or extrinsic tumors. The clinical features include flank pain, abdominal pain, renal failure, as well as signs and symptoms of urinary tract obstruction, bacteremia, etc.

RPF is an inflammatory process involving the retroperitoneum that results in excessive fibrosis and often causes ureteral entrapment, compression, and obstruction leading to hydronephrosis. The primary, idiopathic etiology accounts for 70% of the cases, with the remainder of cases occurring secondarily in response to numerous conditions, including vascular aneurysm with or without grafting; radiation exposure; inflammatory bowel disease; malignancy; or drug exposure, including use of beta-adrenergic blockers or ergot alkaloids.

The most common presentation is colicky flank pain from ureteral obstruction; however, the fibrosis may be so extreme as to entrap the great vessels or renal vasculature, so that

lower extremity edema, hypertension, or hematuria may also occur. On the other hand, ureteral strictures may be asymptomatic and can present with painless hydronephrosis (6,9,10).

### Diagnosis

Preoperative imaging may consist of intravenous pyelography or CT scans, typically demonstrating hydronephrosis and medial deviation of the course of the ureter, either unilaterally or bilaterally. Retrograde pyelograms performed just prior to ureterolysis may provide updated information regarding the course of the ureter and help identify the extent (length) of ureteral entrapment.

### Indications for Surgery

Ureterolysis can be both diagnostic, allowing for biopsy of the retroperitoneal mass, and therapeutic, allowing release of the ureters.

### Alternative Therapy

Traditionally, ureterolysis is performed by the open surgical approach. Many centers will attempt a trial of steroids empirically before surgical correction. Malignant RPF can sometimes be managed primarily by chemotherapy without the need for ureterolysis (6,9).

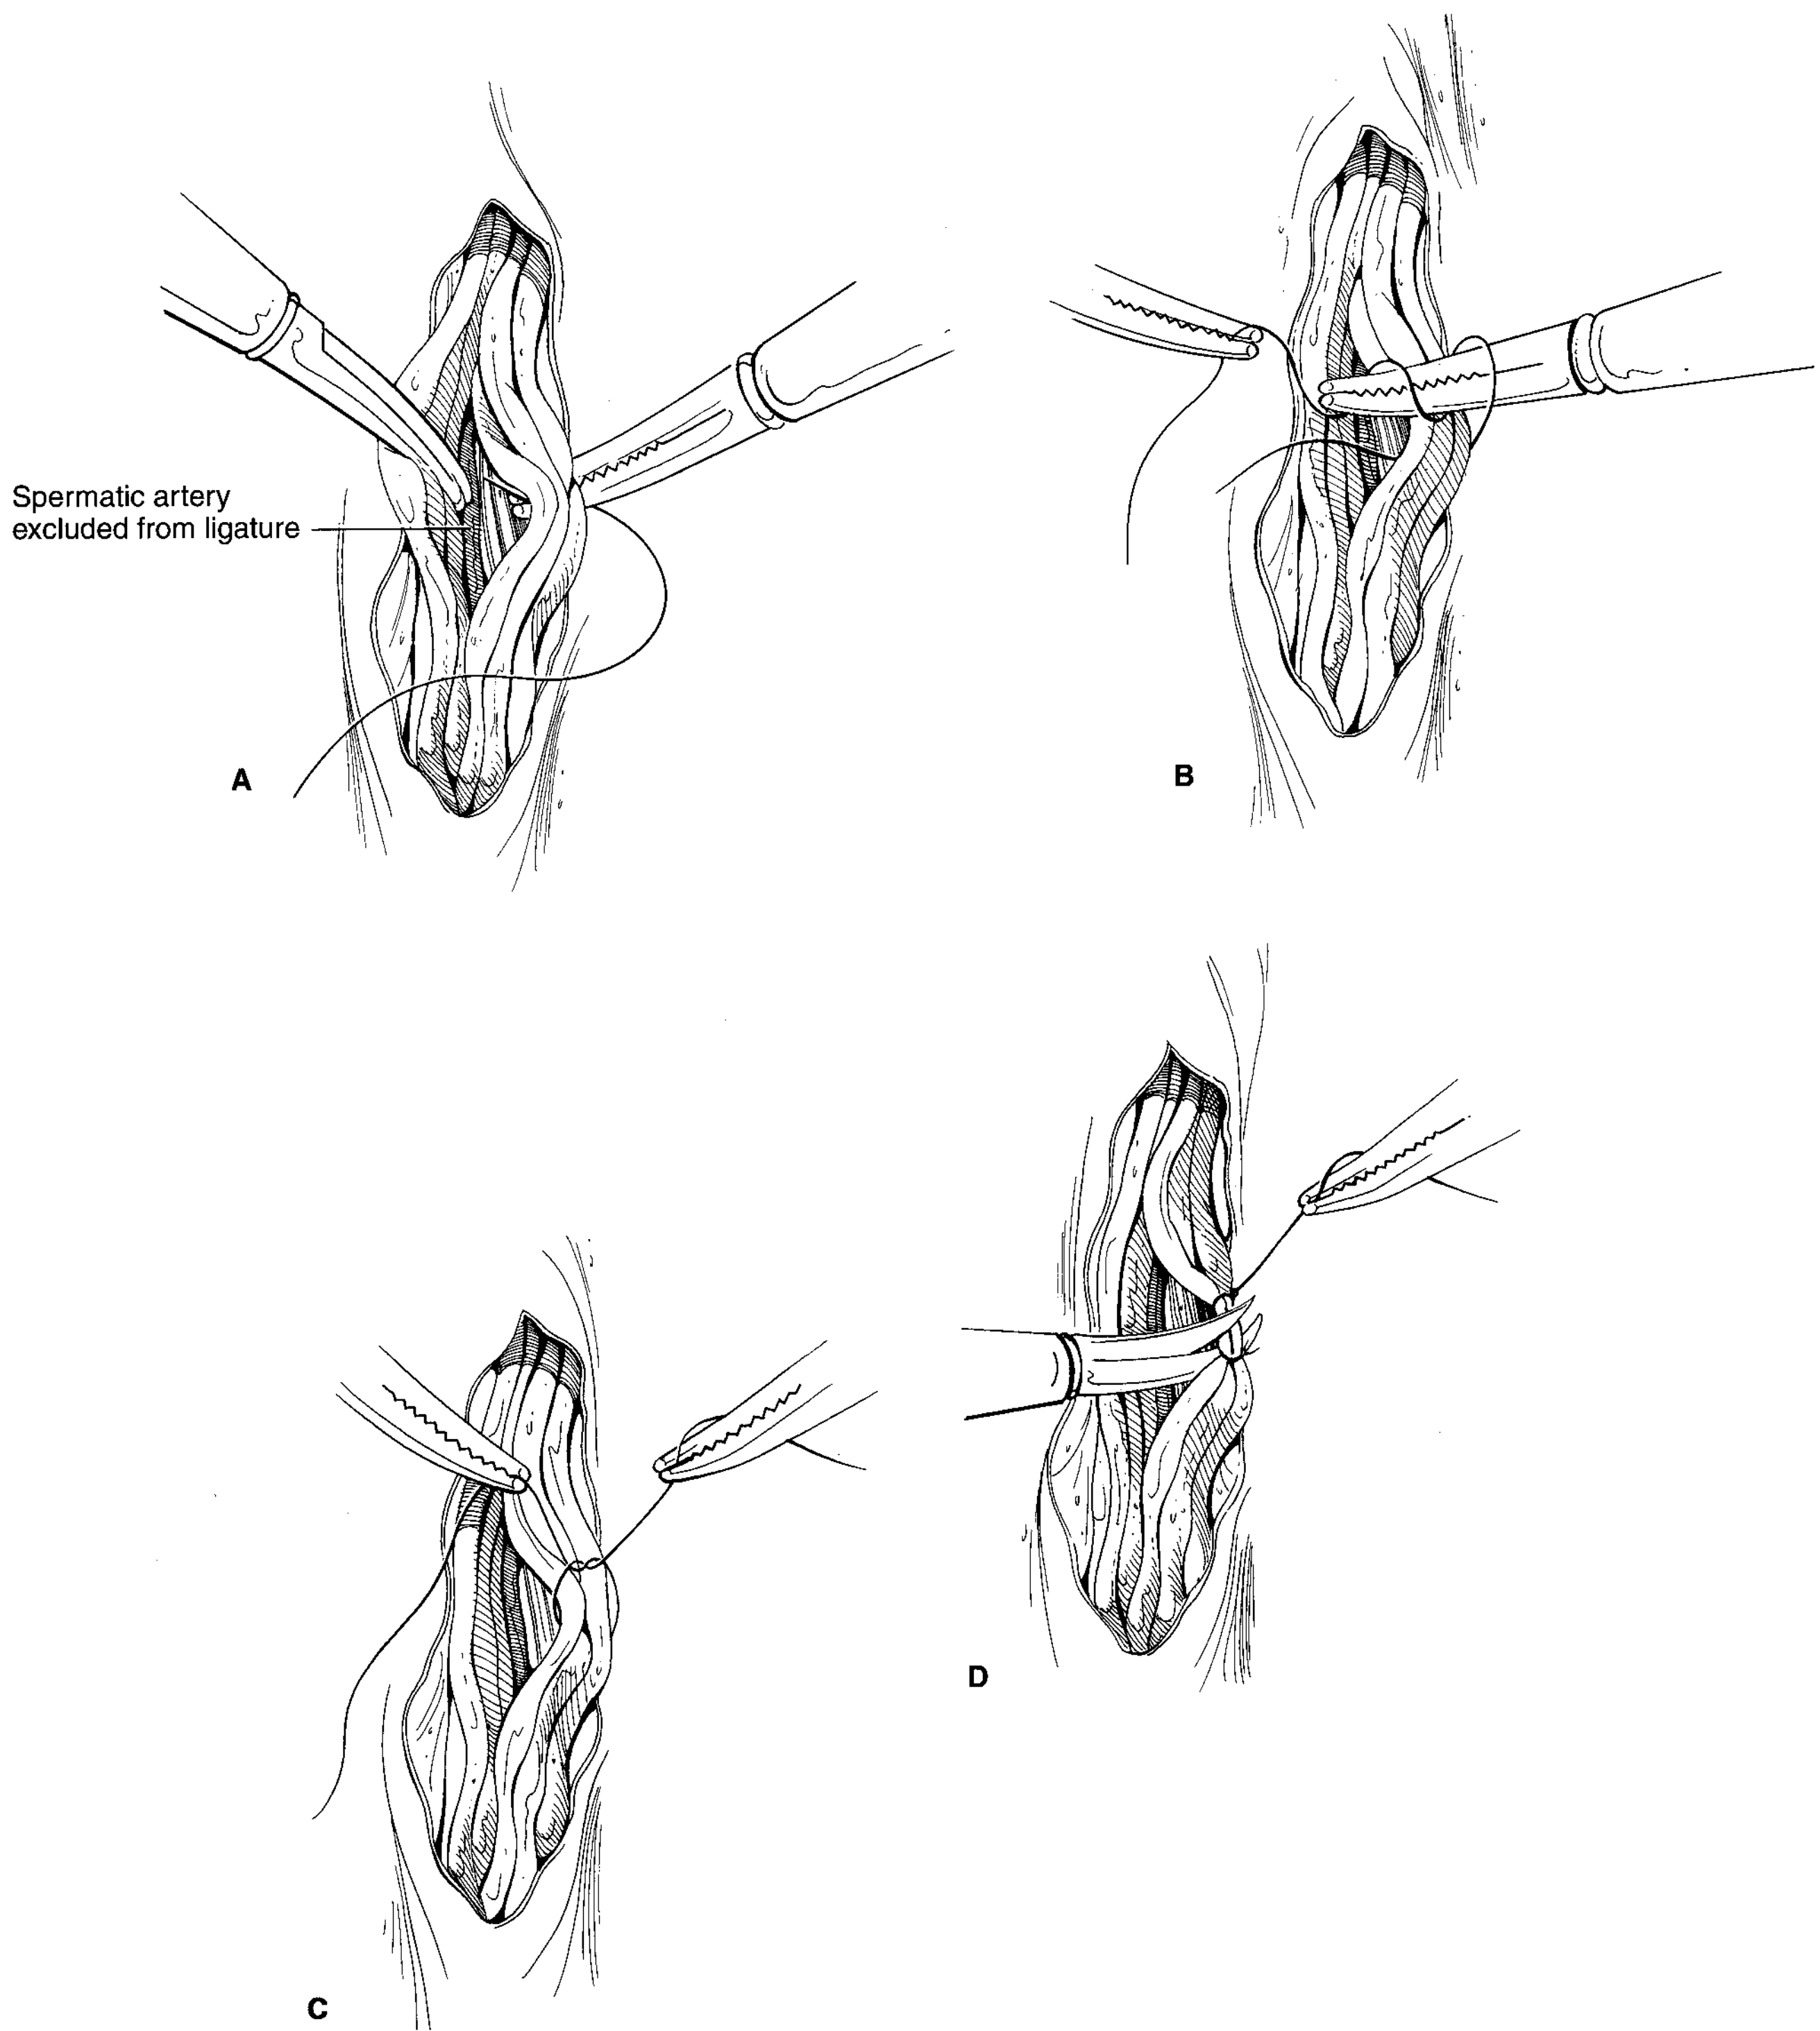

### Surgical Technique

#### Ureterolysis

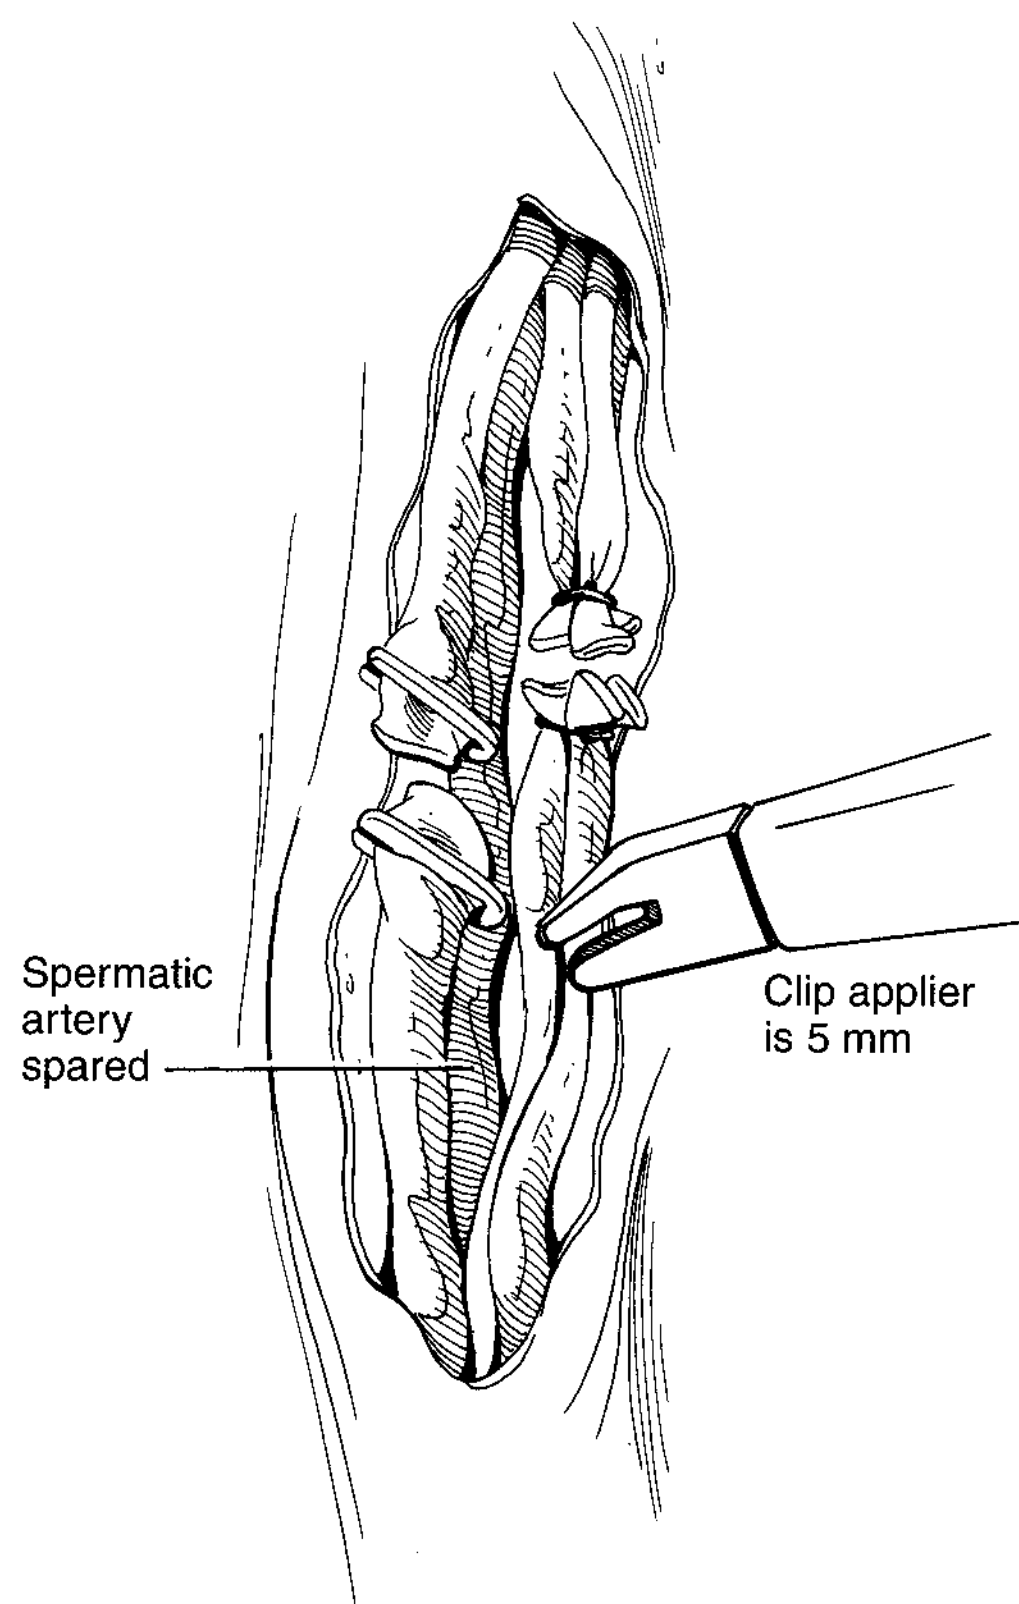

Laparoscopic ureterolysis begins with cystoscopy and retrograde placement of either a double-pigtail stent or a ureteral catheter to aid in identification of the ureter during laparoscopy. Either a regular 5Fr open-ended or lighted catheter may be used. To further aid ureteral delineation from the surrounding dense fibrotic tissue, a super-stiff guide wire may also be placed inside a ureteral catheter (10). Similar to laparoscopic pyeloplasty positioning, the patient is placed in a lateral decubitus position with the ipsilateral side elevated to allow gravity retraction of the bowels. If a bilateral ureterolysis (6,9,10) is planned, the patient may either be left supine or repositioned (this is recommended) after completion of the first side.

The template for port placement will vary depending on the extent of fibrosis and the levels of the ureter involved. A standard pyeloplasty template (see earlier under calculus management) may be sufficient for isolated upper ureteral involvement, but additional ports may be necessary to free the entire ureter.

After creating pneumoperitoneum and rotating the patient, the colon is mobilized along the white line of Toldt and allowed to fall medially. When necessary, this incision is extended over the iliac vessels to allow exposure of the full course of the ureter. Depending on the extent of RPF, the ureters are often retracted medially and may be overlying the great vessels entrapped in dense fibrous scars, making localization difficult.

**FIGURE 135.6** **A:** When performing an artery-sparing varix ligation, the vascular bundle that does not contain the spermatic artery is ligated and then divided. For small venous aggregates or single spermatic veins, the 5-mm reusable clip or suture ligature is utilized based on surgeon preference. A 5- to 10-cm ligature is passed into the abdominal cavity. One end is passed from right to left under the vessels to be ligated, extending only 1 cm beyond the vessels. The other end is long to facilitate instrument tie. **B:** The long end is grasped by the left-hand instrument, allowing sufficient slack to permit easy wrapping around the tip of the right-hand instrument. The instrument tie can be accomplished with two curved dissectors with tips rotated up. Alternatively, instruments specifically designed for laparoscopic suture and ligation may be used. **C:** The nonarterial vascular bundle is ligated. **D:** The spermatic veins are divided between ligatures.

**FIGURE 135.7** Upon completion of the procedure, all spermatic veins have been ligated and divided by either clip or suture. Only the spermatic artery or arteries remain, and arterial patency is documented by Doppler.

If a ureteral catheter was placed, gentle manipulation may help locate the ureter. Alternatively, the distal ureter may be encountered medial to the medial umbilical ligament and traced proximally, or the proximal ureter may be isolated at the ureteropelvic junction and dissected distally. Once positively identified, a window is created around the ureter and vascular tape or a vessel loop is placed around to allow retraction without undue manipulation of the ureter. Combinations of blunt, sharp, and electrocautery dissection are necessary to liberate the ureter from surrounding fibrosis, although the latter should be used sparingly to avoid vascular compromise. For patients with RPF, after the ureter is mobilized, it should be intraperitonealized, and after this is accomplished, the posterior peritoneum is closed with clips or preferably with sutures. If a ureteral catheter was placed at the onset, it should be exchanged for an indwelling self-retaining ureteral stent at this time. Special efforts must be made to rule out malignancy

as the underlying cause of the fibrosis, and multiple biopsies are taken from periureteral tissues and sent for both frozen and permanent analysis.

Laparoscopic ureterolysis is also amenable to hand-assisted laparoscopic approaches and has also been reported using robotic techniques. The principles of ureterolysis can be followed with the use of the intra-abdominal hand to assist in identification and dissection of the ureter (9).

### Management of Ureteral Strictures

For benign, iatrogenic or idiopathic ureteral strictures, the strictured ureteral segment is excised. Caution should be exercised around the iliac vessels and the inferior vena cava so as to prevent vascular injury. The ureteral ends are then spatulated. The posterior walls of the ureteral ends are anastomosed using 4-0 polyglactin sutures. A ureteral stent is then placed in a retrograde fashion utilizing the 5Fr open-ended ureteral catheter, which is removed after a guide wire is placed through it. The anterior end-to-end anastomosis of the ureteral ends is now completed. A closed-suction drain is placed. A Foley catheter drains the bladder postoperatively to maintain a low-pressure urinary drainage system.

If the ureteral stricture is long, and if the anastomosis is under tension, then the management strategy may involve further laparoscopic ureterolysis to ensure a tension-free anastomosis. Rarely, one may have to utilize procedures such as nephropexy to enable a tension-free end-to-end ureteroureterostomy.

### Postoperative Management

The Foley catheter is usually left indwelling for 48 hours. The drain is kept in place for another day or two, then removed. The indwelling stent is removed using a flexible cystoscope 4 to 6 weeks postoperatively. Postoperative imaging is recommended to evaluate for any residual or silent recurrence of the hydronephrosis.

### Outcomes

A recent multicenter review indicated overall success rates of 83% per renal unit (6). This was confirmed by follow-up imaging in these cases. Other institutional series are also favorable (6,9,11).

### Complications

Any complication that can be associated with laparoscopy, including conversion to an open procedure, has been reported. One series reported a conversion rate to open of 17.6% (11).

## CHAPTER 136 ■ TISSUE-ENGINEERING STRATEGIES FOR UROGENITAL REPAIR

ANTHONY ATALA

Congenital disorders, cancer, trauma, infection, inflammation, iatrogenic injuries, or other conditions of the genitourinary system can lead to organ damage or complete loss of function. Most of these situations require eventual reconstructive procedures. These procedures can be performed with native nonurologic tissues (skin, gastrointestinal segments, or mucosa), homologous tissues from a donor (cadaver or living donor kidney), heterologous tissues or substances (bovine collagen), or artificial materials (silicone, polyurethane, Teflon). However, these materials often lead to complications after reconstruction. The implanted tissue is sometimes rejected, and often the inherently different functional aspects of the different tissues or materials used in the reconstruction cause a mismatch in the system. As an example, current methods of replacing bladder tissue with gastrointestinal segments can be problematic due to the opposite ways in which these two tissues handle solutes; urologic tissue normally excretes materials, but gastrointestinal tissue generally absorbs the same materials, and this type of mismatch can lead to metabolic complications as well as infection. The replacement of lost or deficient urologic tissues with functionally equivalent ones would improve the outcome of reconstructive surgery in the genitourinary system. This may soon be possible with novel tissue-engineering techniques.

---

### TISSUE-ENGINEERING BASICS

---

Tissue engineering uses the principles of cell transplantation, materials science, and biomedical engineering to develop biological substitutes that can restore and maintain the normal function of damaged or lost tissues and organs. It can involve injection of functional cells into a nonfunctional site to stimulate regeneration, or it may involve the use of biomaterials. These are natural or synthetic matrices, often termed scaffolds, that encourage the body's natural ability to repair itself and assist in determination of the orientation and direction of new tissue growth. Often, tissue engineering uses a combination of both of these techniques. For example, biomaterial matrices seeded with cells can be implanted into the body to encourage the growth or regeneration of functional tissue.

---

### Biomaterials Used in Genitourinary Tissue Construction

---

Biomaterials in genitourinary tissue engineering function as an artificial extracellular matrix (ECM) and are used to replace biologic and mechanical functions of native ECM found in

tissues in the body. They may serve as simple cell carriers, or they can provide structural support for tissue formation. Biomaterials can be fabricated from synthetic materials, naturally derived substances, or both combined, and they can be configured into liquid, gel, or solid forms depending on the specific needs. These substances facilitate the localization and delivery of cells to desired sites in the body as well as define a three-dimensional space for the formation of new tissues with appropriate structure. They also serve as a guide for the development of new tissues with appropriate function (32,33). Direct injection of cell suspensions without a biomaterial carrier has been attempted, but without this specialized scaffold function, it is difficult to control the localization of transplanted cells (13,55). Furthermore, bioactive signals, such as cell-adhesion peptides and growth factors, can be incorporated along with cells to help regulate cellular function (33). Cell behavior in the newly formed tissue can be regulated by multiple interactions of the cells with their microenvironment, including interactions with cell-adhesion ligands and with soluble growth factors (29). Some materials are designed to carry these factors into the body and release them at a specified rate to assist the cells in the organizational process.

The ideal biomaterial should be biocompatible, promote cellular interaction and tissue development, and possess similar mechanical and physical properties to the tissue to be generated so that the nascent tissue will be able to withstand *in vivo* forces. Generally, three classes of biomaterials have been used for the engineering of genitourinary tissues: naturally derived materials, such as collagen and alginate; acellular tissue matrices, such as bladder submucosa and small intestinal submucosa; and synthetic polymers, such as polyglycolic acid (PGA), polylactic acid (PLA), and polylactic (PLGA). While synthetic polymers can be produced reproducibly on a large scale with controlled properties of strength, degradation rate, and microstructure, naturally derived materials and acellular tissue matrices have the potential advantage of biologic recognition, which can lessen host-versus-graft reactions.

---

### Cells for Urogenital Tissue-Engineering Applications

---

Often, when cells are used for tissue engineering, donor tissue is removed and dissociated into individual cells, which are either implanted directly into the host or expanded in culture, attached to a support matrix, and then implanted. The implanted tissue can be heterologous, allogeneic, or autologous. Ideally, this approach allows lost tissue function to be restored or replaced in toto with limited complications (1–4,6,7).

Autologous cells are the ideal choice, as their use circumvents many of the inflammatory and rejection issues associated with a nonself donor. However, one limitation of cell-based tissue-engineering techniques has been the difficulty of growing specific cell types in large quantities. Even when certain organs, such as the liver, have a high regenerative capacity *in vivo*, *in vitro* expansion of cells derived from these organs has proved to be difficult. However, the discovery of privileged sites for committed precursor cells in specific organs and extensive study of the conditions that promote precursor cell maintenance and differentiation within these sites have begun to overcome some of the limitations associated with cell expansion *in vitro*. Urothelial cells that are present in the bladder, for instance, have been grown in culture in the past, but only with limited success. However, several novel culture protocols have been developed over the past two decades that allow the maintenance of urothelial precursor cells in an undifferentiated state. As these cells can remain in the growth phase, the ability to expand urothelial cultures is vastly improved (18,42,58,62). These studies suggest that it may be possible to collect autologous urothelial cells from human bladders, expand them in culture, and return them to the donor in sufficient quantities for reconstructive purposes (18,23,42,43,48,58). In addition to urothelial cells, methods to induce the *in vitro* expansion of a variety of primary human cells have been developed, making the use of autologous cells for clinical applications a real possibility, though there are still hurdles to overcome.

Another major concern has been that, in cases where cells must be expanded from a diseased organ, there may no longer be enough normal cells present in that organ to begin the process. Recent research suggests that this may not be the case, however. For example, one study has shown that cultured neuropathic bladder smooth muscle cells possess and maintain different characteristics than normal smooth muscle cells *in vitro*, as demonstrated by growth assays, contractility, and adherence tests *in vitro* (44). Despite these differences, when neuropathic smooth muscle cells were cultured *in vitro* and then seeded onto matrices and implanted *in vivo*, the tissue-engineered constructs showed the same properties as the constructs engineered with normal cells (37). It is now known that genetically normal progenitor cells, which are the reservoirs for new cell formation, are present even in diseased tissue. These normal progenitors are programmed to give rise to normal tissue, regardless of whether they reside in a normal or diseased environment. Therefore, the stem cell niche and its role in normal tissue regeneration remains a fertile area of ongoing investigation.

### Stem Cells and Other Pluripotent Cell Types

Most current strategies for tissue engineering depend upon a sample of autologous cells from the diseased organ of the host. In some instances, primary autologous human cells cannot be expanded from a particular organ, such as the pancreas. In these situations, pluripotent human stem cells are envisioned to be an ideal source of cells, as they can differentiate into nearly any replacement tissue in the body.

Embryonic stem (ES) cells exhibit two remarkable properties: the ability to proliferate in an undifferentiated but still pluripotent state (self-renewal), and the ability to differentiate into a large number of specialized cell types (14). They can be isolated from the inner cell mass of the embryo during the blastocyst stage, which occurs 5 days after fertilization. These

cells have been maintained in the undifferentiated state for at least 80 passages when grown using current published protocols (69). In addition, many protocols for differentiation into specific cell types in culture have been published. However, many uses of these cells have been controversial in the United States due to the ethical dilemmas that are associated with the manipulation of embryos in culture.

Adult stem cells have the advantage of avoiding some of the ethical issues associated with embryonic cells, and, unlike embryonic cells, they do not transdifferentiate into a malignant phenotype, so there is a diminished risk of teratoma formation should the cells be implanted *in vivo*. However, adult stem cells are limited for clinical use because expansion to the large quantities needed for tissue engineering is difficult.

Fetal stem cells derived from amniotic fluid and placentas have recently been described and represent a novel source of stem cells (19,20). The cells express markers consistent with human ES cells, such as octamer-4 (OCT4) and stage-specific embryonic antigen-4 (SSEA-4), but they do not form teratomas. The cells are multipotent and are able to differentiate into cells from all three germ layers. In addition, the cells have a high replicative potential and could be stored for future use, without the risks of rejection and without ethical concerns.

Nuclear transfer, or cloning, can serve as another source of pluripotent “stem” cells that could possibly be used for regenerative medicine therapies. Two types of cloning procedures exist: reproductive cloning and therapeutic cloning. Banned in most countries for human applications, reproductive cloning is used to generate an embryo that has identical genetic material as its cell source. This embryo is then implanted into the uterus of a pseudopregnant female to give rise to an infant that is a clone of the donor. While therapeutic cloning also produces an embryo that is genetically identical to the donor nucleus, this process is used to generate blastocysts that are explanted and grown in culture, rather than *in utero*, to produce ES cell lines. These autologous stem cells have the potential to become almost any type of cell in the adult body, and thus would be useful in tissue and organ replacement applications (25). Therefore, therapeutic cloning, which has also been called somatic cell nuclear transfer, may provide an alternative source of transplantable cells that are identical to the patient’s own cells.

Recently, exciting reports have been published of the successful transformation of adult cells into pluripotent stem cells through a type of genetic “reprogramming.” Reprogramming is a technique that involves dedifferentiation of adult somatic cells to produce patient-specific pluripotent stem cells, without the use of embryos. Cells generated by reprogramming would be genetically identical to the somatic cells (and thus, the patient who donated these cells) and would not be rejected. Takahashi and Yamanaka were the first to discover that mouse embryonic fibroblasts (MEFs) and adult mouse fibroblasts could be reprogrammed into an “induced pluripotent state (iPS)” (67). Takahashi and Yamanaka were the first to discover 24 genes that were thought to be important for ES cells and identified 4 key genes that were required to bestow ES cell–like properties on fibroblasts: Oct3/4, Sox2, c-Myc, and Klf4. Mouse embryonic fibroblasts and adult fibroblasts were cotransduced with retroviral vectors, each carrying one of the 4 genes, and transduced cells were selected via drug resistance. The resultant iPS cells possessed the immortal growth characteristics of self-renewing ES cells, expressed genes specific for ES cells, and generated embryoid bodies *in vitro* and teratomas *in vivo*. When iPS cells were injected into mouse blastocysts,

they contributed to a variety of cell types. However, although iPS cells selected in this way were pluripotent, they were not identical to ES cells. Unlike ES cells, chimeras made from iPS cells did not result in full-term pregnancies. Gene expression profiles of the iPS cells showed that they possessed a distinct gene expression signature that was different from that of ES cells. In addition, the epigenetic state of the iPS cells was somewhere between that found in somatic cells and that found in ES cells, suggesting that the reprogramming was incomplete.

These results were improved significantly by Wernig and Jaenisch in July 2007 (70). Fibroblasts were infected with retroviral vectors and selected for the activation of endogenous Oct4 or Nanog genes. Results from this study showed that DNA methylation, gene expression profiles, and the chromatin state of the reprogrammed cells were similar to those of ES cells. Teratomas induced by these cells contained differentiated cell types representing all three embryonic germ layers. Most importantly, the reprogrammed cells from this experiment were able to form viable chimeras and contribute to the germ line like ES cells, suggesting that these iPS cells were completely reprogrammed. Wernig et al. (70) observed that the number of reprogrammed colonies increased when drug selection was initiated later (day 20 rather than day 3 post-transduction). This suggests that reprogramming is a slow and gradual process and may explain why previous attempts resulted in incomplete reprogramming.

It has recently been shown that reprogramming of human cells is possible (66,78). Takahashi and Yamanaka (67) showed that retrovirus-mediated transfection of Oct3/4, Sox2, Klf4 and c-MYC generates human iPS cells that are similar to human embryonic stem (hES) cells in terms of morphology, proliferation, gene expression, surface markers, and teratoma formation. Thomson's group (78) showed that retroviral transduction of Oct4, Sox2, Nanog, and LIN28 could generate pluripotent stem cells without introducing any oncogenes (c-MYC). Both studies showed that human iPS cells were similar but not identical to hES cells.

Another concern is that these iPS cells contain three to six retroviral integrations (one for each factor), which may increase the risk of tumorigenesis. Okita et al. (52) studied the tumor formation in chimeric mice generated from Nanog-iPS cells and found that 20% of the offspring developed tumors due to the retroviral expression of c-myc. An alternative approach would be to use a transient expression method, such as adenovirus-mediated system, since both Jaenisch and Yamanaka showed strong silencing of the viral-controlled transcripts in iPS cells (47,52). This indicates that these viral genes are only required for the induction, not the maintenance, of pluripotency.

Another concern is the use of transgenic donor cells for reprogrammed cells in the mouse studies. In both mouse studies, iPS cells were isolated by selecting for the activation of a drug-resistant gene inserted into endogenous Fbx15, Oct3/4, or Nanog. The use of genetically modified donors hinders its clinical applicability for humans. To assess whether iPS cells can be derived from genetically unmodified donor cells, murine embryonic fibroblast (MEF) and adult skin cells were retrovirally transduced with Oct3/4, Sox2, c-Myc, and Klf4 and ES-like colonies were isolated by morphology, without the use of drug selection for Oct4 or Nanog (47). iPS cells from unmodified donor cells formed teratomas and generated live chimeras. This study suggests that genetically modified donor cells are not necessary to generate iPS cells.

Although this is an exciting phenomenon, it is unclear why reprogramming of adult fibroblasts and reprogramming of mesenchymal stromal cells have similar efficiencies (67). It would seem that cells that are already multipotent could be reprogrammed with greater efficiency, since the more undifferentiated the donor nucleus, the better somatic cell nuclear transfer (SCNT) performs (12). This further emphasizes our limited understanding of the mechanism of reprogramming, yet the potential for this area of study is exciting.

---

## APPLICATION OF TISSUE ENGINEERING TO SPECIFIC UROLOGICAL PROBLEMS

---

### Injectable (Cell) Therapies

---

#### Injectable Chondrocytes

Vesicoureteral reflux (VUR) and stress urinary incontinence (SUI) are two urologic conditions that can result from dysfunction of a specific sphincter muscle. When severe, these conditions are repaired surgically. However, cell-based therapies for both VUR and incontinence would be an important alternative to surgical repair of these conditions. Ideally, such a therapy would be easily administered by injection and well tolerated by the patient. Currently, the injection of bulking agents such as Teflon paste is used clinically to treat VUR in particular, but the biocompatibility of synthetic bulking agents over the long term is a concern. The ideal substance for endoscopic treatment of reflux and incontinence should be injectable, nonantigenic, nonmigratory, volume-stable, and safe for human use.

Toward this goal, long-term studies were conducted to determine the effects of injectable chondrocytes for the treatment of VUR in vivo (3). Chondrocytes were chosen because the use of autologous cartilage for the treatment of VUR in humans would satisfy all of the requirements for an ideal injectable cell-based therapy. Chondrocytes derived from an ear biopsy can be readily grown and expanded in culture. Neocartilage formation can be achieved in vitro and in vivo using chondrocytes cultured on synthetic biodegradable polymers. In the VUR experiments, chondrocytes were suspended in an alginate matrix and injected around the vesicoureteral sphincter. In time, normal cartilage replaced the alginate as the alginate slowly degraded. This system was then adapted for the treatment of VUR in a porcine model (6). These studies show that chondrocytes can be easily harvested and combined with alginate in vitro, that the suspension can be easily injected cystoscopically, and that the elastic cartilage tissue formed is able to correct VUR without any evidence of obstruction.

Two multicenter clinical trials were conducted using this engineered chondrocyte technology. First, patients with VUR were treated at ten centers throughout the United States. The patients had a similar success rate as with other injectable substances in terms of cure. Cartilage formation was not noted in patients with treatment failure. Patients who were cured probably had a biocompatible region of engineered autologous tissue present (22). Secondly, patients with urinary incontinence were treated endoscopically with injected chondrocytes at three different medical centers. Phase 1 trials showed an approximate success rate of 80% at 3 and 12 months postoperatively (9).

### Injectable Muscle Cells

The potential use of injectable, cultured myoblasts for the treatment of SUI has been investigated (15,73). In one study, labeled myoblasts were directly injected into the proximal urethra and lateral bladder walls with a microsyringe in an open surgical procedure. Tissue harvested up to 35 days postinjection contained the labeled myoblasts, as well as evidence of differentiation into regenerative myofibers. This study shows that a significant portion of the injected myoblast population survived and remained *in vivo*. Similar techniques of sphincter-derived muscle cells have been used for the treatment of urinary incontinence in a pig model (64). The fact that cultured myoblasts survive after injection and mature into muscle tissue supports the feasibility of using culture-expanded cells of muscular origin as an injectable bioimplant.

The use of injectable muscle precursor cells has also been investigated for use in the treatment of urinary incontinence due to irreversible urethral sphincter injury or developmental defects. Muscle precursor cells are the quiescent satellite cells found in each myofiber that can proliferate to form myoblasts and eventually myotubes and new muscle tissue. Intrinsic muscle precursor cells have previously been shown to play an active role in the regeneration of injured striated urethral sphincter (71). In a subsequent study, autologous muscle precursor cells were injected into a rat model of urethral sphincter injury, and both replacement of mature myotubes and restoration of functional motor units were noted in the regenerating sphincter muscle tissue (72). This is the first demonstration of the replacement of both sphincter muscle tissue and its innervation by the injection of muscle precursor cells. This suggests the possibility that muscle precursor cells may be a minimally invasive solution for urinary incontinence in patients with irreversible urinary sphincter muscle insufficiency.

In addition, injectable muscle-based gene therapy and tissue engineering were combined to improve detrusor function in a bladder injury model, and this may be a novel treatment option for urinary incontinence (26).

### Injectable Leydig Cells

Patients with testicular dysfunction require androgen replacement for somatic development. Conventional treatment for

testicular dysfunction consists of periodic intramuscular injections of chemically modified testosterone or application of a transdermal testosterone patch. However, long-term nonpulsatile testosterone therapy is not optimal and can cause multiple problems, including erythropoiesis and bone density changes.

A system was designed wherein Leydig cells were microencapsulated for controlled testosterone replacement. Purified Leydig cells were isolated and encapsulated in an alginate-poly-L-lysine solution. The encapsulated Leydig cells were injected into castrated animals, and serum testosterone was measured serially; the animals were able to maintain testosterone levels in the long term (45). These studies suggest that microencapsulated Leydig cells may be able to replace or supplement testosterone in situations where anorchia or testicular failure is present.

## Tissue Therapy: Engineering Complete Structures in the Genitourinary Tract

### Urethra

Various strategies have been proposed over the years for the regeneration of urethral tissue. Woven meshes of PGA (Dexon) have been used to reconstruct urethras in dogs (53). Also, PGA has been used as a cell transplantation vehicle to engineer tubular urothelium *in vivo* (7). Small intestinal submucosa (SIS) without cells was used as an onlay patch graft for urethroplasty in rabbits (35). Finally, a homologous graft of acellular urethral matrix was also used in a rabbit model (63).

Bladder-derived acellular collagen matrix has proven to be a suitable graft for repair of urethral defects in rabbits. In the rabbit model, the neourethras created with these matrices demonstrated a normal urothelial luminal lining and organized muscle bundles shortly after repair (35,63). These results were confirmed clinically in a series of patients with a history of failed hypospadias reconstruction, wherein the urethral defects were repaired with human bladder acellular collagen matrices (Fig. 136.1) (5,16). One of the advantages

**FIGURE 136.1** Tissue engineering of the urethra using a collagen matrix. **A:** Representative case of a patient with a bulbar stricture. **B:** Urethral repair. The strictured tissue is excised, preserving the urethral plate (left), and the matrix is anastomosed to the urethral plate in an onlay fashion on the right. **C:** Urethrogram 6 months after repair. **D:** Cystoscopic view of urethra before surgery (left) and 4 months after repair (right).

of this material over nongenital tissue grafts currently used for urethroplasty (e.g., buccal mucosa) is that the material is “off the shelf.” This eliminates the necessity of additional surgical procedures for graft harvesting, which may decrease operative time, as well as the potential morbidity due to the harvest procedure.

The previous techniques, using nonseeded acellular matrices, were successfully applied experimentally and clinically for onlay urethral repairs. However, when tubularized urethral repairs were attempted experimentally, adequate urethral tissue regeneration was not achieved and complications ensued, such as graft contracture and stricture formation (41). Tubularized collagen matrices seeded with cells have performed better in animal studies. In a rabbit model, entire urethral segments were resected and urethroplasties were performed with tubularized collagen matrices either seeded with autologous cells or without cells. The tubularized collagen matrices seeded with autologous cells formed new tissue that was histologically similar to native urethral tissue (59). The tubularized collagen matrices without cells led to poor tissue development, fibrosis, and stricture formation.

### Bladder

Currently, gastrointestinal segments are commonly used for bladder replacement or repair. However, gastrointestinal tissues are designed to absorb solutes that urinary tissue excretes, and due to this difference in function, multiple complications may ensue, such as infection, metabolic disturbances, urolithiasis, perforation, increased mucus production, and malignancy (30,31,46). Because of the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative reconstructive procedures for bladder replacement or repair. The use of tissue expansion, seromuscular grafts, matrices for tissue regeneration, and tissue engineering with cell transplantation has been investigated.

**Tissue Expansion for Bladder Augmentation.** A system of progressive dilation for ureters and bladders has been proposed as a method of bladder augmentation but has not yet been attempted clinically. Augmentation cystoplasty performed with dilated ureteral segments in animals has resulted in an increased bladder capacity ranging from 190% to 380% (38,61). A system for the progressive expansion of native bladder tissue has also been used for augmenting bladder volumes in animals. Within 30 days after progressive dilation, the neoreservoir volume was expanded at least tenfold. Urodynamic studies showed normal compliance in all animals, and microscopic examination of the expanded neoreservoir tissue showed a normal histology. A series of immunocytochemical studies demonstrated that the dilated bladder tissue maintained normal phenotypic characteristics (61).

**Seromuscular Grafts and De-epithelialized Bowel Segments.** Seromuscular grafts and deepithelialized bowel segments, either alone or over a native urothelium, have also been attempted (10,11,17,24,51,60). Keeping the urothelium intact avoids the complications associated with use of bowel in continuity with

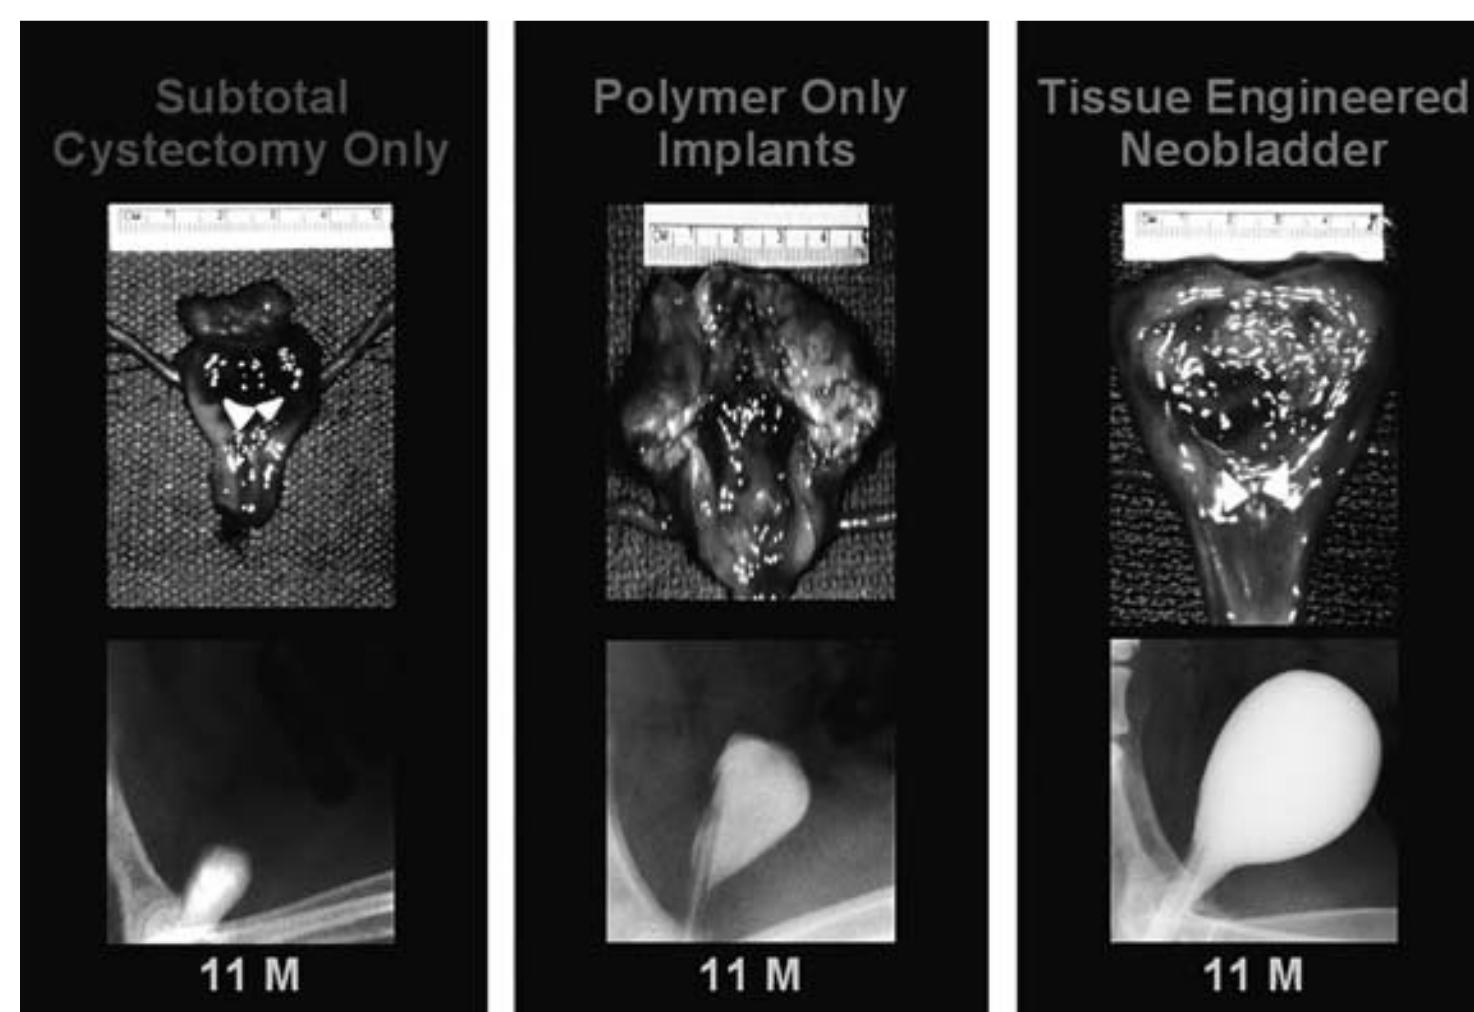

the urinary tract (11,24). An example of this strategy is the combination of the techniques of autoaugmentation with those of enterocystoplasty. An autoaugmentation is performed and the diverticulum is covered with a demucosalized gastric or intestinal segment.

**Matrices for Bladder Regeneration.** Nonseeded allogeneic acellular matrices have served as scaffolds for the ingrowth of host bladder wall components. The matrices are prepared by mechanically and chemically removing all cellular components from bladder tissue (54,57,65,75). The matrices serve as vehicles for partial bladder regeneration, and relevant antigenicity is not evident. One example is SIS, a biodegradable, acellular, xenogeneic collagen-based tissue matrix. SIS was first used in the early 1980s as an acellular matrix for tissue replacement in the vascular field. It has been shown to promote regeneration of a variety of host tissues, including blood vessels and ligaments (8). Animal studies have shown that the nonseeded SIS matrix used for bladder augmentation is able to regenerate *in vivo* (34,36).

In multiple studies using various materials as nonseeded grafts for cystoplasty, the urothelial layer was able to regenerate normally, but the muscle layer, although present, was not fully developed (36,57,65,75). Often the grafts contracted to 60% to 70% of their original size with little increase in bladder capacity or compliance (39,56). Studies involving acellular matrices that may provide the necessary environment to promote cell migration, growth, and differentiation are being conducted. Recently, bladder regeneration has been shown to be more reliable when the SIS was derived from the distal ileum (34). With continued research in this area, these matrices may have a clinical role in bladder replacement in the future.

**Bladder Replacement Using Tissue Engineering.** Cell-seeded allogeneic acellular bladder matrices have been used for bladder augmentation in dogs. A group of experimental dogs underwent a trigone-sparing cystectomy and were randomly assigned to one of three groups. One group underwent closure of the trigone without a reconstructive procedure, another underwent reconstruction with a nonseeded bladder-shaped biodegradable scaffold, and the last underwent reconstruction using a bladder-shaped biodegradable scaffold that was seeded with autologous urothelial and smooth muscle cells (50).

The cystectomy-only and nonseeded controls maintained average capacities of 22% and 46% of preoperative values, respectively. However, an average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements (Fig. 136.2). The subtotal cystectomy reservoirs that were not reconstructed and the polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42% total compliance, respectively). The compliance of the cell-seeded tissue-engineered bladders was almost no different from preoperative values (106%). Histologically, the nonseeded scaffold bladders presented a pattern of normal urothelial cells with a thickened fibrotic submucosa and a thin layer of muscle fibers. The retrieved tissue-engineered bladders showed a normal cellular organization consisting of a trilayer of urothelium, submucosa, and muscle (50).

**FIGURE 136.2** Gross specimens and cystograms at 11 months of the cystectomy-only, nonseeded controls, and cell-seeded tissue-engineered bladder replacements in dogs. The cystectomy-only bladder had a capacity of 22% of the preoperative value and a decrease in bladder compliance to 10% of the preoperative value. The nonseeded controls showed significant scarring with a capacity of 46% of the preoperative value and a decrease in bladder compliance to 42% of the preoperative value. An average bladder capacity of 95% of the original precystectomy volume was achieved in the cell-seeded tissue-engineered bladder replacements, and the compliance showed almost no difference from preoperative values that were measured when the native bladder was present (106%).

A clinical experience involving engineered bladder tissue for cystoplasty reconstruction was conducted starting in 1999. A small pilot study of seven patients was reported, using a collagen scaffold seeded with cells either with or without omentum coverage, or a combined PGA-collagen scaffold seeded with cells and omental coverage (Fig. 136.3). The patients reconstructed with the engineered bladder tissue created with the PGA-collagen cell-seeded scaffolds showed increased compliance, decreased end-filling pressures, increased capacities, and longer dry periods (2). Although the experience is promising in terms of showing that engineered tissues can be implanted safely, it is just a start in terms of accomplishing the goal of engineering fully functional bladders. Further experimental and clinical work is being conducted.

### Kidney

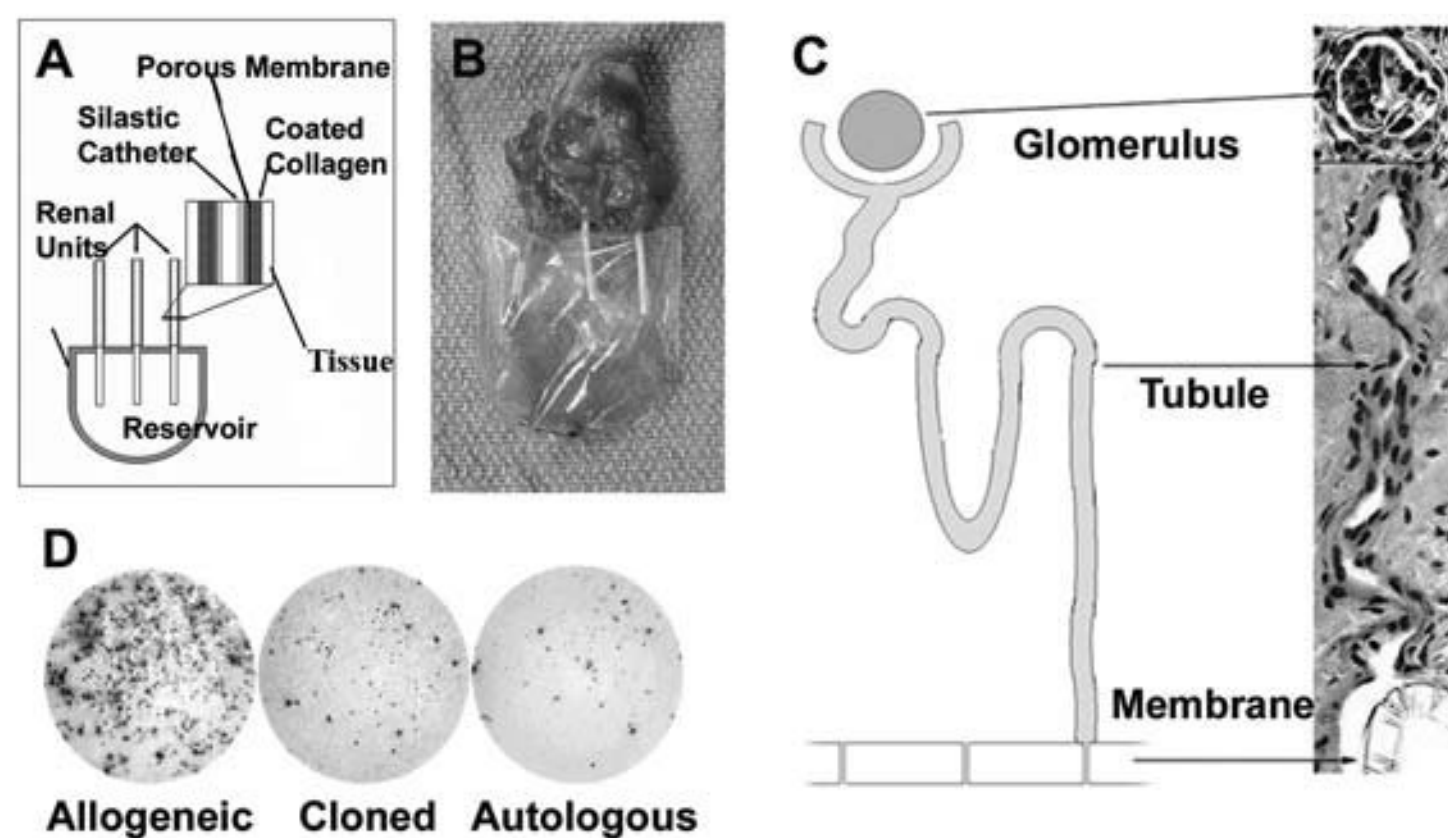

The kidney is the most challenging organ in the genitourinary system to reconstruct because of its extremely complex structure and function. Concepts for a bioartificial kidney are currently being explored. Some investigators are pursuing the replacement of isolated kidney function parameters using extracorporeal units, while others are aiming to replace total renal function with tissue-engineered bioartificial renal structures.

**Ex Vivo Functioning Renal Units.** Dialysis is currently the most common form of renal replacement therapy. However, the relatively high morbidity and mortality resulting from this process have spurred investigators to seek alternative solutions. In an attempt to assess the viability and physiologic functionality of a cell-seeded device to replace the filtration, transport, metabolic, and endocrinologic functions of the kidney, a synthetic hemofiltration device and a device that contained tissue-engineered porcine renal tubules were incorporated into an extracorporeal perfusion circuit, and this was introduced into acutely uremic dogs. Levels of potassium and blood urea nitrogen (BUN) were controlled during treatment with the device. The fractional reabsorption of sodium and water was possible. Active transport of potassium, bicarbonate, and glucose, as well as a gradual ability to excrete ammonia, was observed. These results demonstrated the feasibility of an extracorporeal assist device that is reinforced by the use of proximal tubular cells (27).

Using similar techniques, the development of a tissue-engineered bioartificial kidney consisting of a conventional hemofiltration cartridge in series with a renal tubule assist device containing human renal proximal tubule cells was used in patients with acute renal failure in the intensive care unit. The initial clinical experience with this bioartificial kidney suggests that renal tubule cell therapy may provide a dynamic

**FIGURE 136.3** Construction of an engineered human bladder. **A:** The engineered bladder anastomosed to native bladder tissue with running 4-0 polyglycolic sutures. **B:** Implanted bladder covered with fibrin glue and omentum.

**FIGURE 136.4** Combining therapeutic cloning and tissue engineering to produce kidney tissue. **A:** Illustration of the tissue-engineered renal unit. **B:** Renal unit seeded with cloned cells, 3 months after implantation, showing the accumulation of urine-like fluid. **C:** There was a clear unidirectional continuity between the mature glomeruli, their tubules, and the polycarbonate membrane. **D:** ELISPOT analyses of the frequencies of T cells that secrete IFN-gamma after primary and secondary stimulation with allogeneic renal cells, cloned renal cells, or nuclear donor fibroblasts.

and individualized treatment program as assessed by acute physiologic and biochemical indices (28).

**Creation of Functional Renal Structures in Vivo.** Another approach to improve renal function involves the augmentation of renal tissue with kidney cells expanded in vitro and used for subsequent autologous transplantation. Most recently, an attempt was made to reconstitute renal epithelial cells for the generation of functional nephron units. Renal cells were harvested and expanded in culture. The cells were seeded onto a tubular device constructed from a polycarbonate membrane, which was connected at one end to a Silastic catheter that terminated in a reservoir. The device was implanted in athymic mice. Histologic examination of the implanted devices over time revealed extensive vascularization with formation of glomeruli and highly organized tubulelike structures. Immunocytochemical staining confirmed the renal phenotype. Additionally, yellow fluid was collected from inside the implant, and its creatinine and uric acid concentrations were consistent with the makeup of dilute urine. Further studies have shown the formation of renal structures in cows using nuclear transfer techniques (Fig. 136.4) (40). The expansion of this system to larger, three-dimensional structures is the next challenge awaiting researchers in the urogenital tissue-engineering field.

## Penis

**Reconstruction of Corporal Smooth Muscle.** One of the major components of the phallus is corporal smooth muscle. The creation of autologous functional and structural corporal tissue de novo would be beneficial in cases of congenital abnormality of the genitals and in other situations where reconstruction is functionally and aesthetically necessary. In order to look at the functional parameters of engineered corpora, acellular corporal collagen matrices were obtained from donor rabbit penile tissue, and autologous corpus cavernosal smooth muscle and endothelial cells were harvested, expanded, and seeded on the matrices. The entire rabbit corpora was removed and replaced with the engineered structures. The experimental corporal bodies demonstrated intact structural integrity by cavernosography and showed similar intracorporal pressures by cavernosometry when compared to the normal controls. Rabbits that received scaffolds without cells failed to achieve normal erectile function throughout the study

period. However, mating activity in the animals with the cell-seeded corpora appeared normal by 1 month after implantation. The presence of sperm was confirmed during mating, and sperm was present in all rabbits with the engineered corpora. The female rabbits that mated with the animals implanted with engineered corpora conceived and delivered healthy pups. Animals implanted with the matrix alone were unable to demonstrate normal mating activity and failed to ejaculate into the vagina (74,76).

**Engineered Penile Prostheses.** Although silicone is an accepted biomaterial for penile prostheses, biocompatibility is a concern (49,68). Use of a natural prosthesis composed of autologous cells may be advantageous. In a recent study, the feasibility of applying engineered cartilage rods in situ was investigated (77). Autologous chondrocytes were harvested from rabbit ear and expanded in culture. The cells were seeded onto biodegradable poly-L-lactic acid-coated polyglycolic acid polymer rods and then implanted into the corporal spaces of rabbits. Examination at retrieval showed the presence of well-formed, milky-white cartilage structures within the corpora at 1 month, and the polymer scaffolding had degraded by 2 months. There was no evidence of erosion or infection in any of the implantation sites. Subsequent studies were performed to assess the long-term functionality of the cartilage penile rods in vivo. To date, the animals have done well and can copulate and impregnate their female partners without problems.

## Female Genital Tissues

Congenital malformations of the uterus may have profound implications clinically. Patients with cloacal exstrophy and intersex disorders may not have sufficient uterine tissue present for future reproduction. We investigated the possibility of engineering functional uterine tissue using autologous cells. Autologous rabbit uterine smooth muscle and epithelial cells were harvested and expanded in culture. These cells were seeded onto preconfigured uterine-shaped biodegradable polymer scaffolds, and these were used for subtotal uterine tissue replacement in the corresponding autologous animals. Upon retrieval 6 months after implantation, histological, immunocytochemical, and Western blot analyses confirmed the presence of normal uterine tissue components. Biomechanical analyses and organ bath studies showed that the functional

characteristics of these tissues were similar to those of normal uterine tissue. Breeding studies using these engineered uteri are currently being performed.

Similarly, several pathologic conditions, including congenital malformations and malignancy, can adversely affect normal vaginal development or anatomy. To investigate tissue-engineering methods of generating vaginal tissue for use in these situations, vaginal epithelial and smooth muscle cells of female rabbits were harvested, grown, and expanded in culture. These cells were seeded onto biodegradable polymer scaffolds, and the cell-seeded constructs were then implanted into nude mice for up to 6 weeks. Immunocytochemical, histological, and Western blot analyses confirmed the presence of vaginal tissue phenotypes. Electrical field stimulation studies in the tissue-engineered constructs showed similar functional properties to those of normal vaginal tissue. When these constructs were used for autologous total vaginal replacement, patent vaginal structures were noted in the tissue-engineered specimens, while the non-cell-seeded structures were noted to be stenotic (21).

---

## SUMMARY

---

Tissue-engineering efforts are currently being undertaken for every type of tissue and organ within the urinary system. Most of the effort expended to engineer genitourinary tissues has occurred within the last decade. While some tissue-engineering applications are beginning to enter clinical practice, many of the new tissue-engineering techniques described must be studied further before they can be applied to human disorders. However, recent progress suggests that engineered urologic tissues and cell therapy may have clinical applicability, particularly in reconstruction of this system in children.

## CHAPTER 137 ■ IMAGE-GUIDED THERAPY: CURRENT PRACTICE AND FUTURE DIRECTIONS

PETER PINTO AND HAL B. HOOPER

The use of imaging technology to guide urologic therapy has traditionally found itself limited to one of three modalities: direct visualization, ultrasound, and fluoroscopy. For many urologic conditions these technologies form the bedrock of detection and therapy. For instance, cystoscopy remains the gold standard in the detection, surveillance of, and treatment

for superficial bladder cancer. Although other techniques may be employed, none have yet gained wide acceptance.

The declining cost and ever-increasing resolution of advanced imaging devices such as computerized tomography (CT) and magnetic resonance imaging (MRI) scanners has led to their increased availability. Whereas such devices were once

quite limited in the quality of the data they could provide and were available sporadically at best, their increasing use as a first-line diagnostic tool, along with current medicolegal requirements, has revolutionized a wide variety of diagnostic algorithms across the field of medicine.

The above factors, combined with the increasing interest of both patient and practitioner in reducing the potential morbidity associated with highly invasive interventions, has fueled the investigation of a wide variety of less invasive techniques for the treatment of a variety of urologic diseases. In addition, circumstances beyond the realm of control of the practitioner, both fiscal and patient-driven, incentivize reducing the number of hospital days for the therapy of a given condition. These conditions have given rise to the nascent field of image-guided therapy.

We will discuss image-guided therapy in the broadest sense, including ultrasound, endoscopy, and fluoroscopy, as well as therapeutic techniques guided in real time by CT and MRI scanners.

---

## URINARY TRACT ENDOSCOPY

---

Endoscopy, primarily the management of urinary calculi, represents the historical forefront of image-guided therapy in the field of urology.

Bozzini of Frankfurt is credited with the first endoscopic investigations, popularly dated to 1805 (1). Fisher and Segalas also described the construction and use of cystoscopic apparatuses for urethral visualization in the 1820s (2). These early efforts were quickly abandoned, however, as reflected candlelight was insufficient to adequately illuminate the urinary tract sufficient to facilitate adequate examination or manipulation. It was left to Desmoureaux in 1853 to claim the mantle of “Father of Cystoscopy” and to describe the urethral and vesicular mucosa of a living patient. With the aid of petroleum-fired lamps, reflecting mirrors, and a refinement of Bozzini’s design of two nested metal tubes, he was able to overcome the technical challenges that had stymied his forebears and to perform detailed examination of the lower urinary tract (3).

Technology has, of course, propelled the management of urinary calculi, urothelial tumors, and other urinary tract pathology beyond the imagination of the earliest investigators. A series of technologic evolutions—the use of fiberoptics for light and image transmission, wire-guided flexible metal instruments, laser lithotripsy, and high-definition closed-circuit television picture reproduction—has produced the ability to perform any number of manipulations for a wide variety of conditions. The indications for and details of these therapies are discussed elsewhere in this text, but endoscopy of the urinary system bears mention as the forebear of all other image-guided therapies in the field of urology.

---

## IMAGE-GUIDED THERAPY IN THE MANAGEMENT OF RENAL TUMORS

---

Although there is wide variability between reported series as to the percentage of incidentally detected renal masses (25% to 84% in a review of several recent series [4–6]), the widespread

use of imaging technologies for the diagnosis of routine complaints ensures that this trend will continue.

Many of these masses will be <4 cm in diameter at the time of detection (7), and thus their management choices are varied. Treatment has recently focused on sparing as much renal parenchyma as possible. Nephron-sparing procedures are also essential in the management of the cohort of patients with heritable kidney cancers such as von Hippel-Lindau (VHL) disease, Birt-Hogg-Dube (BHD) syndrome, and hereditary papillary renal cell carcinoma (HPRCC). Many of these patients will require multiple interventions for their renal tumors.

The development of minimally invasive surgical (MIS) techniques utilizing image guidance is often an excellent option for both subsets of patients. Several of the more widely available options, including their relative benefits and risks, are discussed below.

---

## Laparoscopic Partial Nephrectomy with Intraoperative Ultrasound

---

Although the reported complication rate of laparoscopic partial nephrectomy (LPN) varies widely and is highly operator-dependent, recent literature reviews suggest these rates to be comparable with those of open partial nephrectomy (OPN). A recent review of the available published series undertaken by Porpiglia et al. (8) suggests that while the overall rate of hemorrhage is slightly higher in LPN series than in OPN series (mean of 5% versus 3.2%, respectively), the overall rate of surgical complications with LPN is roughly equivalent (4.1% to 38.6% in OPN versus 9% to 33% in reviewed LPN series). Furthermore, recently published data indicate that increased experience with LPN will reduce complication rates to that of OPN (9). Finally, LPN potentially offers shorter length of stay (5.7 versus 2.9 days) and reduced cost when compared with the open approach, making this option attractive to provider and patient alike (10).

Although preoperative imaging is essential for operative planning and choice of port location, tumor location and nature (endophytic versus exophytic) often make definitive laparoscopic lesion identification and determination of margin difficult. Intraoperative ultrasound is thus often employed to assist in tumor location and adequate resection while minimizing the amount of normal parenchyma removed. Additionally, the relationship of the tumor to structures deeper within the renal sinus may be more readily appreciated. In situations where the presence of venocaval thrombus is equivocal by preoperative imaging, intraoperative ultrasound will assist in definitive diagnosis and in-field management and extirpation (11).

In a National Cancer Institute (NCI) published series of patients with hereditary renal carcinoma, intraoperative ultrasound identified tumors that were undetectable by the surgeon in 25% of cases, some as large as 4 cm, of which 50% were pathologically proven renal cell carcinoma (RCC) (12). Campbell et al. (13) report that although the use of intraoperative ultrasound is no more accurate in the detection of tumors than the combination of preoperative CT imaging and direct inspection for multifocal disease, the detection of small

endophytic tumors and of the intrarenal extent of deep tumors was enhanced by its use.

---

## Cryotherapy

---

Cryotherapy has emerged as a viable and widely accepted alternative to surgical management of small renal tumors. In most commercially available systems, tissue cooling is created via a heat-sink effect due to the vaporization of a cryogenic liquid, typically liquid nitrogen or argon, between an inner and outer probe lumen. This rapid cooling is alternated with either a rapid thawing mediated by a separate cryogenic liquid or passive thawing. This process is repeated at least twice in most described techniques, although some groups advocate additional cycles (14). Direct tissue destruction by ice crystal formation, local vascular disruption, induction of apoptotic signals, and immunologically mediated destruction of cells within the ablated area that survive the initial freeze-thaw cycles provide for a highly effective ablative modality (7).

Adequacy of treatment has been shown in a porcine model to require cooling cells to  $-19.4^{\circ}\text{C}$ , though clinical practice commonly chills tissue to  $-40^{\circ}\text{C}$  to ensure adequate tissue destruction. This equates to a roughly 0.5- to 1.0-cm extension of the ice-ball beyond the tumor margin (15). Although widely investigated as a laparoscopic ablative technology, several examples in the available literature support the efficacy and safety of percutaneous cryotherapeutic ablation (PCA) as an image-guided technique (14,16–20).

As mentioned above, PCA techniques vary widely depending upon the chosen imaging modality. The importance of proper probe placement, lesion location and thus accessibility, and the use of an adequate number of probes to generate a sufficient ablative margin must be considered in preoperative planning. Serial imaging throughout treatment to monitor ice-ball margin and its proximity to adjacent structures is essential for both safety and efficacy. The choice of general anesthesia versus sedation varies, with most MRI-based techniques opting for a general approach due to procedure length and the ability to more tightly regulate diaphragmatic excursion. All protocols, however, must take into account the location of adjacent organs and structures, especially in the treatment of anterior renal lesions. Patient positioning, external compression, and needle-based methods such as “hydrodissection” (the introduction of sterile saline between adjacent viscera and the lesion to be ablated), have all been described as safe and effective methods of reducing collateral damage during ice-ball formation (17,19,21).

Gupta et al. (16) describe a series of 27 enhancing tumors treated in 20 patients by a CT-guided, percutaneous approach under conscious sedation. Tumors were located both centrally and peripherally and ranged in size from 1.0 to 4.6 cm. Ice-ball formation was tracked by intermittent, intraprocedural CT, with a margin of over 1.2 cm obtained in all cases through two freeze-thaw cycles and only one major complication (two-unit transfusion) reported. Only one lesion demonstrated enhancement on follow-up CT, with a mean follow-up interval of 5.9 months.

An MRI-guided percutaneous approach in 23 patients is described by Silverman et al. (19). A special procedure room was required due to the presence of a high-field magnet and the choice of general anesthesia. Tumors in this series also

measured from 1.0 to 4.6 cm and were located centrally and peripherally. Two major complications were noted (one 1-unit transfusion and one abscess due to involvement of an adjacent bowel loop). Ice-ball formation was tracked by serial MRIs, and a 5-mm overlap was considered sufficient through two freeze-thaw cycles. Twenty-four of 26 tumors were considered ablated by the first treatment on serial follow-up MRI (mean follow-up of 14 months). A subsequent report by this same group noted that external manual compression of adjacent bowel loops was safe and efficacious at displacing the interested organ from the treatment field in 14 patients, further improving the safety profile of this intervention (17).

The most commonly reported complications of the percutaneous approach are operative site pain and parasthesias, although more serious complications, such as renal fracture, ureterocalyceal injury, hemorrhage, and bowel injury, are certainly possible and have been reported.

As with any percutaneous ablative interventions, the lack of histologic confirmation of complete tumor destruction remains problematic (15). Many centers make use of follow-up imaging with either contrast-enhanced CT or MRI imaging and an interval of 1 to 6 months from treatment to the initial scan. Contrast enhancement in the bed of ablation is most often cited as sufficient evidence of local recurrence and should recommend expeditious biopsy to rule out local recurrence.

Shingleton and Sewell (18) report no radiographic evidence of local tumor recurrence in their MRI-guided PCA cohort of four patients with a median follow-up of 14 months; only one patient required retreatment. Although data from the Cleveland Clinic (22) indicate an excellent short-term correlation between radiographic imaging and pathological analysis with laparoscopic cryoablation, poor correlation was seen in their percutaneous radiofrequency ablation cohort (six patients with a positive posttreatment biopsy and no enhancement on MRI or CT).

---

## Radiofrequency Ablation (RFA)

---

FDA approved in the treatment of soft tissue lesions and long used for the treatment of bone and liver tumors, RFA generates direct tissue damage by the controlled delivery of alternating current. Hyperthermic protein denaturation and membrane destruction result in coagulative necrosis with extensive local tissue destruction. Energy delivery from the generator is controlled by measuring temperature or local tissue impedance at the probe tip, with temperatures in excess of  $70^{\circ}\text{C}$  for 1 minute often considered adequate, although many protocols have been published that differ by institution (4–6,21,23,24). The infusion of hypertonic saline at the probe tip is often employed to decrease impedance, resulting in larger RFA lesions, referred to as “wet” RFA (15).

Of particular concern in RFA is the presence of nearby major vascular structures or tumors more centrally located. Highly vascularized areas suffer from a “heat-sink” effect that will produce temperature variations within the supposed field of ablation. Although long used for focal ablation of the liver, the kidney’s high vascular flux, containing 5 times as much blood per gram as the liver, presents special challenges for successful RFA (25). Such features may prevent tissues from reaching the requisite temperature, preventing adequate tumor destruction. Although this phenomenon has become

less pronounced with the introduction of higher-powered generators, medullary and corticomedullary lesions demonstrate persistently higher failure rates than exophytic cortical lesions (26). Some authors recommend renal artery occlusion to circumvent this effect and have described the execution of such in the laparoscopic literature, although a percutaneous approach would prohibit this precaution (15,27).

RFA also proves challenging when trying to monitor the zone of ablation achieved. Unlike cryotherapy, which generates a clearly demarcated barrier between the involved and spared tissues, RFA generates a lesion that resists easy immediate characterization. As ablated tissues fail to enhance with intravascular contrast, intraprocedural contrast-enhanced imaging may help estimate the amount of cellular destruction achieved. For patients with deranged renal function, however, this may prove problematic, particularly with CT-guided modalities.

A series by Fotiadis et al. (23) has been published in which the ablative properties of ethanol, long used in the treatment of hepatic lesions, was combined with CT-guided percutaneous RFA in the ablation of small renal lesions (mean diameter <3 cm, range 0.8 to 6.0 cm). Animal studies suggest that this approach may cause extensive local thrombosis, thereby diminishing the “heat-sink” effect described above. The amount of ethanol administered centrally within the tumors was quite small, 1.7 mL on average, but the need for reablation was small, with only 6 of 28 patients requiring additional treatment as a result of follow-up imaging, somewhat below the rate of 27.5% cited elsewhere (7,23).

An excellent review of the available literature on percutaneous RFA was recently conducted by Park and Cadeddu (28). They reviewed series performed under ultrasound, CT, and MRI guidance using all widely available commercial electrode systems. Lesion size both in this review and within individual series was noted to be an independent predictor for single-session failure, with 3 cm commonly noted as the breakpoint for retreatment (5,15). They noted a combined minor/major complication rate of 5% to 10%, with pyelocalyceal injuries (stricture and urinoma) and hemorrhage requiring surgical intervention the most common major complications (28). Although the risk of injury to adjacent viscera is low, techniques to further minimize these undesired outcomes have also been successfully explored in light of previous experience with RFA of hepatic lesions, including the interposition of carbon dioxide gas or sterile fluid (21). This review also notes that deliberate RFA of tumors located immediately adjacent to the collecting system should be discouraged due to the high risk of stricture creation and persistent urine leak.

Cancer-specific survival was noted to be excellent, with an aggregate cancer-specific survival of around 95% at a mean follow-up of 19.5 months across series. Salvage nephrectomy or partial nephrectomy was performed in only 1.1% of cases. However, definitive histologic demonstration of complete tumor ablation is lacking in this percutaneous technique. Although previously published reports of skip lesions and incomplete tumor ablation after RFA exist, contrary work indicates that oncologic control with RFA may well be adequate (29,30). Radiologic demonstration of lack of tumor growth or enhancement on CT or MRI at follow-up is typically deemed adequate, with initial scans typically performed at 1 month. Unfortunately, the presence of enhancement on

follow-up imaging does not definitively indicate recurrence, as granulomatous reactions or infection in the ablated bed may also enhance, and absence of enhancement also does not signify complete tumor ablation. Salvage treatment should therefore proceed with deliberation and only after definitive rebiopsy (4,13).

---

## Other Ablative Technologies

---

Although PCA and RFA have both garnered FDA approval for the treatment of small renal lesions, multiple other image-guided ablative modalities are under investigation. Although few of these methods have been evaluated to date beyond modest initial clinical trials, preliminary investigation in animal models and with selected patients continues apace.

Most promising among these emerging technologies is that of high-intensity focused ultrasound (HIFU). By combining a parabolic reflector with a piezoceramic element within an external transducer, highly focused ultrasound waves can be delivered precisely to lesions of interest, quickly (<1 second) raising tissue temperatures in a sharply circumscribed area and producing focal coagulative necrosis via thermal effects and mechanical disruption of membranes via microbubble cavitation (32). Although this phenomenon was realized in the 1940s, advances in technology have decreased the size and power demands of HIFU transducers, thus reviving interest in their use.

Hacker et al. (33) performed transcutaneous HIFU on 19 patients and 24 dogs under general anesthesia prior to radical nephrectomy using in-line ultrasound guidance and a handheld transducer. Although the technique was generally safe, two grade III skin burns were reported in the human arm at higher power settings. The quality of ablation was variable and did not seem to correlate with increases in delivered energy (from 200 to 1,600 W) or pulse duration (1 to 5 seconds). Indeed, some hyperechoic areas visualized during ablation showed no histologic evidence of necrosis, although delayed nephrectomy specimens in the canine arm of the study showed more reliable tissue ablation. Furthermore, the use of in-line ultrasound for intraprocedural guidance was noted as a major limitation. Backscatter during sonication caused by microbubble formation prevented real-time visualization of lesion formation, impairing consistent energy delivery.

Tumor heterogeneity, respiratory motion, and the absorptive and reflective properties of intervening tissues may all contribute to reduce the power applied to the tissue of interest from that generated at the transducer. The transducer has been mounted on a mechanical arm to minimize potential operator error, and the employment of MRI has been hypothesized as a technique for improving guidance (34–36). Major technical hurdles still exist to the successful and widespread deployment of HIFU for the ablation of small renal tumors, but investigation continues at many centers.

There are also several other potential techniques. The use of laparoscopic microwave antennas to induce coagulative necrosis has been successfully tested in a rabbit model and may be adaptable to an image-guided probe-based technique in the future (37). MR-guided laser interstitial therapy, involving the placement of laser fibers directly into malignant tissue, has been investigated under MR guidance, although no published human trials exist at this time (15). Similarly, a number

of catheter-based techniques for the delivery of ablative agents have been reported, but none have yet gained widespread acceptance.

---

## Image-Guided Therapy in the Management of Prostate Cancer (PCa)

---

Asymptomatically elevated PSA levels drive many to choose biopsy, with the detection of small amounts of low-risk disease often being the result. Although early, definitive, whole-gland therapy for these patients offers them a high likelihood of disease-free survival, the potential morbidities involved with the currently available options are significant. Impotence, urinary incontinence, proctitis, and, for those who choose surgical excision, perioperative complications such as deep venous thromboses and injury to adjacent organs are reported risks of whole-gland therapy.

Although it is likely that many men with low-risk disease will die with, rather than of, their PCa, which individuals fall into which category cannot currently be determined prospectively. The impact of whole-gland therapeutic morbidities may potentially produce a profound diminishment in quality of life. Many groups have initiated the investigation of novel focal therapies or the modification of existing treatment modalities in the treatment of PCa to minimize potential intervention-related adverse outcomes.

### Image-Guided Prostate Biopsy

As prostate biopsy remains the gold standard for cancer diagnosis, increased screening has predictably increased the annual number of biopsies performed. Biopsy is typically performed with TRUS guidance in a sextant fashion, and the yield of the most optimistic reported extended biopsy schema (performed exclusively based on elevated PSA) was only 44% (39). For individuals undergoing repeat biopsy, this rate can be expected to fall, with rates as low as 4% to 12% on the fourth attempt and a higher attendant complication rate (40). Many image-guided techniques have been reported that seek to address the shortcoming with this extant biopsy paradigm.

Investigations into the use of MRI, in particular endorectal coil MRI (erMRI), for the detection of prostate cancer has become increasingly widespread. The use of an endorectal coil to reduce the signal-to-noise ratio increases image resolution, particularly of T-2 weighted images, and reduces the amount of time needed to perform spectroscopic and contrast-enhanced studies. Signal-to-noise is also reduced by the use of higher field magnets, and 3-tesla (3-T) devices are increasingly available. Although published results for specificity and sensitivity vary widely across studies and between the widely used modalities, MRI remains the most sensitive available imaging technique for the detection of prostate cancer (41).

Anastasiadis et al. (42) report on their experience with an in-gantry biopsy system guided by erMRI. Twenty-seven men with one prior negative biopsy were sampled in a 1.5-T closed-bore magnet under local anesthetic using an MRI-compatible template, needle guide, and biopsy needles based on T-2 weighted images. The reported yield of 55% was well above that reported in the literature for biopsies performed with TRUS guidance alone.

The NCI group (41) have reported their initial experience with the use of both 1.5- and 3.0-T MRI instruments to

improve the yield of ultrasound-guided transrectal prostate biopsy in a cohort of men at increased risk for PCa. Through a proprietary arrangement with Phillips USA they have developed a system for the registration of previously acquired MRI images with real-time TRUS onto a single platform. Although their initial reported clinical data do not indicate a statistically significant increase in cancer yields, they acknowledge that a number of improvements in their platform have yet to be realized.

A subsequent report by the NCI/Phillips group (43) details the development of a motion-compensation system via the use of closed-loop magnetic tracking for the above-mentioned image fusion platform. *Ex vivo* phantom studies indicate that an accuracy of 2 to 3 mm can be achieved with this refinement in place. Ongoing investigation will determine if this increased accuracy can equate to increased biopsy yield.

### Permanent Prostate Seed Implantation Brachytherapy (PPI)

Available data for the use of intraprostatic radionuclide-containing seeds (I-125 or Pd-103) in the treatment of PCa suggests a durable oncologic outcome as measured by biochemical relapse, whether this treatment modality is used as monotherapy for low-risk disease or is used in combination with external beam radiation therapy (EBRT) for intermediate- and high-risk patients (44).

Treatment planning to ensure that the low-energy photons used in brachytherapy sufficiently cover the prostate volume while minimizing the dose to adjacent structures, particularly the urethra and rectum, is critical. Planning has traditionally consisted of preoperative imaging of the prostate in contiguous segments using a TRUS probe and correlation of these images with biopsy results. This evaluative study is subject to the vagaries of patient positioning, probe angle and attitude, and change in anatomic relationships in the conscious versus the anesthetized patient. The above factors may conspire to produce either “hot” or “cold” spots, adversely affecting either oncologic efficacy or toxicity profiles (44).

Several groups have reported their experience with the use of MRI guidance in both the planning and execution of PPI to improve dosimetric coverage. Researchers have reported on the use of a real-time interventional 0.5-T open-configuration MRI system for preoperative dosimetric planning, probe tracking, and “on the fly” plan modification based on seed deployment as measured by T-2 weighted imaging (45). They used a specially designed MRI-compatible perineal template for the introduction of I-125 sources with the patient in the lithotomy position under general anesthesia. All the required probes and other equipment were also MRI-compatible. In a series of ten patients, they report median seed misplacement at 3 mm, which corresponded to underdosing of 1% to 13%. With the use of online MRI guidance, they were able to recover as much as 12% of this lost coverage with the addition of a median of eight seeds (46).

A collaborative group from Johns Hopkins University and the NCI/NIH (47) describe the use of a closed-bore 1.5-T system for the guided transperineal delivery of high-dose-rate Ir-192 sources in four patients. They constructed an MRI-compatible device combining the endorectal coil and perineal template and placed the patient in the lateral decubitus position for improved access. Three-dimensional reconstructions indicate that this approach delivered the desired radiation

dose to over 90% of the gland, averaging approximately 2-mm needle placement accuracy, with <5% urethral toxicity. Total required time for imaging and therapy was an average of 6 hours.

Muntener et al. (48) have developed a pneumatically actuated, MRI-compatible, fully automated robot for the delivery of PPI. By eliminating the use of electrical circuitry in this device, they report successful use of the device in magnets up to 7 T with no evidence of field perturbation. Furthermore, the device is highly accurate, with a step size of 0.05 mm. Use of this device for the placement of PPI implants in a tissue mockup suggest submillimeter accuracy, with a mean error of 0.72 mm reported in the automated placement of a group of 125 seeds. Although no clinical results are, as yet, reported in this series, continued research is planned.

### Image-Guided Focal Ablation in the Management of PCa

The downward stage migration of PCa in the PSA era has created a situation in which many men may be receiving overtreatment for their disease. As fewer than a third of men diagnosed in this country chose to defer therapy for their disease, according to the NCI SEER database from 1995 to 1999, the evidence suggests that almost 50% of men treated with whole-gland extirpation or irradiation may have died with, rather than of, their disease (49).

This discrepancy, combined with recently published data regarding favorable oncologic-specific survival results with isolated treatment of PCa index lesions, has promoted a widespread

and aggressive investigation of subtotal therapeutic modalities for the treatment of PCa (50). Many image-guided focal ablation methods are under investigation, including focal brachytherapy, laser interstitial ablation, cryotherapy, HIFU, and gamma-knife. However, oncologic outcomes data remain sparse at this time for most of these platforms, with the exception of HIFU and cryotherapy. Yet even in these cases, studies involving their use in concert with sophisticated image guidance are currently quite limited.

Regardless of the modality chosen, the decision of who should receive focal therapy continues to be elusive. Clearly these patients should have organ-confined disease, although there the consensus ends. Despite the fact that PCa is a multifocal disease, data suggest that for clinically relevant tumors, the index lesion, that is to say, the largest focus of PCa found at resection, is of the most interest. Published retrospective data indicate that the overall Gleason score, risk of extracapsular extension, and disease-free survival as a function of tumor volume can be determined with the index lesion in >90% of cases (49).

Though PSA screening and the aforementioned stage migration have consistently reduced the size of this index lesion over the past two decades, the mean size of 2.4 cc is well above the detection limits reported in the literature for erMRI. Reports exist in the literature citing >85% sensitivity for the detection of lesions >1 cm by T-2 weighted eMRI combined with spectroscopy (49,51). Despite these preliminary successes, MRI remains to be validated as a stand-alone method for the detection and staging of PCa.

## CHAPTER 138 ■ ROBOTIC SURGERY

DAVID CANES AND MIHIR M. DESAI

Robotic-assisted laparoscopic prostatectomy is now a routine procedure at many academic and community hospitals worldwide. The next leap forward in robotic technology will likely incorporate technology that is now just on the horizon, including flexible robotics, intraluminal minirobots, haptic feedback integration, and image overlay, to name just a few. Surgical robotic systems will continue to enhance our dexterity and will integrate into our daily operative practice in ways we can scarcely conceive. As Yogi Berra famously said, “It’s tough to make predictions, especially about the future.”

### NOMENCLATURE

An understanding of general robotic nomenclature is essential for the practicing urologist. A partial list is presented in Table 138.1. Purists may argue that the term *robot* is misleading and that *computer-assisted surgery* is more accurate in the current context. However, marketing pressures are likely to retain the terms *robotics* and *robotic surgery* in common usage.

The two broad categories of surgical robotic systems are as follows:

1. Computer-integrated: The operator defines a surgical task that the robot then carries out automatically.
2. Operator-driven: The robot is continuously under surgeon control in a master-slave environment.

### HISTORY OF SURGICAL ROBOTICS

The history of surgical robotics is still in its infancy. The curious reader can find excellent chronologies of the evolution of surgical robotics, both within and outside the urologic arena (1–5). The first fields to incorporate surgical robots were neurosurgery and orthopedics (6), possibly because their anatomy consists of fixed targets readily adaptable to robotic assistance. Minerva, a robotic system for neurosurgery (Integrated Surgical Systems, Davis, CA), is an active powered robot in which CT images are registered with a stereotactic frame encompassing the patient’s head (7). Another system for stereotactic neurosurgery for tumor excision or biopsy is NeuroMate, which includes a 5-degree-of-freedom robotic arm (also developed by Integrated Surgical Systems) (8). ROBODOC (Integrated Surgical Systems) consists of a high-speed rotary cutter fitted with a force sensor to precisely bore a channel in the femoral head to house the implant for hip replacement (9). The femur is fixed in space using a rigid metal frame, with pins in the femoral head.

Although the transition to soft tissue surgery was more challenging, urologic applications subsequently emerged. The prostate is relatively fixed in the pelvis, and since transurethral resection consists of a series of repetitive motions, robotics applications were attempted. The PROBOT, introduced in 1989 from the Imperial College in London, was the first surgical

TABLE 138.1

## ROBOTICS: NOMENCLATURE, TERMS, DEFINITIONS

<b>Actuator</b>	Modifies the state of the environment (motorized by electrical, pneumatic, or hydraulic systems).
<b>Degrees of freedom (dof)</b>	Number of possible motions at a joint. One joint = 1 dof. Movement is either translational or rotational. The human wrist has 3 dof, and the human palm has 7. Conventional laparoscopic instruments have 4 dof. Complete freedom requires a minimum of 6 degrees.
<b>End effector</b>	Instrument with which the robot accomplishes a task. The end effector may be the tool itself, or a grasping tool that is holding another instrument.
<b>Envelope</b>	Arc of space the robot occupies with all of its movements.
<b>Fiducial</b>	A fixed basis of reference, often used for calibration during surgical navigation or image overlay.
<b>Haptics</b>	Tissue contact forces experienced by the surgeon.
<b>Robot</b>	From the Czechoslovakian word <i>robota</i> , meaning “worker”; originated by Karel Capek’s 1921 play, <i>Rossums Universal Robots</i> . One definition: a powered computer-controlled manipulator with artificial sensing that can be reprogrammed to move and position tools to carry out a range of surgical tasks.
<b>Manipulator</b>	The more common geometry, a robotic arm, consisting of a base, a series of joints, and an end effector.
<b>On-line</b>	Category of robotic design in which each movement is dictated by the operator. An example is a <i>master-slave</i> system, in which movements at a joystick are translated to the end effector. Surgeon remains in control.
<b>Off-line</b>	Preprogrammed autonomous robotic systems, such as those used in the automotive manufacturing industry.
<b>Registration</b>	Three-dimensional mapping between the robot, patient, and/or imaging data, such that special relations between robot end effectors are defined. Coordinates are matched such that a point on an image corresponds to an actual point in space.
<b>Remote center of motion (RCM)</b>	Fixed point along a robotic arm or instrument with minimal motion. Designed to coincide with the entry portal into a patient’s body, for instance, at the trocar or fascia level for transabdominal robotic laparoscopic surgery. Applies to surgical rather than industrial robots.
<b>Sensor</b>	Detects the state of the environment by responding to a physical stimulus.
<b>Telemedicine</b>	Using telecommunications technology to provide medical services from a remote location (62).

robotic system used in urology (10–12). The PROBOT was a computer-integrated surgical system in which the robot carried out a predefined task. Ultrasound images were obtained, and the desired resection area was outlined by the surgeon. Cutting trajectories for the robot were computed and then carried out autonomously, followed by electrical diathermy for hemostasis by the surgeon. A safety frame limited motion to 4 degrees of freedom, allowing the resectoscope to move in a conical motion. The robot was first manipulated manually to endure safety, and later powered as an active robot. After this pioneering work in 5 patients, and subsequently in an additional 30 (13), this application did not achieve widespread use.

Transrectal ultrasound-guided prostate biopsy is equally suited to robotic assistance, and such applications soon followed (14,15). Ultrasound images registered the anatomy of the prostate, and transperineal biopsy was performed to within 1 to 2 mm of the desired targets. The ultrasound images were coregistered with patient position coordinates from video cameras. The system did not gain momentum, but other robotic systems have been developed, with renewed interest of late both for biopsy (Fig. 138.1) (16) and for brachytherapy seed placement (17).

Percutaneous needle access to the kidney is another attractive target for robotics, since precision and experience are

**FIGURE 138.1** MrBot, designed for image-guided prostate needle based procedures, is constructed entirely of nonmagnetic materials for MRI compatibility. (Courtesy of Dr. Dan Stoianovici, urobotics laboratory, Johns Hopkins University.)

**FIGURE 138.2** The PAKY robot, with an active injector for percutaneous access. (Courtesy of Dr. Dan Stoianovici, urobotics laboratory, Johns Hopkins University.)

required to translate two-dimensional (2-D) images into a 3-D trajectory, and a robot system would remove the operator from a radiation source when fluoroscopy is used. The first system was developed in London (18), followed thereafter by the Johns Hopkins group using the PAKY (percutaneous access to the kidney) robot (19). The PAKY system originally consisted of a mechanical manipulator, integrating images from biplanar fluoroscopy. In the porcine kidney, the desired calyx was targeted in only 50% of cases due to needle deflection and interference from ribs. The system was modified into PAKY-RCM, consisting of a passive manipulator (7 degrees of freedom), with an active translational needle injector system (Fig. 138.2). When tested clinically, the PAKY robot achieved 87% success in obtaining access in the desired calyx (20).

Another class of surgical robots includes laparoscopic camera robots, of which AESOP (Automated Endoscopic System for Optimal Positioning, Computer Motion, Inc.) achieved the largest commercial success. AESOP was the first active robotic device to garner FDA approval. It used voice control to permit surgeon control of the laparoscope, and it consisted of a 6-degrees-of-freedom (4 active, 2 passive) table-mounted manipulator that has been shown to be steadier than human camera

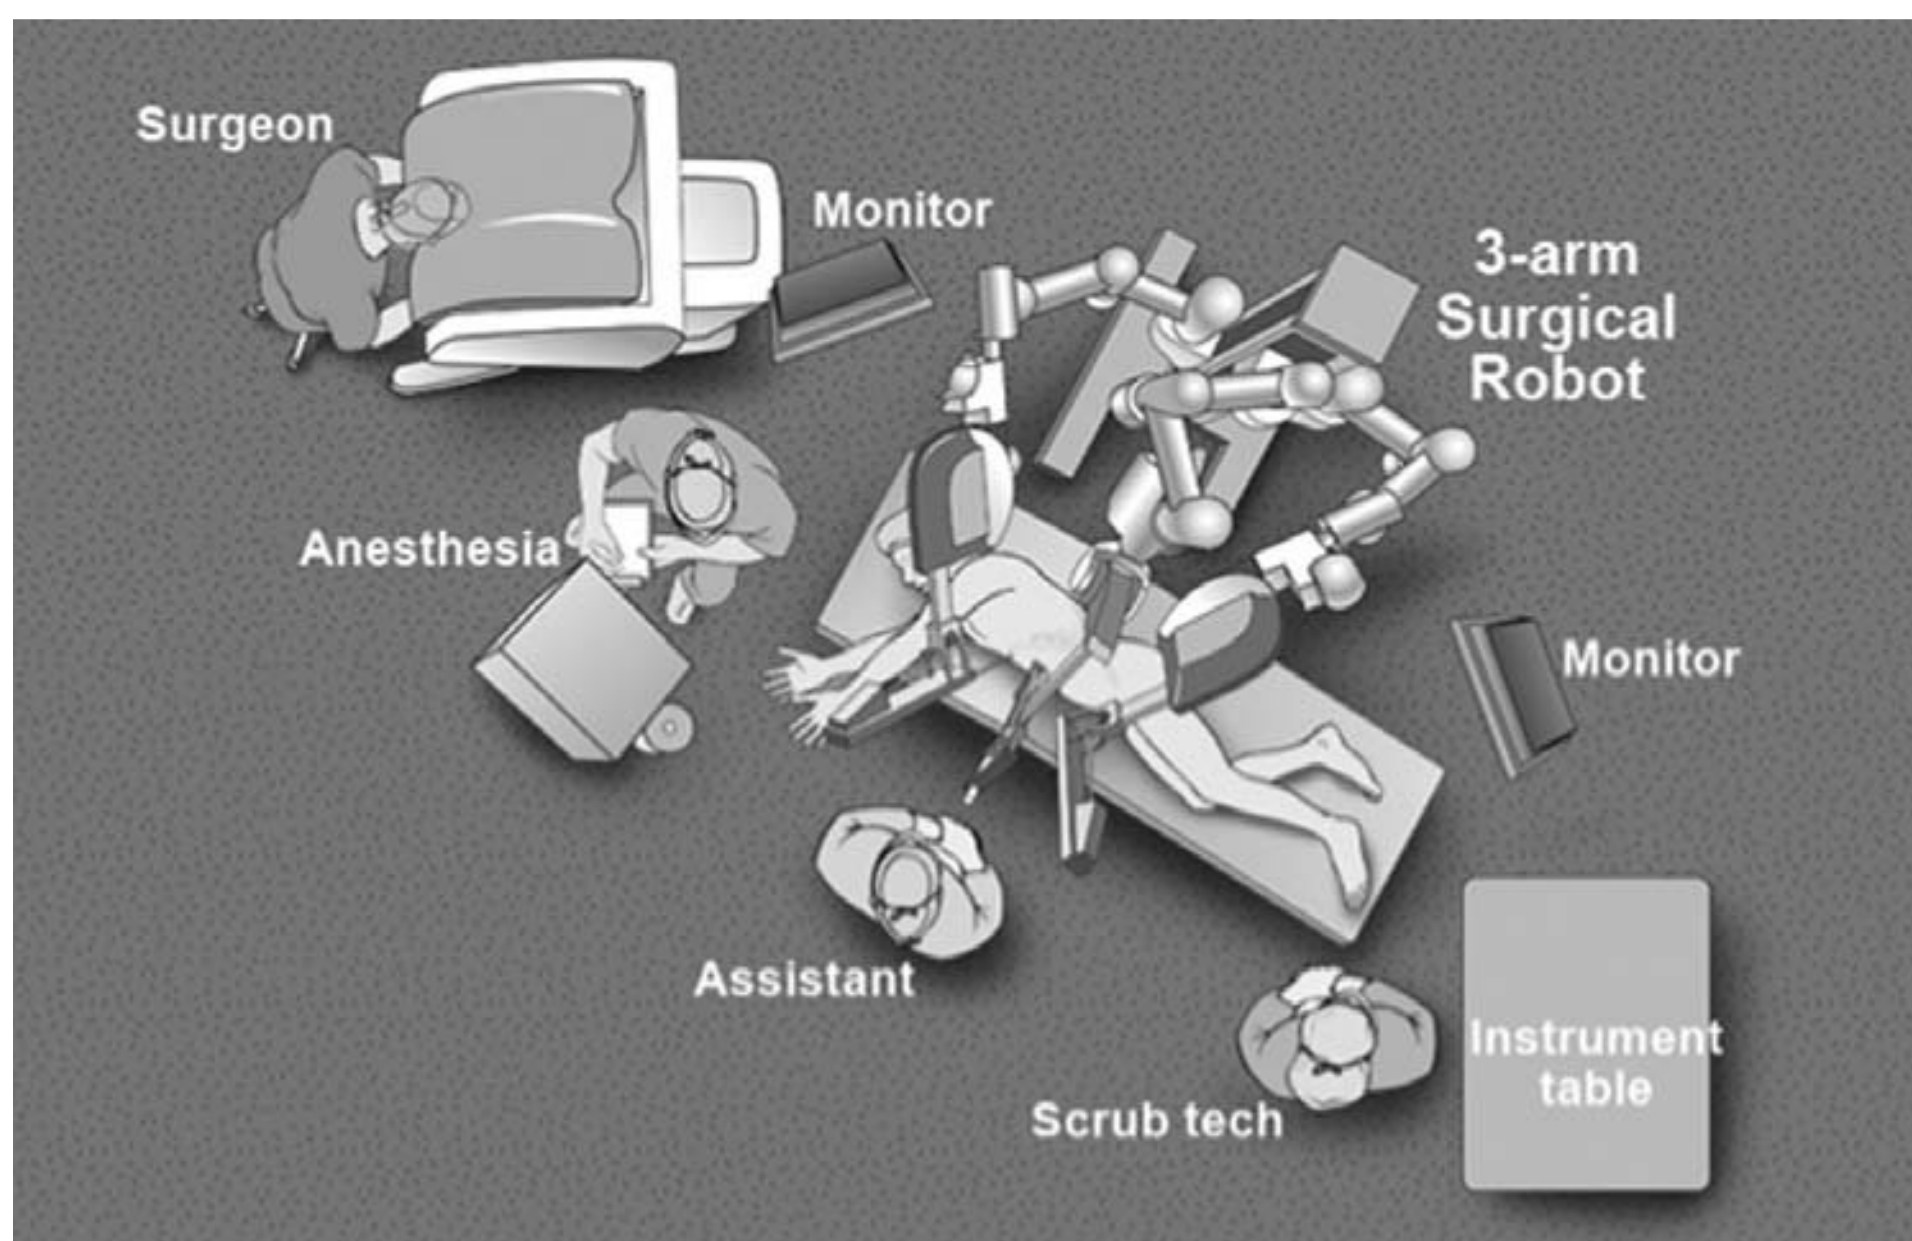

**FIGURE 138.3** Surgeon manipulates working arms of the ZEUS surgical system in front of a 2-D display monitor. (Courtesy of Dr. Ingolf Tuerk, Lahey Clinic Medical Center, Burlington, MA.)

holders (21). AESOP was widely used in urologic laparoscopy before the advent of more sophisticated master-slave systems (22). The system was hampered by slow response during critical situations and by variability in voice-control response, so that an experienced assistant would occasionally need to take over its operation. More recent innovations have allowed eye gaze tracking for AESOP automation (23).

Operator-driven robotic surgical systems gained momentum with FDA approval of both the da Vinci surgical system in 2000 (Intuitive Surgical, Sunnyvale, CA) and the ZEUS surgical system in 2001 (Computer Motion). Both consist of a series of manipulators, one of which holds an endoscope and the others whose end effectors are interchangeable surgical instruments. The ZEUS system, shown in Fig. 138.3, incorporated AESOP for laparoscopic vision. The working arms, each table-mounted, had 6 degrees of freedom.

In 2003 Intuitive Surgical acquired Computer Motion and became the dominant and currently the only source of a commercially available complete telesurgical system. Components of the system are depicted schematically in Fig. 138.4. Benefits

**FIGURE 138.4** Cartoon of a typical operating room setup for the da Vinci robot. The surgeon controls the masters at the console, within sight of the bedside assistant. The three to four robotic arms are mounted on a surgical cart.

**FIGURE 138.5** Wristed instrumentation provides 7 degrees of freedom (left/right, up/down, in/out, rotation, pitch, yaw, open/close).

**FIGURE 138.6** Bedside assistant's view of the four-arm da Vinci surgical system.

of the da Vinci system include 3-D visualization, wristed instrumentation with 7 degrees of freedom (Fig. 138.5), motion scaling, and incorporation of two to three instrument arms alongside the endoscopic arm (Fig. 138.6). The initial da Vinci system consisted of three arms. The latest upgraded version, the da Vinci-S system, incorporates the option of a fourth arm, high-definition vision, and better range of motion of the instruments. High cost and lack of feedback are commonly cited drawbacks to this system.

---

## CLINICAL UROLOGY

---

Just as laparoscopy now pervades urologic practice, robotic counterparts for virtually all procedures are now at least considered feasible (24), and for some procedures they are now standard options in the urologist's armamentarium. Since

detailed techniques are presented elsewhere in this text, the evolution and current status for each procedure are briefly summarized in the following sections.

---

### Robotic-assisted Laparoscopic Radical Prostatectomy

---

The 2-D vision and 4 degrees of freedom inherent to laparoscopic radical prostatectomy can clearly be overcome in expert hands but may have been too insurmountable for widespread diffusion. After the groundwork was established by early pure laparoscopic pioneers (25,26), robotic technology was primed to be applied to the prostate, enveloped within the restrictive confines of the deep pelvis. The first robotic prostatectomy was performed in 2001 (27). The procedure can be performed using a transperitoneal or extraperitoneal approach, and using the three- or four-arm robot. Although functional data are immature, available evidence suggests acceptable complication rates, equivalent short-term measures of local cancer control (margin status) to open surgery, and promising functional results as regards continence and erectile function (28,29). The largest published series to date comes from Menon's group (30), who reported on 2,766 patients undergoing robotic-assisted prostatectomy (RAP) over 6 years. Console time was under 2 hours, estimated blood loss was 200 mL, and 5-year actuarial biochemical-free survival was 84%. The positive margin rate for pT2 disease in the last 200 patients was 4%. Of preoperatively potent men, 79.2% were able to achieve erections sufficient for intercourse. Continence, defined as the use of no >1 pad per day, was achieved in 93% of patients. These results are encouraging, and longer-term outcomes are awaited.

---

### Robotic-assisted Laparoscopic Radical Cystectomy

---

Beecken et al. (31) were the first to report robotic-assisted radical cystectomy and ileal neobladder, in 2003 (31). As with robotic-assisted laparoscopic radical prostatectomy, long-term outcomes with robotic-assisted laparoscopic radical cystectomy are immature, but early indicators are encouraging. Wang et al. (32) prospectively compared 33 patients undergoing robotic cystectomy to 21 patients undergoing open radical cystectomy by a single surgeon. Patients undergoing robotic cystectomy had decreased blood loss, earlier resumption of oral intake, and shorter hospital stay compared to open surgery. Complication rates were equivalent, and operative time was longer in the robotic group. Positive margin rates were statistically equivalent, as were lymph node yields. As is commonly the case, the extirpative portion of the procedure is performed with robotic assistance, and the urinary diversion fashioned with extracorporeal assistance. The robot is redocked for the urethrovesical anastomosis when orthotopic neobladders are chosen. Other groups have confirmed that adequate lymph node yields can be achieved robotically during the course of radical cystectomy, an important factor that will influence the widespread adoption of robotic technology for invasive bladder cancer (33,34).

---

## Robotic-assisted Laparoscopic Pyeloplasty

---

The robotic interface may be ideally suited to perform reconstructive procedures, whereas laparoscopic intracorporeal suturing requires dedicated training and perhaps a steeper learning curve. The first report of laparoscopic pyeloplasty was in 1993 (35). Sung et al. (36) demonstrated the technical feasibility of robotic-assisted laparoscopic pyeloplasty in the laboratory. Subsequently, multiple reports have attested to the safety and efficacy of robotic-assisted laparoscopic pyeloplasty. Currently, the robotic procedure is typically performed using a transperitoneal approach. The initial bowel mobilization and dissection of the ureteropelvic junction (UPJ) may be performed laparoscopically with the robotic system used only for dismemberment and suturing, based on initial surgeon preference. The robotic approach has been successfully utilized in performing various types of UPJ repairs, including dismembered, nondismembered, reduction, vessel transposition, and concomitant pyelolithotomy. A large single-center experience in 92 patients demonstrated durable patency rates comparable to acceptable standards, with 96.7% success at 39 months (37).

---

## Robotic-assisted Laparoscopic Partial Nephrectomy

---

Laparoscopic partial nephrectomy has become a standard option for the small renal mass at high-volume centers, with outcomes equivalent to that of open surgery at 5 years (38). Robotic assistance may allow more physicians to accomplish minimally invasive partial nephrectomy, during which sutured renorrhaphy is considered technically difficult. Although the technical feasibility of robotic-assisted laparoscopic partial nephrectomy has been demonstrated (39,40), its true advantage over other minimally invasive techniques has not been defined (41).

---

## Robotic Nephrectomy

---

The use of robotics for nephrectomy has been infrequently reported, since the standard laparoscopic and hand-assisted nephrectomy have gained widespread acceptance, and adding robotic assistance seems to be of no significant value. Guillonnet and colleagues (42) first reported robotic nephrectomy in 2001 for a hydronephrotic nonfunctioning right kidney using the ZEUS system. The patient-side assistant performed many of the crucial maneuvers required for hilar control. To summarize, the immediate advantages of the robot for radical nephrectomy are less apparent than for other procedures.

---

## Miscellaneous Robotic Procedures

---

The first robotic adrenalectomy was reported by Horgan and Vanuno (43), and shortly thereafter by Desai (44). A more recent large series of 30 patients undergoing robotic adrenalectomy for various indications affirmed its safety, efficacy, and cost (45). With laparoscopic adrenalectomy, which is purely extirpative and relatively straightforward, the advantages of

robotics remain to be defined. The da Vinci robotic system has been applied to a variety of other urologic applications, including donor nephrectomy (46,47), where feasibility and safety has been demonstrated. Motion scaling and tremor reduction have benefited the field of male infertility, and robotic vasovasostomy has been performed with success (48).

---

## FUTURE DIRECTIONS AND ALTERNATIVE ROBOTIC PLATFORMS

---

---

### Flexible Robotics

---

Robotics has the potential to revolutionize endoscopy, just as the da Vinci robotic system has facilitated laparoscopic surgery. Flexible robotics was initially designed for interventional cardiology procedures (49). Ureteroscopy was the initial urologic arena in which flexible robotics was investigated. In standard manual ureteroscopy, typically all locations in the collecting system can be accessed, but breathing movements and lack of stability can make controlling subtle movements difficult. Robotics may potentially allow a level of precision that even the expert ureteroscopist might have difficulty duplicating.

Hansen Medical System (Mountain View, CA) (50) has adapted a robotic catheter system for ureteroscopy. The Sensei robotic catheter, a master-slave system, consists of four components: (a) a surgeon console with an LCD display and master input device (MID), (b) a steerable catheter system, (c) a remote table-mounted catheter manipulator, and (d) an electronic rack. At the workstation (Fig. 138.7), three LCD monitors display endoscopic, fluoroscopic, and other procedure-specific imaging. The MID is a joystick that the surgeon manipulates, and these movements are translated to the catheter tip. An outer catheter sheath (14Fr/12Fr) is first manually positioned, followed by an inner catheter guide (12Fr/10Fr) through which the steerable catheter is inserted. The workstation's remote positioning has the secondary advantage of decreasing radiation exposure to the operating surgeon, much the same way as the PAKY robot removes the endoscopist from the radiation source.

**FIGURE 138.7** Table-mounted robotic manipulator for flexible robotics, Hansen Medical System.

The technical feasibility of robotic ureterorenoscopy has been demonstrated in the porcine model (51). The remarkable tip stability and ease of manipulation were acknowledged during this initial experience. The catheter system could be introduced de novo in eight ureters, while two required balloon dilation. The ureteroscope could be successfully manipulated remotely into 83 of the 85 calices (98%). Kidney stones inserted into the collecting system (4 mm) were successfully treated with a holmium laser fiber. The time required to inspect all calices within a given kidney decreased with experience. Clinical trials with robotic ureterorenoscopy are under way and have not yet been reported.

## NOTES and Miniature Robotics

The separate fields of endoluminal surgery (cystoscopy, ureteroscopy) and standard extraluminal surgery (nephrectomy, adrenalectomy) promise to combine in currently unimaginable ways. NOTES (natural orifice transluminal endoscopic surgery) involves traversing intact hollow viscera (stomach, vagina, colon, bladder) to access intra-abdominal targets for ablative or reconstructive surgery (52). The proper instrumentation required, and the reliable entry/exit strategies to effectively accomplish NOTES, have not been determined. NOTES techniques will require even more complex movements in open spaces. It is these limitations that robotic enhancements hope to address. The open environment of the insufflated peritoneal cavity poses significant challenges. Miniature robots deployed in vivo may potentially advance the field (53). Task-specific miniature robots can be used inside the peritoneum without the typical constraints of an externally actuated flexible endoscopic device. While currently available prototypes now perform simple maneuvers, these have the potential to play a role in the future.

Current miniature robotic prototypes are either fixed-base or mobile robots (54). Fixed-base robots are deployed and positioned and cannot self-navigate from their initial position. A pan and tilt camera, fashioned with LEDs for illumination, a 15-mm diameter conical design, spring-loaded tripod “legs,” and two independent motors controlling camera movement (pan 360 degrees, tilt 45 degrees). This camera was deployed through an abdominal incision and used in conjunction with standard laparoscopic equipment to facilitate porcine cholecystectomy

(55). A second-generation tilting camera has been used in conjunction with a standard laparoscope for canine prostatectomy (54). This initial prototype is a “wired” camera for power input, and wireless prototypes are on the horizon.

In animal studies, a mobile camera has been used to provide sole visualization for abdominal exploration and cholecystectomy (56). In this case, the camera port was therefore unnecessary and the cholecystectomy was performed with two trocars. In another study, the mobile robotic platform has demonstrated the successful biopsy of three samples of hepatic tissue (57). For NOTES applications, successful remote-controlled exploration through a gastrotomy has been performed in the porcine model (58). This was monitored by the endoscopic rather than the robotic camera, but it successfully demonstrated proof of concept. The robot was then retracted into the gastric cavity, and the transgastric incision was closed using two endoclips and one endoloop. Also in pigs, the feasibility of using multiple miniature robots for improving spatial orientation and providing task assistance has been demonstrated (59). Three miniature in vivo robots, shown in Figure 138.8, including a peritoneum-mounted imaging robot, a lighting robot, and a retraction robot, were used in conjunction with a standard upper endoscope to demonstrate various capabilities for NOTES procedures.

## Robotic NOTES

Box et al. (60) reported robotic-assisted NOTES nephrectomy using the da Vinci robotics platform. In this porcine study, a combined transvaginal and transcolonic nephrectomy was performed in 150 minutes. A standard laparoscope was placed through a single 12-mm transumbilical trocar for direct visualization. The specimen was extracted transvaginally. Robotic NOTES was also reported by Haber et al. (61) in ten pigs, in which multiple bilateral upper-tract procedures were performed, including pyeloplasty ( $n = 10$ ), partial nephrectomy ( $n = 10$ ), and radical nephrectomy ( $n = 10$ ). An adjunctive multichannel transumbilical port was employed. The endoscope and one working robotic arm were placed through this port. The second robotic working arm was placed transvaginally. Range of motion was limited by external collision of the robotic arms, but even complex suturing with wristed instrumentation was feasible.

**FIGURE 138.8** Retraction, imaging, and lighting minirobots used for hybrid NOTES procedure. (Photo courtesy of Dr. Dmitry Oleynikov, University of Nebraska Medical Center, Omaha, NE.)

Clearly, a task-specific robotic system will ultimately be better suited to the complexity of NOTES procedures in the future. Instrument collision and lack of flexibility are currently limiting factors of the da Vinci system for this application.

Robotic systems, including flexible robots, *in vivo* miniature robots, or a combination, may impact intraluminal surgery and NOTES in the future.

# CHAPTER 139 ■ ENERGY SOURCES IN UROLOGY

MOSES M. KIM AND RICHARD E. LINK

In urology energy sources have been employed in three broad categories: (a) hemostasis, (b) tissue destruction, and (c) lithotripsy. In all applications, the goal is to precisely focus energy onto the target while minimizing damage to adjacent structures. The advent of feedback-modulated bipolar energy platforms has vastly improved electrosurgical options for open and laparoscopic procedures. Harmonic instruments, utilizing sound waves, are similarly used for hemostasis and tissue division. Electromagnetic energy sources, ranging from low-energy radio waves to high-energy microwaves, are used for tissue ablation of the kidney and prostate. Similarly, cryotherapy uses freeze cycles to destroy prostatic and renal tissue. Lasers of many hues have broad applications in lithotripsy and tissue ablation in both benign and malignant urologic conditions.

Surgical energy sources have made many of today's urologic procedures safer, easier, more effective, and in many cases, less invasive. Future advances in energy technology will likely continue to improve patient care as they become integrated into urologic practice.

## ELECTROSURGERY

### Monopolar

Monopolar cautery uses a high-frequency electric current that passes from a single electrode on the instrument to a second, larger electrode plate beneath the patient. The arcing of current from the first electrode to the point of contact on the tissue leads to coagulation. The resulting local hemostasis decreases blood loss and preserves visibility in the surgical field. Monopolar cautery's limitation is that the current is unregulated as it passes through the body to the second electrode. This can lead to tissue damage distant from the contact point.

With minimally invasive surgery, 90% of the instrument lies outside the visual field and may inadvertently be in contact with vulnerable tissue such as bowel. In the event of insulation failure or capacitive coupling, thermal injury to the viscera may occur. Active electrode monitoring was developed to address this concern. If insulation is damaged, an alarm sounds, alerting the operating room staff. This has greatly decreased the incidence of viscera injury from stray currents in laparoscopic procedures (1).

### Bipolar

Bipolar devices place the first and second electrodes near each other, usually at the working tips of the instrument. This arrangement provides better control of the current and minimizes injury to adjacent tissues. Unlike monopolar cautery, the proximity of the two electrodes allows for coagulation of tissue that is immersed in fluid. Traditional bipolar devices, such as the Kleppinger forceps, provide inconsistent vessel sealing, variable thermal spread (Table 139.1), and charring. Recently, new devices offer more consistent vessel seals and less thermal spread with minimal charring and sticking.

The LigaSure instruments utilize high-current, low-voltage, bipolar radiofrequency (RF) energy combined with a feedback-controlled response system that automatically delivers, and then discontinues, power when tissue sealing is completed. When the Ligasure is activated, denatures collagen and elastin to form a seal. The forceps are fitted with an integral blade that can be utilized efficiently to cut the tissue once it is sealed. The EnSeal has a jaw that contains conductive particles that modulate the energy, minimizing thermal spread and charring. The jaw contains an I-shaped blade that is slowly advanced, thereby simultaneously cutting and sealing the tissue (2).

TABLE 139.1

VESSEL SEALING CAPABILITY AND THERMAL SPREAD OF VARIOUS DEVICES

DEVICE	SIZE OF VESSEL RELIABLY SEALED	THERMAL SPREAD (REF)
Traditional bipolar	1—3 mm	Up to 22 mm (5)
Plasmakinetic (Gyrus)	5 mm	3.5 mm (6)
LigaSure V (5-mm device)	7 mm	2.5 mm (7)
LigaSure Atlas (10-mm device)	7 mm	2 mm (8)
EnSeal	7 mm	<1 mm (2)
Harmonic Scalpel LCS-K5	3 mm	1 mm (9)
Harmonic ACE	5 mm	1 mm (10)

The Gyrus Plasmakinetic (PK) tissue management system utilizes a pulsatile delivery of bipolar energy, allowing for cooling of tissue between pulsations, thus minimizing thermal spread and adherence of charred tissue to the instrument. An audible signal communicates to the surgeon when the tissue is fully sealed. There are various PK instruments available for open, laparoscopic, and transurethral prostatic resections. Saline irrigation may be used with the last-mentioned, decreasing the risk of hyponatremia while providing a similar resection to the standard monopolar resectoscope loop (3,4).

---

## ULTRASOUND

---

### Ultrasonic Surgical Devices

---

Harmonic and SonoSurg are two ultrasound-based instrument systems. The tips vibrate at 55 kHz, causing denaturation of proteins and formation of a coagulum that seals vessels. Earlier models generated temperatures between 50°C and 100°C, whereas the newer Harmonic ACE consistently generates temperatures over 100°C, with peak temperatures exceeding 200°C (11). It has a faster sealing time when compared to earlier models, has a curved blade, and is hand-activated (10). Dual modes provide a faster pulse to seal smaller vessels and a longer pulse to seal larger vessels. At the completion of the pulse cycle, the sealed tissue is cut (12). Immediately following deactivation, heat surges to over 200°C can occur (12). Thus, care must be taken when dissecting with the tips to avoid unintentional tissue injury.

---

### High-Intensity Focused Ultrasound (HIFU)

---

HIFU uses an intense beam of ultrasonic waves to heat and destroy tissue. A small, focused sound wave is delivered to deep, targeted tissue, with minimal damage inflicted to the intervening tissue. The acoustic waves are focused and increased in intensity, and the energy imparted to the tissue can heat it to 70°C to 100°C within a few seconds. Additionally, the acoustic waves can create microbubbles that oscillate and collapse, thereby releasing more energy in a process called cavitation. The combination of both processes heats the tissue, leading to tissue coagulation and destruction.

HIFU of the prostate is delivered by a transrectal transducer that is placed abutting the prostate. Real-time imaging with ultrasound is used to monitor treatment. There are two HIFU systems in wide use today for the treatment of prostate cancer. The technologies are similar with a few salient differences. Ablatherm (EDAP TMS SA, France) places both the therapeutic and imaging transducers in a unique probe, with the focus set at 40 mm. The patient lies in a lateral position on a special table while treatment is delivered from the base to the apex in four to six segments. Sonablate (Focus Surgery Inc, Indianapolis, IN) incorporates the therapeutic and imaging transducer into a single probe, and it has several probes at various focal lengths from 25 to 45 mm. The patient is positioned in dorsal lithotomy on a standard operating table. Treatment is delivered in three coronal cuts, from anterior to posterior. Both devices have rectal wall temperature monitors and cooling devices.

HIFU was first reported for the treatment of prostate cancer in 1995 and is widely used in Europe, Asia, and parts of North and South America. However, it has not been approved by the Food and Drug Administration. Recent studies showed that with refinement of technique, local control rates have increased significantly. Blana et al. (13) showed actuarial biochemical failure-free survival rates at 5 and 7 years to be 77% and 69%. At 5 years, 94.3% were continent and 56.8% were potent. Poissonnier et al. (14) reported a 5-year biochemical- and pathological-free rate of 66%, with an inverse relationship with pretreatment PSA levels: 90% for PSA <4, 57% for PSA between 4.1 and 10.0, and 61% for PSA between 10.5 and 15.0. A PSA nadir of >0.2 ng per mL was associated with a fourfold increased risk of treatment failure. There is a 0.3% to 8.6% rate of acute urinary retention (15). Rectoprostatic fistula, more common in the earlier experience, has now dropped to almost zero with the use of an intrarectal cooling device. HIFU can also be repeated in the event of treatment failure, as there is no maximal dose for this modality. Retreatment rates are as high as 40% for the Ablatherm system and 22% for the Sonablate system (15). Rates of incontinence and impotence are significantly higher after the second treatment.

HIFU has also been used for salvage therapy following radiation failure. A study of 118 patients showed local control rates of 84% with a median PSA nadir of 0.18 ng per mL and 5-year actuarial progression-free survival rates of 78.0%, 49.5%, and 14.0% for low-, intermediate-, and high-risk patients. The continence rate was 57%, and rectourethral fistula occurred in 7% (15).

---

## RADIOFREQUENCY ABLATION

---

### Radiofrequency Ablation for Small Renal Masses

---

Radiofrequency ablation (RFA) utilizes a high-frequency alternating wave (375 to 500 kHz), delivered through a probe, that heats the tissue, leading to coagulative necrosis. It was first used for the ablation of nonresectable liver masses. Since then, multiple studies have highlighted the safety and efficacy of this technology for small renal masses. Currently, the use of RFA for the treatment of small renal masses (<4 cm) has been approved by the U.S. Food and Drug Administration. Commonly, the probe is positioned into the renal mass percutaneously under CT guidance, which requires minimal anesthetic and a short time to full convalescence. The probes can also be placed laparoscopically, and the treatment effect can be monitored either by using real-time ultrasound or by placing temperature probes at the periphery of the target lesion. (For patient selection, see section on cryoablation of small renal masses.)

The literature reports excellent cancer control rates. A recent summary of the literature showed cancer-specific survival of 94.8% after RFA of small renal tumors (mean size of 2.4 cm), with a mean follow-up of 19.5 months. Failures can be reablated or resected via partial or radical nephrectomy. The reablation rate was 8.8%, and the rate of extirpative surgery was 1.1% (16).

## Transurethral Needle Ablation

TUNA (transurethral needle ablation) is a minimally invasive procedure used for the treatment of benign prostatic hyperplasia (BPH). Two monopolar needles at 40 degrees from each other are attached to a catheter perpendicular from its longitudinal axis, which is advanced to the prostate via the urethra. The needles are inserted into a lateral lobe of the prostate and low-level radiofrequency energy of 465 kHz is applied. The tissue around the needle is heated to approximately 100°C, leading to coagulative necrosis. Starting from the bladder neck, the needles are advanced 1 cm after each treatment, eventually ablating the entire length of the prostate to the verumontanum (Fig. 139.1). This is usually an outpatient procedure and takes about 30 minutes; it appears to benefit the symptoms of BPH.

A meta-analysis showed significant improvement of BPH symptoms after TUNA as measured by American Urological Association (AUA) symptom scores. At the 3-month follow-up, there was a 57% decrease in the AUA symptom scores, a rate

**FIGURE 139.1** Transurethral needle ablation (TUNA). Two needles at 40 degrees from each other are attached to a catheter, which is advanced to the prostate via the urethra. The needles are inserted into a lateral lobe of the prostate. Starting from the bladder neck, the needles are advanced 1 cm after each treatment, eventually ablating the entire length of the prostate to the verumontanum. (From [www.medtronic.com](http://www.medtronic.com), with permission.)

**FIGURE 139.2** Transurethral microwave thermotherapy (TUMT). A transurethral catheter containing a microwave antenna is positioned within the prostatic urethra. (From [www.bostonscientific.com](http://www.bostonscientific.com), with permission.)

similar to TURP. However, at time points  $>1$  year, there was greater improvement of symptoms in the transurethral resection of prostate (TRUP) group. Additionally, there was a 10% retreatment rate with TUNA, compared to only a 1% retreatment rate with TURP. However, TUNA patients reported significantly fewer complications than TURP patients, including less impact on sexual function (17).

## Microwave

Transurethral microwave thermotherapy (TUMT) is a minimally invasive modality for the treatment of BPH. A transurethral catheter containing a microwave antenna is positioned within the prostatic urethra. High-energy microwave power heats the tissue to approximately 70°C, leading to coagulative necrosis. A cooling component to the catheter limits thermal damage to the urethra (Fig. 139.2).

Compared to TURP, microwave procedures have lower complication rates and are usually performed as outpatient procedures. Like TUNA, TUMT is somewhat less effective than TURP in improving urinary symptoms. A recent summary of the literature showed an improvement of the AUA symptom score of 64% (19.4 to 6.7), whereas TURP showed an improvement of 77% (19.6 to 4.5) at 12 months (18). Mattiasson et al. (19) reported in a prospective, randomized study that within 5 years, 10% of the TUMT group required retreatment, whereas in the TURP group, only 4.3% required retreatment. Other studies have shown retreatment rates as high as 30% within 5 years (20). Thus, like TUNA, TUMT seems to have significantly less durability than TURP.

For TUMT, advanced age, small prostate volumes, mild to moderate bladder outlet obstruction, and lower amounts of energy delivered are independent predictors of poor outcome (21). D'Ancona et al. developed a nomogram predicting good and bad responders based on age, prostate volume, degree of bladder outlet obstruction (BOO), amount of energy, international prostate symptom score (IPSS), and maximum flow (Q<sub>max</sub>) (22). Additionally, histopathologic findings of lower epithelial-to-stromal ratio and higher vascular density were proposed to

decrease efficacy, but studies have not confirmed this (23). The benefit of being able to perform these office-based procedures on nonoperative candidates, coupled with lower morbidity, should be balanced with the somewhat lower efficacy, especially in patients with poor outcome predictive factors.

---

## CRYOABLATION

---

### Prostate Cancer

---

Freezing is also an effective way to ablate unwanted tissue. Cryoablation was first introduced for the treatment of prostate cancer in the 1960s, but it was abandoned due to its high complication rate at that time. Initially, liquid nitrogen was used, but currently argon gas is the cooling agent of choice. Pressurized argon gas ( $-187^{\circ}\text{C}$ ) is depressurized at the tip of the probe, which allows for cooling at a specific temperature according to the Joule-Thompson effect. Pressurized helium gas ( $67^{\circ}\text{C}$ ) is used to warm the probes in similar fashion.

Real-time imaging with a transrectal ultrasound and a grid similar to that used for brachytherapy is used to guide the placement of the probes. Six or eight probes are placed percutaneously at the perineum, with additional temperature sensor probes at the rectal wall and external urethral sphincter. A urethral warming catheter is also placed. Standard treatment includes two freeze-thaw cycles to  $-40^{\circ}\text{C}$ .

There have been many published studies describing the efficacy of cryotherapy for the primary treatment of prostate cancer. Bahn et al. (24) published a large series of 590 patients showing 7-year actuarial biochemical disease-free survival (bDFS) probabilities in low-, medium-, and high-risk patients of 92%, 89%, and 89%, respectively. Patients were classified as treatment failures according to the American Society of Therapeutic Radiology and Oncology (ASTRO) criteria of three successive increases in PSA. In all patients, the rate of positive biopsy was 13%. Of interest, 94.9% of previously potent patients became impotent following cryotherapy, and 15.9% became incontinent. Other studies report similar results, with rates of erectile dysfunction at 84% to 93% and incontinence at 10%. About 5% of patients required transurethral resection for bladder outlet obstruction (25).

Salvage cryotherapy for recurrent prostate cancer following primary therapy, usually radiotherapy, has been promising. Ng et al. (26) showed that in a series of 187 patients undergoing salvage cryotherapy, patients with pretreatment PSA of  $<4.0$  ng per mL had 5-year and 8-year biochemical recurrence-free rates of 56 and 37%, respectively. For patients with PSA over 10, 5- and 8-year biochemical recurrence-free rates were 14% and 7%. Complication rates are higher for salvage than primary treatment, with incontinence rates up to 20% and rates of rectourethral fistula in the 1% to 3% range (25).

---

### Small Renal Masses

---

Cryoablation of small renal masses employs the same pressurized helium-argon system, but with a smaller probe of 1.47 mm. It is a treatment option for peripheral renal lesions measuring  $<4$  cm and can be placed percutaneously or laparoscopically. Similar to RF ablation, cryotherapy is not as

effective for tumors around the hilum or major vessels, or those abutting the renal pelvis. The percutaneous approach is equally suitable for inferior pole, lateral, or posterior lesions and can be done under ultrasound, CT, or MRI guidance. With the laparoscopic approach for anterior tumors or lesions abutting vital structures, real-time ultrasound is recommended to monitor the formation of the ice ball.

In human studies, a delayed urine leak has been reported only with RF ablation (48) but not with cryoablation, to date suggesting that the collecting system may be more resilient to cryoablation than to RF ablation.

Several studies demonstrated excellent tumor control following cryoablation. Bandi et al. (27) published a study of 78 patients, 58 who underwent laparoscopic cryoablation and 20 who underwent percutaneous cryoablation. At a mean follow-up of 19 months, the recurrence-free survival rate was 98.7%. In another study, Hegarty et al. (28) reported a 5-year follow-up on 66 patients who underwent cryoablation of a small renal mass. Mean tumor size at treatment was 2.3 cm (range 1.0 to 4.5 cm). Six percent of patients developed a recurrence, and the 5-year cancer-specific survival rate was 98%. Thus, cryoablation should be considered when evaluating treatment options for renal masses smaller than 4 cm.

---

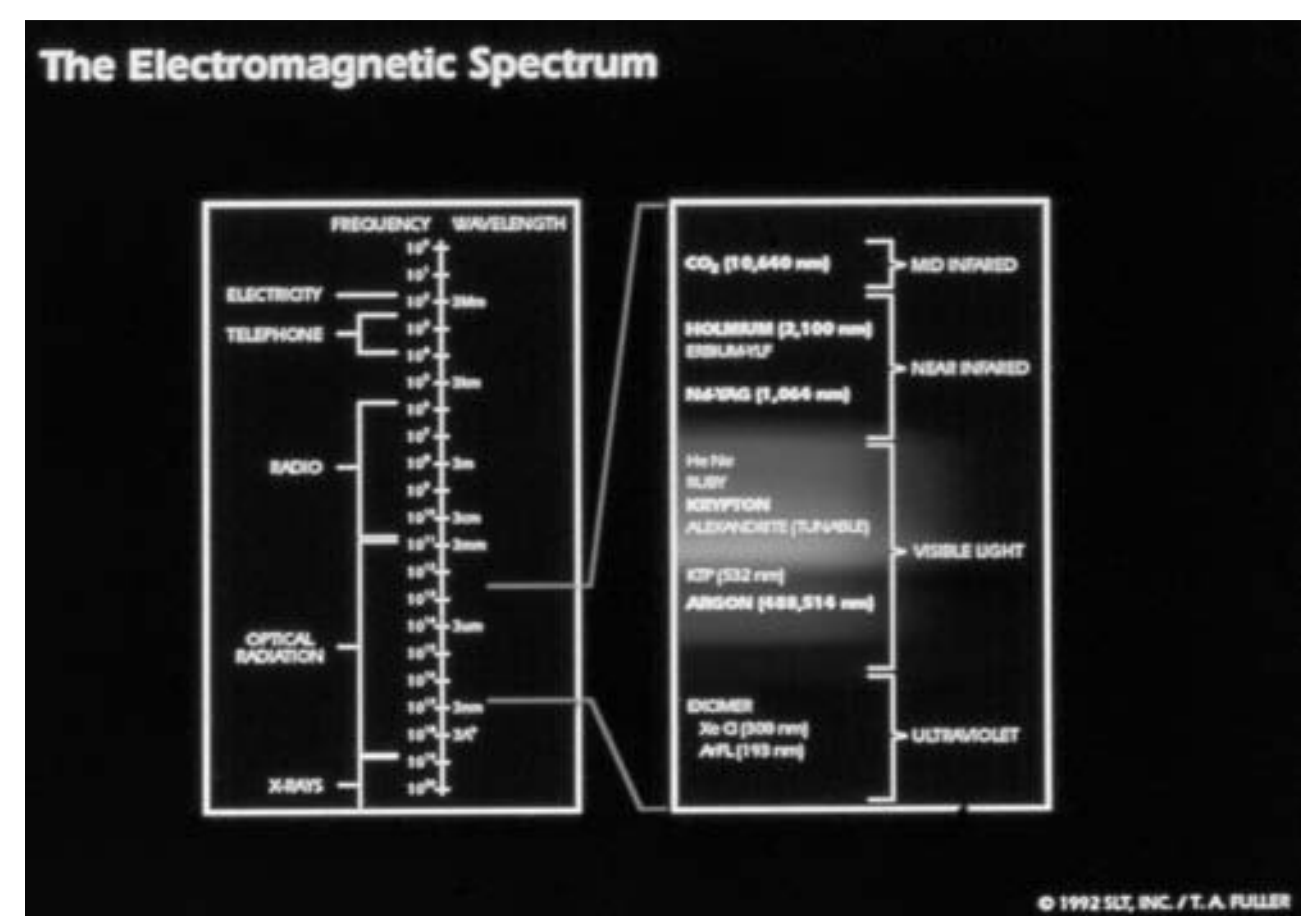

## LASERS

---

### Laser Physics

---

A laser, an acronym for “light amplification by stimulated emission of radiation,” is a focused beam of photons. A lasing medium, be it solid, gas, or liquid, emits photons at a specific wavelength when excited by energy (Fig. 139.3). Different mediums emit light at different wavelengths. In a laser, the medium is surrounded by two mirrors, one that is fully reflective, the other partially reflective. These reflected photons collide with excited electrons, releasing an additional photon in the exact same phase, wavelength, and direction. The photons are released through an aperture in the partially reflective mirror. This generates a laser beam with the same wavelength (monochromatic), phase (coherent), and direction (collimated). The

**FIGURE 139.3** The electromagnetic spectrum. Each laser emits a very specific wavelength, depending on the substance that is excited (lased).

energy of the laser is expressed in joules (J), and the power is the energy delivered per unit time (1 J per second = 1 W).

---

## Laser Biophysics

---

The effect of laser light on tissue is a function of the laser wavelength, tissue absorption characteristics, and power delivered (29). Thermal tissue destruction can be accomplished by either coagulation or vaporization. Capillary coagulation occurs around 60°C to 65°C, and as the tissue temperature increases to 100°C, denaturation of protein and DNA occurs. When the tissue temperature exceeds 100°C, the fluid content of the tissue vaporizes in a plume containing fluid vapor and charred tissue. Following laser treatment, a zone of coagulation necrosis surrounds the site.

By adjusting the wavelength, energy, and time of exposure, tissue effects can be modified to the desired effect. As laser energy is increased, ablation of tissue occurs. At energy levels above the ablation threshold, a focused beam will incise tissue, whereas a lower-power laser causes coagulation and hemostasis. The presence of water will shift the ablation energy to a higher threshold because it cools the tissue. Water also impedes surface ablation and cools the laser fiber to allow a higher-wattage delivery without damage to the fiber. Thus, a higher laser wattage is needed to achieve efficient ablation of the same tissue under water than in air.

The depth of penetration is dependent on both laser and tissue characteristics. In general, a longer wavelength corresponds to greater depth of tissue penetration. Additionally, tissue characteristics that increase laser scatter and energy absorption will decrease penetration. For instance, laser absorption by water or blood will reduce the depth of penetration. These penetration characteristics frequently dictate the type of laser to be used for ablation of tissue in various surgical applications.

---

## Types of Lasers

---

The different types of lasers are discussed following see also Manyak and Warner (29).

### Carbon Dioxide (CO<sub>2</sub>) Laser

The CO<sub>2</sub> laser has an invisible infrared wavelength of 10,600 nm and is usually coupled to a visible helium-neon beam to highlight the target area. The infrared CO<sub>2</sub> beam is absorbed by water, which usually limits its use to surface applications. The CO<sub>2</sub> beam can be directed through a waveguide to allow for use through the laparoscope. Depth of tissue penetration is <0.1 mm with a small area of coagulation necrosis. One of the disadvantages of the CO<sub>2</sub> laser is the production of a plume with potential vaporization of infectious viral particles. This necessitates the use of a high-filtration mask for all cutaneous applications. In addition, the CO<sub>2</sub> laser has poor coagulative properties for vessels over 1.0 mm, and development of oxidized char impedes vaporization of underlying tissue.

### Argon Laser

The argon laser produces wavelengths in the blue-green spectrum (488 to 514 nm) that are absorbed by pigmented molecules such as hemoglobin. The argon beam penetrates 1 to

2 mm in tissue. Advantages include flexible application, minimal plume production, and excellent hemostatic properties. Disadvantages include the need for a dedicated water supply for cooling the laser and the requirement for tinted filters to protect the eyes of operating room staff and patient.

### Neodymium:Yttrium-Aluminum-Garnet (Nd:YAG) Laser

The Nd:YAG laser is a solid-state laser utilizing a crystal seed with neodymium ions to furnish the active medium. The beam is in the near-infrared portion of the light spectrum (1,064 nm) and requires a helium-neon aiming beam for illumination of the target tissue. The Nd:YAG laser is minimally absorbed by water and blood and therefore produces relatively high tissue penetration of 3 to 5 mm with good coagulation. This degree of tissue penetration clearly can be a disadvantage as well. A sapphire tip limits backscatter and enhances the laser cutting properties. Caution is advised due to the extremely high temperatures produced at the tip.

### Potassium Titanyl Phosphate (KTP) Crystal Laser

The KTP crystal laser is generated by passing a rapidly pulsed Nd:YAG beam through a potassium thiophosphate crystal, which doubles the frequency and halves the wavelength to 532 nm. It is strongly absorbed by hemoglobin, and in vascular tissue such as the prostate, the depth of penetration is 1 to 3 mm. There is rapid photothermal vaporization of tissue with excellent hemostasis.

### Holmium:Yttrium-Aluminum-Garnet (Ho:YAG) Laser

Holmium is a rare earth element that, when mixed with YAG, can emit laser radiation at a wavelength of 2,150 nm with a normal pulse duration of 250 ms. This laser operates in the near-infrared portion of the electromagnetic spectrum and is therefore invisible to the human eye. The holmium laser is especially suited for endoscopic procedures because the 2,150-nm wavelength can be transmitted through standard flexible optical fibers. At this wavelength, the pulse is strongly absorbed by water in superficial tissue and provides excellent incisive and tissue ablation properties. Recently, holmium lasers have largely supplanted the use of pulsed dye lasers for lithotripsy of urinary calculi due to their reliability and ease of maintenance.

### Erbium:Yttrium-Aluminum-Garnet (Er:YAG) Laser

Erbium is another rare earth metal used in combination with YAG to produce laser light. This laser emits light at 2,940 nm, which coincides with the water absorption peak in the infrared spectrum. Because of this close approximation with the absorption peak of water, Er:YAG lasers are more efficient in lithotripsy and have more precise tissue ablation with less thermal damage than Ho:YAG lasers. However, the lack of an adequate laser fiber has limited this laser from being more widely used in urology (30).

### Dye Lasers

Dye lasers employ an organic liquid dye as the active medium that is optically excited by another light source. Liquid dyes have complex sets of electronic and vibrational energies, and the wavelength emitted depends on the type of dye used. The

wavelength of these lasers can be changed by simply replacing the dye used for excitation, an important advantage of dye lasers. Pulsed dye lasers have been used for lithotripsy of urinary calculi and for photodynamic therapy. The need to change the dye in these lasers at a regular interval makes them more difficult and expensive to maintain than other lasers.

---

## UROLOGIC LASER PROCEDURES

---

### Laser Applications for Benign Prostatic Hyperplasia

---

The Nd:YAG laser was one of the earliest lasers used for the vaporization of BPH. This approach has been largely abandoned due to long catherizations, irritative symptoms, and infections. With the advent of higher-power Ho:YAG and KTP lasers, this technology has become a viable alternate to electroresection and open prostatectomy.

#### Nd:YAG Laser

The Nd:YAG laser was typically used by aiming the laser beam a short distance from the target tissue, called the “free-beam” method. Contact optical fibers, which deliver the laser energy only when the fiber is in contact with the tissue, were used less often. Visual laser ablation of the prostate (VLAP) is the free-beam method of treatment that uses a fiber with a right-angled tip for beam direction. A summary of published studies showed a significant improvement of obstructive symptoms and low rates of perioperative complications (31). However, despite proper patient selection, approximately one-third of patients did not have sufficient symptom relief (32). Many patients remained catheterized for several days post-treatment due to prostatic edema and the potential for urinary retention. Thus, this procedure has been supplanted by newer laser technologies.

#### Ho:YAG Laser

The holmium laser has been used for ablation as well as enucleation of the prostate. HoLAP (holmium laser ablation of the prostate) utilizes a side-fire laser fiber and paints the wall of the prostate, immediately ablating the tissue. This approach allows for immediate visualization of the ablation site, which is an improvement to the invisible deep tissue damage of VLAP. When compared to TURP, HoLAP had similar efficacy in improving AUA symptom scores but with less bleeding, shorter hospital stay, and more consistent next-day catheter removal. The main drawback cited was the length of the procedure with the 60-W laser (31,33). Currently, with the introduction of the 100-W laser, this technique has been mostly superseded by the enucleation technique.

HoLRP (holmium laser resection of the prostate) utilizes the laser to cut small fragments of prostate that can be removed through the resectoscope sheath. This allows for shorter operative time as compared to HoLAP. HoLEP (holmium laser enucleation of the prostate) uses the laser to resect an entire lobe of the prostate in one piece. The laser cuts in the same plane as the index finger would in an open prostatectomy. The adenoma is shelled out and pushed into the bladder. A morcellator is then used to remove the adenoma from the bladder. With this technique, treatment of prostates as

large as 300 g has been reported (34). Additionally, a randomized trial comparing HoLEP to TURP showed that the laser was better than TURP at improving symptoms. At a minimum 4-year follow-up, measures of maximal flow, symptom scores, potency rates, and continence rates were similar for HoLRP and TURP. HoLEP had less bleeding and shorter catherization time when compared to TURP or open prostatectomy and had similar retreatment rates at 4 years (31,35).

#### KTP Laser (Green Light)

Photoselective vaporization of the prostate (PVP) with the KTP laser has come into widespread acceptance with the advent of the high-power 120-W laser. PVP provides rapid vaporization of the prostate tissue with limited depth of penetration and a thin rim of coagulation. This leaves a resection site similar to TURP and limits delayed necrosis, minimizing the irritative symptoms seen with the Nd:YAG laser. In contrast to HoLEP, there is no need to morcellate the adenoma. This benefit is also a limitation in that no tissue is obtained for histological analysis.

Te et al. (36) showed in a study with 139 patients from six centers that PVP significantly improved the AUA symptom score from 23.9 to 4.3 at 12 months follow-up. PVP also significantly improved Qmax and decreased the postvoid residual while improving the quality-of-life score. Perioperative morbidity was low, with no patients receiving a blood transfusion and a significant proportion avoiding catherizations. The rates of recatherization, dysuria, infection, urethral stricture, incontinence, and bladder neck contracture were similar to those following TURP or HoLEP. A major advantage of PVP is that it can be performed on patients on anticoagulation, including aspirin, clopidogrel, and even warfarin (37). A disadvantage is that in large prostates, PVP can take several hours and may even need to be performed in stages. PVP with green light KTP laser is now considered a viable alternative to the standard TURP, especially in high-risk patients on anticoagulation.

---

## Laser Lithotripsy

---

The most widespread impact of lasers in urology has been in the management of calculi (29). The advent of small rigid and flexible ureteroscopes fitted with holmium lasers has rendered open surgical management of ureteral stones essentially obsolete except in very unusual circumstances.

Laser lithotripsy with pulsed dye lasers is achieved through photoacoustic and photomechanical mechanisms. The discharge of laser energy onto the stone produces a focus of microscopic heating that results in thermal expansion. Further heating leads to ionization of stone material and the formation of plasma, seen as a bright flash of white light (Fig. 139.4). Water is essential for confining the plasma and enhances fragmentation rates approximately tenfold. A cavitation bubble is created that first expands and then collapses, which generates shock waves, causing stone fragmentation (Fig. 139.5). Lithotripsy with the Ho:YAG laser appears to be predominantly a photothermal process that causes chemical decomposition rather than cavitation. This unique mechanism of action allows the holmium laser to be used effectively on all types of stones, including cystine calculi that do not absorb pulsed dye laser energy.

**FIGURE 139.4** Plasma formation from holmium:yttrium-aluminum-garnet laser at urinary calculus interface. Plasma propagates shock wave energy from cavitation.

**FIGURE 139.5** Photomechanical fragmentation of urinary calculus following plasma formation.

Holmium laser energy can be delivered via fibers of several sizes, with the smaller fibers suitable for both flexible and rigid ureteroscopes. Multiple large series have confirmed both the effectiveness and safety of holmium lithotripsy (38). Stone-free rates after laser lithotripsy of upper urinary calculi are in the 90% range for all ureteral calculi and 85% for renal calculi. The safety profile of holmium laser lithotripsy is well documented, with very low perforation and stricture rates. A further advantage to holmium lithotripsy is its efficacy in morbidly obese patients, whose body habitus precludes effective extracorporeal shock wave lithotripsy or percutaneous nephrostolithotomy. Holmium lithotripsy has also proven successful in cases of failed electrohydraulic lithotripsy and creates significantly smaller stone fragments than pneumatic, pulsed dye laser, or electrohydraulic lithotripsy (39). In addition, pediatric urolithiasis and urolithiasis of pregnancy can be safely treated with this technology.

---

### Laser Treatment of Transitional Cell Carcinoma of the Renal Pelvis and Ureter

---

Improvements in endoscopic access to the upper urinary tract have allowed intraluminal laser ablation of papillary transitional cell malignancies. Both the Nd:YAG and Ho:YAG lasers can be delivered via small-diameter optical fibers and have been used for tumor ablation. The Nd:YAG laser is typically set at 20 to 30 W and is activated at a tangential angle, avoiding direct tissue contact, for 2 to 3 seconds. This results in a depth penetration of 5 to 6 mm. The Ho:YAG laser is placed in direct contact with the tumor and set at 1 J and 10 Hz. This laser has a very superficial penetration (0.4 mm) and therefore little risk of perforation, even in the thin-walled ureter. For large tumors (over 1 cm), a tag team approach is often effective: the Nd:YAG laser to first coagulate the bulk of the tumor, followed by the Ho:YAG laser to ablate the residual layers.

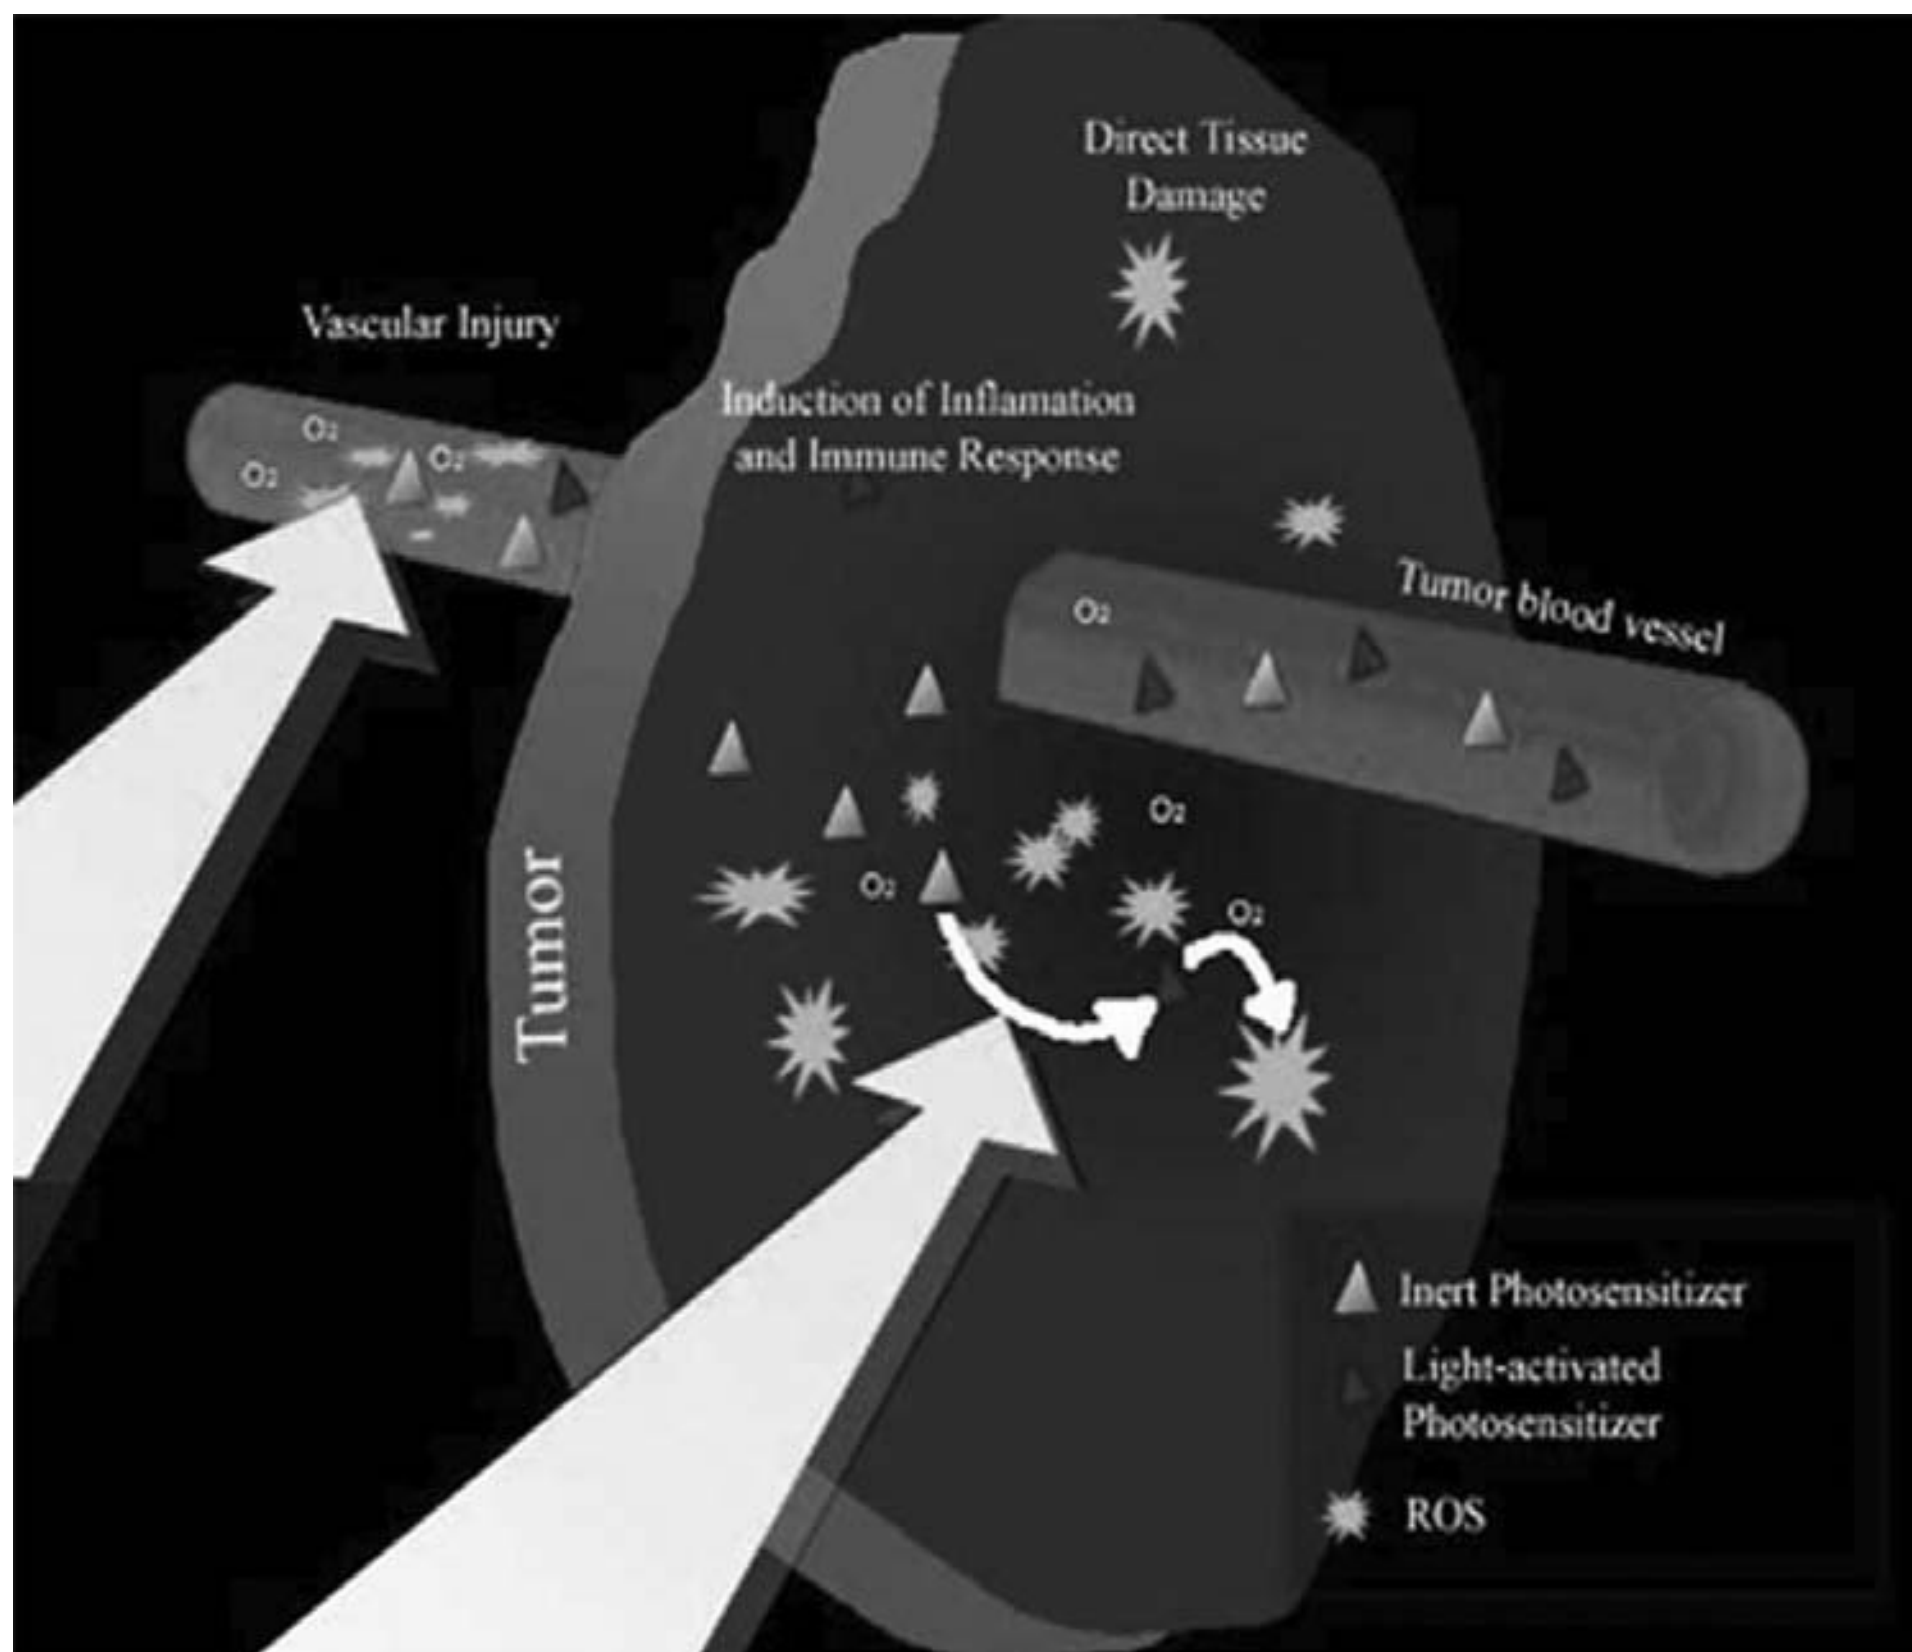

Compared to electrofulguration, laser treatment appears to result in less scarring and stricture formation in the upper urinary tract. Local recurrence is reported to be as high as 74% in patients with renal pelvis and ureteral tumors (40). Recurrence and progression of disease correlate closely with higher grade and stage, so laser thermal destruction of tumors is best reserved for lower-grade, superficial lesions. In patients with specific indications for conservative therapy, however, laser ablation of low-grade upper-tract transitional cell carcinoma (TCC) with close ureteroscopic surveillance is now considered a reasonable alternative to surgical removal. This form of treatment may be especially well suited for patients with lesions in a solitary kidney or with bilateral disease.

---

### Photodynamic Therapy

---

Photodynamic therapy is an intriguing new treatment modality that has been applied to tumors in multiple anatomic locations, including the bladder, skin, esophagus, head and neck, brain, and peritoneal cavity. This technology utilizes a chemical that is activated by light to trigger a photochemical reaction that causes tissue destruction and cell death (Fig. 139.6). The wavelength of the light source should be that which is maximally absorbed by the photosensitizer.

**FIGURE 139.6.** General concept of photodynamic therapy. Light excitation of photosensitizer in presence of  $O_2$  generates reactive oxygen species (ROS), which attack different cellular structures. (From Pinthus JH, Bogaards A, Weersink R, et al. Photodynamic therapy for urological malignancies: past to current approaches. *J Urol* 2006;175:1201, with permission.)

Commonly used photosensitizing agents are derived from porphyrins and chlorophyll. Early experience with Photofrin, a porphyrin-based agent excited at 630 nm, showed efficacy for the treatment of bladder cancer, with response rates of 45% to 80% at 3 months (41). Berger et al. (42) reported the effectiveness of intravesical 5-aminolevulinic acid (5-ALA) in patients with superficial bladder cancer in whom multiple transurethral resections and/or intravesical bacille Calmette-Guérin (BCG) immunotherapy alone had failed. At an average follow-up of 23.7 months (range, 1 to 73), half of the patients were free of tumor. Problems included skin photosensitization, and side-effects included irritative symptoms and bladder shrinkage. However, newer photosensitizers with shorter half-lives and optimization of light doses should improve efficacy and decrease side-effects.

### Laser Treatment of External Genitalia

Lasers are excellent tools for the precise ablation of genital condyloma caused by human papilloma virus (HPV) (29). Excellent therapeutic and cosmetic results have been obtained with the  $CO_2$  and Nd:YAG laser treatment of large penile lesions. Magnification with loupes or an operating microscope is required for multiple smaller lesions. HPV particles can remain viable in the laser plume. Safety precautions for operating room personnel are imperative and include charcoal filtration face masks and a dedicated suction apparatus to capture the laser plume. Nd:YAG treatment of condyloma requires irrigation to cool the tissue during treatment. Treatment of urethral condyloma proximal to the meatus is

not amenable to  $CO_2$  therapy because this laser energy cannot be transmitted via a fiber. Both the Nd:YAG and holmium lasers have been used for urethral condyloma with good results and very few complications.

In addition to benign penile lesions, lasers are currently used for treatment of superficial squamous cell carcinoma of the penis. Successful treatment of premalignant or low-grade penile malignancy (Bowen disease, erythroplasia of Queyrat, bowenoid papulosis) can be achieved using many of the common surgical lasers (Fig. 139.7). Because these lesions are superficial, are often multifocal, and require precise treatment, the  $CO_2$  laser in combination with an operating microscope is often considered the ideal approach. The Nd:YAG and  $CO_2$

**FIGURE 139.7.** An excellent laser cosmetic effect following neodymium:yttrium-aluminum-garnet laser treatment of superficial penile squamous cell carcinoma.

lasers are well suited to treat superficial squamous cell penile lesions with good results reported, but they are not recommended for T1 and T2 squamous cell carcinoma of the penis. Local treatment of Kaposi sarcoma with the Nd:YAG laser has been beneficial for urethral meatal obstruction.

---

## DIAGNOSTIC USE OF LASERS

---

Although the most popular application of lasers to date has been for ablation, their use in endoscopic diagnosis has been increasing. The fluorescent properties of tumors in response to photosensitizing agents have long been of interest for the diagnosis of occult malignancy. In urology, the bladder is the primary focus for this application (43). The most common compounds used for fluorescent detection are porphyrins, which produce a characteristic reddish hue in tissue after exposure to ultraviolet or blue-green visible light. The most promising agent, 5-ALA, can be administered directly into the bladder and so avoids the skin reaction associated with most photosensitizers.

In a randomized prospective study involving 102 patients undergoing transurethral resection of a bladder tumor (44), the use of 5-ALA resulted in a more thorough resection of bladder tumors. Six weeks after the initial resection, second-look cystoscopies showed a 16% recurrence in the 5-ALA group versus 41% in the white light group. Sensitivity was 87% to 97% for 5-ALA and 68% to 85% in the white light group. The specificities for both modalities were similar (43% to 76% for 5-ALA and 31% to 89% for white light). Daniltchenko et al. (45) showed that the improvement in bladder cancer detection at the initial cystoscopy significantly decreased the number of recurrences over a 5-year period.

Optical coherence tomography (OCT) uses inexpensive solid-state red diodes to create a cross-sectional tomographic

image based on optical scattering within tissue (46). OCT is similar to ultrasound pulse-echo imaging but uses optical rather than acoustic reflectivity. Unlike ultrasound, OCT does not require a conducting medium and can image through air or water and with far greater resolution than ultrasound. In combination with endoscopy, OCT offers imaging of the epithelial surface of internal organs and visualization of tissue beneath the surface. Manyak et al. (47) showed in an evaluation of 87 areas in 24 patients that OCT had a sensitivity of 100% and specificity of 87%. The positive predictive value for invasion was 90%. Though a small study, these results appear very promising and will open the way for further trials to elucidate the usefulness of OCT for bladder cancer staging.

---

## CONCLUSION

---

Various energy sources, ranging from cryoablation to microwave to lasers, have been widely adopted into urologic surgery. Bipolar instruments continue to improve electro-surgery, providing better vessel sealing while minimizing current spread. In the treatment of BPH, office-based procedures such as TUNA and TUMT have shown good efficacy in terms of symptom relief, albeit with less durability than TURP. Green light laser has made ablation of the prostate feasible even for patients on anticoagulation. Small renal masses can now be ablated or frozen, instead of being excised. And of course, the holmium laser has completely changed stone surgery, making open surgical removal of stones very rare.

Looking ahead, advances in new technology such as photodynamic therapy or optical coherence tomography will continue to change urologic surgery. In addition, new uses of existing technology, such as in focal therapy for prostate cancer, will continue to make the practice of urologic surgery less invasive with less morbidity and better efficacy.

- Neuroblastoma  
diagnostic criteria, 623  
neonatal observation protocol, 624  
outcomes and complications, 625–626,  
626f, 627t  
staging systems, 623t–624t  
surgical indications, 623–624  
surgical technique, 624–625
- Neurogenic bladder  
female, surgical management, 228–232,  
229t, 230f–232f  
male, surgical management, 229,  
232–235, 233f–234f  
pubovaginal fascial sling, 272
- Neuropathic bladder, catheterizable reservoir  
construction, ileal segments,  
594–595
- Neurovascular bundles, open radical  
retropubic surgery  
prophylactic hemostatic suture placement,  
189, 189f  
prostate separation from, 190
- Nondismembered pyeloplasty, robotic  
techniques, 855, 856f
- No-needle local anesthesia, vasectomy  
anesthesia protocols, 373–375,  
373f
- Nonobstructive azoospermia, testicular  
sperm extraction, 403

No-scalpel vasectomy (NSV), basic techniques, 374–375, 374f–375f  
 NOTES surgical robotics, 924–925, 924f

**O**

Obese patients, orthotopic urinary diversion, with ileal low-pressure reservoir, afferent tubular segment, 564–565, 565f  
 Obturator anatomy, pelvic organ prolapse, 316  
 Occlusion therapy, vesicovaginal fistula repair, 131–132  
 O'Connor technique, vesicovaginal fistula repair, 135  
 Omental interposition, neurogenic bladder reconstruction, 234, 234f  
 Omental wick placement, lymphocele laparoscopic management, 884  
 One-stage cystoprostatectomy, radical technique, 101  
 Onlay bulbar urethroplasty, 239f, 241, 243f  
 Onlay island flap, hypospadias surgery, 707, 709f  
 Open Burch urethropexy, abdominal retropubic therapies, female patients, 289–290, 289f–290f  
 Open distal ureterectomy, laparoscopic technique, 834–835, 834f  
 Open-flank nephrectomy, 847  
 Open nephrectomy, laparoscopic nephrectomy vs., 819  
 Open nephroureterectomy (ONU), laparoscopic procedure vs., 831  
 Open surgical drainage, renal and retroperitoneal abscess, 54–55  
 Open transcolonic ureterosigmoidostomy, 611–613, 611f–613f  
 Orandi repair, pendulous urethral stricture, 237–240, 239f  
 Orchiectomy  
 inguinal  
 alternative therapy, 433–434  
 diagnosis, 433  
 outcomes and complications, 434  
 surgical indications, 433  
 surgical technique, 433–434, 434f–434f  
 simple procedures, 428–432  
 alternative therapy, 428–429  
 epididymal orchiectomy, 431–432, 431f  
 outcomes and complications, 432  
 prostate cancer diagnosis, 428  
 scrotal approach, 429, 429f

- Transvaginal approach
  - urethral diverticulectomy, 216–219, 216t, 217f–219f
  - vesicovaginal fistula repair, 132–134, 132f–133f

- Transvaginal prolapse repair  
 alternative therapy, 336  
 basic principles, 335–336, 336f  
 diagnosis, 336  
 enterocele repair, 336–338, 337f–338f  
 iliooccygeus fixation, 340–341  
 Manchester procedure, 342  
 McCall culdoplasty, 338, 339f  
 mesh-augmented repairs, 341–342, 341f–342f  
 prolapsed uterus preservation, 342  
 sacrospinous ligament fixation, 340, 340f  
 surgical indications, 336  
 uterosacral ligament fixation, 338–340, 339f  
 vault suspension, 338
- Transverse colonic conduit, 549–554  
 alternative therapy, 550  
 diagnostic criteria, 550  
 outcomes and complications, 553  
 palliative techniques, 619, 619f  
 retubularized colon segments, 622, 622f  
 surgical indications, 550  
 surgical technique, 550–553, 550f–553f  
 postoperative care, 553  
 pyeotransverse pyelocutaneostomy, 552, 554f
- Transverse scrotal incision, artificial urinary sphincter, 294–296, 295f–296f
- Transvesical approach  
 bladder diverticulectomy, 115  
 laparoscopic distal ureterectomy, detachment and ligation, 835–836  
 nephroureterectomy, distal ureter management  
 bladder cuff technique, single port, 126–127, 127f  
 bladder cuff technique, two ports, 127–128  
 seminal vesical surgery, 363–364  
 vesicovaginal fistula repair, 136
- Trauma  
 penile trauma  
 penetrating injury, 518–519  
 rupture, 514–516, 515f–516f  
 skin loss, 516–518, 517f  
 renal trauma, 58–64  
 angioembolization, 59–60, 60f  
 diagnosis, 58–59  
 imaging techniques, 59f, 60  
 management, 59  
 nephrectomy, 60  
 outcomes and complications, 63, 63f–64f  
 postoperative care, 63  
 renal exploration, indications for, 60, 60t  
 renovascular injuries, 63, 63f–64f  
 surgical technique, 60–63, 61f–63f
- scrotum  
 alternative therapy, 455  
 avulsion injuries, 457–460, 459f  
 burn injuries, 460, 460f  
 diagnosis, 453–455, 454f–455f  
 Fournier gangrene, 461–462, 462f  
 hematomas and blunt injury, 455–456, 456f  
 outcomes and complications, 462–463  
 penetrating injury, 456–457, 458f  
 radiation injury, 461, 461f  
 surgical indications, 455
- urethral trauma  
 anterior injuries, 246–249, 246f  
 alternative therapy, 247  
 diagnosis, 246–247, 247f  
 indications for surgery, 247  
 outcomes and complications, 248–249  
 surgical management, 248, 248f  
 classification, 250t  
 posterior injuries, 249–36–42  
 alternative therapy, 251  
 diagnosis, 249, 250f, 250t  
 indications for surgery, 250–36–42  
 outcomes and complications, 251–252  
 surgical techniques, 251, 251f  
 surgical management, 245–36–42
- vesical trauma and hemorrhage, 143–149  
 alternative therapy, 146  
 diagnosis, 144–145, 144f–146f  
 outcomes and complications, 147  
 surgical management and technique, 146–147
- Triad syndrome (prune belly)  
 alternative therapy, 656  
 diagnosis, 655  
 epidemiology, 654  
 outcomes and complications, 660–661  
 surgical indications, 655–656  
 surgical technique, 656–660  
 abdominal wall reconstruction, 658  
 distal cutaneous ureterostomy, 657  
 orchiopexy, 658–659, 659f  
 reduction cystoplasty, 658, 658f  
 ureteral reconstruction, 657  
 urethral reconstruction, 659–660, 660f  
 vesicostomy, 656
- Trigone, bladder anatomy, 88–89, 88f
- Trocar placement  
 laparoscopic surgery  
 primary placement, 804–805, 804f  
 removal, 806–807, 806f  
 robotically assisted pyeloplasty, 854, 854f  
 secondary placement, 805, 806f  
 lymphocele laparoscopic management, 882, 882f
- Tube flap reconstructive technique, female urethra, 223, 223f
- Tube graft, female urethra, 223–224, 224f
- Tubularized incised plate (TIP) urethroplasty, hypospadias surgery, 706, 708f

- Urothelial cancer, radical cystectomy for, 92–93
- “Urothelium,” bladder anatomy, 86–88, 87f
- Uterine prolapse  
 transvaginal procedures and preservation of, 342  
 vaginal hysterectomy  
 alternative therapy, 320  
 basic principles, 318–319  
 diagnosis, 320, 320f  
 outcomes and complications, 324–325  
 pathophysiology, 319  
 surgical anatomy, 319  
 surgical technique, 320–324, 321f–325f
- Uterosacral ligament fixation, transvaginal enterocele repair, 338–340, 339f
- Uterus, eversion of, 322–323, 323f
- ## V
- Vagina, rhabdomyosarcoma, childhood, surgical technique, 663–664
- Vaginal hysterectomy, for uterine prolapse  
 alternative therapy, 320–321  
 basic principles, 318–319  
 diagnosis, 320, 320f  
 outcomes and complications, 324–325  
 pathophysiology, 319  
 surgical anatomy, 319  
 surgical technique, 321–324, 321f–325f
- Vaginal prolapse. *See also* Cystocele  
 posterior repair techniques, 343–349  
 alternative therapies, 344–345  
 colporrhaphy, 345–346, 346f–347f  
 diagnosis, 344, 345f  
 outcomes and complications, 348–349  
 perineal body reconstruction, 347, 347f–348f  
 postoperative care, 348  
 site-specific rectocele repair, 346–347  
 surgical techniques, 345–348
- Vaginal reconstruction  
 female radical cystectomy, 108, 111f  
 flap reconstruction, neurogenic bladder, 230–232, 230f–233f  
 vaginal prolapse, 331
- Vaginal vault prolapse (VVP), abdominal sacral colpopexy, 349–354  
 alternative therapy, 351  
 diagnosis, 350–351, 350t  
 indications for, 351, 351f  
 outcomes and complications, 353–354  
 surgical techniques, 351–353, 352f–353f
- Vaginoplasty, 763–764
- Valsalva leak point pressure (VLPP), abdominal retropubic therapies, female patients, 289
- Varicocele  
 alternative therapy, 523–524  
 diagnosis, 523  
 epidemiology, 523  
 laparoscopic ligation of, 899–901, 900f–903f  
 outcomes and complications, 527  
 surgical indications, 523  
 surgical techniques, 524–527, 524f–527f  
 inguinal (Ivanissevich) approach, 525, 525f  
 laparoscopic repair, 525  
 microsurgical varicocelectomy, 525–527, 526f–527f  
 retroperitoneal (Polomo) approach, 524–525, 524f
- Varicocelectomy  
 alternative therapy, 398  
 diagnostic criteria, 398  
 microsurgical technique, 525–527, 526f–527f  
 outcomes and complications, 400  
 surgical techniques, 398–400, 399f–400
- Vasa deferentia  
 dissection, robotically assisted  
 laparoscopic (radical) prostatectomy, 875, 875f  
 open radical retropubic surgery, dissection, 191  
 vasovastostomy procedures  
 anastomosis, 393, 393f  
 exposure, 389–391, 389f–390f  
 preparation, 391, 391f
- Vasal fluid evaluation, vasovastostomy procedures, 391–393, 392f, 392t
- Vascular anastomoses, renal allotransplantation, 66–68, 67f–68f
- Vascularized interposition, neurogenic bladder reconstruction, 234, 234f
- Vascular pedicle dissection and control, laparoscopic radical cystectomy, 887, 887f
- Vas deferens  
 anatomy, 355f–356f, 358  
 blood supply, 358  
 development, 358  
 innervation, 358  
 physical examination, 357–358  
 vasectomy anesthesia protocols, 372–373, 373f  
 vasoepididymostomy preparation, 380–381
- Vasectomy  
 access points, 374–375, 374f–375f  
 alternative therapy, 372  
 anesthesia protocols, 372–374, 373f, 374–375  
 complications, 377–378  
 diagnostic criteria, 372  
 follow-up semen analysis, 375  
 indications for, 372  
 occlusion techniques, 374–375, 374f–375f  
 outcomes, 375–376  
 reversal (*See* Vasovasostomy)  
 surgical technique, 372

- Vasopididymostomy  
 alternative therapy, 380  
 diagnostic criteria, 379–380, 379f  
 indications, 380  
 outcomes and complications, 386  
 surgical techniques, 380–386  
 anastomosis, 383  
 closure, 383  
 elongation maneuvers, 383–384  
 epididymal tubule identification and preparation, 381  
 long double-armed microsutures, 385–386, 385f  
 longitudinal intussusception, 381–386, 382f, 384f  
 single-armed microsutures, 385, 385f  
 vas preparation, 380, 380f
- Vasovasostomy  
 alternative therapy, 388  
 diagnostic procedures, 387  
 indications for, 387–388  
 outcomes and complications, 396–397  
 postoperative care and follow-up, 396  
 prognostic factors, 387–388  
 surgical technique, 388–396  
 anesthesia protocols, 388  
 closure, 396, 396f  
 incisions, 388–389, 388f–389f  
 microdot multilayer microsurgical technique, 393–395, 394f–395f  
 operating room preparation, 388, 388f  
 special circumstances, 395–396, 395f  
 vasa deferentia anastomosis, 393, 393f  
 vasa deferentia exposure, 389–391, 389f–390f  
 vasa deferentia preparation, 391, 391f  
 vasal fluid examination, 391–393, 392f, 392t
- Vault suspension, transvaginal enterocele repair, 338–339, 339f
- Veress needle, transperineal laparoscopy, 801–802, 802f
- Vesical neck reconstruction  
 alternative therapy, 460, 460f  
 diagnostic criteria, 689–690  
 outcomes and complications, 696  
 surgical indications, 690  
 surgical technique, 691  
 fascial sling, bladder neck suspension, 691, 691f  
 Kropp urethral lengthening procedures, 693–694, 694f  
 Pippi Salle urethral lengthening procedure, 694–695, 695f  
 Young-Dees-Leadbetter bladder neck repair, 692–693, 692f–693f
- Vesical trauma and hemorrhage, 143–149  
 alternative therapy, 146  
 diagnosis, 144–145, 144f–146f  
 outcomes and complications, 147  
 surgical management and technique, 146–147
- Vesicopelvic ligament  
 pelvic floor anatomy, 313  
 vaginal prolapse, 326–327, 326f–327f
